FIG. 2. The unit cell content of the TATM–cyclohexane clathrate in the **A** form (*a*) Stereo pair showing the channel cross section down the *a* axis; (*b*) side view (the *a* axis is horizontal).

from the thienyl ring by an average value of 0.06(2) and 0.08(2) Å. The hydrogen atoms of the methyl groups have a fair amount of disorder as indicated by their high thermal parameters. The dihedral angles formed between the three thienyl rings are in the range 68°–81°.

*Description of the cavities in the **A** and **B** forms*

Since the TATM molecule has a relatively rigid structure, the different crystal structures and the cavity type depend upon the size and the shape of the guest molecule and the resulting molecular packing.

The two views in Fig. 2 clearly show that there is a channel-like cavity in the unit cell of the **A** form. Thus, two of the three thienyl rings of one molecule and the acetyl group of another TATM molecule contribute to the formation of the channel. The axis of the channel, parallel to *a*, passes through the crystallographic centres of symmetry at 0 1/2 1/2, 1/2 1/2 1/2, etc. The cyclohexane guest molecules are located on these centres of inversion and are ordered.

The situation in the **B** form is slightly different. It can be seen from Fig. 3 that the cavity is also of the channel type. However, the molecules in the channel of the **B** form adopt a zigzag disposition rather than the linear one of the **A** form. The molecular packing of the TATM molecules in the **B** form is slightly different from that in the **A** form. Thus, the TATM molecules are arranged in such a way that one of the thienyl rings is almost parallel to the *bc* face of the unit cell, while the remaining two thienyl rings form the sides of the channels. The comparison of the *b* and *c* parameters of the **A** form with the *a* and *b* parameters of the **B** form, which are a measure of the channel cross section, reveals that the channels in the **B** are slightly larger than in the **A** form. This increase in the channel section could explain the disorder of the guest molecules. These results confirm some previously published work (3, 7).

Conformation of the cycloalkane guest molecules

The most significant difference between the **A** and **B** forms resides in the structure of the guest molecule. Thus, in the **A** form, the cyclohexane molecule is located on a crystallographic centre of symmetry and is ordered. However, in the **B** form, the cyclohexane molecule is in a general position and has three molecular orientations. These orientations have an occupation factor of 40/35/25 and thus produce a statistical disorder. The cyclohexane guest molecule in both the **A** and **B** forms always has the *chair* conformation, so that the disordered structures in

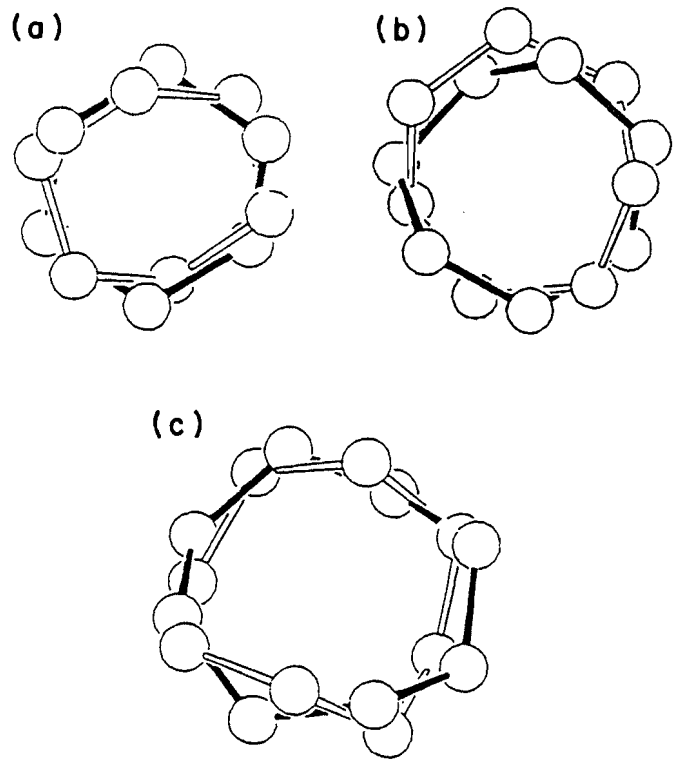

FIG. 4. Molecular orientations of (*a*) cyclohexane; (*b*) cycloheptane; (*c*) cyclooctane.

the **B** form are of the orientational type. Figure 4(*a*) shows the disordered structure for the cyclohexane molecule.

The inclusion compounds of cycloheptane and cyclooctane crystallize only in the **B** form. This may be understood by the fact that these guest molecules are slightly larger and do not fit in the cage of the **A** form, which would result in shorter intermolecular contacts and thus a higher potential energy. In the **B** form, these guest molecules are disordered. The cycloheptane molecule was found in two orientations with respective occupancy factors of 0.709(4) and 0.291(4). The molecules have the same conformation ($g^-gg^-ggg^-g$) so that the disorder is only of an orientational type.

A similar result was obtained for the cyclooctane inclusion compound. Thus, two orientations of the molecule in the same conformation ($gg^-gg^-ggg^-g^-$) were found with occupancy factors of 0.763(3) and 0.237(3), respectively. Figures 4(*b*) and 4(*c*) show the orientational disorder for cycloheptane and cyclooctane in the TATM inclusion compounds. The bond lengths and angles for the six-, seven-, and eight-membered cycloalkane molecules are given in Table 3, while in Table 4 are reported the torsion angles of the guest molecules.

From a crystallographic point of view, the difficulty of refining disordered structures lies in the fact that the electron density map, derived from a difference Fourier synthesis, reflects many possible molecular orientations or conformations within several potential minima. It is thus useful to carry out some molecular dynamics simulations to determine the low-energy orientations, or conformations, which will be useful in confirming or predicting the actual structure.

The results of a molecular dynamics simulation for the cycloheptane and cyclooctane guest molecules in the TATM cavities are shown in Fig. 5. The calculations were started using the molecular conformations α ($g^-gg^-ggg^-g$) and β ($ggg^-ggg^-g^-$)

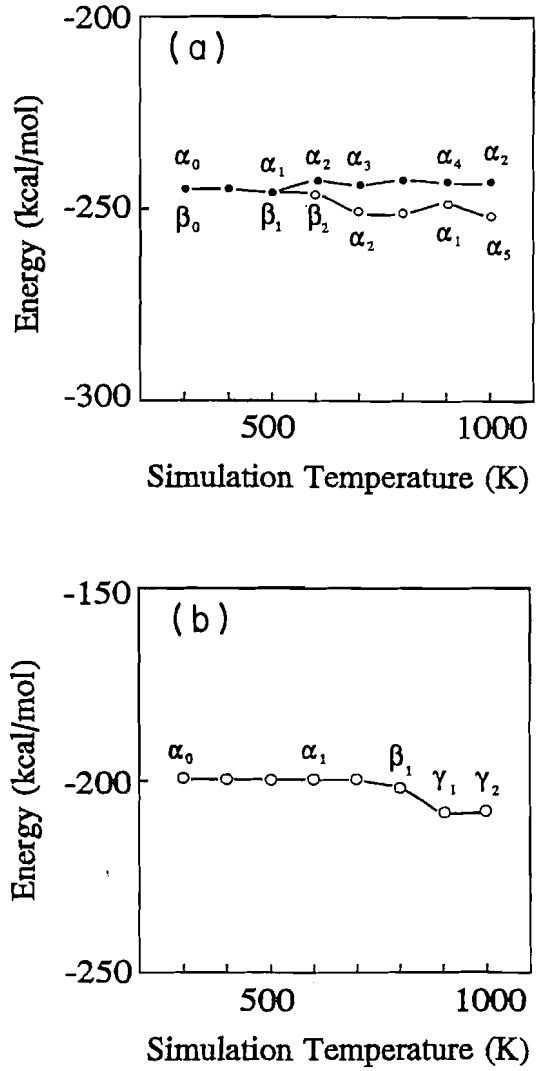

FIG. 5. Molecular dynamics simulation results of (*a*) cycloheptane; (*b*) cyclooctane.

for cycloheptane and the conformation α ($ggg^-g^-ggg^-g^-$) for cyclooctane.

These calculations reveal that the cycloheptane molecule could exist in two conformations, α and β. The molecule in the α conformations takes a number of orientations within the cavity, α_1, α_2, ... etc. The energy barrier to reorientation is about 1 kcal/mol. The situation is different for the molecule in the β conformation. Besides reorienting itself, the molecule undergoes a conformational transformation at 700 K, which brings it into the more energetically stable α conformation. The energy barrier of this is about 2 kcal/mol.

For the cyclooctane molecule, there are three molecular conformations. When the molecule is in the α conformation ($ggg^-g^-ggg^-g^-$), it goes through two conformational transformations at 800 and 900 K, respectively, to arrive at the energetically more stable β ($gg^-gg^-g^-ggg^-$) and γ ($gg^-gg^-ggg^-g^-$) conformations. It is the latter that was observed in the X-ray work.

In conclusion, the X-ray crystal structure determination of the **B** form of the TATM clathrates with six-, seven-, and eight-membered cycloalkanes indicates that all guest molecules have an orientational disorder. Only the energetically stable conformations, the *chair* for the cyclohexane, the α for the cycloheptane, and the γ for cyclooctane, are observed. However, the

molecular dynamics simulation displays more conformations for the more flexible cycloheptane and cyclooctane molecules.

Phomalone, an antifungal metabolite of *Phoma etheridgei*

WILLIAM A. AYER AND LUIS DIEGO JIMENEZ
Department of Chemistry, University of Alberta, Edmonton, AB T6G 2G2, Canada

Received June 23, 1994

WILLIAM A. AYER and LUIS DIEGO JIMENEZ. Can. J. Chem. **72**, 2326 (1994).

The metabolites produced by liquid cultures of *Phoma etheridgei*, a new fungus isolated from black galls of aspen, have been examined. This fungus is antagonistic to the aspen decay fungus *Phellinus tremulae*. The compound responsible for this antagonism has been isolated and its structure elucidated. Phomalone (**1**) is a previously undescribed natural product that possesses the same carbon skeleton as the *Phoma pigmentivora* metabolite LL-D253α. The structure was determined by physical methods, mainly ^{1}H and ^{13}C NMR. INAPT experiments played an important role. Some chemical transformations of phomalone (**1**) are described and it is shown by ^{13}C-labelling experiments to be derived from six acetate units. Phomalone is active against *Phellinus tremulae*. Compounds **4**, **6**, **7**, and **8** are also new natural products produced by *P. etheridgei*.

WILLIAM A. AYER et LUIS DIEGO JIMENEZ. Can. J. Chem. **72**, 2326 (1994).

On a étudié les métabolites produits par des cultures liquides du *Phoma etheridgei*, un nouveau champignon isolé des galles noires de peuplier. Ce champignon est un antagoniste pour le champignon *Phellinus tremulae* qui provoque la détérioration du peuplier. On a isolé le composé responsable de cet antagonisme et on a élucidé sa structure. La phomalone (**1**) est un produit naturel qui n'a pas été décrit antérieurement et qui possède le même squelette carboné que le métabolite LL-D253α du *Phoma pigmentivora*. On a déterminé la structure par des méthodes physiques, principalement le RMN du ^{1}H et du ^{13}C. Des expériences INAPT en joué un rôle important. On décrit quelques transformations chimiques de la phomalone (**1**) et, sur la base d'expériences de marquage au ^{13}C, on démontre qu'elle est obtenue à partir de six unités acétate. La phomalone est active contre le *Phellinus tremulae*. Les composés **4**, **6**, **7** et **8** sont aussi de nouveaux produits naturels produits par le *P. etheridgei*.

[Traduit par la rédaction]

Introduction

Trembling aspen (*Populus tremuloides* Michx.) is the most widely distributed tree species in North America (1). It is a fast-growing pioneer species, intolerant of shade, which thrives in areas disturbed by logging, fire, and other natural disruptions. In Canada, aspen represents more than one half of the net merchantable hardwood timber and 11% of the entire timber resource (2).

The commercial utilization of aspen has increased tremendously in the past decade. In Alberta, aspen accounted for only 2.4% of the total timber harvest in 1980; however, by 1992 this had increased to 18% (3). The reasons for this change include an increasing scarcity of economically accessible softwood timber in Canada and the introduction of new technologies to use this resource more efficiently. The development of oriented strand board (OSB) in the early 1980s contributed substantially to the increased use of this hitherto neglected resource. In the manufacture of OSB, large, thin strands of aspen are bonded together with resins under heat and pressure. Aspen's low density is an advantage in this process, since moderate pressure serves to create a board with good strength. Because of its low lignin and high cellulose content, aspen is also being utilized more in the pulp and paper industry, especially in the chlorine-free chemothermomechanical pulping (CTMP) process (1). Its natural light weight and lack of color, taste, and odor make it deal for chopsticks and popsicle sticks (4).

The greatest limitation on the utilization of aspen is that it is very susceptible to wood decay and straining fungi. Heartwood decay, especially by *Phellinus tremulae*, is often present in a majority of the trees in a mature stand (5). Stored logs and chips of aspen are very susceptible to blue stain fungi (6). Recently it has been found that certain types of black galls occurring as stem deformities on aspen appear to confer protection against decay and stain-causing fungi (7). As part of a collaborative project investigating the nature of this black gall protective effect, we have examined the metabolites of several fungi associated with the black galls (8–11). We report herein on the metabolites of a newly described fungus (12), *Phoma etheridgei*, isolated from the surface of the galls, which has been shown to be antagonistic to the aspen decay fungus *Phellinus tremulae*.

Results and discussion

Phoma etheridgei sp. nov. Hutchison and Hiratsuka is a previously undescribed species of fungus that frequently occurs on the surface of black galls of aspen in central Alberta (12). This fungus shows antagonistic activity in agar culture and on aspen chips against the aspen decay fungus *Phellinus tremulae* and the blue strain fungus *Ophiostoma crassivaginata*. After considerable experimentation it was possible to obtain liquid cultures that consistently produced metabolites that show antifungal activity against *P. tremulae*. The production of active metabolites is very dependent on the inoculum used for the liquid cultures. The use of mycelium from Petri dish agar cultures gave inconsistent results: at times activity was observed, at other times the extracts were inactive. Spore (pycnidia) suspensions of the fungus were found to give more consistent results. *Phoma etheridgei* products pycnidia in Phytone yeast extract agar (PYEA) and malt extract agar (MEA) when grown at 25–30°C under light (λ <360 nm) for 2–4 weeks. Shake cultures in malt extract or Phytone yeast extract liquid media at room temperature for 12–16 days provide bioactive extracts. Activity was determined by bioassay against *P. tremulae* (see Experimental). The activity of the extracts diminished when the growth period was extended beyond 16 days.[1] To facilitate the isolation of the active compounds we found it convenient to add DIAION HP-20 resin (a polystyrene–divinylbenzene copolymer) to the culture medium (14). After fermentation, the resin and adhering mycelium were separated from the broth and the metabolites were eluted from the resin-mycelium with ethyl acetate. When the resin was not used, the mycelium was separated by filtration

[1]Full details of the fermentation studies are provided in ref. 13.

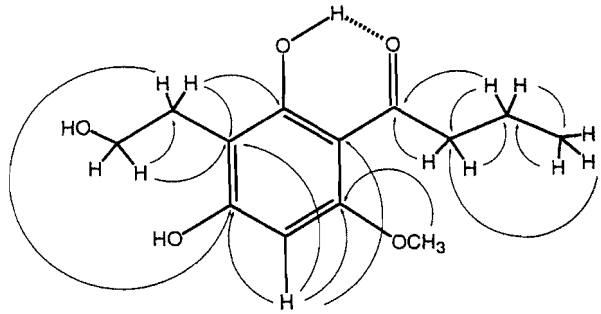
through cheesecloth, and the broth was concentrated and extracted with ethyl acetate. The mycelium was extracted separately but did not yield an appreciable quantity of active metabolites. The resin method provided about 0.25 g/L of metabolites while the extraction method provided approximately 0.1 g/L. TLC analysis indicated that both procedures provided essentially the same mixture of metabolites.

Bioassay (against *P. tremulae*) guided separation of the crude metabolites by flash chromatography over silica gel, followed by high-performance medium-pressure liquid chromatography (HPMPLC) over reverse-phase (C-18) silica gel, gave a crystalline compound, $C_{13}H_{18}O_5$, mp 126–127°C, which we have named phomalone. This compound is responsible for the antifungal activity against *P. tremulae* as described in more detail below.

The structure of phomalone (**1**) was deduced as follows. The molecular formula $C_{13}H_{18}O_5$ was determined by high-resolution electron impact mass spectrometry (HERIMS) and the molecular weight (254 amu) confirmed by chemical ionization mass spectrometry (CIMS). The IR spectrum shows hydroxyl (3200 cm^{-1}) and low-frequency carbonyl (1618 cm^{-1}) absorption. The ^1H NMR spectrum shows a chelated phenolic hydroxyl proton (δ 14.50), a single aromatic hydrogen (δ 6.01), an aromatic methoxyl (δ 3.85), and signals for a 2-hydroxyethyl group (two proton triplets at δ 3.70 and δ 2.74) and a propyl group (triplet (2H) at δ 2.80, quarter (3H) at δ 0.95, tq (2H) at δ 1.66). Acetylation of phomalone gave a triacetyl derivative (**2***a*), confirming the presence of three hydroxyl groups in phomalone. The ketonic carbonyl in triacetylphomalone appears at 1699 cm^{-1} in the IR spectrum. The ^{13}C NMR spectrum of phomalone (acetone-d_6) confirms the presence of a carbonyl group (δ 206.4), three oxygenated aromatic carbons (δ 165.9, 164.3, 162.7), two substituted aromatic carbons (δ 106.9, 105.5), and an upfield unsubstituted aromatic carbon (δ 92.1). The oxygenated methylene carbon appears at δ 62.9, and the methoxyl carbon at δ 55.9. The C-methyl signal appears at δ 14.2, and the remaining methylene carbons at δ 46.3 (C-2), 26.3 (benzylic), and 16.9 (C-3). These data indicate that phomalone is a pentasubstituted benzene bearing two hydroxyls, a methoxyl, a 2-hydroxyethyl, and a 1-butanoyl group. Nuclear Overhauser enhancement (NOE) experiments reveal that the aromatic hydrogen is *ortho* to the methoxyl group, but apparently not *ortho* to the hydroxyethyl group. The chelated carbonyl requires an *ortho* relationship between the butanoyl group and a phenolic hydroxyl, and the very high field position (δ 92.1) of the unsubstituted aromatic carbon and the aromatic hydrogen (δ 6.01) suggests that the aromatic oxygen functions are all *ortho* and *para* to this position. Simpson and co-workers have shown that the *Phoma pigmentivora* metabolite LL-D253α possesses the closely related structure **3** (15). In the ^{13}C NMR spectrum of **3** the aromatic carbon and hydrogen appear at δ 92.7 and δ 6.13, respectively. The absorption for the *unchelated* carbonyl group of **3** is at 1652 cm^{-1} in the IR spectrum.

To define unambiguously the substitution pattern in phomalone we turned to Insensitive Nuclei Assigned by Polarization Transfer (INAPT) (16) experiments. These experiments, carried out in DMSO-d_6 solution, show that the benzylic methylene hydrogens of the hydroxyethyl side chain are correlated with two oxygenated aromatic carbons (δ 164.4 and δ 163.5) as well as the aromatic carbon at δ 104.5 and the oxygenated methylene carbon (δ 59.8). The hydrogens of the methoxyl methyl show correlation with the aromatic carbon at δ 161.0. Thus, the



SCHEME 1

hydroxyethyl group is situated on a carbon *between* two phenolic hydroxyl-bearing carbons. The aromatic hydrogen correlates with the carbon bearing the methoxyl group (δ 161.0), one of the phenolic carbon (δ 163.5), and the two quaternary aromatic carbons. All of the correlations observed are summarized in Scheme 1. These serve to locate the positions of the various substituents on the aromatic ring and establish structure **1** for phomalone.

Treatment of phomalone with *p*-toluenesulfonic acid in refluxing benzene gave a mixture of the two anhydro derivatives **4** and **5**. The formation of these two cyclization products further confirms the location of the hydroxyethyl group. Compound **4** shows carbonyl absorption at 1650 cm^{-1} in the IR, and a chelated phenolic OH proton at δ 14.5 in its NMR spectrum. The ^1H and ^{13}C NMR spectra of **4** are very similar to those of phomalone (**1**), except that the signal for the oxygenated methylene hydrogens is shifted downfield to δ 4.50 (δ 3.70 in **1**). The isomeric compound **5** also shows carbonyl absorption at 1650 cm^{-1}, but now the phenolic OH proton is not chelated and appears at δ 9.5 in the ^1H NMR spectrum. The fact that the carbonyl absorption appears at about the same frequency in both **4** and **5** is not unusual, since both *ortho* and *para* hydroxyl groups in acetophenones cause shifts to lower frequency due to electron-donating effects rather than H-bonding effects (15). Phomalone, with both an *ortho* and a *para* hydroxyl, absorbs at 1618 cm^{-1}. The dihydrobenzofuran **4** also occurs as one of the minor metabolites of *P. etheridgei* (see below).

Acetylation of phomalone with a limited amount of acetic anhydride–triethylamine in CH_2Cl_2 at room temperature affords a mixture of the triacetyl derivative **2***a* and the diacetyl derivative **2***b*. A large excess of the acetylating agent provides only the triacetyl derivative **2***a*. The location of the free hydroxyl group in the diacetate **2***b* is apparent from its ^1H NMR spectrum, which shows a chelated OH signal at δ 14.05. The IR spectra of the acetylated derivatives illustrate nicely the electron-donating effects mentioned above. The ketonic carbonyl appears at 1699 cm^{-1} in **2***a*, 1651 cm^{-1} in **2***b*, and at 1618 cm^{-1} in phomalone (**1**). Irradiation of the aromatic hydrogen in **2***a* causes a 3.6% NOE enhancement of the signal for the methoxyl hydrogens at δ 3.82. The reverse experiment causes 2.9% enhancement of the aromatic hydrogen signal (δ 6.13). INAPT experiments on the triacetate confirmed the atomic connectivity as in phomalone (**1**) itself.

During the course of the separation of phomalone (**1**), several other metabolites of the fungus were isolated and identified. One of these, the dihydrobenzofuran **4**, has already been discussed. Another compound that eluted with **4** on flash chromatography was separated from **4** by preparative TLC. This compound, which we call deoxyphomalone, has the molecular formula $C_{13}H_{18}O_4$ and possesses structure **6**. It is obtained as a

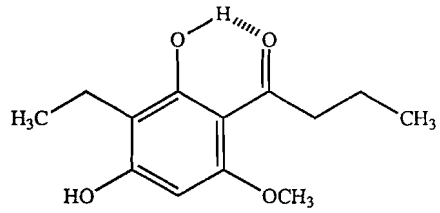
crystalline solid that gives a positive ferric chloride reaction. The spectroscopic properties are very similar to those of phomalone except that the hydroxymethylene proton signal at δ 3.70 is replaced by a methyl triplet at δ 1.12. The benzylic methylene group in **6** appears as a quartet at δ 2.59. Structure **6** is consistent with the data accumulated for this compound.

The next compound eluted also possesses an ethyl group as indicated by ^{1}H NMR. It has the molecular formula $C_{12}H_{14}O_4$ and has structure **7**. It shows hydroxyl and low-frequency carbonyl (1631 cm^{-1}) absorption in its IR spectrum. It is positive to ferric chloride. The ^{1}H NMR spectrum shows two methyl signals, a triplet at δ 1.09 and a doublet at δ 1.40, and two exchangeable phenolic hydrogens, one chelated (δ 12.50). The oxygenated sp^3 carbon appears at δ 73.5 in the ^{13}C NMR spectrum. The compound does not possess a methoxyl group. The remaining hydrogen and carbon signals are similar to those in **6**. Based on the presumed relationship of **7** with phomalone (**1**) and deoxyphomalone (**6**), structure **7** (8-ethyl-5,7-dihydroxy-2-methylchroman-4-one) is proposed for this compound.

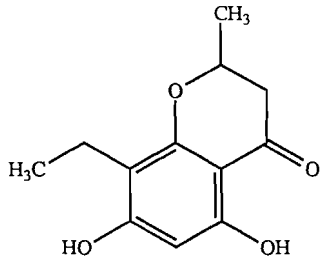
The fraction eluting after phomalone (**1**) in the initial flash chromatography gave material that could not be purified satisfactorily by further chromatography. However, acetylation (Ac_2O–NEt_3–CH_2Cl_2) and preparative TLC provided a colorless oil that shows NMR properties similar to those of triacetylphomalone (**2***a*) except that the signals for the butanoyl side chain are replaced by signals at δ 6.75 (1H) and δ 6.34 (1H), and δ 1.92 (3H), consistent with a 2-butenoyl side chain. The ketonic carbonyl absorbs at 1660 cm^{-1} in the IR spectrum, and the H–H coupling constant for the alkenic hydrogens is 16.5 Hz. This compound is thus the α,β-unsaturated analog **8** of triacetylphomalone (**2***a*), and presumably occurs in the unacetylated form **8***a*.

Bioassays of phomalone (**1**) using the multiwell method (5) show that it completely inhibits the growth of *Phellinus tremulae* at a concentration of 1×10^{-3} mol/L, but has no effect at 1×10^{-4} mol/L. Intermediate concentrations show partial inhibition. It thus appears unlikely that phomalone is responsible for the "black gall effect" described above.

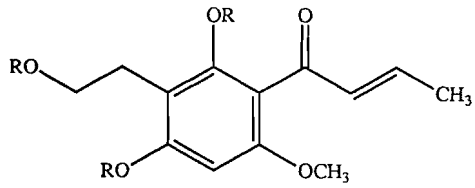
Simpson et al. have shown (17) that compound LL-D253α (**3**) results from the combination of two ketide units (possibly triketide + triketide, but tetra + di, and penta + mono are not excluded). ^{13}C-Labelling experiments using [1,2-$^{13}C_2$]-acetate reveal that phomalone (**1**) also is formed from six acetate units. When [1-^{13}C]-sodium acetate is added to the culture medium, carbons 1, 3, 2′, 4′, and 6′ are labelled, and *both* carbons of the hydroxyethyl are enriched (see Table 1). When [2-^{13}C]-acetate



6



7



8 R = Ac
8*a* R = H

is added, C-2, C-4, C-1′, C-3′, and C-5′ are enriched, as are both carbons of the hydroxyethyl side chain (Table 1). In the case of the [1-^{13}C] label, the benzylic carbon carries more label than the carbinol carbon. The reverse is true in the [2-^{13}C]-acetate case. These results are consistent with the biosynthetic pathway illustrated in Scheme 2, similar to that proposed for LL-D253α (**3**) (17), in which at least a portion of the phomalone (**1**) is formed via the symmetrical cyclopropyl intermediate A shown, accounting for the labelling of both C-5 and C-6. Scheme 2 uses the triketide pathway for illustrative purposes only; the 4+2 and the 5+1 pathways are also possible. We do not wish to imply that it is necessarily the *p*-hydroxyl group that is involved in the formation of the cyclopropyl intermediate.

Phomalone (**1**) and compounds **4**, **6**, **7**, and **8** have not been described previously as natural products.

Experimental

General

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Infrared spectra (IR) were obtained using the following spectrophotometers: Nicolet 7199 FTIR, Nicolet MX-1 FTIR, and Nicolet 750 FTIR. Electron impact mass spectra (EIMS) were obtained using a Kratos AE1 MS50 high-resolution mass spectrometer and a Kratos AE1 MS12 low-resolution mass spectrometer. Chemical ionization mass spectra (CIMS) were recorded on an Kratos AE1 MS-12 mass spectrometer with ammonia as the reagent gas. Ultraviolet (UV) spectra were recorded on a Hewlett Packard 8450A diode array spectrophotometer. Hydrogen nuclear magnetic resonance spectra (^{1}H NMR) were obtained using the following spectrometers: Bruker WH-200 (200 MHz), Bruker AM-400 (400 MHz), and Varian Unity-500 (500 MHz). Carbon-13 nuclear magnetic resonance spectra (^{13}C NMR) were obtained on Bruker AM-300 (75 MHz) and Bruker AM-400 (100.6 MHz) spectrometers. Carbon-13 multiplicities were determined using spin echo *J*-modulated experiments (APT or Attached Proton Test). Nuclear Overhauser Enhancement (NOE) experiments were determined in the difference mode. Homonuclear decoupling experiments were performed by using the Bruker DISNMR software package. Insensitive Nuclei Assigned by Polarization Transfer (INAPT) experiments were performed using the Varian Unity-500 spectrometer. Carbon-13 nuclear magnetic resonance spectra (^{13}C NMR) of labeled material were obtained on a Bruker AM-400 (100.6 MHz) spectrometer. Carbon-13 experiments on labeled material were performed using the Bruker DISNMR software package. A relaxation delay of 4 s was used. High-performance medium-pressure liquid chromatography (HPMPLC) was carried out on ACE Glass Inc. Michel–Miller equipment using a Fluid Metering Inc. model RP-SY solvent pump. High-pressure liquid chromatography (HPLC) analyses were performed on a Waters 600E system controller equipped with a 490E programmable multiwavelength UV detector and a M730 data module. *Phoma etheridgei* spores were counted with a hemacytometer (graduated surface normally used to count blood cells) under a microscope.

Flash chromatography was performed using 230–400 mesh silica gel. DIAION HP 20 was obtained from TCI America, Portland, Oreg.

TABLE 1. Results of [1-^{13}C]- and [2-^{13}C]-sodium acetate labelling experiments[a]

Carbon	δ	% Enrichment [1-^{13}C]-acetate	% Enrichment [2-^{13}C]-acetate
1	202.6	3.5	—
2	45.8	—	6.7
3	17.8	3.2	—
4	13.7	—	7.9
5	24.1	4.9	1.3
6	62.6	1.1	4.6
1′	115.9	—	8.8
2′	156.3	2.7	—
3′	122.6	—	4.2
4′	151.3	2.7	—
5′	104.2	—	5.8
6′	147.6	1.7	—

[a]The spectra of the triacetyl derivative **2***a* were determined in $CDCl_3$ at 100.6 MHz. Normalization of the ^{13}C NMR enrichment was carried out by using the signals for the introduced acetoxyl methyls as the measure of natural abundance. The % enrichment was calculated as described in ref. 18.

Fermentation methods

Liquid cultures

Inocula for liquid cultures were obtained from malt extract agar plates of *P. etheridgei*. After 30 days growth the spores were counted using a hemacytometer. The agar culture was blended with 200 mL of sterile water and the volume of the resulting aqueous suspension was adjusted to contain 10 000 –20 000 spores/mL. A 3 mL aliquot of this spore suspension was used as inoculum for 1 L of liquid media (20 g malt extract, 20 g glucose, 1 g bactopeptone/L). After inoculation, the liquid cultures were shaken at room temperature for 12 days.

Liquid cultures with DIAION HP-20 resin

Liquid cultures were prepared in 10-L batches. A 3-mL aliquot of the aqueous suspension containing 10 000–20 000 spores/mL was used to inoculate 10 1-L portions of sterile malt extract liquid medium in 2-L Erlenmeyer flasks. DIAION HP-20 resin (20 g/L) was added to the liquid medium. After inoculation, the liquid cultures were shaken at room temperature for 12 days.

Labelling experiments

Liquid cultures (2 L) were prepared using spore suspensions as

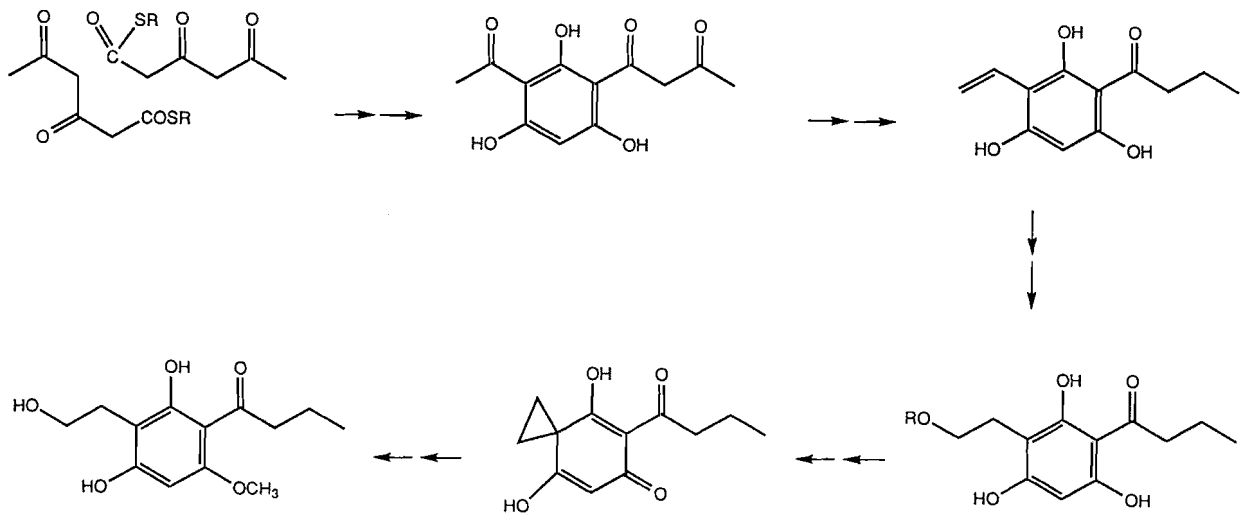
For personal use only.



SCHEME 2

above. A 3-mL aliquot of the aqueous suspension containing 10 000–20 000 spores/mL was used to inoculate 2 1-L portions of sterile malt extract liquid medium in 4-L Erlenmeyer flasks. DIAION HP-20 ion exchange resin (20 g/L) was added. The liquid cultures were shaken at room temperature. After 3 days, a solution of [1-^{13}C]-sodium acetate (15 mL, 0.2 mol/L) was added under sterile conditions. Two similar additions were made on the fifth and seventh day. The *P. etheridgei* culture was kept under shake conditions for a total of 13 days. The same procedure was followed using [2-^{13}C]-sodium acetate and [1,2-$^{13}C_2$]-sodium acetate.

Isolation of metabolites

The floating HP-20 ion exchange resin was decanted from the liquid culture (2 L, 12 days). The remaining resin, which adhered to the mycelium, was separated by vacuum filtration through Whatman filter paper No. 1. The resin and the mixture of resin and mycelium were transferred to a sintered glass filter (porosity D, ASTM 10–20 μm) and extracted with ethyl acetate (1.6 L). The ethyl acetate extract was dried over anhydrous sodium sulfate and concentrated under reduced pressure to give a crude extract (0.457 g). Flash chromatography of the resin extract (10% ethyl acetate in methylene chloride) gave 60 fractions (10 mL each), which were combined, according to TLC analysis, as follows: 1–5 (fraction 1, 6 mg), 6–9 (fraction 2, 14 mg), 10–15 (fraction 3, 9 mg), 15–25 (fraction 4, 23 mg), 26–41 (fraction 5, 0.1 g). Further separation of these fractions afforded five major compounds: 4-hydroxy-6-methoxy-5-(1′-oxobutyl)benzo[*b*]dihydrofuran (**4**); 3-ethyl-2,4-dihydroxy-6-methoxybutyrophenone (**6**); 8-ethyl-5,7-dihydroxy-2-methylchroman-4-one (**7**); phomalone (**1**).

4-Hydroxy-6-methoxy-5-(1′-oxobutyl)benzo[b]dihydrofuran (4)

Flash chromatography of fraction 1 (10% ethyl acetate in methylene chloride) gave 4-hydroxy-6-methoxy-5-(1′-oxobutyl)benzo[*b*]dihydrofuran (**4**) as a white solid (4 mg): R_f 0.30(2% ethyl acetate in methylene chloride); IR ($CHCl_3$, cast): 3250 (OH), 1650 (ketone C=O cm^{-1}); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 14.50 (s, 1H, Ar-O*H*), 5.90 (s, 1H, Ar-*H*), 4.5 (t, 2H, J = 7.0 Hz, -O-CH_2-CH_2-), 3.8 (s, 3H, -OCH_3), 3.2 (t, 2H, J = 7.0 Hz, -CH_2-CH_2-Ar), 2.80 (t, 2H, J = 7.0 Hz, O=C-CH_2-), 1.60 (tq, 2H, $J = J'$ = 7.0 Hz, -CH_2-CH_2-CH_3), and 0.98 (t, 3H, J = 7.0 Hz, -CH_2-CH_3); ^{13}C NMR (100.6 MHz, acetone-d_6) δ: 206.4 (s), 165.9 (s), 164.3 (s), 162.7 (s), 142.6 (s), 132.9 (s), 92.4 (d), 62.9 (t), 55.9 (q), 46.6 (t), 26.4 (t), 18.9 (t), and 14.2 (q); HREIMS, *m/z*: 236.1055 (M$^+$, calcd. for $C_{13}H_{16}O_4$: 236.1062), 193.0501 (100), 149.0241 (30).

3-Ethyl-2,4-dihydroxy-6-methoxybutyrophenone (6)

Flash chromatography of fraction 2 (10% ethyl acetate in methylene chloride) followed by prep-TLC (30% ethyl acetate in hexanes) gave 3-ethyl-2,4-dihydroxy-6-methoxybutyrophenone as a white solid (6 mg); IR ($CHCl_3$, cast): 3200 (OH), 1618 (ketone C=O cm^{-1}); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 14.35 (s, 1H, Ar-O*H*), 5.90 (s, 1H, Ar-*H*), 3.52 (s, 3H, -OCH_3), 2.98 (t, 2H, J = 7.0 Hz, O=C-CH_2), 2.59 (q, 2H, J = 7.0 Hz, -CH_2-CH_3), 1.70 (tq, 2H, $J = J'$ = 7.0 Hz, -CH_2-CH_2-CH_3), 1.12 (t, 3H, J = 7.0 Hz, CH_2-CH_3), and 0.98 (t, 3H, J = 7.0 Hz, CH_2-CH_3); ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 202.3 (s), 164.9 (s), 161.5 (s), 159.6 (s), 109.5 (s), 105.7 (s), 90.1 (d), 55.4 (q), 46.3 (t), 22.3 (t), 18.2 (t), 14.0 (q), 13.4 (q). HREIMS, *m/z*: 238.1207 (M$^+$, calcd. for $C_{13}H_{18}O_4$: 238.1209), 195.0661 (100).

8-Ethyl-5,7-dihydroxy-2-methylchroman-4-one (7)

Flash chromatography of fraction 3 (20% ethyl acetate in methylene chloride) followed by HPMPLC (NP, Si60, 2% ethyl acetate in methylene chloride) and prep. TLC (2% ethyl acetate in methylene chloride) gave 8-ethyl-5,7-dihydroxy-2-methylchroman-4-one as a white solid (1.3 mg): IR ($CHCl_3$, cast): 3133 (-OH), 1631 (ketone C=O), and 1467, 1451 (Ar-H) cm^{-1}. ^{1}H NMR (400 MHz, acetone-*d*6) δ: 12.50 (s, 1H, Ar-O*H*), 9.50 (s, 1H, Ar-O*H*), 6.10 (s, 1H, Ar-*H*), 4.50 (m, 1H, -C*H*), 2.60 (m, 4H, -CH_2-), 1.4 (d, 3H, -CH-CH_3, J = 7.0 Hz), and 1.09 (t, 3H, CH_2-CH_3, J = 7.0 Hz). ^{13}C NMR (acetone-d_6, 100.6 MHz) δ: 191.7 (s), 161.5 (s), 154.5 (s), 155.0 (s), 109.6 (s), 104.2 (s), 90.9 (d), 73.5 (d), 45.9 (t), 22.3 (t), 20.3 (q), 13.4 (q); HREIMS, *m/z*: 222.08944 (M$^+$, calcd. for $C_{12}H_{14}O_4$: 222.0892), 207.0668 (100), 165.0192 (50).

(E)-2,4-Acetoxy-3-(2-acetoxyethyl)-6-methoxy-2′-en-butyrophenone (8a)

Acetylation of fraction 4 gave a brown oil (22 mg). Preparative TLC of this material (10% ethyl acetate in methylene chloride) afforded (*E*)-2,4-acetoxy-3-(2-acetoxyethyl)-6-methoxy-2′-en-butyrophenone as a colorless liquid (2 mg): IR ($CHCl_3$, cast): 1771 (C=O ester), 1738 (C=O ester), 1660 (C=O ketone), 1617 (C=C), 968 (-CH=CH-) cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ: 6.64 (s, 1H, Ar-*H*), 6.75 (dq, 1H, J = 16.5 Hz, J' = 7.0 Hz, O=C-CH=C*H*-), 6.34 (dq, 1H, J = 16.5 Hz, J' = 2.0 Hz, -C*H*=CH-CH_3), 4.11 (t, 3H, J = 7.5 Hz, -CH_2-CH_2-OAc), 3.77 (s, 3H, -O-CH_3), 2.71 (t, 2H, J = 7.5 Hz, Ar-CH_2-CH_2-), 2.38 (s, 3H, -O-C=O-CH_3), 2.23 (s, 3H, -O-C=O-CH_3), 2.03 (s, 3H, -O-C=O-CH_3), and 1.92 (dd, 1H, J = 7.0 Hz, J' = 2.0 Hz, =CH-CH_3); ^{13}C NMR ($CHCl_3$, 100.6 MHz) δ: 202.7 (s), 170.9 (s), 169.1 (s), 168.9 (s), 156.3 (s), 151.3 (s), 147.6 (s), 146.9 (d), 132.5 (d), 120.9 (s), 115.9 (s), 104.3 (d), 62.6 (t), 56.0 (q), 23.9 (t), 21.0 (q), 20.9 (q), and 17.2 (q).

Isolation of phomalone (2,4-dihydroxy-3-(2-hydroxyethyl)-6-methoxybutyrophenone) (1)

HPMPLC on fraction 4 (NP-Si60, 10% ethyl acetate in methylene chloride) followed by HPMPLC (RP-18, 30% water in methanol)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12

afforded phomalone, 2,4-dihydroxy-3-(2-hydroxyethyl)-6-methoxybutyrophenone (75 mg): mp 126–127°C; R_f 0.25 (10% ethyl acetate in methylene chloride); IR ($CHCl_3$, cast): 3200 (OH), 1618 (ketone C=O) cm^{-1}; UV (EtOH): 205, 211, and 293 nm; ^1H NMR (400 MHz, acetone-d_6) δ: 14.50 (s, 1H, Ar-O*H*), 6.01 (s, 1H, Ar-*H*), 3.85 (s, 3H, -OCH_3), 3.70 (t, 2H, J = 7.0 Hz, -CH_2-CH_2OH), 2.80 (t, 2H, J = 7.0 Hz, O=C-CH_2-), 2.74 (t, 2H, J = 7.0 Hz, Ar-CH_2-), 1.66 (tq, 2H, $J = J'$ = 7.0 Hz, -CH_2-CH_2-CH_3), and 0.95 (t, 3H, J = 7.0 Hz, -CH_3); ^{13}C NMR (100.6 MHz, acetone-d_6) δ: 206.4 (s), 165.9 (s), 164.3 (s), 162.7 (s), 106.9 (s), 105.6 (s), 92.1 (d), 62.9 (t), 55.9 (q), 46.6 (t), 26.3 (t), 16.9 (t), and 14.2 (q). HREIMS, *m/z*: 254.1154 (M^+, calcd. for $C_{13}H_{18}O_5$: 254.1158), 223.2343 (100, 211.2345 (93), 193.1111 (63).

Derivatives of phomalone

O,O-Diacetylphomalone (2b)

Triethylamine (0.2 mL) and acetic anhydride (0.2 mL) were added to a solution of phomalone (11 mg) in methylene chloride (2 mL). After stirring for 2 h at room temperature the solution was concentrated under reduced pressure and the residue was dissolved in chloroform (3 mL). Prep-TLC (10% ethyl acetate in methylene chloride) gave phomalone diacetate (**2b**) (11 mg) and phomalone triacetate (mp 82–83°C, 3.5 mg). Diacetylphomalone: IR ($CHCl_3$, cast): 2961 (OH), 1760 (ester C=O), 1734 (ester C=O), 1651 (ketone C=O) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 14.05 (s, 1H, Ar-O*H*), 6.15 (s, 1H, Ar-*H*), 4.18 (t, 2H, J = 7.0 Hz, -CH_2-O-), 3.87 (s, 3H, -OCH_3), 3.01 (t, 2H, J = 7.0 Hz, Ar-CH_2-), 2.86 (t, 2H, J = 7.0 Hz, O=C-CH_2), 2.36 (s, 3H, O=C-CH_3), 2.05 (s, 3H, O=C-CH_3), 1.71 (tq, 2H, $J = J'$ = 7.0 Hz, -CH_2-CH_2-CH_3), and 0.99 (t, 3H, J = 7.0 Hz, -CH_2-CH_3); ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 207.2 (s), 166.9 (s), 155.0 (s), 111.1 (s), 109.1 (s), 103.4 (s), 96.3 (s), 90.9 (d), 62.8 (t), 55.7 (q), 46.6 (t), 22.7 (t), 21.0 (q), 20.9 (q), 17.8 (t), 13.9 (q); HREIMS, *m/z*: 338.13607 (M^+, calcd. for $C_{17}H_{22}O_7$: 338.13657), 278.11542 (56), 236.10486 (64), 193.04978 (100).

Triacetylphomalone (2a)

Triethylamine (0.3 mL) and acetic anhydride (0.3 mL) were added to a solution of phomalone (7.8 mg) in methylene chloride (2 mL). After stirring the mixture for 2 h at room temperature, the solution was concentrated under reduced pressure and the residue was dissolved in chloroform (3 mL). Prep-TLC (10% ethyl acetate in methylene chloride) gave triacetylphomalone (10.5 mg); IR ($CHCl_3$, cast): 1772, 1739 (ester -O-C=O), 1699 (ketone C=O) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 6.13 (s, 1H, Ar-*H*), 4.10 (t, 2H, J = 7.0 Hz, -CH_2-CH_2-), 3.82 (s, 3H, -OCH_3), 2.79 (t, 2H, J = 7.0 Hz, Ar-CH_2-), 2.72 (t, 2H, O=C-CH_2-), 2.40 (s, 3H, O=C-CH_3), 2.27 (s, 3H, O=C-CH_3), 2.05 (s, 3H, -O-C=O-CH_3), 1.66 (tq, 2H, $J = J'$ = 7.0 Hz, -CH_2-CH_2-CH_3), and 0.95 (t, 3H, J = 7.0 Hz, -CH_2-CH_3); ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 202.7 (s), 170.9 (s), 169.9 (s), 169.1 (s), 156.3 (s), 151.4 (s), 147.5 (s), 122.6 (s), 116.0 (s), 104.3 (d), 62.7 (t), 56.1 (q), 45.9 (t), 24.2 (t), 20.9 (q), 20.6 (q), 17.3 (t), 13.7 (q). HREIMS, *m/z*: 380.1468 (M^+, calcd. for $C_{19}H_{24}O_8$: 380.1461), 278.1154 (98), 236.1046 (39).

4-Hydroxy-6-methoxy-5-(1′-oxobutyl)benzo[b]dihydrofuran (4) and 4-hydroxy-6-methoxy-7-(1′-oxobutyl)benzo[b]dihydrofuran (5)

p-*Toluenesulfonic acid method*: *p*-Toluenesulfonic acid monohydrate (5.3 mg) was added to a solution of phomalone (7.5 mg) in benzene (5 mL). After stirring at room temperature for 1.5 h, more (10.6 mg) acid was added and a the mixture was refluxed for 4.5 h with continuous removal of water (Dean–Stark). The solvent was then evaporated under pressure and the residue was dissolved in chloroform (3 mL). Prep-TLC (10% ethyl acetate in methylene chloride) gave **4** and **5** in a 2:1 ratio. Compound **4** (2.2 mg); IR ($CHCl_3$, cast): 3250 (OH), 1650 (ketone C=O), 1450, 1497 (Ar-H) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 9.50 (s, 1H, Ar-O*H*), 5.90 (s, 1H, Ar-*H*), 4.5 (t, 2H, J = 7.0 Hz, -O-CH_2-CH_2-), 3.8 (s, 3H, -OCH_3), 3.2 (t, 2H, J = 7.0 Hz, -CH_2-CH_2-Ar), 2.80 (t, 2H, J = 7.0 Hz, O=C-CH_2-), 1.60 (qt, 2H, $J = J'$ = 7.0 Hz, -CH_2-CH_2-CH_3), and 0.98 (t, 3H, J = 7.0 Hz, -O-CH_2-CH_3); HREIMS: *m/z*: 236.1055 (M^+, calcd. for $C_{13}H_{16}O_4$: 236.1062), 193.0501 (100), 149.0241 (30). Compound **5** (1.4 mg); IR ($CHCl_3$, cast): 3250 (OH), 1650 (ketone C=O), 1450, 1497 (Ar-H) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 14.50 (s, 1H, Ar-O*H*), 5.90 (s, 1H, Ar-*H*), 4.5 (t, 2H, J = 7.0 Hz, -O-CH_2-CH_2-), 3.8 (s, 3H, -OCH_3), 3.2 (t, 2H, J = 7.0 Hz, -CH_2-CH_2-Ar), 2.80 (t, 2H, J = 7.0 Hz, O=C-CH_2-), 1.60 (qt, 2H, $J = J'$ = 7.0 Hz, -CH_2-CH_2-CH_3), and 0.98 (t, 3H, J = 7.0 Hz, -O-CH_2-CH_3); ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 206.4 (s), 165.9, (s), 164.3 (s), 162.7 (s), 142.6 (s), 132.9 (s), 92.4 (d), 62.9 (t), 55.9 (q), 46.6 (t), 26.4 (t), 18.9 (t), and 14.2 (q). HREIMS, *m/z*: 236,1055 M^+, calcd. for $C_{13}H_{16}O_4$: 236.1062), 193.0501 (100), 149.0241 (30).

p-*Toluenesulfonyl chloride method*: *p*-Toluenesulfonyl chloride (45 mg) was added to a solution of phomalone (10 mg) in benzene (15 mL). The mixture was refluxed for 4.5 h. The solvent was then evaporated under reduced pressure and the residue was dissolved in chloroform (3 mL). Prep-TLC (10% ethyl acetate in methylene chloride) gave **4** (5 mg) and **5** (2.5 g).

^{13}C-Labeled phomalone

Isolation of ^{13}C-labelled phomalone

Liquid cultures (2 L, 13 days shaking) were prepared as described above. The floating HP-20 ion exchange resin was decanted from the broth. The remaining resin, which adhered to the mycelium, was separated by vacuum filtration through Whatman paper No. 1. The resin and the resin-mycelium mixture were transferred to a sintered glass filter (porosity D, ASTRM 10–20 μm) and extracted with ethyl acetate (1.6 L). The extract was dried over anhydrous sodium sulfate and concentrated under reduced pressure to give a crude extract (548 mg, after the experiment with [1-^{13}C]-sodium acetate). Flash chromatography of this resin extract (10% ethyl acetate in methylene chloride) followed by HPMPLC (NP-Si60, 10% ethyl acetate in methylene chloride) and HPLC (Waters, μBondapak C-18; gradient: 40% water in methanol to 100% methanol) gave ^{13}C-labelled phomalone (6 mg). The same procedure was repeated with [2-^{13}C]- and [1,2-$^{13}C_2$]-sodium acetate. Triacetylphomalone was prepared as described above.

Bioassay method

Chromatography fractions. The sample was sterilized by filtration through a 0.22-μm Nylon membrane. A 200-μL aliquot was applied directly to the well of the multiwell plate (24-well, flat bottom, Falcon 3047) using a micropipette. The solvent was evaporated in a sterile fumehood for 3 h. The inoculum was obtained from the growing edge of a colony of *Phellinus tremulae* in MEA Petri dishes. After 10 days of growth at room temperature, a plug (7 mm diameter) cut from this culture was placed in each well of the multiwell plate. Four replicates of each sample and a solvent control were evaluated in each multiwell plate. This procedure was repeated for each chromatographic fraction. Inhibition in the radial growth of a colony of *P. tremulae* relative to the control constitutes a positive result.

Pure compounds. The sample was sterilized by filtration through a 0.22-μm Nylon membrane. A 0.25-mL aliquot of a standard solution was applied directly to the well of the multiwell plate (6-well, flat bottom, Falcon 3046) using a micropipette. The solvent was evaporated in a sterile fumehood for 3 h. The inoculum was obtained from the growing edge of a colony of *P. tremulae* in MEA Petri dishes. After 10 days of growth at room temperature, a plug (7 mm diameter) cut from this culture was placed in each well of the multiwell plate. Three replicas of each sample and the solvent control were evaluated for each multiwell plate. This procedure was repeated for seven different concentrations: 4×10^{-3}, 2×10^{-3}, 1×10^{-3}, 4×10^{-4}, 2×10^{-4}, 1×10^{-4}, and 4×10^{-5} mol/L. The bioassay was evaluated by the amount of growth of *P. tremulae*, relative to control, in each well. The radial growth was measured 8, 14, and 30 days after inoculation.

Hydration rate constants and equilibrium constants have been obtained for 9-acridinecarboxaldehyde in aqueous solution. Under acidic conditions where the acridine is protonated, signals for the hydrate and free aldehyde forms can be observed as separate species in the ^{1}H NMR spectrum. Integration provides the hydration equilibrium constant K_{h^+} = [hydrate]/[aldehyde] = 2.5. Using an apparent acidity constant obtained from a spectroscopic titration curve, the rate–pH profile was fitted to provide the hydration constant for the equilibration of the neutral acridines, K_H = 0.07. This analysis also provides the acidity constants for the two acridinium ions, the aldehyde with pK = 3.78 and the hydrate with pK = 5.36. A comparison with the 4-pyridinecarboxaldehdye system reveals that the K_{h^+}: K_h ratios for the acridine and pyridine are the same within experimental error, but that the acridine and acridinium aldehydes are 20-fold less hydrated than their pyridine analogs. A comparison with benzaldehydes reveals that, in their reactivities, the two heterocyclic aldehydes behave in a similar manner. Thus, for example, plots of log k_H for the acid-catalyzed dehydration and hydrations versus log K_h for the equilibrium hydration show single correlation lines including the points for the benzaldehydes and heterocyclic aldehydes (but not the aliphatic aldehydes).

ROBERT A. MCCLELLAND, PRATIMA SUKHAI, KAREN M. ENGELL et POUL E. SORENSEN. Can. J. Chem. **72**, 2333 (1994).

On a mesuré les constantes de vitesse d'hydratation et les constantes d'équilibre de l'acridine-9-carboxaldéhyde en solution aqueuse. En milieu acide, alors que l'acridine peut être protonée, les spectres RMN du ^{1}H permettent d'observer séparément les signaux des formes aldéhydiques et hydratées. L'intégration fournit la constante d'équilibre d'hydratation, K_{h^+} = [hydrate]/[aldéhyde] = 2,5. Utilisant une constante d'acidité apparente obtenue à partir d'une courbe de titrage spectroscopique, on a ajusté le profil vitesse–pH pour déduire la constante d'hydratation pour l'équilibre des acridines neutres, K_H = 0,07. Cette analyse fournit aussi les constantes d'acidité des deux ions acridinium; pour l'aldéhyde, le pK = 3,78 alors que, pour l'hydrate, le pK = 5,36. Une comparaison avec le système pyridine-4-carboxaldéhyde révèle que les rapports K_{h^+} : K_h pour l'acridine et la pyridine sont essentiellement les mêmes, aux erreurs expérimentales près, mais que les aldéhydes de l'acridine et de l'acridinium sont 20 fois moins hydratés que leurs analogues de la série pyridinique. Une comparaison avec les benzaldéhydes révèle que, pour leurs réactivités, les deux aldéhydes hétérocycliques se comportent de manières similaires. Ainsi, par exemple, les courbes des log k_H de la déshydratation ou des hydratations acidocatalysées en fonction du log K_h pour l'équilibre d'hydratation présentent des droites de corrélation unique comportant les points des benzaldéhydes et des aldéhydes hétérocycliques (mais pas des aldéhydes aliphatiques).

[Traduit par la rédaction]

The anticonvulsant drug carbamazepine (5*H*-dibenz[*b*,*f*]-azepine-5-carboxamide) is associated with a significant incidence of idiosyncratic reactions including agranulocytosis. It has been found that many of the drugs that are associated with agranulocytosis are metabolized to reactive species by activated neutrophils (1). The major neutrophil enzyme involved in such oxidations is myeloperoxidase. This enzyme has, as its usual substrate, chloride, which undergoes a two-electron oxidation producing either hypochlorite or an activated chlorine bound to the enzyme that mimics hypochlorite in its behavior. Carbamazepine is indeed oxidized by neutrophils, resulting in covalent binding of radiolabelled drug to the neutrophil (2). The major metabolite in both these and model studies involving hypochlorite is 9-acridinecarboxaldehyde (3). This product can be envisaged to arise from electrophilic chlorination of the C_1=C_2 double bond, followed by ring contraction and replacement of chlorine with oxygen. This aldehyde provides an electrophilic site for reaction with biological nucleophiles, and experiments with labelled material result in a 100-fold greater binding to cells (2).

There were indications that this aldehyde, like its analog 4-pyridinecarboxaldehyde (4), is significantly hydrated in aqueous solution. As part of our studies into the chemical reactivity of 9-acridinecarboxaldehyde, we have therefore carried out a detailed examination of the hydration equilibrium.

Experimental section

9-Acridinecarboxaldehyde

(The following procedure offers a considerable improvement over a literature method, which involves reaction of *m*-chloroperbenzoic acid with iminostilbene, and produces the aldehyde in only a 20–30% yield after chromatography (5).) Carbamazepine (2.1 g, 8.9 mmol) was added to 5 L of water and the mixture was heated to about 80°C to bring the solid into solution. To this was added NaCl (100 g), Na_2HPO_4 (4.5 g, 31.7 mmol), and $NaH_2PO_4 \cdot H_2O$ (51 g, 370 mmol), to form a solution buffered at pH 8. The reaction flask was then allowed to cool. When the temperature reached ~50°C (below which the carbamazepine precipitates), 25 mL of 0.60 *M* sodium hypochlorite in water was added all at once. This corresponds to about 1.5 equivalents of hypochlorite per equivalent of carbamazepine, a ratio which appears to be optimal. The reaction flask was wrapped in aluminum foil (to prevent photochemical degradation of the product), and the mixture stirred at 5–10°C overnight. Filtration provided a reasonably pure brown solid. One recrystallization from CCl_4 provided 1.1 g (60%) of pure material: mp 135–136°C (lit. (5) mp 138–140°C).

^{1}H NMR (200 MHz, DMSO-d_6) δ: 7.79 (t), 7.94 (t), 8.25 (d), 8.7 (d), 11.50 (s).

UV–visible spectra were recorded with a Varian 2200 spectrophotometer, by injecting 10 μL of a stock solution of the aldehyde (0.1 M) in acetonitrile into a 10-mL volumetric flask and filling to the mark with the appropriate solution.

Kinetic experiments were carried out with a Hi-Tech stopped-flow apparatus. In one set of experiments, a solution of the aldehyde (0.0002 M) in 0.002 M HCl was placed in one syringe of the apparatus, and this was mixed with acetate (pH 4.4–5.5), phosphate (pH 5.5–8.0), and borate (pH 8–9) buffers containing 0.002 M NaOH. In a second set of experiments, the aldehyde (0.0001 M) was dissolved in a 1:1 Na_2HPO_4:NaH_2PO_4 solution (0.001 M) and this was mixed with HCl solutions and acetate buffers (pH 3.6–4.3). The pH of the mixed solutions was measured. Sodium chloride was employed to maintain an ionic strength after mixing of 0.1 M. The stopped-flow experiments were carried out at 25°C and 355 nm. The absorbance–time data were digitized, and first-order rate constants were obtained by nonlinear least-squares fitting to the exponential equation

$$\text{absorbance} = A_0 \exp(-k_{obs}t) + \text{base}$$

Replicate kinetic runs agreed to ±2%.

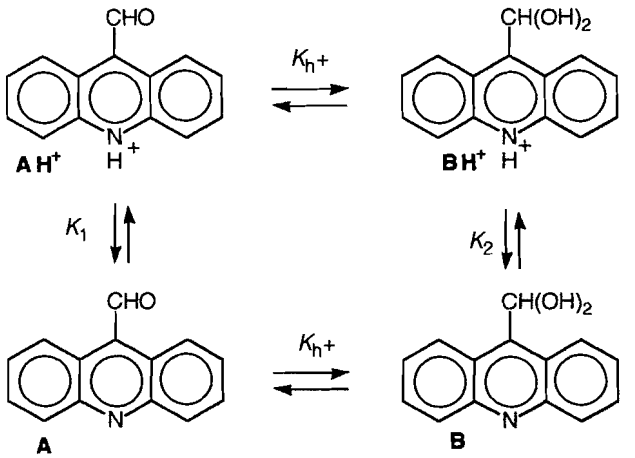
Results and discussion

Scheme 1 summarizes the equilibria that can occur with 9-acridinecarboxaldehyde in aqueous solutions, ignoring strongly basic solutions where ionization of the OH group of the hydrate can also take place.

In acids, protonation of the acridine makes the substrate sufficiently soluble that NMR spectra can be recorded in highly aqueous solutions. With conditions of 0.005 M acridinecarboxaldehyde in D_2O containing 0.02 M DCl plus 10% CD_3CN, a 400 MHz ^{1}H NMR spectrum showed the presence of both the free aldehyde and hydrate forms **AH$^+$** and **BH$^+$**. The most characteristic signals were two singlets, one at 11.4 ppm for the CHO proton and one at 7.5 ppm for the corresponding proton in the hydrate. The ratio of these two was 1:2.5. This was unchanged within experimental error in similar solutions with 20 and 30% CD_3CN. As will be apparent from the analysis of the protonation equilibria, the acid concentration employed in these experiments is sufficient to ensure complete protonation of both the aldehyde and hydrate forms. In consequence, this analysis measures the hydration equilibrium constant K_{h^+}, the value of which is 2.5. This ignores the solvent isotope effect, which would be small and probably not outside the experimental error associated with NMR integration.

A corresponding experiment to determine K_h could not be carried out since solubility problems prevented the recording of NMR spectra in solutions containing enough water for a meaningful result. As illustrated in Fig. 1 (*a*), the UV spectrum of the aldehyde in neutral aqueous solution is similar to one recorded in acetonitrile, where there can be no hydrate. Moreover, both spectra are different from that of acridine, whose chromophore would serve as a model for the hydrate. From these observations we conclude that the equilibrium under neutral conditions favors the free aldehyde, i.e., that K_h is significantly smaller than unity. It can also be noted that, in acids, the spectra of the aldehyde and parent acridine are more similar (Fig. 1(*b*)), consistent with the NMR result showing that the hydrate is the major species under these conditions.

We also determined a spectroscopic acidity constant from the variation in the OD at 355 nm in a series of solutions with pH ranging from 1 to 10 and containing the same concentration of aldehyde (1.0×10^{-4} M). This produced a standard titration



SCHEME 1

curve that was fitted to the appropriate equation to provide an acidity constant of 4.30 ± 0.05. In terms of Scheme 1, this is an apparent acidity constant, as given by the following equation.

$$[1] \qquad K_a(\text{app}) = \frac{K_1 + K_2K_{h^+}}{1 + K_{h^+}}$$

Rate constants for the interconversion of the aldehyde and hydrate forms were obtained in a manner similar to that employed previously for pyridinecarboxaldehydes (4), by taking advantage of the different equilibrium positions in acidic and neutral solutions. Thus, a jump from low to high pH, or vice versa, results initially in a solution where the forms are not at equilibrium. The kinetics of the approach to equilibrium can then be monitored through changes in the UV–visible spectrum. For our experiments we employed a stopped-flow apparatus to carry out the pH jumps, with detection at 355 nm. Experiments were carried out in the two directions, with substrate in dilute acid (0.002 M HCl) being mixed to give solutions with a final pH of 4.4 or greater, and substrate in dilute (0.001 M) pH 7 phosphate buffer being mixed to give solutions with a pH of 4.2 or smaller. Measurements in more acidic solutions (pH <2.4) involved HCl; in all other cases buffers were employed. In these cases catalysis by the buffer was observed, and rate constants were extrapolated to zero buffer concentration. Table 1 lists the rate constants at zero buffer concentration as a function of pH.

In terms of the kinetic analysis for an approach to an equilibrium,

$$[2] \qquad k_{obs} = k_f\left(\frac{[A]}{[A]+[AH^+]}\right) + k_{f^+}\left(\frac{[AH^+]}{[A]+[AH^+]}\right) + k_r\left(\frac{[B]}{[B]+[BH^+]}\right) + k_{r^+}\left(\frac{[BH^+]}{[B]+[BH^+]}\right)$$

where k_f and k_r are the first-order rate constants at a given pH for the reactions of the neutral species in the forward and reverse direction, k_{f^+} and k_{r^+} refer to the forward and reverse processes involving the protonated species, and the terms in parentheses are the fraction of that particular species in the appropriate acid–base equilibrium. Recognizing that $K_h = k_f/k_r$, $K_{h^+} = k_{f^+}/k_{r^+}$, and $K_hK_1 = K_{h^+}K_2$, this can be rewritten as

$$[3] \qquad k_{obs} = (k_rK_2 + k_{r^+}[H^+])\left(\frac{K_{h^+}}{[H^+]+K_1} + \frac{1}{[H^+]+K_2}\right)$$

5.26	0.0980	8.95	8.00
5.90	0.0645	9.15	12.3

Each dehydration can occur with H^+, OH^-, and no catalysis (or water catalysis),

$$[4] \qquad k_r = k_H[H^+] + k_0 + k_{OH}[OH^-]$$

$$[5] \qquad k_{r^+} = k_{H^+}[H^+] + k_{0^+} + k_{OH^+}[OH^-]$$

resulting in the following expression for k_{obs}:

$$[6] \qquad k_{obs} = \left\{k_{H^+}[H^+]^2 + (k_H K_2 + k_{0^+})[H^+] + (k_0 K_2 + k_{OH^+} K_w) + \left(\frac{k_{OH} K_2 K_w}{[H^+]}\right)\right\} \times \left(\frac{K_{h^+}}{[H^+] + K_1} + \frac{1}{[H^+] + K_2}\right)$$

It can be noted that the reactions involving H^+ catalysis on the neutral equilibration and water catalysis on the cationic equilibration are kinetically equivalent and have the same rate–pH dependence, as do the reactions involving water catalysis on the neutral and hydroxide ion catalysis on the cationic equilibration.

Under strongly acidic solutions, $[H^+] > 0.01$, only the terms in $[H^+]^2$ and $[H^+]$ should be important, and $[H^+]$ should be greater than K_1, K_2, so that eq. [6] simplifies to

$$[7] \qquad k_{obs} = k_{H^+}(K_{h^+} + 1)[H^+] + (k_H K_2 + k_{0^+})(K_{h^+} + 1)$$

This predicts a linear relation between k_{obs} and $[H^+]$, and this is observed. Least-squares fitting (for data in solutions with pH <2) gives a slope $= k_{H^+}(K_{h^+} + 1) = (7.2 \pm 0.4)$ M^{-1} s^{-1}, and an intercept $= (k_H K_2 + k_{0^+})(K_{h^+} + 1) = (0.39 \pm 0.02)$ s^{-1}. From the known value of K_{h^+}, this provides values for k_{H^+} of 2.05 M^{-1} s^{-1} and $(k_H K_2 + k_{0^+})$ of 0.111 s^{-1}.

For solutions with pH >7, the last two terms in the first part of the rate law are expected to be important and $[H^+] < K_1$, K_2, so that

$$[8] \qquad k_{obs} = (k_0 K_2 + k_{OH^+} K_w)\left(\frac{K_{h^+}}{K_1} + \frac{1}{K_2}\right) + k_{OH}(K_h + 1)[OH^-]$$

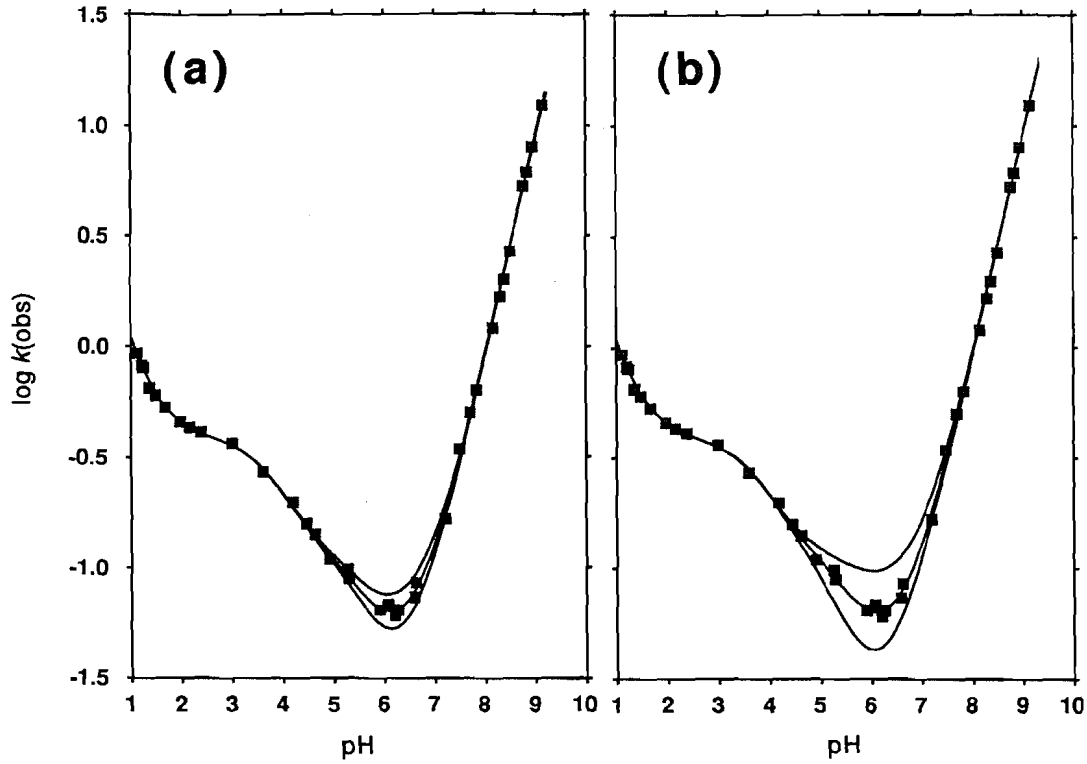

FIG. 2. Rate–pH profile for the equilibrium of the aldehyde and hydrate forms of 9-acridinecarboxaldehyde. The points are experimental, the curves have been calculated according to eq. [6]. The middle curve in each figure represents the best fit, obtained as described in the text, with $k_{H^+} = 2.05$, $(k_H K_2 + k_{0^+}) = 0.111$, $(k_0 K_2 + k_{OH^+} K_w) = 1.71 \times 10^{-7}$, $k_{OH}(K_h + 1) = 8.8 \times 10^5$, $K_{h^+} = 2.5$, $pK_1 = 3.784$, $pK_2 = 5.357$, and $K_h = 0.067$. The other two curves in Fig. 2(*a*) illustrate the result of different values of $(k_0 K_2 + k_{OH^+} K_w)$, 2.3×10^{-7} (top curve) and 1.2×10^{-7} (bottom). In Fig. 2(*b*), pK_1 is varied: $pK_1 = 3.77$, $pK_2 = 5.65$, $K_h = 0.033$ (top), and $pK_1 = 3.81$, $pK_2 = 5.09$, $K_h = 0.133$ (bottom).

This predicts a linear relation in hydroxide ion concentration, and this is also observed. The slope, $k_{OH}(K_h + 1)$, is equal to $(8.8 \pm 0.7) \times 10^5$. The intercept, for data with pH >7, is not statistically relevant.

This analysis of the regions at the pH extremes leaves one rate constant term in eq. [6] unknown, $(k_0 K_2 + k_{OH^+} K_w)$. With respect to the equilibrium constants, there is also only one independent variable. We arbitrarily chose this as K_1, and, with K_{h^+} known and K_a(app) known, calculate the remaining equilibrium constants as follows.

$$[9] \qquad K_2 = \frac{K_a(\text{app})(1 + K_{h^+}) - K_1}{K_{h^+}}$$

$$[10] \qquad K_h = \frac{K_2 K_{h^+}}{K_1}$$

Employing a spread-sheet program, values of the two unknowns were then varied, until a minimum in $[k_{obs}(\text{experimental}) - k_{obs}(\text{calculated eq. [6]})]^2$ was reached. The best fit had $(k_0 K_2 + k_{OH^+} K_w) = 1.71 \times 10^{-7}$, $pK_1 = 3.784$ (and, from this, $pK_2 = 5.357$ and $K_h = 0.067$). The experimental and calculated rate–pH profiles are compared in Fig. 2. As also illustrated, the fitting was sensitive to the value of pK_1, but less sensitive to $(k_0 K_2 + K_{OH^+} K_w)$.

With these various constants now available, the question of the relative importance of the kinetically equivalent mechanisms can be addressed. The quantity $(k_H K_2 + k_{0^+})$, 0.111 s^{-1}, represents a pH-independent rate constant for the equilibration under acidic conditions where both acid–base equilibriums are shifted predominantly to the conjugate acid side ($[H^+] > K_1$, K_2). For $k_H K_2$ to make a 10% contribution to this rate constant, $(k_H K_2 = 0.011)$, k_H is required to be 2.5×10^3 M^{-1} s^{-1}. This is three orders of magnitude larger than k_{H^+}, which is determined unambiguously. This, however, is not the best comparison since the H^+-catalyzed dehydration of the neutral species should be faster than that of the protonated one. As will be domonstrated later, the hydrates of *p*-chloro- or *m*-chlorobenzaldehyde offer better comparisons, since these are not only neutral, but have hydration equilibrium constants similar to the neutral acridine. These benzaldehyde hydrates have $k_H = 1.23 \times 10^3$ M^{-1} s^{-1} (4-Cl) and 4.9×10^2 M^{-1} s^{-1} (3-Cl), from which we conclude that k_H for the neutral acridine is unlikely to be greater than 10^3 M^{-1} s^{-1}. This corresponds to at most a 5% contribution of $k_H K_2$ in the $(k_H K_2 + k_{0^+})$ term. Thus the predominant reaction of this kinetically equivalent pair is the pH-independent equilibration of the protonated species, and $k_{0^+} \sim 0.11$ s^{-1}.

The situation with respect to the other pair of kinetically equivalent reactions is less clear. With $(k_0 K_2 + k_{OH^+} K_w)$ deter-

[a]Rate constants in the hydration direction can be calculated from the relation $k_{hyd} = k_{deh} \times K_H$.
[b]Rate constant could not be obtained because of dominance of a second kinetically equivalent mechanism.
[c]Kinetically equivalent mechanisms. The rate constant k_0 is 0.04 s^{-1} if $k_{OH} < 1 \times 10^6$ M^{-1} s^{-1} so that the k_{OH} process makes less than a 10% contribution. If $k_{OH} = 8 \times 10^6$ s^{-1} (50% contribution), $k_0 = 0.02$ s^{-1}.
[d]Reference 4.
[e]Reference 6.
[f]Reference 7.

mined to be 1.71×10^{-7}, a 10% contribution from $k_{OH^+}K_w$ requires k_{OH^+} to be 1.7×10^6 M^{-1} s^{-1}. This is only twofold larger than k_{OH}, the rate constant for the OH^--catalyzed dehydration of the neutral hydrate. This difference is in the correct direction since, at least with benzaldehyde hydrates, electron-withdrawing substituents increase k_{OH}, with $\rho = +0.5$ (6). On the other hand, a 100% contribution from $k_{OH^+}K_w$ requires $k_{OH^+} = 1.7 \times 10^7$ M^{-1} s^{-1}, and this seems too large. This latter situation would also mean that k_0 would be less than 0.01 s^{-1}, which, in comparison with other hydrates, seems unlikely (see later). Our conclusion is that both reactions likely contribute to the $(k_0K_2 + k_{OH^+}K_w)$ term, and we are unable to unambiguously assign definite values to either k_0 or k_{OH^+}.

It is interesting that with 4-pyridinecarboxaldehyde the $k_{OH^+}K_w$ term is relatively unimportant. This had been assumed in the original kinetic analysis with this system (4), and our analysis of the data shows that this is reasonable. With this aldehyde, $(k_0K_2 + k_{OH^+}K_w)$ is 4.2×10^7, so that for $k_{OH^+}K_w$ to make a 10% contribution, k_{OH^+} must be 4.2×10^6 M^{-1} s^{-1}. This value is 20-fold larger than the value of k_{OH} for the neutral species, and thus it is likely an upper limit. There are two differences that result in the decreased importance of the OH^--catalyzed reaction of the protonated form. The first is that hydroxide ion catalysis seems to be less efficient in the pyridine system. The second is that the pyridinium ions are more acidic, so that under conditions where the hydroxide ion catalyzed processes become important, there is a lower concentration of the protonated pyridine.

Equilibrium constants for the 9-acridinecarboxaldehyde system are given in Table 2, along with those for the analog 4-pyridinecarboxaldehyde. Both aldehydes show significantly more hydration in their protonated forms, with $K_{h^+}/K_h = 37$ (acridine) and 35 (pyridine), numbers that are not statistically different. In each case the acridinealdehydes are 20-fold less hydrated. This is likely a consequence of steric crowding in the hydrate form of this system, associated with interactions of the 9-substituent and the hydrogen atoms at C1 and C8. The similarities in the K_{h^+}/K_h ratio provide confidence in the derivations employed to obtain these numbers. It can be noted that in the pyridine case, the measurable hydration constant was K_h, with K_{h^+} being determined through the analysis of the rate–pH profile. Further consistency is also seen in the 0.6 pK differences between the analogous pyridinium and acridinium

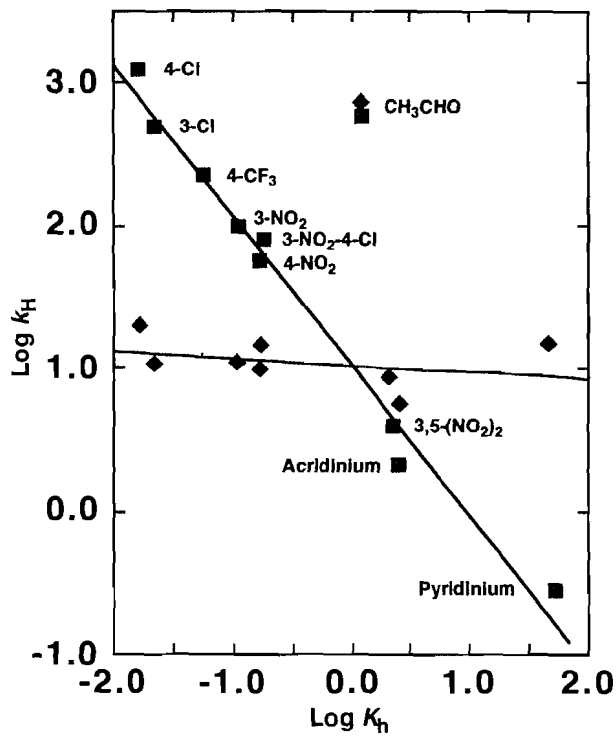

FIG. 3. Correlation of log k_H and log K_h for hydration of aromatic aldehydes. (■) $-k_H$ in dehydration direction. (◆) $-k_H$ in hydration direction. The identity of the substrates for the latter points is the same as that of the vertically related squares. Data for benzaldehydes from ref. 6, for 4-pyridiniumcarboxaldehyde from ref. 4, and for acetaldehyde from ref. 9. Slopes of the lines are −1.04 for the dehydration (correlation coefficient 0.989) and −0.04 for the hydration.

ions, since this is typical of differences for such a comparison (8).

Table 3 summarizes rate constants for the dehydration of the hydrates of the 9-acridine and 4-pyridinecarboxaldehydes, along with two representative benzaldehydes. The conclusion from these data is that the heterocyclic aldehydes behave in a manner similar to the benzaldehydes. Thus the values for k_{OH} for the dehydration all lie in the 10^5–10^6 M^{-1} s^{-1} range while

the k_0 values range from 0.02–0.1 s^{-1}. As shown in Fig. 3, for the acid-catalyzed equilibration, the heterocyclic aldehydes fit rate–equilibrium correlations for the benzaldehyde system. That is, despite their positive charge, the acridinium and pyridinium points in the log k_H–log K_h correlation fall on the same line as the benzaldehydes. Interestingly, changes in the hydration equilibrium constant have by far a larger effect on the dehydration rate constant for H^+ catalysis. It also noteworthy that the points for aliphatic aldehydes do not lie on the same line, as illustrated in Fig. 3 for acetaldehyde.

Refluxing $NbCl_5$ and excess 7-azaindole (Haza) in benzene yielded a solid mixture containing $NbCl_5$(Haza), $NbCl_4(Haza)_2$, the azaindolium ion $(H_2aza)^+$, and the azaindolyl-azaindolium ion $(H_2aza\text{-}aza)^+$. The neutral (Haza-aza) molecule was obtained from the hydrolysed mixture and shown by X-ray diffraction (monoclinic, $P2_1/c$, a = 10.025, b = 13.758, c = 8.416 Å, β = 102.89°, Z = 4, R = 0.035) to result from the coupling of two azaindole units via N7—C6′. This compound was the only oxidation product detected, but concurrent formation of other niobium- and (or) azaindole-containing products keeps the yield of Haza-aza low. Dark green crystals of $[Cu_4O(aza\text{-}aza)_4]Cl_2\cdot 6.5H_2O$ were obtained from (Haza-aza) and $CuCl_2$ in wet methanol. The crystal structure (monoclinic, $C2/c$, a = 17.704, b = 25.240, c = 14.457 Å, β = 116.14°, Z = 4, R = 0.051) shows the presence of a tetranuclear dicationic cluster consisting of a μ_4-oxide ion surrounded by a tetrahedron of Cu(II) atoms. A distorted square-planar coordination is achieved about each copper atom by $(aza\text{-}aza)^-$ ligands each bridging two copper atoms and providing a third nitrogen donor to one of them. For each such cation, the unit cell also includes two chloride ions and 6.5 disordered lattice water molecules. The ^1H NMR and infrared spectroscopy data are discussed.

JACQUES POITRAS et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **72**, 2339 (1994).

Le reflux de $NbCl_5$ et de 7-azaindole (Haza) en excès dans le benzène a conduit à un mélange solide contenant $NbCl_5$(Haza), $NbCl_4(Haza)_2$, l'ion azaindolium $(H_2aza)^+$ et l'ion azaindolyl-azaindolium $(H_2aza\text{-}aza)^+$. Le composé neutre (Haza-aza) a été obtenu à partir du mélange hydrolysé et la diffraction des rayons X (monoclinique, $P2_1/c$, a = 10,025, b = 13,758, c = 8,416 Å, β = 102,89°, Z = 4, R = 0,035) a montré qu'il comporte deux motifs azaindole couplés par N7—C6′. Ce composé est le seul produit d'oxydation décelé, mais la formation concurrente d'autres produits contenant du niobium et (ou) de l'azaindole contribue à garder le rendement en Haza-aza faible. Des cristaux vert foncé de $[Cu_4O(aza\text{-}aza)_4]Cl_2\cdot 6{,}5H_2O$ ont été obtenus par addition de (Haza-aza) à $CuCl_2$ dans le méthanol humide. La structure cristalline (monoclinique, $C2/c$, a = 17,704, b = 25,240, c = 14,457 Å, β = 116,14°, Z = 4, R = 0,051) a révélé la présence d'un agrégat tétranucléaire dicationique contenant un ion μ_4-oxyde entouré d'un tétraèdre d'atomes de Cu(II). Une coordination plane carrée déformée autour de chaque atome de cuivre est complétée au moyen de ligands $(aza\text{-}aza)^-$ qui pontent deux atomes de cuivre et fournissent un troisième azote à l'un d'entre eux. Pour chaque cation complexe, la maille élémentaire renferme en outre deux ions de chlorure et 6,5 molécules d'eau désordonnées non liées au métal. Les données des spectroscopies RMN ^1H et infrarouge sont aussi discutées.

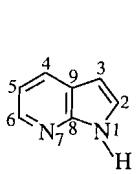
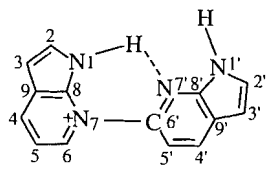
Introduction

In a previous paper (1), we reported on the reactions of niobium and tantalum pentachlorides with 7-azaindole (Haza, structure **I**).[2] Although this ligand can act as a binucleating agent (2–4), the complexes obtained were monomeric and contained unidentate azaindole in the non-deprotonated N7-coordinated form also found for other metals (5–11). With niobium, besides the expected $NbCl_5$(Haza) adduct, the reduced $NbCl_4(Haza)_2$ complex formed, whereas an oxidized species, the unusual azaindolyl-azaindolium ion $(H_2aza\text{-}aza)^+$ (structure **II**),[3] was observed as the counterion in the crystal structures of the $[NbOCl_5]^{2-}$ and $[NbOCl_4(Haza)]^-$ salts. Reduction of $NbCl_5$ to the Nb(IV) state was reported to occur under relatively mild conditions (12), but the oxidation products are usually unknown. The only exception is the NbX_5–pyridine systems (X = Cl, Br) studied by McCarley et al. (13), where oxidation has been shown to lead to the 4-pyridyl-pyridinium cation.



I



II

The present work was undertaken to better understand the redox process and determine whether $(H_2aza\text{-}aza)^+$ is the only oxidation product formed in the $NbCl_5$–Haza system. On the other hand, this coupled species is a promising ligand and its coordinating ability was tested with $CuCl_2$. In a previous work (9), this salt had been found to react well with azaindole and to generate unusual structural patterns. Furthermore, Cu(II) is known to form di- and polynuclear assemblies where the Cu–Cu separations are consistent with the anticipated "bite" of the donor atoms in Haza-aza. Crystallographic work on the material so obtained revealed tridentate coordination of the $(aza\text{-}aza)^-$ ion and provided the first crystal structure on a halogen-free μ_4-OCu_4 cluster.

Experimental

Reactants and techniques

Anhydrous $CuCl_2$ (K & K), $NbCl_5$ (Aldrich, stored in glove box), and 7-azaindole (Aldrich) were used as received. The reactions involving $NbCl_5$ were carried out in standard Schlenk glassware under dry argon. Benzene was dried by distillation over Na and vigorously outgassed immediately before use. The remaining reactions were run in open air in aqueous solutions or in reagent grade solvents.

Samples of $(H_2aza\text{-}aza)_2[NbOCl_5]$ for quantitative analysis or physical measurements were prepared in the glove box. For analysis, they were hydrolysed with 1 M NH_4OH and the mixture was acidified to pH 1 with 1.5 M HNO_3. Chlorine was then determined as AgCl by potentiometric titration with $AgNO_3$. For Nb analysis, the hydrolysed mixture was heated to dryness on a hot plate, then heated in an oven at 1000°C for 24 h (14, 15), and weighed as Nb_2O_5.

The IR spectra (4000–220 cm^{-1}) were recorded with a Perkin–Elmer 783 spectrophotometer on KBr pellets. ^{1}H NMR spectra were taken in $(CD_3)_2SO$ (CIL) with a Varian VXR-300 spectrometer. They were referenced to the residual solvent signal (δ = 2.50 ppm) and converted to the TMS scale.

Preparative work

$(H_2aza\text{-}aza)_2[NbOCl_5]$

This salt precipitated from acetonitrile when this solvent (i.e., acetonitrile) was used to wash the solid produced by refluxing a 2.4:1 Haza:$NbCl_5$ mixture in benzene, as described earlier (1). Scaling up the reaction gave larger samples, which were characterized by elemental analysis, and infrared and NMR spectroscopies. Anal. calcd. for $NbOCl_5C_{28}H_{22}N_8$: Nb 12.3, Cl 23.4; found: Nb 12.1, Cl 22.9. The IR spectrum was identical with the one obtained with the homogeneous crystalline sample used for X-ray work.

When the same reaction was run with a 2:1 Haza:$NbCl_5$ mixture without heating, the colourless crystals precipitated from acetonitrile were much more moisture sensitive than the material originally isolated. By X-ray diffraction work, the composition was determined to be the same, although the unit cell was different (triclinic, $P\bar{1}$, a = 7.705, b = 9.960, c = 10.729 Å, α = 110.93°, β = 96.67°, γ = 104.69°). The structure of this second polymorph will be described elsewhere.[4]

(Haza-aza)

Benzene (35 mL) was added to a mixture of 1.98 g (7.33 mmol) of $NbCl_5$ and 3.02 g (25.6 mmol) of azaindole both weighed in a dry box. The brown suspension was refluxed for 78 h. The resulting orange-brown precipitate was filtered from the colourless solution and dried in vacuo. At this point, this homogeneous solid contained $NbCl_5$(Haza), $NbCl_4(Haza)_2$, $(H_2aza)^+$, and $(H_2aza\text{-}aza)^+$ (see below). This mixture was suspended in 200 mL of 1 M HCl for 24 h, filtered to removed the precipitated Nb_2O_5, and treated with concentrated NaOH to raise the pH to 10. The emulsion was extracted with four 100-mL portions of CCl_4. On each extraction, a yellow precipitate formed at the phase interface and was removed by filtration. The combined solid fractions were washed with 20 mL CCl_4, dried under vacuum, and identified as neutral (Haza-aza). Yield: 0.34 g. This compound was absent from the CCl_4 solution, which contained only Haza. Yellow crystals of (Haza-aza) were obtained by recrystallization in ethanol and the structure was determined by X-ray diffraction (see below). This reaction was rerun several times with similar yields.

The compound can be obtained as the hydrochloride by adding 1 drop of concentrated HCl to (Haza-aza) (0.03 g) suspended in 20 mL of water. The resulting solution is evaporated to dryness, yielding a light yellow precipitate of $(H_2aza\text{-}aza)Cl$.

$[Cu_4O(aza\text{-}aza)_4]Cl_2 \cdot 6.5H_2O$

A solution of (Haza-aza) (0.198 g; 0.85 mmol) in methanol (25 mL) was added to a solution of $CuCl_2$ (0.064 g; 0.48 mmol) dissolved in wet methanol (10 mL). A small amount of an unidentified light green precipitate formed immediately and was filtered. The clear green solution darkened and dark green crystals (0.035 g) appeared. The same crystals were obtained when the same reaction was run on a smaller scale to obtain larger specimens for the X-ray diffraction study described below.

Crystallographic measurements

The crystallographic work on both compounds was carried out on an Enraf–Nonius CAD-4 diffractometer. For (Haza-aza), monoclinic Laue symmetry and systematic absence ($h0l$, $l \neq 2n$; $0k0$, $k \neq 2n$) uniquely defined $P2_1/c$ as the space group. For $[Cu_4O(aza\text{-}aza)_4]Cl_2 \cdot 6.5H_2O$, the Niggli matrix indicated a C-centred monoclinic cell, which was checked with axial photographs. The systematic absences (hkl, $h + k \neq 2n$; $h0l$, $l \neq 2n$) were consistent with space groups $C2/c$ and Cc. The structure was solved and refined in the centric $C2/c$ space group.

Crystal data are given in Table 1. The intensities were measured as described earlier (16). The raw data were corrected for the effects of Lorentz and polarization for both compounds and for absorption (Gaussian integration) in the case of $[Cu_4O(aza\text{-}aza)_4]Cl_2 \cdot 6.5H_2O$.

For both structures, full-matrix least-squares procedures were used to refine the non-hydrogen atoms anisotropically. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with individual weights w based on counting statistics. The scattering curves were from standard sources (17, 18). The anomalous dispersion terms of Cu and Cl were taken from Cromer (19). The calculations were done with NRCVAX (20), SHELX-76 (21), SHELX-86 (22), and local utility programs (23).

Structure resolution and refinement of (Haza-aza)

The structure was solved by the direct methods of SHELX-76 (21). Clear features for 15 non-hydrogen atoms were visible in the E-map. The remaining atoms, including hydrogens, were found from structure factor calculations and ΔF syntheses. All hydrogen atoms were refined isotropically. Residual electron densities in the final ΔF map were between +0.12 and −0.16 e Å^{-3}.

Structure resolution and refinement of $[Cu_4O(aza\text{-}aza)_4]Cl_2 \cdot 6.5H_2O$

The two independent Cu atoms were located by the direct method of SHELX-86 (22). The remaining non-hydrogen atoms, except those of water molecules, were located from subsequent ΔF maps. After refining this model ($R = 0.101$), the ΔF map showed seven residuals (1.4–3.4 e Å^{-3}) between the Cl^- ions. On the basis of separations and heights, it was concluded that these site were partially occupied by disordered uncoordinated water molecules. These water positions were initially assigned occupancies between 0.2 and 1.0, proportional to peak heights. A common isotropic temperature factor was defined for all uncoordinated atoms, namely Cl(1), Cl(2), and water positions O(2)–O(8). This temperature factor was allowed to refine, together with individual occupancies and coordinates. Three chains of two or three water molecules joining two Cl^- ions could be assembled.

(*a*) Cl(2)]-O(2)-O-5-O(2)-[Cl(2), always present, O(5) disordered over two symmetry equivalent sites;

(*b*) Cl(2)]-O(2)-O(3)-O(4)-[Cl(1), not disordered, but present only half of the time;

(*c*) Cl(2)]-O(6)-O(7)-O(8)-[Cl(1), present half of the time and disordered over two orientations. The following idealized occupancy factors, obtained by averaging and normalizing the refined values, were used for the rest of the refinement: O(2) = 1.00; O(3), O(4), O(5) = 0.50; O(6), O(7), O(8) = 0.25. Except for O(3)–O(8), which were refined isotropically, all non-hydrogen atoms were refined anisotropically. The hydrogen atoms in the complex were fixed at idealized positions and recalculated after each cycle. At a late stage, their isotropic temperature factors were refined for two cycles and fixed for the final cycles. Those of water molecules were not located. The general background in the final ΔF map was below ±0.35 e Å^{-3}, except for a few peaks in the range ±|0.5–0.6| eÅ^{-3} near the water molecules and a 0.7 e Å^{-3} residual near Cu(1).

The refined coordinates for the two structures are listed in Tables 2 and 3, respectively.[5]

Results and discussion

$NbCl_5$–azaindole reaction

$NbCl_5$ and excess Haza in refluxing benzene have been shown to give a red-brown insoluble mixture in which $NbCl_5$(Haza), $NbCl_4$(Haza)$_2$, and $(H_2aza)^+$ could be identified (1). When the mixture was washed with acetonitrile, two compounds eventually crystallized from this solvent and they were shown by X-ray diffraction to contain the $(H_2aza\text{-}aza)^+$ cation, thereby identifying this species as an oxidation product. However, with the very small samples available, it could not be established whether this N7—C6′ coupled molecule was the only oxidation product.

The same reaction was first repeated several times on a larger scale and, from the aged filtrates, sizable crystalline samples of the $(H_2aza\text{-}aza)_2[NbOCl_5]$ salt were isolated. A single crystal from each batch was mounted on the diffractometer for unit cell determination and it was generally found to be identical with those described earlier (1). However, when a 2:1 Haza:$NbCl_5$ ratio was reacted without heating, more moisture-sensitive crystals with a different unit cell were obtained. These new crystals were found to correspond to a second polymorph, containing the same $(H_2aza\text{-}aza)^+$ and $[NbOCl_5]^{2-}$ ions differently

[5]The supplementary material includes tables of refined temperature factors, hydrogen coordinates, least-squares plane calculations for both structures, distances and angles for the ligands and the hydrogen bonds in the $[Cu_4O(aza\text{-}aza)_4]^{2+}$ ion, stereoview of packing for Haza-aza, and infrared data. Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen coordinates and distances and angles for the $[Cu_4O(aza\text{-}aza)_4]^{2+}$ ion have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

packed in the cell.[4] Both polymorphs showed the same IR and ^1H NMR spectra, to be discussed below.

In a second step, the raw reaction product was examined for other azaindole-derived products. To this end, after refluxing the $NbCl_5$–azaindole mixture, the solvent was completely removed under vacuum. The solid phase was stirred in dilute aqueous HCl in open air, whereupon all niobium species were quantitatively oxidized and (or) hydrolysed to Nb_2O_5. The insoluble oxide precipitate, which contained no organic matter, was removed by filtration, whereas azaindole and any derived compounds remained as protonated cations in the aqueous phase. Evaporation of this water solution to dryness led to a light yellow solid, whose ^1H NMR spectrum in $(CD_3)_2SO$ showed signals for only two compounds: the strongest set originated from the $(H_2aza)^+$ cation, whereas the remaining peaks were those observed above for the $(H_2aza\text{-}aza)^+$ ion. It was then concluded that the N7—C6′ coupled species is the only oxidation product formed.

Finally, by raising the pH of the above aqueous phase to 10 with NaOH, the cationic species deprotonated and an emulsion of neutral Haza and (Haza-aza) formed. By extraction with CCl_4, Haza was transferred into the organic phase, leaving a light yellow layer of solid (Haza-aza), which was isolated and recrystallized in ethanol. The X-ray structure (see below) confirms that it is the deprotonated form of the $(H_2aza\text{-}aza)^+$ cation described earlier (1).

Although pure (Haza-aza) can be obtained, the reaction is very inefficient in terms of both the ligand and $NbCl_5$. This was anticipated to some extent from the studies of McCarley et al. with neat pyridine (13). These authors indeed found that 30% of the $NbCl_5$ ended up are unreduced $NbCl_5(py)$ (eq. [1]), whereas the redox pathway (70%) required four ligands to form two reduced $NbCl_4(py)_2$ molecules for each pyridyl-pyridinium species obtained (eq. [2]). The coupling process liberated a proton that was quenched by the coupled product itself, becoming a $(Hpy\text{-}py)^{2+}$ cation. For the $NbCl_5$–Haza reaction, a solvent (benzene) had to be used, in which the products were all insoluble. The $(H_2aza)^+$ ion was identified as a major component of the raw product, suggesting that the proton liberated in the coupling process was quenched by an extra Haza molecule instead of the $(H_2aza\text{-}aza)^+$ ion (eq. [3]). The subsequent tests were run using a 7:2 Haza:$NbCl_5$ ratio and special care was taken to isolate all the (Haza-aza) formed, in order to determine the % $NbCl_5$ having been reduced. A series of reactions gave a range of 26–40%, that is, much below the 70% value observed with pyridine.

[1] $NbCl_5 + L \rightarrow NbCl_5(L)\downarrow$

[2] $2\ NbCl_5 + 6\ py \rightarrow 2\ NbCl_4(py)_2\downarrow + (Hpy\text{-}py)Cl_2$

[3] $2\ NbCl_5 + 7\ Haza \rightarrow 2\ NbCl_4(Haza)_2\downarrow + (H_2aza\text{-}aza)^+ + (H_2aza)^+ + 2\ Cl^-$

Since the $NbCl_5(Haza)$ adduct precipitates quantitatively as soon as $NbCl_5$ and Haza are mixed, its very low solubility was first considered as a possible reason for this poor reduction efficiency. However, this explanation was not retained since longer refluxing time produced no detectable improvement. A more likely possibility is that some $NbCl_5$ is used to quench the Cl^- ions liberated in reaction [3] by forming $[NbCl_6]^-$, which would then act as the counterion for the cationic species present. Two qualitative observations support this assumption: $(H_2aza)[NbCl_6]$ is very insoluble in benzene, whereas $(H_2aza\text{-}aza)^+$ is undoubtedly extracted as the $[NbCl_6]^-$ salt when the raw reaction product is washed with acetonitrile, since the precipitate eventually appearing in this solvent is the slightly hydrolyzed $(H_2aza\text{-}aza)_2[NbOCl_5]$ compound. Therefore, the redox pathway is probably better represented by reaction [4], where half of the $NbCl_5$ is wasted in forming $[NbCl_6]^-$ counterions. If this equation applies, the redox pathway would represent 52–80% of the reaction with azaindole, that is, a range close to the

[a] $x, -1/2 - y, 1/2 + z$.

70% value reported for pyridine. Nevertheless, if the reaction takes place by attack on the coordinated ligand in the $NbCl_5(L)$ adduct, as suggested by McCarley et al. (13), the reason for the redox process not going to completion with either pyridine or azaindole is still unclear, since in both cases a large excess of free ligand is still available.

[4] $4\ NbCl_5 + 7\ Haza \rightarrow 2\ NbCl_4(Haza)_2\downarrow + (H_2aza\text{-}aza)[NbCl_6]\downarrow + (H_2aza)[NbCl_6]\downarrow$

Crystal structure of (Haza-aza)

The molecule (Fig. 1) contains two azaindole units coupled via N(7)—C(6′), as reported for $(H_2aza\text{-}aza)^+$. Distances and angles are listed in Table 4. For the cationic form, various structural modifications with respect to azaindole, especially in the azaindolium ring, were pointed out (1). Besides these modifications, changes due to deprotonation are noted here for the neutral form, mainly on the angles in the five-membered ring: at the deprotonation site, the C(2)—N(1)—C(8) angle is reduced by 5.2°, whereas those at C(8), C(9), and C(2) undergo changes of +5.3°, −2.3°, and +3.0°, respectively, keeping the ring planar. Some distortion is transmitted to the six-membered ring via C(8), resulting in variations of −2.0° at C(8) and +2.5° at N(7). As the H(1) proton of $(H_2aza\text{-}aza)^+$ has been removed, no intramolecular N(1)—H(1)···N(7′) bond can form here and the

two azaindole halves are not longer coplanar (dihedral angle ~61°) (Table S-3).[5] Differences of ~2° on the angles around C(6′) are likely related to the conformational difference: any strain due to ring coplanarity in $(H_2aza\text{-}aza)^+$ is removed in the neutral molecule, whereas distortion could result from constraints imposed by packing of the two non-coplanar units in (Haza-aza).

Distances to the weighted least-squares planes are given in Table S-3.[5] In both units, most of the distortion can be regarded

as a slight bend of the two rings about the common bond, by 2.1° for the azaindolyl and 3.2° for the azaindolium unit.

Packing in the unit cell (Fig. S-1)[5] is controlled to a large extent by ring stacking and an intermolecular N(1′)—H(1′)···N(1) hydrogen bond.

Infrared and ^{1}H nuclear magnetic resonance data

A list of infrared frequencies and tentative assignments for $(H_2aza\text{-}aza)_2[NbOCl_5]$, $(H_2aza\text{-}aza)Cl$, and (Haza-aza) are provided as supplementary material.[5]

For the $[NbOCl_5]^{2-}$ salt, a strong and sharp band, missing in the spectrum of the chloride, is observed at 919 cm^{-1} for Nb═O stretching. Between 250 and 350 cm^{-1}, where the organic part makes no contribution, the spectrum contains two very strong ν(Nb—Cl) peaks at 300 and 315 cm^{-1}. Similar frequencies have been reported for these modes in the Cs^+ salt (24). Except for these bands, the spectra of $(H_2aza\text{-}aza)_2[NbOCl_5]$ and $(H_2aza\text{-}aza)Cl$ are essentially superimposable.

The $[H_2aza\text{-}aza]^+$ ion shows features similar to those of azaindole itself (3, 6), but the presence of two nonequivalent units leads to band splitting or broadening throughout the spectrum, as well as small shifts that will not be discussed here. In earlier studies (1, 9, 10), the 350–500 cm^{-1} region, where azaindole itself exhibits well-defined out-of-plane ring vibrations at 428 and 419 cm^{-1}, was found to be sensitive to complexation and useful for identification purposes. The present coupled cation shows five components (near 505, 480, 447, 431, and 349 cm^{-1}, respectively), including these two modes for each type of azaindole unit and probably a new vibration involving the connecting N7—C6′ bond.

In (Haza-aza), the very broad ν(N—H) band of $(H_2aza\text{-}aza)^+$ at ~3200 cm^{-1} is replaced by seven sharper peaks between 2765 and 3115 cm^{-1}, including ν(C—H) components near 3100 cm^{-1}, the ν(N—H) mode near 2900 cm^{-1}, and combinations or overtones. This neutral form can be identified from the five fingerprint components at 520, 478, 440, 420, and 362 cm^{-1}, respectively, and from other small shifts with respect to $(H_2aza\text{-}aza)^+$ (Table S-12).[5]

The ^{1}H NMR data for Haza-aza and the $(H_2aza\text{-}aza)^+$ salts are compared with those of 7-azaindole in Table 5. Doublets of doublets for the mutually coupled H4, H5, and H6 protons in the azaindolium part are assigned on the basis of their relative positions and coupling constants (6, 25). In the other unit, the absence of H6′ leads to doublets for H4′ and H5′. When the five-membered ring is N-protonated, the already coupled C—H protons appear as doublets of doublets because of extra coupling to N—H. Thus, for (Haza-aza), H2′ and H3′ can be differentiated from H2 and H3, respectively, since the latter belong to the deprotonated unit and appear as simple doublets. In the case of $(H_2aza\text{-}aza)^+$, where both units are protonated, the lower-field signal is assumed to originate for the azaindolium part, since this is the trend noted for the six-membered rings.

[a] 1 − *x*, *y*, 1/2 + *z*.

The positive charge on $(H_2aza\text{-}aza)^+$ brings all signals downfield from those of free azaindole. Since this charge is carried mainly by the azaindolium part, the displacements are larger in this unit than in the other (Table 5). The shifts follow a pattern similar to those observed when azaindole is N7-methylated (25) or N7-coordinated to CH_3Hg^+ (6) or $NbCl_5$ (1), but they are ~50% greater. The charge also increases the acidity of the N—H protons, which exhibit individual signals shifted downfield by ~0.8 (azaindolyl) and ~1.3 ppm (azaindolium) with respect to azaindole.

On the basis of the X-ray work on (Haza-aza), the proton lost by $(H_2aza\text{-}aza)^+$ is removed from the azaindolium part. The molecule likely adopts the same structure in solution, since most of the azaindolium protons occur ~0.5 ppm upfield, whereas the effect is generally small (~0.15 ppm) in the other unit. However, H5′ behaves differently, being displaced 0.35 ppm *downfield*: it is not clear whether this reflects a charge redistribution or the conformational difference between (Haza-aza) and $(H_2aza\text{-}aza)^+$. As expected, the N—H proton left in (Haza-aza) is less acidic than it was in $(H_2aza\text{-}aza)^+$, as evidenced from the ~0.3 ppm upfield shift.

(Haza-aza) as ligand

Interesting coordinating capabilities are anticipated for the anion derived from (Haza-aza). The N(1′) and N(7′) sites in the azaindolyl unit are well positioned to bridge a pair of metal atoms, as observed for azaindole itself. With the conformation shown in Fig. 1, the other unit would mainly produce steric hindrance, but further coordination via N(1) would become possible by rotation about the N(7)—C(6′) bond to bring the two units roughly coplanar, as they are in $(H_2aza\text{-}aza)_2[NbOCl_5]$. A test was run with $CuCl_2$ in methanol under the conditions used for earlier studies on the $CuCl_2$–Haza system (9). Dark-green crystals were obtained, whose composition was found to be $[Cu_4O(aza\text{-}aza)_4]Cl_2 \cdot 6.5H_2O$ from X-ray diffraction work.

The $[Cu_4O(aza\text{-}aza)_4]^{2+}$ cation (Fig. 2) contains a μ_4-OCu_4 unit surrounded by four tridentate $(aza\text{-}aza)^-$ ligands. Unlike most compounds containing this core, the cluster is halide-free and Cl^- simply acts as the counterion. Selected distances and angles are listed in Table 6.

For a series of $Cu_4OCl_6L_4$ compounds, Norman et al. (26) noticed that the Cu_4O tetrahedra retain a relatively constant geometry (Cu-O-Cu angle in the 105–113° range). The particular donor arrangement in $(aza\text{-}aza)^-$ and the steric requirements of the large rings result here in a large distortion of the tetrahedron: the Cu-O-Cu angles range from 99.0(3)° to 134.8(3)° (mean 116.3(3)°). However, the Cu—O bond lengths seem to be rather insensitive to distortion: our values (1.921(4) and 1.901(4) Å) agree with those found in $Cu_4OCl_6(Haza)_4$ (mean 1.918 Å) (9) and relates systems from the literature (1.869–1.939 Å, mean 1.908 Å) (26).

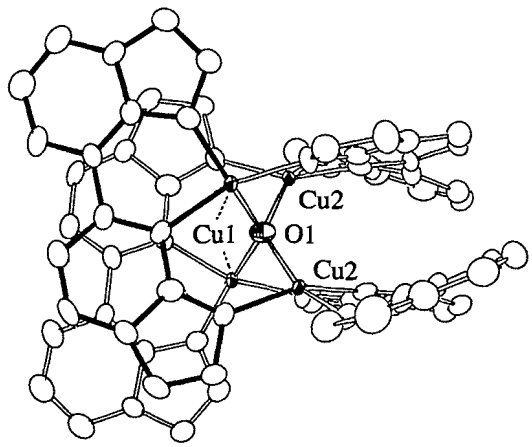

FIG. 2. ORTEP drawing of the $[Cu_4O(aza\text{-}aza)_4]^{2+}$ cation. The central oxygen atom lies on a crystallographic twofold axis running horizontally in the plane of the figure. Two symmetry-equivalent ligands of type 1 (first digit in atomic symbol, one shown with black bonds) lie on the left-hand side, ligands of type 2 are seen approximately edgewise on the right-hand side. Individual atoms are labelled as in structure **II**. Ellipsoids correspond to 50% probability. Hydrogens are omitted for simplicity.

The coordination sphere of copper is best described as a tetrahedrally distorted square plane with *trans* angles between 150.0(4)° and 155.7(3)°. The distortion is further reflected by distances of 0.24–0.61 Å between the N donors and the least-squares planes through $CuON_3$ (Table S-9).[5] The Cu—N distances to the pyridine-type N(17′) and N(27′) atoms (mean 1.990 Å) compare well with those involving the corresponding

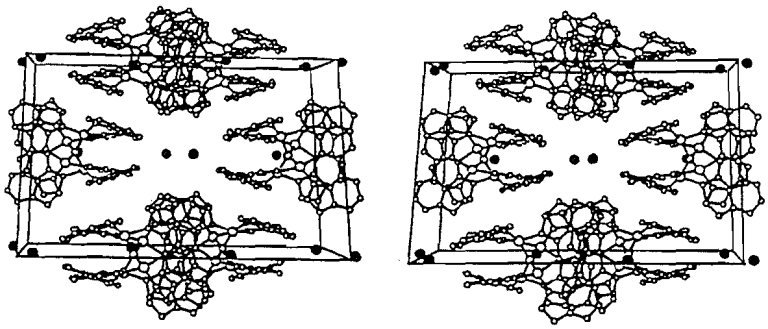

FIG. 3. Stereoview of the unit cell of $[Cu_4O(aza\text{-}aza)_4]Cl_2 \cdot 6.5H_2O$ down the *c* axis (*a* vertical and *b* horizontal). Cl^- ions are shown as black spheres. The disordered water molecules are not shown.

donor atom in $Cu_4OCl_6(Haza)_4$ (mean 1.998 Å) (9), but they are appreciably longer than those to the pyrrole N(11), N(11′), N(21), N(21′) atoms (mean 1.920 Å). This is consistent with the pyridine rings having a greater steric demand than the pyrrole rings, as suggested by the difference found between complexes with pyridines (mean 1.98 Å) (27, 28) and with imidazoles (mean 1.94 Å) (26, 29).

Distances and angles in the coordinated tridentate ligands are listed in Table S-7.[5] Any effect of coordination on bond lengths is obscured by the relatively high esd's (0.01–0.02 Å). Deprotonation of the azaindolyl units reduces the C(*n*2′)-N(*n*1′)-C(*n*8′) angles by 3.4° and produces an equivalent increase of the adjacent N(*n*1′)-C(*n*8′)-C(*n*9′) angles. Variations of ~3° with respect to (Haza-aza) are also noted around C(*n*6′) and N(*n*7), at the junction of the two units, where steric strain imposed by coordination can be absorbed. The two units make a dihedral angle of ~25° in ligand 1 and ~29° in ligand 2 (Table S-8).[5] Each of these units can be regarded as individually planar five- and six-membered rings with a slight bend of 2°–4° about the common C(*n*8)—C(*n*9) or C(*n*8′)—C(*n*9′) bonds (Table S-9).[5]

In the packing diagram (Fig. 3), the $[Cu_4O(aza\text{-}aza)_4]^{2+}$ ions are so oriented that rings in adjacent cations are parallel. There are two types of Cl^- ions, both lying on crystallographic twofold axes: Cl(1) occupies channels parallel to *c* through the origin and the middle of the *ab* face, whereas Cl(2) is nested between consecutive complex ions along *c*. These anions are connected by disordered chains of two or three water molecules (not shown in Fig. 4, data in Table S-10[5]).

In the infrared spectrum of $[Cu_4O(aza\text{-}aza)_4]Cl_2 \cdot 6.5H_2O$,[5] a new strong band is found at 557 cm^{-1} for Cu—O stretching in the Cu_4O core (9, 27, 30, 31). Four components at 330, 310, 300, and 290 cm^{-1} are assigned to Cu–N stretching, a strong band at ~290 cm^{-1} being present for $[CuL_4]^{2+}$ complexes with pyridines (32) and imidazoles (32–37). Since the ligands are deprotonated, the high-frequency region contains no ν(N—H) bands: the strong and broad feature at 3320 cm^{-1} is due to ν(O—H) of the hydrogen-bonded water molecules. Other changes due to ligand deprotonation and coordination are found throughout the spectrum. The five fingerprint bands occur at 510, 475, 446, 430, and 352 cm^{-1}, respectively.

Concluding remarks

Although the N7—C6′-coupled (Haza-aza) molecule is the only oxidized species generated by the redox reaction between $NbCl_5$ and 7-azaindole, the formation of other niobium- and azaindole-containing products renders the conversion inefficient. Efforts are being made to circumvent this problem and devise more practical routes to this ligand, whose potential as assembling ligand is well illustrated by the unusual oxotetracopper cluster stabilized here. These coordinating abilities are being examined for other metal centres and the reactivity of $NbCl_5$ with various N-heterocycles is underway to better understand the coupling mechanism.

AM1 calculational and experimental evidence that a β-nitroxyl group significantly enhances the thermodynamic and kinetic acidities of ketones

NICK HENRY WERSTIUK[1] AND CHANDRA DEO ROY

Department of Chemistry, McMaster University, Hamilton, ON L8S 4M1, Canada

Received June 24, 1994

NICK HENRY WERSTIUK and CHANDRA DEO ROY. Can. J. Chem. **72**, 2348 (1994).

The kinetics of NaOD-catalysed H/D exchange of 3,3,5,5-tetramethylcyclohexanone (**1**), 1-hydroxy-4-oxo-2,2,6,6-tetramethylpiperidine (**2**), 4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl (**3**), 9-hydroxynorpseudopelletierine (**4**), and norpseudopelletierine-9-oxyl (**5**) have been studied in 60:40 dioxane–D_2O (v/v) at 25.0°C. The second-order rate constants are 9.20×10^{-3}, 6.39×10^{-2}, 1.59, 2.20×10^{-2}, and 5.67×10^{-1} L mol^{-1} s^{-1} for **1**, **2**, **3**, **4**, and **5**, respectively. Gas-phase enthalpies of ionization (the values are 363.0, 359.4, 352.0, 360.7, and 354.1 kcal mol^{-1} for **1**, **2**, **3**, **4**, and **5**, respectively) calculated with AM1 correlate with the relative rates of enolization. Thus replacement of the β-hydroxylamino groups of **2** and **4** with a nitroxyl group produces sizable increases in the kinetic and thermodynamic acidities of the hydrogens α to the carbonyl group.

NICK HENRY WERSTIUK et CHANDRA DEO ROY. Can. J. Chem. **72**, 2348 (1994).

Opérant à 25°C, dans un mélange 60 : 40 de dioxane–D_2O (v/v), on a étudié la cinétique de l'échange H/D, catalysé par le NaOH, des 3,3,5,5-tétraméthylcyclohexanone (**1**), 1-hydroxy-4-oxo-2,2,6,6-tétraméthylpipéridine (**2**), 4-oxo-2,2,6,6-tétraméthylpipéridine-1-oxyl (**3**), 9-hydroxynorpseudopelletiérine (**4**) et norpseudopelletiérine (**5**). Les constantes de vitesse du deuxième ordre sont $9{,}20 \times 10^{-3}$, $6{,}39 \times 10^{-2}$, 1,59, $2{,}20 \times 10^{-2}$ et $5{,}67 \times 10^{-1}$ L mol^{-1} s^{-1} respectivement pour les composés **1**, **2**, **3**, **4** et **5**. Les enthalpies d'ionisation en phase gazeuse (les valeurs sont de 363,0, 359,4, 352,0, 360,7 et 354,1 kcal mol^{-1} respectivement pour les composés **1**, **2**, **3**, **4** et **5**) calculées par la méthode AM1 permettent d'établir une bonne corrélation avec les vitesses relatives d'énolisation. Ainsi, le remplacement des groups β-hydroxylamino des composés **2** et **4** par une groupe nitroxyle provoque une augmentation importante des acidités cinétiques et thermodynamiques des hydrogènes en α du groupe carbonyle.

[Traduit par la rédaction]

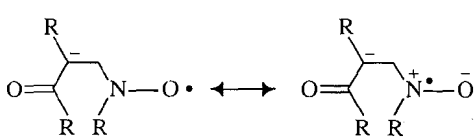
Introduction

While a great deal of research work has been carried out to define the factors, e.g., orbital alignment, steric, torsional, and polar effects, that determine the rates of base-catalyzed α enolization of ketones (1–4), there have been no reports detailing the effect of remote heteroatom-centered radicals on the kinetic and thermodynamic acidities of carbonyl compounds. Our longstanding interest in establishing how remote polar substituents enhance the rates of α and β(homoenolization) enolization of ketones and in using semiempirical calculations to predict and understand variations in the thermodynamic acidities of carbon and oxygen acids (5, 6) motivated us to undertake a calculational and kinetic study of the base-catalysed enolization of five ketones. The group included 3,3,5,5-tetramethylcyclohexanone (**1**), 1-hydroxy-4-oxo-2,2,6,6-tetramethylpiperidine (**2**), 4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl (**3**), 9-hydroxynorpseudopelletierine (**4**), and norpseudopelletierine-9-oxyl (**5**), of which two, **3** and **5**, have a polar nitroxyl group R_2N-O· located β to the enolizable centers.[2] That the nitroxyl group is electron withdrawing is well documented in the literature (7). We chose to study these compounds because the enthalpies of ionization (ΔH_i's) calculated with AM1 (8) indicated that **3** and **5** should enolize much more quickly than **1**, **2**, and **4**. In this communication we report and discuss the results of calculational and experimental studies on **1**–**5**.

The enthalpies of ionization (Table 1) were obtained from the calculated heats of formation of **1**–**5** and their corresponding enolates.[3] The geometrical structures of the optimized geometries of 1-hydroxy-4-oxo-2,2,6,6-tetramethylpiperidine (**2**), 4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl (**3**), 9-hydroxynorpseudopelletierine (**4**), and norpseudopelletierine-9-oxyl (**5**) (**2c**, **3tb**, **4cc**, and **5cc**) and their enolates (**2c-enolate**, **3tb-enolate**, **4cc-enolate**, and **5cc-enolate**) are given in Fig. 1. It is seen that the nitroxyl nitrogens of the ketones and enolates are nearly triangular planar. While chair conformations are found to be the most stable geometrical structures of **1** and **2**, the twist-boat conformer **3tb** of the piperidinoxyl radical is 0.29 kcal mol^{-1} lower in energy than the chair conformer **3c**, in accord with the results of gas-phase electron diffraction studies carried out by Nakken and co-workers on **2** and **3** (10, 11). In the case of 9-

[1] Author to whom correspondence may be addressed.

[2] In principle, a β-nitroxyl group can stabilize a carbanion via a polar effect, through bond and through space, and a hyperconjugative interaction involving a σ* orbital of a C—N bond. It is also possible that the polarity of the nitroxyl group increases upon deprotonation at a β carbon, giving rise to a reflex polar stabilization of the enolate. In terms of resonance theory, the dipolar canonical form written for the nitroxyl group is a more important contributor for the enolate than the ketone.



Support for such a reflex polar stabilization by a nitroxyl group is found in the fact that the AM1 calculations show that there is a differential increase in negative charge on the oxygens of the nitroxyl groups of **3tb** and **5cc** relative to the oxygens of the hydroxyl groups of **2c** and **4cc** upon enolate formation: **2c**, –0.270, **2c-enolate**, –0.291; **3tb**, –0.319, **3tb-enolate**, –0.404; **4cc** –0.271, **4cc-enolate**, –0.306; **5cc**, –0.306, **5cc-enolate**, –0.401.

[3] PCMODEL (9) was used to generate input geometries for the AM1 calculations, which were carried out with the keyword PRECISE to tighten the convergence criteria. UHF calculations were carried out for the hydroxy compounds, the nitroxyl radicals, and their enolates.

[a]In kcal mol^{-1}.

[b]ΔH_i = [ΔH_f (enolate) − ΔH_f (ketone)] − $\Delta H_f(H^+)$; $\Delta H_f(H^+)$ taken as 365.4 kcal mol^{-1}.

[c]The values for the -OH group *syn* and *anti* to the carbonyl and enolate groups, respectively.

TABLE 2. Second-order rate constants and relative rates of H/D exchange of ketones

Ketone[a]	k(L mol^{-1} s^{-1})[b]	Relative rate	Calculated $\Delta\Delta H_i$
1	0.92×10^{-2}[c]	1	0.0
2	6.39×10^{-2}[c]	6.9	−3.6
3	1.59[c,d]	173.1	−11.1
4	2.20×10^{-2}[c]	2.4	−7.1(OH *syn*), −2.3(*anti*)
5	5.67×10^{-1}[c,d]	61.7	−8.9(OH *syn*), −9.4(*anti*)

[a]Substrates **2**, **4**, and **5** were synthesized using procedures reported in the literature (11–14).

[b]In 60:40 dioxane–D_2O(v/v). Ketone concentrations ranged from 0.10 to 0.12 M. Second-order rate constants were obtained by dividing the measured pseudo-first-order rate constant by the base concentration, which was in the range of 0.005–0.04 M. Rates were reproducible with a maximum deviation of <±5% except for **1** where the deviation was ±7.5%.

[c]The uptake of deuterium was monitored with ^{1}H nmr spectroscopy by integrating the appropriate resonances. The signals of the C4 methylene hydrogens of **1** and methyl hydrogens of **2** were used as internal standards. For bicyclic compounds **4** and **5**, the resonances of the bridgehead hydrogens or the equatorial hydrogens α to the carbonyl group (the equatorial hydrogens of **5** exchange at least 100 times more slowly than the axial hydrogens) were used as the internal standards. The radicals were catalytically hydrogenated (PtO_2 in ethanol) to **2** and **4**, which were analysed with ^{1}H nmr spectroscopy.

[d]The H/D exchange of radicals **3** and **5** was extremely fast. The pseudo-first-order rate constants obtained from one-point kinetic runs were divided by the base concentration to calculate the second-order rate constants. The first-order rate constants exhibited a linear relationship with base concentration.

hydroxynorpseudopelletierine, the chair-chair conformation **4cc** is 3.10 kcal mol^{-1} lower in energy than the chair-boat conformation **4cb**, and the isomer with the -OH group *syn* to the carbonyl was found to be only marginally lower in energy than the *anti* diastereomer. But the orientation of the N-OH group has a dramatic effect on the stability of the gas-phase enolates derived from **4cb** and **4cc**; the *syn* enolates (the -OH group is *syn* to the enolate) are 5–6 kcal mol^{-1} lower in energy than the *anti* diastereomers, indicating that a gas-phase enolate ion is stabilized markedly by a single intramolecular hydrogen bond that is aligned perpendicular to the plane of the enolate anion. Even so, we expected that **4** would not exhibit an enhanced acidity in

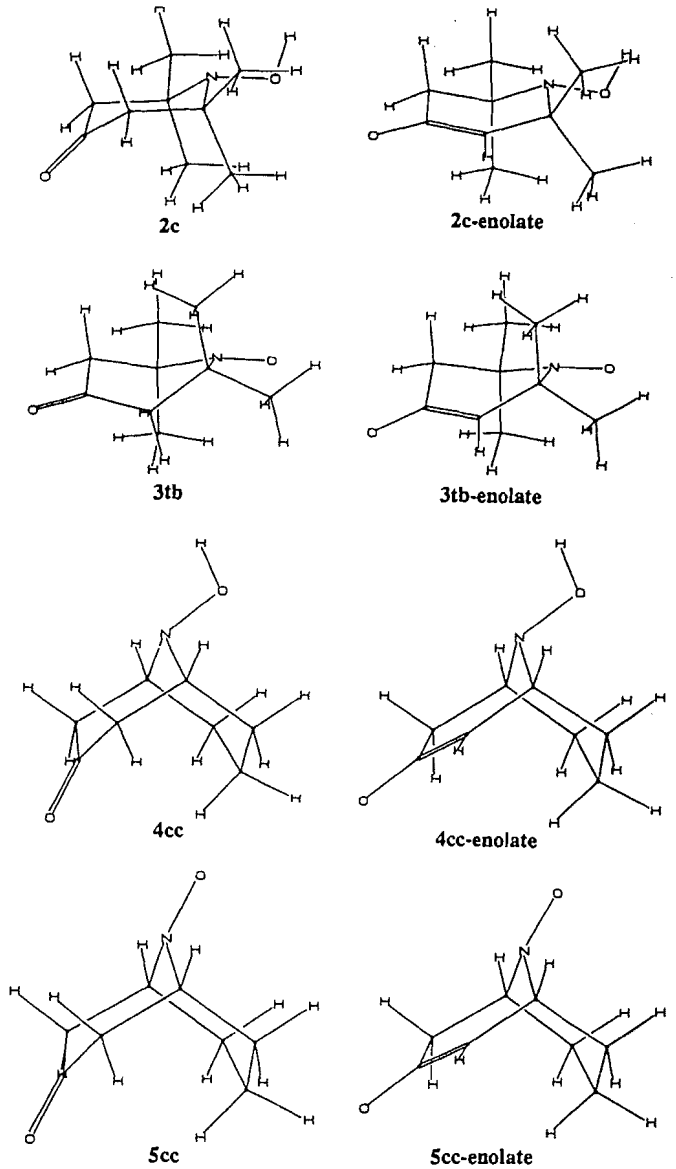

FIG. 1. Geometrical structures of the AM1 optimized geometries of **2c**, **3tb**, **4cc**, **5cc**, and their enolates.

aqueous solution[4] because enolates are solvated intermolecularly by solvent, and axial approach by OH^- at C2 should hinder formation of an intramolecular hydrogen bond to the incipient enolate. In the case of norpseudopelletierine-9-oxyl, the chair-chair conformation **5cc** is 2.86 kcal mol^{-1} lower in energy than the chair-boat conformation **5cb** and the orientation of the nitroxyl oxygen has little effect on the stability of enolates. Because the $\Delta\Delta H_i$'s of **3tb** and **5** were found to be nearly three times the values calculated for **2** and **4**, we expected the nitroxyl compounds to enolize much more quickly than **2** and **4**, and **2** to be more reactive than **1**.

The second-order rate constants for H/D exchange in NaOD/D_2O 60:40 dioxane–D_2O along with the relative rates and the $\Delta\Delta H_i$'s are given in Table 2. It is seen that the relative rates of

[4]We are modelling polycyclic cage compounds bearing hydrophobic cavities calculationally with AM1 to design substrates that will be useful for probing the stabilization of enolates by intramolecular hydrogen bonding in solution.

enolization correlate with the calculational gas-phase ΔH_i's and, as predicted, piperidine-1-oxyl **3** is more reactive than pelletierine-9-oxyl **5**; 1-hydroxypiperidine **2** is slightly more reactive than **4** and both compounds are substantially less reactive than **3** and **5**. As expected, the kinetic acidity of **4** correlates with the calculational ΔH_i of the *anti* diastereomer and not with the ΔH_i of the *syn* isomer. Because there are no σ substituent constants for the nitroxyl and hydroxylamino groups, it will be difficult to assess the relative importances of the polar (inductive and field) and hyperconjugation effects. Even so, the group electronegativities (χ values) calculated by Boyd and Boyd (15) on the basis of a bond critical point model indicate that through-bond electron-withdrawing effects of the nitroxyl and hydroxylamino groups are virtually identical.[5] Because the calculated N-C$(CH_3)_2$-CH=C (34.9°) and N-C$(R)_2$-CH=C (30.2°) torsional angles of **3tb-enolate** and **5cc-enolate** are far from the optimal angle of 90°, hyperconjugation with an adjacent C—N bond plays a minor role in stabilizing the enolates.

The influence of preoxidizing the surface of polycrystalline copper electrodes on the efficiency of the controlled potential electrochemical reduction of nitrobenzene and azobenzene to aniline in basic aqueous methanol has been investigated. Electrodes electrochemically preoxidized to $Cu(OH)_2$ or to Cu_2O gave high yields of aniline (90–100%) with high current efficiencies (88–99%) for the electrohydrogenation of nitrobenzene compared to electrodes preoxidized by air (7–29% of aniline, 64–74% current efficiency). For the electrohydrogenation of azobenzene, copper electrodes preoxidized to Cu_2O were found to be more active (average yield of aniline of 28%, average current efficiency of 55%) than electrodes preoxidized to $Cu(OH)_2$ (3–11% of aniline, 42–53% current efficiency), and electrodes preoxidized by air were inactive (the electrohydrogenation stopped at hydrazobenzene). The improvement of activity induced by preoxidation of the copper surface is linked to the increase of the surface area.

ANNA MARTEL, AMOY KAM CHEONG, JEAN LESSARD et LOUIS BROSSARD. Can. J. Chem. **72**, 2353 (1994).

Nous avons étudié l'influence de l'oxydation préalable d'électrodes de cuivre polycristalline sur l'efficacité de la réduction électrochimique du nitrobenzene et de l'azobenzène en aniline en milieu basique méthanol–eau. Les électrodes préalablement oxydées pour former du $Cu(OH)_2$ ou du Cu_2O ont donné d'excellents rendements en aniline (90–100%) et des efficacités de courant élevées (88–99%) en comparison aux électrodes oxydées à l'air (7–29% d'aniline, efficacité de courant de 64 à 74%) pour l'électrohydrogénation du nitrobenzène. Dans le cas de l'électrohydrogénation de l'azobenzène, les électrodes préoxydées en CuO_2 se sont avérées plus actives (rendement moyen de 28% en aniline, efficacité de courant moyenne de 55%) que les électrodes oxydées en $Cu(OH)_2$ (3–11% d'aniline, efficacité de courant de 42 à 53%) alors que les électrodes oxydées à l'air étaient inactives (arrêt à l'hydrazobenzène). L'augmentation de l'activité est reliée à un accroissement de la surface de l'électrode.

Introduction

The voltammetric reduction of nitrobenzene in basic aqueous or mixed aqueous organic solutions at various electrode materials is a four-electron process (eq. [1])

[1] $PhNO_2 + 4e^- + 3H_2O \rightarrow PhNHOH + 4OH^-$

whereas preparative electrochemical reduction usually gives condensation products resulting mainly from a chemical reaction between phenylhydroxylamine and nitrosobenzene: azoxy, azo, and hydrazobenzene (ref. 1, and references in ref. 2). At the beginning of the century, Löb and Moore (3) reported the formation of aniline in 33% yield, in addition to azoxybenzene (60% yield), in the preparative electrolysis of a suspension of nitrobenzene in 2% aqueous NaOH at a copper cathode, the yield of aniline being increased to 53% in the presence of copper powder (41% yield of azoxybenzene). Stutts et al. (4) reported a 25% yield of aniline for the constant current (80 mA/cm^2) reduction of nitrobenzene in 1 N NaOH (methanol added for solubility) at polycrystalline copper after a charge corresponding to 6 F/mol of nitrobenzene. The yield of aniline was practically the same (28%) at a charge corresponding to 7.5 F/mol of substrate. Cyr et al. (2) obtained substantial yields of aniline in the controlled potential reduction of nitrobenzene at polycrystalline copper in basic (0.14 M KOH) aqueous methanol (45% at −1.0 V vs. SCE and up to 87% at −1.2 V); the other product was phenylhydroxylamine (50% and 8% yield, respectively), the formation of condensation products during the electrolysis being negligible (0–3%).

Clearly, the copper electrode is capable of reducing the unprotonated hydroxylamine. One mechanistic possibility would be a reduction via chemisorbed hydrogen (eq. [3]) generated by the reduction of water (eq. [2]) as proposed for the efficient electrochemical reduction of nitroaromatic compounds to anilines on Devarda copper (5–7). Another mechanistic possibility would be a classical electronation–protonation path (eq. [4]), the reducibility of phenylhydroxylamine on copper being due to its adsorption and to the existence of specific interactions with the metal (8). That adsorption phenomena and specific interactions are operative has been confirmed by voltammetric studies at a Cu microelectrode showing hysteresis phenomena in alkaline media, for phenylhydroxylamine as well as for nitrobenzene, and by particular features of the voltammetric curves for nitrobenzene when compared to those obtained on carbon and mercury (8). A third mechanistic possibility has been proposed (4) and it would involve an electrocatalytic reduction in which an active form of copper generated by the reduction of surface copper oxides and (or) hydroxides (ca. eq. [5]) would reduce nitrobenzene and phenylhydroxylamine with regeneration of the surface copper oxides and (or) hydroxides (ca. eq. [6]). Huang (9) has shown that copper oxides and (or) hydroxides are always present on the surface of copper electrodes, even after careful polishing treatments carried out in the presence of air.

[2] $2H_2O + 2e^- + Cu \rightarrow 2(H)Cu + 2OH^-$

[3] $2(H)Cu + PhNHOH \rightarrow PhNH_2 + H_2O + Cu$

[4] $(PhNHOH)Cu + 2e^- + H_2O \rightarrow PhNH_2 + 2OH^-$

[5] $Cu(OH)_2 + 2e^- \rightarrow Cu^0 + 2OH^-$

[6] $PhNHOH + Cu^0 + H_2O \rightarrow PhNH_2 + Cu(OH)_2$

In the course of investigations on the electrochemical reduction of nitrobenzene at copper electrodes, we noticed variations in the yields of aniline and phenylhydroxylamine with the same electrode as well as with different electrodes. This led us to believe that these variations were caused by variations in the amount and (or) the nature of the oxides/hydroxides present on the surface of the copper electrodes.

In this paper, we report a study of the electrochemical reduction of nitrobenzene and azobenzene in basic aqueous methanol at polycrystalline copper electrodes that have been submitted to an oxidative treatment prior to their use in preparative electrolyses. We describe the various types of oxidative treatment applied and compared the morphology of the surface of the resulting electrodes and their activity (and efficiency) for the conversion of nitrobenzene and azoxybenzene to aniline.

Experimental

The controlled potential preparative electrolyses were carried out with an Electrosynthesis Company (ECS) 410 potentiostat connected in series with an ECS 640 digital coulometer and a Dynascon Corporation 2830 digital ammeter. A two-compartment glass H-cell (the volume of each compartment was 125 mL) having a Nafion-324 (E.I. du Pont de Nemours and Co.) membrane as separator was used. The counter electrode was a platinum grid cylinder (4 cm long and 6 cm in diameter). The reference electrode, a Cole Parmer saturated calomel electrode (SCE), was connected to the catholyte through a fritted glass disc close to the surface of the working electrode facing the counter electrode.

The polycrystalline bulk copper electrodes (grid 3×4 cm, 60 mesh) were made of pure metal (99.9%) purchased from Greening Donald Ltd. Before electrolysis, the copper electrodes were treated by one of the methods A–G described below. For the treatments involving electrochemical oxidations and reductions as well as for the voltammetric curve of Fig. 1, a Princeton Applied Research (PAR) potentiostat, model 173, with a PAR universal programmer, model 175, coupled to a PAR XY recorder, model RE0089, was used.

Treatment A

Cleaning in 50% nitric acid and thorough rinsing.

Treatment B

Cleaning according to the method used by Kyriacou et al. (10). The copper grid was washed with warm dichloromethane and then immersed in concentrated hydrochloric acid for 1 h for degreasing and removal of metallic surface impurities. It was then anodized in 85% w/w phosphoric acid at a current density of 500 mA/cm^2 for 2 min, after which a smooth shiny surface was obtained. It was then washed several times in deionized water.

