We have found only one reference for excess volumes of 2-chloro-2-methylpropane with alkanols (ethanol, 1-hexanol, and 1-decanol) (6) but no references about isomeric butanols.

Experimental

Materials

The liquids used, 1-butanol (better than 99.8 mol%), 2-methyl-1-propanol and 2-methyl-2-propanol (better than 99.5 mol%), and 2-butanol and 2-chloro-2-methylpropane (better than 99 mol%) were obtained from Aldrich. The purity of these chemicals was checked by GLC and exceeded 99 mol%. All isomeric butanols were dried over activated molecular sieves type 0.3 nm from Merck and no further purification was considered necessary.

Table 1 shows the experimental values of density and viscosity for the pure components at 298.15 K compared with those found in the literature (7).

Methods

Densities were determined with an Anton Paar DMA-58 vibrating tube densimeter. The uncertainty of density measurements was ± 0.01 kg m^{-3}. Viscosities were determined using an Ubbelhode viscosimeter with a Schott–Geräte automatic measuring unit model AVS-440, the accuracy of the time flow measurement is ± 0.01 s. Details of calibrations and procedures can be found in an earlier paper (5).

Results and discussion

Measured data of density and viscosity are used to calculate V^E, η^E, and G^{*E} using the following equations:

$$[1] \quad V^E = x_1M_1(\rho^{-1} - \rho_1{}^{-1}) + x_2M_2(\rho^{-1} - \rho_2{}^{-1})$$

$$[2] \quad \eta^E = \eta - (x_1\eta_1 + x_2\eta_2)$$

$$[3] \quad G^{*E} = RT(\ln \nu M - (x_1 \ln \nu_1M_1 + x_2 \ln \nu_2M_2))$$

where M_1 and M_2 are the molecular masses of the components ρ, ρ_1, and ρ_2 are the densities (kg m^{-3}) of the mixture and of the pure components, η, η_1, and η_2 are the absolute viscosities (Pa s) of the mixtures and of the pure components, ν, ν_1, and ν_2 are the corresponding kinematic viscosities (m^2 s^{-1}), calculated as the quotient between η and ρ, M is the molar mass of the mixture, and x_i is the mole fraction of component i in the mixture.

Excess properties are given in Tables 2–4 and are graphically presented in Figs. 1–3. The results were fitted to a Redlich–Kister-type equation:

$$[4] \quad Y^E = x_1(1 - x_1) \Sigma\, a_i(2x_1 - 1)^i$$

where a_0, a_1, etc., are adjustable parameters and x_1 is the mole fraction of 2-chloro-2-methylpropane. The values of the parameters computed by the least squares method are shown in Table 5, together with standard deviation $\sigma(Y^E)$.

The excess volumes for the mixtures containing 2-butanol and 2-methyl-2-propanol are positive, the latter giving a symmetrical curve. For those with 1-butanol V^E are negative over the entire composition range. The mixtures containing 2-methyl-1-propanol have negative values of V^E between $0 < x_1 < 0.7$. V^E values increase in the sequence: 1-butanol < 2-methyl-1-propanol < 2-butanol < 2-methyl-2-propanol.

The butanols are self-associated compounds by hydrogen bonding (8). In the pure state exists an equilibrium between the monomers and linear and cyclic polymers (9). On the other hand, 2-chloro-2-methylpropane is a polar liquid but not self-associated. When the compounds are mixed the behaviour of the mixture may be due to several factors: (*i*) the breaking of the self-association by hydrogen-bonds existing in butanols, this loss of self-association is greater for 2-methyl-2-propanol than for the others. This is supported by the H^E values for the mixtures of n-hexane + isomeric butanols (10); (*ii*) the breaking of the dipole–dipole interactions between chloroalkane molecules. These two effects contribute in a positive way to excess volume; (*iii*) the specific interaction between the Cl group in chloroalkane and the OH group in butanol which has a negative effect on excess volume due to a dipole–dipole interaction with inter-

molecular complex formation (11), and (*iv*) structural factors due to the difference between the shape and size of the two components in the mixture which influence the interstitial positioning of 2-chloro-2-methylpropane between the butanols. In our mixtures the main factors which affect excess volume are the loss of self-association of the butanols and the specific Cl–OH interaction. In the mixture with 1-butanol these effects are compensated for and small excess volume are obtained due to the

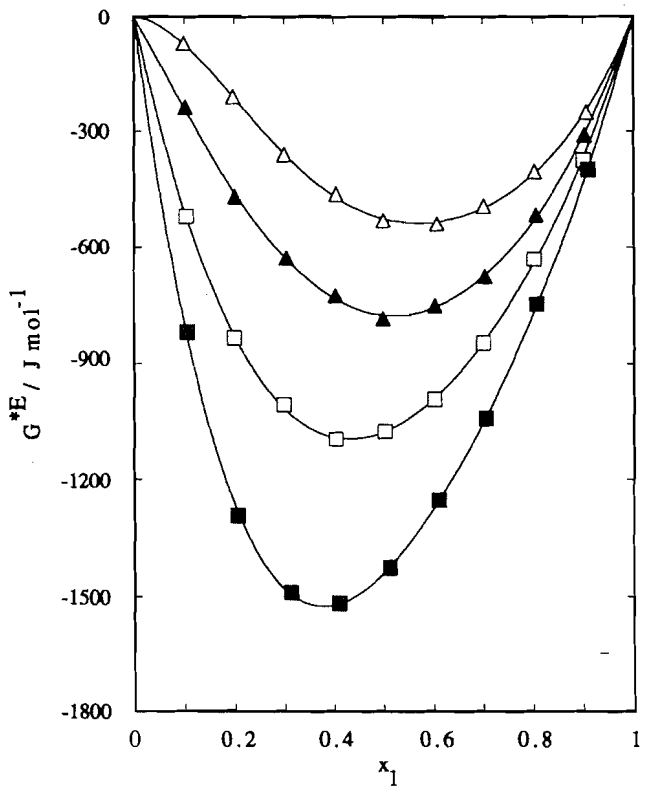

FIG. 3. Excess free energies of activation of flow, G^{*E}, of 2-chloro-2-methylpropane(1) + an isomeric butanol(2) at 298.15 K as a function of mole fraction x_1: (△) 1-butanol; (□) 2-butanol; (▲) 2-methyl-1-propanol; (■) 2-methyl-2-propanol.

fact that the breaking of the molecular order is not very great. On the other hand, with 2-methyl-2-propanol the breaking of the order is greater because the hydrogen bonds are broken to a greater extent, as previously mentioned, and the excess volume is greater. The influence of the molecular structure of the components on volumetric behaviour is shown by the smaller excess volumes for the mixtures containing 1-butanol and 2-methyl-1-propanol which have more open structures to enable the 2-chloro-2-methylpropane, a quasi globular molecule, to situate itself better than the 2-butanol and 2-methyl-2-propanol. It is also noteworthy that the mixture containing 2-methyl-2-propanol gives a symmetrical curve, given the similar shape and size of the two components, this does not apply to the rest of the mixtures studied. The influence of these structural factors can also be seen by comparing the V^E values for the mixtures studied with those of the mixtures containing 1-chlorobutane (3) whose excess volume is greater.

Excess viscosities and excess free energies of activation of flow are negative over the entire composition range. η^E and G^{*E} decrease in the sequence 1-butanol < 2-methyl-1-propanol < 2-butanol < 2-methyl-2-propanol, although η^E values for the mixtures containing 2-methyl-1-propanol and 2-butanol are similar.

The values of η^E and G^{*E} can be interpreted in a similar way to the V^E values. Thus a breaking of the association and the dipole–dipole interactions results in greater fluidity of the molecules, that is to say, a decrease in the viscosity of the mixture with regard to ideal behaviour. On the other hand, the appearance of a specific Cl–OH interaction leads to an increase in viscosity, although this solute–solvent interaction is not very marked.

Received November 18, 1993

STEVEN H. BERTZ, WEIJIANG ZHANG, JAMES M. COOK, MARTHA D. BRUCH, and LYNN W. JELINSKI. Can. J. Chem. **72**,1926 (1994).

The configurational isomers of the title compounds consist of four fused five-membered rings. They contain tightly coupled ^{1}H NMR spin systems, which provide excellent models for establishing the relationships between coupling constants and conformation. Complete chemical shift assignments and spin–spin coupling constants are reported for the title compounds by using high-field (500 MHz) ^{1}H NMR techniques (e.g., 2D homonuclear and heteronuclear experiments, difference NOE enhancements, and computational spin simulations). In addition to the more familiar two- and three-bond couplings, the spectra of **1** and **2** also contain a number of long-range (four- and five-bond) couplings, which provide a stringent test of Barfield's theoretical treatment of four-bond couplings.

STEVEN H. BERTZ, WEIJIANG ZHANG, JAMES M. COOK, MARTHA D. BRUCH et LYNN W. JELINSKI. Can. J. Chem. **72**, 1926 (1994).

Les isomères de configuration des composés mentionnés dans le titre comportent quatre cycles condensés à cinq chaînons. En RMN du ^{1}H, ils contiennent des systèmes de spin fortement liés qui fournissent d'excellents modèles pour établir des relations entre les constantes de couplage et la conformation. Faisant appel à des techniques de RMN du ^{1}H à haut champ (500 MHz) (par exemple, des expériences homonucléaires et hétéronucléaires en 2-D, des rehaussements des différences d'eOn et des simulations de spin par calculs) on a fait les attributions complètes des déplacements chimiques ainsi que des constantes de couplages des composés mentionnnés dans le titre. En plus des couplages bien connus à travers deux et trois liaisons, les spectres des composés **1** et **2** comportent aussi un certain nombre de couplages à longue distance (quatre et cinq liaisons) qui fournissent une méthode stricte de valider le traitement théorique de Barfield des couplages à travers quatre liaisons.

Compounds that consist of multiple fused five-membered rings were named "polyquinanes" by Jacobson (2*a*), who studied their graph-theoretical properties. Muller (3), Jacobson (2*b*), and Woodward (4) proposed that one fascinating polyquinane, triquinacene, could be dimerized to another: dodecahedrane (5). The exceptionally interesting C_{13}-tetraquinane, *endo*-tetracyclo[5.5.1.0.^{2,6}.0^{10,13}]tridecane-4,8,12-trione (**1**), was first prepared by Weiss and Edwards in 1968 (6), and its structure was definitively established by X-ray crystallography in 1973 (7). Shortly thereafter, Bertz proposed **1** as a starting material for dodecahedrane (8*a*),[6] and Baldwin and Beckwith used it to prepare a C_{19}-heptaquinane that might be suitable for "further elaboration towards dodecahedrane" (5*c*).

exo-Tetracyclo[5.5.1.0.^{2,6}.0^{10,13}]tridecane-4,8,12-trione (**2**) was isolated independently by Weiss and co-workers (9) and by Bertz (8*a*, *b*). Its X-ray structure has yet to be determined; its structure was established by the similarity of its spectral data to that of **1** (8*a*, 9). The preparation of molecules as complex as **1** and **2** in two easy steps from simple starting materials (glyoxal and dimethyl 3-ketoglutarate) is remarkable, even among reactions that quickly build molecular complexity (8*c*, 10).

Interest in **1** and **2** was renewed because they provide excellent models for the study of the relationship between ^{1}H NMR coupling constants (*J*) and stereochemistry in five-membered ring systems (8*d*). Furthermore, these molecules exhibit tightly coupled spin systems and, therefore, provide a challenging test of the utility of 2D *J*-resolved NMR techniques. Herein we report complete analyses of the ^{1}H NMR spectra of **1** and **2** based on the Karplus relationship (11), as well as Barfield's theoretical treatment of four-bond coupling constants (12).

2

Results and discussion

The ^{1}H NMR spectra of **1** and **2** are sufficiently complex to require analysis at high magnetic field strengths. The 500 MHz ^{1}H NMR spectra of compounds **1** and **2** are shown in Fig. 1. Although these spectra are considerably simpler than the corresponding spectra obtained at 200 MHz, they nevertheless defy direct analysis. Homonuclear ^{1}H–^{1}H correlated 2D-FT NMR experiments (13) provided qualitative information concerning the proton spin system; however, no quantitative data could be obtained. Difference nuclear Overhauser effect (NOE) enhance-

ments, heteronuclear correlated 2D experiments, and *J*-resolved 2D studies were performed in order to obtain unambiguous assignments of the ^{1}H NMR spectra. Computer spin simulations also provide support for our assignments.

In contrast, the ^{13}C NMR spectra are straightforward to assign (8*a*, 9). Taking advantage of this fact, heteronuclear ^{13}C–^{1}H correlated 2D-FT experiments (14) provided direct assignment of the proton resonances. This technique identified the CH groups, and the protons of the CH_2 groups were associated with their respective carbons, but an unambiguous distinction between the geminal α- and β-protons could not be made with this technique.

Difference NOE experiments (15) in one dimension at 500 MHz were found to provide the best method for distinguishing between the resonances due to the geminal α and β protons. The increased chemical shift separations (in Hz) at the high magnetic field strength (500 MHz) were necessary to avoid saturation of nearby resonances. Two-dimensional NOE experiments did not pick up the small enhancements that provided the key to the assignment of α or β configuration. These assignments were confirmed by the four-bond coupling constants (vide infra).

Initial estimates for the larger (>5 Hz) coupling constants were obtained from *J*-resolved 2D-FT proton spectra (16, 17). The actual coupling constants and shifts must be obtained from computer simulation of the spin system. Due to the large number of spins (14), isomers **1** and **2** do not lend themselves to complete spin simulations. However, by taking advantage of the apparent symmetry of these molecules, the spin systems can be calculated in two parts and, taken together with the data from the 2D-FT experiments, a fine-tuning of the chemical shift and coupling constant data can be achieved.

The chemical shifts of **1** and **2** are summarized in Table 1, and the coupling constant data are listed in Tables 2 and 3, which also contain information on distances and angles. These were calculated for the minimum energy structures as determined by molecular mechanics (MM2) (18). As shown in Fig. 2, the optimal structures for **1** and **2** are chiral. The validity of these results is confirmed by the X-ray structure of **1**, which is very similar to the calculated structure (Fig. 3). The root mean square distance $r^2 = 0.132$, which was calculated by including all atoms. For a more detailed comparison, the distances and angles calculated from the X-ray coordinates are given in Table 10 in the Supple-

mentary Material.[7] In both the solid state and in solution, there must be equal numbers of both enantiomers. The calculated MM2 energies for **1** and **2** are 38.7 and 36.3 kcal mol^{-1}, respectively. The fact that **1** predominates over the more stable **2**, under all reaction conditions (8*a*, 9), remained a mystery until the mechanism of formation was elucidated with the aid of glyoxal-d_2 (8*b*, 8*e*).

As expected, the largest chemical shift differences (δ **1** − δ **2** = 0.3 ppm) occur where the C1—C2 and C6—C7 bonds connect the bicyclo[3.3.0]octanedione subunit and the cyclopentanone subunit. The chemical shifts of the 1, 2, 6, 7, and 13 protons in **1** are downfield from the corresponding protons in **2**

[7]Tables of coupling constant data and angular information (from X-ray and MM2 structures) for **1** and **2** have been deposited and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

due to the mutual deshielding effect of eclipsed C—H bonds (19). The 3β and 5β protons also show a significant difference (−0.2 ppm) between **1** and **2**, since they are on a convex surface in **1**, but on a concave surface in **2**.

Looking at protons within the same molecule, it may be noted that the α and β protons next to the C4-carbonyl differ by only 0.05 ppm in **1**, but by 0.3 ppm in **2**. This is evidence for a conformational change in this relatively flexible five-membered ring upon going from **1** to **2** that, on average, puts the β protons further into the region of deshielding and the α protons further into the cone of shielding (19). This change is not observed in the much more rigid rings of the bicyclo[3.3.0]octanedione subunit, where the α − β differences at C9 and C11 are the same (ca. 0.6 ppm). In fact, the chemical shift of the magnetically equivalent 9α and 11α protons in **1** is virtually identical to the chemical shift of the corresponding protons in **2**, which is also true for the β protons.

In addition to the coupling constants ^nJ (n = 2, 3, 4, 5), where the superscript refers to the number of bonds between the coupled protons (i.e., the graph-theoretical distance), Tables 2 and 3 contain the Euclidean distances between them, as well as the angles θ and ϕ_i (i = 1, 2, 3). We define θ as the angle between the vectors containing the C—H bonds, where the C lies towards the origin of the vector; ϕ_i is a dihedral angle, as defined by Barfield (illustrated for **1** and **2** in Fig. 4). It may be noted that for ^2J, θ is the usual valence angle, and for ^3J, $\phi = \phi_1$ is the usual dihedral angle.

The proton coupling constants for the *endo* and *exo* isomers are similar in many respects. For both **1** and **2**, the values of ^2J are large (19–20 Hz), as expected for geminal protons on a five-membered ring (19). Moreover, the coupling constants for the protons belonging to the bicyclo[3.3.0]octanedione subunit (9α, 11α; 9β, 11β; 10 and 13) are not markedly different in either isomer.

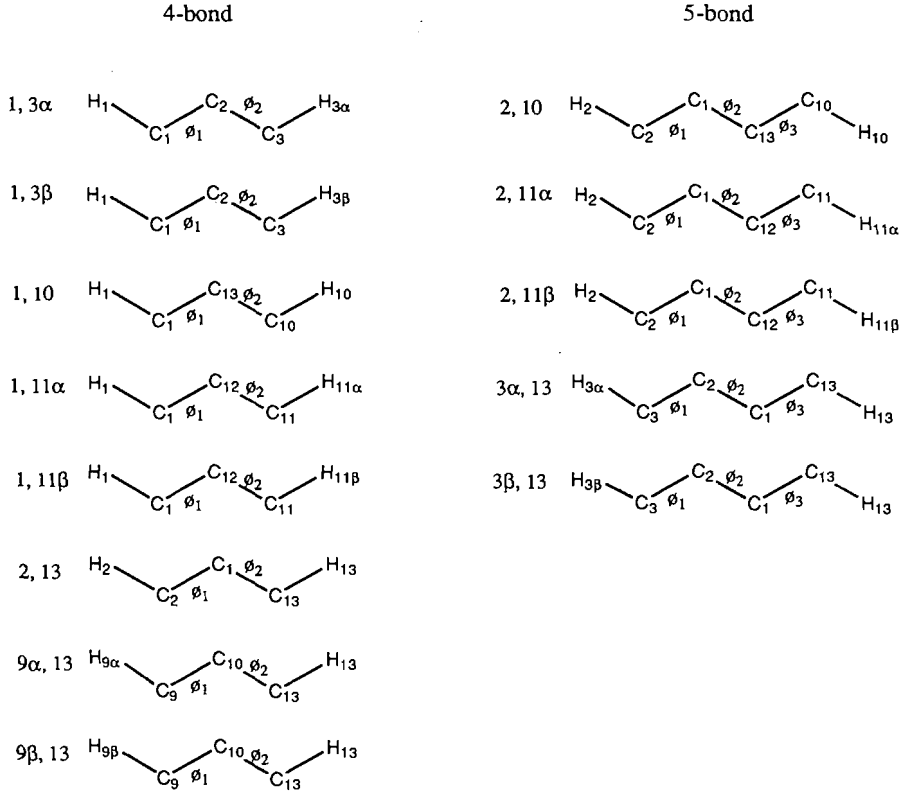

FIG. 4. Coupling paths between pairs of protons with definitions of ϕ_1, ϕ_2 (and ϕ_3) for ^4J (and ^5J).

However, there are marked differences between the isomers in the coupling constants between the 1 and 2 (or 6 and 7) protons. The dihedral angle between these protons in the *endo* isomer is small (ca. 30° average) and the coupling constant is large (10.1 Hz), consistent with the Karplus relation, $^3J = A + B\cos\phi + C\cos 2\phi$ (11*a*). The corresponding coupling constant in the *exo* isomer is small (1.3 Hz), reflecting the ca. 115° (average) dihedral angle between these protons. This information establishes the stereochemistry at the critical ring junction between the triquinancene moiety and the fused cyclopentanone ring. As mentioned above, this stereochemistry is vouchsafed by X-ray crystallography (7).

For **1** the other values of ^3J correlate with the values predicted by the Karplus equation, except for ^3J(H2–H3α) = 8.5 Hz and ^3J(H2–H3β) = 5.5 Hz, which are definitely out of line whether one uses the parameters proposed by Karplus (11*a*) or Bothner-By (11*b*). The ^3J values for **1** calculated for both the minimum energy structure and the symmetrically constrained one are summarized in Table 4, which shows that the best results are obtained by using Bothner-By's parameters in conjunction with the minimum energy (MM2) structure. Since the minimum energy structure is chiral, each value of ^3J is the average of two values, one calculated for each enantiomer. This analysis assumes that the observed spectrum is the time average of the spectra of the enantiomers, to a first approximation. The corresponding data for **2** are summarized in Table 5.

The fact that the couplings between H2 and H3 are opposite to the predictions of the Karplus equation would be of great concern in six-membered rings, perhaps even requiring the revision of the stereochemical assignments. However, in the case of flexible five-membered rings, sometimes $^3J_{cis} > {}^3J_{trans}$ and sometimes $^3J_{trans} > {}^3J_{cis}$, as previously reported for a 3,4-disubstituted cyclopentanone (8*d*). In this case the configurational assignments of the 3α and 3β protons, originally based on the observed NOEs, are confirmed by four-bond couplings ^4J (vide infra).

TABLE 4. Observed and calculated ^3J values for **1**

A critical points analysis (20) of Barfield's equations (12) for the "indirect" (through-bond) contributions to $^4J = f(\phi_1, \phi_2)$ is given in Table 6. The dependence of ^4J on the dihedral angles ϕ_1 and ϕ_2 is much more complicated than the relatively simple functional dependence of $^3J = f(\phi)$, commonly known as "the Karplus equation" (vide supra). Whereas the Karplus equation has a true maximum ($\phi = 180°$), a true minimum ($\phi = 90°$), and one local maximum ($\phi = 0°$), the Barfield equations have a true maximum ($\phi_1, \phi_2 = 180°, 180°$), a true minimum ($\phi_1, \phi_2 = 90°, 90°$), and many local maxima and minima. It is assumed that the "direct" (through-space) contribution to long-range coupling is negligible. (Before proceeding, it should be noted that the labels ϕ_1 and ϕ_2 are interchangeable by symmetry. Thus, if one

is looking for ^4J corresponding to angles near $\phi_1, \phi_2 = 120°, 30°$ and does not find it listed in Table 6, one should look at 30°, 120°. Also, the use of $\phi' = 360 - \phi$ is made possible by the fact that the family of curves is symmetrical about $\phi = 180°$ to within ±10°.) For the most accurate predictions, Barfield's original work should be consulted (12). The ^4J values for the protons related by symmetry in **1** and **2** (planar representations) must be determined independently for their (nonplanar) lowest energy structures and then averaged, as done for ^3J (above). The calculated ^4J values are summarized in Table 7 along with the measured ones. In six of eight cases for **1**, relatively large values of $^4J_{calc} > 0.1$ Hz correspond to relatively large values of $^4J = 0.5$–0.9 Hz, and small values of $^4J_{calc} < 0.1$ Hz correspond to $^4J \approx 0$. The two exceptions involve $^4J_{calc} \approx \pm 0.07$ Hz and $^4J = 0.3$ or 1.8 Hz. Interestingly, the larger discrepancy is the more easily explained: the 1.8 Hz coupling is across a carbonyl group, which is known to enhance the coupling between α and α′ protons (19). The other discrepancy involves the smallest non-zero value of ^4J. Thus, the overall correlation is very good for **1**.

TABLE 7. Observed and calculated ^4J values

Protons	$^4J_{obs}$ (**1**)	$^4J_{obs}$ (**2**)	$^4J_{calc}$ (**1**)	$^4J_{calc}$ (**2**)
1, 3α (7, 5α)	0.9	0.5	0.4	0.5
1, 3β (7, 5β)	0.7	1.4	0.4	0.5
1, 10 (7, 10)	0	0	0.07	0.2
1, 11α (7, 9α)	0.5	0	0.2	0.1
1, 11β (7, 9β)	1.8	1.7	−0.07	0.1
2, 13 (6, 13)	0	0.6	0.05	0.2
9α, 13 (11α, 13)	0.8	0.8	0.3	0.3
9β, 13 (11β, 13)	0.3	0.1	0.07	0.2

In the case of **2**, the largest discrepancy again involves ^4J(H1–H11β), across a carbonyl group. Overall, the correlation is not quite as good as it is for **1**. For example, ^4J(H2–H13) = 0.6 and ^4J(H9β–H13) = 0.1, even though $^4J_{calc} \approx 0.2$ Hz for both.

The alternative approach of calculating angles for a (hypothetical) symmetrical planar structure and then using these angles to determine ^4J gives satisfactory results, but not as good as the more rigorous method presented above. (See Tables 8 and 9, Supplementary Material,[7] for the angles of the planar structures.)

Of special importance is the fact that the ^4J(H1–H3α) and ^4J(H1–H3β) values of **1** and **2** are consistent with the NOE results, which were used to assign the configurations (α vs. β) of the protons on C3 and C5. As discussed above, the values of ^3J(H2–H3α) and ^3J(H2–H3β) are opposite to the predictions of the Karplus equation. This provides dramatic confirmation of our earlier conjecture that ^4J is more reliable than ^3J for flexible five-membered rings (8*d*).

It is easy to see that θ, the angle between the C–H vectors, does not correlate ^4J. For example, in the case of **1**, both the largest (1.8 Hz) and the smallest (0 Hz) values of ^4J have nearly the same value of θ. The Euclidean distance also does not predict the order of ^4J: pairs of protons that are more than 4 Å apart (e.g., H9α–H13 and H11α–H13) have high values for ^4J (0.8 Hz), whereas some protons with shorter distances have $^4J = 0$. Our results support the assumption that the direct, through-space term is negligible for ^4J. In contrast, it has recently been reported that NMR information can be transmitted through up to 14 saturated C—C bonds (21).

The only way we have found to rationalize the large five-bond couplings in **1** involves looking at ϕ_1 and ϕ_3 in the planar structure and noting that ^5J is only observed in those cases for which ϕ_1 and ϕ_3 give a significant value of ^4J. Barfield and Chakrabarti have shown that ^5J is independent of ϕ_2 (12*b*).

Conclusion

The structures of **1** and **2** have been uniquely assigned on the basis of ^{1}H NMR spectroscopy: ^3J can be used to determine stereochemistry about the key C2–C6 ring fusion, but does not correctly assign stereochemistry on the flexible five-membered ring. The relative configurations (α vs. β, as drawn) of the protons on C3 and C5 and on C9 and C11 were determined by NOE experiments and confirmed by ^4J values. A "critical points" analysis of Barfield's equations provides a practical method of estimating the magnitude of ^4J for both "W" and "non-W" spin

systems. The use of ^4J values to predict whether ^5J should be observable is proposed.

Experimental

The ^{1}H NMR spectra were obtained in chloroform-*d* by using Varian XL-200 or JEOL GX-500 NMR spectrometers. The Nicolet spin simulation program NMCSIM was used to calculate the spectra in two parts, since this program can only accommodate seven spins. Molecular mechanics calculations were performed using MM2 (MacroModel version 3.5, Columbia University, New York) on a Silicon Graphics Personal Iris 4D/35 workstation.

Solvation and metal ion effects on structure and reactivity of phosphoryl compounds. Part 4.[1] Dealkylation of phosphate esters by thiophenoxide ion in methanol

MARIAN MENTZ, AGNES M. MODRO, AND TOMASZ A. MODRO[2]

Centre for Heteroatom Chemistry, Department of Chemistry, University of Pretoria, Pretoria 0002, South Africa

Received February 10, 1994

MARIAN MENTZ, AGNES M. MODRO, and TOMASZ A. MODRO. Can. J. Chem. **72**, 1933 (1994).

Second-order rate constants for the demethylation of three phosphate esters by thiophenoxide salts, PhS^-M^+ ($M^+ = Me_4N^+$, K^+, Na^+ Li^+) in methanol-d_4 at 25°C have been measured. In contrast to the demethylation by iodide salts, metallic counterions do not exhibit any catalytic effects on the demethylation rate. The absence of the catalysis indicates that the salts react exclusively as ion pairs, in which an alkali metal ion is not available for the interactions with the phosphoryl group in the transition state.

MARIAN MENTZ, AGNES M. MODRO et TOMASZ A. MODRO. Can. J. Chem. **72**, 1933 (1994).

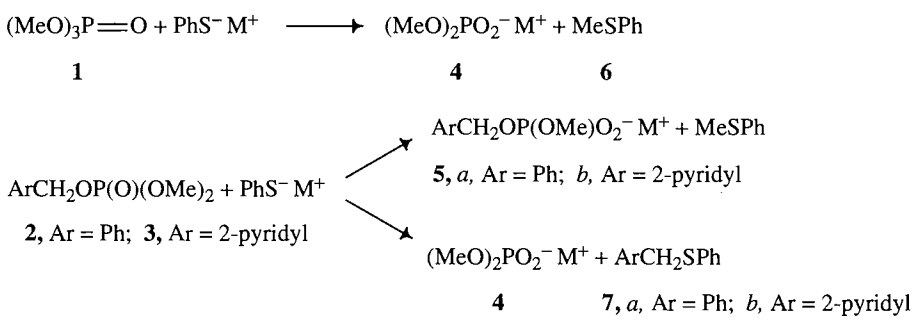
On a mesuré les constantes de vitesse d'ordre deux de la réaction de déméthylation de trois esters phosphoriques par des thiophénolates, PhS^-M^+ ($M^+ = Me_4N^+$, K^+, Na^+, Li^+), dans le méthanol-d_4 à 25°C. Contrairement à la déméthylation par les iodures, l'ion métallique n'a aucun effet catalytique sur la vitesse de déméthylation. L'absence d'effet catalytique indique que les sels réagissent exclusivement comme des paires d'ions dans lesquels l'ion du métal alcalin n'est pas disponible pour les interactions avec le groupe phosphoryle dans l'état de transition.

[Traduit par la rédaction]

We recently reported that the nucleophilic demethylation of methyl phosphinates (1) and phosphates (2) by iodide ion in acetone is catalyzed by alkali metal ions, the effect increasing in the order $R_4N^+ < K^+ < Na^+ < Li^+$. In the discussion of the observed catalytic effects we applied to our reaction the model proposed by Buncel and co-workers for the substitution at phosphorus by ethoxide ion (3), but we did not specify whether the reaction involved free ions (iodide as a nucleophile and the metal ion as a catalyst), or the M^+I^- ion pair. The decrease of the observed rate constants with increase in the iodide salt concentration (4), as well as the dramatic variation of the specific rate constant k_{I^-} with the nature of the counterion, indicated, however, that the interactions of free metal ions, rather than ion pairs, with the organophosphorus substrate are responsible for the catalysis. In this work we report on the results of the O-dealkylation of three phosphate esters by another nucleophilic reagent, thiophenoxide ion, which is frequently used as a demethylating agent in the "triester method" in the synthesis of oligonucleotides (5). The results of this work demonstrate that the phenomenon of metal ion catalysis may depend critically on the state of the Nu^-M^+ salt in the reaction medium.

Results and discussion

Trimethyl (**1**), dimethylbenzyl (**2**), and dimethyl(2-pyridylmethyl) (**3**) phosphates were used as substrates. All three esters reacted smoothly with the thiophenoxide ion in methanolic solution yielding products shown in Scheme 1. The ionic dealkylation products **4** and **5***a*, **5***b* could be easily identified by



SCHEME 1

NMR (^1H and ^{31}P) spectroscopy by comparison with authentic samples. The alkylation products, thioethers **6** and **7***a*, **7***b* were isolated and characterized by ^1H NMR spectroscopy and by oxidation and full characterization of the corresponding sulfones. Since substrates **2** and **3** gave upon dealkylation two pairs of products, intramolecular selectivity of the attack by PhS^- ion was of interest. For **2**, the demethylation/debenzylation ratio (corrected to a single methyl group) is ca. 0.4, contrasting sharply with the negligible contribution of demethylation observed in the reaction of the same nucleophile with dimethylbenzylphenylammonium ion (6). This difference points to the importance of the leaving group in the selectivity of the substitution, which was further confirmed by the results obtained for ester **3**. In this case the (corrected) ratio of the attack at the Me and CH_2 carbon atoms is ca. 0.8, twice the value obtained for **2**. Since the electrophilicity of the methylene α-carbon in **3** is higher than that in **2** (the polar effect of the **2**-pyridyl vs. phenyl

substituents), the higher Me/CH_2 ratio obtained for **3** indicates that other factors than the electrophilicity of the reaction centre determine the selectivity of substitution. On the other hand, the leaving group **5***b* is the anion of a stronger acid than the conjugate acid of **5***a*; thus **5***b* represents the best leaving group in those two phosphates, and this seems to determine the relative rates of substitution. In the case of much poorer leaving groups involved in the dealkylation of quaternary ammonium salts (tertiary amines), the observed intramolecular selectivity (6) is consequently much higher.

The kinetics of the dealkylation reaction were measured and the rate constants for the demethylation determined from the total dealkylation rates and the product distribution. For rates and product studies ^1H NMR spectroscopy was found most reliable. The signals of the methyl and methylene groups of all species shown in Scheme 1, as well as the pyridyl hydrogens of **3**, **5***b*, and **7***b*, were sufficiently separated in the spectra, so it was possible to monitor the concentration changes of both substrates and products in a single sample. The rate data obtained for the dealkylation of **1–3** by four different thiophenoxide salts are summarized in Table 1. For comparison, the last column of the table includes the previously determined (2) effect of the counterions on the relative rate of demethylation of **1** and **3** by iodide salts in acetone. The most obvious result is that for each substrate the nature of the counterion in the PhS^-M^+ reagent, as well as the $[PhS^-M^+]/[ester]$ ratio, has negligible effect on the rate of demethylation. This absence of any metal ion catalysis remains in sharp contrast with the demethylation of **1** and **3** by iodide, where the rate increased dramatically in the order $R_4N^+ \ll K^+ < Na^+ < Li^+$. Westaway and co-workers presented a detailed study on the effect of the form of the reacting nucleophile on the transition state structure of an S_N2 reaction using sodium thiophenoxide in methanol as a nucleophilic system (7). One of their conclusions was that, at concentrations higher than 1.0×10^{-4} M, PhSNa exists in methanol primarily as a solvent-separated ion pair complex of the general formula $[Na^+(solvent)_nPhS^-]_m$. In consequence, depending on the concentration of the nucleophile, they proposed two distinct models for the transition states, one involving a free PhS^- ion, and the other involving the $PhS^-/MeOH/Na^+$ ion pair complex. Since our rate constants were determined for solutions with $[PhS^-M^+]_0 \geq 7.5 \times 10^{-4}$ M, we can assume that all sodium thiophenoxide existed in the reaction medium as a solvent-separated ion pair complex, even at 99% conversion. The same is most likely true for other PhS^- M^+ salts where $M^+ = Li^+$, K^+, but, considering facile dissociation of tetraalkylammonium salts in organic media,[3] it may be only partially true for $M^+ = Me_4N^+$. We have recorded the UV spectra of sodium, lithium, and tetramethylammonium thiophenoxides in methanol in the concentration range 10^{-5}– (4×10^{-4}) M (Fig. 1). For the Na^+ and Li^+ salts, we confirmed Westaway's conclusions by observing the dramatic changes of the value of ϵ_{max} up to the concentrations of ca. (9×10^{-5})–(2×10^{-4}) M, above which no further changes in the ϵ_{max} were observed. The corresponding plot for the Me_4N^+ salt, on the other hand, shows the variation of the ϵ_{max} over the whole concentration range, indicating more complex behavior of this thiophenoxide in methanolic solution. This difference in the behavior of the thiophenoxide salts may be reflected in the rates of the demethylation, which for all substrates used are slightly lower for $M^+ = Li^+$, Na^+, K^+ (av. $k_{rel} = 0.82$) than for $M^+ = Me_4N^+$. It is possible that tetramethylammonium thiophenoxide reacts partially as the free ion, which leads to the rate increase. This is in agreement with the reported (7) slightly higher reactivity of the free ion than the solvent-separated ion pair complex of the ArS^- nucleophile.

We conclude therefore that the alkali metal thiophenoxides

[3]Solvent activity coefficient for the transfer of a cation from MeOH to water is -1.5 for K^+, but $+3.7$ for Bu_4N^+ (8).

[a]Selectivity of dealkylation; 0.5[**5**]/[**4**].

[b]Second-order rate constants k_2 for the demethylation only; corrected to a single methyl group. Since the k_2 values were obtained from rate constants for the decomposition of the substrate and from the product ratio, they are given only to two significant figures.

[c]Taken from ref. 2. The standard of reference ($k_{rel} = 1.0$) was obtained for demethylation by $Bu_4N^+I^-$.

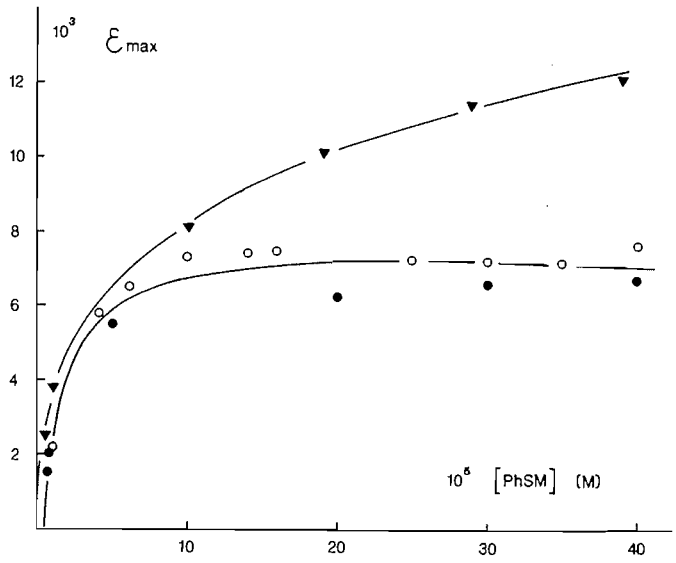

FIG. 1. Variation of the ϵ_{max} (λ_{max} = 265 nm) for the thiophenoxide salts, PhS^-M^+, in methanol; ○, $M^+ = Na^+$; ●, $M^+ = Li^+$; ▼, $M^+ = Me_4N^+$.

react with phosphate esters under the conditions of our experiments exclusively as solvent-separated ion pair complexes, in which the cation cannot be involved with the leaving group, hence is not capable of catalyzing the displacement. In agreement with this conclusion, the product ratio should not vary significantly with the cation; this was, indeed, observed for both substrates. On the other hand, strong catalysis by the same ions observed for the demethylation by iodide suggests the involvement of free metal ions in stabilizing interactions with the leaving group. By applying Westaway's model for the S_N2 transition states (*7b*) to our system, we propose the following models for the transition states for the demethylation of methyl phosphates by iodide ions in acetone, and by thiophenoxide ions in methanol, respectively (Fig. 2).

Experimental section

Methanol-d_4 (Merck, ≥99 at.% D) was dried over molecular sieves (Merck, 0.4 nm) and used without further purification. The thiophenoxide salts were prepared by adding an equimolar amount of the respective hydroxide, M^+OH^-, to an ethanolic solution of thiophenol, removing the solvent, drying the salt under high vacuum and storing in a desiccator over P_4O_{10}. The NMR spectra were recorded on a Bruker AC 300 MHz spectrometer at a probe temperature of 30°C. Chemical shifts are given relative to $SiMe_4$ (^1H) or 85% H_3PO_4 (^{31}P). Coupling constants are given in Hz. UV spectra were recorded on a Varian Cary 2390 spectrophotometer. The mass spectrum was recorded on a Varian MAT-212 double-focusing direct-inlet spectrometer at an ionization potential of 70 eV. Only the major fragments are listed. The oxidizing agent, oxodiperoxymolybdenum(aqua)hexamethylphosphoric triamide, MoO_5H_2OHMPA, was prepared according to the literature procedure (9). Trimethyl phosphate (**1**) (Merck) was distilled immediately before use. Dimethylbenzyl phosphate (**2**) was prepared from dimethylphosphorochloridate and sodium benzylate in toluene; 59%, bp 108°C/0.3 Torr (1 Torr = 133.3 Pa); δ_H ($CDCl_3$): 3.70 (6H, d, J_{HP} 11.2), 5.05 (2H, d, J_{HP} 8.3), 7.31–7.39 (5H, m); δ_P: 1.98. Dimethyl(2-pyridylmethyl) phosphate (**3**) was prepared as described before (10).

Lithium methyl(2-pyridylmethyl)phosphate (5b)

A sample of **3** (0.50 g, 2.29 mmol) was incubated at room temperature in acetone solution (33 mL) containing LiCl (0.32 g, 2.41 mmol) and the progress of the reaction was followed by TLC ($CHCl_3$/EtOH, 9:1). After 30 h the solution was concentrated to a volume of 5 mL and separated by column chromatography ($CHCl_3$/EtOH, 9:1). Fractions containing single product (R_f 0.5) were combined, evaporated, and the residue was recrystallized from ethanol. White powder, mp (dec.) 227°C; δ_H (D_2O): 3.50 (3H, d, J_{HP} 10.8), 4.94 (2H, d, J_{HP} 7.8), 7.38 (1H, dd, J_{HH} 7.9, 4.8), 7.55 (1H, d, J_{HH} 7.9), 7.88 (1H, t, J_{HH} 7.9), 8.46 (1H, d, J_{HH} 4.8); δ_P: 2.43. Anal. calcd. for $C_7H_9LiNO_4P$: C 40.22, H 4.34, N 6.70; found: C 39.8, H 4.1, N 6.45%.

Sodium methylbenzylphosphate (5a) was prepared in the same way from **2** and NaCl; δ_H (D_2O): 3.47 (3H, d, J_{HP} 10.8), 4.84 (2H, d, J_{HP} 7.2), 7.37–7.40 (5H, m); δ_P: 3.74.

Methylphenyl sulphide (6) and phenyl(2-pyridylmethyl) sulphide (7b)

A solution of **3** (1.01 g, 4.65 mmol) and PhSLi (0.54 g, 4.65 mmol) in acetone (30 mL) was kept at room temperature for 2 h. Acetone was removed and the residue was partitioned between chloroform (35 mL) and water (35 mL). The chloroform solution was dried, concentrated to a volume of 5 mL, and the solution was separated by column chromatography (silica gel, $CHCl_3$/EtOH, 9:1). First fraction: **6**, 0.31 g (54%); δ_H ($CDCl_3$): 2.48 (3H, s), 7.13 (1H, m), 7.26 (4H, m). Second fraction: **7b**, 0.36 g (37%); δ_H ($CDCl_3$): 4.23 (2H, s), 7.10–7.30 (7H, m), 7.55 (1H, dt, J_{HH} 7.6, 1.9), 8.50 (1H, d, J_{HH} 1.9).

Methylphenyl (6) and benzylphenyl sulphide (7a) were not isolated but were identified as the corresponding sulfones after oxidation of a mixture of **6** and **7a** obtained in reaction of **2** with PhSLi.

Oxidation of **6**, **7a**, **7b** to sulfones by MoO_5H_2OHMPA was carried out following the literature procedure (11), as described below for the oxidation of **7b**. To a solution of **7b** (0.35 g, 1.74 mmol) in CH_2Cl_2 (10 mL), MoO_5H_2OHMPA (0.91 g, 2.43 mmol) was added and the reaction mixture was stirred at room temperature for 22 h. Another portion of the oxidating agent (0.41 g) was added and the stirring was continued until TLC (CH_2Cl_2/Et_2O, 1:1) showed complete disappearance of **7b** (24 h). After filtration, the CH_2Cl_2 solution was washed with water (30 mL), the water layer was extracted with CH_2Cl_2 (2 × 20 mL), and the combined organic phases were washed with 10%

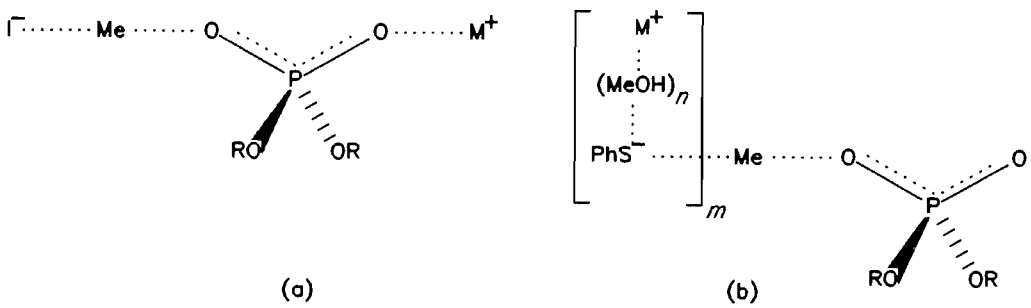

FIG. 2. The S_N2 transition states for the reaction between methyl phosphates and (*a*) free ions of an iodide salt in acetone; (*b*) solvent-separated ion pair complex of a thiophenoxide salt in methanol.

aqueous K_2CO_3, dried, and evaporated. The crude product (87%) was crystallized twice from CH_2Cl_2/Et_2O (1:1) yielding pure phenyl(2-pyridylmethyl) sulfone; mp 156–157°C; δ_H (acetone-d_6): 4.99 (2H, s), 7.30 (2H, m), 7.58 (3H, m), 7.69 (1H, t, J_{HH} 6.0), 7.78 (2H, d, J_{HH} 5.8), 8.03 (1H, d, J_{HH} 6.0); ms, *m/z*: 233 (M^+, 0.01%), 168 ($M^+ - HSO_2$, 78%), 92 ($M^+ - PhSO_2$, 100%). Anal. calcd. for $C_{12}H_{11}NSO_2$: C 61.78, H 4.75, N 6.01; found: C 61.6, H 4.7, N 5.9%.

The mixture of **6** and **7***a* obtained in the reaction of **2** with PhSLi was oxidized in the same way and the products were separated by column chromatography (silica gel, ethyl acetate/CH_2Cl_2, 1:1).

Methylphenyl sulfone, mp 82.5–84.5°C; δ_H ($CDCl_3$): 3.04 (3H, s), 7.56 (2H, dd, J_{HH} 7.7, 7.3), 7.63 (1H, dd, J_{HH} 7.3, 1.2), 7.94 (2H, dd, J_{HH} 7.7, 1.2). Anal. calcd. for $C_7H_8O_2S$: C 53.83, H 5.16; found: C 53.5, H 5.2%.

Phenylbenzyl sulfone, mp 148–149°C; δ_H ($CDCl_3$): 4.29 (2H, s), 7.06 (2H, dd, J_{HH} 8.2, 1.6), 7.20–7.30 (3H, m), 7.42 (2H, t, J_{HH} 9.6), 7.55–7.63 (3H, m). Anal. calcd. for $C_{13}H_{12}O_2S$: C 67.22, H 5.21; found: C 66.9, H 5.0%.

Kinetic measurements

Rate constants were determined as before (1), following the changes of the intensities of the methoxy group signals of substrates and products in the ^1H NMR spectra of reaction mixtures. The methoxy groups gave rise to sharp doublets at the following values of δ_H: **1**, 3.76; **2**, 3.72; **3**, 3.78; **4**, 3.55; **5***a*, 3.53; **5***b*, 3.58. The runs were carried out to at least 75% conversion, and good second-order linear plots were obtained ($r^2 = 0.995–0.999$).

Densities and viscosities of binary aqueous mixtures of nonelectrolytes: *tert*-Butyl alcohol and *tert*-butylamine

PIUS K. KIPKEMBOI AND ALLAN J. EASTEAL

Department of Chemistry, The University of Auckland, Private Bag 92019, Auckland, New Zealand

Received February 4, 1994

PIUS K. KIPKEMBOI, and ALLAN J. EASTEAL. Can. J. Chem. **72**, 1937 (1994).

The density and shear viscosity of mixtures of *tert*-butyl alcohol (BuOH) and *tert*-butylamine (TBA) with water have been determined for various temperatures (288 to 318 K for H_2O + BuOH and 288 to 308K for H_2O + TBA) over the whole composition range. Excess molar volumes and apparent molar volumes of the components of each system were calculated from the density data. In both systems the apparent molar volume of the organic component passes through a minimum in the water-rich region. Both systems exhibit large negative excess molar volumes which are essentially independent of temperature at all compositions. The two systems show pronounced maxima in their shear viscosity isotherms.

PIUS K. KIPKEMBOI et ALLAN J. EASTEAL. Can. J. Chem. **72**, 1937 (1994).

On a déterminé les densités et les viscosités de cisaillement de mélanges d'alcool *tert*-butylique (BuOH) et de *tert*-butylamine (TBA) avec de l'eau, sur l'ensemble des compositions possibles et à diverses températures (allant de 288 K à 318 Kj pour H_2O + BuOH et de 288 K à 308 pour H_2O + TBA). Utilisant les données de densité, on a calculé les volumes molaires en excès et les volumes molaires apparents des composants de chaque système. Dans les deux systèmes, le volume molaire apparent du composant organique passe par un minimum dans la région riche en eau. Les deux systèmes présentes des volumes molaires en excès largement négatifs qui sont essentiellement indépendants de la température, à toutes les compositions. Les deux systèmes présents des maxima importants dans leurs isothermes de viscosité de cisaillement.

[Traduit par la rédaction]

Introduction

There have been a large number of studies on the behaviour of mixtures of water with nonelectrolytes. Most of them have been concerned with water-rich solutions and have discussed structural changes of the solvent water caused by the introduction of nonpolar groups. The unusual thermodynamic properties of nonpolar solutes in water were interpreted by Frank and Evans (1) in terms of the ordering of water molecules around the solute ("iceberg" formation). The molecular phenomena comprise two related processes. First, apolar solutes promote a stabilization of the extensive, but thermally sensitive, hydrogen-bonded network of liquid water, an effect known as "hydrophobic hydration". Second, apolar solutes in water exhibit a tendency to aggregate, i.e., "hydrophobic interaction". Solutes which impose order (promote iceberg formation) are considered to be structure makers, and solutes which decrease order are said to be structure breakers. Importantly, simple hydrocarbons have been shown to increase the order of surrounding water molecules to relatively long range (2).

Organic cosolvents (with polar functional groups such as OH and NH_2) exhibit much larger solubilities in water than do hydrocarbons. However, in dilute solutions the behaviour of organic cosolvents frequently shows features similar to those of hydrocarbons (3). Studies of such features (hydrophobic hydration and interaction) have attracted considerable attention since they have been shown to influence protein conformation and thermodynamic stability (3). The pivotal biological role of H_2O is attributed to its ability to promote aggregation of nonpolar molecules.

As part of an ongoing program in the studies of molecular interactions in aqueous–organic mixtures, we are pursuing detailed thermodynamic investigations on selected water–cosolvent systems (4, 5). The cosolvents studied were chosen because they are relatively hydrophobic yet completely miscible with water in all proportions. Both water + *tert*-butyl alcohol and water + *tert*-butylamine systems are potentially extremely interesting. The large compact hydrocarbon moieties must promote a hydrophobic interaction, while the OH and NH_2 groups can no doubt form hydrogen bonds to water.

Being relatively hydrophobic cosolvents, both BuOH and TBA are attractive compounds in the study of hydration phenomena and may serve as models for more complicated aqueous systems like surfactants, emulsions, and biopolymers. In the hope of obtaining an overall picture of these aqueous binary solutions we have studied the whole composition range. In particular, comparison between the hydroxyl group (—OH) and the amine group (—NH_2) has been investigated since the cosolvents are structurally similar. Although the H_2O + BuOH system has been investigated extensively, there are few data available in the literature for H_2O + TBA mixtures.

The physical properties of water and aqueous mixtures of organic solvents are important for many reasons. In particular, mixing volumes and viscosity effects have theoretical and practical significance, and strong deviations from linearity are often encountered in aqueous liquid mixtures. Precise measurements of volumes and shear viscosities over the whole composition range are necessary to understand the nature of interactions between nonpolar groups and water, the so-called hydrophobic solvation. There have been no previous measurements, so far as we know, of the volumes and viscosities of H_2O + TBA system covering the whole composition range. Also, while many researchers have reported determinations of the partial molar volume of BuOH in the water-rich region of aqueous solutions (6–17) there have been few measurements at high alcohol concentrations over a wide temperature range. In view of the scatter of data found in the literature, measurements of shear viscosity of H_2O + BuOH mixtures were performed for the whole range of concentrations at 288, 298, 308, and 318 K, with special attention paid to the region highly dilute with respect to water.

Experimental

Materials

Tert-Butylamine was supplied by Aldrich or Merck and *tert*-butyl alcohol by Riedel-de Haën. The stated purity of these materials exceeded 99.0 mol%. The solvents were stored over freshly activated

molecular sieves (Union Carbide type 3 Å) for several weeks before use. Ultra-pure water from a Milli-Q reagent-grade water system was used to prepare the aqueous mixtures, and as a calibrating liquid.

Binary mixtures were prepared by mass in 50-cm^3 Erlenmeyer flasks with ground-glass stoppers using a balance with an accuracy of ±0.1 mg. To minimise errors due to evaporation of the organic component, water was weighed in first, followed by the organic solvent. Density and viscosity measurements were carried out soon after sample preparation in order to avoid preferential evaporation and consequential composition changes.

Apparatus

Densities of the pure components and the binary mixtures were measured with an Anton Paar Model DMA 02C vibrating-tube digital densimeter operated in the static mode. The reference liquids used for calibration of the densimeter were 2,2,4-trimethylpentane (99.7+%, HPLC grade), cyclohexane (99+%, spectrograde), and Milli-Q water whose densities were taken from ref. 18. Water and cyclohexane were used as calibrating fluids for H_2O + BuOH while water and 2,2,4-trimethylpentane were used for H_2O + TBA mixtures. The calibration liquids were selected to span a wide density range. Moreover, they can be obtained in high purity and their densities are known with high accuracy for all the temperatures which were investigated. The densities of each pair bracketed the densities of the binary mixtures investigated. The densimeter was calibrated daily and at each temperature.

Kinematic viscosities were measured with factory-calibrated Cannon Ubbelhode suspended-level viscometers. Flow times were measured with a stop watch, and measurements were repeated until flow times agreed within a few tenths of a second. The values of kinematic viscosity were converted to shear viscosities using densities measured at the same time. To check the calibration at each temperature, each viscometer used was recalibrated against water, and in each case the measured viscosity of water agreed to within experimental uncertainty with literature values. A kinematic energy correction was considered to be not necessary on account of long flow times obtained by proper selection of the capillary. The estimated error in the viscosity measurements was within ±0.005 mPa s. All glassware was thoroughly cleaned with warm chromic acid cleaning solution.

Prior to any readings, solutions were thermostatted for at least 20 min. The temperature of the thermostat bath was monitored continuously at each temperature with a precision digital thermometer (Ebro TEX-492). Temperatures were constant to ±0.005 K during measurements at each temperature, and the accuracy of temperature measurement was ±0.05 K. Densities of the pure and mixed fluids were obtained at the temperatures at which viscosity measurements were done.

Results and discussion

The densities of the pure cosolvents are given in Table 1 together with values from the literature, and generally show good agreement with literature data. The densities were estimated by linear extrapolation of the measured dilute solution densities to zero water content by the method of least squares. From the experimental densities, excess molar volumes V^E and single-component apparent molar volumes V_Φ for the two systems were calculated using the equations:

$$[1] \quad V^E = \frac{X_1M_1 + X_2M_2}{\rho} - \frac{X_1M_1 + X_2M_2}{\rho}$$

$$[2] \quad V_\Phi(2) = \frac{X_1M_1(\rho_1 - \rho)}{X_2\rho_1\rho} + \frac{M_2}{\rho}$$

where ρ represents solution density, M, X, and V_Φ denote respectively molar mass, mole fraction, and apparent molar volume, for either mixture component. The measured densities for the two systems at various temperatures are listed in Tables 2 and 3 as a function of the mole fraction of the organic component.

The excess molar volume of a mixture is the consequence of the coupling of different contributions deriving from structural modifications of the pure components, changes in the free volume, interstitial accommodation, and hydrogen bonding of unlike molecules and from other non-specific physical effects. The excess volumes for H_2O + BuOH mixtures at 288, 298, 308, and 318 K are shown in Fig. 1, and for H_2O + TBA mixtures at 288, 293, 298, 303, and 308 K in Fig. 2. Previously reported excess volumes (for the H_2O + BuOH system) are mostly for 298 K. For both systems V^E is large and negative, and not strongly temperature dependent. The sign of V^E for liquid aqueous mixtures can be accounted for by occupation of the free volume of cavities in the open water structure by the other component. For both systems V^E is much larger than for H_2O + CH_3CN mixtures (4) in which it is believed that water–cosolvent interactions are very weak. For the H_2O + BuOH system, the maximum (negative) value of V^E is approximately equal to that for the H_2O + CH_3OH system (5) where the cosolvent molecule has one hydrogen bonding site in each case. It seems likely that the much larger volume contraction in H_2O + TBA mixtures arises at least in part from the additional hydrogen bonding site afforded by the NH_2 group.

Most of the significant changes occurring in aqueous–

organic mixtures are in the water-rich region. Although molar excess functions give information on interactions occurring in mixtures, since they vanish at the composition extremes they may not reveal phenomena in dilute solutions where structural changes of pure components imposed by the interactions between like and unlike molecules can occur. Apparent and partial molar properties, on the other hand, reflect more appropriately characteristic interactions and structural changes induced by the addition of small, increasing amounts of the second component (11). Figures 3 and 4 show that the apparent molar volumes of BuOH and TBA in water vary with composition in a similar fashion, and the sharp V_Φ(cosolvent) minimum in the water-rich region is common to many aqueous non-electrolyte solutions. The trends of the apparent molar volumes of BuOH and TBA in the water-rich region with composition and temperatures are shown in more detail in Figs. 5 and 6. The shapes of the curves for both cosolvents are essentially the same at all temperatures, but the minimum becomes more pronounced and shifts to higher concentration as the temperature is lowered. Similar behaviour is found for $V_\Phi(H_2O)$ in the BuOH-rich region (Fig. 7) where the minimum is also very pronounced and shifts to a higher concentration with decreasing temperature, though it is not as sharp as for V_Φ(BuOH). The volumetric behaviour of H_2O in TBA-rich mixtures is quite different: $V_\Phi(H_2O)$ gradually decreases from a higher value in water to a small value at infinite dilution in TBA as the proportion of amine increases. The volumetric behaviour of H_2O + BuOH mixtures is unusual at both ends of the concentration range, as was also noted by Sakurai (15), whose results are in excellent agreement with ours. A minimum in the apparent molar volume of water in the organic cosolvent-rich region has been observed also in H_2O + tetrahydrofuran mixtures (19). The well-known characteristics of volumetric properties in water-rich regions of

many aqueous non-electrolyte solutions, represented typically by aqueous BuOH and TBA solutions, have been interpreted in terms of the hydrophobic hydration concept (1, 20), although the exact nature of hydrophobic hydration is still unclear. The occurrence of a minimum has been attributed to a balance between the effects of interstitial solution of organic cosolvent

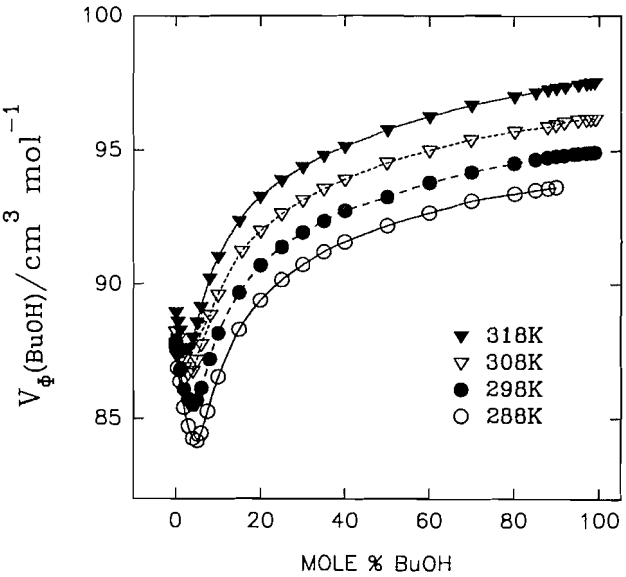

FIG. 3. Apparent molar volume of *tert*-butyl alcohol in water as function of composition and temperature.

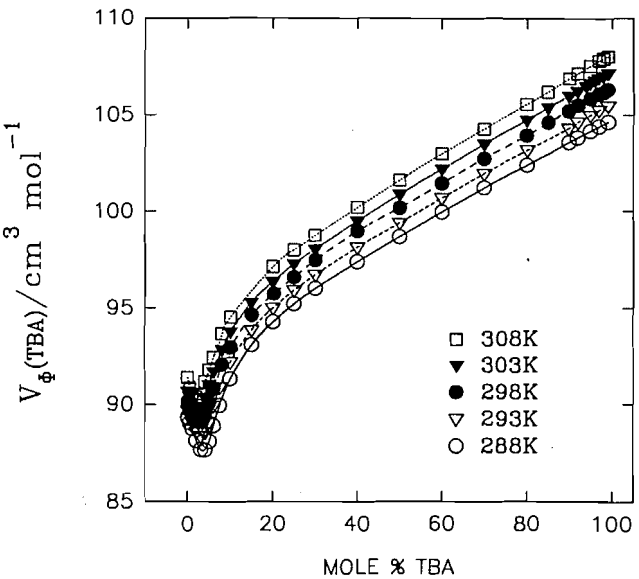

FIG. 4. Apparent molar volume of *tert*-butylamine in water as a function of composition and temperature.

molecules with accompanying enhancement of an ice-like structure in the water, and a breaking of this structure due to loss of free space with increasing concentration of the solute (8, 21). Initially, the addition of BuOH or TBA to water will result in the formation of stronger H-bonds between water molecules that would bring about volume contraction. At the same time, the bulky tertiary alkyl groups of BuOH or TBA occupying cavities in the network structure of water will tend to associate because this causes a free energy decrease. This tendency is known as hydrophobic interaction (8). The structural stabilization produced by the cosolvent becomes more pronounced and eventually reaches a minimum beyond which further addition of solute results in a fairly rapid breakdown of the structural integrity of water. Although the interpretation of the minimum is not unequivocal it probably corresponds to the upper limit of the region where the stabilization of the water structure can take place. Packing of the cosolvent molecules evidently takes place

more effectively up to this concentration due to the interstitial accommodation of the solute molecules within the water structure. The minimum in the $V_\phi(H_2O)$ curve shown in Fig. 7, on the other hand, cannot be attributed to such a structural influence because the open structure of water no longer exists in the BuOH-rich region. It is noteworthy that structure promoting interactions of the two cosolvents persist over a considerable range of temperature, so that at 318 K BuOH is still a powerful structure promoter.

Limiting partial molar volumes of BuOH, TBA, and H_2O, i.e. the infinite-dilution apparent molar volumes, are given in Tables 5 and 6 together with literature data. Our values for both components in the H_2O + BuOH system are in good agreement with published data. For the H_2O + TBA system, the only published data are those of Kaulgud and co-workers (22), which are based on the differential float balance method. Their values for the limiting partial molar volume, V^*(TBA), for TBA in water are 0.75 and 1.11 cm^3 mol^{-1} higher than our results at 288 and 298 K, respectively. These differences can be ascribed to impurities in TBA, their extrapolation method and the different techniques employed in the measurements. The limiting partial molar volumes of water in BuOH and TBA are plotted as a function of temperature in Fig. 8. In both cosolvents $V^*(H_2O)$ is smaller than the molar volume of water. The decrease in volume relative to pure water may be related to the loss of the open structure of bulk water and to the formation of H-bonds between water and solvent molecules (19). $V^*(H_2O)$ in TBA is very small, and at present we cannot offer a convincing explanation of the large difference in the values of $V^*(H_2O)$ in BuOH and TBA, though it must be borne in mind that the amine

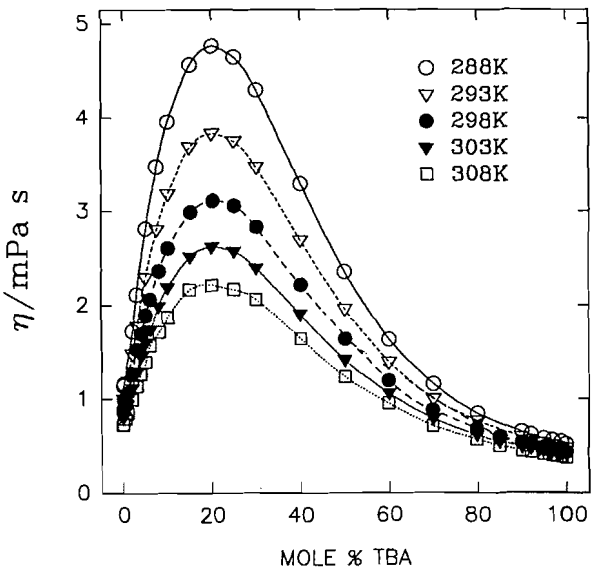

FIG. 12. Viscosity of H_2O + *tert*-butylamine mixtures as a function of composition and temperature.

becomes significantly protonated at low concentration in water, and the extent of protonation increases with increasing dilution. Similarly, as for other organic liquid + water mixtures both V^*(BuOH) and V^*(TBA) are smaller than the molar volumes of the respective pure components at all temperatures. This contraction in volume on mixing organic cosolvent and H2O is surprising at first, since hydrophobic hydration around the organic cosolvent causes an increase in ice-likeness of the solvent, and consequently should cause a decrease in density of the solution. The explanation offered by Nemethy and Scheraga (23) is that hydrophobic hydration occurs with an overall economy of space. As shown in Fig. 9, V^*(BuOH) and V^*(TBA) in water increase with temperature, more significantly for V^*(TBA) than for V^*(BuOH). Both the alcohol and amine show (Fig. 10) negative excess limiting partial molar volumes defined by

$$[3]\quad V^{*E}(i) = V^*(i) - V_m(i)$$

where V_m is the molar volume of pure component i. The magnitude of V^{*E} is larger for TBA than for BuOH, suggesting that the extent of accommodation of TBA in the open cage structure existing in water is greater than for BuOH. Also, the excess limiting partial molar volumes of BuOH and TBA are strongly temperature-dependent, becoming more negative as the temperature increases.

Shear viscosities for aqueous binary mixtures of BuOH and TBA are given in Tables 2 and 4 respectively, and viscosity isotherms are shown in Figs. 11 and 12. Extensive viscosity data at 298 K have been reported for H_2O + BuOH, and our data compare favourably with the literature values. In particular, the val-

ues given by Kenttamaa and co-workers (24) agree with the present data within experimental error but are slightly lower than those of Senanayake and Freeman (25), although the general shape of the curve obtained in all three cases is the same.

Solute–solvent interactions in binary liquid mixtures can lead to extrema in viscosity–composition isotherms, and most binary aqueous mixtures have the characteristic feature that at a particular composition, the viscosity of the solution reaches a value that is larger than the viscosities of either pure component. Addition of BuOH or TBA to H_2O increases the viscosity of the mixture rapidly and the viscosity reaches a maximum at a composition in the water-rich region (Figs. 11 and 12). The viscosities at the maxima are nearly 7.0 and 4.2 times the viscosity of water and appear around 40 and 20 mol% of BuOH and TBA, respectively, at 288 K. Viscosity maxima observed for aqueous mixtures of different organic solvents have been attributed to the formation of association complexes (26–29). An alternative interpretation is that the ascending part of the viscosity–composition curve (water-rich region in Figs. 11 and 12) represents structural promotion in the mixture by gradual formation of clusters of associated species via hydrogen bonding. At lower concentrations, BuOH and TBA molecules are accommodated in cavities within the H_2O structure leading to an enhancement of H_2O network structure. At moderate concentrations, however, there is insufficient free volume for all of the cosolvent molecules in the structural cavities of water, and this results in the BuOH or TBA molecules participating in strong hydrogen bonding with H_2O, producing a more strongly bonded and less compressible structure than in H_2O itself. A gradual aggregation of different types of clusters, viz. H_2O–H_2O, H_2O–cosolvent, and cosolvent–cosolvent, would lead to an increase in viscosity and a maximum value when aggregation is maximum, i.e. maximum structuredness (5, 30). The viscosity maxima sharpen and the heights of the maxima (as in other systems) increase with decreasing temperature. Increased temperature undoubtedly weakens BuOH–H_2O and TBA–H_2O interactions in H_2O-rich mixtures, leading to decomposition of cosolvent–H_2O complexes.

For most water + alcohol systems addition of water decreases the viscosity of the alcohol, whereas for the lower members of a homologous series there is an increase in viscosity. Thus the decrease in viscosity when water is added to *n*-butanol, *n*-pentanol, and *n*-hexanol contrasts sharply with the increase showed by methanol, ethanol, and *n*-propanol (31). *tert*-Butyl alcohol shows both types of behaviour; increased viscosity with initial addition of water at higher temperature, and decreased viscosity at low. The behaviour at 298 K in the alcohol-rich region is very similar to that found for the dielectric constant (32) of this system (Fig. 13). The minima of both properties correspond to the same alcohol content, and it is concluded that the minima are due to solvent structure changes. This conclusion is in accordance with ideas about the formation of Brown–Ives "centrosymmetric" associates, composed of one water and four alcohol molecules (33).

According to Kauzman and Eyring (34) the viscosity of a liquid can be expressed in terms of its activation parameters by the equation

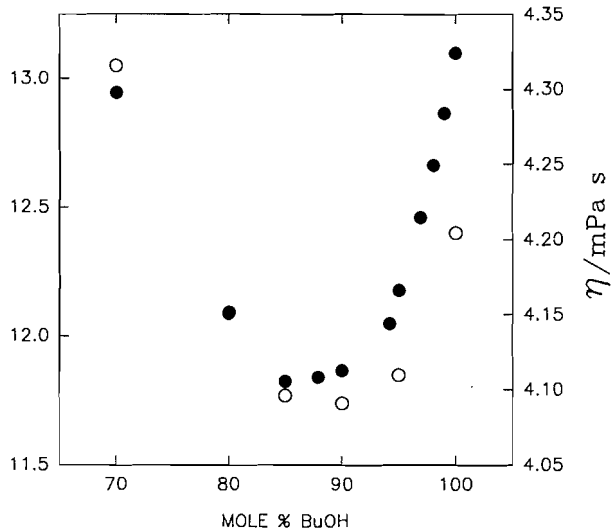

FIG. 13. Viscosity and dielectric constant (32) for H_2O + *tert*-butyl alcohol mixtures at 298 K. The shaded symbols denote viscosity, and the open circles dielectric constant values.

$$[4]\quad \eta = \frac{hN}{V}\exp\frac{\Delta H^*}{RT}\exp\frac{-\Delta S^*}{R}$$

where V/N is the molecular volume of the liquid, ΔH^* is the activation enthalpy for viscous flow, i.e., the energy required for a molecule to reach the top of a potential energy barrier so as to jump into a neighbouring hole, ΔS^* is the corresponding entropy of activation, T is temperature, and R is the gas constant. Since V and ΔS^* do not vary greatly with temperature the above equation can be simplified to the form suggested by Arrhenius (35)

$$[5]\quad \eta = A\exp\frac{E_a}{RT}$$

E_a is the "activation energy" for successive passage of individual molecules from one equilibrium position to another, that is the energy required to create a hole (36). In a hydrogen-bonded system, the motion will involve the breaking of a series of bonds and the formation of new bonds, and since viscous flow may involve the motion of clusters of molecules from one cage structure to another, the activation energy is a mean value for the processes which occur in the fluid. The large viscosity of water, relative to other molecular liquids with similarly sized molecules, can be attributed to the fact that in addition to the energy

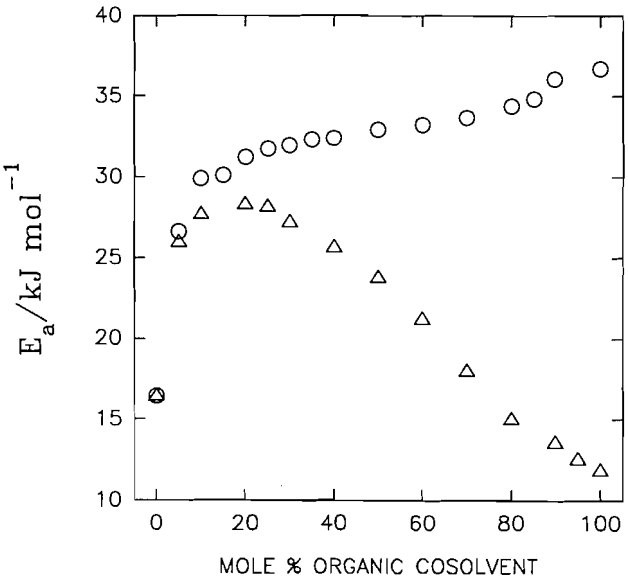

FIG. 14. Activation energies for viscous flow for H_2O + BuOH (○) and H_2O + TBA (▽) mixtures.

required for the formation of holes, the hydrogen bonds between the water molecules have to be broken to achieve an activated state for viscous flow.

Figure 14 shows the activation energies for viscous flow for the two binary systems studied, calculated from linear least squares fits of ln η vs. $1/T$. The estimated uncertainty in E_a is of the order 0.2 kJ mol^{-1}. Whereas E_a progressively increases as the TBA concentration increases up to 20 mol% (also the composition of maximum viscosity) and thereafter regularly decreases for further increase in the amine concentration, in the H_2O + BuOH system the activation energy increases monotonically with the concentration of BuOH. This trend is indicative of the larger energy required to induce translational motion in the alcohol molecule relative to the smaller water or lighter amine molecule. However, the change is larger at both extremes of the solvent composition. The present values are consistent with the limited data reported in the literature (25, 37). Other data appear not to be available for the H_2O + TBA system.

Substituent dependency in pentaamminemetal(II) complexes (M = Ru, Os) of styrenes probed by using carbon-13 nuclear magnetic resonance spectroscopic method and voltammetrical analysis

SHAW-TAO LIN[1] AND JIN-TSUEY JONG

Department of Applied Chemistry, Providence University, Sha-Lu, Taichung Hsien, Taiwan 433-01

Received October 10, 1993[2]

SHAW-TAO LIN and JIN-TSUEY JONG. Can. J. Chem. **72**, 1946 (1994).

The ^{13}C NMR spectra of $[M(NH_3)_5(styrene)]^{2+}$ (M = Ru, Os) demonstrate the substituent dependency of the interaction between the vinyl group and the metal moiety which suggests the modes of bonding. This phenomenon is also observed from the voltammetric analytical results which confirm the substituent dependency of the oxidation potential.

SHAW-TAO LIN et JIN-TSUEY JONG. Can. J. Chem. **72**, 1946 (1994).

Les spectres de RMN du ^{13}C du $[M(NH_3)_5(Styrène)]^{2+}$ (M = Ru, Os) mettent en évidence l'influence des substituants sur l'interaction entre le groupe vinyle et la portion métallique, et cette influence fournit des renseignements sur les modes de liaison. Ce phénomène a été également observé à partir des résultats des analyses voltamétriques qui confirment l'effet des substituants sur le potentiel d'oxydation.

[Traduit par la rédaction]

Introduction

Ruthenium and osmium complexes play an important role in catalytic processes, hence their characteristics have been widely studied (1). The olefin pentaammineruthenium complexes have been synthesized and studied using electrochemical and spectroscopic techniques (2). The cyclic voltammetric (CV) analysis of styrene pentaammineruthenium(II) chloride shows that the interaction between the vinyl group of styrene and ruthenium is independent of the substituent on the phenyl ring (2). NMR spectrometry is a very sensitive tool which can determine the electron density of nucleus in organic as well as organometallic compounds. Certain Pd–styrene and Pt–styrene complexes have been studied by NMR spectroscopic technique (3–6). The correlation between Hammett constants (σ_p or σ^+, σ^-) and $\Delta\delta$ for neutral, anionic and cationic Pt–styrenes were reported (4). We took advantage of this relationship in our study to investigate the substituent dependency of the bonding of styrenes with ruthenium and osmium, we have also used voltammetric analysis in our study.

The $[Ru(NH_3)_5(styrene)]Cl_2$ series was prepared by reducing $RuCl_3(NH_3)_5$ with amalgamated zinc in the presence of styrene (7). After stirring at room temperature for 3 h, the residue was removed by filtration and the excess styrene and solvent were removed under a reduced pressure. The resultant complexes were characterized by ^1H NMR and ^{13}C NMR spectroscopy. The ^1H NMR resonance of the vinyl hydrogens of styrenes shifted upfield by 3 ppm, exhibiting identical coupling patterns as the free styrenes. The chemical shifts of NH_3 protons appeared as two broad signals near 2.0 ppm and 3.9 ppm with an intensity ratio of 4:1 (Table 1). The four *cis* NH_3 ligands were located upfield. The chemical shifts of NH_3 protons and vinyl group protons were found to be substituent dependent. This substituent dependency indicates that the bonding between the metal and the vinyl group is influenced by the substituent and the phenyl ring. The equal chemical shifts of the four NH_3 ligands imply equal shielding by the phenyl ring, indicating free rotation between the metal and the vinyl group.

$[Os(NH_3)_5(styrene)]_2tfms$ (tfms:CF_3SO_3) was prepared by reducing $(NH_4)_2OsCl_6$ with NH_2NH_2, then substituting the chloride by trifluoromethylsulfonate, and finally reducing with amalgamated zinc in the presence of styrene. The resultant yellow complexes exhibited relatively poor solubility in water. The proton chemical shifts of the vinyl protons on the chelated styrene were observed to be similar to their Ru analogues except for an upfield shift of approximately 0.2 ppm (Table 1). The resonances of the aromatic protons were well separated from each other; meanwhile, unresolved patterns from Ru counterpart frequently appeared. A rapid exchange between NH_3 protons and D_2O protons was reported by Shepherd et al. (2). However, we observed NH_3 resonances near 2.3 and 3.25 ppm with relative intensities of 4:1 from the fresh D_2O solution. The lines disappear within 1 h and 16 h for the proton resonances at 2.3 and 3.25 ppm, respectively. Styrene protons showed no change in their resonance, suggesting that the disappearance of the NH_3 proton signal was due to an H–D exchange. Differences in NMR patterns in the aromatic region could imply that there are different bonding modes for styrene–Ru and styrene–Os complexes.

^{13}C chemical shifts are well correlated with the electron density of carbon nucleus (8). Relationships between substituent chemical shifts (SCS) and Hammett constants in aromatic systems have been previously studied (9). We have examined the substituent-dependency of vinyl carbons on styrenes. All chemical shifts were measured relative to NaTMPS in proton–noise decoupled spectra. The chemical shifts of free styrenes and their complexes of Ru and Os are tabulated in Tables 2, 3, respectively. The differences in chemical shifts ($\Delta\delta$) of C_α, C_β between free styrenes and chelated styrenes as shown in Table 2 range from 50 to 60 ppm upfield of the free ligand. On this series of Os complexes, the upfield shifts for C_α and C_β are 70–77 and 80–88 ppm, respectively (Table 3). These could have resulted from a change in the carbon character from sp^2 to sp^3 and from the influence of metal atoms.

The SCS (α, β) values are shifted upfield whenever the substituents on the aromatic rings are electron-donating groups, and vice versa. The substituent dependency of chemical shifts ($\Delta\Delta\delta$) for C_β and C_α varied from +3.09 to −3.42 ppm and +0.72 to −0.83 ppm for 4-Me_2N- to 4-CN groups (Table 2). Inverse substituent effects might possibly result from the altered back-bonding of metal rather than directly from the substituent.

[a]Resonances measured in D_2O at 25°C with NaTPMS as internal reference. Concentration of complexes: 0.22 mM. Δδ represent the shifts from free styrenes to chelated styrenes. Negative values indicate upfield shifts. ΔΔδ represent the difference in Δδ from unsubstituted styrene system.

[b]Concentration of **1***A*: 0.44 mM.

[c]Concentration of **1***A*: 0.66 mM.

[d]The complex was isolated as salt containing PF_6^-. Their chemical shifts of 25.9, 81.5, and 150.3 ppm were assigned for C_α, C_β, and C_1, respectively, with *p*-dioxane as internal reference (66.5 ppm).

The electron-donor groups enhance the electron density of vinyl group through the phenyl ring so as to resist the back-bonding from metal. Figure 1 illustrates the correlation between this dependency and the Hammett substituent constant (σ_p). An inflection apparently arises in the correlation lines with slopes −4.620 (r = 0.9448) and −1.218 (r = 0.9408) for C_β and C_α, respectively. When a substituent is changed, C_β shows a change in chemical shift with a higher sensitivity than C_α, indicating a preferential coordination of the metal centers to the *exo* vinyl substituents of the styrene rather than ring coordination, as stated previously by Shepherd et al. (2). This fact resembles that of anionic Pt–styrene compound series (4). On the Os complexes, for the same substituent the ΔΔδ of C_α and C_β varies from +4.01 to −3.53 ppm, and from −5.34 to +2.74 ppm, respectively (Table 3). The correlation between C_α and C_β on ΔΔδ and resonance parameter (σ^+, σ^-) shows slopes of −2.8777 (r = 0.9773) and +3.1596 (r = 0.9807), respectively (Fig. 2). The σ+ or σ− parameters are used for a better correlation with ΔΔδ indicating that the resonance effects are important for the Os series (10). This phenomenon is similar to that

[a]Resonance measure in D_2O at 25°C with NaTPMS as the internal reference. Concentration of analyte: 0.11 mM.
[b]J = 23.3 Hz.
[c]Too weak to assign.

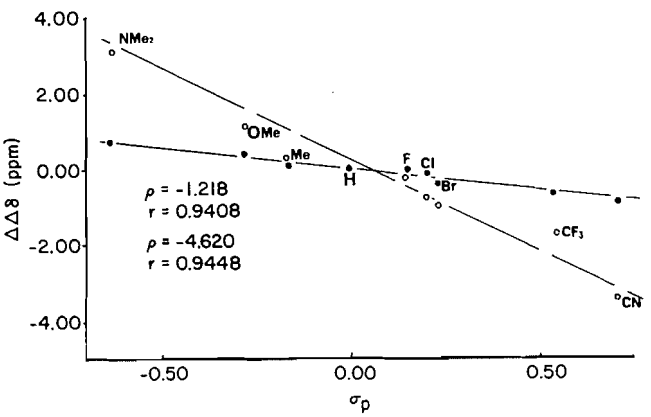

FIG. 1. ^{13}C SCS(α)(○), SCS(β)(●) values in ppm for $(NH_3)_5Ru(styrene)Cl_2$ vs. Hammett substituent constants (σ_p).

shown by neutral and cationic Pt–styrene complexes (4). The σ^+ and σ^- values are larger than that from ethylbenzenes (11) ethenylbenzenes (12). No significant change in chemical shifts is observed from varying concentrations of the analyte **1*A***, suggesting that no change in the dissociation of the ligand (styrene or NH_3) polarizability occurs in this series. Furthermore, no $\eta^2 \rightarrow \eta^4$ interconversion is observed as in (styrene)-Fe(dfepe)$(CO)_2$ (13).

Electrochemical methods are widely used in the study of organometallic compounds to understand their bonding patterns and chemistry. The oxidation potential for a specific electroactive species is expected to be related to their electron density as modulated by metal complexation. Ligands with a higher electron-donating nature would enhance the electron density of metal and lower the oxidation potential. The phenyl ring is capable of transmitting the electron cloud from the substituent

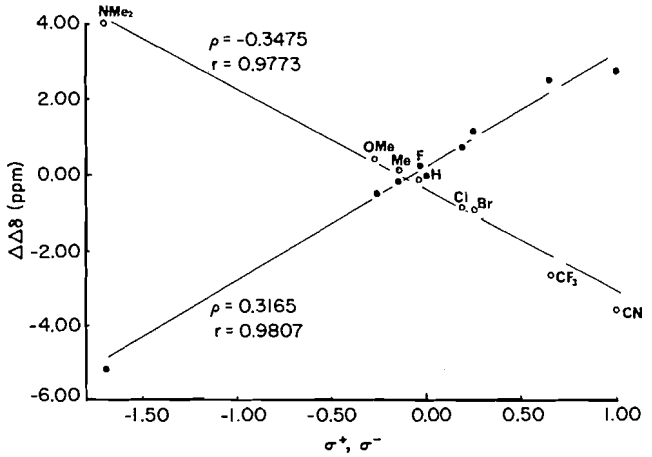

FIG. 2. ^{13}C SCS(α)(○), SCS(β)(●) values in ppm for $[(NH_3)_5Os(styrene)](CF_3SO_3)_2$ vs. Hammett substituents (σ^+, σ^-). The requirement of σ^+, σ^- parameter to obtain a better correlation infers that the resonance mechanism dominates the substituent effect on the bonding between Os and styrenes (10).

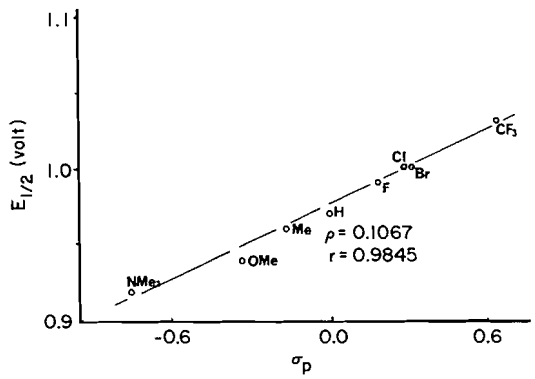

FIG. 3. Oxidation potential $E_{1/2}$ values in volt for $(NH_3)_5Ru(styrene)Cl_2$ vs. Hammett substituent constants (σ_p).

TABLE 4. $E_{1/2}$ values for $(NH_3)_5Ru(styrene)^{3+/2+}$ (**A**) and $(NH_3)_5Os(styrene)^{3+/2+}$ (**B**) complexes

	$E_{1/2}$, V	
Styrene	**A**	**B**
H	0.97	0.49
4-NMe_2	0.92	−0.10
4-OMe	0.94	0.46
4-Me	0.96	0.47
4-F	0.99	0.50
4-Cl	1.00	0.51
4-Br	1.00	0.58
4-CF_3	1.03	0.67
4-CN	0.72	0.61

to the vinyl group in this series of complexes. Therefore, the oxidation potentials of styrene–Ru and styrene–Os should be substituent dependent.

Some electrochemical studies dealing with Ru–styrene and Os–styrene complexes have been previously reported (2). Our results are similar to those found in literature (2). The ruthenium complex exhibits a quasi-reversible $Ru^{3+/2+}$ redux couple at +0.98 V vs. NHE. The osmium complex exhibits reversible redox behavior with $Os^{3+/2+}$ potential of 0.49 V vs. NHE. The $E_{1/2}$ values of series styrenes complexed with either Ru^{2+} or

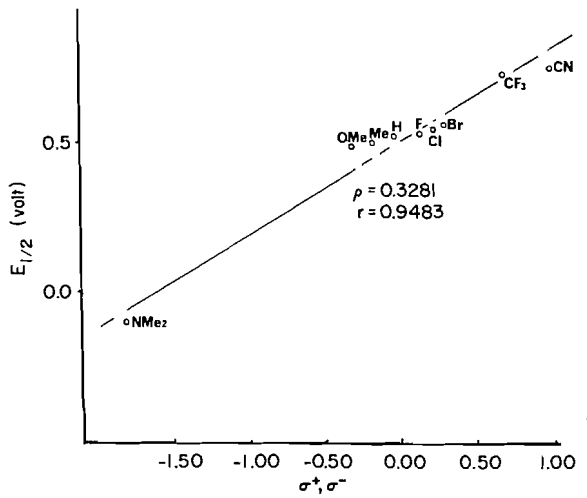

FIG. 4. Oxidation potential $E_{1/2}$ values in volts for $[(NH_3)_5Os(styrene)](CF_3SO_3)_2$ vs. Hammett substituent constant (σ^+, σ^-).

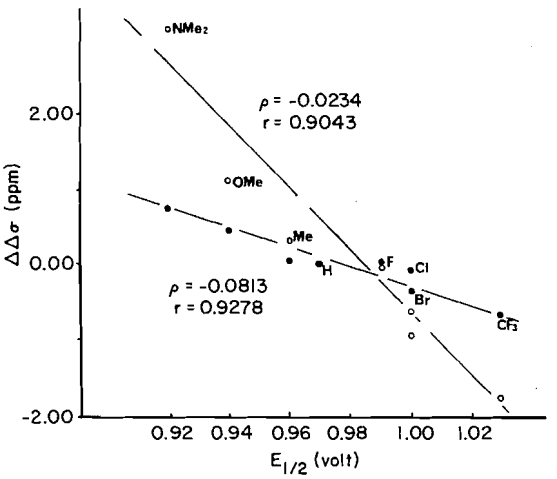

FIG. 5. ^{13}C SCS(α)(○), SCS(β)(●) values in ppm for $(NH_3)_5Ru(styrene)Cl_2$ vs. oxidation potential $E_{1/2}$ in volt.

Os^{2+} are listed in Table 4. The $E_{1/2}$ values in our study vary from +0.92 to +1.03 V and −0.1 to 0.67 V for Ru-, and Os-complexes in the study as the substituent changes from electron-donating character group (NMe_2) to electron-withdrawing group (CF_3). These $E_{1/2}$ values correlate well with the Hammett substituent constant σ corresponding to a slope of 0.1067 (r = 0.9845) and 0.3281 (r = 0.9483) for Ru^{2+} and Os^{2+}, respectively (Figs. 3, 4). The large ρ value indicates that the binding between metal–styrene is more substituent dependent. The correlation between the ΔΔδ and the $E_{1/2}$ are also shown in Figs. 5 and 6. The ΔΔδ of C_α and C_β shows the same correlation relationships with $E_{1/2}$ for Ru series; meanwhile the ΔΔδ of $C_{(\alpha)}$ and C_β displays different relationships with $E_{1/2}$ in the case of Os.

The differences in the substituent dependencies between ruthenium and osmium complexes infer the various fashions in bonding between styrene with ruthenium and osmium. The C_α and C_β display the same substituent dependency implying that both carbons bind with Ru, with back-bonding from the metal influenced by the substituent on the phenyl ring. In the case of Os, while the same substituent dependence on C_α infer that the bonding between C_α and Os is the same as their Ru counterpart. The difference in substituent dependency for C_β suggests

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12

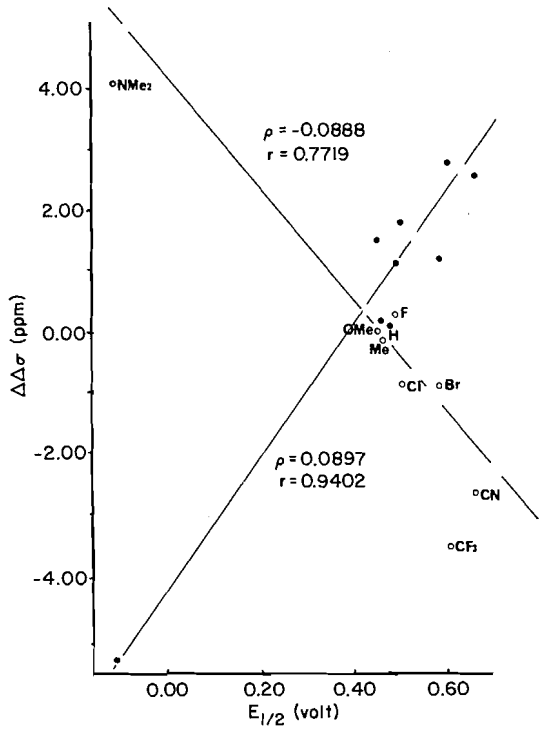

FIG. 6. ^{13}C SCS(α)(○), SCS(β)(●) values in ppm for $[(NH_3)_5Os(styrene)](CF_3SO_3)_2$ vs. oxidation potential $E_{1/2}$ in volt.

another type of interaction between C_β and Os. This interaction is consistent with the previous reports (2) in which a vinyl and an allyl type bonding for the Ru and Os complexes of olefine are proposed. The difference in bonding between the vinylic ligand and metal for Os(II) or Ru(II) is observed in this work by ^{13}C NMR variation in C_α or C_β upon changing of the substituents of the phenyl ring.

Experimental section

Styrenes were obtained either commercially or prepared from the corresponding benzaldehyde via the Wittig reaction (14) $[Ru(NH_3)_5Cl]Cl_2$ and $(NH_4)_2[OsCl_6]$ were obtained from Aldrich Co. $[Ru(NH_3)_5Cl]Cl_2$ (15), $[Ru(NH_3)_5(styrene)]Cl_2$ (2), $[Os(NH_3)_5\text{-}N_2]Cl2$ (16), $[Os(NH_3)_5(tfms)](tfms)_2$ (17), and $[Os(NH_3)_5(styrene)]\text{-}(tfms)_2$ (2) were prepared according to literature.

The ^{13}C NMR data of 0.22 mM of analyte in D_2O were recorded on a Bruker AC-250 spectrometer at 62.9 MHz; 128 K data points were collected within a range of 12 kHz. All chemical shifts were measured relative to NaTMPS in proton–noise decoupled spectra.

Electrochemical studies were performed on an EG&G Princeton Applied Research Model 362, operating in the cyclic voltammetry mode. A glassy-carbon working electrode, potassium chloride calomel electrode (SSCE) as reference, and a Pt-wire auxilliary electrode were employed. The $E_{1/2}$ values were obtained at 4.03×10^{-4} M in 0.1 F NaCl solution with a scan rate of 50 mV/s, $t = 25°C$.

Crystal structure – reactivity correlations in the solid state photochemistry of *N*-(*tert*-butyl)succinimide

TAI Y. FU, JOHN R. SCHEFFER,[1] AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, BC V6T 1Z1, Canada

Received January 25, 1994

TAI Y. FU, JOHN R. SCHEFFER, and JAMES TROTTER. Can. J. Chem. **72**, 1952 (1994).

In order to provide experimental evidence on the stereoelectronic requirements for intramolecular hydrogen atom abstraction by carbonyl oxygen, *N*-(*tert*-butyl)succinimide, **1**, was investigated by the crystal structure – reactivity correlation method. In this method, the success or failure of a given reaction in the crystalline state is correlated with the geometric parameters associated with the process as determined by X-ray crystallography. In the case of *N*-(*tert*-butyl)succinimide, the crystal and molecular structure shows that the molecule adopts a conformation in which there are very close contacts (d = 2.17–2.24 Å) between the carbonyl oxygen atoms and certain γ-hydrogen atoms on the *tert*-butyl group. In accord with these close contacts, ultraviolet irradiation of *N*-(*tert*-butyl)succinimide in the crystalline state leads to transfer of one of the γ-hydrogen atoms from carbon to oxygen. This produces a 1,4-biradical which closes to form a cyclobutanol, and the cyclobutanol undergoes ring opening to afford the final stable product, tetrahydro-1*H*-azepine-2,5-dione, **2**. The crystal and molecular structure of photoproduct **2** is also reported. In contrast to many solid state transformations, there was no discernable melting of the crystals during reaction, and complete conversions of **1** into **2** could be achieved. The isolated chemical yield of photoproduct **2** from the solid state reaction (79%) is in fact considerably higher than that reported by Kanaoka and Hatanaka for the corresponding solution phase process (49%). This permitted the solid state reaction to be followed to 100% conversion by X-ray powder diffractometry, which showed that the process is a single crystal-to-polycrystalline transformation involving a regular and progressive conversion of **1** into **2** with no obvious diffraction peaks that might be attributable to the intermediate cyclobutanol.

TAI Y. FU, JOHN R. SCHEFFER et JAMES TROTTER. Can. J. Chem. **72**, 1952 (1994).

On a utilisé la méthode de corrélation structure-réactivité du cristal dans le but d'obtenir des preuves expérimentales des conditions stéréoélectroniques nécessaires pour l'abstraction intramoléculaire d'un atome d'hydrogène par l'oxygène du carbonyle de la *N*-(*tert*-butyl)succinimide, **1**. Dans cette méthode, le succès ou l'échec d'une réaction donnée dans l'état cristallin est relié aux paramètres géométriques associés au processus réactionnel tels que déterminés par cristallographie de rayons X. Dans le cas de la *N*-(*tert*-butyl)succinimide, la structure cristalline et moléculaire montre que la molécule adopte une conformation dans laquelle les atomes d'oxygène du carbonyle se rapprochent de très près (d = 2,17–2,24 Å) de certains des atomes d'hydrogène en position du groupe *tert*-butyle. Conformément à ces rapprochements étroits, l'irradiation ultraviolette de la *N*-(*tert*-butyl)succinimide à l'état cristallin conduit au transfert d'un des atomes d'hydrogènes en position γ de l'atome de carbone vers l'atome d'oxygène. Ce transfert donne un biradical-1,4 qui par cyclisation conduit au cyclobutanol, et le cyclobutanol par ouverture du cyle conduit au produit final stable la tétrahydro-1*H*-azépine-2,5-dione, **2**. On rapporte également la structure cristalline et moléculaire du produit photochimique **2**. Contrairement à beaucoup de transformations à l'état solide, on n'a pas observé la fusion des cristaux pendant la réaction et on a pu réaliser la transformation complète du composé **1** en composé **2**. Le rendement en produit photochimique **2** isolé à partir de la réaction en phase solide (79%) est en fait considérablement plus élevé que celui rapporté par Kanaoka et Hatanaka pour la réaction correspondante en solution (49%). Ce qui permet de suivre la réaction en phase solide jusqu'à sa transformation à 100% par diffraction de rayons X des poudres laquelle révèle que le processus est la transformation d'un monocristal en un polycristal faisant intervenir une transformation régulière et progressive du composé **1** en composé **2** sans la présence évidente de pics que l'on pourrait attribuer à un intermédiaire cyclobutanol.

[Traduit par la rédaction]

Introduction

One of the goals of our research in solid state organic photochemistry has been to delineate the stereoelectronic requirements for intramolecular hydrogen atom abstraction by carbonyl oxygen. The most widely known general reaction that involves such a process is the photochemical Norrish type II reaction of ketones containing accessible γ-hydrogen atoms (1). Following n,π* excitation of such compounds, the γ-hydrogen atom is transferred from carbon to oxygen through a six-membered transition state, and the resulting 1,4-biradical can revert to starting material or react further to give one or more stable products.

Despite extensive work on the details of this synthetically and mechanistically important reaction, direct experimental evidence on the preferred geometry for the hydrogen atom transfer step is rare. This stems from the fact that most studies have been carried out on conformationally mobile systems for which the exact geometric disposition of the atoms involved in the six-membered transition state is not known. Leaving aside for the moment the important question of ground state versus excited state geometry, if one could establish ground state geometric guidelines for successful hydrogen atom abstraction, one could hope to make the Norrish type II reaction and other similar intramolecular hydrogen abstraction processes predictable through MM2-type force field calculations.

Our approach to this problem has been to study the hydrogen abstraction reactions in the *solid state* and to correlate the success or failure of the reactions with the geometric parameters as determined by X-ray crystallography, the so-called crystal structure – reactivity correlation method. The advantage of this approach is that the ketone reactants are locked in well-defined conformational minima in the solid state for which the intramolecular C=O···Hγ geometry can be accurately measured. A review article summarizing some of our initial results in this area has been published (2).

In this paper we report an application of the crystal structure – reactivity correlation method to the hydrogen abstraction reaction of *N*-(*tert*-butyl)succinimide **1** (Scheme 1). This compound was chosen because it is crystalline and is known to

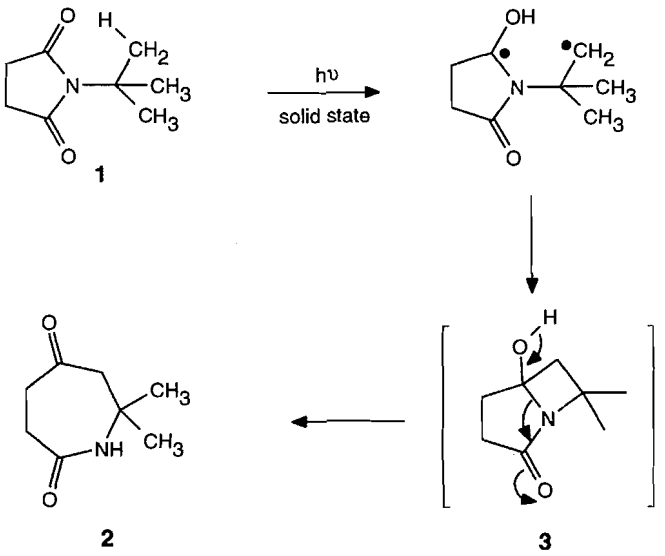

SCHEME 1

undergo a Norrish type II-like photorearrangement in solution (3). A further consideration was that, because the molecule has nine γ-hydrogen atoms, it seemed virtually certain that one or more of them would be located favorably for abstraction in the solid state, regardless of the conformation adopted by the molecule in the crystal.

Experimental

Melting points were taken on a Fisher Johns melting point apparatus and are uncorrected. Infrared spectra were recorded on a Perkin-Elmer 1710 Fourier transform spectrophotometer, and the X-ray powder diffraction measurements were carried out on a Rigaku Geigerflex PMG-VH diffractometer using Ni-filtered Cu-Kα radiation (λ = 1.54184 Å), scan range $5° \leq 2\theta \leq 50°$. Gas chromatographic analyses were performed on a Hewlett-Packard 5890 capillary instrument fitted with a 15 m DB-1 column, flame ionization detector and 3392A integrator. *N*-(*tert*-butyl)succinimide, **1**, was prepared according to the procedure of Schreiber and Fernandez (4) and recrystallized from hexane to afford prisms, mp 44°C (lit. (4) mp 49–50°C).

Photolysis of N-(tert-*butyl)succinimide* ***1*** *in the solid state*

N-(*tert*-Butyl)succinimide, **1** (1.00 g, 6.5 mmol), was ground into a fine powder by means of an agate mortar and pestle and then distributed in a thin layer between two quartz plates. The plates were sealed inside a nitrogen-filled polyethylene bag and irradiated by using a 12 W Canrad-Hanovia low pressure mercury lamp available from Ace Glass, Inc. At intervals, powder diffraction and gas chromatographic analyses were taken of the reaction mixture, the results of which are shown in Figs. 1 and 2. After 12 h, reaction was complete and the product was chromatographed on silica gel (eluting solvent 10% acetone in hexanes) to afford 0.79 g (79%) of tetrahydro-1*H*-azepine-2,5-dione, **2**. The material thus obtained was recrystallized from acetone to afford plates, mp 174.5–175.5°C (lit. (3) mp 175–176°C).

X-ray crystallographic analyses of N-(tert-*butyl)succinimide,* ***1****, and tetrahydro-1*H*-azepine-2,5-dione,* ***2***

Crystallographic data for compounds **1** and **2** appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 23 reflections with $2\theta = 7.9–19.8°$ for **1** and 17 reflections with $2\theta = 89.7–105.8°$ for **2**. The data for **1** and **2** were processed,[2] corrected for Lorentz and polarization effects. A linear decay correction was applied for **2** based on the intensities of three standard reflections, measured every 200 reflections throughout the data collection. Absorption (empirical, based on azimuthal scans for three reflections) correction was also applied for **2**. No decay or absorption corrections were applied for **1**.

Structure analyses of **1** and **2** were initiated in the space groups $P2_1/n$ and $P2_1/c$ respectively on the basis of *E*-statistics, the choices being confirmed by subsequent successful solutions and refinements of the structures. The asymmetric unit of **1** contains two molecules. The structures were solved by direct methods, the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier synthesis. The non-hydrogen atoms were refined with anisotropic thermal parameters. The amide hydrogen atom, H(13), in **2** was refined with isotropic thermal parameters. All the other hydrogen atoms in **1** and **2** were fixed in idealized positions (C—H = 0.95 Å, $B_H = 1.2B_{\text{bonded atom}}$). Corrections for secondary extinction were applied for both structures, the final values of the extinction coefficients being 7.39×10^{-7} for **1** and 1.37×10^{-5} for **2**. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International tables for X-ray crystallography (5). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, and angles appear in Tables 2–4, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and measured and calculated structure factor amplitudes for both structures are included as supplementary material.[3]

Results and discussion

The first study of the photochemistry of *N*-(*tert*-butyl)succinimide **1** was by Kanaoka and Hatanaka in 1976 (3). They reported that irradiation of this compound at 2537 Å in acetonitrile solution leads to a 49% yield of ketolactam **2** and suggested that the reaction involves a Norrish type II γ-hydrogen abstraction, Yang cyclization of the resulting 1,4-biradical to give cyclobutanol **3** (not isolated), and ring opening of **3** to afford **2** (Scheme 1). Similar results were obtained for a number of other succinimide derivatives.

Our first task was to ascertain whether the same reaction can be induced photochemically in the solid state. It can. Crystals of *N*-(*tert*-butyl)succinimide **1**, mp 44°C from hexane, $n \rightarrow \pi^*$ UV $\lambda_{\text{shoulder}}$(MeCN) = 242 nm (ε 112), were irradiated in a Rayonet reactor at 2537 Å under nitrogen. When carefully grown, transparent single crystals of **1** were photolyzed, the extent of conversion to photoproduct **2** (as indicated by gas chromatography) leveled off at approximately 60%, and continued irradiation led to little additional product. The crystals did not change in appearance except for the development of an overall light yellow tinge and an opaque center; no melting was detectable. Gas chromatographic analysis of the crystals indicated a very clean reaction with compound **2** as the only photoproduct. As it seemed likely that the limiting conversion was due to a surface reaction that screens the interior of the crystal, the crystals were ground in a mortar and pestle and photolyzed as a finely divided powder dispersed between two quartz plates. Under these conditions, complete conversions of **1** to **2** could be achieved, and photoproduct **2** could be isolated in 79% yield

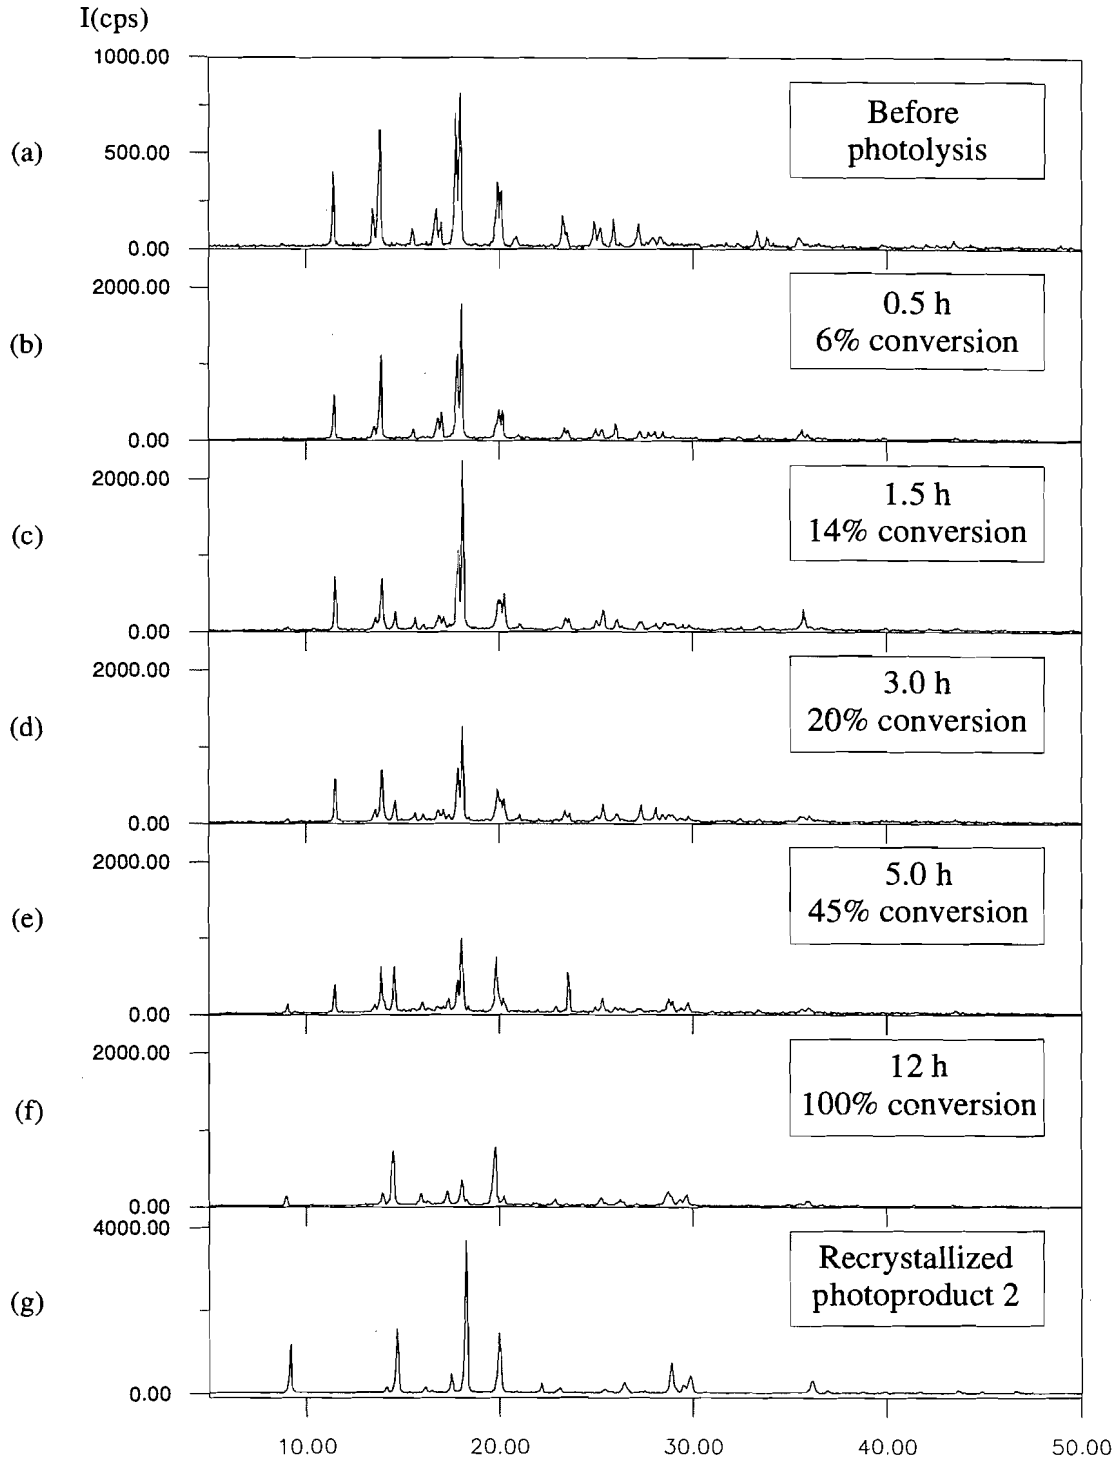

FIG. 1. X-ray powder diffraction pattern at different stages of photolysis of compound **1** ($5° \leq 2\theta \leq 50°$).

following column chromatography to remove traces of the unknown yellow material. The solid state chemical yield is considerably higher than the reported solution phase yield of 49%. Microscopic examination of the polycrystalline sample following complete conversion runs revealed that the majority of the crystallites remained transparent (albeit slightly yellow) with no evidence of melting.

Concomitant with the chemical studies, single crystal X-ray diffraction studies of *N*-(*tert*-butyl)succinimide, **1**, were undertaken. In order to confirm its structure as well as to be able to interpret the X-ray powder diffraction data (vide infra), the X-ray single crystal structure of photoproduct **2** was also determined. Figure 3 shows the results of these investigations. Compound **1** crystallizes in space group $P2_1/n$ with two independent molecules in the asymmetric unit, only one of which is shown in Fig. 3; the other has a very similar (but not identical) conformation. Photoproduct **2** crystallizes in space group $P2_1/c$ with one molecule per asymmetric unit. Details of the crystal structure determinations are given in the Experimental section.

Careful examination of the crystal structure of **1** reveals the

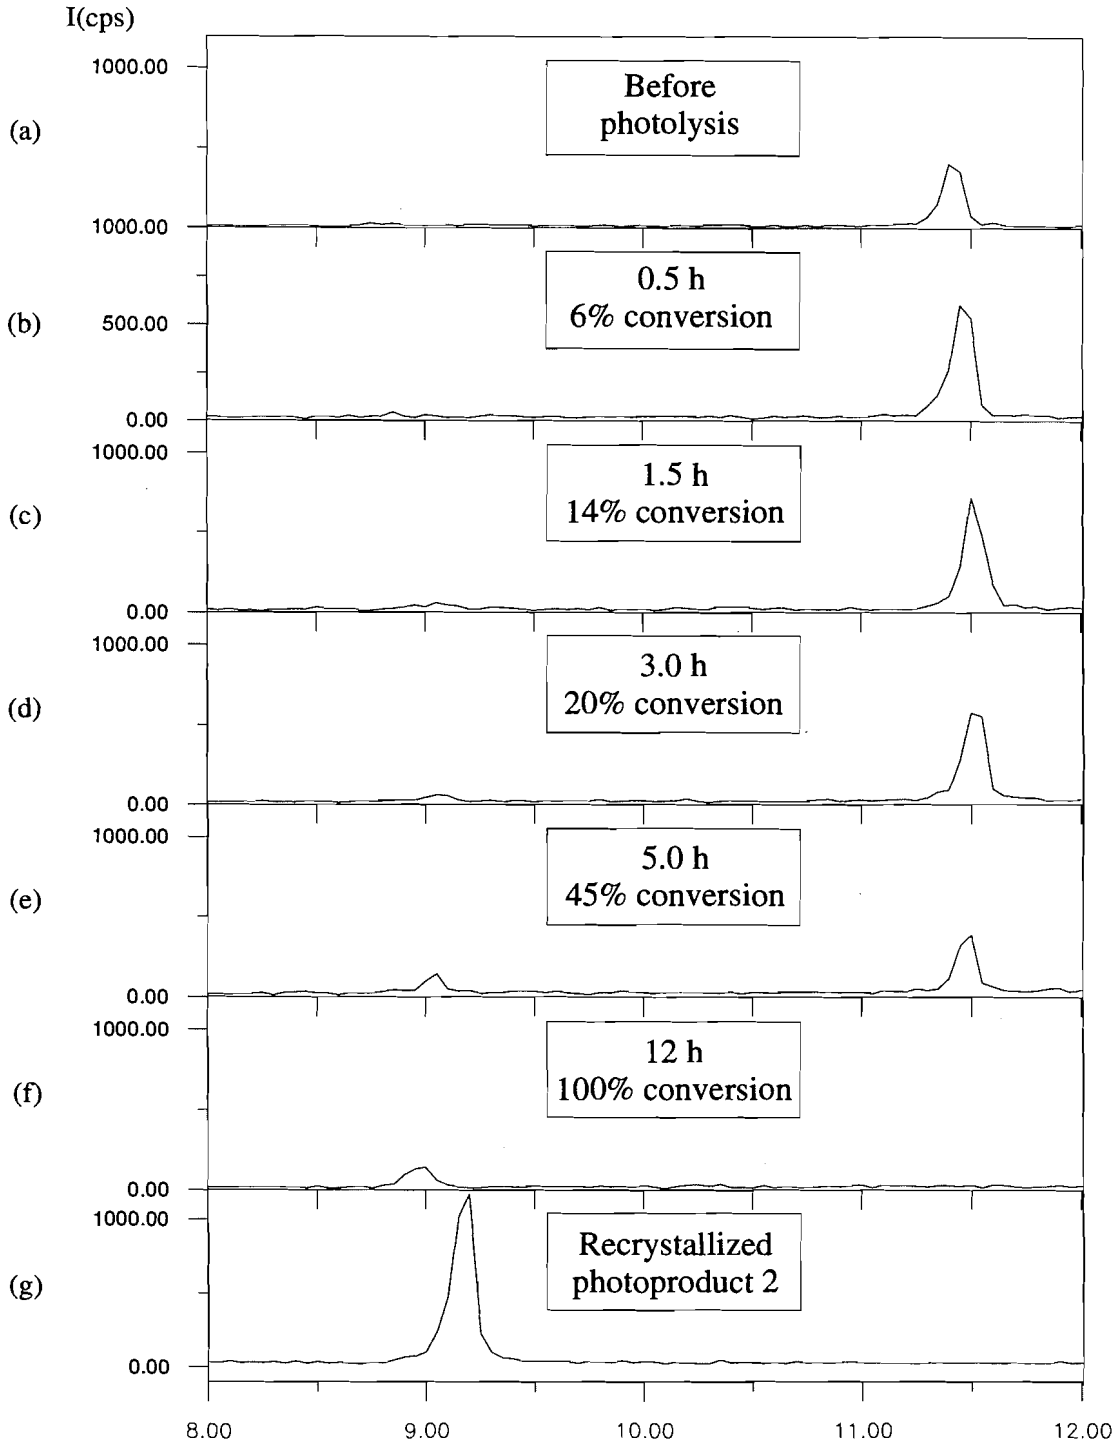

FIG. 2. X-ray powder diffraction pattern at different stages of photolysis of compound **1** ($8° \leq 2\theta \leq 12°$).

approximate planarity of the imide moieties: O1—C1—N1—C4 = 172.8(7)° and O2—C4—N1—C1 = 168.1(6)° (independent molecule 1); O3—C9—N2—C12 = −167.4(6)° and O4—C12—N2—C9 = 166.3(6)° (independent molecule 2). The imide C—N bond lengths are found to be around 1.4 Å and are longer than a normal amide C—N bond distance (1.32 Å). The introduction of an additional carbonyl group clearly results in a decrease in delocalization of the amide nitrogen lone pair. Such an effect has been suggested to be important in the photoreactivity of imides in hydrogen abstraction reactions (6). The crystal structure of photoproduct **2** shows that the amide hydrogen and the ketone carbonyl are held together by intermolecular H bonding: O(1)...H(13) = 2.14 Å; O(1)...N(1) = 2.95 Å.

With the photochemical and crystallographic results in hand, we are now ready to correlate the two in terms of the hydrogen abstraction geometry. As shown in Fig. 4, intramolecular hydrogen atom abstraction may be characterized geometrically by four parameters: d, the C═O···Hγ abstraction distance; ω, the degree to which the abstracted hydrogen atom lies outside the mean plane of the carbonyl group; Δ, the C═O···Hγ angle; and θ, the C—H···O angle (1, 2).

The crystallographically-determined values of these four

Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

parameters for *N*-(*tert*-butyl)succinimide, **1**, are compiled in Table 5. There are six separate values for each parameter because there are three "abstractable" hydrogen atoms for each of the two independent molecules in the crystallographic asymmetric unit. The term "abstractable" refers to hydrogens for which the abstraction distance d is less than 3.1 Å, since our experience (2) and that of others (7) have been that hydrogen atoms that exceed this distance are unreactive towards intramolecular abstraction. Also included in Table 5 are the hypothetical "ideal" values for d, ω, Δ, and θ. The value for d of 2.72 Å comes from the sum of the Van der Waals radii for hydrogen and oxygen (8), and the value of 0° for ω is based on the well-established principle that oxygen utilizes its in-plane n,π* n-orbital for abstraction (9). This orbital makes an angle of between 90° and 120° with the C=O axis depending on the model selected (2), hence the same range of values for Δ; the value of 180° for θ is theoretically based (10).

Four of the six values of d recorded in Table 5 are remarkably short, ranging from 2.17–2.24 Å. These represent the shortest hydrogen abstraction distances yet measured by the crystal structure – reactivity correlation method. These contacts are so short that they should, in fact, be considered as C—H···O hydrogen bonds (11). In other type II systems that we have investigated by the crystal structure – reactivity correlation method, average values for d have been much closer to the hypothetical ideal value of 2.72 Å (2, 12, 13). The four γ-hydrogen atoms that are favored for abstraction in *N*-(*tert*-butyl)succinimide by low values of d are also associated with much more favorable values of ω, Δ, and θ (Table 5). In overall terms, these four hydrogen atoms are better situated for abstraction than any that have been reported heretofore. Of course, there is no way of determining experimentally which of the six hydrogen atoms listed in Table 5 is abstracted, since abstraction of any one of them leads to the same product. Based on literature analogy, however, it seems likely that H(8) (d = 2.88 Å) and H(20) (d = 2.98 Å) are *not* abstracted. This stems from our work with 1,8-cyclohexadecanedione (14), in which it was demonstrated through product studies that abstraction of a γ-hydrogen for which d = 2.72 Å, ω = 53°, Δ = 81°, and θ = 116° completely dominates abstraction of a different γ-hydrogen atom for which d = 2.99 Å, ω = 59°, Δ = 66°, and θ = 117° (Fig. 4). It is necessary at this point to remind the reader that the geometric data

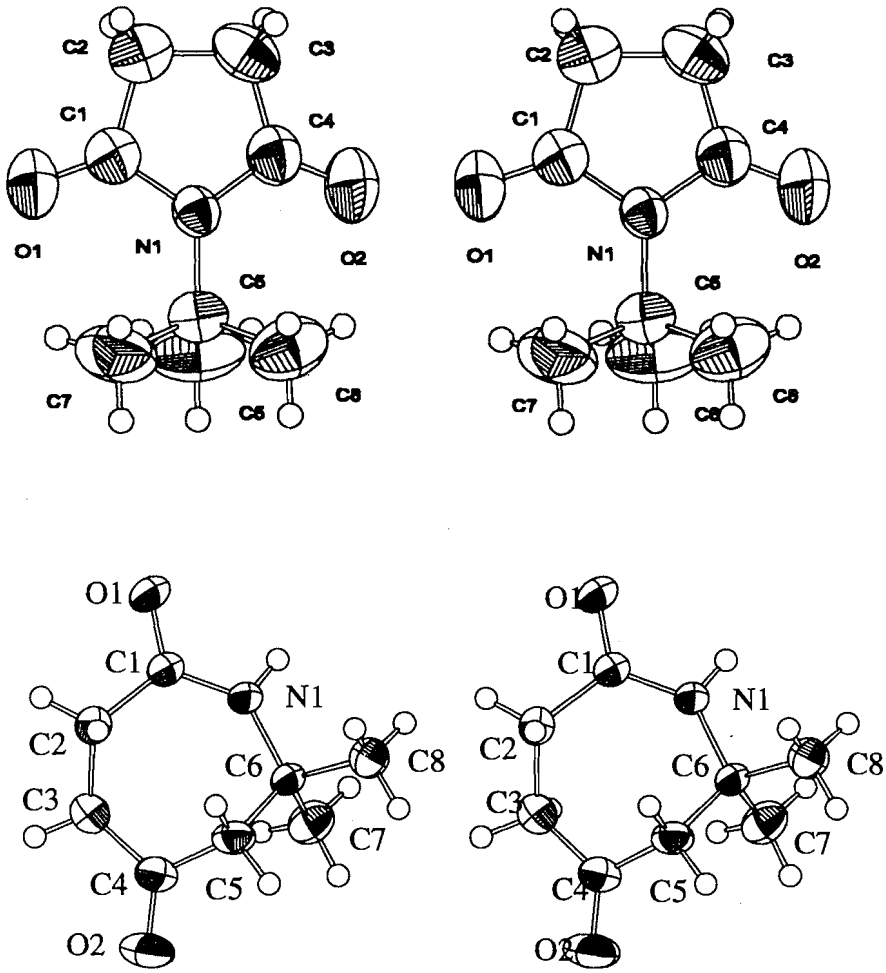

FIG. 3. Stereoscopic views of *N*-(*tert*-butyl)succinimide, **1**, (top) and its photoproduct, tetrahydro-1*H*-azepine-2,5-dione, **2**, (bottom) showing atom labeling; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

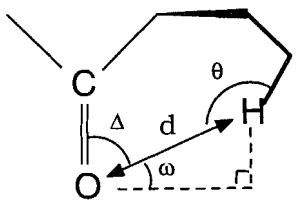

FIG. 4. Definition of geometric parameters *d*, ω, Δ, and θ for intramolecular hydrogen atom abstraction.

reported in Table 5 and discussed above are ground state data. Recent theoretical calculations by Houk et al. indicate that excitation of amides and imides results in pyramidalization of both the carbonyl and amine groups (15). If confirmed, this means that the present crystallographic data should serve as only a rough guideline to hydrogen abstractability in similar compounds.

We turn now to a second aspect of the solid state photochemistry of *N*-(*tert*-butyl)succinimide that interested us, namely the question of whether cyclobutanol **3** could be detected at intermediate stages of the reaction. The course of the photoreaction was followed by solid state Fourier transform infrared spectroscopy and X-ray powder diffractometry. The infrared studies were carried out by recording the FTIR spectra of KBr discs of compound **1** as a function of irradiation time. This showed a regular and progressive transformation of *N*-(*tert*-butyl)succinimide into keto-lactam **2** with no obvious absorptions for cyclobutanol **3**; the final infrared spectrum was identical to that of pure **2**. We tentatively conclude from these results that cyclobutanol **3** undergoes ring opening to **2** nearly as rapidly as it is formed and is present, if at all, only in small steady-state amounts.

A similar conclusion was reached from the X-ray powder diffraction studies. Figure 1 shows the powder diffraction patterns as a function of the extent of conversion as determined by gas chromatography. We interpret the powder patterns in terms of a two component phase diagram in which the starting material **1** and the photoproduct **2** are only partially soluble in the solid state (16). Thus, initial photolysis induces small shifts in the diffraction peaks that correspond to changes in the cell dimensions of the primary solid solution formed between compound **1** and a small amount of photoproduct **2**. Figure 2 shows an expansion of the powder patterns in the region $8° \leq 2\theta \leq 12°$. New diffraction peaks corresponding to a second phase rich in compound **2** (the terminal solid solution) begin to grow in between 6% and 14% conversion as the solubility limit of compound **2** in the primary solid solution is reached. At the same time, the diffraction peaks due to the primary solid solution stop shifting at this two phase stage, and gradually decrease in intensity as reaction proceeds. At complete conversion, the powder pattern indicates that the reaction mixture retains the crystal structure of the

terminal solid solution, which is different from (but very similar to) the crystal structure of the recrystallized photoproduct **2** (Fig. 1*g*). Analysis of other regions of the powder diffraction data lead to identical conclusions.

It seems likely that the single crystal-to-polycrystalline nature of the phototransformation of **1** to **2** is due to the extensive molecular reorganization that is associated with the process along with the polar nature of the photoproduct and its relatively high melting point (174.5–175.5°C). In contrast to single crystal-to-single crystal transformations, which occur when the product molecules form solid solutions with the unreacted starting material in all proportions (17), single crystal-to-polycrystalline reactions take place when the solubility limit of the product in the reactant lattice is reached at a relatively early stage of reaction, and the product begins to "precipitate out" in its own crystal structure (17, 18). In the present instance, it seems quite reasonable that compounds **1** and **2**, which have very different geometries, polarities, and melting points, would have limited mutual solubility.

Photolysis of 3-chloro-3-aryldiazirines in the presence of amines and allyl alcohol

MICHAEL T.H. LIU,[1] YURI N. ROMASHIN, AND T.K. VENKATACHALAM
Department of Chemistry, University of Prince Edward Island, Charlottetown, PE C1A 4P3, Canada

Received March 1, 1994

This paper is dedicated to Professor Charles W. Jefford on the occasion of his 65th birthday

MICHAEL T.H. LIU, YURI N. ROMASHIN, and T.K. VENKATACHALAM. Can. J. Chem. **72**, 1961 (1994).

When photolysis of arylchlorodiazirines is performed in the presence of either alkyl- or allyl-substituted amines, either *N*-alkyl- or *N*-allyl-substituted amines result as the sole high-yield (64–93%) products. Photolysis in the presence of phenylallylamine produces a rearranged product in poor yield (11–15%) whereas the reaction of allyl alcohol with arylchlorocarbene gives exclusively diallyl acetals in high yield (70%). The rate constants for these reactions were obtained by laser flash photolysis. Allyl phenyl ether forms a cyclopropanated product when treated with arylchlorocarbene. The different behaviour of these compounds may be attributed to the nucleophilicity at the nitrogen and oxygen centres of these compounds, when the latter are subjected to the substitutions described above. The formation of a cyclopropanated product when allyl phenyl ether is used differs from the reaction of bis (methoxycarbonyl) carbene with allyl ethers, as reported in the literature. The formation of this cyclopropanated product demonstrates the absence of an oxonium ylide intermediate during the reaction.

MICHAEL T.H. LIU, YURI N. ROMASHIN et T.K. VENKATACHALAM. Can. J. Chem. **72**, 1961 (1994).

La photolyse d'arylchlorodiazirines en présence soit d'amines alkyl- ou allyl-substituées, les seuls produits qui se forment (avec d'excellents rendements allant de 64 à 93%) sont les imines *N*-alkyl- ou *N*-allyl-substituées. La photolyse en présence de phénylallylamine conduit à un produit de transposition, avec un faible rendement (11–15%) alors que la réaction de l'alcool allylique avec l'arylchlorocarbène fournit exclusivement les acétals diallylique avec d'excellents rendements (70%). On a déterminé les constantes de vitesse de ces réactions en faisant appel à la photolyse éclair. Lorsqu'on traite l'oxyde d'allyle et de phényle avec de l'arylchlorocarbène, il se forme un produit cyclopropane. Les comportements divers de ces composés peut être attribué au caractère nucléophile des centres azote et oxygène de ces composés lorsqu'ils sont soumis aux réactions de substitutions décrites plus haut. La formation du dérivé cyclopropane lorsqu'on utilise l'oxyde d'allyle et de phényle diffère de ce qui est rapporté dans la littérature pour la réaction du bis-méthoxycarbonyl-carbène avec des éthers allyliques. La formation de ce dérivé cyclopropane démontre l'absence d'un intermédiaire oxonium ylure durant cette réaction.

Introduction

The reactions of some carbenes with allyl-substituted ethers, amines, and halides have been studied (1) and reviewed (2). In the case of allyldimethylamine and allyldiethylamine, the reactions go through nitrogen ylides as intermediates and are completed by either a 1,2 allylic shift (3) or a 2,3-sigmatropic rearrangement (4). Reactions of carbenes with allylic ethers such as allyl methyl ether, γ-methylallyl ether, and γ, γ-dimethylallyl ether yield products derived from 2,3-sigmatropic rearrangement of an oxonium ylide and a cyclopropanated product (1). Ylide formation in the above cases was favoured by a factor of 3:2 and the steric factor greatly influences the ratio of insertion to addition products.

Earlier reports described the reaction of phenylchlorocarbene with secondary amines such as diethylamine (5a) and of benzylchlorocarbene with alcohols (5*b*,*c*). These reactions led to products derived from the insertion of carbenes into N—H and O—H bonds. The present study investigates the products resulting from the reaction of phenylchlorocarbene with primary amines such as allylamine and a primary alcohol, namely, allyl alcohol.

Results and discussion

3-Chloro-3-aryldiazirines **1** were synthesized by Graham oxidation of the corresponding amidine hydrochlorides (6). Irradiation (350 nm) of the diazirines **1** in hexane (0.1 M) at 25°C yielded arylchlorocarbenes, **2**, which in the presence of a 10-fold excess of allylamine gave *N*-allyl imines **4** in high yield (64–93%) as the only product. These products were isolated by column chromatography, and their structure confirmed by IR, NMR, GC–MS, and by comparison with authentic samples prepared according to literature procedures (7). The formation of imines **4** probably occurs through a three-stage process of ylide **3** formation, followed by 1,2-hydrogen migration and subsequent elimination of HCl (Scheme 1). Several amines of various structures, for example, propylamine, isopropylamine, *n*-butylamine, ethanolamine, and aniline, reveal that a similar mechanism is operating in all cases since the Schiff bases were the only observed product in these reactions.

The reaction of arylchlorocarbene **2** with allyl aniline yields *N*-phenylimines **6** as the only detectable product to be isolated, in poor yield, by column chromatography on alumina (11% for phenylchlorocarbene and 15% for *p*-chlorophenylchlorocarbene). Scheme 2 shows the plausible pathway through which the reaction proceeds in the example cited above.

The formation of imines such as **6** probably proceeds via the nitrogen ylide intermediate **5**, followed by either 1,2-allyic or 2,3-sigmatropic shift and subsequent HCl elimination. The latter process is the possible driving force for product formation in the reaction of arylchlorocarbenes **2** with both primary and secondary amines. The insertion of singlet carbenes, such as arylchlorocarbenes, into the N—H bond of amines likely proceeds via the formation of an ammonium ylide followed by the migration of the hydrogen atom from the nitrogen to the carbon center. Laser flash photolysis (LFP) of 3-chloro-3-aryldiazirine in the presence of diethylamine (5*a*) enabled direct observation of the UV spectrum of ammonium ylide (λ = 340 nm). As a result, the formal insertion into the N—H bond is classified as a two-step process. The lifetime of the ylide is ~30 ns at 25°C when the concentration of diethylamine is 0.05 M. Furthermore, the kinetic parameters for the 1,2 hydrogen shift in this ylide: E_a = 5.9 kcal mol^{-1} and log A = 12.0, have recently been determined (5*d*). In addition, the 1,2-H shift in the ylide was catalyzed by

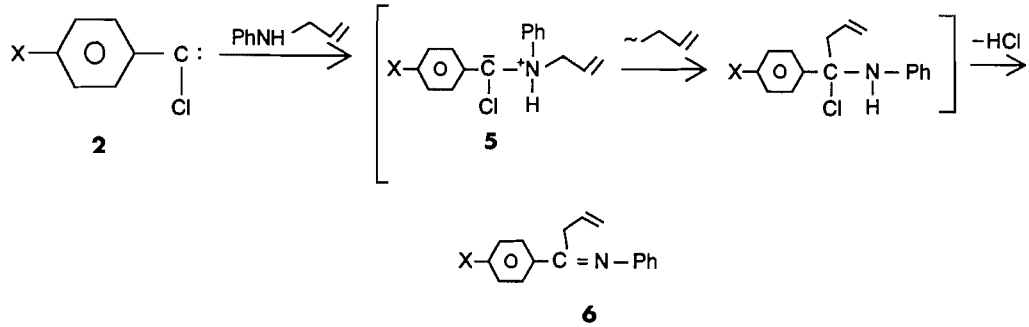

SCHEME 2

the external diethylamine molecule at low temperature. Similarly, we attempted to detect the formation of the ammonium ylide in the LFP of arylchlorodiazirines in isooctane with allylamine and allylaniline. Unfortunately, the ylides **3** or **5** could not be observed in LFP, probably because the rates of disappearance of these ylides are faster than the rates of their formation. Monitoring the C_6H_5–C–Cl and *p*–ClC_6H_4–C–Cl absorptions (5*a*) at 310 nm enabled us to determine the quenching rate constants for the reactions of the carbenes and amine substrates. The reactions were first order with respect to allylamine or allylaniline, as evidenced by the excellent linearity of plots obtained by using eq [1]

$$[1] \quad k_{obs} = k_o + k_q [\text{amine}]$$

where k_{obs} is the observed pseudo-first-order rate constant for transient decay, k_o is the rate constant for decay in the absence of the substrate, and k_q is the rate constant for the reaction of carbene with the substrate.

C_6H_5-$\ddot{C}$-Cl	allylamine	$(1.4 \pm 0.1) \times 10^9\ M^{-1}\ s^{-1}$
C_6H_5-$\ddot{C}$-Cl	allylaniline	$(4.4 \pm 0.2) \times 10^9\ M^{-1}\ s^{-1}$
p-ClC_6H_4-$\ddot{C}$-Cl	allylamine	$(1.6 \pm 0.1) \times 10^9\ M^{-1}\ s^{-1}$
p-ClC_6H_4-$\ddot{C}$-Cl	allylaniline	$(6.3 \pm 0.2) \times 10^9\ M^{-1}\ s^{-1}$

In general, the rate of formation of the ylide is rapid and is close to diffusion controlled. In these cases, the ylide spectra cannot be observed. This suggests that the 1,2 shifts in ylides **3** or **5** must be in the sub-nanosecond range.

The reaction of allyl alcohol with phenylchlorocarbenes indicated that irradiation of diazirines **1** in hexane (0.1 M) at 25°C in the presence of a 10-fold excess of allyl alcohol gave the diallyl acetals **7** in 74–79% yield. The structure of products was confirmed by comparison with authentic samples prepared according to the literature (8). From the results it was clear that cyclopropanes were not detected in GC, GC–MS, and NMR. In search of a mechanism for the reaction of carbenes **2** with allyl alcohol, kinetic studies were carried out by LFP. LFP of 3-chloro-3-*p*-chlorophenyl-diazirine (10^{-3} M) in isooctane (N_2-purged) at 25°C gave rise to a transient (λ = 310 nm) attributed to the absorption of the singlet *p*-$ClC_6H_4\ddot{C}Cl$. The transient was quenched when allyl alcohol was added to the sample in the LFP experiments. When the observed pseudo-first-order rate constants, k_{obs}, for the decay of the transient were plotted against the concentration of allyl alcohol, a pronounced curvature (concave upward) was observed, Fig. 1. This conforms to the observation that the reactions of chlorocarbenes are not first order in alcohol. In fact, Griller et al. (9) have shown that the chlorocarbenes have strong discrimination in their activity toward the monomers and oligomers of various alcohols. For example, *p*-$CH_3OC_6H_4\ddot{C}Cl$ is more reactive toward hydrogen-bonded oligomers than methanol monomers. As well, the reactions of methoxycarbenes with hydroxylic substrates demonstrate that the carbene's activity depends on the function of the alcohol's structure and acidity (10). Since there was no cyclopropane formation in the reaction of *p*-$ClC_6H_4\ddot{C}Cl$ with allyl alcohol, presumably the carbene attacks the oxygen atom rather than the allylic double bond. This assumption is also confirmed by a comparison of the quenching rate constant for *p*-$ClC_6H_4\ddot{C}Cl$ with allyl alcohol at very low concentration, $k_q \sim 10^7 M^{-1}\ s^{-1}$, whereas the rate of cyclopropanation reaction for *p*-$ClC_6H_4\ddot{C}Cl$ with allyl bromide is of an order of lesser magnitude, namely, $k_q \sim 10^6\ M^{-1}\ s^{-1}$ (11). The data for the oligomerization of allyl alcohol are not known, but an excellent straight-line plot, Fig. 1, was obtained when the observed rate constants

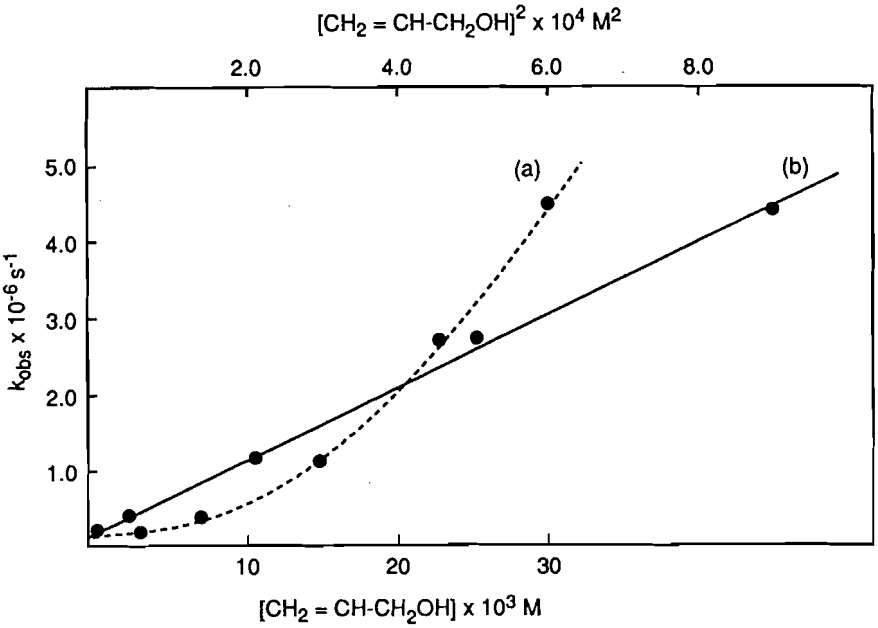

FIG. 1. Plots of pseudo-first-order rate constants vs. allyl alcohol concentrations. (*a*) k_{obs} vs. [CH_2=$CHCH_2OH$]; (*b*) k_{obs} vs. [CH_2=$CHCH_2OH$]^2.

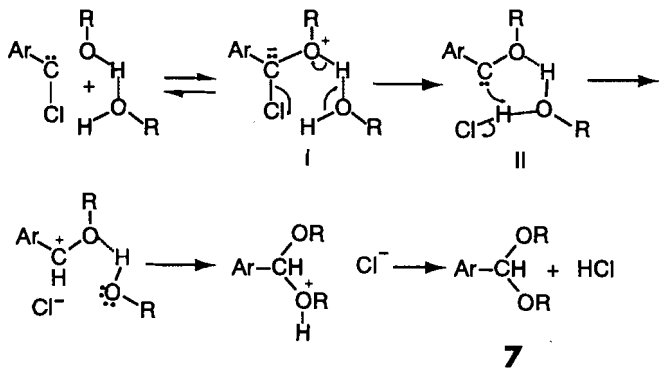

SCHEME 3

were plotted against the square of the allyl alcohol concentration. The slope of the line yielded a third-order rate constant, $\sim 5 \times 10^9$ L^2 mol^{-2} s^{-1}, which agrees with the value derived for the reaction of $C_6H_5CH_2\ddot{C}Cl$ vs. [MeOH]^2 (5*c*).

For the reaction of chlorocarbenes with allyl alcohol, two facts must be taken into consideration: first, no cyclopropanation products were formed; second, the overall reaction is second order in alcohol. It appears that the electrophilic carbene reacts with the nucleophilic alcohol dimer or oligomer by a rate-determining ylide-type interaction (carbene LUMO and alcohol HOMO), as depicted in Scheme 3.

Loss of chloride ion via a six-membered transition state leads to the concomitant formation of a new alkoxycarbene intermediate, which further reacts with a second alcohol molecule to give the final acetal by a variety of mechanisms as discussed in an earlier publication (5*b*). It is also possible to envisage an alternative mechanism involving proton transfer in the ylide, yielding ArCH(Cl)OR and ROH, followed by solvolysis.

These investigations also attempt to establish whether a similarity exists between the reactivity of allylaniline and that of allyl phenyl ether towards arylchlorocarbenes. An examination of the reaction of arylchlorocarbenes **2** with allyl phenyl ether (Scheme 4) shows that the reaction yields chlorocyclopropane **8**, as the only product, in 60% yield.

The total absence of products derived from the 2,3-sigmatropic shift of an oxonium ylide shows that the reaction of arylchlorocarbenes **2** with allyl phenyl ether does not proceed via an oxonium ylide intermediate. This is in marked contrast to the behaviour of bis(methoxycarbonyl)carbene towards allyl-substituted ethers (1). The formation of a cyclopropanated product in this experiment may be due to a change in nucleophilicity at the oxygen centre caused by the introduction of an electron-withdrawing phenyl group in the structure. The difference in the reactivity of arylchlorocarbenes towards ethers in comparison with the reactivity of diazomalonate carbenes with ether could cause such a change in product formation. Also, the difference between the reactivity of allylaniline and allyl phenyl ether towards arylchlorocarbenes may be explained by invoking the nucleophilicity of nitrogen and oxygen centres in stabilizing the ylide intermediate. However, in several instances, the carbene attack was found to favour the nitrogen rather than the oxygen centre. This analogy is in accord with the suggestion of Ando et al. (1) who reported that nucleophilicity differences can cause a variation in the ratio of insertion to addition products.

In conclusion, the behaviour of allyl-substituted amines, such as allylamine and allylaniline, as well as allyl alcohol and allyl phenyl ether, differs when treated with arylchlorocarbenes. This is principally due to the nucleophilicity at the nitrogen and oxygen centres, respectively. This report has also demonstrated that allyl phenyl ether does not react with arylchlorocarbenes via the oxonium ylide intermediate.

Experimental

All of the chemicals used were purchased from the Aldrich Chemical Company. Allylamine, propylamine, butylamine, *sec*-butylamine, and aniline were dried over KOH pellets and distilled prior to use. Solvents such as THF and hexane were refluxed over Na wire and distilled. Solvents were stored over Na wire under argon. All the diazirines were synthesized according to literature procedures (6). Irradiation was performed with a battery of 350-nm lamps in a Rayonet photoreactor until all the diazirine was destroyed. ^{1}H NMR spectra were recorded using a Varian T-60 spectrometer using tetramethylsi-

SCHEME 4

lane as a reference. GC analysis was done on a Varian 6000 series gas chromatograph fitted with a CSP-2 (20m Carbowax) column using a flame ionization detector. Peak areas were integrated using a Hewlett-Packard 3390 integrator and chart recorder. All of the products obtained were subject to GC analysis using proper calibration methods and authentic samples as references. IR spectra were recorded using a Perkin–Elmer 1600 series FTIR instrument. GC–MS were carried out on a Hewlett–Packard HP 5927A MSD instrument. The LFP apparatus in Austin uses a crossed-beam arrangement. A mode-locked Nd: YAG (~10 mJ, pulse width 200 ps) laser provided excitation at 355 nm with a pulsed xenon lamp as monitoring source. The system has a response time of 2 ns. All data collected were signal averaged over 3 shots.

General procedure

A solution of a diazirine (1 mmol), amine (5 mmol), and hexane (10 mL) was irradiated using a battery of 350-nm lamps in a Rayonet photoreactor at 25°C for 7 h. The solution was degassed by bubbling AR through it for a period of 10 min prior to irradiation. The solvent and excess amine were removed in vacuo. The residue was diluted with diethyl ether (30 mL), washed with water (3 × 10 mL), and dried over Na_2SO_4. The products were purified by column chromatography.

Reaction between allylamine and phenylchlorodiazirine. *N*-Allyl benzilidine, **4***a*: yield 90%. IR ν: 1648 cm^{-1}. ^1H NMR (60 MHz, $CDCl_3$) δ: 4.13–4.36 (m, CH_2), 5.0–5.42 (m, CH_2), 5.76–6.47 (m, CH), 7.23–7.96 (m, C_6H_5), 8.20–8.34 (m, CH).

Reaction between allylamine and p-*chlorophenylchlorodiazirine.* *N*-Allyl-*p*-chlorobenzilidine, **4***b*: yield 64%. IR ν: 1649 cm^{-1}. ^1H NMR (60 MHz, $CDCl_3$) δ: 4.13–4.36 (m, CH_2), 5.00–5.42 (m, CH_2), 5.76–6.47 (m, CH), 7.27–7.85 (m, C_6H_4), 8.23–8.37 (m, CH). MS, *m/e*: 181(7), 179(23), 178(65), 153(9), 151(27), 140(8), 138(22), 127(10), 125(30), 113(13), 111(14), 89(52), 75(33), 41(100).

Reaction between allylamine and p-*methylphenylchlorodiazirine.* *N*-Allyl-*p*-methylbenzilidine, **4***c*: yield 93%. IR ν: 1649 cm^{-1}. ^1H NMR (60 MHz, $CDCl_3$) δ: 2.33(s, CH_3), 4.13–4.36 (m, CH_2), 5.00–5.42 (m, CH_2), 5.76–6.47 (m, CH), 5.76–6.47 (m, CH), 7.07–7.81 (m, C_6H_4), 8.18–8.32 (m, CH). HANS CERFONTAIN, YOUSI ZOU, BERT H. BAKKER, and FREEK VAN DE GRIENDT. Can. J. Chem. **72**, 1966 (1994).

The reaction of sulfur trioxide with benzene, the four halogenobenzenes, and six halogenonaphthalenes in dichloromethane as solvent, and with four chlorinated anthracenes in nitromethane as solvent, has been studied by analysis of the resulting mixture of the sulfo derivatives with ^{1}H NMR. The sulfonation of benzene yields initially benzenesulfonic acid and subsequently the 1,3-disulfonic acid (1,3-S_2). The initial sulfonation of the four halogenobenzenes yields ≥98% of the 4-S. Their subsequent sulfonation gives the 2,4-S_2 and in the case of fluoro- and iodobenzene also the 2,4,6-S_3. Monosulfonation of 1-fluoronaphthalene yields only the 4-S, whereas the three other 1-halogenonaphthalenese yield in addition some 5-S. Further sulfonation on any of the four 1-halogenonaphthalene-4-sulfonic acids yields a mixture of the 2,4-S_2 and 4,7-S_2, and eventually also some 2,4,7-S_3, whereas the 1-halogeno-5-sulfonic acids give the corresponding 5,7-S_2. Sulfonation of 2-chloro- and 2-bromonaphthalene yields initially 85% 8-S and 15% 4-S, which are subsequently converted into the 6,8-S_2 and 4,7-S_2, respectively. On reaction with 1.0 mol-equiv. of SO_3, 2-chloroanthracene gives the 9-S, and 9-chloroanthracene gives an 18:82 mixture of the 4-S and 10-S. Both 1,5- and 1,8-dichloroanthracene yield initially the 4-S and subsequently the 4,8-S_2 and 4,5-S_2, respectively.

HANS CERFONTAIN, YOUSI ZOU, BERT H. BAKKER et FREEK VAN DE GRIENDT. Can. J. Chem. **72**, 1966 (1994).

En se basant sur une analyse par RMN du ^{1}H des dérivés sulfoniques des mélanges obtenus, on a étudié la réaction du trioxyde de soufre avec le benzène, les quatre halogénobenzènes et six halogénonaphtalènes dans le dichlorométhane comme solvant et avec quatre anthracènes chlorés dans le nitrométhane comme solvant. La sulfonation du benzène conduit initialement à l'acide benzènesulfonique et subséquemment à l'acide 1,3-disulfonique (1,3-S_2). La sulfonation initiale des quatre halogénobenzènes conduit à ≥98% du 4-S. Leur sulfonation subséquente conduit aux 2,4-S_2 et, dans le cas des fluoro- et iodobenzène, il y a aussi formation des 2,4,6-S_3. La monosulfonation du 1-fluoronaphtalène conduit seulement aux 4-S alors que les trois autres halogénonaphtalènes fournissent aussi un peu du 5-S. La sulfonation subséquente de chacun des acides 1-halogénonaphtalène-4-sulfoniques fournit un mélange des 2,4-S_2 et 4,7-S_2 et éventuellement un peu du 2,4,7-S_3 alors que les acides 1-halogénonaphtalène-5-sulfoniques conduisent aux 5,7-S_2 correspondants. La sulfonation des 2-chloro- et 2-bromonaphtalènes conduit initialement à 85% de 8-S et 15% de 4-S qui sont subséquemment transformés respectivement en 6,8-S_2 et 4,7-S_2. La réaction de 1,0 équivalent molaire de SO_3 avec le 2-chloroanthracène fournit le 9-S alors que le 9-chloroanthracène fournit un mélange 18 : 82 des 4-S et 10-S. Les 1,5- et 1,8-dichloroanthracènes fournissent initialement le 4-S et ultérieurement ils fournissent respectivement le 4,8-S_2 et 4,5-S_2.

[Traduit par la rédaction]

Introduction

The sulfonation of halogenoarenes with chlorosulfuric acid and with concentrated aqueous and fuming sulfuric acid has been studied extensively (2–7). In aromatic substitution, the directing effect of a halogeno substituent is determined by three factors. First, the mesomeric electron release, which decreases in the order F > Cl > Br > I, and which is far more effective in the transition state for *para* than for *ortho* substitution (8, 9). Second, the negative inductive effect, which decreases in the order F > Cl > Br > I, is most effective at the *ortho* and least effective at the *para* position, and third, substitution *ortho* to the halogen is inhibited by steric hindrance, which increases in the order F < Cl < Br < I, as was established by Brand for sulfonation with fuming sulfuric acid (7). The sulfonation of the monohalogenobenzenes in concentrated aqueous sulfuric acid takes place almost exclusively at the 4-position.[5] Under both aprotic and strongly protic sulfonation conditions dehalogenation may occur with substituted bromoarenes and, in particular, with substituted iodoarenes (4, 5, 14).

To allow a proper comparison of the halogenoarenes we have studied the sulfonation of benzene, the four halogenobenzenes, six halogenonaphthalenes, and four chloro-substituted anthracenes under aprotic conditions using sulfur trioxide as reagent.

Results and discussion

The sulfonation of benzene, Hlg-benzene (Hlg = F, Cl, Br, I), 1-Hlg-naphthalene (Hlg = F, Cl, Br and I), and 2-Hlg-naphthalene (Hlg = Cl, Br) with sulfur trioxide using dichloromethane as solvent at ≈22°C has been studied. The results are collected in Tables 1 and 2. In addition a study was made of the sulfona-

[1]Aromatic sulfonation, part 123. Preceding paper: see ref. 1.

[2]For reasons of convenience, all sulfo products have been numbered as for the parent substrate.

[4]Present address: Department of Chemical Engineering, Xiamen University, Xiamen, Fujian, P.R. China.

[5]For the sulfonation of fluoro-, chloro-, bromo-, and iodobenzene in 98.1% H_2SO_4 at 25°C the relative contents of the 4-sulfonic acids (4-S's) are 99.1, 99.1, 98.8, and 97.7%, respectively, and the corresponding partial rate factors for the *para* position in 83–95 wt.% H_2SO_4 are 3.3 ± 0.5, 0.48 ± 0.05, 0.29 ± 0.03, and 0.57 ± 0.12, respectively (10).[6] The small variations of these values illustrate the near balance between the mesomeric and inductive effects of the halogens for substitution at the 4-position.

[6]For the chlorination and bromination of the 1-halogenonappthalenes (1-Hlg-Naph's) the sequence of the relative rates, presuming the halogenation to occur very substantially at the 4-position (11, 12), is very similar to that of the halogenobenzenes, the data for the bromination decreasing in the order 1-F-Naph (3.7) > NaphH (1.00) > 1-I-Naph (0.22) > 1-Cl-Naph (0.13) > 1-Br-Naph (0.09) (13).

[a]S stands for $SO_3^- K^+$.

tion of four chloro-substituted anthracenes with SO_3 in nitromethane at 20°C, the results of which are given in Table 3.

The sulfonation of benzene with 4.0 mol-equiv. of SO_3 yields initially benzenesulfonic acid and subsequently the 1,3-disulfonic acid (1,3-S_2) as the water soluble products. In the halogenobenzene series the initial sulfonation yields very predominantly the 4-S, irrespective of the type of halogen (Table 1).[7] The positional reactivity order in the sulfonation of the four halogenobenzenes is similar to that of $PhOSO_2Me$[8] and $PhOSO_2OMe$ (18), the substituents of which also exhibit both a −I and +M effect.[9]

The further sulfonation of the four halogenobenzene-4-sulfonic acids is very much slower than that of the starting halogenobenzene and leads to the formation of the corresponding 2,4-S_2, and with fluoro- and iodobenzene even to the 2,4,6-S_3. The rates of sulfonation of both the 4-S and 2,4-S_2 are lower for 1-fluoro- and 1-iodobenzene than for 1-chloro- and 1-bromobenzene. This behaviour is in line with the partial rate factor sequence for the bromination of the four 1-halogenonaphthalenes (13).[6]

Halogenonaphthalenes

Sulfonation of 1-fluoronaphthalene with 1.0 mol-equiv. of SO_3 gives only the 4-S, whereas the other three 1-Hlg-naphthalenes yield in addition ≈7% 5-S (Table 2). Again 1-naphthyl methanesulfonate behaves like 1-fluoronaphthalene in that only the 4-S is formed (19). For protiodetritiation of the mono[^{3}H]-1-halogenonaphthalenes the partial rate factors decrease for Hlg = F in the order f_4 (5320) ≫ f_2 (81) ≈ f_8 (62) ≈ f_5 (50) ≫ f_3 (0.2), for Hlg = Cl in the order f_4 (307) ≫ f_8 (50) ≈ f_5 (33) > f_2 (11) > others, and for Hlg = Br in the order f_4 (157) > f_8 (54) > f_5 (29) > f_2 (6.6) > others (20). The very predominant sulfonation of 1-fluoronaphthalene at the 4-position is in line with the partial rate factor sequence for protiodetritiation. Steric effects in hydrogen exchange are significantly smaller than in any other electrophilic substitution, if not entirely absent (21, 22). The very low content of the 1-fluoro-2-S and 8-S is therefore due to electronic effects of the fluorine substituent. Studies with Catalin Stuart space-filling molecular models do predict that the degree of steric hindrance for sulfonation *peri* to the 1-fluoro substituent is only moderate, but that it is very much larger with the other halogens, rendering sulfonation *peri* to these three halogens impossible.

Sulfonation of any of the four 1-halogenonaphthalene-4-sulfonic acids yields a mixture of the 2,4-S_2 and 4,7-S_2. With the 1-fluoro compound the ratio of [2,4-S_2]:[4,7-S_2] is 0.40 ± 0.02, irrespective of the amount of reagent and the reaction time. With 1-chloronaphthalene, using 2.0 and 4.0 mol-equiv. of SO_3, the [2,4-S_2]:[4,7-S_2] ratio decreases from 0.89 to 0.10 (Table 2). These two data are thought to be the kinetically determined and the thermodynamically controlled isomer distributions, respectively. The driving force for the apparent isomerization of the 2,4-S_2 is relief of steric strain between the 1-chloro and 2-sulfo substituents.[10] With 1-bromo- and 1-iodonaphthalene the [2,4-

[7]The sulfonation of chlorobenzene in 1,2-dichloroethane at −12°C (15) and that of bromo- (16) and iodobenzene (17) in liquid sulfur dioxide at −10°C is reported to yield predominantly the 4-S with, in addition, the 2-S and 3-S in yields of 4 ± 2 and 15 ± 2, 0.6 and 3.6, and 0.8 and 0.6%, respectively.

[8]P. de Wit. Private communication.

[9]The 2-fluoro, 2-chloro, and 2-methyl derivatives of $PhOSO_2Me$ react with 2.0 mol-equiv. of SO_3 to give the 4-S and 5-S in ratios of 33:67, 98: ≤2, and 98: ≤2, respectively (18). This infers that, as a first approximation, the *para*-directing effects of the methanesulfonate and fluoro substituents are quite comparable in size, and that these effects are both substantially greater than the *para*-directing effects of the chloro and methyl substituents.

[10]Upon sulfonation of 1,3-dimethoxynaphthalene with SO_3 in nitromethane a similar type of isomerization of the initially formed 4-S into the thermodynamically more stable 7-S was observed (23).

[a]S stands for SO_3^- K^+.

TABLE 3. Sulfonation of chloroanthracenes with 1.0 mol-equiv. of SO_3 in nitromethane at 22°C[a]

Anthracene substituents	Product mixture composition (%, ±3)[b]	
2-Cl	9-S (>90)	
9-Cl	4-S (18)	10-S (82)
1,5-Cl_2	4-S (53)	4,8-S_2 (47)
1,8-Cl_2	4-S (50)	4,5-S_2 (50)

[a]Reaction time 45 min.
[b]S stands for SO_3^- Na^+.

S_2]:[4,7-S_2] ratio appears to be independent of the reaction conditions, with values of 0.07 and 0.16, respectively. These values, which are fairly similar to the eventual ratio found for 1-chloronaphthalene, accordingly indicate that the conversion of 1-bromo- and 1-iodobenzene-4-S into the 2,4-S_2 and 4,7-S_2 is thermodynamically controlled.[11]

Sulfonation of the 1-Hlg-naphthalene-5-sulfonic acids (Hlg = Cl, Br, I) yields the corresponding 5,7-S_2. On reaction of the four 1-halogenonaphthalenes with ≥4.0 mol-equiv. of SO_3, some 2,4,7-S_3 is eventually formed.[12]

Sulfonation of 2-chloro- and 2-bromonaphthalene with 1.0 mol-equiv. of SO_3 yields a mixture containing predominantly 8-S (≈85%) with a small amount of 4-S (≈15%). The eventual products on using 4.0–6.0 mol-equiv. of SO_3 are 6,8- and 4,7-S_2, formed for the 2-chloro and 2-bromo isomer in ratios of 92:8 and 85:15, respectively. The monosulfonation of 2-naphthyl methanesulfonate also yields the 8-S as the predominant product (75%) and in addition small amounts of the 5-S and 6-S (19). Sulfonation of 2-methylnaphthalene with 1.0 mol-equiv. of SO_3 yields mainly the 8-S (49%) with, in addition, 1-S (8%), 4-S (15%), 5-S (15%), and 6-S (14%) (24).

Chloroanthracenes

Sulfonation of 2-chloroanthracene with 1.0 mol-equiv. of SO_3 in nitromethane as solvent gives the 9-S as the very predominant product (cf. Table 3). 2-Methylanthracene behaves quite similarly, the sulfonation product mixture consisting of

[11]Sulfonation of 4-sulfo-1-naphthyl methanesulfonate with SO_3 yields only 4,7-S_2 (19).

[12]It cannot be rigorously excluded that *ipso* sulfodehalogenation (5) has occurred with 1-bromo- and 1-iodonaphthalene-4,7-S_2 with formation of naphthalene-1,4,6(≡1,4,7)-S_3 (cf. Table 5, last entry).

81% 9-S and 19% 10-S (25). 9-Chloroanthracene gives 18% 4-S and 82% 10-S; the sulfonic acid isomer ratio is very similar to that of 9-neopentylanthracene, giving 15% 4-S and 85% 10-S (26).[13] The f_4/f_{10} partial rate factor ratio for the SO_3 sulfonation of 9-chloroanthracene (0.11) is smaller than the f_1/f_9 ratio for anthracene (0.20) (27), indicating that the mesomeric stabilization by the 9-chloro substituent is greater for the transition state leading to the 10-S than for that leading to the 4-S. 1,5-Dichloro- and 1,8-dichloroanthracene undergo sulfonation "*para*" to one of the chlorine atoms giving 4-S; further sulfonation yields the 4,8-S_2 and 4,5-S_2, respectively. The absence of any 9-S in the sulfonation of 1,5-dichloroanthracene may be ascribed to prohibitive steric hindrance by the chlorine substituents. The absence of any 10-S with 1,8-dichloroanthracene then remains notable. The sulfonation of 1-methylanthracene does yield 10% of 10-S, but the main monosulfonation product formed in 90% yield is the 4-S (24). For the sulfonation of both 9-chloro- and 1,8-dichloroanthracene, the mesomeric stabilization of the transition state by chlorine appears to be most effective at the ring containing the chlorine substituent, thus directing the entering sulfo group to the same ring.

Experimental

The halogenobenzenes, halogenonaphthalenes, and 9-chloroanthracene were obtained commercially and used as such. 2-Chloro-, 1,5- and 1,8-dichloroanthracene were synthesized from the corre-

[13]A comparison with 9-methylanthracene would not be significant, since this substrate on reaction with SO_3 undergoes exclusively methyl sulfonation to yield quantitatively 9-anthrylmethanesulfonic acid (27).

sponding anthraquinones by the Meerwein–Ponndorf–Verley reduction (28) and subsequent dehydration, using Al(*O*-cyclohexyl)$_3$ in dry cyclohexanol as solvent at 180°C in yields of 36, 20, and 43%, respectively. The ^{1}H NMR spectra of the substrates and their sulfo product mixtures were recorded using Varian XL-100 and Bruker AC-200 spectrometers.

Sulfonation procedures and analyses

The procedure for the SO_3 sulfonation of all the chloroanthracenes in nitromethane as solvent is as described under Method B in ref. 29. The procedure for all the other substrates is as follows. The desired amount of SO_3 was added to a homogeneous solution of 0.14 mmol of substrate in 0.5 mL of dry dichloromethane at ≈22°C under an argon atmosphere. During the sulfonation, the reaction mixture turned heterogeneous. After the appropriate reaction time, 0.5 mL of water was added, and the mixture heated at 70–80°C for 30 min to hydrolyse any sulfonic anhydride formed (30). The aqueous layer was isolated and neutralized with 10% aqueous potassium or sodium hydroxide and the water was removed by freeze-drying. Subsequently, an ^{1}H NMR spectrum of the resulting potassium or sodium sulfonate salt mixture dissolved in ^2H_2O was recorded for product assignment and the quantitative analysis.

The structural assignments of the sulfo products in the sulfonation mixtures were made on the basis of the observed chemical shifts, absorption area ratios, coupling constants, and excessive spin decoupling through double-resonance experiments. The structural assignments are compiled in Tables 4–6. The compositions of the sulfonation product mixtures were determined by multicomponent ^{1}H NMR analysis on the basis of specific absorptions of the various components (32).

TED SCHAEFER, WING K. CHAN, RUDY SEBASTIAN, ROBERT SCHURKO, and FRANK E. HRUSKA. Can. J. Chem. **72**, 1972 (1994).

The ^1H nuclear magnetic resonance spectra of ethylbenzene-β-^{13}C in CS_2/C_6D_{12} and acetone-d_6 solutions yield long-range $^1H,^1H$ and $^1H,^{13}C$ coupling constants. The $^{13}C\{^1H\}$ NMR spectra yield $^{13}C,^{13}C$ couplings. The conformational dependence of some of these coupling constants is compatible with two values of the barrier to internal rotation about the exocyclic Csp^2—Csp^3 bond. If the fourfold component of the internal rotational potential is not larger than about 20% of the twofold component and the perpendicular conformer is most stable, then the barrier height is probably less than 6 kJ/mol. However, if the stable conformer has a torsion angle of 60° for the exocyclic C—C bond, then the coupling constants are consistent with a twofold barrier of about 23 kJ/mol. Experimental values of $\langle\sin^2\psi\rangle$ and $\langle\sin^2\theta\rangle$, where ψ and θ are the torsion angles for the exocyclic C—C and C—H bonds, respectively, are compared to those obtained from INDO MO FPT computations of the angular dependence of ^nJ(H,C), and ^nJ(H,H), ^nJ(C,C) for $n \geq 3$. For example, the computations very likely give the correct qualitative ψ dependence of ^5J(C,C), yet overestimate its extremum by about a factor of two, either because of an overestimate of the σ–π exchange integrals or because of too large a valence orbital density at the carbon nucleus. Other ^nJ values are discussed in a similar manner and, because optimized geometries are used in the computations, a somewhat more reliable treatment arises for some coupling constants; an example is ^3J(C,C) at small torsion angles.

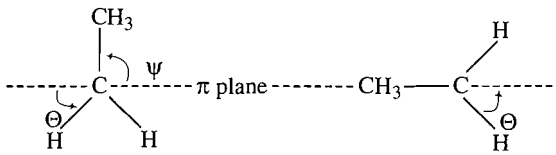
TED SCHAEFER, WING K. CHAN, RUDY SEBASTIAN, ROBERT SCHURKO et FRANK E. HRUSKA. Can. J. Chem. **72**, 1972 (1994).

Les spectres de résonance magnétique du ^1H de l'éthylbenzène-β-^{13}C en solutions dans le CS_2/C_6D_{12} et dans l'acétone-d_6 ont permis d'obtenir les constantes de couplage à longue distance $^1H,^1H$ et $^1H,^{13}C$. Les spectres RMN $^{13}C\{^1H\}$ fournissent les couplages $^{13}C,^{13}C$. La dépendance conformationnelle de quelques unes de ces constantes de couplage est compatible avec deux valeurs pour la barrière à la rotation interne autour de la liaison Csp^2—Csp^3. Si la valeur de composante quaternaire du potentiel rotationnel interne n'est pas supérieure à 20% de la composante binaire et si le conformère perpendiculaire est le plus stable, la hauteur de la barrière est probablement inférieure à 6 kJ/mol. Toutefois, si l'angle de torsion de la liaison C—C exocyclique du conformère stable est égale à 60°, les constantes de couplage sont alors en accord avec une barrière binaire d'environ 23 kJ/mol. On a comparé les valeurs expérimentales de $\langle\sin^2\psi\rangle$ et $\langle\sin^2\theta\rangle$, dans lesquelles ψ et θ sont respectivement les angles de torsion des liaisons C—C et C—H exocycliques, avec celles obtenues par des calculs INDO MO FPT de la dépendance angulaire de ^nJ(H,H), ^nJ(H,C), et ^nJ(C,C) pour $n \geq 3$. Par exemple, les calculs donnent vraisemblablement la dépendance qualitative correcte de ψ de ^5J(H,H) même s'ils surévaluent ses extrêmes par un facteur d'environ deux, soit par une surévaluation des intégrales d'échange σ–π soit par une trop grande densité orbitalaire de valence au niveau du noyau de carbone. On discute de la même manière d'autres valeurs de ^nJ et, parce que l'on utilise de géométries optimisées dans les calculs, on obtient un traitement un peu plus certain pour quelques unes des constantes de couplage; par exemple, ^3J(C,C) à des angles de torsion faibles.

[Traduit par la rédaction]

Introduction

The long-range spin–spin coupling constants between the methylene and ring protons, $^nJ(H,CH_2)$, in ethylbenzene have been precisely determined for a variety of solvent conditions (1). In particular, $^6J(H,CH_2)$ is a σ–π coupling constant and, as such, is proportional to $\sin^2\theta$, θ being the torsion angle about the Csp^2—Csp^3 bond, as in **1**. If the extrema in $^6J(H,CH_2)$ can be



1, Θ = 30°, ψ = 90° **2**, Θ = 60°, ψ = 0°

assessed, those for 0° and 90° in θ, then the measured value of $^6J(H,CH_2)$ provides the average or expectation value, $\langle\sin^2\theta\rangle$, at the temperature of the measurement. The value of $\langle\sin^2\theta\rangle$ indicates the conformation of lowest energy (1), namely, **1**, but can also be related to the barrier to rotation about the Csp^2—Csp^3 bond via classical or quantum mechanical averaging procedures. In this way the apparent sixfold barrier, V_2, is deduced as 5.0 kJ/mol; **2** is then the conformation of highest energy.

Computations at various levels of ab initio molecular orbital theory (1, 2) agree that **1** and **2** represent the conformers of lowest and highest energy, respectively, but predict the presence of a minor fourfold, in addition to the major twofold, component of the internal rotational potential. For example, if a theoretical fourfold component of 0.9 kJ/mol is used to fit the rotational spectrum in the vapor phase (2), then the twofold component is 4.9 ± 0.7 kJ/mol; alternatively, the latter is 7.8 ± 0.7 kJ/mol if the former vanishes. A combined molecular mechanics – molecular orbital method (3) arrives at 4.2 kJ/mol for the energy difference between **1** and **2**. Reference 3 also collects citations to all previous, somewhat contradictory, experimental work on the conformational properties of ethylbenzene. In addition, supersonic molecular jet spectroscopy (4) strongly implies **1** as the most stable conformer.

By way of contrast, the ^1H nmr spectra of 3,5-dibromoethylbenzene, dissolved in a nematic solvent (5), are interpreted to yield a minimum in the internal rotational potential at θ = 60°. It is possible, though perhaps improbable, that the bromine substituents cause a shift in the phase of the potential, although molecular orbital computations on the free molecule do not detect such a shift. It may therefore be that intermolecular forces from the partially ordered solvent molecules are respon-

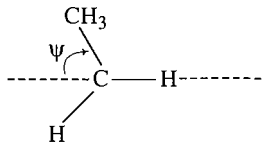
sible for a change in the conformational minimum. The parent molecule has not been studied in the same nematic medium.

While the magnitude of the internal rotational potential in ethylbenzene very likely lies between 4.2 and 9.2 kJ/mol (1–4, 6), and is therefore somewhat uncertain, the further apparent uncertainly in the phase of the potential is also disconcerting. The experimental estimates of the phase favor either **1** or **3** as



3, $\Theta = 60°, 0°$
$\psi = 60°$

the conformer of minimum energy, examples of each alternative being found for the molecule in the vapor as well as in solution.

Now, $^6J(H,CH_2)$ is dominated by a certain region of the internal rotational potential (see **1** and **2**); being proportional to $\sin^2\theta$ it depends on the probability that the two α C—H bonds take on the various angles, θ. The α C—C bond, on the other hand, samples a different region of the internal potential. Because $^6J(H,C)$ and $^5J(C,C)$ are very likely σ, π coupling constants (7) and therefore proportional to $\sin^2\psi$, their measurement should help to further characterize the internal barrier in ethylbenzene. The first purpose of the present work is therefore the analysis of the ^1H nmr spectrum of ethylbenzene-β-^{13}C, yielding the long-range $^nJ(H,H)$ and $^nJ(H,C)$. The ^{13}C $\{^1H\}$ spectra provide the magnitudes of $^nJ(C,C)$. It turns out that $^6J(H,H)$ and $^6J(H,C)$ are consistent with two magnitudes of the internal barrier, one high and corresponding to **3** as the conformer of lowest energy, the other much lower and consistent with **1** as most stable.

INDO MO FPT (8) computations of long-range, σ–π coupling constants have been reasonably successful in the prediction of their qualitative conformational dependence (7, 9, 10). The quantitative predictions are usually less successful, that is, those of the extrema in relationships such as $^nJ = {}^nJ_{90} \sin^2\theta$; hence the need for the use of model compounds in which the conformations are well defined (large barriers). Of course, once the internal potential is known, then, together with experimental values of ^nJ, it is a source of the extrema in ^nJ. Consequently, a comparison with INDO MO FPT computations of ^nJ as a function of conformational angle yields hints as to the causes of disparities between experiment and the semiempirical model. This will be so particularly for long-range coupling constants for which the σ–π electron interactions have a direct dependence on conformational angle. A semiquantitive indication of the disparities can they be had.

While real progress is being made in the ab initio molecular orbital calculations of J, the computational investment (11) is rather high, so that the speed of the INDO MO FPT procedure is of great utility, particularly if estimates of its qualitative and quantitative behaviour are available. Hence the second purpose of this work is a comparison of semiempirical computations of $^nJ(H,C)$ and $^nJ(C,C)$ for ethylbenzene with the experimentally indicated extrema for such coupling constants.

Experimental

The ethylbenzene-β-^{13}C (99% enriched) from Isotec was prepared as 8.0 mol% solutions in CS_2/C_6D_{12}/TMS and acetone-d_6/TMS solvent mixtures (see Table 1 for details). The solutions were filtered into 5 mm o.d. nmr sample tubes, which were then degassed by five freeze–pump–thaw cycles and flame-sealed to provide reasonably symmetric tops. The ^1H nmr spectra were obtained with an AM 300 nmr spectrometer in a manner previously described (7, 12). Acquisition times of the free induction decays ranged from 41 to 51 s for various response regions; as many as 64 decays were coadded in digital form and the digital resolution was 0.012 Hz/point or better. Modest amounts of resolution enhancement were applied by means of convolution and produced satisfactory spectra in the frequency domain. Figure 1 displays an example of such spectra.

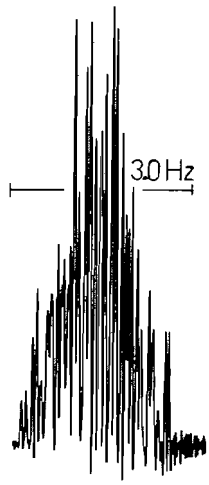


FIG. 1. One of the eight multiplets, near 779 Hz relative to TMS, of the ^1H nmr spectrum at 300 K and 300 MHz of the methylene protons in ethylbenzene-β-^{13}C, dissolved as an 8.0 mol% solution in a CS_2/C_6D_{12}/TMS solvent mixture, is displayed. The splitting of the doublet at the far right is 0.05 Hz. The acquisition times of 32 free induction decays were 51.2 s, the digital resolution was <0.01 Hz/point, and some resolution enhancement procedures were applied. In a first-order spectrum this multiplet would consist of 18 peaks due to the five phenyl protons (3 × 3 × 2). At least 32 peaks are resolved.

STO-3G molecular orbital computations (13) utilized GAUSSIAN 92 (14) and were done at 15° intervals in the conformational angle, ψ (see **1**). All bond angles and lengths were optimized with the constraint that the nuclei of the phenyl group remained in a plane. These geometries were employed in the CNDO/2 and INDO MO FPT (8, 15) computations of ^nJ.

Results and discussion

Spectral analyses

The ^1H nmr spectra were analyzed with the computer program NUMARIT (16), greatly modified by R. Sebastian. The ensuing spectral parameters are found in Table 1. Those coupling constants in common with isotopically unenriched ethylbenzene agree reasonably well with previous values for the latter (1), obtained at different dilutions in the solvents in question.

The ^{13}C nmr chemical shifts and $^nJ(C,C)$ appear in Table 2. The indicated signs of $^nJ(C,C)$ are based on theory as well as on experimental signs for related molecules (8).

The barrier to rotation about the Csp^2—Csp^3 bond

$^6J(H,CH_2)$ is –0.455 Hz in CS_2/C_6D_{12} and –0.454 Hz in acetone-d_6 solutions (Table 1), essentially the same as the corresponding values of –0.455 and –0.451 Hz for more dilute solutions (1) of the unenriched ethylbenzene. As before (1), the apparent twofold barrier follows from a $\langle\sin^2\theta\rangle$ of 0.455/1.16 or 0.392, which, at 300 K, corresponds to 5.0 kJ/mol if **1** is indeed the conformer of lowest energy. For a tetrahedral geometry at the methylene carbon atom, $\langle\sin^2\psi\rangle = 1.5–2\langle\sin^2\theta\rangle$. Then $\langle\sin^2\psi\rangle$

[a]For the samples described in Table 1.
[b]Estimated errors in ^nJ(C, C) are 0.02 Hz.

is 0.716 and, because ^6J(H,C) is −0.463(3) Hz, $^6J_{90}$(H,C) follows as −0.647(5) Hz. A check on this number follows from an experiment with 2,6-dimethoxyethylbenzene (80 vol.% in acetone-d_6), in which the ^{13}C nmr spectrum of the methyl group (1905 free induction decays, acquisition times of 20.5 s, a digital resolution of 0.024 Hz/point) gave ^6J(H,C) as (−)0.65(2) Hz on the basis of a first-order interpretation. By comparison with the internal barrier in 2,6-difluoroethylbenzene (17), which may be as large as 33 kJ/mol and is expected to be very similar to that in the dimethoxy derivative, ^6J(H,C) in the latter is a reasonable approximation to $^6J_{90}$(H,C).

An alternative interpretation of ^6J(H,CH_2) and ^6J(H,C) is based on **3** as the most stable conformer and a twofold barrier. One may note that $\langle\sin^2\theta\rangle$ would then vary between 0.375, for a rigid **3**, and 0.5, for unhindered rotation; the corresponding numbers for $\langle\sin^2\psi\rangle$ would be 0.75 and 0.5. The experimental values of the expectation values would then imply an apparent V_2 of 22.6 kJ/mol. This value appears unreasonably high in view of the fairly high-level molecular orbital computations described in the introduction in this paper.

A third interpretation allows for a substantial fourfold component in the Csp^2—Csp^3 barrier. If V_2 and V_4 have the same sign, as indicated by all available molecular orbital calculations (1, 2), then a $\langle\sin^2\psi\rangle$ of 0.716 at 300 K is compatible with, for example, V_2/V_4 ratios of 6.02/2.0, 8.5/5.0, and 12.0/7.8; it is assumed, as implied by all the theoretical models, that **1** is the most stable conformer. As V_4 increases in magnitude so must V_2, because a pure V_4 barrier entails a $\langle\sin^2\psi\rangle$ of 0.5. The rotational spectrum (2) is compatible with V_2/V_4 of 7.8(7)/0 and 4.9(7)/0.9; the experimental data were not extensive enough to fit V_2 and V_4 simultaneously. It appeared, however, that **1** was the most stable conformer in the vapor. The ratio 4.9(7)/0.9 implies a $\langle\sin^2\psi\rangle$ of 0.70(1) at 300 K, very close to its value in solution, whether in polar or nonpolar solvents (ref. 1 and Table 1). The potential function deduced from dipolar couplings for a solution of 3,5-dibromoethylbenzene in a liquid-crystalline solvent (5) has a $V_2/V_4/V_6$ of 4.4/2.2/−0.8, corresponding to a $\langle\sin^2\psi\rangle$ of 0.66_7 at 300 K, with **3**, however, as the least energetic conformer. This disagreement with the internal potential for ethylbenzene is remarkable in that the bromine substituents, placed symmetrically with respect to the site of the ethyl group, are not expected to change the phase of the potential. Hence intermolecular forces remain as the possible cause of the shift in phase in the nematic solvent.

If, as strongly indicated by the molecular orbital computations for the free molecule, V_4 is of the same sign as V_2 and not

For personal use only.

larger than about 20% of the latter's magnitude, and if the barrier is independent of the isotropic solvent, as indicated by the long-range coupling constants, then the barrier height is probably less than 6 kJ/mol, with **1** as the minimum in energy.

The extrema in ^6J(H,C) and ^5J(C,C)

^6J(H,H) has a $\sin^2\theta$ dependence and its extremum, $^6J_{90}$, is -1.20_4 Hz in toluene (12). If the angle-independent contribution is neglected as an artifact, as discussed in other connections (9, 10, 18), then this magnitude is close to that computed with INDO MO FPT parameterization (9), namely, -1.14_4Hz. As discussed previously (9, 19, 20), this σ–π coupling can be written as ^6J(H,H) α $Q^{H}CHQ^{C}CH$, where $Q^{H}CH$ is the hyperfine interaction parameter representing the coupling between the proton in an aromatic C—H bond and unpaired π electron density (spin density) in a $p\pi$ orbital on the carbon atom of the bond; $Q^{H}CH$ is negative. $Q^{H}CCH$ represents the hyperfine interaction between a β-proton, as in toluene, and the $p\pi$ spin density on the contiguous aromatic carbon atom. $Q^{H}CCH$ is positive and proportional to $\sin^2\theta$. Experimentally, $^6J(H,CH_3)$ in toluene and $^7J(CH_3, CH_3)$ in *p*-xylene, at –0.602(2) Hz(12) and +0.596(9) Hz (recent unpublished measurement for a 50vol./vol.% solution in acetone in this laboratory), are essentially equal in magnitude. The $\sin^2\theta$ dependence of $^7J(CH_3,CH_3)$, as computed by INDO MO FPT methods (9), entails $Q^{H}CCHQ^{H}CCH$ α 1.378 Hz, while the experimental value is 1.200 Hz. These theoretical and experimental data reduce to the relationships, $(Q^{H}CH)^e = -1.00(Q^{H}CCH)^e$, $(Q^{H}CCH)^t = 1.07(Q^{H}CCH)^e$, and $(Q^{H}CH)^t = 0.88_6(Q^{H}CH)^e$; the superscripts refer to theoretical or experimental values.

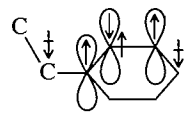
The theoretical and experimental values of ^5J(C,C) and ^6J(H,C) in ethylbenzene can also be discussed in such a manner. Thus, ^6J(H,C) $\propto$ $Q^{H}CHQ^{C}CCC$ and ^5J(C,C) $\propto$ $Q^{C}CHQ^{C}CCC$ and therefore one has $^5J(C,C)/^6J(H,C)$ α $Q^{C}CH/Q^{H}CH$. In aromatic free radicals, $Q^{C}CH$ is positive and represents the hyperfine interaction between the $p\pi$ electron on the carbon atom of a C—H bond and its ^{13}C nucleus (21). In ethylbenzene (Tables 1 and 2), $^5J(C,C)/^6J(H,C)$ = (+)0.75(1)/–0463(3) or –1.62(3). The INDO MO FPT calculations do indeed predict that both coupling constants are proportional to $\sin^2\psi$, as expected for σ–π interactions, but find $^5J_{90}$(C,C) as 1.60 and $^6J_{90}$(H,C) as –0.49 Hz. The theoretical value of $Q^{C}CH/Q^{H}CH$ is therefore –3.26, the experimental value is –1.62(3). It follows that $(Q^{C}CH)^t = 1.78(3)(Q^{C}CH)^e$ and $(Q^{C}CCC)^t = 0.85_8(Q^{C}CCC)^e$. A reparameterization of the theoretical model would involve consideration of the magnitudes of valence *s* orbital densities at carbon and hydrogen and (or) the relevant σ–π exchange integrals, among other matters.

In summary, $(Q^{H}CH)^t = 0.88_6(Q^{H}CH)^e$, $(Q^{H}CCH)^t = 1.07(Q^{H}CCH)^e$, $(Q_{CH})^t = 1.78(Q^{C}CH)^e$, $(Q^{C}CCC)^t = 0.85_8(Q^{C}CCC)^e$, and $(Q^{H}CH)^e = -1.00(Q^{H}CCH)^e = -2.90(Q^{C}CCC)^e = -0.61_7(Q^{C}CH)^e$. These proportionalities will depend somewhat on the geometries assumed for the computations. They will now be used in adjusting the computed π electron contributions to other ^nJ(H,C) and ^nJ(C,C) in ethylbenzene.

$^5J(H,CH_2)$, ^5J(H,C), and ^4J(C,C)

The long-range coupling constant between methyl and *meta* protons in toluene has been written (12) as $^5J(H,CH_3) = 0.336 \sin^2\theta + 0.332 \sin^2(\theta/2) = {}^5J^{\pi} \sin^2\theta + {}^5J^{\sigma} \sin^2(\theta/2)$. Applied to ethylbenzene, one has $^5J(H,CH_2) = 0.336(1.16/1.20)\sin^2\theta + 0.332 \sin^2(\theta/2)$. For an evenfold barrier, $\langle\sin^2(\theta/2)\rangle$ is 0.5 and, because $\langle\sin^2\theta\rangle$ is 0.392, $^5J(H,CH_2)$ is calculated as 0.289 Hz, considered as adequate in that the measured value is 0.299(2) Hz.

A similar parameterization of ^5J(H,C) goes as follows. The INDO MO FPT values are represented by $^5J(H,C) = 0.155 \sin^2\psi + 0.287 \sin^2(\psi/2)$. According to the conclusions in the previous section, one has the correct $^5J^{\pi}$(H,C) as 0.155(1/0.858)(1/0.886) or 0.204 Hz. The measured ^5J(H,C) is 0.187(2) Hz, so that $^5J(H,C) = 0.187(2) = 0.204 \langle\sin^2\psi\rangle + {}^5J^{\sigma} \langle\sin^2(\psi/2)\rangle$, from which $^5J^{\sigma}$ follows as 0.084 Hz. The final relationship is thus $^5J(H,C) = 0.20 \sin^2\psi + 0.08 \sin^2(\psi/2)$. The assumption that ^5J(H,C) vanishes at $\psi = 0°$ is based on the behaviour of ^5J(H,CH) and also on our CNDO/2 computations, which have it as zero; such computations are in agreement with the known numbers for ^5J(H,CH) at $\psi = 0°$ and $\psi = 180°$ (9, 22). In the 2,6-dimethoxyethylbenzene, the magnitude of the splitting, approximating to ^5J(H,C), is 0.21(3) Hz; $\langle\sin^2\psi\rangle$ must be near 1.0. Turning to ^4J(C,C), the INDO MO FPT calculations are reproduced by $^4J(C,C) = -0.130 - 1.561 \sin^2\psi + 0.246 \sin^2(\psi/2)$ while the CNDO/2 numbers have $^4J(C,C) = 0.074 - 0.098 \sin^2\psi + 0.076 \sin^2(\psi/2)$. What ^4J(C,C) is at $\psi = 0°$, the so-called dipper conformation (23), is problematic. It is computed as positive for pentane (23). Here, arbitrarily, the mean of the two computed values at $\psi = 0°$ is taken. Further, the INDO MO FPT value for $^5J^{\pi}$, negative as expected, is too large in magnitude by a factor of 0.858 (1.78). The measured value of ^4J(C,C) is (–)0.53(2) Hz, so that one has $^4J(C,C) = -0.03 - 1.02 \sin^2\psi + 0.46 \sin^2(\psi/2)$. This equation must be regarded as rather tentative; certainly, ^4J(C,C) is expected to be negative for large ψ values where the σ–π contribution is dominant (see **4**). In 2,6-



crossed arrows: nuclear spin rate

4

dichloroanisole, ^4J(C,C) is –0.69(3) Hz(7) and $\langle\sin^2\psi\rangle$ cannot be much less than unity, whereas $\langle\sin^2(\psi/2)\rangle$ is 0.5. Of course, here one has an O—C bond, as opposed to a C—C bond in **4**. Perturbations by the chlorine substituent are also a possibility.

$^4J(H,H)$ and $^4J(H,C)$

The original INDO MO FPT computations (9) of $^4J(H,CH_3)$ in toluene can be found from $-0.34 - 1.01 \sin^2\theta - 0.23 \sin^2(\theta/2)$. Hence $^4J(H,CH_3)$ is predicted to be –0.95 Hz, $\langle\sin^2\theta\rangle$ and $\langle\sin^2(\theta/2)\rangle$ being 0.5. The experimental value is –0.702(1) Hz (12). The coefficient of $\sin^2\theta$ above is to be multiplied by (1/0.886)(1/1.07) or 1.05, becoming –1.06 Hz, according to the approach developed in this work. Of course, the disagreement with experiment is then even larger. A detailed investigation (24) of $^4J(H,CH_3)$ concluded that it should be written as $-1.08 \sin^2\theta - 0.32 \cos^2\theta$, the latter term accounting for other than σ–π interactions. This relationship reproduces the later (12) experimental number exactly; it is also interesting that –1.06 and –1.08 are so similar in magnitude. For ethylbenzene, $\langle\sin^2\theta\rangle$ is –0.392 at 300 K. One then has –0.62 Hz predicted for $^4J(H,CH_2)$, compared to –0.644 Hz in Table 1. It appears that the angle-independent term in the INDO formulation is much too large.

Turning to ^4J(H,C), the INDO MO FPT data again overestimate its value, being reproduced by $-0.27 - 0.43 \sin^2\psi - 0.024 \sin^2(\psi/2)$. The multiplier of $\sin^2\psi$ is to be altered by a factor of (1/0.858)(1/0.886) or 1.31. To obtain agreement with the exper-

For personal use only.

imental value of –0.22(3) Hz would require a substantial change in the theoretical formulation, possibly a positive coefficient, as large as 0.36, of $\sin^2(\psi/2)$; the negative angle-independent term, apparently spurious, is reminiscent of a similar one for $^4J(H,CH_2)$.

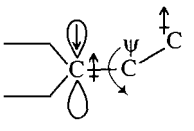
The ψ dependence of $^3J(C,C)$

The INDO MO FPT results can be written as one of the Karplus forms, $^3J(C,C)/Hz = 0.86 \cos^2\psi - 0.41 \cos\psi + 2.28$ or, equivalently, as $^3J(C,C)/Hz = -0.86 \cos^2\psi - 0.41 \cos\psi + 2.28$ or, again equivalently, as $^3J(C,C)/Hz = -0.86 \sin^2\psi + 0.71 \sin^2(\psi/2) + 2.80$. The negative coefficient of cos ψ entails a larger $^3J(C,C)$ in the *trans* than in the *cis* arrangement of the vicinal C—C bonds, unlike the results of a previous computation (25) that, however, also indicate that other than contact contributions to $^3J(C,C)$ are very small. The disagreement at small dihedral angles is very likely a result of the use of a standard geometrical model, leading to unrealistic "close-range nonbonded interactions" (25), in the earlier work.

The large computed values in the vicinity of ψ = 90°C indicate a substantial σ–π electron contribution to $^3J(C,C)$, as previously discussed (24). Its magnitude depends on the degree of π electron spin correlation in the partial double bond, as well as on Q^CCCC Q^CCH; the latter is too large by a factor of 0.86(1.78), according to the discussion above of $^3J(C,C)$. Judging by computations of $^3J(C,C)$ in butane and of the σ–π component of $^3J(C,C)$ in 1-butane (25), $^3J(C,C)$ at 90°C is near zero[2] in the absence of the latter, expected to go as $\sin^2\psi$. If $^3J = {}^3J^\sigma + {}^3J^\pi$ and $^3J^\sigma$ vanishes at 90°, then the theoretical values become $^3J = (3.14 \cos^2\psi - 0.41 \cos\psi) + (2.28 \sin^2\psi)$. Because $\langle\sin^2\psi\rangle$ is 0.716 and $\langle\cos\psi\rangle$ vanishes for an evenfold potential, ^3J becomes 2.52 Hz, as opposed to the experimental value of 2.26 Hz. If it is further assumed that $^3J^\pi$ is to be reduced by the above factor of 1.53, then ^3J become 1.97 Hz, now lower than experiment. Of course, accommodations between the computed values and the present two-mechanism model could be made to reproduce the experimental number for $^3J(C,C)$. In any event, it is remarkable that the original, theoretical equation does not overestimate $^3J(C,C)$ by much. In terms of the present approach it is likely that the σ electron contributions to $^3J(C,C)$ are underestimated by theory; those from the π electrons, overestimated.

Some other $^nJ(H,C)$ and $^nJ(C,C)$ numbers

The CNDO/2 and INDO MO FPT computations agree with the sign indicated in Table 2 for $^2J(C,C)$. The available evidence (7) implies an increase in the magnitude of $^2J(C,C)$ as ψ increases; the INDO values are $^2J(C,C) = -4.84 - 0.95 \sin^2\psi$, in qualitative agreement with the experimental evidence. In line with the previous sections, the coefficient of $\sin^2\psi$ should be reduced by a factor (1/0.858)(1/1.78) or 0.65 because it represents the coupling mechanism in **5**. The value of $^2J(C,C)$ there-



5

fore becomes –4.84 – 0.62 (0.716) or –5.28 Hz. The experimental value of (–) 2.3_5 Hz implies much too large a magnitude of the theoretical through-bond, angle-independent, term (one-centre exchange integrals (15)). The CNDO/2 numbers are given by $^2J(C,C) = -1.55 + 0.41 \sin^2\psi$ and fail to reproduce the correct sign of the angle dependence of $^2J(C,C)$, as might be expected (15).

$^1J(C,C)$ is 33.91(3) Hz in ethylbenzene, as compared to 34.6(3) Hz in ethane (26) in CCl_4 solution. Post Hartree–Fock computations of the contact contribution yield 34.1 for ethane (26). $^1J(C,C)$ does not correlate with the C—C bond length in various molecules (27). $^2J(H,C)$ is –4.95(4) Hz in ethylbenzene and –4.5(3) Hz in ethane (26), while $^1J(H,C)$ is 126.24(3) in the former and 124.93(3) in the latter (26). To within experimental error, the substituent perturbation by the phenyl group is only to 1–2% of the magnitudes of the three coupling constants.

In summary, a comparison of the experimental conformational dependence of at least some of the long-range coupling constants involving ^1H and ^{13}C nuclei in ethylbenzene with INDO MO FPT computations illustrates the need for modifications of the standard algorithm. Examples are given in which theory underestimates or overestimates certain components of the coupling mechanisms.

Solvent perturbations of ^nJ

The intraring $^{3,4,5}J(H,H)$ values display solvent perturbations typical of many phenyl X compounds, as measured in this laboratory; they are not artifacts of the spectral analyses. Thus, $^3J(H,H)$ is larger in acetone-d_6 solution, as is $^4J_{26}$, but $^4J_{24}$ and $^4J_{35}$ either decrease or do not change. $^4J(H,C)$ appears to decrease significantly in magnitude in passing to the polar solvent; a repeated set of experiments is necessary to confirm this result.

Heterocyclic analogs of nucleosides: synthesis and biological evaluation of novel analogs of puromycin[1]

PHILIP G. HULTIN AND WALTER A. SZAREK[2]
Department of Chemistry, Queen's University, Kingston, ON K7L 3N6, Canada

Received July 20, 1993[3]

PHILIP G. HULTIN and WALTER A. SZAREK. Can. J. Chem. **72**, 1978 (1994).

The diastereomeric 1-(piperidin-3′-yl)uracil compounds **20***a*, *b*, and the N^6-dimethyl-9-(piperidin-3′-yl)adenine compounds **21***a*, *b*, have been prepared as analogs of the naturally occurring aminoacyl nucleoside antibiotic puromycin. The diastereomers were separated using high-pressure liquid chromatography, and the absolute configuration of the more mobile diastereomer **20***a* was assigned as (3′*S*,5′*R*) by ^{1}H and ^{13}C nuclear magnetic resonance analysis, and by molecular modelling. Therefore, the less mobile diastereomer **20***b* had the (3′*R*,5′*S*) configuration. The configurations of **21***a* and **21***b* were assigned by analogy with **20***a* and **20***b*. These puromycin analogs have been tested for anti-HIV and antitumor activity in vitro.

PHILIP G. HULTIN et WALTER A. SZAREK. Can. J. Chem. **72**, 1978 (1994).

On a préparé les composés 1-(pipéridin-3′-yl) uracilee **20***a*, *b*, et N^6-diméthyl-9-(pipéridin-3′-yl) adénines **21***a*, *b*, comme analogues de la puromycine, un antibiotique naturel de type aminoacyle nucléoside. On a séparé les diastéréoisomères par chromatographie liquide á haute pression et on a attribué au diastéréoisomère le plus mobile, **20***a*, la configuration absolue (3′*S*,5′*R*) en se basant sur les résultats de la RMN du ^{1}H et du ^{13}C et sur les modèles moléculaires. Par conséquent, le diastéréoisomère le moins mobile, **20***b*, a la configuration (3′*R*,5′*S*). Par analogie avec les composés **20***a* et **20***b* on attribue les configurations des composés **21***a* et **21***b*. On a testé ces analogues de la puromycine in vitro pour leur activité anti-HIV et anti-tumorale.

[Traduit par la rédaction]

Introduction

The nucleoside derivative puromycin (Fig. 1) has been the focus of consistent interest since its discovery 40 years ago in the fermentation broth of *Streptomyces alboniger* (1). This

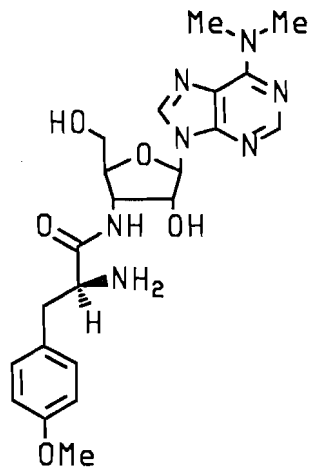

FIG. 1. Puromycin.

potent antibiotic mimics the 3′-end of aminoacyl-tRNA, interrupting protein synthesis on the ribosome (2). Puromycin has antimicrobial, antitumor (3), and antimalarial (4) activities, and is a reversible inhibitor of DNA synthesis (5). However, its therapeutic use is precluded by its extreme toxicity, particularly towards the kidney (6).

To address the problem of toxicity, many analogs of puromycin have been prepared. The ribosyl ring has been replaced by a 3-aminopentopyranose unit (7) or a daunosaminyl group (8), or modified by attachment of the N^6-dimethyladeninyl moiety at the sugar 5′-carbon rather than at the anomeric center (9); however, these modifications afforded no significant biological activities. 2′-Deoxypuromycin was found to be ineffective as an antimicrobial agent (10), as was the 2′,3′-*seco* analog (11). Carbocyclic analogs of puromycin have also been examined. The replacement of the furanose-ring oxygen by a methylene group yielded drugs whose cytotoxicities towards P-388 leukemia were found to be equal to that of puromycin itself (12). The carbocyclic 8-aza analog was identified also as an effective antibiotic (13), whereas a 7-deaza version was not (14). Hydroxycyclopentyl analogs displayed some antitumor effects in *HeLa* cells (15), while the cyclohexyl carbocyclic analog of puromycin was found to be somewhat less active than the cyclopentyl compounds (16).

As part of our ongoing investigation of the synthesis, structure, and biological activities of nucleoside analogs containing a variety of 5- and 6-membered heterocycles in place of the carbohydrate moiety (17), we wished to prepare puromycin analogs **20***a*, *b* and **21***a*, *b* incorporating a piperidine ring. Such compounds should be resistant to removal of the N^6-dimethyladeninyl group in vivo, since the base moiety is not attached by a glycosidic linkage. We wished to look for antitumor effects and activity against HIV. While this work was in progress, Peterson and Vince (18) reported the synthesis of a structurally similar pyrrolidinyl analog.

Results and discussion

Our synthetic strategy involved the construction of a pyrimidine- or purine-ring system on a *cis*-3-amino-5-(hydroxymethyl)piperidine precursor. There are few synthetic approaches available leading to such compounds;[4] however, we felt that lactam **1** (19) would offer the best starting point. Although both enantiomers of this lactam are commercially available,[5] the

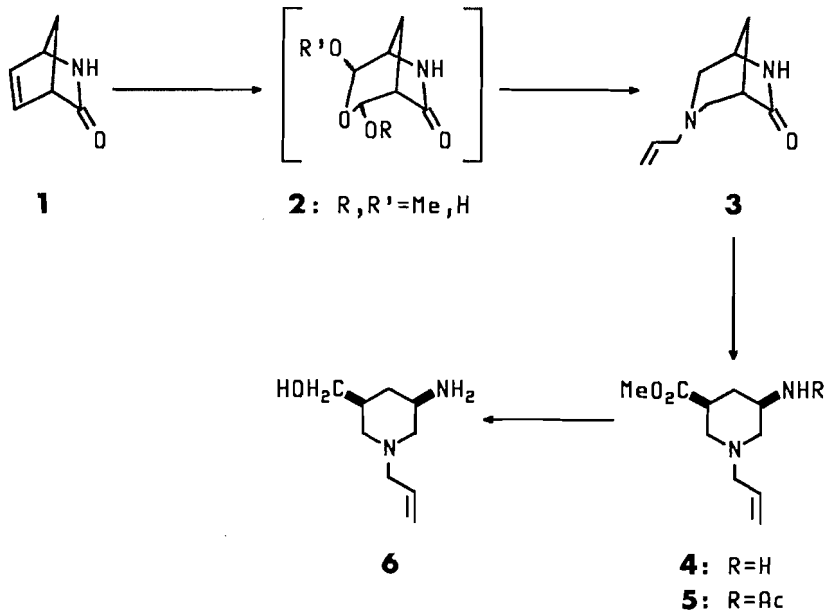

SCHEME 1

price of this material dictated that our nucleoside precursors would be racemic. The diastereomers produced by condensation with the amino acid could be separated and identified at the end of the sequence.

Initial attempts, based on our synthesis of *cis*-3-amino-5-(hydroxymethyl)thiane from **1** by nucleophilic displacement on the derived ditosylate (17), were unsuccessful; elimination products were obtained. Therefore, a reductive amination approach was tried (Scheme 1). Ozonolysis of **1** in methanol, followed by dimethyl sulfide processing, did not produce the expected dialdehyde. The product appeared to be **2**, identified by its ^1H and ^{13}C nmr spectra, which contained signals characteristic of the cyclic ketal structure, as well as by its positive reaction to a 2,4-dinitrophenylhydrazine test. This ketal was immediately subjected to reductive amination with allylamine hydrochloride and sodium cyanoborohydride. Standard conditions (20) failed to give the desired product; however, after considerable experimentation, **3** was obtained in 35% overall yield from **1**. No improvement in the yield could be achieved, and the remainder of the product of the reaction consisted of unidentifiable, highly polar material.

The lactam product **3** proved to be rather unstable, discoloring and decomposing on standing overnight. Accordingly, it was immediately converted into amino ester **4** (69%) by acid-promoted methanolysis. A sample of the amino ester was converted into its crystalline acetamido derivative **5** for analysis, while the bulk of the material was reduced, using lithium aluminium hydride, to afford the key amino alcohol, **6** (67%).

Synthesis of uracil-containing puromycin analogs

The construction of the uracil ring is shown in Scheme 2. Condensation of **6** with the acylisocyanate **7** (21), prepared in situ from the corresponding acid chloride, provided the acylurea derivative **8** (80%). Closure of the ring was effected with dilute sulfuric acid, yielding **9**, which was protected for easier purification as the *tert*-butyldimethylsilyl (TBDMS) ether **10** (82% from **8**).

The allyl blocking group was smoothly removed in 74% yield by a tris(triphenylphosphine)rhodium chloride-promoted hydrolysis, using the method of Laguzza and Ganem (22). The free piperidine was then acylated with *N*-(*tert*-butoxycarbonyl)-L-*p*-methoxyphenylalanine (**12**) (23), using 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC), to provide a 1:1 mixture of diastereomeric protected analogs **13***a*, *b* in 77% yield. It was not possible to separate these diastereomers by chromatographic means.

Synthesis of puromycin analogs

Reaction of **6** with 5-amino-4,6-dichloropyrimidine (Scheme 3) provided the chloropyrimidine derivative **14** in 80% yield. Closure of the purine-ring system with triethyl orthoformate and hydrochloric acid gave the chloropurine **15** (69%), which afforded the N^6-dimethyladenine derivative **16** (93%) on treatment with aqueous dimethylamine. This reaction proved difficult to monitor by tlc, as **15** and **16** co-eluted and had similar responses to visualizing agents. The alcohol group of **16** was silylated to give **17** in 87% yield, and the piperidine ring was deblocked to provide **18** (68%). A quantitative yield of diastereomeric adducts **19***a*, *b* was obtained on treatment of **18** with **12**–EDC. These also proved resistant to chromatographic separation.

Removal of both the silyl ether and *tert*-butyl carbamate protecting groups of **13** and **19** was achieved by treatment with trifluoroacetic acid in either dichloromethane or methanol solution (Scheme 4). Anisole was added as a scavenger for *tert*-butyl cation; *tert*-butylated material was recovered from an experiment on **13** in the absence of scavenger. The resulting diastereomeric uracil-puromycin analogs **20***a*, *b* (87%) and puromycin analogs **21***a*, *b* (93%) were then separated by reverse-phase hplc.

Identification of product diastereomers

With samples of the diastereomeric products in hand, it remained to ascertain their configurations. For this purpose we turned to ^1H nmr spectroscopy. The problem seemed initially to be complicated by the presence of two stable rotamers in all of the spectra, as a result of hindered rotation around the amide C—N bond. Moreover, while spectra of both diastereomers of

20 in D_2O solution were well resolved, the N^6-dimethyladenine compounds **21***a*, *b* were not soluble in this solvent, and gave severely broadened spectra in either $CDCl_3$ or DMSO-d_6 solutions. However, we were intrigued by the presence of the extremely high-field signal (δ 0.249 ppm) in the spectrum of the first-eluting fraction of **20** (Fig. 2(*A*)), which was lacking in

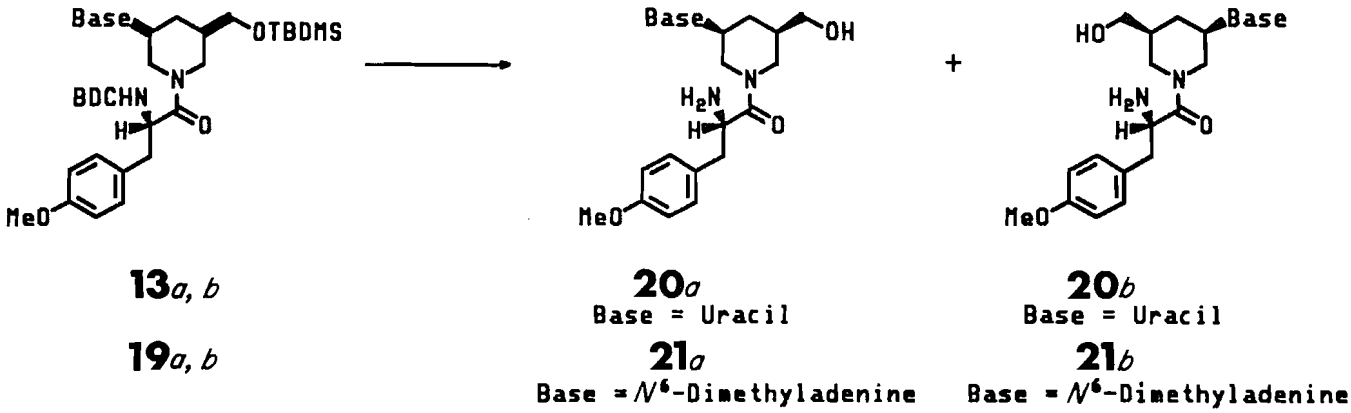

SCHEME 4

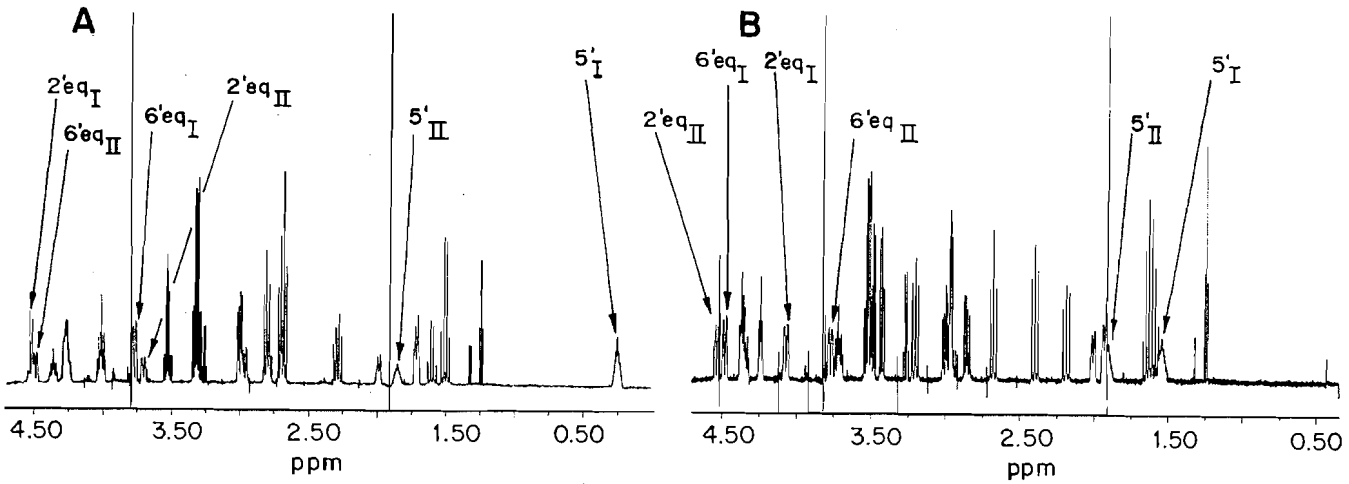

FIG. 2. Aliphatic regions of resolution-enhanced 600-MHz ^{1}H nmr spectra of (*A*) the first-eluting and (*B*) the second-eluting fractions of **20**. Peaks due to the major rotamer are labelled I, and those due to the minor rotamer are labelled II. The triplet at δ 1.142, singlet at δ 1.808, and quartet at δ 3.161 are attributable to $Et_3NH(OAc)$ from the HPLC buffer.

that of the second fraction (Fig. 2(*B*)), and we soon realized that this signal held the solution to our configurational problem.

A ^{1}H-COSY spectrum proved that this anomalously high-field signal arose from the H-5′ proton[6] of the major rotameric form (rotamer I) of the first fraction of **20**. The corresponding signal from H-5′ of the minor rotamer, II, was observed at δ 1.85 ppm. Such a high-field position for a methine proton most likely was due to shielding by the phenyl ring. Such shielding would occur if the ring were "tucked under" the piperidinyl ring. That this situation was only possible for *one* rotamer was evident from the ^{1}H nmr spectra, as was the fact that neither rotamer of the second fraction could adopt such a conformation (Fig. 2(*B*): H-5′$_I$ δ 1.50–1.58 ppm; H-5′$_{II}$ δ 1.87–1.95 ppm). It was clear from the ^3J values of the ring protons that the conformation of the piperidinyl ring was a chair having the 3′ and 5′ substituents equatorially oriented. Therefore, we needed to determine whether the major rotamer of fraction 1 had the carbonyl *syn* to the pyrimidinedione ring, or *anti*. We required also coupling constant and nOe information to set limits on possible side-chain conformations. With these data, we could construct models to ascertain which configuration could adopt the required orientation of the phenyl ring.

The chemical shifts of protons on *N*,*N*-dialkylamides depend on the orientation of the carbonyl: the signals of protons *syn* to the carbonyl are downfield of those of protons *anti* (24). In fraction 1, the signal of H-2′$_{eq}$ (I) is 0.82 ppm downfield of that of H-2′$_{eq}$ (II) and the signal of H-6′$_{eq}$ (I) is 0.72 ppm upfield of that of H-6′$_{eq}$ (II) (see Fig. 2). Carbon chemical shifts also are indicative of amide conformation; however, the *syn* carbon signal occurs *upfield* of that of the *anti* carbon (24). A heteronuclear correlation spectrum showed that the signal of C-2′ (I) is 2.83 ppm upfield of that of C-2′ (II), while the signal of C-6′ (I) is 3.27 ppm downfield from that of C-6′ (II). Further, irradiation of the side-chain H-α produced a 3.3% nOe in the signal of H-6′$_{eq}$ of rotamer I, and a 1.4% nOe in the signal of H-2′$_{eq}$ of rotamer II. These results are consistent with the carbonyl being *syn* to C-2′ and the pyrimidinedione ring in the major rotamer of fraction 1. Similar arguments allowed assignment of the rotamers of fraction 2.

The structures shown in Fig. 3 represent calculated local minima[7] relevant to our nmr observations of carbonyl orienta-

[6]The piperidine-ring system has been numbered according to IUPAC rules.

[7]Computations were performed on an IBM RS/6000 RISC 550 computer operating under AIX. Initial structures approximating the "tucked" and "extended" conformers were constructed based on our ^{1}H nmr data, and minimized using the Dreiding force field as implemented in the program BIOGRAF, from Biodesign, Inc. Energy minimization was accomplished using the conjugate-gradient method with an energy cutoff criterion of 0.001 kcal mol^{-1}. The resulting gas-phase minima were

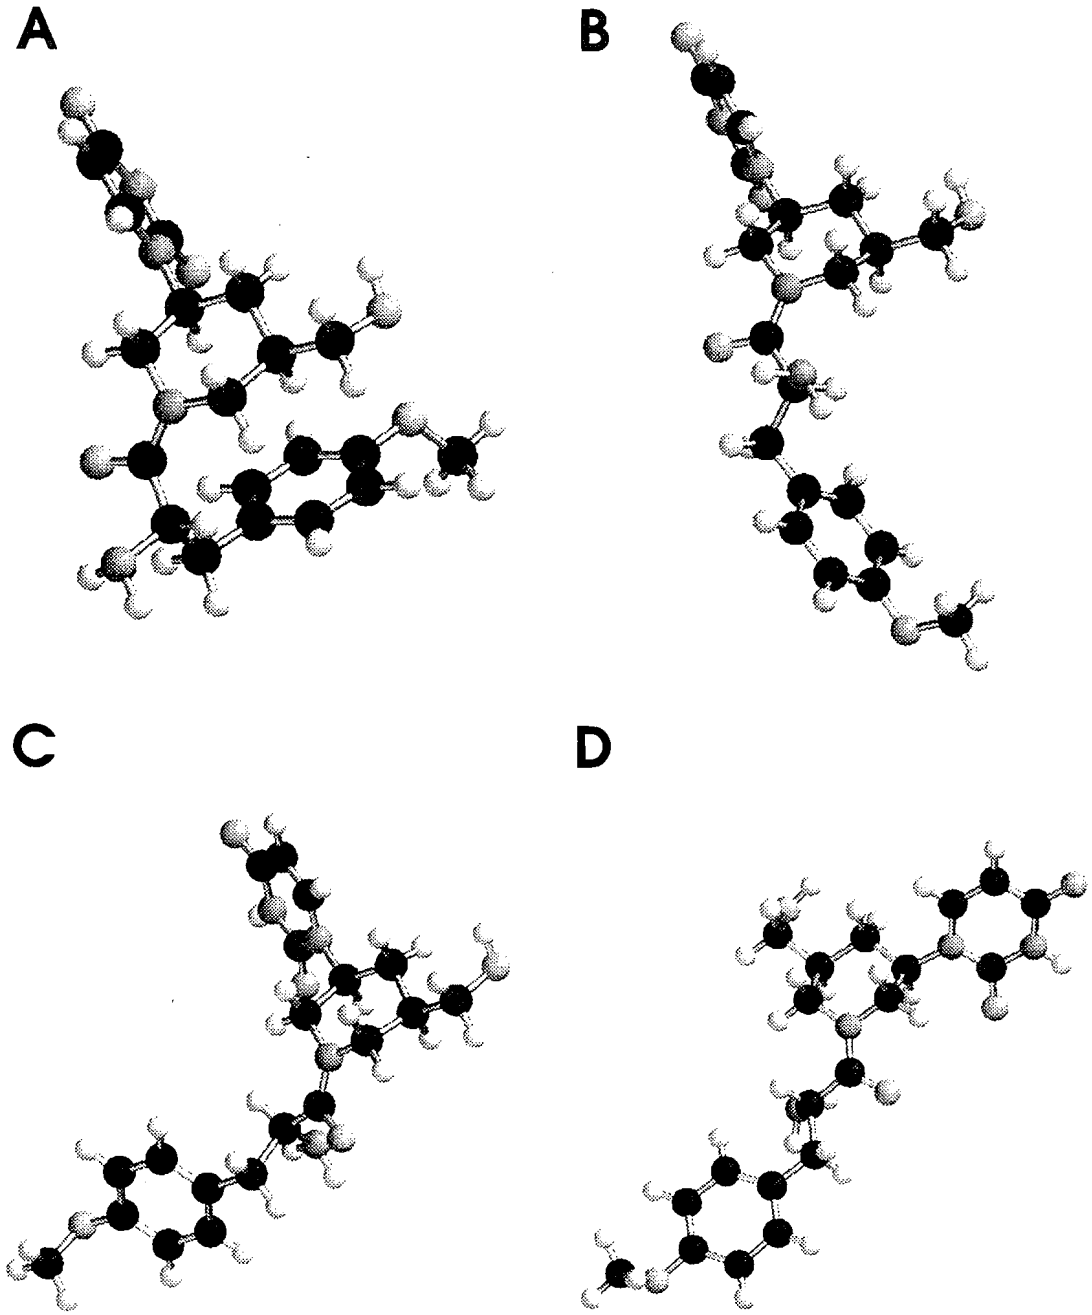

FIG. 3. Possible conformations of analogs **20**. (*A*) The "tucked" conformation of **20***a* with the carbonyl *syn* to the uracil ring. (*B*) An "extended" conformation of **20***a* with the carbonyl *syn*. (*C*) An "extended" conformation of **20***a* with the carbonyl *anti*. (*D*) An "extended" conformation of **20***b* with the carbonyl *syn*. The corresponding "tucked" conformer (not shown) would require overlap of the α-amino group with the C-6′ methylene.

tion and side-chain conformation in **20**. Only the (3′*S*,5′*R*) configuration affords a stable conformation with the carbonyl *syn* and the phenyl ring in the correct position to shield H-5′ (Fig. 3(*A*)). The *anti* rotamer cannot adopt this type of conformation, and must have the side chain extended away from the piperidine ring (Fig. 3(*C*)). The "tucked" conformer shown in Fig. 3(*A*) is the lowest in energy of the structures found for the (3′*S*,5′*R*) configuration, and the calculated torsional angles between H-α and the benzylic H's (55.8° and 171.1°) correspond well to those estimated from ^3J values of rotamer I of the first fraction of **20**, using a modified Karplus equation (25) (50° and 168°).

In the (3′*R*,5′*S*) configuration with the carbonyl *syn*, the α-amino group and the 6′-methylene group would come into contact if the side chain was "tucked under"; both rotamers must exist in conformations having the side chain extended (Fig. 3(*D*)). Therefore, we assign the (3′*S*,5′*R*) stereochemistry **20***a* to fraction 1, and the (3′*R*,5′*S*) stereochemistry **20***b* to the second fraction.

Analogs **21** were not soluble in D_2O, as noted above. The broadened ^1H nmr spectra obtained in $CDCl_3$ solution indicated the presence of an approximately 1:1 mixture of rotamers for both diastereomers; however, there was no high-field signal as

then solvated in a hexagonal lattice of water. The inner cutoff distance was 2.8 Å, the outer cutoff was 8.4 Å, and the lattice spacing was 2.8 Å to give ~3 layers of water. Re-minimization then provided the structures shown in Fig. 3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

in **20***a*. Lowering the temperature failed to "freeze-out" the rotamers above the freezing point of $CDCl_3$. Spectra in DMSO-d_6 solution were also broad; however, raising the temperature to 383 K allowed confirmation of the structure, at the cost of any conformational information. We assigned (tentatively) the (3′*S*,5′*R*) stereochemistry **21***a* to the first-eluting fraction, and the (3′*R*,5′*S*) configuration **21***b* to the second-eluting fraction, by analogy with the pyrimidinedione analogs **20**.

The absence of a "tucked-under" conformation analogous to that of Fig. 3(*A*) for **21** can be explained by the difference in solvents used for the nmr spectra. Such a conformation should be favored in water solutions since it minimizes contact of hydrophobic portions of the molecule with the solvent. In organic solvents, this effect would be unimportant, and extended conformations would result. It is interesting to note that puromycin itself does not adopt such a tucked conformation either in water solution (26), or in the crystal (27), although the phenyl ring is oriented near the 5′-hydroxymethyl group in both states.

Anti-HIV and antitumor assays

Samples of **20***a*, **20***b*, **21***a*, and **21***b* were submitted to the U.S. National Cancer Institute (N.C.I.) for anti-HIV screening by the soluble-formazan assay in human T4 lymphocytes (28). All compounds were inactive in this assay. Some toxicity was observed at high concentrations of **21***a* (1.4×10^{-4} M) but otherwise the compounds had no effect on infected or uninfected cells. Analogs **20***a*, **20***b*, **21***a*, and **21***b* were tested also by N.C.I. against a panel of human leukemia, lung cancer, colon cancer, CNS cancer, melanoma, ovarian cancer, and renal cancer cell cultures. No useful activity was observed in these assays, although **20***a* displayed a weak effect against HL-60(TB) leukemia ($GI_{50} = 5.84 \times 10^{-5}$ M), and **21***a* had a similarly low activity against HL-60(TB) ($GI_{50} = 7.34 \times 10^{-5}$ M) and against non-small-cell lung cancers HOP-18 ($GI_{50} = 4.57 \times 10^{-5}$ M) and HOP-92 ($GI_{50} = 5.70 \times 10^{-5}$ M).

The pyrrolidinyl puromycin analog of Peterson and Vince (18) was reported to be inactive in an assay against P-388 leukemia cells. The authors suggested that the absence of a 2′-OH group may explain this result, as this hydroxyl has been shown to be essential in puromycin itself (10). The lack of activity of the pyrrolidinyl and our piperidinyl analogs **20**–**21** may also be due to differences in conformation. Our compounds prefer to orient the aminoacyl chain below the mean plane of the piperidine ring, while puromycin exists in a C-3′ *endo* conformation in the solid phase (27) and in solution (26), in which the aminoacyl chain lies near or above the plane of the ribosyl ring.

Experimental

The ^{1}H nmr spectra were recorded on a Bruker AMX-600, AM-400, or AC-F 200 spectrometer at 600.140, 400.136, or 200.132 MHz. The signals due to residual protons in the deuterated solvents indicated were used as internal standards except for spectra recorded in D_2O, in which case 3-(trimethylsilyl)propane sulfonic acid sodium salt was added as an internal standard. Chemical shifts are reported in ppm (δ) downfield from the position of tetramethylsilane (TMS). The symbols s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), and br (broadened) are used to describe the multiplicity and shape of the signals. The ^{13}C nmr spectra were obtained at 100.6 MHz on the AM-400 spectrometer or at 50.323 MHz on the AC-F 200 spectrometer, using the JMOD spin-echo sequence (29) to aid in peak identification. Chemical shifts in ppm (δ) downfield from the position of TMS were measured using the solvent signals as internal standards, except for spectra measured in D_2O, where 1,4-dioxane-H_8 (δ 66.5) (30) was added as a standard.

