The output of a pulsed Nd:YAG laser pumped dye laser system (Continuum NY61 and ND60) was used as the photolysis light source. Different dye–solvent combinations enabled us to obtain an output at the desired wavelength. The frequency doubled output of another Nd:YAG laser pumped dye laser combination (Lumonics YM600, HD 500 and Hypertrak 1000 with a BBO crystal) was employed to probe the photofragments. A homemade pulsed (200 μs duration/pulse)

molecular beam valve (7) was used and the seeded beam was extracted by a 1-mm skimmer (Beamdynamics) 20 mm downstream. The TOF-MS used in our setup is of the two-stage Wiley–McLaren design (8) consisting of three stainless steel grids (95% transmittance/grid), a field-free region, and a microchannel-plate detector (Galileo FTD2003). The extraction region is defined by two grids that are separated by 17 mm and biased at 1995 V (repeller grid) and 1500 V (second grid). The acceleration region is 7 mm in length and is limited by this second grid and by a third grid that is held at ground potential. The detector is located in the second chamber at 521 mm distance from the interaction region. The signal from this detector was digitized by a digital oscilloscope (Tektronix 2440) and the data were then transferred to a 25 MHz/386 computer.

In a typical experiment the laser beams pass through the centre of the first vacuum chamber counterpropagating with respect to each other and at right angles to both the molecular beam and the TOF-MS axis. The photolysis beam (approx. 0.7 mJ/pulse) and the probe beam (approx. 0.05 mJ/pulse) were focussed with two 500-mm lenses to a spot of approximately 20 μm diameter in the interaction region. The timing in the experiment, i.e., the firing of the lasers, opening of the pulsed valve, and triggering of the digital oscilloscope, was controlled by a digital delay generator (EG&G 9650) in combination with a 10 channel pulse-delay computer card (Advantech PCL-830). The delay between the photolysis and probe laser was checked with a fast photodiode and set at 5 ns in our experiment.

BrCl was prepared by exposing 380 Torr (1 Torr = 133.3 Pa) of Cl_2 (Matheson) to an excess of liquid Br_2 and Br_2 vapour (Aldrich). The mixture of the gases was used after a 24 h waiting period. To assure that the reaction reached equilibrium an absorption spectrum was recorded and decomposed into the three components. The chemical equilibrium yields fractions of 55% BrCl, 26% Cl_2, and 19% Br_2. The contribution of Cl_2 dissociation to the TOF signal was estimated using these fractions and the known absorption probabilities (3). At the shortest wavelength used (i.e., 389 nm) Cl_2 contributes less than 8% to the signal when detecting the $Cl(^2P_{3/2})$ fragments and less than 1% in the case of the $Cl^*(^2P_{1/2})$ fragments. The influence of Cl_2 impurities is expected to be even less at longer wavelengths. Therefore further purification was superfluous. A 5% dilution of the sample in helium (Matheson, prepurified) was expanded into the vacuum chamber.

The photofragmentation of BrCl can yield bromine and chlorine fragments in their ($^2P_{3/2}$) (Cl or Br) ground states and (or) in their ($^2P_{1/2}$) (Cl* or Br*) spin-orbit excited states. The branching ratio (Cl*/(Cl+Cl*)) of the BrCl photodissociation was investigated at six different wavelengths between 389 and 500 nm. At each excitation wavelength the Cl* and Cl fragments were detected via 2+1 Resonance- enhanced Multiphoton Ionization (REMPI) at the vacuum wavelengths 235.204 and 235.338 nm, respectively. Furthermore the probe laser was scanned in 20 wavelength steps to cover the whole Doppler width of each ^{35}Cl REMPI line. At each photolysis/probe wavelength combination typically 20 laser shots were averaged. The resulting integrated intensities were then normalized with the different transition probabilities for the two states probed.

Under the condition that the ionization step is saturated, the two-photon transition probabilities for the $4p^2P_{1/2} \leftarrow 3p^2P_{1/2}(Cl^*)$ and $4p^2D_{3/2} \leftarrow 3p^2P_{3/2}(Cl)$ transitions used in our experiment were calculated. These calculations were performed assuming that (*a*) a pure L-S coupling scheme and (*b*) only the $3p^4 4s$ intermediate states are involved. The ratio of the calculated intensities of the two transitions is then Cl*/Cl = 0.9. This ratio was verified experimentally[2] and used to normalize the observed signals.

[2]The ratio Cl*/Cl = 0.9 was verified experimentally by measuring the ratio between the linestrengths of the $4p^2P_{1/2} \leftarrow 3p^2P_{1/2}(Cl^*)$ and $4p^2D_{3/2} \leftarrow 3p^2P_{1/2}(Cl^*)$ transitions. This ratio was determined to be 2.0 ± 0.5. Through division by the reported (1 : 2.5) ratio of the linestrengths of the $4p^2D_{3/2} \leftarrow 3p^2P_{1/2}(Cl^*)$ and $4p^2D_{3/2} \leftarrow 3p^2P_{3/2}(Cl)$ transitions (9), we found that the above number of 0.9 is accurate within our experimental limits.

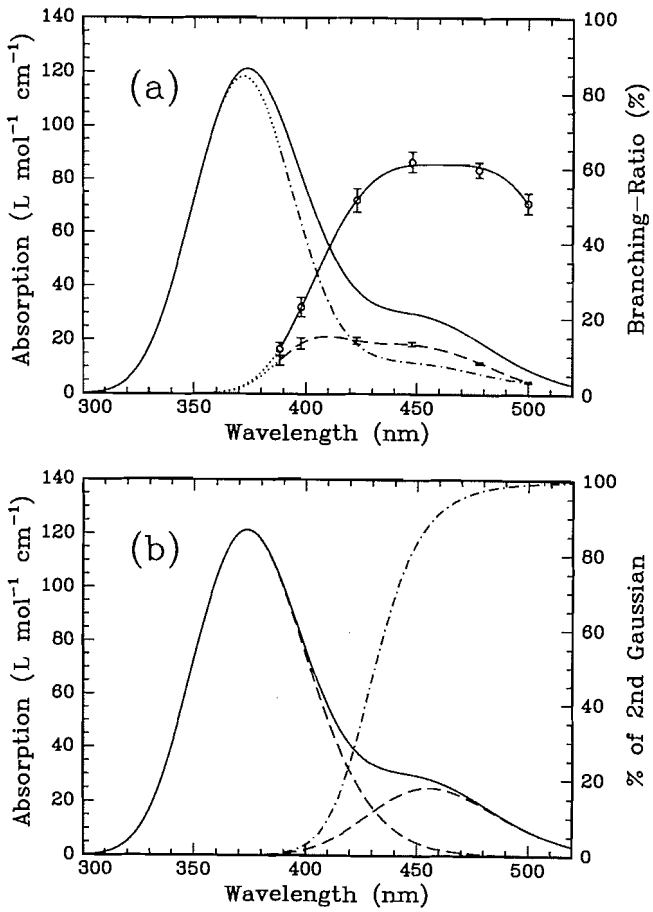

FIG. 2. (*a*) The percentage of the $Cl^*(^2P_{1/2})$ yield as a function of the photolysis wavelength (circles). A smooth curve is used to serve as a guide for the possible Cl* yield between these measurements. Also displayed is the absorption spectrum (solid line) obtained from ref. 3. By multiplying these two curves, the product yield spectra of the Cl* fragment (broken line) and similarly of the Cl fragment (dash-dotted line) were obtained. (*b*) The absorption spectrum of BrCl (solid line) and the two Gaussian curves in which it can be decomposed (broken lines). The percentage of the second Gaussian component is also included (dash-dotted line).

Results and discussion

In Fig. 2*a* the percentage of the Cl* yield from the BrCl photodissociation is displayed as a function of the photolysis wavelength. A smooth fitting curve with four parameters is used to serve as a guide for the possible Cl* yield between these measurements. Also displayed is the absorption spectrum obtained from ref. 3. By multiplication of the two curves one can obtain the product yield spectra of the Cl* fragment and similarly of the Cl fragment. These photofragment yield spectra are also included in Fig. 2*a*.

These results can be better understood in the context of the known exit-channel energetics and the potential energy curves. In the following paragraphs we will therefore describe them first.

Two to four exit channels are energetically accessible at the wavelengths we studied; these channels and their threshold energies, which were calculated based on the ground-state dissociation energy D_e from ref. 6, are listed below:

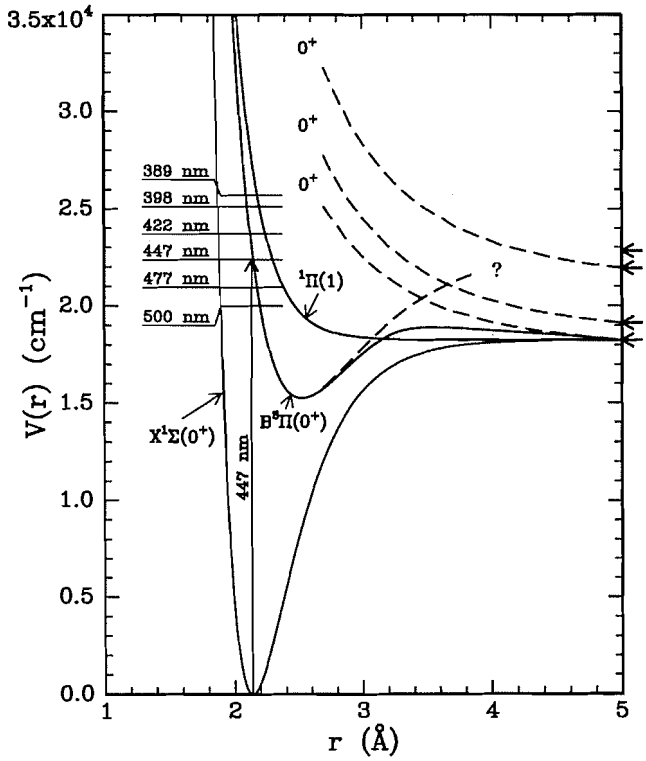

FIG. 3. Sketch of the potential energy curves of BrCl. Non-adiabatic interactions of the $^3\Pi(0^+)$ curve with other (0^+) states yield $Cl(^2P_{3/2})$ and $Cl^*(^2P_{1/2})$ fragments as discussed in the text. The photolysis laser wavelengths used in our experiment are displayed. The locations of the four exit channels are also indicated on the right axis.

$BrCl \rightarrow Br(^2P_{3/2}) + Cl(^2P_{3/2})$	555 nm	$E_{th} = 18022\ cm^{-1}$
$Br(^2P_{3/2}) + Cl^*(^2P_{1/2})$	529 nm	$E_{th} = 18903\ cm^{-1}$
$Br^*(^2P_{1/2}) + Cl(^2P_{3/2})$	461 nm	$E_{th} = 21707\ cm^{-1}$
$Br^*(^2P_{1/2}) + Cl^*(^2P_{1/2})$	443 nm	$E_{th} = 22588\ cm^{-1}$

The excited states responsible for the BrCl absorption in the region of 300–500 nm are believed to be the $^1\Pi(1)$ and the $^3\Pi(0^+)$ states. Drawn schematically in Fig. 3 are the ground state ($X^1\Sigma^+$), the B–$^3\Pi(0^+)$ state, and the $^1\Pi(1)$ state. The A–$^3\Pi(1)$ state, which lies below the B state, was not studied in detail previously and the role that it plays in the absorption was not clear.

The $^1\Pi(1)$ potential energy curve is repulsive near the Franck–Condon region but has a shallow minimum at large internuclear distance. The B state on the other hand has a well-defined minimum located at $r = 2.54$ Å (4) and a small barrier. The $^1\Pi(1)$ and the $^3\Pi(0^+)$ potential curves cross at $r \approx 3.05$ Å; this crossing is responsible for the near-threshold predissociation following excitation to the $^3\Pi(0^+)$ state (4–6). Based on the correlation diagram (10), adiabatic dissociation via the B state is expected to yield both the chlorine and the bromine fragments in their ground states. However, the diabatic dissociation limit was not clearly established. For instance, Clyne and Coxon concluded from semi-quantitative considerations that the diabatic dissociation limit should be Br + Cl* (11), whereas Tellinghuisen and co-workers recently noticed that the diabatic dissociation limit is less likely Br + Cl*, but possibly Br* + Cl (12).

The absorption spectrum was decomposed by Seery and Britton (3) into two Gaussian curves as displayed in Fig. 2*b*. However, these Gaussian curves cannot represent the partial absorption cross sections of the $^1\Pi(1)$ and the $^3\Pi(0^+)$ states, based on the following consideration. The onset of the second Gaussian curve is located around 430 nm whereas considerable amounts of Cl* fragments were observed even at 389 nm. From the correlation diagram (10) and the symmetry of the $^1\Pi(1)$ state it is unlikely that the $^1\Pi(1)$-state dissociation yields significant amounts of the Cl* fragments. The B-state absorption is therefore blue-shifted from the second Gaussian component. This implies, first, that the partial absorption from the $^1\Pi(1)$ state is narrower than expected from the first Gaussian curve, implying a more shallow excited state potential energy curve (13). Secondly, to explain the absorption at long wavelengths the introduction of a third excited state might become necessary. Since the only other allowed excited state lying below the B state is the A–$^3\Pi(1)$ state, this third contribution would then arise from A-state excitation.

As can be seen in Fig. 2*a*, at least two excited states contribute to the photofragment yield spectrum of the Cl fragment. At short wavelengths dissociation through the $^1\Pi(1)$ state is clearly favoured, while at wavelengths longer than 440 nm the $^3\Pi(0^+)$ state is dominant. It is also evident from Fig. 2*a* that dissociation through the $^1\Pi(1)$ state yields negligible amounts of the Cl* fragments, indicating that the dissociation is mainly adiabatic as described before. On the other hand, the dissociation via the B–$^3\Pi(0^+)$ state yields comparable amounts of Cl and Cl* fragments. This observation suggest that extensive non-adiabatic transitions among different potential energy curves are involved in the B-state dissociation. The shape of the branching ratio curve can be understood qualitatively based on the following consideration. In the short wavelength region the Cl* yield increases as the contribution of the B state to the absorption increases. In the long wavelength region there are two possible reasons for the decrease of the Cl* yield: (*a*) the extent of the B-state non-adiabatic interaction decreases with decreasing excitation energy and (*b*) the participation of the A state increases.

The shape of the Cl* yield curve is difficult to understand in the region between 400 and 470 nm, since apart from the maximum at 410 nm a shoulder appears at around 450 nm. If one considers that the Br* + Cl* channel opens at 443 nm and the Br + Cl* channel opens at 529 nm, a possible explanation for the observed Cl* yield curve involves contributions from both Br* + Cl* and the Br + Cl* channels.

In Fig. 3 we display the potential energy curves involved in the BrCl photodissociation according to our current understanding. Based on the correlation diagram (10) and spectroscopy studies (12) at least two (0^+) curves are expected to cross the $^3\Pi(0^+)$ state. The non-adiabatic interactions among these curves are responsible for the observed formation of Cl and Cl* fragments. The shape of the Cl* photofragment yield spectrum may give an indication for partial involvement of the Br* + Cl* channel. But even without this specific conclusion, the inclusion of non-adiabatic interactions in the photodissociation dynamics of BrCl is crucial, as we have demonstrated in this communication.

Further experiments as well as *ab initio* calculations are necessary to fully understand the details of the B-state photodissociation dynamics of BrCl. Direct measurements of the Br*/Br branching ratio are certainly desirable but are complicated by the large absorption cross section of Br_2 in this wavelength

region. Furthermore, these measurements will not allow the distinction between the Br* + Cl* and the Br* + Cl exit channels. However, photofragment TOF spectroscopy of the chlorine fragment provides information about the kinetic energy of the fragments and thereby about the participation of the four exit channels. These experiments are currently being carried out by our group.

Summary

The chlorine spin-orbit branching ratios for BrCl photodissociation were measured at several photolysis wavelengths between 389 and 500 nm. The branching ratios were used to determine the photofragment yield spectra of the Cl and the Cl* fragments. These measurements show that the B–$^3\Pi(0^+)$ state dissociation yields comparable amounts of Cl and Cl* fragments. The shape of the Cl* photofragment yield curve suggests the possible participation of the Br* + Cl* exit channel. Our results indicate that the B-state dissociation involves transitions among at least two (0^+) curves. Furthermore, from the onset of the Cl* formation it is implied that the A state contributes to the absorption in the long wavelength region. More experimental and theoretical studies are necessary to establish a detailed dissociation mechanism.

Received August 26, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

P.E. SISKA and D.R. HERSCHBACH. Can. J. Chem. **72**, 762 (1994).

Angular distributions of alkali atoms produced in crossed-beam reactions of H and D atoms (at ~2800 K) with KF, CsF, KCl, CsCl, and KBr (at ~1100–1200 K) have been measured. For these systems, the reaction exoergicity varies from $\Delta D_0 \sim 17$ kcal/mol for H + KF to −4 kcal/mol for H + KBr; the thermal distribution of the reactant energy peaks near 12 kcal/mol with $E \sim 9$ kcal/mol in relative translation and $W \sim 3$ kcal/mol in vibration and rotation of the alkali halide. Kinematic analysis of the data is carried out by means of a least-squares procedure that includes averaging over the parent beam velocity distributions. The main results are (1) The reaction cross sections Q_r vary from ~1 to 30 Å^2. The magnitude correlates with ΔD_0 and with the identity of the halogen for a given alkali, decreasing as F → Cl → Br. For a given halogen, Q_r is 2–3 times larger for the Cs reaction than for K and about 2 times larger for D than for H. (2) Temperature-dependence measurements for the CsCl case indicate the activation energy (in excess of endoergicity) is near zero. (3) The preferred direction of the reactively scattered alkali atoms with respect to the incident alkali halide varies with the halogen, from mainly forward for the KBr reaction to more sideways for the KF and CsF reactions. (4) The partitioning of energy between product translation E' (M relative to HX) and internal excitation W' (vibration and rotation of HX) can only be roughly estimated; our data are consistent with $E' \sim W$ and $W' \sim E + \Delta D_0$ but a definitive analysis will require product velocity distributions or spectra. These results are discussed in terms of a dynamical model akin to Polanyi's DIPR model. This postulates that the motion of H or D is approximately separable from that of the heavier atoms and the preferred reaction geometry corresponds to a triangular H–X–M complex.

P.E. SISKA et D.R. HERSCHBACH. Can. J. Chem. **72**, 762 (1994).

On a mesuré les distributions angulaires des atomes alcalins produits dans des réactions à faisceaux croisés d'atomes de H et de D (à environ 2800 K) avec du KF, du CsF, du KCl, du CsCl et du KBr (à environ 1100–1200 K). Pour ces systèmes, l'exoergicité de la réaction varie de $\Delta D_0 \sim 17$ kcal/mol pour H + KF à −4 kcal/mol pour H + KBr; la distribution thermique de l'énergie des réactifs passe par un maximum vers 12 kcal/mol avec $E \sim 9$ kcal/mol pour la translation relative et $W \sim 3$ kcal/mol pour la vibration et la rotation des halogénures alcalins. On a effectué l'analyse cinématique des données à l'aide d'une méthode des moindres carrés qui implique de faire la moyenne des distributions de la vitesse du faisceau parent. Les résultats principaux sont : (1) les sections droites de la réaction varient de Q_r ~1 à 30 Å^2. Il existe une corrélation entre l'amplitude et le ΔD_0 ainsi qu'avec la nature de l'halogène d'un métal alcalin donné; elle diminue dans l'ordre F → Cl → Br. Pour un halogène donné, Q_r est trois fois plus important pour une réaction avec le Cs qu'avec le K et 2 fois plus important pour D que pour H; (2) les mesures de dépendance sur la température dans le cas du CsCl indiquent que l'énergie d'activation (en excès par rapport à l'endoergicité) est pratiquement égale à zéro; (3) la direction privilégiée des atomes alcalins dispersés par la réaction par rapport à l'halogénure alcalin incident varie avec l'halogène; alors qu'elle est principalement vers l'avant pour la réaction du KBr, elle est plus dirigée vers les côtés pour les réactions du KF et du CsF; (4) on ne peut faire qu'une évaluation très approximative de la partition de l'énergie entre la translation du produit, E' (M relatif à HX) et l'excitation interne, W' (vibration et rotation de HX); nos données sont en accord avec $E' \sim W$ et $W' \sim E + \Delta D_0$, mais une analyse définitive nécessitera des distributions de la vitesse des produits ou des spectres. On discute de ces résultats en fonction d'un modèle dynamique semblable au modèle DIPR de Polanyi qui fait l'hypothèse que le mouvement de H ou de D peut être séparé d'une façon approximative de celui des atomes plus lourds et que la géométrie réactionnelle privilégiée correspond à un complexe H–X–M triangulaire.

[Traduit par la rédaction]

Introduction

Reactions of hydrogen atoms with alkali halide molecules, H + MX → HX + M, invite study by virtue of the simple electronic structure of the reactants and the promise of instructive comparisons with other archetypical systems. Whereas the bonding change is *covalent* → *ionic* for the extensively studied "electron-jump" or "harpooning" reactions of alkali atoms with covalent halides (1), for the H + MX case the bonding change is *ionic* → *covalent* and might be viewed as "reverse harpooning."

In the entrance channel, the qualitative electronic structure has only one electron outside three closed-shell ions (H^+, M^+, X^-). This resembles the reactions of alkali atoms with alkali halides, which likewise have one electron outside three ion cores (M^+, M'^+, X^-). Beam experiments (2) and trajectory calculations (3) have shown the latter reactions go via a statistical collision complex. One-electron pseudopotential calculations (4) for several of these dialkali halide systems as well as *ab initio* calculations (5) for HLi_2 found that the potential energy surfaces contain deep basins (comparable to or exceeding the reaction exoergicity) for triangular configurations of the complex. For HXM systems, semiempirical surfaces (6) for nearly the full family (M = Li → Rb; X = F → I) as well as *ab initio* calculations (7) for HFLi find the dominant features are not basins but barriers. The geometry of the transition state and the location of the barrier (entrance or exit) shift with the halogen and are governed by the H—X distance at which the electron-jump occurs. The H + MX reaction dynamics can also be expected to show distinctive behavior because of the disparity of time scales for motion of the H atom relative to the heavy atoms (8).

By microreversibility, the hydrogen atom – salt reactions are related to M + HX → MX + H, the subject of a host of experiments and theoretical treatments, especially the Li + HF case (9). Experimental results for those systems include optical

model parameters describing the dependence of reaction probability on collision energy and approach distance (10); on alignment of state-selected reagent molecules (11); variation of the total reaction cross section with collision energy (12) and vibrational (13) or rotational (14) excitation; and analysis of the velocity (15), rotational energy (16), and spatial orientation of angular momentum (17) of the reactively scattered salt molecules. For several M + HX systems, the electron-jump process has been directly observed, in collisional production of ion-pairs (18) and also in electron spin resonance spectra of a matrix-isolated σ^* radical corresponding to the HCl^-K^+ complex (19). By chemical extrapolation, Penning ionization systems such as He* + HCl (with He* acting as a "superalkali") likewise involve σ^* radicals (20).

Unfortunately, the interpretation of M + HX reactive scattering is severely handicapped by kinematic constraints that confine the MX product near the centroid (21). The preferred direction and speed of product recoil in the center-of-mass (cm) system are thus hard to discern from the laboratory data. Nearly isotropic recoil distributions were reported for the K + HBr and K + DBr reactions (15), but somewhat anisotropic, sideways-peaked distributions are also compatible with the data (22). The kinematic constraints were elegantly circumvented in a study of M + TBr reactions (23) by detecting the tritium atoms, which are not confined near the centroid. Sharply backward recoil of the T atoms with respect to the incident TBr was found, a "rebound" mechanism. Such an isotope effect is difficult to explain (24), and subsequent work suggests these results may be unreliable.[2] Microreversibility applied to H + MX offers another approach to this problem, as the kinematics of these reactions is favorable for study of the product recoil direction.

This paper presents angular distribution data for reactions of H and D atoms with five alkali halides. The product recoil distributions in the cm system are found to be quite anisotropic and to show a marked shift from dominantly sideways to forwards as the halogen is varied, F → Cl → Br. These shifts complement the results found for H + X_2 reactions (25), in which the product recoil distributions shift from backwards to sideways as Cl → Br → I, whereas for the H + M_2 reactions (26) the product recoil remains sideways as K → Rb → Cs. The special dynamical features pertinent to reaction of a light atom with a heavy molecule are exemplified by comparison with a model, akin to Polanyi's DIPR model (8), which postulates that the H atom motion is approximately separable from that of the heavy atoms. For this model, the product angular distribution is governed by the combined effects of anisotropy in the potential energy as a function of the molecular orientation and angular momentum constraints resulting from the mass disparity.

Experimental

Figure 1 shows the arrangement of beam sources and detector. The apparatus was essentially the same as in the H + M_2 study (26). The H atom beam was produced by thermal dissociation in a tungsten tube oven (27) (with 0.2 mm slit width) operated at ~2800 K and 1 Torr (= 133.3 Pa); the atom fraction in the beam was ~80%. The salt beam was produced by a double chamber oven (with exit slit 0.2 mm × 7 mm); the supply chamber temperature (~900–1200 K) was chosen to give a salt vapor pressure of ~1–10 Torr and the independently heated orifice chamber was kept ~80–120 degrees hotter to prevent condensation. The collimating slit was also kept at ~700 K to avert clogging. The background pressure in the collision chamber, due largely to ambient H_2 or D_2, was typically 1×10^{-6} Torr during runs.

The total scattering (M + MX) was detected with a Re surface ionization filament operated at ~1700 K, the reactive scattering (M atoms) with a Pt – 8% W alloy filament operated at ~1300 K and preconditioned by heating at ~1600 K for a few minutes in methane at 10^{-4} Torr to render the filament insensitive to alkali halides (28). Both filaments were ribbons, 0.03 mm thick and 0.76 mm wide. To employ phase-sensitive lock-in amplification, the hydrogen beam was modulated at 10 Hz by a two-blade chopper. The chopper was driven by a six-pole synchronous motor with 15 Hz input voltage to avoid pickup and a reference signal was provided by a light bulb and phototransistor on the chopper mount.

The fact that the reactively scattered M atoms can be measured directly on the "methanated" Pt alloy filament made these experiments feasible. For other alkali systems, the reactive scattering signal usually must be obtained as the small difference between the total and nonreactive scattering signals. This would fail for the H + MX systems, as the yield of alkali atoms is relatively small and appears near the salt beam. Here subtraction was still necessary to correct the Pt filament readings for the residual detection of salt molecules and to deduct from the Re readings the alkali atom contribution; however, in each case the difference signals are comparable to the original filament readings. The efficiency of the Re filament is taken as 100% for both M and MX; strong evidence for this is provided by comparison of data taken on W, Re, and Pt under a variety of conditions (29). If the detection efficiency of the "methanated" Pt filament is denoted by g, the reactive and nonreactive signals are related to the filament readings by

$$[1a] \quad I_M = (I_{Pt} - g_{MX} I_{Re})/(g_M - g_{MX})$$

$$[1b] \quad I_{MX} = (g_{MIRe} - I_{Pt})/(g_M - g_{MX})$$

The g_M factor varies appreciably with filament conditions but is roughly ~50% in our experiments, whereas g_{MX} is less than 1%, often much less (30). Thus, g_{MX} can be neglected in the denominators; g_M then enters only as a scale factor in eq. [1a] and thus need not be known to determine the shape of the M angular distribution. The g_{MX} factor was determined at the end of each run by comparing Pt and Re scans of the salt beam. The measured g_{MX} ranged from a maximum of 0.9% to less than 0.01%; the value varied from run to run but tended to correlate with the identity of the halogen (0.9% pertains to CsF, 0.01% to KBr). The work function of the "methanated" Pt filament, as monitored by the electron emission, did not show any appreciable or systematic changes. The Re filament, after prolonged operation in the ~10^{-6} Torr of ambient hydrogen, appeared to "fatigue" with loss of detection efficiency. Sometimes flashing in 10^{-4} Torr of oxygen would revive it, sometimes not. This problem was avoided by merely installing a new Re filament every few weeks.

Figure 2 shows the primary data, Pt and Re filament readings, for scattering of H and D with KX and CsX, where X = F, Cl, Br. For the potassium salts, which have smaller reaction cross sections, the two best sets of Pt data are included. In each case (except H + CsBr), the Pt signals clearly contain a contribution from reactively scattered alkali atoms. This makes the readings on Pt and Re quite different on the two sides of the salt beam. Also, the Pt signal usually falls off more gradually than the Re signal on the small-angle side, where most of the elastic scattering appears. No reactive scattering was observed for H + CsBr; since the reaction is endoergic by 9 kcal/mol, this result was expected. It provided a test of the detection scheme. When the Pt alloy ribbon was preconditioned by heating in oxygen to render it sensitive to MX, the signals obtained were superimposable on the Re data. When the Pt ribbon was preconditioned by heating in methane, the signals obtained were tiny (points at $\Theta = 80°$ and 82°) and after correction for the residual detection of MX (by use of the measured g_{MX} factor), no significant signal remained.

The H + CsF data are typical of the systems with the largest reactive signals. In he scattering zone, the H beam flux was ~10^{15} atoms cm^{-2} s^{-1} (derived from bolometer readings and calibrations (27)), the

[2]L.R. Martin has found in subsequent work with tritium systems that the experimental procedure of ref. 23 failed to give reproducible results (private communication).

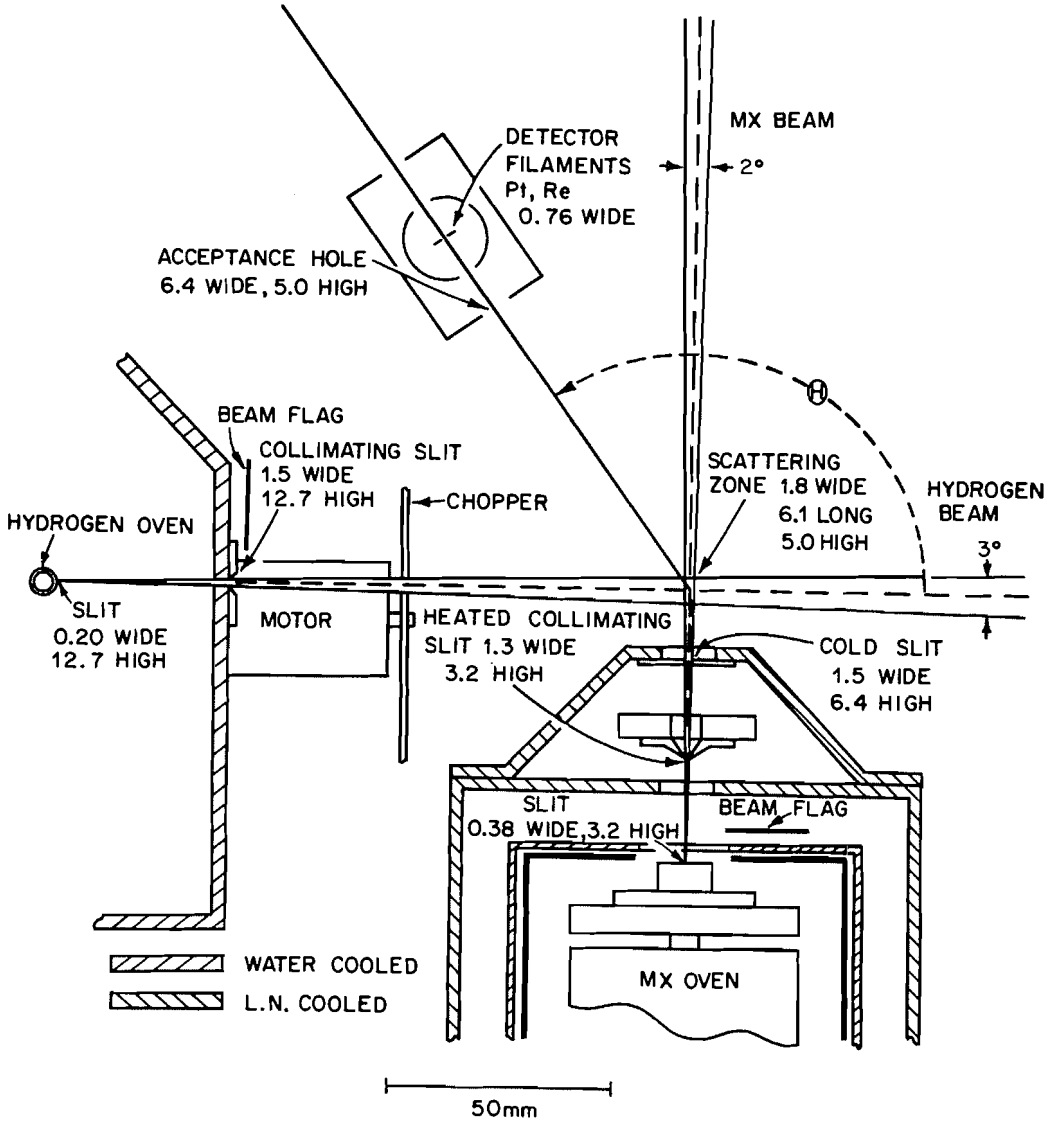

FIG. 1. Schematic of the crossed-beam apparatus. All dimensions are given in mm. Not shown are a bolometer detector (ref. 27) used to monitor the hydrogen atom beam and an additional surface ionization detector used to monitor the salt beam. The LAB scattering angle Θ specifies the direction of the product alkali atom with respect to the hydrogen beam.

salt beam flux was $\sim 2 \times 10^{15}$ molecules cm^{-2} s^{-1} (corresponding to a surface ionization signal of 3×10^{-6} A at the rotating detector). At Θ = 70°, the total scattered flux detected on the Re filament was $\sim 10^9$ molecules cm^{-2} s^{-1} (6×10^{-12} A), of which all but 5% was due to elastic scattering; the scattered flux detected on the Pt filament was 5×10^7 molecules cm^{-2} s^{-1} (3×10^{-13} A), of which about 80% was due to reactively scattered Cs atoms. The H + KBr case gave the smallest reactive signals observed; the salt beam flux and the total scattering at Θ = 70° were somewhat higher than above, but the Pt signal was about an order of magnitude less, with about 90% due to reactively scattered K atoms.

Nonreactive scattering

For these systems, the large mass ratio MX/H or MX/D severely handicaps kinematic transformation of the MX angular distribution data from the laboratory (LAB) to the center-of-mass (cm) system. An approximate transformation was carried out, however, in order to compare results for the nonreactive scattering by H, D, and He. Figure 3 illustrates the kinematic situation for the H + KBr case. The small sphere drawn about the tip of the centroid velocity vector $\boldsymbol{C}$ indicates the locus of the cm velocity $\boldsymbol{u}$ of KBr for purely elastic scattering. Since $|\boldsymbol{u}| < |\boldsymbol{C}|$, the KBr is confined to a narrow range of LAB angles Θ (between 72° and 90°, for the parent beam velocities corresponding to the diagram). In this range, two values of the cm scattering angle θ contribute at each LAB angle. The cm differential cross section $I_{cm}(\theta)$ thus is related to the observed LAB angular distribution by

$$[2] \quad I_{LAB}(\Theta) = J_i I_{cm}(\theta_i) + J_o I_{cm}(\theta_o)$$

The subscripts i and o refer to the inner and outer contributions (illustrated in Fig. 3) and J_i, J_o are the corresponding Jacobian factors for the LAB $\rightarrow$ cm transformation. For these systems, the inner contribution cannot be neglected as usual (29); the elastic scattering sphere is small enough to make J_i and J_o comparable, and usually $\theta_i < \theta_o$, so the inner portion is more intense. Also, the spread in $\boldsymbol{u}$ and $\boldsymbol{C}$ caused by the parent beam velocity distributions and imperfect collimation produces contributions to $I_{LAB}(\Theta)$ outside the nominal range allowed for the most probable beam velocities. To avoid resorting to stochastic calculations, we ignored the intensity in these outside regions as

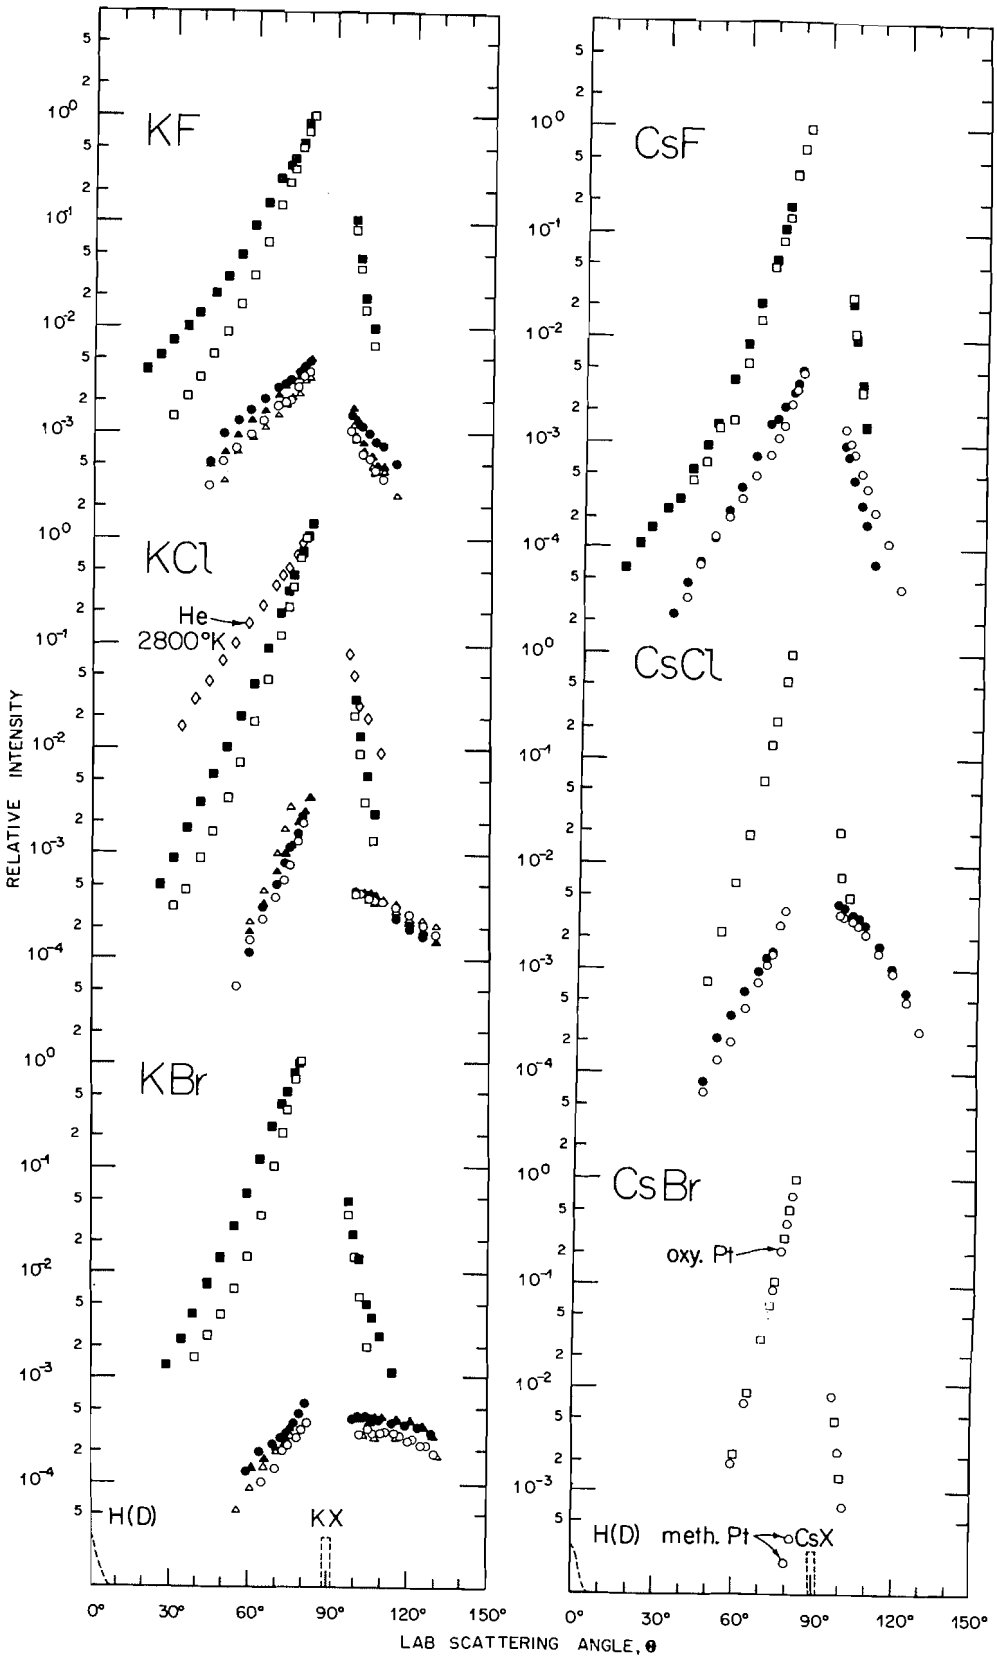

FIG. 2. Primary data collected on the Re (□, ■) and Pt (○, ●, △, ▲) filaments for scattering of six salts by H (open symbols) and D (filled symbols). For K salts, data are shown for two runs (circles and triangles). For KCl, data taken on Re (◇) are also shown for scattering by He; for CsBr, data were taken on Pt in both the oxygenated and methanated modes. The Re data are normalized so that the most intense H point for a given salt is unity, and the D data are also normalized to H at that point.

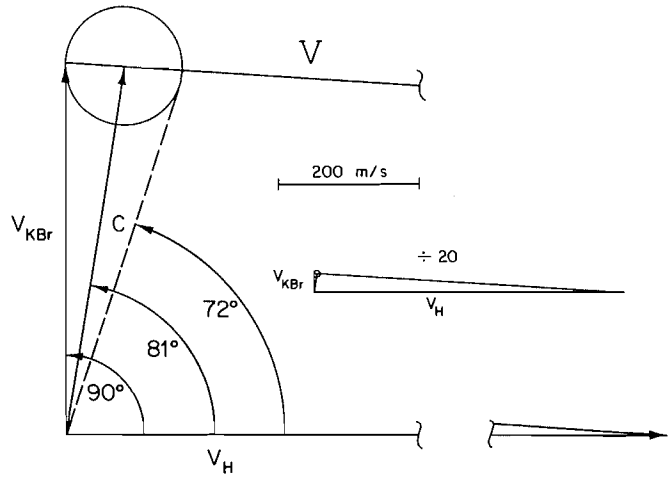

FIG. 3. Kinematic diagram for H + KBr elastic scattering: v_H and v_{KBr} are the most probable beam velocities; $\boldsymbol{C}$ the center-of-mass velocity; $\boldsymbol{V}$ the relative velocity; $\boldsymbol{u}$ the recoil velocity of KBr in the center-of-mass system. Circle shows locus of $\boldsymbol{u}$ vectors allowed by conservation of energy and momentum, which confine LAB elastic scattering within the range Θ = 72–90°. Portions of circle below and above $\boldsymbol{V}$ indicate the "inner" and "outer" branches, respectively, of the LAB → cm transformation. Inset on right shows complete diagram reduced by a factor of 20.

well as any inelastic contributions (probably minor) and derived $I_{cm}(\theta)$ from eq. [2] by a simple iterative procedure that makes use of the fact that the inner and outer branches come from the same function.

Figure 4 gives the resulting cm angular distributions of elastic scattering. Since in each case the most probable centroid velocity vector lies close to the salt beam, and accurate data could not be taken near the beam, most of the accessible LAB scattering transformed into the backward hemisphere ($\theta > 90°$) in the cm system. Two features are of interest:

1. In the LAB data for a given salt (Fig. 2, Re curves), collisions with D produce wider elastic scattering than those with H. The effect is most prominent for KF, the lightest target molecule, and becomes almost negligible for CsF. This is a kinematic isotope effect (seen in the H + M_2 data (26)), since the D atom carries $\sqrt{2}$ times more linear momentum than H at the same temperature. If the LAB → cm transformation were exact and the nonreactive scattering were solely elastic, the cm angular distributions (Fig. 4) for D and H should superimpose since both pertain to the same collision energy. The cm results indeed almost superimpose for each of the four salts studied.

2. The cm angular distributions show a rather strong decline in the $\theta > 90°$ region rather than the flat behavior expected for repulsive wall scattering. The similar decline found for He + KCl indicates that this is due largely to systematic bias introduced by the extensive velocity averaging and unfavorable kinematics. However, it is significant that with H or D the scattered KCl falls off more rapidly than with He; the extrapolated difference is a factor of 5 at θ = 180°, which corresponds to zero impact parameter. This difference can be attributed to reaction at small impact parameters that attenuates the wide-angle elastic scattering, as in K + HBr and other systems (10).

Reactive scattering

The analysis of the M atom scattering is not handicapped by kinematic constraints, since the mass ratio M/HX is comparable to unity, particularly for the potassium reactions. The data provide a fairly good determination of the cm angular distributions but only rough estimates of the product translational energy and total reaction cross sections.

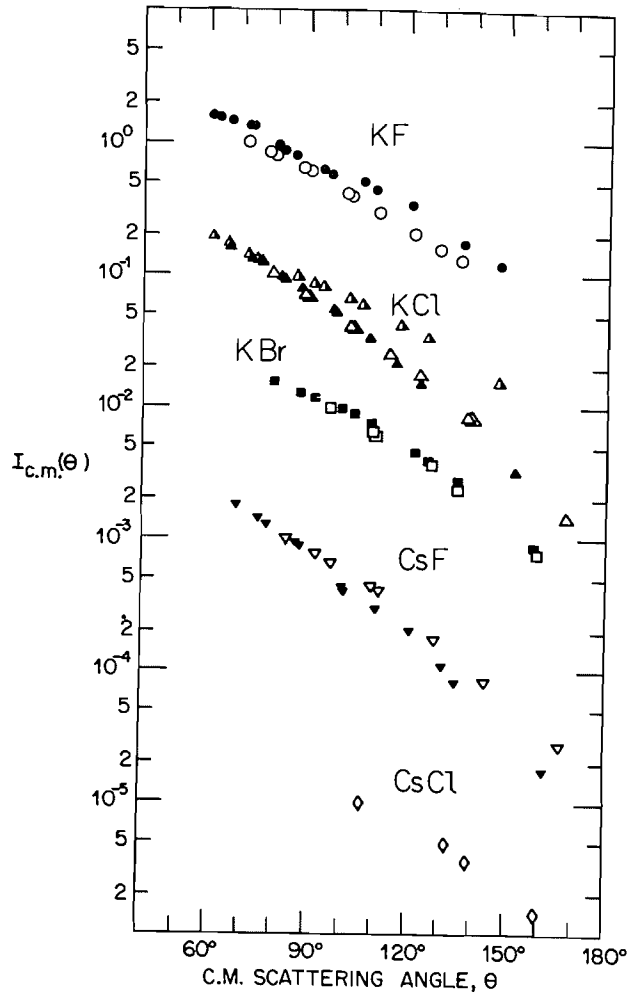

FIG. 4. Angular distributions (center-of mass system) for the elastic scattering of five salts by H (open symbols) and D (filled symbols). For KCl, points are included for scattering by He (half-filled symbols). Normalization for each salt is the same as in Fig. 2.