Treatment C

Cleaning using method A followed by cleaning as described by Shoesmith et al. (11), by applying a reducing pontential of -1.2 V vs. SCE in a 1 M LiOH solution (prepared from anhydrous AR LiOH purchased from Fisher Scientific Co.) in the cell described above until the current decreased to zero. Then the electrode was oxidized as described in ref. 11. An oxidation potential (-0.22 to -0.20 V) corresponding to the formation of $Cu(OH)_2$ (Fig. 1) was applied. When the oxidation current dropped to zero, one redox cycle was completed. The redox cycle (reduction at -1.2 V, then oxidation) was repeated a number of times if required (until the desired amount of charge at the oxidation potential was passed). The electrode was then thoroughly rinsed.

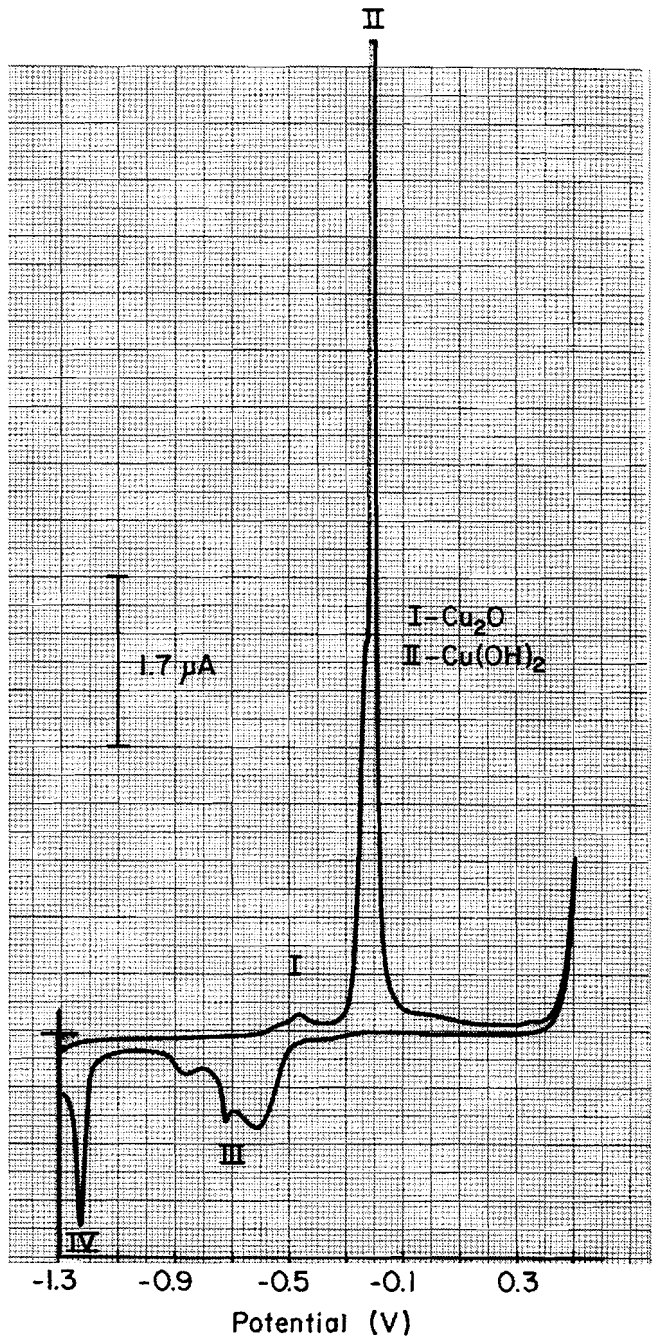

FIG. 1. Cyclic voltammogram of a copper electrode in 1 M aqueous LiOH at 21°C. Scan rate: 2 mV/s; potential (V) vs. SCE.

Treatment D

Same as treatment C except that the oxidation potential (-0.29 to -0.33 V) did correspond to the formation of Cu_2O (Fig. 1).

Treatment E

Cleaning as in treatment C followed by potential pulses at -1.2 and -0.3 V at a period of 1 s until a total charge of 86 C at -0.3 V was passed. Then an oxidation potential of -0.3 V was applied until the current dropped to zero: 336 C.

Treatment F

Cleaning as in treatment C followed by cycling the potential

between −1.3 and +0.1 V at a scan rate of 100 mV/s until the peak corresponding to the oxidation to $Cu(OH)_2$ at −0.22 V stopped increasing.

Treatment G

Same as treatment F but cycling the potential between −1.3 and −0.21 V at a scan rate of 1 mV/s.

Solutions of KOH (0.14 M) in methanol–water 93:7 w/w were prepared from ACS methanol, distilled water, and KOH purchased from BDH. Nitrobenzene and azobenzene were purchased from BDH, aniline from Anachemia, and azoxybenzene from Lancaster Synthesis.

The electrolysis procedure was as follows. After treating the copper electrode as described above (see treatments A–G), it was placed in the cathodic compartment containing the supporting electrolyte solution, then polarized for 30 min at a potential (−0.55 to −1.0 V) generating a current density of 0.2 mA/cm² while bubbling nitrogen through the solution. The current density was then suddenly increased to 3.3 mA/cm² (potential of −1.4 to −1.7 V) for 30 min, during which time reduction of surface oxides occurred as well as hydrogen evolution. The potential was then increased to −1.0 V. A residual current density of 0.2 mA/cm² resulted. The organic substrate was then added, causing an increase of the current. For the reduction of nitrobenzene, the electrolysis was stopped when the current dropped to almost zero. For the reduction of azobenzene, the potential was also initially increased to −1.0 V. At this potential, the electrohydrogenation of azobenzene to hydrazobenzene was fast (large initial currents) and was complete. After a charge corresponding to about 2 mol of electrons (2 F) per mole of substrate, the current dropped almost to the background value so the potential was further decreased to −1.2 V in order to speed up the electrolysis (to increase the current). The electrolysis was stopped after a charge corresponding to 4–5 F/mol of azobenzene and (or) after the current dropped to the background value.

The progress of the electrolyses was followed by gas–liquid chromatography (glc) on a Hewlett Packard (HP) 5790A or 5840A chromatograph equipped with a FID detector and a HP 3390A integrator, using a 30 m long DB-5 fused silica capillary column with the following temperature programming: 80°C for 5 min, increase to 200°C at 10°C/min, and 200°C for 5 min. Products were identified by comparison of retention times with those of authentic samples. Yields and mass balances were determined by the internal standard method. The yield of phenylhydroxylamine was determined after its complete oxidation by air to azoxybenzene and nitrobenzene (2) and the yield of hydrazobenzene was determined after complete air oxidation to azobenzene (2).

The characterization of the electrode surfaces was carried out by scanning electron microscopy (SEM) on a JEOL GSM 840A apparatus. X-ray diffraction analyses were performed with a Rigaku D/MaxB diffractomter. The specific surface areas were determined by the BET method, with nitrogen adsorption, using a Quanta Chrome Quanta Sorb QS-10 apparatus. The double layer capacities were measured by the ac impedance technique, using a PAR potentiostat, model 273, monitored by a Commodore PC2 computer, with a GPIB PC2A interface, and connected to a PAR 5208 lock-in amplifier; the measurements were carried out in 1 M KOH aqueous solutions.

Results and discussion

The potentiodynamic trace of Fig. 1 corresponds to that reported by Shoesmith et al. (11) and displays two oxidation peaks: peak I is ascribed to the formation of Cu_2O, the formation of $Cu(OH)_2$ starts at the shoulder of peak II (the shoulder being located on the cathodic side of the latter), and peak II itself is linked to the formation of $Cu(OH)_2$ only. On the reverse sweep, region III corresponds to the reduction of a Cu(II) solid species and peak IV to the reduction of Cu_2O. Since the nature and amount of the predominant phases are largely dependent on the applied potential where the oxidation is carried out in the region of peak II (11), the copper grid was potentiostatically preoxidized at two different potentials, i.e., −0.3 and −0.2 V, to generate two different oxides as shown by X-ray diffraction analysis (Fig. 2): Cu_2O at −0.30 V (Fig. 2*a*) and $Cu(OH)_2$ at −0.20 V (Fig. 2*b*).

The electrohydrogenation of nitrobenzene at polycrystalline copper electrodes cleaned in nitric acid (treatment A) or polished electrochemically (treatment B) was compared to the electrohydrogenation at copper electrodes electrochemically preoxidized to form $Cu(OH)_2$ (treatment C) or to form Cu_2O (treatment D) at the copper surface. The results are summarized in Table 1. In all cases, the material balance is high. The current efficiencies are higher with electrochemically preoxidized copper electrodes (entries 3 and 4) than the electrodes not electrochemically preoxidized (entries 1 and 2). The most striking feature of Table 1 is the much greater activity of the electrochemically preoxidized copper electrodes for the formation of aniline: yields of aniline of 90–100% in entries 3 and 4 compared to yields of 7–29% in entries 1 and 2. In fact, the yields of aniline and the current efficiencies obtained with electrochemically preoxidized copper electrodes are comparable to those obtained with Devarda copper electrodes under the same conditions: 99% yield, 95% current efficiency (5). With the copper electrodes not electrochemically preoxidized (entries 1 and 2), the amount of hydrazobenzene is relatively important (28–36%). These results differ from those reported by Cyr et al. (2) for electrohydrogenation on a copper plate under the same conditions 0–3% of hydrazobenzene. The hydrazobenzene comes from the reduction of the azoxybenzene resulting from the reaction between nitrosobenzene and phenylhydroxylamine in the bulk of the solution during the electrolysis. Darchen and Moinet (12) have indeed shown that the nitro group is first reduced to

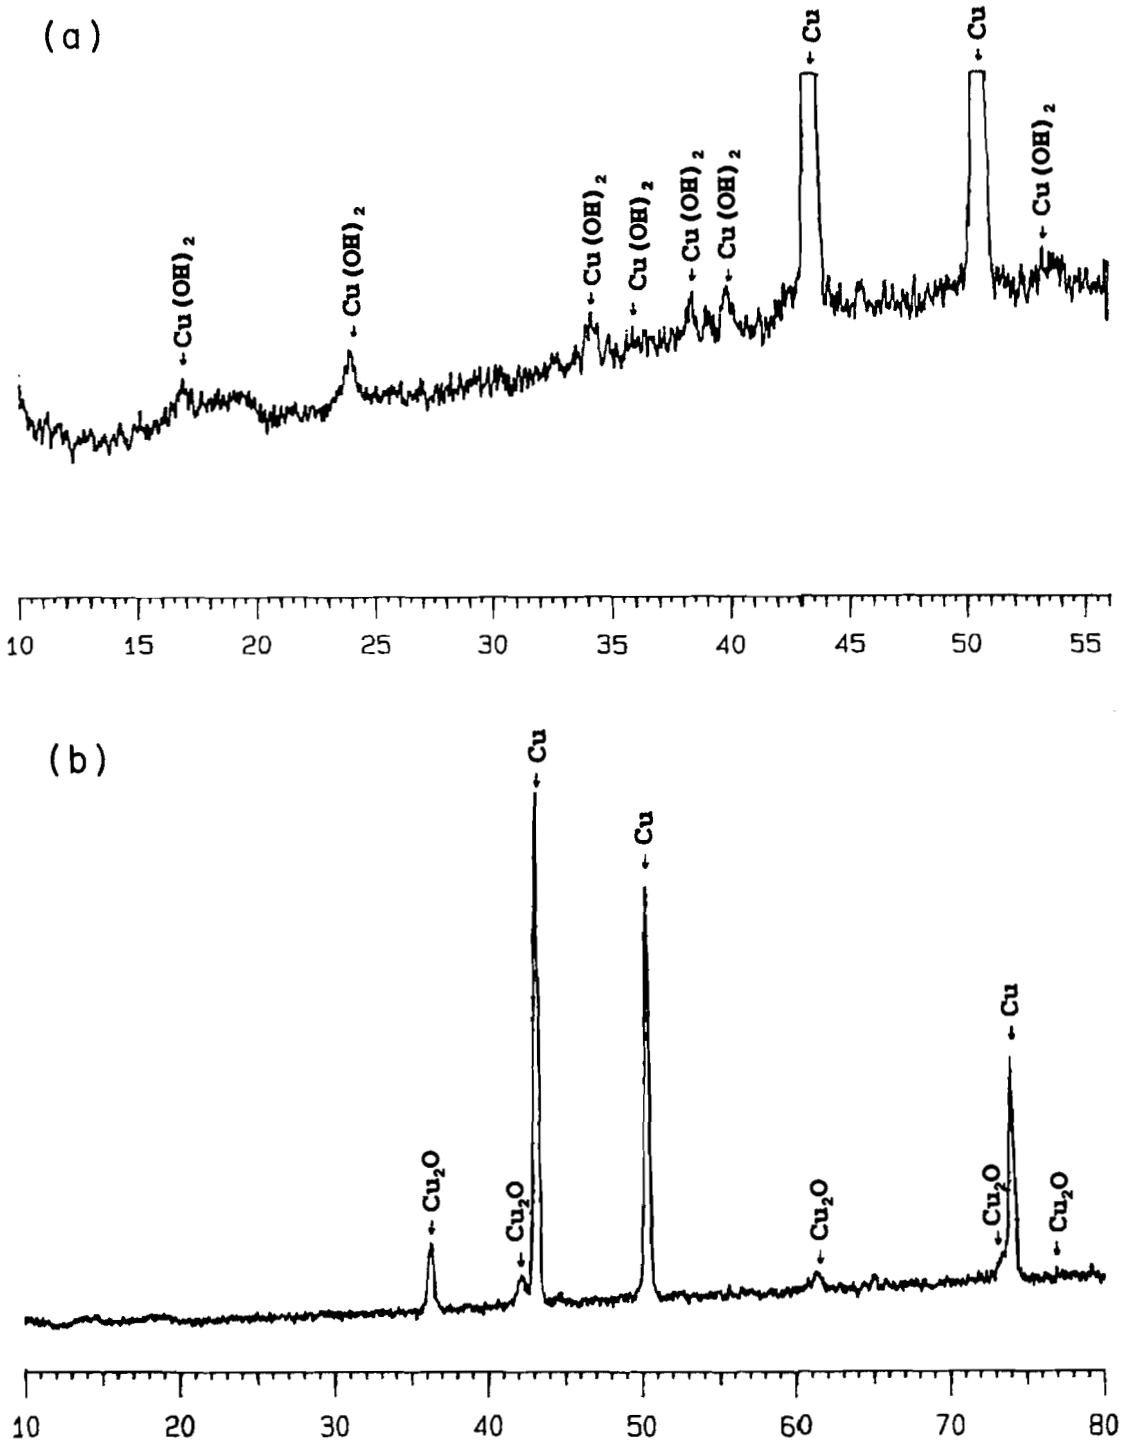

FIG. 2. X-ray diffraction analysis of copper electrodes oxidized in a 1 M aqueous LiOH solution : (*a*) oxidation at −0.30 V vs. SCE; (*b*) at −0.20 V (see the Experimental).

the dihydroxylamine, which is then dehydrated to the nitroso derivative. If dehydration occurs at the surface of the electrode, the nitroso derivative is immediately reduced to the hydroxylamine, whereas if dehydration occurs in solution, the nitroso derivative has a high probability of reacting with the hydroxylamine to give the azoxy derivative (12). It is quite possible then that the intermediate dihydroxylaminobenzene could move away from the electrode surface at a faster rate in the case of a copper grid (this work) than in the case of a copper plate (ref. 2).

A comparison of entries 3 and 4 of Table 1 shows that the activity of the electrochemically preoxidized electrodes for the electrohydrogenation of nitrobenzene does not depend on the nature of the oxide formed at the surface, i.e., $Cu(OH)_2$ (entry 3) or Cu_2O (entry 4). For the electrodes not electrochemically preoxidized, an electrode that has been polished electrochemically prior to the electrohydrogenation (10) (entry 2) is more active than an electrode cleaned in nitric acid (entry 1). This could reflect a greater extent of oxidation by air (larger amount of surface oxides) when the copper grid is polished electrochemically than when it is cleaned in nitric acid. The difference in yields of

[a]A, C, D: same as in Table 1; E: the potential was pulsed between −1.2 and −0.3 V at a period of 1 s followed by oxidation at −0.3 V. F: the potential was cycled between −1.3 and 0.1 V at 100 mV/s; G: the potential was cycled between −1.3 and −0.21 V at 1 mV/s. The oxidation potential(s) and the charge for oxidation are indicated between parentheses.

[b]Double layer capacity determined by ac impedance in aqueous 1 M KOH at 25°C.

[c]In entries 1, 2, and 13, the electrolysis was stopped when the current dropped to the background value.

[d]By glc; there was 100% conversion of azobenzene in all case.

aniline obtained in the two electrolyses of entry 1 with an electrode cleaned in nitric acid shows that using the same electrode and cleaning it the same way before each use does not reproduce exactly the same activity, that is, the same amount of surface oxides by air oxidation.

Cyr et al. (2) have reported that the electrohydrogenation of azobenzene at polycrystalline copper stopped at hydrazobenzene in basic (0.14 M KOH) methanol–water (93:7 w/w); aniline was not detected. On the other hand, at Devarda copper and under the same conditions, the hydrogenolysis of hydrazobenzene was found to be quite efficient (5). Since the copper grid electrochemically preoxidized appeared to be almost as efficient as a Devarda copper electrode for the electrohydrogenation of nitrobenzene to aniline (hydrogenolysis of phenylhydroxylamine), it was of interest to also determine their activity for the hydrogenolysis of hydrazobenzene to aniline. So we studied the electrohydrogenation of azobenzene. The results are recorded in Table 2.

On a copper electrode cleaned in nitric acid (treatment A, entry 1), the current dropped to the background value after a charge corresponding to 2.7 mol of electrons (2.7 F) per mol of azobenzene and no aniline was detected. So there was no hydrogenolysis of hydrazobenzene, as already reported (2). Copper electrodes that had been preoxidized to $Cu(OH)_2$ (treatment C, entries 2–4) were slightly more active since there was some hydrogenolysis of hydrazobenzene (3–11% of aniline). The current in excess of a charge corresponding to 2 F/mol of azobenzene (reduction to hydrazobenzene) was used mainly for hydrogen evolution as shown by the low (≤50%) current efficiencies of entries 3 and 4. Since the conversion rate and current efficiency for the conversion of azobenzene to hydrazobenzene (after 2 F/mol of azobenzene) are close to 100%, a yield of about 10% of aniline and a current efficiency of about 50% for the overall reaction (after 4 F/mole of azobenzene) means that only 10% of the current was effectively used for the hydrogenolysis of hydrazobenzene to aniline (90% for hydrogen evolution). With one redox cycle (reduction at −1.2 V until a zero current was reached, with a subsequent oxidation at −0.2 V until a zero current (11) was reached again, see treatment C of the experimental), it was not possible to go beyond a charge of 40 C for the formation of $Cu(OH)_2$. With three successive redox cycles, it was possible to increase the amount of $Cu(OH)_2$ formed on the electrode surface up to a charge of 70 C (entry 4). This led to a slight improvement of the activity (11% of aniline compared to 3–4% in entries 2 and 3).

The electrodes preoxidized to Cu_2O were found to be more active than those preoxidized to $Cu(OH)_2$, as shown by the higher yields of aniline obtained with the former electrodes (see Table 2, entries 5–11). The charge used to form Cu_2O was varied from 7 C (entry 5) to 100 C (entry 11). There was an increase in the yield of aniline from 10% (entry 5) to 31% (entry 6) upon increasing the preoxidation charge from 7 to 12 C. Increasing the charge from 12 to 100 C (entries 6–11) did not cause any real increase of the yield of aniline (31% yield in entry 6 compared to 27% in entry 11; yields varying from 20 to 40% in entries 6–11 with an average yield of 28%). Therefore, practically only the Cu_2O formed at the surface leads, after reduction, to a surface that is active for the hydrogenolysis of hydrazobenzene. Overall current efficiencies of 60% for an average yield of aniline of 28% (after a charge corresponding to 4 F/mol of azobenzene) corresponds to a current efficiency of about 30% for the hydrogenolysis of hydrazobenzene to aniline (see above).

As in the case of preoxidation to $Cu(OH)_2$, the oxidation to Cu_2O using one reduction (−1.2 V) – preoxidation (−0.3 V) cycle stopped after an oxidation charge of 40 C (treatment D). With four successive reduction–oxidation cycles, a charge of 60 C could be reached and, with six cycles, a charge of 100 C. By first pulsating the potential between −1.2 and −0.3 V at a period of 1 s until a total charge at −0.3 V (oxidation) of 86 C and then applying a potential of −0.3 V, it was possible to reach a charge of 336 C (treatment E, see entry 12). Despite the sig-

nificant increase of the amount of Cu_2O formed in treatment E, there was no improvement of the activity for the hydrogenolysis of hydrazobenzene (41% yield of aniline in entry 12 compared to 40% in entry 8). Other types of treatment, such as submitting the electrode to voltammetric cycles between −1.3 and 0.1 V at 100 mV/s (treatment F, entry 13) or between −1.3 and −0.21 V at 1 mV/s (treatment G, entry 14), until the Cu_2O reduction peak at −0.21 V stopped increasing, did not lead to any improvement of the activity (18% yield of aniline in entry 13, 26% yield in entry 14) when compared to treatment D (entries 6–11, average yield of aniline 28%).

The simplest explanation for the increase of activity of copper electrodes for the hydrogenolysis of N—O and N—N bonds when preoxidizing the surface to $Cu(OH)_2$ or to Cu_2O, which are then reduced in situ, is an increase of the surface area. Indeed, as shown in Tables 1 and 2, the double layer capacity (C_{dl}) for the hydrogen evolution reaction (HER) in aqueous alkali measured by ac impedance and, hence, the roughness of the surface[2] are larger for electrodes that have been electrochemically preoxidized (entry 3 of Table 1; entries 2, 4, 7–9, and 11–14 of Table 2) than for electrodes cleaned in nitric acid and oxidized by air (treatment A, entry 1 of Tables 1 and 2) or electrochemically polished in nitric acid and oxidized by air (treatment B, entry 2 of Table 1), and the former electrodes are more active (higher yields of aniline). Furthermore, electrodes preoxidized to Cu_2O (treatment D, entries 6–11 of Table 2) are more active (20–40% yield of aniline) and have a larger C_{dl} (1330–2430 $\mu F/cm^2$) than electrodes preoxidized to $Cu(OH)_2$ (treatment C, entries 2–4 of Table 2: 3–11% yield of aniline; C_{dl} = 400–490 $\mu F/cm^2$).[2] That the more active electrodes have generally the larger C_{dl} (and hence the larger surface area) is clearly seen from Fig. 3, where the yield of aniline in the electrohydrogenation of azobenzene is correlated to C_{dl}. As expected, the electrodes preoxidized to Cu_2O (treatment D) have a larger specific area measured by BET (1.6–1.7 m^2/g) than electrodes polished by immersion in nitric acid and oxidized by air (treatment A, 0.84 m^2/g). The SEM pictures of some copper electrodes are illustrated in Fig. 4. For Fig. 4*a*, the copper electrode was not electrochemically preoxidized; for Fig. 4*b*, the copper electrode was preoxidized to Cu_2O at −0.33 V up to a charge of oxidation of 40 C and, for Fig. 4*c*, Cu_2O was further reduced to metallic copper. The formation of a dense network of microcracks is noticed in Fig. 4*c*. Consequently, it is deduced that the increase of C_{dl} noticed after formation (treatment D) and reduction of Cu_2O on the copper grid surface (Table 2 and Fig. 3) is induced by morphological changes at the electrode surface. Furthermore, reduction of the oxide (Fig. 4*c*) appears to make the electrode surface still more porous.

The activity of the electrode referred to above (evaluated by the yield of aniline and current efficiency) reflects the competition between the electrohydrogenolysis of phenylhydroxylamine or hydrazobenzene to aniline (eq. [7], where YH-ZH = PhNH-OH or PhNH-NHPh, YH_2 = $PhNH_2$ and ZH_2 = $PhNH_2$ or

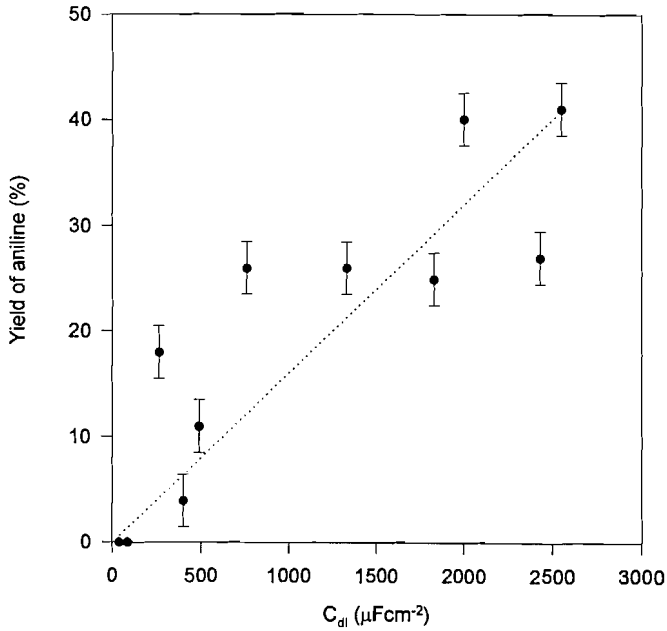

FIG. 3. Correlation between the yield of aniline and the double layer capacity (C_{dl}) of copper electrodes in the electrohydrogenation of azobenzene in basic (0.14 M KOH) methanol–water (93:7 w/w) solution at −1.0 to −1.2 V vs. SCE at room temperature.

H_2O) and the HER (eq. [8]). If reaction [7] was as fast as reaction [8], the yield of aniline from azobenzene, for instance,

[7] $YH - ZH + 2e^- + 2H_2O \rightarrow YH_2 + ZH_2 + 2OH^-$

[8] $2H_2O + 2e^- + 2e^- \rightarrow H_2 + 2OH^-$

would be less than 50% and the current efficiency less than 67%[3] because of a decrease of the rate of reaction [7] due to a diminution of the concentration of YH-ZH as the electrohydrogenolysis proceeds, while the rate of reaction [8] remains more or less constant, water being present in large excess. This is nearly the case for the electrohydrogenation of azobenzene on copper electrochemically preoxidized to Cu_2O (Table 2, entries 7–12) with an average yield of aniline of 30% and an average current efficiency of 59%. When reaction [7] is faster than reaction [8], high yields of aniline and high current efficiencies are obtained, as in the electrohydrogenation of nitrobenzene on electrochemically preoxidized copper electrodes (Table 1, entries 3 and 4; yield of aniline ≥90%, current efficiency ≥88%). The electrohydrogenation of Table 2, entry 1 (on copper electrodes not electrochemically preoxidized), represents the limiting case of reaction [7] being much slower than reaction [8] so that no hydrogenolysis occurred and only the HER was observed (see also Table 2 of ref. 2). Clearly, for a given substrate, the surface area of the electrode has an influence on the competition between reactions [7] and [8]: an increase of the surface area favors reaction [7] over reaction [8] and hence leads to an increase of electrode activity. This can be readily

[2]The C_{dl} of a smooth nickel surface is 20 mF/cm^2 (13) so the surface of copper electrodes not electrochemically preoxidized (treatments A and B, entries 1 and 2 of Table 1) is about two to four times rougher (roughness factor $R = C_{dl}/20$ = 2.1–4.3) than the surface of smooth nickel. The surface resulting from electrochemical preoxidation to $Cu(OH)_2$ (treatment C, entries 2 and 4 of Table 2) is then about 20 times rougher (R = 20–24.5) and the surface resulting form preoxidation to Cu_2O (treatment D, entries 5–11 of Table 2) is between 65 and 122 times rougher (R = 66.5–121.5).

[3]The electrohydrogenation of azobenzene to hydrazobenzene is quantitative and proceeds with 100% current efficiency. For a 50% conversion of hydrazobenzene to aniline with a 50% current efficiency, the overall current efficiency would be 66.6%. In the case of nitrobenzene, assuming a 100% current efficiency for the electrohydrogenation to phenylhydroxylamine, a 50% conversion with a 50% current efficiency for the phenylhydroxylamine to aniline hydrogenation, the overall current efficiency would be 75%.

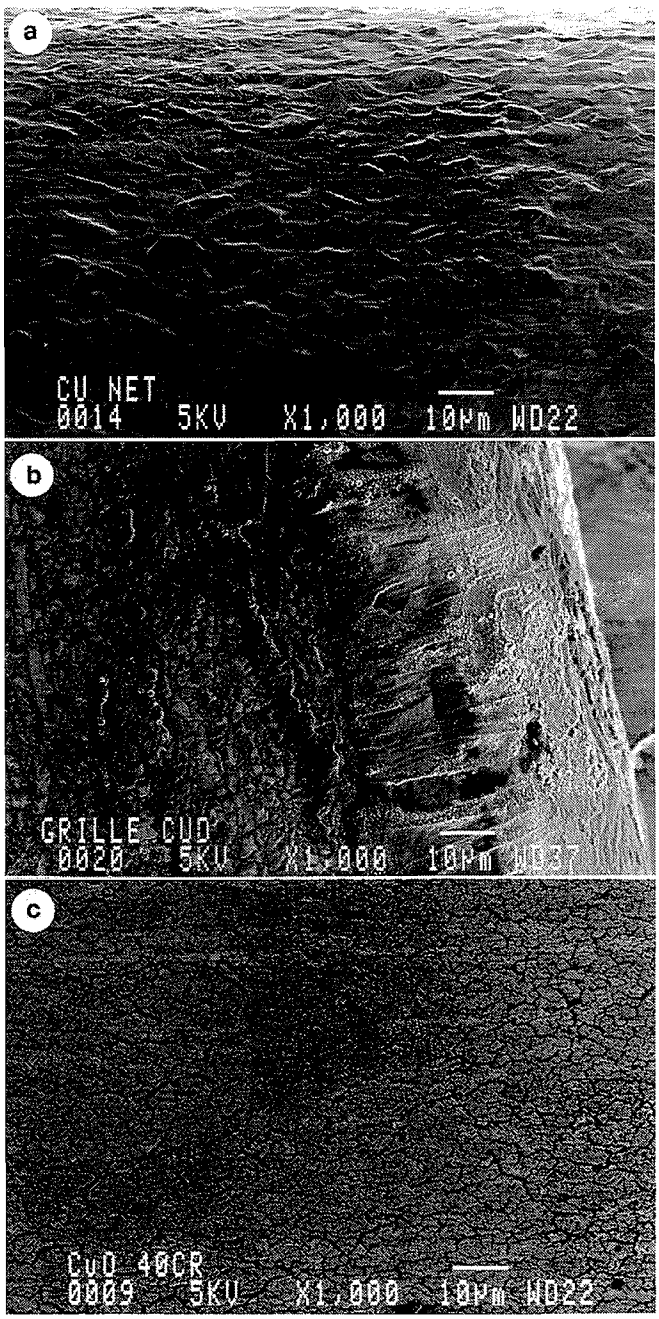

FIG. 4. Scanning electron microscopy pictures of copper electrodes: (*a*) cleaned in nitric acid and further oxidized in air (treatment A); (*b*) oxidized to Cu_2O (treatment D); (*c*) oxidized to Cu_2O (treatment D), which was then reduced at −1.0 V vs. SCE.

explained by an electrocatalytic hydrogenation mechanism (see eqs. [2] and [3]) in which the reaction of phenylhydroxylamine or hydrazobenzene with chemisorbed hydrogen (eq. [9]) competes with the formation of molecular hydrogen from chemisorbed hydrogen (eq. [10]). An increase of the surface area

[9] $2Cu(H) + YH - ZH \rightarrow YH_2 + ZH_2 + Cu$

[10] $2Cu(H) \rightarrow H_2 + Cu$

would then augment the number but also make more readily accessible the sites for the adsorption of the organic substrate (active sites for hydrogenation) and thus increase the mass transfer to these sites as found in the electrocatalytic hydrogenation of phenanthrene on porous nickel electrodes (14). The increase of copper electrode activity upon increasing the surface area can also be accounted for by the two other possible mechanisms of the electrohydrogenation of phenylhydroxylamine and hydrazobenzene if hydrazobenzene behaves as phenylhydroxylamine: by an increase of the number of accessibility of adsorption sites for YH-ZH for the classical electron–protonation mechanism (8) (see eq. [4]) or of active reducing copper sites in the electrocatalytic mechanism described by eqs. [5] and [6] (4).

Conclusion

The activity of polycrystalline copper electrodes for the hydrogenolysis of N—O and N—N bonds can be increased by electrochemically preoxidizing their surface to $Cu(OH)_2$ or to Cu_2O. These electrodes are very active for the electrohydrogenation of nitrobenzene to aniline in alkaline medium (yields of 90–100%, current efficiencies of 88–99%). The hydrogenolysis of hydrazobenzene being more difficult than that of phenylhydroxylamine, the yields of aniline and current efficiencies are much lower than those obtained for the electrohydrogenation of nitrobenzene, but they show clearly that electrodes preoxidized to Cu_2O are more active (an average of 28% for the yield of aniline and 55% for the current efficiency) than electrodes preoxidized to $Cu(OH)_2$ (yield of aniline of 3–11% and current efficiency of 42–53%). The larger activity is related to the increase of active surface area, as evidenced by an increase of the double layer capacity for the HER in alkaline medium from 40 $\mu F/cm^2$ for a non-preoxidized copper electrode to about 400 $\mu F/cm^2$ for an electrode preoxidized to $Cu(OH)_2$ and to about 2000 $\mu F/cm^2$ for an electrode preoxidized to Cu_2O. Devarda copper electrodes are still more active (93% aniline from azobenzene with a current efficiency of 96% (14)) and, indeed, their active surface area is still larger ($C_{dl} > 10^4$ $\mu F/cm^2$).[4] The three mechanisms considered in the introduction would be consistent with an increase of activity due to an increase of the number of active sites for a given geometric area.

Après avoir préparé plusieurs dihydroxamates analogues de l'acide rhodotorulique, nous avons étudié leur mode de complexation du fer(III) et la stabilité des complexes obtenus en fonction du pH, par comparaison avec la ferrioxamine B et le complexe acide acétohydroxamique – fer(III). Cette étude révèle une stoechiométrie des complexes 2 : 3 à pH 7 et 1 : 1 à pH 2 ainsi qu'un comportement électrochimique très différent suivant le pH malgré une complexation totale. La très forte constante de formation ($\log \beta_{110} = 21{,}3$) obtenue à pH 1 avec le ligand *N,N'*-bis(acétylhydroxyamino-3' propyl)-pentyloxy-4 pyridine-2,6 dicarboxamide confirme le fort pouvoir de complexation du fer(III) par ces composés. La relaxivité élevée du complexe fer(III) – *N,N'*-bis(acétylhydroxyamino-3' propyl)-(amino-4'' butyloxy)-4-pyridine-2,6 dicarboxamide permet de considérer ce produit comme un agent de constraste potentiel pour l'imagerie par résonance magnétique.

FRÉDÉRIC CHAUBET, KIEM NGUYEN VAN DUONG, JACQUES COURTIEU, ALAIN GAUDEMER, AURORE GREF, ALVIN L. CRUMBLISS, and MATTHEW T. CAUDLE. Can. J. Chem. **72**, 2361 (1994).

Numerous analogous dihydroxamates of rhodotorulic acid have been prepared, and their mode of complexation of iron(III) and the stability of these complexes studied as a function of pH, for comparison with ferrioxamine B and the complex of acetohydroxamic acid with iron(III). This study has shown that the stoichiometry of the complexes is 2:3 (at a pH of 7) and 1:1 (at a pH of 2), and that, in spite of a complete complexation, their electrochemical behaviour varies greatly with pH. The very strong complexation constant observed ($\log \beta_{110} = 21.3$) at a pH of 1 with the ligand *N,N'*-bis(acetylhydroxamino-3' propyl)-pentyloxy-4 pyridine-2,6-dicarboxamide confirms the strong complexation capacity of iron(III) by these complexes. The high relaxivity of the complex of iron(III) with the *N,N'*-bis(acetylhydroxyamino-3'-propyl)-(amino-4''-butyloxy)-4-pyridine-2,6-dicarboxamide suggests that this product could be a useful contrasting agent for nuclear magnetic imaging.

[Journal translation]

Introduction

Dans la première partie de ce travail nous avons présenté la synthèse d'acides dihydroxamiques **1***a–d* susceptibles de conduire par complexation avec le fer(III) à de nouveaux agents de contraste pour l'imagerie de résonance magnétique (1, 2). Nous présentons maintenant les résultats des études physicochimiques réalisées sur les complexes qu'ils forment en solution avec l'ion ferrique. Les sidérophores polyhydroxamiques forment avec le fer(III) des complexes très stables dans lesquels l'ion ferrique haut spin se trouve dans un environnement octaédrique (3–5). La coexistence en solution de plusieurs isomères géométriques rend difficile l'obtention d'un composé cristallisé analysable par rayons X. L'essentiel des informations structurales sur ces composés provient donc de l'analyse des espèces en solution (6, 7) en particulier en utilisant la spectrophotométrie visible entre 350 et 550 nm, la RPE et la voltamétrie cyclique. La première de ces techniques permet en particulier de différencier les trois types de complexes mono-, di- et trihydroxamates avec le fer(III) car ils présentent des longueurs d'onde d'absorption maximum très différentes et indépendantes du reste de la structure du ligand (8). Dans le cas du complexe fer(III) – acide rhodotorulique, qui présente un nombre élevé d'isomères en solution (6), on a ainsi pu proposer une stoechiométrie Fe_2L_3 (fig. 1). Nous avons étudié dans les mêmes conditions de solvant les complexes formés par le fer(III) avec l'acide acétohydroxamique **2** et la déferriferrioxamine B **3** afin de pouvoir comparer valablement leurs propriétés de complexation déjà bien connues avec celles des ligands **1** dans les mêmes conditions expérimentales. Enfin, nous avons mesuré la relaxivité du complexe fer(III)-**1***d* in vitro, et nous l'avons comparé à la relaxivité du complexe Gd(DTPA) déterminée dans les mêmes conditions.

Materiels et methodes

Les spectres UV–visible ont été enregistrés sur un spectromètre Perkin–Elmer Lambda 5 pour les déterminations des points isosbestiques. Les spectres RPE ont été enregistrés sur un spectromètre Bruker ER 200E fonctionnant en bande X avec une fréquence de 9,4 GHz.

Les valeurs du pH ont été mesurées avec une microélectrode Tacussel raccordée à un pH mètre Tacussel Minisis 5000. Une courbe de calibration de la microélectrode combinée a été réalisée afin de pourvoir corréler le pH mesuré dans le mélange méthanol–eau au pH mesuré dans l'eau. L'électrolyte de la microélectrode était une solution saturée de LiCl dans le mélange méthanol–eau employé. Les titrations potentiométriques ont été effectuées dans une cellule thermostatée à 25,0 ± 0,2°C et sous atmosphère inerte. Les additions de KOH ont été effectuées à l'aide d'une burette automatique Schott ou d'une microburette de précision Gilmont de même que les solutions de fer(III). Chaque courbe de titration a été tracée à partir de 60 points expérimentaux enregistrés avec un pHmètre Corning model 250 raccordé à une électrode combinée à jonction échangeable. Une courbe de calibration de l'électrode a été réalisée suivant la méthode de May et al. (9).

Les mesures spectrophotométriques ont été effectuées à l'aide d'un spectrophotomètre UV–visible Beckman Acta III équipé d'un compartiment de measure thermostaté à 25,0 ± 0,2°C.

Les voltamogrammes ont été enregistrés en utilisant un circuit à trois électrodes : électrode de mesure à carbone vitreux, électrode de référence SCE, contre-électrode de platine. Nous avons utilisé un potentiostat Princeton Applied Research (PAR) 273 comme générateur de signaux électriques et une table traçante X, Y Ifelec 3700. La cellule employée avait une capacité de 2 mL.

Les mesures des temps de relaxation ont été effectuées avec un appareil Bruker AM 250MHz à température ambiante.

Les solvants ont été distillés et l'eau a été ultrafiltrée sur cartouches Millipore. La solution de Gd(DTPA) 0,40 M (Ca-méglumine 0,40 M) dans l'eau a été fournie gracieusement par ORIS bioindustries. La déterriferrioxamine B était un produit Sigma. L'acide acétohydroxamique a été fourni par le professeur Crumbliss.

Spectrophotométrie visible

Les six solutions suivantes ont été préparées : (A) $6{,}9 \times 10^{-3}$ M de chaque ligand dans le méthanol; (B) $Fe(NO_3)_3$ $7{,}25 \times 10^{-2}$ M, HNO_3 0,10 M, $NaNO_3$ 0,10 M dans le mélange méthanol–eau (70 : 30), (C) $NaHCO_3$ $3{,}0 \times 10^{-2}$ M, $NaNO_3$ 10^{-2} M dans le mélange méthanol–eau (70 : 30); (D) $NaNO_3$ $3{,}3 \times 10^{-2}$ M dans l'eau; (E) $NaNO_3$ 10^{-2} M dans le mélange méthanol–eau (70 : 30); (F) HNO_3 $3{,}0 \times 10^{-2}$ M, $NaNO_3$ 10^{-2} M dans le mélange méthanol–eau (70 : 30).

À pH 7

Chaque échantillon comprenait 2,1 mL de la solution (A), un volume de la solution (B) déterminé en fonction du rapport $[Fe^{3+}]/[L]$ choisi, et 0,9 mL de la solution (D). Le mélange a été soniqué pendant 3 min puis le pH a été ajusté entre 6,9 et 7,1 avec la solution (C). Le volume de l'échantillon à été complèté à 5 mL avec la solution (E) dans une fiole jaugée.

À pH 2

La méthode était la même que ci-dessus, mais l'adjustement de la valeur du pH a été effectuée avec la solution (F).

Détermination du point isosbestique

La méthode était la même que ci-dessus, mais le pH a été ajusté à différentes valeurs comprises entre 2,5 et 7,2 à l'aide des solutions (C) et (F).

Dans tous les cas les spectres d'absorption visible ont été enregistrés entre 350 et 550 nm.

Voltamétrie cyclique

Toutes les solutions utilisées ont été préparées à partir d'une solution de $NaNO_3$ 0,10 M dans le mélange méthanol–eau (70 : 30).

Pour les complexes fer(III)–**2** et fer(III)–**3**, une solution stock de $Fe(NO_3)_3$ 10^{-2} M et une solution de ligand 0,10 M toutes deux dans le mélange méthanol–eau (70 : 30) ont été utilisées pour l'étude des complexes en milieu acide (pH <1). La concentration désirée (1–5 mM) a été obtenue par dilution. Pour les complexes préparés avec les ligands synthétisés la quantité nécessaire de ligand a été ajoutée à l'état solide directement dans la cellule à une quantité stoechiométrique de $Fe(NO_3)_3$ 10^{-3} M. Le volume a été complété à 2 mL. Le pH à été ajusté entre 1 et 7 avec $NaHCO_3$ solide ou en solution concentrée dans le mélange méthanol–eau (70 : 30). Les potentiels ont été mesurés par rapport à l'électrode standard au calomel.

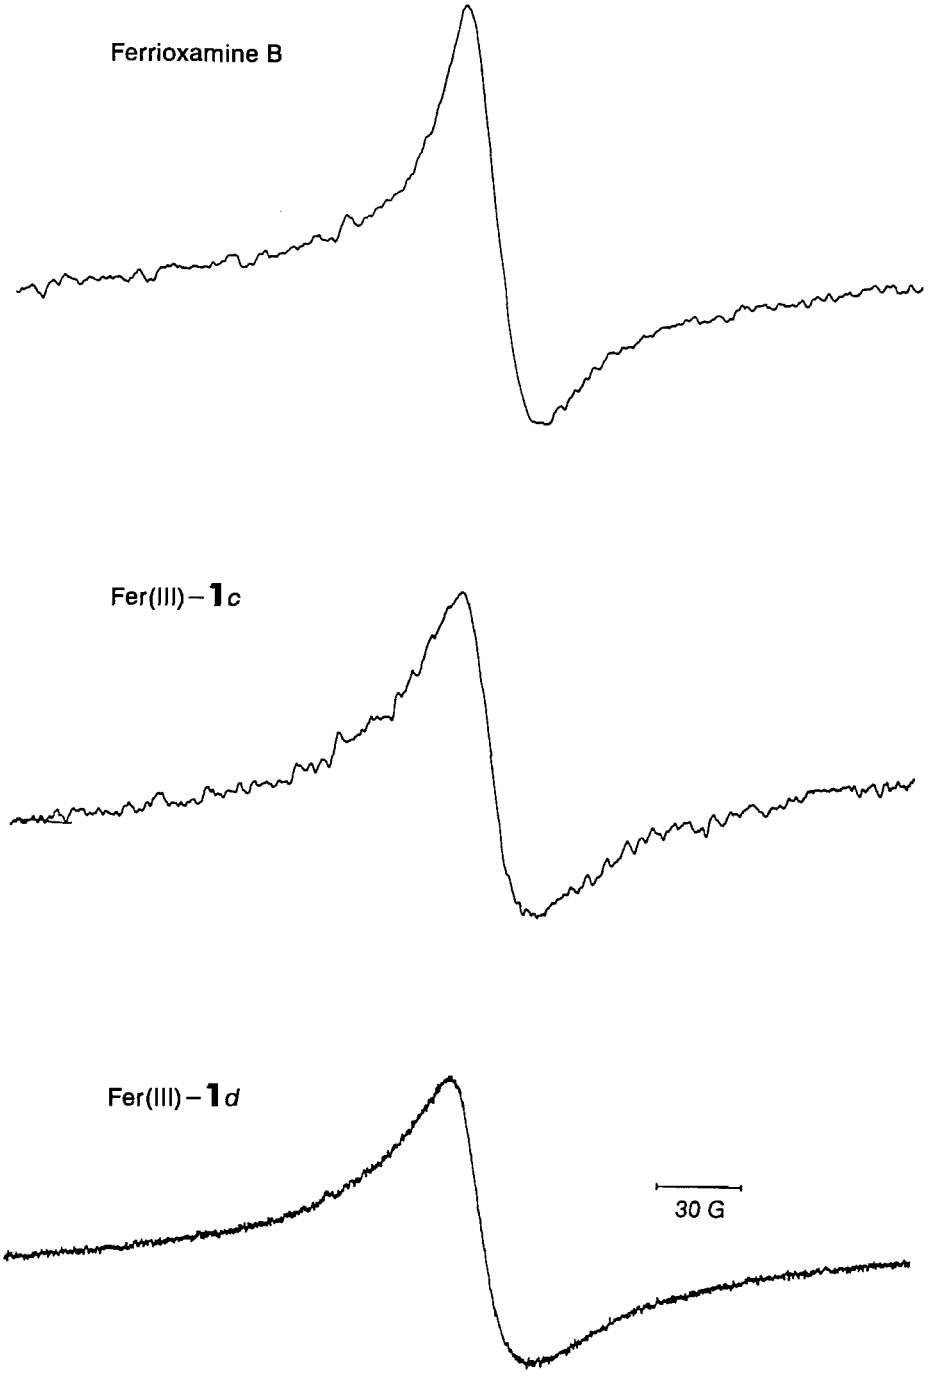

FIG. 2. Spectres RPE dans l'eau des complexes ferrioxamine B (fer(III)–**3**, fer(III)–**1***c* et fer(III)–**1***d*). [fer(III)] = 10^{-3} M, 0,16 M $NaNO_3$, pH 7.

RPE

Les complexes de fer(III) ont été préparés dans l'eau à partir de solutions de $Fe(NO_3)_3$ 10^{-3} M et de ligands $1{,}05 \times 10^{-3}$ M. Le pH a été ajusté à l'aide de $NaHCO_3$ solide et contrôlé au papier pH. Les spectres ont été enregistrés à 110 K.

Constantes d'équilibre

Les solutions de titrage (KOH) ont été préparées par la méthode d'échange d'ion avec l'hydroxyde de baryum (10) et maintenues sous azote débarrassé de O_2 et CO_2 par barbotage dans une solution de Fieser. Le nitrate de potassium a été recristallisé juste avant son utilisation. Le nitrate terrique a été préparé par dissolution de fer métallique dans HNO_3 concentré. $Fe(NO_3)_3{,}9H_2O$ précipité a été recristallisé une fois dans HNO_3 concentré. Toutes les solutions ont été préparées dans le mélange méthanol–eau (30 : 70). La concentration de fer(III) a été établie par réduction en fer(II) et titration du fer(II) par une solution standard de dichromate de potassium. La concentration d'acide dans les solutions de fer a été déterminée par élution sur une colonne échangeuse de cations (Dowex 50W-X8) suivie d'une titration de l'acide libéré par la phénolphtaléine. Les solutions de KOH ont été titrées par l'hydrogènophtalate de potassium. Les valeurs de pK_a ont été obtenues à partir de solutions de ligands 0,10 M dans KNO_3 0,10 M.

La constante de stabilité du complexe FeL^+ a été établie à partir des données spectrophotométriques de complexation par une méthode de moindres carrés non linéaire (11). Un programme appelé MRATIO11 a été développé dans ce but.

TABLEAU 1. Valeurs des coefficients d'absorption molaire par centre métallique et stoechiométrie des complexes formés

Paramètre	Complexe fer(III)–**1***a*	Complexe fer(III)–**1***b*	Complexe fer(III)–**1***c*	Complexe fer(III) – acide rhodotorulique[a]
ε_M (420) pH 7 (M^{-1} cm^{-1})	2640	2720	2460	2700 (425 nm)
ε_M (470) pH 2 (M^{-1} cm^{-1})	1720	1790	1670	1670 (480 nm)
Stoechiométrie pH 7	2:3	2:3	2:3	2:3
Stoechiométrie pH 1	1:1	1:1	1:1	1:1 (pH 2)

[a]Valeurs déterminées dans l'eau par Raymond et coll. à 425 nm (pH 7) et 480 nm (pH 2) (19).

Relaxométrie

Pour le complexe fer(III)–**1***d* : nous avons préparé les solutions suivantes : (A) $Fe(NO_3)_3$ 0,10 M, HNO_3 0,10 M dans l'eau; (B) ligand **1***d* $3,9 \times 10^{-2}$ M dans l'éthanol absolu; (C) $NaNO_3$ 1,0 M dans l'eau; (D) $NaNO_3$ 0,15 M dans le mélange éthanol–eau (40 : 60) contenant 10% de D_2O.

À 800 μL de la solution (B) ont été ajoutés 200 μL de la solution (A) et 240 μL de la solution (C). La solution obtenue a été neutralisée avec 1 équivalent de $NaHCO_3$ (22,0 mg) et le pH a été ajusté à 7 avec $NaHCO_3$ 0,10 M. D_2O (200 μL) a été ajouté et le volume complété à 2 mL dans une fiole jaugée avec de l'eau bidistillée. La solution a été soniquée 3 min. Le titre de cette solution était 0,010 M en fer(III), à pH 7, 0,15 M de $NaNO_3$, dans le mélange éthanol–eau (40 : 60). À l'aide de la solution (D), nous avons préparé six échantillons de concentrations 0,010; 0,008; 0,006; 0,004; 0,002; 0,001 M en fer(III) pour un volume final de 600 μL par échantillon. Pour le complexe Gd(DTPA), six solutions de même titre et de même volume que pour le fer(III) ont été préparées à partir d'une solution mère commerciale de Gd (DTPA) 0,40 M (Ca-méglumine 0,40 M) dans l'eau.

Résultats

Spectres de RPE de la ferrioxamine B et des complexes formés avec le fer(III) à partir des ligands **1***c et* **1***d*

La figure 2 représente les spectres RPE des complexes formés par les ligands **1***c* et **1***d* avec le fer(III) et de la ferrioxamine B enregistrés dans les mêmes conditions. Dans les trois cas le signal unique était à $g = 4,3$. Cette valeur, commune à tous les complexes polyhydroxamiques du fer(III), est caractéristique d'un environnement octaédrique haut spin de l'ion ferrique (6).

Détermination de la stoechiométrie des complexes fer(III)–hydroxamates dans le mélange méthanol–eau (70 : 30)

La proportion méthanol–eau (70 : 30) a été choisie afin d'assurer une bonne solubilisation des ligands et de leurs complexes avec le fer aux concentrations utilisées. La stoechiométrie des complexes formés par le fer(III) et les ligands a été déterminée par la méthode de Job (12) dans ce mélange à pH 2 et pH 7 en maintenant une concentration constante de ligand. Le fer(III) a été utilisé sous forme de $Fe(NO_3)_3$ et conservé en milieu acide fort (HNO_3 10^{-2} M) afin d'éviter la formation d'hydroxydes de fer (13). Le rapport $[Fe(NO_3)_3]/[\text{ligand}]$ n'a jamais été supérieur à deux fois la stoechiométrie car l'absorption entre 350 et 450 nm du nitrate de fer excédentaire augmentait beaucoup l'absorbance totale et pertubait la détermination des coefficients d'absorption molaire.

Nous avons déterminé ainsi la stoechiométrie des complexes formés par les ligands **1***a*, **1***b* et **1***c* avec le fer(III). L'ensemble des résultats est présenté dans le tableau 1. Les figures 3 et 4 représentent les courbes Absorbance = $f([\text{fer(III)}]/[\text{ligand}])$ à pH 2 et pH 7. Le maximum d'absorption, situé à 420 nm à pH 7, s'est déplacé à 470 nm à pH 2. Cette variation s'est accompagnée d'un changement de couleur des solutions qui de jaune orangé sont devenues rouge pâle. L'analyse des courbes a révélé une stoechiométrie 2 : 3 à pH 7 et 1 : 1 à pH 2 dans tous les cas. Les résultats sont résumés dans le tableau 1. L'étude de la variation de l'absorbance en fonction du pH a montré l'existence de points isosbestiques à 450–460 nm.

Étude par voltamétrie cyclique

Les complexes fer(III)–hydroxamates ont fait l'objet de très nombreuses études électrochimiques (14–17) visant à mieux comprendre les mécanismes de transport du fer dans les microorganismes producteurs de sidérophores. Ces études ont montré que dans ces complexes l'ion fer(III) était réduit à des valeurs de potentiel assez fortement négatives conduisant à des complexes de fer(II) beaucoup moins stables. La plupart de ces études ayant été réalisées en utilisant l'eau comme solvant, il nous a paru indispensable, compte tenu de l'insolubilité des ligands **1** dans ce solvant, d'effectuer une étude électrochimique préalable des complexes du fer(III) avec les ligands **2** et **3** dans le mélange méthanol–eau (70 : 30) et de comparer les caractéristiques de ces complexes avec celles des complexes fer(III) – ligands **1** dans les mêmes conditions (solvant, pH, force ionique). Les résultats sont rassemblés dans le tableau 2.

Dans le solvant utilisé et en milieu acide fort (HNO_3 0,10 M), la réduction du fer(III) en fer(II) est irréversible avec des potentiels cathodiques et anodiques respectivement de +0,26 et +0,90 volt ($E_{p1/2}$ = +0,60 V).

Avec l'acide acétohydroxamique **2**, l'étude a été menée à pH 6,9 et pH 2 pour des rapports fer(III)/**2** variable (fig. 5). À pH 6,9, le voltammogramme présente pour un rapport supérieur ou égal à 3 une vague quasi réversible à $E_{1/2} = -0,62$ V correspondant à la réduction du complexe fer(III)–$(\mathbf{2})_3$. À pH 2, quelques soient les valeurs du rapport fer(III)/**2**, on observe la présence de complexes fer(III)–$(\mathbf{2})_3$ et fer(III)–$(\mathbf{2})_3^+$, la réduction de ces deux complexes se manifestant par deux vagues irréversibles quelque soit la vitesse de balayage.

Le comportement de la déferriferrioxamine **3** est différent dans la mesure où l'on n'observe qu'une seule espèce réductible entre pH 1,5 et 7 caractérisée par une vague quasi réversible ($E_{1/2} = -0,70$ V) à cette dernière valeur de pH (fig. 6). Les

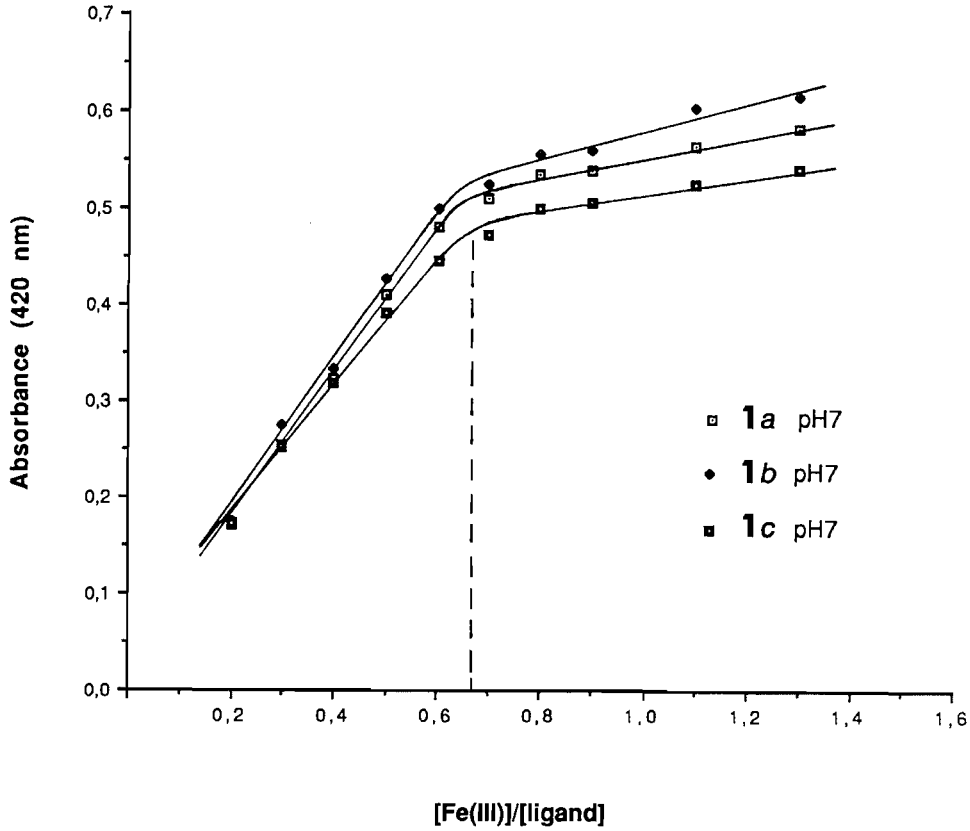

FIG. 3. Détermination de la stoechiométrie en solution des complexes fer(III)–**1***a*, fer(III)–**1***b*, fer(III)–**1***c*. Absorbance à 420 nm = *f*([fer(III)]/[ligand]). [Ligand] = $2{,}9 \times 10^{-4}$ M, pH 7, $NaNO_3$ 0,010 M, méthanol–eau (70 : 30).

TABLEAU 2. Valeurs des potentiels électrochimiques (V) des complexes fer(III)–**1**, fer(III)–**2** et fer(II)–**3** en fonction du pH

		Ligands					
		2	**3**	**1***a*	**1***b*	**1***c*	**1***d*
pH 1–2	red.	−0,26 / −0,60	−0,73	−0,18 / −0,58	−0,36 / −0,75	—	−0,30
	ox	—	—	—	—	—	−0,75
		Irréversible	Irréversible	Irréversible	Irréversible	Adsorption sur électrode	Irréversible
pH 7	red	−0,67	−0,77	−0,75 / −0,63	−0,72 / −0,60	−0,72 / −0,54	−0,75
	ox	−0,58	−0,65	−0,34	−0,30	−0,36	—
	$E_{1/2}$	−0,62	−0,70				
		Quasi réversible	Quasi réversible	Quasi réversible	Quasi réversible	Quasi réversible	Irréversible

valeurs de $E_{1/2}$ observées pour les complexes de fer(III) avec les ligands **2** et **3** sont pratiquement identiques dans le mélange méthanol–eau (70 : 30) et dans l'eau (14, 15, 18) à pH 7–7,5.

Les voltammogrammes des complexes **1***a–d* avec le fer(III) ont été enregistrés dans les mêmes conditions que ci-dessus en utilisant une concentration de $5{,}0 \times 10^{-3}$ M en fer(III) et $7{,}5 \times 10^{-3}$ M en ligand (fig. 7). À pH 7, on observe pour les complexes avec **1***a–d* une seule vague quasi réversibles vers −0,70 V attribuable aux complexes de stoechiométrie $Fe_2(\mathbf{1})_3$. Cette valeur est très proche de celle mesurée pour le complexe avec l'acide rhodotorulique (−0,65 V) (19). À pH 2, on observe avec les ligands **1***a*, **1***b* et **1***d* deux espèces réductibles entre 0 et −0,70 V. Il s'agit sans doute des complexes fer(III)–L^+ et fer$(III)_2$–L_3 en équilibre. Avec **1***c*, un important courant de réduction apparait dès −0,4 V qui ne peut être attribué à la réduction d'un complexe de fer(III) : dans ce cas il y a sans doute un phénomène d'adsorption sur l'électrode dû peut-être à la présence dans ce ligand d'un noyau pyridine non substitué.

Détermination de la constante de formation des complexes fer(III)–ligand dihydroxamique

La stabilité des complexes fer(III)–dihydroxamate a pu être exprimée à l'aide des constantes β_{110} et β_{230} correspondant aux équilibres suivants :

$$Fe^{3+} + L^{2-} \rightleftharpoons FeL^{+}$$

$$\beta_{110} = \frac{[FeL^{+}]}{[Fe^{3+}][L^{2-}]}$$

$$2Fe^{3+} + 3L^{2-} \rightleftharpoons Fe_2L_3$$

$$\beta_{230} = \frac{[Fe_2L_3]}{[Fe^{3+}]^2[L^{2-}]^3}$$

Toutefois, ces constantes ne caractérisent qu'imparfaitement les équilibres de formation des complexes. Ceux-ci sont en effet

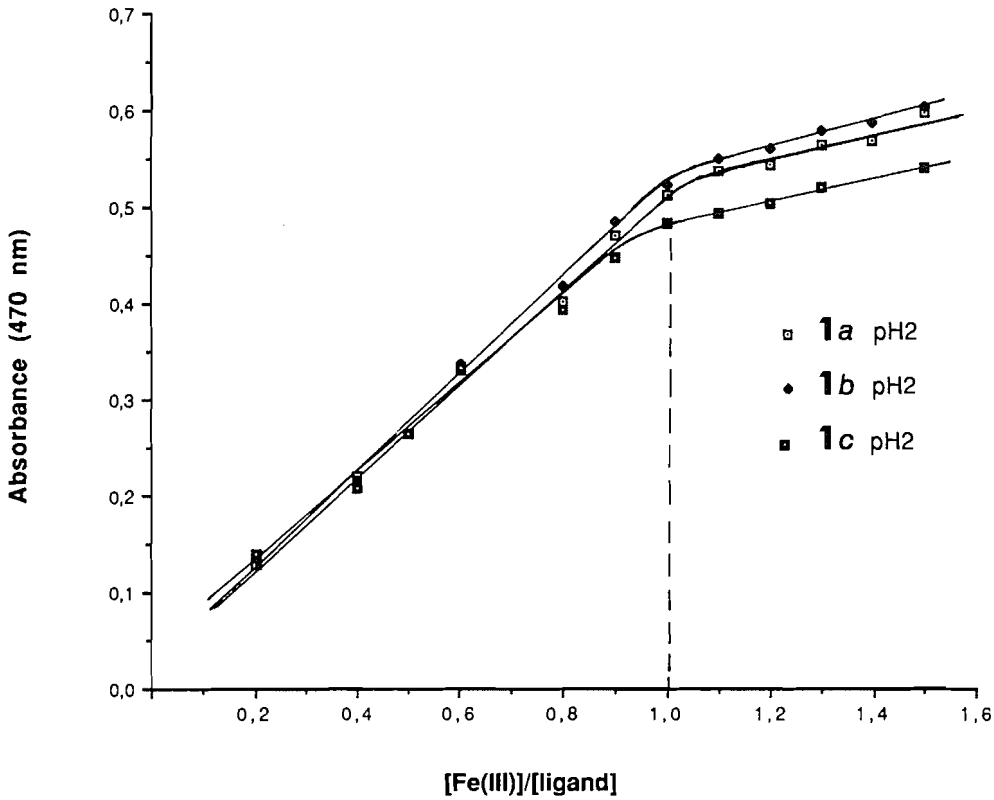

FIG. 4. Détermination de la stoechiométrie en solution des complexes fer(III)–**1***a*, fer(III)–**1***b*, fer(III)–**1***c*. Absorbance à 470 nm = *f*([fer(III)]/[ligand]). [Ligand] = $2{,}9 \times 10^{-4}$ M, pH 2, $NaNO_3$ 0,010 M, méthanol–eau (70 : 30).

dépendants du pH puisque, pour des pH inférieurs à 7, les acides hydroxamiques, de pK_a voisins de 9, sont en grande partie non dissociés et que l'ion Fe^{3+} est hydrolysé. Les équilibres tenant compte de l'influence du pH sont :

$$Fe^{3+} + H_2L \rightleftharpoons FeL^+ + 2H^+$$

$$2Fe^{3+} + 3H_2L \rightleftharpoons Fe_2L_3 + 6H^+$$

La constante d'équilibre effective K_{eff} pour le premier équilibre s'écrit (12) :

$$\log K_{eff} = \log \beta_{FeL} - n \log \alpha_L{}^{-1}$$

avec

$$\alpha_L = (1 + \beta_{011}[H^+] + \beta_{012}[H^+]^2 + \ldots)^{-1}$$

où

$$\beta_{01n} = \frac{[LH_n]^{n+}}{[H^+]^n[L]}$$

sont les constantes d'acidité globales du ligand.

La détermination des constantes de stabilité des complexes fer(III)–dihydroxamate nécessitant une quantité de ligands assez importante, seule la constante du complexe FeL^+ avec le ligand **1***a* a pu être déterminée. Pour l'obtenir, les valeurs des pK_a des groupements hydroxamiques du ligand **1***a* ont été déterminées par titration potentiométrique dans le mélange méthanol–eau (30 : 70). Pour comparaison, le pK_a de **2** a été déterminé dans les mêmes conditions de solvant et dans l'eau pure. Les valeurs de pK_a sont rassemblées dans le tableau 3. On constate

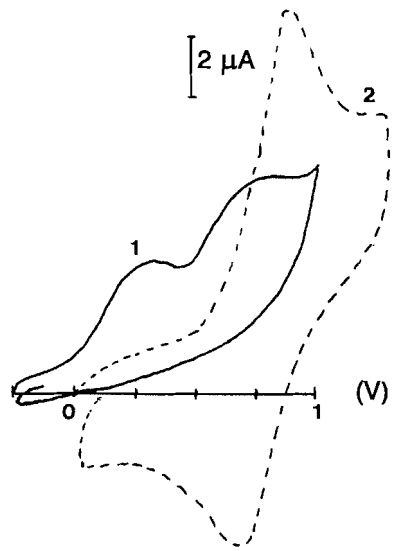

FIG. 5. [Acide acétohydroxamique] = 10 mM, [fer(III)] = 1,0 mM dans le mélange méthanol–eau (70 : 30); électrode de carbone vitreux vs. SCE, 100 mV/s. 1: pH 2; 2: pH 6,9.

que les valeurs sont un peu plus élevées (0,2 à 0,5 unités de pK_a) dans le mélange méthanol–eau (30 : 70) que dans l'eau pure.

La constante d'équilibre pour la réaction : $Fe^{3+} + H_2L \rightleftharpoons FeL^+ + 2H^+$ a été déterminée à pH 1, pour lequel le complexe FeL^+ était seul présent, en mesurant l'absorption entre 350 et 600 nm d'une solution $3{,}0 \times 10^{-4}$ M du ligand **1***a*, en présence de quantités croissantes de Fe^{3+} et en utilisant la valeur ϵ_{470} pour le complexe FeL^+. La constante K_{eff} ainsi obtenue (log K_{eff} = 2,32) à été utilisée pour déterminer log β_{110} = 21,3, à pH 1, con-

For personal use only.

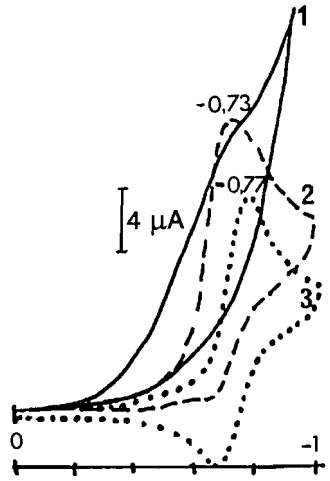

FIG. 6. [3] = 3,0 mM, [fer(III)] = 1,0 mM dans le mélange méthanol–eau (70 : 30); électrode de carbone vitreux vs. SCE, 100 mV/s. 1: pH 1,5; 2: pH 4,4; 3: pH 7.

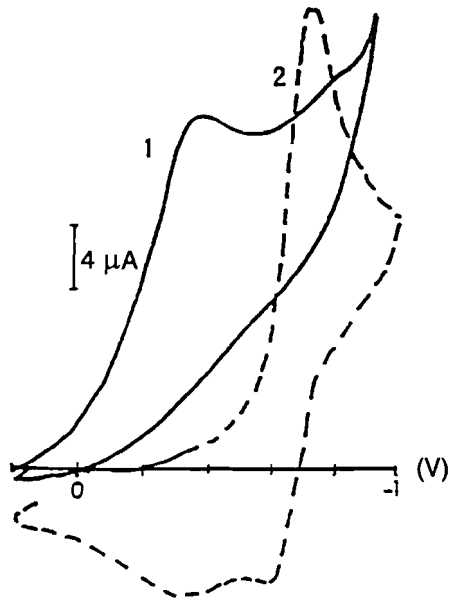

FIG. 7. [1*b*] = 7,5 mM, [fer(III)] = 5,0 mM dans le mélange méthanol–eau (70 : 30); électrode de carbone vitreux vs. SCE, 100 mV/s. 1: pH 1,6; 2: pH 7,1.

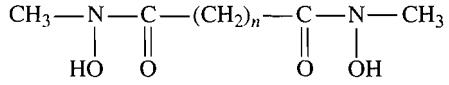
naisant log β_H (avec = $\beta_H = [H_2L]/[H^+][L^{2-}]$). Cette valeur, en accord avec les données obtenues avec d'autres dihydroxamates (19), est un peu plus faible que les valeurs de log β_{110} mesurées par Raymond et coll. (20) pour les complexes FeL^+ où L sont des dihydroxamates de formule générale :



Cette stabilité un peu plus faible du complexe fer(III) – ligand **1***a* est peut être due à des effets stériques provenant de la rigidité du cycle pyridinique et des liaisons amides dans ce complexe.

Nous n'avons pu déterminer la constante log β_{230} pour ce complexe en raison de sa valeur trop élevée.

TABLEAU 3. Valeurs des pK_a de l'acide hydroxamique (AH) et du ligand **1***a* mesurées dans l'eau pure et dans le mélange méthanol–eau (30 : 70)

Ligand	pK_a Mélange H_2O–MeOH	pK_a H_2O
AH[a]	9,95	9,36
	9,16	8,60
1*a*	9,95	9,36
	8,90	8,34

[a]AH = $CH_3N(OH)C(O)(CH_2)_8C(O)N(OH)CH_3$.

Détermination et comparaison de la relaxivité des complexes fer(III)–1d et Gd(DTPA)

En présence d'une espèce paramagnétique, les vitesses de relaxation du spin nucléaire $1/T_1$ et $1/T_2$ se décomposent en la somme d'une contribution diamagnétique du solvant (mouvements moléculaires et échanges chimiques) et d'une contribution de l'espèce paramagnétique (21). In vivo, la contribution diamagnétique en $1/T_1$ est beaucoup plus faible que celle en $1/T_2$. Les contributions paramagnétiques étant équivalentes, l'addition d'un agent paramagnétique a une influence beaucoup plus grande sur le temps de relaxation spin-réseau T_1 que sur le temps de relaxation spin–spin T_2 (22). Nous n'avons donc considéré que l'effet des agents paramagnétiques sur le temps de relaxation T_1, en négligeant les effets sur le temps T_2.

En solution aqueuse, la vitesse de relaxation des noyaux d'hydrogène de l'eau dépend de la concentration c de l'espèce paramagnétique selon la relation expérimentale : $v = v_0 + Rc$ où v_0 est la vitesse de relaxation en absence d'agent paramagnétique et R la relaxivité (mol^{-1} L s^{-1}). R est une fonction complexe des distances et des interactions entre l'espèce paramagnétique et l'eau. Après transformée de Fourier du signal des noyaux d'hydrogène de l'eau, nous avons mesuré l'aimantation de l'échantillon $M_z(t)$ dont la loi d'évolution est : $M_z(t) = A + B \exp(-t/T_1)$ où A et B sont des paramètres tenant compte de la réponse du spectromètre et de l'efficacité de l'impulsion de 180°. Les données ont été traitées par une méthode de moindres carrés non linéaire pour ajuster les paramètres A, B et T_1.

Les deux ions ferriques du complexe $Fe_2(\mathbf{1}d)_3$ étant indépendants, nous avons déterminé les relaxivités par rapport aux concentrations en ion métallique dans chaque cas. La figure 8 représente les droites $1/T_1 = f([\text{Ligand}])$ dont les pentes sont égales à la relaxivité. Les vitesses de relaxation d'un ion fer(III) dans la structure dimère créée en solution avec le ligand **1***d*, dans le domaine de concentration étudié, sont 5 fois plus faibles que celles du complexe Gd(DTPA) dans les mêmes conditions. Ceci se traduit par des valeurs de relaxivité de $4{,}9 \times 10^{-3}$ M^{-1} s^{-1} et $26{,}0 \times 10^{-3}$ M^{-1} s^{-1} respectivement.

Conclusion

L'étude rapportée ci-dessus montre que les ligands **1***a–d* se comportent en solution vis-à-vis du fer(III) de manière très comparable à l'acide rhodotorulique, que ce soit pour la stoechiométrie des complexes, leurs propriétés électrochimiques et la constante de dissociation mesurée avec le ligand **1***a* à pH 1. Ces similitudes suggèrent que le noyau pyridine et les fonctions amides présents dans ces ligands n'entrent pas en compétition avec les groupements hydroxamates pour la com-

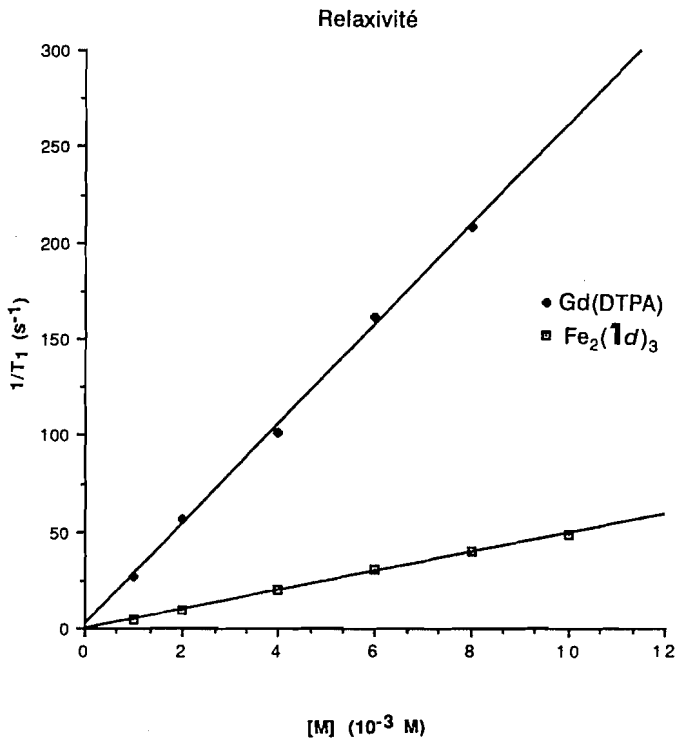

FIG. 8. Courbes $1/T_1 = f([M])$ pour les complexes $Fe_2(\mathbf{1}d)_3$ et Gd(DTPA).

plexation du fer(III). On a pu constater aussi qu'il n'y avait pas de variations sensibles de ces propriétés en remplaçant l'eau comme solvant par un mélange méthanol–eau. La stabilité élevée et la forte relaxivité de ces complexes en font des produits de contraste pour l'IRM potentiellement intéressants. Leur trop faible solubilité dans l'eau constitue toutefois un handicap important qui ne pourra être surmonté qu'en rendant les ligands eux mêmes plus hydrosolubles par l'introduction de substituants chargés positivement ou négativement.

LUIS CAMACHO, JUAN JOSÉ RUIZ, CARMEN SERNA, ANGELA MOLINA, and FRANCISCO MARTÍNEZ-ORTIZ. Can. J. Chem. **72**, 2369 (1994).

A rigorous analytical solution to reverse pulse techniques for a plane electrode expanding with an arbitrary power of time is presented. Our results include the plane approximation for SMDE as well as the expanding plane electrode model for DME. In the case of SMDE, our results have been contrasted with those obtained by numerical solution of the problem, obtaining identical results. Finally, we have compared our treatment with previous solutions in literature.

LUIS CAMACHO, JUAN JOSÉ RUIZ, CARMEN SERNA, ANGELA MOLINA et FRANCISCO MARTÍNEZ-ORTIZ. Can. J. Chem. **72**, 2369 (1994).

On présente une solution analytique rigoureuse pour renverser les techniques de pulsation d'une électrode plane en expansion avec une puissance arbitraire du temps. Nos résultats incluent l'approximation plane de la SMDE ainsi que le modèle de l'électrode plane en expansion de la SME. Dans le cas de la SMDE, on a comparé nos résultats avec ceux obtenus par la solution numérique du problème et les résultats obtenus sont les mêmes. Enfin, on a comparé notre traitement avec les solutions proposées antérieurement dans la littérature.

Introduction

Many authors have studied the problem of the *i–t* Faradaic response of a slow charge transfer reaction to a second potential pulse for several electrode models (1–8). Their solutions can be used in Reverse Pulse (RP) techniques: Reverse Pulse Voltametry (RPV, stationary plane electrode) or Reverse Pulse Polarography (RPP, expanding plane electrode). This application has been explicitly carried out in certain papers (1, 8), while in others the obtained solutions were used only in Differential Pulse (DP) techniques (2–7).

Among double pulse techniques, RP is the least complex and, without doubt, the most powerful in kinetic applications. Up-to-date RP has been applied to the analysis of limiting currents (9–11) yielding qualitative information on the degree of reversibility of the electrode process; this information is similar to that obtained from cyclic voltametry (12). However, the complexity in the resulting analytical solutions and, more importantly, the controversy over the rigor of these solutions, have limited their kinetic applications in practice.

As far as we know, only the equations derived by Matsuda (1); Aoki et al. (3) (expanding plane electrode), and Lovric and Osteryoung (2) and Aoki and Osteryoung (4) (stationary plane electrode) are mathematically rigorous for a slow charge transfer reaction; however, the analytical response deduced by these authors is given by complex integral equations which should be solved numerically in each particular case. The authors of other papers claim to have obtained a rigorous analytical solution to the problem; however, in most of these papers some kind of approximation was used (5-8). These approximations are, in general, very interesting but sometimes not explicitly assumed in the paper. One of the more frequently used approximation is the analytical expression of surface concentrations and concentration gradient of the first pulse remain unaltered during the second pulse, that is to say, the bases of the superposition principle have been applied under conditions in which this principle is not applicable. The applicability of superposition principle to yield rigorous results is restricted to reversible systems, it depends on electrode geometry and on the values of diffusion coefficients of the electroactive couple (2, 13–17).

This paper is to present a rigorous and closed analytical solution to a plane electrode expanding with an arbitrary power of time under conditions relevant to RP techniques, i.e., when the boundary conditions selected for the application of the second pulse correspond to a first step controlled by diffusion. Our results, which used plane approximation for SMDE and expanding plane electrode model for DME, are in excellent agreement with the results obtained by numerical solutions (18, 19). In certain cases, we have also reproduced our solutions using Laplace Transforms.

Theory

Let us consider the following charge-transfer reaction

$$[1] \qquad A + ne^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} B$$

and assume that the area of the plane electrode $q(t) = q_0 t^z$, increases with any power $z \geq 0$ of time t($z = 2/3$ for a DME and $z = 0$ for the planar approximation of a SMDE). Operator $\hat{D}_i$ is given by (20)

$$[2] \qquad \hat{D}_i = \frac{\partial}{\partial t} - D_i \frac{\partial^2}{\partial x^2} - \frac{zx}{t} \frac{\partial}{\partial x} \qquad i = \text{A or B}$$

We shall denote by E_1, E_2, and t_1, t_2, the potential and

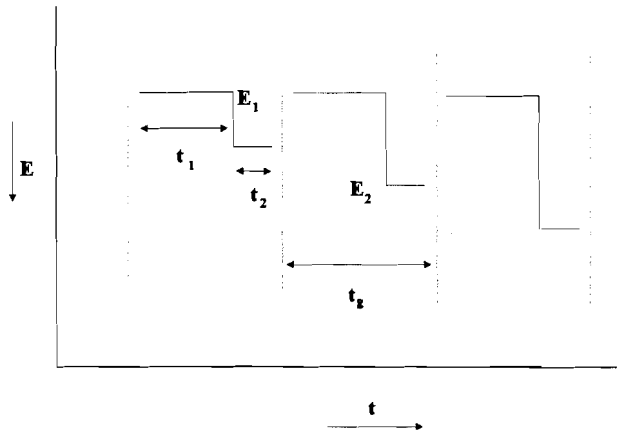

FIG. 1. Potential–time waveform corresponding to the RP technique.

time durations of each pulse, respectively. Likewise, we shall assume these potentials to be superimposed to a linear ramp of potential, which is only effective in successive drops of life time t_d (see Fig. 1). In the RP technique E_1 is always constant and corresponds to a potential at which the reduction process is controlled by diffusion, whereas E_2 shifts to anodic potentials. However, these potential conditions will be applied later. The corresponding currents for each pulse will be called i_1 and i_2, respectively. The signal used in the RP technique is given by $i_2 = i_{RP}$

The experimental time may be divided into two periods. In the first period ($0 \leq t \leq t_1$) the potential is maintained at value E_1. Under these conditions the concentration profiles $C_A^1(x,t)$ and $C_B^1(x,t)$ and the current–time response are given by (21)

$$[3] \qquad \frac{C_A^1(x,t)}{C_A^*} = \frac{C_A^1(s1_A,\chi)}{C_A^*} = 1 + \frac{1}{1+\gamma K_1} \times \sum_{j=1} \frac{(-1)^j \psi_j^z(s1_A)}{\prod_{k=1}^{j} p_k(z)} \chi^j$$

$$[4] \qquad \frac{C_B^1(x,t)}{C_A^*} = \frac{C_B^1(s1_B,\chi)}{C_A^*} = -\frac{\gamma}{1+\gamma K_1} \times \sum_{j=1} \frac{(-1)^j \psi_j^z(s1_B)}{\prod_{k=1}^{j} p_k(z)} \chi^j$$

$$[5] \qquad i_1(t) = nFq_0 t^z \sqrt{\frac{(2z+1)D_A}{\pi t}} \frac{F_z(\chi)}{1+\gamma K_1} C_A^*$$

where

$$[6] \qquad \psi_j^z(s1_i) \equiv \psi_{j/(2z+1)}(s1_i)$$

are the Koutecky functions (22)

$$[7] \qquad \begin{cases} s1_i = \sqrt{\dfrac{(2z+1)}{4tD_i}}\, x \\ \chi = \sqrt{\dfrac{4t}{(2z+1)D_A}} \dfrac{1+\gamma K_1}{K_1^\alpha} k_s \end{cases}$$

$$[8] \qquad K_i = \exp \frac{nF}{RT}(E_i - E^0)$$

and $p_k(z)$ and $F_z(\chi)$ are given in Appendix A.

From $t \geq t_1$ the potential is maintained at E_2. Thus during the second period $0 \leq \tau_2 \leq t_2$ with $t = t_1 + \tau_2$ and the operator $\hat{D}_i$ becomes

$$[9] \qquad \hat{D}_i = \frac{\partial}{\partial \tau_2} - D_i \frac{\partial^2}{\partial x^2} - \frac{zx}{(t_1+\tau_2)} \frac{\partial}{\partial x}$$

the boundary value is now given by

$$[10] \qquad \hat{D}_A C_A = \hat{D}_B C_B = 0$$

$$[11] \qquad \left.\begin{array}{l} \tau_2 = 0,\ x \geq 0 \\ \tau_2 \geq 0,\ x \to \infty \end{array}\right\} \begin{array}{l} C_A^2(x,t) = C_A^1(x,t) \\ C_B^2(x,t) = C_B^1(x,t) \end{array}$$

At $\tau_2 > 0$, $x = 0$

$$[12] \qquad D_A \left(\frac{\partial C_A^2(x,t)}{\partial x}\right)_{x=0} = -D_B \left(\frac{\partial C_B^2(x,t)}{\partial x}\right)_{x=0} = \frac{i_2}{nFq(t)}$$

$$[13] \qquad \frac{i_2}{nFq(t)} = \frac{k_s}{K_2^\alpha}\left(C_A^2(x=0,t) - K_2 C_B^2(x=0,t)\right)$$

As differential equations [10] are linear (see eq. [2] or [9]), any linear combination of solutions is also a solution. Thus, we will suppose that $C_A^2(x,t)$ and $C_B^2(x,t)$ have the form

$$[14] \qquad \begin{array}{l} C_A^2(x,t) = C_A^1(x,t) + \tilde{C}_A(x,t) \\ C_B^2(x,t) = C_B^1(x,t) + \tilde{C}_B(x,t) \end{array}$$

where the superscripts of C_A^i and C_B^i ($i = 1$ or 2) refer to first and second pulse, respectively.

The new unknown functions $\tilde{C}_A(x,t)$ and $\tilde{C}_B(x,t)$ have the advantage that they are solutions for the problem with null initial conditions (see eq. [11]).

When using dimensionless parameters, it is appropriate to assume that $\tilde{C}_A(x,t)$ and $\tilde{C}_B(x,t)$ have the form (22, 23)

$$[15] \qquad \begin{cases} \tilde{C}_A(x,t) = \sum_{j,m} \phi_{j,m}(s2_A)\beta^{j/2} y^m \\ \tilde{C}_B(x,t) = \sum_{j,m} \delta_{j,m}(s2_B)\beta^{j/2} y^m \end{cases}$$

with

$$[16] \qquad s2_i = \frac{x}{2\sqrt{D_i \tau_2}}$$

$$[17] \qquad \beta = \frac{\tau_2}{t_1 + \tau_2}$$

$$[18] \qquad y = \sqrt{\frac{4\tau_2}{D_A}}\, k_s \frac{1+\gamma K_2}{K_2^\alpha}$$

Inserting eqs. [15]–[18] in [10], we obtain

$$[19] \qquad \phi''_{j,m}(s2_A) + 2s2_A \phi'_{j,m}(s2_A) - 2(j+m)\phi_{j,m}(s2_A) = -4zs2_A \phi'_{j-2,m}(s2_A) - 2(j-2)\phi_{j-2m}(s2_A)$$

[20] $$\delta''_{j,m}(s2_B) + 2s2_B\delta'_{j,m}(s2_B) - 2(j+m)\delta_{j,m}(s2_B) = -4zs2_B\delta'_{j-2,m}(s2_B) - 2(j-2)\delta_{j-2m}(s2_B)$$

when $E_1 \rightarrow -\infty(\chi \rightarrow \infty)$ from eqs. [3]–[4] we deduce

[21] $$C_A^1(s1_A = 0,\ \chi \rightarrow \infty) = 0$$

[22] $$C_B^1(s1_B = 0,\ \chi \rightarrow \infty) = \gamma C_A^*$$

[23] $$\gamma\left(\frac{\partial C_A^1(s1_A, \infty)}{\partial s1_A}\right)_{s1_A=0} = -\left(\frac{\partial C_B^1(s1_B, \infty)}{\partial s1_B}\right)_{s1_B=0} = \frac{2\gamma C_A^*}{\sqrt{\pi}}$$

[24] $$i_1(t) = i_{1d}(t) = nFq_0t^z\sqrt{\frac{(2z+1)D_A}{\pi t}}\,C_A^*$$

Therefore, for $\tau_2 \geq 0$, eq. [14] at the surface of electrode takes the form

[25] $$C_A^2(x=0,\ t) = \sum_{j,m}\phi_{j,m}(s2_A = 0)\beta^{j/2}y^m$$

[26] $$C_B^2(x=0,\ t) = \gamma C_A^* + \sum_{j,m}\delta_{j,m}(s2_B = 0)\beta^{j/2}y^m$$

and the surface concentration gradients of species A and B

[27] $$\left(\frac{\partial C_A^2(x,\ t)}{\partial x}\right)_{x=0} = \underbrace{\frac{\sqrt{2z+1}}{2\sqrt{D_At}}\left(\frac{2}{\sqrt{\pi}}\,C_A^*\right)}_{\text{First pulse component}} + \underbrace{\frac{1}{2\sqrt{D_A\tau_2}}\sum_{j,m}\phi'_{j,m}(s2_B = 0)\beta^{j/2}y^m}_{\text{Second pulse component}}$$

[28] $$\left(\frac{\partial C_B^2(x,\ t)}{\partial x}\right)_{x=0} = \underbrace{\frac{\sqrt{2z+1}}{\sqrt{2}D_Bt}\left(\frac{-2\gamma}{\sqrt{\pi}}\,C_A^*\right)}_{\text{First pulse component}} + \underbrace{\frac{1}{2\sqrt{D_B\tau_2}}\sum_{j,m}\delta'_{j,m}(s2_B = 0)\beta^{j/2}y^m}_{\text{Second pulse component}}$$

by substituting eqs. [14], [15] in eq. [11] we deduce that for $s_{2i} \rightarrow \infty$

[29] $$\delta_{j,m}(s2_B) = \phi_{j,m}(s2_A) = 0$$

from eq. [12] with eqs. [27] and [28], it is clear that for $s_{2i} = 0$

[30] $$\gamma\phi'_{j,m}(s2_A = 0) = -\delta'_{j,m}(s2_B = 0)$$

and from eqs. [13], [21], [22], [25]–[27] we obtain

[31] $$\sum_{j,m}\phi'_{j,m}(s2_A = 0)\beta^{j/2}y^m = -\frac{\gamma K_2}{1+\gamma K_2}\,C_A^*y + \frac{y}{1+\gamma K_2}\sum_{k,l}\left(\phi_{k,l}(s2_A = 0) - K_2\delta_{k,l}(s2_B = 0)\right)\beta^{k/2}y^l - 2\sqrt{\frac{2z+1}{\pi}}\,\beta^{1/2}C_A^*$$

In RP, the surface concentrations obtained by the application of first pulse are constant (see eqs. [21], [22]), as a consequence of the condition $E_1 \rightarrow -\infty$. However, it is clear that the first pulse component in the surface concentration gradient (eq. [27] or [28]) always depends on time. Therefore, when the second pulse is applied, the analytical expression of this gradient component changes. This variation is reflected in the last term or the right hand side of eq. [31]. Consequently, our treatment is strictly rigorous.

From eqs. [19], [20], [30], and [31], we deduce the following limiting conditions for the $\phi_{j,m}$ functions
As $s2_i \rightarrow 0$

[32] $$\phi'_{0,1} = -\frac{\gamma K_2}{1+\gamma K_2}\,C_A^*$$

[33] $$\phi'_{1,0} = -2\sqrt{\frac{2z+1}{\pi}}\,C_A^*$$

[34] $$\phi'_{j,m} = \phi_{j,m-1} \quad m \geq 1$$

[35] $$\phi'_{j,0} = 0 \quad \text{unless } j = 1$$

Following the procedure referenced in (23), we solve for the $\phi_{j,m}(s2_A)$ and $\delta_{j,m}(s2_B)$ functions and, therefore, the concentration profiles (which are given in eqs. [A4] and [A5] in Appendix A).

Inserting the $\phi_{j,m}(s2_A)$ function is eq. [13] leads to the following expression for i_{RP}

[36] $$i_{RP}(t) = i_{1d}(t) + nFq_0t^z\sqrt{\frac{D_A}{t_2}}\,C_A^*\{ZG_z(\beta, y) + \mu_dH_z(\beta, y)\}$$

[37] $$Z = -\frac{\gamma K_2}{(1+\gamma)K_2}$$

[38] $$\mu_d = -\frac{2}{y}\sqrt{\frac{(2z+1)\beta}{\pi}}$$

In eq. [36] the G_z series (which is given in Appendix A and refs. 8 and 23) is multiplied by Z. Taking into account that Z can also be written as (eqs. [13], [21], [22], [31])

[39] $$Z = \frac{C_A^1(s1_A = 0,\ \chi \rightarrow \infty) - K_2C_B^1(s1_B = 0,\ \chi \rightarrow \infty)}{C_A^*(1+\gamma K_2)}$$

In the second pulse, the G_z series multiplies the constant component of first pulse (see eqs. [39], [21], [22]). On the other hand, the series H_z (given in Appendix A) is multiplied

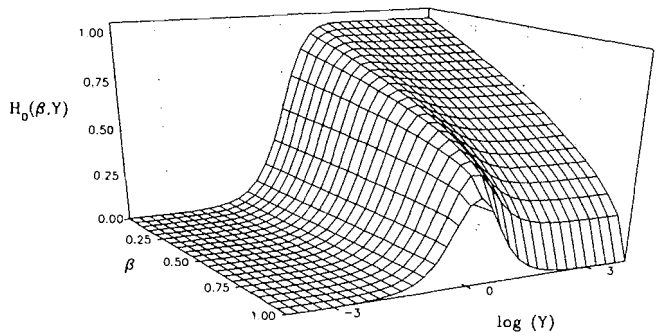

FIG. 2. 3D plot of $H_0(\beta, y)$ vs. β and log y.

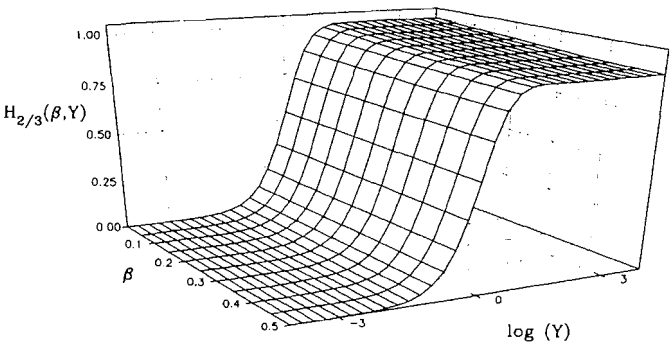

FIG. 3. 3D plot of $H_{2/3}(\beta, y)$ vs. β and log y.

by μ_d and appears as a consequence of the consideration of the disturbance suffered by the first pulse concentration gradient component due to the second pulse application.

i_{RP} was also deduced by making $E_1 \rightarrow -\infty (K_1 \rightarrow 0)$ in eq. [7] in ref. 23. However, eq. [36] differs from eq. [32] in ref. 8, due to the fact that in the deduction of this last equation, the disturbance of the surface gradient of species A originated by the second pulse application is not taken into account. For this reason, in ref. 8 only the G_z series appears.

Results and discussion

Previous to this study, we performed a careful analysis of the properties of the $H_z(\beta, y)$ function (see appendix A). A 3D plot of $H_0(\beta, y)$ is shown in Fig. 2. For $\beta \rightarrow 0$, $H_z(0, y) = G_z(0, y) = F_0(y)$. As β increases and approaches unity, the absolute value of the H_0-function decreases, showing a maximum for y values close to 5.

An analogous plot for $H_{2/3}(\beta, y)$ (Fig. 3) shows a shape similar to Fig. 2. In order to guarantee high accuracy, only the values of $H_{2/3}$ corresponding to $\beta \leq 0.5$ have been presented in Fig. 3. The function $H_{2/3}$ has been evaluated with only five terms of the sum in β, since the general term of this series could not be obtained because of its mathematical complexity (see comments in appendix A). As can be observed, these curves are less dependent on β than those in Fig. 2.

The behavior of eq. [36] has been exhaustively studied and has been compared with the solution given in ref. 8, as well as with the numerical solution obtained in Appendix B (see eqs. [B13]–[B15]). In Fig. 4 the plot of i_{RP}/i_{DC} vs. $E_2 - E^0$ ($i_{DC} = nFq_0t^z\sqrt{D_A/(\pi t_2)}\,C_A^*$) is shown for $k_s = 10^{-4}$ cm/s, $t_1 = 1$ s, $t_2 = 0.4$ s, and $z = 0$. As can be observed, the three solutions almost coincide in the potential range studied. This behavior indicates that, from a practical point of view,

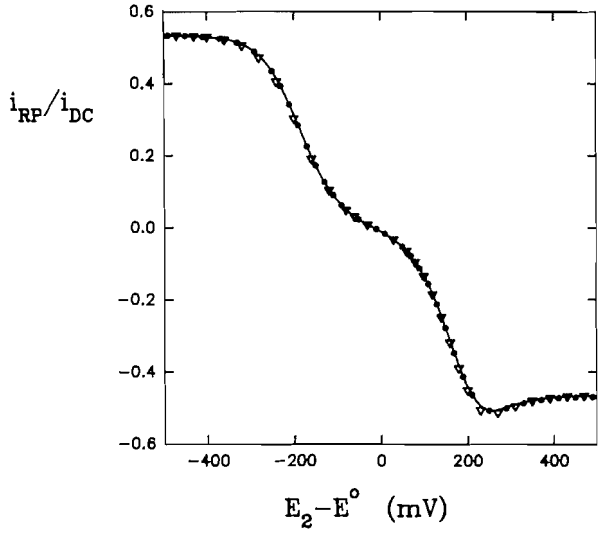

FIG. 4. Plot of i_{RP}/i_{DC} vs. $E_2 - E^0$ for $k_s = 10^{-4}$ cm s^{-1}, $t_1 = 1$ s, $t_2 = 0.4$ s, $n = 1$, $\alpha = 0.5$, $D_A = 10^{-5}$ cm^2 s^{-1}, $\gamma = 1$, and $z = 0$. Solid line corresponds to the predictions of eq. [36]. Triangles correspond to the solution given in ref. 8. Circles correspond to the numerical solution given in Appendix B (eq. [B13] with $r = 160$).

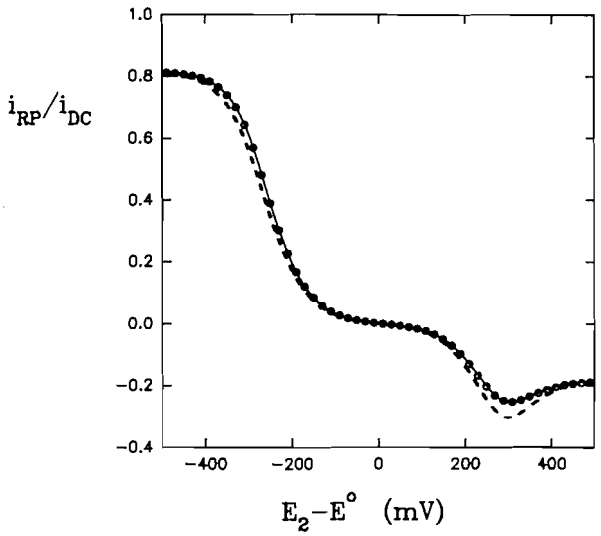

FIG. 5. Plot of i_{RP}/i_{DC} vs. $E_2 - E^0$ for $k_s = 10^{-5}$ cm s^{-1}, $t_1 = 1$ s, $t_2 = 2$ s, $n = 1$, $\alpha = 0.5$, $D_A = 10^{-5}$ cm^2 s^{-1}, $\gamma = 1$, and $z = 0$. Solid line corresponds to the predictions of eq. [36]. Dashed line corresponds to the solution given in ref. 8. Circles correspond to the numerical solution given in Appendix B (eq. [B13] with $r = 160$).

the three analyzed solutions are numerically indistinguishable, even for relatively high values of β in a typical experimental record such as that in Fig. 4 ($\beta = 0.4/1.4 = 0.285$). For $z = 2/3$ the behavior (not shown) is similar.

For larger values of β some deviations are observed in the solution given in ref. 8 with respect to that obtained from eq. [36] and [B15]. In Fig. 5 we have plotted i_{RP}/i_{DC} vs. $E_2 - E^0$ for $k_s = 10^{-5}$ cm/s, $\beta = 2/3$, and $z = 0$. The results obtained from eq. [36] and from the numerical solution of Appendix B are in total agreement. This concordance is maintained for all of our calculations indicating the rigorous character of our treatment (eq. [36]). In Fig. 5, one can also observe how the variation of i_{RP} obtained from the solution given in ref. 8 (dashed line) is different. This discrepancy is only evident in

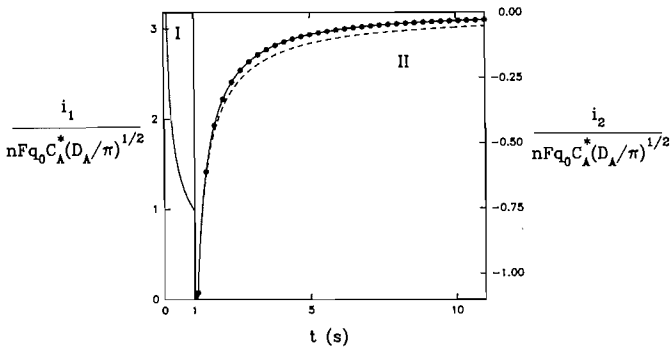

FIG. 6. Plot of $i_j/[nFq_0C_A^*(D_A/\pi)^{1/2}]$ vs t. Part I corresponds to the variation of i_1 (eq. [24]) for $t_1 \leq 1$ s. Part II corresponds to the variation of $i_2 = i_{RP}$ for $t \leq 10$ s and $E_2 - E^0 = 300$ mV. Other conditions as in Fig. 4.

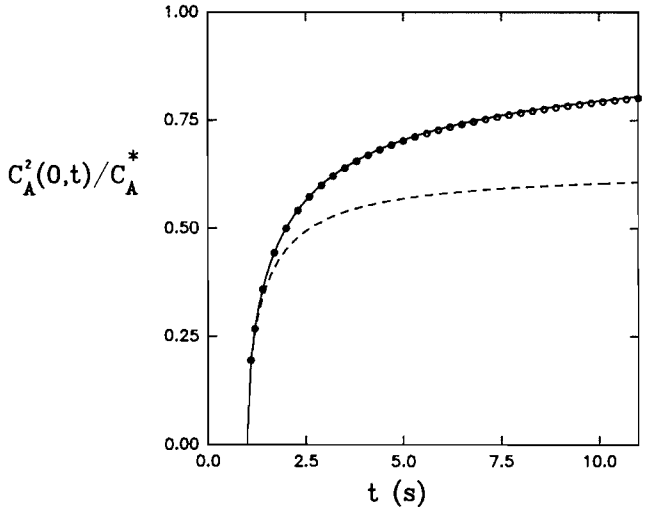

FIG. 7. Plot of $C_A^2(0,t)/C_A^*$ vs t. Solid line corresponds to eq. [40] and dashed line to eq. [45], in both cases with $z = 0$, $k_s \ll 1$ cm s^{-1} and $E_2 \simeq E^0$. Circles corresponds to eq. [B16] with $k_s = 10^{-7}$ cm s^{-1}, $E_2 - E^0 = 0$, and $r = 160$. $t_1 = 1$ s, $t_2 = 10$ s. Other conditions as in Fig. 4.

the extreme conditions under which Fig. 5 has been obtained. The deviations are more prominent at the potential region near the peak, where the error amounts to 18%. To appreciate the magnitude of the deviations at this potential, we have plotted as Fig. 6 a theoretical i–t curve for the same conditions as those of Fig. 5, for $E_2 - E^0 = 300$ mV. Part I of Fig. 6 represents the current (i_1) due to the application of first pulse ($t \leq t_1 = 1$ s and $E_1 - E^0 \longrightarrow -\infty$, eq. [24]), while part II corresponds to the current ($i_2 - i_{RP}$) during the application of second pulse ($t > t_1, t_2 = 10$ s and $E_2 - E^0 = 300$ mV). Again, a total concordance between numerical solution and eq. [36] is observed, while the results obtained from the solution given in ref. 8 only agree for small values of t. For $t - t_1 > 0.5$ s some deviations are observed. For $t_2 = 5$ s the error amounts to 30%.

The solutions from ref. 8 leads to a reasonable agreement with the rigorous solution for i_{RP} (eq. [36]), provided β is small. In general, $\beta = 0.33$ may be considered a limit for the correct use of the solution in ref. 8, as the error is always less than 10%.

Experimentally, deviations from the rigorous solution can

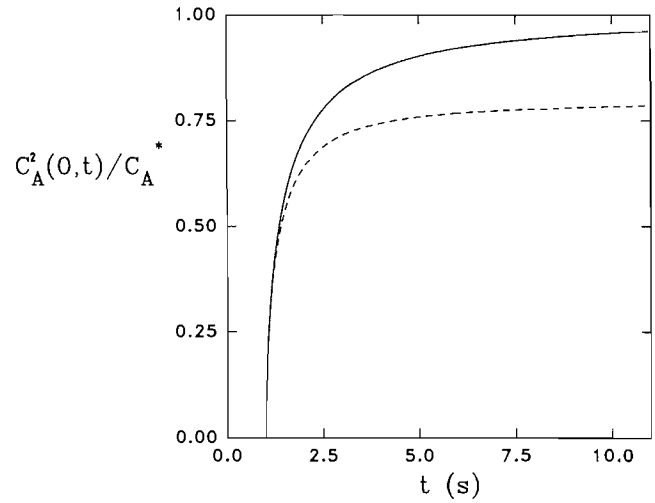

FIG. 8. Plot of $C_A^2(0,t)/C_A^*$ vs t. Solid line corresponds to eq. [40] and dashed line to eq. [45], in both cases with $z = 2/3$, $k_s \ll 1$ cm s^{-1}, $E_2 \simeq E^0$, $t_1 = 1$ s, $t_2 = 10$ s. Other conditions as in Fig. 4.

be observed in careful experiments similar to those described in Figs. 5 and 6.

There is no mention in the literature about the problems inherent to the solution in ref. 8 analyzed in this paper. The reason being experimentally, the RP technique has so far been used for $\beta \leq 0.1$, and therefore the wrong behavior of the solution in ref. 8 cannot be observed.

The final analysis of the three solutions compares the time dependence of surface concentration of reactant, $C_A^2(0,t)$. For this purpose, we have used eq. [A5], corresponding to the prediction made in this paper, eq. [A7] corresponding to the solution given in ref. 8 and eq. [B16], corresponding to the numerical solution to the problem.

Figures 7 and 8 show theoretical curves of $C_A^2(0,t)$ vs. t for $t_1 = 1$ s and $t_2 = 10$ s for $z = 0$ (Fig. 7) and for $z = 2/3$ (Fig. 8). When $t < t_1$ the surface concentration of reactant is zero as a consequence of the large negative potential applied ($E_1 - E^0 \longrightarrow -\infty$). When $t > t_1$ a total agreement between our treatment (eq. [A5]) and our numerical solution (eq. [B16]) is observed, while the values of $C_A^2(0,t)$ obtained from eq. [A7] differ notably from the others. The conditions imposed in Figs. 7 and 8 correspond to a limiting reduction process, selected to quarantee that there is no anodic or cathodic current so that $i_{RP} \longrightarrow 0$. Moreover, under these conditions $\mu_d \gg Z$ (eqs. [37], [38]). Physically, the situation is such that, as a consequence of the absence of any Faradaic current, the surface concentration of species A must return to its initial value: $C_A^2(0, t_2 \longrightarrow \infty) \longrightarrow C_A^*$.

If the conditions of Fig. 7 ($y \ll 1$) are applied to eq. [A5], the following expression is obtained

$$[40] \qquad \frac{C_A^2(0,t)}{C_A^*} = \frac{2}{\pi}\sqrt{(2z+1)\beta}\, h_z(\beta)$$

where

$$[41] \qquad h_0(\beta) = 1 + \sum_{k=1}^{\infty} \frac{(2k-1)!\beta^k}{2^{2k-1}k!(k-1)!(2k+1)}$$

$$[42] \qquad h_{2/3}(\beta) = 1 + \frac{\beta}{18} + \frac{\beta^2}{1080} - \frac{7\beta^2}{1296} - \frac{461\beta^4}{93312} - \cdots$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

We have also solved this problem using Laplace Transform on eq. [B11], and found a solution identical to eq. [40], but in a more compact general form:

$$[43] \qquad \frac{C_A^2(0,t)}{C_A^*} = \frac{2}{\pi} \text{ arc tang } \sqrt{\frac{1}{(1-\beta)^{2z+1}} - 1}$$

where

$$[44] \qquad \sqrt{(2z+1)\beta}\, h_z(\beta) = \text{arc tang } \sqrt{\frac{1}{(1-\beta)^{2z+1}} - 1}$$

The condition $t_2 \longrightarrow \infty$ is equivalent to $\beta \longrightarrow 1$, and, therefore, $C_A^2(0,t)/C_A^* = 1$, for any value of z, which is in accordance with the previous reasoning; the process is very slow, but takes places at infinitely large time. However, the application of the same conditions to eq. [A7] leads to the following result

$$[45] \qquad \frac{C_A^2(0,t)}{C_A^*} = \frac{2}{\pi} \sqrt{\beta(2z+1)}\, g_z(\beta)$$

$$[46] \qquad g_0(\beta) = 1$$

$$[47] \qquad g_{2/3}(\beta) = 1 - \frac{1}{9}\beta - \frac{11}{270}\beta^2 - \frac{10}{567}\beta^3 - \frac{3087}{367416}\beta^4 \ldots$$

If $\beta = 1$, the prediction of eq. [45] is $C_A^2(0,t)/C_A^* = 2/\pi = 0.6366$ (for $z = 0$) and $C_A^2(0,t)/C_A^* = 0.7995$ (for $z = 2/3$), that is to say, eq. [45] is unable to predict the return to initial conditions in the pulse sequence applied in the ideal experiment of Figs. 7 and 8.

It may be surprising that the method applied in ref. 8 allows us to calculate i_{RP} very close to the correct values (even for moderately large β) but it is unable to obtain accurate values of the surface concentrations. The reason of this apparent paradox must be sought in the very structure of eqs. [36] and [A5], as well as in the analysis of the conditions under which these equations coincide with that deduced in ref. 8. When the electrode process is reversible ($k_s \longrightarrow \infty$) or diffusion conditions are applied ($E_2 - E^0 \longrightarrow \pm\infty$), the treatment developed in ref. 8 and our own treatment are the same (conditions under which the superposition principle is applicable). In short, the function $H_z(\beta, y)$ is operative only when the process is not at equilibrium or when y does not increase towards infinity.

If we analyze the expression for the current i_{RP} (eq. [36]), one sees that as the value of y decreases, the importance of the product $\mu_d H_z(\beta, y)$, i.e., of $H_z(\beta, y)/y$ (see eq. [38]) increases while the current i_{RP} simultaneously decreases. For this reason, the difference between eq. [36] and eq. [32] in ref. 8 is not very great in absolute value. Moreover, it should be added that the functions $H_z(\beta, y)$ and $G_z(\beta, y)$ are more similar as y becomes smaller.

The expressions for surface concentration depend on the product $\mu_d H_z(\beta, y)/y = H_z(\beta, y)/y^2$, which also increases as y decreases but $C_A^2(0,1)_{y \ll 1} \neq 0$. For example, while $C_A^2(0,t)$ is strongly dependent on $H_z(\beta, y)$, i_{RP} can be represented approximately by eq. [32] in ref. 8. However, this does not mean the method in ref. 8 can be used indiscriminately. For example, these results should not be used to obtain the current–time response corresponding to posterior pulses, as in the technique called Reverse Differential Normal Pulse (16, 23, 24), or in the Double Differential Pulse Voltammetry technique (25). In these cases the current is obtained from surface concentrations and surface concentration gradients deduced for second pulse, and the use of eq. [A7] leads to inadequate results.

Appendix A

$F_z(\chi)$ is the Koutecky Function. For $z = 0$ (planar approximation of SMDE) and for $z = 2/3$ (planar approximation of DME)

$$[A1] \qquad F_z(\chi) = \sum_{j=0}^{\infty} \frac{(-1)^j \chi^{j+1}}{\prod_{k=0}^{j} p_k(z)}$$

$G_z(\chi)$ is the Galvez Function (8, 26)

$$[A2] \qquad G_z(\beta, \chi) = \sum_{j=0}^{\infty} \frac{(-1)^j \chi^{j+1}}{\prod_{k=0}^{j} p_k(z)} \left\{ 1 - \frac{j\beta}{3(j+2)} - \frac{j(2j+9)}{18(j+2)(j+4)} \cdot \beta^2 \cdot - \cdots \right\}$$

$$[A3] \qquad p_k(z) = p_{k/(2z+1)} = \frac{2\Gamma\left(1 + \frac{k}{4z+2}\right)}{\Gamma\left(\frac{1}{2} + \frac{k}{4z+2}\right)}$$

$$[A4] \qquad p_k p_{k-1} = 2k$$

The surface concentrations of species A and B for $\tau_2 > 0$ are given by

$$[A5] \qquad \frac{C_A^2(0, t)}{C_A^*} = Z\left(\frac{2}{\sqrt{\pi}} \frac{C_z(\beta, y)}{y} - 1\right) + \mu_d\left(\frac{2}{\sqrt{\pi}} \frac{H_z(\beta, y)}{y} - 1\right)$$

$$[A6] \qquad \frac{C_B^2(0, t)}{C_A^*} = \gamma\left(1 - \frac{C_A^2(0, t)}{C_A^*}\right)$$

However, from eq. [16] in ref. 8 with $E_1 \longrightarrow -\infty$, we deduce

$$[A7] \qquad \left(\frac{C_A^2(0, t)}{C_A^*}\right)_{\text{ref. 8}} = (Z + \mu_d)\left(\frac{2}{\sqrt{\pi}} \frac{G_z(\beta, y)}{y} - 1\right)$$

H_z function which appears in eq. [35] is given for $y < 10$ by ($z = 0$)

$$[A8] \qquad H_0(\beta, y) = \sum_{m=0}^{\infty} \frac{(-1)^m y^{m+1}}{\prod_{i=0}^{m} p_i(0)} \left\{ 1 + \sum_{k=1}^{\infty} \frac{(2k-1)!m\beta^k}{2^{2k-1}k!(k-1)!(m+2k)} \right\} = \sum_{m=0}^{\infty} \frac{(-1)^m y^{m+1}}{\prod_{i=0}^{m} p_i(0)} \cdot \text{Hg2}F1[1/2, m/2, 1 + m/2, \beta]$$

where Hg2$F1[a, b, c, z]$ is the hypergeometric function ${}_2F_1(a, b, c, z)$ and for $y > 10$

$$[A9] \qquad H_0(\beta, y) = \sqrt{1-\beta} + \sqrt{\pi} \sum_{k=1}^{\infty} \frac{(-1)^{k-1}(2k-1)!\beta^k}{(k-1)!y^{2k-1}} + \sum_{m=1}^{\infty} \frac{(-1)^m 2(2m-1)!}{(m-1)!y^{2m}} \left(1 - \sum_{k=1}^{\infty} \frac{(2k-1)!(2m+1)\beta^k 2^{1-2k}}{k!(k-1)!(2k-2m-1)}\right)$$

$$= \sqrt{1-\beta} + \sqrt{\pi} \sum_{k=1}^{\infty} \frac{(-1)^{k-1}(2k-1)!\beta^k}{(k-1)!y^{2k-1}} + \sum_{m=1}^{\infty} \frac{(-1)^m 2(2m-1)!}{(m-1)!y^{2m}} \text{Hg2}F1[1/2, -(m+1/2), 1/2 - m, \beta]$$

The function $H_0(\beta, y)$ is defined for $0 \leq \beta \leq 1$, and can be obtained with the desired precision in this interval. The value $\beta = 1$ corresponds to two extreme situations, as are $t_1 = 0$, that is to say, the first pulse does not exists (this situation is physically meaningless, since H is only obtained if the departure point is a perturbed system) or $t_2 \longrightarrow \infty$.

The general term of the sum in β in the above equations has been obtained taking into account the relationship between the coefficients of the series depending on β in the H_0 function and the following expression

$$[A10] \qquad (1-\beta)^{-1/2} = 1 + \sum_{k=1}^{\infty} \frac{(2k-1)!\beta^k}{2^{k-1}k!(k-1)!}$$

For $z = 2/3$ and for $y < 10$ we find

$$[A11]\quad H_{2/3}(\beta, y) = \sum_{m=1}^{\infty} \frac{(-1)^m y^{m+1}}{\prod_{i=0}^{\infty} p_i} \left\{ 1 + \frac{m}{6(m+2)}\beta + \frac{m(7m-6)}{72(m+2)(m+4)}\beta^2 + \frac{7m(13m-34)}{1296(m+2)(m+6)}\beta^3 + \frac{m(1729m^3+9828m^2-23284m-133488)}{31104(m+2)(m+4)(m+6)(m+8)}\beta^4 + \cdots \right\}$$

and for $y > 10$

$$[A12]\quad H_{2/3}(\beta, y) = \sum_{m=1}^{\infty} (-1)^{m+1} y^{-m+1} \left(\frac{\prod_{i=1}^{m} p_{-i}}{p_{-m}} \right) \left\{ 1 + \frac{m}{6(m-2)} + \frac{m(7m+6)}{72(m-2)(m-4)}\beta^2 + \frac{7m(13m+34)}{1296(m-2)(m-6)}\beta^3 + \frac{m(1729m^3-9828m^2-23284m+133488)}{31104(m-2)(m-4)(m-6)(m-8)}\beta^4 + \cdots \right\} = 1 - \frac{1}{6}\beta + \frac{13}{216}\beta^2 + \frac{329}{6480}\beta^3 + \frac{2269}{72576}\beta^4 + \cdots + \frac{1}{3}p_1\beta\left(1 - \frac{5}{6}\beta - \frac{35}{72}\beta^2 - \frac{20}{81}\beta^3 \cdots\right) y^{-1} - \left(2 + \beta - \frac{9}{4}\beta^2 - \frac{511}{648}\beta^3 - \frac{7289}{25920}\beta^4 \cdots\right) y^{-2} - p_1\beta^2\left(\frac{34}{9} - \frac{65}{324}\beta^2 \cdots\right) y^{-3} + 2\left(12 + \frac{10}{3}\beta + \frac{205}{18}\beta^2 - \frac{385}{36}\beta^3 - \frac{20845}{3888}\beta^4 \cdots\right) y^{-4}$$

Equation [A11] suggests us the grouping of β into the expression

$$[A13]\quad (1-\beta)^{-1/6} = 1 + \frac{\beta}{6} + \frac{7\beta^2}{72} + \frac{91\beta^3}{1296} + \frac{1729\beta^4}{31104} + \cdots$$

However, because of its complexity, we can not find a general expression for [A11].
We have also used the relationship

$$[A14]\quad \lim_{k \to m} (m-k) = \pm\frac{p_{-1}}{p_1}$$

in which the upper sign relates to direct treatment and the lower sign to the asymptotic one.

Appendix B

For a stationary plane electrode ($z = 0$), the Faradaic current corresponding to process [1], can be expressed by a Volterra integral of the form (1)

$$[B1]\quad \phi = k - \frac{\lambda}{\sqrt{\pi}} \int_0^t \frac{\phi \mathrm{d}u}{\sqrt{t-u}}$$

where

$$[B2]\quad k = k_s K^{-\alpha}$$

$$[B3]\quad \lambda = \frac{k(1+\gamma K)}{\sqrt{D_A}}$$

$$[B4]\quad \phi = \frac{i}{nFq_0 C_A^*}$$

In double pulse conditions eq. [B1] can written as (1)

$$[B5]\quad \phi_2 = k_2 - \frac{\lambda_2}{\sqrt{\pi}} \left(\int_0^{t_1} \frac{\phi_1 \mathrm{d}u}{\sqrt{t_1+t_2-u}} + \int_{t_1}^{t_1+t_2} \frac{\phi_2 \mathrm{d}u}{\sqrt{t_1+t_2-u}} \right)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

where the subscripts 1 and 2 indicate, respectively, the conditions corresponding to first pulse, E_1 of length t_1 and current i_1 and those corresponding to the second pulse E_2 of length t_2 and current i_2.

Taking into account eq. [B1], eq. [B5] can be rearranged as (27)

$$[B6] \quad \phi_2 - \phi_1 = \left(k_2 - k_1 \frac{\lambda_2}{\lambda_1}\right) - \phi_1 \left(\frac{\lambda_2}{\lambda_1} - 1\right) - \frac{\lambda_2}{\sqrt{\pi}} \int_0^{t_2} \frac{(\phi_2 - \phi_1)\mathrm{d}u}{\sqrt{t_2 - u}}$$

Let us define

$$[B7] \quad \psi = \phi_2 - \phi_1$$

In the conditions of RP, $E_1 - E^0 \longrightarrow -\infty$, therefore $K_1 \longrightarrow 0$, $k_1 \longrightarrow \infty$ and $(k_1/\lambda_1) = (D_A)^{1/2}$, consequently

$$[B8] \quad k_2 - k_1 \frac{\lambda_2}{\lambda_1} \simeq -\gamma K_2 k_2 = -\gamma k_s K_2^{(1-\alpha)} = k_{-2}$$

$$[B9] \quad \frac{\lambda_2}{\lambda_1} - 1 \simeq -1$$

$$[B10] \quad \phi_1(t) = \sqrt{\frac{D_A}{\pi t}}$$

which allows us to rewrite eq. [B6] as follows

$$[B11] \quad \psi = -k_{-2} - \sqrt{\frac{D_A}{\pi(t_1 + t_2)}} - \frac{\lambda_2}{\sqrt{\pi}} \int_0^{t_2} \frac{\psi \mathrm{d}u}{\sqrt{t_2 - u}}$$

The numerical method that followed to solve this integral equation has been previously described in literature (18, 19). In accordance with this method, the integral in eq. [B11] is substituted by

$$[B12] \quad \int_0^{t_2} \frac{\psi \mathrm{d}u}{\sqrt{t_2 - u}} \simeq 2\sqrt{(t_2/r)} \left(\psi_r + \sum_{i=1}^{r-1} \psi_i(\sqrt{r+1-i} - \sqrt{r-i})\right)$$

where r is the number of steps in which t_2 is divided, in such a way that $\Delta t = t_2/r$. Thus ψ_i's evaluated from

$$[B13] \quad \psi_1 = \frac{-k_{-2} - \sqrt{\frac{D_A}{\pi(t_1 + i\Delta t)}} - 2\lambda_2 \sqrt{\frac{\Delta t}{\pi}} \sum_{j=1}^{i-1} \psi_j(\sqrt{i+1-j} - \sqrt{i-j})}{1 + 2\lambda_2 \sqrt{\frac{\Delta t}{\pi}}}$$

where

$$[B14] \quad \psi_1 = \frac{-k_{-2} - \sqrt{\frac{D_A}{\pi(t_1 + \Delta t)}}}{1 + 2\lambda_2 \sqrt{\frac{\Delta t}{\pi}}}$$

The current $i_2 = i_{RP}$ is determined from

$$[B15] \quad \phi_2 = \psi_r + \phi_1 = \psi_r + \sqrt{\frac{D_A}{\pi(t_1 + t_2)}} = \frac{i_{RP}}{nFq_0 C_A^*}$$

Finally, $C_A^2(0, t)$ can be evaluated from

$$[B16] \quad \frac{C_A^2(0, t)}{C_A^*} = \frac{\phi_2/k_2 + \gamma K_2}{1 + \gamma K_2}$$

All the calculations have been carried out with $r = 160$. In all cases, the difference observed in i_{RP} or in $C_A^2(0, t)$ with respect to the predictions of eqs. [36] and [A5], respectively, are always less than 1%.

A. MOLINA, C. SERNA, R. CHICÓN, L. CAMACHO, and J.J. RUIZ. Can. J. Chem. **72**, 2378 (1994).

The general rigorous theory corresponding to double potential step chronoamperometry for a reversible charge transfer reaction in a spherical electrode whose area increases with t^z, where $z \geq 0$, is presented. The static mercury drop electrode ($z = 0$) and the dropping mercury electrode ($z = 2/3$) are addressed specifically. The explicit equations for the current versus time response assuming unequal diffusion coefficients for the oxidized and reduced species are valid when the product is soluble in both the electrolytic solution and the electrode. Comparisons with previous general treatments in the literature are made. The theory is applied to the detection of amalgamation in RP and DNP techniques.

Moreover, in this work we show the origin of errors appearing in some general treatments in the literature, these errors lead to physically meaningless results when amalgamation takes place.

A. MOLINA, C. SERNA, R. CHICÓN, L. CAMACHO et J.J. RUIZ. Can. J. Chem. **72**, 2378 (1994).

On présente la théorie générale rigoureuse correspondant à la chronoampérométrie avec une étape à double potentiel d'une réaction réversible de transfert de charge dans une électrode sphérique dont la superficie augmente comme t^z, où $z \geq 0$. On examine d'une façon spécifique les cas des électrodes avec goutte de mercure statique ($z = 0$) et avec goutte de mercure tombante ($z = 2/3$). Les équations explicites pour le courant en fonction du temps de réponse, en supposant des coefficients de diffusions différents pour les espèces oxydées et réduites, sont valides lorsque le produit est soluble dans le solution électrolytique ainsi que dans l'électrode. On présente des comparaisons avec les traitements généraux rapportés antérieurement dans la littérature. On applique la théorie à la détection d'amalgamation dans les techniques de RP et de DNP.

De plus, dans ce travail, on montre l'origine des erreurs qui apparaissent des quelques traîtements généraux rapportés dans la littérature et qui, lorsqu'une amalgamation se produit, rendent les résultats physiquement sans signification.

[Traduit par la rédaction]

Introduction

In this paper we study the application of a double potential pulse to a reversible charge transfer process at stationary and nonstationary spherical electrodes. We consider the general case when the diffusion coefficients of the oxidized and reduced species are different, and the reduced species can dissolve in the electrolytic solution as well as in the electrode. In order to obtain an exact expression for the response corresponding to the second potential pulse, it is essential to consider the perturbation of the second pulse on the concentration profiles generated by the first potential pulse. Previous investigators (1, 2) have neglected this perturbation.

The difficulties in the calculation of the response to the second potential step for a spherical electrode arise from surface concentrations which are dependent on potential, diffusion coefficients, and time (3–5). Birke et al. (6) first reported that it was necessary to account for the variation of the concentration profiles obtained with the first pulse during the application of the second pulse. They found that this variation can be neglected only when both species are soluble and have equal diffusion coefficients.

The Koutecky approximation has been used when amalgamation is present (7), and the mathematical procedure developed in this work shows clearly that this approximation is valid for any value of the time of application of the second pulse. This can be easily verified from the analytic expressions obtained in this work for a Static Mercury Drop Electrode (SMDE) and a Dropping Mercury Electrode (DME). In the case of SMDE, the expression for i_2 is simple enough to permit direct match of the theoretical and experimental results.

We have applied our equations to the study of double potential step chronoamperometry, and we have analyzed the influence of the electrode sphericity and amalgamation on the *i–t* response. The same considerations have been made for reverse pulse and differential normal pulse techniques. For reverse pulse techniques we have proposed a condition for the formation of amalgam based on measurements of the cathodic and anodic diffusion currents. Brumleve et al. (8) have used the reverse pulse technique to study the influence of spherical diffusion at a SMDE, for processes with and without amalgamation. They used numerical methods to obtain a complicated analytical solution for only the limiting current. Goodisman (5) solved the problem for a SMDE alone did not give explicit solutions that are directly applicable to double pulse techniques. The effect of amalgamation in differential pulse techniques has been studied experimentally for a DME (9) and a SMDE (10). These works clearly demonstrate the lack of a suitable theory that accounts quantitatively for the effect of amalgamation in double pulse techniques.

The equations derived in this paper are applied to double potential step chronoamperometry, reverse pulse (RP) and

differential normal pulse (DNP) techniques to analyze the influence of electrode sphericity and amalgamation on the i–t response. In RP, a criterion for the formation of amalgam based on the measurements of cathodic and anodic currents is proposed. Single pulse techniques including normal pulse (NP), dc voltammetry, or polarography are also considered. Our results do not differ from those previously reported (1, 3, 4, 11) because single pulse techniques do not suffer from the concentration perturbations that must be considered in double pulse methods.

Theory

Consider the following charge-transfer.

[1] $\quad A + ne^- \rightleftharpoons B$

Let us consider a spherical electrode with its area increasing as a power of time, $q(t) = q_0 t^z$ ($z = 0$ for a SMDE and $z = 2/3$ for a DME), and a reversible charge transfer such that the potential is set at the value E_1 in the interval $0 \leq t \leq t_1$ and stepped from E_1 to E_2 at the time $t \geq t_1$ (see Fig. 1). The current for each pulse will be called i_1 and i_2 respectively. See footnote 2 for notations.

The concentration profiles in the interval $0 \leq t \leq t_1$ are given in ref. 1*a*.

[2] $\quad C_A^1(r, t) = C_A^1(s1_A, \xi 1_A) = \rho_0(s1_A) + \xi 1_A \rho_1(s1_A)$

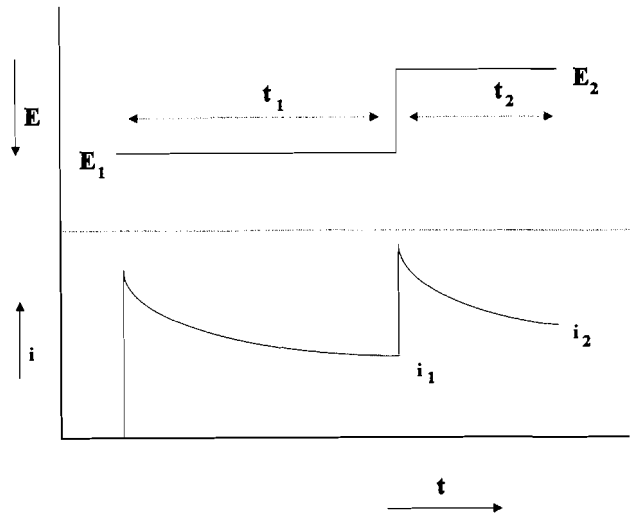

FIG. 1. Potential–time waveform and current–time response to a double potential step.

[3] $\quad C_B^1(r, t) = C_B^1(s1_B, \xi 1_B) = \phi_0(s1_B) + \xi 1_B \phi_1(s1_B)$

with

[4] $\quad s1_i = \sqrt{\dfrac{2z+1}{4D_i t}}(r - r_0)$

[5] $\quad \xi 1_i = \sqrt{\dfrac{4D_i t}{2z+1}}\,\dfrac{1}{r_0}$

[6] $\quad r_0 = \sqrt{\dfrac{A_0}{4\pi}}\,t^{z/2}$

and where $\rho_0(s1_A)$, $\rho_1(s1_A)$, $\phi_0(s1_B)$ and $\phi_0(s1_B)$ are given in ref. 1*a* (eqs. [9]–[17]).

The concentration on the surface of the electrode are

[7] $\quad C_A^1(r_0, t) = A_1 + B_1 \xi 1_A$

[8] $\quad C_B^1(r_0, t) = C_A^1(r_0, t)/K_1$

where we have taken

[9] $\quad A_1 = \dfrac{C_A^* K_1 \gamma}{1 + \gamma K_1}$

[10] $\quad B_1 = \dfrac{4(2z+1)(\gamma \mp 1) C_A^* K_1}{(5z+4)(1+\gamma K_1)^2 \sqrt{\pi}}$

[11] $\quad K_i = \exp[nF(E_i - E_0)/RT]$

If only the first order spherical correction is considered, the current has the expression (1*a*, 4)

[12] $\quad i_1(t) = nFq(t)\sqrt{\dfrac{(2z+1)D_A}{\pi t}}\,C_A^*\,\dfrac{1 + \theta_z \Omega_1 \xi 1_A}{1 + \gamma K_1}$

with

[13] $\quad \theta_z = \dfrac{2(2z+1)P_z}{(5z+4)}$

---

[2]Notation:

$q(t) = q_0 t^z$	time-dependent electrode area ($z = 0$ for a SMDE and $z = 2/3$ for a DME)
$c_i^m(r, t)$	concentration profile of species i (i = A or B) when the first ($m = 1$) or second ($m = 2$) potential pulse is applied
r_0	constant electrode radius for a SMDE. $= at^{1/3}$ for a DME
$a = \left(\dfrac{3m_{Hg}}{4\pi d}\right)^{1/3}$	
m_{Hg}, d	rate of flow and density of mercury
$\xi 1_i = \xi 1_i^0 t^{(1-z)/2}$	(or eq. [5])
$\xi 1_i^0 = 4\sqrt{\dfrac{\pi D_i}{(2z+1)A_0}}$	
$\beta = \dfrac{\tau_2}{t_1 + \tau_2}$	
$\xi 2_i = \xi 1_i \sqrt{(2z+1)\beta}$	
t_1	time elapsed between the application of the first and second pulse
τ_2	time elapsed between the second pulse application and the measurement of the current
$t = t_1 + \tau_2$	
$\gamma = \sqrt{\dfrac{D_A}{D_B}}$	
$K_j = \exp[nF(E_j - E^0)/RT]$	
$i_{DC} = nFq_0 C_A^* \sqrt{\dfrac{D_A}{\pi t_2}}$	
$i_0 = i_{DC}\sqrt{t_2}$	

When two signs appear, the upper sign refers to a solution soluble product and the lower sign to amalgam formation. Other definitions are conventional.

$$[14] \quad P_z \equiv P_{(1-Z)/(2Z+1)} = \frac{2\Gamma\left(1+\frac{1-z}{4z+2}\right)}{\Gamma\left(\frac{1}{2}+\frac{1-z}{4z+2}\right)}$$

$$[15] \quad \Omega_1 = \frac{1 \pm K_1}{1+\gamma K_1}$$

$$[16] \quad \gamma = \sqrt{\frac{D_A}{D_B}}$$

Throughout this paper the upper sign in any equation refers to a reaction product which is soluble in the electrolytic solution whilst the lower sign refers to a product soluble in the electrode (amalgam formation).

The theoretical analysis presented in this paper has been also carried out by taking into account the second order spherical correction. This highly increases the mathematical complexity, without significantly improving the results of the current in the second pulse of the potential, at least when $\xi 1_A^0 \leq 0.35$ (see footnote 2 for notation). Therefore, to make our conclusions as clear as possible without invoking mathematical complexity, we only present our analysis on first order spherical correction.

It is important to note that the surface concentrations of species A and B were dependent on time (see eqs. [7], [8]). However, when $\gamma = 1$ and both species are soluble in the electrolytic solution the surface concentrations depend only on the applied potential E_1 (eqs. [7] and [10]) with upper sign), as is the case for plane electrodes (4, 5).

With $t = t_1 + \tau_2$ the boundary values in the interval $0 \leq \tau_2 \leq t_2$ take the form

$$[17] \quad \hat{D}_A C_A^2(r, t) = \hat{D}_B C_B^2(r, t) = 0$$

$$[18] \quad \tau_2 = 0;\ r = r_0 \begin{cases} C_A^2(r, t) = C_A^1(r, t) \\ C_B^2(r, t) = C_B^1(r, t) \end{cases}$$

$$[19] \quad \tau_2 > 0;\ r \to \pm\infty: \quad C_B^2(r, t) = C_B^1(r, t) = 0$$

$$[20] \quad \tau_2 > 0;\ r = r_0: \quad C_A^2(r_0, t) = K_2 C_B^2(r_0, t)$$

$$[21] \quad \frac{i_2}{nFq(t)} = D_A\left(\frac{\partial C_A^2}{\partial r}\right)_{r=r_0} = \mp D_B\left(\frac{\partial C_B^2}{\partial r}\right)_{r=r_0}$$

where the linear differential operator $\hat{D}_i$ (i = A, B) is given by

$$[22] \quad \hat{D}_1 = \frac{\partial}{\partial \tau_2} - D_1\left(\frac{\partial^2}{\partial r^2} + \frac{2}{r}\frac{\partial}{\partial r}\right) + \frac{z r_0^3}{2r^2(t_1+\tau_2)}\frac{\partial}{\partial r}$$

The linearity of the differential equations involved means that we can search for a solution of the form

$$[23] \quad C_A^2(r, t) = C_A^1(r, t) + \tilde{C}_A(r, \tau_2)$$

$$[24] \quad C_B^2(r, t) = C_B^1(r, t) + \tilde{C}_B(r, \tau_2)$$

where the new functions $\tilde{C}_A(r, \tau_2)$ and $\tilde{C}_B(r, \tau_2)$ are solutions of eq. [17] with null initial conditions (at $\tau_2 = 0$) as it is immediately seen from eq. [18].