EI mass spectra were recorded on a VG Micromass 7070F mass spectrometer at an ionizing voltage of 70 eV, or on a VG Analytical ZAB-E mass spectrometer, and CI spectra were recorded using NH_3 at ~1 Torr (133.3 Pa) as reagent gas; data are given as *m/z* (% relative intensity). The exact masses were determined under EI conditions. The high-resolution measurements were performed by peak matching using perfluorokerosene as a reference standard.

Melting points were determined using a Fisher–Johns apparatus, and are uncorrected. Flash chromatography was performed on Kieselgel 60 (230–400 mesh), and thin-layer chromatography (tlc) was performed on glass plates coated with Kieselgel 60. High-pressure liquid chromatography (hplc) was carried out using a Beckman System Gold instrument.

The homogeneity of the products was established on the basis of chromatographic, spectroscopic (^{1}H and ^{13}C nmr), and melting point determinations.

(±)-3,6-Diaza-7-oxo-3-(2-propenyl)bicyclo[3.2.1]octane (3)

A solution of freshly recrystallized lactam **1** (see ref. 19) (3.00 g, 27.49 mmol) in dry methanol (300 mL) was purged with oxygen, while being cooled to −70°C in a Dry Ice – acetone bath. Ozone was passed through the solution, maintaining a temperature of −70°C or below, until tlc analysis (0.5% methanol in ethyl acetate as eluant) and the presence of the blue color of an excess of ozone indicated completion. The solution was purged of ozone with a stream of nitrogen. Dimethyl sulfide (10 mL) was added and the mixture was stirred for 1 h. The temperature was allowed to rise to 23°C, the solvents were evaporated, and the residue was left in vacuo for several hours. The oily product (6.934 g) was identified as the mixed ketal **2** by ^{1}H and ^{13}C nmr spectroscopy, and by a positive response to a 2,4-dinitrophenylhydrazine test.

The oil **2** was dissolved in *N*,*N*-dimethylformamide (150 mL). To this solution were added 4 Å molecular sieves (15 g), allylamine hydrochloride (2.57 g, 27.5 mmol), and glacial acetic acid (1.6 mL, 27.5 mmol). The stirred mixture was cooled on ice under a nitrogen atmosphere, and sodium cyanoborohydride (3.45 g, 54.96 mmol) was added. The reaction was allowed to proceed overnight, gradually warming to 23°C. Methanol (150 mL) was added, and the mixture was filtered. The filter cake was washed thoroughly with methanol, and the combined filtrates were evaporated. The residue was dissolved in chloroform (100 mL) and the solution was washed with a 10% aqueous solution of potassium carbonate (50 mL). The aqueous layer was extracted with chloroform (2 × 50 mL), and the combined organic layers were dried ($MgSO_4$) and evaporated. The residue was evaporated twice more from toluene to remove residual *N*,*N*-dimethylformamide, before being chromatographed on silica gel (5% (v/v) methanol in chloroform as eluant) to afford **3** as an oil (1.607 g, 35%). The oil could be distilled (bp 130°C, 0.25 Torr) but even carefully purified material was found to discolor and decompose on standing overnight; ^{1}H nmr ($CDCl_3$, 200 MHz) δ: 1.59 (1H, dd, J_{gem} = 11.0 Hz, J_{vic} = 3.0 Hz, H-8_{eq}), 2.19–2.41 (4H, m, H-1, H-2_{ax}, H-4_{ax}, H-8_{ax}), 2.88 (1H, m, H-4_{eq}), 3.06–3.16 (3H, m, H-2_{eq}, =CHCH_2N), 3.71 (1H, m, H-5), 5.06–5.20 (2H, m, H_2C=), 5.69–5.95 (2H, m, =C*H*CH_2, NH); ^{13}C nmr ($CDCl_3$, 50 MHz) δ: 37.548 (C-8), 40.188 (C-1), 50.989 (C-5), 53.444 (C-2), 54.242 (C-4), 59.955 (=CHCH_2N), 117.512 (H_2C=), 134.749 (=*C*HCH_2), 179.942 (C-7).

(±)-(3β,5β)-3-Amino-5-(methoxycarbonyl)-1-(2-propenyl)piperidine (4)

To a solution of lactam **3** (2.80 g, 16.8 mmol) in methanol (50 mL) was added concentrated aqueous hydrochloric acid (3 mL), and the mixture was heated at reflux temperature for 2 h. A further portion of hydrochloric acid (1 mL) was added, and heating was continued. After 5 h, the mixture was cooled, and concentrated. The residue was dissolved in water (40 mL), and the solution was adjusted to pH 9.0 with solid potassium carbonate. The aqueous solution was extracted with chloroform (3 × 50 mL), and the organic extracts were dried ($MgSO_4$) and evaporated. The residual oil was distilled (bp 75–85°C, 0.01 Torr) using a Kugelrohr apparatus, to afford the aminoester **4** (2.29 g, 69%);

^{1}H nmr ($CDCl_3$, 400 MHz) δ: 1.13 (1H, ddd, $J_{3,4ax}$ = 11.0 Hz, $J_{4ax,5}$ = 12.5 Hz, $J_{4ax,4eq}$ = 12.5 Hz, H-4_{ax}), 1.24 (2H, br s, NH_2), 1.60 (1H, dd, $J_{2ax,3}$ = 10.0 Hz, $J_{2ax,2eq}$ = 10.5 Hz, H-2_{ax}), 1.93 (1H, dd, $J_{5,6ax}$ = 11.4 Hz, $J_{6ax,6eq}$ = 11.1 Hz, H-6_{ax}), 2.20 (1H, m, H-4_{eq}), 2.65 (1H, dddd, $J_{4ax,5}$ = 12.5 Hz, $J_{5,6ax}$ = 11.4 Hz, J_{vic} = 4.0 Hz, J_{vic} = 3.8 Hz, H-5), 2.85 (1H, dddd, $J_{2ax,3}$ = 10.0 Hz, $J_{3,4ax}$ = 11.0 Hz, J_{vic} = 4.5 Hz, J_{vic} = 4.0 Hz, H-3), 2.96 (1H, m, H-2_{eq}), 2.99–3.02 (2H, m, =CHCH_2N), 3.07 (1H, m, H-6_{eq}), 3.65 (3H, s, OCH_3), 5.11–5.19 (2H, m, H_2C=), 5.82 (1H, m, =CHCH_2); ^{13}C nmr ($CDCl_3$, 50 MHz) δ: 37.060 (C-4), 41.061 (C-5), 47.639 (C-3), 51.542 (OCH_3), 54.402 (C-6), 61.275 (=CHCH$_2$N), 62.065 (C-2), 117.940 (H_2C=), 134.618 (=CHCH$_2$), 173.791 (C=O).

(±)-(3β,5β)-3-Acetamido-5-(methoxycarbonyl)-1-(2-propenyl)piperidine (5)

Aminoester **4** (85 mg, 0.43 mmol) was dissolved in dry pyridine (1 mL) and the solution was cooled on ice as acetic anhydride (4 drops, excess) was added. The mixture was stirred at 23°C for 1 h, at which point tlc analysis (15% (v/v) methanol in chloroform as eluant) indicated complete reaction. The pyridine was evaporated, and the residue was dissolved in chloroform (10 mL). The solution was washed with a 10% aqueous solution of sodium hydrogen carbonate (2 × 2 mL) and then with brine (2 mL). The organic layer was dried ($MgSO_4$) and concentrated to yield a solid product, 110 mg (quant.). A sample recrystallized from diisopropyl ether had mp 98–100°C; ^{1}H nmr ($CDCl_3$, 400 MHz) δ: 1.53 (1H, br m, H-4_{ax}), 1.95 (3H, s, C(O)CH_3), 1.95–2.13 (2H, br m, H-4_{eq} and H-6_{ax}), 2.34 (1H, br m, H-2_{ax}), 2.70 (1H, m, H-5), 2.79–2.86 (2H, br m, H-2_{eq} and H-6_{eq}), 2.99 (1H, dddd, J_{gem} = 13.5 Hz, J_{vic} = 6.5 Hz, 2 × allylic J's ~1 Hz each, =CHCH_2N), 3.05 (1H, dddd, J_{gem} = 13.5 Hz, J_{vic} = 6.35 Hz, 2 × allylic J's ~1 Hz each, =CHCH_2N), 3.678 (3H, s, OCH_3), 4.02 (1H, m, H-3), 5.13–5.20 (2H, m, H_2C=), 5.81 (1H, m, =CHCH$_2$), 5.88 (1H, br s, NH); ^{13}C nmr ($CDCl_3$, 100 MHz) δ: 23.441 (C(O)CH$_3$), 31.812 (C-4), 40.035 (C-5), 45.124 (C-3), 51.892 (OCH_3), 54.264 (C-6), 57.858 (C-2), 61.194 (=CHCH$_2$N), 118.179 (H_2C=), 134.487 (=CHCH$_2$), 169.376 (amide C=O), 174.38 (ester C=O); ms (EI): 241 (M + H)$^+$ (3.3%), 209 ($M^{+\cdot}$ − $^{\cdot}OCH_3$)$^+$ (5.5%), 181 ($M^{+\cdot}$ − CH_3CONH_2)$^{+\cdot}$ and (or) ($M^{+\cdot}$ − $^{\cdot}COOCH_3$)$^+$ (100%), 140 ($C_7H_{12}N_2O$: $M^{+\cdot}$ − H_2C=$CHCH_2^{\cdot}$ − $^{\cdot}COOCH_3$)$^{+\cdot}$ (89.3%), 122 ($C_8H_{12}N$: 181 − CH_3CONH_2 or $^{\cdot}COOCH_3$)$^+$ (36.9%). (±)-(3β,5β)-3-Amino-5-(hydroxymethyl)-1-(2-propenyl)piperidine (6)

A solution of aminoester **4** (2.20 g, 11.1 mmol) in dry oxolane (15 mL) was added dropwise to a suspension of lithium aluminium hydride (0.50 g, 13.2 mmol) in oxolane (10 mL) at 0°C. The reaction mixture was stirred under a nitrogen atmosphere for 30 min. A further portion of lithium aluminium hydride (255 mg, 6.7 mmol) was added, and stirring was continued for 15 min; tlc analysis (plate pretreated with NH_3 vapor, 15% (v/v) methanol in chloroform as eluant) indicated complete reaction had occurred. The reaction was quenched by cautious addition of water (1 mL), then a 15% (w/v) aqueous solution of sodium hydroxide (1 mL), followed by more water (3 mL), was added. The mixture was warmed to 23°C and stirred for 40 min. Magnesium sulfate was added, and the mixture was filtered. The filter cake was washed with oxolane (25 mL), and the combined filtrates were concentrated to afford an oil. Chromatography on silica gel using the organic layer of a 12:6:1 (v/v/v) chloroform–isopropanol – aqueous ammonium hydroxide mixture as eluant afforded the amino alcohol **6** as a solid (1.251 g, 67%). A sample recrystallized from diisopropyl ether had mp 74–75°C; ^{1}H nmr ($CDCl_3$, 200 MHz) δ: 0.73 (1H, apparent q, J_{app} = 12.0 Hz, H-4_{ax}), 1.47–2.00 (7H, m, H-2_{ax}, H-4_{eq}, H-5, H-6_{ax}, OH, NH_2), 2.83–3.13 (5H, m, H-2_{eq}, H-3, H-6_{eq}, =CHCH_2N), 3.44 (1H, dd, J_{gem} = 10.7 Hz, J_{vic} = 6.6 Hz, CHOH), 3.53 (1H, dd, J_{gem} = 10.7 Hz, J_{vic} = 5.5 Hz, CHOH), 5.06–5.24 (2H, m, H_2C=), 5.86 (1H, m, =CHCH$_2$); ^{13}C nmr ($CDCl_3$, 50 MHz) δ: 37.599 (C-4), 38.361 (C-5), 48.076 (C-3), 56.355 (C-6), 61.761 (C-2), 62.834 (=CHCH$_2$N), 65.895 (CH_2OH), 117.968 (H_2C=), 134.946 (=CHCH$_2$); ms (EI): 170 (M)$^{+\cdot}$ (12.8%), 152 ($M^{+\cdot}$ − H_2O)$^{+\cdot}$ (7.1%), 127 ($M^{+\cdot}$ − H_2C=$CHNH_2$)$^{+\cdot}$ (24.0%), 122 ($M^{+\cdot}$ − H_2O − $^{\cdot}CH_2NH_2$)$^+$ (9.8%), 96 (15.2%), 84 ($C_5H_{10}N$)$^+$ (100%). *(±)-*trans*-3-Ethoxy-*N*-{N′-[(3′β,5′β)-5′-(hydroxymethyl)-1′-(2-propenyl)piperidin-3′-yl]carbamoyl}propenamide (8)*

Following the procedure of Shealy and O'Dell (21*a*), silver cyanate was dried at 60°C and <1 Torr in the dark for 12 h. Distilled *N,N*-dimethylformamide was dried over 4 Å molecular sieves. All glassware was dried overnight at 110°C, and assembled while hot, under a nitrogen atmosphere.

A suspension of silver cyanate (1.055 g, 7.04 mmol) in dry benzene (5 mL) was heated to reflux temperature under a nitrogen atmosphere. After 30 min, a solution of *trans*-3-ethoxypropenoyl chloride (21*b*) (475 mg, 3.52 mmol) in benzene (5 mL) was added. The mixture was boiled for 45 min more. Heating and stirring were stopped, and the suspended solids were allowed to settle from the solution of acylisocyanate **7** over 2 h.

A solution of amino alcohol **6** (400 mg, 2.35 mmol) in *N,N*-dimethylformamide (15 mL) was cooled to −75°C under a nitrogen atmosphere. An 8-mL portion of the solution of **7** (~2.82 mmol) was removed with a syringe, and was added dropwise to the amine solution. The mixture was rapidly warmed to −30°C, and was then stirred for 6 h as the temperature slowly rose to 23°C. The solvents were evaporated under high vacuum, and the residue was chromatographed on silica gel using a gradient of 5% → 7% → 10% (v/v) methanol in chloroform as eluant. Acylurea derivative **8** was obtained as a glassy foam (588 mg, 80%). A sample obtained by recrystallization from diisopropyl ether had mp 113°C; ^{1}H nmr ($CDCl_3$, 400 MHz) δ: 0.97 (1H, ddd, $J_{3',4'ax}$ = 11.8 Hz, $J_{4'ax,5'}$ = 12.8 Hz, J_{gem} = 10.9 Hz, H-$4'_{ax}$), 1.35 (3H, t, J = 7.1 Hz, CH_3), 1.71 (1H, dd, $J_{5',6'ax}$ = 11.1 Hz, J_{gem} = 10.7 Hz, H-$6'_{ax}$), 1.78 (1H, dd, $J_{2'ax,3'}$ = 10.4 Hz, J_{gem} = 10.6 Hz, H-$2'_{ax}$), 1.66–1.82 (1H, br s, OH), 1.88–1.99 (1H, m, H-5′), 2.07 (1H, m, H-$4'_{eq}$), 2.99 (1H, br dd, J_{gem} = 10.7 Hz, $J_{5',6'eq}$ = 3.5 Hz, H-$6'_{eq}$), 2.99–3.08 (2H, m, =CHCH_2N), 3.13 (1H, br dd, J_{gem} = 10.6 Hz, $J_{2'eq,3'}$ = 4.2 Hz, H-$2'_{eq}$), 3.46 (1H, dd, J_{gem} = 10.5 Hz, J_{vic} = 5.6 Hz, CHOH), 3.58 (1H, dd, J_{gem} = 10.5 Hz, J_{vic} = 7.1 Hz, CHOH), 3.92–4.01 (1H, m, H-3′), 3.96 (2H, q, J = 7.1 Hz, OCH_2CH$_3$), 5.11–5.20 (2H, m, H_2C=), 5.34 (1H, d, J = 12.2 Hz, H-2), 5.84 (1H, m, =CHCH$_2$), 7.61 (1H, d, J = 12.2 Hz, H-3), 8.59 (1H, d, J = 7.9 Hz, CHNH), 9.45 (1H, s, C(O)NHC(O)); ^{13}C nmr ($CDCl_3$, 100 MHz) δ: 14.440 (CH_3), 33.928 (C-4′), 37.977 (C-5′), 46.570 (C-3′), 56.057 (C-6′), 58.496 (C-2′), 61.532 (=CHCH$_2$N), 65.593 (CH_2OH), 67.453 (OCH$_2$CH$_3$), 98.030 (C-2), 118.160 (H_2C=), 134.609 (=CHCH$_2$), 154.696 (urea C=O), 162.635 (C-3), 168.376 (C-1); ms (EI): 311 (M)$^{+\cdot}$ (3.1%), 153 ($C_9H_{15}NO$: $M^{+\cdot}$ − EtOCH=CHCONHCONH$_2$)$^{+\cdot}$ (100%), 122 (153 − $^{\cdot}CH_2OH$)$^+$ (18.5%), 99 (EtOCH=CHC≡O)$^+$ (10.6%); ms (CI): 312 (M + H)$^+$ (100%), 272 (M − H_2C=$CHCH_2^{\cdot}$ + 2H)$^+$ (3.6%), 214 ($C_{10}H_{20}N_3O_2$)$^+$ (2.0%), 197 (214 − NH_3)$^+$ (8.8%), 171 ($M^{+\cdot}$ − EtOCH=CHCONHCO$^{\cdot}$)$^+$ (35.0%), 116 (EtOCH=CHCONH$_2$ + H)$^+$ (21.4%). *(±)-1-{(3′β,5′β)-1′-(2-Propenyl)-5′-(*tert*-butyldimethylsilyloxymethyl)piperidin-3′-yl}-2,4(1H,3H) pyrimidinedione (10)*

Enol ether **8** (311 mg, 1 mmol) was dissolved in water (10 mL). The solution was adjusted to pH 1.0 with 1 M sulfuric acid, and then heated at reflux temperature for 20 min. The cooled reaction mixture was stirred at 23°C for 1.5 h more, before being neutralized with solid potassium carbonate. The solvent was removed by freeze-drying, and the solid residues were extracted with 20% (v/v) methanol in chloroform until no further product could be detected in the extracts. The solvent was evaporated to afford pyrimidinedione **9** as its H_2SO_4 salt (337 mg, 93%).

The salt (297 mg, 0.817 mmol) was suspended in dry *N,N*-dimethylformamide (5 mL). Imidazole (218 mg, 3.2 mmol) and *tert*-

For personal use only.

butyldimethylsilyl chloride (180 mg, 1.2 mmol) were added, followed by a catalytic amount of 4-(dimethylamino)pyridine. After stirring under a nitrogen atmosphere for 1.5 h, a further portion of *tert*-butyldimethylsilyl chloride (100 mg, 0.66 mmol) was added, and the reaction was allowed to proceed overnight. Water (10 mL) was added, followed by dichloromethane (10 mL), and the phases were separated. The aqueous layer was extracted with dichloromethane (2 × 10 mL). The combined organic layers were washed with a 10% (w/v) aqueous solution of sodium hydrogen carbonate (2 × 10 mL), and with brine (10 mL). The dried ($MgSO_4$) organic solution was evaporated, and the residue was evaporated once more from toluene to remove traces of *N,N*-dimethylformamide. Chromatography of the residue on silica gel (5% (v/v) methanol in chloroform as eluant) afforded **10** as a foam (314 mg, 82% overall), which became a crystalline solid on a further evaporation from chloroform. A sample recrystallized from water–acetonitrile formed needles; mp 142–143°C; ^{1}H nmr ($CDCl_3$, 200 MHz) δ: 0.03 (6H, s, $Si(CH_3)_2$), 0.87 (9H, s, $SiC(CH_3)_3$), 1.29 (1H, apparent q, J_{app} = 12.2 Hz, H-4′$_{ax}$), 1.69 (1H, dd, $J_{5',6'ax}$ = 11.0 Hz, J_{gem} = 11.1 Hz, H-6′$_{ax}$), 1.87–2.10 (3H, m, H-2′$_{ax}$, H-4′$_{eq}$, H-5′), 2.93–3.16 (4H, m, H-2′$_{eq}$, H-6′$_{eq}$, =CHC*H*$_2$N), 3.49 (2H, apparent d, J_{app} = 5.6 Hz, CH_2OSi), 4.69 (1H, m, H-3′), 5.10–5.23 (2H, m, H_2C=), 5.70 (1H, d, *J* = 8.0 Hz, H-5), 5.82 (1H, m, =C*H*CH$_2$), 7.21 (1H, d, *J* = 8.0 Hz, H-6), 9.49–9.71 (1H, br, NH); ^{13}C nmr ($CDCl_3$, 50 MHz) δ: −5.47 ($Si(CH_3)_2$), 18.252 ($SiC(CH_3)_3$), 25.861 ($SiC(CH_3)_3$), 32.116 (C-4′), 38.278 (C-5′), 52.529 (C-3′), 55.882 (C-6′), 56.912 (C-2′), 61.331 (=CH*C*H$_2$N), 65.522 (CH_2OSi), 102.178 (C-5), 118.207 (H_2C=), 134.520 (=*C*HCH$_2$), 140.846 (C-6), 150.818 (C-2), 163.189 (C-4); ms (EI): 380 (M + H)$^+$ (3.8%), 379 (M)$^{+\cdot}$ (4.0%), 364 (M$^{+\cdot}$ − ·CH$_3$)$^+$ (5.2%), 322 (M$^{+\cdot}$ − *tert*-Bu·)$^+$ (5.5%), 268 (M − pyrimidinedione + H)$^+$ (26.0%), 267 (M$^{+\cdot}$ − pyrimidinedione)$^{+\cdot}$ (100%), 226 (267 − H_2C=CHCH$_2$·)$^+$ (34.5%), 210 (267 − *tert*-Bu·)$^+$ (17.3%), 170 (13.9%), 134 (19.7%), 122 (267 − *tert*-BuSiMe$_2$OCH$_2$·)$^+$ (26.2%). *(±)-1-[(3′*β*,5′*β*)-5′-(*tert*-Butyldimethylsilyloxymethyl)piperidin-3′-yl]-2,4(1*H*,3*H*)pyrimidinedione (**11**)*

Using the procedure and apparatus described by Laguzza and Ganem (22), a solution of allyl amine derivative **10** (310 mg, 0.82 mmol) in 84:16 (v/v) acetonitrile–water (15 mL) was heated at reflux temperature under a stream of nitrogn, in the presence of tris(triphenylphosphine)rhodium chloride (20 mg). Fresh solvent was added during the reaction to maintain a constant volume. After 2.5 h, tlc analysis (10% (v/v) methanol in chloroform as eluant) showed that the reaction was essentially complete. The mixture was cooled, and the solvents were evaporated. The residue was evaporated several times from acetonitrile before being purified by preparative tlc on a 2 mm × 20 cm × 20 cm silica gel plate (E. Merck no. 5717) using 10% (v/v) methanol in chloroform as eluant. The free amine **11** was obtained as a yellowish solid (205 mg, 74%); ^{1}H nmr (CD_3OD, 200 MHz)[8] δ: 0.06 (6H, s, $Si(CH_3)_2$), 0.89 (9H, s, $SiC(CH_3)_3$), 1.55 (1H, apparent q, J_{app} = 12.4 Hz, H-4′$_{ax}$), 1.80–2.01 (2H, m, H-4′$_{eq}$ and H-5′), 2.28 (1H, br dd, Σ*J* = 23.9 Hz, H-6′$_{ax}$), 2.66 (1H, br dd, Σ*J* = 23.4 Hz, H-2′$_{ax}$), 3.01–3.16 (2H, m, H-2′$_{eq}$ and H-6′$_{eq}$), 3.51 (1H, dd, J_{gem} = 10.2 Hz, J_{vic} = 6.2 Hz, CHOSi), 3.55 (1H, dd, J_{gem} = 10.2 Hz, J_{vic} = 5.3 Hz, CHOSi), 4.50 (1H, m, H-3′), 5.67 (1H, d, *J* = 8.0 Hz, H-5), 7.64 (1H, d, *J* = 8.0 Hz, H-6); ^{13}C nmr (CD_3OD, 50 MHz)[8] δ: −5.337 ($Si(CH_3)_2$), 19.334 ($SiC(CH_3)_3$), 26.352 ($SiC(CH_3)_3$), 33.004 (C-4′), 41.400 (C-5′), 49.136 (C-6′), 49.940 (C-2′), 54.474 (C-3′), 66.780 (CH_2OSi), 102.550 (C-5), 143.525 (C-6), 152.699 (C-2), 166.177 (C-4); ms (EI): 340 (M + H)$^+$ (4.0%), 324 (M$^{+\cdot}$ − ·CH$_3$)$^+$ (4.2%), 282 (M$^{+\cdot}$ − *tert*-Bu·)$^+$ (7.1%), 227 (M$^{+\cdot}$ − pyrimidinedione)$^{+\cdot}$ (65.3%), 170 (227 − *tert*-Bu·)$^+$ (100%), 95 (60.1%); ms (CI): 340 (M + H)$^+$ (100%), 228 (7.5%), 227 (9.6%), 170 (8.6%), 113 (pyrimidinedione + H)$^+$ (4.7%), 95 (10.5%). Exact Mass calcd. for ($C_{16}H_{29}N_3O_3Si$ + H): 340.2058; found (hrms): 340.2029.

[8]In $CDCl_3$, all of the nmr signals were observed to be very broad.

*1-[(3′*RS*,5′*SR*)-1′-(2*S*-[*tert*-Butoxycarbamoyl]-3-(4-methoxyphenyl)propanoyl)-5′-(*tert*-butyldimethylsilyloxymethyl)-piperidin-3′-yl]-2,4(1*H*,3*H*)pyrimidinedione (**13**a, b)*

The amine **11** (190 mg, 0.56 mmol) and amino acid derivative **12** (23) (185 mg, 0.63 mmol) were dissolved in dry dichloromethane (15 mL) and the solution was cooled to 0°C. 1-(3-Dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (140 mg, 0.73 mmol) was added, with a further portion of dichloromethane (2 mL). The reaction was stirred under nitrogen for 1.5 h at 0°C. Water (5 mL) was added to quench the reaction. The phases were separated, and the organic layer was washed successively with water (10 mL), a 10% (w/v) aqueous sodium hydrogen carbonate solution (10 mL), and with brine (10 mL) before being dried ($MgSO_4$) and evaporated. The resulting thick yellow oil was chromatographed on silica gel using a slow gradient of 0% → 5% (v/v) methanol in chloroform as eluant. No separation of the product diastereomers was observed, and a 1:1 mixture of **13***a* and **13***b* was obtained as a glassy solid (265 mg, 77%); ^{1}H nmr ($CDCl_3$, 200 MHz)[9] δ: 0.01 (6H, br s, $Si(CH_3)_2$), 0.86 (9H, br s, $SiC(CH_3)_3$), 1.34–1.37 (9H, 2 × s, $OC(CH_3)_3$), 3.73 (3H, 2 × s, $ArOCH_3$), 5.64–5.72 (1H, 2 × d, H-5), 6.74–7.16 (5H, m, phenyl H's and H-6); ^{13}C nmr ($CDCl_3$, 50 MHz)[9] δ: −5.482 ($Si(CH_3)_2$), 18.259 ($SiC(CH_3)_3$), 25.885 ($SiC(CH_3)_3$), 28.329 ($OC(CH_3)_3$), 32.167 (C-4′), 38.060 (C-5′), 45.051 (CH_2Ar), 51.14–51.60 (C-3′), 55.19–55.37 ($ArOCH_3$), 64.41–64.70 (CH_2OSi), 79.66 ($OC(CH_3)_3$), 102.5–102.67 (C-5), 113.48–114.23 (phenyl C-3), 123.24–128.48 (phenyl C-1), 130.44–130.76 (phenyl C-2), 140.34–140.89 (C-6), 150.49–150.62 (C-2), 155.11 (phenyl C-4), 158.51–158.82 (NHC(O)O), 163.24 (C-4), 170.70–171.12 (amide C=O); ms (EI): 617 (M + H)$^+$ (4.9%), 559 (M$^{+\cdot}$ − *tert*-Bu·)$^+$ (2.9%), 543 (M$^{+\cdot}$ − *tert*-BuO·)$^+$ (3.9%), 517 (M − CO_2 − $(CH_3)_2C$=CH_2 + H)$^+$ (11.0%), 499 (M$^{+\cdot}$ − *tert*-BuOC(O)NH$_2$)$^{+\cdot}$ (10.5%), 442 (499 − *tert*-Bu·)$^+$ (100%), 395 ($C_{18}H_{31}N_4O_4Si$)$^+$ (15.7%), 387 (499 − pyrimidinedione)$^{+\cdot}$ (17.1%), 330 (442 − pyrimidinedione)$^+$ (34.7%), 282 (18.8%), 226 (15.6%), 194 (15.0%), 170 (26.9%), 161 (4-OMeArCH=CHC≡O)$^+$ (37.5%), 150 (4-OMeArCH$_2$CH=NH$_2$)$^+$ (50.2%), 121 (4-OMeArCH$_2$)$^+$ (85.4%). *(±)-5-Amino-6-chloro-4-[[(3′*β*,5′*β*)-5′-(hydroxymethyl)-1′-(2-propenyl)piperidin-3′yl]amino]pyrimidine (**14**)*

Following the method of Daluge and Vince (19), a solution of amino alcohol **6** (500 mg, 2.93 mmol), 5-amino-4,6-dichloropyrimidine (971 mg, 5.92 mmol), and triethylamine (2 mL) in *n*-butanol (15 mL) was heated at reflux temperature under a calcium chloride drying tube for 20 h. The solvent was evaporated from the cooled mixture, and a solution of the residue in chloroform was adsorbed onto a small amount of silica gel. This material was applied to a short column of silica gel and eluted with a gradient of ethanol in ethyl acetate (0% → 2% → 5% → 10% → 20% (v/v)). The product-containing fractions were dissolved in a small amount of ethyl acetate, filtered, and the filtrate was evaporated. This process was repeated, to afford **14** (569 mg). The combined insoluble material was rechromatographed on silica gel using 5% (v/v) methanol in chloroform as eluant, to give a further 132 mg of **14**, for a total yield of 701 mg (80%). Recrystallization from water, after treatment with decolorizing carbon, provided very hygroscopic white needles, mp 88–93°C; ^{1}H nmr (CD_3OD, 200 MHz) δ: 1.04 (1H, apparent q, J_{app} = 12.0 Hz, H-4′$_{ax}$), 1.72 (1H, dd, J_{gem} = 11.0 Hz, $J_{5',6'ax}$ = 11.0 Hz, H-6′$_{ax}$), 1.79 (1H, dd, J_{gem} = 10.5 Hz, $J_{2'ax,3'}$ = 10.5 Hz, H-2′$_{ax}$), 1.80–2.17 (2H, m, H-4′$_{eq}$ and H-5′), 3.04–3.15 (3H, m, H-6′$_{eq}$ and =CHC*H*$_2$N), 3.27 (1H, m, H-2′$_{eq}$), 3.40 (1H, dd, J_{gem} = 11.0 Hz, J_{vic} = 6.5 Hz, C*H*OH), 3.50 (1H, dd, J_{gem} = 11.0 Hz, J_{vic} = 6.0 Hz, C*H*OH), 4.25 (1H, dddd, $J_{2'ax,3'}$ = 11.0 Hz, $J_{3',4'ax}$ = 12.0 Hz, $J_{2'eq,3'}$ = 4.0 Hz, $J_{3',4'eq}$ = 4.0 Hz, H-3′), 5.15–5.29 (2H, m, H_2C=), 5.91 (1H, m, =C*H*CH$_2$), 7.77 (1H, s, H-2); ^{13}C nmr (CD_3OD, 50 MHz) δ: 34.671 (C-4′), 39.140 (C-5′), 48.817 (C-3′), 57.355 (C-6′), 59.204 (C-

[9]The ^{1}H and ^{13}C nmr spectra were complicated by hindered rotation in each of the two diastereomers present. Only key diagnostic signals could be distinguished.

*(±)-6-Chloro-9-[(3′β,5′β)-5′-(hydroxymethyl)-1′-(2-propenyl)-piperidin-3′-yl]purine (**15**)*

A solution of chloropyrimidine **14** (546 mg, 1.8 mmol), triethyl orthoformate (10 mL), and concentrated aqueous hydrochloric acid (0.5 mL) was stirred at 23°C for 2 h (31). The excess of the orthoformate was removed by evaporation in vacuo, and the remaining solid was stirred in the presence of 0.5 M aqueous hydrochloric acid (5 mL) for 1 h. The solution was then adjusted to pH 11 with a 15% (w/v) aqueous solution of sodium hydroxide, and extracted with chloroform (3 × 10 mL). The combined organic extracts were washed with brine (5 mL) and dried (MgSO$_4$). Evaporation of the solvent afforded a greasy foam that could not be induced to crystallize. Addition of an excess of aqueous hydrochloric acid followed by evaporation of the solvent provided the hydrochloride salt, which likewise resisted crystallization. The desired chloropurine **15** was obtained by chromatography on silica gel using the organic layer of a 12:6:1 (v/v/v) chloroform–isopropanol – concentrated aqueous ammonia mixture (385 mg, 69%); ^{1}H nmr (CDCl$_3$, 200 MHz) δ: 1.82 (1H, apparent q, J_{app} = 11.7 Hz, H-4′$_{ax}$), 1.93 (1H, dd, ΣJ = 35.09 Hz, H-6′$_{ax}$), 2.03–2.33 (2H, m, H-4′$_{eq}$ and H-5′), 2.43 (1H, dd, J_{gem} = 10.5 Hz, $J_{2'ax,3'}$ = 11.1 Hz, H-2′$_{ax}$), 2.88–3.18 (4H, m, H-6′$_{eq}$, =CHCH_2N, OH), 3.26 (1H, m, H-2′$_{eq}$), 3.62 (2H, apparent d, J_{app} = 5.7 Hz, CH_2OH), 4.79 (1H, dddd, $J_{2'ax,3'}$ = 11.1 Hz, $J_{3',4'ax}$ = 12.0 Hz, $J_{2'eq,3'}$ = 4.0 Hz, $J_{3',4'eq}$ = 4.0 Hz, H-3′), 5.11–5.24 (2H, m, H$_2$C=), 5.84 (1H, m, =CHCH$_2$), 8.16 (1H, s, H-2), 8.71 (1H, s, H-8); ^{13}C nmr (CDCl$_3$, 50 MHz) δ: 33.183 (C-4′), 38.312 (C-5′), 53.136 (C-3′), 55.697 (C-6′), 57.492 (C-2′), 61.249 (=CHCH$_2$N), 65.016 (CH$_2$OH), 118.716 (H$_2$C=), 131.761 (C-5), 134.051 (=CHCH$_2$), 143.45 (C-8), 151.091 (C-4 or C-6), 151.576 (C-6 or C-4), 151.697 (C-2); ms (EI): 308 (M + H)$^+$ (4.7%), 155 (chloropurine + H)$^+$ (3.4%), 153 (C$_9$H$_{15}$NO: M$^{+\cdot}$ − chloropurine)$^{+\cdot}$ (100%), 124 (12.0%), 122 (153 − $\cdot$CH$_2$OH)$^+$ (21.6%), 112 (153 − H$_2$C=CHCH$_2\cdot$)$^+$ (8.7%); ms (CI): 310 (^{37}Cl or ^{18}O M + H)$^+$ (34.4%), 309 (^{13}C or ^{2}H or ^{15}N or ^{17}O M + H)$^+$ (17.7%), 308 (M + H)$^+$ (100%), 157 (^{37}Cl chloropurine + H)$^+$ (3.6%), 155 (^{35}Cl chloropurine + H)$^+$ (10.6%), 154 (C$_9$H$_{15}$NO + H: M − chloropurine + H)$^+$ (19.9%), 153 (M$^{+\cdot}$ − chloropurine)$^{+\cdot}$ (27.1%). *(±)-6-(Dimethylamino)-9-[(3′β,5′β)-5′-(hydroxymethyl)-1′-(2-propenyl)piperidin-3′-yl]purine (**16**)*

Chloropurine **15** (301 mg, 0.98 mmol) was dissolved in 40% (w/v) aqueous dimethylamine (10 mL) and heated at 80°C in a sealed Pyrex tube for 28 h. At this point, tlc analysis (15% (v/v) methanol in chloroform as eluant) apparently indicated no reaction had occurred. The reaction mixture was then heated at reflux temperature for 2 h more, and left at 23°C for 24 h. Again tlc indicated no visible change. The aqueous solution was extracted with chloroform (3 × 10 mL), and the organic extracts were dried (MgSO$_4$) and concentrated. The residue was chromatographed on silica gel (using 10% (v/v) ethanol in ethyl acetate as eluant) to afford a brown oil (290 mg) that proved on ^{1}H nmr analysis to be the desired derivative **16** (93%); ^{1}H nmr (CDCl$_3$, 200 MHz) δ: 1.66 (1H, apparent q, J_{app} = 11.4 Hz, H-4′$_{ax}$), 1.86 (1H, dd, ΣJ = 21.6 Hz, H-6′$_{ax}$), 1.96–2.44 (4H, m, H-2′$_{ax}$, H-4′$_{eq}$, H-5′, OH), 3.00–3.25 (4H, m, H-2′$_{eq}$, H-6′$_{eq}$, =CHCH_2N), 3.50 (6H, br s, N(CH$_3$)$_2$), 3.55 (2H, apparent d, J_{app} = 5.7 Hz, CH_2OH), 4.67 (1H, m, H-3′), 5.06–5.20 (2H, m, H$_2$C=), 5.83 (1H, m, =CHCH$_2$), 7.72 (1H, s, H-2), 8.30 (1H, s, H-8); ^{13}C nmr (CDCl$_3$, 50 MHz) δ: 33.522 (C-4′), 38.515 (N(CH$_3$)$_2$ and C-5′), 51.788 (C-3′), 55.886 (C-6′), 57.949 (C-2′), 61.314 (=CHCH$_2$N), 65.136 (CH$_2$OH), 118.226 (H$_2$C=), 120.272 (C-5), 134.521 (=CHCH$_2$), 136.176 (C-8), 150.213 (C-6), 152.111 (C-2), 154.933 (C-4); ms (EI): 317 (M + H)$^+$ (4.3%), 164 (N^6-dimethyladenine + H)$^+$ (25.5%), 153 (C$_9$H$_{15}$NO: M$^{+\cdot}$ − N^6-dimethyladenine)$^{+\cdot}$ (100%), 124 (14.2%), 122 (153 − $\cdot$CH$_2$OH)$^+$ (24.6%), 112 (153 − H$_2$C=CHCH$_2\cdot$)$^+$ (11.0%). *(±)-6-(Dimethylamino)-9-[(3′β,5′β)-5′-(*tert*-butyldimethylsilyloxymethyl)piperidin-3′-yl]purine (**18**)*

A mixture of **16** (249 mg, 0.79 mmol) and imidazole (107 mg, 1.57 mmol) in dry dichloromethane (5 mL) was treated with *tert*-butyldimethylsilyl chloride (132 mg, 0.87 mmol). After 1 h of stirring at 23°C, a second portion of *tert*-butyldimethylsilyl chloride (50 mg, 0.33 mmol) was added. After a further 1 h, the reaction was quenched by the addition of water (2 mL). The phases were separated, and the organic layer was washed with water (2 mL). The combined aqueous layers were extracted with dichloromethane (5 mL) and the combined organic layers were dried (MgSO$_4$) and evaporated. The oily residue was applied to a short column of silica gel and eluted with a gradient of methanol in chloroform (0% → 10% (v/v)). The product was allowed to stand in vacuo until all traces of silicon-containing impurities had evaporated. Silyl ether **17** was obtained as an oil (295 mg, 87%); ^{1}H nmr (CDCl$_3$, 200 MHz) δ: 1.65 (1H, apparent q, J_{app} = 11.7 Hz, H-4′$_{ax}$), 1.82 (1H, dd, ΣJ = 21.6 Hz, H-6′$_{ax}$), 1.95–2.23 (2H, m, H-4′$_{eq}$ and H-5′), 2.29 (1H, dd, J_{gem} = 11.5 Hz, $J_{2'ax,3'}$ = 11.0 Hz, H-2′$_{ax}$), 2.97–3.15 (3H, m, H-6′$_{eq}$ and =CHCH_2N), 3.21 (1H, m, H-2′$_{eq}$), 4.69 (1H, dddd, $J_{2'ax,3'}$ = 11.0 Hz, $J_{3',4'ax}$ = 12.0 Hz, $J_{2'eq,3'}$ = 4.0 Hz, $J_{3',4'eq}$ = 4.0 Hz, H-3′), 5.08–5.23 (2H, m, H$_2$C=), 5.85 (1H, m, =CHCH$_2$), 7.74 (1H, s, H-2), 8.34 (1H, s, H-8).

Without further purification, the silyl ether **17** was treated with tris(triphenylphosphine)rhodium chloride (50 mg) in an 84:16 acetonitrile–water solvent mixture (22) (20 mL) as described above for the preparation of **11**. Complete reaction, as judged by tlc analysis (15% (v/v) methanol in chloroform eluant), was obtained after 7 h of heating at reflux temperature. After removal of the solvents in vacuo, the residue was purified by preparative tlc on a 2 mm × 20 cm × 20 cm silica gel plate (E. Merck no. 5717) using 10% (v/v) methanol in toluene as eluant. It was necessary to extract the product from the plate by Soxhlet extraction using an 87:13 (v/v) chloroform–methanol mixture, to obtain **18** as an oil (181 mg, 68%); ^{1}H nmr (CDCl$_3$, 200 MHz) δ: 0.034 (6H, s, Si(CH$_3$)$_2$), 0.88 (9H, s, SiC(CH$_3$)$_3$), 1.78 (1H, apparent q, J_{app} = 11.5 Hz, H-4′$_{ax}$), 1.84–2.08 (2H, m, NH and H-5′), 2.24 (1H, m, H-4′$_{eq}$), 2.44 (1H, dd, J_{gem} = 12.6 Hz, $J_{5',6'ax}$ = 10.8 Hz, H-6′$_{ax}$), 2.87 (1H, dd, J_{gem} = 11.6 Hz, $J_{2'ax,3'}$ = 11.6 Hz, H-2′$_{ax}$), 3.23 (1H, m, H-6′$_{eq}$), 3.36–3.60 (9H, m, H-2′$_{eq}$, N(CH$_3$)$_2$, CH$_2$OSi), 4.55 (1H, m, H-3′), 7.74 (1H, s, H-2), 8.33 (1H, s, H-8); ^{13}C nmr (CDCl$_3$, 50 MHz) δ: −5.672 (SiCH$_3$), −5.701 (SiCH$_3$), 18.018 (SiC(CH$_3$)$_3$), 25.638 (SiC(CH$_3$)$_3$), 33.564 (C-4′), 38.237 (br, N(CH$_3$)$_2$), 40.138 (C-5′), 48.572 (C-6′), 51.248 (C-2′), 52.322 (C-3′), 65.275 (CH$_2$OSi), 120.087 (C-5), 135.585 (C-8), 150.056 (C-4), 151.880 (C-2), 154.716 (C-6); ms (EI): 391 (M + H)$^+$ (8.5%), 375 (M$^{+\cdot}$ − $\cdot$CH$_3$)$^+$ (3.4%), 333 (M$^{+\cdot}$ − *tert*-Bu$\cdot$)$^+$ (3.2%), 227 (C$_{12}$H$_{25}$NOSi: M$^{+\cdot}$ − N^6-dimethyladenine)$^{+\cdot}$ (25.3%), 190 (6.3%), 170 (227 − *tert*-Bu$\cdot$)$^+$ (19.0%), 164 (N^6-dimethyladenine + H)$^+$ (100%), 134 (6.9%). Exact Mass calcd. for (C$_{19}$H$_{34}$N$_6$OSi + H): 391.2642; found (hrms): 391.2629.

*6-(Dimethylamino)-9-[(3′RS,5′SR)-1′-(2S-[*tert*-butoxycarbamoyl]-3-[4-methoxyphenyl]propanoyl)-5′-(*tert*-butyldimethylsilyloxymethyl)piperidin-3′-yl]purine (**19**a, b)*

As described above for the preparation of **13**, purine derivative **18** (180 mg, 0.46 mmol) and *N*-(*tert*-butoxycarbonyl)-L-*p*-methoxyphenylalanine (**12**) (23) (152 mg, 0.51 mmol) were dissolved in dry dichloromethane (5 mL) and treated with 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (108 mg, 0.56 mmol) at 0°C. Processing as previously described afforded, after chromatography on silica gel (0% → 2% (v/v) methanol in chloroform as eluant), a 1:1 mixture of the title compounds **19***a*, *b* (309 mg, quant.) as an oil; ^{1}H nmr (CDCl$_3$, 200 MHz)[9] δ: 0.032, 0.045 (6H, 2 × s, Si(CH$_3$)$_2$), 0.886,

*1-{(3′S,5′R)-1′-(2S-Amino-3-(4-methoxyphenyl)propanoyl)-5′-(hydroxymethyl)piperidin-3′-yl}-2,4(1H,3H)pyrimidinedione (**20**a) and 1-{(3′R,5′S)-1′-(2S-amino-3-(4-methoxyphenyl)propanoyl)-5′-(hydroxymethyl)piperidin-3′-yl}-2,4(1H,3H)pyrimidinedione (**20**b)*

The *N*-BOC *O*-TBDMS precursors **19***a,b* (252 mg, 0.41 mmol) were dissolved in dichloromethane (1 mL) and the solution was cooled in an ice bath. A mixture of trifluoroacetic acid (3 mL), anisole (1 mL), and water (0.5 mL) was added, and the mixture was stirred at 0°C for 30 min. It was then allowed to warm to 23°C over 2.5 h. Monitoring by tlc using a 2-butanone–water – acetic acid eluant (40:1:1 (v/v/v)) showed rapid conversion into an intermediate product followed by slow conversion to a ninhydrin-positive, highly polar material. The solvents were evaporated, and the residue was allowed to stand in vacuo to remove traces of anisole. The residual material was then dissolved in a 1:1 (v/v) water–ethanol mixture and applied to a short column of Dowex 50-X2 400 (H^+) ion-exchange resin (~5 mL of resin). The column was thoroughly washed with 1:1 (v/v) water–ethanol, and then eluted with 1:1 (v/v) 1 M aqueous ammonium hydroxide – ethanol. The product-containing fractions were pooled and the solvents were evaporated to give an amorphous mixture of diastereomers **20***a, b* (144 mg, 87%).

The diastereomeric mixture was resolved by reverse-phase hplc on a 300 mm × 7.0 mm Hamilton PRP-1 column. Small portions of the sample were injected onto the column and eluted with a linear gradient of 0.33 M aqueous triethylammonium hydrogen carbonate buffer (pH ~8) and acetonitrile (1.5 mL min^{-1}, 90:10 → 80:20 (v/v) over 20 min, then isocratic for 5 min), monitoring at 254 nm. Fractions were collected and the process was repeated until all of the mixture had been resolved. The fractions containing each product were combined, concentrated on a rotary evaporator to remove the organic solvent, and finally freeze-dried. To remove traces of buffer salts, it was necessary to pass each sample down a Dowex 50 column once more, as previously described, followed by freeze-drying. Samples of leading fraction **20***a* (34 mg, 41%, ~100% diastereomeric excess), and second fraction **20***b* (26 mg, 31%, ~100% diastereomeric excess) were obtained as fluffy solids.

First fraction (**20***a*); $[\alpha]_D^{25}$ +68.04 (*c* 1.02, H_2O); ^{1}H nmr spectra indicated the presence of two rotamers in a 2.26:1.00 ratio. The spectral data for the rotamers are listed separately for clarity.

Major rotamer (amide carbonyl *syn* with respect to the pyrimidinedione ring): ^{1}H nmr (D_2O, 600 MHz, 300 K) δ: 0.249 (1H, m, H-5′), 1.502 (1H, apparent q, J_{app} = 12.2 Hz, H-4′$_{ax}$), 1.711 (1H, m, H-4′$_{eq}$), 2.681 (1H, dd, J_{gem} = 12.2 Hz, $J_{2'ax,3'}$ = 9.1 Hz, H-2′$_{ax}$), 2.70 (1H, dd, J_{gem} = 12.0 Hz, $J_{6'ax,5'}$ = 10.5 Hz, H-6′$_{ax}$), 2.807 (1H, dd, J_{gem} = 12.9 Hz, J_{vic} = 10.4 Hz, ArCH_2), 3.003 (1H, dd, J_{gem} = 12.9 Hz, J_{vic} = 5.1 Hz, ArCH_2), 3.301 (1H, dd, J_{gem} = 11.5 Hz, J_{vic} = 6.07 Hz, C*H*OH), 3.331 (1H, dd, J_{gem} = 11.5 Hz, J_{vic} = 5.5 Hz, C*H*OH), 3.768 (1H, m, H-6′$_{eq}$), 3.801 (3H, s, OCH_3), 4.011 (1H, m, H-3′), 4.23–4.29 (1H, m, H-α), 4.524 (1H, m, H-2′$_{eq}$), 5.808 (1H, d, *J* = 8.01 Hz, H-5), 7.006 (2H, d, *J* = 8.61 Hz, 2 × phenyl H-3), 7.227 (2H, d, *J* = 8.61 Hz, 2 × phenyl H-2), 7.598 (1H, d, *J* = 8.01 Hz, H-6); ^{13}C nmr (D_2O, 100 MHz, 300 K) δ: 30.516 (C-4′), 37.272 (C-5′), 40.213 (ArCH_2), 44.833 (C-2′), 47.765 (C-6′), 51.267 (C-α), 51.419 (C-3′), 55.464 (OCH_3), 62.732 (CH_2OH), 101.850 (C-5), 114.540 (2 × phenyl C-3), 129.132 (phenyl C-1), 130.687 (2 × phenyl C-2), 142.894 (C-6), 152.169 (C-2), 158.065 (phenyl C-4), 166.492 (C-4), 174.157 (amide C═O).

Minor rotamer (amide carbonyl *anti* with respect to pyrimidinedione ring): ^{1}H nmr (D_2O, 600 MHz, 300 K) δ: 1.599 (1H, apparent q, J_{app} = 12.2 Hz, H-4′$_{ax}$), 1.85 (1H, m, H-5′), 1.99 (1H, m, H-4′$_{eq}$), 2.275 (1H, dd, J_{gem} = 13.0 Hz, $J_{5',6'ax}$ = 10.0 Hz, H-6′$_{ax}$), 2.296 (1H, dd, J_{gem} = 12.6 Hz, $J_{2'ax,3'}$ = 9.5 Hz, H-2′$_{ax}$), 2.77–2.83 (1H, dd, J_{gem} = 13.5 Hz, J_{vic} obscured by overlap, ArCH_2), 2.964 (1H, dd, J_{gem} = 13.5 Hz, J_{vic} = 5.6 Hz, ArCH_2), 3.52 (1H, dd, J_{gem} = 11.7 Hz, J_{vic} = 7.2 Hz, C*H*OH), 3.54 (1H, dd, J_{gem} = 11.7 Hz, J_{vic} = 6.0 Hz, C*H*OH), 3.70 (1H, m, H-2′$_{eq}$), 3.794 (3H, s, OCH_3), 4.23–4.29 (1H, m, H-α), 4.36 (1H, m, H-3′), 4.49 (1H, m, H-2′$_{eq}$), 5.808 (1H, d, *J* = 8.01 Hz, H-5), 6.911 (2H, d, *J* = 8.59 Hz, 2 × phenyl H-3), 7.113 (2H, d, *J* = 8.59 Hz, 2 × phenyl H-2), 7.514 (1H, d, *J* = 8.01 Hz, H-6); ^{13}C nmr (D_2O, 100 MHz, 300 K) δ: 30.392 (C-4′), 37.272 (C-5′), 39.421 (ArCH_2), 44.491 (C-6′), 47.661 (C-2′), 51.671 (C-α), 52.600 (C-3′), 55.261 (OCH_3), 63.280 (CH_2OH), 101.850 (C-5), 114.032 (2 × phenyl C-3), 128.475 (phenyl C-1), 130.586 (2 × phenyl C-2), 142.697 (C-6), 152.169 (C-2), 157.966 (phenyl C-4), 166.762 (C-4), 173.586 (amide C═O); ms (EI): 403 (M + H)$^+$ (3.8%), 385 (M + H − H_2O)$^+$ (8.8%), 332 (M + H − HNCO − CO)$^+$ (14.2%), 281 ($M^{+\cdot}$ − 4-OMeArCH$_2^{\cdot}$)$^+$ (84.8%), 150 (4-OMeArCH$_2$CH═NH_2)$^+$ (100%), 121 (4-OMeArCH$_2$)$^+$ (51.5%); ms (CI): 403 (M + H)$^+$ (100%), 226 ($C_{10}H_{16}N_3O_3$: M − aminoacyl + 2H)$^+$ (32.8%), 150 (4-OMeArCH$_2$CH═NH_2)$^+$ (35.3%). Exact Mass calcd. for ($C_{20}H_{26}N_4O_5$ + H): 403.1981; found (hrms): 403.1979.

Second fraction (**20***b*); $[\alpha]_D^{25}$ +51.51 (*c* 1.06, H_2O); ^{1}H nmr spectra indicated the presence of two rotamers in a 1.00:0.91 ratio. The spectral data for the two rotamers are listed separately for clarity.

Predominant rotamer (amide carbonyl *anti* with respect to base): ^{1}H nmr (D_2O, 600 MHz, 300 K) δ: 1.50–1.58 (1H, br m, H-5′), 1.64 (1H, apparent q, J_{app} = 12.2 Hz, H-4′$_{ax}$), 1.93 (1H, m, H-4′$_{eq}$), 2.399 (1H, dd, J_{gem} = 13.5 Hz, $J_{5',6'ax}$ = 11.6 Hz, H-6′$_{ax}$), 2.856 (1H, dd, J_{gem} = 13.6 Hz, J_{vic} = 8.18 Hz, ArCH_2), 3.001 (1H, dd, J_{gem} = 13.6 Hz, J_{vic} = 5.95 Hz, ArCH_2), 3.200 (1H, dd, J_{gem} = 13.7 Hz, $J_{2'ax,3'}$ = 11.1 Hz, H-2′$_{ax}$), 3.504 (1H, dd, J_{gem} = 11.5 Hz, J_{vic} = 6.6 Hz, C*H*OH), 3.531 (1H, dd, J_{gem} = 11.5 Hz, J_{vic} = 5.46 Hz, C*H*OH), 3.716 (1H, m, H-3′), 3.815 (3H, s, OCH_3), 4.169 (1H, m, H-2′$_{eq}$), 4.367 (1H, dd, J_{vic} = 5.95 Hz, $J_{vic'}$ = 8.18 Hz, H-α), 4.481 (1H, m, H-6′$_{eq}$), 5.820 (1H, d, *J* = 8.07 Hz, H-5), 6.972 (2H, d, *J* = 8.64 Hz, 2 × phenyl H-3), 7.211 (2H, d, *J* = 8.64 Hz, 2 × phenyl H-2), 7.561 (1H, d, *J* = 8.07 Hz, H-6); ^{13}C nmr (D_2O, 100 MHz, 300 K) δ: 30.416 (C-4′), 37.442 (C-5′), 39.101 (ArCH_2), 44.577 (C-6′), 47.934 (C-2′), 51.50 (C-α), 53.120 (C-3′), 55.289 (OCH_3), 63.244 (CH_2OH), 101.889 (C-5), 114.287 (2 × phenyl C-3), 128.477 (phenyl C-1), 130.70 (2 × phenyl C-2), 143.02 (C-6), 153.28 (C-2), 157.89 (phenyl C-4), 167.79 (C-4), 174.69 (br, amide C═O).

Second rotamer (amide carbonyl *syn* with respect to pyrimidinedione ring): ^{1}H nmr (D_2O, 600 MHz, 300 K) δ: 1.60 (1H, apparent q, J_{app} = 12.3 Hz, H-4′$_{ax}$), 1.87–1.95 (1H, m, H-5′), 2.01 (1H, m, H-4′$_{eq}$), 2.185 (1H, dd, J_{gem} = 13.3 Hz, $J_{5',6'ax}$ = 12.4 Hz, H-6′$_{ax}$), 2.676 (1H, dd, J_{gem} = 13.7 Hz, $J_{2'ax,3'}$ = 10.5 Hz, H-2′$_{ax}$), 2.95 (1H, dd, J_{gem} = 13.2 Hz, J_{vic} = 7.7 Hz, ArCH_2), 2.97 (1H, dd, J_{gem} = 13.2 Hz, J_{vic} = 6.0 Hz, ArCH_2), 3.424 (1H, dd, J_{gem} = 11.3 Hz, J_{vic} = 6.87 Hz, C*H*OH), 3.485 (1H, dd, J_{gem} = 11.3 Hz, J_{vic} = 5.48 Hz, C*H*OH), 3.771 (1H, m, H-6′$_{eq}$), 3.820 (3H, s, OCH_3), 4.239 (1H, dd, J_{vic} = 7.7 Hz, $J_{vic'}$ = 6.0 Hz, H-α), 4.347 (1H, m, H-3′), 4.534 (1H, m, H-2′$_{eq}$), 5.835 (1H, d, *J* = 8.06 Hz, H-5), 6.960 (2H, d, *J* = 8.64 Hz, 2 × phenyl H-3), 7.156 (2H, d, *J* = 8.64 Hz, 2 × phenyl H-2), 7.624 (1H, d, *J* = 8.06 Hz, H-6); ^{13}C nmr (D_2O,

100 MHz, 300 K) δ: 30.742 (C-4′), 38.207 (C-5′), 38.899 (ArCH_2), 44.760 (C-2′), 47.544 (C-6′), 51.47 (C-α), 51.992 (C-3′), 55.289 (OCH_3), 62.926 (CH_2OH), 101.600 (C-5), 114.108 (2 × phenyl C-3), 128.124 (phenyl C-1), 130.62 (2 × phenyl C-2), 142.98 (C-6), 152.98 (C-2), 157.915 (phenyl C-4), 167.79 (C-4), 174.69 (br, amide C=O); ms (EI): identical to that obtained for **20***a*; ms (CI): identical to that obtained for **20***a*. Exact Mass calcd. for ($C_{20}H_{26}N_4O_5$ + H): 403.1981; found (hrms): 403.1971.

*6-(Dimethylamino)-9-[(3′S,5′R)-(2S-amino-3-[4-methoxyphenyl]propanoyl)-5′-(hydroxymethyl)piperidin-3′-yl]purine (**21**a) and 6-(dimethylamino)-9-[(3′R,5′S)-(2S-amino-3-[4-methoxyphenyl]propanoyl)-5′-(hydroxymethyl)piperidin-3′-yl]purine (**21**b)*

The diprotected precursors **19***a*, *b* (250 mg, 0.37 mmol) and anisole (1 mL) were dissolved in methanol (1 mL), and the solution was cooled in an ice bath. Trifluoroacetic acid (2 mL) was added, and the mixture was stirred at 0°C for 30 min. The reaction was then allowed to warm to 23°C over 2 h, at which point tlc analysis (10% (v/v) methanol in chloroform as eluant, plate pretreated with ammonia vapor) indicated only about 10% conversion. A further portion of trifluoroacetic acid (1 mL) was added, and the reaction was allowed to proceed overnight. The solvents were evaporated, and the residue was processed as described above to give a mixture of diastereomers **21***a*, *b* (158 mg, 93%).

Reverse-phase hplc separation of the diastereomers was carried out by isocratic elution at 2 mL min^{-1} with 20% (v/v) acetonitrile in 0.3 M aqueous triethylammonium hydrogen carbonate buffer (pH ~8). Further processing of the product fractions as previously described gave samples of leading fraction **21***a* (27 mg, 31%, 95% diastereomeric excess) and second fraction **21***b* (23 mg, 27%, 95% diastereomeric excess) as fluffy solids. These products were only minimally soluble in water but dissolved readily in alcohol, chloroform or DMSO.

First fraction (**21***a*); $[\alpha]_D^{25}$ +60.3 (*c* 0.58, $CHCl_3$); ^{1}H nmr (DMSO-d_6, 400 MHz, 383 K)[10] δ: 1.52–1.69 (2H, br m, H-5′ and H-6′$_{ax}$), 1.980 (1H, apparent, q, J_{app} = 11.1 Hz, H-4′$_{ax}$), 2.12 (1H, m, H-4′$_{eq}$), 2.62 (1H, dd, J_{gem} = 13.7 Hz, J_{vic} = 7.2 Hz, ArCH_2), 2.834 (1H, dd, J_{gem} = 13.6 Hz, J_{vic} = 6.1 Hz, ArCH_2), 3.117 (1H, dd, ΣJ = 23.7 Hz, H-2′$_{ax}$) 3.354 (1H, dd, J_{gem} = 10.8 Hz, J_{vic} = 7.4 Hz, C*H*OH), 3.422 (1H, dd, J_{gem} = 10.8 Hz, J_{vic} = 5.5 Hz, C*H*OH), 3.468, (6H, s, $N(CH_3)_2$), 3.735 (3H, s, OCH_3), 3.936 (1H, dd, J_{vic} = 6.1 Hz, $J_{vic'}$ = 7.2 Hz, H-α), 4.25–4.55 (3H, br m, H-2′$_{eq}$, H-3′, H-6′$_{eq}$), 6.822 (2H, d, J = 8.5 Hz, 2 × phenyl H-3), 7.132 (2H, d, J = 8.5 Hz, 2 × phenyl H-2), 8.074 (1H, s, H-2), 8.213 (1H, s, H-8); ^{13}C nmr (DMSO-d_6, 100 MHz, 298 K)[11] δ: 32.464, 32.880 (C-4′), 38.107, 38.805 (C-5′), 40.696, 41.101 (ArCH_2), 44.503, 45.289, 47.620, 48.419 (C-2′ and C-6′), 50.263, 51.587 (C-3′), 52.120, 52.290 (C-α), 54.917, 55.002 (OCH_3), 62.805, 63.288 (CH_2OH), 113.352, 113.645 (2 × phenyl C-3), 119.336, 119.537 (C-6), 130.255, 130.372 (2 × phenyl C-2), 130.503 (phenyl C-1), 149.872, 150.035 (C-4), 151.7 (C-2), 154.280 (phenyl C-4), 157.655, 157.824 (C-5), 173.058, 173.373 (amide C=O); ms (EI): 454 $(M + H)^+$ (3.7%), 453 $(M)^{+\cdot}$ (3.6%), 436 $(M^{+\cdot} - NH_3)^{+\cdot}$ or $(M + H - H_2O)^+$ (1.3%), 332 ($C_{15}H_{22}N_7O_2$: $M^{+\cdot}$ − 4-OMeArC$H_2^{\cdot}$)$^+$ (100%), 304 (14.4%), 164 (*N*^{6}-dimethyladenine + H)$^+$ (67.7%), 150 (4-OMeArCH_2CH=NH_2)$^+$ (7.8%), 134 (9.0%), 121 (4-OMeArCH_2)$^+$ (12.6%). Exact Mass calcd. for $C_{23}H_{31}N_7O_3$: 453.2488; found (hrms): 453.2479.

[10]The product **21***a* was insoluble in D_2O. Its ^{1}H nmr spectra in $CDCl_3$ or DMSO-d_6 indicated the presence of an approximately 1:1 rotameric mixture, but all resonances were severely broadened. Lowering the temperature to the freezing point of $CDCl_3$ did not allow the rotamers to be resolved. The ^{1}H nmr spectra were therefore acquired in DMSO-d_6 solution at 383 K, at which temperature most but not all signals were well resolved at the expense of any conformational information. Over 1–2 h at this elevated temperature, however, the samples discolored. Two-dimensional spectra were therefore not obtained. The ^{13}C nmr spectra could be obtained at room temperature; however, it was not possible to assign signals to individual rotamers.

[11]The signals due to the $N(CH_3)_2$ group were obscured by the DMSO solvent signal. The signal of the purine C-8 (δ 135–137 ppm) was not observed due to slow relaxation.

[12]The signals attributable to the NCH_3 groups are obscured by the solvent signal.

Received March 31, 1994

CLIFFORD C. LEZNOFF, MOUGANG HU, COLIN R. MCARTHUR, YONGNIAN QIN, and JOHAN E. VAN LIER. Can. J. Chem. **72**, 1990 (1994).

2,9,16,23-Tetra-*p*-*n*-butylbenzyloxy-, 2,9,16,23-tetradiphenylmethoxy-, 2,9,16,23-tetramethoxymethoxy-, and 1,8,15,22-tetra-*p*-*n*-butylbenzyloxyphthalocyanines were synthesized from the appropriate phthalonitriles. Metal-free phthalocyanines were converted to their zinc derivatives. Cleavage from the appropriate precursor with trifluoroacetic acid produced 2,9,16,23-tetrahydroxyphthalocyanine and 1,8,15,22-tetrahydroxyphthalocyanine and their zinc derivatives. NMR spectroscopy revealed that all the 2,9,16,23-tetrasubstituted phthalocyanines are the usual mixtures of the 2,9,16,23, 2,9,16,24, 2,9,17,24, and 2,10,16,24 isomers, but the two 1,8,15,22-tetrasubstituted phthalocyanines were formed as *pure single isomers*.

CLIFFORD C. LEZNOFF, MOUGANG HU, COLIN R. MCARTHUR, YONGNIAN QIN et JOHAN E. VAN LIER. Can. J. Chem. **72**, 1990 (1994).

Utilisant les phtalonitriles appropriés comme produits de départ, on a synthétisé les 2,9,16,23-tétra-*p*-*n*-butylbenzyloxy-, 2,9,16,23-tétraphénylméthoxy-, 2,9,16,23-tétraméthoxyméthoxy- et 1,8,15,22-tétra-*p*-*n*-butylbenzyloxyphtalocyanines. On a transformé les phtalocyanines libres de métal en dérivés zinciques. Le clivage du précurseur approprié avec de l'acide trifluoroacétique conduit à la 2,9,16,23-tétrahydroxyphtalocyanine et à la 1,8,15,22-tétrahydroxyphtalocyanine et à leurs dérivés zinciques. La RMN révèle que toutes les phtalocyanines tétrasubstituées en 2,9,16,23 sont formées des mélanges habituels des isomères 2,9,16,23, 2,9,16,24, 2,9,17,24 et 2,10,16,24; toutefois, les deux phtalocyanines substituées en 1,8,15,22 sont des *isomères purs*.

[Traduit par la rédaction]

Introduction

The first synthesis of 2,9,16,23-tetrahydroxyphthalocyanine was reported in 1987 (1) and its phototoxicity in the photodynamic therapy (PDT) of cancer tumours (2–5) investigated (1, 6–8). Previously, it was shown that changes in the length of the spacer group (8) on hydroxyphthalocyanine affected the phototoxicity and in this study we also wished to show variation in the *position* of the hydroxy group on the phthalocyanine ring. The above compound was prepared by the boron tribromide cleavage of 2,9,16,23-tetraneopentoxyphthalocyanine, as the desired synthesis from a hydroxyphthalonitrile only resulted in decomposition of the starting material (1). Although the preparation was basically successful, the reaction conditions were quite critical and the yields were sometimes inadequate because of the incomplete cleavage of the substituted phthalocyanine precursor and the slow decomposition of the tetrahydroxyphthalocyanine under the attempted reaction conditions. In addition, purification of 2,9,16,23-tetrahydroxyphthalocyanine was performed on a silica gel column and the tetrahydroxyphthalocyanine either decomposes on silica gel or is poorly recovered from that media. For example, when a small-scale sample (50 mg) of 2,9,16,23-tetrahydroxyphthalocyananine was purified, the recovery achieved was only 53%, while on a larger scale (1.26 g), the recovery from the column was only 22% (1). Thus, new synthetic and purification methods need to be discovered for the preparation of tetrahydroxyphthalocyanines. Since 2,9,16,23-tetrahydroxyphthalocyanine was originally obtained as a mixture of related isomers, the development of new methods to easily prepare other polyhydroxyphthalocyanines, these mixtures or, more desirably, pure single isomers for PDT were sought.

Benzyl (9), diphenylmethyl (10), and trityl (11) groups are often used to protect phenolic and hydroxy groups (12). These protecting groups are more easily removed than neopentyl moieties to give free phenolic-type functional groups using different methods (13). The methoxymethyl ether moiety (MOM) (or its analogs) is also a useful protecting group for phenols (14). We examined the possibility of preparing tetrahydroxyphthalocyanines by using different kinds of reagents to deprotect the hydroxy blocking groups of the substituted phthalocyanines. In addition, a new procedure was developed to purify tetrahydroxyphthalocyanine.

Identically tetrasubstituted phthalocyanines are almost always synthesized as mixtures of statistical isomers consisting of the 2,9,16,23, 2,9,16,24, 2,9,17,24, and 2,10,16,24 isomers, and very few studies have been directed toward the exclusive formation of one isomer of a tetrasubstituted phthalocyanine (15). Although the 2,9,16,23-tetraneopentoxyphthalocyaninato zinc(II) (16) and 2,9,17,24-tetra-*tert*-butylphthalocyaninato zinc(II) (17) were produced as pure isomers, several reaction steps were used and only low yields were obtained. The synthesis of a single isomer of 1,2-naphthalocyanine has been achieved (18) due to the steric constraints of the benzo substituents, but other 1,8,15,22-tetrasubstituted phthalocyanines gave mixtures of isomers that in one example could be separated by high performance liquid chromatography (HPLC) (19). In this paper we report the exclusive synthesis of two 1,8,15,22-tetrasubstituted phthalocyanines and their zinc derivatives as pure single isomers in high yields under common conditions. We examined the ^{1}H NMR and ^{13}C NMR spectra of these pure compounds and compared these spectra with those of the phthalocy-

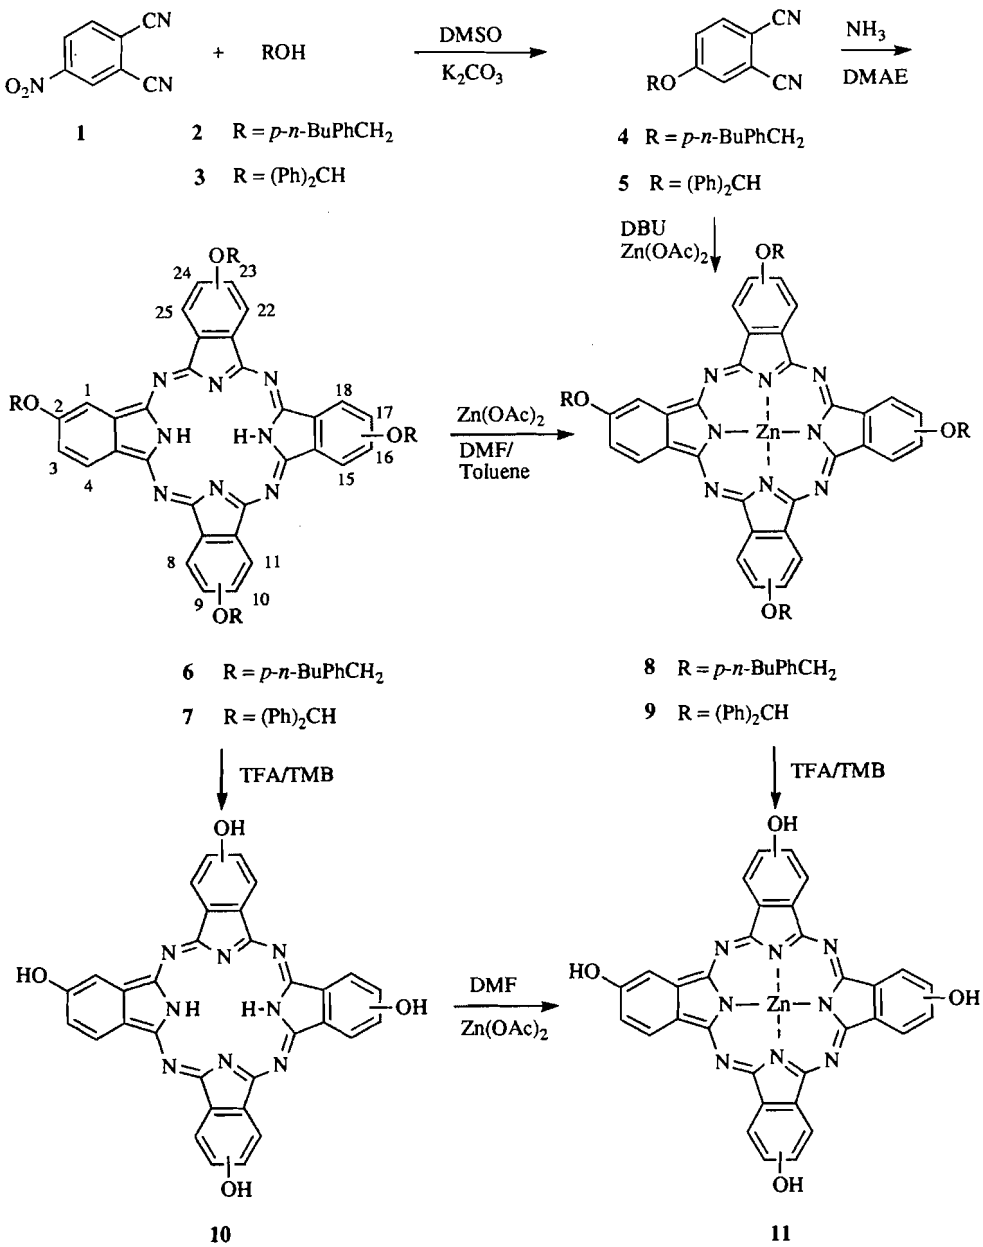

SCHEME 1

anines produced as mixtures of statistical isomers. Analyses of these spectra revealed that all the 2,9,16,23-tetrasubstituted phthalocyanines were indeed mixtures of isomers (for convenience numbered as the 2,9,16,23 derivatives only) but that the 1,8,15,22-tetrasubstituted phthalocyanines were produced as *pure single compounds*.

Results and discussion

The preparation of 2,9,16,23-tetrasubstituted phthalocyanines as mixtures of isomers

Using a new procedure developed in our laboratory (20, cf. ref. 21), 4-nitrophthalonitrile (**1**) reacted with *p*-*n*-butylbenzyl alcohol (**2**) or diphenylmethanol (**3**) in dimethyl sulfoxide (DMSO) at room temperature to give 4-*p*-*n*-butylbenzyloxyphthalonitrile (**4**) or 4-diphenylmethoxyphthalonitrile (**5**) in 90 or 92% yield, respectively (Scheme 1). The self-condensation of **4** or **5** in dimethylaminoethanol gave 2,9,16,23-tetra(*p*-*n*-butylbenzyloxy)phthalocyanine (**6**) or 2,9,16,23-tetra(diphenylmethoxy)phthalocyanine (**7**) in 17 or 25% yield, respectively. Refluxing the metal-free phthalocyanines (Pcs) **6** or **7** with zinc acetate in DMF and toluene gave 2,9,16,23-tetra(*p*-*n*-butylbenzyloxy)phthalocyaninato zinc(II) (**8**) or 2,9,16,23-tetra(diphenylmethoxy)phthalocyaninato zinc(II) (**9**), both in 90% yield. The zinc derivatives **8** and **9** could be prepared directly from **4** and **5**, respectively (22), in an improved procedure. Thus **4** or **5** reacted at 100°C with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (23) as a base and zinc acetate as a template during which ammonia gas was introduced into the reaction. Using this one-step improved procedure, **4** and **5** were produced in overall yields of 65 and 70%, respectively (Scheme 1).

Although catalytic hydrogenation (24), catalytic transfer hydrogenation (25), iodotrimethylsilane and chlorotrimethylsilane (26) couldn't efficiently cleave the alkyoxyphthalocyananines **6** and **7**, cleavage of the metal-free protected Pcs under reflux conditions with trifluoroacetic acid (TFA) (27) in the

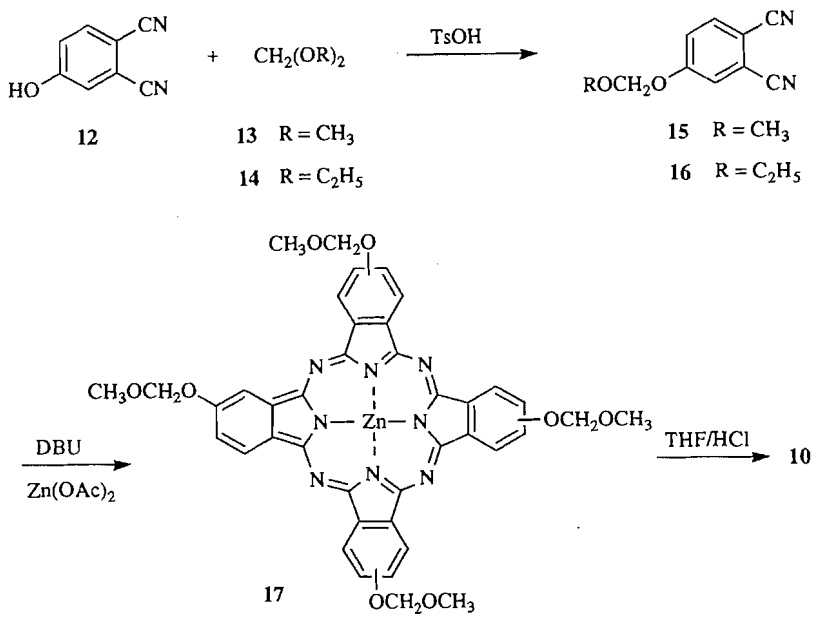


SCHEME 2

presence of a polyalkylbenzene (1,2,4,5-tetramethylbenzene (TMB) in this instance) as a benzyl cation scavenger (28) gave the desired 2,9,16,23-tetrahydroxyphthalocyanine (**10**) in 60–70% yield. Similarly, cleavage for 5 h of the protected zinc Pcs **8** or **9** gave 2,9,16,23-tetrahydroxyphthalocyaninato zinc(II) (**11**) in 84–88% yield. Alternatively, metal-free **10** can be metallated with zinc acetate in DMF–toluene as for **8** to give the zinc Pc **11**. The poor solubility of **10** contributes to the fact that **11** is more easily prepared via **8** or **9** (Scheme 1).

Phenols are usually converted to trityl or methoxymethyl (MOM) ethers by treatment with base and trityl chloride or methoxymethyl chloride. Since 4-hydroxyphthalonitrile (**12**) is unable to react with trityl chloride to give the corresponding ether and is unstable to basic conditions, **12** was treated with dimethoxymethane (**13**) or diethoxymethane (**14**) under acidic conditions (29) to give 4-methoxymethoxyphthalonitrile (**15**) and 4-ethoxymethoxyphthalonitrile (**16**) in 92 and 95% yield, respectively. 2,9,16,23-Tetra(methoxymethoxy)phthalocyaninato zinc(II) (**17**) was prepared from **15** in 30% yield in a previous procedure (23), but similar treatment of **16** gave mostly decomposition products. When the improved procedure as described for **8** and **9** was used, compound **17** was prepared in 60% yield. Treatment of **17** with HCl–THF under reflux conditions gave **10** in 31% yield (Scheme 2). The acidic cleavage conditions resulted in demeltallation of the zinc Pc so that **10** and not **11** was isolated.

Although classical chromatography on silica gel is not suitable for the purification of tetrahydroxyphthalocyanines because of either decomposition on silica gel or poor recovery from that media, gel permeation chromatography resolved this problem and **10** and **11** were readily purified by this latter method.

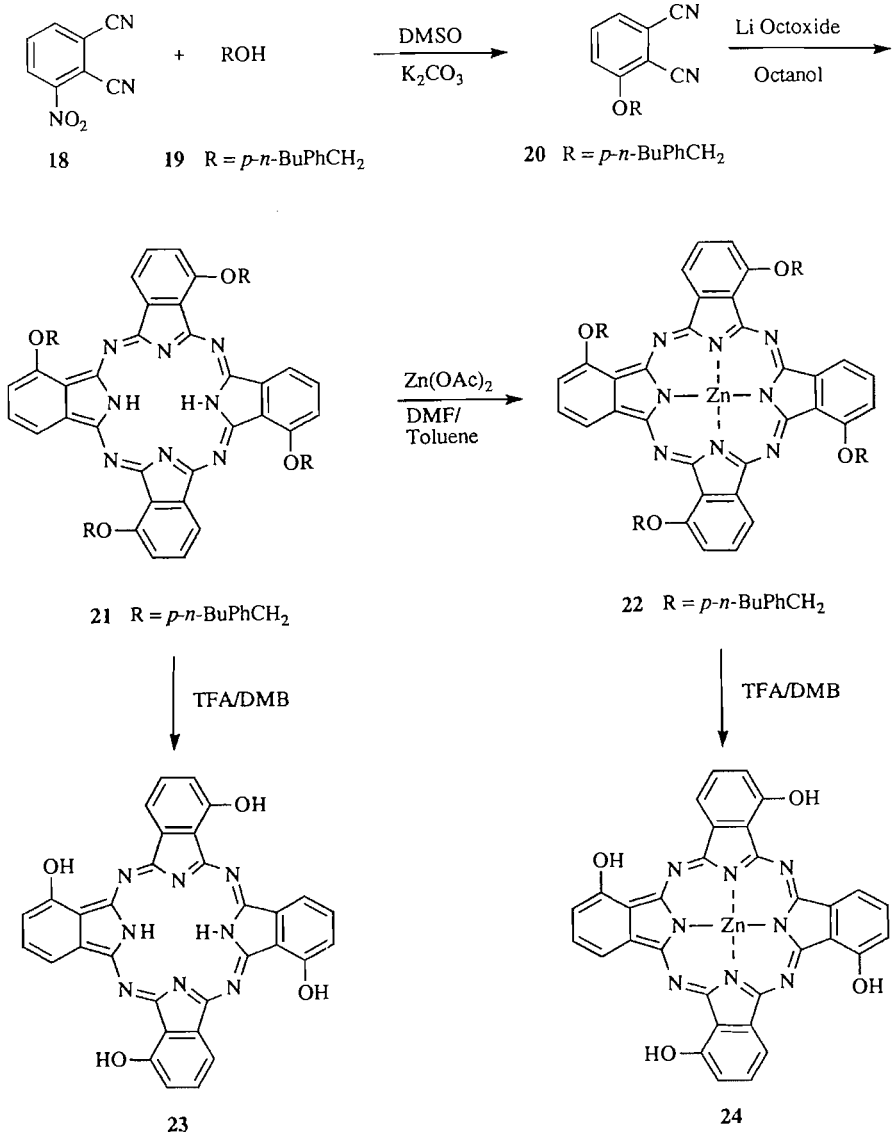
The preparation of 1,8,15,22-tetrahydroxyphthalocyanine as a pure single isomer

3-Nitrophthalonitrile (**18**) reacted with *p-n*-butylbenzyl alcohol (**2**) as for **4** and **5** to give 3-*p-n*-butylbenzyloxyphthalonitrile (**20**) in 95% yield. The usual procedures for preparation of 2,9,16,23-tetrasubstituted phthalocyanines did not subsequently give 1,8,15,22-tetra(*p-n*-butylbenzyloxy)phthalocyanine (**21**) and its zinc derivative (**22**). Phthalocyanines **21** and **22** could be prepared by heating **20** in a solution of lithium octoxide in *n*-octanol (Scheme 3). Quenching the reaction mixture with water and methanol gave the metal-free phthalocyanine **21** in 40% yield. When zinc acetate was added to the reaction mixture at 100°C and the temperature was controlled below or at 100°C, the zinc derivative **22** of the metal-free phthalocyanine could be obtained in 80% yield. 1,8,15,22-Tetrahydroxyphthalocyanine (**23**) and its zinc derivative (**24**) can be prepared as above by cleavage of **21** and **22** with TFA and TMB in 25 and 85% yield, respectively. Pc **22** can easily be prepared from Pc **21** by refluxing it with zinc acetate in DMF–toluene in 85% yield.

Spectroscopic and physical properties

NMR spectroscopy of 2,9,16,23-tetrasubstituted phthalocyanines generally exhibits broad absorptions in the aromatic and other spectral regions due to the presence of four isomers, but occasionally the resonances can be resolved (15, 30). Similarly, 1,8,15,22-tetrasubstituted phthalocyananines or analogs can exist as a distribution of four isomers (15, 31) but in this substitution pattern steric effects can afford a nonstatistical distribution of the four products. More recently, Hanack et al. actually separated all four isomers of 1,8,15,22-, 1,11,15,25-, 1,8,18,22-, and 1,8,15,25-tetrasubstituted phthalocyanines (19). In contrast, in our research, the 1,8,15,22-tetra(*p-n*-butylbenzyloxy)phthalocyanine (**21**) and its zinc derivative (**22**) were produced *exclusively*, presumably due to the greater steric constraints of the *p-n*-butylbenzyloxy substituent. ^{1}H NMR spectra of this phthalocyanine (**21**) and its zinc derivative (**22**) (Fig. 1) show doublet, triplet, and doublet absorbance peaks for protons of the phthalocyanine ring in the downfield region, and only one single peak at 5.9 ppm for protons of the -OCH_2- of the benzyl group in **21** and at 6.3 ppm for protons of the -OCH_2 of the benzyl group in **22** (Fig. 1). The ^{1}H NMR spectrum of 1,8,15,22-tetrahydroxyphthalocyaninato zinc(II) (**24**) (Fig. 1) shows a singlet at 10.56 ppm (phenol group), a doublet at 8.58–8.56, a triplet at 8.28–8.22, and a doublet at 7.83–7.81 ppm for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.



SCHEME 3

the three other protons attached to the phthalocyanine ring, while 2,9,16,23-tetrahydroxyphthalocyaninato zinc(II) (**11**) and its precursor **8** and its isomers show multiplets at 10.65–10.63 ppm (phenol group), 9.19–9.15, 8.70–8.68, and 7.67–7.63 ppm for the other three protons (Fig. 1). The *J*-modulated spin echo (JMOD) ^{13}C NMR spectrum of compound **22** shows only singlet NMR absorbance peaks for those identical carbons that make up the Pc ring. Thus, the NMR spectra support the conclusion that **21–24** exist as single isomers.

Some other physical properties of **21–24**, such as the formation of crystals and their relatively low solubility, support this conclusion. In general, tetrasubstituted Pcs are polymorphic solids due to the presence of statistically produced isomers, 1,8,15,22-Tetra-(*p*-*n*-butylbenzyloxy)phthalocyaninato zinc(II) (**22**) was directly produced as crystalline needles while recrystallization from THF gave square crystals. The solubilities of **21–24** are informative. For example, 2,9,16,23-tetra-(*p*-*n*-butylbenzyloxy)phthalocyanine (**6**) is very soluble in many organic solvents such as dichloromethane, chloroform, DMF, THF, and ethyl acetate, but 1,8,15,22-tetra-(*p*-*n*-butylbenzyloxy)phthalocyanine, its constitutional isomer, does not dissolve in most solvents and only slightly in THF and pyridine. The UV–visible spectra of **21–24** contrast strongly with those of **6**, **8**, **10**, and **11**. For example, **24** exhibits a strong *Q*-band at 719 nm compared to **10** at 684 nm (1, 32). Although tetrahydroxyphthalocyanines cannot be made directly from hydroxyphthalonitriles, the use of appropriate blocking groups can lead to their syntheses both as mixtures of isomers or, in the case of **23** or **24**, as pure single isomers.

Experimental

Matheson high-purity argon was used to maintain inert atmosphere conditions. Thin-layer chromatography (TLC) was performed using silica gel G as the adsorbent. Flash chromatography was performed using silica gel of particle size 20–45 μm. Gel permeation chromatography was performed using Bio-beads, SX-2, 200–400 mesh. Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are uncorrected. Infrared (IR) spectra were recorded on a Pye Unicam SP1000 infrared spectrophotometer using KBr disks. Nuclear magnetic resonance (NMR) spectra for protons and carbons were recorded on a Bruker AM300 NMR spectrometer. The positions of signals are reported in δ units. (The splitting of the signal is described as singlets (s), doublets (d), triplets (t), quartets (q), doublets

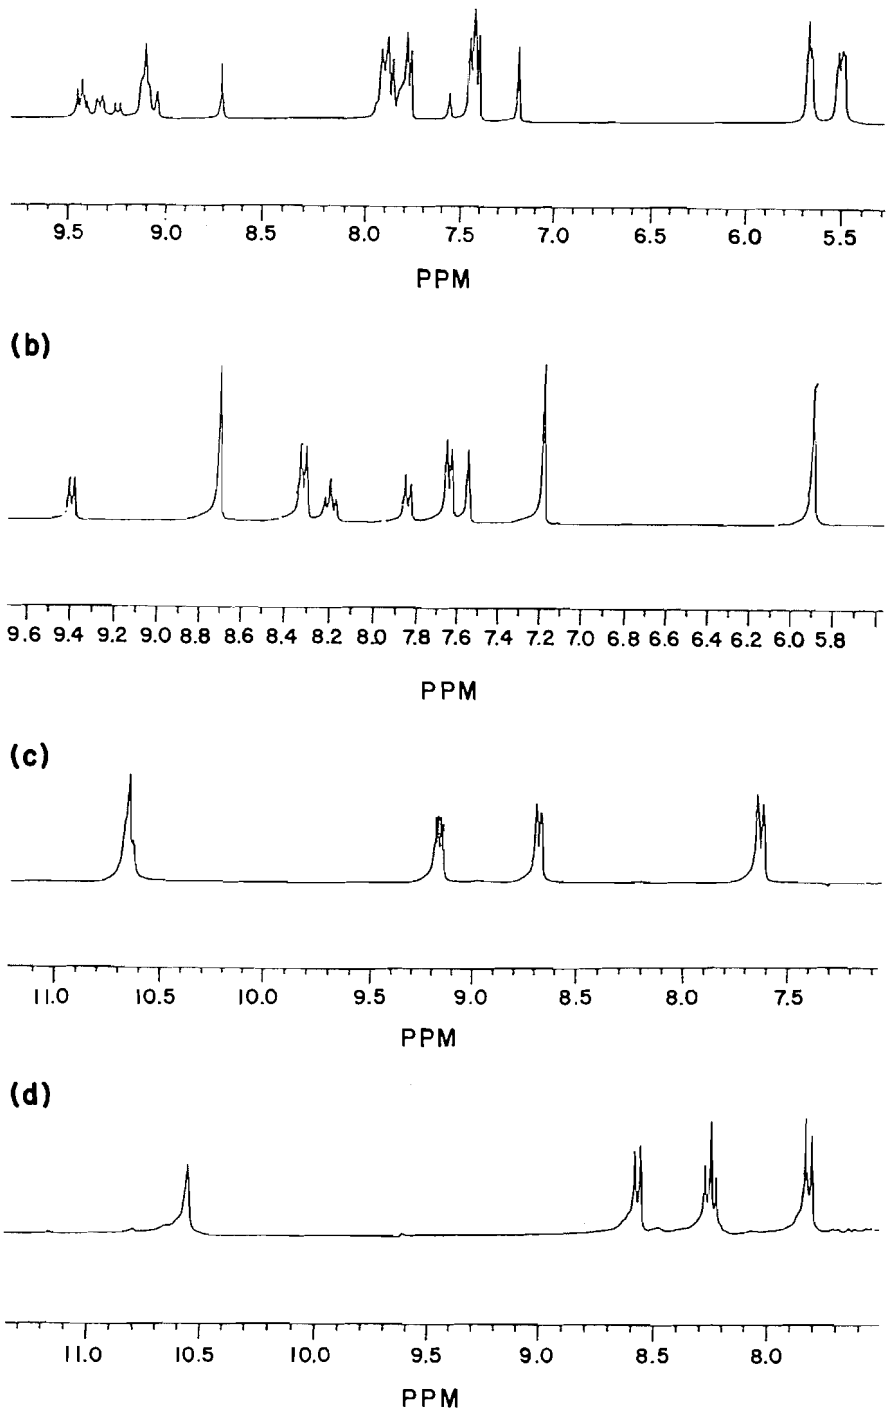

FIG. 1. The ^{1}H nmr spectra of tetrasubstituted phthalocyaninato zinc(II) compounds in pyridine-d_5 (*a*, *b*) and DMSO-d_6 (*c*, *d*); (*a*) 2,9,16,23-tetra(*p*-*n*-butylbenxyloxy)phthalocyaninato zinc(II) (**8**); (*b*) 1,8,15,22-tetra(*p*-*n*-butylbenzyloxy)phthalocyaninato zinc(II) (**22**); (*c*) 2,9,16,23-tetrahydroxyphthalocyaninato zinc(II) (**11**); (*d*) 1,8,15,22-tetrahydroxyphthalocyaninato zinc(II) (**24**); *: peaks of solvent.

of doublets (dd), or multiplets (m).) The ultraviolet–visible spectra (UV) were recorded on a Hewlett–Packard HP8451A diode array spectrophotometer. Mass spectra (MS) were recorded at 70 eV on a VG Micromass 16F mass spectrometer in the EI mode. The FAB spectra were obtained with a Kratos MS-50 triple analyzer mass spectrometer equipped with a FAB ion source of standard Kratos design and Ion Tech atom gun. Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario.

4-p-n-*Butylbenzyloxyphthalonitrile (4)*

Method I (21)

To a solution of 0.52 g (3.0 mmol) of 4-nitrophthalonitrile (**1**) in 10 mL of dimethylformamide (DMF) was added 0.41 g (2.5 mmol) of *p*-*n*-butylbenzyl alcohol (**2**) and 1.05 g (7.5 mmol) of finely ground potassium carbonate. This reaction mixture was stirred at room temperature for 96 h and poured into 30 mL of ice-water to give a yellow precipitate. The precipitate was collected by filtration, washed with cold water, and dried, The crude product was purified by column chromatography on silica gel, using THF–hexane (15:85) as eluant. Evaporation of the solvent gave a pale-yellow solid. Recrystallization of the solid in THF–hexane 3:7 gave 0.54 g (75%) of **4** as white crystals.

Method II

A improved method was used to prepare **4**. To a solution of 0.52 g

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

(3.0 mmol) of **1** in 10 mL of dimethyl sulfoxide (DMSO) was added 0.41 g (2.5 mmol) of **2** and 0.25 g (1.88 mmol) of finely ground potassium carbonate. The mixture was stirred for 96 h. Then another three 0.25-g portions of potassium carbonate were added to the mixture in 20-h intervals and the mixture was pumped under vacuum (20) for 5 min in 10-h intervals during the reaction. Ice-water (30 mL) was added with stirring to the mixture. The precipitate was collected by filtration, washed with cold water, and dried. After column chromatography on silica gel and recrystallization in THF and hexane (3:7), 0.65 g of a white crystalline material **4** was obtained in 90% yield, mp 64.5–65.5°C; IR (KBr, cm^{-1}): 3095, 3040, 2960, 2930, 2860, 2230 (CN), 1590, 1490, 1320, 1250, 1085, 990, 875, 845; ^1H NMR ($CDCl_3$) δ: 7.71–7.68 (d, $J = 4$ Hz, 1H), 7.32–7.21 (m, 6H), 5.11 (s, 2H), 2.65–2.60 (t, $J = 15$ Hz, 2H), 1.65–1.55 (m, 2H), 1.42–1.33 (m, 2H), 0.95–0.90 (t, $J = 15$ Hz, 3H); ^{13}C NMR ($CDCl_3$) δ: 161.89, 143.82, 135.20, 131.78, 128.97, 127.71, 120.09, 119.80, 117.44, 115.69, 107.43, 71.14, 35.37, 33.50, 22.34, 13.90; MS for ($C_{19}H_{18}N_2O$), *m/z* (relative intensity): 291 ($(M + 1)^+$, 18), 247 (19), 147 ($(C_4H_9PhCH_2)^+$, 100), 127 (24), 116 (35), 104 (47), 91 (41), 78 (30), 64 (27), 51 (25). Anal. calcd. for $C_{19}H_{18}N_2O$: 78.59, H 6.25, N 9.65; found: C 78.21, H, 6.47, N 9.50.

4-Diphenylmethoxyphthalonitrile (5)

A procedure previously described for the preparation of **4** (Method II) was used to prepare **5** in 92% yield as white crystals, mp 156–157°C; IR (KBr, cm^{-1}) 3080, 3020, 2950, 2920, 2848, 2230, 2220, 1575, 1468, 1295, 1180, 1040, 820, 790; ^1H NMR ($CDCl_3$) δ: 7.92–7.89 (d, $J = 9$ Hz, 1H), 7.70–7.68 (d, $J = 2.5$ Hz, 6H), 7.55–7.57 (m, 5H), 7.40–7.29 (m, 6H), 6.78 (s, 1H); ^{13}C NMR ($CDCl_3$) δ: 161.09, 139.00, 135.15, 129.05, 128.64, 126.74, 121.14, 120.68, 117.44, 115.54, 115.17, 107.71, 83.16; MS for $C_{21}H_{14}N_2O$, *m/z* (relative intensity): 310 (M^+, 6%), 285 (48), 237 (32), 167 (Ph_2CH^+, 100), 152 (58), 115 (54), 89 (50), 82 (73), 63 (32), 51 (16). Anal. calcd. for $C_{21}H_{14}N_2O$: C 81.27, H 4.55, N 9.03; found: C 81.50, H 4.48, N 9.21.

*2,9,16,23-Tetra(*p-n-*butylbenzyloxy)phthalocyanine (6)*

Compound **4** (0.405 g, 1.4 mmol) was suspended in 5 mL of 2-dimethylaminoethanol (DME). The suspension was heated to 80°C and the phthalonitrile dissolved. A steady stream of ammonia gas was introduced into the solution for 2 h. The temperature was raised to reflux and maintained, along with ammonia introduction, for 10 h. The mixture was cooled to room temperature and centrifuged to give a blue solid. The solid was washed with hexane and methanol. Further purification was performed on a flash silica gel column, eluting with THF and hexane (2:8). Evaporation of the solvent gave 0.069 g (17%) of a shining blue solid, mp >320°C; UV–vis (THF) λ_{max} (log ε): 702 (5.00), 666 (4.97), 638 (4.72), 608 (3.60); IR (KBr, cm^{-1}): 3300 (N-H), 3040, 3020, 2960, 2940, 2862, 1614, 1505, 1480, 1460, 1380, 1320, 1250, 1120, 1100, 1015, 940, 825, 750; ^1H NMR ($CDCl_3$) δ: 7.79–6.95 (m, br, 28H), 4.81–4.70 (m, br, 8H), 2.82–2.68 (t, 8H), 1.69–1.58 (p, 8H), 1.37–1.22 (m, 8H), 1.05–1.01 (t, 12H), −5.95 (s, br, 2H); MS (FAB) for $C_{76}H_{74}O_4$, *m/z* (relative intensity): 1164 ($(M + 2)^+$, 48), 1017 {$((M + 2)680 - R)^+$, 39}, 870 {$((M + 2)680 - 2R)^+$, 56}, 724 {$((M + 2\ 680 - 3R)^+$, 85}, 580 ($(M - 4R)^+$, 79. Anal. calcd. for $C_{79}H_{74}N_8O_4$: C 78.46, H 6.41, N 9.63; found: C 78.79, H 6.60, N 9.45.

2,9,16,23-Tetra(diphenylmethoxy)phthalocyanine (7)

A method previously described for the preparation of **6** was used to prepare **7**. After collection by centrifugation and washing, the crude product was applied onto a flash silica gel column and eluted with toluene. Evaporation of the solvent gave a shining, blue solid in 25% yield, mp >320°C; UV–vis (THF) λ_{max} (log ε): 704 (471), 668 (4.64), 641 (4.20), 605 (4.02), 390 (4.13), 351 (4.34); IR (KBr, cm^{-1}): 3300 (N-H), 3030, 3010, 2820, 1690, 1610, 1500, 1480, 1460, 1400, 1350, 1325, 1235, 1120, 1100, 1020, 750, 700; ^1H NMR ($CDCl_3$) δ: 8.38–808 (m), 7.99–7.80 (m), 7.77–7.29 (m), 7.20–7.10 (m), 6.80–6.71 (m, 8H), −3.92 (b, 2H); MS (FAB) for $C_{85}H_{58}N_8O_4$, *m/z* (relative intensity): 1243 ($(M + 1)^+$, 13), 1076 {$((M + 1)680 - 2R)^+$, 55}, 742 {$((M + 1)680 - 3R)^+$, 65}, 576 {$((M + 1)680 - 4R)^+$, 100}. Anal. calcd. for $C_{84}H_{58}N_8O_4$: C 81.14, H 4.66, N 9.01; found: C 81.21, H 4.03, N 9.15.

*2,9,16,23-Tetra(*p-n-*butylbenzyloxy)phthalocyaninato zinc(II) (8)*

Method I

Compound **4** (0.81 g, 2.8 mmol) was suspended in 10 mL of DME. The suspension was heated to 100°C and a steady stream of ammonia gas passed into the solution for 2 h. To the solution was added 1.5 mL of 1,8-diazatricyclo[5.4.0]undec-7-ene (DBU) followed by 546 mg (3.0 mmol) of zinc acetate after 0.25 h. The introduction of ammonia was continued for 10 h at 100–115°C. The mixture was cooled to room temperature and 30 mL of methanol and water (1:1) was added. The precipitate was collected by centrifugation, and washed with water, methanol, and hexane. Further purification was performed in a flash silica gel column by eluting with THF and hexane (2:8). Evaporation of the solvent gave 0.557 g of a shining, blue solid in 65% yield.

Method II

Compound **8** could also be prepared from **6**. To 116 mg (0.1 mmol) of **6** in 5 mL of toluene and DMF (1:1) was added 91 mg (0.4 mmol) of zinc acetate. The mixture was refluxed for 24 h. The mixture was cooled to room temperature and 10 mL of methanol and water (1:1) was added. The precipitate was collected by centrifugation, and washed with water, methanol, and hexane. The solid was put onto a flash silica gel column and eluted with THF and hexane (3:7). Evaporation of the solvent gave 110 mg (90% yield) of a shining, blue solid as pure **8**, mp >320°C; UV–vis (THF) λ_{max} (log ε): 682 (5.34), 610 (4.41), 350 (4.89); IR (KBr, cm^{-1}): 3040, 3010, 2950, 2930, 2860, 1910, 1735, 1705, 1580, 1532, 1450, 1400, 1325, 1250, 1160, 1100, 1030, 950, 850; ^1H NMR (pyridine-d_5) δ: 9.45–9.05 (m, 8H), 7.95–7.77 (m, 12H), 7.46–7.19 (m, 8H), 5.67–5.49 (m, 8H), 2.67–2.63 (t, 8H), 1.66–1.57 (p, 8H), 1.40–1.28 (m, 8H), 0.93–0.88 (t, 12H); JMOD ^{13}C NMR (pyridine-d_5) δ: 161.41–161.16 (m, 1 × 4C), 153.80–152.84 (m, 2 × 4C), 143.16–143.12 (d, 1 × 4C), 141.30–141.03 (m, 1 × 4C); 135.11–135.08 (d, 1 × 4C), 132.47–132.20 (m, 1 × 4C), 129.22–129.15 (d, 2 × 4C), 128.67–128.59 (d, 2 × 4C), 124.17 (m, b, 1 × 4C), 118.53 (m, b, 1 × 4C), 106.98 (m, b, 1 × 4C), 71.09 (s, 4C), 35.65 (s, 4C), 33.92 (s, 4C), 22.65 (s, 4C), 14.12 (s, 4C); MS (FAB) for $C_{76}H_{72}N_8O_4Zn$, *m/z* (relative intensity): 1226 ($(M + 2)^+$, 62), 1079 {$((M + 2)680 - R)^+$, 63}, 932 {$((M + 2)680 - 2R)^+$, 57}, 785 {$((M + 2)680 - 3R)^+$, 67}, 638 {$((M + 2)680 - 4R)^+$, 100}. Anal. calcd. for $C_{76}H_{72}N_8O_4Zn$: C 74.41, H 5.92, N 9.13; found: C 74.00, H 5.80, N 8.82.

2,9,16,23-Tetra(diphenylmethoxy)phthalocyaninato zinc(II) (9)

The methods (Method I and Method II) previously described for the preparation of **8** were used to prepare **9** in 70 and 90% yield, respectively, as a shining, blue solid, mp >320°C; UV–vis (THF) λ_{max} (log ε): 679 (5.74), 611 (4.71), 351 (5.31); IR (KBr, cm^{-1}): 3030, 3010, 2870, 1610, 1530, 1450, 1380, 1325, 1250, 1210, 1155, 1100, 1025, 845, 785; ^1H NMR (pyridine-d_5) δ: 9.55–9.50 (m, 8H), 8.72–8.07 (m, 4H), 7.94–7.69 (m, 16H), 7.52–7.37 (m, 28H); ^{13}C NMR (pyridine-d_5) δ: 160.68–160.46 (m, 1 × 4C), 154.91–153.15 (m, 2 × 4C), 142.29 (s, 2 × 4C), 141.16–140.9 (m, 1 × 4C), 132.77–132.64 (m, 1 × 4C), 129.26 (s, 4 × 4C), 128.32 (s, 2 × 4C), 127.64 (s, 4 × 4C), 124.44 (m, 1 × 4C), 119.48–119.39 (m, 1 × 4C), 109.50 (m, 1 × 4C), 82.57 (s, 1 × 4C); MS (FAB) for $C_{85}H_{56}N_8O_4Zn$, *m/z* (relative intensity): 1305 ($(M + 1)^+$, 100), 1139 {$((M + 2)680 - R)^+$, 62}, 972 {$((M + 2)680 - 2R)^+$, 33}, 805 {$((M + 2)680 - 3R)^+$, 20}, 638 {$((M + 2)680 - 4R)^+$, 18}. Anal. calcd. for $C_{84}H_{56}N_8O_4Zn$: C 77.21, H 4.32, N 8.58; found: C 76.88, H 3.85, N 8.70.

2,9,16,23-Tetrahydroxyphthalocyanine (10) (1)

To 60 mg (0.052 mmol) of **6** in 5 mL of trifluoroacetic acid (TFA) was added 27.9 mg (0.208 mmol) of 1,2,4,5-tetramethylbenzene (TMB). The mixture was refluxed for 15 h. The TFA was evaporated and the residue was washed with hexane. The residue was dissolved in THF and the solution was put onto a gel permeation column, eluting with THF. Evaporation of the solvent gave 18 mg (60%) of **10** as a green solid. When **7** was used to prepare **10**, the reaction time was 10 h and the yield was 70%; UV–vis (2-methoxyethanol) λ_{max} (log ε): 708 (4.89), 672 (4.85), 639 (4.53), 614 (4.32), 390 (4.40), 342 (4.72), 292 (4.54), 232 (4.45); IR (KBr, cm^{-1}): 3100–3500 (phenolic group), 1610,

Anal. calcd. for $C_{32}H_{18}N_8O_4$: C 66.43, H 3.14, N 19.37; found: C 66.28, H 3.21, N 19.01.

*2,9,16,23-Tetrahydroxyphthalocyaninato zinc(II) (**11**) (1)*

Treatment of **8** and **9** as previously described for the preparation of **10** gave **11**. The reaction times were 5 h for both cleavage reactions and gave **11** in 84 and 88% yield, respectively. Alternatively, compound **11** could be prepared from **10** by refluxing **10** with zinc acetate in DMF in 88% yield. Compound **11** was a blue solid, mp >320°C; UV–vis (THF) λ_{max} (log ε): 684 (5.00), 672 (4.90), 614 (4.44), 348 (4.83); IR (KBr, cm^{-1}): 3100–3500 (broad signal, phenolic group), 1600, 1475, 1300, 1240, 1085, 1040, 945, 745; ^{1}H NMR (DMSO-d_6) δ: 10.65–10.63 (m, 4H (phenolic group)), 9.19–9.15 (m, 4H), 8.70–8.68 (m, 4H), 7.67–7.63 (m, 4H); MS (FAB) for $C_{32}H_{16}N_8O_4Zn$, *m/z* (relative intensity): 640 (M^+, 100). Anal. calcd. for $C_{32}H_{16}N_8O_4Zn$: C 59.88, H 2.51, N 17.46, Zn 10.18; found: C 59.70, H 2.80, N 16.99, Zn 10.51.

*4-Methoxymethoxyphthalonitrile (**15**)*

Toluenesulfonic acid (TsOH, 150 mg), 4-hydroxyphthalonitrile (**12**) (33) (1.50 g, 10.4 mmol), and dimethoxymethane (**13**) (10 mL) were mixed with 200 mL of dry dichloromethane in a round-bottom flask, equipped with a Soxhlet extractor, in which there was a thimble containing 30 g of 4 Å molecular sieves (29). The suspension was protected under argon and heated under reflux with stirring. After every 12 h, 5 mL of fresh **13** was added. After 24 h, the molecular sieves were replaced with fresh sieves. As the reaction proceeded, the solid gradually dissolved. After 48 h under reflux conditions, the mixture was washed twice with 30 mL of a 0.5 M sodium hydroxide solution, twice with 30 mL of distilled water, and was dried with magnesium sulfate. After filtration and evaporation, 1.81 g of a crude yellowish product was obtained. It was then chromatographed on neutral alumina, eluting with ethyl acetate and hexane (4:6), to give 1.80 g (92%) of pure **15** as white yellowish crystals, mp 80–81°C; UV–vis (dichlorobenzene) λ_{max} (log ε): 304 (3.16), 286 (2.60), 278 (2.54); IR (KBr, cm^{-1}): 3100, 3060, 2980, 2960, 2920, 2220 (CN), 1940, 1780, 1600, 1560, 1495, 1450, 1420, 1320, 1310, 1290, 1240 (C-O-C), 1230, 1170, 1090, 990, 920, 890, 850, 730, 700, 660; ^{1}H NMR ($CDCl_3$) δ: 7.72 (d, J = 8.7 Hz, 1H), 7.45 (d, J = 2.4 Hz, 1H), 7.36 (dd, J = 8.7, 2.5 Hz, 1H), 5.27 (s, 2H), 3.50 (s, 3H); ^{13}C NMR ($CDCl_3$) δ: 160.41, 135.20, 121.23, 120.93, 117.44, 115.58, 115.21, 108.34, 94.62, 56.76; MS for $C_{10}H_8N_2O_2$, *m/z* (relative intensity): 188 (M^+, 60), 157 (60), 144 (100), 127 (90), 115 (30), 100 (60). Anal. calcd. for $C_{10}H_8N_2O_2$: C 63.82, H 4.38, N 14.93; found: C 63.82, H 4.29, N 14.88.

*4-Ethoxymethoxyphthalonitrile (**16**)*

4-Hydroxyphthalonitrile (**12**) (1.50 g, 10.4 mmol) was mixed with 200 mL of dry dichloromethane in a round-bottom flask equipped with a Soxhlet extractor containing molecular sieves (4 Å, 30 g). Diethoxymethane (**14**) (10 mL) and 150 mg of TsOH were added to the above suspension. The mixture was then heated under reflux with stirring. After every 12 h, 5 mL of fresh diethoxymethane was added. After 24 h, the molecular sieves were replaced by fresh sieves. As the reaction proceeded, the solid gradually dissolved. After 48 h, the mixture was washed twice with 30 mL of sodium hydroxide solution (0.5 M), twice with 30 mL distilled water, and was dried with magnesium sulfate. After filtration and evaporation, 2.01 g of a yellowish solid was obtained. This solid was then further purified on neutral alumina by column chromatography using ethyl acetate and hexane (4:6). After evaporation of the solvent, the residue was recrystallized from methanol and water to give 2.00 g (95% yield) of pure compound **16** as white or yellowish crystals, mp 56–57°C; UV–vis (dichlorobenzene) λ_{max} (log ε): 306 (3.22), 286 (2.71), 282 (2.64); IR (KBr, cm^{-1}): 3120, 3075, 2980, 2935, 2900, 2200 (-CN), 1935, 1590, 1560, 1495, 1480, 1410, 1400, 1320, 1290, 1240 (C-O-C), 1090, 960, 910, 870, 850, 740; ^{1}H NMR ($CDCl_3$) δ: 7.72 (d, J = 8.7 Hz, 1H), 7.45 (d, J = 2.5 Hz, 1H), 7.36 (dd, J = 8.7, 2.5 Hz, 1H), 5.32 (s, 2H), 3.74 (q, J = 7.0 Hz, 2H), 1.22 (t, J = 7.0 Hz, 3H, 3H); ^{13}C NMR (NMR ($CDCl_3$) δ: 160.62, 135.19, 121.23, 120.93, 117.41, 115.63, 108.19, 93.39, 65.39, 16.01; MS for $C_{11}H_{10}N_2O_2$, *m/z* (relative intensity): 202 (M^+, 10), 157 (40), 144 (100), 127 (40), 116 (20), 100 (20). Anal. calcd. for $C_{11}H_{10}N_2O_2$: C 65.35, H 5.27, N 13.80; found: C 65.34, H 4.99, N 13.85.

*2,9,16,23-Tetra(methoxymethoxy)phthalocyaninato zinc(II) (**17**)*

A suspension of 500 mg (2.66 mmol) of **15** and 2.5 mL of DBU in 2.5 mL of 1-butanol was stirred and heated under reflux. The phthalonitrile dissolved after 10–20 min. Then, 170 mg (0.93 mmol) of dried zinc acetate was added to the solution. After 24 h under reflux, the dark mixture was poured into 150 mL of methanol and water (1:1) to form a precipitate. The precipitate was collected by centrifugation, and washed with water, methanol, and hexane. The crude product was then purified by column chromatography on neutral alumina, eluting with ethyl acetate and hexane (9:1). Evaporation of the solvent gave 197 mg (36.2%) of a dark blue solid **17**. When the procedure previously described for the preparation of **8** was used to prepare the compound, the yield was 60%; UV–vis (2-methoxyethanol) λ_{max} (log ε): 680 (5.15), 672 (5.16), 610 (4.50), 350 (4.85), 286 (4.46), 240 (4.56); IR (KBr, cm^{-1}): 2950 (br), 1610, 1490, 1400, 1350, 1240 (C-O-C), 1210, 1160, 1050, 1000, 930, 830, 780, 750, 730; ^{1}H NMR (DMSO-d_6) δ: 9.10–7.70 (br, 12H), 5.76 (m, 8H), 3.67 (m, 12H); (pyridine-d_5) δ: 9.54–9.36 (m, br, 8H), 8.71 (m, 4H), 5.79–5.70 (d, 8H), 3.64–3.61 (d, 12H); ^{13}C NMR ($CDCl_3$) δ: 108–158; JMOD ^{13}C NMR (pyridine-d_5) δ: 159.6 (m, 1 × 4C), 153.9–153.2 (m, 2 × 4C), 141.0–140.8 (m, 1 × 4C), 133.1 (m, 1 × 4C), 124.3–123.5 (m, 1 × 4C), 119.6 (m, 1 × 4C), 109.1 (m, 1 × 4C), 95.3 (s, 1 × 4C), 56.3 (s, 1 × 4C). Anal. calcd. for $C_{40}H_{32}N_8O_8Zn$: C 58.72, H 3.94, N 13.70, Zn 7.99; found: C 58.55, H 4.10, N 13.62, Zn 8.12.

*2,9,16,23-Tetrahydroxyphthalocyanine (**10**) from **17***

A solution of 82 mg (0.1 mmol) of **17** in 50 mL of hydrochloric acid solution (HCl and 2-methoxyethanol 1:9) was stirred at 80°C overnight and then neutralized with 10% aqueous solution of sodium hydroxide. The solution was then poured into a saturated solution of sodium chloride (150 mL) to precipitate the phthalocyanine. The precipitate was washed twice with water to get rid of sodium chloride and then dissolved in a small portion of DMF and precipitated from toluene to get rid of any incompletely hydrolysed phthalocyanine species. This precipitate was then preabsorbed onto 2 g of classical silica gel and subjected to a classical column chromatography on silica gel, eluting with ethyl acetate and DMF in increasing amounts of DMF. After evaporation of the solvent and precipitation from toluene, 47 mg (31%) of **10** was obtained.

*3-p-n-Butylbenzyloxyphthalonitrile (**20**)*

A procedure previously described for the preparation of **4** (Method II) was used to prepare **20** in 95% yield as white crystals, mp 70–71°C; IR (KBr, cm^{-1}): 3080, 3020, 2950, 2920, 2850, 2250, 2220, 1575, 1470, 1295, 1280, 1180, 1040, 840, 790; ^{1}H NMR ($CDCl_3$) δ: 7.62–7.56 (t, J = 15 Hz, 1H), 7.54–7.16 (m, 7H), 5.24 (s, 2H), 2.64–2.62 (t, J = 15.4 Hz, 2H), 1.62–1.57 (m, 2H), 1.39–1.31 (m, 2H), 0.95–0.90 (t, J = 14.6 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ: 161.14, 143.68, 134.44, 131.75, 128.98, 127.34, 125.30, 117.62, 117.22, 115.32, 113.02, 105.53, 71.57, 35.38, 33.51, 22.34, 13.91; MS for $C_{19}H_{18}N_2O$, *m/z* (relative intensity): 291 ($(M + 1)^+$, 18), 247 (20), 147 ($C_4H_9PhCH_{2+}$, 100), 127 (22), 116 (33), 104 (44), 91 (40), 78 (27), 64 (23), 51 (20). Anal. calcd. for $C_9H_{18}N_2O$: C 78.60, H 6.25, N 9.65; found: C 78.92, H 6.12, N 9.83.

*1,8,15,22-Tetra(p-n-butylbenzyloxy)phthalocyanine (**21**)*

Lithium (0.30 g) was suspended in 30 mL of *n*-octanol. The suspension was heated to 170°C under stirring and kept for 4 h. The homogenous solution was cooled to 40°C, at which point was added 0.35 g (1.2 mmol) of **20** in 4 mL of dried THF. The temperature was raised to 60°C and the mixture kept stirring for 2 h. Then, the temperature was raised to 100°C and stirring was continued for 12 h. The temperature was further raised to 120°C, and stirring continued for another 2 h. The mixture was cooled to room temperature and the reaction was

quenched with methanol and water (1:1) to form a blue precipitate. The precipitate was collected by centrifugation, washed successively with water, methanol, and hexane, and dried to give 126.7 mg (40%) of a dark-green solid **21**, mp >320°C; UV–vis (THF) λ_{max} (log ϵ): 724 (4.70), 690 (4.71), 658 (4.02), 627 (2.95), 395 (3.46), 351 (3.96); IR (KBr, cm^{-1}): 3310 (N-H), 3010, 2960, 2920, 2860, 1665, 1530, 1440, 1385, 1240, 1175, 1145, 1110, 1010, 925, 850; ^1H NMR (pyridine-d_5) δ: 9.48–9.45 (d, J = 7.5 Hz, 4H), 8.34–8.32 (d, J = 7.8 Hz, 8H), 8.27–8.22 (t, J = 15 Hz, 4H), 7.91–7.89 (d, J = 8 Hz, 4H), 7.66–7.63 (d, J = 7.7 Hz, 8H), 5.93 (s, 8H), 2.85–2.80 (t, J = 15 Hz, 8H), 1.83–1.73 (m, 8H), 1.51–1.42 (m, 8H), 1.01–0.96 (t, J = 15 Hz, 12H), −4.2 (br, 2H); MS (FAB) for $C_{79}H_{74}N_8O_4$, *m/z* (relative intensity): 1164 ((M + 2)$^+$, 68), 1017 {((M + 2)680 − R)$^+$, 56}, 870 {((M + 2)680 − 2R)$^+$, 23}, 723 {((M + 2)680 − 3R)$^+$, 100}, 578 {((M + 2)680 − 4R)$^+$, 91}. Anal. calcd. for $C_{76}H_{74}N_8O_4$: C 78.46, H 6.41, N 9.63; found: C 78.22, H 6.63, N 9.24.

1,8,15,22-Tetra(p-n-*butylbenzyloxy*)*phthalocyaninato zinc(II) (22)*

Lithium (0.60 g) was suspended in 60 mL of *n*-octanol. The mixture was heated to 170°C and kept stirring for 4 h. The homogeneous solution was cooled to 40°C, at which point was added 0.52 g (1.79 mmol) of **20** in 5 mL of THF. The solution was slowly heated to 100°C and underwent a colour change from colourless to green. To the green solution was added 326 mg (1.79 mmol) of zinc acetate and the solution was kept stirring for 12 h at 100°C. The temperature was raised to 120°C and stirring was continued for another 2 h. The mixture was cooled to room temperature and quenched with methanol and water (1:1) to form a shining, blue precipitate. The precipitate was collected by centrifugation, washed successively with water, methanol, and hexane, and dried. The blue solid was examined under a microscope and exhibited crystalline needles. Further recrystallization from THF gave 0.44 g (80%) of shining, blue, square crystals **22**.

Compound **22** can also be prepared from **21**. A mixture of 80 mg (0.069 mmol) of **15** and 50 mg of zinc acetate in 5 mL of DMF and toluene (1:1) was refluxed for 24 h. To the mixture was added 10 mL of water, and it was then centrifuged to separate a shining, blue solid. The solid was washed with water, methanol, and hexane, and dried to give 76 mg (90%) of a shining, blue solid **22** as needle or square crystals, mp >320; UV–vis (THF) λ_{max} (log ϵ): 696 (5.34), 665 (4.37), 626 (4.46), 369 (4.45); IR (KBr, cm^{-1}): 3010, 2940, 2920, 2840, 1580, 1485, 1335, 1260, 1235, 1130, 1090, 1060, 1040, 1020, 800, 760, 735; ^1H NMR (pyridine-d_5) δ: 9.44–9.41 (d, J = 7.5 Hz, 4H), 8.34–8.31 (d, J = 6.6 Hz, 8H), 8.24–8.19 (t, J = 15.4 Hz, 4H), 7.88–7.86 (d, J = 8.0 Hz, 4H), 7.68–7.63 (d, J = 7.7 Hz, 8H), 5.91 (s, 8H), 2.85–2.80 (t, J = 15.2 Hz, 8H), 1.83–1.73 (p, 8H), 1.51–1.39 (m, 8H), 1.01–0.96 (t, J = 14.6 Hz, 12H); JMOD ^{13}C NMR (pyridine-d_5) δ: 156.85 (s, 1 × 4C), 154.18 (s, 1 × 4C), 154.07 (s, 1 × 4C), 143.01 (s, 1 × 4C), 142.25 (s, 1 × 4C), 135.20 (s, 1 × 4C), 130.91 (s, 1 × 4C), 129.20 (s, 2 × 4C), 128.62 (s, 2 × 4C), 126.41 (s, 1 × 4C), 116.79 (s, 1 × 4C), 113.68 (s, 1 × 4C), 71.40 (s, 14C), 35.84 (s, 4C), 34.20 (s, 4C), 22.72 (s, 4C), 14.25 (s, 4C); MS (FAB) for $C_{76}H_{72}N_8O_4$, *m/z* (relative intensity): 1226 ((M + 2)$^+$, 100), 1079 {((M + 2)fs20 − R)$^+$, 88}, 932 {((M + 2)fs20 − 2R)$^+$, 96}, 785 {((M + 2)fs20 − 3R)$^+$, 84}, 638 {((M + 2)fs20 − 4R)$^+$, 68}. Anal. calcd. for $C_{76}H_{72}N_8O_4Zn$: C 74.41, H 5.92, N 9.13; found: C 74.21, H 5.18, N 9.07.

1,8,15,22-Tetrahydroxyphthalocyanine (23)

To a suspension of 50 mg (0.043 mmol) of **21** in 10 mL of TFA was added 25 mg (0.19 mmol) of TMB. The suspension was refluxed for 50 h. The TFA was evaporated and the residue was washed with hexane. The green residue was dissolved in THF and put onto a gel permeation column, eluting with THF. Evaporation of the solvent gave 6.2 mg of **23** (25% yield) as a green solid; UV–vis (THF): λ_{max} (log ϵ): 743 (4.69), 7.10 (4.69), 680 (4.00), 648 (2.98), 350 (3.40); IR (KBr, cm^{-1}): 3100–1500 (broad signal, phenolic group), 1620, 1482, 1310, 1284, 1220, 1200, 1095, 1000, 930, 820, 745, 710 cm; ^1H NMR (DMSO-d_6) δ: 10.50 (s, 4H), 8.51–8.45 (d, J = 7.5 Hz, 4H), 8.07–8.05 (t, J = 15 Hz, 4H), 7.68–7.65 (d, J = 7.5 Hz, 4H), −3.5 (br, 2H); MS (FAB) for $C_{32}H_{18}N_8O_4$, *m/s* (relative intensity): 578 (M$^+$, 100).

1,8,15,22-Tetrahydroxyphthalocyaninato zinc(II) (24)

To 109 mg (0.086 mmol) of **22** in 5 mL of TFA was added 46 mg (0.35 mmol) of TMB. The mixture was refluxed for 15 h. The TFA was evaporated and the residue was washed a few times with hexane. The blue solid was dissolved in THF and the solution was put onto a gel permeation column, eluting with THF. Evaporation of the solvent gave 46.8 mg (85%) of **24** as a blue solid; UV–vis (THF) λ_{max} (log ϵ): 719 (4.85), 686 (4.12), 646 (4.13), 344 (4.06); IR (KBr, cm^{-1}): 3100–3500 (broad signal, phenolic group), 1650, 1520, 1430, 1360, 1275, 1215, 1060, 925, 840; ^1H NMR (DMSO-d_6) δ: 10.56 (s, 4H), 8.58–8.56 (d, J = 7.5 Hz, 4H), 8.28–8.22 (t, J = 15 Hz, 4H), 7.83–7.81 (d, J = 7.7 Hz, 4H); MS (FAB) for $C_{31}H_{16}N_8O_4Zn$, *m/z* (relative intensity): 640 (M$^+$, 100). Anal. calcd. for $C_{32}H_{16}N_8O_4Zn$: C 59.88, H 2.51, N 17.46; found: C 59.74, H 2.33, N 16.89.

The photochemistry of 2,3-benzobicyclo[4.2.0]octa-2,4,7-triene

CHARLOTTE LEE ASPLUND, CHRISTOPHER OWEN BENDER,[1] AND DOUGLAS DOLMAN
Department of Chemistry, University of Lethbridge, Lethbridge, AB T1K 3M4, Canada

Received June 1, 1994

CHARLOTTE LEE ASPLUND, CHRISTOPHER OWEN BENDER, and DOUGLAS DOLMAN. Can. J. Chem. **72**, 1999 (1994).

2,3-Benzobicyclo[4.2.0]octa-2,4,7-triene (**11**) was prepared by Shapiro reaction from 2,3-benzobicyclo[4.20]octa-2,7-dien-4-one (**10**). Triene **11** was found to be thermally and photochemically reactive. Benzocyclooctatetraene (i.e., COT **12**) was the unique product formed when solutions of **11** were heated at 150°C for 5.5 h. The direct irradiation of triene **11** gave benzosemibullvalene (i.e., SB **14**, 23%, $\Phi = 0.069$), COT **12** (39%, $\Phi = 0.11$), and naphthalene (8%, $\Phi = 0.025$). Sensitized irradiations of **11** gave SB **14**, (54%, $\Phi = 0.082$), COT **12** (2%, $\Phi = 0.003$), and naphthalene (4%, $\Phi = 0.009$). Studies with deuterium-labelled triene (**11***a*) indicated that the formation of SB **14** from the direct irradiation of triene **11** derives from the operation of two reaction pathways, the major one (83%) of which appears to be a Zimmerman di-π-methane rearrangement; the minor pathway involves a 1,2-shift of the C_1—C_6 bond to C_1—C_5. By contrast, SB **14** formed from sensitized irradiation appears to be provided uniquely by a Zimmerman di-π-methane rearrangement.

CHARLOTTE LEE ASPLUND, CHRISTOPHER OWEN BENDER et DOUGLAS DOLMAN. Can. J. Chem. **72**, 1999 (1994).

On a préparé le 2,3-benzobicyclo[4.2.0]octa-2,4,7-triène (**11**) par la réaction de Shapiro effectuée à l'aide de la 2,3-benzobicyclo[4.2.0]octa-2,7-dièn-4-one (**10**). Le triène **11** est réactif thermiquement et photochimiquement. Le benzocyclooctatétraène (soit, le COT **12**) est l'unique produit formé lorsqu'on chauffe des solutions du composé **11** à 150°C pendant 5.5 h. L'irradiation directe du triène **11** conduit au benzosemibullvalène (soit, le SB **14**, 23%, $\Phi = 0.069$), le COT **12** (39%, $\Phi = 0.11$), et le naphtalène (8%, $\Phi = 0.025$). Des irradiations sensibilisées du composé **11** conduisent au SB **14**, (54%, $\Phi = 0.082$), au COT **12** (2%, $\Phi = 0.003$), et au naphtalène (4%, $\Phi = 0.009$). Des études avec du triène marqué au deutérium (**11***a*) démontrent que pendant des irradiations directe il y a deux mécanismes qui entrent en jeu dans la formation du produit SB **14** : le mécanisme majeur (83%) dérive d'une transposition di-π-méthane de Zimmerman; le mécanisme proposé pour la voie mineure comporte la migration-1,2 de la liaison C_1—C_6 à la liaison C_1—C_5. Par contre, l'isomérie due triène **11** → SB **14** qu'on observe pendant des irradiations sensibilisée se produisent uniquement par la voie d'une transposition di-π-méthane de Zimmerman.

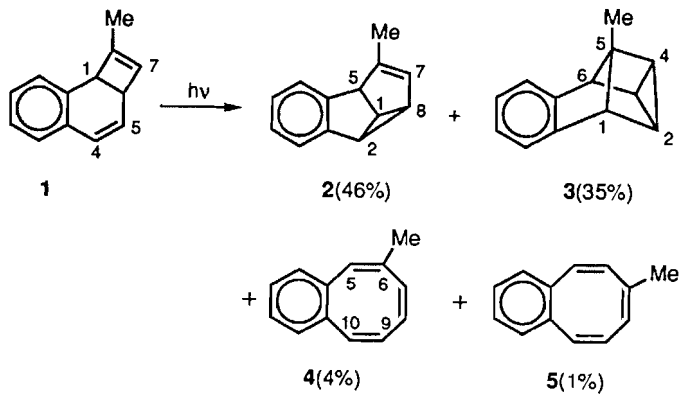
Introduction

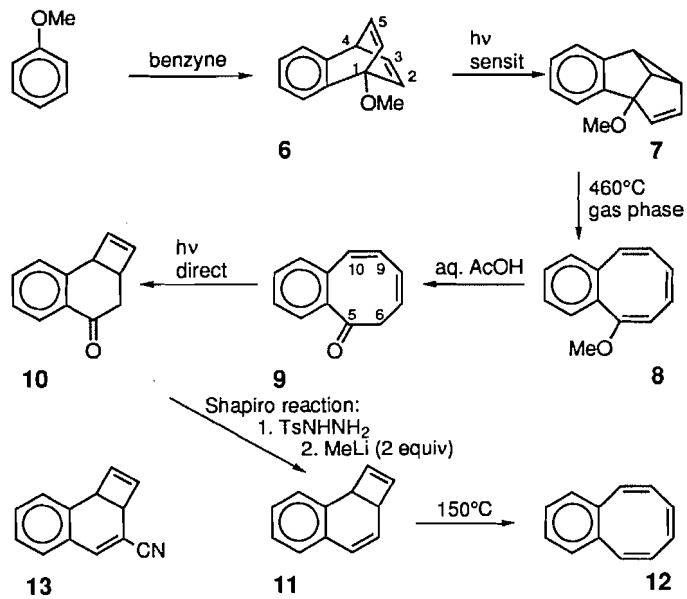
Since Sasse's pioneering study of the photochemistry of 7,8-diphenyl-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene, which was reported over 25 years ago (1), the photoreactivities of more than 20 derivatives of this benzo-triene system have been investigated (2). In many cases the trienes convert to complex polycyclic photoproducts. For example, the methyl derivative **1** gives the isomeric mixture **2**–**5** (Scheme 1) (2*d*). Of particular



SCHEME 1

interest to us was the observation that semibullvalenes (e.g., SB **2**) are often the major products of sensitized and (or) direct irradiation, and hence the trienes offer a synthetic point of entry to the biologically important cyclopentanoid class of compounds.

To date, the unsubstituted benzo-triene has not been reported. We now describe the preparation and photoreactivity of 2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (**11**), and present evidence that the semibullvalene formation from this parent compound arises from two mechanistic pathways.



SCHEME 2

Results

The triene **11** was obtained by a synthetic sequence that paralleled the approach developed by us to prepare the 8-methyl derivative **1**(2*d*). The six-step synthesis, which starts with the Diels–Alder addition of benzyne to anisole, is outlined in Scheme 2. The identification of compounds **6**, **7**, **9**, and **10** was

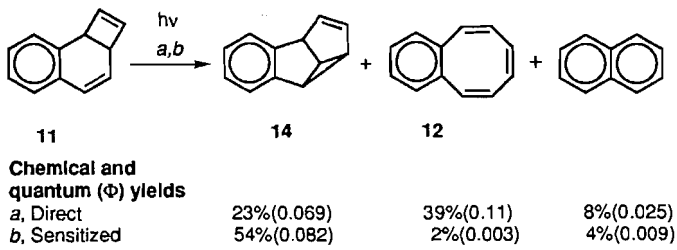
H-8	—	6.13 dd	6.01 d

[a]Run in $CDCl_3$ solvent.

[b]Coupling constants for **11** are: $J_{1,6} = J_{5,6} = 4.5$, $J_{4,5} = 10$, $J_{1,8}$ and $J_{6,7} < 1.0$, and $J_{7,8} = 2.7$ Hz; corresponding coupling constants for the methyl (**1**) and cyano (**13**) derivatives are within 0.5 Hz.



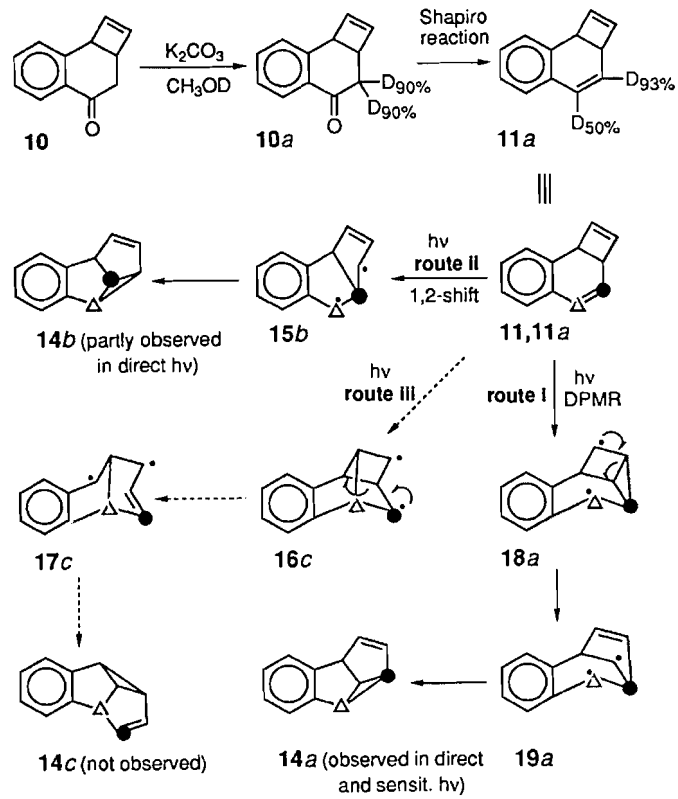
SCHEME 3

straightforward and the spectroscopic details (see Experimental) are analogous to those of the corresponding methyl derivatives encountered in the preparation of the triene **1** (*2d*). In the case of the cyclooctatetraene **8**, the characterization was not carried out because of its ready conversion to the ketone **9** upon attempts at purification with column chromatography.

The structure of triene **11** was assigned mainly on the basis of spectral evidence. Importantly, the ^{1}H NMR signal descriptions, given in Table 1, were in accord with those of the equivalent protons reported for the 8-methyl (**1** (*2d*)) and 5-cyano derivatives (**13**, note structure in Scheme 2 (3)). Further support for structure **11** was provided by the observation that the triene was converted to the known (4) benzocyclooctatetraene **12** on heating in refluxing nonane for 5.5 h. Thus, the parent triene conforms to the normal behaviour of other triene derivatives, all of which undergo thermolysis to give COT product (*2d*, 3, 5). For **11**, the rearrangement is noticeable on GC columns only at temperatures above 110°C.

The photochemistry of triene **11** was investigated on the preparative scale using direct irradiation (Corex filter; $\lambda \geq 280$ nm) and by sensitization with *p*-dimethylaminobenzophenone (at $\lambda \geq 345$ nm). Although both modes of excitation generated benzosemibullvalene (i.e., benzotricyclo[3.3.0.$0^{2,8}$]octa-3,6-diene, **14**), it was the dominant product only in the sensitized runs. The photoproducts are all known compounds (4), and their structures, analytical yields (based on consumed substrate; GC and NMR analysis), and quantum efficiencies are given in Scheme 3.

Mechanistically, the SB product **14** could be produced, in principle, from at least three different routes, all of which have literature precedent in triene derivatives. The pathways (routes i–iii) are outlined in Scheme 4. Route i, the most commonly encountered triene → SB mechanism (*2d*, 6), is a Zimmerman



Structures denoted by "a" and "b" represent compounds doubly labelled with deuterium at positions marked by △ and ●. For structures denoted by a number only (e.g., **11**) △ and ● = H.

SCHEME 4

di-π-methane rearrangement (i.e, DPM rearrangement (7)); route ii is a 1,2-shift process, and has been observed in two cases (6, 8). The third, and least observed, pathway (route iii (3)), involves initial bridging between the distal carbons (i.e., C-4 and C-8) of the vinyl groups.

A convenient method of assessing the possible contributions of these pathways in the formation of SB **14** was provided by determining the label distributions resulting from irradiation of the deuterated triene material **11***a*. The labelled triene was prepared as shown in Scheme 4, starting from deuterium exchange of the methylene protons of the cyclohexanone **10**. The product from the Shapiro reaction was unexceptional in that deuterium incorporation was observed at both C-4 (50%) and C-5 (93%); similar two-site labelling from the tosylhydrazone–alkyllithium procedure was observed and commented on by us in the case of other members of the triene system (*2d*, 9), and a mechanistic rationalization for this phenomenon was proposed by Shapiro (10).

The most important result from the irradiation of the deuterated triene was that the label distributions in the semibullvalene product, as determined by ^{1}H NMR analyses, depended on the mode of excitation used. Thus, direct photolysis led to deuterium attachment at C-1 (16%), at C-2 (50%), and at C-8 (78%), and corresponded to a ca. 5:1 mixture of the isotopic isomers **14***a* and **14***b*. However, the SB product isolated from sensitized irradiation revealed labelling at only two locations: at C-2 (51%) and C-8 (92%), which accords with the presence of 100% of structure **14***a*.

In the case of the COT product, whether generated by direct

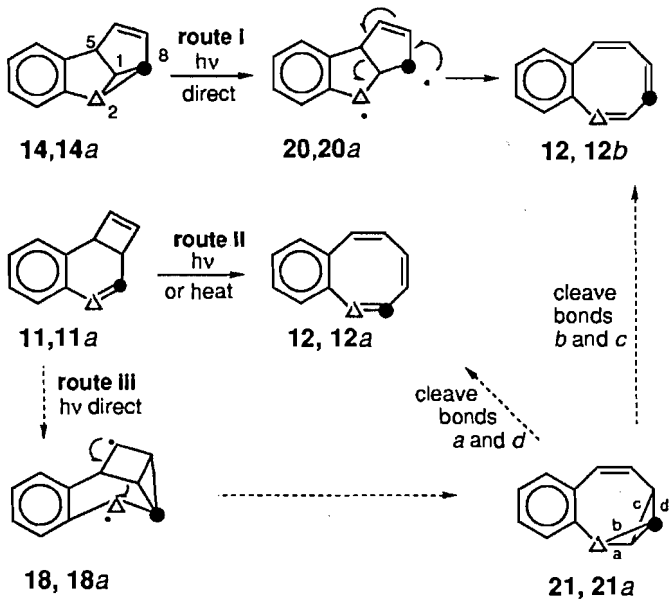
For personal use only.



Structures denoted by "a" and "b" represent compounds doubly labelled with deuterium at positions marked by △ and ●. For structures denoted by a number only (e.g., **14**) △ and ● = H.

SCHEME 5

or sensitized irradiation, the deuterium was positioned at the C-5,10 (51%) and C-6,9 (92%) carbons only. This labelling pattern was the same as that observed in the COT product obtained from thermolysis of triene **11***a*, and corresponds to structure **12***a* (see Scheme 5, route ii).

Lastly, in connection with the labelling results, control experiments were carried out to determine the interconvertibility of the SB and COT photoproducts. We note that, although previous work on the photoisomerizations of SB **14** and COT **12** has been reported, (4), the conditions used were not the same as those employed in the present study. Here, the direct irradiation of SB **14** led to the inefficient formation of COT **12** ($\lambda \geq 280$ nm; $\Phi = 0.007$), and when labelled SB **14***a* was the substrate (Corex filter) the only product (by GC and NMR analysis) was COT **12***b* (48%); Scheme 5, route i). The transformation of SB **14** → COT **12** was first noted by Zimmerman, Givens, and Pagni (4), and involves cleavage of bonds C1—C5 and C2—C8, as shown in route i, Scheme 5. However, the reaction does not interfere as a secondary photoprocess in the conversion of triene **11** → COT **12** since no deuterium was found at the C-7,8 carbons of the labelled COT isolated from irradiations of triene **11***a* (i.e., COT **12***a* is formed, but not COT **12***b*). Attempts at sensitization of SB with *p*-dimethylaminobenzophenone (at $\lambda \geq 345$ nm) failed to produce product. Also, the direct and sensitized irradiations of COT **12**, under the same conditions used for triene **11**, did not lead to observable photochemistry.

Discussion

The deuterium-labelling studies suggest that SB **14**, the major product formed in sensitized irradiations of triene **11**, derives from a sole mechanism that is most reasonably interpreted as a Zimmerman DPM rearrangement from T_1.

In the case of the direct irradiations, the labelling results indicate that the SB is provided by two pathways: a 1,2-shift mechanism (17% route ii, Scheme 4); and a Zimmerman DPM rearrangement (83% route i, Scheme 4). One conclusion from this observation is that the excited state involved in the minor pathway must be S_1 since the same labelling pattern is not observed in the SB product formed in sensitized runs, and it is not formed from the secondary photochemistry of the major primary product COT **12**. Unfortunately, the excited state assignment for the more preferred route to SB **14** (route i) is ambiguous. Analysis of the quantum yield data is consistent with all, part, or none of the DPM rearrangement product being formed from S_1. This latter results stems from application of the expression (11) ${}^1\Phi_{SB} = {}^{dir}\Phi_{SB} - (\Phi_{isc})({}^3\Phi_{SB})$, which sets the limits of the $S_1 \rightarrow T_1$ intersystem crossing efficiency at $0 \leq \Phi_{isc} \leq 0.84$. Use of these same limits for the remaining products from the direct irradiation suggests that at least 98% of COT **12** and at least 68% of the naphthalene must derive from the singlet excited state of triene **11**.

The major S_1 product (COT **12**) from the direct irradiation of triene **11** may arise by a simple $2\sigma_s + 2\pi_s$ electrocyclic opening (12) of the cyclobutene ring (note Scheme 5, route ii). The deuterium-labelling results are in accord with this interpretation. Interestingly, the labelling results do rule out the operation of a pathway to COT **12** that was previously invoked to account for part of the formation of the COT **4** (Scheme 1) from the direct irradiation of the methyl triene **1** (2*d*). The mechanism in question is a variation of a DPM rearrangement, and is shown as route iii in Scheme 5; the thermal isomerization of the proposed octavalene intermediate **21** would be expected to lead to a 1:1 mixture of the COT label isomers **12***a* and **12***b*. Since the deuterium distributions observed in the COT product from **11***a* indicate no labelling at C-7,8, support for the utilization of this pathway in the case of the unsubstituted triene is lacking.

In conclusion, we note that, to date, the semibullvalenes that result from sensitized irradiations of the benzo-trienes appear to be universally provided by a Zimmerman DPM rearrangement (7), and it is only from the S_1 excited state that mechanistic variations in SB production have been observed.

Experimental

Instrumentation and materials

Unless otherwise stated, the ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ solvent at 250 and 62.9 MHz, respectively. The chemical shifts are in δ units and the coupling constants (*J*) in Hz. The abbreviations br, s, d, t, q, and m refer to broad, singlet, doublet, triplet, quartet, and multiplet, respectively. Maxima in the UV spectra are given in nm, with λ_{max} values in parentheses; sh = shoulder. Elemental analyses were performed by Galbraith Labs, Inc., Knoxville, Tenn. Column chromatography was carried out on Silica Gel 60 (Merck; 230–400 mesh) or on Lobar columns (Merck; size B, LiChroprep Si 60). The GC analyses were determined by FID on a DB-23 fused silica capillary column (30 m × 0.25 mm; J&W Scientific). Melting points are uncorrected. Cyclohexane solvent for quantum yields was prepared by scrubbing with 20% fuming sulfuric acid, followed by washing with 10% aqueous sodium hydroxide, drying ($MgSO_4$), and finally distilling from calcium hydride.

General procedures for preparative photolyses

The apparatus consisted of a 450-W Hanovia medium-pressure mercury arc surrounded by a water-cooled quartz immersion well. Unless otherwise stated, the light was filtered through either a cylindrical sleeve of Pyrex or Corex glass. Three types of sample cell were used. Cell A (250-mL sample volume) consisted of a cylindrical well, which surrounded the aqueous filter jacket. Cell A was fitted with gas inlet and exit ports, and sample solutions were magnetically stirred, and purged with argon prior to and during irradiations. Cell B (40-mL sample volume) and Cell C (3.5 mL) were a quartz test-tube-like vessel

and a quartz cuvette, respectively; sample solutions contained therein were deoxygenated by flushing with argon and sealed under a positive pressure; the solutions were magnetically stirred throughout the course of the irradiations.

Diels–Alder addition of benzyne to anisole

Benzene diazonium carboxylate (15), prepared from 10.9 g (79.7 mmol) of anthranilic acid, 18 mL of isoamylnitrite, and 70 mg of trifluoroacetic acid, was added to 500 mL of anisole and stirred at 45–60°C overnight. The resulting mixture was concentrated in vacuo and the residue was taken up in 30 mL of acetone, which was then diluted with 500 mL of hexane. The precipitate was filtered, the filtrate concentrated, and the residue was chromatographed on Silica Gel 60 (0.9 cm × 30 cm) with 1% ethyl acetate–hexane. The main band was concentrated and the residue was rechromatographed on a Lobar Silica Gel column with 1% ethyl acetate–hexane. Crude, yellow barrelene (**6**) was obtained from early fractions. Crystallization from ethanol gave 3.51 g (24%) of colourless 1-methoxy-4-hydro-1,4-ethenonaphthalene (**6**), mp 38–40°C; UV (hexane): 276 (360), 269 (390), 261 (330), 253 sh (380), and 231 sh (1000); ^{1}H NMR; 7.37 (dd, 1H, 1 aromatic, $J = 7$, $J = 1.3$), 7.14 (dd, 1H, 1 aromatic, $J = 7$, $J = 1.3$), 6.82–6.99 (m, 6H, 2 aromatics and 4 olefinics), 4.61 (tt, 1H, H-4, $J_{4,3} = J_{4,5} = 6$; $J_{4,2} = J_{4,6} = 1.5$), 3.83 (s, 3H, methoxyl); ^{13}C NMR: 48.3 (C4), 54.5 (OCH_3), 89.8 (C1), 119.2, 121.9, 123.4, 123.5, 138.4, 140.2, 145.8, and 147.7. Mass spectrum showed molecular ion at *m/e* = 184.08894 (100%); $C_{13}H_{12}O$ requires 184.08882. Anal. calcd. for $C_{13}H_{12}O$: C 84.75, H 6.57; found: C 84.83, H 6.68.

*Sensitized photolysis of barrelene **6***

A 250 mL solution of cyclohexane containing 1.0077 g (5.5 mmol) of barrelene **6** and 30 mL of acetone sensitizer in Cell A was photolyzed with Pyrex-filtered light for 4.5 h. The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (0.9 cm × 20 cm) with 5% ethyl acetate–hexane solvent. The main band was rechromatographed on a Lobar column (3% ethyl acetate–hexane solvent). Short-path distillation (60°C/0.1 Torr; 1 Torr = 133.3 Pa) of the contents of the second band gave 523.5 mg (52%) of 5-methoxybenzotricyclo[3.3.0.0^{2,8}]octa-3,6-diene (**7**), mp 32–34°C; UV (hexane): 281 (720), 274 (790), and 268 sh (600); ^{1}H NMR; 7.14–7.33 (m, 4H, aromatics), 5.65 (d, 1H, H-6, $J_{6,7} = 5$), 5.18 (dd, 1H, H-7, $J_{7,6} = 5$, $J_{7,8} = 2.5$), 3.42 (t, 1H, H-1, $J_{1,2} = J_{1,8} = 6$), 3.38 (s, 3H, methoxyl), 3.24 (t, 1H, H-2, $J_{2,1} = J_{2,8} = 6.5$), and 2.90 (dt, 1H, H-8, $J_{8,1} = J_{8,2} = 6.5$; $J_{8,7} = 2.5$); ^{13}C NMR: 38.0 (C1), 40.2 (C8), 51.1, (C2), 53.1 (methoxyl), 99.2 (C5), 119.6, 120.9 (C7), 125.2, 125.6, 127.3, 135.5, 136.6 (C6), and 148.4; assignments were based on Hetcorr experiments. Mass spectrum showed molecular ion at *m/e* = 184.08870 (100%). Anal. found: C 84.82, H 6.48.

*Thermolysis of semibullvalene **7***

A total of 2.48 g (13.5 mmol) of SB **7** was divided into three equal portions, and each was separately distilled (during 1.5 h) into a Pyrex tube (2 cm × 30 cm) packed with glass beads (0.5 cm diameter) maintained at ca. 460°C by a tube furnace. The pressure was kept at 4 Torr by the passage of nitrogen. The combined thermolysis products, mostly COT **8**, collected in an ice-cooled U-trap, were not purified, but treated directly with 14 mL of 80% aqueous acetic acid. The solution was stirred at room temperature for 48 h, then neutralized with 200 mL of 15% aqueous $NaHCO_3$, and extracted with 300 mL hexane. The extract was washed (2 × 100 mL water), dried ($MgSO_4$), concentrated, and chromatographed on Silica Gel 60 (0.9 cm × 7 cm) with 5% ethyl acetate–hexane solvent. The main band was rechromatographed on a Lobar column (3% ethyl acetate–hexane). Short-path distillation (90°C/0.1 Torr) of the contents of the first fraction gave 787.8 mg (32%) of ketone **9**; IR (Nujol): 1670 (C=O) cm^{-1}; UV (hexane): 369 sh (260), 352 sh (670), 335 sh (1040), 315 sh (2850), and 301 sh (3620); ^{1}H NMR: 8.39 (d, 1H, H-4, $J = 8$), 7.27–7.53 (m, 3H, aromatics), 6.82 (d, 1H, H-10, $J_{10,9} = 12.5$), 6.34 (dd, 1H, H-9, $J_{9,8} = 4.5$, $J_{9,10} = 12.5$), 6.24 (dd, 1H, H-8, $J_{8,9} = 4.5$, $J_{8,7} = 10$), 5.82 (br q, 1H, H-7, $J_{7,9} = 10$, $J_{7,6} = J_{7,6'} = 8$), and 3.37 (d, 2H, H-6 and H-6′, $J_{6,7} = J_{6,7'} = 8$); ^{13}C NMR: 43.7, 127.0, 127.8, 128.7, 130.1, 130.9, 132.0, 132.2, 134.3, 136.7, 137.2, 193.4. Mass spectrum showed molecular ion at *m/e* = 170.07359 (96%), 141 (100%); $C_{12}H_{10}O$ requires 170.07317. Anal. calcd. for $C_{12}H_{10}O$: C 84.68, H 5.92; found: C 85.00, H 5.92.

*Cyclohexanone **10** from photoclosure of ketone **9***

A 250 mL solution of hexane containing 40 mL of piperylene quencher and 392.9 mg (2.31 mmol) of ketone **9** was photolyzed with Pyrex-filtered light for 13 min in Cell A. The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (0.9 cm × 10 cm) with 100 mL of 8% ethyl acetate–hexane solvent. The main band was rechromatographed on a Lobar column with 3% ethyl acetate–hexane solvent. The first band gave 119.8 mg (30%) of recovered ketone **9**; the second band contained 222.4 mg (57%) of colourless cyclohexanone **10**, mp 37–38°C (from hexane); IR (Nujol): 1694 (C=O) cm^{-1}; UV (cyclohexane): 325 (85), 288 (1130); ^{1}H NMR: 7.86 (dd, 1H, aromatic, $J = 1.5$, $J = 7$), 7.51 (dt, 1H, aromatic, $J = 1.5$, $J = 7$), 7.26–7.35 (m, 2H, 2 aromatics), 6.23 (d, 1H, H-8, $J_{8,7} = 2.5$), 6.16 (d, 1H, H-7, $J_{7,8} = 2.5$), 4.13 (d, 1H, H-1, $J_{1,6} = 4$), 3.69 (sym m, 1H, H-6,), 2.89 (dd, 1H, H-5′, $J_{5',5} = 16$, $J_{5',6} = 2$), and 2.74 (dd, 1H, H-5, $J_{5,5'} = 16$, $J_{5,6} = 7.5$); ^{13}C NMR: 38.6, 41.1, 44.7, 126.4, 127.2, 128.5, 133.1, 133.3, 139.0, 144.4, 144.5, and 198.1. Mass spectrum showed molecular ion at *m/e* = 170.07468 (100%). Anal. found: C 85.04, H 5.94.

*Triene **11** from cyclohexanone **10***

A solution of 117.6 mg (0.64 mmol) of *p*-toluenesulfonylhydrazide, 104.2 mg (0.61 mmol) of cyclohexanone **10**, and 0.15 mL of acetic acid in 2 mL of methanol was stirred at room temperature for 72 h. The colourless crystalline product was filtered off and dried in vacuo to give 157.6 mg (76%) of the tosylhydrazone, mp 174–176°C (dec.). The Shapiro reaction (13) was carried out under a nitrogen atmosphere. A stirred slurry of 226.0 mg (0.67 mmol) of the tosylhydrazone in 8 mL of dry ether was cooled to −12°C and 2.0 mL (2.8 mmol) of 1.4 M methyllithium in ether was added during 2 min whereupon an orange solution formed. The solution was stirred at room temperature for 1.25 h, refluxed for 10 min, cooled, and then made slightly acidic by the addition of aqueous ammonium chloride solution. The organic layer was diluted with ether to 20 mL, then washed twice with water and dried ($MgSO_4$). The ether was evaporated and the residue chromatographed on Silica Gel 60 (0.9 cm × 10 cm) with hexane solvent. The first band gave 100.2 mg (97%) of triene **11** as a colourless oil (mp 0–5°C); UV (hexane): 301 sh (520), 291 sh (2390), 279 (5135), 273 sh (5210), and 269 (5690); ^{1}H NMR (400 MHz; $CDCl_3$): see Table 1; ^{13}C NMR: 43.3, 44.2, 125.9, 126.6, 127.6, 127.7, 127.8, 128.2, 131.9, 135.6, 139.8, one carbon missing. Mass spectrum showed molecular ion at *m/e* = 154.07825 (82%), 153 (100%); $C_{13}H_{12}$ requires 154.07825. Anal. calcd. for $C_{12}H_{10}$: C 93.46, H 6.54; found: C 93.46, H 7.61.

*Direct irradiation of triene **11***

A solution of 47.4 mg (0.30 mmol) of **11** and 35.1 mg of dodecane (GC standard) in 40 mL of hexane was irradiated (Corex filter) for 50 min in Cell B (84% conversion by GC). The photolysate composition analysed (as determined by GC peak areas calibrated (peak area versus mass) for the dodecane internal standard against individual photolysate components) for 3.3 mg (7%) of naphthalene, 15.6 mg (33%) of COT **12**, 7.5 mg (16%) of triene **11**, and 9.3 mg (20%) of SB **14**. The polymeric materials were removed from the photolysate by chromatography on Silica Gel 60 (0.9 cm × 10 cm; 100 mL hexane). The elute was rechromatographed on a Labor column with hexane solvent. The first band contained ca. 1 mg (2%) of naphthalene (identified by GC and TLC comparison with an authentic sample); the second band gave 6.1 mg (13%) of recovered triene; the third band gave 13.8 mg (29%) of the known benzocyclooctatetraene (i.e., COT **12**), mp 47–49°C (lit. (4) mp 48–50°C), which was identified by comparison of the ^{1}H NMR spectrum with that reported for authentic **12** (4). The fourth and last band gave 7.9 mg (17%) of a colourless oil (GC purity >98%), which was identified as 3,4-benzotricyclo[3.3.0.0^{2,8}]octa-3,6-diene (i.e., SB

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

14) by comparison of the ^{1}H NMR spectrum with that reported for authentic **14** (4).

*Sensitized irradiation of triene **11***

A solution of 45.0 mg (0.29 mmol) of **11**, 42.1 mg (0.19 mmol) of *p*-dimethylaminobenzophenone, and 31.2 mg of dodecane (GC standard) in 40 mL of cyclohexane was irradiated for 50 min in Cell B, with light filtered through a Pyrex and WG 345 glass (Schott) filter (88% conversion by GC). The photolysate composition analysed (as determined by GC peak areas calibrated (peak area versus mass) for the dodecane internal standard against the individual photolysate components) for 1.5 mg (3%) of naphthalene, 5.4 mg (12%) of triene **11**, ca. 0.7 mg (1.5%) of COT **12**, and 21.4 mg (48%) of SB **14**. The photolysate was first chromatographed on Silica Gel 60 (0.9 cm × 10 cm; 100 mL hexane) to remove polymeric materials and sensitizer, and then rechromatographed on a Lobar column with hexane solvent. The first band contained a trace of naphthalene (identified by GC and TLC comparison with an authentic sample). The second band gave 4.1 mg (9%) recovered triene **11**; the third band gave ca. 0.5 mg (1%) of COT **12**; and the final band gave 19.4 mg (43%) of SB **14** (GC purity >98%).

*Labelled cyclohexanone **10a***

A mixture of 123.0 mg (0.72 mmol) of cyclobutene **10**, 14 mg of potassium carbonate, and 25 mL of methanol-d_1 (99.5% deuterium) was stirred at room temperature during 42 h. The solvent was removed under vacuum (oil pump) and the residue was taken up in hexane (20 mL), washed with D_2O (2 mL), and chromatographed on SG 60 (0.9 cm × 10 cm) with 10% ethyl acetate–hexane. The main band gave 112 mg (91%) of deuterated cyclohexanone **10***a* (90%-d_2 labelled at C-5); ^{1}H NMR: 7.86 (dd, 0.91H, aromatic, J = 1.5, J = 7), 7.51 (dt, 0.99H, aromatic, J = 1.5, J = 7), 7.26–7.35 (m, 1.93H, 2 aromatics), 6.23 (d, 1.11H, H-8, $J_{8,7}$ = 2.5), 6.16 (d, 1.00H, H-7, $J_{7,8}$ = 2.5), 4.13 (d, 1.01H, H-1, $J_{1,6}$ = 4), 3.69 (br d, 0.98H, H-6, $J_{6,1}$ = 4), 2.89 (br, s, 0.09H), and 2.74 (br d, 0.11H, H-5, $J_{5,6}$ = 7.5).

*Deuterium-labelled triene **11** from cyclohexanone **10a***

A solution of 130 mg (0.63 mmol) of *p*-toluenesulfonylhydrazide, 112 mg (0.66 mmol) of cyclohexanone **10***a* and 0.05 mL of acetic acid-d_1 in 0.5 mL of methanol-d_1 was stirred at room temperature for 24 h, and then cooled to –12°C for 18 h. The resulting white crystals were filtered, and dried in vacuo to give 155 mg (70%) of labelled tosylhydrazone, which was then converted to 39.5 mg (56%) of deuterated triene **11***a* by the procedure described above for the preparation of unlabelled triene **11**; ^{1}H NMR: 7.00–7.17 (m, 4.33H, aromatics and residual $CHCl_3$), 6.26 (br s, 0.50H, H-4), 6.13 (d, 0.99H, H-7, $J_{8,7}$ = 2.7), 6.02 (dd, 1.00H, H-8, $J_{7,8}$ = 2.7, $J_{7,6}$ = 0.9), 5.88 (q, 0.07H, H-5, $J_{5,4}$ = $J_{5,6}$ = 4.5), 4.11 (d, 1.06H, H-1, $J_{1,6}$ = 4.5), and 3.64 (d, 1.02H, H-6, $J_{6,1}$ = 4.5), i.e., triene **11***a* is 93%-d_1 labelled at C-5 and 50%-d_1 labelled at C-4.

*Thermolysis of deuterium-labelled triene **11a***

A solution of 8.5 mg (0.055 mmol) of triene **11***a* in 1 mL of *n*-nonane was refluxed (ca. 150°C) for 5.5 h. The thermolysis product was chromatographed on Silica Gel 60 (0.9 cm × 10 cm; hexane), to give 7.3 mg (86%) of COT **12***a*; ^{1}H NMR: 7.17–7.24 (m, 2.07H, aromatics), 6.93–6.99 (m, 2.00H, aromatics), 6.55 (d + br s, 1.49H, H-10 and H-5, $J_{10,9}$ = 11.8), 6.03 (dm, 1.08H, H-6 + H-9, $J_{9,10}$ = 11.5), and 5.88 (d, 2.00H, H-7 and H-8, J = 1.8).

*Direct irradiation of deuterium-labelled triene **11a***

A solution of 15.8 mg (0.10 mmol) of **11***a* in 12 mL of hexane was irradiated (Corex filter) for 50 min in Cell B. The photolysate was worked up as described in the case of the direct irradiation of unlabelled triene **20** to give ca. 0.9 mg (6%) of naphthalene and 2.1 mg (13%) of recovered triene **11***a*, ^{1}H NMR: 7.00–7.17 (m, 4.23H, aromatics and residual $CHCl_3$), 6.26 (br s, 0.50H, H-4), 6.13 (d, 0.99H, H-7, $J_{8,7}$ = 2.7), 6.02 (dd, 0.99H, H-8, $J_{7,8}$ = 2.7, $J_{7,6}$ = 0.9), 5.88 (q, 0.10H, H-5, $J_{5,4}$ = $J_{5,6}$ = 4.5), 4.11 (d, 1.02H, H-1, $J_{1,6}$ = 4.5), and 3.64 (d, 1.01H, H-6, $J_{6,1}$ = 4.5); 4.3 mg (27%) of labelled COT **12***a*, ^{1}H NMR: 7.17–7.24 (m, 2.05H, aromatics), 6.93–6.99 (m, 2.00H, aromatics), 6.55 (d + br s, 1.49H, H-10 and H-5, $J_{10,9}$ = 11.8), 6.03 (dm, 1.10H, H-6 + H-9, $J_{9,10}$ = 11.6), and 5.88 (d, 1.97H, H-7 and H-8, J = 1.6); and 2.2 mg (14%) of a mixture of ca. 83% SB **14***a* and 17% SB **14***b*, ^{1}H NMR: 7.31–7.35 (m, 1.00H, aromatic), 7.04–7.18 (m, 3.19H, aromatics), 5.60 (dd, 0.99H, H-6, $J_{6,7}$ = 5, $J_{6,5}$ = 2.2), 5.21 (d, 1.00H, H-7, $J_{7,6}$ = 5), 3.90 (dd, 1.01H, H-5, $J_{5,1}$ = 6.3, $J_{5,6}$ = 2.3), 3.29 (br t, 0.84H, H-1, $J_{1,5}$ = $J_{1,2}$ = 6), 3.04 (br d, 0.50H, H-2, $J_{2,1}$ = 6.3), and 2.70–2.76 (m, 0.22H, H-8).

*Sensitized irradiation of deuterium-labelled triene **11a***

A solution of 23.7 mg (0.15 mmol) of triene **11***a*, 22.8 mg (0.38 mmol) of *p*-dimethylaminobenzophenone, and 17.4 mg of dodecane (GC standard) in 20 mL of hexane was irradiated for 55 min in Cell B, with light filtered through a Pyrex and WG 345 glass (Schott) filter (69% conversion by GC). The photolysate was worked up as in the case of the sensitized irradiation of unlabelled triene **11**, to give a trace of naphthalene; 6.6 mg (28%) of recovered triene **11***a*, ^{1}H NMR: 7.00–7.17 (m, 4.16H, aromatics and residual $CHCl_3$), 6.26 (br s, 0.48H, H-4), 6.13 (d, 1.00H, H-7, $J_{8,7}$ = 2.7), 6.02 (dd, 1.00H, H-8, $J_{7,8}$ = 2.7 $J_{7,6}$ = 0.9), 5.88 (q, 0.08H, H-5, $J_{5,4}$ = $J_{5,6}$ = 4.5), 4.11 (d, 1.02H, H-1, $J_{1,6}$ = 4.5), and 3.64 (d, 1.02H, H-6, $J_{6,1}$ = 4.5); ca. 0.3 mg (1%) of COT **12***a*, ^{1}H NMR: 7.17–7.24 (m, 2.58H, 2 aromatics and residual $CHCl_3$), 6.93–6.99 (m, 2.00H, aromatics), 6.55 (d + br s, 1.49H, H-10 and H-5, $J_{10,9}$ = 11.8), 6.03 (dm, 1.08H, H-6 + H-9, $J_{9,10}$ = 11.6), and 5.88 (d, 2.00H, H-7 and H-8, J = 1.6); and 8.7 mg (37%) of SB **14***a*, ^{1}H NMR: 7.31–7.35 (m, 1.00H, aromatic), 7.04–7.18 (m, 3.09H, aromatics), 5.60 (dd, 0.99H, H-6, $J_{6,7}$ = 5, $J_{6,5}$ = 2.3), 5.21 (d, 0.99H, H-7, $J_{7,6}$ = 5), 3.90 (dd, 1.02H, H-5, $J_{5,1}$ = 6.3, $J_{5,6}$ = 2.2), 3.29 (br t, 0.98H, H-1, $J_{1,2}$ = $J_{1,5}$ = 6), 3.04 (br d, 0.50H, H-2, $J_{2,1}$ = 6.2), and 2.70–2.76 (m, 0.08H, H-8).

*Direct irradiation of deuterium-labelled SB **14a***

A solution of 4.6 mg (0.03 mmol) of **11***a* in 4 mL of cyclohexane was irradiated (Corex filter) for 11.5 h in Cell C. The photolysate was chromatographed on a Lobar column with hexane solvent. The first band contained ca. 1.0 mg (22%) of COT **12***b* (>98% pure by GC); ^{1}H NMR: 7.17–7.24 (m, 2.13H, aromatics), 6.93–6.99 (m, 2.00H, aromatics), 6.55 (d, 1.56H, H-10 and H-5, $J_{10,9}$ = 11.7), 6.03 (dm, 1.94H, H-6 + H-9, $J_{9,10}$ = 11.7), and 5.88 (d, 1.10H, H-7 and H-8, J = 1.5); the second band gave 2.5 mg (54%) of recovered SB **14***a*.

Quantum efficiencies

Potassium ferrioxalate actionometry (14) was used to determine quantum efficiencies on an optical bench apparatus previously described (15). Cyclohexane solutions (3.0 mL) of reactants (ca. 8.7×10^{-3} M) and sensitizer, if any (*p*-dimethylaminobenzophenone, 5.0×10^{-3} M), were deoxygenated prior to irradiation by flushing with argon. A positive pressure of argon was maintained over the stirred solutions throughout the course of the irradiations. For the direct irradiations of triene **11** and the semibullvalene **14**, light of wavelength 280 nm was used. For sensitized runs the *p*-dimethylaminobenzophenone absorbed >95% of the incident light (366 nm) employed. The quantum yields (Φ's) were obtained from several runs extrapolated to zero conversion. Product analyses were determined by GC (internal dodecane standard).

RAKESH KUMAR, LEONARD I. WIEBE, and EDWARD E. KNAUS. Can. J. Chem. **72**, 2005 (1994).

A mild and efficient methodology for the synthesis of 5-halogeno (iodo, bromo, or chloro) uracil nucleosides has been developed. 5-Halo-2′-deoxyuridines **4***a–c* (84–95%), 5-halouridines **7***a–c* (45–95%), and 5-haloarabinouridines **8***a–c* (65–95%) were synthesized in good to excellent yields by the reaction of 2′-deoxyuridine (**2**), uridine (**5**), and arabinouridine (**6**), respectively, with iodine monochloride, or *N*-bromo (or chloro)succinimide, and sodium azide at 25–45°C. These C-5 halogenation reactions proceed via a 5-halo-6-azido-5,6-dihydro intermediate (**3**), from which HN_3 is eliminated, to yield the 5-halogeno uracil nucleoside. The 5-halo-6-azido-5,6-dihydro intermediate products (**10***a*, **10***b*) could be isolated from the reaction of 3′,5′-di-*O*-acetyl-2′-deoxyuridine (**9**) with iodine monochloride or *N*-bromosuccinimide and sodium azide at 0°C. The isolation of **10***a*, **10***b* indicates that the C-5 halogenation reaction proceeds via a 5-halo-6-azido-5,6-dihydro intermediate.

RAKESH KUMAR, LEONARD I. WIEBE et EDWARD E. KNAUS. Can. J. Chem. **72**, 2005 (1994).

On a mis au point une méthodologie douce et efficace de synthèse des nucléosides des 5-halogéno (iodo, bromo ou chloro) uraciles. On a synthétisé les 5-halo-2′-désoxyuridines (**4***a–c*, 84–95%), 5-halouridines (**7***a–c*, 45–95%) et 5-halorarabinouridines (**8***a–c*, 65–95%) par réactions respectivement de la 2′-désoxyuridine (**2**), de l'uridine (**5**) et de l'arabinouridine (**6**) avec du monochlorure d'iode ou de *N*-bromo(ou chloro)succinimide et de l'azoture de sodium à des températures allant de 25 à 45°C. Ces réactions d'halogénation en C-5 se produisent par le biais d'un intermédiaire 5-halo-6-azido-5,6-dihydro (**3**) à partir duquel il y a élimination de HN_3 et formation du nucléoside du 5-halogénouracile. On a pu isoler les intermédiaires 5-halo-6-azido-5,6-dihydro (**10***a*, **10***b*) lors de la réaction du 3′,5′-di-*O*-acétyl-2′-désoxyuridine (**9**) avec le monochlorure d'iode ou le *N*-bromosuccinimide et l'azoture de sodium à 0°C. En isolant les intermédiaires **10***a*, **10***b*, on confirme que la réaction d'halogénation en C-5 se produit par le biais d'un intermédiaire 5-halo-6-azido-5,6-dihydro.

[Traduit par la rédaction]

Analogs of 5-halouracils constitute a biologically important class of compounds, which possess interesting biochemical and biophysical properties (1), and which have been investigated extensively as antineoplastic and antiviral agents (2). In addition, some 5-chlorouracil nucleoside analogs, which are less cytotoxic, exhibit selective anti-HIV activity (3). Studies utilizing 5-halouracil derivatives have also provided important biochemical information pertaining to their cellular biochemistry, affinity for a nucleoside transporter, enzyme–substrate specificity, and the nature of enzyme–substrate interaction(s). Radiohalogenated uracil nucleosides are useful mechanistic probes to study DNA metabolism (4). Halogenated nucleosides have also been used as synthons for the synthesis of biologically active nucleoside analogs (5–10). Therefore, new methods for the efficient synthesis of 5-halouracil nucleoside derivatives, using mild reaction conditions, are of great interest in medicinal chemistry.

A variety of methods have been developed for electrophilic halogenation at the electron-rich C-5 position of uracil nucleosides (for an excellent review, see ref. 11). Prusoff et al. reported the first 5-iodination of uracil using molecular iodine, generated in situ by oxidation of KI with H_2SO_4 and KIO_3 (12). Prusoff also developed methods involving the reaction of I_2, prepared by oxidation of iodide using HNO_3, or molecular iodine in an organic solvent and water to prepare 5-iodo-2′-deoxyuridine (13). However, these harsh reaction conditions and (or) methodologies often afford a moderate yield of the target 5-iodo product due to decomposition and (or) formation of undesirable side product(s). Iodination of 5-mercurouridine derivatives in aqueous alcohol has been described by Dale et al. (14). *N*-Iodosuccinimide and iodine monochloride (ICl) have also been used for the efficient iodination of some uracil nucleosides (15, 16). An effective conversion of protected or unprotected uracil nucleosides to their 5-halo derivatives has been reported using elemental iodine, or a lithium halide, in the presence of ceric ammonium nitrate (CAN) (17). A number of methods have been reported for the synthesis of 5-bromouracil analogs using bromine–water (18, 19), or bromine in either acetic anhydride (20), dimethyl formamide (21), or pyridine (22). The C-5 chlorination of uracil nucleosides has been reported using Cl_2–H_2O under UV irradiation (23) or Cl_2–HOAc (24). Chlorination of uracil analogs has also been effected using elemental chlorine or *N*-chlorosuccinimide in acetic acid at reflux temperatures (25–27), iodobenzene dichloride in warm acetic acid (16), or 3-chloroperoxybenzoic acid in aprotic solvents containing hydrogen chloride (28).

It has been proposed by Wang (29) that the formation of 5-bromouracil analogs upon reaction of uracils with aqueous bromine proceeds via a 5-bromo-6-hydroxy-5,6-dihydro intermediate (**1**) that dehydrates to afford the 5-bromouracil. It was found that 5-bromo-6-hydroxy-5,6-dihydrouracil (**1***a*) dehydrated to 5-bromouracil in less than 10 min at room temperature. In contrast, only 10% dehydration of the 5-bromo-6-

SCHEME 1

hydroxy-5,6-dihydro derivative of uridine to give 5-bromouridine was observed in 24 h at room temperature. However, when the 5,6-dihydro derivative of uridine was heated on a steam bath, it was quantitatively dehydrated to yield 5-bromouridine. It was observed by Moore and Anderson (30) that the conversion of 5-bromo-6-hydroxy-5,6-dihydrouracil to 5-bromouracil was accelerated by heating or by acid catalysis. The existence of the 5-bromo-6-hydroxy-5,6-dihydrouracil intermediate (**1***b*) was later confirmed by Tee and Banerjee, using ^{1}H NMR spectroscopy (31). 5-Iodo-6-hydroxy-5,6-dihydrouridine was the major product obtained upon reaction of uridine with iodine monochloride in aqueous DMF, along with the minor product 5-iodouridine (32). A 5-iodo-6-methoxy-5,6-dihydro derivative was formed in appreciable yield during the C-5 iodination of 3′,5′-protected-2′-fluoro-2′-deoxyuridine using iodine monochloride in methanol, and on further heating at reflux temperature was converted to the desired 5-iodo-2′-fluoro-2′-deoxyuridine analog (33). A similar reaction of bromine with a 2′,3′-protected uridine in methanol has also been reported to give 5-bromo-6-methoxy-5,6-dihydrouridine (34). During the C-5 chlorination of 2′-fluoro-2′-deoxyuridine with chlorine in acetic acid, 5-chloro-6-acetoxy-5,6-dihydro-1-(2-fluoro-2-deoxy-β-D-ribofuranosyl)uracil was obtained as the major product, which was subsequently converted to 5-chloro-2′-fluoro-2′-deoxyuridine by treatment with aqueous or methanolic ammonia (24). These studies suggest that the electrophilic halogenation of uracil nucleoside derivatives in the presence of water, alcohol, or acetic acid proceeds via a 5-halo-6-hydroxy (alkoxy or acetoxy)-5,6-dihydro intermediate that requires heating or acid–base catalysis for conversion to the 5-halouracil nucleoside. These results indicate that 5-halo-6-hydroxy (alkoxy or acetoxy)-5,6-dihydro derivatives of uracil nucleosides are relatively stable, and that the stability of the 5,6-dihydro intermediate is dependent upon the C-6 substituent.

We now report a mild and efficient procedure for the C-5 halogenation (iodination, bromination, or chlorination) of 2′-deoxyuridine (**2**), uridine (**5**), and arabinouridine (**6**) that proceeds via a 5-halo-6-azido-5,6-dihydro intermediate (**3**) (Scheme 1). The halogenation of **2**, **5**, and **6** was effected using iodine monochloride, or *N*-bromo (or chloro)succinimide, and sodium azide in acetonitrile or 1,2-dimethoxyethane at 0–45°C. The results are summarized in Table 1.

Reaction of 2′-deoxyuridine (**2**), uridine (**5**), or arabinouridine (**6**) with 2.5 mol equiv. of iodine monochloride (ICl) and 4.0 mol equiv. of sodium azide (NaN_3) in acetonitrile at 25°C afforded the corresponding 5-iodo product **4***a*, **7***a*, or **8***a* in 90–96% isolated yields. The corresponding 5-bromo analogs **4***b*, **7***b*, and **8***b* were synthesized in high yield using *N*-bromosuccinimide (NBS) and NaN_3 in 1,2-dimethoxyethane (DME) at 25°C for 24 h. A similar chlorination reaction of **2**, **5**, and **6** using *N*-chlorosuccinimide (NCS) and NaN_3 in DME at 45°C gave the 5-chloro products **4***c*, **7***c*, and **8***c* in 84, 45, and 65% yields, respectively. The chlorination of **2**, **5**, and **6** using NCS and NaN_3 in DME at 25°C proceeded slowly. The 5-chloro-6-azido-5,6-dihydro intermediates are significantly more stable at 25°C than the corresponding 5-iodo (or bromo)-6-azido-5,6-dihydro intermediates. Increasing the reaction temperature from 25°C to 45°C accelerated the rate of the chlorination reaction and the conversion of the 5-chloro-6-azido-5,6-dihydro intermediate to the 5-chloro product. These results suggest the enhanced stability of the 5-chloro-6-azido-5,6-dihydro intermediate, relative to the bromo and iodo analogs, is dependent upon the steric size of the halogen atom at the C-5 position and (or) the relative configurations at the C-5 and C-6 positions. Iodination or bromination of 2′-deoxyuridine (**2**) with ICl or NBS, in the absence of NaN_3, gave a low yield of the respective products. In contrast, chlorination of **2** using NCS, in the absence of NaN_3, did not occur, which indicates that an azido group at the C-6 position plays an important role in these C-5 halogenation reactions. The azido group at the C-6 position of these 5-halo-6-azido-5,6-dihydro intermediates is an excellent leaving group for regeneration of the 5,6-olefinic bond and it provides an attractive alternative to C-6 OH, OMe, or OAc substituents.

The C-5 halogenation of uracil nucleosides using an electrophilic halogen reagent and sodium azide proceeded efficiently under mild reaction conditions. Halogenation of the uracil nucleosides **2**, **5**, and **6** using this methodology in MeCN or DME was assumed to occur via a 5-halo-6-azido-5,6-dihydro intermediate (**3**) as illustrated in Scheme 1. Subsequent elimination of HN_3 would then afford the 5-halogeno products. The 5-

[c]Several products were formed (TLC analysis), some starting material and cleavage product (5-iodouracil) were isolated.
[d]Some starting material remained.

bromo (or iodo)-6-azido-5,6-dihydro intermediate product was isolated in 75 and 29% yields, respectively when 3′,5′-di-*O*-acetyl-2′-deoxyuridine (**9**) was allowed to react with ICl, or NBS, and NaN_3 at a reaction temperature of 0 to −5°C (Scheme 2). The addition of halogenoazides to unsymmetrical olefins has been reported to favor an unsymmetrical bridged halonium intermediate (35, 36) of the type illustrated in Scheme 2. The isolation of the 5-halo-6-azido-5,6-dihydro products (**10***a*,*b*), which existed as a mixture of two diastereomers that differ in configuration at the C-5 and (or) C-6 positions, confirmed the reaction mechanism for the formation of the C-5 halogenated pyrimidine nucleosides prepared using the methodology described. The configuration at the C-5 and C-6 positions ($J_{5,6}$ = 3.0 Hz) was not elucidated for **10***a*, **10***b* since these chiral centers are removed upon regeneration of the 5,6-olefinic bond.

Similar halogenations of 3′,5′-di-*O*-acetyl-2′-deoxyuridine (**9**) could also be effected using an electrophilic halogen reagent and sodium azide in MeCN or DME at 25–45°C. Thus, treatment of **9** with 2.5 mol equiv. of ICl and 4.0 mol equiv. of NaN_3 in MeCN at 25°C proceeded well and gave an excellent yield of 3′,5′-di-*O*-acetyl-5-iodo-2′-deoxyuridine (**11***a*, 94% isolated yield). 3′,5′-Di-*O*-acetyl-5-bromo-2′-deoxyuridine (**11***b*) was synthesized in 95% yield using NBS and NaN_3 in DME at 25°C for 24 h. A similar chlorination of **9** using NCS and NaN_3 in DME at 45°C afforded 3′,5′-di-*O*-acetyl-5-chloro-2′-deoxyuridine (**11***c*) in 89% yield.

In summary, the new and facile halogenation methods described herein have several advantages over most procedures currently available. These advantages include readily available reagents, mild reaction conditions (25–45°C), facile isolation procedures, and high product yields. This methodology avoids the use of acidic and (or) high reaction temperature conditions, which results in the decomposition of labile substrates. This methodology is applicable to the radioiodination (^{123}I, ^{125}I, ^{131}I) of uracil nucleosides and the potential halogenation of oligonucleosides under mild conditions. Robins et al. (17) developed an efficient method for the synthesis of 3′,5′-di-*O*-acetylated and unprotected 5-halouracil nucleosides using elemental iodine, or a metal halogenide (LiI, LiBr, LiCl) and CAN at 80°C. Our methodology provides marginally higher yields using the unprotected uracil nucleosides, and similar yields using 3′,5′-di-*O*-acetyl-2′-deoxyuridine (**9**). Although the Robins procedure is efficient for the chlorination of **9**, chlorination of 2′-deoxyuridine afforded multiple and (or) decomposition products. Halogenated solvents such as dichloromethane must not be used in this methodology since its reaction with sodium azide may lead to potentially explosive polyazidomethane (37, 38).

Experimental

Melting points were determined with a Buchi capillary apparatus and are uncorrected. Nuclear magnetic resonance spectra (^1H NMR, ^{13}C NMR) were determined on a Bruker AM-300 spectrometer using Me_4Si as an internal standard (^1H NMR). The assignment of all exchangeable protons (OH, NH) was confirmed by the addition of D_2O. ^{13}C NMR spectra were acquired using the *J* modulated spin echo technique where methyl and methine carbon resonances appear as positive peaks, and methylene and quaternary carbon resonances appear as negative peaks. Microanalyses were within ±0.4% of theoretical values for all elements listed, unless otherwise indicated. Silica gel column chromatography was carried out using Merck 7734 (60–200 mesh) silica gel. 3′,5′-Di-*O*-acetyl-2′-deoxyuridine (**9**) was prepared according to the reported procedure (39). 2′-Deoxyuridine (**2**), uridine (**5**), and arabinouridine (**6**) were purchased from the Aldrich Chemical Co.

5-Iodo-2′-deoxyuridine (4a)

Iodine monochloride (40 mg, 0.25 mmol) was added slowly during a 5 min period to a suspension of sodium azide (26 mg, 0.4 mmol) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12

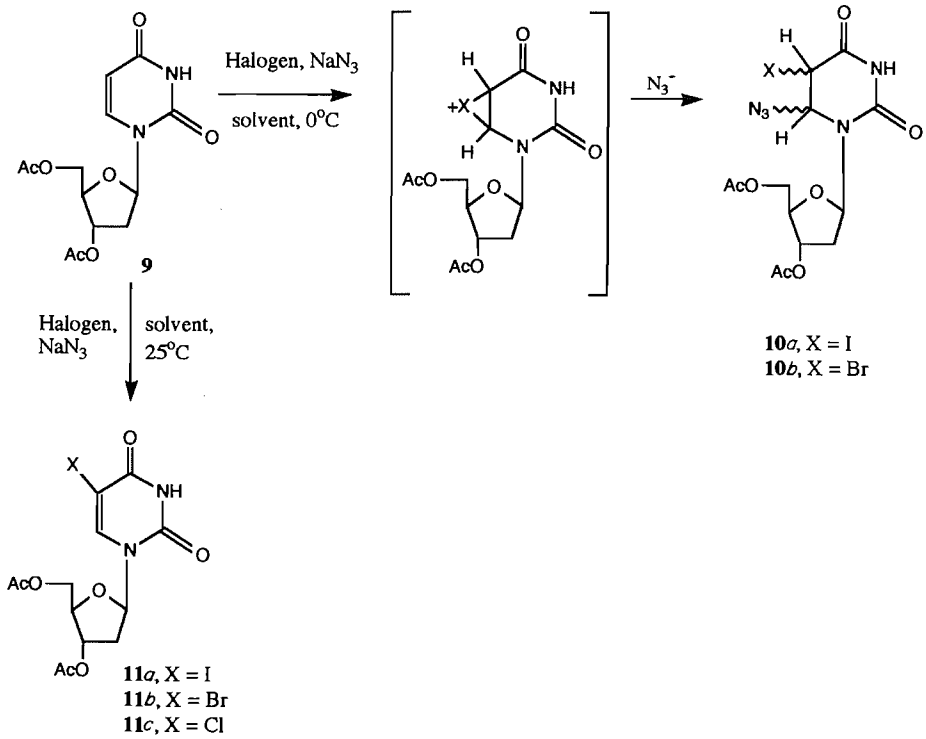

SCHEME 2

acetonitrile (10 mL) at ice-bath temperature with stirring. This mixture was stirred for a further 5 min, a solution of **2** (22.8 mg, 0.1 mmol) in acetronitrile (10 mL) was added and the reaction was warmed to 25°C and stirred for 24 h. Removal of the solvent in vacuo (bath temperature 50°C) and purification of the residue obtained by elution from a silica gel column using chloroform–methanol (85:15, v/v) as eluent afforded **4***a* (34 mg, 96%) (entry 1, Table 1), mp 170–180°C (dec.) (lit. (13) mp 160–180°C (dec.)). The ^{1}H NMR spectrum for **4***a* was identical to that reported (13).

5-Bromo-2′-deoxyuridine (4b)

N-Bromosuccinimide (NBS, 20 mg, 0.11 mmol) was added at 25°C to a suspension prepared by mixing a solution of **2** (22.8 mg, 0.1 mmol) in 1,2-dimethoxyethane (15 mL) with a solution of sodium azide (26 mg, 0.4 mmol) in water (0.1 mL). After stirring the reaction mixture for 24 h at 25°C, the solvent was removed in vacuo (bath temperature 45°C) and the residue was purified by silica gel column chromatography using chloroform–methanol (90:10, v/v) as eluent to give **4***b* (28 mg, 90%) as a solid (entry 6, Table 1), mp 175–179°C (dec.) (lit. (41) mp 187–189°C (dec.)). The ^{1}H NMR spectrum for **4***b* was identical to that reported (41).

5-Chloro-2′-deoxyuridine (4c)

N-Chlorosuccinimide (NCS, 26.6 mg, 0.2 mmol) was added at 25°C to a suspension prepared by mixing a solution of **2** (22.8 mg, 0.1 mmol) in 1,2-dimethoxyethane (10 mL) with a solution of sodium azide (26 mg, 0.4 mmol) in water (0.1 mL) with a solution of sodium azide (26 mg, 0.4 mmol) in water (0.1 mL). The reaction mixture was stirred for 4 h at 45°C. Additional aliquots of NCS (0.2 mL) and sodium azide (0.4 mmol) were added to the reaction mixture. The reaction was allowed to proceed for 4 h at 45°C with stirring. Removal of the solvent in vacuo (bath temperature 45°C) gave a residue that was purified by silica gel column chromatography using chloroform–methanol (90:10, v/v) as eluent to yield **4***c* (22 mg, 84%) as a solid (entry 11, Table 1), mp 173–176°C (lit. (42) mp 178–179.5°C)). The ^{1}H NMR spectrum for **4***c* was identical to the reported spectral data (42).

Iodination of nucleosides 5 and 6

A mixture of **5** or **6** (0.1 mmol), iodine monochloride (0.25 mmol), sodium azide (0.4 mmol), and acetonitrile (10 mL) was stirred at 25°C. After iodination was complete, the products were isolated by column chromatography as described for **4***a*.

5-Iodouridine (7a)

The white solid product was recrystallized from MeOH to give 35 mg (93%) of **7***a* (entry 3, Table 1), mp 207–209°C (dec.) (lit. (12) mp 205–208°C (dec.)).

5-Iodoarabinouridine (8a)

The white solid was recrystallized from MeOH to give 33 mg (90%) of **8***a* (entry 4, Table 1), mp 190–197°C (dec.) (lit. (43) mp 224–227°C (dec.)); ^{1}H NMR (DMSO-d_6) δ: 3.54–3.68 (m, 2H, H-5′), 3.70–3.78 (m, 1H, H-4′), 3.90–4.06 (m, 2H, H-2′, H-3′), 5.18, (t, $J_{5',OH}$ = 4.0, $J_{5'',OH}$ = 4.0 Hz, 1H, 5′-OH), 5.50 and 5.64 (2 br s, 1H each, 2′-OH, 3′-OH), 5.96 (d, $J_{1',2'}$ = 4.5 Hz, 1H, H-1′), 8.10 (s, 1H, H-6), 11.68 (s, 1H, NH). Anal. calcd. for $C_9H_{11}IN_2O_6$: C 29.20, H 2.99, N 7.57; found: C 29.36, H 2.69, N 7.85.

Bromination of nucleosides 5 and 6

A mixture of **5** or **6** (0.1 mmol), *N*-bromosuccinimide, sodium azide, and 1,2-dimethoxyethane (see Table 1) was stirred at 25°C for 24 h. After the bromination reaction was complete, the products were isolated by column chromatography as described for **4***b*.

5-Bromouridine (7b)

This compound was obtained in 95% yield (entry 8, Table 1), mp 190–198°C (dec. (lit. (18) mp 181–184°C (dec.)).

5-Bromoarabinouridine (8b)

This compound was obtained in 95% yield (entry 9, Table 1), mp 182–187°C (dec.) (lit. (43) mp 195–198°C (dec.)); ^{1}H NMR (DMSO-d_6) δ: 3.56–3.66 (m, 2H, H-5′), 3.70–3.80 (m, 1H, H-4′), 3.90–4.08 (m, 2H, H-2′, H-3′), 5.20, 5.52, 5.68 (3 br s, 1H each, 5′-OH, 3′-OH, 2′-OH), 5.96 (d, $J_{1',2'}$ = 4.5 Hz, 1H, H-1′), 8.06 (s, 1H, H-6). Anal. calcd. for $C_9H_{11}BrN_2O_6$: C 33.45, H 3.42, N 8.67; found: C 33.25, H 3.78, N 9.04.

Chlorination of nucleosides 5 and 6

A mixture of **5** or **6** (0.1 mmol), *N*-chlorosuccimide (NCS,

0.2 mmol), sodium azide (0.4 mmol), and 1,2-dimethoxyethane (10 mL) was stirred at 45°C for 6 h. Additional aliquots of NCS (0.2 mmol) and sodium azide (0.4 mmol) were added to the reaction mixture, which was stirred at 45°C for an additional 6 h. The products were purified by silica gel column chromatography as described for **4***c*.

5-Chlorouridine (7c)

Compound **7***c* was obtained in 45% yield (entry 13, Table 1), mp 215–220°C (dec.) (lit. (27) mp 220–223°C (dec.)).

5-Chloroarabinouridine (8c)

Compound **8***c* was obtained in 65% yield (entry 15, Table 1), mp 224–230°C (dec.) (lit. (43) mp 235–237°C (dec.)); ^{1}H NMR (DMSO-d_6) δ: 3.55–3.67 (m, 2H, H-5′), 3.70–3.80 (m, 1H, H-4′), 3.90–4.07 (m, 2H, H-2′, H-3′), 5.20, 5.60, 5.68 (3 br s, 1H each, 5′-OH, 3′-OH, 2′-OH), 5.97 (d, J = 4.5 Hz, 1H, H-1′), 8.06 (s, 1H, H-6), 11.60 (s, 1H, NH). Anal. calcd. for $C_9H_{11}ClN_2O_6$: C 38.78, H 3.97, N 10.05; found: C 38.76, H 3.98, N 10.22.

5-Iodo-6-azido-5,6-dihydro-3′,5′-di-O-acetyl-2′-deoxyuridine (10a)

A mixture of **9** (31.2 mg, 0.1 mmol), sodium azide (20 mg, 0.3 mmol), iodine monochloride (24 mg, 0.15 mmol), and acetonitrile (10 mL) was stirred at −5°C for 12 h. Evaporation of the solvent, work-up and purification of crude product as described for **11***a* yielded **10***a* (14 mg, 29%) as solid and unreacted starting material (**9**). Compound **10***a* was obtained as a mixture of two diastereomers, which could not be separated by silica gel column chromatography; mp 100–105°C (dec.); ^{1}H NMR ($CDCl_3$) (mixture of two diastereomers in a ratio of 2:1) δ: 2.10 and 2.12 (2 s, 3H each, CH_3CO), 2.22–2.3 and 2.32–2.42 (2 m, 1H each, H-2′), 4.16–4.44 (complex m, 3H, H-4′, H-5′), 4.58 and 4.68 (2 d, $J_{5,6}$ = 3.0 Hz, 1H total, H-5), 5.14–5.20 (m, 1H, H-3′), 5.30 and 5.36 (2 d, $J_{5,6}$ = 3.0 Hz, 1H total, H-6), 6.17 and 6.30 (2 t, $J_{1',2'} = J_{1',2''}$ = 6.0 Hz, 1H, H-1′), 8.20 (s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 13.15 and 15.37 (C-5), 20.89 (CH_3CO), 35.45 and 36.67 (C-2′), 63.87 and 63.96 (C-5′), 69.93 and 71.07 (C-6), 74.09 (C-3′), 81.61 and 81.88 (C-4′), 83.80 and 84.72 (C-1′), 149.45 and 149.63 (C-2), 165.45 and 165.70 (C-4), 170.41 and 170.15 (CH_3CO). Anal. calcd. for $C_{13}H_{16}IN_5O_7$: C 32.44, H 3.35, N 14.55; found: C 32.47, H 3.63, N 14.92.

5-Bromo-6-azido-5,6-dihydro-3′,5′-di-O-acetyl-2′-deoxyuridine (10b)

A mixture of **9** (31.2 mg, 0.1 mmol), *N*-bromosuccinimide (18 mg, 0.1 mmol), sodium azide (26 mg, 0.4 mmol) in water (0.1 mL), and 1,2-dimethoxyethane (10 mL) was stirred at 0°C for 1 h. Removal of the solvent in vacuo and purification of crude product by silica gel column chromatography with chloroform–methanol (98:2, v/v) as eluent afforded **10***b* (32 mg, 75%) as a solid. The compound **10***b* was obtained as a mixture of two diastereomers, which could not be separated by silica gel column chromatography; mp 140–142°C (dec.); ^{1}H NMR ($CDCl_3$) (mixture of two diastereomers in a ratio of 3:1) δ: 2.13 and 2.15 (2 s, 3H, each, CH_3CO), 2.16–2.26 and 2.32–2.46 (2 m, 1H each, H-2′), 4.20–4.48 (complex m, 4H, H-5, H-4′, H-5′), 5.17–5.22 (m, 1H, H-3′), 5.37 and 5.42 (2 d, $J_{5,6}$ = 3.0 Hz, 1H total, H-6), 6.18 and 5.34 (2 t, $J_{1',2'} = J_{1',2''}$ = 6.0 Hz, 1H total, H-1′), 7.54 (s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 20.80 (CH_3CO), 35.64 and 36.47 (C-2′), 37.61 and 38.91 (C-5), 63.82 and 63.91 (C-5′), 68.76 and 69.51 (C-6), 74.06 (C-3′), 81.52 and 81.91 (C-4′), 83.86 and 84.70 (C-1′), 149.52 (C-2), 163.71 (C-4), 170.14 and 170.36 (CH_3CO). Anal. calcd. for $C_{13}H_{16}BrN_5O_7$: C 36.21, H 3.03, N 16.24; found: C 36.51, H 3.24, N 15.98.

5-Iodo-3′,5′-di-O-acetyl-2′-deoxyuridine (11a)

This compound was synthesized by the reaction of **9**, according to the iodination procedure reported for **4***a*. Purification of the residue obtained by elution from a silica gel column using chloroform–methanol (95:5, v/v) as eluent afforded **11***a* (41 mg, 94%) (entry 16, Table 1), mp 157–158°C (lit. (40) mp 158–160°C).

5-Bromo-3′,5′-di-O-acetyl-2′-deoxyuridine (11b)

Compound **11***b* was synthesized by the reaction of **9**, according to the bromination procedure reported for **4***b*. Purification of the residue obtained by silica gel column chromatography using chloroform–methanol (95:5, v/v) as eluent afforded **11***b* (37 mg, 95%) as a viscous oil that did not crystallize (entry 20, Table 1) (lit. (17) mp 152.5–153°C); ^{1}H NMR ($CDCl_3$) δ: 2.10–2.24 (m, 7H, H-2′, CH_3CO), 2.50–2.60 (m, 1H, H-2″), 4.26–4.44 (complex m, 3H, H-4′, H-5′), 5.20–5.26 (m, 1H, H-3′), 6.28 (t, $J_{1',2'} = J_{1',2''}$ = 6.0 Hz, 1H total, 1H, H-1′), 7.90 (s, 1H, H-6), 8.78 (s, 1H, NH). ^{13}C NMR δ: 20.73 (CH_3CO), 38.05 (C-2′), 63.66 (C-5′), 73.88 (C-3′), 82.55 (C-4′), 85.53 (C-1′), 97.29 (C-5), 138.59 (C-6), 149.66 (C-2), 158.89 (C-4), 170.09 (CH_3CO) and 170.30 (CH_3CO). Anal. calcd. for $C_{13}H_{15}BrN_2O_7$: C 39.91, H 3.86, N 7.16; found: C 39.84, H 3.83, N 7.08.

5-Chloro-3′,5′-di-O-acetyl-2′-deoxyuridine (11c)

Compound **11***c* was synthesized by the reaction of **9**, according to the chlorination procedure reported for **4***c*. Purification of the product as described for **11***b* yielded **11***c* (31 mg, 89%) as a viscous oil that did not crystallize (entry 22, Table 1) (lit. (17) mp 174.5–175°C); ^{1}H NMR ($CDCl_3$) δ: 2.10–2.26 (m, 7H, H-2′, CH_3CO), 2.50–2.62 (m, 1H, H-2″), 4.28–4.40 (complex m, 3H, H-4′, H-5′), 5.20–5.25 (m, 1H, H-3′), 6.30 (t, $J_{1',2'} = J_{1',2''}$ = 6.0 Hz, 1H total, H-1′), 7.88 (s, 1H, H-6), 8.80 (s, 1H, NH). Anal. calcd. for $C_{13}H_{15}ClN_2O_7$: C 45.03, H 4.36, N 8.08; found: C 45.08, H 4.70, N 8.08.

Excited state acid catalysis of the 2 + 2 photocycloaddition of methyl 2-naphthoate and acetylacetone; the interaction of a nonfluorescent exciplex with H_2SO_4

YUAN L. CHOW[1] AND CARL I. JOHANSSON
The Department of Chemistry, Simon Fraser University, Burnaby, BC V5A 1S6, Canada
Received June 2, 1994

YUAN L. CHOW and CARL I. JOHANSSON. Can. J. Chem. **72**, 2011 (1994).

In this paper, the striking acid catalysis of the photocycloaddition of methyl 2-naphthoate (2MN) to acetylacetone (AA) to give **1** and **2** was traced to the enhanced conversion of the nonemissive *(2MN–AA) exciplex to **1** and **2** by H_2SO_4. The partial reversibility of the exciplex in CH_3CN and CH_3OH was established by extended fluorescence-quenching analysis using oxygen to perturb the system, whereas time-resolved fluorescence kinetics failed to reveal the presence of this exciplex. A similar analytical method demonstrated the interaction of the nonfluorescent *(2MN–AA) exciplex and H_2SO_4 with the rate constants of $k_{ap} = (2 \pm 1) \times 10^9$ M^{-1} s^{-1} in CH_3CN and $(4 \pm 1) \times 10^9$ M^{-1} s^{-1} in CH_3OH. The quantum yield of photocycloadducts was significantly enhanced at high 2MN conversions owing to the retardation of the competing excimer $*(2MN)_2$ formation. In the range of low conversion (<15%) and $[H_2SO_4] \leq 1$ mM, the quantum yield was shown to be proportional to H_2SO_4 concentration; the slope from such plots was analyzed to give k_{ap} values similar to those obtained from the extended fluorescence-quenching analysis. This agreement, along with the elimination of other potential acid catalytic routes, unambiguously proves that the acid catalysis originates from the interaction of the *(2MN–AA) exciplex with H_2SO_4.

YUAN L. CHOW et CARL I. JOHANSSON. Can. J. Chem. **72**, 2011 (1994).

Dans ce travail, on identifie que la catalyse acide remarquable de la photocycloaddition du 2-naphtoate de méthyle (2MN) à l'acétylacétone (AA) conduisant aux composés **1** et **2** est causée par une conversion plus importante de l'exciplexe non radiatif *(2MN–AA) en **1** et en **2** sous l'influence de H_2SO_4. On a mis en évidence la réversibilité partielle de l'exciplexe dans le CH_3CN et le CH_3OH en procédant à une analyse de la désactivation de la fluorescence étendue en utilisant de l'oxygène pour perturber le système alors que la cinétique de la fluorescence résolue en fonction du temps n'a pas révélé la présence de cet exciplexe. Une méthode analytique semblable a permis de démontrer l'existence de l'interaction de l'exciplexe non fluorescent *(2MN–AA) et du H_2SO_4 qui ont des constantes de vitesse de $k_{ap} = (2 \pm 1) \times 10^9$ M^{-1} s^{-1} dans le CH_3CN et de $(4 \pm 1) \times 10^9$ M^{-1} s^{-1} dans le CH_3OH. Dû à une retardement de la formation de l'excimère compétitif $*(2MN)_2$, le rendement quantique des photocycloadduits est grandement augmenté à des conversions élevées de 2MN. À de faibles taux de conversion (<15%) et $[H_2SO_4] \leq 1$ mM, on a démontré que le rendement quantique est proportionnel à la concentration en H_2SO_4; on a analysé la pente de telles courbes pour obtenir des valeurs de k_{ap} semblables à celles obtenues à partir de l'analyse de la désactivation de la fluorescence étendue. Cet accord, pris de concert avec l'élimination des autres routes catalytiques acides potentielles, prouve d'une façon non ambiguë que la catalyse acide trouve son origine dans l'interaction de l'exciplexe *(2MN–AA) avec H_2SO_4.

[Traduit par la rédaction]

Introduction

Upon absorption of light in the UV and visible region there are profound changes in a compound's electronic distribution where this difference may result in an acidity or basicity change from a few to tens of pK_a units (1). Such changes in acidity or basicity can be manipulated to promote reactions or initiate new chemistry. Indeed, a number of groups have taken advantage of the enhanced acidity or basicity in the excited state to promote difficult molecular transformations with high selectivity and regiospecificity (2–4). Mechanistic studies have shown that acid–base reactions can occur with either the excited state species (2) or an intermediate derived from the excited state species (3). The excited state acid–base behaviour is a general phenomenon and its utility has been discussed in a recent review (4).

We have shown that singlet excited naphthoate esters undergo 2 + 2 cycloaddition presumably with the acetylacetone (AA) *cis*-enol tautomer to give adduct **1** and a trace amount (5) of **2** through a cycloaddition intermediate, such as **3**. In the presence of a trace amount (>0.5 mM) of acid, **2** became the major product and this cycloaddition became a synthetically useful reaction when the low quantum yield was enhanced by about an order of magnitude in the presence of Brønsted acids at the millimolar level, wherein H_2SO_4 gave the largest enhancement (5).

Singlet excited state methyl 2-naphthoate (*2MN) has been shown, through product and emission studies (5–7), to interact with H_2SO_4 and AA in CH_3CN and CH_3OH. The fluorescence of *2MN is quenched by H_2SO_4, through associative interaction resulting in the formation of emissive $*2MNH^+$ species by a partially reversible reaction in CH_3CN and a fully reversible reaction in CH_3OH (6). While steady-state as well as time-resolved fluorimetry has demonstrated that the fluorescent $*2MNH^+$ intermediate interacts with AA in both CH_3CN and CH_3OH (6), this pathway has been shown not to be responsible for the acid enhancement of the formation of **1** and **2**, since the quantum yield of photocycloaddition computed from the rate constants gained from fluorimetry can account for, at most, only a small fraction of the observed value (6). The association of *2MN with an acid is therefore most likely an energy-wasting process, or a minor route to **1** and **2** at best. In the concentration range for preparative photocycloaddition (0.01 – 0.1 M), *2MN in CH_3CN forms a weakly fluorescing excimer, which could be quenched by H_2SO_4 but not by AA (7). Examples exist where an excimer could play a key role in photoreactions (8). In the present case, the 2MN excimer is formed with full reversibility, the reverse reaction being so fast that the excimer quenching by H_2SO_4 could not notice-

3 1 2

ably contribute to acid catalysis of the formation of **1** and **2** (7).

It is also possible that the observed acid catalysis has nothing to do with excited species but arises from acid catalysis of the ground state intermediates, such as **3** and its analogues, to promote the product formations. This line of enquiries was not pursued on account of the lack of acid effects on the photocycloaddition of AA to cyclohexene; in this case a cyclobutane analogous to **3** is the intermediate (6).

The overall mechanism of the reaction of *2MN in the presence of AA and H_2SO_4 is summarized in Scheme 1, which contains known processes determined previously (EE and EP pathways (5–7), and the reaction pathway to be discussed in this paper (EA pathway). To avoid complexity, the sum of all first-order reactions for an intermediate is represented as Σk_{e1}, Σk_{p1}, Σk_{d1}, and Σk_{a1}, each of which includes the rate constant of fluorescence (k_f) for the respective species. While it has been suspected that the *(2MN–AA) exciplex could be responsible for the acid catalysis by reacting with H_2SO_4, its lack of fluorescence has prevented access to examine this possibility. In this paper, we describe the detailed kinetic analysis of both fluorescence-quenching and product quantum yield studies that identified the EA pathway as the acid catalysis route. In addition, this paper describes the use of an "extended fluorescence-quenching analysis" on the quenching of 2MN fluorescence to probe this nonemitting exciplex.

Experimental section

Steady-state and dynamic fluorescence study

CH_3CN (BDH, spectrograde), CH_3OH (Mallinckrodt, SpectrAL), cyclohexane, dioxane (Fisher, spectrograde), ethyl ether (Caledon, anhydrous), 2-propanol (Fisher), and H_2SO_4 (Fisher, ACS reagent grade) were used as received. 2MN preparation and AA (Aldrich, 99+%) purification have been discussed previously (6).

Fluorescence-quenching spectra were recorded on either a Perkin–Elmer MPF-44B or Photon Technology International (PTI, South Brunswick, N.J.) LS-100 fluorimeter employing a right-angle cell arrangement at room temperature (25°C). Fluorescence-quenching experiments were performed as previously described (6, 7). Weak exciplex emission was checked for by normalizing the spectra at 2MN's fluorescence λ_{max} such that any change in the emission profile on the low-energy side could be visually inspected. For fluorescence quenching at 77 K (liquid nitrogen), the MPF-44B phosphorescence accessory (Hitachi) was attached with the chopper removed. The low-temperature glass was made from a mixture of 2-propanol and ethyl ether (1:3 v/v) with [2MN] = 0.3 mM and [AA] ranging from 0 to 0.4 M. The fluorimetry cell was a quartz tube with an i.d. of 3 mm. The samples were excited at 338 nm (room temperature) or 335 nm (77 K) and the fluorescence intensity was corrected for the percentage excitation light absorption by AA (9). Fluorescence decay measurements of *2MN were determined by a time-correlated single-photon counting method (10) and described elsewhere (6).

Product quantum yields

The quantum yield measurement method was similar to that previously described (5*a*) except that RPR 3500 Å lamps (16 × 24 W)

were used in place of RPR 3000 Å lamps. The concentrations were [2MN] = 0.02 M, [AA] = 0.08 M, and [H_2SO_4] ranged from 0 to 1 mM. The product formation was determined by GC analysis using octadecane as the internal standard with a 2MN conversion of ca. 12 ± 2% in CH_3CN and 6 ± 2% in CH_3OH. The relative quantum yields were calculated by the definition shown below under the condition of constant light intensity.

$$\Phi_P^T = \frac{\text{(moles of P formed)}}{\text{(number of quanta absorbed)}}$$

$$\Phi_P^T/(\Phi_P^T)^0 = \frac{\text{(moles of product formed) } t^0}{\text{(moles of product formed)}^0 t} = \frac{R_P t^0}{R_P^0 t}$$

The superscript (^{0}) refers to the reference solution ([H_2SO_4] = 0 mM and $(\Phi_P^T)^0 = 0.005$), t is the irradiation time, and R is the GC response relative to the internal standard (i.e., the product GC area divided by the internal standard GC area).

Results

*Quenching of *2MN fluorescence by AA*

2MN fluoresces strongly in various solvents showing a λ_{max} of 356 nm in CH_3CN and 360 nm in CH_3OH with a reported fluorescence quantum yield (Φ_e^0) of 0.30 in either solvent (11). The lifetime of singlet excited 2MN (0.4 mM) in CH_3CN solutions was determined by the single-photon counting technique at 370 nm. The fluorescence decay was adequately fitted by a single exponential, $I_e(t) = A\exp(-t/\tau)$, to give 7.7 ± 0.1 ns (= τ_e) under air and 13.2 ± 0.1 (= τ_e^0) under argon; in CH_3OH they were 7.0 ± 0.1 (= τ_e) and 11.6 ± 0.1 (= τ_e^0), respectively, by a similar determination. These lifetimes were fed into the Stern–Volmer equation, eq. [1*a*], to give the pseudo-first-order rate constants for quenching of 2MN fluorescence by dissolved oxygen, $k_{ox}[O_2]$, that is assumed to be the same for oxygen quenching of any excited state species (12, 13) in the same solvents by a diffusion-controlled process: $k_{ox}[O_2]$ are calculated to be 5.4×10^7 s^{-1} and 5.7×10^7 s^{-1} in CH_3CN and CH_3OH, respectively.

$$[1a] \qquad \tau_e^0/\tau_e = 1 + k_{ox}\tau_e^0[O_2] = 1 + K_{SV}^0[O_2]$$

$$[1b] \qquad = 1 + K_{SV}^a[AA]$$

Applying Henry's law and the known percentage of O_2 in air (20.9%) (14), these figures were multiplied by 4.78 to afford the pseudo-first-order rate constants under pure (100%) O_2; i.e., $k_{ox}[O_2] = 25.8 \times 10^7$ s^{-1} and 27.2×10^7 s^{-1} in CH_3CN and CH_3OH. In this calculation, Henry's law is expected to be obeyed since the O_2 concentration in CH_3CN or CH_3OH is extremely dilute ($x_{O_2} < 0.01$) (15). These rate constants will be used later in the evaluation of the *2MN + AA interaction and *(2MN–AA) exciplex decay rate constants.

The fluorescence decay kinetics of *2MN in the presence of AA (2–14.1 mM) in argon-purged CH_3CN solutions also unexpectedly showed single exponential decay kinetics to afford τ_e^a. The lifetimes listed in Table 1 were plotted according to eq. [1*b*] to give the Stern–Volmer constant (22.6 ± 0.5 M^{-1}) for the interaction of *2MN with AA (see supplementary material,[2] Fig. 6), the nature of which is clarified below. It must be pointed out that a single exponential decay would generally imply irreversible fluorescence quenching (10). However, under certain conditions, partially reversible fluorescence quenching may also show single exponential behaviour due to the failure of deconvolution procedures to resolve a biexponential decay; the present case is another example (6) (vide infra).

[b]τ_e^0.

In frozen solution at 77 K, 2MN fluorescence was not affected by [AA] ≤ 0.4 M, within experimental error, after correction for excitation light absorption by AA. In contrast, at room temperature the 2MN fluorescence intensity was quenched rapidly by AA in cyclohexane, dioxane, and CH_3CN without showing a new emission at up to 50% quenching.

The interaction of *2MN with AA has been shown to give the cycloaddition products (5), where the nonfluorescent *(2MN–AA) exciplex was proposed as the immediate precusor. A steady-state assumption on the process shown in Scheme 1 (EA pathway) afforded eq. [2] describing the quenching of 2MN fluorescence by AA (see Inset Fig. 1). Note that eq. [2] was derived by assuming that both *2MN and *(2MN–AA) are quenched by oxygen with a rate constant k_{ox} (8, 16). The plots of the data under argon, air, and pure oxygen are shown in Fig. 1 (supplementary material,[2] Fig. 7).

$$[2a] \qquad I_e^0/I_e = 1 + K_{SV}^0[O_2] + K_{SV}^a[AA]$$

where $K_{SV}^a = k_{ea}\alpha\tau_e^0$, $K_{SV}^0 = k_{ox}\tau_e^0$ and

$$[2b] \qquad \alpha = (\Sigma k_{a1} + k_{ox}[O_2])/(k_{-ea} + k_{ox}[O_2] + \Sigma k_{a1})$$

$$[2c] \qquad \alpha^0 = \Sigma k_{a1}/(k_{-ea} + \Sigma k_{a1})$$

$$\alpha/\alpha^0 = (k_{-ea} + \Sigma k_{a1})(\Sigma k_{a1} + k_{ox}[O_2])/(k_{-ea} + k_{ox}[O_2]$$

and presence of both AA and oxygen, respectively. For the sake of brevity, the reaction rate constant k_{ar} shown in Scheme 1 is included as part of Σk_{al} in the above equations. As defined in eq. [2*b*], α is the efficiency factor with which the exciplex decays to the ground state and $k_{ea}\alpha$ is the apparent fluorescence-quenching rate constant; τ_e^0 is the *2MN fluorescence decay lifetime at low 2MN concentration ($\cong 10^{-4}$ M where excimer formation is negligible) without AA and oxygen as shown above. The slopes in Fig. 1 (K_{SV}^a) were divided by τ_e^0 to give the apparent quenching rate constants, $k_{ea}\alpha$, which increased at higher oxygen concentrations indicating that the α values also increased; the perturbation of the system by oxygen is measured from the α/α^0 ratio in eq. [2*b*] (Table 2). The intercepts of the plots in Fig. 1 must be equal to $1+K_{SV}^0[O_2]$ as required by eq. [2*a*]. Equation [2*a*] was derived by factoring out the oxygen quenching from the *2MN's lifetime; therefore the K_{SV}^a values can be directly compared. It is immediately clear, from the α/α^0 ratio being greater than unity, that exciplex formation is reversible as required by eq. [2*d*], i.e., k_{-ea} must be significant with respect to Σk_{al}.

*Quenching kinetics of *2MN by AA in the presence of H_2SO_4*

In the presence of a fixed concentration of H_2SO_4 both the fluorescence of *2MN and *2MNH$^+$ (at 466 nm) were reduced by AA (Fig. 2). The modified Stern–Volmer plots for the *2MN fluorescence quenching by AA under argon were

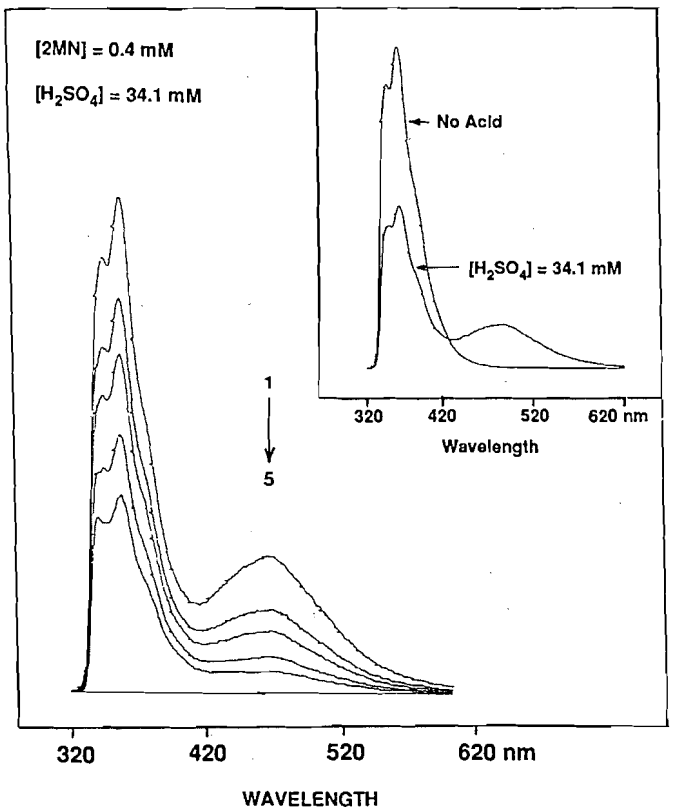

FIG. 2. Example of steady-state fluorescence quenching of 2MN (0.4 mM) by AA in the presence of constant $[H_2SO_4]$ (34.1 mM) in CH_3CN under argon. 2MN fluorescence in the presence of $[H_2SO_4]$ = 34.1 mM where the AA concentrations are 0, 16.4, 28.4, 54.5, and 84.1 mM for spectra 1 → 5. Inset shows the 2MN fluorescence spectra in the absence (I_e^0) and presence of $[H_2SO_4]$ = 34.1 mM.

constructed (Fig. 3); the resemblance to Fig. 1 under oxygen perturbation was obvious.

In analogy to the derivation of eq. [2], eq. [3] was obtained in the presence of the H_2SO_4 perturber for *2MN fluorescence quenching by AA:

$$[3a] \qquad I_e^0/I_e = 1 + k_{ep}\tau_e^0[H_2SO_4] + K_{SV}^h[AA]$$

where $K_{SV}^h = k_{ea}\beta\tau_e^0$

$$[3b] \qquad \beta = (\Sigma k_{a1} + k_{ap}[H_2SO_4])/(k_{-ea} + k_{ap}[H_2SO_4] + \Sigma k_{a1})$$

As the extent of H_2SO_4 dissociation in CH_3CN and CH_3OH is negligible (vide infra), the *(2MN–AA) exciplex is regarded to interact with the undissociated H_2SO_4 as defined by $k_{ap}[H_2SO_4]$. The Stern–Volmer constants (K_{SV}^h) were given from the slopes of these plots (Fig. 3) and were divided by τ_e^0 to give $k_{ea}\beta$ (Table 3). Both these slopes (K_{SV}^h) and the corresponding $k_{ea}\beta$ definitely increased with increasing $[H_2SO_4]$. At this stage our preliminary conclusion was that (*i*) the exciplex must interact with H_2SO_4 to increase the slope, (*ii*) the term $k_{ap}[H_2SO_4]$ in eq. [3*b*] must be significant relative to Σk_{a1} for such an increase to be observed, and (*iii*) the *2MN + AA reaction must be reversible; i.e., k_{-ea} is not insignificant in comparison to Σk_{a1} as we have concluded above.

The quenching of $^*2MNH^+$ fluorescence by AA was determined from Fig. 2*b* according to eq. [4] originally described

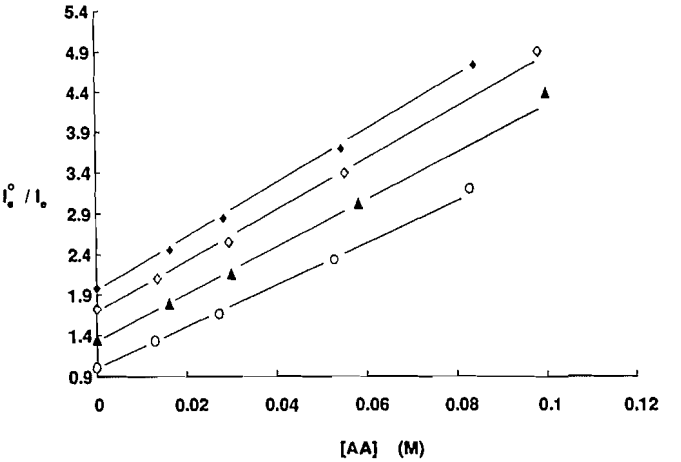

FIG. 3. Modified Stern–Volmer plot for the steady-state fluorescence quenching of 2MN by AA (CH_3CN under argon) in the presence of constant $[H_2SO_4]$: $[H_2SO_4]$ = 0 mM (○); 12.7 mM (▲); 23.5 mM (◇); 34.1 mM (◆).

by Caldwell et al. (17) (Fig. 4), where τ_p is the lifetime of the association species $^*2MNH^+$, and, I_p^0 and I_p represent the $2MNH^+$ fluorescence intensity (monitored at 466 nm in CH_3CN and 470 nm in CH_3OH) in the absence and presence of AA, respectively. I_e^h and I_e represent the *2MN fluorescence intensity in the presence of H_2SO_4 without and with AA.

$$[4a] \qquad (I_p^0/I_p) \div (I_e^h/I_e) = 1 + k_{pa}\tau_p[AA]$$

$$[4a] \qquad \tau_p = (\Sigma k_{p1} + k_{-ep} + k_{pp}[H_2SO_4])^{-1}$$

The $^*2MNH^+$ lifetime (τ_p) was calculated from eq. [4*b*] using the rate constants obtained from the decay kinetics of *2MN in the presence of H_2SO_4 cited from previous papers (Table 4) (6, 7); it must decrease as the $[H_2SO_4]$ increases due to the $k_{pp}[H_2SO_4]$ term. The rate constants for the interaction of $^*2MNH^+$ with AA (k_{pa}) at each $[H_2SO_4]$ were calculated from the slopes ($k_{pa}\tau_p$; see supplementary material,[2] Fig. 8) and the calculated τ_p. These values for k_{pa} are in excellent agreement with those obtained from fluorescence decay measurements (2.1×10^9 M^{-1} s^{-1}) (6). The constancy of k_{pa} (Table 3) in spite of the two different experimental probes, and the use of dynamic and steady state kinetics, is indeed remarkable; this provides support for the proposed mechanism. However, this pathway is unrelated to the acid-catalyzed photocycloaddition as shown previously (6).

Quantum yields of 2MN + AA photocycloaddition promoted by H_2SO_4

The product quantum yield ratios, $\Phi_P^T/(\Phi_P^T)^0$, of solutions containing [2MN] = 0.02 M and [AA] = 0.08 M were determined in the absence and presence of a trace amount of H_2SO_4 with 2MN conversion of ca. 12% (except one) in CH_3CN and ca. 6% in CH_3OH and the results are listed in Table 5. The quantum yield ratios varied linearly with respect to $[H_2SO_4]$ (Fig. 5) with a slope of 6700 ± 300 M^{-1} in CH_3CN and 8900 ± 400 M^{-1} in CH_3OH. The quantum yields rapidly increased by nearly an order of magnitude at about 1×10^{-3} M H_2SO_4; at the 1 mM level the photocycloaddition becomes preparatively useful with a projected quantum yield of 0.04 in CH_3CN and 0.045 in CH_3OH. The use of these slopes to correlate the quantum yield and fluorescence-quenching results (k_{ap} calculation) will be discussed later.