Product angular distributions

Figure 5 shows the LAB angular distributions of reactively scattered alkali atoms. Points within about ±10° of the salt beam had to be omitted because the correction for residual detection of MX in eq. [1] becomes large there. Likewise, points on the small-angle side ($\Theta < 90°$) of the salt beam have more scatter than on the large-angle side ($\Theta > 90°$), due to this correction. The peak positions and shapes of the alkali atom distributions are well determined, however. Also shown are the centroid angular distributions (21) (dashed curves) calculated from the parent beam velocity distributions. The reactive scattering is substantially broader than the centroid distribution in each case and it is displaced towards larger LAB angles, the displacement increasing as F → Cl → Br in the reactant salt. This trend is well outside experimental uncertainties. The shift to wider LAB angles indicates a preference in the cm system for recoil of the product M atoms into the forward hemisphere with respect to the incident MX molecules. By momentum conservation, the HX product molecules prefer the backward hemisphere.

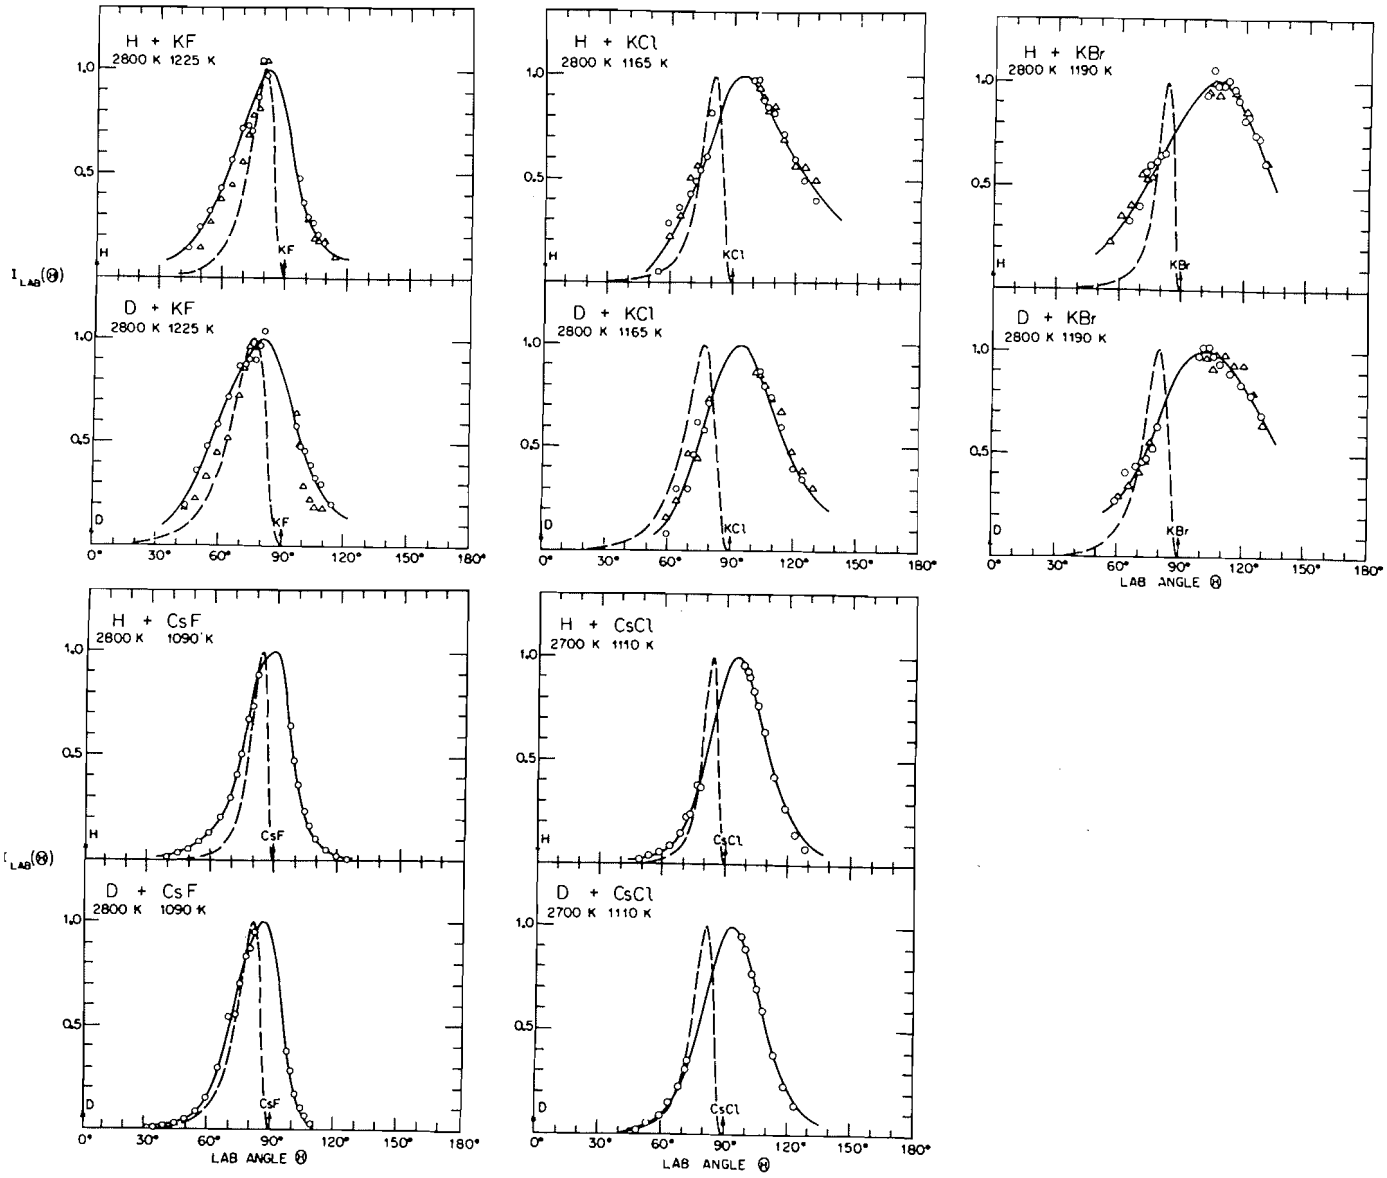

FIG. 5. Angular distributions (laboratory system) of M atoms from reactions of H and D with MX for five salts at the beam temperatures indicated. Ordinates are normalized to unity. Broken curves are centroid distributions; solid curves are calculated from a least-squares kinematic analysis.

The trend with change of the halogen might arise either from a systematic variation of (*i*) the product recoil velocity away from the centroid (small for F reactions, increasing for Cl and Br) or (*ii*) the preferred direction of recoil (more nearly sideways for F, increasingly forward for Cl and Br). A variation of recoil velocity opposite to that required by (*i*) seems likely, both because the reaction exoergicity is large for F reactions but much smaller for Cl and negative or Br, and because the product reduced mass is least for F reactions, most for Br. This is borne out by a kinematic analysis, which confirms that (*ii*) is responsible for the trend with halide.

The LAB → cm transformation was carried out as usual by an indirect procedure (29), since the lack of parent beam velocity analysis prevents a direct transformation. A separable form was assumed for the cm differential reaction cross section,

$$[3] \quad I_{cm}(\theta, u) = T(\theta)U(u)$$

The cm scattering angle for the M atom is defined such that $\theta = 0°$ at the direction of the incident MX beam and $\theta = 180°$ at the H or D beam; the cm velocity u pertains to recoil of the M atom away from the centroid. The angular factor was represented by the first six terms in a Legendre polynomial expansion, the recoil velocity factor by a Maxwellian flux distribution, of the form

$$[4] \quad U(u) = (u/\hat{u})^3 \exp 3/2[1 - (u/\hat{u})^2]$$

The most probable recoil velocity (denoted $\hat{u}$) was chosen by comparing trial calculations with the data, and the Legendre coefficients $(a_0, \ldots a_5)$ were determined by a least-squares method (31). The procedure involves computing LAB product velocity spectra at the desired angles, averaging over 36 combinations of parent beam velocities, and integrating these spectra to obtain the total flux at each LAB angle to be compared with

our data. Velocity analysis of hydrogen atom beams (25) and salt beams (32) under similar conditions indicates substantial deviations from effusive flow, both corresponding to Mach numbers near unity. An empirical number density distribution,

$$[5] \quad N(v) = (v/v^*)^n \exp(n/m)[1 - (v/v^*)^m]$$

was used for both beams, where $n = 8$, $m = 1$, and $v^* = 1.3(2\mathcal{R}T/\mathcal{M})^{1/2}$, with $\mathcal{R}$ the gas constant, T the source temperature (listed in Fig. 5), and $\mathcal{M}$ the molecular weight. The dependence of the cm cross section on initial collision energy was left implicit, since an appropriate functional form is not known and the spread in initial conditions is large. Trial calculations showed that the endoergicity of the KBr and CsCl reactions does not significantly affect the LAB → cm transformation, because the most probable initial collision energy much exceeds the endoergicity (cf. Table 1). The angular widths of the parent beams also proved to have negligible effect. Figure 5 includes the "best fits" (solid curves) to the LAB data obtained from this analysis.

Figure 6 gives the corresponding cm angular distributions, $T(\theta)$. Inspection of the fitting procedure indicates the peak positions are typically determined within about ±20°, but the wobbly structure seen in some of the curves is an artifact. It results from interpolation across the region obscured by the salt beam and Jacobian enhancement of contributions from low recoil velocities (31). However, three properties of qualitative interest appear reliable:

1. The cm product angular distributions for reaction of H and D with a given MX salt are the same, within the experimental resolution.

2. The cm distributions for K and Cs from a given halide show some similarity but the difference seen for the chloride case may be significant.

3. The cm distributions for a given alkali shift from sideways to forward peaking with change of the halogen atom from F → Cl → Br, in accord with the trend inferred from the LAB data.

For two kindred systems, the H + X_2 reactions (25) and the M + X_2 reactions (29), the shapes of the product angular distributions were found to depend primarily on the halogen atom. This holds at least approximately for H + MX, but it should be noted that here the product distributions also correlate with the reaction exoergicities (cf. Table 1). The substantially exoergic KF and CsF reactions give largely sideways scattering; the endoergic KBr and CsCl reactions give forward scattering; and the almost thermoneutral KCl case is intermediate.

Energy disposal in product modes

Energy conservation requires that

$$[6] \quad E' + W' = E + W + \Delta D_0$$

where E and W denote the reagent relative translational and internal excitation energies, primes pertain to the reaction products, and ΔD_0 is the difference in dissociation energies of the HX and MX bonds, measured from the ground vibration–rotation states. Due to the high kinetic energy of the H or D atoms produced by thermal dissociation ($E \sim 9$ kcal/mol) and the high temperatures needed to vaporize the alkali halides ($W \sim 3$ kcal/mol), the distribution of $E + W$ is nearly the same for all the reactions and is very broad. Figure 7 displays the accessible energy domains for the reactions of H or D with KX; those for the CsX reactions are quite similar. The reactions with KCl, CsCl, and KBr are nearly thermoneutral or slightly endoergic; thus, despite the high $E + W$, not much internal excitation of the product HX molecules can occur and usually the second vibrational level ($n = 2$) is out of reach. This is not so for the reactions with KF or CsF; there the exoergicity is sufficiently large to form HF with $n = 2$ or form DF with $n = 3$.

Table 1 lists values of ΔD_0 derived from bond strength data (33) and rough bounds for the product relative translational energy E' and internal energy W' obtained from our kinematic analysis. For these reactions the LAB → cm transformation is rather insensitive to the recoil velocity parameter $\hat{u}$ and since E' is proportional to $\hat{u}^2$, the energy disposal is therefore quite ill defined. We list the nominal best fit value obtained for E' with upper and lower bounds and the corresponding quantities for W' derived from eq. [6]. These values pertain to the H atom reactions; those for D agree within 1–2 kcal/mol in all cases.

Reaction models that uncouple the light-atom and heavy-atom modes in eq. [6], such as the spectator stripping model (34), give the simple propensity rules: $E' \sim W$ and $W' \sim E + \Delta D_0$. These agree well with the nominal E' and W' values of Table 1 for three cases, poorly for the other two, but the bounds are too broad to allow a significant test.

Temperature dependence

For the reactions of H and D with CsCl we carried out a study of the temperature dependence in order to determine the activation energy. This was done by measuring the reactive signal at a fixed LAB angle ($\Theta = 110°$) as a function of the hydrogen oven temperature. It was possible to remain at the same LAB angle because for the temperature range covered (2200–2800 K) the mean H atom velocity shifts by only ~10%; thus the LAB → cm transformation is affected very little (e.g., the θ scale shifts by <0.5°). Complete angle scans done for three different temperatures verified that the shape of the LAB angular distribution is invariant in this range. The change in the cm energy (or reagent translational temperature) is determined to better than 99% by the H atom LAB velocity distribution. Thus, we can employ the usual Arrhenius plot, shown in Fig. 8. The yield of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12

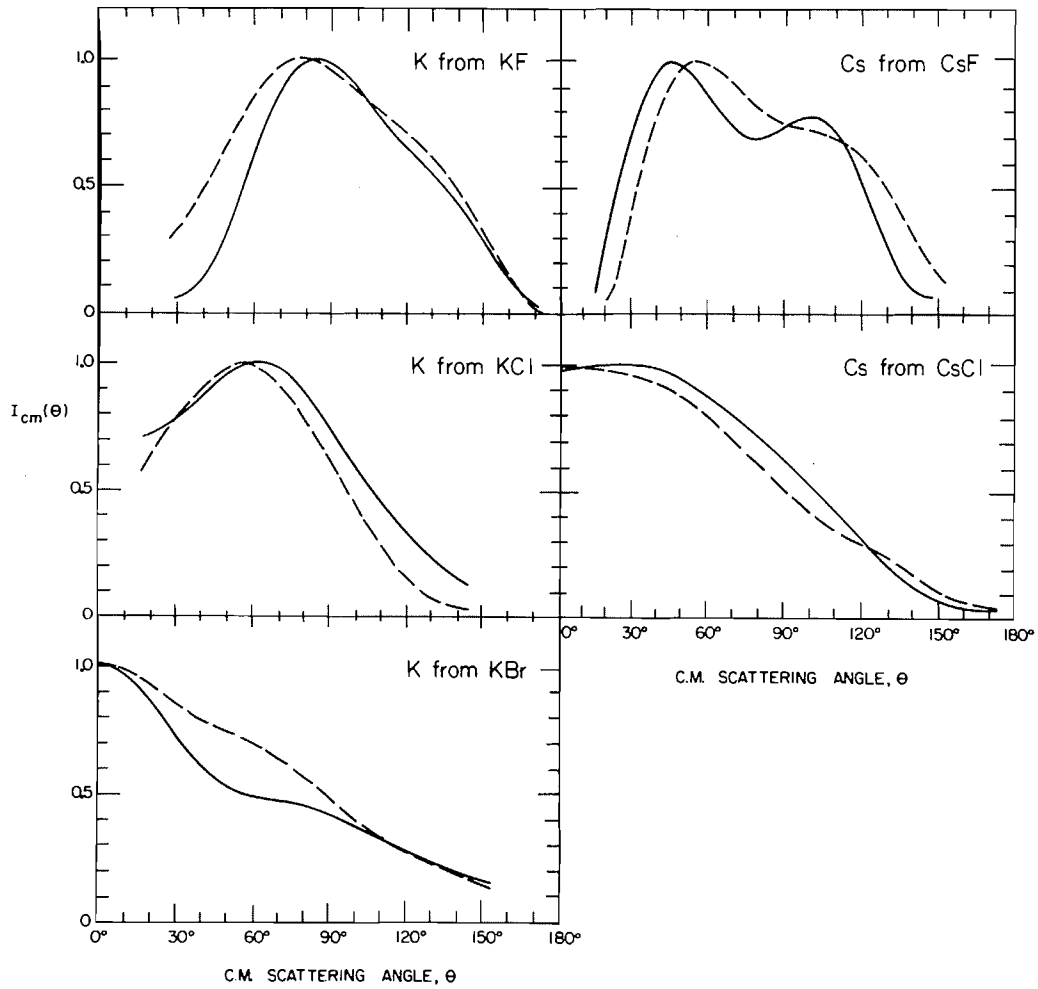

FIG. 6. Angular distributions (center-of-mass system) for product alkali atoms from H (—) and D (---) reacting with five salts. The cm scattering angle θ specifies the direction of the product alkali atom with respect to that of the reagent alkali halide beam.

reactively scattered Cs atoms was corrected for the variation of the percentage of H atoms in the reagent beam by normalizing to the bolometer signal. Since the H atom flux declines substantially with temperature, the uncertainties become sizable at the lower temperatures.

From the slope of the Arrhenius plot, the apparent activation energies are 5.7 and 4.5 kcal/mol, for the H and D reactions, respectively. Since these reactions are endoergic ($\Delta D_0 = -3.3$ and -2.0 kcal/mol for H and D, respectively), our data are consistent with a true activation energy of about $E_a = 2.5$ kcal/mol. An appreciably higher value cannot be accommodated unless the T dependence is assumed to become steeper as T decreases. However, within the error bars the data are also consistent with $E_a \sim 0$, as indicated by the dashed lines shown on the Arrhenius plot.

Total reaction cross section and isotope effect

The three methods usually used to determine the total reaction cross section (29) are not applicable to these reactions. Small-angle elastic scattering could not be observed, so we cannot normalize our data by use of the semiclassical small-angle scattering formula. Likewise, the lack of a complete elastic scattering distribution prevents normalizing to a theoretical value of the total scattering (nonreactive + reactive) cross section. The fact that attenuation of the salt beam could not be observed precludes normalizing to the total amount of MX scattered out of the reagent beam. The method resorted to here is less satisfactory than these usual normalization procedures, but seems adequate for determining the H/D isotope effect and gives at least a rough estimate of the magnitude of the reaction cross section.

The nonreactive scattering distributions of Fig. 4 can all be extrapolated without much ambiguity to 180°. Therefore we decided to normalize these data so that the magnitude of the nonreactive differential cross section there, $I_{cm}(nr; 180°)$ equals that for the hard-sphere cross section. The latter is given by $R^2/4$, where R denotes the sphere radius. This we take to be given by the sum of the covalent radius of the H atom (0.37 Å) and the average of the ionic radii of the M^+ and X^- ions. The resulting values of R, listed in Table 2, are smaller than for van der Waals radii, but seem more appropriate in view of the strongly ionic character of the alkali halide and the fairly high collision energy (0.4 eV). With such a normalization, and the experimentally determined ratio of elastic to reactive scattering, we can evaluate the cm reaction cross section Q_r in absolute units. This involves first integrating the cm angular distribution of reactive scattering, which is easily done using the functional forms specified in eq. [3], to obtain

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

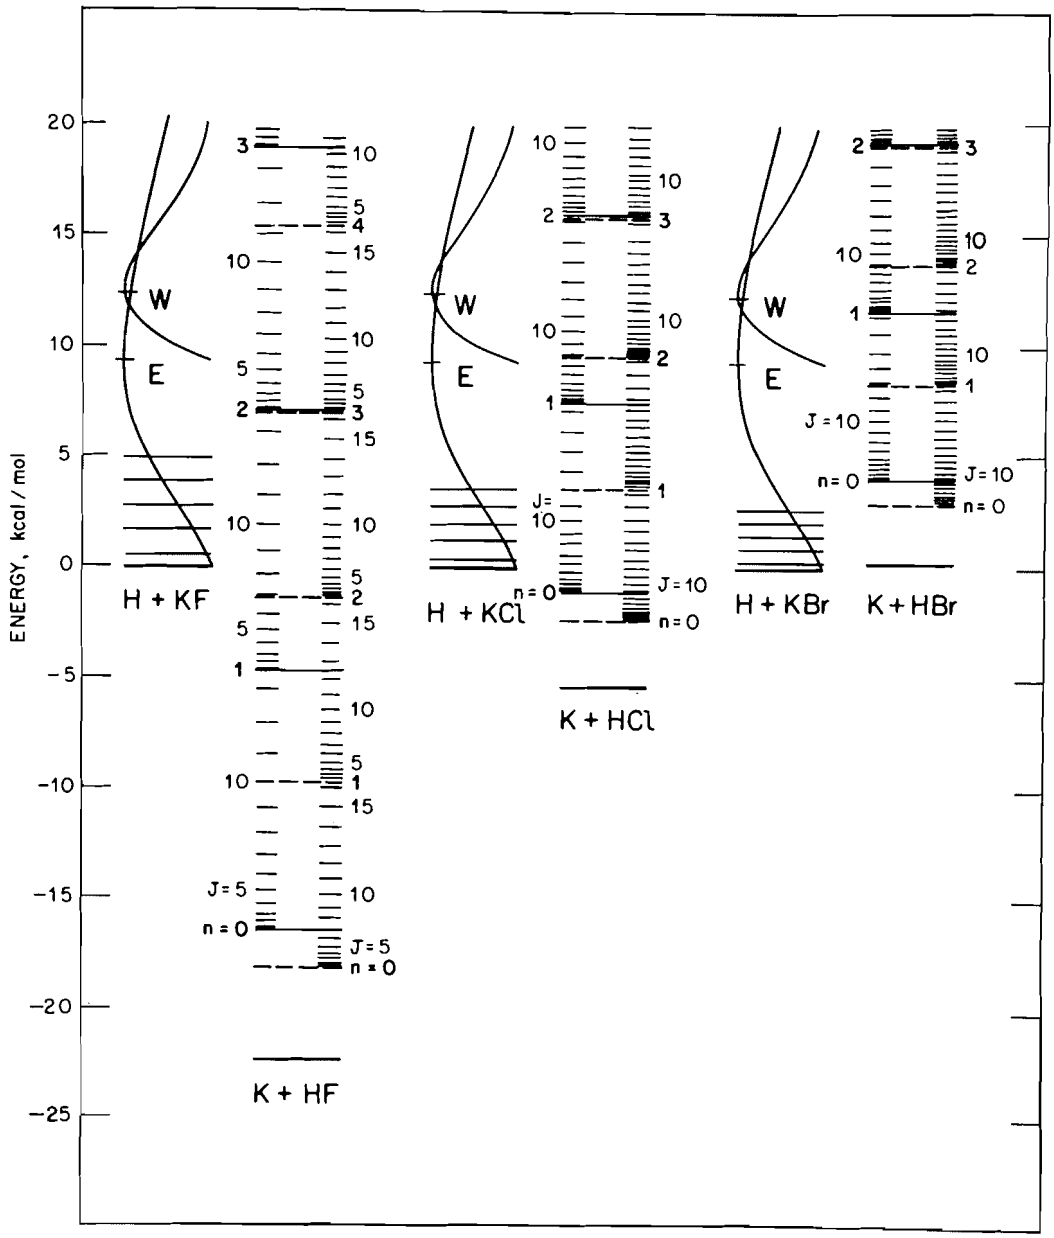

FIG. 7. Energy level diagram for reactants and products of H + KX → HX + K reactions. The curves show the distributions in translational (E) and internal (W) energies of the reactants. In each case, the origin for the W distribution is at the peak of the E distribution. Positions of the first five vibrational levels are indicated for KX and vibration-rotation levels are indicated for HX (left side) and DX (right sided) by the n and J quantum numbers. All levels are drawn in the harmonic oscillator – rigid rotor approximation. Zero of energy in each case pertains to reactants.

$$[7] \quad Q_r = 2\pi N \iint T(\theta)U(u) \sin\theta \, d\theta \, d\, u = 12.52 N a_0 \hat{u}$$

where the factor $12.52 \equiv 4\pi(2/9)\exp(3/2)$ and a_0 is the zeroth-order term in the Legendre expansion of the angular distribution; $\hat{u}$ is the most probable recoil velocity specified in eq. [4]. The normalization constant is given by

$$[8] \quad N = \left\{\frac{1}{4} R^2/[I_{cm}(nr; 180°)]_{rel}\right\} \times \{[I_{LAB}(r; \Theta_N)]_{rel}/[I_{LAB}(r; \Theta_N)]_{calc}\}$$

The subscript "rel" indicates arbitrary relative units; "calc" indicates the result computed from eq. [3] as if $N = 1$. The first bracketed factor converts the cm nonreactive scattering to absolute units, the second normalizes the cm differential reactive cross section to the same units. The LAB angle Θ_N at which N is determined is chosen in a region where the data are smooth; different choices gave consistent results.

Table 2 lists the R values and the total cross sections. The results for Q_r suffer from scatter in the raw data; from the subtraction required to correct the Pt data for nonreactive scattering; from uncertainties in the LAB → cm transformations for both nonreactive and reactive scattering (reflected in values of a_0 and $\hat{u}$); and from the estimation of R. Accordingly, the Q_r values obtained are uncertain by as much as a factor of 10 but likely provide an upper bound since in the first bracket of eq. [8] we neglect attenuation by reaction. The H/D isotope ratios for a

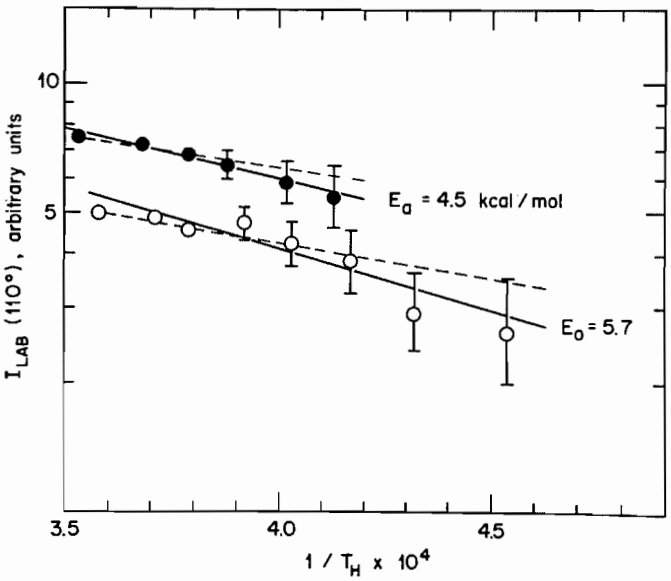

FIG. 8. Temperature dependence of the intensity of Cs atoms reactively scattered at 110° (LAB) from H (○) and D (●) + CsCl. Nominal activation energies are noted; these include the reaction endoergicity. Dashed lines indicate T dependence expected if true activation energy (in excess of endoergicity) is zero. Ordinate units are arbitrary, with data for the two reactions normalized to the ratio of total reaction cross sections.

TABLE 2. Total reaction cross sections[a]

	Salt				
	KF	CsF	KCl	CsCl	KBr
R	1.70	1.87	1.94	2.11	2.01
Q_r(H)	4	12	3	7	1.6
Q_r(D)	8	30	4	14	3

[a]Units are Å for R and Å^2 for Q_r.

given salt should, however, be reliably determined; we see that the cross section for the D reaction is consistently about twice as large as for the H reaction. The Cs/K ratio of the reaction cross sections for a given halide should also be much more reliable than the absolute values; this ratio is roughly 2–3 in favor of the Cs reaction.

Discussion

When a light atom attacks a pair of heavy ones, the large mass disparity fosters an approximate separability of the light atom motions. This has major consequences for the reaction dynamics, amply discussed and illustrated in previous trajectory studies (8, 35) and model treatments (8, 34). Here we consider chiefly features pertaining to the anisotropy of the product angular distributions. We also discuss how our results for H + MX relate to the reverse reactions, M + HX.

As a consequence of the mass disparity, the conservation law for the total angular momentum,

[9] $\mathcal{J} = \boldsymbol{L}' + \boldsymbol{J}' = \boldsymbol{L} + \boldsymbol{J}$

becomes approximately separable into two propensity rules: $\boldsymbol{L} \sim \boldsymbol{L}'$ and $\boldsymbol{J} \sim \boldsymbol{L}'$. For the H + MX case, the first of these holds because the initial orbital angular momentum $\boldsymbol{L}$ from motion of

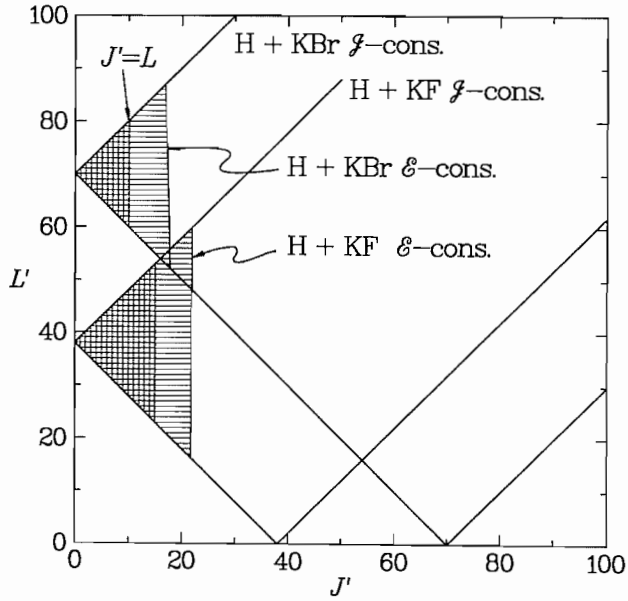

FIG. 9. Illustration of constraints imposed by the conservation laws on the partitioning of angular momentum between product orbital $\boldsymbol{L}'$ and rotational $\boldsymbol{J}'$ motion for the H + KF and H + KBr reactions. The magnitude of the total angular momentum $\mathcal{J}$ was taken to be the most probable $\boldsymbol{J}$ of the salt. The hatched triangular regions show the allowed $(\boldsymbol{L}', \boldsymbol{J}')$ range in each case, whereas the cross-hatched regions indicate the constraint imposed by the $\boldsymbol{J}' \approx \boldsymbol{L}$ model. For both reactions, the initial energy was 12 kcal/mol, corresponding to most probable $E + W = 9 + 3$ kcal/mol, from Fig. 7. The energy available to the products thus is about 29 kcal/mol for the KF reaction, and about 8 kcal/mol for the KBr reaction.

H with respect to MX tends to become the rotational momentum $\boldsymbol{J}'$ of the product HX molecule. Accordingly, the initial thermal rotational momentum $\boldsymbol{J}$ of the heavy-atom pair MX tends to persist as the orbital angular momentum $\boldsymbol{L}'$ of the M and HX products. In our experiments, typically $\boldsymbol{J} \gg \boldsymbol{L}$, by virtue of the high temperature and large moments of inertia of the salt molecules.

Figure 9 illustrates for the reactions of H with KF and KBr the constraints on the product $\boldsymbol{L}'$ and $\boldsymbol{J}'$ resulting from the mass disparity. This diagram was constructed in the usual way by combining the conservation laws for energy and angular momentum with a centrifugal barrier criterion (36). The magnitude of the total angular momentum $\mathcal{J}$ was approximated by the most probable J in a Boltzmann distribution for the salt molecule (38$\hbar$ for KF, 70$\hbar$ for KBr). The energy constraint was derived assuming no product vibrational excitation. An exit impact parameter also had to be assumed; this was chosen as 4 Å in each case, but the curves are insensitive to the choice within a sizable range (2–5 Å). The net result is a rather narrow allowed range for L' and J'. Also indicated is the somewhat narrower constraint imposed by $L = J'$, which takes the propensity rule noted under eq. [9] as an equality, in accord with an ultrasimple spectator stripping model (34).

The distribution of the direction of $\mathcal{J}$ as well as its magnitude is dominated by the rotation of the hot salt molecules. For our near-Maxwellian beam conditions, the spatial distribution of $\boldsymbol{J}$ is expected to be three-dimensionally isotropic (as opposed to that for $\boldsymbol{L}$, which is only isotropic in two dimensions). Even if correlations exist between the product angular momenta $\boldsymbol{L}'$ and $\boldsymbol{J}'$, the isotropy of the total $\mathcal{J}$ will obliterate any evidence of

For personal use only.

such correlation in the product angular distributions. The fact that we observe decidedly anisotropic distributions implies that not all orientations of $\mathcal{J}$, and hence $\boldsymbol{J}$, are equally likely to produce reaction.

Anisotropic impulsive model

We consider a very simple dynamical model (commensurate with the modest quality of our data), which is akin to the spectator model (34) and other impulsive models (37), particularly Polanyi's DIPR model (8). In the sudden limit, the attacking light atom encounters a kinetically frozen target, the heavy molecule. A preferred reaction geometry would then select certain orientations of the molecule, corresponding to alignments of $\boldsymbol{J}$ that foster those orientations. For the prototypical collinear reaction intermediate, coplanar geometries and $\boldsymbol{J} \parallel \boldsymbol{L}$ are preferred. For strongly bent reaction complexes, broadside approach of the light atom and $\boldsymbol{J} \perp \boldsymbol{L}$ might be expected to dominate. When $\boldsymbol{J} \rightarrow \boldsymbol{L}'$, as in the spectator model, the latter case will give rise to predominantly sideways scattering of the reaction products.

The model adopted here, termed the anisotropic impulsive model (AIM), specifies a preferred angle of approach for the H atom, which is averaged over the spread in internal motion of the alkali halide. We enforce $\boldsymbol{L}' = \boldsymbol{J}$ by neglecting any contribution of $\boldsymbol{L}$ to the tangential motion of the products, but allow for an expected small repulsive energy release along the M—X axis. The final relative velocity $\boldsymbol{V}'$ of the products is decomposed into contributions from axial v_a and tangential v_t components. The axial velocity arises from combining the vibrational motion of MX and product repulsion, while the tangential motion is entirely due to MX rotation. Because these components are orthogonal, the Pythagorean relation $V'^2 = v_a^2 + v_t^2$ holds. However, this speed triangle may be oriented anywhere in space, so without further restrictions the angular distribution remains isotropic.

We introduce anisotropy by assigning a fixed orientation angle η of the MX axis with respect to the initial relative velocity $\boldsymbol{V}$, defined so that $\eta = 0$ when H approaches the halide end of the salt molecule. At zero impact, parameter η becomes identical with the polar angle γ between the relative separation vector and the MX axis. For a fixed η, the axial component v_a is fixed in direction along the MX axis, while v_t must lie in a plane perpendicular to this axis. A given $\boldsymbol{V}'$ defines a cone of height $V' \cos\theta$ and half-angle θ, where θ is the cm scattering angle of the M atom product. The edge of this cone may be reached by a range of (v_a, v_t) consistent with the triangle condition above; in general v_a may range from $v_< = V' \cos(\eta - \theta)$ to $v_> = V' \cos(\eta + \theta)$, so long as negative speeds do not result.

For this AIM, finding the cm intensity $I_{cm}(V',\theta)$ is chiefly a matter of compounding the component distributions, $P_a(v_a)$ and $P_t(v_t)$, over the range of velocities that contribute at (V',θ) to yield the desired distribution $P(V',\theta)$. This is done using the convolution relation (38)

$$[10] \quad P(V',\theta) = \int \mathrm{d}\, v_a \int \mathrm{d}\, v_t P_a(v_a) P_t(v_t) \delta(V' - [v_a^2 + v_t^2]^{1/2}) h(v_a - v_<) h(v_> - v_a)$$

where $\delta(x)$ is the Dirac delta function and $h(x)$ the unit step function. The cm intensity is then given by

$$[11] \quad I_{cm}(V',\theta) \propto \frac{V'}{\sin\theta} P(V',\theta)$$

The factor of V' converts P to a flux distribution, and $1/\sin\theta$ accounts for the polar enhancement due to azimuthal averaging. The P_a distribution is compounded (38) from the vibrational distribution $P_{vib}(v_{vib})$, taken as the Boltzmann average of the momentum–space harmonic oscillator wave functions, and the impulse distribution $P_i(v_i)$. For simplicity we choose $P_i(v_i) = \delta(v_i - v_{i0})$, making $P_a(v_a) = P_{vib}(v_a - v_{i0})$. The P_t distribution is taken as the classical rotational Boltzmann distribution P_{rot}, as appropriate for high-temperature heavy rotors. These choices allow the integrals in eq. [10] to be done analytically, yielding an expression for $P(V',\theta)$ in the form of a sum over the vibrational levels of integrals that are readily evaluated by recursion (22). Energy conservation places limits on the impulse velocity v_{i0}. If we define f_i as the fraction of the available energy $E + \Delta D_0$ delivered as product repulsion, then

$$[12] \quad v_{i0} = \left[f_i \frac{2}{\mu'} (E + \Delta D_0) \right]^{1/2}$$

where μ' is the product reduced mass. This completes the formulation.

Specifying η and f_i, along with experimental conditions, allows the calculation of I_{cm}, which can then be averaged over the initial beam velocity distributions and transformed into the LAB frame in the usual way. The AIM computer code (22) designed for this purpose also allows an average over a Gaussian distribution in η. Figure 10 compares specimen calculations of the LAB angular distributions with experiment. For the Cs salts, satisfactory fits were obtained just by varying η, with $f_i = 0$, owing in part to the missing central portion of the experimental data. For the K salts, where the kinematic resolution is better, specifying a small value for f_i greatly improved agreement with experiment. The effects of varying η and f_i are coupled; usually a nonzero f_i allows easier "steering" of the calculated curve into agreement with experiment by varying η. For the H + KBr system the effect of averaging over a range of η is also illustrated; the results indicate that the data are inconsistent with a broad range of orientations. Figure 11 gives the corresponding cm angular distributions. For the "best fit" values, $\eta = 80° \rightarrow 100° \rightarrow 110°$ for the salts as F → Cl → Br. The AIM analysis thus indicates that the preferred reaction geometry is roughly broadside, with only a relatively modest change with halogen. According to this model, much of the systematic increase in forward scattering of the products as F → Cl → Br is due to the angular momentum constraints, which reflect (cf. Fig. 9) both mass and energetic factors.

The $I_{cm}(\theta)$ distributions obtained from kinematic analysis and shown in Fig. 6 are probably more reliable than the AIM results of Fig. 11, because the model imposes additional constraints. However, the comparison serves to illustrate the limited resolution of $I_{cm}(\theta)$ provided by our experiments, since the AIM results account nearly as well for the LAB data (cf. Figs. 5 and 10). The most significant feature, exhibited by both the kinematic analysis and AIM, is that for all except the KF reaction the product alkali atoms appear predominantly in the forward hemisphere of the cm frame with respect to the direction of the alkali halide reagent.

Microreversibility aspects

Despite the host of studies devoted to M + HX reactions, the characterization of the reaction dynamics still suffers from many gaps and conflicts. Via microreversibility, our results for H + MX reactions add three pertinent items, concerning (1) the

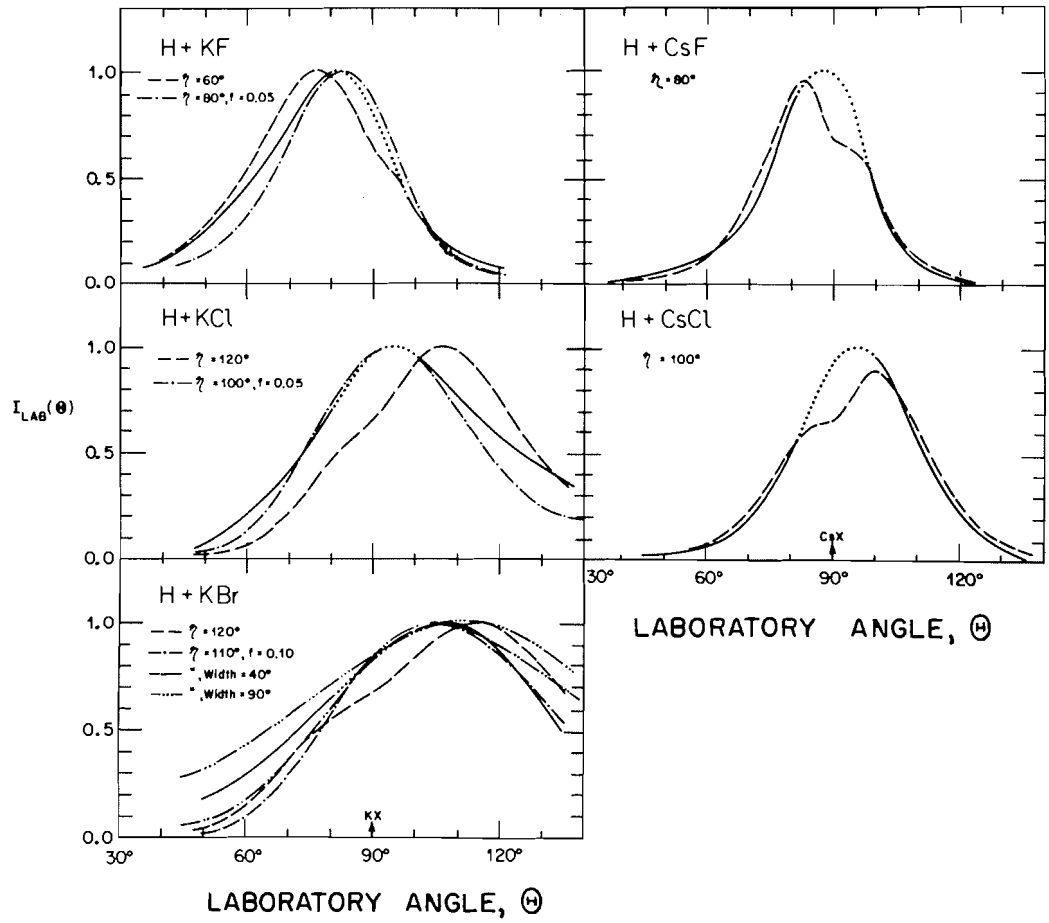

FIG. 10. Comparison of M atom laboratory angular distributions (solid curves) from reaction of H atoms with five salts with impulsive model calculations. Dotted portions of experimental curves indicate regions where data are lacking due to proximity of the parent salt beam.

product angular distributions; (2) the H/D isotope effect of the total reaction cross section; and (3) the Arrhenius activation energy. These items are our most reliable results, but we find that each brings out new questions rather than resolving old ones.

(1) The predominantly forward reactive scattering we observe for H or D + KBr corresponds, when all the cm velocity vectors are reversed, to forward scattering of KBr relative to the incident K direction in reactions with HBr or DBr. This contrasts with (*a*) the nearly isotropic (15) or slightly sideways (22) distributions reported for K + HBr and DBr and (*b*) the sharply backward reactive scattering (23) reported for K + TBr. The contrast may not be significant, as (*a*) is subject to intrinsically poor kinematic resolution and (*b*) may be vitiated by experimental error.[2] However, in our experiments, the peak of the thermal distribution of total energy (~8 kcal/mol re: K + HBr; cf. Fig. 7) is much higher than in (*a*) or (*b*), by typically about 6–7 kcal/mol. As exemplified by our AIM calculations, this energy is high enough to induce forward scattering unless reaction is inhibited by a sizable barrier. The threshold energy for reaction is only 0.4 kcal/mol (re: K + HBr), according to an optical model analysis of the nonreactive scattering (10), but at the low energies of (*a*) and (*b*) even such a small barrier can foster sideways or backward reactive scattering.

(2) We find the isotope ratio $Q_r(H + MX)/Q_r(D + MX) \simeq 0.5$ for all five reactions studied (Table 2) and no discernible isotope effect in the temperature dependence for the CsCl case (Fig. 8) beyond that due to endoergicity. For the reverse reaction, $Q_r(K + HX)/Q_r(K + DX) = 1.4 \pm 0.2$ was found (15), in good agreement with the ratio of 1.3 estimated from optical model analysis (10). This reversal in sense of the H/D isotope effect may again arise because the alkali atom experiments and ours differ markedly in the total energy and angular momentum supplied. Under our conditions, as seen in Fig. 7, the HBr/DBr product has a relatively large amount of energy available for rotation compared to that present in the HBr/DBr reagent in the K + HBr reaction. If the rotational levels are populated statistically, the greater number of available states for DBr (which goes roughly as the square root of the moment of inertia) might produce an isotope effect favoring D over H that would not occur under the conditions of the K + HBr reaction. It is striking that D is also favored over H by about a factor of 2 for reactions with alkali dimers (26).

(3) Our evidence that for H or D + CsCl the activation energy in excess of the endoergicity is near zero (Fig. 8) is qualitatively consistent with experimental results for K + HCl (E_a less than ~1 kcal/mol higher than the 2 kcal/mol endoergicity (12)) and K + HBr ($E_a \sim 0.4$ kcal/mol (10)). Barrier heights derived from a semiempirical valence bond treatment (6) are clearly much too high (~10–15 kcal/mol above zero-point endoergicities for K, Cs + HCl). Our data do not show the predicted increase with alkali atomic number nor any evidence for significant H atom tunneling, as E_a lacks an appreciable isotope effect.

Trajectory studies are needed to examine whether our items

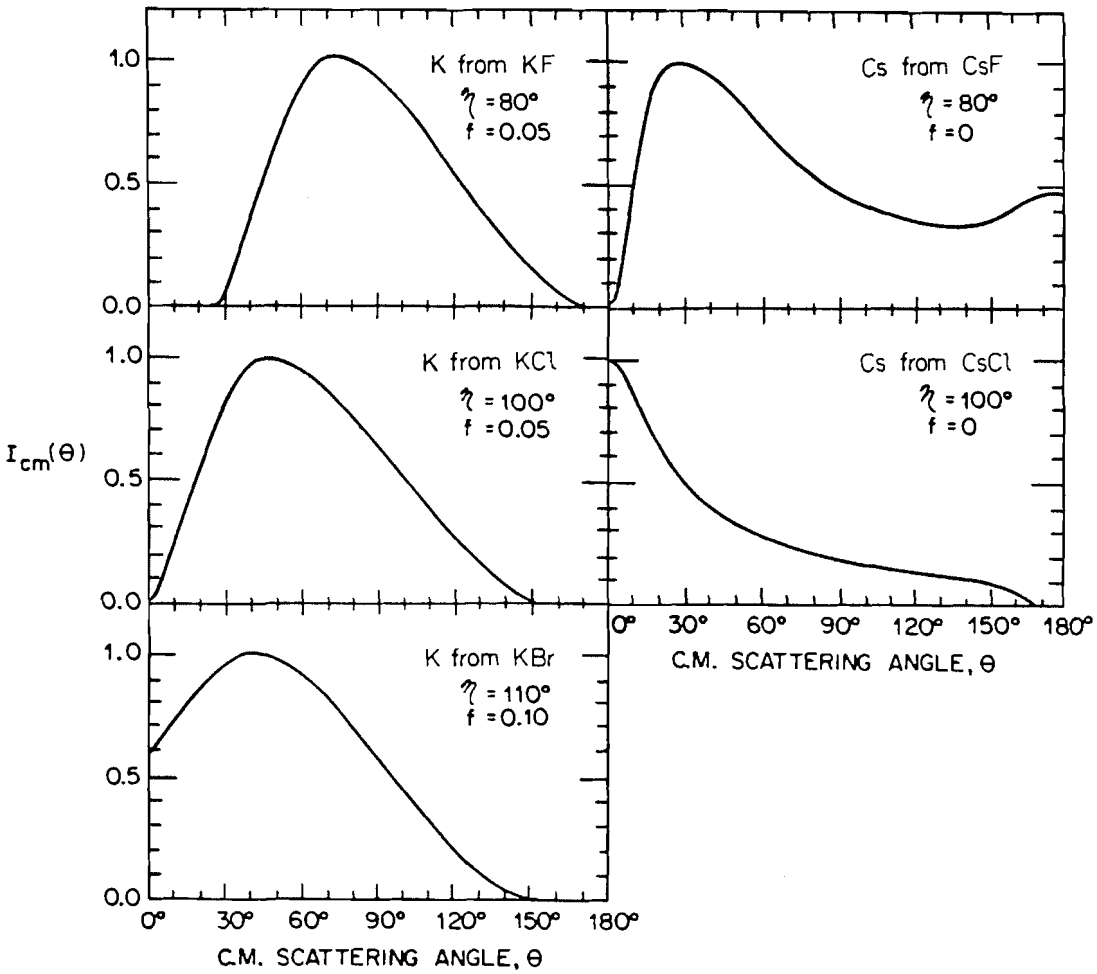

FIG. 11. Impulsive model results for M atom angular distributions in the cm system corresponding to Fig. 10 (dot-dashed curves for K, dashed for Cs).