We seek a solution for the power series

$$[25] \quad \tilde{C}_A(r, \tau_2) = \sum_{i,j} \sigma_{i,j}^{(-)}(s2_A)\xi 2_A^i \beta^{(j-1)/2}$$

$$[26] \quad \tilde{C}_B(r, \tau_2) = \sum_{i,j} \delta_{i,j}^{(\mp)}(s2_B)\xi 2_B^i \beta^{(j-1)/2}$$

where

$$[27] \quad s2_i = \frac{(r - r_0)}{2\sqrt{D_i \tau_2}}$$

$$[28] \quad \xi 2_i = \frac{2\sqrt{D_i \tau_2}}{r_0}$$

$$[29] \quad \beta = \frac{\tau_2}{(t_1 + \tau_2)}$$

Introducing these expressions into eq. [17] leads to the following set of ordinary differential equations for the coefficients $\sigma_{i,j}(s2_A)$ and $\delta_{i,j}(s2_B)$

$$[30] \quad \sigma''_{i,j}(s2_A) + 2s2_A\sigma'_{i,j}(s2_A) - 2(i+j-1)\sigma_{i,j}(s2_A) = -\sum_{m+l+1=i} c_m \sigma'_{i,j}(s2_A) - \sum_{r+p=i} d_r \sigma'_{p,j-2}(s2_A) - 2z\left(i + \frac{j-3}{z}\right)\sigma_{i,j-2}(s2_A)$$

$$[31] \quad \delta''_{i,j}(s2_B) + 2s2_B\delta'_{i,j}(s2_B) - 2(i+j-1)\delta_{i,j}(s2_B) = -\sum_{m+l+1=i} c_m \delta'_{i,j}(s2_B) - \sum_{r+p=i} d_r \delta'_{p,j-2}(s2_B) - 2z\left(i + \frac{j-3}{z}\right)\delta_{i,j-2}(s2_A)$$

where

$$[32] \quad c_m = 2(-1)^m (s2_i)^m$$
$$c_m = 0 \text{ for planar electrodes}$$

$$[33] \quad d_r = 2z(-1)^r (r+2)(s2_i)^{r+1}$$

A rigorous treatment of the problem is complicated since the dimensionless parameters $\xi 1_1$ and $\xi 2_1$ (connected to the electrode sphericity during the first and second pulses, respectively) are not independent. In fact, they are linked as follows:

$$[34] \quad \frac{\xi 2_i}{\xi 1_i} = \sqrt{(2z+1)\beta}$$

The appropriate boundary conditions for $\sigma_{i,j}(s2_A)$ and $\delta_{i,j}(s2_B)$ functions can be deduced from the initial conditions given in eq. [18], the boundary condition in eqs. [19]–[21] and also eq. [34]. Thus when $s2_A, s2_B \to \infty$:

$$[35] \quad \sigma_{i,j} = \delta_{i,j} = 0 \qquad \forall i, j$$

when $s2_A = s2_B = 0$

$$[36] \quad \gamma^{i+1}\sigma'_{i,j} = \mp\delta'_{i,j} \qquad \forall i, j$$

For personal use only.

[37] $$\sigma_{0,1} = -C_A^* Z_2(1+\gamma K_2) + K_2\delta_{0,1}$$

[38] $$\gamma\sigma_{1,0} = -C_A^* Z_2 N_z(1+\gamma K_2) + K_2\delta_{1,0}$$

[39] $$\gamma^i\sigma_{i,j} = K_2\delta_{i,j} \text{ unless } i=1,\ j=0 \text{ and } i=0,\ j=1$$

[40] $$Z_2 = \frac{1}{1+\gamma K_2} - \frac{1}{1+\gamma K_1}$$

[41] $$N_z = \frac{4\sqrt{2z+1}\,(\gamma \mp 1)}{(5z+4)(1+\gamma K_1)\sqrt{\pi}}$$

The expressions for $\sigma_{i,j}(s2_A)$ and $\delta_{i,j}(s2_B)$ are then obtained by the procedure developed in ref. 12, and are given in Appendix (eqs. [A3]–[A8], [A11]–[A22], and [A25]–[A33]).

The surface concentration of both species A and B during the second pulse, for an expanding spherical electrode, can now be found by substituting $r = r_0$ and eq. [A23] in eqs. [23] and [24]. Then we obtain

[42] $$C_A^2(r_0,t) = \frac{C_A^* K_2}{1+\gamma K_2}\left\{\gamma + \frac{4(2z+1)(\gamma \mp 1)}{(5z+4)(1+\gamma K_1)\sqrt{\pi}}\,\xi 1_A\right\} + C_A^* Z_2 \frac{K_2(\gamma \mp 1)}{(1+\gamma K_2)\sqrt{\pi}}\,Q_z(\beta)\xi 2_A$$

[43] $$C_B^2(r_0,t) = C_A^2(r_0,t)/K_2$$

where

[44] $$Q_z(\beta) = 1 - \frac{z(5z+2)}{48}\beta^2 + \frac{z(3z^2-20z-8)}{240}\beta^3\cdots$$

It is worth noting that if $\gamma = 1$ (i.e., $D_A = D_B$) and both species are soluble in the electrolytic solution (upper sign), $C_A^2(r_0,t)$ and $C_B^2(r_0,t)$ depend only on the applied potential E_2, for any type of electrode ($z \geq 0$).

The current time response can also be immediately obtained from eqs. [21], [A9], and [A24].

[45] $$i_2 = i_1(t) + nFq(t)\sqrt{\frac{D_A}{\pi t_2}}\,C_A^* Z_2\left\{f_z(\beta) + \frac{4(2z+1)(\gamma \mp 1)}{(5z+4)(1+\gamma K_1)\gamma\sqrt{\pi}}\,g_z(\beta)\xi 1_A + \frac{\sqrt{\pi}}{2}\,\Omega_2 h_z(\beta)\xi 2_A\right\}$$

where

[46] $$\Omega_2 = \frac{1 \pm K_2}{1+\gamma K_2}$$

[47] $$f_z(\beta) = \sqrt{\frac{(2z+1)\beta}{1-(1-\beta)^{(2z+1)}}}$$

[48] $$g_z(\beta) = 1 + \frac{1}{2}\beta + \frac{2z^2+2z+1}{24}\beta^2 + \frac{2z^2+2z+1}{80}\beta^3\cdots$$

[49] $$h_z(\beta) = 1 - \frac{3z(7z+2)}{128}\beta^2 + \frac{z(z-4)(7z+2)}{256}\beta^3\cdots$$

$f_z(\beta)$ and the series $h_z(\beta)$, in the particular case when $z = 0$ and $z = 2/3$, are coincident with the series $h_0(z,\tau)$ and $h_1(z,\tau)$ given by eqs. [42] and [43] in ref. 1*a* respectively ($\tau \equiv \beta$). On the other hand, the series $g_z(\beta)$ is a new series. It came about as a result of the disturbance on the surface concentrations deduced for the first pulse ($C_A^1(r_0,t)$ and $(C_B^1(r_0,t))$ due to the application of the second pulse. Therefore, eq. [45] in this work does not coincide in general with eq. [41] in ref. 1*a*. Nevertheless, in the special case when $\gamma = 1$ and both species are soluble in the electrolytic solution, eq. [41] in ref. 1*a* (or eq. [36] in ref. 2) and our eq. [45] are the same; because in this particular case the surface concentrations of the electroactive couple are time-independent. On the other hand, if $D_A \neq D_B$ or there is amalgam formation one should use our eq. [45] instead of the equations deduced in refs. 1*a* and 2.

The results expressed by eq. [45] simplify in the following cases:

(*a*) $z = 2/3$ (DME)

[50] $$i_2 = i_1(t) + nFA_0 t^{2/3}\sqrt{\frac{D_A}{\pi t_2}}\,C_A^* Z_2\left\{f_{2/3}(\beta) + \frac{14(\gamma \mp 1)}{11(1+\gamma K_1)\gamma\sqrt{\pi}}\,g_{2/3}(\beta)\xi 1_A + \frac{\sqrt{\pi}}{2}\,\Omega_2 h_{2/3}(\beta)\xi 2_A\right\}$$

where (13)

[51] $$f_{2/3}(\beta) = \sqrt{\frac{7\beta}{3(1-(1-\beta)^{7/3})}}$$

[52] $$g_{2/3}(\beta) = 1 + \frac{1}{2}\beta + \frac{29}{216}\beta^2 + \frac{29}{720}\beta^3 + \cdots$$

[53] $$h_{2/3}(\beta) = 1 - \frac{5}{48}\beta^2 - \frac{25}{432}\beta^3\cdots$$

(*b*) $z = 0$ (SMDE)

[54] $$i_2 = i_1(t) + nFA_0\sqrt{\frac{D_A}{\pi t_2}}\,C_A^* Z_2 \times \left\{1 + \frac{(\gamma \mp 1)}{\sqrt{\pi}\gamma(1+\gamma K_1)}\,g_0(\beta)\xi 1_A + \frac{\sqrt{\pi}}{2}\,\Omega_2\xi 2_A\right\}$$

The expression for $g_0(\beta)$ is given by (14).

[55] $$g_0(\beta) = 1 + \sum_{k=1}^{\infty}\frac{\beta^k(2k-1)!}{k!2^{2k-1}(k-1)!(2k-1)^2} = \sqrt{\beta}\arcsin(\sqrt{\beta}) + \sqrt{1-\beta}$$

[56] $$f_0(\beta) = h_0(\beta) = 1$$

and eq. [54] takes the simpler form

[57] $$i_2 = i_1 + nFA_0 C_A^*\sqrt{\frac{D_A}{\pi}}\left(\frac{1}{1+\gamma K_2} - \frac{1}{1+\gamma K_1}\right) \times \left\{\frac{1}{\sqrt{t_2}} + \frac{\gamma \mp 1}{\gamma(1+\gamma K_1)}\sqrt{\frac{D_A}{\pi}}\,\frac{2}{r_0}\left(\sqrt{\frac{1-\beta}{\beta}} + \arcsin(\sqrt{\beta})\right) + \frac{\sqrt{\pi D_A}}{r_0}\,\frac{1 \pm K_2}{1+\gamma K_2}\right\}$$

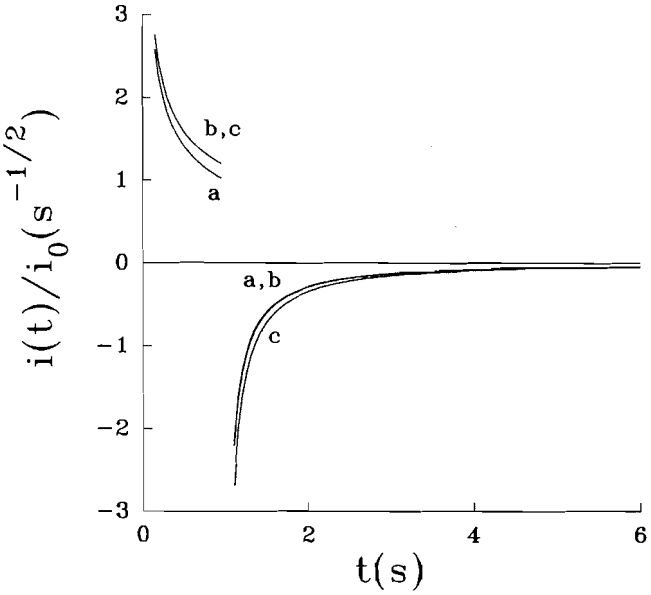

FIG. 2. Influence of the amalgamation on $i/i_0 - t$ recording for a double potential step at a SMDE (eq. [12] with $E_1 \rightarrow -\infty$ and [63]). $\xi 1^0_A = 0.2\ s^{-1/2}$, $t_1 = 1$ s, $n = 1$, and $\gamma = 0.8$. (*a*) Planar electrode, (*b*) solution-soluble product, (*c*) amalgam formation.

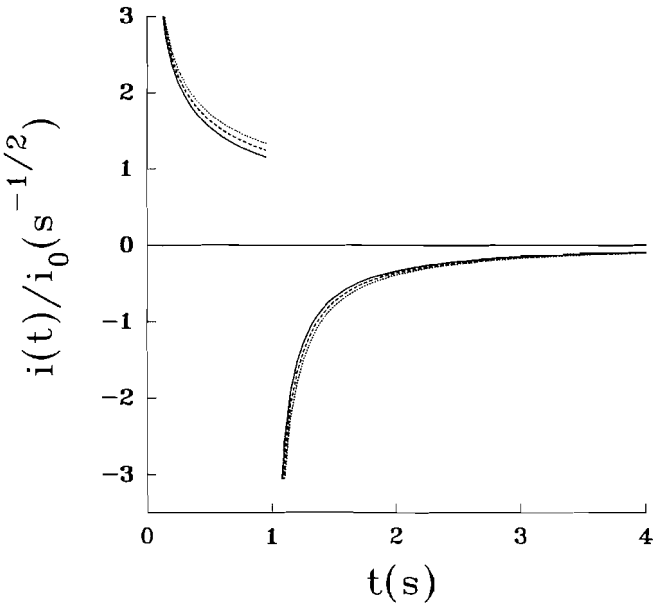

FIG. 3. Influence of sphericity on $i/i_0 - t$ recording for a double potential step when the amalgamation takes place in a SMDE. The values of $\xi 1^0_A$ in $s^{-1/2}$ are (—) 0.15, (– – –) 0.25, (···) 0.35. Other conditions as in Fig. 2.

(*c*) $\xi 1_i = \xi 2_i = 0$ (expanding plane electrode)

$$[58] \qquad i_2 = i_1(t) + nFq(t)\sqrt{\frac{D_A}{\pi t_2}}\, C^*_A Z_2 f_z(\beta)$$

(*d*) $\gamma = 1$ and the reduced species B soluble in the electrolytic solution (upper sign)

$$[59] \qquad i_2 = i_1(t) + nFq(t)\sqrt{\frac{D_A}{\pi t_2}}\, C^*_A Z_2 \left\{ f_z(\beta) + \frac{\sqrt{\pi}}{2}\, \xi 2_A h_z(\beta) \right\}$$

Results and discussion

(A) i–t curves

The i–t response to a single pulse E_2 (normal pulse voltametry or polarography) is directly obtained from eq. [45] by making $E_1 \rightarrow \infty$. In this case we have $K_1 \rightarrow \infty$, $i_1 \rightarrow 0$ and $Z_2 = 1/(1 + \gamma K_2)$, and therefore

$$[60] \qquad i_2 = i_{NP} = nFq(t)\sqrt{\frac{D_A}{\pi t_2}}\, \frac{C^*_A}{1 + \gamma K_2} \times \left\{ f_z(\beta) + \frac{\sqrt{\pi}}{2}\, \Omega_2 \xi 2_A h_z(\beta) \right\}$$

If now we substitute $E_2 \equiv E_1$ (i.e. $\Omega_2 \equiv \Omega_1$), $t_1 \rightarrow 0$ (i.e. $\beta = 1$) and $\xi 2_A = \sqrt{2z+1}\,\xi 1_A$ in eq. [60], it reduces to a dc response, as can be seen from eq. [12]. The following equations are therefore valid:

$$[61] \qquad f_z(\beta = 1) = \sqrt{2z+1} \begin{cases} 1 & (z = 0) \\ \sqrt{7/3} & (z = 2/3) \end{cases}$$

$$[62] \qquad h_z(\beta = 1) = \frac{2}{\sqrt{\pi}}\, \theta_z \begin{cases} 1 & (z = 0) \\ 0.8878 & (z = 2/3) \end{cases}$$

The i_1–t and i_2–t curves obtained under conditions of control by diffusion for both pulses, i.e. $E_1 \rightarrow -\infty$ ($i_1 \equiv i_{D1}$) and $E_2 \rightarrow +\infty$ ($i_2 \equiv i_{D2}$), are shown in Figs. 2 and 3 for a SMDE, and Figs. 4 and 5 for a DME. They allow us to analyze the effects of sphericity and amalgam formation. Under these conditions eq. [45] leads to the following expression for a second pulse current:

$$[63] \qquad -\frac{i_{D2}}{i_0} = \frac{t^z}{\sqrt{t_2}} f_z(\beta) - \sqrt{2z+1}\, t^{z-1/2} + \frac{2t^z\sqrt{D_A}}{r_0} \times \left\{ M_z \frac{(\gamma \mp 1) g_z(\beta)}{\gamma\sqrt{\beta}} \pm \frac{\sqrt{\pi}}{2\gamma} h_z(\beta) - \theta_z \right\}$$

$$[64] \qquad M_z = \frac{4\sqrt{2z+1}}{(5z+4)\sqrt{\pi}}$$

$$[65] \qquad i_0 = nFA_0 C^*_A \sqrt{D_A/\pi}$$

The behaviour of the i_1–t and i_2–t curves is very similar to that shown in Figs. 2–5 when $E_1 - E_0 \leq -2RT/nF$ and $E_2 - E_0 \geq 2RT/nF$.

Since the current i_{D2} is due to the oxidization of species B, which initially is not present in the solution, it is clear that

$$[66] \qquad i_{D2} \rightarrow 0 \text{ when } t_2 \rightarrow +\infty$$

and this condition is verified both when B is soluble in the solution and when it produces amalgamation.

When $t_2 \rightarrow +\infty$ we have $\beta \rightarrow 1$, and therefore, by introducing eqs. [61] and [62] into eq. [63] we obtain (see also eqs. [52] and [55])

$$[67] \qquad g_z(\beta = 1) = \frac{\theta_z}{M_z} \begin{cases} \pi/2 & (z = 0) \\ 1.674 & (z = 2/3) \end{cases}$$

These results can also be obtained from eqs. [52] and [55].

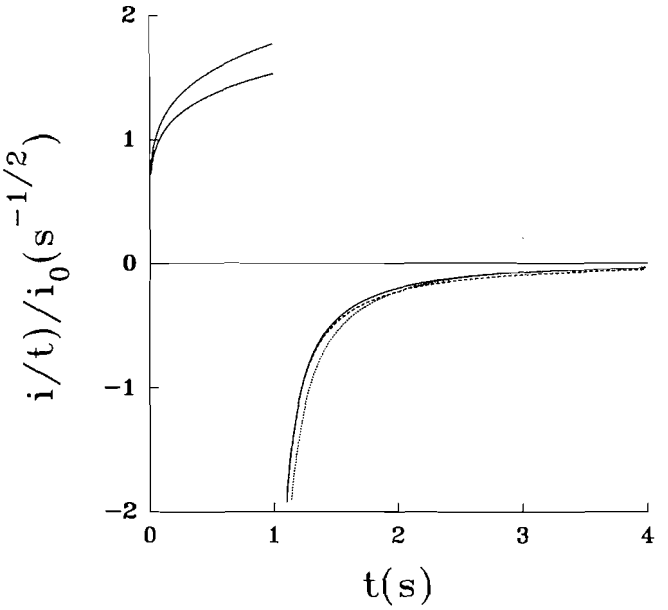

FIG. 4. Influence of the amalgamation on $i/i_0 - t$ recording for a double potential step in a DME (eq. [12] with $E_1 \rightarrow -\infty$ and [63]). $\xi 1^0_A = 0.2\ s^{-1/6}$. (—) Planar electrode, (– – –) solution-soluble product, (···) amalgam formation. Other conditions as in Fig. 2.

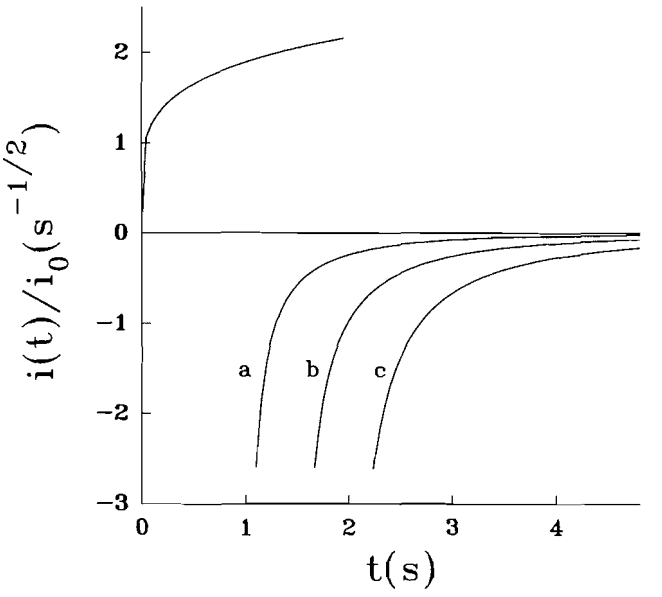

FIG. 5. Influence of the first pulse duration on $i/i_0 - t$ recorder for a double potential step in a DME. $\gamma = 1.3$, $\xi 1^0_A = 0.3\ s^{-1/6}$. The values of t_1 in s are (*a*) 1.0, (*b*) 1.5, (*c*) 2.0. Other conditions as in Fig. 3.

The Koutecky approximation (7) that we introduced in eq. [19] for amalgam formation works very well; this becomes apparent as in all cases:

[68] $\quad i_{D2} \leq 0$ for $0 < t_2 < +\infty$

However, in refs. 1 and 2 condition [68] is not fulfilled when the amalgamation takes place. This becomes clear in Figs. 3 and 4 (curves *b*) in ref. 1*a*, where i_2 suffers a change in sign for $t_2 > t_1$.

As shown in Figs. 2 and 4 SMDE and DME, respectively, the current i_2 is lower when amalgamation is present than

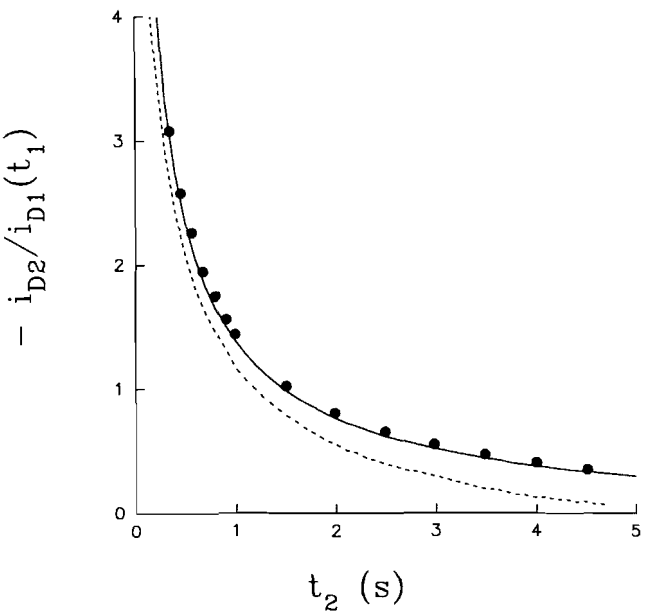

FIG. 6. Amalgam-forming systems: current–time response (●) for the second step in double-potential-step chronoamperometry at an SMDE (Pb(II)/Pb(Hg) system: $C_{Pb(II)} = 0.5$ mM; $[KNO_3] = 0.2$ M) with $E_1 = -0.7$ V, $E_2 = -0.2$ V, $t_1 = 5$ s, and $r_0 = 0.0413$ cm. (—) Current–time curve computed using eqs. [63] and [12]. (– – –) Current–time curve computed using eqs. [65] and [67] in ref. (1*a*).

when both species are soluble in the solution or for a plane electrode.

The effect of sphericity or a SMDE and the effect of the length of the first pulse, t_1, or a DME when species B amalgamates with the electrode are shown in Figs. 3 and 5, respectively.

Equation [63] has been used to explain the behaviour of the system Pb(II)/Pb(Hg) at a SMDE ($z = 0$). The applicability of eq. [63] corresponds to an experimental situation with $E_1 \ll E_0$ ($i_1 = i_{D1}$ cathodic current) and $E_2 \gg E_0$ ($i_2 = i_{D2}$ anodic current). Under these conditions the system Pb(II)/Pb(Hg) has been studied by double potential step chronoamperometry (1*b*). The experimental results from the literature (see Fig. 5 in ref. 1*b*) are shown in Fig. 6 (circles). Other experimental conditions are given in the caption of Fig. 6. The continuous line in Fig. 6 corresponds to the results obtained from eq. [63] with $D_A = 8.1 \times 10^{-6}$ cm^2/s ($D_{Pb(II)}$) and $D_B = 1.33 \times 10^{-5}$ cm^2/s ($D_{Pb(Hg)}$) (1*a*).

Following the procedure in ref. 1*b*, we have plotted $-i_{D2}/-i_{D1}(t_1)$, where $i_{D1}(t_1)$, is the solution of eq. [12] for $E_1 \ll E_0$ and $t = t_1$. As it can be noticed, there is an excellent agreement between experimental and the results obtained from eq. [63].

It has been also included in Fig. 6 the theoretical predictions of the model presented in ref. 1*a* (dashed line). As is observed and stated in ref. 1*b*, that model leads to wrong results for electrode processes with amalgam formation. The reason is that the model does not take into account the perturbation of the second pulse on the concentration profiles generated by the first potential pulse.

(B) Reverse pulse techniques

Reverse pulse techniques (1, 2, 3, 8–10) are based on the choice $E_1 \rightarrow -\infty$ ($K_1 \rightarrow 0$) and a variable potential E_2. The current $I_{RP} = -i_2/i_{DC}$ can then be easily evaluated from eq.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

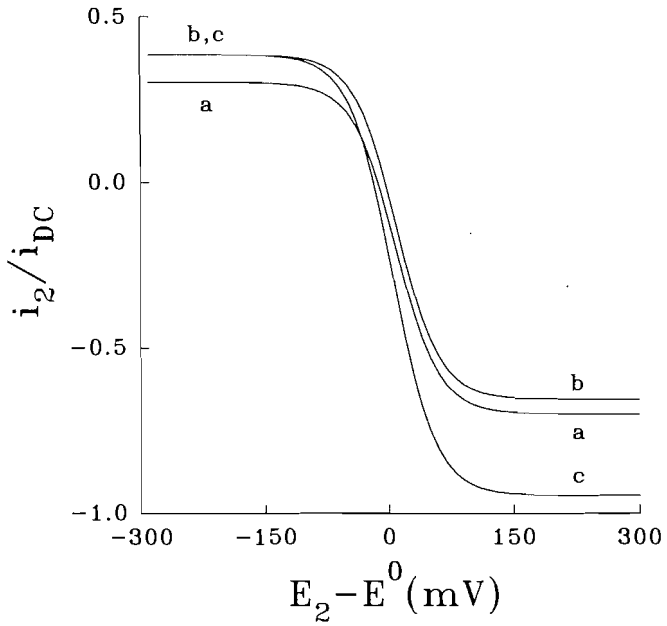

FIG. 7. Reverse pulse voltammograms computed by eq. [45] with $z = 0$ and $E_1 \rightarrow -\infty$. $\xi 1^0_A = 0.3\ s^{-1/2}$, $\gamma = 0.7$, $n = 1$, $T = 298$ K, $\beta = 0.091$. (*a*) Planar electrode, (*b*) solution soluble product, (*c*) amalgam formation.

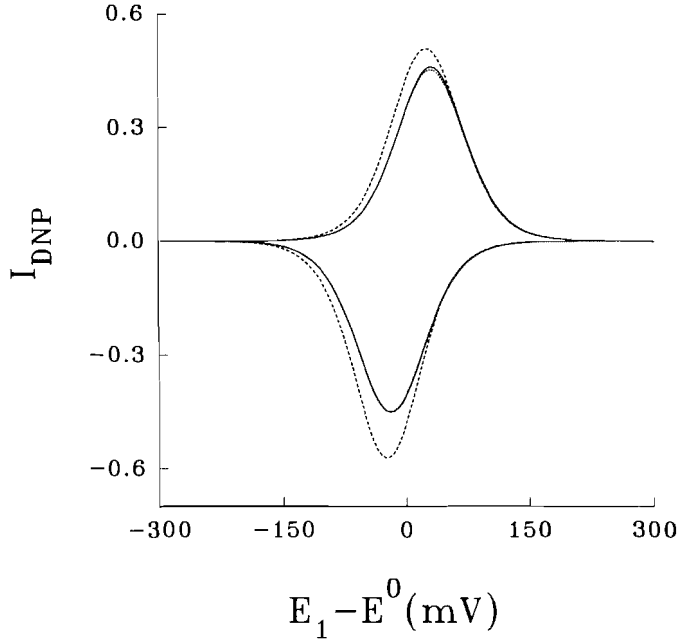

FIG. 8. Influence of amalgam formation in Differential Pulse Voltametry (eq. [76] with $z = 0$). $n = 1$, $\gamma = 0.8$, $\beta = 0.01$, $|\Delta E| = 50$ mV; (—) Solution-soluble product, (– – –) amalgam formation, (· · ·) planar electrode. Other conditions as in Fig. 7.

[45]. An example of application of this technique is shown in Fig. 7. It can be seen that the effect of sphericity is quite remarkable, whether the reaction product is soluble in the electrolytic solution or if it amalgamates.

A criterion to determine if amalgamation occurs in a spherical electrode can be found by analyzing the limiting values of the cathodic, i_{D1}, and anodic, i_{D2}, currents. For the sake of simplicity we consider a SMDE ($z = 0$), and from eq. [12] with $K_1 = 0$ we have

$$[69] \qquad \frac{i_{D1}}{i_{DC}} = \sqrt{\beta}\left(1 + \frac{\sqrt{\pi D_A t}}{r_0}\right)$$

where

$$[70] \qquad i_{DC} = nFA_0C^*_A\sqrt{\frac{D_A}{\pi t_2}}$$

Furthermore, from eqs. [63], [69], and [70]

$$[71] \qquad -\frac{i_{D2} - i_{D1}}{i_{DC}} = 1 + \frac{\sqrt{\pi D_A t_2}}{r_0} \times \left\{1 + \left(\frac{2g_0(\beta)}{\pi\sqrt{\beta}} - 1\right)\left(\frac{\gamma \mp 1}{\gamma}\right)\right\}$$

this equation can also be written as

$$[72] \qquad R = -\frac{i_{D2} - i^P_{D2}}{i_{D1} - i^P_{D1}} = \left(\frac{2g_0(\beta)}{\pi\sqrt{\beta}} - 1\right)\frac{(\gamma \mp 1)}{\gamma}$$

where i^P_{D1} and i^P_{D2} are the limiting values of i_{D1} and i_{D2} when $r_0 \rightarrow \infty$ (planar electrode), respectively, given by (eqs. [69] and [63] with $r_0 \rightarrow \infty$)

$$[73] \qquad i^P_{D1} = i_{DC}\sqrt{\beta}$$

$$[74] \qquad i^P_{D2} = i_{DC}(\sqrt{\beta} - 1)$$

Therefore, eq. [72] gives the ratio between the contributions of sphericity to the first and second pulses. Since the bracket in eq. [74] fulfills the condition

$$[75] \qquad 0 \leq \left(\frac{2g_0(\beta)}{\pi\sqrt{\beta}} - 1\right) \leq \infty \quad \text{for } 1 \geq \beta \geq 0$$

we can make the following classification: (*a*) If $0 \leq R < (2g_0(\beta)/\pi\sqrt{\beta} - 1)$, B is soluble in solution and $\gamma \geq 1$; (*b*) If $R < 0$, B is again soluble, and $\gamma < 1$; (*c*) If $R > (2g_0(\beta)/\pi\sqrt{\beta} - 1)$, then amalgamation is present.

(C) Differential pulse techniques

These techniques are characterized because $\Delta E = E_2 - E_1$ is kept constant. A cathodic record is obtained if $\Delta E < 0$, and an anodic record if $\Delta E > 0$. The response is $I_{DNP} = (i_2 - i_1)/i_{DC}$, which is positive if $\Delta E < 0$ and negative if $\Delta E > 0$, respectively. From eq. [45] we deduce

$$[76] \qquad I_{DNP} = \frac{\sqrt{2z+1}}{1+\gamma K_1}\left\{t^z\sqrt{\beta}[1 + \theta_z\Omega_1\xi 1_A(t)] - t_1^z\sqrt{\beta/(1-\beta)}[1 + \theta_z\Omega_1\xi 1_A(t_1)]\right\} + t^z Z_2\left\{f_z(\beta) + \frac{4(2z+1)(\gamma \mp 1)}{(5z+4)(1+\gamma K_1)\gamma\sqrt{\pi}} \times g_z(\beta)\xi 1_A + \frac{\sqrt{\pi}}{2}\Omega_2 h_z(\beta)\xi 2_A\right\}$$

A criterion for the analysis of electrode processes has been proposed by Birke et al. (6) on the basis of the ratio between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

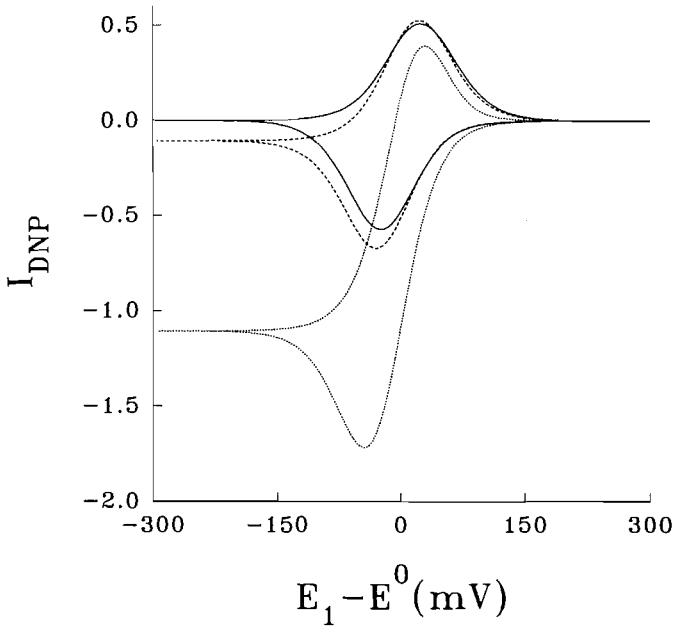

FIG. 9. Differential normal pulse voltagrams (eq. [76] with $z = 0$) when the amalgamation takes place. The values of β are (—) 0.01, (— — —) 0.3, (· · ·) 0.8. Other conditions as in Fig. 8.

the current peaks corresponding to two records with opposite values of ΔE. In this way the same peaks of current in absolute value are obtained in the cathodic and anodic records for a reversible charge transfer in a planar electrode with $\gamma = 1$. On the other hand, for a spherical electrode with amalgam formation the anodic record increases strongly with respect to the cathodic record (see Fig. 8).

The influence of β on the records obtained is shown in Fig. 9. In general, it can be said that amalgam formation increases the current peaks, and also that they are shifted to more positive values of potential.

Appendix

The differential equations [30] and [31] for $i = 0$ are simplified to

[A1] $$\sigma_{0,j}^{(-)''}(s2_A) + 2s2_A\sigma_{0,j}^{(-)'}(s2_A) - 2(j-1)\sigma_{0,j}^{(-)}(s2_A) = -4zs2_A\sigma_{0,j-2}^{(-)'}(s2_A) - 2(j-3)\sigma_{0,j-2}^{(-)}(s2_A)$$

[A2] $$\delta_{0,j}^{(\mp)''}(s2_B) + 2s2_B\delta_{0,j}^{(\mp)'}(s2_B) - 2(j-1)\delta_{0,j}^{(\mp)}(s2_B) = -4zs2_A\delta_{0,j-2}^{(\mp)'}(s2_B) - 2(j-3)\delta_{0,j-2}^{(\mp)}$$

The solutions of these equations (corresponding to an expanding plane electrode of area $q(t) = q_0 t^z$) with the boundary value problem given by eqs. [36], [37], and [39] with $i = 0$, are

[A3] $$\sigma_{0,2n}^{(-)}(s2_A) = 0 \qquad n = 0,\ 1,\ 2\ldots$$

[A4] $$\sigma_{0,1}^{(-)}(s2_A) = -\Psi_0^{(-)}(s2_A)C_A^*Z_2$$

[A5] $$\sigma_{0,3}^{(-)}(s2_A) = \frac{z}{\sqrt{\pi}}\, s2_A e^{-(s2_A)^2} C_A^* Z_2$$

[A6] $$\sigma_{0,5}^{(-)}(s2_A) = \frac{z}{2\sqrt{\pi}}\left\{\frac{z+4}{6} - z(s2_A)^2\right\} s2_A e^{-(s2_A)^2} C_A^* Z_2$$

[A7] $$\sigma_{0,7}^{(-)}(s2_A) = \frac{z}{6\sqrt{\pi}}\left\{\frac{4-z^2}{4} - z(z+2)(s2_A)^2 + z^2(s2_A)^4\right\} s2_A e^{-(s2_A)^2} C_A^* Z_2$$

For personal use only.

[A8] $$\sigma_{0,9}^{(-)}(s2_A) = \frac{z}{24\sqrt{\pi}}\left\{\frac{96-32z-56z^2-3z^3}{40} - \frac{z(8-z)(5z+8)}{12}(s2_A)^2 + \frac{z^2(5z+8)}{2}(s2_A)^4 - z^3(s2_A)^6\right\} s2_A e^{-(s2_A)^2} C_A^* Z_2$$

These functions hold

[A9] $$\sum_{n=0} \sigma_{0,2n+1}^{(-)'}(0)\beta^n = \frac{2C_A^* Z_2}{\sqrt{\pi}} f_z(\beta)$$

where

[A10] $$f_z(\beta) = 1 + \frac{z}{2}\beta + \frac{z(z+4)}{24}\beta^2 + \frac{z(2+z)(2-z)}{48}\beta^3 + \frac{z(96-32z-56z^2-3z^3)}{1920}\beta^4$$

This is equivalent to eq. [47] (13). Moreover

[A11] $$\delta_{0,2n+1}^{(\mp)}(s2_B) = \mp\gamma\sigma_{0,2n+1}^{(\mp)}(s2_B) \quad \text{unless } n = 0$$

[A12] $$\delta_{0,1}^{(\mp)}(s2_B) = -\gamma\sigma_{0,1}^{(\mp)}(s2_B)$$

For $i = 1$ (first order spherical correction) eqs. [30] and [31] become

[A13] $$\sigma_{1,j}^{(-)''}(s2_A) + 2s2_A\sigma_{1,j}^{(-)'}(s2_A) - 2j\sigma_{1,j}^{(-)}(s2_A) = -2\sigma_{0,j}^{(-)'}(s2_A) - 4zs2_A\sigma_{1,j-2}^{(-)'}(s2_A) + 6z(s2_A)^2\sigma_{0,j-2}^{(-)'}(s2_A) - 2(z+j-3)\sigma_{1,j-2}^{(-)}(s2_A)$$

[A14] $$\delta_{1,j}^{(\mp)''}(s2_B) + 2s2_B\delta_{1,j}^{(\mp)'}(s2_B) - 2j\delta_{1,j}^{(\mp)}(s2_B) = -2\delta_{0,j}^{(\mp)'}(s2_B) - 4zs2_B\delta_{1,j-2}^{(\mp)'}(s2_B) + 6z(s2_B)^2\delta_{0,j-2}^{(\mp)'}(s2_B) - 2(z+j-3)\delta_{1,j-2}^{(\mp)}(s2_B)$$

and the solutions are

[A15] $$\sigma_{1,0}^{(-)}(s2_A) = -\frac{C_A^* Z_2 N_z}{\gamma}\Psi_0^{(-)}(s2_A)$$

[A16] $$\sigma_{1,1}^{(-)}(s2_A) = \frac{1}{\sqrt{\pi}}\{e^{-(s2_A)^2} - \Omega_2\Psi_1^{(-)}(s2_A)\}C_A^* Z_2$$

[A17] $$\sigma_{1,2}^{(-)}(s2_A) = \left\{\frac{z}{\sqrt{\pi}} s2_A e^{-(s2_A)^2} - \frac{z-1}{2}[\Psi_0^{(-)}(s2_A) - \Psi_2^{(-)}(s2_A)]\right\}\frac{C_A^* Z_2 N_z}{\gamma}$$

[A18] $$\sigma_{1,3}^{(-)}(s2_A) = \frac{z}{2\sqrt{\pi}}\left\{[\Omega_2 - 4(s2_A)^2]e^{-(s2_A)^2} - \Omega_2[3\Psi_1^{(-)}(s2_A) - 2\Psi_3^{(-)}(s2_A)]\right\}$$

[A19] $$\sigma_{1,4}^{(-)}(s2_A) = \left\{\left(\frac{7z-2}{6} - z(s2_A)^2\right)\frac{z}{2\sqrt{\pi}} s2_A e^{-(s2_A)^2} - \frac{(z-1)(5z+1)}{8}[\Psi_0^{(-)}(s2_A) - 2\Psi_2^{(-)}(s2_A) + \Psi_4^{(-)}(s2_A)]\right\}\frac{C_A^* Z_2 N_z}{\gamma}$$

[A20] $$\sigma_{1,5}^{(-)}(s2_A) = \frac{z}{2\sqrt{\pi}}\left\{\left(\frac{2(13z+4)\Omega_2 - 5z - 2}{24} - \frac{17z+14+6z\Omega_2}{12}(s2_A)^2 + 3z(s2_A)^4\right)e^{-(s2_A)^2} - \frac{(7z+2)\Omega_2}{8}[6\Psi_1^{(-)}(s2_A) - 8\Psi_3^{(-)}(s2_A) + 3\Psi_5^{(-)}(s2_A)]\right\}C_A^* Z_2$$

[A21] $$\sigma_{1,6}^{(-)}(s2_A) = \left\{\left(\frac{3z^2-z-1}{4} - \frac{z(5z+1)}{6}(s2_A)^2 + \frac{z^2}{3}(s2_A)^4\right)\frac{z}{2\sqrt{\pi}} s2_A e^{-(s2_A)^2} - \frac{(z-1)(5z+1)(3z+1)}{16}[\Psi_0^{(-)}(s2_A) - 3\Psi_2^{(-)}(s2_A) + 3\Psi_4^{(-)}(s2_A) + \Psi_6^{(-)}(s2_A)]\right\}\frac{C_A^* Z_2 N_z}{\gamma}$$

Received May 28, 1994

GUANGZHONG ZHANG, YIJIAN SHI, RENÉE MOSI, THAO HO, and PETER WAN. Can. J. Chem. **72**, 2388 (1994).

The photoprotonation of four dialkoxy-substituted benzenes in their excited singlet states has been studied. The parent systems **4** and **5** are regioselectively photoprotonated at the 2-position, with significant quantum efficiencies for deuterium incorporation at acidities greater than pH 2. The structurally related cyclophane derivatives **6** and **7** did not show any deuterium exchange over the same acidity range but fluorescence quenching by proton (in aqueous solution) and laser flash photolysis studies (in 1,1,1,3,3,3-hexafluoro-2-propanol) indicate that photoprotonation does take place with these compounds. Due to structural constraints imposed by the most stable conformation adopted by these molecules (**6** and **7**), the attacking proton (deuteron) is also the proton (deuteron) that is deprotonated from the cyclohexadienyl cation (2,6-dialkoxybenzenonium ion) intermediate, resulting in the absence of incorporation of deuterium.

GUANGZHONG ZHANG, YIJIAN SHI, RENÉE MOSI, THAO HO et PETER WAN. Can. J. Chem. **72**, 2388 (1994).

On a étudié la photoprotonation de quatre benzènes substitués par deux groupes alkoxyles, dans leurs états singulets excités. Les systèmes fondamentaux **4** et **5** sont photoprotonés régiosélectivement en position 2, avec des efficacités quantiques importantes pour l'incorporation du deutérium à des acidités plus grandes qu'un pH de 2. À des degrés d'acidité semblable, les dérivés cyclophanes structuralement apparentés **6** et **7** ne présentent pas d'échange du deutérium; toutefois, des études de désactivation de la fluorescence par les protons (en solution aqueuse) et de photolyse éclair au laser (dans le 1,1,1,3,3,3-hexafluoropropan-2-ol) indiquent qu'il se produit bien un photodéprotonation de ces composés. À cause des contraintes de structure imposées par la conformation stable adoptée par ces molécules (**6** et **7**), le proton (deutéron) qui attaque est aussi le proton (deutéron) qui est déprotoné à partir du cation cyclohexadiényle (ion 2,6-dialkoxybenzénonium) intermédiare; il en résulte donc qu'il n'y a pas d'incorporation de deutérium.

[Traduit par la rédaction]

Introduction

Deuterium exchange of aromatic rings most often proceeds via initial electrophilic attack of the aromatic ring by proton (deuteron) and therefore represents the simplest of all electrophilic aromatic substitution reactions (1, 2). In general, relatively strong acids are required to effect observable reaction rates in the thermal process. We have shown in recent studies (3–6) that dimethoxy-substituted benzenes are particularly prone to undergo deuterium exchange when photolyzed (via the S_1 state) in dilute aqueous D_2SO_4, under conditions where the thermal rate for exchange is not measurable or is negligible. Moreover, we found (4) that 1,3-dimethoxybenzene (**1**) undergoes deuterium exchange primarily at the 2-position, and to a much lesser extent at the 5-position. In contrast, thermal exchanges take place primarily at the 4-position, and to a lesser extent at the 2-position. The difference in sites of protonation between the S_0 and S_1 states of **1** may be readily rationalized by simple HMO theory (4–6), by considering the change in MO coefficients on the benzene ring on promoting an electron from the HOMO to the LUMO. With respect to mechanism, evidence for formation of the expected cyclohexadienyl cation intermediate **2** (2,6-dimethoxybenzenonium ion) (eq. [1]) and derivatives

[1] 
1 **2** **3**

is available from laser flash photolysis (LFP) studies carried out in 1,1,1,3,3,3-hexafluoro-2-propanol (HFP) by McClelland and co-workers (7).

The finding that the 2-position of **1** is a very basic site in S_1 that can be protonated in mild acid naturally invites the investigation of related compounds. In principle, these systems offer a general method for the study of cyclohexadienyl cations under conditions where they could not be generated under thermal (equilibrium) conditions. To this end, Lew and McClelland (8) recently reported the photochemical generation of β-silyl-substituted-1,3-dimethoxycyclohexadienyl cations in HFP. In this paper, we address two structural effects on the excited state photoprotonation process: (*a*) the effect of using two larger alkoxy groups (compared to methoxy) as represented by compounds **4** and **5**; and (*b*) the effect of tethering the two alkoxy groups in two different ways, as represented by cyclophanes **6** and **7**, as probes for a stereoelectronic requirement for proton exchange. We report[2] that both **4** and **5** react with similar efficiency to **1** whereas neither **6** nor **7** undergo measurable deuterium ex-change. However, fluorescence and LFP studies in HFP indicate that cyclophane **7** is photoprotonated almost as efficiently as **4** or **5**, with **6** less efficiently so. The lack of observed deuterium exchange in **6** and **7**

[1]Author to whom correspondence may be addressed.

[2]Full details of the photochemical exchange of **4** and **5** are reported, along with those of several other more closely related systems, in a separate paper (14) concerned with the generality of the reaction for simpler systems.

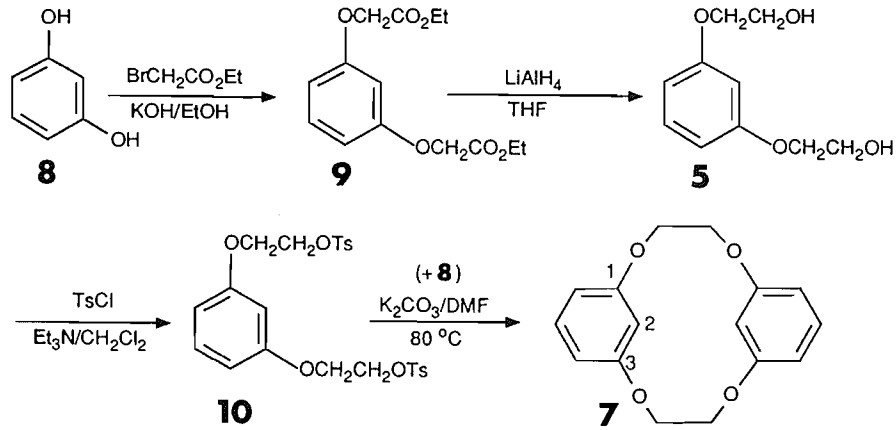
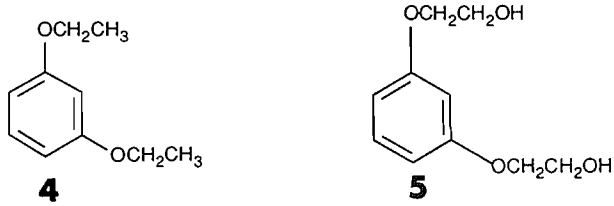


SCHEME 1

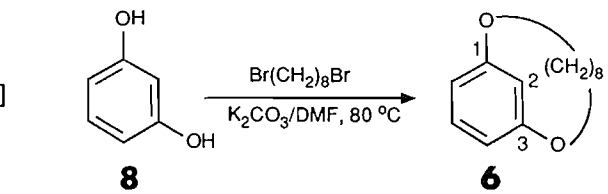


is attributed to the structural constraints imposed by these systems that permit only the attacking proton (deuteron) to be deprotonated from the intermediate cyclohexadienyl cations.

Results and discussion

Materials

Compound **4** was made by alkylation of resorcinol (**8**) with iodoethane. Diol **5** was made from $LiAlH_4$ reduction of diester **9**, which was readily available from the reaction of resorcinol (**8**) with ethyl bromoacetate (Scheme 1). Cyclophane **6** was made from a modified published procedure (9, 10), involving the reaction of resorcinol (**8**) with 1,8-dibromooctane (eq. [2]).



It has been shown (9) that an eight-carbon methylene chain is probably the shortest chain that can successfully tether the 1,3-positions of resorcinol (**8**). Therefore, this eight-carbon chain is expected to impart severe steric interactions with the π-system of the benzene ring of **6**. We were unable to obtain crystals of sufficient quality for an X-ray structure determination. However, a minimized PCMODEL structure shows (Fig. 1) that there are severe steric interactions on one side of the benzene ring, especially in the vicinity of the 2-position. Space filling displays show this congestion even more convincingly. Photoprotonation at the 2-position from the other side would result in pushing the 2-hydrogen into the methylene chain as C2 changes hybridization from sp^2 to sp^3. Based on this analysis, the photoprotonation rate of **6** should be attenuated significantly if not prevented altogether.

Cyclophane **7** was made via the reaction sequence shown in Scheme 1 with an overall yield of ≈2% from resorcinol (**8**).

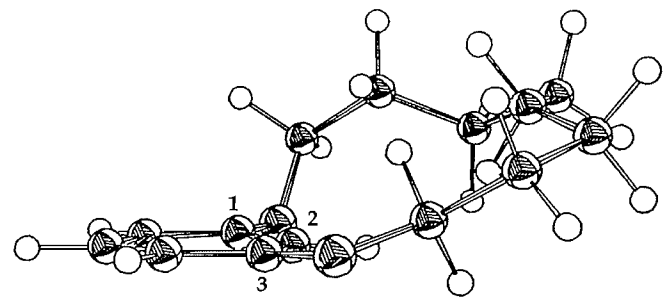


FIG. 1. Minimized structure of **6** from a PCMODEL calculation. Spacing filling presentation shows severe steric congestion on the top face of the benzene ring around and near the 2-position.

Molecular mechanics calculations (PCMODEL) predict that the *anti* conformation will be of lowest energy. This was confirmed by its crystal structure (Table 1 and Fig. 2). Steric interactions around the 2-position (C2) are less severe than is the situation for **6**. As in the case of **6**, the photoprotonation can only take place from one face of the benzene ring. Because the tethering ring is large, the change in hybridization at C2 on protonation can be readily accommodated. This may result in a faster protonation rate than for **6**.

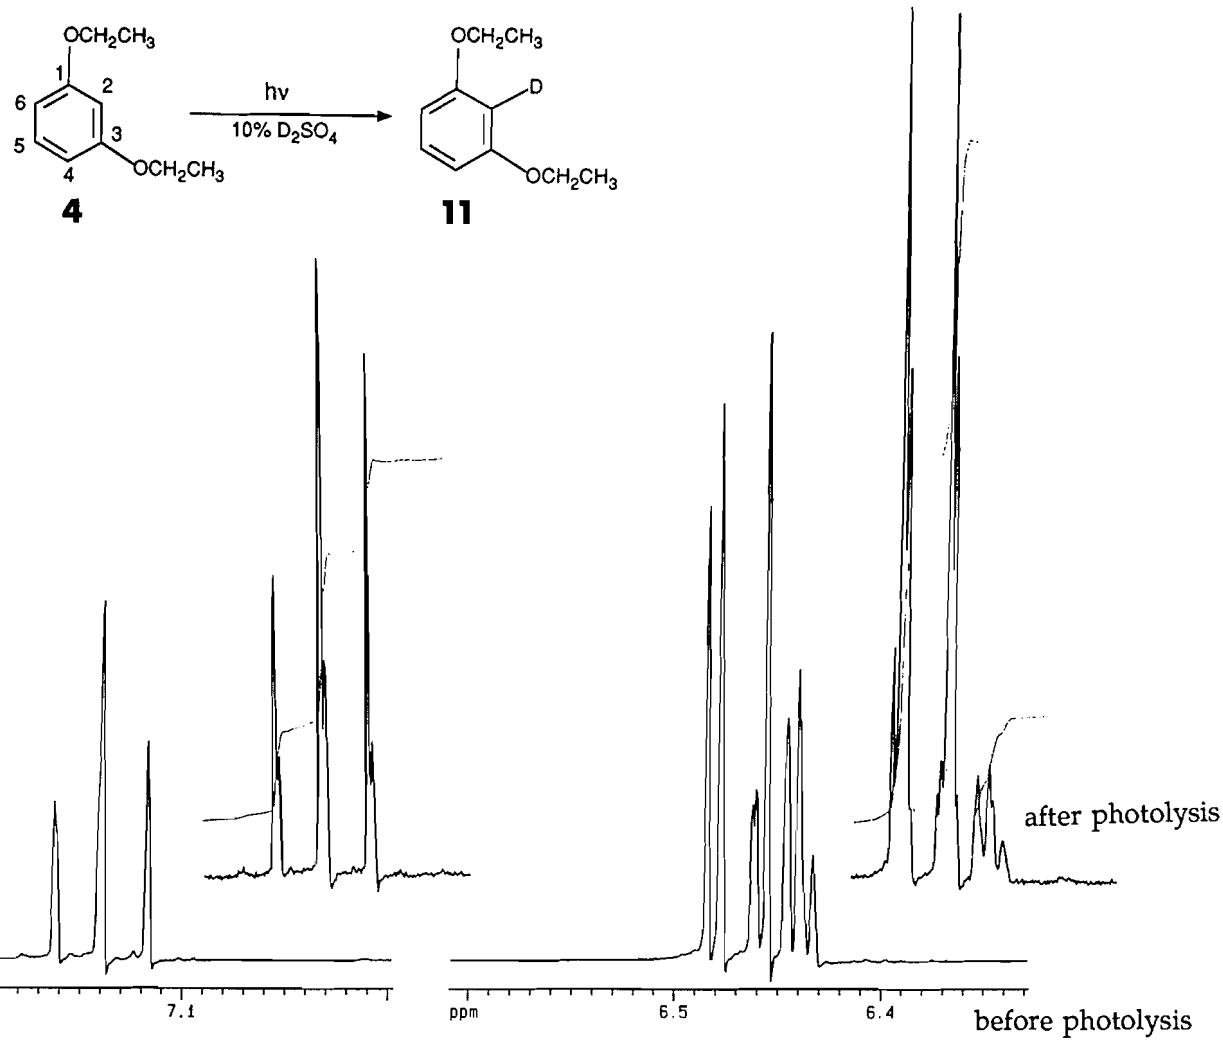

FIG. 3. ^{1}H NMR (360 MHz) spectra (aromatic portion only) of deuterium incorporation for **4** on photolysis in 2:1 10% D_2SO_4 – CH_3CN (60 min). Lower spectrum is unreacted starting material. Upper spectrum is recovered material after photolysis.

Deuterium exchange studies

Photolysis of $\approx 10^{-3}$ M solutions of **4** and **5** in 2:1 aqueous D_2SO_4 – CH_3CN (Rayonet RPR 100 photochemical reactor; 10–60 min; 254-nm lamps; argon purged; ≈15°C) resulted in clean deuterium incorporation into the 2-positions of these compounds when pD ≤ 2. The exchange can be followed readily by 360 MHz ^{1}H NMR, as shown in Fig. 3 for reaction of **4**. On photolysis, the triplet of H2 (δ 6.44, J = 2 Hz) of unre-

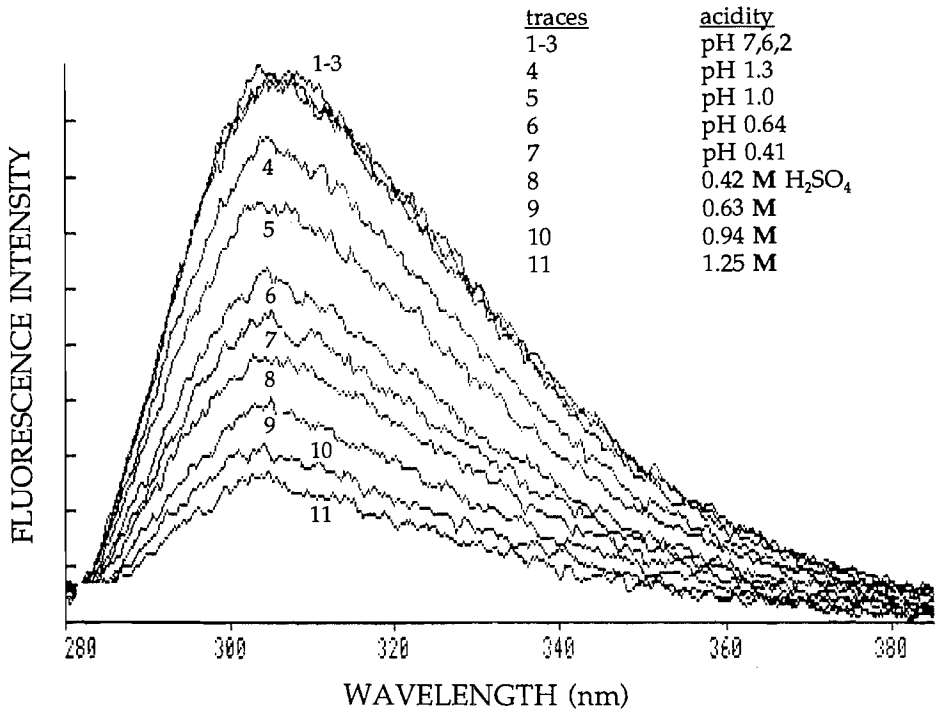

FIG. 4. Fluorescence quenching by protons observed for **7** carried out in 9:1 H_2O–CH_3CN (λ_{ex} = 265 nm).

acted **4** decreased in intensity while a doublet (J = 8 Hz) grows in at δ 6.47, which is attributed to H4 of the exchanged product **11** since coupling to deuterium at the 2-position is not resolvable. In addition, the triplet (J = 8 Hz) of H5 of **11** is slightly further upfield than H5 of unreacted **4** (at δ 7.14). NMR integration of this run gave ≈70% exchange of H2. In general, mass spectra (GC–MS) gave percent deuterium content in close agreement with the values calculated by NMR integration. Similar results were observed for **5**. Thermal exchange was not observed or was insignificant in the range of acidity studied (pD 7–10% (w/w) D_2SO_4). In stronger acids (e.g., 30% D_2SO_4), thermal exchange takes place predominantly at C4 of these compounds (4, 5).

Photolysis of **6** or **7** under the above conditions (or with longer photolysis times, up to 2 h) resulted in complete recovery of unreacted substrate; no deuterium incorporation was observed by NMR or GC–MS. The complete lack of deuterium incorporation is consistent with expectation based on the stereoelectronic requirements for exchange. However, it is not clear at this point whether **6** or **7** is photoprotonated at all. Fluorescence and LFP studies (*vide infra*) were used to address this.

Quantum yields

Quantum yields (Φ) for formation of the corresponding 2-deuterio products from **4** and **5** were measured as a function of medium acidity (8:2 aqueous $D_2SO_4(H_2SO_4)$ – CH_3CN; λ_{ex} = 254 nm) in 3.0-mL quartz cells using GC–MS for analysis. Conversions were kept below 20% to avoid dideuteration. The results are shown in Table 2. Quantum yields (Φ) for exchange were measurable at acidities greater than pD 2, increasing rapidly with increasing acidity in this acidity region. The values are similar to those reported for **1** in our previous study (4). The presence of the extra hydroxyl groups in **5** results in a significant reduction in Φ that can be completely attributed to a reduction in the photoprotonation rate for this compound (*vide infra*).

Steady-state and transient fluorescence studies

Fluorescence emission spectra of **4**–**7** were measured as a function of medium acidity, in wholly aqueous medium for **4**–**6** and with 10% CH_3CN for **7**, the latter being less soluble. Fluorescence emissions from all of **4**–**7** were quenched on increasing acidity, as shown in Fig. 4 for **7**. Stern–Volmer plots of fluorescence quenching were linear, as shown in Fig. 5 for both cyclophanes **6** and **7**. Absolute fluorescence quantum yields were measured in 8:2 H_2O-CH_3CN (water portion at pH 7) using 1,3-dimethoxybenzene (**1**) as reference (Φ_f = 0.14 ± 0.02) (4) and are shown in Table 3. Fluorescence lifetimes were measured at pH 7 using single photon counting and are given in Table 3.

Laser flash photolysis studies

LFP studies (YAG laser; 266 nm; <20 mJ) of **1** and **4**–**7** in 1:1

[a]Fluorescence lifetime from single photon counting, in wholly aqueous solution (pH 7) unless otherwise noted.
[b]Fluorescence quantum yield in 8:2 H_2O–CH_3CN (pH 7) using 1,3-dimethoxybenzene (**1**) as reference (Φ_f = 0.14 ± 0.02) (4).
[c]Quenching rate constant by proton from Stern–Volmer analysis. Equatable to photoprotonation rate constant (k_H).
[d]Data from ref. 4.
[e]Lifetime measured in 9:1 H_2O–CH_3CN (pH 7) due to poor solubility.

H_2O–CH_3CN (pH 7; 5 and 10% H_2SO_4) in a flow cell (oxygen purged) gave a weak ($\Delta OD \leq 0.01$) transient at 460 nm. The initial intensity and the first-order decay of this signal were not significantly affected by the acidity of the medium ($k_{decay} = 1 \times 10^5$ s^{-1} at pH 7). In addition, since none of **1** and **4–7** photoexchange in neutral aqueous solution (**6** and **7** do not exchange even in acid), the transient at 460 nm cannot be a cyclohexadienyl cation. Moreover, McClelland and co-workers (7) have reported LFP results for **1** (and related compounds) in HFP in which the *strongly absorbing* ($\Delta OD \approx 0.1$) photogenerated cation **2** had λ_{max} = 410 nm ($k_{decay} = 4.2 \times 10^3$ s^{-1} at 20°C). Although the 50 nm difference in λ_{max} might be attributable to a solvent shift, the large difference in initial absorbance cannot be readily accounted for unless the quantum yield for photoprotonation (i.e., generation of cyclohexadienyl cation) is much lower in H_2SO_4–CH_3CN than in HFP. To examine this possibility, relative quantum yields for photochemical exchange of **3** (Φ_e) were carried out in HFP and in 5% H_2SO_4 (20% CH_3CN in both solutions) and analysis was carried out by NMR. We reported $\Phi_e = 0.10$ for **3** in 5% H_2SO_4 (4). We found that Φ_e was about a factor of two lower in HFP ($\Phi_e \approx 0.05$), indicating that cation **2** is generated *more* efficiently in aqueous acid (5% H_2SO_4) than in HFP, assuming that the primary isotope effect for loss of proton (deuteron) is similar in the two solvent systems. All of these observations strongly indicate that the 460-nm transient observed in aqueous solution is not due to the cyclohexadienyl cation. It is assigned to the corresponding radical cation since several thermally generated dimethoxybenzene radical cations have λ_{max} near 450 nm (11, 12). Interestingly, the radical cations in our study are probably formed via a one-photon process in aqueous solution (1:1 H_2O–CH_3CN) since a plot of ΔOD vs. laser power (5–33 mJ; intercept of plot went through the origin) for **1** gave good linear plots whereas plotting ΔOD versus the square of the laser power gave curved plots. The conclusion from LFP studies in aqueous solution is that cyclohexadienyl cations of the general type **3** are too short-lived in aqueous solution, even in 10% H_2SO_4, and a picosecond laser system would be required to detect these transients in this medium.

Fluorescence quenching by protons in aqueous medium observed for each of **4–7** (Table 3) indicated that they are all photoprotonated, although with different rates. This implies that cyclohexadienyl cations are formed in aqueous acid in all cases. Because these cations are apparently too short-lived in this medium, we carried out additional LFP studies of **4–7** in HFP, to confirm that all of **4–7** are indeed photoprotonated to give the corresponding cyclohexadienyl cations. Since neither **6** nor **7** undergo exchange, fluorescence quenching results alone for these two compounds are not sufficiently compelling to warrant the conclusion that they are also photoprotonated. LFP of **4–7** in HFP (oxygen-purged samples) gave much stronger transients than those observed in H_2O–CH_3CN. These transients have λ_{max} in the region 415–450 nm with decays unaffected by oxygen but very sensitive to the presence of water and added MeOH. These transients are assigned as the corresponding 1,3-dialkoxybenzenonium ions

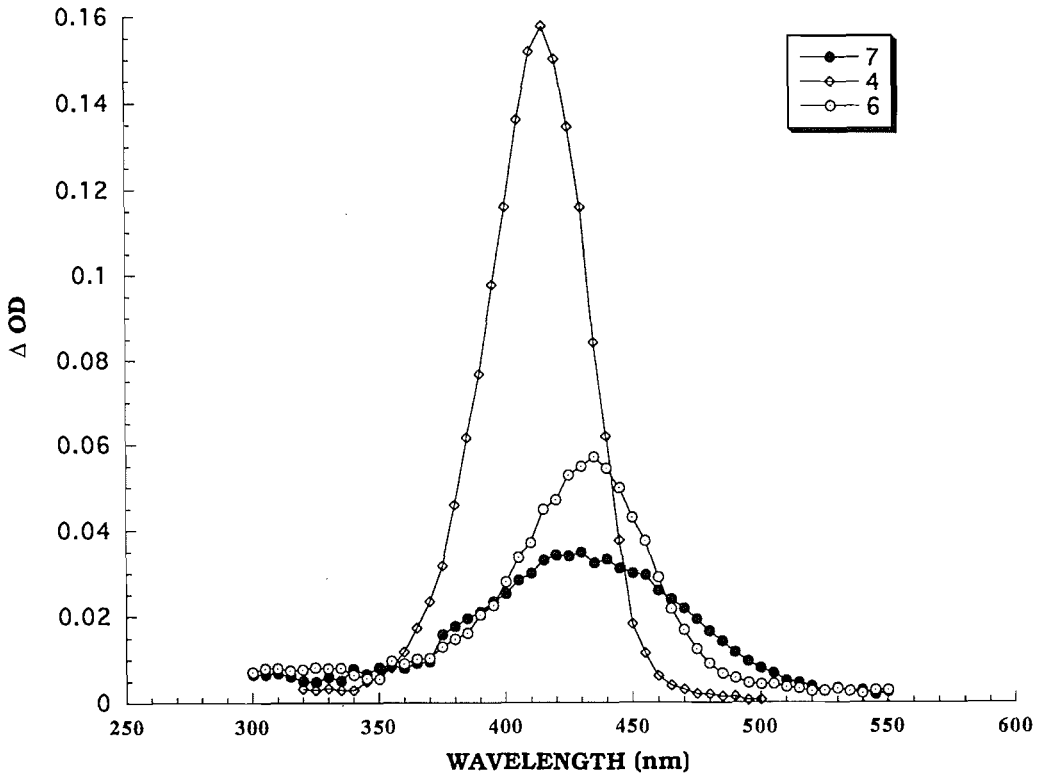

FIG. 6. Overlay of transient spectra observed from LFP studies of **4**, **6**, and **7** in HFP ≈0.5 μs after the laser pulse.

(Fig. 6), generated via photoprotonation in HFP. The transient spectra observed for **4** and **5** are essentially identical to that reported for 1,3-dimethoxybenzenonium ion in HFP (7) with $\lambda_{max} = 415$ nm ($k_{decay} = 2.1 \times 10^4$ s^{-1} and 6.9×10^4 s^{-1} for **4** and **5**, respectively). The initial ΔOD observed for **5** was ≈0.6, a factor of about 2.5 lower than for **4**. This is consistent with the difference in photoprotonation rates (k_q) (Table 3) and quantum yields of exchange (Table 2) measured for these two compounds in aqueous acid. The 1,3-benzenonium ion for **6** is red-shifted ($\lambda_{max} = 485$ nm) with $k_{decay} = 2.8 \times 10^5$ s^{-1}. Similarly, the 1,3-benzenonium ion for **7** is also red-shifted with a broader envelope (λ_{max} = 415–450 nm). Moreover, whereas the transient decays observed for all of **4**–**6** were good first order and independent of wavelength, decays for the transient observed for **7** could not be fitted to a single exponential decay. They could be fitted to the sum of two first-order exponentials, although fitting to higher-order sums was not investigated. Rate constants derived from biphasic fits were dependent on the monitoring wavelength. For example, monitoring the decay at 430 nm gave two components with 1.0 and 4.4 μs lifetimes while monitoring at 480 nm gave 1.2 and 3.9 μs lifetimes. These differences in lifetimes are well above the experimental error normally expected on the LFP system and fitting program used, which are typically <10%. These observations are consistent with our view that the transient observed for **7** is a composite of a variety of 1,3-benzenonium ions. This is reasonable since **7** is conformationally the most flexible system and several very close lower energy conformations are available for either **7** itself or its corresponding 1,3-benzenonium ion. Thus, the results are consistent with photoprotonating several different conformers or the initially photoprotonated single isomer can exist as several relatively stable conformers, or a combination of the two situations.

Conclusions

This study has shown that the 2-position of a variety of 1,3-dialkoxybenzenes is kinetically as basic (as measured by fluorescence quenching rates) as that of the parent 1,3-dimethoxybenzene and that it is possible to design systems in which the attacking proton is the proton that is also deprotonated. Replacement of an ethoxy group (**4**) for methoxy (**1**) resulted in no observable changes in reactivity. The fluorescence parameters for these compounds are essentially the same (Table 3) and LFP studies in HFP show essentially identical spectra for the two 1,3-benzenonium ions. The lower Φ for deuterium exchange observed for **5** compared to that for **4** is due to a lower rate for photoprotonation (k_q) (Table 3). This may be due to the increased solvent congestion present in **5**, due to hydrogen bonding of the hydroxyl groups with solvent water, which retards the rate of protonation. The resulting 1,3-benzenonium ion for **5** was essentially identical to that observed for **4** except that it was it was formed 50% less efficiently (based on initial ΔOD's), consistent with the difference in k_q's (Table 3) and Φ's (Table 2). The main finding in this work is that cyclophanes **6** and **7** are photoprotonated at substantial rates, giving rise to their respective 1,3-benzenonium ions. Steric constraints built into these systems require that only the attacking proton can be deprotonated from the intermediate 1,3-benzenonium ions, resulting in lack of proton exchange for these compounds. Protonation (deuteration) takes place from the more open side as shown in **12** for

7. Since the deuteron is much more exposed than the original proton, it is selectively lost in the re-aromatization step, resulting in lack of deuterium incorporation. Additional studies are in progress that are aimed at learning about controlling these photochemical reactions by appropriate design of substrate structure.

Experimental

General

^{1}H NMR spectra were recorded on Perkin–Elmer R32, Bruker WM 250, or Bruker AM 360 instruments, in $CDCl_3$ (TMS internal standard). Mass spectra were taken on Finnigan 3300 (CI) or Kratos Concept H (EI) instruments. Melting points were obtained on a Koefler hot stage microscope and are uncorrected. Preparative photolyses were carried out in Suprasil quartz cuvettes, 25- or 100-mL quartz tubes using a Rayonet RPR 100 photochemical reactor with 16 × 254 nm lamps. Chemical analysis was performed by Canadian Microanalytical Service, Delta, B.C.

Materials

Resorcinol (**8**), iodoethane, 1,8-dibromooctane, triethylamine, *p*-toluenesulfonyl chloride, and ethyl bromoacetate were purchased from Aldrich and used as received.

*Resorcinol octamethylene ether (**6**)*

To a mechanically stirred solution of K_2CO_3 (15.1 g, 0.11 mol) in 2 L DMF in a 4-L round-bottom flask was added a mixture of resorcinol (3.0 g, 0.027 mol) and 1,8-dibromooctane (7.4 g, 0.027 mol) in 500 mL DMF over the course of 4 days using a slow-addition funnel. During the course of addition, the reaction mixture was kept at ~80°C under N_2. After addition, the mixture was stirred at 80°C overnight and filtered. The filtrate was diluted with an equal amount of CH_2Cl_2 and washed with saturated NaCl solution (5 times) followed by 1 M NaOH solution (3 times). The organic layer was dried over $MgSO_4$. Removal of the solvent gave a brown sticky solid, which was subjected to column chromatography (silica, CH_2Cl_2–hexanes) to give a white solid. Recrystallization from hexane gave 120 mg (2% yield) of white needles, mp 104–105°C (lit. (9) mp 99–100.5°C); ^{1}H NMR (250 MHz), δ: 1.24–1.53 (m, 8H), 1.85–1.93 (m, 4H), 4.09–4.16 (m, 4H), 6.49 (dd, J = 8 Hz and 2 Hz, 2H), 6.61 (t, J = 2 Hz, 1H), 7.10 (t, J = 8 Hz, 1 H); mass spectrum (CI) (*m/z*): 221 ($M^+ + 1$).

*1,3-Diethoxybenzene (**4**)*

To a stirred solution of **8** (15 g, 0.14 mol) in 100 mL acetone was added 25 mL (0.21 mol) iodoethane and 43.2 g (0.31 mol) anhydrous K_2CO_3 with stirring. The mixture was gently refluxed for 8 h. It was then diluted with H_2O (500 mL) and extracted with 3 × 50 mL ether. Evaporation of the ether followed by bulb-to-bulb distillation gave 13.6 g (60%) of **4** as a clear oil. ^{1}H NMR (90 MHz); δ: 1.40 (t, J = 8 Hz, 6H, CH_3), 4.00 (q, J = 8 Hz, 4H, $ArOCH_2$), 6.45 (t, J = 2.4 Hz, 1H, H2), 6.51 (d, J = 8 Hz, 2H, H4), 7.15 (t, J = 8 Hz, 1H, H5).

*Diester **9***

Resorcinol (30.0 g, 0.27 mol) and ethyl bromoacetate (136.5 g, 0.82 mol) were dissolved in 900 mL EtOH, transferred to a 4-L round-bottom flask equipped with a mechanical stirrer (under N_2), and brought to reflux. Excess KOH (45.9 g, 0.82 mol) in EtOH was added dropwise to the refluxing mixture. After addition, the mixture was mechanically stirred and refluxed for 3 days. After cooling, 1 L H_2O was added and the resulting solution extracted with diethyl ether and back-washed with 0.1 M ice-cold NaOH. The extract was dried over $MgSO_4$ and the solvent evaporated. Subsequent bulb-to-bulb distillation afforded 36 g (47%) of **9** as a viscous colourless oil. ^{1}H NMR (90 MHz); δ: 1.3 (t, 6H, J = 6 Hz), 4.2 (q, 4H, J = 6 Hz), 4.6 (s, 4H), 6.5–7.3 (m, 4H).

*1,3-Bis(2′-hydroxyethoxy)benzene (**5**)*

Diester **9** (20 g, 0.07 mol) was dissolved in 250 mL dry THF and excess $LiAlH_4$ (4.0 g, 0.11 mol) was added in portions, after which the reaction mixture was refluxed for 3 h. The solution was allowed to cool and 100 mL of NaCl-saturated H_2O was added. The solution was then acidified with 10% HCl and extracted with several portions of Et_2O. Removal of the solvent gave 11.4 g (81%) of **5** as a white solid, on standing. ^{1}H NMR (360 MHz); δ: 2.04 (t, J = 6 Hz, 2H), 3.92–4.06 (m, 8H), 6.49 (t, J = 2 Hz, 1H) 6.52 (dd, J = 8 Hz and 2 Hz, 2H), 7.17 (t, J = 8 Hz, 1H).

*Ditosylate **10***

Diol **5** (2.0 g, 0.01 mol) was dissolved in 250 mL of CH_2Cl_2 and transferred to a 500-mL round-bottom flask and cooled in an ice bath (~ –5°C). Triethylamine (2.2 g, 21.2 mmol) was added dropwise. A slight excess of *p*-toluenesulfonyl chloride (4.0 g, 20.7 mmol) was then added in portions to the above solution, keeping the temperature no higher than 0°C. After 1 h at 0°C, the stirred reaction mixture was allowed to reach room temperature and was stirred for 4 days. The solution was then washed with H_2O, 1 M HCl, and $NaHCO_3$ and the organic layer dried over $MgSO_4$. Removal of the solvent gave a yellow viscous liquid, which was washed several times with 100% EtOH to remove unreacted *p*-toluenesulfonyl chloride. This material turned into a white solid (2.9 g, 60%), on standing, which was used without further purification in the next step. ^{1}H NMR (90 MHz); δ: 2.4 (s, 6H), 4.1 (t, 4H, J = 6 Hz), 4.3 (t, 4H, J = 6 Hz), 6.25 (t, 1H, J = 2 Hz), 6.4 (dd, 2H, J = 8 Hz and 2 Hz), 7.1 (t, 1H, J = 8 Hz), 7.35 (d, 4H, J = 8 Hz), 7.8 (d, 4H, J = 8 Hz).

*Bis(1,3-phenylene)-14-crown-4 (**7**)*

To our knowledge, this compound has not been reported in the literature although the 1,2 isomer is well known. A mixture of resorcinol (3.8 g, 34.6 mmol) and **10** (7.5 g, 15.7 mmol) dissolved in 300 mL of DMF was slowly added to a solution of 8.7 g (62.9 mmol) of K_2CO_3 in 200 mL DMF kept at 80°C over the course of 4 days. After addition, the mixture was stirred at 80°C overnight and then filtered. An equal volume of CH_2Cl_2 was added to the filtrate, which was then washed several times with brine and 1 M NaOH. The resulting organic layer was dried over $MgSO_4$. Removal of the solvent gave a brown solid, which was subjected to column chromatography (silica; benzene) and prep. TLC. The band at R_f 0.4 was found to be the required adduct **7**. Final recrystallization from 95% EtOH gave 0.15 g (4%) of white crystals, mp 173–174°C. ^{1}H NMR (360 MHz); δ: 4.31 (s, 8H), 6.23 (t, 2H, J = 2 Hz), 6.57 (dd, 4H, J = 8 Hz, 2 Hz), 7.18 (t, 2H, J = 8 Hz); mass spectrum (CI) *m/z*: 273 ($M^+ + 1$). Anal. calcd. for $C_{16}H_{16}O_4$: C 70.58%, H 5.92%; found: C 70.23%, H 5.87%.

Crystal structure analysis

Suitable crystals of **7** were grown from 95% EtOH. The experimental details are listed in Table 1. A Picker diffractometer using a θ/2θ scan was used to collect the data. A total of 2300 reflections were used and 2002 ($I > 1.0\sigma(I)$) were used in the structure refinement. The structure was solved using SHELX-S direct methods (13).[3]

Deuterium exchange studies and quantum yield measurements

Deuterium exchange experiments and quantum yield measurements were carried out as described in a previous study (4). Relative quantum yields of exchange of **3** in HFP and in 5% H_2SO_4 (20% CH_3CN cosolvent) were carried out using 15-mg samples of **3** dissolved in a total of 10 mL solvent. The samples were transferred to 20-mL quartz vessels, purged with argon, and sealed. Photolysis was carried out at 254 nm for 20 min using a merry-go-round assembly. The extent of exchange was calculated by NMR integration of the aromatic protons as described in ref. 4.

[3]Tables of supplementary X-ray data have been deposited and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

These tables have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Fluorescence measurements

Fluorescence spectra were taken on a Perkin–Elmer MPF 66 spectrofluorimeter at ambient temperature (22 ± 2°C) and were uncorrected. Samples were prepared in 3.0 mL Suprasil quartz cuvettes by injecting into the appropriate solvent a determined amount of substrate in CH_3CN (20–50 μL). Spectra run after purging with argon were identical to those run without prior purging. Fluorescence lifetimes were measured using time-correlated single photon counting on a PTI LS-1 instrument and analyses were carried out using standard software supplied by PTI. Samples were prepared as described for fluorescence spectra. All fluorescence decays were good first order.

Laser flash photolysis studies

These experiments were carried out at the University of Victoria LFP Facility at 20 ± 2°C. A Spectra Physics GCR 12 YAG laser at 266 nm (<20 mJ) was used for excitation and signals were digitized with a Tektronix TDS 520 recorder. Samples of OD ≈ 0.3 at 266 nm (10^{-4} M) were prepared in 7-mm quartz cells and purged with oxygen prior to measurement. A flow system was used for runs in H_2O–CH_3CN solutions. Due to the cost of HFP, a flow system was not used in this solvent. Negligible deterioration of signals was observed in HFP if the samples were not excessively irradiated. Rate constants for decay are the average of several runs.

Control of regioselectivity in reactions of dialkylstannylene acetals. Part I. A dramatic reversal of regioselectivity in mono-*p*-toluenesulfonation reactions[1]

XIANQI KONG[2] AND T. BRUCE GRINDLEY[3]

Department of Chemistry, Dalhousie University, Halifax, NS B3H 4J3, Canada

Received May 10, 1994

XIANQI KONG and T. BRUCE GRINDLEY. Can. J. Chem. **72**, 2396 (1994).

The regioselectivities of *p*-toluenesulfonation reactions of dialkylstannylene acetals obtained from a number of carbohydrate-derived terminal 1,2-diols in the absence of added nucleophiles have been explored as functions of the carbohydrate structure, the nature of the alkyl group on tin, the solvent, and the reaction temperature. Virtually all dibutylstannylene acetals react preferentially on the primary oxygen atom, sometimes with excellent regioselectivity. Increasing the steric bulk of the alkyl substituents on tin increases the preference for reaction at the secondary oxygen atom, but at the expense of increased reaction times. Hexamethylenestannylene acetals react at about the same rate as dibutylstannylene acetals; in almost all cases, they react preferentially on the secondary oxygen atom, sometimes with excellent regioselectivity.

XIANQI KONG et T. BRUCE GRINDLEY. Can. J. Chem. **72**, 2396 (1994).

On an examiné l'influence de la structure de l'hydrate de carbone, de la nature du solvant ou des groupes alkyles attachés à l'étain ainsi que de la température réactionnelle sur les régiosélectivités des réactions de *p*-toluènesulfonation des acétals des dialkylstannylènes, obtenus à partir d'un certain nombre de 1,2-diols dérivés d'hydrates de carbone. Pratiquement tous les acétals du dibutylstannylène réagissent d'une façon préférentielle avec l'atome d'oxygène primaire, quelquefois avec d'excellentes régiosélectivités. Une augmentation de l'encombrement stérique des substituants alkyles présents sur l'étain augmente la préférence pour la réaction au niveau de l'atome d'oxygène secondaire; cette sélectivité se fait avec une augmentation du temps de réaction. Les acétals de l'hexaméthylènestannylène réagissent approximativement à la même vitesse que les acétals du dibutylstannylène; dans pratiquement tous les cas, ils réagissent préférentiellement sur l'atome d'oxygène secondaire, quelquefois avec une excellent régiosélectivité.

Introduction

Selective functionalization and chemical manipulation of diols and polyols have been subjects of much interest to organic chemists. This is particularly the case in the field of carbohydrate chemistry. Dibutylstannylene acetals have been shown to be especially useful for this purpose. They were first used by Moffat and co-workers (3) and by David (4) as intermediates that enhanced the nucleophilicity of hydroxyl oxygen atoms and induced regioselective reactions. During the last two decades, dibutylstannylene acetals derived from a wide range of diols and polyols have been observed to react with many types of electrophiles to give predominantly monosubstituted products (5–8). Regioselectivity of monosubstitution ranges from poor to excellent depending on the structure of the substrate, the reaction conditions, and the nature of the electrophile. For particular classes of substrates with common reaction conditions, regioselectivity has become predictable (8). Thus, the dibutylstannylene acetal reaction has become one of the standard methods employed to differentiate among hydroxyl groups in diols and polyols.

For *trans*-1,2-diols on pyranose rings, reaction regioselectivity of the derived dibutylstannylene acetals was related to the dimeric structures assumed by these compounds in solution (9). For stannylene acetals obtained from diols in which the oxygen atoms are diastereotopic, three dimers are possible. Figure 1 illustrates the dimeric structures possible for the dibutylstannylene acetal obtained from 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**1**). The nature of the dimeric mixtures present in solution has been shown to be controlled mainly by steric effects (9). The most populated dimer has the tricoordinate oxygen atoms as far away as possible from the side of the diol that has the most bulky substituents. Dicoordinate oxygen atoms in the dimer are more nucleophilic than tricoordinate oxygen atoms (9). Dibutylstannylene acetals from *trans*-1,2-diols that exist as single symmetric dimers gave highly regioselective reactions on the dicoordinate oxygen atoms in the dimers.

Terminal 1,2-diols in carbohydrates have one large substituent attached to the carbon bearing the secondary oxygen atom. Thus, it was thought that the most populated dimer in the derived dialkylstannylene acetal would have the oxygen atom remote from this substituent, the primary oxygen atom, tricoordinate. Regioselective reactions should then occur on the secondary dicoordinate oxygen atom in the preferred dimer, i.e., for **1**, at O-5 of the 6,6-dimer.

It is well known that primary hydroxyl groups are more reactive than secondary hydroxyl groups in reactions with electrophiles (10). As a result, it is usually possible to perform regioselective acylation reactions on a primary hydroxyl group in a diol or polyol unit. It has been shown that dibutylstannylene acetals of carbohydrate-derived primary–secondary diols react with benzoyl chloride or *p*-toluenesulfonyl chloride in the presence of added nucleophiles or in polar solvents to give higher regioselectivity for reaction at the primary oxygen atoms than direct reactions of the parent diols (11–14). It is thought that the reaction intermediate in the presence of added nucleophiles is the coordinated monomer (8, 15). Alkylating agents also react with stannylene acetals in the presence of added nucleophiles to give excellent yields of the primary monosubstituted products (16–21).

Reversal of regioselectivity to direct reaction at secondary

[1]Part of this work has appeared in a preliminary communication (1). For Part II, see the following publication (2).

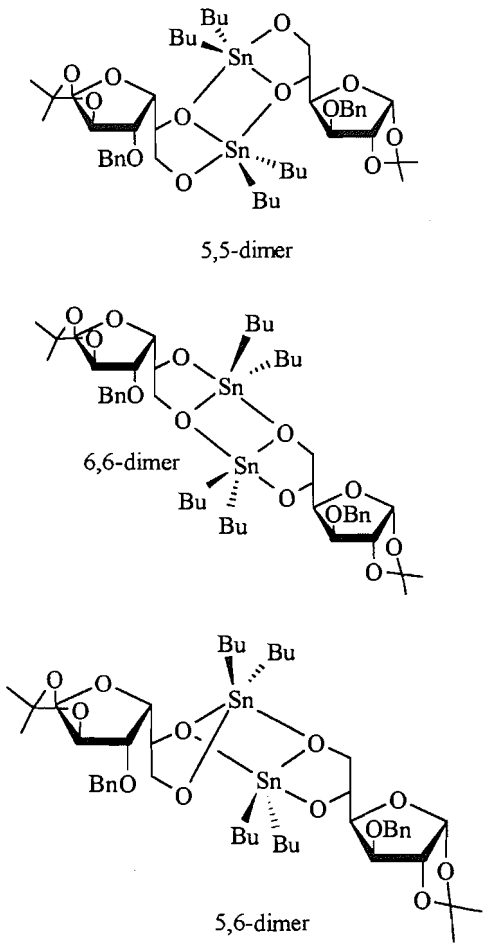

FIG. 1. Structures of dimers possible for the dibutylstannylene acetal of **1**. Dimer nomenclature is based on the numbers of the tricoordinate oxygen atoms (9).

hydroxyl oxygen atoms in the presence of primary hydroxyls is often highly desirable. Oxidation of dibutylstannylene acetals (22, 23) and related tributylstannyl ethers of terminal 1,2-diols with bromine (24–26) or with *N*-bromosuccinimide (27) occurs on the secondary centres. The only acylation reaction for which reversal of regioselectivity was accomplished was benzoylation, performed by Reginato et al. (28). Reactions were performed on simple 1,2-diols not bearing additional electronegative substituents, using dibutystannylene acetals as intermediates in chloroform without added nucleophiles. We have not been able to repeat this work with the regioselectivity reported and others have also reported that this reaction is "troublesome" (29). With dibutylstannylene acetals obtained from carbohydrate-derived terminal 1,2-diols, the initial benzoylation reaction occurs at about the same rate as rearrangement of the initial secondary product to the more stable primary derivative (vide infra), making selective substitution at the secondary centre impossible.

This publication outlines a study of reactions of dialkystannylene acetals from a variety of terminal 1,2-diols with *p*-toluenesulfonyl chloride. The products of these reactions do not rearrange under the reaction conditions. Based on the considerations outlined above, it was thought that *p*-toluenesulfonation reactions, if conducted on dibutylstannylene acetals in the absence of added nucleophiles, would give predominantly secondary substitution. When this proved not to be the case, the reactions of a variety of dialkylstannylene acetals were investigated. Hexamethylenestannylene acetals have been found to give excellent reversed regiochemistry in *p*-toluenesulfonation reactions. In addition, the results of this study have led to a more complete understanding of the source of the regioselectivity obtained in reactions of dialkylstannylene acetals in general that is described in Part II of this series (2).

Results and discussion

The diols used in this study were primary–secondary 1,2-diols derived from monosaccharides, including D-glucose derivatives **1**, **2**, and **3**, D-allose derivatives **4**, **5**, and **6**, a 3-deoxy-D-*ribo*-hexose derivative **7**, a D-mannose derivative **8**, and D-mannitol derivatives **9** and **10**. Dialkyltin oxides prepared for use in this study include diisobutyltin oxide (**12**), diisopropyltin oxide (**13**), dineopentyltin oxide (**14**), dineohexyltin oxide (**15**), dicyclohexyltin oxide (**16**), hexamethylenetin oxide (**17**), dihexyltin oxide (**18**), and di-*tert*-butyltin oxide (**19**). Except for dibutyltin oxide (**11**) and compound **19**, neither the oxide nor an easily accessible precursor was available, and it was necessary to develop a new synthetic approach in order to obtain these dialkyltin oxides in a pure form (30). The dialkylstannylene acetals derived from the dialkyltin oxide are numbered as shown for the D-glucose derivatives, i.e., dibutylstannylene acetals are always indicated by the number of the precursor sugar followed by the designation **sa**.

For all reactions, dialkylstannylene acetals were prepared from diols and dialkyltin oxides (1 mol-equivalent) by reflux in benzene or in toluene with azeotropic removal of water. The dialkylstannylene acetals thus obtained were used directly, without separation or purification, for subsequent reactions.

Reginato et al. reported that benzoylation of simple primary-secondary 1,2-diols (such as propane-1,2-diol) via their dibutylstannylene acetals in chloroform gave highly reversed regioselectivity (28). In initial experiments here, benzoylation reactions were performed on dibutylstannylene acetals **1sa**, and **3sa**, and benzyl 5,6-*O*-dibutylstannylene-2,3-*O*-isopropylidene-α-D-mannofuranoside with benzoyl chloride (1 equiv.) in benzene. Compound **1sa** gave mainly primary benzoate (77%), with some secondary benzoate (15%). This result was very similar to that obtained from benzoylation of **2sa**, the methyl analog of **1sa**, by David et al., where a lower overall yield was reported (46%), but the ratio of primary benzoate to secondary benzoate products (5:1) was identical (11, 22). The other two starting materials also gave predominantly primary benzoates here.

As noted in the introduction, migration of benzoyl groups from the products formed first was observed to occur while the reaction was in progress. Benzoylation of **1sa** in benzene was followed by TLC. At low product conversion, the major product was the secondary benzoate but as the reaction proceeded the apparent product ratio reversed to favour the primary benzoate. Thus, it was concluded that the rate of migration was only slightly slower than that of benzoylation for **1sa**.

An effort was made to repeat the work of Reginato et al. (28) on propane-1,2-diol in which the initial products were trapped with phenyldimethylsilyl chloride. In our hands, the secondary product was favoured (2:1), but not with the good regiochemistry reported (85:15) (28). For the carbohydrate-derived stannylene acetals, it appears that the additional electronegative oxygen atoms present slow the rate of the benzoylation reaction but do not affect the rate of the rearrangement reaction as much.

As a result of the difficulties with rearrangements, *p*-toluenesulfonation was selected as the reaction to study instead of

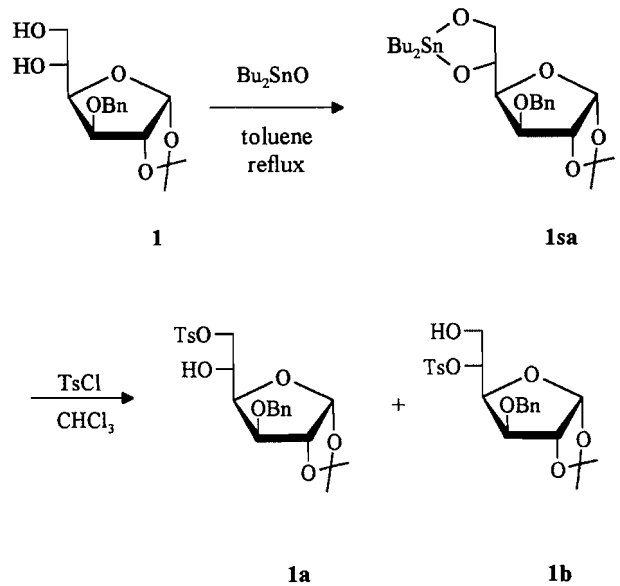
benzoylation. *p*-Toluenesulfonyl groups do not rearrange under the conditions used for reaction.

A typical example of the reaction sequence used for *p*-toluenesulfonation is outlined in Scheme 1. 3-*O*-Benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**1**) was refluxed with one equivalent of dibutyltin oxide in toluene to form the corresponding dibutylstannylene acetal **1sa**. Dry chloroform was added after toluene had been removed on a vacuum line. To the chloroform solution of **1sa** was added 1 equivalent of *p*-toluenesulfonyl chloride. The reaction mixture was kept at room temperature for 20 h and then poured directly onto a column for separation of the mono-*O*-substituted products, 3-*O*-benzyl-1,2-*O*-isopropylidene-6-*O*-*p*-toluenesulfonyl-α-D-glucofuranose (**1a**) and 3-*O*-benzyl-1,2-*O*-isopropylidene-5-*O*-*p*-toluenesulfonyl-α-D-glucofuranose (**1b**). For other reactions, the primary *p*-toluenesulfonate is also numbered by using the number of the parent diol followed by **a** while the secondary product is indicated by **b**.

Structural assignments of products were made primarily from their ^1H and ^{13}C NMR spectra. For instance, for **1a** and **1b**, integrations of the signals of the aromatic protons and aryl methyl protons versus those of the anomeric proton and the isopropylidene methyl groups indicated that both were mono-*O*-*p*-toluenesulfonyl derivatives. The most obvious indication of structure was the appearance of the signal for the OH proton of **1a**; it was a sharp doublet, which could only arise from ^3J coupling to one proton, H-5 of **1a**. The OH signal for **1b** was a broadened signal without obvious coupling. In addition, expected deshieldings were observed for the protons on the carbons bearing the OTs groups. The signals of H-6 and H-6′ moved from



SCHEME 1

3.68 and 3.80 ppm in the spectrum of **1** to between 4.05 and 5.15 ppm in the spectrum of **1a**. The signal of H-5 moved from 4.03 ppm in the spectrum of **1** to 5.04 ppm in the spectrum of **1b**. Similar effects were noted for the corresponding signals in the ^{13}C NMR spectra. In addition, many products could be characterized by comparison with literature data.

Table 1 outlines the results of *p*-toluenesulfonation reactions on all substrates.

The effect of changing the reaction solvent was evaluated using dibutylstannylene acetal **1sa**, which gave mono-*O*-*p*-toluenesulfonates **1a** and **1b** on reaction with 1 equivalent of *p*-toluenesulfonyl chloride at 20°C. The ratios of **1b** to **1a** were 29:71 in acetonitrile, 31:69 in toluene, 43:57 in dichloromethane, and 55:45 in chloroform (entries 1–4). Thus, regioselectivity for reaction at the secondary position was best in chloroform and worst in acetonitrile and toluene, the solvents commonly used in reactions of stannylene acetals. Other stannylene acetals, in particular, **1sc** and **2sc**, showed similar trends in solvent effects on regioselectivity.

The lower selectivity obtained in acetonitrile was probably due to its nucleophilicity. It seems likely that acetonitrile acts as a nucleophile towards the stannylene acetal dimers and releases coordinated monomers so that at least part of the reaction in acetonitrile occurs through these monomeric intermediates. In DMF (17, 20), pyridine (11, 22) or 4-dimethylaminopyridine (14), amines (12, 13), and methanol (12, 13), all of which are more nucleophilic than acetonitrile as measured by, for instance, Gutmann's donor number (31), greater regioselectivity is obtained for reaction at the primary centre.

The lower selectivity obtained in toluene is probably related to the slower reaction rates in this solvent. This point will be discussed in Part II (2).

Lowering the reaction temperature improved regioselectivity somewhat but slowed reaction rates considerably. For instance, *p*-toluenesulfonation of stannylene acetal **1sc** in chloroform at 20°C gave an 88% yield of mono-*O*-substitution products in 48 h with the ratio of **1b** to **1a** being 7:3 (entry 8). The same reaction conducted at 5°C resulted in mono-*O*-substitution products with a yield of 94%. The ratio of **1b** to **1a** increased to 8:2 (entry 9). Similarly, good selectivity at the secondary position for compound **2sc** was also obtained when the reaction was performed at 5°C (**2b** to **2a**, 3:1, entry 22). However, reactions at the lower temperature were very slow, taking 14 d to reach complete conversion of starting material.

Very different regioselectivities were observed from different diols. Comparisons of reactions performed on dibutylstannylene acetals in chloroform at 20°C show that the glucofuranose derivatives gave a slight preference for reaction with the secondary oxygen atom (entries 2 and 19), whereas all the other terminal 1,2-diols (entries 30, 33, 35, 37, 42, 47, and 49) showed a very strong preference for reaction with the primary oxygen atom. These differences in selectivity are probably related to the relative populations of the most populated stannylene acetal dimer with respect to the next most populated dimer and will be further discussed in Part II (2).

Changing the alkyl groups on tin had the largest effect on the regioselectivity of the reaction. These effects were studied in a systematic manner for *p*-toluenesulfonation reactions of the dialkylstannylene acetals of **1** and **2**.

Making the alkyl group longer, for instance, changing from butyl to hexyl, had little effect on the regioselectivity. Compare entries 2 and 16 and also 19 and 27. Branching far from the point of attachment to tin, as for the 3,3-dimethylbutyl (neohexyl) group, also had only slight effects on reaction selectivity. Compare entries 2 and 14 and also 19 and 25.

Branching on the carbon attached to tin and also on the next carbon had substantial effects on both reaction regioselectivity and rate. Replacement of primary butyl groups by secondary isopropyl groups improved the secondary/primary ratio from 55:45 to 69:31 for compound **1** at the expense of a fourfold increase in the time required to complete the reaction. Cyclohexyl groups did not have as large an effect. Introduction of branching on the β-carbon, as in the isobutyl group, had almost the same effect on both selectivity and reaction rate as did changing to an isopropyl group.

Further increases in steric bulk of the alkyl group gave mixed results. The *p*-toluenesulfonation reactions of di-*tert*-butylstannylene acetals were extremely slow and the products were mainly primary *p*-toluenesulfonates. One reaction was conducted on a dineopentylstannylene acetal, entry 28. Here good selectivity was obtained, slightly better than that for the diisopropylstannylene acetal, but the reaction was so slow as to make it impractical.

The trend of increased selectivity for reaction on the secondary oxygen atom as steric bulk increased was only broken for the *tert*-butyl group. This observation suggests that reactions of di-*tert*-butylstannylene acetals proceed through a different intermediate than those of the other dialkylstannylene acetals. A monomer would be expected to react at the more reactive primary oxygen atom. Monomers constitute a larger proportion of the species present in solution as the bulk of the groups around tin is increased both for noncyclic (32) and cyclic[4] dialkoxydialkyltin(IV) derivatives.

In contrast to the relatively minor improvements in regioselectivity obtained when the bulk of the acyclic alkyl groups was increased, use of the cyclic hexamethylenestannylene acetal gave major improvements without the increase in reaction time associated with the larger alkyl groups. Regioselective reactions were obtained at the secondary oxygen atoms for all substrates except for compound **6**, a triol. The reversal in regioselectivity in comparison to the dibutylstannylene acetals is striking: from 45:55 to 4:96 for **1**; from 60:40 to 5:95 for **2**; from 95:5 to 48:52 for **7**; from 100:0 to 30:70 for **8**; from 98:2 to 40:60 for **9**; and from 87:13 to 22:78 for **10**. Reaction times for hexamethylenestannylene acetals are identical for some substrates or slightly longer for others in comparison with dibutylstannylene acetals. The causes of these changes will be discussed in the following paper (2).

Applications of the reactions of hexamethylenestannylene acetals to other types of diols and polyols are currently being investigated.

Experimental

Melting points were determined using a Fisher–Johns melting point apparatus and are uncorrected. Specific rotations were determined with a Perkin–Elmer 141 polarimeter. Flash column chromatography was performed using TLC grade silica gel (60 PF-254, Merck). NMR spectra were recorded on Bruker AC 250F or AMX 400 spectrometers at 20°C for solutions in $CDCl_3$ unless otherwise specified; ^1H NMR spectra were referenced to internal tetramethylsilane (TMS), ^{13}C NMR spectra to internal TMS or to chloroform-*d* as 77.0 ppm, ^{119}Sn NMR spectra to external tetramethyltin as 0.0 ppm. AA′BB′ ^1H NMR patterns were analyzed using the iterative fitting program, LAME8 (33). Mass spectra were measured on a Dupont-CEC 21-104 mass spectrometer at 70 eV ionization and a source temperature of 105°C, using a glass, direct-insertion probe. Accurate masses were measured on a Dupont-CEC 21-110B mass spectrometer at 70 eV ionization and a source temperature of 100°C, using a silica, direct-insertion probe. Microanalyses were performed by Canadian Microanalytical Service Ltd., Vancouver, B.C. Assignments of ^1H NMR spectra were made by first-order analysis using COSY experiments to confirm assignments where necessary; ^{13}C NMR spectra were assigned by HETCOR experiments.

*3,4-Di-*O*-benzyl-1,2-*O*-isopropylidene-D-mannitol (**10**)*

3,4-Di-*O*-benzyl-1,2:5,6-di-*O*-isopropylidene-D-mannitol (20 g), a syrup, prepared according to Gurjar's method (45), $[\alpha]_D^{23}$ +37.2 (*c* 1.0, chloroform) (lit. (45) $[\alpha]_D$ +29.6 and lit. (46) $[\alpha]_D$ +36) was dissolved in 70% ethanol–water (40 mL). Concentrated hydrochloric acid (1.5 mL) was added and the mixture was kept at 40°C for 2.5 h, then cooled to room temperature. Barium carbonate was added to the stirred reaction mixture until it was slightly basic. The solid materials were removed by filtration and the filtrate was concentrated to dryness. The residue was extracted with acetone (200 mL). The combined extracts were dried (K_2CO_3) and the solvent was removed on a rotary evaporator. This residue was stirred with hexane (300 mL) for 1 h at room temperature. The hexane layer was decanted and concentrated to dryness to give starting material (7.04 g). The residue was separated by flash column chromatography with hexane – ethyl acetate as eluant. The first fraction was title compound (**10**), 5.5 g, 47% yield based on consumed starting material, a syrup: $[\alpha]_D^{23}$ +25.8 (*c* 1.0, chloroform); ^{1}H NMR δ: 7.31 (m, 10H, 10Ar-H), 4.76 (d, 1H, *J* = 11.3 Hz, $ArCH_a$), 4.71 (d, 1H, $ArCH'_a$), 4.66 (d, 1H, *J* = 11.3 Hz, $ArCH_b$), 4.61 (d, 1H, $ArCH'_b$), 4.31 (m, 1H, H-2), 4.07 (dd, 1H, $J_{1,1'}$ = 8.24 Hz, $J_{1,2}$ = 6.4 Hz, H-1), 3.97 (dd, 1H, $J_{2,3\text{ or }3,4}$ = 3.4 Hz, $J_{3,4\text{ or }2,3}$ = 5.5 Hz, H-3), 3.95 (dd, 1H, $J_{1',2}$ = 4.9 Hz, H-1′), 3.79 (m, 1H, H-5), 3.75–3.60 (m, 3H, H-6, H-4, H-6′), 2.91 (d, 1H, $J_{OH,5}$ = 5.5 Hz, OH), 2.05 (m, 1H, OH), 1.45 (s, H, CH_3), 1.36 (s, H, CH_3); ^{13}C NMR δ: 137.9, 137.8 (2s, $2C_{arom}$), 128.7, 128.6, 128.5, 128.2, 128.1, 158.0 (6d, $8C_{arom}$), 108.6 (s, C_{acetal}), 79.2 (d, C-3), 78.6 (d, C-4), 76.0 (d, C-2), 74.5, 73.9 (2t, $2C_{benzyl}$), 71.1 (d, C-5), 66.5 (t, C-1), 63.6 (t, C-6), 26.6 (q, CH_3), 25.2 (q, CH_3); mass spectrum: 402, (M^+ 1.7%), 311 ($M^+ - CH_2Ph$, 4.4%), 253 (311 − CH_3COCH_3, 3.4%), 91 ($C_7H_7^+$, 100%). Anal. calcd. for $C_{23}H_{30}O_6$: C 68.64, H 7.51; found: C 68.17, H 7.47.

The second fraction, which crystallized after being kept under toluene, was 3,4-di-*O*-benzyl-D-mannitol, 5.1 g, 48% yield based on consumed starting material; mp 73–75°C; ^{1}H NMR δ: 7.3 (m, 10H, 10Ar-H), 4.65 (m, 4H, 4ArCH), 4.15 (br, 2H, 2OH), 3.90 (br, 2H, H-2, H-5), 3.8–3.6 (m, 6H, H-1, H-1′, H-3, H-4, H-6, H-6′), 3.32 (br, 2H, 2OH); ^{13}C NMR δ: 137.5 (s, $2C_{arom}$), 128.6, 128.3, 128.1 (3d, $8C_{arom}$), 77.8 (d, C-3, C-4), 73.8 (t, $2C_{benzyl}$), 71.5 (d, C-2, C-5), 63.4 (t, C-1, C-6); MS, *m/z*: 91 (100%, $PhCH_2^+$), 163 (5.7%, $M^+/2 - H_2O$), 181 (3.4%, $M^+/2$), 271 (5.3%, M^+ − Bn). Exact Mass calcd. for $C_{13}H_{19}O_6$: 271.118; found: 271.118.

General method for preparation of dialkylstannylene acetals

A 1,2-diol or triol (1 mmol) derived from a monosaccharide was refluxed with 1 equivalent of dialkyltin oxide overnight in benzene (20 mL) or toluene with continuous removal of water in a Dean–Stark apparatus. The solvent was removed on a vacuum line and the stannylene acetal residue was kept under vacuum for an additional half hour. To this residue was added a dry solvent (usually 10 mL), which was used for *p*-toluenesulfonation reaction. The solvent used will be specified for each reaction.

General method for p-*toluenesulfonation reactions*

To the stannylene acetal, prepared as above (1.00 mmol) in a specified solvent (Table 1) was added *p*-toluenesulfonyl chloride (0.191 g, 1.00 mmol) at a specified temperature (Table 1) and the reaction mixture was stirred a specified time (Table 1) until the starting material had disappeared as determined by TLC. Unless specified, the reaction was stopped by adding water and diluting with methylene chloride as follows. To the reaction mixture (1 mmol stannylene acetal and 1 mmol electrophile in benzene (20 mL) or toluene (20 mL), or in chloroform (5 mL), methylene chloride (5 mL), or acetonitrile (5 mL)) was added water (5 mL) and the mixture was stirred for 2 h at room temperature. The mixture was filtered and the filtrate was diluted with methylene chloride (25 mL) and washed with water (15 mL × 2). The organic layer was separated and dried over potassium carbonate. The solvent was removed on a rotary evaporator. The residue thus obtained was separated or purified by means of dry column flash chromatography with hexane – ethyl acetate as the eluent (usually performed in gradient manner). Only information on the characterization of the products is provided below. Yields and selectivities obtained for individual stannylene acetals are listed in Table 1.

*3-*O*-Benzyl-1,2-*O*-isopropylidene-6-*O*-*p*-toluenesulfonyl-α-D-glucofuranose (**1a**)*

The first fraction eluted from the column was the title compound (**1a**), a syrup: $[\alpha]_D^{23}$ −8.0 (*c* 1.0, CH_3OH) (lit. (47) $[\alpha]_D^{20}$ −7.24, $[\alpha]_D^{23}$ −23.7 (*c* 1.1, chloroform); lit. (48) $[\alpha]_D^{20}$ −39.2); ^{1}H NMR δ: 7.27–7.81 (m, 9H, Ar-H), 5.90 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1), 4.71 (d, 1H, *J* = 11.7 Hz, ArCH), 4.62 (d, 1H, H-2), 4.58 (d, 1H, ArCH′), 4.28 (dd, 1H, $J_{5,6}$ = 2.7 Hz, $J_{6,6'}$ = 10.0 Hz, H-6), 4.23 (m, 1H, H-5), 4.19–4.22 (m, 3H, H-3, H-4, H-6′), 2.68 (d, 1H, $J_{OH,5}$ = 5.8 Hz, OH), 2.46 (s, 3H, CH_3-Ar), 1.48 (s, 3H, CH_3), 1.35 (s, 3H, CH_3); ^{13}C NMR δ: 127–145 (12C, Ar-C), 112.0 (s, q-C), 105.2 (d, C-1), 82.18 (d, C-2), 81.93 (d, C-3), 78.3 (d, C-4), 72.3 (t, 2C, $ArCH_2$-C and C-6), 67.4 (d, C-5), 26.8 (q, CH_3), 26.3 (q, CH_3), 21.61 (q, CH_3-Ar).

*3-*O*-Benzyl-1,2-*O*-isopropylidene-5-*O*-*p*-toluenesulfonyl-α-D-glucofuranose (**1b**)*

The second fraction, compound **1b**, was also a syrup: $[\alpha]_D^{23}$ −16.3 (*c* 1.2, chloroform); ^{1}H NMR δ: 7.20–7.76 (m, 9H, Ar-H), 5.85 (d, 1H, $J_{1,2}$ = 3.5 Hz, H-1), 5.04 (m, 1H, H-5), 4.57 (d, 1H, *J* = 11.0 Hz, ArCH), 4.56 (d, 1H, H-2), 4.54 (d, 1H, ArCH′), 4.36 (dd, 1H, $J_{3,4}$ = 2.8 Hz, $J_{4,5}$ = 7.7 Hz, H-4), 4.00 (d, 1H, H-3), 3.92 (m, 1H, H-6), 3.80 (m, 1H, H-6′), 2.40 (s, 3H, CH_3-Ar), 2.26 (br, 1H, OH), 1.46 (s, 3H, CH_3), 1.29 (s, 3H, CH_3); ^{13}C NMR δ: 127–145 (12C, Ar-C), 112.2 (s, q-C), 105.1 (d, C-1), 81.5, 81.3 (2d, C-2 and C-3), 78.8, 78.5 (2d, C-4 and C-5), 72.1 (t, $ArCH_2$-C), 62.3 (t, C-6), 26.8 (q, CH_3), 26.3 (q, CH_3), 21.6 (q, CH_3-Ar).

Compound **1b** was further characterized by conversion to its 6-*O*-benzoate (**1d**); compound **1b** (0.300 g, 0.65 mmol) was dissolved in pyridine (1 mL) and a solution of benzoyl chloride (0.5 mL) in methylene chloride (3 mL) was added in three portions over 20 min with intermittent shaking. After standing for 1 h, the reaction mixture was diluted with methylene chloride (20 mL). The resulting solution was washed with water (10 mL × 2) and the organic layer was dried

(K_2CO_3). After solvent was removed, column purification of the residue afforded compound **1d**, 0.310 g, 86%; mp 68–69°C, $[\alpha]_D^{23}$ −0.7 (*c* 1.35, chloroform) (lit. (49) mp 64–67°C, $[\alpha]_D$ −2.2).

*1,2-O-Isopropylidene-3-O-methyl-6-O-p-toluenesulfonyl-α-D-glucofuranose (**2a**), 1,2-O-isopropylidene-3-O-methyl-5-O-p-toluenesulfonyl-α-D-glucofuranose (**2b**), and 1,2-O-isopropylidene-3-O-methyl-5,6-di-O-p-toluenesulfonyl-α-D-glucofuranose (**2c**)*

The isomer mixture from the reaction with *p*-toluenesulfonyl chloride could not be separated by flash column chromatography in this case. For each reaction, the ratio of 5-*O*-*p*-toluenesulfonate to 6-*O*-*p*-toluenesulfonate was obtained from the average values of the ratios of integrals of several well-separated signals in the ^{1}H NMR spectrum.

Information that was used to confirm the ^{1}H NMR signal assignments used for integration was obtained by *p*-toluenesulfonation of the above reaction mixture as follows. The mixture of isomers (0.384 g, 1 mmol; 5-*O*-*p*-toluenesulfonate to 6-*O*-*p*-toluenesulfonate, 2:8) was dissolved in dichloromethane (5 mL) and pyridine (2 mL) and treated with *p*-toluenesulfonyl chloride (0.96 g, 0.5 mmol) at room temperature for 24 h. Solvents were removed under vacuum. The residue was separated into two components by flash chromatography with hexane – ethyl acetate as eluent. The first fraction (0.1 g) contained 5,6-di-*O*-*p*-toluenesulfonyl-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose (**2c**). The more polar fraction (0.3 g) contained the 6-*O*-*p*-toluenesulfonate, which was pure according to TLC and NMR analyses. Data for characterization of the three compounds are given below.

Compound **2a** was a syrup: $[\alpha]_D^{23}$ −26.8 (*c* 1.2, chloroform) (lit. (50) $[\alpha]_D$ −24); ^{1}H NMR δ: 7.27–7.84 (m, 4H, Ar-H), 5.85 (d, 1H, $J_{1,2}$ = 3.4 Hz, H-1), 4.56 (d, 1H, H-2), 4.26 (dd, 1H, $J_{3,4}$ = 2.8 Hz, $J_{4,5}$ = 8.0 Hz, H-4), 3.79–4.20 (m, 3H, H-5, H-6, H-6′), 3.88 (d, 1H, H-3), 3.43 (s, 3H, OCH_3), 2.94 (d, 1H, $J_{OH,5}$ = 6.0 Hz, OH), 2.45 (s, 3H, CH_3-Ar), 1.46 (s, 3H, CH_3), 1.31 (s, 3H, CH_3); ^{13}C NMR δ: 145.0 (s, C_{arom}), 132.4 (s, $C_{arom\text{-}para}$), 129.9 (d, $2C_{arom\text{-}ortho}$), 128.0 (d, $2C_{arom\text{-}meta}$), 111.86 (s, C_{acetal}), 104.98 (d, C-1), 84.17 (d, C-3), 81.31 (d, C-2), 78.95 (d, C-4), 72.23 (t, C-6), 67.39 (d, C-5), 57.94 (q, OCH_3), 26.76 (q, CH_3), 26.19 (q, CH_3), 21.68 (q, CH_3-Ar).

NMR data could be obtained for compound **2b** by subtraction of the data for compound **2a** from that of the mixture; ^{1}H NMR δ: 7.83 (d, 2H, *J* = 7.7 Hz, $2Ar\text{-}H_{ortho}$), 7.35 (d, 2H, $2Ar\text{-}H_{meta}$), 5.84 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1), 4.93 (m, 1H, H-5), 4.56 (d, 1H, H-2), 4.32 (dd, 1H, $J_{3,4}$ = 3.0 Hz, $J_{4,5}$ = 7.9 Hz, H-4), 3.94–3.75 (m, 2H, H-6, H-6′b), 3.70 (d, 1H, H-3), 3.27 (s, 3H, OCH_3) 2.44 (s, 3H, CH_3-Ar), 2.20 (br, 1H, OH), 1.46, 1.31 (2s, 2 × 3H, $C(CH_3)_2$); ^{13}C NMR δ: 145.0 (s, C_{arom}), 134.0 (s, $C_{arom\text{-}para}$), 129.9 (d, $C_{arom\text{-}ortho}$), 127.9 (d, $C_{arom\text{-}meta}$), 112.2 (s, C_{acetal}), 105.1 (d, C-1), 82.6 (d, C-3), 80.7 (d, C-2), 78.3 (d, C-5), 78.2 (d, C-4), 62.3 (t, C-6), 57.4 (q, OCH_3), 26.7, 26.2 (2q, $C(CH_3)_2$), 21.7 (q, $ArCH_3$).

Compound **2c** was a colourless powder: mp 50–54°C, $[\alpha]_D^{23}$ −21.1 (*c* 1.0, chloroform) (lit. (51) mp 90–93°C, $[\alpha]_D^{22}$ −20); ^{1}H NMR δ: 7.81–7.63 (m, 4H, $4Ar\text{-}H_{ortho}$), 7.36–7.27 (m, 4H, $4Ar\text{-}H_{meta}$), 5.76 (d, 1H, $J_{1,2}$ = 3.6 Hz, H-1), 5.07 (ddd, 1H, $J_{4,5}$ = 7.3 Hz, $J_{5,6}$ = 2.0 Hz, $J_{5,6'}$ = 6.2 Hz, H-5), 4.53 (d, 1H, H-2), 4.33 (dd, $J_{6,6'}$ = 11.2 Hz, H-6), 4.27 (dd, $J_{3,4}$ = 3.1 Hz, 1H, H-4), 4.04 (dd, 1H, H-6′), 3.79 (d, 1H, H-3), 3.34 (s, 3H, OCH_3), 2.45, 2.43 (2s, 2 × 3H, $2ArCH_3$), 1.44, 1.30 (2s, 2 × 3H, $C(CH_3)_2$); ^{13}C NMR δ: 145.1, 144.9 (2s, $2C_{arom}$), 133.7, 132.4 (2s, $2C_{arom\text{-}para}$), 129.8 (d, $4C_{arom\text{-}ortho}$), 128.1, 128.0 (2d, 2 × $2C_{arom\text{-}meta}$), 112.3 (s, $C_{accetal}$), 105.2 (d, C-1), 82.6 (d, C-3), 80.7 (d, C-2), 78.1 (d, C-4), 74.8 (d, C-5), 68.6 (t, C-6), 56.7 (q, OCH_3), 26.8, 26.3 (2q, $C(CH_3)_2$), 21.7 (q, $2ArCH_3$).

*1,2-O-Isopropylidene-5-O-p-toluenesulfonyl-α-D-glucofuranose (**3b**)*

The title compound (**3b**) eluted first from the column and was obtained as colourless crystals: mp 121–122°C, $[\alpha]_D^{23}$ +6.5 (*c* 1.0, chloroform) (lit. (52) mp 122–124°C, $[\alpha]_D^{22}$ +6); ^{1}H NMR δ: 7.27–7.84 (m, 4H, Ar-H), 5.90 (d, 1H, $J_{1,2}$ = 3.6 Hz, H-1), 4.83 (m, 1H, H-5), 4.58 (d, 1H, H-2), 4.36 (br, 1H, H-3), 4.27 (dd, 1H, $J_{3,4}$ = 2.4 Hz, $J_{4,5}$ = 9.3 Hz, H-4), 3.72–3.76 (m, 2H, H-6, H-6′), 3.31 (d, 1H, $J_{OH,3}$ = 4.4 Hz, C_3-OH), 2.47 (s, 3H, $ArCH_3$), 2.05 (br, 1H, C_6-OH), 1.47 (s, 3H, CH_3), 1.31 (s, 3H, CH_3).

*1,2-O-Isopropylidene-6-O-p-toluenesulfonyl-α-D-glucofuranose (**3a**)*

Compound **3a** eluted second from the column and was also obtained as colourless crystals: mp 99–100°C, $[\alpha]_D^{23}$ −5.7 (*c* 1.1, chloroform) (lit. (53) mp 100–101°C, $[\alpha]_D^{23}$ −6); ^{1}H NMR δ: 7.34–7.80 (m, 4H, Ar-H), 5.90 (d, 1H, $J_{1,2}$ = 3.6 Hz, H-1), 4.51 (d, 1H, H-2), 4.35 (br, 1H, H-3), 4.28 (dd, 1H, $J_{5,6}$ = 2.5 Hz, $J_{6,6'}$ = 10.2 Hz, H-6), 4.18 (br, 1H, H-5), 4.10 (dd, 1H, $J_{5,6'}$ = 6.8 Hz, H-6′), 4.01 (dd, 1H, $J_{3,4}$ = 2.7 Hz, $J_{4,5}$ = 7.8 Hz, H-4), 3.73 (br, 1H, OH), 3.50 (br, 1H, OH), 2.45 (s, 3H, $ArCH_3$), 1.45 (s, 3H, CH_3), 1.29 (s, 3H, CH_3).

*1,2-O-Isopropylidene-3-O-methyl-6-O-p-toluenesulfonyl-α-D-allofuranose (**4a**)*

^{1}H NMR δ: 7.79 (d, 2H, *J* = 8.2 Hz, $2Ar\text{-}H_{ortho}$), 7.34 (d, 2H, $2Ar\text{-}H_{meta}$), 5.74 (d, 1H, $J_{1,2}$ = 3.5 Hz, H-1), 4.68 (dd, $J_{2,3}$ = 4.1 Hz, H-2), 4.18–4.09 (m, 2H, H-5, H-6), 4.03 (dd, $J_{5,6'}$ = 8.0 Hz, $J_{6,6'}$ = 10.4 Hz, H-6′), 3.92 (dd, 1H, $J_{3,4}$ = 8.7 Hz, $J_{4,5}$ = 3.5 Hz, H-4), 3.76 (dd, 1H, H-3), 3.42 (s, 3H, OCH_3), 2.79 (d, 1H, $J_{OH,5}$ = 1.7 Hz, OH), 2.45 (s, 3H, $ArCH_3$), 1.55, 1.35 (2s, 2 × 3H, $2CH_3$); ^{13}C NMR δ: 145.0 (s, C_{arom}), 132.6 (s, $C_{arom\text{-}para}$), 129.9 (d, $2C_{arom\text{-}ortho}$), 128.0 (d, $2C_{arom\text{-}meta}$), 113.3 (s, C_{acetal}), 104.2 (d, C-1), 79.6 (d, C-4), 77.4 (d, C-3), 76.9 (d, C-2), 70.5 (t, C-6), 69.1 (d, C-5), 57.9 (q, OCH_3), 26.8, 26.4 (2q, $2CH_3$), 21.6 (q, $ArCH_3$).

*1,2-O-Isopropylidene-3-O-methyl-5-O-p-toluenesulfonyl-α-D-allofuranose (**4b**)*

^{1}H NMR δ: 7.79 (m, 2H, 2Ar-H), 7.34 (m, 2H, 2Ar-H), 5.38 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1), 4.84 (m, 1H, H-5), 4.58 (dd, $J_{2,3}$ = 4.2 Hz, H-2), 3.44 (s, 3H, OCH_3), 2.76 (m, 1H, OH), 2.44 (s, 3H, $ArCH_3$), 1.51, 1.32 (2s, 2 × 3H, $2CH_3$); ^{13}C NMR δ: 144.8 (s, C_{arom}), 133.8 (s, $C_{arom\text{-}para}$), 129.6 (d, $2C_{arom\text{-}ortho}$), 128.0 (d, $2C_{arom\text{-}meta}$), 113.4 (s, C_{acetal}), 103.9 (d, C-1), 81.1 (d, C-5), 79.2 (d, C-4), 77.5 (d, C-3), 76.7 (d, C-2), 61.6 (t, C-6), 57.9 (q, OCH_3), 26.8, 26.5 (2q, $2CH_3$), 21.6 (q, $ArCH_3$).

*1,2-O-Isopropylidene-3,6-di-O-p-toluenesulfonyl-α-D-allofuranose (**5a**)*

The first fraction to elute was the title compound, **5a**, which crystallized and was recrystallized from ethyl acetate and hexane to give colourless crystals: mp 118–119°C (lit. (40) mp 117–118°C); ^{1}H NMR δ: 7.85–7.76 (m, 4H, $4Ar\text{-}H_{ortho}$), 7.35 (m, 4H, $4Ar\text{-}H_{meta}$), 5.69 (d, 1H, $J_{1,2}$ = 3.5 Hz, H-1), 4.69 (dd, $J_{2,3}$ = 4.6 Hz, $J_{3,4}$ = 8.0 Hz, H-3), 4.55 (dd, 1H, H-2), 4.11–4.01 (m, 2H, H-4, H-5), 3.99 (dd, $J_{5,6}$ = 2.5 Hz, H-6), 3.87 (dd, 1H, $J_{5,6'}$ = 7.9 Hz, $J_{6,6'}$ = 10.2 Hz, H-6′), 2.57 (d, 1H, $J_{OH,5}$ = 3.7 Hz, OH), 2.46 (s, 6H, $2ArCH_3$), 1.49, 1.28 (2s, 2 × 3H, $2CH_3$).

*1,2-O-Isopropylidene-3,5-di-O-p-toluenesulfonyl-α-D-allofuranose (**5b**)*

The second fraction, compound **5b**, decomposed quickly: ^{1}H NMR δ: 7.85–7.76 (m, 4H, $4Ar\text{-}H_{ortho}$), 7.38–7.32 (m, 4H, $4Ar\text{-}H_{meta}$), 5.42 (d, 1H, $J_{1,2}$ = 3.4 Hz, H-1), 4.77 (m, 1H, H-5), 4.67 (dd, $J_{2,3}$ = 4.6 Hz, $J_{3,4}$ = 8.6 Hz, H-3), 4.47 (dd, 1H, H-2), 4.17 (dd, 1H, $J_{4,5}$ = 1.6 Hz, H-4), 3.59 (m, 2H, H-6, H-6′), 2.47, 2.45 (2s, 2 × 3H, $2ArCH_3$), 2.10 (t, 1H, $J_{OH,6}$ = 6.6 Hz, OH), 1.43, 1.24 (2s, 2 × 3H, $2CH_3$).

*1,2-O-Isopropylidene-6-O-p-toluenesulfonyl-α-D-allofuranose (**6a**)*

Compound **6a** was obtained as colourless crystals: mp 115–117°C, $[\alpha]_D^{23}$ +30.2 (*c* 1.0, chloroform) (lit. (54) mp 117–119°C, $[\alpha]_D^{23}$ +31.2); ^{1}H NMR δ: 7.77 (m, 2H, $Ar\text{-}H_{ortho}$), 7.35 (m, 2H, $2Ar\text{-}H_{meta}$), 5.74 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1), 4.56 (dd, 1H, $J_{2,3}$ = 5.0 Hz, H-2), 4.24–4.02 (m, 4H, H-3, H-5, H-6, H-6′), 3.73 (dd, 1H, $J_{3,4}$ = 8.5 Hz, $J_{4,5}$ = 4.8 Hz, H-4), 2.99 (d, $J_{OH,3\text{ or }5}$ = 7.5 Hz, OH), 2.72 (d, 1H, $J_{OH,5\text{ or }3}$ = 9.1 Hz, OH), 2.57 (d, 1H, $J_{OH,5}$ = 3.7 Hz, OH), 2.43 (s, 3H, $ArCH_3$), 1.52, 1.34 (2s, 2 × 3H, $2CH_3$), ^{13}C NMR δ: 145, 132 (2s, $2C_{arom}$), 129.9, 127.9 (2d, 2 × $2C_{arom}$), 113.0 (s, C_{acetal}), 103.9 (d, C-1), 78.8 (d, C-2), 78.7 (d, C-4), 72.0 (d, C-3), 70.6 (t, C-6), 69.7 (d, C-5), 26.5 (q, $2CH_3$), 21.6 (q, $ArCH_3$).

*1,2-O-Isopropylidene-5-O-p-toluenesulfonyl-α-D-allofuranose (**6b**)*

This compound was also obtained as colourless crystals: mp 175–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

177°C, $[\alpha]_D^{23}$ +83.8 (*c* 1.0, chloroform) (lit. (54) mp 178–179°C, $[\alpha]_D^{23}$ +85.8 (*c* 0.88, acetone)).

*3-Deoxy-1,2-*O*-isopropylidene-6-*O*-*p*-toluenesulfonyl-α-D-*ribo*-hexofuranose (**7a**) and 3-deoxy-1,2-*O*-isopropylidene-5-*O*-*p*-toluenesulfonyl-α-D-*ribo*-hexofuranose (**7b**)*

The mixture of the 6-*O*-toluenesulfonate and 5-*O*-toluenesulfonate could not be separated. The percentage of each product was obtained from integration of well-separated signals in the ^{1}H NMR spectrum: for compound **7a**, δ 5.73 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1); for compound **7b**, δ 5.49 (d, 1H, $J_{1,2}$ = 3.5 Hz, H-1), 4.27 (m, 1H, H-5).

*Methyl 2,3-*O*-isopropylidene-6-*O*-*p*-toluenesulfonyl-α-D-mannofuranoside (**8a**)*

Treatment of the syrupy product mixture from the reaction of **8sa** with diethyl ether – hexane gave compound **8a** as colourless crystals: mp 95–96°C, $[\alpha]_D^{23}$ +4.1 (*c* 1.0, chloroform) (lit. (55) mp 94–95°C, $[\alpha]_D^{26}$ +4.5); ^{1}H NMR δ: 7.2–7.8 (m, 5H, Ar-H), 4.86 (s, 1H, H-1), 4.79 (dd, 1H, $J_{2,3}$ = 5.8 Hz, $J_{3,4}$ = 3.3 Hz, H-3), 4.55 (d, 1H, H-2), 4.30 (dd, 1H, $J_{6,6'}$ = 10.1 Hz, $J_{5,6}$ = 3.0 Hz, H-6), 4.18 (dd, 1H, $J_{5,6'}$ = 5.9 Hz, H-6′), 4.13 (m, 1H, H-5), 3.90 (dd, 1H, $J_{4,5}$ = 7.8 Hz, H-4), 3.26 (s, 3H, OCH_3), 2.75 (br, 1H, OH), 2.45 (s, 3H, Ar-CH_3), 1.43 (s, 3H, CH_3), 1.31 (s, 3H, CH_3); ^{13}C NMR δ: 144.9 (s, $C_{arom\text{-}para}$), 129.8 (s, C_{arom}), 129.5 (d, $C_{arom\text{-}ortho}$), 127.9 (d, $C_{arom\text{-}meta}$), 112.7 (s, C_{acetal}), 107.0 (d, C-1), 84.6 (d, C-2), 79.6 (d, C-3), 78.0 (d, C-4), 71.5 (t, C-6), 68.0 (d, C-5), 54.6 (q, CH_3O), 25.8 (q, CH_3), 24.5 (q, CH_3), 21.6 (q, CH_3-Ar).

In the ^{1}H NMR spectra of the initial product mixtures, the following signals could be assigned to methyl 2,3-*O*-isopropylidene-5-*O*-*p*-toluenesulfonyl-α-D-mannofuranoside (**8b**), δ: 4.82 (s H-1), 2.40 (t, OH), 3.28 (s, OCH_3), 1.27 and 1.12 (2s, CMe_2). Integrals of the signals of the methoxy groups were used to obtain the isomer ratios reported in Table 1.

*1,2:3,4-Di-*O*-isopropylidene-6-*O*-*p*-toluenesulfonyl-D-mannitol (**9a**)*

The first fraction was the title compound **9a**, a syrup: $[\alpha]_D^{23}$ 19.8 (*c* 1.3, chloroform); ^{1}H NMR δ: 7.80 (m, 2H, Ar-H), 7.32 (m, 2H, Ar-H), 4.29 (dd, 1H, $J_{5,6}$ = 1.6 Hz, $J_{6,6'}$ = 10.3 Hz, H-6), 4.17 (dd, 1H, $J_{1,1'}$ = 8.0 Hz, $J_{1,2}$ = 2.3 Hz, H-1), 4.17 (dd, 1H, $J_{5,6'}$ = 5.3 Hz, H-6′), 4.07–3.94 (m, 2H, H-2, H-1′), 3.82–3.65 (m, 4H, H-5, H-3, H-4, OH), 2.40 (s, 3H, CH_3-Ar), 1.40 (s, 3H, CH_3), 1.33 (s, 3H, CH_3), 1.30 (s, 6H, $2CH_3$); ^{13}C NMR δ: 144.7 (s, $C_{arom\text{-}para}$), 133.0 (s, C_{arom}), 129.8 (d, $2C_{arom\text{-}ortho}$), 128.0 (d, $2C_{arom\text{-}meta}$), 110.3 (s, C_{acetal}), 109.9 (s, C_{acetal}), 80.9 (d, C-4), 79.2 (d, C-3), 76.1 (d, C-2), 71.3 (t, C-6), 70.7 (d, C-5), 67.7 (t, C-1), 26.8 (q, $2CH_3$), 26.3 (q, CH_3), 25.0 (q, CH_3), 21.6 (q, CH_3-Ar). Anal. calcd. for $C_{19}H_{28}O_8S$: C 54.79, H 6.78; found: C 54.48, H 6.77.

*1,2:3,4-Di-*O*-isopropylidene-5-*O*-*p*-toluenesulfonyl-D-mannitol (**9b**)*

The second fraction, compound **9b**, was also a syrup: $[\alpha]_D^{23}$ 10.8 (*c* 0.86, chloroform); ^{1}H NMR δ: 7.82 (m, 2H, Ar-H), 7.33 (m, 2H, Ar-H), 4.78 (m, 1H, H-5), 4.19 (dd, 1H, $J_{3,4\text{ or }4,5}$ = 3.6 Hz, $J_{4,5\text{ or }3,4}$ = 6.4 Hz, H-4), 4.10 (dd, 1H, $J_{1,1'}$ = 8.2 Hz, $J_{1,2}$ = 5.8 Hz, H-1), 4.03–3.73 (m, 5H, H-2, H-1′, H-3, H-6, H-6′), 2.73 (t, $J_{OH,6}$ = 7.0 Hz, OH), 2.43 (s, 3H, CH_3-Ar), 1.37 (s, 3H, CH_3), 1.32 (s, 3H, CH_3), 1.30 (s, 3H, CH_3), 1.27 (s, 3H, CH_3); ^{13}C NMR δ: 145.1 (s, $C_{arom\text{-}para}$), 133.5 (s, C_{arom}), 130.1 (d, $2C_{arom\text{-}ortho}$), 128.1 (d, $2C_{arom\text{-}meta}$), 110.5 (s, C_{acetal}), 110.1 (s, C_{acetal}), 80.8 (d, C-5), 79.1 (d, C-4), 77.6 (d, C-3), 77.0 (d, C-2), 67.6 (t, C-1), 61.3 (t, C-6), 27.2 (q, CH_3), 27.0 (q, CH_3), 26.3 (q, CH_3), 25.2 (q, CH_3), 21.7 (q, CH_3). Anal. calcd. for $C_{19}H_{28}O_8S$: C 54.79, H 6.78; found: C 54.48, H 6.74.