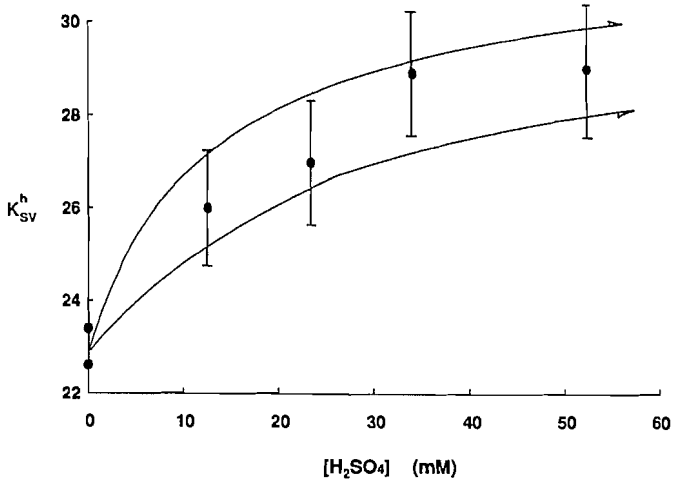

FIG. 4. Plot of the Stern–Volmer constants obtained from Table 3 as a function of $[H_2SO_4]$ in CH_3CN. The upper and lower solid lines are calculated from eq. [4] using the rate constants listed in Table 4 and $k_{ap} = 3 \times 10^9$ M^{-1} s^{-1} and 1×10^9 M^{-1} s^{-1}, respectively.

An examination of the relative quantum yields as a function of percentage conversion indicated a substantial increase at higher conversions (see supplementary material,[2] Fig. 9); i.e., the quantum efficiency increased as the product accumulated. In other words, the product yield was accelerated as the reaction proceeded; any factor that causes higher conversions (e.g., long irradiation time or higher acid concentration) will automatically enhance the quantum yield significantly. It was earlier reported that the acid catalysis asymptotically approaches a maximum at an acid concentration level of 1 mM with a projected quantum yield of 0.16 (5*a*). In that experiment, the high-end data were shown now to have a conversion as high as 50%, though the low-end data remained in the range of only 10–12% conversion. Owing to this apparent self-catalysis, the conversion of 2MN for the photoreactions in Table 5 was controlled in the low and narrow range of 12 ± 2% in CH_3CN and 6 ± 2% in CH_3OH. The self-catalysis is peculiar and reflects the complicated dynamics of the excited state reactions (vide infra).

Discussion

Fluorescence-quenching mechanism

From our earlier reported results (5), we identified that only singlet excited 2MN is the reacting species; i.e., neither singlet excited AA nor triplet excited 2MN is responsible for producing **1** and **2**. In this regard the photocycloaddition of 2MN with AA is quite different mechanistically from that of AA with cyclohexene (de Mayo reaction) (18). The fact that β-diketones exist as two equilibrated tautomers (19) and form ground-state aggregates at low concentrations ($\approx 10^{-3}$ M) (20) may complicate the mechanistic interpretation presented in this paper, hence their relevance must be addressed. The *cis*-enol percentage of AA at infinite dilution is 52.9% in CH_3CN, 68.0% in CH_3OH, and 97.0% in cyclohexane (19). These values roughly parallel the observed Stern–Volmer constants for the quenching of *2MN fluorescence by AA in these solvents (i.e., K^a_{SV} = 68 M^{-1} in cyclohexane (5*b*), 25.1 M^{-1} in CH_3OH, and 23.4 M^{-1} in CH_3CN), thus hinting that the *cis*-enol is the quenching species. From the work of Emsley and Freeman (19*a*), the *cis*-enol percentage does not significantly change over the concentration range used in this study; i.e., for AA mole fractions less than 0.01, the change in *cis*-enol percentage is calculated to be less than 1%. At higher AA concentrations the *cis*-enol percentage is known to decrease for solvents of low dielectric constant ($\epsilon < 26$) and increase for solvents of high dielectric constant ($\epsilon > 26$). In addition, UV absorption experiments have shown that the absorption of AAs is not affected by the presence of H_2SO_4 up to 0.1 M (5*b*); however, at higher concentrations a new absorption band at 430 nm was observed. Of the β-diketones investigated by Nikolov et al. only AA does not form ground state dimers (20). It is clear that there are no substantial changes in the AA *cis*-enol percentage under the conditions of the present investigation in the same solvent.

The lack of fluorescence quenching of *2MN by AA in frozen solution suggested that physical collision between *2MN and AA is required for the quenching act. Evidence for an exciplex was originally concluded by the observations

of a negative temperature effect in fluorescence quenching (5) (in CH_3CN) and an inverse relation of fluorescence-quenching rate constants vis-à-vis increasing solvent dielectric constant (5*b*). While these observations also qualitatively parallel the change in *cis*-enol percentage with temperature and solvent polarity, respectively, it is certain that the variance in *cis*-enol content alone cannot account for them. Using the data of Emsley and Freeman (19*a*) and Mills and Beak (19*b*), the change in *cis*-enol content was estimated to account for only 20% of the observed Stern–Volmer constant variance with temperature and solvent polarity. Therefore, the original conclusion of exciplex formation between *2MN and AA is reasonable and will be validated below as a nonfluorescing intermediate under the conditions of the photocycloaddition.

Fluorescence-quenching kinetic analysis

The oxygen perturbation method, which was originally used by Saltiel and co-workers (16*a*) to probe the reversibility and kinetics for the nonfluorescent benz[*a*]anthracene–*cis*-1,3-pentadiene exciplex, serves nicely to evaluate the quenching pattern of the EA pathway processes in Scheme 1. We have expanded this method to examine the kinetics of an exciplex as a corollary to a reversibility probe (21); this method is particularly useful in unravelling the kinetics of a nonemissive exciplex such as *(2MN–AA). The first step is to obtain the kinetic parameters of the exciplex by eq. [2*d*] where the $k_{ox}[O_2]$ is provided by lifetime measurements and to establish the degree of exciplex formation reversibility. As eq. [2*d*] cannot be rearranged to a convenient linear form, the target data k_{-ea}

and Σk_{a1} were evaluated by trial and error to converge upon the experimental α/α^0 ratio in Table 2. The computation gave only one unique solution as given in Table 4, indicating that $k_{-ea} < \Sigma k_{a1}$. The efficiency factors α and α^0 can be calculated from eqs. [2*b*] and [2*c*], respectively, and are used to calculate the true rate constant of 2MN fluorescence quenching by AA, k_{ea} (Table 2), which has an error margin of ±20%. This error is not unreasonable in view of examining the H_2SO_4 interactions occurring at a remote site from the actual quenching event. The ratio of $k_{-ea}/\Sigma k_{a1} \cong 1/2.5$ in CH_3CN must indicate that the exciplex is reversible, at least partially, and in direct conflict with the observation of single exponential fluorescence decay profiles (Table 1) that would suggest irreversible fluorescence quenching. The failure of deconvolution methods to resolve biexponential fluorescence decay profiles (6, 18*a*, 22) is known and has been shown to arise from masking of one exponential by the more dominant exponential (vide supra) (22). A similar situation was observed in the partially reversible interaction of *2MN with H_2SO_4 in CH_3CN (6).

Using the same methodology applied to probe the kinetics of the derivative exciplex (a method that we wish to call "extended fluorescence-quenching analysis"), the reaction of the invisible exciplex *(2MN–AA) with H_2SO_4 in a low-concentration region can be probed by eq. [3]; the occurrence of such a reaction is clearly indicated by the increasing slopes (K^h_{SV}) in Fig. 3. A plot of K^h_{SV} values against $[H_2SO_4]$ in CH_3CN can be analyzed by fitting of eq. [3*b*] and shown, with the associated error margins, in Fig. 4. Using the necessary rate constants in Table 4, the upper line is calculated using $k_{ap} = 3 \times 10^9$ M^{-1} s^{-1} and the lower line $k_{ap} = 1 \times 10^9$ M^{-1} s^{-1}; i.e., $k_{ap} = (2 \pm 1) \times 10^9$ M^{-1} s^{-1}. In CH_3OH, K^h_{SV} from two steady-state experiments (Table 3) allows an estimate of $k_{ap} = (4 \pm 1) \times 10^9$ M^{-1} s^{-1} by the same procedure. As $[H_2SO_4]$ becomes larger, $k_{ap}[H_2SO_4]$ becomes the dominant term in eq. [3*b*] with $\beta \cong 1$, where K^h_{SV} approaches $k_{ea}\tau^0_e$: the plot in Fig. 4 indeed asymptotically approaches a limiting value of $k_{ea}\tau^0_e$ at about $[H_2SO_4] \geq 0.05$ M.

Product quantum yields

The multitudinous interactions of *2MN in the presence of AA and H_2SO_4 lead to a complex dynamic system for which Scheme 1 is probably a skeletal pattern that adequately represents the observed reactions. It remains to correlate the kinetic data obtained by fluorescence quenching with the experimental quantum yields for **1** and **2** to identify the route of acid catalysis. Previously (6, 7) the maximum possible contributions to the total quantum yield Φ^T_P from (*i*) the *2MNH$^+$ quenching by AA (EP pathway) and (*ii*) 2MN excimer quenching by H_2SO_4 (EE pathway) have been determined to be 10% and nil, respectively; in short, these pathways are either insignificant at most or nonexistent. To estimate the maximum possible contribution from the EA pathway in Scheme 1, it is assumed that the exciplex *(2MN–AA) interacts with H_2SO_4 to give product with unit efficiency. This assumption conveniently circumvents considering a triplex intermediate that may exist but is not experimentally demonstrated. Under photostationary conditions, the product quantum yield derived from the EA pathway can be shown to be given by the expression eq. [5] (2*a*):

$$[5a] \qquad \Phi^T_P = \Phi^{ea}_P + \Phi^{ap}_P = \frac{\varphi(k_{ar} + k_{ap}[H_2SO_4])}{(k_{-ea} + \Sigma k_{a1} + k_{ar} + k_{ap}[H_2SO_4])}$$

$$[5b] \qquad \varphi = \frac{k_{ea}[AA]}{\Sigma k_{e1} + k_{ea}(1 - R_{-ea})[AA] + k_{ep}(1 - R_{-ep})[H_2SO_4] + k_{ed}(1 - R_{-ed})[2MN]}$$

where

$$R_{-ea} = k_{-ea}/(k_{-ea} + \Sigma k_{a1} + k_{ap}[H_2SO_4])$$

$$R_{-ep} = k_{-ep}/(k_{-ep} + \Sigma k_{p1} + k_{pp}[H_2SO_4])$$

$$R_{-ed} = k_{-ed}/(k_{-ed} + \Sigma k_{d1} + k_{dp}[H_2SO_4])$$

φ represents the quantum efficiency of *(2MN–AA) exciplex formation, which is secondarily affected by H_2SO_4 (eq. [5*b*]). R_{-ea}, R_{-ep}, and R_{-ed} represent the dissociation efficiencies of the *(2MN–AA) exciplex, *2MNH$^+$, and 2MN excimer, respectively. Equation [5] is rather formidable but can be simplified under certain conditions as shown below.

From the rate constants in Table 4 and the experimental conditions used in the quantum yield study ([2MN] = 0.02 M and [AA] = 0.08 M) the *(2MN–AA) exciplex formation efficiency φ increases by a calculated 2% over the $[H_2SO_4]$ range of 0–1 mM. Therefore, to a good approximation φ can be considered constant in order to simplify eq. [5]. Under this approximation the ratio of quantum yields in the presence and absence of H_2SO_4, $\Phi^T_P/(\Phi^T_P)^0$, is given by eq. [6].

$$[6] \qquad \Phi^T_P/(\Phi^T_P)^0 \cong \left(\frac{k_{ar} + k_{ap}[H_2SO_4]}{k_{-ea} + \Sigma k_{a1} + k_{ar} + k_{ap}[H_2SO_4]}\right)\left(\frac{k_{-ea} + \Sigma k_{a1} + k_{ar}}{k_{ar}}\right)$$

In addition, within this $[H_2SO_4]$ range the condition $k_{-ea} + \Sigma k_{a1} \gg k_{ar} + k_{ap}[H_2SO_4]$ prevails, hence eq. [6] is further simplified to eq. [7].

$$[7] \qquad \Phi^T_P/(\Phi^T_P)^0 \cong 1 + (k_{ap}/k_{ar})[H_2SO_4]$$

The plot of $\Phi^T_P/(\Phi^T_P)^0$ vs. $[H_2SO_4]$ (Fig. 5) bears out a linear relationship as predicted by eq. [7] under the limiting conditions. This allows us to evaluate k_{ap} directly from these slopes if k_{ar} is known; $k_{ar} = (2.2 \pm 0.4) \times 10^5$ s^{-1} in CH_3CN and $(3.5 \pm 0.8) \times 10^5$ s^{-1} in CH_3OH were calculated from the quantum yield of the photocycloadduct without H_2SO_4 (0.005) (5*a*) using the necessary rate constants in Table 4. In CH_3CN, using the experimental slope of 6700 ± 300 M^{-1}, k_{ap} is calculated to be $(1.5 \pm 0.4) \times 10^9$ M^{-1} s^{-1}. Similarly in CH_3OH (slope = 8700 M^{-1}), $k_{ap} = (3.1 \pm 0.7) \times 10^9$ M^{-1} s^{-1} is obtained. These results agree well with k_{ap} obtained from fluorescence analysis as listed in Table 4. At high H_2SO_4 concentrations where $k_{ap}[H_2SO_4]$ dominates the exciplex reaction, the plot of the quantum yield ratios (eq. [6], such as Fig. 5, should asymptotically approach a limiting value; however, complications from other pathways in solution dynamics would modify the reaction pattern and the quantum yields.

Exciplex involvement in excited state acid catalysis

The convergence of the extended fluorescence-quenching analysis with the quantum yield analysis in terms of the close agreement of the estimated k_{ap} values confirms not only the physical presence of transparent *(2MN–AA) exciplex, but also that its protonation is responsible for the observed acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

catalysis. Though it is logical and predictable that an exciplex, having a certain charge transfer character, is more susceptible to protonation, acid–base interactions of exciplexes with Brønsted acids are likely to be a general phenomenon. The present discovery is, to our knowledge, *the first demonstration of an exciplex participation in intermolecular acid catalysis.* There are some relevant observations. First, the acid catalysis presented in this paper is reminiscent of the effect of acid on the photoaddition of benzene with electron acceptors, such has maleic anhydride (23). In these reactions, the excited ground-state complex is captured by acid and new chemistry is observed. Second, the photonitrosation of 1-naphthol (1-NpOH) by *N*-nitrosodimethylamine (NND) proceeds by intramolecular proton transfer within the *(1-NpOH–NND) exciplex (24). Third, intramolecular proton transfer is known for a number of bimolecular photoreactions involving radical ion pairs (25). What is fascinating in the present case is the size of the molar catalytic efficiency (6700 M^{-1} in CH_3CN and 8900 M^{-1} in CH_3OH), which is experimentally determined in Fig. 5 and approximated to k_{ap}/k_{ar} by eq. [7] under the defined limiting conditions; it shows that the catalytic effect is clearly visible at the 10^{-3} M level. The high catalytic efficiencies and close to diffusion-controlled rate constants of k_{ap} (see Table 4) also require that the reacting species is a highly reactive excited state, but not likely a ground-state species. For comparison, the photohydration of styrenes and phenylacetylenes (26) is reported to have a molar catalytic efficiency of 460 M^{-1} in polar aqueous media that require much larger acid concentrations to show catalytic effect.

Some pertinent comments remain to be made. For the analysis of fluorescence-quenching rate constants described in this paper, the total AA concentration (i.e., [AA] = [*cis*-enol] + [diketone]) has been used as a variable without any correction for the actual *cis*-enol tautomer concentration. We deem it an unnecessary exercise to correct the [AA] since such a correction will only affect the magnitudes of k_{ea} and k_{pa} (Table 4); k_{ea} and k_{pa} can be corrected by dividing by the *cis*-enol tautomer mole fraction. Equations [2*b*]–[2*d*], [3*b*], and [7] are independent of [AA]; hence the rate constants derived from these equations are unaffected.

Secondly, the kinetic parameters in CH_3CN and CH_3OH (Table 4) can be interpreted in terms of the effects from protic and aprotic solvents. The increase in k_{ap} on going from CH_3CN to CH_3OH follows the acid strength of H_2SO_4 in these solvents; i.e., $pK_a = 7.3$ in CH_3CN (27) and 3 in CH_3OH (28), hence H_2SO_4 is not significantly dissociated in these solvents (vide supra). Similarly, it has been shown that the amount of the cycloadducts in CH_3CN, under identical conditions, also follows the pK_a variation; i.e., decreases in the order of $H_2SO_4 > HCl > CF_3CO_2H \sim H_3PO_4$ (5*a*).

The increase in the quantum yields in the high-conversion range obviously arises from changes in kinetic pattern owing to a decrease of the excimer formation process, k_{ed}[2MN], at high conversion; i.e., the EE pathway becomes less important owing to reduced 2MN concentration (vide supra). However, an approximate estimation of the enhancement is less than 5% around the vicinity of 10% conversion where the quantum yield ratios in Fig. 5 were obtained. The estimated enhancement grows very rapidly beyond 20% conversions. More quantitative treatment of the retardation by excimer formation is hampered by reversibility and complex multi-manifold kinetics. Undoubtedly this unproductive EE pathway causes the reduction in the quantum yield; this leads to an unusual conclusion that the quantum yield of photocycloaddition becomes smaller with larger initial 2MN concentrations.

Conclusion

The acid catalysis of the photocycloaddition of singlet excited state 2MN with AA in CH_3CN and CH_3OH is the first demonstration of an interaction of the nonemissive *(2MN–AA) exciplex with a Brønsted acid (H_2SO_4). In contrast, the interaction of the emissive intermediate (*2MNH$^+$) with AA (EP pathway in Scheme 1) (6), or that of the excimer with H_2SO_4 (EE pathway) (7) is not an acid catalytic route to **1** and **2** for this system. The *(2MN–AA) exciplex is formed reversibly, which allows us to use extended fluorescence-quenching analysis to probe the reaction pattern of this nonfluorescent exciplex. This unambiguously identifies the reaction of the exciplex *(2MN–AA) with H_2SO_4 as the key step in the present catalytic process. Exciplex acid–base behaviour is believed to be a general but unrecognized phenomenon. The extended fluorescence-quenching analysis is shown to be a useful technique to perform kinetic analysis of a nonemissive exciplex provided it is reversibly formed.

1994 R.U. Lemieux Award Lecture
Hydrolysis of acetals and ketals. Position of transition states along the reaction coordinates, and stereoelectronic effects[1]

PIERRE DESLONGCHAMPS,[2] YVES L. DORY, AND SHIGUI LI

Laboratoire de synthèse organique, Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke, QC J1K 2R1, Canada

Received June 1, 1994

PIERRE DESLONGCHAMPS, YVES L. DORY, and SHIGUI LI. Can. J. Chem. **72**, 2021 (1994).

Past and recent experimental results on the formation or hydrolysis (or isomerization) of various acetals and ketals including α- and β-glycoside models are presented. Ab initio investigations of simple acetals are also briefly reviewed as well as recent experimental and theoretical support evidence for a synperiplanar effect. A detailed study using the semi-empirical Hamiltonian AM1 defining the reaction pathway in the hydrolysis of various acetals and ketals is reported. This overall study shows that the hydrolysis of acetals and ketals is controlled by powerful stereoelectronic effects.

PIERRE DESLONGCHAMPS, YVES L. DORY et SHIGUI LI. Can. J. Chem. **72**, 2021 (1994).

Des résultats expérimentaux anciens et nouveaux sur la formation ou l'hydrolyse (ou l'isomérisation) de divers acétals et cétals incluant des modèles d'α- et β-glycosides sont présentés. Des études ab initio d'acétals simples sont aussi brièvement rapportées ainsi que de récentes évidences expérimentales supportées théoriquement de l'effet synpériplanaire. Une étude détaillée, à l'aide de l'Hamiltonian semi-empirique AM1, des chemins réactionnels d'hydrolyse de divers acétals et cétals est rapportée. Cette étude globale montre que l'hydrolyse d'acétals et de cétals est contrôlée par de puissants effets stéréoélectroniques.

Introduction

It has been generally accepted that stereoelectronic effects play a major role in acetal hydrolysis (1, 2). We previously postulated (1), on the basis of the antiperiplanar lone-pair hypothesis, that α-glycosides (axial anomer) are hydrolyzed via their ground state chair conformation whereas β-glycosides (equatorial anomer) must first assume a twist-boat conformation in order to have the ring oxygen with a lone pair properly oriented to eject the leaving group. Since it is well known (3, 4) that α- and β-glycosides are hydrolyzed at similar rates, it follows that these compounds must be hydrolyzed via transition states that resemble more closely the geometry of the cyclic oxocarbonium ions rather than that of the protonated glycosides. It was therefore necessary to obtain experimental evidence and theoretical support to establish the position of the transition state along the reaction coordinates in the hydrolysis of acetals and related functions. In this paper, we wish to review our recent published work in this area and to present an AM1 molecular modelling study (5).

We recently discovered (6–8) that a series of hydroxy-enol ethers can undergo cyclization to provide the corresponding spiroketals either under kinetically (CH_3COOH–benzene) or thermodynamically (CF_3COOH–benzene) controlled conditions. For instance, taking bicyclic hydroxy-enol **1** as an example (Scheme 1), this compound gave exclusively spiroketal **8** under thermodynamic control and a 2:3 mixture of **5** and **8** under kinetic control. Spiroketal **8** being much more stable than **5** for steric and stereoelectronic reasons (9), it is the only isomer observed under equilibrating conditions. Under kinetically controlled conditions, upon protonation, **1** must first give the cyclic oxocarbonium ion **2**, which can then be converted into spiroketals **5** and **8** while respecting the antiperiplanar hypothesis. On that basis, **5** is formed via a twist-boat (**3** → **4**) and **8** via a chair pathway (**6** → **7**). If the transition states were late, their geometry would be near that of **4** and **7**, their energy difference would be quite large due to steric reasons, and the exclusive formation of **8** would have resulted. The 2:3 ratio of **5** and **8** observed can only be explained by transition states that are near the structures of the oxocarbonium ions **3** and **6**, respectively. Thus, these results can be explained by postulating early transition states, the early chair-like (near **6**) transition state being slightly favored over the early boat-like (near **3**) transition state.

The above results differ from those previously observed (10, 11) with hydroxypropyl acetal **9** (Scheme 2), as this compound led to the exclusive formation of *cis*-tricyclic acetal **13** under kinetically controlled conditions (*p*-TSOH–CH_3OH, room temperature). An equilibrium mixture (45:55) of *cis* and *trans* acetals **13** and **16** was obtained under reflux conditions. The kinetically controlled formation of **13** can be explained in the following way: upon protonation, **9** gave the cyclic oxocarbonium ion **10**, which can then lead to the *cis* and the *trans* acetals **13** and **16**, respectively, via a chair-like (**11** → **12**) pathway and a twist-boat-like (**14** → **15**) pathway while assuming the antiperiplanar hypothesis. Again, it is relatively easy to understand the exclusive formation of *cis* acetal **13** via an early transition state provided that the incoming hydroxyl group is properly aligned with the π-orbital of the cyclic oxocarbonium ion. Such an alignment, which corresponds closely to the Bürgi–Dunitz angle of attack of a nucleophile on a π-system (12, 13), can be easily attained with **11** but not with **14**, a conclusion that was supported by a molecular modelling study (6).

Concurrent to these experiments, a theoretical study on the anomeric effect in acetals was started in collaboration with F. Grein. In the first study (14), geometry optimizations at the 6-31G** level were performed on various conformers of H_nX-CH_2-YH_m and their protonated counterparts H_nX-CH_2-YH_{m+1}^+ where X and Y are N and O. The relative energies for the neutral systems are shown in Table 1. As expected, conformers having two anomeric effects are more stable than those having only

one, which in turn are more stable than conformers without an anomeric effect. The energy difference does not vary a great deal when oxygen is replaced by nitrogen. Using simple parameters, an energy analysis was performed to explain such different behavior. Energy differences between various conformers can be explained by taking into account an electronic stabilizing term (e_O or e_N), a 1,3-diaxial H—H repulsion term (r), a 1,3-diaxial lone pair – lone pair repulsion term (l), and an intramolecular hydrogen bonding term (h) (see Table 1). Based on ab initio calculations, approximate values $r \cong l \cong -h \cong 1$ kcal/mol were obtained. Applying this model to the systems given in Table 1 led to $e_O = -2$ kcal/mol and $e_N = -2.5$ kcal/mol. The energy values obtained by this simple model are shown in parentheses in Table 1 and are remarkably close to the ab initio values. Overall, this study led to a simple model from which it was possible to estimate qualitatively the underlying electronic energy of stabilization due to the anomeric effect and to separate it from other forms of energy, such as steric and electrostatic energy. The validity of this simple model was confirmed by application to methanetriol and aminomethanediol. Studies of the protonated systems led to a theoretical interpretation of the reverse anomeric effect (15), which would be the result of an electrostatic attraction between a positively charged heteroatom and the electron lone pairs of the neighboring heteroatom.

In a second article (16), more detailed studies were performed on systems H_mX-CH_2-OH with X = N, O, F, C where the OH group was rotated about the C—O bond. This was followed by a Fourier analysis of the energy as a function of the rotation

angle. Again, a decomposition of the energy into a stabilizing electronic component, as a steric component (interaction of rotating OH with neighboring CH_2X group) and a steric–electrostatic component (interaction of OH with XH_m) was performed. The stabilizing electronic component considered to be the fundamental driving force of the anomeric effect was related to the ability of the CH_2OH portion of the molecule to form a double bond. The mechanism leading to anomeric stabilization is thus explained by partial π-bonding. The ideas described in these two papers were combined and extended by Grein (17), leading to much improved values for the electronic portion of the anomeric stabilization energy, which are summarized in Table 2.

These values are larger for nitrogen (e_N) than for oxygen (e_O) because the former is a better electron donor. The e_N and e_O values also increase with the leaving-group ability of the XH_m group. In the protonated series, these values become quite large and in some cases protonation of XH_m leads to the formation of π-complexes due to the high electronegativity of the protonated group. As a result, stereoelectronic effects in acetals are put on a more solid theoretical basis. The π-bonding model also indicated that the *syn* and the *anti* periplanar effects are energetically similar, although processes with the aid of the former are normally sterically disfavored over the latter, eclipsed conformers (*syn* process) being higher energetically than *gauche* conformers (*anti* process) (Scheme 3). Also, due to the large C-XH_{m+1}^+ bond increase found in the protonated species, these calculations suggested that in acetal hydrolysis the geometry of the transition state for the cleavage reaction is likely to be closer to the oxocarbonium ion than to the acetal.

Having obtained theoretical evidence for the synperiplanar effect, tricyclic acetal **17** was synthesized in order to verify whether this effect is operative both in the ozonolysis and the hydrolysis of acetals. Due to its bridged nature, tricyclic acetal **17** has the two lone pairs of the ring oxygen oriented *syn* to both the anomeric C(1)—H and the C(1)—OCH_3 bonds. The CH_3—O bond must also be antiperiplanar to the C(1)—C(2) bond as a result of the *exo* anomeric effect and minimal steric interaction for the CH_3 group. Thus, acetal **17** has one lone pair synperiplanar and one lone pair antiperiplanar to the C(1)—H bond. Normally, acetals that have a lone pair on each oxygen atom antiperiplanar to the C—H bond are very reactive toward ozone (18–20). Since it was observed (21) that acetal **17** is also already oxidized at −78°C, this result constitutes unequivocal experimental evidence that a *syn* stereoelectronic effect can also be operative in the ozonolysis of acetals.

It was also found (22) that tricyclic acetal **17** undergoes hydrolysis under mild acidic conditions (HCl, 0.01 N in water–acetone), yielding the corresponding lactol **20**. Since the endocyclic oxygen of **17** has one lone pair synperiplanar to the C—OCH_3 bond, this result constitutes the first unambiguous experimental evidence that a synperiplanar lone pair can accelerate the hydrolysis of acetals. Accepting the fact that acetals are hydrolyzed via a late transition state, the hydrolysis of **17** must take place via a transition state (**18**) having a geometry near the tricyclic oxocarbonium ion **19**.

Following this work, we studied the reaction pathway for the acid hydrolysis of various acetals using the semi-empirical Hamiltonian AM1.[3] We have examined specific conformations of acetals, their protonated forms, and corresponding oxocarbonium ions, and have looked for transition structures (23) for the cleavage steps. We first examined the hydrolytic pathway of acetals **13** and **16** (Fig. 1). In acetal **13**, the C—O(1) bond is shorter (1.41 Å) than the C—O(2) bond (1.43 Å) due to the anomeric effect (O(1) has one lone pair antiperiplanar to the C—O(2) bond). O(2) is thus more basic, and upon protonation (**21**) the C—O(1) bond shortens (1.36 Å) and the C—O(2) bond

[3]Computational procedure: All the calculations were done at the RHF level. The first input files for MOPAC 6.00 were created by means of SYBYL 6.01 (Tripos Associates, Inc.: 16995 Hanley Rd., Suite 303, St. Louis, Missouri 63144-2913) for IBM RISC 6000 computers. The gradients of the norm of these draft structures were then fully optimized using EF or TS subroutines. Finally, all the transition structures were characterized by only one negative force constant. The calculations were carried out on IBM RISC 6000 computers.

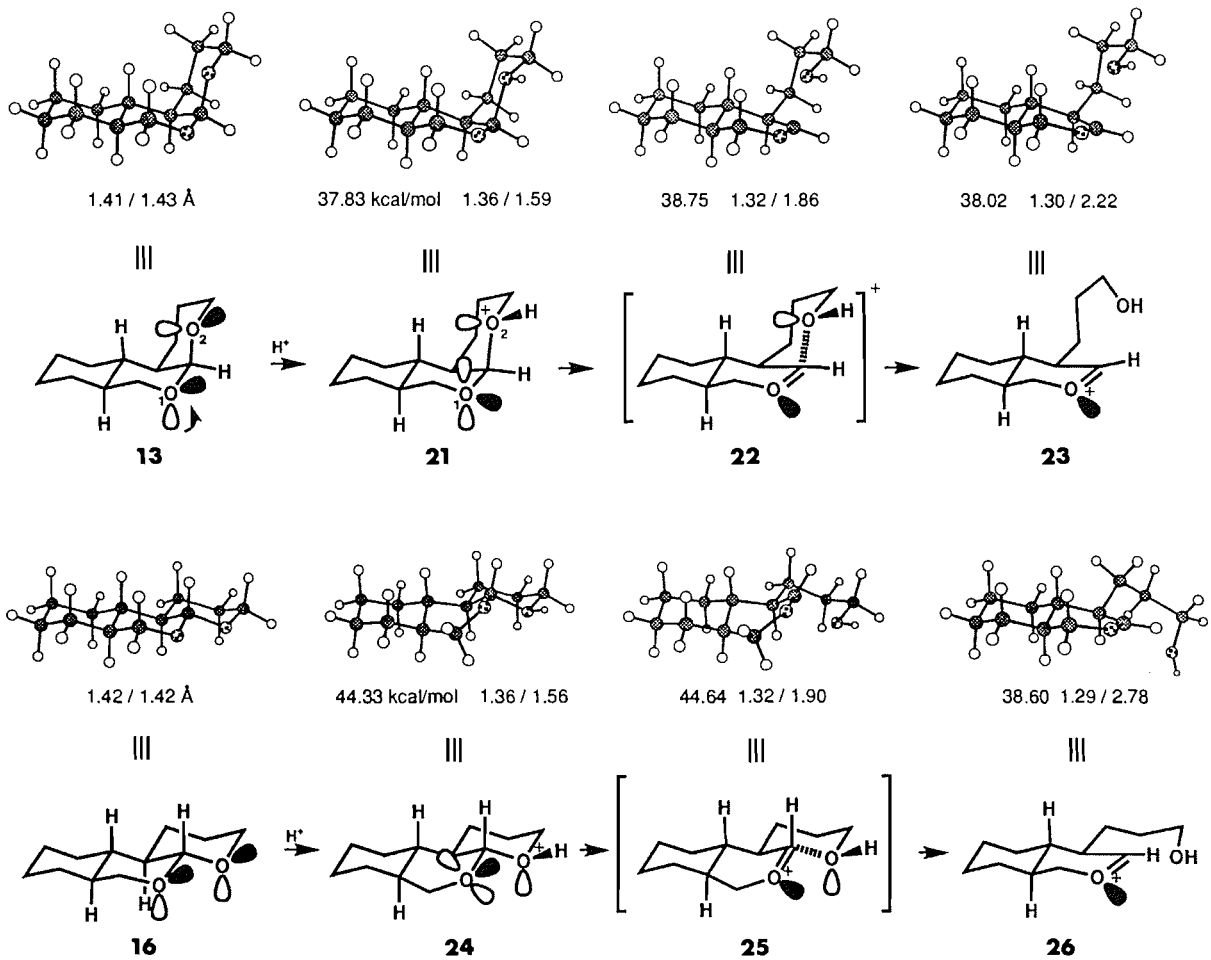

FIG. 1

lengthens (1.59 Å) considerably. This is in agreement with Grein's findings (14, 16, 17) that the anomeric electronic stabilizing effect greatly increases in protonated acetals. As a result, the middle ring flattens considerably and it appears better to draw, for this protonated acetal, an sp_2 hybridized O(1) and a p orbital periplanar to the C—O(2) bond. Transition structure **22** was then found with C—O(1)/C—O(2) bond distances of 1.32 and 1.86 Å with an energy of 38.75 kcal/mol. The geometry of this transition structure is now very close to that of the cyclic oxocarbonium ion **23** found at 38.02 kcal/mol and with C—O(1)/C—O(2) distances of 1.30 and 2.22 Å. The transition structure **22** is about 1.0 kcal/mol higher than the protonated acetal **21** and 0.7 kcal/mol higher than the oxocarbonium ion **23**.

Having no anomeric effect, the two C—O bonds in acetal **16** are of equal length. Upon protonation, **16** provides **24**, with ring B now appearing in a boat form as a result of a strong anomeric effect and a periplanar p orbital. In this case, there is a very small energy barrier after protonation, **24** being at 44.33 and **25** at 44.64 kcal/mol. What is even more important is the comparison between the *cis* and *trans* acetal transition structures. It can be seen that **25** from the *trans* acetal **16** is at a much higher energy (44.64 kcal/mol) than **22** (38.75 kcal/mol) from *cis* acetal **13**. This large difference, which is steric in nature, is a direct consequence of the required periplanar alignment of the p orbital with the neighboring C—O bond. The specific formation of *cis* acetal **13** under kinetically controlled conditions is thus well understood on this basis.

A similar analysis was made for the hydrolysis of spiroketals **5** and **8** (Fig. 2). Each oxygen having one anomeric effect, the two C—O bonds are of equal length in **8**. In **5**, the ring C oxygen having one anomeric effect, the C—O bond lengths vary accordingly (C—O(2)/C—O(1) = 1.42/1.43). Upon protonation, **8** gives **27** at 29.92 kcal/mol; then there is essentially no further energy barrier (**28** = 29.96 kcal/mol) to yield the oxocarbonium ion **29** (25.55 kcal/mol). It can be seen that ring B in **27** (or **28**) is almost a half-chair (or the end of a chair form), which completely flattens in oxocarbonium ion **29**. Upon protonation, **5** provides **30**, with a flattened boat-like conformation, which then provides the half-chair oxocarbonium ion **31**. In this case, no energy barrier was observed between **30** and **31**. Since **30** is about 1 kcal/mol higher than **27**, it follows that the formation of acetal **8** should be slightly favored over acetal **5**, a result in accord with experimentation (**8**:**5** ratio = 3:2).

The most stable conformers **32** and **36** (Fig. 3) of the axial and equatorial methoxytetrahydropyrans were next examined as theoretical models for α- and β-glycosides. The bond length difference in **36** is due to the *exo* anomeric effect. In **32**, each oxygen has one anomeric effect, but the C—OMe bond length was found to be slightly longer. This may be due to a stronger *endo* anomeric effect and (or) to the fact that the C—OMe bond is not part of a ring. As expected, **33** corresponds to a flattened chair and **37** to a flattened boat, **33** and **37** giving then the cyclic oxocarbonium ions **35** and **39** via their respective transition structures **34** and **38**. Since transition structure **38** is slightly higher in energy (≈0.4 kcal/mol) than **34**, it follows that the rate

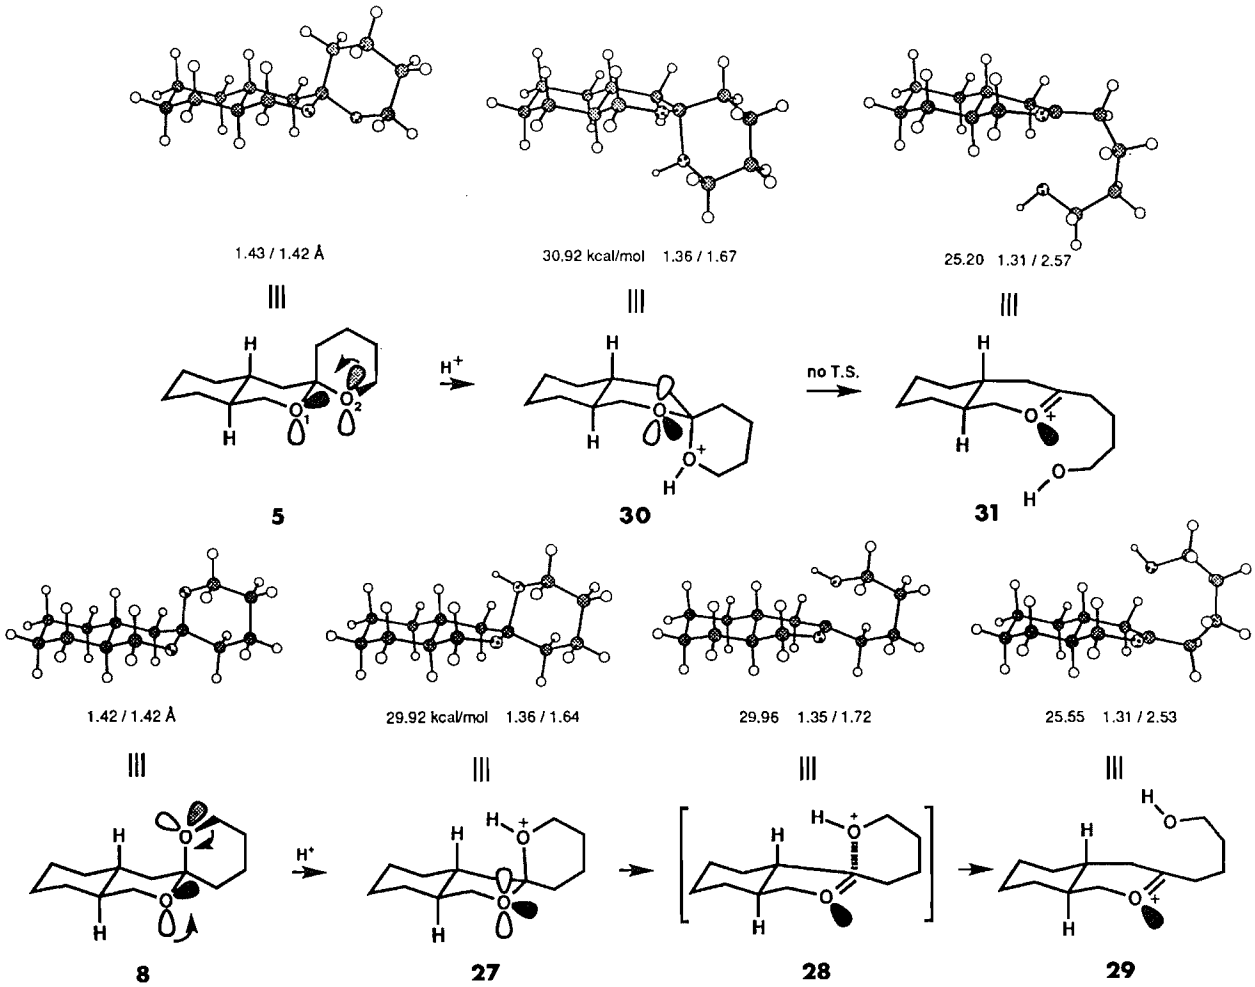

FIG. 2

of hydrolysis of **32** should be slightly faster than **36**. This is in complete accord with the reported hydrolysis of bicyclic acetals **40** and **41** (Scheme 4), which was reported by Eikeren (24). Indeed, the α-anomer **40** is more stable than the β-anomer **41** by 0.45 kcal/mol; on the other hand, **40** is hydrolyzed faster by a factor of 1.5 (≈0.25 kcal/mol). The difference in energy between the two transition states should thus be approximately 0.7 kcal/mol in favor of the α-anomer **40**, in complete agreement with the AM1 calculation. The relative rates of hydrolysis of α- and β-glycosides (3, 4) can thus be explained on the basis that the geometries of their late transition states are close to the half-chair cyclic oxocarbonium ion. In β-glycoside, this transition state can be reached either from a half-chair with a synperiplanar lone pair or via a twist-boat conformation with an antiperiplanar lone pair. Since the twist-boat is attained from the chair via the half-chair, it is thus likely that β-glycosides are hydrolyzed via a *syn* pathway. Such a pathway was previously suggested by Fraser-Reid and co-workers (25, 26) for the hydrolysis of a conformationally rigid β-*n*-pentenylglycoside under neutral conditions by the use of an electrophilic reagent. On the other hand, in α-glycoside the transition state geometry can be obtained directly from the chair conformation with an antiperiplanar lone pair.

Conclusion

The above experimental and molecular modelling studies confirm that proper alignment of an oxygen lone pair periplanar to the leaving group is one of the main driving forces in acetal and ketal hydrolysis.

In acetals, molecular modelling indicates that there is an energy barrier for the cleavage of the protonated form and the transition structure should be late, having a geometry near that of the oxocarbonium ion. More specifically, this transition structure corresponds to a flattened chair in α-glycosides and to a flattened boat in β-glycosides. Also, the hydrolysis of the α-isomer takes place via an antiperiplanar pathway whereas that of the β-isomer probably follows a synperiplanar route. The relative rate hydrolysis of α- and β-glycosides (3, 4) can be readily explained on that basis.

In ketals, AM1 calculations indicate that there is essentially no energy barrier after the protonation step (see Fig. 2); the transition state for the ketal hydrolysis must be very early, having a geometry close to that of their protonated form. The fact that there would be essentially no energy barrier after protonation would be the result of a steric decompression effect of the two alkyl groups present in ketal. As a result and in accord with experimental results, ketals are hydrolyzed at a much faster rate than acetals (27). Also, this rationalization is in accord with the fact that spiroketals such as **5** and **8** are very readily equilibrated with mild acid, whereas isomeric acetals such as **13** and **16**, or the α- and β-glycoside models **40** and **41**, require stronger acidic conditions for equilibration.

Work is now in progress to establish that the slow steps in acetals and ketals are not the same.

Structural studies of ligands for the glycine binding site of the excitatory amino acid receptor complex: 2. 6-bromo-, 6-methyl-, and 6-styryl-1,8-ethano-4-hydro-2,3-quinoxalinedione

MACIEJ KUBICKI,[1] TERESA W. KINDOPP, MARIO V. CAPPARELLI,[2] AND PENELOPE W. CODDING[3]

Departments of Chemistry and of Pharmacology and Therapeutics, University of Calgary, Calgary, AB T2N 1N4, Canada

Received January 7, 1994

MACIEJ KUBICKI, TERESA W. KINDOPP, MARIO V. CAPPARELLI, and PENELOPE W. CODDING. Can. J. Chem. **72**, 2028 (1994).

The crystal structures of three tricyclic quinoxalinedione derivatives, 6-bromo-1,8-ethano-4-hydro-2,3-quinoxalinedione (**1**), 6-methyl-1,8-ethano-4-hydro-2,3-quinoxalinedione hydrate (**2**), and 6-styryl-1,8-ethano-4-hydro-2,3-quinoxalinedione (**3**), are reported. For **1** and **2**, the space groups are $P2_1/n$ with the unit cell parameters for **1**: a = 7.4003(5) Å, b = 8.5799(5) Å, c = 14.3127(9) Å, β = 90.639(6)°, and for **2**: a = 7.0590(2) Å, b = 10.7483(3) Å, c = 13.9509(7) Å, β = 103.290(3)°. For **3**, the space group is $P2_1/c$, with a = 19.3683(10) Å, b = 8.0962(16) Å, c = 19.5801(16) Å, β = 114.028(6)°. Compound **3** crystallizes with two molecules in the asymmetric part of the unit cell; in one of them the styryl group is disordered. The geometries of the 1,8-ethano-4-hydro-2,3-quinoxalinedione fragments are similar in all observations, with the differences mainly caused by the different nature of the substituents in the 6-position. Hydrogen bonds connect the molecules into three-dimensional networks. Head-to-tail π-stacking between molecules connected by a center of symmetry determines the packing modes in **1** and **2** but there is no π-stacking in the crystal structure of **3**. The crystal structures of the three quinoxaline derivative ligands for the glycine receptor suggest a mode of recognition that involves an N—H···*receptor* hydrogen bond, a three-centre hydrogen bond to the neighboring carbonyl groups on the ligand, and π-stacking between ligand and receptor. This mode is consistent with the geometric constraints of the current binding site model but places greater emphasis on hydrogen-bond interactions.

MACIEJ KUBICKI, TERESA W. KINDOPP, MARIO V. CAPPARELLI et PENELOPE W. CODDING. Can. J. Chem. **72**, 2028 (1994).

On a déterminé les structures cristallines de trois dérivés tricycliques de la quinoxalinedione, la 6-bromo-1,8-éthano-4-hydro-2,3-quinoxalinedione (**1**), l'hydrate de la 6-méthyl-1,8-éthano-4-hydro-2,3-quinoxalinedione (**2**) et la 6-styryl-1,8-éthano-4-hydro-2,3-quinoxalinedione (**3**). Les composés **1** et **2** cristallisent dans le groupe d'espace $P2_2/n$ avec, pour **1**, a = 7,4003(5), b = 8,5799(5) et c = 14,3127(9) Å et β = 90,639(6)° et, pour **2**, a = 7,0590(2), b = 10,7483(3) et c = 13,9509(7) Å et β = 103,290(3)°. Le composé **3** cristallise dans le groupe d'espace $P2_1/c$, avec a = 19,3683(10), b = 8,0962(16) et c = 19,5801(16) Å, β = 114,038(6)°. Le composé **3** cristallise avec deux molécules de solvant dans la partie asymétrique du motif de la maille dans un desquels le groupe styryle est désordonné. Les géométries des fragments 1,8-éthano-4-hydro-2,3-quinoxalinedione sont semblables dans tous les composés examinés; les différences sont principalement causées par la nature différente des substituants en position 6. Des atomes d'hydrogène relient les molécules dans des réseaux tridimensionnels. Un entassement π tête-à-queue entre les molécules reliées par un centre de symétrie détermine les modes d'empilement dans les composés **1** et **2**; toutefois, il n'y a pas d'entassement π dans la structure cristalline du composé **3**. Les structures cristallines des trois coordinats dérivés de la quinoxaline pour le récepteur glycine suggère un mode de reconnaissance qui implique une liaison hydrogène N—H···*recepteur*, une liaison à trois centres hydrogènes avec les groupes carbonyles voisins sur le coordinat et l'empilement π entre le ligand et le récepteur. Ce mode est en accord avec les contraintes géométriques du modèle courant du site de liaison, mais il met plus d'emphase sur les interactions des liaisons hydrogène.

[Traduit par la rédaction]

Introduction

Quinoxalinedione (QD) derivatives are highly potent antagonists of the strychnine-insensitive glycine modulatory site of the NMDA receptor contained in the excitatory amino acid receptor complex (1); QD derivatives also show significant antagonistic activity for non-NMDA (i.e., kainate and AMPA) receptors (2). Excitatory amino acids (EAA) are the main neurotransmitters mediating synaptic excitation in the central nervous system (3); therefore, antagonists and agonists for EAA receptors are regarded as potential therapies for numerous CNS disorders, including ischemic brain damage (4) and epilepsy (5). The QD family is particularly useful for structure–activity studies because, in contrast to the other known NMDA receptor antagonists, they do not contain the glycine structural element, and small structural changes produce large differences in biological response. Our previous X-ray crystallographic studies (6, 7) show that there at least two important structural features responsible for biological action: hydrogen bonding and the charge distribution in the molecule. These studies identified a symmetrical pattern of hydrogen bonding for all 6,7-disubstituted QD derivatives, which featured both two-centre hydrogen bonds to the two carbonyl groups and a shared three-centre hydrogen bond in nearly equal proportions. An unsymmerical hydrogen-bonding pattern for the highly active 5,7-dinitro QD compound was observed due to an intramolecular hydrogen bond. Further investigation of these hydrogen-bonding patterns is required to refine the current model of the NMDA receptor glycine modulatory site pharmacophore (8), particularly since the model focuses on an ionic interaction with the glycine carboxyl group rather than hydrogen bonds to the QD carbonyl groups.

We studied the X-ray crystallographic structures of three tricyclic QD derivatives: 6-bromo- (**1**), 6-methyl- (**2**), and the hydrate of 6-styryl-1,8-ethano-4-hydro-2,3-quinoxalinedione (**3**). These compounds display a range of activity against ^{3}H glycine binding; the IC_{50} value for **1** is equal to 13 μM, for **2** 85 μM, and **3** is not active in the binding experiments.[4] The

main reason for these studies was to determine the hydrogen-bonding schemes and the packing modes and to search for an explanation of the activity profile of these compounds.

Experimental

Samples were provided by ICI Americas Inc., Wilmington, Del. Colorless prisms of the three compounds were obtained by slow evaporation from dimethylformamide (**1** and **2**), and an acetone–water mixture (**3**). X-ray intensity data were collected at room temperature on an Enraf–Nonius CAD-4F automated diffractometer with Ni-filtered CuK_α radiation (λ = 1.54178 Å), using an $\omega/2\theta$ scan mode. Accurate unit-cell parameters were obtained by least-squares treatment of the setting angles of 25 reflections Three standard reflections were measured after 2000 s of exposure, the intensities decreased by 12% for **1**, 3.5% for **2**, and 8% for **3** and the data were corrected for this linear decay. Both Lorentz and polarization corrections were applied. An empirical absorption correction was made for compound **1** due to the large μ value (T_{max} = 0.331, T_{min} = 0.199). Additional crystal data are in Table 1.

All three structures were solved by direct methods using SHELXS86 (9). Full-matrix refinement was performed for **1** and **2** and block-matrix refinement for **3** (one symmetrically independent molecule in each block) using the least-squares program of SHELX-76 (10); the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized. All non-hydrogen atoms were refined with anisotropic thermal parameters. For **1**, all hydrogen atoms were found in a ΔF map and their positional and isotropic thermal parameters were refined. For **2**, the hydrogen atoms of the methyl group were disordered and two positions with refined occupancies of 0.5 were defined. In the final cycles the occupancies of the disordered atoms were fixed and the positional and isotropic thermal parameters of all hydrogen atoms were refined. Molecule B of compound **3** showed disorder in the positions of C61 and C62 with occupancies of 0.7 and 0.3 for the two components. Although visible in the ΔF map, the disordered hydrogen atoms were not refined but were allowed to move with the carbon atoms and have U_{iso} values calculated from the respective carbon atom U_{eq} values. All of the other hydrogen atoms were refined with the isotropic thermal parameters. For each structure, an isotropic extinction correction was made during the final stages of refinement.

The atomic scattering factors for non-hydrogen atoms were taken from Cromer and Mann (11), and for hydrogen atoms from Stewart et al. (12). Other computer programs used: ORTEP (13), PLUTO (14), and CSU88 (15). The final atomic coordinates for all structures are given in Table 2.[5] The bond lengths and angles are listed in Table 3.

[5]Tables of anisotropic thermal parameters for non-hydrogen atoms, hydrogen atom fractional coordinates and isotropic thermal parameters, bond lengths and angles involving hydrogen atoms, dihedral angles for non-H atoms, least-squares plane data, and the packing scheme of compound **3** may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada. Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

Tables of H-atom coordinates, bond lengths and angles for H-atoms, and the packing scheme of **3** have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K.

Results

Hydrogen-bond networks connect the molecules into three-dimensional structures. In **1**, the N-H group acts as a donor in a three-centered hydrogen bond with both of the carbonyl oxygen atoms of the molecule and there is a relatively strong C—H···O hydrogen bond. In **2**, the oxygen atom of the water molecule accepts an N—H···O bond and acts as a donor for a three-centre and a two-centre hydrogen bond with the carbonyl oxygen atoms. The N-H group of compound **3** is bonded with one carbonyl oxygen atom (molecule A) or with both carbonyl oxygen atoms (molecule B) in an unsymmetrical three-centre hydrogen bond. Overall, all N-H groups are involved in hydrogen bonds and the carbonyl oxygen atoms are in all but one case involved in three-centre hydrogen bonds. The hydrogen-bond geometry is listed in Table 4 and illustrated in Figs. 1, 2, and 3.

Additionally, as shown in Figs. 4 and 5, there is head-to-tail π-stacking between the neighboring molecules connected by a centre of symmetry in the crystals of **1** and **2**. The distances between the least-squares planes of the molecules at (x, y, z) and ($-x$, $1-y$, $1-z$) are 3.379(2) Å for **1**, and 3.387(2) Å for **2**; and between the molecules at (x, y, z) and ($1-x$, $1-y$, $1-z$) are 3.466(2) Å for **1**, and 3.420(2) Å for **2**. The packing modes of these two compounds are similar.

For compound **3**, the packing mode is quite different. There are two molecules in the asymmetric part of the unit cell; the dihedral angle between the mean planes of the quinoxalinedione moieties is 68.88(4)°, and between the planes of the phenyl rings in the styryl groups is 74.10(10)°. There is no stacking between the molecules, and hydrogen bonds and van der Waals forces are the only factors determining the packing mode.

The quinoxaline fragments in all molecules are nearly planar (the maximum deviation is in molecule **3***b*, which has a dihedral angle of 4.75(9)° between the mean planes). The five-membered rings are approximately coplanar with the quinoxaline fragments (the maximum deviation in molecule **1** shows a interplane angle of 4.84(9)°). The carbonyl oxygen atoms are in the plane of the quinoxaline fragment except in the strong hydrogen bonds in compound **3** where the oxygen atoms deviate by 0.110(2) Å for O3A and 0.104(2) Å for O2B. The bond lengths and angles in the 1,8-ethano-2,3-quinoxalinedione fragments are similar in the four molecules. The attached five-membered ring causes strain in the molecule which is taken up by changes in the geometry of quinoxaline fragment as compared with the compounds without an attached ring (6, 7, 16–18); these changes are mainly visible in the bond angles, as has been observed in acenaphthene derivatives (19–21). In the phenyl ring, the substituent at C6 affects the bond angles; the effects of the methyl and the styryl groups are almost identical (22).

The crystal structure of **3** contains two independent molecules in the asymmetric part of the unit cell. One of these molecules (B) is significantly disordered; the disorder is caused by a rotation of a styryl group. The relevant torsion angles are listed in Table 3 (*c*). Alternative positions for the disordered atoms of the phenyl ring could not be identified due to the nature of the disorder; this failure is reflected in relatively large values for the U_{eq}'s and in the shapes of the thermal ellipsoids, in the poor geometry of ethene bridge in molecule B, and in the large thermal parameters for C5, C6, and C7. Similar disorder was also observed in the crystal structures of related compounds, *trans*-stilbene (23) and *trans*-azobenzene (24). The geometries of the quinoxalinedione moieties in both unique molecules and of the styryl group in molecule A are reasonable;

a normal probability plot for the ordered part of the molecules (25, 26) shows statistical, not systematic, differences in geometry (correlation coefficient of 0.98).

Discussion

Structural analysis of QD derivatives shows that the N-H groups and the carbonyl oxygen atoms are maximally involved in hydrogen bonds (6, 7); these observations, coupled with structure–activity data, suggest that the N-H groups and the carbonyl groups are involved in receptor binding. The most active compound at the glycine receptor is an unsymmetrically substituted QD, 5,7-dinitro-1,4-dihydro-2,3-quinoxalinedione, which shows a hydrogen-bonding pattern that does not involve both N-H groups because of an intramolecular hydrogen bond between the 5-nitro group and one N-H group. This intramolecular bond effectively eliminates one hydrogen-bond donor from molecular "recognition-type" hydrogen bond (7) and suggests that the minimal pharmacophore for QD ligands contains one N-H group and two carbonyl groups; blocking both N-H groups eliminates activity.[4] This suggestion is supported by computations that show that the intramolecular hydrogen bond persists over a wide range of conformations (7). In the compounds reported herein, only one N-H group is present and available for hydrogen bonding; therefore the bonding patterns observed in these structures provide models for the key interactions of the postulated pharmacophoric fragment. All three reported structures shows a consistent pattern of a hydrogen bond involving the N-H groups and a shared three-centre hydrogen bond to the two carbonyl groups. The three-centre hydrogen bond was only present in 50% of the crystal packing patterns of QD derivatives that contain two N-H groups (6, 7), yet is the predominant pattern in the structures with only one N-H group, even when solvent is present in the crystal. The three-centre bond provides some variability in the geometry of recognition because the two sides of the three-centre bond do not have to be equivalent, as is apparent in structure **3**, and may allow accommodation of different sizes of ligand in the receptor site. Thus, these crystal structures provide a model of the key recognition interactions for the minimum molecular features of glycine receptor ligands: (*i*) the donation of an H atom by a single N-H group; and (*ii*) a three-centre hydrogen bond formed by the two contiguous carbonyl groups.

Compound **3** and some QD derivatives with 6,7 phenyl substituents are inactive, either because the binding site has a limited size constraining the distance between the hydrogen-bonding groups and the opposite end of the molecule or because the styryl or phenyl groups are not coplanar with the quinoxaline fragment and ring stacking is disfavored. The crystal structures of all active compounds (6, 7, and this work) show π interactions between planar moieties as a major intermolecular interaction and suggest that this mode of interaction may be important for recognition. Inactive compound **3** does not display π-stacking in the crystal structure.

The results of these studies are consistent with the structural features proposed for the antagonistic pharmacophore of the NMDA receptor glycine modulatory site (5, 27, 28). However, we propose a hydrogen-bond interaction instead of a Coulombic attraction for the carbonyl group. Although partial ionization of the carbonyl group would allow a similar interaction for QD and glycine-like antagonists, the hydrogen-bond interaction is probably favored for the carbonyl group. The hydrogen-bond interaction is directional and spatially restricted by the aromatic nature of the QD framework; thus, the geometric interaction of QD derivatives with the binding site is more specific and more clearly defines the structural features of the binding site.

In summary, the crystal structures of three quinoxaline derivative ligands for the glycine receptor suggest a mode of recognition that involves a N-H···*receptor* hydrogen bond, a three-center hydrogen bond to the neighboring carbonyl groups on the ligand, and π-stacking between ligand and receptor. This mode is consistent with the geometric constraints of the current binding site model but places greater emphasis on hydrogen-bond interactions.

Photodissolution of iron oxides in malonic acid

MARTA I. LITTER, MARINA VILLEGAS, AND MIGUEL A. BLESA,[1]
Departamento Química de Reactores, Comisión Nacional de Energía Atómica, Av. del Libertador 8250, 1429 Buenos Aires, Argentina
Received December 8, 1993[2]

MARTA I. LITTER, MARINA VILLEGAS, and MIGUEL A. BLESA. Can. J. Chem. **72**, 2037 (1994).

The influence of 254-nm irradiation on the dissolution rate of magnetite (Fe_3O_4) and maghemite (γ-Fe_2O_3) suspended in aqueous solutions of malonic acid is analyzed and compared with the dark reaction. The effect of the addition of Fe^{3+}, reductants such as ascorbic acid and oxidants such as Ag^+ or O_2 is described. Photochemical initiation involves the production of $>Fe^{II}$ by electrons photogenerated on the oxide, which triggers thermal dissolution. Experimental results are fitted by analytical and numerical solutions of the set of kinetic equations. The calculated fitting parameters reflect the lower activity of iron oxides in malonic acid compared to EDTA media.

MARTA I. LITTER, MARINA VILLEGAS et MIGUEL A. BLESA. Can. J. Chem. **72**, 2037 (1994).

On a analysé l'influence de l'irradiation à 254 nm sur la vitesse de dissolution de la magnétite (Fe_3O_4) et de la maghémite (γ-Fe_2O_3) en suspension dans des solutions aqueuses d'acide malonique et on l'a comparée aux vitesses de réaction en l'absence de lumière. On décrit aussi l'effet de l'addition du Fe^{3+}, d'agents réducteurs comme l'acide ascorbique et d'oxydants tels que le Ag^+ et le O_2. L'initiation photochimique implique la production de $>Fe^{II}$ par des électrons photogénérés sur l'oxyde et qui provoque la dissolution thermique. On a ajusté les résultats expérimentaux des solutions analytiques et numériques de l'ensemble des équations cinétiques. Les paramètres d'ajustement calculés sont un reflet de l'activité plus faible des oxydes de fer dans l'acide malonique par comparaison avec les milieux contenant de l'EDTA.

[Traduit par la rédaction]

Introduction

Photocorrosion of semiconducting metal oxides in aqueous solutions is a well-documented process (1). Depending on the desired application, corrosion can be an interfering process in photocatalysis or a convenient tool for removal of oxides from surfaces by chemical attack (2). Iron oxides, compared with other more photostable materials such as TiO_2, present quite clearly both possibilities and, depending on the chosen conditions, one will prevail over the other. Some examples of photocatalysis on iron oxides have been reported, including the decomposition of saturated carboxylic acids (3, 4). According to Kormann et al. (5), only compounds which are prone to thermal oxidation and adsorb strongly onto the oxide surface, as sulfite or oxalate, are photooxidized at enhanced rates. On the other hand, photodissolution by carboxylic acids and reductants has been amply documented (6). Photoredox reactions involving iron oxides are also a matter of interest in atmospheric (7) and aquatic environmental chemistry (8–10).

EDTA and oxalic acid in iron oxide suspensions are photooxidized (8, 9, 11–13) in parallel with oxide dissolution. For hematite (α-Fe_2O_3), low dissolution rates are associated with low photooxidation rates. However, Siffert and Sulzberger (9) found relatively high oxalic acid photooxidation rates on α-Fe_2O_3 in strong aerobic conditions, with little corrosion of the oxide. Recent results from one of us (14) showed that maghemite is a good photocatalyst for oxalic acid and EDTA autoxidation, malonic acid being less extensively degraded under the same conditions.

The mechanism of maghemite, magnetite, and hematite photodissolution by oxalic acid and EDTA solutions has been reported previously (8, 11, 12). In this paper, we study the effect of 254-nm irradiation on maghemite and magnetite suspended in malonic acid solutions. Malonic acid is also able to form stable complexes with Fe^{III} in homogeneous solutions ($\log \beta_{101} = 7.50$; $\log \beta_{102} = 13.04$; $\log \beta_{103} = 16.6$; ref. 15), suggesting the possibility of a considerable extent of adsorption and the consequent formation of surface complexes with iron oxides. Some results of iron oxide thermal dissolution in malonic acid have been reported by Suter et al. (16), and a more detailed study has been completed in our laboratories (17). As in analogous systems, aggressitivity is found to be largest at an intermediate pH value, governed by the pH-dependency of the adsorption of weak acids (17, 18), that responds to the stability of iron–malonate complexes and to the need to protonate the surface.

The results presented here are important in the context of the development of solvents for iron oxides in the decontamination of nuclear reactor components. Oxalic acid is a reagent of choice, and the possibility of replacing it by malonic acid has been a matter of interest because of the potential danger of corrosion by oxalic acid. Photochemical initiation of dissolution is presently a possible way to overcome the high passivity of special pieces.

Experimental

Maghemite was the same commercial sample used in previous studies (8, 11, 12). It was composed of acicular particles, its specific surface area being 25 $m^2\ g^{-1}$. Magnetite was prepared in our laboratories as previously described (19). Its specific surface area was 9.7 $m^2\ g^{-1}$ and it was composed by cubo-octahedral particles.

The oxides were characterized by chemical analyses, X-ray diffractometry, SEM and BET surface area measurements.

Malonic acid (Mallinckrodt 99%) was dried under reduced pressure before use. Fresh aqueous solutions in boiled water were prepared in every case immediately before each experiment. All other reagents were of analytical purity and used without further purification. Water was bidistilled in a quartz apparatus.

Thermal and photochemical (254 nm) experiments were carried out as previously described (8, 12). In thermal experiments, N_2 (bubbled through alkaline pyrogallol and water) was passed through the reactor

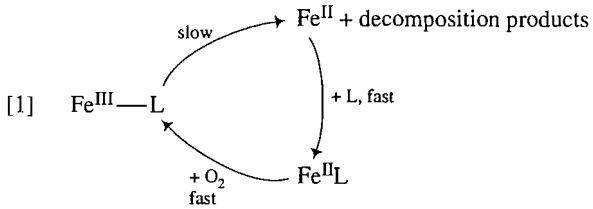
for 20 min before the run, and sampling was started after the addition of the oxide. In some experiments, Fe^{2+} was added in the form of weighed amounts of Mohr salt ($Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$) previously dissolved in some drops of boiled water. Photochemical runs were performed in deoxygenated atmosphere (unless indicated), bubbling N_2 for 10 min and closing the cell before irradiation. Experiments in oxygenated media were carried out by bubbling a water-saturated oxygen stream. Temperature was kept at 55°C (±0.1°C) in all cases. The experiments were performed at pH 4, using NaOH for pH adjustment. When applicable, fresh concentrated deareated ascorbic acid aqueous solution or solid silver nitrate were added in appropriate amounts. Due to the large excess of $Hmal^-$, ionic strength remains constant within 3% in the whole course of the dissolution reaction.

The results of the dissolution experiments were analyzed following the amount of iron dissolved after the runs. No efforts were made to measure the amount of malonic acid decomposed. Malonic acid is potentially capable of reducing Fe^{III}, in a fashion similar to oxalic acid. However, it has been documented that in the course of low temperature thermal dissolution of Fe^{III} oxides, the extent of the redox reaction to yield Fe^{II} is minor. Only at high temperatures (20) or under UV-irradiation, the redox reaction takes place. In the case of oxalic acid, the reaction products of the photochemical reaction with dissolved Fe^{III} are Fe^{II} plus CO_2; in the case of malonic acid, no information is available. The photo-Kolbe reaction, yielding CO_2 plus CH_3COOH, is a well-known decomposition pathway in the course of heterogeneous photolysis (14, 21) that can be viewed as a parallel, competing pathway with reductive photodissolution. At the high levels of malonic acid used in this work, the photo-Kolbe reaction does not deplete the ligand appreciably in the time span of our experiments. Iron was determined by the thioglycolate method (22) after filtration of the samples through 0.2 μm filter membrane. When Ag^+ was added, the suspension was first poured on a diluted NaCl solution, the mixture filtered, and the analysis performed as usual on the filtrate. In the measuring media, the red Fe^{III} species decomposes slowly, but the resulting Fe^{II} complex is rapidly reoxidized in the presence of air and excess ligand; the method therefore measures total iron:



Absorbances were measured in a Shimadzu 210 A spectrophotometer.

Results

The dissolution experiments were performed at pH 4, with 0.6 mol dm^{-3} malonic acid at 55°C. These conditions allow to attain the highest rates of dissolution (17). To supplement the previous study of magnetite dissolution by malonic acid and malonic acid/ferrous salt mixtures (17), some thermal maghemite experiments were performed. The results are summarized in Figs. 1–4. The thermal rates of dissolution (curve 1*a* for γ-Fe_2O_3 and curve 2*f* for Fe_3O_4) are enhanced by ascorbic acid (cf. curves 1*a* vs. 1*e* and 1*f* for γ-Fe_2O_3), and almost completely arrested by O_2 and Ag^+ (not shown). Ferric ion does not change the thermal dissolution rate (not shown).

Irradiation enhances largely the rate of dissolution in the absence of oxidants or reductants (cf. curves 1*a* vs. 3*a*, and 2*f* vs. 2*a*). In the presence of ascorbic acid, photochemical rates are enhanced (cf. curves 3*e* and 3*f* vs. 3*a*), whereas O_2 and Ag^+ are effective to quench dissolution even under light. At a concentration of 2×10^{-4} mol dm^{-3}, Fe^{III} does not influence photochemical rates; at higher concentrations, the effect is uncertain and shall not be further discussed (* in Fig. 2).

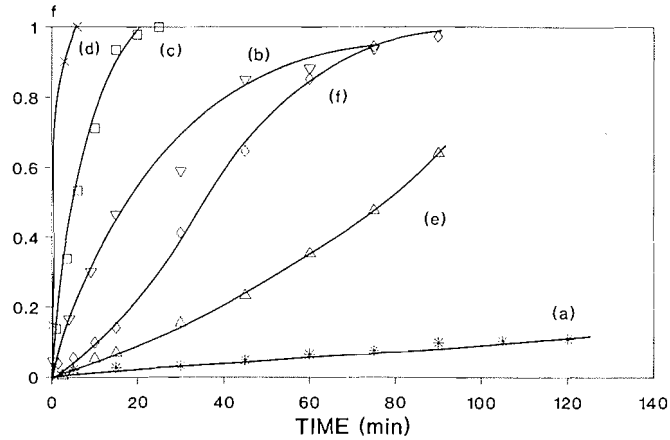


FIG. 1. Iron fraction thermally dissolved from γ-Fe_2O_3 (0.2 g dm^{-3}) by malonic acid (0.6 mol dm^{-3}) at 55°C and pH 4, N_2 atmosphere, as a function of time. (*a*): no other additives (*); (*b*): $[Fe^{2+}]_0 = 6.8 \times 10^{-5}$ mol dm^{-3} (▽); (*c*): $[Fe^{2+}]_0 = 2.0 \times 10^{-4}$ mol dm^{-3} (□); (*d*): $[Fe^{2+}]_0 = 1.0 \times 10^{-3}$ mol dm^{-3} (×); (*e*): [ascorbic acid] = 1.0×10^{-4} mol dm^{-3} (△); (*f*): [ascorbic acid] = 1.0×10^{-3} mol dm^{-3} (◇).

(*a*): no other additives (+); (*b*): $[Ag^+] = 3.0 \times 10^{-3}$ (◇); (*c*): no other additives, O_2 atmosphere (×); (*d*): $[Fe^{3+}] = 2.0 \times 10^{-4}$ mol dm^{-3} (□); (*e*): $[Fe^{3+}] = 1.0 \times 10^{-3}$ mol dm^{-3} (*); (*f*): thermal curve, no other additives (from ref. 17) (△).

Discussion

General mechanism

The general mechanism for the dissolution of an iron oxide in the presence of a reductive ligand in acid media can be described through the following steps (6):

(*a*) Chemisorption preequilibrium:

$$[2] \qquad > Fe^{III} + L^{n-} \overset{H^+}{\rightleftharpoons} > Fe^{III}\text{—}(L^{n-})(H^+)$$

where > denotes the lattice surface of the oxide.

(*b*) Slow acid dissolution of $>Fe^{III}$—L surface complexes:

$$[3] \qquad > Fe^{III}\text{—}(L^{n-})(H^+) \overset{R_H}{\underset{H^+}{\longrightarrow}} (Fe^{III} - L)^{3-n}_{aq}(+H^+)$$

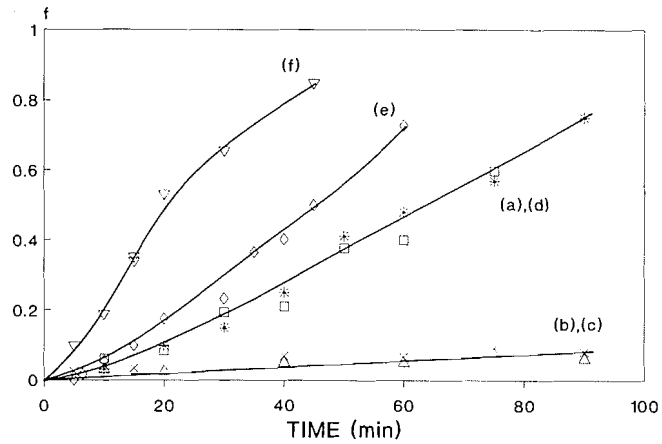

FIG. 3. Iron fraction photochemically (254 nm) dissolved from γ-Fe_2O_3 (0.2 g dm^{-3}) by malonic acid (0.6 mol dm^{-3}) at 55°C and pH 4, N_2 atmosphere except (*c*), as a function of time. (*a*): no other additives (∗); (*b*): $[Ag^+] = 3.0 \times 10^{-3}$ mol dm^{-3} (△); (*c*): no other additives, O_2 atmosphere (×); (*d*): $[Fe^{3+}] = 2.0 \times 10^{-4}$ mol dm^{-3} (□); (*e*): [ascorbic acid] $= 1.0 \times 10^{-3}$ mol dm^{-3} (◇); (*f*): [ascorbic acid] $= 1.0 \times 10^{-2}$ mol dm^{-3} (▽).

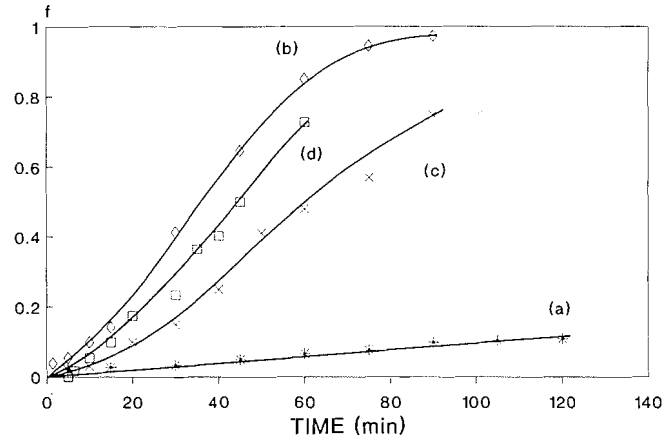

FIG. 4. Effect of ascorbic acid on the thermal and photochemical dissolution of γ-Fe_2O_3 (0.2 g dm^{-3}) by malonic acid (0.6 mol dm^{-3}) at 55°C and pH 4, N_2 atmosphere. (*a*): thermal, [ascorbic acid] = 0 (∗); (*b*): thermal, [ascorbic acid] $= 1.0 \times 10^{-3}$ mol dm^{-3} (◇); (*c*) photochemical, [ascorbic acid] = 0 (×); (*d*) photochemical, [ascorbic acid] $= 1.0 \times 10^{-3}$ mol dm^{-3} (□).

(*c*) Slow reductive dissolution of $>Fe^{III}$—L surface complexes:

$$[4] \qquad >Fe^{III}—(L^{n-})(H^+) \xrightarrow[L]{R_R} >Fe^{II}—(L^{(n-1)})^{\bullet -}(H^+) \longrightarrow Fe^{II}_{aq} + L^{(n-1)})^{\bullet -} + (H^+) \downarrow L^{n-} \; (Fe^{II} - L)^{2-n}_{aq}$$

(*d*) Fast charge transfer reaction between Fe^{II}—L complexes and $>Fe^{III}$ surface centers:

$$[5] \qquad >Fe^{III}—(L^{n-}) + (Fe^{II} - L)^{2-n}_{aq} \xrightarrow[H^+]{k_{Th}} >Fe^{II}—L^{n-}(H^+) + (Fe^{III}—L)^{3-n}_{aq} \downarrow L^{n-} \; (Fe^{II} - L)^{2-n}_{aq}$$

In addition, ferrous complexes in solution suffer fast autoxidation by oxygen or by other oxidants (Ox):

$$[6] \qquad (Fe^{II}—L)^{2-n}_{aq} \xrightarrow[Ox]{k_{Ox}} (Fe^{III}—L)^{3-n}_{aq}$$

For slowly dissolving oxides, traces of O_2 may become important in arresting dissolution through the efficient removal of Fe^{II}.

Under 254-nm irradiation, photochemical initiation produces Fe^{2+}, which triggers thermal dissolution. Equations [7] to [10] must be added to the previous thermal equations [2] to [6]. Also, homogeneous photolysis of Fe^{III}-complexes in solution can take place, after some amount of Fe^{III} is put in solution (eq. [11]).

$$[7] \qquad \text{oxide} + h\nu \xrightarrow{I_a^p} e^-_{cb} + h^+_{vb}$$

$$[8] \qquad e^-_{cb} + h^+_{vb} \xrightarrow{R_C} \text{recombination}$$

$$[9] \qquad >Fe^{III} + e^-_{cb} \xrightarrow{R_{Ph}} >Fe^{II} \longrightarrow Fe^{II}_{aq}$$

$$[10] \qquad h^+ + L \longrightarrow \text{Oxidation products of L}$$

$$[11] \qquad (Fe^{III}—L)^{3-n}_{aq} \xrightarrow{k_h} (Fe^{II}—L)^{(2-n)}_{aq}$$

where I_a^p is the light intensity absorbed by the solid. If S is the instantaneous surface area and V the suspension volume, calling ϕ_1 and ϕ_2 the quantum yields of e^-/h^+ pair formation and recombination respectively, $R_{Ph}S/V = I_a^p\phi_1$ is the rate of heterogenous $>Fe^{II}$ photoproduction (considering recombination negligible), and $R_C = I_a^p\phi_2$. In eq. [11], $k_h = I_a^s\phi_3$ is the specific rate constant, ϕ_3 being the quantum yield of Fe^{II} production in solution through the homogeneous photolysis, and I_a^s the light intensity absorbed by the complex in solution.[3] If S_0 is the initial oxide surface area and f is the dissolved fraction of total iron ($f = (m_0 - m)/m_0$, m_0 and m being the initial and instantaneous oxide mass), for magnetite (cubo-octahedral particles) $S = S_0(1-f)^{2/3}$ and for maghemite (acicular particles) $S = S_0(1-f)^{1/2}$. Therefore, the general rate expressions derived from this mechanism are given by eqs. [12]–[14] for magnetite and [18]–[20] for maghemite.

$$[12] \qquad \frac{d[Fe^{2+}]}{dt} = (0.5R_H + 1.5R_R + 1.5R_{Ph} + 0.5k_{Th}[Fe^{2+}])\frac{S_0}{V}(1-f)^{2/3} - k_{ox}[Ox][Fe^{2+}] + k_h[Fe^{3+}]$$

$$[13] \qquad \frac{d[Fe^{3+}]}{dt} = (R_H + k_{Th}[Fe^{2+}])\frac{S_0}{V}(1-f)^{2/3} + k_{Ox}[Ox][Fe^{2+}] - k_h[Fe^{3+}]$$

[3]Sometimes, direct photolysis of surface $>Fe^{III}$ complexes in their LTMCT band has been invoked, but not documented. A simple analysis of the relative probabilities of exciting the oxide through creating of (e^-, h^+) pairs and through the LTMCT band can be made on the basis of the absorptivity and availability of chromophores (see refs. 11 and 23). The results strongly favor the former pathway. In a very special case (thiocyanate) (24), the LTMCT band could be directly measured; even here, no ensuing photochemistry could be demonstrated (25). Anyhow, even if operative, this alternative pathway leads to the same kinetic expressions.

$$[14] \qquad \frac{df}{dt} = \left(1.5\frac{MV}{m_0}\right)(R_H + R_R + R_{Ph} + k_{Th}[Fe^{2+}])\frac{S_0}{V}(1-f)^{2/3}$$

where M is the FeO_x molar mass. This equation further simplifies when [Ox] = 0 and $k_h[Fe^{3+}] = 0$ to yield

$$[15] \qquad \frac{df}{dt} = \left[\left(1.5\frac{MV}{m_0}\right)(R_H + R_R + R_{Ph}) + 0.5k_{Th}f\right]\frac{S_0}{V}(1-f)^{2/3}$$

It should be noted that eq. [14] is inadequate to describe the length of the induction period whenever an oxidant is present; this issue has been discussed in ref. 8.

Magnetite photodissolution

According to the literature (26), the quantum yield of the photochemical decomposition of aqueous trismalonato–iron(III) complex under near-UV irradiation is three orders of magnitude lower than that of the trisoxalate complex in the same conditions. In agreement, the irradiation at 254 nm of 0.6 mol dm^{-3} malonic acid and 2.0×10^{-4} mol dm^{-3} Fe^{3+} at pH 4 and 55°C under N_2 atmosphere (to simulate the conditions of the heterogeneous system), gives a quantum yield of Fe^{II} production of 5.6×10^{-4} mol $einstein^{-1}$. Thus, the contribution of the k_h term in eqs. [12] and [13] can be neglected and, in the absence of oxidants, the k_{ox} term is also zero; therefore, the approximate eq. [15] is valid. The low quantum yields of Fe^{III}—malonate photodecomposition also explain why the addition of 2×10^{-4} mol dm^{-3} Fe^{3+} does not cause any effect on the rate of photodissolution (see curve *d* in Fig. 2), in contrast to the behavior in EDTA and oxalic acid media (8, 12). Some data suggest that Fe^{III} at higher concentration may also inhibit the onset of photodissolution (see curve 2*e*).

Numerical solution of eq. [15], using the data from the thermal experiments (17) to derive R_R, R_H, and k_{Th}, fits reasonably well the experimental values with $R_{Ph} = 1.0 \times 10^{-11}$ mol cm^{-2} s^{-1} for magnetite photodissolution (Fig. 5).

The addition of strong oxidants such as Ag^+ or O_2 to the irradiated systems almost suppresses dissolution (see curves *b* and *c* in Figs. 2 and 3). The effect is not the simple homogeneous Fe^{2+} oxidation included in the rate eqs. [12] and [13]. Silver salts (under N_2) can produce the following effects: (*i*) oxidation of Fe^{II} to Fe^{III}, not only in bulk solution but also on the oxide surface and (*ii*) competition with $>Fe^{3+}$ for created photoelectrons, thus reducing R_{Ph} (eq. [9]):

As in other cases (27), SEM and EDS examination demonstrated that silver particles are formed by reduction of Ag^+ (Fig. 6).

In the case of oxygen, (*i*) and (*ii*) are again operative. Photoelectron scavenging is represented by eq. [17]:

$$[17] \qquad O_2 + e^-_{cb} \longrightarrow O_2^-$$

The potential of the conduction bandedge of iron oxides (E_{cb} = +0.18 V at pH 4) is not adequate to reduce oxygen to superoxide radical (E = −0.268 E at pH 4) (5), and oxidation of $>Fe^{II}$ to $>Fe^{III}$ before Fe^{II} can be detached from the surface is the main cause of dissolution inhibition. This oxidation implies previous direct interaction between $>Fe^{II}$ and O_2, and a subsequent pathway that obviates the need to form free $\cdot O_2H$ radicals.

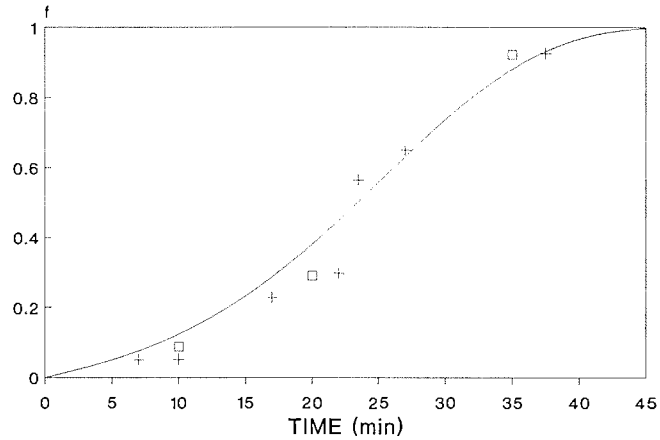

FIG. 5. Fitting of the 254-nm photodissolution curve for Fe_2O_4 in malonic acid at 55°C and pH 4. Experimental data (+) and (□) are those of Fig. 2 (*a*) and (*d*). Solid curve was obtained through the numerical solution of eq. [15] with the parameters of Table 1.

In both cases (Ag^+ or O_2 addition), the low amount of photoproduced $iron_{dissolved}$ hinders a quantitative analysis to evaluate kinetic parameters.

Maghemite dissolution

There was no previous information on the thermal dissolution of maghemite by malonic acid, and we explored this system to obtain the parameters required to describe photodissolution.

Thermal dissolution of maghemite is slower than that of magnetite, due to the lack of structural Fe^{II} in the lattice. In this case, eqs. [18]–[20] apply, which take into account the acicular shape of the particles.

$$[18] \qquad \frac{d[Fe^{2+}]}{dt} = R_R\frac{S_0}{V}(1-f)^{1/2} - k_{ox}[Ox][Fe^{2+}]$$

$$[19] \qquad \frac{d[Fe^{3+}]}{dt} = (R_H + k_{Th}[Fe^{2+}])\frac{S_0}{V}(1-f)^{1/2} + k_{Ox}[Ox][Fe^{2+}]$$

$$[20] \qquad \frac{df}{dt} = \left(\frac{MV}{m_0}\right)(R_H + R_R + k_{Th}[Fe^{2+}])\frac{S_0}{V}(1-f)^{1/2}$$

In the absence of added Fe^{2+}, dissolution is extremely slow, and $S \approx S_0$ in the whole time span of our experiments. The analytical solution of eqs. [18] and [19] setting $k_{ox}[Ox] = 8.3 \times 10^{-3}$ s^{-1}, leads to the values $R_R = 1.5 \times 10^{-14}$ mol cm^{-2} s^{-1}, $R_H = 8.6 \times 10^{-13}$ mol cm^{-2} s^{-1}, $k_{Th} = 4.4 \times 10^{-7}$ dm^3 cm^{-2} s^{-1}. These values fit all the experimental data, submitted to large error margins in the first two values (Fig. 7). Numerical solution of eq. [20], considering area changes and assuming that $[Fe^{2+}]$ is very low, also fits the data (see Fig. 7). The low extent of maximum observed dissolution results in linear f/t predicted relationships that do not warrant further elaborate discussion. Alternatively, a better fitting may be achieved, if the dissolution factors at very short times (<5 min) are attributed essentially to an R_H-type pathway involving fine and very reactive particles. In such a case, a slightly decreased R_H value may be derived (lower by ca. 15%) without sensibly altering other kinetic parameters.

When a ferrous salt is added, such that the contribution to $[Fe^{2+}]$ from [4] and [5] can be neglected, eq. [20] can be integrated assuming an exponential decay of the initial Fe^{2+}

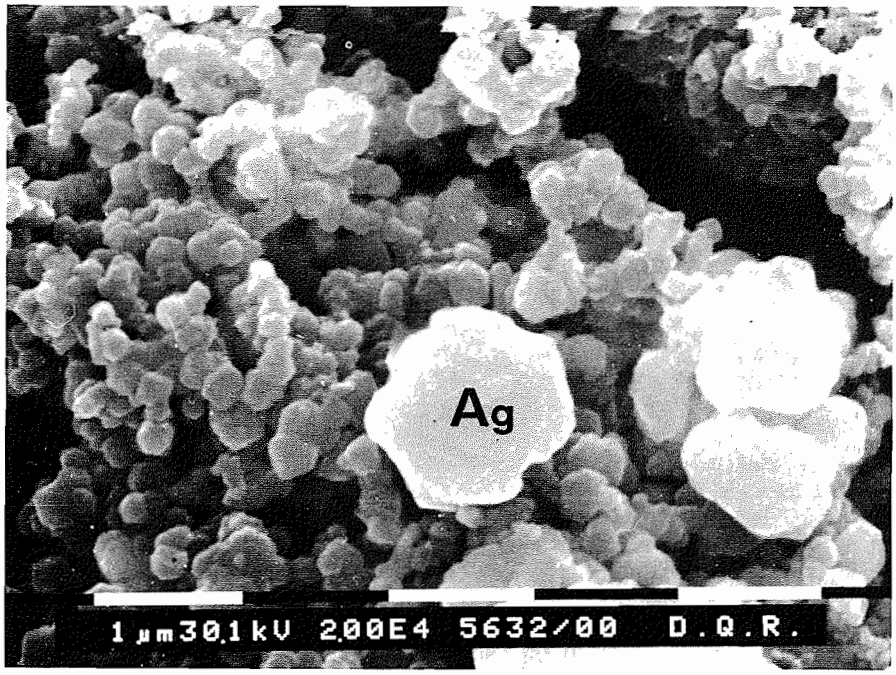

FIG. 6. SEM picture of Fe_3O_4 treated with malonic acid under light in the presence of $AgNO_3$, under retrodispersed illumination; brighter larger particles are shown by EDS to be composed essentially of Ag, whereas smaller darker ones are magnetite.

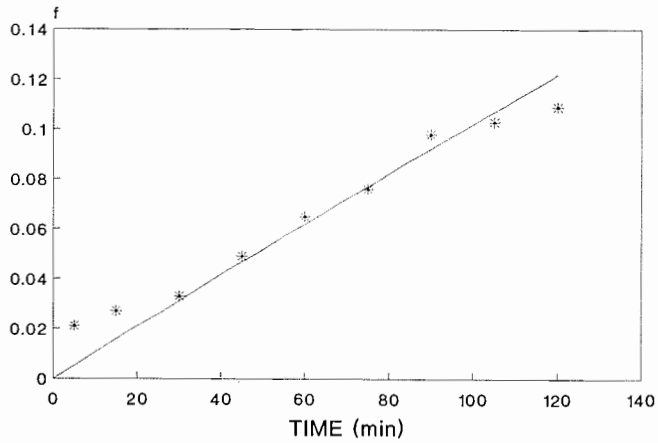

FIG. 7. Fitting of the thermal dissolution curve for γ-Fe_2O_3 in malonic acid at 55°C and pH 4. Experimental data (∗) are those of Fig. 1 (*a*). Solid curve was obtained through the numerical solution of eq. [20] with the parameters of Table 1.

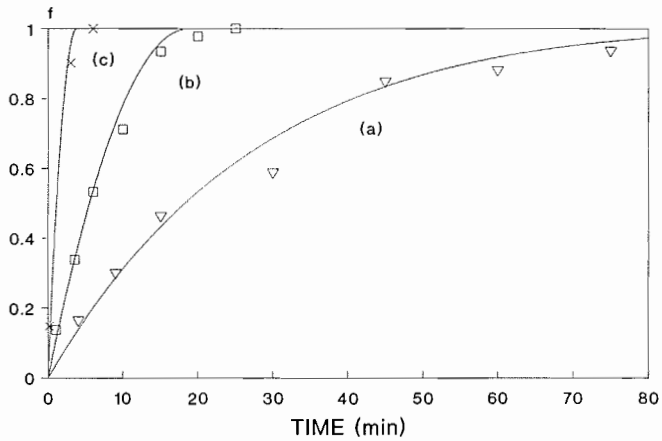

FIG. 8. Fitting of the thermal dissolution curve for γ-Fe_2O_3 in malonic acid at 55°C and pH 4 in the presence of Fe^{2+}. Experimental data (▽), (□), and (×) are those of Fig. 1 (*b*), (*c*), and (*d*), respectively. Solid curves were obtained through the numerical solution of eq. [22] with the parameters of Table 1 and $[Fe^{2+}]_0 = 6.8 \times 10^{-5}$ mol dm^{-3} (*a*), 2.0×10^{-4} mol dm^{-3} (*b*), and 1.0×10^{-3} mol dm^{-3} (*c*), respectively.

concentration with time, due to the entrance of oxygen or the presence of other oxidants, i.e.:

$$[21] \qquad [Fe^{2+}] = [Fe^{2+}]_0 \, e^{-t/\tau}$$

where $\tau = (k_{ox}[Ox])^{-1}$. Equation [20] becomes

$$[22] \qquad \frac{df}{dt} = \left(\frac{MV}{m_0}\right)(R_R + R_H + k_{Th}[Fe^{2+}]_0 \, e^{-t/\tau}) \frac{S_0}{V} (1-f)^{1/2}$$

Using the boundary condition $[Fe^{2+}]_0 = c$, corresponding to experiments with added ferrous salts, the experimental data can be fitted with the same above parameters R_R, R_H, and k_{Th} (see Fig. 8). For the numerical solution of eq. [22], when $[Fe^{2+}]_0 = 6.8 \times 10^{-5}$ mol dm^{-3}, a value of $\tau = 3.6 \times 10^3$ s ($k_{ox}[Ox] = 2.8 \times 10^{-4}$ s^{-1}) was taken, whereas for $[Fe^{2+}]_0 = 2.0 \times 10^{-4}$ and 1.0×10^{-3} mol dm^{-3}, $\tau = \infty (k_{ox}[Ox = 0)$; in this last case, the decay of $[Fe^{2+}]$ due to its oxidation is negligible.

In the presence of ascorbic acid, dissolution rates increase noticeably; the shape of the f/t profile is sigmoidal (see Fig. 1, curves *e* and *f*). Ascorbic acid is a strong reductant known to reduce both dissolved Fe^{III} and iron oxides (28, 29); the original reaction products are dehydroascorbic acid and Fe^{II}. Therefore, it not only prevents oxidation of Fe^{2+} produced through pathway [6] and the reductive pathway, but also reduces any Fe^{3+} produced through reaction [3]. Therefore, eqs.

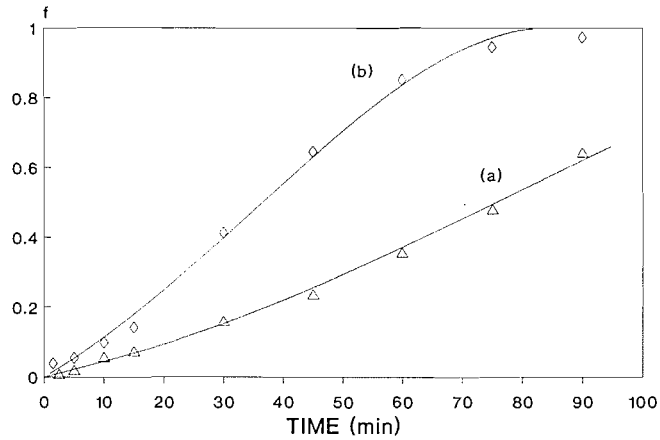

FIG. 9. Fitting of the thermal dissolution curve for γ-Fe_2O_3 in malonic acid at 55°C and pH 4, in the presence of ascorbic acid. Experimental data (△) and (◇) are those of Fig. 1 (*e*) and (*f*). Solid curves were obtained through the numerical solution of eq. [27] (see text); (*a*) [ascorbic acid] = 1.0×10^{-4} mol dm^{-3} (△); (*b*): [ascorbic acid] = 1.0×10^{-3} mol dm^{-3} (◇).

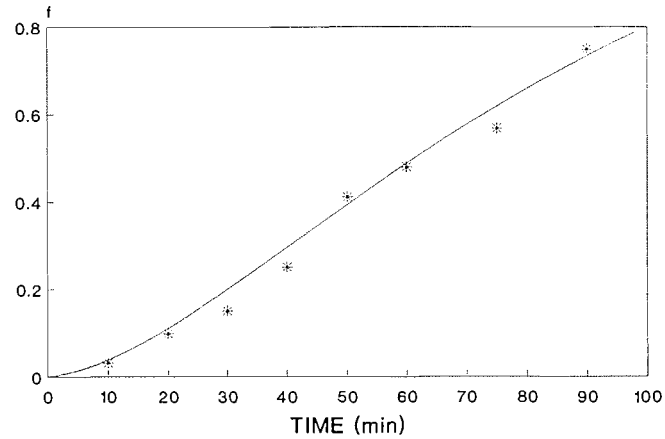

FIG. 10. Fitting of the 254-nm photodissolution curve for γ-Fe_2O_3 in malonic acid at 55°C and pH 4. Experimental data (*) are those of Fig. 3(*a*). Solid curve was obtained through the numerical solution of eq. [30] with the parameters of Table 1.

[4] and [5] prevail from the very beginning. Also, [Ox] = 0 can be safely assumed. Previous studies (29) demonstrated that ascorbate produces large enhancements in R_R, related with the labilizing effect of a facile intramolecular charge transfer in the surface $>Fe^{III}—(L^{n-})$ (H^+) complex (6, 30). Also, the surface complexation equilibrium [2] results in an apparent fractional order of R_R on ascorbate concentration:

$$[23] \qquad R_R = k[LH_n]^{0.5}$$

Equations [18]–[20] simplify to

$$[24] \qquad \frac{d[Fe^{2+}]}{dt} = R_R \frac{S_0}{V}(1-f)^{1/2}$$

$$[25] \qquad \frac{d[Fe^{3+}]}{dt} = k_{Th}[Fe^{2+}] \frac{S_0}{V}(1-f)^{1/2}$$

$$[26] \qquad \frac{df}{dt} = \left(\frac{MV}{m_0}\right)(R_R + k_{Th}[Fe^{2+}]) \frac{S_0}{V}(1-f)^{1/2}$$

Assuming that generation of Fe^{2+}, described by eq. [24], does not depend very much on area changes, we can integrate this equation with $S = S_0$, and rewrite eq. [26]:

$$[27] \qquad \frac{df}{dt} = \left(\frac{MV}{m_0}\right)\left(R_R + k_{Th}R_R \frac{S_0}{V}t\right) \frac{S_0}{V}(1-f)^{1/2}$$

The numerical solution of eq. [27] that fits the experimental data for an initial ascorbic acid concentration of 1.0×10^{-4} mol dm^{-3}, gives $R_R = 3.0 \times 10^{-12}$ mol cm^{-2} s^{-1}. In the case of 1.0×10^{-3} mol dm^{-3} ascorbic acid initial concentration, R_R is somewhat higher (8.5×10^{-12} mol cm^{-2} s^{-1}). The results of the fitting can be seen in Fig. 9. The dependence of R_R on ascorbic acid concentrations is in agreement with eq. [23].

The best fitting k_{Th} value is $1.0 - 1.1 \times 10^{-8}$ dm^3 cm^{-2} s^{-1} for both ascorbic acid concentrations, appreciably lower than the value found in ascorbate-free malonate media. The difference probably indicates a much more efficient bridging between the two metallic centers ($>Fe^{III}$ and Fe^{II}) by malonate.

Under 254-nm irradiation, the applicable kinetic expressions are

$$[28] \qquad \frac{d[Fe^{2+}]}{dt} = (R_R + R_{Ph}) \frac{S_0}{V}(1-f)^{1/2} - k_{ox}[Ox][Fe^{2+}] + k_h[Fe^{3+}]$$

$$[29] \qquad \frac{d[Fe^{3+}]}{dt} = (R_H + k_{Th}[Fe^{2+}]) \frac{S_0}{V}(1-f)^{1/2} + k_{ox}[Ox][Fe^{2+}] - k_h[Fe^{3+}]$$

$$[30] \qquad \frac{df}{dt} = \left(\frac{MV}{m_0}\right)(R_R + R_H + R_{Ph} + k_{Th}[Fe^{2+}]) \frac{S_0}{V}(1-f)^{1/2}$$

The analytical solutions of eqs. [28] and [29] (neglecting area changes) with the previous calculated values of R_R, R_H, and k_{Th} from thermal experiments, fit reasonably well the experimental data up to $f = 0.25$ with $k_{ox}[Ox] = 1.4 \times 10^{-3}$ s^{-1}, when R_{Ph} is set at 3.3×10^{-13} mol cm^{-2} s^{-1}. The numerical solution of eq. [30] with these parameters also fits the data for the whole dissolution curve (see Fig. 10).

As in the magnetite system, the addition of 2×10^{-4} mol dm^{-3} Fe^{3+} does not change the photochemical behavior, and the addition of Ag^+ or O_2 practically suppresses photodissolution (see Fig. 3).

The addition of 1.0×10^{-2} mol dm^{-3} ascorbic acid greatly accelerates photodissolution (see curve *f* from Fig. 3). However, irradiation in fact decreases somewhat the dissolution rates in 1.0×10^{-3} mol dm^{-3} ascorbic acid (cf. curves *b* and *d* from Fig. 4), probably because light essentially produces the direct photolysis or photocatalytic oxidation of ascorbic acid under 254-nm irradiation.

Comparison between magnetite and maghemite in malonic acid, and with EDTA systems

Table 1 shows the kinetic parameters for the thermal and photochemical reactions of malonic acid and EDTA with Fe_3O_4 and γ-Fe_2O_3. R_H value for γ-Fe_2O_3 is derived from curve 1*a* and is believed to be correct to ±5%; the fitting procedure for the other curves in Figs. 1 and 2 is not very sensitive to R_H, but depend crucially on the values assigned to R_R and R_{Ph}; because of the compromise involved in fitting various curves

TABLE 1. Comparison of the kinetic parameters for Fe_3O_4 and γ-Fe_2O_3 in malonic acid and in EDTA

(*a*) Malonic acid / 55°C

Parameter	Fe_3O_4	γ-Fe_2O_3
R_H/mol cm^{-2} s^{-1}	4.2×10^{-14}	8.6×10^{-13}
R_R/mol cm^{-2} s^{-1}	4.2×10^{-13}	1.5×10^{-14}
R_{Ph}/mol cm^{-2} s^{-1}	1.0×10^{-11}	3.3×10^{-13}
$R_H + R_R + R_{Ph}$/mol cm^{-2} s^{-1}	1.1×10^{-11}	1.2×10^{-12}
k_{Th}/dm^3 cm^{-2} s^{-1}	1.8×10^{-7}	4.4×10^{-7}

(*b*) EDTA / 30°C

Parameter	Fe_3O_4	γ-Fe_2O_3
$R_H + R_R + R_{Ph}$/mol cm^{-2} s^{-1}	8.5×10^{-12}	3.5×10^{-12}
k_{Th}/dm^3 cm^{-2} s^{-1}	2.3×10^{-7}	1.2×10^{-7}

with a single set of parameters, the error estimated for R_R and R_{Ph} reflects essentially the changes in the best-fit values in different experiments, and can be set at 10%; the thermal parameters for magnetite, as well as k_{Th} for γ-Fe_2O_3 were obtained in separate experiments and are correct to ±5%. R_{Ph} for magnetite is again correct within 10%.

Even though the interfacial regions on magnetite and maghemite are probably similar (31), the trends in the non-reductive (R_H) and reductive (R_R) pathways are reversed in these oxides. A probable rationale is the better electronic conductivity of Fe_3O_4 coupled with the more defective crystalline framework of γ-Fe_2O_3 that facilitates Fe^{III} transfer.

To photochemical initiation parameter R_{Ph} is lower for γ-Fe_2O_3 as also found in EDTA solutions, a fact that can be explained (12) by a faster recombination of e^-/h^+ pairs, facilitated by defects or vacancies in the oxide structure. In malonic acid, the value of k_{Th} is slightly higher for γ-Fe_2O_3 than for Fe_3O_4. The origin of the difference is not obvious, and does not seem to warrant elaborate interpretations.

As experiments in the malonic acid systems were carried out at higher temperatures than those in EDTA, the similarities in the values of the fitting parameters for both systems reflect the higher reactivity of iron oxides in EDTA media.

Synthèses et caractérisations structurales de complexes perchlorato et triflato anhydres de praseodyme(III)

JEAN LOUIS PASCAL,[1] MUSTHAPHA EL HADDAD, HEICKO RIECK ET FREDERIC FAVIER

Laboratoire des agrégats moléculaires et matériaux inorganiques, Unité de recherche associée au Centre national de la recherche scientique, n° 79, Case Courrier 015, Université Montpellier II, Sciences et Techniques du Languedoc, 34095 Montpellier Cédex 5, France

Reçu le 19 avril 1994

JEAN LOUIS PASCAL, MUSTHAPHA EL HADDAD, HEICKO RIECK et FREDERIC FAVIER. Can. J. Chem. **72**, 2044 (1994).

Les synthèses de $Pr(ClO_4)_3$, $Pr(OTf)_3$ (OTf = CF_3SO_3), $Pr(ClO_4)_3,Cl_2O_6$ et $NO_2Pr(ClO_4)_4$ sont décrites. La spectroscopie de vibration, la diffraction des rayons X sur poudre et l'EXAFS (pour $Pr(ClO_4)_3$) sont utilisés pour caractériser la structure des complexes. $[ClO_4]$ et [OTf] sont tridentés dans $Pr(ClO_4)_3$ et $Pr(OTf)_3$ et Pr est énéacoordiné. Dans $Pr(ClO_4)_3,Cl_2O_6$, le trioxyde de chlore est inséré dans la maille de $Pr(ClO_4)_3$ et présente l'équilibre ionique ↔ covalent. Dans NO_2 $Pr(ClO_4)_4$, on retrouve la structure de $Pr(ClO_4)_3$, le groupement $[ClO_4]$ supplémentaire est faiblement lié à Pr. $Pr(ClO_4)_3$ cristallise dans le système monoclinique ($P2_1/m$), a = 8,608; b = 11,827; c = 7,416 Å; β = 106,29° et V = 724,79 Å^3. L'EXAFS montre que Pr—O = 2,51 Å et Pr—Cl = 3,90 Å. $Pr(ClO_4)_3$ présente des phénomènes de fluorescence intenses lors d'une excitation par la radiation 488 nm d'un laser à argon ionisé.

JEAN LOUIS PASCAL, MUSTHAPHA EL HADDAD, HEICKO RIECK, and FREDERIC FAVIER. Can. J. Chem. **72**, 2044 (1994).

The syntheses of $Pr(ClO_4)_3$, $Pr(OTf)_3$ (OTf = CF_3SO_3), $Pr(ClO_4)_3{\cdot}Cl_2O_6$, and $NO_2Pr(ClO_4)_4$ are described. Vibrational spectroscopy, X-ray powder diffraction, and EXAFS (for $Pr(ClO_4)_3$) are used to characterize the structure of the complexes. $[ClO_4]$ and [OTf] appear as tridentate in $Pr(ClO_4)_3$ and $Pr(OTf)_3$ and Pr is 9-coordinated. In $Pr(ClO_4)_3{\cdot}Cl_2O_6$, chlorine trioxide is included in the lattice of $Pr(ClO_4)_3$ and shows the ionic ↔ covalent equilibrium. In $NO_2Pr(ClO_4)_4$, $Pr(ClO_4)_4^-$ retains the structure of $Pr(ClO_4)_3$, the extra $[ClO_4]$ is weakly bonded to Pr. $Pr(ClO_4)_3$ crystallizes in the monoclinic system ($P2_1/m$), a = 8.608; b = 11.827; c = 7.416 Å; β = 106.29°, and V = 724.79 Å^3. Distances Pr—O = 2.51 Å and Pr—Cl = 3.90 Å are determined by EXAFS. Strong fluorescence phenomena are observed when $Pr(ClO_4)_3$ is excited with the 488 nm line of an ionized Ar laser.

Introduction

Les connaissances sur les complexes perchlorato $[ClO_4]$ ou triflato $[CF_3SO_3]$ ou [OTf] anhydres sont restées pendant longtemps très limitées. La mise au point de méthodes de synthèses efficaces a permis d'entreprendre une étude systématique de ces composés. Citons les travaux de l'école Rosolovskii $[ClO_4]$ (1), de Lawrance et coll. [OTf] (2), Aubke et coll. [OTf] (3) et notre groupe $[ClO_4]$ et [OTf] (4, 5). Un certain nombre de complexes perchlorato et triflato anhydres de lanthanides(III) ont été analysés (6), mais des lacunes subsistent notamment parmi les éléments pouvant présenter un degré d'oxydation IV comme le cérium, le praséodyme... Une étude partielle des complexes de cérium(IV) a été réalisée (7), mais les données sur les complexes de praséodyme se limitent aux complexes solvatés de Pr(III) (8).

Dans les lignes suivantes, les synthèses de $Pr(ClO_4)_3$, $Pr(OTf)_3$, $Pr(ClO_4)_3,Cl_2O_6$ et $NO_2Pr(ClO_4)_4$ sont décrites. La caractérisation structurale par diffraction X sur poudres et spectroscopie de vibration IR et Raman est développée. Une première analyse EXAFS de $Pr(ClO_4)_3$ est proposée. Les phénomènes de fluorescence intenses, observés plus particulièrement lors de l'excitation de $Pr(ClO_4)_3$ et $Pr(OTf)_3$ par un rayonnement laser à la fréquence 488 nm, sont présentés.

Partie expérimentale

Attention : Le trioxyde de chlore et les perchlorates anhydres sont des composés particulièrement réactifs; ils doivent être manipulés avec beaucoup de prudence. Les quantités utilisées doivent être faibles et les réactions étroitement surveillées. Le manipulateur doit être protégé. Les mises en solution dans des solvants organiques sont hasardeuses.

Produits de base

Cl_2O_6, agent perchloratant, est préparé par oxydation de ClO_2 par un mélange O_3/O_2 puis purifié (6). Une distillation fractionnée préablable de HOTf (Fluka) est nécessaire. Les mises en solution aqueuse sont effectuées avec précaution (5). Pr_6O_{11} (Aldrich) est utilisé sans purification préalable. $Pr(ClO_4)_3,nH_2O$ est préparé par réaction de $HClO_4$ (OSI, 70%) sur Pr_6O_{11} et évaporation lente de la solution. Un processus analogue est utilisé pour obtenir $Pr(NO_3)_3,6H_2O$ à partir de HNO_3 (BDH, 70%). Dans ce dernier cas, la température ne doit pas dépasser 72°C afin de prévenir la formation d'oxo–hydroxo nitrato complexes.

La qualité des produits est vérifiée par diffraction X sur poudres ou (et) par spectroscopie Raman. L'analyse chimique des complexes est effectuée selon des méthodes déjà décrites (5, 6).

Préparation des complexes anhydres

Les réactions sont effectuées, sauf indications contraires, sur rampe à vide (9). Les évaporations d'acides se déroulent sous hotte aspirante. Les composés sont manipulés en boite à gants sous azote AGA «4,5» (<5 ppm en H_2O et O_2).

(a) Perchlorates de praséodyme

Pr_6O_{11} est aisément et totalement transformé, par un excès de Cl_2O_6, entre 5 et 15°C, en $Pr(ClO_4)_3,Cl_2O_6$, un solide orange (0,646 g de Pr_6O_{11} donnent 2,288 g de $Pr(ClO_4)_3,Cl_2O_6$ (attendu 2,299 g, soit un rendement par rapport à Pr_6O_{11} ≅ 99,5%). Ce dernier perd Cl_2O_6, sous vide dynamique, dès 50°C, pour donner $Pr(ClO_4)_3$, un solide vert jaune (calc. Pr: 32,08, ClO_4: 67,92; exp. Pr: 31,64, ClO_4: 68,35).

$Pr(ClO_4)_3$ anhydre peut être également obtenu par déshydratation de $Pr(ClO_4)_3,nH_2O$, soit par Cl_2O_6, soit par thermolyse à 200°C sous vide dynamique. Ce dernier processus est souvent décrit dans la littérature pour préparer des perchlorates de lanthanides anhydres (10). On préfère l'éviter car il est aléatoire et risque de conduire à des oxo–hydroxo perchlorato complexes.

$Pr(ClO_4)_3$ se transforme dès 295°C en Pr_2O_3. La décomposition est totale à 320°C.

Par action de Cl_2O_6 sur $Pr(NO_3)_3,6H_2O$, on aboutit à des perchlorato praséodymates de nitryle selon un processus déjà décrit (9) :

[1] $Pr(NO_3)_3,6H_2O + 12\ Cl_2O_6 \xrightarrow{5\text{–}15°C} (NO_2)_3Pr(ClO_4)_6 + 6\ ClO_2 + 3/2\ O_2 + 6\ HClO_4 + 6\ HClO_3$

[2] $(NO_2)_3Pr(ClO_4)_6 \xrightarrow{110\text{–}130°C} NO_2Pr(ClO_4)_4 + 2\ NO_2ClO_4$ (se sublime)

Note : Comme observé précédemment pour des complexes du même type (11), la spectroscopie de vibration et la diffraction de rayons X sur poudres montrent que $(NO_2)_3Pr(ClO_4)_6$ est le mélange $NO_2Pr(ClO_4)_4$–2 NO_2ClO_4. Il est délicat d'obtenir $NO_2Pr(ClO_4)_4$ parfaitement pur, il subsiste toujours des traces de NO_2ClO_4. $NO_2Pr(ClO_4)_4$ se décompose en $Pr(ClO_4)_3$ si l'on essaye de les faire disparaître à $T > 130°C$ (cf. figure 3).

(b) Triflate de praséodyme

Une solution de HOTf (0.5–1 N) contenant Pr_6O_{11}, en quantité légèrement inférieure à la stœchiométrie, est portée à ébullition, sous hotte ventilée. La poudre verte obtenue après évaporation à sec est placée sous vide dynamique (10^{-2} Torr (1 Torr = 133,3 Pa)), à 200°C durant 3 jours. On obtient $Pr(OTf)_3$ anhydre (calc. Pr: 23,96, OTf: 75,43; exp. Pr: 24,57, OTf: 76,03).

HOTf ou AnOTf ($(CF_3SO_2)_2O$) ne conduisent qu'à des mélanges de $Pr(OTf)_3$ et de NO_2OTf lorsqu'ils réagissent avec $Pr(NO_3)_3,6H_2O$,

Note : Devant l'échec de la préparation d'un complexe perchlorato anhydre de Pr(IV) par réaction de l'oxydant énergique Cl_2O_6 sur Pr_6O_{11} et le danger d'une réaction avec le mélange instable $HClO_4$–Cl_2O_7, nous avons essayé de synthétiser un triflate de Pr(IV) suivant : Pr_6O_{11} + HOTf + AnOTf. Après un mois en tube scellé à 130°C, des tests IR et de diffraction X sur poudres indiquent la formation de $Pr(OTf)_3$ et de PrO_2.

Appareillage

Les spectres IR sont enregistrés sur un spectromètre Bomen FTIR DA8. Les échantillons finement broyés sont placés entre deux faces en silicium (111) de 1 mm d'épaisseur, un porte échantillon dont l'étanchéité est assurée par deux joints toriques, les maintient durant l'analyse.

En Raman, on utilise un spectromètre Dilor piloté par un ordinateur PC 286 équipé d'un convertisseur analogique Digimetrix PC Lab 12 bits. La resolution est de 1 cm^{-1}. Les produits, scellés dans des tubes en Pyrex, de faible épaisseur, de 4 mm de diamètre extérieur, sont excités par un laser Spectra Physics à argon ionisé (514,5 ou 488,0 nm, puissance utilisée ≅140 mW). Le sel de chloryle, $Pr(ClO_4)_3,Cl_2O_6$, est refroidi à −180°C pour éviter la décomposition.

Les phénomènes de fluorescence et les raies Raman sont observés simultanément. Les conditions d'échantillonage sont identiques. La largeur des fentes est réduite étant donné la forte intensité des bandes de fluorescence.

$Pr(OTf)_3$ présentant un fond continu de fluorescence parasite à 488 ou 514,5 nm, les spectres Raman sont analysés grâce à un dispositif à transformée de Fourier relié au spectromètre infrarouge cité plus haut. La source lumineuse, 1064 nm, est un laser YAG CVI.

Les diagrammes de diffraction X sur poudres sont enregistrés sur un goniomètre Philips PW 1965/30 automatisé (12). Le porte échantillon est muni d'une fenêtre en beryllium de 0,25 mm d'épaisseur. L'étanchéité est assurée par une graisse inerte au Kelf et du ruban Téflon.

Les enregistrements d'absorption X (EXAFS) ont été effectués au LURE (13) sur DCI (ligne EXAFS 3) avec des caractéristiques de faisceau incident classiques : 1,85 GeV, 200 mA. Le monochromateur utilisé est constitué de deux monocristaux de silicium (311). Leur réglage optimum est réalisé avec une feuille de cuivre étalon de 25 μm en se plaçant au maximum du seuil K : 8979 eV. Avec le praséodyme, on travaille au seuil L_{III} : 5964 eV. Les échantillonnages sont effectués sous azote très sec en boite à gant. $Pr(ClO_4)_3$ finement broyé est intimement mélé à du nitrure de bore et du Nujol très sec. La pâte obtenue est placée dans un intercalaire entre deux feuilles de parafilm. Les spectres sont entregistrés à −180°C.

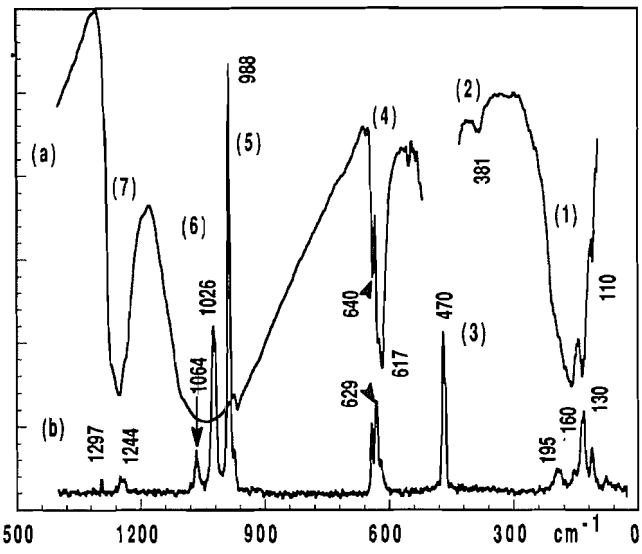

FIG. 1. Spectres IR (*a*) et Raman (*b*) de $Pr(ClO_4)_3$. (1) Réseau + νPr-O; (2) νPr-O (?); (3) $\delta_s ClO_{3p}$; (4) $\delta_{as} ClO_{3p}$ + ρ_r; (5) $\nu_s ClO_p$; (6) $\nu_{as} ClO_p$; (7) νClO_t (O_p : oxygène lié à Pr, O_t : oxygène terminal libre).

Résultats et discussions

Synthèses

La réaction «facile» de Cl_2O_6 sur Pr_6O_{11} est surprenante, en général Cl_2O_6 réagit très difficilement avec les oxydes étant donné leur arrangement cristallin compact (11). Aucune réaction n'est observée avec des oxydes de type Ln_2O_3 (Ln : lanthanides). La formation d'un complexe perchlorato à partir de Pr_6O_{11}, où Pr(IV) prédomine est, semble-t'il, favorisée par le caractère oxydant de Pr(IV) et l'existence d'un Cl(V) dans Cl_2O_6.

La formation d'un sel de nitryle à partir d'un nitrate est normale dans le milieu très acide $HClO_4$–Cl_2O_6 (11). La préparation de $Pr(OTf)_3$ est classique (5).

Note : La synthèse de Pr_2O_3 par décomposition thermique de $Pr(ClO_4)_3$ dès 300°C est intéressante car cet oxyde n'existe pas dans le commerce et est souvent préparé par des méthodes complexes (14).

Analyse structurale

(a) Spectroscopie de vibration

(i) $Pr(ClO_4)_3$. Les spectres de vibration IR et Raman de ce composé sont représentés sur la figure 1. Ils sont analogues à ceux des complexes $M(ClO_4)_2$ (M = Mn (15), Co, Ni (16), Zn (17) et Cd (18)) et $Ln(ClO_4)_3$ (Ln = Y, La, Nd, Sm, Gd et Er) (6). Ils sont caractéristiques d'un engagement tridenté du groupement ClO_4. Étant donné la stœchiométrie et le mode de coordination des perchlorates, Pr est énéacoordiné.

Les principales attributions déduites des résultats précédents sont notées dans la légende de la figure 1. La perte de symétrie du groupement $[ClO_4]$ ($T_d \rightarrow C_{3v}$) entraine des levées de dégénérescence ($\nu_{as} ClO_p$, déformations). La multiplicité de $\nu_s ClO_p$ ou de νClO_t peut s'expliquer par des effets de correlations liés à la symétrie locale autour de Pr (D_3) ou à l'état solide. Ces phénomènes se retrouvent sur les autres spectres de vibrations analysés plus loin.

Les vibrations Pr–O sont localisées autour de 160 cm^{-1} : fréquence inférieure à celles relevées pour les complexes de Ni ou Co (220 cm^{-1}) et Mn ou Zn (≅ 240 cm^{-1}). Ceci implique,

For personal use only.

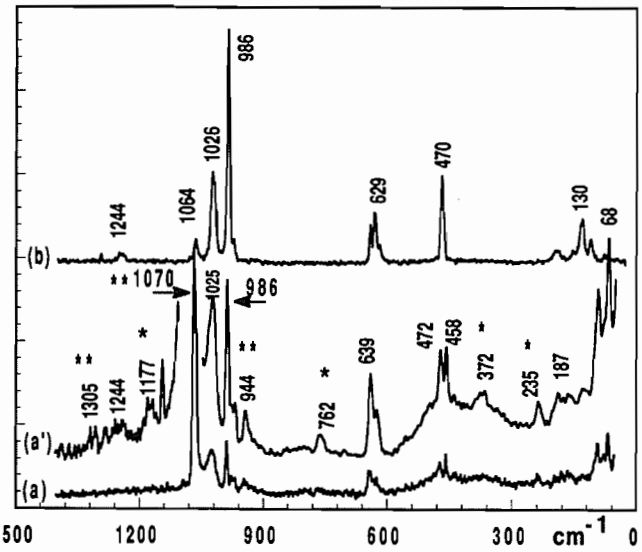

FIG. 2. Spectre Raman de $Pr(ClO_4)_3,Cl_2O_6$ (*a*) et (*a'*) comparé à celui de $Pr(ClO_4)_3$ (*b*). * Cl_2O_6 covalent, ** Cl_2O_6 ionique.

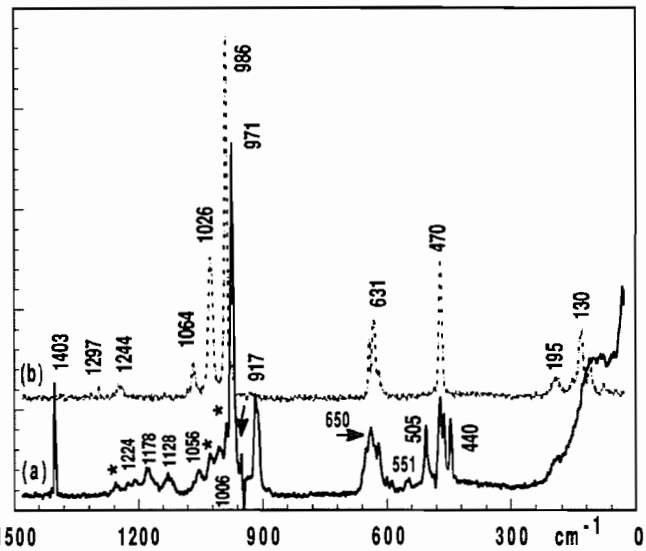

FIG. 3. Spectres Raman de $NO_2Pr(ClO_4)_4$ (*a*) et de $Pr(ClO_4)_3$ (*b*). Traces de NO_2ClO_4 (↓), et de $Pr(ClO_4)_3$ (*) dans $NO_2Pr(ClO_4)_4$.

étant donné le rayon ionique effectif élevé de Pr (128,4 pm pour une coordinance 9 (19)), une liaison Pr—O longue (cf. analyse EXAFS) et corrélativement, un caractère ionique important pour le complexe.

(ii) $Pr(ClO_4)_3,Cl_2O_6$. Le spectre Raman de $Pr(ClO_4)_3,Cl_2O_6$ est représenté sur la figure 2 (*a* et *a'*). On observe, sur la figure 2*a'*, la raie intense à 986 cm^{-1} ($\nu_s ClO_p$) et les raies à 1025 cm^{-1} ($\nu_{as} ClO_p$), 470 cm^{-1} ($\delta_s ClO_p$) et 1244 cm^{-1} (νClO_t) (O_p : oxygène lié à Pr, O_t : oxygène terminal libre), caractéristiques de $Pr(ClO_4)_3$. On relève également, les raies de Cl_2O_6 ionique à 1070 cm^{-1} ($\nu_s ClO_2^+$), 1305 cm^{-1} ($\nu_{as} ClO_2^+$) et 944 cm^{-1} ($\nu_s ClO_4^-$) et celles relatives à Cl_2O_6 covalent, $O_2ClOClO_3$ (20), à 762 cm^{-1} (νClO_p) 1025 et 1177 cm^{-1} (νClO_t), 372 cm^{-1} (ρ_r) et 235 cm^{-1} (ρ_r + δClOCl). On déduit de ces observations que $Pr(ClO_4)_3,Cl_2O_6$ est un mélange de $Pr(ClO_4)_3$ et de Cl_2O_6. Le trioxyde de chlore covalent est en équilibre avec la forme ionique $ClO_2^+ClO_4^-$. $\nu_s ClO_4^-$ apparait ici à 944 cm^{-1} au lieu de 918 cm^{-1} dans l'état solide (21), ClO_4^- ne présente pas d'interactions avec ClO_2^+ comme dans Cl_2O_6 solide pur. Au cours de la thermolyse de $Pr(ClO_4)_3,Cl_2O_6$ on peut isoler, à 55°C, un intermédiaire $Pr(ClO_4)_3,nCl_2O_6$ ($n \cong 0.333$) avec des caractéristiques spectroscopiques analogues au sel initial. L'existence de Cl_2O_6 libre après ce traitement thermique (Cl_2O_6 pur se décompose à la température ambiante) indique que celui-ci est relativement protégé donc vraisemblablement inséré dans la maille de $Pr(ClO_4)_3$. Ceci est en faveur d'une structure présentant des cavités d'accueil pour $Pr(ClO_4)_3$. Un modèle à canaux dérivé de ceux trouvés pour $PrCl_3$ (22) ou $Yb(ReO_4)_3$ (23) est probable.

Le comportement particulier de $Pr(ClO_4)_3,Cl_2O_6$ nous a incité à étudier le sel de nitryle voisin.

(iii) $NO_2Pr(ClO_4)_4$. Le spectre $NO_2Pr(ClO_4)_4$ est comparé à celui de $Pr(ClO_4)_3$ sur la figure 3. NO_2^+ apparait en Raman à 1403 cm^{-1} (ν_s) et 551 cm^{-1} (δ), en IR à 2349, 2365 cm^{-1} (ν_{as}) et 3732, 3740 cm^{-1} (ν_s + ν_{as}). Autour de 1000 cm^{-1}, on relève pour $[ClO_4]$ une séquence de raies : 971, 1006 et 1056 cm^{-1} comparable à celle observée pour $Pr(ClO_4)_3$ (986, 1026 et 1064 cm^{-1}). L'arrangement structural de $Pr(ClO_4)_3$ est conservé. L'abaissement des fréquences est provoqué par un perchlorate faiblement engagé (917, 1128 et 1178 cm^{-1}), analogue

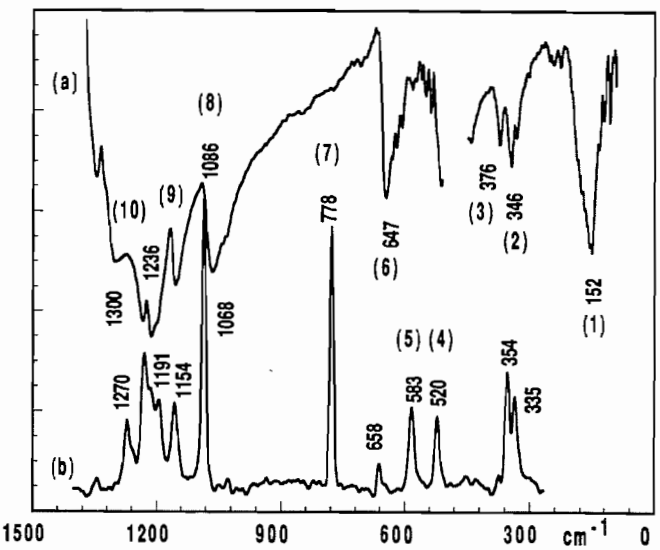

FIG. 4. Spectres IR (a) et Raman (b) de $Pr(CF_3SO_3)_3$. (1) Réseau + νPr-O; (2) $\rho_w SO_3$; (3) ρCS + $\delta_s CF_3$; (4) $\delta_{as} CF_3$; (5) $\delta_s SO_3$; (6) $\delta_{as} SO_3$; (7) $\delta_s CF_3$ + νCS; (8) $\nu_s SO_3$; (9) $\nu_{as} SO_3$; (10) ν_s + ν_{as} CF_3.

à ClO_4^- dans Cl_2O_6 solide (21), où les interactions $ClO_2 \leftrightarrow ClO_4$ sont fortes. Le comportement de $NO_2Pr(ClO_4)_4$ est différent des sels de type $AM(ClO_4)_3$ ($A = ClO_2^+, NO_2^+$; M = Mn, Co, Ni ....) (18), dans lesquels le squelette de $M(ClO_4)_2$ a disparu et où tous les perchlorates bidentés pontants sont équivalents et forment des chaînes $[M(ClO_4)_3]_\infty$.

(iv) $Pr(CF_3SO_3)_3$. Les spectres IR et Raman de $Pr(OTf)_3$ sont représentés sur la figure 4. Dans le domaine des vibrations de [OTf], 200–1500 cm^{-1}, les spectres sont voisins de ceux des composés ioniques (24). Le groupement [OTf] a donc une symétrie C_{3v}. On remarque que les fréquences νCS + δCF_3 : 354 (R). 376 cm^{-1} (IR) et de $\nu_s SO$: 1086 (R), 1068 cm^{-1} (IR) sont plus élevées que celles observées dans l'ion (respectivement $\Delta\nu$ = 14 et 40 cm^{-1}). Cet accroissement de fréquence est caractéristique d'un engagement tridenté du groupement [OTf] autour du métal (5).

Les principales attributions sont signalées dans la légende du

spectre. Les fréquences νM–O sont très proches de celles notées pour les perchlorates, les interactions ligand–praséodyme sont similaires.

(b) Diffraction X sur poudres

Les diagrammes de diffraction X de $Pr(ClO_4)_3$ et de $Pr(OTf)_3$ sont analogues respectivement à ceux des complexes $Ln(ClO_4)_3$ et $Ln(OTf)_3$ (Ln = La, Nd, Sm, Gd, Er) étudiés précédemment (6, 5*b*). Pour un même ligand, les complexes sont isostructuraux, mais vu l'encombrement plus important des triflates, ces derniers diffèrent des perchlorates. Le diagramme de $Pr(ClO_4)_3$ est indexé en fonction des paramètres de maille des complexes $Ln(ClO_4)_3$ (6) (tableau 1). Il cristallise dans le système monoclinique, groupe d'espace $P2_1/m$, a = 8,608; b = 11,827; c = 7,416 Å; β = 106,29°; V = 724,79 Å^3. Avec Z = 4, ceci conduit à une densité de 4,02, plus élevée que celle du complexe hydraté : 3,8 (8*a*).

L'indexation du diagramme de $Pr(OTf)_3$ (tableau 2) est plus délicate étant donné la qualité médiocre du spectre. Le programme de résolution statistique, TREOR (25), en se basant sur

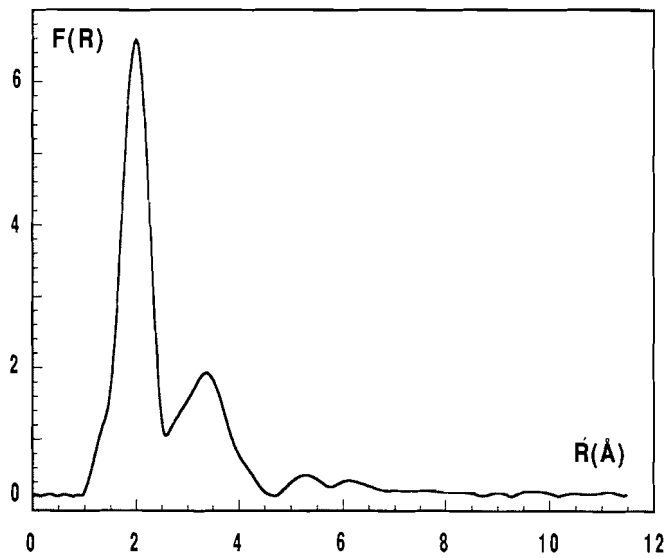

FIG. 5. Transformée de Fourier du spectre EXAFS de $Pr(ClO_4)_3$.

12 raies intenses, ne donne jamais de figures de mérite élevées (≤20%). Une solution possible est le système monoclinique et les paramètres : a = 11,56; b = 10,406; c = 7,346 Å; β = 103,73°; V = 858,55 Å^3.

Les diagrammes de $Pr(ClO_4)_3,Cl_2O_6$ et de $NO_2Pr(ClO_4)_4$ sont trop complexes pour être exploités.

(c) Spectroscopie d'absorption X (EXAFS) de $Pr(ClO_4)_3$

Les données sont analysées en utilisant «EXAFS pour le Mac» de Michalowicz (26). Les différentes étapes de calcul suivent celles décrites dans diverses publications de notre groupe (5*a*–27) (analyse du spectre d'absorption, normalisation, soustraction de l'énergie du préseuil, extraction par polynôme de degré 5 du spectre EXAFS, étude de la transformée de Fourier de ce spectre en utilisant une fenêtre de Kaiser et une pondération en k^3, filtrage des différentes contributions et recherche du meilleur accord théorie–experience en faisant varier les divers paramètres, N : nombre de proches voisins, σ : facteur de Debye–Waller, R : distance atome diffuseur – atome rétrodiffuseur). Les fonctions de phase et d'amplitude sont celles de McKale calculées par une méthode ab initio (28). La transformée de Fourier du spectre EXAFS de $Pr(ClO_4)_3$ est représentée sur la figure 5. Le premier maximum correspond à neuf atomes d'oxygènes à 2,51 Å du praséodyme. On retrouve l'environnement prévu par la stœchiométrie et la coordination tridentée de $[ClO_4]$. Le deuxième maximum est plus complexe mais neuf atomes de chlore à 3,90 Å de Pr sont suffisants pour affiner cette couche (Fig. 6). Ils sont significatifs d'une structure polymère. Si l'on se réfère aux données cristallographiques de $Pr(OH)_2NO_3$ (29) ou $PrCl_3$ (22) et de divers acétates de praséodyme (30), on devrait pouvoir trouver des atomes de Pr autour de 4,20 Å. Il est possible de placer trois atomes de Pr à 4,32 Å d'un autre Pr mais cela n'apporte pas d'amélioration dans l'affinement final (fig. 6). La présence de Pr à cette distance est contredite par les résultats acquis lors de l'analyse EXAFS de $Ni(ClO_4)_2$ et de $Co(ClO_4)_2$ (16), dans lesquels la distance métal–métal est de 4,80 Å, distance nettement plus longue que dans les chlorures correspondants (≅3,54 Å), d'autre part dans $Yb(ReO_4)_3$, la distance minimum Yb–Yb est de 6,07 Å (23). Notons également qu'il est difficile de placer

For personal use only.

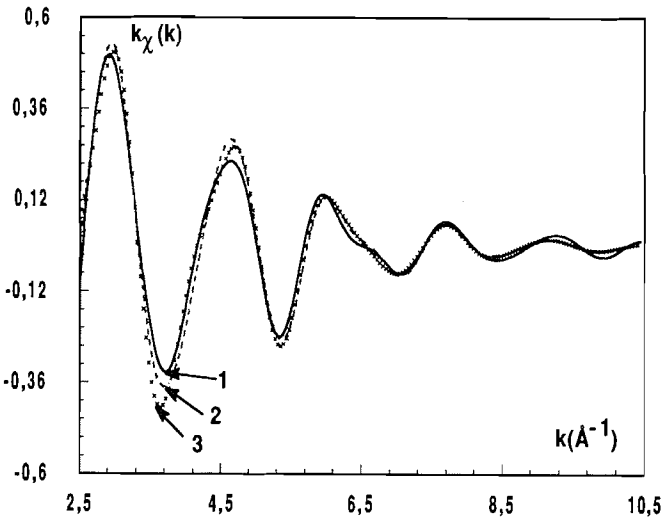

FIG. 6. Spectre EXAFS filtré (1ère et 2ème couche) dans l'espace L_{III} (1) comparé au spectres calculés : (2) contribution de Cl et de Pr dans la 2ème couche (R* = 4,8%); (3) contribution de Cl dans la 2ème couche (R* = 3,8%). * Qualité de l'affinement estimée à partir du facteur résiduel R. ($R = \Sigma_k(k[\chi_{exp}(k)] - k[\chi_{th}(k)])^2k^3/\Sigma_k(k[\chi_{exp}(k)]^2)k^3$)

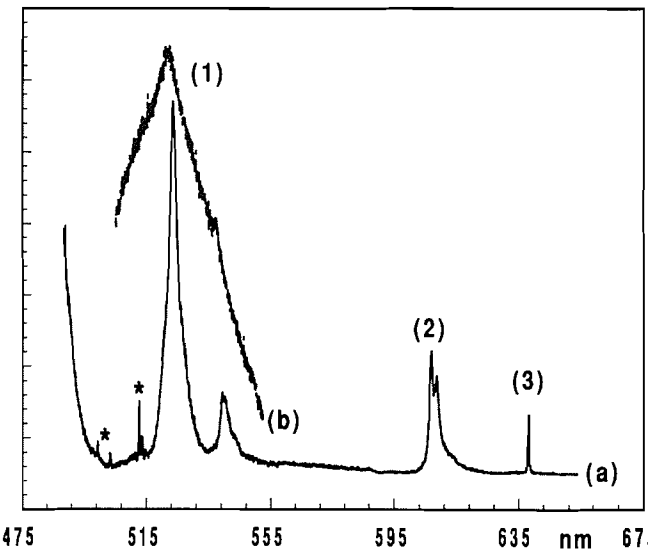

FIG. 7. Spectres de fluorescence de $Pr(ClO_4)_3$ (a) et de $Pr(OTf)_3$ (b). (1) $^3P_0 \rightarrow {}^3H_5$; (2) $^3P_0 \rightarrow {}^3H_6$; (3) $^3P_0 \rightarrow {}^3F_2$. * Raies caractéristiques des vibrations du ligand.

des atomes d'oxygène aux environs de 4 Å. Si l'on considère la somme des distances Pr—O + Cl—O (2,51 + 1,44 Å) (la distance Cl—O est déduite de la relation $((\nu_s^2 + \nu_{as}^2)/2)^{1/2} = f(d(Cl—O))$ (31)), on constate que celle ci est très voisine de la distance Cl—Pr, or comme Pr—O—Cl ne peut être linéaire, les groupements $[ClO_4]$ sont donc distordus comme dans de nombreux complexes perchlorato (32).

(d) Phénomènes de fluorescence

Lorqu'on excite $Pr(ClO_4)_3$ avec la radiation 488 nm (bleu) d'un laser à argon ionisé, on observe des raies très intenses et larges, attribuées sans ambiguité à des phénomènes de fluorescence (fig. 7). De tels effets avaient déjà été notés avec les complexes d'erbium (*5b*, 6). Ils sont plus difficilement observables pour $Pr(OTf)_3$ du fait d'un fond continu de fluorescence parasite important, mais les transitions caractéristiques autour de 530 nm sont présentes. Les attributions sont effectuées en fonction des données de la littérature (33), elles sont données dans la légende du spectre.

Conclusion

Au cours de cette étude, il n'a pas été possible d'isoler de complexes de praséodyme(IV), ce dernier se révélant plus oxydant que les réactifs utilisés tel Cl_2O_6. Malgrè cet échec, l'étude de la famille des complexes à ligands faibles de la série des lanthanides a été enrichie. À côté des complexes «classiques» $Pr(ClO_4)_3$ et $Pr(OTf)_3$, où $[ClO_4]$ et [OTf] jouent le rôle de ligands assembleurs pour donner des structures polymères, on a pu mettre en évidence sans ambiguité, pour la première fois, des sels particuliers : $Pr(ClO_4)_3,Cl_2O_6$ et $NO_2Pr(ClO_4)_4$. Dans le premier, Cl_2O_6 est libre et montre l'équilibre ionique–covalent, alors que dans le second, un $[ClO_4]$ interagit faiblement avec le squelette de $Pr(ClO_4)_3$. Ceci est semble-t'il du à la présence de larges cavités d'accueil au sein de $Pr(ClO_4)_3$ et au comportement différent de ClO_2^+ et NO_2^+. Le premier est souvent en interaction forte avec ClO_4^- (21) alors que ce n'est jamais le cas avec le second (18).

La basicité (ou dureté) très proches de ClO_4^- et de OTf^- $(34)^2$ entraine un comportement identique de $Pr(ClO_4)_3$ et de $Pr(OTf)_3$. Par contre, l'encombrement stérique de [OTf] ne permet pas de préparer de sels analogues à ceux obtenus avec les perchlorates.

Malgré l'absence de modèle, les résultats EXAFS pour $Pr(ClO_4)_3$ sont en accord avec les données de la spectroscopie de vibration et de la littérature (16, 22, 23). Ils permettent d'accroître les connaissances pour des intéractions faibles $[ClO_4] \leftrightarrow$ métal.

Bien que pauvres en informations structurales, les phénomènes de fluorescence méritent d'être signalés, car ils sont rarement observés pour ce type de complexes.

Les résultats structuraux devraient permettre de comprendre et d'étendre la réactivité de ces complexes. Cl_2O_6 «inséré» donne lieu à une chimie plus douce que Cl_2O_6 pur (35) et bon nombre de ces complexes, tels les triflates, voient leur utilisation s'accroître dans le domaine de la catalyse (36).

Remerciements

Les auteurs remercient A. Michalowicz et J. Rozière pour leur aide lors de l'enregistrement des données EXAFS au LURE, D.J. Jones pour des discussions fructueuses et S. Barguès pour sa collaboration scientifique. Ils remercient également le personnel du LURE qui assure la maintenance de l'appareillage. Ils sont gré au CNRS des aides financières accordées.

This paper reports the complete set of minimum energy (i.e. stable) conformations of For-Ala-Ala-NH_2 (containing three peptide bonds), computed by *ab initio* geometry optimization. A more confident *structure and relative energy comparison* of the 49 different relaxed geometries was possible using the HF/3-21G method as compared to empirical (force field) methods. The analysis of the different conformers resulted in a useful structure database, incorporating 30 different β-turns, which will have some relevance to the description of peptide folding. Spectroscopic (e.g. NMR) consequences of the reported *ab initio* calculations are also discussed, and a 3D-structure assignment method for proteins is provided.

ANDRÁS PERCZEL, MICHAEL A. MCALLISTER, PÁL CSÁSZÁR et IMRE G. CSIZMADIA. Can. J. Chem. **72**, 2050 (1994).

Dans ce travail, on rapporte un ensemble complet de conformations d'énergie minimale (c'est-à-dire stable) du For-Ala-Ala-NH_2 (contenant trois liaisons peptidiques), telles que calculées par une optimisation *ab initio* de la géométrie. En utilisant la méthode HF/3-21G plutôt que les méthodes empiriques (de champ de force) il a été possible d'établir une *comparaison plus certaine de la structure et de l'énergie relative* de 49 géométries différentes. L'analyse des différents conformères a conduit à une base de données utile de structures comportant 30 β-tours différents qui présentent un intérêt dans la description du plissement des peptides. On discute aussi des conséquences spectroscopiques (par exemple en RMN) des calculs *ab initio* rapportés et on fournit une méthode d'attribution des structures 3D des protéines.

Introduction

The conformational analysis of small peptides not only has challenging spectroscopic aspects, it also has a role in the understanding of protein folding. Theoretical calculations revealed that for each peptide residue in vacuo, only a limited number of discrete ϕ, ψ backbone torsional angle combinations exist (1, 2). The structure of small peptides in solution is often quoted as "random" (3, 4), since conformational "mixtures" are generally observed in solution. Introducing special experimental conditions (low temperature, special solvation etc.), the population of a single conformer can be increased to such an extent that crystals can be obtained, usually incorporating a single conformer (5–10). Unfortunately, the solid state conformation is not necessarily identical to the dominant structure observed in liquid or gas phase. Unless specific stabilizing effects are present in solution, such as intermolecular H-bonds and/or ion pairs, a detailed conformational analysis of the structures in an equilibrium mixture is rather difficult (3, 4). By contrast, it is possible to investigate the geometrical properties of any *conformer* via theoretical calculations. In addition to earlier molecular mechanics and semi-empirical approaches (11–13), *ab initio* calculations of these systems are now possible (2, 14–16). Such calculations result in a more faithful description of the geometries as well as relative stabilities (i.e. relative energies: ΔE_i). Although these calculations may yield all possible minimum energy structures, regardless of their relative energy, the identification of *all the possible conformers* is still problematic, since it is not known (*i*) how many minima are on a potential energy surface (PES), (*ii*) where these minima are located.

There are two systematic methods to find all minima, regardless of whether molecular mechanics (MM), semi-empirical or *ab initio* calculations are used: (*i*) the analysis of a suitably chosen function fitted to the calculated grid points can result in finding the location of all the minima on a PES (17*a*, footnote 2); (*ii*) multidimensional conformational analysis (MDCA)

[1]Revision received June 27, 1994.

[2]The grid method is thorough but quite expensive since grid points must be generated at least by 30° intervals requiring 12 points along each of the torsional angles (ϕ_i and ψ_i where ($1 \leq i \leq n$). This involves the computation of 12^{2n} grid points where n is the number of amino acid residues in the peptide. For the analysis of For-Ala-Ala-NH_2, where n = 2, the total number of 12^4 = 20736 grid points are expected to be computed. (The planarity of the amide group, ω_1 and/or ω_2 = 180° or 0°, is usually presumed but nevertheless explicitly optimized.)

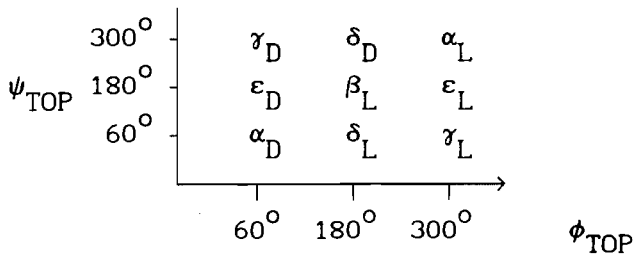

SCHEME 2

(footnote 3, ref. 17*c*) of an ideal PES can also yield the total number of legitimate minima, as well as their approximate locations.

Multidimensional conformational analysis (footnote 3, ref. 17*c*) as applied to *amino acid diamide systems* (e.g. For-Ala-NH_2), predicted (2) the existence of nine minima on the 2D-Ramachandran map (18). Each of these nine minima represents the only energy minimum in a given catchment region (19). The torsional angles are defined according to IUPAC-IUB (footnote 4, ref. 20) as shown on Scheme 1.

The occurrence of the nine minima (labelled as: α_L, α_D, β_L, γ_L, γ_D, δ_L, δ_D, ϵ_L, ϵ_D), are shown in an idealized fashion in Scheme 2 (footnote 4) and Fig. 1. It should be emphasized that Fig. 1 shows the topology of the 2D-Ramachandran map for two full cycles of rotation. Each of the four quadrants, presented in Fig. 1, is the same as the pattern given in Scheme 2. The central square in Fig. 1, defined by broken lines, is the conventional Ramachandran map, but for topological reasons the representation shown in Scheme 2, corresponding to the upper right hand corner of Fig. 1, is suggested.

The large number of *ab initio* points computed by Pople and co-workers (16*g*, *h*), involving 12 × 12 = 144 grid points, yielded the same seven minima (α_D, β_L, γ_L, γ_D, δ_L, δ_D, and ϵ_D) for For-L-Ala-NH_2 as determined using SCF gradient geometry optimizations at the MDCA predicted locations (2, 16*h*). Two conformations (α_L and ϵ_L) from the nine MDCA predicted minima were not found at the HF/3-21G level of theory. This is to be taken as diagnostic of the non-ideal nature of the PES. In order to underline the utility of MDCA let us reemphasize that the 9 set of input data, generated by MDCA, resulted in the same 7 minima (2) as the PES-generated based on the 144 grid points determined by Pople and co-workers (16*h*).

In the solid state, slightly distorted forms of the γ_L backbone substructure (also called C_7^{equ}) or its conformational neighbors (β_L, ϵ_L and δ_L) were extensively observed (22–27) for small

[3]See ref. 17*b* (part of the series The chemistry of functional groups) particularly pages 36–41 including Figs. 23 and 24 as well as Table 20.

[4]It should be noted that according to the IUPAC-IUB convention (19) ϕ and ψ vary between −180° and +180°. For various reasons (2), during conformational analysis it is convenient to use a different cut of the same PES, namely any of the four identical quadrants encircled by solid lines in Fig. 1, ref. 2.

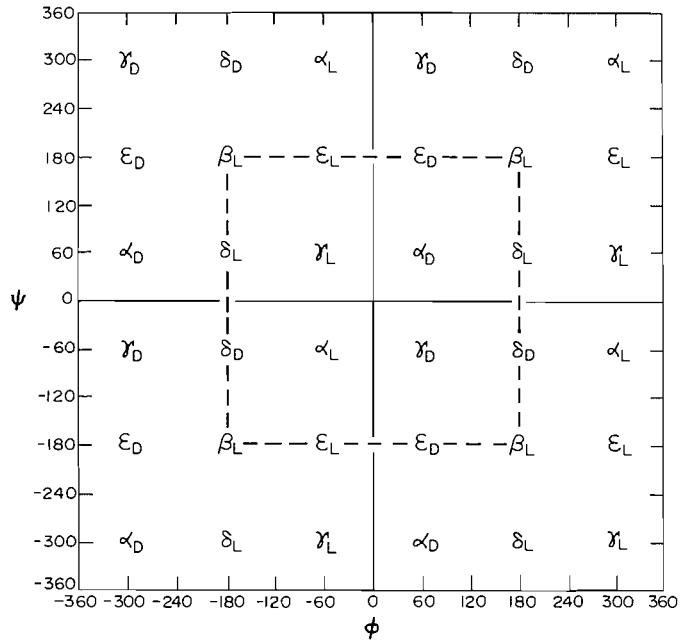

FIG. 1. Idealized PES topology for a single amino acid diamide residue involving two complete cycles of rotation in both ϕ and ψ. Locations of the minima are specified by their names in terms of subscribed greek letters.

amide systems. In solution the presence of the above structures for amino acid diamides has not been confirmed by NMR, CD, or IR spectroscopy. Usually a conformational mixture of an "undefined" number of structures are present; these structures are labelled "random".

Peptides, incorporating three amide functional groups, such as the For-L-Ala-L-Ala-NH_2 (cf. Scheme 3), a representative element of the *diamino acid triamide* system, may adopt a larger variety of backbone conformations, such as type I and/or type II β-turns (21), etc. The existence of the turns, as typical triamide conformations, has been the target of many investigations (28–30), since, in addition to the α-helix ($\phi_i = (-60 \pm 30)°$, $\psi_i = (-45 \pm 30)°)_n$ and the β-pleated sheet ($\phi_i = (-150 \pm$

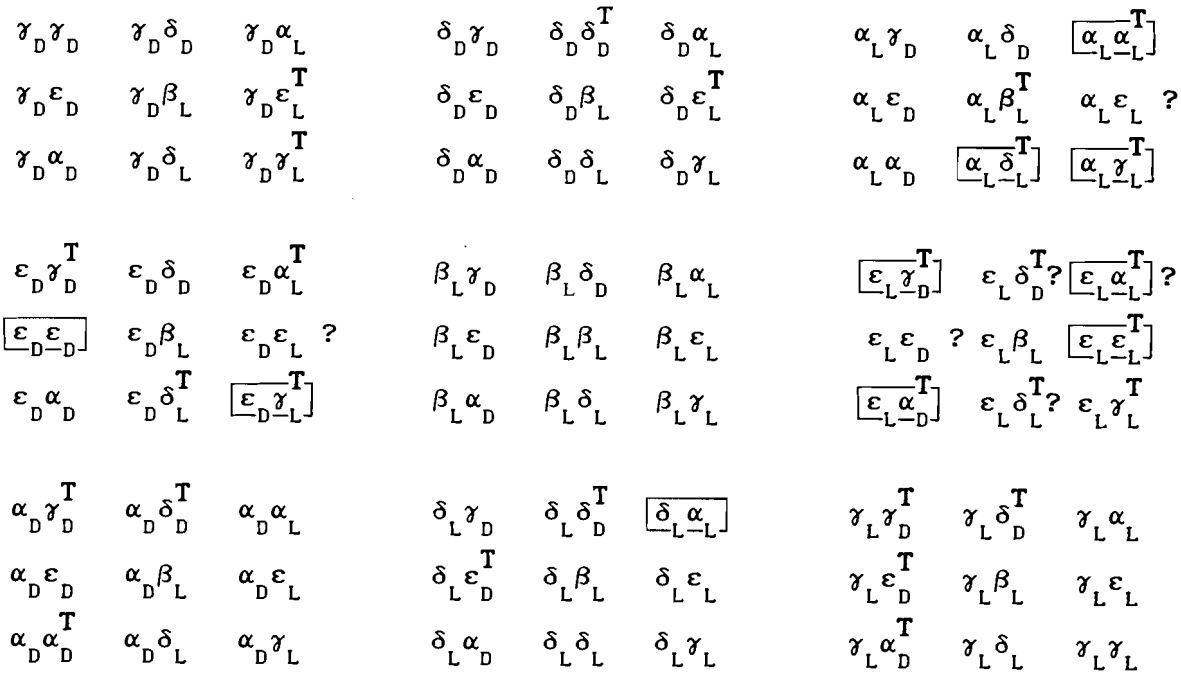

SCHEME 5

30)°, $\psi_i = (+150 \pm 30)°)_n$, the hairpin conformations or β-turns are the third most frequently found (30–37) structural unit in globular proteins (22, 33, 34).

In general β-turn types are defined according to the values of the four torsional angles (ϕ_1, ψ_1, ϕ_2, and ψ_2) as specified by Scheme 4. Only types I, II and III are frequently assigned in globular proteins based on their X-ray structures, but their conformational mirror images, i.e. conformational enantiomers (I, II, and III) as well as the type VI*a,b* and VIII β-turns have only sporadic occurrences. Since types IV, V, and VII β-turns are defined ambiguously their determination is rather questionable in globular proteins since they incorporate β-turns with very different backbone torsional angles (21). The X-ray analysis of protected dipeptides revealed that these structures incorporate intermolecular hydrogen bonds (21–27) which are typical for solid state conformations. Up to the present, the *direct* structural analyses of N- and C-protected dipeptides in the solid state has revealed the existence of approximately 10 different typical conformations of diaminoacid triamides (21).

In contrast to the few recognized structures of triamide systems, as discussed above, a total of 81 distinctly different conformations (38) were predicted by MDCA as shown in Scheme 5. Analysis (38) of a large crystallographic protein data base revealed that all 81 conformations do exist in globular proteins. A total of 30 from these 81 MDCA predicted conformations would qualify (37) as β-turns or reverse turns (36), marked by the **T** superscript in Scheme 5 (cf. ref. 37, Table 1). MDCA, without considering destabilizing or stabilizing interactions, yields 81 legitimate minima. The analysis of triamide substructures in a large protein data base, where all stabilizing interactions are present, suggests the existence of all 81 conformations (38). On the other hand, Molecular Mechanics (MM) calculations confirmed 75 out of the 81 MDCA legitimized conformations. The 6 non-existing conformations at the MM level are marked by question marks (?) in Scheme 5. When we tried to locate these 6 conformations during the MM optimization process using the ECEPP/2 method, the initial minima were shifted to other nearby minima as illustrated in Scheme 6.

Due to the large dimensionality of peptides, force field calculations have traditionally been used to estimate the energetic and geometrical properties of these bio-molecules. The favorable speed and size-tolerance have made these calculations popular. The inherent inaccuracies of these parameterized methods can induce errors in the structure analyses of polypeptides and therefore limit their applicability. The theoretical probability occurrence (p_i^{theo}) of the *i*th conformer is proportional to its relative energy (ΔE_i). The energy of all the conformations can only be obtained by theoretical computations since no experimental method is available to measure all ΔE_i. The purpose of this paper is to evaluate how many of the 81 legitimate conformations (Scheme 5) have intrinsic stability *without* the influence of stabilizing environmental effects. Only *ab initio* type molecular orbital computations can answer such a question accurately and determine the number of N_0 of the 81 legitimate conformations as having an intrinsic stability, while $(81 - N_0)$ conformations will be intrinsically unstable. Nevertheless, these $(81 - N_0)$ unstable, but otherwise legitimate conformations, may be restabilized through H bonds, long-range interactions, or other effects typical in large proteins. This paper

reports *all the* N_0 *ab initio* minimum energy conformations of For-L-Ala-L-Ala-NH_2, since the geometry optimization of all 81 structures was attempted.

Methods

Ab initio SCF computations

The fully relaxed minimum energy conformations were gradient geometry optimized using the GAUSSIAN 90 program (39*a*) on a Cray X-MP/28 super computer. It was found that the HF-SCF method with the 3-21 G basis set (39*b*) provides a reasonably accurate reproduction of experimentally observed geometrical parameters. The $\gamma_L\gamma_L$ conformation was found as the global minimum (E[RHF] = −656.963681 hartree) and was used as a reference point for all relative energy (ΔE_i) calculations.

For *ab initio* SCF computations, the initial geometries of selected triamides were generated on the basis of previously SCF-optimized For-L-Ala-NH_2 structures (2, 16*g*, *h*) and with the use of the 75 ECEPP/2 For-L-Ala-L-Ala-NH_2 geometries (38). Geometry optimizations were carried out under "normal" rather than "tight" conditions. Absolute values of the actual maximum forces along any internal coordinate in the relaxed structures ranged from 2.2×10^{-6} to 2.1×10^{-4} au, while RMS forces ranged between 5.4×10^{-7} and 5.7×10^{-5} au for the gradient-optimized conformations. One may be concerned about the geometry optimization convergency under these "normal" conditions (39*a*) when the optimization is carried out in an internal coordinate system. The ultimate test of accuracy, in this particular case, is not so much the magnitude of the residual force but the "self consistency" of the ϕ and ψ values as these torsional angles characterize peptide conformations. As a test "normal" and "tight" optimizations have been carried out on selected conformations as reported previously (37), and the results are summarized in Table 1. Also, in addition to the $\gamma_L\gamma_L$ conformation reported in Table 1, another one dipeptide conformations ($\delta_L\epsilon_D$) were reoptimized under "tight" optimization conditions and no dramatic changes were observed as discussed towards the end of this paper and summarized in footnote 5. The other usual concern is the role of the basis set size and the omission or inclusion of the correlation energy in determining the accuracy of the computed results. The β_L and γ_L conformations of the For-L-Ala-NH_2 have been reoptimized (40) at the MP2/6311++G[d, p] level of theory and the results are summarized in Table 2. Since, along the torsional mode of motion the conformational regions are separated from each other by several tens of degrees (on the idealized surface the separation is 120°) the variations in torsional angles are not considered to be very dramatic on going from the HF/3-21G to the MP2/6-311++(d, p) levels of theory. In addition, the relative energies are practically the same at these two levels of theory.

[5]To avoid artifact of partial optimization the optimized $\delta_L\epsilon_D$ (more precisely the $\delta_L^*\epsilon_D$) conformation was reoptimized under "tight" optimization criteria. Such a "sever" criterion resulted in $E = -656.954077$ hartrees, maximum force = 5.3E-6 au, and RMS force = 1.5E-6 au. The final torsional angles associated with the ϵ_D subconformation after "tight" optimization changed less than 0.5° (ϕ_2 = +62.4°, ψ_2 = +173.4°), while in the δ_L^* part ϕ_1 was identical with the value reported in Table 6 but ψ_1 changed 3°.

SCHEME 7

Protein data base

As a comparison to the *ab initio* computed peptide conformations, the description of the backbone conformation of 78 selected proteins (41*a*) was also performed. X-ray data of proteins were taken from Brookhaven Protein Structure Databank (BPSD) (41*b*, *c*). Their stereo chemical parameters such as the resolution, the *R* factor, and the core% were taken as recommended (41*d*).

Conformation assignment algorithm

An *A*mino acid *C*onformation *A*ssignment of *P*roteins (ACAP) algorithm was coded in Pascal, which assigns all the amino acid residue backbone conformations to one of the appropriate conformational (α_L, α_D, β_L, γ_L, γ_D, δ_L, δ_D, ϵ_L, and ϵ_D) clusters. The IBM/PC program is available from the authors upon request.

Results and discussions

Minima on the 4D-Ramachandran map

The upper limit (81) of the number of legitimate backbone conformations on the four- dimensional (4D) Ramachandran map associated with For-L-Ala-L-Ala-NH_2 was previously determined by MDCA (38). According to *ab initio* (SCF) geometry optimizations (using a 3-21G basis set) 49 intrinsically stable conformations were found, while 32 migrated (marked by * on Scheme 7) to one of the above 49 stable structures (Scheme 7 and Tables 3–9).

Ab initio calculations of single amino acid diamides (2, 16) revealed that on a 2D-Ramachandran map the α_L and ϵ_L backbone conformations should be regarded as annihilated minimum energy structures. All triamides, incorporating the α_L and/or the ϵ_L substructures, such as [($\alpha_L x_L$, $\alpha_L x_D$), ($x_L\alpha_L$, $x_D\alpha_L$), ($\epsilon_L x_L$, $\epsilon_L x_D$) and ($x_D\epsilon_L$, $x_L\epsilon_L$)], were investigated here with pre-

[a]Torsion angles (ω, ϕ, ψ) in degrees, distances in Ångstroms, forces in au, energy (E) in hartrees, and energy difference (ΔE) in kcal/mol compared to $E(\gamma_L\gamma_L)$ = −656.963681.

[b]The $\alpha_L\alpha_D \rightarrow \delta_L\alpha_D$, $\alpha_L\beta_L \rightarrow \delta_L\beta_L$, $\alpha_L\delta_D \rightarrow \delta_L\delta_D$, $\alpha_L\varepsilon_D \rightarrow \delta_L\varepsilon_D$, $\alpha_L\varepsilon_L \rightarrow \delta_L\beta_L$, $\alpha_L\gamma_D \rightarrow \delta_L\gamma_D \rightarrow \delta_L\gamma_D$ and $\alpha_L\gamma_L \rightarrow \delta_L\gamma_L$ conformation shifts are observed.

[c]The $\alpha_D\varepsilon_D$ conformation was shifted to $\gamma_D\varepsilon_D$.

[d]INI: initial backbone conformation (calculated by ECEPP/2).

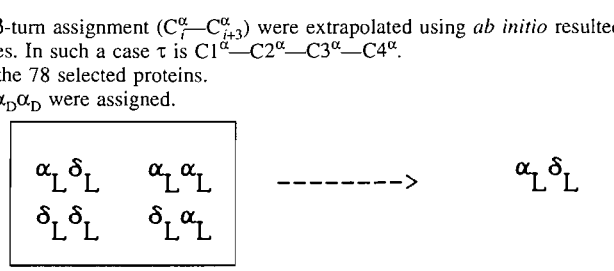
[e]CONV: converged backbone conformation.

[f]MODEL DIS.: C^α_i and C^α_{i+3} in accordance to classical β-turn definition must be shorter than 7 Å. In For-Ala-Ala-NH_2 the two C^α atoms are replaced by hydrogens (H1 and H4*) (cf. Scheme 2), therefore the model distance (d_{model}) is shorter than C^α_i—C^α_{i+3} (Fig. 1) no more than 1.1 Å. In such a case τ is H1—$C2^\alpha$—$C3^\alpha$—H4*.

[g]CRIT DIS.: critical distances for β-turn assignment (C^α_i—C^α_{i+3}) were extrapolated using *ab initio* resulted bond lengths and bond angles, on the basis of the determined N—H and C′—H distances. In such a case τ is $C1^\alpha$—$C2^\alpha$—$C3^\alpha$—$C4^\alpha$.

[h]Number of structures assigned in the 78 selected proteins.

[i]50 $\alpha_D\alpha_D$, 3 $\alpha_D\alpha_D\alpha_D$, and 1 $\alpha_D\alpha_D\alpha_D\alpha_D$ were assigned.



SCHEME 8

caution. Of these, only four conformations ($\alpha_L\delta_L$, $\gamma_L\epsilon_L$, $\gamma_D\epsilon_L$, and $\delta_D\epsilon_L$) turned out to be intrinsically stable. These four unexpectedly stable triamide conformations incorporate for the first time, as stable substructures, the α_L and the ϵ_L subunits, previously annihilated on the 2D-Ramachandran map. It should be noted that among the 32 unstable triamide conformations of the predicted 81 backbone arrangement (Scheme 7), only four ($\alpha_D\epsilon_D$, $\epsilon_D\alpha_D$, $\delta_D\delta_L$, and $\delta_L\delta_L$) are associated with neither the α_L nor the ϵ_L substructures.

At this level of the theory, the $\alpha_L\delta_L$ conformation (type I β-turn) is the only intrinsically stable backbone conformation of the For-Ala-Ala-NH_2 molecule which incorporates the α_L substructure. It is most probable that the intramolecular H-bond (1 ← 4 type H-bond (21), interconnecting the carbonyl oxygen of the formyl group with the amide proton located at the C terminal) (37) plays a crucial role in the stability of the $\alpha_L\delta_L$ conformation. According to earlier X-ray data set analysis (38), the $\alpha_L\delta_L$ was the sixth most frequent conformation among the 81 possible dipeptide structures, preceded only by the $\alpha_L\alpha_L$, $\beta_L\beta_L$, $\epsilon_L\epsilon_L$, $\beta_L\epsilon_L$, and $\epsilon_L\beta_L$ type backbone orientations (see Small Data Base in ref. 38). Some of these structures are the building units of the most frequently observed typical secondary structural elements of proteins; $(\alpha_L\alpha_L)_n \rightarrow$ α helix, $(\beta_L\beta_L)_n \rightarrow$ β-pleated sheet and $(\epsilon_L\epsilon_L)_n \rightarrow$ Poly(L-Proline)II. With the exception of the $\delta_D\alpha_L \rightarrow \delta_D\gamma_L$ conformational shift the α_L substructure is always transformed to the δ_L conformation (in 15 cases out of the total 17 [$\alpha_L x_L$, $\alpha_L x_D$, $x_L\alpha_L$, $x_D\alpha_L$] possibilities). On the other hand, the optimization of any combination of the α_L and δ_L substructures (see Scheme 8) yielded a single conformation, which is the $\alpha_L\delta_L$ (type I β-turn). The intrinsic stability of

[a]The $\delta_D\varepsilon_L$ conformation contains an 8-membered intramolecular H-bond, where O3...H2 = 2.07 Å, O3...N2 = 3.05 Å with an H-bond angle (O3—H2—N2) = +163.1°. Torsion angles (ω, ϕ, ψ) in degrees, distances in Ångstroms, forces in au, energy (*E*) in hartrees, and the energy difference (ΔE) in kcal/mol compared to $E(\gamma_L\gamma_L)$ = −656.963681.

[b]INI: initial backbone conformation (calculated by ECEPP/2).

[c]CONV: converged backbone conformation.

[d]MODEL DIS: C_i^α and C_{i+3}^α in accordance to classical β-turn definition must be shorter than 7 Å. In For-Ala-Ala-NH_2 the two C^α atoms are replaced by hydrogens (H1 and H4*) (cf. Scheme 2), therefore the model distance (d_{model}) is shorter than C_i^α—C_{i+3}^α (Fig. 1) more than 1.1 Å. In such a case τ is H1—$C2^\alpha$—$C3^\alpha$—H4*.

[e]CRIT DIS.: critical distances for β-turn assignment (C_i^α—C_{i+3}^α) were extrapolated using *ab initio* resulted bond lengths and bond angles, on the basis of the determined N—H and C′—H distances. In such a case τ is $C1^\alpha$—$C2^\alpha$—$C3^\alpha$—$C4^\alpha$.

[f]Number of structures assigned in the 78 selected proteins.

[g]191 $\beta_L\beta_L$, 67 $\beta_L\beta_L\beta_L$, 26 $\beta_L\beta_L\beta_L\beta_L$, 6 $\beta_L\beta_L\beta_L\beta_L\beta_L$, 1 $\beta_L\beta_L\beta_L\beta_L\beta_L\beta_L$ were assigned.

the $\alpha_L\delta_L$ conformation, as established by the present *ab initio* SCF computations, in accordance with the frequent occurrence of this structural type in globular proteins, may provide some explanation why type I β-turns are believed to play a cornerstone role in protein folding (21, 42, 43).

The ϵ_L subconformation, which is the other computationally "missing" backbone conformational type in amino acid diamides, was also found for the first time as a legitimate substructure among the For-Ala-Ala-NH_2 conformations. *Ab initio* calculations showed that the unfavorable eclipsed H—N—C^α—C^β orientation ($\approx -20°$) in the ϵ_L backbone conformation results in the annihilation of such a backbone geometry in For-Gly-NH_2, For-Ala-NH_2, For-Val-NH_2 and probably in the other amino acid diamides as well. In contrast, increasing the peptide chain length with an additional amino acid residue resulted in the stabilization of the ϵ_L substructure in three conformations ($\gamma_L\epsilon_L$, $\gamma_D\epsilon_L$, and $\delta_D\epsilon_L$). While $\delta_D\epsilon_L$ and $\gamma_D\epsilon_L$ geometries are perfect β-turns, in accordance with both the distance[6] and the angularity[7] criteria, the $\gamma_L\epsilon_L$ has an extended backbone conformation. Although these are only 3 conformations from the 17 possibilities (Scheme 7), they represent solid evidence that a "favorable" backbone/backbone interaction may "re-stabilize" the "annihilated" ϵ_L minimum. There is no direct influence (like an intramolecular hydrogen bond) between the third and the second amide groups of the molecule, oriented as an ϵ_L conformation. At this stage of the investigation we are not certain about the nature of the interaction that could stabilize the ϵ_L conformation substructure in triamide systems; however, it is conceivable that the negative polarity of the carbonyl oxygen in the central amide moiety may have some indirect stabilizing effect. The increased negative charge on the oxygen may have an influence to stabilize the ϵ_L conformation at the "second half" of the molecule, yielding the stable $\gamma_L\epsilon_L$, $\gamma_D\epsilon_L$, and $\delta_D\epsilon_L$ structures. In the other 14 initial geometries incorporating the ϵ_L substructure ($\epsilon_L x_L$, $x_D\epsilon_L$, $x_L\epsilon_L$, and $\epsilon_L x_D$), generally the $\epsilon_L \rightarrow \beta_L$ conformational shift was observed, resulting in the $\beta_L x_L$, $x_D\beta_L$, and $x_L\beta_L$ conformations in three out of the four cases. However, when the initial geometry falls in the $\epsilon_L x_D$ category the $\delta_D x_D$ backbone conformation was obtained ($\epsilon_L x_D \rightarrow \delta_D x_D$).

[6]According to the distance criterion the C_i^α—C_{i+3}^α distance must be shorter than 7 Å.

[7]According to the angularity (or twisting) parameter (τ), the value of τ (torsional angle involving C_i^α, C_{i+1}^α, C_{i+2}^α, C_{i+3}^α peptide backbone atoms) must be in the $-90° \leq \tau \leq +90°$ range for reverse turns (49).

Typical and unusual conformations

[h]No $\varepsilon_D\varepsilon_D\varepsilon_D$ or longer fragments were assigned.

different conformations as a function of the side chain type can reveal the so-called "backbone/side chain effect". Also, the analysis of selected geometrical parameter changes in homopolymers as a function of the peptide chain length (e.g. For-[Ala]$_i$-NH_2; $1 \le i \le n$) will help in our understanding of the nature of interactions in polypeptides. The third type of data comparison performed in this study was to extract the geometrical parameters of the 9 legitimate backbone conformations of the optimized 49 conformations of For-Ala-Ala-NH_2. The 49 stable triamide conformations yield a total of $49 \times 2 = 98$ single amino acid residue subconformations classified as α_L, β_L, δ_L etc. Scheme 9 demonstrates the grouping of the triamide backbone geometries in order to extract typical ϕ and ψ torsional angle pairs of the 9 legitimate backbone conformations.

Figures 2 and 3 show the distribution of (ϕ, ψ) angle pairs as found in triamides. (Data in Fig. 2 are reported in the conventional $-180° \le \phi \le 180°$, $-180° \le \psi \le 180°$ representation, while a topologically more useful plot is shown in Fig. 3.) The arrangement of the 98 calculated backbone subconformations determines nine clusters, as expected (Fig. 3), where only two of the δ_L-type conformations are shifted away from the anticipated square representing the borders of the appropriate idealized catchment region. However, even these two cases are due to the fact that the average δ_L position (ϕ = −126.2°, ψ = +26.5°) is shifted substantially away from the idealized (ϕ = −180°, ψ = +60°) position of δ_L towards the lower right hand corner of the square. The concentric circles around the cluster "centers" show areas where the deviations from the average structure (Table 10) is smaller than 20°, 40°, or 60°. Many of the points in Fig. 3 are very close to their average value (denoted by the center of a small square in each of the clusters). For example all β_L, ϵ_L, and γ_L points are well within a 20° circle, suggesting

$\alpha_D x$ and $x\alpha_D$ → α_D

$\alpha_L\delta_L$ → α_L

$\beta_L x$ and $x\beta_L$ → β_L

$\gamma_D x$ and $x\gamma_D$ → γ_D

$\gamma_L x$ and $x\gamma_L$ → γ_L

$\delta_D x$ and $x\delta_D$ → δ_D

$\delta_L x$ and $x\delta_L$ → δ_L

$\varepsilon_D x$ and $x\varepsilon_D$ → ε_D

$\gamma_L\varepsilon_L$, $\gamma_D\varepsilon_L$ and $\delta_D\varepsilon_L$ → ε_L

[a]Torsion angles (ω, ϕ, ψ) in degrees, distances in Ångstroms, forces in au, energy (*E*) in hartrees, and the energy difference (ΔE) in kcal/mol compared to $E(\gamma_L\gamma_L)$ = −656.963681. The $\delta_L\alpha_L \rightarrow \alpha_L\delta_L$ and $\delta_L\delta_L \rightarrow \alpha_L\delta_L$ conformational shifts are observed. The $\delta_L\varepsilon_D$ conformation contains an 8-membered intramolecular H-bond, where O3...H2 = 2.07 Å, O3...N2 = 2.99 Å with an H-bond angle (O3—H2—N2) = +151.2°.

[b]The $\delta_L\varepsilon_D$ conformation contains an 8-membered intramolecular H-bond, where O3...H2 = 2.07 Å, O3...N2 = 2.99 Å with an H-bond angle (O3–H2—N2) = +151.2°.

[c]INI: initial backbone conformation (calculated by ECEPP/2).

[d]CONV: converged backbone conformation.

[e]MODEL DIS.: C^α_i and C^α_{i+3} in accordance to classical β-turn definition must be shorter than 7 Å. In For-Ala-Ala-NH_2 the two C^α atoms are replaced by hydrogens (H1 and H4*) (cf. Scheme 2), therefore the model distance (d_{model}) is shorter than C^α_i—C^α_{i+3} (Fig. 1) by no more than 1.1 Å. In such a case τ is H1—$C2^\alpha$—$C3^\alpha$—H4*.

[f]CRIT DIS.: critical distances for β-turn assignment (C^α_i—C^α_{i+3}) were extrapolated using *ab initio* resulted bond lengths and bond angles, on the basis of the determined N—H and C′—H distances. In such a case τ is $C1^\alpha$—$C2^\alpha$—$C3^\alpha$—$C4^\alpha$.

[g]Number of structures assigned in the 78 selected proteins.

that these substructure types are not influenced dramatically by conformational changes in the preceding or following subunit. With the exception of two (2) points, one δ_L and one ϵ_D, all 98 points are within a 40° circle. These two points are called "ghost" conformations and are marked by an asterisk, e.g., δ^*_L and ϵ^*_D. The substructure comparison of homopolymers (e.g. For-$[Ala]_i$-NH_2; $1 \leq i \leq n$) (44–49) in homo subconformations (e.g. $(\gamma_L)_i$; $1 \leq i \leq n$) resulted in small ϕ, ψ deviations in the case of $(\gamma_L)_i$ (44–47) and $(\beta_L)_i$ (44–48) ($1 \leq i \leq 4$) conformations. In contrast, the actual geometry of the α_L backbone type depends strongly on the length of the investigated homopolymer in its $(\alpha_L)_i\delta_L$ (49) conformation (Table 11).

Conformational folding

The importance of some triamide conformations, especially type I (or III) and type II β-turns, is continuously emphasized in the literature (21). Indeed, these conformations are frequently assigned secondary structural elements of globular proteins. Although the classification of β-turns in traditionally given on the basis of the backbone torsional angle values (ϕ_i, ψ_i), as specified in Scheme 4, the degree of folding or unfolding of a β-turn can be defined in a simpler way, based on the twisting of the hairpin conformation. We recently re-introduced (37) the C^α_i—C^α_{i+1}—C^α_{i+2}—C^α_{i+3} torsional angle labelled as τ (see Fig. 2 in ref. 37 and Fig. 1 in ref. 44), that describes the overall angularity of the backbone conformation with values $-180° \leq \tau \leq +180°$. The global minimum (the $\gamma_L\gamma_L$ conformation) has a $\tau_{\gamma L\gamma L}$ = +168.4°, which can quantitatively describe the degree of backbone unfolding since for a perfectly unfolded conformation τ must be ±180°. Considering the traditional criterion that the C^α_1—C^α_4 distance (*d*) must be shorter than 7 Å, only a fraction (18) of the total β-turn conformations (30 structures) should be assigned as β-turn. This paper summarizes all the 49 conformations of the model compound resulting in 30 structures within the $-90° \leq \tau \leq 90°$ angularity range and 19 backbone geometries with $-180° \leq \tau \leq -90°$ or $+90° \leq \tau \leq +180°$ values (see Fig. 4). Depending on the *d* or τ type of "conformation selection rule", both groups of hairpin geometries of For-Ala-Ala-NH_2 consist of a large number of elements. A total of 18 structures are assigned as turns if both the angularity and the distance criteria are applied simultaneously, but as many as 30 conformations are considered folded structures when only the angularity (τ) selection rule ($-80° \leq \tau \leq 90°$) is considered. All the calculated conformations have been observed previously (38), by X-ray data-base analysis of globular proteins. However, the extraction of all the β-turn conformations fulfill-

[g]Number of structures assigned in the 78 selected proteins.

[h]11 $\delta_D\delta_D$, 6 $\delta_D\delta_D\delta_D$, 4 —$(\delta_D)_4$—, 1 —$(\delta_D)_5$—, 1 —$(\delta_D)_7$—, 1 —$(\delta_D)_9$—, 2 —$(\delta_D)_{10}$—, 1 —$(\delta_D)_{12}$—, 1 —$(\delta_D)_{17}$—, 1 —$(\delta_D)_{22}$—, and 1 —$(\delta_D)_{23}$— were assigned.

ing the angularity ($-90° \leq \tau \leq +90°$) or distance ($d \leq 7$ Å) criteria is not possible by an approach such as an X-ray data-base analysis. All existing β-turn conformations can be assigned on the corresponding 4D-Ramachandran (38) type PES; however, many of these conformations that do occur in globular proteins cannot be extracted from X-ray data, because some of these structures have a rare occurrence (small p_i and large ΔE_i).

The functional role of intramolecular hydrogen bonds in the formation of folded conformations is a subject of some controversy. It is shown here that if an α_L substructure is incorporated in a β-turn conformation (e.g. $\alpha_L\delta_L$ in type I β-turn), a favorable H-bond interaction is required to stabilize such a β-turn. By contrast, for β-turns not containing an α_L conformational subunit, the existence of such an $1 \leftarrow 4$ H-bond is not required. Consequently, although the $\alpha_D\alpha_D$ hairpin conformation contains a $1 \leftarrow 4$ type H-bond, in the $\delta_L\delta_D$ conformation (type II′ β-turn) such an intramolecular H-bond is not present. Therefore, it may be concluded, on the basis of these *ab initio* calculations, that while the $1 \leftarrow 4$ H-bond may be present in β-turns, it is not a necessary condition for the intrinsic stability of these structures. Only 5 structures ($\alpha_L\delta_L$, $\alpha_D\alpha_D$, $\alpha_D\delta_D$, $\epsilon_D\delta_L$, and $\gamma_L\delta_D$) of the 30 β-turns, located in this study, incorporate the intramolecular $1 \leftarrow 4$ H-bond ($d_{O..HN} \leq 2.2$ Å).

Spectroscopic aspects of ab initio calculations

The X-ray analysis of crystalline compounds, where typically a single conformer is observed (6–10), can yield extremely valuable information. However, the solid-state structure of a peptide is often modified by "crystal" forces. Therefore, these geometries are not necessarily identical with the dominant conformation adopted in solution, or in the gas phase. Although calculations can yield any minimum energy structure in the environment-free state, the spectroscopic identification of these conformers, or at least conformational regions, is still problematic in solution. The application of the results obtained by *ab initio* calculations may have some relevance to conformational analyses performed by vibrational (50, 51), circular dichroism (52), microwave (53), electron diffraction (54) and NMR (55) spectroscopy. The time scale of the experiment performed in solution has a cornerstone role. The applicability of *ab initio* structures can be different when the time-scale is long (e.g.; NMR) or when spectroscopy reflects a time-resolved structure set (e.g.; CD, FT-IR).

Nuclear Overhauser effect (NOE), such as the ^1H-{^1H}-NOE experiment is the most frequently applied NMR measurement to determine the folding pattern of peptide or protein backbone. It was shown that interproton distances (d_i) can be determined

[f]Number of structures assigned in the 78 selected proteins.

[g]93 $\gamma_L\gamma_L$, 13 $\gamma_L\gamma_L\gamma_L$, 1 $\gamma_L\gamma_L\gamma_L\gamma_L$, 1 $\gamma_L\gamma_L\gamma_L\gamma_L\gamma_L$ were assigned.

(Fig. 5) on the basis of quantitative NOE even for multiple spin systems (55), as accurate as ±0.1 Å[8] For an interpretation of these experimentally determined distances, selected interproton distances are also calculated (usually by Molecular Mechanics and/or Molecular Dynamics calculations), but the empirical nature of the applied parameters used in MM and/or MD computations could introduce significant uncertainties in the distance-data set. Table 12 summarizes 10 possible marker distance values of the 49 different conformers of For-Ala-Ala-NH_2, useful for a quantitative structure assignment (Fig. 5) by NMR. The $d_{N\alpha}(d_{NH(i)/H\alpha(i)})$, $d_{NN}(d_{NH(i)/NH(i+1)})$, and $d_{\alpha N}(d_{H\alpha(i)/NH(i+1)})$ interproton distances have a specific role in the conformation assignment performed by NOE's. While the $d_{N\alpha}$ is a COSY-type connectivity, the $d_{\alpha N}$ and the d_{NN} are sequential NOE information. Although d_{NN} values vary the most ($d_{NN}^{\delta D} \approx 1.9$ Å, $d_{NN}^{\epsilon L} \approx 4.6$ Å) among these three marker distances, they are not too conformation-sensitive since they adopt similar values for the conformationally enantiomeric pairs (e.g. $d_{NN}^{\gamma L} \approx d_{NN}^{\gamma D} \approx 3.7 \pm 0.1$ Å (Table 12). Moreover, for β_L, γ_L, γ_D, ϵ_L, ϵ_D backbone conformations, where distances are large ($d_{NN} > 3.5$ Å), the intensities of the adjacent NOE's are weak or even indistinguishable from noise. In contrast, the other two sequential marker distances ($d_{N\alpha}$, $d_{\alpha N}$) can distinguish between conformational enantiomers since values range between 2.3 and 3.6 Å (e.g. $d_{N\alpha}^{\gamma L} \approx 2.9 \pm 0.1$ Å, $d_{N\alpha}^{\gamma D} \approx 2.25 \pm 0.1$ Å and $d_{\alpha N}^{\gamma L} \approx 2.35 \pm 1$ Å, $d_{\alpha N}^{\gamma D} \approx 3.6 \pm 0.1$ Å). Not counting the occasionally large variation of the $d_{\alpha N}$ (±0.5 Å in ϵ_D and ±0.3 Å in δ_L), the calculated marker distances are typical and indicative of the backbone conformational type, *regardless*

[8]Neglecting the cross-correlation between spins with a high irradiation power (49), all dipolar interactions may be characterized by a single relaxation time, therefore the ratio between two interproton distances (d_j and d_{ref}) is

$$\left(\frac{d_j}{d_{ref}}\right)^6 = \frac{\sigma_{ref}}{\sigma_j}$$

where σ_j and σ_{ref} are the individual cross-relaxation rates via dipole–dipole interaction. The σ_{ref} value is determined as a reference, using for example an appropriate methylene interproton distance d_{ref}. Applying a large pre-irradiation time, compared to T_{1i}, then the individual cross-relaxation rates via dipole–dipole interaction (σ_j) (in the absence of solvent-solute NOE) is

$$\sigma_j = \eta^i(j)/T_{1i}$$

where $\eta_i(j)$ is the enhancement of H_i's proton intensity when H_j is irradiated and T_{1i} is the relaxation time of H_i.

[a]The $\gamma_D\alpha_D \rightarrow \varepsilon_D\alpha_D$ conformational shift is observed. Torsion angles (ω, ϕ, ψ) in degrees, distances in Ångstroms, forces in au, energy (*E*) in hartrees, and energy differences (ΔE) in kcal/mol compared to $E(\gamma_L\gamma_L) = -656.963681$.

[b]INI: Initial backbone conformation (calculated by ECEPP/2).

[c]CONV: converged backbone conformation.

[d]MODEL DIS.: C_i^α and C_{i+3}^α in accordance to classical β-turn definition must be shorter than 7 Å. In For-Ala-Ala-NH_2 the two C^α atoms are replaced by hydrogens (H1 and H4*) (cf. Scheme 2), therefore the model distance (d_{model}) is shorter than C_i^α—C_{i+3}^α (Fig. 1) no more than 1.1 Å. In such a case τ is H1—$C2^\alpha$—$C3^\alpha$—H4*.

[e]CRIT DIS.: critical distances for β-turn assignment (C_i^α—C_{i+3}^α) were extrapolated using *ab initio* resulted bond lengths and bond angles, on the basis of the determined N—H and C′—H distances. In such a case τ is $C1^\alpha$—$C2^\alpha$—$C3^\alpha$—$C4^\alpha$.

[f]Number of structures assigned in the 78 selected proteins.

[g]93 $\gamma_L\gamma_L$, 13 $\gamma_L\gamma_L\gamma_L$, 1 $\gamma_L\gamma_L\gamma_L\gamma_L$, 1 $\gamma_L\gamma_L\gamma_L\gamma_L\gamma_L$ were assigned, no $\gamma_D\gamma_D\gamma_D$ or longer fragments were assigned.

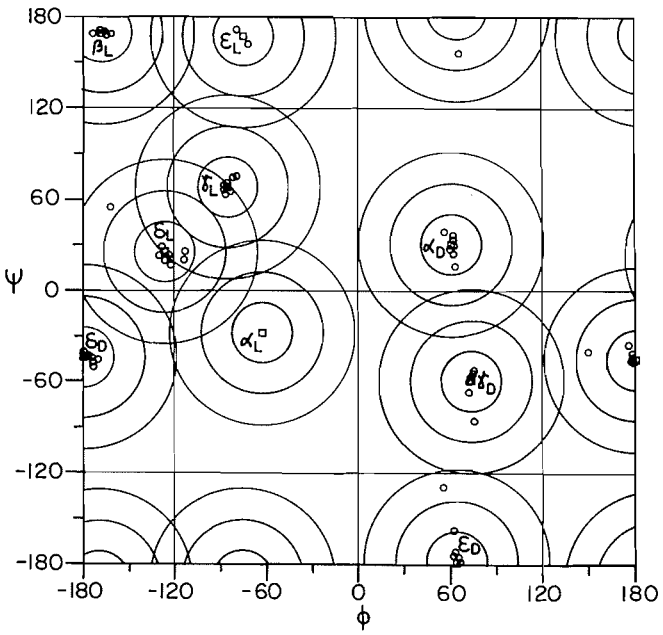

FIG. 2. The location of the "extracted" 9 basic conformations of an amino acid diamide by averaging the appropriate substructures (*) of For-L-Ala-L-Ala-NH_2 obtained from *ab initio* calculations: α_L, −63.9, −23.3; α_D, 61.8, 31.9; β_L, −167.6, 169.9; δ_L, −126.2, 26.5; δ_D, −179.6, −43.7; ϵ_L, −74.7, 167.8; ϵ_D, 64.7, −178.3; γ_L, −84.5, 68.7; γ_D, 74.3, −59.5. The potential energy surface of a single amino acid diamide involves 9 catchment regions in an idealized case (see for details ref. 2). The 9 sets of concentric cycles (3 for each minima) incorporate the area around the "averaged" structure located on a ϕ,ψ map, using a radius of 40°, 50°, and 60°.

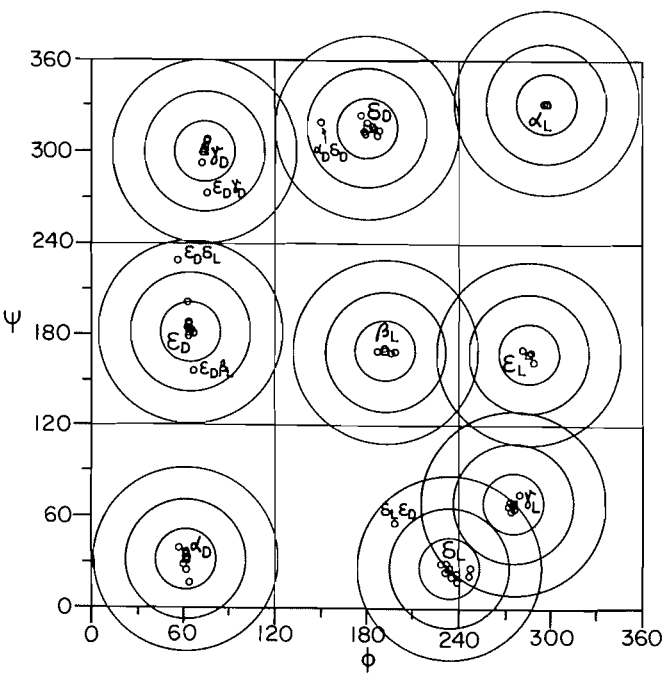

FIG. 3. The same as Fig. 2, using a topologically more useful representation of the same PES (see ref. 2 for the transformation). Note that such a representation of the PES makes the plot of the 9 catchment region possible without truncation.

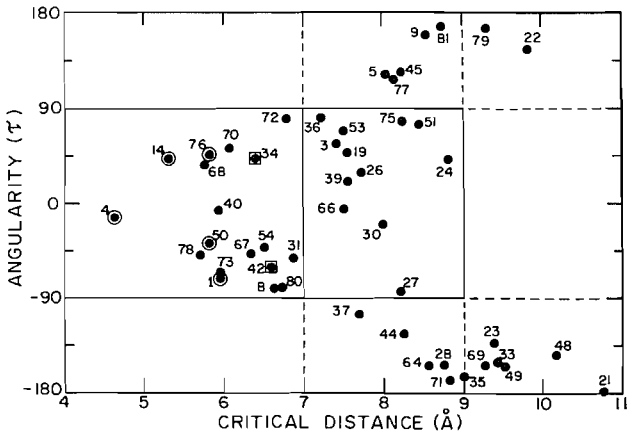

FIG. 4. The angularity τ of the conformation is plotted against the critical distance for the 49 For-Ala-Ala-NH_2 conformations, calculated by HF/3-21G method. (A critical distance, d, which is the separation of the non-bonded C_i^α—C_{i+3}^α atoms, that can be determined from the *ab initio* optimized geometry. The value of τ is also determined from the *ab initio* optimized geometry by calculating the relative orientation of $C1^\alpha$—$C2^\alpha$—$C3^\alpha$—$C4^\alpha$ atoms (see also ref. 37). Since only 49 from the 81 initial conformations was found as stable structures, during *ab initio* geometry optimization only 49 [d, τ] points were plotted:

For personal use only.

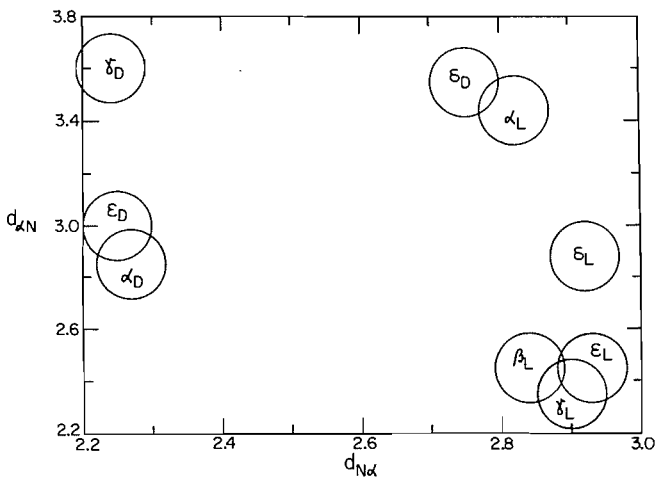

FIG. 6. The location of the 9 different backbone conformations on a $d_{N\alpha}d_{\alpha N}$ space. (The two marker distances are defined as $d_{N\alpha} = d_{NH(i)/H\alpha(i)}$ and $d_{\alpha N} = d_{H\alpha(i)/NH(i+1)}$.) Using also the d_{NN} marker distances further ambiguities can be eliminated.

of the conformation of the preceding or following structural unit. A representation of the 9 backbone conformations based on their $d_{N\alpha}$ and $d_{\alpha N}$ values (Fig. 6) yields 5 significantly different conformational clusters. The inherent error when 1D- and/or 2D-NOE type data are quantified, and converted to interproton distances (58), is large enough that $\beta_L/\gamma_L/\epsilon_L$ structures or the ϵ_D/α_D and δ_D/α_L conformations may not be distinguished simply using their $d_{N\alpha}$ and $d_{\alpha N}$ values. However, with the incorporation of the additional d_{NN} distance type (e.g. $d_{NN}^{\beta L} \approx 4.3 \pm 0.1$ Å/$d_{NN}^{\gamma L} \approx 3.7 \pm 0.2$ Å/$d_{NN}^{\epsilon L} \approx 4.6 \pm 0.1$ Å), all 9 conformers can be reliably assigned (see also Table 12). The conformation of any diamide-type subunit of a protein backbone can be characterized by one of the 9 conformational types (see below). The assignment of these substructures using a combination of the three well known $d_{N\alpha}$, $d_{\alpha N}$, and d_{NN} distances has great importance. Although the determination of interproton distances based on ^{1}H-{^{1}H}-NOE or NOESY spectra is problematic, the secondary structure of a polypeptide can now be assigned not only in term of helices, sheets, or turns but also as accurately as α_L, β_L, γ_L, δ_L, ϵ_L etc.

In the case of a single conformation these d_j's (eq. [1]) are typical for the investigated conformation and are therefore regarded as marker distances. However, in the case of a conformational mixture, these marker distances d_{ji} (that is the interproton distance in the ith conformer) have to be determined by computation for each of the conformers. The experimentally determined interproton distances in the case of conformational mixtures reflect the average interproton distance due to the time scale of the NMR experiment, which makes structure determination of small or medium size peptides extremely difficult. Consequently, the application of NOE-based structural constraints for small or mid-size peptides has serious limitations and requires sophisticated calculations. The reciprocal of the sixth power of the average interproton distance (d_j which is an experimental distance) is the weighted average of the reciprocal of the sixth power of the individual marker distance (d_{ji} which are calculated distances) as shown by the following equation:

$$[1] \quad \frac{1}{d_j^6} = \sum_{i=1} p_i \frac{1}{d_{ji}^6}$$

The weighing coefficient (p_i) is the probability occurrence of the ith conformation in the mixture. Consequently, the spectroscopic determination of peptide conformations requires the

[a]Backbone interproton distances calculated by *ab initio* (HF/3-21G) geometry optimization.
[b]Standard NMR type abbreviations of the marker distances.

quantitative knowledge of these marker distances (d_{ji}) in all the participating conformers (Table 12).

The IR and UV type spectra, containing time-resolved structural information, are rather complex due to the presence of multiple conformations and/or the dynamic aspects of backbone conformation in solution. Moreover, the IR and/or CD spectra provides no insight to structure-sequence correlation. Therefore, the deconvolution of the complex spectra must be followed by the assignment of the component curves to individual conformations, using external data (e.g. calculations resulting in probability occurrences (p_j), NOE structural constraints, etc.).

Description of the proteins 3D structure on the basis of ab initio calculations

At present, no relationship between the amino acid sequence of proteins and their three- dimensional conformation has been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12

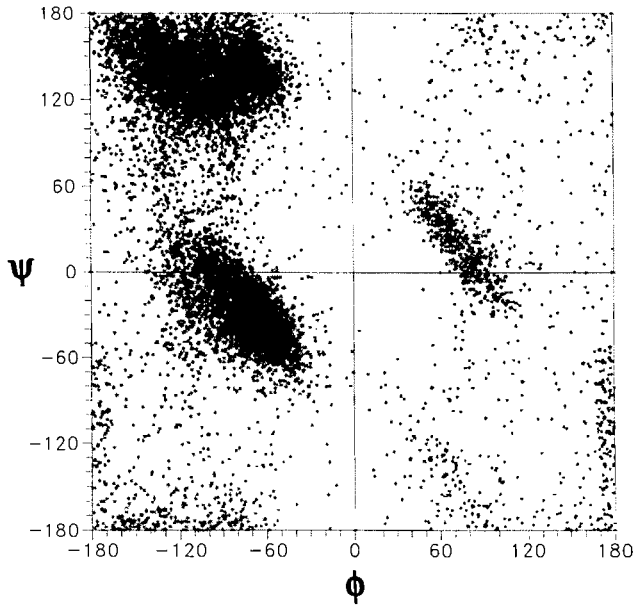

FIG. 7. The ϕ,ψ distribution of 11786 amino acid residues of 78 selected proteins on the basis of their solid state conformations determined by X-ray crystallography. (For the list of the proteins see the Protein Database section.)

found. Although many different approaches have been attempted, resulting in a variety of prediction algorithms, a reliable a priori prediction of protein 3D-structure from its amino acid sequence is still not in sight. A less glamorous but more fundamental task is to classify the already determined backbone conformations. This task is not only useful but could very well be a prerequisite to the discovery of a 3D structure predicting algorithm. The determination of several "central" points on the Ramachandran map, where all the possible backbone conformations of proteins are represented (c.f. Fig. 8), is equivalent to the recognition that certain conformations are playing some "key" role during protein folding. In the past the division of the $-180° < \phi < +180°$, $-180° < \psi < +180°$ space was achieved by the fragmentation of the X-ray determined protein structures (method A), as well as on the basis of the conformations determined by MM calculations (method B). The frequency ratios of subconformations in the investigated protein data set influenced the statistical analyses, introducing inaccuracies into method A. On the other hand, parameterization of the force fields, partially based on X-ray data, can induce errors in the geometrical and energetic description of the resulting structures. Although the two methods differ from each other, their arbitrary character may well be the cause of their limitations. We propose here a third method for the division of the ϕ,ψ surface on the basis of multidimensional conformational analysis combined with *ab initio* calculations. Because all published *ab initio* calculations on amino acid diamides, regardless of the applied basis set or calculation type, resulted in 9 (or fewer) backbone conformations, this value is considered the upper limit. Although HF calculations also have limitations, they can describe conformational properties quite accurately, which is not the case for the semi empirical or force field methods. Therefore, the Ramachandran map ($0° < \phi < +360°$, $0° < \psi < +360°$) was divided into 9 conformation regions labelled for their minima (2). All the 49 different optimized conformations of For-Ala-Ala-NH_2 are also the combination of these 9 (α_L, α_D, β_L, γ_L, γ_D, δ_L, δ_D, ϵ_L, and ϵ_D) legitimate conformations. However, the application of these minima as "central points" on the PES was previously questionable, because two of the 9 minima were annihilated in the case of simple amino acid diamides (2). Also, the degree of conformational distorting effects of the nearest neighbors was unknown. The analysis of the torsional angle distributions of the 12 α_D, 14 β_L, 15 γ_L, 14 γ_D, 12 δ_L, 14 δ_D, 3 ϵ_L, 13 ϵ_D, and 1 α_L subconformations (Scheme 9) yielded a set of average or "central" conformations with high confidence (Table 10 and Figs. 3 and 4). Although conformation-dependent alterations of some substructures was observed (e.g. 4 of the 14 ϵ_D substructures deviate significantly from the average value), in general they are located close to each other as well as to the ϕ, ψ values computed for the appropriate For-Ala-NH_2. The ϕ,ψ distribution of 11786 amino acids incorporated in the 78 selected proteins is reported in Fig. 7. The population of the different regions agrees well with the general expectation that locations around the helical ($\phi = -60°$, $\psi = -30°$) and the extended (β) regions ($\phi = -150°$, $\psi = +150°$) are highly populated. The dimension and the shape of the spot at the top left region (β region) of the Ramachandran map, compared to the "helical area", underlines our interpretation that this is an area that consists of three "centers" such as the β_L, ϵ_L, and γ_L (see Figs. 7 and 3). The location of the 9 "conformational centers" determined by *ab initio* calculations (Figs. 2 and 3) compared with the position of the dense area obtained by simply plotting the ϕ,ψ values of the selected 78 proteins (Fig. 7) resulted in an impressive similarity. The backbone distorting effect of the side chains can also be ignored to some extent since the analysis of other amino acid diamides (e.g. For-Ser-NH_2, For-Gly-NH_2, and For-Val-NH_2) yielded similar locations of backbone conformations.

As an example, the assignment of the 3D structure of a Cytochrome C (1CCR) fragment (Fig. 8) is reported. Using only the classical terms to describe the folding of the backbone (α-helices, β-turns and β-pleated sheets), the 22–23, 26–29, and 32–40 regions of this protein backbone cannot be assigned. The "structure-describing" method reported here, on the other hand, makes the description of the overall backbone structure possible (c.f. Fig. 9.)

The applicability of the "structure-describing" method was checked for all the 78 protein backbone conformations. The structure-assigning power of this method was calculated as a function of the allowed deviation from the "conformation centers" (see Table 12 and Fig. 9). The larger the circles drawn around the 9 centers, the higher the percentage of the ϕ,ψ points determined by X-ray crystallography was accounted for. For example, applying a deviation of 60° (which is the case when all 9 circles have a radius equal to 60°, more than 85% of all the 78 protein backbones can be assigned to one of the 9 conformation types (solid square). By decomposing the total profile into individual conformations (Fig. 9), it is clear that certain conformational types can be described more accurately than others. For example, more than 95% of the ϕ,ψ pairs assigned to right-handed helices in the 78 proteins deviate less than 60° from the *ab initio* determined (and averaged) α_L conformation center. On the other hand, conformational types such as the δ_D or the ϵ_D alternate more, less than 65% of the "total" backbone can be described with a smaller deviation than 60°.

Four points should be emphasized in closing.

(1) The observation that certain substructures have ϕ,ψ torsional angle pairs far away (>40°) from the "conformational centers" does not indicate the failure of the method. In fact, it is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12

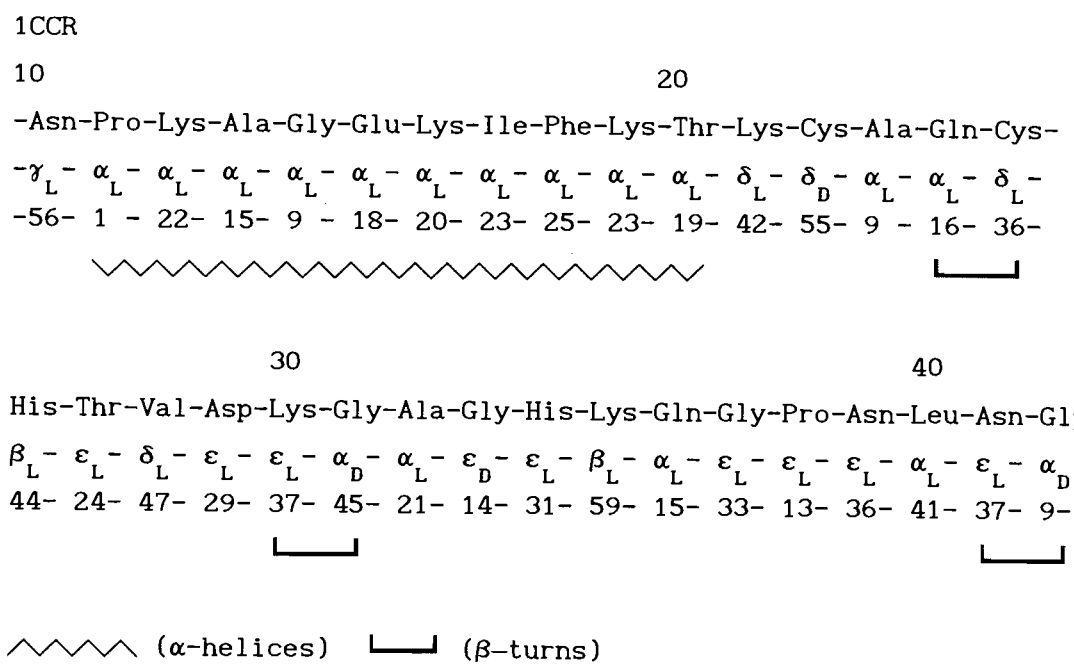

FIG. 8. The structural assignment of a Cytochrome C (1CCR) fragment (between residues 10, 42). Below the amino acid sequence, the structure codes as well as their deviations from the *ab initio* calculated (and averaged) conformations are reported. (According to classical folding description, the 21–23, 26–29, and 32–39 regions cannot be assigned.)

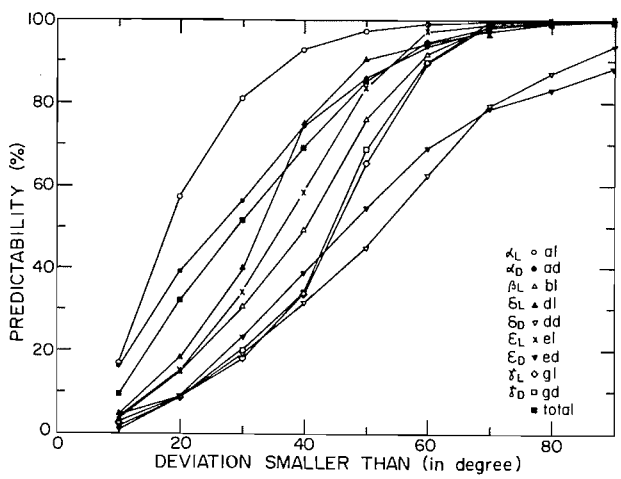

FIG. 9. Describability of the 78 selected protein backbone conformations, using 9 amino acid diamide conformation types. The upper limit of the allowed deviation is plotted against the desirability expressed in percentages. (E.g. 81.2% of the ϕ,ψ pairs assigned in the helical region of the 78 proteins deviate less than 30° from the ab initio determined (and averaged) ϕ,ψ value.

diagnostic that some unusual stabilizing or destabilizing interaction is operative at that particular amino acid residue. For example, the one and only "ghost" δ_L conformation assigned in $\delta_L\epsilon_D$ structure (c.f. Table 6) is located between the circles corresponding to the 40° and 60° radii, while all other 11 δ_L subconformations are located within a 20° radius measured from the δ_L "conformational center". Such an anomaly is diagnostic and indicative of some special intramolecular interaction.[5] In fact the $\delta_L\epsilon_D$ conformation incorporates an "unusual" 8-membered ring (Fig. 10) with all trans amide bonds. In contrast to the familiar 10-membered intramolecular H-bond, such as in $\alpha_L\delta_L$, the more stressful hydrogen bond can be characterized by (*i*) bent N—H...O system, with an angularity of 151.2°; (*ii*) with a significant pyramidalization of the N atom incorporated in the middle amide group; (*iii*) distorted δ_L subconformation. Therefore we think that "ghost" structures, assigned in proteins (Fig. 7) are diagnostic of special intra- or intermolecular interactions.

(*2*) The increase in polypeptide chain length. For a For-$(Ala)_i$-NH_2 ($1 \leq i \leq 4$) molecule, the average $\{\phi,\psi\}$ torsional angle pairs do not change dramatically with i (c.f. Table 10). The increase in basis set size and/or the inclusion of electron correlation did not result in significant conformational changes as demonstrated by Schafer and co-workers (15) in small systems, even when MP2/6-311++G(*d*, *p*) was applied. The observed standard deviation (i.e. $0.5[\Delta\phi + \Delta\psi]^{1/2}$) on the $\{\phi,\psi\}$ PES was smaller than 8° for selected backbone structures, while the largest alteration in the torsional angles was for the γ_L conformation was found to be $\Delta\psi = 15.2°$ on going from HF/3-21G to MP2/6-311++G(*d*, *p*). Our own study (40) showed, as may be seen from Table 2, the maximum alteration is $\Delta\phi = 13.3°$ on going from HF/3-21G to MP2/6-311++G(*d*, *p*) levels of theory with a standard deviation of only 6.7°. All these values are well within the smallest circles of 20° radii shown in Figs. 2 and 3. Certainly, precise determination of the 9 conformational centers depends upon the applied basis set, and could well be modified in future, when high computational power is available, but the basic concept of the conformational assignment will remain intact.

(*3*) All "conformational centers" were determined on the basis of *ab initio* calculations performed on For-$(Ala)_i$-NH_2 ($1 \leq i \leq 4$) molecules. It is obvious that the very simple side chain of such a model compound cannot be representative of the large variety of polar and apolar side chains. However, polyalanine models are the best systems for the investigation of purely backbone/backbone-type interactions. From this perspective all backbone/sidechain interactions are treated as indicative backbone modifying effects. Therefore, when the

[a]For example, when the allowed deviation is smaller then 30°, 51.6% of the total backbone conformation can be described. However, at this limit 81.2% of all the helical regions can be determined.

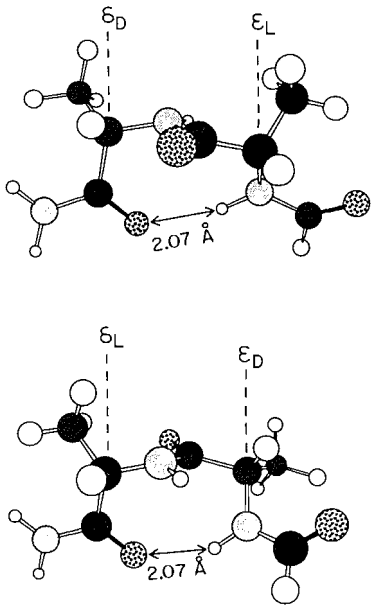

FIG. 10. The $\delta_L^*\epsilon_D$ conformation, where an unusual 8-membered H-bond ring was assigned. The same 8-membered H-bond ring was observed in its conformational enantiomer $\epsilon_L\delta_D$ (not shown).

conformation of an amino acid residue is classified by the ACAP algorithm (introduced here), and when a noticeable deviation is observed we may be certain that the resulted deviation reflects, as a global indicator, all types of interactions that are exerted on the backbone of the protein.

(*4*) All computations reported in this paper were carried out on individual conformations of the For-(L-Ala)$_2$-NH$_2$ molecule without taking into account the explicit or implicit effect of any solvent. Consequently, the present results provide a scale for intrinsic stability (ΔE) with respect to the global minimum ($\gamma_L\gamma_L$) of the 4D-Ramachandran potential energy hypersurface. When at a future date solvation effects on the conformations of For-(L-Ala)$_2$-NH$_2$ molecule are studied, the present results can be used, as a primary standard, to measure the energy lowering due to solvation.

Conclusion

For the first time, *ab initio* type calculations on the multidimensional conformational problem of a diamino acid triamide system resulted in a complete set of relaxed conformations. A large part of the For-Ala-Ala-NH$_2$ geometries are intrinsically stable hairpin (β-turns) conformations 18(30) depending on the applied criteria. This suggests that more β-turn types than expected exist on the basis of X-ray type secondary structure assignment. The 30 β-turn conformations are depicted in ref. 37 and the molecular graphics of the 19 non-β-turn conformations are shown in Fig. 11. Examples for all 49 calculated substructures were found in proteins by analzying the X-ray data of globular proteins. All 9 theoretically predicted backbone conformational types (α_L, α_D, β_L, γ_L, γ_D, δ_L, δ_D, ϵ_L, and ϵ_D) can be adopted as a substructure even for the simple For-Ala-Ala-NH$_2$ molecule. The preceding or following diamide unit can stabilize the α_L and ϵ_L conformations, as substructures, which were found to be intrinsically unstable geometries in the For-Ala-NH$_2$ molecule.

The *ab initio* calculations resulted in structures that can also be analyzed in terms of interproton distances, which are useful parameters for the interpretation of NMR spectra. The calculated marker distances (e.g. $d_{N\alpha}$, $d_{\alpha N}$, d_{NN}) are *typical* for the backbone conformational type, regardless of the conformation of the preceding or following structural unit. Moreover, by simply using the three common, $d_{N\alpha}$, $d_{\alpha N}$, d_{NN} marker distances all 9 different backbone conformers can be distinguished.

The ϕ,ψ distribution of 11786 amino acids, incorporated in 78 selected proteins with known X-ray structures, was analyzed. The conformation of all the 11786 residues were assigned, demonstrating the applicability of the "structure-description" method proposed in this paper.

Hudson, in his editorial article, examined the possibilities of X-ray and NMR protein backbone conformation determination, and concluded (56) that the "story of protein structure (mis)interpretation unfolds with every new β-turn". We believe that the enumeration of all β-turns on the basis of *ab initio* calculations, as well as their assignment in globular protein's X-ray structure, can further enhance structure assignments in the future.

Acetal formation from methyl formate, pinacolone, and benzophenone: equilibrium constants in methanol and water determined by a chain of transacetalization equilibria

J. Peter Guthrie[1] and Junan Guo

Department of Chemistry University of Western Ontario, London, ON N6A 5B7, Canada

Received December 16, 1993[2]

J. Peter Guthrie and Junan Guo. Can. J. Chem. **72**, 2071 (1994).

Transacetalization equilibrium constants can be measured in methanol solution. This allows a ladder of equilibrium constants to be constructed from acetophenone, for which the equilibrium constant for acetal formation has been measured in methanol, to methyl formate, for which it has not. This is the first direct measurement of an equilibrium constant for formation of an acetal of an acyclic ester. We have also determined equilibrium constants for acetal formation from benzophenone and pinacolone. The value for benzophenone is inconsistent with the value reported for the diethyl acetal by Pfeiffer and Adkins (G.J. Pfeiffer and H. Adkins. J. Am. Chem. Soc. **53**, 1043 (1931)). We must conclude that their analytical method was subject to systematic errors.

J. Peter Guthrie et Junan Guo. Can. J. Chem. **72**, 2071 (1994).

On a mesuré les constantes d'équilibre de transacétalisation en solution dans le méthanol. On peut maintenant définir une échelle de constantes d'équilibre allant de l'acétophénone, pour laquelle la constant d'équilibre de formation de l'acétal a été mesurée dans le méthanol, au formate de méthyle, pour lequel cette mesure n'a pas été faite. Il s'agit de la première mesure directe d'une constante d'équilibre pour la formation d'un acétal d'un ester acyclique. On a aussi déterminé les constantes d'équilibre pour la formation d'un acétal à partir de le benzophénone et de la pinacolone. La valeur pour la benzophénone n'est pas en accord avec la valeur rapportée, pour l'acétale de diéthyle, par Pfeiffer et Adkins (G.J. Pfeiffer et H. Adkins. J. Am Chem. Soc. **53**, 1043 (1931)). On doit en conclure que leur méthode analytique devait être l'object d'erreurs systématiques.

[Traduit par la rédaction]

Introduction

Equilibrium constants for acetal formation can often be determined directly (1–7), but for less reactive carbonyl compounds this becomes increasingly difficult. Although there are several independent determinations of the equilibrium constant for acetophenone dimethyl acetal formation (2, 7), there are no values for compounds much less reactive than acetophenone: *p*-methoxyacetophenone is the least reactive compound for which an equilibrium constant has been measured directly (2). Pfeiffer and Adkins (8) extended the study of acetal formation to much less reactive compounds by using transacetalization, with formation of triethyl orthoformate from ethyl formate and ethanol as the reference equilibrium, although in fact they did not know this equilibrium constant and could only determine relative values. This pioneering work was hampered by the limited means available for analyzing the composition of the equilibrium solutions. In fact, the analyses were based on determination of the amount of ethyl formate in solution in ethanol by reaction with sodium metal, leading to production of carbon monoxide.

We have used the free energy of formation of trimethyl orthoformate, based on thermochemical data, as the starting point for calculation of the free energy of formation of orthoformic acid and its mono and dimethyl esters (9). We used the Pfeiffer and Adkins value for the transacetalization equilibrium constant to estimate the free energy of formation of benzophenone dimethyl acetal, from which we estimated the free energy of formation of the hydrate, and hence the equilibrium constant for covalent hydration of benzophenone (10). It was of interest to see if modern analytical methods would allow a more direct determination of the free energy of formation of trimethyl orthoformate and benzophenone dimethyl acetal by equilibrium measurements. We wish now to report the results of such studies. The equilibrations were carried out in methanol, but of greater interest are equilibrium constants in aqueous solution. To determine the free energies of transfer from methanol to water we used the approach of Toullec et al. (2), i.e., using dodecane as an intermediate solvent, not miscible with either water or methanol.

Results

Equilibrium constants for transacetalization

We used acetophenone as our anchor compound, but found that for nmr analysis, the equilibrium constant for transacetalization between acetophenone and trimethyl orthoformate was too far on the side of acetophenone dimethyl acetal to allow us to measure the equilibrium constant. Accordingly we used pinacolone as a bridge compound; from the work of Pfeiffer and Adkins (8) we knew that pinacolone had a considerably smaller tendency to form an acetal than acetophenone. Both the transacetalization equilibria relating pinacolone and acetophenone and pinacolone and methyl formate, could be measured conveniently. All equilibria were followed from both directions, and gave the same equilibrium constant in each case. For benzophenone we expected, based on the results of Pfeiffer and Adkins in ethanol solution (8), that the acetalization would be even more difficult than for methyl formate. However, we found that in fact benzophenone is similar to acetophenone in its reactivity. The results of these experiments are found in Table 1.

$$R^1R^2C(OMe)_2 + R^3R^4C{=}O \rightleftharpoons R^1R^2C{=}O + R^3R^4C(OMe)$$

$$K_{\text{transacetalization}} = \frac{[R^1R^2C=O][R^3R^4C(OMe)_2]}{[R^1R^2C(OMe)_2][R^3R^4C{=}O]}$$

$$= \frac{[R^1R^2C{=}O][MeOH]^2[R^3R^4C(OMe)_2][H_2O]}{[R^1R^2C(OMe)_2][H_2O][R^3R^4C{=}O[MeOH]^2}$$

$$= \frac{K^{R^3R^4CO}_{\text{acetalization}}}{K^{R^1R^2CO}_{\text{acetalization}}}$$

TABLE 1. Transacetalization equilibrium constants in methanol, dodecane, and water[a]

Equation	K_f	K_r	K_{meoh}[b]	K_{dod}[c]	K_{water}[c]
[1]	115.9 ± 5.6	113.3 ± 7.3	114.6	108.6	115.6
[2]	55.5	46.5	51.0	35.6	59.1
[3]	6.1 ± 0.1	5.3 ± 0.4	5.7	34.8	1.5

[a]For transacetalization equilibrium:
Ketone-1 + acetal-2 ⇌ ketone-2 + acetal-1

[1] $PhCOMe + Me_3CC(OMe)_2Me \rightleftharpoons Me_3CCOMe + PhC(OMe)_2Me$

[2] $PhCOPh + Me_3CC(OMe)_2Me \rightleftharpoons Me_3CCOMe + PhC(OMe)_2Ph$

[3] $Me_3CCOMe + HC(OMe)_3 \rightleftharpoons HCOOMe + Me_3CC(OMe)_2Me$

The equilibrium constant was defined as: K = [ketone-2][acetal-1]/[ketone-1][acetal-2]. The activity coefficient ratio did not differ significantly from unity. This was confirmed by experiments showing that the equilibrium constant was concentration independent and that dilution of a system at equilibrium did not change the apparent value of the equilibrium constant.

[b]K_{meoh} is the equilibrium constant in methanol and was measured by ^1H NMR. K_{meoh} is the average of K_f and K_r, which were obtained from reactions run in the forward and reverse directions, respectively.

[c]K_{dod} and K_{water} stand for equilibrium constants in dodecane and water, respectively, and were calculated by the use of free energies of transfer from Table 3.

TABLE 2. Equilibrium constants for acetal formation in methanol, dodecane, and water[a]

	$10^6 K_X$		
Compound	K_{meoh}	K_{dod}	K_{water}
PhCOMe	632.0[b]	328.0[b]	43.8[b]
PhCOPh	281.0[c]	107.0[d]	22.4[d]
Me_3CCOMe	5.51[c]	3.02[d]	0.379[d]
HCOOMe	0.968[c]	0.0869[d]	0.257[d]

[a]K_{meoh}, K_{dod}, and K_{water} are equilibrium constants in methanol, dodecane, and water, respectively, based on the mole fraction standard state for all species.

[b]The values for acetophenone were from ref. 2.

[c]Calculated by combining transacetalization equilibrium constants from Table 1 and the equilibrium constant for acetal formation from acetophenone (2).

[d]Calculated using K_{meoh} and partition constants from Table 3.

Equilibria for acetalization in methanol

By combining the equilibrium constant for the acetalization of acetophenone with the equilibrium constants for transacetalization that we determined, we could calculate equilibrium constants for the acetalization of pinacolone, methyl formate, and benzophenone. These calculations are summarized in Table 2.

Partition constants

Equilibrium constants for partitioning of compounds from methanol to dodecane and from dodecane to water were determined in order to allow the calculation of the free energy of transfer from methanol to water. These results are summarized in Table 3, which also contains data from the literature on the free energies of transfer for water, methanol, acetophenone, and its dimethyl acetal.

Equilibria for acetalization in water

From the free energy of transfer data in Table 3 and the equilibrium constants for acetalization in methanol in Table 2 we have calculated equilibrium constants in water for each of the acetalizations; these values are in Table 2. The value for methyl formate represents the first equilibrium constant for formation of an acetal of an acyclic ester to be directly determined.

Free energies of formation

From the equilibrium constants determined in this work, and the thermodynamic data available in the literature for the carbonyl compounds, we are able to calculate the free energies of formation of the acetals. These values are found in Table 4, along with thermodynamic data for all compounds discussed in this paper. In the case of trimethyl orthoformate this new value, $\Delta G_f(aq) = -88.35 \pm 0.70$ kcal/mol, can be compared with the value previously calculated from thermochemical data, -87.80 ± 0.81 kcal/mol. The agreement is excellent. The value of the equilibrium constant for acetal formation from benzophenone allows determination of another group contribution to the free energy of formation in aqueous solution (11), namely $[C(C_B)_2(O)_2]$.[3] It is also possible to calculate a value for $[CO(C_B)_2]$, which has not previously been reported. Using group contributions from ref. (11) and the free energies of formation in Table 4 we calculate that $[CO(C_B)_2] = -30.1$ and $[C(C_B)_2(O)_2] = 5.47$. Since each value is based on only one compound, they can only be regarded as provisional.