(1)–(3) as well as the many other properties of M + HX systems now known can be reconciled with scaled versions of the available potential energy surfaces. Although several trajectory calculations have been carried out for the Li + HF system, most used a surface with poor asymptotic behavior that produced misleading results (39). This favorite reaction family deserves more comprehensive computer experiments, in the style pioneered by Polanyi (8), to search for what he likes to call "simple stories."

Acknowledgments

With joy we dedicate this paper to John Polanyi, in awe of his exquisite, insightful work and with gratitude for his inspiring example as scientist and citizen and for his warm friendship. We thank Yuan Lee, George Fisk, Walt Miller, Sanford Safron, Bill Stwalley, and Arendt Niehaus for many instructive suggestions; Doug Carlson for cheerful help with some of the experiments; and the National Science Foundation for financial support.

Received August 12, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

J.R. MORTON, F. NEGRI, and K.F. PRESTON. Can. J. Chem. **72**, 776 (1994).

The EPR spectra of a series of C_{60} adducts of the type R_3C_{60} are described and discussed. In every case, two of the three ligands are equivalent, leading to the conclusion that the R_3C_{60} radicals have a plane of symmetry. The unpaired electron distributions in mono- and trisubstituted-C_{60} radicals are computed with the help of the QCFF/PI and MNDO Hamiltonians. It is shown that the hyperfine constants predicted on the basis of the calculated spin densities reproduce well the values observed and suggest a reassignment of framework ^{13}C coupling constants in RC_{60}.

J.R. MORTON, F. NEGRI et K.F. PRESTON. Can. J. Chem. **72**, 776 (1994).

On décrit et on discute des spectres rpe d'une série d'adduits C_{60} du type R_3C_{60}. Dans tous les cas, deux des trois coordinats sont équivalents; ceci conduit à la conclusion que les radicaux R_3C_{60} possèdent un plan de symétrie. Utilisant des hamiltoniens QCFF/PI et MNDO, on a calculé les distributions de l'électron non paire dans les radicaux mono- et trisubstitués-C_{60}. On montre que les contantes hyperfines prédites sur la base des densités de spin calculées reproduisent bien les valeurs observées et elles suggèrent une réattribution des constantes de couplage du ^{13}C du squelette du RC_{60}.

1. Introduction

Our first report (1) of alkyl radical addition to C_{60} concerned the detection by EPR spectroscopy of R_3C_{60} and R_5C_{60}, where R = the benzyl radical, $CH_2C_6H_5$. It seemed at the time that their precursor, $C_6H_5CH_2C_{60}$, and mono-adducts generally, would be difficult to detect because of their reactivity. Subsequent work (2–4) has shown however that, given the right conditions, a wide variety of monoalkyl- and monosilyl-C_{60} radicals can readily be detected. Curiously, it has proven difficult to detect further examples of those types of adducts first observed (R_3C_{60} and R_5C_{60}), in spite of the fact that multiple addition of methyl radicals (1) and hydrogen atoms (5) to C_{60} has been established by mass spectrometry.

In this article we present the EPR spectra of six radicals of general formula R_3C_{60}, including the prototype, H_3C_{60}, and we analyze the experimental results on the basis of quantum-chemical calculations of spin densities. In section 3.1 we show that the EPR spectra are accounted for by assuming an allyl-like structure for the R_3C_{60} radicals. In section 3.2 we present calculations of the spin density distribution for H_3C_{60} and HC_{60} radicals performed by using the semi-empirical QCFF/PI (6) and MNDO (7) Hamiltonians. Finally, the results of the calculations are analyzed and compared with the observed H and ^{13}C hyperfine couplings (hfc) in section 4.

2. Experimental

Pure C_{60} was purchased from Texas Fullerenes, Houston, TX. Reagents enriched in ^{13}C were purchased from CDN Isotopes Inc., Vaudreuil, Que. Saturated solutions (typically 0.003 molar) of C_{60} in various dried, degassed solvents were prepared and stored in a glove-box continuously flushed with dry argon. A 300 mm^3 aliquot of the stock solution was transferred to a 5 mm O.D. Suprasil™ EPR tube fitted with a greaseless stopcock. Other reagents were added to the sample with a microsyringe. The radicals which we identify as R_3C_{60} radicals were generated by UV photolysis of solutions containing dissolved C_{60} and a precursor of the radical R. The radicals R were generated by several methods (8), including photolysis of a ketone R_2CO, an aldehyde RCHO, a chloride RCl, or a bromide RBr (Table 1). Alternatively, an indirect method was used, involving photolysis of di-*tert*-butylperoxide, forming *tert*-butoxy radicals capable of abstracting a hydrogen atom from a hydrocarbon RH.

The solutions were photolysed with the focused light from a Schoeffel 1000 W high-pressure Hg/Xe lamp filtered though water to remove infrared radiation. The photolysis was carried out inside the cavity of the EPR spectrometer, a Varian E-12 instrument fitted with the usual accessories for readout of the temperature of the sample, the microwave frequency and the magnetic field strength. The spectrometer was also equipped with a multichannel analyser for signal/noise improvement. This device was obtained from Scientific Software Services, Bloomington, IL. The spectrometer was operated in the critically coupled mode, and it was necessary to vary the experimental conditions, particularly the temperature and microwave power, in order to optimise the spectra.

3. Results

3.1. *Identification of R_3C_{60} radicals*

It is apparent from the hyperfine interactions listed in Table 1 that three alkyl groups have attached themselves to the C_{60} surface, and that two of them (R) are equivalent and distinct from the third (R′). In five of the six cases, R = R′, and the hyperfine interactions associated with R are very much larger than the corresponding hyperfine interactions of R′. In the sixth case (photolysis of ^{13}C-enriched CCl_4/C_{60}) it seems probable (see below) that the unique ligand R′ is different from the other two.

We have explained elsewhere (3) that the icosahedral symmetry of C_{60} is lowered to C_s by the addition of a single ligand R. In seeking a structure for trialkyl-C_{60} radicals, we are clearly dealing with a similar situation: a species belonging to the C_s point group. Only under this assumption can we accommodate two equivalent ligands R (lying on either side of the symmetry plane), and a unique ligand R′ (lying on the symmetry plane). The structure we propose for trialkyl-C_{60} radicals is shown in Fig. 1. It conforms to the requirements of C_s symmetry, with the symmetry plane passing through R′, C_6, and C_1.

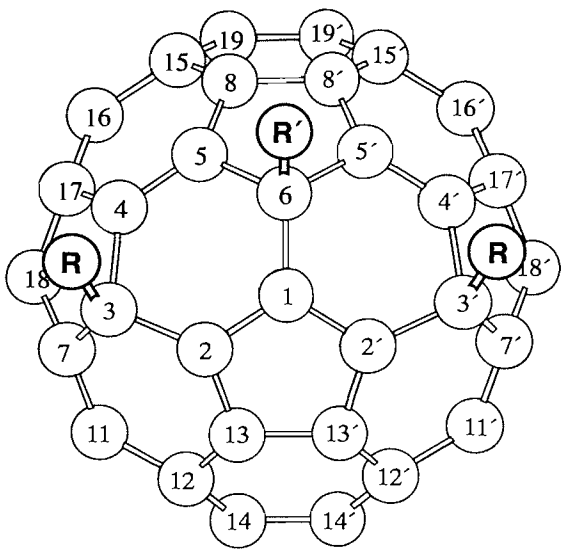

FIG. 1. Atom numbering for the R_3C_{60} radicals. In RC_{60}, R is on C_6 only.

It is interesting to note that this structure is also supported by calculations of the HC_{60} spin density distribution which have recently appeared in the literature (10–13). In fact, most of the theoretical results predict relatively large spin density on the C_3 and $C_{3'}$ carbons of HC_{60} (H on C_6). As a consequence, these positions are particularly reactive and are likely to promote the formation of the H_3C_{60} isomer shown in Fig. 1. Because of the substituents' position, the spin density distribution of the latter radical is expected to be qualitatively similar to that of an allyl radical (9). This deduction is supported by recent MNDO calculations of its unpaired electron distribution (10). Thus, in contrast to monoalkyl-C_{60} radicals, which have a $^2A'$ ground state, trialkyl-C_{60} radicals have a $^2A''$ ground state.

The spectrum of tribenzyl-C_{60} was so powerful that ^{13}C hyperfine structure could be detected in natural abundance,

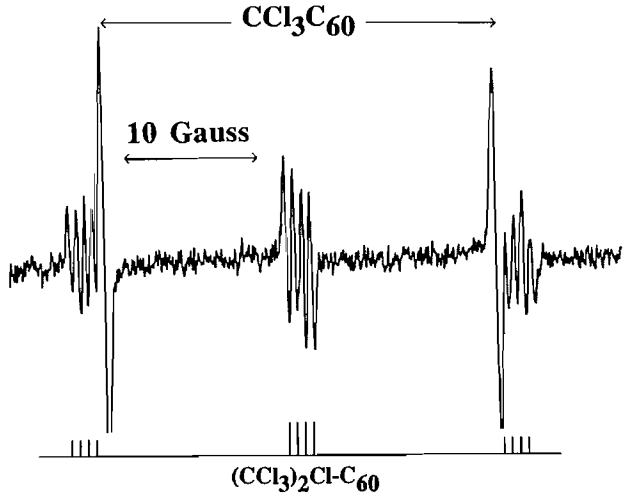

FIG. 2. The EPR spectrum of ^{13}C-enriched $(CCl_3)_2ClC_{60}$ and CCl_3C_{60} in CCl_4 at 325 K.

hyperfine interactions of 19.8, 13.1, and 9.7 Gauss (G) being observed (1). Using toluene enriched in ^{13}C on the α carbon atom, it was seen that the 9.7 G hyperfine interaction originated with the equivalent R (= $^{13}CH_2C_6H_5$) groups, and that there was a smaller interaction of 1.75 G due to R′ (also $^{13}CH_2C_6H_5$). The remaining hyperfine interactions were assigned to C_1 (13.1 G) and C_2, $C_{2'}$ (19.8 G) on the C_{60} surface. This assignment was made by comparison of these hyperfine interactions with those of the allyl radical itself: C_1 = 17.2 G, $C_2 = C_{2'}$ = 21.9 G (9). The correlation between the ^{13}C data of the allyl radical and of tribenzyl-C_{60} confirmed that an allyl-like structure for the latter is a reasonable assumption.

In the case of $(CBr_3)_3C_{60}$, ^{13}C enrichment established the presence of three CBr_3 ligands, two of one kind and one of another, characteristic of an allyl configuration. The same is true of the spectrum of $(CF_3)_3C_{60}$: six equivalent ^{19}F nuclei nuclei have 0.36 G hyperfine interactions (the terminal CF_3 groups), those of the central CF_3 group being unresolved. For R = CCl_3 however, ^{13}C enrichment indicated that R′ was *not* CCl_3 since the expected (small) ^{13}C interaction was not present; instead a hyperfine interaction with a single Cl nucleus was observed. We conclude, therefore, that the spectrum is that of $(CCl_3)_2ClC_{60}$. The initially formed adducts are presumably ClC_{60} and CCl_3C_{60}. The latter was observed, and is stable in the dark (Fig. 2). The former has never been observed. Presumably, ClC_{60} reacts rapidly with chlorine atoms to form diamagnetic products, but when it reacts with CCl_3 radicals $(CCl_3)_2ClC_{60}$ is formed. It, too, is stable with the UV off (Fig. 2). It would appear that the stability of CCl_3C_{60} and $(CCl_3)_2ClC_{60}$ is due to shielding of their reaction sites by the bulky CCl_3 group(s).

It has been suggested that C_{60} or derivatives thereof are present in interstellar space (14, 15) and that hydrogenated C_{60} molecules are carriers of the diffuse interstellar bands in the visible (16) and ultra-violet (17) regions of the spectrum. If it turns out that fullerenes generally, and C_{60} in particular, are present in the interstellar medium, it is possible that the zero-field emissions of HC_{60} and H_3C_{60} eventually will be detectable by radiotelescopes. The zero-field emission of HC_{60} is at 94 MHz (18), a not particularly convenient region of the spectrum, being in the middle of the FM broadcast band. In H_3C_{60} the two equivalent protons have hyperfine interactions of 18.6 G, or 52.1 MHz. The zero-field emission of the $F = 1.5 \rightarrow 0.5$ transition

will therefore be at $1.5 \times 52.1 = 78$ MHz, just outside the FM band and therefore a more attractive proposition to radioastronomers.

3.2. *Radical structures and spin density distributions*

Among the fullerenyl radicals, HC_{60} has been the subject of a considerable number of theoretical studies (10–13, 19), most of which deal with the stability of the exo-radical and the interpretation of the observed μSR spectrum of MuC_{60}. The structures obtained by semi-empirical (10, 11) or *ab initio* methods (12, 13) indicate a localization of the distortion close to the hydrogen atom. A more extensive analysis of the addition of H and F to C_{60} and the stability of polysubstituted-C_{60} has been recently published by Matsuzawa and co-workers (10), who studied up to penta-substituted derivatives using the MNDO Hamiltonian. The authors also compare in a qualitative way calculated spin densities with observed EPR data. However, no attempt has been made to analyze the H and ^{13}C hfc observed for RC_{60} and R_3C_{60}, on the basis of quantum-chemical calculations.

The aim of this study is to show that the spin density distributions calculated for both radicals are consistent with the corresponding EPR spectra. To this end we have calculated the equilibrium structures and unpaired electron distributions of the two prototype radicals, HC_{60} and H_3C_{60}, using a modified version (20) of the QCFF/PI program (6). This model is based on the σ–π separation and uses a quantum chemical scheme only for the π electrons, while it simulates the σ electrons by an empirical potential. The modified version (20) adopted here can perform Half-Electron Self Consistent Field (HE-SCF) calculations (21) followed by Configuration Interaction (CI) for electronic states of any multiplicity. Recently, it was used to produce fairly accurate structures and vibrational frequencies for C_{60} (22), C_{70} (23), and C_{60}^{6-} (24).

The equilibrium structures of the ground state of the two radicals were obtained by using the HE-CI method. Test calculations, performed with various CI dimensions, indicated that the ground configuration is the only determinant that contributes significantly to the ground-state wavefunction (coefficient = 0.99). Hence, all calculations were performed by including a rather small number of determinants. The calculated bond lengths showing the largest deviations from the equilibrium C_{60} structure (1.411 Å and 1.471 Å (22)) are presented in Table 2. Inspection of Table 2 shows that the structures predicted by QCFF/PI are essentially similar to those obtained by previous calculations (10–13). A comparison of the structures calculated for the HC_{60} and H_3C_{60} radicals indicates, as expected, that the distortion of the latter introduced by the additional two hydrogen atoms is larger than for HC_{60}. However, in agreement with MNDO results (10), the distortion is still mainly localized close to the hydrogen atoms.

The spin density distributions listed in Table 3 were calculated for the optimized structures of the two radicals using the QCFF/PI and the MNDO wavefunctions, both obtained by the HE-CI procedure. Because of the RHF nature of the orbitals employed in the calculations only positive, i.e. α spin densities are obtained and spin-polarization contributions are not included. As a consequence, the spin densities shown in Table 3 represent a lower limit for the true positive spin population. However, we are confident that the relative values of the predicted densities are reliable: model calculations on the cyclohexadienyl radical assign 0.42 and 0.26 to the *para* and *ortho* carbon atoms, respectively. Although the absolute values are

[e]R = R' = H.

underestimated by ~20%, the ratio of the two densities, 1.6, compares very well with the ratio of the experimentally deduced spin densities (1.5) (25, 26).

The HC_{60} spin densities listed in Table 3 indicate that the unpaired electron is localized in the neighborhood of the hydrogen atom, with the largest contribution on C_1 followed by C_3 and $C_{3'}$. These predictions are in close agreement with previous semi-empirical calculations (10, 11) and with recent *ab initio* studies (12, 13), although the latter predict an even larger localization on C_1. Among the several calculations, only the PRDDO/UHF results (19) indicate a spin density delocalized over the entire ball. We obtained a similar result by using the MNDO/UHF wavefunction to calculate spin densities, but the spin contamination was so large that the predictions are deemed completely unreliable.

It is interesting to note, as shown in Table 3, that the spin densities calculated by us (columns 1, 2 in Table 3) are very close to those calculated using the MNDO Hamiltonian combined with an RHF approach, and the ROHF (10) or the UHF (11) geometries. Since UHF/MNDO (11) ROHF/MNDO (10) and our HECI/QCFF/PI geometries are somewhat different, this indicates that the spin density distribution is almost independent of the structure, for a relatively large range of HC_{60} structures.

As expected, the spin distribution of H_3C_{60} is rather different from that predicted for HC_{60}. As in the allyl radical itself, the spin density is mainly located on C_2 and $C_{2'}$. However, the calculations also predict a considerable contribution on C_{12} and $C_{12'}$ carbon atoms. As for HC_{60}, our results for H_3C_{60} agree with those obtained at the MNDO-optimized geometry (10). It is worth noting that the prediction of a considerable spin density on C_{12} and $C_{12'}$ provides an explanation for the R_3C_{60} reactivity leading to the formation of the observed penta-substituted R_5C_{60} cyclopentadienyl radicals (1).

4. Discussion

In the previous section we have shown that the results of our calculations provide a picture of the spin density distribution that is in close agreement with most of the studies appearing in the literature. The considerable number of theoretical studies and the qualitative agreement among the predictions made by different methods encourage us to analyze more closely the extent to which the calculated spin densities can account for the experimentally observed hfc.

One of the problems addressed here is the spin population carried by C_1, C_5, and $C_{5'}$, atoms identified by the usual Kekulé formulations as primary locations for the unpaired spin in HC_{60} and its derivatives. There would appear to be a discrepancy between the amount of unpaired electron on these nuclei predicted by the calculations and deduced from EPR experiments (1). A second problem pertains to the spin population on C_2 and $C_{2'}$ in H_3C_{60}. The magnitude of the observed hfc seems to indicate that the spin population on these atoms should be close to that of the allyl radical, while calculations indicate a smaller amount.

In the first part of this section we attempt to shed some light on this subject by establishing a correlation between the observed hfc of mono- and tri-substituted-C_{60} derivatives. In the second part of the discussion we show that the results predicted by the calculations are indeed in satisfactory agreement with the observed H and ^{13}C hfc, and that they suggest a possible reassignment of some of the observed hyperfine interactions to different nuclei.

The proton in HC_{60} (H on C_6) is a "β proton" vis-a-vis the spin-carrying (α) carbons C_1, C_5 and $C_{5'}$. Many years ago Whiffen (27) pointed out that the correct procedure for predicting the β-proton hyperfine splitting in organic π radicals with multiple spin-bearing α carbons is to square the sum of the α-carbon coefficients in the SOMO before multiplying by the conversion factor Q_H:

$$[1] \quad a_H = Q_H \times \left[\sum_o c_o\right]^2$$

where the subscripts indicate that the summation covers only atoms *ortho* to C—H. An identical equation in a_C and Q_C applies to ^{13}C in a ^{13}C—C_{60} configuration. Attention has been recently drawn to Whiffen's relation by Percival and co-workers (11) who compared computed spin densities and observed hyperfine interactions in fullerenyl radicals. The empirical equation [1] has indeed a theoretical justification and it is a legitimate extension of the McConnell relation (28) for those nuclei that bear a fraction of the unpaired electron because of the hyperconjugation effect (29). By applying relation [1] to the hfc of the mono- and trisubstituted-C_{60} radicals, we can obtain a qualitative estimate of $[\Sigma_o c_o]^2$ for the SOMO of the two radicals. The value of Q_H for a β-proton eclipsed by the semi-occupied $2p$ orbital on the adjacent carbon is ca. 50 G (30). In HC_{60} the proton is required by the structure to eclipse $2p$ orbitals whether on C_1, C_5, or $C_{5'}$. Bearing in mind the distinction between organic π-radicals and HC_{60}, we note that with a_{1H} = 33 G in HC_{60}, a Q_H of 50 G implies $(c_1 + 2c_5)^2$ = 0.66, indicating a considerable dispersal of the unpaired spin away from these carbons (c_1 and c_5 SOMO coefficients have the same sign). If we use the hydrogen hyperfine splittings of H_3C_{60} (18.7 G) and the same Q_H we obtain a value of 0.37 for $(c_2 + c_4 + c_7)^2$ which indicates a significant delocalization of the unpaired electron for trisubstituted-C_{60} radicals also.

Besides the actual magnitude of $[\Sigma_o c_o]^2$, which depends on the value assumed for Q_H or Q_C, eq. [1] provides a useful relation between the hfc observed for mono- and trisubstituted-C_{60} radicals. The values of a_{1H}, a_{2H}, a_{1C}, and a_{2C} for R = H and various alkyls are listed in Table 4. Plotting a_{1H} or a_{1C} against a_{2H} or a_{2C} gives the graph shown in Fig. 3, where the data points are fitted to a least-squares straight line whose slope is 1.99 ± 0.10. According to eq. [1], and with the reasonable assumption that the Q_X (X = H, C) constants are the same for mono- and trisubstituted-C_{60} radicals, the value of the slope in Fig. 3 indicates that

$$[2] \quad \frac{(c_1 + 2c_5)^2}{(c_2 + c_4 + c_7)^2} = \sim 2$$

for all the observed pairs of radicals. An obvious explanation of this experimental result is that the distribution of the unpaired electron on the C_{60} surface is substantially independent of the chemical nature of the substituent, and that, to a good approximation, it is determined only by the number and position of the substituents.

The latter observation is of some relevance: first, it indicates that calculations performed for the prototype radicals can be used to interpret the EPR spectra of other mono- or trisubstituted-C_{60} radicals. Second, it provides a criterion with which to assess the reliability of the theoretical predictions. A primary requirement of the calculations is that they lead to a value of ratio [2] close to 2.

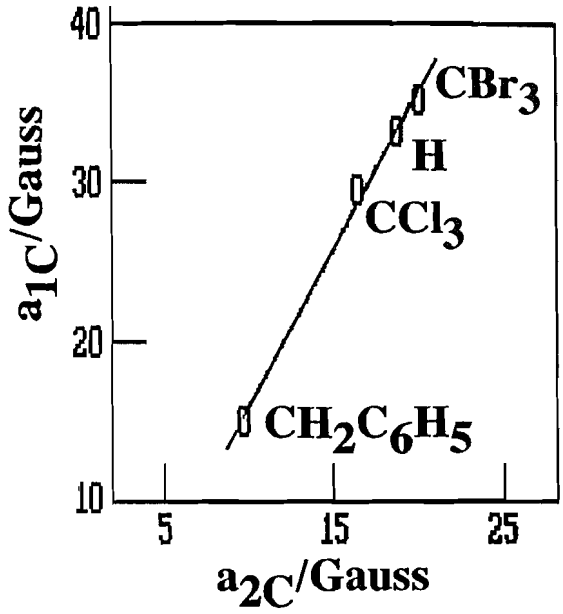

FIG. 3. Graph of a_{1H} and a_{1C} in HC_{60} and RC_{60} radicals against a_{2H} and a_{2C} in H_3C_{60} and R_3C_{60} radicals. The line is a least-squares fit to the data. The labels beside each point identify the ligands H and R.

It is interesting to note that a ratio of 2 would be obtained by assuming the most simplistic distribution of the unpaired electron for the two radicals, namely 1.0 spin density on C_1 for HC_{60} and 0.5 on C_2 and $C_{2'}$ for H_3C_{60}. As a consequence, if we assume that the unpaired electron in H_3C_{60} is localized only on C_2 and $C_{2'}$, as the comparison between hfc for H_3C_{60} and the allyl radical would suggest, and we assume a 0.58 spin density (9) on each of the two nuclei, we are led to the conclusion that the HC_{60} spin density on C_1 should be close to 1.2, a value not compatible with the observed isotropic $^{13}C_1$ hyperfine coupling (17.8 G). This supports the results of the calculations, which predict some delocalization of the unpaired electron for both radicals.

To evaluate relation (2) we employ the spin densities obtained by the QCFF/PI method. As already pointed out, these spin densities are very close to those obtained here and in previous studies (10, 11), using the MNDO Hamiltonian. However, we choose to use the QCFF/PI wavefunction because it conforms more strictly to the assumption of a perturbative description of the hyperconjugation effect implicit in eq. [1]. In fact, spin densities are calculated by QCFF/PI only for the sp^2 carbon atoms, since only p electrons are described quantum-chemically by the method. On the other hand, MNDO calculates spin densities for all the atoms. In terms of perturbation theory, QCFF/PI densities are obtained from a zero order wavefunction, without the inclusion of the perturbation due to the hydrogen atoms, which is described by eq. [1]. On the other hand, MNDO spin densities do include the perturbation, i.e., they account for the hyperconjugation effect, and thus for the appearance of a non-zero spin density in the $1s$ hydrogen and $2s$ carbon orbitals.

By using the c_o coefficients deduced from columns 1 and 5 in Table 3 we obtain $[\Sigma_o c_o]^2$ = 0.70 for HC_{60}. For H_3C_{60}, $[\Sigma_o c_o]^2$ = 0.41 (by including only C_2 and C_7 contributions) or $[\Sigma_o c_o]^2$ = 0.39 (by including also the negative contribution of

[e]Tentative assignment.

the coefficient of atom C_4, bearing a spin density of 0.0003). Hence, the predicted ratio (2) is 1.71 or 1.82, respectively, in very good agreement with the slope of Fig. 3, and, in particular, in excellent agreement with the experimental ratio a_{1H}/a_{2H} = 1.77.

Similar values for the ratio of coefficients squared in relation [2] are obtained by using the spin densities on the C_{60} surface calculated by the MNDO method. In addition, MNDO results provide a double check by means of the predicted H 1*s* spin densities, which are directly proportional to the H hfc. The ratio of the 1*s* H spin densities listed in Table 3, 0.021/0.012 = 1.75, is also in excellent agreement with the experimental value of a_{1H}/a_{2H}. Although the absolute values of these spin densities are underestimated, it is worth noting that this tendency of the semi-empirical method can be corrected by scaling the calculated spin densities. In fact, a similar calculation for the cyclohexadienyl radical predicts a spin density of 0.032 on the β proton. Hence, the calculated ratio of the β proton hfc in cyclohexadienyl and that of HC_{60} is 0.032/0.021 = 1.52 which compares very well with the ratio of the observed hfc: 48 G/ 33 G = 1.45.

The above discussion indicates that the calculated spin distributions account for the observed H and ^{13}C—C_{60} hfc of RC_{60} and R_3C_{60}. We have also estimated the hfc of the C_{60} carbon atoms using the Karplus–Fraenkel relation (31)

$$[3]\quad a_C = \left(S^C + \sum_{i=1}^{3} Q^C_{CC'}\right)\rho^\pi + \sum_{i=1}^{3} Q^C_{C'C}\rho^\pi_i$$

and assuming $Q^C_{CC'} = -20.9$ G, $Q^C_{CC'} = 30.0$ G (32) and the standard value of −12.7 G for the S_C parameter. We use the above values for the former two parameters, deduced for bond lengths of 1.50 Å (32), according to most of the calculated bond lengths close to the substituents. Inspection of the computed hfc, listed in Table 5, shows a close agreement with the experimental data, also listed in Table 5: the largest hfc of both radicals are satisfactorily reproduced by the calculations. In particular, the computed hyperfine splittings indicate that one of the two hfc observed at ~9 G for HC_{60} and previously assigned to C_5 should be reassigned to C_2. It is interesting to note that a similar conclusion is also supported by recent *ab initio* calculations (12, 13). Although these calculations predict too large a hfc for C_1, they indicate similar hfc for atoms C_2 and C_3. In addition, comparison of the calculated hfc of H_3C_{60}, listed in Table 5, indicates that the hyperfine splitting observed at 13.1 G may arise from carbons (C_1, C_{12}, $C_{12'}$) that are accidentally equivalent. The experimental determination of the sign of the hyperfine splittings will be of crucial importance to substantiate the reassignments proposed here. Relative sign determination for H and ^{13}C is possible, in principle, by muon level-crossing (26) or ENDOR experiments. The consistency of the present results is of particular importance since it indicates that semi-empirical predictions of the spin distributions for such large systems are reliable.

Bond energies for cationic bare metal hydrides of the first transition series: a challenge to density functional theory

TOM ZIEGLER AND JIAN LI

Department of Chemistry, University of Calgary, Calgary, AB T2N 1N4, Canada

Received July 19, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

TOM ZIEGLER and JIAN LI. Can. J. Chem. **72**, 783 (1994).

Density functional methods based on the Local Density Approximation (LDA) and its nonlocal extensions (LDA/NL) are used to calculate the bond energies, as well as the bond lengths and vibrational frequencies of the high spin, open shell first-row transition metal hydride cations MH^+. The $D_{298}(M^+—H)$ LDA/NL bond energies are in good agreement with experiment for the early transition metals with errors within 5 kcal/mol. However, the error increases to 6–13 kcal/mol for the late metal hydrides. An analysis based on atomic properties such as 4*s* ionization potentials and 4*s* to 3*d* promotion energies revealed that the large error in bonding energies among the late transition metals can be attributed to an overestimation of the exchange energy in the DFT schemes. It is shown that a simple remedy, based on a thermodynamic cycle, can improve the agreement between experimental and theoretical bond energies. However, simple cationic bare metal complexes such as MH^+ remains a challenge to approximate DFT.

TOM ZIEGLER et JIAN LI. Can. J. Chem. **72**, 783 (1994).

On a utilisé des méthodes de densité fonctionnelle basées sur l'approximation de la densité locale (LDA) et ses extensions non locales (LDA/NL) pour calculer les énergies de liaison, ainsi que les longueurs de liaison et les fréquences vibrationnelles de spin élevé, des cations, MH^+, des hydrures des métaux de transition de la première rangée avec une couche ouverte. Les énergies de liaison $D_{298}(M^+—H)$ LDA/NL sont en bon accord (avec des erreurs inférieures à 5 kcal/mol) avec les résultats expérimentaux pour les premiers métaux de transition. Une analyse basée sur les propriétés atomiques telles que les potentiels d'ionisation 4*s* et les énergies de promotion de 4*s* à 3*d* révèlent que l'erreur importante dans les énergies de liaison observée avec les derniers métaux de transition peut être attribuée à une surévaluation de l'énergie d'échange dans les schémas DFT. On montre qu'un remède simple, basée sur un cycle thermodynamique, peut améliorer la concordance entre les énergies de liaison expérimentales et théoriques. Toutefois, avec des complexes métalliques cationiques simples, tels que MH^+, l'approximation du DFT demeure un défi.

[Traduit par la rédaction]

I. Introduction

Accurate data on metal–hydrogen (and metal–carbon) bonds are essential for a quantitative assessment of reaction enthalpies in organometallic processes and might even help addressing mechanistic issues. The efforts to obtain accurate bond enthalpies in this field was pioneered by Skinner (1*a*), Pilcher and Skinner (1*b*), Halpern (1*c*), and Connor (1*e*). Since then, organometallic thermochemistry has grown into a vast body of data with the aid of an impressive arsenal of experimental methods. This development has most recently been reviewed by Simoes and Beauchamp (1*d*).

Theoretical methods have had considerable success in providing accurate data on bond strength of small organic molecules. Thus, Pople and co-workers (2, 3) have recently shown that enthalpies of formation for small organic molecules can be calculated within chemical accuracy (± 2 kcal mol^{-1}) in the "Gaussian-1" (G1) as well as the revised "Gaussian-2" (G2) methods. Bond dissociation energies for simple diatomic metal hydrides can also be calculated to the same degree of accuracy (4). However, G2 calculations on larger organic molecules, let alone transition metal complexes, are still impractical.

Becke (5) has in a series of seminal papers, shown that methods based on Density Functional Theory (6, 7) (DFT) afford bond energies of nearly the same quality as the G2 *ab initio* technique. Becke's investigation made use of a DFT approach in which the Local Density Approximation (LDA) (8, 9) has been augmented by nonlocal (10–15) corrections, LDA/NL. DFT-based calculations on bond energies for small organic molecules have also been carried out by others (16).

The LDA/NL method has recently been implemented at the self-consistent level (17) and applied to molecular structures (18). It was demonstrated (17, 23) that nonlocal corrections greatly improves the accuracy of metal–ligand and metal–metal bond distances. Studies on transition state structures have also been carried out by the nonlocal method (19). DFT-based methods have in addition been applied successfully to studies on IR spectra of main group molecules (20) and transition metal complexes (21).

Our knowledge of metal–hydride (and metal–alkyl) bond dissociation energies comes from studies of two distinctly different classes of compounds. The first involves 18-electron RML_n systems where the metal centre is coordinatively saturated by ancillary ligands other than the R group. The second class comprises bare metal complexes, M—R, in which the metal centre is coordinatively unsaturated. The 18-electron systems have a direct bearing on the kind of compounds normally studied in organometallic chemistry. However, only a few experimental M—R bond energies are available from this category. We have in previous studies (22, 23) validated the nonlocal method with respect to the sparse experimental data from 18-electron systems. It was concluded that the LDA/NL scheme for this type of compounds afford M—R bond energies within ± 5 kcal/mol of experiment.

The number of accurate M—R bond energies among the coordinatively unsaturated M—R complexes is large in comparison to the saturated 18-electron systems, thanks to several new experimental gas phase techniques developed over the last decade (1*d*, 24). However, there has been surprisingly few (25) DFT-based calculations on bare atom complexes in spite of their small size, and no systematic evaluation has been undertaken on the ability of DFT methods to reproduce experimental findings for this class of compounds.

We shall here consider the smallest of the bare metal complexes, the MH^+ hydrides. We shall demonstrate that bond energies in these systems are poorly described by the existing DFT-based methods for hydrides of late transition metals, in contrast to M—L bond strength among the saturated 18-electron complexes. The error sources will further be analysed by performing calculations on the electron affinities and $4s$ to $3d$ promotion energies of the cations, M^+. The main objective of this study has been to point to a series of molecules that can serve as a testing ground for improvements of the existing DFT-based methods.

II. Computational details and basic theory

The reported calculations were all carried out by utilizing the HFS-LCAO program system A-MOL, developed by Baerends et al. (26, 27*a*) and vectorized by Ravenek (27*b*). The numerical integration procedure applied for the calculations was developed by te Velde et al. (28). The geometry optimization procedure was based on the method implemented by Versluis and Ziegler (29). Vibrational frequencies were evaluated from force constants calculated by numerical differentiation of the energy gradients (20*e*). The electronic configurations of the molecular systems were described by an uncontracted triple-ζ STO basis set (30) on the metal ($3d$, $4s$, and $4p$) as well as a double-ζ STO basis set (30*b*) on hydrogen ($1s$). Hydrogen were given an extra polarization function: $2p_H$ ($\zeta_{2p} = 2.0$). The $1s^2 2s^2 2p^6$ configuration on the metal centers was assigned to the core and treated by the frozen-core approximation. A set of auxiliary (31) s, p, d, f, and g STO functions, centered on all nuclei, was used to fit the molecular density and present Coulomb and exchange potentials accurately in each SCF cycle.

We have compared results from different levels of DFT. The simplest is the Xα or Hartree–Fock–Slater scheme (8) in which the exchange correlation energy is approximated by Slater's exchange expression from the homogeneous electron gas without considering the corresponding correlation term. In the Local Density Approximation (LDA) (9*a*), both exchange and correlation from the homogeneous electron gas are included based on the parametrization due to Vosko et al. (9*b*). Stoll et al. (32) have pointed out that the LDA approximation exaggerate correlation between electrons of the same spin. They have suggested that this correlation be removed altogether. Two nonlocal corrections will be considered. The first is the exchange correction due to Becke (13*d*), and the second Perdew's (14*c*) correction to correlation. We shall refer to the scheme included Becke's and Perdew's corrections as LDA + B + P. The two nonlocal corrections take into account that the density in atoms and molecules is inhomogeneous. Perdew's correction removes, in addition, the deficiencies in the original LDA scheme pointed out by Stoll et al. (32). The application of approximate density functional theory to organometallic chemistry has been reviewed recently (6, 33).

The state energies for molecules and atoms were evaluated by the multiplet method due to Ziegler et al. (34) using nonspherical densities (35) and a complex representation (36) of the orbitals. As examples, the ^4F state of $Ti^+(4s^1 3d^2)$ was described by the state function $|\bar{4}_s^+ 3\bar{d}_2^+ 3\bar{d}_1^+|$ whereas the $^3\Phi$ state of TiH^+ is represented by $|\bar{\sigma}^+ \bar{\sigma}^- \bar{\phi}_2^+ \bar{\pi}_1^+|$.

III. Results and discussion

The formation of MH^+ from M^+ and H involves the pairing of an electron on M^+ of, say, α-spin with an electron on H of β-spin. The pair will be situated in a M—H σ-bonding orbital, σ_{MH}. The additional electrons on M^+ are only slightly perturbed as MH^+ is formed and remain in d-based orbitals retaining their spin polarisation. The energetics of this spin-pairing process have several contributions. In the first place, the spin pairing increases the stabilisation due to the correlation energy between electrons of opposite spins by $\Delta E_{XC}^{\alpha\beta}$. Further, the number of interacting electrons of the same spin are going to increase in those cases where the metal has additional electron of β-spin. This will be the case for late transition metals, Fe–Cu, and results in a stabilising contribution, $\Delta E_{XC}^{\beta\beta}$, from the exchange part of the exchange-correlation energy. Also, the formation of σ_{MH} might constitute a transfer of charge between M^+ and H or between $4s$ and $3d$. In the first case, we have a stabilising charge transfer contribution, ΔE_{ct}, in the second a stabilising polarisation contribution, ΔE_{pol}.

It is clear from the discussion above that the M—H bond formation is influenced by several factors, and that an accurate determination of the M—H bond energy will require a balanced description of all these factors. We shall now examine how well the different factors are represented in DFT-based methods by comparing atomic energy differences from experiments with the corresponding values evaluated with various levels of DFT theory. The atomic calculations are particularly appropriate since the electronic structure of MH^+ is largely atomic in nature (4*a–d*). Further, atomic studies will allow us to study several of the factors mentioned above, one at a time.

Electron affinities

Table 1 displays the electron affinities (37), A_I, for M^+ anions of the first transition series corresponding to the process

$$[1] \quad 3d^{n-2}4s^1 + e^- \rightarrow 3d^{n-2}4s^2$$

It follows from the discussion above that A_I should have a positive contribution from $\Delta E_{XC}^{\alpha\beta}$ as the $4s^2$ electron pair is formed. There will in addition be a positive contribution to A_I from $\Delta E_{XC}^{\beta\beta}$ among the late transition metals, Fe–Cu, as the

added electron of, say, β spin, interacts with *d*-electrons of the same spin-polarization on M^+. Thus, the process in eq. [1] is in many ways analogous to the formation of MH^+.

Table 1 reveals that the simple HFS scheme (8) underestimates all electron affinities. This is to be expected since the HFS method completely neglects electron correlation between electrons of different spins, and thus lacks the positive contribution to A_I from $\Delta E_{XC}^{\alpha\beta}$. In the LDA case $\Delta E_{XC}^{\alpha\beta}$ is present and we see an increase in the calculated values for A_I. For the early to middle transition metal cations, Sc^+ to Mn^+, the LDA values are in good agreement with experiment. The average deviation is only 0.05 eV. These are the elements for which the contribution from $\Delta E_{XC}^{\beta\beta}$ is absent since the captured electron has a spin polarization different from that of the valence electrons on M^+. Thus, it would seem that LDA provides an accurate estimate of $\Delta E_{XC}^{\alpha\beta}$. On the other hand, the affinities calculated by LDA for the late transition metal cations, Fe^+–Cu^+, are too large. For these elements $\Delta E_{XC}^{\beta\beta}$ becomes important, and we attribute the deviation between theory and experiment to an overestimation of the exchange term $\Delta E_{XC}^{\beta\beta}$. The size of $\Delta E_{XC}^{\beta\beta}$ is to a first approximation, proportional to the number of electrons on M^+ of the same spin as that of the captured electron, and that is mostly likely why the gap between experiment and theory increases from Fe^+ to Cu^+.

Becke's nonlocal exchange correction (13*d*) combined with Perdew's nonlocal correlation correction (14*d*), LDA + B + P, are seen to reduce the calculated electron affinities, Table 1, and improve the agreement with experiment for the late transition metals. Thus, the mean deviation for Fe^+—Cu^+ is reduced from 0.35 eV in the LDA case to 0.12 eV in the LDA + B + P case. However, the affinities remain too large due to an overestimation of $\Delta E_{XC}^{\beta\beta}$. The deviation between experiment and theory would increase by 0.1 eV if relativistic correction were taken into account according to estimates by Kutzler and Painter (35). It is thus clear that nonlocal corrections to the exchange (13*d*) only in part are able to correct the substantial error in the LDA exchange energy.

Kutzler and Painter (35) have previously studied the same series. Their LDA and LDA/NL results are quite similar to ours although they used the nonlocal functional due to Langreth and Mehl (10). However, Kutzler and Painter did not provide an interpretation of their data in terms of $\Delta E_{XC}^{\alpha\beta}$ and $\Delta E_{XC}^{\beta\beta}$. This interpretation is needed here in order to understand the MH^+ results.

Kutzler and Painter (35) have also calculated electron affinities in which a 3*d* orbital is occupied. They found in this case even larger deviations from experiment. It seems that the exchange between electrons in 3*d* orbitals is even more exaggerated than the exchange between electrons in, respectively, 3*d* and 4*s* orbitals. This has already been noted by Gunnarson and Jones (38).

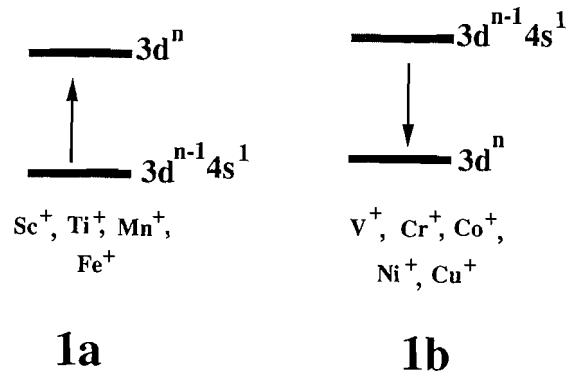
Promotion energies

We have calculated the promotion energy E_{4s-3d} corresponding to the process

[2] $3d^{n-1}4s^1 \rightarrow 3d^n$

for the series of first row transition metal cations. A comparison of calculated and experimental (37) promotion energies should enable us to judge how well DFT-based methods are able to evaluate the term ΔE_{pol} discussed above.

Of the two configurations $3d^{n-1}4s^1$ and $3d^n$, the first is favored by having the smallest electron–electron repulsion whereas $3d^n$ has the most stabilizing exchange energy, at least in the cases where $3d^{n-1}4s^1$ and $3d^n$ have the same numbers of electrons with α and β spins, respectively. Both trends can be attributed to the fact that exchange as well as Coulomb interactions between electrons in the compact *d*-orbitals are stronger than the same interactions between electrons in 4*s* and 3*d* orbitals, respectively, with different radial extents (4*a*).



SCHEME 1

The Sc^+, Ti^+, Mn^+, and Fe^+ cations have a $3d^{n-1}4s^1$ ground state, **1***a*, and thus a positive E_{4s-3d} promotion energy, Table 2, whereas V^+, Cr^+, Co^+, Ni^+, and Cu^+ all have a $3d^n$ ground state, **1***b*, with a negative promotion energy, Table 2 (Scheme 1). The HFS method is seen to underestimate E_{4s-3d} for Ti^+ and Fe^+ with the $3d^{n-1}4s^1$ ground state configuration, **1***a*. The inclusion of correlation, LDA, does not change the calculated values much since the $3d^{n-1}4s^1$ and $3d^n$ configurations have the same number of electrons with α and β spins, respectively.

It appears that the local methods have a bias in favor of $3d^n$ over $3d^{n-1}4s^1$ (Table 2). The bias comes from the exchange energy which is overestimated for both configuration, but most in the $3d^n$ case. This is so (38) since the exchange between electrons in 3*d* orbitals is even more exaggerated than the exchange between electrons in 3*d* and 4*s* orbitals, respectively, as already pointed out by Gunnarsson and Jones (38).

TABLE 3. Bond energies (kcal/mol) of first-row transition metal hydride cations MH^+

	ScH^+	TiH^+	VH^+	CrH^+	MnH^+	FeH^+	CoH^+	NiH^+	CuH^+
Ground states	$^2\Delta$	$^3\Phi$	$^4\Delta$	$^5\Sigma$	$^6\Sigma$	$^5\Delta$	$^4\Phi$	$^3\Delta$	$^2\Sigma$

Exp[b]	57 ± 2	54 ± 2	48 ± 1	33 ± 2	49 ± 3	50 ± 1	47 ± 1	40 ± 2	22 ± 3

[a]The numbers in parentheses (*xyz*) represent the occupation numbers of nonbonding electrons in σ, π, and δ orbitals, respectively.
[b]Reference 1*d*.

It also follows from Table 2 that nonlocal corrections, LDA + B + P, do little to improve the agreement with experiment. Thus these corrections are not able to correct the imbalance in the exchange energies between the $3d^{n-1}4s^1$ and $3d^n$ configurations introduced by the local methods. The same conclusion has been reached by Kutzler and Painter (35).

For the V^+, Cr^+, Co^+, Ni^+, and Cu^+ systems with the $3d^n$ ground state configuration, **1***b*, we see again that HFS favors the $3d^n$ compared to $3d^{n-1}4s^1$. The E_{4s-3d} promotion energies are all too negative, and this trend is not significantly changed by either LDA or the nonlocal LDA + B + P scheme, Table 2.

We shall shortly see how the bias introduced by the local methods in favor of $3d^n$ over $3d^{n-1}4s^1$ is carried over into the DFT description of the electronic structure in MH^+.

The D(M^+—H) bond energy in MH^+

We define the electronic bonding energy $D_e(M^+—H)$ of MH^+ as

$$[3]\quad D_e(M—H^+) = E(MH^+, \text{ground state}) - E(M^+, \text{ground state}) - E(H, {}^2S)$$

For $D_0(M^+—H)$ the vibrational zero point energy correction has been added to $D_e(M—H^+)$. Additional standard rotational, vibrational, and translational corrections were added to evaluate $D_{298}(M^+—H)$ which can be compared directly with experiment (1*d*). The calculated $D_{298}(M^+—H)$ values are compared to experiment in Table 3. The ground state electronic configurations determined by the DFT methods, Table 3, correspond to those obtained previously by Ohanessian and Goddard (4*a*).

We find that the HFS method underestimates $D_{298}(M^+—H)$ for the entire series, and we attribute this to the lack of correlation. Thus, the HFS method completely neglects the positive contribution to $D_{298}(M^+—H)$ from $\Delta E_{XC}^{\alpha\beta}$ due to the pairing of the two electrons in σ_{MH}. This is analogous to the underestimation of A_I by the HFS method due to the neglect of $\Delta E_{XC}^{\alpha\beta}$ from the electron pairing in the $4s^2$ shell.

The $\Delta E_{XC}^{\alpha\beta}$ term is included in the LDA approach and we now find, as expected, an increase in the calculated bond energies. Unfortunately, this increase leads to overbinding, even among the early to middle transition systems. It is a general observation that LDA provides bond energies that are too large (6*a*). In fact, the nonlocal corrections (10–14), LDA + B + P, were introduced in order to remedy this shortcoming. The factors responsible for the overbinding have been analysed by Tschinke and Ziegler (39).