*3,4-Di-*O*-benzyl-1,2-*O*-isopropylidene-6-*O*-*p*-toluenesulfonyl-D-mannitol (**10a**)*

Separation of the two *p*-toluenesulfonates was accomplished with difficulty. The first fraction, compound **10a**, was a syrup: $[\alpha]_D^{24}$ 27.2 (*c* 0.90, chloroform); ^{1}H NMR δ: 7.76 (m, 2H, Ar-H), 7.4–7.2 (m, 12H, Ar-H), 4.69 (d, 1H, *J* = 11.6 Hz, $ArCH_a$), 4.65 (d, 1H, $ArCH_a'$), 4.60 (d, 1H, *J* = 11.3 Hz, $ArCH_b$), 4.49 (d, 1H, $ArCH_b'$), 4.24 (m, 1H, H-2), 4.17 (dd, $J_{5,6}$ = 6.4 Hz, $J_{6,6'}$ = 10.2 Hz, H-6), 4.08 (dd, 1H, $J_{5,6'}$ = 5.2 Hz, H-6′), 4.03 (dd, 1H, $J_{1,1'}$ = 8.7 Hz, $J_{1,2}$ = 6.4 Hz, H-1), 3.99 (m, 1H, H-5), 3.89 (dd, $J_{2,3}$ = 6.1 Hz, $J_{3,4}$ = 2.8 Hz, H-3), 3.85 (dd, $J_{1',2}$ = 6.4 Hz, H-1′), 3.66 (dd, 1H, $J_{4,5}$ = 7.6 Hz, H-4), 2.48 (br, 1H, OH), 2.42 (s, 3H, CH_3-Ar), 1.42 (s, 3H, CH_3), 1.33 (s, 3H, CH_3); ^{13}C NMR δ: 145.0, 137.7, 137.4, 132.4, (4s, $4C_{arom}$), 130.0, 128.5, 128.4, 128.22, 128.20, 128.0, 127.97 (7d, $14C_{arom}$), 108.7 (s, C_{acetal}), 78.9 (d, C-3), 78.1 (d, C-4), 76.0 (d, C-2), 74.5 (t, CH_2Ar), 74.0 (t, CH_2Ar), 71.6 (t, C-6), 69.2 (d, C-5), 67.7 (t, C-1), 26.6 (q, CH_3), 25.1 (q, CH_3), 21.7 (q, CH_3-Ar). Anal. calcd. for $C_{30}H_{36}O_8S$: C 64.73, H 6.52; found: C 64.38, H 6.58.

*3,4-Di-*O*-benzyl-1,2-*O*-isopropylidene-5-*O*-*p*-toluenesulfonyl-D-mannitol (**10b**)*

The second fraction, compound **10b**, was also a syrup: $[\alpha]_D^{24}$ 19.3 (*c* 0.90, chloroform); ^{1}H NMR δ: 7.78 (m, 2H, Ar-H), 7.4–7.2 (m, 12H, Ar-H), 4.84 (m, 1H, H-5), 4.74 (d, 1H, *J* = 11.3 Hz, $ArCH_a$), 4.65 (s, 2H, $ArCH_2$-b), 4.63 (d, 1H, $ArCH'_a$), 4.08 (m, 1H, H-2), 3.99 (dd, $J_{1,1'}$ = 8.3 Hz, $J_{1,2}$ = 6.1 Hz, H-1), 3.96–3.91 (m, 2H, H-6, H-4), 3.87 (dd, 1H, $J_{1,2}$ = 6.1 Hz, H-1′), 3.83 (m, 1H, H-6′), 3.68 (dd, 1H, $J_{3,4}$ = 4.3 Hz, $J_{2,3}$ = 6.1 Hz, H-3), 2.24 (t, $J_{OH,6}$ = 6.4 Hz, OH), 2.43 (s, 3H, CH_3-Ar), 1.38 (s, 3H, CH_3), 1.30 (s, 3H, CH_3); ^{13}C NMR δ: 145.2, 137.8, 137.5, (4s, $4C_{arom}$), 130.0, 128.5, 128.4, 128.2, 128.1, 128.0, 127.9 (7d, $14C_{arom}$), 108.9 (s, C_{acetal}), 83.2 (d, C-5), 80.4 (d, C-4), 79.3 (d, C-3), 76.2 (d, C-2), 75.0 (t, CH_2Ar), 74.7 (t, CH_2Ar), 66.7 (t, C-1), 61.3 (t, C-6), 26.5 (q, CH_3), 25.2 (q, CH_3), 21.7 (q, CH_3). Anal. calcd. for $C_{30}H_{36}O_8S$: C 64.73, H 6.52; found: C 63.72, H 6.49.

*Benzoylation of 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**1**)*

To a solution of **1sa** (1 mmol) in benzene was added powdered 4Å molecular sieves (1 g). A solution of freshly distilled benzoyl chloride (0.15 g, 1 mmol) in benzene (12 mL) was added dropwise over 20 min and the mixture was stirred for 4 h. The molecular sieves were removed by filtration and the resulting solution was worked up in the standard way. Chromatographic separation afforded first 6-*O*-benzoyl-3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**1e**) as a syrup: 0.320 g, 77%; ^{1}H NMR δ: 7.30–8.10 (m, 10H, Ar-H), 5.97 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1), 4.73 (d, 1H, *J* = 11.7 Hz, ArCH), 4.65 (d, 1H, H-2), 4.63 (dd, 1H, $J_{5,6}$ = 2.8 Hz, $J_{6,6'}$ = 11.7 Hz, H-6), 4.58 (d, 1H, ArCH′), 4.42 (dd, 1H, $J_{5,6'}$ = 6.0 Hz, H-6′), 4.33 (m, 1H, H-5), 4.24 (dd, 1H, $J_{3,4}$ = 3.1 Hz, $J_{4,5}$ = 5.0 Hz, H-4), 4.15 (d, 1H, H-3), 3.2 (br, 1H, OH), 1.48 (s, 3H, CH_3), 1.32 (s, 3H, CH_3); and then 5-*O*-benzoyl-3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**1f**), also as a syrup: 0.062 g, 15%; ^{1}H NMR δ: 7.1–8.0 (m, 10H, Ar-H), 5.95 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1), 5.45 (m, 1H, H-5), 4.63 (d, 1H, H-2), 4.56 (d, 1H, $J_{ArCH,ArCH'}$ = 11.3 Hz, ArCH), 4.54 (dd, 1H, $J_{3,4}$ = 3.2 Hz, $J_{4,5}$ = 6.0 Hz, H-4), 4.37 (d, 1H, ArCH′), 4.08 (dd, 1H, $J_{5,6}$ = 3.0 Hz, $J_{6,6'}$ = 12.5 Hz, H-6), 4.02 (d, 1H, H-3), 3.96 (dd, 1H, $J_{5,6'}$ = 4.2 Hz, H-6′), 2.5 (br, 1H, OH), 1.53 (s, 3H, CH_3), 1.33 (s, 3H, CH_3).

*6-*O*-Benzoyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**3e**)*

To a solution of compound **3sa** (1 mmol) in toluene (20 mL) was added a solution of benzoyl chloride (0.15 g, 1.05 mmol) in chloroform (7 mL) at −5°C with vigorous magnetic stirring. The cold bath was removed after 30 min and the mixture was kept at room temperature for 3 h. After work-up, recrystallization of the residue from ethyl acetate afforded the title compound as colourless crystals: 0.20 g, 75%; mp 194–195°C (lit. (56) mp 196°C); ^{1}H NMR (DMSO-d_6) δ: 7.51–8.03 (m, 5H, Ar-H), 5.82 (d, 1H, $J_{1,2}$ = 3.6, H-1), 5.32 (d, 1H, *J* = 5.0, OH), 5.23 (d, 1H, *J* = 5.7, OH), 4.47 (dd, 1H, $J_{5,6}$ = 1.9 Hz, $J_{6,6'}$ = 11.3 Hz, H-6), 4.42 (d, 1H, H-2), 4.20 (dd, 1H, $J_{5,6'}$ = 5.4 Hz, H-6′), 4.09 (dd, 1H, $J_{3,4}$ = 2.3 Hz, $J_{4,5}$ = 4.9 Hz, H-4), 4.04 (m, 1H, H-5), 4.02 (d, 1H, H-3), 1.37 (s, 3H, CH_3), 1.27 (s, 3H, CH_3).

*Benzyl 6-*O*-benzoyl-2,3-*O*-isopropylidene-α-D-mannofuranoside (**8e**)*

Benzyl 2,3-*O*-isopropylidene-α-D-mannofuranoside (0.31 g, 1 mmol) and dibutyltin oxide (0.274 g, 1.1 mmol) were refluxed overnight in benzene (20 mL) with azeotropic removal of water. The solution was cooled to room temperature and a solution of benzoyl chloride (0.191 g, 1 mmol) in benzene (6 mL) was added. After the reaction

mixture had been stirred for 30 min, standard work-up yielded a colourless solid that was recrystallized from ethyl acetate and hexane to give the title compound (**8e**) as colourless crystals: 0.290 g, 70%; mp 116–118°C, ^{1}H NMR δ: 7.25–8.08 (m, 10H, Ar-H), 5.14 (s, 1H, H-1), 4.91 (dd, 1H, $J_{2,3}$ = 5.9 Hz, $J_{3,4}$ = 3.6 Hz, H-3), 4.68 (d, 1H, H-2), 4.63 (dd, 1H, $J_{5,6}$ = 2.9 Hz, $J_{6,6'}$ = 11.7 Hz, H-6$_a$), 4.62 (d, 1H, J = 11.7 Hz, ArCH), 4.90 (dd, 1H, $J_{5,6'}$ = 6.6 Hz, H-6′), 4.46 (d, 1H, ArCH′), 4.32 (m, 1H, H-5), 4.06 (dd, 1H, H-4), 3.01 (d, 1H, $J_{OH,H-5}$ = 5.7 Hz, OH), 1.50 (s, 3H, CH_3), 1.34 (s, 3H, CH_3).

*Benzylation of 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose (1)*

To a solution of compound **1sa** (1 mmol) in benzene (20 mL) was added powdered 4 Å molecular sieves (1.5 g), tetrabutylammonium iodide (0.406 g, 1.1 equiv.) and benzyl chloride (0.140 g, 1.1 mmol). The mixture was refluxed for 3 d. Insoluble material was removed by filtration, then standard work-up followed by flash chromatography yielded 3,6-di-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**1g**) as a syrup: 0.24 g, 60%, $[\alpha]_D^{23}$ −20.6 (*c* 1.1, chloroform) (lit. (57) $[\alpha]_D^{25}$ −25.9 and lit. (58) $[\alpha]_D^{23}$ −14.5), ^{1}H NMR δ: 7.30–7.35 (m, 10H, Ar-H), 5.92 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1), 4.66 (d, 1H, J = 12.6 Hz, ArCH), 4.59 (d, 1H, H-2), 4.51–4.60 (m, 3H, 3 ArCH), 4.1–4.2 (m, 3H, H-3, H-4, H-5), 3.73 (dd, 1H, $J_{5,6}$ = 2.8 Hz, $J_{6,6'}$ = 9.7 Hz, H-6$_a$), 3.60 (dd, 1H, $J_{5,6'}$ = 5.6 Hz, H-6′), 2.72 (br, 1H, d, OH), 1.48 (s, 3H, CH_3), 1.31 (s, 3H, CH_3) and 3,5-di-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**1h**), also as a syrup: 0.041 g, 10%, ^{1}H NMR δ: 7.25–7.31 (m, 10H, Ar-H), 5.91 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1), 4.67 (d, 1H, J = 11.6 Hz, ArCH$_a$), 4.63 (d, 1H, J = 11.2 Hz, ArCH$_b$), 4.62 (d, 1H, H-2), 4.48 (d, 1H, ArCH$_a$), 4.47 (d, 1H, ArCH$_b$′), 4.30 (dd, 1H, $J_{3,4}$ = 3.1 Hz, $J_{4,5}$ = 8.6 Hz, H-4), 4.11 (d, 1H, H-3), 3.77–3.95 (m, 3H, H-5, H-6, H-6′), 1.80 (br, 1H, OH), 1.49 (s, 3H, CH_3), 1.31 (s, 3H, CH_3).

Received May 10, 1994

XIANQI KONG and T. BRUCE GRINDLEY. Can. J. Chem. **72**, 2405 (1994).

The ^{119}Sn NMR spectra of dialkylstannylene acetals derived from a number of carbohydrate-based terminal 1,2-diols have been recorded. The spectra of chloroform-*d* solutions at room temperature of most of these dialkylstannylene acetals were consistent with the presence of single symmetric dimers only although some did contain small proportions of higher oligomers. A general mechanistic scheme is presented that explains the regioselectivity of *p*-toluenesulfonation reactions of dialkylstannylene acetals presented in the preceding paper. In the scheme, the reaction intermediates are the dialkylstannylene acetal dimers. For *p*-toluenesulfonation reactions, equilibration between the three possible dimers is faster than reaction with *p*-toluenesulfonyl chloride. Reaction regioselectivity depends both on the position of the dimer equilibrium and on the rates of reaction of individual dicoordinate oxygen atoms in the dimers. The general scheme was also used to explain the regioselectivity obtained for the very fast oxidation reactions of dialkylstannylene acetals with bromine or *N*-bromosuccinimide. In these kinetically controlled reactions, regiochemistry is determined by the initial reaction of dicoordinate oxygen atoms in the most populated dimer(s) with the electrophilic oxidizing reagent.

XIANQI KONG et T. BRUCE GRINDLEY. Can. J. Chem. **72**, 2405 (1994).

On a déterminé les spectres RMN du ^{119}Sn d'acétals de dialkylstannylènes obtenus à partir d'un certain nombre de 1,2-diols dérivés d'hydrates de carbone. Les spectres de la plupart de ces acétals de dialkylstannylène, obtenus à la température ambiante, pour des solutions dans le chloroforme-*d*, sont en accord avec la présence de dimères symétriques uniques, même si certains contiennent de faibles proportions d'oligomères de masses plus élevées. On propose un schéma mécanistique général pour expliquer la régiosélectivité des réactions de *p*-toluènesulfonation des acétals de dialkylstannylènes présentées dans la communication précédente. Dans ce schéma, les intermédiaires réactionnels sont les acétals de dialkylstannylènes dimères. Pour les réactions de *p*-toluènesulfonation, l'équilibre entre les trois dimères possibles est plus rapide que la réaction avec le chlorure de *p*-toluènesulfonyle. La régiosélectivité de la réaction dépend à la fois de la position de l'équilibre du dimère et des vitesses de réaction des atomes d'oxygène dicoordinés individuels dans les dimères. On a aussi utilisé le schéma général pour expliquer la régiosélectivité observée lors de réactions d'oxydation très rapides des acétals de dialkylstannylènes par le brome ou par la *N*-bromosuccinimide. Dans ces réactions sous contrôle cinétique, la régiochimie est déterminée par la réaction initiale des atomes d'oxygène dicoordinés dans le(s) dimère(s) le(s) plus populeux avec le réactif oxydant électrophile.

[Traduit par la rédaction]

Introduction

Dialkylstannylene acetals have become important intermediates for the regioselective substitution of diols and polyols by electrophiles (3). Despite the considerable interest in their applications, a full understanding of the causes of the remarkable regioselectivity observed in their reactions has not been achieved. The preceding paper outlines the large effects of changing the alkyl groups in dialkylstannylene acetals on the regioselectivity obtained in reactions on dialkylstannylene derivatives of carbohydrate-derived terminal 1,2-diols with *p*-toluenesulfonyl chloride (2). In a previous publication, we related the regioselectivity obtained in reactions on dibutylstannylene acetals of *trans*-1,2-diols to the species present in solution (4). The current results demonstrate that the previous conclusions were oversimplified; this publication outlines a more complete description of the causes of the regioselectivity obtained in reactions of dialkylstannylene acetals.

The system used for numbering compounds in the previous paper (2) is also employed here for compounds up to compound **10**; other compounds in this paper are numbered starting with compound **11**.

X-ray diffraction studies of crystalline dibutylstannylene acetals obtained from ethylene glycol, 2,2-dibutyl-1,3,2-dioxastannolane (**11**) (5), and from 1,3-propanediol, 2,2-dibutyl-1,3,2-dioxastannane (**12**) (6), have shown that these compounds are polymers in the solid state. More highly substituted stannylene acetals are mostly present as dimers in the solid state (7–9), although one has been found to be a pentamer (10). In solution, compounds **11** and **12** exist as highly temperature dependent mixtures of dimers and oligomers that shift towards the less aggregated species as the temperature is raised (6, 11). More substituted compounds, such as carbohydrate-derived stannylene acetals, have been found to be present in solution mainly as dimers (4, 9). When the two hydroxyl oxygen atoms in the parent diol are diastereotopic, three dimeric structures are possible (see Fig. 1 in the preceding paper (2)). The major factor determining which of the three dimers is most populated has been shown to be steric effects between the two monomeric sections of each dimer molecule (4).

Tin-119 NMR spectroscopy is the best method available to study the composition of solutions of dibutylstannylene acetals (4, 6, 11). The region of the NMR spectrum where absorption occurs is related to the coordination status of the tin atoms; tetracoordinate tin atoms in dialkoxydialkyltin compounds absorb at chemical shifts greater than −40 ppm, pentacoordinate tin atoms absorb between −80 and −190 ppm, and hexacoordinate tin atoms have shifts less than −200 ppm. Since tetracoordinate tin atoms are only present in monomers, only pentacoordinate tin atoms are present in dimers, and only trimers and higher oligomers contain hexacoordinate tin atoms, the nature of the species present can be established easily from chemical shifts. The

[a]Spectra were recorded in $CDCl_3$ solution in sealed tubes at 20°C, chemical shifts are in ppm from external tetramethyltin at 20°C.

[b]Coupling constants are in Hz; no entry indicates that the coupling constant could not be measured (see text).

[c]The minor peak.

numbers of signals present in the pentacoordinate regions are employed here to study dimerization and thus to evaluate the contribution of the populations of particular dimers in determining the degree of regioselectivity of dialkylstannylene acetals in mono-*O*-substitution reactions.

In addition, a kinetic analysis of the mechanism of the reactions of stannylene acetals with electrophiles in the absence of added nucleophiles is developed that comprehensively explains, for the first time, the causes of the regioselectivity observed in the reactions of these compounds.

Results and discussion

Tin-119 NMR spectra

The NMR spectra of most dialkylstannylene acetals described in Part I (2) were recorded as a function of temperature. All NMR samples were prepared carefully on a vacuum line to avoid atmospheric moisture, then sealed. Tin-119 NMR chemical shifts are listed in Table 1. The ^{119}Sn NMR spectra of most dialkylstannylene acetals contained a single sharp peak at room temperature with a chemical shift typical of pentacoordinate tin atoms (4, 11). If tin atoms are only present in pentacoordinate environments, the only species present are dimers. The line widths varied considerably due to exchange processes for some compounds and other factors (see later). When the lines were very narrow, additional small ^{117}Sn satellite signals were observed in the ^{119}Sn NMR spectra due to ^2J coupling to ^{117}Sn atoms in the 7.5% of the ^{119}Sn-containing molecules that also contained ^{117}Sn atoms. As previously noted (12), observation of such coupling confirms that these compounds contained two or more tin atoms, consistent only with dimers or higher oligomers.

The major effect on the chemical shifts of the tin atoms in the dimeric dialkylstannylene acetals studied here was the nature of the alkyl substituents on tin. The shifts fall into three groups according to the nature of the alkyl groups as follows: (*i*) stannylene acetals that have two primary alkyl groups attached to tin; (*ii*) stannylene acetals with two secondary alkyl groups attached to tin; (*iii*) hexamethylenestannylene acetals. The first type gives chemical shifts (−115 to −124 ppm) typical of those observed for pentacoordinate tin atoms in dimeric 2,2-dibutyl-1,3,2-dioxastannolanes, regardless of the structure of the alkyl group attached to tin. For instance, the signals of the tin atoms in compounds **2sa** and **2sh** have very similar chemical shifts, −118.8 ppm for those in **2sa**, and −120.2 ppm for those in **2sh**, even though the former compound possesses two *n*-butyl groups and the latter has two sterically hindered neopentyl groups. A single sharp peak in each ^{119}Sn NMR spectrum at room temperature suggests that only one of the three possible dimers is being observed. In previous work, ^{119}Sn NMR spectra of stannylene acetals that contained more than one species at room temperature were either broad or contained more than one line (4, 11). The ^{13}C NMR spectra of the type (*i*) compounds are also consistent with single dimeric species because only single sets of peaks were observed.

The tin atoms in the diisopropylstannylene acetals **1sc**, **2sc**,

4sc, and **8sc** and dicyclohexylstannylene acetal **2sf** absorb at lower frequencies, −169 to −186 ppm. Only single lines were observed for all compounds. These chemical shift values are halfway between those of the first type and that of a di-*tert*-alkylstannylene acetal, 2,2-di-*tert*-butyl-1,3,2-dioxastannolane, −225 ppm (9). This latter compound was shown to exist as a dimer both in the solid state and in solution (9, 13). Thus, di-*sec*-alkylstannylene acetals also exist in solution as single symmetric dimers to the level of detection by ^{119}Sn NMR spectroscopy.

The tin atoms in the five hexamethylenestannylene acetals absorbed in a narrow chemical shift range, −93 to −100 ppm. The substantial differences in shifts of signals from tin atoms in five- and six-membered rings (14) has been attributed to bond-angle changes and it seems likely that a similar effect causes the shift to higher frequencies for these hexamethylene derivatives. C-Sn-C bond angles in hexamethylenestannylene acetals are slightly smaller than those in most acyclic dialkylstannylene acetals (see later).

Variable temperature spectra

Low-temperature ^{119}Sn NMR spectra of a number of dialkylstannylene acetals were recorded in chloroform-*d* and a few were also recorded in toluene-d_8. The glucofuranose derivatives will be considered first. In chloroform-*d*, all derivatives showed single lines at all temperatures, consistent with the presence of single dimers. These results are summarized in Table 1.

The ^{119}Sn NMR spectra of compound **2sa** were recorded at 134.6 MHz for a 0.20 M solution in toluene-d_8. It had previously been noted (4) that stannylene acetals are more aggregated in toluene than in chloroform, and this was also observed here. At room temperature, one peak was present at −119.0 ppm with a line width of 115 Hz. As the temperature was lowered, this signal broadened, and then split. By −20°C, three sharp equal-intensity signals at −112.9, −115.7, and −287.6 ppm had emerged from the main peak, which had broadened and moved to a lower frequency. The three sharp equal-intensity signals can only be assigned to a trimer, since one signal (at −287.6 ppm) is in the hexacoordinate tin region. By −40°C, the major peak was ca. 35 ppm wide and centred at −127.0 ppm. As the temperature was lowered further, the main peak sharpened and moved to more positive frequencies, being 25 ppm wide at −123.0 ppm at −50°C, 12 ppm wide at −122.0 ppm at −60°C, 7 ppm wide at −120.0 ppm at −70°C, 7 ppm wide at −119.5 ppm at −80°C, and 7 ppm wide at −119.3 ppm at −90°C. The trimer peaks gradually decreased in relative intensity, and were negligible at −90°C.

The outcome of this process was the observation of two peaks at the lowest temperature studied (−90°C), one at −269.2 ppm, and another, two to three times larger, at −119.3 ppm. It seems likely that the coalescence process was for a dimer–tetramer equilibrium. The tetramer has to have C_2 symmetry to give only one peak in each of the pentacoordinate and hexacoordinate regions of the spectrum. It was observed

For personal use only.

previously that hexacoordinate peaks in tetramers are less shielded than those in trimers (13). The dimer peak and the pentacoordinate tin tetramer peak occurred at the same chemical shift for **2sa** in toluene-d_8.

Rates of interconversion and activation barriers can be obtained from coalescence processes. In the current situation, increasing the rate of dimer–tetramer exchange caused the dimer signal at −119.0 ppm to coalesce with the two tetramer signals at −119.3 ppm (pentacoordinate tin) and at −269.6 ppm (hexacoordinate tin). The populations of the species present were changing rapidly as a function of temperature, and also the chemical shifts were changing somewhat as a function of temperature, particularly that of the signal at −269.6 ppm. The main factor that influences the magnitude of $\Delta G^{\ddagger}$ is the temperature of coalescence, not the rate constant at coalescence. Coalescence of the two signals that are farthest apart causes most of the line broadening (15, 16). A coalescence temperature of −45 ± 5°C and a chemical shift difference of 2.0×10^4 Hz yield $k = 4.5 \times 10^4$ s^{-1} and $\Delta G^{\ddagger} = 8.4 \pm 0.2$ kcal mol^{-1}, using the equation for the coalescence of equally populated singlets, $k = \pi\Delta\nu/\sqrt{2}$ (15). If the amount of broadening at coalescence is used to estimate the population of the minor exchanging partner using equations developed by Okazawa and Sorenson (16), a line broadening of 40 ppm at coalescence gives a population of the minor partner of 25%. Using equations developed in the same paper, $k = 2.7 \times 10^4$ and $\Delta G^{\ddagger} = 8.6 \pm 0.2$ kcal mol^{-1}. The dimer–trimer barrier is more difficult to estimate but a T_c of −5°C and a $\Delta\nu$ of 10 000 Hz gives $\Delta G^{\ddagger}$ of 10.3 kcal mol^{-1} using the coalescence equation (15).

The spectra of benzyl 5,6-*O*-dibutylstannylene-2,3-*O*-isopropylidene-α-D-mannofuranoside were slightly more complex. At room temperature in chloroform-*d*, a single peak was at −114.8 ppm for a 0.40 M sample and at −114.3 ppm for a 0.15 M sample, with a $J_{\text{Sn-119,Sn-117}}$ value of 140.5 Hz. The ^{119}Sn NMR spectrum of the 0.15 M sample contained no additional signals at low temperature but the spectrum of the 0.40 M sample contained small amounts of trimer peaks at −111.6, −117.1, and −274.9 ppm. From peak heights, the ratio [trimer]/[dimer] was 0.072 at −60°C. A 0.15 M sample of the same compound in toluene-d_8 precipitated at low temperature but at 25°C contained a broad peak (half-height line width, 3 ppm at 134.6 MHz) at −120.1 ppm plus a much smaller broad peak at about −112 ppm. The small broad peak probably contained the signals of the pentacoordinate tin atoms in the trimer that were starting to coalesce. The analogous methyl glycoside showed similar behaviour.

The spectra of the allofuranose derivatives were still more complicated. Figure 1 shows variable temperature spectra of a 0.33 M solution of compound **4sa** in chloroform-*d*. At room temperature, a slightly broadened peak at −119.5 ppm was accompanied by a small broad peak on the positive frequency side. By −20°C, in addition to the main peak at −117.9 ppm, small peaks were clearly visible at −112.8, −119.6, −123.9, and −277.4 ppm. The peak at −277.4 ppm increased in intensity as the temperature was lowered, as did that at −119.6 ppm, and these two peaks were about the same size at −60°C. The signal at −277.4 ppm must be assigned to the hexacoordinate tin atom in a trimer; a signal at −119.6 ppm was due to the same trimer; a third signal is still needed. The only possibility is that the third signal overlapped with the major peak. The two other small signals present at −20°C in the pentacoordinate region could be due to either dimers or trimers. The very small signal that appeared at about −295 ppm in the −60°C spectrum must

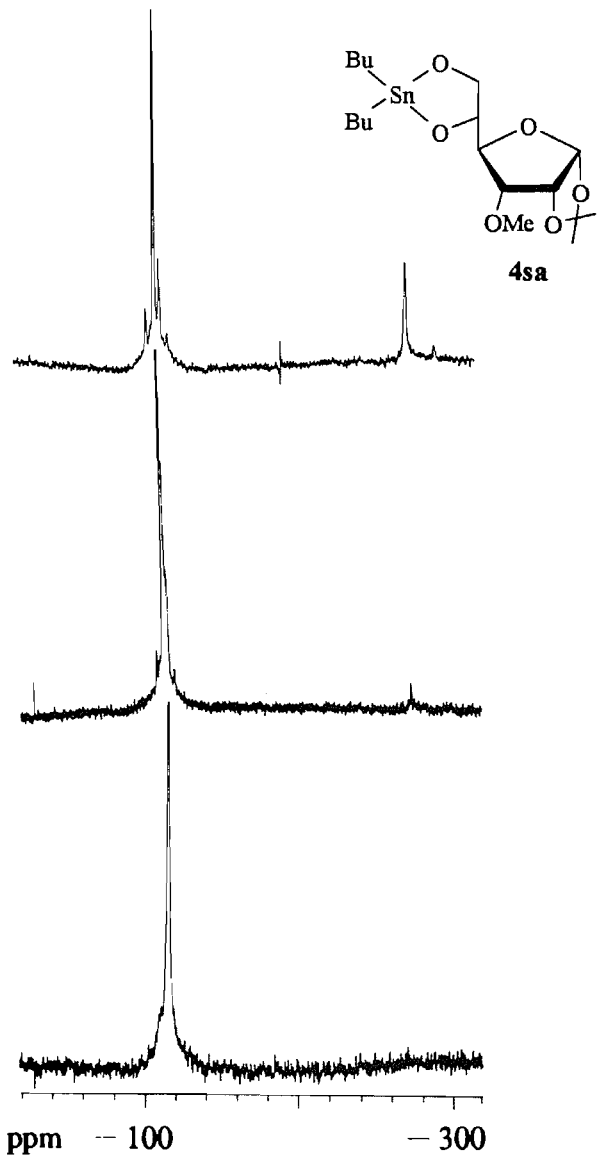

FIG. 1. 134.6 MHz ^{119}Sn NMR spectra of a 0.33 M solution of 5,6-*O*-dibutylstannylene-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-allofuranose (**4sa**) in chloroform-*d* at, from the top, −60°C, −20°C, 20°C. The top 25% of the major peak has been cut off in each case.

be assigned to a second trimer, because the ^{119}Sn NMR spectrum of a tetramer would contain a signal that was less shielded than that of the trimer at −277 ppm (13).

The stannylene acetals with the most complicated behaviour in solution were the derivatives of 1,2-*O*-isopropylidene-α-D-allofuranose (7). The ^{119}Sn NMR spectra of a 0.30 M solution of compound **7sa** in chloroform-*d* at 20°C contained one large peak at −121.8 ppm plus a much smaller one at −130.8 ppm. When the temperature was raised the minor signal broadened and coalesced with the major signal at about 60°C, then reappeared when the temperature was lowered, proving that it was not an impurity. The minor signal is probably due to a second 5,6-*O*-dibutylstannylene dimer. It cannot be due to a 3,5-dimer because tin atoms in six-membered-ring stannylene acetals absorb at very different ^{119}Sn NMR chemical shifts, approximately 60 ppm more shielded (6). Cooling the sample to 0°C produced a new signal at −332.4 ppm, plus another new signal at −138.1 ppm. These latter signals continued to grow as the

[a]The numbers in parentheses are the chemical shift increments, $\Delta\delta = \delta_{\text{stannylene acetal}} - \delta_{\text{diol}}$.

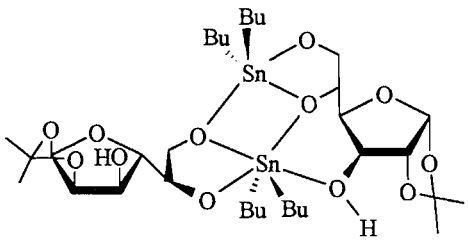

FIG. 2. The probable structure of the major species present in chloroform solutions of 5,6-*O*-dibutylstannylene-1,2-*O*-isopropylidene-α-D-allofuranose (**6sa**) below 0°C: a 5,6-dimer with additional coordination from O-3.

temperature was lowered, until by −50°C the ratio of intensities was 6:6:1:1 for the peaks at −137.4, −331.9, −129.2, and −120.9 ppm, respectively. The ratio of signal intensities of the −137.4 and −331.9 ppm signals was also 1:1 at intermediate temperatures. The position of the hexacoordinate tin signal is about the same as that (−346.1 ppm) of the hexacoordinate peak in trimeric 2,2-dibutyl-1,3,2-dioxastannane, in which the tin atom is in a six-membered ring (6). The signals of hexacoordinate tin atoms in five-membered 2,2-dibutyl-1,3,2-dioxastannolane rings always appear at positions less shielded than −300 ppm. The most likely structure for this species is an unsymmetrical dimer in which O-3 of the monomer unit having O-5 tricoordinate coordinates with the tin atom of the other monomer unit (see Fig. 2).

In summary, oligomerization of dialkylstannylene acetals depends on the structure of their precursors. For the dialkylstannylene acetals of glucofuranose derivatives, only single symmetric dimers were observed in chloroform-*d* at all temperatures. The stannylene acetals of allofuranose derivatives were present as dimers at room temperature. At lower temperatures higher oligomers were also observed. For one compound, the dibutylstannylene acetal of 1,2-*O*-isopropylidene-α-D-allofuranose, a second dimer was present as a minor species even at room temperature.

There are known to be large temperature effects on dimer–oligomer equilibria (4, 11). Even for compounds in which oligomers are dominant at −100°C, dimers constitute the majority of the species present at room temperature.

Dimer structure

The three possible dimeric structures of dialkylstannylene acetals derived from primary–secondary 1,2-diols (a primary,primary dimer, a primary,secondary dimer, and a secondary,secondary dimer) are illustrated in Fig. 3. It has been shown that steric effects are the major factor in determining dimer populations (4, 11). On this basis, the stability of the three dimers decreases in the order: primary,primary dimer (p,p dimer) to primary,secondary dimer (p,s dimer) to secondary,secondary dimer (s,s dimer). In the secondary,secondary dimer, there are steric interactions between the R groups on each monomer unit and the R′ groups on the tin atoms of the other monomer unit, causing significant destabilization. Only in primary,primary dimers can this steric interaction be fully avoided (see Fig. 3). Therefore, if only a single ^{119}Sn NMR signal is observed in the pentacoordinate region, the single symmetric dialkylstannylene acetal dimer present must be a primary,primary dimer.

Carbon-13 NMR chemical shifts provided useful information about the structures of the dimers for dibutylstannylene acetals derived from *trans*-diols (4). The formation of a dibutylstannylene acetal had only a slight effect on the chemical shift of most carbon atoms but caused the signal of the carbon atom attached to the dicoordinate oxygen atom to be significantly deshielded (by 3.5–4.4 ppm) and that of the carbon adjacent to the latter carbon but outside the stannylene acetal ring to be somewhat deshielded (by 1.6–3.3 ppm).

The data obtained from stannylene acetals are compared with their precursors in Table 2. In contrast to the earlier result (4),

the chemical shift changes for the signals of the carbons inside the stannylene acetal rings, i.e., C-5 and C-6, were generally quite small, except when the alkyl group on tin was secondary. In this case, the signal of C-6 was deshielded by variable amounts (1.5–5.5 ppm). A relatively constant feature was that the signal of the carbon atom next to the stannylene acetal ring, i.e., C-4, was deshielded on stannylene acetal formation (by 0.3–4.8 ppm, avg. 3.0 ± 1.3 ppm). Perhaps this latter observation is related to the modest deshielding previously observed (4) for the carbon outside the stannylene acetal ring but adjacent to the carbon bearing the dicoordinate oxygen atom. In any case, it is clear that the chemical shifts of the carbons inside the stannylene ring are not strongly affected by ring formation, consistent with only slight changes in charge density on ring formation. This observation is in contrast to previous assumptions (17), but is consistent with conclusions drawn earlier in this laboratory (4).

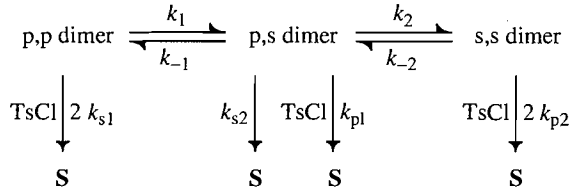
Mechanistic discussion

Although only a single sharp line corresponding to a primary,primary dimer was observed in the ^{119}Sn NMR spectra of most dialkylstannylene acetals at temperatures from −60°C to +60°C in chloroform-*d*, other dimers or higher oligomers must be present at concentrations that are below the level of detection by NMR spectroscopy. Based on previous experience in this laboratory (4), it was expected that reaction would take place on the dicoordinate oxygen atoms of the dimers that were predominant in solution. This process would lead only to secondary substitution, contrary to observation (2). Several possible explanations for this difference from expectation were considered but only that outlined below fits the effects of substitution on regioselectivity.

Primary oxygen atoms are inherently much more reactive than secondary oxygen atoms. In stannylene acetal dimers, dicoordinate oxygen atoms are much more reactive than the tricoordinate oxygen atoms. If all products are formed through stannylene acetal dimers and only dicoordinate oxygen atoms react, the primary *p*-toluenesulfonate (**P**) is obtained from the secondary,secondary dimer (s,s dimer) and the primary,secondary dimer (p,s dimer), and the secondary *p*-toluenesulfonate (**S**) is formed from the primary,primary dimer (p,p dimer) and the p,s dimer.

A comprehensive mechanistic scheme is shown in Scheme 1. More elaborate schemes involving oligomers and (or) monomers can be ruled out as follows. Oligomers will not be reactive intermediates because they are much less populated than dimers and the segments that contain the reactive dicoordinate oxygen atoms, the terminal units, would have about the same reactivity as similar segments in dimers. On electronic grounds, monomers should be less reactive than dimers because the oxygen atoms in monomers are not activated by being bonded to an electron-rich pentacoordinate tin atom. In support of this statement, tributylstannyl ethers, which normally exist as monomers with tetracoordinate tin, are much activated for reaction when an adjacent oxygen atom has the correct orientation to form an intermediate with a pentacoordinate tin atom (18). In addition, monomers are very much less populated than dimers. It is also assumed that only dicoordinate oxygen atoms react.

Another possible complication may be the chloride ions released as the *p*-toluenesulfonation reaction proceeds. These could act as added nucleophiles and produce additional intermediates. However, as noted in the preceding paper (2), in the presence of added nucleophiles, substitution occurs mainly on the primary oxygen atom. If this effect was important here, reaction regioselectivity should shift towards the primary product as the reaction proceeds and the concentration of the chloride ion increases. No such shift was observed and excellent regioselectivity for reaction on the secondary oxygen atoms was observed for many substrates. Therefore, this factor was not included in the mechanistic scheme.



SCHEME 1. p,p: primary,primary; p,s: primary,secondary; s,s: secondary,secondary; **P**: primary *p*-toluenesulfonate; **S**: secondary *p*-toluenesulfonate; k_{s1}, k_{s2}: rate constants for reaction at secondary dicoordinate oxygen atoms; k_{p1}, k_{p2}: rate constants for reaction at primary dicoordinate oxygen atoms; k_1, k_{-1}, k_2, k_{-2}: rate constants for dimer interconversion.

The following equations can be derived from the reaction pathway outlined in Scheme 1,

[1] $$d[\mathbf{S}]/dt = 2\,k_{s1}[p,p][TsCl] + k_{s2}[p,s][TsCl]$$

[2] $$d[\mathbf{P}]/dt = k_{p1}[p,s][TsCl] + 2\,k_{p2}[s,s][TsCl]$$

$$K_1 = k_1/k_{-1}$$

and

$$K_2 = k_2/k_{-2}$$

where [p,p] is the concentration of the p,p dimer, [p,s] is the concentration of the p,s dimer, [s,s] is the concentration of the s,s dimer, K_1 and K_2 are dimer equilibrium constants, and the other terms are defined in the scheme.

The environments of the dicoordinate secondary oxygen atoms in the p,p dimer and in the p,s dimer are very similar and the environments of the dicoordinate primary oxygen atoms in the p,s dimer and in the s,s dimer are almost the same. On this basis, it will be assumed that $k_{s1} = k_{s2} = k_s$, $k_{p1} = k_{p2} = k_p$, and $K_1 = K_2 = K = k_1/k_{-1}$, where k_s and k_p are rate constants for reaction at secondary and primary dicoordinate oxygen atoms in dimers and K is the dimer equilibrium constant.

From the ^{119}Sn NMR spectral measurements, it was shown that [p,p] $\gg$ [p,s] for all compounds. For the same reasons that make the p,p dimer more stable than the p,s dimer, [p,s] $\gg$ [s,s]. Therefore, it can be concluded that k_{s1}[p,p] $\gg$ k_{s2}[p,s] and k_{p1}[p,s] $\gg$ k_{p2}[s,s].
Thus, eqs. [1] and [2] simplify to

[3] $d[\mathbf{S}]/dt = 2\,k_s[p,p][TsCl]$

[4] $d[\mathbf{P}]/dt = k_p[p,s][TsCl]$

The ratio of the increment of the product at the secondary oxygen atom to that at the primary oxygen atom can be expressed as follows:

[5] $d[\mathbf{S}]/d[\mathbf{P}] = (2\,k_s/k_p)([p,p]/[p,s])$

Two limiting kinetic situations can be considered with respect to the p,s dimer; either it is in equilibrium with the major p,p dimer or it is at a steady-state concentration. When $k_p \ll k_{-1}$, the p,p dimer and the p,s dimer are in equilibrium and [p,p]/[p,s] = $1/K$, which leads to

[6] $d[\mathbf{S}]/d[\mathbf{P}] = (2\,k_s/k_p)(1/K)$

Thus, the regioselectivity of the *p*-toluenesulfonation reaction, or the ratio of the increment of the product at the secondary oxygen atom to that at the primary oxygen atom, depends only on the relative reactivity of the dicoordinate secondary and primary oxygen atoms and the relative populations of the p,p dimer and the p,s dimer.

When k_p is larger than k_{-1}, the concentration of the p,s dimer can be assumed to be in a steady state. Under these conditions, the concentrations of p,p dimer and p,s dimer are related by the following:

$$k_1[p,p] = k_{-1}[p,s] + k_p[p,s][TsCl]$$

$$[p,p]/[p,s] = (k_{-1} + k_p[TsCl])/k_1$$

Thus, eq. [5] becomes

[7] $d[\mathbf{S}]/d[\mathbf{P}] = (2\,k_s/k_p)\{(k_{-1} + k_p[TsCl])/k_1\}$

Since under normal reactions conditions [TsCl] is $\geq$1 M, if $k_p \gg k_{-1}$ k_p[TsCl] > k_{-1}, and therefore

[8] $d[\mathbf{S}]/d[\mathbf{P}] = 2\,k_s[TsCl]/k_1$

Therefore, the ratio of the amount of reaction at the secondary hydroxyl oxygen atom to that at the primary hydroxyl oxygen atom would increase with the increase of the concentration of TsCl used for the reaction, if indeed $k_{-1} < k_p$[TsCl]. The tosylation reaction is quite slow. Thus, k_p[TsCl] is expected to be less than k_{-1}. Not surprisingly, reaction on **8sc** at concentrations of *p*-toluenesulfonyl chloride of 0.10 and 1.2 M gave identical product ratios within experimental error. Therefore, it can be concluded that *p*-toluenesulfonation reactions occur under conditions in which dimer equilibration is much faster than reaction.

When the dimers are in equilibrium, eq. [6] applies. Regioselectivity for reaction on the secondary oxygen atom is determined by the product of two factors, the inverse of the dimer equilibrium constant, $1/K$, and the ratio of the relative reactivities of the dicoordinate secondary oxygen atoms to that of the dicoordinate primary oxygen atoms, k_s/k_p. For a given starting diol, increasing the bulk of the alkyl groups on tin will increase the intermonomer steric effects about the tricoordinate secondary oxygen atom. The already small population of the minor p,s dimer will decrease further. Thus, K will decrease and $1/K$ will increase, causing the relative amount of secondary product to increase. Altering alkyl groups on the tin atom in its dialkylstannylene acetals will also change k_s/k_p, but the differential effect is probably not large. In fact, increasing the bulk of the alkyl groups would be expected to decrease the reactivity of the dicoordinate oxygen atoms on secondary positions more than that on primary positions because the former are already sterically hindered. As outlined in the preceding paper (2), the introduction of sterically hindered alkyl groups on tin increases the selectivity for reaction at the secondary position. Thus, changing the alkyl groups on tin has a larger effect on the equilibrium constant between the p,p and p,s dimers than on the rate constants for reaction at the two types of oxygen atoms.

Introducing a cyclic hexamethylene group on tin causes by far the largest effect on the regioselectivity of the reaction. The most reasonable explanation of this change is that replacement of the two butyl groups on tin by a hexamethylene group has a larger effect on K than does replacement by sterically hindered acyclic groups. A cyclic group on tin will be considerably restricted in its motion and will be unable to adopt very different orientations to escape the steric interactions present when a secondary oxygen atom is tricoordinate.

Another factor that may be important in causing the improved regioselectivity of reactions of hexamethylenestannylene acetals is the somewhat different geometry about tin in these compounds. In the one crystal structure available for a dimeric dibutylstannylene acetal (7, 8), the dicoordinate oxygen atom is apical in a very distorted trigonal bipyramid at tin. All bond angles to tin in stannylene acetals derived from 1,2-diols are approximately fixed by the fact that the oxygen and tin atoms are in fused four- and five-membered rings. The equatorial butyl groups have C-Sn-C bond angles of 133.2(5)° and 128.4(4)°. The C-Sn-C bond angle in hexamethylenetin(IV) bischloroacetate is 122.2(3)°(19). Thus, the hexamethylenestannylene acetal C-Sn-C bond angle required by ring formation is likely to impose strain on the acetal that could result in more reactive apical oxygen atoms. This would be particularly true if, in the reaction mechanism, cleavage of the apical tin–oxygen bond occurs as the apical oxygen atom is forming a bond to the electrophile. This factor would increase the rate of reaction and, by raising the energy of the starting materials, decrease the difference in rates of reaction of dicoordinate primary and secondary oxygen atoms. In addition, the dicoordinate oxygen atoms in hexamethylenestannylene acetals may be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12

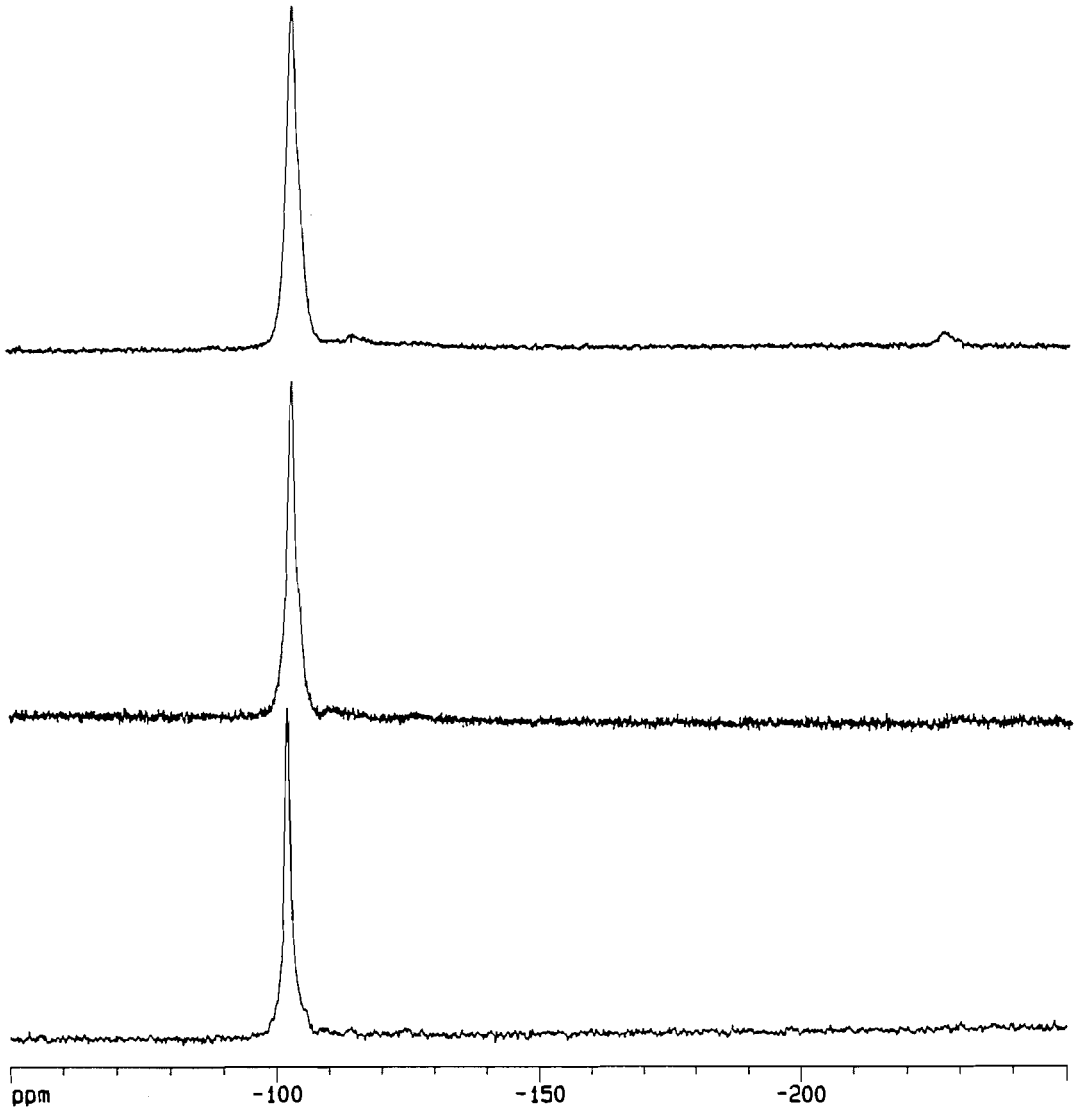

FIG. 4. 149.2 MHz ^{119}Sn NMR spectra of a 0.30 M solution of the hexamethylenestannylene acetal of ethane-1,2-diol (**13**) in chloroform-*d* at, from the top, −60°C, −20°C, 0°C.

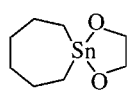
electrophiles than those in dibutylstannylene acetals because the very mobile butyl groups (7, 8) will populate some conformations that hinder approach to the dicoordinate oxygen atoms by electrophiles.



13

Supporting evidence about changes in geometry of hexamethylenestannylene acetals with respect to that of dibutylstannylene acetals was obtained from a study of the equilibrium mixtures present in solutions of the hexamethylenestannylene acetal of ethane-1,2-diol, spiro[4.6]1,4-dioxa-5-stannaundecane (**13**). Figure 4 shows ^{119}Sn NMR spectra of a 0.30 M solution of **13** in chloroform-*d* at 0°C, −40°C, and −60°C. The mole fraction of dimer was calculated from integrals of the areas of the large pentacoordinate tin peak and the hexacoordinate tin peak with the following assumptions. The hexacoordinate tin peak is due to trimer, but the trimer pentacoordinate tin peak is coincident with the pentacoordinate tin peak of the dimer. On this basis, the mole fraction of dimer of the hexamethylenestannylene acetal of ethylene glycol was 0.90 at −60°C. In comparison, the mole fraction of dimer for a much more dilute solution of the dibutylstannylene acetal of ethylene glycol at −73°C was 0.14 (4, 11). Evidentially, hexamethylenestannylene acetals favour dimers over higher oligomers much more than do acyclic dialkylstannylene acetals bearing alkyl groups of comparable bulk.

One cause of the difference between the two types of stannylene acetals is the steric restriction of C-Sn-C angles by ring formation in the hexamethylenestannylene acetal. In pentacoordinate tin sites of dibutylstannylene acetals, C-Sn-C bond angles average 127.8 ± 5.1°, whereas in structures where the tin atom is hexacoordinate the bond angles are larger, averaging 138.1 ± 3.0° (6). Stannacycloheptane rings are unable to accommodate the larger bond angles required in higher oligomers as easily and thus their formation is disfavoured. Additional support for this point comes from the fact that the C-Sn-C bond angle in hexamethylenetin bischloroacetate (122.3°) is

[c]Calculated using eq. [9] (20).

much smaller than those in acyclic dialkyltin dicarboxylates (136 ± 5°) (19).

The magnitudes of one-bond tin–carbon coupling constants ($^1J_{Sn\text{-}119,C\text{-}13}$) in butyltin derivatives have been related to the sizes of C-Sn-C bond angles (θ) by eq. [9] (20) and a very similar relationship has been developed for methyltin derivatives (21). Therefore, it is likely that this relationship will give reasonable values of bond angles for most organotin derivatives.

$$[9] \quad {}^1J_{Sn\text{-}119,C\text{-}13} = (9.99 \pm 0.73)\theta - (746 \pm 100)$$

Table 3 lists $^1J_{Sn\text{-}119,C\text{-}13}$ values and bond angles calculated with eq. [9]. The C-Sn-C bond angles for the hexamethylenestannylene acetals calculated in this way are somewhat smaller than those of acyclic dialkylstannylene acetals, in agreement with the above discussion, and it is clear that further expansion of a bond angle as required for hexacoordination at tin would cause strain.

Application to literature problems

The regiochemistry obtained in oxidation reactions of stannylene acetals with bromine or *N*-bromosuccinimide is often the reverse of that obtained from other reactions of stannylene acetals with electrophiles (3,22–24). This reversal can be explained by means of the above mechanistic considerations. Oxidation of dibutylstannylene acetals derived from primary–secondary 1,2-diols yields α-hydroxyketones with very high regioselectivity (22, 24). Oxidation with bromine is complete almost instantaneously at room temperature and with *N*-bromosuccinimide is complete between 1 and 20 min (24). Formation of *p*-toluenesulfonate esters from dialkystannylene acetals is much slower, taking between 12 h and 2 d to go to completion with one equivalent of *p*-toluenesulfonyl chloride at room temperature if the alkyl group is not large.

A pathway for the oxidation reaction that is consistent with the results presented here is outlined in Figure 5.

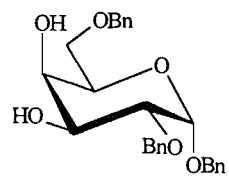
The first step in the oxidation reaction is the same as in all other reactions of stannylene acetals, an electrophilic addition to the dicoordinate oxygen atom. It is followed by elimination of hydrogen bromide to give the carbonyl group. Both steps are very fast at room temperature but the overall reaction slows if base is not present to remove the hydrogen bromide (22, 25).

The products obtained in oxidation reactions of terminal 1,2-diols are consistent with control by the relative populations of dibutylstannylene acetal dimers present in solution. As discussed above, the only detectable species of a dibutylstannylene acetal of a carbohydrate-derived primary–secondary 1,2-diol by ^{119}Sn NMR spectroscopy in solution is the p,p dimer. If the oxidation reaction occurs as shown in Fig. 5, initiated by electrophilic attack at the dicoordinate oxygen atom, the secondary oxygen atom in the p,p dimer, the corresponding α-hydroxyketone results (22, 24). Thus, the second kinetic situation, in which the population of the minor dimer is in a steady state, applies.

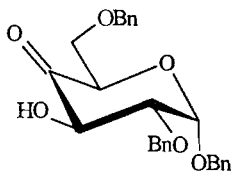
Under these conditions the product ratio can be predicted from eq. 8, adapted to the oxidation reaction under steady-state conditions as eq. [10],

$$[10] \quad d[\mathbf{S}]/d[\mathbf{P}] = 2\,(k_s/k_1)[O]$$

where [O] is the concentration of oxidizing reagent. The product ratio is determined by the relative rates at which the major dimer goes to product or to minor dimer. Product formation is undoubtedly considerably faster than dimer interconversion for bromine oxidation and, most probably, is also faster for NBS oxidation.



14



15

This conclusion also explains many results in the literature where the regioselectivity obtained in oxidation by bromine was different from that obtained in other reactions. For example, bromine oxidation of the dibutylstannylene acetal of benzyl 2,6-di-*O*-benzyl-α-D-galactopyranoside (**14**) in benzene gave only the 4-keto product (**15**) in a yield of 69% at room temperature, whereas benzoylation of this dibutylstannylene acetal under the same conditions as used for oxidation resulted in a 74% yield of 3-*O*-benzoyl derivative after 24 h (22). The only experimental evidence available about the structures of the dimers present for stannylene acetals derived from *cis*-1,2-diols on pyranose rings comes from the X-ray structure of methyl 4,6-*O*-benzylidene-2,3-dibutylstannylene-α-D-mannopyranoside, where the terminal units of the pentamer in the crystal have the axial oxygen atoms dicoordinate (10). Examination of models suggests that having the axial oxygen atom tricoordinate would bring one of the butyl groups on tin over the pyranose ring, causing severe steric destabilization. Both of these considerations indicate that dimers having the equatorial oxygen atoms tricoordinate are considerably favoured, i.e., the 3,3-dimer for the stannylene acetal of **14**. Oxidation will then trap the 3,3-dimer by reaction at the axial dicoordinate oxygen atom, O-4. All the other reactions of stannylene acetals are slower, which allows dimer equilibration to take place so that

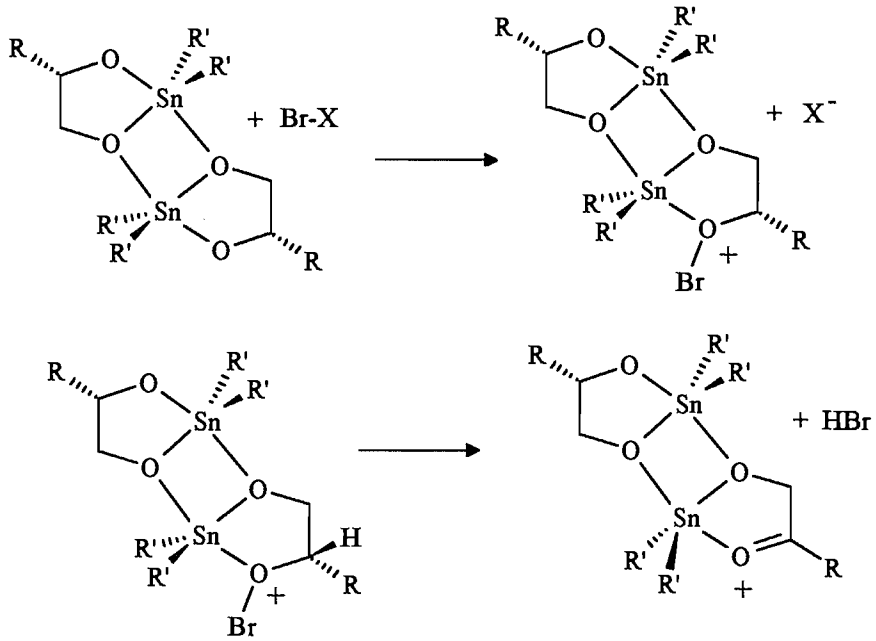

FIG. 5. A pathway for the oxidation of stannylene acetals.

the much more reactive equatorial oxygen atom, O-3, in the less populated 3,4-dimer reacts preferentially.

Conclusions

Dialkylstannylene acetals derived from primary,secondary 1,2-diols are present in solution predominantly as dimers. Steric effects are most important in determining which of the three possible dimers are most populated. The symmetrical dimer with the secondary oxygen atoms dicoordinate is favoured and the preference increases with both the size of the substituent on the secondary centre and the size of the alkyl groups on tin.

A mechanistic scheme has been developed that explains the regioselectivity observed in reactions of the above stannylene acetals with electrophiles in the absence of added nucleophiles. The key factor is the equilibrium between the major symmetrical dimer, which only reacts at the secondary oxygen atom, and the minor nonsymmetrical dimer, which reacts at the more reactive primary oxygen atom. For slow reactions, such as *p*-toluenesulfonylation, regioselectivity is determined by the product of the ratio of the rate constants for reaction at the two sites and the inverse of the dimer equilibrium constant, that is, by competition between the position of the equilibrium and the relative reactivity of the two oxygen atoms. For fast reactions, primarily oxidation, regioselectivity is determined by the position of the equilibrium.

Experimental

NMR spectra were recorded on Bruker AC 250F or AMX 400 or Nicolet NT-360 NB spectrometers; ^{13}C NMR spectra were referenced to internal tetramethylsilane (TMS) or to chloroform-*d* as a secondary reference at 77.0 ppm; ^{119}Sn NMR spectra were referenced to external tetramethyltin at 20°C. The variable temperature ^{119}Sn NMR spectra of dibutylstannylene acetals were recorded at 134.6 MHz on the Nicolet NMR spectrometer, those of the other stannylene acetals at 149.2 MHz on the Bruker AMX spectrometer.

Preparation of dialkylstannylene acetal samples for NMR spectroscopy

The mixture of a carbohydrate-derived diol (1 mmol) and dialkyltin oxide (1 mmol) was refluxed overnight in toluene (20 mL) with azeotropic removal of water. The solvent was removed under reduced pressure and the residue was dried under vacuum for 1 h. Dry chloroform-*d* or toluene-d_8 (3 mL) was distilled through a vacuum line onto the residual stannylene acetal. The solution was filtered, transferred under vacuum through a bridge into a pre-connected NMR tube, and then the tube was sealed. Tin-119 and carbon-13 NMR data for dialkylstannylene acetals are listed in Tables 1–3.

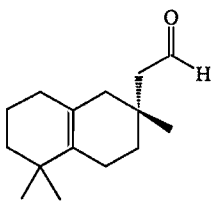
Introduction

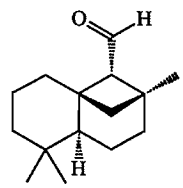
Acanthodoris nanaimoensis is a colorful nudibranch found in the shallow intertidal zone of British Columbia's coast line. It is one of the nudibranchs characterized by the fruity odor. The odoriferous principle of this nudibranch could be extracted with methanol and the sweet smelling oil residue, which was obtained in small quantities, was shown to possess antibacterial activity against *Bacillus subtilis* and *Staphylococcus aureus*, and antifungal activity against *Phythiam ultimum* and *Rhyzoctonia solani* (1).

The odor of the oily residue was later found to be due to a mixture of aldehydes. Three major components were subsequently identified as nanaimoal (**1**), acanthodoral (**2**), and isoacanthodoral (**3**) (2–4).

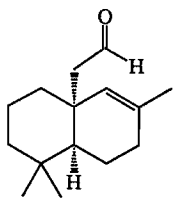
Herein we wish to report the details of the total synthesis,[2] in racemic form, of isoacanthodoral, which confirms the structural assignment of this structurally novel natural product.[3]



1



2

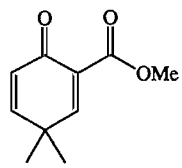


3

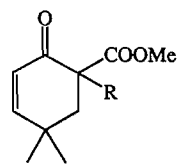
Results and discussion

During the course of our synthetic studies on himachalenes (6), the Diels–Alder reaction of 2-carbomethoxy-4,4-dimethyl-2,5-cyclohexadienone (**4**)[4] and isoprene was investigated. Interestingly, under boron trifluoride catalysis, the cycloaddition gave mainly the abnormal *anti-para* adduct **7** (64% yield) along with a small amount (28% yield) of the expected *para* adduct **8**.

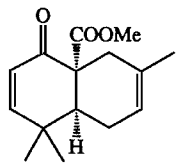
Adduct **7** is an attractive starting substrate that has almost the complete carbon skeleton for the synthesis of isoacanthodoral (**3**). Complete reduction of the α,β-unsaturated ketone moiety, modification of the carbomethoxy group to an acetaldehyde unit, and isomerization of the isolated double bond are all that is required to furnish compound **3**. These transformations were experimentally realized as follows.



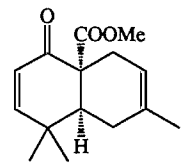
4



5 R=H
6 R=Br



7



8

To reduce the enone moiety, compound **7** was treated with triethylsilane in the presence of tris(triphenylphosphine)rhodium(I) chloride (Wilkinson's catalyst) (6, 7). The silyl enol ether **9** thus obtained in 97% yield was subsequently hydrolyzed with aqueous potassium bicarbonate in methanol to give crystalline keto ester **10** (mp 41–42°C) in quantitative yield. For the

[2]For preliminary communication, see ref. 5.

[3]Isoacanthodoral could not be isolated in pure form. Its structural assignment was carried out on the corresponding 2,4-dinitrophenylhydrazone (4).

[4]This compound was previously prepared from keto ester **5** via selenium dioxide oxidation (6). An improved procedure has since been developed, involving bromination of **5** with *N*-bromosuccinimide followed by dehydrobromination of the resulting bromide **6** with 1,8-diazabicyclo[5.4.0]undec-7-ene.

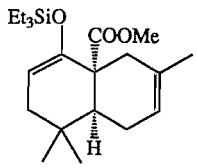
removal of the ketone carbonyl, keto ester **10** was subjected to thioketalization with 1,2-ethanedithiol in the presence of boron trifluoride etherate to generate the thioketal **11**.

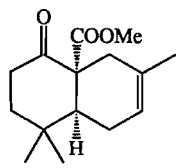
Upon Raney nickel reduction, compounds **12** and **13** were obtained in a 1:1 ratio and an overall yield of 80%. This means that the desired ester **12** was produced in only 40% yield.

An improved route to compound **12** employed the stepwise reduction of the ketone carbonyl, first to the alcohol level and then deoxygenation. Thus, keto ester **10** was dissolved in methanol and cooled to –40°C. Slow addition of sodium borohydride to the solution and a short reaction time (15 min) gave 95% of a mixture of epimeric alcohols **14** and **15** in 5:1 ratio. The stereochemistry of these alcohols at C-2 was proven by the following NOE experiments. Irradiation of the proton at C-2 (δ 3.90) in the major isomer **14** gave an 8% enhancement of the signal at δ 1.93, attributed to the proton at C-6. On the other hand, irradiation of the C-2 proton (δ 3.60) in the minor isomer **15** gave no enhancement of the signal at δ 2.15–2.30 for the C-6 proton and two others.

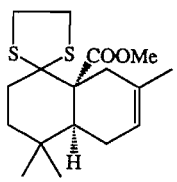
It is noteworthy that in the reduction of **10**, higher temperature or longer reaction time led to the production of the over-reduced product **16**. The reduction of the ester moiety is thought



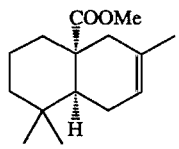
9



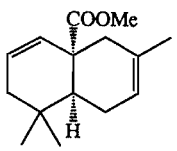
10



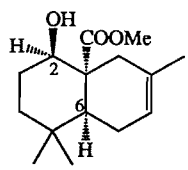
11



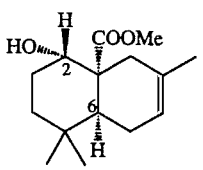
12



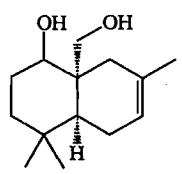
13



14



15



16

to proceed through a four-membered ring lactone, formed after the initial reduction of the ketone carbonyl, or through an intramolecular hydride transfer from the boron-C-2 oxygen complex formed after the initial reduction.

To remove the hydroxy group present in compounds **14** and **15** the corresponding xanthates were prepared. Each of the hydroxy esters **14** and **15** was treated with sodium hydride in 1,2-dimethoxyethane to give the corresponding sodium alkoxide, followed by reaction with carbon disulfide to generate the sodium xanthate. The salt was alkylated in situ with methyl iodide to produce the corresponding methyl xanthate in quantitative yield. The reduction of xanthates **17** and **18** in pure form or as a mixture with tri-*n*-butyltin hydride in the presence of a catalytic amount of azobisisobutyronitrile (8) afforded ester **12** in virtually quantitative yield.

Having successfully removed the unnecessary functionalities from "ring A", it remained to carry out the following transformations in order to complete the synthesis of isoacanthodoral. The ester group in compound **12** must be converted to an acetaldehyde unit and the double bond must be moved to the adjacent position. We chose to modify the ester group first.

Homologation by one carbon unit can be carried out in a number of ways (9–14). A frequently used procedure involves the Wittig reaction (13, 14) of an aldehyde with methoxymethylenetriphenylphosphorane, followed by hydrolysis of the resulting enol ethers.

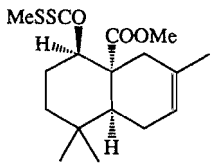
Several attempts were made to reduce ester **12** directly to aldehyde **19**. When ester **12** was treated with diisobutylaluminum hydride (15) in toluene at –78°C, reduction did not take place. When the reaction was carried out at room temperature, only a 20% yield of the desired aldehyde was obtained. This aldehyde was produced more effectively by a two-step sequence as follows.

Treatment of ester **12** with lithium aluminum hydride in dry ether gave the alcohol **20** as a crystalline solid in 96% yield. When alcohol **20** was subjected to Swern oxidation (16), aldehyde **19** was formed in 80% yield. Unfortunately, compound **19** proved to be quite volatile, making its isolation rather difficult.

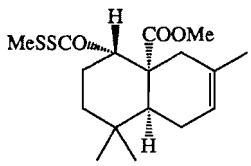
Another good method for the conversion of alcohols to the corresponding aldehydes involves the use of pyridinium chlorochromate on alumina (17). This method is especially useful when the product is unstable or volatile. Treatment of alcohol **20** with pyridinium chlorochromate on alumina in dichloromethane at room temperature for 2 h gave an 88% yield of aldehyde **19**, which did not require further purification.

Addition of aldehyde **19** to a deep red benzene solution of methoxymethylenetriphenylphosphorane gave a 1:1 mixture of *cis* and *trans* enol ethers **21** in 98% yield. However, attempts to hydrolyze **21** under a variety of acidic conditions led invariably to decomposition of the material. The desired aldehyde was not detected. Several demethylating agents such as chlorotrimethylsilane and sodium iodide in acetonitrile (18), phenyl dichlorophosphate and sodium iodide (19), and sodium ethylthiolate (20) were also examined. In all cases, the starting material was recovered intact. A vinyl ether exchange reaction catalyzed by mercury(II) salts (21, 22) was also attempted. Mercury(II) nitrate was added to a solution of enol ethers **21** in acetonitrile–water (5:1). After 2 h at room temperature, the starting material was completely consumed. Unfortunately, no identifiable products were isolated.

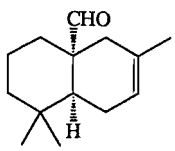
In reassessing the synthetic strategy it was deemed appropriate to move the existing endocyclic double bond first, since most of the difficulties encountered were likely due to this double bond. Direct isomerization of the double bond was attempted. α,β-Unsaturated keto ester **7** was dissolved in carbon tetrachloride and refluxed overnight in the presence of trifluoroacetic acid. Only starting material was recovered. Under the same conditions, keto ester **10** was also recovered intact. At this point, it seemed unlikely that a clean direct isomerization of the double bond could be achieved. Therefore, a functional



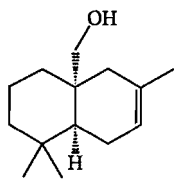
17



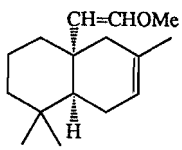
18



19



20



21

group must be introduced to the disubstituted end of the double bond followed by elimination.

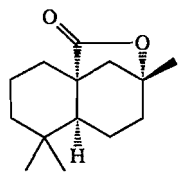
Ester **12** has only two functional groups, making it a good candidate for the introduction of the required functional group. Treatment of ester **12** in hexane saturated with hydrogen bromide or hydrogen chloride gas at room temperature gave a crystalline product that did not contain any halogen atoms. Apparently hydrohalogenation had not taken place. A strong absorption at 1753 cm^{-1} in the infrared spectrum, the absence of the ester group and the double bond in the ^1H nmr spectrum, and the molecular ion peak corresponding to $C_{14}H_{22}O_2$ in the mass spectrum indicated the formation of lactone **22**. When ester **12** was treated with *p*-toluenesulfonic acid in refluxing benzene, lactone **22** was also obtained in 90% yield.

Compound **22** would arise if the double bond of compound **22** is protonated and the incipient tertiary carbocation is attacked intramolecularly by the carbonyl oxygen rather than by the external nucleophile (halogen). Although it was not possible to introduce a halogen to the double bond, an oxygen atom was efficiently incorporated. This would, hopefully, allow for the subsequent regeneration of a double bond at the required position. To accomplish this, it was necessary to convert the lactone ring to a hydroxy ester. The combinations of sodium methoxide – methanol, sodium ethoxide – ethanol, and sodium isopropoxide – isopropyl alcohol were used in attempts to cleave the lactone ring in compound **22**. Examination of the reaction in each case, by thin-layer chromatography, showed that, even though the starting material was consumed, the lactone was regenerated upon work-up.

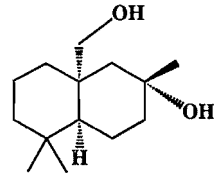
Another alternative was to reduce the lactone completely to a diol. Thus, **22** was treated with lithium aluminum hydride in ether and diol **23** was formed in 97% yield.

At this point, it was necessary to decide whether to introduce the double bond or to extend the side chain first. In an unsuccessful attempt to extend the angular chain, the primary alcohol was oxidized with pyridinium chlorochromate on alumina. The unstable hydroxy aldehyde thus obtained was immediately subjected to a Wittig reaction with methoxymethylenetriphenylphosphorane. Complete decomposition of the starting aldehyde occurred without apparent formation of the desired product. These results prompted us to examine the approach of regenerating the double bond before extension of the angular chain.

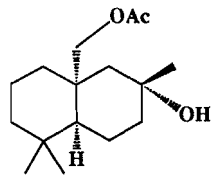
To avoid problems during the dehydration reaction, it was deemed necessary to protect the primary alcohol first. Selective protection was readily achieved as follows. Freshly distilled acetic anhydride was added to a solution of diol **23** in dry pyridine. After overnight at room temperature, hydroxy acetate **24** was isolated in 90% yield.



22



23



24

Several methods for the dehydration of hydroxy acetate **24** were examined, including the use of copper(II) sulfate on silica gel (23), thionyl chloride in pyridine (24), and phosphorus oxychloride in pyridine (25). A mixture of isomeric olefins was always obtained. The results are given in Table 1.

As can be seen from Table 1, the dehydration reaction with copper(II) sulfate impregnated on silica gel in refluxing benzene (Entry 1) gave predominantly the undesirable acetate **26**. No change in the product ratio was observed when benzene was replaced with toluene. When xylenes were used, complete decomposition occurred. In contrast, when the dehydration was carried out in refluxing ether, no reaction took place.

Thionyl chloride in pyridine gave a mixture of olefins **25** and **26** in equal amounts, when the reaction was carried out at room temperature (Entry 2). When the temperature was decreased to 5°C (Entry 3), the rate of reaction decreased as expected but the product ratio remained the same.

Similar results were obtained with phosphorus oxychloride in pyridine at a temperature range of –30°C to 20°C (Entries 4–6). With the aid of 4-dimethylaminopyridine (DMAP), however, the formation of the desired isomer **25** was enhanced at the expense of **26**. It appears that preferential formation of **25** is highly dependent upon the ratio of the reagents and the reaction temperature (Entries 7–12). The best results were obtained when the reaction was carried out at –40°C in pyridine using 10 equivalents of phosphorous oxychloride and 5 equivalents of DMAP (Entry 12). Under these conditions a 3:1 mixture of acetates **25** and **26** was obtained in virtually quantitative yield.

It is noteworthy that in virtually all the cases examined a very small amount (<4% by ^1H nmr, showing a pair of broad doublets at δ 4.69 and 4.57 (J = 1 Hz each)) of the exocyclic olefin **27** was also produced. However, all attempts to isolate this

compound by chromatography were unsuccessful, probably due to isomerization of the double bond to the more stable endocyclic position on silica gel.

Isomeric olefins **25** and **26** were found to be inseparable. For characterization purposes, compound **26** was produced via a different route. Alcohol **20** was acetylated with acetic anhydride in pyridine to give pure **26**.

The mixture of acetates **25** and **26** was hydrolyzed with an aqueous solution of potassium carbonate in methanol. After refluxing for 2.5 h a mixture of hydroxy olefins was obtained in 98% yield. Separation of alcohols **20** (20%) and **28** (70%) was achieved by flash chromatography on silica gel.

The studies on the dehydration of hydroxy acetate **24** depleted our stock of this material. It was necessary to prepare more Diels–Alder adducts, to separate isomer **7** required for the synthesis, and then to repeat the reaction sequence leading to alcohol **28**. It has been reported that ionic hydrogenation can be performed using trialkylsilanes and a strong acid or boron trifluoride (26–30). Under these conditions, an α,β-unsaturated ketone can be reduced to the saturated ketone or alcohol, depending on the quantities of the acid and the reducing agent used. Therefore, ionic hydrogenation presented itself as a good option for the reduction of the α,β-unsaturated ketone group in compound **7**. Compounds **7** and **8** were used to study the selective reduction of the enone system to the saturated ketone using the ionic hydrogenation conditions described by Kurzanov et al. (28). When a mixture of **7** and **8** was treated with triethylsilane and trifluoroacetic acid, in a ratio of 1:1:10, respectively, in refluxing carbon tetrachloride only partial reduction was observed. A variety of reduction products was obtained along with unreacted starting material. The reaction was repeated several times using different temperatures and reaction times. Invariably, a complex mixture was formed. Kurzanov also reported (28) the direct reduction of an α,β-unsaturated ketone to the corresponding alcohol by the use of a higher concentration of triethylsilane. When a mixture of keto esters **7** and **8** was treated with 3 equivalents of triethylsilane and 10 equivalents of trifluoroacetic acid in refluxing carbon tetrachloride, the starting material was consumed in 9 h and a mixture of products was obtained. Complete separation of these products proved to be difficult. Nevertheless, a combination of crystallization and flash chromatography allowed for the separation of four major compounds **29–32**. Lactone **29** (65%) and ether **31** (29%) were produced in 94% yield from keto ester **7**, while lactone **30** (30%) and ether **32** (36%) were obtained in 66% yield from keto ester **8**. There was a small fluctuation of the ratio of each pair of the products in different experiments. However, the total yield of each pair was rather reproducible.

a petroleum ether solution of the products mixture. Recrystallization from the same solvent gave a white solid with a melting point of 132–133°C. Lactone **30** sometimes crystallized from the products mixture together with the isomeric lactone **29**. At other times it remained in the mother liquor until the separation by flash chromatography was carried out. The stereochemistry at C-8 in lactones **29** and **30** could not be unambiguously assigned. An NOE experiment on **29** including irradiation of the C-8 hydrogen did not produce any conclusive evidence.

Of the four compounds **29–32**, **29** and **31** are potentially useful for the current studies. In practice, attempted cleavage of the ether ring present in the minor compound **31** under acidic conditions failed to give any desired hydroxy lactone **33**. The conversion of trifluoroacetate lactone **29** to lactone **22**, prepared previously via a different route, requires the cleavage of a carbon–oxygen bond. The cleavage of a sterically hindered ester group has been demonstrated by Barton et al. (31) by the use of metallic lithium in ethylamine at –78°C. When lactone **29** was subjected to reduction under these conditions for 1 h the only product obtained in 56% yield was hydroxy lactone **33**.

Pète and co-workers (32) have reported that carboxylic esters are readily reduced to the hydrocarbon level in hexamethylphosphorous triamide – water (95:5) upon irradiation with 254-nm UV light. In our case irradiation of **29** with a 12-W low-pressure mercury lamp for 3 h gave again the hydroxy lactone **33** as the only product in approximately 50% yield.

In a successful indirect procedure, trifluoroacetate **29** was hydrolyzed with 10% aqueous potassium carbonate in methanol at room temperature to give hydroxy lactone **33** in almost quantitative yield after 24 h. Similar results were obtained by the use of sodium methoxide in methanol at room temperature. As expected, the reaction proceeded more rapidly and the starting material was completely consumed after 10 h. Recrystallization of **33** from ether afforded white crystals that start subliming at 105°C and have a melting point of 120°C.

Reaction of hydroxy lactone **33** with sodium hydride in 1,2-dimethoxyethane followed by addition of carbon disulfide gave the corresponding sodium xanthate, which was trapped with methyl iodide to form methyl xanthate **34** in 61% yield. The modest yield is probably due to the sterically hindered hydroxy group. Reduction of the xanthate **34** was carried out under the conditions used previously for the conversion of compounds **17** and **18** to ester **12**. Refluxing a toluene solution of xanthate **34** with tri-*n*-butyltin hydride, in the presence of a catalytic amount of azobisisobutyronitrile, gave a 71% of lactone **22** identical in all respects with the lactone obtained previously by the acid-catalyzed cyclization of ester **12**.

Application of the same reaction sequence (**29**→**33**→**34**→**22**) to the mixture of trifluoroacetate lactones **29** and **30** gave isomeric lactones **22** and **35**. The two isomeric lactones were readily separated by flash chromatography on silica gel. Based on these findings, a practical route that allowed the preparation of compound **22** in large quantity was developed as follows. An equimolar mixture of isomeric keto esters **7** and **8** was converted to esters **12** and **36** using the route developed earlier for the transformation of pure keto ester **7** to compound **12**, via hydrosilylation, sodium borohydride reduction, xanthate formation, and tri-*n*-butyltin hydride reduction. The mixture of **12** and **36** was treated with *p*-toluenesulfonic acid in benzene. Purification by flash chromatography on silica gel gave lactone **22** (41% yield) and its isomer **35** (42% yield). By the use of this synthetic sequence a large quantity of **22** was readily obtained in five simple operations with one chromatographic separation. This compound was subsequently reduced to diol **23**, which was converted to alcohol **28** via hydroxy acetate **24** and olefin **25** according to the procedure described earlier.

The conversion of alcohol **28** to the target molecule **3** requires the modification of the angular substituent. This was achieved in the following manner. Alcohol **28** was oxidized with pyridinium chlorochromate on alumina in dichloromethane. Filtration followed by careful concentration of the filtrate gave the volatile aldehyde **37** in 94% yield. Aldehyde **37** underwent a Wittig reaction with methoxymethylenetriphenylphosphorane in benzene – dimethyl sulfoxide. A 1:1 mixture of enol ethers **38** and **39** was obtained in 93% yield. Flash chromatography on silica gel pretreated with 1% triethylamine in petroleum ether and eluting with the same solvent system resulted in the separation of these isomers. The use of triethylamine was found to be crucial in order to avoid the hydrolysis of the enol ether functional group during the chromatography. The ^{1}H nmr spectrum of the faster moving isomer displays signals for the vinylic hydrogens of the enol ether moiety at δ 5.64 and 4.27. Each signal appears as a doublet with a small coupling constant of 7 Hz indicating the presence of a *Z* double bond. Accordingly, structure **38** was assigned to this compound. The protons attached to the enol ether double bond are displayed at δ 6.11 and 4.71 in the ^{1}H nmr spectrum of the more polar isomer **39**. The *E* configuration of this double bond is apparent from the large coupling constant of 13 Hz.

To complete the synthesis of isoacanthodoral it remained to hydrolyze the enol ethers **38** and **39**. During the purification of these compounds by flash chromatography on silica gel, it was observed that substantial hydrolysis occurred, apparently due to the acidity of the adsorbent. It was necessary to use triethylamine in order to circumvent this problem. However, for the conversion of enol ether moiety to the aldehyde, one would take advantage of the ability of silica gel to induce the hydrolysis for the desired conversion. To enhance the acidity of the silica gel, it was washed with glacial acetic acid and then petroleum ether. A flash chromatography of enol ethers **38** and **39** was carried out using this material with ether – petroleum ether elution. Hydrolysis indeed occurred and the desired aldehyde was formed. However, a substantial amount of the starting enol ethers was also recovered. In another experiment, silica gel was prewashed with 70% perchloric acid and then petroleum ether, and flash chromatography was carried out. In this case a greater amount of aldehyde was obtained along with the recovery of a small quantity of the enol ethers. However, a substantial loss of material also took place. In a more successful experiment, the mixture of enol ethers was applied to a column containing acetic acid-washed silica gel and the elution with 0–5% ether – petroleum ether was carried out after 24 h. In this manner, complete hydrolysis occurred and a virtually quantitative yield of the desired aldehyde was obtained. The synthetic isoacanthodoral **3** thus obtained in racemic form shows characteristic aldehyde absorptions at 2845, 2720, and 1720 cm^{-1} in the infrared spectrum. Its ^{1}H nmr spectrum shows a diagnostic aldehyde signal at δ 9.73 as a doublet of doublets (J = J' = 3 Hz) due to the coupling with the adjacent methylenic protons at δ 2.71 (dd, J = 15, J' = 3 Hz) and 2.13 (dd, J = 15, J' = 3 Hz). A slightly broad doublet (J = 1 Hz) at δ 5.23 could be readily assigned to the vinylic hydrogen. Three methyl signals are displayed at δ 1.65 (vinylic), 1.00, and 0.91 (*gem*-dimethyl), each as a singlet. A ^{13}C nmr Distortionless Enhancement by Polarization Transfer (DEPT) experi-

For personal use only.

ment was employed to determine the multiplicity of each carbon in the molecule. On the basis of this experiment the following assignments were made: δ 204.8 (-*C*=O), 135.5 (-CH=*C*-), 129.9 (-*C*H=*C*-), 57.2 (-CH_2CHO), 46.3 (C-6), 40.1 (-CH_2-), 38.5 (-CH_2-), 38.2 (C-1), 34.2 (C-7), 32.4 (=C(CH_3)), 28.9 ((-CH_2-), 26.4 (-CH_3), 23.5 (-CH_3), 19.9 (-CH_2-), and 19.2 (-CH_2-). A molecular peak at *m/z* 220.1821 in the high-resolution mass spectrum was consistent with the molecular formula $C_{15}H_{24}O$.

A comparison of the ^{1}H nmr, ^{13}C nmr, and mass spectral data of the synthetic material with those reported (3) for the natural isoacanthodoral readily establishes that they are identical. Naturally occurring isoacanthodoral was isolated in very small quantities, sufficient only to obtain spectroscopic data (^{1}H nmr, ^{13}C nmr, and ms) (3). The complete structural assignment was carried out by means of X-ray crystallography on the 2,4-dinitrophenylhydrazone derivative (4).

To further confirm the identity of our synthetic (±)-isoacanthodoral, it was converted to the 2,4-dinitrophenylhydrazone derivative by treatment with 2,4-dinitrophenylhydrazone (3% in ethanol – water – H_2SO_4 (2:2:1)) at room temperature for 3 h. Flash chromatography of the crude product on silica gel (0–5% ether in petroleum ether), followed by recrystallization from ether – petroleum ether, gave orange needles with a melting point of 144–146°C. The spectral data of this material were found to be in good agreement with those described for the 2,4-dinitrophenylhydrazone derivative (**40**) of the natural material.

In conclusion, the marine natural product isoacanthodoral (**3**) has been synthesized in racemic form from 2-carbomethoxy-4,4-dimethyl-2,5-cyclohexadien-1-one in ca. 38% overall yield, using an intermolecular Diels–Alder approach.

Experimental

General

Melting points were measured on a Köfler hot stage apparatus and are uncorrected. Elemental analyses were carried out using a Perkin Elmer 240-B for C, H, N detection. Infrared spectra (ir) were obtained on a Nicolet 7199 FTIR spectrophotometer. Mass spectra (ms) were determined using a AEI Kratos MS-50 high-resolution mass spectrometer attached to a Data General Nova 2 with Kratos DS-55 software. Proton nuclear magnetic resonance spectra (^{1}H nmr) were obtained using one of the following spectrometers: Bruker WH-200 (200 MHz), Bruker AM-300 (300 MHz), or Bruker AM-400 (400 MHz). Coupling constants are recorded to within ± 0.5 Hz. Carbon-13 nuclear magnetic resonance spectra (^{13}C nmr) were run on a Bruker AM-300 (75 MHz) or a Bruker AM-400 (100.6 MHz). Two methods were used to determine the carbon-13 multiplicities: the distortionless enhancement by polarization transfer (DEPT) experiment with proton decoupling using a Bruker software microprogram (DEPT.AUR) and the attached proton test (APT). Peaks in antiphase (a) with deuteriochloroform were assigned as methyls or methines, while peaks in phase (p) correspond to methylenes or quaternary carbons. Aldehydic carbonyls appear in antiphase with $CDCl_3$ and other carbonyls in phase with the deuteriochloroform signal. Nuclear Overhauser Enhancement (NOE) experiments were obtained after computer subtraction of the off-resonance irradiated spectrum from the irradiated spectrum. Positive enhancements are defined as signals in antiphase with the irradiated signal. Immediately before the experiment each sample was deoxygenated by passing helium gas through the solution for 10 min. Reaction yields are quoted with a degree of purity better than 95% as determined by nmr spectroscopy.

Materials

Products were purified either by flash chromatography using silica gel 60 (230–400 mesh), distillation using a Kugelrohr apparatus, or by fractional crystallization. Reactions were monitored by thin-layer chromatography using Merck aluminum-backed plates precoated with silica gel 60 GF_{254}. Solvents were dried and distilled prior to use as follows: ether and 1,2-dimethoxyethane from a blue–purple solution of sodium benzophenone ketyl under an argon atmosphere; toluene, benzene, pyridine, dichloromethane, and dimethyl sufloxide from calcium hydride or lithium hydride.

6-Bromo-6-carbomethoxy-4,4-dimethyl-2-cyclohexen-1-one (6)

6-Carbomethoxy-4,4-dimethyl-2-cyclohexen-1-one (**5**) (5.12 g, 28.12 mmol) was dissolved in carbon tetrachloride (25 mL) and the reaction vessel was protected from light. *N*-Bromosuccinimide (10.00 g, 56.24 mmol) was added to the solution. After 10 h at room temperature, the suspension was filtered and the filtrate was concentrated. The residue was distilled using a Kugelrohr apparatus (100°C/0.8 Torr; 1 Torr = 133.3 Pa) to yield **6** (6.82 g, 93%) as a pale yellow oil: ir ($CHCl_3$ cast): 1734 (ester) and 1698 (α,β-unsaturated ketone) cm^{-1}; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 6.68 (dd, 1H, J = 10, J' = 2 Hz, -C*H*=CHCO), 6.05 (d, 1H, J = 10 Hz, -CH=C*H*CO), 3.82 (s, 3 H, -OCH_3), 3.03 (dd, 1 H, J = 14, J' = 2 Hz, -C*H*HCBr), 2.53 (d, J = 14 Hz, -CH*H*CBr), 1.28 (s, 3 H, -CH_3), and 1.13 (s, 3 H, -CH_3); ^{13}C nmr APT (75 MHz, $CDCl_3$) δ: 187.7 (p), 169.0 (p), 158.5 (a), 124.1 (a), 61.9 (p), 53.7 (a), 48.8 (p), 35.2 (p), 30.1 (a), and 27.6 (a); ms M^+: 260.0048 (calcd. for $C_{10}H_{13}O_3Br$: 260.0049).

2-Carbomethoxy-4,4-dimethyl-2,5-cyclohexadien-1-one (4)

Bromide **6** (6.80 g, 26.0 mmol) was dissolved in benzene (30 mL) and 1,8-diazabicyclo[5.4.0]undec-7-ene (5.8 mL, 39 mmol) was added dropwise at room temperature with stirring. After 2 h the solid, which had formed during the reaction, was removed by filtration using a sintered glass funnel packed with Florisil as filter-acid. The filtrate was extracted with ether (3 × 20 mL). The combined

organic extracts were washed successively with 5% HCl solution (2 × 20 mL), water (1 × 20 mL), saturated sodium bicarbonate solution (1 × 20 mL), and brine (1 × 20 mL). The organic solution was then dried ($MgSO_4$), filtered, and concentrated. Bulb-to-bulb distillation (100°C/0.5 Torr) of the concentrate gave 3.70 g (78%) of **4** (6) as a colorless oil.

(1R, 6S*)-1-Carbomethoxy-5,5,9-trimethylbicyclo[4.4.0]deca-3,8-dien-2-one (7) and (1R*, 6S*)-1-carbomethoxy-5,5,8-trimethylbicyclo[4.4.0]deca-3,8-dien-2-one (8)*

2-Carbomethoxy-4,4-dimethyl-2,5-cyclohexadien-1-one (**4**) (8.75 g, 48.6 mmol) was dissolved in dry ether (350 mL) and the solution cooled with an ice–water bath. Isoprene (97 mL, 0.97 mol) was added. Then boron trifluoride etherate (3 mL, 11.7 mmol) was slowly introduced into the reaction flask by means of a syringe. The reaction mixture was stirred at room temperature for 96 h. Aqueous saturated sodium bicarbonate (75 mL) was carefully added to the reaction mixture. The organic layer was separated and the aqueous layer extracted with ether (3 × 50 mL). The organic extracts were combined, washed with water (2 × 20 mL) followed by brine (1 × 20 mL), dried ($MgSO_4$), filtered, and concentrated to afford a colorless oil. Purification by flash chromatography on silica gel (0–10% ether in petroleum ether) gave a mixture of Diels–Alder adducts (11.60 g, 96%) **7** and **8** in a 7:3 ratio. The major isomer was isolated by fractional crystallization by seeding the ether solution of the mixture of the adducts with pure crystals of compound **7**, which were obtained by preparative high-pressure liquid chromatography of the mixture using a Waters Associates Prep LC/System 500 instrument charged with a silica gel cartridge, using a solution of 5% ethyl acetate in *n*-hexane as eluent. Repeated crystallization with seeding (×3) yielded 4.00 g (35%) of compound **7** (6) as white crystals: mp 97–98°C; ir ($CHCl_3$ cast): 1739 (ester) and 1667 (α,β-unsaturated ketone) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 6.54 (d, 1 H, J = 10 Hz, -C*H*=CHCO), 5.86 (d, 1 H, J = 10 Hz, -CH=C*H*CO), 5.32 (br s, 1 H, -C(CH_3)=C*H*-), 3.72 (s, 3 H, -COOCH_3), 2.66 (ddd, 1 H, J = 6, J' = 4, J'' = 1, -C(CH_3)$_2$C*H*CH_2-), 2.49 (d, 1 H, J = 17 Hz, -C*H*HC(CH_3)=), 2.12 (d, 1 H, J = 17 Hz, -CH*H*C(CH_3)=), 2.10–2.00 (complex, 2 H, -CH_2CH=C(CH_3)-), 1.64 (s, 3 H, -C(CH_3)=CH-), 1.14 (s, 3 H, -C(CH_3)$_2$), and 0.99 (s, 3 H, -C(CH_3)$_2$); ^{13}C nmr APT (100.6 MHz, $CDCl_3$) δ: 197.3 (p), 173.1 (p), 157.8 (a), 131.3 (p), 124.1 (a), 119.3 (a), 57.6 (p), 52.4 (a), 40.6 (a), 36.1 (p), 33.3 (p), 30.5 (a), 24.4 (p), 23.8 (a), and 23.1 (a); ms M^+: 248.1418 (calcd. for $C_{15}H_{20}O_3$: 248.1412). Anal. calcd. for $C_{15}H_{20}O_3$: C 72.54, H 8.12; found: C 72.36, H 8.04. The mother liquor was found to consist of adducts **7** and **8** in nearly equal amount.

(1R, 6S*)-1-Carbomethoxy-5,5,9-trimethyl-2-triethylsiloxybicyclo-[4.4.0]deca-2,8-diene (9)*

A dichloromethane solution of keto ester **7** (3.50 g, 14 mmol) was allowed to evaporate to dryness slowly in order to produce very fine crystals. These were suspended in triethylsilane (4.5 mL, 28 mmol), and tris(triphenylphosphine)rhodium(I) chloride (64 mg, 0.07 mmol) was added. The slurry was stirred for 5 h at room temperature, then additional triethylsilane (4.5 mL, 28 mmol) was added. The reaction mixture was stirred overnight, after which time all the solid keto ester dissolved. The reaction mixture was diluted with petroleum ether, filtered through Florisil contained in a sintered glass funnel, and concentrated under reduced pressure. Purification of the residue by flash chromatography on silica gel (0–10% ether in petroleum ether) gave silyl enol ether **9** (4.95 g, 97%) as a colorless oil: ir ($CHCl_3$ cast): 1742, 1729 (ester) and 1670 (olefin) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 5.35 (br s, 1 H, -C=C*H*-), 4.67 (dd, 1 H, J = 6, J' = 2 Hz, -SiO-C=C*H*-), 3.65 (s, 3 H, -COOCH_3), 2.66 (br, d, 1 H, J = 17 Hz, -SiOC=CHC*H*H-), 2.25–1.90 (complex, 5 H), 1.79 (dd, 1 H, J = 17, J' = 6 Hz, -SiOC=CHCH*H*-), 1.67 (br s, 3 H, =CCH_3), 0.97 (complex, 15 H, -C(CH_3)$_2$ and -Si(CH_2CH_3)$_3$, and 0.66 (q, 6 H, J = 7 Hz, -Si(CH_2CH_3)$_3$); ^{13}C nmr APT (100.6 MHz, $CDCl_3$) δ: 176.3 (p), 151.0 (p), 131.9 (p), 118.8 (a), 99.1 (a), 51.9 (a), 51.5 (p), 42.1 (a), 39.7 (p), 35.1 (p), 32.3 (p), 31.0 (a), 23.5 (p), 23.3 (a), 22.6 (a), 6.7 (a), and 5.1 (p); ms M^+: 364.2440 (calcd. for $C_{21}H_{36}O_3Si$: 364.2434).

(1R, 6S*)-1-Carbomethoxy-5,5,9-trimethylbicyclo[4.4.0]deca-8-en-2-one (10)*

Silyl enol ether **9** (1.00 g, 2.75 mmol) was dissolved in methanol and a 10% aqueous solution of potassium bicarbonate (50 mL) was added. The mixture was stirred at room temperature for 10 h, then poured into water. The water layer was extracted with dichloromethane (3 × 10 mL). The combined organic extracts were washed successively with water (2 × 10 mL) and brine solution (1 × 10 mL), then dried ($MgSO_4$), filtered, and concentrated. Purification of the residue by flash chromatography on silica gel (0–5% ethyl acetate in petroleum ether) gave a quantitative yield of keto ester **10** (0.69 g) as white crystals: mp 41–42°C; ir (neat): 1743, 1731 (ester) and 1711 (ketone) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 5.32 (br s, 1 H, -C=C*H*-), 3.70 (s, 3 H -COOCH_3), 2.60–2.45 (complex, 3 H), 2.37 (br s, 2H), 2.10 (complex d, 1 H, J = 18 Hz, -C*H*HCH=C(CH_3)-), 1.90 (complex d, 1 H, J = 18 Hz, -CH*H*CH=C(CH_3)-), 1.82 (dd, 1 H, J = 7, J' = 6 Hz), 1.72 (dd, 1H, J = 9, J' = 6 Hz), 1.68 (s, 3 H, -C(CH_3)=CH-), 1.10 (s, 3 H, -CH_3), and 1.02 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 207.3 (p), 172.9 (p), 129.8 (p), 118.4 (a), 59.6 (p), 51.6 (a), 43.4 (a), 37.5 (p), 34.9 (p), 33.0 (p), 32.6 (p), 29.8 (a), 23.6 (p), 23.5 (a), and 22.4 (p); ms M^+: 250.1578 (calcd. for $C_{15}H_{22}O_3$: 250.1569). Anal. calcd. for $C_{15}H_{22}O_3$: C 71.95, H 8.86; found: C 71.64, H 8.78.

(1R, 2R*, 6S*)-1-Carbomethoxy-5,5,9-trimethylbicyclo[4.4.0]dec-8-en-2-ol (14), (1R*, 2S*, 6S*)-1-carbomethoxy-5,5,9-trimethylbicyclo[4.4.0]dec-8-en-2-ol (15) and (1R*, 6S*)-1-hydroxymethyl-5,5,9-trimethylbicyclo[4.4.0]dec-8-en-2-ol (16)*

Sodium borohydride (0.46 g, 12.2 mmol) was slowly added during 30 min to a stirred, cooled (–40°C) solution of keto ester **10** (1.80 g, 7.2 mmol) in methanol (15 mL). The reaction mixture was left to react for 15 min, a saturated aqueous solution of ammonium chloride (1 mL) was added and the resulting mixture allowed to warm to room temperature. The mixture was extracted with dichloromethane (2 × 10 mL). The combined organic extracts were washed with water (2 × 5 mL) and brine (1 × 5 mL), dried ($MgSO_4$), filtered, and concentrated. Purification of the concentrate by flash chromatography on silica gel (0–30% ethyl acetate in petroleum ether) led to the isolation of two epimeric alcohols **14** and **15** (1.70 g, 95%) in a ratio of 5:1. The major alcohol (**14**) was obtained as a colorless oil: ir ($CHCl_3$ cast): 3470 (alcohol) and 1737 (ester) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 5.27 (br s, 1 H, -C(CH_3)=C*H*-), 3.90 (ddd, 1 H, J = 9, J' = 7, J'' = 4 Hz, -C*H*OH), 3.72 (s, 3 H, -OCH_3), 2.45 (d, 1 H, J = 16 Hz, -C*H*HC(CH_3)=), 2.12 (d, 1 H, J = 16 Hz, -CH*H*C(CH_3)=), 2.05 (m, 2 H, -CH_2CH=), 1.93 (dd, 1 H, J = 7, J' = 1.5 Hz, -C(CH_3)$_2$C*H*CH_2-), 1.88 (d, 1 H, J = 4 Hz, -O*H*), 1.73 (dd, 1 H, J = 4, J' = 2 Hz, -C*H*HCHOH), 1.70 (dd, 1 H, J = 7, J' = 4 Hz, -CH*H*CHOH), 1.68 (s, 3 H, -C(CH_3)=CH-), 1.47 (ddd, 1 H, J = 13.5, J' = 3.5, J'' = 3.5 Hz, -C*H*HC(CH_3)$_2$-), 1.40 (ddd, 1 H, J = 13.5, J' = 10, J'' = 7 Hz, -CH*H*C(CH_3)$_2$-), 0.94 (s, 3 H, -CH_3), and 0.83 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 177.6 (p), 131.8 (p), 119.7 (a), 75.4 (a), 52.4 (p), 52.2 (a), 41.9 (a), 39.3 (p), 33.1 (p), 32.8 (a), 28.5 (p), 27.2 (p), 24.4 (p), 23.5 (a), and 21.7 (a); ms M^+: 252.1729 (calcd. for $C_{15}H_{24}O_3$: 252.1726). The minor alcohol **15** was obtained as white needles: mp 42–44°C; ir ($CHCl_3$ cast): 3529 (alcohol) and 1739 (ester) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ 5.35 (br s, 1 H, -C(CH_3)=C*H*-), 3.70 (s, 3 H, -OCH_3), 3.60 (ddd, 1 H, J = 10, J' = 7, J'' = 7 Hz, -C*H*OH), 3.06 (br s, 1 H, -O*H*), 2.49 (d, 1 H, J = 17 Hz, -C*H*HC (CH_3)=CH-), 2.30–2.15 (complex, 3 H, -CH*H*C(CH_3)=CH-, -C(CH_3)$_2$C*H*CH_2- and -CH*H*CH=C(CH_3)-), 2.00 (m, 1 H, -C*H*H-CH=), 1.87 (dd, 2 H, J = 13, J' = 7 Hz, -CH_2CHOH), 1.66 (br s, 3 H, -C(CH_3)=CH-), 1.54 (ddd, 1 H, J = 14, J' = 14, J'' = 7 Hz, -CH*H*C(CH_3)$_2$-), 1.40 (ddd, 1 H, J = 14, J' = 5.5, J'' = 5 Hz, -C*H*HC(CH_3)$_2$-), 0.96 (s, 3 H, -CH_3), and 0.89 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 178.8 (p), 129.6 (p), 119.8 (a), 69.7 (a), 51.4 (a), 49.7 (p), 40.4 (a), 35.3 (p), 33.7 (p), 33.5 (p), 29.5 (a), 27.8 (p), 24.7 (p), and 23.1 (a); Further elution gave diol **16** in 3–5% yield. Recrystallization from acetone gave white needles, which started subliming at 150°C: ir (Nujol): 3290 (alcohol) cm^{-1}; ^1H nmr (400 MHz, CD_3OD) δ: 5.22 (br s, 1 H, -C(CH_3)=CH-), 4.51 (br s, 1 H, -O*H*), 3.65 (dd, 1 H, J = 12, J' = 4 Hz, -C*H*OH), 3.53 (d, 1 H, J = 10 Hz,

-C*H*HOH), 3.26 (d, 1 H, J = 10 Hz, -CH*H*OH), 3.22 (br d, 1 H, J = 1 Hz, -O*H*), 2.00–1.30 (complex, 9 H), 1.54 (s, 3 H, -C(C*H*$_3$)=CH-), 0.82 (s, 3 H, -C*H*$_3$), and 0.75 (s, 3 H, -CH$_3$); ^{13}C nmr (100.6 MHz, CD_3OD) δ: 132.5, 121.2, 121.0, 74.7, 67.4, 43.1, 40.9, 34.5, 33.4, 30.5, 27.7, 24.2, 24.0, and 22.4; ms M$^+$: 224.1774 (calcd. for $C_{14}H_{24}O_2$: 224.1777).

(1R, 2R*, 6S*)-1-Carbomethoxy-3,7,7-trimethyl-10-(methylmercaptothiocarbonyloxy)bicyclo[4.4.0]dec-3-ene (**17**), and (1R*, 6S*, 10S*)-1-carbomethoxy-3,7,7-trimethyl-10-(methylmercaptothiocarbonyloxy)bicyclo[4.4.0]dec-3-ene (**18**)*

Sodium hydride (80% dispersion in mineral oil, 0.95 g, 32 mmol) was slowly added to a cooled (0°C) solution of hydroxy ester **14** or **15** (or the mixture of both) (2.00 g, 7.94 mmol) in 1,2-dimethoxyethane (34 mL). After 20 min carbon disulfide (1.8 mL, 29.8 mmol) was introduced to the reaction vessel, followed by methyl iodide (6.2 mL, 100 mmol). The reaction mixture was then allowed to warm up to room temperature. After 10 h of stirring the solution was poured into ice-water. The aqueous layer was extracted with ether (3 × 15 mL). The combined ether extracts were washed with water (1 × 15 mL) and brine (1 × 15 mL), dried ($MgSO_4$), filtered, and concentrated. Purification of the concentrate by flash chromatography on silica gel (0–10% ether in petroleum ether) gave a quantitative yield of the xanthate **17** or **18** (or the epimeric mixture) (2.70 g). Compound **17** was isolated as a yellow oil: ir ($CHCl_3$ cast): 1737 (ester) and 1240 (xanthate) cm^{-1}; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 5.96 (dd, 1 H, J = 11.5, J' = 4.5 Hz, -C*H*OCSSCH$_3$), 5.26 (br s, 1 H, -C(CH$_3$)=C*H*-), 3.62 (s, 3 H, -OC*H*$_3$), 2.54 (d, 1 H, J = 18 Hz, -CH*H*C(CH$_3$)=CH-), 2.52 (s, 3 H, -SCH$_3$), 2.28 (d, 1 H, J = 18 Hz, -C*H*HC(CH$_3$)=CH-), 1.98–2.06 (complex, 4 H, -C(CH$_3$)$_2$C*H*CH$_2$-, -CHC*H*$_2$CH=, and -C*H*HCHO), 1.79 (dddd, 1 H, J = 12, J' = 12, J'' = 8.5, J''' = 8.5 Hz, -CH*H*CHO), 1.69 (s, 3 H, -C(C*H*$_3$)=CH-), 1.52 (dd, 2 H, J = 8.5 J' = 3.5 Hz, -C*H*$_2$C(CH$_3$)$_2$CH-), 0.96 (s, 3 H, -C*H*$_3$), and 0.87 (s, 3 H, -C*H*$_3$); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 214.9 (p), 175.5 (p), 131.9 (p), 119.3 (a), 86.8 (a), 52.5 (a), 51.1 (p), 42.6 (a), 38.9 (p), 33.1 (p), 32.6 (a), 29.8 (p), 24.1 (p), 23.6 (a), 23.4 (p), 21.9 (a), and 18.8 (a); ms M$^+$: 342.1315 (calcd. for $C_{17}H_{26}O_3S_2$: 342.1338). Compound **18** was isolated as a red oil: ir ($CHCl_3$ cast): 1738 (ester) and 1232 (xanthate) cm^{-1}; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 5.74 (dd, 1 H, J = J' = 3 Hz, -C*H*OCSSCH$_3$), 52.8 (br s, 1 H, -C(CH$_3$)=C*H*-), 3.55 (s, 3 H, -OC*H*$_3$), 2.55–2.45 (m, 1 H, -C*H*HCHO-), 2.50 (s, 3 H, -SC*H*$_3$), 2.34 (d, 1 H, J = 18 Hz, -C*H*HC(CH$_3$)=), 2.26 (d, 1 H, J = 8 Hz, -CH*H*CHO-), 2.13 (d, 1 H, J = 18 Hz, -CH*H*C(CH$_3$)=), 2.06 (br s, 1 H, -C(CH$_3$)$_2$C*H*CH$_2$-), 2.00 (ddd, 1 H, J = 15, J' = 7, J'' = 4 Hz, -CHC*H*HCH=), 1.88 (ddd, 1 H, J = 14, J' = 4, J'' = 2 Hz, -CHCH*H*CH=), 1.54 (s, 3 H, -CH$_2$C(C*H*$_3$)=CH-), 1.46 (ddd, 1 H, J = 14, J' = 13, J'' = 4 Hz, -C*H*HC(CH$_3$)$_2$-), 1.23 (ddd, 1 H, J = 14, J' = 4, J'' = 4 Hz, -CH*H*C(CH$_3$)$_2$-), 0.96 (s, 3 H, -C*H*$_3$), and 0.81 (s, 3 H, -CH$_3$); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 213.9 (p), 174.6 (p), 129.3 (p), 121.7 (a), 84.1 (a), 52.0 (a), 50.2 (p), 37.8 (a), 34.9 (p), 34.0 (p), 33.3 (p), 32.9 (a), 24.3 (p), 23.5 (a), 22.2 (p), 21.5 (a), and 18.4 (a).

(1R, 6S*)-1-Carbomethoxy-3,7,7-trimethylbicyclo[4.4.0]dec-3-ene (**12**)*

Argon was bubbled for 30 min through a solution of xanthate **17** or **18** (or the mixture) (2.60 g, 7.7 mmol) in dry toluene (100 mL), then tri-*n*-butyltin hydride (3.10 mL, 11.5 mmol) was added followed by a catalytic amount of azobisisobutyronitrile (54 mg, 0.33 mmol). The solution was refluxed for 10 h, cooled down, and concentrated under reduced pressure. Purification of the residue by flash chromatography on silica gel (0–5% ether in petroleum ether) gave ester **12** (1.73 g, 95% yield) as a colorless oil: ir (neat): 1730 (ester) cm^{-1}; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 5.30 (br s, 1 H, -C(CH$_3$)=C*H*-), 3.68 (s, 3 H, -OC*H*$_3$), 2.32 (d, 1 H, J = 18 Hz), 2.20–2.00 (complex, 3 H), 1.64 (s, 3 H, -CH$_2$C(C*H*$_3$)=), 1.60–1.50 (complex, 4 H), 1.45 (m, 1 H), 1.36 (dddd, 1 H, J = 15, J' = 15, J'' = 7, J''' = 2 Hz), 1.24 (m, 1 H), 0.96 (s, 3 H, -C*H*$_3$), and 0.88 (s, 3 H, -C*H*$_3$); ^{13}C nmr APT (100.6 MHz, $CDCl_3$) δ: 178.8 (p), 131.2 (p), 119.8 (a), 51.6 (a), 46.2 (p), 41.3 (a), 39.2 (p), 36.4 (p), 33.5 (p), 31.7 (a), 24.7 (p), 24.1 (a), 23.3 (a), and 18.9 (p); ms M$^+$: 236.1780 (calcd. for $C_{15}H_{24}O_2$: 236.1776).

(1R, 6S*)-1-Hydroxymethyl-3,7,7-trimethylbicyclo[4.4.0]dec-3-ene (**20**)*

Lithium aluminum hydride (0.20 g, 5.27 mmol) was slowly added to a cooled (ice-water) ether solution (8 mL) of ester **12** (0.24 g, 1.03 mmol). The solution was stirred for 3 h at room temperature before it was poured into a saturated aqueous ammonium chloride solution (5 mL). The organic layer was separated and the aqueous layer extracted with dichloromethane (3 × 5 mL). The combined organic extracts were washed with water (2 × 5 mL) and brine (2 × 5 mL), dried ($MgSO_4$), filtered, and concentrated. Purification of the concentrate by flash column chromatography (0–15% ether in petroleum ether) gave alcohol **20** (0.21 g, 96%) as a crystalline solid: mp 67–68°C; ir ($CHCl_3$ cast) 3280 cm^{-1} (alcohol); ^{1}H nmr (400 MHz, $CDCl_3$) δ: 5.29 (ddd, 1 H, J = 7, J' = 3, J'' = 1.5 Hz, -C(CH$_3$)=C*H*-), 3.39 (d, 1 H, J = 10 Hz, -C*H*HOH), 3.27 (d, 1 H, J = 10 Hz, -CH*H*OH), 2.16–2.00 (complex, 3 H), 1.62 (s, 3 H, -C(C*H*$_3$)=CH-), 1.50–1.10 (complex, 9 H), 0.94 (s, 3 H, -C*H*$_3$), and 0.84 (s, 3 H, -C*H*$_3$); ^{13}C nmr APT (100.6 MHz, $CDCl_3$) δ: 131.6 (p), 119.7 (a), 71.4 (p), 42.4 (p), 41.2 (a), 37.4 (p), 34.4 (p), 34.3 (p), 33.7 (p), 33.3 (a), 23.6 (a), 23.5 (p), 21.8 (a), and 18.3 (p); ms M$^+$: 208.1833 (calcd. for $C_{14}H_{24}O$: 208.1827). Anal. calcd. for $C_{14}H_{24}O$: C 80.70, H 11.62; found: C 80.87, H 11.65.

(1R, 6S*)-1-Formyl-3,7,7-trimethylbicyclo[4.4.0]dec-3-ene (**19**)*

Pyridinium chlorochromate impregnated on alumina (1.19 g, 0.93 mmol/g) was added to a solution of alcohol **20** (114 mg, 0.55 mmol) in dry dichloromethane (7 mL). The reaction mixture was stirred at room temperature for 2 h, and filtered through Florisil using a sintered-glass filter. The reaction mixture was washed with dichloromethane (10 mL). Concentration of the dichloromethane solution, using a rotary evaporator under slightly reduced pressure (the compound is rather volatile), afforded a colorless oil, which was pure as demonstrated by nmr analysis (99 mg, 88%); ir (neat): 2840, 2700 and 1724 (aldehyde) cm^{-1}; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 9.32 (s, 1 H, -C*H*O), 5.32 (br s, 1 H, -C(CH$_3$)=C*H*-), 2.10–1.90 (complex, 4H), 1.67 (s, 3 H, -C(C*H*$_3$)=CH-), 1.70–1.44 (complex, 5 H), 1.35 (m, 1 H), 1.24 (m, 1 H), 0.96 (s, 3 H, -C*H*$_3$), and 0.86 (s, 3 H, -C*H*$_3$); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 205.6 (a), 130.7 (p), 120.5 (a), 49.1 (p), 40.6 (a), 39.4 (p), 33.3 (p), 31.7 (a), 29.8 (p), 24.2 (a), 23.9 (a), 23.5 (p), and 18.2 (p); ms M$^+$: 206.1673 (calcd. for $C_{14}H_{22}O$: 206.1670). Anal. calcd. for $C_{14}H_{22}O$: C 81.48, H 10.75; found: C 81.62, H 10.70.

(1R, 6S*)-1-(2-Methoxyethenyl)-3,7,7-trimethylbicyclo[4.4.0]dec-3-ene (**21**)*

Potassium hydride (35% oil dispersion, 0.105 g, 1.04 mmol) was washed with ether (3 × 1 mL), and the washings were discarded. The dry potassium hydride was covered with benzene (1 mL), then dimethyl sulfoxide (0.55 mL) was added at room temperature. After all of the solid had dissolved, a solution of (methoxymethyl)triphenylphosphonium chloride (374 mg, 1.09 mmol) in benzene (0.5 mL) was added and the resulting mixture allowed to react until a deep red-burgundy color solution developed (about 30 min). Aldehyde **19** (41 mg, 0.2 mmol) in benzene (0.5 mL) was added slowly and the reaction mixture was stirred for 10 h. The reaction mixture was poured into ice-water and extracted with ether (4 × 2 mL). The organic extracts were combined, washed with water (1 × 2 mL) and brine (1 × 2 mL), dried ($MgSO_4$), filtered, and concentrated to yield a colorless oil. Purification of the oil by bulb-to-bulb distillation (100°C/1 Torr) gave 45.5 mg (98%) of a 1:1 mixture of enol ethers **21**; ir (neat): 1651 (olefin) and 1205 (ether) cm^{-1}; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 6.18, 5.63 (d, 1 H, J = 13 Hz; d, 1 H, J = 7.5 Hz, -CH=C*H*OCH$_3$), 5.32 (br s, 2 H, -C(CH$_3$)=C*H*-), 4.77, 4.17 (d, 1 H, J = 13 Hz; d, 1 H, J = 7.5 Hz, -CH=C*H*OCH$_3$), 3.52, 3.48 (both s, 3 H each, -CH=CHOC*H*$_3$), 2.32–2.12 (complex, 4 H), 2.05 (br d, 2 H, J = 18 Hz), 1.85 (br d, 1 H, J = 16.5 Hz), 1.61 (br s, 6 H, -C(C*H*$_3$)=CH-), 1.70–1.05 (complex, 15 H), 0.92, 0.90, 0.83, and 0.81 (all s, 3 H each, 4 × -C*H*$_3$); ^{13}C nmr (100.6 MHz, $CDCl_3$) δ: 145.1, 144.6, 132.4, 131.3, 120.7 120.2, 118.6, 116.0, 59.6, 55.9, 47.0, 44.7, 42.2, 41.6, 39.2, 38.1, 37.8, 36.9, 36.6, 36.2, 34.0, 33.9, 33.6, 24.4, 24.2, 23.9, 23.6, 22.5, 22.3, 19.2, and 18.8; ms M$^+$: 234.1984 (calcd. for $C_{16}H_{26}O$: 234.1984).

*B. From xanthate **34***

Tri-*n*-butyltin hydride (75 mg, 0.25 mmol) and a catalytic amount of azoisobutyronitrile (~10 mg) were added to a solution of xanthate **34** (56 mg, 0.17 mmol) in toluene. Argon was bubbled through the solution for 20 min, then the reaction mixture was refluxed for 10h. Concentration of the solution in vacuo and purification of the product by flash chromatography on silica gel (0–15% ether in petroleum ether) gave lactone **22** (27 mg, 71%).

(1R, 3R*, 6S*)-1-Hydroxymethyl-3,7,7-trimethylbicyclo[4.4.0]-decan-3-ol (**23**)*

A solution of lactone **22** (1.84 g, 8.3 mmol) in ether (60 mL) was cooled in an ice-water bath. After 10 min, lithium aluminum hydride (1.55 g, 40.8 mmol) was carefully added and the resulting mixture allowed to warm to room temperature. After 1 h the reaction mixture was cooled with an ice-water bath. After an addition 1 h, water (10 mL) was slowly added, followed by aqueous 10% sodium hydroxide (10 mL) and then water again (10 mL). The resulting mixture was filtered. The water layer was extracted with ethyl acetate (3 × 15 mL). The organic layers were combined, washed with water (2 × 5 mL) and brine (1 × 5 mL), dried ($MgSO_4$), filtered, and concentrated. Crystallization of the concentrate from petroleum ether gave diol **23** (1.82 g, 97%) as a crystalline solid: ir ($CHCl_3$ cast): 3349 (alcohol) cm^{-1}; ^{1}H nmr (300 MHz, $CDCl_3$) δ: 3.98 (d, 1 H, J = 11 Hz, -C*H*HOH), 3.14 (d, 1 H, J = 11 Hz, -CH*H*OH), 1.97 (m, 2 H, -CH_2C(CH_3)OH), 1.80–1.30 (complex, 10 H), 1.23 (s, 3 H, -C(CH_3)OH), 1.20–1.10 (br d, 1 H, J = 6 Hz), 0.98 (s, 3 H, -CH_3), and 0.95 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 74.1 (p), 70.6 (p), 43.0 (p), 42.6 (a), 40.5 (p), 38.7 (p), 37.9 (p), 36.2 (p), 34.3 (p), 33.4 (a), 33.2 (a), 26.8 (a), 19.3 (p), and 18.2 (p); ms M$^+$: 226.1924 (calcd. for $C_{14}H_{26}O_2$: 226.1933). Anal. calcd. for $C_{14}H_{26}O_2$: C 74.27, H 11.58; found: C 73.87, H 11.43.

(1R, 3R*, 6S*)-1-Acetoxymethyl-3,7,7-trimethylbicyclo[4.4.0]-decan-3-ol (**24**)*

Diol **23** (1.80 g, 8.05 mmol) was dissolved in pyridine (10 mL) at room temperature. Acetic anhydride (7.6 mL, 80.5 mmol) was added and the reaction mixture stirred overnight. Methanol (4 mL) was added and the resulting mixture was stirred for an additional 3 h before water (10 mL) was added. The mixture was extracted with ether (3 × 10 mL). The organic extracts were combined and washed successively with aqueous 5% HCl solution (2 × 10 mL), water (2 × 10 mL), and brine (1 × 5 mL), dried ($MgSO_4$), filtered, and concentrated. The oily residue was purified by flash chromatography on silica gel (0–10% ethyl acetate in petroleum ether) to afford hydroxy acetate **24** as a colorless oil (1.95 g, 90%): ir ($CHCl_3$ cast): 3480 (alcohol), 1737 and 1720 (acetate) cm^{-1}; ^{1}H nmr (300 MHz, $CDCl_3$) δ: 4.31 (d, 1 H, J = 11 Hz, -C*H*HOAc), 4.14 (d, 1H, J = 11 Hz, -CH*H*OAc), 2.07 (s, 3 H, -COCH_3), 2.00–1.80 (m, 1H), 1.73 (dd, 1 H, J = 14, J' = 4 Hz), 1.67 (dd, 1 H, J = 6, J' = 4 Hz), 1.50–1.28 (complex, 7 H), 1.22 (s, 3 H, -C(CH_3)OH), 1.27 –1.10 (complex, 3 H), 0.98 (s, 3 H, -CH_3), and 0.97 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 171.4 (p), 73.1 (p), 70.2 (p), 42.5 (p), 42.3 (a), 42.1 (p), 37.1 (p), 36.3 (p), 35.9 (p), 34.3 (p), 33.2 (a), 33.1 (a), 27.3 (a), 21.2 (a), 19.4 (p), and 18.1 (p); ms M$^+$: 268.2033 (calcd. for $C_{16}H_{28}O_3$: 268.2039).

(1R, 6R*)-1-Acetoxymethyl-3,7,7-trimethylbicyclo[4.4.0]dec-2-ene (**25**) and (1R*, 6S*)-1-acetoxymethyl-3,7,7-trimethylbicyclo-[4.4.0]dec-3-ene (**26**)*

Hydroxy acetate **24** (1.39 g, 5.18 mmol) and 4-dimethylaminopyridine (3.16 g, 25.9 mmol) were dissolved in a solution of dry pyridine (55 mL). After cooling the solution to –40°C, phosphorus oxychloride (4.80 mL, 51.8 mmol) was added and the mixture allowed to react at –40°C for 12 h. The reaction was quenched with water (5 mL). The resulting solution was allowed to warm to room temperature and extracted with dichloromethane (3 × 15 mL). The extracts were combined, washed successively with aqueous 5% HCl solution (3 × 20 mL), water (2 × 10 mL), and brine (1 × 10 mL), dried ($MgSO_4$), filtered, and concentrated. A colorless oil, which did not require further purification, was obtained (1.25 g, 97%). It consisted of separable acetate **25** and **26** in a ratio of 3:1 (ratio obtained by ^{1}H nmr area integration); ir ($CHCl_3$ cast): 1742 and 1735 (acetate) cm^{-1}; ^{1}H nmr (300 MHz, $CDCl_3$), major isomer **25**: δ: 5.05 (br s, 1 H, -C*H*=C(CH_3)-), 3.96 (d, 1 H, J = 10.5 Hz, -C*H*HOAc), 3.75 (d, 1 H, J = 10.5 Hz, -CH*H*OAc), 2.22 (br s, 1 H, -C*H*HC(CH_3)=), 2.16 (br s, 1 H, -CH*H*C(CH_3)=), 2.05 (s, 3 H, -COCH_3), 1.62 (d, 3 H, J = 1 Hz, -C(CH_3)=CH-), 1.50–1.00 (complex, 9 H), 0.96 (s, 3 H, -CH_3), and 0.92 (s, 3 H, -CH_3); minor isomer **26**: δ: 5.28 (br s, 1 H, -C(CH_3)=C*H*-), 3.87 (d, 1 H, J = 10.5 Hz, -C*H*HOAc), 3.78 (d, 1 H, J = 10.5 Hz, -CH*H*OAc), 2.24 (br s, 1 H, -C*H*HC(CH_3)=), 2.18 (s, 1 H, -CH*H*C(CH_3)=), 2.08 (s, 3 H, -COCH_3), 1.60 (d, 3 H, J = 1 Hz, -CH=C(CH_3)-), 0.92 (s, 3 H, -CH_3), and 0.83 (s, 3 H, -CH_3), other peaks were overlapped with those of the major isomer; ^{13}C nmr APT (75.5 MHz, $CDCl_3$), major isomer **25**; δ: 171.3 (p), 137.0 (p), 120.5 (a), 71.4 (p), 41.6 (p), 41.5 (a), 35.4 (p), 34.7 (p), 34.3 (p), 33.9 (p), 32.6 (a), 23.5 (a), 23.4 (p), 21.7 (a), 21.0 (a), and 18.2 (p); minor isomer **26**: δ: 171.4 (p), 131.2 (p), 119.9 (a), 72.2 (p), 42.2 (p), 36.1 (p), 33.8 (p), 33.4 (a), 23.6 (a), and 18.2 (p), other peaks were overlapped with those of the major isomer; ms M$^+$: 250.1930 (calcd. for $C_{16}H_{26}O_2$: 250.1933).

(1R, 6S*)-1-Hydroxymethyl-3,7,7-trimethylbicyclo[4.4.0]dec-2-ene (**28**) and (1R*, 6S*)-1-hydroxymethyl-3,7,7-trimethylbicyclo-[4.4.0]dec-3-ene (**20**)*

The mixture of acetates **25** and **26** (1.43 g, 5.7 mmol) was dissolved in methanol (15 mL) at room temperature and a saturated aqueous solution of potassium carbonate (15 mL) was added. The mixture was refluxed for 2.5 h and then cooled. Methanol was removed under reduced pressure and the remaining aqueous solution was extracted with ethyl acetate (3 × 10 mL). The combined extracts were washed with water (2 × 10 mL) and brine (1 × 5 mL), dried ($MgSO_4$), filtered, and concentrated. Purification of the concentrate by flash chromatography on silica gel (0–3% ether and 1% of 2-propanol in petroleum ether) gave alcohol **20** (270 mg, 22%) as a crystalline solid. Further elution gave alcohol **28** (835 mg, 70%) as a colorless oil; ir ($CHCl_3$ cast): 3256 (alcohol) cm^{-1}; ^{1}H nmr (300 MHz, $CDCl_3$) δ: 5.01 (br s, 1 H, -C*H*=C(CH_3)-), 3.43 (d, 1 H, J = 11 Hz, -C*H*HOH), 3.27 (d, 1 H, J = 11 Hz, -CH*H*OH), 1.94 (complex, 3 H), 1.80–1.70 (m, 1 H), 1.75 (s, 3 H, -CH=C(CH_3)-), 1.55–1.10 (complex, 8 H), 1.00 (s, 3 H, -CH_3), and 0.91 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 137.6 (p), 128.3 (a), 71.5 (p), 41.8 (a), 40.9 (p), 40.7 (p), 35.0 (p), 33.7 (p), 32.2 (a), 29.0 (p), 25.7 (a), 23.6 (a), 19.8 (p), and 19.2 (p); ms M$^+$: 208.1827 (calcd. for $C_{14}H_{24}O$: 208.1828).

(1S, 4S*, 8R*, 9R*)-9-carbomethoxy-1,5,5-trimethyl-11-oxatricyclo[6,2,1,$0^{4,9}$]undecane (**31**), and (1S*, 3S*, 7R*, 8R*)-8-carbomethoxy-1,4,4-trimethyl-11-oxatricyclo[5.3.1.$0^{3,8}$]-undecane (**32**)*

A mixture of isomeric keto esters **7** and **8** (1:1.75) (0.45 g, 1.8 mmol) was dissolved in CCl_4 (2 mL). Triethylsilane (0.86 mL, 5.42 mmol) and trifluoroacetic acid (1.39 mL, 18 mmol) were added, and the reaction mixture was refluxed for 9 h. The solution was cooled to room temperature, washed with water (3 × 2 mL) and brine (1 × 2 mL), dried ($MgSO_4$), filtered, and concentrated. Purification of the concentrate by flash chromatography on silica gel (0–5% ether petroleum ether) gave, in the following order, compounds **31** (85 mg, 29%), **32** (106 mg, 36%), **29** (100 mg, 65%), and **30** (84 mg, 30%). Yields are calculated from the original nmr ratio of the respective keto esters. Spectroscopic data obtained for these compounds are as follows. Compound **31**, a colorless oil: ir (neat): 1730 (ester) and 1250 (-C-O-) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 4.43 (dd, 1 H, $J = J' = 2$ Hz, -C*H*O-), 3.66 (s, 3 H, -COOCH_3), 2.24 (dd, 1 H, $J = 2$, $J' = 1$ Hz), 1.90–1.40 (complex, 10 H), 1.30 (s, 3 H, -OCCH_3), 0.90 (s, 3 H, -CH_3), and 0.82 (s, 3 H, -CH_3); ^{13}C nmr APT (75 MHz, $CDCl_3$) δ: 176.1 (p), 78.5 (p), 76.7 (a), 51.8 (a), 51.7 (p), 48.4 (p), 41.8 (a), 37.9 (p), 34.1 (p), 29.8 (a), 27.9 (p), 26.7 (a), 26.2 (a), 23.6 (p), and 20.2 (p); ms M^+: 252.1725 (calcd. for $C_{15}H_{24}O_3$: 252.1726). Compound **32**, a colorless oil: ir (neat): 1729 (ester) and 1250 (ether) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 4.42 (br s, 1 H, -C*H*O-), 3.68 (s, 3 H, -OCH_3), 2.28 (dd, 1 H, $J = 9$, $J' = 7$ Hz), 2.00–1.50 (complex, 9 H), 1.29 (s, 3 H, -C(CH_3)O-), 0.95 (dd, 1 H, $J = 14$, $J' = 5$ Hz), 0.89 (s, 3 H, -CH_3), and 0.82 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 176.0 (p), 74.8 (p), 76.6 (a), 51.8 (p), 51.6 (a), 48.3 (p), 41.8 (a), 37.9 (p), 34.0 (p), 29.8 (a), 27.8 (p), 26.6 (a), 26.1 (a), 23.5 (p), and 20.1 (a); ms M^+: 252.1727 (calcd. for $C_{15}H_{24}O_3$: 252.1726). (1R, 4S*, 9R*)-8-Hydroxy-1,5,5-trimethyl-11-oxatricyclo[7.2.1.^{4,9}]-dodecan-10-one (**33**)*

Trifluoroacetate ester **29** (500 mg, 1.5 mmol) was dissolved in methanol (5 mL). Sodium methoxide (122 mg, 2.25 mmol) was added and the mixture stirred at room temperature overnight. After quenching the reaction with water, the solution was extracted with ethyl acetate (3 × 3 mL). The extracts were combined and washed successively with aqueous 5% HCl (1 × 3 mL), water (1 × 3 mL), and brine (1 × 2 mL). The organic solution was dried ($MgSO_4$), filtered, and concentrated. Upon crystallization from ether, white crystals of **33** (350 mg, 98%) were obtained: mp 120°C (it starts subliming at ~105°C); ir ($CHCl_3$ cast): 3470 (-OH), 1773 and 1757 (lactone) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 3.79 (dd, 1 H, $J = 11$, $J' = 4$ Hz, -C*H*OH), 2.96 (br s, 1 H, -O*H*), 2.11 (d, 1 H, $J = 11$ Hz, -CC*H*HC(CH$_3$)O-), 1.92 (d, 1 H, $J = 11$ Hz, -CCH*H*C(CH$_3$)O-), 1.80–1.10 (complex, 9 H), 1.37 (s, 3 H, -C(CH_3)O-), 0.90 (s, 3 H, -CH_3), and 0.82 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 180.1 (p), 83.2 (p), 70.2 (a), 55.9 (p), 42.6 (a), 38.8 (p), 35.6 (p), 34.1 (p), 33.8 (p), 32.6 (a), 27.8 (p), 25.2 (a), 22.8 (a), and 19.7 (p); ms M^+: 238.1571 (calcd. for $C_{14}H_{22}O_3$: 238.1563). Anal. calcd. for $C_{14}H_{22}O_3$: C 70.54, H 9.31; found: C 70.64, H 9.48.

(1R, 4S*, 9R*)-8-(Methylmercaptothiocarbonyloxy)-1,5,5-trimethyl-11-oxatricyclo[7.2.1.$0^{4,9}$]dodecan-10-one (**34**)*

Hydroxy lactone **33** (205 mg, 0.8 mmol) was dissolved in 1,2-dimethoxyethane under an argon atmosphere. Sodium hydride (130 mg of an 80% dispersion in mineral oil, 4.3 mmol) was added slowly with stirring. After 20 min, carbon disulfide (0.52 mL, 8.6 mmol) and methyl iodide (0.27 mL, 4.3 mmol) were added. The solution was stirred for 10 h, then the reaction mixture was poured into ice-water. The aqueous layer was extracted with ether (3 × 3 mL). The organic layers were combined, washed successively with aqueous 10% NaOH (1 × 2 mL), bleach (2 × 2 mL), water (1 × 2 mL), and brine (1 × 2 mL), dried ($MgSO_4$), filtered, and concentrated to give **34** (173 mg, 61%) as a colorless oil. After crystallization from ethyl acetate – petroleum ether, white crystals were obtained: mp 180–181°C; ir ($CHCl_3$ cast): 1775 (lactone), 1224 and 1062 (xanthate) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 5.77 (dd, 1 H, $J = 9$, $J' = 4$ Hz, -C*H*OCSSCH$_3$), 2.52 (s, 3 H, -SCH_3), 2.32–2.10 (complex, 3 H), 1.90–1.70 (complex, 3 H), 1.70–1.30 (complex, 5 H), 1.50 (s, 3 H, -C(CH_3)O-), 1.06 (s, 3 H, -CH_3), and 0.97 (s, 3 H, -CH_3); ^{13}C nmr (75.5 MHz, $CDCl_3$) δ: 214.5, 177.6, 82.9, 81.3, 53.9, 42.9, 38.1, 37.7, 34.3, 33.6, 32.3, 25.3, 24.1, 22.7, 19.6, and 19.0; ms M^+: 328.1169 (calcd. for $C_{16}H_{24}O_3S_2$: 328.1159). Anal. calcd. for $C_{16}H_{24}O_3S_2$: C 58.51, H 7.37; found: C 58.38, H 7.47.

(1R, 4S*, 9R*)-1,5,5-Trimethyl-11-oxatricyclo[7.2.1.$0^{4,9}$]dodecan-10-one (**22**) and (1R*, 3S*, 8R*)-1,4,4-trimethyl-10-oxatricyclo-[6.2.2.$0^{3,8}$]dodecan-9-one (**35**)*

A mixture of isomeric keto esters **12** and **36** (1:1, 27 mg, 0.96 mmol) was dissolved in benzene. *p*-Toluenesulfonic acid monohydrate (500 mg, 2.6 mmol) was added and the reaction flask connected to a Dean–Stark apparatus for water removal. The solution was refluxed for 3 h and then cooled down to room temperature. The organic layer was washed successively with water (2 × 2 mL), saturated aqueous sodium bicarbonate solution (2 × 3 mL), water (1 × 2 mL), and brine (1 × 2 mL), dried ($MgSO_4$), filtered, and concentrated. Purification of the concentrate by flash chromatography on silica gel (0–15% ether in petroleum ether) gave white crystals of lactone **22** (87 mg, 41%) identical with an authentic sample obtained previously from pure ester **12**. Further elution gave lactone **35** (89 mg, 42%) as a colorless oil: ir ($CHCl_3$ cast): 1734 (lactone) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ 2.38 (ddd, 1 H, $J = 14$, $J' = 12.5$, $J'' = 4$ Hz), 1.95–1.30 (complex, 11 H), 1.42 (s, 3 H, -C(CH_3)O-), 1.16 (ddd, 1 H, $J = 13$, $J' = J'' = 5$ Hz), 1.04 (s, 3 H, -CH_3), and 0.86 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 178.9 (p), 80.5 (p), 43.5 (a), 40.6 (p), 40.5 (p), 34.2 (p), 33.9 (p), 32.5 (a), 32.1 (p), 30.6 (p), 25.6 (a), 24.5 (p), 20.7 (a), and 17.9 (p); ms M^+: 222.1616 (calcd. for $C_{14}H_{22}O_2$: 222.1619).