Discussion

Our method for determining transacetalization equilibrium constants should be general. The main limitations are the limited dynamic range of NMR analysis and the problem of overlap between the peaks used for analysis and other peaks from species in solution. The former problem forces us to use integration of a peak from a minor species relative to a ^{13}C satellite of a peak from a major species. With more intermediate compounds, and more steps to the ladder, this could be overcome. The latter problem will restrict application to more elaborate structures but will become less important as higher field NMR instruments become more available.[4]

We were distressed to find that our results did not bear out those of Pfeiffer and Adkins (8). The discrepancy is shown in Fig. 1, which contrasts the results from the two methods. To allow direct comparison we calculated equilibrium constants for transacetalization involving methyl formate/trimethyl orthoformate as the reference reaction. Admittedly Pfeiffer and Adkins (8) worked in ethanol with triethyl orthoformate and diethyl acetals, but the discrepancies seem too large for the relatively modest effects expected for replacement of methyl by ethyl. Adkins and Adams found very similar equilibrium constants for acetal formation from acetaldehyde and methanol, ethanol, propanol, or butanol (1). We are forced to conclude that there were systematic errors in the work of Pfeiffer and Adkins (8). The problem doubtless lies in their analytical procedure, the conversion of ethyl formate to carbon monoxide by the action of sodium on the ethanol solution. Although the mechanism of this reaction does not appear to have been elucidated, it is not hard to imagine that benzophenone could interfere, by transient formation of a ketyl. An investigation of the kinetics of this reaction found that there is a smooth decomposition of ethyl formate under the influence of ethoxide ion in ethanol, which leads to a temperature-dependent equilibrium with carbon mon-

[3]Following Benson (24) we use C_B to mean aromatic carbon; thus $\{C(C_B)_2(O)_2\}$ is the contribution from a carbon bonded to two aromatic rings and two oxygen functions.

[4]We currently have routine access to 200 or 300 MHz NMR instruments. Preliminary experiments at 60 MHz were less promising because of problems of peak overlap and sensitivity. Still higher fields would be even better.

PhCOMe	2.47
$PhC(OMe)_2Me$	3.45

[a] P_{m-d} and P_{d-w} are the partition constants from methanol to dodecane and those from dodecane to water. G_{m-d}, G_{d-w}, and G_{m-w} are the free energies of transfer from methanol to dodecane, from dodecane to water, and from methanol to water, respectively. Both the partition constants and the free energies of transfer are based on the molar concentration. In the determination of partition constants, activity coefficients were assumed to be unity and this was confirmed by the observation that the measured values were concentration independent. Free energies of transfer are given in kcal/mol.

[b] Measured by UV.

[c] Measured by ^{1}H NMR.

[d] Calculated from values in ref. 2, correcting to the standard states used in this paper.

[e] 1 M water in methanol to liquid water.

[f] Liquid methanol to 1 M methanol in water.

TABLE 4. Free energy of formation data for compounds discussed in this paper[a]

[a] Standard states are ideal 1 M solutions in water or methanol, with an infinitely dilute reference state. For water in water or methanol in methanol, the standard state is the pure liquid. Except as noted, ΔG_f in water is taken from ref. 11 and ΔG_f in methanol is calculated from ΔG_f in water using the free energies of transfer from Table 2. Free energies are given in kcal/mol.

[b] Calculated from the equilibrium constants for transacetalization, found in Table 1, and the free energies of formation of the other reactants, taken from this table.

[c] Reference 10.

oxide (12). Methyl formate is produced industrially by the reaction of carbon monoxide with methanol and a catalytic amount of sodium methoxide at 70°C and 20–200 bar (1 bar = 100 kPa) (13). An unavoidable conclusion is that the set of transacetalization equilibrium constants reported by Pfeiffer and Adkins (8) must be considered unreliable, and should be redetermined.

Initially we had used the Pfeiffer and Adkins (8) value for acetal formation from benzophenone as the basis for an estimate of the equilibrium constant for hydration of benzophenone (10). This value was considerably less favorable than for the hydration of acetophenone, as seemed reasonable from a naive assumption that *two* conjugated phenyl groups would favor the carbonyl group relative to acetal more effectively than one. From this perspective the observation that the equilibrium constants for acetalization (and hence for hydration) of benzophenone and acetophenone are quite similar seems most surprising. There is, however, general agreement, both from theoretical calculations (14, 15), and from experimental investigations (16, 17), that the benzene rings in benzophenone are twisted substantially away from coplanarity with the carbonyl. The exact angle in solution is not yet well established, with estimates varying from 26.2° (14) to 36° (16), and the angle in the solid, a twist angle of 33° with respect to the plane of the carbonyl (18), may well be influenced by packing. Benzophenone adopts a nonplanar conformation in order to relieve nonbonded interactions of the *ortho* hydrogens. As a consequence the conjugative stabilization in benzophenone need not be greater than in acetophenone. Ab initio calculations (3-21G) suggested that conjugation becomes more important as the benzophenone molecule twists toward planarity; the planar conformation was calculated to be more stable than the book conformation[5] by 7 kcal (14), although both are less stable than the twisted form. Although there will not be extra conjugation in benzophenone, there is an extra electron withdrawing substituent relative to acetophenone. Thus it should not be surprising that benzophenone and acetophenone have similar equilibrium constants for acetalization.

With revised equilibrium constants for acetalization in hand,

[5] In the book conformation both dihedral angles about the C_B—CO bonds are 90°.

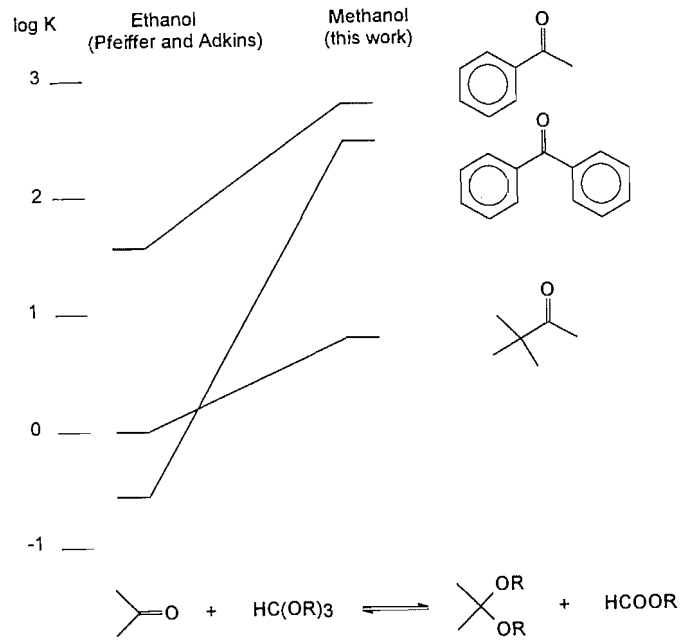

FIG. 1. Comparison of log K values for transacetalization in ethanol and methanol.

we can now calculate the equilibrium constants for hydration of the carbonyl compounds. We do this by means of the correlation we found between the free energy for the hypothetical hydrolysis (corrected for steric and symmetry effects) and the sum of the σ^* values for the other three groups on the central carbon (19).

$$R^1R^2R^3C\text{-}OCH_3 + H_2O \rightleftharpoons R^1R^2R^3C\text{-}OH + CH_3OH$$

$$\Delta G = 0.54 - 0.63\Sigma\sigma^* + \text{steric correction} + \text{symmetry correction}$$

Applying this procedure twice we obtain the equilibrium constant for hydrolysis of an acetal to the corresponding covalent hydrate, and from this and the equilibrium constant for acetal formation it is easy to calculate the equilibrium constant for hydration. The values so calculated are found in Table 5. The calculation requires values for the difference in strain between acetal and hemiacetal and between hemiacetal and hydrate. These strain energies were calculated as before (19) using the scheme introduced by Pihlaja (20, 21).

What are the prospects for extension of this transacetalization procedure? We have examined the question of whether transacetalization equilibrium constants could be measured for other, less reactive esters by similar experiments. It seems probable that it will be possible, but only if a suitable ladder can be constructed, because transacetalization equilibrium constants must be in the range from 0.01 to 100, in order to be practical for NMR analysis. By the use of more hindered ketones (which might react very slowly) and esters with electron-withdrawing groups it should be possible to do this. On the other hand, extension to amides appears unlikely, because of the need for acid catalysis of the transacetalization reaction. Acid, except at very low concentrations (high pH values), would protonate the amine, pulling alcoholysis of the amide or amide acetal to completion. At very low acid concentrations, transacetalization would be very slow, and substantial concentrations of amine would need to be present to maintain the concentration of amide.

TABLE 5. Equilibrium constant for addition of water to ketones

Ketone	log K	
	Liquid water[a]	1 M water[b]
$(CH_3)_3C\text{-}CO\text{-}CH_3$	−6.18	−7.93
$(C_6H_5)_2CO$	−5.04	−6.78
		−8.68[c]

[a] $K = [R^1R^2C(OH)_2]/[R^1R^2C{=}O]$, dimensionless.
[b] $K = [R^1R^2C(OH)_2]/[R^1R^2C{=}O][H_2O]$, M^{-1}.
[c] Reference 10, based on data from ref. 8.

It is of interest to see how well the acetalization equilibrium for pinacolone could have been predicted by simple additivity schemes such as we have recently published. When we calculate the free energy of formation of pinacolone dimethyl acetal using the published group contributions and an estimate of strain derived from MM3 (22) calculations,[6] we obtain a value of −46.82 kcal/mol, which may be compared with the value derived from our transacetalization equilibrium constant, −46.93. In calculating the strain in pinacolone dimethyl acetal we must allow for the strain inevitably present in the groups $[C(C)_2(O)_2]$ and $[C(C)_4]$. We do this by using the disproportion reaction:

$$(CH_3)C\text{-}C(OCH_3)_2\text{–}CH_3 + CH_3\text{–}CH_3 \rightleftharpoons C(CH_3)_4 + (CH_3)_2C(OCH_3)_2$$

This allows us to calculate the extra strain in pinacolone dimethyl acetal that is not implied by the groups in ethane, neopentane, and acetone dimethyl acetal. The net strain so calculated is 10.18 kcal/mol. These calculations are detailed in the Appendix.

The provisional group contributions for $[CO(C_B)_2]$ and $[C(C_B)_2(O)_2]$ that we have calculated should provide a guide for estimating free energies of other diaryl ketones and the corresponding acetals, but until further data are available they should be used with caution.

Experimental

Materials

1 M methanolic HCl solution was made by adding 0.7 mL of acetyl chloride to 10 mL of methanol at 0°C. All reagents were from BDH or Aldrich and were used without further purification except as follows: Acetophenone, pinacolone, methyl formate, and trimethyl orthoformate were purified by distillation. The dimethyl acetals of acetophenone, pinacolone, and benzophenone were synthesized by acid-catalyzed reaction of the ketone with trimethyl orthoformate in methanol, and purified by distillation (acetophenone and pinacolone diemthyl acetals) or by recrystallization from methanol (benzophenone dimethyl acetal). Methanol was dried by reaction with magnesium followed by distillation under nitrogen. The water concentration was checked by Karl Fischer titration using a Metrohm 684KF coulometer; the value found was 68 μg/mL.

[6] As contained in MM3(89) obtained through QCPE, without further parameterization.

Partition constant determination

For each compound a stock solution was prepared (volumetric flask) in the solvent in which it is less soluble. This stock solution (4–7 mL) was mixed with 7–4 mL of the other solvent in a volumetric tube with a standard taper stopper, shaken vigorously for 10 min, transferred into a centrifuge tube, and sealed using foil and parafilm; it was then placed in a constant temperature bath set at 25°C and left overnight. Finally, the two partition phases were separated carefully by centrifugation and the relative concentrations of the two phases were measured by UV or H NMR. In the determination of partition constants of benzophenone or its dimethyl acetal between dodecane and water and of pinacolone dimethyl acetal, the test compound was introduced in dodecane instead of in water because of the large difference in limiting solubilities. Also in these cases the partition systems were stirred overnight at 25°C instead of just shaken for 10 min to make sure that partition equilibrium was reached.

In the case of acetals, 0.1 M aqueous NaOH solution was used as the water phase to inhibit acetal hydrolysis. pH 7 buffer (from BDH, contains 5.775 g/L of Na_2HPO_4 and 3.538 g/L of KH_2PO_4) was used as the water phase for methyl formate for analogous reasons. Usually the relative concentration was measured directly except that benzophenone dimethyl acetal was first hydrolysed to benzophenone.

In the UV determination of benzophenone, benzophenone dimethyl acetal, and pinacolone, samples of the two partition phases were usually diluted in a common solvent: methanol and a 0.1 M $HClO_4$ solution in 90% methanol:10% water were used for benzophenone and its dimethyl acetal, respectively. For pinacolone, however, the samples of the two partition phases were diluted in the corresponding solvent and then analyzed using the appropriate molar extinction coefficients: λ = 288, log ϵ = 1.32 in dodecane (this work), λ = 278, log ϵ = 1.48 in water (23); and λ = 282, log ϵ = 1.40 in methanol (23).

In the H NMR determination of methyl formate, methyl orthoformate, and pinacolone dimethyl acetal, 0.35 mL of the dodecane or methanol phase was added to 0.35 mL of $CDCl_3$ containing methyl acetate as internal reference, and 0.35 mL of the water phase was added to 0.35 mL D_2O containing methyl acetate as internal reference for methyl formate determination and sodium acetate for the other cases. In the determination of the partition constant of pinacolone dimethyl acetal between dodecane and water, the relative concentration in the water phase was obtained by the use of ^{13}C-satellite of the methyl group in sodium acetate as reference because the concentration of pinacolone dimethyl acetal was very low.

Transacetalization equilibrium constant determination

To an NMR tube was added the appropriate amount of each reactant, 0.38 mL of a 1 M solution of HCl in methanol, and enough methanol to give a total volume of 1.5 mL. Then the NMR tube was sealed using a torch and put into the constant temperature bath at 25°C. The transacetalization equilibrium reactions were carried out in the NMR tube and the approach to equilibrium was followed by NMR using a Gemini-200. Relative concentrations of all species at equilibrium were measured by the NMR integrations. For most of the cases, protio methanol was used to prevent the deutero–proton exchange between CD_3OD and CH_3COR and consequently an external deuterium lock was used. However, for the equilibrium starting with pinacolone and benzophenone dimethyl acetal, because the relative equilibrium concentration of the pinacolone dimethyl acetal was very low, 15% of CD_3OD was added to the system after equilibrium was reached, in order to give an internal lock. Analysis was carried out by measuring the ratio of the ^{13}C-satellite of the *tert*-butyl group in pinacolone and the peak of the *tert*-butyl group in pinacolone dimethyl acetal. Some typical initial concentrations of the reactants for both directions are listed as follows:

Me_3CCOMe + $HC(OMe)_3$ ⇌	$Me_3CC(OMe)_2Me$ +	HCOOMe
1.01 M	2.01 M	0 M 0 M
0 M	0 M	0.5 M 1.5M

The water-promoted pathway of peptide cleavage by carboxypeptidase A has been studied by semiempirical (AM1) quantum mechanical calculations. A relatively large model for the CPA-active site elements plus substrate has been designed, using two imidazoles and one acetate as the Zn^{2+} ligands, acetate as the proton acceptor (simulating Glu-270), and *N*-ethylacetamide as the peptide-like substrate. This model, although simpler than the natural one, is one of the largest used for theoretical calculations on CPA catalytic mechanisms. To ensure that this model is able to mimic the natural system, it has been compared with the structure of the $(Gly)_3$-L-Tyr + water + CPA complex resulting from several molecular dynamics/energy minimization simulations. Among the different steps involved in the water-promoted pathway proposed by Lipscomb's group, the attack of the oxygen atom that comes from the activated water molecule to the carbon atom of the peptide bond of the substrate has been found to be the rate-determining step, with a high enthalpy barrier of 37.9 kcal/mol. However, this enthalpy barrier is dramatically decreased when a positive charge, simulating Arg-127, is included near the scissile carbonyl. The reported results seem to favour the occurrence of the mechanism studied and indicate the limitations of using simple elements for the theoretical analysis of enzyme-catalyzed reactions.

SILVIA ALVAREZ-SANTOS, ANGELS GONZÁLEZ-LAFONT, JOSÉ M. LLUCH, BALDOMERO OLIVA et FRANCESC X. AVILÉS. Can. J. Chem. **72**, 2077 (1994).

Utilisant des calculs semiempiriques de mécanique quantique (AM1), on a étudié la voie de clivage des peptides par la carboxypeptidase A (CPA), catalysée par l'eau. On a mis au point un modèle relativement grand des éléments du site actif de la CPA avec le substrat qui utilise deux imidazoles et un acétate comme ligands du Zn^{2+}, un acétate comme accepteur de proton (simulant le Glu-270) et le *N*-éthylacétamide comme substrat semblable à un peptide. Ce modèle, même s'il est plus simple que le modèle naturel, est un des plus grand qui a été utilisé pour des calculs théoriques sur les mécanismes catalytiques de la CPA. Afin de s'assurer que ce modèle peut imiter le comportement du système naturel, on l'a comparé avec la structure du complexe $(Gly)_3$-L-Tyr + eau + CPA qui résulte de plusieurs simulations de dynamique moléculaire et minimisation de l'energie. Parmi les différentes étapes impliquées dans la voie catalysée par l'eau proposée par le groupe de Lipscomb, on a trouvé que l'étape déterminant la vitesse de la réaction est l'attaque de l'atome d'oxygène, provenant de la molécule d'eau activée, sur l'atome de carbone de la liaison peptidique du substrat et qu'elle est accompagnée d'une barrière enthalpique élevée (37,9 kcal/mol). Toutefois, il se produit une diminution dramatique de cette barrière lorsqu'on introduit une charge positive, ressemblant à celle de l'Arg-127, près du carbonyle à être scindé. Les résultats rapportés antérieurement semblent favoriser l'existence du mécanisme étudié et ils indiquent les limitations à l'usage d'éléments simples pour l'analyse théorique des réactions catalysées par les enzymes.

[Traduit par la rédaction]

Introduction

Bovine carboxypeptidase A (peptidyl-L-amino acid hydrolase; EC 3.4.17.1, abbrev. CPA) is a zinc metalloexopeptidase of 307 residues (MW = 34 472), and a well-studied enzyme (1–6). This protease preferentially hydrolyzes peptide or ester bonds at the C-terminus of polypeptide substrates with hydrophobic (aromatic or aliphatic) residues. The three-dimensional structure of CPA, alone and bound to different organic or organopeptidase inhibitors, has been determined by X-ray diffraction at high resolution (1,7–10). These studies allowed definition of four of the five previously proposed substrate binding sites from kinetic analyses (S1′, S1, S2, S3, and S4) (2, 4, 11, 12).

In contrast, the experimental characterization of the CPA catalytic site (S1) and of the catalytic intermediates has been more controversial (5, 13–16). In addition to the indirect evidence from the above-mentioned X-ray analyses (5, 7), enzyme kinetics studies together with chemical modification and site-directed mutagenesis experiments (17–22) indicated the residues involved in the hydrolytic mechanism. Glu-270 and Arg-127 (besides the Zn^{2+} at the active site) appear as the most directly involved, while Arg-145, Asn-144, Tyr-248, and Arg-71, among others, seem to be important for conferring the proper position, distortion, and environment to the substrate (23, 24).

Two alternative pathways have been proposed for the catalytic mechanism, both involving a precatalytic interaction between the C-terminal carboxyl with Arg-145/Asn-144 and between the carboxyl of the scissile C-terminal peptide bond with the zinc. The first is a nucleophilic pathway in which Glu-270 acts as an active base that attacks the scissile carbonyl to form a water-labile intermediate (25). The second is a water-promoted pathway in which zinc, assisted by Glu-270, forms a hydroxyl with a nearby water molecule, followed by the attack

of the hydroxyl on the scissile carbonyl (15, 26, 27). A significant amount of experimental material about one or the other mechanism has been found (28). The accumulation of intermediates with the substrate bound to the enzyme (presumably the acyl enzyme) in hydrolytic experiments on ester substrates at low temperature is one of the most conclusive pieces of evidence in favour of the nucleophilic pathway for ester substrates, but not for peptidic substrates (29). On the other hand, experiments on peptide substrates are generally more in favour of the water-promoted pathway (30).

Theoretical approaches have also been used to throw light on the above mechanistic problems. Several authors have made molecular orbital calculations on the catalytic mechanism of CPA. Hayes and Kollman (31) studied the electrostatic environment effect on the scissile peptide bond of a substrate. Scheiner and Lipscomb (32) showed that the action of an electrophile at the carbonyl group of a substrate was effective in enhancing the hydrolysis. Nakagawa and Umeyama (23) showed that three arginine residues were important for the binding of a substrate to CPA. Subsequently, simulating some ligands of zinc with point fractional charges, Nakagawa and co-workers demonstrated that the Zn-coordinated water molecule acts as a proton donor for Glu-270 (33). In addition, the electrostatic effect of Zn^{2+} and its ligands and the electron delocalization between Zn^{2+} and the water seem to play a significant role in lowering the barrier height of the proton transfer mentioned above, which is the first step of the water-promoted pathway.

Recently Alex and Clark (34) reported an AM1 study of the water-promoted mechanism of peptide cleavage by CPA. They used a rather complete set of ligands for the Zn^{2+} atom, with two imidazoles (representing His-196 and His-69), an acetate molecule (representing Glu-72), and a formiate (which represents Glu-270). However, the substrate simulated by the authors, a formamide molecule, is too simple to be able to mimic the behaviour of natural, long, peptide substrates in the active site of the enzyme. Oversimplified substrate-like molecules in their interaction with CPA have also been studied by Kollman and co-workers (24) using molecular dynamics approaches.

The purpose of the present paper is to study the water-promoted pathway of peptide cleavage by CPA in such a way that some of the limitations of the previous studies can be overcome. We have combined molecular dynamics and quantum mechanical calculations and used longer peptide-like substrates towards this aim.

Computational details

Quantum mechanical calculations

The calculations were carried out by using the standard AM1 (35) procedure, as implemented in the AMPAC (36) package of computer programs.

All geometry minima were obtained by minimizing the energy with respect to all geometrical variables by using the Davidon–Fletcher–Powell (DFP) method (37, 38). The location of transition states was done by using the McIver–Komornicki gradient minimization technique (39). The characterization of both kinds of stationary points, minima and transition states, was carried out by diagonalizing their Hessian (force constant) matrices and looking for zero or one-negative eigenvalues, respectively.

Molecular dynamics calculations

The X-ray crystallographic coordinates of CPA with crystallographic water molecules (ref. 5cpa (7) in the Protein Data Bank; PDB) and Gly-L-Tyr/CPA complex (ref. 3cpa (40) in the PDB) were used to build the model of CPA with a substrate. Two glycines were added to the substrate (Gly-L-Tyr) found in 3cpa to build the $(Gly)_3$-L-Tyr tetrapeptide. This tetrapeptide substrate alone was then energy-minimized by 1000 steps of steepest descent without SHAKE (41, 42) and with position constraints over all the atoms of the crystallographic Gly-L-Tyr. The optimized tetrapeptide was positioned in the active site of CPA (3cpa) by superimposition over all the atoms of the crystallographic Gly-L-Tyr.

The substrate was added to CPA (5cpa) by superimposition of the main-chain atoms of CPA (3cpa) over the main-chain atoms of CPA (5cpa). The crystallographic water molecules (5pca) were removed, with the exception of the water molecule number 571, which was bound to the Zn atom of CPA (5cpa). The structure resulting from these steps was taken as the initial model to seed a molecular dynamics simulation of the active site of CPA plus substrate. Hereafter in this paper, this structure will be called **MD-0**.

The Zn atom and the atoms that are bound to it (one nitrogen of the imidazole groups of His-69 and His-196, the two oxygens of the carbonyl group of Glu-72, and the oxygen of the water molecule number 571) were constrained in their crystallographic position throughout all of the following steps of the procedure to model the active site of CPA plus the substrate.

Molecular dynamics (MD) and energy minimization (EM) were derived with the GROMOS program package (42). The standard GROMOS NIS (Non Inertial Solvent) (D4) potential energy function was used to simulate the effect of solvent waters for the MD simulations and energy minimizations in a simplified way. In the NIS force field (43, 44), the acidic and basic side chains, which may be charged species in solution, are neutralized to mimic the presence of surrounding counterions. His-196 and His-69 have their exchanging imidazole proton not at the Nδ, but rather at the Nε position (HisB in the GROMOS topology file definitions); thus the coordination to the Zn atom is done by the pair of free electrons of the nitrogen sp^2 orbital.

Electrostatic forces were evaluated with a clean twin-range cutoff technique. All nonbonded forces within 8 Å were evaluated at each simulation step. Electrostatic forces at distances between 8 and 13 Å were reevaluated every 10 steps. A 2-fs time step was used in the integration when the bond lengths were constrained by SHAKE, and a time step of 0.5 fs was used in the integration when the bond lengths were not constrained. The temperature of the MD simulations analyzed was set at 293 K, and a temperature relaxation time of 0.1 ps was used to maintain the system in a weak coupling bath (45).

Results and discussion

To study the chemical mechanism of peptide cleavage by CPA by means of the semiempirical, quantum mechanical AM1 procedure, we had to design a simplified model of the active site of CPA plus the substrate.

Design and validation of the substrate/CPA-active site complex

The following compounds were considered as key elements for the design of the active site of CPA plus the substrate: Zn^{2+} and its ligands (two imidazoles and one acetate) and a proton acceptor (one acetate) for the active site of CPA; and a simplified peptide-like species (*N*-ethylacetamide) for the substrate. The system defined with these key elements was optimized by

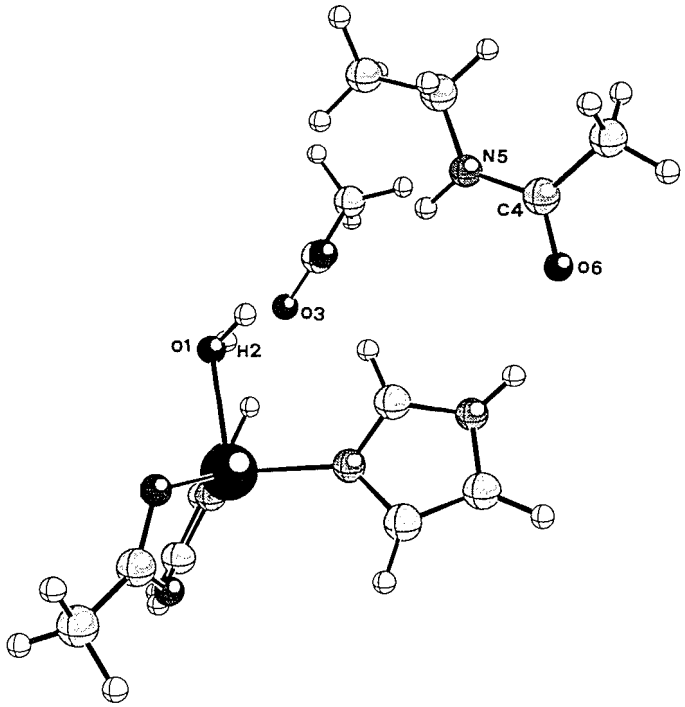

FIG. 1. AM1 optimized structure of the quantum mechanical model (**QM-1**) for the substrate/CPA-active site complex.

an AM1 semiempirical procedure. The optimization provided the initial structure **QM-1** (see Fig. 1), which was used to seed the quantum mechanical analyses of the catalytic mechanism of peptide cleavage.

To ensure that the **QM-1** structure was able to mimic the natural system, we wished to compare this structure with the real conformation of the substrate/CPA-active site complex. However, this experimental substrate/CPA complex does not exist (there are several crystallographic structures of complexes of CPA with inhibitors, but there is none with a substrate). As an alternative procedure we decided to compare the **QM-1** structure with the model resulting from applying MD and EM on the **MD-0** structure (the optimized tetrapeptide $(Gly)_3$-L-Tyr + water 571 + CPA structure) as defined in the Computational Details section.

We found that the initial **MD-0** structure was not in equilibrium, the energy being extremely high due to the nonbonded interactions between the substrate and the CPA. A new structure where the substrate became relaxed within the active site, but assuring that the whole system remains at the same region of the potential energy surface, is required. For this purpose we used a 10 ps MD run with the NIS force field, without SHAKE, and with no other restrictions other than those defined in the Computational Details section for the MD and EM simulations. Subsequently, a further optimization run of 5000 steps of steepest descent with SHAKE and with position constraints over the carbonyl carbon of Gly-3 of the substrate was used to approximate the substrate towards the proper positions in the active site, giving rise to the **MD-1** structure (it should be noted that Gly-3 is of functional importance in the above model because it is linked to Tyr-4, with which it establishes the scissile peptide bond). However, in the NIS force field the Zn atom did not have any charge, while the atoms that are coordinated to Zn had negative partial charges. As a consequence, the minimization was not enough to properly pull Gly-3 into the active site and the hydrogens of the water molecule 571 were incorrectly oriented.

From the former results it became evident that the NIS force field used was unable to simulate the natural substrate/CPA system in which the substrate is within the active site. Two overcome this limitation we decided to submit the **MD-1** structure to a further EM/MD procedure in order to reach a new state of equilibrium, but now to use the partial charges provided by the semiempirical approach (AM1) for the atoms of the active site, while the partial charges of the rest of the system were taken from the NIS force field (hereafter the new force field will be called NIS-AM1-cpa). In this procedure two consecutive EM runs of 5000 steps of steepest descent with the NIS-AM1-cpa force field (and with SHAKE) were used to pull and relax, respectively, the substrate into the active site. In the first run the position of the carbonyl carbon of Gly-3 of the substrate was still constrained at the position of the **MD-0** structure, while in the second run this constraint was removed. The structures obtained were designated **MD-2** and **MD-3**, respectively.

In the **MD-2** structure the distance between the carbonyl carbon of Gly-3 of the substrate and the oxygen of water 571 was 2.6 Å, and we observed that the hydrogens of water 571 were reoriented to face the carbonyl oxygens of the side chain of the Glu-270 of CPA. The **MD-3** structure became more relaxed, with the substrate kept in a proper position (the distance between the scissile carbonyl atom of the substrate and the oxygen of water 571 was 2.8 Å).

A further 10 ps MD simulation of the system (with SHAKE, and the NIS-AM1-cpa force field), involving the sampling of 5000 conformers, was performed to obtain an average **MD** structure (defined as the **MD-4** structure). At this structure the distance between the scissile carbonyl carbon of the substrate and the oxygen of water 571 slightly increased to 3.4 Å. It is interesting to note that the hydrogen bonds between the carbonyl oxygen of Glu-270 and the hydrogens of water 571 were observed to be present from the **MD-2** to the **MD-4** structures.

Finally, the **MD-4** structure was used to test the adequacy of the **QM-1** model. A comparison between both structures clearly shows that **QM-1** reproduces the relative orientation and the hydrogen bond network of the main groups that intervene in the active center – substrate interaction quite well. This fact justifies the choice of the **QM-1** structure as a model to study the reaction mechanism of the cleavage of the substrate by CPA.

Reactivity at the active site

Once the quantum model (**QM-1**) has been validated by means of MD/EM simulations, we can initiate the study of the different steps of the mechanism involved in the water-promoted pathway proposed by Lipscomb's group for the CPA-catalyzed proteolysis. For the sake of clarity we present the relative energies of reactants, transition states, and intermediates schematically over the course of the process in Fig. 2. In Figs. 1 and 3 the different localized stationary points are presented with a tridimensional perspective. These pictures will be very useful in describing the Lipscomb mechanism as follows.

The first step of the complete process is the water activation promoted by zinc and assisted by acetate. This consists of the hydrogen (H2) extraction by O3, one of the acetate oxygen atoms, from O1 of the water molecule coordinated to zinc. The second step of the mechanism is the attack of O1, which comes from the activated water molecule, on the carbon atom (C4) of

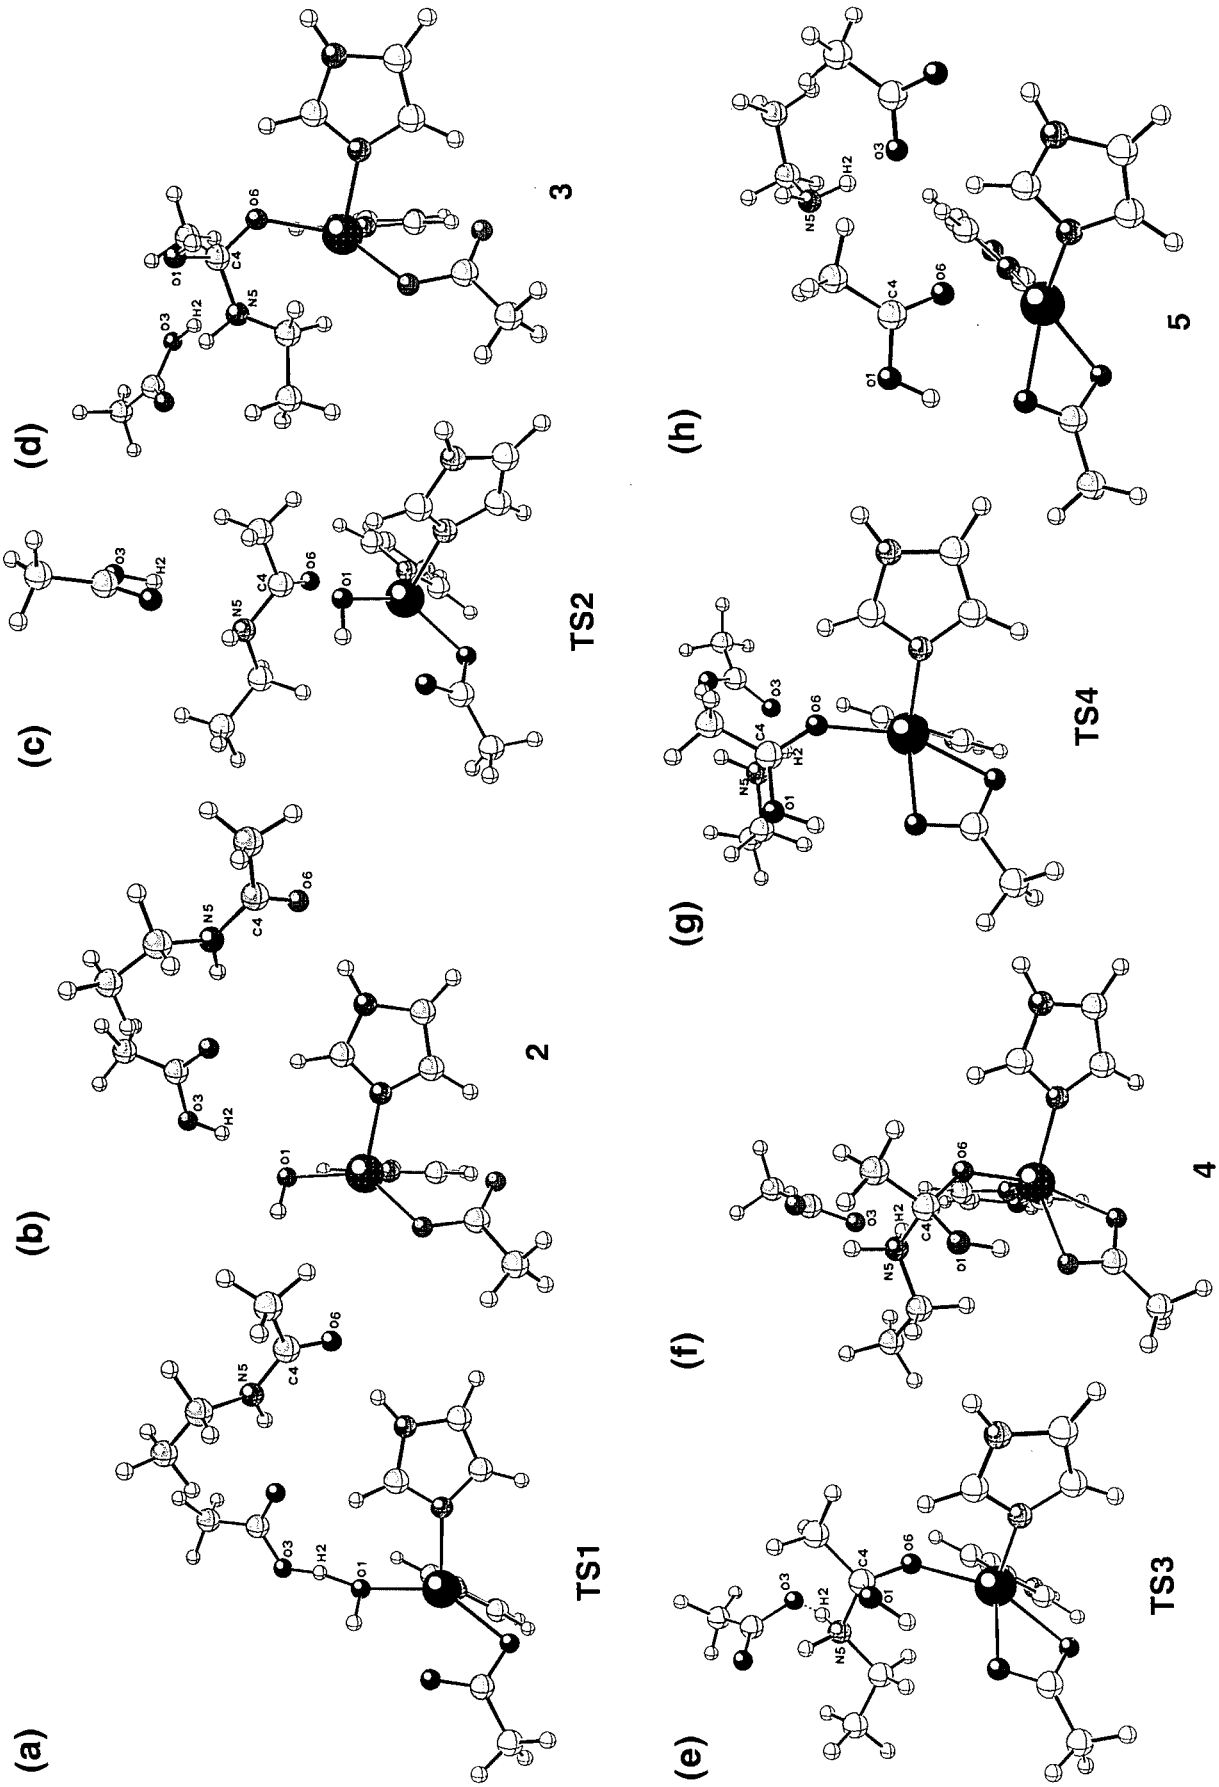

FIG. 3. 3-D optimized structures for the stationary points ((*a*) **TS1**; (*b*) **2**, (*c*) **TS2**, (*d*) **3**, (*e*) **TS3**, (*f*) **4**, (*g*) **TS4**, (*h*) **5**) drawn schematically in Fig. 2.

the peptide bond of the substrate. As a consequence of this attack the zinc atom changes from coordination to O1 to coordination to O6, the carbonyl oxygen atom of the substrate, in order to stabilize the increase of the negative charge of that oxygen atom. This process, with an enthalpy barrier of 37.9 kcal/mol, is the rate-determining step of the mechanism.

The third step consists of the hydrogen (H2) transfer from O3 to the nitrogen (N5) atom of the peptide bond of the substrate. In spite of this hydrogen transfer, the C4—N5 peptide bond does not break at this stage although the C4—N5 distance increases up to 1.58 Å. The peptide bond cleavage takes place at the next step with an energy barrier of 6.28 kcal/mol. The resulting amine molecule remains at the active site in structure **5** by means of a hydrogen bond formed with the acetate molecule: N5—H2···O3.

The global process is endothermic with an enthalpy change of 10.9 kcal/mol. As we have already mentioned, the enthalpy barrier obtained for the rate-determining step is nearly 38 kcal/mol, about twice the corresponding value previously obtained by Alex and Clark (34) using their more simplified system.

Taking into account the limitations of the AM1 semiempirical method, AM1 values of about 20 kcal/mol have recently been considered reasonable to theoretically validate a reaction mechanism (34, 46). However, we think that the rate-determining enthalpy barrier obtained in the present paper clearly exceeds the error that can be attributed to the AM1 methodology. At this point two alternatives can be envisaged: first, that the mechanism proposed by Lipscomb's group for the CPA-catalyzed proteolysis is not valid; secondly, that our model system is still too simplified, missing key functional groups positioned near the scissile peptide bond. For instance, crystallographic and site-directed mutagenesis studies (10, 19) suggest that Arg-127 is a key amino acid in the hydrolysis of peptides by carboxypeptidase A. The guanidinium group of Arg-127 is hypothesized to stabilize the oxyanion of the tetrahedral intermediate (structure **3** in Fig. 2) formed by the attack of water on the scissile carbonyl bond.

To perform a preliminary test of that hypothesis we have recalculated the second step of the mechanism, introducing a positive charge of 1.0 au located at 3.2 Å from O6 (according to X-ray crystallographic data (10)). This positive charge, attempting to represent the effect of the Arg-127 molecule, has been used in this test to avoid the huge increase of computational time that would be involved if a complete arginine side chain was introduced. Now the enthalpy barrier of the rate-determining step dramatically decreases to 22.7 kcal/mol. This stabilization comes from the combined interaction of Zn^{2+}, as mentioned above, and the positive charge with the scissile carbonyl oxygen (O6) in structure **3**.

This preliminary result using a positive charge suggests that the inclusion of more chemical groups may justify the water-promoted pathway proposed by Lipscomb and co-workers for the CPA-catalyzed peptide cleavage. More theoretical work is required to confirm this assumption. Towards this aim, further calculations on the complete mechanism, including additional key residues (as Arg-127), are now in progress in our laboratory.

Finally, from the results obtained in the present work, an important and interesting warning emerges. It is clear that quantum mechanical studies on biochemical systems are unattainable, unless drastic simplifications are imposed. In cases like the one treated here, these simplifications refer to both the substrate and the active site of the enzyme, and have to be chosen with caution. The substrate has to be modelled in such a way that the main features of the active center – substrate interaction (i.e., relative orientation and hydrogen bond network) are reproduced. In this sense, the comparison of quantum mechanical structures with experimental or numerical simulation data (Monte Carlo or Molecular Dynamics methods) are very useful in order to warrant the validity of the model. The substrate (a formamide) used by Alex and Clark (34) is probably too simple for the real, active center – substrate interactions to be correctly reproduced; in this way it is unable to provide a suitable representation of the CPA-active site plus the substrate. This fact leads to an enthalpy barrier for the rate-determining step that is not comparable with the value corresponding to our longer, more realistic, peptide-like substrate: *N*-ethylacetamide.

On the other hand, the main residues involved in the reaction mechanism have to be identified and taken into account in the design of the active center. It should be emphasized that the catalytic properties of the enzyme are a consequence of the stabilizing interactions of the substrate with several key residues. If one of these key groups is not included, the catalytic behaviour is not reproduced by the theoretical calculations, this fact suggesting that the real enzyme would not work in absence of this residue. The role of arginine 127 in the hydrolysis of peptides catalyzed by CPA can be a good example of this point.

Structural studies on dioxan-2-ylium ions; intramolecular attack of an oxygen atom on a carbenium ion centre

RONALD F. CHILDS,[1] GUOGONG J. KANG, TERESA A. WARK, AND CHRISTOPHER S. FRAMPTON
Department of Chemistry, McMaster University, Hamilton, ON L8S 4M1, Canada

Received January 18, 1994

RONALD F. CHILDS, GUOGONG J. KANG, TERESA A. WARK, and CHRISTOPHER S. FRAMPTON. Can. J. Chem. **72**, 2084 (1994).

As models for the ionization of orthoesters, a series of 1,3-dioxan-2-ylium salts have been prepared and characterized. The properties of 1,3-dioxan-2-ylium hexachloroantimonate **1**, 5-ethoxymethyl-1,3-dioxan-2-ylium hexachloroantimonate **2**, 2-methyl-5-ethoxymethyl-1,3-dioxan-2-ylium hexachloroantimonate **3**, and 2-phenyl-5-ethoxymethyl-1,3-dioxan-2-ylium hexachloroantimonate **4**, have been studied by ^{1}H and ^{13}C NMR spectroscopy. The structures of **3** and **4** have been determined using X-ray crystallography. Salts **3** and **4** both crystallize in monoclinic crystal systems. For **3**, the space group is *C*2/*c*, with a = 30.192(4) Å, b = 9.613(2) Å, c = 12.742(2) Å, β = 109.71(1)°, V = 3482(1) Å^3, and Z = 8. Complex **4** crystallizes in the space group $P2_1/n$, with a = 10.638(2) Å, b = 11.849(2) Å, c = 16.970(3) Å, β = 106.84(1)°, V = 2047(1) Å^3, and Z = 4. The geometries of **3** and **4** are similar with the ether oxygen disposed over the dioxan-2-ylium ring. However, the interaction between the ether oxygen and the cationic centre is not significant due to the large internuclear distance observed. The cation **5**, in which the carbon chain length between the ether oxygen and C(5) was increased, was prepared. This ion was found to undergo a reversible, intramolecular rearrangement resulting in the formation of 1-methyl-4-acetoxymethyl-tetrahydrofuranyl oxonium hexachloroantimonate **11**.

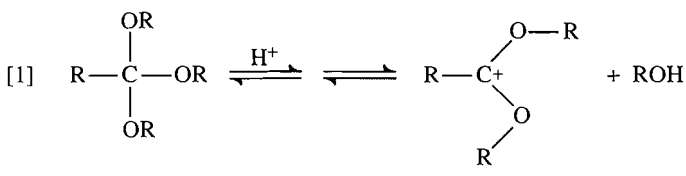
RONALD F. CHILDS, GUOGONG J. KANG, TERESA A. WARK et CHRISTOPHER S. FRAMPTON. Can. J. Chem. **72**, 2084 (1994).

On a préparé et caractérisé une série de sels 1,3-dioxan-2-ylium comme modèles pour l'ionisation des orthoesters. Faisant appel à la RMN du ^{1}H et du ^{13}C, on a étudié les propriétés de l'hexachloroantimonate du 5-éthoxyméthyl-1,3-dioxan-2-ylium (**1**) de l'hexachloroantimonate du 5-éthoxyméthyl-1,3-dioxan-2-ylium (**2**), de l'hexachloroantimonate du 2-méthyl-5-éthoxyméthyl-1,3-dioxan-2-ylium (**3**) et de l'hexachloroantimonate du 2-phényl-5-éthoxyméthyl-1,3-dioxan-2-ylium (**4**). On a déterminé les structures des composés **3** et **4** par diffraction des rayons X. Les sels **3** et **4** cristallisent tous les deux dans le système monoclinique. Pour le composé **3**, le groupe d'espace est *C*2/*c*, avec a = 30,192(4), b = 9,613(2) et c = 12,742(2) Å, β = 109,71(1)°, V = 3482(1) Å^3 et Z = 8. Pour le composé **4**, le groupe d'espace est $P2_1/n$, avec a = 10,638(2), b = 11,849(2) et c = 16,970(3) Å, β = 106,84(1)°, V = 2047(1) Å^3 et Z = 4. Les géométries des composés **3** et **4** sont semblables et l'oxygène de l'éther est disposé au-dessus du cycle dioxan-2-ylium. Toutefois, l'interaction entre l'oxygène de l'éther et le centre cationique n'est pas important du à la grande distance internucléaire qui est observée. On a préparé le cation **5** dans lequel la longueur de la chaîne carbonée entre l'oxygène de l'éther et le C(5) est augmentée. On a trouvé que cet ion subit un réarrangement intramoléculaire réversible conduisant à la formation de l'hexachloroantimonate du 1-méthyl-4-acétoxyméthyl-tétrahydrofuranyl oxonium.

[Traduit par la rédaction]

Introduction

The acid-catalysed reactions of carboxylic acids, carboxylic acid derivatives, and orthoesters involve the transient formation of carbenium ions with two oxygen-containing substituents (1). These substituents can be either hydroxy, alkoxy, aryloxy, or combinations of these groupings depending on the nature of the reaction under consideration. The overall acid-catalysed transformations of the carboxylic acid family of functional groups normally involves the formation and reaction of a cascade of di-oxygen-substituted carbenium ions. A commonly encountered reversible step in these transformations involves the reaction of an intermediary cation with a Lewis base to give a tri-oxygen-substituted species, eq. [1].



The formation and reverse ionization of orthoesters is a good example of the acid-catalyzed transformation of carboxylic acid derivatives. The steric requirements of this type of reaction have been extensively studied by Deslongchamps and co-workers (2). These workers have advanced the theory of stereoelectronic control in order to account for the selectivities observed in the reactions of cyclic materials (3).

In previous papers in this series we have reported the determination of the structures of a series of oxygen-substituted carbenium ions using X-ray diffraction techniques (4, 5). Not only are these structures informative about the geometry and charge distribution of the cations but the crystal packing in the lattice provides information on the attack of a nucleophile on this type of cation. In most crystal lattices a planar carbenium-ion carbon is found to be situated between two anions, one above and one below the carbenium-ion plane, with a Lewis base atom in the anion interacting with the positive centre. A limited number of examples have been found where a carbenium-ion centre has only a single Lewis base atom in close proximity and in these instances there is a small degree of pyramidalization of the cationic centre (6). In all the instances studied thus far it has been found that the cation–anion distances are not only very similar, but are typically close to the sum of the van der Waals radii of the carbenium carbon and the "attacking" Lewis base atom of the counterion.

In principle, if examples of carbenium ions could be found in which the distance between the cationic centre and a Lewis base atom was significantly reduced from the sum of the appropriate van der Waals radii, then the geometric changes associated with movement along the reaction coordinate of one of these ionization reactions could be probed. Such a study would not only par-

allel in cationic systems the pioneering work of Dunitz and co-workers on the reactions of a neutral carbonyl compound with a nitrogen nucleophile (7) but would provide a greatly expanded dimension to the structural work on ionization processes reported by Kirby and co-workers (8).

In the work described in this present paper we describe the preparation and structure determination of some stable dialkoxy-substituted carbenium ions in which there is an intramolecular ether oxygen atom positioned so that it can undergo nucleophilic attack on the positive centre. It was our hope, by providing an appropriately positioned intramolecular Lewis base, to be able to prepare a series of cations in which there could be a close association of the cationic centre and the "attacking" atom. The cyclic systems chosen for study should also provide information on the related orthoester ionizations studied by Deslongchamps and co-workers (2).

Results and discussion

The strategy used in this work was to prepare a series of 5-substituted 1,3-dioxan-2-ylium cations in which the substituent at C(5) would contain an ether oxygen atom. By varying the chain length of the C(5) group and altering the stability of the carbenium ion by changing the substituent on C(2), the cationic centre, it was hoped to be able to control the degree of interaction between the ether oxygen and the charged centre.

The preparation and characterization of 1,3-dioxan-2-ylium ions has previously been described (9). In this work we attempted to prepare the cations **1–5** by ionization of the corresponding 2-ethoxy-1,3-dioxanes **6–10** with $SbCl_5$ in CH_2Cl_2, eq. [2].

[2] 
6	R = R' = H	**1**
7	R = H, R' = $CH_2OCH_2CH_3$	**2**
8	R = CH_3, R' = $CH_2OCH_2CH_3$	**3**
9	R = C_6H_5, R' = $CH_2OCH_2CH_3$	**4**
10	R = CH_3, R' = $CH_2CH_2OCH_3$	**5**

The dioxane **6** is a known compound (10). In the case of **7–10** the dioxanes were prepared via a method similar to that of Boering and Levy (11) involving reaction of the appropriately substituted 1,3-propanediol with an orthoester, eq. [3].

[3] $R'—CH(CH_2OH)_2 \xrightarrow[R—C(OEt)_3]{} \mathbf{6–10}$

R = H, CH_3, C_6H_5
R' = H, $CH_2OCH_2CH_3$, $CH_2CH_2OCH_3$

Cations **1–4** were readily prepared as stable, moisture-sensitive solids by using a similar procedure to that described by Meerwein et al. (9*a*). The salts were purified by washing several times with carbon tetrachloride, yielding colourless solids. Proton and carbon-13 NMR spectra of solutions of **1–4** were obtained and in each case the spectra were consistent with the assigned structures, Tables 1 and 2. The ^{1}H and ^{13}C chemical shifts found here for the dioxanylium ring atoms are similar to those described by Chalova et al. (9*b*) for 1,3-dioxan-2-ylium tetrafluoroborate and by Paulsen and Schuttpelz for 2-methyl- and 2-phenyl-1,3-dioxan-2-ylium perchlorates (5*c*). The ring proton NMR shifts of **1** and **3** are shifted downfield as compared to those of the corresponding 1,3-dioxanes (12).

Paulsen and Schuttpelz suggested, on the basis of MINDO calculations and an analysis of coupling constants, that 1,3-dioxan-2-ylium cations adopt an envelope conformation in which C(4)-C(5)-C(6) forms the flap and the 5-alkyl substituents preferentially adopt a pseudo-equatorial position, eq. [4]

[4] 
(9*b*). In the case of **2**, **3**, and **4** it would appear from the ^{1}H NMR spectra that each of these cations adopts a single conformation in solution. The resonances of the methylene protons at C(4) (and C(6)) of **2–4** are different, occurring at different chemical shifts from each other (9*b*). Each of the methylene proton resonances occurs as a doublet of doublets. The largest coupling constant observed (11.7–11.8 Hz) corresponds to the geminal coupling constant between the two methylene protons. The smaller coupling constant (4.0–4.6 Hz) represents coupling between the proton on C(5) and each of the methylene protons. The magnitude of this smaller coupling constant and the fact that the cou-

[c]CD_2Cl_2, −10°C.
[d]Chemical shifts for the phenyl ring carbon atoms: C(12)/C(16) 131.8 ppm, C(13)/C(15) 130.2 ppm, C(14) 140.2 ppm.
[e]For **5**, the chemical shift is given for C(8).

pling constants between either C(5)-H and the pseudo-equatorial or pseudo-axial methylene protons is almost the same indicates that for cations **2**–**4** the C(5) substituents are in the pseudo-axial positions (13). Thus the oxygen-containing C(5) substituents in **2**–**4** adopt a different conformation to that found by Paulsen and Schuttpelz for 5-alkyl-substituted 1,3-dioxan-2-ylium cations (9*b*). It would seem clear that some form of interaction of the oxygen substituent in the C(5) substituent of these cations with the positive centre at C(2) is sufficient to overcome the steric preference for the equatorial conformation in 5-alkyl-substituted 1,3-dioxan-2-ylium ions.

Comparison of the ^1H NMR spectra of **2** with its precursor **7** is instructive in determining the nature of the interaction of the oxygen-containing C(5) substituent with the cationic centre. As can be seen from the data in Table 1, the largest downfield shifts occurring on ionization of **7** are those associated with H(2), H(4), and H(6). Such downfield shifts are expected in the formation of a cation such as **2**. On the other hand, little perceptible change in chemical shift is observed with H(9), suggesting that there is no significant transfer of positive charge to the ether oxygen in **2**. This conclusion is substantiated by the structural work described later. Comparison of the ^1H and ^{13}C NMR chemical shifts, Tables 1 and 2, respectively, of the various resonances associated with the C(5) substituent indicates that there are no significant differences attributable to substituent variation at C(2).

Structure determinations

The crystal structures of **3** and **4** were determined by X-ray crystallographic methods with diffraction data being collected at low temperatures. Crystal data, atomic positional parameters, and selected bond distances and angles for the two salts are given in Tables 3, 4, and 5, respectively. The structures of the two cations are shown in Figs. 1 and 2. Data on important planes are summarized in Table 6. Full details of the structure solutions are given in the experimental section and the supplementary material deposited with this paper (see footnote 4).

Examination of Figs. 1 and 2 shows that in each cation the dioxanylium ring adopts an envelope conformation with C(4)-C(5)-C(6) forming the flap. The conformation of both cations can be understood in terms of three planes. Atoms O(1), C(2), O(3), and C(11) lie in a plane (plane *A*) with a maximum deviation of 0.006 Å. A second plane, *B*, is formed by O(3), C(4), C(6), and O(1) and the third plane, *C*, by C(4), C(5), and C(6). The angles between planes *A* and *B* in **3** and **4** are 3.3° and 6°, respectively, whereas those between planes *A* and *C* are 129.1° for **3** and 126.3° for **4**. It is interesting that the dihedral angle between the envelope flap (C(4)-C(5)-C(6)) and the base of the envelope (O(1)-O(3)-C(4)-C(6)) for trimethylene carbonate is 47°, which is the same as found for **3** and **4** (47.8°) (14).

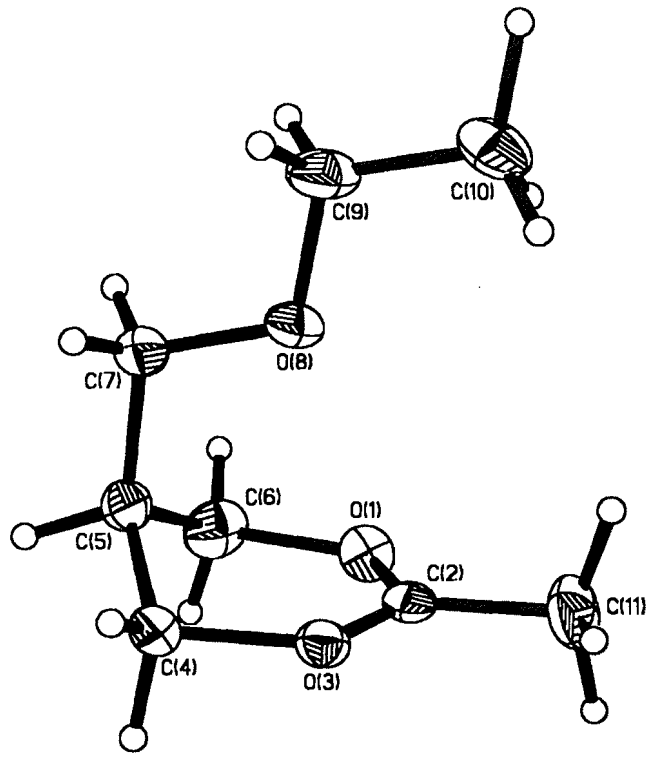

FIG. 1. Thermal ellipsoid plot for **3**.

Within the ring for **3** and **4**, the corresponding bond lengths found are not significantly different from one another. The O(1)—C(6) bond distances of 1.491(8) Å in **3** and 1.471(5) Å in **4** and the O(3)—C(4) bond distances of 1.470(7) Å in **3** and 1.481(5) Å in **4** are similar to one another, but longer than those found in corresponding neutral esters.[2] The average $-H_2C—O-$ distance in **3** and **4** is 1.478(17) Å,[2] significantly greater than that of 1.428 Å found in the silver hexafluoroantimonate complex of 1,3-dioxane $\{[Ag(1,3\text{-}C_4H_8O_2)_3]AsF_6\}$. However, in this silver complex the oxygen atoms are bonded to the metal centre.

The O(1)—C(2)/O(3)—C(2) bond distances in both cations are intermediate between those of C—O single and double

[2]The errors for mean bond lengths are given by $\sigma_D = (\Sigma_n(D - d_n)^2/n(n-1))$, where D is the mean bond distance of n independent variables.

[a]Equivalent isotropic *U* defined as one third of the trace of the orthogonalized U_{ij} tensor.

display a significant dependence on the substituent at C(2). Previous results obtained with 2-phenyl-1,3-dioxolan-2-ylium trifluoromethanesulfonate and 2-methyl-1,3-dioxolan-2-ylium perchlorate showed a significant difference between the corresponding bond lengths in the methyl- and phenyl-substituted ions (4*c*). It is not clear why no corresponding difference in the C^+—O bonds is observed with **3** and **4**.

Compound **4** has a twist angle of 17.3° between the -O-C^+-O- portion of the molecule and the phenyl ring. This is larger than the corresponding angle of 2° found from the single crystal study of 2-phenyl-1,3-dioxolan-2-ylium trifluoromethanesulfonate (4) and from MM2 calculations for the corresponding neutral benzoates (17). However, the twist angle in **4** is smaller than the twist angle found between the dialkoxycarbenium fragment and the aryl portion of the molecules for diethoxyphenylmethylium hexachloroantimonate (38.9°), dimethoxy-*p*-methoxyphenylmethylium hexachloroantimonate (30.5°), and diethoxy-2,4,6-trimethyphenylmethylium hexachloroantimonate (64.6°) (18).

As can be seen from Figs. 1 and 2, in both **3** and **4** the 5-ethoxymethyl substituent has adopted a pseudo-axial conformation in the crystal lattice. This conformation is in accord with the finding of the solution NMR studies discussed above. In each case the oxygen atom of the ethoxymethyl substituent is located over the top of the cationic centre of the ions. Atoms C(7), O(8), C(9), and C(10) of the ethoxymethyl groups form a

[a]Displacements given in angstrom units (Å).
[b]Angles given in degrees.

fourth plane, *D*, in each cation. The angles between planes *D* and *A* in **3** and **4** are 86.2° and 86.4°, respectively. The conformation of the ethoxymethyl group in each cation is such that plane *D* bisects the six-membered dioxanylium ring in such a way as to place the ether oxygen atom O(8) approximately equidistance from O(1) and O(2) and over C(2).

Examination of the bond distances and angles for the ethoxymethyl substituent gives an indication of the degree of interaction between the oxygen in this fragment and the cationic centre. The angle at C(7)-O(8)-C(9) is 112.5(5)° for **3** and 116.9(4)° for **4**. These values are similar to those reported for diethyl ether in a crystal lattice (19). As well, the corresponding C—C and C—O bond lengths in **3** and **4** are similar to those found for diethyl ether (19). This would indicate that the interaction between the ether oxygen of the dioxan-2-ylium cation and the cationic centre is not strong enough to perturb the ether geometry. The C(2)—O(8) distances in **3** (2.783 Å) and **4** (2.679 Å) are long and close to the sum of the van der Waals radii of the two atoms. In oxonium ions the C—O distances are typically short. For example, in Et_3O^+ the average C—O distance is 1.47 Å, while in Ph_3O^+ it is 1.50 Å (20).

It is interesting that the ether oxygen atoms in both **3** and **4** are arranged nearly symmetrically over the carbenium carbon. This can be seen by examining the displacement of O(8) from the plane defined by C(2)-C(7)-C(9). The geometry of O(8) is planar with the oxygen out of the plane by 0.059 Å for **3** and 0.040 Å for **4**. Alkyl-substituted oxonium ions generally adopt a pyramidal conformation, while the triaryl-substituted oxonium ions are nearly planar. The conformations of **3** and **4** provide models of the early stages of the attack of an oxygen nucleophile on a dialkoxy-substituted carbenium ion.

The anions and cations in **3** and **4** pack as discrete molecules, as seen in Figs. 3 and 4, respectively. This is in contrast to other oxygen-substituted carbenium systems in which there is interaction between the cationic centre and the anion (4*c*). For **3**, the rows of cations pack with the six-membered rings parallel with the ether bridge directed toward the ring of the next ion. The direction of the rows alternates throughout the lattice. The two distinct anions pack between the cations rows as alternate rows. The closest nonbonded anion and cation interaction is 2.544 Å, between Cl(2) and one of the 2-methyl protons. However, the closest approach of the anion to the cationic centre is 3.381 Å (C(2) and Cl(1)).

For **4**, the cations pack as pairs of ions with the ether portions directed toward one another with the phenyl rings parallel, but not directly under one another. The closest nonbonded interaction between the anions and cations is Cl(3) and the phenyl ring proton H(6′) with a distance of 2.801 Å. The closest anion–cation contact involving the cationic centre is C(2) and Cl(6) at a distance of 3.290 Å. The closest distances between cations and

anions for **3** and **4** are close to the sum of the van der Waals radii of the appropriate atoms. No significant interactions occur between the cations and anions and thus the anions do not help to stabilize the positive charge as was found for other systems (4).

Intramolecular rearrangement of 5

The ionization of dioxane **10** with $SbCl_5$ in CH_2Cl_2 appeared to proceed in the same manner as the reactions of **6–9** described above, with the formation of a colourless solid. However, ^1H NMR analysis of solutions of this solid in CD_2Cl_2 at −10°C revealed the presence of a mixture of cations, the minor component of which appeared to be **5**.

Recrystallization of the solid, followed by its careful dissolution at low temperatures in SO_2, and recording of its ^1H NMR spectrum at temperatures below −70°C showed that only a single cation was present. As the temperature of the solution was warmed above −70°C this cation isomerized to the same mixture as was isolated from the reaction mixture produced on the attempted formation of **5**. The cation obtained after dissolution of the recrystallized solid was identified as **11** on the basis of its ^1H NMR, ^{13}C NMR, and IR spectra. The proton NMR of **11** is similar to that of methyl tetrahydrofuranyl oxonium (21). From the peak at 1720 cm^{-1} in the IR spectrum and the resonance at 172.5 ppm in the ^{13}C NMR spectrum, it was determined that **11** contains a carbonyl group. The equilibrium is shown in eq. [5].

[5] 
20% 80%

5 **11**

Comparison of the NMR spectra of the mixture of **5** and **11** with those of **11** on its own allowed for the determination of the NMR spectra for **5**. The spectra obtained were found to be similar to those reported for **1–4** with the exception of the resonances due to the terminal ether portion of the molecule. The major difference between the proton spectra for **5** and the other cations is the coupling of the ring methylene protons to the proton on C(5). A large coupling constant was found between H(5) and the protons on C(4)/C(6) (10.8 Hz/11.5 Hz). This large coupling constant indicates that the C(5) substituent of **5** preferentially adopts a pseudo-equatorial conformation.

The interconversion of **5** and **11** can be viewed as intramolecular nucleophilic substitution by an oxygen atom on a $-CH_2-O-$ fragment where the displaced oxygen atom formally carries a positive charge. Previous work in this laboratory has shown that the C—O bond of an alkoxy-substituted carbenium ion is longer than would normally be expected in a neutral system and that there is considerable transfer of positive charge onto the alkyl group, eq. [6] (4).

Experimental section

General methods

All manipulations were carried out under an N_2 atmosphere. Solvents were reagent grade, distilled from the appropriate drying agent prior to use. NMR experiments were recorded on a Bruker AM500 or a Bruker WM250 spectrometer using internal standards and chemical shifts are reported in δ (ppm).

Preparation of ethyl-2-ethoxymethyl malonate

To a suspension of 5.29 g of NaH in 150 mL of dry ether was slowly added 35.3 g of ethyl malonate with mechanical stirring at room temperature. The reaction was stirred for 3 h, cooled to 0°C, and $C_2H_5OCH_2Cl$ (25 g in 25 mL of dry ether) was added slowly with vigorous stirring. After the mixture was stirred for 1 h, water was added, the ether layer was separated, and the aqueous layer was washed with ether. The combined ethereal extracts were washed with water and dried with $MgSO_4$. After the ethereal extracts were dry, the solution was concentrated by rotary evaporator and the vacuum distilled with a short fractionating column; bp 74–76°C/0.5 Torr (1 Torr = 133.3 Pa). Yield: 44%. ^1H NMR ($CDCl_3$): 4.17 (q, 4H, J = 7 Hz), 3.47 (q, 2H, J = 7 Hz), 3.55–3.80 (m, 3H), 1.32 (t, 6H, J = 7 Hz), 1.20 (t, 3H, J = 7 Hz).

Preparation of ethyl methoxyethylmalonate

Ethyl methoxyethylmalonate was prepared following the method described for ethyl-2-ethoxymethyl malonate; bp 92–95°C/0.5 Torr (lit. (22) bp 110–111°C/6 Torr). Yield: 45%.

Preparation of 2-ethoxymethyl-1,3-propanediol

Ethyl ethoxymalonate (21.0 g) in 50 mL of dry THF was added dropwise to a suspension of 6.9 g of $LiAlH_4$ in 100 mL of dry THF at 0°C with stirring. The mixture was refluxed for 5 h, after which 7 mL of water was added, followed by 7 mL of 15% KOH and 21 mL of water. The mixture was again refluxed for 0.5 h and the solid was then removed by filtration. The THF and water were removed by rotary evaporator. The residue was then dissolved in ether and dried with $MgSO_4$. After the $MgSO_4$ was removed by filtration, the solvent was removed and the remaining oil was distilled under vacuum; bp 84–88°C/0.5 Torr. Yield: 54%. ^1H NMR ($CDCl_3$): 3.20–3.70 (m, 10H), 2.80 (m, 1H) 1.03 (t, 3H, J = 7 Hz).

Preparation of 2-methoxyethyl-1,3-propanediol

2-Methoxyethyl-1,3-propanediol was prepared following the method described for 2-ethoxymethyl-1,3-propanediol from ethylmethoxyethyl malonate; bp 86–90°C/0.5 Torr. Yield: 59%. ^1H NMR ($CDCl_3$) 3.30–3.65 (m, 8H), 3.23 (s, 3H), 1.40–1.85 (m, 3H).

Preparation of 2-ethoxy-1,3-dioxane, 6

A mixture of ethyl orthoformate (4.44 g) and 1,3-propanediol (2.28 g) was distilled at 150°C. After the theoretical amount of ethanol had been distilled, the residue was distilled under vacuum; bp 49–50°C/10 Torr (lit. (9*b*) bp 156°C). Yield: 40%. ^1H NMR ($CDCl_3$): 5.23 (s, 1H), 4.25–3.60 (m, 4H), 3.63 (q, 2H, J = 7 Hz), 1.67 (m, 2H), 1.20 (t, 3H, J = 7 Hz).

Preparation of 2-ethoxy-5-ethoxymethyl-1,3-dioxane, 7

2-Ethoxy-5-ethoxymethyl-1,3-dioxane was prepared from 2-ethoxymethyl-1,3-propanediol and ethyl orthoformate following the method described for 2-ethoxy-1,3-dioxane; bp 62–66°C/0.5 Torr. Yield: 37%. ^1H NMR ($CDCl_3$): 5.18 (s, 1H), 3.50–4.30 (m, 4H), 3.60 (q, 2H, J = 7 Hz), 3.40 (q, 2H, J = 7 Hz), 3.35 (d, 2H, J = 7 Hz), 1.75–2.08 (m, 1H), 1.15 (t, 3H, J = 7 Hz), 1.03 (t, 3H, J = 7 Hz).

Preparation of 2-ethoxy-2-methyl-5-ethoxymethyl-1,3-dioxane, 8

Compound **8** was prepared from 2-ethoxymethyl-1,3-propanediol and ethyl orthoacetate following the method described for 2-ethoxy-1,3-dioxane; bp 92–100°C/0.5 Torr. Yield: 40%. ^1H NMR ($CDCl_3$): 3.10–4.20 (m, 10H), 1.42–2.0 (m, 1H), 1.36, 1.33 (2 singlets, 3H), 0.97–1.23 (m, 6H). ^1H NMR suggests a mixture of *cis* and *trans* isomers.

Preparation of 2-ethoxy-2-phenyl-5-ethoxymethyl-1,3-dioxane, 9

2-Ethoxy-2-phenyl-5-ethoxymethyl-1,3-dioxane was prepared from 2-ethoxymethyl-1,3-propanediol and ethyl orthobenzoate following

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

the method described for 2-ethoxy-1,3-dioxane; bp 104–108°C/0.5 Torr. Yield: 53%. ^{1}H NMR ($CDCl_3$): 7.22–7.63 (m, 5H), 3.13–4.96 (m, 10H), 1.65–2.10 (m, 1H), 1.0–1.17 (m, 6H).

Preparation of 2-ethoxy-2-methyl-5-methoxyethyl-1,3-dioxane, ***10***

2-Ethoxy-2-methyl-5-methoxyethyl-1,3-dioxane was prepared from 2-methoxyethyl-1,3-propanediol and ethyl orthobenzoate following the method described for 2-ethoxy-1,3-dioxane; bp 68–70°C/0.5 Torr. Yield: 44%. ^{1}H NMR ($CDCl_3$): 3.25–4.23 (m, 8H), 1.73–2.10 (m, 1H), 1.66–1.95 (m, 2H), 1.35 (s, 3H), 1.13 (t, 3H, J = 7 Hz).

Preparation of 1,3-dioxan-2-ylium hexachloroantimonate, ***1***

The preparation of the hexachloroantimonate salts was performed in a similar manner for each species. A sample procedure, which is a modification of Meerwein's method, is described below (9). 2-Ethoxy-1,3-dioxane (444 mg) in 1.5 mL of dry CH_2Cl_2 was added slowly to 1.8 g of $SbCl_5$ in 1 mL of dry CH_2Cl_2 at −30°C with stirring under a nitrogen atmosphere. The reaction mixture was stirred for 2 h at −10°C. CCl_4 was then added and the white precipitate was collected by filtration. The solid was washed 3 times with CCl_4 and dried by vacuum. Yield: 55%. 5-Ethoxymethyl-1,3-dioxan-2-ylium hexachloroantimonate, **2**, yield 20%; 2-methyl-5-ethoxymethyl-1,3-dioxan-2-ylium hexachloroantimonate, **3**, yield 35%; 2-phenyl-5-ethoxymethyl-1,3-dioxan-2-ylium hexachloroantimonate, **4**, yield 58%; 5-ethoxymethyl-1,3-dioxan-2-ylium hexachloroantimonate, **5**, yield 20% (as determined by NMR spectroscopy); 1-methyl-4-acetoxymethyltetrahydrofuranyl oxonium hexachloroantimonate, **11**, yield 36%. IR (KBr): 1720 cm^{-1}. ^{1}H NMR (SO_2, −70°C): 5.08 (J = 7.8, 5.8 Hz), 4.97 (J = 7.8, 7.8 Hz), 4.94 (J = 7.8, 7.8 Hz), 4.84 (J = 6.4, 7.8 Hz), 4.17, 4.57 (s, 3H), (doublet of multiplets, 2H), 3.30 (s, 1H), 2.59 (doublet of multiplets, 2H), 2.13 (s, 3H). ^{13}C NMR (CD_3NO_2, −10°C): 172.5 (s), 90.9 (s), 90.6 (s), 74.0 (s), 64.3 (s), 38.5 (s), 28.6 (s), 20.7 (s).

X-ray data collection and reduction

Crystals of **3** and **4** were obtained by vapour diffusion of hexanes into methylene chloride solutions of the respective compounds at room temperature. Suitable crystals were selected and sealed in Lindemann capillaries under a nitrogen atmosphere. Diffraction experiments were performed at low temperature on a Nicolet P3 diffractometer for **3** (187 K) and a Siemens R3m/V for **4** (173 K), using MoKα (λ = 0.710 69 Å) and AgKα (λ = 0.56086 Å) radiation, respectively. The initial orientation matrices were obtained from 15 reflections for **3** (22.5° < 2θ < 29.9°) and 23 (14.59° < 2θ < 34.99°) reflections for **4**. The observed extinctions were consistent with a triclinic space group for **3** and the monoclinic space group $P2_1/n$ for **4**. For **3**, h, $\pm k$, $\pm l$ data (2θ ≤ 45°) were collected with two standard reflections monitored every 48 reflections, while $+h$, $+k$, $\pm l$ data (2θ ≤ 45°) were collected for **4** with three standard reflections recorded every 97 reflections. The standard reflection intensities showed no statistically significant change over the duration of the data collection for either **3** or **4**. The methods of selection of scan rates and initial data treatment for **3** have been described (23). For **4**, data were collected with a scan range of 1.0° below $K\alpha_1$ and 1.0° above $K\alpha_2$, using a background to scan time ratio of 0.5. Corrections were made for Lorentz-polarization factors for all data. A semiempirical absorption correction was applied to the data for **4**. The triclinic cell found for **3** was subsequently revealed to be a $C2/c$ monoclinic cell, which is related to the original cell by the matrix (1, 0, 2; 1, 0, 0; 0, 1, 0).

Structure solution and refinement

The coordinates of the antimony atoms were found from a three-dimensional Patterson synthesis with use of the program SHELX-86 (24) for **3** and SHELXTL PLUS (25) for **4**. Full-matrix least-squares refinement of these coordinates, followed by a three-dimensional electron density synthesis revealed the positional parameters of all the non-hydrogen atoms and confirmed those of the heavy atoms. The refinement was carried out using full-matrix least-squares techniques on F, minimizing the function $\Sigma w(F_o - F_c)^2$, where the weight, w, is defined as $4F_o^2/2\sigma(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes, respectively. The temperature factors of the non-hydrogen atoms, which were previously isotropic, were made anisotropic, and further cycles of refinement revealed the positional parameters of the hydrogen atoms. The hydrogen atoms for **3** were included in the final cycles with U fixed at 0.05 Å, while all of the hydrogen thermal parameters for **4**, except for the ethyl fragment, were allowed to refine. The methyl group was defined as a rigid rotor, while the methylene protons of the ethyl group were fixed to have the same thermal parameter. The difference map showed no other chemically reasonable site for C10 of compound **4**; therefore, any disorder present at C10 was unresolvable. Correction for secondary extinctions was not necessary. Throughout the refinement, scattering curves (26), and anomalous dispersion corrections (27) were applied to the curves for antimony and chlorine. Calculations for **3** were performed on a Vax 6420 computer, while for **4** the initial data reduction was performed on a Vax 6420 computer, but the structure solution was accomplished using a Comptech 486/33 computer. Programs used for **3** include XTAL (28) for data reduction and least-squares plane calculations, SHELX-86 (24) for structure solution, and SHELX-76 (29) for structure refinement. For **4**, the program used was SHELX-86 (24) for data reduction and the PC version of SHELXTL PLUS (30) for structure solution and refinement. Crystal data are given in Table 3, positional parameters are given in Table 4, and selected bond lengths and angles are given in Table 5. Anisotropic displacement coefficients (Table S1), anion bond lengths and angles (Table S2), phenyl ring bond lengths and angles (Table S3), hydrogen atom parameters (Table S4), and bond lengths and angles involving hydrogen atoms (Table S5), have been deposited as supplementary material.[3]

Conclusion

The NMR spectroscopy and X-ray crystallography results have shown that there is no significant interaction between the oxygen of the ethoxymethyl substituent and the carbon carrying the positive charge. The planarity of the O(1)-C(2)-C(11)-O(3) fragment, the distance from the oxygen of the ether substituent to the cationic centre, and the structural similarity of the ethoxymethyl portion of the molecule to diethyl ether show that the ether oxygen does not interact with the cationic centre in a manner that would model ionization of an orthoester. However, the disposition of the ethoxymethyl ligand demonstrates that there is a stabilization energy associated with the adopted conformation, as one would expect the ether fragment to be oriented away from the dioxan-2-ylium ring, as was found for 2-methyl-5-methoxyethyl-1,3-dioxan-2-ylium hexachloroantimonate **5**. The challenge remaining for this study is to find a system in which O(8), the ether oxygen, is more tightly bound to the carbenium-ion centre. In principle, changing its C(2) substituent to an electron-withdrawing one could effect this change; however, we have been unsuccessful in our attempts to generate such ions.

The complexation of *N*-acetylcysteine (RSH) with hydrogen peroxide has been studied experimentally and theoretically. Experimentally we have measured the evolution of RSH, H_2O_2, and RSSR (*N*-acetylcystine) as a function of time. Surprisingly, H_2O_2 decays by a biphasic process, which is not the case for RSH and RSSR. In the first stage of the kinetics, H_2O_2 disappears without oxidizing the thiol function of RSH. By analogy with glutathione (GSH), the formation of a complex between RSH and H_2O_2 has been proposed. The thermodynamic equilibrium constant of complex formation has been determined. Theoretical calculations were performed within the SIBFA method to pinpoint the sites of complexation in isolated and hydrated states. A mixed "discrete–continuum" model was used to evaluate the solvent effect. The two stable complexes found in isolated state have different behaviour under the influence of the solvent. Comparison with complexed GSH is discussed.

JLIL ARROUB, JACQUELINE BERGÈS, ZOHREH ABEDINZADEH, JACQUELINE LANGLET et MONIQUE GARDÈS-ALBERT. Can. J. Chem. **72**, 2094 (1994).

Nous avons effectué l'étude expérimentale et théorique de la réaction de complexation de la *N*-acétylcystéine (RSH) avec l'eau oxygénée. Au point de vue expérimental, nous avons mesuré l'évolution de RSH, H_2O_2 et RSSR (*N*-acetylcystine) en fonction du temps. D'une manière surprenante, H_2O_2 décroit par un processus biphasique alors qu'il n'en est pas de même pour RSH et RSSR. Dès le début de la cinétique, H_2O_2 disparaît sans oxyder la fonction thiol de RSH. Par analogie avec le glutathion (GSH), la formation d'un complexe entre RSH et H_2O_2 a été proposée. La constante d'équilibre de formation de ce complexe a été déterminée. Des calculs théoriques menés selon la méthode SIBFA ont été effectués afin de préciser les sites de complexation des états isolé et hydraté. Un modèle mixte "discret-continuum" a été utilisé pour évaluer l'effet de solvant. Les deux complexes stables calculés dans l'état isolé ont des comportements différents en présence de solvant. La comparaison de ces résultats avec ceux du glutathion complexé est discutée.

Introduction

N-acetylcysteine, RSH (Fig. 1*a*), is a drug that counteracts oxidative stress and replenishes glutathione, GSH (1). It is also considered a therapeutic agent for AIDS (1–5). Furthermore, RSH structure is similar to the central part of GSH (Fig. 1*b*). Thus as a contrast to GSH/H_2O_2 complexation (6), complexation of *N*-acetylcysteine with hydrogen peroxide was studied. As we know, GSH is an intracellular cysteine-containing tripeptide (γ-glutamylcysteinylglycine) which plays many essential roles in vivo, particularly as a defence against electrophylic xenobiotics and intracellular oxidants (free radicals, reactive oxygen intermediates, i.e. H_2O_2) (1).

In our previous work (6) on the oxidation kinetics of glutathione (GSH) by hydrogen peroxide at neutral pH and in the absence of glutathione peroxydase, we have shown that an important amount of H_2O_2 disappears without oxidizing the thiol function. The formation of a chelate (hydrogen bonds) between GSH and H_2O_2 is presumed to follow

[1] $GSH + H_2O_2 \rightleftarrows [GSH]...H_2O_2]$

The equilibrium constant has been determined as 1950 ± 50 (6). It has also been shown that glutathione disulfide, GSSG, is the main product formed via two different routes of oxidation, one contributing 80–85% and the other 10–15% (2) of the overall process.

Moreover, theoretical calculations in the framework of the SIBFA (Sum of Interactions Between Fragments computed Ab-initio) and CHARMm methods have been performed to investigate the possibility of intermolecular hydrogen bonds between glutathione and hydrogen peroxide (7–9). According to these studies, the GSH ionized glutamyl NH_3^+ and COO^- groups as well as glycyl COO^- group and to a certain extent CO and NH of peptide groups are the privileged interaction sites for forming complexes with H_2O_2.

In this work we have studied experimentally and theoreti-

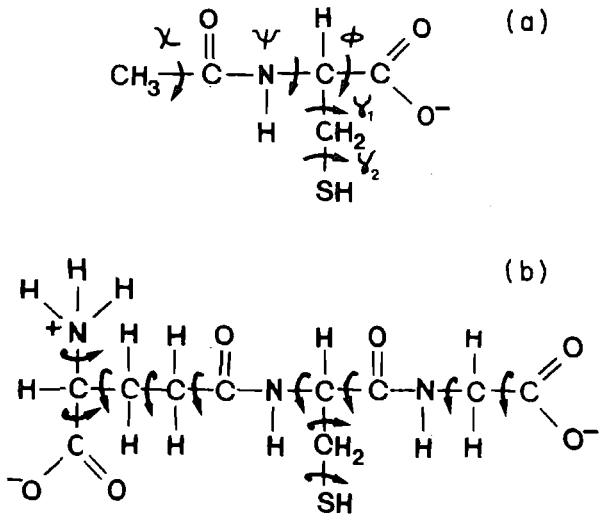

FIG. 1. (*a*) *N*-acetylcysteine (RSH) anion. Definition of the degrees of rotational freedom. (*b*) Glutathione (GSH) anion.

cally the possibilities and sites of complexation of *N*-acetylcysteine with hydrogen peroxide (this paper). As can be seen, the drug molecule contains GSH, thiol, glycyl COO^- and one peptide group, but it contains neither the second peptide part nor the glutamyl groups as the GSH molecule. In the following paper (26) we have performed a kinetic analysis of the overall process in the oxidation of RSH with H_2O_2.

Materials and method

A. Chemicals

Chemicals were the purest grade available and were used without further purification. The only exception was *N*-acetylcystine (RSSR) which was synthesized by acetylation of L-cystine according to ref. 10. RSH and 5,5′-dithiobis(2-nitrobenzoic acid) were supplied by Sigma Chemical Co.; hydrogen peroxide, sodium acid phosphate were from Merck. All solutions were prepared with Millipore water, the purity of which was confirmed by conductivity measurements ($10^{-6}\ \Omega^{-1}\ cm^{-1}$).

Thiol concentration was determined with Ellman's reagent (11), 5,5′-dithiobis(2-nitrobenzoïc acid) which undergoes a thiolate disulphide exchange reaction to yield 2-nitromercaptobenzoïc acid. This product was measured spectrophotometrically (λ_{max} = 412 nm, ϵ_{412} = 13600 ± 600 $mol^{-1}\ L\ cm^{-1}$) against an appropriate blank. Notice that Ellman's reagent characterizes all free SH groups and we have tested that this assay is not modified in presence of H_2O_2.

Hydrogen peroxide concentrations were measured spectrophotometrically by the titanium sulfate method (12, 13) using ϵ_{410} = 700 $mol^{-1}\ L\ cm^{-1}$. We can see later that in this method only free hydrogen peroxide is measured, complexed hydrogen peroxide or peroxide bonds in a molecule are excluded in the measurement. Moreover, it should be noted that titanium reagent does not react with RSH. Dilute buffered aqueous hydrogen peroxide solutions (5×10^{-4} to 5×10^{-3} mol L^{-1}) were stable at least for one day, showing nonspontaneous metallic cations induced dismutation.

N-Acetylcystine (RSSR) concentration was determined by spectrophotometric absorption at 250 nm where the thiol, RSH, does not absorb. According to Beer's law the differential extinction coefficient of *N*-acetylcystine, RSSR, 330 ± 4 $mol^{-1}\ L\ cm^{-1}$ at 250 nm has been obtained. Note that at this wavelength, the extinction coefficient of RSH equals zero and for H_2O_2, ϵ_{250} = 25 $mol^{-1}\ L\ cm^{-1}$ (14). Figure 2 shows the differential absorption spectrum of RSSR versus RSH. As can be seen, this spectrum gives two absorption bands at 214 and 250 nm, both differential bands are characteristic of RSSR.

For differential spectrophotometric measurements of reaction mixtures, we used two chamber cells; each has an optical path of 0.4375 cm. The reference cell contained H_2O_2 in one chamber (the concentration of H_2O_2 in this chamber is double that in the mixture, $[H_2O_2] = 2[H_2O_2]_{reaction\ mixture}$) and RSH in the other chamber (the concentration of RSH in this chamber is double that in the reaction mixture, $[RSH] = 2\ [RSH]_{reaction\ mixture}$. The measure cell contained the same reaction mixture, in each chamber.

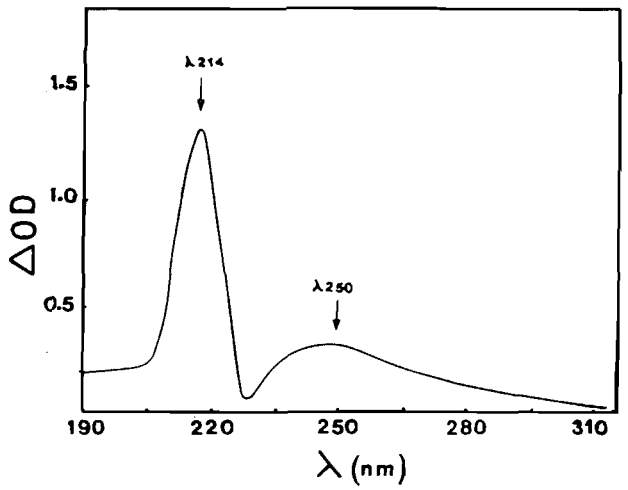

FIG. 2. Differential absorption spectra of the disulfide form and *N*-acetylcysteine.

Oxygen concentration was determined by Gilson oxygraph model IC TS-KI.

All solutions were prepared just prior to use and buffered at pH7 in a 10^{-2} mol L^{-1} phosphate medium.

B. Method of calculations

Both intra- and intermolecular energies have been calculated simultaneously within the framework of the SIBFA method (Sum of Interactions Between Fragments computed Ab-initio) (15–17).

1. Intermolecular energy (15, 16)

Following an additive procedure, the intermolecular energy is expressed as the sum of five contributions:

$$[1] \quad E_{Inter} = E_{El} + E_{Pol} + E_{Rep} + E_{Disp} + E_{CT}$$

This method has the following characteristic features: (*a*) Use of a multicenter (atom and middle of bonds), multipolar (up to quadrupoles) expansion derived (18) from an ab-initio SCF molecular function for the calculations of *electrostatic* and *polarization* components, E_{El} and E_{Pol}. (*b*) Computation of the *repulsion* term, E_{Rep}, as a sum of "bond–bond", "bond–lone pair" and "lone pair – lone pair" interactions. (*c*) *Dispersion*, E_{Disp}, is decreased because of an overestimation of energy at short distances. (*d*) Explicit evaluation of the *charge-transfer*, E_{CT}, contribution between lone pairs in the molecule that behaves as an electron donor and the hydrogen atom in the molecule that behaves as an electron acceptor.

2. Intramolecular energy (17).

In the SIBFA method, a molecule is built out of constituting molecular fragments separated by single bonds. In fact, one calculates the variation in conformational energy as a sum of interaction energies from inter fragments

$$[2] \quad E_{Intra} = \sum_{i=1}^{N} \sum_{j=i+1}^{N} E'_{Inter}(i,j)$$

where N is now the number of fragments.

E'_{Inter} is calculated as a sum of the four first terms in eq. [1], plus a term denoted E_{Tor} which is a transferable torsional energy contribution, calibrated for elementary rotations around single bonds (for more details concerning this method see refs. 15 to 17).

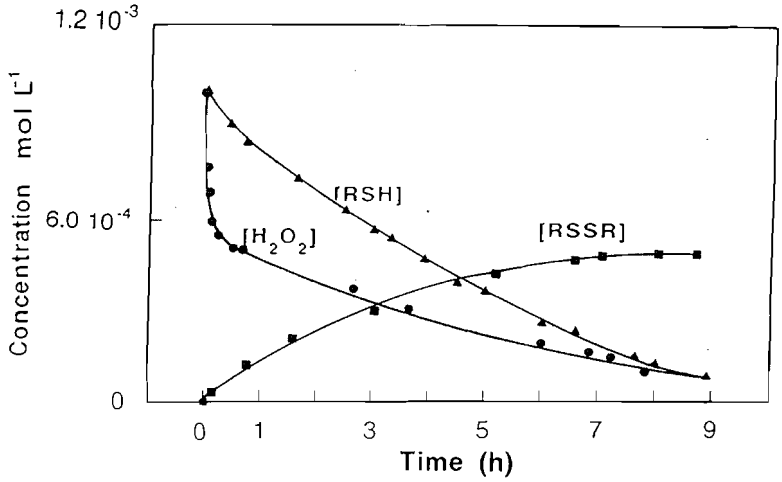

FIG. 3. Kinetic evolutions of hydrogen peroxide (●), *N*-acetylcysteine (▲), and *N*-acetylcystine (■) as a function of time. $[RSH]_0 = [H_2O_2] = 10^{-3}$ mol L^{-1}, phosphate buffer 10^{-2} mol L^{-1}, pH 7.

3. Solvent effect

Two models may be used: (*a*) The *microscopic (or discrete)* model in which the water molecules surrounding the solute are explicitly taken into account and the solute–water and water–water interaction energies are calculated within the SIBFA framework. (*b*) The *macroscopic (or continuum)* model. In this model, the solute molecule is represented by a charge distribution inside a cavity. It is surrounded by a continuous medium (the solvent) characterized by macroscopic properties (dielectric constant, molecular volume...). The details of this model are given in refs. 19 and 20. The following is a summary of this methodology. A thermodynamic quantity involved in the solvation process are separated into three terms, cavitation, dispersion–repulsion, and electrostatic. *The cavitation energy* is calculated using the Reiss–Pierrotti expressions (21). The *dispersion–repulsion terms* are calculated using the potential functions for pairs of atoms, *i* and *j*, that belong to the solvent and the solute molecules, respectively (this is consistent with the methodology initially proposed for pure liquid hydrocarbons (22). *The electrostatic* interaction between the solute and the solvent is expressed in terms of the reaction potential of the solvent polarized by the solute. The solvent is represented by a dielectric medium and a simple method is used to calculate the fictive charge density to represent the reaction potential.

To evaluate these three terms, we must first choose the shape of the cavity. Here we follow Huron and Claverie's proposal (22) by using the exact molecular shape of the solute. In practice this shape is made of the Van der Waals spheres of atoms that form the solute.

Experimental results and discussion

The oxidation of *N*-acetylcysteine, RSH (initial concentrations from 0.4×10^{-3} to 4×10^{-3} mol L^{-1}) by hydrogen peroxide (initial concentrations from 0.5×10^{-3} to 2.5×10^{-3} mol L^{-1}) has been studied in buffered aqueous medium at pH 7 (phosphate concentration 10^{-2} mol L^{-1}) as a function of time. Ten different experiments have been performed (see Table 1, the three first columns), each characterized by different initial concentrations of RSH and H_2O_2. The initial concentration ratio, $[RSH]_0/[H_2O_2]_0$, ranged between 0.2 and 8. Thus we have studied the cases with $[RSH]_0$ higher than $[H_2O_2]_0$ and $[H_2O_2]_0$ higher than $[RSH]_0$.

Moreover, we have tested the eventual decomposition of H_2O_2 according to the Haber–Weiss reaction by adding a transition metal chelator (EDTA) to the reaction mixture. However, we did not observed any modification in the kinetic experiments.

As an example, we reported in Fig. 3 the changes in the concentration of RSH, H_2O_2, and RSSR (the disulfide form of *N*-acetylcysteine) as a function of time, when the initial concentrations of RSH and H_2O_2 are equimolar (10^{-3} mol L^{-1}) (phosphate buffer 10^{-2} mol L^{-1}, pH 7). The decay of *N*-acetylcysteine and the appearance of its oxidized disulfide form are concomitant processes while the decrease in hydrogen peroxide is characterized by biphasic kinetics. During a very short time (~10 min) a significant quantity of H_2O_2 ($\sim[H_2O_2]_0/2$) disappears, then the remaining hydrogen peroxide decays slowly until the end of the reaction. Neither the disulfide RSSR, nor *N*-acetylcysteine, RSH, present a similar initial fast kinetic phase. The differential absorption spectra recorded as a function of time (Fig. 4) for the same experiment ($[RSH]_0 = [H_2O_2]_0 = 10^{-3}$ mol L^{-1}, phosphate buffer 10^{-2} mol L^{-1}, pH 7) exhibit two increasing absorption bands around 214 and 250 nm that characterize RSSR (see Materials and Methods). To confirm that both differential absorption bands at 214 and 250 nm are related to RSSR, we have compared the inapparent first order kinetics at 214 and 250 nm (see Fig. 4 inset). The similarity in the two slopes of the straight lines at 214 and 250 nm ($(1.1 \pm 0.2) \times 10^{-4}$ s^{-1} and $(1.3 \pm 0.2) \times 10^{-4}$ s^{-1} respectively at 214 nm and 250 nm) implies first order kinetics and hence the formation of only one product RSSR.

Nearly the end of the reaction (~9 h), the concentrations in RSH, H_2O_2, and RSSR are 0.5×10^{-4} mol L^{-1}, ≈0 mol L^{-1}, and 0.5×10^{-3} mol L^{-1}. Hence 95% of RSH and H_2O_2 have disappeared and [RSSR] formed equals $[RSH]_0/2$. Therefore 2 moles of RSH consume 2 moles of H_2O_2 to give 1 mol of RSSR, in contrast to the classical stoichiometry in which 2 mol of RSH react with 1 mol of H_2O_2 to give 1 mol of RSSR. According to our observation, it seems 1 mol of hydrogen peroxide has disappeared without oxidizing the thiol function.

To understand what has happened with hydrogen peroxide, the following experiments have been performed:

(*1*) The eventual formation of oxygen during the reaction of RSH with hydrogen peroxide has been tested using a Gilson Oxygraph (see Experimental section). Samples were prepared at equimolar concentrations ($[RSH]_0 = [H_2O_2]_0 = 10^{-3}$ mol L^{-1}, phosphate buffer 10^{-2} mol L^{-1}, pH 7). However, we observed no formation of oxygen at the beginning or during the reaction. Hence H_2O_2 does not oxidize or disproportionate.

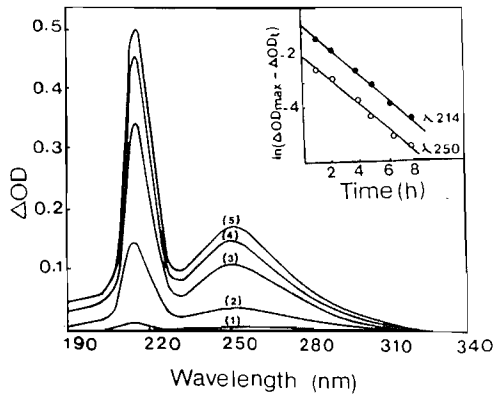

FIG. 4. Differential absorption spectra recorded as a function of time. $[RSH]_0 = [H_2O_2]_0 = 10^{-3}$ mol L^{-1}, phosphate buffer 10^{-2} mol L^{-1}, pH 7, optical path 4.375 mm. (*1*) 4 min after mixing, (*2*) 47 min, (*3*) 184 min, (*4*) 312 min, (*5*) 420 min. In inset, first order kinetic plots against time at 214 and 250 nm.

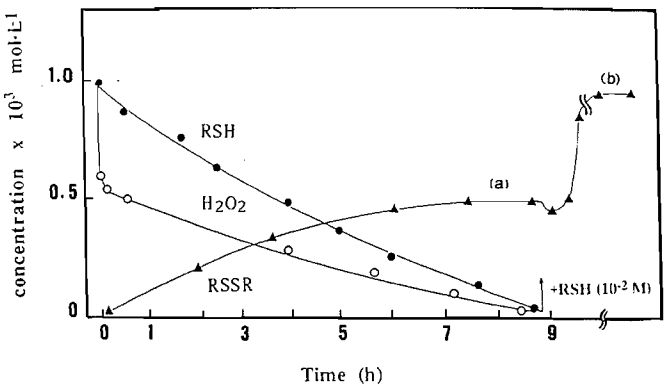

FIG. 5. Addition of RSH at the end of a reaction. Initial reaction: $[RSH]_0 = [H_2O_2]_0 = 10^{-3}$ mol L^{-1}, phosphate buffer 10^{-2} mol L^{-1}, pH 7. (*a*) [RSSR] before addition of RSH, (*b*) [RSSR] after addition of RSH.

(*2*) If an excess of RSH ($\approx 10^{-2}$ mol L^{-1}) was added at the end ($\approx$ 9 h) of the experiment ($[RSH]_0 = [H_2O_2]_0 = 10^{-3}$ mol L^{-1}, phosphate buffer 10^{-2} mol L^{-1}, pH 7), we could observe an extra amount of RSSR ($\approx 4.5 \times 10^{-4}$ mol L^{-1}), which involved consuming almost the entire initial concentration of H_2O_2 (see Fig. 5).

(*3*) The addition of catalase 10^{-7} mol L^{-1}, 9 h after the start of the reaction ($[RSH]_0 = [H_2O_2]_0 = 10^{-3}$ mol L^{-1}, phosphate buffer 10^{-2} mol L^{-1}, pH 7), leads to the formation of $\approx 5 \times 10^{-4}$ mol L^{-1} oxygen, whereas there was no free H_2O_2 (determined by the titanium method) detected.

(*4*) The classical stoichiometry has been observed when [RSH] was in large excess (2×10^{-2} mol L^{-1}) compared with $[H_2O_2]_0$ (10^{-3} mol L^{-1}) see Experimental results in ref. 26).

Thus, these experiments explain the residual oxidizing power of the end product, which could proceed from a "bound hydrogen peroxide" [RSSR...H_2O_2].

These experiments could be summarized as follows:

[2] $2RSH + 2H_2O_2 \rightarrow [RSSR...H_2O_2] + 2H_2O$

[3] $[RSSR...H_2O_2] + 2RSH \rightarrow 2RSSR + 2H_2O$

Reaction [2] represents the overall oxidation of RSH by H_2O_2

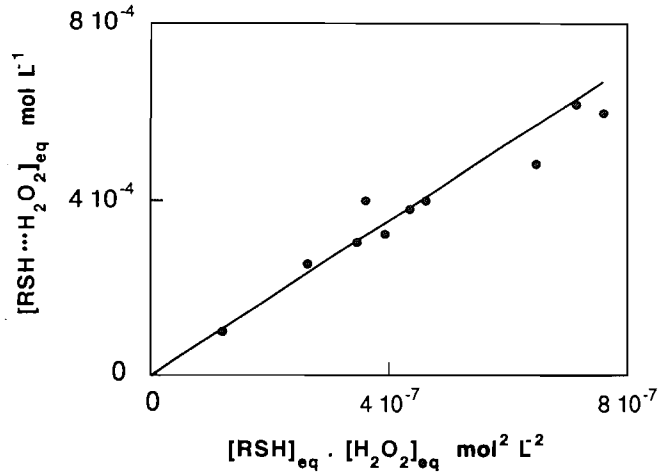

Fig. 6. Chelate concentration at equilibrium as a function of $[RSJ]_{eq} \times [H_2O_2]_{eq}$. Phosphate buffer 10^{-2} mol L^{-1}, pH 7.

leading to the final complexed product [RSSR...H_2O_2] (when the initial concentration of RSH and H_2O_2 are of the same order or magnitude). Reaction [3] explains the stoichiometric oxidation of RSH when it is in large excess. These overall reactions composed of several steps.

In this work, we have focused our attention on the fast initial decay of hydrogen peroxide in the presence of *N*-acetylcysteine. In the case of glutathione, the hypothesis of the initial formation of a chelate (hydrogen bonds) between glutathione and hydrogen peroxide, according to reaction [1], had been proposed. A similar process could be invoked to explain our experimental results with *N*-acetylcysteine, the fast initial decay of H_2O_2 resulting from the formation of a chelate between *N*-acetylcysteine and hydrogen peroxide:

[4] $RSH + H_2O_2 \rightleftarrows [RSH...H_2O_2]$.

The reaction could be considered the first step of the overall reaction [2].

We have determined the equilibrium constant K_4 by measuring [RSH], $[H_2O_2]$, and [RSH...H_2O_2] at equilibrium. These values are reported in Table 1. It has been established that the titanium sulfate method allowed one to measure only the free hydrogen peroxide and not bound hydrogen peroxide in the chelate. Concentration of H_2O_2 at equilibrium, $[H_2O_2]_{eq}$, has been determined by extrapolating to $t = 0$ the slow decay of H_2O_2. The concentration of chelate at equilibrium is deduced from $[H_2O_2]_0 - [H_2O_2]_{eq}$. Ellman's reagent, which measures the thiol concentration, gives the sum of concentrations of free *N*-acetylcysteine and its chelated form. Hence the concentration of *N*-acetylcysteine at equilibrium is calculated as the difference between the initial concentration of RSH and the concentration of chelate at equilibrium. In Fig. 6 are reported the values of $[RSH—H_2O_2]_{eq}$ as a function of the product $[RSH]_{eq} \times [H_2O_2]_{eq}$. The slope of the straight line following is the equilibrium constant: 880 ± 80 (Table 1). This number is of the same order of magnitude as that for glutathione (1950 ± 50 (2)).

Theoretical results and discussion

To formulate a model for the formation of a molecular complex in a solvent requires the following information: (*1*) *intermolecular energy*, to identify the geometrical arrangement of the molecules entering into the complex and the interaction

energy; (*2*) *intramolecular energy*, to account for the conformation of each partner forming the complex; and (*3*) *the solvent effect.*

In the discrete model, the number of water molecules surrounding the solute is important because of their long range effects. The water molecules may interact strongly with the solute (these are the "hydration" water molecules) or they may form several solvation shells. Here, computation time within the SIBFA framework is considerable. For example, in GSH complexation (3–5), water molecules in the first solvation shell interact strongly with the solute; they are therefore not at random but are extremely oriented with respect to the solute. After the first solvation shell, interaction with the solute weakens and bulk solvent may be used as a first approximation. In the continuum model, the orientation effects exerted by the solute on the water molecules in the first shell are not taken into account. A good compromise is therefore the "discrete–continuum model": i.e. a solute + *N*w strongly interacting water molecules surrounded by a continuum (*N*w is the number of "hydration water molecules").

In this work, N_w is chosen according to a criterion on energy, i.e. $E_{s-w} \leq -5.4$ kcal/mol (-22.6 kJ/mol), since 5.4 kcal/mol is the water dimer interaction energy. We called "hydration energy" (E_{Hydra}), the intermolecular energy between solute and the *N*w hydration molecules. The system "solute + N_w water molecules" is fully optimized (intra + inter energies) within the SIBFA method.

We have not calculated the free enthalpy energy, so we cannot directly correlate our theoretical to our experimental association constant *K*. We correlated the calculated energy values to enthalpy, thus we evaluated the stability of a complex.

1. Conformation of RSH

There are no experimental data on the geometry of RSH. However, since RSH is very similar to the central part of GSH (cystein unit), we have used the geometry and the special dihedral angles as determined (for this unit) in the glutathione crystal structure (23) (conformation A in Table 2).

(i) Isolated state

We have performed a complete automatic optimization of the five dihedral angles (Fig. 1*a*) and picked several conformations from an energy sub-map $E = f(\Phi, \Psi)$. From these conformations we got a unique optimized conformation O, characterized by a weak intramolecular H-bond between the carboxylate and the NH groups (d_{OH} = 2.51 Å) (Table 2). This conformation is stabilized with respect to the initial conformation A: $\Delta E_{intra} = E_{intra_O} - E_{intra_A} = -10.2$ kcal/mol (-42.6 kJ/mol).

TABLE 2. Dihedral angles in the initial and optimized conformations of RSH

Conformations	Φ	Ψ	γ_1	γ_2	χ
A	29.17	57.98	185.29	180.0	103.32
O	305.33	64.53	170.80	185.15	275.33

(ii) Hydrated state

According to the energetics criterion there are eleven hydration water molecules interacting with RSH in the O conformation. For comparison, we performed an intermolecular energy optimization of the system RSH + eleven water molecules, RSH being present in the initial conformation A (structure A′).

The total energies ($E_{tot} = E_{intra} + E_{inter}$) for the two structures A′ and O′ were compared. We define $\Delta E_{tot} = E_{tot_O} - E_{tot_A}$. In fact, even when considering a 2.6 kcal/mol (10.9 kJ/mol) intramolecular energy loss, the optimized hydrated structure O′ lies 16.9 kcal/mol (70.6 kJ/mol) below A′.

Note that apart from the usual "hydration" water molecules that are linked to the CO_2^-, CO, NH, or SH group, there are other water molecules that form H bonds with the two interaction sites at the RSH molecule of O′ structure (Fig. 7). These water molecules interact more strongly than the other water molecules; they form what we call a "water bridge". The first water molecule interacts with both the CO_2^- and NH groups while the second one is located between the CO_2^- and SH groups. Furthermore, in both structures A′ and O′, a water molecule acts as a proton donor towards the two oxygens of the carboxylate group, forming a cyclic dimer.

Similar strong water bridges have been suggested for the hydrated structures of GSH (3–5). Some of them contribute to the stabilization of the folded conformations, strengthening the intramolecular H bonds between polar and charged groups. However, we wish to emphasize the fact that the distance between the oxygen in the water molecule and SH group in RSH (2.86 Å) is longer than any other H-bond distance in RSH and in GSH ($d < 2.5$ Å).

2. Conformation of H_2O_2

We did not attempt any optimization of the isolated state of H_2O_2 since a number of experimental and theoretical data (*ab initio* calculations using extended basis) yield a dihedral angle τ of 120° (24).

E_{inter} (H_2O_2)	−16.4	−15.0

[a]All energies in kcal/mol.

In the hydrated state, three water molecules satisfy the energetics criterion and yield a stable conformation.

3. *RSH...H_2O_2 complexes*

(i) Isolated state

As shown in a previous work concerning glutathione complexation (3–5), the preferred sites for H_2O_2 are the ones occupied by the water molecules that form H-bonded bridges. Thus we adopted these as our initial positions while keeping RSH and H_2O_2 in their "hydrated" form, and then performed a complete optimization of intra- and intermolecular energies. Table 3 gives an insight to the stability of these complexes. It can be seen that, when the H_2O_2 molecule replaces the water molecule, the interaction energies are lowered by ≅ 2 kcal/mol (8.4 kJ/mol). Furthermore, it can be noticed that the two cyclic complexes that involve either the NH and CO_2^- groups (I) or the SH and CO_2^- groups (II) in the RSH, have nearly the same stability.

In complex I, the CO_2^- and NH groups have rather similar relative positions as in the glycyl residue of GSH. Thus this complex is nearly the same as the one denoted Cgly—gly for [GSH...H_2O_2] (8) but is lower in energy (−16.4 kcal/mol (−68.6 kJ/mol)) by −12.9 kcal/mol (−53.9 kJ/mol) calculated for Cgly—gly. The less favourable interaction energy obtained for GSH probably arises from repulsive contributions between H_2O_2 and the rest of GSH molecule.

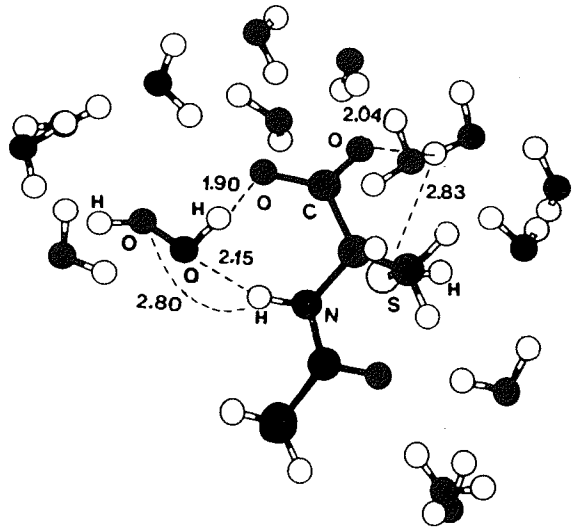

FIG. 8. Hydrated structure of the stable structure of [RSH...H_2O_2] complex. Intermolecular H-bonds are represented by dashed lines, lengths are in Å.

We cannot compare complex II for RSH with that for GSH since the relative positions of CO_2^- and SH groups are different in the two molecules. Effectively, in GSH, H_2O_2 forms a bridge between the glutamyl and cysteyl residues whereas in RSH, both CO_2^- and SH groups belong to the cystein molecule.

Though the two complexes are comparable in stability, we may note that the intermolecular H bonds in complex II are longer than those calculated for complex I (similar results have been obtained in the hydrated state, see Fig. 7).

(ii) Hydrated state

The two stable complexes obtained in the isolated state were surrounded by fourteen water molecules. We have performed complete intra- and intermolecular optimizations on these complexes. Let us define $\Delta E_{hydra} = E_{hydra}(RSH...H_2O_2) - E_{hydra}(RSH) - E_{hydra}(H_2O_2)$, $\Delta E_{tot_1} = \Delta E_{intra} + \Delta E_{hydra} + E_{inter}(RSH...H_2O_2)$; ($\Delta E_{intra}$ is calculated with respect to the complex in the isolated state).

When hydration water molecules are taken into account, it may be noticed that both complexes I and II are destabilized. In fact, this effect is more important for complex II, for which the total energy (ΔE_{tot_1}) is calculated to be ≅ −2 kcal/mol (−8.4 kJ/mol) versus a value of −15 kcal/mol (−62.7 kJ/mol) in vacuo. Thus we may conclude that such a complex cannot really exist in water. The behaviour of complex I is quite different, complexation leads to a 1.8 kcal/mol (7.5 kJ/mol) intramolecular energy gain and to a 9.2 kcal/mol (38.5 kJ/mol) hydration energy loss. However, as a whole, this complex remains stable $\Delta E_{tot_1} = -9.0$ kcal/mol (−37.6 kJ/mol). In Fig. 8 it can be noticed that, apart from the H bonds between H_2O_2 and RSH, there is still a water molecule located between SH and CO_2^- groups.

We are conscious of the fact that the hydration water molecules represent only a part of the whole solvent, so we explore the total effect upon complex I. We therefore performed calculations within the discrete–continuum model. The different energy contributions (including both intermolecular and solvation energies) are calculated following the scheme defined in Fig. 9 and their values are listed in Table 4.

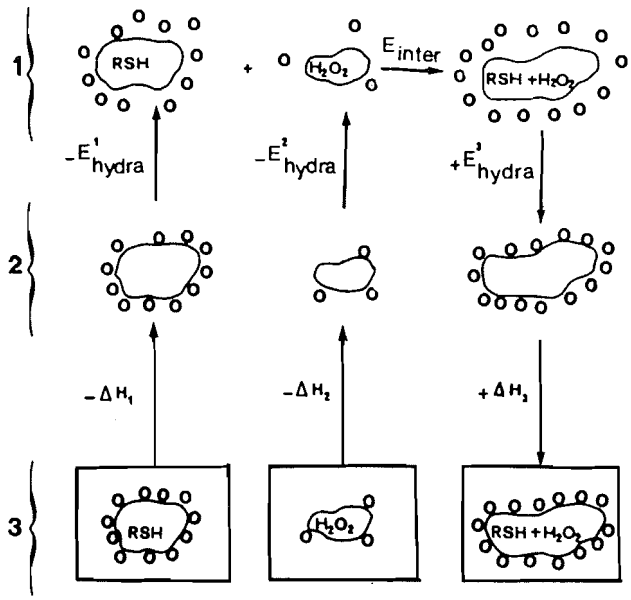

FIG. 9. Scheme of the intermolecular and solvation energies for the RSH and H_2O_2 molecules and [RSH...H_2O_2] complex in the isolated state (level 1), in the hydrated state: with the "hydration water molecules" (level 2) + the bulk solvent (level 3). Water molecules are represented by small circles.

TABLE 4. Variation in intermolecular energies for two solvation models: discrete (model 1), discrete–continuum (model 2)[a]

Model	$-E^1_{Hydra}$	$-E^2_{Hydra}$	E^3_{Hydra}	ΔE_{Intra}	ΔE_{Tot_1}
1	138.6	21.1	−167.0	−1.8	−9.0
Model	ΔH_1	ΔH_2	ΔH_3	ΔH_s	ΔE_{Tot_2}
2	−102.6	−29.8	−130.1	2.3	−6.7

[a]Energy contributions are defined in Fig. 8. $\Delta H_s = \Delta H_3 - \Delta H_1 - \Delta H_2$; $\Delta E_{tot_2} = \Delta E_{tot_1} + \Delta H_s$ (all values in kcal/mol).

From our results (Table 4) it appears that there is an additional energy loss (ΔH_s = 2.3 kcal/mol (9.6 kJ/mol) due to the bulk solvent effect. In fact, the effect of hydration water molecules upon complexes represents the major portion (≅80%), but not the total, of the solvent effect. However, this complex remains stable with ΔE_{tot_2} = −6.7 kcal/mol (−28 kJ/mol) which must remain as the energy of the hydrated complex (versus −16.4 kcal/mol (−68.6 kJ/mol) in the isolated state).

At this stage of our work, let us point out that our energies values are related to the change in enthalpy for binding but not to change in free enthalpy since we did not take entropic effects into account. However, we must emphasize the fact that the orders of magnitude of these enthalpy values are comparable to those obtained experimentally for molecular interactions involving cyclic H bonds between two nucleic bases (25).

Conclusion

Our objectives were (*i*) to examine the possibility for *N*-acetylcysteine to complex with hydrogen peroxide in the first stage of the kinetics and (*ii*) to determine theoretically the most probable site(s) of complexation.

From an experimental kinetic point of view, we have shown that there is a fast initial decay of hydrogen peroxide without a concomitant oxidation of thiol function of RSH. By analogy with the kinetic reaction of GSH/H_2O_2, we attributed this initial decay of H_2O_2 to the formation of a chelate between RSH and H_2O_2. We have determined the corresponding equilibrium constant (880 ± 80), which is of the same order of magnitude as that for GSH/H_2O_2 (1950 ± 50).

Moreover, it can be noticed that, when the initial concentrations of RSH and H_2O_2 are of the same order of magnitude, the end product could be RSSR...H_2O_2 since the final solution exhibits a strong oxidizing power. Since we have established the possible existence of the RSH...H_2O_2 complex, we can reasonably suppose a similar complex for RSSR. Furthermore, the interaction sites for RSSR should be more or less similar to those for RSH.

From a theoretical point of view, we have proposed a model for the complex by studying the intermolecular and intramolecular energies and evaluating the solvent effect. Let us look at two main features: (*i*) in the isolated state there are isoenergetic complexes, in which H_2O_2 form an H-bonded bridge between CO_2^- and either NH (I) or SH (II) groups and (*ii*) the solvent has a rather strong destabilizing effect, which is more influential in complex II that has longer H bonds than in the complex I which remains stable in water.

When we compare the formation of the complexes RSH...H_2O_2 and GSH...H_2O_2, we note that (*i*) the sites of complex formation are similar although they are more numerous in GSH (up to four possible sites, depending on whether the conformation was extended or folded) and (*ii*) the binding energies for the both complexes in vacuo are of the same order of magnitude (between −13 and −25 kcal/mol (−54 and −105 kJ/mol)) and are reasonable. These observations could explain qualitatively the slight difference between the two equilibrium constants. However, at this stage of our work, we cannot explain our experimental equilibrium constants because of we do not know the entropic factors.

We therefore conclude that both RSH and GSH can rapidly complex H_2O_2. We are tempted to speculate or the protective effect of RSH/GSH against the toxicity of H_2O_2. Since the complexation occurs before the reduction of H_2O_2, we might infer a secondary antioxidant defence mechanism against the excess H_2O_2.

Acknowledgments

We thank Pr. C. Ferradini for her keen interest in our work and her constant encouragement. We thank Dr. R. Azerad for helpful discussion and for the synthesis of the disulfide. We are indebted to Dr. J. Caillet for valuable discussions. We also wish to thank the Groupement Scientifique "Modelisation Moléculaire" IBM-CNRS for providing us with computer facilities on 3090-600E.

On *N*-acetylcysteine. Part II. Oxidation of *N*-acetylcysteine by hydrogen peroxide: kinetic study of the overall process

ZOHREH ABEDINZADEH,[1] JLIL ARROUB, AND MONIQUE GARDÈS-ALBERT

Laboratoire de Chimie Physique, URA 400 CNRS, Université René Descartes, 45, rue des Saints-Pères, 75270 Paris, Cedex 06, France

Received February 1, 1994

ZOHREH ABEDINZADEH, JLIL ARROUB, and MONIQUE GARDÈS-ALBERT. Can. J. Chem. **72**, 2102 (1994).

The oxidation kinetics of *N*-acetylcysteine (RSH) by hydrogen peroxide has been studied at neutral pH at different concentration ratios from 0.2 to 20 (4×10^{-4} mol $L^{-1} \leq [RSH]_0 \leq 2 \times 10^{-2}$ mol L^{-1}, 10^{-4} mol $L^{-1} \leq [H_2O_2]_0 \leq 10^{-2}$ mol L^{-1}). In all the cases studied, *N*-acetylcystine (RSSR) is the only oxidized product formed. Our kinetic data have focused on the importance of the concentration ratio to reach the stoichiometric oxidation of *N*-acetylcysteine by hydrogen peroxide. Indeed non-stoichiometric oxidation of RSH occurs at relatively low concentration ratios ($R < 2.5$) whereas stoichiometric oxidation is observed when $R > 2.5$. Moreover, it has been shown that in the first minutes of the reaction there is the formation of a complex between RSH and H_2O_2, the stoichiometry of the complex being RSH concentration-dependent for a given R ($R > 2.5$). Reaction mechanisms have been quantitatively established and the k values of each step determined.

ZOHREH ABEDINZADEH, JLIL ARROUB et MONIQUE GARDÈS-ALBERT. Can. J. Chem. **72**, 2102 (1994).

On a étudié la cinétique de l'oxydation de la *N*-acétylcystéine (RSH) par le peroxyde d'hydrogène, à un pH neutre, à divers rapports de concentration allant de 0,2 à 20 (4×10^{-4} mol $L^{-1} \leq [RSH]_0 \leq 2 \times 10^{-2}$ mol L^{-1}, 10^{-4} mol $L^{-1} \leq [H_2O_2]_0 \leq 2 \times 10^{-2}$ mol L^{-1}). Dans tous les cas étudiés, le seul produit formé est la *N*-acétylcystine (RSSR). Nos données cinétiques mettent l'accent sur l'importance du rapport de concentrations nécessaire à l'atteinte de la stoechiométrie. En effet, l'oxydation non stoechiométrique de RSH se produit pour des rapports de concentrations relativement faibles ($R < 2,5$) alors que l'oxydation stoechiométrique est observée lorsque $R > 2,5$. De plus, on a montré que dans les premières minutes de la réaction, il y a formation d'un complexe entre le RSH et le H_2O_2 dont la stoechiométrie, pour une valeur donnée de R ($R > 2,5$), dépend de la concentration du RSH. On a établi quantitativement les mécanismes de réaction et on a déterminé les valeurs de k de chacune des étapes.

[Traduit par la rédaction]

Introduction

The univalent reduction of molecular oxygen results in the formation of reactive oxygen intermediates, so-called reactive oxygen species, that may disrupt cellular function by direct or indirect oxidation of cellular lipids, proteins, and nucleic acids (1–7). It is clear that the cells have developed an extensive collection of antioxidant defence. However, there are situations, both physiological and pathological, in which cells are exposed to an unusually high load of oxidants and free radicals (oxidative stress). Elevated quantities of reactive oxygen species, including H_2O_2, are also produced during the metabolism of certain xenobiotics and are often associated with the initiation of lipid peroxidation and acute toxicity (8, 9). Many authors have implicated reactive oxygen species as important causative agents of aging and of several human diseases. Inactivations of unusual quantities of reactive oxygen species by antioxidant therapy has been proposed by many authors (10–12).

In this framework *N*-acetylcysteine (RSH) has been widely used as an antioxidant in vivo and in vitro. For example, it decreases the toxicity of diquat to hepatocytes (13), protects animals against paracetamol hepathotoxicity (14), and it serves as the antidote of choice for paracetamol overdose in humans (15). It has received attention as an antioxidant for components of cigarette smoke (16, 17) and for treatment of various respiratory diseases (18). Recently, there have been several reports suggesting that *N*-acetylcysteine is cardioprotective against ischemia/reperfusion injury (19, 20) and finally several authors have proposed *N*-acetylcysteine as a therapeutic agent in AIDS (Acquired Immunodeficiency Syndrome) (21–25).

Although it is not clear the mechanisms by which *N*-acetylcysteine might be able to act as an oxidant scavenger in vivo, some authors suggest that the antioxidant properties of RSH come as a result of direct of oxidant species and others propose that RSH acts as a precursor of the natural antioxidant glutathione; or a combination of these two modes of action.

Concerning the antioxidant action of *N*-acetylcysteine towards hydrogen peroxide, it has been shown to react slowly with H_2O_2 (26), and an approximate rate of reaction of *N*-acetylcysteine with H_2O_2 was given by Aruoma et al. (27) (0.85 mol^{-1} L s^{-1}) by following only the loss of *N*-acetylcysteine in the reacting mixture in less than one half-live.

We have therefore investigated the mechanism of oxidation of RSH by H_2O_2 to better understand the process by which RSH might be able to act as a direct oxidant scavenger. The kinetics of this reaction has been studied in neutral aerated aqueous medium at different concentrations: 4×10^{-4} mol $L^{-1} \leq [RSH]_0 \leq 2 \times 10^{-2}$ mol L^{-1}, 10^{-4} mol $L^{-1} \leq [H_2O_2]_0 \leq 10^{-2}$ mol L^{-1}, and at different ratios of $[RSH]_0/[H_2O_2]_0$ (0.2 to 20).

Materials and methods

See ref. 29 for the experimental and theoretical approaches of the *N*-acetylcysteine/H_2O_2 complexation.

Experimental results

Kinetics for the reaction of *N*-acetylcysteine with hydrogen peroxide are functions of the concentration ratios R ($R = [RSH]_0/[H_2O_2]_0$). For a given value of R, they depend on the

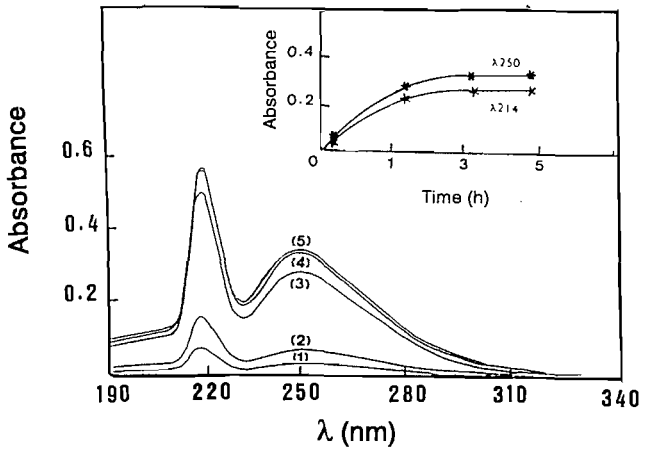

FIG. 1. Differential absorption spectra of the reaction mixture: $R = [RSH]_0/[H_2O_2]_0 = 0.2$, $[RSH]_0 = 2 \times 10^{-3}$ mol L^{-1}, $[H_2O_2]_0 = 10^{-2}$ mol L^{-1}, phosphate buffer 10^{-2} mol L^{-1}, pH 7, $l = 0.875$ cm. Reference: $[RSH]_0 = 4 \times 10^{-3}$ mol L^{-1}, $[H_2O_2]_0 = 2 \times 10^{-2}$ mol L^{-1} ($l = 0.4375$ cm) (two chambers cell, see ref. 29, Materials and methods section). (*1*) 03 min, (*2*) 0.9 min, (*3*) 1 h 10 min, (*4*) 2 h 10 min, (*5*) 3 h after the start of the reaction. In inset, evolutions of the absorbances as a function of time at λ 250 nm and λ 214 nm.

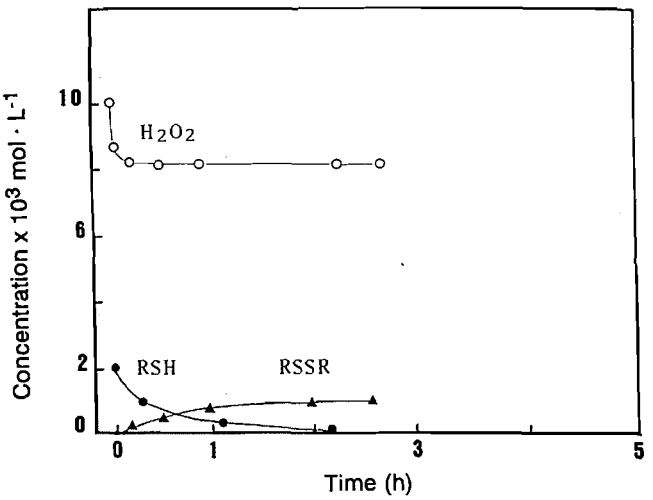

FIG. 2. Kinetic evolution of hydrogen peroxide (○), *N*-acetylcysteine (●), and *N*-acetylcystine (▲) as a function of time. $R = [RSH]_0/[H_2O_2]_0 = 0.2$, $[RSH]_0 = 2 \times 10^{-3}$ mol L^{-1}, $[H_2O_2]_0 = 10^{-2}$ mol L^{-1}, phosphate buffer 10^{-2} mol L^{-1}, pH 7.

concentrations of RSH. Thus we have studied reactions corresponding to $R < 2.5$ (see § I); $R \geq 2.5$ (see § II); and finally for a given R ($R > 2.5$), the effect of the thiol concentration (see § III).

I. Kinetic results for R < 2.5

(a) Differential absorption spectra of the reaction mixture

In Fig. 1, as an example, are reported the differential absorption spectra of a solution containing $[RSH]_0$ 2×10^{-3} mol L^{-1} and $[H_2O_2]_0$ 10^{-2} mol L^{-1} ($R = 0.2$, phosphate buffer 10^{-2} mol L^{-1}, pH 7) at various times after mixing. The differential absorption spectrum (*1*) recorded 3 min after mixing shows two maxima at 214 and 250 nm. These absorptions increase until the end of reaction (spectra (*2*) to (*5*)).

The kinetics at 250 and 214 nm are reported in the inset of Fig. 1. These curves appear to increase rather quickly for an hour, then they grow slowly until the end of reaction. These absorptions have been attributed to RSSR ($\Delta\epsilon_{250} = 330$ mol^{-1} L cm^{-1}). At the end of the reaction, the disulfide concentration is 1×10^{-3} mol L^{-1} which corresponds to the total transformation of RSH into RSSR. Consequently, we can assume that the thiol is stoichiometrically oxidized into RSSR.

(b) Evolution of RSH, H_2O_2, and RSSR

For the same experiment ($[RSH]_0 = 2 \times 10^{-3}$ mol L^{-1}, $[H_2O_2]_0 = 10^{-2}$ mol L^{-1}, $R = 0.2$, phosphate buffer 10^{-2} mol L^{-1}, pH 7) we have reported in Fig. 2, the simultaneous changes in $[H_2O_2]$, [RSH], and [RSSR] as a function of time. Note that the concentration of RSSR has been determined as previously described in I(*a*). As can be seen, the concentration of hydrogen peroxide decreases abruptly, while RSH disappears slowly and RSSR emerges slowly. Indeed, the changes in concentration end in about 2 h for RSH and RSSR whereas for H_2O_2 the change ends in about 30 min after reaction starts. Moreover, the initial drop in H_2O_2 (75% of the total H_2O_2 decay) occurs in less than 2 min. Similar trends have also been observed in $R = 1$ (see ref. 29, Experimental results). This drop has been attributed to the rapid complexation of H_2O_2 by RSH without oxidizing the thiol group in RSH. Thermodynamic equilibrium constant of complexation has been estimated using the method described in ref. 29. In the case of $R = 0.2$ we have found $K = 850$, which is in agreement with the results in ref. 29 (Discussion) ($K = 900 \pm 100$).

At the end of the reaction (~2 h), the final concentrations of RSH, H_2O_2, and RSSR equal to 0, 8×10^{-3} mol L^{-1} and 10^{-3} mol L^{-1}. Hence the amounts of RSH and H_2O_2 consumed are 2×10^{-3} mol L^{-1} and 2×10^{-3} mol L^{-1}. At the end of the reaction, 1 mol of RSH reacts with 1 mol of H_2O_2 to give half a mole of RSSR. The same has been observed for three other experiments ($R = 0.4$, 0.6, 1, see Table 1).

To follow the course of the hydrogen peroxide, we performed the following tests: (*i*) At the end of an experiment ($R = 1$) when no free H_2O_2 was present we have added catalase (10^{-7} mol L^{-1}). We observed the formation of the dioxygen whose concentration equals to the final concentration of RSSR. (*ii*) When we added an excess of RSH at the end of the experiment ($R = 1$) when no free H_2O_2 was present we observed the formation of extra RSSR. (*iii*) We have tested the eventual formation of dioxygen during our kinetic studies ($R = 1$) by Gilson Oxygraph. Any formation of dioxygen observed was due to disproportionation.

Thus, these tests demonstrated the residual oxidizing power of the end product, which might come from the presence of a "bound hydrogen peroxide compound" or from a peroxide bond in the final oxidized product [RSSR...H_2O_2]. It should be noted that these three tests were performed at $R = 1$, since in other cases ($R = 0.2$, 0.4, 0.6) there is always free H_2O_2 remaining in the medium at the end of the reaction. The free H_2O_2 may interfere with the bound hydrogen peroxide.

II. Kinetic results for R > 2.5

(a) Differential absorption spectra of the reaction mixture

As can be seen in Fig. 3 ($[RSH]_0 = 4 \times 10^{-3}$ mol L^{-1}, $[H_2O_2]_0 = 5 \times 10^{-4}$ mol L^{-1} ($R = 8$, phosphate buffer 10^{-2} mol L^{-1}, pH 7) the differential spectra exhibit two maxima at 214 and 250 nm, showing the formation of RSSR as a function of

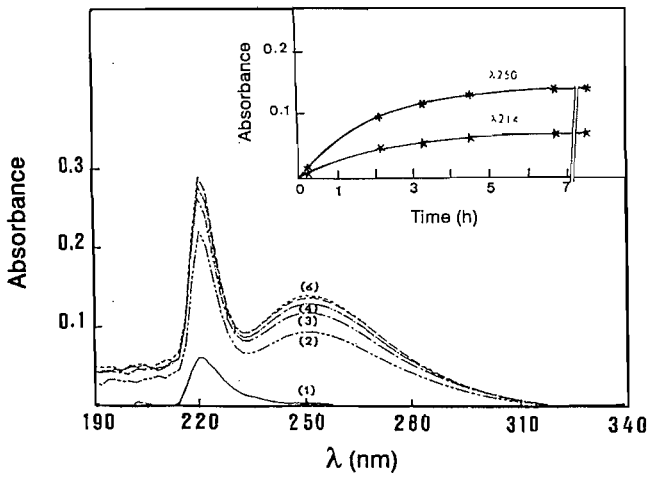

FIG. 3. Differential absorption spectra of the reaction mixture: $R = [RSH]_0/[H_2O_2]_0 = 8$, $[RSH]_0 = 4 \times 10^{-3}$ mol L^{-1}, $[H_2O_2]_0 = 5 \times 10^{-4}$ mol L^{-1}, phosphate buffer 10^{-2} mol L^{-1}, pH 7, l = 0.875 cm. Reference: $[RSH]_0 = 8 \times 10^{-3}$ mol L^{-1}, $[H_2O_2]_0 = 10^{-3}$ mol L^{-1} (l = 0.4375 cm) (two chambers cell, ref. 29 Materials and methods section). (*1*) 3 min, (*2*) 2 h 10 min, (*3*) 3 h 15 min, (*4*) 4 h 30 mn, (*5*) 5 h 20 min, (*6*) 6 h 40 mn after the start of the reaction. In inset, evolutions of the absorbances as a function of time at λ 250 nm and λ 214 nm.

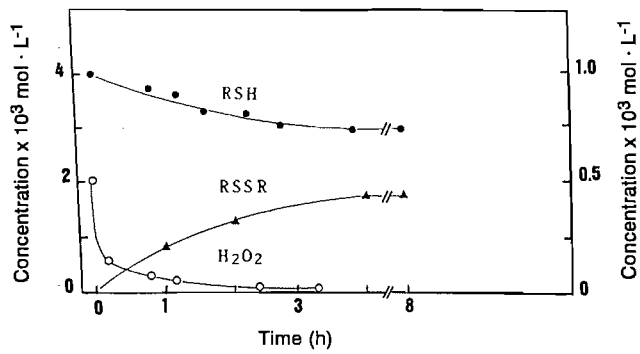

FIG. 4. Kinetic evolution of hydrogen peroxide (○), *N*-acetylcysteine (●), and *N*-acetylcystine (▲) as a function of time. $R = [RSH]_0/[H_2O_2]_0 = 8$, $[RSH]_0 = 4 \times 10^{-3}$ mol L^{-1} (left scale), $[H_2O_2]_0 = 5 \times 10^{-4}$ mol L^{-1} and [RSSR] (right scale), phosphate buffer 10^{-2} mol L^{-1}, pH 7.

time (spectra (*1*)–(*5*)). Figure 3 inset shows the absorbances at 214 and 250 nm. These absorptions increase as a function of time, until they reach a plateau in ~7 h. Notice that these spectra are similar to that observed for $R < 2.5$, meaning that the only oxidized final product is RSSR. At the end of the reaction, the concentration of RSSR is found to be 4.2×10^{-4} mol L^{-1}, showing that 84% of H_2O_2 have oxidized RSH to RSSR.

(b) Changes in [RSH], [H_2O_2], and [RSSR]

For the same experiment ($[RSH]_0 = 4 \times 10^{-3}$ mol L^{-1}, $[H_2O_2]_0 = 5 \times 10^{-4}$ mol L^{-1}, $R = 8$, phosphate buffer 10^{-2} mol L^{-1}, pH 7) it is reported in Fig. 4 the changes in [RSH], $[H_2O_2]$, and [RSSR] with time. We notice the decrease in $[H_2O_2]$ and the slow changes in [RSH], [RSSR], as in the case of $R < 2.5$. The rapid disappearance of H_2O_2 is related to the initial complexation of RSH by H_2O_2. Thermodynamic equilibrium constant of complexation in this case is 875, which is in agreement with the equilibrium constant determined in ref. 29, Discussion section.

At the end of the reaction (~7 h), the final concentrations of RSH, H_2O_2, and RSSR equal to 3×10^{-3}, 0, and 4.2×10^{-4} mol L^{-1}. Thus at the end of the reaction, 2 mol of RSH have reacted with 1 mol of H_2O_2 to give 1 mol of RSSR. The same has been observed for all experiments having concentration ratios of $R > 2.5$. This is the normally accepted stoichiometry when excess thiol reacts with hydrogen peroxide.

III. Effect of different concentrations of RSH on a given R ($R > 2.5$)

We have studied the effect of higher RSH concentrations when R = 10, 15, and 20 ($[RSH]_0 \geq 10^{-2}$ mol L^{-1}). Figure 5 ($[RSH]_0 = 2 \times 10^{-2}$ mol L^{-1}, $[H_2O_2]_0 = 1.33 \times 10^{-3}$ mol L^{-1} (R = 15, phosphate buffer 10^{-2} mol L^{-1}, pH 7) shows the changes in concentrations of H_2O_2, RSH, and RSSR with time. As in previous experiments (see § I and II), there is an initial fast drop in $[H_2O_2]$, and while about 65% of H_2O_2 disappears, RSH does not oxidize into RSSR. Then, the thiol concentration decreases slowly for 4 h while at the same time RSSR is slowly formed and H_2O_2 slowly disappears. The overall reaction shows that 2 mol of RSH react with 1 mol of H_2O_2 to give 1 mol of RSSR, a stoichiometry characteristic of $R > 2.5$. However, complexation of H_2O_2 cannot be explained by 1 mol of H_2O_2 reacting with 1 mol of RSH (reaction [1]). Indeed, with reaction [1], the thermodynamic equilibrium constant for complexation is found to be smaller by one order of magnitude (≈100 instead of 900 ± 100). It is the same observation for the two R's (R = 10, $[RSH]_0 = 10^{-2}$ mol L^{-1}, $[H_2O_2]_0 = 10^{-3}$ mol L^{-1}; and $R = 20$, $[RSH]_0 = 2 \times 10^{-2}$ mol L^{-1}, $[H_2O_2]_0 = 10^{-3}$ mol

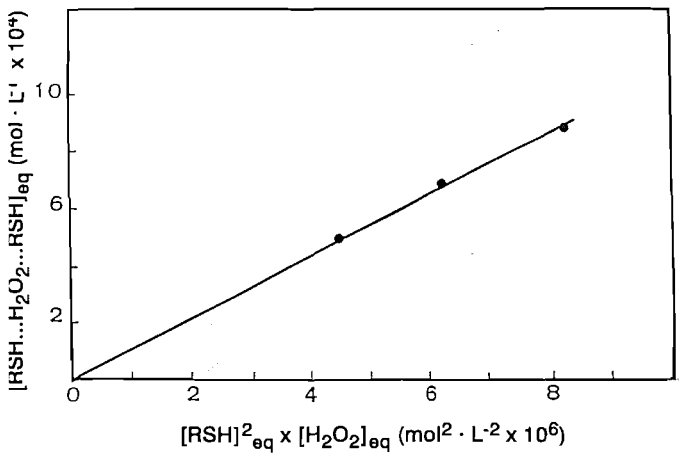

FIG. 6. Chelate concentration at equilibrium $[RSH...H_2O_2...RSH]_{eq}$ as a function of $[RSH]_{eq}^2 \times [H_2O_2]_{eq}$. Phosphate buffer 10^{-2} mol L^{-1}, pH 7.

L^{-1}) for which the equilibrium constants are the same order of magnitude (≈ 100). Hence we propose yet another type of complexation reaction in which 2 mol of RSH complex with 1 mol of H_2O_2 (reaction [2]). This mechanism is compatible with high concentrations of RSH in the medium.

[2] $2\ RSH + H_2O_2 \rightleftarrows [RSH...H_2O_2...RSH]$

Equilibrium constant K_2 is determined by measuring [RSH], $[H_2O_2]$, and $[RSH...H_2O_2...RSH]$ at equilibrium. These values are shown in Table 2. Note that the titanium sulphate method allows one to assay only the free hydrogen peroxide and not the bound hydrogen peroxide in the chelate. Concentration of H_2O_2 at equilibrium, $[H_2O_2]_{eq}$, has been determined by extrapolating to $t = 0$ the subsequent slow decrease in $[H_2O_2]$. The concentration of chelate at equilibrium has been deduced from the difference $[H_2O_2]_0 - [H_2O_2]_{eq}$. Ellman's reagent, which assays the thiol concentration, gives the sum of free *N*-acetylcysteine and its chelated form. Hence the concentration of *N*-acetylcysteine at equilibrium is calculated as the difference between the initial concentration of RSH and two times concentration of the chelate at equilibrium. In Fig. 6 are reported the values of $[RSH...H_2O_2...RSH]_{eq}$ as a function of the product $[RSH]^2_{eq} \times [H_2O_2]_{eq}$. The slope of the straight line is 110 ± 5.

Discussion

We propose the following scheme to interpret our results:

[1] $RSH + H_2O_2 \rightleftarrows [RSH...H_2O_2]$

[2] $RSH + H_2O_2 \rightleftarrows [RSH...H_2O_2...RSH]$

[3] $2\ [RSH...H_2O_2] \rightarrow [RSSR...H_2O_2] + 2H_2O$

[4] $[RSSR...H_2O_2] + 2RSH \rightarrow 2\ RSSR + 2H_2O$

[5] $[RSH...H_2O_2...RSH] \rightarrow RSSR + 2H_2O$

Reaction [1] represents the complexation of H_2O_2 by RSH to yield $[RSH...H_2O_2]$. This reaction has already been discussed in ref. 29, the preceding paper. The equilibrium constant at low concentrations of RSH ($<10^{-2}$ mol L^{-1}) has been determined. Experimental K_1 is 880 ± 80 (see preceding paper). The overall reaction [2] is the complexation of H_2O_2 by 2 mol of RSH when [RSH] is high ($\geq 10^{-2}$ mol L^{-1}). The equilibrium constant K_2 has been found to equal 110 ± 5. Reaction [3] involves the formation of complexed RSSR from the reaction of $[RSH...H_2O_2]$ with itself. Similar reaction has been proposed for glutathion (28). The formation of RSSR is consistent with the following experimental results: (*i*) at the end of the reaction, when there is no free H_2O_2, the addition of catalase stimulates the formation of oxygen and (*ii*) the addition of an excess of RSH leads to the formation of an extra RSSR equal to bounded H_2O_2 (see Experimental results and discussion in preceding paper). Reaction [3] takes place when a non-stoichiometric process is observed, that is, $R < 2.5$. Reaction [4] represents the action of RSH with the complexed RSSR. This occurs when R is > 2.5 (the concentration of the remaining thiol is less than 10^{-2} mol L^{-1}). Similar reaction has been suggested for glutathion (28). We propose that reaction [5] is an unimolecular decay of the second complex $[RSH...H_2O_2...RSH]$ to give the non-complexed disulfide RSSR.

The corresponding rate constants have been determined by numerical analyses of the kinetic differential equations using an iteration program. This calculation has been performed for three different experimental conditions: (*1*) $R < 2.5$, [RSH] < 10^{-2} mol L^{-1}; (*2*) $R > 2.5$, [RSH] < 10^{-2} mol L^{-1}; (*3*) $R > 2.5$, [RSH] > 10^{-2} mol L^{-2}.

In the first case ($R < 2.5$, [RSH] < 10^{-2} mol L^{-1}) we only take reactions [1], [−1], and [3] into consideration since the oxida-

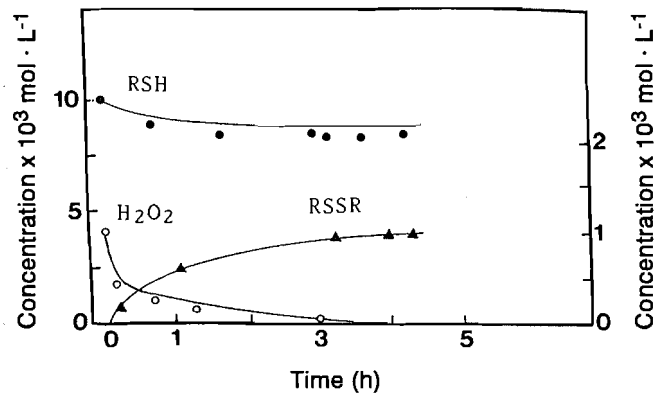

FIG. 7. Comparison between the computed kinetic curves and the experimental points [RSH] + [RSH...H_2O_2] (●), [H_2O_2] (○), [RSSR...H_2O_2] (▲): $R = [RSH]_0/[H_2O_2]_0 = 10$, $[RSH]_0 = 10^{-2}$ mol L^{-1} (left scale), $[H_2O_2]_0 = 10^{-3}$ mol L^{-1} and [RSSR] (right scale), phosphate buffer 10^{-2} mol L^{-1}, pH 7 (points are experimental).

tion of RSH by H_2O_2 is non-stoichiometric, the final product is the chelate [RSSR...H_2O_2]. Using this kinetic scheme we have calculated the three rate constants k_1, k_{-1}, and k_3 (using a known experimental equilibrium constant $K_1 = 880 \pm 80$): $k_1 = 25 \pm 5$ mol^{-1} L s^{-1}, $k_{-1} = 0.03 \pm 0.1$ s^{-1}, $K_1 = 900 \pm 100$, $k_3 = 0.5 \pm 0.2$ mol^{-1} L s^{-1}.

The calculated curves (R = 0.2, 0.4, 0.6, 1) are in perfect agreement with experimental curves, (see as an example for R = 0.2, Fig. 2 where curves are calculated).

Hence the kinetic scheme [1], [−1], and [3] seems to be consistent with the overall oxidation process (reaction I)

[I] $2\ RSH + 2\ H_2O_2 \rightarrow [RSSR...H_2O_2] + 2\ H_2O$

In the second case ($R > 2.5$, [RSH] < 10^{-2} mol L^{-1}) we have determined the rate constant of reaction [4], k_4. Under these conditions, reactions [1], [−1], [3], and [4] are taken into considerations, since the overall oxidation is stoichiometric. Using k_1, k_{-1}, and k_2 reported above, $k_4 = 40 \pm 10$ mol^{-1} L s^{-1} provides the best agreement with all the experimental curves. As an example, see Fig. 4 for R = 8 (the curves are calculated).

Consequently, the kinetic sequence [1], [−1], [3], and [4] is consistent with the overall stoichiometric oxidation process (reaction II).

[II] $2RSH + H_2O_2 \rightarrow RSSR + 2\ H_2O_2$

In the third case ($R > 2.5$, [RSH] > 10^{-2} mol L^{-1}) the rate constants k_2, k_{-2} (given that the experimental equilibrium constant $K_2 = 110 \pm 5$) and k_5 have been determined. Here we used the kinetic scheme [2], [−2], and [5]. The following k values provide the best agreement with the experimental curves (as an example see Fig. 7 for R = 10): $k_2 = 90 \pm 20$ mol^{-2} L^2 s^{-1}; $k_{-2} = 0.9 \pm 0.1$ s^{-1}; $K_2 = 110 \pm 20$; $k_5 = 0.03 \pm 0.01$ s^{-1}.

Thus the kinetic scheme [2], [−2], and [5] is in agreement with the overall stoichiometric oxidation process (reaction II)

[II] $2RSH + H_2O_2 \rightarrow RSSR + 2\ H_2O$

However, it should be noted that the fits are equally good using the full kinetic scheme (reactions [1], [−1], [2], [−2], [3], [4], and [5]) with the same theoretical rate constants used as above.

As to reaction [2], it is obvious that it is not an elementary step. It has been suggested[2] that another way of expressing reaction [2] is

[2′] $[RSH...H_2O_2] + RSH \rightleftarrows [RSH...H_2O_2...RSH]$

Nevertheless, we have no experimental proof to support [2′]. However, we have put the hypothesis to test, since K_2 would be $K_1K_{2'}$. Indeed the fits agree reasonably well with the reaction sequence [1], [−1], [2′], [−2′], [3], [4], and [5]. It should be noted that only k_5 is different by a factor of 3 (0.1 ± 0.05).

Conclusion

Our purpose was to quantitatively determine the mechanism and the kinetic parameters describing the action of hydrogen peroxide with *N*-acetylcysteine in aqueous medium buffered at pH 7. The analysis of the reaction mixture as a function of time, was performed using (*1*) Ellman's reagent to assay the thiol function of RSH and of the eventual complexes [RSH...H_2O_2] and [RSH...H_2O_2...RSH], (*2*) the titanium method to determine free H_2O_2, and (*3*) the differential absorbances of the aqueous solution in the UV region to assay the concentration of the disulfide of *N*-acetylcysteine, RSSR and of the eventual complex [RSSR...H_2O_2]. Thus the overall reaction is known at each stage of the kinetics and particularly at the end of the reaction.

The striking features of the reaction of *N*-acetylcysteine with hydrogen peroxide are summarized as follows. First of all, we have shown the importance of the concentration ratio R ($[RSH]_0/[H_2O_2]_0$) in the kinetic evolution since non-stoichiometric oxidation of RSH occurs when $R < 2.5$ whereas stoichiometric oxidation occurs when $R > 2.5$. Secondly, we have confirmed the formation of a complex between H_2O_2 and RSH in the first minutes of the reaction under all experimental conditions as described in the preceding paper. However, stoichiometry of the complex is dependent on the concentration of RSH at the highest R values ($R > 2.5$).

The rate constants for each step in the reaction mechanism have been calculated and they are in very good agreement with all experimental kinetic data.

The comparison of these results with those obtained with another thiol, the glutathione GSH (28) shows several similarities: (*i*) the formation of a complex between GSH and H_2O_2, [GSH...H_2O_2], with a K value of the same order of magnitude ($K = 2000 \pm 700$ (28)) as in the case of *N*-acetylcysteine ($K = 900 \pm 100$); (*ii*) a non-stoichiometric oxidation process for the lowest values of $R = [GSH]/[H_2O_2]$ (28) as for RSH.

The scavenging of H_2O_2 by RSH and GSH before reacting to give the disulfide certainly contributes to the antioxidant properties of the two biological systems. It is tempting to contemplate if other molecules with similar structures might exhibit similar interesting properties.

Acknowledgments

The authors wish to thank Professor C. Ferradini for her keen interest in their work and her constant encouragement and invaluable participation in this project. They thank Dr. R. Azerad for helpfull discussion and for the synthesis of the disulfide. They also thank B. Champion for NMR technical assistance.

The thermally induced [2+3] cycloadditions of certain monocyclic aziridines to dimethyl 1-cyclobutene-1,2-dicarboxylate are described. The structures of the resulting bicyclic adducts were established unambiguously by X-ray analyses. The stereochemistries of the [2+3] adducts were interpreted in terms of dipole–dipole interactions and secondary orbital interactions. In certain cases an initial thermal conrotatory ring opening of the cyclobutene to 2,3-di(methoxycarbonyl)-1,3-butadiene precedes the [2+3] cycloaddition, affording the unexpected pyrrolidine adducts **12***a* and **12***b*. The structures and stereochemistries of the latter established by X-ray analysis strongly suggest that secondary orbital interactions between the phenyl and ester groups control and stereochemistry of the reactions.

KIYOSHI MATSUMOTO, HIROKAZU IIDA, TAKANE UCHIDA, YOSHIMI YABE, AKIKAZU KAKEHI et J. WILLIAM LOWN. Can. J. Chem. **72**, 2108 (1994).

On décrit les cycloadditions[2+3] induites thermiquement de certaines aziridines monocycliques sur le cyclobut-1-ène-1,2-dicarboxylate de diméthyle. On a déterminé les structures des adduits bicycliques formés par diffraction des rayons X. On interprète les stéréochimies des adduits [2+3] en fonction d'interactions dipôles et d'interactions orbitalaires secondaires. Dans certains cas, l'ouverture initiale conrotatoire thermique du cyclobutène en 2,3-di(méthoxycarbonyl)buta-1,3-diène précéde la cycloaddition [2+3] et fournit les adduits inattendus **12***a* et **12***b*, dérivés de la pyrrolidine. Les structures et les stéréochimies de ces derniers, déterminées par diffraction des rayons X, suggèrent fortement que des interactions orbitalaires secondaires entre les groupes phényle et ester contrôlent la stéréochimie des réactions.

[Traduit par la rédaction]

Introduction

The thermal and photochemically induced electrocyclic opening of aziridines **1** and their subsequent [2+3] cycloaddition to a variety of dienophiles are of considerable theoretical and synthetic interest (1). Several cyclobutenes have been found to serve as effective dienophiles and dipolarophiles in such reactions (2). Indeed, monocyclic aziridines **1** undergo 1,3-dipolar cycloaddition with dimethyl 1-cyclobutene-1,2-dicarboxylate **2** to give the corresponding 1:1 adducts (3), whereas reactions of 1,1a-dihydro-1,2-diarylazirino[1,2-*a*]quinoxalines, bicyclic aziridines, with **2** gave the 1,2-fused 4,5-dihydro-1*H*-azepines (4). We now describe in full detail the former reactions including the confirmed stereochemistry of representative 1:1 adducts by X-ray analyses (5).

Results and discussion

Refluxing a solution of 2-benzoyl-1-cyclohexyl-3-phenylaziridine (**1***a*) with an equimolar amount of dimethyl 1-cyclobutene-1,2-dicarboxylate (**2**) in dry benzene for 7 h under nitrogen produced only one (**3***a*) of the two possible isomers in 50% yield (Scheme 1). Similarly, smooth cycloadditions of *p*-substituted aroylaziridines **1***b–e* to **2** gave the corresponding 1:1 adducts (Scheme 2) in moderate to good yields (Table 1). It is well documented that *cis*- and *trans*-aroylaziridines cycloadd even with powerful dipolarophiles by equilibration via the *trans*-azomethine ylide intermediate (6, 7). Indeed, reaction of the stereochemically pure samples of *cis*- and *trans*-2-benzoyl-1-cyclohexyl-3-phenylaziridines gave the same adducts in approximately the same yields. When **1** was treated with the deuterated aziridine (**1***a*; 63% labeled at the 2-position), the ^{1}H NMR spectrum of the adduct showed a singlet with intensity of ca. 0.4 H, at δ6.00 which allowed an unambiguous assignment of H_b. The assignment of the geometry is based upon the ^{1}H NMR data (Table 1) and the well-documented observation that a ring proton or ester methyl protons are shielded by a *cis-vic*-phenyl group (8, 9). Furthermore, the chemical shifts of H_a, H_b, and the ester methyl protons have values in accord with those of the reported pyrrolidine adducts (10, 11). The stereochemistry of the adducts was unambiguously confirmed in the cases of **3***a* and **3***c* by their single crystal X-ray diffraction analyses (Fig. 1).

Interpretations of the stereochemistry of [2+3] and [2+4] (Diels–Alder reactions) and related 1,3-dipolar reactions have been made in terms of secondary orbital interactions, dispersion forces, steric repulsion, dipole–dipole interaction, charge transfer interaction, and inductive effects. The present results may be

[c]In refluxing xylene.

explained by dipole–dipole interactions (Scheme 3) (1).[2] Alternatively, the results can also be interpreted by the secondary orbital interaction between aryl and ester group and local dipole–dipole interaction between ester and aroyl groups. An unfavorable interaction between ester and aroyl groups exists in the transition state complex leading to **6**. The observed stereochemistry of addition of maleic anhydride or *N*-phenylmaleimide and dimethyl maleate to 2-aroylaziridines (10, 12) is consistent with either of these interpretations.

cis- and *trans*-1-Benzyl-2,3-diphenylaziridines (**7***a*, **7***b*) underwent completely stereospecific cycloaddition with **2** to give the adducts **8***a* and **8***b*, respectively (Scheme 4).[3] The determinations of the stereochemistries were made by the same rule as above by ^{1}H NMR (Experimental) and were confirmed by X-ray analyses (Fig. 2). The thermal conrotatory ring-opening of symmetrical *cis*-aziridine **7***a* to *trans*-**7***a* is structurally unambiguous. In contrast, the conrotation of *trans*-aziridine **7***b* can take place in two senses (Scheme 5), leading to the *cis*-azomethine ylide in either the **10** or the **11** conformations. The W-form is reported to be generally more stable (13). Thus, the exclusive formation of **8***b* can be interpreted by the secondary orbital interaction between ester and phenyl groups (Scheme 6).

[2]According to CNDO/2 calculations of **2** (LUMO), **1**(*trans*) (HOMO), and **1**(*cis*) (HOMO), there were no significant differences (X = H, MeO, and NO_2) between $\Delta E_{2\text{-}1trans}$ and $\Delta E_{1cis\text{-}2}$ (K. Matsumoto, H. Konishi, and X. Shi, unpublished results), suggesting that electrostatic interaction might be more important. More sophisticated calculations are planned.

[3]In another experiment, a higher yield of adduct was obtained (see Table 1); the degree of purity of **1** seems to be crucial to the yield.

Next, *cis*- and *trans*-1,2,3-triphenylaziridines, less reactive aziridines than 1-benzyl-2,3-diphenylaziridines, were investigated. Reaction of *cis*-1,2,3-triphenylaziridine (**7***c*) with dimethyl 1-cyclobutene-1,2-dicarboxylate (**2**) in refluxing dry toluene gave two types of 1:1 adducts in 17 and 38% yields. The latter product was readily proven to be the normal 1:1 adduct (**8***c*) based upon the ^{1}H and ^{13}C NMR spectra. Similarly, from *trans*-1,2,3-triphenylaziridine (**7***d*) and **2** in refluxing dry toluene, the normal 1:1 adduct (**8***d*) and an unidentified 1:1 adduct were obtained in 26 and 10% yields, respectively.[2] The structure of the former adduct was established by X-ray analysis (Fig. 3). Preliminary assignment of these other unidentified adducts was based upon their ^{1}H and ^{13}C NMR spectra (14). However, the reaction steps that would lead to these products were so unusual that we decided to perform X-ray analyses of these adducts. Fortunately, suitable crystals for the X-ray analyses were obtained by recrystallization from ethanol. Based upon their X-ray analyses, the structures of these adducts were confirmed to be **12***a* and **12***b* (Scheme 7), respectively (Fig. 4). The formation of **12***a* and **12***b* is readily explained by thermal ring-opening of the cyclobutene to 2,3-di(methoxycarbonyl)-1,3-butadiene (**11**) (15), followed by 1,3-dipolar cycloaddition to the azomethine ylides (**13**, **14**) generated from **7***c* and **7***d*. The reactions were completely stereospecific with respect to the aziridines.

It is interesting to note that the phenyl and ester groups are in *cis* relationship in all the adducts (**3**, **8**, and **12**) described here, suggesting that the secondary orbital interaction between phenyl and ester groups is important in controlling the stereochemistry of the reactions, though steric hindrance due to the

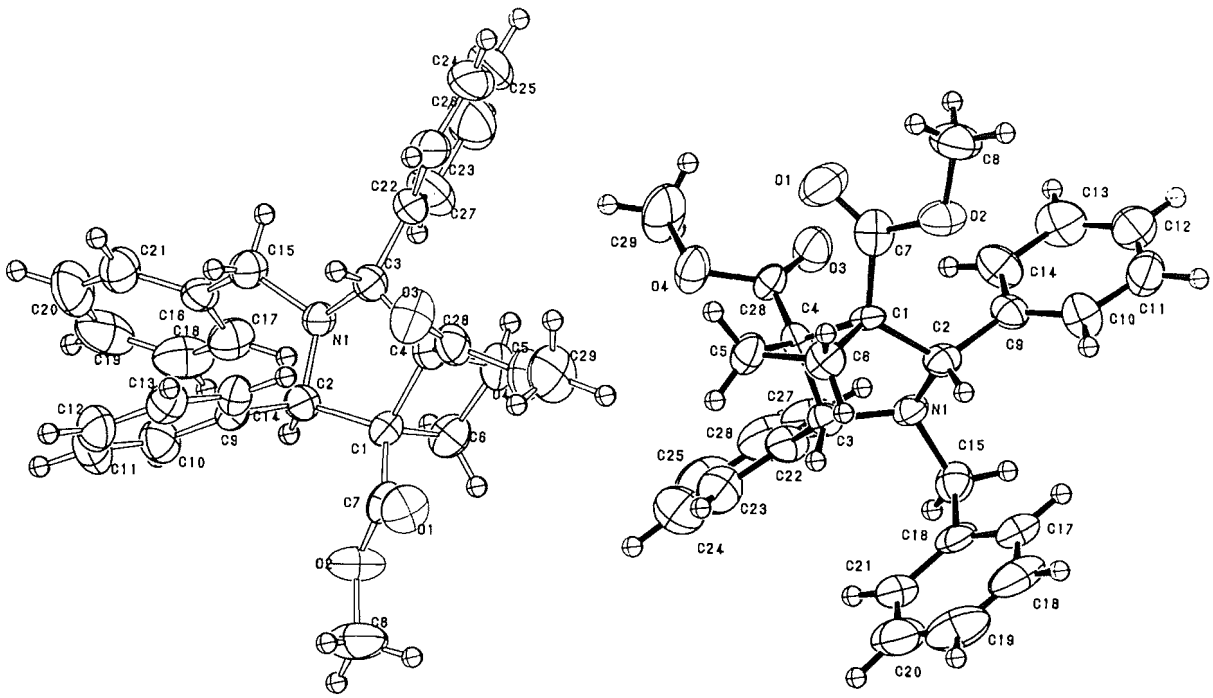

FIG. 2. ORTEP drawings of compounds **8***a* and **8***b*.

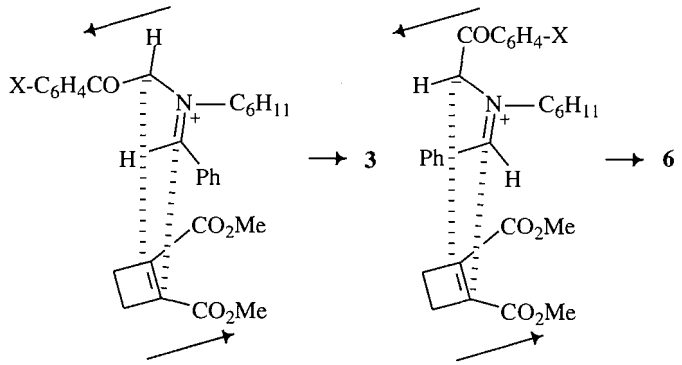

SCHEME 3

cyclobutene methylene moiety and the phenyl group cannot be excluded at present. This interpretation is in agreement with the stereochemical result that 2,3-diphenylindenone oxide (**15**) (16) undergoes thermal-symmetry-forbidden disrotatory 1,3-dipolar cycloadditions via a carbonyl ylide with **2** to give the adduct **16** (Scheme 9) whose structure was also determined by X-ray analysis (Fig. 5). Furthermore, the stereochemical results (16) obtained from **15** and symmetrical olefinic dipolarophiles are also in accord with the above interpretation.

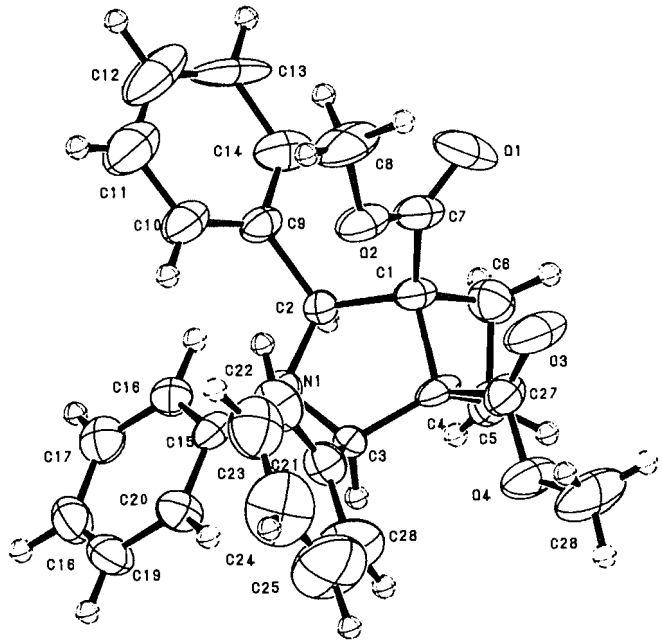

FIG. 3. ORTEP drawings of compounds **8***d*.

Experimental

General

Melting points were taken on a Yanagimoto micro-melting point apparatus and are uncorrected. The ^{1}H NMR spectra were measured either on a Hitachi R40 (90 MHz) or on a JEOL JNM EX270 (270 MHz), or JNM-ALPHA500 (500 MHz) instrument. ^{13}C NMR spectra were recorded either on a JEOL JNM-FX90Q or JNM-EX270 or JNM-ALPHA500 pulsed Fourier transform spectrometer operating at 22.49 MHz, 67.80 Hz, and 125.65 Hz, respectively. Aziridines were prepared following the procedures described in ref. 9. The cyclobutene was prepared according to the procedure of McDonald and Reitz (17). Chemical shifts are expressed in parts per million dowfield from internal tetramethylsilane. Partial proton decoupling was used to distinguish between individual carbon atoms. Preparative medium-pressure liquid chromatography was carried out using a column (25 × 310 mm) prepacked with silica gel (Lobar, LiChroprep Si60, Merck).

Reaction of 2-aroyl-1-cyclohexyl-3-phenylaziridine (1) with dimethyl 1-cyclobutene-1,2-dicarboxylate (2): general procedure

A solution of **1** (3 mmol) and **2** (3.1 mmol) in dry benzene (20 mL) was heated under reflux for 7 h. After evaporation of the solvent, the residue was chromatographed on silica (Wako Gel C-200) using benzene as eluent, giving the adducts **3**. The analytical samples were obtained by recrystallization from petroleum ether.

*Reaction of 1-benzyl-2,3-diphenylaziridines (**5**) with dimethyl 1-cyclobutene 1,2-dicarboxylate (**2**): general procedure*

A solution of **7** (4 mmol) and **2** (4.1 mmol) in dry benzene (20 mL) was heated under reflux for 14 h. After evaporation of the solvent, the residue was chromatographed on silica (Wako Gel C-200) using benzene as eluent, giving the adducts **8**. The analytical samples were obtained either by recrystallization from petroleum ether or ethanol–hexane.

*Reaction of 1,2,3-triphenylaziridines (**7**) with dimethyl 1-cyclobutene-1,2-dicarboxylate (**2**): general procedure*

A solution of **7** (5 mmol, 1.9 mmol) and **2** (5.1 mmol, 9.3 mmol) in dry toluene (30 mL, 50 mL) was heated under reflux. After evaporation of the solvent, the residue was chromatographed on silica (Wako Gel C-100) using ethyl acetate–hexane (15:75) as eluent, giving the adducts **8** and **12**.

The analytical samples were obtained by recrystallization from ethanol–hexane. In another run, a solution of **7** (3.7 mmol) and **2** (13.3 mmol) in dry xylene (90 mL) was refluxed and worked up as above.

Dimethyl trans-*2,3,4-triphenyl-3-azabicyclo[3.2.0]heptane-1,5-dicarboxylate (**8**c)*

IR (KBr): 1732, 1598, 1500, 1453, 1260, 1205, 1155, 1118, 750, 693 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.68–1.80, 2.26–2.70 (4H, C-6, 7-CH_2 × 2), 3.20 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3), 5.40 (s, 1H, C-4H), 6.12 (s, 1H, C-2H), 6.71–7.33 (m, 15H, Ar-H); ^{13}C NMR ($CDCl_3$) δ: 20.3, 29.0 (each t, C-6, 7), 51.5 (q, OCH_3), 52.4 (q, OCH_3), 59.2, 61.8 (each s, C-1, 5), 68.8, 75.5 (each d, C-2, 4), 118.4, 119.2, 127.1, 127.2, 127.4, 127.6, 128.0, 128.3, 128.7 (each d, Ph-*o*, *m*, *p*), 138.5, 138.6, 145.4 (each s, Ph-*ipso*), 171.8 (s, C═O), 173.2 (s, C═O); MS *m/z*: 441 (M$^+$), 381, 226, 180. Anal. calcd. for $C_{28}H_{27}O_4N$: C 76.17, H 6.16, N 3.17; found: C 76.35, H 6.26, N 3.19.

Dimethyl cis-*2,3,4-triphenyl-3-azabicyclo[3.2.0]heptane-1,5-dicarboxylate (**8**d)*

IR (KBr): 1740, 1597, 1495, 1455, 1300, 1240, 1195, 1125, 750, 697 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.38–2.48, 2.66–2.74 (m, 4H, C-6, 7-CH_2 × 2), 3.23 (s, 6H, OCH_3 × 2), 5.17 (s, 2H, C-2, 4-H), 6.45–7.62 (m, 15H, Ar-H); ^{13}C NMR ($CDCl_3$) δ: 29.1 (5, C-6, 7), 51.1 (q, OCH_3 × 2), 62.1 (s, C-1, 5), 75.8 (d, C-2,4), 115.5, 118.5, 127.4, 127.6, 127.9, 128.6 (each d, Ph-*o*, *m*, *p*), 140.1, 147.9 (each s, Ph-*ipso*), 171.9 (s, C═O); MS *m/z*: 441 (M$^+$), 293, 270, 180. *Reaction of 2,3-diphenylindenone oxide (**15**) with **2***

A solution of **15** (3 mmol) and **2** (6 mmol) in dry toluene (30 mL) was heated under reflux for 3 days. After evaporation of the solvent, the residue was titrated with ethanol to give the 1:1 adduct **16** as colorless crystals in 60% yield. An inspection of the residue by TLC and NMR showed only the 1:1 adduct **16**. Yield 60%; mp 272–273°C; ^{1}H NMR ($CDCl_3$) δ: 1.70–1.82, 2.34–2.67 (4H, C-8, 9-CH_2 × 2), 3.53 (s, 3H, OCH_3), 3.58 (s, 3H, OCH_3), 6.90–6.98, 7.35–7.70, 8.02–8.08 (m, 14H, Ar-H); ^{13}C NMR ($CDCl_3$) δ: 22.2, 24.9 (each t, C-8, 9), 52.1 (q, OCH_3), 52.2 (q, OCH_3), 62.7, 65.9 (each s, C-1, 7), 89.1, 91.9 (each d, C-2, 6), 126.1, 127.0, 127.9, 127.9, 128.0, 128.2, 128.4, 128.9, 132.1 (each d, Ph-*o*, *m*, *p*), 130.7, 135.1, 139.0, 146.0 (each s, Ph-*ipso*), 171.5, 171.7 (each s, C═O), 192.4 (s, C═O). Anal. calcd. for $C_{29}H_{24}O_6$: C 74.35, H 5.16, found: C 74.23, H 5.13.

Crystal structure determination

Summaries of the crystal data and structure refinement details are given in Tables 2–9.[4] The structure was solved by a direct method (18), and refined by full-matrix least squares. The atoms other than hydrogen were refined anisotropically. The atomic scattering factors for all atoms and the anomalous dispersion correction factors for atoms other than hydrogen were taken from the literature (19–21). All calculations were performed using the TEXSAN (22) crystallographic software package of the Molecular Structure Corporation.

Received March 21, 1994

WOLFGANG KLIEGEL, HENNING AMT, HARALD BECKER, UTE LAUTERBACH, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **72**, 2118 (1994).

The synthesis of a number of variously substituted *N*-alkyl 2-hydroxyaminoalkanols **3** and their reactions with phenylboronic acid are detailed. The crystalline products proved to be 1:2 condensates **4** in a few cases and 1:1 condensates **5** in all the other cases studied. Crystals of 2-mesityl-6,6-pentamethylene-1,3-dioxa-4-aza-2-boracyclohexane, **5***l*, are triclinic, $a = 11.540(2)$, $b = 10.402(3)$, $c = 8.440(2)$ Å, $\alpha = 108.86(2)°$, $\beta = 97.62(2)°$, $\gamma = 89.36(2)°$, $Z = 2$, space group $P\bar{1}$; and those of 4,4′-methylenebis(6,6-pentamethylene-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane) benzene solvate, **15a**·C_6H_6, are monoclinic, $a = 22.690(1)$, $b = 16.867(1)$, $c = 8.4783(9)$ Å, $\beta = 104.912(8)°$, $Z = 4$, space group $C2/c$. The structures were solved by direct methods and refined by full-matrix least-squares procedures to $R = 0.037$ and 0.035 ($R_w = 0.035$ and 0.044) for 3190 and 2084 reflections with $I \geq 3\sigma(F^2)$. respectively.

WOLFGANG KLIEGEL, HENNING AMT, HARALD BECKER, UTE LAUTERBACH, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **72**, 2118 (1994).

On décrit la synthèse d'un certain nombre de *N*-alkyl 2-hydroxyaminoalcanols substitués (**3**) ainsi que leurs réactions avec l'acide phénylboronique. Il s'avère que, dans quelques cas, les produits cristallins obtenus sont les produits de condensation 1 : 2 (**4**) alors que, dans tous les autres cas étudiés, ce sont les produits de condensation 1 : 1 (**5**). Les cristaux du 2-mésityl-6,6-pentaméthylène-1,3-dioxa-4-aza-2-boracyclohexane, **5***l*, sont tricliniques, groupe d'espace $P\bar{1}$, avec $a = 11,540(2)$, $b = 10,402(3)$, $c = 8,440(2)$ Å, $\alpha = 108,86(2)°$, $\beta = 97,62(2)°$ et $\gamma = 89,36(2)°$ et $Z = 2$; ceux du 4,4′-méthylènebis(6,6-pentaméthylène-2-phényl-1,3,-dioxa-4-aza-2-boracyclohexane) solvaté par le benzène, **15***a*·C_6H_6, sont monocliniques, groupes d'espace $C2/c$, avec $a = 22,690(1)$, $b = 16,867(1)$ et $c = 8,4783(9)$ Å, $\beta = 104,912(8)°$ et $Z = 4$. On a résolu les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés jusqu'a des valeurs de $R = 0,037$ et 0,035 ($R_w = 0,035$ et 0,044) pour respectivement 3190 et 2084 reflexions avec $I \geq 3\sigma(F^2)$.

[Traduit par la rédaction]

Introduction

In a previous work (1) we described the synthesis of two *N*-alkylated 2-hydroxylaminoalkanols of type **3**, and the products of their reactions with phenylboronic acid. These products turned out to possess different molecular structures: in one case a bicyclic pyroboronate structure **4**, formed by the incorporation of two phenylboronic acid moieties and a transannular N→B coordinative bond, and in another a monocyclic phenylboronate structure **5** that exists in the solid state as a BONBON dimer of type **8**, in which two chair-form BONCCO rings are joined by a pair of N→B bonds. Both molecular structures, **4** and **8**, have been established by X-ray crystallographic analyses (1). The monomeric BONCCO boronate ring system of type **5** had already been obtained from certain hydroxamic acid derivatives **3** (R = acyl) (2) as well as from the use of the sterically hindered mesitylboronic acid in the condensation reaction with *N*-unsubstituted 2-hydroxyaminoalkanols **3** (R = H) (3). The semiplanar "sofa" conformation adopted by these BONCCO cycloboronates **5** is consistent with that reported for other diol-boronates (cf. refs. 2, 3). In order to produce additional examples of the six-membered BONCCO cycloboronate ring system we synthesized a number of variously substituted *N*-alkyl 2-hydroxyaminoalkanols **3**(*a–p*) by reduction of the nitrones **1** or **2** with KBH_4 or $LiAlH_4$, and reacted them with phenylboronic acid. The crystalline products proved to be 1:2 condensates in a few cases (**4***a–c*) and 1:1 condensates in all the other cases studied (**5***d–p*). The bicyclic structure of **4**, characterized in detail by an X-ray crystallographic study (1), is confirmed by the ^{11}B nmr spectra that display two signals of equal peak area: one near $\delta(Et_2OBF_3) \approx 29$ ppm indicative of a trivalent sp^2 boron, and another near 15 ppm, indicative of the presence of a tetracoordinated sp^3 boron in the compounds **4**.

The 1:1 reaction products give ^1H nmr spectra consistent with the different possible structures **5–9**. From the considerations and findings discussed in our previous work (1) it could be assumed that the constitution **5** and its dimeric form **8**, respectively, are the most probable ones. The ^{11}B nmr spectra of the examples **5***h,i,k,l,m*, and *n* show the expected signals for tricoordinated (sp^2) boron at $\delta(Et_2OBF_3) = 27.5$, 27.3, 27.5, 28.3, 27.6 and 27.9 ppm, respectively, confirming the cycloboronate structure **5**, at least in solution. Dimeric associates of type **8** in the solid state, however, could not be ruled out. The infrared spectra (KBr pellets) corroborate the monomeric character of **5** in the solid state (with the exception of **5***d* and **5***e*, see Experimental) because of the strong ν_{16} phenyl ring stretching vibrations at 1600 cm^{-1} which are normally found in the spectra of trigonal planar phenylboronates (ref. 1, and references therein). An X-ray crystallographic analysis of one of the 1:1 condensation products, **5***l*, has been performed in order to provide unambiguous proof of the cycloboronate structure **5** in the solid state.

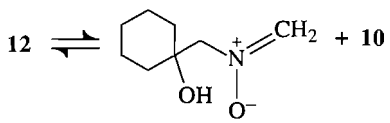
A related structural problem arose from the reaction of arylboronic acids with compounds containing two *N*-alkylhydroxylaminoalkanol groups in a geminal or vicinal arrangement, namely the aminal **12** and the ethylenediamine derivative **13**. The aminal **12** could be prepared as a 2:1 condensation product of the hydroxylamine **10** and formaldehyde.[2] Compound **13** was synthesized by reduction of the glyoxal-bisnitrone **11** with $LiAlH_4$. Both of the tetrahydroxy compounds, **12** and **13**, gave bisarylboronates upon reaction with arylboronic acids. The elemental analyses as well as the infrared, ^1H nmr, and ^{11}B nmr spectra show that all of the four hydroxyl functions in each molecule are involved in the condensation reaction, so that a pyroboronate formation at only one of the "1,3-diol" groupings (**14**), as for type **4** compounds, can be excluded. Thus, structures **15** and **16** seemed very likely, although there are other possibilities of biscycloboronate condensation products as formulated in **17**–**20**. Further support for **15** and **16** comes from the strong ν_{16} phenyl ring stretching bands at 1600 cm^{-1} in the infrared spectra that are typical for non-tetracoordinated phenylboronates (like compound **5** (ref. 1, and references therein)). The EI mass spectra of **15** and **16**, however, give only very small molecular peaks (M^+). Both types of compound display a parent peak of a methyleniminium ion (Fig. 1), indicating an

[2]As shown by ^1H nmr and mass spectrometry, the aminal **12** dissociates easily into a formaldehyde nitrone and the hydroxylamine **10**, in an elimination/addition equilibrium:



This kind of dissociation in solution or gaseous state has been reported for other *N*,*N*′-dihydroxyaminals (4).

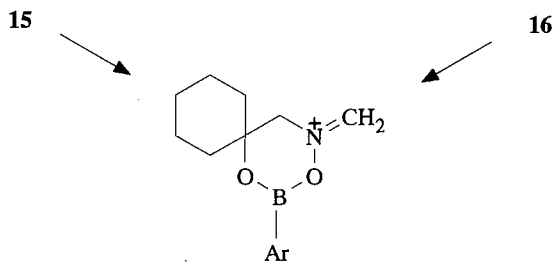

FIG. 1. Mass spectral fragmentation pattern of **15** and **16**.

easy dissociation of a C—N aminal bond in the case of **15**,[3] and of the C—C ethylene bond connecting the two BONCCO rings in **16**. To provide additional structural certainty, especially for the pyroboronate type **15** (with a relatively labile aminal function), an X-ray crystallographic analysis of **15***a*, which formed good crystals as a 1:1 benzene solvate, was carried out.

Experimental

N-*Benzylidene-3-hydroxy-2-methyl-2-butanamine* N-*oxide* (**1**,R^1 = H, $R^2 = R^3 = R^4 = CH_3$, $R^5 = C_6H_5$)

3-Hydroxyamino-3-methyl-2-butanol (5) (0.24 g, 2 mmol) and benzaldehyde (0.21 g, 2 mmol) are reacted as described previously (5). Yield: 0.34 g (82%) of colorless crystals. Mp 67°C (from benzene/petroleum ether), Infrared (KBr): 3220 (O—H), 1585 cm^{-1} (C=N). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.19 (d, J = 7 Hz, O—C—CH_3), 1.54 and 1.61 (s and s, $C(CH_3)_2$), 3.89 (q, J = 7 Hz, O—CH), 4.58 (s, broad, exchangeable, OH), 7.17–7.37 (m, 4 aromatic H and N=CH), 8.05–8.02 (m, 2 aromatic H). Anal. calcd. for $C_{12}H_{17}NO_2$: C 69.54, H 8.27, N 6.76; found: C 69.39, H 8.29, N 6.76.

N-*(2-Hydroxyethylidene)methanamine* N-*oxide* (**2**a, $R = CH_3$, $R^1 = R^2 = H$)

Glycolaldehyde (1.20 g, 20 mmol) and *N*-methylhydroxylamine hydrochloride (1.67 g, 20 mmol) are dissolved in 20 mL of ethanol (96%). A solution of K_2CO_3 (1.38 g, 10 mmol) in 5 mL of water is added under stirring. After 48 h the precipitated KCl is filtered off and the solvent removed in vacuo. The residue is taken up in 50 mL of absolute ethanol, and after filtration the ethanol is distilled off. The remaining oil is not purified further and is used in subsequent reactions as a crude product (see below). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 3.65 (s, NCH_3), 4.15 (s, broad, exchangeable, OH), 4.35 (d, J = 4 Hz, CH_2O), 6.92 (t, J = 4 Hz, N=CH).

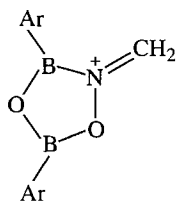
N-*(2-Hydroxyethylidene)cyclohexanamine* N-*oxide* (**2**b, $R = C_6H_{11}$, $R^1 = R^2 = H$)

Glycolaldehyde (0.60 g, 10 mmol) and *N*-cyclohexylhydroxylamine (1.14 g, 10 mmol) are dissolved in 50 mL of absolute ethanol and refluxed for 1 h. After removal of solvent in vacuo, the oily residue is taken up in a small amount of ethanol and ether and stored 24 h at −18°C. Yield: 0.76 g (49%) colorless needles. Mp 127°C (from ethanol/ether). Infrared (KBr): 3280 (O—H), 1615 cm^{-1} (C=N). ^1H nmr (90 MHz, $CDCl_3$): δ (ppm) = 1.03–2.22 (m, $(CH_2)_5$), 3.44–3.84 (m, =N—CH), 4.39 (d, J = 4 Hz, O—CH_2), 4.89 (s, broad, exchangeable, OH), 6.98 (t, J = 4 Hz, N=CH). Anal. calcd. for $C_8H_{15}NO_2$: C 61.12, H 9.62, N 8.91; found: C 61.02, H 9.84, N 8.67.

N-*(2-Hydroxypropylidene)cyclohexanamine* N-*oxide* (**2**c, $R = C_6H_{11}$, $R^1 = H$, $R^2 = CH_3$)

2-Hydroxypropanal (6) (2.22 g, 30 mmol) and *N*-cyclohexylhydroxylamine (3.45 g, 30 mmol) are dissolved in 30 mL of absolute ethanol and stirred at room temperature for 48 h. The solvent is removed in vacuo, and the residue recrystallized from ethanol. Yield: 4.42 g (86%) of colorless needles. Mp 129°C (from absolute ethanol). Infrared (KBr): 3210 (O—H), 1605 cm^{-1} (C=N). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.04–2.02 (m, $(CH_2)_5$), 1.39 (d, J = 7 Hz, O—C—CH_3), 3.64 (m, =N—CH), 4.71 (m, O—CH), 5.61 (s, exchangeable,

[3]The relatively high stability of the methyleniminium cation and the dissociation of the aminal **15** is reminiscent of the dissociation pattern of the corresponding *N,N'*-dihydroxyaminals **12** (see footnote 2) and also the mass spectral fragments of aminal-derived pyroboronates (4):



OH), 6.85 (d, J = 5 Hz, N=CH). Anal. calcd. for $C_9H_{17}NO_2$: C 63.13, H 10.01, N 8.18; found: C 63.09, H 10.15, N 7.97.

N-*(2-Hydroxyethylidene)phenylmethanamine* N-*oxide* (**2**d, R = $CH_2C_6H_5$, $R^1 = R^2 = H$)

Glycolaldehyde (1.20 g, 20 mmol) and *N*-benzylhydroxylamine hydrochloride (1.38 g, 10 mmol) are reacted as described for **2***a*, and the remaining residue is recrystallized from absolute ethanol and ether. Yield: 2.30 g (70%) of colorless platelets. Mp 82–84°C (from ethanol/ether). Infrared (KBr): 3300, 3170 (broad, O—H), 1610 cm^{-1} (C=N). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 4.15 (s, very broad, exchangeable, OH), 4.35 (d, J = 5 Hz, O—CH_2), 4.83 (s, N—CH_2), 6.88 (t, J = 5 Hz, N=CH), 7.37 (s, 5 aromatic H). Anal. calcd. for $C_9H_{11}NO_2$: C 65.44, H 6.71, N 8.48; found: C 65.41, H 6.71, N 8.57.

N-*(2-Hydroxypropylidene)diphenylmethanamine* N-*oxide* (**2**e, R = $CH(C_6H_5)_2$, $R^1 = H$, $R^2 = CH_3$)

2-Hydroxypropanal (1.48 g, 20 mmol) and *N*-benzhydrylhydroxylamine (7) (3.98 g, 20 mmol) are reacted as described for **2***c*. Yield: 4.21 g (82%) of colorless crystals. Mp 110–111°C (from ethanol/ether). Infrared (KBr): 3290 (O—H), 1590 cm^{-1} (C=N). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.34 (d, J = 7 Hz, CH_3), 4.71 (m, O—CH), 5.47 (s, broad, exchangeable, 2 OH), 6.15 (s, N—CH), 6.82 (d, J = 5 Hz, N=CH), 7.32 (s, 10 aromatic H). Anal. calcd. for $C_{16}H_{17}NO_2$: C 75.27, H 6.71, N 5.49; found: C 75.47, H 6.71, N 5.64.

*1-(*N-*Cyclohexyl*-N-*hydroxyamino)-2-propanol* (**3**a)

To a solution of **2***c* (1.71 g, 10 mmol) in 60 mL of methanol a solution of KBH_4 (1.08 g, 20 mmol) in 15 mL of water is added dropwise over a period of 30 min. After 24 h the excess KBH_4 is decomposed with tartaric acid, the methanol distilled off in vacuo, and the remaining aqueous solution brought to pH 9–10 using aqueous Na_2CO_3, solution. After extraction with 3 × 70 mL of dichloromethane, the collected dichloromethane solutions are dried with $MgSO_4$ and evaporated in vacuo. The residue is crystallized from benzene/petroleum ether. Yield: 1.56 g (90%). Mp 79°C. Infrared (KBr): 3250 cm^{-1} (O—H). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.03–2.17 (m, —$(CH_2)_5$—), 1.18 (d, J = 7 Hz, CH_3), 2.62 (m, N—CH_2C and N—CH(C,C)), 4.05 (m, O—CH), 5.28 (s, broad, exchangeable, OH). Anal. calcd. for $C_9H_{19}NO_2$: C 62.39, H 11.05, N 8.08; found: C 62.36, H 11.18, N 7.96.

*2-(*N-*Benzyl*-N-*hydroxyamino)ethanol(***3**b)

2*d* (0.66 g, 4 mmol) and KBH_4 (0.54 g, 10 mmol) are reacted as described for **3***a* (see above). The oily residue is not purified further and is used as crude product in subsequent reactions. ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 2.75 (t, J = 5 Hz, N—CH_2CO), 3.62 (t, J = 5 Hz, O—CH_2), 3.69 (s, N—CH_2(Ph)), 4.40 (s, very broad, exchangeable, 2 OH), 7.17 (s, 5 aromatic H).

*2-(*N-*Benzyl*-N-*hydroxyamino)-1-propanol* (**3**c)

N-Benzylidene-1-hydroxy-2-propanamine *N*-oxide (**1**, $R^1 = R^2 = R^3 = H$, $R^4 = CH_3$, $R^5 = C_6H_5$) (5) (2.15 g, 12 mmol) and KBH_4 (3.24 g, 60 mmol) are reacted as described for **3***a*. The oily residue is analytically pure. Yield: 2.05 g (94%) of a colorless oil. Infrared (film): 3100–3600 cm^{-1} (broad, O—H). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.05 (d, J = 6 Hz, CH_3), 2.91 (m, J = 6 Hz, O—CH), 3.49 (d, J = 6 Hz, CH_2CO), 3.65 and 3.96 (d and d, J = 12 Hz, N—CH_2 (Ph)), 4.53 (s, very broad, exchangeable, 2 OH), 7.30 (s, 5 aromatic H). Anal. calcd. for $C_{10}H_{15}NO_2$: C 66.27, H 8.34, N 7.73; found: C 66.34, H 8.19, N 7.43.

*2-(*N-*Hydroxy*-N-*methylamino)ethanol* (**3**d)

2*a* (crude product, 0.9 g, 10 mmol) and KBH_4) (1.08 g, 20 mmol) are reacted as described for **3***a*. The oily residue is not further purified and is used as crude product in subsequent reactions. ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 2.4 (m_c, N—CH_3 and N—CH_2C), 3.5 (m_c, O—CH_2 and 2 OH).

*1-(*N-*Hydroxy*-N-*methylaminomethyl)cyclohexanol* (**3**e)

3-Hydroxy-5,5-pentamethylene-1,3-oxazolidine[4] (9) (1.57 g, 10 mmol) and KBH_4 (1.08 g, 20 mmol) are reacted as described for **3***a*. The oily residue is used as crude product in further reactions.

*1-(*N-*Ethyl*-N-*hydroxyaminomethyl)cyclohexanol* (**3**f)

N-Ethylidene-(1-hydroxycyclohexyl)methanamine *N*-oxide (**1**, $R^1 + R^2$ = —$(CH_2)_5$—, $R^3 = R^4 = H$, $R^5 = CH_3$) (8) (1.71 g, 10 mmol) and KBH_4 (1.08 g, 20 mmol) are reacted as described for **3***a*. The oily residue is used as crude product in further reactions.

*2-(*N-*Cyclohexyl*-N-*hydroxyamino)ethanol* (**3**g)

2*b* (3.14 g, 20 mmol) and $LiAlH_4$ (0.76, 20 mmol) are suspended in 150 mL of dry ether. After refluxing for 5 h, hydrolysis is carried out with water under cooling with ice, and subsequent acidification with 6N HCl. The mixture is neutralized with $NaHCO_3$, the ether layer separated, and the aqueous phase extracted with an additional 3 × 40 mL of ether. The combined ether solutions are dried over Na_2SO_4 and evaporated in vacuo. The reside is crystallized from benzene/petroleum ether. Yield: 2.04 g (65%) of colorless crystals. Mp 60–62°C. Infrared (KBr): 3500–2600 cm^{-1} (broad, O—H). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 0.71–2.17 (m, —$(CH_2)_5$—), 2.32–2.70 (m, N—CH(C,C)), 2.87 (t, J = 5 Hz, N—CH_2), 3.79 (t, J = 5 Hz, O—CH_2), 6.11 (s, exchangeable, 2 OH). Anal. calcd. for $C_8H_{17}NO_2$: C 60.35, H 10.76, N 8.80; found: C 60.52, H 11.17, N 8.60.

*1-(*N-*Cyclohexylmethyl*-N-*hydroxyaminomethyl)cyclohexanol* (**3**h)

N-Cyclohexylmethylene-(1-hydroxycyclohexyl)methanamine *N*-oxide (**1**, $R^1 + R^2$ = —$(CH_2)_5$—, $R^3 = R^4 = H$, $R^5 = C_6H_{11}$) (8) (1.20 g, 5 mmol) and KBH_4 (0.54 g, 10 mmol) are reacted as described for **3***a*. The residue is crystallized from absolute ethanol. Yield: 0.91 g (75%) of colorless crystals. Mp 74°C. Infrared (KBr): 3410, 3250 cm^{-1} (O—H). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 0.66–1.98 (m, —$(CH_2)_5$— and C_6H_{11}), 2.52 (d, J = 6 Hz, N—$CH_2C_6H_{11}$), 2.71 (s, N—CH_2CO), 3.31 and 5.70 (s and s, broad, exchangeable, 2 OH). Anal. calcd. for $C_{14}H_{27}NO_2$: C 69.67, H 11.28, N 5.80; found: C 69.67, H 11.35, N 5.71.

*2-(*N-*Benzyl*-N-*hydroxyamino)-2-methylpropanol* (**3**i)

N-Benzylidene-1-hydroxy-2-methyl-2-propanamine *N*-oxide (**1**, $R^1 = R^2 = H$, $R^3 = R^4 = CH_3$, $R^5 = C_6H_5$) (5) (0.97 g, 5 mmol) and KBH_4 (1.08 g, 20 mmol) are reacted as described for **3***a*. The residue is crystallized from benzene/petroleum ether. Yield: 0.90 g (92%) of colorless crystals. Mp 107°C. Infrared (KBr): 3460, 3360 cm^{-1} (O—H). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.12 (s, 2 CH_3), 3.12 (s, very broad, exchangeable, OH), 3.38 (s, OCH_2) 3.70 (s, NCH_2), 4.88 (s, very broad, exchangeable, OH), 7.26 (s, 5 aromatic H). Anal. calcd. for $C_{11}H_{17}NO_2$: C 67.66, H 8.78, N 7.17; found: C 67.72, H 8.82, N 6.97.

*3-(*N-*Benzyl*-N-*hydroxyamino)-3-methyl-2-butanol* (**3**j)

N-Benzylidene-3-hydroxy-2-methyl-2-butanamine *N*-oxide (**1**, $R^1 = H$, $R^2 = R^3 = R^4 = CH_3$, $R^5 = C_6H_5$) (this work, see above) (1.04 g, 5 mmol) and KBH_4 (1.08 g, 20 mmol) are reacted as described for **3***a*. The residue is crystallized from benzene/petroleum ether. Yield: 0.72 g (69%) of colorless crystals. Mp 86°C. Infrared (KBr): 3460, 3360 cm^{-1} (O—H). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.09 (s, 2 CH_3), 1.10 (d, J = 6 Hz, $OCCH_3$), 3.37 (s, very broad, exchangeable, OH), 3.78 (q, J = 6 Hz, OCH), 3.79 (s, NCH_2), 5.10 (s, very broad, exchangeable, OH) 7.30 (s, 5, aromatic H). Anal. calcd. for $C_{12}H_{19}NO_2$: C 68.87, H 9.15, N 6.69; found: C 68.90, H 9.17, N 6.55.

*1-(*N-*Benzyl*-N-*hydroxyaminomethyl)cyclohexanol* (**3**k)

N-Benzylidene-(1-hydroxycyclohexyl)methanamine *N*-oxide (**1**, $R^1 + R^2$ = —$(CH_2)_5$—, $R^3 = R^4 = H$, $R^5 = C_6H_5$) (5) (1.16 g, 5 mmol)

[4]This is the ring tautomer of *N*-methylene-(1-hydroxycyclohexyl)-methanamine *N*-oxide (**1**, $R^1 + R^2$ = —$(CH_2)_5$—, $R^3 = R^4 = R^5 = H$). The ring/chain tautomerism of other aliphatic aldonitrones of this type has already been reported (8).

and KBH_4 (0.54 g, 10 mmol) are reacted as described for **3***a*. The residue is crystallized from benzene/petroleum ether. Yield: 0.76 g (66%) of colorless platelets. Mp 85–86°C. Infrared (KBr): 3470, 3210 cm^{-1} (O—H). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.03–1.88 (m, —$(CH_2)_5$—), 2.71 (s, NCH_2CO), 3.40 (s, broad, exchangeable, OH), 3.82 (s, $NCH_2C_6H_5$), 6.02 (s, broad, exchangeable, OH), 7.11–7.40 (m, 5 aromatic H). Anal. calcd. for $C_{14}H_{21}NO_2$: C 71.45, H 8.99, N 5.95; found: C 71.40, H 9.15, N 5.74.

*1-[*N*-(4-Chlorophenylmethyl)-*N*-hydroxyaminomethyl]cyclohexanol (**3**l)*

N - (4 - Chlorophenylmethylene) - (1 - hydroxycyclohexyl)methanamine *N*-oxide (**1**, $R^1 + R^2$ = —$(CH_2)_5$—, $R^3 = R^4$ = H, R^5 = 4-ClC_6H_4) (5) (1.34 g, 5 mmol) and KBH_4 (0.54 g, 10 mmol) are reacted as described for **3***a*. The residue is crystallized from benzene. Yield: 1.00 g (74%) of colorless small needles. Mp 113°C. Infrared (KBr): 3390, 3180 cm^{-1} (O—H). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.07–1.83 (m, —$(CH_2)_5$—), 2.17 (s, NCH_2CO), 3.04 (s, broad, exchangeable, OH), 3.78 (s, $CH_2C_6H_4Cl$), 5.64 (s, very broad, exchangeable, OH), 7.21 (s, 4 aromatic H). Anal. calcd. for $C_{14}H_{20}ClNO_2$: C 62.33, H 7.47, N 5.19; found: C 62.17, H 7.49, N 5.00.

*2-[*N*-Hydroxy-N-(4-nitrophenylmethyl)amino]-2-methylpropanol (**3**m)*

1-Hydroxy-2-methyl-*N*-(4-nitrophenylmethylene)-2-propanamine *N*-oxide (**1**, $R^1 = R^2$ = H, $R^3 = R^4 = CH_3$, R^5 = 4-$NO_2C_6H_4$) (5) (2.38 g, 10 mmol) and KBH_4 (1.08 g, 20 mmol) are reacted as described for **3***a*. The residue is crystallized from benzene. Yield: 1.17 g (49%) of yellowish crystals. Mp 113–114°C. Infrared (KBr): 3600–3200 (broad, O—H), 1525 cm^{-1} (NO_2). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.12 (s, 2 CH_3), 2.70 (s, broad, exchangeable, OH), 3.43 (s, NCH_2), 3.83 (s, OCH_2), 5.30 (s, broad, exchangeable, OH), 7.45 and 8.07 (d and d, *J* = 8 Hz, AA′BB′ system, 4 aromatic H). Anal. calcd. for $C_{11}H_{16}N_2O_4$: C 54.99, H 6.71, N 11.66; found: C 55.58, H 6.87, N 11.36.

*1-[*N*-Hydroxy-N-(4-nitrophenylmethyl)aminomethyl]cyclohexanol (**3**n)*

(1-Hydroxycyclohexyl)-*N*-(4-nitrophenylmethylene)methanamine *N*-oxide (**1**, $R^1 + R^2$ = —$(CH_2)_5$—, $R^3 = R^4 = CH_3$, R^5 = 4-$NO_2C_6H_4$) (5) (1.39 g, 5 mmol) and KBH_4 (1.08 g, 20 mmol) are reacted as described for **3***a*. The residue is crystallized from benzene. Yield: 1.13 g (81%) of yellow needles. Mp 125–126°C. Infrared (KBr): 3380, 3140 (O—H), 1510 cm^{-1} (NO_2). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.08–1.86 (m, —$(CH_2)_5$—), 2.81 (s, NCH_2CO), 2.96 (s, broad, exchangeable, OH), 3.95 (s, $NCH_2C_6H_4NO_2$), 5.83 (s, broad, exchangeable, OH), 7.51 and 8.14 (d and d, *J* = 8 Hz, AA′BB′ system, 4 aromatic H). Anal. calcd. for $C_{14}H_{20}N_2O_4$: C 59.99, H 7.19, N 9.99; found: C 60.01, H 7.29, N 9.87.

*1-[*N*-(4-Dimethylaminophenylmethyl)-N-hydroxyaminomethyl]cyclohexanol (**3**o)*

N-(4-Dimethylaminophenylmethylene)-(1-hydroxycyclohexyl)methanamine N-oxide (**1**, $R^1 + R^2$ = —$(CH_2)_5$—, $R^3 = R^4 = CH_3$, R^5 = 4-$(CH_3)_2NC_6H_4$) (5) (1.38 g, 5 mmol) and KBH_4 (1.62 g, 30 mmol) are reacted as described for **3***a*. The residue is crystallized from benzene/petroleum ether. Yield: 0.75 g (54%) of colorless crystals. Mp 69–70°C. Infrared (KBr): 3370, 3250 cm^{-1} (O—H). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.19–1.77 (m, —$(CH_2)_5$—), 2.72 (s, NCH_2CO), 2.94 (s, $N(CH_3)_2$), 3.75 (s, $NCH_2C_6H_4N(CH_3)_2$), 6.67 and 7.17 (d and d, *J* = 9 Hz, AA′BB′ system, 4 aromatic H); OH signals not observed.

*1-(*N*-Benzhydryl-N-hydroxyamino)-2-propanol (**3**p)*

2*e* (1.53 g, 6 mmol) and KBH_4 (0.65 g, 12 mmol) are reacted as described for **3***a*. The residue is crystallized from benzene. Yield: 1.35 g (87%) of colorless crystals. Mp 137–138°C. Infrared (KBr): 3430, 3300 cm^{-1} (O—H). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.09 (d, *J* = 6 Hz, CH_3), 2.62 (d, *J* = 5 Hz, NCH_2), 3.14 (s, broad, exchangeable, OH), 4.07 (m, OCH), 4.37 (s, $NCHPh_2$), 5.26 (s, broad, exchangeable, OH), 7.08–7.51 (m, 10 aromatic H). Anal. calcd. for $C_{16}H_{19}NO_2$: C 74.68, H 7.44, N 5.44; found: C 74.70, H 7.44, N 5.45.

*1-Cyclohexyl-7-methyl-3,5-diphenyl-2,4,6-trioxa-1-azonia-3-bora-5-boratabicyclo[3.3.0]octane (**4**a)*

3*a* (0.51 g, 3 mmol) and phenylboronic acid 0.73 g, 6 mmol) are dissolved in 20–30 mL of benzene and refluxed for 1 h with continuous removal of water using a Dean Stark trap. After evaporation in vacuo the residue is crystallized from benzene/petroleum ether. Yield: 0.85 g (78%) of colorless needles. Mp 130°C. Infrared (KBr): 1605 cm^{-1} (phenyl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 0.74–2.10 (m, —$(CH_2)_5$—), 1.42 (d, *J* = 6 Hz, CH_3), 2.67 (m, NCH and 1 H of NCH_2), 3.32 and 3.45 (d and d, 1 H of NCH_2), 4.27 (m, OCH), 7.18–7.53 (m, 6 aromatic H), 7.57–7.77 (m, 2 aromatic H), 7.81–8.01 (m, 2 aromatic H). ^{11}B nmr (64.2 MHz, $CDCl_3/Et_2OBF_3$): δ (ppm) = 29.2 ($w_{1/2}$ = 640 Hz) and 14.5 ($w_{1/2}$ = 300 Hz); ratio of peak areas: 1:1. Anal. calcd. for $C_{21}H_{27}B_2NO_3$: C 69.47, H 7.50, B 5.96, N 3.86; found: C 69.36, H 7.50, B 6.19, N 4.01.

*1-Benzyl-3,5-diphenyl-2,4,6-trioxa-1-azonia-3-bora-5-boratabicyclo[3.30]octane (**4**b)*

3*b* (crude product, 0.50 g, 3 mmol) and phenylboronic acid (0.73 g, 6 mmol) are reacted as described for **4***a*. Yield: 0.91 g (85%) of colorless crystals. Mp 128–129°C (from benzene/petroleum ether). Infrared (KBr): 1600 cm^{-1} (phenyl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 3.04 (m, NCH_2CO), 3.44 and 3.94 (d and d, *J* = 15 Hz, AB system, NCH_2Ph), 4.07 (m, OCH_2), 7.17–7.53 (m, 11 aromatic H), 7.61 – 7.78 (m, 2 aromatic H), 7.80–7.98 (m, 2 aromatic H). ^{11}B nmr (64.2 MHz, $CDCl_3/Et_2OBF_3$): δ (ppm) = 29.2 ($w_{1/2}$ = 640 Hz) and 14.7 ($w_{1/2}$ = 340 Hz); ratio of peak areas: 1:1. Anal. calcd. for $C_{21}H_{21}B_2NO_3$: C 70.65, H 5.93, N 3.92; found: C 70.64, H 5.94, N 3.94.

*1-Benzyl-8-methyl-3,5-diphenyl-2,4,6-trioxa-1-azonia-3-bora-5-boratabicyclo[3.3.0] octane (**4**c)*

3*c* (0.72 g, 4 mmol) and phenylboronic acid (0.98 g, 8 mmol) are reacted as described for **4***a*. Yield: 1.18 g (80%) of colorless crystals. Mp 126°C (from benzene/petroleum ether). Infrared (KBr): 1600 cm^{-1} (phenyl C=C). ^1H nmr (90 MHz), $CDCl_3$/TMS): δ (ppm) = 0.68 (d, *J* = 6 Hz, CH_3), 3.16–4.15 (m, CH_2CHN), 3.54 and 3.88 (d and d, *J* = 14 Hz, AB system, NCH_2Ph), 7.11–7.50 (m, 11 aromatic H), 7.56–7.72 (m, 2 aromatic H), 7.81–8.00 (m, 2 aromatic H). ^{11}B nmr (64.2 MHz, $CDCl_3/Et_2OBF_3$): δ (ppm) = 28.6 ($w_{1/2}$ = 640 Hz) and 15.1 ($w_{1/2}$ = 340 Hz); ratio of peak areas: 1:1. Anal. calcd. for $C_{22}H_{23}B_2NO_3$: C 71.21, H 6.25, N 3.78; found: C 71.23, H 6.25, N 3.85.

*4-Methyl-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (**5**d)*[5]

3*d* (0.27 g, 3 mmol) and phenylboronic acid (0.37 g, 3 mmol) are reacted as described for **4***a*. The residue was crystallized from absolute ethanol. Yield: 0.25 g (47%) of colorless thin needles. Mp 126°C. ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 2.87 (s, CH_3), 3.00 (t, *J* = 4 Hz, NCH_2C), 4.24 (t, *J* = 4 Hz, OCH_2), 7.15–7.40 (m, 3 aromatic H), 7.57–7.77 (m, 2 aromatic H). Anal. calcd. for $C_9H_{12}BNO_2$: C 61.07, H 6.83, N 7.91; found: C 61.06, H 6.93, N 7.80.

*4-Methyl-6,6-pentamethylene-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (**5**e)*

3*e* (0.48 g, 3 mmol) and phenylboronic acid (0.37 g, 3 mmol) are reacted as described for **4***a*. Yield: 0.57 g (78%) of colorless oil, the crystallization of which could not be induced. Infrared (film): 1600

[5]The solid state infrared spectrum (KBr pellet) of **5***d*, which lacks the ν_{16} band, and the X-ray crystallographic analysis of a homologous compound that has a comparable infrared spectrum (1) suggest that **5***d* should also exist as a dimer of the type **8** in the crystalline state and should be named: *1,6-dimethyl-2,7-diphenyl-3,8,11,12-tetraoxa-1,6-diazonia-2,7-diboratatricyclo[5.3.1.1^{2,6}]dodecane.*

cm^{-1} (phenyl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.17–2.05 (m, —$(CH_2)_5$—), 2.74 (s, CH_3), 2.78 (s, NCH_2CO), 7.03–7.32 (m, 3 aromatic H), 7.50–7.73 (m, 2 aromatic H). Anal. calcd. for $C_{14}H_{20}BNO_2$: C 68.60, H 8.22, N 5.71; found: C 68.86, H 8.25, N 5.38.

*4-Ethyl-6,6-pentamethylene-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (5*f)

3*f* (0.52 g, 3 mmol) and phenylboronic acid (0.37 g, 3 mmol) are reacted as described for **4***a*. The residue was crystallized from absolute ethanol. Yield: 0.49 g (63%) of colorless crystals. Mp 36°C. Infrared (KBr): 1600 cm^{-1} (phenyl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.10–2.02 (m, —$(CH_2)_5$—), 1.27 (t, J = 7 Hz, CH_3), 2.78 (s, NCH_2CO), 2.89 (q, J = Hz, NCH_2CH_3), 7.13–7.38 (m, 3 aromatic H), 7.63–7.81 (m, 2 aromatic H). Anal. calcd. for $C_{15}H_{22}BNO_2$: C 69.52, H 8.56, B 4.17, N 5.40; found: C 69.49, H 8.60, B 4.16, N 5.31.

*4-Cyclohexyl-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (5*g)

3*g* (0.80 g, 5 mmol) and phenylboronic acid (0.61 g, 5 mmol) are reacted as described for **4***a*. The residue was crystallized from absolute ethanol. Yield: 0.82 g (67%) of colorless crystals. Mp 73°C. Infrared (KBr): 1605 cm^{-1} (phenyl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 0.92–2.32 (m, —$(CH_2)_5$—), 2.45–2.82 (m, NCH(C,C)), 3.02 (t, J = 4 Hz, NCH_2), 4.13 (t, J = 4 Hz, OCH_2), 7.10–7.38 (m, 3 aromatic H), 7.57–7.71 (m, 2 aromatic H). Anal. calcd. for $C_{14}H_{20}BNO_2$: C 68.60, H 8.22, N 5.71; found: C 68.63, H 8.37, N 5.78.

*4-Cyclohexylmethyl-6,6-pentamethylene-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (5*h)

3*h* (0.72 g, 3 mmol) and phenylboronic acid (0.37 g, 3 mmol) are reacted as described for **4***a*. The residue was crystallized from absolute ethanol. Yield: 0.69 g (70%) of colorless crystals. Mp 81°C. Infrared (KBr): 1600 cm^{-1} (phenyl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 0.79–2.03 (m, C_6H_{11} and —$(CH_2)_5$—), 2.63 (d, J = 7 Hz, $NCH_2C_6H_{11}$), 2.75 (s, NCH_2CO), 7.17–7.37 (m, 3 aromatic H), 7.60–7.81 (m, 2 aromatic H). ^{11}B nmr (64.2 MHz, $CDCl_3/Et_2OBF_3$): δ (ppm) = 27.5 ($w_{1/2}$ = 420 Hz). Anal. calcd. for $C_{20}H_{30}BNO_2$: C 73.40, H 9.24, N 4.28; found: C 73.45, H 9.31, N 4.49.

*4-Benzyl-5,5-dimethyl-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (5*i)

3*i* (0.20 g, 1 mmol) and phenylboronic acid (0.12 g, 1 mmol) are reacted as described for **4***a*. The residue was crystallized from absolute ethanol. Yield: 0.20 g (71%) of colorless platelets. Mp 86–87°C. Infrared (KBr): 1600 cm^{-1} (phenyl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.26 (s, 2 CH_3), 3.88 (s, NCH_2CH_2O), 7.19–7.45 (m, 8 aromatic H), 7.53–7.71 (m, 2 aromatic H). ^{11}B nmr (64.2 MHz, $CDCl_3/Et_2OBF_3$): δ (ppm) = 27.5 ($w_{1/2}$ = 360 Hz). Anal. calcd. for $C_{17}H_{20}BNO_2$: C 72.62, H 7.17, N 4.98; found: C 72.61, H 7.21, N 4.99.

*4-Benzyl-5,5,6-trimethyl-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (5*j)

3*j* (0.21 g, 1 mmol) and phenylboronic acid (0.12 g, 1 mmol) are reacted as described for **4***a*. The residue was crystallized from absolute ethanol. Yield: 0.25 g (85%) of colorless crystals. Mp 97°C. Infrared (KBr): 1600 cm^{-1} (phenyl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.15 and 1.25 (s and s, $C(CH_3)_2$), 1.36 (d, J = 6 Hz, CH_3CO), 3.92 (s, NCH_2), 4.11 (q, J = 6 Hz, OCH), 7.13–7.46 (m, 8 aromatic H), 7.52–7.72 (m, 2 aromatic H). Anal. calcd. for $C_{18}H_{22}BNO_2$: C 73.24, H 7.51, N 4.75; found: C 73.30, H 7.51, N 4.80.

*4-Benzyl-6,6-pentamethylene-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (5*k)

3*k* (0.54 g, 2 mmol) and phenylboronic acid (0.24 g, 2 mmol) are reacted as described for **4***a*. The residue was crystallized from benzene/petroleum ether. Yield: 0.59 g (92%) of colorless crystals. Mp 76–78°C. Infrared (KBr): 1600 cm^{-1} (phenyl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.01–2.04 (m, —$(CH_2)_5$—), 2.78 (s, NCH_2CO), 4.04 (s, NCH_2Ph), 7.12–7.47 (m, 8 aromatic H), 7.62–7.81 (m, 2 aromatic H). ^{11}B nmr (64.2 MHz, $CDCl_3/Et_2OBF_3$): δ (ppm) = 27.5 ($w_{1/2}$ = 380 Hz). Anal. calcd. for $C_{20}H_{24}BNO_2$: C 74.78, H 7.53, N 4.26; found: C 74.75, H 7.61, N 4.26.

*4-(4-Chlorophenylmethyl)-6,6-pentamethylene-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (5*l)

3*l* (0.27 g, 1 mmol) and phenylboronic acid (0.12 g, 1 mmol) are reacted as described for **4***a*. The residue was crystallized from absolute ethanol/ether. Yield: 0.33 g (92%) of colorless crystals. Mp 86°C. Infrared (KBr): 1600 cm^{-1} (phenyl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.04–2.05 (m, —$(CH_2)_5$—), 2.76 (s, NCH_2CO), 4.00 (s, $CH_2C_6H_4Cl$), 7.11–7.38 (m, 7 aromatic H), 7.57–7.78 (m, 2 aromatic H). ^{11}B nmr (64.2 MHz, $CDCl_3/Et_2OBF_3$): δ (ppm) = 28.3 ($w_{1/2}$ = 430 Hz). Anal. calcd. for $C_{20}H_{23}BClNO_2$: C 67.54, H 6.52, B 3.04, Cl 9.97, N 3.94; found: C 67.37, H 6.63, B 3.18, Cl 9.88, N 3.82. Crystals suitable for X-ray analysis were obtained by slow recrystallization from ethanol (99.5%).

*4-(4-Nitrophenylmethyl)-5,5-dimethyl-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (5*m)

3*m* (0.24 g, 1 mmol) and phenylboronic acid (0.12 g, 1 mmol) are reacted as described for **4***a*. The residue was crystallized from absolute ethanol. Yield: 0.26 g (79%) of yellowish crystals. Mp 94°C. Infrared (KBr): 1605, 1600 (aryl C=C), 1515 cm^{-1} (NO_2). ^1H nmr (400 MHz, $CDCl_3$/TMS): δ (ppm) = 1.22 (s, $C(CH_3)_2$), 3.90 (s, OCH_2), 4.01 (s, NCH_2), 7.18–7.40 (m, 3 aromatic H), 7.56–7.61 (m, 2 aromatic H), 7.64 and 8.25 (d, and d, J = 9 Hz, AA′BB′ system, $C_6H_4NO_2$). ^{11}B nmr (64.2 MHz, $CDCl_3/Et_2OBF_3$): δ (ppm) = 27.6 ($w_{1/2}$ = 380 Hz). EI mass spectrum (70 eV): m/z = 326 (58%, M^+), 311 (100%, $M^+ - CH_3$), 240 (5%), 191 (26%), 136 (62%, $CH_2C_6H_4NO_2$), 120 (64%), 106 (16%), 90 (14%), 78 (22%).

*4-(4-Nitrophenylmethyl)-6,6-pentamethylene-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (5*n)

3*n* (0.56 g, 2 mmol) and phenylboronic acid (0.24 g, 2 mmol) are reacted as described for **4***a*. The residue was crystallized from absolute ethanol. Yield: 0.59 g (80%) of yellowish crystals. Mp 116°C. Infrared (KBr): 1605, 1600 (aryl C=C), 1515 cm^{-1} (NO_2). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.21–2.08 (m, —$(CH_2)_5$—), 2.87 (s, NCH_2CO), 4.09 (s, $NCH_2C_6H_4NO_2$), 7.11–7.35 (m, 3 aromatic H), 7.45–7.68 (m, 2 aromatic H), 7.56 and 8.16 (d and d, J = 9 Hz, AA′BB′ system, $C_6H_4NO_2$). ^{11}B nmr (64.2 MHz, $CDCl_3/Et_2OBF_3$): δ (ppm) = 27.9 ($w_{1/2}$ = 390 Hz). Anal. calcd. for $C_{20}H_{23}BN_2O_4$: C 65.59, H 6.33, B 2.95, N 7.65; found: C 65.61, H 6.43, B 3.06, N 7.61.

*4-(4-Dimethylaminophenylmethyl)-6,6-pentamethylene-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (5*o)

3*o* (0.28 g, 1 mmol) and phenylboronic acid (0.12 g, 1 mmol) are reacted as described for **4***a*. The residue was crystallized from absolute ethanol. Yield: 0.30 g (82%) of colorless crystals. Mp 92°C. Infrared (KBr): 1610, 1600 cm^{-1} (aryl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.22–2.01 (m, —$(CH_2)_5$—), 2.75 (s, NCH_2CO), 2.95 (s, $N(CH_3)_2$), 4.01 (s, $NCH_2C_6H_4NMe_2$), 6.69 (d, J = 9 Hz, AA′BB′ system, 2 aromatic H), 7.17–7.42 (m, 5 aromatic H), 7.69–7.86 (m, 2 aromatic H). Anal. calcd. for $C_{22}H_{29}BN_2O_2$: C 72.53, H 8.02, N 7.69; found: C 72.53, H 8.09, N 7.69.

*4-Benzhydryl-6-methyl-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (5*p)

3*p* (0.51 g, 2 mmol) and phenylboronic acid (0.24 g, 2 mmol) are reacted as described for **4***a*. The residue was crystallized from absolute benzene. Yield: 0.51 g (74%) of colorless crystals. Mp 185–186°C. Infrared (KBr): 1600, 1595 cm^{-1} (shoulder, aryl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.30 (d, J = 6 Hz, CH_3), 2.50/2.64 and 3.02/3.15 (d/d and d/d, J = 12/8 Hz, NCH_2), 4.44 (m, OCH), 4.80 (s, $NCHPh_2$), 7.09–7.54 (m, 15 aromatic H). Anal. calcd. for $C_{22}H_{22}BNO_2$: C 76.99, H 6.46, N 4.08; found: C 77.02, H 6.48, N 4.15.

N,N′-*Ethanediylidenebis[1-hydroxycyclohexyl)methylamine]* N,N′-*dioxide (11)*

1-(*N*-Hydroxyaminomethyl)cyclohexanol **10** (5) (1.45 g, 10 mmol)

For personal use only.

and glyoxal monohydrate (0.38 g, 5 mmol) are dissolved in 20 mL of ethanol. After 1 day at room temperature the solution is partially evaporated in vacuo and cooled down for crystallization which is complete after a few days. Yield: 1.56 g (100%) of colorless crystals. Mp 188–189°C. Infrared (KBr): 3370 (O—H), 1530 cm^{-1} (C—N). ^1H nmr (60 MHz, d_6-DMSO/TMS): δ (ppm) = 1.40 (m_c, 2 —$(CH_2)_5$—), 3.86 (s, 2 NCH_2), 4.70 (s, exchangeable, 2 OH), 7.80 (s, N=CH). EI mass spectrum (70 eV, 240°C): *m/z* = 312 (3%, M^+), 197 (38%), 156 (19%), 140 (16%), 99 (100% $C_6H_{11}O$), 95 (41%) 81 (63%). Anal. calcd. for $C_{16}H_{28}N_2O_4$: C 61.51, H 9.03, N 8.96; found: C 61.19, H 9.02, N 8.93.

N,N′-*Dihydroxy*-N,N′-*bis(1-hydroxycyclohexylmethyl)methanediamine (**12**)*

1-*N*-Hydroxyaminomethyl)cyclohexanol **10** (5) (0.28 g, 2 mmol) and formaldehyde (0.1 g 35% aqueous solution, 1 mmol) are dissolved in 20 mL ethanol and stored at room temperature for 1 day. After evaporation in vacuo the residue is crystallized from benzene. Yield: 0.28 g (93%) of colorless crystals. Mp 104–105C. ^1H nmr (100 MHz, $CDCl_3$/TMS)[6]: δ (ppm) = 1.2–2.9 (m, 2 —$(CH_2)_5$—), 2.75 (s, 44% of NCH_2CO of **12**), 2.94 (s, 56% of NCH_2 of **10**), 3.63 (s, 44% of NCH_2N of **12**), 3.76 (s, 56% of NCH_2CO of the formaldehyde nitrone of **10**; cf. footnote 2), 4.3–4.9 (m, broad, exchangeable, 4 OH), 6.41 (q, AB system, 56% of N=CH_2 of the formaldehyde nitrone of **10**). EI mass spectrum (70 eV, 120C): *m/z* = 157 (100%, H_2C=N(O)CH_2C(OH)$(CH_2)_5$=formaldehyde nitrone of **10**), 140 (41%), 139 (55%), 127 (67%), 114 (39%), 112 (49%), 99 (73%, $C_6H_{11}O$), 95 (82%), 81 (95%). Molecular mass (cryoscopic determination in $CHCl_3$): 157 (formaldehyde nitrone of **10**, see footnote 2). Anal. calcd. for $C_{15}H_{30}N_2O_4$: C 59.57, H 9.99, N 9.26; found: C 59.17, H 9.90, N 9.10. Determination of the formaldehyde content (gravimetrically with dimedone (10)), after hydrolysis: calcd. for **12**: 10%; found: 12%.

N,N′-*Dihydroxy*-N,N′-*bis(1-hydroxycyclohexylmethyl)-1,2-ethanediamine (**13**)*

11 (3.12 g, 10 mmol) and $LiAlH_4$ (0.76 g, 20 mmol) are suspended in 100 mL of dry ether and refluxed for 6 h. After 24 h stirring at room temperature the reaction mixture is hydrolyzed with water and ice-cooling, and subsequently mixed with 6N HCl until the $Al(OH)_3$ precipitate redissolves. The mixture is brought to pH 7–8 using $NaHCO_3$ and the solid product that forms in the layer between the two phases is separated. The ether phase is dried over Na_2SO_4 and evaporated in vacuo. The residue is combined with the previously separated product. Yield: 1.77 g (56%) of colorless crystals. Mp 153°C (from absolute ethanol). Infrared (KBr): 3460, 3160 cm^{-1} (O—H). ^1H nmr (90 MHz, d_6-DMSO/TMS): δ (ppm) = 1.50 (m, 2 —$(CH_2)_5$—), 2.60 (s, 2, NCH_2CO), 2.81 (s, NCH_2CH_2N), 3.89 (s, exchangeable, 2 OH), 7.77 (s, exchangeable, 2 OH). Anal. calcd. for $C_{16}H_{32}N_2O_4$: C 60.73, H 10.19, N 8.85; found: C 60.47, H 10.39, N 8.61.