The inclusion of nonlocal correction, LDA + B + P, reduces all calculated bond energies, Table 3, and bring the $D_{298}(M^+—H)$ values for the early to middle transition metals in acceptable agreement with experiment. The bond energies for these systems are now determined with the same accuracy (±5 kcal/mol) as the M—L bond strengths among saturated 18-electron complexes.

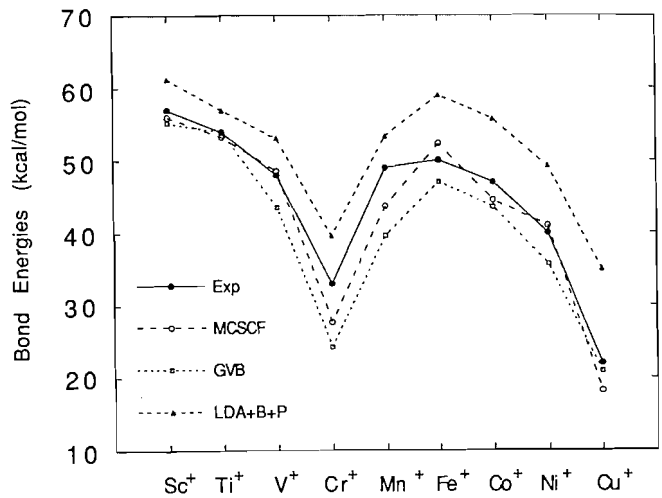

FIG. 1. Calculated and experimental bonding energies for first-row transition metal hydride cations.

However, we note a substantial overbinding at the end of the series for FeH^+, NiH^+, CoH^+, and CuH^+, even after the inclusion of nonlocal corrections. We attribute the overbinding for the late transition metal hydrides to an overestimation of $\Delta E_{XC}^{\beta\beta}$ from the exchange interaction between the electron on hydrogen and the electrons on M^+ of the same spin-polarisation. The situation is quite similar to that encountered for the electron affinities of M^+ among the late transition metal cations Fe^+ to Cu^+, where A_I was overestimated due to an exaggerate contribution from $\Delta E_{XC}^{\beta\beta}$. We shall suggest a possible remedy for this shortcoming after a comparison of our calculations with results from other theoretical studies (4*a*, 4*c*).

Figure 1 depicts LDA + B + P bonding energies together with experimental data and results from GVB (4*a*) as well as MCPF (4*c*) calculations. It can be seen from Fig. 1 that the bonding energies decrease from ScH^+ to CrH^+, jump up at MnH^+, and decrease again from FeH^+ to CuH^+. Ohanessian and Goddard (4*a*) explained this double-valley picture in terms of exchange energy loss (4*b*), which reflects the important role of nonbonding electrons. The DFT-based methods as well as the GVB and MCPF schemes are all able to reproduce the double valley trend. We note further that the GVB and MCPF methods underestimate $D_{298}(M^+—H)$ in contrast to the LDA + B + P method where the calculated bond energies, as already discussed, are too large.

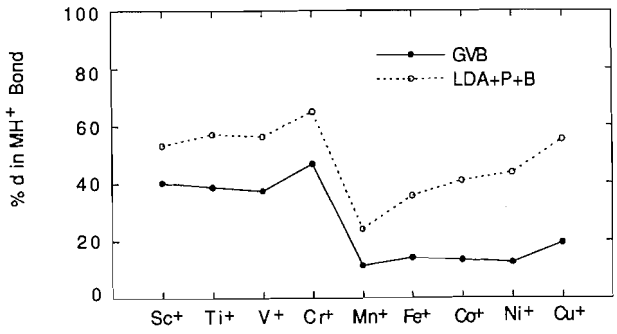

FIG. 2. Percentages of $3d$ orbital character in the M^+—H σ orbital of first-row transition metal hydride cations. Only GVB and LDA + B + P values are shown.

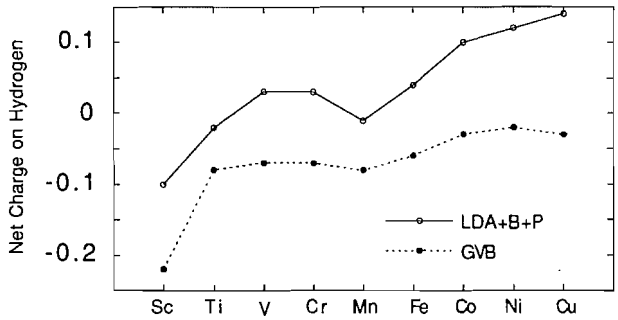

FIG. 3. Total charge on hydrogen in the M^+—H σ orbital of first-row transition metal hydride cations. Only GVB and LDA + B + P values are shown.

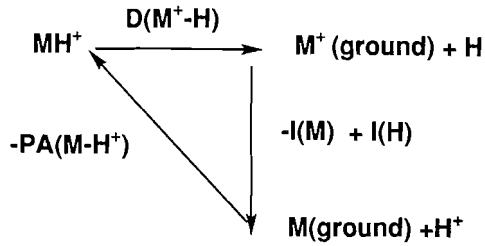
The nature of the M^+—H bond can be analysed by investigating the composition of the σ_{MH} orbital. Figure 2 displays the percent contribution to σ_{MH} from the d orbital in the case of the LDA + B + P and GVB (4*a*) methods. The two schemes exhibit the same trends along the series. However, the DFT scheme tends consistently to put more electrons in the d orbital. We can rationalise this by the bias towards the d^n configuration discussed previously. The bias is in particular noticeable for the late transition metals Fe to Cu, Fig. 2. The MCPF method (5) gives a d percentage similar to that of the GVB scheme for early transition metals. For the later transition metals MCPF provides a d percentage between GVB and LDA + B + P. Pettersson et al. (5) attributed the difference between GVB and MCPF to a better description of the $3d$–$3d$ correlation in the latter method.

Figure 3 displays the charge on hydrogen throughout the series as a measure of the polarisation in the M—H bond. Data are given for GVB as well as LDA + B + P. The trends are the same for the two methods with more charge on hydrogen at the beginning of the series among the electropositive early transition metals and less charge at the end among the more electronegative late transition metals. However, in absolute terms the GVB and LDA + B + P results differ. The GVB scheme has a negative charge on hydrogen throughout the series whereas LDA + B + P has hydrogen positively charged with the exception of Sc and Ti. We note in particular the increase in the positive charge on hydrogen for the late transition elements Fe–Cu and attribute it again to the energy stabilisation of the d-orbitals.

Protonation energies and revised bond energies

As a remedy for reducing the large error in the calculated bond energies for FeH^+ to CuH^+, one might consider the following thermodynamic cycle



2

SCHEME 2

The cycle in Scheme 2 allows us to express $D(M^+—H)$ as

[4] $D(M^+—H) = PA(M—H^+) + I(M) - I(H)$

The protonation process for the late transition metals does not change the number of interacting electrons of the same spin or opposite spin, in contrast to the formation of MH^+ from H and M^+. Thus, $PA(M—H^+)$ should be determined more accurately than $D(M^+—H)$ since the error from $\Delta E_{XC}^{\beta\beta}$ is absent.

The theoretical $PA(M—H^+)$ values reported in Table 4 correspond to the process

[5] $M(\text{exp. ground state}) + H^+ \rightarrow MH^+(\text{ground state}) - PA(M—H^+)$

and they were calculated (see footnote to Table 4) as

[6] $$PA(M—H^+)_{est} = E_{cal}(MH^+) - E_{cal}(M, \text{LDA + B + P ground state}) + E_{exp}(M, \text{LDA + B + P ground state}) - E_{exp}(M, \text{exp. ground state}) - E_{cal}(H^+)$$

We see from Table 4 that the average deviation between estimated, eq. [6], and experimental $PA(M—H^+)$ values is as low as 3.5 kcal/mol.

We can next recalculate the $D(M^+—H)$ bond energies according to

[7] $D(M^+—H)_{est} = PA(M—H^+)_{est} + I_{exp}(M) - I_{exp}(H)$

The error in the estimated bond energies has now decreased to within 5 kcal/mol, Table 4.

The rather *ad hoc* procedure introduced in this section can not hide the fact that the present generation of approximate DFT methods has serious deficiencies. It is clear that new approximate functional will have to give a more accurate account of $\Delta E_{XC}^{\beta\beta}$ in atoms and the related bare metal complexes.

Bond lengths and frequencies in MH^+

The optimized M^+—H bond lengths and calculated vibrational frequencies are displayed in Tables 5 and 6. Since no experimental data are available, we have to compare the DFT results with high quality *ab initio* calculation.

The bond lengths calculated by the various DFT methods are quite similar, in particular for LDA and LDA + P + B. The DFT

TABLE 4. Protonation energies of Fe—Cu and bond energies of FeH^+—CuH^+[a]

distances are in general shorter than the bond lengths obtained from *ab initio* GVB (4*a*) and MCPF (4*c*) calculations. This is consistent with the fact that the DFT bond energies are too large whereas the *ab initio* bond strength are underestimated.

From ScH^+ to CuH^+, the DF bond lengths decrease monotonically while the *ab initio* bond lengths exhibit a peak at MnH^+. The peak has been attributed (4*a*) to a half-filled 3*d* shell at Mn^+.

The vibrational frequencies obtained by LDA and post-LDA methods compare well with *ab initio* results. Remarkably, the LDA + B + P values are somewhat close to those obtained by the MCPF method. The post-LDA corrections trend to decrease the frequencies.

IV. Concluding remarks

We have carried out DFT-based calculations on the cationic bare metal hydrides, MH^+, for the first transition series. It has been demonstrated that $D_{298}(M^+—H)$ values evaluated by the nonlocal LDA + B + P method are overestimated for the early to middle transition metals. However, the error of ±5 kcal is comparable to that observed in calculation on M—L bond energies among saturated 18-electron complexes.

The $D_{298}(M^+—H)$ bond energies calculated by the nonlocal method for the late transition metals are much larger, with a maximum of 13 kcal/mol for CuH^+. We have further shown that the large error can be attributed to an overestimation of the exchange by the DFT-based methods. The error in the exchange energy is also responsible for the large *d*-population in the MH^+ systems compared to *ab initio* results.

Infrared chemiluminescence in a mixed reaction situation: F + CH_4 and F + $CHCl_3$

M. Maneshkarimi and H. Heydtmann[1]

Institut für Physikalische und Theoretische Chemie der J.W. Goethe Universität, Marie Curie Str. 11, D-60439 Frankfurt am Main, Germany

Received June 29, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

M. Maneshkarimi and H. Heydtmann. Can. J. Chem. **72**, 790 (1994).

Infrared chemiluminescence from the product molecule HF (DF) was observed for the F + CH_4(CD_4) and F + $CHCl_3$ reactions under low-pressure flow conditions. The reactions with methane and deuterated methane showed the well-known vibrational inversion effect. For the mixed reaction situation F + CH_4(CD_4) + $CHCl_3$ it can be shown by switching between CH_4 and CD_4 that no special relaxation effects are present. The HF (DF) spectra can be explained by results from the isolated reactions. A non-inverted distribution was confirmed for F + $CHCl_3$.

M. Maneshkarimi et H. Heydtmann. Can. J. Chem. **72**, 790 (1994).

On a observé de la chimiluminescence infrarouge à partir des molécules produites HF (DF) au cours des réactions H + CH_4(CD_4) et F + $CHCl_3$ effectuées dans des conditions de faibles pressions d'écoulement. Les réactions avec le méthane et avec le méthane deutére présentent l'effet bien connu d'inversion vibrationnelle. Pour la situation de la réaction mixte F + H + CH_4(CD_4) + $CHCl_3$, on peut montrer, en passant du CH_4 au CD_4 qu'il n'existe pas d'effet de relaxation spécial. On peut expliquer les spectres HF (DF) par les résultats de réactions isolées. On a pu confirmer la présence d'une distribution qui n'est pas inversée pour F + $CHCl_3$.

[Traduit par la rédaction]

Introduction

For more than 25 years IR chemiluminescence has been an accepted technique to obtain information about the reaction dynamics of elementary processes (1). Chemiluminescence studies of F atom reactions with polyatomic hydrides are numerous (1–3) because the product molecule HF is especially suitable for such experiments (high Einstein coefficients for the rotational–vibrational states, fundamental band emission in an experimentally well-accessible range).

Two different types of experiment have been used in the past. The so-called arrested relaxation (AR) technique using a low-pressure, fast flow system was introduced by Polanyi (1) and is also used in this work (4). The second technique, flowing afterglow (FA), employs a carrier gas in a fast flow system and hence the reactions take place at distinctly higher pressures, typically at about 1 Torr (133 Pa). Both methods have been used for many reactions and, in a comparative study from the Kansas and the Frankfurt laboratories, some of these results have been reported together (2, 5). The results are usually presented as vibrational distributions of the HF molecule and these vibrational distributions are in most cases independent of the method used. Thus there is good agreement between the work of several laboratories for the reaction

[1] $F + CH_4 \rightarrow HF\ (v \leq 3) + CH_3$

which was measured in Frankfurt by the AR technique to yield: $N_{v=1} : N_{v=2} : N_{v=3} = 0.16 : 0.74 : 0.10$. This reaction has a recommended rate constant at 298 K of 6.64×10^{-11} cm^3 molecule^{-1} s^{-1} (6) and also serves as a standard here.

Another reaction used in the reported work is

[2] $F + CD_4 \rightarrow DF\ (v \leq 4) + CD_3$

Its rate constant at standard conditions is reported to be 4.24×10^{-11} cm^3 molecule^{-1} s^{-1} (6). Remarkable differences were noted for the reaction

[3] $F + CHCl_3 \rightarrow HF\ (v \leq 4) + CCl_3$

for which FA yielded (2): $N_{v=1} : N_{v=2} : N_{v=3} : N_{v=4} = 0.22 : 0.32 : 0.37 : 0.09$ and AR gave rise to a mean distribution (with F_2 as a precursor of F-atoms) $N_{v=1} : N_{v=2} : N_{v=3} = 0.72 : 0.23 : 0.5$ (2).

Nazar and Polanyi (3) were the first to report IR chemiluminescence data for this reaction. They used very low molecular flows but their total flow rate was in the range 2.5–20 μmol s^{-1}. The vibrational distributions documented in Table 4 of their paper depended somewhat on the flow conditions, but are qualitatively equal to the ones quoted above, i.e., $N_{v=1} > N_{v=2} > N_{v=3}$.

The presence of only one microscopic reaction channel, namely, direct H-abstraction on a ps time scale, was proposed by us for the FA conditions. A second microscopic channel (F-atom addition and slow elimination of HF from the primary complex) was additionally introduced to explain the AR results (2). Unexpectedly, these revealed a lack of inversion between the vibrational levels $v = 1$ and $v = 2$ as well as between $v = 2$ and $v = 3$. It was argued that both microscopic channels are present, but that the addition–elimination channel predominates. The addition–elimination is suppressed under FA conditions by stabilization of the addition complex. The assumption of two distinct reaction channels was corroborated by the disagreement between the rate constants for eq. [3]. Clyne et al. determined the rate constant $k_{298} = 0.42 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} (7, 8), whereas Setser and his group arrived at $k_{298} = 0.14 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} from observation of the IR emission (2).

Some doubts, however, remained whether special relaxation effects may take place in this system. Such effects have been discussed before for similar experimental conditions concerning the reaction F + HBr (9). This work presents new results using an inlet system of three concentric nozzles, with which competitive reactions could be studied. Competitive hydrogen abstractions from two RH compounds, which both yield HF

products, should reveal such an effect, because if strong relaxation occurs it must occur for HF from *both* reactions. Reaction [3] is very suitable for such a study in this system because no interference from secondary reactions has to be feared. The results indeed confirm that under arrested vibrational relaxation conditions at low pressure a different vibrational distribution for the HF product molecules ensues, distinct from the one found for higher pressures (FA conditions).

Experimental

All experiments were performed in an apparatus similar to the one used before (4), the only major change being a new inlet system, which is similar to the one described by Sloan and co-workers (9, 10). A schematic picture of this setup is given in Fig. 1. The reaction vessel is pumped by an effective diffusion pump (pumping capacity 5000 L/s). The inlet system consists of three concentric quartz tubes, which can be moved relative to each other. The tubes are connected to each other by Swagelok joints made from stainless steel. This system is fixed to a lid that closes the reaction vessel on the top side but mobility relative to the lid was also provided for. The tubes were covered with Teflon (PTFE-Spray, Safematic Nidda, Germany) in order to avoid wall reactions, especially atom recombinations.

The central tube (nozzle 1) has an internal diameter of 0.8 cm and is equipped with a deflector plate for lateral injection of hydrocarbon into a stream of F atoms. The idea was to effect thorough mixing of the gases before the center of the White cell was reached by the flowing gas. The next tube, which has an internal diameter of 1.5 cm, forms the annular nozzle 2, the outermost tube with an internal diameter of 2.6 cm is the annular nozzle 3. F atoms could be produced in all three inlet tubes by flowing CF_4 or F_2 inside those tubes and fitting a microwave cavity on the outside; 2450 MHz and a power of 90 W were used. The White cell, with mirrors 12 cm in diameter, collects the infrared light emitted from the HF (DF) molecules from a volume near the horizontal plane in the middle of the vessel. The reaction volume is surrounded by a cold wall (77 K) to effect complete wall relaxation of vibrationally excited hydrogen fluoride.

For taking the spectra an FTIR instrument (BIORAD) was used. The adopted resolution was usually 2 cm^{-1}. The crude spectra were treated in the usual manner. The total concentration of emitting HF, G_I, was measured for each run by adding the heights of all lines (after corrections by Einstein coefficients and instrument function). This sum was expressed relative to thermal emission at a selected wavelength from the background signal. G_1 gave valuable qualitative information, for example, finding the best nozzle arrangement. Also subtraction of spectra was exercised and played a very important role in this work. This was only done for experiments that were performed under similar conditions on the same day; essentially only methane was exchanged for deuterated methane. The subtraction was done line by line using the corrected spectra. The usefulness of this procedure will become clear in discussing the results shown in Table 2.

Results

1. The F + CH_4 reaction

Table 1 gives results of some of the many experiments performed to test our new inlet system. Experiment 1 shows that with retracted nozzles 1 and 2 a condition can be reached where relaxation is extensive and the signal becomes too low to be measurable. Under these circumstances most of the reaction enthalpy must have been transformed to translational energy by the time HF arrived in the central plane of the White cell. Radiational relaxation can be considered negligible as stated in our earlier work (4) because of the high pumping capacity. Relaxation due to gas collisions and wall collisions must be very effective with this special configuration of our new nozzle system. Changing the inflow of CF_4 from nozzle 2 to nozzle 3 yields a signal that shows relaxation (expts. 2 and 3) but certainly the effective reaction volume has moved downward. Satisfactory populations are reached in experiment 10 since the N_v ratios are the same as in the best of our earlier experiments. In this experiment perhaps some rotational relaxation has happened but this is of no interest for our present paper.

Some remarks are useful concerning the rotational structure. The rotational distribution for HF (v = 1, 2) is, for the most favorable flow conditions, not very different from the Boltzmann shape (see Fig. 1 of ref. 5): the distributions both peak at $J = 2$, but higher populations for $J \geq 7$ are observed. This feature is also true for F + $CHCl_3$. A Boltzmann distribution at 300 K reaches very low populations beyond $J = 6$. In conclusion, little relaxation of rotational states is necessary to reach the Boltzmann shape. Secondly, relaxation is observed for the higher J levels but is so slow that non-Boltzmann rotational populations exist under all conditions of our experiments.

Runs 4, 5, 6, and 8 show intermediate cases with occurrence of slight vibrational relaxation. Experiments 7 and 9 are included because they show that the choice of the precursor molecule, CF_4 or F_2, is of no relevance to the results. However, the signal intensity G_I of no. 7 compared to no. 6 and of no. 9 compared to no. 8 is much stronger due to a better yield of F atoms from the fluorine gas. Experiments 11 and 12 show the effect of added argon ([Ar]/[CH_4] = 10). In no. 11 argon was mixed with the CH_4 flow into nozzle 1; in no. 12 argon was introduced separately into the external nozzle 3. Especially in the former case relaxation is observed due to a high Ar partial pressure in the local reaction volume.

Other experiments, which are not described in detail, were concerned with the vertical position of the total inlet system. As for the reaction F + CH_4, the highest intensities were measured

when the nozzle system was moved about 1 cm downward as compared with the conditions of Table 2.

2. The F + $CHCl_3$ reaction

The first experiments were of the same kind as those described in greater detail for the F + CH_4 system. Two experiments showing results for F + $CHCl_3$ only, namely, nos. 2 and 10, are included in Table 2. These two experiments differ in the choice of the precursor molecule, but they yield about the same distribution. The precursor effect was more noticeable in our former experiments (2). As described before, other experiments tested the effect of the vertical position of the entire nozzle system. For the reaction F + $CHCl_3$ a better signal was achieved for a rather high (upward) position of this system, higher than actually used in Table 2. The position chosen was equal to the position in experiments 4–12 of Table 1. This position was considered a good compromise between the best position found for the two molecular reagents.

The main results are based on experiments that used flows in all three concentric nozzles; such experiments are illustrated by the results in Table 2. For understanding, it is important to realize that chloroform is always added to the central nozzle 1, methane, always to nozzle 3. Experiment 1, Table 2, for example, has the central nozzle not in use, i.e., shut off. In this manner CH_4 is introduced differently than in the experiments in section 1, but the resulting vibrational distribution (see expt. 1) still shows strong inversion between levels 1 and 2. The first four lines of Table 2 show the results for the separate reactions [1] and [3], both reactions in competition, and finally competitive results for reactions [2] and [3]. The amounts of CD_4 and (or) $CHCl_3$ added were chosen as reported in order to create roughly the same reaction rate as for methane; in other words, the smaller rate constants were compensated by higher partial pressures. That this expectation is met can be seen from the G_I values. As expected, experiments 2 and 4 of the table under discussion render very similar distributions and also show comparable HF emission intensities. CD_4 in experiment 4 was added to create similar flow conditions and to investigate the relaxation effects of $CHCl_3$ on DF and of CD_4 on HF. The relaxation effect for the latter is negligible as can be seen from the results of experiments 2 and 4. For the former case the evaluation of the DF distribution ($N_{v=1} : N_{v=2} : N_{v=3} : N_{v=4} = 0.13 : 0.16 : 0.56 : 0.15$) shows that the large excess of $CHCl_3$ and the reaction product of [3] has only a small effect. The differences (3 − 4) were obtained by subtraction of absolute line intensities as described in detail in the experimental section. Similar differences were extracted from the spectra of experiments 5–8 with different CF_4 flows. Experiments 9–12 are parallel to experi-

ments 1–4 but with F_2 as a precursor molecule. Also, here CD_4, DF, and CD_3 radicals have no special effect on the HF vibrational distribution.

Figures 2*a* and 2*b* visualize the change in distributions for HF $v = 1$, $v = 2$, and $v = 3$ in these switching experiments and also give the subtraction results.

Discussion

In the earlier paper of Wickramaaratchi et al. (2) the difficulty in obtaining agreement between the work of two laboratories using the same method was discussed extensively. In an AR apparatus there is the possibility of gas phase relaxation of excited species whenever the concentrations of relaxing species are too high. It must be remembered that radicals are also present and that the relaxation effects of these radicals is difficult to assess. Furthermore, wall relaxation, especially at the warmer parts of the reaction vessel, cannot be entirely excluded; this type of relaxation necessarily varies with construction of the reaction vessel.

As already emphasized in the results section, there is no significant mutual effect of reactions [2] and [3] when these reactions are mixed (experiments 4, 6, 8, and 12 of Table 2). The procedure of subtracting spectra of two competitive experiments, as described before and documented for four cases in Table 2, shows that a distribution is obtained in each case that resembles very closely the primary HF distribution from reaction [1]. It must be borne in mind that relative populations of an experiment are already uncertain by 10%, therefore the distribution obtained by subtraction must have an even larger error.

We conclude that reactions [1] and [3] studied simultaneously in the same reaction vessel and under suitable conditions do not influence each other. Hence the reaction F + $CHCl_3$ at low pressure produces HF with a primary vibrational distribution without any inversion and the main features of this vibrational distribution are not due to relaxation effects. If relaxation occurred, relaxed difference spectra would be expected. There is no doubt also that the FA experiments, which were carefully planned and performed, yield reliable results. We propose that different microscopic processes occur under different conditions and that the explanation attempted before (2) still is the best solution. It is strongly recommended that molecular beam experiments be performed in order to clarify the detailed dynamics of reaction [3].

Two-dimensional sublimation of CO_2 on NaCl(100), prepared by cleaving a single crystal in situ under ultrahigh vacuum, was observed by polarization Fourier transform infrared spectroscopy. At the transition pressure $p_t(T) < 1 \times 10^{-10}$ mbar in the temperature range $45 \leq T/\mathrm{K} \leq 75$ the 2D solid and the ideal 2D lattice gas coexist in a 2D thermodynamic equilibrium. The temperature dependence of the spreading pressure $\pi(T)$ of the coexisting 2D lattice gas yields the enthalpy of the 2D sublimation $\Delta H_S^{2D} = (3.0 \pm 0.1)$ kJ/mol. In the two-dimensional sublimation reorientation of the CO_2 molecules takes place; both the polar and the azimuthal molecular angles change.

J. HEIDBERG, E. KAMPSHOFF, R. KÜHNEMUTH et O. SCHÖNEKÄS. Can. J. Chem. **72**, 795 (1994).

On a observé, par spectroscopie infrarouge à transformation de fourier polarisée, la sublimation bi-dimensionnelle du CO_2 sur du NaCl(100) préparé par clivage in situ d'un cristal unique sous vide très poussé. À la pression de transition $p_t(T) < 1 \times 10^{-10}$ mbar dans l'intervalle de température allant de $45 \leq T/\mathrm{K} \leq 75$ le solide 2D et le réseau 2D gazeux idéal coexistent dans un équilibre thermodynamique 2D. L'effet de la température sur l'étalement de la pression $\pi(T)$ des réseaux 2D gazeux coexistants donne l'enthalpie de la sublimation 2D $\Delta H_S^{2D} = (3{,}0 \pm 0{,}1)$ kJ/mol. Il se produit une réorientation des molécules de CO_2 dans la sublimation bi-dimensionnelle; les deux angles polaire et azimutale changent.

[Traduit par la rédaction]

Introduction

In physisorption, the weak interaction between molecules and solids has been studied for many years. A new topic is the stereodynamics of chemical reactions between surface-aligned and oriented physisorbed molecules (1). This paper reports on the thermodynamics of a two-dimensional phase transition with molecular reorientation as revealed by polarization infrared spectroscopy. The system studied is CO_2 physisorbed on NaCl(100), which can be considered a model for physisorption. It has become important also in geology, in sea spray chemistry, as well as in industrial applications and waste technology. Rock salt in the extended North German salt domes contains, besides the brine inclusions and water from the associated hydrated minerals, primary gases adsorbed on the crystal boundaries or trapped in inclusions. Knowledge of the behaviour of such primary gases as CO_2, CH_4, H_2O, and HCl is essential when planning the safety aspects for a final repository of radioactive waste in the salt domes (2). To model the behaviour of these simple gases in the salt domes, studies of the gas adsorption on NaCl(100) under well-defined conditions are necessary. Especially those thermodynamic measurements yielding adsorption isotherms, heats of adsorption, and two-dimensional phase transitions give insight into the gas–surface interaction. The results can also be used to describe migration processes along the salt surfaces.

It is well known that physisorption systems such as small molecules and rare gas atoms on single crystal surfaces can undergo two-dimensional (2D) phase transitions. They have been studied both experimentally and theoretically for several years (3–5). Only a few methods are suitable for highly sensitive detection of a 2D lattice gas at very low coverages ($\theta \leq 0{,}01$). One of these methods, thermal energy He scattering, has been used to study the system Xe–Pt(111) (6). The heat of 2D vaporization could be measured directly from the temperature-dependent density of the coexisting 2D lattice gas, but also independently as the difference between the isoteric heats of adsorption of the coexisting 2D phases (6). High-resolution Fourier transform infrared (FTIR) spectroscopy of adsorbed molecules can yield additional information concerning, for example, adsorption geometries and lateral adsorbate interaction, especially dynamic dipole–dipole coupling within the adlayer. Recent examples are CO–Ru(001) (7) and PF_3–Pt(111) (8). In these systems coexistence of 2D lattice gas and 2D islands could be detected, but thermodynamic quantities like heats of adsorption and 2D phase transition were not derived.

Here we present results of polarized FTIR spectroscopy of the adsorption system CO_2–NaCl(100). This adsorption system has become the object of many investigations in recent years (9–17). In our group a two-dimensional phase transition at pressure $p_t(T)$ within the adsorbate has been observed on NaCl(100) samples prepared in air (11). With the integrated absorption of the asymmetric ν_3 stretching vibration as a measure of the surface coverage θ, two adsorbate phases can be distinguished. At $p < p_t$ the 2D lattice gas is the stable phase, the CO_2 molecules being oriented parallel to the surface as derived from the polarization dependency of the single ν_3 absorption band (11). This result is in full agreement with several theoretical calculations (11, 17). At pressures $p_t \leq p \leq p_0$ (p_0 being the vapor pressure of 3D-solid CO_2 at temperature T), the 2D solid is observed, indicated by a characteristic ν_3 doublet. In combination with isotope dilution experiments (11), low-energy electron diffraction (LEED) (18), and helium atom scattering (HAS) results (19) we derived a (2×1) monolayer structure for the 2D solid. Within the framework of the experimental data two independent theoretical models, namely spectra simulation and calculation of the minimum of the potential energy, give details on the structure (15). The unit cell with symmetry *pg* contains two energetically equiv-

alent molecules, which are tilted by 34° ± 5° with respect to the surface. The projections of neighbouring translationally inequivalent molecules onto the surface enclose an angle of 80° ± 5°. The ν_3 doublet results from a correlation field within the adsorbate. Other IR studies gave comparable results (12, 20).

Even more interesting spectral and thermodynamic features are measured on NaCl(100) prepared by cleaving a single crystal in situ under ultrahigh vacuum. All IR absorptions become remarkably sharper and hence more intense since they retain the same integrated absorptions as on air-cleaved samples. The ν_2 bending vibration of the 2D solid CO_2, being split into a quartet as a result of a combined site symmetry and correlation field splitting, has an instrument-limited linewidth of only 0.04 cm^{-1} at a sample temperature of 5 K, which is the sharpest reported absorption of an adsorbate (14). More detailed thermodynamic information about the adsorbate is also available now. In particular, the coexistence of 2D lattice gas and 2D solid that was not detected in the adsorption measurements on air-cleaved NaCl(100) samples is now observable. Hence it is now possible to measure directly the two-dimensional sublimation equilibrium within the adsorbate.

Experimental

The results reported below were performed in an experimental setup that will be described here briefly. A more detailed description is given in refs. 11 and 16. The setup consists of an FTIR spectrometer (Bruker IFS 113v with transfer optics according to Heidberg, Hoge, Warskulat), an UHV chamber, and an external detector compartment. The UHV chamber contains a liquid helium cryostat and the cleavage device, consisting of anvil and blade, for the NaCl samples. The temperatures reported were measured by Au(Fe)/NiCr and NiCr/Ni thermocouples mounted to the sample and sample holder. The CO_2 pressure was determined by a quadrupole mass spectrometer, taking into account the total pressure given by an ion gauge, which was calibrated against a spinning rotor gauge. The interferogram was monitored by a liquid nitrogen cooled InSb detector. We used an angle of (50 ± 1)° for the incident IR light, which was polarized by means of a wire-grid polarizer. The adsorption isotherms were measured with $^{13}C^{16}O_2$ to avoid overlap of the adsorbate signal with rovibrational transitions of atmospheric $^{12}C^{16}O_2$ present in the residual gas of the interferometer and the detector compartment. The thermodynamics of the adsorbate was found to be independent of the CO_2 isotope used, within the error limits (11). Isotope contamination of $^{13}C^{16}O_2$ by $^{13}C^{16}O^{18}O$ and $^{13}C^{18}O_2$ is present in the gas and in the adsorbate. This influences the linewidth and peak absorption of the main component due to vibrational coupling between the same isotopic species within the ordered 2D solid CO_2 on NaCl(100) (11). On the other hand the integrated absorption, which was calculated for all isotopes, is not affected. We can therefore neglect this spectral effect within this thermodynamic study.

Results and discussion

The systematic thermodynamic investigation of the adsorption of CO_2 on NaCl(100) started by measuring several adsorption isotherms. Some of these isotherms at sample temperatures 87, 91, 93, and 96.3 K are displayed in Fig. 1. Every isotherm shows a characteristic shape with a vertical step at pressure $p = p_t(T)$ indicating the two-dimensional first-order phase transition within the adsorbate. Adsorption isotherms calculated according to the Fowler–Guggenheim model for localized adsorbates (21) are also displayed. The corresponding fit parameters, which are not needed in this work, will be discussed elsewhere. Experimental details will be described using the isotherm at 91 K. In Fig. 2 some of the ν_3 spectra measured at 91 K are shown to explain the spectral features connected with the pressure-dependent behaviour of the adsorbate. It should be mentioned that in Fig. 2 only the ν_3 region of the isotope $^{13}C^{16}O_2$ is displayed. All other isotopes present in the 3D gas phase were also detected in the adsorbate and have been taken into account in the determination of the surface coverage. The first signal observable at lowest coverages is a broad, polarization-independent absorption at 2276 cm^{-1} with a full width at half maximum (FWHM) of 4–6 cm^{-1}. Increasing the CO_2 pressure enlarges the FWHM of this absorption to 10–15 cm^{-1}. This signal appears to be different at each NaCl(100) sample used and therefore is attributed to CO_2 adsorbed on surface defects, mainly steps. The bonding and localization of this adsorbate species is probably the strongest. In comparison to the integrated absorption of the full monolayer, the integrated adsorption due to defects was determined to be between 0.01 and 0.11 for the different samples used. The area of this signal is only weakly dependent upon pressure; it grows slowly over more than two orders of magnitude in pressure. From $p \approx 0.1p_t$ to $p = p_t$ a single sharp absorption at 2278.9 cm^{-1} with a FWHM <0.4 cm^{-1} was detected (e.g., top spectra in Fig. 2). Its integrated absorption increases linearly with the CO_2 pressure. This observation proves the validity of the 2D ideal gas law (21). The single peak is therefore in concert with the absence of any spectral coupling effects attributed to the 2D lattice gas phase of CO_2 on NaCl(100). From the polarization dependency of this signal the parallel orientation of the molecules in the 2D lattice gas with respect to the surface can be derived, as predicted from theoretical calculations (11, 17). At pressure $p = p_t = 4 \times 10^{-8}$ mbar (1 bar = 100 kPa) the ν_3 spectra change remarkably, indicating the onset of the 2D phase transition accompanied by a reorientation of the CO_2 molecules and distinct changes of both polar and azimuthal molecular angles. As can be seen in Fig. 2, two additional absorptions at 2283.0 and 2275.0 cm^{-1} with FWHM 1.5 and 1.9 cm^{-1} appear along with the absorption of the 2D lattice gas. The integrated absorptions of these two signals increase, whereas the absorption of the 2D lattice gas decreases (see Fig. 2). During the phase transition the density of both coexisting phases remains constant. The density ρ of the 2D lattice gas is given by the number of 2D lattice gas molecules per NaCl(100) unit cell not occupied by the 2D solid. The density of the 2D solid is equal to the density of the full monolayer at $p = 10p_t(T)$ as inferred from a complete lineshape analysis. At the end of the condensation process the coverage of the surface has changed from about $\theta \approx 0.01$ to $\theta \approx 0.95$ of the full monolayer at constant pressure p_t. Even after several hours at $p = p_t$ the absorption of the 2D solid stayed at the value of $\theta \approx 0.95$. Only further increase of the CO_2 pressure by about one order of magnitude resulted in an increase of the coverage up to $\theta = 1$. Above p_t we find the well-known ν_3 doublet of 2D solid CO_2 on NaCl(100) for over two magnitudes of pressure. The structure and dynamic behaviour of this phase have been described elsewhere (14–16). Further increase of the CO_2 pressure to $p \geq p_0$ leads to new IR absorptions corresponding to multilayer formation.

We now want to view the 2D phase transition in more detail. As can be seen in the spectra, both phases coexist at $p = p_t(T)$. Taking into account the structural details known about the phases from our recent work, the arrangement displayed in Fig. 3 describes this coexistence. The enthalpy of the 2D sublimation can be determined by the following procedure.

We prepared the adsorbate at $\theta \approx 0.15$ on both the front and back face of the crystal by dosing with a capillary at substrate

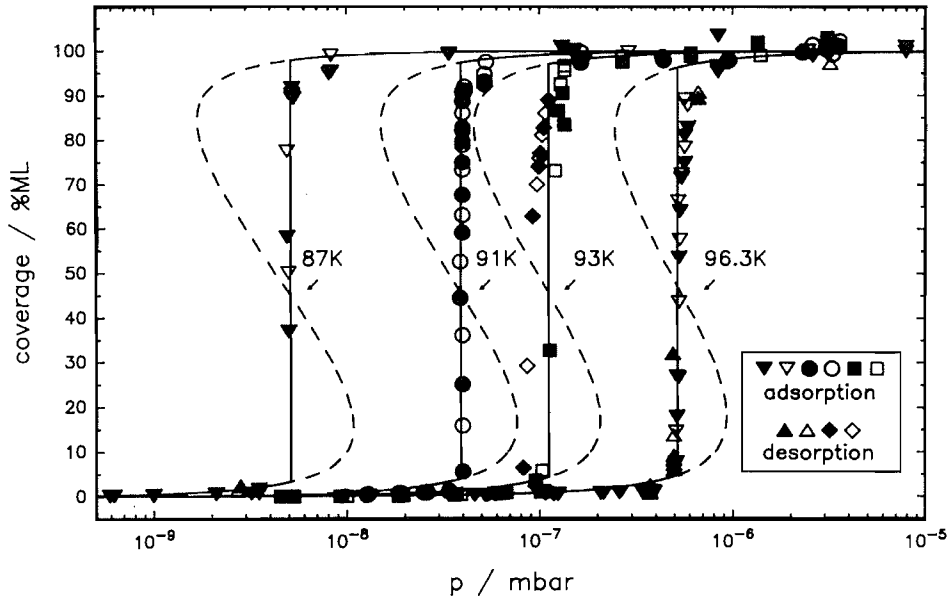

FIG. 1. Adsorption isotherms of $^{13}C^{16}O_2$ on NaCl(100) (UHV-cleaved) at 87 K, 91 K, 93 K, and 96.3 K with fits according to the Fowler–Guggenheim model. The surface was prepared by cleaving a single crystal in situ under ultrahigh vacuum. Coverages were determined from *p*- (full symbols) and *s*-polarized spectra (open symbols).

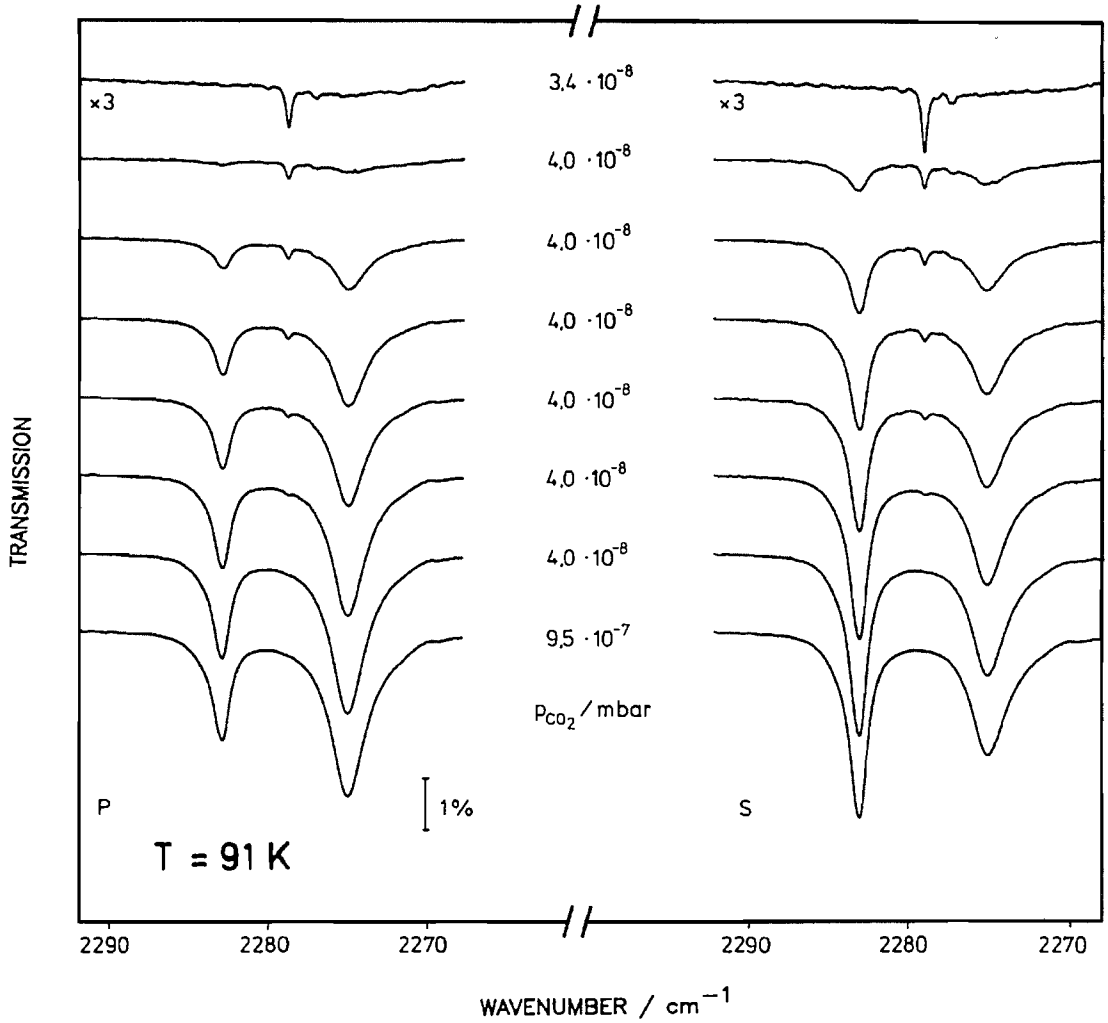

FIG. 2. The *p*- and *s*-polarized FTIR spectra of $^{13}C^{16}O_2$ on NaCl(100) (UHV-cleaved) at 91 K: 2D lattice gas (top), 2D solid (bottom), and coexistence of these phases. All spectra were measured with a resolution of 0.16 cm^{-1} and calculated from the interferogram using a Blackman–Harris apodisation function and a zero-filling factor of two. Note the increased ordinate scaling by a factor 3 in the top spectra.

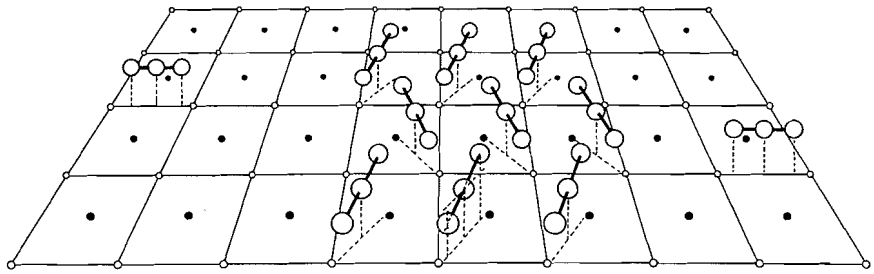

FIG. 3. Model of the coexisting 2D lattice gas and 2D solid CO_2 on NaCl(100).

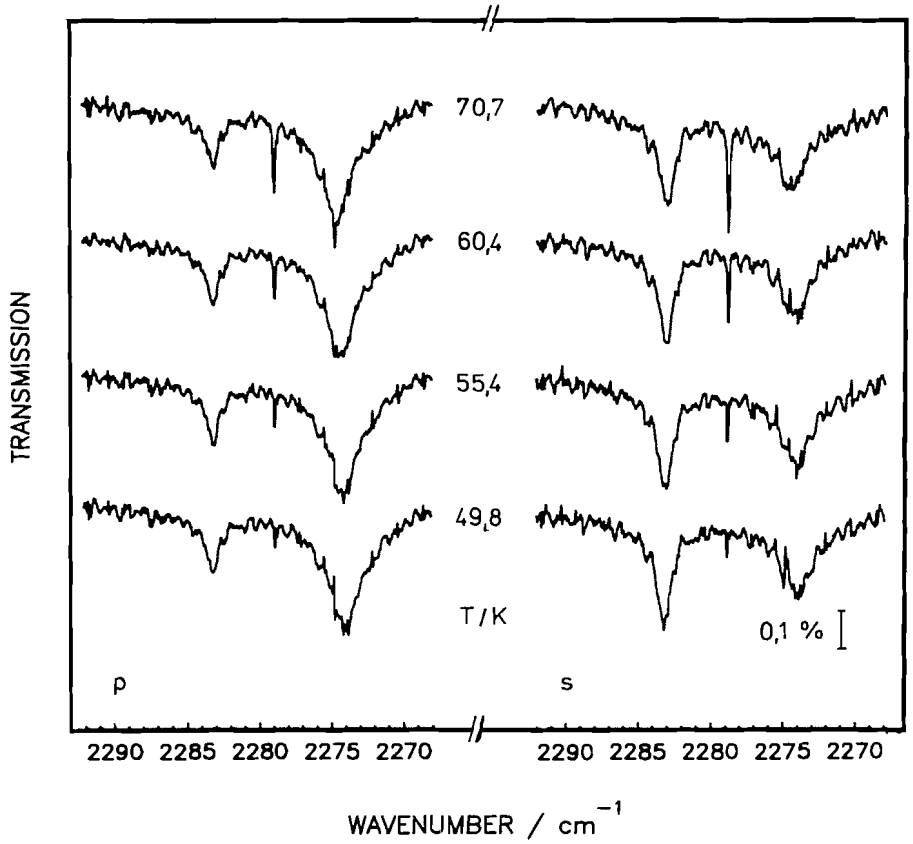

FIG. 4. Temperature-dependent p- and s-polarized FTIR spectra of $^{13}C^{16}O_2$ on NaCl(100) (UHV-cleaved) at constant coverage $\Theta \approx 0.15$ ($\Theta_{DEFECT} \approx 0.08$, $\Theta_{GAS} + \Theta_{SOLID} \approx 0.07$).

temperature $T = 77$ K and a CO_2 background pressure of $p < 2 \times 10^{-11}$ mbar. The adsorbate consists of the 2D lattice gas and the 2D solid in thermodynamic equilibrium, as well as of CO_2 molecules adsorbed at defects ($\theta_{DEFECT} \approx 0.08$). The 2D lattice gas density at temperature T is not affected by θ_{DEFECT}. For a given adsorbent θ_{DEFECT} was constant at different temperatures and their transition pressures $p_t(T)$ as derived from the adsorption isotherms for $T \geq 87$ K. Isosteric decrease of the substrate temperature leads to formation of the 2D solid, whereas the absorption of the 2D lattice gas becomes smaller (Fig. 4). This effect is reversible when heating up the sample. For each temperature the density ρ of the 2D lattice gas on the (100) terraces can be calculated from the coverages θ_{GAS} and θ_{SOLID}:

$$[1] \qquad \rho = \Theta_{GAS}/(1 - \Theta_{SOLID})$$

Both coverages are derived from the integrated absorptions of the corresponding ν_3 signals for a given polarization, corrected by the absorption of CO_2 adsorbed at surface defects:

$$[2] \qquad \Theta_{GAS} = \frac{fA_{GAS}}{A_{ML} - A_{DEFECT}}$$

$$[3] \qquad \Theta_{SOLID} = \frac{A_{SOLID}}{A_{ML} - A_{DEFECT}} = \frac{A_{TOTAL} - A_{DEFECT} - A_{GAS}}{A_{ML} - A_{DEFECT}}$$

A_{GAS}, A_{ML}, A_{TOTAL}, A_{DEFECT}, and A_{SOLID} denote the integrated absorptions over the ν_3 spectral region at a given polarization of the 2D lattice gas, the full monolayer (= saturated coverage at $p = 10p_t(T)$), the submonolayer under study, the adsorbate at defects, and the 2D solid, respectively. The factor f, determined from the Fresnel equations, takes into account the different orientations of the CO_2 molecules in the 2D lattice gas and the 2D solid. The effect on f of the dipole–dipole

HEIDBERG ET AL.