(1R, 6S*)-1-Formyl-3,7,7-trimethylbicyclo[4.4.0]dec-2-ene (**37**)*

Pyridinium chlorochromate impregnated on alumina (0.9 mmol/g, 14.10 g, 12.7 mmol) was added to a solution of alcohol **28** (530 mg, 2.55 mmol) in dry dichloromethane (30 mL). The suspension was stirred at room temperature for 5 h. The mixture was filtered, concentrated, and the residue was purified by flash chromatography on Florisil (eluting with dichloromethane) to afford aldehyde **37** as a colorless oil (495 mg, 94%): ir ($CHCl_3$ cast): 2795, 2740 and 1719 (CHO) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 9.27 (d, 1 H, $J = 2$ Hz, -C*H*O), 4.65 (br s, 1 H, -C*H*=C(CH$_3$)-), 2.15–1.95 (complex, 3 H), 1.86 (ddt, 1 H, $J = 12$, $J' = 5$, $J'' = 2$ Hz), 1.68 (s, 3 H, -CH=C(CH_3)-), 1.60–1.00 (complex, 7 H), 0.95 (s, 3 H, -CH_3), and 0.86 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 204.4 (a), 139.5 (p), 121.9 (a), 53.7 (p), 44.6 (a), 34.6 (p), 33.4 (p), 31.3 (p), 30.2 (a), 28.2 (a), 27.8 (p), 23.7 (a), 20.0 (p), and 19.0 (p); ms M^+: 206.1665 (calcd. for $C_{14}H_{22}O$: 206.1670).

(1R, 6S*)-1-((Z)-2-Methoxyethenyl)-3,7,7-trimethylbicyclo[4.4.0]-dec-2-ene (**38**) and (1R*, 6S*)-1-((E)-2-methoxyethenyl)-3,7,7-trimethylbicyclo[4.4.0]dec-2-ene (**39**)*

Potassium hydride (35% dispersion in oil, 1.00 g, 8.78 mmol) was washed with ether (3 × 5 mL) under an argon atmosphere and then suspended in benzene (40 mL) at room temperature. Dimethyl sulfoxide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

(10 mL) was slowly added. When all the potassium hydride had reacted and the evolution of hydrogen had ceased, (methoxymethyl)triphenylphosphonium chloride (3.50 g, 10.2 mmol) was added. After 2 h of stirring, the solution developed a deep red–burgundy color. At this point aldehyde **37** (424 mg, 2.06 mmol) in a small amount of benzene was added. The reaction mixture was stirred for an additional 2 h and then quenched with water (10 mL). The aqueous layer was extracted with ether (3 × 10 mL). The combined organic layers were washed with water (1 × 5 mL) and brine (1 × 5 mL), dried ($MgSO_4$), filtered, and concentrated. Bulb-to-bulb distillation (70°C/2.5 Torr) of the concentrate gave a colorless oil (452 mg, 93%) consisting of a 1:1 mixture of enol ethers **38** and **39** as determined by nmr analysis. Purification by flash chromatography on silica gel (1% triethylamine in petroleum ether) afforded *cis*-enol ether **38** as a colorless oil (205 mg): ir ($CHCl_3$ cast): 1654 (C=C) and 1109 (C-OCH_3) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 5.64 (d, 1 H, J = 7 Hz, =C*H*OCH_3), 5.12 (br s, 1 H, -C*H*=$C(CH_3)$-), 4.27 (d, 1 H, J = 7 Hz, -C*H*=$CHOCH_3$), 3.52 (s, 3 H, -OCH_3), 2.10–1.80 (complex, 3 H), 1.75 (ddd, 1 H, J = 13, J' = 6, J'' = 3 Hz), 1.62 (s, 3 H, -CH=$C(CH_3)$-), 1.56–1.20 (complex, 7 H), 1.11 (s, 3 H, -CH_3), and 0.89 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 143.9 (a), 131.6 (a), 129.9 (p), 118.2 (a), 59.6 (a), 48.3 (a), 40.7 (p), 36.5 (p), 34.0 (p), 33.5 (p), 31.0 (p), 30.9 (a), 30.8 (a), 23.4 (a), 21.3 (p), and 19.8 (p); ms M^+: 234.1989 (calcd. for $C_{16}H_{26}O$: 234.1984). Continued elution gave *trans*-enol ether **39** as a colorless oil (195 mg): ir ($CHCl_3$ cast): 1644 (C=C) and 1209 (C-OCH_3) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 6,11 (d, 1 H, J = 13 Hz, -CH=C*H*OCH_3), 4.92 (br d, 1 H, J = 1.5 Hz, -C*H*=$C(CH_3)$-), 4.71 (d, 1 H, J = 13 Hz, -C*H*=$CHOCH_3$), 3.48 (s, 3 H, -OCH_3), 1.90–1.78 (m, 1 H), 1.62 (s, 3 H, -CH=$C(CH_3)$-), 1.60–1.05 (complex, 8 H), 1.02 (s, 3 H, -CH_3), and 0.89 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 146.1 (a), 132.7 (p), 131.4 (a) 116.3 (a), 56.0 (a), 49.3 (a), 38.9 (p), 36.4 (p), 34.0 (p), 31.9 (a), 29.9 (p), 28.2 (a), 23.4 (a), 20.5 (p), and 19.3 (p); ms M^+: 234.1985 (calcd. for $C_{16}H_{26}O$: 234.1984).

(1R, 6S*)-1-(2-Oxoethyl)-3,7,7-trimethylbicyclo[4.4.0]dec-2-ene ((±)-isoacanthodoral) (3)*

A column containing silica gel was eluted with a petroleum ether solution containing 1% acetic acid and 1% water. A mixture of enol ethers **38** and **39** (25 mg, 0.107 mmol) was placed in the column and eluted slightly. The column was allowed to stand for 24 h. Elution with 0–5% ether in petroleum ether afforded (±)-isoacanthodoral (**3**) (23 mg, 97%) as a colorless fragrant oil: ir ($CHCl_3$ cast): 2845, 2720, and 1720 (CHO) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 9.73 (dd, 1 H, J = J' = 3 Hz, -C*H*O), 5.23 (d, 1 H, J = 1 Hz, -C*H*=$C(CH_3)$-), 2.71 (dd, 1 H, J = 15, J' = 3 Hz, -C*H*HCHO), 2.13 (dd, 1 H, J = 15, J' = 3 Hz, -CH*H*CHO), 2.00–1.70 (complex, 4 H), 1.65 (s, 3 H, -CH=$C(CH_3)$-), 1.50–1.11 (complex, 7 H), 1.00 (s, 3 H, -CH_3), and 0.91 (s, 3 H, -CH_3); ^{13}C nmr DEPT (75.5 MHz, $CDCl_3$) δ: 204.8 (d), 135.5 (s), 129.9 (d), 57.2 (t), 46.3 (d), 40.1 (t), 38.5 (t), 38.2 (s), 34.2 (s), 32.4 (q), 28.9 (t), 26.4 (q), 23.5 (q), 19.9 (t), and 19.2 (t); ms M^+: 220.1821 (calcd. for $C_{15}H_{24}O$: 220.1827).

(1R, 6S*)-1-(2-Oxoethyl)-3,7,7-trimethylbicyclo[4.4.0]dec-2-ene 2,4-dinitrophenylhydrazone (40)*

Aldehyde **3** (20 mg, 0.09 mmol) was dissolved in ethanol (0.5 mL). A 3% solution of 2,4-dinitrophenylhydrazine (1 mL, 0.15 mmol) in water, ethanol, and H_2SO_4 (2:7:2) was added and the resulting mixture was stirred for 3 h. After addition of H_2O (2 mL), the reaction mixture was extracted with dichloromethane (3 × 3 mL). The organic extracts were washed with H_2O (2 × 1 mL) and brine (1 × 1 mL), dried ($MgSO_4$), filtered, and concentrated under reduced pressure. The orange residue was redissolved in dichloromethane, and petroleum ether added to precipitate a red solid. The precipitate was filtered off and the filtrate passed through Florisil with petroleum ether elution. The solution was concentrated to give an oil, which was purified by flash chromatography on silica gel (0–5% ether in petroleum ether). Recrystallization from ether – petroleum ether gives 2,4-DNP derivative **40** (28.8 mg, 80%) as orange needles. The following physical properties of this compound were found to be identical with those reported for the 2,4-DNP derivative of the naturally occurring isoacanthodoral: mp 144–146°C; ir ($CHCl_3$ cast): 3302 (NH), 1618 (C=N), and 1516 (NO_2) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 11.02 (br, s, 1 H, -CH=N-N*H*-), 9.12 (d, 1 H, J = 2.5 Hz), 8.29 (ddd, 1 H, J = 9.5, J' = 2.5, J'' = 1 Hz), 7.93 (d, 1 H, J = 9.5 Hz), 7.46 (dd, 1 H, J = J' = 6 Hz), 5.14 (br, s, 1 H, -CH=$C(CH_3)$-), 2.79 (dd, 1 H, J = 14, J' = 6 Hz), 2.24 (dd, 1 H, J = 14, J' = 6 Hz), 1.95 (m, 3 H), 1.75 (m, 1 H), 1.67 (s, 3 H), 1.60–1.10 (complex, 7 H), 1.04 (s, 3 H, -CH_3), and 0.91 (s, 3 H, -CH_3); ^{13}C nmr APT (75.5 MHz, $CDCl_3$) δ: 152.1 (a), 145.2 (p), 137.8 (p), 135.5 (p), 130.3 (a), 130.0 (a), 128.8 (p), 123.6 (a), 116.6 (a), 46.5 (p), 45.8 (a), 40.2 (p), 38.9 (p), 38.2 (p), 34.3 (p), 32.3 (a), 28.9 (p), 26.5 (a), 23.5 (a), 19.9 (p), and 19.2 (p); ms M^+: 400.2116 (calcd. for $C_{21}H_{28}N_4O_4$: 400.2110). Anal. calcd. for $C_{21}H_{28}N_4O_4$: C 62.79, H 7.05, N 14.00; found: C 62.38, H 7.05, N 13.65.

X-ray structures of triphenylphosphine and 1,2,5-triphenylphosphole products with dimethyl acetylenedicarboxylate tetramer[1]

MARTIN B. HOCKING[2] AND FRANCES W. VAN DER VOORT MAARSCHALK
Department of Chemistry, University of Victoria, Victoria, BC V8W 3P6, Canada

Received March 21, 1994

MARTIN B. HOCKING and FRANCES W. VAN DER VOORT MAARSCHALK. Can. J. Chem. **72**, 2428 (1994).

A tetramer of dimethyl acetylenedicarboxylate, tetramethyl 4-methoxy-5-[1,2,3-tris(methoxycarbonyl)-2-cyclopropen-1-yl]-7-oxabicyclo[2.2.1]hepta-2,5-diene-1,2,3,6-tetracarboxylate **3**, was recovered from old stocks of the monomer, and was also prepared thermally from the monomer by a variation of a previous method. NMR data and an X-ray crystal structure were determined for a red 1:1 adduct of this ester with triphenylphosphine. This red adduct, tetramethyl 4-methoxy-5-[1,2,3-tris(carbomethoxy)-3-triphenylphosphoranylidenepropen-1-yl]-7-oxabicyclo[2.2.1]hepta-2,5-diene-1,2,3,6-tetracarboxylate **5**, crystallized in the triclinic space group $P\bar{1}$ (No. 2) with two molecules in the unit cell (a = 12.315(2) Å, b = 12.321(2) Å, c = 14.652(2) Å, α = 110.60(1)°, β = 90.62 (1)°, and γ = 103.22(1)°). Refinement converged at R = 0.0694 (R_w = 0.0986) for 542 parameters using 4714 reflections with $I > 2\sigma(I)$. Triphenylphosphine oxide did not react with tetramer **3**. Reaction of the tetramer of dimethyl acetylenedicarboxylate **3** with 1,2,5-triphenylphosphole gave an orange product with concomitant loss of a furan triester. NMR data confirmed that this was not a simple adduct, and examination of a crystal by X-ray established the structure as the dichloromethane complex of tetramethyl 1,9,10-triphenyl-1-phospha(V)tricyclo[5,2,1,$0^{5,10}$] deca-1,3,5,8-tetraene-2,3,4,6-tetracarboxylate **10**. This orange product crystallized in the monoclinic space group $P2_1/c$ (No. 14) with four molecules in the unit cell (a = 10.056(2) Å, b = 14.280(1) Å, c = 23.892(3)Å, α = 90.0°, β = 94.15(1)°, and γ = 90.0°). Refinement converged at R = 0.0683 (R_w = 0.0710) for 540 parameters using 3180 independent reflections with $I > 3\sigma(I)$. The tetramer **3** did not react with 1,2,5-triphenylphosphole-1-oxide quickly, but after 9 months gave a white, probably polymeric, product.

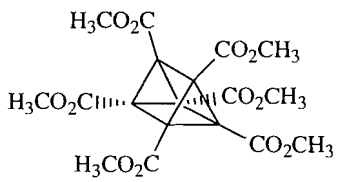
MARTIN B. HOCKING et FRANCES W. VAN DER VOORT MAARSCHALK. Can. J. Chem. **72**, 2428 (1994).

On a isolé un tétramère de l'acétylènedicarboxylate de diméthyle, le 4-méthoxy-5-[1,2,3-tris(méthoxycarbonyl)-2-cyclopropèn-1-yl]-7-oxabicyclo[2.2.1]hepta-2,5-diène-1,2,3,6-tétracarboxylate de tétraméthyle (**3**), à partir de vieux stocks du monomère et on l'a aussi préparé thermiquement à partir du monomère, par une variation d'une méthode antérieure. On a déterminé les données de la RMN et, faisant appel à la diffraction des rayons X, on a déterminé la structure d'un adduit 1 : 1 de cet ester avec la triphénylphosphine. Cet adduit rouge, le 4-méthoxy-5-[1,2,3-tris(carbométhoxy)-3-triphénylphosphoranylydènepropèn-1-yl]-7-oxaboicyclo[2.2.1]hepta-2,5-diène-1,2,3,6-tétracarboxylate de tétraméthyle (**5**), cristallise dans le groupe d'espace triclinique $P\bar{1}$ (No. 2) avec deux molécules par motif et a = 12,315(2), b = 12,321(2) et c = 14,652(2) Å, α = 110,60(1)°, β = 90,62 (1)° et γ = 103,22(1)°). L'affinement converge à R = 0,0694 (R_w = 0,0986) pour 542 paramètres utilisant 4714 réflexions avec $I > 2\sigma(I)$. L'oxyde de triphénylphosphine ne réagit pas avec le tétramère **3**. La réaction du tétramère de l'acétylènedicarboxylate de diméthyl avec le 1,2,5-triphénylphosphole fournit un produit orange avec la perte concomitante d'un triester de furane. Les données de RMN confirment qu'il ne s'agit pas d'un adduit simple et une étude par diffraction des rayons X a permis d'en établir la structure; il s'agit du complexe du 1,9,10-triphényl-1-phospha(V)tricyclo[5.2.1,$0^{5,10}$]déca-1,3,5,8-tétraène-2,3,4,6-tétracarboxylate de tétraméthyle (**10**) avec du dichlorométhane. Ce produit orange cristallise dans le group d'espace $P2_1/c$ (No. 14) avec quatre molécules par motif et a = 10,056(2), b = 14,280(1) et c = 23,892(3) Å, α = 90,0°, β = 94,151(1)° et γ = 90,0°. L'affinement converge à R = 0,0683 (R_w = 0,0710) pour 540 paramètres utilisant 3180 réflexions avec $I > 3\sigma(I)$. Le tétramère **3** ne réagit pas rapidement avec le 1-oxyde de 1,2,5-triphénylphosphole; après 9 mois, il fournit un produit blanc, probablement un polymère.

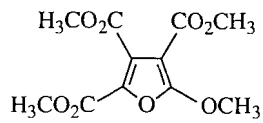
[Traduit par la rédaction]

Introduction

A thermally produced condensation trimer and a tetramer of dimethyl acetylenedicarboxylate apparently were first described and partially characterized by Thayer, who also examined the dienophilic character of the cyclopropene ring component of the tetramer (1). Hexamethyl mellitate and structure **1** were considered for the trimer, and rejected. Subsequently two groups examined the physical and chemical properties of trimethyl 2-methoxyfurantricarboxylate **2**, a dimeric product less a carbon derived from the monomeric acetylene ester, and devised plausible pathways for its formation (2, 3). A third laboratory reacted supposed furan **2**, which has some similar properties to the dimethyl acetylenedicarboxylate (DMADC) tetramer **3**, with triphenylphosphine and obtained a red product formulated as the zwitterion **4** (4). This adduct has a very similar elemental analysis and physical properties to those of the reaction product from the DMADC tetramer with triphenylphosphine, and therefore it was probably the same material (5).



1



2

The structures of both the DMADC tetramer as **3** and the triphenylphosphine adduct as 5 were better established by the subsequent combined contributions of Kauer and Simmons, LeGoff and LaCount, and Gericke and Winterfeldt (5–7). Gericke and Winterfeldt also provided the well-supported structure **6** for the trimer originally described by Thayer.

We were interested in confirming the rather unusual structure of the tetramer of dimethyl acetylenedicarboxylate via an X-ray

structure of a crystal of either the compound itself or of a derivative of the tetramer in which the bulk of the skeleton of the tetramer remained intact, such as the triphenylphosphine adduct. It was also intended to test restricted rotational features that were previously reported for certain ester-stabilized phosphoranes (8) and were likely to be observable for several of the target compounds synthesized for the structural study. If feasible, evaluation of the rotational energy barriers of the target molecule(s) could also be made via NMR coalescence temperatures to probe molecular features giving rise to the restricted rotation.

Results and discussion

Isolation and preparation of tetramer 3

The first samples of tetramer isolated from 17-year-old bottle of almost completely crystalline dimethyl acetylenedicarboxylate (DMADC) gave 13 methyl singlets (10 well resolved, 3 with evidence of overlapping) with 4 closely spaced pairs in the 3.75–3.55 ppm shift range in the 250 MHz ^{1}H NMR spectrum (Table 1). Since only eight (or fewer) resonances were expected for the tetramer this multiplicity was taken as suggestive of the existence in this sample of two very similar tetramer isomers, not noticed by the previous workers perhaps because of the lower-frequency spectrometers used. It was not the photochemically produced isomer **7**, since this has only two types of ester methyls, which give ^{1}H NMR resonances at 3.74 (6H) and 3.79 ppm (18H) (6).

To explain the very similar NMR spectra observed it was thought possible, for example, that the methoxyl and the cyclopropene moieties could be on opposite sides rather than on the same side of the oxanorbornadiene ring in the postulated two isomers, **3** and **9**. Examination of a possible pathway from the DMADC monomer to the tetramer showed that it would be difficult to perceive mechanistically how this particular possibility could occur directly (Scheme 1). However, this could be envisaged by a reverse Diels–Alder reaction of the tetramer **3** to the

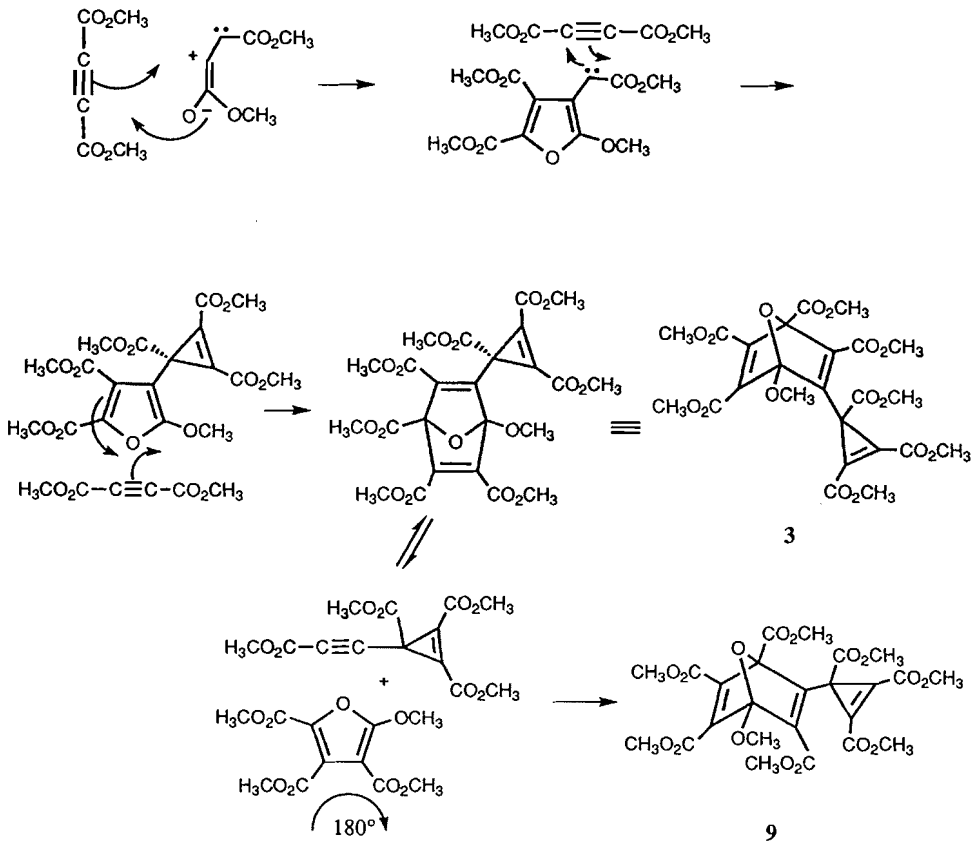
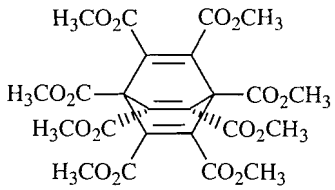


SCHEME 1. A possible pathway to the dimethyl acetylenedicarboxylate tetramer **3** and its postulated isomer **9** (extended from ref. 6).

TABLE 2. Results of thermal equilibration experiments with the tetramer of dimethyl acetylenedicarboxylate **3** in nitrogen atmosphere

Temperature, °C[a]	Time, h	Composition by 250 MHz ^{1}H NMR
111	0.3	No change
111	3	Ca. 90% original tetramer, + 10% possible isomer
111	18	No tetramer; seven new compounds (TLC)
111	20	Extensive decomposition
137	2.3	No tetramer; six new compounds
137	24	Severe decomposition.

[a]Runs at 111°C contained added hydroquinone and were heated by the vapours of boiling toluene. Runs at 137°C (performed first) had no hydroquinone present, and were heated by the condensed vapour of boiling of mixed xylenes.



7

cyclopropenyl acetylene **8** and furan **2** followed by a 180° rotation of either product, and a forward Diels–Alder recyclization could conceivably give this result. This possibility is supported by the earlier 18% recovery of **6** from a vacuum pyrolysis of the methanol addition product of the tetramer **3** by Gericke and Winterfeldt (7). Significant attention therefore was directed towards resolution of the supposed isomeric mixture, both from old, spontaneously formed, tetramer samples present in old DMADC monomer as well as by examination of fresh, thermally prepared, tetramer, to try to answer this question.

Tetramer recoveries from spontaneously tetramerized monomer ranged from about 80% from a 17-year-old, almost completely crystallized, sample of DMADC to about 20% for recovery from viscous but noncrystalline samples of less old DMADC and for fresh, thermally prepared, tetramer samples. Use of a nitrogen atmosphere did not significantly alter our yields of thermally produced tetramer from the 20–25% previously reported (5). None of the samples isolated from spontaneously produced material, nor those from subsequent thermal preparation, showed the same near doubling of ester methyl proton NMR resonances observed in the initially isolated sample. Attempts to observe formation of the second "isomer" by thermal equilibration of isolated tetramer under a nitrogen atmosphere, either with or without radical inhibitor present, were also unsuccessful (Table 2).

[a][(Relative intensity of low field isomer) − (relative intensity of isomer mixture)]/[relative intensity of isomer mixture] × 100.

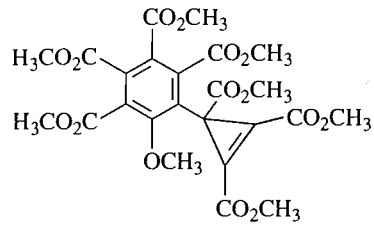
Chemical ionization mass spectra of the originally isolated tetramer mixture relative to more recent, thermally prepared, tetramer gave significantly different fragmentation susceptibilities (Table 3). Therefore, a few small-scale experiments were conducted to reveal any differential reactivity of the tetramer isomer towards triphenylphosphine or 1,2,5-triphenylphosphole. These also failed to give any conclusive answers. Further experiments to confirm the formation of isomer(s) of tetramer **3** were therefore abandoned.

Several attempts were made to deoxygenate the tetramer using triiron dodecacarbonyl and triiron nonacarbonyl under mild conditions. These experiments were directed towards confirmation of both the structures of the tetramer and whether our interpretation of the isomers present under some conditions, i.e., **3** and **9**, was correct from the nature of the aromatic product(s) **10** that would result. It was also possible that the observed second "isomer" was spontaneously deoxygenated tetramer **3**. Although examination of the chromatographed reaction mixture under the best conditions demonstrated conversion of the starting material to two compounds, neither corresponded to the structure **10**.

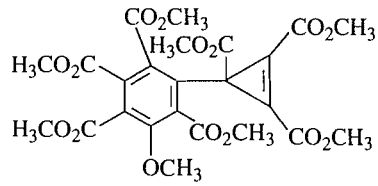
Adduct of tetramer 3 with triphenylphosphine

Since the thermal ellipsoids determined from an X-ray crystal structure of the low melting point tetramer were likely to be large, it was decided to first obtain a crystal structure for the tetramer–triphenylphosphine adduct **5**. Only in the event of an unexpected structure for this adduct would it be necessary to attempt a crystal structure of the tetramer itself.

The yield of the crude red tetramer–triphenylphosphine adduct prepared in ether was nearly 90% and after one recrystallization gave material melting at 212–214°C, the same as previously recorded (5). Electron impact and MALDI (matrix assisted laser desorption ionization) mass spectra confirmed the required molecular weight of 831. While the adduct is thermally stable at temperatures up to the melting point, observation of major fragment ions at *m/z* 558.3 and 262.1 in the electron impact mass spectrum indicates loss of the furan **2** or the equivalent, and triphenylphosphine (*m/z* 830.7 − 272.2, and 262.3, respectively), as significant components of either its thermal or electron impact fragmentation pathways. The ester methyl/methoxyl region of the 360 MHz ^1H NMR adduct shows 14 peaks in the shift range 3.91–2.89 ppm.



10*a*



10*b*

X-ray quality crystals of a 1:1 complex of the tetramer–triphenylphosphine adduct **5** with dichloromethane were obtained by recrystallization of the crude product from a mixture of dichloromethane and ether. Figure 1 gives an ORTEP representation of the molecular structure excluding hydrogen atoms, which were not sought (Tables 4–7). This endorses structure **5** for the adduct, as first proposed by Kauer and Simmons (5). It also strongly supports the structure **3** originally put forward by LeGoff and LaCount for the DMADC tetramer itself (6).

A gross feature of interest from this crystal structure, from intersecting plane dihedral angle calculations, is that the oxygen bridge of the oxanorbornadiene moiety remains approximately equally spaced between the triphenylphosphine substituent side and the two-ester substituent side of the bridged ring, despite the steric bulk of the former (Fig. 2). Bond angle and torsion angle calculations also give quite even spacing between the A, B, and C phenyls on the phosphorus of 106°, 107°, and 108°, respectively. Also each phenyl is tilted to a similar angle of somewhat more than 90° away from the P1—C1 axis to the extent of 107°, 113°, and 115°, as would be expected. This "tilt" is the reason that the angles between the phenyls do not total 360°, and can be likened to a propellor in which the blades (phenyls) lie outside the plane of rotation. An interesting feature of this analogy, emerging from torsion calculations, is the wide differences found for the angle of "pitch" of the phenyl "blades" expressed relative to the plane of rotation of 42.14(4)°, 137.(4)°, and 75.9(4)°, respectively. The B ring shows a relatively fine pitch whereas the C ring is almost feathered (with respect to the *axis* of rotation).

Detailed examination reveals a P1—C1 bond distance of 1.748(3) Å, close to the 1.728 Å reported by Kennard et al. (9) for a P=C double bond in a cyclopentylidene phosphorane and significantly shorter than the 1.87 Å normally expected for a

[a]Estimated standard deviations are given in parentheses. Phenyl and ester bond distances, which were all normal, have been deposited (see footnote 3).

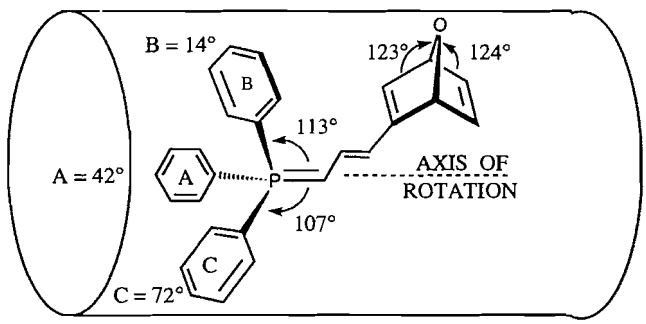

FIG. 2. Three-dimensional illustration of the dihedral angles, and of the pitch of the phenyl groups in the red triphenylphosphine–tetramer adduct **5**, omitting ester and ether groups for clarity.

phosphorus–carbon single bond (10). This establishes the existence and position of the phosphorane P=C double bond. While carbon–carbon single and double bonds in the chain are apparently about 0.1 Å shorter and 0.03 Å longer, respectively, than expected, these differences are of a similar magnitude to their estimated standard deviations. This indicates that there is little or no measurable electron delocalization along the chain. The *trans* and *transoid* orientations of ester groups on the chain were as expected. The chain ester group (C21, C22) adjacent to the oxanorbornadiene moiety was found to have a small disorder problem concerning the approximately 180° rotation of the ester group. This was resolved by using two sites for C22, with complementary occupation factors of 0.48 and 0.52. Figure 1 has been drawn with C22 attached to O12. The rest of the structure is unexceptional.

A likely pathway for the formation of this adduct is given in Scheme 2. This proposal suggests an initial electrophilic attack of the cyclopropene by triphenylphosphine that may proceed in two discrete steps or as a concerted process, as shown. This is followed by ketonization of the resulting enol to give the observed product. Two of the four possible resonance-stabilized forms are shown.

An attempt to react the tetramer **3** with triphenylphosphine oxide in ether at room temperature resulted in recovered starting materials, as expected.

SCHEME 2. A possible pathway for the formation of the red triphenylphosphine–DMADC tetramer adduct **5**.

*The reaction of tetramer **3** with 1,2,5,-triphenylphosphole*

The reaction of excess tetramer with 1,2,5-triphenylphosphole at room temperature was much slower than with triphenylphosphine, and incomplete. However, if afforded the same orange crystalline product as obtained in 61% yield by short-term heating of a solution of equivalents amounts of the two reactants. An analogous product to that obtained with the tetramer and triphenylphosphine was anticipated for this reaction. However, an ^{1}H NMR spectrum of the product showed only four ester methyls, rather than the eight expected. Also the MALDI mass spectrum gave an M + 1 of 610 rather than the 882 value required for the analog expected. Hence the product was not a simple adduct of the component reagents.

Apart from the four chemically different ester methyls, the

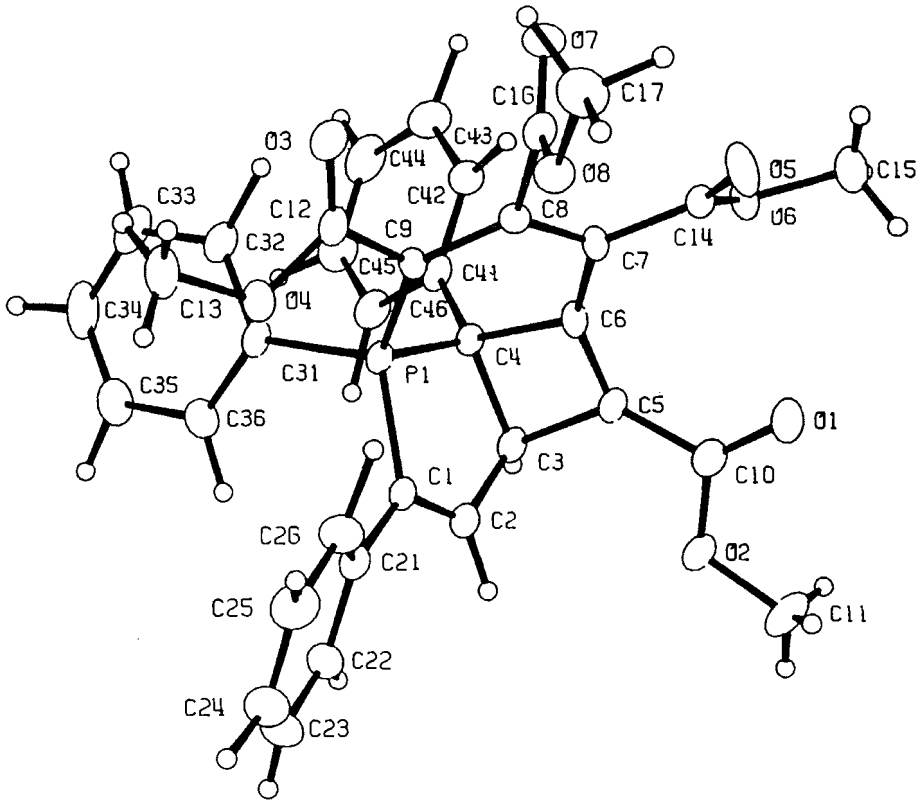

FIG. 3. ORTEP representation of the crystal structure of the orange product **11**, prepared from DMADC tetramer **3** plus 1,2,5-triphenylphosphole.

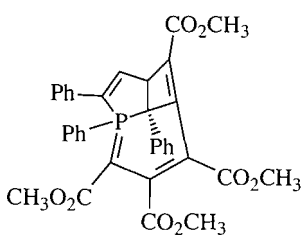
^{1}H NMR spectrum of the phosphole product demonstrated the presence of one methine hydrogen coupled to one olefinic hydrogen, with the latter also subject to a large coupling to phosphorus. This information had to be accommodated by the structure of the product. Consideration of earlier vacuum pyrolysis results of Gericke and Winterfeldt with the DMADC tetramer itself (7) and our own experience with other acetylenic adducts of the phosphole (11) led to the postulation of **11** as a possible structure. The signal for one of the ester methyls in the ^{1}H NMR spectrum was broadened, perhaps by the proximity to phosphorus (12), which is provided for by this structure. The red colour, too, is supported by the presence of the P=C chromophore conjugated to the multiple double-bonded system of this proposal.



11

The three-fused-ring structure **11** originally deducted from the available NMR information for this new compound was confirmed by an X-ray structure determination of a single crystal selected from material recrystallized from a dichloromethane–hexane mixture. Figure 3 gives an ORTEP representation of the molecular structure, including hydrogen atoms that were resolved (Tables 8–10). The fusion of the cyclobutene, phosphacyclopentene, and phosphacyclohexadiene rings obtained in this product is evident in this representation. Cocrystallized dichloromethane was also observed in this crystal but the thermal values of the atoms of the solvent molecule were higher and thus obscured several of the atoms of the molecule of interest. For this reason the solvent was excluded from the structure shown although the fractional atomic coordinates, interatomic distances, and bond angles are included in Table 8 and Supplementary Tables S.5 and S.6.[3]

Mean plane and dihedral angle calculations allow further broad stereochemical interpretations. The four carbons of the phosphacyclopentene are approximately coplanar with a χ^2 of 37 for the displacements from the best mean plane. The χ^2's reported are calculated by squaring the perpendicular deviations from the best mean plane, of each of the atoms specified, and then summing these. C1 and C4 are 0.054 and 0.034 Å below the plane, C2 and C3 are 0.041 and 0.009 Å above, while the phosphorus lies virtually in the best mean plane at +0.003 Å. The dihedral angle between the mean plane of this four-carbon fragment and the plane defined by the C1-P1-C4 atoms in the phosphacyclopentene is 5.0°. This is a slightly flat-

[3]Tables of bond lengths and angles and anisotropic temperature parameters for both crystals **5** and **11** are available as supplementary material (Tables S1–S11) and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, ON K1A 0S2, Canada.

Tables of bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

ter ring than the equivalent angle calculated from the mean plane deviations reported for the atoms of the parent phosphole itself (13), which is 6.2°. The cyclobutene has a pronounced twist to it with C4 and C5 deviating 0.042 and 0.054 Å to one side of the mean plane and C3 and C6 deviating to about the same extent on the other (χ^2 = 263). Excluding C4, the atoms of the phosphacyclohexadiene are also nearly coplanar, with individual deviations of 0.008 Å or less and a χ^2 of 5.1. C4 is substantially below this mean plane by 0.649 ± 0.005 Å.

Dihedral angle calculations for the three-component central rings clearly demonstrate the cage-like core to this molecule. The angles for the intersecting mean planes at ring junctions P1—C4, C4—C6, and C3—C4 come out to be 57°, 42°, and 73°, respectively. A rotated ORTEP representation omitting hydrogen atoms illustrates more clearly the effect of this core semi-cage on the overall shape of the molecule (Fig. 4). Also evident from this representation is the near-orthogonal alignment to the mean plane of the phosphacyclohexadiene taken up by the three phenyls, minimizing steric interactions. The P—C9 distance, with a bond length of 1.736 Å, is 0.13 Å shorter than the normal P—C single bond, and quite similar to the 1.728 Å previously reported for a P═C double bond (9). Hence this

[a]Estimated standard deviations are given in parentheses. Phenyl, ester, and hydrogen bond angles, which were all normal, have been deposited (see footnote 3).

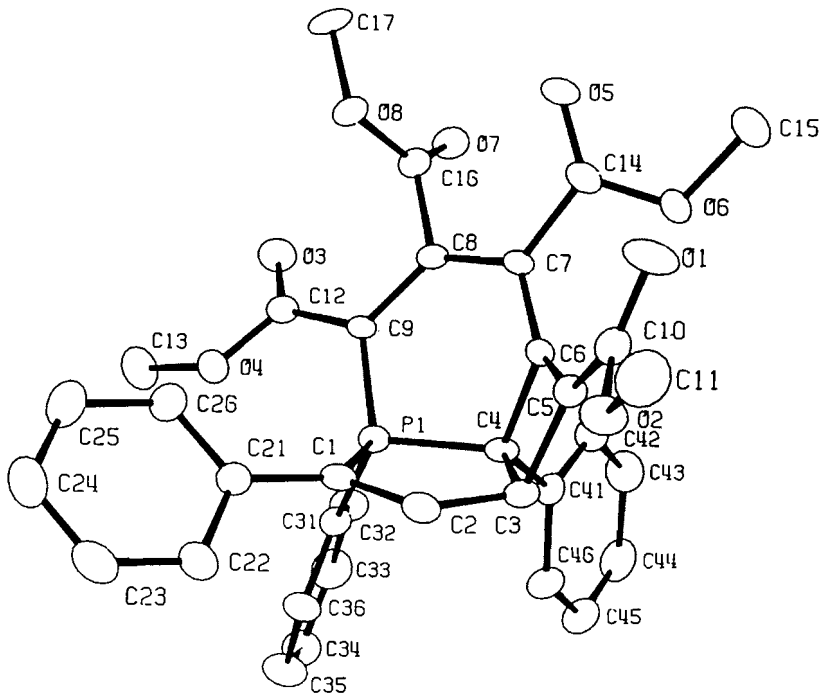

FIG. 4. ORTEP representation of the orange compound **11** without hydrogen atoms, rotated to illustrate the core semi-cage structure.

establishes the position of the phosphorane linkage. A possible indication of some charge delocalization from the positively charged phosphorus atom to the P-phenyl is indicated by a P—C31 bond length of 1.792 Å, 0.08 Å shorter than the normal. All other bond lengths to phosphorus and the olefinic and saturated linkages of the rest of the molecule are normal. The bond angles of the cyclobutene are all 90 ± 5°.

A possible pathway to the orange product **11** is given in Scheme 3. Nucleophilic attack of the cyclopropene of the tetramer by the phosphorus of the phosphole initially gives the same type of intermediate as the final product with triphenylphosphine. This process might proceed in two discrete steps, or in a concerted process as illustrated. A 2+2 intramolecular cycloaddition of a relatively reactive residual olefinic double bond in the phosphole component of this intermediate then follows, together with a reverse Diels–Alder reaction releasing furan **2** from the oxanorbornadiene component of the initial unstable adduct. Ketonization of the initially formed enol then

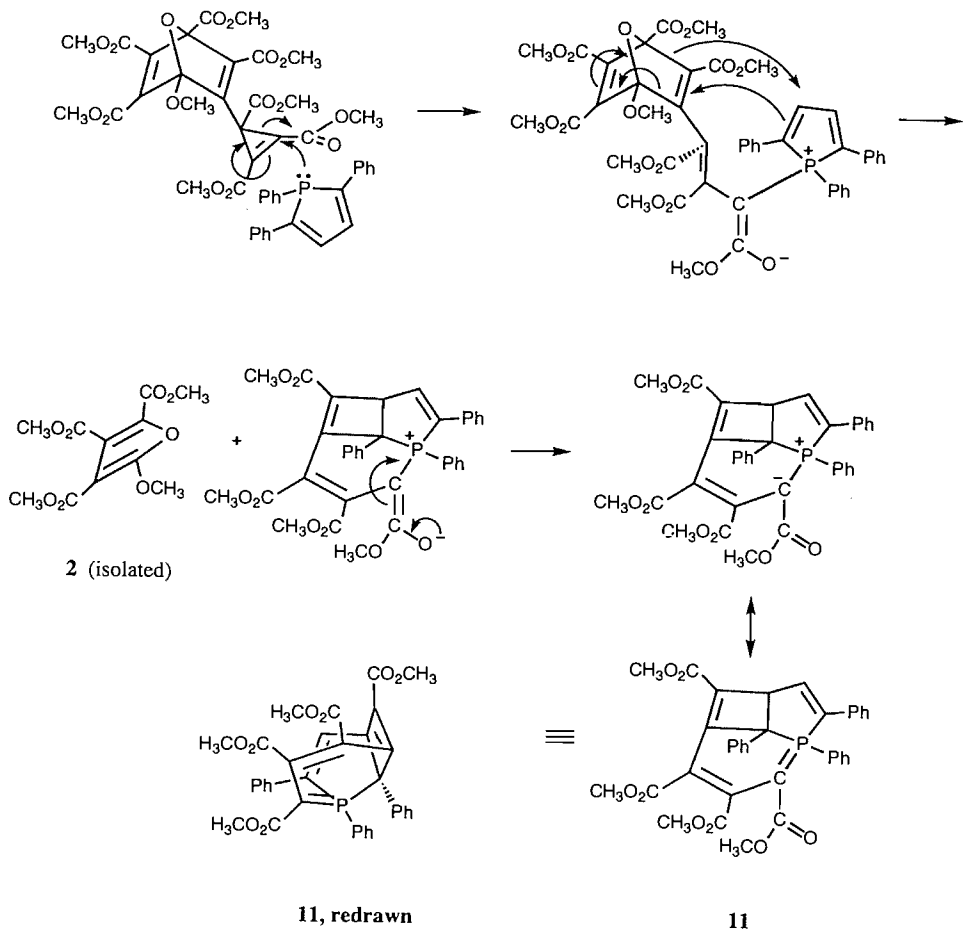

SCHEME 3. A possible pathway to the orange semi-cage product **11** from the reaction of the DMADC tetramer **3** with 1,2,5-triphenylphosphole.

gives the observed product. Two of the four possible resonance-stabilized forms are shown.

Support for the proposed pathway would be obtained if furan **2** could be observed among the products during the reaction of the tetramer **3** with 1,2,5-triphenylphosphole. The physical properties of the furan **2** are known from previous preparations by others via vacuum pyrolysis of the tetramer (7), and by thermal or other treatment of the acetylene ester itself (2,3). Accordingly, a reaction between the tetramer and phosphole specifically designed to detect the presence of the furan **2**, if formed, was carried out. The total partially isolated furan obtained from this experiment by solvent chromatography represented the equivalent of about 830 mg, or 84% of that theoretically expected from the starting amount of tetramer. The furan recovery was confirmed by isolation, from a portion of this material, of 225 mg of crystalline material of the correct melting point and ^{1}H NMR spectrum. This outcome, while it does not exclude other possible pathways to the orange product, is consistent with the pathway given.

Conclusions

We have duplicated and added refinements to earlier methods of isolation of an interesting tetramer of dimethyl acetylenedicarboxylate. With access to high-frequency NMR it has been possible to provide evidence of the presence of two, probably very similar, isomeric forms of this tetramer. Despite additional evidence of this isomeric interpretation of the NMR spectra, it has not been possible to conclusively confirm this by chemical or physical means.

Confirmation of the structure and stereochemistry of the acetylenic tetramer was obtained from an X-ray crystal structure of the triphenylphosphine adduct. Reacting 1,2,5-triphenylphosphole with the tetramer gave a new phosphorus-containing heterocycle of fused 4-, 5-, and 6-membered rings with concomitant loss of a substituted furan. Structural confirmation of this novel semi-cage product was obtained through a further X-ray crystal structure determination.

Experimental

Infrared spectra were recorded on KBr pellets using a Perkin-Elmer model 1130 instrument. Ultraviolet spectra were obtained on a Philips PU 8740 UV–VIS spectrophotometer in solvents as specified. Bruker WM 250 or Bruker AMX 360 spectrometers were used to collect magnetic resonance data at the appropriate frequency for nuclei of interest, as specified. Spectra were obtained at ambient temperature on samples dissolved in deuteriochloroform, unless otherwise specified. Shift and coupling assignments were aided by decoupling and COSY experiments, when necessary. Mass spectra were determined using a Finnegan 3300 GC–MS system, a Kratos Concept H (high field) instrument, or a Kratos MALDI (Matrix Assisted Laser Desorption Ion) time-of-flight spectrometer. For spectra from the latter instrument an ionizing matrix of 2,5-dihydroxybenzoic acid (DHB) – fucose containing a trace of trifluoroacetic acid (placed using acetonitrile) was used, first in the normal mode for rapid scanning and finally in Reflectron mode for optional resolution. Gramicidin S (Gram.SH$^+$ = m/z 1142) was used to calibrate the MALDI instrument. Melting points were carried out on a Reichert 7905 hot-stage microscope or on a Gallenkamp MF-370 Kofler aluminum block apparatus, and are uncorrected. Commercially prepared sheets (Polygram silica gel G, 254 μm UV indicator) visual-

ized by daylight, and by medium (365 μm) and short wave (254 μm) UV illumination, were used for thin-layer chromatography (TLC) for reaction monitoring or solvent chromatography screening tests. A Varian model 5000 liquid chromatograph was used for high-pressure chromatographic separations.

*Tetramer **3** of dimethyl acetylenedicarboxylate (DMADC)*

Isolation from 17-year-old sample

A small sample of the solids removed from a 17-year-old, half-used bottle of almost fully crystallized "DMADC" was triturated with 100% ethanol, and the resulting slurry was suction filtered. The filter cake of white crystals was rinsed with fresh solvent and dried, 5.6 g(ca. 80% recovery), mp 94–96°C. The tetramer mixture mass spectrum is given in Table 3. ^{1}H NMR of isomer mixture (250 MHz): 3.88 ppm (7.4 rel. intensity), 3.86 (12.6), 3.85 (11.0), 3.84 (18.0), 3.82 (9.2), 12.3H; 3.75 (7.1), 3.73 (9.2), 3.2H; 3.71 (6.6) 3.69 (8.5), 3.1H; 3.64 (6.9), 3.62 (9.1), 2.9H; 3.57 (6.8), 3.55 (9.3), 2.6H.

A 2.4 g portion of the crystalline sample above was recrystallized from 95% ethanol. First crop, 21 mg; ^{1}H NMR (250 MHz): 3.89 ppm (8.6 rel. intensity), 3.87 (12.7), 3.85 (10.8), 3.76 (8.4), 3.72 (8.9). A small portion of the mother liquor from this crystallization examined by thin-layer chromatography (TLC; developer 28:72 v/v acetone: toluene) showed four discrete spots, R_f values 0.075 (streak), 0.261, 0.36, 0.44 (streak). Tetramer blank R_f was 0.522. ^{1}H NMR (250 MHz) of a further portion of this material showed that it consisted of a complex mixture of compounds, probably contributed to by partial hydrolysis.

Samples of crystalline material dissolved in 100% ethanol, ethanol–methanol mixtures, and cyclohexane–dichloromethane mixtures were put through a high-pressure liquid chromatograph using a C_{18} reverse phase column (CSC-S, ODS2 10 μm, 25 cm × 0.46 mm), using a UV detector set at 215 nm. No isomer resolution was obtained.

*Isolation of tetramer **3** from 16-year-old DMADC*

A 1.01 g sample from a less old bottle of partially used viscous yellow (but non-crystalline) DMADC in a round-bottomed flask was heated by a silicone oil bath at 60°C under reduced pressure (1 Torr = 133.3 Pa) for 4 h and at 75°C for 4.5 h. TLC (20:80 acetone:toluene v/v) on the 0.707 g residue demonstrated the presence of the tetramer **3**, plus four other compounds, R_f values 0.0, 0.069, 0.118, 0.24, 0.32 (tetramer). Removal of DMADC monomer from another sample of old DMADC under reduced pressure (1 Torr) for 24 h at room temperature gave a 28% weight loss plus a similar residue composition.

A total of 1.195 g of combined viscous residues from which most of the monomeric ester had been removed was column chromatographed on silica gel (Baker Ltd., 60–200 mesh; packed column, 56 × 3.5 cm diam) eluting ca. 200 mL fractions 1–6 with ethyl acetate:ether (10:90 v/v). DMADC monomer (by ^{1}H NMR; 89 mg) was recovered from fraction 2. Fraction 3 (113 mg, pale yellow glass) was mostly the tetramer **3** (^{1}H NMR), which was also present together with other compounds in fraction 4 (135 mg, pale yellow glass). Fractions 5 and 6 (30 and 5 mg) were mixtures, without tetramer present. A further seven fractions (two using ethyl acetate:ether, 20:80 v/v; and five using 100% acetone) yielded a total of about 400 mg of brown gums.

Similar treatment of a further 10-year-old partially crystalline sample of dimethyl acetylene dicarboxylate showed the presence of only the low-field isomer of the tetramer, both on initial examination and from the NMR spectra of differentiated fractions.

*Preparation of **3** from fresh dimethyl acetylenedicarboxylate*

Aldrich DMADC (49.71 g; 43.0 mL) in a 250 mL round-bottomed flask was thoroughly flushed with nitrogen and, still under nitrogen, was heated by a stirred silicone oil bath at 85°C. In this inert-atmosphere modification of the method of Kauer and Simmons (5), small aliquots of the liquid were removed via syringe through a serum cap at 7–8 day intervals and examined by ^{1}H NMR for the extent of conversion to DMADC tetramer **3** (Table 1). After 23 days the viscous amber liquid, now about 61% by weight or 28 mol% tetramer, was poured into a crystallization dish and covered for 3 days. The oily crystalline mass obtained was triturated with ether, and the resulting slurry suction-filtered to give 5.94 g of clear crystals of the tetramer **3**, mp 97–100°C. ^{1}H NMR spectra all showed the presence of only the low-field isomer in all fractions (details, Table 1). Slow evaporation of the ether enabled recovery of a further 3.47 g of the tetramer in three crops, mp 96–100°C, 98–101°C, and 97–100°C, respectively. ^{13}C NMR (250 MHz): carbonyl carbons, 168.7 ppm (1.6 rel. intensity), 164.4 (1.6), 163.5 (1.5), 161.3 (1.3), 160.8 (1.5), 159.3 (1.3), 156.8 (1.7), 156.7 (1.8), 156.1 (1.4); unassigned carbons, 145.2 (1.3), 143.9 (1.2), 116.6 (1.1), 113.6 (1.8), 112.8 (2.1), 86.0 (0.4), 55.7 (6.7), 53.3 (10.7), 53.2 (14.2), 52.9 (9.2), 52.7 (8.9), 52.4 (8.3), 52.1 (7.5); ether methyl, 33.5 (0.54). Total tetramer recovery by recrystallization was 9.41 g (18.9%).

Examination of the residue left after evaporation of the solvent from the mother liquor by TLC (acetone:toluene, 30:70 v/v) gave five spots, R_f values 0.283, 0.434, 0.509, 0.547 (tetramer), and 0.604. This, and ^{1}H and ^{13}C NMR spectra, indicated that several compounds were present. A 0.924 g portion of this tetramerization residue was column-chromatographed on silica gel (Baker Ltd., 60–200 mesh; column 200 × 20 mm diameter) eluting fractions 1–3 with acetone:ether 25:75 v/v and 4 with acetone:ether, 50:50 v/v. Recoveries from fractions 2 and 3 indicated, by TLC (acetone:toluene, 15:85) and ^{1}H NMR, that mixtures were obtained. Fraction 2:four compounds; R_f values of 0.14, 0.24, 0.35, and 0.55; NMR, 30 peaks in 3.44–4.07 ppm range. Fraction 3: three compounds; R_f values 0.0, 0.13, 0.26; NMR, 32 peaks in 2.60–3.91 ppm range.

*Attempted isomerizations of the tetramer **3***

A small sample (0.10–0.52 g) of crystalline tetramer alone, or usually with 10–15% by weight of added hydroquinone, was placed in a test tube, sealed with a serum cap, and then flushed with nitrogen for several minutes. While keeping the test tube and contents under a positive pressure of nitrogen, the sample was heated by boiling solvent and vapour using toluene, bp 111°C, for the lower temperature experiments, and mixed xylenes, bp 137–144°C. for the higher temperatures. After the intended heating period the tetramer sample was allowed to cool to room temperature and the contents examined by TLC, or ^{1}H NMR, or a combination of both methods (summary, Table 2).

A tetramer sample heated at 140°C for 24 h without added hydroquinone had no residual tetramer and TLC indicated that five new compounds had formed. Development by acetone:toluene 50:50 v/v gave R_f values of 0.02, 0.30, 0.46, 0.57 (blue fluorescence), and 0.65 for these compounds. The R_f value for the tetramer spot under these conditions was also 0.57 but this showed no fluorescence.

A tetramer sample heated at 111°C for 3 h appeared by ^{1}H NMR to be ca. 90% unchanged tetramer plus ca. 10% of two or three similar compounds. TLC (acetone:toluene 10:90 v/v) gave four compounds, R_f values 0.04, 0.08, 0.21 (streak), 0.30. The R_f value of the tetramer under these conditions was 0.18. All other heating experiments except the shortest gave results intermediate between these extremes.

*Attempted deoxygenation of tetramer **3** with iron carbonyls*

Modifications of the methods of Best et al. (14) were employed. To nitrogen-flushed solutions of about 220 mg of the tetramer **3** in 20–30 mL of benzene was added a solution of exactly 1 equivalent of the iron carbonyl compound ($Fe_3(CO)_{12}$, or $Fe_3(CO)_9$) in benzene, still under nitrogen. After 3 h at 45–50°C or 7 h at room temperature, monitored by thin-layer chromatography, the solvent was removed under reduced pressure. The residue was taken up in solvent and chromatographed on Merck Kieselgel using methylene chloride, or ethyl acetate. No discrete, fully aromatic compounds were resolved on checking the various chromatography fractions by 250 MHz ^{1}H NMR.

*Reaction of the DMADC tetramer **3** and triphenylphosphine*

Tetramer **3** (635 mg), prepared by the last method described, was dissolved in 200 mL of ether at room temperature and a solution of triphenylphosphine (644 mg) in 20 mL of ether was added with stirring. During ca. 5 min the solution changed from colourless to a deep red. After suction filtration of the reaction solution and slow evaporation of the filtrate, red prisms formed, and were filtered; yield 574 mg,

For personal use only.

mp 206–209°C. A further 253 mg was recovered in two crops, mp 207–210°C and 210–213°C, giving a total product recovery of 827 mg (89% on DMADC). A portion of this material (781 mg) was recrystallized twice more from dichloromethane–ether (ca. 5 mL) to give 640 mg of pure red crystals of the adduct **5** mp 212–214°C (lit. (5) mp 213–214°C), that were suitable for X-ray crystal structure determination. ^{1}H NMR (360 MHz): aromatic protons, 7.82 ppm, quartet, J_{PH} 7.9, J_{HH} 2.3 Hz; and 7.71 ppm, quartet, J_{PH} 7.9, J_{HH} 4.0 Hz, total 6H; aromatic multiplet, 7.50–7.36 ppm, (total 9 H); ester methyl, and methoxyl protons (no evidence of ^{31}P coupling, from decoupling experiments), 3.91, 3.84, 3.83, 3.78, 3.76, 3.74, (10.2H); 3.64, 3.63, (5.5H); 3.54 (2.1H); 3.43, 3.41, 3.32, (3.0H); 2.94 and 2.89 ppm, (3.2H). ^{31}P NMR (360 MHz) ^{1}H decoupled): 20.36 ppm (rel. intensity 4.07), 18.37 (8.00). ^{13}C NMR (360 MHz): carbonyl carbons (some coupled to ^{31}P), 171.0 ppm (rel. intensity 0.48), 170.4 (0.35), 168.6 (0.28), 168.5 (0.32), 167.1 (0.54), 166.7 (0.39), 165.5 (0.44), 165.3 (0.95), 164.5 (1.48), 163.3 (0.43), 162.5 (0.59), 161.2 (0.54), 160.9 (1.00); aromatic and olefinic carbons (some coupled to ^{31}P), 144.9 ppm (rel. intensity 0.24), 143.2 (0.51), 137.7 (0.57), 134.6 (1.8), 134.5 (1.7), 134.1 (10.7), 134.0 (10.9), 131.8 (5.3), 131.8 (3.8), 128.6 (14.9), 128.4 (14.8), 128.3 (3.5), 126.5 (1.4), 125.5 (1.3), 116.5 (0.27); ester methyl and methoxyl carbons, 55.4 ppm (rel. intensity 2.4), 53.1 (1.7), 53.0 (2.2), 52.4 (4.5), 52.0 (3.4), 51.8 (1.5), 51.6 (4.1), 51.4 (3.7), 50.9 (0.67), 50.1 (1.8), 50.2 (2.3); quaternary carbons, 52.2 ppm (intensity 0.29), 15.17 (0.93). Mass spectra of this purified material after removal of the solvent (32 h, 80°C, 1 Torr): Kratos MALDI, M + 1: 831; calcd. for $C_{42}H_{40}O_6P$, MH^+: 831.8; Kratos Concept H EI spectrum, M^+: 830.4; ^{13}C isotopic peaks (% of M^+): 831.4 (47), 832.4 (15), 833.4 (3.5); calcd. for $C_{42}H_{39}O_6P^+$: 830.8, 831.8 (47), 832.8 (22), 833.8 (10); major fragment ions at *m/z* 183.0, 262.1, 313.3 (small), 368.4, 499.2, 558.3, 771.4, 815.4.

*Reaction of tetramer **3** with triphenylphosphine in nonpolar solvent*

DMADC tetramer (2.09 g) was added, with stirring, to excess triphenylphosphine (1.5 g) dissolved in benzene. The solution instantaneously changed from colourless to deep red. It was then reduced in volume, cold ethanol was added, and the solution was allowed to crystallize. Filtration gave 2.84 g (96% on tetramer) of deep red crystals.

A small sample of the red crystals was recrystallized twice from acetone, yielding material melting at 203–207°C. UV (95% EtOH), nm (log ϵ): 202 (4.72), 223.3 (4.43), 254.5 (3.91), 458.1 (3.57); ($CHCl_3$), (log ϵ): 241 (4.17), 262.4 (3.80), 268.9 (3.77), 275.5 (3.70), 301.6 (3.45), 471.3 (3.91). IR (KBr) cm^{-1}: 2960w, 2922w, 2860w, 1740m, 1690m, 1630m, 1490w, 1430w, 1260m, 1140w, 1100w, 1030w, 720w, 700w. ^{1}H NMR (250 MHz): aromatic protons, 7.30–7.89 ppm; ester methyl protons, 3.91, 3.88, 3.83, 3.78, 3.76, 3.74, 3.63, 3.55, 3.44, 3.41, 3.33, 2.94, 2.90 ppm; ^{31}P relative to external phosphoric acid, 20.76, 18.79 ppm. ^{13}C NMR: carbonyl carbons, 165.3, 164.45, 162.5, 160.9 ppm; aromatic and olefinic carbons, 137–125 ppm; ester methyl and methoxyl carbons, 55.4–50.1 ppm (details given above).

*Attempted reaction of tetramer **3** and triphenylphosphine oxide*

Triphenylphosphine oxide (153 mg; 0.58 mmol) was dissolved with stirring into a solution of the tetramer **3** (231 mg; 0.41 mmol), previously dissolved in 5 mL of diethyl ether and held at room temperature for 5 days. TLC chromatograms indicated little or no change during this period. Evaporation of the ether and trituration of the residue gave 211 mg of colourless crystals, mp 98–102°C, and an IR spectrum identical to that of an authentic sample of the tetramer.

Colourless crystals (180 mg) were obtained from the concentrated mother liquor, mp 155–158°C. An IR spectrum indicated, by comparison with that of an authentic sample, that this was slightly impure triphenylphosphine oxide.

*Reaction of tetramer **3** with 1,2,5-triphenylphosphole at room temperature*

Finely ground phosphole (0.527 g; 1.69 mmol) was added with stirring to a solution of the finely ground tetramer (1.315 g; 2.31 mmol) in 100 mL of benzene at room temperature. The solution was stirred at room temperature for 4 days and then reduced in volume and allowed to crystallize.

The first crop of yellow crystals (198 mg) was unreacted phosphole, as indicated by ^{1}H NMR (60 MHz). A second crop of colourless crystals was unreacted tetramer (507 mg), identified by ^{1}H NMR (250 MHz) by singlets at 3.88, 3.86, 3.86, 3.84, 3.76, 3.71, 3.60, and 3.58 ppm. Crude orange crystals (354 mg; 34%, 56% with recovered phosphole) were then obtained in two crops. The best portion of this was recrystallized from 95% ethanol to give pure product **11**, mp 165–171°C. UV (95% EtOH), nm (log ϵ): 205 (4.87), 227 sh (4.59), 309.5 (4.27), 448.6 (3.83). IR (KBr) cm^{-1}: 3015w, 2995w, 2940w, 1740m, 1720m, 1700m, 1680m, 1620w, 1460m, 1440m, 1430m, 1365m, 1220s, 1200s, 1190s, 1120w, 1090w, 700w, 695w, 680w. ^{1}H NMR (360 MHz): vinylic proton, quartet, 7.91 ppm, J_{HH} 3.46, J_{PH} 38.7 Hz; aromatic protons, 6.89–7.58; methine proton, doublet, 4.52 ppm, J_{HH} 3.16 Hz; methoxy protons, 3.99, 3.73, 3.71, and 3.13 ppm; decoupled ^{31}P relative to external 85% phosphoric acid, 25.48 ppm. ^{13}C NMR (250 MHz): carbonyl carbons, 165.2, 165.1, 164.8, 161.9 ppm; aromatic and olefinic carbons, 153–122 ppm; ester methyls, 52.6, 52.0, 51.3, 50.1 ppm; methine carbon, doublet, 57.7 ppm, J_{PC} 6.31 Hz.

*Reaction of tetramer **3** with 1,2,5-triphenylphosphole with heating*

The tetramer (1.28 g; 2.25 mmol) was added with stirring to a solution of the phosphole (0.68 g; 2.17 mmol) dissolved in 100 mL toluene at room temperature, and then heated to 70–80°C for 4 h. The solution slowly changed colour from yellow to orange and thin-layer chromatography (toluene:ethanol, 95:5 v/v) at intervals indicated that only the product obtained at room temperature was being formed. On allowing the solution to cool, orange crystals of **11**, 0.803 g (61%), were produced, mp 164–170°C. Recrystallization from 210 mL of warm toluene gave pure material, 0.476 g (36%), mp 168–171°C (dec.).

*X-ray quality crystals of the phosphole product **11***

Slow recrystallization of 592 mg of the orange crystalline product **11**, from 300 mL diethyl ether plus 1% dichloromethane, yielded 51 mg of orange crystals, mp 157–159°C. These became opaque and powdery after a standing at room temperature for a short period of time. Crystallization of 274 mg of the orange compound from a dichloromethane: hexane mixture (2:3 v/v, ca. 10 mL) gave a recovery of 250 mg of suitable crystals of a 1:1 dichloromethane:compound **11** complex, mp 160–162°C (dec.). ^{1}H NMR (360 MHz): olefinic proton; 7.97 ppm, dd, J_{HH} 3.4 J_{PH} 41.8 Hz, (1 H); aromatic protons, 7.52 ppm, d, J_{HH} 5.1 Hz, (2 H); multiplet, 7.369 ppm (rel. intensity 0.37), 7.366 ppm (0.38), 7.363 (0.38), 7.359 (0.25), 7.35 (1.00), 7.343 (0.93), 7.339 (0.58), 7.335 (0.68), 7.33 (1.34), 7.32 (4.47), 7.317 (4.15), 7.31 (1.50), 7.30 (2.37), 7.290 (0.79), 7.288 (0.81), 7.285 (0.78), 7.280 (0.61), 7.275 (0.71), 7.24 (1.09), total area 5.74; double triplet, 7.15 ppm, J_{PH} 3.6, J_{HH} 7.56 Hz (meta protons of phenyl on P), area 1.87; aromatic multiplet, 7.02 ppm (rel. intensity 2.13), 7.01 (2.94), 7.00 (2.85) total area 2.85; 6.93 (1.33), 6.92 (1.23), 6.91 (0.87), total area 1.87; methine proton, 4.50 ppm, d, J_{HH} 3.4 Hz, (1 H); ester methyl protons, 3.97, 3.71, 3.69, and 3.12 ppm (each 3H). ^{13}C NMR (360 MHz): carbonyl carbons (some split or broadened by coupling to ^{31}P), 165.2 ppm (intensity 0.42), 165.1 (0.44), 164.78 (0.46), 161.79 (1.45), 161.76 (1.33); aromatic and olefinic carbons (some coupled to ^{31}P), 153.5 (0.83), 153.4 (1.03), 153.2 (0.83), 143.8 (0.33), 135.7 (1.12), 135.0 (1.02), 133.3 (1.35), 133.0 (0.73), 132.9 (0.81), 132.81 (3.93), 132.78 (4.42), 131.7 (6.19), 131.6 (5.81), 129.3 (6.39), 128.7 (8.72), 128.5 (12.12), 128.4 (16.00), 128.21 (8.61), 128.16 (8.14), 127.50 (7.65), 127.46 (7.84), 127.4 (4.81), 127.3 (3.97), 123.5 (1.70), 122.5 (1.50), 98.6 (0.53); quaternary carbon α to phosphorus, 60.3 ppm, d, J_{CP} 104.8 Hz; methine carbon β to phosphorus; 57.6 ppm, d, J_{CP} 7.0 Hz; ester methyl carbons, 52.6 ppm (rel. intensity 0.81), 51.9 (7.16), 51.3 (5.20), 50.0 (4.76). ^{31}P NMR (360 MHz): ^{1}H decoupled; 25.5 ppm (rel. intensity 11.00), 24.9 (4.40); this coalesced to a single peak at 313 K (40°C) at 25.42 ppm shift; coupled ^{31}P; overlapping dd (apparent triplet) 25.1 ppm (9.2, 11.0, 4.7), J_{H1P} ca. 40, JJ_{H2P} ca. 60 Hz. Mass spectrum: Kratos MALDI, M + 1: 610; also reproducibly 612, 614, 616 (M + 3, M + 5, M + 7); calcd. for $C_{35}H_{29}PO_8H^+$: 609.6.

*Reaction of tetramer **3** with 1,2,5-triphenylphosphole for associated products*

Tetramer (2.037 g, 3.58 mmol), was added to a solution of 1,2,5-triphenylphosphole (1.035 g; 3.31 mmol) in 250 mL of toluene and the flask and contents thoroughly flushed with nitrogen. The solution was heated at 80–100°C under nitrogen for 20 h after which time the volume was reduced to 50 mL and allowed to crystallized with slow evaporation. The resulting orange crystals were separated by filtration, and rinsed with toluene, 770 mg (38%; 49% with recovered phosphole), mp 158–162°C (dec.). The volume of the mother liquor was reduced to 10 mL and then allowed to crystallize, to recover 0.235 g of yellow needles, mp 180–183°C, identified as the starting phosphole.

For detailed examination of coproducts, a 1.765 g portion of the residual evaporated mother liquor, 1.974 g, was preadsorbed on 2.9 g of silica gel and loaded onto a silica gel column (Baker Ltd, 60–200 mesh, 53 cm × 3.5 cm diameter). The first seven fractions were eluted with 20% acetone – 80% diethyl ether, v/v, and the solvent removed, redissolved in deuteriochloroform, and examined for composition by 250 MHz ^{1}H NMR. Fractions 1 (225 mL) and 2 (100 mL) eluted nothing. Fraction 3 (100 mL) eluted 81 mg of a yellow, partially crystalline, glass that was ca. 80% furan **2**, by integration; resonances at 4.19 ppm (rel. intensity 17.4), 3.92 (17.1), 3.82 (17.0), 3.77 (14.9). The remainder of this fraction appeared to be starting phosphole, or its oxide. Fraction 4 (50 mL) gave 481 mg of a pale yellow glass that was a mixture of the starting phosphole or its oxide, the furan **2** and the tetramer **3** (approx. 9, 69, and 22 mol% respectively), by integration. This furan sample gave resonances at 4.19 ppm (rel. intensity 15.2), 3.90 (16.7), 3.83 (11.6), 3.74 (10.2), and the tetramer **3** at 3.87 (10.9), 3.85 (13.3), 3.81 (17.1), 3.75 (16.6), 3.69 (9.3), 3.62 (8.4), 3.56 (7.5). Fraction 5 (100 mL) eluted 680 mg of an orange glass that was a mixture of several compounds, unreacted tetramer being the only identifiable and largest component (51 mol%, by integration). Fractions 6–10 (100–225 mL each) gave unpromising mixtures that were not examined further.

Rechromatography of combined fractions 3 and 4 on silica gel and elution with 20% ethyl acetate – 80% toluene enabled isolation of a total of 225 mg of colourless crystals of the furan **2**, mp 115–120°C (lit. (2) mp 117–118°C; (5) mp 118–119.2°C; (3) mp 121°C) from the two middle fractions. ^{1}H NMR (250 MHz); δ: 4.22 (3.0), 3.93 (3.9), 3.84 (4.3), and 3.78 ppm (3.4 relative intensity).

*Reaction of tetramer **3** with 1,2,5-triphenylphosphole-1-oxide*

Short term

The oxide (214 mg; 0.652 mmol) was added with stirring to 407 mg (715 mmol) of the tetramer dissolved in 20 mL of dry benzene. The solution was refluxed for 5 h with no visible change, confirmed by TLC. The solution was held at room temperature for a further 7 days, and then concentrated and allowed to crystallize. The first crop was 202 mg of recovered phosphole oxide, mp 235–239°C, confirmed by IR. The second crop was 297 mg of colourless crystals, mp 98–101°C, which was unreacted tetramer **3** (IR).

Long term

The oxide (134 mg; 0.4 mmol) was added to 231 mg (0.406 mmol) of DMADC tetramer dissolved in 30 mL of benzene and allowed to stand for 9 months. The yellow colour of the phosphole oxide gradually dissipated to become nearly colourless, with accompanying deposition of an amorphous white powder. The solvent was then removed and the solid residue was triturated with acetone. The residual insoluble white powder (231 mg) was dried at room temperature, mp 320°C (dec.). This solid was insoluble in all common solvents. A mass spectrum (CI) could not be obtained. IR (KBr) cm^{-1}: 3050m, 3010m, 2930w, 1588m, 1485m, 1427m, 1295w, 1250w, 1190m, 1162s, 1100s, 1055w, 1027w, 915w, 750s, 715m, 687s, 645w, 585w, 500m.

X-ray crystallography

The experimental parameters and crystal data for both compounds are given in Table 4. In both cases data were collected at 20°C, and scattering factors for uncharged atoms were used (15). The unit cell and matrix for the red triphenylphosphine adduct **5** were refined using 25 2θ measurements in the range 50°–63°, each measured in both the positive and negative directions. Intensity measurements were made in the 2θ range 0.1°–120° from *h,k,l* 0,–13,–15 to 13,13,15. Three standard orientation reflections –4,6,0; 0,4,4; and 5,2,3 were measured every 3600 seconds of X-ray exposure time. The measurements were corrected for absorption using an empirical absorption correction on the Nonius ($\mu = 12.13$ cm^{-1}), then the EMPABS program[4] was run on the mainframe computer. The phase problem was solved and refined by SHELX-76[5] using direct methods. All non-hydrogen atoms were found for the main molecule. A small disorder problem was noted for C22, which had a site occupation factor of 0.48 where placed and (1–0.48) for C22′ for the equivalent position bonded to O11. The refinements converged with a maximum shift/esd of 0.069. The final difference map had a maximum of 0.49 e Å^{-3}, indicating that nothing had been missed. The final residuals were $R = 0.0694$, and $R_w = 0.0986$ for 542 parameters and 4714 independent reflections ($I > 2\sigma(I)$). Results are given in Tables 5–7.

The unit cell and matrix for the orange phosphole product **11** were refined using 25 2θ measurements in the range 34°–95°, again measured in both the positive and negative directions. Intensity measurements were made in the 2θ range 0.1°–130° from *h,k,l* –11,0,0 to 11,16,27. Three standard orientation reflections –4,2,6; 0,2,11; and 4,7,6, were measured every 3600 seconds of X-ray exposure time. The measurements were corrected for absorption using an empirical absorption correction on the Nonius ($\mu = 25.98$ cm^{-1}), then the EMPABS program was run on the mainframe computer. The phase problem was solved by SHELXS[6] Patterson methods and refined by SHELX-76. All atoms, including hydrogens, were found and refined. The refinements converged with a maximum shift/esd of 0.04 for hydrogens and 0.02 for non-hydrogens. The final difference map had a maximum of 0.4 e Å^{-3}, which indicated that nothing had been missed. The final residuals were $R = 0.0683$, and $R_w = 0.0710$ for 540 parameters and 3180 independent reflections ($I > 3\sigma(I)$). Results are given in Tables 8–10.

Micellar catalysis in mixed anionic/cationic surfactant systems

YVETTE L. FAVARO AND VINCENT C. REINSBOROUGH
Department of Chemistry, Mount Allison University, Sackville, NB E0A 3C0, Canada

Received July 27, 1994

YVETTE L. FAVARO and VINCENT C. REINSBOROUGH. Can. J. Chem. **72**, 2443 (1994).

Dye solubility and stopped-flow kinetic studies were conducted in sodium dodecylsulfate/dodecyltrimethylammonium bromide and sodium dodecylsulfate/decyltrimethylammonium bromide micellar solutions with excess anionic surfactant. The enhanced rate in the presence of anionic micelles of the $Ni^{2+}_{(aq)}$/pyridine-2-azo-*p*-dimethylaniline (PADA) complexation reaction was used as a probe of the mixed micellar situation. PADA solubilities and the kinetic parameters derived through the Robinson model for micellar catalysis were consistent with a complete incorporation of the cationic surfactant into the sodium dodecylsulfate micelles.

YVETTE L. FAVARO et VINCENT C. REINSBOROUGH. Can. J. Chem. **72**, 2443 (1994).

On a effectué des études de solubilité de colorant et de cinétique à flux stoppé dans des solutions micellaires de dodécylsulfate de sodium/bromure de dodécyltriméthylammonium et de dodécysulfate de sodium/bromure de décyltriméthylammonium dans lesquelles l'agent tensioactif est en excès. On a utilisé l'augmentation de la vitesse de la réaction de complexation $Ni^{2+}_{(aq)}$/pyridine-2-azo-*p*-diméthylaniline (PADA) en présence de micelles anioniques comme sonde d'une situation micellaire mixte. Les solubilités du PADA et les paramètres cinétiques obtenus à l'aide du modèle de Robinson pour les catalyses micellaires sont en accord avec une incorporation complète de l'agent de surface cationique dans les micelles de dodécylsulfate de sodium.

Introduction

From both the industrial and theoretical points of view, surfactant mixtures are currently of much interest because, for reasons not quite clear, they are more efficient than single surfactants in a wide variety of applications. Anionic/cationic surfactant mixtures are an especially intriguing subset because the opposite charges must give rise to unusual solution aggregates of "pseudononionic" character (1). As if by way of confirmation, their limited miscibility ranges point to contentious forces at work that find early resolution in phase separation or liquid crystal formation, sometimes preceded by vesicle formation (2). Yet, the form and composition of the "micelles" present in solution are problematic. To this end, solubility and rate enhancement studies have been undertaken in the anionic-rich side of the phase diagram for solutions of sodium dodecylsulfate (SDS) with added dodecyltrimethylammonium bromide (DTAB) (X = 0.10, 0.20 and 0.30) or decyltrimethylammonium bromide (DeTAB) (X = 0.10 and 0.20). Both techniques have been shown in this laboratory to be informative of and sensitive to structural micellar adaptations resulting from additives (3), solubilizates (4) and surfactant mixtures (5–8). The chosen concentration ranges mirror the complete miscibility ranges in SDS-rich solutions. Beyond these mole fractions in DTAB or DeTAB at room temperature, the solutions are cloudy or give rise to precipitates.

Experimental

Solubilities of the hydrophobic dye, pyridine-2-azo-p-dimethylaniline (PADA), were obtained spectrophotometrically in mixed surfactant systems at 25.0°C as described previously (8, 9). Kinetic data on the $Ni^{2+}_{(aq)}$/PADA complexation reaction were obtained at the same temperature by mixing $NiNO_3$ and PADA solutions in a Cantech stopped-flow apparatus under pseudo-first-order conditions (10^{-3} mol dm^{-3} Ni^{2+} and 10^{-5} mol dm^{-3} PADA) at pH 7.2 ± 0.1. Surfactants and other reagents were the best available commercially.

Results and discussion

(a) Solubilities

The solubility of PADA in SDS solutions increases in proportion to the surfactant concentration beyond the critical micelle concentration (CMC) until at 0.18 mol dm^{-3} SDS (Fig.1), it is approximately a thousand times greater than its value in water (1.5×10^{-4} mol dm^{-3} (10)). At SDS concentrations lower than the CMC (8.5 mmol dm^{-3} SDS), the solubility of PADA shows little change from its pure water value. Similarly micellar DTAB increases the solubility of PADA about 500 times at 0.18 mol dm^{-3} DTAB. When the CMC of DTAB, which is twice as large in value, is taken into account (0.0153 mol dm^{-3} DTAB from the break in the solubility curve; agreed with literature values (11)), PADA is seen to be equally well solubilized by DTAB as by SDS. Despite their differences in charges either micelle

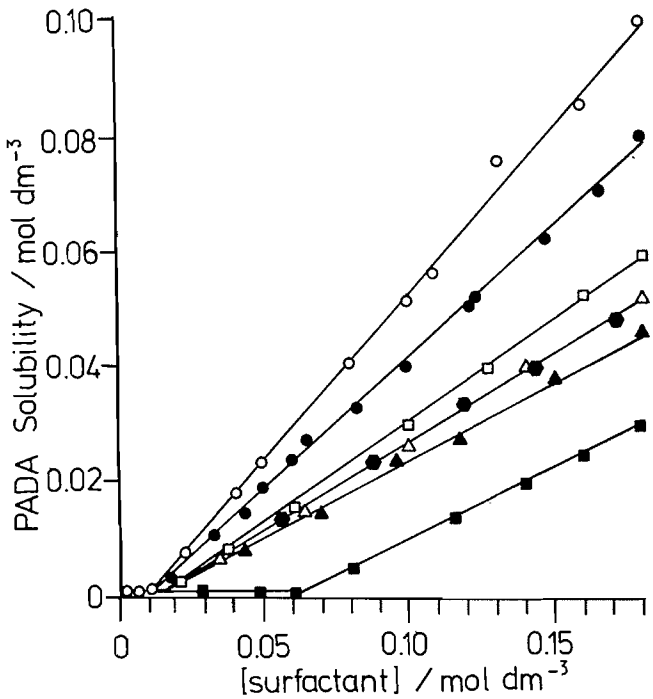

FIG. 1. Solubility of PADA as a function of total surfactant concentration: ○ SDS, □ DTAB, ■ DeTAB, ● SDS-DTAB (X_{DTAB} = 0.10) and SDS–DeTAB (X_{DeTAB} = 0.10), △ SDS–DTAB (X_{DTAB} = 0.20), ⬣ SDS–DeTAB (X_{DeTAB} = 0.20), ▲ SDS–DTAB (X_{DTAB} = 0.30).

[a]From PADA solubilities

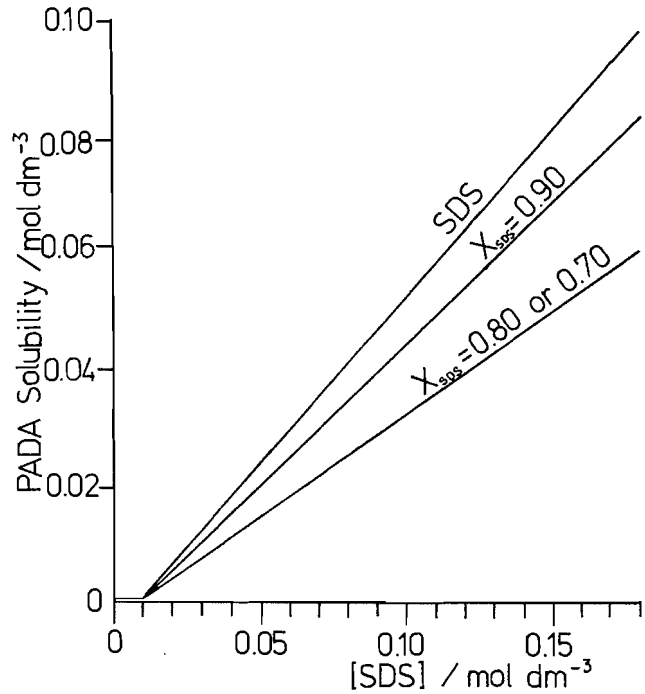

FIG. 2. Solubility of PADA as a function of SDS concentration in mixed micelles containing DTAB and DeTAB. (cf. Fig. 1 for an explanation of data points).

must present a similarly favorable hydrophobic interior environment to PADA.

When DTAB is added to SDS micellar solutions, the solubility of PADA is still enhanced but not as markedly (Fig. 1). In fact, in the X_{DTAB} = 0.30 system, the solubility of PADA per total surfactant is less than what it is in pure DTAB. Comparing solubilities on a total surfactant basis may not be the correct yardstick because it presumes that SDS and DTAB are in such a form as to be both promoting PADA solubilization in a similar manner. If, on the other hand, in SDS-rich solutions, the solubilizing agents are SDS micelles into which DTAB and PADA have been simply assimilated (9, 12), a more informative approach might be to plot solubility against SDS concentration. When this is done (Fig. 2), DTAB is still is seen as working adversely against PADA solubilization but for the X_{DTAB} = 0.20 and X_{DTAB} = 0.30 systems the depressant effect is the same.

DeTAB has a much greater CMC (0.061 mol dm^{-3} DeTAB from solubility measurements; again in ageement with the literature (11)) as befits its shorter chain length and at 0.18 mol dm^{-3} DeTAB solubilizes PADA about 200 times better than does pure water (Fig. 2). In SDS mixes to X_{DeTAB} = 0.20 beyond which concentration the solutions become cloudy, DeTAB acts roughly in the same fashion and to the same extent as DTAB in modifying PADA solubility despite the fact that it has greater disparity acting as a surfactants between DeTAB and SDS than that between DTAB and SDS. These data support the view that DeTAB and DTAB become totally absorbed into SDS micelles in the clear, SDS-rich part of the phase diagrams. The two cationic surfactants are assimilated as in the case of any hydrophobic molecule, without causing any great change in the SDS micelle size or shape (2).

The CMC values of the mixtures as revealed by PADA solubility data are listed in Table 1. The remarkable constancy among the values reinforces the notion that DTAB and DeTAB act interchangebly in determining the properties of the SDS micelles which act as their host.

One method by which the solubilization power of surfactants on solutes such as PADA can be compared quantitatively is through the association constant K_{PADA}, defined as $(S - S_0)/(C_T - CMC)S_0$ where S and S_0 are the solubilities of PADA in the micellar solution and in pure water respectively and C_T – CMC is the surfactant concentration in micellar form (C_T is the total surfactant concentration) (9). K_{PADA} values emerge as the slopes of the linear plots of $(S - S_0)/S_0$ against $(C_T - CMC)$ and are listed in Table 1 for the systems investigated.

(b) Rate enhancements

An extremely sensitive, indirect method of monitoring anionic micellar change is through rate enhancements that the micelles exert on the $Ni^{2+}_{(aq)}$/PADA complexation reaction (3–7). Below the CMC, the observed rate constant is simply the pure water value but the onset of micellization is heralded by a dramatic increase in the forward reaction. This occurs when oppositely charged $Ni^{2+}_{(aq)}$ ions and hydrophobic PADA are attracted to the anionic micelles for different reasons. As the micelles multiply with increasing surfactant concentration, the rate enhancements diminish as the reactants become effectively diluted in the concentrated micelle region. The measure of this rate enhancement is conveniently expressed as R, the ratio of k_{obs} in micellar solution ($^{m}k_{obs}$) to k_{obs} in water alone. Figure 3 depicts the R values for the SDS–DTAB system when X_{DTAB} = 0, 0.10, 0.20, and 0.30 and Fig. 4 for the SDS-DeTAB system when X_{DeTAB} = 0, 0.10 and 0.20.

If cationic surfactants are incorporated into the anionic micelles in some form, the effectiveness of the anionic micelles to act as catalysts for the probe reaction will decrease since the electrostatic attraction between $Ni^{2+}_{(aq)}$ and the mixed micelle is decreased. The PADA solubility treatment above shows that

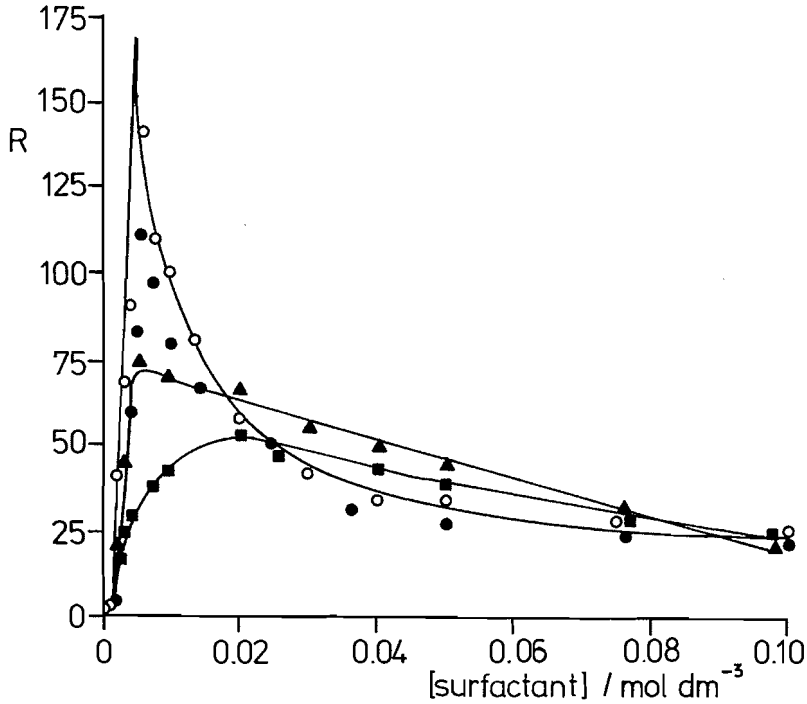

FIG. 3. Rate enhancements (R) of Ni^{2+}/PADA complexation in mixed SDS–DTAB systems: ○ SDS, ● SDS–DTAB (X_{DTAB} = 0.10), ▲ SDS–DTAB (X_{DTAB} = 0.20), ■ SDS–DTAB (X_{DTAB} = 0.30). To avoid confusion, the best-fit curve is omitted for the X_{DTAB} = 0.10 system.

PADA is slightly less attracted to mixed micelles than to pure SDS micelles and this will also lead to a slight reduction in R when switching from the SDS–DTAB system to the SDS–DeTAB system. Figures 3 and 4 confirm this conclusion. The Robinson model for the probe reaction occurring in both the bulk of the solution and in the micelles gives the following relationship for $^{m}k_{obs}$ (9, 10):

$$^{m}k_{obs} = {}^{m}k_f[Ni^{2+}]/\{CV[1 + (CK_{Ni})^{-1}][1 + (CK_{PADA})^{-1}]\}$$

where $^{m}k_f$ is the second-order rate constant in micellar solution which can be reasonably assumed to equate its value in aqueous solution (1.2×10^3 dm^3 mol^{-1} s^{-1}), C is the micellar surfactant concentration, i.e., the total surfactant concentration less the CMC, and V is the molar reaction volume of the surfactant. For mixed systems, the total concentration includes both surfactants. The parameter V usually is approximately the same as the molar volume of the surfactant. K_{Ni} is defined analogously to K_{PADA}, i.e., $K_{Ni} = [Ni^{2+}]_m/C[Ni^{2+}]_b$ where subscripts m and b denote the micellar surface and bulk solution pseudophases respectively. Curve-fitting of the kinetic data to the above expression yields K_{Ni} and V parametrically while K_{PADA} is obtained from solubility measurements as outlined previously. Table 1 lists the best fit values for K_{Ni} and V and estimates of the maximum value of R (R_{MAX}) for each investigated surfactant system. The system SDS–DTAB (X_{DTAB} = 0.30) was not included in this analysis since the fitted results were erratic, as might be expected on approaching a phase transition. Cationic surfactants inhibit the probe reaction so that the kinetically derived parameters could not be obtained for DTAB and DeTAB.

The first simple micellar model to explain the solubility and kinetic data for the mixtures would have the anionic and cationic micelles form independently, i.e., with no intermingling of monomeric surfactant ions. Thus, in the mixtures, SDS micelles would form first as the concentration of total surfactant was increased. The formation of the cationic micelles would occur at much higher concentrations (extreme right of Figs. 3 and 4), and this would have a catastrophic effect on the observed rate enhancements as PADA but not $Ni^{2+}_{(aq)}$ would be extracted from the solution. No abrupt quenching of the rate enhancement was observed. Also, the R_{MAX} values and the shape of the R curve, among other quantities, would not be as drastically changed as Figs. 3 and 4 indicate they were, if the cationic surfactant was simply a spectator ion. Even given the fact that the present analysis neglects ionic strength and excluded volume considerations, it is clear that this scenario of two "pure" micelles is not supported by the kinetic and solubility data for the systems at hand.

A more likely picture is that SDS micelles are formed which then solubilize the cationic surfactant monomers. The percent of DTAB or DeTAB solubilization is open to question but Kamenka et al. (2) have reported that their tracer self-diffusion and specific electrode potentiometry results signify that all the DTAB is accommodated by SDS micelles without any appreciable increase in size. Our work concurs with this assessment. A total incorporation of oppositely charged DTAB or DeTAB into the SDS micelles would have to occur to explain the precipitous decline of K_{Ni} from 220 to 30 when 20 mol% of cationic surfactant is present. On being assimilated within the SDS micelles, the cationic monomers displace the Na^+ counterions leading to a lower effective micellar charge (2). At 30 mol% DTAB, the kinetic analysis according to the Robinson equation by which the values of K_{Ni} and V might be obtained proved intractable, signifying a breakdown in the modelling situation. Indeed, Kamenka et al. (2) had found evidence of vesicle formation beyond 30 mol% in this same system and, in an allied system involving SDS, Marques et al. (13) reported vesicles in even dilute surfactant solutions. Spontaneous vesicle formation is commonplace with catanionic surfactants that are essentially 1:1 combinations of anionic and cationic surfactants but with the counterions removed (14). Catanionic "micelles" represent a

For personal use only.

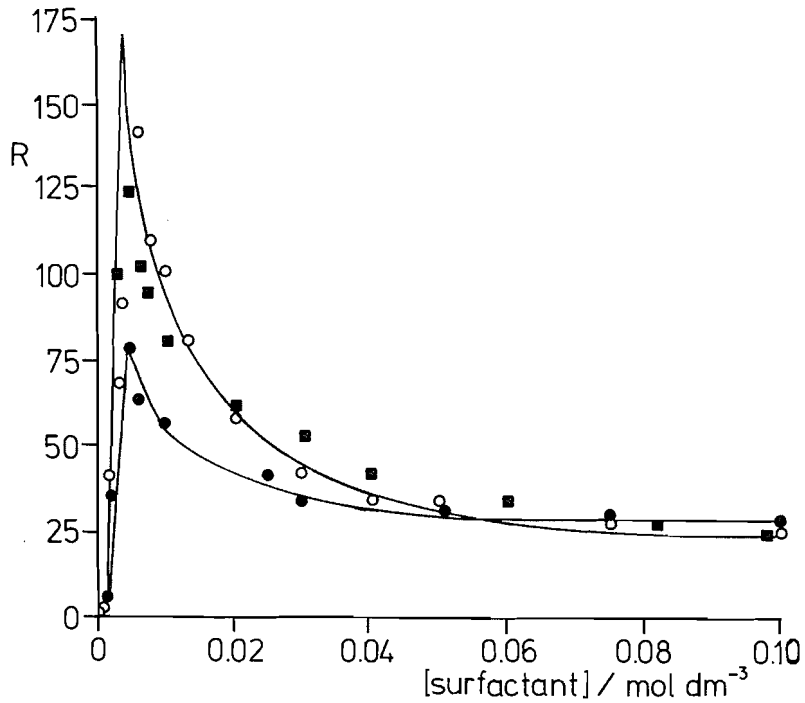

FIG. 4. Rate enhancements (R) of Ni^{2+}/PADA complexation in mixed SDS–DeTAB systems: ○ SDS, ■ SDS–DeTAB (X_{DETAB} = 0.10), ● SDS–DeTAB (X_{DeTAB} = 0.20). To avoid confusion, the best-fit curve is omitted for the X_{DeTAB} = 0.10 system.

no-charge situation but even at 30 mol% DTAB the electrostatic attraction experienced by $Ni^{2+}_{(aq)}$ with the mixed micelle or vesicle must be greatly reduced.

Another telling parameter that emerges from the Robinson model is the reaction volume which for either DTAB or DeTAB at $X = 0.20$ is reduced roughly to a third of the value found in pure SDS micelles (Table 1). To account for this dramatic reduction in V for a micelle that has not undergone a change in size, only about one in every three SDS monomers can be effective in attracting $Ni^{2+}_{(aq)}$ to the mixed micelle (PADA is equally well incorporated into cationic or anionic micelle when the surfactant chain lengths are comparable). If ion-pairing between oppositely charged monomers were occurring, then it might be expected that in a 20 mol% DTAB or DeTAB system three of every four SDS monomers would be available as micellar binding sites for $Ni^{2+}_{(aq)}$. This would lead to about a 30% reduction in V, which is much less than what is actually observed. Clearly, the incorporation of the oppositely charged surfactant monomer into the micelle is more seriously disruptive to the SDS micelle in its role in promoting the Ni^{2+}/PADA complexation reaction.

Rather than forming a distinctive ion-pair with an SDS monomer, a DTAB or DeTAB monomer might simply find itself in the mixed micelle with SDS monomers as the next nearest neighbours. This would be a region of the micelle to which $Ni^{2+}_{(aq)}$ would be minimally attracted and thus a large fraction of nominally "free" SDS monomers would be eliminated as possible $Ni^{2+}_{(aq)}$ micellar binding sites. An argument in this vein makes the observed 70% reduction in reaction volume in SDS micellar systems containing 20 mol% DTAB or DeTAB more reasonable. Mixed micellar systems of this type clearly do not admit yet of comprehensive solutions but their study is worth pursuing because of the valuable insight their interesting properties must provide for micellization phenomena in general.

GUANGZHEN G. MENG, BRIAN R. JAMES, KIRSTEN A. SKOV, and MLADEN KORBELIK. Can. J. Chem. **72**, 2447 (1994).

Water-soluble, *meso*-substituted porphyrins are synthesized by sulfonation or methylation of the phenyl or pyridyl groups, respectively, of some non-water-soluble functionalized porphyrins that we have recently synthesized (Can. J. Chem. **72**, 1894 (1994)). Twelve anionic sulfonated and seven cationic methylpyridinium porphyrins, usually containing other functional groups (phenyl, pyridyl, nitro- and amino-phenyl), are reported on. Twelve of these porphyrins are new, and all nineteen porphyrins are characterized by ^{1}H NMR. UV–VIS data are presented for the isolated porphyrins, while mass spectral data are noted for selected compounds. Partition coefficients of the porphyrins in octanol–water, and the accumulation of the porphyrins in HT-29 cells of a human-cancer tumor, were measured and both were inversely related to the charges of the porphyrins. The 11 porphyrins soluble in biological buffer solutions are basically nontoxic to Chinese hamster ovary (CHO) cells in oxic or hypoxic conditions or to aerobic HT-29 cells at the 100 μM concentration used (which is sometimes limited by solubility). No significant X-ray radiosensitization was observed for selected porphyrins toward CHO cells at the 100 μM concentrations used, but some photosensitized cell kill (using 630 nm light) was observed using the disodium salt of 5,10-bis(4-pyridyl)-15,20-bis(4-sulfonatophenyl)porphyrin (**24**).

GUANGZHEN G. MENG, BRIAN R. JAMES, KIRSTEN A. SKOV et MLADEN KORBELIK. Can. J. Chem. **72**, 2447 (1994).

On a synthétisé des porphyrines hydrosolubles, substituées en *méso*, en procédant à la méthylation ou à la sulfonation respectivement des groupes phényles ou pyridyles de quelques porphyrines fonctionnalisées, non solubles dans l'eau, qui ont été synthétisées récemment (Can. J. Chem. **72**, 1894 (1994)). On présente des données relatives à 12 porphyrines anioniques sulfonées et à 7 porphyrines méthylpyridinium cationiques, qui contiennent généralement d'autres groupes fonctionnels (phényle, pyridyle, nitro- et amino-phényle). Douze de ces porphyrines sont nouvelles et on a caractérisé les dix-neuf par RMN du ^{1}H. On présente des données d'UV–visible pour les porphyrines isolées et on rapporte de données de spectres de masse pour certains composés. On a mesuré les coefficients de partition des porphyrines dans un mélange octanol–eau ainsi que leur accumulation dans les cellules tumorales HT-29 du cancer humain; les deux ensembles de données présentent une relation inversée avec les charges des porphyrines. Les onze porphyrines solubles dans des solutions de tampon biologique sont essentiellement non toxique pour les cellules des ovaires du hamster chinois (OHC), dans des conditions oxiques ou hypoxiques, ou pour les cellules aérobiques HT-29, à la concentration de 100 μM utilisée (qui est quelquefois limitée par la solubilité). On n'a pas observé de radiosensibilisation marquée aux rayons X des porphyrines aux cellules OHC aux concentrations de 100 μM utilisées; toutefois, on a observé que quelques cellules ont été tuées par photosensibilisation (utilisant de la lumière à 630 nm) lorsqu'on a utilisé de sel disodique de la 5,10-bis(4-pyridyl)-15,20-bis(4-sulfonatophényl)porphyrine (**24**).

[Traduit par la rédaction]

Introduction

Synthetic water-soluble porphyrins have been reported to accumulate in tumors (1), and such compounds containing pyridinium, sulfonato, or carboxylato substituents, and their metal complexes, have also been briefly noted to be effective radiosensitizers, although no experimental details were given for the synthetic work (2). In a search for more effective radiosensitizers, modified water-soluble porphyrins and their metallated derivatives became of interest to us (3) because of their potential to accumulate in tumors, their potential to act as radiosensitizers during irradiation of cells, and their ease of testing in aqueous buffers.

The well-known anionic porphyrin, 5,10,15,20-tetra(4-sulfonatophenyl)porphyrin, abbreviated as Tet(SPh)P (**21**) in this work (Fig. 1), also labelled TSPP or $TPPS_4$ by others (4), has four negative charges and this may prevent easy diffusion of this porphyrin through highly hydrophobic, biological bilayers. Less highly charged anionic porphyrins, including $TPPS_3$ (5-phenyl-10,15,20-tris(4-sulfonatophenyl)porphyrin) (5–7), *cis*- and *trans*-$TPPS_2$ (5,10-diphenyl-15,20-bis(4-sulfonatophenyl)-porphyrin and (5,15-diphenyl-10,20-bis(4-sulfonatophenyl)-porphyrin) (6, 7), $TPPS_1$ (5,10,15-triphenyl-20-(4-sulfonatophenyl)porphyrin) (6, 7), and (APh)T(SPh)P (5-(4-aminophenyl)-10,15,20-tris(4-sulfonato-phenyl)porphyrin) (**17**) (8), have also been addressed in the literature for medicinal interests, and the results encouraged further investigations by us on similar compounds containing a larger variety of functional substituents. A few cationic porphyrins, including Tet(MPy)P (**30**), T(MPy)PhP (**32**), *cis*- and *trans*-B(MPy)DPhP (**35** and **36**), have been reported in connection with their DNA binding properties (9), their photosensitizing abilities in photodynamic therapy (PDT) (10), and aspects of their solution chemistry (11). Some of these reports appeared during the course of our studies (3).

In the present work, the synthesis, characterization, and results from some *in vitro* studies of certain designed water-soluble porphyrins are presented. The structures of the new porphyrins (**19**, **20**, **22**, **24–29**, **31**, **33**, and **34**) are included in Fig. 1. The porphyrins with nonionic substituents, which served as synthetic precursors in the present work, have been reported elsewhere (*3a*). An example of the basic synthesis is shown in Fig. 2: a nitro group is introduced into the porphyrin structure in order to increase the reduction potential (*3a*), which is believed to be important for radiosensitizers containing this group (12), followed by introduction of two sulfonate groups to increase aqueous solubility. The remaining anionic porphyrins are synthesized similarly; the amino group is incorporated by reduction of the nitro group prior to, or sometimes during, the sulfonation. The cationic porphyrins are synthesized by methylation of the pyridyl groups of prefunctionalized porphyrins, some of which also contain nitro substituents. All the sulfonated porphyrins are isolated as sodium salts, and all the cationic porphyrins are finally isolated as chloride salts. The counterions (Na^+ for anionic porphyrins and Cl^- for cationic porphyrins, unless otherwise specified) are omitted in the names and abbreviations (Fig. 1), when the emphasis is on the porphyrin structure, for clarity of presentation.

Experimental

General methods and materials

The precursor porphyrins **1–16** were synthesized according to our recently published procedures (*3a*). Other chemicals used, including alumina (activities I–III) and silica gel, were as described previously (*3a*), as was instrumentation for NMR and UV–VIS; ^1H references were TMS (in DMSO-d_6) (s = singlet, d = doublet, q = quartet, m = multiplet, b = broad). Mass spectroscopy (EI and FAB techniques) and microanalyses were performed in service laboratories in this department. An anion (Cl^-) exchange resin (Amberlite, IRA-402) was a BDH product. A sample of Photofrin II, a clinically used photosensitizer drug, was obtained from Quadralogic Technologies, Inc.

Dialysis was carried out in a 1.0 L beaker. A 10 × 3 cm piece of molecular porous membrane tubing (1000 Mol. Wt. cutoff, Spectra/Por) was rinsed with distilled water, and then one end was closed with string. The porphyrin sample was dissolved in a minimum amount of distilled water (2–10 mL), and the resultant solution was transferred into the tubing; the other end of the tubing was then closed with string. This dialysis "bag" was put into the beaker containing distilled water (~800 mL), and the contents were stirred for 2 h. The solution outside the dialysis bag was replaced by distilled water and dialysis continued for another 2 h, after which the solution in the bag was evaporated to dryness. Acetone (10 mL) was then added to the residue, the suspension was filtered, and the solid was collected and air-dried.

For biological tests, stock solutions (1.0 mM) of the compounds were made by dissolving the compounds in double-distilled water. The so-called "drug solutions", made by dilution of the stock solutions using the appropriate medium, were sterilized by filtering using 10 mL disposable syringes and Nalgene 0.22 μm filter units.

A centrifuge (Sorvall RC-3) was operated at 600 RPM at 4°C for separating cells from solution. The cell concentration was determined using a Coulter cell counter (Coulter Electronic Inc.). Media containing: no serum and no $NaHCO_3$, 10% bovine serum (Gilco) and no $NaHCO_3$, and 10% serum and 0.2% $NaHCO_3$, are labelled –/–, +/–, and +/+, respectively.

The cells used in the toxicity and radiosensitization assays were obtained from a CHO (Chinese hamster ovary) cell line. The cells were routinely grown in a spinner culture flask in α+/+ medium (Gilco), and the cell solutions were maintained at 37°C in an "Incu-cover" incubator (Associated Biomedic Systems) under an atmosphere of 95% air and 5% CO_2 (Canadian Liquid Air Co.). The cell cultures were diluted daily to maintain exponential growth (doubling time was approximately 13 h).

Drug accumulation and photosensitization assays were performed using cells from an HT-29 (human-cancer tumor) cell line, which was maintained as a monolayer in tissue flasks (Falcon) in RPMI+/+ medium (Gilco) at 37°C under an atmosphere of 95% air and 5% CO_2. The cultures were trypsinized (0.1% trypsin solution) twice a week (doubling time was approximately 24 h).

Porphyrin synthesis

The precursor porphyrins used in the various syntheses are included in Table 1.

Sulfonation reactions were performed using a modified literature procedure (4). The synthesis procedure for each of the porphyrins was about the same, and is described generally as follows:

The precursor porphyrin (~0.50 g) was mixed well with concentrated H_2SO_4 (10 mL) in a 50 mL round-bottom flask. The flask was stoppered and heated in an oil bath at 100–110°C for 4–12 h (see below). The mixture was then cooled to room temperature, and ice-cold water (50 mL) was added slowly. The mixture was carefully neutralized with concentrated NaOH and dilute Na_2CO_3 to pH = 8–9, while being cooled in an ice bath. After being concentrated by evaporation to about 20 mL, the solution was cooled in an ice bath, when a precipitate of inorganic salts (mainly Na_2SO_4) formed; this was filtered off and washed with MeOH (50 mL). To the aqueous MeOH filtrate was added 100 mL MeOH, when more inorganic salt precipitated. This mixture again was filtered and then the filtrate was evaporated to dryness on a Rotovap. The purple residue, a mixture of porphyrin product and inorganic salts, was washed with MeOH until only a light yellow solid remained; if the purple colour of the residue could not be washed out by MeOH, then the residue was dissolved in minimum hot water, reprecipitated with MeOH, and then filtered. The purple MeOH solution (typically 100–200 mL) was evaporated to dryness, and the purple residue was collected and dried under vacuum at 100°C overnight to give the crude product.

For Na_4Tet(SPh)P (**21**), made from precursor **1**, the crude product was redissolved in MeOH (100 mL) and the solution was filtered to remove some insoluble impurity. The filtrate volume was reduced to ~20 mL by evaporation, and then acetone (~200 mL) was added with stirring; the resulting brown precipitate was collected by filtration. This MeOH–acetone reprecipitation procedure was repeated three more times, and the final brown, very hygroscopic, product was dried at 100°C under vacuum. Another form of the product was made by evaporating to dryness aqueous solutions of the brown material. The resulting bright purple flakes were collected and dried at room temperature under vacuum; this material (60% yield) was not hygroscopic.

For the other isolated sulfonated porphyrins (**17**, **19**, **20**, and **22–25**), the crude products were generally either purified by dialysis or (and) by repetitive MeOH–acetone reprecipitation (3 times). Products purified by dialysis were collected by evaporation of aqueous solutions, were dried under vacuum, and were not hygroscopic, while products purified by reprecipitation were hygroscopic and thus, for elemental analysis, were handled under N_2. The actual purification method used for each of these porphyrins is indicated in Table 1 together with elemental analyses and reaction times used, the overall yields being 70–80%.

The crude product from the sulfonation of *cis*-(NPh)DPhPyP (**10**) was dissolved in MeOH (~30 mL), loaded on a column of silica gel (3 × 30 cm), and the column was eluted by a mixture of CH_2Cl_2 and CH_3OH (1:3). The major band was identified by ^1H NMR as *cis*-(NPh)PyB(SPh)P (**22**) (Table 2). The MeOH solution of the crude product (13%) from the sulfonation (100°C, 0.5 h) of the mixture of *cis*- and *trans*-B(NPh)DPhP (**8** and **9**) was loaded on a column of silica gel and, after elution by 1:1 MeOH/CH_2Cl_2, three products were separated; these were identified by ^1H NMR as B(NPh)B(SPh)P (mixture of **26** and **27**), (APh) (NPh)B(SPh)P (mixture of **28** and **29**), and B(APh)B(SPh)P (mixture of **19** and **20**) (see Results and discussion section).

The methylation of TetPyP (**6**) to give **30** was carried out according to the literature procedure (6), when the pyridinium porphyrins are first isolated as tosylate salts. Briefly, TetPyP (0.50 g) was mixed with 50

For **30**: 713 [M – 3Cl]$^+$, 694, 678* [M – 4Cl]$^+$, 663 [M – 4Cl – CH_3]$^+$, 648 [M – 4Cl – $2CH_3$]$^+$, 633 [M – 4Cl – $3CH_3$]$^+$. For **31**: 723, 707* [M – 3Cl]$^+$, 692 [M – 3Cl – CH_3]$^+$, 677 [M – 3Cl – $2CH_3$]$^+$. For **32**: 697 [M – 2Cl]$^+$, 662* [M – 3Cl]$^+$, 646. For **33**: 752, 736* [M – 2Cl]$^+$, 721 [M – 2Cl – CH_3]$^+$. For **35**: 661, 646* [M – 2Cl]$^+$, 631 [M – 2Cl – CH_3]$^+$.
[h]Satistactory elemental analysis was not obtained; for example with x = 4, C 53.50 (60.07), H 5.22 (4.55), N 10.18 (12.74).

mL DMF in a 100 mL round-bottom flask, and the mixture was heated with stirring almost to boiling to dissolve the porphyrin; methyl *p*-toluenesulfonate (~2 mL) was added and the solution was then refluxed for 4 h. The methylated pyridiniumporphyrin tetra(tosylate) (cf. **30**) formed as a precipitate when this solution was cooled at ~0°C; this precipitate was filtered off, washed with acetone, and air-dried.

cis- and *trans*-DPhBPyP (**3**, **4**), PhTPyP (**5**), *cis*- and *trans*-B(NPh)BPyP (**11**, **12**), and (NPh)TPyP (**13**), were methylated under conditions similar to those described above (0.20 g porphyrin, 20 mL DMF, 1 mL methyl *p*-toluenesulfonate, 4 h), but the tosylate salts of the methylated porphyrins (**35** and **36**, **32**, **33** and **34**, and **31**, respectively) did not precipitate from the cooled reaction solutions. These were thus reduced in volume by evaporation to ~10 mL; acetone (~100 mL) was then added with stirring, and the resulting mixtures were filtered. The precipitated purple tosylate salts of the methylated porphyrin were then washed with acetone (~20 mL) and dried under vacuum at room temperature. The methylated products **34–36** were further washed with cold water (~20 mL), and then dried under vacuum at room temperature.

The tosylate salts were converted to the corresponding chloride salts by passing an aqueous solution of the porphyrin through an anion exchange column (Cl^-). The aqueous solutions of the tosylate salts of Tet(MPy)P (**30**), (NPh)T(MPy)P (**31**), and T(MPy)PhP (**32**) were obtained by stirring the products in hot water (~20 mL for 0.2 g porphyrin). The tosylate salts of *cis*- and *trans*-B(MPy)B(NPh)P (**33**, **34**), and *cis*- and *trans*-B(MPy)DPhP (**35**, **36**) were dissolved by stirring these materials (0.2 g) with the exchange resin (~2 mL) in hot water (40 mL). The purple aqueous solutions from the anion exchange resin were evaporated to dryness, and acetone (~10 mL) was added to the residues; the suspensions were filtered, and the collected materials dried under vacuum at 100°C. The overall yields of methylation followed by anion conversion were ~90%.

The chloride salts of *cis*- and *trans*-B(MPy)B(NPh)P (**33**, **34**), and *cis* and *trans*-B(MPy)DPhP (**35**, **36**), were further purified by dialysis in attempts to obtain better elemental analyses. These attempts were successful except in the case of **34**, where a satisfactory analysis was not obtained; an observed low solubility of **34** leads to difficulties in purification.

[b]Signals for the pyrrole and 2,6-methylpyridinium protons overlap.

FAB mass spectral data for selected porphyrins are noted in footnote *g* of Table 1. The ^{1}H NMR data of all the anionic and cationic porphyrins are given in Tables 2 and 3, respectively; the spectra recorded in DMSO-d_6 were independent of concentration from 0.002 to 0.02 M, and we assume aggregation phenomena are not important in this solvent (3*b*, 3*c*). The UV–VIS spectra of the water-soluble porphyrins in aqueous solution are complicated because of aggregation phenomena, which is more fully discussed elsewhere (3*b*, 3*c*). Table 4 presents such spectral data at one concentration (1.0×10^{-5} M) in distilled water.

Partition coefficients

The porphyrin free bases (as sodium or chloride salts) were dissolved in distilled water saturated with *n*-octanol (10 mL) to make 5×10^{-6} M solutions which were convenient for absorbance measurements (A_e values) at the Soret-band maximum. Each solution (5.00 mL) was then mixed with *n*-octanol saturated with water (5.00 mL), shaken for 1 h, and centrifuged (600 RPM, 5 min) in order to separate the layers. The absorbances of the aqueous fractions (A_f) were then remeasured at the Soret maximum. Partition coefficient (P) values were then calculated as $(A_e - A_f)/A_f$, and are listed in Table 4. The method follows a standard procedure (13).

Accumulation in cells

Accumulation of the porphyrins by human cancer cells was determined using a fluorometric assay (14). The HT-29 cells (1×10^6) were seeded into 10 cm Petri dishes with 15 mL RPMI+/+ medium and incubated at 37°C for 2 d to form subconfluent monolayers. The drug solutions (17 mL) at 100 μM were made from each of the drug stock solutions by dilution in RPMI–/+ medium. The Petri dishes with subconfluent monolayers were rinsed with phosphate buffer saline solution (PBS) three times to remove traces of serum in the medium and thus avoid interactions between the drugs and serum; then the drug solution (5 mL) was added to each of three Petri dishes, which were wrapped immediately in Al foil to avoid possible photosensitization, and then incubated for 1 h. Thereafter, the drug solutions were decanted, and the dishes rinsed with PBS solution three times. The

[c]*P* values <0.01 are presented as 0.
[d]Minimum ε values, because the compound is impure (see text).

cells were harvested using a rubber policeman instead of trypsinization to avoid possible interactions with the drugs, and were resuspended into 10 mL PBS solution by vortexing (for another wash) in dilution tubes. Controls were also done with identical experiments, but without the drug treatment. Cells in two such controls were also harvested and counted, the average giving the number of cells per Petri dish.

Cells in the PBS solution were centrifuged, and the PBS solution was poured off. ScintiGest solution (from Fisher Scientific, 10%, 5.00 mL) was added to each of the dilution tubes, which were then wrapped in Al foil to prevent possible photo-destruction of the drugs. The solutions were kept at 37°C for at least 24 h to digest the cells. Standard solutions at 0.10–5 μM, made by diluting 100 μM drug solution with 10% ScintiGest, were also wrapped in foil and treated similarly at 37°C.

The concentrations of the drugs in the digested solutions were measured by fluorescence using a Farrent Optical System 3 scanning spectrometer at the maxima for excitation (scanned from 380 to 500 nm) and emission (scanned from 600 to 700 nm). Results were calibrated by using standard solutions of each drug. At least two or three experiments were performed for each porphyrin. Some samples were too concentrated for the measurements, and so were diluted 10–50 times; the diluted samples were again wrapped in foil and kept at 37°C for at least another 12 h to assure reproducible results.

Toxicity

The toxicities of the compounds were measured by incubating CHO cells with the 100 μM drug solutions for various time intervals (to a maximum of 3 h) under 1 atm (101.3 kPa) of either air (oxic conditions) or N_2 (hypoxic conditions), as described in the literature (15).

Toxicity was also assessed with subconfluent monolayers of HT-29 cells for some selected porphyrins. The experiments were performed as in the "cell accumulation" experiments except that two Petri dishes were treated with each drug solution, one being incubated in the dark at 37°C for 1 h, and the other for 2 h. The drug solutions were then poured off, and the cells were rinsed with PBS, trypsinized, and added into dilution tubes containing 10 mL of PBS solution. The cell concentrations were counted, and ~2×10^5 cells were taken from each tube and added to another dilution tube containing 10 mL of RPMI+/– medium; these cells were washed again, counted, and plated. The colonies were stained (methylene blue, Gilco) and counted 13 d later. The plate efficiency (PE) values were calculated as (number of colonies)/(number of cells plated).

Radiosensitization in hypoxic conditions

A published procedure was followed for the radiosensitization assays (15, 16). Irradiation was performed using an X-ray source (Philips, 250 kV, 0.5 mm Cu). A suspension of CHO cells in a drug solution of α–/– or α+/– medium, stirred under N_2 at 37°C for 1 h to produce hypoxic conditions, was chilled at 0°C at least for 5 min before irradiation. After irradiation, the cells were washed, counted, and plated; colonies were counted 7 d later. The surviving fraction (SF) was calculated as (PE with irradiation)/(PE without irradiation). The survival curves were obtained by plotting log SF vs. radiation dose (17). The sensitization enhancement ratio (SER) was calculated at 1% survival, which is commonly chosen for comparison (17), as (dose without drug)/(dose with drug).

Photosensitization

These experiments were carried out following an established procedure (18) with minor changes. HT-29 cells (1×10^6) were seeded into tissue culture flasks 2 d before experiments. The subconfluent monolayers were then treated with 30 or 50 μM drug solutions (5 mL) as described in the cell accumulation experiments except that cells were harvested by trypsinization (6 min). Cells were counted, and 2×10^6 cells were taken and washed with 10 mL of PBS solution, resuspended in 1 mL of cold PBS solution, and chilled in ice.

A tunable light source (Photo Technology International Inc., model 500) was adjusted to 630 ± 10 nm. To a Petri dish, placed on ice that had been covered with a black cloth, was added 120 μL of cell solution, and the sample was then irradiated to a certain dose; 100 μL of solution was recovered and added to a dilution tube containing 9.9 mL of RPMI–/+ medium. The doses used under aerobic conditions were typically 0, 0.25, 0.50, 0.75, 1.0, 1.5, 2.0 J/cm^2 (maximum exposure being ~1 min) and a new Petri dish was used for each sample. The diluted samples were then washed with RPMI–/+ medium, counted, and plated. Colonies were stained and counted 13 d later; PE values were calculated as in toxicity experiments.

Results and discussion

Synthesis and characterization of the porphyrins

There are several literature reports on the sulfonation of TetPhP (**1**) to synthesize Tet(SPh)P (**21**) (4, 7, 19–22); the sulfonation procedures reported here are essentially the same as a literature one (4) except that shorter reaction times are employed. Preliminary studies on the reaction time for different types of porphyrins were also carried out. Samples were taken of the reaction mixture at different reaction times, and the porphyrin samples were then isolated (as described in the synthesis procedure), and their ^1H NMR spectra recorded. The degree of sulfonation was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12

For personal use only.

calculated by the integration ratio of the peaks for the sulfonatophenyl and the phenyl protons, which are readily distinguished (Table 2 and ref. 3*a*). The more pyridyl groups present, the longer the reaction time needed. For instance, sulfonation of (NPh)TPhP (**7**) to give **17** is complete in 0.5 h; for *cis*-(NPh)DPhPyP (**10**) to give **22** requires 6 h reaction time; and sulfonation time for *cis*- or *trans*-DPhBPyP (**3** or **4**, 12 h) to give **24** or **25**, respectively, is longer than that required for TetPhP (**1**, 4 h). A pyridyl substituent, which would be protonated in the acidic conditions, was never sulfonated, as expected under these conditions.

Major differences have been reported (4, 7, 19–22) for purification of the sulfonated porphyrin Tet(SPh)P (**21**). Following studies in 1962 by Winkelman (20) on the localization of sulfonated TetPhP in tumors, Fleischer et al. (19) developed a synthetic method using six precipitations of the ammonium salt of **21** from MeOH by addition of acetone. Srivastava and Tsutsui (4) later used lime to precipitate the excess acid as calcium sulfate and then isolated **21** as the sodium salt following recrystallization from aqueous EtOH. Busby et al. (21) pointed out problems with these procedures, and reported a dialysis method to purify Na_4(Tet(SPh)P). Celite and Sephadex G-10 have also been used to chromatographically purify ammonium salts of (**21**) (22), and (APh)T(SPh)P (**17**) (8), respectively. Most recently, Sutter et al. (7) used *o*-phenanthroline to separate **21** from an aqueous acid solution.

We found that the "neutralization by lime" method (4) gave **21** contaminated by Ca salts, while use of $Ba(OH)_2$ gave coprecipitation of the sulfonated barium porphyrin. Use of a Sephadex G-10 chromatography column gave a low yield because of absorption of the porphyrin by the stationary phase. Dialysis was shown to be a good purification method for all the sulfonated porphyrins, although **21** tended to diffuse through the membrane, resulting in a low yield. Related to the effectiveness of the dialysis process are probably the different aggregation properties of the various sulfonated porphyrins, which are discussed elsewhere (3*b*, 3*c*).

Solvation of ionic porphyrins by water molecules (hydration) is a well-known phenomenon that gives rise to difficulties in determining elemental analyses. Taking Tet(SPh)P compounds (**21**) as an example, our Na_4 salt dried at 100°C analyzed well for a decahydrate and the ^{1}H NMR spectra in DMSO-d_6 showed free water to the amount of 10 ± 2 molecules per porphyrin; Srivastava and Tsutsui (4) reported only N and S analyses for the Na_4 salt, also dried at 100°C, a dodecahydrate being formulated, while more vigorous drying (at 150°C) gave a compound formulated as anhydrous and again only percent N and S were given (21). No analysis was given for the phenanthrolinium salt (7). The C, H, and N analyses reported for the $(NH_4)_4$ salt corresponded to a nonahydrate (19, 22). All of the porphyrins synthesized are hydrated, as evidenced by ^{1}H NMR data, which support at least semi-quantitatively the formulations given in Table 1. The ^{1}H data (Tables 2 and 3) reveal the presence in all cases, except for some geometrical isomers (see below), of just a single porphyrin species. We did not attempt to remove hydrated water completely because handling of hygroscopic samples for biological experiments is inconvenient and inappropriate.

The ^{1}H NMR spectra of Na_4Tet(SPh)P (**21**) in D_2O and in DMSO-d_6 have been reported before (4, 21, 23), and the data obtained here (Table 2) agree with the literature data. The assignments of the resonances are discussed below.

Sulfonation of the nitro precursor (NPh)TPhP (**7**) for 30 min gave the amino product Na_3(APh)T(SPh)P (**17**) instead of the expected nitro product Na_3(NPh)T(SPh)P (**18**); the yield was ~40%, relatively low compared to the 80% yield of **17** formed from sulfonation of (APh)TPhP (**14**). The reducing species is probably an intermediate formed by destruction of the porphyrin. Longer reaction times decrease the yield of the amino species (e.g., 13% after 4 h), but do not give a sulfonated nitro porphyrin. The characteristic signals for an aminophenyl substituent are readily seen in a ^{1}H NMR spectrum, and are easily distinguished from those of a nitrophenyl substituent (Table 2, cf. **17** and **22**).

Porphyrin **17** as the trisodium salt was prepared previously by Kruper et al. via sulfonation of **14** (8). Elemental analysis data were not reported, but the ^{1}H NMR data in DMSO-d_6 match closely those we give in Table 2; the UV–VIS spectrum of the tris(ammonium) salt in 0.1 M $(NH_4)_2CO_3$ was reported as λ_{max} ($\epsilon \times 10^{-3}$, M^{-1} cm^{-1}): 415(295), 529(12.3), 562(10.0), and 643(4.1), but the concentration used was not quoted and thus comparison with our data (Table 4) is not very meaningful. The other six isolated, analyzed sulfonated porphyrins (**19**, **20**, **22**–**25**), and those characterized just by ^{1}H NMR data (**26**–**29**), were not reported on previously, although data on a Ni(II) complex of **23** have appeared (24).

Sulfonation of pure *cis*- and *trans*-B(APh)DPhP (**15** and **16**, respectively) gives the expected bisaminophenyl, bis(sulfonated)phenyl compounds **19** and **20**, respectively.

Some nitro-reduction is again observed during sulfonation of the mixture of *cis*- and *trans*-B(NPh)DPhP (**8** and **9**). The ^{1}H NMR spectra of the three products isolated after a column separation are shown in Fig. 3 and Table 2, and are consistent with each product being a mixture of *cis* and *trans* isomers. In spectrum A, the two doublets (8H) in the δ 8.5–8.7 region correspond to two NPh substituents; in spectrum B, the intensity of these two doublets is reduced to 4H, while two doublets (4H) at δ 7.02 and 7.87 appear, corresponding to one APh; in spectrum C, only the peaks (8H) for APh are observed. The products, corresponding to spectra A, B, and C, are thus identified as a mixture of *cis*- and *trans*-B(NPh)B(SPh)P (**26** and **27**), a mixture of *cis*- and *trans*-(APh)(NPh)B(SPh)P (**28** and **29**), and a mixture of *cis*- and *trans*-B(APh)B(SPh)P (**19** and **20**), respectively. The patterns of the pyrrole signals of various porphyrin structures have been discussed in our recent paper (3a); for a *cis* isomer with two different *meso* substituents, e.g., **19**, the pyrrole protons are expected to give two singlets and two doublets, while for a *trans* isomer, e.g. **20**, two doublets are expected. In the spectrum of pure **19**, synthesized by sulfonation of **15**, each of the two expected pyrrole singlets overlaps with one of the two expected pyrrole doublets in the δ 8.7–9.0 region. The expected two doublets for the pyrrole protons of the pure *trans* isomer (**20**) appear at essentially the same frequencies as the other two doublets (or singlets) of the *cis* isomer, so that the spectrum of the isomer mixture looks similar in this region to the spectrum of the *cis* isomer. Attempted separation of each of the *cis*- and *trans*-isomer mixtures using silica gel failed, and the mixtures were only isolated in sufficient amounts for recording NMR spectra. The trend in the singlets for the *N*-pyrrole protons, at δ –2.91, –2.84, and –2.78 for the bis(nitro), mono(amino)–mono(nitro), and the bis(amino) species, respectively, can be rationalized in terms of electronic effects of the substituents (see below).

Sulfonation of *cis*-(NPh)DPhPyP (**10**) in a 6 h reaction time gives the unreduced nitroporphyrin *cis*-(NPh)PyB(SPh)P (**22**) as the major product, although a minor contaminant, an amino-

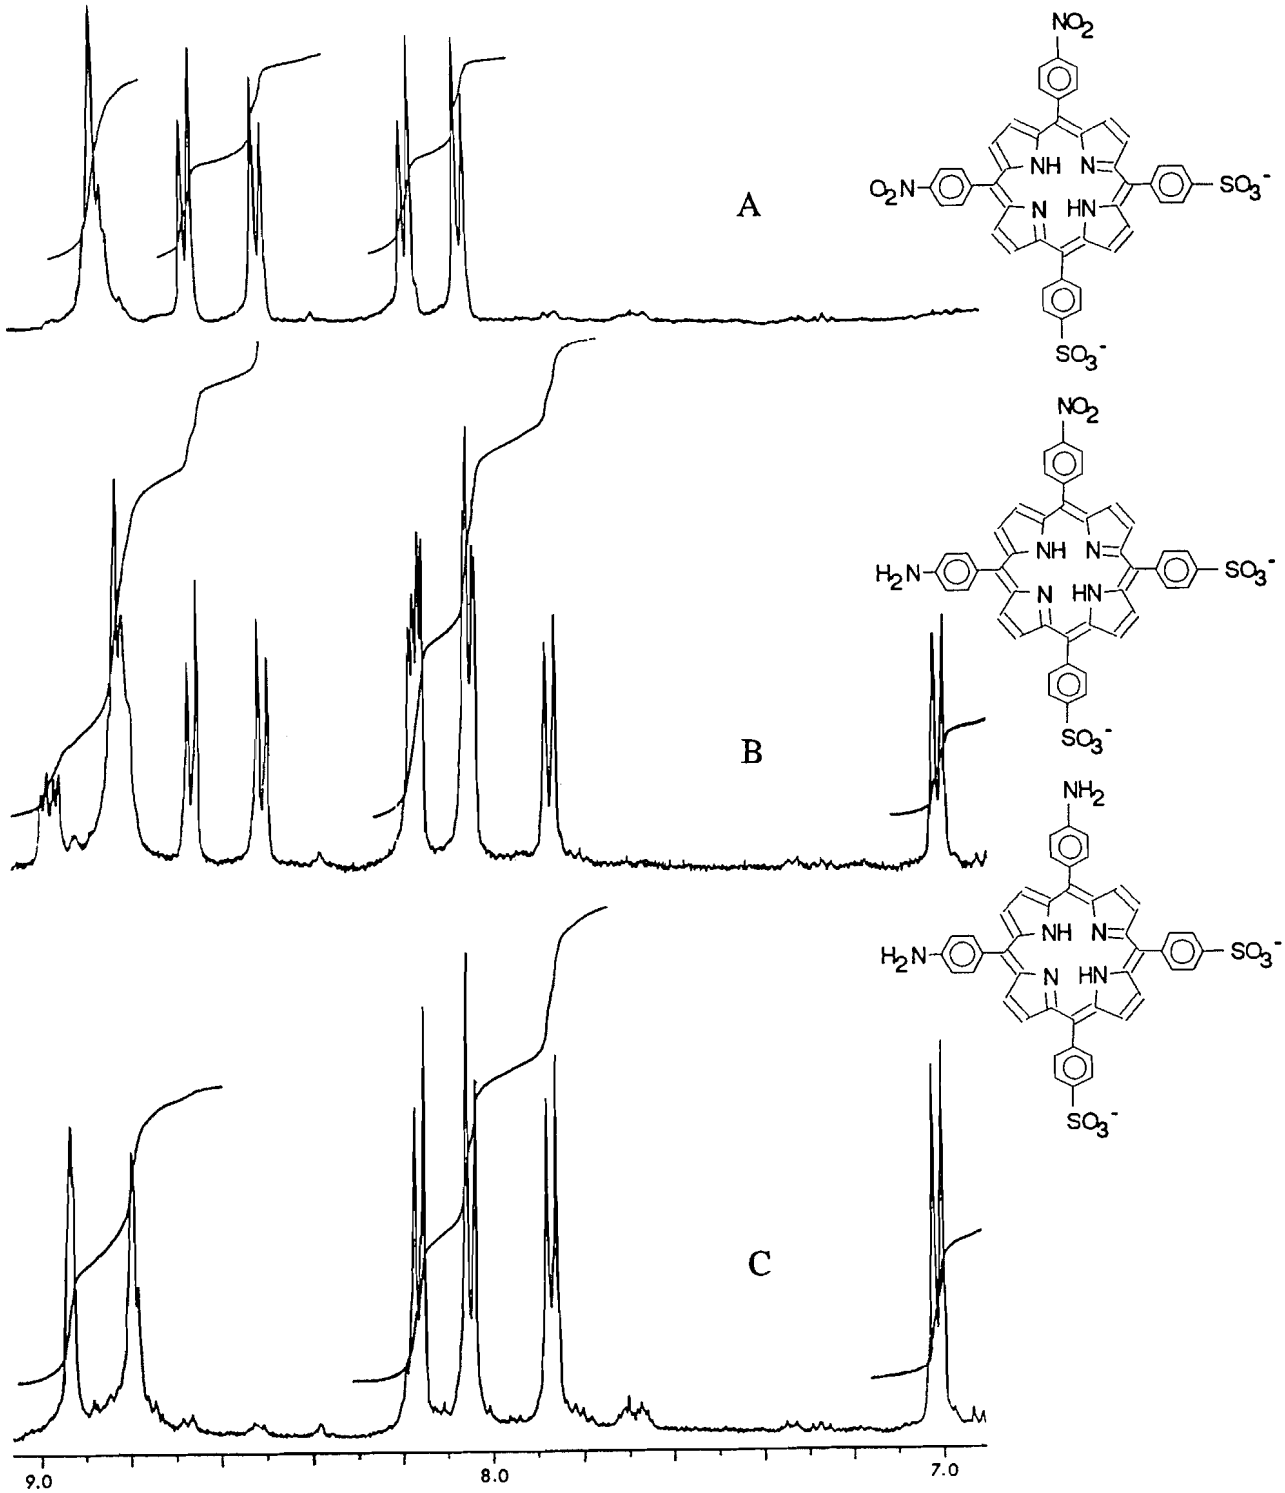

FIG. 3. ^{1}H NMR spectra of **26** and **27** (*A*), **28** and **29** (*B*), and **19** and **20** (*C*) in DMSO-d_6; the structures drawn are for the *cis* isomers, but the spectra refer to *cis/trans* mixtures.

substituted product, as evidenced by ^{1}H NMR, was removed using column chromatography. Compared to the (NPh)TPhP (**5**) system, the presence of the protonated pyridyl in **10** in acidic solution might stabilize this porphyrin structure against electrophilic attack and perhaps limit the formation of an intermediate reducing species. The ^{1}H NMR spectra of samples taken at different reaction times show that a reaction time of 6 h was optimal, because more amino porphyrin was formed with longer reaction times, and incomplete sulfonation was evident with shorter reaction times.

Methylation of pyridyl moieties on a porphyrin was easily performed with methyl 4-toluenesulfonate in DMF with a high yield, as described in the literature (6), although we found that a reaction time of 4 h was adequate instead of overnight as reported; prolonged reaction times caused complications in isolation of the product. The tosylate salts of the dicationic porphy-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

rins **33–36** are insoluble in cold water or acetone, but are soluble in a mixture of these two solvents, presumably because organic solvents including acetone break up the aggregation of such porphyrins (25) and therefore increase their solubility in water. Some water-soluble impurities in these dicationic products were washed off using cold water.

The perchlorate salt of the diacid of Tet(MPy)P (**30**) (26), and the tetra(tosylate)salt of the free base porphyrin (6) have been synthesized previously, but characterized only by elemental analysis and UV-VIS spectra in aqueous solution. The tetrachloride salt has been noted in later literature (2, 27), but NMR data for this salt were reported only recently (28) along with those for the chlorides of T(MPy)PhP (**32**), and *cis*- and *trans*-B(MPy)DPhP (**35** and **36**), while our studies were in progress. However, elemental analyses for the chlorides were not reported, while the ^{1}H NMR spectra were reported in D_2O, CD_3OD, or CD_3OD–CD_2Cl_2 without specific reference to the solvent used for each compound, and the UV–VIS spectra in aqueous solutions were reported without mention of concentration (28). The literature ^{1}H NMR data for **30**, **32**, **35** and **36** (28) appear to be somewhat less well resolved than ours (Table 3); there is general agreement, and differences of up to 0.7 ppm that are noted for certain resonances probably reflect differences in solvent. The reported UV–VIS data are in reasonable agreement with ours (Table 4), but our λ_{max} values are consistently lower (by 2–5 nm) than those reported.