*4,4′-Methylenebis(6,6-pentamethylene-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane) (**15**a)*

12 (0.60 g, 2 mmol) and phenylboronic acid (0.49 g, 4 mmol) are dissolved in 20 mL of benzene and refluxed for 1 h with continuous removal of water using a Dean-Stark trap. The solvent is partially (about 1/2 of the volume) distilled off, and after the addition of petroleum ether the solution is stored at −18°C. The crystallization (after a few days) yields 0.52 g (55%) of colorless crystals which are recrystallized from ethanol. Mp 78–81°C. Infrared (KBr): 1600 cm^{-1} (phenyl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.14–2.04 (m, 2 —$(CH_2)_5$—), 3.12 (s, 2 NCH_2CO), 4.17 (s, NCH_2N), 7.18–7.42 (m, 6 aromatic H), 7.62–7.81 (m, 4 aromatic H). ^{11}B nmr (64.2 MHz, $CDCl_3$/Et_2OBF_3): δ (ppm) = 27.5 ($w_{1/2}$ = 640 Hz). EI mass spectrum (70 eV, 150°C); *m/z* = 474 (0.7%, M^+), 244 (100%, M^+ − PhB[$ONCH_2C(CH_2)_5O$]) 140 (2%), 105 (3%, PhBOH), 95 (6%), 81 (3%). Anal. calcd. for $C_{27}H_{36}B_2N_2O_4$: C 68.39, H 7.65, N 5.91; found: C 68.50, H 7.74, N 6.04

Crystals suitable for X-ray analysis were obtained by recrystallization from benzene/petroleum ether, and contain 1 mol of benzene. Mp 55–56°C. The ^1H nmr spectrum of **15***a*·C_6H_6 in $CDCl_3$ (TMS) shows an additional signal: δ (ppm) = 7.31 (s, 6 aromatic H). Anal. calcd. for $C_{27}H_{36}B_2N_2O_4$+C_6H_6: C 71.76, H 7.67, B 3.91, N 5.07; found: C 71.47, H 7.78, B 3.83, N 4.99.

*4,4′-Methylenebis[2-(4-methoxyphenyl)-6,6-pentamethylene-1,3-dioxa-4-aza-2-boracyclohexane] (**15**b)*

12 (0.30 g, 1 mmol) and 4-methoxyphenylboronic acid (0.30 g, 2 mmol) are reacted as described for **15***a*. Yield: 0.45 g (84%) of colorless crystals. Mp 134–135°C (from benzene/petroleum ether). Infrared (KBr): 1600 cm^{-1} (slightly broadened, aryl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.15–2.03 (m, 2 —$(CH_2)_5$—), 3.10 (s, 2 NCH_2CO), 3.78 (s, 2 OCH_3), 4.15 (s, NCH_2N), 6.82 and 7.65 (d, and d, *J* = 8 Hz, AA′BB′ system, 8 aromatic H), EI mass spectrum (70 eV, 125°C): *m/z* = 534 (0.2%, M^+), 274 (100%, M^+ − 4-$MeOC_6H_4$-$BOCH_2C(CH_2)_5O$), 134 (8%, 4-$MeOC_6H_4BO$), 124 (6%), 95 (16%), 81 (4%). Anal. calcd. for $C_{29}H_{40}B_2N_2O_6$: C 65.20, H 7.55, N 5.24, found: C 65.25, H 7.67, N 5.30.

*4,4′-Ethylenebis(6,6-pentamethylene-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane) (**16**a)*

13 (0.32 g, 1 mmol) and phenylboronic acid (0.24 g, 2 mmol) are dissolved in 50 mL of benzene and refluxed for 10 min. Crystallization commences in the boiling solution and is complete after cooling down to room temperature. The precipitate is separated and recrystallized. Yield: 0.46 g (94%) of colorless crystals. Mp 169°C (from $CHCl_3$/petroleum ether). Infrared (KBr): 1600 cm^{-1} (phenyl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.14–2.11 (m, 2 —$(CH_2)_5$—), 2.92 (s, 2 NCH_2CO), 3.29 (s, NCH_2CH_2N), 7.13–7.41 (m, 6 aromatic H), 7.63–7.82 (m, 4 aromatic H). ^{11}B nmr (64.2 MHz, $CDCl_3$/Et_2OBF_3): δ (ppm) = 28.9 ($w_{1/2}$ = 640 Hz). EI mass spectrum (70 eV, 125°C): *m/z* = 488 (0.1%, M^+), 411 (14%, M^+ − C_6H_5), 393 (7%), 285 (4%), 258 (6%), 244 (100%, 1/2 M^+), 228 (4%), 168 (6%), 140 (8%), 105 (5%, PhBOH), 95 (18%) 81 (4%). Anal. calcd. for $C_{28}H_{38}B_2N_2O_4$: C 68.88, H 7.85, B 4.43, N 5.74; found: C 68.71, H 7.95, B 4.60, N 5.62.

*4,4′-Ethylenebis[2-(2-methylphenyl)-6,6-pentamethylene-1,3-dioxa-4-aza-2-boracyclohexane] (**16**b)*

13 (0.32 g, 1 mmol) and 2-methylphenylboronic acid (0.27 g, 2 mmol) are reacted as described for **16***a*. Yield: 0.47 g (86%) of colorless small needles. Mp 145–146°C (from $CHCl_3$/petroleum ether). Infrared (KBr): 1600 cm^{-1} (aryl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.07–2.08 (m, 2 —$(CH_2)_5$—), 2.53 (s, 2 CH_3), 2.92 (s, 2 NCH_2CO), 3.27 (s, NCH_2CH_2N), 6.89–7.32 (m, 6 aromatic H), 7.61–7.78 (m, 2 aromatic H). ^{11}B nmr (64.2 MHz, $CDCl_3$/Et_2OBF_3): δ (ppm) = 28.1 ($w_{1/2}$ = 640 Hz). Anal. calcd. for $C_{30}H_{42}B_2N_2O_4$: C 69.79, H 8.20, B 4.19, N 5.43; found: C 69.79, H 8.40, B 4.24, N 5.33.

*4,4′-Ethylenebis[2-(1-naphthyl)-6,6-pentamethylene-1,3-dioxa-4-aza-2-boracyclohexane] (**16**c)*

13 (0.32 g, 1 mmol) and 1-naphthylboronic acid (0.35 g, 2 mmol) are reacted as described for **16***a*. Yield: 0.58 g (91%) of colorless crystals. Mp 189–200°C (from $CHCl_3$/petroleum ether). Infrared (KBr): 1595, 1580 cm^{-1} (weak, strong, aryl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.01–2.12 (m, 2 —$(CH_2)_5$—), 3.02 (s, 2 NCH_2CO), 3.37 (s, NCH_2CH_2N), 7.22–7.52 (m, 6 aromatic H), 7.63–8.04 (m, 6 aromatic H), 8.56–8.80 (m, 2 aromatic H). ^{11}B nmr (64.2 MHz, $CDCl_3$/Et_2OBF_3): δ (ppm) = 27.7 ($w_{1/2}$ = 640 Hz). Anal. calcd. for $C_{36}H_{42}B_2N_2O_4$: C 73.49, H 4.76, B 3.67, N 4.76; found: C 73.56, H 7.49, B 3.65, N 4.84.

*X-ray crystallographic analysis of **5**l and **15**a·C_6H_6*

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 36.1–38.9° for **5***l* and 56.6–82.3° for **15***a*. The

[6]In solution ($CDCl_3$) the aminal **12** dissociates into the hydroxylamine **10** and the formaldehyde nitrone of **10** (see footnote 2).

[a]Temperature 294 K, Rigaku AFC6S diffractometer, Mo-K_α (λ = 0.71069 Å) or Cu-K_α (λ = 1.54178 Å) radiation, graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, stationary background counts at each end of the scan (scan/background time ratio 2:1, up to 8 rescans), $\sigma^2(F^2) = [S^2(C + 4B)]/Lp^2$ (S = scan rate, C = scan count, B = normalized background count), function minimized $\Sigma w(|F_o| - |F_c|)^2$ where $w = 4F_o^2/\sigma^2(F_o^2)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2}$. Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(F^2)$.

intensities of three standard reflections, measured every 200 reflections throughout the data collections, decayed linearly by 2.6% and 2.8% for **5***l* and **15***a*, respectively. The data were processed,[7] corrected for Lorentz and polarization effects, decay and absorption (empirical, based on azimuthal scans for three reflections).

The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from an E-map or from subsequent difference Fourier syntheses. The structure analysis of **15***a*·C_6H_6 was initiated in the centrosymmetric space group $C2/c$ on the basis of the E-statistics. This choice was confirmed by the subsequent successful solution and refinement of the structure. The **15***a* molecule has exact C_2 symmetry. The benzene solvate molecule in **15***a*·C_6H_6 is two-fold disordered about a crystallographic C_2 axis. A split-atom anisotropic model was employed, the site occupancy factors being adjusted as the refinement progressed to result in approximately equal thermal parameters for the two components of the disorder. Non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms of **5***l* were refined with isotropic thermal parameters and those of **15***a*·C_6H_6 were fixed in idealized positions (C—H = 0.98 Å, B_H = $1.2B_{bonded\ atom}$). A correction for secondary extinction was applied for **15***a*·C_6H_6, the final value of the extinction coefficient being 6.13(6) × 10^{-6}. Neutral atom scattering factors for all atoms (11*a*) and anomalous dispersion corrections for the non-hydrogen atoms (11*b*) were taken from the International tables for X-ray crystallography. Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, bond angles, and intra-annular torsion angles appear in Tables 2–5, respectively. Stereoviews of the **5***l* and **15***a* molecules are shown in Figs. 2 and 3, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least-squares planes are included as supplementary material.[8] Measured and calculated structure factor amplitudes are available from the authors.

[a] $B_{eq} = (8/3)\pi^2\Sigma\Sigma U_{ij}a_i^*a_j^*(\mathbf{a}_i\cdot\mathbf{a}_j)$.

Results and discussion

The X-ray analyses of **5*l*** and **15*a*** both confirm the presence of six-membered cycloboronate ring systems (Figs. 2 and 3). In each case a trigonal planar sp^2-hybridized boron atom forms part of the planar portion of the six-membered heterocycle that has a "sofa" (semiplanar) conformation, typical for this type of cyclic boronic ester. This 1,3-dioxa-4-aza-2-boracyclohexane ring type has so far only been found for *N-un*substituted derivatives having bulky enough (e.g. mesityl) *B*-aryl groups (3), or for *N*-acyl derivatives (2). Thus, **5*l*** and **15*a*** are the first examples of *N*-alkyl derivatives of this type of boron heterocycle to be characterized in the solid state by X-ray crystallography.

The other *N*-alkyl derivatives of the types **5**, **15**, and **16** can generally be assumed to possess similar cycloboronate moieties with trivalent sp^2 boron atoms. The *N*-methyl derivative **5*d***, however, appears to have a dimeric structure **8** with twofold

[a]Primes and double primes refer (here and elsewhere) to symmetry operations: $-x, -y, 1-z$ and double primes: $1-x, -y, 2-z$.

N→B coordination like that reported for the homologue **8** (R = $R^1 = CH_3$, $R^2 = R^3 = R^4 = H$) (1), at least for the solid state (cf. footnote 5). The other *N*-methyl compound, **5***e*, could not be obtained in crystalline form. Nevertheless, it seems that a small *N*-substituent, such as the methyl group in **5***d* or in its previously reported homologue (1), and at least one ring C—H group (R^1 and/or $R^2 = H$) are necessary for the formation of the dimer **8**, stabilized by a pair of transannular C—H···O interactions in the solid state (1).

Some of the *N*-alkylhydroxylaminoalkanols **3** were observed to react preferentially with 2 mol of phenylboronic acid to give the bicyclic pyroboronates **4**, no matter what molar ratio of **3** and phenylboronic acid was applied (1). As already mentioned (1), it is not yet understood which competitive factors control of formation of the crystalline product, either **4** or **5**, out of the reaction equilibrium during the condensation of **3** and phenylboronic acid.

The six-membered BONCCO rings in **5***l* and **15***a* have slightly distorted "sofa" conformations (see Table 5) with C(1) and C(2) on the flaps, respectively. The five-atom BONCCO ring segments (excluding the carbon atoms on the flaps) are planar to within 0.071(2) Å for **5***l* and 0.091(2) Å for **15***a*. Both compounds display a minor deviation from co-planarity of the *B*-phenyl ring and the planar O—B—O ring segment of the BONCCO heterocycle (the angles between normals to the boron coordination group and phenyl ring mean planes are 13.1° for **5***l* and 7.7° for **15***a*). The B—C(phenyl) bond lengths of 1.560(2) Å for **5***l* and 1.561(2) Å for **15***a* are similar to those observed for other related phenylboronates. The boron coordination group is planar within experimental error in **15***a*, while that in **5***l* shows a small (but statistically significant) deviation from planarity (maximum displacement 0.012(2) Å for B, $\chi^2 = 51.0$ for CBO_2).

The N—O bonds in both compounds (**5***l*: 1.462(2) Å, **15***a*: 1.451(1) Å) are comparable to those in the *N*-unsubstituted mesitylboronate (3) (1.46(1) and 1.469(9) Å) that has a similar BONCCO ring system, but are considerably longer than those in the *N*-acyl derivatives (2) (1.402(3) and 1.401(1) Å). This difference between the N—O bond lengths is clearly a consequence of the *N*-alkyl substitution in contrast to the electron-withdrawing *N*-acyl substitution. The remaining geometric parameters of the BONCCO ring systems in **5***l* and **15***a* are in

B(1)—O(1)—N(1)—C(a)	38.6(2)	44.9(2)
O(1)—N(1)—C(a)—C(b)	−65.4(2)	−67.6(1)
N(1)—C(a)—C(b)—O(2)	56.3(2)	55.0(1)
C(a)—C(b)—O(2)—B(1)	−21.1(2)	−21.1(2)
C(b)—O(2)—B(1)—O(1)	−3.5(2)	0.1(2)
O(2)—B(1)—O(1)—N(1)	−5.9(2)	−11.8(2)
C(g)—C(b)—C(c)—C(d)	−52.9(2)	−53.1(2)
C(b)—C(c)—C(d)—C(e)	56.2(2)	56.4(2)
C(c)—C(d)—C(e)—C(f)	−56.3(2)	−56.6(2)
C(d)—C(e)—C(f)—C(g)	54.7(2)	54.9(2)
C(e)—C(f)—C(g)—C(b)	−53.0(2)	−53.3(2)
C(f)—C(g)—C(b)—C(c)	51.3(2)	51.8(2)

[a]C(a–g) correspond, respectively, to C(1–7) for **5*l***, and to C(2–8) for **15*a***.

good agreement. In both compounds the oxygen substituent, O(2), is situated at an axial position of the spiro-connected cyclohexane ring. The cyclohexane rings in the two compounds have virtually identical, slightly distorted chair conformations (see Table 5).

The **15*a*** molecule has exact C_2 symmetry in the solid state, the twofold axis passing through the central aminal carbon atom C(1). The C—N bonds of the N—C—N (aminal) grouping in **15*a*** (1.457(2) Å) are not significantly different from those reported for the *N*,*N*′-dihydroxyaminal derived from *N*-methylhydroxylamine that has the same (C,O)N—C—N(C,O) moiety as **15*a*** (N—C = 1.452(3) Å) (12). The N—C—N angle in **15*a***, however, is somewhat compressed (to 104.1(2)°), presumably as a result of crystal packing effects.

The crystal structure of **5*l*** consists of discrete molecules separated by normal van der Waals distances, the shortest intermolecular distance between non-hydrogen atoms being Cl(1)···B(1)($-x$, $-y$, $1-z$) = 3.409(2) Å. Compound **15*a*** crystallizes as a 1:1 benzene solvate with the benzene molecules disordered about a twofold axis (see Experimental). The packing in **15*a***·C_6H_6 is also dominated by van der Waals forces; the shortest distance between non-hydrogen atoms of the structural moieties involves a molecule of **15*a*** and a benzene molecule: B(1)···C(15a) ($1/2-x$, $1/2-y$, $2-z$) = 3.45(3) Å.

ALLAN W. REY, ROBERT DROGHINI, JAMES L. DOUGLAS, PURUSHOTHAM VEMISHETTI, SUSAN D. BOETTGER, SAIBABA RACHA, and JOHN L. DILLON. Can. J. Chem. **72**, 2131 (1994).

A convenient, high-yielding procedure has been developed for the kilogram-scale synthesis of (±)-*cis*-3-acetoxy-4-phenylazetidin-2-one (**3**), a β-lactam that has been used in the semi-synthesis of Taxol®. The Staudinger reaction between hydrobenzamide (**5**) and acetoxyacetyl chloride in the presence of a base provided the α-benzylideneiminotoluene protected β-lactam **8**. Without isolation of the intermediate β-lactam, the protecting group was removed under various reductive or hydrolytic conditions. The overall yields were about 80%. The synthesis of other (±)-*cis*-4-aryl- and 4-heteroarylazetidin-2-ones by this methodology has also been accomplished. These compounds are of value for the synthesis of 3′-Taxol® side-chain analogs and their preparation demonstrates the generality of this approach.

ALLAN W. REY, ROBERT DROGHINI, JAMES L. DOUGLAS, PURUSHOTHAM VEMISHETTI, SUSAN D. BOETTGER, SAIBABA RACHA et JOHN L. DILLON. Can. J. Chem. **72**, 2131 (1994).

On a mis au point une méthode donnant d'excellents rendements et appropriée pour la synthèse de kilogrammes de la (±)-*cis*-3-acétoxy-4-phénylazétidin-2-one (**3**), un β-lactame qui peut être utilisé dans la semi-synthèse du Taxol®. La réaction de Staudinger entre l'hydrobenzamide (**5**) et le chlorure d'acétoxyacétyle, en présence d'une base, conduit au β-lactame **8** protégé par un α-benzylidèneiminotoluène. Sans procéder à l'isolement du β-lactame intermédiaire, on a enlevé le groupe protecteur sous diverses conditions de réduction ou d'hydrolyse. Les rendements globaux sont d'environ 80%. Utilisant cette méthodologie, on a aussi réalisé la synthèse d'autres (±)-*cis*-4-aryl- et 4-hétéroarylazétidin-2-ones. Ces composés sont utiles pour la synthèse d'analogues du 3′-Taxol® portant des chaînes latérales différentes et leur préparation démontre la généralité de cette approche.

[Traduit par la rédaction]

Introduction

Taxol® (paclitaxel, **1**), a potent antineoplastic agent isolated from the bark of the Pacific yew tree (*Taxus brevifolia*), has proven to be very effective for the treatment of various cancers (for recent reviews, see ref. 1). The labour-intensive extraction/purification procedure required and the limited supply of yew trees have motivated extensive research into obtaining paclitaxel from alternative sources. An early solution was supplied by Greene and Guéritte-Voegelein (2) who prepared paclitaxel semi-synthetically by coupling the hydroxyl at the C-13 position of appropriately protected 10-deacetylbaccatin III (**2**) with a derivative of *N*-benzoyl-(2*R*,3*S*)-3-phenylisoserine. The needles of the ornamental bush *T. baccata* provide a renewable and relatively abundant source (1 g/kg) of the diterpenoid **2**. More recently, Holton (3) patented a method for the semi-synthesis of paclitaxel by acylating protected baccatin III with a derivative of *cis*-3-hydroxy-4-phenylazetidin-2-one. A semi-synthetic route of this type is expected to be the source of most paclitaxel by 1994 (4). A key intermediate in syntheses of the paclitaxel side chain by Holton (3) and others (5) was (±)-*cis*-3-acetoxy-4-phenylazetidin-2-one (**3**). Many other workers have used β-lactams as paclitaxel side-chain synthons (6).

The procedure used by Holton (3) for the preparation of **3** is depicted in Scheme 1. On laboratory scales (i.e., <100 g), this procedure is acceptable. However, for production purposes (i.e., kilogram-scale), the ceric ammonium nitrate (CAN) oxidative removal of the *para*-methoxyphenyl (PMP) group on **4** becomes problematic due to the large quantities of CAN required for the reaction.[3] Other more cost-effective and convenient approaches to **3** were examined. Also, paclitaxel's unique biological profile (8) combined with its unusual chemical architecture make it an important lead for a new series of chemotherapeutic agents. Thus, a route to **3** that could be generalized to allow the synthesis of side-chain analogs of **1** would be desirable.

Results and discussion

The use of hydrobenzamide (**5**) as the imine precursor in the Staudinger reaction (for a recent review, see ref. 9) was reported in 1969 by Wells and Lee (10). Thus, the [2 + 2] cycloaddition reaction between hydrobenzamide and the ketene derived from azidoacetyl chloride furnished, after deprotection, (±)-*cis*-3-azido-4-phenylazetidin-2-one (**7**, Scheme 2). Using a slightly modified Staudinger reaction but identical deprotection conditions, Manhas et al. (11) prepared the same compound in 1981. Both groups employed 10% HCl (aq) for the deprotection and isolated the intermediate hydrochloride salt (**6**).

Applying similar methodology to the preparation of (±)-*cis*-3-acetoxy-4-phenylazetidin-2-one (i.e., using acetoxyacetyl

[1]A subject patent application on this process was filed with the U.S.A. Patent Office, April 23rd, 1993 (*N*-Substituted 2-Azetidinones, USSN No. 08/052,434). An addendum was filed on December 13th, 1993 (USSN No. 08/165,610).

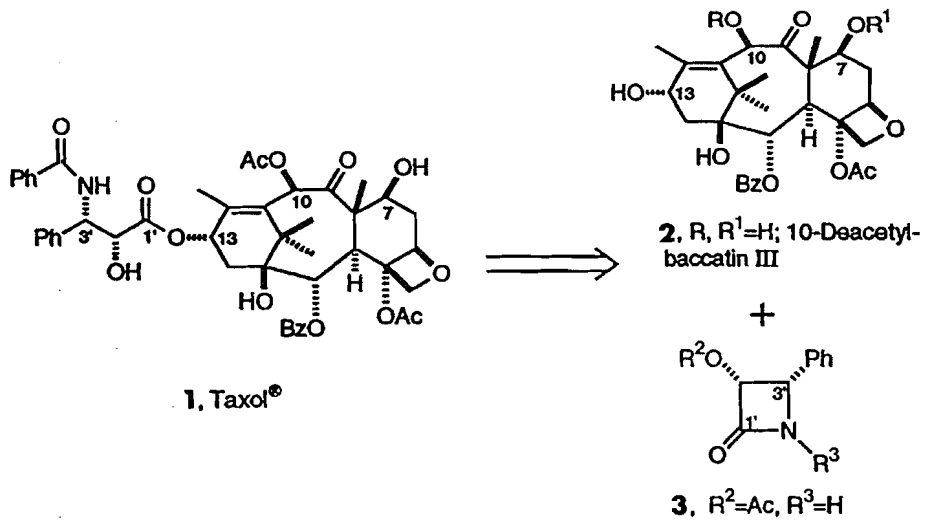

FIG. 1

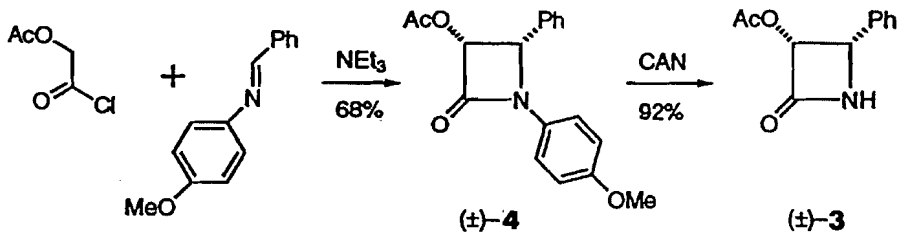
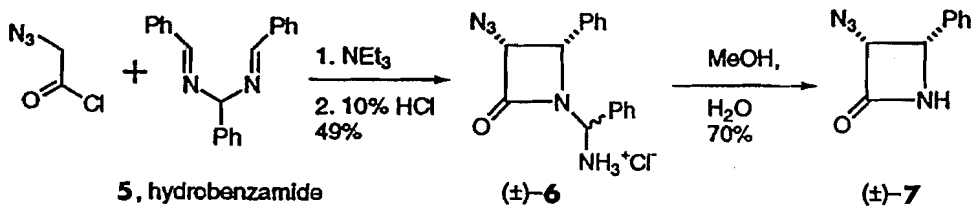


SCHEME 1



SCHEME 2

chloride instead of azidoacetyl chloride) gave low yields of product (13%), presumably due to the instability of the β-lactam ring and the 3-acetoxy group to aqueous HCl. However, it was noted that the intermediate α-benzylideneiminotoluene-(BIT) protected azetidin-2-one **8** (Scheme 3) could be isolated in acceptable quantities. An investigation was undertaken to find better methods for BIT-group deprotection, relative to the one employed previously (10, 11). Other objectives included the optimization of the Staudinger reaction and the development of a telescoped method that would avoid isolation of the intermediate BIT-lactam.

Synthesis of BIT-lactam 8

The starting material, hydrobenzamide, is commercially available (Lancaster). For this work, it was readily prepared in 250-g batches by condensing benzaldehyde with 30% ammonium hydroxide in 2-propanol (20°C, 3 d, 97%). The product was then collected by filtration. This method is a modification of a preparation described by Nicholson and Portez (12).

The reaction between hydrobenzamide and acetoxyacetyl chloride in the presence of triethylamine afforded, after an aqueous extractive work-up, predominantly the BIT-protected azetidin-2-one **8** as a mixture of diastereomers (^{1}H nmr; 85% by hplc) (Scheme 3). No (±)-*trans*-3,4-azetidin-2-one was detected by hplc and ^{1}H nmr comparison with the authentic compound (6*c*). The only other clearly identifiable side-products were the *bis*-lactam **9**[4] (~9%, hplc) together with small amounts of free azetidin-2-one **3** and benzaldehyde.

By optimizing the amount of acetoxyacetyl chloride (AAC), the rate of addition of AAC, and the reaction temperature, it was possible to minimize the amount of *bis*-lactam **9** formed to <1.5% (hplc) and to maximize the amount of BIT-lactam (91%) (see experimental section for optimized reaction conditions). Suitable solvents were dichloromethane, toluene, and ethyl acetate. Both triethylamine and *N,N*-diisopropylethylamine (Hünig's base) were acceptable as bases; however, Hünig's base allowed the Staudinger reaction to be accomplished at lower temperatures (−20°C vs. 5°C) and in shorter reaction times (5 h vs. 18 h).

Deprotection of BIT-lactam 8

As mentioned, 10% HCl (aq) has been used (10, 11) for deprotection of the adduct formed between azidoacetyl chloride

[4]The *bis*-lactam **9** was formed by reaction of 2 equivalents of acetoxyacetyl chloride with 1 equivalent of hydrobenzamide. The methods that were used to convert **8** into **3** failed to convert **9** into **3**.

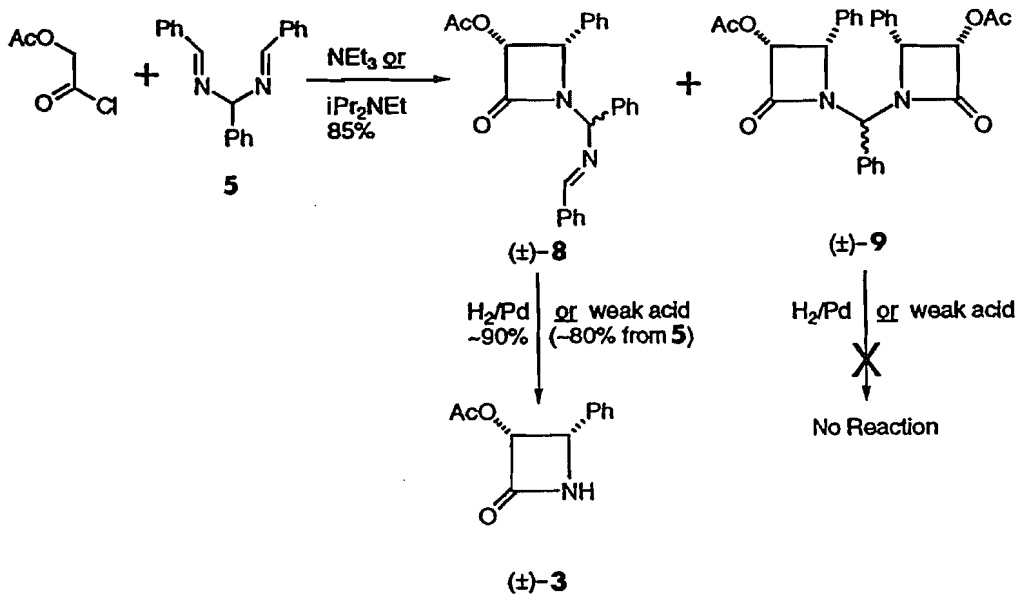

SCHEME 3

and hydrobenzamide. Deprotection of **8** using similar conditions (1% and 10% HCl) provided low yields of product. The ^{1}H nmr spectrum of the crude reaction mixture indicated a mixture of open-chain acids with and without the acetoxy moiety.

Initial attempts to purify the BIT-lactam **8** by silica gel chromatography gave mainly the deprotected azetidin-2-one **3**.[5] The lability of the BIT group to silica gel suggested that other higher yielding methods of deprotection might be available. Indeed, various reagents were found to be significantly more effective than aqueous HCl and are described in the experimental section. The deprotection protocols that were most amenable to scale-up were catalytic hydrogenation (e.g., Pd/C or $Pd(OH)_2$, Method 1), weak-acid hydrolysis (e.g., 75% aqueous acetic acid, Method 2), or 30% aqueous sodium bisulfite (Method 3). Reductive deprotection using sodium cyanoborohydride in methanol (23°C, 1 h) gave equivalent results on smaller scales. The overall isolated yields using the optimized deprotection conditions were in the 70–80% range.

This versatility in terms of deprotection is a valuable feature of the BIT group. It should, for example, be amenable to the synthesis of 3-substituted azetidin-2-ones, which may be sensitive to either acid hydrolysis or catalytic hydrogenation conditions.

Telescoping the sequence

In terms of operational simplicity, a telescoped procedure that would not require isolation of the BIT-lactam **8** was desirable. Thus, after the Staudinger reaction and aqueous extractive processing were complete, the organic layer was submitted to the deprotection conditions described above. For instance, when using the hydrogenation-mediated deprotection method (Method 1), the Staudinger reaction was performed in ethyl acetate. After the aqueous washings, the catalyst was added and the mixture hydrogenated using a Parr apparatus.[6] The catalyst was removed by filtration and the organic layer was washed with 1 *N* HCl to remove the dibenzylamine by-product as its hydrochloride salt. Subsequent concentration of the organic layer precipitated the desired azetidin-2-one **3**.

For the telescoped, weak-acid-mediated hydrolysis, the best option found was to perform the Staudinger reaction in dichloromethane followed by addition of an aqueous mixture of the desired acid (Method 2). Complete BIT-group removal was effected by warming the reaction mixture to ~40°C. The aqueous layer was then neutralized by addition of aqueous NaOH and, after phase separation, the product was precipitated out of the organic layer using heptane.

The Staudinger reaction was accomplished in ethyl acetate for the bisulfite-mediated deprotection (Method 3). After aqueous work-up, the organic layer was treated with aqueous sodium bisulfite at 50°C. Separation and concentration of the organic phase provided **3**.

In all cases, (±)-*cis*-3-acetoxy-4-phenylazetidin-2-one was obtained as a white crystalline product of excellent purity (>99%, hplc). All of these reactions were performed on scales of at least 100 g of starting hydrobenzamide. For the acetic acid mediated hydrolysis, the telescoped sequence was performed on kilogram-scale without having an adverse effect on the yield or purity of **3** obtained.

The separation of the racemic intermediate **3** to give the enantiomeric side-chain precursor of paclitaxel (2′*R*,3′*S*) has been described by Holton (3) using optical resolution of the diastereomeric Mosher's esters of (±)-*cis*-3-hydroxy-4-phenylazetidin-2-one (formed at the 3-position after saponification of the acetoxy moiety). In addition, the kinetic resolution of **3** and derivatives of **3** using highly enantioselective and practical chemoenzymatic methods has been described by Sih et al. (5*a*) and Patel et al. (5*b*).

Analogs of the paclitaxel side chain

To demonstrate the generality of this hydrobenzamide methodology for construction of synthetically useful β-lactams (e.g., refs. 6*g*, 13) and the synthesis of potentially therapeutically useful 3′-paclitaxel side-chain analogs (refs. 6*j*, 6*k*, and 6*l*), a series of analogs of **3** were prepared (Table 1).

The requisite hydroanisamide, hydrofuramide, hydrothien-

[5]BIT-lactam **8** has since been purified by Florisil® chromatography.

[6]Other experiments have demonstrated that these hydrogenations may be performed using a H_2-filled balloon although the deprotection reaction was slower (reaction time ~2 d).

TABLE 1. 4-Analogs of (±)-*cis*-3-acetoxy-4-phenylazetidin-2-one (**3**) prepared by the hydrobenzamide method

Compound	Overall yield (%)	Method of deprotection
(±)-*cis*-3-Acetoxy-4-*p*-methoxyphenylazetidin-2-one, **10**	75	Hydrogenation
(±)-*cis*-3-Acetoxy-4-(2′-furanyl)azetidin-2-one, **11**	61	Hydrogenation
(±)-*cis*-3-Acetoxy-4-(2′-thienyl)azetidin-2-one, **12**	75	Acetic acid
(±)-*cis*-3-Acetoxy-4-*p*-methylphenylazetidin-2-one, **13**	70	Bisulfite

amide, and hydrotoluamide were readily prepared in a manner similar to that described for hydrobenzamide (12). Acetoxyacetyl chloride was used as the ketene equivalent and the reactions were performed with inputs of at least 10 mmol of the starting imine.

Conclusions

A practical procedure that is suitable for the preparation of kilogram quantities of (±)-*cis*-3-acetoxy-4-phenylazetidin-2-one (**3**) was developed. This compound has been used in the semi-synthesis of paclitaxel (3, 5). The key step was the Staudinger reaction between hydrobenzamide and acetoxyacetyl chloride. Subsequent removal of the BIT-protecting group was achieved by hydrogenation, and hydrolytic or reductive protocols.

In terms of many process aspects (processing volumes, cost of reagents, yields, etc.), this methodology is superior to the CAN oxidative removal of the PMP group used previously for the preparation of (±)-*cis*-3-acetoxy-4-phenylazetidin-2-one (3).

The generality of this protocol was demonstrated by the synthesis of several (±)-*cis*-3,4-substituted azetidin-2-ones. These compounds are of use for the synthesis of paclitaxel side-chain analogs. As well, hydrobenzamide methodology may be of general use for the improved synthesis of 4-aryl- or 4-heteroaryl-substituted β-lactams.

Experimental

Melting points were determined on a Büchi 510 melting point apparatus and are not corrected. The ^{1}H nuclear magnetic resonance (^{1}H nmr) spectra were taken on a Bruker AC200SY instrument operating at 200 MHz. Chemical shifts are expressed in parts per million (ppm) downfield from internal tetramethylsilane. The ^{13}C nmr spectra were recorded on a Bruker AMX 400 instrument operating at 100.6 MHz. The carbon chemical shifts are quoted in parts per million (ppm) with reference to $CDCl_3$ (77.0 ppm) or $(CD_3)_2SO$ (39.6 ppm). Mass spectra (ms) were recorded on a Fisons VG Quattro Fast Ion Bombardment mass spectrometer. The infrared spectra (ir) were recorded on a Perkin–Elmer 781 infrared spectrophotometer. Ultraviolet (uv) spectra were recorded on a Hewlett–Packard 8451A diode array spectrophotometer. Elemental analyses were performed by Bristol-Myers Squibb Pharmaceutical Research Institute, Analytical R&D, Syracuse. Solvents and reagents used were reagent grade. High-performance liquid chromatography (hplc) was performed on a Hewlett–Packard 1090 Series 2 system with a diode array detector at 220 nm. A 30 cm × 3.9 mm 10 μ-Bondapack C_{18} column was used. The eluent was 40:60 CH_3CN:0.01M KH_2PO_4 (pH 7.4). Karl-Fischer titrations were performed using a Metrohm 655 Dosimat – Karl-Fischer Automat titrator.

*Telescoped preparations of (±)-*cis*-3-acetoxy-4-phenylazetidin-2-one (3)*

Method 1. Hydrogenation over Pd/C with isolation of intermediate BIT-lactam 8

*A. (±)-*cis*-3-Acetoxy-1-[(phenyl)(phenylmethyleneimino)methyl]-4-phenylazetidin-2-one (8).* Triethylamine (16.8 mL, 121 mmol) was added to a solution of hydrobenzamide (**5**) (30.00 g, 101 mmol) in ethyl acetate (150 mL). With stirring and under a blanket of argon, this mixture was cooled to 5°C and a solution of acetoxyacetyl chloride (12.5 mL, 116 mmol) in ethyl acetate (300 mL) was added dropwise over 1.5 h. After 16 h at 5°C, the reaction mixture was allowed to warm to 20°C (1.5 h). The organic layer was washed successively with saturated aqueous NH_4Cl (2 × 120 mL), saturated aqueous $NaHCO_3$ (120 mL), and brine (120 mL). The BIT-lactam **8** was isolated at this stage by drying the organic phase over $MgSO_4$, filtering, and removing the solvent in vacuo. This provided the crude protected β-lactam **8** in quantitative yield as a red glassy solid; hplc purity (area): 87.9% (1:1 mixture of diastereomers). For purposes of characterization, this compound was purified by Florisil® chromatography (ethyl acetate – hexane (1:4)) and recrystallized from ethyl acetate – hexane to yield **8** as a white solid; hplc purity (area): 98.3%; ir ν_{max} (KBr): 1763 (C=O), 1641 (C=N), cm^{-1}; UV λ_{max} (methanol): 216, 252 nm; ^{1}H nmr ($CDCl_3$) δ: 8.45 (s, 1H, N=CH), 7.80–7.85 (m, 1H, Ph), 7.60–7.65 (m, 1H, Ph), 7.26–7.50 (m, 9H, Ph), 7.00–7.10 (m, 4H, Ph), 6.28 (s, 0.5H, NCHN), 6.23 (s, 0.5H, NCHN), 5.81 (d, J = 4.8 Hz, 0.5 H, H-3), 5.76 (d, J = 4.8 Hz, 0.5 H, H-3), 5.30 (d, J = 4.8 Hz, 0.5 H, H-4), 4.75 (d, J = 4.8 Hz, 0.5 H, H-4), 1.63 (s, 3H, CH_3CO); ms (FAB), *m/z*: 399 (M^+ + H, 4%), 294 (M^+ − PhCHN, 17%).

*B. (±)-*cis*-3-Acetoxy-4-phenylazetidin-2-one (3).* The crude BIT-lactam **8** from above was redissolved in ethyl acetate (500 mL) and carefully transferred, under a stream of argon, to a Parr flask containing 10% palladium on activated carbon[7] (6.00 g). This mixture was treated with hydrogen (4 atm; 1 atm = 101.3 kPa) for 20 h at which point the catalyst was removed by filtration through a pad of Celite®. The filter cake was slurried in ethyl acetate (200 mL), stirred (10 min), filtered, and rinsed with ethyl acetate (100 mL). The filtrates were combined and the organic layer was washed with 10% HCl (300 mL). Both layers were filtered to remove the white precipitate (dibenzylamine·HCl), which was rinsed with ethyl acetate (100 mL). The phases were separated and the organic layer was washed with another portion of 10% HCl (200 mL). The combined 10% HCl washes were re-extracted with ethyl acetate (200 mL) and the combined organic layers were washed with saturated aqueous $NaHCO_3$ (300 mL) and brine (250 mL). The organic layer was dried over $MgSO_4$, filtered, and concentrated in vacuo to a volume of 75 mL. This mixture was cooled to 4°C and the precipitated product isolated by filtration. The filter cake was washed with hexane (200 mL) to provide 16.1 g (78% overall yield from hydrobenzamide) of β-lactam **3** as white needles, mp 150–151°C; hplc purity (area): 99.8%; ir ν_{max} (KBr): 3210 (N-H), 1755, 1720 (C=O) cm^{-1}; UV λ_{max} (methanol): 218, 260 nm; ^{1}H nmr ($CDCl_3$) δ: 7.30–7.38 (m, 5H, Ph), 6.54 (br s, D_2O exchangeable, 1H, NH), 5.87 (dd, J = 2.7, 4.7 Hz, 1H, H-3), 5.04 (d, J = 4.7 Hz, 1H, H-4), 1.67 (s, 3H, CH_3CO); ^{13}C nmr (DMSO-d_6) δ: 168.6, 165.0, 135.9, 128.0, 127.9, 127.3, 78.0, 56.0, 19.7; moisture content (by KF): 0.17%. Anal. calcd. for $C_{11}H_{11}NO_3$: C 64.38, H 5.40, N 6.83; found: C 64.07, H 5.34, N 6.77.

Method 2. Hydrolysis with 75% acetic acid

To hydrobenzamide (100.0 g, 335 mmol) in dichloromethane (335

[7]Wet 10% Pd/C (50% water content) was used as catalyst with identical results.

mL) was added *N,N*-diisopropylethylamine (67.1 mL, 385 mmol). This mixture was cooled to −20°C under N_2 and a solution of acetoxyacetyl chloride (39.6 mL, 368 mmol) in dichloromethane (185 mL) was added dropwise over 5 h. After the reaction was complete (<5% hydrobenzamide by hplc), water (330 mL) was added in one portion and the temperature was increased to 5°C. The phases were separated and the aqueous layer was washed with another 100 mL of dichloromethane. The combined organic layers were treated with acetic acid (150 mL, 2.62 mol) and water (50 mL). The reaction mixture was stirred and warmed to reflux (~40°C). After about 4 h, the hydrolysis was judged complete (<2% **8** by hplc) and the reaction mixture was cooled to 15°C. The pH was adjusted to 6.9 by the addition of 3.75 *N* NaOH (705 mL) over 2 h, keeping the temperature between 10 and 20°C. The mixture was warmed to 25°C to redissolve partially precipitated **3** and the phases separated. The aqueous phase was washed with a portion of dichloromethane (100 mL) and the organic layers combined (~850 mL). The organic layer was then cooled to −5°C–0°C and heptane (850 mL) was added over 1 h with stirring. The resulting slurry was stirred for an additional 1 h at this temperature at which point the solid was collected by filtration. The filter cake was washed with cold 10% dichloromethane in heptane (200 mL). This provided 54.4 g (79% yield from hydrobenzamide) of β-lactam **3** as off-white needles; hplc purity (area): 100%.

Method 3. Hydrolysis with 30% sodium bisulfite

To hydrobenzamide (50.00 g, 167 mmol) in ethyl acetate (500 mL) and under an atmosphere of argon was added triethylamine (26.9 mL, 193 mmol). This mixture was cooled to 5°C and a solution of acetoxyacetyl chloride (18.9 mL, 176 mmol) in ethyl acetate (200 mL) was added dropwise over 1.5 h with stirring. After another 2 h, the stirring was discontinued and the reaction mixture was maintained at 5°C for 17 h. The mixture was diluted with water (250 mL) and the layers separated. The aqueous phase was washed with another portion of ethyl acetate (100 mL) and the organic phases combined and treated with sodium bisulfite (75.0 g) in water (250 mL). The resulting biphasic solution was vigorously stirred (overhead stirrer) at 50 ± 2°C until the hydrolysis was judged complete by tlc (~4 h). The phases were separated and the organic layer was washed with water (150 mL) and then dried over $MgSO_4$, filtered, and concentrated in vacuo to a volume of 100 mL. This mixture was cooled to ~4°C and stirred for 2 h. The precipitated product was isolated by filtration. The filter cake was washed with cold ethyl acetate (25 mL) to provide 20.6 g (60% overall yield from hydrobenzamide) of β-lactam **3** as white needles; hplc purity (area): 99.3%.

*(±)-*cis*-3-Acetoxy-4-*p*-methoxyphenylazetidin-2-one (**10**) by Method 1*

The β-lactam **10** was prepared according to Method 1, except that hydroanisamide (14) was used instead of hydrobenzamide. Thus, hydroanisamide (5.00 g, 12.9 mmol), triethylamine (2.15 mL, 15.4 mmol), and acetoxyacetyl chloride (1.59 mL, 14.8 mmol) gave a solution of the protected β-lactam in ethyl acetate (80 mL). This solution was treated with H_2 (4 atm) over 10% palladium on activated carbon (1.00 g). Standard processing and removal of the solvent in vacuo furnished 4.28 g of a crude solid. A portion (300 mg) was purified by preparative tlc (20 cm × 20 cm × 2 mm silica gel; ethyl acetate – hexane (1:1)) and recrystallized from dichloromethane–hexane to provide 160 mg (75% overall yield from hydroanisamide) of the 4-(*p*-methoxyphenyl) β-lactam **10** as white crystals, mp 110–111°C; hplc purity (area): 99.7%; ir ν_{max} (KBr): 3218 (N-H), 1751, 1728 (C═O) cm^{-1}; UV λ_{max} (methanol): 208, 230, 276 nm; ^1H nmr ($CDCl_3$) δ: 7.24 (d, J = 9.0 Hz, 2H, Ar), 6.89 (d, J = 8.7 Hz, 2H, Ar), 6.23 (br s, D_2O exchangeable, 1H, NH), 5.83 (dd, J = 2.7, 4.6 Hz, 1H, H-3), 4.99 (d, J = 4.6 Hz, 1H, H-4), 3.81 (s, 3H, $ArOCH_3$), 1.73 (s, 3H, CH_3CO). Anal. calcd. for $C_{12}H_{13}NO_4$: C 61.27, H 5.57, N 5.95; found: C 61.04, H 5.49, N 5.88.

*(±)-*cis*-3-Acetoxy-4-(2′-furanyl)azetidin-2-one (**11**) by Method 1*

The β-lactam **11** was prepared according to Method 1 except that hydrofuramide (15) was used instead of hydrobenzamide. Thus, hydrofuramide (80.48 g, 300 mmol), triethylamine (50.2 mL, 360 mmol), and acetoxyacetyl chloride (37.0 mL, 344 mmol) gave a solution of the protected β-lactam in ethyl acetate (1.5 L). This solution was treated with H_2 (4 atm) over 10% palladium on activated carbon (12.0 g). The catalyst was removed by filtration through Celite® and the reaction mixture treated with decolourizing charcoal (30 g, Norit®). After the standard aqueous processing, the organic layer was concentrated to a volume of 160 mL. This mixture was cooled to 4°C and the precipitated product was isolated by filtration. The filter cake was rinsed with diethyl ether and hexane (100 mL of each) to provide 36.0 g (61% overall yield from hydrofuramide) of the 4-(2′-furanyl) β-lactam **11** as white needles, mp 118–119°C; hplc purity (area): 99.4%; ir ν_{max} (KBr): 3203 (N-H), 1756, 1726 (C═O) cm^{-1}; UV λ_{max} (methanol): 222 nm; ^1H nmr ($CDCl_3$) δ: 7.44 (t, J = 1.3 Hz, 2H, furyl), 6.39 (d, J = 1.3 Hz, 1H, furyl), 6.21 (br s, D_2O exchangeable, 1H, NH), 5.88 (dd, J = 2.2, 4.6 Hz, 1H, H-3), 5.05 (d, J = 4.6 Hz, 1H, H-4), 1.92 (s, 3H, CH_3CO). Anal. calcd. for $C_9H_9NO_4$: C 55.39, H 4.65, N 7.18; found: C 55.76, H 4.64, N 6.95.

*(±)-*cis*-3-Acetoxy-4-(2′-thienyl)azetidin-2-one (**12**) by Method 2*

The β-lactam **12** was prepared according to Method 2 for the preparation of **3** except that hydrothienamide was used instead of hydrobenzamide. Thus, hydrothienamide (30.0 g, 94.8 mmol), triethylamine (15.9 mL, 114 mmol), and acetoxyacetyl chloride (11.6 mL, 109 mmol) gave a solution of the protected β-lactam in ethyl acetate. In this case, the ethyl acetate was removed in vacuo to provide the crude intermediate protected β-lactam as a viscous oil. A portion of this oil (0.431 g, 1.03 mmol) was redissolved in dichloromethane (2.93 mL) and treated with acetic acid (0.35 mL, 6.1 mmol) and water (0.15 mL). After 2.5 h at reflux, the reaction mixture was diluted with dichloromethane (50 mL) and washed with saturated aqueous $NaHCO_3$ (2 × 75 mL) and brine (50 mL). The organic layer was concentrated in vacuo to a brown oil, which was purified by silica gel chromatography (ethyl acetate – hexane (1:10 to 3:2)) to give 0.154 g (75% overall yield from hydrothienamide) of the 4-(2′-thienyl) β-lactam **12** as a white solid, mp 101.4–103.3°C; ir ν_{max} (KBr): 3216 (N-H), 1752, 1724 (C═O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.32 (dd, J = 1.5, 4.7 Hz, 1H, thienyl), 7.03 (m, 2H, thienyl), 6.75 (br s, D_2O exchangeable, 1H, NH), 5.86 (dd, J = 2.7, 4.6 Hz, 1H, H-3), 5.27 (d, J = 5.3 Hz, 1H, H-4), 1.83 (s, 3H, CH_3CO); ^{13}C nmr ($CDCl_3$) δ: 169.3, 165.5, 138.4, 127.1, 127.07, 126.2, 78.3, 54.0, 20.0. Anal. calcd. for $C_9H_9NO_3S$: C 51.17, H 4.29, N 6.63; found: C 51.17, H 4.31, N 6.48.

*(±)-*cis*-3-Acetoxy-4-*p*-methylphenylazetidin-2-one (**13**) by Method 3*

The β-lactam **13** was prepared according to Method 3 except that hydrotoluamide (15) was used instead of hydrobenzamide. Thus, hydrotoluamide (10.00 g, 29.4 mmol), triethylamine (4.91 mL, 35.2 mmol), and acetoxyacetyl chloride (3.63 mL, 33.8 mmol) gave a solution of the protected β-lactam in ethyl acetate (150 mL). This solution was treated with water (50 mL) and sodium bisulfite (15 g). This biphasic mixture was vigorously stirred at 50°C for 15 h and the organic and aqueous layers were separated. The organic layer was washed with water (50 mL) and brine (50 mL), dried over $MgSO_4$, and concentrated in vacuo to 20 mL. The mixture was cooled to 5°C and the precipitated product was isolated by filtration and rinsed with cold ethyl acetate (10 mL) and hexane (20 mL) to provide 2.59 g of **13**. Subsequent evaporation of the filtrate and recrystallization from ethyl acetate yielded another two crops of material (1.27 and 0.65 g) to furnish a total of 4.51 g (70% overall yield from hydrotoluamide) of the β-lactam **13** as white needles, mp 130–131°C; hplc purity (area): 99.8%; ir ν_{max} (KBr): 3192 (N-H), 1778, 1752 (C═O) cm^{-1}; UV λ_{max} (methanol): 222, 266 nm; ^1H nmr ($CDCl_3$) δ: 7.13–7.22 (m, 4H, Ar), 6.29 (br s, D_2O exchangeable, 1H, NH), 5.85 (dd, J = 2.6, 4.7 Hz, 1H, H-3), 5.00 (d, J = 4.7 Hz, 1H, H-4), 2.35 (s, 3H, $ArCH_3$), 1.70 (s, 3H, CH_3CO). Anal. calcd. for $C_{12}H_{13}NO_3$: C 65.74, H 5.98, N 6.39; found: C 65.85, H 5.91, N 6.40.

Specionin (**1**) was synthesized in seven steps from aucubin (**2**), an abundant iridoid form *aucuba japonica*. In a "no-choice" bioassay, specionin and several of its derivatives showed only modest antifeedant activity against the spruce budworm, while other derivatives were devoid of activity.

ANMAR K. MOHAMMAD-ALI, T.H. CHAN, A.W. THOMAS, B. JEWETT et G.M. STRUNZ. Can. J. Chem. **72**, 2137 (1994).

On a synthétisé la spécionine (**1**) en sept étapes à partir de l'aucubine (**2**), un iridoïde abondant de l'*aucuba japonica*. Dans un essai biologique sans choix, la spécionine et plusieurs de ses dérivés n'ont montré qu'une activité modeste comme antiappétent contre la tordeuse des bourgeons de l'épinette alors que d'autres dérivés n'ont aucune activité.

[Traduit par la rédaction]

Introduction

Because of problems associated with the widespread use of synthetic broad-spectrum pesticides, alternative strategies in the management of insect pests in forestry and agriculture are required. The spruce budworm, *Choristoneura fumiferana*, inflicts severe damage to the forest resource in Canada (1). A strategy that has been considered for the control of spruce budworm is to employ antifeedants to interfere with larval feeding behaviour (2–4). The approach offers the potential advantage that antifeedants could protect current year foliage while leading indirectly to budworm mortality without being generally toxic (5).

In screening programs using various insects, a number of natural products have been found to have antifeedant activity (6). Of particular interest to the spruce budworm problem is the report by Chang and Nakanishi that an active antifeedant compound, specionin (**1**), had been isolated from the leaves of *Catalpa speciosa* Warder (Bignoniaceae) (7, 8). Specionin was reported to be active at 50–100 ppm. Several chemical syntheses of **1** have since been reported (8–11) but without further biological studies. As part of our ongoing program in the chemical and biological studies of spruce budworm antifeedants (2–4, 12), we have undertaken the synthesis of specionin.

Chemical synthesis

Most previous syntheses of specionin have been designed to construct the iridoid skeleton through the oxidative cleavage of fused cyclopentenes (13), or retro-aldol cleavage of a 2 + 2 cycloadduct (14) or the Norrish type I cleavage of a norbornanone (8). Curran et al. (11), on the other hand, took advantage of an intramolecular cycloaddition of nitrile oxide onto a dihydropyran. All these were lengthy multistep syntheses and give low overall yield of the final, optically active, product. Alternatively, specionin could be synthesized from the iridoid natural product catapol (8).

We previously proposed (2) the use of the natural iridoid glycoside, aucubin (**2**), for the synthesis of specionin. Aucubin is present to the extent of about 1% of fresh plant weight in the leaves of *Aucuba japonica* (15) and can be extracted and purified in large quantities. It had been used as starting material for the synthesis of prostaglandins (16). However, aucubin is degraded extensively under the acidic conditions usually required for removal of the glycosidic linkage. Under the mildest ethanolysis conditions reported by us previously, aucubin rearranged to give **3** with migration of the double bond (2).

Recently, Falck and co-workers reported on the unique ability of triphenylphosphine hydrobromide (TPHB) to promote the addition of oxygen nucleophiles to glucals to give the corresponding acetals without the double bond rearrangement (Ferrier reaction) (17). On the basis of this report, we became interested in using TPHB for the ethanolysis of aucubin. Aucubin was first peracetylated with acetic anhydride in pyridine and dimethylaminopyridine (DMAP) to give **4** (Scheme 1). Ethanolysis of **4** with 20 mol% of TPHB in dichloromethane gave the bis-ethoxy acetal **5** in 60% yield. ^{1}H NMR showed clearly the removal of the sugar moiety and the addition of two ethoxy groups. However, ^{13}C NMR indicated the presence of four diastereomers arising from all possible configurations of the ethoxy groups. At this stage, we did not separate these isomers and proceeded with the synthesis using the mixture. Attempted epoxidation of **5** with *m*-chloroperbenzoic acid (mCPBA) was not successful. Accordingly, the acetate groups were cleaved with NaOMe to give a mixture of the monoacetates **6** and **7** and

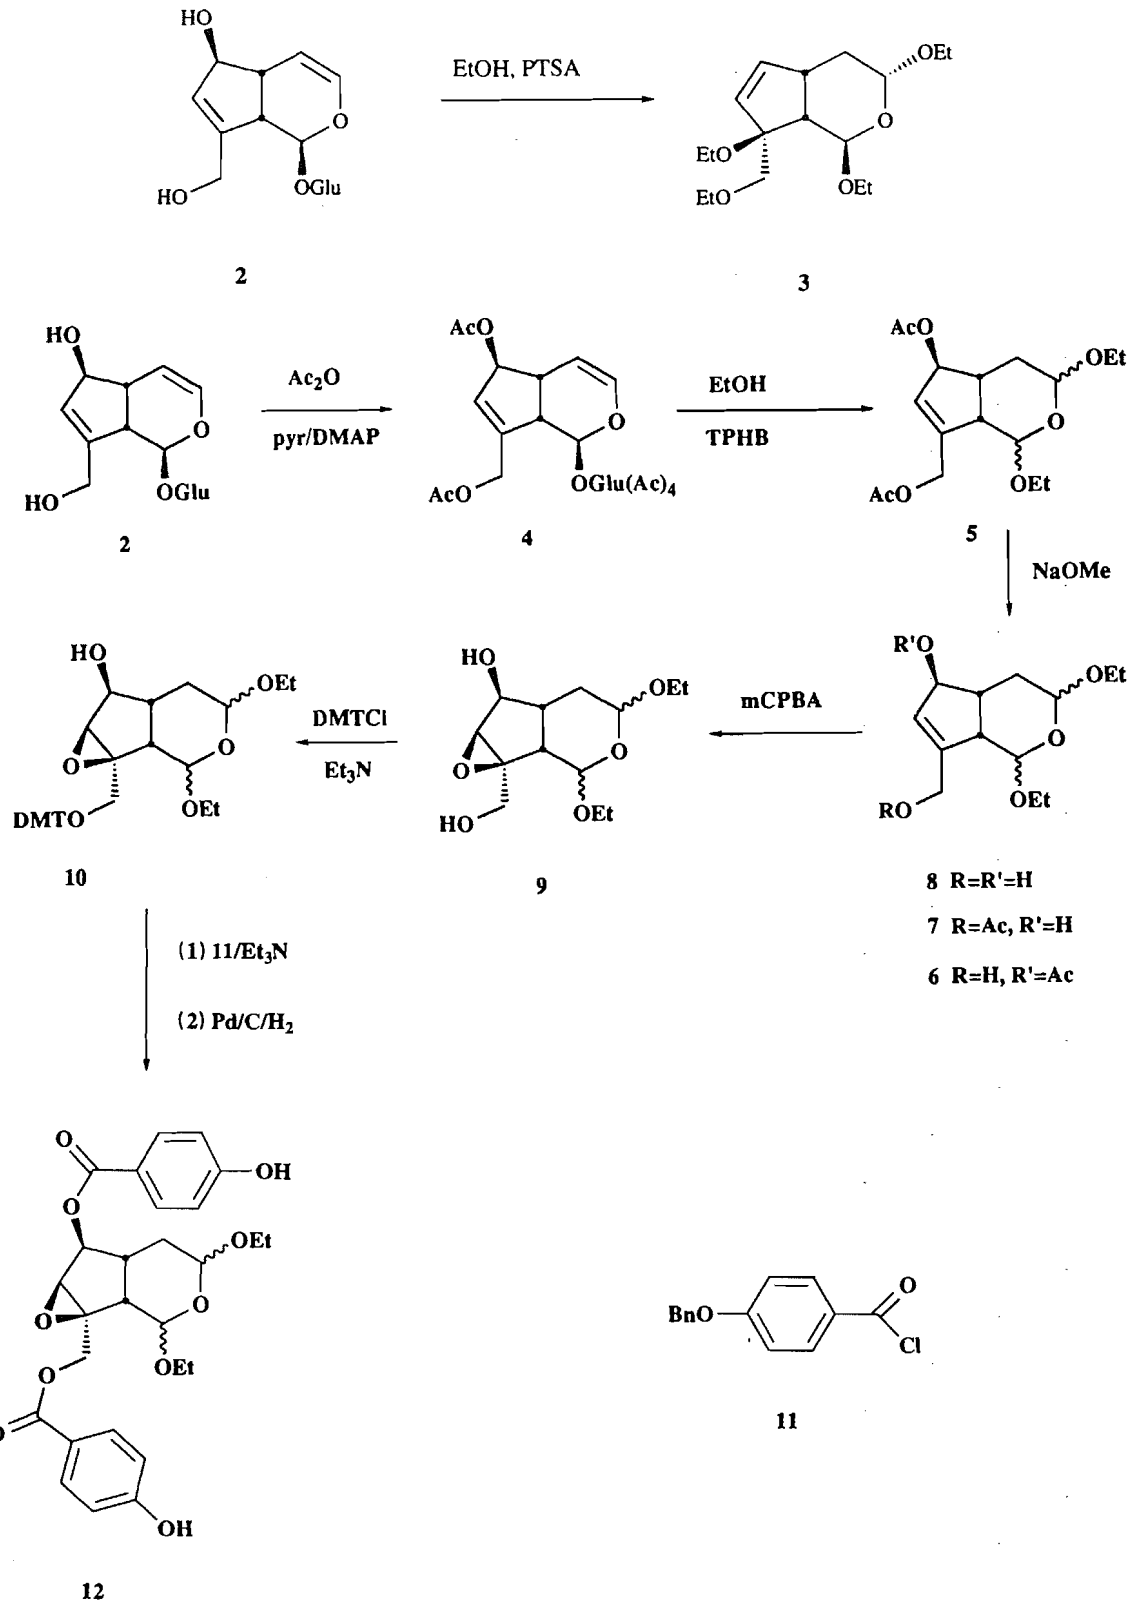

SCHEME 1

the diol **8**, the ratio of which depended on reaction time. The three compounds could be separated by flash column chromatography. Allowing the reaction to proceed for sufficient time, the diol **8** was obtained as the major product in 69% yield. Epoxidation now of **8** with mCPBA afforded the β-epoxide **9** in 60% yield. The ^{1}H NMR spectral data of **9** were compared with those reported in the literature (8). This comparison indicated that in the mixture of stereoisomers constituting **9**, the second most abundant isomer had the same stereochemistry as that of (−)-specionin.

Before benzoylation of the C-6 hydroxyl group, the primary hydroxyl group had to be protected. The use of silicon protect-

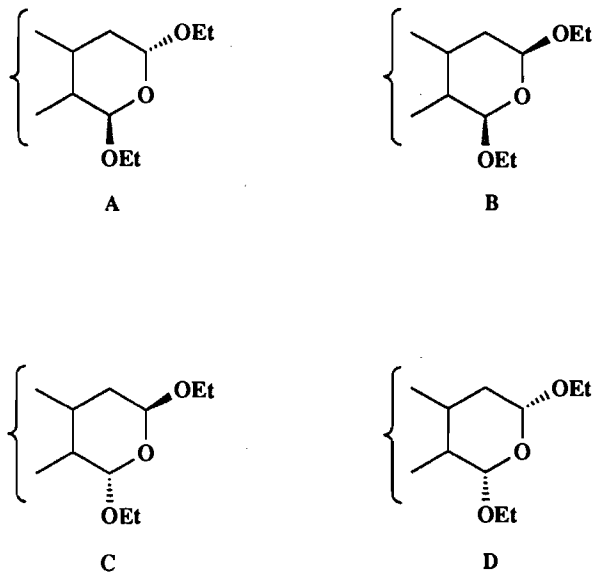
SCHEME 2

ing groups for this purpose has been reported but gave both the mono- and di-silylated compounds (8). We selectively protected the primary hydroxyl as its 4,4′-dimethoxytrityl (DMT) ether by reacting **9** with DMT chloride and triethylamine. The mono-DMT ether **10** was obtained in 75% yield. The coupling of **10** with an excess (4 equivalents) of *p*-benzyloxybenzoyl chloride (**11**) in the presence of triethylamine gave a product that, without purification, was treated with palladium hydroxide on carbon and cyclohexene to effect deprotection. To our surprise, the deprotected product, obtained in 60% yield, was clearly not specionin or any of its isomers. The material obtained was identified as the diester **12** (as a mixture of isomers) on the basis of ^{1}H and ^{13}C NMR and a HMQC experiment which indicated the coupling of the C-10 methylene protons with a carbonyl carbon. To explain the formation of **12**, it was assumed that the triethylamine hydrochloride formed was sufficiently acidic to remove the DMT protecting group. The unmasked primary hydroxy function was then benzoylated by the acid chloride.

The reaction was then repeated using less of the acid chloride **11** and for a shorter reaction time. Under these conditions, **13** and **14** were formed in a ratio of 3:1 in a combined yield of 55% (Scheme 2). The two diastereomers could be separated by column chromatography and were assigned the indicated stereochemistry. The minor isomer **14** was debenzylated over palladium on carbon with hydrogen to give pure (−)-specionin after silica gel column chromatography. Its proton NMR data were identical to the literature values (8). Similar debenzylation of the major isomer **13** gave the isomer of specionin, **15**, whose proton NMR was also identical with those reported in the literature (8).

Some comments need to be made regarding the difference in



SCHEME 3

stereoselectivity in the various syntheses of specionin reported in the literature. Obviously, the bis-ethoxy acetal structure can lead to four possible stereoisomers A, B, C, and D (Scheme 3). Structure C has the relative configuration corresponding to specionin. Previous syntheses of specionin that used *p*-toluenesulfonic acid (PTSA) for the ethanolysis step gave different diastereomeric mixtures. Vandewalle and co-workers reported a ratio of 4:4:1:1 for A, B, C, and D, respectively (8). In Hussain and Leonard's synthesis, A, B, and C were initially formed in

the ratio of 10:10:1, respectively, and D was not reported (9). Whitesell and Allen reported that only the C isomer was formed (10). Finally, Vandewalle, Leonard, and co-workers (8, 9) and Curran et al. (11) all reported that when the mixture of isomers of specionin was subjected to equilibration conditions ($BF_3.OEt_2$ or PTSA in EtOH), the ratio was changed in favour of specionin. The results of these equilibration reactions suggest that the stereochemistry of the bis-acetal in specionin is the thermodynamically stable arrangement. Nevertheless, it remains difficult to reconcile the different ratios of isomers produced under different reaction conditions. We suggest that the different ratios of diastereomeric mixtures reported could be due to the presence of different functionalities on the cyclopentane ring, particularly at the C-6 position. With intermediates where the cyclopentane (ene) ring has no substituent at C-6, as in Vandewalle's synthesis, or a hydroxy group at C-6, as in our synthesis, a mixture of all four diastereomers resulted, with the C arrangement being the minor isomer. In cases where the cyclopentane ring has the bulky *p*-hydroxy- or *p*-benzyloxybenzoate group present at C-6, then the specionin structure C predominated in the equilibration step, as in Leonard's, Whitesell's, or Curran's syntheses. A similar conclusion was recently drawn by Leonard and Hussain (9*b*). In our synthesis, even though specionin was obtained as the minor isomer, it is clear that the major isomer **15** could be equilibrated into specionin. Our synthesis represents therefore a seven-step sequence for the conversion of the readily available aucubin into specionin.

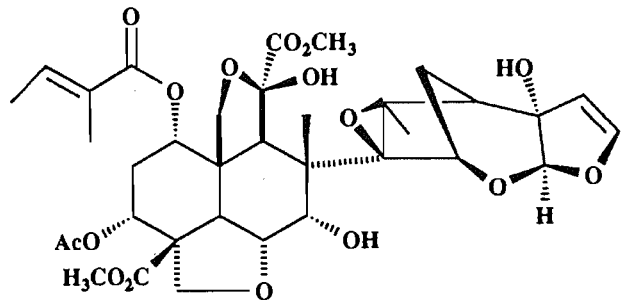
Biological studies

Many experimental designs have been devised to assess the antifeedant effect of a compound. These experiments generally fall into two broad classes, namely "choice" or "no-choice" assays. The occasional disparity between results reported for the efficacy of a given antifeedant compound, using different criteria and methodology, highlights the necessity to use care in designing a bioassay that will yield the most appropriate information for the system under investigation (18). A "choice" type of bioassay is appropriate for polyphagous insects that have access to several plant species. A "no-choice" test was preferred for spruce budworm larvae in the present study, as these larvae are oligophagous and alternate food sources are not usually available in the forest.

Diet containing between 0.023 and 0.60% wet weight of the test compounds was prepared by treating lyophilized artificial diet (19) with a solution of the compound, usually in methylene chloride, and then removing the solvent completely at 30°C on a rotatory evaporator. The residual powder was rehydrated to 80% water content with 0.4% aqueous potassium sorbate solution (fungicide). Control diets were treated as above with solvent alone, or were untreated. Newly emerged 2nd-instar larvae were reared individually on the diets (19) at 24°C, 17-h photoperiod, 25 replicates per test compound and control. After 17 days, the larvae were sacrificed and their mean development stage (i.e., mean instar) determined.

Specionin and a number of its derivatives were tested for antifeedant activity against the spruce budworm (Table 1). The result for each compound tested should be compared with that for the corresponding control. The biological assay showed that the development of larvae reared from 2nd instar on specionin (with 10% of **15** present) at 230 ppm was not significantly retarded from the control. Moreover, all the derivatives tested at 1500 ppm were found to be essentially inactive. Compounds **9** and **10** were moderately active when tested at 3000 ppm, and compound **8** was also moderately active when tested at 6000 ppm. These observations are in contrast to reported activity of specionin at 50 ppm (7). We must only attribute the difference to the type of bioassays used or to the possible presence of another active component in the leaf extract studied by Nakanishi.

These results should also be compared with the potent biological activity of azadirachtin (**16**) against spruce budworm



16

Azadirachtin

larvae. In a similar "no-choice" bioassay, but starting with 3rd instars instead of 2nd instars, a concentration of 1.2 ppm of azadirachtin (in the form of 0.3% azadirachtin in Margosan-O, a commercial preparation of neem oil) stopped development (12). Future studies on the use of antifeedants for the control of spruce budworm should be directed at azadirachtin and related compounds (20).

Experimental

General

For all moisture-sensitive reactions, glassware was oven-dried at 200°C and cooled in a desiccator. All reactions were run under an argon atmosphere, dried by being passed through a column of indicating Drierite and potassium hydroxide, unless otherwise noted. Materials were obtained from commercial suppliers unless noted otherwise. Temperatures of reactions refer to bath temperatures. Solvents were dried as follows: tetrahydrofuran distilled from Na/benzophenone; hexane, pyridine, ethyl acetate, dichloromethane distilled from calcium hydride; methanol distilled from magnesium methoxide; triethylamine stored over sodium hydroxide pellets. Solvents were evaporated under reduced pressure using a Buchi rotary evaporator. Melting points (mp) were determined on a Gallenkamp block and were uncorrected. Flash column chromatography was performed using BDH Silica Gel 60 (230–400 mesh ASTM). Thin-layer chromatography was performed on commercial Merck silica gel 60 F_{254} precoated plates supplied by Merck Co. Visualization was effected by ultraviolet fluorescence (UV) or by spraying the plates with an anisaldehyde – sulfuric acid spray. Proton nuclear magnetic resonance (^1H NMR) spectra were taken on Varian XL-200, XL-300, XL-500, and JEOL 270 instruments. The data are reported in parts per million (ppm) relative to the TMS reference line with the multiplicity (s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; b, broad), coupling constants in hertz, and the number of protons also given for the major isomer in the cases of stereoisomeric mixtures. Carbon-13 nuclear magnetic resonance (^{13}C NMR) spectra were recorded on Varian XL-300 (75.4 MHz) or JEOL-270 (67.8 MHz) instruments. Infrared (IR) spectra were obtained on an Analect AQS-18 FT-IR instrument and are reported in reciprocal centimeters (cm^{-1}). Solution spectra were obtained using sodium chloride cells of 0.2 mm thickness. Low- and high-resolution ammonia chemical ionization (CI) mass spectra were recorded on Hewlett–Packard 5980A and ZAB 2F HS instruments, respectively. Aucubin was generously provided by Dr. J.T. Edward of McGill University (15*b*).

Compound 4

To a suspension of aucubin (1.02 g, 3.0 mmol) in THF (20 mL), pyridine (1.5 mL, 18 mmol) was added. Acetic anhydride (1.6 mL, 18 mmol) was then added followed by the addition of a few crystals of 4-dimethylaminopyridine. The reaction mixture was stirred for 4 h at ambient temperature. The solution was diluted with ether and washed 3 times with 5% aqueous HCl solution, dried with magnesium sulfate, filtered, and evaporated under reduced pressure. The residue was then purified by flash column chromatography using hexane – ethyl acetate mixture, 1:1 ratio, to give **4** as a solid (1.56 g), mp 112–112.5°C, in 87% yield. FTIR ($CHCl_3$): 2960, 2259, 1755, 1660, 1432, 1371, 1231, 1045, 969, 911; ^{1}H NMR ($CDCl_3$): 6.16 (dd, J = 1.9 and 6.2 Hz, 1 H), 5.85 (bs, 1 H), 5.29 (bs, 1 H), 5.24 (t, J = 9.5 Hz, 1 H), 5.16 (d, J = 4.0 Hz, 1 H), 5.10 (t, J = 9.8 Hz, 1 H), 5.02 (dd, J = 8.1 and 9.6 Hz, 1 H), 4.91 (dd, J = 3.2 and 6.3 Hz, 1 H), 4.85 (d, J = 8.0 Hz, 1 H), 4.74 (bs, 2 H), 4.28 (dd, J = 4.5 and 12.3 Hz, 1 H), 4.15 (dd, J = 2.1 and 12.5 Hz, 1 H), 3.72 (ddd, J = 2.3, 2.4, and 9.9 Hz, 1 H), 3.19 (m, 1 H), 2.82 (m, 1 H), 2.1 (s, 3 H), 2.09 (s, 3 H), 2.04 (s, 3 H), 2.03 (s, 3 H), 2.027 (s, 3 H), 2.01 (s, 3 H); ^{13}C NMR ($CDCl_3$): 170.6, 170.4, 170.2, 170.00, 169.2, 169.0, 144.3, 139.6, 127.1, 103.9, 95.8, 93.4, 82.3, 72.3, 71.9, 70.4, 68.1, 61.5, 61.1, 46.6, 39.00, 20.9, 20.6, 20.4; MS (CI): 616 (100, M + NH_4^+); HRMS calcd. for $C_{27}H_{38}N_1O_{15}$: 616.2241; found: 616.2244.

Compound 5

Triphenylphosphine hydrobromide (TPHB) (0.012 g, 0.037 mmol) was added to a dichloromethane solution of acetylated aucubin **4** (0.119 g, 0.185 mmol) and absolute ethanol (0.027 mL, 0.444 mmol). The mixture was refluxed overnight, then excess solvent was evaporated. The residue was redissolved in ether. The organic layer was washed with saturated aqueous sodium bicarbonate and brine, dried with magnesium sulfate, filtered, and evaporated under reduced pressure. The residue was then subjected to flash column chromatography using hexane – ethyl acetate (2:1) as the eluent to give **5** (anomeric mixture, 38 mg, 60% yield). FTIR ($CDCl_3$): 2979, 2932, 2362, 2263, 1733, 1450, 1376, 1242, 1106, 1022; ^{1}H NMR ($CDCl_3$): 5.80 (s, 1 H), 5.77 (s), 5.74 (s), 5.58 (m), 5.36 (bs, 1 H), 5.26 (bs), 4.95 (dd, J = 5.1 and 5.5 Hz, 1 H), 4.79 (dd, J = 4.9 and 4.7 Hz), 4.65 (bs, 2 H), 4.63 (d, J = 8.1 Hz, 1 H), 4.47 (d, J = 5.6 Hz), 4.2 (dd, J = 3.5 and 3.9 Hz), 3.84 (dq, J = 7.2 and 9.5 Hz, 2 H), 3.49 (dq, J = 7.2 and 9.5 Hz, 2 H), 3.23 (m), 3.16 (d, J = 9.0 Hz), 2.89 (t, J = 7.7 Hz, 1 H), 2.82 (t, J = 7 Hz), 2.65 (m), 2.56 (dd, J = 5.8 and 5.8 Hz), 2.46 (m, 1 H), 2.09 (s, 3 H), 2.02 (s, 3 H), 1.81 (m, 1 H), 1.52 (ddd, J = 6.8, 3.6, and 6.8 Hz, 1 H), 1.19 (dt, J = 7.0 Hz, 6 H); ^{13}C NMR ($CDCl_3$): 15.1, 20.8, 21.2, 29.5, 29.6, 29.7, 30.6, 38.9, 39.8, 40.4, 41.0, 48.0, 48.1, 48.3, 49.2, 61.7, 61.9, 61.9, 62.5, 63.1, 63.2, 63.7, 63.8, 63.8, 64.4, 65.5, 82.4, 83.0, 84.0, 84.7, 95.3, 96.21, 96.8, 96.9, 97.4, 97.2, 97.5, 100.2, 125.5, 126.0, 127.2, 128.0, 128.8, 130.9, 143.2, 144.5, 145.0, 145.3, 170.4, 170.5, 170.5, 171.0, 171.0, 171.2; MS (CI): 360 (4, M + NH_4^+), 177 (35), 180 (35), 209 (58), 226 (73), 237 (100).

Compounds 6, 7, and 8

Sodium methoxide (0.07 g, 1.29 mmol) was added to a solution of **5** (0.20 g, 0.59 mmol) in dry methanol (5 mL). The mixture was stirred for 3 h at room temperature. The solution was filtered and evaporated under reduced pressure. The material was then subjected to flash column chromatography using hexane and ethyl acetate (3:1) as eluent to separate compounds **6**, **7**, and **8**. Compound **8** (anomeric mixture) was obtained as a colorless oil (0.10 g, 69% yield). FTIR ($CDCl_3$): 3470, 2978, 2929, 2244, 1710, 1438, 1418, 1361, 1223, 1117, 1092, 1038, 1007, 964, 940; ^{1}H NMR ($CDCl_3$): 5.78 (d, J = 1.0 Hz, 1 H), 5.74 (s),

Compound ***9***

mCPBA (0.18 g, 1.03 mmol) was added to a dichloromethane solution of **8** (0.13 g, 0.519 mmol). After 1 h at ambient temperature, an additional portion of mCPBA was added to the reaction mixture and stirring was maintained for 1 h at room temperature. Saturated aqueous sodium bicarbonate was added and the mixture was stirred for 30 min. The mixture was evaporated under vacuum and the material was then subjected to flash column chromatography, using hexane and ethyl acetate (1:3) as the solvent system to give **9** (anomeric mixture) as a colorless oil (0.082 g) in 58% yield. FTIR ($CDCl_3$): 3588, 2979, 2932, 2264, 1440, 1381, 1343, 1118, 1074, 1031, 970; ^{1}H NMR ($CDCl_3$): 4.99 (d, J = 3.9 Hz, 1 H), 4.96 (d, J = 3.2 Hz), 4.81 (dd, J = 2.7 and 7.0 Hz), 4.73 (dd, J = 3.5 and 9.0 Hz), 4.59 (d, J = 9.2 Hz, 1 H), 4.45 (dd, J = 8.5 and 1.0 Hz, 1 H), 4.13 (dd, J = 1.0 and 7.5 Hz), 4.04 (d, J = 13.4 Hz, 1 H), 4.00 (dd, J = 7.1 and 9.3 Hz), 3.95 (d, J = 12.6 Hz, 1 H), 3.82 (dq, J = 7.1 and 9.3 Hz, 1 H), 3.70 (dq, J = 7.1 and 9.6 Hz, 1 H), 3.68 (d, J = 12.5 Hz), 3.51 (d, J = 1.2 Hz), 3.47 (dq, J = 7.1 and 9.5 Hz, 1 H), 3.468 (d, J = 1.5 Hz, 1 H), 3.46 (dq, J = 7.1 and 9.5 Hz, 1 H), 2.69 (dd, J = 4.2 and 7.4 Hz, 1 H), 2.60 (dd, J = 3.3 and 8.5 Hz), 2.36 (dd, J = 7.0 and 9.0 Hz, 1 H), 1.97 (m, 3 H), 1.86 (m, 1 H), 1.27 (t, J = 7.1 Hz), 1.20 (t, J = 7.1 Hz, 3 H), 1.20 (t, J = 7.0 Hz), 1.18 (t, J = 7.0 Hz, 3 H); ^{13}C NMR ($CDCl_3$): 98.2, 96.3, 93.8, 93.5, 77.1, 75.1, 72.2, 69.5, 66.4, 65.4, 64.5, 63.7, 63.2, 63.1, 62.7, 61.0, 60.6, 60.4, 53.7, 41.5, 40.1, 36.3, 36.2, 31.6, 29.1, 28.7, 26.3, 15.1, 15.0; MS (CI): 292 (10, M + NH_4^+), 229 (60), 246 (72), 279 (100).

Compound ***10***

4,4′-Dimethoxytrityl chloride (0.080 g, 0.23 mmol) was added to a solution of **9** (0.043 g, 0.15 mmol) in dichloromethane (3 mL). Excess triethylamine (0.15 mL) was added to the reaction mixture, which was then stirred overnight at room temperature. Toluene was added and the mixture was evaporated to dryness under reduced pressure. The material was then redissolved in ethyl acetate, washed with brine, dried with magnesium sulfate, filtered, and evaporated under reduced pressure. The product was then subjected to flash column chromatography using hexane – ethyl acetate in a ratio of 2:1, respectively, to give **10** (anomeric mixture) as a colorless oil (68.3 mg) in 75% yield. FTIR ($CDCl_3$): 3595, 2976, 2933, 2840, 2362, 2252, 1703, 1608, 1580, 1463, 1382, 1343, 1300, 1151, 1006, 974, 938, 898; ^{1}H NMR ($CDCl_3$): 0.81 (t, J = 7.1 Hz), 0.88 (t, J = 7.1 Hz), 1.17 (t, J = 7.1 Hz, 3 H), 1.21 (t, J = 7.1 Hz, 3 H), 1.22 (t, J = 7.1 Hz), 1.28 (t, J = 7.1 Hz), 1.72 (m, 1 H), 1.84 (m, 1 H), 1.95 (m, 1 H), 2.22 (t, J = 8.4 Hz, 1 H), 2.37 (dd, J = 7.5 and 9.2 Hz), 2.80 (m), 2.93 (m), 3.15 (d, J = 10.7 Hz), 3.25 (d, J = 11.8 Hz, 1 H), 3.32 (d, J = 7.5 Hz), 3.46 (m, 2 H), 3.63 (d, J = 11.5 Hz, 1 H), 3.69 (m, 2 H), 3.78 (s, 6 H), 3.79 (s), 3.82 (s), 3.85 (s, 1 H), 4.01 (m), 4.34 (d, J = 8.8 Hz, 1 H), 4.47 (bs, 1 H), 4.60 (d, J = 9.2 Hz), 4.68 (d, J = 4.1 Hz), 4.74 (dd, J = 2.3 and 7.8 Hz), 4.93 (d, J = 3.6 Hz, 1 H), 5.00 (d, J = 3.7 Hz), 6.83 (d, J = 8.9 Hz, 4H), 7.31 (m, 9H); ^{13}C NMR ($CDCl_3$): 158.5, 158.5, 144.9, 144.5, 136.24, 136.0, 136.0, 135.6, 130.1, 130.0, 128.2, 128.1, 127.8, 127.8, 126.8, 126.7, 113.2, 113.1, 113.1, 97.9, 96.9, 93.8, 93.2, 85.9, 85.7, 76.8, 75.6, 69.5, 65.1, 65.0, 63.9, 63.2, 62.6, 62.3, 62.1, 61.2, 60.4, 55.2, 53.8, 42.6, 40.1, 37.0, 36.6, 31.7, 29.3, 28.87, 26.6, 15.3, 15.1, 14.9, 14.8, 14.74; MS, FAB (glycerol) calcd. for $C_{34}H_{41}O_8$: 577.2801; found: 577.2804.

p-*Benzyloxybenzoyl chloride (****11****)*

To a stirred mixture of 4-benzyloxybenzaldehyde (1.14 g, 5.3 mmol) and magnesium sulfate (1.14 g) in acetone (30 mL) was added potassium permanganate (1.08 g, 2.1 mmol) over 2 h. The mixture was stirred at room temperature for an additional 30 min. The solvent was evaporated under reduced pressure and the solid residue was treated with 3 × 50 mL of hot water and filtered. The cold aqueous solution was washed with chloroform, then acidified with hydrochloric acid and extracted with chloroform. The organic layer was dried over magnesium sulfate, filtered, and evaporated under reduced pressure, to give 1.06 g of *p*-benzyloxybenzoic acid as white solid material, 88% yield, mp 167–168°C. FTIR ($CHCl_3$): 3073, 1690, 1605, 1254, 1240, 1168. MS (CI): 246(100, M + NH_4^+), 229(90, MH^+), 228(48, M + NH_4^+ − H_2O), 211(48). To a cold solution (0°C) of *p*-benzyloxybenzoic acid (0.13 g, 0.58 mmol) and oxalyl chloride (0.065 mL, 0.75 mmol) in dichloromethane (10 mL), a few drops of DMF were added and the solution was stirred for 2 h. The reaction mixture was evaporated under reduced pressure to give **11** (0.158 g) as white solid, mp 166–167°C (98% yield). FTIR ($CHCl_3$): 2263, 2240, 2226, 1771, 1739, 1601, 1262, 1210, 1165, 941. ^{1}H NMR ($CDCl_3$): 5.15 (s, 2 H), 7.03 (d, J = 9.0 Hz, 2 H), 7.40 (m, 5H), 8.08 (d, J = 9.0 Hz, 2 H); MS (CI): 248(19), 246(58, M + NH_4^+), 211(100).

Compound ***12***

To a solution of **10** (10 mg, 0.017 mmol) in dichoromethane (3 mL) was added triethylamine (0.009 mL, 0.068 mmol) and *p*-benzyloxybenzoyl chloride (**11**, 0.008 g, 0.034 mmol). After 48 h stirring at room temperature, a further equal amount of triethylamine and the acid chloride was added and the mixture was stirred for 24 h. A few drops of ethanol were then added and the mixture was diluted with diethyl ether, washed with saturated aqueous sodium bicarbonate and brine, dried with magnesium sulfate, filtered, and evaporated under reduced pressure. The product **12** (7.1 mg, 0.014 mmol) was then dissolved in ethanol (0.11 mL) and cyclohexene (0.057 mL), 20% palladium hydroxide on carbon (0.7 mg, 1:10 catalyst:substrate by weight) was added, and the suspension was stirred under reflux for 2 h. The catalyst was removed by filtration and the filtrate was evaporated to dryness. The resulting material was then subjected to flash column chromatography using hexane – ethyl acetate (4:1) as the eluent to give **12** (anomeric mixture) as an oil in 60% yield. ^{1}H NMR ($CDCl_3$): 7.96 (d, J = 8.5 Hz, 2 H), 7.93 (d, J = 9.0 Hz, 2 H), 6.85 (d, J = 8.5 Hz, 2 H), 6.83 (d, J = 9.0 Hz, 2 H), 5.84 (bs, 2 H), 5.65 (d, J = 9.0 Hz, 1 H), 5.02 (d, J = 4.0 Hz, 1 H), 4.77 (d, J = 9.0 Hz, 1 H), 4.76 (d, J = 12.5 Hz, 1 H), 4.44 (d, J = 12.5 Hz, 1 H), 4.00–3.94 (dq, J = 7.0 and 9.0 Hz, 1 H), 3.88 (s, 1 H), 3.77–3.72 (dq, J = 7.0 and 9.0 Hz, 1 H), 3.55–3.45 (m, 2 H), 2.52 (d, J = 9.0 Hz, 1 H), 2.47 (dt, J = 7.0 Hz, 1 H), 1.88–1.78 (m, 2 H), 1.24 (t, J = 7.0 Hz, 3 H), 1.19 (t, J = 7.0 Hz, 3 H); ^{13}C NMR ($CDCl_3$): 15.01, 15.03, 26.5, 32.9, 41.6, 58.7, 62.1, 63.3, 64.6, 77.4, 93.7, 97.9, 115.2, 115.3, 122.30, 122.32, 132.0, 132.2, 160.0, 160.1, 165.8, 166.5.

Compounds 13 and 14

To a solution of **10** (84 mg, 0.146 mmol) in dichloromethane (10 mL) was added triethylamine (0.082 mL, 0.58 mmol) and *p*-benzyloxybenzoyl chloride (0.072 g, 0.29 mmol). The mixture was stirred for 24 h. A few drops of ethanol were then added, the mixture was diluted with diethyl ether and washed with saturated aqueous sodium bicarbonate and brine, dried with magnesium sulfate, filtered, and evaporated under reduced pressure. The residue was then subjected to flash column chromatography using hexane – ethyl acetate (40:1) as eluent to give separately compounds **13** and **14** in a ratio of 3:1 in a combined yield of 55% (0.031 g).

Compound 13. ^{1}H NMR ($CDCl_3$): 8.01 (d, J = 9.0 Hz, 2 H), 7.41 (m, 5H), 6.99 (d, J = 9.0 Hz, 2 H), 5.57 (dd, J = 8.9 and 1.2 Hz, 1 H), 5.12 (s, 2 H), 5.01 (dd, J = 3.8 and 1.6 Hz, 1 H), 4.73 (d, J = 8.7 Hz, 1 H), 4.10 (d, J = 13.4 Hz, 1 H), 4.05 (dq, J = 7.1 and 9.3 Hz, 1 H), 3.77 (d, J = 1.2 Hz, 1 H), 3.74 (dq, J = 7.1 and 9.8 Hz, 1 H), 3.62 (d, J = 13.4 Hz, 1 H), 3.55 (dq, J = 7.1 and 9.3 Hz, 1 H), 3.48 (dq, J = 7.1 and 9.7 Hz, 1 H), 2.45 (m, 2 H), 1.82 (m, 2 H), 1.62 (bs, 1 H), 1.390 (t, J = 7.1 Hz, 3 H), 1.23 (t, J = 7.1 Hz, 3 H).

Compound 14. ^{1}H NMR ($CDCl_3$): 1.22 (t, J = 7.1 Hz, 3 H), 1.23 (t, J = 7.1 Hz, 3 H), 1.80 (m, 1 H), 2.0 (m, 1 H), 2.43 (d, J = 8.0 Hz, 1 H), 2.77 (dd, J = 8.5 and 3.9 Hz, 1 H), 3.46 (m, 1 H), 3.49 (m, 1 H), 3.70 (d, J = 1.3 Hz, 1 H), 3.74 (d, J = 12.3 Hz, 1 H), 3.82 (m, 1 H), 3.85 (m, 1 H), 3.98 (d, J = 12.3 Hz, 1 H), 4.71 (d, J = 9.2 Hz), 4.86 (dd, J = 2.6 and 6.5 Hz, 1 H), 4.94 (d, J = 4.6 Hz), 4.99 (d, J = 1.9 Hz), 5.03 (d, J = 3.9 Hz, 1 H), 5.11 (s, 2 H), 5.24 (m), 5.34 (dd, J = 1.3 and 7.9 Hz, 1 H), 5.55 (dd, J = 1.3 and 9.1 Hz), 6.97 (d, J = 9.2 Hz, 2 H), 7.40 (m, 5 H), 8.00 (d, J = 9.2 Hz, 2 H).

Compound 15

A mixture of **13** (7.0 mg; 0.014 mmol) and 10% palladium on carbon (5 mg) in ethanol (2 mL) was stirred under a hydrogen atmosphere for 3 h. The mixture was diluted with ethyl acetate, and filtered through Celite. The product was then subjected to flash column chromatography using ethyl acetate and hexane (4:6) as eluent to give **15** as a colorless oil (4.3 mg) in 78% yield. ^{1}H NMR ($CDCl_3$): 7.98 (d, J = 9.0 Hz, 2 H), 6.85 (d, J = 9.0 Hz, 2 H), 5.58 (dd, J = 1.0 and 8.7 Hz, 1 H), 5.30 (b, 1 H), 5.02 (dd, J = 1.5 and 4.5 Hz, 1 H), 4.73 (d, J = 8.5 Hz, 1 H), 4.10 (dd, J = 3.2 and 13.5 Hz, 1 H), 4.05 (dq, J = 7.0 and 9.0 Hz, 1 H), 3.78 (d, J = 1.0 Hz, 1 H), 3.74 (dq, J = 7.0 and 9.5 Hz, 1 H), 3.62 (dd, J = 11.0 and 13.5 Hz, 1 H), 3.55 (dq, J = 7.0 and 9.0 Hz, 1 H), 3.48 (dq, J = 7.0 and 9.5 Hz, 1 H), 2.52 (dd, J = 3.5 and 11.5 Hz, 1 H), 2.48–2.41 (m, 2 H), 1.85 (ddd, J = 3.5, 5.5, and 14.5 Hz, 1 H), 1.82 (dt, J = 1.5 and 14.5 Hz, 1 H), 1.30 (t, J = 7.0 Hz, 3 H), 1.23 (t, J = 7.0 Hz, 3 H); ^{13}H NMR ($CDCl_3$): 14.8, 14.9, 26.3, 32.6, 40.7, 58.0, 61.2, 63.2, 64.6, 65.2, 77.1, 93.6, 97.8, 115.0, 121.3, 132.0, 160.1, 166.1.

Specionin (1)

A mixture of **14** (3.0 mg, 0.006 mmol) and 10% palladium on carbon (2 mg) in ethanol (2 mL) was stirred under a hydrogen atmosphere for 3 h. The mixture was diluted with ethyl acetate, and filtered through Celite. The material was then subjected to flash column chromatography using ethyl acetate and hexane (4:6) as eluent to give **1** as a colorless oil (1.8 mg) in 79% yield. ^{1}H NMR ($CDCl_3$): 7.98 (d, J = 9.0 Hz, 2 H), 6.86 (d, J = 9.0 Hz, 2 H), 5.36 (dd, J = 8.5 and 1.5 Hz, 1 H), 5.06 (d, J = 4.0 Hz, 1 H), 4.88 (dd, J = 7.0 and 2.5 Hz, 1 H), 3.99 (d, J = 12.5 Hz, 1 H), 3.83 (m, 2 H), 3.77 (s, 1 H), 3.75 (d, J = 1.5 Hz, 1 H), 3.72 (d, J = 12.5 Hz, 1 H), 3.48 (m, 2 H), 2.78 (dd, J = 4.0 and 8.0 Hz, 1 H), 2.42 (m, J = 5.3, 8.0, and 8.5 Hz, 1 H), 1.99 (ddd, J = 2.5, 5.3, and 13.8 Hz, 1 H), 1.83 (dt, J = 7.0 and 13.8 Hz, 1 H), 1.24 (t, J = 7.0 Hz, 3 H), 1.20 (t, J = 7.0 Hz, 3 H).

Lithium tetraphenylborate tetrahydrate, $[Li(OH_2)_4]BPh_4$ (LiTBw; tetragonal, $I4_1/a$, $a = 27.566(2)$ Å, $c = 12.228(2)$ Å, $Z = 16$) is remarkable in that the four H_2O molecules coordinating the Li^+ ion all form O—H...π hydrogen bonds to the phenyl groups of the anion. LiTBw thus appears to be the first reported example of such an exhaustive O—H...π coordination and can be described as a 3-dimensional, completely H-bonded polymer in which all the H_2O hydrogens are bonded to phenyl groups and all the phenyl groups are involved in O—H...phenyl bonds. Six of the O—H...phenyl bonds are essentially normal and two are highly bent, possibly bifurcated. The existence of the H-bonds has been corroborated from variable-temperature FT-ir spectra of weakly deuterated LiTBw. The O—Li—O angles in the LiO_4 coordination tetrahedron (of symmetry C_1) exhibit large departures from the tetrahedral angle, two of the angles bisected by a quasi-S_4 axis being 118.3° and 122.5°, respectively. An *ab initio* (6-31G*) investigation of the $Li(OH_2)_4^+$ and $Be(OH_2)_4^{2+}$ cations has shown that such large O—M—O angles are to be expected even in the free ions and are thus not necessarily the result of packing effects. A detailed comparison with several $Li(OH_2)_4^+$ and $Be(OH_2)_4^{2+}$ salts provides a rationale for the observed $M(OH_2)_4^{n+}$ (M = Li, Be) geometries.

PRADIP K. BAKSHI, SERGEY V. SEREDA, OSVALD KNOP et MICHAEL FALK. Can. J. Chem. **72**, 2144 (1994).

Le tétrahydrate du tétraphénylborate de lithium, $[Li(OH_2)_4]BPh_4$ (LiTBw; tétragonal, $I4_1/a$, $a = 27,566(2)$ et $c = 12,228(2)$ Å et $Z = 16$) est remarquable par le fait que les quatre molécules d'eau qui se coordonnent à l'ion Li^+ forment toutes des liaisons hydrogène O—H...π avec les groupes phényles de l'anion. Le LiTBw semble donc être le premier exemple à avoir été rapporté d'une coordination O—H...π aussi extensive; on peut le décrire comme un polymère tridimensionnel à liaisons hydrogène dans lequel toutes les molécules d'eau sont liées aux groupes phényles et tous les groupes phényles sont impliqués dans des liaisons O—H...phényle. Six des liaisons O—H...phényle sont essentiellement normales et deux sont fortement recoudées et possiblement bifurquées. L'existence de liaisons hydrogène a été corroboré par des spectres FT-ir à température variable de LiTBw faiblement deutéré. Les angles O—Li—O du tétraèdre de coordination du LiO_4 (de symétrie C_1) présentent des différences importantes par rapport aux angles tétraédriques; deux de ces angles sont bissectés par un axe quasi-S_4 de respectivement 118,3 et 122,5°. Une étude *ab initio* (6-31G*) des cations $Li(OH_2)_4^+$ et $Be(OH_2)_4^{2+}$ montre que l'on peut s'attendre à de tels grands angles O—M—O même dans les ions libres et qu'ils ne résultent pas nécessairement d'un effet d'empilement. Une comparaison détaillée des plusieurs sels $Li(OH_2)_4^+$ et $Be(OH_2)_4^{2+}$ fournit une explication pour les géométries observées pour le $M(OH_2)_4^{n+}$ (M = Li, Be).

[Traduit par la rédaction]

The study and demonstration of hydrogen bonding to aromatic π systems in crystals is a relatively new field of enquiry (for a brief historical review see ref. 2). Reported examples of such bonding have been so sporadic and uncommon that even simple situations involving one or two X—H...π(aromatic) bonds have received prominent exposure (3–6). The crystal-structure determination of the hitherto unreported lithium tetraphenylborate tetrahydrate, $[Li(OH_2)_4]BPh_4$ (LiTBw for short), has now shown that the X—H...π bonding can be much more extensive: in this crystal the Li^+ cation is completely coordinated by *eight* O—H...phenyl bonds, and all the phenyl groups are H-bonded. LiTBw is thus the first example of such maximum O—H...π engagement.

The crystallography of LiTBw (see below) has been supplemented by examination of the ir spectrum of the isotopically decoupled water molecules in this crystal between 10 K and room temperature, and by an *ab initio* treatment of the free $Li(OH_2)_4^+$ cation. The Li—$4H_2O$ coordination in LiTBw is also compared with that in $[Li(OH_2)_4](UO_2)AsO_4$ (= LiUAw) (7) and also with its nearest formal analog, Be—$4H_2O$, in $[Be(OH_2)_4]SO_4$ (= BeSw) (8, 9) and $[Be(OH_2)_4](NO_3)_2$ (= BeNw) (10).

Crystal structure

The crystal data of LiTBw are listed in Experimental. The atom positions and the interatomic distances and bond angles are given in Tables 1 and 2. The positions and isotropic temperature factors of the hydrogens (Table A), the anisotropic thermal parameters of the nonhydrogen atoms (Table B), and the deviations of the C and B atoms from the best planes through the phenyl-ring skeletons (Table C) have been deposited.[5]

LiTBw has a large centrosymmetric tetragonal unit cell: $a = 27.566(2)$ Å, $c = 12.228(2)$ Å, $Z = 16$. Systematic absences detected by the data reduction procedure were consistent with space group symmetry $I4_1/a$. However, the positional parame-

[a]The numbers in parentheses quoted with the means are standard deviations of the sample means; they do not include the esd's of the component values. The corrected distances and angles are from a TLS analysis of the cation (see text).

ters z(B) and z(Li) turned out to be remarkably close to multiples of 1/8, and even the corresponding x and y values were not far from multiples of 1/8. Since fractional atom coordinates equal to $n/8$ are characteristic of tetragonal subgroups of the cubic space groups $Fd\bar{3}m$, $Fd\bar{3}c$, and $Ia\bar{3}d$, the indices of the observed reflections were carefully examined for possible consistency with the maximal subgroups of these cubic groups, $I4_1/amd \subset Fd\bar{3}m$ and $I4_1/acd \subset Fd\bar{3}c$, $Ia\bar{3}d$, both of which contain $I4_1/a$ as a maximal subgroup of index two. The examination, however, confirmed the $I4_1/a$ symmetry assignment. A signifi-

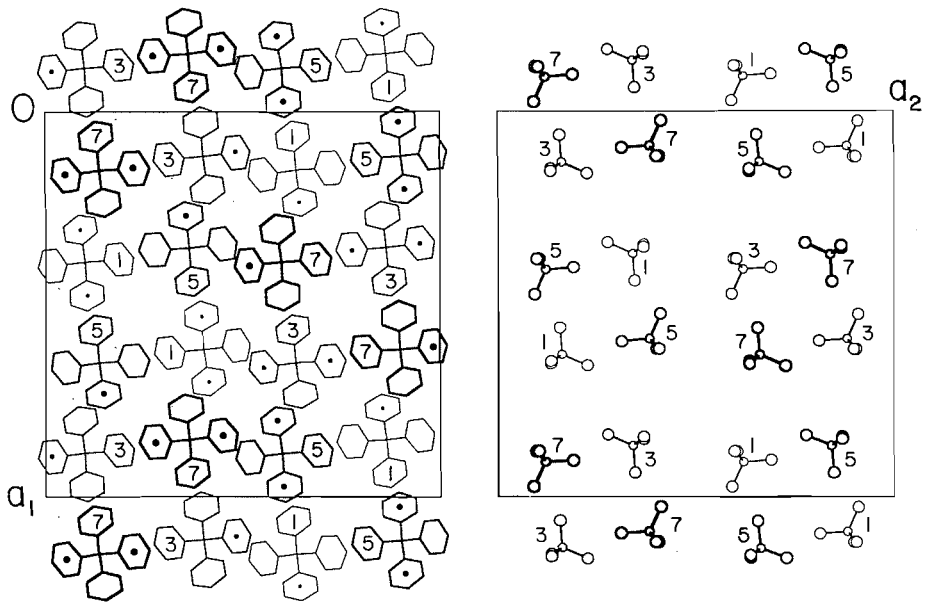

FIG. 1. Projection of the LiTBw unit cell on (001) (origin at centre of symmetry). (*Left*) Packing of anions. The number n identifies ring 1 (cf. Table 1) and indicates the approximate z(B) expressed as $n/8$. Phenyl rings pointing upward from the page are marked with a dot. (*Right*) A matching projection of the cation packing. The number n indicates the approximate z(Li) = $n/8$ fractional coordinate.

cant number of large F_o's had indices incompatible with either of the two space groups, and the corresponding $R_{merg} \sim 60\%$ values calculated for the latter were clearly unacceptable. The departures of the B and Li positions from multiples of 1/8 are therefore genuine and the ion packing in LiTBw may thus be regarded as the result of a frustrated though nearly successful attempt to achieve a higher symmetry.

Each Li atom is tetrahedrally coordinated by four water molecules. The geometry of the LiO_4 coordination tetrahedron approximates D_{2d} symmetry, with the quasi-S_4 axis almost parallel to [$\bar{3}$40] for the Li position listed in Table 1. The mean Li—O distance uncorrected for thermal motion, 1.933(7) Å (Table 2), is comparable to the corresponding uncorrected distance in the LiO_4 tetrahedron of LiUAw, 1.955(4) Å, and to the uncorrected mean Li^{iv}—O distance in $LiB(OH)_4$ (11), 1.967(35) Å.

The O—Li—O angles α bisected by the quasi-S_4 axis of the LiO_4 tetrahedron, 118.3 and 122.5°, depart substantially from the tetrahedral angle. From geometrical considerations for an S_4 tetrahedron[6] the mean associated O—Li—O angle $\bar{\alpha}'$, 104.3(10)° (Table 2), should correspond to $\bar{\alpha}$ = 120.4°. This value is the same as the observed mean, α = 120.4(21)°, which indicates that the LiO_4 tetrahedron is close to S_4 symmetry, but it does not explain why the observed α are so large. This matter is considered in more detail below.

The tetraphenylborate (TB) anion (Table 2), although of crystallographic symmetry C_1, is dimensionally not far from D_{2d}. The geometry of its $BC(\alpha)_4$ core is, within the statistics, indistinguishable from the corresponding mean geometry (based on many TB anions) reported in ref. 2. The planarity of the phenyl rings is satisfactory (Table C).

The overall organization of the LiTBw structure is presented in Fig. 1. The structure can be thought of as consisting of cation + anion columns ||c with $\bar{4}$ as the column axis (projecting to x, y = (0, ± ¼) and (½, ± ¼) in the figure). In each column the B and Li atoms are arranged at the alternate corners of B_4Li_4 cuboids, which are easily identifiable on superposing the left and right parts of Fig. 1. Neighbouring columns are related by centres of symmetry between the columns (projecting to x, y = (0, 0), (½, 0) etc. in the figure).

[6]In a tetrahedron of symmetry S_4 the angles α and α′ are related by $\tan^2(\alpha'/2) = 1 + 2\tan^{-2}(\alpha/2)$.

Thermal motion

The anisotropic thermal parameters of the nonhydrogen atoms are reasonable, with the exception of U_{22}[O(1)] = 0.128 and in particular U_{22}[O(3)] = 0.240 and U_{11}[O(4)] = 0.210 Å^2 (Table B). The orientations and magnitudes of the thermal ellipsoids on these oxygens are displayed in the lower-left half of Fig. 2, where a portion of the structure is projected on (001) to provide a favourable view.

To see whether these large U_{ii} values are accidental or arising from correlated motions we tested the LiO_4 tetrahedron for rigid-body behaviour. The TLS analysis resulted in $R(U_{ij})$ = 6.7%, $R_w(U_{ij})$ = 5.9%, and rms(U_{ij}) = 0.0048 as against rms[esd(U_{ij})] = 0.0063 Å^2, i.e. the LiO_4 motion is reasonably consistent with the rigid-body-motion model, and the above three largest U_{ii} values are satisfactorily explained as resulting mainly from a large-amplitude libration about the principal libration axis L_3 practically ||c (Fig. 2, upper right). The mean amplitudes about the three principal axes of libration are L_1, 3.4°; L_2, 5.6°; and L_3, 10.1°.

The Li—O distances and O—Li—O angles corrected on the rigid-body-motion model are listed in Table 2.

Hydrogen bonding

The $Li(OH_2)_4^+$ cation is coordinated by four pairs of phenyl groups, each pair from a different anion (Fig. 3*A*). The geometry of this environment is strongly suggestive of O—H...π bonding. Difference Fourier maps showed evidence of two hydrogen atoms each between two of the oxygens and their nearest phenyl rings, and of one hydrogen each between the other two oxygens and their nearest phenyl rings, but their positions could not be ascertained with complete confidence. Unlike in the case of N—H...π bonds in tetraphenylborates of

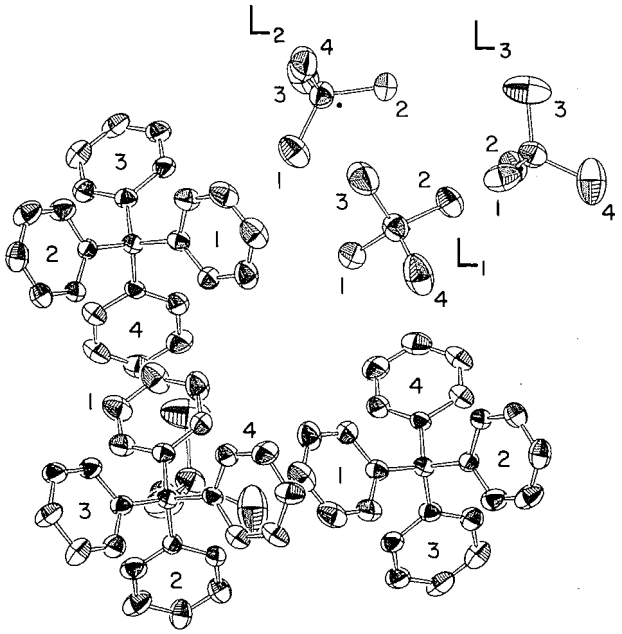

FIG. 2. Projection of a portion of the LiTBw structure on (001). Orientation as in Fig. 1; *xyz* of Li as in Table 1; 50% probability thermal ellipsoids. The phenyl rings are numbered 1–4. Note the large ellipsoids of O(3) (under ring 1) and O(4) (under ring 4) in the LiO_4 tetrahedron. *Upper right*: projections of the LiO_4 tetrahedron down its principal axes of libration L_1–L_3 (rigid-body-motion model, see text). The numbers refer to the oxygen atoms; the black dots indicate the position of the LiO_4 centroid. The projection down L_3 is to be compared with the projection of LiO_4 (from the structure refinement) down in the main figure; the two scales approximately match.

secondary and tertiary organic ammonium cations (2, 12), the H atoms of a water molecule cannot be placed geometrically, and the results of refining some of the H_2O molecules as rigid bodies (using the information from the difference maps) were not sufficiently conclusive. Without unambiguous location of the H(O) atoms the present *crystallographic* evidence of O—H...π bonding in LiTBw is therefore indirect but (as shown below) no less compelling.

The problem with defining the length and direction of an H...phenyl bond is discussed in detail in ref. 2 where, *faute de mieux*, the centre π_c of the phenyl ring is used as an "anchor" point of the bond, and the mean O...C distance and its standard deviation serve to describe the geometric relation (distance and attitude) of the H_2O molecule to the phenyl ring. This usage is adopted in the following.

The distances from an oxygen atom to the centre of the nearest phenyl ring range from 3.27 to 4.13 Å and the π_c...O...π_c angles, from 86° to 125° (Table 2, Fig. 3). With the exception of the two longest distances, 4.03 and 4.13 Å, this O...π_c range coincides with that for the corresponding distances in Table 5 of ref. 2, 3.12 to 3.54 Å. The two exceptions involve the oxygen atoms O(3) and O(4), each having one very large U_{ii} value (cf. above). Significantly, while the pair of phenyl rings nearest O(1) belongs to one anion, and ditto for O(2), the two rings nearest O(3) belong each to a different anion, and similarly for O(4). Further, the corresponding π_c...O...π_c angles at O(1) and O(2) are 86° and 90°, respectively, but those at O(3) and O(4) are 123° and 125°, pointing to the existence of strongly bent or bifurcated O—H...π bonds.

Conforming to the principle (which to our knowledge has no known exceptions, cf. ref. 13) that *all* H_2O hydrogens in a crystalline salt hydrate are always engaged in H-bonding, LiTBw is a three-dimensional, completely H-bonded polymer in which all the H_2O hydrogens are bonded to phenyl groups and all the phenyl groups are involved in O—H...phenyl bonds. In this respect LiTBw resembles BeSw (8, 9) and $[C(CH_2NH_3)_4]^{4+}(SO_4^{2-})_2$ (14), both of which also contain complete three-dimensional systems of H-bonds. However, while the Li and Be compounds dissolve readily in water, the high ion charges in the tetrakis(ammoniomethyl) sulfate conspire to make it very insoluble. The effects of ion charge in LiTBw and BeSw are compared below.

TABLE 3. Oxygen to ring centre and mean oxygen to carbon distances (Å) in LiTBw[a]

Distance	d(O...π_c)	$\bar{d}$(O...C)[b]	Δ[c]
O(1)...R1	3.57(9)	3.82(26)	0.73(13)
O(1)...R2	3.27(10)	3.55(7)	0.18(13)
O(2)...R3	3.30(11)	3.58(17)	0.43(17)
O(2)...R4	3.46(11)	3.73(16)	0.45(13)
O(3)...R1	4.13(10)	4.20(59)	1.78(14)
O(3)...R4	3.53(12)	3.79(26)	0.73(13)
O(4)...R1	3.34(10)	3.61(18)	0.50(13)
O(4)...R4	4.03(11)	4.22(62)	1.77(14)

[a]For coordinates of equivalent atom positions see Table 2.
[b]The standard deviation (in parentheses) of the mean does not include the esd's.
[c]$\Delta = d_{max}$(O...C) – d_{min}(O...C) for a phenyl ring.

The involvement of the phenyl groups in the H-bonding is not uniform (Fig. 3*B*). Rings 1 and 4 are each bonded from *both* sides, while rings 2 and 3 are bonded from one side only. The O...π_c distances to the latter are also the shortest O...π_c distances in the crystal, 3.27 and 3.30 Å, respectively, consistent with the unbalanced H...phenyl interaction.

The d(O...π_c) and the mean oxygen-to-ring-carbon d(O...C) distances are compared in Table 3. The standard deviations of the mean O...C distances (which do not include the esd's) can be taken as a measure of the inclination of the O...π_c vector to the ring plane (Fig. 4*A*).

The differences Δ between the longest and the shortest O...C distances in a ring vary quasi-linearly with d(O...π_c) ($r^2 = 0.97$, $\sigma = 0.11$ Å; Fig. 4*B*). The d(O...π_c) in this crystal are larger than the mean for normal (i.e. essentially straight) O—H...π bonds in ref. 2, but they fall within the corresponding range for bifurcated N—H...2π bonds and are entirely within the range for the two trifucated N—H...3π bonds reported there (cf. Fig. 4*B* and discussion in ref. 2).

Infrared spectrum of HDO and H_2O in LiTBw

Since the positions of the H_2O hydrogens could not be established with complete confidence and a suitable neutron-diffraction experiment could not be easily arranged, it seemed worthwhile to corroborate the existence of H-bonding in LiTBw by noncrystallographic means. This could in principle be accomplished by examining the ir spectrum of H_2O in the crystal for ν(OH) frequency lowering were it not for the well-known complications encountered with standard ir spectra of H_2O in hydrates, viz. the extensive vibrational coupling and Fermi resonance in the ν(OH) region which preclude satisfactory resolution of absorptions originating in the individual O—H groups. A technique developed to circumvent these difficul-

ties (13, 15, 16) and employed here uses a weakly deuterated sample, thereby replacing a suitably small proportion of the H_2O molecules in the crystal by isotopically isolated (decoupled) HDO molecules. LiTBw was thought to offer a particularly challenging test of the power of this technique, given the eight distinct but very similar O—H groups weakly bonded to the phenyl groups: the four HDO molecules corresponding to the four asymmetric H_2O molecules should give rise to eight ν(OD) absorptions, all of them with frequencies lowered with respect to a non-H-bonded standard, and to four δ(HOD) absorptions. In addition, the temperature dependence of the ν(OD) frequency should provide information on the *type* of H-bond (17).

In the following we present only the ν(OD) of HDO and the δ(HOD) of H_2O regions of the FT-ir spectrum of a LiTBw sample with an estimated 3% of the H_2O hydrogen replaced by deuterium (figs. 5–8). The δ(HOD) absorptions were too weak to be observed.

The HOH bending region of the 10 K spectrum (Fig. 5) contained two resolved doublets with frequencies between 1594 and 1617 cm^{-1}. These four absorptions of comparable intensity are consistent with the presence of four nonequivalent sets of H_2O molecules in the crystal. With increasing temperature the four bands underwent shifts to higher frequencies, but there was no obvious indication of a thermally-induced phase transition in the δ(HOH) vs. T plot (Fig. 6). The doublet at the higher frequency (1611.7 and 1616.5 cm^{-1}, respectively) may correspond to H_2O molecules with stronger H-bonding than the doublet at the lower frequency (1594.1 and 1598.0 cm^{-1}). This would be consistent with the normal O(1)—H...phenyl and O(2)—H...phenyl bonds, and with one normal and one bifurcated O—H...phenyl bonds each for O(3) and O(4) (Fig. 3*A*).

In the ν(OD) region of the 10 K spectrum there were five resolved absorptions instead of the expected eight (Fig. 7). Four of these were closely-spaced peaks of equal weight, at 2619.6, 2623.4, 2626.3, and 2631.1 cm^{-1}. The fifth, at 2643.9 cm^{-1}, had an approximately fourfold weight but showed no sign of incipient splitting. However, with increasing temperature this band split into several components. Without a reliable analytic deconvolution (not attempted here) of the composite band the

number of the components could not be established with certitude, but it was at least three and probably four (Fig. 8).

The temperature coefficient $d\nu/dT$ of the ν(OD) frequency was positive for three of the four bands in the lower-frequency quartet but negative for the fourth. For the bands in the higher-frequency group, it was positive for one and negative for the other outer band, and probably positive (or at least not negative) for the inner components. Since $d\nu/dT > 0$ is associated with normal and $d\nu/dT < 0$ with highly bent or branched H-bonds (17), at least five of the eight O—H...phenyl bonds are normal (i.e. essentially straight) and two are highly bent or branched. This is consistent with the crystallographic finding. However, a detailed 1:1 correlation is not possible, partly because the H atoms have not been located with sufficient confidence, partly

because of the progressive loss of definition of the ν(OD) spectrum as the temperature approaches ambient. The reason for the coalescence of the higher-frequency absorptions at 10 K is not understood in structural terms at present. A low-temperature structure determination of LiTBw to match at least some of the low-temperature spectra is planned for a later date.

The above ν(OD) stretching frequencies are among the highest reported for crystalline salt hydrates (13) (the gas-phase ν(OD) of HDO is 2727 cm^{-1}). While direct comparisons cannot be made, it may be noted that the isotopically decoupled ν(ND) stretching and δ(HND) bending frequencies in NH_4BPh_4 (18, 19) which correspond to N—H...phenyl interactions are, respectively, $\nu_1(NH_3D^+)$ = 2363.6(3) amd $\nu_{4bc}(NH_3D^+)$ = 1232.3(3) cm^{-1} at 10 K, and 2362.0(6) and 1234.3(6) cm^{-1} (extrapolated) at 293 K, i.e. close to the estimated "nonbonded" frequencies obtained by extrapolation for the NH_3D^+ in crystals (18).

Ab initio calculations

As pointed out above, the LiO_4 coordination tetrahedron in LiTBw is almost of $S_4 \subset D_{2d}$ symmetry, with the two O—Li—O "valence" angles α equal to 118.3° and 122.5°. The question arises, are these large departures from the tetrahedral angle fortuitous, caused by packing and H-bonding exigencies, or are they essentially intrinsic to the $Li(OH_2)_4^+$ cation and thus to be expected? Further, to what extent can $Li(OH_2)_4^+$ be regarded as a chemical rather than crystallographic entity, i.e. can the Li—O interaction be described as a chemical bond?

To shed some light on these questions, the equilibrium geometry of the $Li(OH_2)_4^+$ ion was optimized at the RHF/STO-3G, 6-31G, and 6-31G* levels (Table 4) . The Li—O distance and the angle α are both seen to increase with the size of the basis set, and their 6-31G* values are comparable to those observed in the crystal (Table 5): the 6-31G* Li—O distance is indistinguishable from the corrected Li—O distance in LiTBw, and the calculated α is equal to the smaller of the two observed α angles, 118.3°. Since 6-31G* optimization usually yields reasonably realistic equilibrium molecular geometries, this agreement between calculation and experiment suggests that the reason for the large α values in the crystal resides in the ion itself.

This finding contrasts strongly with the significant angular distortion of the LiO_4 tetrahedron (of symmetry S_4) in the tetragonal LiUAw (7). Here the distortion is *in the opposite direction:* the O—Li—O angle α bisected by the S_4 axis is *smaller* than the associated O—Li—O angle α′, while the Li—O distance, 1.955(4) Å, is comparable to that in LiTBw: α = 105.1(2)°, α′ = 111.7(2)°. The departure of this α from the tetrahedral angle is −4.4°, but the difference between α(6-31G*) of $Li(OH_2)_4^+$ and the α in LiUAw amounts to +13.4°.

Differences in the angular distortion of this magnitude cannot be glossed over. To strengthen our confidence in the *ab initio* result for $Li(OH_2)_4^+$ we therefore optimized the geometry of the nearest analog of this cation, $Be(OH_2)_4^{2+}$, for which two reliable crystal-structure determinations are available, viz. those of BeSw (8, 9) and BeNw (10). In both salts the symmetry at Be is S_4: in BeSw (neutron diffraction) the H...H vector in the H_2O molecule is inclined by only ~2° to (001), i.e. the cation symmetry is practically D_{2d}. The 6-31G* optimization in D_{2d} symmetry (Table 4) resulted in *d*(Be—O) = 1.643 Å, α = 116.4°, α′ = 106.1°. The uncorrected *d*(Be—O) is 1.618(4) Å in BeSw and 1.616(5) Å in BeNw. the α and α′ angles in BeSw are

117.0(2)° and 105.8(2)°, respectively (Table 5), and 111.5(2)° and 108.5(2)° in BeNw. The anticipated correction for thermal motion would be of the order of 0.02–0.03 Å for the distance and 0.2° for the angle. This would bring the experimental d(Be—O) values in both salts, and the α in BeSw, in good agreement with the 6-31G* value. In BeNw, however, α is considerably smaller than the 6-31G* value.

Closer examination of the LiUAw structure reveals the likely, crystallographic reason for the large distortion. The LiO_4 and AsO_4 tetrahedra are arranged in columns ∥c. In each column the Li and As atoms, on a common S_4 axis, alternate, so that each LiO_4 tetrahedron is sandwiched between two AsO_4^{3-} ions. The water hydrogens are oriented in such a way that one forms a H-bond to an anion oxygen *within* the column, at an O_w..O_w distance of 2.783(5) Å (H(2)...O_{As} = 1.860(4) Å) and an O_w—H(2)—O_{As} angle of 167.5(4)°, while the other forms an O_w—H(1)...O_{As} bond *between* columns, at O_w..O_w = 2.953(6) Å (H(1)...O_w = 1.979(6) Å) and an O_w—H(1)...O_w angle of 161.8(5)°. The O_w—H(1)...O_w bonds are situated in layers ∥(001); the U_{22} of H(1) is large, ~0.15 Å^2. The LiO_4 tetrahedron is thus attached to its two, highly-charged AsO_4^{3-} neighbours by four O_w—H(2)...O_{As} bonds, two of which engage the upper and two the lower anion. These H-bonds are stronger than the lateral, intercolumn O_w—H(1)...O_w bonds. The O_{As}...O_{As} edge of the anion which faces the Li atom is 2.65 Å long, compared to the matching O_w..O_w separation of 3.10 Å. This disparity in length and the skewing of the AsO_4 tetrahedron about S_4 relative to the LiO_4 tetrahedron thus force the H_2O molecules to adopt a compromise orientation which satisfies neither the intra- nor the inter-column H-bonding properly (witness the O—H...O angles and the large U_{22} of H(1)) and which in addition tends to close up the angle α.[7] This situation is thus substantially different from that in LiTBw, where the single charge on the anion is diffuse and the phenyl groups exert only weak additional influence on the H-bonds.

[7]The angular distortion of the AsO_4 tetrahedron is practically the same as that of LiO_4: α = 105.2(1)°, α′ = 111.6(1)°.

In the tetragonal BeSw the Be and S atoms are segregated on different S_4 axes, so that the O_w—H...O_S bonds (O_w—H...O_S ~ 172°) are *between* columns, i.e. lateral. Each H_2O molecule (H—O—H = 112.7°) forms two H-bonds to O_S oxygens. These O_S have the same z but are from two different anion neighbours. Every O_S atom participates in two H-bonds, with the result that the BeSw crystal is completely and three-dimensionally H-bonded. Although the anion is compact and carries a double charge, the overall arrangement in the structure is such that it minimizes, by adjustment of the c/a ratio and of the angle of rotation of the BeO_4 and SO_4 tetrahedra about their respective S_4 axes, the angular distortion of BeO_4 from its "free-ion" geometry in $Be(OH_2)_4^{2+}$. The SO_4 tetrahedron is only slightly distorted.

In BeNw, which too is tetragonal, the O—Be—O angle α is reduced from the free-ion geometry value of 116.4° to 111.5°. This reduction appears to be connected with the layer-type arrangement of the planar NO_3^- ions in sheets ∥(001), at average vertical heights of $n/8$, $n = \pm(1, 5)$, with the Be atoms at $z = 0, \frac{1}{2}$. The O_w—H...O_N bonds are in part in the NO_3^- layers, in part cross-linking them, whereby they connect, laterally, the columns of the cations with the columns of the nitrate ions, again in an exhaustive H-bonding manner.

It would seem that where the H-bonding interaction is weak and not strongly reinforced by ion-charge interaction, and especially when the acceptors are mostly in neighbouring ion columns, the angular distortion of the MO_4 tetrahedron of the $M(OH_2)_4^{n+}$ cation from its free-ion geometry is not severe. This is the case in LiTBw, where the H-bonding and Coulombic interactions are weak, and also in BeSw, for the reasons suggested above. In LiUAw, however, the $Li(OH_2)_4^+$ cation is constrained, by its two AsO_4^{3-} H-bonding partners in the same column, to undergo an angular distortion which not only is significant with respect to the tetrahedral angle but very large with respect to the *ab initio* geometry of the cation. In providing a rationale for the existence of the angular deviations of the LiO_4 and BeO_4 tetrahedra in their respective $M(OH_2)_4^{n+}$ cations in crystals, the above examination of the observed ion geometries reconciles theory with experiment and vindicates the essential

For personal use only.

correctness of the *ab initio* stereochemistry. The agreement of the observed and calculated Li—O and Be—O distances supports the view that the M—OH_2 interaction in the two tetrahydrated M^{n+} ions is chemical in nature and not the result of packing exigencies in the crystal (for the structure and dynamics of these cations in solution see ref. 20).

Experimental

Preparation

The NaCl precipitate that formed on combining acetone solutions of LiCl and $NaBPh_4$ was filtered off. The filtrate was evaporated almost to dryness, the solid was redissolved in acetone and the NaCl residue was filtered off again. This step was repeated twice. The final evaporate was dissolved in water and allowed to crystallize by slow evaporation at room temperature.

X-ray diffraction

Data acquisition

Rigaku AFC5R single-crystal diffractometer, Mo $K\alpha$, λ = 0.71069 Å (graphite monochromator); $T \sim 18$°C. Crystal size, 0.3 × 0.35 × 0.4 mm^3; θ-range, 2–23° (cell dimensions and orientation matrices from 24 reflections); $\mu_{Mo} = 0.70\ cm^{-1}$. Total reflections measured, 3586; unique total, 3422; unique used, 1176 ($I > 3\sigma(I)$), $R_{merg} = 3.9\%$. Like most tetraphenylborates, LiTBw is a weak scatterer (cf. ref. 1).

Crystal data

$BC_{24}H_{28}LiO_4$, fw 398.2. Tetragonal, a = 27.566(2) Å, c = 12.228(2) Å, V = 9291(3) $Å^3$, Z = 16. $F(000)$ = 3392 e, ρ_c = 1.139(1) g/cm^3. Space group, $I4_1/a$ (no. 88). Systematic absences: hkl, $h + k + l$ odd; $hk0$, h, k odd; $0kl$, $k + l$ odd; hhl, l odd; $00l$, $l \neq 4n$; $h00$, h odd; $h\bar{h}0$, h odd.

Structure solution and refinement

Direct methods; programs used, refs. 21–23. Function minimized, $w(|F_o| - |F_c|)^2$; unit weights; d/p = 4.3. Temperature factor, $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$. H(C) atoms placed geometrically and not refined (C—H, 1.08 Å, $U_{iso}(H) = 1.2B_{eq}(C)$); H(O) atoms, see text. $R = 4.7\%$, $R_w = 5.0\%$, G.O.F. = 3.21. Max/min residual electron density in final difference map, $-0.25/0.18\ e^{-3}$.

Tables A (positional parameters and U_{iso} of the H atoms), B (anisotropic thermal parameters of the nonhydrogen atoms), and C (deviations of the C and B atoms from the best planes through the phenyl-ring skeletons and angles between the best planes) have been deposited.[5]

Infrared spectrum

The sample used was authenticated shortly before use by X-ray diffraction. It was then dissolved in 3% D_2O, evaporated to dryness, and mulled in fluorolube. The mull was supported on CaF_2 plates. The spectra, at 2 cm^{-1} resolution, between 10 K and room temperature were obtained using a Bomem DA3.02 FT-ir spectrometer fitted with a closed-cycle He refrigerator.

Ab initio calculations

These were performed using the GAMESS (24) system. When the optimizations of $Li(OH_2)_4^+$ were started in S_4 symmetry, they invariably converged to D_{2d} symmetry. The $S_4 \rightarrow D_{2d}$ convergence was confirmed by a separate optimization directly in D_{2d} symmetry. This was therefore the symmetry adopted from the outset for $Be(OH_2)_4^{2+}$. For previous calculations on $Be(OH_2)_4^{2+}$ see refs. 20, 25, and 26; on hydrated Li^+ species, ref. 27.

Acknowledgements

We wish to thank Mr. Ping Seto for obtaining the FT-ir spectra. This investigation was supported by a Natural Sciences and Engineering Research Council of Canada (NSERC) research grant to O.K.

ELIZABETH A. INNES, IMRE G. CSIZMADIA, JEAN-LOUIS RIVAIL, MICHEL LOOS, and ÁRPÁD KUCSMAN. Can. J. Chem. **72**, 2153 (1994).

Sulfuranes, containing hypervalent or 10 valence electron central sulfur atoms of the type $CH_3(H)SCl_2$ (**I**), $H_2N(H)SCl_2$ (**II**), $HO(H)SCl_2$ (**III**), $(H_2N)_2SCl_2$ (**IV**), and $(HO)_2SCl_2$ (**V**) have been studied by *ab initio* MO computations. All sulfuranes exhibited pseudo trigonal bipyramide structure as appropriate 5 valence electron pairs. The two chlorine atoms were in apical positions and the other two ligands were in equatorial position. The fifth electron pair was a lone pair, also located in an equatorial position. The lone pair "pushed away" the S—Cl bonds from the ideal axis of the trigonal bipyramide and therefore the ClSCl bond angle was always less than 180°. With the changing conformations of the equatorial groups the axial bond lengths are varied. Even though the compounds had constitutionally identical S—Cl bonds at certain torsional angles of the equatory ligands the two S—Cl bond lengths became unequal. The difference between the two bond lengths was used as a measure of the extent of unevenness of the sulfurane structures. This led to the creation and annihilation of certain critical points on the conformational Potential Energy Surfaces.

ELIZABETH A. INNES, IMRE G. CSIZMADIA, JEAN-LOUIS RIVAIL, MICHEL LOOS et ÁRPÁD KUCSMAN. Can. J. Chem. **72**, 2153 (1994).

Utilisant des calculs d'OM *ab initio*, on a étudié des sulfuranes contenant des atomes de soufre nucléaires hypervalents ou à 10 électrons du type $CH_3(H)SCl_2$ (**I**), $H_2N(H)SCl_2$ (**II**), $HO(H)SCl_2$ (**III**), $(H_2N)_2SCl_2$ (**IV**) et $(HO)_2SCl_2$ (**V**). Tous les sulfuranes présentent des structures pseudo-trigonales bipyramidales, comme on peut s'y attendre pour des produits comportant cinq paires d'électrons de valence. Les deux atomes de chlore sont toujours dans les positions apicales et les deux autres coordinats sont dans des positions équatoriales. La cinquième paire d'électrons est une paire libre qui est aussi placée dans une position équatoriale. La paire libre d'électrons déforme les liaisons S—Cl par rapport à l'axe idéal de la bipyramide trigonale; l'angle de la liaison ClSCl est donc toujours inférieur à 180°. Avec les changements dans les conformations des groupes équatoriaux, les longueurs des liaisons axials varient. Même si les composés comportent des liaisons S—Cl qui sont constitutionnellement indentiques, les longueurs des deux liaisons S—Cl deviennent inégales à certains angles de torsion des cooordinats équatoriaux. On a utilisé les différences entre les longueurs des deux liaisons comme mesure des disparités dans les structures des sulfuranes. Ces mesures ont conduit à la création et à l'annihilation de certains points critiques sur les surfaces d'énergie potentielle des conformations.

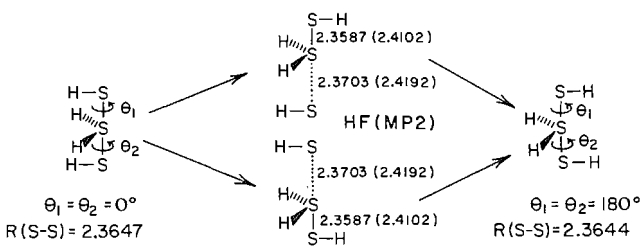
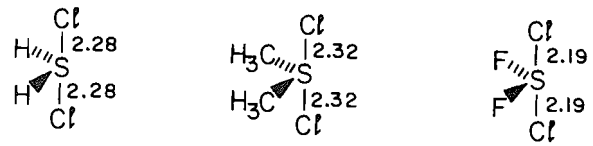
Introduction

We have previously introduced (1) the principle of conformationally induced double degenerate unevenness in sulfuranes using simple model compounds such as HS—SH_2—SH. The unevenness of these constitutionally symmetric sulfuranes is manifested in the two nonequivalent apical bond lengths, shown below, computed at the Hartree–Hock (HF) and Møller–Plesset (MP) levels of theory:



In the above figure, bond lengths (Å) without parentheses are those obtained by HF at a 4-31G* level of theory; bond lengths (Å) in parenthesis are the MP2 results obtained at the same basis set level. (The left- hand side, the central and right-hand side structures are labelled in ref. 1 as **IV**(0_2), **IV**(0_1), and **IV**(0_0) respectively.)

When the *apical* SH groups are replaced by Cl, conformational induction disappears. Replacing the *equatorial* hydrogens by CH_3 or F groups and maintaining the two chlorine atoms in the apical positions resulted in no anomalies (2) as illustrated by the structures below:



The above figure represents gradient optimized geometries for R_2SCl_2 (where R = H, CH_3, and F) obtained (2) at a 3-21G* basis set level. The two S—Cl bond lengths are identical even though no C_{2v} symmetry has been enforced.

However, when NH_2 or OH groups are introduced at the two equatorial positions the preliminary gradient optimized geome-

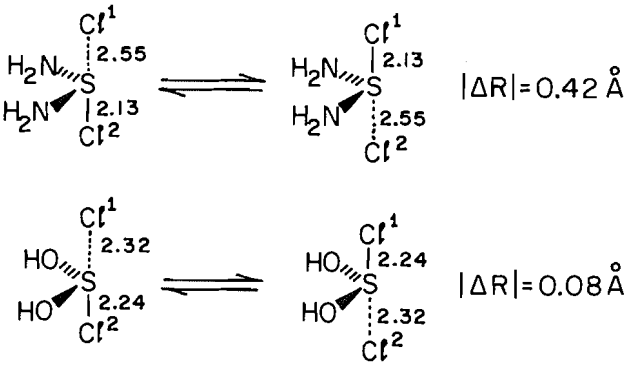
For personal use only.

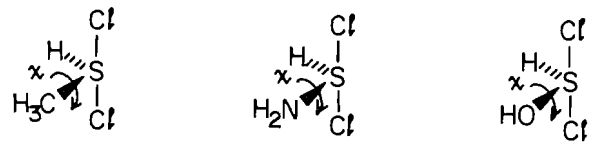
tries (2) showed the existence of doubly degenerate uneven sulfuranes.[1] The extent of unevenness may be measured by the difference of the two apical (S—Cl) bond lengths: $\Delta R = [R(S—Cl^1)] - [R(S—Cl^2)]$.



Results and discussions

These somewhat surprising preliminary results (2) discussed in the introduction, namely, that constitutionally symmetric $(H_2N)_2SCl_2$ and $(HO)_2SCl_2$ have different bond lengths, immediately posed four questions which formed the basis of the present paper. (*1*) Would the same effect emerge if only one equatorial NH_2 (or OH) group were present in the molecule with a rotational angle (χ) about the N—S or O—S bond?[2] (*2*) What is the stereoelectronic basis for the very existence of such uneven structures for constitutionally symmetric molecules? (*3*) Is the effect of equatorial CH_3 groups fundamentally different from those of equatorial NH_2 and OH groups? (*4*) In the case of two equatorial NH_2 (or OH) groups what features does the conformational potential energy surface (PES), such as $E = E(\chi_1, \chi_2)$, have? Note that χ_1 and χ_2 are the two S—N (or S—O) rotational angles.

The first three questions can be answered by studying the following compounds:



Typical conformations of **I**, **II**, and **III** with varying χ values are shown in Scheme 1 below. (Note that in the case of **III** only the "hybridized" lone pair with directionality is shown. The other, orthogonal, canonical lone pair, analogous to the unhybridized 2*p* on oxygen is not shown.)

The variation of the total molecular energy (*E*), typical bond lengths, and bond orders (BO) (3) with the rotational angle (χ) about the C—S, N—S or O—S bonds are shown in Fig. 1 for $H_3C(H)SCl_2$ (**I**), $H_2N(H)SCl_2$ (**II**), and $HO(H)SCl_2$ (**III**) having two chlorine atoms in the apical positions. This figure clearly illustrates the following variation in average equatorial bond orders: BO(C—S) < BO(N—S) ≈ BO(O—S). Furthermore, in the case of **II** and **III**, at certain χ values the BO of the two apical S—Cl bonds were computed to be quite different, while in the case of **I** these two S—Cl BO values remained very close to each other. Thus the conformational induction effect of the CH_3 group is present but it is not so pronounced. For the N—S and O—S bonds, however, the larger BO corresponds to a conjugative amplification of this effect. The principal geometrical parameters of **I**, **II**, and **III** as functions of rotation about the S—CH_3, S—NH_2, and S—OH bonds are listed in Tables 1, 2, and 3, respectively. It should perhaps be emphasized that the ClSCl bond angle is changing with conformational change but is always smaller than 180°. In view of the above results we may answer the first three questions.

(*1*) The effect is present even if only one heteroatom (N or O) is located in an equatorial position. However, in the case of one NH_2, the unevenness ($|\Delta R| > 0$) does not occur at the minimum energy conformation.

(*2*) At certain χ values in **II** and **III** the two chlorine atoms

OH(180)	2.273	2.276	168.147

[1]Preliminary gradient optimized geometries for X_2SCl_2 (where X = NH_2 or OH) obtained by HF at a 3-21G* basis set level. Each constitutionally identical pairs show the double degeneracy of the sulfurane structure as defined in ref. 1.

[2]The rotational angles were defined analogously to the torsional angles specified in the IUPAC convention but not with respect to the XSX (X = C, N, O) planes. Rather it was defined with respect to the bisecting plane of the ClSCl bond angle. Thus our rotational angles are related to the conventional torsional angles and they are identical at 0°, ±90°, ±180° but differ slightly at the in-between regions.

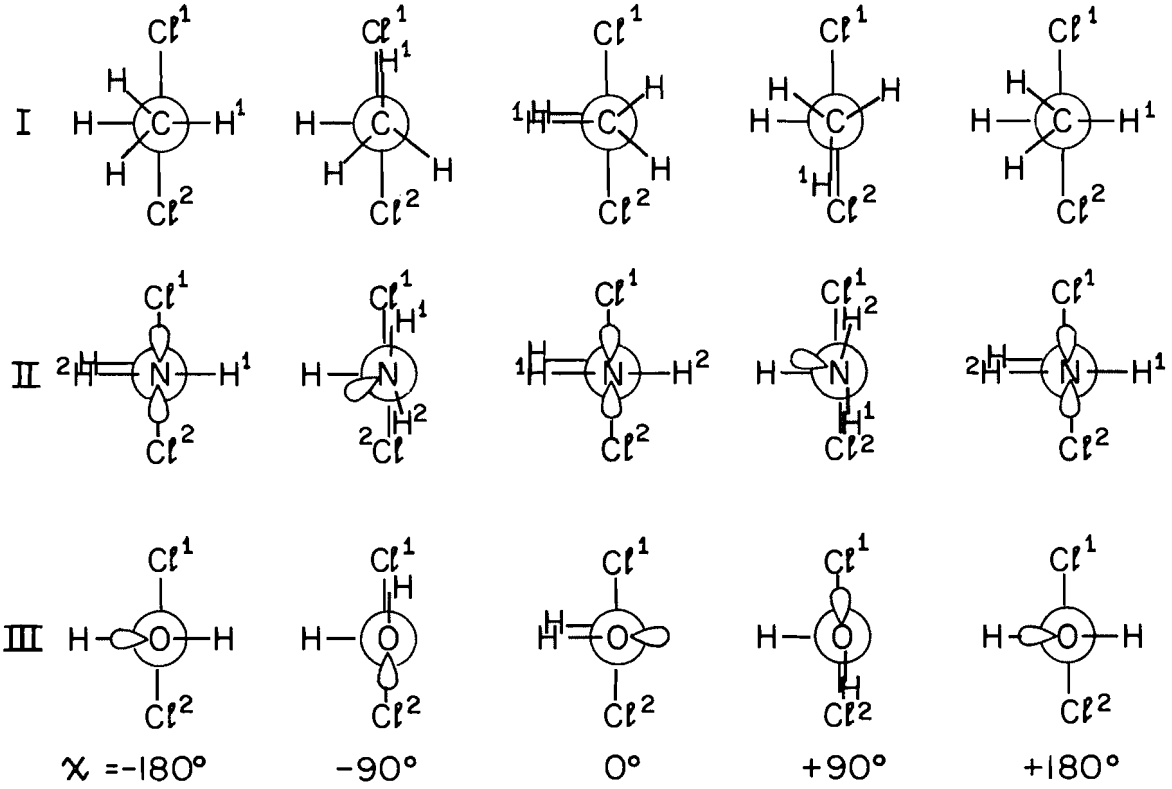

SCHEME 1

become nonequivalent. If such conformations also favour a stereoelectronic effect, i.e. the formation of a partial double bond between N—S or O—S, then this bond strengthening in the equatorial plane amplifies the S—Cl bond stretch along a nearly orthogonal direction. (*a*) In the case of oxygen (**III**) the partial double bond formation and coupled S—Cl bond stretch occurs when the minimum energy conformation is reached. In this particular conformation one of the oxygen lone pairs is in alignment with the σ* S—Cl orbital for a favourable stereoelectronic interaction. Consequently, at this conformation ($\chi \approx 90°$) the BO for the C—S bond, one of the S—Cl bonds, is shorter with a maximum BO while the other S—Cl bond is longer with a minimum BO. (*b*) The changing pyramidality of nitrogen with the varying rotational angle (χ) makes the situation more complicated for **II**. At the minimum energy conformation ($\chi \approx 90°$) the N—S BO is minimum. This may be expected since the lone pair of the slightly pyramidal N is nearly orthogonal to Cl—S—Cl line, thus there is no chance for partial double bond formation. However, at the rotational angle $\chi = 180°$ the N becomes fully planar and its lone pair is evenly distributed towards the top and bottom apical S—Cl bonds. Consequently, the two S—Cl bonds become identical, with a modest stretch, since partial double bond formation is now possible.

(*3*) The equatorial CH_3 group is able to carry out conformational induction but this induction is not amplified further conjugatively because this ligand cannot form a partial C—S double bond. Consequently, the overall effect is very small amounting to nothing more than hyperconjugation (ΔR = 0.0093 Å at $\chi = -90°$ for **I**, however for **III** the ΔR value is about 40 times larger: ΔR = 0.3871 Å at $\chi = -96.35°$).

In order to answer the last question the PES, $E = E(\chi_1, \chi_2)$, had to be explored. Considering the PES of $(H_2N)_2SCl_2$ (**IV**) and $(HO)_2SCl_2$ (**V**) it is prudent to start with a prediction of the ideal surface with the aid of multidimensional conformational analysis or MDCA (4) as it has also been applied in a previous article concerning uneven sulfuranes (1). The indices of the critical points for **IV** and **V** are given in the central column and at the top of Fig. 2.

Since the topological periodicities of the component model potential energy curves for NH_2 and OH were 2 (which may be inferred from Fig. 2 as 1–0–1–0–1) the idealized surface for each case had $2 \times 2 = 4$ minima. Consequently, the number of minima (N_0), the number of saddle points (N_1) and the number of maxima (N_2) obeyed the following alternating sum rule:

$$N_0 - N_1 + N_2 = 0$$
$$4 - 8 + 4 = 0$$

However, due to the excessive interaction between the geminal NH_2 (or geminal OH) groups the idealized surfaces are substantially modified. In the case of **IV** each minimum (labelled as 0) is split up to two minima and a saddle point (labelled as 1) in between. In the case of **V** two saddle points and a minimum collapsed into one saddle point according to the previously recognized (5) selection rules. Consequently, the alternating sum rule for the computed PES assumed the following form:

	$N_0 - N_1 + N_2 = 0$
$(H_2N)_2SCl_2$	$8 - 12 + 4 = 0$
$(HO)_2SCl_2$	$2 - 6 + 4 = 0$

The computed surfaces for the two compounds (shown at the right hand side column of Fig. 2) clearly indicate eight degen-

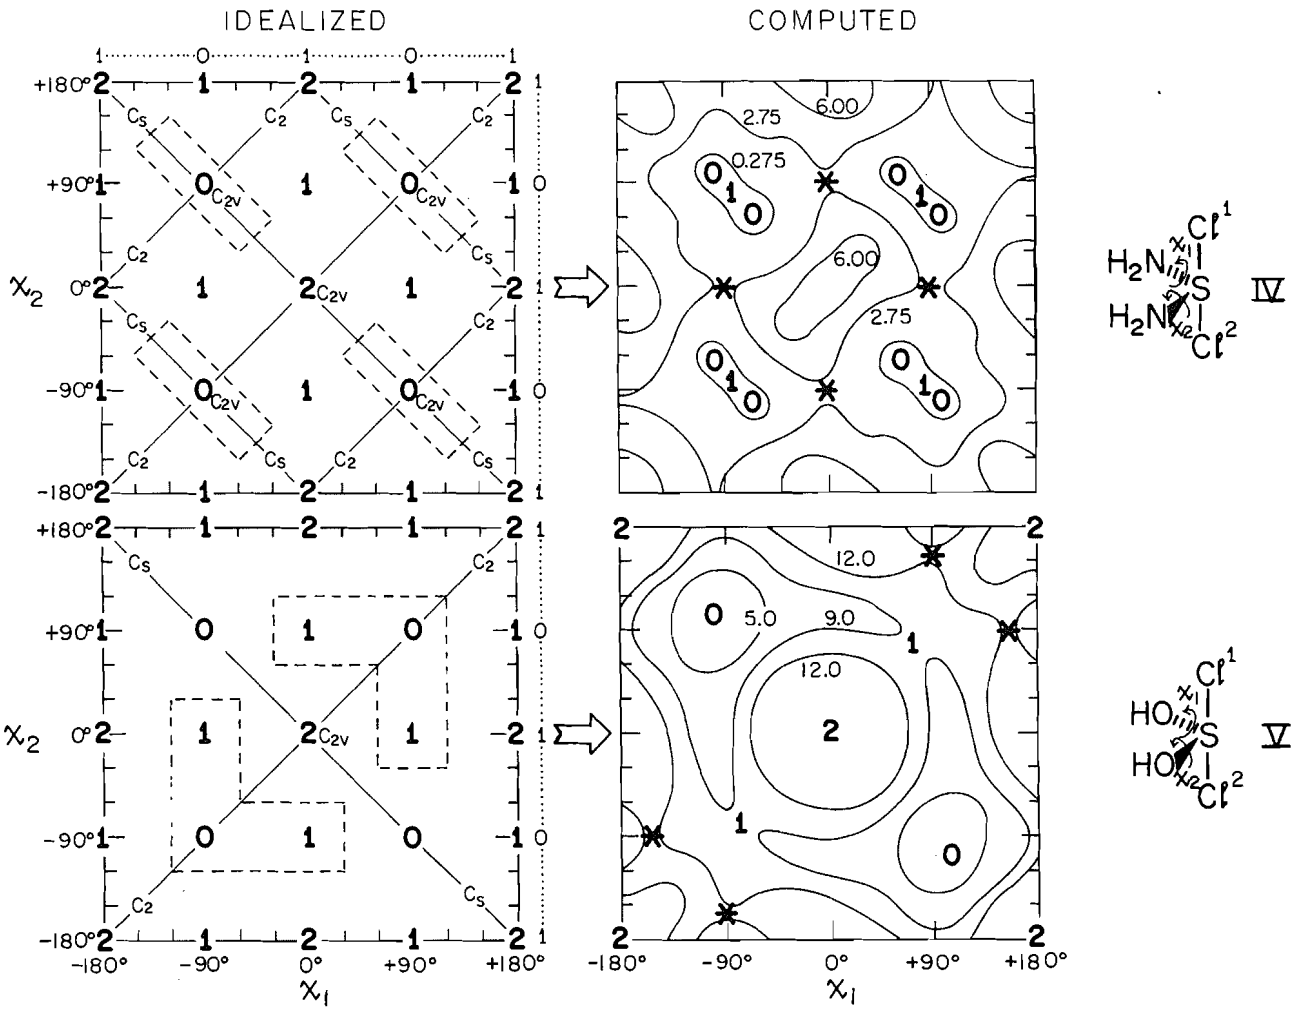

FIG. 2. Topology of the conformational PES, $E = E(\chi_1, \chi_2)$, of $(H_2N)_2SCl_2$ (**IV**) and $(HO)_2SCl_2$ (**V**). At the left hand side the idealized surfaces are given as predicted from the component potential energy curves, $E = E(\chi)$, presented in the lower part of Fig. 1. At the left hand side the location of the critical points, predicted by MDCA, are specified by the index of the critical points (**0** for minima, **1**, for saddle points, and **2** for maxima). At the right hand side, the location of only those critical points that have been determined by gradient optimization are indicated by their index. (An * marks the anticipated location of each of those saddle points that were not gradient optimized.)

erate catchment regions (6) for **IV** and two degenerate catchment regions (6) for **V**. Typical conformations of **IV** and **V** with varying χ_1 and χ_2 values are shown in Scheme 2 and the main geometrical parameters for compounds **I** and **V** are summarized in Table 4.

It is interesting to note that there is constant shift in geometry, away from the idealized minimum energy conformations. Although this can be seen qualitatively in Fig. 2, it is summarized quantitatively in Tables 5 and 6.

In closing, it should be mentioned that several uneven structures of constitutionally symmetric sulfuranes have been reported (cf. ref. 7). However, as pointed out by Volatron and Eisenstein (8) these observations have been attributed to the anisotropy of crystal packing.

The rate constants for the reactions of horseradish peroxidase compound I (k_1) and compound II (k_2) with three 4-substituted arylboronic acids, which enhance chemiluminescence in the horseradish peroxidase catalyzed oxidation of luminol by hydrogen peroxide, were determined at pH 8.6, total ionic strength 0.11 M, using stopped-flow kinetic measurements. For comparison, the rate constants of the reactions of 4-iodophenol with compounds I and II were also determined under the same experimental conditions. The three arylboronic acid derivatives and their rate constants are: 4-biphenylboronic acid, $k_1 = (1.21 \pm 0.08) \times 10^6\ M^{-1}\ s^{-1}$, $k_2 = (4.6 \pm 0.2) \times 10^5\ M^{-1}\ s^{-1}$; 4-bromophenylboronic acid, $k_1 = (5.5 \pm 0.2) \times 10^4\ M^{-1}\ s^{-1}$, $k_2 = (3.6 \pm 0.2) \times 10^4\ M^{-1}\ s^{-1}$; and 4-iodophenylboronic acid, $k_1 = (1.1 \pm 0.2) \times 10^5\ M^{-1}\ s^{-1}$, $k_2 = (1.3 \pm 0.1) \times 10^4\ M^{-1}\ s^{-1}$. 4-Biphenylboronic acid, which shows comparable luminescent enhancement to 4-iodophenol, has the highest reactivity in the reduction of both compounds I and II among the three arylboronic acid derivatives tested.

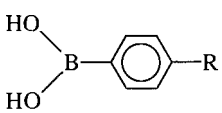
WEIMEI SUN, XIAOYING JI, LARRY J. KRICKA et H. BRIAN DUNFORD. Can. J. Chem. **72**, 2159 (1994).

Opérant à un pH de 8,6 et un force ionique totale de 0, 11 M et faisant appel à des techniques de mesures cinétiques à flux stoppé, on a déterminé les constantes de vitesse des réactions des composés I (k_1) et II (k_2) de la peroxydase du raifort avec trois acides arylboroniques substitués en position 4 qui augmentent la chimiluminescence de l'oxydation, catalysée par la peroxydase du raifort, du luminol par le peroxyde d'hydrogène. Pour fins de comparaison, on a aussi déterminé les constantes de vitesse des réactions du 4-iodophénol avec les composés I et II dans les mêmes conditions expérimentales. Les trois dérivés d'acides arylboroniques et leurs constantes de vitesse sont : acide 4-biphénylboronique, $k_1 = (1{,}21 \pm 0{,}08) \times 10^6\ M^{-1}\ s^{-1}$, $k_2 = (4{,}6 \pm 0{,}2) \times 10^5\ M^{-1}\ s^{-1}$, acide 4-bromophénylboronique, $k_1 = (5{,}5 \pm 0{,}2) \times 10^4\ M^{-1}\ s^{-1}$, $k_2 = (3{,}6 \pm 0{,}2) \times 10^4\ M^{-1}\ s^{-1}$ et acide 4-iodophénylboronique, $k_1 = (1{,}1 \pm 0{,}2) \times 10^5\ M^{-1}\ s^{-1}$, $k_2 = (1{,}3 \pm 0{,}1) \times 10^4\ M^{-1}\ s^{-1}$. Parmi les trois dérivés de l'acide arylboronique qui ont été examinés, l'acide 4-biphénylboronique, qui présente une augmentation de la luminescence comparable à celle du 4-iodophénol, est le plus réactif dans la réduction des composés I et II.

[Traduit par la rédaction]

Introduction

Recently, certain arylboronic acid derivatives have been shown to function as enhancers in the chemiluminescent horseradish peroxidase (HRP) catalyzed oxidation of luminol (1). The most potent enhancers are 4-bromo-, 4-iodo-, and 4-biphenylboronic acids. The structures of the biphenyl and phenyl compounds are as follows:



where R = Br, I, or phenyl. These compounds increase the light emission in the HRP-catalyzed reaction of luminol by >10-fold and also reduce the background light emission from the luminol–peroxide assay reagent. The light emission increases rapidly during a 1–5 min period depending upon the enhancer used, and then decays slowly over a 30–60 min period. Previously other compounds that are enhancers have been discovered and these include substituted phenols, naphthols, aromatic amines, and benzothiazoles (2–7). The phenolic enhancers have been most extensively studied and a mechanism for the enhancement proposed (8). It involves a preferential and rapid reaction of the phenol with compound I and compound II to form phenoxyl radicals. These then react with luminol to form luminol radicals, which react further in a light-generating reaction.

The rate constants for the reaction of luminol and a series of enhancers with compound I (k_1) and compound II (k_2) have been measured and, in accordance with the proposed mechanism, the rate constants for the enhancers are higher than the rate constants for luminol (e.g., luminol, $k_1 = 2.3 \times 10^6\ M^{-1}\ s^{-1}$ and $k_2 = 7.2 \times 10^4\ M^{-1}\ s^{-1}$; 4-iodophenol, $k_1 = 5.5 \times 10^6\ M^{-1}\ s^{-1}$ and $k_2 = 4.0 \times 10^6\ M^{-1}\ s^{-1}$) (9–11).

In this study we have determined the rate constants for selected 4-substituted arylboronic acids with HRP compounds I and II in order to determine if the mechanism of enhancement is similar to that with phenols.

Experimental

Horseradish peroxidase (type VI-A) was obtained from Sigma Chemical Co. The concentration of the enzyme solution was determined spectrophotometrically at 403 nm using a molar absorptivity of $1.02 \times 10^5\ M^{-1}\ cm^{-1}$ (12). The purity number (A_{403nm}/A_{280nm}) of the enzyme solution was 3.1. The concentration of H_2O_2, obtained from BDH Chemicals, was determined after appropriate dilution using the horseradish peroxidase assay (13). *p*-Cresol was obtained from J.T. Baker Chemical Co. and its concentration was determined by weight.

Luminol	2.3×10^6 (at pH 8.0)[a]	7.2×10^4 (at pH 8.0)[a]

[a]See ref. 10.

4-Biphenylboronic acid was from Aldrich, and 4-bromophenylboronic acid was from Lancaster. 4-Iodophenylboronic acid was synthesized by Cookson Chemicals Ltd., Southampton.

For each substrate, a stock solution of around 2.5 mM concentration was prepared by dissolving a weighed amount of the compound in a small amount of dimethyl sulfoxide (DMSO, < 200 μL) and then in a certain volume of deionized water. All substrate solutions were stored in dark brown bottles to prevent photochemical reactions. The substrate solution for each experiment was then made by diluting the stock solution to the desired concentration with Tris–HCl buffer, ph 8.6, just before the measurement.

0.1 M Tris(hydroxymethyl)methylamine–HCl buffer at pH 8.6 and 0.01 M tris(hydroxymethyl)methylamine–HCl buffer at pH 9.1 were prepared. The ionic strengths of the buffers were 0.01 M and 0.001 M, respectively. Analytical grade reagent K_2SO_4, obtained from AnalaR, was used to keep the total ionic strength of the solutions at 0.11 M. A Fisher Scientific Accumet pH meter 25 was used for pH measurements.

All solutions were prepared using water purified by a Milli-Q water purification system from Millipore.

HRP-I, stable for 6 min, was prepared by the addition of 1 equivalent of H_2O_2 to the native enzyme in deionized water of ionic strength 0.11 M by adding K_2SO_4 as an inert salt. HRP-II, stable for at least 10 min, was prepared in 0.01 M Tris-HCl buffer of pH 9.1 by adding 1 equivalent of H_2O_2 and 0.5 molar equivalent of *p*-cresol to the native enzyme solution. Optical spectra of native enzyme, HRP-I, and HRP-II were recorded on a Beckman DU 650 spectrophotometer. The stability of the HRP-I and HRP-II solutions was confirmed each day before the stopped-flow experiments.

The stopped-flow measurements were made using a Photal Rapid Reaction Analyzer model RA-601 equipped with a 1-cm observation cell. Experimental curves were recorded and stored in the computer interfaced to the rapid reaction analyzer. A pH-jump method was used for all stopped-flow experiments to attain the final pH of 8.6.

For measurement of rate constants involving HRP-I, one cuvette contained stable HRP-I in deionized water, pH 5.7, ionic strength 0.11 M by adding K_2SO_4; the other cuvette contained substrate in 0.1 M Tris–HCl buffer, pH 8.6, total ionic strength 0.11 M. After the two solutions were mixed, the final pH was 8.6. The HRP-I reactions were monitored at 412 nm, the isosbestic point between native enzyme and HRP-II (14).

For measurement of rate constants involving HRP-II, one cuvette contained stable HRP-II in 0.01 M Tris–HCl buffer, pH 9.1, total ionic strength 0.11 M; the other cuvette contained substrate in 0.1 M Tris–HCl buffer, pH 8.6, total ionic strength 0.11 M. After the mixing of the two solutions, the final pH was 8.6. The HRP-II reactions were monitored at 430 nm, the isosbestic point between native enzyme and HRP-I (14).

The enzyme concentration for all kinetic measurements was 1 μM. At least at 10-fold excess of substrate was used to maintain pseudo-first-order conditions. Six to eight traces were collected for each substrate concentration. Measurements of relative absorbance at regular time intervals from the recorded exponential traces followed by a nonlinear least-squares analysis gave the observed pseudo-first-order rate constants (k_{obs}). The mean value of k_{obs} obtained from the recorded traces was taken. The linear slope of the plot of k_{obs} versus substrate concentration gives the apparent second-order rate constant (k_{app}).

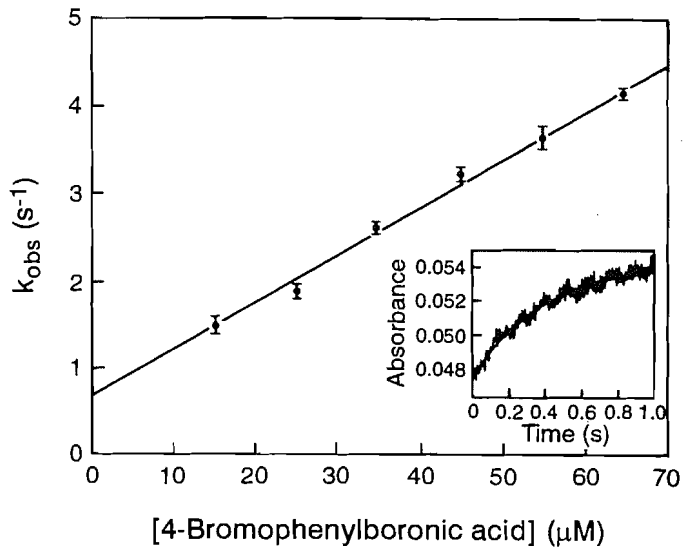

FIG 1. Plot of k_{obs} versus 4-bromophenylboronic acid concentration for the oxidation of 4-bromophenylboronic acid by horseradish peroxidase compound I. The reactions were carried out in Tris–HCl buffer, pH 8.6, ionic strength 0.11 M; [HRP-I], 1.0 μM. The inset shows an example of first-order exponential trace monitored at 412 nm (35 μM 4-bromophenylboronic acid) followed by a nonlinear least-squares analysis from which k_{obs} was obtained.

The pH dependence of light emission of the 4-biphenylboronic acid enhanced chemiluminescent oxidation of luminol catalyzed by horseradish peroxidase was determined as follows. Luminol–hydrogen peroxide reagents were prepared in different Tris buffer (0.1 M, pH 7.58, 8.10, 8.58, 9.12, 9.26). Sodium luminol (12.5 mg) was dissolved in 50 mL of the buffer, 15.5 μL of hydrogen peroxide (30% w/v) was mixed with 0.5 mL of the same buffer, and these two solutions were combined and protected from light. Stock solutions of 4-biphenylboronic acid (20 mM in DMSO) and HRP (1 mg/mL in 0.1 M Tris buffer) were diluted in Tris buffer (0.1 M, pH 8.58). The luminol–hydrogen peroxide reagent (100 μL), 4-biphenylboronic acid (10 μL, 1 mM), and HRP (10 μL, 20 ng/mL) were mixed in a microwell and light emission intensity was measured in a mL-3000 luminometer (Dynatech Laboratories Inc, Chantilly, Va).

Results

Determination of the rate constants of the reactions involving HRP-I

With substrate in excess of HRP-I, pseudo-first-order kinetics was observed. An example is shown in the inset of Fig. 1. The corresponding differential expression is

$$[1] \quad -d[\text{HRP-I}]/dt = k_{obs}[\text{HRP-I}]$$

where k_{obs} is the observed pseudo-first-order rate constant. The

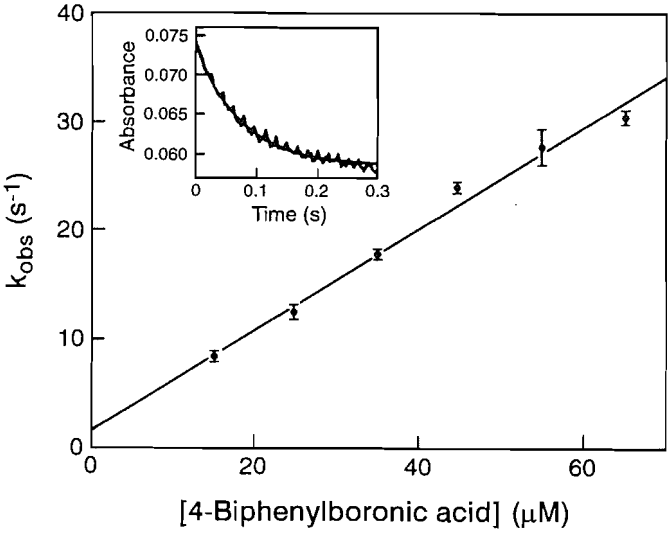

FIG 2. Plot of k_{obs} versus 4-biphenylboronic acid concentration for the oxidation of 4-biphenylboronic acid by horseradish peroxidase compound II. The reactions were carried out in Tris–HCl buffer, pH 8.6, ionic strength 0.11 M; [HRP-II], 1.0 μM. The inset shows an example of first-order exponential trace monitored at 430 nm (25 μM 4-biphenylboronic acid) followed by a nonlinear least-squares analysis from which k_{obs} was obtained.

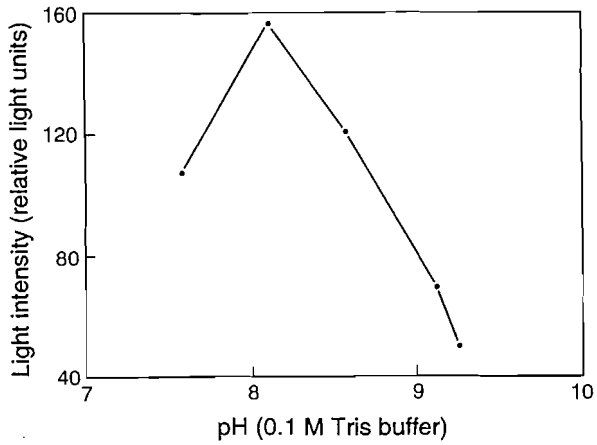

FIG 3. pH dependence of light emission of the 4-biphenylboronic acid enhanced chemiluminescent oxidation of luminol catalyzed by horseradish peroxidase. Luminol–hydrogen peroxide reagents were prepared in different Tris buffers (0.1 M, pH 7.58, 8.10, 8.58, 9.12, 9.26) by mixing two solutions of 12.5 mg of sodium luminol in 50 mL of the buffer and 15.5 μL of 30% (w/v) hydrogen peroxide in 0.5 mL of the same buffer. Stock solutions of 4-biphenylboronic acid and HRP were diluted in Tris buffer (0.1 M, pH 8.58). After mixing 100 μL of the luminol–hydrogen peroxide reagent with 10 μL of 1 mM 4-biphenylboronic acid and 10 μL of 20 ng/mL HRP in a microwell, the light emission intensity was measured.

apparent second-order rate constant, k_{app}, is related to k_{obs} by the equation

[2] $k_{obs} = k_{app}[\text{substrate}]$

Values of k_{app} were obtained from the slopes of plots of k_{obs} versus substrate concentration, as shown by an example in Fig. 1. The intercept in Fig. 1 is zero, within experimental error. The apparent second-order rate constants for the reactions of HRP-I with 4-biphenylboronic acid, 4-bromophenylboronic acid, 4-iodophenylboronic acid, and 4-iodophenol are listed in Table 1.

Determination of the rate constants of the reactions involving HRP-II

One example is shown in the inset of Fig. 2. The corresponding differential rate expression is

[3] $-\text{d[HRP-II]} / \text{d}t = k_{obs}[\text{HRP-II}]$

and the apparent second-order rate constant, k_{app}, is related to k_{obs} by eq. [2]. Values of k_{app} were then obtained from the slopes of plots of k_{obs} versus substrate concentration, as shown by an example in Fig. 2. The intercept in Fig. 2 is zero, within experimental error. The apparent second-order rate constants for the reactions of HRP-II with 4-biphenylboronic acid, 4-bromophenylboronic acid, 4-iodophenylboronic acid, and 4-iodophenol are collected in Table 1.

The pH dependence of light emission intensity from the 4-biphenylboronic acid enhanced reaction is shown in Fig. 3.

Discussion

It was observed that the light emission in the HRP-catalyzed reaction of luminol was at its maximum at pH 8.6 in the presence of certain phenols and therefore this pH was chosen for the comparison with the arylboronic acid derivatives (1). The rate constants of the reactions of three 4-substituted arylboronic acids with HRP-I and HRP-II were therefore measured at this pH.

The rate constants of the reactions of HRP-I and HRP-II with 4-iodophenol were determined previously by Hodgson and Jones (9), and are $k_1 = 5.5 \times 10^6\ M^{-1}\ s^{-1}$ and $k_2 = 4.0 \times 10^6\ M^{-1}\ s^{-1}$ at pH 7.0, ionic strength 0.11 M. The effect of pH on the rate constants was also measured (9). The HRP-I reaction rate with 4-iodophenol shows a pH-independent phase in the pH range of 7.0–8.7 followed by a decrease at pH higher than 8.7, whereas the log of the rate constant for the HRP-II reaction, plotted versus pH, has a slope of –1 in the pH range of 7–10. In the present study, we determine values of the rate constants at pH 8.6 as follows: $k_1 = 5.6 \times 10^6\ M^{-1}1\ s^{-1}$, which is the same within experimental error as that at pH 7.0, and $k_2 = 1.8 \times 10^6\ M^{-1}\ s^{-1}$, which is smaller, as expected, than the value at pH 7.0. Our data for 4-iodophenol thus are in accord with the data previously reported (9).

The rate constant for the reaction of 4-biphenylboronic acid with HRP-I is of the same order of magnitude as that for 4-iodophenol, whereas the bromo and iodo derivatives have lower reactivities. All three boronic acids have lower reactivities towards HRP-II than 4-iodophenol, again with the bromo and iodo derivatives slower than biphenylboronic acid (Table 1).

The pK_a value of 4-iodophenol is 9.22 (15). Therefore, the percentage of 4-iodophenol in its ionized form is 19.4% at pH 8.6. The pK_a values of 4-biphenylboronic acid (in 50% EtOH) and 4-bromophenylboronic acid (in 52% EtOH) are 10.80 and 9.14, respectively (16, 17). According to these pK_a values, the approximate percentage of the compounds in their ionized forms at pH 8.6 is about 0.63% for 4-biphenylboronic acid and 22.4% for 4-bromophenylboronic acid.

The data at pH 8.6 would appear to indicate that if the arylboronic acid is unionized there is greater enhancement. However, at lower pH there is a smaller percentage of ionization of the arylboronic acids and luminescence enhancement is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

reduced (Fig. 3). An explanation for the pH dependence of the HRP-catalyzed luminescent reactions can be found in a pulse radiolysis study of aqueous luminol reactions (18) and in the numerous pH-dependent studies of HRP-II reactions (19).

Several key rate constants in the luminol reactions leading to light emission were measured in the pulse radiolysis study of Lind et al. (18). The pH dependence of the formation of a hydroperoxide intermediate from the luminol diazasemiquinone radical roughly parallels the pH dependence of light emission, which reaches a plateau value at ~pH 10. Thus the radiation-induced luminescence is strongest at high pH. HRP-II reactions are dependent upon a key acid–base group in the active site which has a pK_a value of 8.6 (19). If this group is protonated HRP-II is reactive; if it is deprotonated HRP-II is totally unreactive. Thus for the HRP-catalyzed reaction, at low pH luminescence intensity is low because of the luminol chemistry, and at very high pH it is low because the enzyme cycle is blocked by the accumulation of unreactive HRP-II. In the vicinity of pH 8.6 conditions are optimal because HRP-II is reactive and there is sufficient accumulation of diazasemiquinone radicals.

Thus although the pH dependence of the HRP–luminol reaction can be explained, the mechanistic details of the effect of arylboronic acid enhancers is less clear. Hodgson and Jones (9) noted that the best phenolic luminescent enhancer in the HRP-catalyzed light-emitting reaction, 4-iodophenol, reacts more rapidly than predicted by the Hammett $\rho\sigma$ correlation for phenols (20–23) and also exhibits a nontypical pH–rate profile. They suggest that because of the enhanced reactivity of 4-iodophenol, free radicals formed from it attack unreacted luminol, enhancing the production of luminol semiquinone radicals and thus enhancing chemiluminescence. On the other hand, Vlasenko et al. examine the possibility that the enhancer facilitates a higher steady concentration of HRP-I that in turn facilitates greater reactivity of luminol (11). They conclude that the latter possibility does not lead to a large enough enhancement.

4-Biphenylboronic acid causes a greater luminescence enhancement than that of 4-iodophenol, yet the rate constant for the reaction of 4-biphenylboronic acid with HRP-I is smaller than that for 4-iodophenol; and with HRP-II it is much smaller. Unlike 4-iodophenol, the rate constants for the arylboronic acid type enhancers are not much higher than the rate constants for luminol (Table 1). Therefore, it appears that the arylboronic acid derivatives may have a different mechanism of enhancement from that for phenolic enhancers.

Lewis acid catalyzed Diels–Alder reactions of two useful dienyl phosphate esters[1]

HSING-JANG LIU, WAISENG MARTIN FENG, JEUNG BEA KIM, AND ERIC N.C. BROWNE[2]

Department of Chemistry, The University of Alberta, Edmonton, AB T6G 2G2, Canada

Received June 1, 1994

HSING-JANG LIU, WAISENG MARTIN FENG, JEUNG BEA KIM, and ERIC N.C. BROWNE. Can. J. Chem. **72**, 2163 (1994).

The Lewis acid catalyzed Diels–Alder reactions of dienyl phosphate esters **1** and **2** were examined. 2-Diethylphosphoryloxy-1,3-butadiene (**1**) was found to react with a variety of α,β-unsaturated carbonyl compounds under Lewis acid catalysis with excellent regioselectivity to give synthetically useful cyclohexene derivatives. The adducts were produced in accordance with the normal rules governing the Diels–Alder addition. In the presence of stannic chloride acyclic α,β-unsaturated ketones such as ethyl vinyl ketone and methyl vinyl ketone reacted rapidly with diene phosphate **1** to give exclusively the *para*-addition products **8** and **9** in excellent yields. When diene **1** was treated with the complex cyclic enone ester **14** in the presence of ferric chloride the single *para*-rule adduct **15** was obtained in good yield. The stannic chloride catalyzed Diels–Alder reactions of *trans*-2-diethylphosphoryloxy-1,3-pentadiene (**2**) were also studied. Diene phosphate **2** reacted efficiently with a number of acyclic α,β-unsaturated ketones such as methyl vinyl ketone, ethyl vinyl ketone, and *trans*-3-penten-2-one with complete regio- and stereoselectivity to give single cyclohexene derivatives **38**, **39**, and **40**.

HSING-JANG LIU, WAISENG MARTIN FENG, JEUNG BEA KIM et ERIC N.C. BROWNE. Can. J. Chem. **72**, 2163 (1994).

On a étudié les réactions de Diels–Alder catalysées par les acides de Lewis des esters **1** et **2**, phosphates de diényle. On a trouvé que, sous catalyse par les acides de Lewis, le 2-diéthylphosphoryloxybuta-1,3-diène (**1**) réagit avec une variété de composés carbonylés α,β-insaturés avec une excellent régiosélectivité pour conduire à des dérivés du cyclohexène qui sont utiles en synthèse. Les adduits se produisent selon les règles normales gouvernant les additions de Diels–Alder. En présence de chlorure stannique, les cétones α,β-insaturées, telles que l'éthyl vinyl cétone et la méthyl vinyl cétone, réagissent rapidement avec le phosphate diénique **1** pour donner exclusivement les produits d'addition *para*, **8** et **9**, avec d'excellents rendements. Lorsqu'on traite le diène **1** avec l'ester cyclohexénonique complexe **14**, en présence de chlorure ferrique, seul l'adduit *para*, **15**, a été obtenu avec un bon rendement. On a aussi étudié les réactions de Diels–Alder catalysées par le chlorure stannique du *trans*-2-diéthylphosphoryloxybuta-1,3-diène (**2**). Le phosphate diénique **2** réagit d'une façon efficace avec un certain nombre de cétones α,β-insaturées, telles que la méthyl vinyl cétone, l'éthyl vinyl cétone et la *trans*-pent-3-én-2-one, avec des régio- et stéréosélectivités complètes pour donner uniquement les dérivés cyclohexéniques **38**, **39** et **40**.

[Traduit par la rédaction]

Introduction

In the past decade Diels–Alder reactions of heterosubstituted 1,3-dienes with dienophiles have increasingly been developed as valuable methods for the synthesis of highly functionalized ring systems. Recent advances in the comprehension of electronic and steric effects governing this reaction[3] have been accompanied by the use of new specifically functionalized dienes and dienophiles to produce hitherto unattainable substitution patterns both regioselectively and stereoselectively.[4] The introduction of one or more hetero substituents on the diene invariably has an effect on the regiochemistry of the cycloaddition and permits further transformations of the adducts that take advantage of the relationship between the hetero substituents and the newly formed carbon–carbon double bonds. For example silyloxy-substituted butadienes (13–15) have come into widespread use in natural product syntheses. Unfortunately, these types of dienes and the cycloaddition products derived from them are rather labile under acidic or basic conditions, or even in polar solvents.

In a practical sense, the instability of these compounds is sometimes a serious problem in the Diels–Alder reaction as well as in further transformations of the adducts. On the other hand, enol phosphates are significantly more stable while retaining a high degree of synthetic versatility. 2-Diethylphosphoryloxy-1,3-butadiene (**1**) has been found (28, 29) to be an oxygen-substituted diene of unusual stability. Liu and Ngooi have used the analogue *trans*-2-diethylphosphoryloxy-1,3-pentadiene (**2**) to add to 2-carbomethoxy-2-cyclohexen-1-one (**3**) with excellent stereoselectivity in the synthesis (30, 31) of petasitolone (**4**) *via* adduct **5**. In the same study they also found that the addition of *trans*-2-trimethylsilyloxy-1,3-pentadiene (**6**) to the dienone ester **3** gave the corresponding adduct as a mixture of degradation products, the two epimeric diketones **7**, in much poorer yield (31, 32). The diketones **7** apparently result from hydrolysis of the expected Diels–Alder adducts under the reaction conditions.

Dienyl phosphates such as **1** and **2** represent attractive intermediates to serve as the diene component in Diels–Alder reactions. The previous brief study of dienyl phosphate **1** as a diene in the Diels–Alder reaction examined only thermal conditions (28, 29). The potential utility of dienyl phosphates in diene synthesis coupled with the observed stability of these compounds towards acidic conditions led us to undertake a study of the synthetic utility of **1** and **2** in Lewis acid catalyzed Diels–Alder reactions, which are characteristically faster (33–35), more stereoselective (36), and more regioselective (37–39) than the corresponding uncatalyzed cycloadditions. The details of this investigation are described.

Results and discussion[5]

The previously reported (28, 29, 42, 43) 2-diethylphosphoryloxy-1,3-butadiene (**1**) was conveniently prepared in our

laboratories by a modification of the method of Ireland and Pfister (44) by treatment of methyl vinyl ketone with lithium diisopropylamide in tetrahydrofuran at −78°C followed by trapping of the resulting enolate ion with diethyl chlorophosphate. Diene **1** was obtained as a colorless oil in 75% yield. Dienyl phosphate **1** can be stored at 0°C over a long period of time without apparent decomposition. *trans*-2-Diethylphosphoryloxy-1,3-pentadiene (**2**) was obtained (30, 31) in a similar manner from *trans*-3-penten-2-one and diethyl chlorophosphate, which gave diene **2** as a stable (0°C) colorless oil in 41% yield (31).

The Diels–Alder reactions of dienes **1** and **2** with a variety of dienophiles were carried out under Lewis acid catalysis. The various adducts were identified by their spectral characteristics, especially by ^1H nmr decoupling and nOe experiments, and by chemical modification where necessary. A brief study of the effect of changing the catalyst on the products of the additions of diene **1** was conducted. The results of the cycloadditions, structural assignments, and catalyst study are discussed.

1. Diels–Alder reactions of 2-diethylphosphoryloxy-1,3-butadiene (1)

Diene **1** was subjected to reaction with a variety of α,β-unsaturated carbonyl compounds in methylene chloride solution at 0°C, using stannic chloride as the catalyst. In general the Diels–Alder additions of **1** proceeded rapidly and in excellent yield with very small excesses of the diene. In most cases the recovery of intact unreacted diene **1** rendered the incorporation of that intermediate nearly quantitative. Unfortunately the yields of addition to simple cyclic enones were disappointing.[6] The usual rules of Diels–Alder addition (45, 48–51) were followed. The results are summarized in Table 1. Although structural assignments relied heavily on ^1H nmr, ^{13}C nmr, and nOe experiments, several of the adducts of **1** required further chemical modification in order to unambiguously establish their structures. These conversions are summarized in Scheme 1. The details of the Diels–Alder additions and the corresponding structural assignments will be discussed in sequence.

Cycloadditions and structural assignments

It is known that the Diels–Alder reaction with a 2-substituted diene can lead to a mixture of regioisomers (49), and complete orientational reversal in violation of the *para* rule has been observed (51, 52). We wished to prove conclusively that the addition of dienyl phosphate **1** to ethyl vinyl ketone (Entry 1) gave *para*-addition product **8** and not regioisomer **30**. Accordingly, the Diels–Alder adduct **8** was treated with sodium hydroxide in refluxing methanol. Two compounds were obtained, in 44 and 12% yields. The minor product, obtained as a yellow oil, was positively identified as diketone **20** since, due to symmetry, it showed only seven signals in the ^{13}C nmr spectrum. The major compound was obtained as a white solid that was identified as hydroxy ketone **21**. Compound **21** was clearly derived from **20** by intramolecular aldol condensation. The isolation of compound **20** confirmed that adduct must possess the regiochemistry depicted in structure **8**, arising from addition according to the *para* rule.

Diels–Alder addition of **1** to methyl vinyl ketone (Entry 2) also followed the normal *para* rule. The spectral data were consistent with assignment of structure **9** to the adduct. To establish the regiochemistry conclusively the Diels–Alder adduct was treated with sodium hydroxide in refluxing methanol and gave a diketone in 27% yield. As in the case of degradation product **20**, the ^{13}C nmr spectrum indicated that the diketone had symmetrical structure **22** (four non-carbonyl signals) and not unsymmetrical structure **31** (six non-carbonyl signals). It followed that the Diels–Alder product must possess the regiochemistry depicted in structure **9**.

Several noteworthy features were observed for the stannic chloride catalyzed reaction of methyl vinyl ketone and diene phosphate **1**; the fast reaction rate, the excellent yield, and the complete regioselectivity. In contrast, the thermal addition of methyl vinyl ketone to 2-dimethylphosphoryloxy-1,3-butadiene (29) produced two inseparable regioisomers in a 2:1 ratio.

Preliminary analysis of the spectral data for the single adduct of **1** with *trans*-3-penten-2-one (Entry 3) did not distinguish between structure **10** resulting from normal *para* addition and the regioisomeric structure **32** resulting from anti-*para* addition. The observation of two large *trans*-1,2-diaxial coupling constants of 10 Hz each for the methine proton adjacent to the ketone at δ2.42 in the ^1H nmr spectrum confirmed the *trans* configuration of the two methine protons predicted by the *cis* principle of Diels–Alder addition. It remained to determine the regiochemistry of the adduct. A conclusive proof was achieved by aromatization of the adduct, a technique that has been developed and used with considerable success by this group (31, 51, 52). The adduct was treated with *N*-bromosuccinimide in refluxing carbon tetrachloride. The reaction gave a rather complex mixture of products from which aryl ketone **23** was isolated in 19% yield. The ^1H nmr spectrum of this derivative showed one aromatic proton adjacent to the acyl group as a relatively deshielded doublet at δ7.78 with a coupling constant of 8.5 Hz. The spectral data, particularly the coupling pattern of

[6]This result is typical of the characteristic difficulty in achieving Diels–Alder additions to simple cyclic enones (32, 45–47, and references therein).

[a]The distinct sets of signals in the spectrum of the mixture were separable on the basis of their relative peak areas (8:1).

[b]Because of carbon–phosphorus coupling, a doublet was observed for each of these carbons.

product mixture and this was supported by the ^{13}C nmr spectrum of the mixture, which showed two distinct sets of signals listed in Table 2. The signal due to C-3 of **11**, which is linked to a relatively more electron deficient sp^2 carbon (C-2), should appear at lower field than the signal due to C-6, which is attached to an sp^2 carbon (C-1) that is relatively less electron deficient. Furthermore, C-3 of **11** should appear as a doublet due to carbon–phosphorus coupling while a singlet should be observed for C-6. Similarly the signal assigned to C-3 of **12** should appear at lower field than that of C-6 while a doublet should appear for the C-6 signal due to carbon–phosphorus coupling. The ^{13}C nmr spectrum (Table 2) showed that the major set of signals was consistent with these expectations for structure **11** while the minor set of signals agreed with structure **12**.

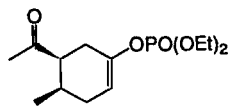
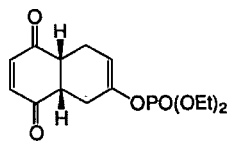
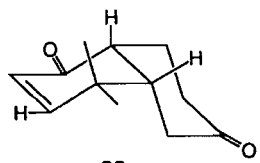
31



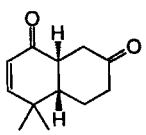
32



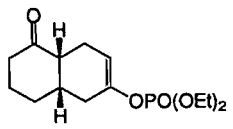
33



26*a*



34



35

Rigorous proof of the regiochemistry of adducts **11** and **12** was achieved by aromatization. The 8:1 mixture of Diels–Alder adducts was treated with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in refluxing benzene. An inseparable 11:1 mixture of two isomeric aryl ketones was obtained in 79% yield. The major set of ^1H nmr signals for the mixture showed aryl doublets at δ7.79 and 7.32 typical of *para*-substituted benzenes. The minor set consisted of two multiplets at δ7.78 and 7.47 attributable to a *meta*-substituted benzene ring. These data established that aryl ketone **24** was the major component and **25** the minor component of the derivative mixture and consequently the assignments of structure **11** to the major Diels–Alder adduct and **12** to the minor adduct were confirmed.

The infrared spectrum of the Diels–Alder cycloaddition product of **1** with *p*-benzoquinone (Entry 5) clearly indicated that the initially formed adduct **33** had undergone subsequent aromatization, as expected via bis-enolization under the influence of the acidic reaction conditions, to produce the aromatic enol phosphate **13**. This structural assignment was confirmed by the ^{13}C nmr spectrum, which indicated the presence of eight sp^2 carbons.

When the dienone ester **14** (51–53) was treated with diene **1** in the presence of stannic chloride at 0°C (Entry 6) the cycloaddition reaction proceeded slowly. After 65 h it gave an inseparable 9:2 mixture of two isomeric adducts in 23% yield. The starting dienophile **14** was obtained in 68% recovery. On the basis of the spectral data and the *cis* principle the structures **15** and **16** were tentatively assigned to the two adducts. Identification of compound **15** as the major adduct and, by inference, **16** as the minor one followed from analysis of pure **15** obtained in subsequent catalyst studies detailed below.

The determination of the regiochemistry of the pure isolated adduct **15** was achieved by the decarbomethoxylation approach previously developed (51, 52) for adducts of **14**. The adduct **15** was treated with lithium iodide dihydrate (54) in refluxing 2,4,6-collidine to give a mixture of two chromatographically separable epimeric diketones **26** and **27** (1:6, in 70% yield) resulting from concomitant decarbomethoxylation and cleavage of the enol phosphate ester. The *cis* ring junction of the minor diketone **26** was confirmed by the ^1H nmr spectrum, which showed a long-range W-coupling of 2 Hz in the signal (δ6.56) due to the proton at C-3. Conformational analysis showed that the protons on C-3 and C-4a can assume a W configuration only when the two rings are *cis*-fused as shown in formula **26*a***. In accord with the assigned *cis* fusion, treatment of **26** with aqueous sulfuric acid in refluxing ethanol gave complete epimerization to the *trans* isomer **27** in 87% yield.

The regiochemistry of the *trans*-diketone **27** was determined by a study of the ^1H nmr spectrum including a nuclear Overhauser enhancement (nOe) experiment. Saturation of the *gem*-dimethyl singlet at δ1.12 caused substantial enhancement of signals corresponding to protons on C-4a (18%), C-5 axial (13%), C-5 equatorial, and C-8a (total 22%). This experiment allowed the complete solution of the coupling patterns of the axial and equatorial protons at C-5. The C-5 axial proton was a doublet of doublets with two large couplings of 13 Hz each while the C-5 equatorial was also a doublet of doublets with a large germinal coupling constant of 13 Hz and a small vicinal coupling constant of 4 Hz. This indicated that the group at C-6 must be the saturated ketone carbonyl as in structure **27** and not a methylene group as in **34**. With the regiochemistry of **27** and, by inference, **26** clearly established, the assignment of structure **15** to their precursor was confirmed.

The addition of **1** to 2-cyclopenten-1-one (Entry 7) gave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

problematic results. The major component of the product mixture was identical with ketone phosphate **9** representing 75% of the mixture by ^{1}H nmr integration. Based on 75% of **9** and 25% of **17** and (or) **18**, the carbon and hydrogen contents of the mixture should be 52.67 and 7.59%, respectively. The microanalytical results were consistent with this calculation showing 52.42% carbon and 7.58% hydrogen. The isolation in 57% yield of aryl ketone **24**, on treatment of the mixture with *N*-bromosuccinimide in refluxing carbon tetrachloride, provided additional proof for the identity of by-product **9**.

Compound **9** could have been derived from the Diels–Alder reaction between diene phosphate **1** and methyl vinyl ketone, arising from acid-catalyzed cleavage of the former during the relatively long reaction time. However, when diene phosphate **1** was treated with stannic chloride in ether at room temperature for 44 h compound **9** was formed only in a comparatively small quantity. Similarly no by-product **9** was isolated after the relatively long reaction time used in the addition of **1** to **14** (Entry 6). Apparently the presence of 2-cyclopentenone facilitated the cleavage of the diene phosphate **1** to methyl vinyl ketone. Rigorous structural assignment of the minor adducts **17/18** was not carried out.

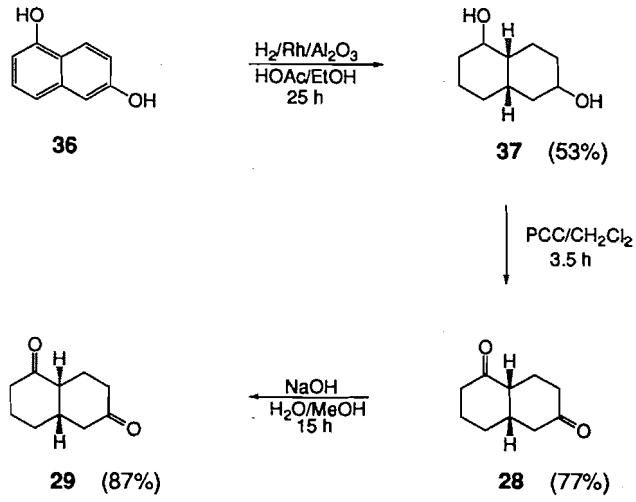
Addition of 2-cyclohexen-1-one (Entry 8) to diene **1** in the presence of stannic chloride gave a chromatographically separable mixture of a single adduct and by-product **9**. With a view to determining the ring junction stereochemistry, the pure adduct was treated with sodium carbonate in aqueous methanol at room temperature for 20 h and also with aqueous sodium hydroxide in methanol at room temperature for 23 h. In both cases the starting material was recovered unchanged. Since the compound was not affected under conditions that are expected to induce epimerization, we presume that the originally formed *cis* adduct **35** had undergone epimerization[7] to give the more stable *trans* isomer **19** during the reaction or purification.

To verify its regiochemistry the Diels–Alder adduct **19** was treated with sodium hydroxide in aqueous methanol giving two separable products (11:1) in 87% yield. The minor and major products were shown to be identical with *cis*- and *trans*-diketones **28** and **29**, respectively, confirming the regiochemistry of the adduct **19**.

Authentic *cis*- and *trans*-diketones **28** and **29** were easily prepared from 1,6-dihydroxynaphthalene (**36**) by the route summarized in Scheme 2. Compound **36** was hydrogenated using 5% rhodium on alumina in acetic acid and ethanol to give diol **37**. The transformation of diol **37** to *cis*-diketone **28** was achieved in 77% yield by treatment with pyridinium chlorochromate (55) in methylene chloride. By treatment with sodium hydroxide in aqueous methanol, *cis*-diketone **28** was isomerized to *trans*-diketone **29** in 87% yield.

Catalyst studies on additions of ***1***

The Diels–Alder reaction of dienone ester **14** and diene **1** was found to be highly dependent on the particular Lewis acid used. The results of a study of the Diels–Alder reactions of diene **1** with dienone ester **14** using different Lewis acid catalysts are summarized in Table 3. When this cycloaddition was run in the presence of boron trifluoride etherate at room temperature the reaction occurred more rapidly than with stannic chloride to give a single adduct in 48% yield that was identical with the



SCHEME 2. Preparation of authentic diketones **28** and **29**.

major product **15** obtained previously from the stannic chloride catalyzed reaction. The use of ferric chloride as a catalyst in the addition of **1** to **14** was also examined.[8] At room temperature adduct **15** was obtained as the sole product in 61% yield. The yield was improved to 71% when the reaction temperature was reduced to 0°C. Clearly ferric chloride is the catalyst of choice for the preparation of this particular Diels–Alder adduct.

In an attempt to improve the Diels–Alder reaction of **1** to cyclohexenone several other Lewis acids such as ferric chloride, aluminum chloride, zinc chloride, and boron trifluoride etherate were briefly examined. Unfortunately all of these catalysts gave results inferior to those obtained with stannic chloride. With ferric chloride, aluminum chloride, and zinc chloride no detectable amount of product was formed even over an extended reaction time. With boron trifluoride etherate the reaction did occur but the yield of the adduct was found to be considerably poorer than with stannic chloride.

2. Diels–Alder reactions of trans*-2-diethylphosphoryloxy-1,3-pentadiene (2)*

Diene phosphate **2** was subjected to Diels–Alder reaction with several α,β-unsaturated ketones using stannic chloride as the catalyst in ether or methylene chloride and at temperatures ranging from 0°C to −30°C. In general the Diels–Alder additions of **2** proceeded in good to excellent yield with small excesses of the diene. As with **1** the usual orientational and stereochemical rules (45, 48, 49), particularly the *para* rule (51, 52) and *endo* rule (32, 51, 57), were followed with a very high degree of selectivity. The structures of the adducts of **2** were unambiguously assigned on the basis of their spectral data including ^{1}H nmr decoupling experiments. The results are summarized in Table 4. The details of the additions and structural assignments will be discussed below.

Cycloadditions and structural assignments

In the presence of 1 equivalent of stannic chloride, ethyl vinyl ketone (Entry 9) reacted rapidly with diene phosphate **2** in methylene chloride at 0°C to give a single adduct in 61% yield. The spectral data allowed the assignment of structure **38** to the

[7]The epimerization of the initially formed products under Lewis acid catalyzed conditions is sometimes observed. See for example ref. 47.

[8]A profound catalytic effect of ferric chloride in Diels–Alder additions to **14** was previously observed and exploited (51, 56).

TABLE 4. Stannic chloride catalyzed Diels–Alder reactions of diene phosphate **2**[a]

Entry	Dienophile	$SnCl_4$ (equiv.)	Solvent	Time (h)	Temp. (°C)	Yield[b]	Adduct (ratio)[c]
9		1	CH_2Cl_2	0.25	0	61%	 **38**
		0.5	Et_2O	24	-30	81%	
10		1	Et_2O	0.09	-30	72%	 **39**
		0.5	Et_2O	14	-30	79%	
11		1	Et_2O	11	0	72%	 **40**
12		1	CH_2Cl_2	0.5	0	52%	 **41**
		1	CH_2Cl_2	6.5	-20	60%	
13	 **3**	0.5	Et_2O	6	-30	66%	 **5** **42** (6:1)

[a]All the reactions were carried out under a nitrogen or argon atmosphere with 1.5 equivalents of diene **2**.
[b]The yields were calculated based on the amounts of the dienophiles used.
[c]Ratio was determined by ^1H nmr integration.

adduct and ^1H nmr decoupling experiments confirmed the regiochemical and stereochemical assignments. A one-proton signal appeared as a doublet of doublets of doublets ($J = 13$, $J' = 7$, $J'' = 4$ Hz) at δ2.72, which was assigned to the methine proton adjacent to the ketone carbonyl. This signal was coupled to a one-proton multiplet at δ2.83 assigned to the allylic methine proton. Irradiation of the signal at δ2.83 caused a change in the signal at δ2.72 to a doublet of doublets ($J = 13$, $J' = 7$ Hz). This irradiation also led to a collapse of the vinylic proton signal at δ5.53 from a multiplet to a broad singlet and the methyl doublet (δ0.81) collapsed to a singlet. This demonstrated proximity of the keto methine and allylic methine protons confirmed the regiochemistry of the adduct **38**. The coupling constant of 13 Hz observed for the methine proton adjacent to the ketone indicated that this proton must possess an axial orientation. Its established coupling with the allylic methine proton (4 Hz) indicated an equatorial orientation for the latter proton and thus a *cis* relationship for these two protons in **38** was confirmed.

The Diels–Alder reaction of ethyl vinyl ketone with **2** was also run at −30°C in ether using 0.5 equivalent of stannic chloride. Although the reaction was much slower under these conditions, a substantially improved yield (81%) was obtained for the adduct **38**.

Under stannic chloride catalysis (1 equiv.) diene phosphate **2**

For personal use only.

reacted very rapidly with methyl vinyl ketone (Entry 10) in ether at −30°C to give a single adduct, **39**, in 72% yield. In the ^{1}H nmr spectrum a one-proton doublet of doublets of doublets (J = 10, J' = J'' = 5 Hz) at δ2.71 was assigned to the methine proton adjacent to the ketone carbonyl group. By decoupling experiments this proton was shown to be coupled with a proton at δ2.86 with a small coupling constant of 5 Hz. The latter was further coupled with the methyl protons at δ0.87 and the vinyl proton at δ5.56. On the basis of these results, as was found for **38**, the stereochemistry and regiochemistry of structure **39** were assigned to the Diels–Alder adduct.

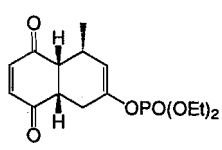
When a smaller amount of stannic chloride (0.5 equiv.) was used the reaction of methyl vinyl ketone with dienyl phosphate **2** was much slower but the yield of adduct **39** was improved (79%).

Addition of **2** to *trans*-3-penten-2-one (Entry 11) under stannic chloride catalysis in ether at 0°C gave a single adduct **40** in 72% yield. The regiochemistry was indicated by the ^{1}H nmr spectrum. The signal due to the proton at C-4 (δ2.61) was a distinct doublet of doublets with coupling constants of 11 and 5 Hz, indicating that the proton had only two neighboring protons. When the multiplet at δ2.75 (C-3 proton) was irradiated the C-4 proton signal collapsed to a doublet with a coupling constant of 11 Hz. At the same time the methyl doublet at δ0.86 changed to a singlet and the multiplet at δ5.55 due to the vinylic proton sharpened to give a broad singlet. This confirmed the position of the allylic methine adjacent to the keto methine proton of **40**. The stereochemistry of the adduct was demonstrated by the splitting pattern of the doublet of doublets at δ2.61 due to the C-4 proton. The presence of a large coupling constant of 11 Hz and a small one of 5 Hz indicated that this proton was axial and further coupled to an axial proton (C-5 proton, J = 11 Hz) and an equatorial proton (C-3 proton, J = 5 Hz).

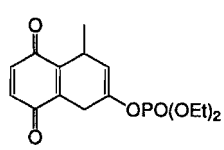
Under stannic chloride catalysis, diene phosphate **2** reacted rapidly with 1,4-benzoquinone (Entry 12) in methylene chloride at 0°C to give an aromatic compound in 52% yield. The spectral data showed that, as had occurred with **33**, the initially formed Diels–Alder adduct **43** had aromatized via bis-enolization to give compound **41** during the reaction or isolation.

In an attempt to improve the yield of adduct **41** the Diels–Alder reaction was run in ether at −30°C for 36 h. Interestingly, in addition to the desired product **41** (24% yield), the unexpected oxidation product **44** was formed in 24% yield. A more successful preparation of **41** was achieved (60% yield) when the reaction was carried out in methylene chloride at −20°C using 3 equivalents of the diene **2**.

The addition of **2** to enone ester **3** (Entry 13) to give adducts **5** and **42** has already been described in detail (32, 46) and was used in the total synthesis of petasitolone (**4**) (31).



43



44

Conclusion

In conclusion, diene phosphates **1** and **2** have been shown to be useful substrates in Diels–Alder reactions under Lewis acid catalysis. They react with a variety of α,β-unsaturated ketones in good to excellent yields, with efficient conversions of the dienes and with high regio- and stereoselectivity to give synthetically useful cyclohexene derivatives. The dienes and products are found to be unusually stable towards acidic conditions compared to other oxygen-substituted dienes such as silyloxy and alkoxy dienes. The application of Lewis acids to the Diels–Alder reactions of diene phosphates is, therefore, more successful and potentially useful than other oxygen-substituted dienes.

Experimental

General

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Elemental analyses were performed by the microanalytical laboratory of this department. Infrared (ir) spectra were recorded on a Perkin–Elmer model 457 or Nicolet 7-199 FT-IR spectrophotometer and, except where otherwise stated, were obtained on solutions in chloroform. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded on a Varian HA-100, HA-100/Digilab, Bruker WH-200, or WH-400 spectrometer and, except where otherwise stated, were obtained on solutions in deuterochloroform with tetramethylsilane as internal reference. The ^{13}C nmr spectra were recorded on a Bruker HFX-90/Nicolet 1085, Bruker WH-200, or WH-400 system and were obtained on solutions in deuterochloroform using tetramethylsilane as internal reference. The following abbreviations are used: s = singlet, d = doublet, t = triplet, q = quartet, and m = multiplet. Mass spectra (ms) were recorded using an A.E.I. model MS9, MS12, or MS50 mass spectrometer. Anhydrous magnesium sulfate was used for drying organic solutions. Crystalline samples were recrystallized before submitting for elemental analysis. Flash chromatography (58) was used routinely for purification and separation of product mixtures.

Materials

Ether and benzene were freshly distilled over lithium aluminum hydride. Dichloromethane was freshly distilled over phosphorus pentoxide. Anhydrous stannic chloride was purchased from Fluka Chemical Corp. and was used without further purification. Nitrogen and argon were passed through a purification train of Fieser's solution (59), saturated aqueous lead acetate, concentrated sulfuric acid, and potassium hydroxide pellets. Diene **2** was prepared according to the published procedure (31). Lithium iodide dihydrate – collidine reagent was prepared as previously reported (51). Dienone ester **14** was prepared according to the published procedure (52, 53). *trans*-3-Penten-2-one was prepared according to the method of Odom and Pinder (60). 1,6-Dihydroxynaphthalene **37** was commercially available. Enone ester **3** was prepared according to the published procedure (32, 61).

2-Diethylphosphoryloxy-1,3-butadiene (1)

To a solution of diisopropylamine (4.1 g, 40.3 mmol) in tetrahydrofuran (50 mL) at 78°C and under an atmosphere of argon, was added a 1.6 M solution of *n*-butyllithium in hexane (25.2 mL, 40.3 mmol) with stirring. After 10 min, a solution of methyl vinyl ketone (2.59 g, 37.0 mmol) in tetrahydrofuran (20 mL) was added dropwise over 10 min. After another 10 min, diethyl chlorophosphate (13.8 g, 80 mmol) was added. The reaction mixture was allowed to warm up to room temperature. Ice-cold water (200 mL) was then added and the resulting mixture was extracted with a solution of ether and *n*-hexane (1:1; 4 × 200 mL). The extracts were washed with water, dried, combined, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with a 20% solution of ethyl acetate in hexane, gave a yellow oil that was further purified by bulb-to-bulb distillation at 83–85°C/1.5 Torr (1 Torr = 133.3 Pa) to give diene **1** (5.70 g, 75% yield) as a colorless oil: ir ($CDCl_3$ cast): 1643, 1594 (C=C), 1274, 1022, and 1002 (phosphate) cm^{-1}; ^{1}H nmr δ: 6.17 (ddd, 1H, J = 3 Hz, J' = 10 Hz, J'' = 17 Hz, CH_2=C*H*-), 5.57 (d, 1H, J = 17 Hz, C*H*H=CH-), 5.20 (d, J = 10 Hz, CH*H*=CH-), 5.08 (dd, 1H, J = 4 Hz, J' = 2 Hz, C*H*H=C-O-), 4.74 (dd, 1H, J = J' = 2 Hz, CH*H*=C-O-), 4.18 (qd, 4H, J = J' = 7 Hz, 2 × -OCH_2-), and 1.35 (dt, 6H, J = 1 Hz,

For personal use only.

J' = 7 Hz, 2 × -OCH_2CH_3); ^{13}C nmr δ: 151.3 (d),[9] 131.4 (d), 116.0, 101.3 (d), 64.4 (d), and 16.1 (d); ms M^+: 206.0704 (calcd. for $C_8H_{15}PO_4$: 206.0708). Anal. calcd. for $C_8H_{15}PO_4$: C 46.60, H 7.33; found: C 46.39, H 7.28.

1-Diethylphosphoryloxy-4-(1-oxopropyl)-1-cyclohexene (8)

Diene **1** (773 mg, 3.75 mmol) was dissolved in dichloromethane (2 mL) under an atmosphere of nitrogen. The solution was cooled to 0°C and anhydrous stannic chloride (753 mg, 2.89 mmol) was added dropwise to the stirred solution over 2 min followed by addition of ethyl vinyl ketone (243 mg, 2.89 mmol). After stirring at 0°C for 1 h the reaction mixture was diluted with dichloromethane. Then 5% aqueous sodium bicarbonate was added and the resulting emulsion was filtered with suction. The filtrate was extracted with dichloromethane and the extracts were combined, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 25% acetone in petroleum ether, gave diene **1** (144 mg, 19% recovery). Continued elution gave enol phosphate **8** (787 mg, 94% yield) as a light yellow oil: ir: 1710 (ketone C=O), 1680 (enol phosphate C=C), 1277 and 1035 (phosphate) cm^{-1}; ^{1}H nmr δ: 5.52 (br s, 1H, -CH=C-), 4.17 (m, 4H, 2 × -OCH_2-), 2.53 (m, 2H, -CH_2CO-), 1.38 (m, 6H, 2 × -OCH_2CH_3), and 1.08 (t, 3H, J = 7 Hz, CH_3CH_2CO-); ^{13}C nmr δ: 212.7, 147.0 (d), 108.8 (d), 64.0 (d), 45.2, 33.8, 26.9 (d), 25.4, 24.6, 15.9 (d), and 7.5; ms M^+: 290.1278 (calcd. for $C_{13}H_{23}PO_5$: 290.1283). Anal. calcd. for $C_{13}H_{23}PO_5$: C 53.78, H 8.00; found: C 53.87, H 7.96.

4-(1-Oxopropyl)-1-cyclohexanone (20) and 4-hydroxy-3-methylbicyclo[2.2.2]octan-2-one (21)

Enol phosphate **8** (251 mg, 0.87 mmol) was dissolved in methanol (14 mL) and aqueous 0.5 N sodium hydroxide (14 mL) was added with stirring. The reaction mixture was heated at reflux under an atmosphere of argon. After 5 h the mixture was cooled to 0°C, poured into cold aqueous 10% hydrochloric acid, and extracted with methylene chloride and then with ethyl acetate. The combined extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (1:3:6), gave diketone **20** (16 mg, 12% yield) as a yellow oil: ir: 1711 (ketone C=O) cm^{-1}; ^{1}H nmr δ: 2.82 (tt, 1H, J = 10 Hz, J' = 4 Hz, -COCH-), 2.58 (q, 2H, J = 7 Hz, CH_3CH_2CO-), and 1.10 (t, 3H, J = 7 Hz, -CH_3); ^{13}C nmr δ: 212.2, 209.8, 47.6, 39.8, 34.0, 28.1, and 7.7; ms M^+: 154.1000 (calcd. for $C_9H_{14}O_2$: 154.0994). Continued elution gave hydroxy ketone **21** as a white solid (59 mg, 44% yield): mp 123–127°C; ir: 3420 (-OH) and 1710 (ketone C=O) cm^{-1}; ^{1}H nmr δ: 2.58 (br s, 1H, D_2O exchangeable, -OH), 2.25 (m, 2H, -CHCOCH-), and 1.16 (d, 3H, J = 7 Hz, CH_3); ^{13}C nmr δ: 216.7, 71.7, 53.1, 41.3, 34.3, 27.4, 22.9, 21.8, and 9.3; ms M^+: 154.1002 (calcd. for $C_9H_{14}O_2$: 154.0993).

1-Diethylphosphoryloxy-4-(1-oxoethyl)-1-cyclohexene (9)

Diene **1** (783 mg, 3.80 mmol) was dissolved in methylene chloride (2 mL) and the solution was cooled to 0°C under an atmosphere of nitrogen. Anhydrous stannic chloride (753 mg, 2.89 mmol) was added dropwise to the stirred solution over 2 min, followed by methyl vinyl ketone (203 mg, 2.90 mmol). After stirring at 0°C for 1.5 h the reaction mixture was diluted with methylene chloride. Then aqueous 5% sodium bicarbonate was added and the resulting emulsion was filtered with suction. The filtrate was extracted with methylene chloride and then with ethyl acetate, and the combined extracts were dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (1:3:6), gave the diene **1** (119 mg, 15% recovery). Continued elution gave pure Diels–Alder adduct **9** (797 mg, 100% yield) as a colorless oil: ir (film): 1710 (ketone C=O), 1685 (enol phosphate C=C), 1276 and 1035 (phosphate) cm^{-1}; ^{1}H nmr δ: 5.53 (br s, 1H, -CH=C-), 4.18 (m, 4H, 2 × -OCH_2-), 2.20 (s, 3H, CH_3CO-), and 1.38 (m, 6H, 2 × -OCH_2CH_3); ^{13}C nmr δ: 209.8, 147.1 (d), 108.7 (d), 64.0 (d), 46.2, 27.8, 26.9 (d), 25.2, 24.5, and 15.9 (d); ms M^+: 276.1125 (calcd. for $C_{12}H_{21}PO_5$: 276.1127). Anal. calcd. for $C_{12}H_{21}PO_5$: C 52.17, H, 7.66; found: C 52.42, H 7.70.

4-(1-Oxoethyl)-1-cyclohexanone (22)

Adduct **9** (200 mg, 0.72 mmol) was dissolved in methanol (11 mL) and aqueous 0.5 N sodium hydroxide (11.6 mL) was added with stirring. The reaction mixture was heated at reflux under an atmosphere of argon. After 3.5 h the reaction mixture was cooled to 0°C and cold aqueous 5% hydrochloric acid was added. The resulting mixture was extracted with methylene chloride and then with ethyl acetate. The combined extracts were dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (1:3:6), gave diketone **22** (27 mg, 27% yield) as a yellow oil: ir: 1710 (ketone C=O) cm^{-1}; ^{1}H nmr δ: 2.80 (tt, 1H, J = 10 Hz, J' = 4 Hz, -COCH-), and 2.24 (s, 1H, CH_3CO-); ^{13}C nmr δ: 48.5, 39.7, 28.0, and 27.8 (two carbonyl carbons did not appear); ms M^+: 140.0844 (calcd. for $C_8H_{12}O_2$: 140.0837).

1-Diethylphosphoryloxy-5β-methyl-4α-(1-oxoethyl)-1-cyclohexene (10)[10]

To a solution of diene **1** (729 mg, 3.54 mmol) in dichloromethane (2 mL) at 0°C and under an atmosphere of nitrogen, anhydrous stannic chloride (709 mg, 2.72 mmol) was added followed by *trans*-3-penten-2-one (228 mg, 2.71 mmol). After stirring for 40 h the reaction mixture was diluted with dichloromethane and aqueous 5% sodium bicarbonate was added. The resulting mixture was extracted with dichloromethane. The extracts were combined, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (1:1:3), gave diene **1** (150 mg, 21% recovery). Continued elution gave pure enol phosphate **10** (706 mg, 90% yield) as a pale yellow oil: ir: 1711 (ketone C=O), 1275 and 1036 (phosphate) cm^{-1}; ^{1}H nmr δ: 5.48 (br s, 1H, -CH=C-), 4.16 (m, 4H, 2 × -OCH_2-), 2.42 (ddd, 1H, J = J' = 10 Hz, J'' = 5.5 Hz, -COCH-), 2.10 (s, 3H, CH_3CO-), 1.36 (m, 6H, 2 × -OCH_2CH_3), and 0.98 (d, 3H, J = 6 Hz, CH_3CH-); ^{13}C nmr δ: 210.6, 146.4 (d), 108.0 (d), 63.9 (d), 53.0, 34.9 (d), 30.5, 29.1, 26.1, 19.2, and 15.8 (d); ms M^+: 290.1284 (calcd. for $C_{13}H_{23}PO_5$: 290.1284). Anal. calcd. for $C_{13}H_{23}PO_5$: C 53.79, H 7.98; found: C 54.05, H 7.98.

1-Diethylphosphoryloxy-3-methyl-4-(1-oxoethyl)benzene (23)

To a solution of adduct **10** (101 mg, 0.35 mmol) in carbon tetrachloride (5 mL), *N*-bromosuccinimide (124 mg, 0.70 mmol) was added with stirring under an atmosphere of nitrogen. The reaction mixture was heated at reflux for 1 h, then the mixture was cooled to room temperature, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 20% acetone in petroleum ether, gave impure aryl ketone **23**. Further purification by Kuhgelrohr distillation at 110°C under 1.0 Torr pressure, followed by preparative thin-layer chromatography on silica gel developed twice with 2% acetone in ether, gave pure aryl ketone **23** (19 mg, 19% yield) as a light yellow oil: ir (film): 3060 (aryl C-H), 1684 (ketone C=O), 1610 and 1580, (aryl C=C), 1278, and 1031 (phosphate) cm^{-1}; ^{1}H, nmr δ: 7.78 (d, 1H, J = 8.5 Hz, C-5 Ar-H), 7.18 (dd, 1H, J = 8.5 Hz, J' = 2.5 Hz, C-6 Ar-H), 7.14 (d, 1H, J = 2.5 Hz, C-2 Ar-H), 4.27 (m, 4H, 2 × -OCH_2-), 2.59 (s, 3H, CH_3Ar or CH_3CO-), 2.56 (s, 3H, CH_3Ar or CH_3CO-), and 1.38 (m, 6H, 2 × -OCH_2CH_3); ms M^+: 286.0974 (calcd. for $C_{13}H_{19}PO_5$: 286.0970).

1-Diethylphosphoryloxy-4-(1-oxoethyl)-1,4-cyclohexadiene (11) and 1-diethylphosphoryloxy-5-(1-oxoethyl)-1,4-cyclohexadiene (12)

To a solution of diene **1** (942 mg, 4.57 mL) in methylene chloride (3 mL) at 0°C and under an atmosphere of nitrogen, anhydrous stannic chloride (886 mg, 3.40 mmol) was added followed by 3-butyn-2-one

[9] ^{13}C nmr signals indicated by (d) appeared as ^{13}C–^{31}P coupled doublets in the broadband decoupled spectrum.

[10] The stereochemical designations used in this and all other chemical names used in this section denote relative stereochemistry. All compounds used and obtained were racemic.

(230 mg, 3.38 mmol). After stirring for 18 h the mixture was diluted with methylene chloride. Aqueous 5% sodium bicarbonate was added and the resulting emulsion was filtered. The filtrate was extracted with methylene chloride and the extracts were combined, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (2:3:5), gave diene **1** (225 mg, 24% recovery). Continued elution gave a mixture of enol phosphates **11** and **12** (747 mg, 81% yield) as a pale yellow oil. The ^{1}H nmr spectrum of the mixture showed two sets of signals in an integral ratio of 8:1. The major set, assigned to **11**, showed signals at δ: 6.82 (m, 1H, -CO-C=CH-), 5.58 (m, 1H, -CH=C-O-), 4.18 (m, 4H, 2 × -OCH_2-), 3.16 (m, 2H, -CH_2-), 3.03 (m, 2H, -CH_2-), 2.23 (s, 3H, CH_3CO-), and 1.36 (m, 6H, 2 × -OCH_2CH_3). The other set, assigned to **12**, showed signals at δ: 6.86 (m, 1H, -CO-C=CH-), 5.52 (m, 1H, -CH=C-O-), 4.18 (m, 4H, 2 × -OCH_2-), 3.16 (m, 2H, -CH_2-), 3.03 (m, 2H, -CH_2-), 2.34 (s, 3H, CH_3CO-), and 1.36 (m, 6H, 2 × -OCH_2CH_3). The ^{13}C nmr spectrum of the mixture also showed two sets of signals. The major set, assigned to **11**, showed signals at δ: 196.6, 142.6 (d), 135.4, 134.6, 107.1 (d), 63.4 (d), 28.8 (d), 24.3, 24.0, and 15.2 (d). The minor set, assigned to **12**, showed signals at δ: 196.4, 145.0 (d), 135.7, 135.3, 104.8 (d), 63.4 (d), 26.9, 26.2 (d), 24.3, and 15.2 (d). The mixture also showed the following data: ir: 1705 (enol phosphate), 1670 (ketone C=O), 1277 and 1031 (phosphate) cm^{-1}; ms M$^+$: 274.0968 (calcd. for $C_{12}H_{19}PO_5$: 274.0970). Anal. calcd. for $C_{12}H_{19}PO_5$: C 52.55, H 6.93; found: C 52.25, H 6.91.

*1-Diethylphosphoryloxy-4-(1-oxoethyl)benzene (**24**) and 1-diethylphosphoryloxy-3-(1-oxoethyl)benzene (**25**)*

An 8:1 mixture of Diels–Alder adducts **11** and **12** (157 mg, 0.57 mmol) was dissolved in benzene (2 mL). 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone (145 mg, 0.64 mmol) was added and the reaction mixture was then heated at reflux under an atmosphere of nitrogen. After 2 h the reaction mixture was cooled to room temperature, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (2:3:5), gave a mixture of aryl ketones **24** and **25** (118 mg, 79% yield). The ^{1}H nmr spectrum of the mixture showed two sets of signals in an integral ratio of 11:1. The major set, assigned to **24**, showed signals at δ: 7.79 (d, 2H, J = 9 Hz, 2 × -CO-C=CH-), 7.32 (dd, 2H, J = 9 Hz, J' = 1 Hz, 2 × -HC=C-O-), 4.24 (m, 4H, 2 × -OCH_2-), 2.58 (s, 3H, CH_3CO-), and 1.36 (m, 6H, 2 × -OCH_2CH_3). The other set, assigned to **25**, showed signals at δ: 7.78 (m, 2H, 2 × -CO-C=CH-), 7.47 (m, 2H, 2 × Ar-H), 4.24 (m, 4H, 2 × -OCH_2-), 2.60 (s, 3H, CH_3CO-), and 1.36 (m, 6H, 2 × -OCH_2CH_3). The mixture also showed the following data: ir: 3060 (aryl C-H), 1686 (ketone C=O), 1600 and 1505 (aryl C=C), 1267, and 1035 (phosphate) cm^{-1}; ms M$^+$: 272.0816 (calcd. for $C_{12}H_{17}PO_3$: 272.0813). Anal. calcd. for $C_{12}H_{17}PO_5$: C 52.93, H 6.31; found: C 53.01, H 6.20.

*2-Diethylphosphoryloxy-5,8-dihydroxy-1,4-dihydronaphthalene (**13**)*

Diene phosphate **1** (505 mg, 2.45 mmol) was dissolved in methylene chloride (2 mL) and the solution was cooled to 0°C. Anhydrous stannic chloride (487 mg, 1.87 mmol) was added under an atmosphere of nitrogen, followed by *p*-benzoquinone (198 mg, 1.83 mmol). After stirring for 5 h the viscous solution was diluted with methylene chloride and water was added. The resulting emulsion was filtered by suction and the filtrate was extracted with methylene chloride. The extracts were combined, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (1:3:6), gave traces of diene **1**. Continued elution gave adduct **13** (532 mg, 93% yield). Recrystallization from acetone–ether gave bright white needles, soluble in methanol or hot acetone but insoluble in ether: mp 124.5–126.5°C; ir (KBr): 3320 (-OH), 3010 (aryl C-H), 1705 (enol phosphate C=C), 1615 and 1491 (aryl C=C), 1287, and 1038 (phosphate) cm^{-1}; ^{1}H nmr (CD_3OD) δ: 6.50 (s, 2H, 2 × Ar-H), 5.64 (m, 1H, -CH=C-O-), 4.18 (m, 4H, 2 × -OCH_2-), 3.36 (slightly broad s, 4H, 2 × -C=C-CH_2-), and 1.36 (m, 6H, 2 × -OCH_2CH_3); ^{13}C nmr (CD_3OD) δ: 148.5, 146.5 (d), 122.0, 121.7, 113.5, 113.4, 109.1 (d), 65.9 (d), 28.2 (d), 25.9, and 16.3 (d); ms M$^+$: 314.0921 (calcd. for $C_{14}H_{19}PO_6$: 314.0919). Anal. calcd. for $C_{14}H_{19}PO_6$: C 53.50, H 6.11; found: C 53.71, H 6.15.

*8aβ-Carbomethoxy-6-diethylphosphoryloxy-4,4-dimethyl-4aβ,5,8,8a-tetrahydro-1(4H)-naphthalenone (**15**) and 8aβ-carbomethoxy-7-diethylphosphoryloxy-4,4-dimethyl-4aβ,5,8,8a-tetrahydro-1(4H)-naphthalenone (**16**)*

*A. Adduct **15** from $FeCl_3$ catalysis*

To a solution of dienone ester **14** (306 mg, 1.69 mmol) and diene phosphate **1** (691 mg, 3.35 mmol) in ether (2.5 mL) at 0°C and under an atmosphere of nitrogen, anhydrous ferric chloride (270 mg, 1.66 mmol) was added. After stirring for 72 h water was added and the resulting mixture was extracted with dichloromethane. The extracts were combined, washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (1:3:6), gave diene **1** (326 mg, 47% recovery). Continued elution gave enone phosphate **15** (462 mg, 71% yield) as a pale yellow oil: ir: 1747, 1731 (ester C=O), 1675 (ketone C=O), 1275, and 1029 (phosphate) cm^{-1}; ^{1}H nmr δ: 6.60 (d, 1H, J = 10 Hz, -CO-CH=C*H*-), 5.90 (d, 1H, J = 10 Hz, -CO-C*H*=CH-), 5.50 (br s, 1H, -CH=C-O-), 4.15 (m, 4H, 2 × -OCH_2-), 3.74 (s, 3H, -OCH_3), 1.35 (m, 6H, 2 × -OCH_2CH_3), 1.22 and 1.15 (both s, 6H, -$C(CH_3)_2$); ^{13}C nmr δ: 196.4, 172.0, 157.7, 145.7 (d), 123.7, 108.3 (d), 64.2 (d), 56.1, 52.5, 41.8, 36.0, 30.1, 27.8, 26.5 (d), 23.1, and 15.9 (d); ms M$^+$: 386.1498 (calcd. for $C_{18}H_{27}PO_7$: 386.1494). Anal. calcd. for $C_{18}H_{27}PO_7$: C 55.94, H 7.06; found: C 55.85, H 7.11.