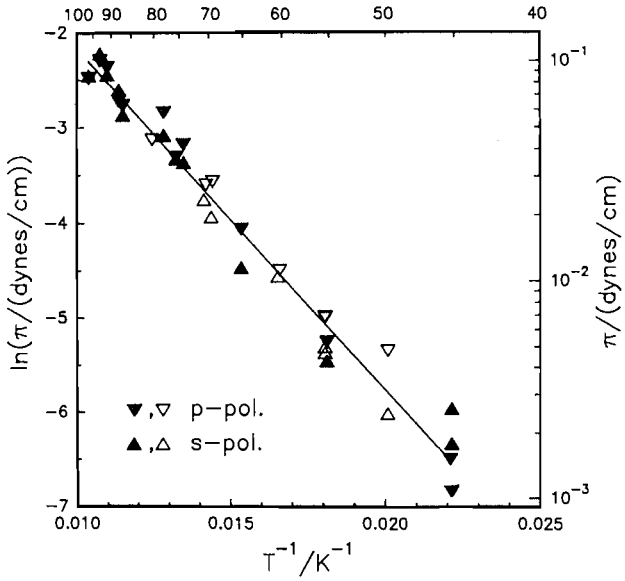

FIG. 5. 2D Clausius–Clapeyron plot of the spreading pressure π of the coexisting 2D lattice gas with temperature T for the 2D sublimation of CO_2 on NaCl(100) (UHV-cleaved). Data points were measured with decreasing (full symbols) and increasing temperature (open symbols).

coupling and the electronic screening in the 2D solid can be neglected, as shown by calculation of the complete line shapes using the gas phase values for the vibrational and electronic polarizibilities.

An exponential increase of density ρ of the coexisting 2D lattice gas with T is observed. Using the value of ρ, the spreading pressure π can be also calculated using the 2D ideal gas equation [4] (21):

$$[4] \qquad \pi = \rho kT/\beta$$

$\beta = a_0^2$ denotes the area of the substrate unit cell with $a_0 = 3.96$ Å for NaCl(100). A 2D Clausius–Clapeyron plot (Fig. 5) gives the enthalpy ΔH_S^{2D} of the 2D sublimation (22):

$$[5] \qquad \left(\frac{\partial \ln \pi}{\partial 1/T}\right)_{\text{coex}} = -\frac{\Delta H_S^{2D}}{R}$$

The slope of this plot yields $\Delta H_S^{2D} = (3.0 \pm 0.1)$ kJ/mol. Analyzing adsorption isosteres, the isosteric heats of adsorption for the 2D lattice gas and the 2D solid on NaCl(100) have been determined as $q_{st}^g = (32.4 \pm 1.1)$ kJ/mol and $q_{st}^s = (35.6 \pm 1.3)$ kJ/mol, respectively (23). The difference between these two values agrees very well with ΔH_S^{2D} determined directly from the spectra measured at coexistence of 2D lattice gas and 2D solid.

Considering these results, FTIR spectroscopy appears again as a well-suited nondestructive method to study physisorption systems like CO_2 on NaCl(100). Structural, dynamic, and thermodynamic information about the adsorbate can be derived from the IR spectra.

As is well known, in three-dimensional space the triple point of CO_2 lies above 100 kPa, so that the solid sublimes and the 3D liquid cannot exist at normal atmospheric pressure. Further work is directed to a better understanding of the 2D phase equilibria, its basis, the 2D phase rule, and the concept of chemical component in the adsorbate CO_2 on NaCl(100). The existence of a 2D critical point for the 2D sublimation should be examined.

Phase-plane geometries in enzyme kinetics

SIMON J. FRASER[1] AND MARC R. ROUSSEL

Chemical Physics Theory Group, Department of Chemistry and Scarborough College, University of Toronto, Toronto, ON M5S 1A1, Canada

Received June 23, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

SIMON J. FRASER and MARC R. ROUSSEL. Can. J. Chem. **72**, 800 (1994).

The transient and steady-state behaviour of the reversible Michaelis–Menten mechanism [R] and Competitive Inhibition (CI) mechanism is studied by analysis in the phase plane. Usually, the kinetics of both mechanisms is simplified to give a modified Michaelis–Menten velocity expression; this applies to the CI mechanism with excess inhibitor and to mechanism [R] in the product inhibition limit. In this paper, [R] is treated *exactly* as a plane autonomous system of differential equations and its true (dynamical) steady state is described by a line-like slow manifold $\mathcal{M}$. Initial velocity experiments for [R] no longer strictly correspond to the hyperbolic law (as in the irreversible Michaelis–Menten mechanism) and this leads to corrections to the standard integrated rate law. Using a new analysis, the slow dynamics of the CI mechanism is reduced from a three-dimensional system to a planar system. In this mechanism transient decay collapses the trajectory flow onto a two-dimensional "slow" surface Σ; motion on Σ can be treated *exactly* as projected dynamics in the plane. This projected flow may differ in important ways from that of two-step mechanisms, e.g., it may lack a proper steady state. The relevance of these more accurate dynamical descriptions is discussed in relation to experimental design and metabolic function.

SIMON J. FRASER et MARC R. ROUSSEL. Can. J. Chem. **72**, 800 (1994).

Nous présentons une analyse du mécanisme Michaelis–Menten réversible [R] et du mécanisme d'inhibition compétitive (CI) dans le plan de phase. Normalement, on simplifie les équations différentielles découlant de ces deux mécanismes par l'approximation de l'état stationaire; la vitesse réactionelle est ainsi mise dans la forme de Michaelis et Menten. Par contre, nous démontrons que le mécanisme [R] est exactement descriptible par un système d'équations différentielles planaire possédant une courbe intégrale (la courbe intégrale lente, $\mathcal{M}$) qu'approchent toutes les autres solutions après la période transitoire. Dans un traitement exact, la vitesse initiale ne décrit plus nécessairement une courbe hyperbolique, même pour le mécanisme de Michaelis et Menten; nous présentons une méthode pour obtenir les corrections et en dérivons les premiers termes. Les équations différentielles du mécanisme d'inhibition compétitive peuvent aussi être réduites à un système planaire puisque le mode transitoire le plus rapide porte un point dans l'espace de phase à la surface intégrale lente Σ. Le mouvement d'un point représentatif sur Σ peut donc être projeté sur un plan de phase. L'écoulement projeté peut cependant être très différent de ce qu'on retrouve dans le cas d'un mécanisme vraiment planaire comme [R]. Par exemple, il peut n'y avoir aucune courbe intégrale lente en tant que telle. L'analyse exacte de la cinétique que nous prônons a d'importantes conséquences, et pour les expériences exécutées en laboratoire, et pour notre entendement du métabolisme.

1. Introduction

The coupled ordinary differential equations (ODEs) of all two-step stoichiometric reaction mechanisms can be reduced to plane autonomous systems (1). Even three-step mechanisms can be reduced to planar flows if a transient mode is removed by adiabatic elimination (2). This procedure of "planarization" of the full system produces an accurate global picture of the system's slow time evolution.[2] Representations of this kind are important because they expose conceptual errors in the analysis of standard, supposedly well-understood mechanistic models, and they can also provide accurate solutions to the governing ODEs. The dynamics of these planar systems is often richer than the standard picture permits. The importance of this aspect of enzyme kinetics has been emphasized by Walter (3).

In this paper, we apply dynamical systems analysis to the transient and steady-state kinetics of two *inhibition* models in enzyme kinetics: the reversible Michaelis–Menten mechanism [R], and the Competitive Inhibition (CI) mechanism.

Mechanism [R] corresponds to the reaction scheme (4):

$$\text{[R]} \qquad \mathrm{E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} P + E}$$

where E is enzyme, S substrate, C = ES enzyme–substrate complex, and P is product. In [R], product P competes with substrate S for the active site on the enzyme. Note that the irreversible Michaelis–Menten mechanism [I] (5), which lacks any inhibition effects, corresponds to taking the limit $k_{-2} \to 0$; this gives

$$\text{[I]} \qquad \mathrm{E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C \overset{k_2}{\rightarrow} P + E}$$

Since [I] is a particular case of [R], the analysis for [R] can immediately be specialized to [I] by taking the limit $k_{-2} \to 0$. Both [I] and [R] have two reaction steps and therefore two independent concentrations.

Competitive inhibition is usually modelled by the following mechanism

$$\text{[CI]} \qquad \begin{aligned} &\mathrm{E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C \overset{k_p}{\rightarrow} E + P} \qquad \text{[I]} \\ &\mathrm{E + I \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} H} \qquad \text{[Inh]} \end{aligned}$$

where I is an inhibitor species and H (= EI) is enzyme–inhibitor complex (4); microscopically, the (inert) inhibitor

[1]Author to whom correspondence may be addressed. Telephone: (416)-978-4650. FAX: (416)-978-8775. E-mail: sfraser@alchemy.chem.utoronto.ca

[2]Here planarization implies that the dynamical description of the *slow* time evolution of the system is projected onto a plane, so information about initial conditions and transient motion is eliminated in this description.

molecule I competes with substrate S for the active site. The catalysis [I], which is just the irreversible Michaelis–Menten reaction, has two degrees of freedom and the inhibition step [Inh] has one, so the evolution of the CI mechanism has three independent concentrations.

The quasi-steady-state velocity expression for both these mechanisms can, in suitable limits, be written in the form

$$v = \frac{V_{max}[S]}{K_M(1 + [I]/K_i) + [S]}$$

where V_{max} is the maximal reaction velocity, [S] substrate and [I] "inhibitor" concentration, K_M the Michaelis constant, and K_i the inhibitor constant. Alternatively, this formula for v can be written as the standard hyperbolic law

$$v = \frac{V_{max}[S]}{K_M^{app} + [S]}$$

where K_M^{app} is the apparent Michaelis constant. In the case of mechanism [R] this phenomenological formula describes the product-inhibition limit, where the product P can sequester free enzyme E to form a complex, but this complex cannot regenerate substrate S. In the CI mechanism, I represents a true inhibitor whose (total) concentration must be sufficiently large for this steady-state expression to hold. We will examine the relationship of such approximate expressions to precise and often more realistic dynamical descriptions where these approximations break down. Thus our study provides a sound mathematical framework for *in vivo* biochemical reactions, where enzyme, substrate, and inhibitor concentrations are often comparable (6). The dynamical consequences of this living environment cannot be inferred just from a knowledge of the "asymptotic" parameters V_{max} and K_M. For example, dynamical effects in the CI mechanism caused by changes in total inhibitor concentration have been studied by Straus and Goldstein (7).

To understand the hyperbolic law in a broader dynamical context some history of earlier steady-state theory is helpful. In biochemical systems, rate laws are obtained by formal linear modelling of nonlinear equations of motion. The underlying linear approach appeared in the nineteenth century (8), and the adaptation of this method to nonlinear enzyme systems was made famous by the work of King and Altman (9). However, since dynamical variables appear in the rate coefficients in this method the system is effectively non-autonomous: some procedure must be introduced to account for the time dependence of the formal rate-coefficient matrix of the quasi-linear scheme. Unless this is done there is no hope of producing a systematic, convergent procedure of reaching the true steady-state solution (slow time evolution) of the ODEs governing the system. Indeed, a related form of perturbation theory for chemical reactions was introduced by Hirschfelder (10). He described an approximate perturbation treatment of the evolution of a model bimolecular mechanism although he did not indicate how to extend his method to a convergent procedure for complete steady-state solution of this mechanism. Singular perturbation methods did tackle this problem in a systematic way (11). However, not all chemical reactions separate into "inner" and "outer" solutions in the clean way required by singular perturbation theory, nor is the "small parameter" uniquely determined even in stiff systems (12). An unambiguous way of resolving all these difficulties is to carry out a global analysis of the trajectory flow in the geometrical setting of the phase space, Γ, of species concentrations. To demonstrate the power and insight provided by this geometrical approach we study the [R] and CI mechanisms, which can both be reduced to plane autonomous systems. These mechanisms display unusual features and show that standard steady-state analysis breaks down easily.

In the global, geometrical picture, chemical kinetics is viewed as a flow governed by ODEs in Γ (13–17). In the simplest case relaxation in such systems corresponds to a cascade through a set of smooth, nested structures of decreasing dimension so that in the final stages of relaxation the representative point for the system moves on a *two-dimensional surface* $\Sigma(\subset \Gamma)$, then traverses a *line*, the slow manifold $\mathcal{M}(\subset \Sigma)$, and finally comes to rest at the stable equilibrium $\mathcal{P}(\in \mathcal{M})$. Experimentally this cascade corresponds to relaxation processes in the physically accessible part Γ^+ of Γ. Certainly in all closed, stoichiometric two-step systems the simple picture just described holds; this is demonstrated by our treatment of mechanism [R]. In contrast, for some parameter regimes in the CI mechanism, this hierarchical collapse is interrupted (18): the system flow no longer simply contracts from flow on a surface to flow on a line; instead the line-like motion may occur on disconnected pieces separated by a region where the motion is intrinsically two-dimensional.

To carry out a global analysis, a combination of mathematical tools must be used: functional equations, perturbation methods, and linearized analysis. To begin, the motion can be formally separated into "fast" and "slow" variables, as in center manifold theory (19–21). By writing the fast variables as smooth functions of the slow variables and introducing the velocity components defined by the governing ODEs, *differential equations*[3] for the system's invariant manifolds[4] are obtained. These differential equations are rearranged to give *functional equations* for the invariant manifolds. If such a functional equation defines a contraction, mapping its solution can be found exactly by iteration (13–17, 21). Geometrically, this solution corresponds to an invariant manifold which rapidly "attracts" the surrounding flow. The equations for the slow manifold $\mathcal{M}$ contain far more "kinetic" information than the usual Steady-State Approximation (SSA) or Equilibrium Approximation (EA) formulas. Similarly, the equation for the surface Σ contains more information than the usual linearized analysis for transient relaxation. To complement this global method, a linearized analysis of the flow (Jacobian) at the equilibrium point determines local bifurcation structure. Finally, perturbation methods provide closed formulas for limiting cases. Together, these techniques allow us to build a complete and essentially exact dynamical picture of the system. And this picture overcomes the errors and limitations of the standard steady-state analysis.

In recent years several new theoretical approaches to nonlinear kinetics have been developed. These have arisen from an interest in the time evolution of large sets of coupled reactions, particularly gas-phase reactions in flames (22). Turányi et al. (23) considered general methods for testing the accuracy of the quasi-steady-state approximation in such cases. In a re-

[3]These differential equations are ODEs for the line-like slow manifold $\mathcal{M}$ and partial differential equations for the slow surface Σ.

[4]A manifold is invariant if it is transformed (continuously) into itself under the flow, i.e., for any point $x_0 = x(0)$ in the manifold, its image $x(t, x_0)$ after time t lies in the manifold.

cent paper Li et al. (24) used singular perturbation methods to determine approximate lumping schemes for some important nonlinear biochemical models; their method can, in principle, be used to describe the transient and steady-state kinetics for large chemical systems.[5] However, they point out that there is no general method for finding global invariant manifolds for nonlinear reactions. The description of the slow time evolution of the systems they consider can ultimately be related to geometrical structures, i.e., surface-like or line-like slow manifolds. In the present paper we use iteration methods to solve the functional equations and so determine the corresponding (slow) invariant manifolds. It may even be convenient to expand the functional equation if it contains a radical (branch point) or if we are interested in a solution near an irreversible limit. However, this is not the only method for solving such functional equations or for finding invariant manifolds. As we have previously shown, such structures can be determined either numerically (25) or by perturbation theory (15, 18).

The scheme of the paper follows:

In Sect. 2 we discuss mechanism [R]. For [R] the functional equation for the slow manifold is formally quadratic, and in the irreversible limit becomes a singular perturbation problem. We treat this case carefully to demonstrate the differences between the reversible [R] and irreversible [I] cases. We show that reversibility produces corrections to the usual steady-state initial velocity and integrated rate law formulas for mechanisms [I] and [R].

In Sect. 3 we treat a planar model of the CI mechanism. While this mechanism can be reduced exactly to a three-dimensional system, most of its interesting dynamics can be captured by a planar system, including the bifurcations accompanying the appearance of a global steady state. This cautions against the uncritical use of methods that *assume* the existence of such a global steady state.

In Sect. 4 we compare our results with the standard treatment and discuss the experimental implications of our analysis, arguing that improved methods would yield a far clearer interpretation of relaxation and steady-state kinetics.

2. Reversible Michaelis–Menten mechanism [R]

The phase-space analysis of the kinetics of the reversible mechanism [R] (25) is now developed; this leads through a singular perturbation treatment to the corresponding irreversible mechanism [I] (14, 15, 17).

The system of coupled ODEs for [R] is

$$[1] \qquad \dot{e} = -k_1 es + (k_{-1} + k_2)c - k_{-2}ep$$

$$[2] \qquad \dot{c} = k_1 es - (k_{-1} + k_2)c + k_{-2}ep$$

$$[3] \qquad \dot{s} = -k_1 es + k_{-1}c$$

$$[4] \qquad \dot{p} = k_2 c - k_{-2}ep$$

Since there are *four* species in this system the corresponding phase space is four-dimensional; we write $\Gamma = \Gamma_4 = s \times c \times e \times p$.[6] However, there are also *linear* constants of the motion: adding eqs. [2], [3], and [4] gives

$$\dot{c} + \dot{s} + \dot{p} = 0$$

which integrates to

$$[5] \qquad c + s + p = m_s$$

where m_s is the conserved total substrate concentration.[7] Similarly, adding eqs. [1] and [2] gives

$$\dot{e} + \dot{c} = 0$$

which integrates to

$$[6] \qquad e + c = m_e$$

where m_e is the conserved total enzyme concentration. The existence of these two linear constants of the motion means that there is a *planar* two-dimensional coset[8] parameterized by m_s and m_e, say $\Gamma_2(m_s, m_e) \subset \Gamma_4$, to which the corresponding family of trajectories is restricted. Two natural projections exist for the flow in $\Gamma_2(m_s, m_e)$, namely, those onto $s \times c$ and onto $s \times p$. The $(s \times p)$ representation formally preserves the symmetry of mechanism [R] but the $(s \times c)$ representation is related to previous work (14, 15, 17) and also to the way that experimentalists discuss enzyme kinetics, so this representation will be used here. Therefore, introducing eqs. [5] and [6] into eqs. [2] and [3] gives the plane autonomous system

$$[7] \qquad \dot{c} = k_1(m_e - c)s - (k_{-1} + k_2)c + k_{-2}(m_e - c)(m_s - s - c)$$

$$[8] \qquad \dot{s} = -k_1(m_e - c)s + k_{-1}c$$

This system, which is fully equivalent to the original four-dimensional system [1]–[4], is now used to give a description of the slow time evolution for mechanism [R].[9]

2.1 Standard approximations and equilibria of mechanism [R]

The SSA is obtained by setting $\dot{c} = 0$ in eq. [7]; this gives a quadratic equation for c whose "negative" branch corresponds to the SSA, i.e., the $(\dot{c} = 0)$ isocline or c nullcline. The equation for this nullcline can be reduced to the first-order perturbation expression

$$[9] \qquad c_{SSA}(s; \eta) = \frac{m_e s}{s + K_S} + \eta \frac{m_e K_S}{(s + K_S)^2}\left(m_s - s - \frac{m_e s}{s + K_S}\right) + O(\eta^2)$$

where η is the rate constant ratio

$$\eta = \frac{k_{-2}}{k_1}$$

and

$$K_S = \frac{k_{-1} + k_2}{k_1}$$

[5]Reference 24 contains many references to the early lumping methods used in chemical engineering and to the recent developments of this method applied to nonlinear systems.

[6]This space is given the usual Euclidean metric: if P_1 and P_2 are two points in Γ_4, then the distance function d between them is given by $d(P_1, P_2) = [(s_1 - s_2)^2 + (c_1 - c_2)^2 + (e_1 - e_2)^2 + (p_1 - p_2)^2]^{1/2}$.

[7]Because of the symmetry in mechanism [R] this could equally well be called "total product" concentration.

[8]This coset is *not* a linear manifold (subspace) since it does not contain the origin of Γ_4.

[9]The fast motion, from any initial condition, can be obtained by Taylor series methods. This method is discussed in ref. 25.

is the Michaelis constant for the forward reaction S $\longrightarrow$ P.[10] For $\eta = 0$, eq. [9] gives the c nullcline for mechanism [I], i.e.,

$$c_{SSA}(s;\, 0) = \frac{m_e s}{s + K_S}$$

The EA corresponds to the ($\dot{s} = 0$) isocline or s nullcline, obtained by setting $\dot{s} = 0$ in eq. [8]:

$$[10] \qquad c_{EA}(s) = \frac{m_e s}{s + K_1}$$

where K_1 is the "equilibrium" constant for the first step in [R], so

$$K_1 = \frac{k_{-1}}{k_1}$$

Evidently, K_S and K_1 can be related by

$$K_S = K_1 + \epsilon$$

where

$$\epsilon = \frac{k_2}{k_1}$$

Note that c_{EA} is independent of η.[11] The graphs of SSA and EA are shown in Fig. 1 together with the phase trajectories. These trajectories all move into a trapping region lying between the SSA and EA nullclines, towards a unique trajectory, the slow manifold $\mathcal{M} = \mathcal{M}(\eta)$, which represents the true *dynamical steady state* of [R].

The disappearance of the reversible step in going from [R] to [I] produces important changes in the global topology of the flow; both singular and non-singular effects occur and these are related to the two branches of the quadratic equation(s) underlying mechanism [R]. This important feature is omitted in standard treatments of [R] but is central to a procedure for systematic improvement to these standard treatment. The basic quadratic character is most simply illustrated by a discussion of the behaviour of the equilibria in [R].

It is evident from the flow pattern in Fig. 1 that the EA and SSA nullclines intersect at two equilibria (●): The (lower) physical equilibrium $\mathcal{P}_+ = \mathcal{P}_+(\eta)$ is *stable* and its position moves smoothly as $\eta \longrightarrow 0$; the (upper) unphysical equilibrium $\mathcal{P}_- = \mathcal{P}_-(\eta)$ is *unstable* and its position moves in a singular way (to infinity) as $\eta \longrightarrow 0$. These equilibria of mechanism [R] are given by setting $\dot{c} = \dot{s} = 0$ in eqs. [7] and [8]. This gives a quadratic equation in s (or c) with solutions $s_\pm$ (or $c_\mp$); the root s_+ corresponds to the physical equilibrium and s_- to the unphysical equilibrium in $s \times c$. To $O(\eta)$ the physical

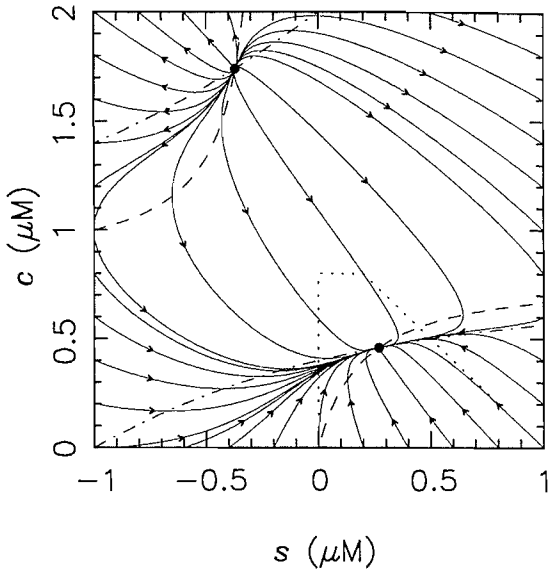

FIG. 1. Trajectories for the reversible Michaelis–Menten mechanism at: $m_e = 8.0 \times 10^{-7}$ M, $m_s = 1.0 \times 10^{-6}$ M, $k_1 = 1.0 \times 10^7$ M^{-1} s^{-1}, $k_{-1} = 2.0$ s^{-1}, $k_2 = 1.0$ s^{-1}, $k_{-2} = 5.0 \times 10^6$ M^{-1} s^{-1}. The flow pattern is shown near both equilibria $\mathcal{P}_\pm$ indicated by ●. Arrows indicate the direction of the flow. The upper left ● marks the unstable node $\mathcal{P}_-$; this is a "source" of the trajectory flow. The lower right ● marks the stable node $\mathcal{P}_+$; this is a "sink" for the trajectory flow. The broken curves (– –) are the two branches of the hyperbola corresponding to the EA. The flow crosses the EA branches vertically everywhere. The dot-dash curves (– · – ·) are the two (nearly hyperbolic) branches corresponding to the SSA. The flow crosses these curves horizontally everywhere. The dotted trapezium (· · ·) in the lower right corner shows the boundary of the physical domain. Note how the flow becomes trapped between the EA and SSA nullclines near the stable equilibrium $\mathcal{P}_+$.

equilibrium $\mathcal{P}_+(\eta)$ is located in $s \times c$ at[12]

$$s_{eq}^+ = s_+(\eta) = \eta \frac{K_1 m_s}{\epsilon}, \qquad c_{eq}^+ = \eta \frac{m_e m_s}{\epsilon}$$

in $\Gamma_2 = s \times c$. As $\eta \longrightarrow 0$ the position of $\mathcal{P}_+(\eta)$ moves smoothly to the origin of $s \times c$. Its position vector can easily be extended to $\Gamma(m_e, m_s) \subset \Gamma_4$ using the constants of the motion, m_s and m_e. Thus the two remaining coordinates of $\mathcal{P}_+(\eta)$ in Γ_4 are

$$e_{eq}^+ = m_e \left(1 - \eta \frac{m_s}{\epsilon}\right), \quad p_{eq}^+ = m_s \left[1 - \eta \frac{(m_e + K_1)}{\epsilon}\right]$$

The overall equilibrium constant K_{eq} is defined by

$$K_{eq} = \frac{k_1 k_2}{k_{-1} k_{-2}} = \frac{p_{eq}^+}{s_{eq}^+}$$

so that, formally to $O(\eta^0)$,

$$K_{eq}(\eta) = \frac{p_{eq}^+(\eta)}{s_{eq}^+(\eta)} = \frac{\epsilon}{\eta K_1} + O(\eta^0)$$

[10]For the reversible case, $\eta > 0$, the SSA nullcline given by eq. [9] is *not* the lower branch of a rectangular hyperbola. In standard initial velocity experiments, the initial condition is $s(0) = m_s$ (variable), $e(0) = m_e$ (constant), and $p(0) = 0$. The set of experimental results corresponds to recording data for the event $\dot{c} = 0$ on every sample trajectory, i.e., to crossing the non-hyperbolic SSA nullcline. This implies that curvature can appear in any of the standard linearized plots. This possibility has not been discussed in the literature.

[11]It is useful to think of η and ϵ as small parameters, since we are interested in the case where the rate of product formation is intrinsically small, i.e., k_2 is small and therefore ϵ is small. Also, we consider the limit where the recombination of product with enzyme becomes vanishingly small, i.e., k_{-2} and therefore η both tend to zero.

[12]The sign +/− on $\mathcal{P}_\pm(\eta)$ denotes the physical/unphysical equilibrium, not the branch of the quadratic equation: in the quadratic equation for $c(\eta)$, the branch $c_-(\eta)$ corresponds to the physical solution and the branch $c_+(\eta)$ to the unphysical solution, whereas the opposite is true for $s(\eta)$.

For personal use only.

but, in fact, the $O(\eta^{-1})$ term is exactly K_{eq}; it can be extended to give the Haldane (26) relation for mechanism [R].

The behaviour of the flow near equilibrium is governed by the first-order decay exponents there. For nearly all initial conditions the relevant exponent will be the one with smaller magnitude. For example, in the irreversible mechanism [I] this decay constant or eigenvalue is commonly written as V_{max}/K_M, i.e., $k_2 m_e/K_S$ here, but this is only approximate. We show later that the correction depends on m_e/K_S for mechanism [I]. We now tackle the dynamics near equilibrium by linearizing the ODEs there.

The linearized stability analysis at $\mathcal{P}_+(\eta)$ is carried out as follows. In the neighbourhood of an equilibrium, the equation of motion is

$$\frac{d}{dt}\begin{pmatrix}\delta c\\ \delta s\end{pmatrix} = \begin{pmatrix}\frac{\partial \dot c}{\partial c} & \frac{\partial \dot c}{\partial s}\\ \frac{\partial \dot s}{\partial c} & \frac{\partial \dot s}{\partial s}\end{pmatrix}\begin{pmatrix}\delta c\\ \delta s\end{pmatrix}$$

At $\mathcal{P}_+(\eta)$ the Jacobian in this equation can be written as

$$J(\eta) = J_0 + \eta J_1$$

where

$$J_0 = \begin{pmatrix}-(k_{-1}+k_2) & k_1 m_e\\ k_{-1} & -k_1 m_e\end{pmatrix}$$

is the Jacobian at the origin, i.e., $\mathcal{P}_+(0)$, and

$$J_1 = \frac{1}{\epsilon}\begin{pmatrix}-[k_{-1}m_s + k_2(m_s+m_e)] & -m_e(k_1 m_s + k_2)\\ k_{-1}m_s & k_1 m_e m_s\end{pmatrix}$$

is the perturbation matrix.

The eigensystem of J_0 is easily constructed. The eigenvalues are

[11]
$$\lambda_\pm = \frac{-(k_{-1}+k_2+k_1 m_e) \pm \sqrt{(k_{-1}+k_2+k_1 m_e)^2 - 4k_1 k_2 m_e}}{2}$$

with left eigenvectors

$$\langle \pm| = \left(1, \frac{k_{-1}+k_2+\lambda_\pm}{k_{-1}}\right)$$

and right eigenvectors

$$|\pm\rangle = \left(\frac{k_1 m_e + \lambda_\pm}{k_{-1}}, 1\right)^T$$

where ^{T} indicates the transpose (column) vector. Then, using the usual Rayleigh–Schrödinger procedure (27), to $O(\eta)$ the perturbed eigenvalues are

$$\lambda_\pm(\eta) = \lambda_\pm + \eta\frac{\langle \pm| J_1 |\pm\rangle}{\langle \pm|\pm\rangle}$$

and the perturbed right eigenvectors are

$$|\pm;\eta^1\rangle = |\pm\rangle + \eta\frac{|\mp\rangle\langle\mp| J_1|\pm\rangle}{\langle\mp|\mp\rangle(\lambda_\pm - \lambda_\mp)}$$

As usual, these $O(\eta)$ eigenvectors give an $O(\eta^2)$ leading correction to the eigenvalues. The perturbed left eigenvectors are

$$\langle \pm;\eta^1| = \langle\pm| + \eta\frac{\langle\pm| J_1|\mp\rangle\langle\mp|}{(\lambda_\pm - \lambda_\mp)\langle\mp|\mp\rangle}$$

These formulas for the perturbed left and right eigenvectors preserve normalization and orthogonalization to $O(\eta)$ so that $\langle \pm;\eta^1|\pm;\eta^1\rangle = \langle\pm|\pm\rangle + O(\eta^2)$ and $\langle\pm;\eta^1|\mp;\eta^1\rangle = 0 + O(\eta^2)$.

Similarly, to $O(\eta)$, the unphysical equilibrium $\mathcal{P}_-(\eta)$ is located in $s \times c$ at

$$s_{eq}^- = s_-(\eta) = -K_1\left(1 + \eta\frac{m_e}{\epsilon}\right),$$

$$c_{eq}^- = \frac{\epsilon}{\eta} + m_e + m_s + K_1 - \eta\frac{m_s m_e}{\epsilon}$$

and the additional coordinates in Γ_4 are

$$e_{eq}^- = -\frac{\epsilon}{\eta} - m_s - K_1 + \eta\frac{m_s m_e}{\epsilon},$$

$$p_{eq}^- = -\frac{\epsilon}{\eta} - m_e + \eta\frac{m_e(m_s + K_1)}{\epsilon}$$

This unstable equilibrium moves to infinity as $\eta \to 0$, and in principle this singular motion leads to interesting changes in the directional behaviour of the vector field "at infinity" as $\eta \to 0$. Since there is no unperturbed solution for $\mathcal{P}_-(\eta)$ at $\eta = 0$ we have to solve the eigensystem directly (see Lefschetz, ref. 1, Chap. 9).

2.2 Slow manifold integrated rate law for mechanism [R]

We now consider the problem of finding the slow manifold for mechanism [R] and to the related question of solving the steady-state equation of motion to get the integrated rate law (28).

Dividing eq. [7] by eq. [8] gives the trajectory equation

$$c' = \frac{\dot c}{\dot s} = \frac{dc}{ds}$$

$$= \frac{k_1(m_e - c)s - (k_{-1}+k_2)c + k_{-2}(m_e - c)(m_s - s - c)}{-k_1(m_e - c)s + k_{-1}c}$$

where $(.)' \equiv d(.)/ds$. This can be rearranged[13] to give the following quadratic functional equation

[12] $$\eta c^2 - [(s + K_1)(1 + c') + \epsilon + \eta(m_s + m_e - s)]c + m_e s(1 + c') + \eta m_e(m_s - s) = 0$$

The formal solution of eq. [12] is

[13]This differential equation can be also solved by the perturbation method discussed in refs. 15 and 18 but here we consider the perturbation expansion of the functional equation itself since we are interested in the way the solution coalesces with the irreversible case as $\eta \to 0$.

[13] $$c_{\pm}(s;\eta) = \frac{1}{2\eta}\left\{(s+K_1)(1+c')+\epsilon+\eta(m_s+m_e-s)\pm\sqrt{[(s+K_1)(1+c')+\epsilon+\eta(m_s+m_e-s)]^2-4\eta[m_e s(1+c')+\eta m_e(m_s-s)]}\right\}$$

This is the fundamental equation arising from our analysis, since the iterative or perturbation solution of its "negative" branch gives a sequence of functions that converges to a limit function, $c_{-}^{*}(s;\eta)$ say, which is the formula for the slow manifold $\mathcal{M}$ for mechanism [R]. Equation [13] can be rewritten as

[14] $$c_{\pm}(s;\eta) = \frac{B_0+\eta B_1 \pm \sqrt{[B_0+\eta B_1]^2-4\eta(C_0+\eta C_1)}}{2\eta}$$

where

$$B_0 = (s+K_1)(1+c')+\epsilon$$

$$B_1 = m_s + m_e - s$$

$$C_0 = m_e s(1+c')$$

$$C_1 = m_e(m_s - s)$$

Equations [13] and [14] are exact. Since the formal solution $c_{\pm}(s;\eta)$ is two-branched the perturbation treatment of eq. [14] is now developed to identify the "physical" and "unphysical" branches and to expose the relation between the reversible and irreversible cases.[14]

At small η the functional equation [14] presents a singular perturbation problem, or at least a problem where the "positive" branch $c_{+}(s;\eta)$, which is $O(\eta^{-1})$, behaves in a singular way as $\eta \to 0$ and where the "negative" branch $c_{-}(s;\eta)$, which is $O(\eta^{0})$, behaves normally as $\eta \to 0$. For small η, the positive branch of eq. [14] gives

$$c_{+}(s;\eta) = \frac{B_0}{\eta} + B_1 - \frac{C_0}{B_0} + O(\eta)$$

so

$$\lim_{\eta\to 0} c_{+}(s;\eta) = \infty$$

Similarly the negative branch gives

[15] $$c_{-}(s;\eta) = \frac{C_0}{B_0} + \eta\left(\frac{C_1}{B_0} - \frac{C_0 B_1}{B_0^2} + \frac{C_0^2}{B_0^3}\right) + O(\eta^2)$$

Thus, as $\eta \to 0$, c_{-} reduces to the functional equation for mechanism [I], i.e.,

$$\lim_{\eta\to 0} c_{-}(s;\eta) = c_{-}(s;0) = \frac{C_0}{B_0} = \frac{m_e s(1+c')}{(s+K_1)(1+c')+\epsilon}$$

which has been studied before (14, 15, 17, 25). The c_{-} branch therefore gives the physically relevant solution, i.e., the slow manifold $\mathcal{M}$ for mechanism [R]. Since this equation is only accurate to $O(\eta)$, it is solved approximately. The solution procedure will be considered after the meaning of the SSA and EA has been discussed in relation to eq. [15].

The functional equation [15] gives an interesting meaning to the SSA and EA. Any *horizontal* line $c(s)$ = const. implies $c' = 0$ so that the image of this line under the functional equation is the SSA, i.e., the c nullcline which trajectories cross *horizontally*.[15] Similarly, any *vertical* line implies $c'(s) = \infty$ so its image under the functional equation is the EA, i.e., the s nullcline which trajectories cross *vertically*. In fact it is very convenient to use the formula for the EA or the SSA as a starting function for finding the equation for $\mathcal{M}$ iteratively under eq. [15].

There are other interesting limits for eq. [13]. In the product inhibition case, which is a type of irreversible inhibition (29), formally, at least, the first step becomes irreversible, so $k_{-1} \to 0$. In the van Slyke–Cullen case (30) both steps are irreversible, i.e., $k_{-1} = k_{-2} = 0$. The change in trajectory flow as the kinetics approaches the product inhibition limit is shown in Fig. 2; here all the parameters except k_{-1} are the same as in Fig. 1. In Fig. 2*a*, k_{-1} is small but non-zero. Notice that the EA lies (in part) near to the c axis, because "equilibrium" between C and E + S is less and less easily achieved as k_{-1} decreases. Figure 2*b* shows the product inhibition limit, obtained formally by setting $k_{-1} = 0$ in mechanism [R].[16] The s nullcline has become the union of the lines $s = 0$ and $c = m_e$; the equilibrium point has migrated to the c axis. The product inhibition limit, $k_{-1} \to 0$, changes the flow in the physical region, whereas the reduction of [R] to [I], as $k_{-2} \to 0$, also changes the global flow structure, e.g., $\mathcal{P}_{-}(\eta) \to \infty$ as $\eta \to 0$.

We now turn to the problem of finding the integrated rate law or progress curve for mechanism [R]. Geometrically the progress curve is identified with the slow manifold and dynamically it corresponds to progress along this manifold.

Usually, the integrated rate law is derived from the SSA, but the functional equation [15] allows improved expressions to be obtained. The additional corrections that arise become larger as the reaction progresses and so are increasingly important in the middle and late stages of reaction. Indeed, these corrections are what distinguish the structure of $\mathcal{M}$, which underlies the integrated rate law, from the structure of the SSA or c nullcline, which underlies initial velocity experiments.

Since the dynamical steady state of mechanism [R] corresponds to progress along $\mathcal{M}$, a sequence of approximations to the integrated rate law can be found from the corresponding sequence of formulas for $\mathcal{M}$. To get such sequences, eq. [15] is written as an iterative scheme; this scheme defines a contraction mapping on a space of smooth functions with fixed

[14]The branch point associated with the radical in the functional equation [13] can cause difficulties in functional iteration.

[15]In agreement with this interpretation, eq. [9], which is the perturbation expansion to $O(\eta)$ of the exact solution of the quadratic equation for the SSA nullcline, is also the image of any horizontal line, $c(s)$ = const, under eq. [15] which is the functional equation to $O(\eta)$ for $\mathcal{M}$ for mechanism [R].

[16]It has been remarked in ref. 4 that in more realistic models of the product inhibition limit, intermediate complexes should be considered.

point $c_-^*(s;\eta)$, so that $\mathcal{M} = \text{graph}\{c_-^*(s;\eta)\}$. In fact, from its form, eq. [15] maps rational functions into rational functions so $c_-^*(s;\eta)$ is approximated by an infinite sequence of convergent rational functions.[17] The formulas for $c_{EA}(s;\eta)$ in eq. [10] and for $c_{SSA}(s;\eta)$ in eq. [9] represent the EA and SSA respectively in the $s \times c$ plane. These are first approximations to the formula for $\mathcal{M}$ and they improve as $s \longrightarrow \infty$. However, they are not necessarily good in the crossover region from zeroth order to first order kinetics (where [R] really has no order). An improved approximation for $\mathcal{M}$ is obtained by introducing $c'_{EA}(s;\eta)$ in the right of eq. [15] to get a straightforward if lengthy $O(\eta)$ perturbation solution. Similarly, $c'_{SSA}(s;\eta)$ can be put on the right of eq. [15] to get some of the $O(\eta^2)$ correction for $\mathcal{M}$ as well.

For mechanism [R] slow (dynamical steady-state) motion is intrinsically one-dimensional, so the evolution equation is

$$[16] \qquad \dot{s} = -k_1(m_e - c_-^*(s;\eta))s + k_{-1}c_-^*(s;\eta)$$

where c_-^* is the formula for $\mathcal{M}$ or a good approximation to it.[18] If $c_{SSA}(s;0)$ is used in eq. [16] (which is separable) we get the standard integrated rate law for mechanism [I], i.e.,

$$[17] \qquad V_{max}t = s(0) - s(t) + K_S \ln\left[\frac{s(0)}{s(t)}\right]$$

where $V_{max} = m_e k_2$. Rigorously speaking, eq. [17] describes constrained evolution along the SSA or c nullcline for mechanism [I]. At $\eta = 0$, the long-time behaviour of this equation is dominated by the divergent logarithmic term, which predicts that

$$s(t) \sim \exp\left(-\frac{V_{max}}{K_S}\,t\right)$$

or, equivalently,

$$\lim_{t\to\infty} -\frac{\ln s(t)}{t} = \frac{V_{max}}{K_S}$$

This behaviour should be compared with the result predicted by eq. [11] for the asymptotic decay exponent, which is

$$[18] \qquad \lim_{t\to\infty} -\frac{\ln s(t)}{t} = -\lambda_+ \approx \frac{V_{max}}{K_S}\left(1 - \frac{m_e}{K_S}\right)$$

so there is an $O(m_e)$ correction to the decay eigenvalue. This result can be recovered from a more accurate description of the motion along the slow manifold. Thus, using the first iterate of $c_{EA}(s)$ under eq. [15] in eq. [16] gives

$$[19] \qquad V_{max}t = s(0) - s(t) + K_S \ln\left[\frac{s(0)}{s(t)}\right] + m_e \ln\left[\frac{s(0)}{s(t)}\right] + m_e \ln\left[\frac{s(t)+K_1}{s(0)+K_1}\right]$$
$$+\frac{\eta}{\epsilon}\left\{K_S s + [(K_1 - m_s)K_S + m_e K_1]\ln s + m_e \epsilon \ln(s + K_S) + \frac{K_1 K_S m_s}{s}\right\}\Bigg|_{s(0)}^{s(t)}$$

The first three terms in the first line comprise the standard formula for mechanism [I]. The fourth and fifth $O(m_e)$ terms are iterative corrections under eq. [15]. The first line implies that K_S is the Michaelis constant and that the fourth term is the $O(m_e)$ correction in eq. [18] to the decay eigenvalue λ_+ of eq. [11]. Depending on parameter values and data-fitting procedures in experiments, this correction to the decay eigenvalue can be important at long times, i.e., near the equilibrium of the system. The second line in eq. [19] is the correction, proportional to η/ϵ, as in s_{eq}^+ etc., for the reversible step which changes [I] into [R].

Setting $k_{-1} = 0$ in eq. [19], implying that $K_1 = 0$, gives the product inhibition result for the integrated rate law as

$$[20] \qquad V_{max}^{PI}t = s(0) - s(t) + \epsilon \ln\left[\frac{s(0)}{s(t)}\right]$$
$$+ \eta[s - m_s \ln s + m_e \ln(s + \epsilon)]\Big|_{s(0)}^{s(t)}$$

At $\eta = 0$ this corresponds to van Slyke–Cullen integrated rate law and gives the decay eigenvalue as $\lambda_+ \approx -k_1 m_e$ in this limit.

[17]Since each iteration creates a higher degree polynomial in the numerator and denominator of this sequence of rational functions, the limit is a transcendental function.

[18]For an approach that provides a general formalism for treating the transient (fast) and slow motion together as a singular perturbation problem see ref. 24.

The perturbation solutions discussed above are only approximate since they arise from the $O(\eta)$ approximation to the functional equation for the slow manifold. To get very accurate formulas for $\mathcal{M}$ (when η is large) the exact relation [13] must be used. The c_- branch of this functional equation possesses the contraction mapping property under iteration, which automatically guarantees that sequences of iterates converge to a unique fixed-point function $c_-^*(s;\eta)$, i.e., the formula for the slow manifold (trajectory) $\mathcal{M}(\eta)$ for mechanism [R].

3. Planarized competitive inhibition mechanism

We now discuss the CI mechanism because its dynamics can be reduced to a planar system after the elimination of a fast transient. Nevertheless, relaxation in the CI mechanism still shows several distinct relaxation regimes (18), and we study the one displaying the richest transient behaviour.

We write this motion using c, s, and i as dynamical variables with total enzyme $m_e = e + c + h$ and total inhibitor $m_i = i + h$ as conserved variables. Thus the rate equations for the CI mechanism (Scheme [CI]) are

$$\dot{s} = -k_1 s(m_e - c - m_i + i) + k_{-1}c$$
$$[21] \qquad \dot{c} = k_1 s(m_e - c - m_i + i) - (k_{-1} + k_p)c$$
$$\dot{i} = -k_2 i(m_e - c - m_i + i) + k_{-2}(m_i - i)$$

Important changes in transient behaviour described by the system [21] take place as the total amount of inhibitor, m_i, is reduced. (These effects could also be detected experimentally.)