Dialysis was also attempted for final purification of all the methylpyridinium-porphyrin chlorides, but a major loss of product was observed during dialysis of Tet(MPy)PCl_4 (**30**), this probably reflecting different aggregation properties of this compound in comparison to those of the other cationic porphyrins (3*b*, 3*c*).

Methylpyridinium porphyrins containing nitrophenyl moieties (**31**, **33** and **34**) have not been reported previously.

Assignments of ^{1}H NMR resonances

The resonances given in Tables 2 and 3 for the NPh, Py, and APh protons of the anionic porphyrins, and for the NPh and Ph protons of the cationic porphyrins, were assigned using the shielding parameters method that we discussed recently (3*a*). The H–H coupling characteristics of these substituents were also discussed in the same report (3*a*). To similarly assign SPh proton resonances (two doublets, J_{HH} = 8.0 Hz) for the anionic porphyrins requires the NMR data for TetPhP (**1**) in DMSO-d_6, which are not available because of low solubility of **1** in DMSO, and the shielding parameters (29) for the sulfonato substituent on a phenyl ring, which have also not been reported. However, the two doublets of the SPh protons in the spectrum of Tet(SPh)P (**21**) in DMSO-d_6 were assigned unambiguously by using partial deuteration at the 2,6-positions (23), and our assignments in Table 2 have been made accordingly: the resonances at δ ~8.18 and ~8.05 are attributed to the 2,6- and 3,5-SPh protons, respectively. The ^{1}H NMR spectra of the phenyl-containing porphyrins **32**, **35**, and **36** (Table 3) show the 2,6- and 3,4,5-phenyl protons at δ ~8.22 and ~7.90, respectively, and thus substitution of the 4-phenyl proton by sulfonato (an electron-withdrawing group) is expected to give an increase in both δ values, i.e., positive shielding parameters are expected for a sulfonato substituent (29). Our data yield a plausible shielding parameter value of ~ +0.15 ppm for the *ortho* (3,5) positions, but a rather surprising value of ~ –0.04 for the *meta* (2,6) positions. By considering the data for PyT(SPh)P (**23**) in Table 2, and that the introduction of a methyl group onto a pyridyl should result in a positive shielding parameter for both *meta* and *ortho* protons, the peaks of the MPy protons (which appear as two doublets with J_{HH} = 6.0 Hz) of cationic porphyrins can be assigned, with the 3,5-MPy protons at δ 9.46–9.55 and the 2,6-MPy protons at δ 9.00–9.03 (Table 3). Our assignments agree with those in literature reports (28, 30), although the studies involve different solvents.

The pyrrole proton signals in the spectra of the water-soluble porphyrins are broad and (or) overlap each other except in the spectra of the aminophenyl-sulfonatophenyl porphyrins, **17**, **19**, and **20** (Tables 2 and 3). Using the method that we discussed recently (3*a*), and considering that APh and SPh are electron-donating and electron-withdrawing groups, respectively, some of the pyrrole resonances can then be assigned. For example, the doublet at δ 8.99 (J = 4.3 Hz) for (APh)T(SPh)P (**17**) is assigned to H_3 and H_7 (see Fig. 1 for the numbering system), and the broad singlet at δ 8.85 (6H) comprises an overlapping doublet (2H, H_2 and H_8) and singlet (4H, H_{12}, H_{13}, H_{17}, and H_{18}) Similarly for *cis*-B(APh)B(SPh)P (**19**), the δ 8.92 signal is an overlapping singlet (H_7 and H_8) and doublet (H_3 and H_{12}), and the δ 8.79 signal is an overlapping singlet (H_{17} and H_{18}) and doublet (H_2 and H_{13}). In the spectrum of *trans*-B(APh)B(SPh)P (**20**), the doublet at δ 8.94 is assigned to H_3, H_7, H_{13}, and H_{17}, and the doublet at δ 8.79 to H_2, H_8, H_{12}, and H_{18}.

A singlet corresponding to the *N*-pyrrole protons (2H) always appears at δ –2.8 to –3.1 ppm. With the presence of an electron-donating group, e.g., APh, this signal appears at relatively lower field, while the reverse is seen for an electron-withdrawing group, e.g., SPh and MPy. Thus, the *N*-pyrrole protons of **17** (one APh, three SPh) resonate at δ –2.80, while those of **21** (four SPh) resonate at δ –2.95, and those of **30** (four MPy) resonate at even higher field, δ –3.10. If this trend is a more general one, the data for the *N*-pyrrole protons (see Tables 2 and 3, and data in ref. 3*a*), imply electron-withdrawing strengths in the order: MPy > NPh > Py > SPh > Ph > APh. Some of the relative electron-withdrawing strengths are well established (NPh > SPh > Ph > APh) (31), while others are not so well known (e.g., MPy > NPh > Py > SPh) and may, at least partly, be specific to porphyrin systems.

Mass spectral and partition coefficient data

As noted in footnote *g* of Table 1, the major peaks for selected anionic porphyrins in the anionic FAB spectra (3-nitrobenzyl alcohol matrix) are $(M - Na)^-$ or $(M - 2Na + H)^-$. The EI mass spectrum of (Tet(MPy)P)Cl_4 (**30**) was also recorded; 678 ($(M - 4Cl)^+$, 100%), 679 (52%), 680 (52%), and 681 (27%) were the main peaks detected. The main peaks in an EI spectrum of (T(MPy)PhP)Cl_3 (**32**) were at 618 ($(M - 3Cl - 3CH_3)^+$, 100%) and 619 (43%). The data from cationic FAB spectra (3-nitrobenzyl alcohol matrix) of selected cationic porphyrins are also noted in footnote *g*, and the major peaks are those of the porphyrin fragments without the counterions. Sari et al. (28) have reported FAB mass spectral data for **30**, **32**, and **35**, but in different matrices; in contrast to our data, major peaks corresponded to species with complete loss of methyl groups.

A partition coefficient value (P) is one factor that determines the ability of a drug to diffuse through biomembranes (32), and such values determined here are presented in Table 4. It should be noted that their determination depends on the validity of Beer's law for the porphyrins in aqueous solutions, while deviation from this are commonly found because of aggregation of the porphyrins (3*b*, 3*c*). Nevertheless, the measurements pro-

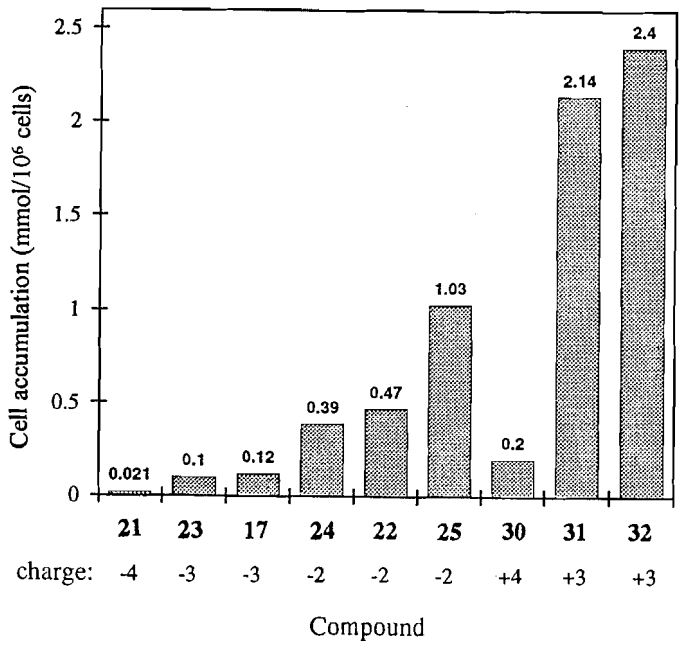

FIG. 4. Drug accumulation in HT-29 cells; data for the dicationic porphyrins, **33** and **35**, were in the 12–25 mmol/10^6 cells range.

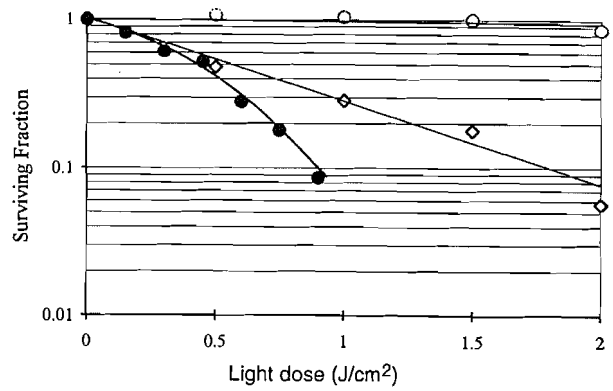

FIG. 5. Photosensitization using 630 nm radiation by compounds **30** (30 μM) ○, **24** (50 M) ◇, and Photofrin II (25 μg/mL) ●, with HT-29 cells.

vide a good approximation of the trends of the *P* values with structure; the error in *P* values is estimated to be 10–25%.

The anionic porphyrins with charges of –3 or –4 (**17**, **21**, **23**) are, not surprisingly, very lipophobic ($P < 0.01$), but those with a charge of –2 (**19**, **20**, **22**, **24**, **25**) are relatively lipophilic (P = 0.16–0.82). Cationic porphyrins are seen to be more lipophilic than anionic porphyrins with equivalent charges, and indeed some of the cationic porphyrins are highly lipophilic (P = 13, 17 for **36** and **35**, respectively) (P values of 0.1, 1.0, and 10 imply 10, 50, and 90% extraction, respectively, into the *n*-octanol). Of note, replacement of a phenyl by the more polar nitrophenyl (**33** and **34** vs. **35** and **36**) gives a significant decrease in *P* values, and a similar but less marked trend is seen on replacing an aminophenyl by pyridyl (**24** and **25** vs. **19** and **20**). The effect of charge distribution, as reflected in *cis* vs. *trans* isomers (**19/20**, **24/25**, **33/34**, **35/36**) is not significant. The effects of structural changes on the partition coefficients are of importance for the design of porphyrin drugs.

In vitro *activities*

All the porphyrins or porphyrin mixtures listed in Tables 2 and 3 are soluble in water. However, the solubilities of the porphyrins **19**, **20**, **34**, and **36** in water are low (<0.1 mM), and in the biological media are even lower; thus, these compounds were not tested in *in vitro* experiments.

The accumulation of porphyrins (**17**, **21–25**, **30–33**, and **35**) in HT-29 cells was studied, and some results are shown in Fig. 4. The data for the dicationic species **33** and **35** were variable and in the range 12–25 mmol/10^6 cells (i.e., 5–10 times the values for **31** or **32**). In general, the accumulation values increase with decreasing charge within both the anionic and cationic series; the cationic species have accumulation values typically an order of magnitude greater than an anionic species of the same charge, which is consistent with the fact that cell membranes are negatively charged. The net charge seems the dominant factor, incorporation of the nitro (**22**), amino (**17**) or pyridyl group(s) (**22–25**) having little effect; the charge distribution also seems significant (*trans*-(**25**) > *cis* (**24**)), this possibly reflecting difference in the mode of interaction of the porphyrins with cell membranes.

Rationalization of the accumulation data is clouded by possible aggregation of the porphyrins which affects the size of the solution species and is governed by the nature, charge, and position of the substituents (3*b*, 3*c*); the degree of aggregation, which could also possibly affect spectral measurements used for the concentration values, could depend on experimental conditions, particularly on the concentration of the cells and particles from cell digestion that could vary in the experiments. The degree of aggregation for anionic species increases with charge as determined within the series **21** < **23** ≈ **17** < **25** (3*b*, 3*c*), which correlates with the accumulation trend, suggesting aggregation could be an important factor.

Some selected water-soluble porphyrins (**17**, **21–25**, and **30**) at 100 μM were nontoxic toward CHO cells for incubation up to 3 h under oxic or hypoxic conditions. Tests on **31** and **32** gave highly irreproducible data, for example, giving SF values of 0–0.7 for "identical" conditions, which were conventional and included exposure to background light; photosensitization processes with background light could be involved, although **31** and **32** were not toxic toward HT-29 cells with 630 nm light in photosensitization studies. Porphyrins **31** and **32** (and **33** and **35**) were nontoxic toward HT-29 cells under oxic conditions in the dark.

The photosensitization studies used an established *in vitro* assay (18) with HT-29 cells using red light. Of porphyrins **23–25** and **30–32**, only **24** shows photosensitization activity and this porphyrin required about twice the light dose of a Photofrin II sample to obtain the same cell kill under corresponding conditions (Fig. 5). Tet(SPh)P (**21**), under certain conditions, is reported to have photosensitizing properties superior to those of Photofrin II (1, 33). The quantum yield of singlet oxygen and the DNA damage produced by light, in the presence of **21** and Tet(MPy)P, have also been studied by others from the interest of PDT (10, 34).

The porphyrin free bases **17**, **21–23**, and **30–33** have very weak, if any, radiosensitization effects, with SER values being in the range 0.92–1.04 either in a medium with or without added serum under hypoxic conditions; both sets of conditions were employed because the presence of serum was reported (35) to result in lower accumulation of Photofrin II, which is a mixture of hematoporphyrin derivatives. Contrary to expectation (see

For personal use only.

Introduction), the presence of nitro groups within **22**, **31**, and **33** did not generate effective radiosensitizers; indeed, the SER values of 0.92–0.94 for these porphyrins imply slight radioprotection. Of note, cobalt(III) complexes of some of the porphyrins do show radiosensitizer ability under corresponding conditions, the most effective being a complex of **33** with SER = 1.22 (*3b*). O'Hara et al. (2) noted that **21** and **30** are ineffective as radiosensitizers, while some cobalt and copper derivatives of these porphyrins, whose characterization was not discussed, were reported to be effective with SER values up to 2.4. The synthesis, characterization, and biochemical studies (including radiosensitization data) on metallo derivatives of porphyrins (of Co, Cu, Zn, and Pt) described in this paper are discussed elsewhere (*3b*, *3c*).

Although the *in vitro* studies reveal disappointing results regarding the potential of the synthesized porphyrins for activity as cytotoxins, and photo- or radiosensitizers, the data from partition coefficient and cell accumulation experiments do assist in designing structures of potential drugs. In any case, the data are very preliminary and further investigations, including variations in drug concentration, cell line, and light wavelength, are ongoing.

Reçu le 23 avril 1994

JACQUES PERROCHEAU, ROBERT CARRIÉ et JEAN-PIERRE FLEURY. Can. J. Chem. **72**, 2458 (1994).

La thermolyse des 1,2,3-triazolines **4**, **5**, **6** permet l'obtention des aziridines correspondantes seulement lorsque X = Y = CO_2Me et encore avec une faible rendement. Par contre la photolyse ou l'évolution en présence d'acide trifluoroacétique donne de bons résultats à condition d'opérer à une température suffisamment basse. L'étude de la thermolyse de **4**–**6** montre un nouveau mode d'évolution des 1,2,3-triazolines non encore signalé dans la littérature. La grande facilité d'élimination du groupement paratoluènesulfonate ou benzoate est certainement le facteur déterminant dans le comportement de ces composés.

JACQUES PERROCHEAU, ROBERT CARRIÉ, and JEAN-PIERRE FLEURY. Can. J. Chem. **72**, 2458 (1994).

Thermolysis of 1,2,3-triazolines **4**, **5**, **6** leads to the corresponding aziridines only when X = Y = CO_2Me, and then with a very low yield. However, photolysis or evolution in the presence of trifluoroacetic acid gives good results when carried out at sufficiently low temperature. The thermolysis study of **4**–**6** shows a new route to 1,2,3-triazoline decomposition that has not yet been mentioned in the literature. The easy elimination of the paratoluenesulfonate or benzoate group explains this particular behaviour.

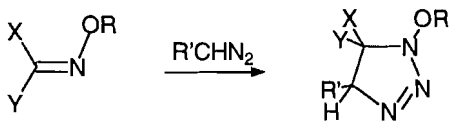
Description des résultats

Dans un travail antérieur (1), nous avons montré que les esters d'oximes **1**, **2** et **3** réagissent avec divers diazocomposés pour conduire aux 1,2,3-triazolines **4**–**6** (Fig. 1).



1 : R = Ts — **4**
2 : R = $COC_6H_4(pZ)$, (Z = H, NO_2) — **5**
3 : R = COMe — **6**

a : X = CN, Y = CO_2Me
b : X = Y = CO_2Me

A : R' = H
B : R' = $(MeO)_2CH$
C : R' = Me
D : R' = Ph

FIG. 1

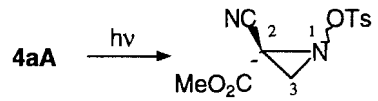
L'évolution thermique et photochimique de ces adduits fait l'objet de ce mémoire. L'étude de la photolyse et le comportement des triazolines marquées à l'azote 15 a facilité l'analyse du comportement thermique relativement complexe de ces composés.

I. Photolyse de quelques 1,2,3-triazolines O-tosylées

La photolyse permet d'obtenir facilement les aziridines. L'identification de celles-ci dans les produits de thermolyse en a été ainsi facilitée.

Seule la photolyse des triazolines **4** (R = Ts) a été étudiée. La thermolyse de ces triazolines ne permet pas l'obtention des aziridines correspondantes sauf lorsque X = Y = CO_2Me, où elles sont obtenues avec des rendements de 30–40%.

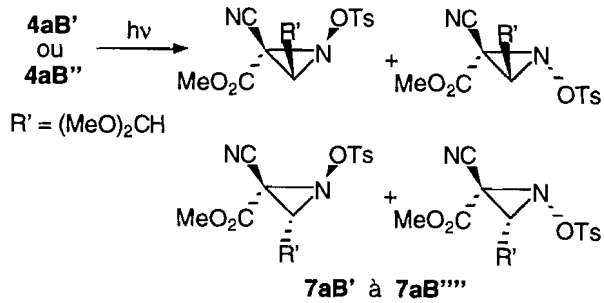
Par contre, la photolyse en solution dans le dichlorométhane à −40°C conduit aux aziridines de façon pratiquement quantitative. La photolyse de **4aA** (X = CN, Y = CO_2Me, R' = H) donne le mélange des deux aziridines diastéréoisomères **7aA'** et **7aA"** (proportions relatives 70/30) (Fig. 2).



4aA —hν→ **7aA'** et **7aA"**

FIG. 2

Pour la triazoline **4aB** (deux diastéréoisomères **4aB'** et **4aB"** dont les stéréochimies ne sont pas attribuées) la formation des quatre aziridines diastéréoisomères **7aB** est observée (Fig. 3).



4aB' ou **4aB"** —hν→ **7aB'** à **7aB""**

R' = $(MeO)_2CH$

FIG. 3

Pour chaque triazoline, les proportions relatives de ces quatre aziridines sont précisées dans le tableau 1.

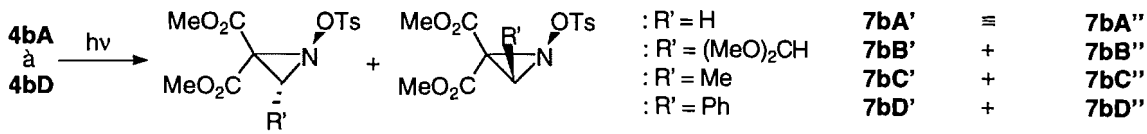

FIG. 4

De même les triazolines **4bA–4bD** donnent les aziridines **7bA–7bD** (Fig. 4).

Lorsque X = CN et Y = CO_2Me, il est nécessaire d'opérer à la température la plus basse possible pour éviter la cycloréversion du diazométhane.

Avec la triazoline **4bA**, à −40°C, on observe dans le produit brut de la réaction 5% d'oxime **8bA** (Schéma 1), composé principalement formé lors de la thermolyse. Ces observations peuvent expliquer les résultats Kostyanovsky et al. (3) : lors de la photolyse de l'ester diéthylique correspondant à **4bA** à −10°C, ils obtiennent à côté de l'aziridine une proportion importante de produits de thermolyse (19% d'oxime de départ, 44% d'oxime correspondant à **8bA**) (Fig. 5).

Les caractéristiques de rmn ^1H confirment la structure des aziridines **7** obtenues. Elles figurent dans le tableau 1. Lorsque X = Y = CO_2Me avec R′ = H, la non-équivalence des protons cycliques et des groupements esters est la conséquence de la haute barrière d'inversion de l'azote. Kostyanovsky et al. (3) ont montré que dans ce type de composés, les groupements précédents restent non équivalents même si le spectre est enregistré dans le diphényléther ou l'α-bromonaphtalène à 200°C.

Remarques : (*i*) L'attribution d'une stéréochimie aux différentes aziridines diastéréoisomères obtenues n'a pas été faite. (*ii*) Certaines aziridines ne sont pas très stables. Par exemple, on constate pour **7bD′** et **7bD″** une évolution totale de l'isomère majoritaire en 45 min après sa dissolution dans le chloroforme à température ambiante.

*II. Thermolyse des 1,2,3 triazolines **4**, **5**, et **6***

Les triazolines **4**, **5** et **6** sont des composés thermiquement peu stables. En solution dans le benzène ou le chloroforme, leur décomposition est totale à température ambiante (6 h – 5 jours suivant la substitution).

Le schéma 1 résume les évolutions thermiques possibles pour les triazolines et propose une interprétation mécanistique de ces évolutions (les composés isolés sont encadrés). Cette tentative de rationalisation du comportement thermique des 1,2,3-triazolines est susceptible d'expliquer les résultats expérimentaux obtenus. Il subsiste toutefois des incertitudes puisqu'un certain nombre d'intermédiaires ne sont pas mis en évidence.

II.1. Triazolines diesters (X = Y = CO_2Me)

Avec les triazolines diesters (X = Y = CO_2Me), la cycloréversion est observée uniquement lorsque R′ = H et 8% de tosylate de méthyle **15** sont mis en évidence à l'aide de la rmn dans le produit brut de thermolyse de la triazoline **4bA**. Comme nous le verrons dans la suite, ce tosylate ne peut résulter que de l'action de l'acide paratoluènesulfonique sur le diazométhane libéré par cycloréversion. Dans tous les autres cas (R′ ≠ H), les oximes **8**, **9** et **10** (55–65%) et les aziridines **7**, **11** et **12** (45–35%) sont exclusivement obtenues. Ces composés sont caractérisés à l'aide de la rmn (voir partie expérimentale, les caractéristiques des aziridines tosylées **7** sont données dans le tableau 1).

Kostyanovsky et al. (3) ont déjà signalé la formation des composés **8** et proposé pour la formation de ces derniers, soit le processus synchrone 2s + 2s + 2s **23** soit le réarrangement du biradical singulet **24** (Fig. 6).

23 **24**

FIG. 6

Les migrations radicalaires de groupements esters n'étant à notre connaissance jamais observées, la première proposition parait plus vraisemblable.

La formation des aziridines **7**, **11**, et **12** peut résulter de la cyclisation du biradical **24** (voie **c**) ou de la substitution nucléophile intramoléculaire de **13** (voie **f**) qui provient de la rupture hétérolytique de la liaison N1—N2 des triazolines diesters (voie **b**).

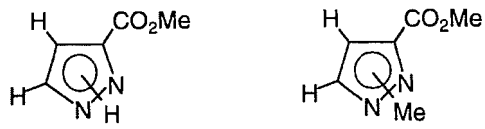
II.2. Triazolines ester nitriles (X = CN, Y = CO_2Me)

II.2.1. Cycloréversion en diazocomposés et esters d'oximes. L'évolution la plus importante est la cycloréversion (≈50% R′ = H à ≈80% R′ = $(MeO)_2CH$)). Cette rétrocycloaddition peut être concertée (voie **a**) ou s'effectuer en deux étapes (voie **b** puis voie **e**). L'oxime O-substituée est identifiée dans tous les cas dans le produit brut de la réaction à l'aide de la rmn par comparaison avec un échantillon authentique.

Le diazoacétal $(MeO)_2CHCHN_2$ est mis en évidence par identification avec un échantillon authentique, lors du suivi de la thermolyse de **4aB** (mélange des deux isomères **4aB′** et **4aB″**) à l'aide de la rmn. La cycloréversion du diazométhane a été vérifiée de deux manières dans le cas plus particulièrement étudié de la triazoline **4aA**.

1. La thermolyse en présence d'acide benzoïque entraîne la formation de benzoate de méthyle identifié à l'aide de la chromatographie de partage gaz–liquide par comparaison avec un échantillon authentique.

2. Si la décomposition est effectuée après addition de propiolate de méthyle, on peut caractériser les pyrazoles **25** et **26** (proportion relative 55/45) ainsi que l'oxime **1a** (62%) à l'aide de la rmn (Fig. 7).



25 **26**

FIG. 7

Remarque : L'addition du diazométhane au propiolate de méthyle donne préférentiellement **25** qui est méthylé pour donner **26** si la réaction est effectuée en présence d'acide paratoluènesulfonique. Les diazocomposés (R′ = H et CH_3) réagissent sur l'acide paratoluènesulfonique (triazolines issues de **1a**, **1b**), les acides benzoïque ou (pNO_2)benzoïque (triazolines issues de **2a**) ou l'acide acétique (triazoline issue de **3a**) pour donner les paratoluènesulfonates, benzoates ou acétates de méthyle ou d'éthyle **15–17** identifiés en rmn ^1H et en chromatographie de partage gaz–liquide par comparaison avec des échantillons authentiques.

II.2.2. Évolution avec perte d'azote. Avec les triazolines **4aC** et **5aC** (R′ = Me) et **4aD** (R′ = Ph), les oxazoles **21** ou **22** sont obtenus, ce qui implique une étape dans laquelle il y a rupture de la liaison entre les deux carbones cycliques des triazolines. Ceci conduit à l'hypothèse suivante : l'azirine **18** résultant de la cyclisation de **14** (R′ ≠ H) peut être protonée sur l'azote par l'acide ROH présent dans le milieu selon un mécanisme mentionné par Taniguchi et collaborateurs (4). L'entité **19** par un réarrangement concerté du type $2\pi s + 2\sigma a$ peut donner **20** puis **21** (ou **22**) en libérant un proton de sorte que le processus est catalytique du point de vue de l'acide.

En partant de l'oxime **1a** marquée à l'azote 15 (52%), on obtient l'oxazole **21** (R = Me) marqué à 52%. Le mécanisme proposé rend compte de cette observation.

Lorsque R′ = H, à côté des oximes **1** ou **2** provenant de la cycloréversion et des esters **15** ou **16**, la réaction conduit à des composés pâteux amorphes, sans doute des polymères présentant en rmn un massif large entre 3,4 et 3,9 ppm (C_6D_6). Il est connu (5) que les azirines correspondantes sont peu stables et polymérisent facilement.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

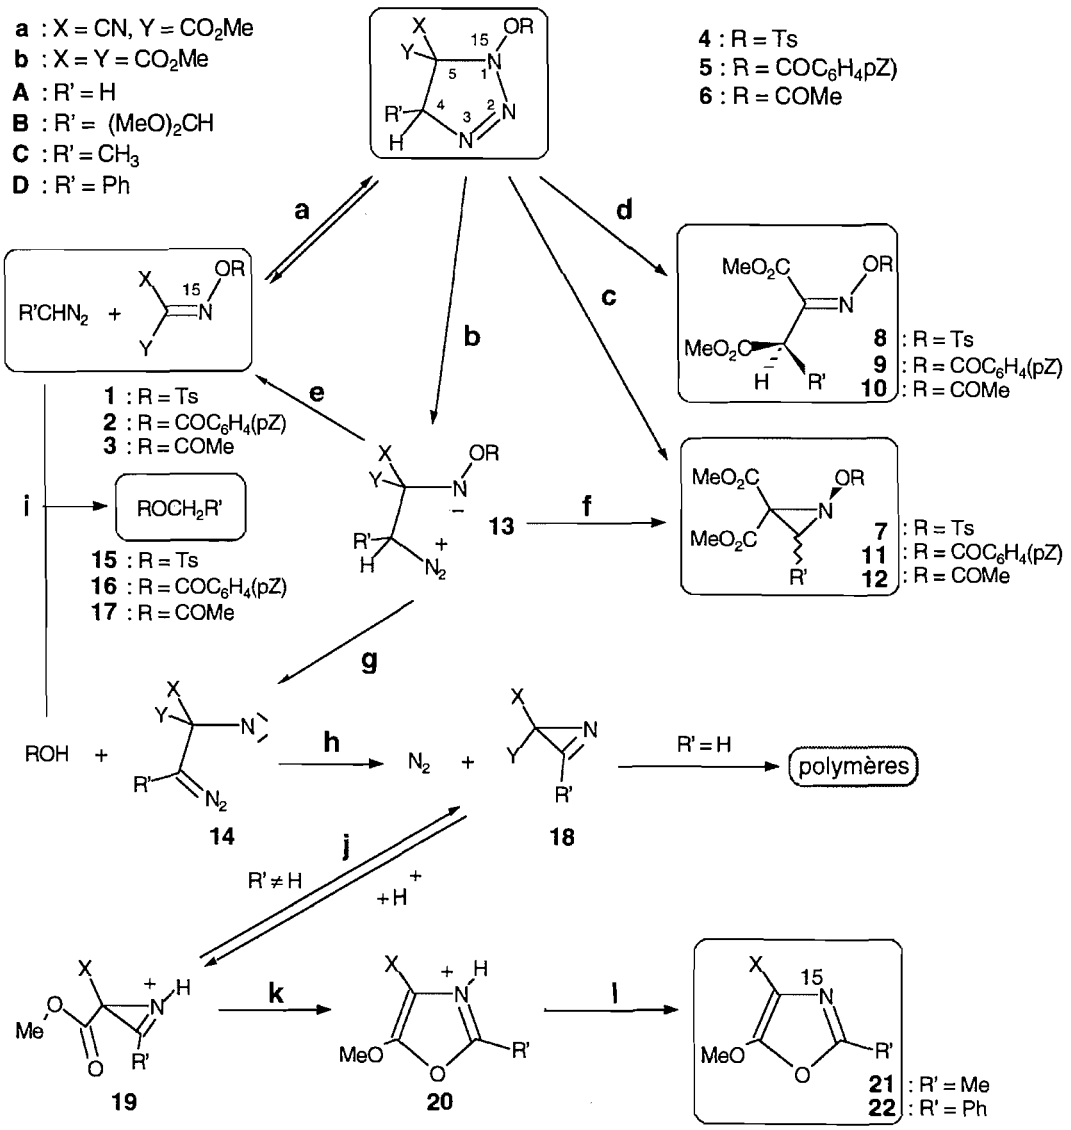


SCHÉMA 1

Enfin les aziridines **7bA′** et **7bA″** (X = CN, Y = CO_2Me, R = Ts, R′ = H), qui peuvent être obtenues par photolyse, n'évoluent pas dans le milieu réactionnel. Ces aziridines ne sont donc pas des intermédiaires dans la formation des oxazoles **21** ou **22**.

Le mécanisme d'évolution des triazolines avec perte d'azote implique donc une rupture hétérolytique entre les atomes N1 et N2 conduisant à **13**. Un tel comportement est signalé dans la littérature (6). L'évolution de **13** est explicitée dans le schéma 1. Le composé **13** donne **14** avec élimination du composé ROH qui est susceptible de réagir avec les diazocomposés libérés dans la cycloréversion.

Remarques : Les essais de préparation de 1,2,3-triazolines disubstituées en 4, intéressantes pour étudier l'évolution des entités analogues à **13**, ont échoué. La faible réactivité du diphényldiazométhane, l'instabilité du diazopropane ne permettent pas d'isoler les triazolines correspondantes.

II.2.3. Structure des oxazoles 21 et 22. En ce qui concerne **21** l'infrarouge, la spectrométrie de masse, la rmn ^1H et ^{13}C sont en accord avec la structure proposée mais ne permettent pas de distinguer **21** de son isomère isoxazole **27** qui pourrait résulter du réarrangement de **19** (Fig. 8).

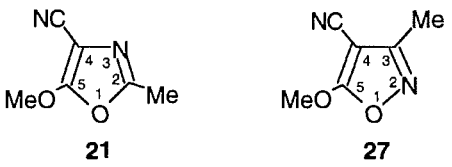

FIG. 8

L'enregistrement du spectre de rmn ^{13}C du dérivé **21** marqué à l'azote 15 (marquage à 52%) apporte un argument décisif. Le carbone du groupement nitrile (δ = 112,4 ppm) est couplé avec l'azote 15. La valeur de la constante observée (7,8 Hz) est caractéristique d'un couplage $^2J_{^{13}C^{15}N}$ lorsque le noyau est en *cis* de la paire libre. Elle est incompatible avec un couplage ^3J et donc avec la structure **27** (7). Dans la mesure où l'on compare deux carbones de même hybridation, il semble bien établi que la proximité de la paire libre est le facteur prépondérant contribuant à la valeur de la constante $^2J_{^{13}C^{15}N}$ (8, 9).

On remarquera que pour X = CN, Y = CO_2Me et R′ = CH_3, l'oxazole obtenu est le même quelle que soit la nature de R. L'analogie des déplacements chimiques des carbones cycliques

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

de **21** et du composé phénylé correspondant conduit à attribuer à ce dernier la structure **22**.

II.3 Conclusion

En ce qui concerne l'évolution thermique des triazolines **4**, **5** et **6**, les points suivants doivent être soulignés :

1. Le remplacement d'un groupement nitrile par un groupement ester (X = Y = CO_2Me) augmente la stabilité thermique des triazolines. Cette observation est valable quels que soient R et R′ (R = Ts, PhCO, Ac; R′ = H, Me, Ph, $(MeO)_2CH$).

2. De même, le remplacement d'un groupement tosyle par un groupement benzoyle augmente la stabilité thermique. Un groupement acétyle la renforce davantage.

3. L'ordre de stabilité croissante en fonction de R′ est le suivant : $(MeOH)_2CH$ > H > Me, Ph. Si X = Y = CO_2Me, on isole dans tous les cas les adduits primaires. Avec X = CN, Y = CO_2Me, ces derniers ne sont pas mis en évidence lorsque R′ = Me ou Ph.

La cycloréversion est une voie d'évolution importante lorsque X = CN, Y = CO_2Me. Dans un premier temps elle a pu faire croire à l'absence de réactivité des esters d'oxime **1a** lorsque les essais d'addition sont effectués à la température ambiante.

*III. Évolution des triazolines **4aA** et **4bA** en présence d'acide trifluoroacétique*

L'action de l'acide trifluoroacétique sur la triazoline **4bA** a déjà été étudiée par Kostyanovsky et al. (3). Il est ainsi possible d'obtenir dans de bonnes conditions l'aziridine correspondante.

Nous avons repris cette étude à −20°C en solution dans le chloroforme, température où les triazolines **4aA** et **4bA** sont stables. L'acide trifluoroacétique en quantité stœchiométrique conduit avec d'excellents rendements aux aziridines **7aA′**, **7aA″** d'une part et **7bA** d'autre part. Les caractéristiques de ces composés ont été données précédemment lors de l'étude de la photolyse des triazolines. **7aA′** et **7aA″** sont obtenues dans les mêmes proportions (70/30) que lors de la photolyse de la triazoline correspondante.

La protonation de la triazoline facilite la rupture de la liaison N1—N2 conduisant à l'entité **13** protonée qui évolue de façon spécifique vers l'aziridine correspondante.

*IV. Réaction des oximinomalodinitriles **28** et **29** avec le diazométhane et le diazoéthane*

Les composés **28** et **29** sont préparés selon le schéma de réaction suivant, variante au mode opératoire décrit par Fleury et al. (9) (Fig. 9).

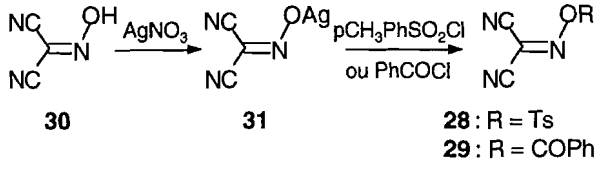

FIG. 9

Avec **28**, l'addition du diazométhane aussi réalisée par Fleury et collaborateurs (10) conduit, lorsqu'elle est effectuée à −20°C, au composé **32′** (52%) accompagné de son isomère **32″** (16%) et du tosylate de méthyle (22%) (intégration des signaux N-Me des différents composés par rapport aux signaux des méthyles des groupements tosyles) (Fig. 10).

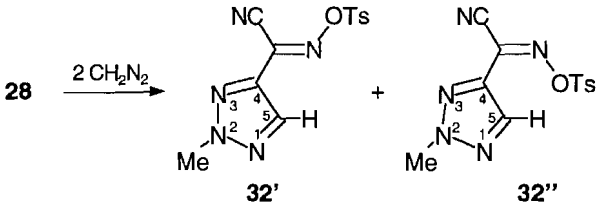

FIG. 10

L'addition du diazométhane à **29** donne le mélange des triazoles **33** (38%) et **34** (ou **35**) (31%). La formation du benzoate de méthyle (21%) et d'un produit non identifié (10%), qui présente un signal attribuable par rmn à un méthyle lié à l'azote, est observé (évaluation rmn) (Fig. 11).

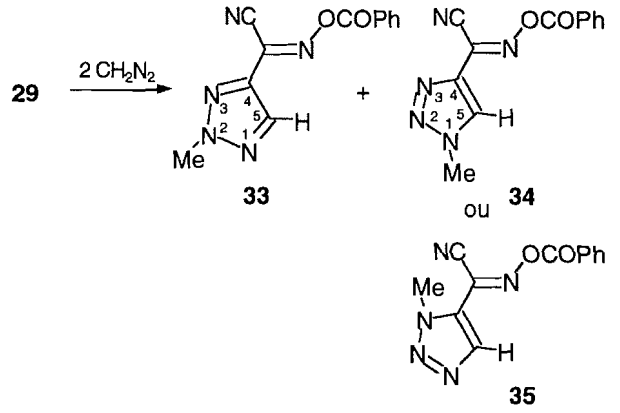

FIG. 11

Les structures de **32′** et de **32″** ont déjà été établies sans ambiguïté par Fleury et collaborateurs (9). De plus, ces auteurs ont montré que **32′** s'isomérise en **32″** en milieu chlorhydrique.

Étant donné l'analogie des caractéristiques de rmn ^{13}C entre **32″** et le produit prépondérant obtenu à partir de **29**, la structure **33** est attribuée à ce dernier. Contrairement à ce qui est observé avec **28**, le second produit ne semble pas être l'isomère géométrique de **33** et la structure **34** (ou **35**) lui est attribuée à l'aide de la rmn ^{13}C. Les déplacements chimiques des carbones des groupements nitriles de **33** et de **34** (ou **35**) sont pratiquement identiques (107,8 et 107,6 ppm). S'il s'agissait d'une isomérie *syn-anti* du motif oxime, les données de la littérature (11) laisserait prévoir une différence notable entre ces deux déplacements chimiques comme il est observé pour **32′** (106,7 ppm) et **32″** (110,9 ppm, $\Delta\delta_{C\equiv N}$ = 4,2 ppm).

Remarque : Contrairement à ce qui est observé avec **32′**, le traitement de **33** en milieu acide dans le méthanol ne conduit pas à l'isomère géométrique attendu mais à l'oxime **36** (Fig. 12), caractérisé à l'aide de la rmn et de la spectroscopie de masse, et au benzoate de méthyle (rmn ^1H).

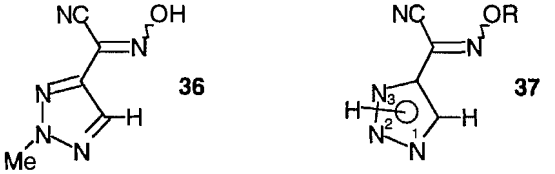

FIG. 12

For personal use only.

Discussion et conclusion

1. Les composés **32′**, **32″**, **33** et **34** (ou **35**) résultent de l'addition préférentielle sur la triple liaison C≡N en *anti* par rapport au groupement OR de l'oxime. L'addition s'effectue préférentiellement sur le groupement nitrile le moins encombré stériquement. De telles additions sur des groupements nitriles activés ont déjà été signalées dans la littérature (12); c'est en particulier le cas des cyano-2 coumarines (13) et de l'α-fluorocinnamonitrile (14).

2. Dans un premier temps, la cycloaddition du diazométhane conduit au triazole tautomère **37** pour lesquels la méthylation par une seconde molécule de diazocomposé peut s'effectuer sur l'un ou l'autre des trois azotes cycliques (azote 1, 2 ou 3) (15). Elle est plus ou moins facile selon la substitution. La méthylation des cycloadduits primaires est facilitée dans notre cas par des traces d'acide paratoluènesulfonique ou benzoïque présentes dans le milieu.

3. La formation de tosylate ou de benzoate de méthyle ne peut s'expliquer que par une cycloaddition compétitive sur la double liaison C=N de l'oxime. La 1,2,3-triazoline correspondante, produit cinétique de la réaction, évolue alors selon le schéma 1. Avec le diazoéthane l'addition sur la double liaison C=N de **28** est exclusivement observée. Seule l'oxime tosylée de départ et le tosylate d'éthyle, résultant respectivement de la cycloréversion et de l'évolution de l'adduit primaire, sont mis en évidence.

Partie expérimentale

L'appareillage de rmn suivant a été utilisé :

Appareil à onde continue JEOL MH100 (100 MHz). Appareil à onde continue Bruker WP 80 CW (80 MHz). Appareil à transformée de Fourier Bruker WP 80 DS (80 MHz pour le proton et 20 MHz pour le carbone 13) du Centre Régional de Mesures Physiques de l'Ouest (C.R.M.P.O.). Appareil à transformée de Fourier Bruker AC 300 P (300 MHz pour le proton et 75 MHz pour le carbone 13) commun aux U.R.A. n° 704 et 415. Le solvant utilisé pour l'enregistrement des spectres de RMN ^1H et ^{13}C est $CDCl_3$ sauf indication contraire. Les déplacements chimiques (δ) sont exprimés en parties par million (ppm) par rapport au tétraméthylsilane (TMS) utilisé comme référence interne. Les constantes de couplage sont exprimées en hertz. Les notations suivantes sont utilisées : s : singulet; d : doublet; t : triplet; q : quadruplet; m : multiplet ou massif non analysable; dq : double quadruplet; tt: triple triplet; tm : triple multiplet; etc.... Les caractéristiques de rmn concernant les protons aromatiques ne sont pas données.

Les spectres de masse sont enregistrés à l'aide d'un spectromètre Varian MAT 311 du C.R.M.P.O. L'énergie du faisceau électronique est de 70 eV, l'intensité du courant d'émission 300 μA et la tension d'accélération des ions 3 kV.

Les analyses élémentaires sont effectuées au Laboratoire Central de Microanalyse du C.N.R.S. de Lyon.

Les points de fusion sont déterminés sur un banc chauffant Kofler et ne sont pas corrigés.

La préparation des oximes **1**, **2**, **3** et des triazolines **4**, **5** et **6** a été décrite dans un mémoire antérieur (1).

I. Photolyse des 1,2,3-triazolines ***4***

Mode opératoire général

Les photolyses à basse température (−40 à −50°C) sont effectuées dans un réacteur refroidi dans un cryostat. La réfrigération de la double enveloppe en Pyrex entourant la lampe est assurée par une circulation d'éther de pétrole à −50°C. Les triazolines sont dissoutes sous atmosphère d'azote dans 250 cm^{-3} de dichlorométhane anhydre préalablement refroidi. La solution est dégazée par barbotage d'azote puis irradiée à l'aide d'une lampe Philips HPK 125 W.

I.1. Photolyse de la triazoline ***4aA***. La photolyse de 1,00 g de triazoline **4aA** demande 20 h. Le spectre de rmn ^1H du résidu après distillation du solvant montre la formation des deux aziridines **7aA′** et **7aA″**. Le résidu repris à l'éther abandonne 0,8 g de cristaux (F = 102–108°C, mélange 70/30 des deux isomères (analyse rmn)) (Rdt = 87%).

Les deux isomères sont séparés à l'aide de la chromatographie sur colonne de silice (25 g, éluant : éther/éther de pétrole 50/50). On sépare ainsi successivement : (*i*) 0,05 g de l'aziridine minoritaire (F = 118°C); (*ii*) 0,13 g d'un mélange 60 : 40 (majoritaire/minoritaire); (*iii*) 0,23 g de l'aziridine majoritaire (F = 136°C). **7aA′** (ou **7aA″**), isomère majoritaire 70%; rmn ^{13}C, δ : 37,6 (dd, aspect de triplet, $^2J_{CH} \approx {}^2J'_{CH}$ = 3, C2); 44,8 (dd, $^1J_{CH}$ = 177 et 184, C3); 111,5 (dd, $^3J_{CH}$ = 3 et 5, *C*≡N); 162,1 (s, *C*O_2Me). **7aA″** (ou **7aA′**), isomère minoritaire 30%; rmn ^{13}C, δ : 38,1 (dd, aspect de triplet, $^2J_{CH} = {}^2J'_{CH}$ = 3, C2); 43,0 (dd, $^1J_{CH} \approx {}^1J'_{CH}$ = 181, C_3); 113,6 (dd, aspect de triplet, $^3J_{CH} \approx {}^3J'_{CH}$ = 4, *C*≡N); 159,1 (s, *C*O_2Me). **7aA′** et **7aA″**, analyse : $C_{12}H_{12}N_2O_5S$, calc. % : C 48,64; H 4,08; N 9,45. Mélange (60/40) : tr. : C 48,43; H 4,02; N 9,45. Isomère majoritaire : tr : C 48,66; H 4,02; N 9,31.

I.2. Photolyse de la triazoline ***4aB′***. La photolyse de 950 mg du dérivé **4aB′** (Déc. 120–125°C) demande 12 h pour être totale. Après analyse à l'aide de la rmn (tableau 1), le résidu (800 mg sous forme d'huile) est purifié par filtration sur 10 g de silice (éluant : éther/éther de pétrole 50/50). On obtient ainsi 640 mg de cristaux, mélange des aziridines **7aB** diastéréoisomères (Rdt = 70%; F = 119–122°C). **7aB**, analyse : $C_{15}H_{18}N_2O_7S$ (mélange d'isomèrs dont la composition est donnée dans le tableau 1), calc. % : C 48,64; H 4,90; N 7,56; tr. : C 48,89; H 4,96; N 7,67.

I.3 Photolyse de la triazoline ***4aB″***. La solution de 900 mg de triazoline **4aB″** (Déc. 90–95°C) est irradiée pendant 11 h. Après analyse à l'aide de la rmn (tableau 1), l'huile résiduelle (800 mg) est purifiée par filtration sur 15 g de silice. On obtient 650 mg de cristaux, mélange des aziridines dont la composition est donnée dans le tableau 1 (F = 118–120°C; Rdt = 77%).

I.4. Photolyse de la triazoline ***4bA***. La photolyse de 700 mg de triazoline **4bA** est totale en 10 h. Après élimination du solvant l'aziridine **7bA** cristallise. Elle est essorée et lavée à l'éther. On obtient 525 mg de cristaux (F = 90–92°C; Rdt = 82%) (litt. (3), F = 90–91°C; Rdt = 73%). **7bA**, rmn ^{13}C, δ : 41,4 (dd, $^1J_{CH}$ = 176 et 181, C_3); 49,8 (signal partiellement masqué par ceux des groupements méthoxyles, C2); 53,3 et 53,7 (q, $^1J_{CH}$ = 148 et 148, CO_2CH_3); 161,9 et 164, 8 (2s, *C*O_2Me).

I.5. Photolyse de la triazoline ***4bB***. La photolyse est effectuée sur 1,23 g de triazoline. Après 7 h d'irradiation à −40°C, la réaction est totale. L'analyse rmn du produit brut montre la formation exclusive des aziridines **7bB′** et **7bB″** (proportions relatives 70/30). Après distillation du solvant, l'huile brute reprise à l'éthanol abandonne 1,10 g de cristaux (mélange des deux isomères). Une recristallisation dans l'éthanol fournit un premier jet (0,80 g) de cristaux (F = 82–84°C). Les eaux mères sont évaporées, le résidu après filtration sur silice (éluant : éther/éther de pétrole 50/50) donne 250 mg de cristaux. On obtient ainsi 1,05 g du mélange 70/30 des deux isomères **7bB′** et **7bB″** (Rdt global = 90%, F = 84–88°C). **7bB″** ou **7bB″**, isomère majoritaire, rmn ^{13}C, δ : 50,7 (dd, $^1J_{CH}$ = 178, $^2J_{CH} \approx$ 2, C3); 53,5 (d, $^2J_{CH}$ = 3, C2); 53,4 et 53,8 (q, $^1J_{CH}$ = 149 et 148, CO_2CH_3); 55,5 (qd, $^1J_{CH}$ = 143, $^3J_{CH}$ = 5, (CH_3O_2CH); 98,3 (dqd, $^1J_{CH}$ = 171, $^3J_{CH}$ = 9, $^2J_{CH}$ = 4, $(CH_3O)_2CH$); 161,3 et 164,8 (qd aspect de quintuplet, $^3J \approx {}^3J'$ = 4, *C*O_2Me). Spectre enregistré sur le mélange des isomères **7bB′** et **7bB″**. **7bB′** et **7bB″** mélange (70/30), analyse : $C_{16}H_{21}NO_9S$, calc. % : C 47,64; H 5,25; N 3,47; tr. : C 47,54; H 5,16; N 3,42.

I.6. Photolyse de la triazoline ***4bC***. La photolyse de 2,00 g de triazoline **4bC** demande 3 h pour être totale. L'analyse rmn montre la formation, à côté des deux aziridines **7bC′** (78%) et **7bC″** (15%), d'un troisième produit (7%) qui n'a pas été identifié. Ce dernier présente un doublet à 1,37 ppm attribuable à un groupement méthyle couplé avec un hydrogène.

Après élimination du solvant le résidu cristallise (1,70 g). Une recristallisation dans l'éthanol permet d'obtenir dans un premier jet, 1,20 g de l'isomère majoritaire (F = 90–92°C) et dans un deuxième jet 0,18 g d'un mélange 50/50 des deux isomères (analyse rmn) (rendement global = 77%). **7bC′**, isomère majoritaire, rmn ^{13}C, δ : 8,4 (q, $^1J_{CH}$ = 131, CH_3-C); 47,4 (dq, $^1J_{CH}$ = 174, $^2J_{CH}$ = 5, C3); 51,1 (d, $^2J_{CH}$ = 4, C2); 53,0 et 53,3 (q, $^1J_{CH}$ = 148, CO_2CH_3); 161,7 et 165,6 (qd

For personal use only.

aspect de quintuplet, $^3J \approx {}^3J' = 4$, CO_2Me). **7bC′** et **7bC″** (mélange 70/30), analyse : $C_{14}H_{17}NO_7S$, calc. % : C 48,97; H 4,99; N 4,08. Isomère maj. F = 90–92°C : tr. : C 49,01; H 5,06; N 4,08. Mélange 50/50 des isomères : tr. : C 49,19; H 4,91; N 4,17.

*I.7. Photolyse de la triazoline **4bD**.* La photolyse de 2,30 g de triazoline **4dD** est conduite dans les conditions décrites précédemment. Après 10 h 30 min d'irradiation, l'analyse rmn montre la disparition complète de la triazoline et la formation des aziridines **7bD′** et **7dD″**. Celles-ci évoluent à température ambiante, elles sont caractérisées uniquement à l'aide de la rmn.

*II. Évolution thermique des triazolines **4**, **5**, **6***

II.1. Triazolines diesters (X = Y = CO_2Me)

*II.1.1. Triazolines **4bA**.* La décomposition est totale en 16 h à température ambiante (solutions benzéniques). L'analyse en rmn ^1H des produits bruts montre la formation des oximes **8bA** (58%), de l'aziridine **7bA** (29%) et du tosylate de méthyle (12%). Kostyanovsky et al. (3) opérants dans des conditions différentes n'observent pas les mêmes proportions de ces composés.

Nous avons déjà précisé les caractéristiques rmn de **7bA** (tableau 1). **8bA**, rmn ^1H, δ : 2,45 (s, CH_3-Ph); 3,66 et 3,85 (2s, 3H, CO_2CH_3); 3,78 (s, 2H, CH_2-CO_2-CH_3).

*II.1.2. Triazoline **4bC**.* En solution benzénique (10 cm^{-3}) à température ambiante, la triazoline **4bC** (1,20 g) est totalement décomposée en 5 h. Le spectre de rmn ^1H du produit brut montre la formation de l'oxime **8bC** (62%) et des deux aziridines **7bC′** et **7bC″**. Après distillation sous pression réduite du benzène, le résidu (1,15 g) est chromatographié sur colonne de silice (90 g, éluant : éther/éther de pétrole : 50/50) on recueille, successivement, 240 cm^{-3} de solution ne contenant aucun produit, et 180 cm^{-3} de solution de **8bC** pur, soit 0,56 g de cristaux qui après recristallisation à froid dans le mélange éther/éther de pétrole fondent à 72–73°C (0,50 g). **8bC**, rmn ^1H, δ : 1,37 (t, J = 7,0, $CHCH_3$); 2,47 (s, CH_3-Ph); 3,66 et 3,85 (2s, CO_2CH_3); 4,11 (q, J = 7,0, CH_3CH). **8bC**, rmn ^{13}C, δ : 13,4 (dq, $^1J_{CH}$ = 131, $^2J_{CH}$ = 6, $CHCH_3$); 21,8 (qt, ^1J = 127, ^3J = 4, CH_3Ph); 38,1 (dq, ^1J = 131, ^2J = 4, CH_3CH); 52,6 (q, ^1J = 148, CH_3O); 53,4 (q, ^1J = 149, CH_3O); 157,9 (dq, ^2J = 8, ^3J = 4, C=N-O); 161,8 (dq aspect de quintuplet, $^3J \approx {}^3J' \approx 4$, =C-$CO_2CH_3$); 170,1 (m, CH-$CO_2CH_3$). Les attributions sont confirmées par des irradiations sélectives à 1,37 et 3,85 ppm. **8bC**, analyse : $C_{14}H_{18}NO_7S$, calc. % : C 48,83; H 5,27; N 4,07; tr. : C 48,80; H 5,06; N 4,12.

Les autres fractions (170 mg et 150 mg) sont constituées de mélanges de **8bC** et des aziridines **7bC′** et **7bC″** qui n'ont pu être séparées. Les aziridines sont caractérisées par comparaison avec des échantillons authentiques obtenus lors de la photolyse de la triazoline correspondante.

*II.1.3. Triazoline **5bA** (Z = H).* La décomposition est totale en 4 jours à température ambiante (solution chloroformique). L'analyse en rmn ^1H des produits bruts montre la formation de l'oxime **9bA** (60%) et de l'aziridine **11bA** (40%). **9bA**, rmn ^1H, δ : 3,70 et 3,96 (2s, CO_2CH_3); 3,84 (s, CH_2-CO_2CH_3). **11bA**, rmn ^1H, δ : 2,94 et 3,24 (système AB, ^2J = 3,2, H cycliques); 3,77 et 3,90 (2s, CO_2CH_3).

*II.1.4. Triazoline **6bA**.* À 1,8 g d'oxime **3b** (0,9 × 10^{-2} mol) partiellement dissous dans 5 cm^3 d'éther sec refroidis à −50°C, on ajoute en une seule fois 45 cm^{-3} d'une solution de diazométhane (1,8 × 10^{-2} mol) également refroidie à −50°C. La solution est abandonnée 1 nuit à −20°C. Les cristaux formés sont essorés et lavés à l'éther de pétrole. On obtient 1,8 g de triazoline **6bA** (Rdt = 83%) fondant à 74°C avec décomposition.

Un échantillon dissous dans $CDCl_3$ du produit ainsi obtenu est abandonné à température ambiante. Après 11 jours la décomposition est totale. L'analyse à l'aide de la rmn ^1H montre la formation des composés **10bA** (34%) et **12bA** (66%). **10bA**, rmn ^1H, δ : 2,26 (s, CH_3CO); 3,72 et 3,92 (2s, CO_2CH_3); 3,80 (s, CH_2-CO_2CH_3). **12bA**, rmn ^1H, δ: 2,20 (s, CH_3CO); 2,80 et 3,04 (système AB, ^2J = 3,3, H cycliques); 3,78 et 3,84 (2s, CO_2CH_3).

*II.1.5. Triazoline **6bC**.* À une suspension, maintenue dans un bain réfrigérant à −50°C, de 1,0 g d'oxime **3b** (4,9 × 10^{-3} mol) dans 1 cm^{-3} d'éther sec, on ajoute en une seule fois 17 cm^{-3} d'une solution éthérée de diazoéthane (9,8 × 10^{-3} mol) (solution maintenue au préalable sur KOH à −20°C pendant 1 heure avant utilisation). L'ensemble est abandonné pendant 1 nuit à −20°C. Les cristaux formés sont essorés puis lavés à l'éther de pétrole froid. On obtient ainsi 1,2 g de **6bC** (Rdt = 95%) fondant avec décomposition à 72°C.

L'évolution thermique est sommairement étudiée à l'aide de la rmn sur un échantillon de **6bC** dissous dans $CDCl_3$. La transformation est totale après 5 jours à la température ambiante. La rmn ^1H met en évidence la formation de l'oxime homologuée **10bC** (54%) et des aziridines **12bC′** (24%) et **12bC″** (22%). **10bC**, rmn ^1H, δ : 1,43 (d, ^3J = 7,0, $CHCH_3$); 2,23 (s, CH_3-Ph); 3,66 et 3,89 (2s, CO_2CH_3); 4,16 (q, ^3J = 7,0, $CHCH_3$). **12bC′** et **12bC″**, isomère majoritaire (24%), rmn ^1H, δ : 1,33 (d, ^3J = 6,0, $CHCH_3$); 3,30 (q, ^3J = 6,0, $CHCH_3$); 3,89 et 3,95 (2s, CO_2CH_3); isomère minoritaire (22%), rmn ^1H, δ : 1,51 (d, ^3J = 6,0, $CHCH_3$); 3,01 (q, ^3J = 6,0, $CHCH_3$); 3,83 et 3,89 (2s, CO_2CH_3).

II.2. Triazolines ester nitrile (X = CN, Y = CO_2Me)

*II.2.1. Triazoline **4aA**.* En solution dans le benzène ou le chloroforme (0,5–0,9 mol/L), la décomposition est totale après 6–8 h à la température ambiante. L'oxime **1a** (50%) et le tosylate de méthyle **15** (50%) sont mis en évidence à l'aide de la rmn ^1H (la décomposition est effectuée dans le tube de rmn en solution dans C_6D_6). De plus, le tosylate de méthyle est caractérisé par couplage chromatographie de partage gaz–liquide – spectrométrie de masse.

Exemple de tentative de séparation des différents composés à l'aide de la chromatographie sur couche mince, séparation effectuée (éluant dichlorométhane) sur le produit résultant de la thermolyse de 310 mg de triazoline dans le benzène. On récupère une première fraction (151 mg) R_f = 0,7 qui est un mélange d'oxime **1a** et de tosylate de méthyle. Les autres constituants du mélange ne migrent pas. On récupère ainsi 51 mg d'une poudre brune (pas de fusion définie) n'ayant pas migré et qui ne présente en rmn (C_6D_6) aucun signal à part un massif non résolu entre 3,4 et 3,9 ppm (polymères provenant de l'évolution de **18**).

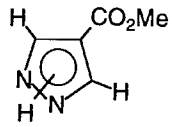
II.2.2. Mise en évidence de la formation de diazométhane

II.2.2.1. Piégeage avec l'acide benzoïque. Dans un tube on introduit 50 mg (1,5 × 10^{-4} mol) de triazoline **4aA**, 20 mg d'acide benzoïque (1,6 × 10^{-4} mol) et 0,4 cm^{-3} de benzène deutérié. On abandonne pendant 6 h à température ambiante le tube fermé par un septum. La chromatographie de partage gaz–liquide (colonnes DOW 11 et QF 1) et la rmn ^1H permettent d'identifier le benzoate de méthyle formé (comparaison avec un échantillon authentique).

II.2.2.2. Piégeage avec le propiolate de méthyle. Dans un tube pour échantillon de rmn, on introduit une solution de 100 mg de triazoline **4aA** (3,1 × 10^{-4} mol) et de 52 mg de propiolate de méthyle (6,2 × 10^{-4} mol) dans 0,4 cm^{-3} de benzène deutérié. Le tube est fermé par un septum. L'enemble est abandonné 48 h à température ambiante. L'enregistrement du spectre de rmn montre la présence de l'oxime tosylée **1a** et des pyrazoles **25** et **26** (proportions relatives 55/45). **25**, rmn ^1H, (C_6D_6), δ : 3,58 (s, CO_2CH_3); 6,78 (d, ^3J = 2,2); 7,68 (d, ^3J = 2,2). **26**, rmn ^1H, (C_6D_6), δ : 3,42 et 3,90 (2s, N-CH_3 et CO_2-CH_3); 6,76 (d, ^3J = 2,5); 7,41 (d, ^3J = 2,5).

II.2.3. Addition du diazométhane au propiolate de méthyle. À 300 mg (3,6 × 10^{-3} mol) de propiolate de méthyle dissous dans 25 cm^3 d'éther refroidi à −20°C, on ajoute par fractions 6 cm^{-3} d'une solution de diazométhane (3,4 × 10^{-3} mol) dans l'éther. Après 1 nuit à −20°C le pyrazole majoritaire **25** qui cristallise est essoré (300 mg; F = 138–139°C). Le solvant du filtrat est éliminé par distillation. On obtient ainsi 145 mg d'une huile incolore analysée à l'aide de la rmn. Elle est essentiellement constituée des pyrazoles **25** (77%) et **38** (23%). La formation de ce dernier n'est pas signalée dans la littérature (16) (Fig. 13). **38**, rmn ^1H : (C_6D_6), δ : 3,57 (s, CO_2CH_3); 7,24 et 8,07 (2s, H cycliques).

À une solution de 100 mg (7,9 × 10^{-4} mol) de pyrazole **25** en solution dans 5 cm^{-3} de dichlorométhane, on ajoute 15 mg d'acide paratoluènesulfonique (≈7,9 × 10^{-5} mol) monohydraté (F = 105°C). Ce dernier se dissout très progressivement. On abandonne le mélange 1



38

FIG. 13

demi-heure à −20°C puis on ajoute 2 cm^{-3} de solution éthérée de diazométhane (2 équivalents). Après 1 nuit à −20°C, le solvant est distillé, le résidu est repris avec 40 cm^{-3} dichlorométhane. La phase organique est lavée à l'eau et séchée sur Na_2SO_4. Après distillation du solvant l'analyse rmn du résidu montre que l'huile obtenue contient un mélange de pyrazole méthylé **26** (71%), de pyrazole non transformé (17%) et de tosylate de méthyle (12%).

*II.2.4. Triazoline **4aC**.* On dissout 2,50 g (9×10^{-3} mol) d'oxime **1a** dans 10 cm^{-3} de THF (ou 2,00 g dans 5 cm^{-3} de dichlorométhane). Après refroidissement à −50°C, on ajoute par fractions 65 cm^{-3} d'une solution éthérée de diazoéthane ($1{,}8 \times 10^{-2}$ mol). L'ensemble est abandonné 1 nuit à −20°C (on constate au bout de 2 heures la décoloration complète de la solution). Le solvant est distillé sous pression réduite (1–2 Torr; 1 Torr = 133,3 Pa) en dessous de −10°C. Le spectre de rmn enregistré immédiatement montre l'existence de tosylate d'éthyle (50%) et de l'oxazole **21** (50%). La triazoline n'est pas mise en évidence.

La séparation des composés formés est réalisée sur colonne d'alumine neutre (Merck 90, activité I) que l'on désactive au préalable à l'aide d'un mélange éther/éther de pétrole (20/80) réalisé avec de l'éther ordinaire non séché. On utilise 25 g d'alumine pour 0,40 g d'huile, l'éluant étant le mélange éther anhydre/éther de pétrole (20/80). On recueille successivement, 50 cm^{-3} de solution ne contenant pas **21** puis 175 cm^{-3} d'une solution contenant 150 mg d'oxazole **21** pur. **21**, ir (nujol) ν : 2228 (-C≡N lié au noyau aromatique), absence d'absorption attribuable à aun groupement ester; rmn ^{1}H, δ : 2,38 (s, CH_3C); 4,22 (s, CH_3O); rmn ^{13}C, δ : 13,8 (q, ^1J = 131, CH_3-C); 59,9 (q, ^1J = 149, CH_3O-); 87,4 (s, =*C*-CN); 112,9 (s, -*C*≡N); 152,3 (q, ^2J = 7, N=*C*-CH_3); 164,7 (q, ^3J = 4, =*C*-OCH_3); spectrométrie de masse : Masse calculée pour $C_6H_6N_2O_2$, $M^{\cdot+}$: 138,043; trouvée : 138,043.

L'identification à l'aide de la chromatographie de partage gaz–liquide (phase stationnaire DOW 11) et à l'aide de la rmn ^{1}H du tosylate d'éthyle est effectuée sur le produit brut (comparaison avec un échantillon authentique, F = 35°C (17)).

Remarque : L'addition du diazoéthane sur l'oxime **1a** marquée à l'azote 15 à 52% (dosage isotopique à l'aide de la spectrométrie de masse) est effectuée dans les mêmes conditions que précédemment : 16 cm^{-3} de solution éthérée de diazoéthane ($3{,}8 \times 10^{-2}$ mol) sont ajoutés à une solution dans le dichlorométhane (≈1 cm^{-3}) refroidie à −50°C de 0,45 g d'oxime **1a** ($1{,}6 \times 10^{-3}$ mol). On obtient après évaporation des solvants 0,67 g d'huile colorée.

En raison de la difficulté de séparation de l'oxazole et du tosylate d'éthyle, les données spectroscopiques sont enregistrées sur le mélange après filtration de l'huile brute (mélange 50/50 d'oxazole **21** et de tosylate d'éthyle) sur 10 g de silice (élution par 100 cm^{-3} de mélange 50/50 d'éther/éther de pétrole).

Les caractéristiques de l'oxazole **21** marqué à l'azote 15 sont les suivantes. **21**, rmn ^{13}C : spectre totalement découplé, δ : 13,3 (d, $^2J_{^{12}C^{15}N}$ = 5,9, CH_3-C=); 59,9 (q, ^1J = 149, CH_3O-); 87,6 (=*C*-C≡N)[2]; 112,4 (d, $^2J_{^{12}C^{15}N}$ = 7,8, -*C*≡N); 152,1 (N=*C*-CH_3)[2]; 164,7 (s, =*C*-OCH_3).

L'analyse isotopique est effectuée à l'aide de la spectrométrie de masse. Conditions d'enregistrement : température de la source : 130°C, température de la canne d'introduction directe 80°C et 25°C respectivement pour **1a** et **21**.

Les mesures de l'intensité des pics $M^{\cdot+}$ et $M+1^{\cdot+}$ permettent après correction des contributions isotopiques naturelles, le pourcentage relatif de l'espèce marquée et non marquée pour l'oxime **1a** et pour l'oxazole **21** :

	Ion	Formule	%	Masse trouvée	Masse calculée
1a	$M^{\cdot+}$	$C_{11}H_{10}N_2O_5S$	48	282,031	282,031
	$(M+1)^{\cdot+}$	$C_{11}H_{10}{}^{15}N^{14}NO_5S$	52	283,028	283,028
21	$M^{\cdot+}$	$C_6H_6N_2O_2$	48	138,043	138,043
	$(M+1)^{\cdot+}$	$C_6H_6{}^{15}N^{14}NO_2$	52	139,040	139,040

*II.2.5. Triazoline **4aD**.* À une solution de 1,60 g d'oxime **1a** ($5{,}7 \times 10^{-3}$ mol) dissous dans 9 cm^{-3} de dichlorométhane refroidie à −50°C, on ajoute en une seule fois 1,20 g de phényldiazométhane (1×10^{-2} mol) en solution dans 14 cm^{-3} d'éther. L'ensemble est abandonné à −20°C pendant 4 jours. Le précipité formé est essoré. On obtient ainsi 0,40 g de cristaux (F = 107–109°C) d'oxazole **22**, Rdt = 28%. Une recristallisation dans le méthanol fournit 0,20 g de produit fondant à 109°C. **22**, rmn ^{1}H, δ : 4.27 (s, CH_3O); rmn ^{13}C, δ : 60,1 (q, ^1J = 149, CH_3O); 113,0 (s, -*C*≡N); 89,0 (s, =*C*-CN); 152,3 (t, ^3J = 5, N=*C*-Ph); 164,7 (q, ^3J = 5, =*C*-OCH_3). Analyse : $C_{11}H_8N_2O_2$, calc. % : C 66,00; H 4,03; N 13,99; tr. : C 66,10; H 3,97; N 13,99.

Le filtrat initial est conservé encore 2 jours à −20°C. On n'observe pas la formation d'autres précipités. Les solvants sont éliminés à la température ambiante. Un essai de distillation sous pression réduite (100–120°C/4×10^{-3} Torr) du résidu (2,2 g) n'a pas permis de séparer le tosylate de benzyle (signaux en rmn ^{1}H à 3,70 ppm, 2H et 2,40 ppm, 3H) des produits de décomposition du phényldiazométhane.

*II.2.6. Triazoline **5aA** (Z = H).* Le produit brut résultant de l'addition du diazométhane sur l'oxime **2a** (Z = H) après distillation de l'éther à basse température est abandonné dans le chloroforme à température ambiante une journée. La formation du benzoate de méthyle est mise en évidence à l'aide de la chromatographie de partage gaz–liquide (phase stationnaire DOW 11, comparaison avec un échantillon authentique).

*II.2.7. Triazoline **5aA** ($Z = NO_2$).* La décomposition du produit brut résultant de la réaction du diazométhane sur l'oxime **2a** ($Z = NO_2$) est totale en 8 h en solution benzénique à température ambiante. L'enregistrement du spectre rmn ^{1}H du produit brut montre uniquement la formation de l'oxime **2a** (60%) et de *p*-nitrobenzoate de méthyle (30%). Ceux-ci sont caractérisés par comparaison avec des échantillons authentiques (rmn ^{1}H pour **2a**, rmn et chromatographie pour le *p*-nitrobenzoate de méthyle **16** ($Z = NO_2$, $R' = H$).

*II.2.8. Triazoline **5aC** ($Z = NO_2$).* L'oxime **2a** ($Z = NO_2$) (2,0 g; $6{,}8 \times 10^{-3}$ mol) est dissoute dans 10 cm^{-3} de THF ou de dichlorométhane. À cette solution refroidie à −50°C, on ajoute par fractions 50 cm^{-3} de solution éthérée de diazoéthane ($1{,}4 \times 10^{-2}$ mol). On note l'apparition immédiate d'une coloration rouge. La solution est alors abandonnée 12 h à −20°C (elle est complètement décolorée après 2 h). Le solvant est distillé sous pression réduite sans dépasser −10°C. Le spectre de rmn ^{1}H est alors immédiatement enregistré. L'oxazole **21** (25%) et le paranitrobenzoate d'éthyle (43%) ont été caractérisés à l'aide de la rmn ^{1}H. À côté, deux autres composés qui n'ont pas été identifiés (25% et 7%, intégration des signaux méthoxycarbonyle) sont mis en évidence. Les caractéristiques de rmn ^{1}H de **21** ont été donné lors de l'étude de la triazoline **4aC**. p-$NO_2C_6H_4CO_2Et$, rmn ^{1}H, δ : 1,43 (t, ^3J = 7, OCH_2CH_3); 4,48 (q, ^3J = 7, OCH_2CH_3).

*II.2.9. Triazoline **6aA**.* La triazoline **6aA** est obtenue lors de la réaction de **3a** avec le diazométhane. Étant donné la difficulté d'obtention de cette triazoline (Rdt = 10%), l'étude systématique de son évolution thermique n'a pas été effectuée.

En solution benzénique la décomposition est totale en 20 h à température ambiante. L'analyse à l'aide de la rmn ^{1}H du produit brut montre la formation d'oxime acétylée **3a** (53%), d'acétate de méthyle (28%) et de trois produits minoritaires (9%, 7%, 8%) dont les structures n'ont pas été déterminées.

*II.2.10. Évolution des triazolines **4aA** et **4bA** en présence d'acide trifluoroacétique.* Dans un tube muni d'une tubulure latérale et contenant 2 cm^3 de chloroforme anhydre refroidi à −50°C, on introduit sous

2. Constante de couplage $^1J_{^{13}C^{15}N}$ non mesurable, doublets masqués par le signal du produit non marqué, ^1J < 2 Hz.

courant d'azote sec 300 mg de triazoline **4aA**. Une quantité stœchiométrique (774 mg) d'acide trifluoroacétique anhydre est additionnée goutte à goutte à l'aide d'une seringue au travers d'un septum. L'ensemble est abandonné à −20°C pendant 1 nuit. Après distillation du chloroforme et de l'acide trifluoroacétique, la rmn montre la formation prépondérante (90%) des aziridines **7aA′** et **7aA″** (70/30). Ces produits sont identifiés après comparaison avec les aziridines obtenues par photolyse de la triazoline correspondante. La structure du produit minoritaire (10%) n'a pas été déterminée. Il présente en rmn ^{1}H un signal à 4,04 ppm attribuable à un groupement méthoxyle.

L'action de l'acide trifluoroacétique sur **4bA** est étudié dans les mêmes conditions que pour **4aA** en solution dans 0,3 cm^{-3} de chloroform deutérié (0,1 g de **4bA**). L'analyse rmn après 1 nuit à −20°C montre la formation exclusive de l'aziridine **7bA** identifiée par comparaison avec le composé obtenu lors de la photolyse de **4bA**.

*II.3. Réaction des dicyanooximes **28** et **29** avec les diazométhane et éthane*

*II.3.1. Préparation du sel d'argent **31**.* La technique de Longo (18) est utilisée. Au mélange de 3,3 g de malonodinitrile (5×10^{-2} mol) et de 6,0 g (1×10^{-1} mol) d'acide acétique glacial refroidi par un bain de glace, on ajoute lentement (0,5 h) et sous agitation 6,9 g de nitrite de sodium (1×10^{-1} mol) en solution dans le minimum d'eau (environ 10 cm^{-3}). On laisse réagir pendant 4 h puis on dilue avec 200 cm^{-3} d'eau et on ajoute une solution de 3,5 g (5×10^{-2} mol) de nitrate d'argent dans 100 cm^{-3} d'eau. Le sel d'argent qui précipite sous forme de cristaux jaune, est essoré puis séché au dessiccateur à potasse. On obtient 9,8 g de cristaux (Rdt = 97%), $F \geq 270$°C avec décomposition.

*II.3.2. Préparation de **28**.* À une solution de 2,9 g ($1,5 \times 10^{-2}$ mol) de chlorure de paratoluènesulfonyle dans 100 cm^{-3} de benzène, on additionne sous azote 3,1 g ($1,5 \times 10^{-2}$ mol) du sel d'argent de l'oxime. Deux gouttes de pyridine sont ajoutées à la suspension précédente. Après 5 min, le solide présent dans la solution est blanc (AgCl). On agite pendant 10 min à 40–50°C. On filtre AgCl qui est lavé au benzène. L'addition d'éther de pétrole au filtrat permet d'obtenir 2,4 g de produit solide. Après concentration de la solution un deuxième jet (0,3 g) est isolé. La recristallisation des deux jets précédents, à froid dans le mélange CH_2Cl_2/éther de pétrole, donne 2,6 g de **28**, (F = 114–115°C; Rdt = 68%) (lit. (12) F = 114°C).

*II.3.3. Préparation de **29**.* Sous azote et agitation 2,0 g (1×10^{-2} mol) du sel d'argent de l'oxime sont mis en suspension dans 15 cm^{-3} de benzène anhydre. Toujours sous agitation, 1,6 g ($1,1 \times 10^{-2}$ mol) de chlorure de benzoyle sont ajoutés en une seule fois. L'addition d'une goutte de pyridine permet de faire démarrer la réaction (disparition du sel d'argent de couleur jaune au profit d'un autre précipité blanc (AgCl)). Après 30 min d'agitation, AgCl est essoré, lavé au benzène. L'addition d'éther de pétrole au filtrat après concentration à l'évaporateur rotatif permet la cristallisation du produit. On obtient ainsi 1,8 g de cristaux de **29** (F = 110°C; Rdt = 90%) (litt. (9) F = 104–106°C).

*II.3.4. Réaction du diazométhane avec l'oxime tosylée **28**.* L'oxime tosylée **28** (1,0 g; $4,0 \times 10^{-3}$ mol) est dissous dans un mélange de 100 cm^{-3} d'éther et 30 cm^{-3} de THF. Après refroidissement de l'ensemble à −20°C, on ajoute 50 cm^{-3} d'une solution éthérée de diazométhane ($1,7 \times 10^{-2}$ mol). L'addition effectuée par fractions provoque l'apparition immédiate d'une coloration rouge. L'ensemble est abandonné 4 jours à température ambiante. Le spectre de rmn ^{1}H du produit brut de la réaction est enregistré après élimination des solvants à température ambiante. Il est ainsi possible de mettre en évidence les composés **32′** (52%), **32″** (16%) et le tosylate de méthyle (22%). Les pourcentages relatifs sont évalués en intégrant les signaux du groupement méthyle lié au noyau aromatique. Après ébullition dans le benzène (10 cm^{-3}), la composition du mélange obtenu n'est pratiquement pas modifiée. Le benzène est distillé, l'addition d'un peu d'éthanol à 95°C provoque la cristallisation du triazole **32′** qui fond à 139–140°C (litt (9) F = 138–139°C) après recristallisation dans l'éthanol à 95°C.

Un mélange de triazole **32′** (40 mg), de méthanol (1 cm^{-3}) et d'acide chlorhydrique concentré (0,26 cm^{-3} d'HCl à 27–29%) est maintenu à reflux pendant 14 h (10). Après distillation des solvants, le composé **32″** (80%) est caractérisé à l'aide dc la rmn. Il reste 20% de triazole **32′**.

Le composé **32″** n'a pas été purifié. Les travaux de Fleury et collaborateurs (9) indiquent que ce composé fond à 165°C. Ces mêmes auteurs ont donné et discuté les caractéristiques de rmn ^{13}C des composés **32′** et **32″**.

*II.3.5. Réaction du diazoéthane avec l'oxime **28**.* À la solution de 1,0 g ($4,0 \times 10^{-3}$ mol) de **28** dans 10 cm^{-3} de dichlorométhane refroidie à −30°C, on ajoute par fractions 20 cm^{-3} de solution éthérée de diazoéthane ($\approx 8 \times 10^{-3}$ mol). L'ensemble est abandonné à −20°C pendant 1 nuit. Après distillation des solvants à basse température (−10 à 0°C), l'analyse du produit brut à l'aide de la rmn montre exclusivement l'oxime tosylée **28** (35%) et le tosylate d'éthyle **15**, R′ = CH_3 (65%).

L'huile obtenue (1,1 g) est chromatographiée sur colonne de silice (30 g) (éluant : éther/éther de pétrole 50/50). On recueille successivement : (*i*) 50 cm^{-3} d'une solution d'oxime **28** (F = 114°C après recristallisation dans le mélange CH_2Cl_2/éther de pétrole), identifiée à l'aide de la rmn ^{1}H par comparaison avec un échantillon authentique; (*ii*) 100 cm^{-3} d'un mélange de tosylate d'éthyle et d'oxime **28**; (*iii*) 50 cm^{-3} d'une solution de tosylate d'éthyle. Celui-ci est caractérisé en rmn ^{1}H par comparaison avec un échantillon authentique (F = 35°C).

*II.3.6. Réaction du diazométhane avec l'oxime **29**.* L'oxime benzoylée (1,00 g; 5×10^{-3} mol) est dissoute dans 20 cm^{-3} de dichlorométhane. À cette solution refroidie à −30°C, on ajoute par fractions 35 cm^{-3} d'une solution éthérée de diazométhane ($1,5 \times 10^{-3}$ mol). L'ensemble est abandonné à −20°C pendant 1 nuit. Le précipité formé est essoré, on obtient 0,67 g de cristaux. Leur analyse à l'aide de la rmn montre qu'il s'agit d'un mélange des triazoles **33** (41%) et **34** (ou **35**) (44%) et de **36** (15%). Après distillation à basse température (−10 à 0°C) des solvants, l'huile obtenue, reprise au méthanol, abandonne 0,37 g de cristaux (F = 115–120°C), mélange (70/30) des triazoles **33** et **34** ou **35** (analyse rmn). Une recristallisation dans le méthanol ne permet pas d'isoler un isomère pur.

Les triazoles ont été séparés par chromatographie sur couche mince à partir de 650 mg d'un mélange de **33** et **34** (ou **35**) (SiO_2, éluant CH_2Cl_2/C_6H_6 : 67/33) R_f (**33**) = 0,34 (180 mg), R_f (**34** ou **35**)) = 0,14 (400 mg). Cette chromatographie permet d'isoler en petite quantité (20 mg) le triazole **36** (F = 228°C). **33**, F = 134°C, rmn ^{1}H, δ : 4,22 (s, N-C*H*$_3$); 8,19 (s, H cyclique); rmn ^{13}C, δ : 42,6 (q, $^1J_{CH}$ = 143, N-*C*H$_3$); 107,8 (s, C≡N); 131,9 (s, *C*=N-O); 133,9 (d, $^1J_{CH}$ = 199, C5); 138,1 (d, $^2J_{CH}$ = 11, C4); **34** (ou **35**), F = 152°C (méthanol), rmn ^{1}H, δ : 4,43 (s, N-C*H*$_3$); 8,22 (s, H cyclique); rmn ^{13}C, δ : 39,1 (q, $^1J_{CH}$ = 144, N-*C*H$_3$); 107,6 (s, C≡N); 126,9 (d, $^2J_{CH}$ = 10, C4); 128,1 (s, *C*=N-O); 138,7 (d, $^1J_{CH}$ = 199, C5). **33** et **34** (ou **35**), analyse : $C_{12}H_9N_5O_2$, calc. % : C 56,47; H 3,55; N 27,44. **33**, tr. % : C 56,35; H 3,54; N 27,23. Mélange **33** + **34** (ou **35**) (70/30), tr. % : C 56,44; H 3,47; N 27,30. **36**, F = 228°C, rmn ^{1}H δ : 4,26 (s, N-C*H*$_3$); 7,89 (s, H cyclique), absence de signaux attribuables aux protons aromatiques; spectrométrie de masse: Masse calculée $C_5H_5N_5O$ (M^+) : 151,049; trouvée : 151,049.

Une quantité (0,32 g) du mélange des triazoles **33** et **34** (ou **35**) (70/30) dissoute dans 5 cm^{-3} de méthanol et additionné de 2 cm^{-3} d'acide chlorhydrique concentré est maintenu au reflux pendant 24 h. L'analyse du produit brut de la réaction à l'aide de la rmn ^{1}H ne permet l'identification que du benzoate de méthyle (comparaison avec un échantillon authentique).

Received July 5, 1994

EDWARD PIERS and RENATO T. SKERLJ. Can. J. Chem. **72**, 2468 (1994).

Treatment (tetrahydrofuran (THF), room temperature or reflux) of the alkyl 2-alkynoates **9–26** with $(Me_3Sn)_2$ in the presence of a Pd(0) catalyst ($(Ph_3P)_4Pd$) provides good to excellent yields of the corresponding alkyl (*Z*)-2,3-bis(trimethylstannyl)-2-alkenoates **47–64**. The latter substances are thermally labile and, as demonstrated by a number of examples, are transformed upon heating (75–95°C) into the thermodynamically more stable *E* isomers. The Pd(0)-catalyzed addition of $(Me_3Sn)_2$ to *N,N*-dimethyl-2-alkynamides **44–46** is quite slow and the initially formed products ((*Z*)-*N,N*-dimethyl-2,3-bis(trimethylstannyl)-2-alkenamides) rearrange to the corresponding *E* isomers at room temperature.

EDWARD PIERS et RENATO T. SKERLJ. Can. J. Chem. **72**, 2468 (1994).

La réaction des alk-2-ynoates d'alkyles **9–26** avec le $(Me_3Sn)_2$, en présence du catalyseur Pd(0) ($(Ph_3P)_4Pd$) à la température ambiante, dans du tétrahydrofurane fournit d'excellent rendements des (*Z*)-2,3-bis(triméthylstannyl)alcén-2-oates d'alkyles correspondants **47–64**. Ces dernières substances sont thermolabiles et, tel que démontré par une série d'exemples, elles sont transformées par chauffage (75–95°C) en isomères *E* thermodynamiquement plus stables. L'addition, catalysée par le Pd(0), du $(Me_3Sn)_2$ sur les *N,N*-diméthylalk-2-ynamides **44–46** sont très lentes et les produits qui se forment initialement, les (*Z*)-*N,N*-diméthyl-2,3-bis(triméthylstannyl)alc-2-énamides) se réarrangent en isomères *E* correspondants à la température ambiante.

[Traduit par la rédaction]

Introduction

It has been shown (1, 2) that the palladium(0)-catalyzed addition of hexamethyldistannane to 1-alkynes **1** produces, stereoselectively, (*Z*)-1,2-bis(trimethylstannyl)-1-alkenes **2** in fair to excellent yields (eq. [1]).[2] The analogous process does not work well when non-terminal alkynes are used as substrates (2) or when hexabutyldistannane is employed as the reagent (ref. 2; see, however, ref. 5). The products **2** have been shown to be of use for the preparation of functionalized 2-trimethylstannyl-1-alkenes (6).

In connection with our continuing interest in the use of bifunctional compounds for organic synthesis and our desire to develop a new general method to prepare configurationally defined tetrasubstituted alkenes, we describe in this paper the details of an investigation (7) that showed that reaction of α,β-acetylenic esters with $(Me_3Sn)_2$ in the presence of a catalytic amount of $(Ph_3P)_4Pd$ provides, cleanly and efficiently, alkyl (*Z*)-2,3-bis(trimethylstannyl)-2-alkenoates **4** (eq. [4]). Furthermore, it was found that substances **4** are thermally unstable and, when warmed to 75–95°C, rearrange smoothly to the corresponding *E* isomers **5** (eq. [3]). Finally, we report that Pd(0)-catalyzed additions of $(Me_3Sn)_2$ to *N,N*-dimethyl-2-alkynamides **6** are also achievable processes, although, in these cases, the initially formed *Z* addition products **7** generally isomerize to the *E* isomers **8** under the conditions necessary to effect the original addition (eq. [4]).

Results and discussion

Preparation of alkyl 2-alkynoates and N,N-*dimethyl-2-alkynamides*

The α,β-acetylenic esters employed in this study are listed in Chart 1. Compound **9** is commercially available, while many of the other substrates have been reported previously.[3] The esters **15** and **26** were prepared as shown in Scheme 1. Sequential treatment of 1,5-hexadiyne (**27**) with MeLi and methyl chloroformate in THF gave a mixture of the monoester **29** (36%) and the diester **31** (40%), which were separated by chromatography on silica gel. In similar fashion, substances **30** and **32** were derived from 1,7-octadiyne (**28**). Hydrogenation of **29** in hexane provided methyl 6-hepten-2-ynoate (**15**) while reaction of **30** with *B*-bromo-9-borabicyclo[3.3.1]nonane (*B*-Br-9-BBN) in dichloromethane (11) afforded methyl 8-bromo-8-nonen-2-ynoate (**26**).

Ethyl 5-chloro-2-pentynoate (**18**) and the corresponding bromide **19** were obtained as follows. Treatment of 3-butyn-1-ol (**33**) with PCl_3 in *N,N*-dimethylformamide (DMF) (12) gave the

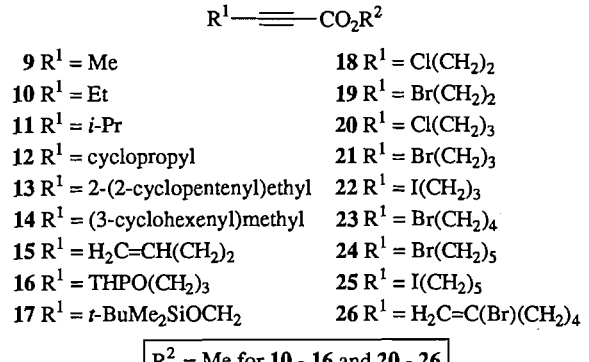

CHART 1

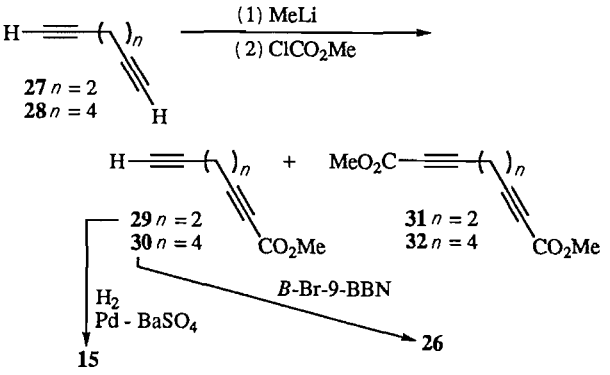


SCHEME 1

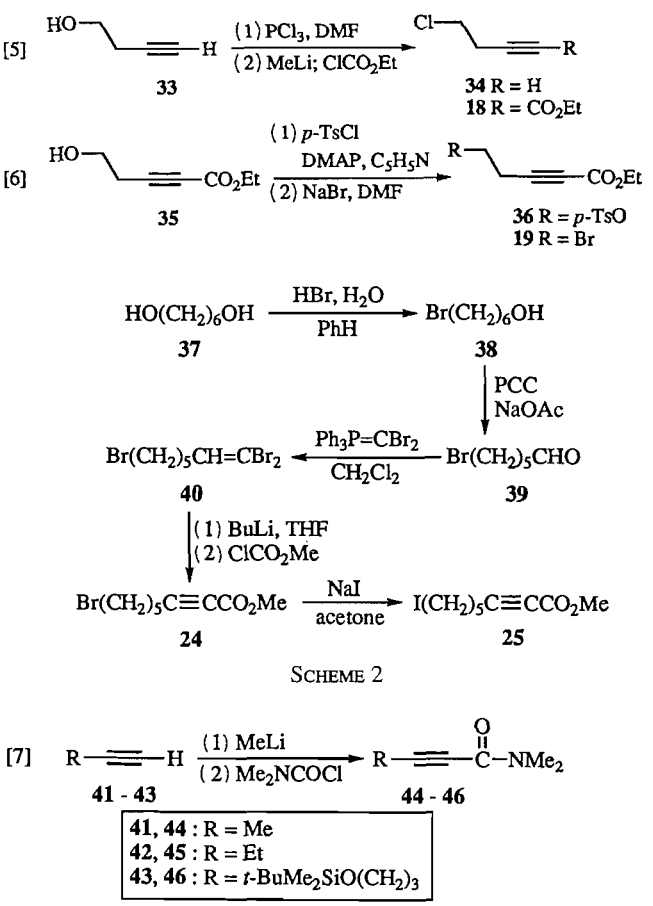
chloride **34**, which was readily transformed into the ethyl ester **18** (eq. [5]). On the other hand, conversion (*p*-toluenesulfonyl chloride (*p*-TsCl), 4-(*N*,*N*-dimethylamino)pyridine (DMAP), pyridine) of ethyl 5-hydroxy-2-pentynoate (**35**)[4] into the *p*-toluenesulfonate **36**, followed by reaction of **36** with NaBr in DMF, produced the bromide **19** (eq. [6]).

Treatment of 1,6-hexanediol (**37**) with 48% aqueous HBr in refluxing benzene gave the bromo alcohol **38** (see Scheme 2). Oxidation (pyridinium chlorochromate (PCC), CH_2Cl_2) of the latter material provided the bromo aldehyde **39**, which, upon reaction with (dibromomethylene)triphenylphosphorane (prepared from Ph_3P and CBr_4 in the presence of zinc dust (13)), gave the tribromoalkene **40**. Sequential treatment of **40** with BuLi (2.5 equiv.) and methyl chloroformate (13) in THF afforded the ester substrate **24**. Upon reaction with excess NaI in acetone, **24** was transformed into the corresponding iodide **25**.

The *N*,*N*-dimethyl-2-alkynamides **44–46** used in this investigation were prepared by sequential treatment of the corresponding 1-alkynes **41–43** with MeLi and *N*,*N*-dimethylcarbamyl chloride in THF (eq. [7]). The preparation of the functionalized 1-pentyne **43** has been reported (14).

Conversion of alkyl 2-alkynoates into alkyl (Z)-2,3-bis(trimethylstannyl)-2-alkenoates

Initial experimentation, using substrate **9**, quickly disclosed that the Pd(0)-catalyzed addition of $(Me_3Sn)_2$ to the triple bond of α,β-acetylenic esters is a clean, efficient process. After a solution of **9** in THF containing $(Me_3Sn)_2$ (1 equiv.) and



SCHEME 2

41, 44 : R = Me
42, 45 : R = Et
43, 46 : R = *t*-BuMe$_2$SiO(CH$_2$)$_3$

$(Ph_3P)_4Pd$ (~0.01 equiv.) had been stirred at room temperature for 14 h, analysis (thin-layer chromatography (tlc)) of the mixture indicated that the starting material **9** has been transformed into a single product. Isolation of the latter material provided ethyl (*Z*)-2,3-bis(trimethylstannyl)-2-butenoate **47** in 95% yield (see Table 1, entry 1).

The generality of this addition reaction was demonstrated by the conversion of the α,β-acetylenic esters **10–26** into the corresponding bis(trimethylstannyl)-2-alkenoates **48–64**. The results are summarized in Table 1.

Collectively, the substrates **9–26** contain a diverse array of functionality, including carbon–carbon double bonds (Table 1, entries 5–7), a tetrahydropyranyl ether (entry 8), a silyl ether (entry 9), primary halides (Cl, Br, I) (entries 10–17), and an alkenyl bromide (entry 18). Thus, the addition process can be effected successfully in the presence of a variety of functional groups. In nearly all of the cases studied, the reactions were clean and, although not optimized, the yields are consistently good to excellent.

Initially, the additions were carried out at room temperature (entries 1–4, 8). However, under these conditions the conversions were found to be quite sluggish when the size of R^1 in the substrate was more bulky than methyl or primary alkyl (see entries 3 and 4). Fortunately, when the reactions were performed at elevated temperatures (normally in refluxing THF), the times required to complete the additions dropped significantly.

Analysis (tlc) of aliquots of the reaction mixture involving ethyl 5-bromo-2-pentynoate (**19**) as substrate (entry 11) showed that, as the reaction progressed, the formation of the product **57** was accompanied by the production of a number of minor uni-

[4]We thank Dr. John Wai for a sample of this compound.

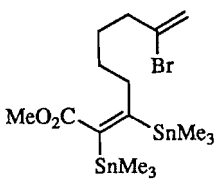
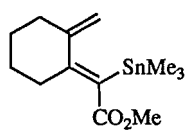
[a]The reactions were performed using ~1 equiv. of $(Me_3Sn)_2$ and ~0.01–0.02 equiv. of $(Ph_3P)_4Pd$ in THF at room temperature (A) or under reflux (B). Any changes from these conditions are noted.
[b]Yield of chromatographically purified product.
[c]The reaction mixture was heated at 55–60°C.
[d]The Pd(0) catalyst was prepared from $Pd(OAc)_2$ and Ph_3P and the reaction was carried out at 60°C in the presence of Et_3N.

dentified substances. Nevertheless, work-up of the reaction mixture when most of the starting material had been consumed, followed by chromatography of the crude material on silica gel, gave **57** in 66% yield.

The experiment summarized in entry 18, Table 1, also requires brief comment. At the outset, it was recognized that, under the reaction conditions, the initially formed product **64** derived from addition of $(Me_3Sn)_2$ to the substrate **26** could undergo intramolecular Pd(0)-catalyzed cross-coupling (15–17) to give the diene **65**. However, for unknown reasons, treatment (THF, room temperature, 20 h) of **26** with $(Me_3Sn)_2$ in the presence of $(Ph_3P)_4Pd$ gave back mainly starting material. When the reaction was carried out in refluxing THF, a number of unidentified products were produced (tlc analyses). Use of other solvents (MeCN, PhH, or 1,2-dimethoxyethane) did not lead to significant improvement. On the other hand, use of THF as solvent and a Pd(0) catalyst formed from $Pd(OAc)_2$, Ph_3P, and Et_3N (18) produced the "normal" addition product **64** in 64% yield (entry 18). Interestingly, under these conditions, **64** was not converted into the diene **65**.



64



65

During the course of the studies described above, it became apparent that the (*Z*)-2,3-bis(trimethylstannyl)-2-alkenoate products **47–64** are thermally unstable. Although the relatively volatile product **47** was found to be stable to distillation (70–75°C/0.1 Torr (1 Torr = 133.3 Pa)), attempted distillation of other products with greater molecular masses led to rearrangement. For example, when methyl (*Z*)-6-chloro-2,3-bis(trimethylstannyl)-2-hexenoate (**58**) was distilled (90–95°C/0.01 Torr), the acquired liquid was shown to consist of **58** and another substance, in a ratio of ~2:1, respectively. Chromatographic separation of the two substances, along with appropriate spectral analyses, showed that the minor component in the distillate was methyl (*E*)-6-chloro-2,3-bis(trimethylstannyl)-2-hexenoate. Thus, during the distillation process, the primary *Z* product **58** had undergone partial isomerization to the corresponding *E* isomer.[5] In view of these and other similar observations, the products listed in Table 1 were generally not distilled. In each case, last traces of solvent were removed from the chromatographically purified product by subjecting the material to reduced pressure (vacuum pump, ~0.05 Torr) for a period of 1–2 h.

A possible pathway for the Pd(0)-catalyzed addition of $(Me_3Sn)_2$ to α,β-acetylenic esters **3** is shown in Scheme 3.[6] Oxidative addition of the palladium catalyst to the Sn–Sn bond of the distannane would give the palladium(II) species **66**. Coordination of **66** with the substrate **3** to provide **67**, followed by insertion of the triple bond into one of the tin–palladium bonds,

[5]The facile, thermally induced rearrangement of alkyl (*Z*)-2,3-bis(trimethylstannyl)-2-alkenoates into the corresponding *E* isomers will be discussed in the next section of this paper (vide infra).

[6]A similar pathway has been evoked to account for the *Z* configuration of products derived from the Pd(0)-catalyzed addition of disilanes to 1-alkynes (19).

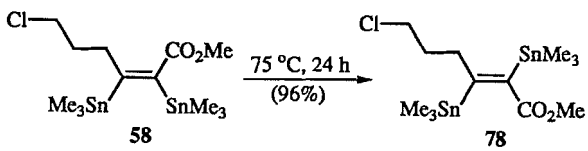
would afford **68**. Finally, reductive elimination would produce the observed product **4** and regenerate the Pd(0) catalyst.

Conversion of alkyl (Z)-2,3-bis(trimethylstannyl)-2-alkenoates into alkyl (E)-2,3-bis(trimethylstannyl)-2-alkenoates

As mentioned above, alkyl (*Z*)-2,3-bis(trimethylstannyl)-2-alkenoates are thermally labile. To investigate this phenomenon more thoroughly, a stirred, neat sample of the enoate **58** was heated at approximately 75°C. After a period of 24 h, analysis (tlc) indicated the absence of starting material and the clean production of another substance. Distillation (~105°C/0.1 Torr) of the pale yellow oil afforded the *E* isomer **78** in 96% yield (eq. [8]).

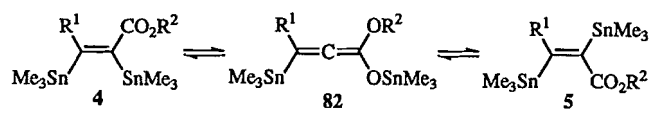
[8]



To demonstrate the generality of this isomerization process, a number of (*Z*)-2,3-bis(trimethylstannyl)-2-alkenoates were subjected to thermolysis. The results of these experiments are summarized in Table 2. As can been seen from the tabulated data, the rearrangement process is compatible with the presence of a variety of functional groups and the yields of the *E* products are generally good to excellent. Only the thermolysis of **64** (Table 2, entry 13) did not produce a clean product. Analysis (tlc) of the material derived from heating **64** showed that the production of **81** was accompanied by the formation of minor amounts of other substances. Furthermore, a small amount of an unidentified, insoluble solid was also produced. Nevertheless, chromatography of the crude mixture after complete disappearance of starting material provided **81** in 66% yield.

It is also pertinent to point out that the (*Z*)-2,3-bis(trimethylstannyl)-2-alkenoates are not completely stable to storage for long periods of time. For example, the *Z* compounds **47–50** and **55**, when stored at 5°C for several months, slowly became pale yellow and were shown to contain minor amounts of the corresponding *E* isomers (**69–72**, **77**). Furthermore, in each case, a small amount of insoluble solid material was formed.

It appears reasonable to propose that the facile rearrangement of **4** into **5** proceeds via a trimethylstannyl allenoate intermediate **82** (Scheme 4). Thus, reversible, thermally induced migration of the α-trimethylstannyl group[7] from carbon to the ester carbonyl oxygen would produce **82**. A second migration of the Me_3Sn moiety back to the α carbon, but to the side of the molecule opposite to the β-Me_3Sn group, would give the *E* isomer **5**. Presumably, the relief of steric repulsion between the two as



SCHEME 4

[7]The labile nature of the carbon–tin bond associated with the α-Me_3Sn function has been demonstrated by the facility with which this group undergoes transmetallation (MeLi, THF, −98°C) (20).

Me_3Sn groups in **4** is primarily responsible for the observation that the equilibrium between **4** and **5** favors the latter substances.

Configurational considerations

On the basis of literature precedents concerning the stereochemical outcome of Pd(0)-catalyzed additions of $(Me_3Sn)_2$ to 1-alkynes (1, 2), it seemed entirely reasonable to conclude that the products derived from similar reactions involving α,β-acetylenic ester substrates would possess the *Z* configuration. Furthermore, the fact that the addition products, upon thermolysis, are cleanly transformed into the corresponding geometric isomers, along with the reasonable prediction that the *E* isomers would be more stable than the *Z* substances, provides further support for the conclusions regarding product stereochemistry. Nevertheless, explicit evidence for the configurational assignments was obtained by use of ^1H nmr spectroscopy. For example, the configuration of each of the diastereomers **58** and **78** (see eq. [8]) was confirmed by nuclear Overhauser enhancement (nOe) difference experiments. In the spectrum of **58**, irradiation at δ 3.70 (OMe signal) caused enhancement of the resonance due to *one* of the 9-proton Me_3Sn singlets (δ 0.25). On the other hand, irradiation at δ 3.71 (OMe) in the spectrum of **78** increased the intensity of *both* of the Me_3Sn singlets (δ 0.17, 0.26). These results, along with those of similar experiments involving other geometrically isomeric pairs, clearly show that the configuration of each of the primary products derived from Pd(0)-catalyzed addition of $(Me_3Sn)_2$ to 2-alkynoates is *Z*, while the configuration of substances obtained from thermolysis of these products is *E*.

Spectral data derived from alkyl (Z)- and (E)-2,3-bis(trimethylstannyl)-2-alkenoates

The ^1H nmr spectroscopic data derived from alkyl (*Z*)-2,3-bis(trimethylstannyl)-2-alkenoates **47**–**64** and from the *E* isomers **69**–**81** are summarized in Table 3. These data show that the difference (Δδ) between the chemical shifts of the two 9-proton Me_3Sn signals in a given substance is related to its geometric configuration. In each of the *Z* isomers (general formula **4**, Chart 2) the two Me_3Sn resonances have very similar chemical shifts (Δδ = 0–0.03 ppm). On the other hand, the corresponding Δδ values for the *E* isomers (formula **5**, Chart 2) vary from 0.03 to 0.11 ppm, but, with the exception of compound **71** (Table 3, entry 6), are in the range 0.08–0.11 ppm. Thus, these Δδ values may be employed as a diagnostic tool in assigning the configuration of alkyl 2,3-bis(trimethylstannyl)-2-alkenoates.

Interestingly, the ^1H nmr spectroscopic signals due to the C-4 (γ) proton(s) in the (*Z*)-2,3-bis(trimethylstannyl)-2-alkenoates are commonly found at *higher* field than the corresponding resonances for the *E* isomers (Table 3, entries 1–4, 7, 8, 11–18, 21, 22, 25–28, 30, 31).[8] This finding is unusual. Generally, in α,β-unsaturated esters, γ protons *cis* to the ester function resonate at lower field than γ protons in the corresponding geometric isomers. This is certainly the case in a fairly large number of alkyl (*E*)- and (*Z*)-3-trimethylstannyl-2-alkenoates (general formulas **83**, **84**, Chart 2) that have been prepared in our laboratories (9, 10, 14, 21). The C-4 proton(s) in the *E* compounds **83** consistently resonate at lower field than the C-4 proton(s) of the corresponding *Z* isomers **84**.

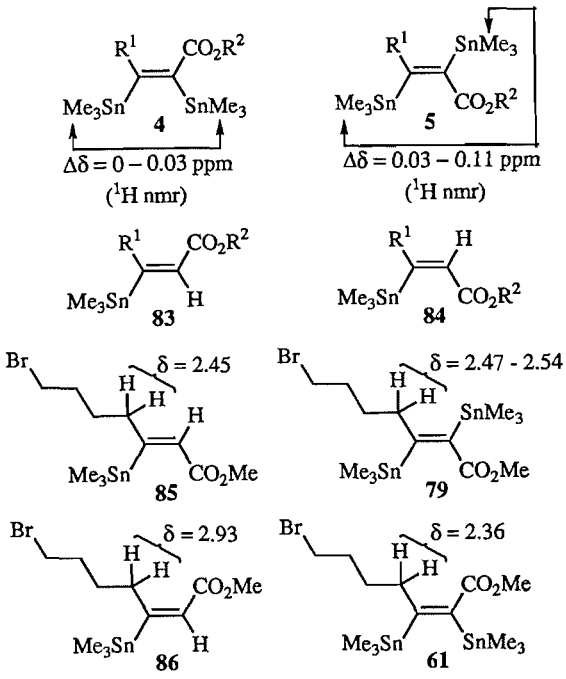

CHART 2

An examination of available data (9, 10, 14, 21, present work) indicates that, in general, the chemical shifts of the γ protons of a given pair of substances of general structures **5** and **84** (Chart 2) are quite similar. In contrast, replacement of the C-2 hydrogen of **83** with a $SnMe_3$ function (to give **4**) results in a significant *upfield* shift of the resonance due to the C-4 proton(s). This phenomenon is illustrated by the ^1H nmr chemical shift data shown in conjunction with the set of compounds **85**, **79**, **86**, and **61** (Chart 2). Similar trends are exhibited by other sets of substances structurally related to those shown in Chart 2. Thus, it appears that the "anomalous" (relative) chemical shifts of the γ protons in the nmr spectra of **4** and **5** are related to the presence of the C-2 Me_3Sn function in the *Z* isomers **4**. Although the reason(s) underlying this phenomenon is (are) obscure, it is evident that these observations can also be of assistance in assigning the geometry of substances of general structure **4** and **5**.

Table 4 contains a summary of the ^{13}C nmr chemical shift data derived from a selected number of alkyl (*Z*)- and (*E*)-2,3-bis(trimethylstannyl)-2-alkenoates. It is apparent from these data that, irrespective of molecular constitution or geometric configuration, the carbonyl carbons of these materials resonate at nearly the same position (δ ~172). More interesting and informative are the patterns observed for the chemical shifts of the olefinic carbons (C-2, C-3). For each pair of geometric isomers, C-2 of the *Z* isomer resonates at *lower* field than that of the *E* compound. In contrast, the signal for C-3 of the *Z* substance appears at *higher* field than the corresponding resonance of the *E* isomer. For the α carbons (C-2) the chemical shift differences (Δδ values) for the various isomeric pairs are quite small, ranging from ~2 ppm (substances **55**, **77**, Table 4, entries 11, 12) to nearly 6 ppm (compounds **47**, **69**, entries 1, 2). On the other hand, the Δδ values for the β carbons (C-3) are considerably larger and range from about 11 ppm (**55**, **77**, entries 11, 12) to approximately 21 ppm (**47**, **69**, entries 1, 2).

[8]The only exception to this generalization involves the pair of geometric isomers **49** and **71** (Table 3, entries 5, 6). In these two substances, the C-4 protons have similar chemical shifts (Δδ = 0.11 ppm), but the γ proton of the *Z* isomer **49** gives rise to a signal *downfield* from that of the *E* isomer **71**.

[a]All spectra were run at 400 MHz, except those of entries 1 and 2 (80 MHz), entries 3, 7, 17, 18, and 20 (270 MHz), and entry 6 (300 MHz).
[b]Chemical shifts (δ values) were measured relative to the signal for $CHCl_3$ (δ 7.25).
[c]Singlet = s; doublet = d; triplet = t; quartet = q; multiplet = m.
[d]The $^2J_{Sn-H}$ values associated with the Me_3Sn signals are in the range 50–56 Hz.

The ^{13}C nmr chemical shift assignments for carbons 1, 2, and 3, as outlined in Table 4, were confirmed by suitable nmr correlation experiments. An example is given in Table 5, which summarizes HMQC (22, 23) and HMBC (24, 25) data for the geometrically isomeric pair of substances **58** and **78**.[9] These data clearly show that the ^{13}C nmr signals at δ 172.1 and 172.0 for **58** and **78**, which exhibit no correlations, are due to the carbonyl carbons. On the other hand, the HMBC correlations associated with the pairs of resonances at δ 150.8 and 163.2 (isomer **58**) and at δ 145.5 and 182.3 (isomer **78**) allow unambiguous assignment of the ^{13}C nmr signals of the olefinic carbons as well.

On the basis of the data given in Tables 4 and 5, as discussed above, it is evident that ^{13}C nmr spectroscopy can be very helpful in determining the configuration of alkyl 2,3-bis(trimethylstannyl)-2-alkenoates.

A summary of selected $^{119}Sn-^{13}C$ coupling constants obtained from the ^{13}C nmr spectra of a number of alkyl 2,3-bis(trimethylstannyl)-2-alkenoates is given in Table 6. It can be seen that the $^2J_{Sn-C}$ values related to coupling between ^{119}Sn of the C-3 Me_3Sn group and ^{13}C of the C-4 allylic carbon (column A in Table 6) are, for each isomeric pair, nearly equal. The only exception to this generalization relates to the isomers **55** and **77**, which contain an electronegative oxygen function on the allylic (C-4) carbon. For these substances, the $^2J_{Sn-C}$ value in question is 6 Hz larger in the *E* isomer than in the *Z* compound (Table 6, entries 11, 12).

In contrast to the data given in column A, Table 6, the $^{119}Sn-^{13}C$ coupling constants related to coupling between ^{119}Sn of the C-2 Me_3Sn function and ^{13}C of the allylic carbon ($^3J_{Sn-C}$, column B, Table 6) do provide diagnostic information regarding double bond configuration. For a given pair of geometric isomers, the magnitude of this coupling constant for the *Z* isomer is consistently larger than that derived from the corresponding *E* compound. For the isomeric pairs shown in Table 6, the difference in $^3J_{Sn-C}$ values varies from 6 Hz (compounds **49**, **71**; entries 5, 6) to 15 Hz (substances **55**, **77**; entries 11, 12).

The ^{119}Sn nmr spectroscopy of alkyl 2,3-bis(trimethylstannyl)-2-alkenoates has also been studied briefly. The acquired data are given in Table 7. In nearly all of the *E* isomers that were investigated, the chemical shifts of the ^{119}Sn signals of the two $SnMe_3$ groups are very similar and show up at about −50 ppm. An exception to this generalization is exhibited by substance **71** (Table 7, entry 2), in which the two ^{119}Sn resonances have quite different chemical shifts (δ −60.2, −44.5). In the spectra of the two *Z* isomers that were recorded, the δ values for the two ^{119}Sn signals were again quite similar (~ −36 ppm), but were found to be ~14 ppm to higher field that the corresponding resonances for the *E* isomers (Table 7, entries 6–9).

A striking feature of the data given in Table 7 is the difference in the $^3J_{Sn-Sn}$ values for the *Z* and *E* isomers. The coupling constants for the *E* substances are consistently greater than 500 Hz, while, as shown by entries 6 and 8, the corresponding *J* values for the *Z* isomers are smaller by more than 200 Hz (see also ref. 2). These observations, along with those related to ^{119}Sn chemical shifts (vide supra), provide yet another method for determining the double bond configuration of alkyl 2,3-bis(trimethylstannyl)-2-alkenoates.

Conversion of N,N-*dimethyl-2-alkynamides into* (E)-N,N-*dimethyl-2,3-bis(trimethylstannyl)-2-alkenamides*

The investigations described above showed, inter alia, that

[a]All spectra were recorded at 111.8 MHz, using $CDCl_3$ as solvent.
[b]Chemical shifts (δ, in ppm) were measured relative to the signal for Me_4Sn (δ = 0).
[c]Coupling constants are given in Hz and represent coupling between the two ^{119}Sn isotopes.

$(Me_3Sn)_2$ in the presence of $(Ph_3P)_4Pd$ in THF at room temperature (Table 1, entry 1), the corresponding process employing *N*,*N*-dimethyl-2-butynamide (**44**) as starting material was quite sluggish. Nevertheless, analysis (tlc) of the reaction mixture after a reaction time of 44 h showed the absence of the starting material **44** (see Scheme 5). However, tlc analysis of the crude material derived from the reaction mixture showed the presence of two products, which were separated by chromatography on silica gel. The major and minor products (isolated in yields of 50 and 13%) proved to be (*Z*)-*N*,*N*-dimethyl-2,3-bis(trimethyl-

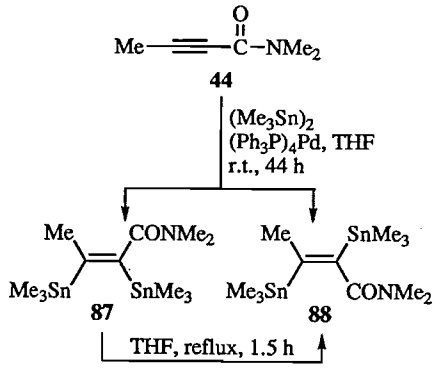
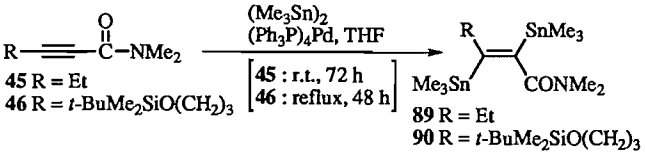


SCHEME 5



SCHEME 6

stannyl)-2-butenamide (**87**) and the corresponding *E* isomer **88**, respectively. When a solution of **87** in THF was refluxed for 1.5 h, it was transformed cleanly into **88**.

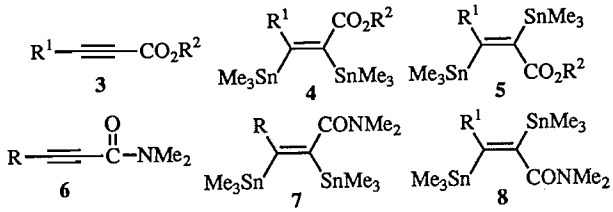
Subjection of the acetylenic amides **45** and **46** to the reaction conditions shown in Scheme 6 provided the *E* alkenamides **89** and **90** in isolated yields of 48 and 63%, respectively. The crude materials derived from these reactions did not show the presence of the corresponding *Z* alkenamides and thus it is presumed that, under the reaction conditions, the primary *Z* products rearranged to the *E* isomers.

This brief study revealed that the Pd(0)-catalyzed addition of $(Me_3Sn)_2$ to *N,N*-dimethyl-2-alkynamides is much slower than the corresponding reaction involving alkyl 2-alkynoates as substrates. Furthermore, it is evident that (*Z*)-*N,N*-dimethyl-2,3-bis(trimethylstannyl)-2-alkenamides are notably less stable than alkyl (*Z*)-2,3-bis(trimethylstannyl)-2-alkenoates. Although thermal rearrangement of the latter substances to the corresponding *E* isomers is quite slow even at elevated temperatures (see Table 2), the reactions summarized in Schemes 5 and 6 show that (*Z*)-*N,N*-dimethyl-2,3-bis(trimethylstannyl)-2-alkenoates are transformed into the corresponding *E* isomers under relatively mild conditions.

Conclusion

The investigations described in this paper showed that alkyl (*Z*)-2,3-bis(trimethylstannyl)-2-alkenoates (**4**) are readily prepared by reaction of α,β-acetylenic esters **3** with $(Me_3Sn)_2$ in the presence of a catalytic amount of $(Ph_3P)_4Pd$. The conversions are generally clean and efficient and the presence of various functional groups in the R^1 group of the substrates **3** does not interfere with the addition process. The products **4** were found to be thermally unstable and, upon heating, are cleanly converted into the thermodynamically more stable *E* isomers **5**.

The Pd(0)-catalyzed addition of $(Me_3Sn)_2$ to *N,N*-dimethyl-2-alkynamides (**6**) can also be carried out, although this process is considerably slower than the conversion of **3** into **4**. Furthermore, the primary products derived from **6** (*Z*)-*N,N*-dimethyl-2,3-bis(trimethylstannyl)-2-alkenamides (**7**), are much less stable than the analogous esters **4** and rearrange to the corresponding *E* isomers **8** even at room temperature.



The use of substances of general structures **4**, **5**, and **8** as intermediates for organic synthesis will be the subject of future reports.

Experimental

General information

Distillation temperatures, which refer to short-path (Kugelrohr) distillations, and melting points are uncorrected. Proton (^1H), carbon (^{13}C), and tin (^{119}Sn) nuclear magnetic resonance (nmr) spectra were recorded using $CDCl_3$ solutions. Signal positions in ^1H nmr spectra were measured relative to the signals for Me_4Si (δ 0) (internal standard) or $CHCl_3$ (δ 7.25), while resonances in ^{13}C and ^{119}Sn nmr spectra were measured relative to the signals for $CDCl_3$ (δ 77.0) and Me_4Sn (δ 0) (internal standard), respectively. In ^{13}C nmr spectra, multiplicity was determined from attached proton test (APT) experiments. Tin–hydrogen and tin–carbon coupling constants (J_{Sn-H}, J_{Sn-C}) are given as the average of the ^{117}Sn and ^{119}Sn values, unless otherwise stated. Tin–tin coupling constants (J_{Sn-Sn}) are given as ^{119}Sn values. Molecular mass determinations (high-resolution mass spectrometry) for substances containing Me_3Sn groups are based on ^{120}Sn (unless stated otherwise) and were made on the ($M^+ - Me$) peak (26). Flash chromatography (27) and conventional column chromatography were carried out with 230–400 and 70–230 mesh silica gel (E. Merck), respectively. Thin-layer chromatography (tlc) was accomplished with commercial aluminum- or plastic-backed plates (E Merck, Type 5554 or 5735, respectively). Gas–liquid chromatography (glc) was performed on instruments equipped with flame ionization detectors and 25 m × 0.21 mm fused silica columns coated with cross-linked SE-54. Commercial $(Me_3Sn)_2$ (Organometallics Inc.) was stored under an inert atmosphere in a glove box and was generally distilled (water aspirator pressure) just prior to use. $(Ph_3P)_4Pd$ was obtained from the Aldrich Chemical Company, was stored and weighed under an inert atmosphere (glove box), and was used without further purification. Other reagents and solvents were purified and dried using standard methods. Aqueous NH_4Cl–NH_4OH (pH 8) refers to a solution prepared by addition of aqueous ammonia (58%, ~50 mL) to saturated aqueous NH_4Cl (~950 mL).

Note: Unless otherwise stated, all reactions were carried out under an atmosphere of dry argon in flame-dried glassware.

Note: All compounds for which high-resolution mass measurements are given exhibited clean ^1H nmr spectra and showed one spot on tlc analyses.

*Methyl 2,6-heptadiynoate (**29**) and dimethyl 2,6-octadiyndioate (**31**)*

To a cold (−78°C), stirred solution of 1,5-hexadiyne (**27**) (1.72 g, 22 mmol) in 120 mL of dry THF was added a solution of MeLi (29 mmol) in Et_2O and the mixture was stirred at −78°C for 15 min and at −20°C for 1 h. Methyl chloroformate (31 mmol) was added and the solution was stirred at −20°C for 1 h and at room temperature for 1 h. Saturated aqueous $NaHCO_3$ and Et_2O were added and the phases were separated. The aqueous phase was extracted with Et_2O. The combined organic extracts were washed (saturated aqueous $NaHCO_3$, brine), dried ($MgSO_4$), and concentrated. Column chromatography (90 g silica gel, 2:3 petroleum ether – Et_2O) of the residual material, followed by distillation (90–93°C/20 Torr; 110–115°C/0.05 Torr (1 Torr = 133.3 Pa)) of the oils obtained, gave 1.07 g (36%) of the monoester **29** (a colorless oil) and 1.71 g (40%) of the diester **31** (a colorless solid).

Compound **29** displayed ir (neat): 3295, 2333, 1713, 1435, 1338–1100 (br), 1078 cm^{-1}; ^1H nmr (300 MHz) δ: 2.08 (t, 1H, J = 2 Hz),

2.44–2.52 (m, 2H), 2.55–2.62 (m, 2H), 3.78 (s, 3H). Exact Mass calcd. for $C_8H_7O_2$ ($M^+ - H$): 135.0446; found: 135.0448.

Compound **31** showed mp 63–64°C (from MeOH–H_2O); ir (CCl_4): 2237, 1733, 1435, 1300–1200 (br), 1077 cm^{-1}; ^1H nmr (300 MHz) δ: 2.64 (s, 4H), 3.79 (s, 6H). Exact Mass calcd. for $C_{10}H_{10}O_4$: 194.0579; found: 194.0574.

*Methyl 6-hepten-2-ynoate (**15**)*

To a stirred solution of the monoester **29** (1.06 g, 7.83 mmol) in 50 mL of hexane was added 106 mg of 10% palladium-on-barium sulfate and the reaction mixture was stirred under an atmosphere of hydrogen at room temperature. After 2.15 h, analysis of an aliquot by glc indicated that the starting material had been consumed. Removal of the solvent, column chromatography (20 g silica gel, 17:1 petroleum ether – Et_2O) of the residual material, and distillation (85–95°C/20 Torr) of the acquired oil afforded 790 mg (73%) of the heptenynoate **15**, a colorless oil that showed ir (neat): 3081, 2332, 1718, 1643, 1258, 921 cm^{-1}; ^1H nmr (300 MHz) δ: 2.28–2.48 (m, 4H), 3.73 (s, 3H), 5.06 (dd, 1H, J = 10, 2 Hz), 5.10 (dd, 1H, J = 17, 2 Hz), 5.83 (ddt, 1H, J = 17, 10, 6 Hz). Exact Mass calcd. for C_7H_7O (M^+ –OMe): 107.0497; found: 107.0504.

*Ethyl 5-chloro-2-pentynoate (**18**)*

To stirred, dry *N*,*N*-dimethylformamide (50 mL) was added, dropwise, PCl_3 (2.5 mL) and the mixture was stirred at room temperature for 90 min. To the resultant yellow slurry was added 3-butyn-1-ol (**33**) (6.7 mL) and stirring was continued for 40 min. The crude product was distilled (70–110°C) from the reaction mixture. The colorless distillate was then fractionally distilled to afford 7 g (42%) of 4-chloro-1-butyne (**34**), bp 80–85°C, which exhibited ^1H nmr (80 MHz) δ: 2.11 (t, 1H, J = 2.5 Hz), 2.68 (dt, 2H, J = 2.5, 7 Hz), 3.63 (t, 2H, J = 7 Hz).

To a cold (−78°C), stirred solution of the chloride **34** (4.4 g, 50 mmol) in dry THF (100 mL) was added a solution of MeLi (55 mmol) in Et_2O. After the mixture had been stirred at −78°C for 10 min and at −20°C for 1 h, ethyl chloroformate (5.7 mL, 60 mmol) was added and stirring was continued for 1 h at −20°C and 1 h at room temperature. The mixture was diluted with Et_2O and the resultant solution was washed (twice with aqueous sodium bicarbonate and twice with brine), dried ($MgSO_4$), and concentrated. Flash chromatography (300 g silica gel, 9:1 petroleum ether – Et_2O) of the crude product and distillation (80–82°C/0.02 Torr) of the acquired oil gave 5.0 g (63%) of the chloro pentynoate **18**, a colorless oil that was homogeneous by glc analyses and exhibited ir (film): 2235, 1710, 1258, 1090, 760 cm^{-1}; ^1H nmr (80 MHz) δ: 1.32 (t, 3H, J = 7 Hz), 2.83 (t, 2H, J = 7 Hz), 3.65 (t, 2H, J = 7 Hz), 4.20 (q, 2H, J = 7 Hz). Exact Mass calcd. for $C_5H_4{}^{35}ClO$ (M^+ –OEt): 114.9950; found: 114.9950.

*Ethyl 5-bromo-2-pentynoate (**19**)*

To a stirred solution of ethyl 5-hydroxy-2-pentynoate (**35**)[4] (563 mg, 4.26 mmol) in 25 mL of dry CH_2Cl_2 was added *p*-toluenesulfonyl chloride (1.21 g, 6.34 mmol), dry pyridine (0.69 mL, 8.53 mmol), and 4-(*N*,*N*-dimethylamino)pyridine (0.5 g, 4.1 mmol). After the mixture had been stirred at room temperature for 30 h, it was concentrated under reduced pressure. Petroleum ether (50 mL) was added to the residual material and the resultant solution was washed (10% hydrochloric acid, 20 mL; saturated aqueous $NaHCO_3$, 20 mL; water, 20 mL), dried ($MgSO_4$), and concentrated. Flash chromatography (20 g silica gel, 1:1 petroleum ether – EtOAc) of the crude product, followed by distillation (80°C/0.05 Torr) of the acquired oil, provided 600 mg (47%) of the *p*-toluenesulfonate **36**, a colorless oil that displayed ^1H nmr (80 MHz) δ: 1.32 (t, 3H, J = 7 Hz), 2.50 (s, 3H), 2.75 (t, 2H, J = 7 Hz), 4.17 (t, 2H, J = 7 Hz), 4.22 (q, 2H, J = 7 Hz), 7.37, 7.72 (d, d, 2H each, J = 8 Hz).

To a stirred solution of the ester **36** (570 mg, 1.93 mmol) in 10 mL of dry *N*,*N*-dimethylformamide was added NaBr (0.6 g, 7.7 mmol) and the solution was stirred at room temperature for 3 days. Water (10 mL) and petroleum ether (20 mL) were added and the aqueous phase was washed (3 × 15 mL) with petroleum ether. The combined organic solutions were washed (water, 20 mL), dried ($MgSO_4$), and concentrated. Distillation (80°C/0.05 Torr) of the residual oil produced 365 mg (90%) of the bromo ester **19**, a colorless oil that displayed ir (neat): 2241, 1713, 1256, 1075 cm^{-1}; ^1H nmr (80 MHz) δ: 1.30 (t, 3H, J = 7 Hz), 2.75–3.02 (m, 2H), 3.30–3.57 (m, 2H), 4.20 (q, 2H, J = 7 Hz). Exact Mass calcd. for $C_5H_4{}^{81}BrO$ (M^+ –OEt): 158.9446; found: 158.9443.

*6-Bromo-1-hexanol (**38**)*

To a stirred solution of 1,6-hexanediol (**37**) (5.0 g, 42.3 mmol) in 100 mL of dry benzene was added 6.76 mL (84.6 mmol) of 48% aqueous HBr. A Dean–Stark water trap was attached to the reaction flask and the mixture was refluxed for 23 h. The cooled solution was washed (6 N aqueous NaOH, 50 mL; 10% hydrochloric acid, 50 mL; brine, 100 mL), dried ($MgSO_4$), and concentrated. Analysis (glc) of the crude product showed that it consisted of a mixture of the desired bromo alcohol **38** and the corresponding dibromide. Column chromatography (20 g silica gel, elution with petroleum ether and then with Et_2O) and distillation (58–60°C/0.05 Torr) afforded 5.84 g (70%) of the bromo alcohol **38**, a colorless oil that showed ir (neat): 3300 (br), 1450, 1060 cm^{-1}; ^1H nmr (270 MHz) δ: 1.33–1.52 (m, 3H), 1.59 (quintet, 2H, J = 7 Hz), 1.89 (quintet, 2H, J = 7 Hz), 3.42 (t, 2H, J = 7 Hz), 3.65 (t, 2H, J = 7 Hz). Exact Mass calcd. for $C_6H_{11}{}^{81}Br$ ($M^+ - H_2O$): 164.0025; found: 164.0021.

*6-Bromohexanal (**39**)*

To a stirred solution of PCC (6.1 g, 28.3 mmol) and NaOAc (0.58 g, 7.1 mmol) in 25 mL of dry CH_2Cl_2 was added a solution of the alcohol **38** (2.58 g, 14.2 mmol) in 55 mL of dry CH_2Cl_2. The brown mixture was stirred for 1.5 h at room temperature and then was poured into 300 mL of Et_2O. The mixture was passed through a short column of Florisil (20 g, elution with Et_2O). Concentration of the combined eluate, followed by distillation (55–60°C/0.05 Torr) of the remaining oil, provided 1.76 g (69%) of the aldehyde **39**, a colorless oil that displayed ir (neat): 2700, 1708, 1450, 1280 cm^{-1}, ^1H nmr (270 MHz) δ: 1.39–1.55 (m, 2H), 1.58–1.72 (m, 2H), 1.87 (quintet, 2H, J = 7 Hz), 2.40 (td, 2H, J = 7, 1 Hz), 3.49 (t, 2H, J = 7 Hz), 9.75 (t, 1H, J = 1 Hz). Exact Mass calc. for $C_6H_{10}{}^{79}BrO$: 176.9916; found: 176.9919.

*1,1,7-Tribromo-1-heptene (**40**)*

To a stirred solution–suspension of Ph_3P (5.13 g, 19.5 mmol) in 100 mL of dry CH_2Cl_2 was added CBr_4 (19.5 mmol) and zinc dust (19.5 mmol). After the reaction mixture had been stirred at room temperature for 23 h, a solution of 6-bromohexanal (**39**) (1.76 g, 9.77 mmol) in 20 mL of dry CH_2Cl_2 was added dropwise over a period of 20 min. The resulting mixture was stirred for 2 h. Petroleum ether (350 mL) was added, and the supernatant solution was decanted from the heavy oil. The oil was dissolved in CH_2Cl_2 (70 mL). Petroleum ether (350 mL) was added to the solution and, again, the supernatant solution was decanted. Concentration of the combined petroleum ether solutions, followed by distillation (80°C/0.05 Torr) of the remaining oil, afforded 3.15 g (96%) of the tribromide **40**, a colorless oil that showed ir (neat): 1620, 1450, 800 cm^{-1}; ^1H nmr (270 MHz) δ: 1.41–1.56 (m, 4H), 1.81–1.95 (m, 2H), 2.08–2.19 (m, 2H), 3.41 (t, 2H, J = 7 Hz), 6.40 (t, 1H, J = 7 Hz). Exact Mass calcd. for $C_7H_{11}{}^{81}Br_3$: 337.8354; found: 337.8354.

*Methyl 8-bromo-2-octynoate (**24**)*

To a cold (−78°C), stirred solution of 1,1,7-tribromo-1-heptene (**40**) (3.15 g, 9.32 mmol) in 120 mL of dry THF was added a solution of BuLi (23.3 mmol) in hexane. The mixture was stirred at −78°C for 1 h, at room temperature for 1 h, and then was recooled to −20°C. Methyl chloroformate (10.25 mmol) was added and the solution was stirred at −20°C for 1 h and at room temperature for 1 h. Saturated aqueous $NaHCO_3$ and Et_2O were added and the organic phase was washed (saturated aqueous $NaHCO_3$, brine), dried ($MgSO_4$), and concentrated. Distillation (90°C/0.05 Torr) of the crude product provided 1.95 g (89%) of the bromo ester **24**, a colorless oil that showed ir (neat): 2200, 1700, 1430, 1078 cm^{-1}; ^1H nmr (270 MHz) δ: 1.54–1.68 (m, 4H), 1.89 (quintet, 2H, J = 7 Hz), 2.38 (t, 2H, J = 7 Hz), 3.41 (t, 2H, J = 7 Hz), 3.77 (s, 3H). Exact Mass calcd. for $C_8H_{10}{}^{81}BrO$ (M^+ –OMe): 202.9896; found: 202.9896.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

*Methyl 8-iodo-2-octynoate (**25**)*

Sodium iodide (2.48 g, 16.5 mmol) was added to a stirred solution of methyl 8-bromo-2-octynoate (**24**) (970 mg, 4.13 mmol) in 40 mL of dry acetone. The mixture was refluxed for 7.5 h and then was cooled and concentrated. Petroleum ether (40 mL) and water (20 mL) were added to the residual material. The organic phase was washed twice with water (15 mL) and then was dried ($MgSO_4$) and concentrated. Distillation (80–85°C/0.05 Torr) of the crude product gave 1.08 g (93%) of the iodo ester **25**, a colorless oil that showed ir (neat): 2236, 1714, 1256 cm^{-1}; ^1H nmr (300 MHz) δ: 1.50–1.70 (m, 4H), 1.88 (quintet, 2H, J = 7.5 Hz), 2.49 (t, 2H, J = 7.5 Hz), 3.22 (t, 2H, J = 7.5 Hz), 3.80 (s, 3H). Exact Mass calcd. for $C_9H_{13}IO_2$: 279.9962; found: 279.9965.

*Methyl 2,8-nonadiynoate (**30**) and dimethyl 2,8-decadiyndioate (**32**)*

A solution of MeLi (31.2 mmol) in Et_2O was added to a cold (−78°C), stirred solution of 1,7-octadiyne (**28**) (2.54 g, 24.0 mmol) in 70 mL of dry THF and the mixture was stirred at −78°C for 10 min and at −20°C for 1 h. Methyl chloroformate (33.5 mmol) was added and stirring was continued at −20°C for 1 h and at room temperature for 1 h. Saturated aqueous $NaHCO_3$ and Et_2O were added. The organic phase was separated, washed (saturated aqueous $NaHCO_3$, brine), dried ($MgSO_4$), and concentrated. Column chromatography (100 g silica gel, 2:3 petroleum ether – Et_2O) of the crude product provided two oils. Distillation (100°C/0.05 Torr; 160°C/0.05 Torr) of these materials gave 1.58 g (40%) and 1.71 g (32%) of the monoester **30** and the diester **32**, respectively.

Compound **30**, a colorless oil, displayed ir (neat): 3296, 2238, 1718, 1436, 1260, 1080 cm^{-1}; ^1H nmr (300 MHz) δ: 1.60–1.81 (m, 4H), 1.98 (t, 1H, J = 2 Hz), 2.23 (dt, 2H, J = 2, 7 Hz), 2.39 (t, 2H, J = 7 Hz), 3.76 (s, 3H). Exact Mass calcd. for $C_{10}H_{11}O_2$ (M^+ −H): 163.0759; found: 163.0757.

Compound **32**, a solid, exhibited mp 34°C (from MeOH–H_2O); ir (CCl_4): 2245, 1733, 1456, 1279, 1084 cm^{-1}; ^1H nmr (300 MHz) δ: 1.68–1.80 (m, 4H), 2.32–2.48 (m, 4H), 3.78 (s, 6H). Exact Mass calcd. for $C_{11}H_{11}O_3$ (M^+ −OMe): 191.0708; found: 191.0714.

*Methyl 8-bromo-8-nonen-2-ynoate (**26**)*

To a cold (0°C), stirred solution of *B*-bromo-9-borabicyclo[3.3.1]nonane (4.02 mmol) in 5 mL of dry CH_2Cl_2 was added dropwise, over a period of 10 min, a solution of methyl 2,8-nonadiynoate (**30**) (300 mg, 1.83 mmol) in 5 mL of dry CH_2Cl_2. The mixture was stirred at 0°C for 3 h, 1 mL of HOAc was added, and stirring was continued at 0°C for 1 h. Aqueous NaOH (3 M, 12 mL) and aqueous H_2O_2 (30%, 2 mL) were added and the mixture was stirred at room temperature for 30 min. The mixture was extracted with petroleum ether (3 × 20 mL). The combined extracts were washed (water, 15 mL; saturated aqueous $NaHCO_3$, 15 mL; water, 15 mL), dried ($MgSO_4$), and concentrated. Column chromatography (15 g silica gel, 4:1 petroleum ether – Et_2O) of the crude product and distillation (130°C/0.05 Torr) of the acquired oil afforded 388 mg (87%) of the ester **26**, a colorless oil that showed ir (neat): 2238, 1718, 1631, 1435, 1261, 1079 cm^{-1}; ^1H nmr (270 MHz) δ: 1.54–1.72 (m, 4H), 2.36 (t, 2H, J = 7 Hz), 2.44 (t, 2H, J = 7 Hz), 3.76 (s, 3H), 5.41 (d, 1H, J = 1.5 Hz), 5.58 (d, 1H, J = 1.5 Hz). Exact Mass calcd. for $C_9H_{10}{}^{81}BrO$ (M^+ −OMe): 214.9896; found: 214.9894.