*B. Adduct mixture **15** and **16** from $SnCl_4$ catalysis*

To a solution of dienone ester **14** (428 mg, 2.38 mmol) and diene phosphate **1** (641 mg, 3.11 mmol) in methylene chloride (4 mL) at 0°C and under an atmosphere of argon, was added anhydrous stannic chloride (619 mg, 2.38 mmol). After stirring for 65 h, the reaction mixture was diluted with methylene chloride and a 5% aqueous sodium bicarbonate solution (20 mL) was added. The resulting mixture was filtered and the filtrate was extracted with methylene chloride. The extracts were combined, dried, filtered, and concentrated. The residue was subjected to flash chromatography on silica gel. Elution with 30% ethyl acetate in hexane gave diene phosphate **1** (142 mg, 22% recovery) and dienone ester **14** (291 mg, 68% recovery). Continued elution gave an inseparable mixture of adducts **15** and **16** (9:2, 206 mg, 23% yield). The ^{1}H nmr spectrum of the mixture showed two sets of signals in an integral ratio of 9:2. The major set was due to adduct **15** (see above) and the minor set was assigned to adduct **16** with signals at δ: 6.67 (d, 1H, J = 10 Hz, -CO-CH=C*H*-), 5.93 (d, 1H, J = 10 Hz, -CO-C*H*=CH-), 5.54 (br s, 1H, -CH=C-C-O-), 4.15 (m, 4H, 2 × -OCH_2-), 3.74 (s, 3H, -OCH_3), 1.35 (m, 6H, 2 × -OCH_2CH_3), 1.20 and 1.12 (both s, 6H, -$C(CH_3)_2$). The mixture also showed the following spectra data: ir ($CDCl_3$ cast): 1745, 1735 (ester C=O), 1675 (ketone C=O), 1272, and 1027 (phosphate) cm^{-1}; ms M$^+$: 386.1500 (calcd. for $C_{18}H_{27}PO_7$: 386.1494).

*4,4-Dimethyl-4,4aβ,5,7,8,8aβ-hexahydro-1,6-naphthalenedione (**26**) and 4,4-dimethyl-4,4aβ,5,7,8,8aα-hexahydro-1,6-naphthalenedione (**27**) from enone phosphate **15***

Enone phosphate **15** (355 mg, 0.92 mmol) was dissolved in lithium iodide dihydrate – collidine reagent (3.19 mL, 3.83 mmol) and heated at reflux with stirring. After 2.5 h the mixture was cooled to room temperature, poured into cold aqueous 5% hydrochloric acid, and extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 10% ether in methylene chloride, gave pure diketones **26** and **27** (124 mg, 70% yield) in an ^{1}H nmr integral ratio of 1:6. Pure **26** was separated from **27** by a second flash chromatography on silica gel. Elution with acetone and ether in petroleum ether (1:3:6) gave diketone **26**: ir: 1714 (ketone C=O), and 1677 (ketone C=O) cm^{-1}; ^{1}H nmr δ: 6.56 (dd, 1H, J = 10 Hz, J' = 2 Hz, -CO-CH=C*H*-), 6.00 (d, 1H, J = 10 Hz, -CO-C*H*=CH-), 1.36 and 1.11 (both s, 6H, -$C(CH_3)_2$); ms M$^+$: 192.1150 (calcd. for $C_{12}H_{16}O_2$:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

192.1150). Continued elution gave diketone **27**: ir: 1711 (ketone C=O) and 1678 (ketone C=O) cm^{-1}; ^1H nmr δ: 6.71 (d, 1H, J = 10 Hz, -CO-CH=C*H*-), 5.91 (d, 1H, J = 10 Hz, -CO-C*H*=CH-), 2.09 (ddd, 1H, J = J' = 13 Hz, J'' = 4 Hz, C-4a *H*), and 1.12 (s, 6H, $-C(CH_3)_2$); ^{13}C nmr δ: 210.0, 198.7, 160.0, 126.1, 48.0, 44.1, 41.8, 40.3, 36.0, 27.2, 26.2, and 20.4; ms M^+: 192.1156 (calcd. for $C_{12}H_{16}O_2$: 192.1151).

4,4-Dimethyl-4,4aβ,5,7,8,8aα-hexahydro-1,6-naphthalenedione (27) from diketone 26

Diketone **26** (5.68 mg) was dissolved in ethanol (0.5 mL) and aqueous 10% sulfuric acid (0.5 mL) was added with stirring. The reaction mixture was then heated at reflux. After 3 h the mixture was cooled to room temperature, diluted with water, and extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 10% ether in methylene chloride, gave a diketone (4.92 mg, 87% yield) that was identical in ^1H nmr and ir spectra, as well as silica gel thin-layer chromatographic behaviour, to the *trans*-diketone **27** obtained directly from **15**.

3-Diethylphosphoryloxybicylo[4.3.0]non-3-en-7-one (17) and (or) 4-diethylphosphoryloxybicyclo[4.3.0]non-3-en-7-one (18)

To a solution of diene phosphate **1** (748 mg, 3.63 mmol) in methylene chloride (5 mL) at 0°C and under an atmosphere of argon, were added anhydrous stannic chloride (316 mg, 1.21 mmol) and 2-cyclopenten-1-one (100 mg, 1.21 mmol). After stirring for 54 h, the reaction mixture was diluted with methylene chloride. Aqueous 5% sodium bicarbonate was added. The resulting emulsion was filtered and the filtrate was extracted with methylene chloride. The extracts were combined, washed with water, dried, and concentrated. Flash chromatography of the residue on silica gel, eluting with 50% ethyl acetate in hexane, gave diene **1** (336 mg, 45% recovery). Continued elution gave a mixture (162 mg) consisting of 75% of ketone **9** and 25% of adduct(s) **17** and (or) **18** (12% yield) as indicated by the ^1H nmr, which displayed two sets of signals in an integral ratio of 3:1. The major signals were identical to those of ketone **9**. The minor signals were attributed to **17** and (or) **18**: δ: 5.50 (br s, 1H, -CH=C-O-), 4.10 (m, 4H, 2 × $-OCH_2-$), and 1.32 (m, 6H, 2 × $-OCH_2CH_3$). The mixture also showed the following spectral data: ir ($CDCl_3$ cast): 1741 (ketone C=O, **17/18**), 1709 (ketone C=O, **9**), 1682 (enol phosphate C=C), 1275, and 1034 (phosphate) cm^{-1}; ms M^+: 288.1124 (**17/18**, calcd. for $C_{13}H_{21}PO_5$: 288.1127) and 276.1126 (**9**, calcd. for $C_{12}H_{21}PO_5$: 276.1127).

6-Diethylphosphoryloxy-3,4,4aβ,5,8,8aβ-1(2H)-naphthalenone (19)

To a solution of diene **1** (1.206 g, 5.85 mmol) in ether (1.5 mL) and methylene chloride (1.5 mL) at 0°C and under an atmosphere of nitrogen, anhydrous stannic chloride (399 mg, 1.53 mmol) was added followed by 2-cyclohexen-1-one (141 mg, 1.47 mmol). After stirring at room temperature for 34 h the reaction mixture was diluted with methylene chloride. Aqueous 5% sodium bicarbonate was added. The resulting emulsion was filtered by suction and the filtrate was extracted with methylene chloride. The extracts were combined, washed with water, dried, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (2:3:5), gave diene phosphate **1** (779 mg, 65% recovery). Continued elution gave a mixture of adducts **19** and **9** (224 mg). The adduct **19** (151 mg, 34% yield) was separated from **9** by extensive column chromatography on silica gel. Pure **19** showed the following data: ir: 1710 (ketone C=O) cm^{-1}; ^1H nmr δ: 5.50 (br s, 1H, -CH=C-O-), 4.18 (m, 4H, 2 × $-OCH_2-$), and 1.36 (m, 6H, 2 × $-OCH_2CH_3$); ^{13}C nmr δ: 210.7, 145.6 (d), 109.4 (d), 64.1 (d), 49.4, 41.8, 40.2, 35.2 (d), 32.2, 25.9, 23.0, and 16.0 (d); ms M^+: 302.1273 (calcd. for $C_{14}H_{23}PO_5$: 302.1274). Anal. calcd. for $C_{14}H_{23}PO_5$: C 55.65, H 7.67; found: C 55.72, H 7.66.

2,3,4,4aβ,5,7,8,8aβ-Octahydro-1,6-naphthalenedione (28) and 2,3,4,4aβ,5,7,8,8aα-octahydro-1,6-naphthalenedione (29)

A. From adduct 19

Enone phosphate **19** (200 mg, 0.66 mmol) was dissolved in methanol (1 mL) and cooled by an ice bath. Then aqueous 5 N sodium hydroxide (1.5 mL) was added. After stirring at room temperature for 20 h, the mixture was acidified with aqueous 5% hydrochloric acid and extracted with ether. The extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 30% ethyl acetate in hexane, gave diketones **28** and **29** (1:11, total 95 mg, 87% yield).

B. From 1,6-dihydroxynaphthalene (36)

(a) Hydrogenation of 36. A mixture of diol **36** (4.01 g, 25 mmol), 5% rhodium on alumina (2.3 g), and acetic acid (0.8 mL) in ethanol (20 mL) was placed in a Parr hydrogenation apparatus. The reaction mixture was shaken under 50 psi (1 psi = 6.9 kPa) of hydrogen at room temperature for 25 h. Filtration and concentration, followed by flash chromatography of the residue on silica gel, eluting with 30% ethyl acetate in hexane, gave diol **37** (2.5 g, 53% yield): ir ($CDCl_3$ cast): 3347 and 3268 (OH) cm^{-1}; ^1H nmr ($CDCl_3$–$(CD_3)_2SO$) δ: 3.90 (br s, 2H, 2 × -OH) and 3.54 (m, 2H, 2 × -C*H*-OH); ^{13}C nmr δ: 72.1, 66.3, 56.7, 42.0, 37.2, 34.4, 32.4, 29.5, 27.4, and 17.8; ms M^+: 170.1308 (calcd. for $C_{10}H_{18}O_2$: 170.1307).

(b) Oxidation of diol 37. To a solution of pyridinium chlorochromate (586 mg, 2.73 mmol) in methylene chloride (5 mL) at room temperature under an atmosphere of argon was added diol **37** (150 mg, 0.89 mmol) with stirring. After 3.5 h, the reaction mixture was diluted with ether, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 30% ethyl acetate in hexane, gave *cis*-diketone **28** (114 mg, 77% yield): ir ($CDCl_3$ cast): 1709 (ketone C=O) cm^{-1}; ^1H nmr δ: 1.5–2.8 (complex, 14H); ^{13}C nmr δ: 211.5, 210.9, 48.7, 44.1, 41.1, 40.7, 38.2, 29.0, 25.0, and 22.9; ms M^+: 166.0993 (calcd. for $C_{10}H_{14}O_2$: 166.0994).

(c) Epimerization of cis*-diketone 28.* Diketone **28** (90 mg, 0.54 mmol) was dissolved in methanol (1 mL). Then 1.5 N aqueous sodium hydroxide (1 mL) was added. The reaction mixture was stirred at room temperature under an atmosphere of argon for 15 h. The resulting solution was extracted with ether. The extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 30% ethyl acetate in hexane, gave *trans*-diketone **29** (78 mg, 87% yield): ir ($CDCl_3$ cast): 1693 (ketone C=O) cm^{-1}; ^1H nmr δ: 1.5–2.5 (complex 14H); ^{13}C nmr δ: 209.9, 209.3, 52.9, 48.1, 45.5, 41.5, 40.2, 33.0, 26.1, and 25.1; ms M^+: 166.0990 (calcd. for $C_{10}H_{14}O_2$: 166.0994).

1-Diethylphosphoryloxy-3β-methyl-4β-[1-oxopropyl]-1-cyclohexene (38)

To a solution of diene phosphate **2** (834 mg, 3.79 mmol) and ethyl vinyl ketone (240 mg, 2.85 mmol) in ether (2 mL) at −30°C and under an atmosphere of nitrogen, anhydrous stannic chloride (377 mg, 1.45 mmol) was added. After stirring for 24 h the reaction mixture was diluted with ether. Aqueous 5% sodium bicarbonate was added and the resulting emulsion was filtered by suction. The filtrate was extracted with methylene chloride and the extracts were combined, washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (2:3:5), gave the diene **2** (157 mg, 19% recovery). Further elution gave pure enol phosphate **38** (703 mg, 81% yield) as a pale yellow oil: ir: 1710 (ketone C=O), 1680 (enol phosphate C=C), 1273, and 1033 (phosphate) cm^{-1}; ^1H nmr δ: 5.53 (m, 1H, -CH=C-O-), 4.16 (m, 4H, 2 × $-OCH_2-$), 2.83 (m, 1H, -C*H*CH_3), 2.72 (ddd, 1H, J = 13 Hz, J' = 7 Hz, J'' = 4 Hz, -COCH-), 1.33 (m, 6H, 2 × $-OCH_2CH_3$), 1.02 (t, 3H, J = 7 Hz, CH_3CH_2-CO-), and 0.81 (d, 3H, J = 6.5 Hz, -CHC*H*$_3$); ^{13}C nmr δ: 211.6, 146.8 (d), 114.6 (d), 63.6 (d), 48.6, 33.7, 29.6, 26.7 (d), 18.0, 15.8, 15.5 (d), and 7.0; ms M^+: 304.1432 (calcd. for $C_{14}H_{25}PO_5$: 304.1439). Anal. calcd. for $C_{14}H_{25}PO_5$: C 55.24, H 8.30; found: C 55.27, H 8.06.

1-Diethylphosphoryloxy-3β-methyl-4β-(1-oxoethyl)-1-cyclohexene (39)

To a solution of diene phosphate **2** (801 mg, 3.64 mmol) and methyl vinyl ketone (196 mg, 2.80 mmol) in ether (2 mL) at −30°C and under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

an atmosphere of nitrogen, anhydrous stannic chloride (731 mg, 2.81 mmol) was added. After stirring for 5 min the reaction mixture was diluted with ether. Aqueous 5% sodium bicarbonate was added and the resulting emulsion was filtered by suction. The filtrate was extracted with dichloromethane and the extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (2:3:5), gave diene **2** (205 mg, 26% recovery). Continued elution gave pure enol phosphate **39** (586 mg, 72% yield) as a pale yellow oil: ir (neat): 1709 (ketone C=O), 1678 (enol phosphate C=C), 1273, and 1027 (phosphate) cm^{-1}; ^1H nmr δ: 5.56 (m, 1H, -CH=C-O-), 4.18 (m, 4H, 2 × -OCH_2-), 2.86 (m, 1H, -C*H*CH_3), 2.71 (ddd, 1H, J = 10 Hz, J' = J'' = 5 Hz, -COCH-), 2.17 (s, 3H, CH_3CO-), 1.35 (t, 6H, J = 7 Hz, 2 × -OCH_2CH_3), and 0.87 (d, 3H, J = 7 Hz, -$CHCH_3$); ^{13}C nmr δ: 209.5, 147.3 (d), 114.9 (d), 64.0 (d), 50.2, 29.7, 28.3, 27.0 (d), 18.2, 15.8, and 15.9 (d); ms M^+: 290.1283 (calcd. for $C_{13}H_{23}PO_5$: 290.1283). Anal. calcd. for $C_{13}H_{23}PO_5$: C 53.77, H 8.00; found: C 54.05, H 7.94.

*1-Diethylphosphoryloxy-3α,5β-dimethyl-4α-(1-oxoethyl)-1-cyclohexene (**40**)*

To a solution of diene **2** (783 mg, 3.56 mmol) and *trans*-3-penten-2-one (204 mg, 2.43 mmol) in ether (2 mL) at 0°C and under an atmosphere of argon, anhydrous stannic chloride (620 mg, 2.38 mmol) was added. After stirring for 11 h the reaction mixture was diluted with ether. Aqueous 5% sodium bicarbonate was added and the resulting emulsion was filtered by suction. The filtrate was extracted with dichloromethane and the extracts were combined, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (2:3:5), gave pure adduct **40** (529 mg, 72% yield, no diene **2** recovery) as a light yellow oil: ir: 1710 (ketone C=O), 1658 (enol phosphate C=C), 1270, and 1033 (phosphate) cm^{-1}; ^1H nmr δ: 5.55 (m, 1H, -CH=C-O-), 4.19 (m, 4H, 2 × -OCH_2-), 2.75 (m, 1H, -C*H*-CH=), 2.61 (dd, 1H, J = 11 Hz, J' = 5 Hz, -COCH-), 2.17 (s, 3H, CH_3CO-), 1.36 (t, 6H, J = 7 Hz, 2 × -OCH_2CH_3), 0.96 (d, 3H, J = 6 Hz, CH_3CHCH_2-), and 0.86 (d, 3H, J = 7 Hz, CH_3CHCH=); ^{13}C nmr δ: 209.2, 145.9 (d), 114.4 (d), 63.8 (d), 56.3, 35.1 (d), 30.3, 30.0, 24.6, 19.3, 16.7, and 15.7 (d); ms M^+: 304.1445 (calcd. for $C_{14}H_{25}PO_5$: 304.1440). Anal. calcd. for $C_{14}H_{25}PO_5$: C 55.24, H 8.30; found: C 55.16, H 8.18.

*2-Diethylphosphoryloxy-5,8-dihydroxy-4-methyl-1,4-dihydronaphthalene (**41**)*

To a solution of diene **2** (598 mg, 2.72 mmol) and *p*-benzoquinone (195 mg, 1.80 mmol) in dichloromethane (2 mL) at 0°C and under an atmosphere of nitrogen, anhydrous stannic chloride (465 mg, 1.79 mmol) was added. After stirring for 30 min water was added and the resulting emulsion was filtered with suction. The filtrate was extracted with dichloromethane and the extracts were combined, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with acetone and ether in petroleum ether (2:3:5), gave aromatic enol phosphate **41** (308 mg, 52% yield, no diene **2** recovery), which was recrystallized from acetone – petroleum ether to give light yellow crystals: mp 130.5–132.0°C; ir: 3304 (-OH), 1700 (enol phosphate C=C), 1492 (aromatic C=C), 1247 and 1035 (phosphate) cm^{-1}; ^1H nmr (acetone-d_6) δ: 7.86 (br s, 2H, D_2O exchangeable, 2 × -OH), 6.60 and 6.59 (both s, 1H each, 2H, 2 × Ar-H), 5.72 (m, 1H, -CH=C-O-), 4.20 (m, 4H, 2 × -OCH_2-), 1.33 (m, 6H, 2 × -OCH_2CH_3), and 1.27 (d, 3H, J = 7 Hz, -$CHCH_3$); ^{13}C nmr (acetone-d_6) δ: 148.2, 145.9 (d), 127.3, 121.5, 115.2 (d), 113.8, 113.2, 64.9 (d), 31.4, 28.1 (d), 22.6, and 16.4 (d); ms M^+: 328.1075 (calcd. for $C_{15}H_{21}PO_6$: 328.1075). Anal. calcd. for $C_{15}H_{21}PO_6$: C 54.86, H 6.46; found: C 54.84, H 6.46.

Received June 17, 1994

PIERRE D. HARVEY, PETER JOHNSTON, and NEIL J. COVILLE. Can. J. Chem. **72**, 2176 (1994).

The properties of the heteronuclear metal–metal bonds in the unbridged $[\eta^5\text{–}C_5H_5)Fe(CO)_2Re(CO)_{5-n}(CNR)_n]$ and $[(\eta^5\text{–}C_9H_7)Fe(CO)_2Re(CO)_{5-n}(CNR)_n]$ complexes ($n = 0, 1, 2$; R = *tert*-butyl (*t*Bu) and 2,6-dimethylphenyl (Xy)) and the two equatorially substituted isomers of $[MnRe(CO)_8(CN\text{-}tBu)_2]$ have been investigated theoretically by Extended Hückel Molecular Orbital calculations (EHMO) and experimentally by UV–visible spectroscopy, electrochemistry, and by microRaman or FT-Raman spectroscopy. The expected $d\sigma^*$ orbital is the lowest unoccupied molecular orbital (LUMO), mainly fabricated by interactions of the metal d_{z^2} orbital, but the $d\pi^*$ and $d\sigma$ orbitals are the highest occupied molecular orbital (HOMO) and HOMO-1, respectively, as demonstrated experimentally from the UV–visible spectra. The EHMO computations demonstrate the mixing between these two $d\pi^*$ (and $d\delta$) and $d\sigma$ MO orbitals. The influence of substituent effects on the spectroscopic and electrochemical properties is complicated and is interpreted in terms of inductive effects and relative destabilisation of the $d\sigma$, $d\pi^*$, and $d\sigma^*$ molecular orbitals. Finally, the metal–metal stretching frequencies for four mixed metal dimers (MnRe and FeRe) are reported.

PIERRE D. HARVEY, PETER JOHNSTON et NEIL J. COVILLE. Can. J. Chem. **72**, 2176 (1994).

Utilisant des calculs théoriques d'orbitales moléculaires de Hückel étendues et des méthodes expérimentales incluant de la spectroscopie UV–visible, de l'électrochimie et des spectroscopies microRaman et Raman par transformation de Fourier, on a étudié les propriétés des liaisons métal–métal hétéronucléaires des complexes non pontés $[\eta^5\text{–}C_5H_5)Fe(CO)_2Re(CO)_{5-n}(CNR)_n]$ et $[(\eta^5\text{–}C_9H_7)Fe(CO)_2Re(CO)_{5-n}(CNR)_n]$ ($n = 0, 1, 2$; R = *tert*-butyl (*t*Bu) et 2,6-diméthylphényle (Xy)) ainsi que de deux isomères substitués d'une façon équatoriales des isomères $[MnRe(CO)_8(CN\text{-}tBu)_2]$. L'orbitale $d\sigma^*$ attendue est l'orbitale moléculaire basse vacante (BV), obtenue principalement par les interactions de l'orbitale d_{z^2} du métal; toutefois, tel que démontré expérimentalement par les spectres UV–visible, les orbitales $d\pi^*$ et $d\sigma$ sont respectivement orbitales moléculaires hautes occupées HOMO et HOMO-1. Des calculs EHMO démontre l'existence d'un mélange entre ces deux orbitales moléculaires $d\pi^*$ (et $d\delta$) et $d\sigma$. L'influence des effets des substituants sur les propriétés spectroscopiques et électrochimiques est complexe et on l'interprète en fonction d'effets inductifs et de déstabilisation relative des orbitales moléculaires $d\sigma$, $d\pi^*$ et $d\sigma^*$. Enfin, on rapporte les valeurs des fréquences d'élongation métal–métal des quatre dimères métalliques (MnRe et FeRe).

[Traduit par la rédaction]

Introduction

The nature of covalent (1) and dative (2) heteronculear metal–metal bonds is of current interest. These dimers appear to be polar, and chemical and physical properties often differ between heteronuclear binuclear complexes and the homonuclear dimers (1). In this paper we will describe the heteronuclear metal–metal bond from the extended Hückel molecular orbital theoretical point of view, in particular for the complex $(\eta^5\text{–}C_5H_5)Fe(CO)_2Re(CO)_5$, in an attempt to rationalize those differences. We also report the influence of substitution effects on such metal–metal bond properties as the $d\sigma \rightarrow d\sigma^*$ and $d\pi^* \rightarrow d\sigma^*$ transition energies (UV–visible), oxidation potential (cyclic voltametry), and $\nu(MM')$ (Raman spectra). It will be shown that unusual properties with respect to the homonuclear systems are often observed.

Experimental Section

Materials

The bimetallic compounds were synthesized according to literature methods (3–7). 2-Methyltetrahydrofuran (2MeTHF; Aldrich Chemical Co) was purified by refluxing over sodium/benzophenone, and fractional distillation.

Instruments

The UV–visible spectra were recorded on a Cary model 17 spectrometer. The experimental procedure used was the same as previously outlined in ref. 8. The uncertainties in the measured λ_{max} for the glass solutions at 77 K was at most 0.5 nm. The microcrystalline samples were sealed in Pyrex capillaries for the Raman measurements, which were made on an Instruments S.A. Raman spectrometer equipped with a U-1000 Jobin–Yvon 1.0-m double monochromator employed at the 514.5-nm green line of a Spectra Physics model 164 argon ion laser (typically 10–20 mW at the samples) for excitation. The spectra were calibrated against the emission lines of a standard neon lamp, and the peak positions are considered to be accurate to ± 0.2 cm^{-1}. The FT-Raman spectra for the solid samples were obtained on a Bruker IFS 66/CS FT-IR spectrometer coupled with an FRA106 FT-Raman module using a Nd: YAG laser (1064 nm excitation) and a Notch filter (cutoff ~ 70 cm^{-1}).

Electrochemistry

Electrochemical measurements were made on argon degassed CH_3CN (Aldrich Chemical Co.; refluxed and distilled over CaH_2) solutions containing 0.1 M TBA(PF_6) (tetra-*n*-butylammonium hexafluorophosphate; Aldrich Chemical Co.; recrystallized three times from EtOH) as the supporting electrolyte. Cyclic voltammetric measurements were performed with a PAR 173 potentiostat and a PAR 175 universal programmer. Pt disk electrodes were polished with alumina for 5 min with 1:1 CH_3OH/H_2O before use. Coulometry measurements were

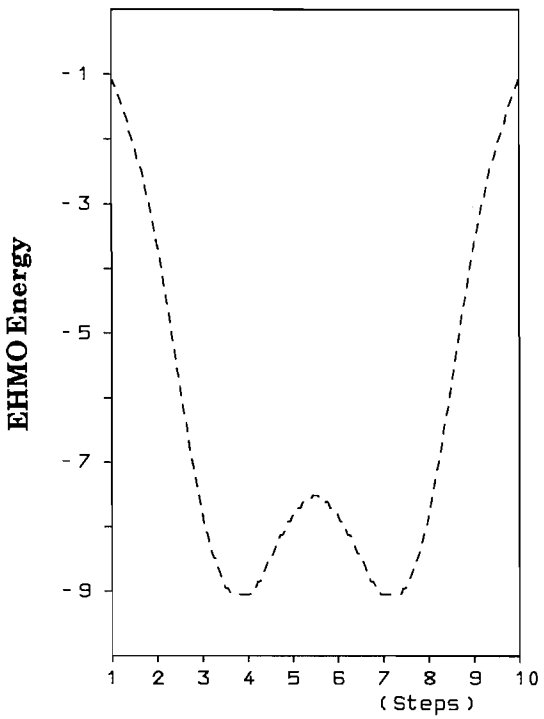

FIG. 1. Plot of the total EHMO energy as a function of the (η^5–C_5H_5)—Fe—Re$(CO)_{eq}$ dihedral angle. Each step represents 10° going from 0° (step 1) to 90° (step 10). The energy difference between the maximum and minimum values is 0.019 eV (i.e., each division on the "y" axis is 0.002 375 eV). The ReFe distance was set at 2.888 Å.

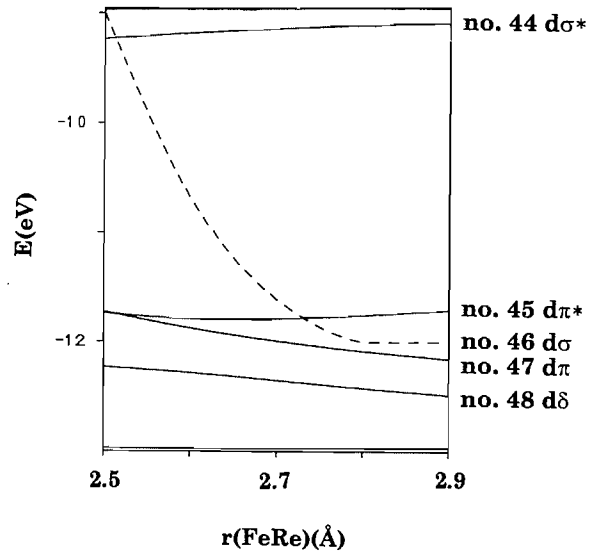

FIG. 2. MO diagram for (η^5–C_5H_5)Fe$(CO)_2$Re$(CO)_5$ (where the dihedral angle is 45°) as a function of the Fe—Re distance. The dotted line is the total EHMO energy of the molecule. Each step represents 0.10 Å going from 2.5 to 2.9 Å.

performed with a H-cell with Pt-gauze working and auxillary electrodes. All potentials are versus SSCE.

Computational details

All MO calculations were of the extended Hückel type (EHMO) using a modified version of the Wolsberg–Helmholz formula (9). The atomic parameters used for C, O, and H are taken from refs. 10–12. For Fe and Re, the atomic parameters used were from refs. 13 and 14, respectively. All distances (C═O, M—C, C═C, and C—H) and angles were taken from the X-ray crystallographic data for (η^5–C_5H_5)Fe$(CO)_2$Re$(CO)_5$ (4). The geometry has been kept intact during the computations, as reported for the X-ray crystal structure (4) (except for the (η^5–C_5H_5)Fe—Re$(CO)_{eq}$ twist angle (45°)). The distance Fe—Re was varied from 2.50 to 2.90 Å (see discussion in the text). A detailed description of the graphic programs used in this work can be found in ref. 15.

Results and discussion

1. *Molecular orbital analysis*

To assess the role of orbital interactions on the heteronuclear metal–metal bonded complexes (η^5–C_5H_5)Fe$(CO)_2$Re$(CO)_5$), it is important to establish the appropriate geometry of the molecule to be used in EHMO calculations. Initially a (η^5–C_5H_5)—M′—M$(CO)_{eq}$ dihedral angle of 16°, corresponding to that observed in the crystal structure analysis (4), was used. However, this resulted in anomalous results in that the $d_{Fe—Re}$ bond length was predicted to be much less than that observed in the structural analysis.

Further investigations have revealed the source of the problem. A plot of the total EHMO energy as a function of the (η^5–C_5H_5)-Fe-Re$(CO)_{eq}$ dihedral angle is shown in Fig. 1. This clearly indicates two minima at ~28° and ~62° with a maximum at 45°. The barrier between the two minima is very small (~30 cm^{-1}, in vacuo) and is presumed to arise from steric interactions between the C_5H_5 and CO ligands on the respective metal atoms. In solution, exchange between these two conformers should be facile and should lead to an average dihedral angle of 45°. For computational purposes, this configuration (C_s point group) was assumed.

Based upon the earlier theoretical and experimental work by Gray *et al.* (16, 17) and more recently by Nakatsuji et al. (2) on the covalently σ-bonded metal–metal $M_2(CO)_{10}$ dimers (M = Mn, Re), one can unambiguously predict that the metal–metal bond in the d^7–d^7 system will be formed using the d_{z^2}–d_{z^2} metal–metal interaction, and that the lowest energy electronic transitions will be either $d\sigma \rightarrow d\sigma^*$ (M = Re) or $d\pi^* \rightarrow d\sigma^*$ (M = Mn). However, mixing between the $d\pi^*$ (or $d\pi$) and $d\sigma$ molecular orbitals is not expected to be extensive.

Before detailed analysis of the dimer, one should state that for the Re$(CO)_5$ fragment (referred to as the Re fragment in the text below), the computed ordering for the *d* orbitals is as follows: $d_{x^2-y^2} > d_{z^2} > d_{xz} = d_{yz} > d_{xy}$, which is in agreement with previous *ab initio* molecular orbital calculations (2). These metal orbitals generate the $d\delta$, $d\sigma$, $d\pi = d\pi$, and $d\delta$ molecular orbitals, respectively, in the homonuclear dimers. For the (η^5–C_5H_5)Fe$(CO)_2$ fragment (referred to as the Fe fragment in the text below), the computed molecular orbital ordering is $d\sigma$, $d\delta$, $d\pi$, $d\delta$, $d\pi$ (nomenclature adopted from ref. 16). This ordering is the same as previously reported for the (η^5–C_5H_5)Mo$(CO)_3$ fragment (16). Importantly, the d_{z^2} orbital of the Fe fragment is located ~0.5 eV above the d_{z^2} orbital of the Re fragment, indicating evidence of a covalent polarity in the metal–metal bond. This difference is not great enough to invoke the possibility of a dative metal–metal bond. Nakatsuji et al. (2) computed the d_{z^2} orbital energies for mixed metal dimers known to exhibit a dative metal–metal bond; the differences between the two fragments in $OsW(CO)_{10}$ and $OsCr(CO)_{10}$ are of the order of 4.0–6.5 eV, according to the *ab initio* results.

The MO analysis of the (η^5–C_5H_5)Fe$(CO)_2$Re$(CO)_5$ complex turned out to be more interesting than anticipated. The computed total energy as a function of the metal–metal distance 2.5–2.9 Å (Fig. 2) shows a flat minimum ranging from 2.8 to

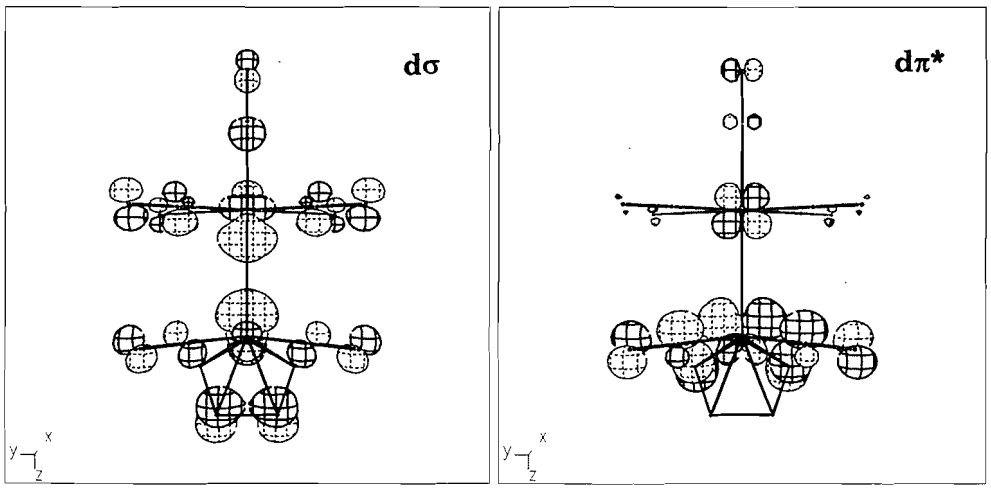

FIG. 3. The MO picture for the HOMO ($d\pi^*$) and HOMO-1 ($d\sigma$) for the $(\eta^5\text{–}C_5H_5)Fe(CO)_2Re(CO)_5$ complex. Note that the $d\sigma^*$ orbital is identical in shape to the $d\sigma$ one with the exception that the dz^2 orbital of the Re atom is inverted in sign to promote antibonding Re–Fe interactions. The dihedral angle is 45°, and the Re—Fe distance is 2.88 Å in this plot.

2.9 Å. These values compare particularly well with experiment (2.888 Å). The energy difference between the maximum energy distance (2.5 Å) and the minimum one (2.8–2.9 Å) is 0.655 eV (i.e., 5.28×10^3 cm^{-1}), and is mostly due to electronic factors. This is indeed observed via the stabilization of the MO no. 45 and no. 47, which are the $d\sigma$ and $d\pi$ MO's, respectively (Fig. 2). These MO's are now briefly described with respect to the atomic contributions.

The LUMO (MO no. 44 = $d\sigma^*$) and the HOMO-1 (no. 46 = $d\sigma^*$) are composed of p_z(CO) and metal d_{z^2} orbitals (Fe and Re) as expected, but also include some M *s* and p_z characteristics. The addition of these later orbitals has the effect of modifying the shape of the orbital located at the M atom in order to increase the lobe size located along "z" axis, hence promoting Fe–Re interactions. A picture of the HOMO-1 (MO no. 46) is shown in Fig. 3. In addition, the Fe fragment also provides a weak but non-negligible CO(p_y), Fe(d_{xy}), and Fe(d_{yz}) contribution, due to the close proximity in energy of the $d\pi$ and $d\delta$ orbitals of the Fe fragment to the $d\sigma$(Fe–Re) MO. The HOMO is the $d\pi^*$ (MO no. 45) as shown in Fig. 3, and is composed of Re(d_{yz}) and Fe(d_{yz}) orbitals (generating the $d\pi$ Fe–Re interactions), and some amount of Fe d_{xy}, d_{xy} and Re d_{xz} orbitals as well as some CO ligand orbitals. Again mixing is also noted. The HOMO-2 (no. 47) is the $d\pi$ orbital, also exhibiting some mixing similar to that of the $d\pi^*$ orbital. These computations clearly indicate that the $d\pi^*$ MO lies above the $d\sigma$ orbital, as experimentally observed. The EHMO $d\pi^* \rightarrow d\sigma^*$ and $d\sigma \rightarrow d\sigma^*$ transition energies at r(FeRe) = 2.9 Å (~2.6 eV (20 970 cm^{-1}) and ~3.1 eV (25 000 cm^{-1}), respectively, compare favourably with the UV–visible data below (i.e, 22 300 and 27 700 cm^{-1}, respectively).

2. *Electrochemistry*

The cyclic voltammetric properties have also been investigated to address the effect of substitution on the heteronuclear metal–metal bond. In all complexes investigated, the oxidation waves are irreversible and are associated with a return wave in the reduction region of the cyclic voltammogram. Coulometric measurements suggest that the redox processes involve two electrons. No other reduction wave is observed in the –2.0–0.0 V range. A typical cyclic voltammogram is shown in Fig. 4 and the peak potentials for the oxidation process $E^{+/0}$ are reported in Table 1. The results in each instance are consistent with an

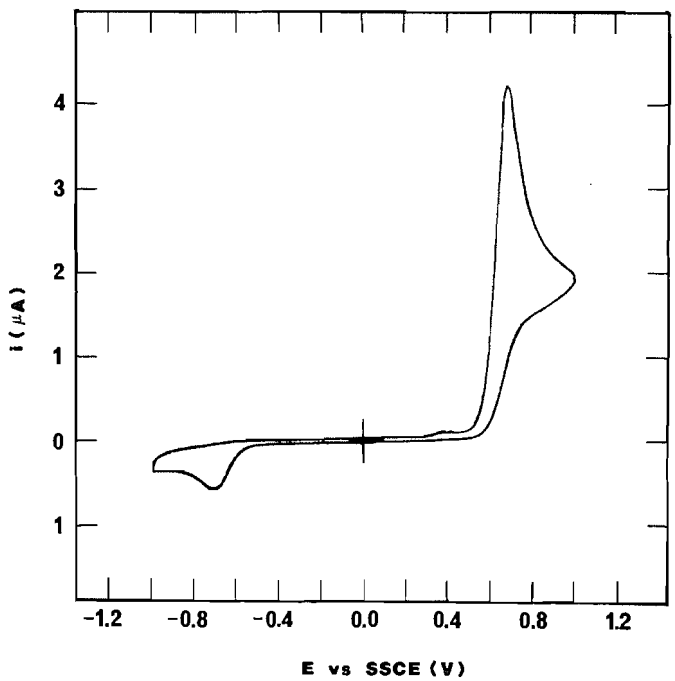

FIG. 4. Cyclic voltammogram for the oxidation of $[(\eta^5\text{–}C_5H_5)Fe(CO)_2Re(CO)_5]$ in CH_3CN containing 0.1 M TBA(PF_6) at room temperature. Scan rate 500 mV s^{-1}.

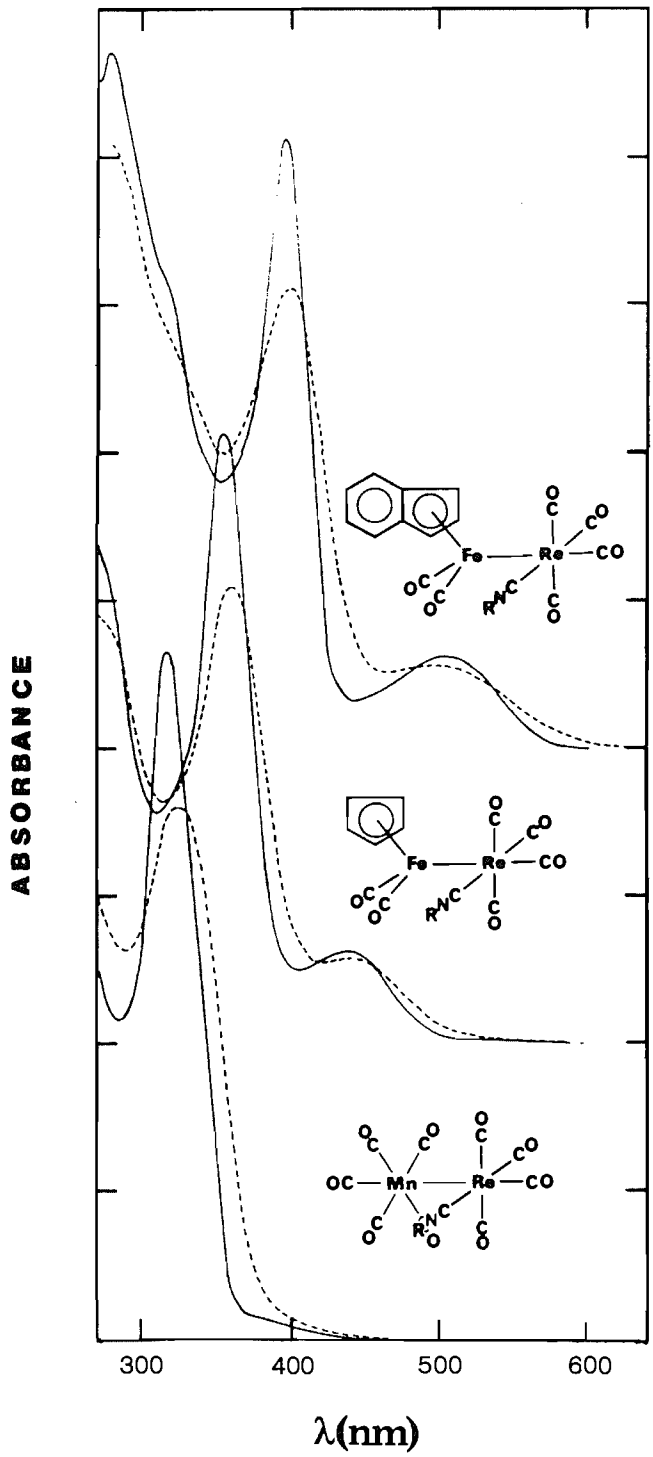

FIG. 5. Comparison of the absorption of the $[(\eta^5\text{–}C_5H_5)Fe(CO)_2Re(CO)_{5-n}(CNR)_n]$ complexes; $n = 0$–2; R = *t*Bu, in 2MeTHF at 293 (...) and 77 K (...). Corrected for the base line and glass contraction.

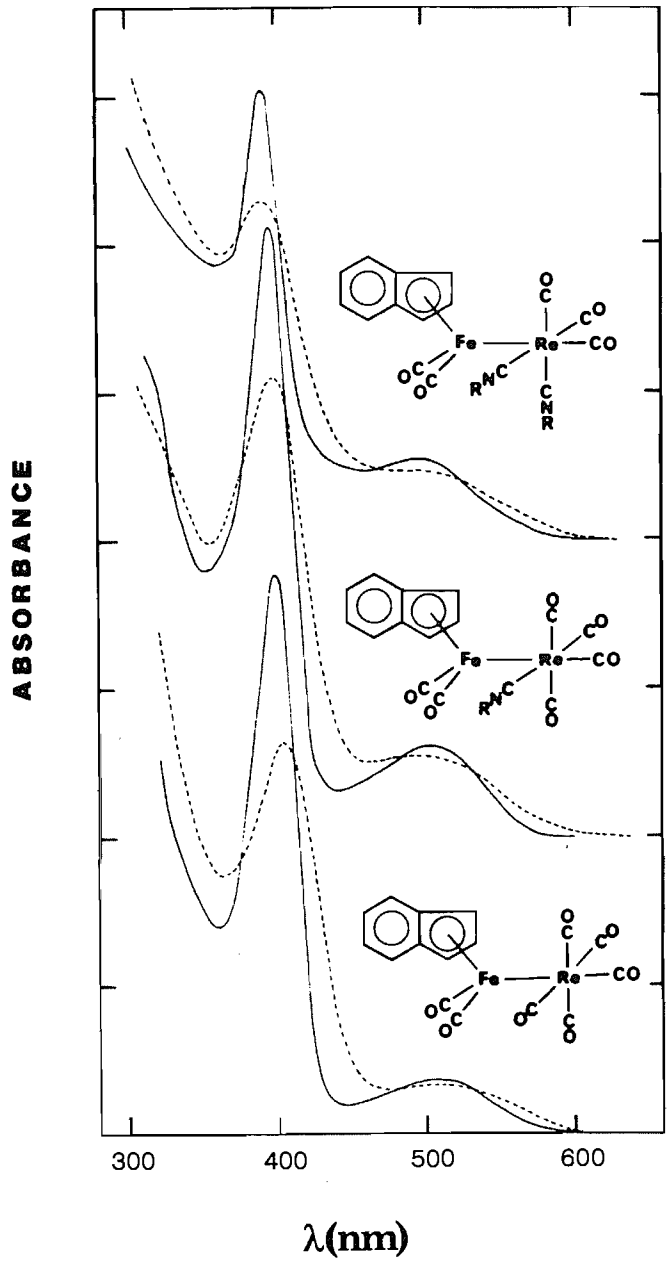

FIG. 6. Comparison of the absorption spectra of the $[X\text{-}Re(CO)_4(CN\text{-}t\text{Bu})]$ complexes: X = $Mn(CO)_5$, $(\eta^5\text{–}C_5H_5)Fe(CO)_2$, $(\eta^5\text{–}C_9H_7)Fe(CO)_2$, in 2MeTHF at 293 (...) and 77 K (...). Corrected for the base line and glass contraction.

increase in electronic density around the M–M bond when substitution of CO and (or) $\eta^5\text{–}C_5H_5$ is made regardless of the site of substitution! This is also consistent with the published IR data (3–7). Indeed red shifts of the ν(CO) peaks are observed upon the replacement of CO by CNR and $\eta^5\text{–}C_5H_5$ by $\eta^5\text{–}C_9H_7$.

3. *Electronic spectra of the FeRe complex*

Typical room temperature and 77 K UV–visible spectra (Table 2) of the complexes in 2MeTHF are shown in Figs. 5 and 6. The spectra are similar to other heterobimetallic d^7–d^7 single-bonded complexes (18, 19) and show a strong absorption in the 320–450 nm range ($\epsilon \sim 26\,000 \pm 300\ M^{-1}\ cm^{-1}$; room temperature) and a weaker band ($\epsilon \sim 4500 \pm 800\ M^{-1}\ cm^{-1}$; room temperature) in the 450–520 nm region. Upon cooling to 77 K, the intense bands sharpen and blue-shift slightly. No new band that could be associated with a bridged species appears at low temperature. Based upon their absorptivities, transition energies, and their temperature dependence, the electronic bands are confidently assigned to $d\sigma \rightarrow d\sigma^*$ and $d\pi^* \rightarrow d\sigma^*$ transitions for their intense and weak features, respectively.

Upon substitution of CO by CN-*t*Bu in the $[(ring)Fe(CO)_2Re(CO)_5]$ complexes, small *blue* shifts of the electronic

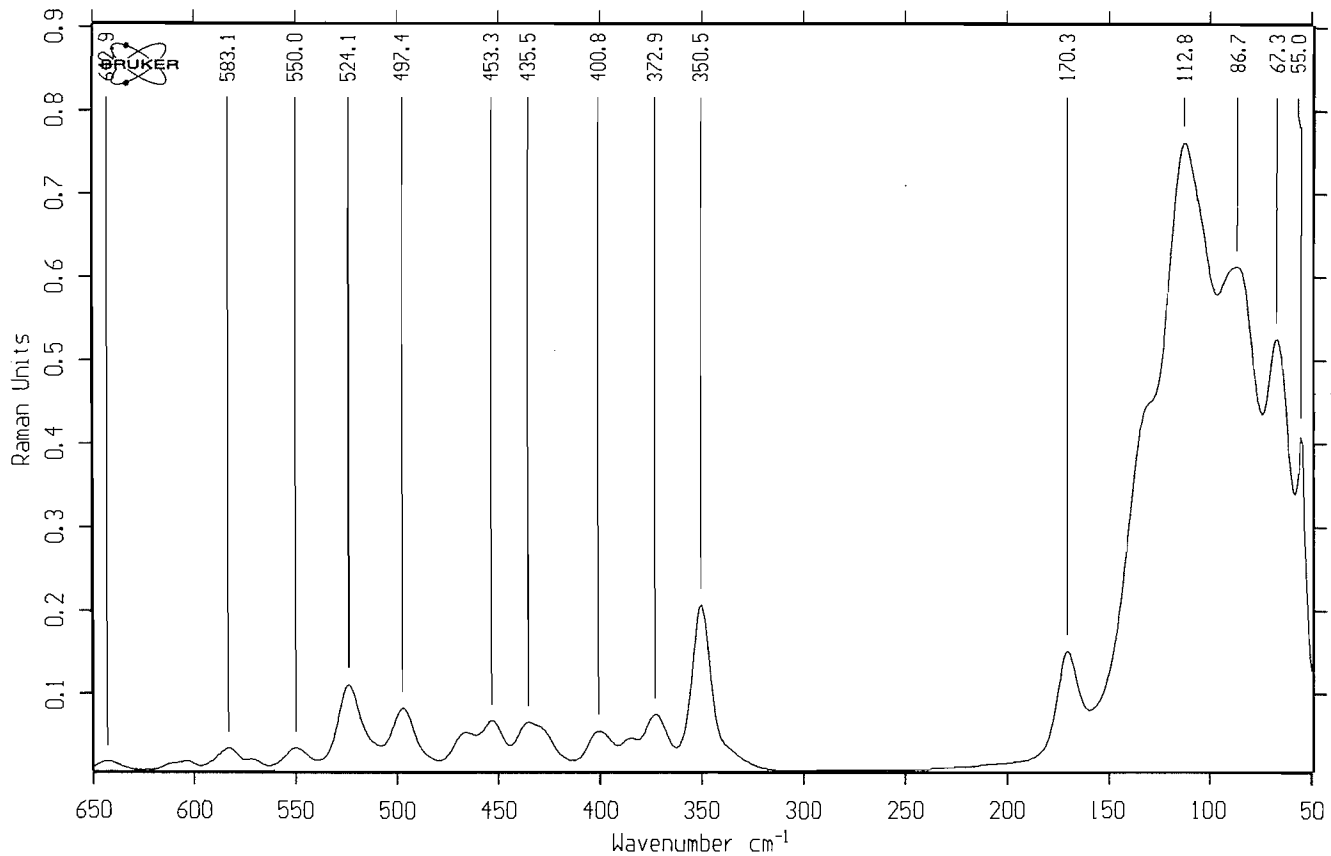

FIG. 7. FT-Raman spectrum of solid $(\eta^5\text{-}C_5H_5)Fe(CO)_2Re(CO)_4(CN\text{-}t\text{Bu})$ at 293 K. Experimental conditions: 200 scans, 4 cm^{-1} resolutions, corrected for the Notch filter, 75 mW laser power. The 170 cm^{-1} is the peak of interest in this work ν(FeRe).

bands are observed (see Fig. 7): ~3–4 nm (~350 cm^{-1} for each CO ligand replaced) for the $d\sigma \rightarrow d\sigma^*$ and ~3 nm (~100 cm^{-1} for each CO ligand replaced) for the $d\pi^* \rightarrow d\sigma^*$ bands. For the $[Re_2(CO)_{10-n}(CNR)_n]$ complexes (n = 0–4; R = *t*Bu, Me, $CH_2C_6H_5$), a regular *red* shift of 800 cm^{-1} for each CO ligand replaced was observed and was associated with the better σ-donor and poorer π-acceptor capacity of the CNR ligand relative to the CO ligand (8). To our knowledge, the blue shift observed in the $[(ring)Fe(CO)_2\text{–}Re(CO)_{5-n}(CN\text{-}t\text{Bu})_n]$ compounds (ring = $\eta^5\text{–}C_5H_5$, $\eta^5\text{–}C_9H_7$) on increasing n is unprecedented.

Replacement of CO by CNXy at the Re atom in the [(ring)

[m]For $(\eta^5\text{-}C_5H_5)Fe(CO)_2Re(CO)_4$(CN-*t*Bu) and for $(\eta^5\text{-}C_9H_7)Fe(CO)_2Re(CO)_4$(CNXy) assuming that r(MM′) is little affected by the CNR substitution.

$Fe(CO)_2Re(CO)_5$] complexes (ring = η^5–C_5H_5, η^5–C_9H_7) produces unusually small red shifts (2 nm or ~100 cm^{-1} for each CO ligand replaced) for both electronic $d\sigma \rightarrow d\sigma^*$ and $d\pi^* \rightarrow d\sigma^*$ bands. In the [$Re(CO)_{10-n}(CNXy)_n$] complexes (n = 0–4), the red shift of these electronic bands was much larger upon substitution of CO by CNXy (~1600 cm^{-1} per CO ligand replaced) and was associated with a strong inductive electron-withdrawing effect due to the presence of the phenyl group (8). By replacing the η^5–C_5H_5 group in [$(\eta^5\text{–}C_5H_5)Fe(CO)_2$-$Re(CO)_{5-n}(CNR)_n$] complexes ($n$ = 0–2; R = *t*Bu, Xy) with a η^5–C_9H_7 group, large red shifts of ~40 nm and ~60 nm (~2700 cm^{-1}) for the $d\sigma \rightarrow d\sigma^*$ and $d\pi^* \rightarrow d\sigma^*$ bands, respectively, are observed (see Fig. 6).

The $MnRe(CO)_{10}$ dimer can also be considered as a polar molecule since the $d\sigma$ orbital of the $Mn(CO)_5$ fragment lies above the $Re(CO)_5$ fragment by ~1.2 eV according to recent *ab initio* calculations (2). The UV–visible spectra of [$MnRe(CO)_{10}$] and both isomers [$MnRe(CO)_9$(CN-*t*Bu)] are similar, and the electronic spectra of the [$Mn(CO)_5Re(CO)_4$(CN-*t*Bu)] complex in 2MeTHF at room temperature and at 77 K are shown in Fig. 6 as an example. The complexes [$MnRe(CO)_{10}$], [$Mn(CO)_4$(CN-*t*Bu)$Re(CO)_5$], and [$Mn(CO)_5Re(CO)_4$(CN-*t*Bu)] have $d\sigma \rightarrow d\sigma^*$ bands (77 K) at 313, 314, and 317 nm, respectively. The red shift induced by the substitution at the Mn atom (~1 nm or ~100 cm^{-1}) is smaller than the red shift induced by substitution at the Re atom (4 nm or ~400 cm^{-1}).

The "take home" lesson from the UV–visible measurements is that the red shifts of the $d\sigma \rightarrow d\sigma^*$ (and $d\pi \rightarrow d\sigma^*$) bands upon CO substitution (by CNR) are not as extensive in the heteronuclear complexes as in the homonuclear dimers. On some occasions even blue shifts are observed. In these cases, one has to conclude that the anti-bonding $d\sigma^*$ MO orbital is also *destabilized* (during the substitution), and the degree of destabilization depends upon the nature of the fragments and the entering ligand.

4. *Bond lengths and stretching frequencies*

The spectroscopic data and metal–metal bond distances for several d^7–d^7 $M(CO)_5$–X complexes (M = Mn, Re, X = organometallic fragment) are presented in Table 3. The assignment for ν(M–M′) (metal–metal stretching frequency) were made on the basis of comparison with well-known binuclear compounds (20, 21). In the case of the mixed Re–Fe dimers, only two spectra were successfully recorded as the compounds were very sensitive to laser degradation. A typical spectrum is presented in Fig. 7. According to the literature, the ν(FeM) values should range between 150 and 200 cm^{-1} (20) for singly bonded dimers or trimers. For $(\eta^5\text{–}C_5H_5)Fe(CO)_2$–$Re(CO)_4$ (CN-*t*Bu), only one peak was found in this range and was hence assigned to ν(FeRe). The peaks below 120 cm^{-1} are due to lattice modes and are generally intense. To support this assignment, the far-IR spectrum was also acquired using the polarity of the molecule to induce some IR activity. Indeed, a weak peak was found at ~175 cm^{-1}. No Raman polarization study was successfully

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

undertaken due to the accelerated laser-induced decomposition of the compounds in solutions. For the $(\eta^5\text{–}C_9H_7)Fe(CO)_2\text{-}Re(CO)_4$ (CNXy) dimer, two peaks were observed in the expected range (191 cm^{-1}, medium; 203 cm^{-1}, weak). An IR peak of medium intensity was located at 203 cm^{-1}. We also noticed that this 203 cm^{-1} peak is often present in the CNR complexes. There was no sign of the 191 cm^{-1} peak in the IR spectrum: presumably it was hidden by the 203 cm^{-1} peak. Based upon the relative intensity argument and the 203 cm^{-1} peak activity in the IR spectrum (for CNR complexes), the assignment for ν(FeRe) at 191 cm^{-1} is preferred.

For the substituted $MnRe(CO)_{10}$ species, the micro-Raman spectra were easy to interpret since the strong and sharp peak associated with ν(MnRe) was readily found at around 155 cm^{-1}. This is the position predicted by the literature (22). While it is well established that CO ligand substitution by a phosphine or an isocyanide group leads to a slight decrease in the r(MM′) (1), we find that ν(MM′) slightly increased in this study (see Table 3 for details). The reverse should have been observed. There is no easy explanation for this behaviour and, tentatively, one can only suggest that low-frequency vibrational mode mixing may be at the origin of this unusual result.

It is also interesting to note that the FeRe dimers exhibit the smallest $d\sigma \rightarrow d\sigma^*$ transition energies, the shortest metal–metal bond distances, and the largest ν(MM′) values. A large part of the reason for these observations is that (*i*) the $(\eta^5\text{–}C_5H_5)Fe(CO)_2$ fragment is energetically different from the $Re(CO)_5$ fragment, (*ii*) third-row elements generally exhibit smaller covalent radii than do fourth- and fifth-row elements, and (*iii*) the lower Fe mass generates higher ν(MM′) values (cf. $\nu = 2\pi C)^{-1}(F/\mu)^{1/2}$).

Molecular and crystal structure of a mixed-phosphine ligand Tc(II) complex, $Tc(PMe_2Ph)_2(DMPE)Cl_2$

FERNANDE D. ROCHON,[1] ROBERT MELANSON, AND PI-CHANG KONG

Département de chimie, Université du Québec à Montréal, C.P 8888, Succ. Centre-ville, Montréal, QC H3C 3P8, Canada

Received February 14, 1994

FERNANDE D. ROCHON, ROBERT MELANSON, and PI-CHANG KONG. Can. J. Chem. **72**, 2183 (1994).

The reaction of $Tc(PMe_2Ph)_3Cl_3$ with an excess of bis(dimethylphosphino)ethane (DMPE) in ethanol solution produced a yellow compound, which was identified by X-ray diffraction methods as a mixed-ligand Tc(II) complex, $Tc(PMe_2Ph)_2(DMPE)Cl_2$. The compound crystallizes in the $P2_1/c$ space group with a = 12.899(6), b = 13.142(8), c = 19.088(9) Å, β = 121.13(3)°, V = 2770(2) Å^3, Z = 4, R = 0.061, and R_w = 0.051. The geometry around the Tc atom is octahedral with the chloro ligands *trans* to each other, while the two PMe_2Ph ligands are in *cis* positions. The Tc—Cl bond distances are 2.431(5) and 2.431(5) Å while the Tc—P bond lengths are 2.434(4) and 2.435(4) Å for PMe_2Ph and 2.400(4) and 2.398(4) Å for the bidentate DMPE ligand. An increase of multiple bonding of the Tc—P bond, as the oxidation state of Tc decreases, is suggested.

FERNANDE D. ROCHON, ROBERT MELANSON et PI-CHANG KONG. Can. J. Chem. **72**, 2183 (1994).

La réaction du $Tc(PMe_2Ph)_3Cl_3$ avec un excès de bis(diméthylphosphino)éthane (DMPE), en solution dans l'éthanol fournit un composé jaune que l'on a identifié par des méthodes de diffraction des rayons X comme un complexe à coordinats mixtes du Tc(II), le $Tc(PMe_2Ph)_2(DMPE)Cl_2$. Le composé cristallise dans le groupe d'espace $P2_1/c$ avec a = 12,899(6), b = 13,142(8), et c = 19,088(9) Å, β = 121,13(3)°, V = 2770(2) Å^3, Z = 4, R = 0,061, and R_w = 0,051. La géométrie autour de l'atome de Tc est octaédrique, avec deux coordinats chloro en *trans* l'un par rapport à l'autre alors que les deux ligands PMe_2Ph sont en positions *cis*. Les longueurs des liaisons Tc—Cl sont de 2,431(5) et 2,431(5) Å alors que celles des liaisons Tc—P sont de 2,434(4) et 2,435(4) Å pour le ligand PMe_2Ph et 2,400(4) et 2,398(4) Å pour le ligand bidentate DMPE. Les résultats suggèrent l'existence d'une augmentation du caractère multiple de la liaison Tc—P avec une diminution de l'état d'oxydation du Tc.

Introduction

The chemistry of technetium has recently become very important, especially because of the use of the isotope ^{99m}Tc in nuclear medicine. For several years, it was used for bone scanning and recently it has been used to study the heart, the brain, the kidneys, the liver, and other organs and also tumor tissue. A good review on medical diagnostic imaging with complexes of ^{99m}Tc was published in 1987 by Clarke and Podbielski (1). Recent advances in this area have been published in a book edited by Nicolini, Bandoli, and Mazzi (2).

We recently started a research project on the synthesis of mixed-ligand Tc complexes with ligands that could be of some interest to the radiopharmaceutical industry. Few mixed-ligand Tc complexes have been reported in the literature. To be useful in the radiopharmaceutical industry, the methods must be simple and adaptable to the use of industrial kits. One type of ligands under study in our laboratory is phosphine derivatives, both monodentate and bidentate. It has been shown that $[Tc(DMPE)_2Cl_2]^+$ (DMPE = bis(dimethylphosphino)ethane) accumulates in the heart of animals (3,4). In humans, the retention time in the heart is too short, probably due to a reduction of the complex to a neutral Tc(II) species that washes out of the heart (5,6). Neutral *trans*-$^{99m}Tc(DMPE)_2X_2$ was found to cross the blood–brain barrier in rats and thus might provide the basis for brain-perfusion imaging agents (7).

Phosphines react with metals in high oxidation states not only as complexing agents but also as reductants. The reaction of NH_4TcO_4 with PR_3 in acidic ethanol solution produces, depending on the conditions, $Tc(PR_3)_2Cl_4$ or (except if R = Ph) $Tc(PR_3)_3Cl_3$ (8). In these reactions, no other reducing agent is used. We recently prepared and characterized several such complexes. These compounds were used as starting material for the preparation of mixed-ligand complexes with Tc in low oxidation states. One such reaction with DMPE produced an interesting Tc(II) compound, which was characterized by X-ray diffraction. The results of this study are described below.

Experimental section

Ammonium pertechnetate ($NH_4{}^{99}TcO_4$) was obtained from Oak Ridge National Laboratory. It was recrystallized in nitric acid (**caution**: ammonium pertechnetate in acid medium will produce some radioactive volatile compound) and dissolved in water. A 0.286 M solution was prepared. All manipulations were made in a laboratory approved for low-level radioactive material (^{99}Tc is a β emitter with a particle energy of 0.292 MeV and a half-life of 2.13×10^5 years). Dimethylphenylphosphine and DMPE were bought from Aldrich.

$Tc(PMe_2Ph)_3Cl_3$ was synthesized according to the method published by Mazzi et al. (8).

$[Tc(PMe_2Ph)_2(DMPE)Cl_2$

$Tc(PMe_2Ph)_3Cl_3$ (0.19 g) was added to a solution containing 1 g of DMPE in 20 mL of ethanol. The solution was left at room temperature until most of the solvent had evaporated. The oily residue was washed with ether, and then dissolved in ethanol. Slow evaporation of the solvent produced crystals suitable for X-ray diffraction methods.

Crystallographic measurements and structure resolution

The yellow crystal was selected after examination for homogeneity under a polarizing microscope. The unit cell parameters were obtained by least-squares refinement of the angles 2θ(16–25°), ω, and χ for 15 well-centred reflections on a Syntex $P\bar{1}$ diffractometer using graphite-monochromatized MoKα radiation. Scan rates and data treatment have already been described (9). Corrections were made for Lorentz-polarization effects, and the anomalous dispersion terms of Tc, P, and Cl were included in the calculations (10).

The coordinates of the Tc atom were determined from the three-dimensional Patterson map and the positions of all the other non-hydrogen atoms were found by the usual Fourier methods. The refinement of the structure was done by full-matrix least-squares analysis

minimizing $\Sigma w(|F_o| - |F_c|)^2$. Most H atoms could be located, but they were fixed at their calculated positions with a $U_{eq} = 0.076$ Å^2. For the methyl H atoms, at least one H was obtained from a difference Fourier map and the positions of the remaining atoms were calculated. Individual weights $w = 1/\sigma^2(F)$ were applied. An isotropic secondary-extinction correction (11) was included in the calculations. The refinement of the scale factor, coordinates, and anisotropic temperature factors of all the non-hydrogen atoms converged to $R = 0.061$ and $R_w = 0.051$. There were a few residual peaks (<0.38 e Å^{-3}) in the close environment of the Tc atom.

The scattering curves of Cromer and Waber (12) were used except for the hydrogen atoms (13). The calculations were done on a Cyber 830 with programs already described (9).

Crystal data and experimental details of the X-ray diffraction study

Compound: $Tc(PMe_2Ph)_2(DMPE)Cl_2 \cdot C_{22}H_{38}Cl_2P_4Tc$; Fw, 596.26; space group: $P2_1/c$; $a = 12.899(6)$, $b = 13.142(8)$, $c = 19.088(9)$ Å, $\beta = 121.13(3)°$, $V = 2770(2)$ Å^3, $Z = 4$, $F(000) = 1228$, $\lambda(MoK\alpha) = 0.710\ 69$ Å, $\rho_{calcd} = 1.429$ Mg m^{-3}, $\mu(MoK\alpha)$ 0.93 mm^{-1}, 2θ max. 55°, octants: $h, k, \pm l, h, 0 \rightarrow 15, k, 0 \rightarrow 17, l, -24 \rightarrow 21$; scan technique and speed; $2\theta/\theta$, 2°–24°/min; standard reflections: 4 0 –4, 0 2 –6, 1 4 –3; no. of independent reflections: 6228, no. of observed reflections: 1925; $I_{net} > 3.0\sigma$; $R = \Sigma||F_o| - |F_c|| / \Sigma|F_o| = 0.061$; $R_w = [\Sigma w(|F_o| - |F_c|)^2 / \Sigma|F_o|^2]^{1/2} = 0.051$; $\Delta/\sigma(\max) = 0.45$; $S = [\Sigma w(|F_o| - |F_c|)^2/(m-n)]^{1/2} = 1.50$.

Results and discussion

Complexes of the types $Tc(PR_3)_2Cl_4$ and $Tc(PR_3)_3Cl$ are good starting material for the synthesis of low oxidation state Tc compounds. In an attempt to synthesize mixed-ligand complexes, we studied the reaction of $Tc(PMe_2Ph)_3Cl_3$ with a bidentate ligand, bis(dimethylphosphino)ethane in ethanol. We obtained yellow crystals, which were studied by X-ray diffraction methods. The results have shown that the compound is a neutral Tc(II) mixed-ligand complex, $Tc(PMe_2Ph)_2(DMPE)Cl_2$.

The refined atomic parameters of the structure are listed in Table 1. A labelled diagram of the molecule is shown in Fig. 1. The bond distances and angles are shown in Table 2. The geometry around the Tc atom is octahedral with the two Cl ligands located in *trans* position to each other and the two monodentate phosphines in *cis* position to each other. The angles around the Tc atom are close to 90° and 180°, but there are some distortions caused by the presence of the bidentate ligand. The chelate angle P(1)—Tc—P(2) is only 80.1(1)°, as was observed in other Tc-bidentate phosphine complexes (14–20).

				2.461 2.443(3)–2.480(1)	2	18, 44

The two bond distances Tc—Cl are 2.431(5) Å, very similar to those reported for the Tc(II) compounds, *trans*-$Tc(DPPE)_2Cl_2$, (2.410(1) and 2.438(1), DPPE = bis(diphenylphosphino)ethane (16)) and *trans*-$Tc(PPh(OEt)_2)_4Cl_2$ (2.41(1) and 2.42(1), (21)). A brief survey (Table 3) of several related Tc(III) (16, 18, 22–28) and Tc(IV) (23, 29–32) octahedral structures containing Cl ligands located in *trans* position to each other has shown that the observed Tc(II)—Cl bond distances are larger than those observed for Tc(III) (d^4 configuration with two unpaired electrons) and Tc(IV) (d^3, with three unpaired electrons) complexes (ave. 2.335 and 2.337 Å, respectively). It seems that the addition of a fourth electron does not

change the radius of the Tc atom, probably because it is paired in the low energy, t_{2g} orbital. But the addition of a fifth electron (Tc(II) has a d^5 configuration) in the lower energy orbitals (t_{2g} in an octahedral field with only one unpaired electron) seems to increase the Tc—Cl bond distances significantly, as expected.

The Tc—P bond distances are 2.400(4) and 2.398(4) Å for the bidentate DMPE ligand. The reported values for Tc(II)-bidentate phosphine ligands vary from 2.39 to 2.47 Å (14, 16, 20, 33, 34) with an average value of 2.42 Å. For the monodentate ligands, the Tc—P bonds are slightly longer, 2.434(4) and 2.435(4) Å. Values ranging from 2.39 to 2.42 (21, 35) have been reported for Tc—P (monodentate, *trans* to P). A survey of 40 related octahedral structures containing Tc—P bonds in *trans* position to a P atom was made for monodentate and bidentate phosphines. The results show that for all oxidation states, except Tc(II) (few Tc(II) structures were reported with monodentate phosphines), the Tc—P bonds are longer by about 0.02 Å for monodentate ligands. This trend is attributed mainly to steric interactions. It was shown that the Tc—P bond distance increases in the order $PMe_2Ph < PEtPh_2 < PPh_3$ (36). Furthermore, the aromatic R groups on the phosphine ligands decrease the σ donor properties, thus weaker bonds are formed. For example, the Tc—P bonds in *trans*-$Tc(PR_3)_2Cl_4$ are 2.524(2), 2.541(1), and 2.556(1) Å for PMe_3, PEt_3, and $PMePh_2$, respectively (30, 32). For bidentate phosphines, a similar trend has been observed. For *trans*-$[Tc(DMPE)_2Cl_2]^+$, the average Tc—P is 2.435(2) Å (18), while it is 2.501(1) Å for *trans*-$[Tc(DPPE)_2Cl_2]^+$ (16) and *trans*-$[Tc(DPPE)_2Br_2]^+$ (15).

A comparison of the reported Tc(II)—P bond distances (in *trans* position to another P), including our values, with those observed for Tc(III) and Tc(IV) compounds, has shown that Tc(II) bonds are significantly shorter. The average values are 2.478 Å (monodentate) and 2.456 Å (bidentate) for Tc(III) and 2.518 (monodentate) and 2.500 Å (tetradentate) for Tc(IV). It has been suggested that the oxidation state of Tc has little effect on its bond length (37). Since bond lengths vary with several factors, including geometry and the ligand located in *trans* position, we have surveyed only octahedral structures and looked at Tc—Cl bonds in *trans* position to Cl and Tc—P bonds in *trans* position to P. The results are shown in Table 3. More data are needed to make definite conclusions on these bond distances, but the data can be useful for future data search. The observed bond ranges are fairly large but it can be suggested that the values are not completely independent of the number of *d* electrons. Several factors must be considered in order to understand the variations: the bulkiness and aromaticity of the ligands (already discussed), the configuration of the metallic center, the charge on the complex, and the possibility of π back-donation to the ligand. Cl is usually not classified as a π-acceptor. Therefore the main factor affecting the Tc—Cl bond should be the number and arrangement of the electrons, which has already been discussed.

Phosphines can accept π-electron density from the metal. Tc in a low oxidation state (≤ 3) is a soft metal and should form π bonds with phosphines. Examination of the Tc—P values in Table 3 shows that the Tc(IV) bonds (2.50–2.52 Å) are longer than the Tc(V) bonds (2.46–2.49 Å), which can be ascribed to an increased number of unpaired electrons (three vs. two). Tc(IV) and Tc(V) are hard metallic centers and no π bonds are expected. For the Tc(III) compounds, the distances are reduced to average values of 2.46 and 2.48 Å. Since the Tc(III)—Cl and Tc(IV)—Cl bonds are identical, the shorter Tc(III)—P bonds compared to Tc(IV)—P bonds cannot be ascribed only to the pairing of the fourth electron. We suggest that the presence of π bonds in Tc(III) compounds is mostly responsible for the decrease. The hypothesis is further confirmed by the Tc(II)—P bond distances, which are significantly shorter, contrary to the Tc(II)—Cl values.

All these data indicate that the configuration of Tc and the number of unpaired electrons are not sufficient to account for these observations, especially when we compared the Tc—P values with the Tc—Cl bonds. We suggest that the decrease of the Tc—P bond distance as the number of electrons increases is due to an increase of multiple bonding of the bond as the oxidation state of Tc decreases.

The average P—C distance is 1.83(2) Å. The angles around the P atom in DMPE are close to the tetrahedral value for the Tc—P—C(ethane) angles (avg. 109.5(7)°), but are larger for Tc—P—CH_3 (avg. 119.7(6)°) angles. The internal angles around C(3) and C(4) are normal (avg. 109(1)°). For the PMe_2Ph ligands, the Tc—P—CH_3 angles (avg. 115.3(5)° are smaller than the Tc—P—C(phenyl) angles (avg. 119.6(5)°) due to the bulkiness of the phenyl groups. All the C—P—C bond angles are smaller than the tetrahedral value, with an average angle of 101.5(8)°. The average C—C bond distance in the phenyl groups is 1.38(2) Å, with an average C—C—C angle of 120(1)°.

A drawing of the packing of the ions inside the unit cell is included in the supplementary material.[2] No hydrogen bonding is expected in this compound. The packing consists of layers of molecules centered at $z = \sim 0$ and ~ 0.5, parallel to the *ab* plane. The molecules are held together only by van der Waals forces.

The possible effects of paramagnetic relaxation on the apparent volumes of activation for exchange reactions in solution, as measured by NMR at high pressures, are considered. Two model paramagnetic systems that do not undergo ligand exchange on the NMR time scale were examined: tri(acetylacetonato)chromium(III) in various perdeuterated solvents, and tris(ethylenediamine)nickel(II) ion in ethylenediamine solvent. No pressure dependence was discernible up to 200 MPa for the chemical shifts of ^{1}H (exemplifying nuclei of spin 1/2) in the Cr(III) complex, or of solvent ^{14}N (representing quadrupolar nuclei) in the Ni(II)–ethylenediamine case. The line widths $\Delta\nu_{1/2}$, however, were significantly dependent on pressure. For ^{1}H in the Cr complex, the increase of $\Delta\nu_{1/2}$ with pressure was less than expected from the theory of scalar interactions, and was small enough to imply that any contribution from this source to the observed volume of activation in exchanging systems may be neglected. For ^{14}N in liquid ethylenediamine, the increase of $\Delta\nu_{1/2}$ with pressure was significantly greater when a paramagnetic solute was present. Thus, before the observed $\Delta\nu_{1/2}$ at a pressure P (in MPa) measured by the NMR of a quadrupolar nucleus can be used to obtain a chemical exchange rate for a paramagnetic solute, it should be reduced by an amount $\Delta\nu_{1/2}{}^0 \exp\{\theta(P - 0.1)(\Delta V_V{}^{\ddagger}/RT + \kappa)\}$, where $\Delta V_V{}^{\ddagger}$ is the activation volume for viscous flow and κ the compressibility of the solvent, $\Delta\nu_{1/2}{}^0$ is the linewidth at 0.1 MPa in the absence of chemical exchange, and θ is a scaling factor between 0 and 1. The factors $\Delta\nu_{1/2}{}^0$ and $\theta(\Delta V_V{}^{\ddagger}/RT + \kappa)$ are obtainable from measurements with a chemically equivalent, nonexchanging, paramagnetic solute.

HIDEO D. TAKAGI, KAYOKO MATSUDA, SEN-ICHI AIZAWA, SHIGENOBU FUNAHASHI, STEPHEN D. KINRADE et THOMAS W. SWADDLE. Can. J. Chem. **72**, 2188 (1994).

On considère les effets possibles de la relaxation paramagnétique sur les volumes apparents d'activation des réactions d'échange en solution, tels que mesurés par la RMN à pressions élevées. On a examiné deux systèmes paramagnétiques modèles qui ne subissent pas d'échange de coordinat à l'échelle de temps de la RMN : le tri(acétylacétonato)chrome(III) dans divers solvants perdeutérés et l'ion tris(éthylènediamine)nickel(II) dans l'éthylènediamine comme solvant. Pour les déplacements chimiques du ^{1}H (représentant le spin 1/2) du complexe de chrome(III) ou du ^{14}N (représentant les noyaux quadripolaires) présents dans le cas du nickel(II)–éthylènediamine, on n'a pas pu décelé de relation avec la pression jusqu'à 200 MPa. Toutefois, les largueurs des raies, $\Delta\nu_{1/2}$, varient beaucoup avec la pression. Pour le ^{1}H du complexe de chrome, l'augmentation du $\Delta\nu_{1/2}$ avec la pression est moins importante que celle prévue par la théorie des interactions scalaires et elle est suffisamment faible pour impliquer que toute contribution de cette source au volume d'activation observé dans les systèmes subissant un échange peut être négligée. Pour le ^{14}N dans l'éthylènediamine liquide, l'augmentation du $\Delta\nu_{1/2}$ avec la pression est beaucoup plus importante lorsqu'un soluté paramagnétique est présent. Donc, un $\Delta\nu_{1/2}$ d'un noyau quadripolaire obtenu à une pression donnée P (en MPa) par une mesure de RMN doit, avant d'être utilisé pour obtenir une vitesse d'échange chimique d'un soluté paramagnétique, être réduit par une quantité égale à $\Delta\nu_{1/2}{}^0 \exp\{\theta(P - 0{,}1)(\Delta V_V{}^{\ddagger}/RT + \kappa)\}$ dans laquelle $\Delta V_V{}^{\ddagger}$ est le volume d'activation pour un écoulement visqueux et κ est la compressibilité du solvant, $\Delta\nu_{1/2}{}^0$ est la largueur de la raie à 0,1 MPa en l'absence d'échange chimique et θ est un facteur scalaire entre 0 et 1. On peut obtenir les facteurs $\Delta\nu_{1/2}{}^0$ et $\theta(\Delta V_V{}^{\ddagger}/RT + \kappa)$ en faisant de mesures à l'aide d'un soluté paramagnétique chimiquement équivalent qui ne s'échange pas.

[Traduit par la rédaction]

Introduction

The volume of activation $\Delta V^{\ddagger}$ (= $-RT(\partial \ln k/\partial P)_T$, where k is a rate constant at pressure P and temperature T) is frequently used in the elucidation of mechanisms of ligand substitution and electron transfer reactions in solution (1, 2). In particular, analysis based on the high-pressure NMR technique has provided a significant amount of mechanistic information (2). The estimation of exchange rate constants by the NMR technique is usually carried out by a line-shape analysis based on the Swift–Connick equation (3) or the slow- or fast-exchange approximations (2). However, relatively little attention has been paid to the effect of pressure on the relevant NMR parameters (4–6). It is well known that natural line widths of solvent signals without chemical exchange are influenced significantly by the presence of paramagnetic molecules (7). As the nuclear spin relaxation depends strongly on the mobility of the molecules and (or) the electric field gradient around the observed nuclei, the possibility arises that the relaxation time and chemical shift may be significantly influenced by the applied pressure in the presence of paramagnetic molecules.

In this article, we examine the pressure dependence of ^{1}H and ^{14}N signals, representing spin-1/2 and quadrupolar nuclei, respectively, in the presence of paramagnetic nuclei. The results

are discussed on the basis of the extended Solomon–Bloembergen–Morgan (SBM) theory (8).

Experimental

Tri(acetylacetonato)chromium(III) (acetylacetone = 2,4-pentanedione, "Hacac") and tris(ethylenediamine)nickel(II) trifluoromethanesulfonate (ethylenediamine = 1,2-diaminoethane, "en") were synthesized by the literature methods (9, 10). Acetonitrile-d_3 (MSD Isotopes) was distilled twice from phosphorus pentoxide in a vacuum line before use. Other perdeuterated solvents, also from MSD Isotopes, were used without further purification. Ethylenediamine (Wako Pure Chemical Co. Ltd.) was purified by vacuum distillation after treatment with sodium (10, 11).

NMR measurements were carried out by using specially designed high-pressure probeheads with Bruker WH-90 (12) and JEOL GX-270 (13) NMR spectrometers for the ^{1}H and ^{14}N observations, respectively. The temperature of the sample solutions was controlled by passing either thermostated water or air through the jackets of the respective probeheads. Perfluorohexane was used as a pressurizing fluid for the observation of ^{1}H, and Daifloil no. 1 (Daikin Kogyo Co.) for ^{14}N measurements.

Results

The pressure dependences of the chemical shift ($\Delta\nu$) and line width ($\Delta\nu_{1/2}$) of methyl protons in coordinated acetylacetone on tri(acetylacetonato)chromium(III) ion (0.03–1.0 mol kg^{-1}) were observed at 90.02 MHz in various perdeuterated solvents. The results are listed in Table 1. The chemical shift of the methyl proton signal relative to that of the internal benzene signal as a reference was not affected by the applied pressure up to 200 MPa. Benzene was chosen as a reference material as little or no interaction with $Cr(acac)_3$ was found in previous studies (12).

The line width $\Delta\nu_{1/2}$ of the proton signal was, however, obviously dependent on pressure (Table 1). Plots of $\ln(\pi\Delta\nu_{1/2})$ (i.e., $\ln T_2^{-1}$, where T_2 is the nuclear transverse relaxation time) vs. pressure for the methyl proton signals on the coordinated acetylacetone were linear, as shown in Fig. 1. As $Cr(acac)_3$ is substitution-inert, the line-width change caused by the applied pressure is attributable to the variation in T_2 of protons through

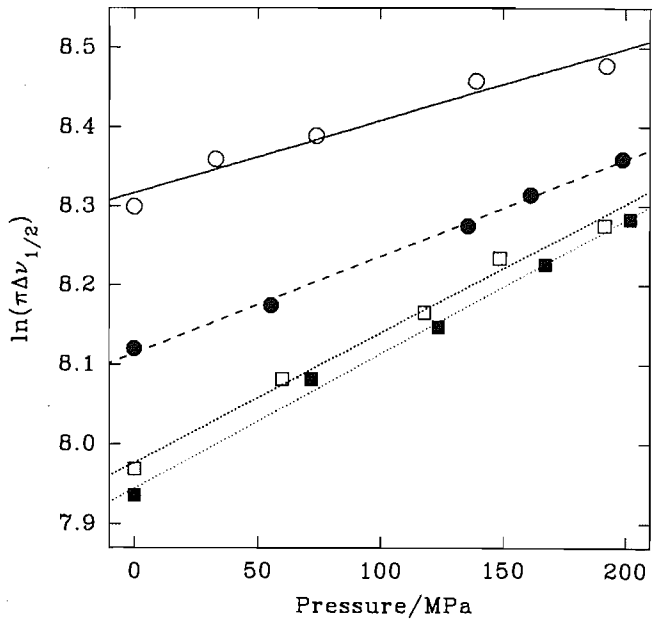

FIG. 1. Pressure dependence of the line widths of the methyl protons on tri(acetylacetonato)chromium(III) (0.1 mol kg^{-1}) in selected solvents at 24.9°C. the change in the rotational correlation time τ_R of molecular tumbling. As the relaxation of nuclei on the coordinated ligand occurs essentially through the scalar interaction, the correlation time for this process should be directly related to the electron spin relaxation time τ_e of the central paramagnetic metal ion.

It was not possible to observe the line width of ^{14}N in coordinated ethylenediamine in $Ni(en)_3^{2+}$ because of the very strong electronic interaction between coordinated nitrogen atoms and the central paramagnetic metal ion, together with the intrinsically broad line width characteristic of quadrupolar nuclei. Instead, the pressure dependence of the ^{14}N line width of *bulk* ethylenediamine was measured with and without the presence of the $Ni(en)_3^{2+}$ ion and results are listed in Table 2. Errors in $\Delta\nu_{1/2}$ were less than ±1%. No pressure dependence of the chemical shift was observable. Semi-logarithmic plots of $\pi\Delta\nu_{1/2}$ (= T_2^{-1}) against pressure, with and without the presence of 0.1145 mol kg^{-1} $Ni(en)_3^{2+}$, are shown in Fig. 2. Both plots are linear, but both the $\pi\Delta\nu_{1/2}$ values and the slope ($(2.73 \pm 0.08) \times 10^{-3}$ vs. $(2.00 \pm 0.06) \times 10^{-3}$ MPa^{-1}) are larger for $Ni(en)_3^{2+}$/en than for pure ethylenediamine, which implies the operation of an extra relaxation process in the presence of Ni(II). Figure 3 shows that the ^{14}N line-broadening due to the presence of Ni(II) is quite strongly dependent on pressure: the slope of the semi-logarithmic plot is $(5.3 \pm 0.4) \times 10^{-3}$ MPa^{-1}, corresponding in volume terms to 13 cm^3 mol^{-1}. Thus, the practice in exchange studies of subtracting the natural line width of the solvent from the exchange-broadened $\Delta\nu_{1/2}$ at various pressures may yield erroneous values of k and $\Delta V^{\ddagger}$ for the exchange process at paramagnetic centres.

Discussion

Proton NMR

The fractional chemical shift $\Delta\nu/\nu$ caused by the presence of paramagnetic species is generally expressed by the following two equations, corresponding to the Fermi contact (FCS) and

the pseudo-contact (or dipolar) (PCS) terms, respectively (14, 15):

$$[1]\quad \Delta\nu/\nu = -A_c(\gamma_e/\gamma_N)g_e\beta_e S(S+1)/3k_BT\ (\text{FCS})$$

$$[2]\quad \Delta\nu/\nu = -(3\cos^2\phi - 1)(g_\parallel^2 - g_\perp^2)\beta_e^2 S \times (S+1)/9k_BTr^3\ (\text{PCS})$$

Here, A_c is the Fermi contact coupling constant, g_e is the electronic Landé splitting factor, γ_e and γ_N are the magnetogyric ratios of the electron and the nucleus, respectively, β_e is the Bohr magneton, S is the electronic spin quantum number, k_B is Boltzmann's constant, T is the temperature, r is the distance from the paramagnetic centre to the observed nucleus, ϕ is the angle between r and the principal symmetry axis of the molecule, and $g_\parallel$ and $g_\perp$ are, respectively, the components of g_e parallel and perpendicular to this axis. As the terms that appear in the isotropic FCS interaction are not pressure sensitive, the Fermi contact term is not pressure dependent, as Nielson et al. (4) have verified experimentally. The pseudo-contact term, however, might be expected to show some pressure dependence, as the interaction distance r in eq. [2] is dependent on pressure. The pressure dependence of the anisotropic PCS interaction is expressed by eq. [3], in which κ_i is the compressibility of the complex ion, P is the pressure in MPa, and r_0 is the value of r at atmospheric pressure:

$$[3]\quad \{\partial(\Delta\nu/\nu)/\partial P\}_T = (\text{constant}/T)\exp\{\kappa_i(P - 0.1) - 3\ln r_0\}$$

For complexes of first-row transition metals, however, κ_i is on the order of 10^{-5} MPa^{-1} (16), so that the pressure dependence of the chemical shift should be negligible over the usual range of pressures (0.1–200 MPa), as was indeed observed in our ^1H NMR experiments on $Cr(acac)_3$ in four different solvents (Table 1) and in those of Newman et al. (6) on $Ni(CH_3CN)_6^{2+}$ in CH_3CN.

Unlike the chemical shift, however, the ^1H line width $\Delta\nu_{1/2}$ did exhibit a degree of pressure dependence (Table 1 and Fig. 1). Intramolecular scalar interactions between ^1H and unpaired electrons control the rate of transverse relaxation (15) and hence $\Delta\nu_{1/2}$:

$$[4]\quad T_{2sc}^{-1} = [A_c^2 S(S+1)/3][\tau_e + \tau_e/\{1 + (\omega^2 - \omega_I^2)\tau_e^2\}]$$

where T_{2sc}^{-1} ($\approx \pi\Delta\nu_{1/2}$) is the rate of transverse relaxation by unpaired electrons, ω_s and ω_I are the Larmor frequencies of the electron and nuclear spins, respectively, and τ_e is the electron spin relaxation time. Usually, $\omega_s^2\tau_e^2$ is very large, so that the term $\tau_e/\{1 + (\omega_s^2 - \omega_I^2)\tau_e^2\}$ can be neglected and T_{2sc}^{-1} is effectively proportional to τ_e. For small ions in solution, τ_e may be taken to be proportional to the solution viscosity η (17). On the

other hand, the outer sphere relaxation time for the proton, T_{2os}, is related to the dipole–dipole interactions expressed by eq. [5] (14):

$$[5] \quad T_{2os}^{-1} = 8\pi\gamma_I^2\gamma_S^2 S(S+1)N\eta/5k_BT$$

where N denotes the concentration of the paramagnetic species.

Thus, the pressure dependence of T_2^{-1} $(= T_{2sc}^{-1} + T_{2os}^{-1})$ is, in principle, determined by the pressure dependence of the viscosity, and this in turn can be presented in terms of the Stearn–Eyring volume of activation for viscous flow $\Delta V_V^{\ddagger} = RT[(\partial \ln \eta/\partial P)_T - \kappa]$, where κ is the isothermal compressibility of the solvent (18).[2] For normal liquids, over relatively low ranges of P (here, 0.1–200 MPa), $(\partial \ln \eta/\partial P)_T$ is sensibly constant, and we might therefore anticipate that a plot of ln $\pi\Delta\nu_{1/2}$ vs. P would give a straight line of slope $[(\Delta V_V^{\ddagger}/RT) + \kappa]$. Although these plots are indeed linear for ^1H in $Cr(acac)_3$ in various solvents (Fig. 1), their slopes are only a fraction θ of the theoretical value (Table 3):

$$[6] \quad T_{2(P)}^{-1} = T_{2(0)}^{-1} \exp[\theta(\Delta V_V^{\ddagger}/RT + \kappa)(P - 0.1)]$$

where $T_{2(P)}$ and $T_{(0)}$ are the values of T_2 at pressures P and 0.1 MPa, respectively.

This result echoes the findings of several authors (20–26) that the pressure dependences of the longitudinal relaxation times T_1 of protons in many liquids are smaller than expected from those of the corresponding bulk viscosities. The essence of the generally accepted explanation, first advanced by Benedek and Purcell (20), is that an increase in pressure restricts translational motion more severely than it restricts molecular rotation (24). Accordingly, following the approach of McClung and Kivelson (27), the Stokes–Einstein–Debye expression for the rotational correlation time τ_R,

$$[7] \quad \tau_R = V\eta/k_BT$$

where V is the molecular volume, can be modified by introduction of parameters f_{stick}, which is a pressure-independent function of molecular shape, and C, which is a measure of the rotational–translational coupling (26), such that generally $0 < f_{stick}C \leq 1$:

$$[8] \quad \tau_R = V\eta f_{stick}C/k_BT + \tau_O$$

[2]In effect, $\Delta V_V^{\ddagger}/RT$ is the pressure derivative of the logarithm of the *kinematic* viscosity (18*b*).

In the present context, the zero-viscosity correlation time τ_O can be disregarded, and it may be assumed that T_2 depends on τ_R in the same way as does T_1. The key point is that C generally diminishes with increasing pressure, partially offsetting the increase in η. It follows that $0 < \theta \leq 1$.

The following formalism is therefore proposed to distinguish exchange broadening from that of, for example, paramagnetic relaxation and probehead distortion:

$$[9] \quad \Delta\nu_{1/2(obs)} = \Delta\nu_{1/2(exch)} + \Delta\nu_{1/2}{}^0 \exp[\theta(P - 0.1)(\Delta V_V^{\ddagger}/RT + \kappa)]$$

Here, $\Delta\nu_{1/2(obs)}$ is the observed line width at half maximum, $\Delta\nu_{1/2(exch)}$ is the contribution of chemical exchange, and $\Delta\nu_{1/2}{}^0$ is the line width measured at 0.1 MPa in the absence of chemical exchange. The parameter $[\theta(\Delta V_V^{\ddagger}/RT + \kappa)]$ can be obtained experimentally from measurements on chemically similar nonexchanging systems, and so the correction of pressure effects on line widths for paramagnetic effects becomes possible.

Nitrogen-14 NMR

For quadrupolar nuclei, Merbach et al. suggested that the scalar interaction is also the dominant relaxation process for the nuclei on the coordinated ligand (5). Therefore, eq. [6] may again be applicable to the estimation of the extra broadening of line widths of quadrupolar nuclei on the ligand directly coordinated to paramagnetic metal ions. However, for the outer-sphere interactions it is well known that quadrupolar relaxation is usually the dominant relaxation pathway for nuclei with spins greater than 1/2. For such nuclei in a molecule in solution, the quadrupolar relaxation time, T_{2q}, in the motional narrowing limit may be expressed by the following equation:

$$[10] \quad T_{2q}^{-1} \approx T_{1q}^{-1} = (3\pi^2/10)[(2I+3)/I^2(2I-1)] \times (e^2qQ/h)^2(1 + \xi^2/3)\tau_R$$

in which e^2qQ/h is the nuclear quadrupolar coupling constant, I is the nuclear spin quantum number (= 1 for ^{14}N), and ξ represents the deviation of the electric field gradient from axial symmetry (28). As τ_R is related to the solvent viscosity, the pressure dependence of T_{2q} may again be expected to be partly related to the volume of activation $\Delta V_V^{\ddagger}$ of viscous flow of the solvent. For neat liquid ethylenediamine, neither $\Delta V_V^{\ddagger}$ nor the compressibility κ are known; however, ln T_2^{-1} for ^{14}N is a linear function of pressure (Fig. 2) with slope $(2.00 \pm 0.06) \times 10^{-3}$ MPa^{-1}, which corresponds to a volume of activation $\Delta V_R^{\ddagger}$ of

4.9 ± 0.2 cm^3 mol^{-1} for rotational diffusion. This may be compared with $\Delta V_R^{\ddagger} = 6.3$ cm^3 mol^{-1} for diffusion of acetonitrile by rotation perpendicular to the C_{3v} axis, obtained from the pressure dependence of the ^{14}N line width of liquid CH_3CN (29).

The additional broadening caused by the addition of $Ni(en)_3^{2+}$ ion to ethylenediamine, together with the steep slope of the plot in Fig. 3, implies the existence of strong outer-sphere interactions between ^{14}N of the bulk solvent and paramagnetic $Ni(en)_3^{2+}$. One of the authors has reported, on the basis of the Swift–Connick plot, that outer-sphere relaxation characterized by the relaxation time T_{os} is indeed the dominant process for the Ni(II)–ethylenediamine solvent exchange system under the conditions used in this experiment (10). These outer-sphere interactions may again be expected to correlate with τ_R, as discussed above. As the plots shown in Figs. 2 and 3 are linear within the experimental uncertainty, the dependence of line width on the applied pressure may reasonably be expressed by an equation similar to eq. [3], and the relatively large correction to $\Delta\nu_{1/2(obs)}$ for the paramagnetic contribution may again be made through eq. [9].

Conclusion

In this article, we report the pressure dependence of the chemical shifts and line widths of ^{1}H in a coordinated ligand, and of ^{14}N in a bulk solvent, under the influence of paramagnetic metal ions. The chemical shifts of ^{1}H and ^{14}N were independent of pressure up to at least 200 MPa. The line width of the proton signal in $Cr(acac)_3$, however, showed a small but measurable dependence on pressure. As the pressure effect on the proton line widths was smaller than that expected from the theory of scalar interactions, a scaling factor θ, representing the pressure dependence of the rotational–translational coupling, was introduced in eq. [6]. Since θ is substantially less than 1, a conservative upper limit to the paramagnetic correction to the pressure effect on ^{1}H relaxation can be calculated from the pressure dependence of solvent viscosity, where this is known. In practice, the paramagnetic correction to pressure effects on ^{1}H line widths will be much less than this. For the quadrupolar nucleus ^{14}N, the pressure dependence of the line width was significant even in the absence of a paramagnetic solute. In the presence of paramagnetic molecules in solution, a relatively large pressure effect on the ^{14}N line width was observed even when chemical exchange was not significant.

Thus, activation volumes for exchange reactions, obtained from line-broadening measurements using ^{1}H or other spin-1/2 nuclei, may be reliable within experimental accuracy even without correction for the extra broadening caused by the outer-sphere interactions between the observing nucleus and a paramagnetic solute, which is consistent with experience in previous studies (2, 6, 12). On the other hand, when quadrupolar nuclei are used for the observation of exchange kinetics, volumes of activation obtained by high-pressure NMR methods may not be valid without corrections for the pressure dependence of the natural line widths using the method described here. For water, the factor $(\Delta V_V^{\ddagger}/RT + \kappa)$ at near-ambient temperatures is only about 5×10^{-4} MPa^{-1}, so that paramagnetic corrections to $\Delta V^{\ddagger}$ for exchange reactions will generally be less than the experimental uncertainty even for measurements using quadrupole nuclei. For many commonly used nonaqueous solvents including ethylenediamine, $\Delta V_V^{\ddagger}$ or κ values are not available at present, but quantitative correction of $\Delta V^{\ddagger}$ is still possible through NMR measurements on chemically similar nonexchanging systems using eq. [9].

1994 Syntex Award Lecture
Anionic electrophiles, protein modification, and artificial blood[1]

RONALD KLUGER[2]

Lash Miller Laboratories, Department of Chemistry, University of Toronto, Toronto, ON M5S 1A1, Canada

Received June 16, 1994

RONALD KLUGER. Can. J. Chem. **72**, 2193 (1994).

Monomethyl esters of acyl phosphates (mixed anhydrides of carboxylic and phosphoric acids) are being developed as site-directed acylating agents for amino growps in proteins. In an illustrative application, these anionic materials are shown to bind to a positively charged region of hemoglobin where they convert amino groups to amides. Bifunctional acyl methyl phosphates cross-link hemoglobin to give a variety of products, some of which have the oxygen-binding properties anticipated for materials that can serve as an alternative to red cells in transfusions. Higher yields of desired products result from the use of a trifunctional analogue. Kinetic patterns of the reactions of a series of alkyl amines and methyl aroyl phosphates indicate that the transition state for formation of the amide involves almost complete development of positive charge on nitrogen.

RONALD KLUGER. Can. J. Chem. **72**, 2193 (1994).

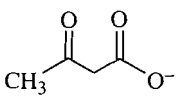
On a développé des méthodes permettant d'utiliser les esters monométhylés des phosphates d'acyles (anhydrides mixtes des acides carboxylique et phosphorique) comme agents d'acylation orientées vers les sites de groupes aminés des protéines. Dans une application typique, on a montré que ces matériaux anioniques se lient à une région chargée positivement de l'hémoglobine et qu'ils transforment alors les groupes aminés en amides. Les phosphates bifonctionnels acyle méthyle provoquent une réticulation de l'hémoglobine conduisant à une variété de produits dont quelques-uns possèdent les propriétés de liaison à oxygène recherchées pour des matériaux pouvant servir comme alternative aux globules rouges lors de transfusions. On obtient de meilleurs rendements des produits désirés lorsqu'on utilise un analogue trifonctionnel. Les patrons de la cinétique des réactions d'une séries d'alkylamines et de phosphates de méthyle et d'aroyle indiquent que l'état de transition de la formation de l'amide implique un développement pratiquement complet de la charge positive sur l'azote.

[Traduit par la rédaction]

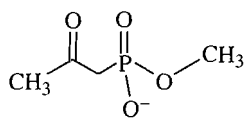
We have been developing methyl acyl phosphates as a new type of highly specific reagent for the modification of proteins (1–4). We have found convenient routes for preparing a variety of acyl derivatives and have demonstrated the utility of these compounds in specifically cross-linking human hemoglobin so that the modified protein can be used in medical applications, such as carrying oxygen in a transfusion medium (5–8).

Methyl acetyl phosphate

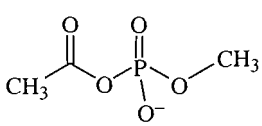
When we began our study, we were aware of no specific attempt to use acyl phosphate monoesters as reagents for protein modification. However, there were a number of studies that indicated that they would be worth trying. We had been studying enzymes that catalyze reactions of acetoacetate and found that 3-ketophosphonate monoesters, such as methyl acetonylphosphonate, are competitive inhibitors (9).



Acetoacetate



Methyl acetonylphosphonate



Methyl acetyl phosphate

Extending the analogy, methyl acetyl phosphate might bind and also react with nucleophiles. Di Sabato and Jencks reported in 1961 that phenyl acetyl phosphate monoanion is stable in nuetral solution (half-life of about 100 h) and reacts rapidly with amines to produce amides (10, 11). Based on this reaction pattern, acyl phosphate monoesters, such as methyl acetyl phosphate, might be especially useful for the selective modification of proteins. If they associate with the protein, then they could acylate amino groups of the protein with minimal competing hydrolysis. Since they are negatively charged, they would bind at sites that attract anions (12).

A major obstacle to testing this hypothesis was the lack of a practical route to methyl acetyl phosphate. While acetyl phosphate can be made from acetic anhydride and potassium phosphate (13), the reaction of methyl phosphate and acetic anhydride does not give methyl acetyl phosphate in useful, isolable quantities. However, we had already prepared dimethyl acetyl phosphate (14) and had also used sodium iodide in acetone to monodemethylate a very reactive phosphate triester (15). While dimethyl acetyl phosphate is a very reactive and unselective acylating agent, reaction with sodium iodide in dry acetone quantitatively converts the diester to the monoester sodium salt, leaving the anhydride intact (1).

We found that methyl acetyl phosphate binds competitively with acetoacetate to D-3-hydroxybutyrate dehydrogenase at high pH and inactivates the enzyme in a few minutes (1, 2). Methyl acetyl phosphate is very stable in neutral water at 25°C with a half-life of 160 h (1). Our report of these results led Manning to recognize that the molecule might be an alternative to cyanate for the selective modification of hemoglobin.

The treatment of sickle cell disease with chemicals has been a significant medicinal target. Cerami, Manning, and co-workers showed that cyanate selectively carbamylates amino groups in a positively charged central cavity of hemoglobin, the site to which 2,3-diphosphoglycerate (DPG) binds (16). The alteration

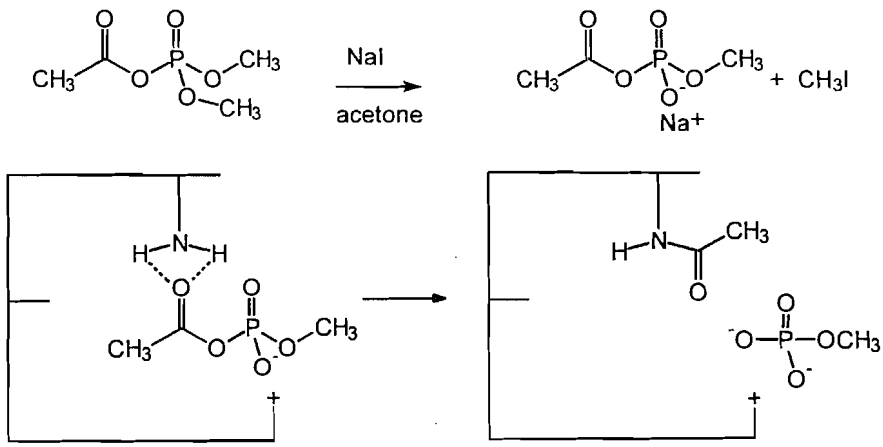
For personal use only.



of hemoglobin's oxygen affinity by modification of this site reduces the tendency of sickle cell hemoglobin to undergo sickling (the condition blocks circulation of the red cells). When cyanate proved to be unsuitable for further development for the treatment of sickle cell disease (due to its causing peripheral neuropathy), other anionic acylating agents were examined. Klotz et al. prepared and studied a variety of substituted salicylates, some of which proved to react selectively with amino groups in the region to which DPG binds (17).

Methyl acetyl phosphate and hemoglobin

Manning suggested that we jointly investigate the utility of methyl phosphate. The work in Manning's laboratory with Pospischil and Ueno established that methyl acetyle phosphate preferentially acetylates amino groups in the DPG-binding site of human hemoglobin, making it a potentially less toxic alternative to cyanate (16). The reagent is highly selective, reacting mainly with two of the 24 amino groups per αβ dimer, the ϵ-amino group of β-lys-82, and the α-amino group of the β-N-terminal valine (3, 18). Further work from Manning and coworkers indicated that methyl acetyl phosphate is an effective anti-sickling agent and can also be used as a general acetylating agent for identifying sites that bind anions (19, 20).

Since methyl acetyl phosphate is highly selective in its reactions with hemoglobin, it appeared that acyl phosphate monoesters in general might be useful in site-directed protein modification. As anions, the reagents would be attracted to positively charged regions and, as anionic electrophiles, they should react with uncharged nucleophiles in preference to anions. Thus, they would react with amino groups in the regions that were associated with other positively charged groups. However, our synthesis of methyl acetyl phosphate could not be easily extended to many other acyl derivatives since the acid chloride serves as the solvent for the reaction.

Chemicals that selectively modify hemoglobin are also an important resource in the development of hemoglobin-based oxygen carriers, replacements for red cells in transfusions. Red cells are the key component in a blood transfusion, being the material that gives blood the ability to carry adequate amounts of oxygen to tissues and organs via the circulatory system. The membranes of the red cells are subject to viral infection and their antigenic properties are the basis for the human blood type groups. Hemoglobin is the predominant protein within the red cell, reversibly and cooperatively binding oxygen (four molecules of oxygen per hemoglobin tetrarner.) Outside the red cell, native hemoglobin is not a satisfactory oxygen-carrying material. The tetramer dissociates into dimers that are passed through the kidney and into the urine. As well, 2,3-diphosphoglycerate (DPG) in the red cell promotes release of oxygen from hemoglobin. In free circulation, where DPG concentration is low, native hemoglobin does not release oxygen to a useful extent (21).

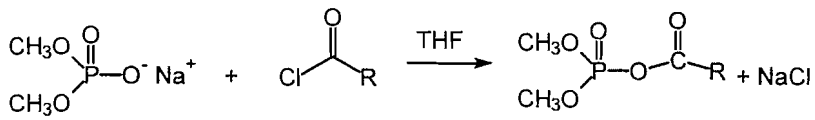
Difunctional acyl phosphate methyl esters and cross-linking hemoglobin

The problems with native hemoglobin as a substitute for hemoglobin in red cells might be overcome by appropriate chemical modification of hemoglobin. The tetramer can be held together by covalently connecting one dimer to another by a chemical cross-link (22). If the cross-link also reduces the oxygen affinity in analogy to the effect of DPG, then both major problems would be overcome. Since methyl acetyl phosphate reacts at the site to which DPG binds, it is possible that such a reaction might also lead to an appropriate decrease in oxygen affinity of the modified hemoglobin. A cross-linker that is directed to the DPG site could combine the needed properties. Therefore, a general synthesis of acyl phosphate monoesters, including difunctional materials, became desirable on several counts. Klotz's pioneering work with dibromosalicylate esters of dicarboxylic acids had shown that cross-linking can be made to occur with some degree of selectivity.

First of all, the reaction of acetyl chloride and trimethyl phosphate to produce dimethyl acetyl phosphate, the precursor to methyl acetyl phosphate, is very slow and inefficient, requiring days of heating. Andrew Grant in our laboratory found that the simple expedient of using the more reactive acetyl bromide in place of acetyl chloride makes the reaction occur more rapidly and efficiently. However, the method did not extend to diacid bromides, potential precursors of cross-linkers, since these tended to form anhydrides. An efficient alternative was devised by Grant in collaboration with Stephen Bearne. They found that sodium dimethyl phosphate reacts efficiently with acid chlorides and diacid chlorides to produce the corresponding dimethyl acyl phosphate or bis(dimethyl phosphate) in tetrahydrofuran. To encourage reaction by increasing solubility, crown ethers were added. However, we found that the yield increased with decreasing amounts of crown ether. The reaction was most efficient in the absence of crown ethers (4).

The product could be converted to the corresponding methyl acyl phosphate or bis(methyl phosphate) by reaction with sodium iodide in acetone. Thus, we converted a number of diacid chlorides to diacyl bis(methyl phosphates). The method

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.



also permitted us to make methyl benzoyl phosphate and aromatic-substituted derivatives. The latter compounds served as the basis for physical organic studies of the reactivity of methyl acyl phosphates.

We then began an ongoing collaboration with Richard T. Jones of Oregon Health Sciences University. Jones had done extensive research that had focused on the determination of structures of mutant and modified hemoglobins. Reaction of the bis(dimethyl) diacyl phosphates with hemoglobin gave a variety of products whose structures were analyzed in Oregon. The method involves HPLC separations and analysis of the products of proteolytic digestion. With Jones' help we also began to do structural analyses in our laboratory. Daniel T.-b. Shih, also of Oregon Health Sciences University, joined this collaboration based on his interest in the oxygen-binding properties of modified hemoglobins.

In consultation with Jones and Shih we decided to prepare potential cross-linkers in which the span between the two acyl functions was relatively rigid so that we could develop an understanding of the effects of length and site of the cross-link. The derivatives were from the following relatively rigid dicarboxylic acids: fumaric, isophthalic, terephthalic, *trans*-stilbene-3,3′-dicarboxylic, and *trans*-stilbene-4,4′-dicarboxylic. The approximate distances between cross-linked amino groups with these reagents are 6.1, 7.3, 7.5, 13.2, and 16 Å, respectively. Human hemoglobin A was reacted with about 1.5 equivalents each of bis(methyl acyl phosphates) and the products separated on an AX-300 anion exchange column. The individual modified hemoglobins were collected and their oxygen-binding properties determined. The hemoglobins were also separated into ferrohemes and globin chains on a C-4 reverse-phase HPLC column. Since amino acid sequences of the tryptic peptides of hemoglobin are known, the site of an acylated amino residue is easily localized because the adjacent peptide is no longer susceptible to cleavage by trypsin, a digestive enzyme that is specific for peptides adjacent to basic amino acids. Acid hydrolysis and amino acid analysis of the peptides is used to confirm the contents of the peptides.

The products of the reaction of hemoglobin and the methyl acyl phosphates reflected our expectation that reaction in the DPG site at residues lys-82 and val-1 of the β chains would be predominant. Different product patterns appear when hemoglobin is reacted after being deoxygenated compared to when the hemes are occupied by CO (or dioxygen). In deoxyhemoglobin, most cross-links were between val-1 of one β subunit and lys-82 of the other β subunit. With carbonmonoxy-hemoglobin the cross-links form mainly between the ϵ-amino groups of the two lys-82 residues of the β subunits (8).

Properties of cross-linked hemoglobins

All the cross-linked hemoglobins we produced show a high degree of cooperativity in their binding of oxygen. The Hill coefficient at 50% saturation (n_{50}) is a common empirical indicator of the extent of cooperativity in the binding of oxygen to hemoglobin and is related to the slope of a tangent to a curve measuring oxygen bound as a function of oxygen pressure at half saturation. With four ligands, as in hemoglobin, $1 < n_{50} < 4$. Noncooperative binding gives $n_{50} = 1$. In the red cell, binding of

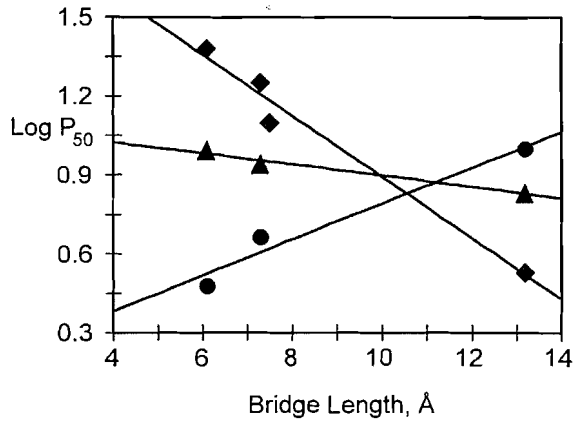


FIG. 1. Variation of oxygen affinity of cross-linked human hemoglobin as a function of site and structure of cross-link: (◆) β-lys-82 (ϵ-amino) to β′-val-1 (α-amino); (●) β-lys-82 (ϵ-amino) to β′-lys-82 (ϵ-amino); (▲) β-lys-82 (ϵ-amino), not cross-linked.

oxygen is highly cooperative and n_{50} is ~3. In all the cross-linked hemoglobins in our studies n_{50} is >2.

There is a considerable variation in affinities of the cross-linked hemoglobins for oxygen. In the case of those cross-linked from val-1 to lys-82, there appears to be a systematic and approximately linear variation between the length of the cross-link and log P_{50}. (P_{50} is the oxygen pressure necessary to cause the hemoglobin oxygen-binding sites to be 50% occupied. Since this is related to the free energy of binding, correlation is logical between a property and the log P_{50}.)

The relationship indicates that for hemoglobin cross-linked from β-val-1 to β′-lys-82, the shorter the cross-link, the lower the oxygen affinity. For materials linked between the two β-lys-82 residues, the relationship has a smaller slope with opposite sign: the longer the cross-link, the lower the oxygen affinity (8). The physical basis of these relationships and tests with further examples are the subjects of ongoing research.

The Monod model for hemoglobin's oxygen affinity assumes the existence of two states, R ("relaxed") and T ("tense"), with high and low oxygen affinities, respectively. If deoxy-hemoglobin is cross-linked in the T state, then relaxation of the protein to the R state upon oxygen binding (axial movement of αβ dimers with respect to one another) is reduced. The shorter the cross-link, the less movement is possible toward the conformation of the R state. On the other hand, if CO hemoglobin, in which the protein is in the R form, is cross-linked, then the shorter the cross-link, the more difficult it will be for the protein to move to the T conformation of the deoxygenated state (21).

Based on the oxygen-binding curves of the derivatives and the typical oxygen pressures in arterial and venous blood, the isophthalyl (or benzene-1,3-dicarboxyl) derivative (cross-linked between residues β-val-1 and β′-lys-82) appears to be the most suitable to be tried as a red cell substitute. However, this is only one component of the mixture that results from the reaction. The reagent also links residues val-1 and lys-82 of the same subunit and produces a significant amount of material linking the lys-82 residues of the two β subunits. In addition, some derivatives are not cross-linked but instead involve sin-

For personal use only.

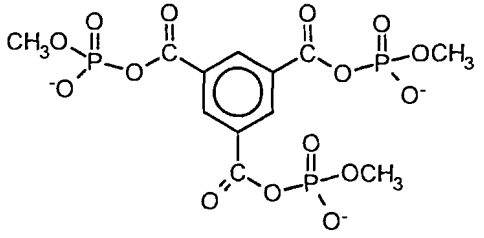
gle-chain modifications. For a modified hemoglobin to be produced on a useful scale, there has to be more of the desired product.

Trifunctional reagents for efficient cross-linking

There are two logical approaches to this problem. The first is to change conditions to favor the desired product. The results we had did not indicate that any particular conditions would do this. Variation in pH, temperature, mode of addition, ionic strength, and buffer were considered and some were tested with and without modest success. The second approach involves changing the reagent. Acyl phosphate monoesters were probably the most likely type of compound to give the desired product. The span of the isophthalyl geometry was what we were seeking, so that could not be changed. The operational problem is that if an undesired cross-link is produced, there is no further reaction possible since the reagent has two reaction sites. If the reagent has more reaction sites, then the possibility of having further reactions produce useful cross-links occurs even if an undesired cross-link has been formed. This should be a suitable solution if the desired cross-link requires holding the protein in a conformation that is less relaxed. A survey of known tricarboxylic acids led to trimesic acid, benzene-1,3,5-tricarboxylic acid. The reagent trimesoyl tris(methyl phosphate), TMMP, should produce cross-links with the isophthalyl geometry. To the extent that undesirable products result from consumption of the reagent by undesired reactions, the third reaction site gives the reagent a "second chance" at making the proper connection. On the other hand, if the desired val-1 to lys-82 linkage between chains occurs as the initial reaction, it is likely that an additional cross-link would not be undesirable. Jolanta Wodzinska found that preparation of the trifunctional reagent required gentler conditions than for the bifunctional reagents. Dealkylation at three sites with sodium iodide had not previously been attempted but conditions were found that led to a successful procedure (7).



TMMP

When TMMP was reacted with deoxyhemoglobin, chromatography revealed many fewer products than are formed with the isophthalyl reagent. Analysis of the globin chains and proteolytic digests showed that the major products are hemoglobins in which cross-links between val-1 and lys-82 of the β subunits are the predominant products. In particular, about 30% was triply cross-linked between both lys-82 ϵ-amino groups and the amino group of one N-terminal valine. The second major product was cross-linked from one β-lys-82 ϵ-amino group of one subunit and one β-N-terminal valine of the other dimer. In this case, the third functional group of the reagent did not react. Thus, TMMP produces a significant change in product distribution in the positive direction (7).

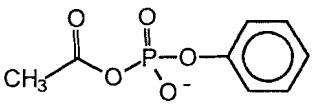
Analysis of products as a function of time reveals that the various products form in parallel. Therefore, the compound with two links is not a precursor to the one with three. Based on this result, we proposed that there must be structural variations that lead to the different products since in principle the triply linked species must be preceded by a doubly linked species. If there were two isomeric doubly linked species, the results could be understood. Because an amide bond at the β-val-1 amino group is created in the reaction, it is possible that the two cases differ by being *E* or *Z* at this pseudo-double bond. Structural studies of these compounds by X-ray crystallography are dealing with this issue. Interestingly, X-ray crystallographic structure determination by Richard Brennan at Oregon Health Sciences University revealed that the isophthalyl 1-82 cross-linked species is a mixture of *E* and *Z* stereoisomers.

The oxygen-binding properties of the hemoglobins cross-linked by TMMP and containing val-1 to lys-82 cross-links were measured by Shih and shown to be the same as those of the isophthalyl cross-linked material. Earlier workers had proposed that additional negative charges in the DPG site would affect oxygen affinity (23). This work shows that for the case of the isophthalyl distance at least, the only significant consideration in controlling oxygen affinity of modified hemoglobins is the site and size of the cross-link, supporting the validity of the correlation (8).

Further work with TMMP and hemoglobin has been undertaken at Hemosol, Inc., under the direction of Diana Pliura and Gordon Adamson in collaboration with our group. They have found convenient ways to produce large of amounts of usefully cross-linked hemoglobin.

Reaction patterns of methyl acyl phosphates

To understand the basis of the reagents' selectivity, it is necessary to have a reasonable idea of transition states and intermediates in the reaction mechanism. The use of Brönsted plots for a series of amine nucleophiles gives a measure of charge development in the transition state and other details (24).



As in all reactions involving amines as nucleophiles, the rate of reaction of amines with acyl phosphate monoesters depends on the concentration of the unprotonated amine and of the electrophile:

$$v = k\,[\text{amine}][\text{AcP}]$$

$$\log v = \log k + \log [\text{amine}] + \log [\text{AcP}]$$

Since log [amine] will depend on pH with a slope of 1.0, at a lower pH, each pH decreases lowers free amine concentration about tenfold. For an amine of p*K* 10, at pH 7 only about one molecule in 1000 will be unprotonated, i.e., the rate is lowered by a factor of 1000. In addition, we found that β_{nuc} for the reaction is 0.91. Thus the Brönsted-like expression for β_{nuc} is

$$\log k = \beta_{nuc}(pK_a) + c$$

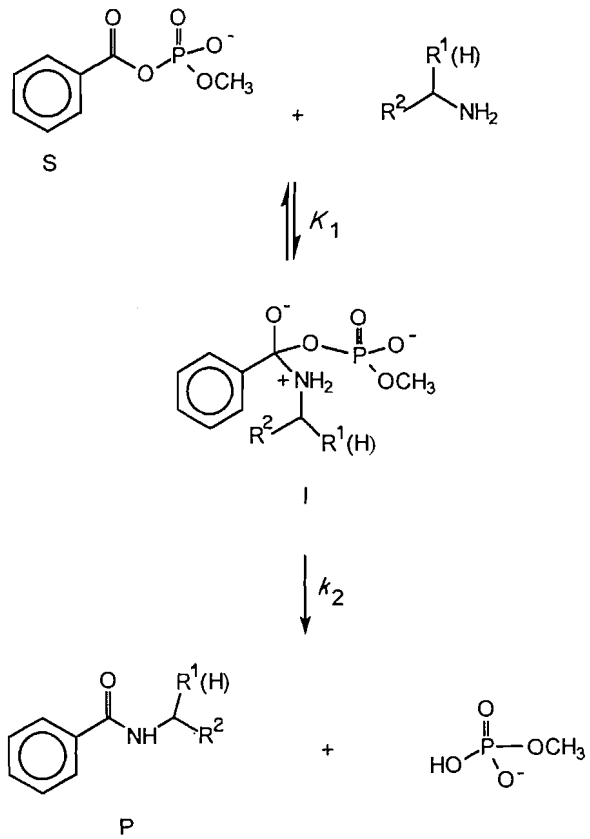
$$\log k_1 - \log k_2 = \beta_{nuc}(pK_{a1} - pK_{a2})$$

$$\log k_1/k_2 = 0.91\ (\Delta\ pK_a)$$

Therefore the less basic nucleophile will undergo the faster

reaction in neutral solutions. In the case of proteins, the α-amino group of the N-terminus is less basic than the ϵ-amino group of a lysine residue. In the modification of hemoglobin with methyl acyl phosphates, this factor will favor reaction at the N-terminal valine of the β chain over reaction of the ϵ-amino group of β-82-lys. On the other hand, if the reagent has a preferred orientation upon binding to the protein, then the effect is minimal.

A general mechanism for the reaction of benzoyl methyl phosphate with an amine is shown below (Scheme 1). Formation of a high-energy tetrahedral addition intermediate is followed by rate-determining breakdown of the intermediate.



SCHEME 1

With the second step rate determining, the observed second-order rate coefficient (k, corrected for the concentration of free amine) is equal to the product of the equilibrium constant (K_1) for the addition of the amine to the substrate and the rate constant for the decomposition of the intermediate ($k2$) (24).

$$v = k_{obs}[BMP][RNH_2] = K_1k_2[BMP][RNH_2]$$

$$k_{obs} = K_1k_2$$

The slope of the plot of log k_{obs} vs. pK_a of RNH_3^+ gives β_{nuc}:

$$\beta_{nuc} = \delta \log k_{obs}/\delta\ pK_a$$

$$\beta_{nuc} = \delta \log K_1/\delta\ pK_a + \delta \log k_2/\delta\ pK_a$$

The observed value for β_{nuc} of 0.91 implies the retention of about 90% of a positive charge on the amino group in the rate-determining transition state. The first term in the sum of the expression for β_{nuc} is 1.0 since the addition of amines to the carbonyl group generates a series of protonated amines. The observed value for β_{Nuc} is 0.9, making $\delta \log k_2/\delta\ pK_a = 0.1$. This means that the rate of the decomposition of the tetrahedral intermediate depends very little on the basicity of the amine and the transition state is early on the reaction coordinate. On the other hand, the extent of formation of the intermediate is very sensitive to the basicity of the amine. In the process of protein modification, the reversibility of the initial step provides an additional opportunity for selectivity.

Additional work in our group has diversified these results by using other cross-linkers and by taking advantage of products that retain a reactive center after the cross-link has formed. The retained functional group permits the addition of nucleophilic materials, which could be delivered as a hemoglobin conjugate in circulation (25, 26).

KARL GRIESBAUM, GILBERT KIESEL, HENRI MERTENS, PETRA KRIEGER-BECK, and HENNING HENKE. Can. J. Chem. **72**, 2198 (1994).

HCl-catalyzed reactions of the hemiperacetals 3-methoxy-3-methyl-7-hydroxy-1,2-dioxepane (**1***a*) and 3-methoxy-3-methyl-6-hydroxy-1,2-dioxane (**1***b*) and of the related ozonides 1-methyl-6,7,8-trioxabicyclo[3.2.1]octane (**2***a*) and 1-methyl-5,6,7-trioxabicyclo[2.2.1]heptane (**2***b*) gave peroxidic monocyclic (**11**—**13**), bicyclic (**14**), and (or) tricyclic (**15**) products. By contrast, reactions of the peracetals corresponding to **1***a* and **1***b*, viz., 3-methyl-3,7-dimethoxy-1,2-dioxepane (**13***a*) and 3-methyl-3,6-dimethoxy-1,2-dioxane (**13***b*) gave only non-peroxidic products. Reactions of the persubstituted peracetals 3,6-dimethoxy-3,6-dimethyl-1,2-dioxane (**25**) and 3,6-dimethoxy-3-isopropyl-6-methyl-1,2-dioxane (**27**) also gave non-peroxidic products, which resulted from fragmentation of the carbon skeletons.

KARL GRIESBAUM, GILBERT KIESEL, HENRI MERTENS, PETRA KRIEGER-BECK et HENNING HENKE. Can. J. Chem. **72**, 2198 (1994).

Les réactions catalysées par le HCl des hémiperacétals 3-méthoxy-3-méthyl-7-hydroxy-1,2-dioxépane (**1***a*) et 3-méthoxy-3-méthyl-6-hydroxy-1,2-dioxane (**1***b*) et des ozonides apparentés 1-méthyl-6,7,8-trioxabicyclo[3.2.1]octane (**2***a*) et 1-méthyl-5,6,7-trioxabicyclo[2.2.1]heptane (**2***b*) conduisent respectivement aux produits peroxydés monocycliques (**11**–**13**) et bicyclique (**14**) et (ou) tricyclique (**15**). Par opposition, les réactions des peracétals correspondants à **1***a* et **1***b*, les 3-méthyl-3,7-diméthoxy-1,2-dioxépane (**13***a*) et 3-méthyl-3,6-diméthoxy-1,2-dioxane (**13***b*) ne donnent que des produits non peroxydés. Les réactions des peracétals persubstitués 3,6-diméthoxy-3,6-diméthyl-1,2-dioxane (**25**) et 3,6-diméthoxy-3-isopropyl-6-méthyl-1,2-dioxane (**27**) fournissent aussi des produits non peroxydés qui résultent de la fragmentation des squelettes carbonés.

[Traduit par la rédaction]

Introduction

Ozonolyses of a number of unsaturated cyclic compounds in methanol have been reported to give cyclic hemiperacetals (1–4). In line with this, we found that ozonolysis of 1-methylcyclopentene in methanol gave **1***a*, **8***a*, and **11***a* in a molar ratio of 90:8:2 (5). By contrast, ozonolysis of the same substrate in 1 N HCl – methanol gave 9% of a mixture of **5***a* and **6***a*, 75% of **7***a*, and a number of minor by-products (6). The non-peroxidic products **5***a*, **6***a*, and **7***a* were most likely formed via **1***a* as an intermediate, as reaction of isolated **1***a* in 1 N HCl – methanol afforded 8% of **5***a* + **6***a*, and 67% of **7***a* (6). When we followed the latter reaction by ^{1}H nmr spectroscopy and by thin-layer chromatography, we observed that a series of peroxidic intermediates were formed on the way from **1***a* to **5***a*, **6***a*, and **7***a*, as evidenced by the transient appearance of ^{1}H nmr signals and of spots of peroxidic compounds in the chromatograms. In an attempt to identify such intermediates, we have now treated **1***a* and, based on the questions raised by the ensuing results, the related peroxidic compounds **2***a*, **1***b*, **2***b*, **13**a, **13***b*, **25**, and **27** under less acidic conditions in the presence and absence of methanol.

Results and discussion

Reactions of cyclic hemiperacetals **1**a, **1**b, *and of ozonides* **2**a, **2**b

Reaction of **1***a* with HCl–methanol at room temperature gave **2***a*, **5***a*, **7***a*, **8***a*, **11***a*, **12***a*, and **13***a* in the proportions reported in Table 1. By chromatographic separation we have isolated **2***a*, a mixture consisting of **5***a*, **7***a*, **8***a*, *cis*-**11***a*, and *trans*-**11***a*, and the individual compounds *cis*-**12***a*, *trans*-**12***a*, *cis*-**13***a*, and *trans*-**13***a*. The structures of the known compounds **2***a* (7), **5***a* (6), **7***a* (6), **8***a* (5), *cis*-**11***a* (5), and *trans*-**11***a* (5) were assigned based on the identity of their ^{1}H nmr data with those of authentic samples. The structures of the hitherto unknown peroxidic products *cis*-**12***a*, *trans*-**12***a*, and *cis*-**13***a* and *trans*-**13***a*[2] have been assigned based on their ^{1}H nmr and mass spectra and by reductions with triphenylphosphine to give **6***a*, or **5***a* after further treatment of **6***a* with HCl–methanol. The stereochemical assignments of the isomers of **12***a* and of **13***a* are based on the assumption that the *cis*-isomers exhibit higher chromatographic R_f values. Additional evidence for the structure of **12***a* was accrued from the following facts: reduction of **12***a* with dimethyl sulfide gave 2 molar equivalents of dimethyl sulfoxide, and the ^{1}H nmr signals for the CH_3(C) groups of *cis*-**12***a* and of *trans*-**12***a* appeared 0.15 ppm downfield from those of *cis*- and *trans*-**13***a*, whereas the CH signals for **12***a* and for **13***a* had nearly the same chemical shift values. This indicates that the CH_3O group in **12***a* is attached to the CH moiety and, hence, the a priori also conceivable, isomeric structure of 7-hydroperoxy-3-methoxy-3-methyl-1,2-dioxepane is ruled out. A particular feature of peroxide **13***a* is the fact that it is not reduced by dimethyl sulfide at room temperature within 24 h.

For the acid-catalyzed conversion of **1***a* to give the products listed in Table 1, there are apparently three initial steps, viz. (*i*) loss of OCH_3 followed by ring closure with OH to give ozonide **2***a*, (*ii*) exchange of OH for OCH_3 to give **13***a*, and (*iii*) acid-catalyzed ring opening of **1***a* to give **3***a*, which, in turn, undergoes the following sequence of subsequent reactions: hydrolysis of **3***a* to give **6***a*, addition of the coproduced hydrogen peroxide

and methanol to the aldehyde group of **6***a* to give **8***a*, cyclization of **8***a* to give **11***a*, and reaction of **11***a* with hydrogen peroxide or with methanol to give **12***a* and **13***a*, respectively.

The low yield in the acid-catalyzed conversion of **1***a* into ozonide **2***a* is presumed to be due to the instability of **2***a* in HCl–methanol. Indeed, **2***a* underwent a fast reaction in HCl–methanol at room temperature to give the same products in similar proportions as were obtained starting from **1***a* (Table 1). This can be rationalized by acid-catalyzed cleavage of the C—O bond of the ether bridge in **2***a* to give **1***a* or by sequential cleavage of the C—O bond of the peroxide bridge, and of the ether bridge in **2***a* to give **8***a* via **4***a*, **10***a*, and **9***a*.

In line with the reasoning that the presence of methanol lowers the yield of ozonide **2***a* obtained from **1***a*, the reaction of **1***a* in HCl–$CDCl_3$, i.e., in the absence of added methanol, gave a higher yield (16%) of **2***a* than the reaction in HCl–methanol (1%). Additional products from the reaction of **1***a*, in HCl–$CDCl_3$ were 23% of **12***a*, 24% of **13***a*, 5% of **14***a*, and 5% of **15***a*. The formation of **14***a* and of **15***a* is explained by considering **2***a* as the key intermediate. In agreement with this, reaction of **2***a* in HCl–$CDCl_3$ gave **14***a* and **15***a* as the major products, albeit at low conversion of **2***a*.

The structure of **14***a* has been confirmed by comparison of the ^{13}C nmr data obtained from our material with those from an

TABLE 1. Products from the reactions of **1***a*, **1***b*, **2***a*, and **2***b* in HCl–methanol

Substrate	Reaction time (h)	Product distribution (mol%) 2	5	7	8 + 11	12	13	15
1*a*	1	1	18	17	12	14	38	—
2*a*	2	2	22	11	17	17	31	—
1*b*	5	—	12	—	6	—	60	22
2*b*	30	—	24	—	13	—	38	10[a]

[a]In addition, ca. 15% of **1***b* was present in the product mixture.

authentic sample (9). The structural assignment of **15***a* is based on its ^{1}H nmr and mass spectral data and, as well, on single-crystal X-ray diffraction. The latter analysis demonstrates that the centrosymmetric molecule **15***a* is closely related to a C_{16} fragment of the diamond structure (Fig. 1). In analogy with a variety of cyclodecane derivatives, in which some of the hydrogen atoms are very close (10), the increased angle of 119.2° at the ether bridge and especially the torsional angle of the C-O-O-C unit of 158.4° instead of 180° as in diamond, are attributed to repulsive interactions between the oxygen lone pairs. This view is supported by the fact that, in the carbocyclic rings, precisely those CH_2 groups are involved in short transannular contacts that in **15***a* are replaced by oxygen atoms, and therefore it is not surprising that the results of minimum-energy calculations for 10-membered cycloalkanes (10, 11) compare well with the observed angle pattern of **15***a* (see Table 3). The O—O distance of 1.476 Å for the peroxide bond is the expected length (12, 13).

For the formation of **14***a* and of **15***a* we assume a common path from **2***a* via **4***a* to **10***a*, and from thereon the separate routes **10***a* → **9***a* → **14***a* and **10***a* → **15***a*. The essential features of this reaction course are similar to those proposed for the $SbCl_5$- or $ClSO_3H$-catalyzed reaction of **2***a*, which gave **14***a* but not **15***a* (9). There is, however, precedence for the formation of other dimeric ozonides of type **15**, though only starting from monomeric ozonides that are unsaturated in the ozonide ring. Hence, such educts are more reactive (15, 16).

Reaction of **1***b* with HCl–methanol at room temperature gave **5***b*, **8***b*, **11***b*, **13***b*, and **15***b*, yet no detectable amounts of **2***b*, **12***b*, and **14***b* (Table 1). Reaction of **2***b* with HCl-methanol gave the same products and, in addition, **1***b* (Table 1). Similar results were obtained when **1***b* was treated with *p*-toluenesulfonic acid in $CDCl_3$. From the crude product of the latter reaction, a mixture of **8***b*, *cis*-**11***b*, and *trans*-**11***b*, a mixture of *cis*-**13***b* and *trans*-**13***b*, and pure **15***b* were isolated. For the formation of these products we assume the pertinent reaction paths outlined in Scheme 1.

The structures of the previously known compounds **5***b* (17), **6***b* (5), **7***b* (18), **8***b* (5), *cis*-**11***b* (5), and *trans*-**11***b* (5) were assigned based on the identity of their ^{1}H nmr data, and in the case of **5***b*, **6***b*, and **7***b* also of their gc retention times, with those of authentic samples prepared according to literature procedures. The structures of the hitherto unknown peroxidic products *cis*-**13***b*, *trans*-**13***b*, and **15***b* were assigned based on the identity of their ^{1}H nmr data with those of independently prepared authentic samples. *cis*- and *trans*-**13***b* were prepared by the previously reported ozonolysis of 5-hexene-2-one in methanol (5), followed by acid treatment of the crude ozonolysis product. The stereochemical assignments of *cis*-**13***b* and of *trans*-**13***b* are based on the assumption that the *cis*-isomer has the higher gc retention time.

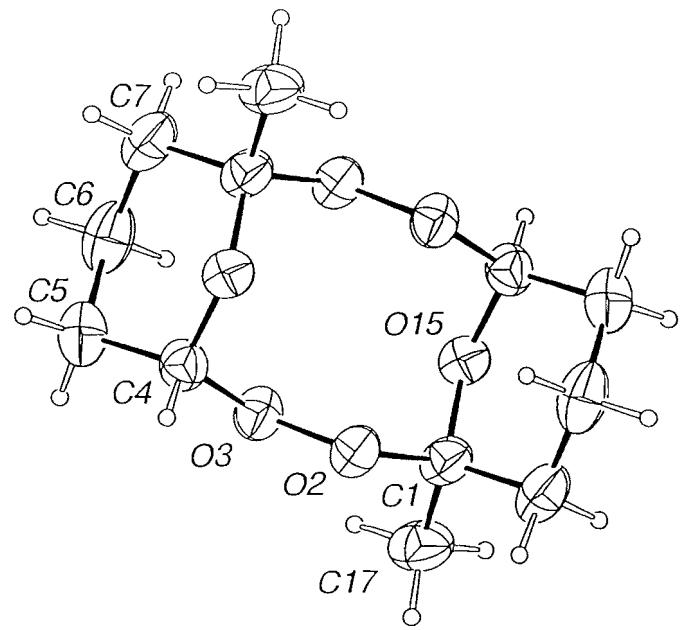

FIG. 1. ORTEP view (14) of the centrosymmetric molecule of **15***a* as found in the crystal. All thermal ellipsoids are drawn at the 50% probability density level. Hydrogen atoms are represented as open circles of arbitrary size.

*Reactions of cyclic peracetals 13*a, *13*b, *25, and 27*

Reactions of **13***a* and of **13***b* with anhydrous HCl in $CDCl_3$ differed considerably from those of the corresponding hemiperacetals **1***a* and **1***b* in two ways: they occurred quickly, within minutes even at 0°C, and they afforded exclusively non-peroxidic products. Reaction of **13***a* with HCl gave **7***a*, **19**, and **20** in relative proportions of 53:25:22, along with methanol and minute amounts of methyl acetate and methyl formate. This result can be rationalized by protonation of the peroxide bond in **13***a* to give **16***A* and **16***B*. Opening of C—O bond of the peroxide moiety in **16***A* provides **17**, which reacts further with water to give hydroperoxide **8***a*, in line with reported acid-catalyzed hydrolysis reactions of peracetals (19). Finally, acid-catalyzed dehydration of **8***a* yields **7***a*. Opening of the C—O bond of the peroxide moiety in **16***B* provides **18**, which reacts further with water to give methanol, H_2O_2, and **6***a*. Intramolecular aldol condensation (20) of **6***a* provides **19**, which by addition of HCl gives **20**. Since steps **8***a* → **7***a* and **6***a* → **19** result in the coproduction of water, adventitious amounts of water at the outset of the reaction are sufficient to effect these reaction sequences.

Reaction of **13***b* with anhydrous HCl gave **7***b* and **24** in relative proportions of 59:41, along with methyl formate and methanol. For the formation of these products we assume **21** as the

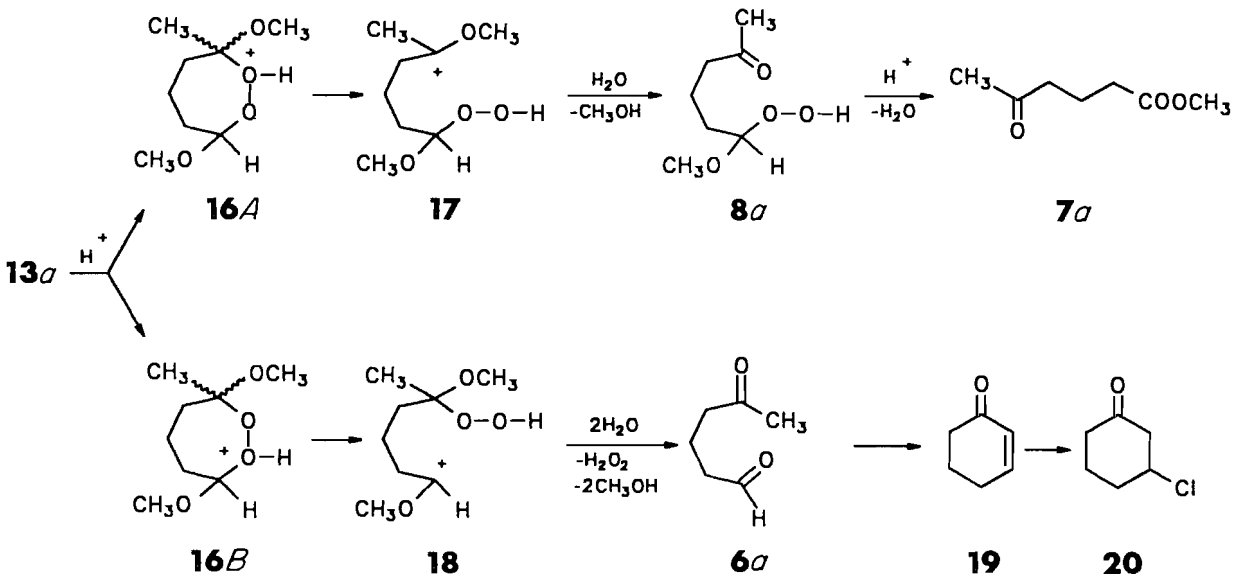
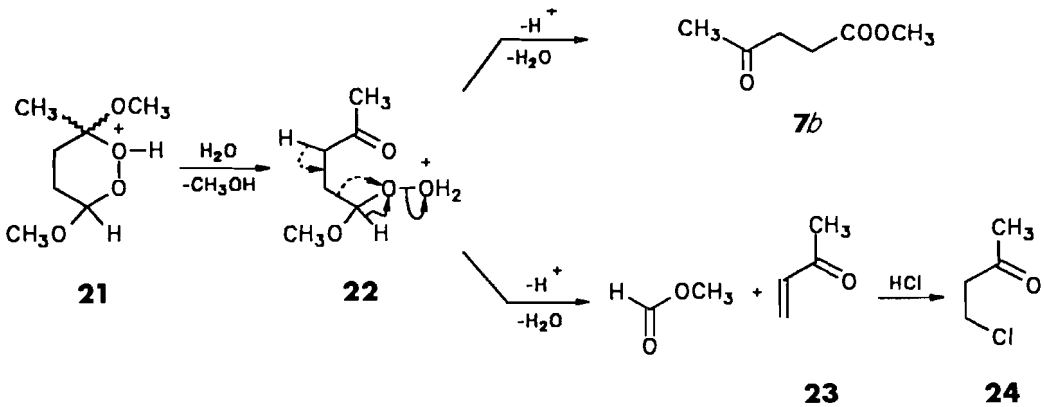


SCHEME 2



SCHEME 3

central intermediate, which gives **22** by rupture of the C—O bond and subsequent reaction of the ensuing carbenium ion with water, followed by loss of methanol. Fragmentation of **22** in the sense indicated by the solid arrows affords **7*b***, whereas fragmentation of **22** in the sense of the dotted arrows yields methyl formate and **23**, which in turn reacts with HCl to give **24**. The latter fragmentation step of **22** is probably favored by the fact that the ensuing double bond is in conjugation to the carbonyl group in **23**. This reasoning would explain why no fragmentation product was observed in the acid catalyzed reaction of the homologous peracetal **13*a***, since the expected unsaturated ketone would not be conjugated.

The fact that fragmentation of **13*b*** occurred only in one direction, viz., by elimination of methyl formate yet not by elimination of methyl acetate, raised the question whether 3,6-dialkyl-substituted 3,6-dimethoxy-1,2-dioxanes do not undergo HCl-catalyzed fragmentations. To examine this, we treated **25** and **27** with anhydrous HCl in $CDCl_3$ at 0°C. In both cases a rapid reaction, which was terminated within a few minutes, occurred. From **25** we obtained **26** and **24** in a molar ratio of 1:1, along with methanol. From **27** we obtained **24** and **29** in a molar ratio of ca. 1:7, along with **26**, **28**, and methanol. This shows that 3,6-dialkyl-substituted 3,6-dimethoxy-1,2-dioxanes undergo fragmentation as the single major HCl-catalyzed reaction, as opposed to the monoalkyl-substituted 3,6-dimethoxy-1,2-dioxane **13*b***, which underwent fragmentation and γ-keto-ester formation in a ratio of ca. 2:3.

Experimental section

*Reaction of **1**a in HCl–methanol*

A solution of 1.50 g (9.3 mmol) of **1***a* (5) in 5.0 mL of 0.35 N HCl – methanol was stirred at room temperature for 1 h, neutralized with solid $NaHCO_3$, and concentrated by evaporation of ca. 3 mL of methanol at room temperature and 15 Torr. (1 Torr = 133.3 Pa) Flash chromatography (21) (column 2.2 × 136 cm, 226 g of silica gel; pentane: diethyl ether, 7:3 (1 L), 1:1 (0.5 L), then pentane) of the liquid residue (3.70 g) gave 2 mg (<1%) of **2***a*, 400 mg of a mixture of **5***a*, **7***a*, **8***a*, *cis*-**11***a*, and *trans*-**11***a*, 40 mg (2%) of *cis*-**12***a*, 90 mg (5%) of *trans*-**12***a*, 180 mg (11%) of *cis*-**13***a*, and 180 mg (11%) of *trans*-**13***a*.

*Reaction of **2**a in HCl–methanol*

In a similar manner, a solution of 1.0 g (7.7 mmol) of **2***a* (7) in 10.0 mL of 0.35 N HCl – methanol was stirred at room temperature for 2 h, neutralized, and concentrated by removal of ca. 6 mL of methanol. Flash chromatography (conditions as above) of the liquid residue (4.80 g) gave 305 mg (25%) of a mixture of **5***a* and **7***a*, 190 mg (15%) of a mixture of **8***a*, *cis*-**11***a*, and *trans*-**11***a*, 75 mg (5%) of *cis*-**12***a*, 97 mg (7%) of *trans*-**12***a*, 95 mg (7%) of *cis*-**13***a*, and 105 mg (8%) of *trans*-**13***a*.

*Reductions of compounds **12**a with DMS*

Solutions containing 15 mg (0.084 mmol) of *cis*-**12***a* or of *trans*-**12***a* in 0.3 mL of $CDCl_3$ were admixed with 0.168 mmol of dimethyl sulfide and kept at room temperature. After 20 min, ^{1}H nmr analysis showed the signals of **8***a* (δ 2.15), of *cis*-**11***a* (δ 3.48), and of *trans*-**11***a* (δ 3.53). After several days, small samples were removed, concentrated by evaporation, and analyzed by glc (50-m capillary column, 5% phenylmethyl silicone SE 54, 50–180°C at 7°C/min) to show **6***a* (t_R: 9.06 min) as the major product. Then, the remaining major parts of the reaction mixtures were treated with 1 N HCl – methanol at room temperature for several hours, neutralized with solid $NaHCO_3$, and concentrated by evaporation. Analysis of the residue by ^{1}H nmr showed the presence of **5***a* (δ: 1.46 – 173 (m, 4H), 2.14 (s, 3H), 2.33 – 2.60 (m, 2H), 3.32 (s, 6H), 4.36 (m, 1H) and of dimethyl sulfoxide (δ: 2.62 (s, 6H) in a molar ratio of 1:2.

cis-*3-Methyl-3,7-dimethoxy-1,2-dioxepane* (cis-***13**a*): colorless liquid; ^{1}H nmr ($CDCl_3$, TMS) δ: 1.29 (s, 3H) 1.40–2.07 (m, 6H), 3.38 (s, 3H), 3.48 (s, 3H), 4.77 (t, J = 5.2 Hz, 1H); ^{13}C nmr ($CDCl_3$, TMS) δ: 18.35, 20.15, 33.82, 40.29, 49.10, 55.32, 106.95, 107.22; Cl-MS *m/e* (%): 176 (52) $[M]^+$, 145 (72) $[M - OCH_3]^+$, 101 (84) $[M - HCOOCH_3 - CH_3]^+$, 85 (100) $[M - HCOOCH_3 - OCH_3]^+$. Anal. calcd. for $C_8H_{16}O_4$: C 54.53, H 9.15; found: C 54.37, H 8.98.

trans-*3-Methyl-3,7-dimethoxy-1,2-dioxepane* (trans-***13**a*): colorless liquid; ^{1}H nmr ($CDCl_3$, TMS) δ: 1.27 (s, 3H), 1.36–2.10 (m, 6H), 3.36 (s, 3H), 3.53 (s, 3H), 4.84 (t, J = 3.3 Hz, 1H); ^{13}C nmr ($CDCl_3$, TMS) δ: 18.56, 19.23, 35.38, 38.48, 48.98, 56.96, 107.77, 109.77; Cl-MS *m/e* (%): 176 (23) $[M]^+$, 145 (27) $[M - OCH_3]^+$, 101 (49) $[M - HCOOCH_3 - CH_3]^+$, 85 (100) $[M - HCOOCH_3 - OCH_3]^+$. Anal. calcd. for $C_8H_{16}O_4$: C 54.53, H 9.15; found: C 54.38, H 8.95.

*Reductions of compounds **13**a with triphenylphosphine*

Solutions containing 8.8 mg of *cis*-**13***a* and 24.6 mg of *trans*-**13***a*, respectively, in ca. 0.4 mL of $CDCl_3$ were admixed with 1.5 molar equivalents of triphenylphosphine and with 5 molar equivalents of CH_3OD and kept at room temperature for 22 h. Analysis by ^{1}H nmr showed the presence of **5***a*, which was formed in yields of 85 and 96%, respectively, as determined with the help of 1,1,2,2-tetrachloroethane as internal standard.

*Reactions of **1**a in HCl–$CDCl_3$*

A solution of 0.20 g (1.23 mmol) of **1***a* in 4 mL of $CDCl_3$ was admixed with one drop of $CDCl_3$, which was saturated with gaseous HCl, and the mixture was stirred for 24 h at room temperature in a sealed flask. The mixture was neutralized with solid $NaHCO_3$, the solvent was removed by vacuum evaporation at room temperature, and the residue was separated by flash chromatography (column 2 × 60 cm, 85 g of silica gel; pentane:diethyl ether, 2:1) to give 25 mg (16%) of **2***a*, 50 mg (23%) of *cis*-**12***a* and *trans*-**12***a*, 45 mg (24%) of a mixture containing **2***a*, *cis*-**13***a*, and *trans*-**13***a*, 8 mg (5%) of **14***a*, and 8 mg (5%) of **15***a*.

*1-Methyl-2,3,5,6,11-pentaoxa-4-(4-oxopentyl)-bicyclo[5.3.1]undecane (**14**a):* ^{13}C nmr ($CDCl_3$, TMS) δ: 14.09, 19.10, 24.74, 25.32, 28.01, 29.82, 31.05, 42.93, 98.00, 102.19, 108.85, 207.71.

*1,8-Dimethyl-2,3,9,10,15,16-hexaoxatricyclo[9.3.1.1^{4,8}]hexadecane (**15**a):* colorless solid, mp 181°C (dec.); ^{1}H nmr ($CDCl_3$, TMS) δ: 1.50 (s, 6H), 1.59–2.09 (m, 12 H), 5.25–5.37 (m, 2H); Cl-MS *m/e* (%): 261 (92) $[M + 1]^+$. Anal. calcd. for $C_{12}H_{20}O_6$: C 55.37, H 7.75; found: C 55.53, H 8.08.

*Reduction of **15**a with DMS*

A solution of **15**a and excess DMS in $CDCl_3$ was kept at room temperature for 1 week. Analysis by ^{1}H nmr showed that no reaction had occurred. Upon addition of trace amounts of water, however, reduction occurred, and ^{1}H nmr analysis after 10 h showed the presence of ca. 30% of **6**a.

*Reaction of **2**a in HCl–$CDCl_3$*

A solution of 90 mg (0.7 mmol) of **2***a* in 4 mL of $CDCl_3$ was treated for 4 days as described above for **1***a*. Separation of the residue by flash chromatography (column 1.5 × 30 cm, 20 g of silica gel, pentane:diethyl ether, 1.5:1) gave 40 mg (44%) of recovered **2***a*, 30 mg (18%) of **14***a*, and 13 mg (7%) of **15***a*.

*Reaction of **1**b in HCl–methanol*

A solution of 32 mg (0.21 mmol) of **1**b (5) in 0.3 mL of $CDCl_3$ was admixed with 3 mL of 0.35 N HCl – methanol and left at room temperature for 5 h. Analysis by ^{1}H nmr showed the presence of **5**b, **8**b, **11**b, **13**b, and **15**b in the proportions reported in Table 1.

*Reaction of **2**b in HCl–methanol*

A solution of 13.8 mg (0.12 mmol) of **2***b* (5), 0.3 mL of $CDCl_3$, and 0.3 mL of 0.3 N HCl – methanol was stirred at room temperature for 30 h. Analysis by ^{1}H nmr showed the presence of **5***b*, **8***b*, **11***b*, **13***b*, **15***b* in the proportions reported in Table 1, and also ca. 15% of **1***b*.

*Reaction of **1**b in p-toluenesulfonic acid $CDCl_3$–methanol*

A solution consisting of 300 mg (2.0 mmol) of **1***b* (5), 1 mg of *p*-tol-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

uenesulfonic acid, 3 mL of $CDCl_3$, and 5 μL of methanol was stirred at room temperature for 4 days, neutralized with solid $NaHCO_3$, and concentrated by distillation at room temperature and 15 Torr. Flash chromatography (column 1 × 60 cm, 30 g silica gel; pentane:diethyl ether, 7:3) of the liquid residue (1.5 mL) gave 30 mg (10%) of a mixture of **8***b*, *cis*-**11***b*, and *trans*-**11***b*, 25 mg (8%) of a mixture of *cis*-**13***b* and *trans*-**13***b*, and 37 mg (16%) of **15***b*.

Independent preparation of cis-***13***b *and* trans-***13***b

A solution of 3.2 g (32.6 mmol) of 5-hexene-2-one in 20 mL of methanol was ozonized to exhaustion at –75°C. The cold solution was purged with nitrogen, admixed with ca. 50 mg of *p*-toluenesulfonic acid, and stirred for 24 h at room temperature. It was neutralized with solid $NaHCO_3$ and evaporated at room temperature and 15 Torr. Flash chromatography (column 2.2 × 140 cm, 226 g of silica gel; pentane:diethyl ether, 6:1) of the residue (6.2 g) gave 1.30 g (25%) of a mixture of *cis*-**13***b* and *trans*-**13***b*, and 138 mg (0.2%) of *cis*-**13***b*. From 200 mg of the above mixture of *cis*- and *trans*-**13***b*, 40 mg of *trans*-**13***b* was obtained by hplc separation (column 32 × 120 mm, Li Chrosorb Si-60; pentane:diethyl ether, 6:1).

cis-*3-Methyl-3,6-dimethoxy-1,2-dioxane* (cis-***13***b)*:* colorless liquid; ^{1}H nmr ($CDCl_3$, TMS) δ: 1.31 (s, 3H), 1.52–2.17 (m, 4H), 3.36 (s, 3H), 3.47 (s, 3H), 4.80–4.84 (m, 1H); El-MS *m/e* (%): 162 (0.1) $[M]^+$; gc,t_R: 10.67 min (50-m capillary column SE 54, 50–180°C at 7°C/min). Anal. calcd. for $C_7H_{14}O_4$:C 51.84, H 8.70; found: C 51.83, H 8.59.

trans-*3-Methyl-3,6-dimethoxy-1,2-dioxane* (trans-***13***b)*:* colorless liquid; ^{1}H nmr ($CDCl_3$, TMS) δ: 1.31 (s, 3H), 1.69–2.05 (m, 4H), 3.35 (s, 3H), 3.56 (s, 3H), 4.83–4.87 (m, 1H); gc,t_R: 11.21 min (conditions as above). Anal. calcd. for $C_7H_{14}O_6$: C 51.84, H 8.70; found: C 51.91; H 8.58.

Independent preparation of ***15***b

A solution of 2.94 g of natural rubber in a mixture of 70 mL of tetrachloromethane, 130 mL of pentane, and 11 mL of methanol was prepared, ozonized, and worked up as described previously (5). Of the remaining residue, 2.0 g was dissolved in 15 mL of trichloromethane, admixed with a solution of 50 mg of *p*-toluenesulfonic acid in 50 μL of methanol, and stirred for 7 h at room temperature. The solution was neutralized with solid $NaHCO_3$ and then evaporated at room temperature at 15 Torr. From the residue (3 mL), 200 mg of **15***b* was obtained by flash chromatography (column 2.2 × 120 cm, 220 g of silica gel; pentane:diethyl ether, 2.5:1). It was sublimated at room temperature and 10^{-3} Torr.

*1,7 - Dimethyl - 2,3,8,9,13,14 - hexaoxatricyclo[8.2.1.1^{4,7}]tetradecane (**15**b):* colorless solid, mp 120°C (dec.); ^{1}H nmr ($CDCl_3$, TMS) δ: 1.46 (s, 6H), 1.71–2.72 (m, 8H), 5.50–5.63 (m, 2H); Cl-MS *m/e* (%): 233 (6) $[M + 1]^+$. Anal. calcd. for $C_{10}H_{16}O_6$: C 51.75, H 6.94; found: C 51.78, H 6.87.

Reaction of ***13***a *in HCl–$CDCl_3$*

A solution of 25 mg (0.14 mmol) of **13***a* in 0.8 mL of $CDCl_3$ was flushed with gaseous HCl at 0°C; ^{1}H nmr analysis showed that after 8 min **13***a* was completely consumed. Gas–liquid chromatography and gc–ms analysis (50-m capillary column, 5% phenylmethyl silicone SE 54, 50–180°C at 7°C/min) showed the presence of **7***a* (t_R: 14.34 min; *m/e* 144), **19** (t_R: 10.75 min; *m/e*: 96), and **20** (t_R: 14.27 min; *m/e*: 134, 132) in relative proportions of 53:25:22, along with 5% of methanol (t_R: 5.71 min), 2% of methyl acetate (t_R: 7.16 min), and 1% of methyl formate (t_R: 5.98 min). The mixture was neutralized with solid $NaHCO_3$ and separated by flash chromatography (column 1.5 × 30 cm, 15 g silica gel; pentane:diethyl ether, 3:2 (300 mL), diethyl ether) to give 7 mg (29%) of **7***a*, 4 mg (14%) of **19**, and 3 mg (12%) of **20**.

*5-Oxo-methylhexanoate (**7**a):* ^{1}H nmr ($CDCl_3$, TMS) δ: 1.89 (quint., J = 7.1 Hz, 2H), 2.15 (s, 3H), 2.35 (t, J = 7.1 Hz, 2H), 2.52 (t, J = 7.1 Hz, 2H), 3.68 (s, 3H).

*Cyclohexene-3-one (**19**):* ^{1}H nmr ($CDCl_3$, TMS) δ: 1.97–2.08 (m, 2H), 2.33–2.46 (m, 4H), 6.01 (dt, J = 10.0 and 2.0 Hz, 1H), 6.98–7.05 (m, 1H).

*3-Chlorocyclohexanone (**20**):* ^{1}H nmr ($CDCl_3$, TMS) δ: 1.72–1.91 (m, 1H), 2.02–2.12 (m, 1H), 2.17–2.32 (m, 2H), 2.39–2.48 (m, 2H), 2.59–2.72 (m, 1H), 2.82–2.92 (m, 1H), 4.38–4.48 (m, 1H).

Reaction of ***13***b *in HCl–$CDCl_3$*

A solution of 37 mg (0.23 mmol) of **13***b* in 0.6 mL of $CDCl_3$ was flushed with gaseous HCl at 0°C. Analysis by ^{1}H nmr showed that after 4 min **13***b* was consumed and that **7***b* (δ 3.68, s) and **24** (δ 2.20, s) were present in relative proportions of 59:41, along with methyl formate (δ 8.06) and methanol (δ 3.49). Analysis by glc and gc–ms (column 0.3 × 300 cm, 5% Nitrilesiliconoil on Chromosorb G; 60–160°C at 4°C/min) with the help of authentic samples confirmed the identity of **7***b* (t_R: 20.41 min; *m/e*: 130), of **24** (t_R: 13.63 min; *m/e*: 108, 106), and of the other components.

Reaction of ***25*** *in HCl–$CDCl_3$*

A solution of 73 mg (0.41 mmol) of **25** (22) in 0.8 mL of $CDCl_3$ was flushed with gaseous HCl at 0°C. Analysis by ^{1}H nmr showed that after 2 min **25** was consumed and that **26** (δ 2.06, s) and **24** (δ 2.22, s) were present in a molar ratio of 1:1, along with methanol (δ 3.50, s). Analysis by glc and gc–ms (conditions as above) with the help of authentic samples confirmed the identity of **26** (t_R: 3.31 min; *m/e*: 74), **24** (t_R: 13.59 min; *m/e*: 108, 106), and methanol (δ 3.50, s).

Reaction of ***27*** *in HCl–$CDCl_3$*

A solution of 35 mg (0.17 mmol) of **27** (22) in 0.7 mL of $CDCl_3$ was flushed with gaseous HCl at 0°C. Analysis by ^{1}H nmr showed that after 2 min **27** was consumed and that **24** (δ 2.20, s) and **29** (δ 1.12, d) were present in a molar ratio of 1:7, along with **26** (δ 2.06, s), **28** (δ 1.07, d), and methanol (δ 3.48, s). Analysis by glc and gc–ms (conditions as above) with the help of authentic samples confirmed the identity of **24** (t_R: 13.61 min; *m/e*: 108, 106), **26** (t_R: 3.34 min; *m/e*: 74), **28** (t_R: 4.23 min; *m/e* 102), **29** (t_R: 13.61 min; *m/e*: 136, 134), and methanol.

X-ray structure analysis of ***15***a

Single crystals were grown from n-pentane:ether (65:35) solution. A suitable little block bounded by the faces (011), (100), (01$\bar{1}$) and the corresponding counterfaces, of dimensions 0.50 × 0.56 × 0.70 mm^3, was cut from a larger specimen and enclosed in a glass capillary. Crystal data: $C_{12}H_{20}O_6$, fw = 260.3, monoclinic, $P2_1/c$, a = 6.550(2), b = 10.414(3), c = 9.840(3) Å, β = 108.29(2)° at room temperature, V = 637.3 Å^3, Z = 2, D_{calc} = 1.356 mg mm^{-3}, μ_{lin} = 0.101 mm^{-1} for MoKα radiation.

Data collection was done on a Siemens–Stoe diffractometer equipped with a pyrolytic graphite monochromator; all 3989 reflections *h*, ±k, ±l with 2θ ≤ 60° were measured and finally merged into 1857 independent intensity data. Scan mode: 40 steps with Δω = Δ2θ = 0.03°, extra steps for α_1/α_2 dispersion, background determined from 6 points each at the beginning and at the end of a reflection profile, counting time between 0.5 and 1.5 s per step depending on $I/\sigma(I)$. Three standard reflections were recorded at regular intervals for scaling purposes; the overall loss of intensity was less than 1.3%. Corrections were made for background intensity and Lorentz and polarization effects.

The structure was solved with the aid of MULTAN (23). Parameter refinement with CRYLSQ (24) included anisotropic temperature factors and an isotropic extinction correction (r^* = 1089(9)) according to Larson (25) with individual path lengths calculated from the shape of the crystal. The quantity minimized was $\Sigma w(|F_o| - |F_c|)^2$ with weights *w* derived from counting statistics. All hydrogen atoms appeared in a difference Fourier synthesis (24). Their positions were refined with the thermal *B* values kept at a fixed level. The final $R = \Sigma||F_o| - |F_c||\Sigma|F_o|$ was 0.034 (113 free parameters, full-matrix refinement, 1410 reflections above the significance level of $I > 3\sigma(I)$; R = 0.046 for all 1857 independent reflections). A plot of the molecule is shown in Fig. 1. Distances and angles as

TABLE 2. Fractional crystallographic coordinates for all non-hydrogen atoms of the asymmetric unit of **15***a*. The numbering scheme refers to Fig. 1. Equivalent *B* values (26) as calculated from the anisotropic thermal parameters

An energy-resolved study of the fragmentation reactions of alkyl ammonium ions[1]

NANCY L. BOSMA AND ALEX. G. HARRISON[2]

Department of Chemistry, University of Toronto, Toronto, ON M5S 1A1, Canada

Received May 31, 1994

NANCY L. BOSMA and ALEX. G. HARRISON. Can. J. Chem. **72**, 2205 (1994).

The unimolecular metastable ion and low-energy collision-induced fragmentation reactions of alkyl ammonium ions $R_nH_{4-n}N^+$ ($n = 2$ to 4, R = n-C_3H_7 and n-C_4H_9) have been studied and breakdown graphs expressing the % fragment ion abundances as a function of the centre-of-mass collision energy have been established. The dialkyl and trialkyl ammonium ions fragment primarily by olefin ([R − H]) elimination or by formation of the alkyl ion R^+ (with rearrangement to the more stable secondary structure). By contrast the tetraalkyl ammonium ions show both elimination of [R − H] and elimination of an alkane, which is C_5H_{12} for the propyl compound C_7H_{16} for the butyl compound. The results are interpreted in terms of competition between heterolytic bond cleavage to form a $[R^+{---}NH_{4-n}R_{n-1}]$ complex and homolytic bond cleavage to form a $[R_{n-1}H_{4-n}N^{+\cdot}{---}{}^{\cdot}R]$ complex. The former complex fragments either to form R^+ or undergoes internal proton transfer to form $R_{n-1}H_{4-n}NH^+ + [R - H]$, while the latter complex fragments by alkane elimination resulting from attack of R˙ on the α-CC bond of the alkyl group. For the propyl ammonium ions plausible potential energy profiles are established which show that the former complex is favoured for $n = 2$, 3 while the two complexes have similar energies for $n = 4$.

NANCY L. BOSMA et ALEX. G. HARRISON. Can. J. Chem. **72**, 2205 (1994).

On a étudié l'ion unimoléculaire métastable et les réactions de fragmentation induites par des collisions de base énergie des ions alkylammonium $R^nH_{4-n}N^+$ ($n = 2$ à 4, R = n-C_3H_7 et n-C_4H_9) et on a déterminé les graphiques de bris en pourcentage des abondances ioniques des fragments en fonction de l'énergie de collision du centre de masse. Les ions ammonium di- et tri-alkylés se fragmentent principalement par l'élimination d'une oléfine [R − H] ou par la formation de l'ion alkyle R^+ (avec une transposition vers la structure secondaire qui est plus stable). Par ailleurs, les ions ammonium tétraalkylés donnent aussi bien l'élimination d'un alcéne [R − H] que celle d'un alcane qui est le C_5H_{12} pour le composé propylé et C_7H_{16} pour le composé butylé. On interprète les résultats en fonction d'une compétition entre des bris hétérolytique (conduisant à un complexe $[R^+{---}NH_{4-n}R_{n-1}]$) et homolytique (conduisant à un complexe $[R_{n-1}H_{4-n}N^{+\cdot}{---}{}^{\cdot}R]$). Le premier complexe se fragmente soit pour former du R^+ ou pour subir un transfer interne de proton conduisant à $R_{n-1}.H_{4-n}NH^+ + [R - H]$, alors que le dernier se fragmente par une élimination d'alcane provenant d'une attaque de R˙ sur la liaison α-CC du groupe alkyle. Pour les ions ammonium, on a déterminé les profils plausible d'énergie potentielle et ils démontrent que le premier complexe est favorisé pour $n = 2$ et 3 alors que les deux complexes ont des énergies semblables lorsque $n = 4$.

[Traduit par la rédaction]

Introduction

The low energy fragmentation reactions of simple protonated alkyl amines ($R_1(R_2)_2NH^+$, R_2 = H or CH_3), prepared by Brønsted acid chemical ionization, have been extensively studied in this laboratory (1, 2). When the alkyl group R_1 is propyl or larger, the dominant fragmentation reactions on the metastable ion time scale lead to formation of the alkyl ion R_1^+ or to elimination of an alkene (R_1 − H) to form a protonated amine of lower carbon number. These results have been rationalized (2) in terms of a fragmentation mechanism involving the initial formation of a $[R_1^+{---}NH(R_2)_2]$ ion/dipole complex which either may separate to form R_1^+ (accompanied by H-migration to form a secondary or tertiary carbenium ion) or may undergo internal proton transfer resulting in olefin elimination and formation of a protonated amine. The alkyl ion and protonated amine products also dominate the low energy collision-induced dissociation (CID) mass spectra (3); however, the high energy CID mass spectra show (3–5) significant fragmentation by way of alkane elimination.

In contrast to the protonated amines, tetraalkyl ammonium ions, R_4N^+, show very abundant elimination of alkanes in metastable ion fragmentation reactions and in both low energy and high energy CID studies (6–11). The nominal alkanes eliminated correspond to RH and to (R˙ + [R − CH_2]˙), the latter either as an alkane or as two alkyl radicals. The mechanisms for alkane elimination have not been clearly established nor has it been clearly delineated why the dominant fragmentation reactions of protonated amines differ from the fragmentation reactions of tetraalkyl ammonium ions. It appeared that a study of both the unimolecular fragmentation reactions and the energy-resolved (ERMS) (12–14) collision-induced fragmentation reactions of $R_nH_{4-n}N^+$ ($n = 2$–4) ions might provide insight into these questions. The present work reports such a study for the n-propyl and n-butyl systems. The results obtained are interpreted in terms of a mechanism for fragmentation of the ions in which there is a competition between heterolytic and homolytic cleavage of the $R_nH_{4-n}N^+$ ion with the former leading to alkene elimination and alkyl ion formation while the latter leads to alkane elimination. Plausible potential energy profiles are presented to rationalize the reaction competition observed.

Experimental

All experimental work was carried out using a VG Analytical ZAB-2FQ mass spectrometer which has been described in detail previously (15). Briefly, the instrument is a reversed-geometry (BE) double-focussing mass spectrometer which is followed by a third stage consisting of a deceleration lens systems, a radio-frequency (rf)-only quadrupole collision cell and a quadrupole mass analyzer.

In the unimolecular metastable ion fragmentation studies the appropriate ion beam was mass selected by the magnetic sector and underwent unimolecular fragmentation in the field-free region between the magnetic and electric sectors, with the fragment ions being analyzed according to their kinetic energy by scanning the voltage applied to the electric sector, the so-called MIKES technique (16). In addition, the appropriate ion beam was mass-selected by the BE double-focussing mass spectrometer, decelerated to 50 eV kinetic energy and underwent

unimolecular fragmentation in the rf-only quadrupole cell in the absence of collision gas. The fragment ions were detected by scanning the final mass-analyzing quadrupole.

In the low energy collisional activation studies the ion beam was again mass-selected by the BE instrument at 6 keV ion energy, decelerated to the appropriate collision energy (2.5 to 60 eV, laboratory scale) and introduced into the quadrupole collision cell containing N_2 at a pressure of 3×10^{-7} torr (1 torr = 133.3 Pa) as indicated by the ionization gauge attached to the pumping line for the region. The results are presented in the following as graphs of the percentage fragment ion abundance versus the centre-of-mass collision energy. In both the unimolecular and CID studies 20–50 2 s scans were accumulated on a Tracor Northern multichannel analyzer.

The alkyl ammonium ions were prepared by fast atom bombardment (FAB) ionization using an Ar atom beam of 7–8 keV kinetic energy. For the tetraalkyl ammonium ions the appropriate tetraalkyl ammonium bromide was dissolved in a glycerol matrix and subjected to atom bombardment while for the dialkyl and trialkyl ammonium ions the appropriate amine was dissolved in a thioglycerol/2,2′-dithioethanol (saturated with oxalic acid) matrix and subjected to atom bombardment. All chemicals were obtained from Aldrich Chemical Co., Milwaukee.

Results and discussion

The relative fragment ion abundances observed for unimolecular fragmentation of the *n*-propyl ammonium ions in the quadrupole cell in the absence of collision gas are presented in Table 1. For the dipropyl and tripropyl ammonium ions the dominant metastable ion fragmentation results in the elimination of neutral propene, i.e.,

$$[1] \quad (C_3H_7)_nH_{4-n}H^+ \rightarrow (C_3H_7)_{n-1}H_{4-n}NH^+ + C_3H_6$$

with possible minor fragmentation to form $C_3H_7^+$ and by elimination of C_3H_8. However, it should be noted that the alkyl ammonium ions appear to have large cross-sections for collision-induced dissociation and we cannot preclude the possibility of minor contributions from CID processes. In contrast to the dipropyl and tripropyl systems, the tetrapropyl ammonium ion shows elimination of C_5H_{12} as the base peak in the metastable ion spectrum with significant elimination of C_3H_6 and C_3H_8 also being observed. These metastable ion fragmentation reactions of the tetrapropyl ammonium ion have been reported previously by Ohashi et al. (8); they also reported observation of loss of C_3H_7 in metastable ion fragmentation of the tetrapropyl ion, a reaction which we do not observe. Alkyl radical loss from tetraalkyl ammonium ions is commonly observed in high energy CID (8, 9, 11) but is not observed in low energy CID in this work nor in the work of Mesdach et al. (10); this implies that alkyl radical loss has a high onset energy which is not achieved in low energy CID.

The metastable ion fragmentation reactions of the *n*-butyl ammonium ions (Table 2) parallel those of the propyl ammonium ions. Thus, the dibutyl and tributyl ammonium ions show

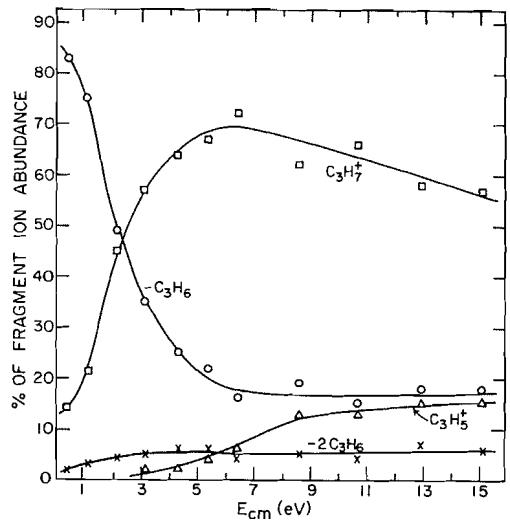

FIG. 1. Breakdown graph for $(n\text{-}C_3H_7)_2H_2N^+$.

predominant elimination of butene (C_4H_8) with minor formation of $C_4H_9^+$, while the tetrabutyl ammonium ion shows significant elimination of C_7H_{16} in competition with elimination of C_4H_8 and C_4H_{10} in metastable ion fragmentation reactions. We also recorded the unimolecular fragmentation reactions occurring in the drift region between the magnetic and electric sectors; the results obtained were in good agreement with the data reported in Tables 1 and 2. The fragmentation reaction resulting in nominal elimination of C_7H_{16} from $(C_4H_9)_4N^+$ has been proposed earlier (8–10) to involve sequential elimination of $C_4H_9^{\cdot}$ and $C_3H_7^{\cdot}$, viz

$$[2] \quad (C_4H_9)_4N^+ \xrightarrow{-C_4H_9} (C_4H_9)_3N^{+\cdot} \xrightarrow{-C_3H_7} (C_4H_9)_2NCH_2^+$$

rather than direct elimination of C_7H_{16} (reaction [3]).

$$[3] \quad (C_4H_9)_4N^+ \rightarrow (C_4H_9)_2NCH_2^+ + C_7H_{16}$$

Reaction [2] would be ca. 87 kcal mol^{-1} more energy demanding than reaction [3] and would not be expected to compete with the alternative of elimination of C_4H_8 (for a more complete discussion of the energetics see below); hence we conclude that the observation of nominal elimination of C_7H_{16} in metastable ion fragmentation reactions implies direct elimination of the species as a stable neutral rather than as two radicals. A similar conclusion has been reached by Beranová and Wesdemiotis (11) with respect to C_3H_8 elimination from $(C_2H_5)_4N^+$.

The low energy CID data for the propyl ammonium ions are shown in Figs. 1 to 3 as plots of the % fragment ion abundance as a function of the centre-of-mass collision energy. The similar data for the butyl amonium ions are presented in Figs. 4 to 6.

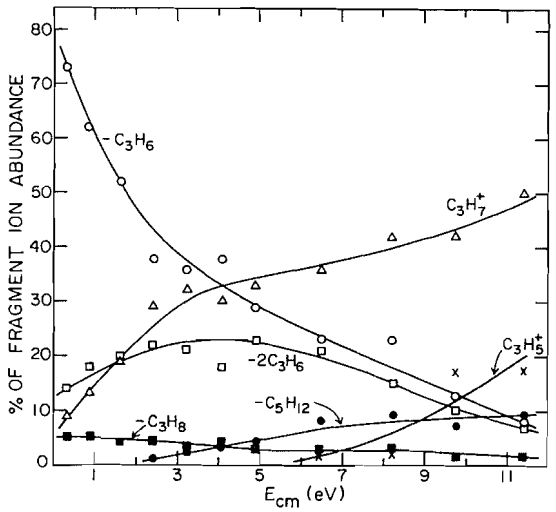

FIG. 2. Breakdown graph for $(n\text{-}C_3H_7)_3HN^+$.

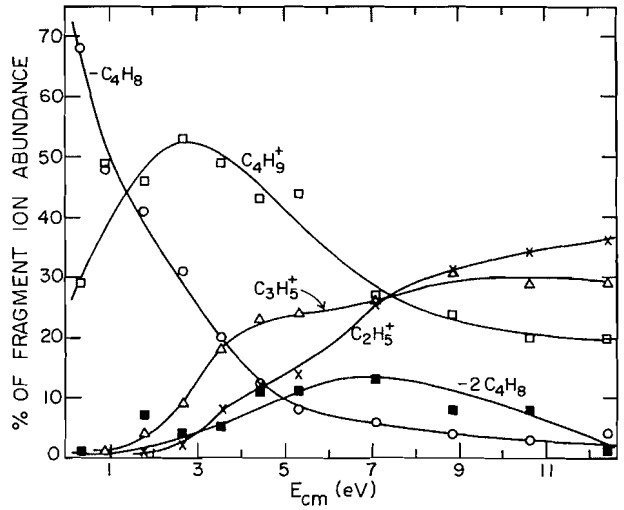

FIG. 4. Breakdown graph for $(n\text{-}C_4H_9)_2H_2N^+$.

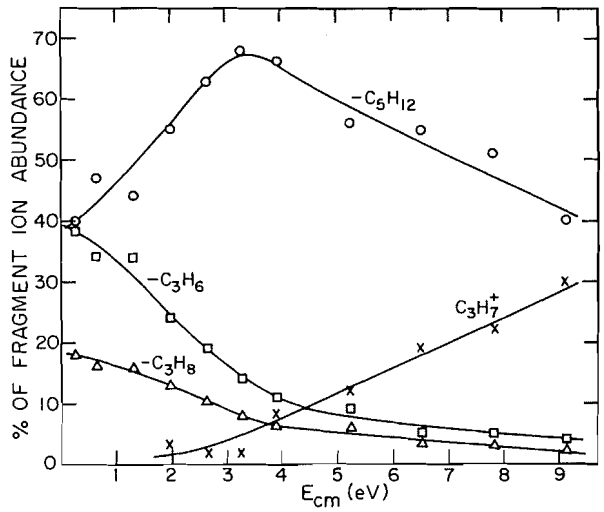

FIG. 3. Breakdown graph for $(n\text{-}C_3H_7)_4N^+$.

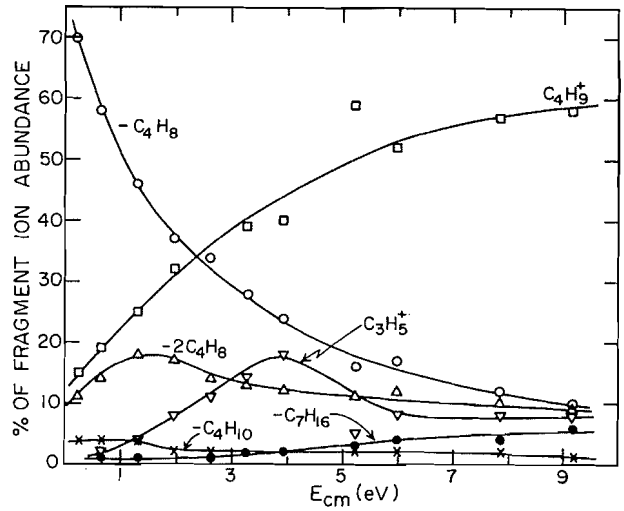

FIG. 5. Breakdown graph for $(n\text{-}C_4H_9)_3HN^+$.

The relative ion signals at the lowest collision energies are in essential agreement with the metastable ion data of Tables 1 and 2.

The breakdown graph for $(C_3H_7)_2H_2N^+$ (Fig. 1) shows that elimination of propene is the dominant low energy fragmentation reaction with formation of $C_3H_7^+$ increasing rapidly in importance with increasing collision energy. The breakdown graph is in good agreement with that reported earlier by Reiner et al. (3) for $(C_3H_7)_2H_2N^+$ ions produced by Brønsted acid chemical ionization of dipropyl amine. The breakdown graph for $(C_3H_7)_3HN^+$ (Fig. 2) is very similar in also showing dominant elimination of propene at the lowest collision energies with $C_3H_7^+$ increasing in importance at higher collision energies. In addition, elimination of two molecules of propene to form $C_3H_7NH_3^+$ is observed at the lowest collision energies as well as minor elimination of C_3H_8. However, elimination of C_5H_{12} from $(C_3H_7)_3HN^+$ obviously is a higher energy process and is observed only at higher centre-of-mass collision energies.

In contrast to the dipropyl and tripropyl ammonium ions, CID of the tetrapropyl ammonium ion (Fig. 3) leads to almost equal elimination of C_3H_6 and C_5H_{12} at the lowest collision energies with a more minor elimination of C_3H_8. With increasing collision energy the C_5H_{12} elimination channel increases in importance at the expense of the other two primary fragmentation channels. The $C_3H_7^+$ ion is formed only at higher collision energies and its increase appears to correlate with the decrease in the abundance of the $(C_3H_7)_2NCH_2^+$ product formed by C_5H_{12} elimination, suggesting that it may arise by further fragmentation of the latter ion. In this regard, it is interesting to note that elimination of C_3H_6 from $(C_3H_7)_2NCH_2^+$ is proposed (17, 18) to proceed through a $[C_3H_7^+\text{----}CH_2{=}NC_3H_7]$ complex, which may, under collisional activation conditions, fragment to yield $C_3H_7^+$.

The butyl ammonium ions show (Figs. 4 to 6) a behaviour similar to the propyl ammonium ions in their fragmentation following collisional activation. For $(C_4H_9)_2H_2N^+$ the primary fragmentation reactions involve elimination of C_4H_8 and formation of $C_4H_9^+$, with the former being favoured at lower collision energies. At higher collision energies $C_4H_9^+$ and its fragmentation products, $C_3H_5^+$ and $C_2H_5^+$, are favoured. Similarly, for $(C_4H_9)_3HN^+$ elimination of C_4H_8 and formation of $C_4H_9^+$ are the dominant fragmentation processes, although elimination of two C_4H_8 molecules and elimination of C_4H_{10} are observed as minor low energy fragmentation routes. Note that elimination of C_7H_{16} is observed as a minor fragmentation process at higher collision energies. The lowest energy CID

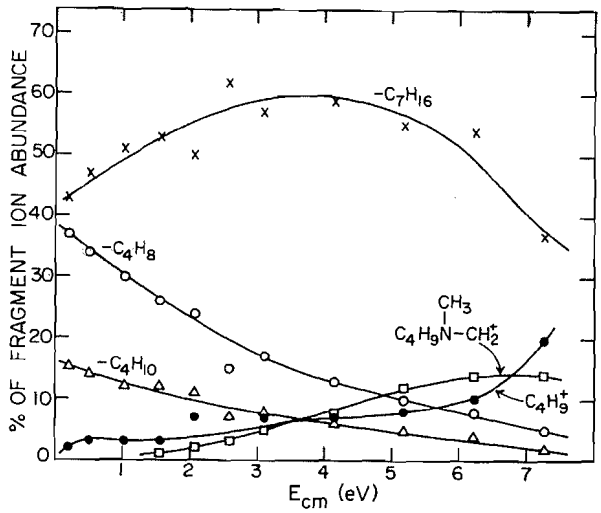

FIG. 6. Breakdown graph for $(n\text{-}C_4H_9)_4N^+$.

processes for $(C_4H_9)_4N^+$ correspond to elimination of C_4H_8, elimination of C_4H_{10} and elimination of C_7H_{16}; the latter reaction (eq. [3]) is analogous to the elimination of C_5H_{12} for the tetrapropyl ammonium ion. The $(C_4H_9)_2NCH_2^+$ (*m/z* 142) ion formed in reaction [3] has been shown (19) to fragment further by elimination of propene (reaction [4])

[4] $(C_4H_9)_2NCH_2^+ \rightarrow (C_4H_9)CH_3NCH_2^+$ (*m/z* 100) + C_3H_6

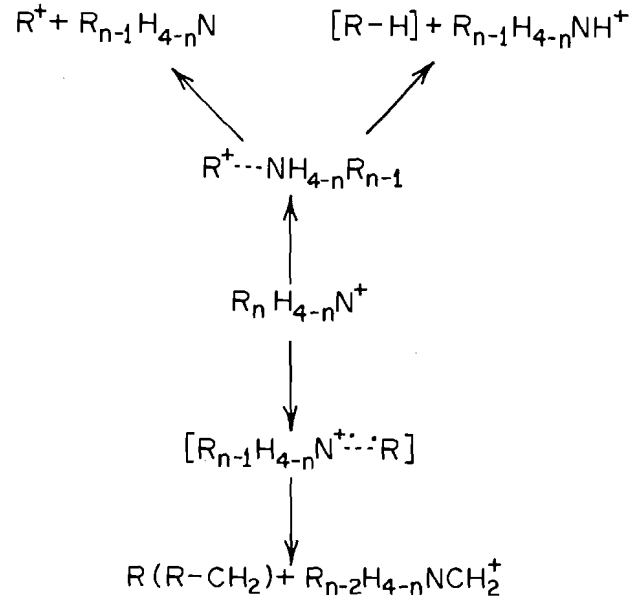
and, in agreement, we see *m/z* 100 as a significant product at higher collision energies. Rolando and co-workers (10) have provided evidence that $C_4H_9^+$ is a secondary fragmentation product rather than a primary product for the tetrabutyl ammonium ion; the results of Fig. 6 suggest that this is largely so although the mechanism by which $C_4H_9^+$ is formed is not clear.

Mechanistic and energetic considerations

The fragmentation of alkyl and dialkyl ammonium ions formed by Brønsted acid CI has been considered (2, 3) to proceed by formation of a $[R^+\text{----}NH_2R']$ ion/dipole complex;[3] this complex may fragment either by H^+ transfer from R^+ to the amine to form $R'NH_3^+$ or by simple cleavage to form R^+. In contrast, the fragmentation of tetraalkyl ammonium ions has been considered (7–11) to proceed by homolytic cleavage of the C—N bond to form a complex[3] $[R^{\cdot}\text{---}^{\cdot+}NR_3]$ which may fragment to form $R_3N^{+\cdot}$ or may fragment by alkane elimination proceeding by way of H atom or alkyl group abstraction by $R^{\cdot}$ in the complex. As a logical merging of these separate mechanisms, we propose that these two routes for the fragmentation of alkyl ammonium ions are in competition as outlined in the generalized Scheme 1 and that the relative energetics will determine which fragmentation route predominates.

Figures 7 to 9 present plausible potential energy profiles for fragmentation of the three *n*-propyl ammonium ions studied in this work; the relevant thermochemical data used to derive these profiles are summarized in the Appendix. In drawing these profiles we have assumed, in line with previous work (20), that the

[3]Although these species are described as complexes, it is not clear, in the absence of high level theoretical calculations, whether they exist in potential wells (true complexes) or whether they represent only saddle points on the potential energy curve and, thus, should be identified as transition states.



SCHEME 1

incipient *n*-propyl ion rearranges to the *i*-propyl structure during heterolytic bond cleavage and a plausible energy barrier for this process is included. We also have estimated a binding energy of 20 kcal mol^{-1} for the $[i\text{-}C_3H_7^+\text{----}NH_{4-n}(C_3H_7)_{n-1}]$ ion/dipole complex in line with previous estimates (20, 21). The binding energy in the $[R_{n-1}H_{4-n}N^{+\cdot}\text{----}^{\cdot}R]$ complex is unknown. We have assumed a value of 15 kcal mol^{-1}, in line with the lower dipole moment of $R^{\cdot}$, although this value may be subject to considerable error.

The potential energy profile of Fig. 7 clearly shows that fragmentation of the dipropyl ammonium ion by way of the $[i\text{-}C_3H_7^+\text{---}NH_2C_3H_7]$ complex is favoured energetically by a substantial amount and, experimentally, this is the fragmentation channel observed (Fig. 1). For the tripropyl ammonium ion the potential energy profile of Fig. 8 shows that heterolytic bond cleavage still is favoured, although the energy difference between the two complexes is less. In line with this potential energy profile we observe elimination of propene and formation of $i\text{-}C_3H_7^+$ at low collision energies with minor elimination of C_5H_{12} at higher collision energies (Fig. 2). As Fig. 9 shows the two possible fragmentation routes of $(C_3H_7)_4N^+$ are very similar in energy requirements and, in agreement with this potential energy profile we observe (Fig. 3) that elimination of C_3H_6 and elimination of C_5H_{12} are in competition with each other at the lowest collision energies and also in the metastable ion fragmentation reactions (Table 1).

We have not included in Figs. 7 to 9 the fragmentation channel which results in elimination of C_3H_8 since the heats of formation of the product ions, $(C_3H_7)_{n-2}H_{4-n}NCH^+CH_2CH_3$, are difficult to estimate. However, if this reaction also proceeds by way of the intermediate $[(C_3H_7)_{n-1}H_{4-n}N^{+\cdot}\text{---}^{\cdot}C_3H_7]$ one might anticipate that the dependence of the fragment ion intensity on collision energy would be similar to that of the C_5H_{12}-loss fragment. This is not so; indeed, for $(C_3H_7)_3HN^+$, the C_3H_8-loss channel is observed as a minor route even at the lowest collision energies. This raises the possibility that C_3H_8 elimination occurs, at least in part, by a direct 1,2-elimination without the intermediacy of the $[(C_3H_7)_{n-1}H_{4-n}N^{+\cdot}\text{---}^{\cdot}C_3H_7]$ complex.

Thermochemical data are not available to derive potential energy profiles for the butyl ammonium ions. However, it is

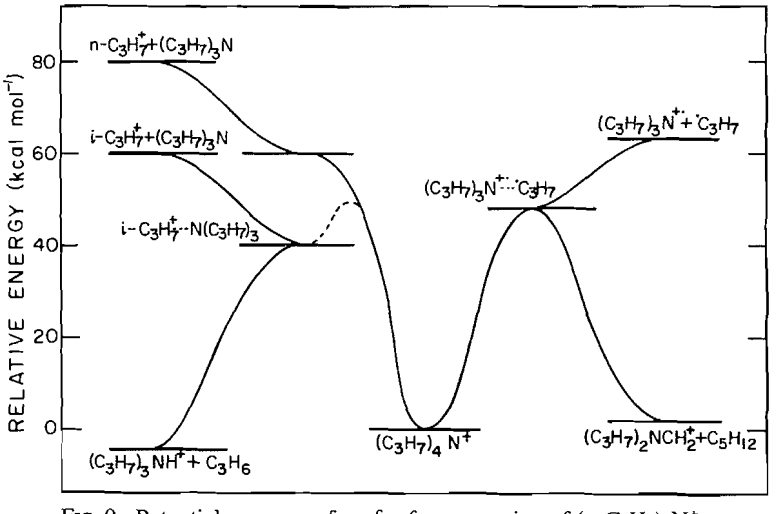

FIG. 9. Potential energy surface for fragmentation of $(n\text{-}C_3H_7)_4N^+$.

likely that these potential energy surfaces would be very similar to those for the propyl ammonium ions. Certainly the experimental breakdown graphs are very similar for ammonium ions with the same degree of alkyl substitution.

Beranová and Wesdemiotis (11) have suggested that the competition between the two reaction channels is determined by the relative ionization energies of $R_{n-1}H_{4-n}N$ and $R^{\cdot}$. That this might be so is seen from the thermochemical pathways indicated in Scheme 2 where $RE(R_nH_{4-n}N^+)$ is the recombination energy of the ion and an electron. Thus, for the competing reactions

[5] $R_nH_{4-n}N^+ \rightarrow R^+ + R_{n-1}H_{4-n}N$

[6] $\rightarrow R^{\cdot} + R_{n-1}H_{4-n}N^{+\cdot}$

[a]From Lias et al. (22).

it follows that

[7] $\Delta H_5 - \Delta H_6 = IE(R^{\cdot}) - IE(R_{n-1}H_{4-n}N)$

Table 3 records ionization energies, taken from Lias et al. [22], relevant to the ethyl, propyl and butyl ammonium ion systems. For the tetraethyl ammonium ion the relative ionization energies suggest dominant fragmentation by way of the $[(C_2H_5)_3N^{+\cdot}\text{---}{}^{\cdot}C_2H_5]$ complex as has been observed by Beranová and Wesdemiotis (11). For the triethyl ammonium ion system the relevant ionization energies are very similar. Experimentally, unimolecular fragmentation of $(C_2H_5)_3HN^+$ on the metastable ion time scale results entirely in elimination of C_2H_4 (23) and C_2H_4 elimination is the dominant CID reaction at low collision energies although elimination of C_3H_8 becomes the dominant reaction as the collision energy is increased (3). These results imply that the $[C_2H_5^+\text{---}NH(C_2H_5)_2]$ complex is slightly lower in energy that the $[(C_2H_5)_2HN^{+\cdot}\text{---}{}^{\cdot}C_2H_5]$ complex. The comparison of ionization energies gives the relative energies of the separated species not the relevant ion/neutral complexes.

For the propyl and butyl ammonium ions the conclusions derived from a comparison of ionization energies are in agreement with the experimental observations only if we assume that IE(R˙) refers to the secondary alkyl radical not the primary alkyl radical. For example, the comparison of IE(n-$C_4H_9^{\cdot}$) = 8.02 eV with IE((n-$C_4H_9)_2NH$) = 7.69 eV would suggest that C_7H_{16} elimination should be observed as a prominent, if not the dominant, fragmentation reaction of the tributyl ammonium ion, contrary to the experimental observations. However, comparison of IE(s-$C_4H_9^{\cdot}$) = 7.25 eV with IE((n-$C_4H_9)_2HN$) = 7.69 eV predicts elimination of C_4H_8 and formation of $C_4H_9^+$ as the dominant fragmentation reactions, in agreement with the experimental observations. Of course, rearrangement to the secondary structure for the incipient alkyl ion is what we have assumed in deriving the potential energy surfaces of Figs. 7 to 9.

In conclusion, the present work has shown that the fragmentation of alkyl ammonium ions, regardless of the extent of alkyl substitution, can be rationalized in terms of competitive homolytic and heterolytic bond cleavages to form ion/neutral complexes, which display specific fragmentation modes. Homolytic bond cleavage, which eventually results in alkane elimination, is favoured by extensive alkyl substitution which lowers the ionization energy of the alkyl amine in the complex. With decreasing alkyl substitution heterolytic bond cleavage, resulting eventually in alkene elimination and alkyl ion formation, becomes the energetically favoured fragmentation route.

Appendix

The thermochemical data used to derive the potential energy surfaces of Figs. 7 to 9 are summarized in Table 4. Unless otherwise noted these data are taken from Lias et al. (22).

$\Delta H_f^0((n$-$C_3H_7)_4N^+)$ = 93 kcal mol^{-1} has been estimated by assuming ΔH^0 = −80 kcal mol^{-1} for the reaction

[A1] n-$C_3H_7^+ + (n$-$C_3H_7)_3N \rightarrow (n$-$C_3H_7)_4N^+$

in line with standard enthalpy changes of −84 kcal mol^{-1} and −90 kcal mol^{-1}, respectively, for the reactions

[A2] n-$C_3H_7^+ + n$-$C_3H_7NH_2 \rightarrow (n$-$C_3H_7)_2NH_2^+$

[A3] n-$C_3H_7^+ + (n$-$C_3H_7)_2NH \rightarrow (n$-$C_3H_7)_3NH^+$

The absolute value of $\Delta H_f^0((n$-$C_3H_7)_4N^+)$ is not essential to the arguments based on Fig. 9 since formation of either complex from the ammonium ion is substantially endothermic.

$\Delta H_f^0(C_3H_7NHCH_2^+)$ and $\Delta H_f^0((C_3H_7)_2NCH_2^+)$ also have been estimated. However, again the absolute values are not essential since elimination of C_5H_{12} from $[(CD_3H_7)_{n-1}H_{4-n}N^{+\cdot}$---$^{\cdot}C_3H_7]$ is very exothermic in all cases. Note, however, that elimination of $C_3H_7^{\cdot}$ + $C_2H_5^{\cdot}$ from this complex would be substantially endothermic (ΔH^0 = 35 kcal mol^{-1}) and, if the two radicals were eliminated, fragmentation to $C_3H_7^{\cdot}$ + $(C_3H_7)_{n-1}H_{4-n}N^{+\cdot}$ would be more likely (ΔH^0 = 15 kcal mol^{-1}). Thus, we conclude that the nominal alkane elimination does correspond to elimination of the alkane rather than two alkyl radicals. Similar considerations apply to the elimination of C_7H_{16} from the butyl ammonium ions.

Isotherme 75°C, du système quaternaire réciproque H_3PO_4–K_2SO_4–H_2SO_4–K_3PO_4–H_2O. Étude des nappes du liquidus

NÉJI BOURGUIBA ET TAHAR JOUINI[1]

Département de chimie, Faculté des sciences de Tunis, Campus Universitaire, 1060 Tunis, Tunisie

Reçu le 11 mars 1994

NÉJI BOURGUIBA et TAHAR JOUINI. Can. J. Chem. **72**, 2212 (1994).

Les nappes du liquidus de l'isotherme isobare (75°C, 1 atm) du système considéré ont fait l'objet d'une étude systématique permettant de tracer les lignes de niveau d'eau constant du système. Leur investigation a été menée au moyen de coupes isopléthiques judicieusement situées. Leurs positions ont été choisies de manière à compléter l'information sur les nappes déduites des systèmes ternaires limitant le quaternaire et des lignes à double saturation établis au cours de travaux antérieurs. Les mesures de solubilité ont été effectuées par conductimétrie. Quatre coupes isopléthiques : K_2SO_4–KH_2PO_4, K_2SO_4–K_2HPO_4, $KHSO_4$–K_2HPO_4 et $KHSO_4$–KH_2PO_4 ont été déterminées en totalité. Les deux premières sont des sections quasi-ternaires du système. Neuf portions de coupes ont été, également, établies pour préciser notre connaissance du liquidus. Les nappes limitant respectivement le domaine de $KHSO_4$ et de $K_8(H_2PO_4)_{1+X}(HSO_4)_{7-X}$ présentent une allure tournante qui révèle un phénomène de solubilité rétrograde en fonction de la teneur en eau.

NÉJI BOURGUIBA and TAHAR JOUINI. Can. J. Chem. **72**, 2212 (1994).

The liquidus curves at 75°C, 1 atm, of the system under consideration have been studied systematically by means of solubilities determined conductimetrically, and lines of constant water content have been deduced. The study used isoplethic sections chosen to complete data on previous measurements of limiting ternary systems and lines of double saturation. Four isoplethic sections: K_2SO_4–KH_2PO_4, K_2SO_4–K_2HPO_4, $KHSO_4$–K_2HPO_4, and $KHSO_4$–KH_2PO_4 were determined, the first two of which are quasi-ternary systems. A total of nine portions of the curves were measured to extend knowledge of the liquidus. The limiting curves in the field of $KHSO_4$ and $K_8(H_2PO_4)_{1+X}(HSO_4)_{7-X}$ show curvature, which reveals retrograde solubility as a function of water content.

Introduction

L'étude du système H_3PO_4–K_2SO_4–H_2SO_4–K_3PO_4–H_2O à 75°C et 1 atm (= 101,3 kPa), a été abordée lors d'étapes antérieures par l'établissement des systèmes ternaires limites (1) puis des lignes limites de domaines de cristallisation (2). En outre une phase solide a été caractérisée par détermination structurale aux rayons X (3).

Le présent travail complète l'établissement de cette isotherme par l'investigation des nappes du liquidus et le tracé des lignes de niveau d'eau constant.

L'intérêt pour ce système s'explique par son exploitation potentielle dans la fabrication d'engrais phosphopotassiques, comme nous l'avons justifié dans une publication antérieure (1).

Techniques expérimentales

Elles ont été précédemment décrites (1, 2). Nous nous limitons ici à rappeler le système de coordonnées de Jänecke, utilisé pour la représentation du quaternaire. Dans ce mode, le repère est un prisme droit à base carrée. Le point représentatif d'un mélange situé à l'intérieur du prisme est défini par les variables X, Y et Z.

L'abscisse X et l'ordonnée Y sont respectivement les pourcentages de moles d'équivalents d'ions phosphates et de protons :

$$X = \frac{3 \times 10^2 n\mathrm{PO_4}^{3-}}{N} \qquad Y = \frac{10^2 n\mathrm{H}^+}{N}$$

où n représente le nombre de moles de l'entité concernée et N la neutralité électrique du milieu.

$$N = n\mathrm{H}^+ + n\mathrm{K}^+ = 2n\mathrm{SO_4}^{2-} + 3n\mathrm{PO_4}^{3-}$$

La cote Z, portée par les arêtes verticales du prisme, exprime le nombre de mole d'eau correspondants à 100 moles d'équivalents de sels :

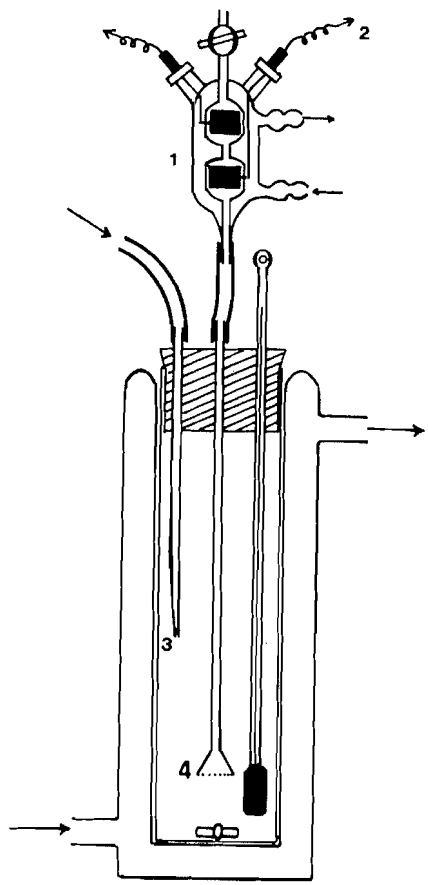

FIG. 1. Dispositif de mesures conductimétriques. 1 : Cellule conductimétrique. 2 : Liaison avec le pont de Wheatstone. 3 : Tube relié à une pipette graduée permettant l'addition d'eau au mélange. 4 : Filtre plongeur permettant de séparer la solution saturée de ses cristaux lors de la mesure.

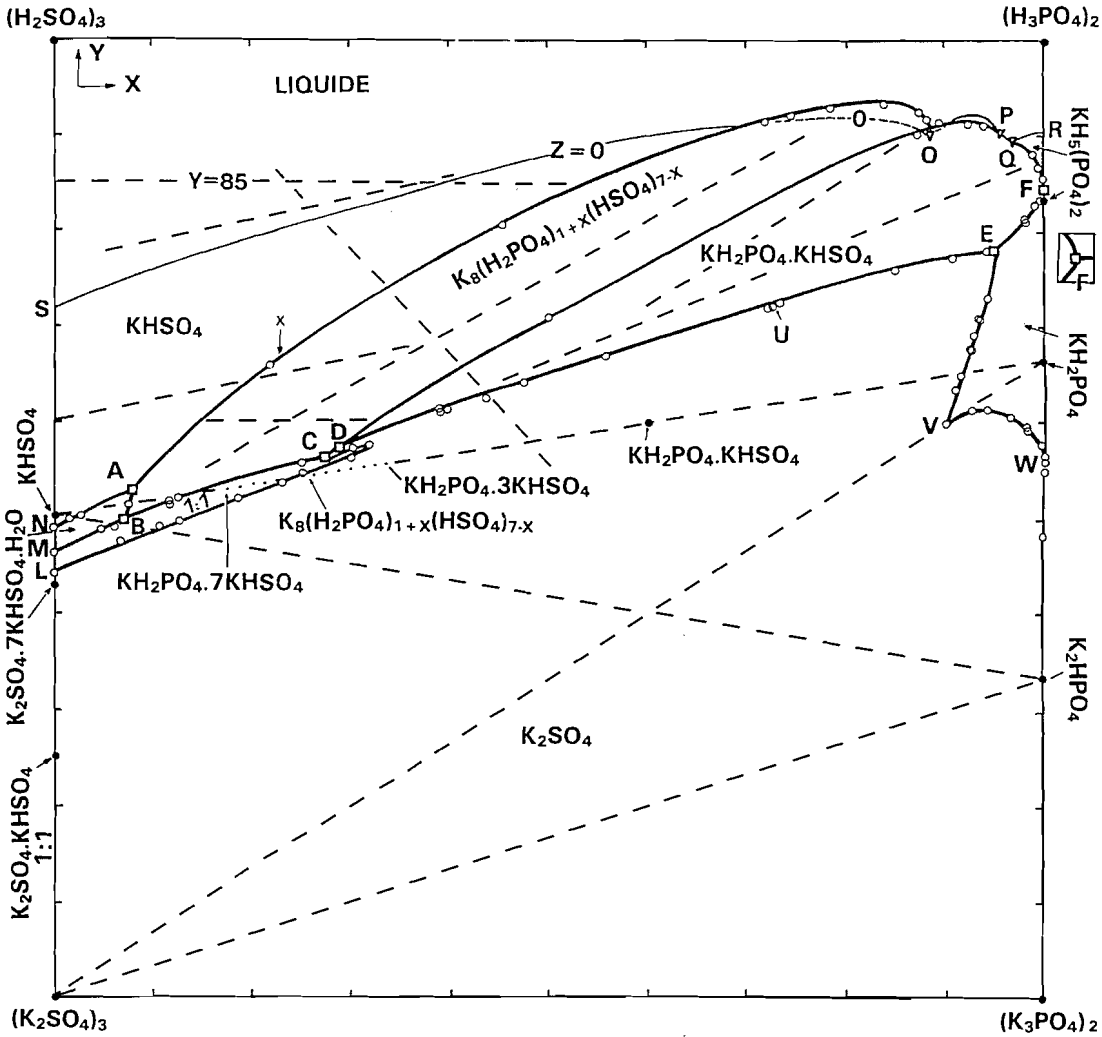

FIG. 2. Représentation des traces des coupes isopléthiques étudiées en projection sur le carré de base (– – –) ainsi que des lignes de deux sels (O—O—) établies précédemment (2).

$$Z = \frac{10^2 n\mathrm{H_2O}}{N}$$

Le point représentatif de l'eau pure est ainsi rejeté à l'infini (N tendant vers 0).

L'établissement des nappes du liquidus a été effectuée par conductimétrie (4–6) au moyen de coupes perpendiculaires au carré de base du prisme de Jänecke. Elles sont caractérisées par une relation linéaire entre X et Y et appelées coupes isopléthiques.

Dans cette méthode nous partons d'un mélange hétérogène de composition connue, appartenant au plan de la coupe étudiée. Ce mélange est soumis à l'agitation dans un vase à double enveloppe thermostaté (figure 1) jusqu'à établissement de l'équilibre, vérifié de la manière suivante. Une petite quantité de la solution est aspirée dans une cellule conductimétrique, également thermostatée et reliée à un pont de Wheatstone. Aprés mesure de la résistance R la solution est refoulée dans l'ensemble de départ. Cette opération est repétée jusqu'à obtention d'une valeur constante. On procède alors à la measure de solubilité, par ajouts successifs de quantités connues d'eau distillée et mesures de R, selon le protocole précédent.

Le tracé de la courbe donnant la résistance en fonction du volume d'eau présente une brisure à chaque changement de variance du système, en particulier la dernière correspond à la quantité d'eau, complémentaire, nécessiare pour dissoudre tout le solide présent. C'est-à-dire pour amener le point représentaitif du mélange de départ à percer la nappe du liquidus. On en déduit la cote Z du point de cette nappe ayant les mêmes coordonnées X et Y que le mélange étudié.

La cellule conductimétrique utilisée, de constante 106 cm^{-1}, est de type Metrohm 660 (figure 1) et le pont de Wheatstone est de marque General-Radio de type impédance bridge B-1650.

Résultats expérimentaux

Les coupes à étudier ont été choisies de manière à compléter l'information sur les nappes de solubilité déduites des systèmes ternaires limitant le quaternaire (1) et des lignes à double saturation (2) établies précédemment. Elles sont représentées à la figure 2 qui comporte également les traces des coupes étudiées.

Les coordonnées des points caractéristiques appartenant aux systèmes ternairs limites déterminées dans un mémoire antérieur (1) et utilisées dans le présent travail sont rappelées au tableau 1.

Étude des coupes isopléthiques

1. Coupe isopléthique K_2SO_4–KH_2PO_4

Les résultats obtenus sont donnés à la figure 3 et au tableau 2.

Cette section ($Y = 2X/3$) constitue une coupe quasi-ternaire du système, en effet, elle ne traverse aucun domaine de sel étranger au plan considéré. Les seules phases solides observées sont les composés de départ.

Les coordonnées du point invariant **b** ont été déterminées par analyse de la solution en équilibre avec K_2SO_4 et KH_2PO_4.

e	100	33,33	166	35,70	0,00	26,91	37,39	$K_2SO_4 + K_2HPO_4$

(*d*) Coupe isopléthique : $KHSO_4$–KH_2PO_4 ($Y - X/6 = 50$)

Points caractéristiques	Solutions saturées: Coordonnées de Jänecke *X*	*Y*	*Z*	Composition pondérale %K_2O	%SO_3	%P_2O_5	%H_2O	Phases solides en équilibre
b	2,5	50,42	160	24,25	40,51	0,61	34,63	$KHSO_4 + K_2SO_4{\cdot}7KHSO_4{\cdot}H_2O$
c	7,5	51,25	180	23,25	37,47	1,80	37,48	$K_2SO_4{\cdot}7KHSO_4{\cdot}H_2O + KH_2PO_4{\cdot}7KHSO_4$
d	12,5	52,08	185	22,91	35,53	3,00	38,56	$K_2SO_4{\cdot}KHSO_4 + K_8(H_2PO_4)_{1+x}(HSO_4)_{7-x}$
e	22,5	53,75	260	19,85	28,25	4,85	47,05	$K_2SO_4 + K_2SO_4{\cdot}KHSO_4$
f	91,5	65,25	335	15,21	3,16	20,13	61,50	$K_2SO_4 + KH_2PO_4$

Signalons que la courbe de solubilité **cb** est croissante de **c** vers **b**. Cette allure peu courante s'explique dans ce cas par la définition de la cote *Z* qui fait intervenir les ions H^+ et PO_4^{3-} n'existant pratiquement pas en solution à pH ≈ 5. En effet, le composé KH_2PO_4 se dissocie pour donner, dans ce domaine de pH, essentiellement K^+ et $H_2PO_4^-$.

Un calcul tenant compte de ces dernières espèces ioniques a été effectué. Les résultats présentés au tableau 2 et à la figure 3 revèlent une décroissance de *Z'* de **c'** vers **b'**, comme attendu. Mais pour une raison d'homogéneité nous devons garder la même définition de *X* et *Z* dans tout le diagramme.

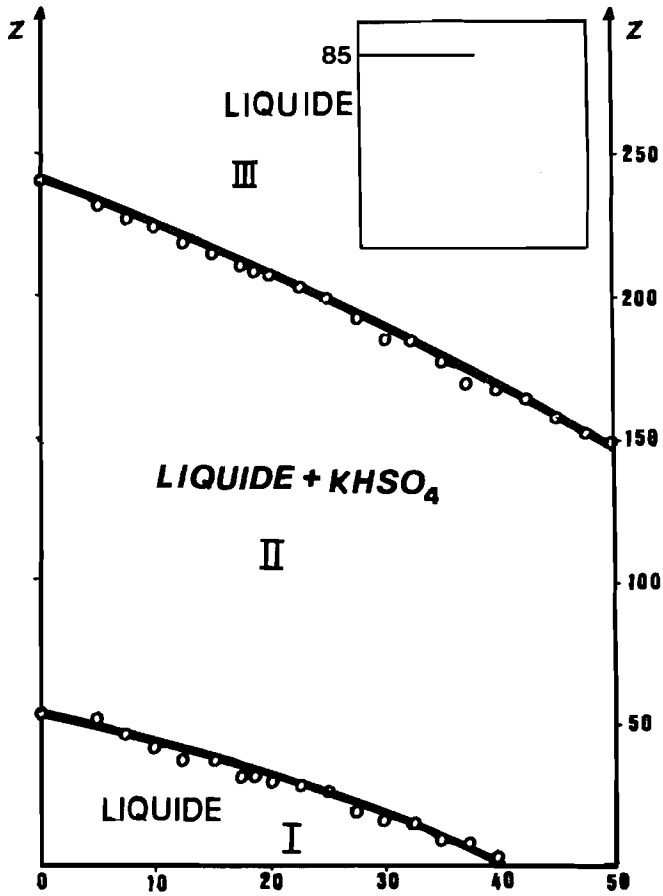

FIG. 7. Coupe isopléthique $Y = 85$. Double intersection avec la nappe de $KHSO_4$ révèlant l'allure tournante de cette dernière. La trace de la coupe est représentée dans le carré.

Cependant un liquidus peut présenter une allure croissante pour un composé à solubilité congruente (7).

Une approche thermodynamique de cette question est en cours d'étude.

2. Coupe isopléthique K_2SO_4–K_2HPO_4

La section K_2SO_4–K_2HPO_4 ($Y = X/3$) constitue également une coupe quasi-ternaire du système (figure 4, tableau 3). Les sels qui s'y manifestent sont les composés de départ. Cependant, le domaine de K_2SO_4 englobe presque tout le diagramme. Il en résulte que le point invariant **b** est pratiquement collé à l'axe représentant le système binaire K_2HPO_4–H_2O. Le point **b** a été localisé par analyse de la solution invariante où coexistent K_2SO_4 et K_2HPO_4.

3. Coupe isopléthique $KHSO_4$–K_2HPO_4 ($Y + X/6 = 50$)

Les résultats obtenus sont rassemblés à la figure 5 et au tableau 3.

Les domaines traversés par cette coupe correspondent aux phases solides suivantes : $KHSO_4$, $K_2SO_4 \cdot 7KHSO_4 \cdot H_2O$, $K_2SO_4 \cdot KHSO_4$, K_2SO_4 et K_2HPO_4.

Les points caractéristiques **b**, **c** et **d** sont situés à l'intersection du plan de la coupe étudiée avec les lignes monovariantes précédemment établies (2).

4. Coupe isopléthique $KHSO_4$–KH_2PO_4 ($Y - X/6 = 50$)

Dans cette section (figure 6, tableau 3), les phases solides observées sont : $KHSO_4$, $K_2SO_4 \cdot 7KHSO_4 \cdot H_2O$, la solution solide $K_8(H_2PO_4)_{1+x}(HSO_4)_{7-x}$, $K_2SO_4 \cdot KHSO_4$, K_2SO_4 et KH_2PO_4.

La remarque du paragraphe précédent concernant la localisation des points caractéristiques reste valable.

5. Coupe isopléthique $Y = 85$

L'étude de cette section limitée à l'intervalle $0 \leq X \leq 55$ a été entreprise dans le but de mettre en évidence l'allure du liquidus de la nappe de cristallisation de $KHSO_4$.

Les résultats sont présentés à la figure 7. Ils révèlent que l'intersection du plan de cette coupe avec la nappe relative à $KHSO_4$ s'effectue suivant deux courbes distinctes. On en déduit l'allure tournante de la nappe de $KHSO_4$ qui rencontre deux fois la section $Y = 85$. Il en résulte un phénomène de solubilité rétrograde en fonction de la teneur en eau : partant d'un mélange liquide situé dans le domaine I, l'addition d'eau provoque la précipitation de $KHSO_4$, lorsque le point représentatif du mélange pénètre dans le domaine II. En poursuivant l'addition d'eau le sel se redissout lorsque le mélange entre dans le domaine III.

6. Autres coupes

Dans le but de compléter notre connaissance du liquidus, différentes portions de coupes ont été établies. Leurs projections, sur le carré de base, sont données à la figure 2.

Seule les intersections de ces coupes avec la partie supérieure du liquidus ont été déterminées dans les régions où se manifeste le phénomène de solubilité rétrograde en fonction de la teneur en eau.

Lignes de niveau d'eau constant du système

En utilisant les informations déduites des études précédentes : systèmes ternaires limites (1), lignes à double saturation (2) et celles déduites des coupes isopléthiques établies au cours de ce travail, nous avons tracé sur la figure 8*A* les courbes de niveau d'eau constant du système. Elle comporte également les projections, sur les plans horizontal et frontal, des lignes de deux sels, établies précédemment (2).

Les agrandissements de deux parties de la figure 8*A* sont représentés dans les figures 8*B* et 8*C*.

On observe que certaines lignes de niveau d'eau constant coupent en projection d'autres représentées en pointillé. Ce phénomène se manifeste dans une partie du domaine de $KHSO_4$ et dans une mesure moindre pour la solution solide $K_8(H_2PO_4)_{1+x}(HSO_4)_{7-x}$. Il est dû à l'allure tournante du liquidus. Dans ces régions, les normales au plan percent les nappes deux fois. Il en résulte le phénomène de solubilité rétrograde en fonction de la teneur en eau, mis en évidence dans la coupe décrite au paragraphe 5.

Pour visualiser la rotation de la nappe de $KHSO_4$ nous en donnons à la figure 9 une vue en perspective cavalière.

Ce travail complète notre connaissance de l'isotherme 75°C du système quaternaire réciproque H_3PO_4–K_2SO_4–H_2SO_4–K_3PO_4–H_2O. Ces résultats joints à ceux obtenus pour l'isotherme 25°C du même système (8–10) peuvent être exploités par les intéressés pour l'optimisation des procédés de fabrication d'engrais phosphopotassiques.

Un travail envisageant différentes situations est en cours d'étude.

Nuclear magnetic resonance study of complexes formed between conjugated Schiff bases and carboxylic acids

H. LE-THANH AND D. VOCELLE[1]

Département de Chimie, Université du Québec à Montréal. C.P. 8888, Succ. A, Montréal, PQ, H3C 3P8, Canada

Received July 5, 1993[2]

H. LE-THANH and D. VOCELLE. Can. J. Chem. **72**, 2220 (1994).

The NMR spectra of the proton located in a N^+---H---^-O bond formed in the reaction of a conjugated Schiff base (SB) with a carboxylic acid (HA) in a non-polar solvent indicate that this proton is rapidly exchanging with other protons present in the system. For this study, two SB were used: all-*trans*-retinylidene *tert*-butylamine (RBA) and *trans,trans*-2,4-heptadienylidene *tert*-butylamine (HBA), and five carboxylic acids having pK_a's between 0.66 and 4.87.

^{1}H NMR spectra were taken at 293 and 233 K in $CDCl_3$ of systems of SB:HA using different ratios of acid to SB. Results indicate that the rapid proton exchanges are temperature and concentration dependent. Finally, the results are related to the natural pigments rhodopsin and bacteriorhodopsin.

H. LE-THANH et D. VOCELLE. Can. J. Chem. **72**, 2220 (1994).

Des spectres de RMN du proton localisé dans une liaison N^+---H---^-O formée à partir d'une réaction d'une base conjuguée (SB) et d'un acide carboxylique (HA) dans un solvant non polaire indiquent que ce proton s'échange rapidement avec d'autres protons présents dans le système. Pour cette étude, deux SB ont été utilisées : la toute *trans*-rétinylidène *tert*-butylamine (RBA) et la *trans,trans*-2,4-heptadiénylidène *tert*-butylamine (HBA) et cinq acides carboxyliques ayant des pK_a variant de 0,66 à 4,87. Les spectres de ^{1}H RMN ont été pris à 293 et 233 K dans le $CDCl_3$ à différents ratios de SB et HA. Les résultats montrent que les échanges de proton sont sensibles à la température et aux ratios d'acides utilisés. Finalement, les résultats sont discutés en rapport avec deux pigments naturels, la rhodopsine et la bactériorhodopsine.

Introduction

The formation of Schiff base:carboxylic acid complexes (abbreviated SB:HA) has not been studied extensively and yet the interest for these structures could well be quite important since in two photosensitive pigments — rhodopsin and bacteriorhodopsin — these complexes could be present. For example, some years ago, several groups have submitted the idea that, in the visual pigment rhodopsin, the retinylidene chromophore could be protonated via a proton relay transfer mechanism involving possibly many carboxylic acids, phenols, or water molecules (1–5). Recently, Khorana and his collaborators (6*a*–*g*) have shown that in bacteriorhodopsin, three amino acids participated in the protonation of the retinylidene chromophore while with rhodopsin, Glu-113 with the possible help of Glu-122 was the protonating agent of the chromophore. Other groups arrived at similar conclusions (7–9). However, Nathans (10) has shown that when the Schiff base chromophore is deprotonated (as when Glu-113 is changed to Gln-113), reprotonation could reappear in the presence of small anions such as iodide.

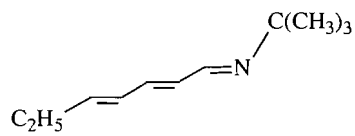
The existence of a proton relay transfer in model systems of rhodopsin has been used by us to explain the results obtained on models studied by different spectroscopic techniques (11–13). Such a mechanism requires the high mobility of the protons engaged in this process and it is the goal of this work to show that such mobility is present in the SB:HA systems. Recently, we were able to demonstrate the existence of complexes between simple unconjugated Schiff bases and carboxylic acids (14) by studying the NMR behaviour of the proton located in the N^+---H---^-O bond in such complexes. Scheme 1 presents the results obtained in this study.

The present work extends the previous study to conjugated Schiff bases and more particularly to all-*trans* retinylidene Schiff base, a good model for the chromophore of rhodopsin. Thus, it is the purpose of this research to discuss what possible role proton exchanges could play in systems where proton translocations are present.

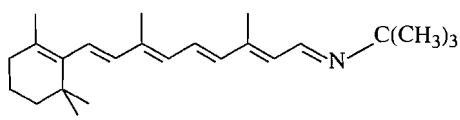
Two Schiff bases are used in this work: *trans,trans*-2,4-heptadienylidene *tert*-butylamine (HBA) and all-*trans*-retinylidene *tert*-butylamine (RBA). We picked the first base because it is a conjugated Schiff base whose NMR spectra are easy to investigate and the second because of its relevance with rhodopsin or bacteriorhodopsin. To study the behaviour of the "acidic" proton (that is N^+---H---^-O), several different carboxylic acids were used: a strong acid, trichloroacetic acid (TCA); a moderately strong acid, monochloroacetic acid (MCA); a still weaker acid, propionic acid (PRO) with a pK_a in the same range as the second carboxylic group in glutamic acid or aspartic acid; and finally with both aspartic and glutamic acids protected by BOC for the amino group and benzyl ester for the α acid group (abbreviated GBE and ABE).

Experimental

HBA and RBA were prepared by using *trans,trans*-2,4-heptadienal (Aldrich Co.) and all-*trans*-retinal (Aldrich Co.) and *tert*-butylamine according to a method already described elsewhere (15). The structures of these two Schiff bases are shown below.