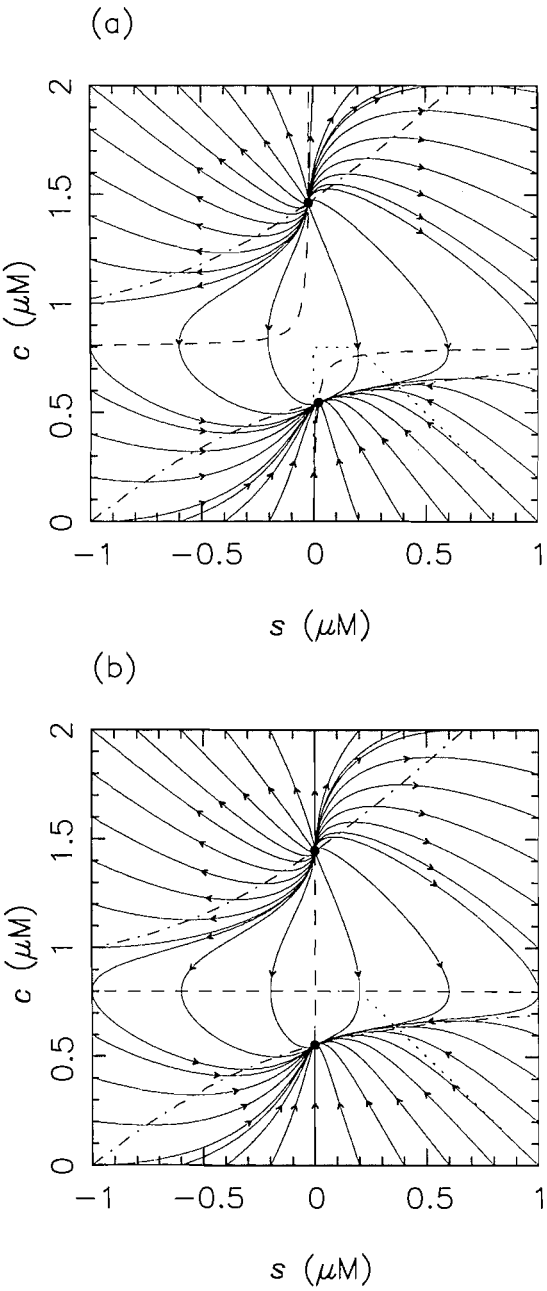

FIG. 2. The changes in the flow for mechanism [R] approaching the product inhibition limit ($k_{-1} \rightarrow 0$) are shown. All parameters are the same as in Fig. 1 apart from k_{-1}; the various curves and regions have the same meaning. (*a*) Flow for $k_{-1} = 0.1\ s^{-1}$ (which is smaller than that in Fig. 1). Note how the EA (--) has become sharply bent. (*b*) Flow for $k_{-1} = 0.0\ s^{-1}$. This is the product inhibition limit. Note how the EA has become a degenerate hyperbola, i.e., the straight lines formed by the *c* and *s* axes. The equation for the *s* nullcline (cf. eq. [8]) factors in this limit.

At very large m_i, at least one of the two concentrations i and h must be large so the equilibration in step [Inh] is faster than the steps in reaction [I] and corresponds to the fastest transient. Total inhibitor concentration m_i can be reduced until the relaxations in [Inh] and [I] occur at comparable rates; this signals crossover behaviour that occurs at $m_i = m_i^{(2)}$ in the notation of ref. 18. For values of $m_i < m_i^{(2)}$ the equilibration in reaction [I] is the fastest step at large s. However, at small s, unusual relaxation dynamics can arise from competition between the

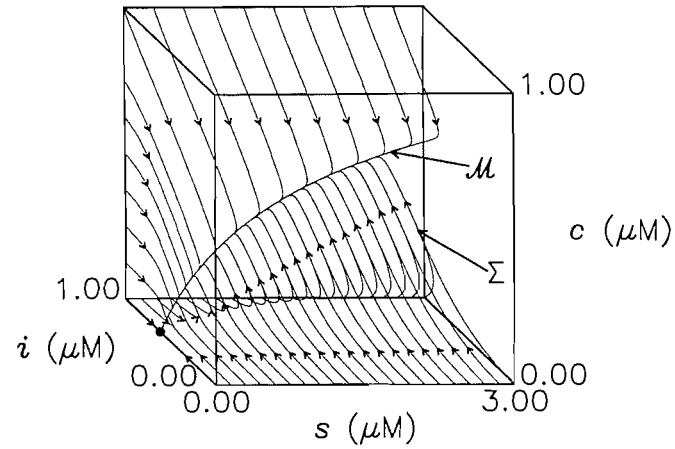

FIG. 3. Some trajectories for the CI mechanism at: $m_e = 1.0 \times 10^{-6}$ M, $m_i = 1.0 \times 10^{-6}$ M, $k_1 = 1.0 \times 10^7\ M^{-1}\ s^{-1}$, $k_{-1} = 10.0\ s^{-1}$, $k_2 = 8.0 \times 10^7\ M^{-1}\ s^{-1}$, $k_{-2} = 80.0\ s^{-1}$, $k_p = 1.0\ s^{-1}$. Arrows indicate the direction of the flow. Note how the trajectories first approach a well-defined (sloping) surface Σ before moving towards the slow manifold $\mathcal{M} \subset \Sigma$. A representative point on $\mathcal{M}$ follows this unique trajectory to the equilibrium point on the i axis, indicated by ●.

first-order decay in the catalysis [I] and the equilibration in step [Inh]. It is the regime $m_i < m_i^{(2)}$ that we study.

For $m_i < m_i^{(2)}$, the fast transient decay in the three-dimensional phase space $\Gamma = s \times c \times i$ corresponds to collapse of the trajectory flow onto a two-dimensional surface Σ. This relaxation is shown in Fig. 3. The surface Σ intersects the $s \times i$ plane in the i axis and has a single-valued projection onto this plane.

These geometrical characteristics correspond to the fact that the equilibration in reaction [I] is fast so that c is a "fast" or entrained variable (2). Thus the geometry of the medium velocity or slow dynamics in Σ is captured by projection onto the $s \times i$ phase plane.

To simplify the description of the dynamics we move the origin of the coordinate system to the equilibrium of the system [21] at

$$s_{eq} = 0$$

[22] $$c_{eq} = 0$$

$$i_{eq} = \tfrac{1}{2}\{m_i - m_e - K_i + \Delta_i^{1/2}\}$$

where the discriminant

[23] $$\Delta_i = (m_e + m_i + K_i)^2 - 4m_e m_i$$

is always positive and

$$K_i = \frac{k_{-2}}{k_2}$$

is the dissociation or inhibitor constant for the complex H = EI. Using displacement dynamical variables defined by

$$s = s_{eq} + \delta s$$

[24] $$c = c_{eq} + \delta c$$

$$i = i_{eq} + \delta i$$

and the additional equilibrium coordinate

$$e_{eq} = \tfrac{1}{2}\{m_e - m_i - K_i + \Delta_i^{1/2}\}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12

the system [21] can be written as

$$\delta\dot{s} = -k_1 e_{eq}\delta s + k_{-1}\delta c + k_1\delta s(\delta c - \delta i)$$

[25] $$\delta\dot{c} = k_1 e_{eq}\delta s - (k_{-1} + k_p)\delta c - k_1\delta s(\delta c - \delta i)$$

$$\delta\dot{i} = -[k_2(i_{eq} + e_{eq}) + k_{-2}]\delta i + k_2 i_{eq}\delta c + k_2\delta i(\delta c - \delta i)$$

To find the equation for the surface function $\phi = \phi_\Sigma$ for Σ, we write

[26] $$\delta c = \phi(\delta s, \delta i)$$

and differentiate with respect to time to get

[27] $$\delta\dot{c} = \frac{\partial\phi}{\partial\delta s}\delta\dot{s} + \frac{\partial\phi}{\partial\delta i}\delta\dot{i}$$

Substituting eqs. [25] and rearranging gives the functional equation for ϕ as

[28] $$\phi(\delta s, \delta i) = \frac{\delta s(e_{eq} + \delta i)\left(1 + \frac{\partial\phi}{\partial\delta s}\right) + \alpha\delta i(i_{eq} + e_{eq} + \delta i + K_i)\frac{\partial\phi}{\partial\delta i}}{\epsilon + (\delta s + K_E)\left(1 + \frac{\partial\phi}{\partial\delta s}\right) + \alpha(i_{eq} + \delta i)\frac{\partial\phi}{\partial\delta i}}$$

where[19]

$$\epsilon = k_p/k_1$$

$$K_E = k_{-1}/k_1$$

$$K_S = K_E + \epsilon$$

$$\alpha = k_2/k_1$$

Notice that eq. [28] has no explicit time dependence since the underlying ODEs are autonomous. We find the fixed-point function $\phi^*(\delta s, \delta i)$ of eq. [28] iteratively: taking $\phi_0 = $ const. on the right of eq. [28] gives $\partial\phi_0/\partial\delta s = \partial\phi_0/\partial\delta i = 0$ so that ϕ_1, the iterate of ϕ_0 under eq. [28], is

[29] $$\delta c = \phi_1(\delta s, \delta i) = \frac{\delta s(e_{eq} + \delta i)}{\delta s + K_S}$$

Replacing δc with ϕ_1 in the system [25] gives the (projected) plane autonomous system

[30] $$\delta\dot{s} = -k_1 e_{eq}\delta s + k_{-1}\frac{\delta s(e_{eq} + \delta i)}{\delta s + K_S} + k_1\delta s\left[\frac{\delta s(e_{eq} + \delta i)}{\delta s + K_S} - \delta i\right]$$

$$\delta\dot{i} = -[k_2(i_{eq} + e_{eq}) + k_{-2}]\delta i + k_2 i_{eq}\frac{\delta s(e_{eq} + \delta i)}{\delta s + K_S} + k_2\delta i\left[\frac{\delta s(e_{eq} + \delta i)}{\delta s + K_S} - \delta i\right]$$

The flow of this plane autonomous system near its equilibrium at $(\delta s_{eq}, \delta i_{eq}) = (0, 0)$ imitates the quasi-planar flow on Σ near equilibrium, where only the linear terms contribute. However, the system [30] also captures important features of the dynamics far from equilibrium and so provides a faithful global model. For, expanding eq. [28] asymptotically at large δs shows that eq. [29] is asymptotically correct to $O(\delta s^0)$, so that the planarized representation of the system [30] is correct to this order also. This argument shows that the velocity components $\{\delta\dot{s}, \delta\dot{i}\}$ are never large on Σ, i.e., they are $O(\delta s^0)$. Also, in the far-from-equilibrium regime the surface function ϕ_1 has a hyperbolic-law contribution and also an important cross-term $\delta i\delta s$. If the form for ϕ_1 is simplified in any way, important features of the (true) flow on Σ are *lost* in the planarized representation, so in some sense the functional form of the system [30] provides a *minimal model* of the relaxed flow in the underlying system.[20] We now analyse this planar model flow.

Figure 4 shows the deformation of the flow defined by the planarized velocity functions [30] as the experimental parameter m_i is varied. For some values of the rate constants, a region of complex eigenvalues and eigenvectors of the Jacobian $\boldsymbol{J} = \partial\{\dot{s}, \dot{c}, \dot{i}\}/\partial\{s, c, i\}$ interrupts the slow manifold. This important property is associated with the breakup of the line-like slow manifold in the CI mechanism (18), behaviour that differs geometrically from that of any stoichiometric two-step system. However, the imitation of these changes in flow structure on Σ in a planar system is a great simplification over the full three-dimensional description since the eigensystem at equilibrium can be easily solved. This means that the defective character of the flow at the bifurcation value of m_i can be understood. We now examine this.

In the neighbourhood of equilibrium, the planarized system gives the following linearized equation of motion

[31]

$$\frac{d}{dt}\begin{pmatrix}\delta s\\ \delta i\end{pmatrix} = \begin{pmatrix}-\frac{k_p e_{eq}}{K_S} & 0\\ \frac{k_2 i_{eq} e_{eq}}{K_S} & -[k_2(i_{eq} + e_{eq}) + k_{-2}]\end{pmatrix}\begin{pmatrix}\delta s\\ \delta i\end{pmatrix}$$

where the Jacobian matrix of the velocity functions [30] has been evaluated at the equilibrium ($\delta s = \delta i = 0$) to give the matrix $\boldsymbol{J}_{eq}$ in eq. [31]. Since $\boldsymbol{J}_{eq}$ is in lower triangular form, its eigenvalues, $\lambda_{1,2}$ say, are equal to the diagonal elements. Therefore the characteristic equation takes the form $|\boldsymbol{J}_{eq} - \lambda\boldsymbol{I}| = (\lambda_1 - \lambda)(\lambda_2 - \lambda)$, where the eigenvalue

$$\lambda_1 = -\frac{k_p e_{eq}}{K_S}$$

has right eigenvector

[32] $$\boldsymbol{u}_1 = (\delta s_1, \delta i_1)^T = \left(\frac{K_S[k_2(i_{eq} + e_{eq}) + k_{-2}] - k_p e_{eq}}{k_2 i_{eq} e_{eq}}, 1\right)^T$$

and the eigenvalue

$$\lambda_2 = -[k_2(i_{eq} + e_{eq}) + k_{-2}]$$

has eigenvector

[33] $$\boldsymbol{u}_2 = (\delta s_2, \delta i_2)^T = (0, 1)^T$$

[19]This notation is identical with that in ref. 18. This is slightly modified from that in Sect. 2 of the present paper.

[20]The asymptotic expansion of the functional equation [28] in powers of δs^{-1} implies that the starting function $\phi_0 = e_{eq} + \delta i$ gives a version of ϕ_1 that is asymptotically correct to $O(\delta s^{-1})$ as $\delta s \to \infty$. However, the additional terms in this version of ϕ_1 are not required to capture the dynamical and bifurcation behaviour discussed here.

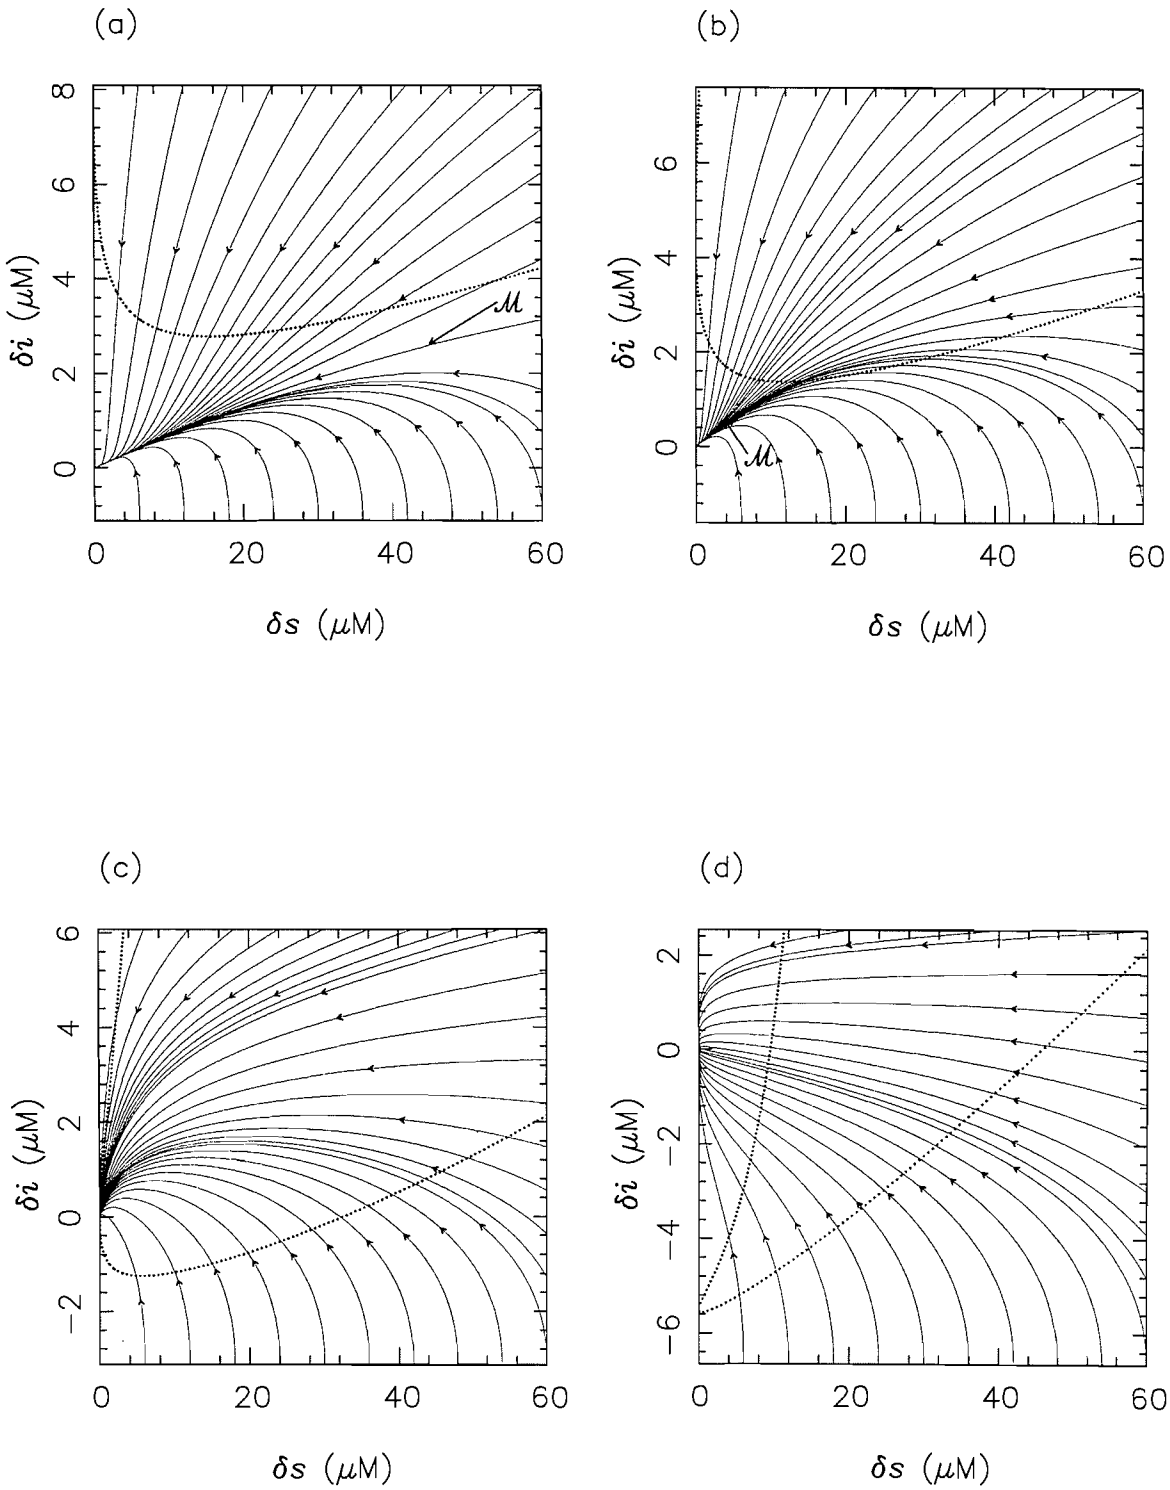

FIG. 4. The panels in this figure represent the change in the planarized flow pattern as m_i decreases through the bifurcation value $m_i^{(1)}$. Arrows represent the flow direction and the equilibrium is always at the origin in the displacement coordinates δi and δs. Locally the slow manifold $\mathcal{M}$ at the equilibrium $\delta s = \delta i = 0$ changes from a direction pointing into the interior of the physical region to the direction of the i axis. Different relaxation scenarios for the CI mechanism are illustrated. In all panels $m_e = 9.2 \times 10^{-6}$ M, $k_1 = 4.6 \times 10^7$ M^{-1} s^{-1}, $k_{-1} = 42.0$ s^{-1}, $k_2 = 2.2 \times 10^6$ M^{-1} s^{-1}, $k_{-2} = 43.0$ s^{-1}, and $k_p = 710.0$ s^{-1}. In each case, the flow on Σ, for the full system (cf. eq. [25]) projected onto $s \times i$ is indistinguishable from the planarized flow shown by the full system. (*a*) Flow for $m_i = 1.5 \times 10^{-4}$ M $> m_i^{(1)}$. At large m_i, $\mathcal{M}$ is well defined and lies in the interior of the physical region. The dotted curve is the boundary of the region (upper right) of complex eigenvalues for the Jacobian of the flow; this curve does not intersect $\mathcal{M}$. (*b*) Flow for $m_i = 1.0 \times 10^{-4}$ M $> m_i^{(1)}$. The complex-eigenvalue region intersects $\mathcal{M}$. The segment of $\mathcal{M}$ lying between the complex-eigenvalue region and the equilibrium is indicated. (*c*) Flow for $m_i = 4.4 \times 10^{-5}$ M $= m_i^{(1)}$. At this bifurcation (crossover) value for m_i, the boundary of complex-eigenvalue region just touches the equilibrium (origin) and there is only one relaxation eigenvector along the δi axis ($\mathcal{M}$ locally) in this, the defective, case. (*d*) Flow for $m_i = 1.0 \times 10^{-5}$ M $< m_i^{(1)}$. Below the bifurcation value of m_i, the "slow" direction is the δi axis ($\mathcal{M}$ locally). The "fast" direction is nearly the δs axis. The complex-eigenvalue region now separates the neighbourhood of the equilibrium from the large δs (asymptotic) region.

i.e., the i axis. Clearly, the eigenvalues of $\boldsymbol{J}_{eq}$ are always real for physically reasonable parameter values. When $\lambda_1 = \lambda_2$, which occurs at $m_i = m_i^{(1)}$ in the notation of ref. 18, there is only *one* eigenvector and the eigensystem is defective. This degenerate case is not structurally stable, since any small parameter change removes the degeneracy.[21] The triangular form of $\boldsymbol{J}_{eq}$ means that lifting this degeneracy produces a discontinuity in the motion of the slowest relaxation direction:

1. For $m_i > m_i^{(1)}$, $\lambda_2 < \lambda_1 < 0$, and, figuratively speaking, the slow eigenvector $\boldsymbol{u}_1$ in eq. [32] points towards equilibrium from inside the physical part of $s \times i$.

2. As $m_i \rightarrow m_i^{(1)}$, $\boldsymbol{u}_1$ rotates towards the i axis, i.e., $\boldsymbol{u}_2$, and at $m_i = m_i^{(1)}$ (the defective case) $\lambda_2 = \lambda_1 < 0$ and $\boldsymbol{u}_1 = \boldsymbol{u}_2$ from eqs. [32] and [33], i.e., the i axis has become the slow eigenvector.

3. For $m_i < m_i^{(1)}$, $\lambda_1 < \lambda_2 < 0$, and the i axis, i.e., $\boldsymbol{u}_2$ given by eq. [33], remains the slow eigenvector. Thus the *velocity of rotation* of the slow direction changes abruptly as m_i passes through $m_i^{(1)}$.

We now compare the eigenvalues of the planarized system with those of the underlying three-dimensional system [25]. This can be understood geometrically.

1. The "fast" transient eigenvalue and its eigenvector, which is transversal to Σ, describe the rapidly decaying mode eliminated by planarization, so this mode has no analogue in the planarized system.

2. The $s \times i$ plane and the surface Σ both contain the i axis (as long as m_i is not too large (18)), so near equilibrium they have a wedge-like intersection with the i axis as the "hinge" or edge. Consequently, the i axis and the corresponding eigenvalue λ_2 are invariant under planarization and comprise a common eigensystem of the full and planarized systems.

3. Provided ϕ^* representing Σ is known accurately, the remaining eigenvalue of the full system and the projection of its eigenvector onto $s \times i$ will be close to λ_1 and $\boldsymbol{u}_1$, respectively, of the planarized systems. Accordingly, the approximation ϕ_1 for ϕ^* gives $\lambda_1 = -k_p e_{eq}/K_S$. This compares well with the corresponding eigenvalue in Σ called λ_+ in ref. 18. When e_{eq}/K_S is small, $\lambda_+ = -k_p e_{eq}/(e_{eq} + K_S)$, which is close to λ_1. Similarly, the inclination of the surface Σ to the plane $s \times i$ at the equilibrium point is given by $\partial\phi_1/\partial\delta s = e_{eq}/K_S$, so the wedge-angle arctan (e_{eq}/K_S) will be small when $\lambda_1 \approx \lambda_+$.

Broadly speaking, motion in the planar system always corresponds to attraction to $\mathcal{M}$ at large s but this segment of $\mathcal{M}$ may stop before equilibrium is reached. The final approach towards equilibrium is then along the i axis. The functional equation for the surface Σ is a single scalar equation in the partial derivatives of two independent variables (16), whereas the functional equation for $\mathcal{M}$ is a vector equation in the ordinary derivatives of (the same) two variables.

The planarized motion and bifurcation discussed above are illustrated in Fig. 4. The panels in this figure show the change in the planarized flow pattern as m_i passes through the crossover value $m_i^{(1)}$. Locally the slow manifold at the equilibrium $\delta s = \delta i = 0$ moves from a position that points into the interior of the physical region to a fixed position lying along the i axis.

4. Discussion

We have examined two important enzyme inhibition mechanisms whose evolution can be treated as two-variable dynamical systems in the phase plane. These particular reaction schemes have not been treated thoroughly before and we have been able to give a complete description of their transient and steady-state kinetics. Although these mechanisms are different chemically they were treated by the same overall mathematical strategy. Algebraically, this approach combines local linearization with global functional equation methods; geometrically it relates local flow features to global "scattering" structures in phase space.

For the first example, the reversible Michaelis–Menten mechanism [R], the standard treatment obtains approximate expressions for the steady-state velocity and the integrated rate law (28). We have related these expression to the standard steady-state approximation for the irreversible mechanism [I], and have given first correction terms using functional iteration. This procedure is systematic and converges to the exact dynamical steady state, the slow manifold, so that additional corrections can be directly obtained. Because the underlying geometry of the phase flow is used to obtain our functional equations, the resulting formulas possess the *same* formal structure as the standard SSA and EA, in contrast to expressions from singular perturbation theory (11). In our procedure the slow dynamics is restricted by a constraint equation to a curve in the phase plane. And because it is a systematic, convergent method, it generates a sequence of such curves that accumulates at the slow manifold. This limit curve contains exact information about the slow time evolution of mechanism [R]. This convergent procedure should be compared with the standard treatment where important errors arise. These errors come from failure to use all conserved total concentrations, or approximate use of such conservation laws.[22] This omission has either lead to geometrically ambiguous formulas or it has prevented systematic improvement because the underlying equations are not properly closed. This is also related to the failure to argue consistently even when using the standard SSA or EA. In either of these approximations one differential equation is replaced by an algebraic constraint — this implies a perfectly respectable dynamical system. However, it is commonly assumed that the conserved variables in the constrained system are the same as those for the full system of differential equations. This assumption is *false*, and in the treatment of the reversible mechanism [R] it leads to inconsistencies. Formulas obtained under the flawed assumption cannot be used as a basis for a more accurate treatment.

We now outline an experimental procedure justified by our analysis. Normally, experimentalists treat mechanisms [I] and [R] by different procedures, particularly if they believe that the reversible step in [R] is important. In the product inhibition limit it is also reasonable to treat the first step in [R] as irreversible, so that product inhibition is just a special case of [R]. In [I] the flow structure is determined by the values of the specific rate constants (fixed at fixed temperature) and a *disposable* constant m_e, the total enzyme concentration. Since an experiment is begun with separate samples of E and S it is natural to work at fixed m_e. However, in mechanism [R]

[21]The chemical example of defectiveness given here should be compared to critical damping in mechanical systems. In this case the eigensystem is also defective but the Jacobian is not in lower triangular form. Consequently, the eigenvalues also depend on the off-diagonal elements and the defective case separates a regime of real eigenvalues from one with complex eigenvalues. This fundamental difference arises from the fact that mechanical systems have an inertial term whereas chemical systems do not.

[22]This omission appears in some of the books in ref. 4.

($k_{-2} > 0$), and the product inhibition case ($k_{-2} > 0, k_{-1} = 0$), total substrate m_s must also be fixed to correspond to the same underlying phase-space structures in a series of experiments. This condition is not satisfied in initial velocity experiments as they are normally performed for [R] since the initial condition is $\{s(0) = m_s, c(0) = m_e, p(0) = 0\}$ (at $t = 0$); the starting value $s(0) = m_s$ in this initial condition is varied from experiment to experiment, which changes the underlying slow manifold $\mathcal{M}(m_s)$ and nullclines. In contrast, working at fixed m_s and m_e fixes these structures. This suggests that using these total concentration constraints would improve statistical fitting of data from repeated experiments using either initial velocities or progress curves.

The second example of competitive inhibition is a three-step mechanism, governed by a three-dimensional system of ODEs, which displays varied transient behaviour (7, 18). For example, at intermediate inhibitor concentrations, imitating those often found *in vivo* (6), the ODEs of the CI mechanism can be reduced to a planar system[23] because there is fast relaxation from the "volume" of phase space towards a smoothly curved "slow" surface Σ with a *single-valued* projection on some (Euclidean) plane, which is $s \times i$ here; the dynamics in this plane can be given exactly in terms of the velocities of its natural coordinates, $\dot{s}$ and $\dot{i}$, and the equation $c = \phi(s, i)$ of the slow surface Σ. Relaxation in this system displays more interesting dynamics than the two-step mechanism [R]. For some parameter values, the slow manifold in the planarized CI mechanism consists of two pieces separated by a region where the motion is intrinsically two-dimensional. (Such behaviour is not found in [R] or any other two-step mechanisms because in such cases the slow manifold is a single, infinite curve connecting the asymptotic regime to the stable equilibrium.) The intrinsically two-dimensional behaviour of the CI flow is associated with small-magnitude, complex-conjugate eigenvalues (with negative real part) for the flow Jacobian in the local linearization of the velocity field. In contrast, the one-dimensional behaviour on the bits of the slow manifold is connected with a unique (real) smallest magnitude eigenvalue in this linearization. These features allow a precise description to be given of the breakdown of steady-state methods in experiments on the CI mechanism. But we argue that it is just this regime, inaccessible to standard analysis, which is of most interest in living systems, because enzyme and inhibitor concentrations are often comparable *in vivo* and just these circumstances encourage the replacement of the usual one-dimensional steady state by intrinsically two-dimensional behaviour. The fixed phase-space structures, e.g., Σ, studied here underlie the behaviour of open systems in which the metabolic pathway flux corresponds to high local concentrations of enzyme (6).

The entire dynamics of these planar systems, and indeed higher dimensional systems, can be studied by the same mathematical methods. Principally, functional equation methods are used because they define contraction mappings that converge rapidly to the phase-space structure underlying the "slow" dynamics, namely, the slow-transient surface Σ or slow manifold $\mathcal{M}$. Furthermore, this method is formally very simple because it depends on differentiation, and is in the same general class as the standard steady-state methods. Thus these standard results make their appearance on the way to getting the exact answer. However, the CI study shows that even approximate solutions contain most of the essential ingredients of the exact dynamics and that these features can be displayed in a global, consistent geometrical way.

Finally, it should be noted that functional equations are solvable by both the analytic treatment given here and by numerical methods. A numerical treatment may be required in the case of mechanisms with third- or higher-order steps and may be used in dealing with mechanisms with a large number of independent concentrations. However, algebraic manipulators such as Maple make feasible a semi-numerical approach in which explicit functional equations are numerically iterated. A fully numerical implementation of our functional equation method is perfectly feasible as it requires only techniques used in implicit-method ODE solvers.

[23]Planarization is always possible in the CI mechanism because oscillatory transients never arise (31). The particular case studied is one of two possible planar regimes: One exists at high inhibitor concentration, and the other at low or intermediate inhibitor concentration. This difference is determined by the orientation of Σ in Γ, which may affect the choice of projected variables.

Molecular dynamics study of the surface diffusion of large adsorbates: III. Role of adsorbate shape

YEHUDA ZEIRI

Department of Physics, Nuclear Research Center – Negev, P.O. Box 9001, Beer-Sheva 84190, Israel

Received July 7, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

YEHUDA ZEIRI. Can. J. Chem. **72**, 813 (1994).

The present study is dedicated to the investigation of the relationship between the surface diffusion mechanism of large adsorbates and the adsorbate shape. Three different shapes of model adsorbates were examined: linear chains, branched chains, and cyclic molecules. It was found that the surface diffusion mechanism of linear and branched chain adsorbates is quite similar, while a markedly different diffusion mechanism is observed for cyclic adsorbates. For all types of adsorbates the temperature dependence of the diffusion coefficient was found to obey an Arrhenius expression. The results of the simulations have shown good qualitative agreement with the available experimental data.

YEHUDA ZEIRI. Can. J. Chem. **72**, 813 (1994).

Cette étude porte sur la relation existant entre le mécanisme de diffusion en surface des gros adsorbats et la forme de l'adsorbat. On a examiné trois modèles d'adsorbats de forme différente : des molécules à chaîne linéaire, des molécules à chaîne ramifiée et des molécules cycliques. On a trouvé que le mécanisme de diffusion en surface des molécules à chaîne linéaire est tout à fait semblable à celui des molécules à chaîne ramifiée, tandis qu'on observe un mécanisme de diffusion nettement différent pour les adsorbats de forme cyclique. Pour tous les types d'adsorbats, on a trouvé que l'effet de la température obéit à une expression d'Arrhénius. Les résultats des simulations révèlent un bon accord qualitatif avec les données expérimentales disponibles.

1. Introduction

The characterization of the transition state in various gas phase processes involving molecular systems has been a major research topic in a number of laboratories. During the past two decades Professor J.C. Polanyi and co-workers made major contributions to this field. However, the unique assignment of a transition state along the path of a system from initial to final configurations is not always possible. In the following we shall demonstrate a situation where the large number of degrees of freedom in a molecular system prevents the assignment of a unique transition state. In particular, we shall examine in detail the motion of large adsorbates along a solid surface. It will be argued that for such systems a more realistic description of the surface diffusion is in terms of a large sequence of energy barriers associated with the motion of the adsorbate along the surface.

The surface diffusion of adsorbed species plays an important role in many processes related to the chemistry and physics of gas–surface interactions. Surface diffusion constitutes a direct probe of the adsorbate–surface and adsorbate–adsorbate interaction potentials (see, for example, ref. 1). Moreover, the mobility of adsorbates may constitute the rate-limiting step in many technologically important processes. Hence, a detailed understanding of the surface diffusion mechanism in various systems is highly desirable.

It is well established that for small adsorbates the surface diffusion may be described as a random walk of the ad particle among the various adsorption sites on the surface (1). Such a description seems to be suitable for adsorbates whose size is small compared to the magnitude of the surface unit cell. In such systems it is usually possible to define adsorption sites that are, in many cases, associated with high symmetry sites in the surface unit cell (strongest adsorbate–surface bonds). The minimum energy path between two neighboring adsorption sites usually shows the existence of an energy barrier that is assigned as the activation energy for the diffusion process or transition state. The magnitude of this activation energy, E_{diff}, is determined by the nature of the adsorbate–surface interaction. In most cases, the magnitude of E_{diff} is larger than the thermal energy of the system, kT (where k is the Boltzmann constant and T is the system temperature). As a result, the motion of the ad particle along the surface can be described as a sequence of random jumps among the adsorption sites. Since in most situations $E_{diff} \gg kT$ these jumps can be considered as rare events.

This situation may change markedly if the size of the adsorbate is large compared with the surface unit cell. These type of systems include the adsorption of polyatomic molecules onto single crystal surfaces. For such systems the terms "best adsorption site" and "transition state" cannot be defined uniquely. In other words, it is expected, due to the large number of degrees of freedom in the system, that many of the possible configurations will correspond to similar adsorbate–surface binding energies. The transition between two neighboring adsorption sites, in this subspace of configurations, may pass through an activation barrier. Thus, the motion of the adsorbate along the solid surface may be associated with a sequence of energy barriers instead of a single well-defined transition state. Hence, a sequence of barriers is expected to dominate the diffusive motion of the adsorbate along the surface. In many systems, the energy difference between these barriers may be of the order of kT. In such systems the surface diffusion of large adsorbates cannot be described any longer as a random walk process but should be viewed as a quasi-continuous motion along the surface.

Recently, George and co-workers (2) discussed the results of experimental surface diffusion studies of a number of n-alkanes on a Ru(001) surface. In addition, studies of the surface diffusion of cycloalkanes as well as other isomers were reported by the same group (3). The surface diffusion coefficient, D, of these adsorbates was measured using the laser-induced thermal desorption (LITD) method (4). These studies indicated that the variation of D as a function of temperature, for all the ad-molecules investigated, could be described by an Arrhenius behavior. It was found that the values of E_{diff} obtained for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

n-alkanes increased linearly with the carbon chain length, while in most cases the pre-exponential factors remained nearly constant (2, 3).

Moreover, temperature-programmed desorption (TPD) measurements have shown that the activation energy for desorption, E_{des}, also increases linearly as a function of the chain length, while the corrugation ratio, $\Omega = E_{diff}/E_{des}$, remains practically constant. In addition, it was found that in most cases D is coverage independent (i.e., for *n*-alkanes (2), for cyclopropane and cyclohexane (3*a*), and for isopentane (3*c*)) while strong coverage dependence of the surface diffusion was observed for cyclopentane (3*a*) and neopentane (3*b*). Based on these experimental results, George and co-workers suggested that the surface diffusion of such polyatomic adsorbates can be described by a concerted motion of the ad-particles along the surface (2, 3).

These experimental studies have stimulated a number of theoretical investigations whose goal was to obtain understanding of the mechanism that describes the surface diffusion of large adsorbates. In earlier studies (5) we utilized the molecular dynamics (MD) approach for simulations of the surface diffusion of large *n*-alkane-like adsorbates on a W(100) surface. These calculations were aimed to investigate the influence of chain length (5*a*) and chain stiffness (5*b*) on the mechanism by which large adsorbates move along a solid surface. In the following we shall refer to these studies as paper I and paper II, respectively. The MD results suggested a nonlinear scaling between E_{diff} and the chain length. Moreover, it was found that for long chains (containing $n = 10$ or more carbons) the surface diffusion process can be described as a sequential motion of segments of the adsorbed species, while for short chains, $n = 3$ and 6, concerted motion, suggested by the experimental data, represents a reliable description of the surface diffusion.

Another theoretical study (6) utilized MD simulations to investigate the conformations associated with the diffusional motion of *n*-pentane on a metallic surface. These calculations were performed using potential functions similar to those used in papers I and II except for the interaction among the chain atoms. For the latter, a more realistic potential, including angular terms related to the rotation of neighboring bonds, was used. The results of this study (6) suggested that the *n*-pentane exhibits a number of well-defined conformations during its concerted motion along the surface. The number of observed conformations was found to depend on the symmetry of the solid surface, while the transition between the various conformations could be described as a rare event.

The next section contains a brief description of the theoretical model used in the present study, while Sect. 3 is devoted to description and discussion of the results. A short summary is given in the last section.

2. The theoretical model

The present study is an extension of papers I and II. The goal in this investigation was to examine the relationship between the surface diffusion mechanism of large adsorbates and the shape of the adsorbed species. We have considered the low coverage limit where the interactions among the adsorbates can be ignored. Hence, this study includes simulations of the surface diffusion of single adsorbates. Five different shapes of model adsorbates were considered: linear and branched chains with $n = 6$ and $n = 10$ and a ring with $n = 6$. In the following we shall refer to these model adsorbates as: *n*-hexane, *n*-decane, isohexane, isodecane, and cyclohexane, respectively. The different adsorbates considered are shown schematically in Fig. 1.

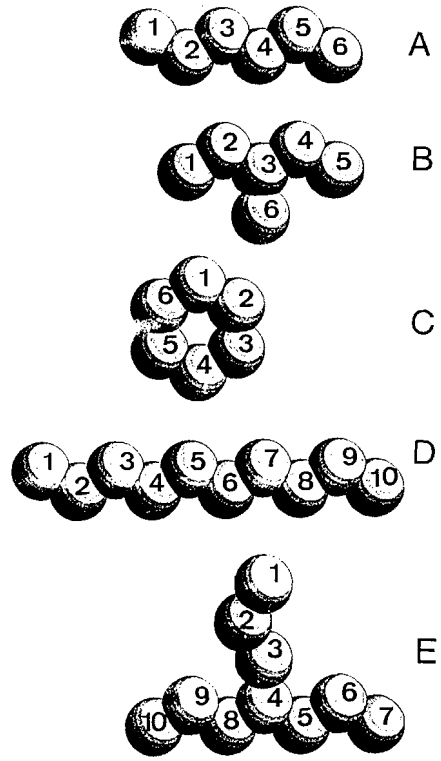

FIG. 1. Schematic description of the various adsorbates investigated.

The details of the calculations in the present study are similar to those described in papers I and II (5). The generalized Langevin approach, GLE (7, 8), was used to describe the thermal motion of the solid surface. The primary zone was described by 169 W atoms arranged in a single layer of 13 × 13 atoms. The rest of the solid was represented by 221 fictitious particles that surrounded the primary zone. These were attached to primary zone atoms whose bonds to atoms outside the primary zone were truncated. For each type of adsorbate 20 trajectories were calculated at any given temperature. Termination of the trajectory occurred if the maximum number of integrating steps was reached (i.e., 40 000 steps, which corresponds to 40 ps) or if the adsorbate migrated outside the region spanned by the primary zone. At the beginning of each trajectory the adsorbate–surface system was allowed to thermalized for a period of about 4–5 ps. The thermalization period was terminated when the average kinetic energy of the system reached the predefined system temperature. The momentary positions and velocities at the end of the thermalization period were used as initial conditions for the trajectory.

The potential function describing the various interactions in the system was constructed as a sum of three terms:

$$[1] \quad V(\boldsymbol{R}, \boldsymbol{X}, \boldsymbol{S}) = V_{SLAB}(\boldsymbol{R}, \boldsymbol{S}) + V_{AD-S}(\boldsymbol{R}, \boldsymbol{X}) + V_{AD}(\boldsymbol{X})$$

where $\boldsymbol{R}$, $\boldsymbol{X}$, and $\boldsymbol{S}$ represent the position vectors of the primary zone atoms, the adsorbate atoms, and the fictitious particles, respectively.

The three terms in eq. [1] correspond to the interaction among the primary zone particles (W atoms and fictitious particles), interaction between the adsorbate and the surface, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

the interaction among the atoms constituting the adsorbate, respectively. The functional form of these three terms was taken to be identical to those used in papers I and II. In the evaluation of the last term, $V_{AD}(X)$, we used the parameters that correspond to "stiff" chains in ref. 5*b*. The only modification of the potential in the present calculations, as compared to those of papers I and II, is related to the parameters used to evaluate the adsorbate–surface interaction term, V_{AD-S}. In the present simulations the binding energy used in the Lennard–Jones potentials was $\epsilon_{RX} = 0.7$ kcal/mol as opposed to 0.722 kcal/mol used in papers I and II. The result of this minor modification is a small decrease in the calculated values of E_{diff} as will be discussed below. For a more detailed description of the MD approach and the potential functions used the reader is referred to ref. 5.

3. Results and discussion

3.1. Pre-exponentials and activation energies

For all the adsorbates discussed below we performed simulations at four different temperatures, $T = 300$, 450, 600, and 800 K. This range of T was chosen to be able to obtain reliable diffusion coefficients during the limited time that could be simulated using the MD approach. The diffusion coefficient for any given adsorbate and system temperature was calculated using the Einstein formula (9):

$$[2] \quad D_{t\to\infty} = \frac{1}{4}\langle[\boldsymbol{X}_{CM}(t_0 - t) - \boldsymbol{X}_{CM}(t_0)]^2\rangle_{Nt}/t$$

where $\boldsymbol{X}_{CM}$ is the adsorbate center-of-mass position vector and $\langle\ldots\rangle_{Nt}$ represents an average over time steps. For a given adsorbate and surface temperature the diffusion coefficient was obtained as an average over the 20 trajectories calculated.

An Arrhenius form was assumed for the dependence of D on T. The results for the five adsorbates considered are shown in Fig. 2. These results clearly indicate that the dependence of D on T obeys an Arrhenius form. These data allow the extraction of the pre-exponential factor, D_0, and the activation energy for diffusion, E_{diff}. These quantities, as obtained from the data shown in Fig. 2, are summarized in Table 1. Inspection of the observed D_0 and E_{diff} values shows that for the three adsorbates with $n = 6$ there is some spread in the pre-exponential factor; however, considering the errors in the calculated values of D_0, these quantities are practically identical (exhibiting at most a factor of two in the corresponding D values). A somewhat larger spread is observed in the values of E_{diff}. Here, we find that *n*-hexane and isohexane exhibit almost identical activation energies for diffusion, while the corresponding value for cyclohexane is much smaller. Note that this difference in the magnitude of E_{diff} results in an order of magnitude difference in the corresponding values of the diffusion coefficients. Similar qualitative behavior of D_0 and E_{diff} for different shapes of adsorbates was observed experimentally (3). In addition, the activation energies for desorption obtained for the various hexane-like adsorbates are very similar and decrease in the order *n*-hexane > isohexane > cyclohexane. As a result, the corrugation ratios for *n*-hexane and isohexane are identical while that of cyclohexane is somewhat smaller. Similar examination of the results obtained for the two adsorbates with $n = 10$ indicates that the linear and branched chains exhibit different D_0, as well as different E_{diff} and E_{des} values. However, the variation of the two activation energies is such that the corrugation ratio of these two adsorbates remains practically constant.

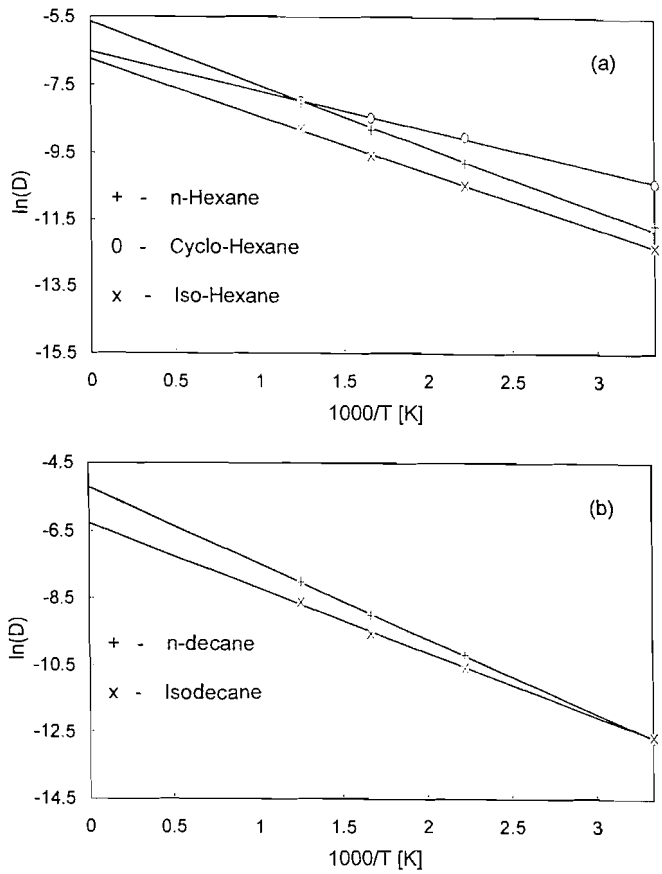

FIG. 2. Arrhenius plots of the surface diffusion coefficients for: (*a*) three different shapes of hexane-like molecules and (*b*) two different shapes of decane-like molecules.

TABLE 1. Calculated values of D_0, E_{diff}, E_{des}, and Ω for the various adsorbates considered. The units used for the pre-exponential factor are cm^2/s and for the activation energies kcal/mol

Adsorbate	$D_0 \times 10^4$	E_{diff}	E_{des}	Ω
n-Hexane	17.9 ± 4.1	3.4 ± 0.2	11.1 ± 0.1	0.31
Isohexane	7.9 ± 2.3	3.3 ± 0.2	10.6 ± 0.1	0.31
Cyclohexane	9.8 ± 2.4	2.3 ± 0.2	10.1 ± 0.1	0.23
n-Decane	36.4 ± 7.0	4.5 ± 0.15	17.1 ± 0.1	0.26
Isodecane	12.7 ± 3.1	3.8 ± 0.10	16.1 ± 0.1	0.24

The results of the hexane-like adsorbates indicate that both *n*-hexane and isohexane move along the surface according to a similar mechanism, while cyclic adsorbates move according to a different mechanism. Moreover, the surface diffusion mechanism for larger adsorbates (*n*-decane and isodecane) seems to be different than that of the hexane-like molecules. In the following we shall discuss the detailed surface diffusion mechanism of these model adsorbates.