General procedure 1. Conversion of 1-alkynes into N,N*-dimethyl-2-alkyamides*

To a cold (−78°C), stirred solution of the 1-alkyne in dry THF (~2 mL per mmol of alkyne) was added a solution of MeLi (1 equiv.) in Et_2O. The mixture was stirred at −78°C for 30 min and at −20°C for 1 h. *N,N*-Dimethylcarbamyl chloride (1.1 equiv.) was added and the mixture was stirred at −20°C for 1 h and at room temperature for 2 h. Saturated aqueous $NaHCO_3$ (~0.25 mL per mmol of starting material used) was added, the mixture was stirred at room temperature for 2 h, and then was diluted with Et_2O. The phases were separated and the aqueous phase was thoroughly extracted with Et_2O. The combined extracts were washed (saturated aqueous $NaHCO_3$), dried ($MgSO_4$), and concentrated. Distillation of the remaining liquid produced the amide product.

The following compounds were prepared via this method.

N,N-*Dimethyl-2-butynamide (**44**)*

The crude product derived from 50 mmol of propyne (**41**) was distilled (100°C/20 Torr; lit. (28) bp 98–102°C/17–18 Torr) to give 4.51 g (81%) of **44**, a colorless oil that displayed ir (neat): 2240, 2210, 1630, 1400 cm^{-1}; ^1H nmr (80 MHz) δ: 2.02 (s, 3H), 2.98, 3.22 (s, s, 3H each).

N,N-*Dimethyl-2-pentynamide (**45**)*

Distillation (125–130°C/12 Torr) of the crude product obtained from 50 mmol of 1-butyne (**42**) afforded 5.32 g (85%) of the amide **45**, a colorless oil that showed ir (neat): 2230, 2200, 1630, 1400, 1190 cm^{-1}; ^1H nmr (100 MHz) δ: 1.06 (t, 3H, J = 7.5 Hz), 2.23 (q, 2H, J = 7.5 Hz), 2.82, 3.06 (s, s, 3H each). Exact Mass calcd. for $C_7H_{11}NO$: 125.0841; found: 125.0843.

N,N-*Dimethyl-6-*tert*-butyldimethylsiloxy-2-hexynamide (**46**)*

Distillation (140–145°C/0.8 Torr) of the crude product acquired from 1.88 g (9.5 mmol) of 5-*tert*-butyldimethylsiloxy-1-pentyne (**43**) (14) provided 2.34 g (92%) of the amide **46**, a colorless oil that displayed ir (neat): 2210, 1630, 1390, 1110, 840 cm^{-1}; ^1H nmr (80 MHz) δ: 0.02 (s, 6H), 0.86 (s, 9H), 1.77 (m, 2H), 2.45 (t, 2H, J = 7 Hz), 2.97, 3.19 (s, s, 3H each), 3.70 (t, 2H, J = 6 Hz). Exact Mass calcd. for $C_{13}H_{24}NO_2Si$ (M^+ −Me): 254.1576; found: 254.1576.

General procedure 2. Conversion of alkyl 2-alkynoates into alkyl (Z)-2,3-bis(trimethylstannyl)-2-alkenoates

To a stirred solution of the alkyl 2-alkynoate (1 equiv.) in dry THF (~15 mL per mmol of substrate) was added $(Me_3Sn)_2$ (1 equiv.) and $(Ph_3P)_4Pd$ (0.009–0.02 equiv.) and the mixture was stirred at room temperature or at reflux temperature for the time specified in Table 1. Concentration of the reaction mixture afforded a dark oil that was purified by column chromatography on silica gel. Since the products (colorless oils) are thermally unstable and, therefore, were not distilled, last traces of solvent were removed by subjection of each product to reduced pressure (vacuum pump, 0.05 Torr) for 1–2 h at room temperature.

General procedure 3. Conversion of alkyl (Z)-2,3-bis(trimethylstannyl)-2-alkenoates into alkyl (E)-2,3-bis(trimethylstannyl)-2-alkenoates

A stirred sample of the (Z) substrate in a round-bottomed flask was heated (neat) at the temperature and for the time specified in Table 2. The acquired yellow oil was purified by direct distillation (receiving bulb cooled to −10°C) or by flash chromatography (silica gel, elution with petroleum ether – Et_2O) prior to distillation. Each alkyl (*E*)-2,3-bis(trimethylstannyl)-2-alkenoate was obtained as a colorless oil.

The following compounds were prepared by means of general procedures 2 and 3. The nmr spectroscopic data derived from all or a selected number of these substances are shown in Tables 3–7.

*Ethyl (Z)- and (E)-2,3-bis-(trimethylstannyl)-2-butenoates (**47** and **69**)*

Column chromatography (30 g silica gel, 19:1 petroleum ether – Et_2O) of the crude product obtained from ethyl 2-butynoate (**9**) (344 mg, 3.07 mmol) and $(Me_3Sn)_2$ (3.07 mmol) in the presence of $(Ph_3P)_4Pd$ (0.043 mmol) gave 1.29 g (95%) of **47**, which exhibited ir (neat): 1702, 1200, 1040, 775 cm^{-1}. Exact Mass calcd. for $C_{11}H_{23}O_2Sn_2$ (M^+ −Me): 426.9743; found: 426.9743.

Flash chromatography (5 g silica gel, 17:1 petroleum ether – Et_2O) of the yellow oil obtained from heating **47** (78 mg), followed by distillation (70–75°C/0.1 Torr) of the acquired oil gave 64 mg (82%) of the *E*-isomer **69**, which exhibited ir (neat): 1685, 1230, 775 cm^{-1}. Exact Mass calcd. for $C_{11}H_{23}O_2Sn_2$ (M^+ − Me): 426.9743; found: 426.9743.

*Methyl (Z)- and (E)-2,3-bis(trimethylstannyl)-2-pentenoates (**48** and **70**)*

Reaction of methyl 2-pentynoate (**10**) (8) (1.13 g, 9.94 mmol) with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

$(Me_3Sn)_2$ (9.94 mmol) in the presence of $(Ph_3P)_4Pd$ (0.113 mmol), followed by column chromatography (40 g silica gel, 19:1 petroleum ether – Et_2O) of the crude product, provided 3.88 g (88%) of the *Z* isomer **48**, which displayed ir (neat): 1708, 1191, 771 cm^{-1}. Exact Mass calcd. for $C_{11}H_{23}O_2Sn_2$ (M^+ − Me): 426.9743; found: 426.9747.

Heating of the *Z* substance **48** (71 mg), followed by purification of the yellow oil by flash chromatography (5 g silica gel, 17:1 petroleum ether – Et_2O) and distillation (90–95°C/0.05 Torr), produced 58 mg (82%) of the *E* isomer **70**, which showed ir (neat): 1693, 1224, 772 cm^{-1}. Exact Mass calcd. for $C_{11}H_{23}O_2Sn_2$ (M^+ − Me): 426.9743; found: 426.9741.

*Methyl (Z)- and (E)-4-methyl-2,3-bis(trimethylstannyl)-2-pentenoate (**49** and **71**)*

Treatment of methyl 4-methyl-2-pentynoate (**11**) (9) (856 mg, 6.85 mmol) with $(Me_3Sn)_2$ (6.85 mmol) and $(Ph_3P)_4Pd$ (0.068 mmol) and column chromatography (35 g silica gel, 9:1 petroleum ether – Et_2O) of the crude product afforded 2.82 g (90%) of the *Z* product **49**, which displayed ir (neat): 1705, 1190, 770 cm^{-1}. Exact Mass calcd. for $C_{12}H_{25}O_2Sn_2$ (M^+ −Me): 440.9899; found: 440.9909.

Distillation (90–95°C/0.05 Torr) of the yellow oil obtained from heating a sample of **49** (417 mg) gave 407 mg (98%) of the *E* isomer **71**, which showed ir (neat): 1688, 1220, 775 cm^{-1}. Exact Mass calcd. for $C_{12}H_{25}O_2Sn_2$ (M^+ − Me): 440.9899; found: 440.9896.

*Methyl (Z)- and (E)-3-cyclopropyl-2,3-bis(trimethylstannyl)-propenoate (**50** and **72**)*

Column chromatography (20 g silica gel, 9:1 petroleum ether – Et_2O) of the crude product derived from reaction of methyl 3-cyclopropylpropynoate (**12**) (9) (304 mg, 2.45 mmol) with $(Me_3Sn)_2$ (2.45 mmol) in the presence of $(Ph_3P)_4Pd$ (0.043 mmol) afforded 916 mg (83%) of the *Z* ester **50**, which exhibited ir (neat): 1703, 1200, 770 cm^{-1}. Exact Mass calcd. for $C_{12}H_{23}O_2Sn_2$ (M^+ −Me): 438.9742; found: 438.9743.

Distillation (~100°C/0.05 Torr) of the yellow oil obtained from heating **50** (412 mg) produced 344 mg (83%) of the *E* isomer **72**, which displayed ir (neat): 1685, 1220, 775 cm^{-1}. Exact Mass calcd. for $C_{12}H_{23}O_2Sn_2$ (M^+ − Me): 438.9742; found: 438.9745.

*Methyl (Z)- and (E)-5-(2-cyclopentenyl)-2,3-bis(trimethylstannyl)-2-pentenoate (**51** and **73**)*

Reaction of methyl 5-(2-cyclopentenyl)-2-pentynoate (**13**) (9) (122 mg, 0.68 mmol) with $(Me_3Sn)_2$ (0.68 mmol) in the presence of $(Ph_3P)_4Pd$ (0.007 mmol), followed by column chromatography (5 g silica gel, 17:3 petroleum ether – Et_2O) of the crude product, afforded 255 mg (73%) of the *Z* product **51**, which showed ir (neat): 1700, 1200, 770 cm^{-1}. Exact Mass calcd. for $C_{16}H_{29}O_2Sn_2$ (M^+ −Me): 493.0212; found: 493.0216.

Distillation (~130°C/0.05 Torr) of the liquid derived from heating a sample of the *Z* substance **51** (158 mg) gave 128 mg (81%) of the *E* isomer **73**, which showed ir (neat): 1685, 1225, 775 cm^{-1}. Exact Mass calcd. for $C_{16}H_{29}O_2Sn_2$ (M^+ − Me): 493.0212; found: 493.0218.

*Methyl (Z)- and (E)-4-(3-cyclohexenyl)-2,3-bis(trimethylstannyl)-2-butenoate (**52** and **74**)*

Column chromatography (5 g silica gel, 17:3 petroleum ether – Et_2O) of the crude material acquired from treatment of methyl 4-(3-cyclohexenyl)-2-butynoate (**14**) (9) (89 mg, 0.5 mmol) with $(Me_3Sn)_2$ (0.5 mmol) in the presence of $(Ph_3P)_4Pd$ (0.007 mmol) afforded 188 mg (74%) of the *Z* ester **52**, which exhibited ir (neat): 1703, 1640, 1190, 780 cm^{-1}. Exact Mass calcd. for $C_{16}H_{29}O_2Sn_2$ (M^+ − Me): 493.0212; found: 493.0209.

Distillation (~150°C/0.05 Torr) of the yellow oil acquired from heating a sample of **52** (170 mg) produced 150 mg (88%) of the *E* isomer **74**, which showed ir (neat): 1685, 1640, 1220, 775 cm^{-1}. Exact Mass calcd. for $C_{16}H_{29}O_2Sn_2$ (M^+ − Me): 493.0212; found: 493.0206.

*Methyl (Z)- and (E)-2,3-bis(trimethylstannyl)-2,6-heptadienoate (**53** and **75**)*

Column chromatography (20 g silica gel, 17:3 petroleum ether – Et_2O) of the dark oil acquired from reaction of methyl 6-hepten-2-ynoate (**15**) (350 mg, 2.53 mmol) with $(Me_3Sn)_2$ (2.53 mmol) in the presence of $(Ph_3P)_4Pd$ (0.045 mmol) produced 1.0 g (85%) of the *Z* ester **53**, which displayed ir (neat): 1708, 1641, 1191, 770 cm^{-1}. Exact Mass calcd. for $C_{13}H_{25}O_2Sn_2$ (M^+ − Me): 452.9898; found: 452.9896.

Flash chromatography (5 g silica gel, 17:3 petroleum ether – Et_2O) of the yellow oil derived from heating a sample of **53** (155 mg), followed by distillation (95–100°C/0.05 Torr) of the acquired oil, afforded 125 mg (81%) of the *E* ester **75**, which showed ir (neat): 1692, 1641, 1229, 770 cm^{-1}. Exact Mass calcd. for $C_{13}H_{25}O_2Sn_2$ (M^+ − Me): 452.9898; found: 452.9907.

*Methyl (Z)- and (E)-6-(tetrahydropyranyloxy)-2,3-bis(trimethylstannyl)-2-hexenoate (**54** and **76**)*

Treatment of methyl 6-(tetrahydropyranyloxy)-2-hexynoate (**16**) (9) (365 mg, 1.6 mmol) with $(Me_3Sn)_2$ (1.6 mmol) in the presence of $(Ph_3P)_4Pd$ (0.015 mmol), followed by column chromatography (20 g silica gel, 1:1 petroleum ether – Et_2O) of the crude brown oil, produced 734 mg (83%) of the *Z* ester **54**, which exhibited ir (neat): 1700, 1190, 1030, 730 cm^{-1}. Exact Mass calcd. for $C_{17}H_{33}O_4Sn_2$ (M^+ − Me): 541.0423; found: 541.0425.

Distillation (~155°C/0.05 Torr) of the yellow oil obtained from heating a sample of **54** (705 mg) gave 652 mg (93%) of the *E* ester **76**, which displayed ir (neat): 1686, 1190, 1030, 780 cm^{-1}. Exact Mass calcd. for $C_{17}H_{33}O_4Sn_2$ (M^+ − Me): 541.0423; found: 541.0426.

*Ethyl (Z)- and (E)-4-(*tert*-butyldimethylsiloxy)-2,3-bis(trimethylstannyl)-2-butenoate (**55** and **77**)*

Column chromatography (10 g silica gel, 9:1 petroleum ether – Et_2O) of the crude brown oil acquired from reaction of ethyl 4-(*tert*-butyldimethylsiloxy)-2-butynoate (**17**) (9) (205 mg, 0.85 mmol) with $(Me_3Sn)_2$ (0.85 mmol) in the presence of $(Ph_3P)_4Pd$ (0.011 mmol) provided 403 mg (83%) of the *Z* ester **55**, which showed ir (neat): 1698, 1170, 1060, 840, 770 cm^{-1}. Exact Mass calcd. for $C_{17}H_{37}O_3SiSn_2$ (M^+ − Me): 557.0556; found: 557.0549.

Flash chromatography (10 g silica gel, 97:3 petroleum ether – Et_2O) of the yellow oil obtained from heating a sample of **55** (162 mg), followed by distillation (~135°C/0.05 Torr) of the acquired oil, gave 140 mg (86%) of the *E* ester **77**, a colorless oil that displayed ir (neat): 1698, 1640, 1230, 845, 780 cm^{-1}. Exact Mass calcd. for $C_{17}H_{37}O_3SiSn_2$ (M^+ −Me): 557.0556; found: 557.0556.

*Ethyl (Z)-5-chloro-2,3-bis(trimethylstannyl)-2-pentenoate (**56**)*

Column chromatography (35 g silica gel, 23:2 petroleum ether – Et_2O) of the crude product derived from reaction of ethyl 5-chloro-2-pentynoate (**18**) (742 mg, 4.64 mmol) with $(Me_3Sn)_2$ (4.64 mmol) in the presence of $(Ph_3P)_4Pd$ (0.056 mmol) provided 2.02 g (89%) of the *Z* ester **56**, a colorless oil that displayed ir (neat): 1702, 1186, 773 cm^{-1}. Exact Mass calcd. for $C_{12}H_{24}{}^{35}ClO_2Sn_2$ (M^+ − Me): 474.9509; found: 474.9503.

*Ethyl (Z)-5-bromo-2,3-bis(trimethylstannyl)-2-pentenoate (**57**)*

Reaction of ethyl 5-bromo-2-pentynoate (**19**) (347 mg, 1.69 mmol) with $(Me_3Sn)_2$ (1.69 mmol) in the presence of $(Ph_3P)_4Pd$ (0.034 mmol), followed by column chromatography (20 g silica gel, 9:1 petroleum ether – Et_2O) of the crude product (dark oil), gave 600 mg (66%) of the *Z* ester **57**, a colorless oil that showed ir (neat): 1698, 1186, 770 cm^{-1}. Exact Mass calcd. for $C_{12}H_{24}{}^{81}BrO_2Sn_2$ (M^+ − Me): 520.8985; found: 520.8982.

*Methyl (Z)- and (E)-6-chloro-2,3-bis(trimethylstannyl)-2-hexenoate (**58** and **78**)*

Column chromatography (40 g silica gel, 19:1 petroleum ether – Et_2O) of the crude dark oil derived from reaction of methyl 6-chloro-2-hexynoate (**20**) (10) (1.0 g, 6.25 mmol) with $(Me_3Sn)_2$ (6.25 mmol) in the presence of $(Ph_3P)_4Pd$ (0.062 mmol) afforded 2.62 g (86%) of the *Z* ester **58**, a colorless oil that displayed ir (neat): 1698, 1195, 770 cm^{-1}. Exact Mass calcd. for $C_{12}H_{24}{}^{35}ClO_2Sn_2$ (M^+ − Me): 474.9509; found: 474.9518.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

Distillation (~105°C/0.1 Torr) of the pale yellow oil acquired from heating a sample of the *Z* ester **58** (477 mg) produced 457 mg (96%) of the *E* ester **78**, a colorless oil that crystallized on standing: mp 30–31°C; ir (KBr): 1691, 1227, 771 cm^{-1}. Exact Mass calcd. for $C_{12}H_{24}{}^{35}ClO_2Sn_2$ (M^+ − Me): 474.9509; found: 474.9510.

*Methyl (Z)-6-bromo-2,3-bis(trimethylstannyl)-2-hexenoate (**59**)*

Column chromatography (30 g silica gel, 19:1 petroleum ether – Et_2O) of the crude product acquired from reaction of methyl 6-bromo-2-hexynoate (**21**) (9) (644 mg, 3.14 mmol) with $(Me_3Sn)_2$ (3.14 mmol) in the presence of $(Ph_3P)_4Pd$ (0.043 mmol) gave 1.41 g (84%) of the *Z* ester **59**, a colorless oil that showed ir (neat): 1700, 1200, 780 cm^{-1}. Exact Mass calcd. for $C_{12}H_{24}{}^{81}BrO_2Sn_2$ (M^+ −Me): 520.8985; found: 520.8988.

*Methyl (Z)-6-iodo-2,3-bis(trimethylstannyl)-2-hexenoate (**60**)*

Reaction of methyl 6-iodo-2-hexynoate (**22**) (9) (756 mg, 3.0 mmol) with $(Me_3Sn)_2$ (3.0 mmol) in the presence of $(Ph_3P)_4Pd$ (0.06 mmol), followed by column chromatography (50 g silica gel, 23:2 petroleum ether – Et_2O) of the acquired dark oil, provided 1.37 g (79%) of the *Z* ester **60**, a colorless oil that displayed ir (neat): 1705, 1190, 771 cm^{-1}. Exact Mass calcd. for $C_{12}H_{24}IO_2Sn_2$ (M^+ − Me): 566.8867; found: 566.8882.

*Methyl (Z)- and (E)-7-bromo-2,3-bis(trimethylstannyl)-2-heptenoate (**61** and **79**)*

Reaction of methyl 7-bromo-2-heptynoate (**23**) (9) (600 mg, 2.74 mmol) with $(Me_3Sn)_2$ (2.74 mmol) in the presence of $(Ph_3P)_4Pd$ (0.043 mmol), followed by column chromatography (45 g silica gel, 19:1 petroleum ether – Et_2O) of the crude product, afforded 1.17 g (78%) of the *Z* ester **61**, a colorless oil that showed ir (neat): 1698, 1290, 770 cm^{-1}. Exact Mass calcd. for $C_{13}H_{26}{}^{81}BrO_2Sn_2$ (M^+ − Me): 534.9141; found: 534.9148.

Flash chromatography (10 g silica gel, 17:1 petroleum ether – Et_2O) of the pale yellow oil derived from heating a sample of the *Z* ester **61** (101 mg), followed by distillation (~130°C/0.05 Torr) of the acquired liquid, gave 81 mg (80%) of the *E* ester **79**, a colorless oil that exhibited ir (neat): 1692, 1224, 770 cm^{-1}. Exact Mass calcd. for $C_{13}H_{26}{}^{79}BrO_2Sn_2$ (M^+ − Me): 532.9161; found: 532.9164.

*Methyl (Z)- and (E)-8-bromo-2,3-bis(trimethylstannyl)-2-octenoate (**62** and **80**)*

Column chromatography (30 g silica gel, 9:1 petroleum ether – Et_2O) of the dark oil derived from reaction of methyl 8-bromo-2-octynoate (**24**) (930 mg, 3.98 mmol) with $(Me_3Sn)_2$ (3.98 mmol) in the presence of $(Ph_3P)_4Pd$ (0.063 mmol) afforded 1.85 g (83%) of the *Z* ester **62**, a colorless oil that exhibited ir (neat): 1707, 1191, 771 cm^{-1}. Exact Mass calcd. for $C_{14}H_{28}{}^{79}BrO_2Sn_2$ (M^+ −Me): 546.9317; found: 546.9321.

Flash chromatography (10 g silica gel, 9:1 petroleum ether – Et_2O) of the pale yellow oil obtained from heating a sample of the *Z* ester **62** (120 mg), followed by distillation (~130°C/0.05 Torr) of the acquired oil, gave 106 mg (88%) of the *E* ester **80**, a colorless oil that displayed ir (neat): 1691, 1230, 772 cm^{-1}. Exact Mass calcd. for $C_{14}H_{28}{}^{79}BrO_2Sn_2$ (M^+ − Me): 546.9317; found: 546.9321.

*Methyl (Z)-8-iodo-2,3-bis(trimethylstannyl)-2-octenoate (**63**)*

Column chromatography (40 g silica gel, 93:3 petroleum ether – Et_2O) of the dark oil derived from reaction of methyl 8-iodo-2-octynoate (**25**) (1.07 g, 3.82 mmol) with $(Me_3Sn)_2$ (3.82 mmol) in the presence of $(Ph_3P)_4Pd$ (0.048 mmol) gave 1.77 g (76%) of the *Z* ester **63**, a colorless oil that displayed ir (neat): 1707, 1191, 770 cm^{-1}. Exact Mass calcd. for $C_{14}H_{28}IO_2{}^{118}Sn^{120}Sn$ (M^+ − Me): 592.9174; found: 592.9170.

*Methyl (Z)- and (E)-8-bromo-2,3-bis(trimethylstannyl)-2,8-nonadienoate (**64** and **81**)*

To a stirred solution of $Pd(OAc)_2$ (2.7 mg) in 1 mL of dry THF was added Ph_3P (6.4 mg) and dry Et_3N (114 μL). After the mixture had been stirred at 60°C for 1 h, $(Me_3Sn)_2$ (0.41 mmol) and a solution of methyl 8-bromo-8-nonen-2-ynoate (**26**) (100 mg, 0.41 mmol) in 1 mL of dry THF were added. The resulting yellow solution was refluxed for 2 h. Removal of the solvent, column chromatography (10 g silica gel, 9:1 petroleum ether – Et_2O) of the remaining dark liquid, and subjection of the acquired colorless oil to reduced pressure (vacuum pump, 0.05 Torr, 1.5 h) afforded 149 mg (64%) of the *Z* ester **64**, which exhibited ir (neat): 1708, 1630, 1191, 770 cm^{-1}. Exact Mass calcd. for $C_{15}H_{28}{}^{79}BrO_2Sn_2$ (M^+ − Me): 558.9317; found: 558.9312.

Flash chromatography (10 g of silica gel, 9:1 petroleum ether – Et_2O) of the yellow liquid derived from heating a sample of the *Z* ester **64** (80 mg), followed by distillation (~145°C/0.05 Torr) of the acquired oil, gave 53 mg (66%) of the *E* ester **81**, a colorless oil that showed ir (neat): 1691, 1630, 1226, 770 cm^{-1}. Exact Mass calcd. for $C_{15}H_{28}{}^{81}BrO_2Sn_2$ (M^+ − Me): 560.9298; found: 560.9306.

General procedure 4. Conversion of N,N*-dimethyl-2-alkynamides into (E)-*N,N*-dimethyl-2,3-bis(trimethylstannyl)-2-alkenamides*

To a stirred solution of the *N,N*-dimethyl-2-alkynamide (1 equiv.) in dry THF was added $(Me_3Sn)_2$ (1 equiv.) and $(Ph_3P)_4Pd$ (~0.01 equiv.) and the mixture was stirred at room temperature (substrates **44**, **45**) or at reflux temperature (substrate **46**) for the times specified in Schemes 5 and 6. Concentration of the reaction mixture, followed by purification of the crude product by chromatography and distillation (receiving bulb cooled to −10°C), provided the product.

*(Z)- and (E)-*N,N*-Dimethyl-2,3-bis(trimethylstannyl)-2-butenamide (**87** and **88**)*

Reaction of *N,N*-dimethyl-2-butynamide (**44**) (269 mg, 2.43 mmol) with $(Me_3Sn)_2$ (2.43 mmol) in the presence of $(Ph_3P)_4Pd$ (0.023 mmol) in dry THF (20 mL), followed by flash chromatography (25 g silica gel, 1:1 petroleum ether – EtOAc), gave two products, in a ratio of about 4:1. Distillation (~105°C/0.1 Torr) of the minor product produced 140 mg (13%) of the *E* amide **88**, while subjection of the major product to reduced pressure (vacuum pump, 0.1 Torr, 1.5 h) provided 540 mg (50%) of the *Z* amide **87**. When a solution of the latter substance in dry THF was refluxed for 1.5 h, it was cleanly converted into the *E* isomer **88**.

The *Z* amide **87**, a colorless oil, displayed ir (neat): 1620, 1390, 1160, 770 cm^{-1}; ^1H nmr (270 MHz) δ: 0.20, 0.22 (s, s, 9H each, $^2J_{Sn-H}$ = 54 Hz in each case), 1.94 (s, 3H, $^3J_{Sn-H}$ = 45 Hz, $^4J_{Sn-H}$ = 11 Hz), 2.91 (s, 3H), 2.95 (s, 3H). Exact Mass calcd. for $C_{11}H_{24}NOSn_2$ (M^+ − Me): 425.9902; found: 425.9909.

The *E* amide **88** exhibited ir (neat): 1620, 1390, 1170, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.12, 0.25 (s, s, 9H each, $^2J_{Sn-H}$ = 53 Hz in each case), 2.05 (s, 3H, $^3J_{Sn-H}$ = 46 Hz, $^4J_{Sn-H}$ = 11 Hz), 2.92 (s, 6H). Exact Mass calcd. for $C_{11}H_{24}NOSn_2$ (M^+ − Me): 425.9902; found: 425.9906.

*(E)-*N,N*-Dimethyl-2,3-bis(trimethylstannyl)-2-pentenamide (**89**)*

Column chromatography (30 g silica gel, 1:1 petroleum ether – Et_2O) of the crude product obtained from reaction of *N,N*-dimethyl-2-pentynamide (**45**) (565 mg, 4.42 mmol) with $(Me_3Sn)_2$ (4.42 mmol) and $(Ph_3P)_4Pd$ (0.045 mmol) in dry THF (70 mL), followed by distillation (105–108°C/0.1 Torr) of the acquired liquid, gave 960 mg (48%) of the *E* amide **89**, a colorless oil that displayed ir (neat): 1620, 1385, 1160, 775 cm^{-1}; ^1H nmr (80 MHz) δ: 0.15 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.25 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.00 (t, 3H, *J* = 7 Hz), 2.32 (q, 2H, *J* = 7 Hz), 2.92 (s, 6H); ^{13}C nmr (75.4 MHz) δ: −8.0 (q, $^1J_{Sn-C}$ = 319 Hz), −7.6 (q, $^1J_{Sn-C}$ = 327 Hz), 14.6 (q, $^3J_{Sn-C}$ = 8 Hz), 34.0 (q), 36.0 (t, $^2J_{Sn-C}$ = $^3J_{Sn-C}$ = 65 Hz), 38.0 (q), 151.4 (s), 162.0 (s), 173.4 (s); ^{119}Sn nmr (111.8 MHz) δ: −47.8; −50.5 (s, s, $^3J_{Sn-Sn}$ = 644 Hz). Exact Mass calcd. for $C_{12}H_{26}NOSn_2$ (M^+ − Me): 440.0058; found: 440.0052.

*(E)-*N,N*-Dimethyl-6-(*tert*-butyldimethylsiloxy)-2,3-bis(trimethylstannyl)-2-hexenamide (**90**)*

Reaction of *N,N*-dimethyl-6-(*tert*-butyldimethylsiloxy)-2-hexynamide (**46**) (159 mg, 0.59 mmol) with $(Me_3Sn)_2$ (0.59 mmol) and $(Ph_3P)_4Pd$ (0.008 mmol) in dry THF (20 mL), followed by column chromatography (20 g silica gel, 4:1 petroleum ether – EtOAc) of the

crude product and distillation (~170°C/0.1 Torr) of the acquired liquid, afforded 222 mg (63%) of the *E* amide **90**, a colorless oil that showed ir (neat): 1620, 1380, 1100, 840, 780 cm^{-1}; ^1H nmr (400 MHz) δ: 0.06 (s, 6H), 0.16, 0.25 (s, s, 9H each, $^2J_{Sn-H}$ = 54 Hz in each case), 0.91 (s, 9H), 1.57 (quintet, 2H, J = 6 Hz), 2.33–2.42 (m, 2H), 2.92 (s, 3H), 2.94 (s, 3H), 3.64 (t, 2H, J = 6 Hz); ^{13}C nmr (75.4 MHz) δ: −8.0 (q, $^1J_{Sn-C}$ = 327 Hz), −7.6 (q, $^1J_{Sn-C}$ = 328 Hz), −5.7 (q), 18.3 (s), 25.9 (q), 33.5 (t), 34.2 (q), 38.3 (q), 40.3 (t, $^2J_{Sn-C} = {}^3J_{Sn-C}$ = 63 Hz), 63.0 (t), 152.5 (s), 160.5 (s), 173.7 (s). Exact Mass calcd. for $C_{19}H_{42}NO_2SiSn_2$ (M^+ − Me): 584.1029; found: 584.1031.

Introduction

Depuis leur découverte, les dérivés pyrroliques ont pris une grande extension. Ces molécules présentent des propriétés phytosanitaires (1–3) ou pharmacologiques (4–7) importantes. Le noyau pyrrole se trouve incorporé à de nombreux produits naturels très importants, tels que les pigments biliaires (8) ou les porphyrines (9).

De nombreuses méthodes de synthèse de dérivés pyrroliques sont décrites dans la littérature. On retiendra, parmi les plus connues, les méthodes de Hantzsch (10, 11), de Knorr (12, 13), de Paal-Knorr (14, 15), ou celles faisant intervenir des ylures de nitriles (16), des acétyléniques (17), des vinylazirines (18), des furanes (19). Les dérivés pyrroliques disubstitués, uniquement en positions 3 et 4, sont d'un accès difficile. On peut les préparer à partir du succinate d'éthyle (20–22), du tosylmethyl isonitrile (23–25) ou enfin par retro Diels–Alder (26–28).

La synthèse de pyrrole à partir de pyrrolidine n'a été étudiée que dans deux cas dans la littérature. La photolyse de pyrrolidines en présence de benzophénone, comme accepteur d'hydrogène, conduit au pyrrole correspondant (29). Le 1,2,5-triphenylpyrrole a pu être obtenu par déshydrogénation de la pyrrolidine de départ, au reflux du *p*-cymène, et en présence de chloranil (30). Nous proposons dans cette étude une nouvelle méthode de synthèse de composés pyrroliques, par oxydation avec du dioxyde de manganèse, sous irradiation micro-ondes.

Partie Expérimentale

Généralités

Points du fusion, non corrigés en capillaires (appareil Tottoli, Büchi). Spectres IR : en suspension dans le Nujol ou sous forme de film, entre lames CaF_2, enregistrés sur un spectromètre Perkin–Elmer 257. Spectres de RMN ^1H : déplacements chimiques en ppm par rapport au TMS; constantes de couplage en Hz; appareil Bruker AC 250. Les analyses élémentaires ont été effectuées par le service de microanalyse de l'École Nationale Supérieure de Chimie de Toulouse. En outre, les chromatographies analytiques sont effectuées sur plaque de silice Riedel-de-Haen réf. 37333.

Au cours de ce travail, nous avons utilisé comme four domestique à micro-ondes (multimode) le Brandt ME 210 B à la puissance maximum de 850 W; utilisation du plateau tournant et de petits Erlenmeyers de Pyrex de 25 mL.

Composés **1**a–**1**j

Les pyrrolidines **1***a* et **1***b* sont des produits commerciaux; **1***c* et **1***d* ont été préparés par débenzylation (31) de la pyrrolidine obtenue d'après la littérature (32, 33); **1***e* par réduction par $LiAlH_4$ de **1***c*; **1***f* par traitement à la soude (26) de **1***c*; **1***g* après méthylation (34) de **1***c*; **1***h* après débenzylation (31) puis méthylation (34) de la pyrrolidine préparée d'après la référence 32; **1***i* d'après la littérature (33) et enfin **1***j* par action du ditosylate sur **1***e*.

Composés **2***a*–**2***j*

Méthode générale : 0,01 mol de **1***a*–**1***j* est solubilisée dans 20 mL de dichlorométhane. On rajoute à cette solution 0,05 mol de dioxyde de manganèse et 3 g de silice. La suspension est évaporée à sec, puis, irradiée sous micro-ondes; le produit recherché est obtenue après trois lavages avec 100 mL de dichlorométhane après avoir été soniqué chaque fois 5 min au bac à ultrasons. Après filtration, le solvant est évaporé et le produit isolé après séparation sur une colonne de silice avec un rendement de 58–96% (tableau 1).

2*a* : Paramètres comparables au produit commercial (F = 62°C (35)).

2*b* : IR (entre lames) : 1703 (C═O) cm^{-1}. RMN ^1H comparable aux données de la littérature (36).

2*c* : F = 143°C (litt. (22) F 151–152°C). RMN ^1H comparable aux données de la littérature (22). IR (KBr) : 3160 cm^{-1} (NH), 1740 (C═O) cm^{-1}.

2*d* : F = 247°C (litt. (23) F 243–245°C). RMN ^1H ($CDCl_3$) : 7,34 (s, 2H, pyr.); 3,69 (s, 6H, CH_3). IR (KBr) : 3148 cm^{-1} (NH), 1732 (C═O) cm^{-1}.

Résultats

Nous avons été amenés à réaliser la synthèse des composés pyrroliques **2***a*–**2***j* à partir des pyrrolidines **1***a*–**1***j* (Schéma 1, Tableau 1). Les produits de départ sont, soit des produits commerciaux, soit des produits déjà décrits dans la littérature, ou obtenus par débenzylation (31) suivie dans certains cas d'une méthylation (34).

Depuis environ 8 ans de nombreuses publications sont consacrées à l'utilisation de fours micro-ondes en chimie, et les fours domestiques sont en passe de devenir un outil courant de laboratoire. On retiendra les cinq mises au point (37–41). L'utilisation des micro-ondes a été étendue également à la chimie hétérocyclique (42–44).

Nous avons pu accéder en quelques minutes (3–7), dans un four à micro-ondes commercial, aux dérivés pyrroliques attendus. Après imprégnation de la pyrrolidine de départ sur un support de silice, par déshydrogénation effectuée en présence de cinq équivalents de dioxyde de manganèse, on obtient les composés pyrroliques **2***a*–**2***j*. La structure des composés obtenus a été confirmée par RMN, IR, analyse élémentaire ou spectrographie de masse pour **2***j*.

Sauf dans le cas de **2***b*, les composés obtenus ne présentent pas de substituants sur les carbones en α de l'azote. De telles molécules sont susceptibles de se polymériser par voie électrochimique.[2]

Le macrocycle **2***j* est le premier exemple de macrocycle pyrrolique disubstitué en positions 3 et 4.

Les composés ont pu être obtenus avec un excellent rendement (58–96%) bien supérieur à celui existant dans la littérature et qui fait appel à la photodeshydrogénation de pyrrolidines (30–50%).

La réaction d'oxydation par MnO_2 peut être réalisée par chauffage classique au reflux du toluène. Dans le cas de **2***a* la réaction est terminée après 5 h de chauffage avec un rendement de 71% alors que sous micro-ondes il est de 96% après seulement 3 min d'irradiation.

Cette augmentation du rendement sous micro-ondes résulte du moindre séjour des produits à haute température, mais aussi de l'absence de surchauffe évitant les phénomènes de décomposition locale.

En conclusion, nous présentons dans ce travail une nouvelle méthode de synthèse de pyrroles qui sont obtenus par action du dioxyde de manganèse sur les pyrrolidines. L'activation sous micro-ondes dans un four domestique implique un bref chauffage, évite l'utilisation de solvant et conduit à de bons rendements.

Remerciement

Nous remercions A. Colomer pour l'enregistrement des spectres IR.

Speed of sound, viscosity, and refractive index of multicomponent systems: analysis of experimental data from the Bertrand–Acree–Burchfield equation

J.D. PANDEY,[1] P. JAIN, AND V. VYAS
Department of Chemistry, University of Allahabad, Allahabad – 211 002, U.P., India
Received February 22, 1994

J.D. PANDEY,[1] P. JAIN, and V. VYAS. Can. J. Chem. **72**, 2486 (1994).

The speed of sound in and the viscosity and refractive index of two ternary mixtures (I) toluene + *n*-heptane + *n*-hexane and (II) cyclohexane + *n*-heptane + *n*-hexane, and six binary combinations of these constituents have been measured experimentally. The excess values of these properties are calculated and the results are analysed using the Bertrand–Acree–Burchfield (BAB) model. All the experimental and theoretical values are in fairly reasonable agreement.

J.D. PANDEY,[1] P. JAIN, et V. VYAS. Can. J. Chem. **72**, 2486 (1994).

On a déterminé expérimentalement la vitesse du son dans ainsi que la viscosité et l'indice de réfraction de deux mélanges tertiaires ((I) toluène + *n*-heptane + *n*-hexane et (II) cyclohexane + *n*-heptane + *n*-hexane) ainsi que de six des mélanges binaires qui y contribuent. On a calculé les valeurs en excès et on a analysé les résultats à la lumière du modèle théorique de Bertrand–Acree–Burchfield (BAB). On a trouvé que l'accord entre les valeurs expérimentales et théoriques de toutes les propriétés en excès est raisonnable.

Introduction

A thorough knowledge of thermodynamic and transport properties of multicomponent liquid systems is essential in many industrial applications such as design calculation, heat transfer, mass transfer, and fluid flow etc. Various empirical, semi-empirical, and group contribution methods for computing the thermodynamic properties of multicomponent systems have been thoroughly reviewed by Acree (1), Singh et al. (2–4) used the graphical–theoretical approach to analyse the experimental data on molar excess volume and molar excess enthalpies of ternary non-electrolyte solutions. Flory's statistical mechanical theory (5) in combination with the method used by Patterson and Rastogi (6), has been successfully used to evaluate activity coefficient (7), heat of mixing (7), surface tension (8–10), sound velocity (11–13), excess volume (14, 15), and viscosity (16) of various multicomponent liquid systems. In all these methods, properties of multicomponent systems have been calculated using properties of the pure components. However, a more promising approach to predict the thermodynamic and physical properties of multicomponent liquid systems using binary combinations of their constituents has been developed by Bertrand, Acree, and Burchfield (1, 17, 18). There are a number of equations (1) to compute excess enthalpy, excess free energy, and other excess thermodynamic properties of multicomponent systems from the excess properties of these binary combinations, provided the composition of the binary combinations is similar to the ternary combinations. Bertrand et al. modified this approach by considering binary systems with components at the same molar ratio as in the ternary systems and evaluated excess enthalpy, excess Gibbs free energy, and excess volume for the ternary systems. The Bertrand–Acree–Burchfield method has not been applied to transport properties. Many important properties such as sound velocity, isothermal compressibility, internal pressure, surface tension etc. have not been estimated using this approach. Recently Acree and Teng (19) tested the applicability and limitations of a newly derived semi-empirical relationship (20) that includes contributions from both two-body and three-body interactions.

This work is to determine density, sound velocity, viscosity, and refractive index of two ternary non-electrolyte solutions (I) toluene + *n*-heptane + *n*-hexane and (II) cyclohexane + *n*-heptane + *n*-hexane. To use the Bertrand–Acree–Burchfield method to estimate sound velocity, refractive index, and viscosity of these ternary systems, we measured the same properties in the respective binary mixtures. The theoretical sound velocity, refractive index, and viscosity values obtained from the Bertrand–Acree–Burchfield method were compared to the experimental values. A slight modification in the Bertrand–Acree–Burchfield method was adopted.

Experimental

AnalaR grade toluene, *n*-heptane, *n*-hexane, and cyclohexane were obtained from M/S BDH Chemicals Ltd., Poole, England. These were purified by double distillation and dried in accordance with the usual procedure. All measurements were carried out while using a thermostatically-controlled water-bath where temperature had been set and maintained by a Beckmann thermometer, which was calibrated against a platinum resistance thermometer. The variation in the temperature was not allowed to exceed ±0.01°C during the measurements.

The speed of sound (c) in all liquid systems was measured using an ultrasonic interferometer. To determine the velocity of sound a single crystal-controlled variable path ultrasonic interferometer having a frequency of 2.0 MHz has been used. This method has been described in earlier papers (21, 22), and the estimated error is found to be ±0.07%.

Viscosities (η) of the various liquid systems were determined using a pre-calibrated Ubbelhode-type viscometer. This method is based on the measurement of the time in which a constant volume of liquid flows through a capillary. Uncertainty in the viscosity measurement has been found to be ±0.01%.

The refractive indices of various liquid systems have been measured using Abbe's refractometer. The temperature was kept constant by maintaining a constant flow of water from a thermostat through the outer jacket of the cell. Measured refractive indices were found to be accurate to ±0.0002 units. Other experimental details have been discussed in an earlier paper (17).

Theoretical

A number of equations have been proposed (1–19) to predict the thermodynamic excess properties of multicomponent systems. These methods have been critically reviewed by Acree

[1]Author to whom correspondence may be addressed.

(1). However, the most accurate method to estimate the physical and thermodynamic excess properties was developed by Bertrand, Acree, and Burchfield (17–19). They have developed an equation based on a model ternary system to study the thermodynamic properties of solute in simple binary solvents. This equation obeys the general mixing equation,

$$[1]\qquad \Delta Z^{ex}_{123} = (n_1\gamma_1 + n_2\gamma_2 + n_3\gamma_3)^{-1}(n_1\gamma_1 n_2\gamma_2 A_{12} + n_1\gamma_1 n_3\gamma_3 A_{13} + n_2\gamma_2 n_3\gamma_3 A_{23})$$

where Z_{ij} represents any extensive thermodynamic property described in terms of interaction parameters A_{ij} and weighting factor γ_i. By suitable manipulations, eq. [1] can be rearranged to

$$[2]\qquad \Delta Z^{ex}_{123} = \frac{\{(n_1+n_2)(f_1+f_2)x_1^*x_2^*\gamma_1\gamma_2 A_{12}\}}{(x_1^*\gamma_1 + x_2^*\gamma_2)} + \{\frac{(n_1+n_3)(f_1+f_3)x_1^*x_3^*\gamma_1\gamma_3 A_{13}\}}{(x_1^*\gamma_1 + x_3^*\gamma_3)} + \{\frac{(n_2+n_3)(f_2+f_3)x_2^*x_3^*\gamma_2\gamma_3 A_{23}\}}{(x_2^*\gamma_2 + x_3^*\gamma_3)}$$

where

$$[3]\qquad f_i = \frac{x_i\gamma_i}{(x_1\gamma_1 + x_2\gamma_2 + x_3\gamma_3)}$$

and the subscript * represents the composition of a binary system which would be formed if all the third components were removed, so that for an i–j system,

$$[4]\qquad x_i^* = (1 - x_j) = \frac{x_i}{(x_i + x_j)}$$

Review of eq. [2] shows that for the systems obeying this equation, the properties of contributing binary systems would obey (per mole of ternary solution) the following equation:

$$[5]\qquad \Delta\bar{Z}^{ex}_{ij} = \frac{x_i^*x_j^*\gamma_i\gamma_j A_{ij}}{(x_i^*\gamma_i + x_j\gamma_j)}$$

For one mole of ternary solution eq. [2] can be rearranged to

$$[6]\qquad \Delta\bar{Z}^{ex}_{123} = (x_1+x_2)(f_1+f_2)(\Delta\bar{Z}^{ex}_{12})^* + (x_1+x_3)(f_1+f_3)(\Delta\bar{Z}^{ex}_{13})^* + (x_2+x_3)(f_2+f_3)(\Delta\bar{Z}^{ex}_{23})^*$$

or in general, for multicomponent systems,

$$[7]\qquad \Delta\bar{Z}^{ex}_{123....N} = \sum_{i=1}^{N}\sum_{j>i}(x_i+x_j)(f_i+f_j)(\Delta\bar{Z}^{ex}_{ij})^*$$

A number of methods have been suggested for the evaluation of weighting factors which are a rough measure of the skew of the binary excess mixing property from a symmetric curve with an extremum at the equimolar composition. A method for the calculation of the ratio of raw weighting factors has been given by Bertrand et al. (15).

$$[8]\qquad \gamma_i = (100N)\Big/\left[\frac{\gamma_1^{raw}}{\gamma_i^{raw}} + \frac{\gamma_2^{raw}}{\gamma_i^{raw}} + \frac{\gamma_3^{raw}}{\gamma_i^{raw}} + \ldots + \frac{\gamma_N^{raw}}{\gamma_i^{raw}}\right]$$

In a reasonable modified approach volume fraction can be used in place of weighted mole fractions and the equation takes the following form:

$$[9]\qquad \Delta Z^{E}_{12....N} = \sum_{i=1}^{N}\sum_{j>i}(x_i+x_j)(\phi_i+\phi_j)(\Delta Z^{E}_{ij})$$

where x_i and x_j are the mole fractions of multicomponent systems; and ϕ_i and ϕ_j are their respective volume fractions and ΔZ^{E}_{ij} can be more appropriately taken as the experimental excess property of the constituent binary combinations at the same molar ratio of the components as in a multicomponent system.

In subsequent studies eq. [9] has been used to determine the excess ultrasonic velocity, excess viscosity, and excess refractive indices of two ternary systems for which eq. [9] takes the form,

$$[10]\qquad (\Delta c^{E}_{123}) = \sum_{i=1}^{2}\sum_{j>i}(x_i+x_j)(\phi_i+\phi_j)(\Delta c^{E}_{ij})$$

$$[11]\qquad (\Delta\eta^{E}_{123}) = \sum_{i=1}^{2}\sum_{j>i}(x_i+x_j)(\phi_i+\phi_j)(\Delta\eta^{E}_{ij})$$

$$[12]\qquad (\Delta n^{E}_{123}) = \sum_{i=1}^{2}\sum_{j>i}(x_i+x_j)(\phi_i+\phi_j)(\Delta n^{E}_{ij})$$

Values of the sound velocity, viscosity, and refractive index are then calculated using the following equations:

$$[13]\qquad c = c_{id} + (\Delta c^{E}_{123})$$

$$[14]\qquad \eta = \eta_{id} + (\Delta\eta^{E}_{123})$$

$$[15]\qquad n = n_{id} + (\Delta n^{E}_{123})$$

where

$$[16]\qquad c_{id} = x_1c_1 + x_2c_2 + x_3c_3$$

$$[17]\qquad \eta_{id} = x_1\eta_1 + x_2\eta_2 + x_3\eta_3$$

$$[18]\qquad n_{id} = x_1n_1 + x_2n_2 + x_3n_3$$

The results so obtained were compared with the experimental findings and with the results of those theories which utilise the properties of single components to predict the thermodynamic properties of multicomponent liquid mixtures.

Finally, the theoretically predicted results were examined in the light of average percentage deviations (σ) and standard error (δ) calculated from the expressions:

$$[19]\qquad \sigma = \frac{1}{N}\sum_{i=1}^{N}[(Z_{i_{expt}} - Z_{i_{calc}})/Z_{i_{expt}}] \times 100$$

and

$$[20]\qquad \delta = \frac{1}{N}\sum_{i=1}^{N}[(Z_{i_{expt}} - Z_{i_{calc}}) \times 100/Z_{i_{expt}}]^2$$

where Z is any measured and theoretically computed property and N is the total number of sets.

Results and discussion

Sound velocity, viscosity, and refractive index of two ternary liquid mixtures — toluene + *n*-heptane + *n*-hexane (I) and cyclohexane + *n*-heptane + *n*-hexane (II) have been predicted using the respective experimental excess properties of their constituent binary liquid mixtures. In this paper a modified Bertrand–Acree–Burchfield approach has been utilized, where weighted mole fractions have been replaced by volume fractions and values of the experimental excess properties for constituent binary liquid systems have been used at the same molar ratio as these are in the ternary liquid mixtures. The values of sound velocity (c), viscosity (η), and refractive index (n) are presented in Table 1.

Mole fractions of the constituent binary mixtures were calculated to ensure that they are in the same molar ratio as in the ternary liquid mixture. The values of c, η, and n at the new mole fractions were determined graphically from the experimental values. Using these values the excess properties of binary liquid mixtures were evaluated. These values, compiled in Tables 2*b*, 2*c*, 2*d* and 3*b*, 3*c*, 3*d* were then used to predict Δc^E_{123}, $\Delta\eta^E_{123}$, and Δn^E_{123} for systems I and II using eqs. [10] to [12]. Respective values of sound velocity, viscosity, and refractive index of mixtures were then calculated using eqs. [13] to [15]. These values are compiled in Tables 2*a* and 3*a* for systems I and II respectively, and their percentage deviations were recorded in Tables 4 and 5. A close look at Tables 4 and 5 reveals that the percentage deviations in the computation of sound velocity is 1.92 and 0.70 respectively for

systems I and II. This shows that the results are in excellent agreement with the experimental findings, and are much better than those obtained when computed using the Flory–Patterson approach by Pandey et al. (11–16). This method yields better results because the predictions are made using the thermodynamic properties of pure components and excess velocities of constituent binary liquid mixtures. Here, all possible binary interactions are considered and are easily accountable by using the experimental excess velocities. More encouraging results were obtained while predicting the viscosity and refractive index of ternary systems. The standard error in computing viscosity was found to be 3.58 and 1.51 for systems I and II. Viscosity of the same ternary liquid mixtures was predicted using empirical, semi-empirical, and statistical approaches and the standard error in most cases was found to be more than 5%. Thus, this approach has an advantage over other methods to predict the viscosity of the multicomponent systems using data of the pure components. The deviations may be due to the polarity and size effects of the components. In systems I and II, an increase in η with increasing concentration of the

For personal use only.

first and second component contributes to the filling up of the third component into the empty sites afforded by the first and second components. For refractive index, the standard errors were found to be 0.12 and 0.93 for systems I and II, respectively, indicating an excellent agreement with the experimental results. Hence, this approach can be used to predict refractive indices more accurately.

The most important feature of this type of equation is that it is applicable to both integral and differential mixing properties and is independent of the manner in which the binary mixing data are represented. It provides reasonably accurate predictions. The excess properties of the multicomponent systems containing more than three liquids can also be successfully expressed in terms of the contributing ternary solutions as

$$\Delta\bar{Z}^{ex}_{123\ldots N} = (N-2)^{-1}\sum_{i=1}\sum_{j>i}\sum_{k>j}^{N}(x_i + x_j + x_k)(\phi_i + \phi_j + \phi_k)(\Delta\bar{Z}^{ex}_{ijk})$$

However, this equation is not expected to be as useful as eq. [9] due to the scarcity of ternary data and tediousness of obtaining the same molar ratios in the ternary liquid mixture as is present in multicomponent liquid systems. We conclude, therefore, that the modified Bertrand–Acree–Burchfield approach can be successfully applied to predict various excess thermodynamical parameters in the case of multicomponent liquid systems.

An AM1 calculational study of the Diels–Alder addition of maleic anhydride to C5-substituted pentamethylcyclopentadienes and 2,5-dimethylthiophene oxide. An attempt to ascertain the factors controlling the π-facial selectivities and relative reactivities

NICK HENRY WERSTIUK AND JIANGONG MA

Department of Chemistry, McMaster University, Hamilton, ON L8S 4M1, Canada

Received February 28, 1994

NICK HENRY WERSTIUK and JIANGONG MA. Can. J. Chem. **72**, 2493 (1994).

The Diels–Alder reactions of maleic anhydride (**1**) with a group of C5-substituted cyclopentadienes and 2,5-dimethylthiophene oxide (**5**) have been studied with the semi-empirical method AM1. We find that the facial selectivities and relative reactivities found experimentally for six dienes (**2***a*–**2***f*) are accurately reproduced at this level of theory. The results of the calculational study provide no concrete support for the proposal that σ–σ* hyperconjugation in the transition state – an interaction between a σ bond at C5 of the cyclopentadiene and the incipient σ bonds *anti* to it (the Cieplak effect) — is the major source of the *syn* facial selectivity observed for **2***a*–**2***d*. In addition, the relative reactivities and facial selectivities are predicted for a number of cyclopentadienes which will be synthesized and studied experimentally.

NICK HENRY WERSTIUK et JIANGONG MA. Can. J. Chem. **72**, 2493 (1994).

Faisant appel à la méthode semi-empirique AM1, on a étudié les réactions de Diels-Alder de l'anhydride maléique (**1**) avec un certain nombre de cyclopentadiènes substitués en position 5 et avec l'oxyde du 2,5-diméthylthiophène (**5**). On a trouvé que, à ce niveau de la théorie, il est possible de reproduire fidèlement les sélectivités faciales et les réactivités relatives observées expérimentalement pour les six diènes (**2***a*–**2***f*). Les résultats de l'étude par calculs ne fournit aucun support concret pour la proposition qui a été faite selon laquelle de l'hyperconjugaison σ–σ* dans l'état de transition – une interaction entre une liaison σ au niveau C5 du cyclopentadiène et les liaisons σ qui se forment *anti* par rapport à elles (effet Cieplak) – serait la cause principale de la sélectivité faciale *syn* observée avec les composés **2***a*–**2***d*. De plus, on a prédit les réactivités relatives et les sélectivités faciales d'un certain nombre de cyclopentadiènes qui seront synthétisés et étudiés expérimentalement.

[Traduit par la rédaction]

Introduction

The synthetic utility of the Diels–Alder reaction is well established although the ability to control the facial selectivity which would render the reaction enantioselective with asymmetric planar 1,3-dienes and potentially generate five or more chiral centres in one operation, is limited in the absence of chiral auxiliaries. In the reaction of C5-substituted cyclopentadienes where π-facial diastereoselectivity has been observed in the absence of chiral auxiliaires, the origin of the selectivity is still imperfectly understood even though a wide range of substrates have been studied experimentally (1–16) and computationally (17–25). These investigations revealed that a number of factors are important and various suggestions have been advanced as possible sources of the pattern observed. These include steric effects, complexation between diene and dienophile, secondary orbital interactions, polarizability, electrostatic interactions, orbital mixing, and transition state hyperconjugation. This latter interpretation proposed by Cieplak for reactions of cyclohexanones is based on the concept of transition state stabilisation by σ donation from an adjacent σ bond into the vacant σ* orbital associated with the incipient bond (26, 27). This explanation was used to account for the *syn* approach of 2,3-dimethylbutadiene to C5-fluoroadamantane-2-thione (28) and rationalize the preference observed for addition *anti* to the antiperiplanar σ bond that is the better donor in the reactions of dienophiles with C5-substituted pentamethylcyclopentadienes (29, 30) and 2,5-dimethylthiophene oxide (15). Clearly, it is desirable to continue research in this area to gain a complete understanding of the factors which affect the π-facial selectivity so that the stereochemistry of D–A reactions of C5-substituted cyclopentadienes can be predicted with certainty and the adducts utilized for the total synthesis of complex molecules. In fact, we showed by means of a calculational and ultraviolet photoelectron spectroscopic study of C5-substituted pentamethylcyclopentadienes (**2***a*, **2***c*, **2***d*, **2***e*, **2***f*, and **2***h*) that n–π orbital mixing (the orbital mixing rule (17, 25)) in the HOMO of **2***a*, **2***c*, and **2***d* is not the source of the *syn* facial selectivity observed in reactions of these dienes with maleic anhydride and *N*-phenylmaleimide (31).

TABLE 1. Facial selectivities and relative rates of Diels–Alder reactions of C5-substituted pentamethylcyclopentadienes with maleic anhydride

[b]Determined by integration of ^{1}H nmr spectra of the total reaction mixture.
[c]The dienophile was *N*-phenylmaleimide.
[d]Addition *syn* to C—H.

In this paper we document the results of an AM1 (32) calculational study of the Diels–Alder (D–A) reactions of maleic anhydride (**1**) with C5-substituted pentamethylcyclopentadienes(**2***a*–**2***k*), 2,3,4,5-tetramethylcyclopentadienes (**3***a* and **3***b*) mono-substituted cyclopentadienes (**4***a* and **4***b*) and 2,5-dimethylthiophenoxide (**5**). The objectives of the study were (*a*) to determine whether the facial selectivities and relative reactivities found experimentally (Table 1) are accurately calculated with AM1, (*b*) to ascertain, by studying SiR_3-substituted ana-

logues and analyzing the changes in the C5—X and C5—R bond lengths and the charges (X, C5, and R) whether a hyperconjugative interaction — the frontier MOs were to be examined as well — between the incipient C—C bonds and the best σ donor is the source of the π-facial selectivities and relative reactivities of cyclopentadienes and, (*c*) to predict facial selectivities which could be verified experimentally.

Results and discussion

Calculations

Reaction coordinate potentials and transition structures for *syn* and *anti* addition of maleic anhydride (**1**) to the group of substituted cyclopentadienes (**2***a*–**2***k*, **3***a*, **3***b*, **4***a*, and **4***b*) and **5** were calculated with AM1 using version 2.1 of AMPAC (32). In one series of calculations, the geometry of the D–A product was optimized, then the incipient bonds (icbs) were lengthened in one step to 1.9 Å; the optimized 1.9 Å geometry was used as the starting point to complete the *retro* Diels–Alder reaction by stretching the icbs to 3.5 or 3.8 Å in 0.1 Å increments. In a second series of calculations, the 2.8 Å geometry of each complex was optimized first, then the D–A addition was completed by shortening the icibs to 1.9 Å. The 1.9 Å geometry was used as the input to compute the optimized geometry of the final product. MMX-optimized input geometries generated with PCMODEL (33) were used as starting points for the AM1 calculations and the icbs were forced to be equal through the use of the keyword SYMMETRY because this was the only convenient way to calculate the energy profiles. The keyword PRECISE was use to tighten the convergence criteria. A two-step approach was to locate the transition structures (TSs). First, the optimized geometry near the maximum of the potential energy profile was calculated with the icbs fixed at 2.15 Å, then the TS was obtained by refining the 2.15 Å geometry with a SIGMA or NLLSQ calculation.[1] In the case of **2***a*, **2***b*, **2***c*, **2***d*, **2***e*, **3***a*, **4***a*, and **4***b*, the forced equivalence of the icbs did not yield symmetrical TSs of C_s symmetry because the substituents bearing lone pairs adopted the lowest energy conformation with respect to the CH_3 (and SiH_3) group or hydrogen or C5. That is, the CH_3—C5—X—H(CH_3) torsional angles were not 0 or 180°. The incipient bond lengths (icbls) of the TSs located in this way are given in Table 2. The icbls fall in the region of 2.15 Å, in accordance with the results of calculational studies on other cyclopentadienes (34). FORCE calculations were carried out to ensure that transition structures located had one imaginary frequency, and this was found to be the case. That these vibrations involve motions of the atoms of the incipient bonds which could lead to the product formation was clearly seen with PC-VIBRATE (35), computer software which animates normal modes of vibration calculated with semi-empirical and *ab initio* quantum chemistry programs. Calculations were also carried out on **2***c* and **2***e* by stepping across the potential energy surface from the transition structures to the 1.9 Å and 3.8 Å complexes in 0.1 Å increments. The potentials were identical to those calculated with the 1.9 Å and 2.8 Å complexes as the starting

points. To ensure that the calculations with the forced equivalence of the icbls gave realistic TSs, SIGMA/NLLSQ calculations were carried out on the *syn* and *anti* TSs of **2***a*, **2***c*, **2***e*, **2***i*, **2***j*, **3***a*, **3***b*, **4***a*, **4***b*, and **5** — the geometries of the TSs with equal icbls were used as the input — without the equivalence constraint. The results for **2***a*, **2***c*, **2***e*, **2***i*, **2***j*, **3***b*, and **5** are given in parentheses in Table 2. It is seen that the icbls differ slightly from those obtained with the equivalence constraint with the largest differences being found in the case of the *anti* TSs, except in the case of **2***i*. Similar results were obtained for **3***a*, **4***a*, and **4***b*. Even so, the ΔH_fs of the TSs (the values are given in parentheses in Tables 3 and 4) remain virtually unchanged. FORCE calculations on these TSs yielded imaginary frequencies which were virtually identical to the frequencies calculated

for the TSs in which the icbls were forced to be equal. The ΔH_fs of **1**, the cyclopentadienes, and **5** were calculated and summed to give the enthalpy of each D–A reaction at infinite separation of the reactants. These data along with the ΔH_fs of the final products, the TSs and the activation enthalpies are given in Tables 3 and 4. The C5—X and C5—R (R = CH_3, SiH_3, $Si(CH_3)_3$, or H) and S—O bond lengths of the starting dienes, the 2.8 Å complexes, the TSs and the final products are given in Tables 5 and 6. Displays of the potentials for *syn* (closed circles) and *anti* (open circles) addition of **1** to a selected group of cyclopentadienes are given in Figs. 1 to 5. The sum of the heats of formation of **1** and the diene corresponding to the enthalpy of the reaction with the reactants at an infinite separation is plotted as a data point (■) at 3.9 Å.

Calculational facial selectivities and relative reactivities

The TS for *syn* addition of **1** to **2***a* was found to be lower in energy than the *anti* diastereomer in accord with the high *syn* facial selectivity found experimentally (Table 1). It is seen in Fig. 1 that the increases in the ΔH_fs of the *syn* and *anti* complexes of **1** and **2***a* are virtually identical up to icbls of 3.5 Å, then the values diverge. Based on the geometrical structures of the 3.6 Å- and 3.4 Å-icbl *anti* complexes of **2***a* (structural formulas not shown), it appears that the differential increase in the

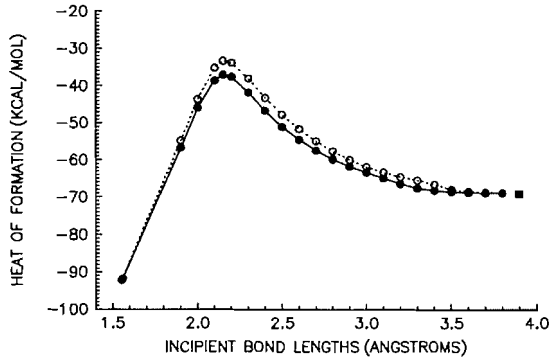

FIG. 1. Displays of the potentials for *syn* (filled circles) and *anti* (open circles) addition of **1** to 5-aminopentamethylcyclopentadiene (**2***a*).

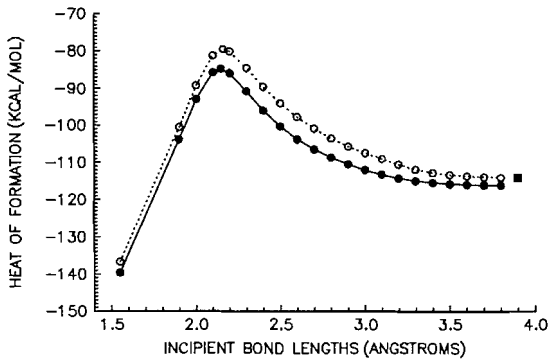

FIG. 2. Displays of the potentials for *syn* (filled circles) and *anti* (open circles) addition of **1** to 5-hydroxypentamethylcyclopentadiene (**2***c*).

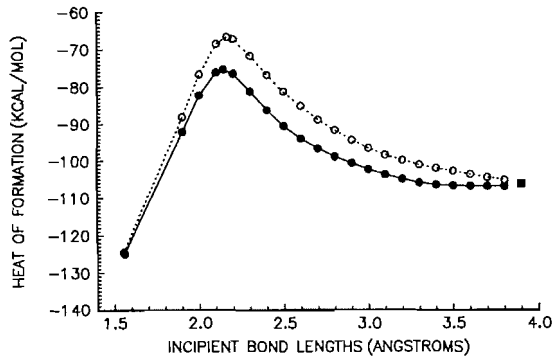

FIG. 3. Displays of the potentials for *syn* (filled circles) and *anti* (open circles) addition of **1** to 5-hydroxy-5-silamethyl-1,2,3,4-tetramethylcyclopentadiene (**3***b*).

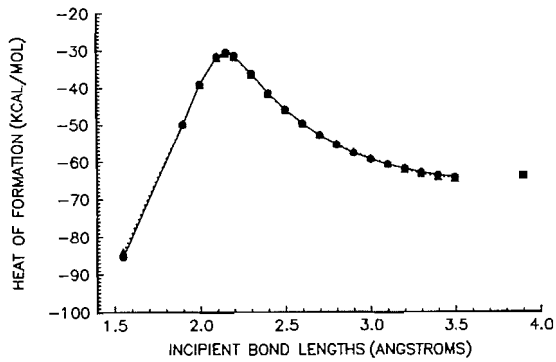

FIG. 4. Displays of the potentials for *syn* (filled circles) and *anti* (filled triangles) addition of **1** to 5-methylthiopentamethylcyclopentadiene (**2***e*).

energy of the *anti* complex at icbls of 3.6 Å occurs as **1** reorientates to maximize overlap of the π systems and initiate C—C bond formation. This effect undoubtedly derives from a steric interaction between the methyl group and the vinyl hydrogens of **1**. In the case of the *syn* complex, a reorientation of **1** occurs when the icbls are between 3.3 and 3.1 Å (structural formulas not shown), leading to a barely perceptible inflection in the potential. It appears that a differential steric interaction is one of factors responsible for the addition of **1** *syn* to the amino group of **2***a*. The data point (■) at 3.9 Å corresponds to the sum of the ΔH_fs of **1** and **2***a*.

As was the case for **2***a*, the *syn* TS of acetamide **2***b* was found to be lower in energy than the *anti* diastereomer (plots not shown) in accord with the experimental results (Table 1). The ΔH_fs also diverge at 3.4 Å as found for **2***a*. At icbls of 3.8 Å, the heats of formation of the *syn* and *anti* complexes are −103.99 and −104.58 kcal/mol, respectively, close to the sum of the ΔH_fs of **1** and **2***b* (−103.97 kcal/mol).

Displays of the potentials of *syn* and *anti* addition of **1** to hydroxy compound **2***c* are given in Fig. 2. The data at 3.9 Å is the sum of the ΔH_fs (−113.75 kcal) of **1** and **2***c*. The calculational ΔH_fs of the *syn* and *anti* complexes with icbls of 3.8 Å are −116.10 and −114.10 kcal, respectively. As was computed for **2***a* and **2***b*, addition of **1** *syn* to the methyl group leads to a discernible increase in the energy of the complex when the icbls approach 3.3 Å. As found in the case of **2***a* and **2***b*, this occurs

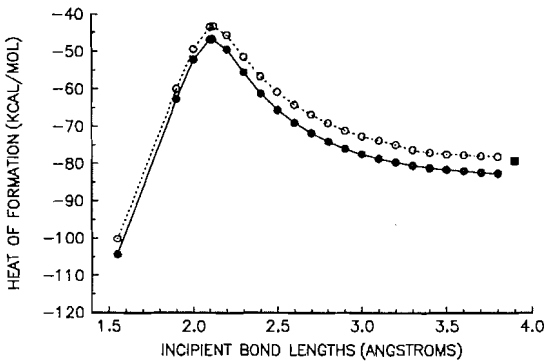

FIG. 5. Displays of the potentials for *syn* (filled circles *syn* to S—O) and *anti* (open circles) addition of **1** to 2,5-dimethylthiophene oxide (**5**).

when **1** reorientates to maximize overlap of the π systems and to initiate bond formation. That the *syn* complex with icbls of 3.8 Å is lower in energy than the reactants at infinite separation suggests that an additional differential stabilising interaction develops early for *syn* addition but not in the *anti* case. This means that it may be possible to use the $\Delta\Delta H_f$s when the icbls are in the region of 3.8 Å or less to identify cases where long-range effects come into play to stabilise or destabilise the D–A complexes. And the *syn* D–A product by calculation is 2.93 kcal/mol lower in energy than the *anti* isomer. Additional calculation studies on the *syn* and *anti* products — the HO—C5 and CH_3—C5 dihedral angles were driven 180° in 15° increments — did not establish the source of this difference. It appears that a combination of a stabilising complexation interaction, a steric effect, and a difference in product stabilities can account for the stereoselectivity observed for the addition of **1** to **2***c*. While it would be useful to establish experimentally whether the *syn* adduct is thermodynamically more stable than the *anti* isomer, it may not be easy to achieve this goal. To obtain a sufficient amount of the *anti* adduct and to carry out equilibration studies will be difficult.

To gain additional information on the role of the methyl groups in determining the facial selectivity and relative reactivities of cyclopentadienes, the additions of **1** to 5-hydroxy-1,2,3,4-tetramethylcyclopentadiene (**3***a*), 5-hydroxycyclopentadiene (**4***a*), and 5-acetoxycyclopentadiene (**4***b*) were also studied with AM1. Given that addition *syn* to the OH group is preferred for **2***c*, it is surprising that *anti* attack is the low energy pathway in the case of **3***a*. Because *syn* facial selectivities (to the OH and OAc groups) are calculated for the addition of **1** to **4***a* and **4***b* (Table 4), the opposite facial selectivities calculated for **2***c* and **3***a* do not result from differential steric effects between the C—H and C—OH groups. Although the addition of **1** to **3***a* has not been studied experimentally, the *syn* selectivities calculated for **4***a* and **4***b* are supported by the fact that ethene adds *syn* to the OAc group of **4***b* (1). According to the results from calculation, the *anti* D–A product of **3***a* is 1.99 kcal/mol lower in energy than the *syn* isomer and this could be the primary reason for the preferred *anti* addition of **1** to this diene. It would be worthwhile to prepare **3***a* and experimentally determine the facial selectivity and its reactivity relative to **2***c* (35). Given that from calculation, $\Delta H^{\ddagger}$ for **3***a* is larger (30.05 kcal/mol) than $\Delta H^{\ddagger}$ for **2***c* (28.90 kcal/mol), **3***a* should be less reactive than **2***c*.

The effect of replacing the C5—CH_3 bond with a better σ donor on the facial selectivity and reactivity was probed through a study of 5-hydroxy-5-silamethylpentamethylcyclopentadiene (**3***b*). Displays of the potentials for the *syn* and *anti* additions of **1** to **3***b* are given in Fig. 3. Although the difference in the energies of the *syn* and *anti* TSs is greater than in the case of **2***c*, from calculation, the activation enthalpy for addition *syn* to the OH group of **3***b* is 1.82 kcal/mol higher than the enthalpy of activation for *syn* addition to **2***c*. Because a Si—C bond is a better σ donor than a CH_3—C bond, this result suggests that transition state hyperconjugation in the transition state is not the major factor controlling π-facial selectivity in the D–A reactions of C5-substituted pentamethylcyclopentadienes. It would certainly be of interest to synthesize **3***b* or its 5-(1-silaethyl) analogue and test the AM1 results from calculations (36).

As was seen in the case of **2***c*, the difference in the $\Delta H^{\ddagger}$s of the *syn* and *anti* complexes of **2***d* develops early and the *syn* transition structure was found to be lower in energy than the *anti* one in keeping with the experimental results (Table 3) (potentials not shown). The factors which control the facial selectivity and reactivity of **2***c* also prevail in **2***d*.

When AM1 parameters for C, H, and S were used in the calculations on **2***e*, *syn* addition was found to be the low energy pathway, a result which is not in keeping with the 9:1 *anti* selectivity found experimentally (Table 1). On the other hand, when mixed parameters were used (C and H, AM1; S, MNDO), the *anti* TS was calculated to be 0.40 kcal/mol lower in energy than the *syn* TS in accord with the *anti* facial selectivity found experimentally. The potentials are displayed in Fig. 4 (*syn* addition, filled circles; *anti* addition, filled triangles). Prior to the development of the AM1 sulfur parameters, calculations with mixed AM1/MNDO parameters were considered to be acceptable, but not ideal (37). While we recognise that calculations of this type should be avoided in general, we view the mixed parameter computations as test calculations. We have found two additional cases where the results of mixed-parameter calculations on low-valent sulfur compounds — the interaction between sulfur lone pairs and the cyclopentadiene π system (31) and the potential for twisting about the Ph—SCH_3 bond of substituted thioanisoles (38) — appear to correlate better with experimental results than full AM1 calculations.

That addition of **1** *syn* to C5—H of pentamethylcyclopentadiene (**2***f*) is the low energy process (Table 3) is in keeping with the facial selectivity found experimentally. Four additional cyclopentadienes — 5-silamethylpentamethylcyclopentadiene (**2***g*), hexamethylcyclopentadiene (**2***h*), 5-trimethylsilyl-1,2,3,4,5-pentamethylcyclopentadiene (**2***i*) and 5-trifluoromethylpentamethylcyclopentadiene (**2***j*) — were studied as well. According to calculations, **1** is expected to add selectively *anti* to the SiH_3 group of **2***g*, the $(CH_3)_3Si$ group of **2***i*, and the CF_3 group of **2***j*. For **2***g*, a difference in the energy between the *syn* and *anti* complexes develops early at 3.8 Å when **1** reorientates to maximized the overlap of the π systems, then the gap increases further at 3.3 Å (potentials not shown). This is a consequence of the fact that a SiH_3 group is bulkier (the Si—H bond lengths are 1.46 Å) than a methyl group (the C—H bond lengths are 1.10 Å). Even so, given the fact that the Si—C bond is a better σ donor than a C—O bond, it is surprising that the enthalpy of activation for *anti* addition to **2***g* is virtually identical ($\Delta H^{\ddagger}$ = 33.12 kcal/mol) to the enthalpy of activation for addition of **1** to **2***h* ($\Delta H^{\ddagger}$ = 33.06 kcal/mol) (Table 3). Because the trimethylsilyl group is bulkier than a methyl group, in calculation, preference for addition *anti* to this group is not surprising. However, that the calculational enthalpy for **2***i* is nearly identical (32.12 kcal/mol) to the activation enthalpy of **2***h* (33.06 kcal/mol) is unexpected. That addition *anti* to the CF_3

[f]Addition *syn* to C—H.

group is preferred in the case of **2***j* is also surprising and suggests that the differential steric effect of a trifluoromethyl group outweighs the differential electron-donating ability of a CH_3—C bond. These calculational results also suggest that the Cieplak effect is probably not the major factor responsible for variation in rates and facial selectivities found in the additions of maleic anhydride and *N*-phenylmaleimide to C5-substituted cyclopentadienes. It would be instructive to synthesize **2***i* and **2***j* and establish whether the predictions made on the basis the AM1 calculations are borne out by experimental studies (36).

To establish the effect of protonating the amino group of **2***a*, the addition of **1** to **2***k* was studied as well. Unlike the case the **2***a*, the *anti* complex is lower in energy (2.3 kcal/mol) than the *syn* complex when the icbls are 3.5 Å, but a crossover in the relative energies occurs when the icbs are shortened to 2.5 Å leading to the *syn* TS being marginally lower in energy (0.24 kcal) than the *anti* diastereomer (Table 3). This means that a much lower *syn* facial selectivity is expected for **2***k* than is found for **2***a*, not what would be expected if transition state hyperconjugation is the major factor determining the stereoselectivity of the D–A addition. Furthermore, based on the calculated $\Delta H^{\ddagger}$s, **2***k*, and of course **2***j*, will be inert relative to the other compounds of the series.

Figure 5 displays the potentials for the *syn* and *anti* addition of **1** to **5** calculated with AM1. The *syn* TS is 3.69 kcal/mol lower in energy than the *anti* TS (Table 4). As found for **2***c*, the difference in energy develops early and is maintained through to the transition structures. Noteworthy is the fact that the *syn* D–A adduct is calculated to be substantially lower in energy (4.15 kcal/mol) than the *anti* adduct. It appears that this is another case where the thermodynamic stability of the final product plays a role in determining the facial selectivity. As in the case of **2***c*, it may be a difficult task to establish the relative stabilities of the *syn* and *anti* D–A products experimentally. Even so, it has been established that **1** adds to **5** and yields a single adduct, but crystals suitable for X-ray analysis were not obtained. Because *p*-quinone adds *syn* to the S—O bond of **5** (15, 16), it is certain to be the *syn* adduct as predicted with AM1.

If $\Delta\Delta S^{\ddagger} \approx 0$ for the series of dienes studied with AM1 — this is a reasonable assumption because the dienes are very similar structurally — then the $\Delta\Delta H^{\ddagger}$s calculated for **2***a*, **2***b*, **2***c*, and **2***d* (−3.76 to −5.28 kcal/mol (Table 3) correlate well with high *syn* facial selectivities found for the addition of **1** to these dienes (Table 1). And the $\Delta\Delta H^{+}$(*syn* − *anti*) of 0.40 kcal/mol calculated for **2***e* correlates with the *anti* selectivity of 9:1 observed experimentally. In the case of pentamethylcyclopentadiene the computed $\Delta\Delta H^{+}$(*syn* − *anti*) (−2.03 kcal/mol) is larger than expected on the basis of the 4:1 *syn* selectivity observed experimentally. This result suggests that AM1 overestimates the differential steric interaction between the *syn* methyl group at C5 and the vinyl hydrogens of the incoming dieneophile relative to a hydrogen at C5 by about 1.5 kcal/mol. Even if the differences in the *syn/anti* TS energies of **2***a*, **2***b*, **2***c*, and **2***d* are reduced by 1.5 kcal/mol, the adjusted $\Delta\Delta H^{+}$s which range between −2.25 and −3.84 kcal/mol still correlate well with the facial selectivites found for **2***a*–**2***d*. Table 7 shows the calculated transition structure enthalpies, the facial selectivites, and relative reactivities found experimentally. From these data is seen that AM1 also accurately predicts the relative reactivities of the cyclopentadienes with **2***c* and **2***f* being the most reactive compounds. According to the AM1 calculations, **2***j* and **2***k* should be inert under the conditions used to carry out the cycloadditions to the other cyclopentadienes. On the basis of the calculated ΔH^{+}s, we expect that thiophene oxide **5** will be less reactive than **2***c*, yet it should exhibit the same reactivity as **2***a* and **2***b*.

Transition structure geometries

As is seen in the geometrical structures (see Figs. 6(*a*) and 6(*b*)), there is a distinct pyramidalisation of the C2 and C3 carbons of the TSs for addition to **2***c*. This pyramidalisation which bends the methyl groups towards the incoming dieneophile is not related to the factor(s) determining the *syn* facial selectivity because it occurs in *syn* and *anti* TSs and in the case of **2***e* which exhibits an *anti* preference. The same deviation from planarity — the hydrogens at C3 and C4 bend towards **1** — is seen in TSs for *syn* and *anti* addition of **1** to 2,5-dimethylthiopheneoxide (**5**). It is possible that this pyramidalisation which may arise from the fact that sp^2 hybridization is not maintained at these carbons during the addition — the C1—C2 and C2—C3 bond lengths are 1.42 Å for the addition of **1** to **2***c* and the other pentamethylcyclopentadienes — and there is relief of torsional strain is a general feature of the D–A reactions of substituted cyclopentadienes. Regardless of its source, this pyramidalisation may be important in determining the rates and stereochem-

istry of Diels–Alder reactions of dienes and dieneophiles bearing bulky groups. It is interesting to note that this pyramidalisation is evident in the complexes with icbls of 2.8 Å (geometrical structures not shown) even though bonding at the bridgehead carbons C1 and C4 is not greatly advanced.

Analysis of changes in C5—X and C5—CH_3 bond lengths

In the case of additions to **2***a*–**2***d*, the CH_3—C5 bonds of the *syn* TSs are marginally longer than the CH_3—C5 bonds of the *anti* structures (Table 5). For hydroxy compound **2***c*, one of the most reactive compounds in the series, the CH_3—C5 bond *anti* to the incipient bonds of the *syn* TS is 0.012 Å longer than the CH_3—C5 bond of the *anti* diastereomer. A lengthening of the $Si(R)_3$—C5 bonds is also found for silyl compounds **2***g*, **2***i*, and **3***b* when addition occurs *anti* to the $Si(R)_3$ groups. While these results are in accord with the hyperconjugation model, it is unlikely that the differences are related to the major factor(s) responsible for the *syn* π-facial selectivity. This is so because the difference in the HO—C5 bond lengths is found to be larger — the HO—C5 bond of the *anti* transition structure is 0.021 Å longer than the HO—C5 bond of the *syn* transition structure — than the difference computed for the CH_3—C5 bonds. The same results were obtained for **2***d* and **3***b* (Table 6) and the mono-substituted dienes **4***a* and **4***b* (data not shown). An added complication in interpreting the differences in the *syn* and *anti* bond lengths at C5 and relating the results to the major factor controlling the facial selectivity is the fact that, in general, the X—C5 and CH_3—C5 bonds are shorter in the final product than in the starting diene (Tables 5 and 6). For **2***e* the C5—SCH_3 bond is longer in the *anti* transition structure than in the *syn* analogue; in the case of the silyl-substituted compounds, the Si—C bonds in of the final products are longer than the Si—C bonds of the dienes. To establish how small a change the CH_3—C5 bond length affects the energy of the TS, the CH_3—C5 bond length of the *syn* TS of **2***c* (originally 1.526 Å) was set to the bond length of the *anti* TS (1.514 Å) and an optimized geometry of the hypothetical TS was computed with a SIGMA calculation. That this geometrical structure was only 0.06 kcal/mol higher in energy than the fully optimized transition structure shows that the energy of the transition structure is relatively insensitive to small changes in the bond lengths at C5 at AM1 level of theory. Yet the facial selectivities and the relative reactivities for the D–A reactions of a group of cyclic dienes are calculated with good accuracy. While Coxon and McDonald (34) concluded on the basis of an AM1 study of the D–A addition of ethene to 5,5-disubstituted cyclopentadienes that transition state hyperconjunction was important in determining the facial selectivity, on the basis of our calculations on pentamethylcyclopentadienes, it is not possible to connect the small changes in the CH_3—C5 and X—C5 bond lengths to the major factor determining the *syn* facial selectivities found for **2***a*, **2***c*, and **2***d* with any degree of certainty.

Analysis of charges on atoms

The charges on the atoms X, C5, and the carbon of the methyl group attached to C5 of the *syn* and *anti* transition structures are given in Tables 8 and 9. If there is differential hyperconjugative interaction with the CH_3—C5 bond in the *syn* and *anti* transition structures then the C atom of the C5 methyl should be more positive in the *syn* transition structure than the *anti* one. Although this is the case — the differences range between 0.015 and 0.037 units of charge — similar differences are computed for the nitrogen and oxygen atoms of the *anti* TSs of **2***a*, **2***c*, and **2***d*. The situation is reversed for the *anti* and *syn* methyl groups in the *syn* and *anti* additions to acetamide **2***b*. With mixed AM1 parameters, the positive charge on the sulfur of the *anti* transition structure of **2***e* was computed to be larger than the charge on the sulfur of the *syn* analogue. Calculations with full AM1 parameters gave the opposite result. That the N atom of the *anti* transition structures of **2***k* is more negative than the N atom of the *syn* structure suggests the incipient bonds *release electrons hyperconjugatively to the polar C5—X bonds.* We recognise that the magnitudes of the atom charges calculated at the semiempirical level of theory on the whole are inaccurate, and if any interpretation/analysis of the values is attempted at all, it should be on the basis of trends. For the group of structurally similar cyclopentadienes examined in this study, we find no trends in the changes in the atom charges which could provide support for the hyperconjugation model.

Analysis of frontier molecular orbitals

The FMOs of the *syn* transition structure of **2***c* obtained with AM1 and PSI88 (39) are given in Fig. 7. Of the six frontier MOs displayed, only HOMO-3 (two spacial orientations of this MO are displayed) exhibits an involvement of the σ framework including the C5—CH_3 bond. But there is no marked interaction of σ framework (orbitals) with the π system of the dieneophile **1**. The plots of HOMO-3 and HOMO-4 suggest that the oxygen lone pairs are involved in bonding

interactions; in HOMO-3 there appears to be an interaction between the lone pair on oxygen and the π system of the dieneophile in accord with Anh's proposal (16). The point here is that no MO or combination of MOs corresponds to the array of orbitals written to describe hyperconjugative interactions in terms of the Cieplak effect (29). Six frontier MOs of the *anti* transition structure are given in Fig. 8. HOMO-3 and HOMO-4 also indicate the involvement of the oxygen *lps* in bonding interactions. While care should be exercised in interpreting orbital coefficients obtained at the semiempirical level of theory, we are confident that the FMO analysis presented here is valid because we showed in an earlier study (31) that the AM1 FMOs calculated for **2***c* and **2***e* were virtually identical to *ab initio* FMOs obtained at the HF/4-31G**//HF/4-31G level of theory. In the case of **2***e* which exhibits an *anti* selectivity, HOMO-2 (MO displays not shown) shows that there is an interaction between the sulfur *lps* and one of the incipient C—C bonds. HOMO-3 exhibits an interaction between the C5—SCH_3 σ bond and the π system of **1**. The reason that the sulfur *lps* of the methylthio group do not interact with the dienophile is seen in the *syn* TS (Fig. 9); the C5—SCH_3 bond length of 1.8 Å makes overlap with the π system of the dienophile impossible.

Conclusions

AM1 accurately reproduces the π-facial selectivities and relative reactivities — differential steric and complexation effects and differences in the thermodynamic stabilities of the final products rather than transition state hyperconjugation appear to be the controlling factors — of a group of C5-substituted cyclopentadienes. This indicates that semi-empirical calculations will be useful for predicting the relative rates and facial selectivities of D–A reactions of cyclopentadienes.

Studies on the interaction of selenite and selenium with sulphur donors. Part 2. A kinetic study of the reaction with 2-mercaptoethanol

WIMAL AMARATUNGA[1] AND JOHN MILNE

Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, ON K1N 6N5, Canada

Received July 18, 1994

WIMAL AMARATUNGA and JOHN MILNE. Can. J. Chem. **72**, 2506 (1994).

Selenous acid is reduced by 2-mercaptoethanol in water to elemental selenium in two stages.

$$H_2SeO_3 + 4HOC_2H_4SH \rightarrow HOC_2H_4SSeSC_2H_4OH + HOC_2H_4SSC_2H_4OH + 3H_2O$$

$$HOC_2H_4SSeSC_2H_4OH \rightarrow Se + HOC_2H_4SSC_2H_4OH$$

The reactions have been followed by spectrophotometry and by proton and ^{77}Se NMR spectroscopy. The mechanism of the first stage parallels that proposed for butyl thiols in 60% dioxane but nucleophilic attack by RS^- rather than RSH on the Se(IV) intermediate, $RSSeO_2^-$, is of greater significance for 2-mercaptoethanol than for *n*-butylthiol. The signals of three intermediates are observed in the Se-77 NMR spectra of a mixture undergoing the first reaction stage. These arise from $HOC_2H_4SSeO_2^-$, $(HOC_2H_4S)_2SeO$, and an asymmetric intermediate that chemical shift evidence suggests is the sulfinic acid ester, $HOC_2H_4S(O)SeSC_2H_4OH$. The second stage involves coordination of the bis(thio)selenide by thiolate followed by decomposition to disulfide and selenium. Evidence is presented to support a reaction mechanism involving nucleophilic attack exclusively at Se(II) and not at S(II) as suggested in previous work. This stage is strongly accelerated at basic pH and, at pH 8.3 and above, both the first and second stages can take place simultaneously.

WIMAL AMARATUNGA et JOHN MILNE. Can. J. Chem. **72**, 2506 (1994).

L'acide sélénieux est réduit par le 2-mercaptoéthanol dans l'eau pour conduire au sélénium élémentaire, en deux étapes.

$$H_2SeO_3 + 4HOC_2H_4SH \rightarrow HOC_2H_4SSeC_2H_4OH + HOC_2H_4SSC_2H_4OH + 3H_2O$$

$$HOC_2H_4SSeC_2H_4OH \rightarrow Se + HOC_2H_4SC_2H_4OH$$

On a suivi les réactions par spectrophotométrie et par spectroscopie RMN du ^1H et du ^{77}Se. Le mécanisme de la première étape est parallèle à celui proposé pour les butylthiols, dans le dioxane à 60%; toutefois l'attaque nucléophile par le RS^- plutôt que celle du RSH sur l'intermédiaire Se(IV), $RSSeO_2^-$, est plus importante que celle du 2-mercaptoéthanol sur le *n*-butylthiol. On peut observer les signaux de trois intermédiaires en RMN du ^{77}Se d'un mélange dans la première étape de la réaction. Ils proviennent du $HOC_2H_4SSeO_2^-$, du $(HOC_2H_4S)_2SeO$ et d'un intermédiaire asymétrique pour lequel une structure d'ester sulfinique, $HOC_2H_4S(O)SeSC_2H_4OH$, est suggérée par le déplacement chimique. La deuxième étape implique une coordination du bis(thio)sélénure par le thiolate suivie par la décomposition en disulfure et en sélénium. On présente des données qui supportent un mécanisme réactionnel impliquant une attaque nucléophile exclusivement au niveau du Se(II) et non pas au niveau du S(II) tel que suggéré dans un travail antérieur. Cette étape est fortement accélérée en milieu basique; à des pH de 8,3 et plus, les deux premières étapes peuvent se produire simultanément.

[Traduit par la rédaction]

Introduction

The antioxidant and cancer-inhibiting properties of selenium in biological systems have stimulated great interest in its biochemistry (1, 2). It is generally accepted (3, 4) that selenium(IV) undergoes reduction to a bis(alkylthio)selenide, RSSeSR, in living systems, according to a reaction first demonstrated to take place by Ganther (5),

[1] $$4\,RSH + H_2SeO_3 \rightarrow RSSeSR + RSSR + 3\,H_2O$$

Some thiosulfinate is also produced in the case of bulky thiols (6). It has been shown (5) that the bis(thio)selenides are readily decomposed to elemental selenium and the disulfide in the presence of excess thiolate under basic conditions.

[2] $$RSSeSR \xrightarrow[RSH]{} Se + RSSR$$

This is the basis of a turbidimetric method of analysis for Se(IV), using 2-mercaptoethanol as the reducing agent (7). The reduction of selenite by 2-mercaptoethanol at neutral to basic pH in the presence of excess HOC_2H_4SH is a two-stage process. There is an initial stage during which the solution remains clear, followed by a stage when the solution becomes turbid due to the formation of elemental selenium. For selenium analysis this method is complicated by the dissolution of selenium by excess thiolate, which has been shown to be a result of selenothiolate formation (8).

[3] $$Se + RS^- \rightleftharpoons RSSe^-$$

Kice et al. have studied the kinetics of reactions [1] (6) and [2] (9) for butyl thiols in 60% aqueous dioxane solutions. Their proposed mechanism for reaction [1] proceeds by formation of the bis(alkylthio)selenoxide, $(RS)_2SeO$, which, after rearrangement to RSOSeSR, undergoes further attack by 2 moles of RSH to form RSSeSR and RSSR. Peracetic acid oxidation of *t*-BuSSeSBu-*t* in $CDCl_3$ has provided evidence for the formation of the RSOSeSR intermediate (10). The Se-77 NMR chemical shift of this intermediate suggests that it is an oxygen-bridged species but it may also be a sulfinic acid ester, RS(O)SeSR. Evi-

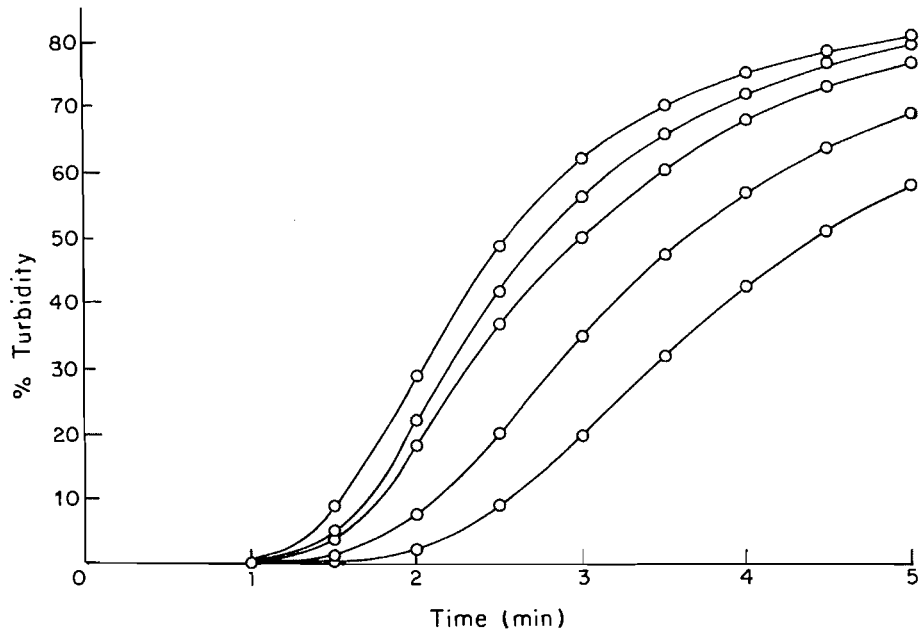

FIG. 1. Turbidity plots at 600 nm for $c(H_2SeO_3) = 5.0 \times 10^{-4}$ mol L^{-1} and $c_i(HOC_2H_4SH) = 6.0 \times 10^{-3}$, 5.4×10^{-3}, 4.8×10^{-3}, 4.2×10^{-3}, and 3.6×10^{-3} mol L^{-1}.

dence for the formation of this intermediate in the reduction of Se(IV) (reaction [1]) is, however, lacking.

The mechanism for reaction [2] is thought to proceed by bimolecular nucleophilic attack of RS^- in RSSeSR at sulphur.

[4] $RS^- + RSSeSR \rightarrow RSSR + SeSR^-$

This would then proceed to give elemental selenium by the reverse of equilibrium [3] (8).

Our interest in the course of the metabolism of selenite in bacterial systems and the stability of Se(II) in such systems (11) led us to explore the chemistry of the Se(IV)–thiol interaction. As a model thiol we chose 2-mercaptoethanol, which is a relatively simple molecule, is readily available, and has the advantage of being water soluble.

Experimental section

Kinetics

The rates of the two steps of the first stage of the reduction of selenous acid by 2-mercaptoethanol (reaction [1]) were followed by spectrophotometry at 310 nm. The solutions became pale yellow during this stage. The second stage (reaction [2]) was followed by transmission turbidimetry at 600 nm. During this stage, the solutions became orange-red turbid. The rate for the first stage could also be monitored at 600 nm through the length of the induction period before the solutions became turbid. Solutions of SeO_2 (Aldrich) and 2-mercaptoethanol (Aldrich) in the millimolar range were made up in 0.050 M potassium phosphate buffer in the pH range 6.85–8.40, and in acetate buffer at pH 5.5. All solutions were made up with distilled water purged of oxygen. The change in absorbance with time was followed in a water-jacketed 1 cm pathlength silica cell at 25.0 ± 0.1°C in a Varian DMS 90 or Varian/Cary 1E spectrophotometer.

The first stage of the reduction was followed initially via the induction period before the solutions became turbid. The induction period was determined by extrapolation of the turbidity curve at its steepest slope to zero absorbance. The rate was taken as selenous acid concentration ($c(H_2SeO_3)$) divided by induction period. The first stage was also followed by monitoring the rate of increase in absorbance at 310 nm due to the formation of $HOC_2H_4SSeO_2H$ (reaction [5], pH 5.5) and $(HOC_2H_4S)_2Se$ (reactions [6], [7], and [8], pH 6.85). This wavelength was chosen to avoid any absorbance by selenite, thiol, or buffer. For reactions [5] and [6] (first stage), the change in concentration over time was taken as the rate for the mean concentrations of the reacting species.

The second stage of the reduction was followed by turbidimetry. The rate was determined from the slope of absorbance vs. time plots at the point of half-reaction ($t_{1/2}$: $[HOC_2H_4SSeSC_2H_4OH] = 1/2\ c_i(HOC_2H_4SSeSC_2H_4OH)$). This procedure was felt to be more accurate than that of Apak and co-workers (7), because of the uncertainty in the initial slopes.

NMR spectra

The Se-77 NMR spectra were measured with a Bruker AMX 500 spectrometer operating at 95.48 MHz. A 90° tip angle and 2 s pulse delay were used. The samples were contained in 10 mm diameter precision NMR tubes. The mixtures were made up at 0°C from deoxygenated aqueous solutions of HOC_2H_4SH and SeO_2 (4:1 mole ratio) and placed immediately in the spectrometer probe held at 0°C. All chemical shifts were measured by sample replacement with respect to saturated selenous acid in water at 22°C (12). The chemical shifts are all listed relative to $\delta(Me_2Se) = 0.0$ ppm ($\delta(Me_2Se) = \delta(H_2SeO_3) + 1300$ ppm (12)).

The proton NMR spectra were measured using a Varian FT300 spectrometer. The chemical shifts were measured relative to the known $\delta(Me_4Si)$ of HOC_2H_4SH and $HOC_2H_4SSC_2H_4OH$ in D_2O solution (8). The chemical shifts measured at 9°C are referred to Me_4Si at 20°C. The temperature coefficient for these signals was found to be 0.02 ppm/°C.

Results and discussion

Under most of the conditions used in this work (pH > 6.5, millimolar $c(HOC_2H_4SH)$ and $c(Se(IV))$, the two stages of the reduction were readily observed, as shown in Fig. 1. Any interference from reaction [3] is negligible under these conditions, as indicated by a consideration of the dissociation constant for HOC_2H_4SH (2.5×10^{-10} mol L^{-1} (13)) and the equilibrium constant for reaction [3] (0.33 (8)). The two stages represented by reactions [1] and [2] will be considered.

Induction period; reaction [1]

In general, without excess RSH ($c(RSH)/c(H_2SeO_3) \leq 4.0$) and at acid pH, RSSeSR is produced according to reaction [1] (5, 8) and subsequent reduction by reaction [2] is slow. A

kinetic study of this stage has been made for *t*-BuSH and *n*-BuSH in 60% aqueous dioxane (6) and a mechanism has been proposed consisting of two kinetically distinguishable steps, an initial equilibrium,

$$[5] \quad H_2SeO_3 + RSH \underset{k_r}{\overset{k_f}{\rightleftharpoons}} RSSeO_2H + H_2O$$

followed by the slow step,

$$[6] \quad RSSeO_2H + RSH \xrightarrow[k_1]{\text{slow}} (RS)_2SeO + H_2O$$

This reaction is followed by several rapid steps to produce RSSeSR and RSSR.

$$[7] \quad (RS)_2SeO \xrightarrow{\text{rapid}} RSOSeSR$$

$$[8] \quad RSOSeSR + RSH \xrightarrow{\text{rapid}} RSSeSR + RSOH$$

$$[9] \quad RSOH + RSH \xrightarrow{\text{rapid}} RSSR + H_2O$$

Rates for the reaction of HOC_2H_4SH and H_2SeO_3 (4:1 mole ratio; pH = 6.85) determined from the induction period, assuming complete reaction to $(HOC_2H_4S)_2Se$ before any Se turbidity occurs, are given in Table 1 for constant $c_i(H_2SeO_3)$ ($= 5 \times 10^{-4}$ mol L^{-1}) and varying $c(HOC_2H_4SH)$. As shown in previous work (6) and demonstrated below for HOC_2H_4SH, the equilibrium constant for reaction [5] is large and formation of $HOC_2H_4SSeO_2H$ is essentially complete. The induction period is then determined principally by reaction [6], which has been shown to be second order (See Tables 1 and 3). The rate calculated from the induction period will be lower than the true rate for the starting concentration and better corresponds to the concentrations at half-reaction. An estimate of the rate constant for [6], k_1, may be calculated from the rates and the half-reaction concentrations assuming reaction [5] is complete, and these are given in Table 1 ($k_1 = 5.8 \pm 0.4$ L mol^{-1} s^{-1}).

The steps represented by reactions [5] and [6] may be studied separately. At pH 5.5, reaction [5] proceeds at a conveniently slow rate and may be distinguished from reaction [6], which is much slower at this pH. The rates of these individual steps were studied by spectrophotometry. The spectral changes for the various steps are shown in Fig. 2. Individually, selenite, 2-mercaptoethanol, and buffer exhibit weak absorbances below 250 nm, which are not significant relative to the absorbance of the Se(IV) species formed and are ignored. As reaction [5] proceeds, the spectra show an increase in absorbance at 260 nm with the production of $HOC_2H_4SSeO_2H$. At pH 6.85 and above, reaction [5] is rapid and is followed by a decrease in the absorbance of this peak accompanied by an increase in absorbance at 225 and 300 nm. The absorbance at 300 nm arises from a broad peak centred at 263 nm. Two isosbestic points at 242 and 273 nm are observed, consistent with the presence of two species, one of which has two peaks in this region of the spectrum. These changes are due to the formation of $(HOC_2H_4S)_2Se$, according to reaction [6], followed by reactions [7] and [8], which are rapid. The decrease in the 260 nm peak is not as large as might be expected because the $(HOC_2H_4S)_2Se$ and the disulfide, $HOC_2H_4SSC_2H_4OH$, formed in subsequent reactions, also absorb in this region.

The first step of this stage, reaction [5], is governed by the differential rate law,

$$[10] \quad \text{Rate} = k_f[H_2SeO_3][HOC_2H_4SH] - k_r[HOC_2H_4SSeO_2H]$$

The absorbance data at 310 nm, which are free of interferences from acetate buffer, HOC_2H_4SH, and H_2SeO_3, are readily fit to this rate law for an extinction coefficient, $\epsilon_{310}(HOC_2H_4SSeO_2H)$ of 500 L mol^{-1} cm^{-1}, $k_f = 5.6$ L mol^{-1} s^{-1}, and $k_r = 1.6 \times 10^{-3}$ s^{-1}, as shown in Table 2. The equilibrium constant for reaction [5] is then 3500 L mol^{-1} at pH 5.5, which is to be compared with 300 L mol^{-1} for *t*-BuSH and a much larger value for *n*-BuSH in 60% dioxane at comparable pH (6).

At pH = 6.85, reaction [5] goes rapidly to completion (<15 s) and the peak at 260 nm, due to $HOC_2H_4SSeO_2H$, begins to decrease in intensity, while the absorbance at 225 and 300 nm increases, due to the formation of $(HOC_2H_4S)_2Se$, which is rapidly formed from $(HOC_2H_4S)_2SeO$ via reactions [7] and [8]. The rate constant, k_1, for the second-order rate law,

$$[11] \quad \text{Rate} = k_1[HOC_2H_4SSeO_2H][HOC_2H_4SH]$$

was calculated from the absorbances given in Table 3. The extinction coefficients used were $\epsilon_{310}(HOC_2H_4SSeO_2H) = 480$ L mol^{-1} cm^{-1}, which is slightly smaller than the value determined at pH 5.5, and $\epsilon_{310}((HOC_2H_4S)_2Se) = 645$ L mol^{-1} cm^{-1}, which was measured for a 4:1 HOC_2H_4SH/H_2SeO_3 molar mixture in unbuffered water ($c(HOC_2H_4S)_2Se) = 1.0 \times 10^{-3}$ mol L^{-1}) after complete reaction, according to eq. [1]. This gave $k_1 = 6 \pm 1$ L mol^{-1} s^{-1}, which compares well with the initial value of k_1 estimated from the induction period at pH 6.85.

The induction period, during which reactions [5] and [6] of the first stage of the reduction are rate determining, decreases with increasing pH. The rates for this stage, at $c_i(H_2SeO_3) = 5.0 \times 10^{-4}$ mol L^{-1} and $c_i(HOC_2H_4SH) = 2.0 \times 10^{-3}$, are plotted against pH in Fig. 3. At pH = 6.85, the rate of the first step (k_f) is

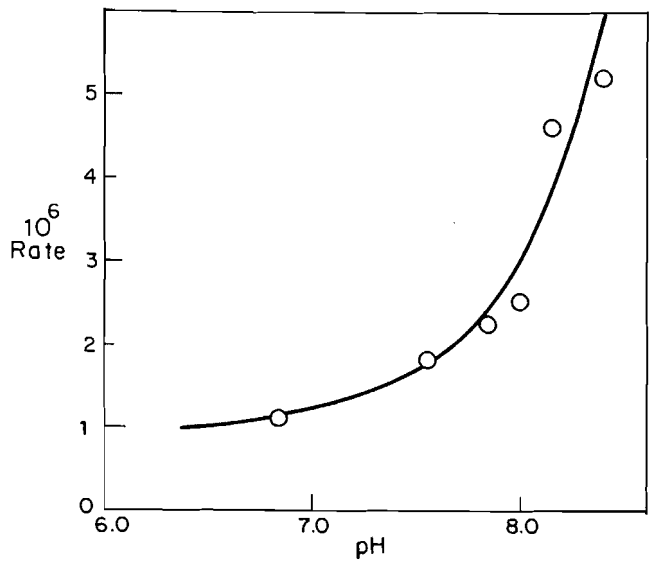

FIG. 3. Variation in the rate of reaction [6] with pH as determined from the induction period.

too rapid for measurement by normal methods and the pH effect illustrated in Fig. 3 must arise in the second step. Many pathways contribute to reaction [6] (6) that are dependent upon the ionic dissociation equilibria of $HOC_2H_4SSeO_2H$ and HOC_2H_4SH and the rates of the reactions between the various thiol and thioselenous acid species formed. For purposes of fitting the rate curve in Fig. 3 over the range of pH studied (6.85–8.40), the contribution of the $HOC_2H_4SSeO_2H_2^+$ ion was ignored and only the equilibria,

$$[12]\quad HOC_2H_4SSeO_2H \overset{K_a}{\rightleftharpoons} H^+ + HOC_2H_4SSeO_2^-$$

$$[13]\quad HOC_2H_4SH \overset{K_s}{\rightleftharpoons} H^+ + HOC_2H_4S^-$$

and the rates of the reactions,

$$[14]\quad HOC_2H_4SSeO_2H + HOC_2H_4SH \xrightarrow{k_{RSH}} (HOC_2H_4S)_2SeO + H_2O$$

$$[15]\quad HOC_2H_4SSeO_2H + HOC_2H_4S \xrightarrow{k_{RS^-}} (HOC_2H_4S)_2SeO + OH^-$$

$$[16]\quad HOC_2H_4SSeO_2^- + HOC_2H_4SH \xrightarrow{k^-_{RSH}} (HOC_2H_4S)_2SeO + OH^-$$

$$[17]\quad HOC_2H_4SSeO_2^- + HOC_2H_4S^- \xrightarrow[H_2O]{k^-_{RS^-}} (HOC_2H_4S)_2SeO + 2\ OH^-$$

were considered. The equilibrium and rate expressions for [12]–[17] and the mass balance for selenium species may be used to derive the expression,

$$[18]\quad \frac{d[(HOC_2H_4S)_2SeO]}{dt} = c_{Se}[HOC_2H_4SH] \times \frac{k_{RSH}[H^+] + k_{RS^-}K_s + k^-_{RSH}K_a + k^-_{RS^-}K_aK_s/[H^+]}{[H^+] + K_a}$$

where c_{Se} represents total Se species concentration. Using the dissociation constant for HOC_2H_4SH (13), the observed variation in rate with pH in Fig. 3 could be best reproduced by choosing $k_{RSH} = 5 \times 10^{-3}$ L mol^{-1} s^{-1}, $K_a = 1.2 \times 10^{-4}$ mol L^{-1}, $(k_{RS^-}K_s + k^-_{RSH}K_a) = 5 \times 10^{-4}$ s^{-1}, and $k^-_{RS^-} = 1.2 \times 10^2$. Unlike the previous work with *n*-BuSH and *t*-BuSH, which extended only up to pH 7.0, it was not possible to produce the strong increase in rate with increasing pH without inclusion of reactions [16] and [17]. Since the rate-determining step may be considered in general as a nucleophilic attack on Se(IV), it is to be expected that the rate constants for reactions involving $HOC_2H_4S^-$, reactions [15] and [17], will be large relative to those involving HOC_2H_4SH and that the rate will increase significantly with increasing pH. It should be noted that $k^-_{RS^-}$ is much greater than k_{RSH} in spite of the unfavourable combination of two anions, $HOC_2H_4SSeO_2^-$ and $HOC_2H_4S^-$, in reaction [17].

NMR spectra, reaction [1]

The Se-77 NMR spectrum of a solution 0.30 mol L^{-1} in SeO_2 and 0.60 mol L^{-1} in HOC_2H_4SH at 0°C shows two signals at δ = 1296 and 671 ppm with intensities 1.0 and 1.8, respectively. When the solution is warmed to 20°C, two equally intense signals are observed at 1298 and 681 ppm. The signal at 1298 ppm, which is shifted to lower frequency at the lower temperature, is due to unreacted H_2SeO_3 (12). The reported temperature coefficient for H_2SeO_3 is 0.094 ppm/K (12), which accounts well for the shift with temperature observed here. The 681 ppm signal is due to $(HOC_2H_4S)_2Se$, which has δ = 684 ppm for a saturated solution in pure water (8). The 1:1 intensity ratio of the room temperature spectrum corresponds to complete reaction according to eq. [1], which for a 2:1 HOC_2H_4SH/H_2SeO_3 mole ratio solution would result in a 1:1 $(HOC_2H_4S)_2Se/H_2SeO_3$ mole ratio mixture. The reported temperature coefficients for Se species, 0.025–0.094 ppm/K (12, 14), do not account for the chemical shift from 671 to 681 ppm when the temperature is raised to 20°C. This, and the nearly 2:1 intensity ratio of the 671 and 1296 ppm peaks at 0°C, shows that this shift is not due to the bis(thio)selenide but is probably a result of the initial formation of $HOC_2H_4SSeO_2H$ or $(HOC_2H_4S)_2SeO$ in the solution.

The Se-77 NMR spectra of a solution of 0.20 mol L^{-1} H_2SeO_3 and 0.80 mol L^{-1} HOC_2H_4SH at 0°C, studied over an 80 min time period, are shown in Fig. 4. No signal for selenous acid is observed in the spectra of any of these 4:1 HOC_2H_4SH/H_2SeO_3 solutions, showing that step 1 takes place rapidly at neutral pH even at 0°C. At 20 min, the spectrum consists of a strong signal at 667 ppm with a weak signal at 683 ppm due to trace formation of $(HOC_2H_4S)_2Se$. The formation of trace amounts of $(HOC_2H_4S)_2Se$ was unavoidable in spite of cooling, due to the difficulty in efficient mixing of the reactant solutions in the NMR tube with these 4:1 solutions and the favourable conditions for reaction [2] in the presence of excess HOC_2H_4SH (vide infra). At 40 min, the 667 ppm signal has fallen in intensity and new signals at 670 and 685 ppm appear. At 60 min both of the signals at lower chemical shift have disappeared and only the signal at 685 ppm and a new signal at 683 ppm, due to the final product, $(HOC_2H_4S)_2Se$, are observed. Finally at 80 min only the signal due to the bis(hydroxyethylthio)selenide is observed. This signal is broadened ($w_{1/2} \sim$ 0.75 ppm) due to the presence of some insoluble bis(hydroxyethylthio)selenide (8). The sequence of changes is readily interpreted in terms of the various species formed in the mechanism proposed by Kice et al. (6). The first signal observed after 20

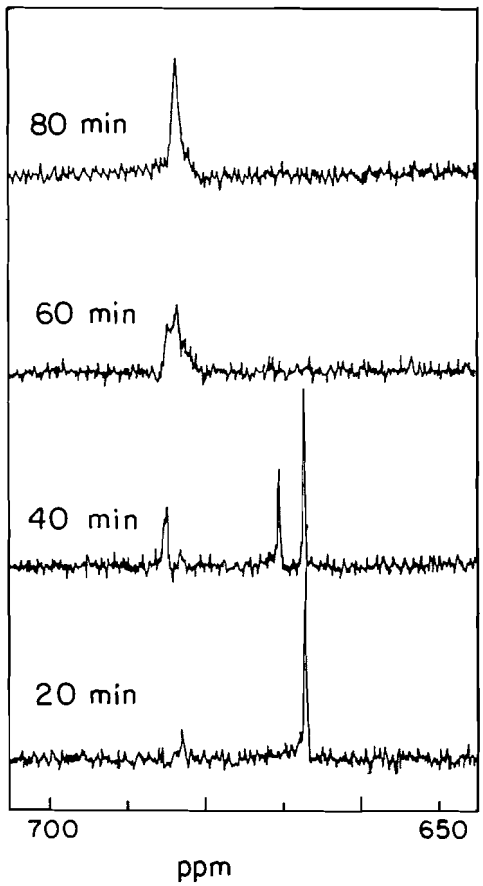

FIG. 4. ^{77}Se NMR spectra of a HOC_2H_4SH/H_2SeO_3 mixture ($c(HOC_2H_4SH)$ = 0.80 mol L^{-1}; $c(H_2SeO_3)$ = 0.20 mol L^{-1}; unbuffered, 0°C), taken at various times.

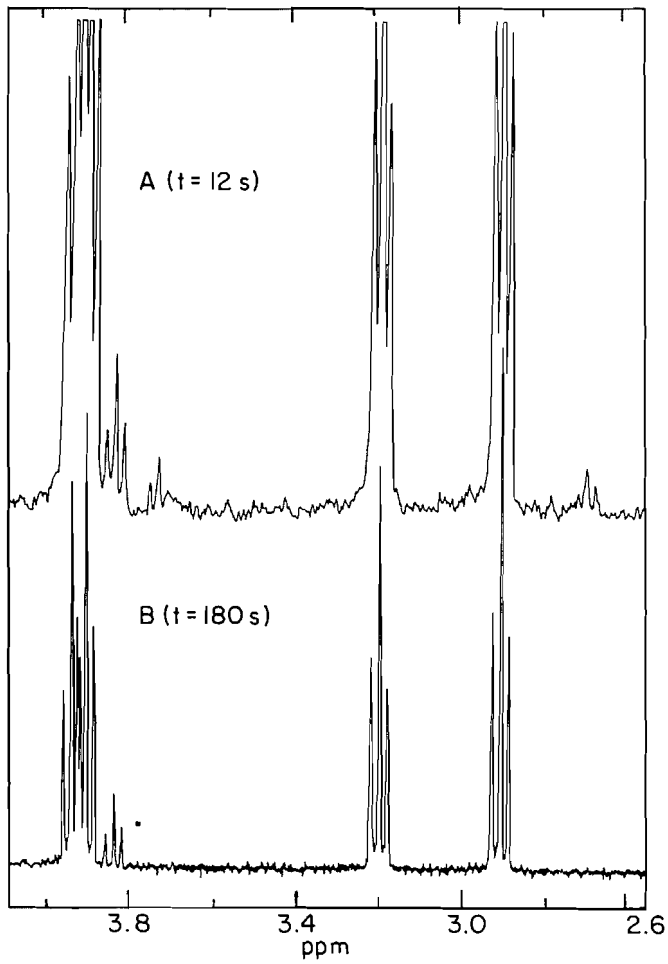

FIG. 5. Proton NMR spectra of a HOC_2H_4SH/H_2SeO_3 mixture ($c(HOC_2H_4SH)$ = 0.21 mol L^{-1}; $c(H_2SeO_3)$ = 0.054 mol L^{-1}, unbuffered, 9°C), taken at (*A*) 12 s; (*B*) 180 s.

min, at 667 ppm, is assigned to $HOC_2H_4SSeO_2H$, which is relatively rapidly formed in solution in reaction [5]. Excess HOC_2H_4SH in solution then causes the slower reaction [6] to proceed, with the formation of $(HOC_2H_4S)_2SeO$, for which δ = 670 ppm. This species rapidly rearranges to a third intermediate, which may be $HOC_2H_4OSSeSC_2H_4OH$ or $HOC_2H_4S(O)SeSC_2H_4OH$ by reaction [7], producing the signal at 685 ppm. Subsequent reactions with excess thiol via eqs. [8] and [9] then give the final product, $(HOC_2H_4S)_2Se$, with δ = 683 ppm.

The Se-77 signals for $HOC_2H_4SSeO_2H$ and $(HOC_2H_4S)_2SeO$ at 667 and 670 ppm are the lowest observed for Se(IV) species (15). The Se-77 chemical shifts for Se(IV) species range from 738 to 1479 ppm (16). No examples of Se-77 NMR spectra of Se(IV) species with Se—S bonds have been reported but, on the basis of the comparable electronegativities of carbon and sulphur, Se(IV) species with bonded sulphur would be expected to have shifts near those of selenoxides, which lie at the low-frequency end of the reported range. The chemical shift of the asymmetric *t*-BuSOSeSBu-*t* intermediate in the oxidation of $(t\text{-BuS})_2Se$ with peracetic acid has a Se-77 chemical shift at 854 ppm (10). A weaker signal at 845 ppm was also observed by these authors and this may be due to the selenoxide, $(t\text{-BuS})_2SeO$, on the basis of the present work, where the shift of the selenoxide, $(HOC_2H_4S)_2SeO$, lies 15 ppm to lower frequency from the signal for the asymmetric intermediate.

The intermediate, formed by the rearrangement of $(HOC_2H_4S)_2SeO$, is a Se(II) species and has an asymmetric structure. The structure is confirmed by the ^1H NMR spectrum given in Fig. 5 for a 0.054 M H_2SeO_3 and 0.21 M HOC_2H_4SH solution in D_2O at 9°C. It was not possible to prepare a 4:1 molar ratio HOC_2H_4SH/H_2SeO_3 solution even at temperatures just above the freezing point (4°C) in a 5 mm diameter NMR tube without causing some formation of elemental selenium. To prevent such precipitation, a slight stoichiometric excess of H_2SeO_3 (<5%) was necessary. Because of inefficient mixing and the slightly higher temperature of the experiment, the ^1H spectra show the progress of the reaction at a later period relative to the ^{77}Se spectra. The spectrum at 12 s (trace A) shows two overlapped triplets centred near 3.9 ppm, due to methylene protons bound to carbon next to oxygen, and two separated triplets of approximately equal intensity at 2.92 and 3.21 ppm, due to methylene protons on carbon next to sulphur, in $HOC_2H_4SSC_2H_4OH$ and $HOC_2H_4SSeSC_2H_4OH$, respectively (8). In addition, there is a triplet at 3.85 ppm and two broad weak triplets of equal intensity at 2.71 and 3.74 ppm. At 180 s (trace B) these two latter signals are no longer observed and are assigned, for this reason, to the short-lived symmetric $(HOC_2H_4S)_2SeO$ intermediate, perhaps undergoing rapid exchange with $HOC_2H_4SSeO_2H$. The asymmetric intermediate, which lies kinetically between $(HOC_2H_4S)_2SeO$ and the final products of the first stage, may be the oxygen-bridged compound, $HOC_2H_4SOSeSC_2H_4OH$, or the sulfinate, $HOC_2H_4S(O)SeSC_2H_4OH$, either of which will give a spectrum

consisting of four triplets of equal intensity. The triplet at 3.85 ppm is assigned to the methylene protons on carbon, next to sulphur(II) bound to oxygen or next to sulphur(IV). These protons are expected to have a chemical shift that differs, to the greatest extent, from the signals of the other methylene protons. The remaining protons bound to carbon next to sulphur in this asymmetric intermediate lie under the triplet due to the similar protons in $HOC_2H_4SSC_2H_4OH$ at 2.92 ppm, as judged by the increased intensity of this peak relative to that of $(HOC_2H_4S)_2Se$ at 3.21 ppm. The remaining four methylene protons on carbon bound to the OH group lie under the overlapped triplets at 3.9 ppm. The higher frequency triplet of the overlapped triplets at 3.93 ppm (^3J = 6.0 Hz) arises from $(HOC_2H_4S)_2Se$, and the lower frequency signal at 3.90 ppm (^3J = 5.7 Hz) from the $HOC_2H_4SSC_2H_4OH$, based on δ and ^3J reported in previous work (8). The signal of the methylene protons on carbon bound to the OH group in the asymmetric species lies under this latter triplet. This assignment of the ^1H NMR spectrum of the asymmetric intermediate is confirmed quantitatively by the signal intensities. The sum of the areas under the signals at 2.92 and 3.21 ppm is less than that of the overlapped triplets at 3.9 ppm by the area of the triplet at 3.85 ppm, confirming that this triplet is due to methylene protons on carbon bound to sulphur and not those on carbon bound to a hydroxyl group. Moreover, the difference in intensity of the signals at 2.92 and 3.21 ppm equals the intensity of the peak at 3.85 ppm, which verifies the assignment of the methylene protons on the carbon bound to sulphur(II) next to selenium in the asymmetric intermediate at 2.92 ppm.

Similar observations have been made for solutions of 4:1 HOC_2H_4SH/H_2SeO_3 mole ratio without excess H_2SeO_3 but, in the spectra of these solutions, the ratio of the signals of the disulfide to those of the bis(thio)selenide are much greater than 1:1 due to decomposition of the selenide via reaction [2], which may take place if thiol is available for further reduction (vide infra). In these experiments, the signals of the asymmetric intermediate disappear on warming as reactions [8] and [9] go to completion.

The asymmetric intermediate may be the oxygen-bridged species, $HOC_2H_4SOSeSC_2H_4OH$, or the sulfinate, $HOC_2H_4S(O)SeSC_2H_4OH$. The significant deshielding of the methylene protons on carbon bound to sulphur linked to oxygen relative to the those on carbon bound to sulphur in the bis(thio)selenide (–0.63 ppm) supports binding to S(IV) just as convincingly as binding to S(II). The two possibilities cannot be differentiated on the basis of ^1H NMR. Some comment may, however, be made about the structure of the asymmetric intermediate from the Se-77 chemical shift. Kice et al. (10) have presented Se-77 NMR chemical shift evidence to support the formation of the oxygen-bridged species as the product formed by peracetic acid oxidation of *t*-BuSSeSBu-*t* in $CDCl_3$. In their work, the shift of the asymmetric oxidation product (854 ppm) lies ca. 300 ppm to higher frequency from the bis(*tert*-butylthio)selenide, *t*-BuSSeSBu-*t* (565 ppm), which is unexpected, if a sulfinate is formed, in view of the similar shifts of selenium(II) in the related selenoselinates and diselenides (10, 16). For this reason, it was suggested (6, 10) that the asymmetric intermediate is an oxygen-bridged species rather than a sulfinate. In the present work the shift of the asymmetric intermediate (685 ppm) lies 2 ppm to higher frequency of the shift of the bis(thio)selenide (683 ppm), which suggests that the asymmetric intermediate is a sulfinate. We favour the sulfinate for two additional reasons: (*a*) we have been unable to find any precedent for the formation of an oxygen link between divalent chalcogens (S and Se at least), and (*b*) in the chemistry of organosulphur compounds, -SOC- linkages normally rearrange to sulfoxide, -S(O)C-, structures (17). Until definitive evidence is forthcoming, however, which asymmetric intermediate is formed remains unanswered and, indeed, both possibilities may exist, depending upon the reaction conditions and direction (oxidation or reduction) chosen. It is interesting to note that the sulfinate would be favourably stabilized by the formation of a six-membered ring, $HOCH_2CH_2S(O)SeSCH_2CH_2OH$, in the case of 2-mercaptoethanol while such stabilization would not be possible for butyl thiols, and this may account for the different asymmetric intermediates.

Reduction to elemental selenium, reaction [2]

In the presence of excess HOC_2H_4SH, the bis(thio)selenide is further reduced to Se and $HOC_2H_4SSC_2H_4OH$, according to reaction [2]. In earlier studies of the reactions of nucleophiles with bis(alkylthio)selenides, little evidence for the formation of elemental selenium was reported (9). Under the conditions used (pH > 10, considerable excess of nucleophile, 60% aqueous dioxane), equilibria like [3] would keep selenium in solution. For all of the nucleophilic anions used, soluble selenoanions may be formed ($BuSSe^-$, $SeCN^-$, $SeSO_3^{2-}$, $SePh^-$). In our studies, which were carried out at near neutral pH and with a low concentration of excess thiol, elemental selenium was formed. The rates were measured by determining the slope of plots of percent turbidity against time (Fig. 1) at the point of 50% reduction to Se ($t_{1/2}$). This procedure minimizes interference from reaction [6] of the first stage. The data given in Table 4 show that the rate is first order in HOC_2H_4SH and $(HOC_2H_4S)_2Se$ and the rate law is given by,

$$[19] \quad \text{Rate} = k_2[(HOC_2H_4S)_2Se][HOC_2H_4SH]$$

It was reported previously (7) that this rate was second order in initial $c(HOC_2H_4SH)$ but allowance for the thiol consumed in reaction [1] shows reaction [2] to be first order in the excess thiol. Overall second-order kinetics have also been observed for the reaction of bis(butylthio)selenides with nucleophiles in 60% dioxane and nonaqueous media (9). Earlier work (7) showed that the rate of reaction [2] increases with pH. The results in Table 4 show that, at pH = 7.35, k_2 is 22 ± 2 L mol^{-1} s^{-1}, while, at pH = 6.85, k_2 is 4.2 ± 0.3 L mol^{-1} s^{-1}. The increased rate at higher pH is due to increased concentration of the thiolate anion, $HOC_2H_4S^-$, which is a stronger nucleophile than the thiol. Previous work with butyl thiols has provided evidence that nucleophilic attack on bis(butylthio)selenides takes place both at sulphur and selenium (9). The evidence that two independent mechanisms are involved is based on steric arguments and analogy with other nucleophilic substitutions, particularly by phenyllithium, on bis(butylthio)selenides. The polarity of the SeS bond favours nucleophilic attack at Se and an alternate mechanism for reaction [2] may proceed via a preequilibrium step.

$$[20] \quad HOC_2H_4S^- + (HOC_2H_4S)_2Se \overset{K}{\rightleftharpoons} (HOC_2H_4S)_3Se^-$$

followed by decomposition of the complex anion,

$$[21] \quad (HOC_2H_4S)_3Se^- \xrightarrow{k_2'} HOC_2H_4SSC_2H_4OH + SeSC_2H_4OH^-$$

and dissociation of the thioselenide (8),

2.6	2.6	0.81	23	4.4×10^3	

[a] $c_i((HOC_2H_4S)_2Se) = c(H_2SeO_3)$ at the point of completion of stage 1.
[b] Excess $c(HOC_2H_4SH)$ after completion of stage 1 (reaction [1]).
[c] Determined from the slope of the turbidity vs. time plot at the point of half reaction ($t_{1/2}$).
[d] Calculated at half-reaction, $[(HOC_2H_4S)_2Se] = c_i((HOC_2H_4S)_2Se)/2$.

[22] $SeSC_2H_4OH^- \underset{(23°C)}{\overset{K=3.0}{\rightleftharpoons}} SC_2H_4OH^- + Se$

At the concentrations and pH's employed in this work, dissociation via reaction [22] would be virtually complete. Thus, the thiolate acts as a catalyst for the decomposition of the bis(thio)selenide. According to this mechanism, overall second-order kinetics would be observed and k_2 in reaction [19] then becomes $Kk_2'K_s/[H^+]$, where K_s is the acid dissociation constant for 2-mercaptoethanol (7, 13). Values of Kk_2' at the two pH's are listed in Table 4 and, while the agreement between the two mean values ($(2.4 \pm 0.2) \times 10^3$ M^{-1} s^{-1} (pH = 6.85) and $(4.1 \pm 0.4) \times 10^3$ M^{-1} s^{-1} (pH = 7.35)) is better than that for k_2, the variation is greater than that caused by the uncertainty in the pH measurement. The faster rate at higher pH may be, in part, due to a parallel reaction mechanism involving direct nucleophilic attack by OH^-.

[23] $(HOC_2H_4S)_2Se + OH^- \rightarrow (HOC_2H_4S)_2SeOH^-$

[24] $(HOC_2H_4S)_2SeOH^- \rightarrow HOC_2H_4SS_2H_4OH + SeOH^-$

[25] $SeOH^- \rightleftharpoons Se + OH^-$

Further studies will be needed to confirm this.

Even for solutions with HOC_2H_4SH/H_2SeO_3 stoichiometric ratios of 4:1 and less, where no excess HOC_2H_4SH is available for reaction [2], Se turbidity is observed. Previous studies (7) have shown that the rate of increase in percent turbidity with time increases with pH (7.62–9.28) for solutions with 4:1 HOC_2H_4SH/H_2SeO_3 mole ratio ($c(H_2SeO_3) = 5 \times 10^{-4}$ M). We have confirmed this observation for the pH range 7.85–8.40. At the 4:1 stoichiometric ratio, sufficient thiol is present for the completion of reaction [1] and, indeed, only the bis(thio)-selenide is formed under more acid conditions, provided that any excess of thiol is avoided. However, under more basic conditions, reaction [2] is sufficiently accelerated (see Table 4) that, before reaction [1] is complete and all free thiol is consumed, reaction [2] may proceed to give elemental Se. The limiting amount of Se produced will depend upon the relative rates of reactions [1] and [2] and, thus, upon the pH. For this reason differing plateaus of constant turbidity would be expected at constant $c(H_2SeO_3)$ with different pH's and this is exactly what is observed (7). The maximum percent turbidity observed at 4:1 HOC_2H_4SH/H_2SeO_3 increases with pH. From Fig. 3, it is seen that the rate of reaction [1] increases by 35% when the pH is increased from 6.85 to 7.35 but that of reaction [2] increases over 400% for the same pH range, as seen from Table 4.

NMR spectra, reaction [2]

An attempt was made to observe the ^1H NMR signal of the complex anion, $(HOC_2H_4S)_3Se^-$, by measuring the spectrum of a 0.013 mol L^{-1} solution of $(HOC_2H_4S)_2Se$ (and $HOC_2H_4SSC_2H_4OH$), containing 0.003 mol L^{-1} HOC_2H_4SH in D_2O at 9°C. The initial trace, taken 15 s after mixing, exhibited the spectrum shown in Fig. 6. The spectrum consists of the two triplets at 2.92 and 3.88 ppm, due to $HOC_2H_4SSC_2H_4OH$, two broad peaks at 3.22 and 3.96 ppm, due to $(HOC_2H_4S)_2Se$, and two weak broad signals at 2.74 and 3.86 ppm, due to HOC_2H_4SH. The HOC_2H_4SH and $(HOC_2H_4S)_2Se$ are undergoing intermolecular exchange via equilibria [13] and [20]. In addition, the complex ion, which has a T-shaped structure according to Valence Shell Electron Pair Repulsion (VSEPR) theory, may undergo an intramolecular exchange of axial and equatorial (HOC_2H_4S) groups. These exchange processes will broaden the individual members of the methylene triplets and lead to the signals observed. The signals, due to $(HOC_2H_4S)_2Se$, still show some vestige of proton–proton coupling, especially the signal at 3.96 ppm, which is expected to show the effect of the exchange to a lesser extent, since this signal arises from methylene protons more distant from the site of exchange. A slight turbidity was noted at this stage but the signal intensities for $(HOC_2H_4S)_2Se$ and $HOC_2H_4SSC_2H_4OH$ are equal within the error in measurement, indicating that reduction to Se had just begun to take place. The spectrum of the solution at 120 s exhibits the sharp triplets due to the disulfide, very weak signals due to HOC_2H_4SH, and broad but distinct triplets due to $(HOC_2H_4S)_2Se$. The intensity of these latter peaks at 3.21 and 3.95 ppm is much less at this point than those due to the disulfide, showing that significant reduction via reaction [2] has occurred. After 15 h at room temperature the bis(thio)selenide peaks are barely perceptible, no thiol peaks are observed, but the disulfide triplets are still strong. Inasmuch as the thiol acts as a catalyst for reaction [2] and is not consumed in the reaction,

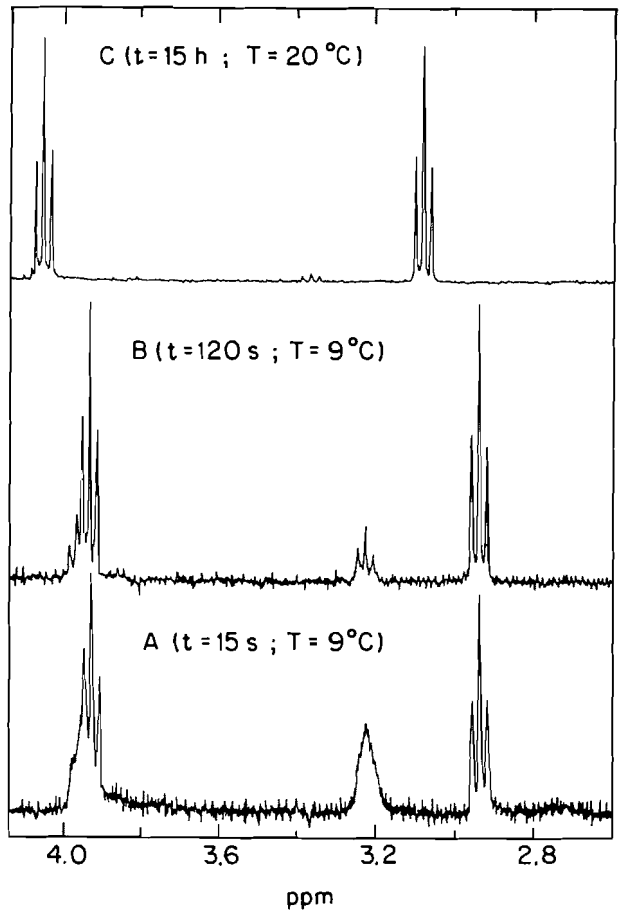

FIG. 6. Proton NMR spectra of a $(HOC_2H_4S)_2Se/HOC_2H_4SH$ mixture ($c((HOC_2H_4S)_2Se) = 0.013$ mol L^{-1}; $c(HOC_2H_4SH) = 0.003$ mol L^{-1}, unbuffered at (*A*) 15 s, (*B*) 120 s (9°C), and (*C*) 15 h (20°C)

its disappearance requires explanation. Thiols are subject to oxidation by oxygen (18) and the reaction is catalyzed by elemental selenium.[3]

$$[26] \quad 4\,RSH + O_2 \xrightarrow[Se]{} 2\,RSSR + 2\,H_2O$$

Thus, the generation of Se by reaction [2] accelerates the oxidation of the catalyst for the second stage, HOC_2H_4SH, by the ambient oxygen in the NMR tube over the course of several hours at room temperature. This also accounts for the presence of a trace of bis(hydroxyethylthio)selenide at the end of the experiment, because the catalyst is consumed by reaction [26] before reaction [2] is complete. The increasing resolution of the triplets with time, due to the bis(hydroxyethylthio)-selenide, is a result of the decreasing rate of exchange with decreasing concentration of bis(hydroxyethylthio)selenide and thiol.