E,E-2,4-heptadienylidene *tert*-butylamine (HBA)



all-*trans*-retinylidene *tert*-butylamine (RBA)

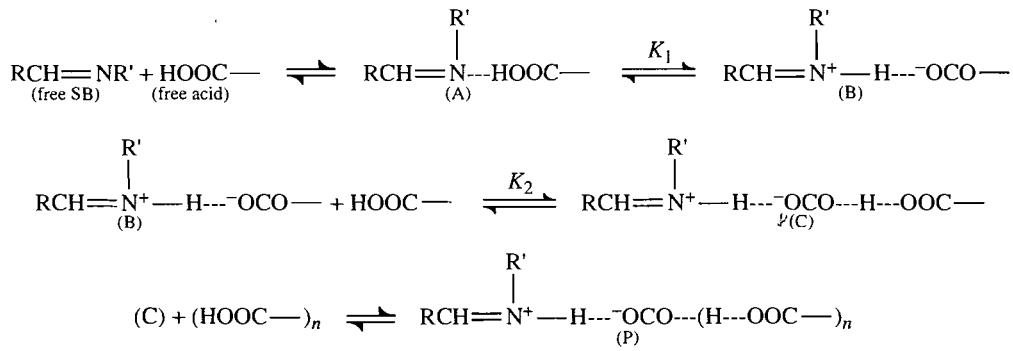

SCHEME 1

Since these Schiff bases are rather unstable, they were always freshly prepared or distilled before use. All acids (Aldrich Co; the protected amino acids ABE and GBE were obtained from Sigma), except PRO which was dried over activated molecular sieve (3Å), were kept under vacuum in a desiccator and in the presence of P_2O_5. No hydrolysis was noted under these conditions (in the NMR spectra the aldehydic proton would show if hydrolysis had occurred). Deuterated chloroform (Merck, Sharp & Dohme) was used as received and was quite satisfactory. To prove the absence of HCl or DCl in this solvent, a UV spectrum of RBA (10^{-5} M) in $CDCl_3$ was taken. No trace of absorption was observed in the 440 nm region, indicating the absence of any protonated SB. One could always argue that these precautions were not enough and that the model systems could contain trace amounts of water and of HCl. First of all, if some water molecules were indeed present, the protonated SB would immediately hydrolyze, producing all-*trans* retinal and the primary amine and this would be seen in the NMR spectra. Secondly, no trace of HCl (or DCl) could be detected in $CDCl_3$. But to insure that point and following the comments of one of the referees, we undertook two parallel NMR studies using in one case $CDCl_3$ kept over some molecular sieves, the other using $CDCl_3$ eluted twice on a basic alumina column and then kept over molecular sieves. With a strong acid like TCA or with a weaker one like MCA, at 233 K, the NMR spectra of RBA taken in both solvents were almost identical.

The concentration of the imines was 0.1 M for all spectra. All operations concerning the preparation of the samples were carried out under a dry nitrogen atmosphere (in a glovebox) and the spectra were recorded immediately after. A Bruker WH-400/DS (400 MHz) spectrometer was used for the study. Since the chemical shifts of the N^+---H---$^-$O proton vary with the concentrations of the acid, the spectra of the acids alone in $CDCl_3$ were always taken at the same concentrations as the ones used in conjunction with the SB.

Results and discussion

First, it is necessary to label the three kinds of "acidic" protons that are present in our system. H_{NO} will refer to the proton located between a protonated Schiff base (hereafter, PSB) and its counterion (v.g. N^+---H---$^-$O). H_{OO} will represent the proton between two carboxylic groups (v.g. O---H---O) in structures encompassing PSB and at least two carboxylic acids and finally, H_a is the proton between two carboxylic acids existing in a dimeric or polymeric forms. This can be visualized in Fig. 1. It must be remembered that carboxylic acids usually exist as dimers in nonpolar solvents (16).

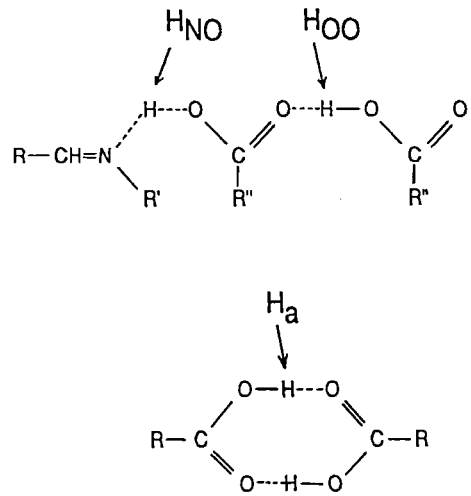

FIG. 1. Structure of a 1:2 complex showing two labile protons and structure of the dimeric form of an acid.

Depending on the conditions used, the "acidic" protons are expected to appear as a sharp or a broad singlet or a doublet. If there is rapid exchanges between the "acidic" protons, a sharp singlet should be observed. If the speed of the exchange is slower some peak broadening is expected. Finally, when the H_{NO} proton, for all practical purposes, stops to exchange with the other protons, a doublet will be formed since H_{NO} will couple with the azomethine proton (that is, the proton at C_{15} for RBA).

In proton exchange studies it is important to check for the presence of water and acid molecules since these will promote the exchanges. As indicated in the Experimental, all the data were collected in stringent anhydrous conditions and no trace amount of acid (like HCl) was observed. This means that the proton exchanges present in our study are due solely to the "acidic" protons of HA.

Table 1 presents the chemical shifts for H_{NO}, H_{OO}, and H_a for the systems consisting of RBA and five acids: TCA, MCA, PRO, ABE, and GBE in deuterated chloroform at 293 and 233 K while Fig. 2 shows a portion of the NMR spectra in the region above 10 ppm for the system of RBA with different molar ratios of TCA and at two different temperatures. Figure 2*a* shows that a rather broad peak at 14.72 ppm (J = 16 Hz) is present for a system consisting of an equimolar mixture of RBA and TCA at 293 K, whereas in Fig. 2*b* a doublet appears at 14.47 ppm for the same system at 233 K. In the first case, the

[c]Unresolved peaks.

peak is assigned to H_{NO} since under the same concentration, H_a has a chemical shift of 10.87 and 12.29 ppm at 293 and 233 K, respectively. The broadness of the 14.72 ppm peak means that, at 293 K, the proton is rapidly exchanging with other "acidic" protons. At 233 K, the presence of a doublet for H_{NO} at 14.47 ppm signifies that the rate of proton exchange has slowed down considerably and that its coupling with the aldimine proton can now be observed. Thus at 233 K, the fact that H_{NO} is a doublet means that this proton must stay on the nitrogen atom long enough (compared to the time scale of NMR) to be coupled with the aldimine proton. The effect of lowering the temperature has been seen and discussed before, notably by Al-Dilaimi et al. (17).

Figure 2*c* shows the NMR spectrum of RBA and TCA in a 1:2 ratio at 293 K. Two peaks are observed. The rather slender peak at 13.43 ppm is assigned to H_{OO} and the doublet, as before, must belong to H_{NO}. That the peak at 13.43 ppm is H_{OO} rather than H_a is easily explained by the fact that at the same concentration, the proton of the pure TCA appears at 11.47 ppm. The fact that H_{NO} appears as a not too well resolved doublet means that the rate of exchange of this proton with the other "acidic" protons of the system has slowed down by adding an excess of TCA.

With a larger excess of TCA (ratio of 1:5) and at the two specified temperatures, H_{NO} appears as a doublet (see Table 1) as it would be expected, whereas all the H_{OO} (integration of four protons) appear as a singlet located at 12.66 ppm (at 293 K) and 13.40 ppm (at 233 K). The fact that a unique singlet is obtained here means that H_{OO} is exchanging rapidly with all the other "acidic" protons in the milieu with the exception of H_{NO} which is strongly held by the positive nitrogen atom of the SB. This is not surprising since H_{NO} is structurally different from H_{OO} or H_a while all the H_{OO} protons are similar between themselves and their differences with H_a become small (as seen by the convergence of their chemical shift values).

When an excess of the SB is used instead of the acid (v.g. 1:0.5 in Table 1), H_{NO} appears as a broad peak at 10.94 and 11.61 ppm when the spectra are taken at 293 and 233 K, respectively. Under these conditions proton exchanges are again present.

With MCA, H_{NO} appears as a doublet only at 233 K and with a ratio of SB:acid of 1:2 and 1:5. This result is expected since MCA, being a weaker acid than TCA, would require stronger conditions in order to allow the protonated SB to hold tightly to its proton. As indicated in Table 1, the differentiation between H_{NO} and H_{OO} cannot be made at 293 K, whatever the SB:HA ratios, since both have the same chemical shifts. However, at 233 K, H_{NO} and H_{OO} do appear at different chemical shifts but this difference is much less than with TCA (compared values of more than 2 ppm for TCA and values of 1.0–1.6 ppm for MCA). Proton exchanges are here the rule rather than the exception.

When PRO, a much weaker acid than MCA or TCA, is used at room temperature, as Table 1 indicates, almost no PSB can be seen since the chemical shifts of the "acidic" protons fall closely to the values of H_a. At 233 K, some protonation is observed (more highly deshielded peaks) but even with a very large excess of acid (v.g. 1:10), no doublet can be detected. These results mean that at 293 K, the SB is largely unprotonated whereas at 233 K some PSB is present as well as proton exchanges.

[a]Expressed in molar ratios of HBA:acids.
[b]d = doublet, otherwise a singlet.
[c]Unresolved peaks.

The results obtained with GBE are similar to those of PRO which is not surprising since both acids have nearly the same pK_a's. However, the deshielding values of H_{NO} and H_{OO} is somewhat higher with GBE than with PRO, indicating that protonation could be somewhat higher. With ABE, which is slightly more acidic than GBE, differences in chemical shifts are seen for H_{NO} and H_{OO} only when the molar ratio of RBA:ABE reaches 1:5. Characteristically, H_{NO} still appears as a singlet thus indicating that the rate of proton exchange is still too fast compared to the time scale of NMR.

Similar data for HBA and three acids (TCA, MCA, and PRO) are shown in Table 2. For the three acids, the ratios of the SB to the acid varied from 1:0.5 to 1:5. Unless otherwise indicated, and as before, the chemical shift values are for singlets.

At 293 K, the data shown in Table 2 indicate that with HBA, H_{NO} is always a singlet whatever the acid used. With an excess of the carboxylic acid, for MCA and PRO, H_{NO} cannot be differentiated from H_{OO} since both have identical chemical shifts (indicated in Table 2 as unresolved peaks). However, for TCA at 233 K and at ratios of 1:2 and 1:5, H_{NO} appears as a doublet like in the previous case for RBA; thus here, both HBA and RBA behave similarly and the difference in conjugation does not seem to play a major role. With a ratio of 1:5 in TCA, data in Table 2 show that all the H_{OO} are exchanging rapidly between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

themselves and the chemical shifts of these protons tend towards the values of H_a as it was also the case for RBA.

All these results can be used to gain some insight about the behaviour of the proton located in a N^+---H---^-O bond in systems where protonated Schiff bases are rapidly exchanging protons with the milieu.

First, depending on the protonating agent, the SB can be fully or partially protonated. Even when fully protonated as in the case with the strong acid TCA, the proton in the N^+---H---^-O bond is exchanging rapidly with other "acidic" protons. Only when excess acid or low temperature is used does the proton appear as a doublet, meaning that the rate of exchange has slowed down and that the coupling of H_{NO} with the aldimine proton can be seen. With weaker acids like PRO, GBE, and ABE that mimic aspartic and glutamic acids present in the natural pigments, the exchange rate is always very fast in a nonpolar solvent.

The results obtained in this study do not contradict those found for unconjugated systems (14). For conjugated SB, the main point here is that the N^+---H---^-O bond, being highly polarizable (18^{e-g}), also has a highly mobile proton that can exchange quite easily with other "acidic" protons. Extrapolated to the pigments these results suggest that the protonated retinal Schiff base has an "acidic" proton which is not tightly held by the positive nitrogen atom in the salt bridge (as in structure B in Scheme 1). This could explain, in part, why proton translocation in both rhodopsin and bacteriorhodopsin occurs so readily.

Acknowledgements

The NMR spectra were obtained at the Centre régional de RMN de haut champ of Université de Montréal. This study was made possible by grants received from the National Research Council (AO-943) and the Fonds pour la formation de chercheurs et l'aide à la recherche (FCAR) of Québec.

Contrary to expectations, many primary hydroxy groups are completely unreactive in glycosylation reactions, or give the desired glycosides in very low yields accompanied by products of many side reactions. Hydrogens of such primary hydroxyls are shown to be intramolecularly hydrogen bonded. Intermediates formed by nucleophilic attack by these hydroxyls on activated glycosylating agents may resist hydrogen abstraction. This resistance to proton loss is postulated to be the origin of the observed unreactivity. It is shown that successful glycosylations take place under acidic conditions under which such hydrogen bonds cease to exist. Accordingly, direct galactosylations of the normally unreactive 5′-hydroxyls of nucleosides were accomplished for the first time with a galactose trichloroacetimidate donor in chloroform under silver triflate promotion. It is noted that such galactosylated anticancer nucleosides may have improved biological specificity.

DENNIS M. WHITFIELD, STEPHEN P. DOUGLAS, TING-HUA TANG, IMRE G. CSIZMADIA, HENRIANNA Y.S. PANG, FREDERICK L. MOOLTEN et JIRI J. KREPINSKY. Can. J. Chem. **72**, 2225 (1994).

Contrairement à ce que l'on peut prévoir, plusieurs groupes hydroxyles primaires ne réagissent pas du tout au cours des réactions de glycosylation ou avec seulement de faibles rendements accompagnés de plusieurs sous-produits. On a démontré que les hydrogènes de ces hydroxyles primaires sont impliqués dans des liaisons hydrogènes. Les intermédiaires qui se forment par attaque nucléophile de ces hydroxyles sur des agents activés de glycosylation peuvent résister à la réaction d'enlèvement de l'hydrogène. Cette résistance à la perte d'un proton se produit en milieu acide alors que de telles liaisons hydrogènes cessent d'exister. On a réalisé pour la première fois des galactosylations directes des hydroxyles normalement non réactifs en 5′ des nucléosides en utilisant comme donneur un trichloroacétimidate de galactose dans le chloroforme sous promotion par le triflate d'argent. Il a été suggéré que de tels nucléosides anticancéreux galactosylés pourraient avoir une spécificité biologique améliorée.

[Traduit par la rédaction]

Introduction

Glycosylation of carbohydrate primary hydroxyls usually proceeds smoothly and many examples of glycosylations of OH-6 of hexopyranosides,[4] using Koenigs–Knorr, Helferich, and related procedures, have been described (3). However, we have observed surprisingly unreactive primary hydroxyl groups with certain acceptors. In our experience with difficult glycosylations, these acceptors often contained benzyl or allyl protecting groups (4). Similar observations have been made in other laboratories as well (e.g., P. Sinaÿ, V.V. Bencomo, personal communications). The common-sense explanation is that steric hindrance renders the primary hydroxyl groups inaccessible to the glycosylating agent. We were intrigued by reports of surprising difficulties (5) in the glycosylation of the primary O-5′ H of nucleosides (6, 7). Not only are orthoesters (8) formed when using an ester protective group at C-2 under common Koenigs–Knorr reaction conditions, but even this

[4]There has been little interest in the syntheses of oligosaccharides through the OH-5 of pentofuranoses; this is perhaps because the 1–5 linkage is very rare among naturally occurring oligosaccharides.

reaction is sluggish and low yielding (9). To invoke steric effects of bulky protective groups resulting in inaccessibility of reactive sites did not seem quite correct in the case of nucleosides since no large protective groups were present in the reported cases. Consequently, we wondered whether intramolecular interactions such as hydrogen bonding between the hydroxyl and a lone pair or a π-electron system may be responsible for this unreactivity.

The success, although very limited, of the Bredereck modification of the Koenigs–Knorr reaction involving 2-deoxynucleosides such as thymidine (**T1**) indicated that these effects may indeed be of importance. In the Bredereck reaction, the primary hydroxyl is protected with a trityl group and glycosylations are performed under acidic conditions (10). Obviously, since the hydrogen atom of the 5′-hydroxy group is not present, it cannot participate in hydrogen bonding. This observation supports our hypothesis that glycosylations should be successful in the absence of the hydrogen bonding. In addition, glycosylations should occur if the hydrogen bond breaks under the reaction conditions.

To control effectively the outcome of glycosylations, the factors limiting reactivity should be determined. Because of our long-standing interest in a polymer-supported design (11) for synthesis of oligosaccharides in which such control is essential, we have undertaken a program investigating the origins of the low reactivity of such primary hydroxyls. We are also exploring a novel concept of cancer therapy based on the assumption that, under certain conditions, 5′-galactosylation yields nucleoside

anticancer drugs that can be specifically targeted against neoplastic cells (see Appendix I). We have already demonstrated (1) through ab initio mechanical calculations the existence of non-covalent interactions in nucleosides and of the potential for hydrogen bonding between the O5′-H and the nucleoside base in low-polarity solvents (12). To the best of our knowledge, direct glycosylation of nucleoside 5′-hydroxyl groups has not yet been reported. Consequently, we had to develop methodologies, capable of overcoming this hydrogen bonding, for the preparation of 5′-galactosylated nucleosides araC (**Ar2**), 2-deoxycytidine (**C2**), and thymidine (**T2**).

Results

Conformation of acceptor nucleosides

To determine the origins of the unusual unreactivity of primary hydroxyls of aglycons such as **Ar3**, **C3**, and **T3** (intermediates for the synthesis of **Ar2**, **C2**, and **T2**, see Scheme 1), and considering the hypothesis that such hydroxyls may be involved in intramolecular hydrogen bonding, their conformations in dry CD_2Cl_2 (to mimic the glycosylation conditions) were determined by NMR spectrometry. Infrared spectrometry was also used to probe the presence of internal hydrogen bonding in these substances.

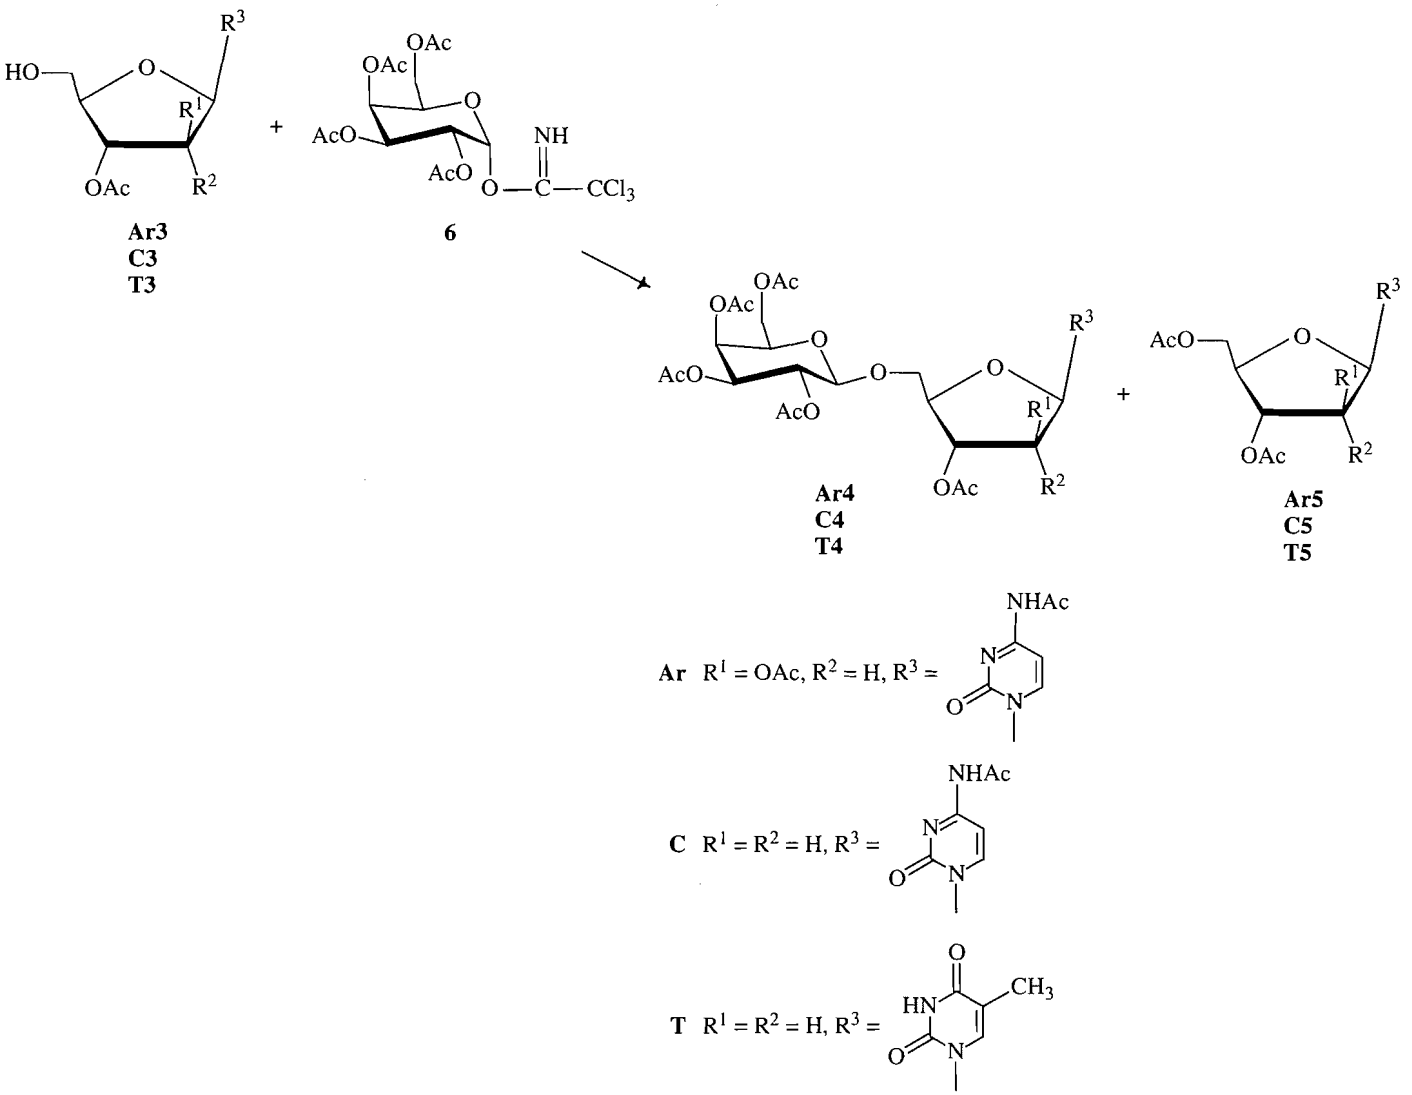
*Deoxycytidine derivative **C3***

A. Nuclear magnetic resonance spectrometry

The data for deoxycytidine derivative **C3** in CD_2Cl_2 solution (cf. also ref. 1) have shown that **C3** exists in one overall predominant conformation. It is the *syn* conformation (cf. Fig. 1 for definition (13)) about the glycosidic linkage, as indicated by a large NOE between the anomeric proton H-1′ and the base H-6 and the *gauche-gauche* ($\gamma = 60°$) conformation for the hydroxymethylene group (based on the small values of the coupling constants $J_{4',5'}$ and $J_{4',5''}$, 2.7 and 2.9 Hz, see Table 3). Such a general conformation allows for a hydrogen bond between O-5′ H and the base carbonyl O-2. In the more acidic deuterated chloroform, the NOE between the H-1′ and H-6 diminished (8.1% → 5.1%), consequently the distance may have increased between O-5′ H and the base carbonyl O-2.

B. Infrared spectrometry

Stretching vibrations of a free OH group are normally absorbing in the frequency range 3610–3645 cm^{-1}, and the intra- and intermolecular hydrogen bonds give rise to an absorption in the frequency range 3200–3600 cm^{-1}. The two hydrogen bondings can be distinguished since the intermolecular hydro-



SCHEME 1. Galactosylation of nucleosidic O-5′H.

gen bonding diminishes with increased dilution of the sample, and consequently the absorption band disappears, while in the case of the intramolecular hydrogen bonding the absorption band remains unchanged. Intermolecular hydrogen bonding is not expected to occur at concentrations below 0.5 molar (14). If an NH group is present in the molecule, N–H stretching vibrations interfere since they give rise to a broad absorption between 3000 and 3500 cm^{-1}, thus overlapping with the absorption due to the OH vibrations.

To mimic the glycosylation conditions, the IR measurements have to be done in CH_2Cl_2, in which **C3** is not very soluble. At the highest concentration possible (1.3 mM), OH stretching vibrations in **C3** are found as a shoulder at 3620 cm^{-1} (free OH) of 3404 cm^{-1} (superimposed OH intramolecular bonding and NH). These absorptions did not change on further dilution until the sample became too dilute to record the spectrum.

Arabinocytidine derivative ***Ar3***

A. Nuclear magnetic resonance spectrometry

The arabinosylcytosine derivative **Ar3** exists in an *anti-syn* equilibrium with the *anti* conformation predominating, since the presence of the O-2′ acetate disfavours the *syn* conformation (15); cf. Fig. 1*a* for the definition of *syn* and *anti*, and the variations of the angle χ within the definition. The small NOE (cf. Fig. 2) between H-1′ and H-6 indicates that for **Ar3** the *anti* conformation, $\chi = 180°$,[5] most likely predominates over the *syn* conformation (16). The conformation around the hydroxymethylene moiety is indicated by the small (3.7 Hz) and medium (5.1 Hz) H-4′–H-5′ and H-4′–H-5″ couplings (see Table 1), nearly identical before and after D_2O exchange (cf. Fig. 3). Such couplings are consistent with an equilibrium between the *gauche-gauche* ($\gamma = 60°$) and the *gauche-trans* ($\gamma = 180°$) rotamers about C-4′–C-5′ (17). Further evidence of such an equilibrium is obtained from NOE measurements after irradiation of H-5′ or H-5″. In both cases a moderate intensity NOE was observed to H-3′ as well as to H-4′. In the *gauche-gauche* conformation only H-5″ (proR) is close enough to H-3′ to expect an observable NOE, while in the *gauche-trans* conformation H-5″ comes close to H-4′.

Another hydrogen bond is possible between O-5′ H and O-2′ in the *gauche-gauche* conformation. Such a hydrogen bond would be best accommodated in the C-2′ *endo* conformation of

[5]The *anti* conformation has been recognized as the predominant conformation for most nucleosides (ref. 43); the parent compound Ara C, **Ar1**, adopts the *anti* conformation in the crystalline state (44). Cf. also ref. 18.

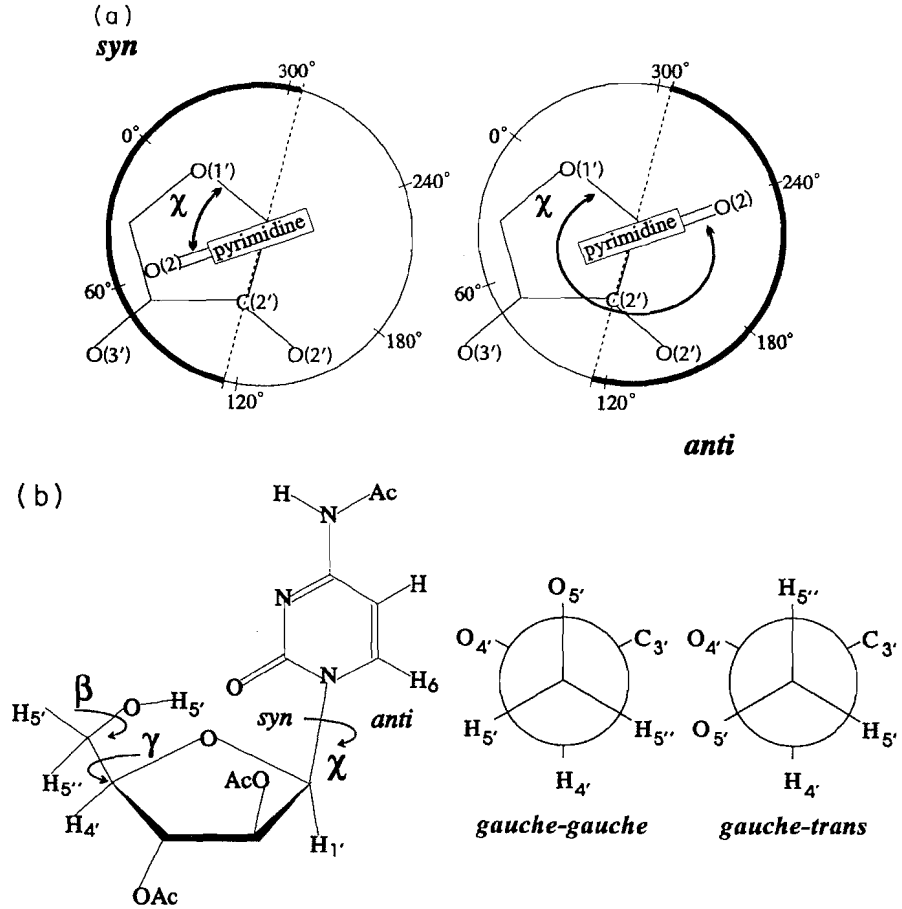

FIG. 1. Definitions of conformational parameters of nucleosides. Part (*a*) is reproduced from Saenger (13), with permission.

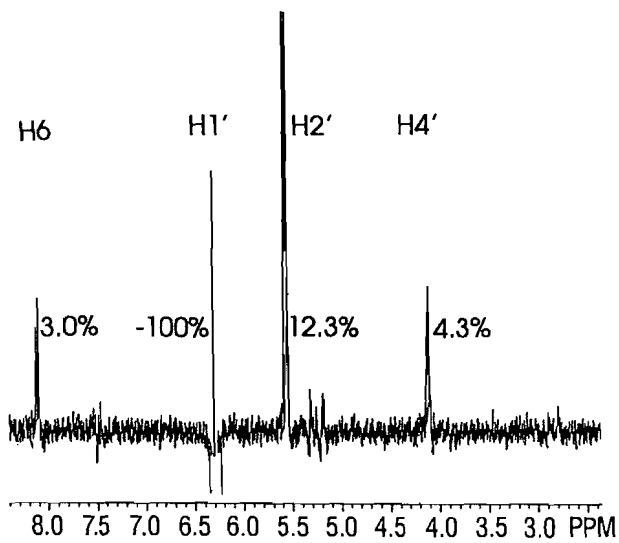

FIG. 2. Partial 500 MHz ^{1}H NMR spectrum of **Ar3** in CD_2Cl_2 solution. Difference 500 MHz ^{1}H NMR nuclear Overhauser effect spectrum of **Ar3** in CD_2Cl_2 solution after irradiation of anomeric H-1′ showing a small NOE to H-6.

the furanoside ring. This ring conformation is deduced from the small values of $J_{3',4'}$ (see Table 1). However, the small values of $J_{1',2'}$ and $J_{2',3'}$ are consistent with a mixture of conformers C-2′ *endo* and C-3′ *endo* (18).

B. Infrared spectrometry

The infrared spectrum of **Ar3** at a concentration of 7.2 mmol (the maximal concentration of freely soluble **Ar3**) displays two broad absorption bands for OH and NH stretching vibrations at 3482 cm^{-1} that did not change on dilution. No free OH absorption could be identified in the spectrum (cf. also Wechter, ref. 19). The absence of the absorption for free OH from the spectra of **Ar3** may seem somewhat puzzling since it appears to suggest that the hydrogen-bonded (O-5′ H...O-2) conformation predominates, while the NMR spectrometry would at first glance indicate that only a certain percentage of **ArC** in the conformational equilibrium is in a hydrogen-bonded *syn* conformation. However, hydrogen bonding from the O-5′ H can be directed to other acceptors than O-2 (18).

*Thymidine derivative **T3***

The thymidine derivative **T3** was not investigated in detail since key resonances overlapped. However, the small $J_{4',5'}$ and $J_{4',5''}$ coupling constants suggest that this derivative resembles the intramolecularly hydrogen-bonded conformation of **C3**.

Thus it is very likely that the deoxycytidine and thymidine derivatives having a free 5′-hydroxyl exist predominantly in an intramolecularly hydrogen-bonded conformation, O-5′ H...O-2. This hydrogen-bonded conformation may also be a significant component of the conformational equilibrium of the arabinosylcytosine derivatives, in addition to other hydrogen bondings.

Synthesis of 5′-galactosylated nucleosides

The known acetylated nucleosides **Ar3** (19), **C3** (20), and **T3**,[6] having a free 5′-hydroxyl, were prepared as follows: N-acetylation of the free amino group (when present), temporary regioselective protection of the 5′-hydroxyl with the dimethoxytrityl (DMT) group, acetylation of the secondary hydroxyls, and removal of the DMT group. Attempts to selectively react the 5′-hydroxyl with DMT chloride without prior N-acetylation led to considerable substitution with DMT at the amino group. Even mild conditions for the removal of the DMT group with 1% dichloroacetic acid in CH_2Cl_2 led to some unavoidable nucleoside glycosidic bond cleavage necessitating a chromatographic purification.

These derivatives with a free 5′-hydroxyl did not give the desired galactosylated nucleosides with acetobromogalactose under standard Koenigs–Knorr conditions. However, they could all be galactosylated with 2,3,4,6 tetra-*O*-acetyl α-D-galactopyranosyl trichloracetimidate **6** (21) in CH_2Cl_2 promoted by

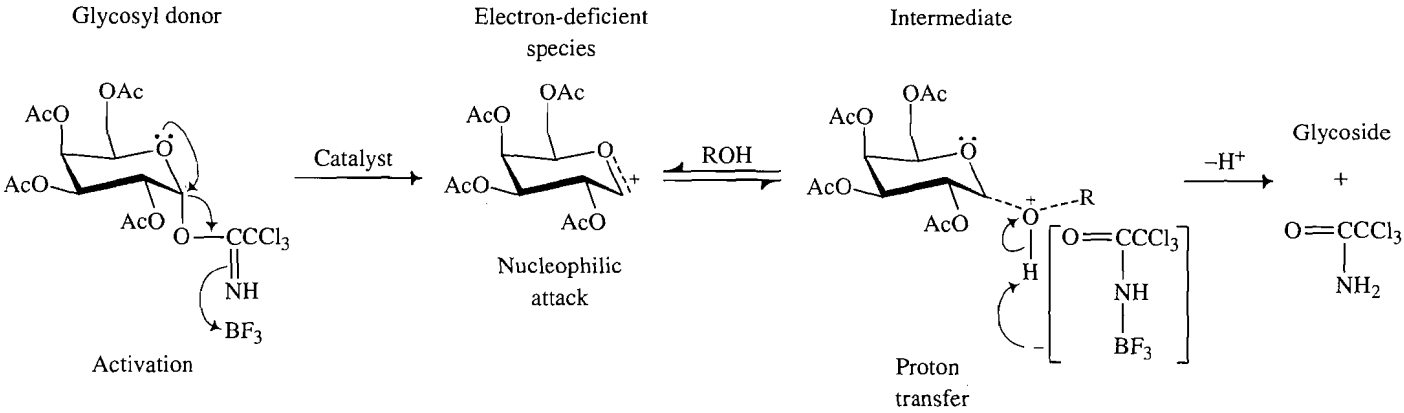


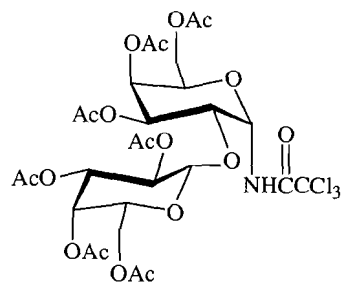
SCHEME 2. Simplified mechanism of the glycosylation reaction showing three principal stages of the reaction: activation, nucleophilic attack, and hydrogen loss. A protonated intermediate is formed in the second step of this reaction sequence. This intermediate must lose the proton to give the desired glycoside. In most cases the deprotonation is facile; it may become difficult if the hydrogen present in the intermediate is stabilized by an intramolecular hydrogen bond.

$BF_3{\cdot}Et_2O$ (22) to give the desired galactosides **Ar4**, **C4**, and **T4**. In all cases galactosylation was accompanied by significant acetate transfer from O-2 of the galactosyl imidate to the 5′-hydroxyl, giving the known nucleoside peracetates **Ar5** (23), **C5** (24), and **T5** (25) in ratios 1.25:1 (**Ar4**:**Ar5**), 0.23:1 (**C4**:**C5**), and 0.36:1 (**T4**:**T5**). No other nucleoside-containing products were observed. Imidate **6** and $BF_3{\cdot}Et_2O$ were used in equimolar quantities; when $BF_3{\cdot}Et_2O$ was used in catalytic amounts, acetate transfer predominated, and the overall yields were low. Variations in the temperature or the rate of addition of the $BF_3{\cdot}Et_2O$ had little effect and $BF_3{\cdot}Et_2O$ had to be added to a mixture of the imidate and the acceptor (26). Some nucleoside (base–sugar) cleavage occurred when reaction times exceeded 1 h.

Acetate transfer is not uncommon and has often been reported to compete with glycosylation reactions (27). To suppress this transfer, other Lewis acids were examined. $ZnBr_2$, although reported to eliminate acetate transfer (28), gave only complex mixtures. Triethylsilyl triflate (TESOTf) (29) gave results similar to those obtained with $BF_3{\cdot}Et_2O$. Silver triflate, recently described as a promoter of glycosylation reactions with trichloroacetimidates (30) in CH_2Cl_2, *significantly suppressed* acetate transfer, raising the ratio of glycosylation to transfer from 0.23:1 to 1.67:1 (**C4**:**C5**).

Further suppression of the acetate transfer reaction was achieved by changing the solvent from CH_2Cl_2 to the more acidic $CHCl_3$; using $BF_3{\cdot}Et_2O$ improved the ratio from 0.23:1 to 0.5:1 (**C4**:**C5**) in favour of the glycoside, and using silver triflate improved the ratio even further to 3.33:1 (**C4**:**C5**). The ratio for **Ar4**:**Ar5** improved to 20:1 from 1.25:1 using AgOTf in $CHCl_3$.

The peracetylated galactosylated nucleosides and the products of the acetate transfer reaction (peracetylated nucleosides) were separated by chromatography on silica gel followed by size-exclusion chromatography on Sephadex LH-20. During the silica gel chromatography a major by-product, the peracetylated disaccharide Galβ1,2GalαNHCOCCl$_3$ (**7***a*), was isolated. Its structure was determined by NMR and mass spectrometries; in particular, a strong ^{1}H NMR NOE between the β-Gal H-1 and the H-2 of the α-Gal residue established the β1–2 interglycosidic linkage. The α-NHCOCCl$_3$ anomer **7***a* was accompanied by a variable small amount of the β-anomer **7***b*. Both **7***a* and its anomer arise from the galactosylation of the monosaccharide formed after transfer of the acetate from O-2 of **6**, and imidate rearrangement of **6** (31).



7*a*

The desired glycosylated nucleosides were finally obtained by removing both O- and N-acetate protective groups with DBU-catalysed transesterefication.

Preliminary biological assays

The galactosylated compounds exhibited the increased specificity in toxicity for cell types expressing the lacZ gene while they were nontoxic to other cells. This is the basic requirement for one approach to overcoming the low-selectivity problem associated with cancer chemotherapeutics (see Appendix II).

Discussion

The understanding of glycosylation reactions has been greatly advanced during the last two decades through the efforts of many chemists, and particularly through the pioneering insights into anomeric effects by R.U. Lemieux and his colleagues (32). It is clear that currently most common methods for the formation of glycosidic linkages proceed via nucleophilic substitution at the electron-deficient anomeric carbon as shown in Scheme 2. Details of the mechanism are less clear and apparently vary among different experimental designs. Despite these possible variations, it would be intuitively anticipated that primary hydroxyl groups (e.g., O-5H in pentofuranoses or O-6H in hexopyranoses) should always be reasonably reactive nucleophilic partners in glycosylation reactions. It is not, however, the case for nucleosides.

The results reported in this article suggest that 2′-deoxycytidine derivative **C3** assumes a conformation indicative of a hydrogen bond from the 5′-hydroxyl to the 2-carbonyl group and ab initio calculations and topological bond-path determinations confirm this conclusion (1). The NMR and infrared data demonstrate that analogous derivatives of thymidine, **T3**, and

arabinofuranosyl cytosine, **Ars**, also exist in such hydrogen-bonded conformations, at least to some extent. The O-5′ H of **Ar3** may be engaged in other hydrogen bonding (18).

The hydroxyl groups acting as hydrogen bond donors should have increased electron density at the oxygen (33), and this increase in the electron density should in turn make this oxygen a better (more reactive) nucleophile. Thus such a hydroxyl should be more reactive in a glycosylation reaction than the same hydroxyl would be, if not engaged in hydrogen bonding. Eventually the glycosylating agent becomes bound in a protonated intermediate that is still intramolecularly hydrogen bonded as portrayed in Scheme 2. To obtain the desired glycoside from the reaction, *this hydrogen must be abstracted.* Until this happens, the protonated intermediate remains in equilibrium with other species and therefore can become involved in competing reactions. For instance, the newly formed glycosidic bond can break, thus recreating the electron-deficient species, which may be diverted into other reaction pathways as illustrated in Scheme 3. These pathways, which involve the loss of the 2-O-acetyl and result in acetyl transfer to the aglyconic hydroxyl a well as in 1,2 disaccharides, can effectively compete (cf. the formation of the disaccharides **7***a*, *b*).

It is also important to appreciate that for donors like trichloroacetimidates, once the electron-deficient species is formed, it cannot form the original donor again because the imidate is transformed into an amide after activation. This amide or its complex with a Lewis acid can also act as a nucleophile. Lewis acids such as $BF_3{\cdot}Et_2O$ or silver triflate can also bind to nucleosides; this explains the requirements for larger than equimolar amounts of such acids in successful glycosylations. By such binding the Lewis acids may break up the intramolecular hydrogen bonding: it was shown in the previous communication (1) that complexation at the N-3 of the nucleoside by BF_3 markedly destabilized the hydrogen-bonded conformer. The intramolecular hydrogen bond can be further destabilized by solvent effects; for instance, successful 5′-galactosylations in chloroform (see also footnote 7) are described in this article.

Concluding remarks

We have attempted in this article to explain the origins of the low reactivity of primary hydroxyls acting as acceptors of glycosylating agents. We formulated a hypothesis that such unreactive primary hydroxyls are involved in intramolecular hydrogen bonding. Led by this hypothesis, we devised conditions in which this unreactivity can, at least to some extent, be overcome. Although we developed the argument using nucleosides as examples, it is equally applicable to glycosylations of any substrate, including oligosaccharides, in which the hydroxyl is involved in an intramolecular hydrogen bond. Clearly, more work, using suitably designed experimental strategy, is necessary to provide additional evidence for this hypothesis.

It is also worth noting that the aromatic ring of protecting groups, so commonly used in oligosaccharide synthesis (e.g., benzyls), can be the acceptor in hydrogen bonds as is well known from conformational studies of proteins. π-Type hydrogen-bonded complexes between benzene with acceptors HA or H_nA (including H_2O) have been described both experimentally (34) and theoretically (35). One of the possible ways (both a single or a bifurcated hydrogen bond is possible) to form this type of bonding in $C_6H_6{\cdot}H_2O$ is shown in Fig. 4. Assuming that such a hydrogen bond is sufficiently strong (typically 2–4 kcal mol^{-1}), the reaction mechanism portrayed in Scheme 2 applies to glycosylations of such hydroxyls as well. Examples from this laboratory of such glycosylations will be published in due course.

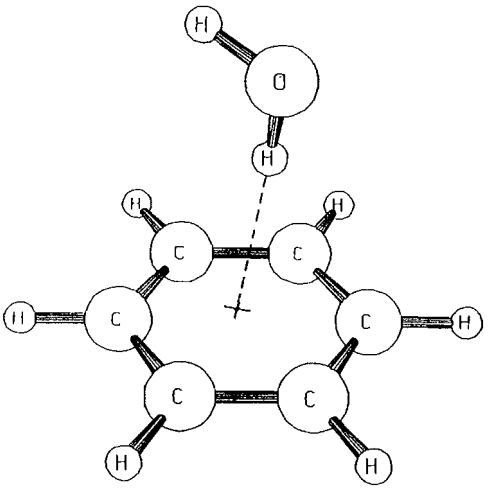

FIG. 4. One of the possible ways to form π-type hydrogen-bonded $C_6H_6{\cdot}H_2O$ complexes. One hydrogen atom of the water molecule is above the centre of the benzene ring and the O—H bond is almost perpendicular to the plane of the benzene ring. One minimum is found using the semiempirical Parametric Method 3 (PM3) method (41), the hydrogen bonding energy ΔE (PM3) = −1.39 kcal mol^{-1}. It has been shown that a similar intramolecular π-type hydrogen bonding in which an aromatic ring is the acceptor is not uncommon (42) and that such bonds are one of the stabilization forces of protein conformations.

Experimental

General methods

Thin-layer chromatography (TLC) was performed on silica gel $60F_{254}$ (Merck) plates and visualized by spraying with 50% aqueous sulfuric acid and heating at 200°C. Silica gel (230–400 mesh, Toronto Research Chemicals) was used for flash chromatography. All starting materials were dried overnight in vacuo (10^{-3} Torr; 1 Torr = 133.3 Pa) over KOH or P_2O_5 prior to use, and the solvents were distilled from appropriate drying agents. Solutions were concentrated at 1 Torr pressure in a rotary evaporator.

All compounds were characterized by ^1H (Tables 1, 3, and 5) and ^{13}C NMR (Tables 2, 4, and 6). To the best of our knowledge, the complete NMR spectra of the known compounds **AR3**, **AR5**, **C3**, **C5**, **T3**, and **T5** have not yet been reported. ^1H NMR assignments were made by standard decoupling techniques and all coupling constants were determined by first-order analysis of peak separations where possible. In the case of the fully deprotected compounds in D_2O solutions, the methylene protons were analyzed using inversion–recovery experiments with short delays (0.2−0.4 s) after the 180° pulse. With optimum delays, the short T_1's of the methylene hydrogens allowed the signals for these protons to be observed, whereas all other signals were either nulled or inverted (longer T_1's). ^{13}C NMR spectra of the title compounds were assigned by ^{13}C–^1H correlation, and of protected compounds by comparison to the literature (36, 37). All spectra are consistent with the proposed structures.

H and ^{13}C NMR spectra were recorded at 500 (125, ^{13}C) MHz with a Bruker AM 500 spectrometer or at 300 (75.5, ^{13}C) MHz with a Bruker AM 300 spectrometer, both at the NMR Spectrometry Laboratory of the Carbohydrate Research Centre, University of Toronto. Spectra were obtained either in $CDCl_3$ containing a trace of TMS (0 ppm, ^1H and ^{13}C) as the internal standard or in D_2O (99.98%, Ald-

[7]Another example is silver triflate promoted galactosylation (by trichloroacetimidate, **6**) of a 5-fluorouridine derivative in chloroform at elevated temperature (45).

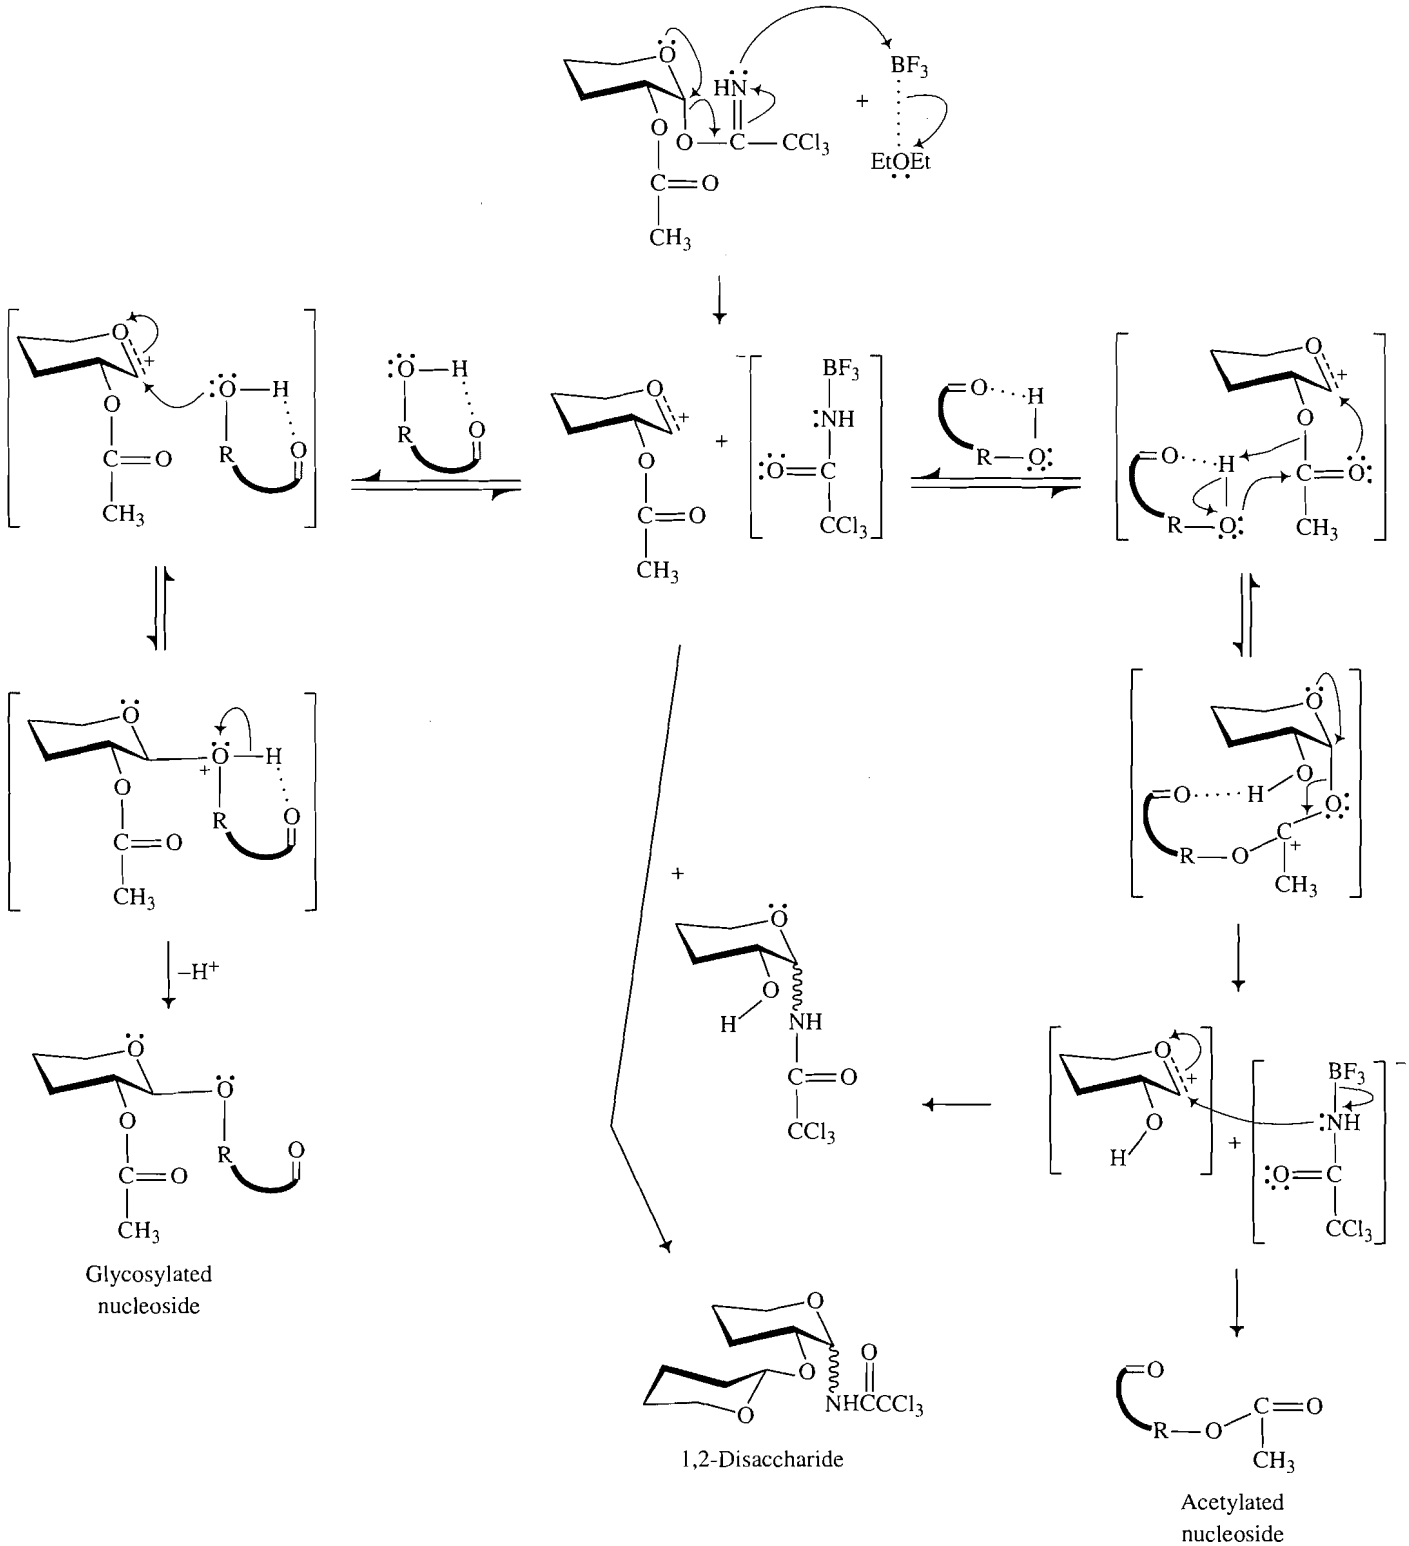

SCHEME 3. The glycosylation reaction is diverted from yielding the desired glycoside to a formation of by-products. The + and − signs represent electron deficiency or excess rather than true charges. The pyran ring represents properly protected pyranosides, BF_3 is used as an example of a promoter or catalyst.

rich) containing a trace of acetone (2.225 ppm relative to internal DSS, ^1H, and 30.5 ppm, ^{13}C) as the internal standard using the δ(ppm) scale. Spectra in CD_2Cl_2 were referenced to the residual $CHDCl_2$ (5.32 ppm) for ^1H spectra or to the ^{13}C resonance (53.6 ppm). Samples in CD_2Cl_2 had activated powdered 4 Å molecular sieves added directly to the NMR tube to ensure the complete removal of any residual water. For D_2O exchange, 1 drop of D_2O was added to the NMR tube, mixed vigorously, and then left to equilibrate with added molecular sieves before the spectra were obtained. NOE spectra were obtained in the 1D difference mode using an internal reference; the solutions were not de-

gassed.[8] Inversion–recovery experiments used the standard Bruker software for T_1 determinations.

UV spectra were recorded with a Cary 20 UV–VIS spectrophotometer. Infrared spectra of compounds in saturated CH_2Cl_2 solutions were recorded with a Nicolet FTIR 5DX instrument. These solutions were subjected to stepwise dilutions to halve the previous concentration, and recorded again.

[8]A referee has suggested that traces of oxygen in solutions may significantly influence the quantitation of the NOE measurements. Although the specimens were not purged free of air, a possible experimental error would not exceed 15% as can be seen from the comparison of T_1's in $CDCl_3$ for **Ar3** before and after purging (data after purging are in parentheses): NH, 0.70 (0.71); H5, 1.55 (1.79); H6, 1.20 (1.32); H1′, 1.17 (1.46); H2′, 1.31 (1.46); H3′, 1.35 (1.53); H4′, 1.14 (1.24); H5′ + H5″, 0.41 (0.46); O5′H, 0.84 (0.82).

[a]Hex = hexose.
[b]For molecular formulae, see Experimental.

All mass spectra were recorded with a VG Analytical ZAB-SE mass spectrometer at the Mass Spectrometry Laboratory of the Carbohydrate Research Centre, University of Toronto. For Fast Atom Bombardment (FAB) the samples dissolved in methanol were loaded onto a target that contained 1–2 μL of glycerol and thioglycerol (3:1) and were bombarded by neutral xenon atoms (8 keV and 1 mA anode current) generated by an Ion-Tech Saddle Field ion gun. The spectra were recorded using the multichannel analyzing mode with a VG 11-250 data system. For low-resolution FAB-MS, the resolution was set at 1000 and the instrument was calibrated with CsI. For high-resolution FAB-MS measurements, i.e., 10 000 resolution (10% valley definition), 2% polyethylene glycol (avg. mol. wt. 300 or 600) was added to the matrix as internal calibrant and a narrow mass range was scanned using the accelerating voltage.

Electron-impact mass spectra (EI) were recorded using the direct insertion probe, and the source conditions were 200°C, 70 eV, and the electron trap current 100 μA. Resolution was approximately 1000 for low-resolution spectra and 10 000 for high-resolution spectra. Perfluoroalkane used as internal calibrant was introduced into the ion source via the septum inlet and the high-resolution spectra were acquired by scanning the magnet.

All derivatives of sufficient volatility, i.e., protected nucleosides, were characterized by electron ionization mass spectrometry, EIMS, and the title galactosylated nucleosides by fast-atom-bombardment mass spectrometry, FAB-MS. All new compounds purified by chromatography gave satisfactory elemental composition as determined by high-resolution MS spectra. The mass spectra of the peracetylated nucleosides exhibit facile elimination of ketene or acetic acid from the original molecules or fragment ions but otherwise the fragment ions are very similar to those reported for the trimethylsilyl derivatives (38, 39). Ions characteristic of the carbohydrate and base moieties are summarized in Table 7. In the case of the compounds **Ar3** and **C3**, the free hydroxyl group was also blocked by the trimethylsilyl group to confirm the presence of the free hydroxyl group at the 5′-position by observing the *m/z* 103 ion in the derivatized compounds (35, 36).

N^4-*Acetyl-1-[2′,3′-di*-O-*acetyl*-β-D-*arabinofuranosyl] cytosine* (***Ar3***)

1-[β-D-Arabinosyl]cytosine (**Ar1**, 3.0 g, 12.3 mmol) was dissolved in dry methanol (300 mL) and acetic anhydride (3.0 mL) and refluxed under argon. Additional portions of acetic anhydride were added after 1 h and, again, after 2 h (40). After heating for a total of 3 h, the mixture was concentrated to about 10 mL, cooled on ice, and diethyl ether (100 mL) was added. The resulting white precipitate was isolated by filtration with suction. The dried solid was dissolved in dry pyridine (60 mL) containing 4-dimethylaminopyridine (20 mg) under argon, dimethoxytrityl chloride (6.27 g; 18.5 mmol) was added, and the mixture was stirred at room temperature for 24 h. Another portion (0.9 g) of dimethoxytrityl chloride was added and stirring was continued for another 8 h. At this time TLC (1% CH_3OH:CH_2Cl_2) indicated that the reaction was complete, and the flask was cooled in an ice-bath, acetic anhydride (18 mL) was added dropwise by a syringe, and the mixture was stirred overnight in the ice-bath. After warming up to room temperature, the volatiles were removed by evaporation in high vacuum, and the residue was subjected to chromatography on a column of silica gel eluted sequentially with 500 mL CH_2Cl_2, 1% CH_3OH:CH_2Cl_2, 3% CH_3OH:CH_2Cl_2, and 5% CH_3OH:CH_2Cl_2, to yield slightly impure solid peracetylated 5′-dimethoxytritylated compound (6.0 g). After drying, the solid was dissolved in CH_2Cl_2 (150 mL) and a 1% solution of $CHCl_2COOH$ in CH_2Cl_2 (1.5 mL; 18.3 mL) was added dropwise under argon. After stirring was continued for another 5 min, solid $NaHCO_3$ (1.6 g; 20 mmol) was added and the reaction mixture was stirred for another 10 min. The solids were filtered off, rinsed with $CHCl_3$, and the combined filtrates were evaporated to dryness. The residue was at once subjected to chromatography on a column of silica gel and eluted sequentially with 1% CH_3OH:CH_2Cl_2, 3% CH_3OH:CH_2Cl_2, 5% CH_3OH:CH_2Cl_2, and 10% CH_3OH:CH_2Cl_2 to yield slightly impure **Ar3** (3.5 g; 77%). After repeated chromatography on silica gel with 5% CH_3OH:CH_2Cl_2, a pure specimen of **Ar3** ($C_{15}H_{19}N_3O_8$) was obtained: $[\alpha]_D$ +96.3 (*c* 0.30, CH_3OH:CH_2Cl_2 1:15); UV: 304, 245 nm (CH_2Cl_2) (lit. (16) UV 299, 249 nm); IR: 3482, 3295, 1754, 1727, 1674, 1655 (sh), 1628 cm^{-1} (CH_2Cl_2) (lit. (19) IR 3400, 3280, 3240, 1750, 1710, 1655 cm^{-1}).

N^4-*Acetyl-1-[3′*-O-*acetyl-2′-deoxy*-β-D-*ribofuranosyl] cytosine* (***C3***)

Compound **C3** ($C_{15}H_{19}N_3O_7$) was prepared in a manner analogous to that described for **Ar3**; yield 40%; $[\alpha]_D$ +54.9 (c 0.36, CH_3OH:CH_2Cl_2 1:15); UV: 302, 245 nm (CH_2Cl_2) (lit. (20) UV 296, 247 nm); IR: 3620, 3404, 1739, 1727, 1662, 1632 cm^{-1} (CH_2Cl_2).

N^4-*Acetyl-1-[2′,3′-di*-O-*acetyl-5′-(2,3,4,6-tetra*-O-*acetyl*-β-D-*galactopyranosyl)*-β-D-*arabinofuranosyl] cytosine* (***Ar4***)

Procedure A

To a solution of **Ar3** (300 mg, 0.81 mmol) in CH_2Cl_2 (20 mL) containing activated powdered 4 Å molecular sieves (500 mg) was added a solution of trichloroacetimidate **6** (520 mg; 1.22 mmol) in CH_2Cl_2 (36.6 mL) at 5°C, followed by $BF_3{\cdot}Et_2O$ (150 μL; 1.22 mmol). After stirring for 40 min, solid NH_4HCO_3 (100 mg) was added and stirring was continued for another 10 min. The solids were filtered off, rinsed with CH_2Cl_2, and the combined filtrates were evaporated to dryness. The residue was subjected to flash chromatography on silica gel, which on elution with 3% CH_3OH:CH_2Cl_2, followed by 5% CH_3OH:CH_2Cl_2, yielded fractions containing **6**, decomposition products of **6**, disaccharide **7** (see below), and a mixture of galactosylated

For personal use only.

nucleoside **Ar4** and peracetylated nucleoside **Ar5** (total 296 mg). This mixture was further chromatographed on Sephadex LH-20 in CH_3OH:$CHCl_3$ (4:3) to give **Ar4** (174 mg, 20%) and a fraction containing **Ar5** contaminated with **Ar4**. The latter fraction, after a repeated chromatography on LH-20, yielded an additional small amount of **Ar4** and pure N^4-*acetyl-1-[2',3',5'-tri*-O-*acetyl*-β-D-arabinofuranosyl] cystosine (**Ar5**) ($C_{17}H_{21}N_3O_{17}$, $[\alpha]_D$ +118.2 (*c* 4.25, CH_2Cl_2) (lit. (footnote 6) $[\alpha]_D$ +87); UV: 304, 245 nm (CH_2Cl_2)). The fractions containing **Ar4** were further purified by flash chromatography on silica gel in 4% CH_3OH:$CHCl_3$ to yield pure **Ar4** ($C_{29}H_{37}N_3O_{17}$; 120 mg, 14%), $[\alpha]_D$ +52.0 (*c* 0.59, CH_2Cl_2); UV: 303, 244 nm (CH_2Cl_2). FAB-MS showed *m/z*: 700 (MH^+), 658 ($MH^+ - CH_2CO$), 370 (MH^+ − hexose − H_2O), and 331 (hexose). The observed Exact Mass value of MH^+ is 700.2215 (calcd. 700.2201).

Procedure B

Alcohol **Ar3** (500 mg, 1.37 mmol), trichloracetimidate **6** (945 mg, 1.92 mmol), and silver triflate (458 mg, 1.8 mmol) were dried together at high vacuum overnight. Chloroform (5 mL), freshly distilled from CaH_2, was added to this mixture of solids under an atmosphere of argon at room temperature. The reaction mixture was stirred for 24 h and then diisopropylethylamine (5 drops) was added, the solids were filtered off and rinsed with dichloromethane (2 × 23 mL), and the combined filtrate plus washings were washed with cold 0.05 M HCl (3 × 50 mL) and cold saturated aqueous bicarbonate (1 × 50 mL). The organic layer was dried with $MgSO_4$, filtered, and evaporated to dryness. The residue was purified by sequential chromatography on silica gel and Sephadex LH20 (cf. procedure A) to yield 394 mg, 41% of **Ar4**.

N-*[2-O-(2,3,4,6-Tetra*-O-*acetyl*-β-D-*galactopyranosyl)-3,4,6-tri*-O-*acetyl*-α-D-*galactopyranosyl] trichloroacetamide* (*7a*)

The fractions containing **7***a*, *b* (cf. the preparation of **Ar4**) were subjected to another chromatography on silica gel using ethyl acetate:hexane (3:2) as eluent, yielding **7***a* contaminated with *N*-[2-*O*-(2,3,4,6 tetra-*O*-acetyl-β-D-galactopyranosyl)-3,4,6-tri-*O*-acetyl-β-D-galactopyranosyl] trichloroacetamide (**7***b*). ^{1}H NMR: 7.33 (d, $J_{1,NH}$ 5.0, NH), 5.77 (t, $J_{1,2}$ 5.4, $J_{1,NH}$ 5.0, αGal H1), 5.38 (m, *J* 1.9, αGal H4), 5.35 (brd, $J_{3,4}$ 3.4, $J_{4,5} < 0.5$, βGal H4), 5.11 (dd, $J_{1,2}$ 7.5, $J_{2,3}$ 9.6, βGal H2), 5.11 (dd, $J_{2,3}$ 9.6, $J_{3,4}$ 3.6, αGal H3), 4.98 ($J_{2,3}$ 9.6, $J_{3,4}$ 3.4, βGal H3), 4.62 (d, $J_{1,2}$ 7.5, βGal H1), 4.18 (dd, $J_{1,2}$ 5.4, $J_{2,3}$ 9.6, αGal H2), 4.16 (m, αGal H6 and H6'), 4.13 (m, αGal H5), 4.11 (dd, $J_{6,6'}$ −11.3, $J_{5,6}$ 6.6, βGal H6), 4.08 (dd, $J_{6,6'}$ −11.3, $J_{5,6'}$ 6.2, βGal H6'), 3.93 (brdd, $J_{5,6}$ 6.6, $J_{5,6'}$ 6.2, βGal H5), 2.16, 2.12, 2.08, 2.06, 2.04, 2.03, 1.97 (7 × s, CH_3CO); ^{13}C NMR: 170.4 (2), 170.0 (2) 169.9, 169.5, 169.0 (CH_3COO), 162.5 CON, 101.7 βGal C1, 92.2 CCl_3, 78.0 αGal C1, 72.7, 71.0, 70.4, 68.9, 68.7, 67.9, 66.9, 66.7 (αGal and βGal C2, C3, C4 and C5), 61.1 and 60.8 (αGal and βGal C6), 20.62(4), 20.58(2), 20.5 (CH_3CO). FAB-MS exhibited fragments at *m/z* 780 (MH^+), 619 (peracetylated hexose − hexose), and 331 (peracetylated hexose). Exact Mass: calcd. for $C_{28}H_{37}NO_{18}Cl_3$: 780.1076; found: 780.1074.

N^4-*Acetyl-1-[2'-deoxy-2',3'-di*-O-*acetyl-5'-(2,3,4,6-tetra*-O-*acetyl*-β-D-*glactopyranosyl)*-β-D-*ribofuranosyl] cytosine* (***C4***)

Compound **C4** ($C_{27}H_{35}N_3O_{15}$, $[\alpha]_D$ +6.93 (*c* 0.37, CH_2Cl_2); UV: 303, 243 nm (CH_2Cl_2)) was prepared as described for **Ar4**. Yield 9% (procedure A) and 35% (procedure B). FAB-MS exhibited ions at *m/z* 642 (MH^+), 600 ($MH - CH_2CO$)$^+$, and 331 (peracetylated hexose). Exact Mass calcd. for $C_{27}H_{35}N_3O_{15}$: 642.2146; found: 642.2128. Compound **C4** was accompanied by N^4-*acetyl-1-[2'-deoxy-3',5'-di*-O-*acetyl*-β-D-ribofuranosyl] cytosine (**C5**), ($C_{15}H_{19}N_3O_7$, $[\alpha]_D$ +71.4 (*c* 12.4, CH_2Cl_2); UV: 304, 244 nm (CH_2Cl_2), (lit. (21) UV 307, 239 nm). The compounds **C4** and **C5** were separated by chromatography on silica gel and Sephadex LH20.

1-[3'-O-*Acetyl-2' deoxy-5'-(2,3,4,6-tetra*-O-*acetyl*-β-D-*galactopyranosyl)*-β-D-*ribofuranosyl] thymine* (***T4***)

Compound **T4** ($C_{26}H_{34}N_2O_{15}$, $[\alpha]_D$ −13.2 (*c* 0.67, CH_2Cl_2); UV: 262 nm (CH_2Cl_2)) was prepared as described for **Ar4**. Yield 24% (procedure A). FAB-MS exhibited ions at *m/z* 637(MNa^+), 615 (MH^+), 573 ($MH - CH_2CO$)$^+$, and 331 (peracetylated hexose). Exact Mass calcd. for $C_{26}H_{34}N_2O_{15}$: 615.2037; found: 615.2040. Compound **T4** was accompanied by *1-[2'-deoxy-3',5'-di*-O-*acetyl*-β-D-ribofuranosyl] thymine (**T5**).

1-[5'-β-D-*Galactopyranosyl*-β-D-*arabinofuranosyl] cytosine* (***Ar2***)

Peracetylated galactosylated nucleoside **Ar4** (120 mg) was dissolved in CH_3OH (20 mL) under argon, DBU (5 drops) was added, and the mixture was stirred overnight. After an addition of toluene (15 mL), the reaction mixture was concentrated using a rotary evaporator until a precipitate appeared. The solid was filtered off, rinsed with toluene and CH_2Cl_2, and then redissolved in CH_3OH and subjected to chromatography on LH-20 using $CHCl_3$:CH_3OH 4:3. Pure **Ar2** (62 mg, 89%) ($C_{15}H_{22}N_3O_{10}$, $[\alpha]_D$ +93.0 (*c* 0.13, CH_3OH); UV: 273, 230 nm (CH_3OH)) was obtained. FAB-MS exhibited ions at *m/z* 406 (MH^+), 244 (MH^+ − hexose), and 112 (base + 2H). Exact Mass calcd. for $C_{15}H_{22}N_3O_{10}$: 406.1462; found: 406.1469.

1-[2'-Deoxy-5'-β-D-*galactopyranosyl*-β-D-*ribofuranosyl] cytosine* (***C2***)

Compound **C2**; yield 71% ($C_{15}H_{22}N_3O_9$, $[\alpha]_D$ +51.3 (*c* 0.37, CH_3OH); UV: 273, 230 nm (CH_3OH)) was prepared as described for **Ar2**. FAB-MS exhibited ions at *m/z* 390 (MH^+), 228(MH^+ − hexose), and 112 (base + 2H). Exact Mass calcd. for $C_{15}H_{22}N_3O_9$: 390.1512; found: 390.1502.

1-[2'-Deoxy-5'-β-D-*galactopyranosyl*-β-D-*ribofuranosyl] thymine* (***T2***)

Compound **T2** ($C_{16}H_{24}N_2O_{10}$, $[\alpha]_D$ +11.2 (*c* 0.42, CH_3OH:H_2O 3:2); UV: 264, 202 nm (CH_3OH)) was prepared as described for **Ar2**. Yield 96%; FAB-MS exhibited ions at *m/z* 427 (MNa^+), 405 (MH^+), 243 (MH^+ − hexose), and 127 (base + 2H). Exact Mass calcd. for $C_{16}H_{24}N_2O_{10}$: 405.1509; found: 405.1544.

Appendix I

Many cancer chemotherapeutic agents are capable of eradicating cancer cells. Practical clinical problems arise from the low selectivity of these agents: they kill normal healthy cells along with the cancerous ones, albeit at a slower rate. A significant increase in selectivity would dramatically enhance the curative potential of such drugs. For instance, if the cytotoxicity of β-D-arabinofuranosylcytosine, Ara C (**Ar1**), clinically used for treatment of leukemias, can be abolished by glycosylation of the drug, and if a suitable glycosidase is present only in the neoplastic cells, then this glycosylation would bring about the desired increase in the selectivity. One of us has been investigating such a scenario for future cancer chemotherapies (cf. ref. 2 for a review). The glycosidase employed is β-galactosidase, the product of the *Escherichia coli* β-galactosidase (lacZ) gene, inserted artificially into cancer cells. Galactosylation of Ara C then masks the toxicity of the nucleoside until the masking β-galactoside is removed inside such a cell, and Ara C is activated. Galactosylation of an Ara C antagonist, i.e., 2-deoxy-β-D-ribofuranosylcytosine (**C1**), would result in analogous deactivation of this nucleoside. To permit direct testing of this hypothesis, galactosylated nucleosides 5′-β-galactosyl β-D-arabinofuranosylcytosine (**Ar2**) and 5′-β-galactosyl 2-deoxy-β-D-ribofuranosylcytosine (**C2**) were required.

Appendix II

Galactosylation presumably turns the active compounds into proactive ones: e.g., toxic Ara C (**Ar1**) is turned into nontoxic Gal-Ara C (**Ar2**), which should become toxic again after the hydrolysis of the galactose–arabinose linkage using β-galactosidase. Two cell lines were used: (1) mouse fibroblasts *psi-2* capable of packaging retroviral genetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

information into infectious viral particles that can transfer the information to new cells, and its subline *psi-2 BAG* α containing retroviral information that includes β-galactosidase (lacZ) gene from *Escherichia coli*; and (2) murine sarcoma cell line *K3T3* from which a subline *K3T3 lacZ+* was created by exposing *K3T3* cells to *lacZ*-bearing virus released from *psi-2 BAG* α. As expected, Ara C (**Ar1**), added to the growth medium, was equally toxic to all the above cell lines and sublines. When Gal-Ara C (**Ar2**) was used, it was toxic to the sublines expressing lacZ gene, i.e., to *psi-2 BAG* α and *K3T3 lacZ+* cells, albeit about two orders of magnitude less than Ara C (**Ar1**), while non-toxic to the lines without lacZ gene (*psi-2* and *K3T3*).

Galactosylated compounds **C2** and **T2** were also used to examine rescue effects of deoxycytidine and thymidine. For instance, when cells are grown in the presence of Ara C (**Ar1**), they can be saved from death by an addition into the medium of deoxycytidine that acts as an antidote to the toxicity of **Ar1**. When such an experiment has been performed with *K3T3* and *K3T3 lacZ+* cells and galactosylated deoxycytidine (**C2**), only the line containing lacZ gene showed a slight rescue effect. A similar small rescue effect was observed when *psi-2 BAG* α cells (but not *psi-2* cells) were exposed to a "HAT" (hypoxanthin–aminopterin–thymidine) regimen in which galactosylated thymidine (**T2**) was substituted for thymidine as an antidote to aminopterin toxicity.

The low level of activity of galactosylated compounds in lacZ-containing cell lines may reflect, at least in part, two possible causes: first, the galactosylated compound **Ar2** is inefficiently taken up by the cells or, second, the rate of release of toxic **Ar1** in the cells is slow. The latter may happen since the enzyme is originally targeted for the Galβ1-4Gal linkage and so it may be less active for the Galβ1-5Ara linkage. Studies to clarify these issues and remedy the situation are underway.

MICHEL BELLETÊTE, RANJIT S. SARPAL, and GILLES DUROCHER[1]. Can. J. Chem. **72**, 2239 (1994).

The spectroscopic and photophysical parameters of neutral and cationic species of the following molecules have been discussed: 2-phenyl-3,3-dimethyl-3*H*-indole (**1**), 2-[(*p*-amino)phenyl]-3,3-dimethyl-3*H*-indole (**2**), 2-[(*p*-dimethylamino)phenyl]-3,3-dimethyl-3*H*-indole (**3**), 2-[(*p*-amino)phenyl]-3,3-dimethyl-5-carboethoxy-3*H*-indole (**4**), 2-[(*p*-methylamino)phenyl]-3,3-dimethyl-5-carboethoxy-3*H*-indole (**5**), 2-[(*p*-dimethylamino)phenyl]-3,3-dimethyl-5-carboethoxy-3*H*-indole (**6**). Solvatochromic shifts have been interpreted in terms of the nature of the substituent groups and the state of solute–solvent interactions and complexation. The theoretical radiative decay rate constant (k_F^t) along with the bandwidth of the absorption profile of the different species involved have been used to discuss the geometrical changes from one species to the other in the ground state. The mirror-image relationship between absorption and fluorescence spectra has proven to be a good tool to discuss any geometrical changes occurring in the excited state. A radiationless torsional mechanism takes place in the excited state relaxation of the various species. The protonation of the ring nitrogen atom generates a highly planar cationic species which retains its conformation in the relaxed excited state. The very effective quenching of the monocation fluorescence is interpreted by the formation of a non-emissive TICT state.

MICHEL BELLETÊTE, RANJIT S. SARPAL et GILLES DUROCHER[1]. Can. J. Chem. **72**, 2239 (1994).

On discute des paramètres spectroscopiques et photophysiques des espèces neutres et cationiques suivantes: 2-phényl-3,3-diméthyl-3*H*-indole (**1**), 2-[(*p*-amino)phényl]-3,3-diméthyl-3*H*-indole (**2**), 2-[(*p*-diméthylamino)phényl]-3,3-diméthyl-3*H*-indole (**3**), 2-[(*p*-amino)phényl]-3,3-diméthyl-5-carboéthoxy-3*H*-indole (**4**), 2-[(*p*-méthylamino)phényl]-3,3-diméthyl-5-carboéthoxy-3*H*-indole (**5**) et 2-[(*p*-diméthylamino)phényl]-3,3-diméthyl-3*H*-indole (**6**). On interprète les déplacements solvatochromiques en fonction de la nature des substituants et de l'état des interactions et de la complexation soluté–solvant. On a utilisé les constantes théoriques de vitesse de la dégénérescence radiative (k_F^t) de concert avec la largeur de bande du profile d'absorption des différentes espèces impliquées pour discuter des changements de géométrie se produisant d'une espèce à l'autre dans l'état fondamental. On a prouvé que la relation d'image dans un miroir entre les spectres d'absorption et de fluorescence est un bon outil pour discuter de tout changement géométrique se produisant dans l'état excité. Un mécanisme de torsion sans radiation se produit dans la relaxation de l'état excité des diverses espèces. La protonation de l'atome d'azote dy cycle génère une espèce cationique très plane qui retient sa conformation dans l'état excité relaxé. On interprète la désactivation très efficace de la fluorescence du monocation par la formation d'un état TICT qui ne donne pas d'émission.

[Traduit par la rédaction]

1. Introduction

The photophysical and photochemical properties of a molecule are determined by the nature and energy of its electronically excited states. Solvatochromism has proven to be a sensitive function of the dipole moment as well as any geometrical changes of the molecules in the excited state. In other words, solvatochromic shifts can be taken as experimental evidence in support of these changes (1–4).

Since natural photosynthesis involves charge separation on a molecular level, there has been widespread interest in designing model systems in order to mimic these processes occurring in nature. Bichromophoric molecules with donor (D) and acceptor (A) substituents form a special class of such molecules (5–7). The prime function for these molecules is to ensure a charge separation via fast electron transfer and then subsequently stabilize the resulting charged species. The main action is the interplay between the strength of donor and acceptor moieties. Marcus theory has been the most successful and also the most documented in explaining these processes (8, 9). Testing of the Marcus theory has become nowadays a usual practice in the field (10). Grabowski et al. (11) and Rettig (12) have identified another class of molecules in which the D and A moieties involved in charge separation are orbitally decoupled and in a perpendicular configuration. This class of excited states has been named the twisted intramolecular charge transfer (TICT) state (11, 12).

In an attempt to investigate the phenomenon of solvatochromism and electron transfer and to identify their usefulness in probing microheterogeneous media, we have synthesized molecules **1** to **6** whose structures have been described in our recent paper (13) and are reproduced in Fig. 1. The donor properties of the amino group are altered by the substituent methyl groups. Similarly, the acceptor properties of the indole moiety are enhanced by substituting an ethyl ester group at the position *para to* the amino substituents. During the course of our work (14–18), we have observed that the first electronic transition is always of $\pi\pi^*$ nature in both the absorption and fluorescence processes. Changes in the spectral shifts have been used to evaluate the dipole moments of the ground and first singlet excited states, which compared favorably with the results of INDO-S calculations (15). The first excited singlet state is more polar by a factor of two in all cases studied (16, 17). AMPAC and INDO-S calculations have also shown that the phenyl moiety is not coplanar with the rest of the molecule and is allowed to librate within the kT energy barrier. This torsional movement is responsible for the geometrical changes happening in the ground and excited states and also provides an important deactivation pathway for the S_1 state in nonpolar media.

The identification of the various species present in water has been recently described (13). The acid–base chemistry has resulted in four species in molecules **2** and **3**, whereas the ester-substituted **4**, **5**, and **6** molecules give rise to an additional anion due to ester hydrolysis. The various species observed in molecules **2** and **3** are as follows: neutral form, monocation due to

ring nitrogen protonation, and dication due to the protonation of terminal amino as well as ring nitrogen group. The anion formed in **2** is due to amino group deprotonation, whereas in **1** it is due to the ring carbon deprotonation. In molecules **4**, **5**, and **6**, the order of protonation and the resulting species produced are the same as in **2** and **3** except for the fact that the ester hydrolysis leads to the formation of an additional anion (13).

As a continuation of our studies, this paper reports on the spectroscopic and photophysical properties of molecules **1** to **6** (see Fig. 1) in water as a function of pH since such species can be used as probes for microheterogeneous media (19). It is shown that the main deactivation pathway of the relaxed excited state of the neutral 3*H*-indoles in nonpolar media occurs via a torsional movement involving the amino group and/or the phenyl ring. Protonation of the indole ring greatly enhances the ground state planarity of these molecules. Nevertheless, fluorescence emissions of the cations are very weak, this is interpreted as due to the possible occurrence of a non-emissive TICT (twisted internal charge transfer) channel in the decay mechanism.

2. Experimental section

Synthesis, purification, absorption spectroscopy and methodology have already been described (13). The modified Hammett's acidity scale and Yagil's basicity scale used here to fix the pH values and the method for preparing the solutions have also been described (13). Fluorescence quantum yields of all the mentioned species were measured using molecules **3** as a standard in ethanol (ϕ_F = 0.33). The theoretical radiative decay rate constants (k_F^t) have been calculated from the Strickler and Berg relationship (18, 20). Fluorescence lifetime values larger than 0.2 ns were obtained from a multiplexed time-correlated single photon counting fluorimeter (Edinburg Instruments, Model 299T), as described in ref. 21. The short lifetimes (<0.2 ns) were measured on a time-correlated single photon-counting system which uses a synchronously pumped cavity dumped, rhodamine 6G-dye laser pumped by a mode-lacked argon ion laser as an excitation source. Details are given in ref. 16.

3. Results and discussion

3.1 Neutral species

The absorption and fluorescence spectral characteristics of **1** to **6**, and their dependency on acidity, have been studied in ref. 13. It was observed that the neutral species is present in water at pH = 9. Spectral characteristics of the neutral species in water and some of the representative solvents at 300 K are listed in Table 1. Table 2 reports on the photophysical parameters obtained in the same solvents. All molecular fluorescence decay curves could be fitted to a single exponential function except for molecules **4**, **5**, and **6** in water, where only multiple exponential functions can accurately describe the fluorescence decays. The corresponding preexponential factors and lifetimes for these three molecules in aqueous medium are **4** (A_1 = 0.59, τ_1 = 126 ps; A_2 = 0.015, τ_2 = 1060 ps), **5** (A_1 = 0.81, τ_1 = 73 ps; A_2 = 0.009, τ_2 = 700 ps; A_3 = 0.002, τ_3 = 1800 ps), and **6** (A_1 = 0.63, τ_1 = 82 ps; A_2 = 0.009; τ_2 = 1030 ps; A_3 = 0.001, τ_3 = 2030 ps). For each molecule the first component is mainly responsible for the overall fluorescence spectrum ($A_1\tau_1/\Sigma_i A_i\tau_i > 0.8$) and thus Table 2 reports on the shortest lifetimes of **4**, **5**, and **6** in water.

In the present set of molecules, it is well-known that the lowest energy transition is of the $\pi\pi^*$ type is polarized along the long molecular axis (14–17, 22). Table 1 shows that the energy of the absorption spectrum of these molecules in *n*-heptane decreases from **1** to **3** and from **4** to **6**. This strongly supports the fact that the electronic delocalization from the terminal nitrogen atom toward the indole ring increases with the electron donor and acceptor properties of the amino and ester groups. INDO/S calculations also corroborated this (15, 16, 22). As electronic delocalization along the long molecular axis is more favoured, the oscillator strength of the first electronic transition increases. Indeed, the oscillator strengths calculated by INDO/S equal to 0.41 (22), 1.08 (15), 1.12, 1.23, and 1.29 (16) for molecules **1** and **3** to **6** respectively.

The theoretical radiative transition probability in this work is obtained from the absorption and fluorescence spectra via the Strickler and Berg relationship (18, 20):

$$[1]\quad k_F^t = 2.88 \times 10^{-9} n^2 \langle \bar{\nu}_F^{-3} \rangle_{av}^{-1} \int \frac{\epsilon(\bar{\nu})}{\bar{\nu}}\, d\bar{\nu}$$

where

$$\langle \bar{\nu}_F^{-3} \rangle_{av}^{-1} = \frac{\int I_F(\bar{\nu}) d\bar{\nu}}{\int \bar{\nu}^{-3} I_F(\bar{\nu}) d\bar{\nu}}$$

By dividing k_F^t by A ($= n^2 \langle \bar{\nu}_F^{-3} \rangle_{av}^{-1}$), one obtains an expression which is proportional to the Einstein coefficient for the absorption process or to the square of the transition moments, that are independent of both the refractive index of the solvents and the spectral shift in the various solvents. These corrected k_F^t and k_F values are reported in Table 3. One can see that the k_F^t/A values in *n*-heptane follow the trend of the oscillator strength calculated from INDO/S except for the unsubstituted molecule **1**.

We have shown recently that these molecules are not rigid and that the phenyl ring can librate to a certain extent within the kT energy barrier (14–17, 22). The freedom of this motion should be reduced when the electronic delocalization throughout the molecule is increased. As a result, a sharpening of the absorption band is expected together with an increase in the

transition moment. Indeed, going from **1** to **6** in *n*-heptane, the FWHM of the absorption band decreases, reaching its smallest value for **6** where the electronic delocalization is the highest. Table 2 shows that the k_{nr} values of these molecules in *n*-heptane also decrease with a decrease in the fluorescence transition energy and a concomitant increase in the electronic delocalization throughout the molecule. This supports the assumption that the main radiationless deactivation pathway is the motion of the Ph_C ring (14–17, 22). As the electronic delocalization increases, the molecule becomes less flexible, consequently k_{nr} is reduced. The increase in the rigidity of the molecule in the relaxed excited singlet state is also reflected by the sharpening of the fluorescence spectra going from **1** to **6**.

We have recently shown with the help of INDO/S calculations that the dipole moments of these molecules in their ground and first singlet excited states are relatively high (15, 16). Consequently dipole–dipole interactions are expected to lower the energy of the absorption as well as the fluorescence band. Table 1 reports on the Stokes shift of all the molecules in nonpolar, polar aprotic, and protic solvents. The Stokes shift increases for molecule **1** going from *n*-heptane to water. However, for all other molecules the Stokes shift is always larger in *n*-heptane than in polar solvents. These results are in contrast with those obtained for similar kind of polar molecules like *N*-substituted anilines (2, 3) and 4-aminophthalimide (3) which show larger Stokes shifts in polar solvents. This is interpreted in terms of specific interactions (complexation) with the solvents involved in the solvation process. The present set of molecules possesses three polar and/or hydrogen bond accepting sites which are the lone pairs of the terminal nitrogen, the tertiary ring nitrogen and the carbonyl oxygen (for molecules **4** to **6**) whereas the terminal amino group in molecules **2**, **4**, and **5** is a hydrogen bond donor site. The carbonyl and the tertiary ring nitrogens have rather localized electron lone pairs whereas in the terminal amino group, electron migration occurs toward the indole ring. Thus in these molecules a combination of all these effects is expected and their magnitude depends upon the preference of the complexation sites.

One can see in Table 1 that the absorption bands in molecules **2** to **5** are blue shifted going form methanol to water. This suggests that stronger specific interactions occur at the terminal nitrogen atom in the case of water. Since water and methanol have similar polarity function ($f(D) = 2(D - 1)/(2D + 1)$, this suggests that water is acting as a better hydrogen bond donor to the lone pair of the terminal amino group in the ground electronic state. Previous workers (2, 3) have also observed this effect in aniline, *N*-methylaniline, and *N*,*N*-dimethylaniline. These chromophores represent the donor part of the molecules studied here. The interaction of the amino lone pair with water via hydrogen bonding is also highlighted in the FWHM and ϵ values. The former property increases much more in going from methanol to water, for molecules **2** to **6** compared to molecule **1** where water interacts with the tertiary nitrogen lone pair alone. This suggests that the hydrogen bonding interactions involving the lone pair of the terminal nitrogen atom reduce the conjugation of the amino group with the rest of the molecule and thus are responsible for the blue shifting and for the decrease in the ϵ values observed in water. As a result, the freedom of motion of the phenyl moiety is increased causing a broadening of the absorption band due to the existence of more conformers within

the kT energy barrier. In contrast to the ground state behavior, it can be seen in Table 1 that the FWHM value of the fluorescence bands decreases going from *n*-heptane to water, which is consistent with the regular observed red shift. This suggests that these molecules in their first relaxed singlet excited states are more planar in polar and/or hydrogen bonding environments. This could occur via solute–solvent specific interactions (complexation) formed mostly at the ring nitrogen atom (23–26). This process would favour the electronic delocalization toward the indole part of the molecule and increase the planarity of the complex. In solvent mixtures of methylcyclohexane (MCH) and acetonitrile, dipole–dipole interactions were proposed to stabilize the ground state complex and the exciplex (excited state complex) of these kinds of solutes whereas in mixtures of MCH/ethanol or dioxane/water, hydrogen bonding interactions are involved (23–26). Since water is a much better proton donor than methanol, it is not surprising to observe that the fluorescence bands measured in pure water are sharper than those obtained in pure methanol.

The existence of specific interactions at the indole nitrogen ring is also emphasized by the reported values of k_{nr} in polar aprotic and protic solvents; these values are much smaller than those obtained in *n*-heptane with the notable exceptions of **4** to **6** in water (Table 2). The abnormally high values of k_{nr} for the ester derivatives in water will be discussed in the next section. The existence of these hydrogen bonding interactions might be the reason why the fluorescence decay curves of molecules **4**, **5**, and **6** in water can be fitted only with multiple exponential functions. Since fluorescence decay curves for **2** and **3** are accurately described with single exponential functions, hydrogen bonding at the terminal nitrogen atom does not seem to be involved in the multiexponential decays. Thus the second and third small components in the multiexponential decay curves could originate mainly via hydrogen bonding interactions at the carbonyl site and/or from various conformational hydrogen bonding complexes involving the nitrogen ring atom. Proton donation to water from the amino group is also excluded since the triexponential decay is also obtained for molecule **6**.

To get more insight about conformational changes involved in the relaxation of the Franck–Condon state, the mirror-image relationship between the absorption and fluorescence spectra can be verified. Recently, we have shown that for the ester derivatives, the mirror-symmetry is well respected in nonpolar solvents (16). The modified absorption spectrum $(\epsilon(\bar{\nu})/\bar{\nu}$, the modified fluorescence spectrum $F(\bar{\nu})/\bar{\nu}^3$, and its reflection $F(2\bar{\nu}_0 - \bar{\nu})/(2\bar{\nu}_0 - \bar{\nu})^3$ about $\bar{\nu}_0$ plotted as a function of ν are displayed in Fig. 2*B* for molecule **6** as well as its monocation in water. It could be noticed that the mirror-symmetry is not effective for the neutral form of **6** in water (Fig. 2*B*). The absorption profile is much broader than the fluorescence profile. This means that the ground state complex geometry differs from the relaxed excited state complex geometry in pure polar protic and/or aprotic solvents. The same conclusions were previously obtained in mixed solvents (24–26). This is further supported by comparing the k_F and k_F^t values. In *n*-heptane where the mirror-symmetry is respected, the k_F^t values are approximately equal to the k_F values for all molecules. On the other hand, in polar protic and aprotic solvents, $k_F < k_F^t$, reflecting the differ-

ence in the charge delocalization in both complexes. These geometrical changes between the ground and relaxed excited singlet states of these complexes in polar aprotic and protic solvents are thus responsible for the anomaly observed in the Stokes shifts of the molecules in these environments.

3.2. Charged species

The various spectroscopic and photophysical parameters of the cationic species in water are reproduced in Tables 3 and 4 along with those of the neutral species. The selected pH values in these tables were determined from the absorption and fluorescence spectral dependence upon acidity (13).

3.2.1 Molecules 2 and 3

A. Monocation

Since protonation is an extreme case of hydrogen bonding by a solvent with the basic centers, its effect on spectral and photophysical characteristics forms an essential part of this work. Highly intense, large red-shifted and structured absorption bands have been obtained. They are explained as follows: once the tertiary ring nitrogen atom is protonated it becomes a better acceptor and pulls the electron density away from the terminal amino group. Consequently, the electronic delocalization is increased (13), thus reducing the freedom of the torsional movement of the phenyl moiety. This effect is well reflected in the bandwidth (FWHM) which is highly narrowed as compared to that of the neutral species. High k_F^t values also support the notion of an increased planarity. It is well known that the ground state geometry is responsible for the electronic transition dipole moments in the absorption process and is characterized by k_F^t. All the above-mentioned parameters support an increased planarity that follows the order **3** > **2** > **1**, which means that a better donor group increases the planarity of the ground state monocation.

Contrary to the absorption spectral characteristics, the position of the fluorescence maxima of the monocations were not significantly shifted with respect to the neutral species (13). Moreover, the mirror-symmetry relationship for the monocations was found to be well respected in both **2** and **3** (similar as in Fig. 2*C*). This shows that geometrical changes, if any, in the monocation during the relaxation of the FC state are minor. This is interpreted in terms of the formation of a highly planar rigid structure C (Scheme 1) (13) in the ground state itself. Very small Stokes shifts compared to that of the neutral species also support the formation of the rigid structure C. A similar kind of rigid structure was not observed in the monocation of molecule **1**. This shows that the presence of a donor group on the Ph_C ring is an essential requirement to impart extra rigidity to these monocations.

On the other hand, the k_{nr} values of the monocations of molecules **2** and **3** are drastically higher compared to those of the neutral species. Since the protonation of molecule **1** does not really affect the k_{nr} value, an increase in k_{nr} upon protonation is also primarily related to the donor properties of the terminal amino group. The dimethylamino substituent is a better electron donor than the amino group and it is not surprising to observe that an increase in k_{nr} caused by the protonation of the ring nitrogen atom. Thus k_{nr} is larger for **3** than it is for **2**. To see the effect of the relaxation of the Franck–Condon excited state on the photophysics of neutral and monocation species in water, the excitation and fluorescence spectra as well as the fluorescence lifetimes have been measured in ice at 77 K (Table 5). From these results, one can see that, at 77 K, the excitation spectra of both species of **2** are red shifted compared to the room temperature spectra whereas the fluorescence spectra are much less affected. Since there is no relaxation of the Franck–Condon excited state at 77 K, it implies that the planar ground state geometry is also responsible for the fluorescence emission observed in aqueous solutions for the monocation. The strong quenching of the fluorescence emission following protonation in an aqueous solution can then be ascribed to a radiationless channel involving the rotation of the dimethylamino or dimethylanilino groups. This channel is effectively eliminated in rigid matrices and the fluorescence lifetimes reach their maximum (2.6 ns) for both the neutral and the cationic species. The fluorescence quantum yields measured in *n*-heptane are very instructive in this regard. They show that in an aprotic solvent, protonation increases the planarity in the relaxed excited state of cation **2** compared to the neutral species. The same conclusion can also be applied for species **1** even though the effect is smaller for the unsubstituted chromophore.

Grabowski and other researchers have defined a new class of excited states commonly known as twisted intramolecular charge transfer state (TICT), which involves a 90° rotation of the donor group and a complete charge separation on the perpendicular donor and acceptor moieties (11, 12). These TICT states are considerably stabilized in polar solvents but their fluoresence is generally weak because of the small k_F values (11). The monocations of **1** to **3** also show weak fluorescence bands. To check if these bands originate from a TICT state, the fluorescence of these species has been measured in *n*-heptane; characteristics for **1** and **2** are reported in Table 5. It can be noted that the positions of the fluorescence bands are not very much altered by the hydrogen bonding ability of the solvent i.e., going from *n*-heptane to water. Thus these bands do not arise form TICT fluorescence. We have recently suggested with the help of INDO/S calculations that the quenching of the monocation fluorescence could arise from the formation of a non-emissive TICT state involving the rotation of the dimethylamino group (13). Many molecules have been reported to deactivate via the formation of non-fluorescent TICT states (27–29). Their ϕ_F and τ_F values have been shown to decrease with the polarity of the environment but are restored in highly viscous media. For example, substituted benzopyrylium dyes, which are structurally similar to the monocations of **2** and **3**, have been described in terms of non-fluorescent TICT state formation (27, 28). Coumarin dyes are other examples in which a fluorescence intramolecular charge transfer structure (ICT), quite similar to the C structure in our molecules, is first formed and then relaxes to a TICT state (29).

B. Dication

The spectral characteristics of the dications are similar to those of the monocation of **1**. An indication that electron delocalization from the terminal amino group to the indole ring is hindered is reflected in the high energy of the absorption bands (13). This is confirmed by the low k_F^t and k_F values which indicate that the dications are even more twisted than the molecules in their neutral forms. This allows more freedom of motion for the phenyl moiety and consequently the dication's absorption and fluorescence bands are broader than those observed for the neutral species (Table 3). This is in agreement with the fact that the k_{nr} values of the dications are higher by an order of magnitude compared to those reported for the neutral species in water (Table 3).

3.2.2 Ester-substituted molecules

A. Monoanion

These molecules are in their neutral forms from pH 7 to 9. At pH 9, a new species starts to appear and its formation is complete at pH ≈ 12. This species has been assigned to a monoanion (MA) formed following the hydrolysis of the ester group (13). The geometry of this species is not much altered compared to that of the neutral species. Indeed, Table 4 shows that the bandwidth of the absorption and fluorescence bands (FWHM) as well as k_F^t and k_F are similar for both species. However, judging by the FWHM values of the absorption and fluo-

rescence bands it is clear that the torsional movement of the molecule in the anionic form is hindered in the relaxed excited state.

It is important to point out here that the k_{nr} values for the anion are one order of magnitude lower than those for the neutral molecule. This is because once the hydrolysis has taken place, the negative charge generated is delocalized on the ester group and indole moiety, negating its electron acceptor properties. This supports, as argued in the previous sections, that k_{nr} is mainly related to the donor–acceptor properties of the substituent groups and the occurrence of a possible non-radiative TICT state in the neutral and cationic species.

B. Monocation

The effect of protonation on the ring nitrogen of ester derivatives is similar to that described for **2** and **3** above. However, since an ester substituent is present as an acceptor group, the electronic delocalization becomes more effective. Indeed, the absorption and fluorescence bandwidths of **4** and **6** are smaller than those of **2** and **3** (Tables 3 and 4). The fact that k_F^l values of **4** and **6** are higher than those of **2** and **3** supports that assumption. This shows that the presence of an ester group at the *para* position of the 3*H*-indoles makes the whole indole moiety a better acceptor. This helps in attaining more planarity in the ground and excited states by delocalizing the charge density of the terminal amino group.

In our previous paper (13), we show that the excited state pK_a value (pK_a^*) evaluated by the Förster cycle method using absorption spectral data for all molecules were considerably higher for the ring nitrogen protonation equilibrium. The pK_a^* value for the same equilibrium has been reported for 2-(*p*-aminophenyl) benzimidazole (30), which is structurally similar to **2** to certain extent. The difference between pK_a and pK_a^* (abs) for 2-(*p*-aminophenyl) benzimidazole is ~6 units, which is small compared to the difference in **2** (~10 units). A higher value for **2** and as a matter of fact in all the molecules may be due to the fact that the freedom of the torsional movement in these systems is restricted upon ring nitrogen atom protonation. That would imply that the geometry of the molecule changes from one species to another in the different equilibria involving the ring protonation.

The mirror-image relationship for the monocation of **6** is shown in Fig. 2*C*. It can be seen that the mirror-symmetry is well respected, confirming the formation of a highly planar structure as observed for **2** and **3**. Like these molecules, the ester derivatives have very high k_{nr} values that shows strong dependence over the donor properties of the *N*-alkyl amino substituents. This justifies the fact that the charge transfer properties are highly dependent upon the donor and acceptor capabilities of the attached moieties. This will be the topic of a forthcoming paper.

As suggested for the fluorescence quenching of **2** and **3** monocations, one might expect that the excited state relaxation of the ester derivatives in their cationic forms might involve the formation of a TICT non-emissive state. The protonation of the ring nitrogen favours the charge transfer process from the terminal amino group toward the indole ring. The presence of the ester group favours this mechanism, e.g., k_{nr} (**4**) > k_{nr}(**2**) and k_{nr}(**6**) > k_{nr} (**3**) for the molecules in their cationic form. Moreover, as mentioned in the first part of this paper, the fluorescence of molecules **4**, **5**, and **6** are quenched even in their neutral forms in water (see Table 2). This strongly suggests that the TICT formation mechanism is plausible for the ester-substituted neutral molecules in water but not in methanol. This TICT formation process would require protonation or strong hydrogen bonding interactions at the ring nitrogen site to occur. Methanol does not seem to form hydrogen bonds strong enough to favour the charge transfer process toward the indole ring. If one compares the k_{nr} values in methanol and water for neutral **2** and **3**, the fluorescence of **2** is enhanced in water whereas the fluorescence of **3** is quenched in aqueous medium. Thus, on the one hand, an amino group is not a good enough electron donor to produce efficient charge transfer; on the other hand, a weak charge transfer process may occur for the molecule having only a dimethylamino group as the terminal donor group. However, the combined effects of an amino group and an ester substituent favour the charge transfer process to a great extent.

C. Dication

A Decrease in planarity upon terminal amino group protonation of the ester-substituted molecules is evident from the various spectroscopic parameters reported in Table 4. All the photophysical parameters were affected similarly to molecules **2** and **3**, hence similar explanations hold. However, the FWHM of the absorption and fluorescence bands as well as the k_F^l and k_F values indicate that the ester derivatives in their dicationic forms are more rigid than the dications of molecules **2** and **3** (Tables 3 and 4). This is supported by the k_{nr} values which are lower for molecules **4** to **6**.

3.3 Is a TICT state involved in these systems?

No direct experimental proof exists to support the TICT assumption since the *A* (TICT) state, if exists, is not an emitting state.

What we know is that the neutral molecules are involved in ground state complexes in polar protic or aprotic solvents. Studies of molecule **3** in solvent mixtures of *n*-alkanes/ethanol or *p*-dioxane/ethanol or water have shown complexes of 1:1 stoïchiometry with well-defined isosbestic points in the absorption spectra (24–26). In pure polar solvents, as is the case in this paper, one can think about ground state complexes stabilized by dipole–dipole interactions (acetonitrile) or by hydrogen-bonding interactions (methanol, water) that involve the indole ring nitrogen electron lone pair. Water brings about another hydrogen bonding site at the terminal amino group nitrogen in the electronic ground state of these molecules. We have no evidence for the complexation of the ester carbonyl group.

As far as the excited state is concerned, when polar protic or aprotic molecules are added to a non-polar solvent containing molecule **3**, an isosbestic point is obtained and both the fluorescence lifetime and quantum yield increases considerably (25, 26). These results have been demonstrated to fit an over all kinetics where the ground state complexes are not emissive but an excited-state complex (exciplex) less polar than the ground state complex is formed with a rate that is diffusion-controlled (24–26). The rationale for complexes of different nature involved in the ground and excited relaxed singlet states is based on the following data (26):

(*1*) Weak bathochromic shifts are observed in fluorescence compared to the absorption with polar solvent addition to a non-polar solvent. (*2*) The fluorescence bandwidths get smaller and smaller with further addition of polar solvents. (*3*) The quenching of the fluorescence band assigned to molecule **3** in the non-polar solvent is diffusion-controlled. (*4*) When molecule **3** is studied in a mixture of ethanol–isopentane–ether 2:5:5 (EPA) from room temperature to 77 K, a red shift is observed in the

[b]Generated using trifluoroacetic acid (0.2% v/v) (19).

absorption but a blue shift is observed in the fluorescence, indicating that there is a different geometry between the two complexes.

Tables 1, 2, and 5 show that all the 3*H*-indole molecules studied here in pure solvents conform to points 1 to 4 such that one can ascertain that complexes of different nature (more polar and less planar in the ground state than in the relaxed excited state) are responsible for the absorption and fluorescence spectra. This is also confirmed by the different values of the radiative decay rate constants (k_F^l and k_F). In other words, the free molecules exists only in *n*-heptane where the geometry of the ground and relaxed excited states is approximately the same ($k_F^l = k_F$ and an excellent mirror-image relationship). The main deactivation channel in this environment has been shown to be the Ph_C ring torsion which is hindered by increasing the viscosity of the medium (15) (see Table 5).

This work shows clearly that complexation is another way of hindering the torsional movement in all these molecules. Methanol and acetonitrile behave approximately the same way in that they both reduce the Ph_C ring libration when compared to a nonpolar medium (same k_{nr}). Moreover, this phenomenon is independent of the electron donor–acceptor properties of the molecules. But water, which is a strong proton donor, behaves totally differently. A new excited state deactivation channel is created, causing a marked increase in the radiationless decay. This new channel is promoted by increasing the electron donor property of the anilino moiety and/or the electron-acceptor property of the indole ring. Protonation at the indole nitrogen (monocation) strongly favors this deactivation channel, protonation at the amino nitrogen (dications) inhibits it, and in monoanions the channel completely disappears. Since neutral molecules are complexed at both sites in the ground electronic states in water, it is then not surprising that there is no fast deactivation by this channel.

What we also know from the semiempirical INDO/S molecular orbital calculations based on uncomplexed neutral molecules and monocations to which we have added the dipole–dipole interaction energy components in water, is that the TICT state occurring from the rotation of the dimethylamino group in **3** is both energetically and kinetically feasible in these systems (13, 31). Examples are known in the literature of TICT state formation favored by ground state hydrogen bonding formation on 4-(dialkylamino) pyrimidines (32–34). Both **a** and **b** fluorescence appeared and was influenced by the proton-donating ability of the *n*-alcohols. However, the corresponding monocations did not show any trace of luminescence at room temperature. Both fluorescences coming from the LE (*b*) and TICT (*a*) states are totally quenched. The decay of the higher energy fluorescence **b** in the neutral species is a multiexponential function reflecting the diversity of complexes giving rise to this band. Because the long-wave emission **a** has a very fast rise and a mono-exponential decay, the authors concluded that only one of the hydrogen-bonded species is able to form the TICT state, and tentatively suggested that that species was hydrogen-bonded at the N1 atom. These results are rather similar to ours except that in our case we do not have access to the TICT **a** band but we have access to the **b** fluorescence in both neutral and cationic species.

Concluding remarks

The main deactivation pathway of the relaxed excited state of the neutral 3*H*-indoles in nonpolar media as well as the anions and dications in water occurs via a torsional movement involving the amino group and/or phenyl ring. When this motion is reduced by the viscosity and/or by the complexation to the solvent or by weak hydrogen bonding, the radiationless decay rate constant decreases. The hindrance of torsion in these molecules in the ground and relaxed excited states is reflected by a sharpening of the absorption and fluorescence bands. This mechanism is highly dependent on the donor/acceptor proper-

For personal use only.

ties of the substituent in the *para* positions, these properties affect the extent of electronic delocalization over the whole molecule.

Protonation of the indole ring greatly enhances the ground state planarity of the molecule. The planarity of the molecule is retained in the relaxed excited state as judged by the excellent mirror-symmetry relationship observed between the absorption and fluorescence spectra in the monocations. Nevertheless, the fluorescence intensities of the cations are very weak. We have interpreted this phenomenon by a plausible formation of a non-emissive TICT state involving the rotation of the amino group and/or the aniline moiety. This mechanism could also be responsible for the fluorescence quenching observed for neutral molecules **3** to **6** in water via hydrogen bonding interactions at the ring nitrogen.

Oxygen transfer reactions. 2. A comparison of the reactions of ruthenium tetroxide, chromyl chloride, and permanganate with thianthrene 5-oxide[1]

BONNIE L. MAY, HENRY YEE, AND DONALD G. LEE[2]
Department of Chemistry, University of Regina, Regina, SK S4S 0A2, Canada

Received May 27, 1994

BONNIE L. MAY, HENRY YEE, and DONALD G. LEE. Can. J. Chem. **72**, 2249 (1994).

Products obtained from the oxidation of thianthrene 5-oxide, **SSO**, have been used to compare oxygen transfer mechanisms for three high-valent transition metals. Oxidation of **SSO** by benzyltriethylammonium permanganate in methylene chloride gives the corresponding sulfone, thianthrene 5,5-dioxide (**SSO_2**), as the exclusive product. Oxidation of **SSO** by ruthenium tetroxide also gives **SSO_2** as the predominant product along with minor amounts of the disulfoxide, thianthrene 5,10-dioxide (**SOSO**). However, the converse is observed when chromyl chloride is used as the oxidant; **SOSO** is the major product. It is suggested that oxygen transfers from permanganate and ruthenium tetroxide are initiated by complexation between the central metal atom and the oxygen end of the S=O dipole, while oxidation by chromyl chloride is likely initiated by an alternative mechanism, possibly a single electron transfer.

BONNIE L. MAY, HENRY YEE et DONALD G. LEE. Can. J. Chem. **72**, 2249 (1994).

On a utilisé les produits obtenus lors de l'oxydation du thianthrène 5-oxyde, **SSO**, pour comparer les mécanismes de transfert d'oxygène de trois métaux de transition de valence élevée. L'oxydation du **SSO** par le permanganate de benzyltriéthylammonium dans le chlorure de méthylène conduit à la sulfone correspondante, le thianthrène 5,5-dioxyde (**SSO_2**), comme seul produit. L'oxydation du **SSO** par le tétroxyde de ruthénium fournit aussi le **SSO_2** comme produit prépondérant aux côtés de quantités mineures du disulfoxyde, le thianthrène 5,10-dioxyde (**SOSO**). Toutefois, on a observé l'inverse lors d'oxydations avec le chlorure de chromyle; le **SOSO** est alors le produit majeur. On suggère que les transferts d'oxygène à partir du permanganate et du tétroxyde de ruthénium sont initiés par une complexation de l'atome métallique central et le portion oxygénée du dipôle S=O alors que l'oxydation par le chlorure de chromyle est vraisemblablement initiée par un autre mécanisme, possiblement un transfert unique d'électron.

[Traduit par la rédaction]

Introduction

Oxygen tranfers from transition metals to nonmetals are useful for organic synthesis (1) and essential for human life (2). The latter reactions usually involve porphyrin-complexed transition metals such as those found in hemoglobin (3) whereas the oxidants commonly used in organic synthesis are often high-valent transition metals with oxygen or halogen ligands (4). Although the oxidants may exist as neutral molecules, oxyanions, or complexes, most contain a common structural element, the metal–oxo bond, M=O (5). Despite the importance of these reactions, a detailed understanding of the way in which oxygen is transferred has not been achieved (4, 5).

Many oxygen transfers employed in organic synthesis are accompanied by significant bond transformation in the reductant. For example, the oxidation of alkanes to ketones by iron(V) compounds involves the cleavage of two carbon–hydrogen bonds as well as an oxygen transfer (6), while the asymmetric dihydroxylation of terminal alkenes by osmium tetroxide involves the cleavage of a carbon–carbon π-bond as well as the formation of two C—O and two H—O bonds (7). However, when the reductants are sulfides ($L_nMO + R_2S \rightarrow L_nM + R_2SO$) direct transfers not involving the cleavage or formation of other bonds occur (8, 9). Because these reactions are free of complications associated with the cleavage and (or) formation of other bonds, they provide a good vehicle for the study of oxygen transfers.

In this paper we wish to compare results that were obtained from a study of oxygen transfers to thianthrene 5-oxide (**SSO**) by ruthenium tetroxide, chromyl chloride, and permanganate ion. Thianthrene 5-oxide was chosen as the reductant because it contains sulfur atoms in two different oxidation states and can be used to quantify the selectivity of various reagents with respect to the oxidation of sulfides and sulfoxides (10–12). Oxidation of **SSO** by an oxidant with a high selectivity for sulfoxides results in formation of the corresponding sulfone, **SSO_2**, while the disulfoxide, **SOSO**, is obtained when the oxidant is selective for sulfides. Further oxidation of either of these two products results in the formation of thianthrene 5,5,10-trioxide, **$SOSO_2$**, as illustrated in Scheme 1.

The parameter, X_{SO}, defined in eq. 1, has been used as a quantitative measure of an oxidant's selectivity for sulfoxide oxidation (10–12). Under conditions where little or no **$SOSO_2$** is produced, X_{SO} is simply the mole fraction of **SSO_2** in the product.

$$[1] \quad X_{SO} = \frac{N_{SSO_2} + N_{SOSO_2}}{N_{SSO_2} + N_{SOSO} + 2N_{SOSO_2}}$$

The two sulfurs present in thianthrene 5-oxide are expected to have substantially different electron densities as illustrated by the resonance structures for **SSO** depicted in eq. [2]. Because of this, the magnitude of X_{SO} has been interpreted theoretically to be an indication of the electronic nature of oxygen transfer reagents. Those oxidants that preferentially oxidize sulfoxide sulfur and thereby produce X_{SO} values close to unity are considered to be nucleophiles; i.e., they react more readily with an electron-deficient sulfur. Conversely, those oxidants that selectively oxidize the sulfide sulfur, and produce small X_{SO} values, are considered to be electrophiles. X_{SO} has thus been used as a scale of nucleophilicity or electrophilicity to guide mechanistic predictions, although complexation prior to

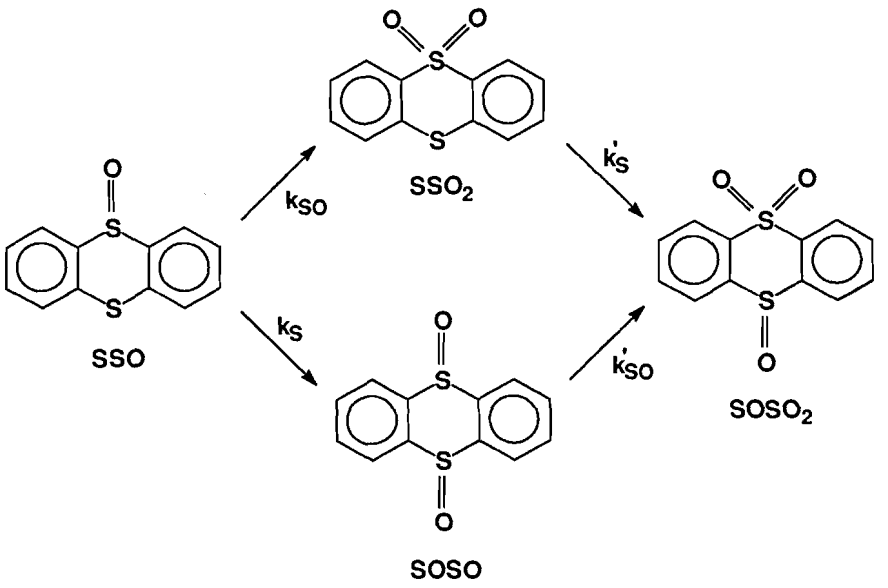

SCHEME 1. The oxidation of thianthrene 5-oxide.

oxygen transfer can reduce the effectiveness of its application in this way (10).

[2] 
Experimental

Materials

Thianthrene 5-oxide, **SSO**, was prepared according to the procedure reported by Gilman and Swayampati (13): Thianthrene, **SS**, (5.0 g, 23 mmol) was stirred and refluxed in 81 mL of glacial acetic acid. Dilute HNO_3 (2.9 mL of conc. HNO_3 plus 6.3 mL of water) was added dropwise. The solution turned yellow and a brown gas, presumably N_2O_4, was released. After refluxing for an additional 15 min, the solution was poured into 300 mL of ice water. The white solid that precipitated was suction filtered, washed with water, and vacuum dried. Purification by flash chromatography followed by recrystallization from cyclohexane gave white, needle-like crystals, mp 148.5–149.5°C (lit. (14) mp 143.0–143.5°C). ^{1}H NMR ($CDCl_3$) δ: 7.35 (td, J = 7.5 and 2, 2H), 7.50 (td, J = 7.5 and 1.5, 2H), 7.55 (dd, J = 7.5 and 2, 2H), 7.90 (dd, J = 7.0 and 2, 2H). Anal. calcd. for $C_{12}H_8S_2O$: C 62.04, H 3.47; found: C 61.98, H 3.20. GC–MS analysis of this product indicated that it contained 1.4% unoxidized thianthrene that could not be removed by column chromatography or repeated recrystallization.

Benzyltriethylammonium permanganate was prepared by adding a saturated aqueous solution of $KMnO_4$ (4.16 g, 0.0264 mol) dropwise to a stirred solution of benzyltriethylammonium chloride (6.00 g, 0.0264 mol) in 100 mL of water (15). The dark purple precipitate that formed was collected under suction and vacuum dried over phosphorus pentoxide. It was recrystallized by dissolving in a minimum of hot methylene chloride, adding an equal amount of carbon tetrachloride, and cooling, mp 125–127.5°C (lit. (15) mp 114°C (dec.)). ^{1}H NMR ($CDCl_3$) δ: 1.6 (t, J = 7, 9H), 3.5 (q, J = 7, 6H), 4.7 (s, 2H), 7.6 (m, 5H). The UV–VIS spectrum exhibited four peaks between 500 and 575 nm that are characteristic of permanganate ion (16).

Ruthenium tetroxide was prepared by oxidation of ruthenium dioxide hydrate (0.4 g) with $NaIO_4$ (3.2 g, 0.015 mol) in a stirred heterogeneous solution of water (50 mL) and carbon tetrachloride (50 mL) at 0°C for 30 min (17). The carbon tetrachloride layer, now bright yellow, was separated and stored at 5°C over a few crystals of $NaIO_4$. Concentration was determined spectrophotometrically using known extinction coefficients (18).

Chromyl chloride was obtained commercially (Alfa Inorganics) and used without further purification.

Methylene chloride, the solvent used in these reactions, was carefully distilled from solid $KMnO_4$ before use.

Oxidations

Benzyltriethylammonium permanganate (0.1–0.2 g), dissolved in methylene chloride (50–100 mL), was added dropwise to a stirred solution of **SSO** (0.20 g, 0.86 mmol) in methylene chloride (20 mL). When the reaction was complete, MnO_2 was removed by suction filtration through a short column of alumina or silica and the products were eluted with acetone. The solvents were removed by rotary evaporation and the products vacuum dried (1 Torr (= 133.3 Pa)).

Ruthenium tetroxide (0.2–0.5 mmol) dissolved in carbon tetrachloride was added dropwise to a stirred solution of **SSO** (0.20 g, 0.86 mmol) in methylene chloride (20 mL). When the reaction was complete, RuO_2 was removed by suction filtration through 5 mm of Celite and the Celite washed with acetone to remove all products. After removal of the solvents by rotary evaporation, the products were vacuum dried.

Chromyl chloride (0.15–0.51 mmol), dissolved in methylene chloride (40 mL), was added dropwise to a stirred solution of **SSO** (0.20 g, 0.86 mmol) in methylene chloride (20 mL). The final solution was reddish-brown. 2-Propanol (3 mL) was added to reduce any excess oxidant. The solution was filtered through a short column of silcia gel (0.5 cm TLC grade silica and 3 cm 200–400 mesh silica gel) to remove the brown color. The column was eluted with acetone to recover all products. The solution was concentrated to about 40 mL and added to a similar volume of dilute aqueous NaCl. The products were extracted with 2 × 30 mL of CH_2Cl_2. Insoluble material at the interface was not collected because TLC showed it to contain no products. The extracts were filtered through silica once more to remove residual brown coloration and rotary evaporated to dryness.

Characterization of products

Thin-layer chromatography using 20:80 = 2-propanol:petroleum ether as the mobile phase indicated from four to six compounds present in the product mixture obtained from each reaction. These were separated using dry flash chromatography and characterized by gas chromatography (mass selective detector) and ^{1}H NMR (200 mHz). Thianthrene, **SS**: R_f = 0.87. ^{1}H NMR ($CDCl_3$) δ: 7.15 (dd, J = 6 and 3, 4H), 7.40 (dd, J = 6 and 3, 4H). Thianthrene 5-oxide, **SSO**: R_f = 0.71. ^{1}H NMR ($CDCl_3$) δ: 7.36 (td, J = 7.5 and 2, 2H), 7.50 (td, J = 7.5 and

Thianthrene 5,5,10-trioxide, **$SOSO_2$**: R_f = 0.43. ^{1}H NMR ($CDCl_3$) δ: 7.70 (m, 4H), 8.07 (dd, J = 7.5 and 1.5, 4H). Thianthrene 5,10-dioxide, **SOSO**: R_f = 0.13. ^{1}H NMR ($CDCl_3$) δ: 7.60 (dd, J = 6.0 and 2.0, 4H), 8.03 (dd, J = 6.0 and 2.0, 4H). Thianthrene 5,5,10,10-tetroxide, **SO_2SO_2**: R_f = 0. ^{1}H NMR (DMSO-d_6) δ: 8.05 (dd, J = 6.0 and 2.5, 4H), 8.33 (dd, J = 6.0 and 2.0, 4H).

Disproportionation of thianthrene 5-oxide

As noted above, thianthrene 5-oxide used in these experiments contained 1.4% thianthrene, **SS**, that could not be removed by column chromatography or repeated recrystallization. When oxidized by permanganate or chromyl chloride, the amount of **SS** present in the product decreased, presumably because it had been oxidized to **SSO**. When the oxidant was ruthenium tetroxide, however, the amount of **SS** in the product was always greater than 1.4%. This additional **SS** appears to have come from the disproportionation of **SSO** (to **SS** and **SOSO** or **SSO_2**). A similar reaction was observed to occur when a solution of RuO_2 and **SSO** was stirred for a few hours. No reaction was observed, however, when **SSO** was stirred with MnO_2.

Results

The products were analyzed by HPLC. Chromatograms were obtained using a Dionex Series 4000i liquid chromatograph fitted with an Alltech, Econosphere, 250-mm silica (5 μm) column and a Perkin Elmer UV detector operated at 258 nm. Integration was performed manually. The flow rate was 2.0 mL/min and the solvent protocol was 80% hexane, 20% 2-propanol (1.0–3.5 min), gradient (3.5–7.0 min), 35% hexane, 65% 2-propanol (3.5–10.5 min). Injection was started at 1.0 min and stopped at 1.5 min.

Using pure compounds, standard curves of concentration vs. peak area were prepared for **SS**, **SSO**, **SOSO**, **SSO_2**, **$SOSO_2$**, and **SO_2SO_2** under these conditions. The results obtained from triplicate experiments with each oxidant are summarized in Tables 1–3. The estimated uncertainties are ±2% in individual concentration measurements and ±10% in the X_{SO} values.

Discussion

The results summarized in Tables 1–3 clearly indicate that there is a substantial difference in selectivity for the three high-valent transition metal oxidants under consideration, with permanganate showing the greatest selectivity for oxygen transfer to a sulfoxide sulfur. This result is consistent with the work of Ogura et al. (19) who found that methyl (methylthio)methyl sulfoxide, **1**, was oxidized by permanganate to methyl (methylthio)methyl sulfone, **2**, in 97% yield. It also explains why monosulfones, and not disulfoxides, are the usual products

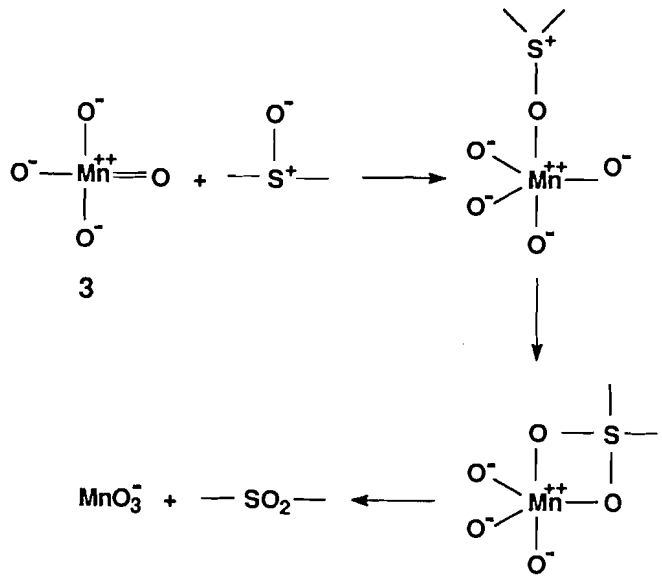
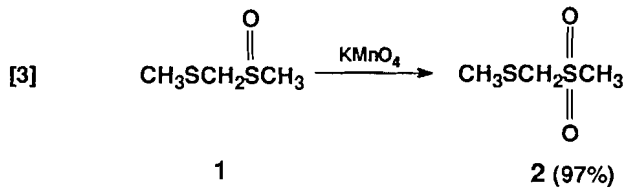
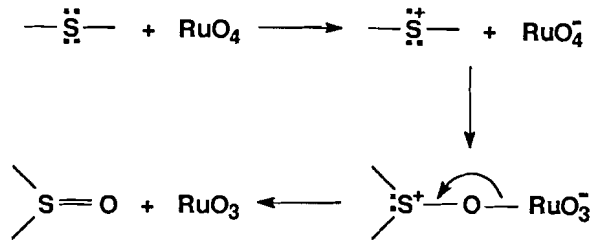


SCHEME 2. The oxidation of a sulfoxide by permanganate.

obtained from the oxidation of *gem*-disulfides by permanganate (20).



From a comparison with other permanganate oxidations, it seems likely that oxygen transfer is preceded by complexation between the oxidant and the reductant (21). It is known that the manganese atom in permanganate is approximately dipositive with the oxygen atoms bearing corresponding negative charges as depicted in structure 3 (22). It therefore seems likely, on the basis of electrostatic considerations, that complex formation would involve interaction between the manganese atom and the oxygen end of the sulfoxide dipole as in Scheme 2. Oxygen transfer could then occur as indicated. The product, manganate(V) ion, also suggested as an intermediate in other permanganate oxidations (23), would likely be reduced very rapidly to manganese(IV) by electron capture from the solvent.



SCHEME 3. The oxidation of a sulfide by RuO_4.

A similar mechanism would account for the oxidation of **SSO** to **SSO_2** by ruthenium tetroxide. However, the observation of some **SOSO** in the products of this reaction indicates that the sulfide sulfur is also oxidized by RuO_4, although at a substantially slower rate. Such an oxidation may be initiated by electron transfer to give perruthenate and a radical cation as in Scheme 3. Since the medium is nonpolar, it is unlikely, as envisaged in Scheme 3, that these ions would diffuse out of the solvent cage prior to oxygen transfer.

It is also possible that the small amount of **SOSO** observed in the product when **SSO** is oxidized by RuO_4 could be due to the reactions of RuO_3, which is a by-product of these reactions.

The observation that transfer of oxygen to the sulfide sulfur is the main reaction when **SSO** is oxidized by chromyl chloride indicates that an alternative reaction mechanism must pertain. By analogy with the preceding discussion, a single electron transfer mechanism may be considered as a possibility for the reactions of this oxidant. This suggestion is also consistent with other known chemical properties of chromyl chloride. Recent results, described by Cook and Mayer (24), provide strong evidence for the intermediacy of cyclohexyl radicals during the oxidation of cyclohexane by chromyl chloride, and free radical intermediates have also been suggested for the Etard reaction (Cl_2CrO_2 + $ArCH_3$), which ultimately yields arylaldehydes (25).

A tentative mechanism involving electron transfer as the initial reaction has been outlined in Scheme 4.

The difference between chromyl chloride and other transition metal oxides or oxyanions may be associated with different modes of polarization of the M=O and M—Cl bonds. Polarization of the metal oxo bond (M=O ↔ M—O$^-$) places a greater positive charge on the metal while the converse would be true for metal–chlorine bonds (M—Cl: ↔ M=Cl) (26). Permanganate could therefore be considered as a resonance hybrid of the

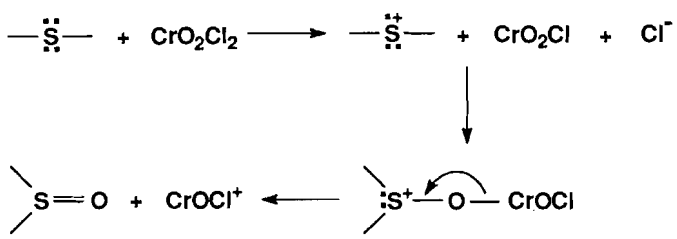
For personal use only.



SCHEME 4. The oxidation of sulfide by CrO_2Cl_2.

structures depicted in eq. [4] (22), while the corresponding structures for chromyl chloride would be those in eq. [5]. A reduction of the positive charge on chromium as compared to manganese, suggested by these resonance structures, and the presence of an electron-deficient chlorine ligand could promote an electrostatic interaction between the ligand and the nonbonding electrons of sulfur that would initiate an alternative reaction such as a single electron transfer.

In any event it is clear from these results that there is a fundamental difference between the oxygen transfer reactions of

[4] 
[5] 
chromyl chloride and the other two oxidants considered in this study. For this reason the extensive experimental and theoretical information currently available for chromyl chloride oxidations (24, 27) may not be directly applicable to an understanding of other high-valent transition metal oxidants.

Spin diffusion in a triblock thermoplastic elastomer

GYUNGGOO CHO AND ALMERIA NATANSOHN[1]
Department of Chemistry, Queen's University, Kingston, ON K7L 3N6, Canada

Received June 14, 1994

GYUNGGOO CHO and ALMERIA NATANSOHN. Can. J. Chem. **72**, 2255 (1994).

A triblock copolymer thermoplastic elastomer (SEBS) consisting of an ethylene–butylene random-copolymer rubbery domain flanked by rigid polystyrene short blocks has been analyzed using novel solid-state NMR techniques. ^{13}C NMR relaxation measurements suggest that at the $T_1(H)$ level (minimum observable phase size of about 18 nm) the material appears homogeneous, but at the $T_{1\rho}(H)$ level (minimum observable phase size of about 3 nm) the expected two distinct phases are noted. Two-dimensional WISE spectra (high-resolution ^{13}C – broadline ^1H) show the different mobility in the two phases. A broad component associated with the highly mobile rubbery phase indicates the presence of an interface. The mobile phase is selected using a dipolar filter pulse sequence and the magnetization is allowed to transfer to the rigid polystyrene phase during a period called "mixing time." From the growth of the polystyrene magnetization during the mixing period, the size of the dispersed polystyrene phase can be calculated to be 16 ± 2 nm.

GYUNGGOO CHO et ALMERIA NATANSOHN. Can. J. Chem. **72**, 2255 (1994).

Faisant appel aux nouvelles techniques de la RMN de l'état solide, on a analysé un élastomère thermoplastique, un copolymère à trois blocs (SEBS) formé du domaine caoutchouté d'un copolymère aléatoire d'éthylène–butylène flanqué de petits blocs de polystyrène rigide. Les mesures de relaxation de la RMN du ^{13}C suggèrent que, au niveau $T_1(H)$ (taille minimale de la phase observable d'environ 18 nm), le produit semble homogène, mais que au niveau $T_{1\rho}(H)$ (taille minimale de la phase observable d'environ 3 nm), on peut noter les deux phases distinctes attendues. Le spectre WISE bidimensionel (^{13}C à haute résolution et ^1H avec des raies larges) montre la mobilité différente dans les deux phases. Une composante importante associée à la phase caoutchouté très mobile indique la présence d'une interface. On choisit la phase mobile en utilisant un filtre dipolaire à séquence pulsée et on permet à la magnétisation de se transférer à la phase polystyrène rigide au cours d'une période que l'on appelle «temps de mélange». En se basant sur la croissance de la magnétisation du polystyrène durant le période de mélange, on a calculé que la taille de la phase polystyrène dispersée est de 16 ± 2 nm.

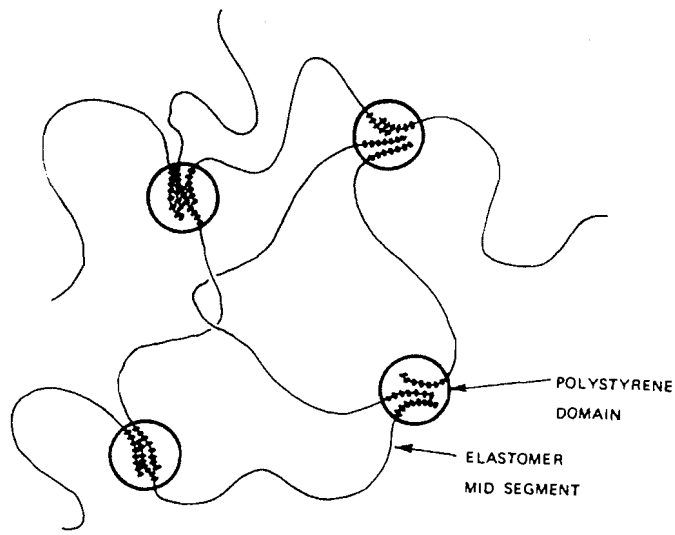
[Traduit par la rédaction]

Introduction

Phase-separated materials have proven to be quite useful due to their enhanced mechanical properties. Probably the best known example of such a material is high-impact polystyrene, which consists of a polystyrene matrix with a dispersed rubber phase. As the name says, this material has better impact properties than polystyrene itself. In fact, most polymer materials are being mixed with other polymers or fillers or other materials, to improve some of the properties and (or) lower costs. The degree of mixing in a multiphasic material is crucial for the properties exhibited by that material. The dispersion of the minor phase as well as the nature and thickness of the interface separating the two components are the most important parameters.

One method to analyze mixing in polymer materials makes use of ^{13}C CPMAS NMR spectroscopy. High-resolution spectra are obtained in the solid state on materials as they are being used. Selective excitation of one of the components (based on mobility differences) followed by spin diffusion to the other phase was proposed in 1966 by Goldman and Shen (1) as a procedure to determine domain sizes. Since then, various similar techniques have been proposed (2–7). One of those is the "dipolar filter" proposed by Spiess and co-workers (8) and subsequently applied to some soft–hard polymer pairs (9–12).

Thermoplastic elastomers are such phase-separated polymer systems consisting of a dominant rubbery phase and a dispersed rigid phase. The dispersed rigid phase acts as a physical crosslink, replacing the usual chemical crosslink in commercial rubber. Its advantage is that the products can be reprocessed at temperatures exceeding the softening temperature of the hard



SCHEME 1 (ref. 13)

domains. For this reason there is considerable interest in thermoplastic elastomers. One class of thermoplastic elastomers are triblock copolymers of the type hard–soft–hard. The molecular weight of the hard segments is much lower than that of the soft segment, thus making the rubbery phase the dominant one. The typical morphology of a thermoplastic elastomer is represented in Scheme 1. We have chosen SEBS, a triblock copolymer of styrene–(ethylene-*co*-butylene)–styrene to investigate its phase structure using various available solid-state NMR techniques.

Experimental

The thermoplastic elastomer sample was obtained from Shell Labo-

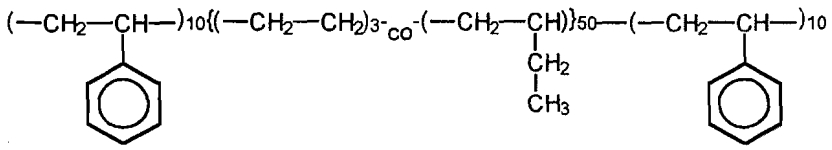

SCHEME 2

ratories (Houston, Tex.) and used without modification. The degree of polymerization of the styrene blocks was 10 and the degree of polymerization of the ethylene-*co*-butylene block was 50 (13). The molar ratio of ethylene to butylene units in the rubber segment was determined by solution ^{1}H NMR to be 3:1. The formula of the SEBS sample is shown in Scheme 2.

Proton-decoupled solid-state ^{13}C NMR spectra were obtained on a Bruker ASX-200 spectrometer operating at 50.29 MHz (200 MHz proton resonance). All spectra were obtained at room temperature with spinning of 5.5 kHz (chosen to produce spinning side-bands outside of the region of interest in the spectra). No spinning side-bands suppression was necessary. The proton $\pi/2$ pulse was 3.6 μs, the cross-polarization time was 1.5 ms, and the delay between pulses was 5 s.

Proton spin-lattice relaxation times in the rotating frame ($T_{1\rho}$(H)) were measured using carbon detection in a pulse sequence with increasing proton spin locking times (14). The two-dimensional WISE (WISE = WIdeline SEparation) and the dipolar filter pulse sequences are shown schematically in Fig. 1 (8). For the WISE experiment (Fig. 1*a*) 512 complex points were used in the carbon domain and 64 points in the proton domain with an increment of 4 μs. The dipolar filter pulse sequence (Fig. 1*b*) was used in two ways. One procedure involved complete saturation of the whole NMR spectrum, using 300-μs delays between pulses in the dipolar filter and 5 repetitions of the filter. Then the magnetization was allowed to recover during the mixing time in order to measure T_1(H) for all the carbon peaks. The phase cycling pulse (PC in Fig. 1*b*) was not used for the T_1(H) measurements. In the second procedure, selection of the mobile phase was achieved with cycles of 12 $\pi/2$ proton pulses repeated 9 times and with spacings of 7 μs between them. For the dipolar filter, the PC pulse was used to eliminate the T_1(H) effect in spin diffusion.

Results and discussion

Dynamic mechanical measurements of this SEBS sample indicate two glass transition regions, one for the rubbery phase at about –40°C and the other one for the polystyrene domains at about 110°C (13). Glass transitions are usually visible when the phases have dimensions greater than about 10 nm. To confirm the presence of the two phases, proton spin-lattice relaxation times can be used. The ^{13}C CPMAS NMR spectrum of SEBS is shown in Fig. 2. Some assignments are straightforward; for example, the peaks at about 130 ppm and at about 150 ppm belong to the protonated aromatic carbons and to the *ipso* aromatic carbon of the polystyrene, respectively. In the aliphatic region, assignments can be made using a dipolar dephasing procedure (15). Due to the relatively high mobility of the rubbery phase, a longer dipolar dephasing time is required to eliminate its carbon signals in the spectrum. Thus, at 50 μs most of the signals around 40 ppm are dephased, thus they can be assigned to the methylene and methine carbons of the polystyrene. The most intense signals between 30 and 40 ppm are assigned to the methylene carbons in the rubbery phase. The methine carbons of the rubber resonate in the signal centered at 40 ppm, while the methyl appears at about 13 ppm.

It is well known that the proton spin-lattice relaxation is related to spin diffusion among the abundant spins and that it can be used as a probe for the phase structure of polymer blends (16). T_1(H) is usually smaller than a second and $T_{1\rho}$(H) is around 10 ms in polymer materials. Thus each of these parameters will

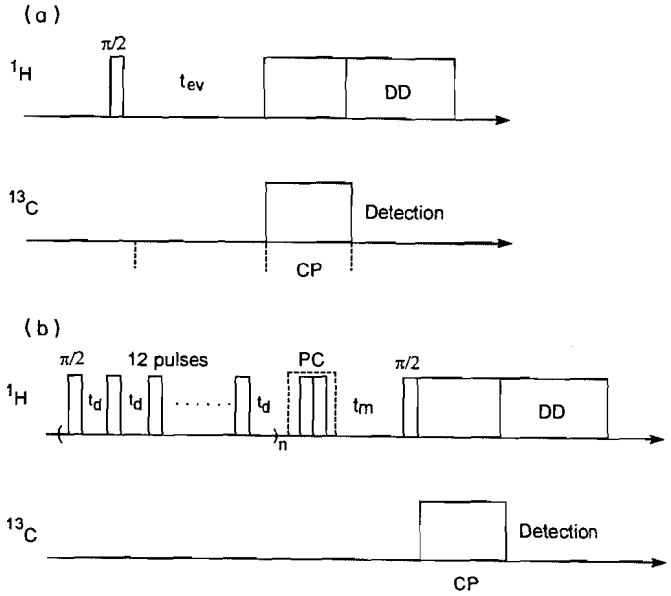

FIG. 1. Pulse sequences for: (*a*) WISE; (*b*) dipolar filter and T_1(H) measurements.

give information about phase structure at a different level. One can estimate the minimum size of various phases from the spin traveling distance obtained with eq. [1]:

$$[1] \quad \langle x \rangle = \frac{4}{3} Dt$$

where D is the diffusion coefficient and t is the timescale represented by the relaxation measurement (17). The proton spin-lattice relaxation time constants for the two phases were measured using the signals at 130 ppm (polystyrene) and 32 ppm (rubber). T_1(H) is the same for all carbons in the material (310 ± 20 ms), while $T_{1\rho}$(H) is different for the polystyrene phase (7.0 ms) and for the rubber (2.6 ms). Using eq. [1] and the spin diffusion coefficient of polystyrene of (0.8 ± 0.2) × 10^{-15} m^2/s (8), one can estimate the phase sizes from the relaxation parameters. The polystyrene is the dispersed phase, hence its size will have to be smaller. A spin traveling distance of 18.2 nm is obtained from T_1(H). At this level, the material appears homogeneous (a single relaxation parameter). From $T_{1\rho}$(H) a minimum phase size of 2.7 nm is obtained for polystyrene. This means that the dispersed polystyrene phase dimension has to be greater than 2.7 nm and smaller than 18.2 nm in order to exhibit a two-phase behaviour for $T_{1\rho}$(H) and a monophasic behaviour for T_1(H). This agrees with the preliminary estimate from the dynamic mechanical measurements (13) that the phases have to be greater than about 10 nm.

To confirm the very different mobility of the two phases, a 2D-WISE spectrum was run and Fig. 3 shows the result. The projection on the carbon axis is shown as the carbon spectrum. There is a clear difference in the widths of the proton spectra for the two components, and Fig. 4 shows the two slices taken at 32 ppm and at 130 ppm. The aromatic protons show a half-height

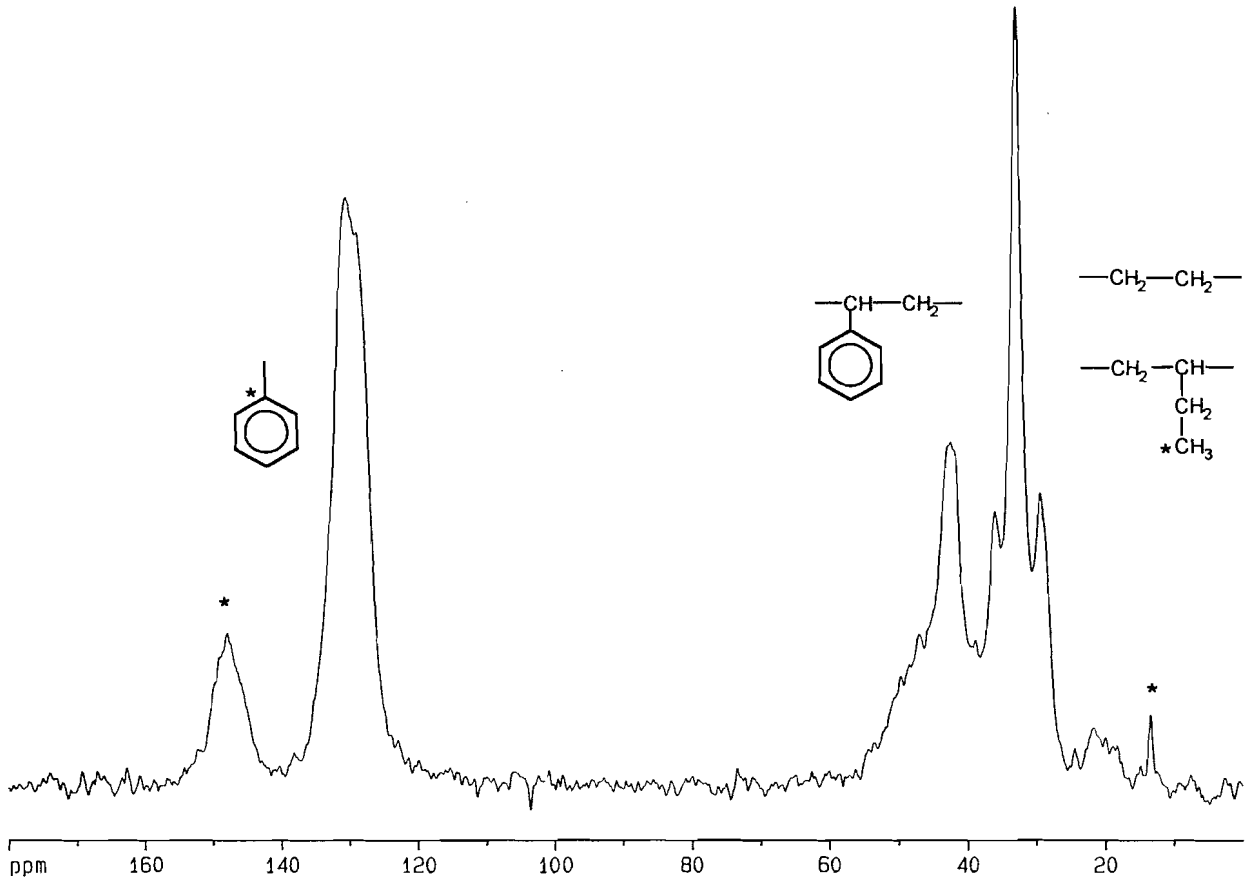

FIG. 2. ^{13}C CPMAS NMR spectrum of SEBS. The assignments are given on the spectrum. A weak spinning side-band can be seen at about 20 ppm.

linewidth of 60.5 kHz, while at 32 ppm there seem to be two superimposed broadline proton spectra. The narrow spectrum belongs to the rubber phase and has a half-height linewidth of 12 kHz. The presence of a broader component in the rubber signal may suggest that a small part of the rubber has a restricted kind of motion and it is fairly reasonable to assume that the rubber surrounding the polystyrene domains may be less mobile than the bulk of the rubbery phase. In fact, the presence of such a broad component in a two-phase system has been previously explained as being part of the interface (11). Due to the difference in linewidth between the rubber and the polystyrene and to the fact that the rubber is the dominant phase, most of the signal intensity in the 2D spectrum in Fig. 3 is concentrated in the aliphatic region. The polystyrene signal may sometimes be lost in the noise, as is the case with the *ipso* carbon. The WISE spectrum demonstrates that there is a significant difference in mobility between the rubbery phase and the polystyrene rigid phase.

The dipolar filter sequence in Fig. 1*b* contains a very important part: the phase cycling pulse applied previous to the mixing time. If this pulse is omitted, all signals grow in intensity as a function of mixing time, due to the spin-lattice relaxation. When this pulse is present, however, a loss of absolute intensity is detected in the spectra and a correction factor of $\exp(t_m/T_1)$ has to be applied to the measured intensities (8), where t_m is the mixing time shown in Fig. 1*b*. Figure 5 shows the spectra obtained with the dipolar filter sequence at various mixing times. The selection is sampled at 50 μs mixing time, and already at 10 ms the polystyrene signals are very visible, which is an indication of fairly fast spin diffusion. The equilibrium (a

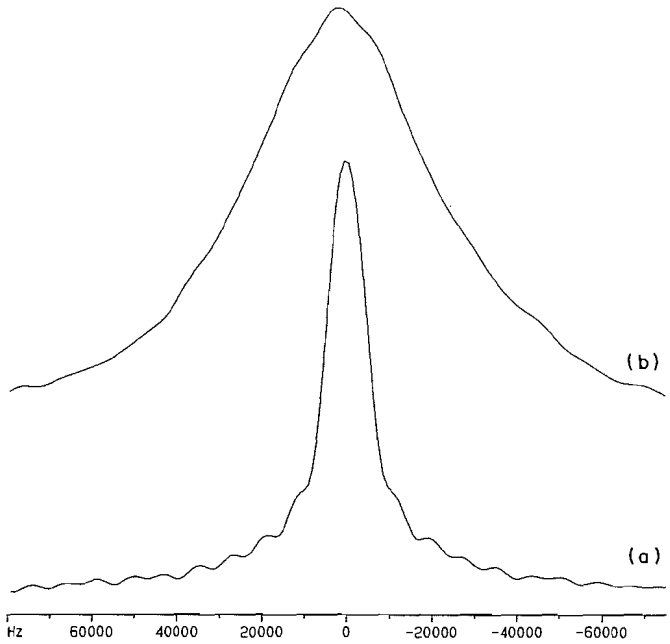

FIG. 4. Two slices taken from the WISE spectrum shown in Fig. 3:(*a*) 32 ppm; (*b*) 130 ppm.

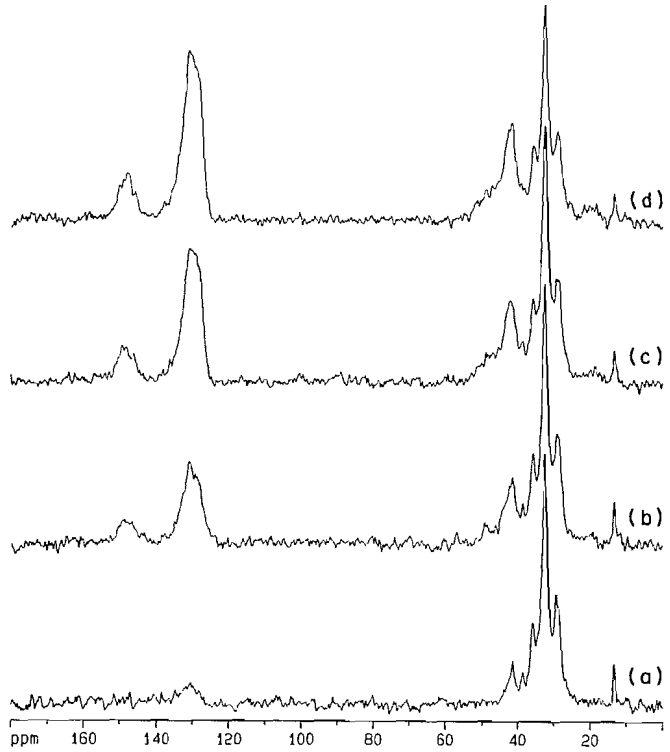

FIG. 5. Spectra of SEBS obtained after the dipolar filter selection at various mixing times (*a*) 50 μs; (*b*) 10 ms; (*c*) 30 ms; (*d*) 50 ms.

spectrum with its components in the same ratio as a spectrum obtained without selection) is obtained at about 300 ms. One would normally expect that as the polystyrene signals increase, some decrease should be noted for the rubber signals, because the selection–transfer procedure eliminates the polystyrene magnetization and the whole source of magnetization in the spectrum comes from the rubber signals. This decrease is not very noticeable, and the reason is that the rubber is the main component and each of its structural units has 4.5 times more protons than the structural unit of the polystyrene. This is a very "rich" source for magnetization and its decrease is insignificant compared to the increase in magnetization of the polystyrene.

Equation [2] describes how the size of the dispersed domains can be determined as a function of the proton density of each phase (ρ_{HA}, ρ_{HB}), the volume fraction of each phase (ϕ_A, ϕ_B, one of which, the polystyrene in this case, is ϕ_{dis}, the volume fraction of the dispersed phase), the dimensionality (ϵ), the diffusion coefficients for each phase (D_A, D_B), and $(t_m^*)^{1/2}$ (8). In a similar manner, the long distance can be calculated using the size of the dispersed domains and the formula in eq. [3].

$$[2] \qquad d_{dis} = \left(\frac{\rho_{HA}\phi_A + \rho_{HB}\phi_B}{\phi_A\phi_B}\right) \times \frac{4\epsilon\phi_{dis}\sqrt{D_A D_B}}{\sqrt{\pi}\left(\sqrt{D_A}\rho_{HA} + \sqrt{D_B}\rho_{HB}\right)} \sqrt{t_m^*}$$

$$[3] \qquad d = \frac{d_{dis}}{\sqrt[\epsilon]{\phi_{dis}}}$$

Both equations [2] and [3] have been derived for the general case of a blend composed of two polymers, which may be bound (as in this case of triblock copolymers) or mixed together. The equations have also been shown to be valid for a random distribution of two types of structural units (8).

Most of the parameters in eq. [2] are known or can be approximated. From the composition of the terpolymer and the densities of polystyrene and of polyethylene (low density, similarly branched) the volume fraction of each phase can be calculated. The proton densities are similary calculated using the proton fractions in each component. The spin diffusion coefficient of polystyrene has been reported (8), while the spin diffusion coefficient of the rubber block can be approximated with that of polybutadiene ($(0.05 \pm 0.015) \times 10^{-15}$ m^2/s) (12), mainly because it is obtained by hydrogenation of the polybutadiene blocks. The dimensionality of this block terpolymer is 2, i.e., the morphology is cylindrical (13). The square root of t_m^* can be found from extrapolating the straight line of initial magnetization growth as shown in Fig. 6.

Using the parameters discussed above, a domain size of 16 ± 2 nm is obtained for the dispersed polystyrene and a long period of 31 ± 5 nm is obtained for the combination of the dispersed and major phase. The error was estimated by introducing the lower values of the diffusion coefficients for the two components to obtain the smallest estimate of the dispersed size (13.8 nm) and then the higher values for the largest estimate (17.7 nm). The calculated median value (15.6 nm) was taken as the average domain size.

If the average size of the polystyrene domains is indeed about 16 nm, then the results obtained for the relaxation parameters are easy to explain. T_1(H) is about 0.3 s, reflecting domain sizes of about 18 nm. By measuring T_1(H), the polystyrene phases are just small enough to be undetectable. $T_{1\rho}$(H) detects phases down to 2.7 nm. As the polystyrene phase is greater than that, the $T_{1\rho}$(H) measurements show the presence of two phases. As for the dynamic mechanical results, the polystyrene phase is greater than the 10 nm believed necessary to show the glass transition.

Regarding the interface in this triblock copolymer, the data

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

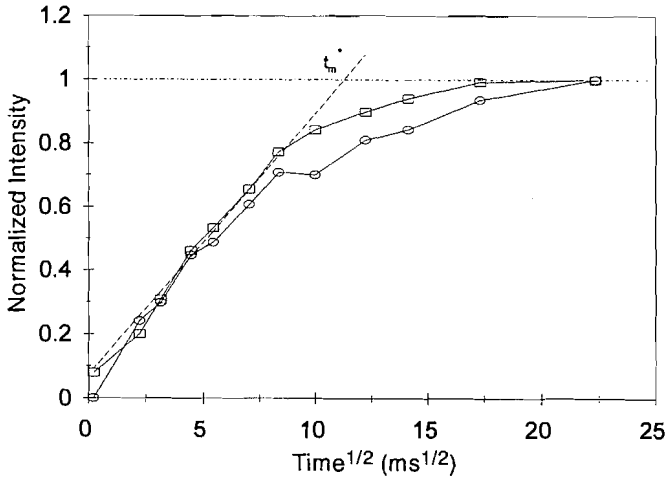

FIG. 6. Magnetization growth for two polystyrene signals at 150 and 130 ppm. The open circles represent the 150 ppm signal.

here could be modeled assuming such an interface exists. In fact the presence of the broader background on the relatively narrow proton slice of the rubber (Fig. 4) is indicative of an interface, according to the literature (11). We believe that more theoretical background is necessary to calculate such an interfacial thickness.

Finally, this triblock copolymer fits fairly well the developed models for magnetization transfer presented in the literature for other block copolymers (8, 11, 12), i.e., the two phases of all these systems are chemically bonded to each other. In most of the "real life" phase-separated systems, the two phases have no chemical bond and sometimes not even a physical interaction. The model for magnetization transfer in such systems has to be different; some of them may even have fairly good dispersion but no magnetization transfer due to the physical barrier between phases.

Conclusions

Solid-state NMR techniques can be used to obtain information about the phase structure and dimensions in a triblock thermoplastic elastomer. In the case of SEBS, the size of the polystyrene dispersed phase has been determined to be of the order of 16 nm with a cylindrical morphology.

The tube-inhabiting marine worm, *Cephalodiscus gilchristi* has been found to produce a series of cytotoxic and antineoplastic disteroidal alkaloids. A substantial study concerned with discovery of new cell growth inhibitory constituents of this marine animal has led to isolation of cephalostatins 14 (**5***a*) and 15 (**5***b*). The structures were determined by interpretation of spectral data, principally high-field (400 and 500 MHz) NMR and HRFABMS combined with NMR spectral relationships to cephalostatin 1 (**4**) where the structure was previously assigned by X-ray crystal structure analysis. The stereochemical assignments were established employing the ROESY NMR technique. Both new cephalostatins significantly inhibited growth of the P388 lymphocytic leukemia and a selection of human cancer cell lines. The two new cephalostatins further enhance knowledge of structure–activity parameters for these potentially important steroidal alkaloids.

GEORGE R. PETTIT, JUNPING XU, YOSHITATSU ICHIHARA, MICHAEL D. WILLIAMS et MICHAEL R. BOYD. Can. J. Chem. **72**, 2260 (1994).

On a trouvé que le ver marin habitant un tube, *Cephalodiscus gilchristi*, produit une série d'alcaloïdes distéroïdaux cytotoxiques et antinéoplastiques. Une étude importante relative à la découverte de nouveaux constituants de cet animal marin inhibants la croissance de nouvelles cellules a conduit à l'isolement des céphalostatines 14 (**5***a*) et 15 (**5***b*). On a déterminé le structures par l'interprétation des données spectrales obtenues principalement par RMN à champ élevé (400 et 500 MHz) et par HRFABMS combiné avec des relations spectrales avec la céphalostatine 1 (**4**) dont la structure a été attribuée antérieurement par diffraction des rayons X. Les attributions stéréochimiques ont été faites par la technique REOSY de la RMN. Les deux nouvelles céphalostatines inhibent fortement la croissance de la leucémie lymphocytaire P388 ainsi qu'une sélection de cellules humaines cancéreuses. Les deux nouvelles céphalostatines augmentent nos connaissances sur les paramètres structure–activité de ces alcaloïdes stéroïdaux potentiellement importants.

Introduction

Considerable research effort is currently being focused on discovery of new marine animal antineoplastic and (or) cytotoxic constituents based on nitrogen, oxygen, and (or) sulfur heterocyclic systems (2–15). Among the nitrogen heterocyclic compounds, dolastatins 10 (16) (**1**) and 15 (17) (**2**), ecteinascidin 729 (9) (**3**), and cephalostatin 1 (**4**) (18) are especially noteworthy. All are at various stages of preclinical or clinical development. To increase the supply of cephalostatin 1 and expand knowledge of structure–activity relationships in the important cephalostatin series (18–22) we have been utilizing a large-scale (450 kg wet wt., includes coenecium) recollection of the relatively small (~5 mm long) Southwest Indian Ocean marine worm *Cephalodiscus gilchristi* (Pterobranchia, Hemichordata Phylum). Previously we described the isolation and structural elucidation of cephalostatins 1–13 (1, 18–22), disteroidal alkaloids that are powerful human cancer cell line and murine P388 lymphocytic leukemia (PS system) cell growth inhibitors (ED_{50} 10^{-7}–10^{-9} μg/mL). Further investigation of the antineoplastic and (or) cytotoxic constituents of this marine worm have now resulted in discovery of two new disteroidal alkaloids, cephalostatins 14 (**5***a*) and 15 (**5***b*), with potent activity against a diverse group of human solid tumor types (in vitro) in the U.S. National Cancer Institute's (NCI) disease-oriented anticancer screen. We describe here the isolation and structure determination of these two novel alkaloids as well as their significant cancer cell growth inhibitory activity.

Results and discussion

The most recent scaled-up acquisition of *Cephalodiscus gilchristi* (450 kg wet wt.) was conducted in 1990 in the Indian Ocean off southeast Africa and was initially stored in methanol. Preliminary solvent partition separations of the methanol extract were performed as recently summarized (19) to yield a PS-active methylene chloride fraction (ED_{50} 0.044 μg/mL) that was chromatographed repeatedly on Sephadex LH-20 (eluents: methylene chloride – methanol 3:2, hexane–toluene–methanol 3:1:1, hexane–2–propanol–methanol 8:1:1, and hexane – methylene chloride – methanol 5:1:1) to afford several principal fractions. Final purification by reversed phase HPLC on C-8 silica gel columns using 10:10:12 acetonitrile–methanol–water as eluent furnished cephalostatin 14 (**5***a*) (32 mg, 7.1×10^{-6}% yield) and 15 (**5***b*) (5.1 mg, 1.2×10^{-6}% yield). Cephalostatins 14 and 15 caused significant inhibition of the murine leukemia (PS ED_{50} 4.1×10^{-3} μg/mL and 2.5×10^{-2} μg/mL, respectively) cell line.

Cephalostatin 14 (**5***a*) was obtained as a colorless powder and found to have molecular formula $C_{54}H_{72}N_2O_{12}$ by HRFABMS data (*m/z* 963.4974 $[M + Na]^+$, Δ −0.9 mmu). The UV absorption maxima at 305 (shoulder) and 288 nm (log ε 3.96) implied the presence of the same pyrazine chromophore as that of ceph-

alostatins 1–13. All signals of the ^1H and ^{13}C NMR were rigorously assigned by analyses of the APT, ^1H,^1H-COSY, ^{13}C,^1H-COSY, TOCSY, and HMBC spectra. From these NMR results combined with high-resolution, fast-atom-bombardment mass spectra (HRFABMS) and UV data, cephalostatin 14 (**5*a***) was established as a new member of the series. By comparing the 1D and 2D NMR data of cephalostatin 14 (**5*a***) with those earlier assigned to cephalostatin 1 (**4**, by X-ray crystal structure) it became apparent that all the NMR signals attributed to the right-side steroid unit of alkaloid **4** also appeared in the spectra of cephalostatin 14 (**5*a***). The HMBC analysis helped confirm this conclusion. Furthermore, it was found that the A′, E′, and F′ rings in the left-side unit corresponded to those of cephalostatin 1. Two carbon signals belonging to a double bond (δ 123.6 d and 165.77 s) and a carbonyl signal were observed in the left-side unit of steroid **5*a***. The ^{13}C chemical shift of the carbonyl group in cephalostatin 14 was found shifted upfield about 10 ppm by comparison with that of steroid **4**. In turn, this indicated that the carbonyl group was conjugated with a double bond, which was supported by UV absorption at 230 nm.

From ^1H,^1H-COSY and TOCSY results, it was concluded that the carbonyl group should be at C-12′ with the double bond between C-9′ and C-11′. Meanwhile, HMBC correlations were found between the hydrogen atom at C-11′ (δ 6.47) and the carbon atoms at C-10′ (δ 39.66 s), C-9′ (δ 165.78 s), and C-13′ (δ 52.1 s). By following the coupling network from the C-21′–CH_3 (δ 1.38 d, 14.84 q) using ^1H,^1H-COSY, TOCSY, and HMBC correlations, it was found that C-15′ (δ 3.75 brs, 57.56 d) must share an epoxy group with C-14′ (δ 71.58 s). Further-

more, a tertiary hydroxyl group was deduced, by elimination, to be located at C-8′. The HMBC correlations from the hydrogen atom of C-11′ to carbon C-8′ (δ 70.23 s) and from the hydroxyl hydrogen of C-8′ (δ 6.92 s) to carbons C-9′, C-8′, and C-7′ (δ 24.56 t) also supported this assignment. Consequently, the structure of cephalostatin 14 was established as **5*a***.

Cephalostatin 15 (**5*b***) was also obtained as a colorless non-crystalline powder. The UV and ^{1}H and ^{13}C NMR spectra data were found to be very similar to those of steroid **5*a*** except for the addition of one methyl signal. HRFABMS suggested molec-

ular formula $C_{55}H_{74}N_2O_{12}$ ($[M + H]^+$ 955.5318, Δ −0.2 mmu), which supported the presence of an additional methyl group. Assignments using APT, ^1H,^1H-COSY, ^{13}C,^1H-COSY, TOCSY, and HMBC spectra showed that cephalostatins **5***a* and **5***b* shared the same right-side steroidal unit. Cephalostatin 15 was also found to possess a carbonyl group at C-12′ (δ 201.67 s), a double bond between C-11′ and C-9′ (δ 123.9 and 165.92 s), an epoxy group between C-14′ and C-15′ (δ 77.99 s and 58.02 d), and a tertiary hydroxyl group at C-8′ (δ 70.96 s) in the left-side steroidal unit. Based on the proton–proton coupling system around the F′ ring and the HMBC correlations between the extra methyl proton signals (28′-CH_3, δ 1.08 d) and C-23′ (δ 86.87 d), C-24′ (δ 51.55 d), and C-25′ (δ 81.28 s), the methyl group (28′-CH_3) was confirmed to be at C-24′. From observed nOe correlations involving the atom pairs C-26′–CH_3 (δ 1.18 s) and C-28′–CH_3 (δ 1.08 d), C-27′–CH_3 (δ 1.26 s) and C-24′–βH (δ 2.03 m), the C-28′–CH_3 was assigned to the α face of the F′ ring as with the α-OH at C-23′. Therefore, the structure of cephalostatin 15 was determined to be **5***b*.

Analyses of the ROESY spectra obtained for cephalostatins 14 and 15 revealed cross peaks that showed the relative stereochemistry of the right-side unit to be identical with that of cephalostatin 1 (**4**). Some interesting nOe interactions were detected that showed effects between the C-8′ β-OH (**5***a*, 6.92 ppm and **5***b*, 6.88 ppm), C-7′ β-H (**5***a*, 1.82 ppm and **5***b*, 1.82 ppm), and C-15′–H (**5***a*, 3.75 ppm and **5***b*, 3.68 ppm), and C-18′–H_2 (**5***a*, 4.68 ppm and **5***b*, 4.72 ppm), C-19′–CH_3 (**5***a*, 1.43 ppm and **5***b*, 1.36 ppm), and C-8′ β-OH in both left-side units of cephalostatins **5***a* and **5***b* (Tables 2 and 4 and Figs. 1 and 2). The results clearly indicated that the configuration of the proton at C-15′ must be β and the epoxy group must be below the face of the D′ ring in the α configuration.

Cephalostatins 14 (**5***a*) and 15 (**5***b*) were comparatively evaluated, along with cephalostatin 1 (**4**), in the U.S. National Cancer Institute's human tumor disease-oriented in vitro primary screen (23–26). Each compound was tested in quadruplicate at each of three different concentration ranges (10^{-6}, 10^{-7}, and 10^{-8} M upper limits; five $\log_{10}$-spaced concentrations in each range) against the entire group of 60 cell lines making up the screening panel. The standard (**4**) yielded the expected overall panel GI_{50} value of approximately 1 nM, and produced the distinctive mean-graph "fingerprint" of differential cellular response (23) that is typical of all members of the cephalostatin series heretofore studied (e.g., see ref. 19). In the present investigation, **5***a* and **5***b* also produced the characteristic cytotoxicity profile, as confirmed by comparing (23, 25) pattern-recognition analyses; the TGI-based correlation coefficients were 0.75 and 0.80 for **5***a* and **5***b*, respectively, against the standard (**4**). Although the latter analyses implied that the cytotoxic mechanism(s) of these newest cephalostatins did not diverge substantially from the rest of the series, the overall panel-averaged cytotoxic potencies were somewhat less (e.g., 100 nM and 68 nM for **5***a* and **5***b*, respectively) compared to the benchmark compound (**4**).

Results of the study of human cancer cell growth inhibition clearly emphasized that modification of the "left-side" moiety by introduction of the 8β-hydroxy-11-ene-12-one and (or) the 14, 15α-epoxy system served to reduce in vitro activity. Pre-

sumably, the α orientation of the epoxide was primarily responsible for this effect. In our early studies of steroidal bufadienolides against the P388 cell line, the 14, 15β-epoxides were found more potent. Further useful structure–activity information should be obtained by discovery and evaluation of new cephalostatins, and research toward those objectives is in progress.

Experimental

General procedures

Solvents used for column chromatography were freshly distilled. Sephadex LH-20, particle size 25–100 μm, used in gel permeation and partition column chromatographic separations, was obtained from Pharmacia Fine Chemicals AB, Uppsala, Sweden. The TLC plates were viewed under shortwave UV light and then developed by 20% sulfuric acid or 3% ceric sulfate – 3 N sulfuric acid spray reagent followed by heating at approximately 150°C. Uncorrected melting points were observed with a Kofler-type mp apparatus. Optical rotations were determined employing a Perkin–Elmer model 241 polarimeter. UV spectra were obtained by using a Hewlett–Packard 8450 UV–VIS spectrometer. For high-pressure liquid chromatography separations, Phenomenex Prepex (particle size 5–20 μm, diameter 10.0 mm × length 25 cm, C8) was used in the reversed phase mode with Altex (model 110A) solvent metering pumps and Gilson HM UV detection at 288 nm. The ^1H and ^{13}C NMR, APT, ^1H,^1H-COSY, and ^{13}C,^1H-COSY spectra were recorded with a Bruker AM-400 instrument equipped with an ASPECT-3000 computer. The TOCSY (mixing times of 45 and 60 ms), HMQC (optimized for $^1J_{H-C}$ = 140 Hz), HMBC (optimized for $^nJ_{H-C}$ = 8.2 Hz), and ROESY (mixing times of 100 and 150 ms) (27) data were recorded using a Varian 500 NMR spectrometer. HRFAB mass spectra were obtained employing a Kratos MS-50 spectrometer.

Animal extraction and solvent partition sequence

Approximately 450 kg (wet wt.) of *Cephalodiscus gilchristi* was recollected in the summer of 1990 in the Indian Ocean off Southeast Africa by SCUBA (ca. −20 m). The total marine worm collection was extracted with 70% methanol (3×) and the extract was subjected to the solvent partition sequence (19, 28, 29) previously described to yield an active (97 g, PS ED_{50} 0.044 μg/mL) dichloromethane fraction.

*Isolation of cephalostatins 14 (**5a**) and 15 (**5b**)*

The P388 cell line was utilized for bioassay-guided separation (cf. Scheme 1) of the active dichloromethane fraction (97 g). Six fractions (A–F) were obtained from this fraction by Sephadex LH-20 chromatography with methanol as eluent. Active fraction D (PS ED_{50} 1.4×10^{-2} μg/mL) was chromatographed on a column of Sephadex LH-20 with dichloromethane–methanol (3:2) as eluent to give three main fractions G, H, and I. The most active material (H, PS ED_{50} 0.0032 μg/mL) was separated on a Sephadex LH-20 column employing hexane–

toluene–methanol (3:1:1) to provide the next nine principal fractions (J–R). Active fraction P (PS ED_{50} 0.007 μg/mL) and fraction O (PS ED_{50} 0.018 μg/mL) were subjected to partition column chromatographic steps using Sephadex LH-20 with hexane–2-propanol–methanol (8:1:1) followed by hexane–dichloromethane–methanol (5:1:1) as eluents to yield fractions S and T. Final separation and purification of cephalostatins 14 (**5***a*) and 15 (**5***b*) was achieved by reversed phased HPLC (C8) with methanol–acetonitrile–water (5:5:6) as the mobile phase. By this means the two pure, and PS cytostatic, substances cephalostatins 14 (**5***a*) and 15 (**5***b*) were isolated from fractions T and S, respectively. *Cephalostatin 14* (**5***a*) (32 mg, 7.1×10^{-6}% yield, ED_{50} 0.0041 μg/mL): mp >300°C, $[\alpha]_D$ +80.9 (*c* 0.11, CH_3OH); TLC: R_f 0.12 (SiO_2, solvent: hexane–$CHCl_3$–CH_3OH, 11:9:2); UV (CH_3OH log ε) λ: 305 (shoulder), 288 (3.96), 230 (3.69) nm; IR (KBr) *ν*: 3418, 2928, 1674, 1449, 1400, 1233, 1101, 1057, 995, 949, 901 cm^{-1}; and HRFABMS, *m/z* $[M + Na]^+$, calcd. for $C_{54}H_{72}N_2O_{12}Na$: 963.4983; found: 963.4974. *Cephalostatin 15* (**5***b*) (5.2 mg, 1.2×10^{-6}% yield, ED_{50} 0.025 μg/mL): mp >300°C; $[\alpha]_D$ +71.5 (*c* 0.34, CH_3OH); TLC: R_f 0.15 (SiO_2, solvent: hexane–$CHCl_3$–CH_3OH, 11:9:2); UV (CH_3OH log ε) λ: 305 (shoulder), 288 (3.96), 228 (shoulder), 202 (4.25) nm; IR (KBr) *ν*: 3439, 2924, 1674, 1451, 1400, 1171, 1101, 1049, 941, 889 cm^{-1}; HRFABMS, *m/z* $[M + H]^+$, calcd. for $C_{55}H_{75}N_2O_{12}$: 955.5320; found: 955.5318. The ^1H and ^{13}C NMR assignments and the ^1H–^{13}C long-range correlations from the HMBC experiments have been recorded in Tables 1 and 3 (2). The nOe correlations from the ROESY experiments are shown in Tables 2 and 4.

A comparison of nickel boride and Raney nickel electrode activity in the electrocatalytic hydrogenation of phenanthrene

BEHZAD MAHDAVI, PRZEMYSLAW LOS, MARIE JOSÉE LESSARD, AND JEAN LESSARD[1]

Centre de recherche en électrochimie et électrocatalyse, Département de chimie, Université de Sherbrooke, Sherbrooke, QC J1K 2R1, Canada

Received July 14, 1994

BEHZAD MAHDAVI, PRZEMYSLAW LOS, MARIE JOSÉE LESSARD, and JEAN LESSARD. Can. J. Chem. **72**, 2268 (1994).

The electrocatalytic activity of nickel boride in the electrocatalytic hydrogenation (ECH) of phenanthrene in ethylene glycol – water at 80°C has been compared to that of Raney nickel and fractal nickel. The intrinsic activity of the electrode material (*real electrode activity*) is the same for nickel boride and Raney nickel electrodes and is lower for fractal nickel electrodes. The *apparent electrode activity* of nickel boride pressed powder electrodes (Ni_2B electrodes) is less than that of codeposited Raney nickel (RaNi) electrodes and pressed powder fractal nickel/Raney nickel (Ni/RaNi = 50/50 to 0/100) electrodes. The apparent activity of Ni_2B electrodes is improved by adding sodium chloride to the powder and dissolving it after pressing (Ni_2B–NaCl electrodes). The Ni_2B–NaCl electrodes have the same apparent activity as codeposited RaNi and pressed powder Ni/RaNi (20/80 to 0/100) electrodes. The apparent and real electrode activity of Ni/RaNi electrodes increases with the RaNi content up to a 20/80 ratio. The Tafel and alternating current (ac) impedance parameters were determined for the hydrogen evolution reaction (HER) in 1 M aqueous sodium hydroxide at 25°C at nickel boride and at codeposited RaNi electrodes. The intrinsic electrocatalytic activity for HER, expressed by the ratio of the exchange current density over the roughness factor (I_0/R), is similar for Ni_2B, Ni_2B–NaCl, and codeposited RaNi electrodes. Surface characterization of Ni_2B and Ni_2B–NaCl electrodes was carried out by BET, ac impedance, scanning electron microscopy, and mercury porosimetry. No direct relation between the apparent electrode activity in ECH and the surface measured by BET and ac impedance was found. The ac impedance measurements were also carried out in the presence of sodium *trans*-cinnamate.

BEHZAD MAHDAVI, PRZEMYSLAW LOS, MARIE JOSÉE LESSARD et JEAN LESSARD. Can. J. Chem. **72**, 2268 (1994).

L'activité électrocatalytique du borure de nickel est comparée à celle du nickel de Raney et du nickel fractal pour l'hydrogénation électrocatalytique (HEC) du phénanthrène dans le glycol d'éthylène – eau à 80°C. L'activité intrinsèque du matériau d'électrode (*activité réelle de l'électrode*) est la même pour le borure de nickel et le nickel de Raney et moindre pour le nickel fractal. *L'activité apparente* (activité de l'électrode) des électrodes de poudre de borure de nickel pressée (électrodes Ni_2B) est moindre que celle des électrodes de nickel de Raney (RaNi) codeposé et des électrodes de poudres de nickel fractal/nickel de Raney (Ni/RaNi = 50/50 à 0/100) pressées. L'activité apparente des électrodes Ni_2B est accrue par addition de chlorure de sodium à la poudre métallique puis dissolution de ce dernier après pressage (électrodes Ni_2B–NaCl). Les électrodes Ni_2B–NaCl ont la même activité apparente que les électrodes RaNi codéposé et les électrodes de poudre Ni/RaNi (20/80 à 0/100) pressées. L'activité apparente et l'activité réelle des électrodes Ni/RaNi croît avec la proportion de RaNi jusqu'à un rapport de 20/80. On a obtenu les paramètres de Tafel et d'impédance ac pour la réaction du dégagement d'hydrogène (RDH) en milieu hydroxyde de sodium aqueux 1 M à 25°C sur les électrodes de borure de nickel et les électrodes RaNi codeposé. L'activité électrocatalytique intrinsèque pour la RDH, exprimée par le rapport du courant d'échange sur le facteur de rugosité (I_0/R), est sensiblement la même pour les électrodes Ni_2B, Ni_2B–NaCl et RaNi codeposé. La surface des électrodes Ni_2B et Ni_2B–NaCl est caractérisée par BET, impédance ac, microscopie électronique à balayage et porosimétrie au mercure. Il n'y a pas de relations directes entre l'activité apparente en HEC et la surface mesurée par BET et impédance ac. Les mesures d'impédance ont aussi été effectuées en présence de *trans*-cinnamate de sodium.

Introduction

The electrocatalytic hydrogenation (ECH) of an unsaturated organic molecule in aqueous or mixed aqueous–organic media involves the mechanism described by reactions [1]–[4] where M represents the metallic surface, (H)M chemisorbed hydrogen, and (Y = Z)M the adsorbed organic substrate (1). The first step is the electroreduction of water (or hydronium ions) with the formation of adsorbed hydrogen on the electrode surface (Volmer reaction [1]), followed by reaction of the adsorbed substrate (Y = Z)M with chemisorbed hydrogen (reaction [3]). There is a competition between hydrogenation (reaction [3]) and the desorption of hydrogen by an electrochemical (Heyrovský reaction [5]) and (or) chemical (Tafel reaction [6]) pathway.

[1] $2H_2O(H_3O^+) + 2e^- + M \rightarrow 2\,(H)M + 2OH^-(H_2O)$

[2] $Y = Z + M \rightarrow (Y = Z)M$

[3] $(Y = Z)M + 2(H)M \rightarrow (YH\text{–}ZH)M$

[4] $(YH\text{–}ZH)M \rightarrow YH\text{–}ZH + M$

[5] $(H)M + H_2O + e^- \rightarrow H_2 + M + OH^-$

[6] $(H)M + (H)M \rightarrow H_2 + M$

The competition between ECH and the HER may also be represented as in Scheme 1. Since, in the ECH of organic substrates, the sole processes occurring are hydrogenation and hydrogen evolution (1), the current efficiency is a measure of the competition between the two reactions. This competition depends on a number of factors such as the substrate, the reaction conditions, and the electrode (1). For a given substrate and given reaction conditions, the current efficiency for the ECH becomes, therefore, a measure of the electrode activity.

Using the ECH of phenanthrene (**1**) under given electrolysis conditions (see below), we have compared the activity of nickel

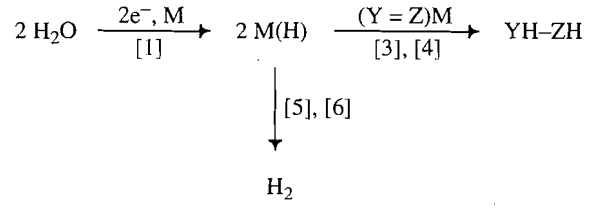

SCHEME 1

electrodes made of different nickel material (P-1 nickel boride, Raney nickel, and fractal nickel), and compared the activity of electrodes made of the same material but differing by the surface structure and surface area: unmodified (Ni_2B) and modified (Ni_2B–NaCl) nickel boride electrodes made of pressed P-1 nickel boride powder (NaCl being dissolved after pressing), codeposited Raney nickel (RaNi) electrodes (1), and pressed RaNi powder electrodes. The effect of varying the relative proportion of the fractal nickel (Ni) and RaNi on the activity of pressed Ni/RaNi electrodes was also investigated. The results reported in this paper show that the current efficiency and the conversion rate reflect the *apparent activity* of the electrode for the ECH of **1** in the specified electrolysis conditions and that the apparent activity depends on the electrode material and, for a given material, on the surface structure and surface area of the electrode as determined by mercury porosimetry, BET, and ac impedance measurements. The results also show that the ratio of the yield of the most highly hydrogenated products, octahydrophenanthrenes (octa-as **4** + octa-s **5** = Σ octahydrophenanthrenes) to the conversion rate, defined as coefficient β_{oct}, represents the intrinsic or *real activity* of the electrode material for the ECH of **1** under the specified electrolysis conditions. The intrinsic electrocatalytic activity of Ni_2B, Ni_2B–NaCl, and codeposited RaNi electrodes in the hydrogen evolution reaction (HER) in 1 M aqueous sodium hydroxide at 25°C, as expressed by the ratio I_0/R of the exchange current density I_0 (obtained from Tafel curves) to the roughness factor R (obtained by ac impedance measurements), was also determined, together with the influence of sodium *trans*-cinnamate, a water-soluble unsaturated organic substrate, which is electrohydrogenated by ECH, on the double layer capacity of these electrodes.

Experimental

Electrolyses

A two-compartment glass H-cell with a jacketed cathodic compartment (volume of each compartment 25 mL) having a Nafion-324 (E.I. du Pont de Nemours & Co) membrane (1.8 cm^2) as separator was connected to a Haake D8 constant temperature circulating bath filled with ethylene glycol. The counter electrode was a glassy carbon plate (≈12 cm^2) and the electrolyses were carried out with a 410 potentiostatic controller, 640 digital coulometer, and 2830 digital multimeter (Electrosynthesis Company). Phenanthrene (224 μmol, 9 mM solution) was dissolved in a stock solution (25 mL) of sodium chloride (0.1 M) and boric acid (0.1 M) in ethylene glycol – water (24:1 v/v) by stirring and heating slightly on a hot plate. The solution was then poured into the cathodic compartment. The anodic compartment was filled with the above stock solution (25 mL) of sodium chloride and boric acid. The cathodic compartment was heated to 80°C while deaerated (N_2), the cathode and the counter electrode were immersed and a constant current of 16 mM (J = 250 mA/dm^2) was applied. The cathodic solution was stirred magnetically. Aliquots (0.2 mL) were extracted with ether after the addition of a saturated NaCl solution (1 mL) and analyzed by vapour phase chromatography (vpc). The products were identified by comparison of retention times with those of authentic samples. The same system and method were used for the ECH of *trans*-cinnamic acid (448 μmol, 18 mM solution) in 25 mL of a 1 M aqueous solution of sodium hydroxide at room temperature. Aliquots were acidified before extraction with ether.

Electrodes

P-1 nickel boride (Ni_2B) was obtained by reduction of nickel acetate with sodium borohydride in an aqueous solution containing sodium hydroxide. It was prepared by following, with slight modifications, a procedure already described (2): 300 mL of an aqueous solution of sodium borohydride and sodium hydroxide was added to 1000 mL of the nickel acetate solution over a 3 h period. The product of the reaction (a black porous precipitate) was filtered on a fritted glass funnel with suction (water pump), washed with absolute ethanol, and dried at 50°C. The X-ray diffraction spectrum was identical to that reported for amorphous Ni_2B (2, 3–6). The particles had a spherical shape with an average diameter approximately equal to 0.5 μm according to scanning electron microscopy (SEM). The electrodes were obtained by pressing the particles at p = 800 or 400 MPa at room temperature. Nickel boride – sodium chloride (Ni_2B–NaCl) electrodes were prepared in two ways. One was to first put 0.3 g of NaCl in the mold, add 1.7 or 3 g of nickel boride powder, and then put 0.3 g of NaCl on top of the nickel boride powder. The other way was to first mix 3 g of nickel boride powder with 4.5–7 g of crystalline NaCl (BDH Company), then add 0.3 g of NaCl in the mold, add the mixture of nickel boride and NaCl, and add 0.3 g of NaCl on top. The mixing of nickel boride with NaCl was made in two ways: (*i*) mechanical mixing of the nickel boride particles with NaCl crystals (Ni_2B–NaCl(b-solid/s)); (*ii*) nickel boride particles suspended in an aqueous solution of NaCl and evaporation of the water under reduced pressure (Ni_2B–NaCl(b-solution/s)). After pressing, the Ni_2B–NaCl precursory electrode was immersed for 10 min in water to completely dissolve the sodium chloride at the surface and partly dissolve (2–2.5 g) the sodium chloride within the electrode disc. The geometric surface area of the electrodes was 2π cm^2 according to the diameter of the pressed fixed piston (2 cm). The codeposited Raney nickel electrodes consisted of Raney Ni particles dispersed in a nickel matrix, had a geometric area of 6.4 cm^2, and were prepared according to the previously described method (1). The nickel/Raney nickel pressed powder (Ni/RaNi) electrodes were prepared by pressing a mixture of fractal powder with Raney nickel alloy powder (Aldrich Company) at p = 800 MPa and room temperature. The pressed powder electrodes containing RaNi were activated by leaching in 10% aqueous NaOH for 3 h at 50°C.

Alternating current impedance measurements

Tafel and ac impedance measurements were carried out using systems and procedures analogous to those used in refs. 4 and 7–12, and using an ac amplitude of 5 mV peak-to-peak in 1 M aqueous sodium hydroxide in the absence and in the presence of *trans*-cinnamic acid, its concentration ranging from 9 to 90 mM.

Results and discussion

The ECH of phenanthrene (**1**) at unmodified (Ni_2B) and modified (Ni_2B–NaCl) pressed nickel boride powder electrodes (see below), at codeposited Raney nickel (RaNi) electrodes, and at pressed fractal nickel/Raney nickel (Ni/RaNi) electrodes was carried out on 9 mM solutions under conditions reported by Robin et al. (1) to be the best for the ECH of **1** at codeposited RaNi electrodes: ethylene glycol containing 4% of water as solvent, a slightly acidic medium containing boric acid (0.1 M) as buffer, and sodium chloride (0.1 M) as supporting electrolyte, 80°C. Two types of nickel boride electrodes were investigated: unmodified electrodes made of pressed nickel boride powder (Ni_2B electrodes), and modified electrodes made of nickel boride powder pressed with sodium chloride followed by total or partial dissolution of the sodium chloride (Ni_2B–NaCl electrodes). Electrolyses were performed under steady current control (dc) and the charge passed was 300 C (14 moles of electrons

[a]Electrolysis conditions: 224 μmol of phenanthrene (9 mM solution); 0.1 M NaCl; 0.1 M H_3BO_3; T = 80°C; charged passed (Q) = 300 C (14 moles of electrons per mole of phenanthrene).

[b]The nickel boride electrodes were prepared by pressing the Ni_2B or Ni_2B–NaCl powder at p = 800 MPa (except for entry 2).

[c]The conversion rate and yield of products were determined by vpc analysis. The yields are based on converted phenanthrene (material balance >99%).

[d]For all Ni_2B–NaCl electrodes, NaCl was added both at the bottom (0.3 g) and at the top (0.3 g) of the powder layer before pressing and was dissolved afterwards by immersing electrodes in water. In entries 4, 5, and 6 the amount of NaCl mixed intimately into the Ni_2B powder is indicated. "Solid" means that the Ni_2B powder was mixed with crystalline NaCl. "Solution" means that the Ni_2B powder was suspended in an aqueous solution of NaCl followed by the evaporation of water under reduced pressure.

[e]β_{oct} = (**4** + **5**)/conversion rate.

[f]Three electrolyses were performed using three different electrodes prepared in the same way and the range of values obtained for the conversion rate, yield of products, current efficiency, and β_{oct} is indicated.

[g]See ref. 1. Geometric area: 6.4 cm^2; 0.27–0.49 g of precursory alloy (48–66% in the nickel matrix).

[h]Prepared by pressing the Raney alloy powder at p = 800 MPa, followed by leaching in 10% aqueous NaOH for 3 h at 50°C.

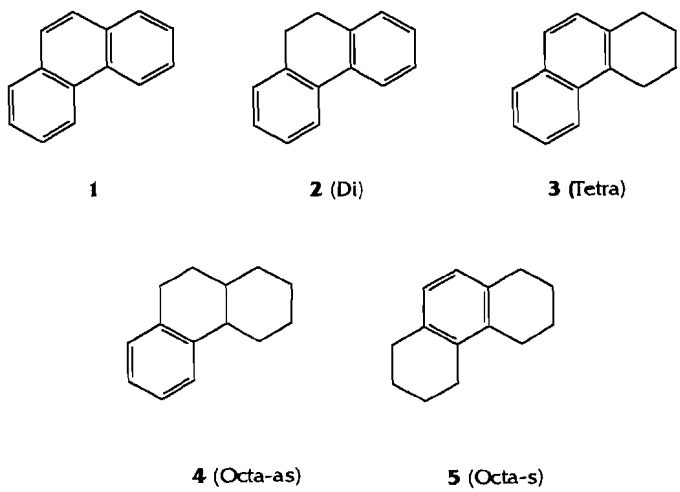

FIG. 1. The hydrogenated products of ECH of phenanthrene (**1**).

per mole of phenanthrene). The products formed were 9,10-dihydrophenanthrene (**2**), tetrahydrophenanthrene (**3**), and the octahydrophenanthrenes (octa-as **4** and octa-s **5**) (Fig. 1). The octahydrophenanthrenes are not electrohydrogenated under the above conditions (1) and therefore the maximum current efficiency for a charge corresponding to 14 moles of electrons per mole of **1** is 57%.

Nickel boride electrodes

The results of entries 2 and 3 of Table 1 show that Ni_2B electrodes pressed at 400 MPa (entry 2) have the same activity as electrodes pressed at 800 MPa (entry 3). A comparison of the results of entry 1 with those of entries 2 and 3 demonstrates clearly that increasing the amount of Ni_2B in a Ni_2B electrode by a factor 1.8 has no effect on the conversion rate and the current efficiency. This shows that the electrocatalytic hydrogenation takes place only at the surface of the electrode disc. With the aim of increasing the active surface area of the electrode, Ni_2B–NaCl electrodes were prepared by adding sodium chloride to the Ni_2B powder before pressing, then removing NaCl totally or partly from the precursory electrode disc to obtain the actual electrodes (see the Experimental). Two types of Ni_2B–NaCl electrodes were used: Ni_2B–NaCl(s) electrodes for which NaCl was present only at the surface of the precursory electrode (see entry 4); Ni_2B–NaCl(bs) electrodes for which NaCl was present both within the bulk and at the surface of the precursory electrode (see entries 5–7). It is clear from a comparison of the results of entries 4–7 with those of entries 1 and 3 that the activity of the Ni_2B–NaCl electrodes is higher than that of the Ni_2B electrodes, as shown by the higher conversion rates and better current efficiencies in entries 4–7. Furthermore, the activity of a Ni_2B–NaCl(bs) electrode is better than that of a Ni_2B–NaCl(s) electrode: higher conversion rates (78–84%) and better current efficiencies (35–37%) in entries 5 and 6 than in entry 4 (53–56% and 24–25%, respectively). However, Ni_2B–NaCl(bs) electrodes are mechanically less stable than Ni_2B–NaCl(s) electrodes. It was noticed that the Ni_2B–NaCl(b-solution/s) electrodes prepared by suspending the Ni_2B powder in a NaCl solution and evaporating water (entry 7) had a better mechanical stability than Ni_2B–NaCl(b-solid/s) electrodes prepared by mixing the Ni_2B powder with crystalline NaCl (entries 5 and 6), but the activity of the latter was slightly higher. Therefore, for the same amount of catalytic material and for the same geometric surface area, it is possible to increase the conversion rate and current efficiency (*apparent activity* of the electrode) with a simple modification in electrode design: adding sodium chloride before pressing the nickel boride powder and dissolving it afterwards. Clearly, this modification in electrode design has led to a change in surface area and (or) in surface structure that favors the ECH process over the HER. As can be seen from Table 1, the coefficient β_{oct} (ratio of the yield of octahydrophenanthrenes (**4** + **5**) to the conversion rate) determined at a

charge of 300 C (14 moles of electrons per mole of phenanthrene) is constant from entry 1 to entry 7 and equal to about 0.56. This ratio in thus independent of the surface area and surface structure. It depends only on the nature of the catalytic material and represents the intrinsic activity of P-1 nickel boride for the ECH of phenanthrene under the electrolysis conditions used. It can therefore be utilized to evaluate the *real activity* of any electrode material for the ECH of phenanthrene under given conditions.

Raney nickel electrodes

The results of the ECH of phenanthrene (**1**) at codeposited RaNi electrodes and at pressed powder RaNi electrodes presented in entries 8 and 9 of Table 1 show that the two types of Raney nickel electrodes have the same apparent activity. This means that they have very similar active surface requirements (see below) for the ECH of phenanthrene even though the leaching conditions are quite different. For the codeposited RaNi electrodes, leaching of the Raney alloy particles embedded in the nickel matrix was carried out in 30% aqueous NaOH for 7 h at 80°C (1) and, for the pressed powder RaNi electrodes, the pressed Raney alloy precursory electrodes were leached in 10% aqueous NaOH for 3 h at 50°C. In the pressed electrodes, it was necessary to use much milder leaching conditions in order to leach only the top layers of the disc and prevent the pressed particles from falling apart. X-ray fluorescence shows that the amount of aluminium left in the top layers of a pressed electrode is about 6% compared to 1% in a codeposited RaNi electrode. As expected, the two types of electrodes made of the same material, Raney nickel, have the same real activity, as seen from the β_{oct} value (average value 0.55–0.57). Interestingly, P-1 nickel boride and Raney nickel have the same intrinsic (real) activity for the ECH of phenanthrene under the electrolysis conditions used (same average β_{oct} value of 0.56, compare entries 1–7 with entries 8 and 9, respectively). The apparent activity of the Raney nickel electrodes (entries 8 and 9) is the same as that of Ni_2B–NaCl(b-solid/s) electrodes (entries 5 and 6) for which NaCl crystals were both intimately mixed within the nickel boride powder and present at the surface of the disc before its dissolution (see the Experimental). From the results of Table 1, it is clear that the apparent electrode activity for the ECH process does not depend only on the intrinsic activity of the electrode material and, therefore, a direct evaluation of the intrinsic activity of different electrode materials for the ECH of organic substrates cannot always be made from the apparent electrode activity. For instance, the nickel boride electrodes of entries 1–3 (Ni_2B unmodified electrodes) are clearly less active than Raney nickel electrodes (entries 8 and 9) for the ECH of phenanthrene although both P-1 nickel boride and Raney nickel have the same intrinsic activity.

Table 2 reports on the comparison of the apparent and real activity, for the ECH of phenanthrene, of pressed fractal nickel electrodes (entry 1) and pressed Raney nickel electrodes (entry 7), and on the effect of mixing fractal nickel particles with Raney particles in various proportions on these activities (entries 2–6). Clearly, fractal nickel (β_{oct} = 0.25, entry 1) is a less active electrode material (real electrode activity) than Raney nickel (β_{oct} = 0.55, entry 7). As a result, the apparent activity of fractal nickel electrodes is much lower (much smaller conversion rates and current efficiencies) than that of Raney nickel electrodes. For the Ni/RaNi electrodes (entries 2–6), as the proportion of Raney nickel is increased (decreasing Ni/RaNi ratio), the real activity and thus the apparent activity increase until the proportion of RaNi reaches 80% (entry 4). At this point, the Ni/RaNi (20/80) electrodes have the same activity (real and apparent) as the 100% RaNi electrodes (entry 7). The activity for ECH is related to the competition between hydrogenation (eq. [3]) and hydrogen evolution (eq. [4] and (or) [5]), as already mentioned (see Scheme 1 also), and for a Ni/RaNi ratio of 20/80 the influence of Ni is too small to be detected within the experimental error. The ECH of phenanthrene on Ni/RaNi electrodes confirms that β_{oct} does reflect the activity of the catalytic material, since the β_{oct} value varies between that of a 100% fractal Ni electrode and that of a 100% RaNi electrode as the Ni/RaNi ratio decreases.

phenanthrene, we determined their intrinsic activity and their real surface for the HER in 1 M NaOH at 25°C using Tafel plots and ac impedance measurements (4, 7–12). Such studies could not be carried out on the pressed RaNi electrodes because of the continuous leaching of the Raney alloy particles inside the disc during the experiments, causing the particles to fall apart. For the determination of the double layer capacity (C_{dl}) by ac impedance, the CPE model was used (eqs. [7] and [8] (13) where ω is the angular frequency of the ac signal, T is a constant, ϕ is the phase angle related to the surface roughness, R_s is the solution resistance, and parameter A is equal to $1/R_{ct}$ where R_{ct} is the charge transfer resistance (4, 7–12, 14)). For an ideally flat electrode, ϕ is equal to 1 and thus T is equal to C_{dl}. The roughness factor R was estimated from the experimental values of the capacity of the double layer divided by 27.9 $\mu F/cm^2$, the capacity of a platinum smooth surface (15).

$$[7] \quad Z_{CPE} = 1/T(j\omega)^{\phi}$$

$$[8] \quad T = C_{dl}^{\phi}(R_s^{-1} + A)^{(1-\phi)}$$

Figure 2 shows the dependency of ϕ on the overpotential (η)

[d]Mean values obtained from the experimental C_{dl} values measured at different overpotentials (see Fig. 3).
[e]Real current density.

for different nickel boride electrodes. The ϕ value is the highest (0.83) for an electrode of Ni_2B powder pressed at 800 MPa. It is smaller for an electrode of Ni_2B powder pressed at 400 MPa (ϕ = 0.68) and also for the Ni_2B–NaCl electrodes (ϕ = 0.65–0.75). Thus, the latter electrodes behave more like the limiting case of a true porous electrode for which ϕ is equal to 0.5 (11). The mean ϕ value for a codeposited RaNi electrode is 0.75. In Fig. 3, the decrease of C_{dl} with η for the various nickel boride electrodes used in Table 1 is shown. For the codeposited RaNi electrodes C_{dl} also decreases with η (16). This decrease is due to hydrogen bubbles formed on the surface (17). The roughness factors R presented in Table 3 were estimated from the mean value of the experimental C_{dl} values measured at the different overpotentials (see Fig. 3). The codeposited RaNi electrodes have the highest R value and the various nickel boride electrodes have different R values. This will be discussed below (see *Surface studies*).

Based on the overpotential at 150 mA/cm^2 (η_{150}), the electrocatalytic activity of the nickel boride and codeposited RaNi electrodes for the HER in 1 M aqueous NaOH at 25°C decreases in the order: Ni_2B–NaCl(s) (η_{150} = 165 mV, entry 3) > codeposited RaNi (η_{150} = 175 mV, entry 6) > Ni_2B (unmodified) (η_{150} = 182–183 mV, entries 1 and 2) > Ni_2B–NaCl(bs) (η_{150} = 203–207 mV, entries 4 and 5). The decreasing order of apparent activity of these same electrodes for the ECH of phenanthrene in ethylene glycol at 80°C and pH 3–6 (see discussion above and Table 1) is as follows: codeposited RaNi (entry 8) ~ Ni_2B–NaCl(b-solid/s) (entries 5 and 6) > Ni_2B–NaCl(b-solution/s) (entry 7) > Ni_2B-NaCl(s) (entry 4) > Ni_2B (unmodified) (entries 1–3). Therefore there is no direct relation between the electrode activity in the ECH of phenanthrene under the conditions used and the electrode activity for the HER in aqueous alkali. It was likewise found that for RaNi and RaNiXY (XY = CoCr, CrMo, CrTi, CuCr, CuTi, and CrTi) electrodes, there was no direct relation between the activity of the electrodes in the two electrolytic processes: the most active electrode for the ECH of phenanthrene was the RaNi electrode, which was less active than the RaNiXY electrodes for the HER in alkaline solution.[2] Interestingly, the intrinsic electrocatalytic activity for the HER, expressed by the ratio of the exchange current density over the roughness factor (I_0/R), is of a similar order of magnitude ((2–4) $\times 10^{-7}$) for all the electrodes of Table 3 just as the real electrode activity of these same electrodes for the ECH of phenanthrene was the same (average β_{oct} value of 0.55–0.57, Table 1). This shows that the intrinsic activity for the HER is determined by the electrode material and not by the surface structure and the real surface area, as is the real activity in the ECH of phenanthrene (see above). It is coincidental that two different electrode materials, nickel boride and Raney nickel, give the same real electrode activity for the ECH of phenanthrene. For instance, RaNiXY electrodes have a lower real activity for the ECH of phenanthrene than RaNi electrodes.[2]

[c]Obtained from BET measurements and based on the mass of Ni_2B for Ni_2B–NaCl electrodes.
[d]Taken from Table 3, entries 1, 3, and 4.
[e]Obtained from mercury porosimetry measurements.

Two of the electrodes of Table 3, the Ni_2B (unmodified) (entries 1 and 2) and Ni_2B–NaCl(s) (entry 3) electrodes, have a negative (−30 mV) open circuit potential (o.c.p.) (obtained by extrapolating the low-current part of the Tafel curve to zero current) while the three others (entries 4–6) have an o.c.p. of 0 mV. A negative o.c.p. has been attributed to hydrogen absorption to form metal hydrides (4, 18).

Electrocatalytic activity and surface of nickel boride electrodes

We have shown above (see *Nickel boride electrodes*) that modifying the nickel boride electrodes made of pressed powder, by adding NaCl before pressing and dissolving it afterwards, caused an increase of the apparent activity for the ECH of phenanthrene (Table 1), and suggested that their improved activity was related to a change in surface area and (or) structure. To clarify this point, surface studies were carried out on nickel boride electrodes having different apparent activities for the ECH of phenanthrene by determination of the specific surface area using the BET method, by scanning electron microscopy (SEM), and by pore size measurements using mercury

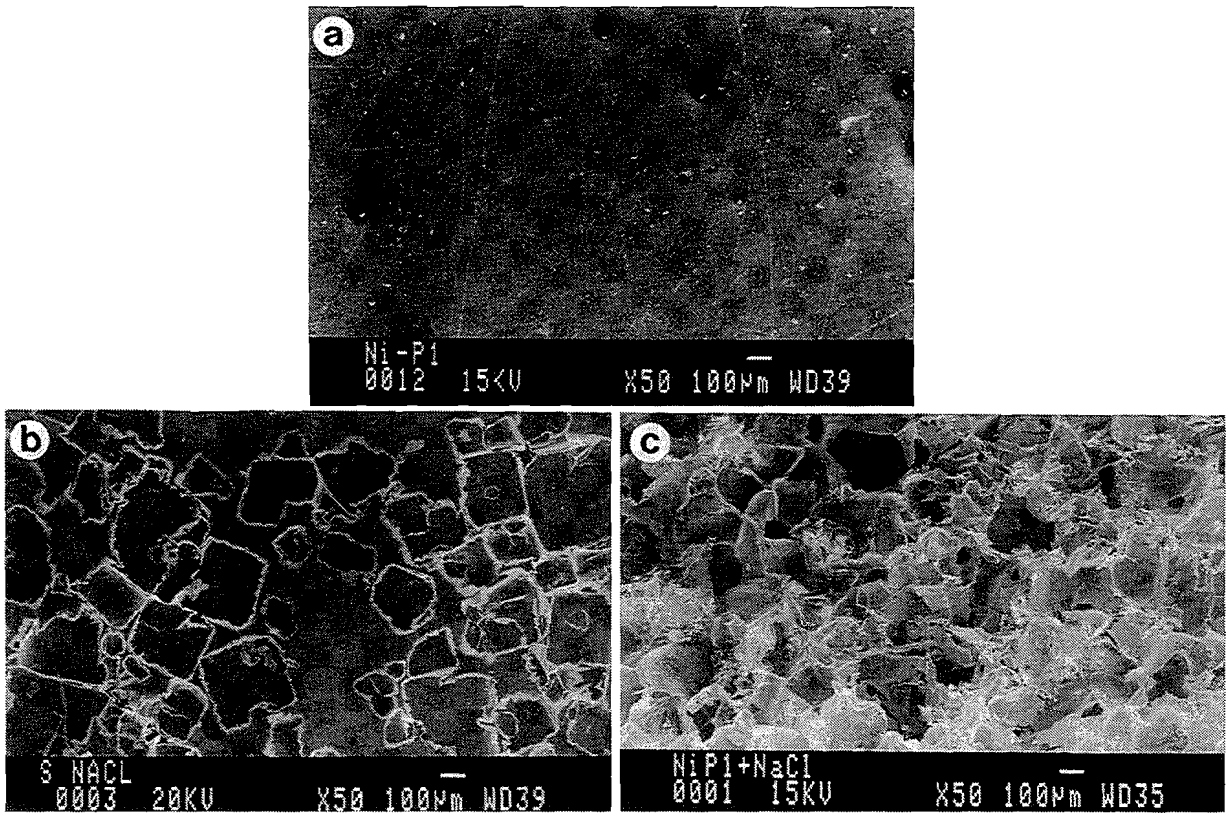

FIG. 4. SEM pictures of pressed nickel boride powder electrodes after removing NaCl: (*a*) Ni_2B; (*b*) Ni_2B–NaCl(s); (*c*) Ni_2B–NaCl(b-solid/s).

porosimetry. The data for Ni_2B, Ni_2B–NaCl(s), and Ni_2B–NaCl(b-solid/s) electrodes (order of increasing apparent activity) are collected in Table 4 (entries 1–3, respectively) together with the roughness factor (*R*) for the HER in alkaline medium. The SEM pictures are shown in Fig. 4.

The specific surface area of the pressed Ni_2B powder (entry 1) is exactly the same as that of the free powder (10 m^2/g), which means that pressing did not remove any site accessible to the nitrogen molecules. The specific surface area decreases slightly from the least active Ni_2B electrode (entry 1) to the most active Ni_2B–NaCl(b-solid/s) electrode (entry 3). So there is no direct correlation between the permeability to nitrogen molecules and the apparent activity for the ECH of phenanthrene. There is no direct correlation between the specific surface area and either the roughness factor or the electrocatalytic activity based on η_{150} for the HER in alkaline medium: the Ni_2B electrode with the largest specific surface area (entry 1) does not have the largest roughness factor and the highest electrocatalytic activity. One possible cause for the lack of correlation between the specific surface area and the activity in the electrocatalytic processes studied could be the difference in the nature of the interface: a gas–solid interface in the BET measurements and a solution–solid interface in the ECH process and the HER. Furthermore, the solid is polarized in the electrochemical processes. When comparing the two electrocatalytic processes, there is no direct correlation between the apparent electrode activity for the ECH process and the electrode activity for the HER, as already pointed out. The latter activity refers to the overpotential for the HER in aqueous alkali and the overpotential is determined by the rate of the slow step, which is the electrochemical desorption of chemisorbed hydrogen (Heyrovský step [5]) on nickel boride electrodes (4). The apparent activity for the ECH process refers to the competition between the hydrogenation step [3] and desorption of chemisorbed hydrogen (eqs. [5] and (or) [6]), that is, on the relative rates of reaction [3] and reactions [5] and (or) [6]. Since the hydrogenation step involves the reaction between the adsorbed organic substrate and chemisorbed hydrogen, accessibility of the sites for the adsorption of the former (mass transfer to the active sites) is bound to play a role in the ECH reaction (see below). Thus the surface requirements for the ECH reaction are expected to differ from those of the HER in which only chemisorbed hydrogen is involved. Therefore the most active electrode in the ECH process (the Ni_2B–NaCl(s-solid/s) electrode in this case) does not necessarily have to be the most active electrode in the HER under different electrolysis conditions, as experimentally found (the Ni_2B–NaCl(s) electrode is the most active in the HER).

There is good agreement between the SEM pictures (Fig. 4) and the size of the pores determined by mercury porosimetry. The Ni_2B and Ni_2B–NaCl(s) electrodes have pores of the same size (diameter of 0.012 µm, Table 4, entries 1 and 2) and appear to have the same compactness on the SEM pictures (Figs. 4*a* and 4*b*, respectively). In Fig. 4*b*, the prints left by the NaCl crystals after their dissolution are clearly seen and the surface in contact with solution should be larger in the case of the Ni_2B–NaCl(s) electrodes, and, indeed, the roughness factor of the latter electrode is larger (17 400 in entry 2 compared to 10 000 in entry 1 for the Ni_2B electrode). As result, the Ni_2B–NaCl(s) electrode is more active both for the ECH of phenanthrene (compare entry 4 with entries 1–3 of Table 1) and the HER in alkaline medium (lower η_{150} in entry 3 than in entries 1 and 2 of Table 3). The Ni_2B–NaCl(b-solid/s) electrodes resulting from intimate mixing of NaCl crystals within the nickel boride pow-

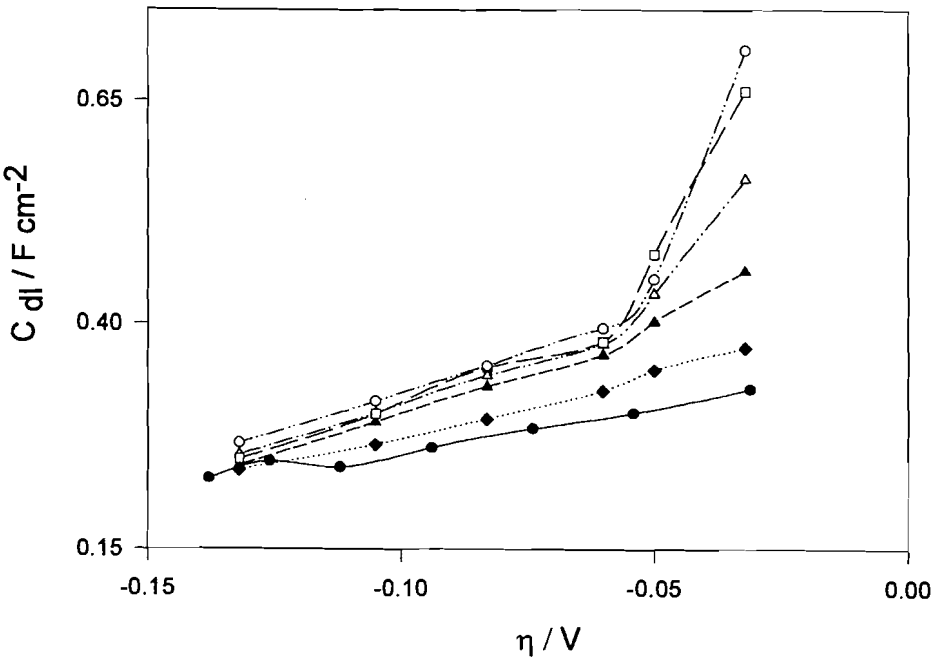

FIG. 5. Double layer capacities as a function of the overpotential and the *trans*-cinnamic acid concentration for a Ni_2B electrode in 1 M NaOH at 25°C: (●) C = 0 mM; (◆) C = 9 mM; (▲) C = 27 mM; (△) C = 45 mM; (□) C = 72 mM; (○) C = 90 mM.

der plus the addition of NaCl at the surface have much larger pores (Table 4, entry 3) than the two other electrodes (entries 1 and 2) and also appear quite different (much rougher) on the SEM picture (compare Fig. 4*c* with Figs. 4*a* and 4*b*). Surprisingly, the Ni_2B–NaCl(b-solid/s) electrode has also the same roughness factor (R = 9000) as a Ni_2B electrode (R = 9000–10 000) and is the least active (has the highest η_{150}) of the three electrodes of Table 3 for the HER. Thus, the solution–solid interface and the number of sites for the chemisorption of hydrogen are not increased in the less closely packed structure of a Ni_2B–NaCl(b-solid/s) electrode. However, the Ni_2B–NaCl(b-solid/s) electrode has the highest apparent activity of the three electrodes of Table 3 for the ECH of phenanthrene and this could be explained by a larger number of readily accessible sites for the adsorption of phenanthrene (ECH active sites) due to the larger pores. For probing the existence of more readily accessible adsorption sites for the organic substrate in the Ni_2B–NaCl(b-solid/s) electrode, we carried out ac impedance measurements on Ni_2B and Ni_2B–NaCl(b-solid/s) electrodes in the presence of sodium *trans*-cinnamate in 1 M NaOH at 25°C, after the work of Kam Cheong et al. (16). They found that C_{dl} of codeposited Raney electrodes in 1 M KOH at 25°C is increased in the presence of potassium *trans*-cinnamate, a water-soluble substrate that is electrohydrogenated by ECH, and attributed this increase to its adsorption on the electrode. According to their hypothesis, for a given concentration of sodium *trans*-cinnamate, the increase of C_{dl} should be more pronounced for an electrode having sites that are more readily accessible for the adsorption and hydrogenation of the organic substrate. And in agreement with this hypothesis, the maximum C_{dl} value at low overpotential (> −0.05 V, close to the o.c.p. obtained from the Tafel curves) (see Figs. 5 and 6) is reached at a lower concentration of sodium *trans*-cinnamate (C = 27 mM, Fig. 6) on a less closely packed Ni_2B–NaCl(b-solid/s) electrode, which should have more readily accessible sites for adsorption and hydrogenation of the organic substrate, than on a Ni_2B electrode (C = 90 mM, Fig. 5). The higher apparent activity of the former electrode would then be related to the accessibility of the ECH active sites and thus to the efficiency of the mass transfer of the organic substrate to these sites. It is interesting to note in Figs. 5 and 6 that the increase of C_{dl} with the concentration of sodium *trans*-cinnamate occurs only at low overpotentials. At these low overpotentials, the current density is about the same as that used for the ECH electrolyses. At higher overpotentials (η < −0.1 V), the HER predominates and bubbles of hydrogen cover the surface of the electrode; the presence and concentration of *trans*-cinnamate have little effect on C_{dl}. This suggests that at these potentials there is little adsorption of the organic substrate on the electrode surface because an effective mass transfer to the active sites is prevented by the bubbles of hydrogen covering the surface and (or) because at more cathodic potentials there is desorption of sodium *trans*-cinnamate. We emphasize the fact that a Ni_2B–NaCl(b-solid/s) electrode, which is more active than a Ni_2B electrode for the ECH of phenanthrene in ethylene glycol – water containing H_3BO_3 at 80°C (see Table 1), is also more active for the ECH of sodium *trans*-cinnamate in 1 M aqueous NaOH at 25°C as shown by the higher current efficiency and conversion rate in entry 2 of Table 5 than those in entry 1. Thus the electrodes show the same behaviour in these two ECH reactions despite the different conditions.

Conclusion

We have shown in this paper that the apparent electrode activity for the ECH of phenanthrene (as measured by the conversion rate, the yield of octahydrophenanthrenes, and the current efficiency) of nickel boride electrodes is increased by pressing the P-1 nickel boride powder with NaCl and dissolving it afterwards. This increase of activity does not correspond to an increase in the specific surface area measured by the BET method and does not correlate directly either with the roughness factor (obtained from ac impedance measurements on the HER in aqueous alkaline medium) or with the electrocatalytic activity for the HER in aqueous alkaline medium (based on the η_{150} value determined from Tafel curves). The fact that the increase of C_{dl} with the concentration of sodium *trans*-cinnamate, which is electrohydrogenated to sodium 3-phenylpropaonate in aque-

ous alkaline medium, was steeper (maximum C_{dl} reached at lower concentrations of cinnamate) for a more active electrode together with the pore size effect (larger pore diameter for the most active electrode as determined by mercury porosimetry and as confirmed by SEM) led to the conclusion that the apparent activity for the ECH of phenanthrene depends not only on the true area of the solution–solid interface but also the accessibility of the active sites, that is, on the mass transfer of the organic substrate to the active sites.

The ratio of the yield of octahydrophenanthrenes to the conversion rate (defined as β_{ocl}) was found to be independent of the true area of the solution–solid interface and the accessibility of the active sites since it is the same for all the nickel boride electrodes (modified and unmodified) investigated. It depends only on the electrode material and thus must represent the true or real electrode activity for the ECH of phenanthrene under given conditions. Similarly, the intrinsic activity for the HER in alkaline medium as measured by the ratio of exchange current density to the roughness factor (I_0/R) is the same for all nickel boride electrodes studied. It is noteworthy that nickel boride and Raney nickel electrodes have the same real activity for the ECH of phenanthrene and the same intrinsic activity for the HER in basic aqueous medium. Fractal nickel is much less active than Raney nickel as electrode material (real activity and apparent activity) for the ECH of phenanthrene and the activity of Ni/RaNi electrodes increases with the RaNi content up to a 20/80 ratio. With 20% of less fractal nickel, its influence on the activity of Ni/RaNi electrodes is not detected within the experimental errors.

Received June 10, 1994

AATTO LAAKSONEN AND HELENA KOVACS. Can. J. Chem. **72**, 2278 (1994).

Using molecular dynamics simulations, the motion and intermolecular interactions of the ions of silver nitrate are studied in aqueous solution and compared to the results obtained from simulations of molten $AgNO_3$. The particularly interesting and experimentally frequently studied modes of reorientational motion (*in-plane* and *end-over-end*) of the planar nitrate ion have been determined from the simulation results. In accordance with earlier experimental results, the correlation times for the *end-over-end* rotation in aqueous solution are longer than those for the *in-plane* rotation, while the opposite is found to hold in the melt. In addition, the rotational motion of the nitrate ion in aqueous solution is experimentally studied using ^{14}N relaxation measurements. Good agreement is found between the reorientational correlation times obtained from MD simulations and from NMR relaxation measurements.

AATTO LAAKSONEN ET HELENA KOVACS. Can. J. Chem. **72**, 2278 (1994).

Utilisant des simulations de dynamique moléculaire, on a étudié le mouvement et les interactions intermoléculaires des ions du nitrate d'argent en solution aqueuse et on a comparé les résultats à ceux obtenus à partir de simulations de $AgHO_3$ fondu. Sur la base des résultats de simulation, on a déterminé les modes particulièrement intéressants et les plus fréquemment étudiés expérimentalement du mouvement de réorientation (*dans le plan* et *bout sur bout*) de l'ion de nitrate d'argent. En accord avec les résultats expérimentaux antérieurs, les temps de corrélation de la rotation *bout sur bout* en solution aqueuse sont plus longs que ceux de la rotation *dans le plan* alors que l'on observe l'inverse dans le sel fondu. De plus, faisant appel à de mesures de relaxation du ^{14}N, on a étudié expérimentalement le mouvement de rotation de l'ion nitrate en solution aqueuse. On a trouvé un bon accord entre les temps de corrélation de réorientation obtenus à partir de simulations de dynamique moléculaire et des mesures de relaxation en RMN.

1. Introduction

Anion solvation is very different from cation solvation, particularly in the case of molecular anions. Ionic motion and interactions in aqueous nitrate solutions have attracted the interest of several spectroscopic groups since the late sixties. These studies include IR, Raman, depolarized Rayleigh scattering and NMR techniques (1–17). In the earlier works the main concern was to find the origin of the behaviour of the $\nu_3(E')$ mode, which appears as a broad doublet in Raman and IR spectra (1–4). The unperturbed nitrate ion is trigonal planar with D_{3h} symmetry. Raman studies, even carried out at relatively low concentrations of nitrate ions, showed rather clear evidence of a perturbation ($D_{3h} \rightarrow C_{2v}$), which was observed when the $E'(D_{3h})$ mode showed a tendency to split into A_1 and B_1 components (2). Because the Raman and IR spectra were not identical, it was first assumed that the nitrates were rotating in a cage of water molecules, giving rise to the perturbation. Lockwood later showed (3) through calculations of the spectra that the primary cause of the splitting of the ν_3 band were not the rotations, but rather the interactions with the local environments. This was also the conclusion of Findlay and Symons (4) who suggested that one or two hydrogen bonds between the nitrate and the water molecules were likely to cause the lowering of the symmetry. At higher salt concentrations, possible contact or solvent separated ion pairing between the nitrate and the cation could contribute to the perturbing effect. Apparently the nitrate ion is very sensitive to variations in solution environment and is therefore an ideal agent to study molecular ionic solutions.

In aqueous nitrate solution, strong hydrogen bonds are involved in vibrational and rotational–reorientational relaxation processes, which are responsible to the line broadening of the solution–state spectra (5–17). In addition, large effects are brought about by varying the temperature or the ion concentration. In general, vibrational correlation times decrease upon increasing ion concentration, while the opposite is true for the rotational correlation times. Particularly large effects are observed by varying the cation species. Highly polarizing cations with small ionic radii, such as, Li^+, Be^+, Be^{2+} or Mg^{2+} have a very large impact on the reorientational motion when the ion concentration is increased, while the effect is small, for example, for ammonium ion, because it can easily replace the water molecules while leaving the hydrogen bonding network intact.

Polarized Raman spectra can be used to obtain both the vibrational and reorientational contributions to the relaxation processes of polyatomic molecules in the liquid state. The isotropic line shape contains the pure vibrational motion of the molecule and its Fourier transform gives the vibrational correlation. The origin of the vibrational line broadening processes can be described either in terms of vibrational dephasing or energy relaxation between the vibrational states. The anisotropic spectra is a product of both vibrational and reorientational motion and it has to be first deconvoluted in order to separate the reorientational motion from the vibrational motion. This procedure is valid under assumption that cross-correlations between the reorientational and vibrational motions are negligible. In other

words the time scales of these motions should be sufficiently well separated.

NMR studies of rotational-reorientational motion, on the other hand, are free from cross-correlation effects. Also, because of the sensitivity of the method, it is possible to study more diluted solutions by using NMR, than by using IR or Raman spectroscopy (11, 13). However, the NMR method mainly gives the long time behaviour of the correlation functions, while the short time behaviour can be studied by Raman techniques through band analysis. Therefore, a combination of the Raman and NMR techniques should be a very powerful experimental method in studies of molecular motions in pure liquids and solutions.