3.2. Surface diffusion mechanism: hexane-like adsorbates

Let us first consider the three different hexane-like adsorbates. The mean square end-to-end distances, R^2_{ete} (5), for typical trajectories of *n*-hexane and isohexane at $T = 800$ K are shown in Fig. 3. For the linear chain R^2_{ete} is defined between atoms 1 and 6 while for isohexane this quantity corresponds to the distance between atoms 1 and 5 (see Figs. 1*a* and 1*b*). Inspection of these results shows that the magnitude of R^2_{ete} for

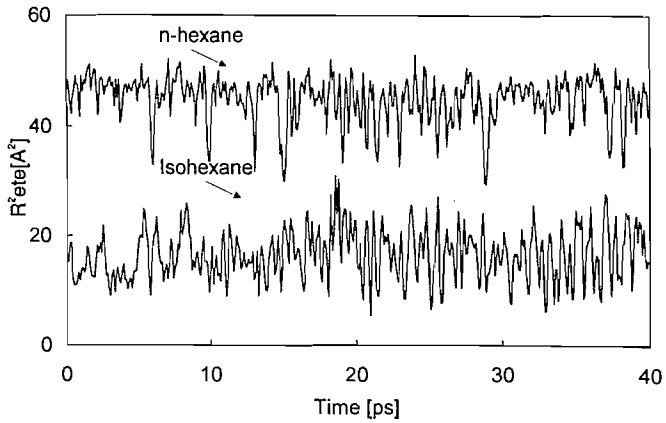

FIG. 3. Variation of the mean square end-to-end distance during typical trajectories of *n*-hexane and isohexane at $T = 800$ K. Note that the results associated with *n*-hexane were shifted by 15.0 Å^2.

both adsorbates fluctuates rapidly around the mean values (29.6 ± 0.1 Å^2 for *n*-hexane and 16.1 ± 0.1 Å^2 for isohexane). For both adsorbates one can observe instances during which the magnitudes of R^2_{ete} are quite a bit smaller (or larger in the case of isohexane) than the average values. These correspond to various bent (or stretched) configurations of the adsorbates on the surface. It should be noted that the lifetime of these bent/stretched configurations is similar for both adsorbates, of the order of 0.5–2.0 ps. Animation of a number of typical trajectories for these two adsorbates indicated that during most of the simulation their motion can be described as a concerted motion of the molecule as a whole. However, occasionally these adsorbates can be found, for a short duration, in a highly bent (or stretched) configuration.

Two configurations are demonstrated in Fig. 4 for the isohexane-like molecule. These configurations correspond to the most stable and most unstable (largest and smallest adsorbate–surface binding, respectively) configurations found in a typical trajectory of the isohexane molecule. It is clear that the stable configurations are associated with an adsorbate that is practically parallel to the solid surface (Figs. 4*a* and 4*c*) while the high-energy unstable conformations correspond to adsorbates whose molecular plane is basically normal to the surface (Figs. 4*b* and 4*d*). Note that this type of high-energy configuration (like the one shown in Fig. 4) is quite rarely observed and occurs mainly at the higher T values investigated.

Similar examinations of R^2_{ete} for the cyclohexane-like adsorbate (corresponding to distances of opposite atoms in the ring) have shown that this quantity is practically constant during the trajectory. This is evidence that the molecular shape is not distorted appreciably even at high surface temperatures. The animation of some typical trajectories for cyclohexane-like adsorbate suggested that the surface diffusion of such molecules is dominated by two types of basic rotational motion. The first, and most frequent one, corresponds to the rotation of the adsorbate in a plane parallel to the surface around an axis that is normal to the surface and points through the center of mass of the molecule. This rotational motion is coupled to a translational movement of the molecule along the surface. Hence, the net result is that, during the motion of the molecule center of mass along the solid surface, the orientation of the atoms changes with respect to the location of the center of mass of the adsorbate. In the following we shall term this type of rotational motion as "in-plane rotation" and use the abbreviation IPR. It

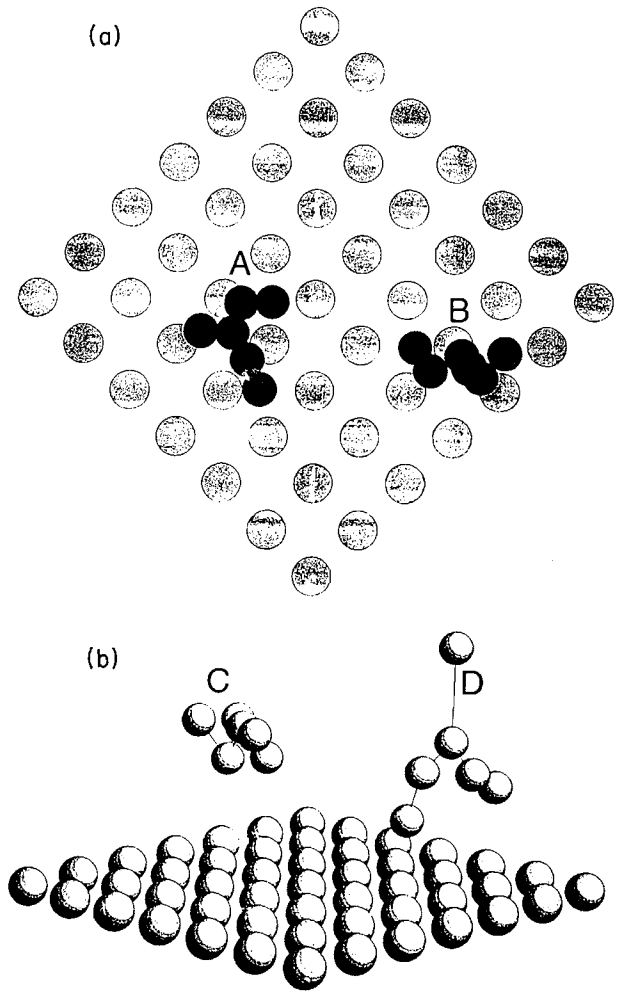

FIG. 4. Top and side views of the configurations associated with the most stable ((*a*) and (*c*)) and most unstable ((*b*) and (*d*)) configurations obtained during a typical trajectory of isohexane-like adsorbate at $T = 600$ K. Note that the normal adsorbate–surface distances were scaled by a factor of 1.5.

has to be noted that during most of the simulated period the molecular plane (the plane containing the adsorbate, which is basically planar, see Fig. 1*c*) is practically parallel to the solid surface.

The second type of rotational motion is related to a flip of the molecular plane around an axis that is parallel to the surface. The transition state in such a movement corresponds to a configuration where the molecular plane is normal to the solid surface. We shall term this type of rotation "flip over" and designate it by FO.

The energy barrier for the in-plane rotation is determined by the surface corrugation as seen by the adsorbate, while the activation energy for a flip-over movement corresponds to an extensive weakening of the adsorbate–surface binding. It should be noted that geometries in which the molecular plane is normal to the surface were also observed prior to a desorption event. Since a large activation energy is associated with the FO movement, it may be viewed as a rare event compared to the IPR motion, and the probability of its occurrence is expected to be a sensitive function of the surface temperature. Both rotational motions described above may be regarded as a concerted motion of the adsorbate as a whole.

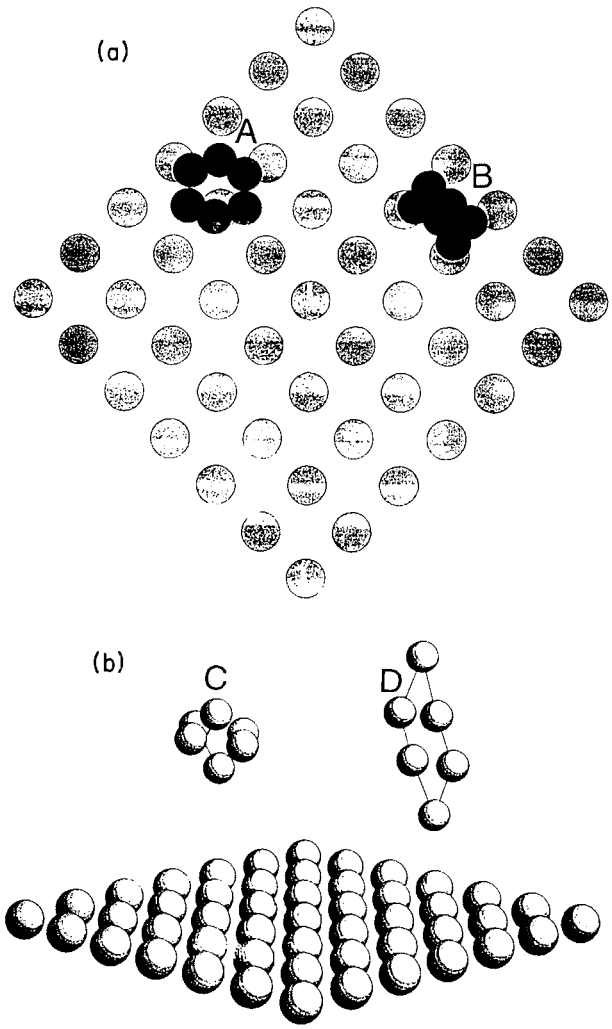

FIG. 5. Same as in Fig. 4 for a cyclohexane-like adsorbate at T = 800 K.

The adsorption configurations of cyclohexane for the strongest and weakest molecule–surface binding during a typical trajectory are shown in Fig. 5. Inspection of these results shows that "good" adsorption configurations of the cyclohexane are those in which the molecule is adsorbed parallel to the surface as shown in Figs. 5*a* and 5*c*. The configuration associated with weak adsorbate–surface binding coincides in this case with the transition state during a flip-over movement, Figs. 5*b* and 5*d*. At this configuration only three atoms of the cyclohexane are strongly interacting with the surface while the other three are located farther away and have only a small contribution to the adsorbate–surface binding.

To obtain a more quantitative description of these rotational motions we monitored two quantities during the evolution of the trajectories. The first corresponds to the distance (along the surface normal) between the molecular center of mass and the surface plane. The second quantity was the azimuthal angle of one of the ring atoms relative to the position of the molecular center of mass. The results obtained in two typical trajectories at T = 300 and 800 K are shown in Fig. 6. At the low temperature, T = 300 K, the average distance between the molecular center of mass and the surface, Z(c.m.), is 2.5 Å. Oscillations around this average value are clearly seen, Fig. 6*a*, where the largest amplitude observed is approximately 0.25 Å. The corresponding variation in the azimuthal angle of one of the ring atoms is shown in Fig. 6*b*. No flip-over movements were detected during this trajectory.

TABLE 2. Calculated values of the average angular velocity of adsorbed cyclohexane. Units of temperature are in degrees K while the angular velocity is given in terms of rad/s

T	$\omega_R(\times 10^{-13})$
300	1.08 ± 0.025
450	1.34 ± 0.032
600	1.61 ± 0.053
800	1.83 ± 0.047

Inspection of the corresponding results at the high temperature, Figs. 6*c* and 6*d*, shows that at some instances large-amplitude oscillations in Z(c.m.) are observed (i.e., ΔZ(c.m.) ≈ 0.75 Å) together with a major variation of the azimuthal angle during the trajectory. Careful examination of Fig. 6*d* shows that a highfrequency rotational motion, associated with the IPR movements, is superimposed on a low-frequency and large amplitude rotation that is related to the FO movements. In particular, near t = 10 and 17 ps the cyclohexane performed two flip-over movements that are manifested by large-magnitude oscillations in Z(c.m.), Fig. 6*c*, together with a corresponding rapid change in the azimuthal angle from approximately 270° to 90°, Fig. 6*d*. Hence, at T = 800 K, the high thermal energy manifests itself by the occurrence of combinations of the two rotational motions. Comparison of the results in Figs. 6*b* and 6*d* shows that the frequency of the oscillations associated with the IPR motion increases as a function of the surface temperature.

To demonstrate this point, we used the variation of the azimuthal angle to calculate the average angular velocity, ω_R, of the cyclohexane at the various surface temperatures considered. The calculated values of ω_R are summarized in Table 2. Inspection of these results shows that ω_R increases monotonically with elevation of the surface temperature. Since the adsorbate is in thermal equilibrium with the substrate, the increase in ω_R as a function of T is directly related to the increased thermal energy in the system. As a result, at elevated T values larger portions of the available configuration space are sampled by the adsorbate during its trajectory. Moreover, the thermal fluctuations of the adsorbed molecule at high surface temperatures is expected to result in an increased frequency by which the adsorbate–surface geometries (which correspond to energy barriers associated with the IPR motion) are sampled. Hence, the IPR movements, which dominate the adsorbate motion at low temperatures, are expected to become more rapid at higher surface temperatures. In addition, at elevated temperature the FO movements become more probable. It should be emphasized that the high T values used in the present study were required because of the short period during which the dynamics of large adsorbate surface diffusion could be simulated using the MD approach. It is believed that the mechanisms governing the diffusional motion of large adsorbates, as observed in these calculations, constitute a qualitatively accurate description of the process. Namely, both IPR and FO movements do occur at any surface temperature; the only question is what are the probabilities associated with each one of these types of motion. The MD simulations suggest that the probability for the IPR motion is much larger than that of the FO movement for temperatures at which the experiments are performed. However, even at such

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12

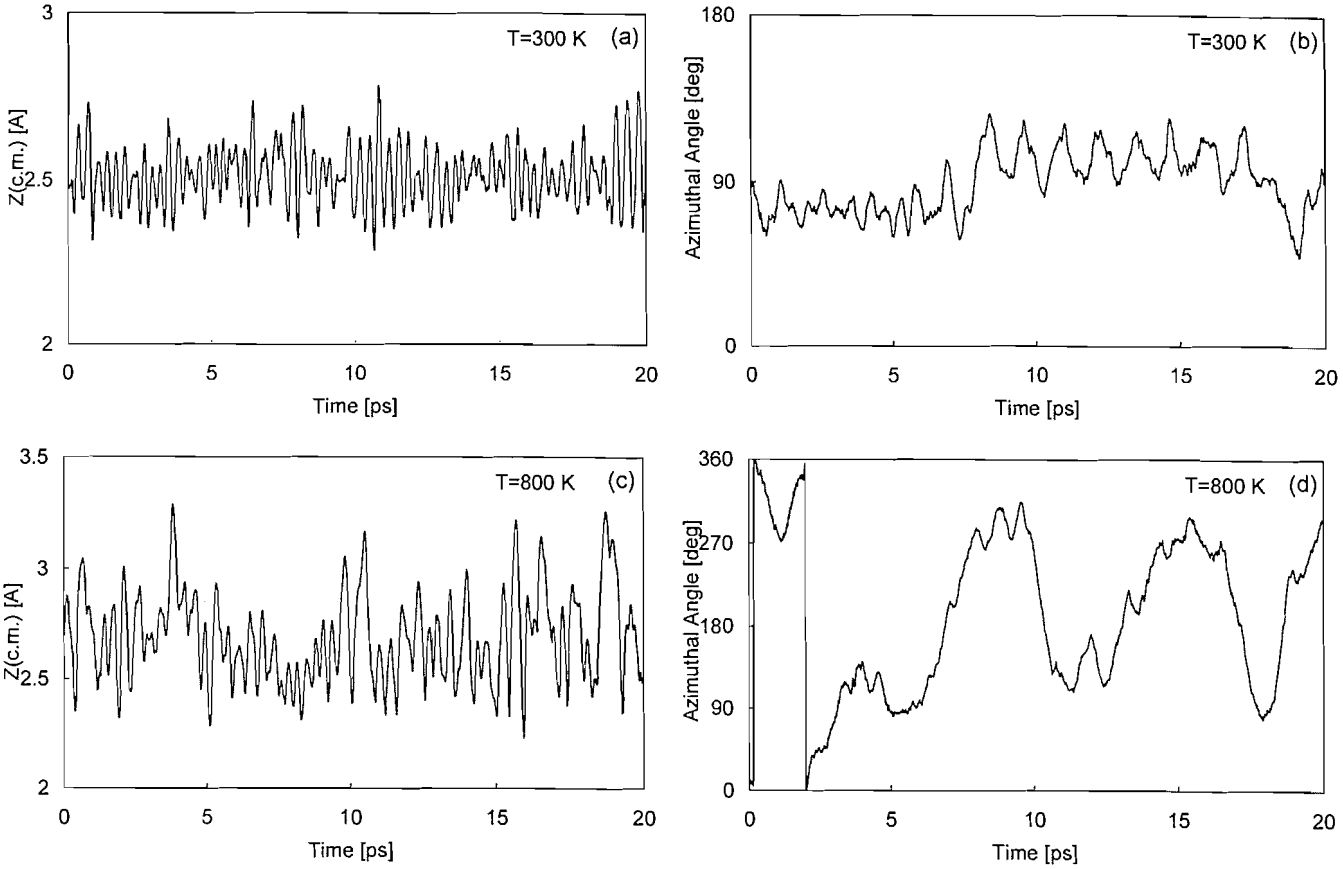

FIG. 6. Variation of the center of mass normal position, Z(c.m.), ((*a*) and (*c*)) and of the azimuthal angle associated with an atom in the ring ((*b*) and (*d*)) during typical trajectories of cyclohexane at two surface temperatures, $T = 300$ K ((*a*) and (*b*)) and $T = 800$ K ((*c*) and (*d*)).

low T values, non-zero probability is expected for the occurrence of the FO-type motion (during the experimental time scale).

3.3. *Surface diffusion mechanism: decane-like adsorbates*

Next we shall examine the mechanism that dominates the surface diffusion of the larger adsorbates. Inspection of Table 1 shows that the calculated values of both E_{diff} and E_{des} for *n*-decane and isodecane are larger than those obtained for the hexane-like adsorbates. However, the decreased corrugation ratio for these adsorbates indicates that the variation of the energy barrier for diffusion with adsorbate size is not linear. This nonlinear relationship between E_{diff} and the adsorbate size has been discussed in papers I and II. Comparison of the activation energies for diffusion obtained for linear and branched adsorbates shows that the influence of the molecular shape is much more pronounced for these larger molecules (as compared to the case of $n = 6$). This pronounced difference between *n*-decane and isodecane is related to the change in the mechanism dominating the surface diffusion of the larger adsorbates as compared to the various hexane-like molecules.

The results presented in papers I and II suggested that the surface diffusion mechanism of adsorbates the size of hexane (or smaller) is dominated by a concerted motion of the adsorbed species, while in the case of larger adsorbates a mechanism associated with segmental motion is dominant. Two basic segmental movements of large adsorbates, termed edge rotation, ER, and central segment rotation, CSR, were identified (5). Hence, the differences between the surface diffusion of *n*-decane and isodecane will be discussed with relation to this segmental mechanism.

The variation of the mean square end-to-end distance during two typical trajectories of *n*-decane and isodecane is shown in Fig. 7. In the case of isodecane, Fig. 7*b*, the various R^2_{ete} correspond to the distances between atoms 1–7, 7–10, and 1–10, respectively (see Fig. 1*e*). Inspection of the results for *n*-decane, Fig. 7*a*, shows that the adsorbate is occasionally "trapped" in highly bent configuration during its motion along the surface. These bent configurations are manifested by a large decrease in the value of R^2_{ete} (upper curve in Fig. 7*a*). The lifetimes of such bent configurations vary in the range of 1–5 ps. The mean square difference of the normal distance between the chain ends, R^2_{ete}(N), is also shown in Fig. 7*a* (bottom curve). It is clear that some of the bent configurations are related to large R^2_{ete}(N) values. This correlation between R^2_{ete}(N) and R^2_{ete}, together with the results discussed in papers I and II, manifests the role of the segmental movements during the surface diffusion of *n*-decane. Comparison of these results with the variation of R^2_{ete} for isodecane, Fig. 7*b*, shows some marked differences. First, the frequency at which the bent configurations occur in the case of isodecane is noticeably larger than that for *n*-decane. In addition, the lifetimes associated with these bent configurations are shorter than the corresponding value for *n*-decane.

The R^2_{ete} values, associated with bent conformations of different "end pairs" in the case of isodecane, are in many cases highly correlated. This correlation is due to the shape of the adsorbate; for example, if one end of the molecule performs an ER movement it is expected that one R^2_{ete} value associated with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

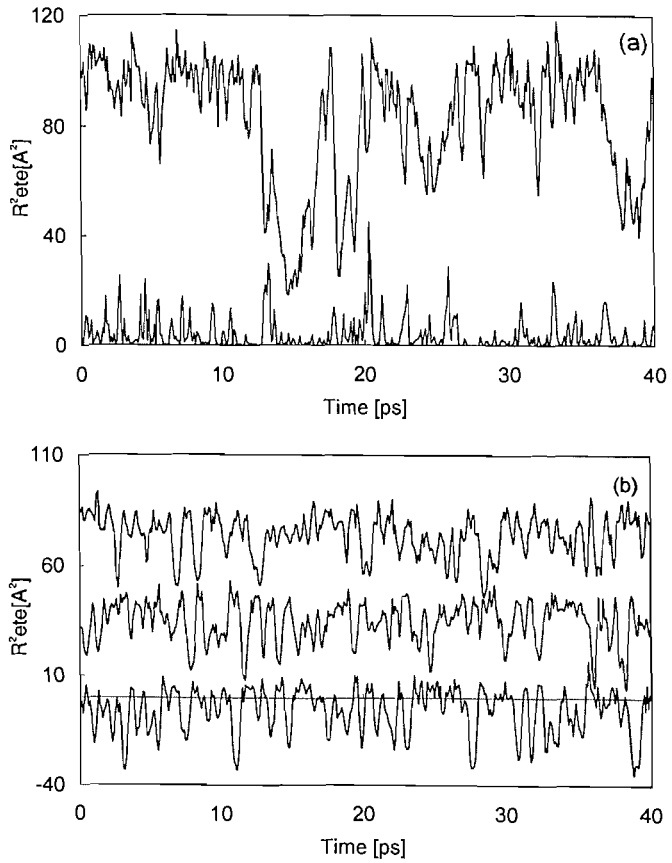

FIG. 7. Variation of the mean square end-to-end distance during two typical trajectories of *n*-decane (*a*) and isodecane (*b*). In the case of *n*-decane the top curve represents R^2_{ete}, while the mean square difference of the end-to-end normal distance (multiplied by 5.0) is also shown (bottom curve). In the case of isodecane, the three curves correspond to the variation of R^2_{ete} between atoms: 1–7 (top curve, shifted by 40 Å^2), 7–10 (middle curve), and 1–10 (bottom curve, shifted by −40 Å^2). For the definition of this numbering see Fig. 1*e*.

this end will increase while the other will decrease. These differences between *n*-decane and isodecane suggest that the edge rotation type of movements dominates the surface diffusion of isodecane while both ER and CSR segmental movements (and their combinations) contribute in the case of *n*-decane. Two geometries of isodecane are illustrated in Fig. 8. Here, top and side views of the configurations corresponding to the largest (Figs. 8*a* and 8*c*) and smallest (Figs. 8*b* and 8*d*) values of isodecane–surface binding, in a typical trajectory, are shown. It is clear that the low binding configuration is related to a situation in which a segment of the adsorbate is elevated during an edge rotational movement. The size of the segment that performs the ER motion is dictated by the shape of the isodecane. It is expected that during a CSR movement the isodecane should reach a geometry similar to the one shown in Fig. 4*d* for isohexane. Such a configuration corresponds to a large decrease in the adsorbate–surface binding and has a very low probability at the *T* values examined here. Hence, it was never observed in the present simulations.

This difference in the details of the surface diffusion mechanism of these two types of adsorbates results in the observed discrepancy in the calculated E_{diff} values. Inspection of the animation of typical trajectories, for both adsorbates, supports the conclusions of the discussion presented above.

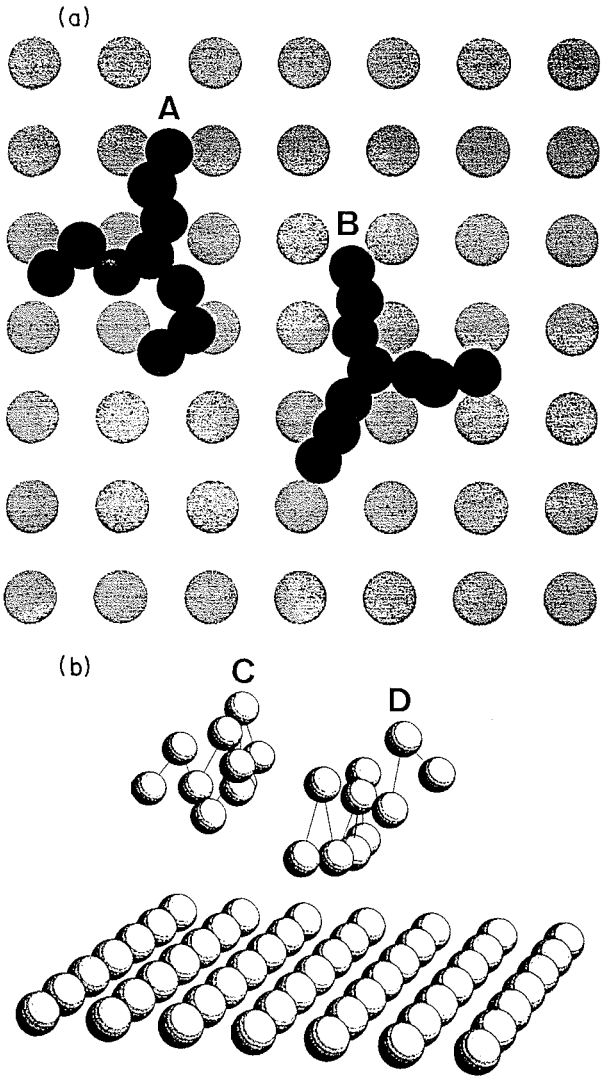

FIG. 8. Same as in Fig. 4 for a isodecane-like adsorbate at T = 450 K.

4. Summary

Molecular dynamics simulations were performed to examine the relationship between the surface diffusion mechanism and the adsorbate shape. It was found that the surface diffusion of medium size adsorbates, such as various shapes of hexane, can be described in terms of a concerted motion of the adsorbed species. This is in agreement with the experimental results. In addition, the variation of the calculated pre-exponential factors and the activation energies for surface diffusion as a function of adsorbate shape were found to be in good qualitative agreement with the experimental observations.

The simulations have shown that the mechanism by which cyclic adsorbates move along the surface can be attributed to two basic rotational movements, which were termed in-plane-rotation and flip over. The first type of rotational motion, IPR, is the dominant one while the FO movements are rare events that involve the motion across relatively high activation energy barriers. Hence, the FO-type movement becomes more frequent at elevated surface temperatures.

For larger adsorbates the surface diffusion mechanism was found to be dominated by segmental movements. This is in accordance with previous theoretical results (5). Once the seg-

mental motion dominates the diffusion along the surface, branched chains were found to diffuse more quickly than linear chains. This difference is associated with the natural division of such adsorbates into small segments dictated by the shape of branched molecules. In the case of branched adsorbates the "edge rotational" movements were found to be the most important, while, for linear chains, combinations of ER and CSR were found to dominate their surface diffusion mechanism.

Spectrally resolved bound–free fluorescence emission spectra for the excitation of several vibrational levels in the excited $B\ ^2\Sigma^+$ electronic state of the van der Waals molecule ^{11}BAr are presented. This excited state emits to the ground $X\ ^2\Pi$ and low-lying $A\ ^2\Sigma^+$ states, both of which correlate with the ground state atomic asymptote B($2p\ ^2P$) + Ar. Because of the large differences in equilibrium internuclear separations, the emission occurs mainly to the repulsive walls. In order to gain more information on this portion of the potential energy curves, the experimental emission spectra were compared with simulated spectra derived from *ab initio* calculated B–Ar interaction potentials. The simulated spectra reproduce the experimental spectra well if the lower-state potential energy curves are shifted slightly inward. This discrepancy is consistent with our previous observation that the *ab initio* calculations slightly overestimate the vibrationally averaged internuclear separation, which we determined experimentally. This reflects the difficulty of accurately calculating weak van der Waals interaction energies.

EUNSOOK HWANG, PAUL J. DAGDIGIAN et MILLARD H. ALEXANDER. Can. J. Chem. **72**, 821 (1994).

On a mesuré les spectres d'émission de fluorescence, résolus en fonction des espèces liées et libres, pour l'excitation de plusieurs niveaux vibrationnels de l'état électronique excité $B\ ^2\Sigma^+$ de la molécule de van der Waals ^{11}BAr. Cet état excité émet vers les états fondamentaux ($X\ ^2\Pi$) ou presque ($A\ ^2\Sigma^+$) qui assurent tous les deux une corrélation avec l'asymptote de l'état fondamental atomique B($2p\ ^2P$) + Ar. À cause des grandes différences dans les séparations d'équilibre internucléaires, l'émission se produit principalement vers les surfaces répulsives. Afin d'obtenir plus d'information sur cette partie des courbes d'énergie potentielle, on a comparé les spectres d'émission expérimentaux avec les spectres simulés par des calculs *ab initio* des potentiels d'interaction B–Ar. Si les courbes d'énergie potentielle de l'état de basse énergie est légèrement déplacé vers l'intérieur, les spectres simulés reproduisent bien les spectres expérimentaux. La différence est en accord avec l'observation antérieure selon laquelle les calculs *ab initio* surestiment légèrement la séparation internucléaire vibrationnelle moyenne qui est déterminée expérimentalement. Ceci reflète la difficulté de calculer d'une façon précise les faibles interactions de van der Waals.

Introduction

Supersonic beam and laser spectroscopic methods have been extensively employed to observe transitions between bound vibrational levels of weakly bound diatomic metal – rare gas van der Waals complexes, as illustrated by recent representative studies involving metals in a number of chemical groups (1–17). With the resulting derived spectroscopic data, considerable information has been obtained on the attractive portions of the potential energy curves of the ground and excited electronic states. It would also be interesting to extract similar information on the repulsive parts of these curves from analysis of continuum spectra.

In a recent paper (17), we reported a collaborative experimental and theoretical study of the BAr van der Waals complex. This metal – rare gas complex contains the lightest element of the group 13 family and has a relatively small number of electrons so that accurate electronic structure calculations could be carried out for the ground and excited electronic states of this system. Similar all-electron calculations on other weakly bound metal – rare gas complexes have performed (18–21). A number of the complexes of heavier members of this series (AlRg, InRg) have been spectroscopically studied by other groups (11–16). In our study of BAr, we observed (17), using laser fluorescence excitation of a pulsed supersonic beam, a progression of ^{11,10}BAr bands in the $B\ ^2\Sigma^+ - X\ ^2\Pi_{1/2}$ system, which correlates with the boron atomic $3s\ ^2S - 2p\ ^2P$ transition. The experimental parameters were compared with the results of *ab initio* calculations of the BAr $X\ ^2\Pi$, $A\ ^2\Sigma^+$, and $B\ ^2\Sigma^+$ potential energy curves. In order to obtain accurately the interaction energies of this weakly bound system, multireference, internally contracted, configuration-interaction calculations were carried out.

There was reasonable agreement between the experimental and theoretical results. For the $X\ ^2\Pi$ ground state, the average internuclear separation in the ground vibrational level, defined as $R_0 = [\langle R^{-2}\rangle_{v=0}]^{-1/2}$, was predicted by the calculations to be ~0.1 Å larger than that derived from the experimental B_0'' rotational constant. The experimental Λ doubling parameter p_0'' for the $X\ ^2\Pi$ state was found to be reasonably well reproduced by a theoretical modeling of this parameter. The Λ doubling in the $X\ ^2\Pi$ state arises from spin–orbit and coriolis interactions with $^2\Sigma^{\pm}$ states (22), and the spectroscopic parameter p_0'' is most sensitive to the average separation of the $X\ ^2\Pi$ state and the primarily repulsive $A\ ^2\Sigma^+$ state, both of which correlate with the ground B($2p\ ^2P$) + Ar asymptote. In contrast to our calculation (17), an earlier complete active space self-consistent field (CASSCF) calculation on BAr did not recover any of the weak binding in the BAr $X\ ^2\Pi$, $A\ ^2\Sigma^+$, and $B\ ^2\Sigma^+$ states (23), because dispersion interactions were not included.

More extensive data on the BAr excited $B\ ^2\Sigma^+$ state, consisting of term values and rotational constants for several vibrational levels of two isotopomers, were experimentally obtained so that it was possible to assign v' vibrational quantum numbers and to generate an RKR potential for this state (17). One of the more interesting features of our experimental BAr fluorescence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

excitation spectrum was that the last two bands in the v' progression were broadened and showed no rotationally resolved features. This suggests that the highest observed vibrational levels are quasibound and that the potential energy curve of the $B\ ^2\Sigma^+$ state has a barrier at long range. In similar fashion, the *ab initio* calculations on this electronic state also exhibited a barrier. The electronic structure of this state is difficult to describe accurately, and the most extensive calculations were able to recover only ~40% of the experimentally estimated dissociation energy of ca. 1 100 cm^{-1}. An estimate of the barrier height of ~140 cm^{-1} was obtained by comparing the experimental widths for the highest two vibrational levels with Lorentzian line widths calculated with a combined experimental and scaled theoretical $B\ ^2\Sigma^+$ potential energy curve. The presence of barriers has been inferred in the corresponding $B\ ^2\Sigma^+$ states of heavier group 13 – rare gas complexes (12, 15, 16).

In the present paper, we report spectrally resolved bound–free fluorescence emission spectra for the excitation of several vibrational levels in the excited $B\ ^2\Sigma^+$ electronic state. Because of the large difference in the equilibrium internuclear separation between the $X\ ^2\Pi$ and $B\ ^2\Sigma^+$ states, this emission occurs mainly to the repulsive wall of the lower state, as well as to the $A\ ^2\Sigma^+$ state. Thus, comparison of the experimental emission spectra with simulated spectra calculated using *ab initio* potential energy curves will provide additional information on the repulsive regions of the X and A potentials, which are not probed by bound–bound spectroscopy.

While continuum spectra have long been known in molecular spectroscopy (24), they have not been widely employed to determine repulsive potential energy curves. In recent years, methodologies have been developed for the inversion of continuum spectra to yield such repulsive curves (25–27). The wavenumbers of the extrema in the spectra determine the potential energy curves, while intensity information can be used to derive the transition moment function. Fawzy et al. (28) have recently reported such a study for the determination of the repulsive potential in the InAr van der Waals molecule. Fortuitously, this system also involves a group 13 metal – rare gas complex and is a higher homologue of BAr. The InAr $X\ ^2\Pi$ spin–orbit splitting is much greater than that in BAr so that the $B\ ^2\Sigma^+ - X_1\ ^2\Pi_{1/2}$, $X_2\ ^2\Pi_{3/2}$ emissions are resolved. It was possible to invert the experimental data to obtain a pointwise repulsive potential for the InAr($X_1\ ^2\Pi_{1/2}$) state (28). Overlapping of the $B\ ^2\Sigma^+ - X\ ^2\Pi_{3/2}$ and $B\ ^2\Sigma^+ - A\ ^2\Sigma^+$ emission prevented extraction of the repulsive potentials of the lower states of these transitions by this inversion method. Bound–free spectra involving excitation of the $^3\Sigma^+$ state correlating with the Hg($7\ ^3S_1$) + M asymptote have been observed in optical–optical double resonance studies of the HgAr (29) and HgNe (30) van der Waals molecules. As in the $B\ ^2\Sigma^+$ states of the group 13 – rare gas complexes, these states have barriers in their potential energy curves.

Because of the spectral overlap of the B–X and B–A emissions and the availability of high-quality *ab initio* calculations for the relevant electronic states in BAr (17), we have taken a different approach for the analysis of our experimental BAr bound–free emission spectra. Rather, we will compare them with simulated spectra derived using the *ab initio* repulsive potentials. The adequacy of these potentials will be judged by how well the simulated and experimental spectra agree. As already anticipated by the difference between the experimental and *ab initio* vibrationally averaged internuclear separations R_0 (17), it will be necessary to shift the repulsive potentials of the lower $X\ ^2\Pi$ and $A\ ^2\Sigma^+$ states inward to get good agreement. This comparison is facilitated by the availability of a potential energy curve for the upper $B\ ^2\Sigma^+$ state which reliably reproduces spectroscopic observations connected with this state (17).

Experimental apparatus

The apparatus employed for the experimental portion of this work was a modification of the apparatus which we previously employed (17) for the observation of the BAr $B\ ^2\Sigma - X\ ^2\Pi_{1/2}$ transition.

Boron atoms were produced by 193 nm photolysis of diborane diluted 150:1 in a Ar/He mixture, and the van der Waals complex was formed in the supersonic expansion from a pulsed valve (General Valve series 9). The nozzle orifice diameters of 0.2 and 0.5 cm were employed, and the backing gas pressure was 5–7 atm. The chamber in which the molecular beam was generated was pumped by an unbaffled 10 in. diffusion pump. The ArF excimer photolysis laser (Lambda Physik EMG101MSC) was focused with a 30 cm f. l. lens at the tip of the nozzle, and the pulse energy was approximately 2 mJ. At high excimer laser pulse energies, the beam temperature (as measured by the B atom $^2P_{1/2,3/2}$ spin–orbit population ratio) was found to increase, with a decrease (17) in the intensity of the BAr spectral features. The positions of the nozzle and the focused laser spot could be independently adjusted while the chamber was evacuated.

Boron atoms and BAr van der Waals complexes were detected 1.5 cm downstream of the nozzle with a frequency-doubled dye laser (Lambda Physik LPD3002E) scanning the wavelength region around the boron atom $3s\ ^2S \leftarrow 2p\ ^2P$ transition near 249.8 nm. The laser line width in these experiments was 0.3 cm^{-1}. The dye laser was fired at a variable delay after the photolysis laser to allow for the molecular transit time from the photolysis to the detection zones. For the recording of dispersed emission spectra, the laser-excited fluorescence was imaged with a telescope onto a 0.25 m Fastie-Ebert spectrometer (Jarrell–Ash 82-410, operated in second order at a spectral bandpass of 1 nm) and detected through an order-sorting filter (Schott UG-5) by a photomultiplier (EMI 9813QB), whose output was directed to a gated integrator (Stanford Research Systems SRS250) and then to a chart recorder and/or laboratory computer. Wavelength calibration was verified with Hg atomic lines and the ultraviolet laser radiation.

Experimental results

Dispersed emission spectra were taken for excitation of the ^{11}BAr($B\ ^2\Sigma^+$) $v' = 5$–8 vibrational levels. The excited vibrational levels $v' = 5$–7 were prepared by tuning the laser to the Q_1 head of the respective $B\ ^2\Sigma^+ - X\ ^2\Pi_{1/2}$ (v',0) band. Figure 1 presents the spectra obtained. To gauge the importance of dye laser scattered light and emission excited by the photolysis laser alone, we also took spectra with the dye laser tuned off atomic or molecular features. The spectra shown in Fig. 1 have been corrected for the transmission of the order-sorting filter, and the background emission has been subtracted. In the worst case, the dye laser scattered light contributed at most 5% (for $v' = 5$) to the integrated signal of the near resonant emission feature; for higher v' levels, this background was even less. The excimer laser induced emission was also considerably smaller than the laser scattered light signal.

The undulatory behavior of the spectra reflect interferences between the upper state vibrational and lower state continuum wave functions. Each panel in Fig. 1 has a similar qualitative appearance. The displacements of corresponding extrema in the spectra appear at smaller displacements from the excitation wavenumber with increasing v'. This reflects the tendency for the emission to occur at larger internuclear separations, and hence to lower parts of the lower state repulsive walls, as v' increases. We found from our previous theoretical study (17) of BAr($X\ ^2\Pi$) that this state had three bound vibrational levels.

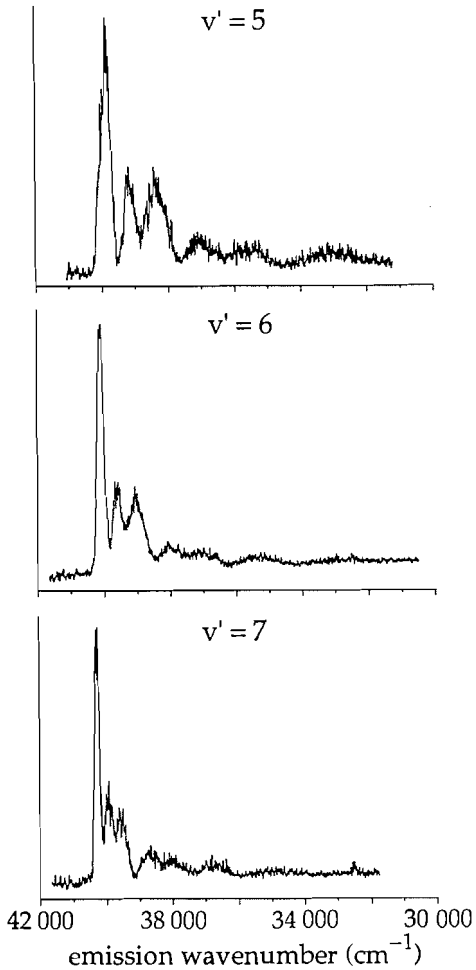

FIG. 1. Experimental dispersed emission spectra for excitation of the ^{11}BAr($B\ ^2\Sigma^+$) $v' = 5$–7 vibrational levels.

The spacings between these levels are considerably smaller than our spectral resolution and the emissions to these bound levels, which occur on the high-wavenumber side of the strong near-resonant feature, are not resolved. The fraction of the radiative decay to these bound levels is quite small because of the poor overlap of the $B\ ^2\Sigma^+$ and $X\ ^2\Pi$ bound vibrational wave functions. The spin–orbit splitting in the $X\ ^2\Pi$ state (17) is even smaller than the vibrational spacings and is also not resolved.

For $v' = 8$, the laser was tuned to the peak of the rotationally unresolved feature. Figure 2 displays the spectrum obtained in this case. This emission spectrum has a different qualitative character from those shown in Fig. 1, consisting mainly of emission near the excitation wavenumber. In the laser fluorescence excitation spectrum (17), no rotational structure could be discerned in the $B\ ^2\Sigma^+ - X\ ^2\Pi_{1/2}$ (8,0) band, in contrast to lower bands in the progression. This broadening was found to be due to predissociation of the $v' = 8$ level through the barrier in the excited state. From comparison of the experimental spectra with simulated spectra, the predissociation width was estimated to be ~ 2 cm^{-1}. The predissociation rate derived from this width is considerably greater than the radiative decay rate (approximately equal to the atomic B $3s\ ^2S \rightarrow 2p\ ^2P$ decay rate of ca. 2×10^8 s^{-1} (see below)), and the $v' = 8$ vibrational level is expected to decay primarily through predissociation. This process leads to the formation of electronically excited B($3s\ ^2S$) atoms, which decay through the $3s\ ^2S \rightarrow 2p\ ^2P$ transition, leading to the strong

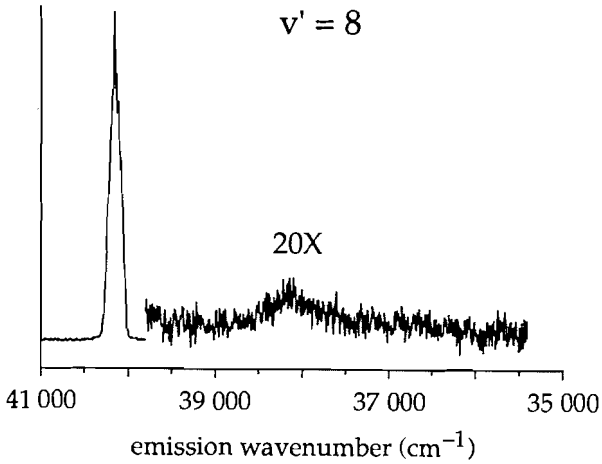

FIG. 2. Experimental dispersed emission spectrum for excitation of the ^{11}BAr($B\ ^2\Sigma^+$) $v' = 8$ vibrational level. The signal in the spectral region to the red of 39 800 cm^{-1} has been amplified by a factor of 20.

atomic feature observed in the emission spectrum and the lack of the undulatory *molecular* features seen in Fig. 1.

Theoretical calculations and simulation of the emission spectra

In order to gauge the reliability of the *ab initio* potential energy curves for the lower BAr electronic states, the experimental dispersed emission spectra presented above are compared with simulated spectra generated using these curves. The continuum emission intensity for the radiative decay of electronically excited BAr($B\ ^2\Sigma^+$, v') at photon energy $h\nu$ is proportional to

$$[1] \quad I(h\nu) \propto |\langle B\ ^2\Sigma^+, v'|\mu|E\rangle|^2$$

where $|B\ ^2\Sigma^+, v'\rangle$ is the vibrational wave function of the electronically excited level, $|E\rangle$ is the lower state continuum wave function, and μ is the electronic transition moment. The energy E equals $E(B\ ^2\Sigma^+, v') - h\nu$, where $E(B\ ^2\Sigma^+, v')$ is the excited state energy relative to the B($2p\ ^2P$) + Ar asymptote. The continuum wave function in eq. [1] is taken as energy normalized (31), i.e.

$$[2] \quad \lim_{R\rightarrow\infty} |E\rangle = (2\mu_{BAr}/\pi\hbar^2 k)^{1/2} \sin(kR - l\pi/2 + \eta)$$

where k is the asymptotic wave vector, μ_{BAr} is the B—Ar reduced mass, l is the orbital angular momentum, and η is the phase shift.

As discussed above, the $B\ ^2\Sigma^+$ excited levels can decay to both the $X\ ^2\Pi$ and $A\ ^2\Sigma^+$ states, so that the B–X and B–A continuum emission spectra will overlap. We must properly weight the relative contributions from these two transitions. We define the electronic transition dipole moments according to the modern convention (32) as

$$[3] \quad \mu(B - X) = \langle B\ ^2\Sigma^+(\Lambda = 0)|\mu_{-1}|X\ ^2\Pi(\Lambda = +1)\rangle$$

and

$$[4] \quad \mu(B - A) = \langle B\ ^2\Sigma^+(\Lambda = 0)|\mu_0|A\ ^2\Sigma^+(\Lambda = 0)\rangle$$

In terms of the Cartesian components of the molecular orbitals, these can be expressed as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

[5] $\mu(B - X) = -\langle B\sigma|\mu_x|X\pi_x\rangle$

and

[6] $\mu(B - A) = \langle B\sigma|\mu_z|A\sigma\rangle$

In the atomic limit, in which the electronic wave functions of the $X\ ^2\Pi$ and $A\ ^2\Sigma^+$ states are described as boron atomic $2p_{x,y}$ and $2p_z$ orbitals, respectively, the magnitudes of the *B–X* and *B–A* transition moments would be equal.

While several $B\ ^2\Sigma^+$ rotational levels are excited by the dye laser, only levels of low rotational angular momentum are prepared. Excitation of the Q_1 head with a dye laser radiation of 0.3 cm^{-1} bandwidth prepares BAr($B\ ^2\Sigma^+$) molecules with $J' = 0.5–2.5$ (17). Moreover, the possible change of the total angular momentum J can be only 0 or ± 1 upon radiative decay. Accordingly, a centrifugal potential was not added to the potential energy curves. Test calculations were carried out for nonzero nuclear angular momentum N (assumed to be the same for the upper and lower states). The computed emission spectra for $N = 0$ and 10 were found to be virtually identical.

Since the spin–orbit splitting is not resolved in the $X\ ^2\Pi$ state, we can sum over the spin–orbit levels. However, the rotational/fine-structure states do play a role in that the sum over the allowed final angular momentum quantum numbers affects the relative intensities of the *B–X* and *B–A* emissions. With the above convention (32) for the transition moments, the sum of the rotational intensity factors over all possible final orbital and electronic angular momentum quantum numbers out of a given $B\ ^2\Sigma^+$ level equals 4 $(2J' + 1)$ for the $B\ ^2\Sigma^+ - X\ ^2\Pi$ transition and 2 $(2J' + 1)$ for the $B\ ^2\Sigma^+ - A\ ^2\Sigma^+$ transition. Thus, the intensities calculated from eq. [1] for the former transition must be multiplied by factor of 2 relative to the latter.