The enthalpy and entropy of activation for reaction [2] were determined from data listed in Table 5 and found to be $\Delta H^{\ddagger} = 82 \pm 4$ kJ mol^{-1} and $\Delta S^{\ddagger} = 172 \pm 4$ J K^{-1} mol^{-1}. The large positive entropy of activation is not consistent with a bimolecular mechanism and supports a pre-equilibrium step, reaction [20], followed by a unimolecular dissociation, reaction [21]. In 60% dioxane the reaction of *t*-BuSH with *t*-BUSSeSBu-*t* gives $\Delta H^{\ddagger} = 64 \pm 4$ kJ mol^{-1} and $\Delta S^{\ddagger} = -75 \pm 12$ J K^{-1} mol^{-1} (9). In this case the measured $\Delta S^{\ddagger}$ supports an associative mechanism.

[a]Determined from the slope of the turbidity vs. time plot at the point of half-reaction.

Conclusion

The reduction of H_2SeO_3 by HOC_2H_4SH in aqueous solution takes place in two distinct stages, each involving more than one step and similar to the mechanism proposed by Kice et al. (6, 9, 10) for butyl thiols in 60% dioxane. The first stage involves two slow steps. There is an initial formation of 2-hydroxyethylthioselenous acid, $HOC_2H_4SSeO_2H$, in a process akin to the formation of $XSeO_2H$ (X = Cl, Br) by equilibria known for solutions of H_2SeO_3 in aqueous HCl (19) and HBr (20). This step (reaction [5]) proceeds very rapidly at pH 6.85 with a rate comparable to that observed for *n*-BuSH in 60% dioxane (6). However, at this pH, the rate of the forward reaction of [5] for butylthiols decreases with increasing pH while that for HOC_2H_4SH increases. These opposing trends are the result of the different degrees of dissociation of the two thiols. For *n*-butyl thiol in the pH range 0.2–8.0, the rate is dominated by nucleophilic attack of undissociated *n*-BuSH ($pK_a = 10.65$ (21)) on H_2SeO_3 and $HSeO_3^-$ (6) but for HOC_2H_4SH ($pK_a = 9.6$ (13)) at this pH, the thiolate ion is the most important nucleophile in determining the rate and its concentration increases with pH. The second step of the first stage (reaction [6]) proceeds more slowly than the first and involves coordination of another molecule of thiol to form $(HOC_2H_4S)_2SeO$, parallel to the formation of X_2SeO in HX (X = Cl, Br) solutions from $XSeO_2H$ (19, 20). This rate-determining step of the first stage is more rapid for HOC_2H_4SH in water than for *n*-BuSH or *t*-BuSH in 60% dioxane, due also to the greater degree of dissociation of HOC_2H_4SH, compared to *n*-BuSH, as well as the change of solvent. Several rapid steps complete this stage with the formation of bis(hydroxyethylthio)selenide. In the second stage this selenide undergoes further thiolate coordination at Se parallel to the related SeX_2 compounds (X = Cl, Br), which form SeX_3^- and SeX_4^{2-} anions (22, 23), and the complex undergoes further reaction to give disulfide and $HOC_2H_4SSe^-$ ion, which rapidly dissociates to thiolate and elemental selenium (8). The positive $\Delta S^{\ddagger}$ measured for this stage favours a dissociative rate-controlling step rather than the nucleophilic attack at sulphur.

Received April 14, 1994

STEPHEN P. MEZYK and DAVID M. BARTELS. Can. J. Chem. **72**, 2516 (1994).

Arrhenius parameters for the reaction of hydrogen atoms with acetone, 2-butanone, propionaldehyde, and butyraldehyde in aqueous solution have been directly measured by electron paramagnetic resonance free induction decay (FID) attenuation measurements. For these compounds, absolute scavenging rate constants at 25°C of $(1.97 \pm 0.10) \times 10^6$, $(3.82 \pm 0.32) \times 10^7$, $(8.11 \pm 0.47) \times 10^7$, and $(1.14 \pm 0.07) \times 10^8$ dm^3 mol^{-1} s^{-1}, with corresponding activation energies of 30.7 ± 1.3 (7.5–52.8°C), 40.1 ± 0.7 (8.1–74.5°C), 22.2 ± 0.9 (8.0–39.0°C) and 23.8 ± 0.8 (5.4–67.7°C) kJ mol^{-1} were measured, respectively. Competition kinetic measurements have established that greater than 95% of ·H atom reaction with 2-butanone is by abstraction.

STEPHEN P. MEZYK et DAVID M. BARTELS. Can. J. Chem. **72**, 2516 (1994).

Faisant appel à des mesures d'atténuation de la décroissance par induction libre (FID) de la résonance paramagnétique électronique, on a déterminé directement les paramètres d'Arrhenius de la réaction des atomes d'hydrogène avec l'acétone, la butan-2-one, le propionaldéhyde et le butyraldéhyde en solutions aqueuses. Pour ces composés, les constantes absolues des vitesses de piégeage, à 25°C, sont: $(1{,}97 \pm 0{,}10) \times 10^6$, $(3{,}82 \pm 0{,}32) \times 10^7$, $(8{,}11 \pm 0{,}47) \times 10^7$, et $(1{,}14 \pm 0{,}07) \times 10^8$ dm^3 mol^{-1} s^{-1} alors que les énergies d'activation sont respectivement de: 30,7 ± 1,3 (7,5–52,8°C), 40,1 ± 0,7 (8,1–74,5°C), 22,2 ± 0,9 (8,0–39,0°C) et 23,8 ± 0,8 (5,4–67,7°C) kJ mol^{-1}. Des mesures de cinétiques compétitives ont permis d'établir que plus de 95% de la réaction des atomes ·H avec la butan-2-one se fait par enlèvement.

[Traduit par la rédaction]

Introduction

Radioactive iodine is generally recognized as the most hazardous fission product that could be released to the environment in the event of a severe nuclear accident (1). Although most iodine is released as the soluble, non-volatile iodide, the high radiation fields expected following a reactor accident have been shown to significantly affect the iodine chemistry that occurs (2, 3). Of particular concern are the reactions that lead to volatile products, such as low molecular weight iodoalkanes (4).

In an attempt to understand the process of iodoalkane formation, a systematic investigation has been initiated (5) using irradiated aqueous iodide solutions containing 2-butanone (MEK) as a prototypical organic impurity. The steady-state irradiation of aqueous MEK solutions produces a large number of product species (6); thus to ensure a complete understanding of proposed mechanisms, computer modelling is required. Such modelling is dependent on having accurate rate constant data available for the aqueous radiolysis species reactions with MEK and its subsequent degradation products.

Unfortunately no kinetic data could be found in the literature for the radiation chemistry of MEK itself, or for one of its breakdown products, propionaldehyde (propanal). In a recent investigation (7), rate constants and activation energies were determined for hydrated electron and hydroxyl radical reaction with these carbonyls, using the techniques of pulsed electron radiolysis and absorption spectroscopy. However, the pulse radiolysis of these compounds in acidic solutions containing *t*-butanol showed no change in the visible or near-uv absorption spectrum, and thus no measurement of their reaction rate constant with the hydrogen atom was possible at that time.

This paper reports our direct measurement of rate constants and activation energies for the reaction of hydrogen atoms with propanal and MEK in aqueous solution. For comparative purposes, values for butyraldehyde and acetone have also been determined. Because of its great specificity, direct EPR detection of the decay of the ·H atom following electron pulse radiolysis was the monitoring method of choice (8, 9). The pulsed EPR-based free induction decay (FID) attenuation method (10–15) used in this study has been demonstrated to be particularly advantageous for such rate constant measurements because of the simple pseudo-first-order scavenging kinetics generally obtained.

Experimental

The experimental procedure for determining ·H atom reaction rate constants has been described in great detail in several previous publications (10–13), and thus only a short description shall be given here. Hydrogen atoms were generated in aqueous solution by pulse radiolysis, using 3 MeV electrons from a Van de Graaff accelerator. A 35 ns microwave probe pulse was applied to the sample immediately after irradiation, and the resulting free induction decay of the ·H atom low-field ($m_I = +\frac{1}{2}$) EPR transition was recorded on a digital oscilloscope. Typically 500–2000 shots were averaged to measure each FID, at a repetition rate of 120 Hz.

Stock acid solutions were prepared by addition of $HClO_4$ (Mallinkrodt, A.R. Grade, 69.05%) to Millipore filtered water, to give pH 0.0, 1.0, and 2.0 standards. Actual acid concentrations were determined by standardization of the concentrated acid against 1.029 N HCl (Aldrich, Volumetric Standard). A total aqueous sample of ~190 mL was recirculated through a flat cell within an EPR cavity at a high flow rate, such that the actual volume irradiated in each pulse was less than 0.10 mL.

Scavenging experiments were performed by the successive injection of known volumes of acetone (Aldrich, HPLC grade, 99.5%+), butyraldehyde (Aldrich, 99%), MEK (Aldrich, HPLC grade, 99.5%+),

or propanal (Aldrich, 99%+) to an initial known volume of solution that had been fully de-oxygenated by bubbling with argon. Accuracy of these concentrations is estimated to be better than 3%.

The measured scavenging rate constants for all four systems of this study were found to have a slight dependence on radiation dose. A typical result for hydrogen atom scavenging of propanal at 22.4°C and pH 1.0 is shown in Fig. 1. The general expression of the effective damping rate of the FID in these experiments is given by (10–13).

$$[1] \quad \frac{1}{T_2\,(\text{eff})} = \frac{1}{T_2^0} + k_s[S] + \Sigma k_{ex}^i\,[R_i]$$

where $k_s[S]$ is the ·H atom scavenging rate, and $\Sigma k_{ex}^i[R_i]$ represents the spin-dephasing contribution of second-order spin exchange and recombination reactions between ·H atoms and other free radicals. The latter term in eq. [1] is responsible for the shift in intercept seen in Fig. 1, as the total free radical concentration $\Sigma[R_i]$ increases. The scavenging reaction converts hydrogen atoms into other free radicals, and the corresponding change in $k_{ex}{}^i$ during the five microsecond experimental time period is responsible for the small change in the slopes. As explained in a previous publication (14), the positive change in slope with increasing dose implies that the carbon-centred product radicals are more efficient spin-exchange partners for ·H than other ·H atoms. The systematic error due to this second-order chemistry can be avoided by either working with very small initial ·H atom concentrations, or by extrapolation to a "zero dose" limit (14).

The primary technique used in this study was extrapolation to zero dose. For example, for propanal at 22.4°C, actual rate constants of $(1.02 \pm 0.01) \times 10^8$, $(8.79 \pm 0.14) \times 10^7$, and $(7.97 \pm 0.32) \times 10^7$ dm^3 mol^{-1} s^{-1} were obtained for the 25, 12, and 5 ns pulses used respectively (see Fig. 1). These pulse widths corresponded to relative doses of 11.2, 5.3, and 1.4, where an absolute dose of ca. 3.0 kRad/pulse was estimated for the 25 ns pulse. These relative values were simply the measurement of the average beam current on a shutter positioned before the irradiation cell, and were assumed to be proportional to the actual dose given to the sample. The beam current values were monitored frequently to correct for any slight drift.

The extrapolation of these dose-dependent values to zero dose is shown in Fig. 2. An excellent linear relationship is obtained, and a limiting, zero dose, value of $(7.65 \pm 0.54) \times 10^7$ dm^3 mol^{-1} s^{-1} was calculated. This behaviour was consistent for all four systems of this study (see values for butyraldehyde at 22.4°C also in Fig. 2).

In an attempt to improve the precision of these extrapolated values, and to minimize the total dose delivered to low carbonyl concentrations, some single point experiments were also performed at very reduced doses (typically about 50% of the normal 5 ns pulse). Excellent agreement was obtained between these two methods. The single point measurements for butyraldehyde at 25.9°C of $(1.21 \pm 0.11) \times 10^8$ dm^3 mol^{-1} s^{-1} is in excellent agreement with the extrapolated value at 25.5°C of $(1.14 \pm 0.07) \times 10^8$ dm^3 mol^{-1} s^{-1}.

Both techniques were used to obtain dose-corrected scavenging rate constants for each compound over a range of temperature, with individual values given in Table 1. The corresponding Arrhenius plots are shown in Fig. 3.

To determine the fractions of addition and abstraction for hydrogen atom reaction with MEK, total hydrogen yield measurements were performed. Stock solutions of 0.10 mol dm^{-3} $HClO_4$ were saturated with argon before adding the required amounts of 2-propanol (Aldrich, 99.5% HPLC grade) or 2-propanol-d_8 (Aldrich, 99.7 atom %D) and MEK by direct injection. Aliquots of these solutions (10.00 mL) were sealed in a 50.0 mL flask and then irradiated (56 kRad) in a ^{60}Co Gammacell at ~28°C. The gas analyses, for H_2 and HD respectively, were performed using a VG Instruments MM 8-80 magnetic sector mass spectrometer, calibrated using standard H_2/HD gas mixtures.

·H atom reaction with acetone

The reaction of aqueous hydrogen atoms with acetone

$$[2] \quad \cdot H + CH_3COCH_3 \rightarrow \text{products}$$

was chosen for study in order to provide a comparison with the MEK data, and also because reaction rate constants have been determined previously, both by EPR (16) and chemical (17–19) methods. Rate constants in this study were determined using 1.0 mol dm^{-3} $HClO_4$ solution, as the fast reaction of acetone with hydrated electrons, k = 6.5×10^9 dm^3 mol^{-1} s^{-1} (20), caused a major reduction in the ·H atom yield for less acidic conditions.

The literature room temperature rate constants are somewhat scattered, with reported values ranging from 0.8 to 2.8×10^6 dm^3 mol^{-1} s^{-1} (16–19). The corrected, zero-dose, rate constant for hydrogen atom reaction with acetone at 23.7°C in this study is $(1.71 \pm 0.11) \times 10^6$ dm^3 mol^{-1} s^{-1}. The individual extrapolated values over the temperature range 7.5–52.8°C are given in Table 1, with the Arrhenius plot (Fig. 3) well described by the equation

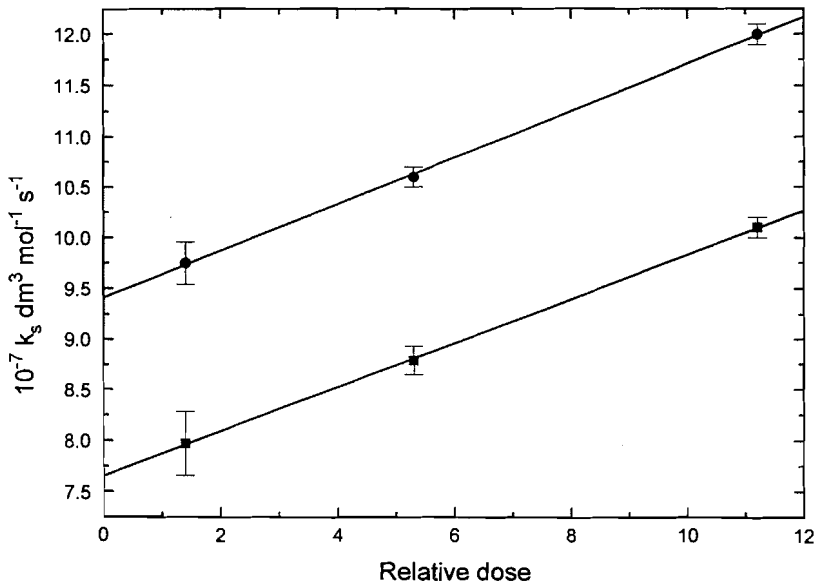

FIG. 2. Rate constant extrapolations to zero dose for propanal (■) at pH 1.0 and 22.4°C, and butyraldehyde (●), pH 1.0 and 22.4°C.

TABLE 1. Summary of the dose-corrected, temperature-dependent scavenging rate constants for hydrogen atom reaction with acetone, MEK, propanal, and butyraldehyde

Species	Temperature °C	Scavenging rate constant dm^3 mol^{-1} s^{-1}
Acetone	7.5	$(9.78 \pm 0.31) \times 10^5$
	16.8	$(1.32 \pm 0.06) \times 10^6$
	23.7	$(1.71 \pm 0.11) \times 10^6$
	25.7	$(1.97 \pm 0.10) \times 10^6$
	42.9	$(4.10 \pm 0.29) \times 10^6$
	52.8	$(5.68 \pm 0.59) \times 10^6$
MEK	8.1	$(1.48 \pm 0.19) \times 10^7$
	16.8	$(2.52 \pm 0.36) \times 10^7$
	25.0	$(3.82 \pm 0.32) \times 10^7$
	44.1	$(1.10 \pm 0.13) \times 10^8$
	74.5	$(3.86 \pm 0.27) \times 10^8$
Propanal	8.0	$(4.59 \pm 0.41) \times 10^7$
	17.0	$(6.13 \pm 0.41) \times 10^7$
	22.4	$(7.65 \pm 0.54) \times 10^7$
	25.0	$(8.11 \pm 0.47) \times 10^7$
	39.0	$(1.17 \pm 0.12) \times 10^8$
Butyraldehyde	5.4	$(5.60 \pm 0.23) \times 10^7$
	22.4	$(9.41 \pm 0.49) \times 10^7$
	25.5	$(1.14 \pm 0.07) \times 10^8$
	25.9	$(1.21 \pm 0.11) \times 10^8$
	39.6	$(1.80 \pm 0.19) \times 10^8$
	54.8	$(2.54 \pm 0.19) \times 10^8$
	67.7	$(3.71 \pm 0.23) \times 10^8$

[3] $\ln k_2 = (26.9 \pm 0.5) - (3690 \pm 160)/T$

with k_2 and T in units of dm^3 mol^{-1} s^{-1} and K respectively. This corresponds to an activation energy of 30.7 ± 1.3 kJ mol^{-1}.

It has previously been shown that there are two possible pathways for hydrogen atom to react with acetone (17, 21), either by abstraction of a methyl hydrogen atom, or by addition to the carbonyl bond. At room temperature, a branching ratio of 2.0:1 in favour of hydrogen atom abstraction has been determined (21). Unfortunately no branching ratios have been determined at other temperatures, and thus the individual activation energies for each process in acetone could not be established.

·H atom reaction with MEK

An identical procedure was followed for the measurement of the rate constant for hydrogen atoms reaction with MEK,

[4] $\cdot H + CH_3CH_2COCH_3 \rightarrow$ products

where in pH 2.0 solution at 25.0°C an extrapolated, limiting dose, value of $(3.82 \pm 0.32) \times 10^7$ dm^3 mol^{-1} s^{-1} was obtained. Similar measurements were performed over the temperature range 8.1–74.5°C (see Table 1). The calculated Arrhenius plot for all data is shown in Fig. 3, and for this compound, the temperature-dependent rate constant is given by

[5] $\ln k_4 = (33.7 \pm 0.3) - (4820 \pm 80)/T$

corresponding to an activation energy of 40.1 ± 0.7 kJ mol^{-1}.

This activation energy is significantly higher than determined for acetone, but at the same time, the MEK reaction is much faster due to a very large pre-exponential factor, 4.3×10^{14} dm^3 mol^{-1} s^{-1}. For MEK it can be assumed that the hydrogen atom reaction of abstraction from the terminal methyl groups would be similar to that for acetone. Thus the factor of twenty increase in the room temperature rate constant suggests that 95% or more of the hydrogen atom reaction with MEK consists of abstraction from the additional methylene group or addition to the carbonyl bond.

To establish the reaction mechanism the addition/abstraction ratio was determined at 28°C, using the competition technique established previously for acetone (21). It was found that the measured molecular hydrogen yield from an irradiated aqueous solution containing 1.0×10^{-3} mol dm^{-3} 2-propanol at pH 1.0 was unchanged upon the addition of $(0.2–1.0) \times 10^{-3}$ mol dm^{-3} MEK. Furthermore, when these experiments were repeated using fully deuterated 2-propanol, the decrease in the measured HD yield was concomitant with an increase in the H_2 yield. Analysis of these changes using standard competition kinetics indicated that more than 95% of the hydrogen atom reaction with MEK was by ·H atom abstraction to give H_2. As the rate constants for hydrogen atom reaction with MEK are far larger than those for acetone over the entire temperature range studied, the 40.1 kJ mol^{-1} activation energy measured essentially corresponds to only the abstraction process.

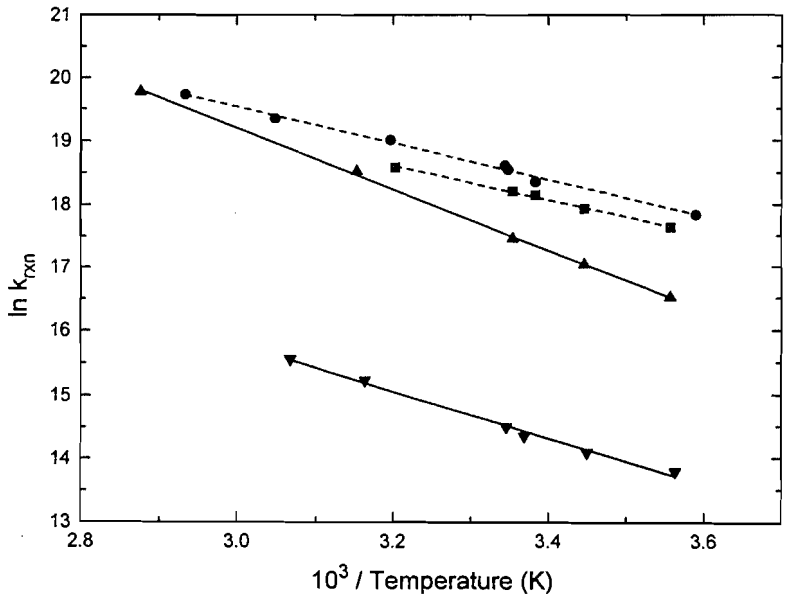

FIG. 3. Arrhenius plots of ln k_s vs. $1/T$ for propanal (■), MEK (▲), butyraldehyde (●), and acetone (▼). Lines correspond to calculated values of equations given in text.

This result is very surprising, because one typically expects faster abstractions from methylene than from methyl groups due to the weaker C—H bonds (22–24). Thus we expect roughly 10 kJ mol^{-1} lower activation energy for abstraction from MEK than from acetone. This ordering is indeed observed in the gas phase ·H abstractions by the methyl radical, where the activation energies are 40.5 kJ mol^{-1} for acetone, 31 kJ mol^{-1} for MEK, and 30 kJ mol^{-1} for diethyl ketone (23). One should consider the possible involvement of the hydrated and enol forms for the ketone. In room temperature water, the enol fraction of MEK is only 3×10^{-8} (25), while the hydrated form is believed to be less than 10^{-3} (22, 26). In order for either form to dominate the overall measured reaction rate, their ·H scavenging reactions would need to be orders of magnitude greater than diffusion-controlled, an obviously impossible situation. The possibility of an impurity that dominates the scavenging by virtue of its diffusion-limited rate can likewise be dismissed. The diffusional activation energy for ·H atoms is approximately 15 kJ mol^{-1} (27), so again we would expect an activation energy lower than that observed for the acetone reaction.

In order to explain the anomalously high activation energy for the MEK reaction with ·H atoms, we are forced to postulate some specific effect of solvation, which provides a large degree of entropic compensation for the higher energy abstraction process. We can suggest two possible concerted reactions. One possibility is that abstraction at the methylene position stimulates the hydration of the carbonyl bond. Hydration of substituted acetones has been shown to occur with overall positive entropy change (28), as required to account for the large pre-exponential factor. A second possibility is suggested by consideration of the enol structure of MEK, which converts the terminal methyl groups into allylic positions, with much weaker C—H bonds (23, 24). One can imagine an abstraction from the terminal methyl group, aided by a simultaneous keto–enol conversion process involving a water molecule in the solvation shell. Further investigation of this MEK scavenging reaction is clearly needed to establish the reaction pathway. Time-resolved EPR detection of the product radicals is planned.

·H atom reaction with propanal

The overall ·H atom scavenging rate constants at pH 1.0 and 22.4°C for the reaction

[6] $\cdot H + CH_3CH_2CHO \rightarrow$ products

were measured for temperatures over the range 8.0–39.0°C (Table 1). The temperature-dependent rate constant behaviour (Fig. 3) of reaction [6] is given by

[7] $\ln k_6 = (27.1 \pm 0.3) - (2670 \pm 100)/T$

This corresponds to an activation energy of 22.2 ± 0.9 kJ mol^{-1}.

This activation energy is much lower than that obtained for either of the ketones studied, suggesting a new reaction channel is available. Previous room temperature studies of ·H atom reaction with aldehydes (21, 29) have identified abstraction of the aldehydic hydrogen as the dominant (>90%) reaction channel. If we take our room temperature MEK rate constant of 3.8×10^7 dm^3 mol^{-1} s^{-1}, and add it to 3.4×10^7 dm^3 mol^{-1} s^{-1}, the rate constant reported for acetaldehyde (21) (aldehydic abstraction), we obtain a number very close to the 8.1×10^7 dm^3 mol^{-1} s^{-1} determined for propanal.

The lower measured activation energy for the overall hydrogen atom reaction with propanal implies that the abstraction from the aldehydic group has a much lower activation energy than abstraction at the methylene or methyl groups. Unfortunately no branching ratios for these two reactions have been determined. If the rate constant for hydrogen atom abstraction from the rest of the molecule (assumed to be the value from MEK) is subtracted from the measured values for propanal, the resulting Arrhenius plot gives an activation energy of ~12 kJ mol^{-1} for the aldehydic abstraction process.

·H atom reaction with butyraldehyde

The measurement of Arrhenius parameters for the reaction

[8] $\cdot H + CH_3CH_2CH_2CHO \rightarrow$ products

at pH 1.0 was performed as a comparison to the propanal system, to allow extension of the temperature range of these measurements, and because experimental difficulties (i.e. low boiling points) prevented determination of rate constants for either the formaldehyde or acetaldehyde systems using equipment on hand. The Arrhenius plot for butyraldehyde is also shown in Fig. 3, and is well characterized by the equation

[9] $\ln k_8 = (28.1 \pm 0.3) - (2870 \pm 95)/T$

This activation energy of 23.8 ± 0.8 kJ mol^{-1} is in very good agreement with the value for propanal, indicating that the same mechanisms of hydrogen atom abstraction also occur for butyraldehyde.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

In summary, the rate constants and competition measurements have shown that the dominant mechanism of hydrogen atom reaction with MEK and propanal is by abstraction. The surprising difference in activation energies between MEK and acetone scavenging leaves some doubt as to the preferred position of ·H atom abstraction in the longer chain carbonyl compounds. We plan an EPR study of these free radical products in order to establish the reaction mechanism and branching ratios as a function of temperature.

The anomeric effect in anionic systems XH_m-CH_2-NH^- and XH_m-CH_2-CH_2^-, with XH_m = F, OH, NH_2 and CH_3

CAMILLA SCOTT AND FRIEDRICH GREIN[1]

Department of Chemistry, University of New Brunswick, Bag Service No. 45222, Fredericton, NB E3B 6E2 Canada

Received June 10, 1994

CAMILLA SCOTT and FRIEDRICH GREIN. Can. J. Chem. **72**, 2521 (1994).

Ab initio geometry optimizations were performed at the RHF/6-31+G* level on anionic acetal-like systems of the form XH_m-CH_2-NH^- and XH_m-CH_2-CH_2^-, with XH_m = F, OH, NH_2, and CH_3. Using Fourier analysis combined with energy decomposition methods, the electronic part of the anomeric stabilization, *e*, has been evaluated. For the NH^- systems, e_N- was calculated to be –16.5 for F, –5.2 for OH, –2.7 for NH_2, and –1.0 for CH_3. For the CH_2^- systems the e_C- values are –8.1 for F, –5.3 for OH, –3.0 for NH_2 and –1.2 for CH_3. The units are kcal/mol. Comparing the trends in calculated energies, bond distances, and charges with those obtained for the model compounds CH_2-NH and CH_2-CH_2, the anomeric effect can be understood as the tendency of the anion to form a π-bond in the CH_2-NH^- or CH_2-CH_2^- portion of the molecule, caused by charge transfer from this portion to XH_m. The CH_3-CH_2-NH^- and CH_3-CH_2-CH_2^- systems form an exception.

CAMILLA SCOTT et FRIEDRICH GREIN. Can. J. Chem. **72**, 2521 (1994).

On a effectué des optimisations *ab initio* de géométries au niveau RHF/6-31+G* sur des systèmes ressemblant à des acétals des formes XH_m-CH_2-NH^- et XH_m-CH_2-CH_2^- dans lesquelles XH_m = F, OH, NH_2 et CH_3. Faisant appel à une analyse de Fourier combinée avec des méthodes de décomposition d'énergie, on a évalué la partie anomérique de la stabilisation, *e*. Pour les systèmes NH^-, on a évalué que les valeurs de e_N- sont –16,5 pour F, –5,2 pour OH, –2,7 pour NH_2 et –1,0 pour CH_3. Pour les systèmes CH_2^- les valeurs de e_C- sont –8,1 pour F, –5,3 pour OH, –3,0 pour NH_2 et –1,2 pour CH_3. Les unités sont les kcal/mol. Une comparaison des tendances dans les énergies, les longueurs de liaisons et les charges calculées avec les valeurs correspondantes obtenues pour les composés modèles CH_2-NH et CH_2-CH_2, on peut comprendre l'effet anomérique comme une tendance de l'anion à former une liaison π dans les portions CH_2-NH^- ou CH_2-CH_2^- des molécules, provoquée par un transfert de charge de cette portion au XH_m. Les systèmes CH_3-CH_2-NH^- et CH_3-CH_2-CH_2^- forment une exception.

[Traduit par la rédaction]

1. Introduction

Over the past 30 years the anomeric effect (ae) has been studied for many different systems of molecules. Recently, papers by Grein and Deslongchamps, to be referred to as papers I (1) and II (2), considered systems of neutral and protonated acetals. In a third paper, III, Grein (3) combined the energy decomposition model first outlined in paper II with the Fourier analysis model given in paper I. In the present study, previous work is extended to include anionic acetal-like systems XH_m-CH_2-YH_n^-, with XH_m = F, OH, NH_2, and CH_3, and YH_n^- = NH^- and CH_2^-.

The main purpose of the energy decomposition method is to separate the electronic part of the anomeric stabilization from the steric and electrostatic contributions. In the Fourier analysis, the rotation of the YH_n hydrogens of compounds XH_m-CH_2-YH_n about the C–Y axis is broken down into V_1, V_2, and V_3 components corresponding to the first three terms in the Fourier series, having periods of 360°, 180°, and 120°, respectively. The electronic part of the anomeric stabilization energy is seen to be related to the V_2 component. The combination of these two methods allows for an assessment of the potential for the occurrence and strength of the anomeric effect in a molecule.

The electronegativity differences between the X and Y atoms in XH_m-CH_2-OH, XH_m-CH_2-NH_2, and corresponding protonated systems are essential to the understanding of the anomeric effect. The more electronegative XH_m is, compared to OH or NH_2, the greater the electronic stabilization from the anomeric effect due to OH or NH_2. For example, in the NH_2 systems, the very electronegative XH_m = F system had an electronic parameter e_N of –3.6 kcal/mol compared to the XH_m = NH_2 system for which e_N was –1.0 kcal/mol.

The anionic XH_m-CH_2-CH_2^- systems are commonly referred to as carbanions. Despite the fact that a large number of organic reactions involve carbanions as reactive intermediates, they are not well understood. Carbanions act as strong bases or nucleophiles in reactions such as electrophilic substitutions. They are an interesting class of compounds because, unlike other molecules, they are destabilized by ethyl and other electron-donating groups. Usually, carbanions acting as intermediates in organic reactions are bonded to groups that stabilize through inductive effects or resonance.

The fact that the XH_m-CH_2-CH_2^- ions studied here are not stabilized indicates that if they exist they are not as common as other carbanions. For example, F-CH_2-CH_2^- is not stable due to β-elimination of the fluorine atom. The *n*-propyl anion CH_3-CH_2-CH_2^- is actually known and exists as an ion pair with such species as Li^+. NH_2-CH_2-CH_2^- is more stable than OH-CH_2-CH_2^- due to the acidities of the other hydrogens. Experimental chemists are presently working on possible OR-CH_2-CH_2^- systems.

A number of theoretical studies have previously been performed on anionic acetal-like systems (4–9). For example, Schleyer and Kos (4) investigated cases with X = F, O, and N, in connection with assessing the importance of negative hyperconjugation. For such systems, negative hyperconjugation is the interaction of a filled *p* orbital on the carbon in CH_2^- with the C—X bonding and antibonding orbitals. The extent of this interaction is dependent on the electronegativity of X. For example, with F this orbital interaction is large and there is a great amount of stabilization, accompanied by a shortening of the C—C bond and lengthening of the C—X bond. Negative (or anionic) hyperconjugation is equivalent to the anomeric effect in anionic systems. Theoreticians studying the negative hyperconjugation effect (4–6) and related topics (7, 9) in anionic acetals compared the energies of the 180° conformer, in which

negative hyperconjugation is at a maximum (lone pair on CH_2^- antiperiplanar to the C—X bond), with that of the 90° conformer where negative hyperconjugation is turned off (lone pair on CH_2^- rotated 90° relative to C—X bond).

The paper by Schleyer and Kos (4) was written in response to a controversy over whether the stabilizing effect seen in $F\text{-}CH_2\text{-}CH_2^-$ was due to negative hyperconjugation or to polarization. Streitweiser et al. (5) supported the polarization idea by showing that there was no charge transfer involved. In reply to this, Schleyer and Kos (4) disagreed with the conclusions of Streitweiser et al. and stated that the definition of hyperconjugation is the interaction of orbitals, independent of charge transfer, but that both charge transfer and polarization can be the result of hyperconjugation. Discrepancies in their findings from those of Streitweiser et al. were shown to result from restrictions placed on geometries. For example, Streitweiser et al. used fixed bond lengths and angles whereas Schleyer and Kos did not. Schleyer and Kos found the energy difference between the 180° conformer (negative hyperconjugation) and the 90° conformer (no negative hyperconjugation) to be 10.2 kcal/mol for $F\text{-}CH_2\text{-}CH_2^-$ (4-31+G) and 6.5 kcal/mol for $NH_2\text{-}CH_2\text{-}CH_2^-$ (3-21+G). Apeloig and Rapporport (7) obtained energy differences of 10.1 and 4.8 kcal/mol, respectively, calculated at the STO-3G level.

An interesting result obtained by Schleyer and Kos (4), which was reviewed by Reed and Schleyer (8), was that in $F\text{-}CH_2\text{-}CH_2^-$ β-elimination occurs, leading to dissociation into F^- and ethylene. This 1,2 elimination in $F\text{-}CH_2\text{-}CH_2^-$ had previously been studied by Bach, Badger, and Lang (9).

The main objective of this paper is to demonstrate that the anomeric effect applies to anionic acetal-like systems as well as to their neutral and protonated counterparts, and to obtain estimates of the stabilization energies, in particular their electronic components.

2. Methods

Geometry optimizations were carried out at the SCF level with the 3-21G* and 6-31+G* basis sets, using the GAUSSIAN 86 program (10). Only the values obtained from 6-31+G* calculations are reported. In our previous studies on the anomeric effect, the 6-31G** and 6-31+G* basis sets were employed. For the anionic systems to be treated in this paper, diffuse basis functions (+) are essential.

For the anionic acetal-like systems $XH_m\text{-}CH_2\text{-}YH_n^-$, with X = F, O, N, and C, and Y = N and C, the dihedral angles of the XH_m and YH_n^- hydrogens were held at certain values while the other parameters, bond lengths, bond angles, and remaining dihedral angles, were optimized. For purposes of the energy decomposition method the hydrogen dihedral angles were fixed to obtain the correct geometry for 0, 1, and 2 anomeric effects (0ae, 1ae, 2ae). Examples are shown in structures **1–4** for the $OH\text{-}CH_2\text{-}NH^-$ system. For use in the Fourier analysis method

the XH_m hydrogens were fixed anti (a) for OH and staggered (s) for NH_2 and CH_3 relative to the $CH_2\text{-}YH_n$ fragment of the molecule. The term anti refers to a dihedral angle of 0° for the OH hydrogen, whereas staggered refers to dihedral angles of ±120° for the NH_2 hydrogens and 0°, ±120° for the CH_3 hydrogens. All dihedral angles refer to the plane XCZ, where Z is shown in structure **5**. With the XH_m hydrogens held in these positions the NH^- (CH_2^-) hydrogens were rotated about the C—N (C—C) bond. Calculations were performed at dihedral angles ϕ of 0° (±60°), 60° (0°, 120°), 120° (60°, 180°), and 180° (±120°) referring to the plane XCZ. Numbers in parentheses refer to the CH_2^- systems. Examples are given in structures **5–12**.

3. Results for energy analysis model

3.1 The XH_m-CH_2-NH^- systems

In the simple picture of lone pairs (*l*p) of electrons located in sp^3 positions, the anomeric effect is caused be a lone pair antiperiplanar (app) to the C—X or C—Y bond. Therefore, in structure **1** there is 0ae, whereas **2**, **3**, and **4** have 1ae(O), 1ae(N), and 2ae's, respectively.

In Table 1, energies relative to the most stable conformer as well as optimized C—N and C—X distances are given for the 0ae, 1ae, and 2ae conformers of F-CH_2-NH^-, and OH-CH_2-NH^-, NH_2-CH_2-NH^-. As seen from the relative energies, 1ae is more stable than the corresponding 0ae, and 2ae is more stable than 1ae. The 2ae conformer of F-CH_2-NH^- forms a complex (a loosely bound structure of type F^-...CH_2NH), with a long

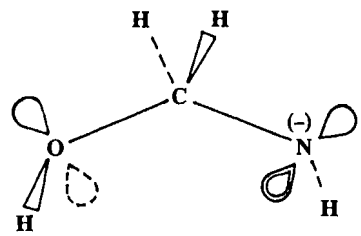
CH_3-CH_2-NH^-	0.02 1.4278/1.5318		0.00 1.4249/1.5500	

C—F distance of 2.82 Å. The energy lowerings for CH_3-CH_2-NH^- are essentially zero, which illustrates the point that the anomeric effect is not applicable to this system. The trends in bond lengths are as expected, with an ae from N causing the C—N bond to shorten and the C—X bond to lengthen.

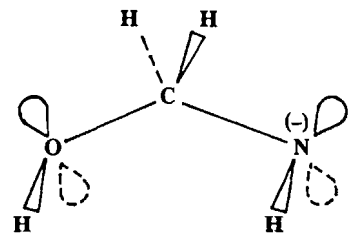
Following the procedures outlined in papers II and III, an energy analysis was carried out for the XH_m-CH_2-NH^- systems. The energy differences between various conformers are described by certain parameters, such as the electronic component, called *e*; 1,3-diaxial H–H repulsions, labelled *r*; 1,3-diaxial *l*p–*l*p repulsions, labelled *l*; and intramolecular "hydrogen bonding" (1,3-diaxial H-*l*p interactions), labelled *h*. The 1,2 hydrogens and bonds are staggered for all of the conformers, so these interactions do not need to be included in the analysis.

The values of the parameters *r*, *l*, and *h* have to be estimated in order to obtain the value of *e* from the calculated energy differences. The 6-31+G* energy difference between g,g-OH-CH_2-NH^-, **13***a*, and g,g*-OH-CH_2-NH^-, **13***b*, is 3.85 kcal/mol. For NH_2-CH_2-NH^- the sterically favoured 1ae(N^-) conformer, **14***a*, is 3.75 kcal/mol (6-31+G*) more stable than the 1ae(N^-) conformer, **14***b*. For both systems the energy difference is given by the formula $\Delta E = l + r - 2h$. For the methoxy



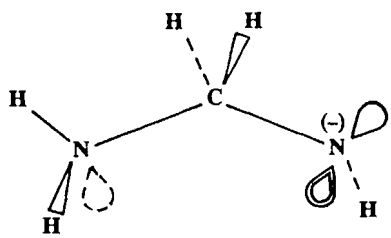
$e_O + e_{N^-} + 2h$

13*a*



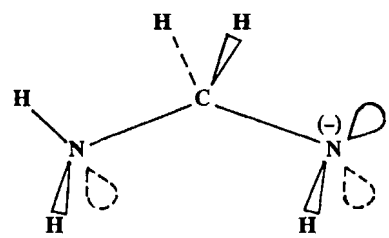
$e_O + e_{N^-} + r + l$

13*b*



$e_{N^-} + 2h$

14*a*



$e_{N^-} + l + r$

14*b*

system discussed in paper II, *h* was estimated to be about −1 kcal/mol. Using this value for *h*, $l + r$ is approximately equal to 2 kcal/mol. To make this method more applicable, only half or whole integers (in kcal/mol) will be used, so $l = r = 1$ kcal/mol will be assumed as in our previous work.

Applying this model to the systems given in Table 1 allows for an estimate of the electronic contribution *e* to the anomeric effect. This is the anomeric stabilization energy (difference between $\phi = 0°$ and $\phi = 120°$) after steric and electrostatic components were removed. The procedure is outlined in paper II. The value of e_{N^-} is –25 for the X = F, –5 for the X = O, –3 for the X = N, and –2 for the X = C system. In e_{N^-} the subscript indicates that the electronic portion of the anomeric effect is due to electron donation from (the formal) N^-. As well, values of $e_N \cong$

–3.5 for the NH_2-CH_2-NH^- system and $e_O \cong -4.5$ for the OH-CH_2-NH^- system were calculated (all in kcal/mol).

3.2 The XH_m-CH_2-CH_2^- systems

For the systems XH_m-CH_2-CH_2^-, with XH_m = F, OH, NH_2, and CH_3, the simple definition for the anomeric effect as given in the previous section yields 0ae for structure **15**, 1ae(O) for **16**, 1ae(C^-) for 17, and 2ae for **18**.

In Table 2, relative energies and optimized C—C and C—X distances are given for the 0ae, 1ae, and 2ae conformers of the various XH_m-CH_2-CH_2^- systems. From the relative energies it can be seen that again the 1ae conformer is more stable than the 0ae conformer and, in turn, 2ae is more stable than 1ae. The energy lowerings for all systems are significant except for CH_3-CH_2-CH_2^-, as expected.

The 6-31+G* energy difference between the 1ae(O) conformation of OH-CH_2-CH_2– and the sterically hindered 1ae(O) is 5.17 kcal/mol. For NH_2-CH_2-CH_2^-, the energy difference (6-31+G*) between the staggered 0ae conformer and its eclipsed version is 4.77 kcal/mol. For both of these systems $\Delta E = l + r - 2h$. Using a value of –1 kcal/mol for the h parameter, $l + r$ is equal to about 3 kcal/mol. Using only half or whole integers, l and r are best fitted to be 1.5 kcal/mol each.

This model applied to the systems listed in Table 2 gives e_{C^-} values of about –8 for F, –5 for OH, –4 for NH_2, and –2 for the CH_3 system (kcal/mol). Also, values of $e_O \cong -6$ kcal/mol for the OH-CH_2-CH_2^- system and $e_N \cong -4.5$ kcal/mol for NH_2-CH_2-CH_2^- are obtained.

The trend for the e_{C^-} values is as expected, with the highest e_{C^-} obtained for the F system, decreasing to the OH, the NH_2, and finally the CH_3 system. It is interesting to note that for the OH system e_O is more negative than e_{C^-}, and a similar situation applies to the NH_2 system. This means that for the a-OH-CH_2-CH_2^- system a lone pair on O donating into C^- is more stabilizing than lone pair donation the other way around (or C^- is more electronegative than O).

Schleyer and Kos (4) reported that under the restraint of C_s symmetry, F-CH_2-CH_2^- optimized to a planar C_{2v} complex, with a large C—F distance. The 1ae (C_s) conformer studied here, however, had the dihedral angles of the CH_2 hydrogens

fixed at ±120°, and therefore a planar complex could not be formed. The same situation applies to the 180° conformer of F-CH_2-CH_2^-, which is identical in structure. Due to the restrictions on dihedral angles imposed in this study, β-elimination, leading to F^- + C_2H_4, could not take place.

4. Results for the Fourier analysis model

4.1 The XH_m-CH_2-NH^- systems

In this study the NH^- hydrogen of XH_m-CH_2-NH^- was rotated around the C—N bond, with the XH_m hydrogens held at fixed dihedral angles relative to the CH_2 hydrogens, as explained earlier. XH_m was chosen to be F (**5**), a-OH (**6**), s-NH_2 (**7**), and s-CH_3 (**8**). Relative energies, optimized C—N and C—X distances, and Mulliken charges on NH^- and XH_m for NH^- dihedral angles φ of 0°, 60°, 120°, and 180° are given in Table 3. The dihedral angle φ = 0° corresponds to the 0ae conformation in the case of the a-OH system and to the 1ae(X) conformation for F and s-NH_2. For φ = 120°, one ae has to be added, resulting in the 1ae conformer for a-OH, and 2ae for F and s-NH_2. Again, the F-CH_2-NH^- system forms a F^-...CH_2NH complex at 120°, corresponding to the 2ae conformer of Table 1.

In Table 4, the Fourier constants V_1–V_3 are given for these systems. The constants are obtained by fitting the relative energy values of Table 3 to the formula:

$$[1]\quad \Delta E(\phi) = (V_1/2)(1 - \cos\phi) + (V_2/2)(1 - \cos 2\phi) + (V_3/2)(1 - \cos 3\phi)$$

At φ = 0° and 360°, ΔE = 0; therefore all of the relative energies of Table 3 were calculated with respect to the energy at φ = 0°. According to eq. [1], V_3 has maxima at 60° and 180° and minima at 0° and 120°. V_3 represents the threefold repulsion the NH^- hydrogen receives when it eclipses the two C—H bonds at 60° and 300° and C—X bond at 180°. Since the NH^- hydrogen is staggered relative to CH_2X at 0°, V_3 is positive. The value of the V_3 parameter is expected to be close to that of the energy difference between the staggered and eclipsed conformers of CH_3NH^-, which was calculated to be 2.00 kcal/mol at the 6-31+G* level. Such is the case for all systems except F-CH_2-NH^-. The large V_3 value of 12.80 kcal/mol for the latter system is due to the formation of a complex at φ = 120° (seen from the bond distances in Table 3). Since this conformer is very stable compared to the 60° and 180° conformers, a very large positive V_3 results.

From eq. [1], V_1 has a maximum at 180° and a minimum at 0°. The sign of V_1 is negative if the 180° conformer is more stable than the 0° conformer. V_1 results from steric (H–H repulsions) and electrostatic effects (*l*p–*l*p repulsions and H–*l*p attractions). Components of V_1 relate to the energy parameters *r*, *l*, and *h* used previously in the energy decomposition model. According to eq. [1], $V_1 = \Delta E(180) - V_3$. For F-$CH_2$-$NH^-$ and a-OH-CH_2-NH^-, $\Delta E(180°)$ is the difference between intramolecular 1,3-hydrogen bonding at 180° (negative) and lone pair repulsions at 0° (positive). This situation causes $\Delta E(180)$ to be negative and hence V_1 to be negative (since V_3 is positive). For F-CH_2-NH^-, V_1 is large and negative due to the fact that $\Delta E(180)$ is small and negative whereas V_3 is large and positive. For s-NH_2 and s-CH_3, $\Delta E(180)$ is the difference between 1,3 H–H repulsions at 180° (+) and 1,3 internal hydrogen bonding at 0° (−), causing $\Delta E(180)$ and V_1 (since $\Delta E(180) > V_3$) to be positive.

According to eq. [1], the V_2 parameter has a maximum at φ = 90° and is zero at 0° and 180°. This term results from the electronic part of the anomeric effect. It is always negative and decreases in magnitude from X = F to X = C. V_2 is exceptionally large for the F system owing to the high stabilization received upon the formation of a complex at φ = 120°.

According to Table 3, anomeric stabilization (i.e., $E(120°)$ is lower than $E(0°)$, or $\Delta E(120°)$ is negative) is received by all of the systems except $XH_m = CH_3$. This situation can be explained on the basis of the Fourier constants. According to eq. [1], $\Delta E(120) = 0.75(V_1 + V_2)$. For the F and a-OH systems both V_1 and V_2 are negative, meaning that φ = 120° is more stable than φ = 0° via the V_1 term (steric and electrostatic) and φ = 90° is more stable than φ = 0° via the V_2 term (electronic stabilization). A combination of negative V_1 and V_2 results in a large sta-

TABLE 5. Comparison of e_{N^-} values in kcal/mol, calculated by Fourier analysis with e_{N^-} values obtained from energy analysis

XH_m-CH_2-NH^-	Fourier e_{N^-}	Energy e_{N^-}
F-CH_2-NH^-	−16.5	−25
a-OH-CH_2-NH^-	−5.2	−5
s-NH_2-CH_2-NH^-	−2.7	−3
s-CH_3-CH_2-NH^-	−1.0	−2

bilization at $\phi = 120°$. Therefore, the anomeric stabilization in these two systems is a combination of favourable electronic as well as steric and electrostatic effects as one rotates from $\phi = 0°$ (0ae) to $\phi = 120°$ (1ae).

For s-NH_2, V_1 is positive and V_2 is negative but the electronic effect V_2 is large enough to compensate for the V_1 value such that there is still considerable stabilization at $\phi = 120°$. For the CH_3 system, V_1 is positive and V_2 negative but in this case the sum $V_1 + V_2$ is close to zero so there is no significant stabilization at 120°. Since $\Delta E_{ae} = \Delta E(120°) = 0.75\ (V_1 + V_2)$, the electronic component of the ae stabilization e_{N^-} can be calculated as $0.75V_2$, which gives −16.5 for F, −5.2 for a-OH, −2.7 for s-NH_2, and −1.0 for s-CH_3 (all in kcal/mol).

In Table 5, the e_{N^-} values found from the Fourier analysis model are given and compared with those found previously by the energy decomposition model. Except for F-CH_2-NH^-, which is characterized by complex formation, the agreement is quite good.

4.2 The XH_m-CH_2-CH_2^- systems

The same analysis was also performed for the systems XH_m-CH_2-CH_2^-, where again XH_m = F (**9**), a-OH (**10**), s-NH_2 (**11**), and s-CH_3 (**12**). For symmetry reasons, $\phi(CH_2) = 0°$ was chosen such that the rotating CH_2 hydrogens have dihedral angles of ±60° relative to the plane CCZ (**9**). For $\phi(CH_2) = 60°$, the dihedral angles are 0°, 120°; for $\phi(CH_2) = 120°$ the dihedral angles are 60°, 180°; and for $\phi(CH_2) = 180°$ they are ±120°. Except for the fixed dihedral angles of the CH_2 and the XH_m hydrogens (as described earlier), all geometry parameters were allowed to optimize.

The calculated energy differences, C—C and C—X distances, and Mulliken charges on CH_2^- and XH_m are given in Table 6. In Table 7 the Fourier constants obtained by fitting the relative energies into eq. [1] are presented. The V_3 parameter describes the threefold repulsion the rotating CH_2^- receives when eclipsing the CH_2X group. At $\phi = 0°$ and 120° CH_2^- is eclipsed relative to CH_2X whereas at $\phi = 60°$ and 180° this steric interaction is minimal, therefore V_3 is negative. The V_3 parameter should have a value close to the energy difference between the eclipsed and staggered forms of CH_3-CH_2^- (−2.39 kcal/mol in 6-31+G*). This holds true, as seen from Table 7 in which V_3 for XH_m-CH_2-CH_2^- ranges from −2.61 to −2.92 kcal/mol.

As before, V_1 represents the steric and electrostatic effects. The V_1 term in eq. [1] has a maximum (or minimum) at 180° and is zero at 0°. For F-CH_2-CH_2^- and a-OH-CH_2-CH_2^-, $\Delta E(180°)$ is the difference between lone pair repulsion at 0° (positive) and intramolecular hydrogen bonding at 180° (negative). Therefore, both $\Delta E(180°)$ and V_1 (= $\Delta E(180) - V_3$) are negative. For s-NH_2 and s-CH_3, $\Delta E(180°)$ is the difference between intramolecular hydrogen bonding at 0° (−) and hydrogen repulsion at 180° (+). The sign of $\Delta E(180°)$ cannot be determined by qualitative means. From Table 6 the values of $\Delta E(180°)$ for the s-NH_2 and s-CH_3 systems are −1.53 and −1.63 kcal/mol, respectively, leading to a positive V_1.

The V_2 parameter, which contains the electronic part of the anomeric effect, is positive and decreases in value starting from the XH_m = F to the XH_m = CH_3 systems. For the XH_m-CH_2-CH_2^- systems the anomeric stabilization is given by $\Delta E_{ae} \equiv E(180°) - \Delta E(60°)$. For the F and a-OH systems V_1 is negative and V_2 positive, therefore both terms stabilize the system when going from 0ae (60°) to 1ae (180°). In other words, the observed energy lowering has electrostatic/steric and electronic components. On the other hand, for s-NH_2 and s-CH_3, V_1 and V_2 are positive. The stabilization of these two systems results from favourable V_2 (electronic), which is counteracted by an unfavourable V_1 (steric/electrostatic).

Calculating e_{C^-} as $-0.75V_2$ gives $e_{C^-} = -8.1$ for F-CH_2-CH_2^-, −5.3 for a-OH-CH_2-CH_2^-, −3.0 for s-NH_2-CH_2-CH_2^-, and −1.2 kcal/mol for s-CH_3-CH_2-CH_2^-. In Table 8 the e_{C^-} values obtained by the Fourier method are given and are compared with the corresponding e_{C^-} values obtained earlier from the energy analysis method. In all cases, the agreement is good.

In the paper by Schleyer and Kos (4), mentioned earlier, the energy difference between the 90° and the 180° conformer for systems XH_m-CH_2-CH_2^- was given as 10.2 and 6.5 kcal/mol for X = F and N, respectively. (For OH-CH_2-CH_2^- the a-OH conformation, chosen here, was not considered.) Using the Fourier series to calculate the energy of the 90° conformer, the corresponding energy differences obtained in this work are 13.9 for X = F, 9.7 for X = O and 4.7 for X = N, in kcal/mol.

5. Application of the π-bonding model

The electronic part of the anomeric effect will now be explained as the tendency of the CH_2-YH_n component of XH_m-CH_2-YH_n^- to form a π bond. To do this the trends in relative energies, bond distances, and Mulliken charges of the XH_m-CH_2-YH_n^- systems will be compared with the corresponding trends of the CH_2=YH_n molecule.

The CH_2 hydrogen dihedral angles in CH_2=NH were held at ±90° (planar) and the HNC angle at 109.5°. In previous cases, the CH_2 group was held in pyramidal position (±60°), in order to better mimic the situation in XH_m-CH_2-NH_2^-. However, the optimization process for some dihedral angles led to badly distorted structures, causing inconsistencies in the calculated energies and C—N bond distances. The NH portion of the molecules was rotated from 0° to 180°, with the same convention as illustrated in structures **5–8**. The resulting bond distances, relative energies, and Mulliken charges from the 6-31+G* geometry optimizations are given in Table 9.

The trend in relative energies for the CH_2=NH molecule is as expected, with the least stable conformer at $\phi = 0°$, increasing in stability to $\phi = 90°$ and then decreasing to $\phi = 180°$. The conformers at $\phi = 180°$ and 60° have the same energies as those of $\phi = 0°$ and 120°, respectively, due to the symmetry of the molecule. For the pyramidal (±60°) conformer of CH_2=NH, the 180° geometry would be at lower energy than for 0° due to steric hindrance between the CH_2 and NH hydrogens at 0°.

Table 3 shows that the F-CH_2-NH^- and a-OH-CH_2-NH^- systems have the same trend in energies as the CH_2=NH molecule. For s-NH_2 the 180° conformer is less stable than the 0° conformer. This is due to the fact that there is steric hindrance between the staggered NH_2 hydrogens and the NH hydrogen at $\phi = 180°$. The trends for the CH_3 systems are quite unlike those

of the π-bonded molecule, which indicates that the ae is not applicable for this system.

The C—N bond length for the CH_2=NH molecule decreases from the conformer at ϕ = 0° to ϕ = 90° and then increases to ϕ = 180°. This trend is the same as found for the F and a-OH systems. For the s-NH_2 system the largest bond distance is obtained at ϕ = 180° instead of at ϕ = 0° due to steric factors. For the s-CH_3 system the C—N distances show no similarity at all to the CH_2=NH molecule.

For studying the π-bonding model in the XH_m-CH_2-CH_2^- systems reference calculations on CH_2=CH_2 were performed. For one CH_2 group the dihedral angles were fixed in pyramidal position (±60°). The hydrogens of the other CH_2 group were rotated, with the ϕ angles defined analogously to structures **9**–**12**. The relative energies and C—C distances of CH_2=CH_2 are given in Table 10.

In comparing the trend in relative energies of the CH_2=CH_2 molecule with those of XH_m-CH_2-CH_2^- (Table 6) it is seen that all systems except CH_3-CH_2-CH_2^- follow the same trend. An increase in relative energy between ϕ = 0° and 120° is followed by a decrease down to ϕ = 180°. The trend in C—C bond lengths shown in Table 6 is also similar to that of CH_2=CH_2, except for CH_3−CH_2-CH_2^-. The bond lengths increase from ϕ = 0° to 120° and then decrease at ϕ = 180°. For CH_2=CH_2 the bond at ϕ = 0° is shorter than at ϕ = 180° but the situation is opposite for the XH_m-CH_2-CH_2^- systems. This difference is considered to be due to steric interaction between CH_2 and XH_m in the XH_m-CH_2-CH_2^- systems. The fact that the CH_2^- portion of XH_m-CH_2-CH_2^- is least negative (most positive) at ϕ = 0° indicates increased π bonding.

The π-bonding model shows clearly that the anomeric effect is not applicable to CH_3−CH_2-CH_2^- since it has no similarities with CH_2=CH_2.

6. Discussion and conclusion

The energy parameters e_{N^-} and e_{C^-} obtained by Fourier analysis are summarized in Table 11. These parameters were designed to capture the electronic part of the anomeric stabilization energy. The anomeric effect occurs when NH^- of XH_m-CH_2-NH^- is rotated from ϕ(NH) = 0° to ϕ(NH) = 120° or CH_2^- of XH_m-CH_2-CH_2 from ϕ(CH_2) = 60° to 180°. The values of e_{N^-} and e_{C^-} were calculated as $0.75V_2$ or $-0.75V_2$, respectively, and are similar to the corresponding values obtained by the energy decomposition model.

TABLE 11. Energy parameters (as obtained by Fourier analysis) e_{N^-} and e_{C^-} in kcal/mol for electronic component of anomeric effect due to N and C, for systems XH_m-CH_2-NH^- and XH_m-CH_2-CH_2^-

XH_m	e_{N^-}	e_{C^-}
F	−16.5[a]	−8.1[b]
a-OH	−5.2	−5.3
s-NH_2	−2.7	−3.0
s-CH_3	−1.0	−1.2

[a]Formation of complex.
[b]Value is −23.8 kcal/mol when restrictions on dihedral angles of 180° conformer are removed (see text).

TABLE 12. Comparison of e_{N^-} values (in kcal/mol) obtained for XH_m-CH_2-NH^- with e_N values obtained in paper III for XH_m-CH_2-NH_2 and XH_{m+1}^+-CH_2-NH_2

XH_m	XH_m-CH_2-NH^-	XH_m-CH_2-NH_2	XH_{m+1}^+-CH_2-NH_2	
F	−16.5	−3.6	(a-FH^+)	−30.6
a-OH	−5.2	−1.9	(s-OH_2^+)	−17.3
s-NH_2	−2.7	−1.0	(s-NH_3^+)	−5.7

One important point illustrated by this analysis is the significance of the relative electronegativities of the X and Y atoms. For an anomeric effect to occur by rotation of YH_n^-, the X atom of XH_m-CH_2-YH_n^- must be more electronegative than Y^-. For the XH_m-CH_2-NH^- systems, it is clear that for XH_m = F, a-OH, and s-NH_2 the X atoms are more electronegative than N^-, and therefore the anomeric effect is applicable. For XH_m = CH_3 the question of anomeric stabilization is not so obvious. The small negative e_{N^-} value of −1.00 kcal/mol for this system indicates no, or only a very small amount of anomeric stabilization. The π-bonding model does not support an anomeric effect in CH_3-CH_2-NH^- (and CH_3-CH_2-CH_2^-).

CH_2^- in the XH_m-CH_2-CH_2^- systems is less electronegative than NH^- in the corresponding XH_m-CH_2-NH^- systems, which should result in larger anomeric effect values when compared to the NH^- systems. Slightly larger values were found for all of the systems except for XH_m = F. In the case of F-CH_2-NH^- the formation of a complex results in an extremely large negative V_2, hence a larger e_{N^-} compared to e_{C^-} of the corresponding CH_2^- system, where no complex is found.

Using both models it has been shown that steric and electrostatic effects can either enhance or reduce the anomeric stabilization caused by the electronic component.

A comparison of e_{N^-} values from this paper with e_N values for the corresponding neutral and protonated systems taken from paper III is given in Table 12. Since the electronegativity difference between NH_2 and XH_m is not as large as between NH^- and XH_m, the anionic systems have much larger electronic components of the anomeric stabilization than the corresponding neutral systems. The e_{N^-} values for the OH and NH_2 systems are about 2.7 times larger than the respective e_N values. For the F system the factor is 4.6, due to formation of a complex for the ϕ = 120° conformer of F-CH_2-NH^-.

A comparison with the e_N values of the protonated systems, where the protonation takes place at the XH_m portion of the molecule, is more difficult, since it is not obvious which combination, XH_m vs. NH^-, or XH_{m+1}^+ vs. NH_2, should have the larger electronegativity difference. The difficulty is compounded by the formation of complexes for a-FH^+ and s-OH_2^+. Considering only the species not affected by complexing, i.e., e_{N^-} of s-NH_2-CH_2-NH^- versus e_N of s-NH_3^+-CH_2-NH_2, one sees that the e_N value of the latter system is about twice as large as the corresponding e_{N^-}. It appears that the larger stabilization goes to the cationic system.

It was mentioned in the Introduction that when optimizing the geometry of F-CH_2-CH_2^- without any restrictions there is no stable minimum, and the anion dissociates to F^- + C_2H_4. Under the restriction of C_s symmetry, this system forms a complex with large CF distance. Due to the additional restrictions placed on the dihedral angles of the CH_2^- hydrogens in this work, no complex is formed here. On the other hand, under very similar conditions, the optimization of F-CH_2-NH^- leads to a complex when the dihedral angle is chosen to be 120°, corresponding to maximal stabilizing interaction of the lone pair on NH^- with the CF bond. The optimized CF distance in the complex is 2.82 Å.

Since the electronegativity difference between F and YH_n^- is larger for the CH_2^- than for the NH^- system, the results obtained here appear to contradict expectations. However, the reason for this behaviour can be seen in the details of the restrictions. For the NH^- system, a planar CH_2=NH can still be formed, since the dihedral angles of the CH_2 hydrogens are free. For the CH_2^- system, however, the hydrogens of CH_2^- (not of CH_2) are held at ±120°, preventing the formation of planar CH_2=CH_2.

The geometry of the planar C_s complex of F-CH_2-CH_2^- was optimized using the 6-31+G* basis set. The CF distance is found to be 2.966 Å (2.93 Å in 3-21+G). Using for F-CH_2-CH_2^- the 180° energy of −37.69 kcal/mol (instead of −6.17 from Table 6), corresponding to the difference between the 0° and the planar 180° conformer, the Fourier constants for this system are recalculated to be V_1 = −24.34, V_2 = 31.77, and V_3 = −13.35 kcal/mol, compared with −3.33, 10.75, and −2.84, kcal/mol, respectively, from Table 7. Therefore, a revised value for e_{C^-} of F-CH_2-CH_2^- is −23.8 kcal/mol, significantly lower than −16.5 kcal/mol obtained for e_{N^-} of F-CH_2-NH^-.

In summary, it has been shown that the anomeric effect in anionic systems of type XH_m-CH_2-NH^- and XH_m-CH_2-CH_2^-, caused by donation of electrons from the formally negative atom, is quite pronounced. The electronic part of the energy stabilization is larger than for corresponding neutral systems, varying from about −3 to −16 kcal/mol for NH_2 to F substituents. These findings should be of interest in the understanding of carbanions, as well as in the design and utilization of other anionic systems.

For systems XH_m-CH_2-YH_n^-, the anomeric effect caused by electronic charge on X being transferred to Y (the opposite to what was done here) is expected to be small or nonexistent, especially if X and Y are confined, as in the present case, to the atoms C, N, O, and F.

Studies on the anomeric effect for first-row/second-row combinations, including neutral, protonated, and anionic systems, have been performed. The results and their analysis following the methods presented here will be published shortly.

Realistic, detailed images of proteins and tertiary structure elements: *ab initio* quality electron density calculations for bovine insulin

P. DUANE WALKER AND PAUL G. MEZEY[1]

Mathematical Chemistry Research Unit, Department of Chemistry and Department of Mathematics and Statistics, University of Saskatchewan, Saskatoon, SK S7N 0W0, Canada

Received August 15, 1994

P. DUANE WALKER and PAUL G. MEZEY. Can. J. Chem. **72**, 2531 (1994).

Detailed, *ab initio* quality electron density calculations are reported for the elements of the tertiary structure of bovine insulin, a protein containing 773 atoms in 51 residues. The high resolution 3D images of the molecular body and tertiary structure elements of insulin are computed using the new Molecular Electron Density Lego Assembler (MEDLA) method. The high, intermediate, and low electron density images show detailed, intricate shape features not revealed before. The MEDLA technique serves as a *computational microscope* for chemical, biochemical, pharmaceutical, and drug design applications.

P. DUANE WALKER et PAUL G. MEZEY. Can. J. Chem. **72**, 2531 (1994).

On a effectué des calculs *ab initio* détaillés de densité électronique pour les élements de la structure tertiaire de l'insuline bovine, une protéine contenant 773 atomes dans 51 résidus. Pour obtenir des images tridimensionnelles à haute résolution de l'ensemble moléculaire et des éléments de la structure tertiaire de l'insuline, on a fait appel à la nouvelle méthode de l'assembleur légo de la densité électronique moléculaire (MEDLA). Les images à densités électronique élevée, intermédiaire et basse présentent des caractéristique détaillées qui n'avaient pas été révélées antérieurement. La technique MEDLA peut servir de *microscope de calcul* pour des applications chimiques, biochimiques, pharmaceutiques ainsi que dans l'esquisse de médicaments.

[Traduit par la rédaction]

Introduction

For the visualization of the detailed shape features of proteins, the usual fused sphere models, solvent accessible surfaces, and motif patterns can provide a valuable, but only rough representation of the molecular shape features. The fuzzy electronic charge clouds form the actual molecular bodies in reality, therefore, faithful images of these charge clouds provide a valuable tool for chemistry. At present, the resolution of X-ray diffraction techniques is still insufficient for detailed shape analysis of the low density ranges of macromolecules. Up till now, the formidable computational problems have prevented the macromolecular applications of *ab initio* electron density calculations, so successful for small molecules.

The main obstacles of *ab initio* quantum chemical computations of electron densities for macromolecules are now circumvented. Here we report detailed, *ab initio* quality electron density calculations for bovine insulin, a protein of 773 atoms. The new Molecular Electron Density Lego Assembler (MEDLA) method (1), calculating and displaying electron density clouds at high resolution, serves as a *computational microscope* for proteins. No earlier experimental or computational method could generate protein images of similar accuracy and detail for the whole range of chemically important electron densities.

The MEDLA approach is suitable for the construction of inexpensive and reasonably accurate electron densities for large molecules. This method is based on a simple electron density fragment additivity principle and an algorithm described earlier (1). Fuzzy, mutually interpenetrating molecular fragment densities are computed for smaller molecules by an *ab initio* method using a suitable basis set (in our case, 6-31G**). These fragment densities are stored in a data bank and can be used as building blocks for the construction of electron densities of larger molecules, by selecting and arranging the interpenetating fuzzy charge clouds of density fragments so that the nuclear positions match those in the target molecule. If fragment densities are recombined to form the density of the molecule they are derived from, then the reconstuction is *exact* on the given *ab initio* level. The computed electronic density is highly accurate (at the given *ab initio* level) even if the fragment densities are combined to form a new molecule (1, 2). The MEDLA method of building electron densities for large molecules extends the scope of earlier methods for the analysis of global and local shapes of molecules (3).

The MEDLA computation for ordinary proteins uses only 22 types of electron density fragments from our MEDLA density fragment data bank. Several versions of these fragments, within a range of possible distorted nuclear geometries had been previously calculated as fuzzy electron density contributions within some smaller parent molecules, using the Gaussian 90 *ab initio* program and the 6-31G** basis set (4). These parent molecules can be chosen in several distorted configurations. Accordingly, each fragment type is represented by several versions in the data bank, where the versions differ by minor deviations in the local nuclear geometry and/or they are taken from parent molecules with different local surroundings. The best matching version of the fragment is selected from the database in order to mimic the actual nuclear arrangement and the effects of the surroundings of the given fragment in the target molecule. In principle, the direct *ab initio* result of the target molecule can be reproduced at the given basis set level to any desired accuracy by taking each fragment with the exact local nuclear arrangement from a large enough parent molecule where the local surroundings also match within a large enough neighborhood. If a new version of a fragment is required, a direct *ab initio* computation is carried

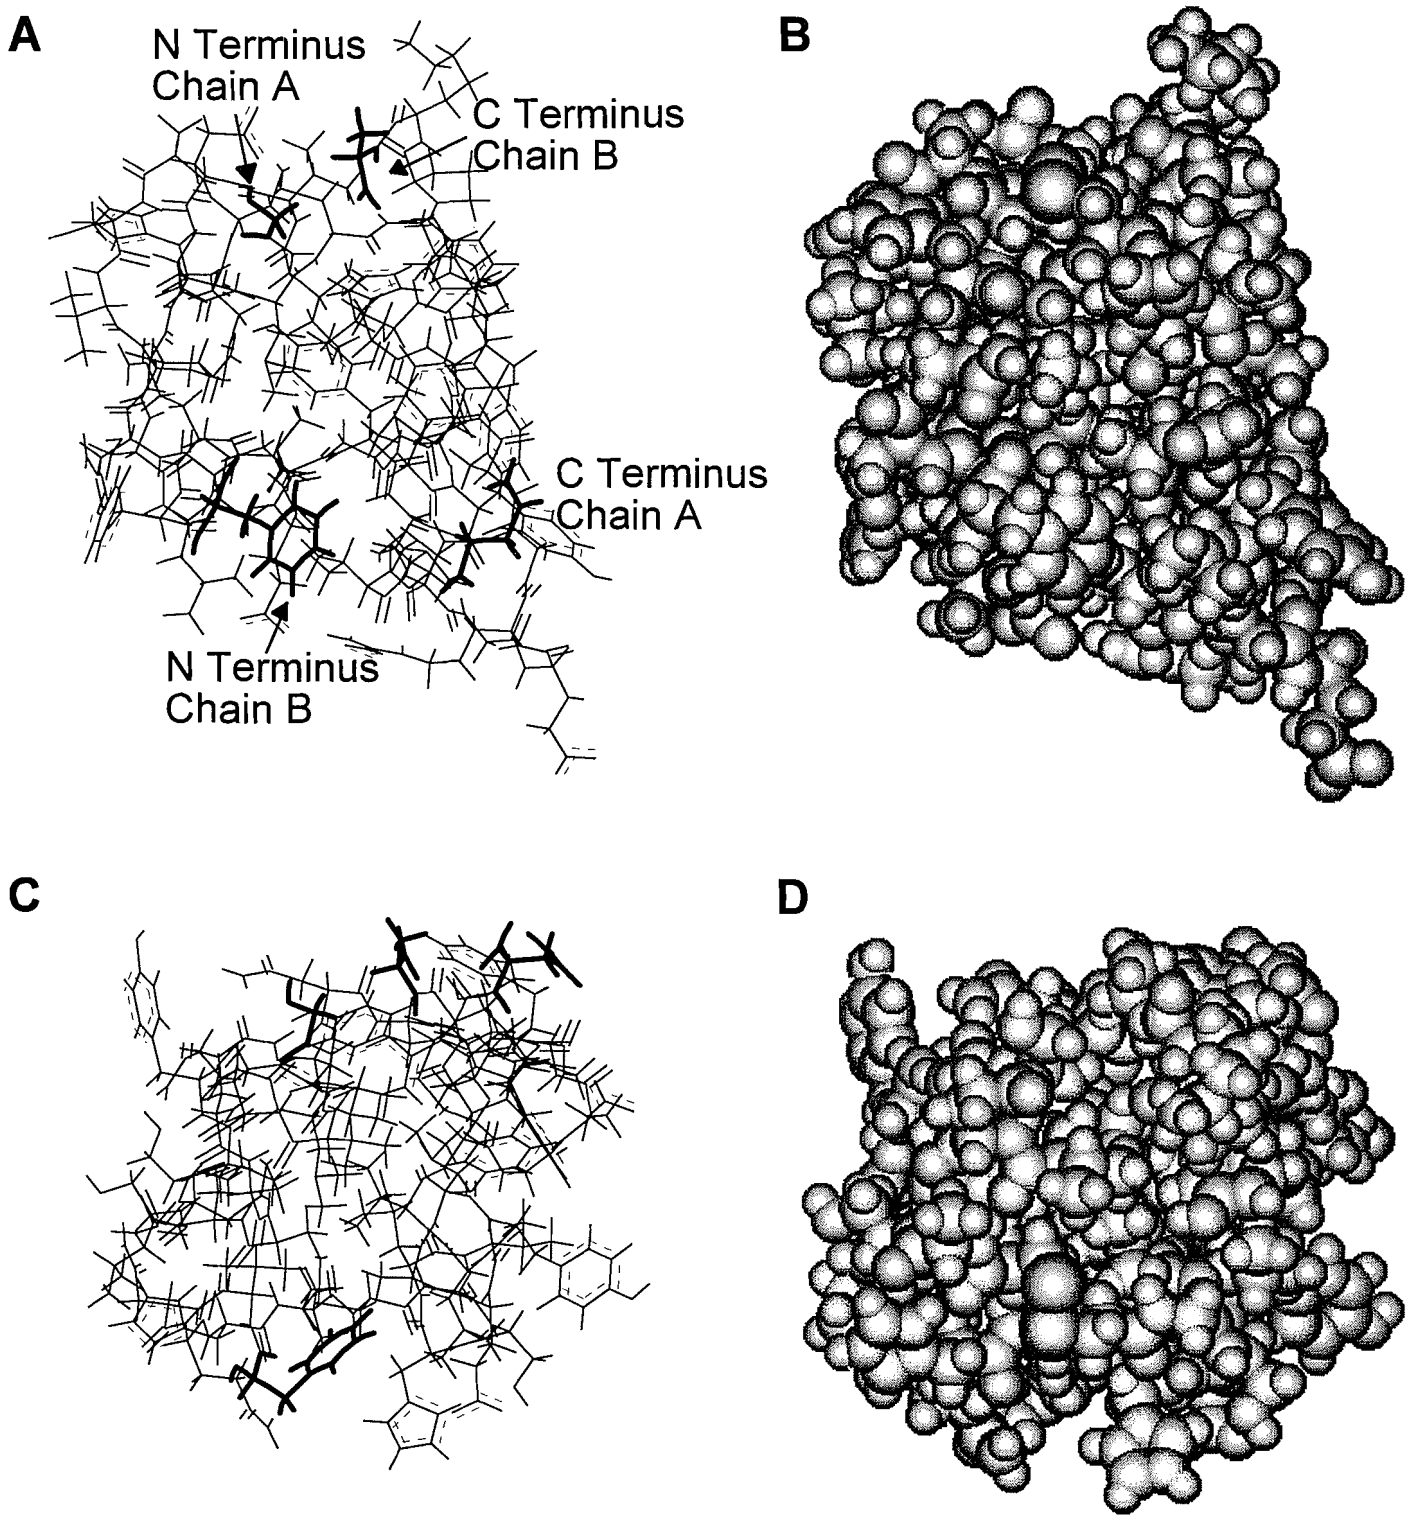

FIG. 1. Two views of the conventional wire frame model of the bonding pattern (A and C) and of the "space filling" fused spheres model (B and D) of the bovine insulin molecule. The second perspective (C and D) is the top view of the first one (A and B). The N and C termini of both chains A and B are indicated. The fused sphere model gives only a crude description of the space-filling properties and shows many artificial features, such as the seams between spheres.

out for a small molecule that contains the fragment with the required local geometry and surroundings, and the new density fragment is added to the MEDLA database. Typical fragment densities are those for the peptide bond moiety, aromatic rings, and the CH_2 group; additional technical details are given in refs. 1 and 2. Test calculations (1, 2) of numerical similarity measures have shown that, for both directly linked and hydrogen-bonded structures, as well as for molecular moieties of density overlap interactions in folded structures, the MEDLA densities are of better quality than densities obtained by direct 3-21G *ab initio* calculations. The differences between the 6-31G** MEDLA and direct 6-31G** *ab initio* electron densities are

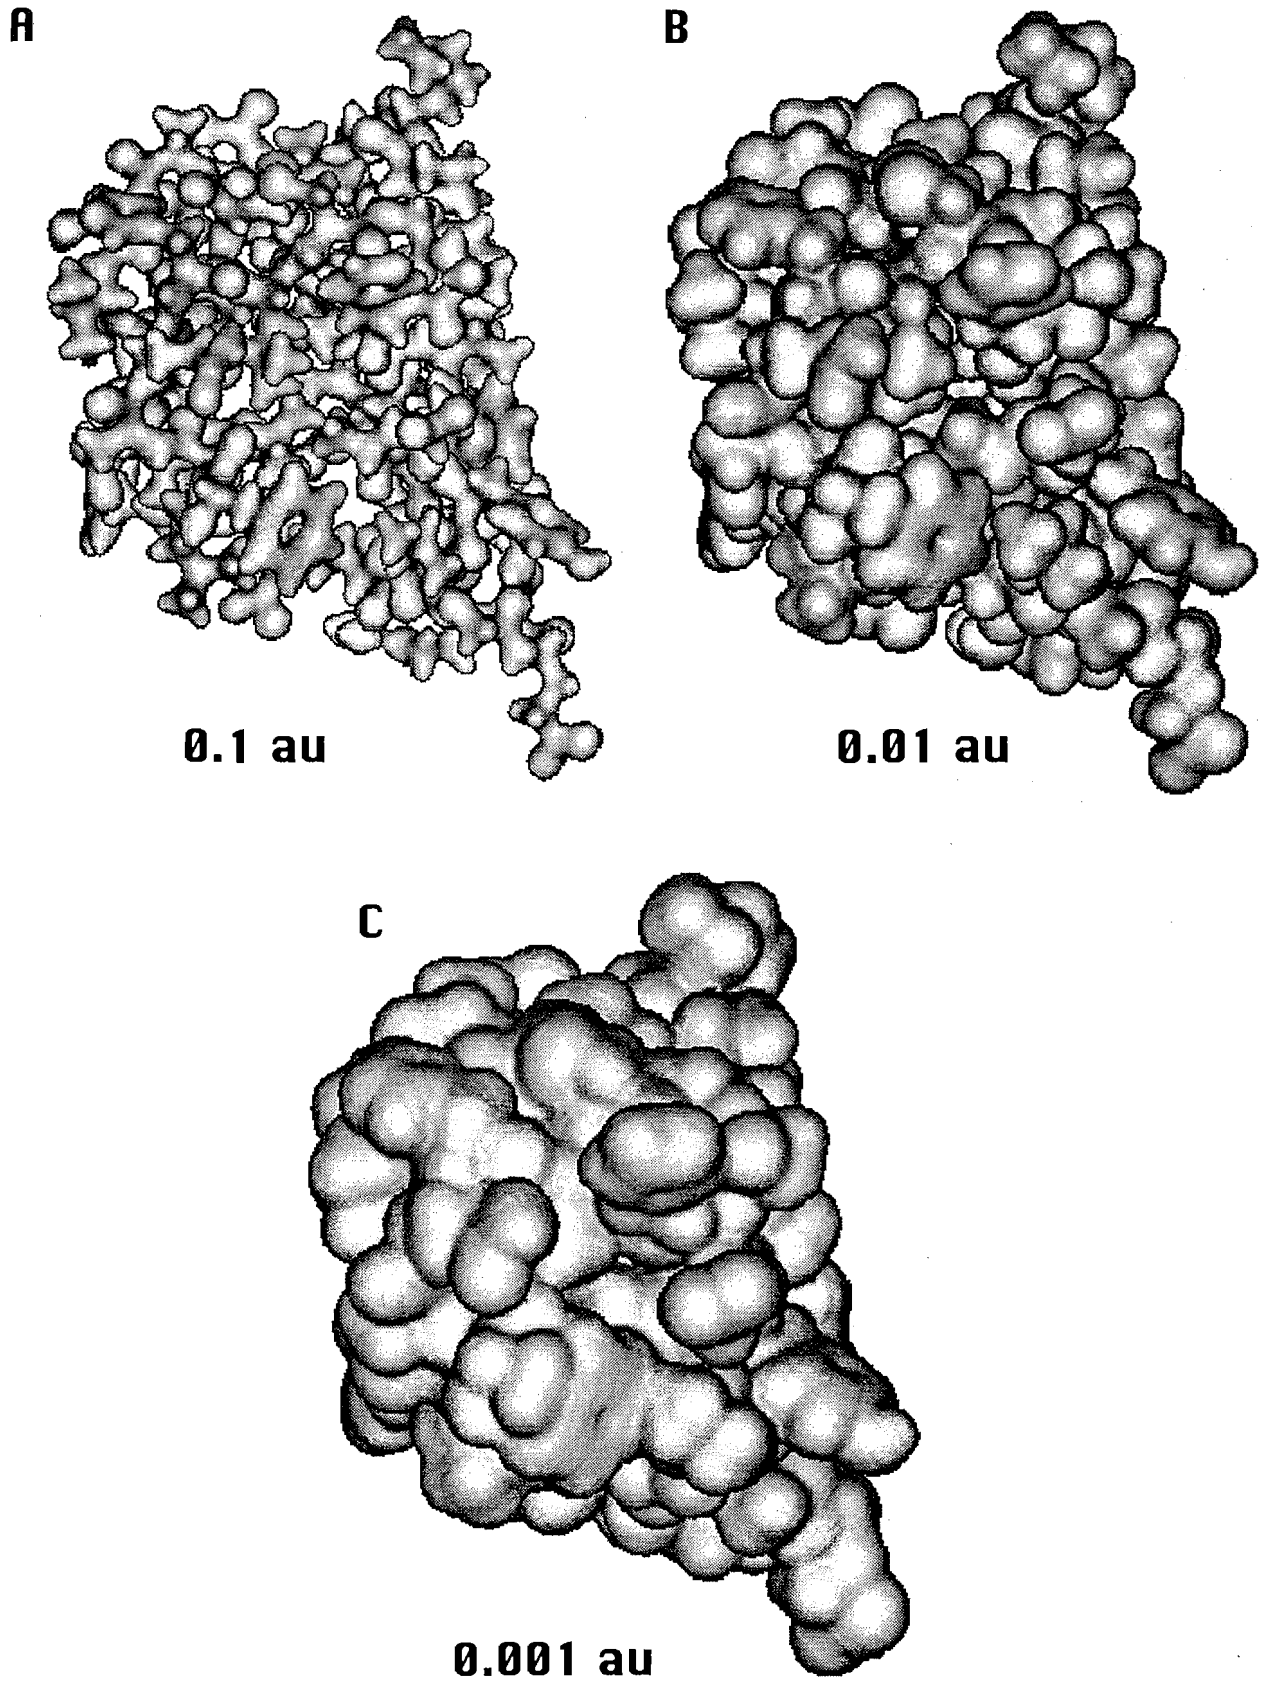

FIG. 2. Realistic views of three MEDLA molecular isodensity contours, MIDCO's A, B, and C, of density thresholds of 0.1 au (au = atomic unit), 0.01 au, and 0.001 au, respectively, are shown for the bovine insulin protein from the first of the two perspectives specified in Fig. 1. Just like a sequence of Russian wooden dolls, isodensity surface C contains B, and B contains A. High density MIDCO's describe the actual bonding pattern as it is generated by the electronic cloud in reality, intermediate density MIDCO's clearly show some additional interactions such as hydrogen bonds, whereas low density MIDCO's describe the realistic space filling shape and size features of the fuzzy, low density electronic charge cloud.

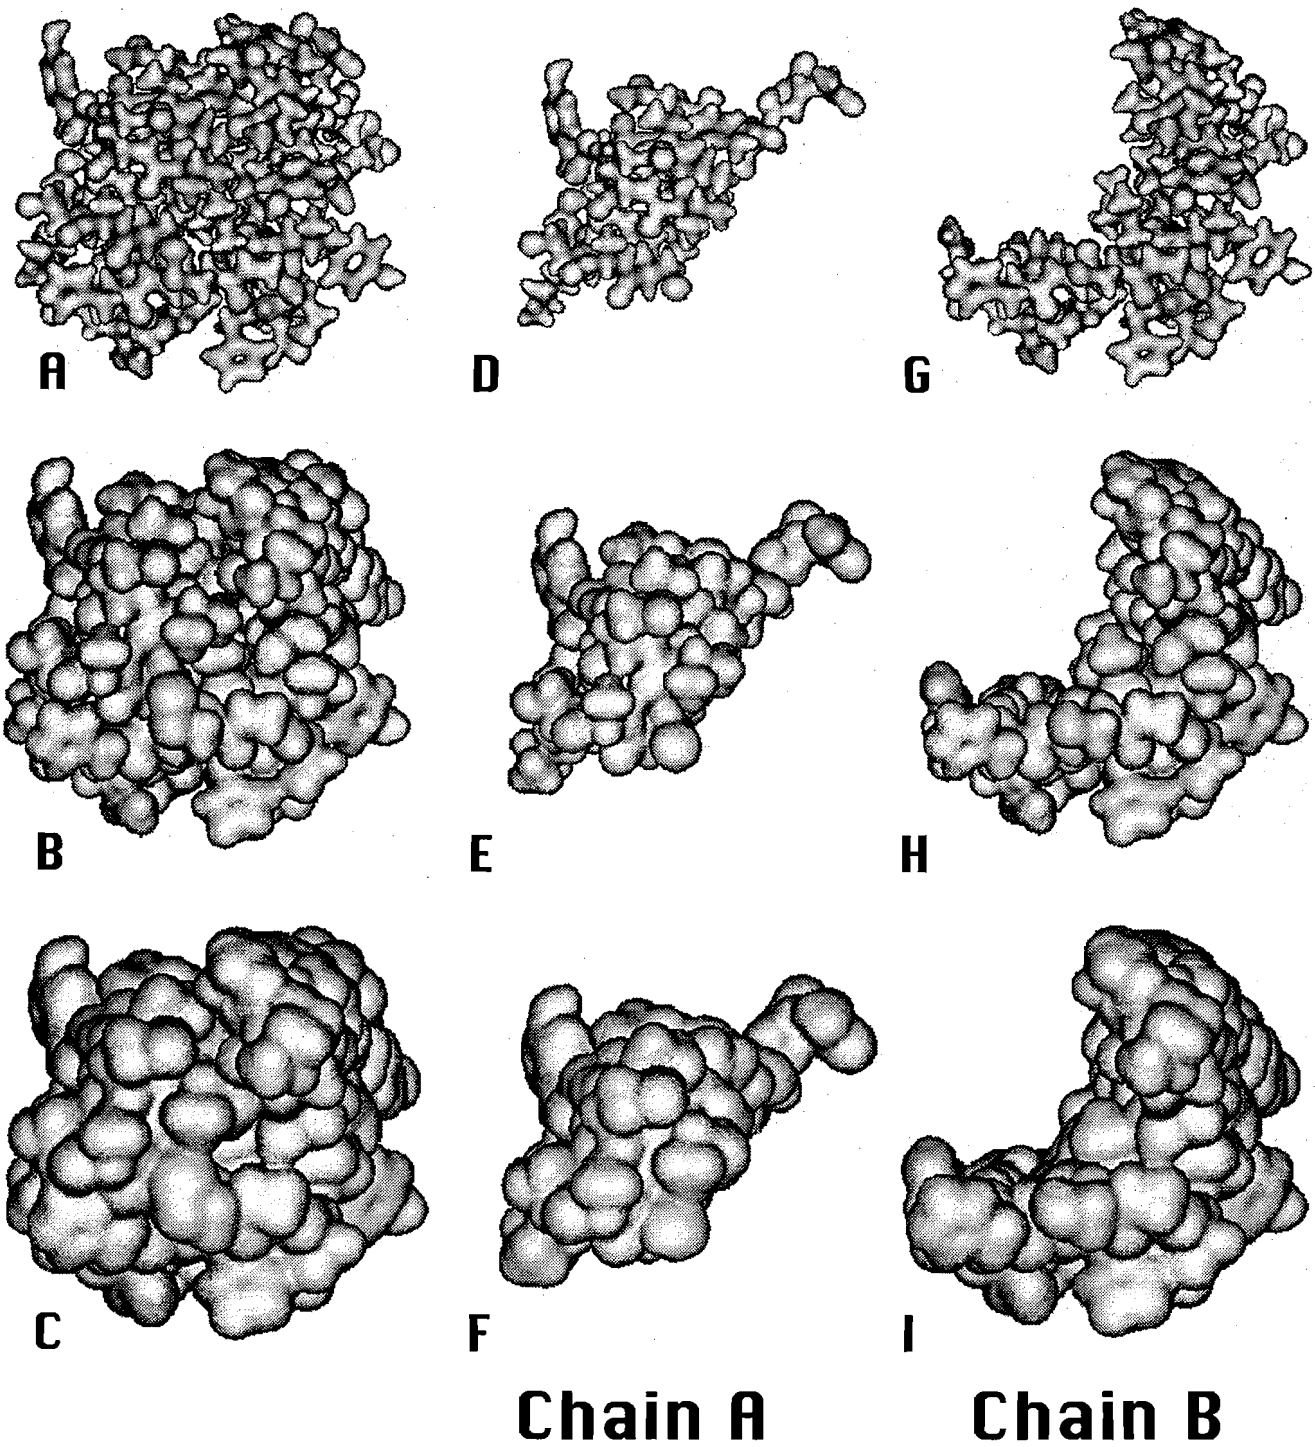

FIG. 3. Views of MEDLA MIDCO's are shown from the second of the two perspectives specified in Fig. 1, for the bovine insulin protein (contours A, B, and C) and for two of its superfragments, chain A (contours D, E, and F), and chain B (contours G, H, and I). MIDCO surfaces of three density thresholds, 0.1 au (contours A, D, and G), 0.01 au (contours B, E, and H), and 0.001 au (contours C, F, and I) are shown.

much less than those between the direct 3-21G and direct 6-31G** *ab initio* electron densities. In fact, the 6-31G** MEDLA and direct 6-31G** *ab initio* results were found visually indistinguishable (1, 2). These tests indicate that the MEDLA results are of better quality than direct 3-21G *ab initio* results, and for shape analysis purposes, 6-31G** *ab initio* and 6-31G** MEDLA are of comparable quality. The electron density calculations can be performed for any desired nuclear geometry, for example, those assumed to occur in any protein folding process. In this study, the crystallographic coordinates of insulin were used; these are available from the Protein Data Bank (5).

At present, the electron density distribution for bovine insulin could not be calculated using conventional *ab initio* techniques, due to the insurmountable RAM memory requirements of storing and retrieving an astronomical number of integrals. Even if these constraints were circumvented, we estimate that a direct calculation would take more than a decade of CPU time

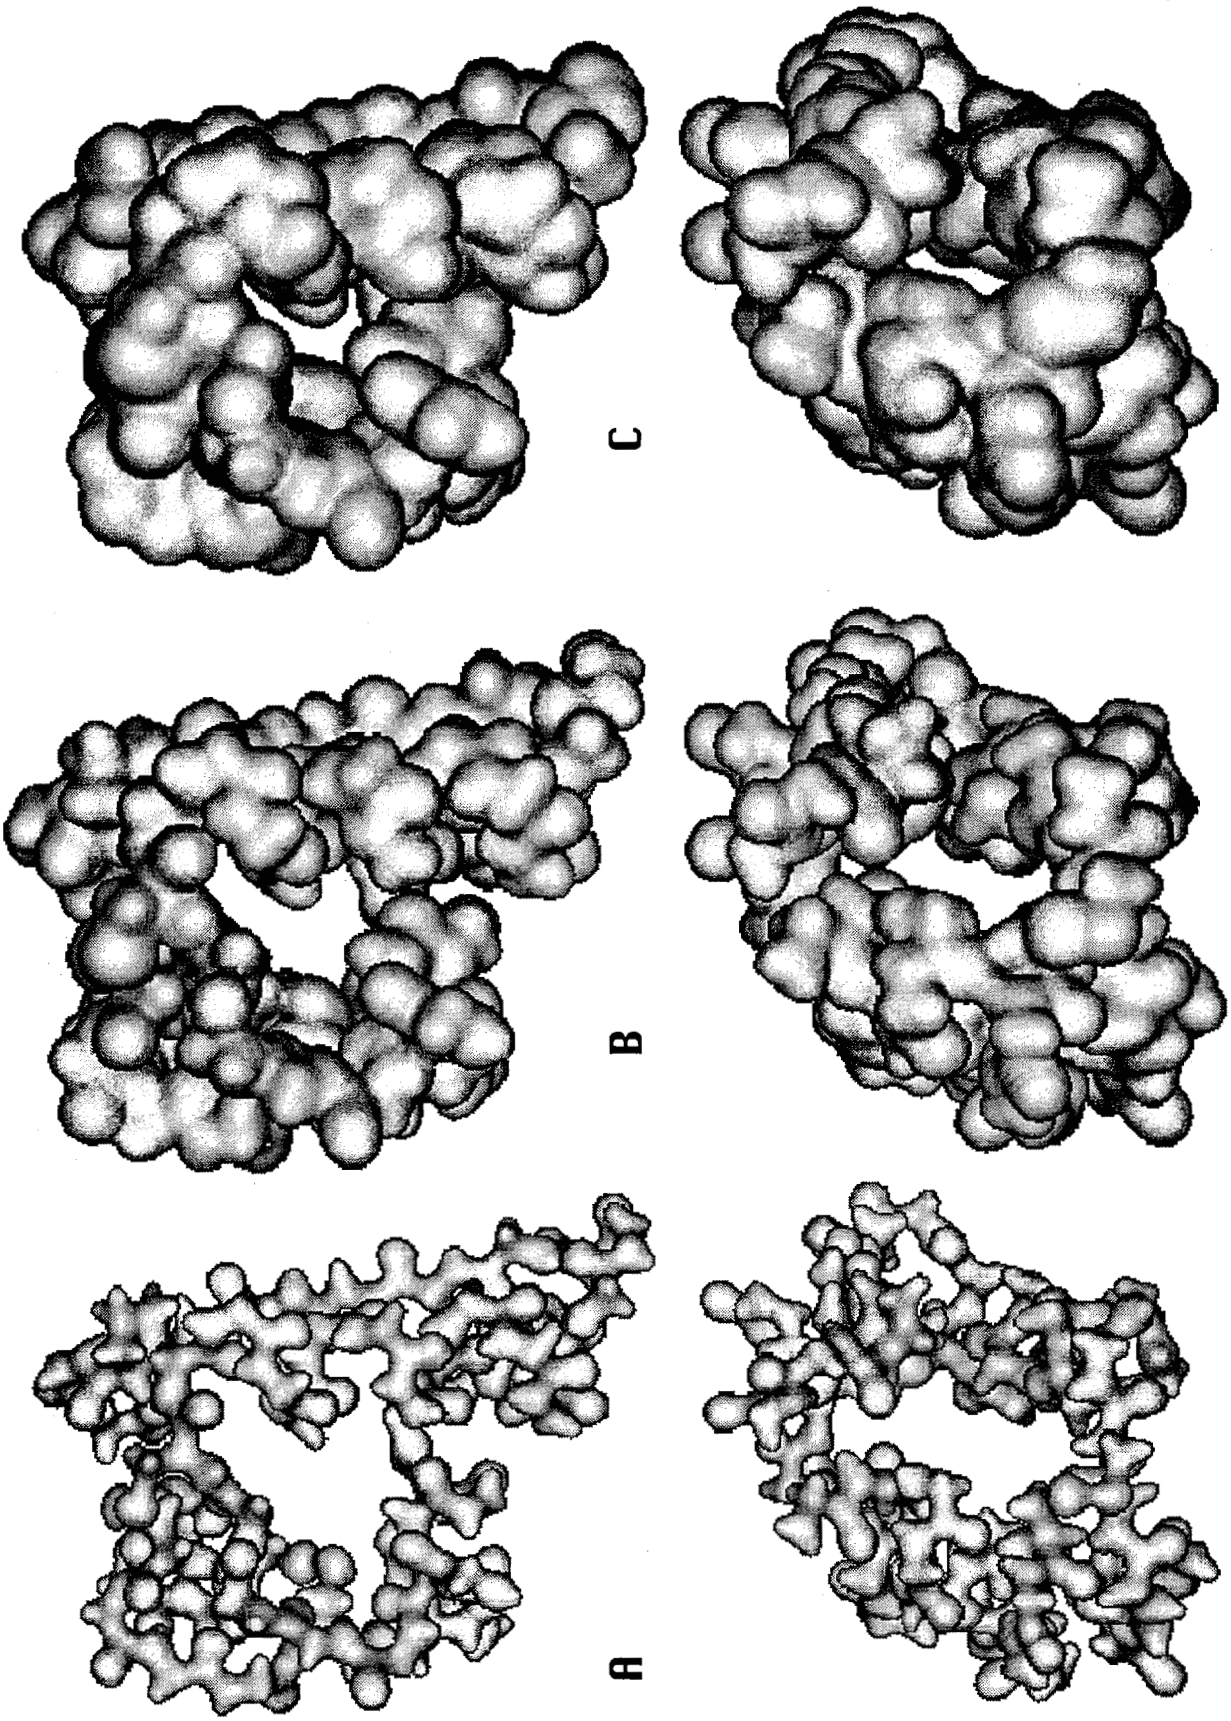

FIG. 4. Views of MEDLA MIDCO's of density thresholds of 0.1 au (contours A and D), 0.01 au (contours B and E), and 0.001 au (contours C and F) are shown for the bare backbone superfragment of the bovine insulin protein from the first (contours A, B, and C) and second (contours D, E, and F) of the perspectives specified in Fig. 1.

on a Cray supercomputer. Using our MEDLA program (6), the entire computation took only 15 min CPU time on a KPC Titan 3000 workstation.

Local regions and structural elements of a protein can be studied in detail: the electron density can be computed for the entire protein or for any "superfragment" (any collection of molecular MEDLA fragments). Bovine insulin is used to illustrate this feature of the method. This protein contains two chains; chain A of 21 amino acids and chain B of 30 amino acids. Two disulfide linkages connect the two chains; a third disulfide bond links two cysteines within chain A. The three superfragments chosen are the individual chains A and B, and the truncated protein backbone without sidechains, clearly showing the secondary structure.

In Fig. 1 two views of the bonding pattern and of a conventional fused sphere model of insulin are shown; the second arrangement is the top view of the first one. The N and C terminals of both chains A and B are identified. The same two perspectives are used for selected MEDLA densities displayed in Figs. 2–4. In Fig. 2, three molecular isodensity contours (MIDCO's), A, B, and C, of density thresholds of 0.1 au (atomic unit), 0.01 au, and 0.001 au respectively, are shown for the complete bovine insulin protein from the first of the two perspectives. In Fig. 3, the top views of the same three MIDCO's are shown, together with the corresponding MIDCO's of the chain A and chain B superfragments. In Fig. 4, both the side and top views of the backbone superfragment are shown for each of the above three density thresholds.

The richness of detail available ftom the MEDLA MIDCO's is evident from these figures. The "tight", (a = 0.1) density threshold MIDCO's in Figs. 2–4 provide a realistic view of the bonding patterns using the actual density domains (3) of the protein and three of its most important superfragments. Neither ball-and-stick models nor fused-sphere van der Waals surfaces or current models of solvent accessible surfaces are able to realistically represent this dense part of the electronic charge cloud, especially in the internuclear regions near the midpoints of formal bonds. The intermediate threshold (a = 0.01 au) images represent MIDCO's where the space filling aspects of globular proteins as well as interactions such as hydrogen bonding become apparent. The bulky, a = 0.001 density threshold MIDCO's are suitable for detailed molecular size considerations, conventionally approached using fused-sphere van der Waals surfaces. These MIDCO's properly represent the size and shape features at a density where mutual interpenetations of charge clouds between neighbor groups not formally linked by direct bonds also occur. Conventional, fused-sphere van der Waals models fail to represent these features. Note that the MEDLA computation generates the entire electronic density for the protein, hence MIDCO's for any other density thresholds, different from 0.1, 0.01, and 0.001 au, can also be displayed.

The fine details of the mutual arrangement of chains A and B are recognizable from the MEDLA MIDCO's. The two chains "hug" each other while surrounding many of their side chains within the space in between them, whereas the backbone superfragment serves as a formal skeleton. In three, mutually perpendicular views of the backbone superfragment (not all shown in Fig. 4), each image shows a central hole, implying that a quasi-cubic cage structure can model the large-scale pattern of the backbone density. This simple, polyhedral representation follows the spirit of the polyhedral models suggested by Murzin and Finkelstein (7), Chothia (8), and Maggiora and co-workers (9).

The MEDLA method describes the shapes of electronic charge density clouds that make up the molecular bodies in reality. The MEDLA approach opens up new possibilities: it can be used as a computational microscope to show accurate images of proteins. The example of bovine insulin illustrates that the MEDLA method is suitable for a detailed description of both global and local shapes of proteins and their structural elements. The speed and accuracy of the method suggests many biochemical, pharmaceutical and drug design applications, where the detailed shapes of structural elements are of importance.

A study of the vacuum pyrolysis of 6,6-dihalobicyclo[3.1.0]hexanes with HeI ultraviolet photoelectron spectroscopy

NICK HENRY WERSTIUK,[1] CHANDRA DEO ROY, AND JIANGONG MA
Department of Chemistry, McMaster University, Hamilton, ON L8S 4M1, Canada

Received July 15, 1994

NICK HENRY WERSTIUK, CHANDRA DEO ROY, and JIANGONG MA. Can. J. Chem. **72**, 2537 (1994).

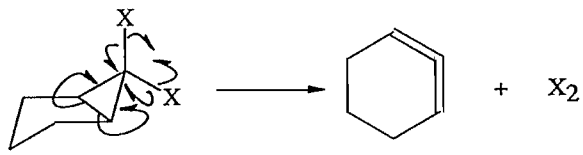
To establish the utility of using a high-power CW (continuous wave) CO_2 laser as a directed heat source for preparing organic transients targeted for gas-phase ultraviolet photoelectron spectroscopic studies, we studied the vacuum pyrolysis of 6,6-dibromobicyclo[3.1.0]hexane (**1***a*), 6,6-dichlorobicyclo[3.1.0]hexane (**1***b*), and *exo*-6-bromo-*endo*-6-chlorobicyclo[3.1.0]hexane (**1***c*). While it has already been established that **1***a* and **1***b* rearrange to the 2,3-dihalocyclohexenes **3***a* and **3***b*, respectively, when heated in the condensed phase, upon vacuum pyrolysis **1***a* and **1***b* readily eliminate HX — not the dihalogens — and give the 2-halo-1,3-cyclohexadienes **2***a* and **2***b* in high yield. That 2,3-dibromocyclohexene (**3***a*) does not eliminate HBr at the laser power used to pyrolyze **1***a* and **1***b* and that bromochloro compound **1***c* selectively loses HCl to form **2***a* suggests that the 1,3-elimination of HX occurs in a concerted fashion without isomerization of the cyclopropane.

NICK HENRY WERSTIUK, CHANDRA DEO ROY et JIANGONG MA. Can. J. Chem. **72**, 2537 (1994).

Afin de déterminer l'utilité de l'usage de laser au CO_2 CW à haute énergie comme source de chaleur dirigée pour la préparation d'espèces organiques transitoires nécessaires pour des études de spectroscopie photoélectronique ultraviolette en phase gazeuse, on a étudié la pyrolyse sous vide des 6,6-dibromobicyclo[3.1.0]hexane (**1***a*), 6,6-dichlorobicyclo[3.1.0]hexane (**1***b*) et *exo*-6-bromo-*endo*-6-chlorobicyclo[3.1.0]hexane (**1***c*). Alors qu'il a déjà été établi que les composés **1***a* et **1***b* se réarrangent en 2,3-dihalocyclohexènes (**3***a* et **3***b* respectivement) lorsqu'on les chauffe en phase condensée, leur pyrolyse sous vide conduit plutôt à une élimination de HX — et non pas à une élimination de dihalogène — et à une formation des 2-halocyclohexa-1,3-diènes, avec d'excellents rendements. Le fait que le 2,3-dibromocyclohexène (**3***a*) n'élimine pas de HBr avec le puissant laser utilisé pour effectuer la pyrolyse des composés **1***a* et **1***b* et que le composé bromochloro **1***c* perde sélectivement du HCl pour former le composé **2***a* suggère qu'une élimination-1,3 de HX se produit d'une façon concertée, sans isomérisation en cyclopropane.

[Traduit par la rédaction]

When combined with semiempirical or ab initio calculations of molecular orbital eigenvalues (orbital energies) and eigenvectors, ultraviolet photoelectron (pe) spectroscopy gives information about the electronic structure and bonding of stable compounds and transient species that is provided by no other experimental technique. Up to the present, transient species studied with pe spectroscopy were prepared pyrolytically by passing labile precursors through electrically heated furnaces centimeters in length (1, 2). To facilitate the preparation and detection of a wide range of organic transients in the gas phase, we interfaced a tunable, 50-W CW CO_2 laser[2] with a recently modified, locally built pe spectrometer (3) in order to use the focussed laser beam as a directed heat source to produce a short (2–3 mm), very hot, contact zone whose temperature is readily altered by tuning the laser to a suitable line. Our interest in preparing and detecting the highly reactive distorted cyclical allene 1,2-cyclohexadiene led us to the CO_2 laser – pes apparatus, its first application to research in the field of organic transients, to study the vacuum pyrolysis of 6,6-dihalobicyclo[3.1.0]hexanes **1***a*, **1***b*, and **1***c*. We chose to study these compounds because cleavage of the C1—C5 bond followed by extrusion of dihalogen (the reaction could be concerted) is a possible route to 1,2-cyclohexadiene (Scheme 1), which is generated in solution (7) and apparently can be trapped and detected at low temperature using the matrix isolation method (8, 9). This communication documents the results of a study of the vacuum pyrolysis of **1***a*, **1***b*, and **1***c* with pe spectroscopy.



SCHEME 1

Figure 1 displays the pe spectra obtained in this study.[3] Fig-

[1]Author to whom correspondence may be addressed.

[2]Several examples of the application of CO_2 lasers in the field of pe spectroscopy have been documented in the chemical literature. Allen et al. obtained the gas-phase pe spectra of KCl, KBr, and KI by vaporizing the compounds (a stainless steel reservoir was used to hold the samples) with the focussed beam of a 50-W laser (4). Using a 50-W laser to vaporize CdSe contained in a boron nitride sample holder, Streets and Berkowitz obtained the pe spectrum of Se_2 (5). We thank a referee for bringing the work of Allen and Berkowitz to our attention. Using a 50-W CO_2 laser as a directed heat source to heat a nozzle, Bartell et al. obtained highly vibrationally excited stable molecules (6). In addition to heating a nozzle, we plan to use the focussed CO_2 laser beam to thermolyze molecules directly should they absorb strongly in the region of 1100–1000 cm^{-1}, to generate transients by vaporizing solid organic targets suspended in the source, and to carry out sensitized pyrolysis of compounds in the presence of infrared sensitizers such as CO_2, NH_3, or CH_3F.

[3]The 7 mm diameter laser beam is focussed to a 2 mm diameter beam with a convex ZnSe lens and directed through a ZnSe window in the source housing to impinge on a nozzle located on the tip of a probe. A 3 mm o.d. quartz tube constricted to an i.d. of 1 mm was used as the nozzle because quartz has a high melting point and, more importantly, it exhibits a very low lateral thermal conductivity. This produces a high-temperature zone that is approximately 2 mm in length. Measurements with a thermocouple placed in contact with the inner wall of the nozzle showed that even at 26 W the temperature of the hot zone is in the region of 500 ± 50°C. At the highest power level (>60 W), the tightly focussed beam of the Edinburgh Instruments model PL5 CW CO_2 laser in this study vaporizes quartz. The gas-phase pyrolysis reactions were carried out at a source pressure of (3–3.5) × 10^{-3} Torr (1 Torr = 133.3 Pa) with 20–50 mg of liquid sample placed in a 10-mL Pyrex reservoir attached to the external section of the probe.

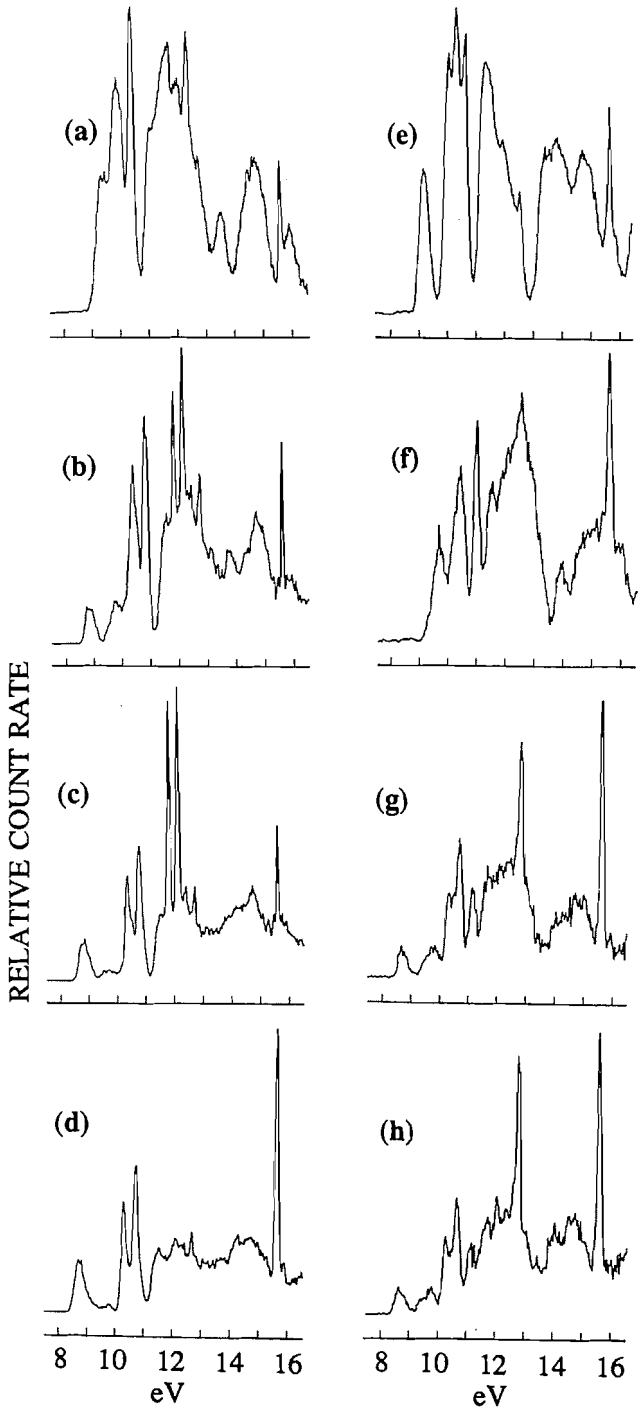

FIG. 1. (*a*) HeI ultraviolet photoelectron spectrum of 6,6-dibromobicyclo[3.1.0]hexane (**1***a*) at ambient temperature; (*b*) pe spectrum of the pyrolyzate at a laser power of 26 W; (*c*) pe spectrum at 35 W; (*d*) pe spectrum of 2-bromo-1,3-cyclohexadiene (**2***a*) at ambient temperature; (*e*) pe spectrum of 2,3-dibromocyclohexene (**3***a*) at ambient temperature; (*f*) pe spectrum of *anti*-6-bromo-*syn*-6-chlorobicyclo[3.1.0]hexane (**1***c*) at ambient temperature; (*g*) pe spectrum of the pyrolyzate at a laser power of 26 W; (*h*) pe spectrum at 42 W. The peak at 15.6 eV in each spectrum is the low-IP peak of N_2, which is used as the calibrant.

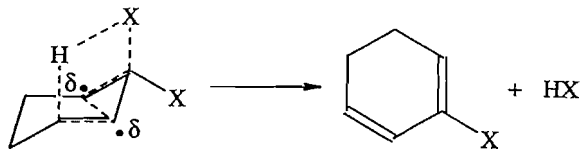
ure 1(*a*) is the spectrum of **1***a* acquired at ambient temperature without heating the nozzle. At a laser power of 26 W, the spectrum (Fig. 1(*b*)) exhibits a new broad band at 8.9 eV along with a pair of sharp peaks centered at 12 eV. When the temperature of



SCHEME 2

the quartz nozzle is increased by tuning the laser to a 35-W line, the intensities of the bands at 8.9 and 12 eV increase and there is a concomitant decrease in the relative intensities of the starting material peaks (Fig. 1(*c*)). The sharp bands centered at 12 eV are due to HBr (10) and the remaining peaks correspond exactly to the pe spectrum (Fig. 1(*d*)) of an authentic sample of 2-bromo-1,3-cyclohexadiene (**2***a*). Dichloro compound **1***b* pyrolyzes under the same conditions yielding HCl and 2-chloro-1,3-cyclohexadiene (**2***b*) (spectra not shown). At higher power levels (>40 W), **1***a* and **1***b* yield benzene, which was identified on the basis of a pe spectrum of an authentic sample.[4] To establish that **2***a* is not formed by 1,2-elimination of HBr from 2,3-dibromocyclohexene (**3***a*), known to be the product of thermal rearrangement of **1***a* in the condensed phase (11), we prepared **3***a* (the pe spectrum is shown in Fig. 1(*e*)) and studied its pyrolysis at 26 and 42 W. Unlike **1***a*, which readily loses HBr at 26 W and pyrolyzes completely at 35 W, the pyrolysis of **3***a* is incomplete even at 42 W (spectrum not shown), indicating that it is not an intermediate in the pyrolysis of **1***a*. To study the stereochemistry of the 1,3-elimination of HX, we prepared (12) and pyrolyzed bromochloro compound **1***c*. The pe spectrum of **1***c* acquired at ambient temperature is displayed in Fig. 1(*f*). As seen in Fig. 1(*g*), **1***c*, like **1***a*, pyrolyzes at 26 W. The peaks at 8.8, 10.3, and 10.7 eV are assigned to **2***a*[5] and the sharp peak at 12.8 eV corresponds precisely to the lowest ionization potential (IP) peak of HCl (10). As indicated by the weak peaks centered at 12 eV (Fig. 1(*h*)), a small amount of HBr is only formed at 42 W, the power level that produces a nozzle temperature sufficient to produce benzene from **2***a*;[4] the lowest-IP band of benzene is seen as part of the overlapped peak at 9.3 eV. At 60 W (spectrum not shown), approximately 50% of **2***a* is converted to benzene, which is recognizable from a peak at 9.3 eV and broad bands centered at 12 and 14.5 eV (10). The results of this study indicate that the three-membered ring of **1***a*, **1***b*, and **1***c* undergoes a disrotatory opening and initiates the cleavage of the *endo* C—X bond, which leads to 1,3-elimination of HX (Scheme 2). This study also establishes that the CO_2 laser – pes apparatus will be generally useful for studying the vacuum pyrolysis of organic compounds.

To block 1,3-elimination of HX and perhaps force the extrusion of X_2, we plan to synthesize and thermolyze 6,6-dibromo-

[4]Isomerization of the 2-halo-1,3-cyclohexadienes to the 5-halo-1,3-cyclohexadienes via consecutive 1,5-hydrogen shifts followed by a facile four-centered 1,2-elimination of HX is the most probable route to benzene.

[5]The orbital energies of the three highest occupied MOs of **2***a* (the torsional angle between the double bonds is 7.9°) calculated with AM1 are 9.01, 10.67, and 11.03 eV, respectively. The HOMO (9.01 eV) is predominately the π_- combination of the diene unit mixed with the π-type group orbitals of the methylene groups and to a smaller extent with n_{Br} The HOMO-1 (10.67 eV) is the π_+ combination of the diene heavily mixed with n_{Br} HOMO-2 is mostly n_{Br} mixed with the σ orbitals of the diene unit. That HOMO-2 has more n_{Br} character than HOMO-1 is supported by the fact that the peak at 10.7 eV (Fig. 1(*d*)) is sharper than the peak at 10.3 eV.

2,2,4,4-tetramethylbicyclo[3.1.0]hexane (**4***a*) and 6,6-dichloro-2,2,4,4-tetramethylbicyclo[3.1.0]hexane (**4***b*). Because geminal dihalocyclopropanes are easily synthesized by dihalocarbene addition to alkenes, we also plan to carry out pyrolyses with a preparative-scale apparatus to determine the scope and limitations of the gas-phase 1,3-elimination of HX as a synthetic route to a wide range of cyclic and acyclic 2-halogenated 1,3-dienes.

Br^+ Transfer to reactive alkenes from the bromonium ion of adamantylideneadamantane

A.A. Neverov and R.S. Brown[1]

Department of Chemistry, University of Alberta, Edmonton, AB T6G 2G2, Canada

Received September 8, 1994

A.A. Neverov and R.S. Brown. Can. J. Chem. **72**, 2540 (1994).

The transfer of Br^+ from the bromonium ion of adamantylideneadamantane (**1**-$Br^+/CF_3SO_3^-$) to the reactive alkenes cyclohexene, ω-alken-1-ols, **3***a–c*, and 4-pentenoic acid, **4**, in 1,2-dichloroethane at 25°C has been investigated. ^1H NMR analysis of the reactions of equimolar **1**-$Br^+/CF_3SO_3^-$ and olefin indicates the products to be the expected cyclic ones in the cases of **3***a–c* and **4**, and *trans*-2-bromocyclohexyltrifluoromethane sulfonate in the case of cyclohexene, along with adamantylideneadamantane (Ad=Ad). Detailed kinetic analysis shows that the reaction rates are suppressed by the addition of free Ad=Ad, suggestive of a common species rate depression. In the case of certain of the cyclization reactions such as that of 4-penten-1-ol, **3***a*, the cyclization reaction is bimolecular in acceptor olefin. A primary deuterium kinetic isotope effect of 2.0 on the cyclization of **3***a*-OH relative to **3***a*-OD exists. The role of the second molecule appears to be that of a general base in assisting the cyclization of an intermediate ω-hydroxy cyclic bromonium ion. A general mechanistic scheme for Br^+ transfer from **1**-Br^+ to the reactive alkenes is proposed.

A.A. Neverov et R.S. Brown. Can. J. Chem. **72**, 2540 (1994).

On a étudié le transfert du Br^+ de l'ion bromonium de l'adamantylidèneadamantane (**1**-$Br^+/CF_3SO_3^-$) à des alcènes réactifs, comme le cyclohexène, les ω-alcèn-1-ols (**3***a–c*) et l'acide pent-4-ènoïque (**4**), dans le 1,2-dichloroéthane, à 25°C. Une analyse par RMN du ^1H des réactions équimolaires du (**1**-$Br^+/CF_3SO_3^-$) avec les oléfines indique que les produits sont, en plus de l'adamantylidèneadamantane (Ad=Ad), les dérivés cycliques attendus dans les cas **3***a–c* et **4** et le sulfonate du *trans*-2-bromocyclohexyltrifluorométhane dans le cas du cyclohexène. Une étude cinétique détaillée montre que les vitesses de réactions sont supprimées par l'addition de Ad=Ad libre; ceci suggère une diminution de vitesse par une espèce commune. Dans le cas de certaines réactions de cyclisation, tel que celle du pent-4-èn-1-ol (**3***a*), la réaction de cyclisation est bimoléculaire en oléfine accepteur. Il existe un effet isotopique cinétique primaire du deutérium de 2,0 lors de la cyclisation du **3***a*-OH par rapport à celle du **3***a*-OD. La deuxième molécule semble jouer le rôle d'une base générale qui assiste la cyclisation d'un ion ω-hydroxy bromonium cyclique intermédiaire. On propose un mécanisme général pour le transfert de Br^+ du **1**-Br^+ à des alcènes réactifs.

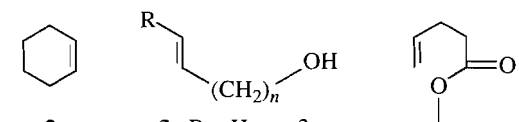
[Traduit par la rédaction]

Early studies by Wynberg and co-workers (1*a*) and Olah et al. (1*b*) indicated that the bromonium ion/tribromide salts of adamantylideneadamantane (**1**-Br^+/Br_3^-) were capable of irreversible Br_2 transfer to acceptor olefins such as cyclohexene or 2,3-dimethyl-2-butene to form the corresponding *trans* dibromides. However, subsequent studies (2) made it likely that the actual brominating species was free Br_2 since it was shown that when **1**-Br^+/Br_3^- is dissolved, a complex equilibrium between olefin **1**, Br_2, the Br_2:**1** charge transfer complex, and **1**-Br^+/Br_3^- is instantly established. We have recently shown that the triflate salts of **1**-Br^+ and **1**-I^+ undergo an extremely fast direct X^+ exchange with the parent olefin (eq. [1]) (3).

[1] 
1-Br^+
1-I^+ **1**

The facility of this process suggests that three-membered halonium-ion/olefin exchanges might be a general but heretofore overlooked phenomenon. In support of this latter speculation, it is of note that communication between a bromonium ion of an *n*-pentenyl or *n*-hexenyl glucoside and the two parent olefins has been recently demonstrated by Rodebaugh and Fraser-Reid (4). Herein we report that the use of **1**-$Br^+/CF_3SO_3^-$ as a Br^+ transfer agent allows unusual insight into the mechanism of bromocyclization of ω-alkene-1-ols.

The Ad=Ad bromonium triflate (**1**-$Br^+/CF_3SO_3^-$) is relatively stable at 25°C in non-nucleophilic solvents such as chlorinated hydrocarbons or CH_3CN. We have studied preliminarily



2 **3***a* R = H, *n* = 3; *b* R = H, *n* = 4; *c* R = CH_3, *n* = 3 **4**

the Br^+ transfer from cf. **1**-$Br^+/CF_3SO_3^-$ to a number of olefins, monitoring the reaction progress at equimolar concentration by ^1H NMR. Representative olefins include cyclohexene, **2**, the ω-alken-1-ols, **3***a–c*, and 4-pentenoic acid, **4**, and the products formed in essentially quantitative yield (by ^1H NMR) are the expected ones (4) given in Table 1.

The kinetics of the various transfer reactions were monitored in 1,2-dichloroethane (DCE) at 25°C by determining the initial

TABLE 1. Reaction products formed from reaction of equimolar **1**-$Br^+/CF_3SO_3^-$ and various olefins in $ClCD_2CD_2Cl$

Olefin	Product	Olefin	Product
3*a*		**3***c*	Cyclohexene		**4**	3*b*			

rate of loss of absorbance at 260 nm of 3.5×10^{-4} M solutions of **1**-$Br^+/CF_3SO_3^-$ in the presence of various concentrations of the above olefins.[2,3] The so-determined rate constants (k_{obs}) are given as Supplementary Material.[4] There are three general observations of note. First, in all cases added Ad=Ad significantly slows the reaction. In some cases, as shown for **3***a* in Fig. 1, plots of k_{obs} vs. [Ad=Ad] at a given concentration of **3***a* asymptotically approach the *X*-axis, signifying an absence of reaction at high Ad=Ad concentration. In other cases (**3***b*, *c*, cyclohexene), the added Ad=Ad does not suppress the reaction completely: rather, the rate reaches some limiting value at high [Ad=Ad] as shown in Fig. 1 for **3***c*. Second, in most cases, the cyclization reactions in DCE have a second-order dependence on concentration of acceptor olefin. Third, in the case we investigated in the most detail (cyclization of **3***a*), there is a significant primary deuterium kinetic isotope effect (*D*kie) on the cyclization reaction for **3***a*-OH relative to **3***a*-OD.

All the above observations can be accommodated by the general mechanism given in Scheme 1 from which can be derived the kinetic expression given in eq. [2] assuming a steady state in the nascent bromonium ion **6**. In the scheme there are three channels for product formation; namely, (*a*) direct collapse of an ol:**1**-Br^+ complex, **5**;[5] (*b*) dissociation of this complex into free Ad=Ad and **6**, the latter undergoing spontaneous cyclization; or (*c*) a similar dissociation to **6** with the latter's cyclization being promoted by a second molecule of ol. The fact that Ad=Ad suppresses the rate is attributable to a common species rate depression where Ad=Ad reacts with free **6** to revert to the starting materials or complex **5**. The observation that in some cases added Ad=Ad cannot fully suppress the reaction requires

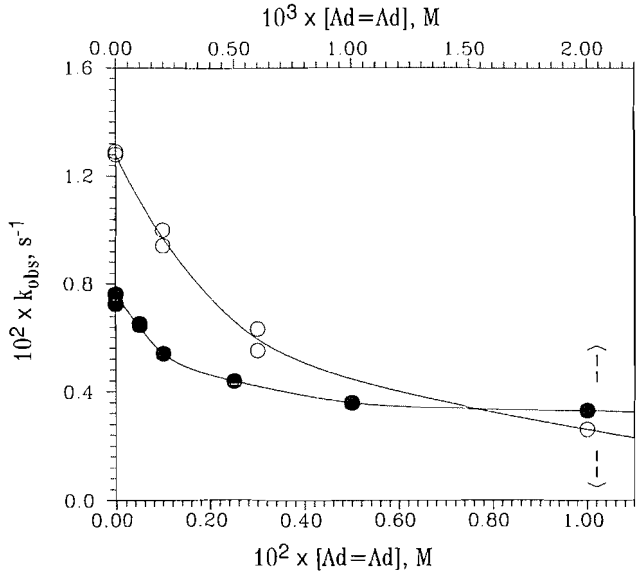

FIG. 1. Plots of k_{obs} vs. [Ad=Ad] for Br^+ transfer from **1**-$Br^+/CF_3SO_3^-$ to **3***a* (○) and **3***c* (●) in DCE at 25°C; [**3***a*] = 0.004 M; [**3***c*] = 0.0002 M.

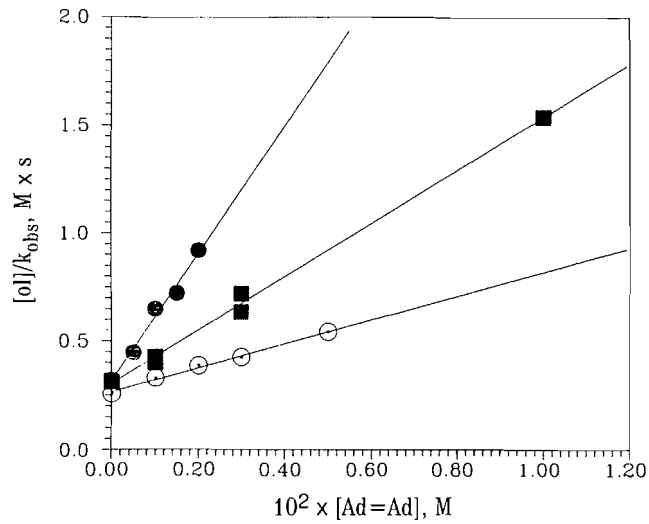

FIG. 2. Plots of [ol]/k_{obsd} vs. [Ad=Ad] for Br^+ transfer from **1**-$Br^+/CF_3SO_3^-$ to various [**3***a*] in DCE at 25°C; ● [**3***a*] = 0.0016 M; ■ [**3***a*] = 0.004 M; ○ [**3***a*] = 0.008 M.

that there be some ol:**1**-Br^+ complex that is not driven backward by external Ad=Ad, but can produce cyclized products. It seems most reasonable to suggest that putative complex **5**[5] is on the reaction pathway for forming free Ad=Ad and **6**.

$$[2] \quad k_{obs} = k_3K_{eq}[ol] + \frac{k_1K_{eq}[ol](k_2'[ol] + k_2)}{k_{-1}[Ad{=}Ad] + (k_2'[ol] + k_2)}$$

We deal first with an example (cyclization of **3***a*) that allows considerable simplification of eq. [2]. Since a high added Ad=Ad concentration completely suppresses the reaction (Fig. 1), k_3K_{eq}[ol] in eq. [2] is not kinetically significant. This allows linearization of eq. [2] into the form of eq. [3] so that a plot of [ol]/k_{obs} vs. [Ad=Ad] yields a straight line, the intercept of which refers to k_1K_{eq}, the slope relating to the partitioning of the intermediate between product formation and reversal. Shown in Fig. 2 are the linear plots for Br^+ transfer from **1**-$Br^+/CF_3SO_3^-$

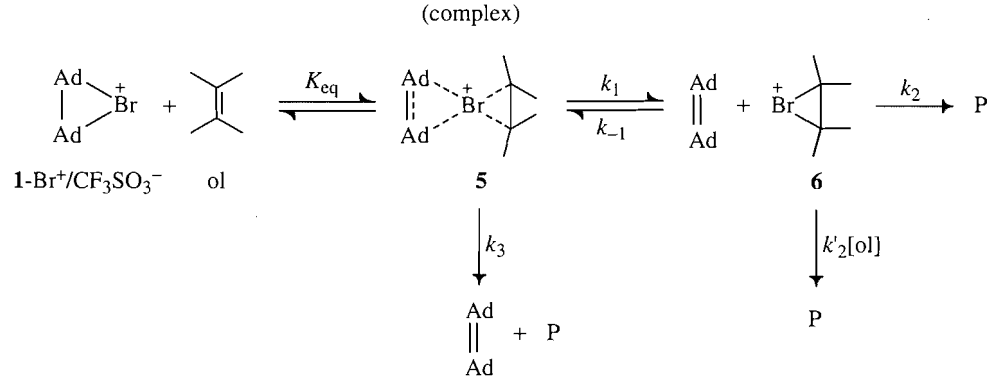
[2]Using an OLIS® modified Cary 17 UV–visible spectrophotometer, k_{obs} determined by initial rate methods monitoring ΔAbs for the initial 5–10% of the reaction:

$$k_{obs} = \frac{(\Delta Abs/\Delta t)}{([\mathbf{1}\text{-}Br^+/CF_3SO_3^-]_i \cdot \epsilon_{260})}$$

[3]**1**-$Br^+/CF_3SO_3^-$ exhibits a strong but featureless UV band between 300 nm and the solvent cutoff (240 nm in $ClCH_2CH_2Cl$), ϵ_{260} = 3200 M^{-1} cm^{-1}.

[4]Tables of primary kinetic data for transfer of Br^+ from **1**-$Br^+/CF_3SO_3^-$ to acceptor olefins **3***a–c*, **4**, and cyclohexene are available as supplementary material and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

[5]Such a complex has been determined to be energetically favored by the theoretical calculations for the ethylene bromonium ion/ethylene system (3).



(ol = acceptor olefins such as **3**, **4**, or cyclohexene)

SCHEME 1

TABLE 2. Kinetic parameters for Br^+ transfer reactions from **1**-$Br^+/CF_3SO_3^-$ to various acceptor olefins in $ClCH_2CH_2Cl$ at 25°C[a]

Olefin	$k_1 K_{eq}$ ($M^{-1} s^{-1}$)	$k_3 K_{eq}$ ($M^{-1} s^{-1}$)	k_2'/k_{-1} (or k_2/k_{-1})
3*a*	3.5 ± 0.3	—	0.63 ± 0.04[b]
3*a*-OD	3.0 ± 0.2	—	0.33 ± 0.03[b]
4-Pentenoic acid (**4**)	$(7.2 \pm 0.6) \times 10^{-2}$	—	$(7.1 \pm 0.4) \times 10^{-4}$[c]
Cyclohexene	$(6.0 \pm 0.1) \times 10^{-1}$	$(5.2 \pm 0.1) \times 10^{-1}$	$(5 \pm 2) \times 10^{-3}$[d]
3*b*	$(2.7 \pm 0.3) \times 10^{-1}$	$(8.0 \pm 2.0) \times 10^{-2}$	0.33 ± 0.05[b]
3*c*	$(2.3 \pm 0.3) \times 10^{1}$	$(1.1 \pm 0.3) \times 10^{1}$	0.32 ± 0.07[b]

[a]Determined from initial rate methods (see footnote 2).
[b]Refers to k_2'/k_{-1} (Scheme 1); unitless.
[c]Refers to k_2/k_{-1}; no second order in [4-pentenoic acid] dependence of reaction rate observed; units M.
[d]Refers to k_2/k_{-1}; no second order in [cyclohexene] dependence of reaction rate observed; units M assuming $CF_3SO_3^-$ ion pair collapse.

to **3***a* at various concentrations of the latter. The inverse dependence of the slopes on **3***a* concentration indicates that a second molecule of **3***a* is required to promote product formation from the nascent bromonium ion **6** (i.e., k_2' [ol] >0 in Scheme 1). Numerical evaluation of the partitioning of **6** is allowed by plotting the intercept/slope ratio vs. [ol] as in eq. [4]. For **3***a* the k_2'/k_{-1} ratio is 0.57 ± 0.1, while the k_2/k_{-1} is indistinguishable from zero: thus spontaneous breakdown of **6** to product is kinetically insignificant under these reaction conditions, and such breakdown can only occur via the involvement of a second molecule of **3***a*.

$$[3] \quad \frac{[ol]}{k_{obs}} = \frac{k_{-1}[Ad{=}Ad]}{k_1 K_{eq}(k_2'[ol] + k_2)} + \frac{1}{k_1 K_{eq}}$$

$$[4] \quad \text{intercept/slope} = \frac{k_2'[ol]}{k_{-1}} + \frac{k_2}{k_{-1}}$$

The second molecule appears to function as a general base as in eq. [5] wherein its OH group removes the proton of **6** (4) during the cyclization.

Consistent with this is the fact that 1-pentanol promotes the cyclization reaction of **3***a* and **1**-Br^+. A plot of k_{obs} vs. [1-pentanol] (1.6×10^{-3} M **3***a*, 2×10^{-3} M Ad=Ad, 3.5×10^{-4} M **1**-Br^+) shows a saturation behavior such that at high concentration of 1-pentanol the rate-limiting step becomes formation of **6** from **3***a* plus **1**-Br^+. That the k_2' step involves deprotonation of **6** is supported by the primary *D*kie of 2.0 for $(k_2'/k_{-1})_{3a\text{-OH}/3a\text{-OD}}$.

[5] $\xrightarrow[k_{-1}[Ad{=}Ad]]{k_1}$ 
6, L = H,D

For other olefins such as **3***b*, **3***c*, and cyclohexene, added Ad=Ad does not fully suppress the reaction so that $k_3 K_{eq}$[ol] in eq. [2] is kinetically significant, and cyclization occurs directly from complex **5**. For cyclohexene, a second molecule is not required for product formation, so that product formation results from ion-pair collapse, both on and off the complex.

NLLSQ fitting of k_{obs} vs. [Ad=Ad] to eq. [2] yields the parameters $k_1 K_{eq}$, $k_3 K_{eq}$, and k_2'/k_{-1}. These are given in Table 2 along with the comparable parameters for **3***a*-OH and **3***a*-OD derived as above.

There are several important and fundamental points brought to light during this study. Use of **1**-Br^+ as a Br^+ transfer agent allows a much deeper insight into the mechanistic subtleties of the halocyclizations than was previously possible. We previously established that the thermoneutral Br^+ exchange between **1**-Br^+ and Ad=Ad occurs at 4×10^7 $M^{-1} s^{-1}$ at 25°C, the associated $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ being 1.8 kcal mol^{-1} and −21 cal

K^{-1} mol^{-1} (3). The k_{-1} rate constant for Br^+ transfer from bromonium ions of mono-, di-, and trisubstituted olefins back to Ad═Ad should be as fast or faster than the thermoneutral **1**-Br^+/Ad═Ad transfer since those processes must be exothermic and the transition states somewhat less restrictive in terms of entropy. Indeed, it is the rapidity of the k_{-1} process that competes with, and therefore allows, kinetic assessment of the fast cyclization/deprotonation of **6**.