In studying the reorientations of nitrates, two types of rotations are of particular interest: the *end-over-end* rotation of the three-fold symmetry axis (assuming the unperturbed nitrate) and the *in-plane* rotation of the vector perpendicular to the C_3-axis. The tumbling, *end-over-end* rotation (or the perpendicular mode) can be probed by Raman or ^{14}N NMR spin–lattice (T_1) measurements and the spinning, *in-plane* rotation around the C_3-axis (or the parallel mode) by ^{17}O NMR T_1 measurements. In general, the correlation time τ_2 for the perpendicular reorientational motion of planar symmetric molecules, of which benzene is one of the most thoroughly studied case (18–20), is observed to be longer than that for the parallel motion. This means that the rotation around the symmetry axis is less hindered than the rotation of the symmetry axis itself, since in the latter case the rotation involves displacement of the molecules in the solvation sphere. For the nitrates in aqueous solution, the opposite behaviour has been observed in previous studies. The *in-plane* rotations are found (11, 13) to be more hindered than the *end-over-end* rotations at any concentration (10). The strong hydrogen bonds between the nitrate oxygens and the water hydrogens are assumed be an important cause to this unusual behaviour (11, 13).

The pure inorganic nitrates form highly conducting liquids in melts. Many nitrates melt at sufficiently low temperatures so they can rather easily be used in spectroscopic studies. Fused nitrate salts have been extensively studied using spectroscopic techniques (21–42), X-ray and neutron diffraction measurements (43–46) and computer simulations (46–48). There are many similarities in the behaviour of nitrates in liquids (or even in crystals) and in solution and it is therefore useful to correlate results from both the liquid and solution state studies.

Silver nitrate is a particularly interesting molecule. As a solid, $AgNO_3$ is a colourless crystal which melts at 212°C. It is highly soluble in water and in many organic solvents. The crystal structure (49, 50) is found to be rather unusual with six nitrates forming a cavity for two silver atoms. The silver atoms are above the nitrate plane, off the C_3-axis. It has even been suggested that silver ions are found in molten salt (27) in the same locations as they are in concentrated aqueous solutions (51).

In the present work, we have carried out molecular dynamics (MD) computer simulations to study the motion and intermolecular interactions of the hydrated ions of $AgNO_3$ in aqueous solution. The main objective of our work is to investigate the rotational-reorientational motion of the planar anionic nitrate in some detail and especially investigate the role of hydrogen bonds to the rotational motion. We also carried out MD simulations of molten silver nitrate to correlate the behaviour of the ions in the melt with that in aqueous solution and to study the rotational motion without hydrogen bonds. The results from the simulation of molten salt provide a reference for a possible occurrence of ion-pairs in aqueous nitrate solution. The MD simulations of aqueous solution were combined with ^{14}N NMR relaxation measurements to obtain corresponding experimental information about the rotational correlation times. A similar study of $AgNO_3$ in acetonitrile and in water/acetonitrile mixture is in progress.

TABLE 1. Physical specification of the simulated systems

Density (g cm^{-3})	1.0	4.35	1.05

2. NMR measurements

Nitrogen-14 relaxation measurements were performed at 9.4 T on a Jeol GX 400 MHz NMR spectrometer at the concentration used in the MD simulation (see next section). The transverse relaxation rate for ^{14}N in NO_3^- was determined manually from the linewidths through the relationship: $T_2^{-1} = \pi\Delta\nu_{1/2}$. Assuming extremely narrowing conditions, the correlation time, τ_2, was calculated by using the following equation.

$$[1]\quad \frac{1}{T_1^Q} = \frac{1}{T_2^Q} = \frac{3}{10}\pi^2\frac{2I+3}{I^2(2I-1)}\chi^2\tau_2$$

Quadrupolar coupling constant, χ = 745 kHz was used for $^{14}NO_3^-$, which is a solid state value for $NaNO_3$ (52). Two measurements were recorded and the relaxation rate is taken as an average. The experimental uncertainty is estimated to 10%.

3. Physical models and computational methods

Constant volume (NVE) molecular dynamics simulations were carried out for $AgNO_3$ dissolved in water in 4:252 proportions. Also, both components, $AgNO_3$ and H_2O, were simulated as pure liquids to be used as references in the anlaysis of the results. A summary of the physical states and characteristic simulation parameters is given in Table 1. The pure water simulation is denoted by **I**, the $AgNO_3(l)$ simulation by **II**, and the mixture simulation by **III**.

Both molecular species, i.e. water and nitrate were kept rigid throughout the simulations and the equations of motions were solved using fifth order Nordsieck–Gear predictor–corrector integration scheme (53, 54). The rotational motion was treated using the second order quaternion scheme by Sonnenschein (55). The pair potentials of site–site (1–6–12) type are given in standard Lennard–Jones plus electrostatic form. The potential parameters for water (SPC) were taken from Berendsen et al. (56). For $AgNO_3$, we used standard epsilon values of ϵ(Ag) = 300 K, ϵ(N) = 37 K and ϵ(O) = 37 K, and sigmas σ(Ag) = 2.10 Å, σ(N) = 3.10 Å and σ(O) = 3.00 Å. The charge in units of $|e|$ are q(Ag) = 1.0, q(N) = 1.31, and q(O) = −0.77. The cross-interaction terms were constructed using the so-called Lorentz–Berthelot combination rules (57, 58). The long-range electrostatic interactions were treated using the Ewald summation techniques and the minimum image convention was used together with the periodic boundary conditions to maintain constant density and to prevent condensation at walls of the simulation cell (59). The simulations were extended to 70 ps for the

pure liquids (water and molten $AgNO_3$) and to 100 ps for the mixture. All simulations were performed using a modified version of McMoldyn package (60) on a Convex C220 computer.

4. Static and structural properties

4.1 Pair interaction energies

The pairwise interaction energies of the simulated systems are reported in Table 2. In get more information, the short-range Lennard-Jones and the long-range electrostatic contributions are separated. The total water–water interaction energies are −42.3 kJ/mol for pure water at 300 K. The corresponding value reported by Jorgensen et al. (61) is 42.6 kJ/mol for SPC water in their comparison of different water models at 25°C. The total potential energy for water in the mixture is −37.4 kJ/mol, which is considerably higher than for pure water. The water–Ag^+ and water–NO_3^- energies are of same magnitude, the electrostatic contributions being completely dominant. These are, in fact, an order of magnitude larger than the corresponding Lennard–Jones energies. The total ion–ion energy in the melt is −193.1 kJ/mol. In solution, the ion–ion interaction energies are vanishingly small, an indication of the ions being well dissolved and hydrated by water molecules. No ion-pairing effects or clustering is observed in the simulation of the aqueous solution.

4.2 Structural results

The solvent structure is disturbed by the presence of the solute particles. It is of particular interest to study how the hydrogen bonding network of liquid water is affected after dissolving salt into it. In our analysis, we have not differentiated between bulk and hydration water, Instead, we used pure water as reference. The ion concentration is high enough that most water molecules are involved in the hydration of Ag^+ and NO_3^- ions, making the differentiation meaningless.

Radial distribution functions (RDF) are convenient presentations of the simulated liquid structure. Water–water radial distribution functions are given in Fig. 1*a–c* of the pairs O–O, O–H, and H–H for pure water and for water in a mixture. Water in a mixture seemed more structured than pure water. Many monatomic ions tend to break the structure of the water surrounding them, thus are called structure breakers. Hydrophobic solutes tend to enhance the water structure exerting a structure-making effects on water. In the case of a mixture of silver cations and polyatomic nitrate anions, the solvation mechanism is an interplay of many different types of interactions; it is therefore difficult to rationalize in simple terms.

Figures 2*a* and *b* display the RDFs between the ion sites and water sites. Hydration number for Ag^+ is estimated to be between 0.3 to 4.0 (62, 63), depending on the method used in the estimation. Due to fast solvent exchanges at Ag^+, the signals from hydration and bulk water cannot be separated in the ^{17}O spectrum and no estimates of $n(Ag^+)$ are reported. The first, very sharp, peak of the simulated $g(r_{Ow—Ag})$, shown in Fig. 2*a*, contains 5.4 water-oxygens when integrated to the first minimum at 3.25 Å. The radial distribution function between the water-oxygen and the nitrate-nitrogen shows a maximum at 3.5 Å, indicating that water molecules do not closely coordinate to the nitrogen but rather to the oxygen. From the RDF curve we can calculate up to eight water molecules in the first hydration shell around the nitrate by integrating to the first minimum at 4.1 Å. Figure 2*b* shows the corresponding radial distribution functions between the water-hydrogen and the ion-atoms. Both water-hydrogens are found within the first maximum at 3.0 Å around the silver ion. The $g(r_{H—O})$ curve shows a very strong hydrogen bond structure with the first maximum at 1.75 Å followed by a broader second maximum due to the second water hydrogen, not involved in the hydrogen bond with the nitrate. The second maximum also contains a weaker subsidiary peak, corresponding to a pair between the hydrogen-bonded water hydrogen (responsible to the first maximum) and both the nearest neighbouring nitrate oxygens.

Figures 3*a–c* show the radial distribution functions for Ag–Ag, Ag–N, and Ag–O pairs, respectively, between the ions. Each figure contains the RDF curves for both the melt and the solution in a direct comparison. The small number of ions in the solution, however, gives rise to some statistical noise. It is immediately evident that there are no direct contacts between the bare ions in the simulated solution, as the first peaks found in the molten salts are absent in the solution. However, there is an evidence for weaker contacts for $Ag^+(aq)$–$Ag^+(aq)$ pairs (Fig. 3*a*) and $Ag^+(aq)$ with the oxygen sites in NO_3^- (Fig. 3*c*).

In the melt, the first peak for $g(r_{Ag—O})$ is found at 2.4 Å which is the same distance at that found by Yamaguchi et al. (45) from neutron diffraction of molten $AgNO_3$. The X-ray diffraction work by Holmberg and Johansson (44) for $AgNO_3(l)$ gives a Ag–O distance of 2.45 Å. It can be deduced from the radial distribution functions between the nitrate and silver ions that there are five Ag^+ ions around the nitrate in the first coordination sphere with a radius of 2.4–4.2 Å. Two of the Ag^+ ions give the first peak of $g(r_{Ag—N})$ curve in Fig. 3*b* at a distance of 3.7 Å, which can be assigned to the silver ions, one above and one below the plane. The remaining three are found at a distance of 2.4 Å from the nitrate oxygens (Fig 3*c*). The second maximum at 4.1 Å in $g(r_{Ag—O})$ is at the distance to the other oxygens in the same nitrate or to an oxygen in a neighbouring nitrate.

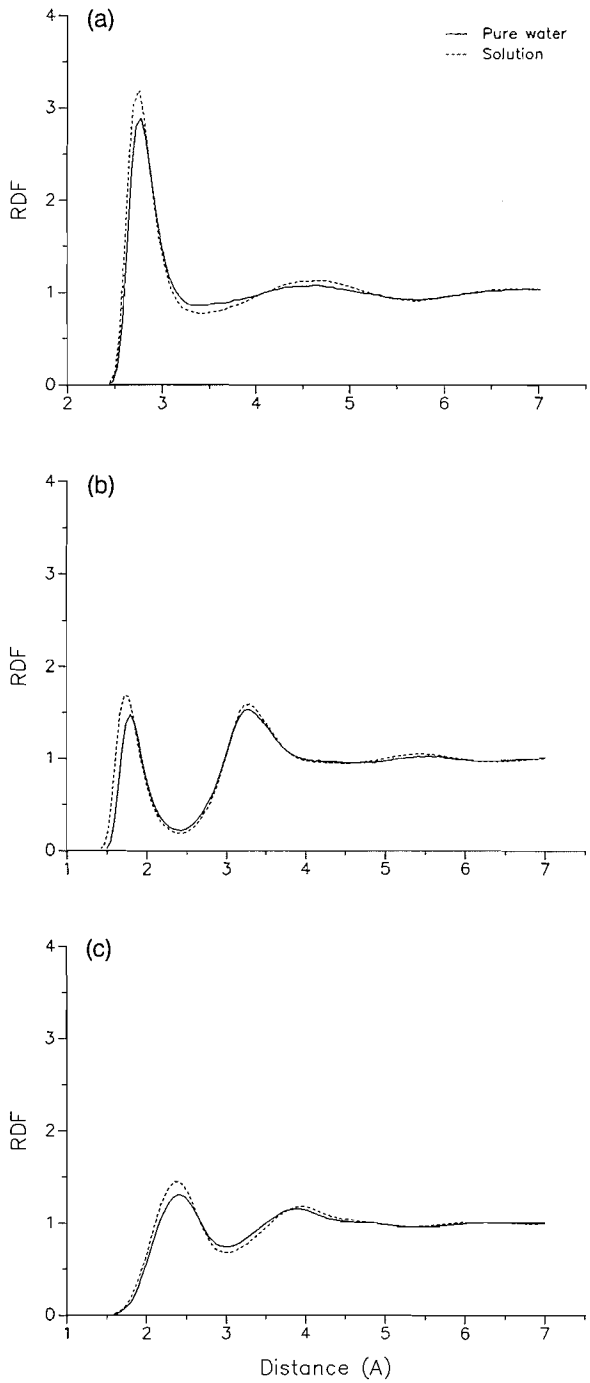

FIG. 1. Radial distribution functions for pure water and water in $AgNO_3$ solution. Oxygen–oxygen (*a*), oxygen–hydrogen (*b*) and hydrogen–hydrogen (*c*).

Figures 4*a–c* correspondingly show the structural pair correlations between the nitrate sites N—N, N—O, and O—O, respectively. In the solution there is hardly any structure to be observed between the nitrate sites, since they are strongly hydrated by the water. In the melt, all three figures show qualitatively the same features, the first peak being found between 3 and 4 Å. All the simulated ionic pair distribution functions in Figs 3 and 4 for the $AgNO_3$ melt are very similar to the ones obtained by Adya et al. (46) in their MD and X-ray work for $NaNO_3$(*k*).

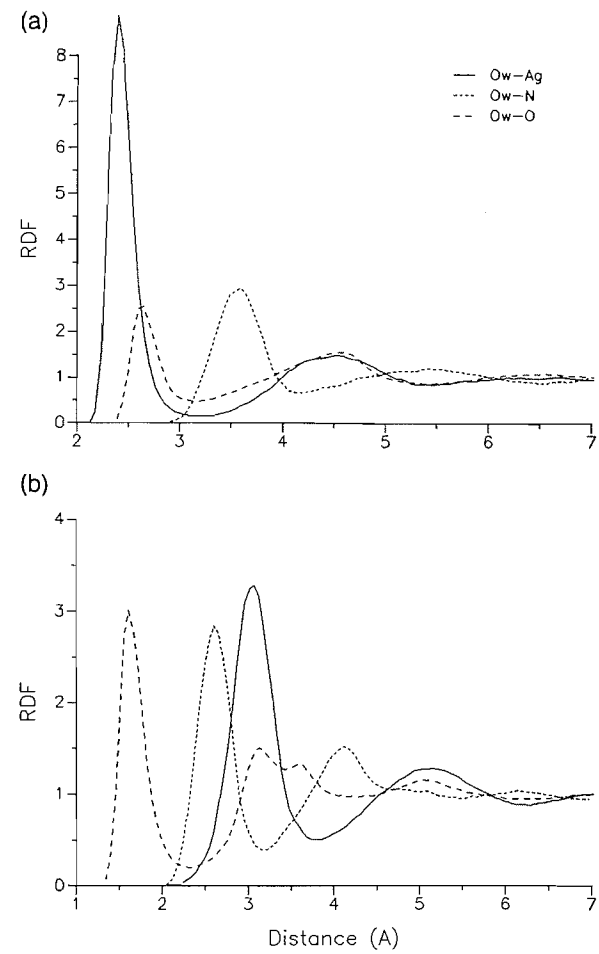

FIG. 2. Radial distribution functions between water oxygen (*a*)/ water hydrogen (*b*) and Ag, N, and O atoms, respectively.

5. Dynamic properties

5.1 Translational motion

The simulated translational diffusion coefficients for water and ions are given in Table 3. Diffusion coefficients are calculated from the translational velocity correlation times as:

$$[2] \quad D_v = \frac{kT}{M}\int_0^\infty \frac{\langle v(t)\ v(0)\rangle}{\langle v(0)\ v(0)\rangle}\,dt$$

The diffusion coefficient for pure water, 4.35×10^{-9} m^2 s^{-1}, obtained from the simulation, is close to the value of 4.4×10^{-9} m^2 s^{-1}, obtained by Teleman et al. (64) using the same water model. This value, however, is a factor of two larger than the experimental diffusion coefficient for pure water at room temperature, which is known to be a property of the SPC model.

In the presence of $AgNO_3$, the translational motion for water molecules is reduced by 20%. There is also a difference of 15° between the two simulations, the mixture simulated being carried out at the higher temperature of 315 K, thus the actual reduction should be more. According to the simulation results, both ions are more mobile in solution than in the melt, where the motion of the ions is hindered by the strong interionic interactions. In solution, the strongly hydrated Ag^+ ions (see Fig. 2) clearly follow water dynamics. At the same time, the mass effect of the hydrated ions slows down the average diffusion

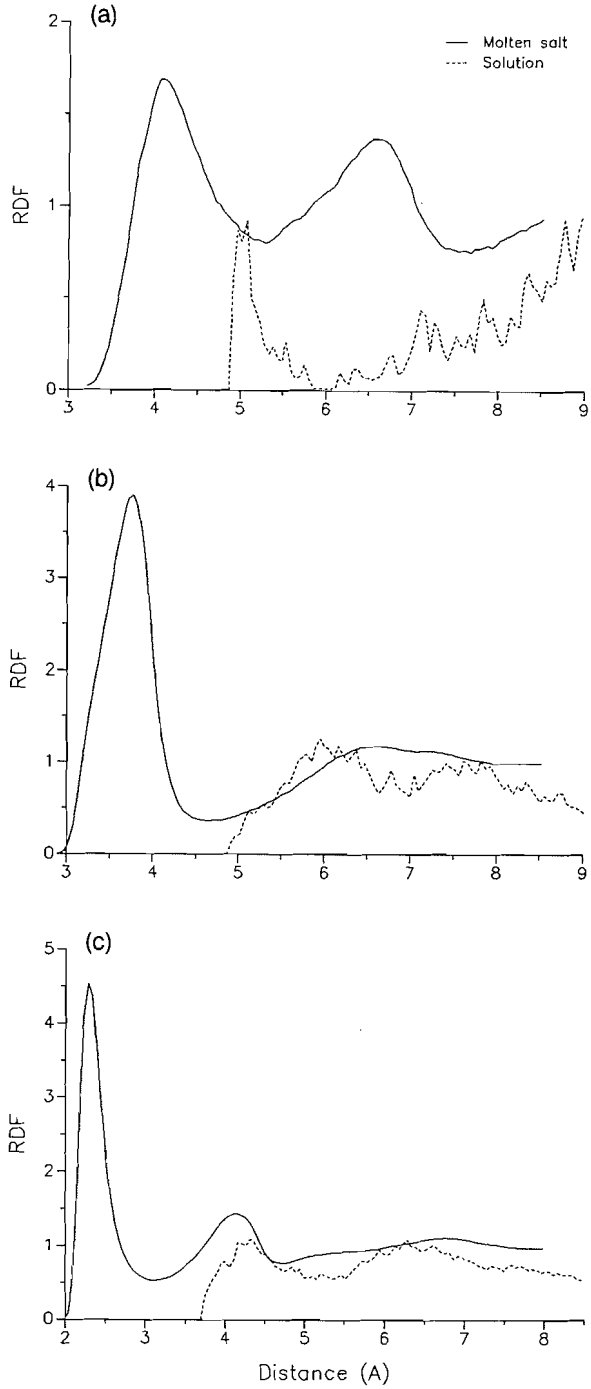

FIG. 3. Radial distribution functions $g(r_{Ag-X})$: X = Ag (*a*), X = N (middle) and X = O (*b*) in molten salt and in water solution.

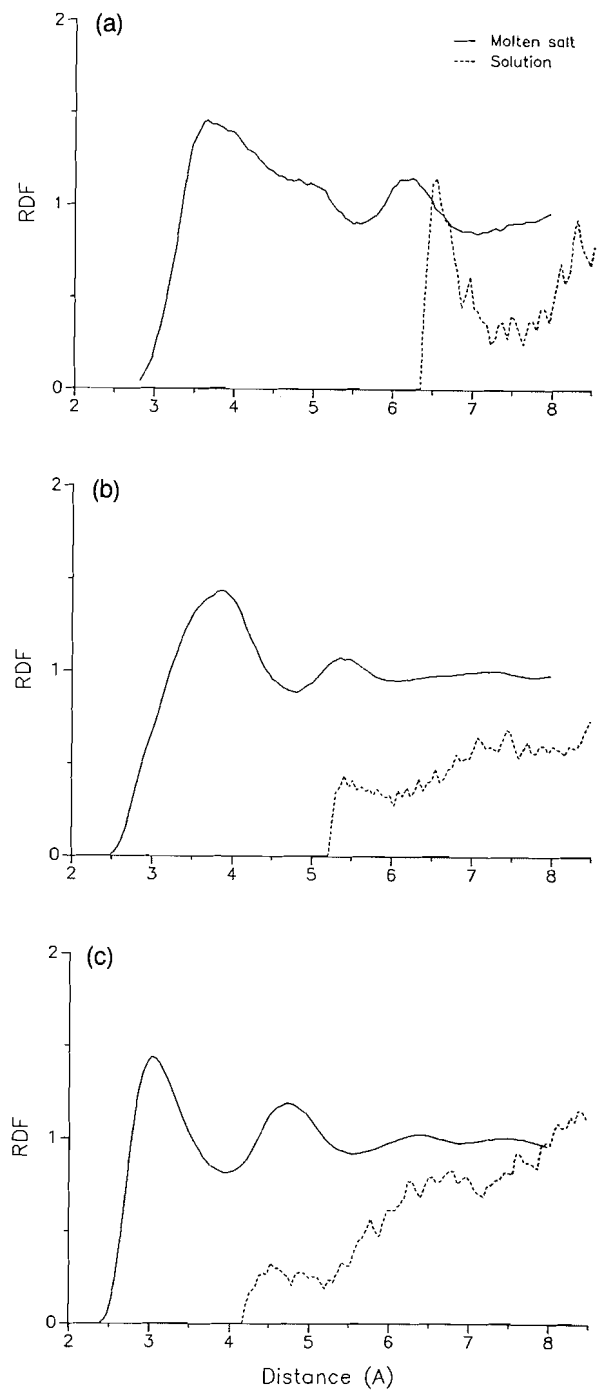

FIG. 4. Radial distribution functions: $g(r_{N-N})$ (*a*), $g(r_{N-O})$ (*b*), and $g(r_{O-O})$ (*c*) in molten salt and in water solution.

rate of the water. In the same way, the nitrate ions also follow the water dynamics, having approximately the same diffusion rate as the silver ions. The nitrates are hydrated by strong, long-living hydrogen bonds (see Fig. 2). The experimental values for the nitrate diffusion in the melt of $NaNO_3$ (1.48×10^{-9} m^2/s at 623 K) and for $LiNO_3$ (1.15×10^{-9} m^2/s at 620 K) are quoted in ref. 46 and 47, respectively. Our simulated result is 0.70×10^{-9} m^2/s at 595 K.

The velocity autocorrelation functions for (VACF) show very deep negative portions in the molten salt for both Ag^+ (Fig. 5) and NO_3^- (Figs 6*a* and *b*), which are missing in the solution curves. The anticorrelation in the VACF curves is an effect due to strong intermolecular interactions an ion or a molecule experiences in the solvation shell, making it bounce back and forth inside the cage. In solution the VACF curves show a distinct change in the decay rate after approximately 0.1 ps for the both ions, indicating a breakup of the water cage.

5.2 Rotational–reorientational motion

To study the reorientational motion of the molecules, we have placed a unit vector along the dipole axis of the water molecule and perpendicular to the molecular plane of the nitrate ion

TABLE 3. Diffusion coefficients (in 10^{-9} m^2 s^{-1})

Species	Diffusion coefficient		
	Run I	Run II	Run III
H_2O	4.35	—	3.5
Ag^+	—	0.7	2.4
NO_3^-	—	0.7	2.5

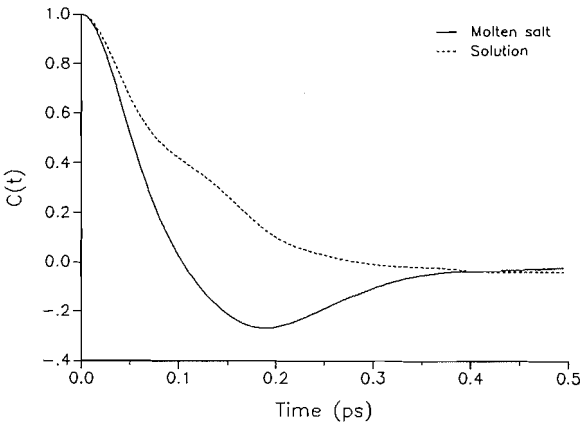

FIG. 5. Velocity autocorrelation functions for Ag^+ in molten salt and in water solution.

TABLE 4. Reorientational correlation times (in ps)

Parameter		Value		
		Run I	Run II	Run III
H_2O	τ_{10}	2.44	—	4.08
	τ_{20}	0.80	—	1.59
NO_3^- (*end-over-end*)	τ_{10}	—	15.5	6.15
	τ_{11}	—	14.5	8.50
	τ_{20}	—	5.15	1.85
	τ_{21}	—	5.00	2.10
	τ_{22}	—	5.00	3.00
NO^{3-} (*in-plane*)	τ_{10}	—	14.5	6.6
	τ_{20}	—	5.04	2.72

and calculated the normalized time correlation functions over the spherical harmonics:

$$[3] \quad C_{lm}(t) = \frac{\langle Y_{lm}(t)\ Y_{lm}(0)\rangle}{\langle Y_{lm}(0)\ Y_{lm}(0)\rangle}$$

The calculated correlation times, τ_{1m} and τ_{2m}, obtained after integrating over the area under the time correlation function $C_{lm}(t)$ in eq. [3], are gathered in Table 4.

Water: The reorientational motion of the water molecules is very much affected after dissolving the nitrate into the solution. The reorientational correlation times for water are nearly doubled, compared to the corresponding values for pure water. This is because a large part of the water molecules are involved in hydration, the rotational motion of these waters become more hindered. The reorientational motion in pure water appears to be more diffusional than in the solution. This can be seen from the ratio τ_1/τ_2, which is close to 3 in pure water while it deviates considerably from the diffusional behaviour in the solution.

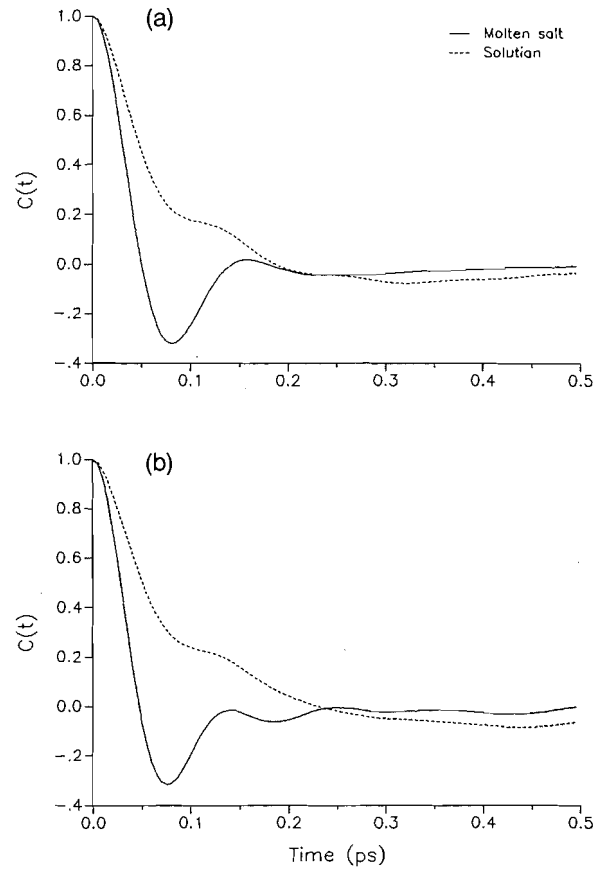

FIG. 6. Velocity autocorrelation functions for the nitrate ion in molten salt and in water solution. Parallel motion (*a*), perpendicular motion (*b*).

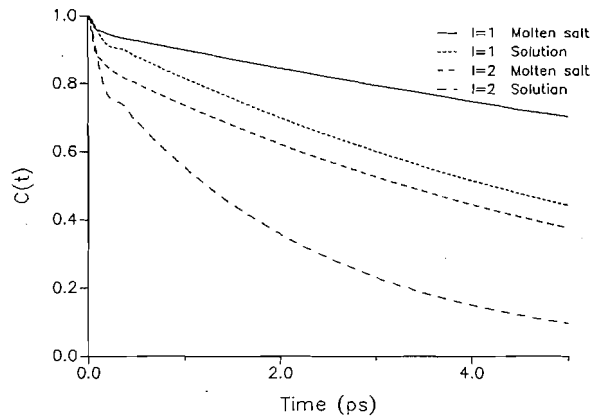

FIG. 7. Reorientational time correlation functions $C_{10}(t)$ and $C_{20}(t)$ for the nitrate ion in molten salt and in water solution.

Nitrate: The unit vector along the C_3-axis allows us to study the *end-over-end* orientations. In Fig. 7 are given normalized reorientational time correlation functions $C_{10}(t)$ and $C_{20}(t)$ for the tumbling motion of the symmetry axis both in solution and in liquid. The curves calculated from the solution data are characterized by the same behaviour typically observed in reorientational correlation functions for water. After a fast initial decay, and the rate always to indicate a pronounced librational motion because of extended hydrogen bonding. Note that this is not found in the corresponding curves from molten salt data. Fur-

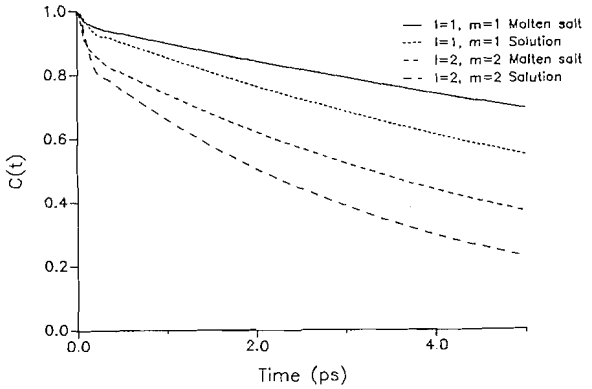

FIG. 8. Reorientational time correlation functions $C_{11}(t)$ and $C_{22}(t)$ for the nitrate ion in molten salt and in water solution.

thermore, the decay change appears at 0.1–0.2 ps, approximately the same time as the decay change for water, indicating that the librational motions of the nitrogens and the water molecules are coupled. Coupled rotation between water and nitrate in aqueous solutions in terms of a "cogwheel effect" has already been discussed by Whittle and Clarke (7) in their depolarized light scattering study of NO_3^- in water solutions. Kato et al. (6) have discussed the appearance and life time of the Gaussian initial decay in the rotational time correlation function, which was obtained from Fourier transformed Raman spectra for the reorientational motion of the symmetry axis. The initial short time behaviour ($t < 0.15$ ps) corresponds to jumps of about 17° on average. The effective moment of inertia for NO_3^- was found to be more than three times larger compared to that for a free nitrate, indicating strong water–nitrate interactions.

The nitrate ion is a symmetric top molecule. We can therefore obtain the $\tau^{(i)}10$ and $\tau^{(i)}20$ correlation times for the *in-plane* rotations using *end-over-end* correlation times τ_{1m} and the relationship (20):

$$[4] \quad \tau^{(i)}10 = \tau_{11} \text{ and } \tau^{(i)}20 = 0.25\tau_{20} + 0.75\tau_{22}$$

The reorientational time correlation functions $C_{11}(t)$ and $C_{22}(t)$ are calculated using eq. [3] and are given in Fig. 8. They have the same general behaviour as the curves in Fig. 7. The time correlation functions in Figs 7 and 8 are shown only to 5 ps, although they have been calculated up to 10 ps in the simulations.

While Raman spectra provide information on the perpendicular motion, the perpendicular mode can be studied by ^{14}N NMR and the parallel mode by ^{17}O relaxation. It can be mentioned that Nicholas and Wasylishen have reported a useful correlation between the ^{14}N and ^{17}O NMR relaxation data for the nitrate in aqueous solution (13). The reorientational motion of the nitrates and the anisotropy between the parallel and perpendicular motions have been observed to be very much dependent on the counterions present in the solution and the ion concentration (13, 14), but not so much dependent on the temperature (13). Nicholas and Wasylishen obtained a correlation time 0.94 ps for the perpendicular motion of a free nitrate (11, 13). Whittle and Clarke (7) reported a correlation time of 2.4 ps as the limiting value for the nitrate ion in aqueous solution from depolarized light scattering. Adachi et al. (15) have measured the limiting, cation-independent values by combining Raman and NMR techniques to be 1.25 and 1.9 ps for perpendicular and parallel motions, respectively, measured at 298 K in H_2O. In a subsequent study on solvent isotopic effects, the same authors report the corresponding values measured in D_2O to be 1.42 and 2.17 ps (16). Our corresponding simulated values obtained at 315 K are 1.85 and 2.72 ps. Our ^{14}N relaxation measurement for the perpendicular (*end-over-end*) motion at 315 K gives a correlation time of 1.61 ps, which is close to the simulated value. In solution or melt, the tumbling motion is more diffusive than the spinning motion, in accordance with the experimental findings based on the Lorentzian line shape obtained from Raman studies for the perpendicular mode. At high concentrations the line shape is found to become non-Lorentzian (7), an effect due to cation–anion interactions. In the melt the simulated *in-plane* correlation time is slightly shorter than the *end-over-end* correlation time. This is in agreement with the observation by Kato et al. (48) in their MD simulations of molten $LiNO_3$. For the *end-over-end* motion of nitrate ion in liquid $AgNO_3$, Kato and Takenaka reported a correlation time of 3.1 ps using Raman. Our corresponding simulated value is 5.15 ps.

Shen et al. (65) have recently calculated optimized hydrogen bond structures between a nitrate ion and a single water molecule at the SCF level using DZ + P basis sets. They found one C_{2v} complex in which one single water molecule has two simultaneous, rather bent hydrogen bonds, the energy of which was 2.6 kcal/mol lower than that in the conventional hydrogen bond. The simulated radial distribution functions (Fig. 2) do not show evidence of double hydrogen bonds. It should be remembered that the quantum mechanical calculations correspond to vacuum or low density gaseous conditions at 0 K. In aqueous solutions at room temperature the water molecule hydrogen bonded to the nitrate experiences concurrence from other water molecules in the close neighbourhood to form H bonds. Moreover, the thermal motion at finite temperature effectively decreases the lifetimes of the hydrogen bonds. In the calculations of Shen et al. (65), the water molecule in the double hydrogen bond had its HOH angle reduced to 99.3°. In the simulation, an equilibrium water geometry was used, where the HOH bond angle 104.5°. However, double hydrogen bonds are observed experimentally in several dimers and complexes and the calculations of Shen et al. clearly show how strong hydrogen bonds are between nitrate and water. Consequently the strong hydrogen bond coupling to water has a strong impact on the rotational motion of the nitrate and its unusual reversed anisotropy. More experimental and theoretical studies are needed to resolve the mechanism in detail.

Mixed alkali effect in $0.2[xKNO_3 + (1 - x)NaNO_3] + 0.8$glycerol systems

SEKH MAHIUDDIN[1]

Department of Chemistry, North Eastern Hill University, Bijni Complex, Laitumkhrah, Shillong-793003, India

Received October 25, 1993

SEKH MAHIUDDIN. Can. J. Chem. **72**, 2286 (1994).

Density, electrical conductivity, and fluidity of $0.2[xKNO_3 + (1 - x)NaNO_3] + 0.8$glycerol systems were measured as functions of temperature (363.15 to 428.15 K) and composition (0.0 to 1.0 mole fraction). Densities were linear functions of temperature. The temperature dependence of conductivity and fluidity has been analysed by using the Vogel–Tammann–Fulcher (VTF) equation. Deviation from additivity has been observed in the electrical conductivity, fluidity isotherms to a lesser extent, and in electrical conductivity under isofluidity condition. The onset of the mixed alkali effect (MAE) in the present system has been explained by the anion polarization model.

SEKH MAHIUDDIN. Can. J. Chem. **72**, 2286 (1994).

On a mesuré les densités, les conductivités électriques et les fluidités des systèmes contenant $0,2[xKNO_3 + (1 - x)NaNO_3] +$ 0,8glycérol en fonction de la température (de 363,15 à 428,15 K) et des fractions molaires (de 0,0 à 1,0). Les densités varient d'une façon linéaire avec la température. On a analysé la relation entre la température et les conductivités et les fluidités en faisant appel à l'équation de Vogel–Tammann–Fulcher (VTF). On a observé une déviation de l'additivité avec la conductivité électrique et, à un degré moindre, avec les isothermes de fluidité ainsi qu'avec la conductivité dans les conditions d'isofluidité. On explique le début de l'effet des métaux alcalins mixtes observé dans ce système en faisant appel au modèle de polarisation de l'anion.

[Traduit par la rédaction]

Introduction

When one alkali ion is replaced by another in an oxide glass and ionic melt several properties (preferably dynamic) vary as a function of composition in a highly non-additive fashion, a phenomenon usually referred to as mixed alkali effect (MAE). This phenomenon has been well documented by several authors (1–12) and is more pronounced in ionic and mass transport properties (2).

To date very few studies on the MAE using hydrate melt (6–12) as solvent have been made. Moynihan (6), in his studies using $xNaNO_3 + (0.2 - x)KNO_3 + 0.8Ca(NO_3)_2.4.09H_2O$ system failed to observe MAE in conductivity in the temperature range −5 to 70°C. But Ingram et al. (13) observed deviation in viscosity and conductivity while studying $xK_2SiO_3 + (1 - x)Na_2SiO_3 + 7H_2O$ systems in the temperature range −70 to 20°C. The observed shallow minima in conductivity and viscosity isotherms was considered an evidence for the onset of MAE. In earlier systems (9–12) containing hydrate melt as medium the MAE in fluidity and/or viscosity has been detected but to a lesser extent (ca. 4%). In all these systems MAE was found to depend on the temperature range of the study and the total alkali metal ion concentration. Moynihan (6) suggested that MAE may only be observed in systems with high viscosity and conductivity. On the other hand, based on their studies Easteal and Emson (7) suggested that MAE becomes significant when the total alkali metal ion concentration in the system is high.

Therefore, in this study we have made an attempt to find MAE by measuring the density, viscosity, and electrical conductivity of $0.2[xKNO_3 + (1 - x)NaNO_3] + 0.8$glycerol systems due to the fact that glycerol is having inherent glass-forming tendency and high viscosity.

Experimental section

Both KNO_3 and $NaNO_3$ (BDH, LR grade) were recrystallized twice from distilled water and dried over P_2O_5 in a vacuum desiccator. Glycerol (EM, reagent grade) was used as solvent. Maximum water content in glycerol was found to be <1% when the observed density value was compared with the reported value (14) at 20°C.

KNO_3 was found to be soluble up to 20 mol% at about 100°C and the composition of the system in this study was chosen to be $0.2[xKNO_3 + (1 - x)NaNO_3] + 0.8$glycerol. Accordingly six samples were prepared, keeping the total alkali ion concentration at 0.2 mole fraction. The densities of the systems were measured accurate to 0.01% by using a precalibrated single stem pyknometer. A suspended level Cannon–Ubbelhode viscometer of viscometer constant 1.243×10^{-6} $m^2 s^{-2}$ was used to measure the viscosity. Conductivity measurements (at 1 kHz) of all solutions were made by using a Philips PR9500 conductivity bridge and a dip-type cell of cell constant 198 m^{-1}. Viscosity and conductivity data were found to be reproducible to within ±1%. Density, viscosity, and electrical conductivity were measured as functions of temperature (363.15 to 428.15 K) and composition, $x = 0.0$ to 1.0 mole fraction. All measurements were made in a thermostated oil bath (Ultra Thermostat type NBE) that maintained the temperature to ±0.02 K.

Results and discussion

Measured density data (ρ) of $0.2[xKNO_3 + (1 - x)NaNO_3] +$ 0.8glycerol systems are found to be linear functions of temperature and are presented in Table 1. Composition dependence of density isotherms at four temperatures are illustrated in Fig. 1. Density data were least-squares fitted to the polynomial equation in composition up to second degree and the maximum% deviation of ρ_{obs} from ρ_{cal} was found to be 0.56%. The interesting point to note from Fig. 1 is the deviation from additivity (≃0.8%) at lower temperature (298.15 K) in the ρ vs. x plot (Fig. 1) and decreases at higher temperature and the density isotherm becomes linear at 398.15 K. Similar positive deviation from additivity (≃0.7%) in density isotherm was found in the $(1 - x)K_2O + xLi_2O + 2SiO_2$ glass systems (2) at 293.15 K.

The measured values of conductivity (κ) and fluidity ($\phi = 1/\eta$) of the systems under study are presented in Table 2 and Fig. 2 in the form of an Arrhenius plot. From Fig. 2 it is apparent that both κ and ϕ show a slight non-Arrhenius temperature dependence. Such a temperature dependence of transport properties (κ, ϕ) is an inherent nature of the concentrated electrolyte and

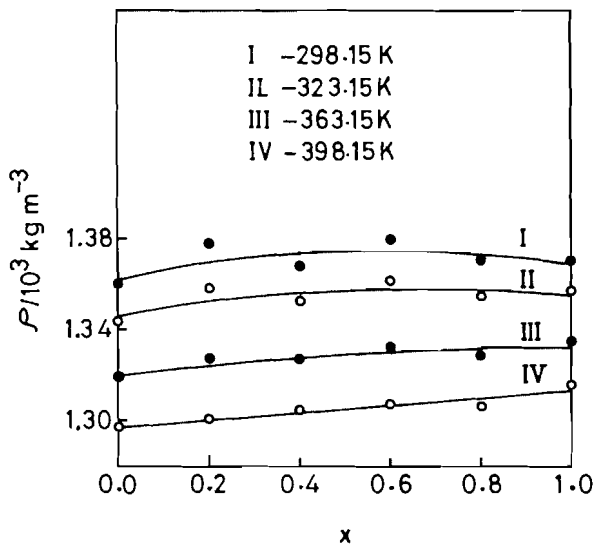

FIG. 1. Variation of density versus composition for $0.2[x\mathrm{KNO_3} + (1 - x)\mathrm{NaNO_3}]$ + 0.8glycerol systems under isothermal condition (open and closed circles represent observed values and solid curves represent values calculated (from polynomial equation up to second degree), respectively).

ionic melt systems. The conductivity and fluidity values were, therefore, least-squares fitted to the Vogel–Tammann–Fulcher (VTF) equation of the form considering the insignificant contribution of the preexponential temperature term

$$[1] \quad Y(\kappa, \phi) = A_y \exp[-B_y/(T - T_{0y})]$$

where Y refers to either conductivity or fluidity, A_y and B_y are the adjustable parameters, and T_0 is the ideal glass transition temperature. The least-squares fitted values of A_y, B_y, and T_{0y} are presented in Table 3.

A relatively high T_{0y} value has been obtained for the present system. Similarly a high value for T_0 was observed by Sangma et al. (9) and Ingram et al. (13) while investigating MAE in ternary systems. On the other hand, similar high value for T_0 was also found for binary hydrate melts (15–17).

The presence of MAE in our system has been examined by plotting T_{0y}, A_y, and B_y versus x, $x = \mathrm{K^+/(K^+ + Na^+)}$ in Fig. 3. From Fig. 3 it is evident that the T_0 values for both κ and ϕ vary non-linearly. Such a positive deviation from additivity in T_0 vs. x (Fig. 3) may be attributed to the onset of MAE in the present system.

Although non-linear variations (generally negative deviation) in experimental glass transition temperature, T_g, and in ideal glass transition temperature, T_0, with alkali ion concentration were reported for mixed alkali systems containing hydrate

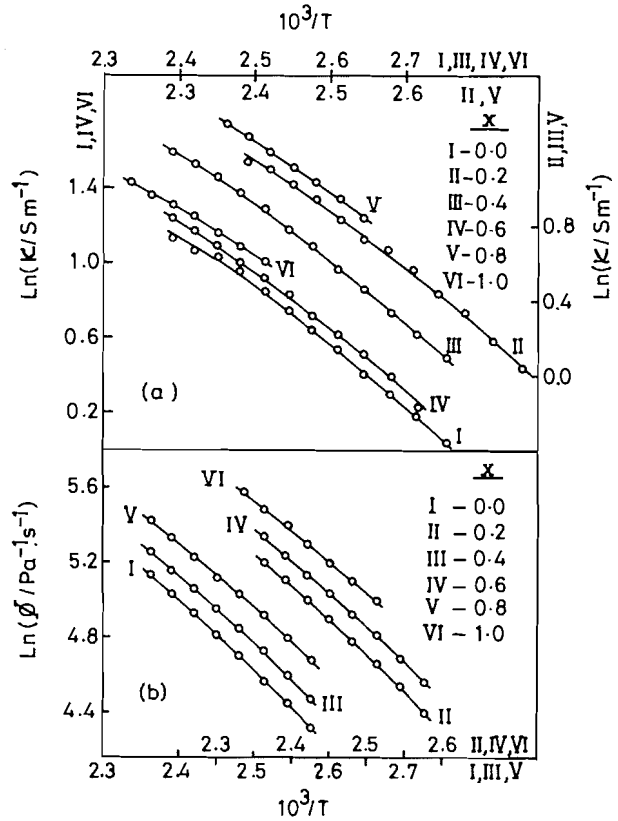

FIG. 2. Arrhenius plots for (*a*) conductivity and (*b*) fluidity of $0.2[x\mathrm{KNO_3} + (1 - x)\mathrm{NaNO_3}]$ + 0.8glycerol systems.

(6, 7, 10, 12) and anhydrous (18, 19) melts, to date no report on positive deviation in T_0 with composition in mixed alkali system has been made. On the other hand, T_0 was also reported to vary linearly with alkali ion fraction in $0.2[x\mathrm{NaNO_3} + (1 - x)\mathrm{KNO_3}] + 0.8\mathrm{Ca(NO_3)_2.4.09H_2O}$ (6), $0.3[x\mathrm{KSCN} + (1 - x)\mathrm{NaSCN}] + 0.7\mathrm{Ca(NO_3)_2.4.06H_2O}$ (9), and in $x\mathrm{K_2SiO_3} + (1 - x)\mathrm{Na_2SiO_3} + 7\mathrm{H_2O}$ (13) systems. In general, an irregular trend in T_0 vs. composition are reported for binary (15, 16) as well as ternary (9, 10) melts containing hydrated salts and in all such cases an alternative method suggested by Moynihan et al. (16) was normally adopted for data analysis. In our system, as a consequence, the positive deviation in the T_0 vs. x plot in Fig. 3 could be illusory. One of the reasons may be pointed out that in the temperature ranges of the study the conductivity and fluidity data in the present system vary by factors of 1.5 to 3 and the computed values of T_0 parameter may not be precise.

The composition dependence of A_y and B_y parameters are illustrated in Fig. 3. From Fig. 3 it is apparent that both A_y and B_y parameters vary non-linearly with negative deviation. Similar negative deviation in A vs. x plot was found in $0.3[x\mathrm{KSCN} + (1 - x)\mathrm{NaSCN}] + 0.7\mathrm{Na_2S_2O_3.5.1H_2O}$ system (11). However, we observed that the variations of the VTF parameters (A_y, B_y, and T_{0y}) with composition (9–11) are interrelated.

In mixed alkali metal ion systems in hydrate melt medium an interdependence between the three VTF parameters was recently observed (12), as represented by empirical relationships of the type

$$[2] \quad \ln A_y = A_{1y} + A_{2y}[B_y/T_{0y}]$$

$$[3] \quad 1/B_y = B_{1y} + B_{2y}T_{0y}$$

[a]Value of parameter for fluidity in parentheses.

where A_{1y}, A_{2y}, B_{1y}, and B_{2y} are all empirical constants. The above empirical relationships between A_y, B_y, and T_{0y} are found to hold reasonably well in the present system as is evident from Fig. 4. The validity of such empirical relationships actually indicates that the composition dependence of the T_{0y} parameter alone can fully govern the composition dependence of transport properties of mixed alkali metal ion system in a hydrate melt medium.

An attempt has been made to describe the observed nature of the composition dependence of both κ and ϕ on x (Fig. 5) by least-squares fitting the κ and ϕ data for the present system to an empirical equation of the form

$$[4] \quad Y(\kappa, \phi) = a_y \exp(b_y x + c_y x^2)$$

where a_y, b_y, and c_y are empirical constants. Equation [4] was successfully used by Sangma et al. (9) to explain the composition dependence of observed conductivity and/or fluidity data for $0.3[xKSCN + (1 - x)NaSCN] + 0.7Ca(NO_3)_2.4.06H_2O$, and the reported data for $xK_2O + (1 - x)Na_2O + 3SiO_2$ (6) and $0.45[xLiNO_3 + (1 - x)KNO_3] + 0.55Ca(NO_3)_2.4.09H_2O$ (8) systems and a reasonably good fit was obtained. The least-squares fitted values of the parameters of eq. [4] for the conductivity and fluidity for the present system are given in Table 4. A reasonably good fit has been obtained as is apparent from Fig.

[a]Parameters for fluidity in parentheses.

5. It is evident form Fig. 5 that in the temperature range of the study κ exhibits negative deviation from additivity whereas ϕ shows slightly narrow deviation from additivity. The maximum deviation from additivity was estimated to be ≃4% for conductivity and ≃3.5% in the case of fluidity at 398.15 K which is more than the uncertainty involved in the measured data. The deviation from additivity both in κ and ϕ isotherms decreases at higher temperatures.

In mixed alkali systems containing Na^+ and K^+ ions in hydrate melt medium the maximum negative deviation was found to be ≃4% (9, 12) at 328 K. On the other hand, about 11% negative deviation from additivity was reported in the similar mixed alkali system containing Li^+ and K^+ ions (8). One of the key parameters for the significant MAE may be attributable to the large difference in the radii of the alkali ions in addition to the low temperature study and the higher alkali ion concentration in the mixed alkali systems. The small amount of MAE in

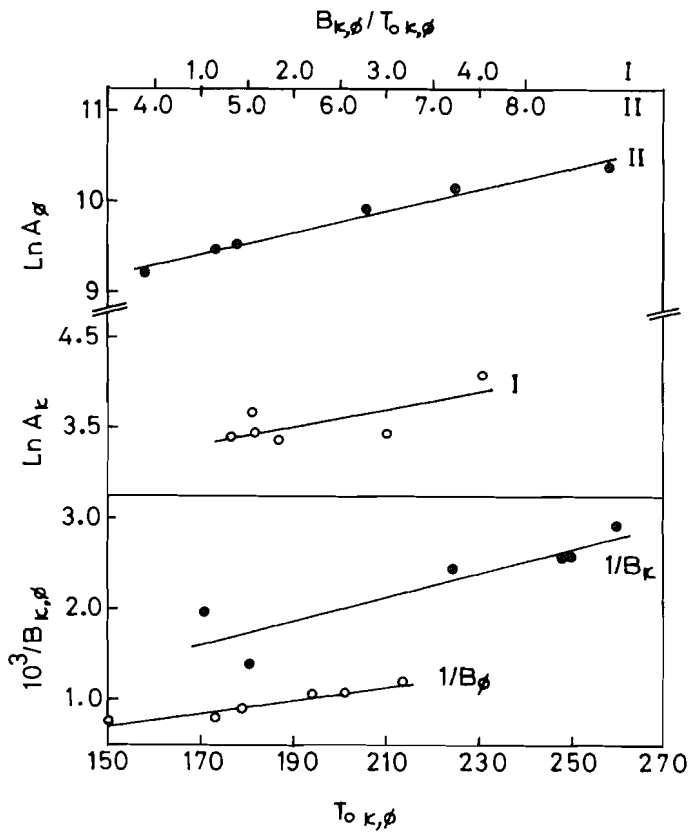

FIG. 4. Plots of ln $A_{\kappa,\phi}$ vs. $B_{\kappa,\phi}/T_{0\kappa,\phi}$ and $1/B_{\kappa,\phi}$ vs. $T_{0\kappa,\phi}$ for $0.2[x\mathrm{KNO_3} + (1 - x)\mathrm{NaNO_3}] + 0.8$glycerol systems (open and closed circles represent observed values and solid lines represent values calculated (from eqs. [2] and [3]), respectively).

the present systems (≃4% negative deviation in κ and ϕ isotherms) may be due to the type of alkali ions (Na^+–K^+) present with $\Delta F = 0.04$ (ΔF is the difference in field strength) (20) in comparison to $\Delta F = 0.10$–0.14 for Li^+–K^+ ion (where maximum deviation of 11% was found (8)) resulted in non-rigid type structure in the present system.

According to the idea of solid-like conduction mechanism proposed by Moynihan (6) the structure of the mixed alkali system must be fixed. Therefore, based on the above argument isofluidity condition may be one of the important criteria to detect MAE in the electrical conductivity. Variation of κ with composition at different fluidity values are illustrated in Fig. 6. Electrical conductivity values at constant fluidity both within and outside the experimental ranges of fluidity required were calculated using eq. [1] and the least-squares fitted values of A_y, B_y, and T_{0y} parameters (Table 3). From Fig. 6 it is apparent that the percentage deviation from additivity in conductivity at low fluidity is higher, decreasing in value at higher fluidities, and becoming almost linear at $\phi = 100$ Pa^{-1} s^{-1}. Moynihan (6) suggested that the largest apparent deviation from linearity under low fluidity condition is due to the long time scale for the rearrangement of the local structure compared to that required for local diffusion of alkali cations from site to site. Similar explanation may also be used on the present system.

Several theories and model (21–24) have been proposed to account for the onset of MAE in ternary oxide glass and hydrate melt. The cation interaction theory seems to be more appropriate for the system not having such a rigid-network type structure. The anion polarization model (APM) proposed by

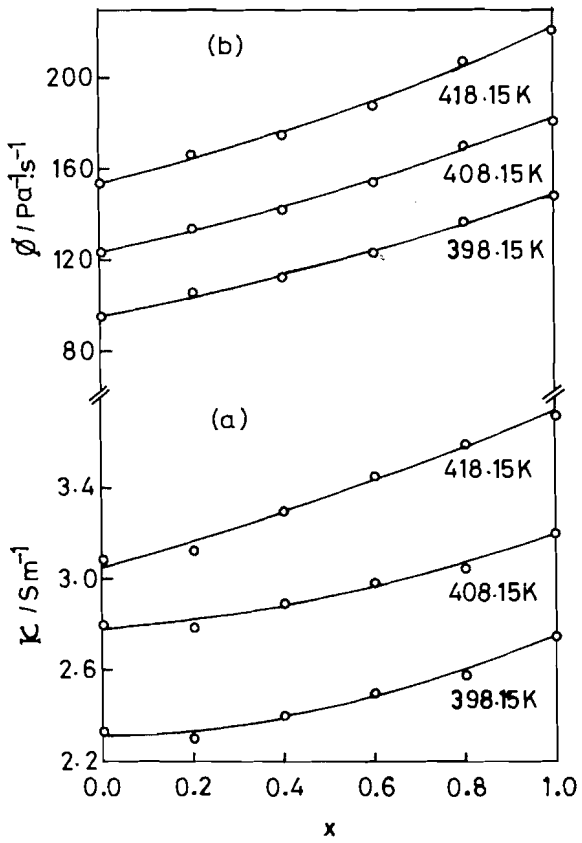

FIG. 5. Plots of (*a*) conductivity and (*b*) fluidity versus composition for $0.2[xKNO_3 + (1 - x)NaNO_3] + 0.8$glycerol systems under isothermal condition (open circles and solid curves represent observed and calculated values (from eq. [4], Table 4), respectively).

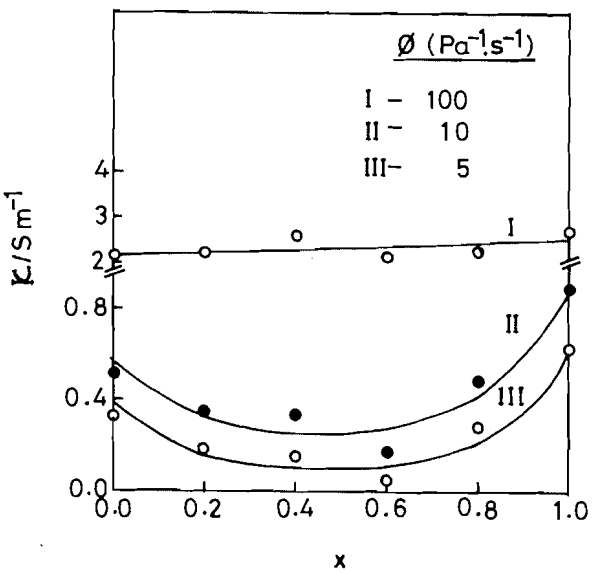

FIG. 6. Plots of conductivity versus composition under isofluidity condition (open and closed circles represent observed values and solid lines represent values calculated (from eq. [4]), respectively).

Moynihan and Laity (22, 25) is one such cation interaction theory. The APM has been used earlier to explain MAE on the electrical conductivity in hydrate melt medium (8, 10). The APM may, therefore, also be used to explain MAE in electrical conductivity and fluidity in a glycerol medium. According to this model, the NO_3^- ion experiences an average symmetrical field when the glycerol medium contains either $NaNO_3$ or KNO_3. On the other hand, when the medium contains both Na^+ and K^+ ions, some of the NO_3^+ ions find themselves between electrical fields of differing intensities. This results in a competitive polarization of the anion and generates an asymmetric electrical field around NO_3^-, causing the NO_3^- ion to be more polarized towards the Na^+ ion. As a result, the internal mobilities of Na^+ and K^+ ions are affected, thereby causing a net deviation from additivity.

Photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction. Part 7: methanol, conjugated dienes, and 1,4-dicyanobenzene[1]

KIMBERLY A. MCMANUS AND DONALD R. ARNOLD[2]

Department of Chemistry, Dalhousie University, Halifax, NS B3H 4J3, Canada

Received May 24, 1994

KIMBERLY A. MCMANUS and DONALD R. ARNOLD. Can. J. Chem. **72**, 2291 (1994).

The scope of the photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction has been extended to include conjugated dienes: 1,3-butadiene (**9**), 2-methyl-1,3-butadiene (**10**), 2,3-dimethyl-1,3-butadiene (**11**), and 2,5-dimethyl-2,4-hexadiene (**12**). Acetonitrile–methanol solutions of the dienes **9**, **10**, and **11**, and 1,4-dicyanobenzene (**1**), with and without codonor (biphenyl (**5**)), were irradiated with a medium-pressure mercury vapour lamp through Pyrex. Both 1,2- and 1,4-addition products were formed in approximately equal amounts (combined yields of photo-NOCAS products, 50–65%). In marked contrast, when an acetonitrile–methanol solution of 2,5-dimethyl-2,4-hexadiene (**12**), **1**, and **5** was irradiated, only the 1,4-addition product, *trans*-2-(4-cyanophenyl)-5-methoxy-2,5-dimethyl-3-hexene (**22**, 82%), was obtained. This photolysate also contained a small amount of another 1,4-addition product, that which had incorporated cyanide ion instead of methanol, *trans*-2-(4-cyanophenyl)-2,2,5-trimethyl-3-hexenenitrile (**23**, 2%). Irradiation of an acetonitrile solution (no methanol) of **12**, **1**, and **5** gave **23** in good yield (68%). An excellent yield (80%) of **23** was obtained upon irradiation of an acetonitrile solution of **1**, **12**, **5**, potassium cyanide, and 18-crown-6. Addition of 2,4,6-trimethylpyridine (collidine, **25**), a mild, non-nucleophilic base, to the reaction mixture diverts the reaction involving **12** from photo-NOCAS products to 1:1 substitution products; 3-(4-cyanophenyl)-2,5-dimethyl-1,4-hexadiene (**26**), *trans*-5-(4-cyanophenyl)-2,5-dimethyl-1,3-hexadiene (**27**), (*Z*)-1-(4-cyanophenyl)-2,5-dimethyl-2,4-hexadiene (**28**), and (*E*)-1-(4-cyanophenyl-2,5-dimethyl-2,4-hexadiene (**29**) were formed. The mechanisms of these reactions are discussed and an explanation for the observed regio- and stereoselectivity is given.

KIMBERLY A. MCMANUS et DONALD R. ARNOLD. Can. J. Chem. **72**, 2291 (1994).

On a élargi le domaine d'application de la combinaison photochimique nucléophile–oléfine, la réaction de substitution aromatique photo-NOCAS, de façon à inclure les dienes conjugués suivants : buta-1,3-diène (**9**), 2-méthylbuta-1,3-diène (**10**), 2,3-diméthylbuta-1,3-diène (**11**) et 2,5-diméthylbuta-1,3-diène (**12**). On a soumis des solutions acétonitrile–méthanol des dienes **9**, **10** et **11** avec le 1,4-dicyanobenzène (**1**), avec ou sans codonneur (biphényle **5**), avec une lampe à vapeur de mercure à pression moyenne à travers du Pyrex. Les produits d'additions 1,2 et 1,4 se forment en quantités approximativement égales (rendements combinés des produits de photo-NOCAS, 50–65%). Par ailleurs, lorsqu'on irradie une solution acétonitrile–méthanol du 2,5-diméthylbuta-1,3-diène (**12**) avec les composés **1** et **5**, il ne se forme que du produit d'addition 1,4, le *trans*-2-(4-cyanophényl)-5-méthoxy-2,5-diméthylhex-3-ène (**22**, 82%). Ce photolysat contenait aussi une faible quantité d'un autre produit d'addition 1,4, celui qui incorpore un ion cyanure à la place du méthanol, le *trans*-2-(4-cyanophényl)-2,2,5-triméthylhex-3-ènenitrile (**23**, 2%). Une irradiation d'une solution des composés **12**, **1** et **5** dans l'acétonitrile (sans méthanol) fournit le produit **23** avec un bon rendement (68%). On obtient un excellent rendement (80%) du produit **23** par irradiation d'une solution dans l'acétonitrile des composés **1**, **12**, **5**, avec du cyanure de potassium et de la 18-couronne-6. L'addition au mélange réactionnel de 2,4,6-triméthylpyridine (collidine, **25**), une base non nucléophile douce, empêche la réaction du composé **12** pour donner des produits de photo-NOCAS et provoque plutôt la formation des produits de substitution 1 : 1 suivants : 3-(4-cyanophényl)2,5-diméthylhexa-1,4-diène (**26**), *trans*-5-(4-cyanophényl)-2,5-diméthylhexa-1,3-diène (**27**), (*Z*)-1-(4-cyanophényl)-2,5-diméthylhexa-2,4-diène (**28**) et (*E*)-1-(4-cyanophényl)-2,5-diméthylhexa-2,4-diène (**29**). On discute des mécanismes de ces réactions et on propose une explication pour les régio- et stéréo-sélectivités observées.

[Traduit par la rédaction]

Introduction

Among the first examples of the photochemical nucleophile–olefine combination, aromatic substitution (photo-NOCAS) reaction were the combination of methanol, 2,3-dimethyl-2-butene (**2**), and 1,4-dicyanobenzene (1) (reaction [1]); and the combination of methanol, 2-methylpropene (**6**), and 1,4-dicyanobenzene (**1**) (reaction [2]) (3*a*, 3*b*). These are synthetically useful processes that provide a single-step pathway to alkylation of an aromatic, with formation of a difunctional molecule.

A mechanism for the photo-NOCAS reaction has been proposed and supported (Scheme 1) (1, 3). The reaction is initiated by photo-induced single electron transfer to the singlet excited state of 1,4-dicyanobenzene (**1**) from the olefin (Scheme 1; steps 1 and 2). The resulting olefin radical cation is attacked by methanol, giving a β-alkoxy alkyl radical (step 3). This radical can either couple with the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\cdot}$) at the *ipso* position (step 4) or the radical may be reduced to the anion by the radical anion (step 4a). Subsequent protonation of the anion leads to ethers. Formation of ethers by this mechanism is the usual result with phenyl-substituted olefins (3*c*, 3*d*). Phenyl substitution lowers the reduction potential of the radical so that reduction by the radical anion ($\mathbf{1}^{-\cdot}$) is favourable. Ethers may also result from disproportionation of the β-alkoxy alkyl radical.

Addition of an electron transfer photosensitizer (e.g., phenanthrene (**4**)) or a codonor (e.g., biphenyl (**5**)) has been shown to increase the efficiency of the reaction (Scheme 1; steps 6 and 7) (1, 3). Addition of a photosensitizer (electron transfer) to the reaction mixture can increase the efficiency of the reaction simply by absorbing more light. The excited singlet state of the photosensitizer (electron transfer), phenanthrene (**4**), can donate an electron to 1,4-dicyanobenzene (**1**) to give the photosensitizer radical cation and 1,4-dicyanobenzene radical anion. The photosensitizer radical cation may then oxidize the olefin (steps 6b, 6c, and 7). The explanation we favour for the

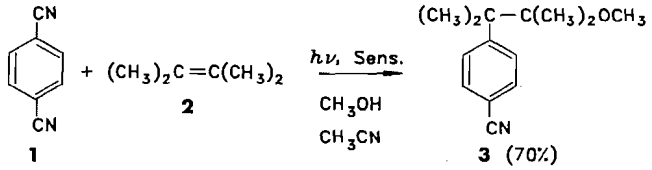
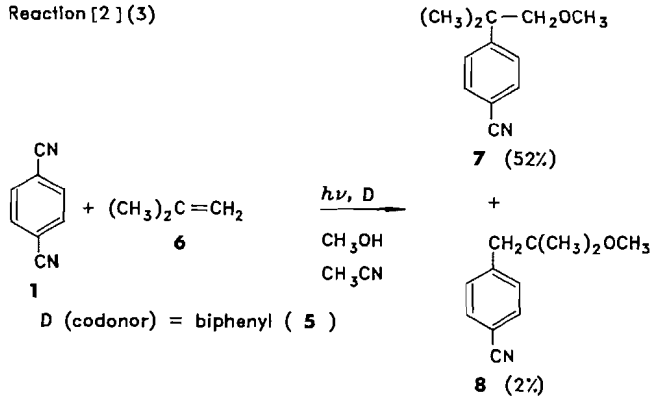
Reaction [1] (3)



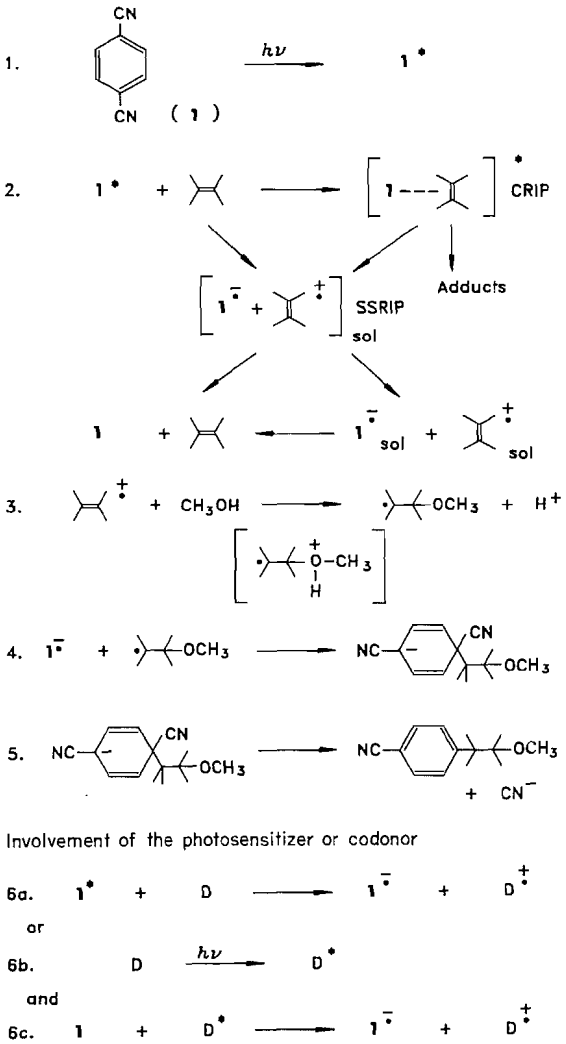
Sens. (photosensitizer) = phenanthrene (**4**)

Reaction [2] (3)

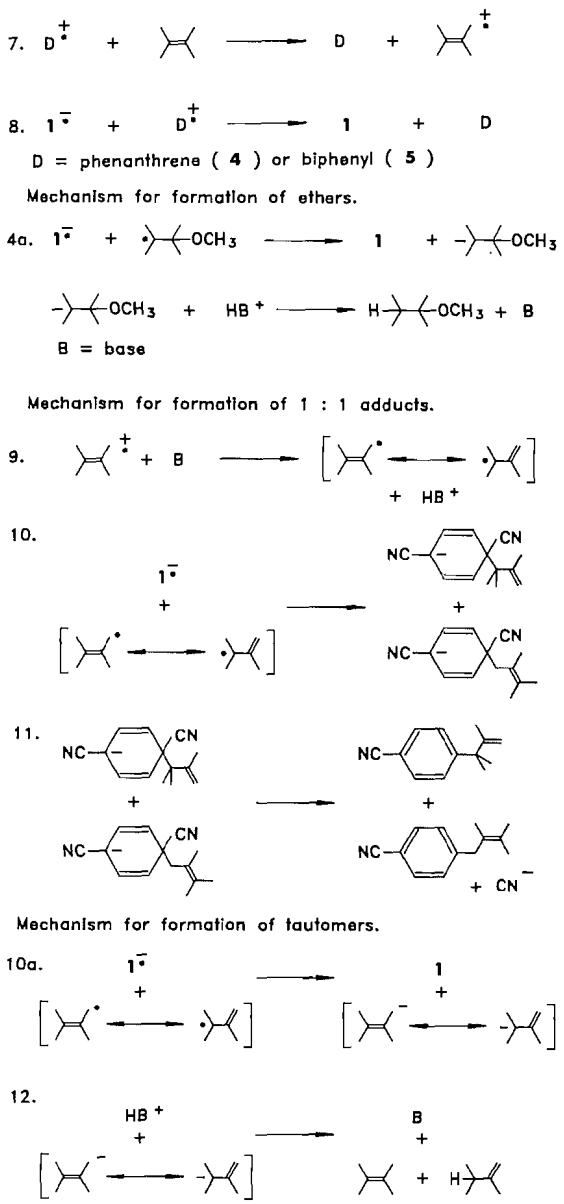


D (codonor) = biphenyl (**5**)

Mechanism for formation of photo-NOCAS products



Involvement of the photosensitizer or codonor



SCHEME 1

effect of added codonor involves differences in the efficiency of radical ion pair escape for the olefin–1,4-dicyanobenzene radical ion pair compared to the codonor–1,4-dicyanobenzene radical ion pair. The reorganization energy is thought to be larger for the olefin–1,4-dicyanobenzene radical ion pair than for the codonor–1,4-dicyanobenzene radical ion pair. The smaller reorganization energy leads to a decrease in the rate of back electron transfer and, thus, greater escape from the solvent cage and a consequent increase in the efficiency of the reaction (Scheme 1; steps 2 and 8) (4).

Deprotonation of the radical cation of the olefin may compete with reaction with nucleophile (Scheme 1, step 9) (3). Deprotonation may in fact dominate in the absence of nucleophile (methanol) (3). The resulting allylic radical may then couple with the 1,4-dicyanobenzene (**1**) radical anion at the *ipso* position (step 10), followed by loss of the cyanide anion, to give the 1:1 (olefin:aromatic) substitution product(s) (step 11). If, however, the reduction potential of the allylic radical is less (i.e., less negative) than that of 1,4-dicyanobenzene, the radical

may be reduced (step 10a); subsequent protonation of the ambident anion will then give the tautomer (step 12) (*3e*, *3f*).

Several olefins have been examined under these varying reaction conditions and the regio- and stereoselectivity of the photo-NOCAS reaction has been defined (1, 3). Recent studies, which have focused on the reactivity of nonconjugated dienes, have provided additional insight into the mechanism (*1a*). The scope of the photo-NOCAS reaction has now been extended to include conjugated dienes, providing a simple procedure for the direct allylic alkylation of the aromatic. The proposed mechanism has been confirmed and expanded. There have been few reports of the reactivity of the radical cations of these dienes (5–9). This work has provided additional insight into the regio- and stereoselectivity of these reactions.

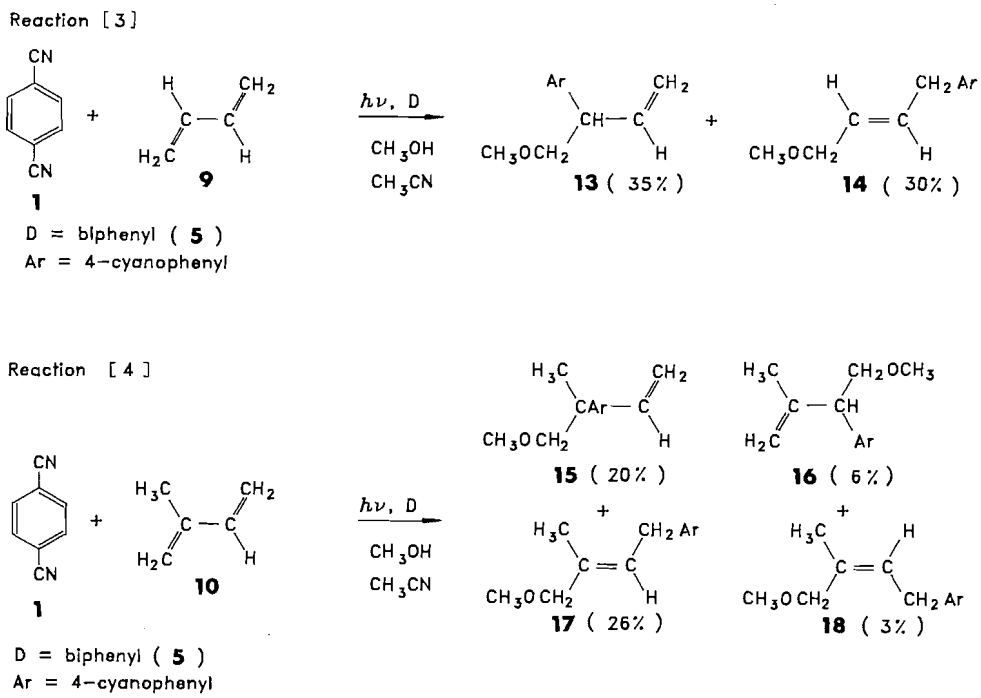
Results

The conjugated dienes chosen for study were the 1,3-butadiene homologues: 1,3-butadiene (**9**), 2-methyl-1,3-butadiene (**10**), 2,3-dimethyl-1,3-butadiene (**11**), and 2,5-dimethyl-2,4-hexadiene (**12**). Acetonitrile–methanol (3:1) solutions of 1,4-dicyanobenzene (**1**) and the conjugated diene were irradiated with a medium-pressure mercury vapour lamp through Pyrex. The products were 1:1:1 (methanol:diene:**1**) photo-NOCAS adducts.

The progress of the reaction was monitored by capillary column gas chromatography with a flame ionization detector (gc/fid). The first indication of the structure of the products was obtained from a gas chromatograph equipped with a mass selective detector (gc/ms). The photo-NOCAS products were generally isolated by medium-pressure liquid chromatography (mplc). The yields were based upon 1,4-dicyanobenzene (**1**) as the limiting reagent; the diene was generally present in excess. In cases where the photo-NOCAS adducts were difficult to separate, a total weight of the combined products was obtained, and the ratio(s) of the isomers was determined by gc/fid. Usually the ratio of products was not dependent upon the extent of conversion, these ratios remaining constant during the irradiation. The exception was reaction [6] where the ratio of products was dependent upon irradiation time. Yields and product ratios, shown in the illustrations, are for reactions taken to complete conversion of **1**. Structural assignments of the products were based primarily upon detailed analysis of ^{1}H and ^{13}C nmr spectra.

An acetontrile–methanol (3:1) solution of 1,3-butadiene (**9**), 1,4-dicyanobenzene (**1**), and biphenyl (**5**) was irradiated; 3-(4-cyanophenyl)-4-methoxy-1-butene (**13**, 35%) and *trans*-1-(4-cyanophenyl)-4-methoxy-2-butene (**14**, 30%) were isolated (reaction [3]). Compound **13** is a 1,2-addition product, whereas compound **14** results from 1,4-addition. The *cis* isomer of **14** was not detected.

Four photo-NOCAS adducts were produced upon irradiation of a solution of 2-methyl-1,3-butadiene (**10**), **1**, and **5** in acetonitrile–methanol (3:1). The structures and yields of these products were as follows: 3-(4-cyanophenyl)-4-methoxy-3-methyl-1-butene (**15**, 20%), 3-(4-cyanophenyl)-4-methoxy-2-methyl-1-butene (**16**, 6%), (*E*)-4-(4-cyanophenyl)-1-methoxy-2-methyl-2-butene (**17**, 26%), and (*Z*)-4-(4-cyanophenyl)-1-methoxy-2-methyl-2-butene (**18**, 3%) (reaction [4]). Isomers **15** and **16** are 1,2-addition products. Isomers **17** and **18** are the result of 1,4 addition and their combined yield makes this the major mode of addition. The *E* isomer, **17**, is dominant. Both



major products, **15** and **17**, are the result of initial addition of the nucleophile (methanol) to the terminal end of the more highly substituted double bond.

A solution of 2,3-dimethyl-1,3-butadiene (**11**), **1**, and **5** in acetonitrile–methanol (3:1) was irradiated. Three major photo-NOCAS adducts were formed: (3-(4-cyanophenyl)-4-methoxy-2,3-dimethyl-1-butene (**19**, 30%), (*E*)-1-(4-cyanophenyl)-4-methoxy-2,3-dimethyl-2-butene (**20**, 15%), and (*Z*)-1-(4-cyanophenyl)-4-methoxy-2,3-dimethyl-2-butene (**21**, 8%) (reaction [5]). In this case the 1,2-addition product (**19**) was the major adduct; 1,2 addition (30%) is favoured over 1,4 addition (23%).

An acetonitrile–methanol (3:1) solution of 2,5-dimethyl-2,4-hexadiene (**12**), **1**, and **5** was irradiated to give two photo-

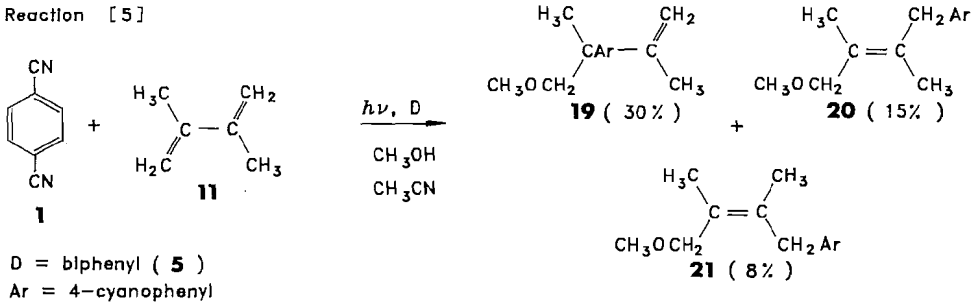
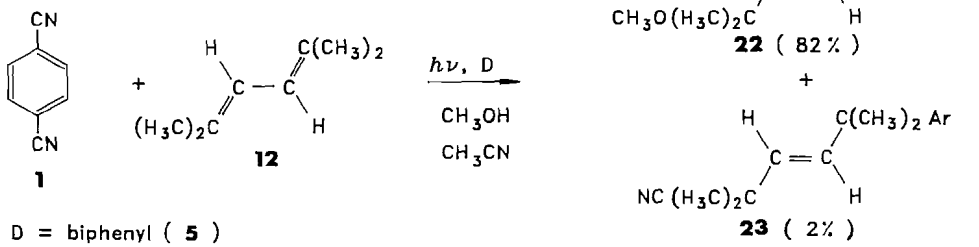
Reaction [5]



D = biphenyl (**5**)
Ar = 4-cyanophenyl

Reaction [6]



D = biphenyl (**5**)
Ar = 4-cyanophenyl

NOCAS adducts: *trans*-2-(4-cyanophenyl)-5-methoxy-2,5-dimethyl-3-hexene (**22**, 82%) and *trans*-5-(4-cyanophenyl)-2,2,5-trimethyl-3-hexenenitrile (**23**, 2%) (reaction [6]; yields are based on essentially complete conversion of **1**). The major product, **22**, was the expected 1,4-addition product. The minor product, **23**, was not the typical photo-NOCAS product involving methanol, diene, and **1**, but, instead, it results from the combination of cyanide ion, diene, and **1**. The ratio of **22/23** changes during the irradiation; increasing irradiation time, ratio **22/23** decreases. The ratio of **22/23** = 40 when the irradiation was continued until almost complete consumption of **1**. Biphenyl (**5**) had little effect on this reaction; a slight increase in the efficiency was observed but no effect on the product ratio. There was no cyano adduct (**23**) formed when lithium perchlorate (0.1 M) was added to the photolysis mixture. A similar irradiation involving **12**, **1**, and **5** in an acetonitrile solution, without added methanol, gave a 68% yield of **23**, this yield was also based on essentially complete conversion of **1**.

No analogous cyano adducts were detected in the reactions described above with conjugated dienes **9**, **10**, and **11**. Furthermore, when these irradiations were carried out in acetonitrile alone (without added methanol), no cyano adducts were produced.

Several experiments were performed in an attempt to determine the mechanism of the reaction leading to formation of **23**. A photochemically initiated free radical chain mechanism was ruled out; no adducts were formed in a thermal reaction (110°C) to which the free radical chain initiator di-*tert*-butyl peroxide had been added.

Another possible mechanism for the formation of **23** would involve reaction of the contact radical ion pair (CRIP) formed upon irradiation of a charge transfer complex (CTC) between **1** and **12**. A CTC does form between **1** and **12**. The uv-absorption spectra of acetonitrile solutions with a constant concentration of **1** and varying concentrations of **12** were recorded. Figure 1 illustrates the uv-absorption spectrum, in the long-wavelength region, of an acetonitrile solution of **1** (0.06 M) as a function of diene concentration ([**12**]). Figure 2 is a plot (Benesi–Hildebrand) of the absorption due to the CTC (320 nm). The associ-

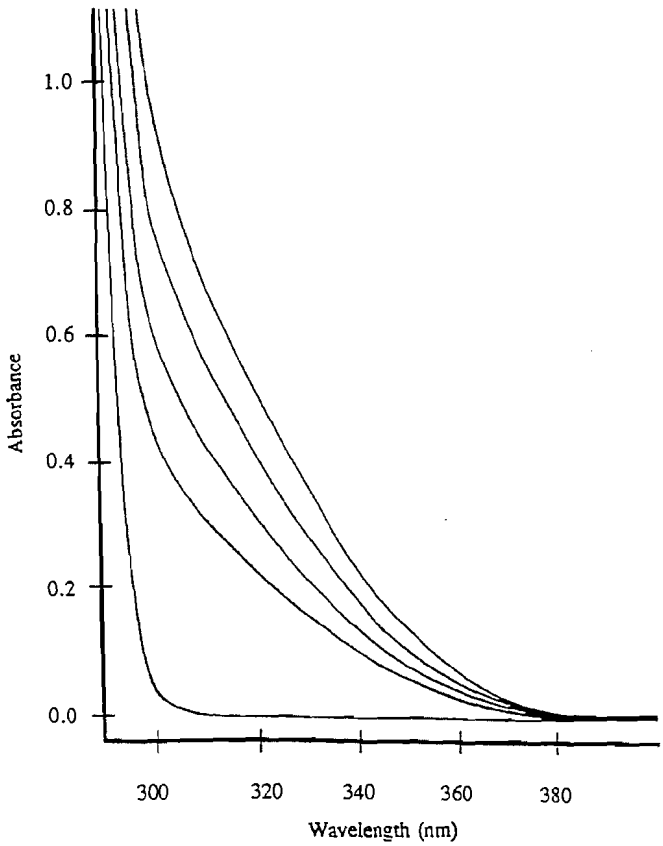


FIG. 1. The uv-absorption spectrum of 1,4-dicyanobenzene (**1**) (0.06 M), in acetonitrile, as a function of varying concentrations of 2,5-dimethyl-2,4-hexadiene (**12**) (see Fig. 2 for concentrations).

ation constant, calculated from the slope of the line, is $K_a = 2.0$ M^{-1}. The product ratio, **22/23**, was determined upon selective excitation of the charge transfer transition. This experiment was carried out using standard acetonitrile–methanol solutions of **1** and **12**, placed in a Pyrex tube with an outer Pyrex vessel. The outer vessel was filled with a solution filter consisting of varying concentrations of **1** (0.0–0.1 M) in acetonitrile–methanol. The rate of formation of the photo-NOCAS adducts decreased significantly with increasing concentration of **1** in the filter solution; however, the ratio of adducts (**22/23**) followed the same pattern as in the reaction without filter solution. The ratio (**22/23**) decreases from an initial maximum >55 to <30 at complete conversion of **1**.

Formation of the photo-NOCAS adducts, **22** and **23**, can be photosensitized (electron transfer). An acetonitrile–methanol solution of **1**, **12**, and a photosensitizer (electron transfer), anthracene (**24**), was irradiated through a glass filter that absorbed light of wavelengths shorter than 330 nm. Under these conditions only **24** absorbs light; no reaction occurred upon irradiation of an acetonitrile–methanol solution of **1** and **12**, without added **24**, through this filter. The ratio of methanol and cyanide ion incorporated products, at complete consumption of **1**, was essentially the same (**22/23** = 40).

In another relevant experiment, the possibility of incorporating added cyanide ion was tested. An acetonitrile–methanol solution of **1**, **12**, and added $K^{13}CN$ (2×10^{-2} M) was irradiated. The ratio of photo-NOCAS adducts was greatly decreased (**22/23** = 1) and there was a >80% increase in the relative intensity of the $(M + 1)^{+\cdot}$ peak, for the molecular ion, in the mass spectrum of **23** formed at low conversion. Irradiation of an acetonitrile solution of **1**, **12**, **5**, KCN, and crown ether (18-crown-6) gave an excellent yield (80%) of **23** (reaction [7]).

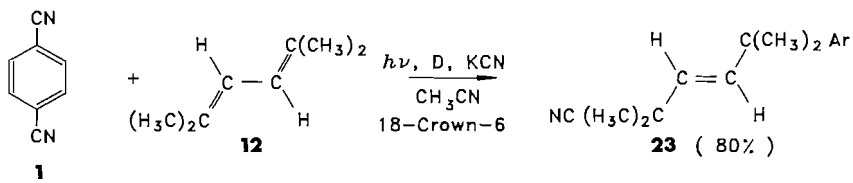
Reaction [7]



D = biphenyl (**5**)
Ar = 4-cyanophenyl

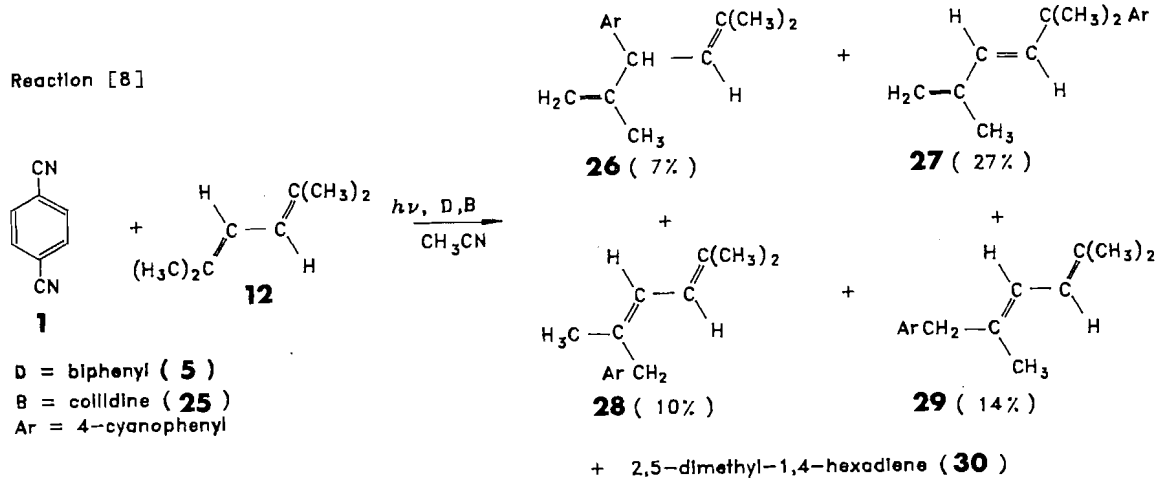
An acetonitrile solution of 2,5-dimethyl-2,4-hexadiene (**12**), **1**, **5**, and 2,4,6-trimethylpyridine (collidine, **25**) was irradiated to give 1:1 substitution products: 3-(4-cyanophenyl)-2,5-dimethyl-1,4-hexadiene (**26**, 7%), *trans*-5-(4-cyanophenyl)-2,5-dimethyl-1,3-hexadiene (**27**, 27%), (*Z*)-1-(4-cyanophenyl)-2,5-dimethyl-2,4-hexadiene (**28**, 10%), and (*E*)-1-(4-cyanophenyl)-2,5-dimethyl-2,4-hexadiene (**29**, 14%) (reaction [8]). The tautomer of 2,5-dimethyl-2,4-hexadiene (**12**), 2,5-dimethyl-1,4-hexadiene (**30**), was also formed. The structure of **30** was confirmed by comparison (retention time and mass spectrum) with an authentic sample (1*a*, 10). The 1:1 substitution products (**26–29**) were minor products in reactions [6] and [7], and a small amount of the cyanide adduct (**23**) was observed in reaction [8].

Structural assignments

The products were generally isolated from the crude photolysate by medium-pressure liquid chromatography (mplc) on silica gel. Structural assignments were based primarily upon analysis of the ^1H and ^{13}C nmr spectra. Mass and infrared spectra and elemental analyses were also useful. In one case, **28**, the structure was determined by X-ray crystallography.

The photo-NOCAS adducts, 3-(4-cyanophenyl)-4-methoxy-1-butene (**13**) and *trans*-1-(4-cyanophenyl)-4-methoxy-2-butene (**14**), were isolated from the irradiation of an acetonitrile–methanol (3:1) solution of 1,3-butadiene (**9**), 1,4-dicyanobenzene (**1**), and biphenyl (**5**) (reaction [3]). The ^1H and ^{13}C nmr spectra provide good evidence for the structure of **13** as the *anti*-Markovnikov 1,2-adduct. The low-field singlet (3.33 ppm) in the ^1H nmr spectrum is indicative of the methoxy methyl group. The multiplet (3.70 ppm) is an ABC second-order pattern for the protons of the methylene group next to an oxygen and that of the benzylic/allylic methine group. A terminal alkene is supported by two doublets and the multiplet (5.10, 5.19, and 5.96 ppm) in the vinyl proton region. A multiplet for the vinyl proton on carbon-2 exhibits *trans*, *cis*, and vicinal coupling (17.2, 10.4, and 6.6 Hz, respectively). The typical AA′XX′ pattern in the aromatic region of the ^1H nmr spectrum is indicative of the 4-cyanophenyl group.

Even though the signal, in the ^1H nmr spectrum, due to the



methylene and methine hydrogens could not be rigorously analyzed, the presence of these groups was evident from the observed coupling in the ^{13}C nmr spectrum. The methine carbon appears as a low-field doublet (49.63 ppm) shifted by allylic and aryl substitution. The methylene carbon appears as a triplet (75.40 ppm) indicative of a methoxy-substituted methylene. The signals due to a carbon adjacent to an oxygen generally occur at lower field (72–94 ppm), compared to those adjacent to the 4-cyanophenyl group (37–55 ppm) (1, 3). The terminal alkene is further supported by methylene and methine carbon signals appearing in the vinyl region of the ^{13}C nmr spectrum.

Compound **14** was identified as *trans*-1-(4-cyanophenyl)-4-methoxy-2-butene. The ^{1}H nmr spectrum exhibits a singlet (3.33 ppm) indicative of a methoxy methyl group. Two doublets (3.45 and 3.90 ppm) represent methylene groups, aryl and methoxy substituted, respectively. Protons adjacent to oxygen generally occur at lower field (3.2–3.7 ppm) than those adjacent to the 4-cyanophenyl group (2.4–3.0 ppm) (1, 3). Two doublets of triplets appear in the vinyl region of the ^{1}H nmr spectrum, each representing a vinyl proton adjacent to a methylene group. The coupling constant (15.4 Hz) between the vinyl protons is indicative of the *trans* configuration. The infrared spectrum shows a C–H bending frequency at 953 cm^{-1}, further supporting a *trans* alkene. An AA'XX' pattern in the aromatic region of the ^{1}H nmr is indicative of a 4-cyanophenyl group.

In the ^{13}C nmr spectrum of **14**, there is a triplet (38.68 ppm), which indicates a methylene group substituted by the 4-cyanophenyl group. There is a lower field quartet (58.00 ppm), which is consistent with the methyl of the methoxy group, and a triplet (76.62 ppm), which indicates a methylene carbon bonded to the methoxy group. Two vinyl methine groups are present (129.05 ppm and 132.20 ppm).

An acetonitrile–methanol solution of 2-methyl-1,3-butadiene (**10**), **1**, and **5** was irradiated and the resulting photolysate gave four photo-NOCAS adducts: **15**, **16**, **17**, and **18**. Adduct **15** was identified as 3-(4-cyanophenyl)-4-methoxy-3-methyl-1-butene. The ^{1}H nmr of **15** is very similar to compound **13**. The ABC multiplet for **13** has now been simplified to an AB pattern, indicating a methylene group adjacent to a quaternary stereogenic centre. In the ^{13}C nmr spectrum, an aryl-substituted quaternary carbon is observed (46.11 ppm).

Compound **16** was identified as the 1,2-addition product resulting from attack at the less substituted end of the diene; this product is 3-(4-cyanophenyl)-4-methoxy-2-methyl-1-butene. Again, the ^{1}H nmr of **16** is very similar to that of compound **13**. A less complex AMX pattern is observed due to the substitution of a methyl group on carbon-2 of the double bond. The vinyl region shows two singlets representing the geminal protons on carbon-1. The ^{13}C nmr spectrum exhibits a triplet (112.59 ppm) for the terminal vinyl methylene and the quaternary vinyl carbon shows up as a singlet (144.02 ppm).

Compound **18** was identified as the 1,4-addition product having the *Z* configuration, (*Z*)-4-(4-cyanophenyl)-1-methoxy-2-methyl-2-butene. The aliphatic region of the ^{1}H nmr spectrum exhibits a singlet corresponding to a methyl group and a singlet at higher frequency for the methoxy methyl group. A doublet appears at 3.48 ppm, representing a methylene group substituted by both aryl and vinyl groups, and a singlet appears at 3.99 ppm, representing a methoxy-substituted methylene group. The distinction between these methylene groups, assigned on the basis of chemical shift, establishes the regiochemistry of the adduct (1, 3).

A vinyl proton appears as a triplet (5.50 ppm, J = 7.4 Hz) resulting from coupling to the higher field methylene group (3.48 ppm). Therefore, the aryl-substituted methylene group is vicinal to the vinyl proton. Since only one vinyl proton is present, the methyl group and methoxy-substituted methylene group must be the other substituents on the double bond.

The ^{13}C nmr spectrum provides further evidence for structure **18**. A triplet at 34.04 ppm indicates an aryl-substituted methylene group, a triplet at 70.96 ppm shows a methoxy-substituted methylene group, a vinyl methine group is observed at 125.72 ppm, and a vinyl quaternary carbon at 134.74 ppm.

The decision in favour of the *Z* configuration for **18** was based upon the results of a double irradiation experiment leading to a nuclear Overhauser effect (nOe). The methylene groups were irradiated and the nOe recorded. When the methoxy-substituted methylene group was irradiated, an enhanced signal was observed for the methyl group, methoxy methyl group, and for the aryl-substituted methylene group. This shows the methoxy-substituted methylene group is *syn* to the aryl-substituted methylene group. Further proof of the *Z* configuration was provided by irradiating the aryl-substituted methylene group. An nOe was seen for the methoxy-substituted methylene group, the vinyl proton, and the aryl protons.

Compound **17** is the configurational isomer of **18**; (*E*)-4-(4-cyanophenyl)-1-methoxy-2-methyl-2-butene. The ^{1}H and ^{13}C nmr spectra show characteristic patterns similar to those of compound **18**. The *E* configuration was assigned on the basis of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

the observed nOe. When the methoxy-substituted methylene group was irradiated, an enhancement was observed for the signal due to the methyl and the methoxy methyl groups. When the aryl-substituted methylene group was irradiated, an nOe was seen for the methyl group and the aryl hydrogens. These observations support the *E* configuration and confirm the regiochemical assignment for **17**.

When an acetonitrile–methanol solution of 2,3-dimethyl-1,3-butadiene (**11**), **1**, and **5** was irradiated, compounds **19**, **20**, and **21** were produced (reaction [5]). Compound **19** was identified as an *anti*-Markovnikov 1,2-addition product, 3-(4-cyanophenyl)-4-methoxy-2,3-dimethyl-1-butene. The ^{1}H and ^{13}C nmr spectra were similar to those of compound **15**. Unlike **15**, there are only two vinyl protons, instead of three, and they appear as slightly broadened singlets in the vinyl region of the ^{1}H nmr spectrum, indicative of a terminal, disubstituted double bond. In the ^{13}C nmr spectrum, there are signals due to a vinyl carbon with no bonded protons (148.13 ppm) and a vinyl methylene (112.19 ppm).

Compound **20** was identified as the 1,4-addition product having the *E* configuration, (*E*)-1-(4-cyanophenyl)-4-methoxy-2,3-dimethyl-2-butene. The ^{1}H and ^{13}C nmr spectra are similar to those of compound **17**. The main difference is one additional methyl group, which shows up as a singlet in the ^{1}H nmr spectrum and a quartet in the ^{13}C nmr spectrum. The ^{1}H nmr spectrum, also, exhibits no vinyl protons but two vinyl quaternary carbons are identified in the ^{13}C nmr spectrum. The *E* configuration was assigned by nOe. The methoxy-substituted methylene group was irradiated and an nOe was observed for two methyl groups and the methoxy methyl group. When the aryl-substituted methylene group was irradiated, an nOe was observed for two methyl groups. This information supports a *trans* configuration of the methylene groups; thus, **20** has an *E* configuration.

Compound **21** was identified as a 1,4-addition product with *Z* configuration: (*Z*)-1-(4-cyanophenyl)-4-methoxy-2,3-dimethyl-2-butene. The ^{1}H and ^{13}C nmr spectra exhibit similar characteristic patterns to those of compound **20**. The observed nuclear Overhauser effect (nOe) was used to determine the *Z* configuration of **21**. The methoxy-substituted methylene group was irradiated and an enhanced signal was observed for one methyl group and the aryl-substituted methylene group. The aryl-substituted methylene group was irradiated and an nOe was observed for the other methyl group and the methoxy-substituted methylene group. This information confirms that the methylene groups are *syn* to one another and that **21** has a *Z* configuration.

Irradiation of an acetonitrile–methanol solution of **1**, **5**, and 2,5-dimethyl-2,4-hexadiene (**12**) yields two 1,4-adducts, **22**, and **23** (reaction [6]). The major product, **22**, was identified as *trans*-2-(4-cyanophenyl)-5-methoxy-2,5-dimethyl-3-hexene. The structural proof of compound **22** comes neatly from the ^{1}H nmr, ^{13}C nmr, and infrared spectra. There are two singlets in the aliphatic region of the ^{1}H nmr spectrum; each represents two chemically equivalent methyl groups. A low-field singlet (3.16 ppm) indicates the presence of a methoxy methyl group and an AA′XX′ pattern in the aromatic region indicates the 4-cyanophenyl group. Two doublets appear in the vinyl region, each with a coupling (16 Hz) typical of a *trans* configuration. The infrared spectrum shows a C–H bending frequency at 970 cm^{-1}, further supporting the *trans* configuration for this alkene.

In the ^{13}C nmr spectrum of **22**, there is a singlet (40.73 ppm) supporting a quaternary carbon substituted by a 4-cyanophenyl group and a quartet (50.29 ppm) representing a methoxy methyl group. The methoxy group is bonded to a quaternary carbon, which shows up as a singlet (74.73 ppm).

Compound **23** was identified as *trans*-5-(4-cyanophenyl)-2,2,5-trimethyl-3-hexenenitrile. The nmr spectra of **23** are very similar to those of compound **22**. The main differences in the spectra of the two compounds is that in **23** there is no methoxy group; and the ^{13}C nmr spectrum shows that there are two cyano groups present in the molecule (singlets at 118.90 and 123.52 ppm). Both cyano groups are affixed to quaternary centres, one singlet (34.56 ppm) representing an alkyl quaternary carbon, and another singlet (109.99 ppm) representing an aryl carbon.

An acetonitrile–collidine solution (without added methanol) of **12**, **1**, and **5** was irradiated and gave four 1:1 substitution products: **26**, **27**, **28**, and **29** (reaction [8]). Compound **26** was identified as 3-(4-cyanophenyl)-2,5-dimethyl-1,4-hexadiene. The aliphatic region of the ^{1}H nmr spectrum exhibits three singlets assigned to the methyl groups. A methine proton on carbon-3 is a doublet (4.20 ppm, J = 9.2 Hz), which is indicative of an allylic and benzylic methine group. A doublet in the vinyl region indicates one vinyl proton coupled to a vicinal proton. The presence of a terminal disubstituted olefin is supported by two singlets in the vinylic region. The typical AA′XX′ pattern in the aromatic region of the ^{1}H nmr spectrum supports the presence of the 4-cyanophenyl group.

In the ^{13}C nmr spectrum of **26**, there is a doublet (51.47 ppm), which is consistent with an aryl substituted methine group, there is a triplet (112.54 ppm), which is consistent with a methylene group of a terminal double bond, and there is a doublet (124.38 ppm), which supports a vinyl methine group. There are also two singlets for vinyl carbons.

Compound **27** was identified as *trans*-5-(4-cyanophenyl)-2,5-dimethyl-1,3-hexadiene. The aliphatic region of the ^{1}H nmr exhibits two singlets; the signal at 1.45 ppm represents two chemically equivalent methyl groups, while the signal at 1.84 ppm represents the other methyl group. The presence of a terminal disubstituted olefin is supported by two singlets in the vinylic region. Two doublets appear in the vinyl region of the ^{1}H spectrum, each representing a vinyl proton adjacent to an allylic quaternary carbon. The coupling constant (16.0 Hz) between the vinyl protons is indicative of the *trans* configuration. The infrared spectrum shows a C–H bending frequency of 951 cm^{-1}, further supporting a *trans* configuration. An AA′XX′ pattern in the aromatic region of the ^{1}H nmr spectrum is indicative of a 4-cyanophenyl group.

The ^{13}C nmr spectrum of **27** exhibits a singlet (40.95 ppm), which is consistent with an aryl-substituted quaternary carbon. There is a triplet (116.04 ppm), which is indicative of the terminal vinyl methylene group; two doublets (130.14 and 138.25 ppm) and a singlet in the vinyl region of the ^{13}C nmr spectrum indicate two vinyl methine groups and a vinyl-disubstituted carbon.

Compound **28** was identified as (*Z*)-1-(4-cyanophenyl)-2,5-dimethyl-2,4-hexadiene. The ^{1}H nmr exhibits three singlets in the aliphatic region, indicative of three methyl groups. A low-field singlet (3.52 ppm) shows a methylene group substituted with an aryl group. In the vinyl region there are two doublets (J = 11.3 Hz) indicative of the two adjacent methine groups. An AA′XX′ pattern in the aromatic region of the ^{1}H nmr spectrum is indicative of a 4-cyanophenyl group. The ^{13}C nmr spectrum of **28** indicates a methylene group substituted by a 4-

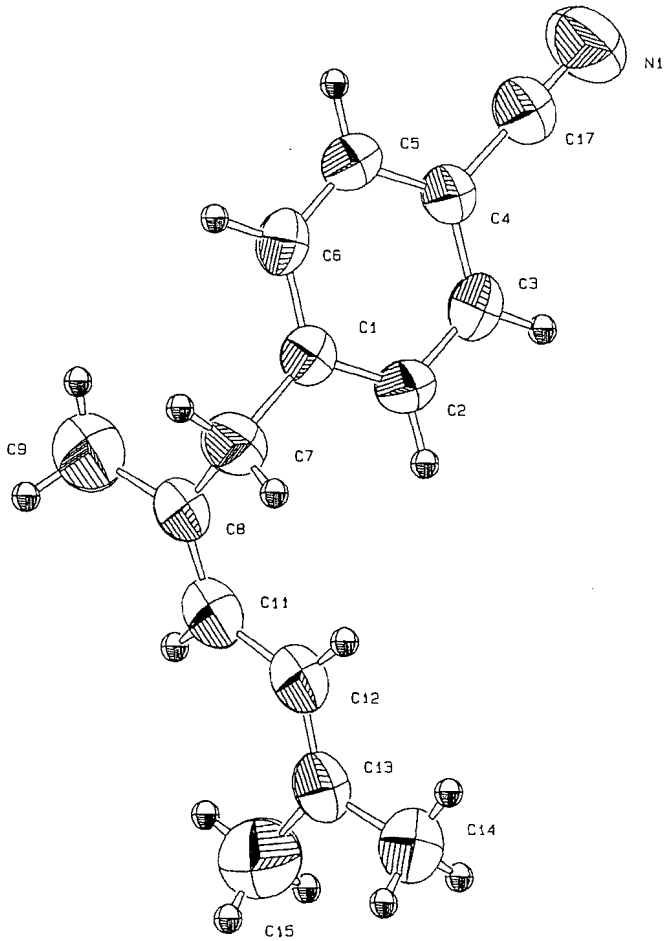

FIG. 3. X-ray crystallographic structure of (*Z*)-1-(4-cyanophenyl)-2,5-dimethyl-2,4-hexadiene (**28**).

cyanophenyl group (38.12 ppm), two doublets (120.40 and 124.02 ppm) for two vinyl methine groups, and two singlets (132.20 and 135.02 ppm) for the other two vinyl carbons. The *Z* configuration, as well as the overall structure of **28**, was firmly established by X-ray analysis of a single crystal (Fig. 3).[3]

Compound **29** was identified as the configurational isomer of **28**, (*E*)-1-(4-cyanophenyl)-2,5-dimethyl-2,4-hexadiene. The ^1H and ^{13}C nmr are very similar to those of the *Z* isomer.

Discussion

These results (reactions [3]–[8]) can be accounted for by the extended mechanism shown in Scheme 1. Initial excitation of 1,4-dicyanobenzene (**1**) (step 1) is achieved by irradiation with a medium-pressure mercury vapour lamp through Pyrex. The dienes, **9–12**, do not absorb light transmitted through Pyrex (>280 nm). Single electron transfer from the diene to the singlet excited state of **1** and formation of the solvent-separated radical ion pair (SSRIP) is thermodynamically favourable. The ΔG_{et} for this process, calculated by the Weller equation (eq. [9]) is exergonic by more than 20 kJ mol^{-1} (Table 1); therefore, the singlet excited state of **1** should be quenched, by the single electron transfer mechanism, at the diffusion-controlled rate in every case (11).

TABLE 1. The oxidation potentials of the dienes **9–12** and the calculated free energy change (ΔG) for the electron transfer process from the diene to the electronic excited singlet state of 1,4-dicyanobenzene (**1**)

Diene	$E_{1/2}^{ox}$ (V)	ΔG_{et} (kJ/mol)[a]
1,3-Butadiene (**9**)	2.37[c]	−25.0
2-Methyl-1,3-butadiene (**10**)	2.25[b]	−36.6
2,3-Dimethyl-1,3-butadiene (**11**)	2.16[b]	−45.3
2,5-Dimethyl-2,4-hexadiene (**12**)	1.24[b]	−134

[a]Based upon the Weller equation (reaction [9]) (11); $E_{0,0}$(**1**) 408.4 kJ/mol, $E_{1/2}^{red}$(**1**) −1.66 V; the Coulombic attraction term was taken to be 5.40 kJ/mol (3*a*).

[b]Oxidation potentials were measured at a platinum electrode relative to the saturated calomel electrode (SCE) using tetraethylammonium perchlorate (0.1 M TEAP) as the electrolyte in acetonitrile. The anodic wave was irreversible, the half-wave potential was estimated by substracting 0.028 V from the peak potential (12).

[c]This potential was reported by Neikam and Desmond (13), versus the silver/silver ion (Ag/0.1 N Ag^+) reference electrode; it as relating to the SCE by adding 0.34 V.

[9] $\Delta G_{et} = F[E_{1/2}^{ox}(D) - E_{1/2}^{red}(A) - e/\epsilon\alpha] - E_{0,0}(A)$

Photo-NOCAS adducts were obtained upon irradiation of acetonitrile–methanol solutions of **1** and the dienes. Addition of photosensitizer (electron transfer) or codonor to the irradiation mixture generally increases the efficiency of the reaction and the yield of adducts (steps 6–8).

Step 3 determines the regiochemistry of adduct formation. In every case, initial attack of the nucleophile (methanol or cyanide ion) occurs at a terminal position of the diene. This is consistent with previous results involving addition to monoalkenes where formation of *anti*-Markovnikov adducts is favoured (1, 3). The initial intermediate, formed upon attack of methanol on the diene radical cation, is the distonic radical cation. This intermediate may be bridged (3).

The addition of nucleophile (methanol) to the radical cation of 2-methyl-1,3-butadiene (**10**$^{+\cdot}$) occurs at the more heavily substituted double bond (carbon-1); the combined yield of adducts **15**, **17**, and **18** (49%) is significantly greater than the yield of **16** (6%). Attack at this position, the end of the more heavily substituted double bond, leads to formation of the more stable allylic radical. In addition, the more heavily substituted double bond bears the greater proportion of positive charge. Both of these factors contribute to the regiochemistry of the reaction.

The next step in the proposed mechanism involves coupling of the allylic radical with the radical anion, **1**$^{-\cdot}$, at the *ipso* position, a position of high spin density. Attack at the alternative ends of the ambident allylic radical leads to 1,2 and 1,4 addition. Reactions [3], [4], and [5] show little regioselectivity. In reaction [3], with the allylic radical from **9** where the alternative positions are secondary (1,2) or primary (1,4), 1,2 addition is slightly favoured. In reaction [4], with the allylic radical from **10** where the alternative positions are tertiary (1,2) or primary (1,4) addition is slightly favoured. In reaction [5], with the allylic radical from **11** where the alternative positions are ter-

For personal use only.

tiary (1,2) or primary (1,4), 1,2 addition is favoured. In marked contrast, in reaction [6], where the alternative positions are secondary (1,2) or tertiary (1,4), 1,4 addition is the exclusive reaction. A tentative explanation for these observations is preferential attack at the centre of higher spin density, moderated by steric interactions.

The results from reaction [6] were particularly interesting, firstly, because of the specific formation of one regio- and stereoisomer (**22**) in high yield, and secondly, because of the competitive formation of the cyanide adduct (**23**) in low yield. Related cyanide ion adducts were not detected in reactions [3], [4], or [5]. However, incorporation of cyanide ion in photo-NOCAS products has been observed before. The nitrile is a minor product in the photo-NOCAS reaction of methanol, 2,3-dimethyl-2-butene (**2**), and 1,4-dicyanobenzene (**1**) (reaction [1]) (3). The concentration of cyanide ion during the course of reaction [6] must be very low (initially, $[CN^-] = 0$). This competitive formation of nitrile can be inhibited by the addition of lithium perchlorate, which presumably coordinates with the cyanide ion.

Clearly, the radical cation $\mathbf{12}^{+\cdot}$ is the most stable of the diene radical cations studied; the oxidation potential of **12** is relatively low (Table 1). This increased radical cation stability leads to greater selectivity toward reaction with nucleophile (14). Under these conditions, the relative reactivity of alternative nucleophiles will become evident. Cyanide ion is significantly more reactive as a nucleophile than is methanol. The nucleophilicity of cyanide ion in methanol, for the S_N2 reaction with methyl iodide, is greater than that of methanol by more than 10^6 (15)! Measured (flash photolysis) rates of reaction of the radical cations of substituted styrenes toward methanol and cyanide ion reflect this difference. The second-order rate constant for the nucleophilic attack of cyanide ion on the radical cation of 4-methoxystyrene in acetonitrile–water (1:4) was measured to be 1.0×10^8 M^{-1} s^{-1}; with methanol as the nucleophile the rate constant is 3.0×10^4 M^{-1} s^{-1} (14*a*).

When the irradiation of **1**, **12**, and **5** is carried out in acetonitrile, without added methanol, the nitrile adduct **23** is formed in high yield. The only source of cyanide ion in this reaction is that from the 1,4-dicyanobenzene (**1**), presumably lost in the rearomatization step (step 5). The initial concentration of cyanide may be generated in step 5, following the addition of water to the diene radical cation. A small amount of adventitious water is, no doubt, present in the (dried) acetonitrile. Added cyanide ion is efficiently incorporated (reaction [7]).

The possibility that the nitrile adduct was formed by reaction of the contact radical ion pair (CRIP) resulting from excitation of the charge transfer complex, was effectively ruled out by the observation that the product ratio (**22**/**23**) is essentially the same when the charge transfer transition is selectively excited. Furthermore, this ratio is the same when the reaction is photosensitized (electron transfer). Under these conditions, the radical anion, $\mathbf{1}^{-\cdot}$, and the radical cation, $\mathbf{12}^{+\cdot}$, are certainly formed separately solvated.

The stereoselectivity for the formation of *cis* and *trans* 1,4-addition products reflects the equilibrium ratio of s-*cis* to s-*trans* conformations of the starting material. The diene radical cation prefers to be planar and thus maintain its conformation. The intermediate allylic radical also prefers to be planar (16). Consequently, the initial conformation of the starting diene is maintained in the final photo-NOCAS adducts (16). There is good evidence that the s-*trans* conformation of these dienes (**9**–**12**) is preferred (17). Differences in the energy of the s-*trans*–s-*cis* conformations can be calculated by molecular mechanics (MM3), Table 2 (18). The observed ratios of s-*trans* to s-*cis* configuration of the photo-NOCAS adducts are in good agreement with these calculated energy differences: from **9**, 100% (calculated composition at 10°C, 92% s-*trans*); from **10**, 90% (89%); from **11**, 65% (66%); and from **12**, 100% (99%), *trans*-1,4-addition.

TABLE 2. Calculated relative steric energies and s-dihedral angles for the s-*trans*–s-*cis* conformations of the dienes **9**–**12**

Diene		ΔE (kJ/mol)[a]	∠1234 (°)
1,3-Butadiene (**9**)	s-*trans*	0	180.0
	s-*cis*	5.90 (9.75)[b]	0.0
2-Methyl-1,3-butadiene (**10**)	s-*trans*	0	180.0
	s-*cis*	4.88 (4.85)[b]	0.1
2,3-Dimethyl-1,3-butadiene (**11**)	s-*trans*	0	180.0
	s-*cis*	1.61 (3.26)[c]	0.0
2,5-Dimethyl-2,4-hexadiene (**12**)	s-*trans*	0	180.0
	s-*cis*	11.65	61.8

[c]Reported value, using the MMP1 (1973) force field (18*a*).

The photo-NOCAS reaction involving **1** and **12** can be diverted to 1:1 (diene:aromatic) substitution products by the addition of a non-nucleophilic base, 2,4,6-trimethylpyridine (collidine, **25**) (reaction [8]). The radical cation $\mathbf{12}^{+\cdot}$ is acidic (19). Deprotonation leads to the 2,4-dienyl radical, which can react at all three ambident positions. Coupling with the 1,4-dicyanobenzene anion radical, at the *ipso* position, occurs preferentially at the end of the allylic radical, to give the conjugated diene products, **27**–**29**.

Reduction of the alkyl-substituted 2,4-pentadienyl radical by the anion radical is now competitive with coupling. The reduction potential of the 2,4-dienyl radical is low enough that the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\cdot}$) can reduce the radical to the anion, which, upon protonation, yields the tautomer (**30**) (steps 10a and 12). Alkenyl methyl ethers were not formed in reactions [3]–[7]. The reduction potentials of alkyl-substituted 2-propenyl radicals are greater (more negative) than that of 1,4-dicyanobenzene (**1**) (−1.66 V, SCE) (20).

Conclusions

1. The scope of the photo-NOCAS reaction has been extended to include conjugated dienes. Yields can be high (reactions [6] (82%) and [7] (80%)). This process has synthetic utility.

2. The extended mechanism (Scheme 1) can account for all the observations.

3. The regiochemistry is consistent with initial attack of nucleophile (methanol) at that terminal position of the diene radical cation which leads to formation of the more stable allylic radical. Subsequently, both 1,2 and 1,4 adducts can result. Coupling of the allylic radical with the radical anion occurs at the position of higher spin density.

4. The more heavily substituted, and therefore more stable, radical cations show significant selectivity toward reaction with nucleophile; the rate of reaction with cyanide ion is appreciably greater than with methanol.

5. Competitive formation of the nitrile, by attack by cyanide ion released in the rearomatization step, can be prevented by addition of lithium perchlorate to the irradiation mixture.

For personal use only.

6. The stereochemistry of 1,4-adduct formation reflects the equilibrium conformation of the initial diene.

7. In the presence of non-nucleophilic base, deprotonation of the diene radical cation gives the allylic radical, which subsequently leads to formation of 1:1 (diene:aromatic) adducts.

Experimental

General information

^1H and ^{13}C nmr spectra were obtained from Bruker 250, 300, and 400 spectrometers or from a Nicolet 360 NB nmr spectrometer. Spectra were recorded in parts per million and frequencies are relative to tetramethylsilane. Infrared spectra (ir) were recorded on an air-purged Perkin–Elmer 180 grating spectrometer and are reported in wave numbers (cm^{-1}) relative to the 1601.4 cm^{-1} absorption band of polystyrene film. Elemental analyses were performed by Canadian Microanalytical Service Ltd., B.C. Exact mass determinations were obtained using a ZAB-E spectrometer. Melting points were determined using a Cybron Corporation Thermolyne apparatus with a digital thermocouple and are corrected. Ultraviolet (uv) absorbance spectra were recorded using a Cary Varian 219 spectrometer and are reported in nanometres (nm). Product yields were determined using a Hewlett–Packard (HP) 5890 gas chromatograph with a DB-1701 fused silica WCOT column (20 m × 0.25 mm, 0.4-μm film thickness) and a calibrated flame ionization detector (gc/fid) and are based upon 1,4-dicyanobenzene (**1**) as the limiting reagent. An HP 3392A integrator was interfaced with the gc/fid to obtain peak areas. An HP 5890 gas chromatograph with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33-μm film thickness) interfaced with an HP 5970 mass selective detector (gc/ms) was also used for product analyses. Mass spectra are reported as *m/z* (relative intensity). Separation of product mixtures was generally carried out using preparative medium-pressure liquid chromatography (mplc) (*3b*). The mplc consists of a 2.5 cm × 1 m column packed with thin-layer chromatography (tlc) grade silica gel (without binder, 7747 Merck) at a pressure of 15 psi using helium (1 psi = 6.9 kPa). Connected to the mplc was a uv spectrophotometer – fraction collector that collects ca. 10-mL fractions. Dry column flash chromatography (dc/fc) was also used (21). The column was packed with thin-layer chromatography grade silica gel (without binder, 7747 Merck). Fraction sizes were ca. 5 mL. Preparative-GC (prep/gc) was carried out using a Varian Aerograph A700 or 920.

Materials

Acetronitrile (Fisher ACS grade) was distilled twice, first from sodium hydride and then from phosphorous pentoxide. It was then passed through a column of basic alumina, refluxed over calcium hydride for 24 h (under a nitrogen atmosphere), fractionally distilled (under nitrogen), and stored over molecular sieves (3 Å) (22). Methanol was distilled and then stored over molecular sieves (4 Å). 1,4-Dicyanobenzene (**1**) (Aldrich) was purified by treatment with activated carbon in methylene chloride, followed by recrystallization from 95% ethanol. Tetraethylammonium perchlorate (TEAP) (Aldrich) was recrystallized three times from water and then dried in a vacuum oven for 15 h, 70°C, 0.25 Torr (1 Torr = 133.3 Pa). 1,3-Butadiene, 99% (**9**), 2-methyl-1,3-butadiene, 99% (**10**), 2,3-dimethyl-1,3-butadiene, 98% (**11**), and 2,5-dimethyl-2,4-hexadiene, 99% (**12**) were obtained from the Aldrich Chemical Co. Biphenyl (**5**) (Eastman Kodak Co.) was recrystallized from methanol. 2,4,6-Trimethylpyridine (collidine, **25**) (BDH) was purified by distillation.

Irradiations

Irradiations were generally carried out on solutions of acetonitrile–methanol (3:1) with 1,4-dicyanobenzene, the diene, and with or without a codonor. Solutions were irradiated in either 2 cm i.d. Pyrex tubes or 5 mm Pyrex nmr tubes, which were degassed by nitrogen ebullition. These samples were irradiated at 10°C using a CGE 1-kW or a Hanovia 450-W medium-pressure mercury vapour lamp contained in a water-cooled Pyrex and quartz immersion well, respectively, unless otherwise noted.

Cyclic voltammetric measurements

Cyclic voltammetry was used to obtain the oxidation potential of the dienes. The apparatus has been described (23). The working electrode was a platinum sphere (1 mm diameter) and the counter electrode was a platinum wire. The reference electrode was a saturated calomel electrode (SCE), which was connected to the solution (TEAP 0.1 M, acetonitrile) through a Luggin capillary. The dienes were purified by prep/gc using a 0.95 cm × 350 cm aluminum column packed with 40% SE-30 on Chromosorb W 60/80 NAW. The diene concentration was ca. 0.005 M. The anodic wave was irreversible; the half-wave potential was taken as 0.028 V before the anodic peak potential (12).

*Formation of the methanol, 1,3-butadiene (**9**), and 1,4-dicyanobenzene (**1**) photo-NOCAS adducts **13** and **14** (reaction [3])*

A solution of 1,3-butadiene (**9**) (1.2 g, 0.022 mol), 1,4-dicyanobenzene (**1**) (1.0 g, 0.0078 mol), and biphenyl (**5**) (1.2 g, 0.0078 mol) in acetonitrile–methanol (3:1, 60 mL) was degassed by nitrogen ebullition for 5 min and irradiated for 98 h using a 450-W lamp at 10°C. The solvent was removed to yield a crude photolysate. Unreacted 1,4-dicyanobenzene (**1**), precipitated from the photolysate by the addition of a mixture of hexanes and ethyl acetate, was removed by filtration. The crude photolysate was separated by dc/fc (diameter: 50 mm) eluting with 10% ethyl acetate in hexanes. The products eluted in the order **13** followed by **14**.

*3-(4-Cyanophenyl)-4-methoxy-1-butene (**13**)*

The yield was 35%: infrared (PE-180) ν: 3081(w), 2981(m), 2931(m), 2881(m), 2829(m), 2239(s), 1636(w), 1606(m), 1503(m), 1476(w), 1456(w), 1411(w), 1377(w), 1181(m), 1111(s), 991(w), 971(w), 946(w), 903(m), 821(m); ^1H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 3.33 (s, 3H, OCH_3), 3.70 (m, 3H, H of methylene and methine groups), 5.10 (d, 1H, $^3J_{1trans-2}$ = 17.2 Hz, vinyl H (1*trans*-H)), 5.19 (d, 1H, $^3J_{1cis-2}$ = 10.4 Hz, vinyl H (1*cis*-H)), 5.96 (m, 1H, $^3J_{1trans-2}$ = 17.2 Hz, $^3J_{1cis-2}$ = 10.4 Hz, $^3J_{2-3}$ = 6.6 Hz, vinyl H (2-H)), 7.35 (d, 2H, $^3J_{2'-3'}$ = 8.3 Hz, $^3J_{5'-6'}$ = 8.3 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.60 (d, 2H, $^3J_{2'-3'}$ = 8.3 Hz, $^3J_{5'-6'}$ = 8.3 Hz, H's adjacent to cyano-substituted aryl carbon ((3′-H, 5′-H)); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 49.63 (d, 129.8 Hz, CH, aryl substituted), 58.95 (q, 141.4 Hz, OCH_3), 75.40 (t, 141.9 Hz, OCH_2), 110.39 (s, quaternary aryl carbon, cyano substituted), 117.08 (t, 157.6 Hz, terminal vinyl CH_2), 118.87 (s, CN), 128.79 (d, 160.1 Hz, aromatic CH adjacent to alkyl-substituted aryl carbon), 132.18 (d, 165.4 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 137.26 (d, 155.2 Hz, vinyl CH), 146.98 (s, quaternary aryl carbon, alkyl substituted); ms *m/z*: 51(51), 62(25), 63(52), 75(42), 89(66), 114(30), 115(96), 116(82), 127(25), 140(77), 141(25), 142(47), 156(45), 157(100), 187(19). Exact Mass calcd. for $C_{12}H_{13}NO$: 187.0997; found: 187.0992.

trans-*1-(4-Cyanophenyl)-4-methoxy-2-butene (**14**)*

The yield of **14** was 30%: infrared (PE-180) ν: 2978(w), 2928(m), 2898(m), 2803(m), 2223(s), 1603(m), 1503(m), 1448(w), 1413(w), 1381(w), 1193(w), 1173(w), 1113(s), 953(m), 893(w), 828(w), 803(m); ^1H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 3.33 (s, 3H, OCH_3), 3.45 (d, 2H, $^3J_{3-4}$ = 6.7 Hz, CH_2, aryl-substituted (4-H)), 3.90 (d, 2H, $^3J_{1-2}$ = 5.5 Hz, CH_2, methoxy-substituted (1-H)), 5.64 (m, 1H, $^3J_{2-3}$ = 15.4 Hz, $^3J_{1-2}$ = 5.5 Hz, vinyl H (2-H)), 5.83 (m, 1H, $^3J_{2-3}$ = 15.4 Hz, $^3J_{3-4}$ = 6.7 Hz, vinyl H (3-H)), 7.30 (d, 2H, $^3J_{2'-3'}$ = 8.1 Hz, $^3J_{5'-6'}$ = 8.1 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.57 (d, 2H, $^3J_{2'-3'}$ = 8.1 Hz, $^3J_{55'-6'}$ = 8.1 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 38.68 (t, 128.7 Hz, CH_2, aryl substituted), 58.00 (q, 140.2 Hz, OCH_3), 76.62 (t, 139.2 Hz, OCH_2), 110.00 (s, quaternary aryl carbon, cyano substituted), 118.93 (s, CN), 129.05 (d, 157.1 Hz, vinyl CH), 129.31 (d, 160.9 Hz, aromatic CH adjacent to alkyl-substituted aryl carbon), 130.69 (d, 163.8 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 132.20 (d, 150.6 Hz, vinyl CH), 145.55 (s, quaternary aryl carbon, alkyl substituted); ms *m/z*: 51(38), 58(24), 63(33), 71(100), 72(22), 75(22), 76(20), 89(48), 115(40), 116(49), 127(25), 128(24),

129(24), 140(25), 154(25), 155(20), 187(1). Anal. calcd. for $C_{12}H_{13}NO$: C 76.97, H 7.00, N 7.48; found: C 76.70, H 7.09, N 7.45.

*Formation of the methanol, 2-methyl-1,3-butadiene (**10**) and 1,4-dicyanobenzene (**1**) photo-NOCAS adducts **15–18** (reaction [4])*

A solution of 2-methyl-1,3-butadiene (**10**) (2.6 g, 0.04 mol) (the stabilizer, hydroquinone, was removed by distillation at atmospheric pressure), 1,4-dicyanobenzene (**1**) (2.5 g, 0.02 mol), and biphenyl (**5**) (6.0 g, 0.04 mol) in acetonitrile–methanol (3:1, 160 mL) was degassed by nitrogen ebullition for 5 min and irradiated for 136 h using a 450-W lamp. The crude photolysate was separated by mplc using a linear solvent gradient of hexanes – dichloromethane. Products were eluted in the order **15**, **16**, **18**, and **17**. Several fractions were combined and rechromatographed by dc/fc and mplc to achieve purity of the four photo-NOCAS products.

*3-(4-Cyanophenyl)-4-methoxy-3-methyl-1-butene (**15**)*

The yield of **15** was 20%: infrared (PE-180) ν: 3087(w), 2977(m), 2927(m), 2877(m), 2827(m), 2232(s), 1602(w), 1603(m), 1502(m), 1477(w), 1452(w), 1412(w), 1382(w), 1362(w), 1272(w), 1192(w), 1180(w), 1107(s), 1012(w), 982(w), 962(w), 902(m), 820(m); ^{1}H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 1.40 (s, 3H, CH_3), 3.31 (s, 3H, OCH_3), 3.53 (d, 1H, $^2J_{4-4'}$ = 9.1 Hz, H of methylene group (4-H)), 3.57 (d, 1H, $^2J_{4-4'}$ = 9.1 Hz, H of methylene group (4′-H)), 5.08 (d, 1H, $^3J_{1trans-2}$ = 17.6 Hz, terminal vinyl H (1*trans*-H), 5.20 (d, 1H, $^3J_{1cis-2}$ = 10.8 Hz, terminal vinyl H (1*cis*-H)), 6.02 (dd, 1H, $^3J_{1trans-2}$ = 17.6 Hz, $^3J_{1cis-2}$ = 10.8 Hz, vinyl H (2-H)), 7.45 (d, 2H, $^3J_{2'-3'}$ = 8.2 Hz, $^3J_{5'-6'}$ = 8.2 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.57 (d, 2H, $^3J_{2'-3'}$ = 8.2 Hz, $^3J_{5'-6'}$ = 8.2 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 23.06 (q, 128.0 Hz, CH_3) 46.11 (s, quaternary carbon, aryl substituted), 59.29 (q, 141.1 Hz, OCH_3), 79.68 (t, 142.3 Hz, OCH_2), 109.89 (s, quaternary aryl carbon, cyano substituted), 114.27 (t, 156.7 Hz, terminal vinyl CH_2), 118.99 (s, CN), 127.79 (dd, 161.6 Hz, 5.0 Hz, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.83 (dd, 165.4 Hz, 4.2 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 142.83 (d, 154.6 Hz, vinyl CH), 150.88 (s, quaternary aryl carbon, alkyl substituted); ms *m/z*; 51(55), 53(27), 63(42), 75(33), 76(28), 77(42), 89(44), 115(45), 116(100), 127(49), 128(54), 129(89), 140(55), 141(27), 154(36), 156(89), 170(42), 171(55), 201(13). *Formation of the methanol, 2,3-dimethyl-1,3-butadiene (**11**), and 1,4-dicyanobenzene (**1**) photo-NOCAS adducts **19–21** (reaction [5])*

A solution of 2,3-dimethyl-1,3-butadiene (**11**) (1.2 g, 0.02 mol) (the stabilizer, hydroquinone, was removed by distillation at atmospheric pressure), 1,4-dicyanobenzene (**1**) (1.9 g, 0.02 mol), and biphenyl (**5**) (1.1 g, 0.01 mol) in acetonitrile–methanol (3:1, 120 mL) was degassed by nitrogen ebullition for 5 min and irradiated for 144 h using a 450-W lamp at 3°C. The crude photolysate was separated by mplc using a linear gradient of hexanes – (50% dichloromethane, 50% hexanes). Products were eluted in the order **19**, **21**, and **20**. Further separation of **20** and **21** was achieved by dc/fc (diameter: 50 mm; eluent: 10% ethyl acetate – 90% hexanes).

*3-(4-Cyanophenyl)-4-methoxy-2,3-dimethyl-1-butene (**19**)*

The yield of **19** was 30%: infrared (PE-180) ν: 2979(m), 2929(m),

*Formation of the methanol, 2,5-dimethyl-2,4-hexadiene (**12**), and 1,4-dicyanobenzene (**1**) photo-NOCAS adducts **22** and **23** (reaction [6])*

A solution of 2,5-dimethyl-2,4-hexadiene (**12**) (4.9 g, 0.04 mol), 1,4-dicyanobenzene (**1**) (2.8 g, 0.02 mol), and biphenyl (**5**) (6.7 g, 0.04 mol) in acetonitrile-methanol (3:1, 180 mL) (freshly distilled) was degassed by nitrogen ebullition for 15 min and irradiated for 123 h using a 450-W lamp (irradiation time is only 18 h using a 1-kW lamp equipped with a quartz immersion vessel). The yield of the crude mixture was 12.8 g. This crude mixture was partially separated by mplc using a linear solvent gradient of hexanes–dichloromethane. Products were eluted in the order **22**, **23**, followed by unreacted **1**. Unreacted **1** was recovered by adding hexanes to the mixture; **1** precipitated and was then removed by filtration. Fractions containing mixtures were combined and rechromatographed (dc/fc; dimensions 50 mm × 65 mm) eluting with 10% diethyl ether/90% hexanes. Fractions containing pure **23** were dissolved in methanol; **23** crystallizes upon cooling. The crystals were repeatedly washed with methanol and dried in vacuo.

trans-*2-(4-Cyanophenyl)-5-methoxy-2,5-dimethyl-3-hexene (**22**)*

The yield of **22** was 82% (based on almost complete conversion of **1**): the melting point was 44.6–45.6°C; infrared (PE-180) ν: 2970(s), 2930(m), 2821(w), 2230(s), 1608(m), 1501(m), 1465(m), 1401(w), 1379(m), 1362(m), 1292(w), 1255(w), 1170(m), 1160(w), 1072(s), 1020(w), 1000(w), 970(m), 825(s), 750(w), 725(w); ^{1}H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 1.28 (s, 6H, two CH_3 groups), 1.42 (s, 6H, two CH_3 groups), 3.16 (s, 3H, OCH_3), 5.48 (d, 1H, $^3J_{3-4}$ = 16.2 Hz, vinyl H), 5.72 (d, 1H, $^3J_{3-4}$ = 16.2 Hz, vinyl H), 7.43 (d, 2H, $^3J_{2'-3'}$ = 8.4 Hz, $^3J_{5'-6'}$ = 8.4 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.59 (d, 2H, $^3J_{2'-3'}$ = 8.4 Hz, $^3J_{5'-6'}$ = 8.4 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}H nmr (90.80 MHz, $CDCl_3$) δ: 25.90 (q, 126.2 Hz, CH_3), 28.57 (q, 126.7 Hz, CH_3), 40.73 (s, quaternary carbon, aryl substituted), 50.29 (q, 140.2 Hz, OCH_3), 74.73 (s, quaternary carbon, methoxy substituted), 109.64 (s, quaternary aryl carbon, cyano substituted), 119.01 (s, CN), 126.94 (dd, 158.6 Hz, 5.2 Hz, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.99 (dd, 165.5 Hz, 4.8 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 132.87 (d, 146.9 Hz, vinyl CH), 138.03 (d, 148.9 Hz, vinyl CH), 154.39 (s, quaternary aryl carbon, alkyl substituted); ms *m/z*: 55(23), 73(53), 77(26), 99(96), 116(53), 154(31), 168(58), 170(27), 181(31), 196(71), 228(100). Hz, aromatic CH adjacent to alkyl-substituted aryl carbon), 129.08 (d, 149.5 Hz, vinyl CH), 132.12 (d, 169.8 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 138.90 (d, 152.1 Hz, vinyl CH), 153.38 (s, quaternary aryl carbon, alkyl substituted); ms *m/z*: 51(7), 77(8), 89(6), 115(7), 116(16), 127(8), 128(8), 140(8), 142(20), 143(8), 153(8), 154(15), 155(12), 168(8), 170(100), 171(12), 181(9), 196(29), 238(1). Anal. calcd. for $C_{16}H_{18}N_2$: C 80.63, H 7.61, N 11.76; found: C 80.41, H 7.78, N 11.57.

*Formation of the 2,5-dimethyl-2,4-hexadiene (**12**) photo-NOCAS adduct **23**, using acetonitrile as solvent and added KCN, 18-crown-6 (reaction [7])*

A solution of 2,5-dimethyl-2,4-hexadiene (**12**) (1.9 g, 0.017 mol), 1,4-dicyanobenzene (**1**) (0.6 g, 0.005 mol), biphenyl (**5**) (1.3 g, 0.0084 mol), KCN (0.45 g, 0.0069 mol), and 18-crown-6 (0.10 g, 0.38 mmol) in 40 mL of acetonitrile (freshly distilled) was degassed by nitrogen ebullition for 5 min and irradiated for 24 h using a 1-kW lamp equipped with a quartz immersion vessel. The crude photolysate was separated by mplc, eluting with a hexanes – (50% ether, 50% hexanes) solvent gradient. The yield of *trans*-5-(4-cyanophenyl)-2,2,5-trimethyl-3-hexanenitrile (**23**) was 80% (based on almost complete conversion of **1**).

*Formation of the 2,5-dimethyl-2,4-hexadiene (**12**), 1,4-dicyanobenzene (**1**) 1:1-adducts **26**, **27**, **28**, and **29**, by irradiation of an acetonitrile–2,4,6-trimethylpyridine (**25**, collidine) solution (reaction [8])*

A solution of 2,5-dimethyl-2,4-hexadiene (**12**) (4.3 g, 0.04 mol), 1,4-dicyanobenzene (**1**) (2.6 g, 0.02 mol), and biphenyl (**5**) (1.5 g, 0.01 mol) in 160 mL of acetonitrile and 2.4 mL of collidine (**25**) was degassed by nitrogen ebullition for 15 min and irradiated for 100 h using a 1-kW lamp. The solvent was removed and the crude photolysate was separated (mplc) with hexanes as the eluent. The products eluted in the order: **26**, **27**, **28**, followed by **29**.

*3-(4-Cyanophenyl)-2,5-dimethyl-1,4-hexadiene (**26**)*

The yield of **26** was 7%: infrared (PE-180) ν: 2977(s), 2927(s), 2857(m), 2237(s), 1647(w), 1607(m), 1503(m), 1442(m), 1377(m), 1174(w), 1112(w), 1022(w), 880(m), 847(w), 827(m), 797(m), 722(w); ^{1}H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 1.62 (s, 3H, CH_3), 1.66 (s, 3H, CH_3), 1.78 (s, 3H, CH_3), 4.20 (d, 1H, $^3J_{3-4}$ = 9.2 Hz, H of methine group (3-H)), 4.83 (s, 1H, terminal vinyl H), 4.91 (s, 1H, terminal vinyl H), 5.36 (d, 1H, $^3J_{3-4}$ = 9.2 Hz, vinyl H (4-H)), 7.32 (d, 2H, $^3J_{2'-3'}$ = 8.2 Hz, $^3J_{5'-6'}$ = 8.2 Hz, H's adjacent to alkyl-substituted aryl carbon (2'-H, 6'-H)), 7.58 (d, 2H, $^3J_{2'-3'}$ = 8.2 Hz, $^3J_{5'-6'}$ = 8.2 Hz, H's adjacent to cyano-substituted aryl carbon (3'-H, 5'-H)); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 18.03 (q, 127.3 Hz, CH_3), 21.07 (q, 126.5 Hz, CH_3), 25.95 (q, 127.1 Hz, CH_3), 51.47 (d, 126.8 Hz, CH, aryl substituted), 109.82 (s, quaternary aryl carbon, cyano substituted), 112.54 (t, 156.0 Hz, terminal vinyl CH_2), 119.11 (s, CN), 124.38 (d, 156.0 Hz, vinyl CH), 128.69 (d, 159.9 Hz, aromatic CH adjacent to alkyl-substituted aryl carbon), 132.15 (d, 163.3 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 134.19 (s, vinyl quaternary carbon), 146.37 (s, quaternary carbon), 149.32 (s, quaternary carbon); ms *m/z*: 55(11), 77(16), 116(46), 127(26), 140(23), 142(28), 153(23), 154(47), 168(100), 170(28), 196(87), 211(23). *Photosensitized (electron transfer) irradiation of **1** and **12***

A solution of **1** (31 mg, 2.4×10^{-4} mol), **12** (0.07 mL, 4.9×10^{-4} mol), and the photosensitizer (electron transfer), anthracene (**24**) (18 mg, 9.9×10^{-5} mol), in 4 mL of acetonitrile–methanol (3:1), was irradiating using a 1-kW lamp in a quartz immersion vessel. The light was passed through a glass filter, which absorbs light of wavelengths shorter than 330 nm. After 3 h, analysis (gc/fid) of an aliquot showed the ratio of **22/23** = 40. No reaction occurred when a solution of **1** and **12** was irradiated, without added **24**, under identical conditions.

In the presence of sodium methoxide in catalytic amounts, conjugated azoalkenes easily react with α-unsubstituted-or α-substituted-β-dicarboxylate derivatives to give at first hydrazonic derivatives, by 1,4-conjugate addition, and, by increasing sodium methoxide up to stoichiometric amounts, new polyfunctionalized 1-amino-1*H*-pyrrol-2(3*H*)-ones.

ORAZIO A. ATTANASI, LUCIA DE CRESCENTINI, FRANCO SERRA-ZANETTI et ELISABETTA FORESTI. Can. J. Chem. **72**, 2305 (1994).

En présence de quantités catalytiques de méthylate de sodium, les azoalcènes conjugués réagissent avec les dérivés β-dicarboxylates, substitués ou non en α, pour donner en premier lieu des dérivés hydrazoniques, par addition-1,4 conjuguée. Lorsqu'on augmente les quantités de méthylate de sodium pour arriver à des proportions stoechiométrique, il y a formation de nouvelles 1-amino-1*H*-pyrrol-2(3*H*)-ones polyfonctionnalisées.

[Traduit par la rédaction]

Introduction

It is recognized that the synthesis of new heterocycles represents an important area of research of immense academic and industrial importance (1).

Conjugated azoalkenes have attracted increasing attention because of their potential use in the synthesis of heterocycles and a great deal of effort has been directed by our group towards the development of a convenient strategy for the synthesis of a variety of widely substituted new 1-aminopyrrole derivatives.

The reaction of conjugated azoalkenes with many compounds containing active methine and methylene groups gives polyfunctionalized 1-aminopyrrole derivatives via a preliminary 1,4-conjugate addition, followed by subsequent intramolecular cyclization of the hydrazonic intermediates first obtained (2).

In the course of our previous investigations, cyano or ketonic carbonyl groups had frequently been observed to be effective in the internal heterocyclization processes of the 1,4-adduct intermediates, but several other activating groups exhibited no efficiency in the ring-closure processes (3, 4). We also studied in detail the reactions, in different molar ratios, of conjugated azoalkenes with alkylcyanoacetates $RO_2C\text{-}CH_2\text{-}CN$, in which we always observed ring closure on the cyano group and never on the ester group (3).

It was noteworthy therefore, that in the reactions of conjugated azoalkenes with ethylphenylcyanoacetate Ph-CH(CN)-COOEt, the 1,4-adducts did not behave in the same way, and intramolecular heterocyclization was effective on the ester group with loss of an alcohol molecule to yield previously unknown 1-amino-3-cyano-3-phenyl-1*H*-pyrrol-2(3*H*)-ones in good to excellent yields (5). In this latter case, in fact, the ring closure on the ester group appeared to be favoured, probably because the final products 1-amino-1*H*-pyrrol-2(3*H*)-ones are more stable than the 2-iminopyrrolines arising from the heterocyclization on the cyano group.

This occurrence prompted us to turn our attention to a possible general procedure for the synthesis of new classes of pyrrolin-2-ones from the reaction between conjugated azoalkenes and β-dicarboxylate derivatives possessing one or two active hydrogen atoms (i.e., α-substituted- or α-unsubstituted-β-diesters).

We examined the possibility of carrying out a straightforward synthesis of pyrrolin-2-ones in a stable form in view of the biological activity associated with a variety of pyrrole derivatives (6, 7), especially as building blocks in the construction of antiviral and antitumour DNA antibiotics (8).

The ability to prepare the desired polyfunctionalized compounds by a simple and efficient procedure seemed to us particularly attractive.

Results and discussion

The reaction of conjugated azoalkenes **1***a–f* with an equimolecular amount of diethyl methylmalonate (**2***a*) or diethyl phenylmalonate (**2***b*) proceeded easily at room temperature and produced the pertinent hydrazonic derivatives **3***a–l* in the presence of sodium methoxide in catalytic amounts. These products can be isolated in good yields by chromatography on a silica gel column, crystallized, and characterized. When they were subsequently treated with a stoichiometric amount of sodium methoxide in tetrahydrofuran (THF), the related 1-amino-1*H*-pyrrol-2(3*H*)-ones (**4***a–l*) were isolated in good yields by column chromatography, crystallized, and characterized (Scheme 1).

More conveniently, the synthesis of 1-amino-1*H*-pyrrol-2(3*H*)-ones **4***a–l* may be directly achieved in one pot by treating conjugated azoalkenes **1***a–f* with diethyl methylmalonate (**2***a*) or diethyl phenylmalonate (**2***b*). At the beginning, the reaction can be carried out in the presence of a catalytic amount of sodium methoxide to afford hydrazonic intermediates **3***a–l* with complete disappearance of the azoalkene (monitored by TLC).

[a]All reaction times were 0.1 h.
[b]Yields of pure isolated products.

At this point, a further addition in situ of sodium methoxide, up to the stoichiometric amount, induces the ready cyclization of the hydrazonic intermediates **3***a–l* into 1-amino-1*H*-pyrrol-2(3*H*)-ones **4***a–l*. Yields of hydrazones **3***a–l* and 1-amino-1*H*-pyrrol-2(3*H*)-ones **4***a–l* are given in Table 1.

Presumably, the reaction takes place by a base-catalyzed nucleophilic attack from the active methine group of α-substituted-β-diesters containing one active hydrogen atom to the azo-ene system of conjugated azoalkene, resulting in the 1,4-addition (Michael-type) of the diester residue to the azoalkene molecule to provide the preliminary formation of the hydrazonic compound. In the presence of sodium methoxide in stoichiometric amounts, this compound undergoes ring closure by means of internal nucleophilic attack from the C=N nitrogen atom on the ester carboxyl group, with consequential loss of an alcohol molecule. Under these conditions, the reaction stops and gives 1-amino-1*H*-pyrrol-2(3*H*)-one.

Also the reactions of conjugated azoalkenes **1***a–f* (Scheme 2) at room temperature with an equimolecular amount of dimethyl malonate (**2***c*) or dibenzyl malonate (**2***d*) readily led to the related hydrazonic derivatives **5***a–i* in the presence of sodium methoxide in catalytic amounts. These products (**5***a–i*) were crystallized in good yield and utilized for the smooth preparation, by addition of the stoichiometric amount of sodium methoxide in THF and subsequent treatment by strongly acid cation exchanger, of pertinent 1-amino-1*H*-pyrrol-2(3*H*)-ones **6***a–i*, bearing a hydrogen atom in position 3 and probably susceptible to tautomeric equilibrium (Scheme 2) (6, 9, 10).

More conveniently, the synthesis of 1-amino-1*H*-pyrrol-2(3*H*)-ones **6***a–i* from conjugated azoalkenes **1***a–f* by treatment with dimethyl malonate (**2***c*) or dibenzyl malonate (**2***d*) may be directly achieved in one pot in the same way as broadly described above for the synthesis of products **4**. Yields of the hydrazones **5***a–i* and 1-amino-1*H*-pyrrol-2(3*H*)-ones **6***a–i* are listed in Table 2.

The first and the second step of this reaction follow the same pathway as previously discussed in detail. In this case, however, the 1,4-adducts contain, in position α to a carbonyl group,

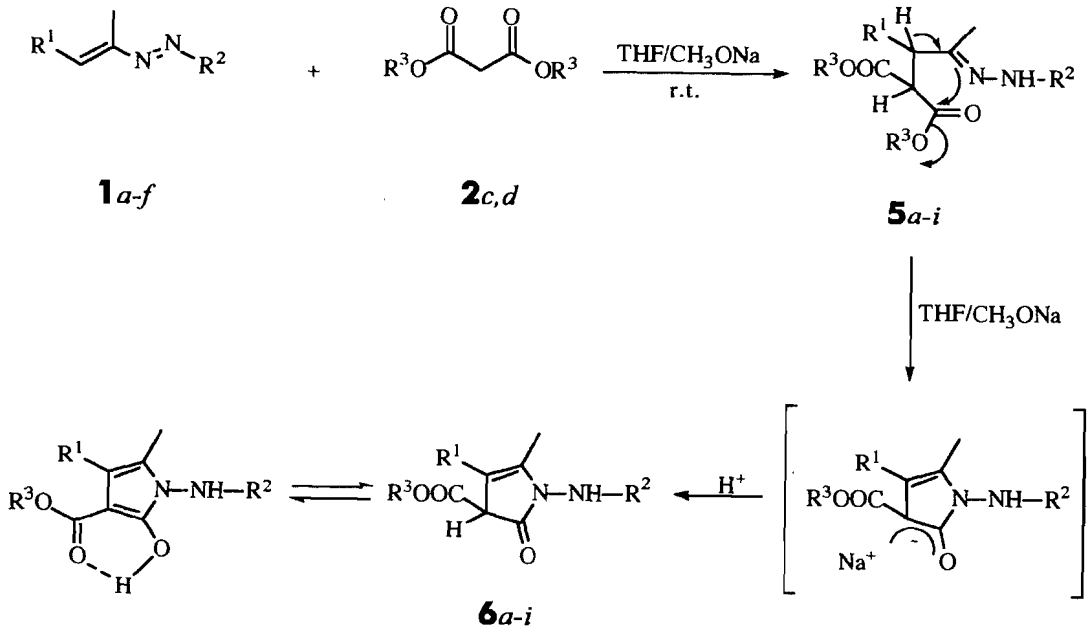
For personal use only.



1*a-f* **2***c,d* **5***a-i* **6***a-i*

SCHEME 2

a further hydrogen atom probably able to tautomerize (Scheme 2).

When conjugated azoalkenes **1***a–f* reacted with dibenzyl malonate (**2***d*) to produce related 1-amino-1*H*-pyrrol-2(3*H*) ones **6***g–i*, the loss of the alcohol molecule was demonstrated by isolation of benzyl alcohol in quantitative yield from the residual solution after filtration of solid reaction products. Benzyl alcohol was detected by TLC, isolated, and characterized by comparison with an authentic specimen. This result supports the reaction mechanism pictured in Scheme 2.

Furthermore, in early experiments, we studied the reactions between conjugated azoalkenes with nitriles containing active methylene groups (i.e., malononitrile, β-cyanoesters, β-cyanoamides) in the ratio 2:1. Double conjugated additions afforded bis-1,4 adducts that underwent double ring closure on the cyano group to give pyrrol[2,3-*b*]pyrroles (3, 4).

From these findings we went on to explore the reactions between conjugated azoalkenes **1***a–f* and dimethyl malonate (**2***c*) or dibenzyl malonate (**2***d*) in the ratio 2:1, but very poor yields of bis adducts were obtained, reactions did not go to completion, and reaction times were very slow.

To tentatively improve the yields of bis adducts, we also tried the 1,4-conjugate addition of the hydrazonic intermediates **5***a–i* to the heterodienic system of the azoalkenes **1***a–f* in the presence of sodium methoxide. All attempts were unsuccessful, because a preferential cyclization to the 1-amino-1*H*-pyrrol-2(3*H*)-ones prevented the conjugated addition to a further molecule of azoalkene.

In conclusion, this simple procedure really represents a useful entry to a new class of pyrrole derivatives not obtainable by other methods (11). In fact, all the pyrrole ring positions may be simultaneously functionalized with different substituents that are very difficult to introduce separately. These substituents may be selected in advance by varying the functionalization both on the starting conjugated azoalkenes (2) and β-diester derivatives. Moreover, some of these functional groups appear to be suitable for further structural modifications.

In former studies on the simple monocyclic pyrrolinones (or 2-hydroxypyrroles) as terminal rings of the bile pigments, Fischer and Plieninger formulated the products as 2-hydroxypyrroles (9), but more recently it was reported, based on NMR studies, that 2-hydroxypyrroles exist predominantly in the tautomeric pyrrolin-2-one form (10).[4] However, spectroscopic evidence indicates the considerable presence of the enol form, in solution. Further investigations are presently in progress to better clarify the nature of this tautomeric equilibrium.

Experimental section

General

Products **1***a–d*(12) and **1***e–f*(13) were prepared as described previously. Products **2***a–d* were commercial materials and were used without further purification. All melting points were recorded on a capillary melting point apparatus and are uncorrected. IR spectra were obtained as Nujol mulls, and ^{1}H NMR spectra were measured in DMSO-d_6 solution. Chemical shifts (δ) are reported in ppm, downfield from Me_4Si as internal standard. Machery–Nagel precoated silica gel SIL G-25 UV_{254} plates (0.25 mm) were employed for analytical thin-layer chromatography (TLC), Baker silica gel (0.063-0.200 mm) for column chromatography, and Merck I strongly acid cation exchanger for Na^+/H^+ exchange.

Preparation of hydrazones 3a–l and 5a–i

To a stirred solution of azoalkene (**1***a–f*) (1 mmol) in THF (3 mL) was added dropwise a solution of β-diester (**2***a–d*) (1 mmol) and sodium methoxide (0.1 mmol) in THF (3 mL). The mixture was magnetically stirred at room temperature (~5 min) until the reaction was completed (monitored by TLC). Products **3***a–l* were purified by chromatography on a silica gel column (elution with cyclohexane – ethyl acetate mixtures) and then crystallized from THF–*n*-pentane. Products **5***a–i* were crystallized by partial evaporation of the reaction solvent and by addition of *n*–pentane to this crude reaction.

[4]To unambiguously confirm the structure of these compounds, an X-ray diffraction study of methyl 4-benzyl-oxycarbonyl-2-methyl-5-oxo-1-(*N'*-phenylureido)-1,4-dihydropyrrole-3-carboxylate (**6***h*) was carried out. Structure determination confirmed that, in the solid state, the pyrrole derivatives reported here exist in the keto form, but a final unsatisfactory all-data agreement index $R = 0.3924$ prevented us from publishing these results in the text.

Ethyl 4-(carbamoylhydrazono)-2-(ethoxycarbonyl)-3-(methoxycarbonyl)-2-phenylpentanoate (**3**g): mp 153–160°C; crystallized from THF–*n*-pentane; IR: 3440 (NH), 3290, 3170 (NH, NH_2 overlap), 1735 (C=O), 1705 (C=O), 1695 (C=O), and 1590 (C=O) cm^{-1}; ^1H NMR: 1.10–1.22 (6H, m, 2 × CO_2*CH_2*Me), 1.96 (3H, s, Me), 3.67 (3H, s, CO_2Me), 4.08–4.18 (4H, m, 2 × CO_2*CH_2*Me), 4.69 (1H, s, CH), 5.43 and 6.25 (2H, 2 br s, NH_2, D_2O-exch.), 7.28–7.33 (5H, m, Ph), and 9.21 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{19}H_{25}N_3O_7$: C 56.01, H. 6.18, N 10.31; found: C 56.15, H 6.18, N 10.31.

Ethyl 4-(carbamoylhydrazono)-2,3-(diethoxycarbonyl)-2-(phenylpentanoate (**3**h): mp 161–164°C; crystallized from THF–*n*-pentane; IR: 3430 (NH), 3270, 3150 (NH, NH_2 overlap), 1720 (C=O), 1700 (C=O), 1685 (C=O), and 1585 (C=O) cm^{-1}; ^1H NMR: 1.02–1.16 (9H, m, 3 × CO_2CH_2*Me*), 1.89 (3H, s, Me), 4.02–4.12 (6H, m, 3 × CO_2*CH_2*Me), 4.60 (1H, s, CH), 5.34 and 6.16 (2H, 2 br s, NH_2, D_2O-exch.), 7.19–7.27 (5H, m, Ph), and 9.14 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{20}H_{27}N_3O_7$: C 57.0, H. 6.46, N 9.97; found: C 57.19, H 6.35, N 10.06.

Ethyl 2-(ethoxycarbonyl)-3-(methoxycarbonyl)-2-(phenyl-4-(N′-phenylcarbamoylhydrazono)pentanoate (**3**i): mp 178–180°C; crystallized from THF–*n*-pentane; IR: 3350 (NH), 3200 (NH), 3080 (NH), 1745 (C=O), 1725 (C=O), 1680 (C=O), and 1595 (C=O) cm^{-1}; ^1H NMR: 1.05–1.12 (6H, m, 2 × CO_2CH_2*Me*), 2.03 (3H, s, Me), 3.64 (3H, s, CO_2Me), 4.07–4.12 (4H, m, 2 × CO_2*CH_2*Me), 4.82 (1H, s, CH), 6.90–7.44 (10H, m, 2 × Ph), 7.70 (1H, s, NH, D_2O-exch.), and 9.74 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{25}H_{29}N_3O_7$: C 62.10, H 6.05, N 8.69; found: C 61.98, H 6.21, N 8.86.

Ethyl 2,3-(diethoxycarbonyl)-2-phenyl-4-(N′-phenylcarbamoylhydrazono)pentanoate (**3**j): mp 138–141°C; crystallized from THF–*n*-pentane; IR: 3340 (NH), 3190 (NH), 3060 (NH), 1750 (C=O), 1725 (C=O), 1675 (C=O), and 1590 (C=O) cm^{-1}; ^1H NMR: 1.03–1.16 (9H, m, 3 × CO_2CH_2*Me*), 2.03 (3H, s, Me), 4.02–4.14 (6H, m, 3 × CO_2*CH_2*Me), 4.80 (1H, s, CH), 6.93–7.48 (10H, m, 2 × Ph), 7.72 (1H, s, NH, D_2O-exch.), and 9.75 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{26}H_{31}N_3O_7$: C 62.76, H 6.28, N 8.45; found: C 62.67, H 6.39, N 8.36.

Ethyl 2-(ethoxycarbonyl)-3-(methoxycarbonyl)-4-(methoxycarbonylhydrazono)-2-phenylpentanoate (**3**k): mp 139–141°C; crystallized from THF–*n*-pentane; IR: 3310 (NH), 1750 (C=O), 1730 (C=O), and 1695 (C=O) cm^{-1}; ^1H NMR: 1.08–1.17 (6H, m, 2 × CO_2CH_2*Me*), 1.67 (3H, s, Me), 3.58 (6H, s, 2 × CO_2Me), 4.10–4.21 (4H, m, 2 × CO_2*CH_2*Me), 4.49 (1H, s, CH), 7.27 (5H, s, Ph), and 9.79 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{20}H_{26}N_2O_8$: C 56.87, H. 6.20, N 6.63; found: C 57.06, H 6.11, N 6.81.

*Ethyl 4-*tert-*butoxycarbonylhydrazono)-2,3-(diethoxycarbonyl)-2-phenylpentanoate* (**3**l): mp 90–93°C; crystallized from THF–*n*-pentane; IR: 3250 (NH), 1780 (C=O), 1730 (C=O), and 1690 (C=O) cm^{-1}; ^1H NMR: 1.08–1.17 (9H, m, 3 × COX_2CH_2*Me*), 1.40 (9H, s, *t*-Bu), 1.61 (3H, s, Me), 4.00–4.21 (6H, m, 3 × CO_2*CH_2*Me), 4.44 (1H, s, CH), 7.27 (5H, s, Ph), and 9.38 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{24}H_{34}N_2O_8$: C 60.39, H. 7.16, N 5.85; found: C 60.39, H 7.33, N 5.74.

Methyl 4-carbamoylhydrazono)-2,3-(dimethoxycarbonyl)pentanoate (**5**a): mp 138–140°C; crystallized from THF–*n*-pentane; IR: 3450 (NH), 3440 (NH), 3300 (NH_2), 3190 (NH_2), 1730 (C=O), 1695 (C=O), 1665 (C=O), and 1640 (C=O) cm^{-1}; ^1H NMR: 1.86 (3H, s, Me), 3.60–3.65 (9H, m, 3 × CO_2*CH_2*Me), 3.91 (1H, d, J = 10 Hz, CH), 4.23 (1H, d, J = 10 Hz, CH), 6.25 (2H, br s, NH_2, D_2O-exch.), and 9.33 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{11}H_{17}N_3O_7$: C 43.57, H. 5.65, N 13.86; found: C 43.49, H 5.79, N 13.98.

Methyl 4-carbamoylhydrazono)-3-(ethoxycarbonyl)-2-(methoxycarbonyl)pentanoate (**5**b): mp 119–122°C; crystallized from THF–*n*-pentane; IR: 3530 (NH), 3400 (NH), 3200 (NH_2), 1750 (C=O), 1730 (C=O), 1690 (C=O), and 1640 (C=O) cm^{-1}; ^1H NMR: 1.16 (3H, t, J = 7 Hz, CO_2CH_2*Me*), 1.86 (3H, s, Me), 3.61 (3H, s, CO_2Me), 3.65 (3H, s, CO_2Me), 3.88 (1H, d, J = 10 Hz, CH), 4.10 (2H, q, J = 7 Hz, CO_2*CH_2*Me), 4.21 (1H, d, J = 10 Hz, CH), 6.20 (2H, br s, NH_2, D_2O-exch.), and 9.32 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{12}H_{19}N_3O_7$: C 45.42, H. 6.04, N 13.24; found: C 45.35, H 6.21, N 13.16.

Methyl 2,3-(dimethoxycarbonyl)-4-(N′-phenylcarbamoylhydrazono)pentanoate (**5**c): mp 145–147°C; crystallized from THF–*n*-pentane; IR: 3380 (NH), 3200 (NH), 3090 (NH), 1740 (C=O), 1720 (C=O), 1700 (C=O), and 1600 (C=O) cm^{-1}; ^1H NMR: 1.94 (3H, s, Me), 3.58 (3H, s, CO_2Me), 3.66 (6H, s, 2 × CO_2Me), 4.03 (1H, d, J = 10 Hz, CH), 4.48 (1H, d, J = 10 Hz, CH), 7.00–7.61 (5H, m, Ph), 8.48 (1H, s, NH, D_2O-exch.), and 9.86 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{17}H_{21}N_3O_7$: C 53.82, H 5.58, N 11.08; found: C 53.99, H 5.39, N 11.15.

Methyl 3-(ethoxycarbonyl)-2-(methoxycarbonyl)-4-(N′-phenylcarbamoylhydrazono)pentanoate (**5**d): mp 130–132°C; crystallized from THF–*n*-pentane; IR: 3370 (NH), 3210 (NH), 3100 (NH), 1745 (C=O), 1730 (C=O), 1700 (C=O), and 1605 (C=O) cm^{-1}; ^1H NMR: 1.18 (3H, t, J = 7 Hz, CO_2CH_2*Me*), 1.95 (3H, s, Me), 3.59 (3H, s, CO_2Me), 3.66 (3H, s, CO_2Me), 4.01 (1H, d, J = 10 Hz, CH), 4.13 (2H, q, J = 7 Hz, CO_2*CH_2*Me), 4.46 (1H, d, J = 10 Hz, CH), 7.00–7.61 (5H, m, Ph), 8.46 (1H, s, NH, D_2O-exch.), and 9.85 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{18}H_{23}N_3O_7$: C 54.96, H 5.89, N 10.68; found; C 55.13, H 5.75, N 10.74.

*Methyl 2,3-(dimethoxycarbonyl)-4-(methoxycarbonylhydrazono)-pentanoate (**5**e)*: mp 127–129°C; crystallized from THF–*n*-pentane; IR: 3230 (NH), 3150 (NH), 1730, 1710 (C=O overlap), and 1640 (C=O) cm^{-1}; ^1H NMR: 1.87 (3H, s, Me), 3.61–3.66 (12H, m, 4 × CO_2Me), 3.88 (1H, d, J = 10 Hz, CH), 4.08 (1H, d, J = 10 Hz, CH), and 10.03 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{12}H_{18}N_2O_8$: C 45.28, H 5.70, N 8.80; found: C 45.16, H 5.82, N 8.96.

*Methyl 4-(*tert*-butoxycarbonylhydrazono)-3-(ethoxycarbonyl)-2-(methoxycarbonyl)pentanoate (**5**f)*: mp 90–93°C; crystallized from THF–*n*-pentane; IR: 3230 (NH), 3150 (NH), 1745, (C=O), 1730 (C=O), 1720 (C=O), 1690 (C=O), and 1640 (C=O) cm^{-1}; ^1H NMR: 1.15 (3H, t, J = 7 Hz, CO_2CH_2*Me*), 1.43 (9H, s, *t*-Bu), 1.86 (3H, s, Me), 3.61 (3H, s, CO_2Me), 3.66 (3H, s, CO_2Me), 3.84 (1H, d, J = 10 Hz, CH), 4.05–4.11 (3H, m, CH and CO_2CH_2Me), and 9.71 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{16}H_{26}N_2O_8$: C 51.33, H 7.0, N 7.48; found: C 51.21, H 7.17, N 7.39.

*Benzyl 2-(benzyloxycarbonyl)-4-(carbamoylhydrazono)-3-(methoxycarbonyl)pentanoate (**5**g)*: mp 110–112°C; crystallized from THF–*n*-pentane; IR: 3520 (NH), 3400 (NH), 3180 (NH_2), 1745, (C=O), 1720 (C=O), 1685 (C=O), and 1630 (C=O) cm^{-1}; ^1H NMR: 1.85 (3H, s, Me), 3.56 (3H, s, CO_2Me), 3.94 (1H, d, J = 10 Hz, CH), 4.43 (1H, d, J = 10 Hz, CH), 5.04–5.20 (4H, m, 2 × CO_2CH_2Ph), 6.27 (2H, br s, NH_2, D_2O-exch.), 7.27–7.34 (10H, m, 2 × CO_2CH2*Ph*), and 9.33 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{23}H_{25}N_3O_7$: C 60.65, H 5.53, N 9.23; found: C 60.51, H 5.71, N 9.09.

*Benzyl 2-(benzyloxycarbonyl)-3-(methoxycarbonyl)-4-(N′-phenylcarbamoylhydrazono)pentanoate (**5**h)*: mp 152–154°C; crystallized from THF–*n*-pentane; IR: 3360 (NH), 3190 (NH), 1755, (C=O), 1730 (C=O), 1680 (C=O), and 1640 (C=O) cm^{-1}; ^1H NMR: 1.91 (3H, s, Me), 3.57 (3H, s, CO_2Me), 4.07 (1H, d, J = 10 Hz, CH), 4.84 (1H, d, J = 10 Hz, CH), 5.14–5.20 (4H, m, 2 × CO_2CH_2Ph), 7.00–7.58 (15H, m, Ph and 2 × CO_2CH_2*Ph*), 8.47 (1H, s, NH, D_2O-exch.) and 9.80 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{29}H_{29}N_3O_7$: C 65.53, H. 5.50, N 7.90; found: C 65.39, H 5.41, N 7.75.

*Benzyl 2-(benzyloxycarbonyl)-3-(methoxycarbonyl)-4-(methoxycarbonylhydrazono)pentanoate (**5**i)*: mp 118–120°C; crystallized from THF–*n*-pentane; IR: 3230 (NH), 1735, and 1700 (C=O overlap) cm^{-1}; ^1H NMR: 1.86 (3H, s, Me), 3.56 (3H, s, CO_2Me), 3.64 (3H, s, CO_2Me), 3.93 (1H, d, J = 10 Hz, CH), 4.24 (1H, d, J = 10 Hz, CH), 5.08–5.15 (4H, m, 2 × CO_2CH_2Ph), 7.31–7.34 (10H, m, 2 × CO_2CH_2*Ph*), and 10.07 (1H, s, NH, D_2O-exch.). Anal. calcd. for: $C_{24}H_{26}N_2O_8$: C 61.27, H 5.57, N 5.95; found: C 61.27, H 5.73, N 6.09.

*Conversion of hydrazones **3**a–l into 1-amino-1*H*-pyrrol-2(3*H*)-ones **4**a–l*

To a stirred solution of hydrazone (**3***a–l*) in THF (3 mL) was added a solution of sodium methoxide (1 mmol) in methanol (1 mL). The conversion to give products **4***a–l* occurred rapidly, under magnetic stirring at room temperature (~5 min), and was monitored by TLC. The reaction mixture was concentrated to a small volume under reduced pressure, the residue was dissolved in ethyl acetate, and the solution extracted with aqueous sulphuric acid (1%). The organic phase was separated, washed with water, dried with magnesium sulphate, and concentrated under reduced pressure. Products **4***a–l* were purified by chromatography on a silica gel column (elution with cyclohexane – ethyl acetate mixtures), and then crystallized from ethyl ether – light petroleum, bp 30–60°C, or dichloromethane – light petroleum, bp 30–60°C.

*Direct preparation of 1-amino-1*H*-pyrrol-2(3*H*)-ones **4**a–l*

To a stirred solution of azoalkene (**1***a–f*) (1 mmol) in THF (3 mL) was added dropwise a solution of β-diester (**2***a, b*) (1 mmol) and sodium methoxide (0.1 mmol) in THF (3 mL). When the reaction at room temperature was completed, affording hydrazones (**3***a–l*) (monitored by TLC), a solution of sodium methoxide (1 mmol) in methanol (1 mL) was added directly to the reaction. The conversion to afford products **4***a–l* occurred rapidly, under magnetic stirring at room temperature (~5 min), and was monitored by TLC. The reaction mixture was then treated as described in detail above for the isolation of the same products **4***a–l*.

*Methyl 4-ethoxycarbonyl-2,4-dimethyl-5-oxo-1-ureido-1,4-dihydropyrrole-3-carboxylate (**4**a)*: mp 138–140°C; crystallized from dichloromethane – light petroleum, bp 30–60°C; IR: 3440 (NH), 3290, 3250, 3190 (NH, NH_2 overlap), 1750 (C=O), 1705 (C=O), 1645 (C=O), and 1615 (C=O) cm^{-1}; ^1H NMR: 1.07 (3H, t, J = 7 Hz, CO_2CH_2*Me*), 1.44 (3H, s, Me), 2.25 (3H, s, Me), 3.63 (3H, s, CO_2Me), 4.06 (2H, q, J = 7 Hz, CO_2CH_2Me), 6.33 and 6.39 (2H, 2 s, NH_2, D_2O-exch.), and 8.65 and 8.96 (1H, 2 s, NH, D_2O-exch.), Anal. calcd. for: $C_{12}H_{17}N_3O_6$: C 48.16, H 5.73, N 14.04; found: C 48.05, H 5.65, N 14.15.

*Ethyl 4-ethoxycarbonyl-2,4-dimethyl-5-oxo-1-ureido-1,4-dihydropyrrole-3-carboxylate (**4**b)*: mp 102–106°C; crystallized from dichloromethane – light petroleum, bp 30–60°C; IR: 3435 (NH), 3290, 3250, 3190 (NH, NH_2 overlap), 1745 (C=O), 1705 (C=O), 1640 (C=O), and 1615 (C=O) cm^{-1}; ^1H NMR: 1.05–1.21 (6H, m, 2 × CO_2CH_2*Me*), 1.45 (3H, s, Me), 2.26 (3H, s, Me), 4.00–4.15 (4H, m, 2 × CO_2CH_2Me), 6.29 and 6.36 (2H, 2 s, NH_2, D_2O-exch.), and 8.62 and 8.93 (1H, 2 s, NH, D_2O-exch.). Anal. calcd. for $C_{13}H_{19}N_3O_6$: C 49.84, H 6.11, N 13.41; found: C 49.75, H 6.26, N 13.32.

*Methyl 4-ethoxycarbonyl-2,4-dimethyl-5-oxo-1-(N′-phenylureido-1,4-dihydropyrrole-3-carboxylate (**4**c)*: mp 149–151°C; crystallized from ethyl ether – light petroleum, bp 30–60°C; IR: 3300 (NH), 3210 (NH), 1760 (C=O), 1710 (C=O), 1650 (C=O), and 1605 (C=O) cm^{-1}; ^1H NMR: 1.10 (3H, t, J = 7 Hz, CO_2CH_2Me), 1.49 (3H, s, Me), 2.31 (3H, s, Me), 3.66 (3H, s, CO_2Me), 4.10 (2H, q, J = 7 Hz, CO_2CH_2Me), 6.95–7.46 (5H, m, Ph), 9.19 (1H, s, NH, D_2O-exch.), and 9.37 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{18}H_{21}N_3O_6$: C 57.59, H 5.64, N 11.19; found: C 57.44, H 5.73, N 11.38.

*Ethyl 4-ethoxycarbonyl-2,4-dimethyl-5-oxo-1-(N′-phenylureido-1,4-dihydropyrrole-3-carboxylate (**4**d)*: mp 236–239°C; crystallized from ethyl ether – light petroleum, bp 30–60°C; IR: 3310 (NH), 3200 (NH), 1760 (C=O), 1720 (C=O), 1675 (C=O), and 1615 (C=O) cm^{-1}; ^1H NMR: 1.08–1.23 (6H, m, 2 × CO_2CH_2*Me*), 1.51 (3H, s, Me), 2.32 (3H, s, Me), 4.05–4.18 (4H, m, 2 × CO_2CH_2Me), 6.96–7.48 (5H, m, Ph), 8.19 (1H, s, NH, D_2O-exch.), and 9.59 (1H, s, NH, D_2O-exch.). Anal. calcd. for $C_{19}H_{23}N_3O_6$: C 58.60, H 5.95, N 10.79; found: C 58.78, H 5.81, N 10.93.

*Methyl 4-ethoxycarbonyl-1-(methoxycarbonylamino)-2,4-dimethyl-5-oxo-1,4-dihydro-pyrrole-3-carboxylate (**4**e)*: mp 109–111°C; crystallized from ethyl ether – light petroleum, bp 30–60°C; IR: 3240 (NH), 1770 (C=O), 1750 (C=O), 1730 (C=O), 1675 (C=O), and 1635 (C=O) cm^{-1}; ^1H NMR: 1.08 (3H, t, J = 7 Hz, CO_2CH_2*Me*), 1.45 (3H, s, Me), 2.28 (3H, s, Me), 3.67 (3H, s, CO_2Me), 3.88 (3H, s, CO_2Me), 4.05 (2H, q, J = 7 Hz, CO_2CH_2Me), and 10.35 (1H, br s, NH, D_2O-exch.). Anal. calcd. for $C_{13}H_{18}N_2O_7$: C 49.68, H 5.77, N 8.91; found: C 49.53, H 5.95, N 8.83.

*Ethyl 1-(*tert*-butoxycarbonylamino)-4-ethoxycarbonyl-2,4-dimethyl-5-oxo-1,4-dihydropyrrole-3-carboxylate (**4**f)*: mp 72–75°C; crystallized from ethyl ether – light petroleum, bp 30–60°C; IR: 3245 (NH), 1765 (C=O), 1740 (C=O). 1730 (C=O), 1680 (C=O), and 1635 (C=O) cm^{-1}; ^1H NMR: 1.05–1.21 (6H, m, 2 × CO_2CH_2*Me*), 1.42 (9H, s, *t*-Bu), 1.45 (3H, s, Me), 2.26 (3H, s, Me), 3.97–4.18 (4H, m, 2 × CO_2CH_2Me), and 10.01 (1H, br s, NH, D_2O-exch.). Anal. calcd. for $C_{17}H_{26}N_2O_7$: C 55.13, H 7.08, N 7.56; found: C 55.02, H 7.22, N 7.47.

Conversion of hydrazones **5**a–i *into 1-amino-1*H*-pyrrol-2(3*H*)-ones* **6**a–i

To a stirred solution of hydrazone (**5***a–i*) (1 mmol) in THF (3 mL) was added a solution of sodium methoxide (1 mmol) in methanol (1 mL). The conversion to give products **6***a–i* occurred rapidly, under magnetic stirring at room temperature (~5 min), and was monitored by TLC. Products **6***a–i*, after partial evaporation of the reaction solvent, were crystallized by addition of ethyl ether to the crude reaction, dissolved in water and treated by the strongly acid cation exchanger. The aqueous solution was extracted with ethyl acetate and the organic phase was separated, dried with magnesium sulphate, and concentrated under reduced pressure. After this treatment, products **6** crystallized as follows: **6***a*, **6***b* from tetrahydrofuran – *n*-pentane, **6***c*, **6***d*, and **6***h* from ethyl acetate, **6***g* from dichloromethane – light petroleum, bp 30–60°C, while products **6***e*, **6***f*, and **6***i* are oils.

*Direct preparation of 1-amino-1*H*-pyrrol-2(3*H*)-ones* **6**a–i

To a stirred solution of azoalkene (**1***a–f*) (1 mmol) in THF (3 mL) was added dropwise a solution of β-diester (**2***c*, *d*) (1 mmol) and sodium methoxide (0.1 mmol) in THF (3 mL). When the reaction was completed, affording hydrazones **5***a–i* (monitored by TLC), a solution of sodium methoxide (1 mmol) in methanol (1 mL) was added directly to the reaction. The conversion to afford products **6***a–i* occurred rapidly, under magnetic stirring at room temperature (~5 min), and was monitored by TLC. The reaction mixture was then treated as described in detail above for the isolation of the same products **6***a–i*.

*Methyl 4-methoxycarbonyl-2-methyl-5-oxo-1-ureido-1,4-dihydropyrrole-3-carboxylate (***6a***)*: mp 166–168°C; crystallized from tetrahydrofuran – *n*-pentane; IR: 3440 (NH), 3330, 3190 (NH_2 overlap), 1760, 1680, 1640, and 1610 (C=O overlap) cm^{-1}; ^1H NMR: 2.26 (3H, s, Me), 3.65 (6H, s, 2 × CO_2Me), 4.37 and 4.44 (1H, 2 s, CH, D_2O-exch.), 6.28 and 6.40 (2H, 2 s, NH_2, D_2O-exch.), and 8.68 and 8.76 (1H, 2 s, NH, D_2O-exch.). Chemoenzymatic enantioselective synthesis of baclofen

ROBERT CHÊNEVERT[1] AND MICHEL DESJARDINS

Département de chimie, Faculté des sciences et de génie, Université Laval, Québec, QC G1K 7P4, Canada

Received June 17, 1994

ROBERT CHÊNEVERT and MICHEL DESJARDINS. Can. J. Chem. **72**, 2312 (1994).

We report two different chemoenzymatic enantioselective syntheses of baclofen based on the distinction between enantiotopic ester groups in compounds bearing a prochiral centre. In the first approach, the key step is the highly stereoselective enzymatic hydrolysis of dimethyl 3-(4-chlorophenyl)glutarate by chymotrypsin in an aqueous medium. In the second approach, the key step is the enzyme-catalyzed esterification of 2-(4-chlorophenyl)-1,3-propanediol by acetic anhydride in the presence of a lipase in an organic medium.

ROBERT CHÊNEVERT et MICHEL DESJARDINS. Can. J. Chem. **72**, 2312 (1994).

Nous décrivons deux synthèses chimio-enzymatiques des énantiomères du baclofen basées sur une distinction de groupements ester énantiotopiques dans des composés comportant un centre prochiral. Dans la première approche, l'étape-clé est une hydrolyse stéréosélective du 3-(4-chlorophényl)glutarate de diméthyle par la chymotrypsine en milieu aqueux. Dans la seconde approche, l'étape-clé est une estérification enzymatique du 2-(4-chlorophényl)-1,3-propanediol par l'anhydride acétique en présence d'une lipase en milieu organique.

Introduction

The neutral amino acid γ-aminobutyric acid (GABA) is an inhibitory neurotransmitter related to the control of neuronal activity in the central nervous system and to the regulation of several physiological mechanisms (1). GABA has been shown to act through at least two different receptor sites with different binding properties ($GABA_A$ and $GABA_B$ receptors) (1, 2). Baclofen or 4-amino-3-(4-chlorophenyl)butanoic acid is an analog of GABA but, unlike GABA, it can cross the blood–brain barrier. Baclofen is the reference selective agonist for the $GABA_B$ receptor, and racemic baclofen is widely used as an antispastic agent (1). The enantiomers of this compound differ in their pharmacodynamic and toxicological properties; the (–) enantiomer is much more active but also more toxic than the (+) enantiomer (3–5). The *R* configuration was assigned to the more active enantiomer on the basis of X-ray crystallography (6). Enantiomers of baclofen have been obtained by resolution of racemates (5) and (*R*)-baclofen has been prepared from (*S*)-pyroglutamic acid (7). Also, a synthesis of (*R*)-baclofen using the Evans' oxazolidinone chiral auxiliaries has been reported (8). We report here two different chemoenzymatic syntheses of optically active baclofen based on the distinction between enantiotopic ester groups in compounds bearing a prochiral centre (9, 10).

Results and discussion

The first approach to the synthesis of both enantiomers of baclofen is based on the enzyme-catalyzed enantioselective hydrolysis of dimethyl 3-(4-chlorophenyl) glutarate (**4**) in an aqueous medium. The reaction sequence is shown in Scheme 1. Esterification of 4-chlorocinnamic acid **1** with methanol in the presence of an acidic resin as a catalyst gave ester **2**. The base-catalyzed (sodium methoxide) Michael-type reaction of dimethyl malonate with **2** gave the triester **3**. The demethoxycarboxylation of **3** on heating in aqueous dimethyl sulfoxide containing sodium chloride (11) led to the diester **4**. A screening for the enantioselective hydrolysis of **4** was started using a variety of commercially available hydrolytic enzymes. Among the tested enzymes, only α-chymotrypsin and pig liver esterase (PLE) could recognize **4** as substrate. Thus, when compound **4** was hydrolyzed in aqueous buffer (pH 7.7) under the catalysis of chymotrypsin, chiral mono-ester (***R***)-**5** was obtained in 85% yield and with a high enantiomeric excess (ee ≥ 98%). The enzymatic reaction was indicated by a decrease of pH, which was maintained at its initial value by the addition of aqueous sodium hydroxide. The reaction was monitored by the consumption of base, and the reaction stopped completely when 1 equivalent of base was consumed. Hydrolysis of **4** in the presence of pig liver esterase (PLE) in aqueous DMSO (40%) gave the other enantiomer in a lower enantiomeric yield (ee = 80%). The optical purity of compound **5** was determined by ^{1}H NMR (300 MHz) analysis and further confirmed by HPLC analysis of the diastereomeric amides, obtained by reaction of mono-ester **5** with (*R*)-1-(phenyl)ethylamine in the presence of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC).

The carboxyl group of **5** was converted to an amino group with retention of configuration through a Curtius rearrangement. Thus, the mono-ester was treated with ethyl chloroformate at 0°C in acetone and then with sodium azide. Acetone was replaced by toluene; the solution was heated to 100°C and the resulting isocyanate was hydrolyzed with aqueous HCl to give (*R*)-(–)-baclofen hydrochloride (***R***)-**6**. The *S* enantiomer of baclofen was also obtained from the same mono-ester (***R***)-**5**. Ammonolysis of **5** under pressure produced the corresponding amide **7**, which was submitted to a Hoffmann rearrangement with bis(trifluoroacetoxy)iodobenzene (12), then acidification to give (*S*)-(+)-baclofen hydrochloride (***S***)-**6**. Both enantiomers were purified by ion exchange chromatography.

The second approach was based on the enzyme-catalyzed esterification of 2-(4-chlorophenyl)-1,3-propanediol (**11**) by acetic anhydride in the presence of a lipase in an organic medium. The synthesis is illustrated in Scheme 2. Esterification of *p*-chlorophenylacetic acid (**8**) with ethanol in the presence of an acidic resin gave ester **9**. The reaction of ethyl *p*-chlorophenylacetate **9** with diethyl carbonate in the presence of sodium hydride gave diester **10**. This diester was reduced to the diol **11** by lithium aluminium hydride. Esterification of 2-(4-chlorophenyl)-1,3-propanediol (**11**) by acetic anhydride (13) in benzene, in the presence of porcine pancreatic lipase (PPL), gave the hemi-ester (***S***)-**12** in high enantiomeric yield (ee ≥ 96%). The enantiomeric purity was determined by ^{1}H NMR analysis in the presence of tris[(heptafluoropropylhydroxymethylene)-*d*-cam-

SCHEME 1

phorato]Europium III as a chiral shift reagent. Hemi-ester **12** was treated with mesyl chloride in the presence of triethylamine to give **13**. Displacement of the mesylate with cyanide afforded **14**. The ester **14** was then hydrolyzed, and the product **15** was converted to the mesylate **16**. The enantiomeric purity (ee ≥ 97%) of **16** was determined by ^{19}F NMR analysis of the corresponding (*S*)-MTPA derivative (Mosher ester). Displacement of this mesylate with sodium azide gave azido-nitrile **17**. The azido group was reduced by triphenylphosphine in water–THF to the corresponding amine, and the nitrile was hydrolyzed in acidic water in a one-pot reaction to give (*R*)-baclofen (***R***)-**6**.

Guanti et al. (14) found that the hydrolysis of diacetate **18** by PPL gave the hemi-ester (***R***)-**12** (Scheme 3). Therefore the two procedures (acylation and hydrolysis by PPL) can be considered complementary for the final product configuration, and consequently both enantiomers of baclofen are accessible from the same diol **11**, using PPL as the catalyst.

The present report represents another example of the versatility and the usefulness of the chemoenzymatic approach to the synthesis of both enantiomers of bioactive compounds.

Experimental

Melting points were recorded on a Thomas–Hoover apparatus and uncorrected. Infrared spectra were recorded using a Beckman IR-4250 spectrometer. ^1H NMR (300 MHz) and ^{13}C NMR (75.5 MHz) spectra were recorded on a Bruker AC-300 instrument. Optical rotations were measured using a JASCO DIP-360 polarimeter (sodium light, cell length = 10 cm, *c* = g/100 mL). Mass spectra were determined on a Hewlett–Packard 5989-A instrument using an ionization energy of 70 eV. Chymotrypsin (EC 3.4.21.1, type II, from bovine pancreas), PLE (EC 3.1.1.1, porcine liver esterase), and PPL (EC 3.1.1.3, type II, from porcine pancreas) were purchased from Sigma Chemical Co.

Methyl p-chlorocinnamate (2)

To a solution of *p*-chlorocinnamic acid **1** (18.22 g, 99.8 mmol) in methanol (150 mL) was added 2,2-dimethoxypropane (12.47 g, 119.7 mmol) and 2 g of an acidic ion exchange resin (Dowex-WX4). The mixture was refluxed overnight, cooled to room temperature, filtered,

and the solvent was evaporated. The crude product was taken up in ether and this organic phase was washed with brine, dried ($MgSO_4$), and evaporated. The product was recrystallized in methanol–water to yield **2** (18.64 g, 95%); mp 74–75°C. IR (KBr) ν_{max}: 3030, 2900–3000, 1910, 1700, 1630, 1590, 1490 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.64 (d, J = 16.0 Hz, 1H), 7.45 (m, J_1 = 9.0 Hz, 2H), 7.36 (m, J_1 = 9.0 Hz, 2H), 6.41 (d, J = 16.0 Hz, 1H), 3.81 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 166.97, 143.25, 136.06, 132.74, 129.10, 129.02, 118.29, 51.77 MS *m/z* (relative intensity): 198 (M^+, ^{37}Cl, 12), 196 (M^+, ^{35}Cl, 43), 167 (29), 165 (100), 139 (32), 137 (13).

Dimethyl 3-(p-chlorophenyl)-2-methoxycarbonylglutarate (3)

Clean sodium (690 mg, 30 mmol) cut in small pieces was added to anhydrous methanol (20 mL) under dry atmosphere. After all the sodium was dissolved, the solution was cooled to 0°C. A solution of methyl *p*-chlorocinnamate (5.063 g, 25.7 mmol) and dimethyl malonate (3.964 g, 30 mmol) in anhydrous THF (15 mL) was added dropwise. The mixture was then refluxed for 1.5 h. The solvent was evaporated and water (50 mL) was added to the crude oil. The product was taken up in ether and this organic phase was dried ($MgSO_4$) and evaporated. The crude product was recrystallized from hexane to yield triester **3** (7.202 g, 85%); mp 85–86°C. IR (neat) ν_{max}: 2840–2950, 1730, 1490, 1370, 830, 700 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.24 (m, 2H), 7.16 (m, 2H), 3.87 (m, 1H), 3.72 (d, J = 10.0 Hz, 1H), 3.71 (s, 3H), 3.51 (s, 3H), 3.48 (s, 3H), 2.86 (dd, J_1 = 5.0 Hz, J_2 = 15.0 Hz, 1H), 2.66 (dd, J_1 = 9.0 Hz, J_2 = 15.0 Hz, 1H). ^{13}C NMR ($CDCl_3$) δ: 171.03, 167.88, 167.42, 138.17, 132.95, 129.22, 128.48, 56.63, 52.66, 52.39, 51.37, 40.71, 38.02. MS *m/z* (relative intensity): 330 (M^+, ^{37}Cl, 4), 328 (M^+, ^{35}Cl, 14), 211 (36), 209 (100), 167 (13), 165 (39), 157 (19), 155 (56).

Dimethyl 3-(p-chlorophenyl)glutarate (4)

A solution of ester (2.513 g, 7.64 mmol), water (0.275 g, 15.2 mmol), and sodium chloride (0.447 g, 7.64 mmol) in DMSO (15 mL) was refluxed for 4 h. The solvent was evaporated and the residue was taken up in ether. The organic phase was washed three times with brine, dried ($MgSO_4$), and evaporated. The crude product was recrystallized in ether – petroleum ether to yield **4** (1.629 g, 79%); mp 61–62°C. IR (neat) ν_{max}: 2995, 2940, 2840, 1730, 1490, 1430, 1090, 1010, 820 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.25 (m, 2H), 7.14 (m, 2H), 3.61 (m, 1H), 3.57 (s, 6H), 2.71 (dd, J_1 = 7 Hz, J_2 = 16.0 Hz), 2.59 (dd, J_1 = 8.0 Hz, J_2 = 16.0 Hz). ^{13}C NMR ($CDCl_3$) δ: 171.57, 140.93, 132.54, 128.61, 128.49, 51.46, 40.08, 37.53. MS m/z (relative intensity): 272 (M^+, ^{37}Cl, 6), 270 (M^+, ^{35}Cl, 18), 212 (100), 210 (31), 165 (21), 154 (19), 152 (59), 138 (19).

Enzymatic hydrolysis of diester 4

The diester **4** (247 mg, 0.91 mmol) was suspended in a phosphate buffer (0.05 M, pH 7.70) and a drop of surfactant Triton X-100 was added to the mixture. Chymotrypsin (300 mg) was added and the pH of the solution was maintained at its initial value by addition of 0.1 M

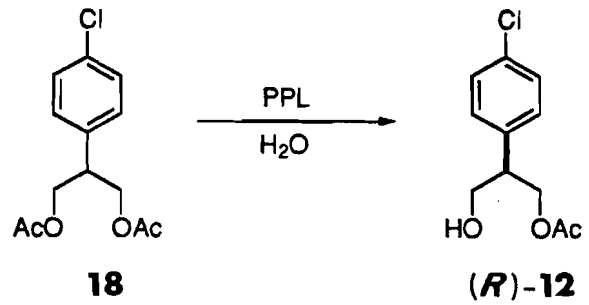

SCHEME 3

aqueous NaOH. After the addition of 1 equivalent of base (30 h), the enzyme was eliminated by ultrafiltration. The pH of the aqueous solution was raised to 9 and the aqueous phase was extracted with ether to remove unchanged diester. The aqueous phase was then acidified to pH 2.0 with cold 2 M aqueous HCl and was extracted with ether. Combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated to yield **5** (190 mg, 85%). $[\alpha]_D^{25}$ +4.1 (*c* 2.6, $CHCl_3$). IR (neat) ν_{max}: 2800–3650, 1690–1730, 1490, 1090, 1010, 820 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.26 (d, *J* = 8.5 Hz, 2H), 7.14 (d, *J* = 8.5 Hz, 2H), 3.6 (m, 1H), 3.57 (s, 3H), 2.63 (m, 4H). ^{13}C NMR ($CDCl_3$) δ: 177.16, 171.66, 140.61, 132.66, 128.70, 128.52, 53.15, 51.73, 40.27, 37.38. MS *m/z* (relative intensity): 258 (M^+, ^{37}Cl, 9), 256 (M^+, ^{35}Cl, 16), 227 (7), 225 (22), 198 (11), 196 (47), 154 (16), 152 (56).

*(R)-Baclofen [(**R**)-6]*

A solution of acid **5** (492 mg, 1.92 mmol) in dry acetone (10 mL) was cooled to 0°C and triethylamine (400 μL) was added, followed by the dropwise addition of ethyl chloroformate (275 μL, 2.9 mmol). The solution was stirred at 0°C for 15 min and then at 25°C for 40 min. The solution was cooled to 0°C and sodium azide (152 mg, 2.34 mmol) in water (3 mL) was added dropwise. The mixture was stirred for 2 h at 0°C, poured into ice water (100 mL), and extracted with ether. The ether extracts were dried ($MgSO_4$), and the ether was evaporated. The crude acylazide was dissolved in toluene (10 mL) and the solution was refluxed for 8 h. The solvent was evaporated to leave an oil, which was dissolved in cold 6 N HCl. The solution was refluxed for 2 h, cooled to room temperature, washed with ether, and evaporated. The crude product was dissolved in a 1 N HCl solution (2 mL), and the solution was applied to an ion exchange resin (Dowex 50X2-200). The chlorides were eliminated by washing the column with distilled water; then the amino acid was eluted with a solution of triethylamine 10% in water. The ninhydrin-positive fractions were collected, evaporated, and the crude product was recrystallized (water–ethanol) to yield (*R*)-baclofen (124 mg, 30%). $[\alpha]_D^{25}$ –1.5 (*c* 0.2, H_2O) (lit. (8) $[\alpha]_D$ –1.7 (*c* 0.2, H_2O)). IR (KBr) ν_{max}: 3500–2200, 1630, 1570, 1400, 1160, 1100, 830, 730 cm^{-1}. ^1H NMR (D_2O + NaOD) δ: 7.15 (d, *J* = 8.0 Hz, 2H), 7.04 (d, *J* = 8.0 Hz, 2H), 2.84 (m, 1H), 2.63 (dd, J_1 = 6.0 Hz, J_2 = 15.0 Hz, 1H), 2.52 (dd, J_1 = 10.0 Hz, J_2 = 15.0 Hz, 1H), 2.33 (dd, J_1 = 7.0 Hz, J_2 = 15.0 Hz, 1H), 2.18 (dd, J_1 = 9.0 Hz, J_2 = 15.0 Hz, 1H). ^{13}C NMR (D_2O + NaOD) δ: 181.03, 141.46, 131.47, 129.34, 128.46, 46.10, 45.17, 42.19.

3-(p-Chlorophenyl)glutaramide 7

To a cooled (–30°C, CCl_4 – Dry Ice) solution of hemi-ester **5** (641 mg, 2.50 mmol) in methanol (5 mL) placed in a pressure tube was added an excess of liquid ammonia. The reaction mixture was kept at 40°C for 48 h, then the tube was cooled to –30°C and opened carefully to allow the excess ammonia to evaporate. The solvent was evaporated and the crude product was purified by flash chromatography (ether 90% – methanol 10%) to yield amide **7** (516 mg, 85%). $[\alpha]_D^{25}$ –6.5 (*c* 1.2, MeOH). IR (neat) ν_{max}: 3420, 3400, 2920, 1700, 1590, 1200, 1100, 1090, 1010, 820 cm^{-1}. ^1H NMR (methanol-d_4) δ: 7.27 (s, 4H), 3.60 (m, 1H), 2.59 (m, 4H). ^{13}C NMR (methanol-d_4) δ: 176.54, 175.61, 143.09, 133.38, 130.22, 129.44, 42.76, 41.49, 39.65. MS *m/z* (relative intensity): 241 (M^+, ^{35}Cl, 9), 225 (27), 197 (20), 196 (9), 152 (26), 138 (100), 140 (34).

*S-Baclofen [(**S**)-6]*

A solution of amide **7** (188 mg, 0.78 mmol) in water–acetonitrile (1:1, v/v, 5 mL) was treated with [bis(trifluoroacetoxy)iodo]benzene (442 mg, 1.03 mmol) and the mixture was stirred at room temperature for 24 h. The reaction mixture was diluted with water and extracted with ether to remove starting materials and iodobenzene. The aqueous phase was concentrated (2 mL), and the product was purified by ion exchange chromatography as described above to yield (*S*)-baclofen (71 mg, 42%). $[\alpha]_D^{25}$ +1.4 (*c* 0.2, H_2O) (lit. (5) $[\alpha]_D^{25}$ +1.4 (*c* 1, H_2O).

*Ethyl p-chlorophenylacetate (**9**)*

4-Chlorophenylacetic acid **8** (19.42 g, 114 mmol) was dissolved in anhydrous ethanol (150 mL). 2,2-Dimethoxypropane (14.24 g, 137 mmol) and Dowex-WX4 ion exchange resin (2 g) were added, and the mixture was refluxed overnight. The resin was filtered, the solvent was evaporated in vacuo, and the residue was taken up in ether. The organic phase was washed twice with brine, dried on $MgSO_4$, and evaporated to yield ester (21.28 g, 94%); mp 33–34°C; bp 78°C (0.3 Torr. 1 Torr = 133.3 Pa). IR (KBr) ν_{max}: 2990, 1730, 1595, 1490, 1370, 1090, 1015, 800 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.24 (m, 4H), 4.14 (q, *J* = 7.0 Hz, 2H), 3.57 (s, 2H), 1.24 (t, *J* = 7.0 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.88, 132.79, 132.41, 130.44, 128.48, 60.90, 40.62, 14.14. MS *m/z* (relative intensity): 200 (M^+, ^{37}Cl, 10), 198 (M^+, ^{35}Cl, 29), 127 (66), 125 (100), 89 (21).

*Diethyl p-chlorophenylmalonate (**10**)*

To a mixture of sodium hydride (0.66 g, 13 mmol) and diethyl carbonate (3.80 mL, 31 mmol) in anhydrous tetrahydrofuran (15 mL) was added dropwise a solution of ester **9** (1.24 g, 6.2 mmol) in anhydrous tetrahydrofuran (5 mL). The mixture was refluxed for 2 h, cooled, neutralized with a saturated aqueous solution of ammonium chloride (30 mL), and extracted with ether. The combined organic phases were washed with saturated $NaHCO_3$ and brine, and dried over sodium sulfate. After evaporation of solvent, the residue was purified by vacuum distillation to yield diester **10** (1.20 g, 71%); bp 116–118°C (0.3 Torr). IR (neat) ν_{max}: 2980, 2940, 2900, 1740, 1595, 1490, 1410, 1320, 1090, 1030, 860 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.33 (s, 4H), 4.57 (s, 1H), 4.20 (q, *J* = 7.0 Hz, 4H), 1.24 (t, *J* = 7.0 Hz, 6H). ^{13}C NMR ($CDCl_3$) δ: 167.55, 134.10, 131.13, 130.52, 128.59, 61.88, 57.19, 14.99. MS *m/z* (relative intensity): 272 (M^+, ^{37}Cl, 18), 270 (M^+, ^{35}Cl, 59), 199 (37), 197 (100), 169 (66), 152 (69), 127 (32), 125 (97).

*2-(p-Chlorophenyl)-1,3-propanediol (**11**)*

Lithium aluminum hydride (5.0 g, 125 mmol) was suspended in anhydrous ether (125 mL) at 0°C under a dry N_2 atmosphere. Diester **10** (16.72 g, 61.8 mmol) was added dropwise and the reaction mixture was stirred at 25°C for 12 h. The mixture was acidified with 10% HCl (200 mL) and extracted with ether. The combined extracts were washed with brine, dried over sodium sulfate, and concentrated. The crude product was purified by flash chromatography (silica gel, ether – petroleum ether, 4:1) to yield diol **11** (11.188 g, 97%); mp 51–52°C. IR (KBr) ν_{max}: 3100–3600, 2920, 2880, 1590, 1490, 1200, 1060, 950, 820 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.21 (m, 4H), 3.96 (dd, J_1 = 11.0 Hz, J_2 = 7.0 Hz, 2H), 3.88 (dd, J_1 = 11.0 Hz, J_2 = 7.0 Hz, 2H), 3.04 (m, *J* = 7.0 Hz, 1H), 2.26 (br s, 2H). ^{13}C NMR ($CDCl_3$) δ: 137.86, 132.57, 129.17, 128.57, 64.83. (MS *m/z* (relative intensity): 188 (M^+, ^{37}Cl, 2), 186 (M^+, ^{35}Cl, 6), 157 (4), 155 (10), 140 (31), 138 (100), 91 (24).

*Lipase-catalyzed acylation of **11***

To a stirred solution of diol **11** (205 mg, 1.10 mmol) was added porcine pancreatic lipase (200 mg) supported on Celite (13) and acetic anhydride (105 μL, 1.11 mmol). The reaction was monitored by TLC and was complete after 4 h. The solid enzyme preparation was filtered off and the solvent was evaporated in vacuo. The crude product was purified by flash chromatography on silica gel (ether – petroleum ether, 3:2) to yield monoester **12** (234 mg, 93%). $[\alpha]_D^{25}$ +15.3 (*c* 0.98, $CHCl_3$). IR (neat) ν_{max}: 3100–3700, 2860–2960, 1730, 1495, 1250, 1095, 1040, 1015, 825 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.28 (d, *J* = 8.5 Hz, 2H), 7.16 (d, *J* = 8.5 Hz, 2H), 4.31 (d, *J* = 6.5 Hz, 2H), 3.77 (d, *J* = 6.0 Hz, 2H), 3.08

(m, J = 6.5 Hz, 1H), 2.33 (br s, 1H), 2.00 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 171.23, 137.59, 132.83, 129.35, 128.64, 64.64, 63.29, 46.43, 20.70. MS *m/z* (relative intensity): 228 (M^+, 0.2), 170 (27), 168 (8), 140 (33), 138 (100).

*1-Acetoxy-2-(*p*-chlorophenyl)-3-mesyloxypropane (**13**)*

A solution of **12** (1.423 g, 6.22 mmol) in anhydrous THF (65 mL) was prepared under nitrogen. The solution was cooled to 0°C and triethylamine (0.92 mL, 6.60 mmol) was added first, and then methanesulfonyl chloride (0.76 mL, 9.81 mmol) was added dropwise. The solution was stirred for 3 h while the temperature was increased to 25°C. The solvent was evaporated and the residue was taken up in ether (200 mL). The organic phase was washed with a 1 N HCl solution, with a saturated $NaHCO_3$ solution (three times), dried and concentrated. The crude product was purified by flash chromatography (silica gel, elution with ether – petroleum ether, 3:2) to yield **13** (2.051 g, 93%). $[\alpha]_D^{25}$ +6.8 (c 3.8, $CHCl_3$). IR (neat) ν_{max}: 3020, 2900–2980, 1730, 1590, 1490, 1350, 1165, 1090 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.27 (m, 4H), 4.44 (d, J = 6.5 Hz, 2H), 4.34 (m, 2H), 3.39 (m, J = 6.5 Hz, 1H), 2.91 (s, 3H), 2.05 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.57, 135.47, 133.73, 129.30, 129.02, 69.13, 63.69, 43.54, 37.33, 20.73.

*4-Acetoxy-3-(*p*-chlorophenyl)propionitrile (**14**)*

To a solution of mesylate **13** (126 mg, 0.41 mmol) in anhydrous DMSO (5 mL) was added finely pulverized sodium cyanide (26 mg, 0.53 mmol). The solution was stirred at 45°C for 12 h. The solvent was evaporated in vacuo and the residue was taken up in ether (100 mL). The organic phase was washed several times with water, dried over magnesium sulfate, and evaporated. The crude product was purified by flash chromatography (silica gel, elution with ether – petroleum ether, 1:1) to yield nitrile **14** (82 mg, 84%). $[\alpha]_D^{25}$ +130 (c 1.1, $CHCl_3$). IR (neat) ν_{max}: 2950, 2240, 1735, 1595, 1490, 1360, 1230, 1090, 1010, 820 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.24 (d, J = 6.5 Hz, 2H), 7.19 (d, J = 8.5 Hz, 2H), 4.33 (dd, J_1 = 6.0 Hz, J_2 = 11.0 Hz, 1H), 4.21 (dd, J_1 = 8.0 Hz, J_2 = Hz, 1H), 3.32 (m, J = 6.0 Hz, 1H), 2.79 (dd, J_1 = 7.0 Hz, J_2 = 18.0 Hz, 1H), 2.66 (dd, J_1 = 9.0 Hz, J_2 = 18.0 Hz, 1H), 2.05 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.21, 136.19, 133.83, 129.08, 128.57, 117.42, 65.70, 40.57, 21.21, 20.70. MS *m/z* (relative intensity): 239 (M^+, ^{37}Cl, 0.1), 237 (M^+, ^{35}Cl, 0.3), 235 (0.3), 179 (31), 177 (100), 139 (11), 137 (30).

*4-Hydroxy-3-(*p*-chlorophenyl)propionitrile (**15**)*

To a solution of **14** (27 mg, 0.11 mmol) in THF and methanol (4 mL, ratio 10:1) was added a 0.1 N NaOH solution (600 μL) and the solution was stirred at room temperature for 30 min. The solution was poured into ethyl acetate and the organic phase was decanted, washed with a saturated $NaHCO_3$ solution and with brine, dried over magnesium sulfate, and evaporated. The crude product was purified by flash chromatography on silica gel (elution with ether – petroleum ether, 70:30) to yield **15** (17 mg, 77%). $[\alpha]_D^{25}$ +27.5 (c 1.3, $CHCl_3$). IR (neat) ν_{max}: 3200–3600, 2920, 2870, 2240, 1595, 1490 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.30 (d, J = 8.5 Hz, 2H), 7.15 (d, J = 8.5 Hz, 2H), 3.78 (dd, J_1 = 5.5 Hz, J_2 = 11.0 Hz, 1H), 3.68 (dd, J_1 = 7.0 Hz, J_2 = 11.0 Hz, 1H), 3.08 (m, J = 7.0 Hz, 1H), 2.78 (dd, J_1 = 17.0 Hz, J_2 = 6.0 Hz, 1H), 2.62 (dd, J_1 = 17.0 Hz, J_2 = 8.0 Hz, 1H), 2.20 (br s, 1H). ^{13}C NMR ($CDCl_3$) δ: 137.17, 133.34, 128.84, 128.68, 118.31, 64.52, 43.46, 20.34. MS *m/z* (relative intensity): 197 (M^+, ^{37}Cl, 3), 195 (M^+, ^{35}Cl, 6), 166 (4), 164 (12), 140 (31), 138 (100).

*4-Mesyloxy-3-(*p*-chlorophenyl)propionitrile (**16**)*

To a cold (0°C), stirred solution of **15** (610 mg, 3.12 mmol) in dry THF (35 mL) under a N_2 atmosphere was added triethylamine (0.5 mL, 3.6 mmol), followed by dropwise addition of methanesulfonyl chloride (0.30 mL, 3.6 mmol). The solution was stirred for 2 h while the temperature raised to 25°C. The solvent was evaporated and the residue was taken up in dichloromethane. The organic phase was washed with a 1 N HCl solution, a saturated $NaHCO_3$ solution, dried ($MgSO_4$), and evaporated. The crude product was purified by flash chromatography on silica gel (elution with dichloromethane – ethyl acetate, 97:3) to yield **16** (776 mg, 91%). $[\alpha]_D^{25}$ +14.1 (c 1.5, $CHCl_3$). IR (neat) ν_{max}: 3015, 2940, 2240, 1595, 1495, 1420, 1350, 1275, 1095, 920–980 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.38 (d, J = 8.5 Hz, 2H), 7.22 (d, J = 8.5 Hz, 2H), 4.46 (dd, J_1 = 10.5 Hz, J_2 = 5.5 Hz, 1H), 4.36 (dd, J_1 = 10.5 Hz, J_2 = 7.5 Hz, 1H), 3.43 (m, J = 7.0 Hz, 1H), 3.01 (s, 3H), 2.87 (dd, J_1 = 17.0 Hz, J_2 = 7.0 Hz, 1H), 2.75 (dd, J_1 = 17.0 Hz, J_2 = 7.5 Hz, 1H). ^{13}C NMR ($CDCl_3$) δ: 135.02, 134.29, 129.29, 128.75, 117.22, 70.10, 40.69, 37.29, 20.60. MS *m/z* (relative intensity): 275 (M^+, ^{37}Cl, 1), 273 (M^+, ^{35}Cl, 3), 235 (1), 233 (2), 179 (36), 177 (100), 166 (19), 164 (58).

*4-Azido-3-(*p*-chlorophenyl)butyronitrile (**17**)*

To a solution of mesylate **16** (772 mg, 2.82 mmol) in dry DMF (27 mL) was added finely pulverized sodium azide (229 mg, 3.52 mmol). The solution was stirred overnight at 40°C under a N_2 atmosphere, then stirred at 80°C for 2 h. The solvent was evaporated in vacuo and the residue was taken up in ether. The organic phase was washed with a saturated $NaHCO_3$ solution, with brine, dried ($MgSO_4$), and concentrated. The crude product was purified by flash chromatography on silica gel (elution with ether – petroleum ether, 30:70) to yield **17** (508 mg, 82%). $[\alpha]_D^{25}$ –1.4 (c 1.5, $CHCl_3$). IR (neat) ν_{max}: 2910, 2860, 2080, 1490, 1445, 1410, 1085 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.34 (d, J = 8.5 Hz, 2H), 7.18 (d, J = 8.5 Hz, 2H), 3.66 (dd, J_1 = 12.5 Hz, J_2 = 6.5 Hz, 1H), 3.56 (dd, J_1 = 12.5 Hz, J_2 = 7.0 Hz, 1H), 3.16 (m, J = 7.0 Hz, 1H), 2.76 (dd, J_1 = 9.0 Hz, J_2 = 6.0 Hz, 1H), 2.64 (dd, J_1 = 9.0 Hz, J_2 = 7.0 Hz, 1H). ^{13}C NMR ($CDCl_3$) δ: 136.62, 133.78, 129.03, 128.50, 117.39, 54.27, 40.90, 21.18. MS *m/z* (relative intensity): 192 (15), 166 (39), 164 (100), 140 (24), 138 (62), 130 (9), 128 (45).

*(R)-Baclofen [(**R**)-6]*

To a solution of **17** (218 mg, 0.99 mmol) in dry THF (5 mL) under a N_2 atmosphere was added triphenylphosphine (285 mg, 1.09 mmol) and the mixture was stirred at room temperature for 3 h. Water (20 μL) was added and the solution was stirred for 3 h, then poured into ether. The amine product was extracted from the organic phase with a 1 N HCl solution. The aqueous phase was washed with ether and its pH was fixed at 9 by addition of NaOH. This basic aqueous solution was extracted three times with ether. The combined organic phases were dried over Na_2CO_3 and concentrated. The solid product was dissolved in a 6 N HCl solution (2 mL) and the solution was stirred at room temperature for 18 h, and then refluxed 1 h. Water was evaporated in vacuo to yield a white solid, which was dissolved in a 1 N HCl solution (2 mL) and purified by ion exchange chromatography as described above to yield (*R*)-baclofen (97 mg, 46%). $[\alpha]_D^{25}$ –1.7 (c 0.2, H_2O) (lit. (7) $[\alpha]_D^{20}$ –2 (c 0.2, H_2O); lit. (8) $[\alpha]_D$ –1.7 (c 0.2, H_2O)).

LI PANG and FRANÇOIS BRISSE. Can. J. Chem. **72**, 2318 (1994).

Tris(5-acetyl-3-thienyl)methane (TATM) forms inclusion compounds with cyclohexane, -heptane, and -octane in a host/guest ratio of 2:1. The clathrate compounds have been studied by X-ray crystallography. The inclusion compound with cyclohexane crystallizes in two distinct triclinic unit cells of space group $P\bar{1}$: in the **A** form, the unit cell dimensions are a = 8.622(2), b = 10.194(2), c = 12.795(2) Å, α = 79.09(1)°, β = 72.74(1)°, γ = 84.89(1)°, V = 1053.9(4) Å^3 (220 K); for the **B** form, a = 11.668(4), b = 13.729(3), c = 14.227(4) Å, α = 89.40(3)°, β = 77.20(4)°, γ = 76.24(4)°, V = 2157(1) Å^3 (room temperature). In the **A** form the cavity is of the channel type but the guest molecule is located on a centre of inversion while in the **B** form the cavity is also of the channel type but the guest molecule is in a general position. The inclusion compounds of cycloheptane and cyclooctane crystallize only in the **B** form. The guest molecules in the **B** form are disordered. Conformational analyses of the guest molecules have also been performed by a combination of molecular dynamics and energy minimization.

LI PANG et FRANÇOIS BRISSE. Can. J. Chem. **72**, 2318 (1994).

Le tris(5-acétyl-3-thiényl)méthane (TATM) forme des composés d'inclusion avec les cyclohexane, -heptane et -octane avec un rapport hôte/invité de 2 : 1. On a étudié ces clathrates par diffraction des rayons X. Le composé d'inclusion avec le cyclohexane cristallise dans deux mailles tricliniques distinctes du groupe d'espace $P\bar{1}$: dans la forme **A**, a = 8,622(2), b = 10,194(2) et c = 12,795(2) Å, α = 79,09(1)°, β - 72,74(1)° et γ = 84,89(1)°, V = 1053,9(4) Å^3 (220 K) alors que, dans la forme **B**, a = 11,668(4), b = 13,729(3) et c = 14,227(4) Å, α = 89,40(3)°, β = 77,20(4)° et γ = 76,24(4)°, V = 2157(1) Å^3 (température ambiante). Dans la forme **A**, la cavité est du type canal dans lequel la molécule invitée se trouve sur un centre d'inversion alors que, dans la forme **B**, la cavité est du type canal dans lequel la molécule invitée se trouve en une position générale. Les composés d'inclusion des cycloheptane et cyclooctane ne cristallisent que dans la forme **B**. Les molécules invitées dans la forme **B** sont désordonnées. On a réalisé une analyse conformationnelle des molécules invitées par une combinaison de dynamique moléculaire et de minimisation d'énergie.

[Traduit par la rédaction]

Introduction

Tris(5-acetyl-3-thienyl)methane (TATM) has been found to form inclusion compounds with a large number of organic molecules (1). The crystal and molecular structures of a few TATM inclusion compounds, with ethyl acetate, benzene, *n*-hexane, ethanol, cyclononanone, and carbon tetrachloride, have been published in recent years (2–7). From these X-ray determinations, it was shown that the crystals of the TATM inclusion compounds are usually triclinic except for the cyclononanone clathrate, which belongs to the monoclinic system (6). Furthermore, the guest molecules always have higher thermal parameters than the TATM host molecules, which is evidence for a statistical or dynamic disorder effect. To analyze the order–disorder effect and the molecular conformation of the guest molecules in the TATM inclusion compounds, we have performed an X-ray study of the TATM clathrates with six- (**1′** and **1**), seven- (**2**) and eight-membered cycloalkanes (**3**), respectively, at room temperature or at 220 K, as well as some molecular dynamics simulations of the TATM clathrates **2** and **3**.

Experimental

Preparations

The host TATM molecule was synthesized according to the method described by Yakubov et al. (8) and was characterized by ^{1}H nmr ($CDCl_3$/TMS): δ (ppm) = 2.49, 2.77 (s, 2H, thiophene), 4.41 (s, 1H, CH), 7.49 (s, 9H, $-CH_3$); MS: 388; and melting point 125–128°C (recrystallized from $CHCl_3$). The crystals of the inclusion compounds were obtained by a slow recrystallization of the TATM host molecule from cyclohexane, cycloheptane, and cyclooctane solvents, respectively. The crystals of the **A** and **B** forms were obtained using different recrystallization conditions. Thus, the **A** form resulted from a slow cooling of the TATM–cyclohexane solution (5°C/day) whereas the **B** form was obtained by a relatively quick cooling of the solutions (1°C/h). The host/guest ratios of 2:1 were determined by crystal density measurements (flotation in KI/H_2O).

*X-ray crystallographic analysis of **1′**, **1**, **2**, and **3***

Single crystals were selected and mounted on the tip of a glass fibre. The structures were determined on an Enraf–Nonius CAD4 single crystal diffractometer. Lattice constants were determined by least-squares refinement using 25 well-centered reflections in the range 20° < θ < 25°. The crystals of **1′**, **2**, and **3** were measured at low temperature (220 K) and that of **1** at room temperature. Intensity data were collected using Cu $K\alpha$ graphite monochromatized radiation in the ω–2θ scan mode with a scan width defined by $\Delta\omega$ = (0.80 + 0.14 tan θ)° and a scan rate of 16.48° min^{-1}. The structures were solved by direct methods using the MULTAN80 program (9) for **1′** and the SHELXS86 program (10) for **1**, **2**, and **3**. The structures were refined through full-matrix least-squares calculations based on F's by using the NRCVAX program (11) for **1′** and the SHELX76 program (12) for **1**, **2**, and **3**.

All the non-hydrogen atoms of the TATM molecule were refined with anisotropic thermal parameters. The positions of the hydrogen atoms were calculated,[3] and their isotropic thermal parameters were refined.

The guest molecules in the **A** form are ordered, while in the **B** form they are always disordered. The models of the disordered structures were established from difference Fourier syntheses and refined by constraining the C—C bond distances to 1.54 ± 2 Å and the nonbonded distances to 2.56 ± 5 Å (for **1**) or to 2.95 ± 2 Å (for **2** and **3**). The non-hydrogen atoms of the guest molecule in **1′** and only those of the major structure of the guest molecules in **2** and **3** were refined anisotropically. Occupancy factors of 0.40, 0.35, and 0.25 were fixed in **1**, while those

of 0.709(4) and 0.291(4) in **2** and 0.763(3) and 0.237(3) in **3** were refined. The positions of the hydrogen atoms of the guest molecules were calculated (d(C—H) = 0.95 Å, θ(C-C-H) = 109.5°). The scattering factors were taken from ref. 13. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$, where $w^{-1} = \sigma^2(F_o) + g(F_o)^2$, and $S = [\Sigma(|F_o| - |F_c|)^2/(m - n)]^{1/2}$.

A summary of the crystal data, intensity measurements, and refinement results is presented in Table 1. Atomic coordinates[4] are given in Table 2 while the molecular structure of **1′** and the atomic numbering scheme adopted are shown in Fig. 1.

Conformational analyses of 2 and 3

The conformational behaviour of cycloheptane and cyclooctane in **2** and **3** has been studied by a combination of energy minimization and molecular dynamics simulation in the solid state at different temperatures. The calculations were performed using the HyperChem™ Release 2 package[5] running on a 80486-50Hz IBM compatible personal computer.

Since the crystallographic structures of the TATM host molecules are always well defined, the geometry of the TATM molecules was fixed during the calculation and only the conformational energy of the two guest molecules in the unit cells was minimized. Consequently, 32 TATM molecules, whose geometries were taken directly from the crystallographic work, were chosen to build the host cavities inside the unit cells of **2** and **3**. The initial structures of the cycloheptane and the cyclooctane guest molecules were taken from the two models determined in this X-ray study.

The conformational search of the guest molecules in **2** and **3** was carried out using the quenched molecular dynamics method.[6] Thus, two guest molecules inside the host cavity were subjected to molecular dynamics simulation at different temperatures in order to cross over the energy barriers and to obtain possible conformations in a local minimum. Following the molecular dynamics simulation at a given temper-

[4]Lists of the atomic coordinates, bond lengths and angles, torsion angles, anisotropic thermal parameters, and least-squares planes data may be purchased from: The Depository of Unpublished Data Document Delivery, CISTI, National Research Council Canada, Ottawa ON K1A 0S2, Canada.

Tables of atomic coordinates and bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

[6]Quenched dynamics is a combination of high-temperature molecular dynamics and energy minimization. This process can determine a conformation in a relatively deep local minimum in reasonable time space. See HyperChem's manual, Computational Chemistry, Autodesk, Inc., Publication 100033-02, assy no. 100210, 1992.

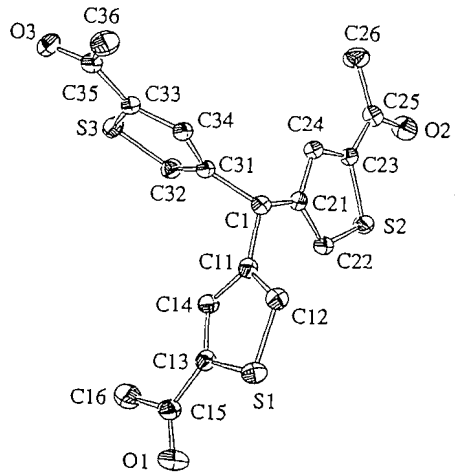
[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.
[b] $U_{eq} = \frac{1}{3}$ of the trace of the orthogonalized U_{ij} tensor.

ature, the structures of the guest molecules were minimized through a molecular mechanics force field (14) using the MM+ force field.[7] The molecular dynamics simulations were performed using a constant temperature bath at 300, 400, 500, 600, 700, 800, 900 and 1000 K, respec-

[7] The MM+ force field is an extension of MM2. Its bond and angle terms can contain higher-order terms than the standard quadratic. See HyperChem's manual, Computational Chemistry, Autodesk, Inc., Publication 100033-02, assy no. 100210, 1992.



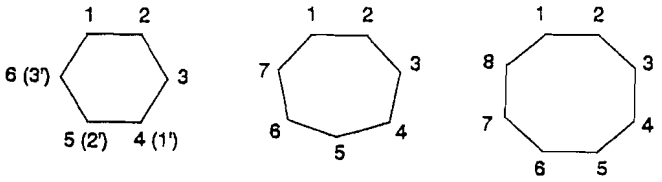


FIG. 1. Structure of the TATM molecule of **1′** and schematic diagrams of the six-, seven-, and eight-membered cycloalkanes and their atomic numbering.

tively. The molecules were allowed to equilibrate for a period of 1 ps. A time step of 0.001 ps and a relaxation time of 0.1 ps were used in the integration algorithm. The energy minimization employed the Polak–Ribiere conjugate gradient technique. The minimization was concluded after the maximum derivative of all atoms was less than 0.005 kcal mol^{-1} $Å^{-1}$. Atoms outside a cut-off sphere centered at 1/2 1/2 1/2 with a 12 Å radius were not considered in the calculation.

Results and discussion

The crystal data of interest for the TATM inclusion compounds under investigation are presented in Table 1. The cyclohexane inclusion compounds **1′** and **1** crystallize in two distinct triclinic forms. The crystal of the **A** form contains two TATM molecules and one guest molecule whereas there are four TATM molecules and two cyclohexane molecules in the unit cell of the **B** form. The volume of the unit cell of the **B** form is about twice that of the **A** form. No phase transition was observed between these two forms in the range 220–295 K so that these phases are independently stable and depend only upon the recrystallization procedure. The guest molecules in the **B** form are always disordered due to a slightly larger cavity. The following occupancy factors were evaluated: 40/35/25, 71/29, and 76/24 for the guest molecules in **1**, **2**, and **3**, respectively.

Structure of tris(5-acetyl-3-thienyl)methane (TATM)

The molecular structures of the TATM molecule in the **A** and **B** crystal forms are very similar (Fig. 1) and close to those of previously published work (2–7). Selected bond lengths and angles of the TATM molecules in **1′** and **1–3** are compared in Table 3. The acetyl groups are nearly coplanar with the thienyl rings, since the oxygen atoms and the methyl groups deviate

TABLE 3. (*a*) Average bond lengths (Å) and (*b*) bond angles (deg) for TATM molecules in **1′**, **1**, **2**, and **3** (n = 1, 2, and 3, the number of the thienyl ring)