In order to calculate BAr emission spectra, we employed a hybrid potential for the upper $B\ ^2\Sigma^+$ potential energy curve consisting of the experimental RKR curve around the minimum, the long-range *ab initio* potential scaled to match the RKR energy at the outer $v' = 7$ turning point, and an R^{-12} extrapolation at short range. This potential, which is described in detail in our previous paper (17) on BAr, yielded resonance widths for the quasibound $v' = 8$ and 9 levels which were in reasonable agreement with experimentally estimated widths and reproduced well the observed $B\ ^2\Sigma^+$ vibrational energy spacings (17).

The potential energy curves for the lower $X\ ^2\Pi$ and $A\ ^2\Sigma^+$ electronic states were those obtained from our *ab initio* calculations (17). Additional, equivalent calculations were carried out at shorter internuclear distances to extend the repulsive walls of these curves, as well as to generate additional long-range points. As described in detail previously (17), CASSCF (33) calculations with three electrons in four active orbitals (2*s* and 2*p* of B) were performed, using state averaging (34–36) to obtain a single set of CASSCF orbitals for the $X\ ^2\Pi_x$, $X\ ^2\Pi_y$, and $A\ ^2\Sigma^+$ states. Multireference, internally contracted, configuration-interaction (MR-CI) calculations were then carried out. The effect of higher-order excitations was estimated with the multi-reference averaged coupled-pair functional method (MR-ACPF) of Gadnitz and Alrichs (37). The calculations were performed with the MOLPRO suite of *ab initio* programs (38). Table 1 lists the full set of calculated interaction energies for the $X\ ^2\Pi$ and $A\ ^2\Sigma^+$ states. The top panel of Fig. 3 shows the *X*, *A*, and *B* potential energy curves. On the scale of this figure, the wells in the curves are not evident. The avoided crossing of *A* and *B* states seen in this figure occurs well inside the inner turning points of the $B\ ^2\Sigma^+$ vibrational levels so that it will not affect the calculated emission spectra.

transition moments, expected for the atomic limit, is reasonably well obeyed over most of the significant range of internuclear separations. From the magnitude of the transition moments extrapolated to infinite separation (0.72 au), we estimate the radiative lifetime of the B($3s\ ^2S$) state to be 4.9 ns, or an oscillator strength of 0.063 for the $3s$–$2p$ transition. This is in reasonable agreement with the range of oscillator strengths reported from various experiments (0.055 (39), 0.090 (40), 0.062 (41), 0.087 (42) and calculations (0.067 (43), 0.069 (44)). Below $R \sim$ 2.6 Å, the BAr B–A transition moment varies rapidly and changes sign, because of the avoided crossing of the lowest two $^2\Sigma^+$ electronic states.

The simulated spectra were obtained by calculating the B–X and B–A intensities with eq. [1] as a function of E. The bound $B\ ^2\Sigma^+$ vibrational wave functions and the continuum $X\ ^2\Pi$ and $A\ ^2\Sigma^+$ wave functions were computed by Numerov integration (see, for example, ref. 45) of a one-dimensional Schrödinger equation. The integral in eq. [1] was then computed numerically using spline fits of the *ab initio* transition moments.

Figure 4 compares the experimental emission spectrum obtained for the excitation of the $B\ ^2\Sigma^+\ v' = 6$ vibrational level with simulated spectra. It can be seen in the top panel of Fig. 4 that this simulation does not predict well the energies at which the extrema in the emission spectrum occur. Specifically, the extrema are predicted to appear at energies (relative to the B($2p\ ^2P$) + Ar atomic asymptote) too large as compared with the experimental energies. This suggests that the repulsive walls of the *ab initio* potentials are appearing at too large internuclear separations. This discrepancy is consistent with our previous observation (17) that the *ab initio* vibrationally averaged internuclear separation R_0 is larger than our experimental estimate by ~0.1 Å.

We have investigated whether simple changes in the lower state *ab initio* potential energy curves could bring the experimental and simulated spectra into better agreement. In the lower panels of Fig. 4, we compare the $v' = 6$ experimental emission spectrum with simulated spectra for which the $X\ ^2\Pi$ and $A\ ^2\Sigma^+$ potential energy curves were both shifted inward by 0.1 and 0.2 Å. After a shift of only 0.1 Å the extrema are still predicted to occur at too high energy. However, with a shift of 0.2 Å we reproduce well the locations of the extrema and the relative intensities in the experimental spectrum.

The relative contributions of the B–X and B–A transitions are indicated in the simulated spectra displayed in Fig. 4. It can be seen that only the former (both bound–free and bound–bound transitions) contributes to the intense near-resonant peaks. Moreover, the maxima at ~600 and 1200 cm^{-1} are also peaks in

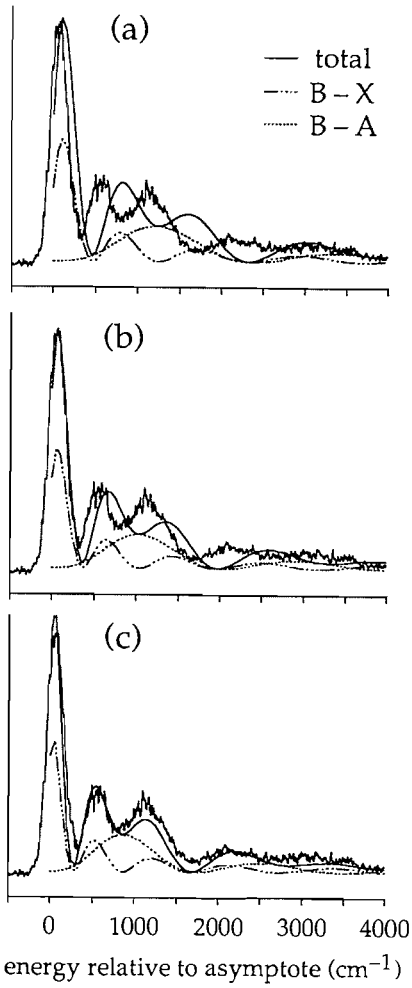

FIG. 4. Comparison of the experimental $v' = 6$ emission spectrum with simulated spectra with (*a*) no, (*b*) a 0.1 Å, and (*c*) a 0.2 Å inward shift of the $X\ ^2\Pi$ and $A\ ^2\Sigma^+$ potential energy curves. The contributions of the B–X and B–A transitions to the spectrum are separately indicated. As discussed in the text, the B–X intensity must be multiplied by 2 in the simulated total emission spectrum. For clarity, the spectra have been truncated at energies 4000 cm^{-1} above the B($4p\ ^2P$) + Ar asymptote.

the B–X emission. The first B–A maximum, which results from a constructive interference involving the overlap of the outer lobe of the $B\ ^2\Sigma^+$ vibrational wave function with the inner lobe of the $A\ ^2\Sigma^+$ continuum wave function, appears between these two peaks. The B–A transition does not contribute at smaller energies because $A\ ^2\Sigma^+$ potential energy curve is more repulsive than that of the $X\ ^2\Pi$ state.

Figure 5 presents a comparison of the experimental spectra for excitation of $v' = 5$ and 7 with simulated spectra calculated using 0.2 Å shifted $X\ ^2\Pi$ and $A\ ^2\Sigma^+$ potentials. As with $v' = 6$, the agreement of experimental and simulated spectra is quite good.

As discussed above, we found (17) from bound state spectroscopy that the average value of the B—Ar distance, as measured by the quantity R_0, was predicted by the *ab initio* potentials to be ~0.1 Å larger than the experimental estimate, obtained from the measured X state rotational constant B_0. A uniform translation of the X state potential curve inward by 0.2 Å lowers the calculated value of R_0 by 0.165 Å, to 3.538 Å, now in somewhat better agreement with the experimental value of

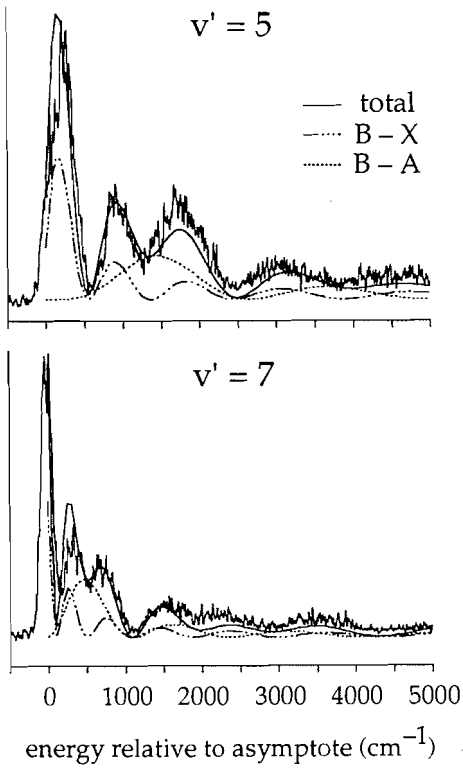

FIG. 5. Comparison of the experimental $v' = 5$ and 7 emission spectra with simulated spectra for which the $X\ ^2\Pi$ and $A\ ^2\Sigma^+$ potential energy curves were shifted inward by 0.2 Å. The contributions of the *B–X* and *B–A* transitions to the spectrum are separately indicated. As discussed in the text, the *B–X* intensity must be multiplied by 2 in the simulated total emission spectrum.

R_0 (3.606 ± 0.007 Å). This implies that perfect agreement with experiment would require a modification of the *ab initio* potential energy curves that is more complex than a simple shift.

Discussion

The present paper demonstrates clearly that bound–free emission spectra, originating from an excited state of a molecular van der Waals complex down to the repulsive wall of the electronic ground state, can provide detailed information on the repulsive wall of the latter. This region is not probed directly in conventional laser excitation fluorescence spectroscopy. Since molecular van der Waals complexes are usually prepared in supersonic jets, so that the internal energy is small, measurable absorption usually takes place out of only the lowest vibrational level of the complex. Thus, fluorescence excitation spectroscopy of van der Waals complexes provides information on the ground state potential energy only in the vicinity of the bottom of the well.

The present study on BAr and the previous investigation (28) of InAr shows that dispersed bound–free fluorescence emission spectra can provide significant information on the repulsive wall of the ground electronic state of the complex. In the present case, where two electronic states correlate with the electronic ground state of the atomic asymptote, the features seen in the emission spectra are primarily sensitive to the least repulsive of the ground state potential energy curves ($X\ ^2\Pi$) and provide relatively little information on the more repulsive ($A\ ^2\Sigma^+$) curve. Similarly, Fawzy et al. (28) were able to carry out a semiclassical inversion of their data to yield a pointwise representation of the ground InAr($X_1\ ^2\Pi_{1/2}$) potential energy curve but were not able to obtain such complete information on the two states ($X_2\ ^2\Pi_{3/2}, A\ ^2\Sigma^+$) correlating with the spin–orbit excited asymptote In($5p\ ^2P_{3/2}$) + Ar.

Fawzy et al. (28) also employed the intensities of the maxima in their InAr bound–free spectra to estimate the $B\ ^2\Sigma^+ - X_1\ ^2\Pi_{1/2}$ transition moment function. They found that this function is approximately a constant over the range 2.9 to 3.8 Å. This constancy is consistent with the idea that the metal atom chromophore in such a weakly bound molecule is essentially unaffected by the presence of the rare gas atom until rather small internuclear separations, as is shown by our calculated BAr *B–X* and *B–A* transition moment functions, displayed in Fig. 3.

The present study demonstrates conclusively that our *ab initio* potentials for the two lowest electronic states of BAr, which correlate with the ground state atomic asymptote [B($2p\ ^2P$) + Ar], are a bit too repulsive. Shifting them inward slightly (~0.2 Å) led to a much better simulation of the experimental spectra. In fact, the calculations will certainly also underestimate the depth of the van der Waals well, for which no correction was made in the present simulation. A more complex scaling of the *ab initio* curves was not attempted here. This would certainly become justified, were additional experimental information, in particular the positions of the excited vibrational levels of the $X\ ^2\Pi$ state, to become available.

Received August 30, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

M.A. CARPENTER, M.T. ZANNI, D.J. LEVANDIER, D.F. VARLEY, and J.M. FARRAR. Can. J. Chem. **72**, 828 (1994).

We present the angular and kinetic energy distributions for the products of the proton transfer reaction $O^- + HF \rightarrow OH + F^-$ at center-of-mass collision energies of 45.0 and 55.8 kJ mol^{-1} (0.47 and 0.58 eV, respectively). At both collision energies, the product angular distributions show forward–backward symmetry, characteristic of the decay of a transient complex living at least several rotational periods. The product kinetic energy distributions show structure that is clearly attributable to the formation of OH in $v' = 0$, 1, and 2. The kinetic energy distribution for a single vibrational state of OH is equivalent to the rotational state distribution for that state. At the higher collision energy, the product kinetic energy distribution shows a clear angular dependence, from which we infer a transition to more direct dynamics involving low impact parameter collisions that access the repulsive wall of the potential surface in bent geometries. The vibrational energy in the products decreases with increasing collision energy, with f_V', the fraction of available energy appearing in vibration, decreasing from 0.28 to 0.22 over the reported collision energy range. We attribute this behavior to a transition from mixed energy release of a **Heavy + Light–Heavy** collision system dominated by the strong attractive well to induced repulsive energy release as the system reaches the low energy repulsive wall of the potential energy surface.

M.A. CARPENTER, M.T. ZANNI, D.J. LEVANDIER, D.F. VARLEY et J.M. FARRAR. Can. J. Chem. **72**, 828 (1994).

On a mesuré les distributions d'énergie angulaire et cinétique des produits de la réaction de transfert de proton $O^- + HF \rightarrow OH + F^-$ au centre de énergies de collision massique, soit 45,0 et 55, 8 kJ mol^{-1} (0.47 et 0.58 eV respectivement). Aux deux énergies de collision, les distributions angulaires du produit présentent une symétrie avant/arrière qui est caractéristique d'un décomposition d'un complexe transitoire qui vit au moins plusieurs périodes de transition. Les distributions d'énergie cinétique du produit montrent une structure qui est clairement attribuable à la formation de OH dans $v' = 0$, 1 et 2. La distribution de l'énergie cinétique pour un seul état vibrationnel de OH est équivalente à la distribution de l'état rotationnel de cet état. À des énergies de collision plus élevées, la distributuion de l'énergie cinétique du produit présente une dépendance angulaire bien marquée à partir de laquelle on peut déduire la présence d'une transition vers une dynamique plus directe impliquant des collisions à faible paramètre d'impact qui atteignent la mur répulsif de la surface de potentiel des géométries recourbées. L'énergie vibrationnelle des produits diminue avec une augmentation de l'énergie de collision, alors que f_V', la fraction d'énergie disponible apparaissant dans la vibration, diminue de 0,28 à 0,22 pour la plage d'énergie de collision rapportée. On attribue ce comportement à une transition d'une perte d'énergie mixte d'un système de collision **Lourd + Léger–Lourd** sous la domination d'un puits d'attraction important vers une perte d'énergie par répulsion induite lorsque le système atteint le faible mur d'énergie répulsive de la surface d'énergie potentielle.

[Traduit par la rédaction]

Introduction

The study of gas phase ion–molecule reactions has applications ranging from electrical discharges, atmospheric chemistry, and combustion processes to plasma chemistry and etching in semiconductor systems. (1) The development of techniques for investigating ionic reactions has proceeded rapidly in the last several years, (see, for example, ref. 2) with special emphasis on understanding the dynamics of such collisions, i.e., energy disposal, direct vs. complex mechanisms, and preferred collision geometries. The study of gas phase proton transfer reactions has been particularly active, with a variety of techniques including molecular beams (3–5), drift and selected ion flow tubes (6, 7), infrared emission (8, 9), and laser-induced fluorescence (LIF) (10, 11) applied to this class of chemical interactions over collision energies from thermal to those approaching covalent bond strengths. It has been particularly fruitful to compare dynamics of ionic systems with those of analogous neutral systems. For example, a comparison of product state distributions in reactions such as F^- and F with hydrogen halides, e.g., F^- + HCl with F + HCl (8, 9, 12), has shown that the vibrational state distributions for the ionic and neutral processes are remarkably similar despite the fact that the ionic system has a deep potential energy well. The pioneering work of Polanyi and co-workers (13, 14) has provided the conceptual basis for understanding these results, namely that the kinematic effect of the **Heavy + Light–Heavy** mass combination dominates energy partitioning and collision dynamics. In proton transfer reactions in particular, the angle between the entrance and exit channels of the potential energy surface in scaled and skewed coordinates (15) is quite small, near 20° for particle transfer between bases of moderate mass. Trajectory studies by Polanyi and collaborators (16–19) on such surfaces have shown that product energy release is determined more by the initial conditions of a trajectory than by details of the potential surface itself. At low collision energies, these studies show that reaction occurs through the mechanism of "mixed energy release", in which proton transfer occurs when both the breaking bond in the reagents and the bond forming in the products are extended. Reagent translation appears in product vibration in collisions governed by mixed energy release. Furthermore, a comparison of energy partitioning in systems exhibiting mixed energy release at low collision energies with results taken at enhanced translational

energy shows an effect Polanyi terms "induced repulsive energy release", in which incremental reagent translation appears in product translation. This effect arises as collisions sample the low energy repulsive wall of the potential surface with both the breaking and forming bonds compressed.

In this paper, we present crossed beam measurements on the proton transfer system (heats of formation are from ref. 20)

[1] $O^- + HF \rightarrow OH + F^-$ $\Delta H° = -46$ kJ mol^{-1}

at center-of-mass collision energies of 45.0 kJ mol^{-1} (0.47 eV) and 55.8 kJ mol^{-1} (0.58 eV). We have already reported on the results of this system at the lower collision energy (21, footnote 4). In this paper, we present a more complete analysis of the lower energy results, as well as results at a higher energy that complement our understanding of **Heavy + Light–Heavy** dynamics, particularly in light of the concepts of mixed energy release and induced repulsive energy release as conceptualized by Polanyi.

Previous studies of this system by Hamilton et al. (10) in thermal energy flow tube measurements and more recent drift tube studies by Knutsen et al. (11) have yielded product state distributions over an expanded range of incident kinetic energies up to 22 kJ mol^{-1}. Those studies showed that, relative to the thermal energy reference data, incremental translation appears to be partitioned preferentially into product vibration. Knutsen et al. have interpreted these observations as a consequence of the attractive well on the potential surface, estimated from *ab initio* calculations to be 187 kJ mol^{-1} relative to the reagents (22). The drift tube experiments showed that the fraction of the total available energy appearing in product vibration increases linearly with increasing translation up to 15 kJ mol^{-1}, consistent with mixed energy release on the **Heavy + Light–Heavy** potential energy surface. Our crossed beam work at 45 kJ mol^{-1} showed that this linear trend began to break down as a larger fraction of incremental reagent translation appeared in product translation, consistent with Polanyi's notion of induced repulsive energy release. We commented that the enhanced translation in the crossed beam experiments may allow collisions to move out of the deep ion-induced dipole potential well and onto the low energy repulsive wall. We noted that at higher energies, we would expect this trend to continue, with product vibrational excitation decreasing significantly as the low energy repulsive wall transforms reagent translation into product translation on the highly skewed O^- + HF potential energy surface.

In this paper, we report on higher energy measurements and demonstrate clearly that incremental translation begins to probe the low energy repulsion. We also show that the product energy distributions have a strong angular dependence, despite evidence that the reaction proceeds through a collision complex living a significant fraction of a rotational period. The observations provide a more detailed signature for reactions undergoing a transition from collision complex-mediated to direct dynamics.

Experimental

The crossed beam apparatus used for this study has been described in detail in previous work (3, 4, 23). We produced O^- ions by electron impact on N_2O at a pressure of ~0.01 torr. Following acceleration and magnetic mass analysis, the ion beam was collimated to 1–2° by electrostatic optics. The neutral beam was produced by passing 500 torr of He through a sample bulb containing HF held at −45°C with an acetonitrile/liquid N_2 bath. At this temperature the HF vapor pressure is ~40 torr. The mixture was expanded through a 0.07 mm nozzle, collimated to 2° by a 1 mm electroformed skimmer and 3.5 mm square aperture, modulated at 30 Hz to allow for background correction, and allowed to pass into the collision chamber where it intersects the collimated ion beam. Products were detected as a function of laboratory angle, energy and mass using a rotatable electrostatic energy analyzer – quadrupole mass filter equipped with a dual microchannel plate ion detector. The resolution of the energy analyzer is 0.07 eV in the laboratory coordinate system. The energy scale was calibrated in a separate experiment by resonant charge transfer from NO^- also produced by electron impact on N_2O, to NO expanded supersonically in the crossed beam.

We collected F^- product flux distributions as function of laboratory kinetic energy at selected laboratory angles, measuring an angular distribution by integrating the signal over energy to normalize the data. Energy and angular distributions were measured with a multichannel scaler implemented with CAMAC modular electronics. In this study, we measured product fluxes at 20 to 26 angles over the laboratory scattering angle range from –2° to 112° measured relative to the ion beam direction. At each angle, reactive fluxes were binned into 80 kinetic energy channels, giving a total of 1600 to 2080 data points for each experiment from which to construct the center of mass kinetic energy and angular distributions.

Results

The experiments were performed at collision energies of 45.0 and 55.8 kJ mol^{-1}. Figure 1 shows experimental data at the higher collision energy, along with the results of an iterative deconvolution data analysis program we describe later. The kinematic Newton diagram at the bottom of the figure shows the concentric circles corresponding to the formation of F^- *in concert with* OH in specific vibrational states with quantum numbers $v' = 0$, 1, and 2. The laboratory speeds at which these vibrational states appear for a given laboratory scattering angle are marked in the figure, showing clear correspondence with the structure in the experimental data. Our analysis of these data is directed toward extracting angular and kinetic energy distributions for product formation, vibrational state populations, and characteristics of the OH rotational state distributions within each vibrational state.

Analysis

In our earlier report on this system (21), we employed the integration fitting method for analyzing the center-of-mass cross sections. This method assumes that the center-of-mass cross section, $I_{c.m.}(u,\theta)$, defined in terms of the center-of-mass speed u and scattering angle θ, can be written as a product function of center-of-mass speed distributions $f^{v'}(u)$ and angular distribution functions $g^{v'}(\theta)$ for each vibrational state. The center-of-mass scattering angle θ is defined such that F^- products moving in the direction of the initial HF projectile in the center-of-mass are defined to scatter through 0°.[5] With this definition, forward scattered F^- products correspond to large impact parameter collisions. The function data $f^{v'}(u)$ and $g^{v'}(\theta)$

[4]The collision energy we reported in ref. 21 has been revised upward by 10% owing to a more accurate procedure for calibrating the energy zero of our detection system.

[5]Note that this definition of scattering angles is the opposite of our usual definition, employed in ref. 21, in which the incident ion direction in center of mass coordinates defines forward scattering. The definition employed in this paper is more physically intuitive, since the direction of the product we detect, F^-, is referred to the center of mass direction of HF, from which F^- originates.

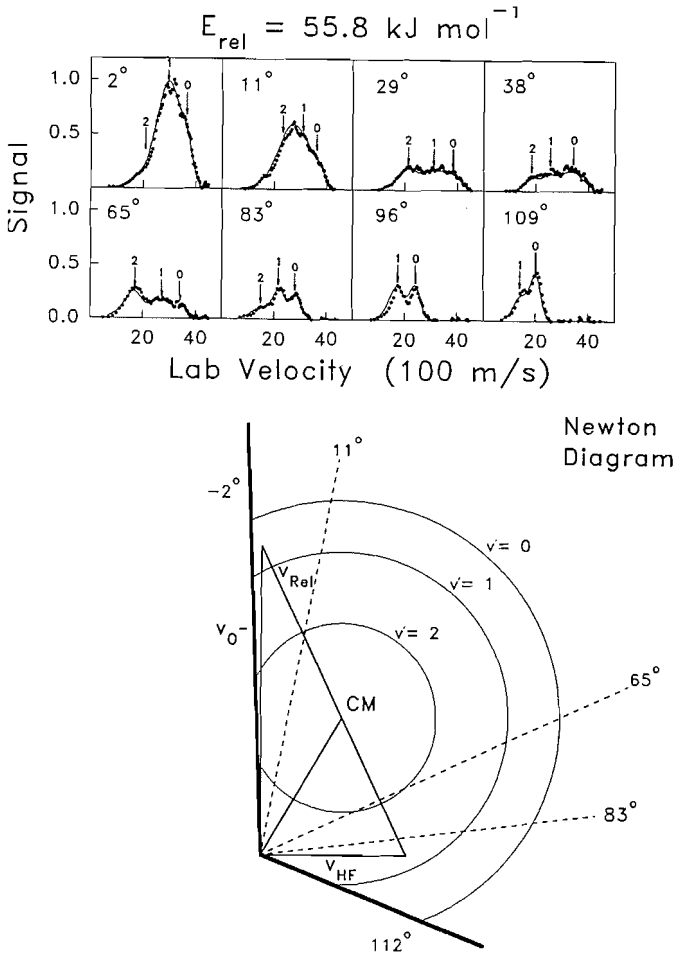

FIG. 1. Experimental F^- reactive flux data and Newton diagram for O^- + HF reactive collisions at a relative energy of 55.8 kJ mol^{-1}. The experimental data points (····) have been transformed to velocity space for comparison with the results of kinematic calculations (——), and the vertical arrows indicate the velocities at which the corresponding OH vibrational states appear in the fluxes.

depend on a small parameter set that is optimized to fit the laboratory data when the center-of-mass data are transformed to the laboratory. This procedure yielded a satisfactory fit to the data, although the intensities produced by the calculations were significantly smaller than experiment for wide laboratory scattering angles near the HF beam. We discovered that the assumption of separation of the variables u and θ in the center-of-mass cross section was responsible for this discrepancy, which became increasingly important with increasing collision energy. We therefore applied the iterative deconvolution procedure of Siska (26), in which we invert transformation relation [2]

$$[2] \quad I_{lab}(v,\Theta) = \sum_{i=1}^{N} f_i I_{c.m.}(u_i,\theta) \frac{v^2}{u_i^2}$$

while deconvoluting the dispersion in the initial beam velocities. This procedure yields a grid of center-of-mass intensities $I_{c.m.}(u_i,\theta)$ defined on the set of points in laboratory velocity space at which the experimental data were acquired. When transformed to the laboratory with suitable averaging over initial beam conditions the center-of-mass intensities $I_{c.m.}(u,\theta)$ recover the laboratory data with a standard deviation of 4%. The

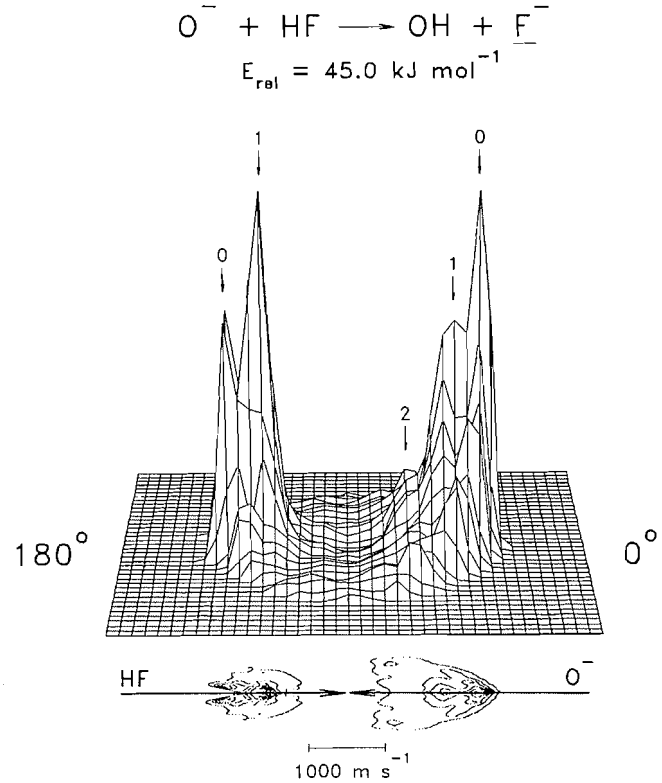

FIG. 2. Barycentric polar flux axonometric plots and contour projections for the F^- product in the O^-+ HF reaction at a collision energy of 45.0 kJ mol^{-1}. Structure in the flux plot corresponds to contributions from OH produced v' = 0, 1, and 2 as labelled.

center-of-mass intensity grid is intrinsically nonseparable in the variables u and θ. The center-of-mass intensities that we obtain in this way provide a more faithful reproduction of the laboratory data than those constructed from integration fitting. We employ a linear bivariate interpolation algorithm to calculate values of the deconvoluted flux on a Cartesian grid in the center-of-mass velocity space. In Figs. 2 and 3, we present three dimensional axonometric representations of the center-of-mass scattering fluxes for F^- production at both collision energies. The data plotted in these figures are the results of pointwise deconvolution of the experimental data, and embody the noise of the original data, amplified by the deconvolution procedure.

The three dimensional flux maps shown in Figs. 2 and 3 have peaks at 0° and 180° in center-of-mass coordinates, showing clear symmetry about 90°. Flux distributions with this symmetry are generally diagnostic of the decay of a transient complex living at least several rotational periods (25, 26), supporting calculations that predict the existence of an O^-·HF complex stable relative to O^- + HF by 187 kJ mol^{-1} (22). In the decay of such a transient complex, the products "forget" the direction of initial reagent approach and the energy distributions are independent of scattering angle. Nevertheless, the fact that we observed a strong angular dependence to the product state distributions implies that the collision complex model is not quantitatively applicable, a point we address in detail below.

The strong nonseparability of the data in u and θ implies that portraying the product kinetic energy distribution by integrating the center-of-mass fluxes over the full range of scattering angles $0° \leq \theta \leq 180°$ will result in a significant loss of dynamical information. In order to visualize the strong angular depen-

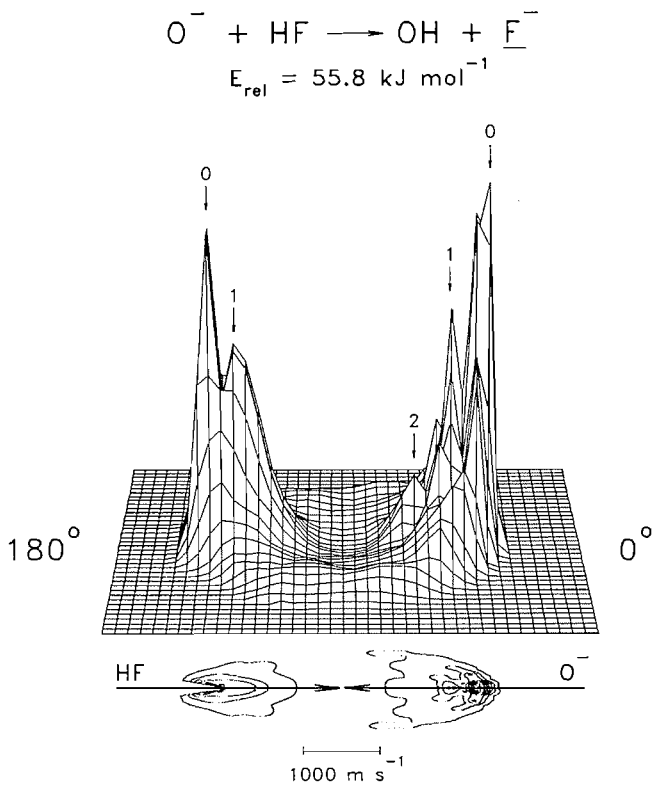

FIG. 3. Barycentric polar flux axonometric plots and contour projections for the F^- product in the O^- + HF reaction at a collision energy of 55.8 kJ mol^{-1}. Structure in the flux plot corresponds to contributions from OH produced in $v' = 0$, 1, and 2 as labelled.

dence of the product energy distributions, we have divided the full angular scattering range $0° \leq \theta \leq 180°$ into n smaller bins, each of width $180°/n$, and have computed the partial kinetic energy distribution for the kth bin by integration over the appropriate angular range:

$$[3] \quad P_k(E'_T) \propto u^{-1} \int_{(k-1)(\pi/n)}^{k(\pi/n)} I(u,\theta) \sin\theta \, d\theta \text{ for } 1 \leq k \leq n$$

In Figs. 4 and 5, we show kinetic energy distributions obtained by dividing the angular range into six bins. In the lower collision energy experiment, shown in Fig. 4, the product recoil distributions show a weak dependence on angular range, but the resolution of the distributions into contributions from individual vibrational states is roughly constant, independent of angular range. The relative contributions from the OH vibrational state populations reflect the fact that the angular distributions are state dependent. The near constancy of the widths of the individual components reflects the independence of product rotational excitation on scattering angle.

At the higher collision energy, the product recoil distributions shown in Fig. 5 have a much stronger angular dependence. F^- scattering in the angular range from 30° to 180° results in kinetic energy distributions that can be resolved into three components, but the individual components are quite broad. In contrast, however, the vibrational states are much more completely resolved for F^- scattered in the angular range from 0° to 30°, this observation indicates that the distributions of OH rotational energy for each vibrational state are significantly narrower for such collisions. F^- products scattered in the forward hemisphere relative to incoming HF correspond to collisions in which O^- strips a proton from HF, the F^- product following the initial HF direction, and OH recoiling in the opposite direction. The implications of this observation are that such collisions take place over fairly narrow ranges of impact parameter. The product recoil distributions show that OH formation through direct stripping collisions becomes increasingly important as the collision energy is raised. This behaviour is characteristic of collisions on potential surfaces with strong attractive components.

It is possible to use the angle-dependent kinetic energy distributions for each vibrational state to estimate OH rotational population distributions (27). Because our experiments lack rotational resolution, estimating the rotational distribution from a continuous kinetic energy distribution for the production of a single vibrational level is only of limited validity. Nevertheless, estimates of the mean rotational excitation for each vibrational state as well as the widths of the distributions provide information diagnostic of the potential surface. At the lower collision energy of 45 kJ mol^{-1}, the product rotational state distributions are angle independent. For OH in $v' = 0$ and 1, the most probable J' is approximately 15, decreasing to 12 in $v' = 2$. These quantum numbers correspond to rotational energies of 54 and 35 kJ mol^{-1} respectively. In energy space, the full widths at half maximum of the distributions are 30 kJ mol^{-1} for $v' = 0$ and 1, decreasing to 20 kJ mol^{-1} for $v' = 2$.

At the higher collision energy of 55.8 kJ mol^{-1}, the widths of the product rotational state distributions have a significant angular dependence, although the most probable energies are reasonably independent of angle. For backward angles, OH is formed with most probable J' values between 13 and 15 independent of vibrational state. The widths of these distributions decrease monotonically with increasing vibration: for OH in $v' = 0$, the rotational distribution is 70 kJ mol^{-1} wide, decreasing to ~50 kJ mol^{-1} for $v' = 1$ and 40 kJ mol^{-1} for $v' = 2$. In the forward direction, corresponding to stripping collisions, the widths of the rotational distributions are significantly narrower than for the backward direction, ranging from 30 kJ mol^{-1} for $v' = 0$ and 1 to 22 kJ mol^{-1} for $v' = 2$. Corresponding numbers for backward scattering are more than a factor of two larger. The principal trend in the experimental data is the development of much broader distributions in OH rotation for backward scattered F^- products. Collisions yielding such products correspond to low impact parameter encounters. In the collinear limit, proton transfer would result in F^- scattered through 180°; larger impact parameters result in sideways-peaked product distributions, until large impact parameters result in stripping collisions.

The angular distributions for the individual vibrational states of the products can be obtained by integrating the center-of-mass fluxes over the appropriate ranges of speeds. Those distributions are shown in Figs. 6 and 7. At the lower collision energy, the angular distributions for forming OH in $v' = 0$ and 1 show forward–backward symmetry, indicative of a collision complex contribution to the scattering. The $v' = 2$ state, formed only 5 kJ mol^{-1} above threshold, has an asymmetric angular distribution favoring forward scattering, corresponding to a stripping collision through a large impact parameter. At the higher collision energy, the angular distributions for all three states of OH show approximate forward backward symmetry. The $v' = 2$ state is now formed 16 kJ mol^{-1} above threshold, and the asymmetry we observed earlier is now gone.

The vibrational state populations for OH ($v' = 0$, 1, and 2), reported in Table 1, were extracted numerically from the exper-

imental data by decomposing the structure in the data into contributions from individual vibrational states and transforming the data to the center-of-mass using the iterative deconvolution procedure. The resultant center-of-mass fluxes were then integrated over appropriate ranges of u and θ to yield vibrational state probabilities. In the integration-fitting procedure we employed in our earlier report on this system, we assumed relative vibrational state populations in the center-of-mass system, varying the amplitudes and shapes of the recoil distributions for each state to fit the data. The method did not correctly recover all of the flux in $v' = 0$ or 1. The iterative deconvolution procedure recovers the experimental data more faithfully, but more accurate state population estimates require a set of data covering all center-of-mass space. Inspection of the contour plots of Figs. 2 and 3 indicates that a "wedge" of intensity is missing near 180°, comprised primarily of flux in OH ($v' = 0$). In order to estimate the $v' = 0$ vibrational state population, we assumed

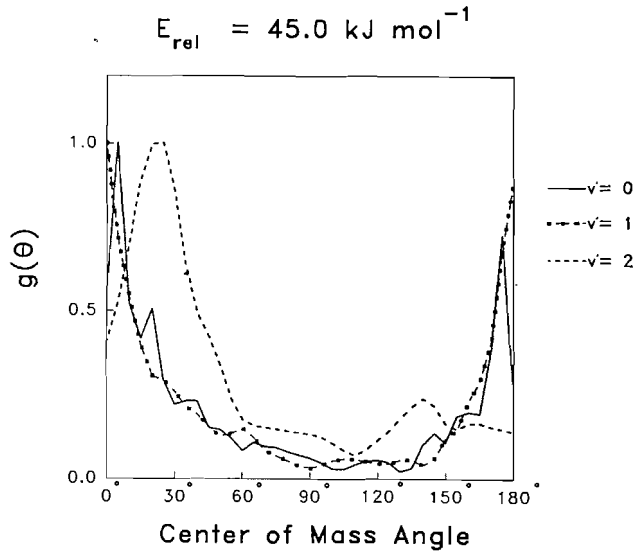

FIG. 6. Center of mass state-resolved angular distributions for OH ($v' = 0$, 1, and 2) at a collision energy of 45.0 kJ mol^{-1}.

that the wedge intensity across the gap was constant and equal to the value of the flux at the apex of the wedge. Such an approximation may underestimate the flux into $v' = 0$, making

our estimates of the amount of energy appearing in product vibrational excitation an upper limit. Reasonable estimates for the missing flux indicate that our reported value for the $v' = 0$ state population may be low by a few percentage points at most, underscoring our claim that our tabulated state populations result in upper limits on the product vibrational excitation.

The evidence we have presented from angular distribution measurements for the participation of a transient collision complex living several rotational periods has motivated us to compare the measured vibrational product state distributions with the results of angular momentum conserving statistical phase space theory calculations (28). The calculations are performed by evaluating the number of OH product quantum levels accessible from an O^-·HF complex with specified total angular momentum; the total energy accessible to the products is the sum of the collision energy and the reaction exothermicity, 91.0 and 101.8 kJ mol^{-1} for the two collision energies reported here. Angular momentum partitioning in the exit channel is determined by the centrifugal barrier of the separating products. The total angular momentum is computed by assuming a Langevin thermal rate and an $E^{-1/2}$ dependence of the reactive cross section. This estimate yielded a value of $70\hbar$ at both energies. The product state populations vary by less that 1% for $10\hbar$ variations in the total angular momentum. That comparison is made both in Table 1 and in Figs. 8 and 9. At the lower collision energy for which results are shown in Fig. 8, the deviations between experiment and theory are significant, with more $v' = 1$ and less $v' = 0$ formed than predicted by theory. We have already commented (21) that this preference for product vibrational excitation is a reflection of specific nonstatistical dynamics on the O^- + HF potential surface in which the long range attraction in the entrance channel accelerates the reagents together in a manner that mimics a direct reaction. At the higher collision energy, less energy appears in product vibration. The experimental distribution more closely approximates phase space theory, although the reaction shows significant evidence of deviating from collision complex behavior. As we discuss later, the partitioning of excess translation into product translation reflects the accessibility of the low energy repulsion as collision energy increases.

The critical issue in understanding how energy dependent trajectories probe the potential energy surface in this study comes from assessing how incremental translational energy is partitioned into product vibration. Figure 10 shows a plot of the average value of the fraction of the total energy in product vibration, $f_{V'}$, as a function of the total energy. The variable $f_{V'}$ is defined as follows:

$$[4] \quad f_{V'} = \sum_{v'=0}^{2} P_{v'} E_{v'} E_{\text{total}}$$

In this expression, $P_{v'}$ is the probability of populating the v' quantum state of OH and E_{total} is the total energy accessible to the system, defined by the sum of reagent collision and internal energy and reaction exothermicity as follows:

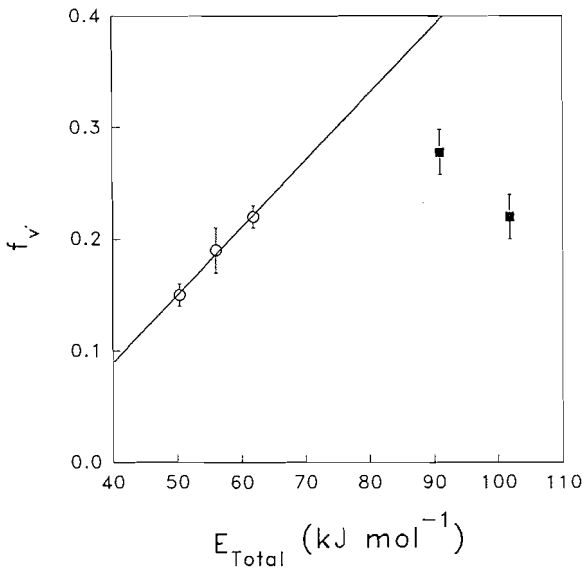

FIG. 10. Fraction of total energy in product vibration, $f_{V'}$, vs total available energy E_{total}. The three lower energy points are from refs. 10, 11 at collision energies of 3.8, 9.6, and 15.4 kJ mol^{-1}, while the filled symbols (■) correspond to the collision energies of the present study.

$$[5] \quad E_{total} = E_{rel} + E_{vib} + E_{rot} - \Delta H^\circ$$

This expression employs mean values when there exists a distribution in energy. HF reagents in the drift tube studies have a significant thermal rotational energy contribution while HF reagents produced by seeded supersonic expansion in the present experiments are rotationally cold. The graph shows data from the drift tube studies as well as from the experiments reported here and illustrates a number of important points. In the lower collision energy experiments done in flow tubes at collision energies up to 15 kJ mol^{-1} (E_{total} = 62 kJ mol^{-1}), $f_{V'}$ increases linearly with collision energy, consistent with mixed energy release. At 45 kJ mol^{-1} collision energy (E_{total} = 91 kJ mol^{-1}), the value of $f_{V'}$ continues to increase but departs from linearity as less of the incremental reagent translation appears to be partitioned into product vibration than at the lower energies. That trend is underscored in the highest collision energy experiment, as $f_{V'}$ now decreases, indicating that an even higher fraction of the incremental translational energy of the reagents appears in product translation. The data thus suggest that trajectories explore new portions of the potential energy surface at these higher collision energies.

Discussion

We have commented in our earlier study of the O^- + HF system that a discussion of energy partitioning on a specific potential surface must be concerned with two issues: *baseline* energy partitioning at a specific reference energy, e.g., thermal; and the effect of *incremental* energy, either in the form of internal or translational excitation, on the baseline. Previous studies on **Heavy + Light–Heavy** reaction systems show that the dynamics are dominated by kinematics rather than specific features of the potential energy surface itself. The extensive trajectory studies of Polanyi and co-workers (16–19) shows that reactive collisions on such highly skewed surfaces are direct, with a strong propensity to cut the corner separating the entrance and exit valleys. These motions correspond to light atom transfer from configurations extended from equilibrium bond lengths with little momentum transfer to the departing heavy atoms, yielding reaction products that are highly vibrationally excited. The thermal energy studies of ref. 10 on the O^- + HF system are also consistent with baseline energy partitioning into product vibration via this mechanism of mixed energy release.

The concept of "induced repulsive energy release" was introduced by Polanyi and co-workers to address partitioning of incremental translational energy on **Heavy + Light-Heavy** potential surfaces (12). In this picture, reactive trajectories with excess translation penetrate far into the "corner" of the highly skewed potential surface where both the forming and breaking bonds are compressed. The trajectory moves into the exit valley with little motion perpendicular to the reaction coordinate, yielding products with high translational excitation. Depending on the extent to which the collision geometry in the corner is bent, the nascent products will partition some of the incident translation into product rotation. The trajectory therefore explores a new portion of the potential surface relative to reference trajectories at lower energies.

The deep potential well of the O^- + HF system, estimated from *ab initio* calculations to lie 187 kJ mol^{-1} below the reagents, adds new factors to the nature of mixed energy release on **Heavy + Light-Heavy** potential energy surfaces. In the flow and drift tube studies of refs. 10 and 11, a fourfold increment in relative translational energy from 3.8 to 15.4 kJ mol^{-1} results in a linear increase in the fraction of the total energy appearing in product vibration, shown in Fig. 10. As we noted in our previous discussion, this linear increase is consistent with corner cutting trajectories and mixed energy release. Because the increment in translational energy is only 6% of the O^-·HF well depth, these reactive trajectories explore essentially the same regions of the potential energy surface over the full collision energy range, and thus "induced repulsive energy release" does not apply. Energy partitioning mimics the mixed energy release case where proton transfer occurs in geometries in which both breaking and forming bonds are extended.

At the higher collision energies of the beam experiments, 45.0 and 55.8 kJ mol^{-1}, the increments in translation over the thermal energy baseline collision energy are 41 and 52 kJ mol^{-1}, respectively, representing 22 to 28% of the O^-·HF well depth. In this case, the incremental energy allows collisions to access additional regions of the potential energy surface, in particular the repulsive wall. Corner cutting trajectories are less important in this energy regime as high translation in conjunction with the highly skewed nature of the **Heavy + Light–Heavy** potential surface forces trajectories past the well and onto the low energy repulsive wall. The fact that collisions at these higher energies show significant deviations from statistical behavior in the product vibrational state distributions with an enhanced propensity to partition reagent translation into product translation supports the claim that at these energies, the influence of the well in the reaction dynamics is giving way to low energy repulsive forces.

Induced repulsive energy release may impart a significant torque on the newly formed product as the three atom collision system moves from the corner into the exit channel. Trajectory studies by Polanyi and co-workers (12) have demonstrated that this effect manifests itself as a partitioning of incremental reagent translation into product translation and rotation: $\Delta T \rightarrow \Delta T' + \Delta R'$. Although buffer gas collisions in the thermal energy measurements (10, 11) prevent the determination of product

For personal use only.

rotational energies and therefore do not give us a baseline for rotational energy, the constancy of nascent product rotational excitation in our own data suggests that incremental translation appears primarily in product translation, with product rotational angular momenta of no more than 12–15$\hbar$. However, a very distinct broadening of the rotational energy distributions for low impact parameter encounters appears in the higher collision energy data. The widths of the rotational distributions for these collisions are approximately twice as large as for products scattered into the opposite hemisphere. For such low impact parameter collisions, the acceleration of the approaching reagents by the long range attraction projects the system onto the low energy repulsive wall in bent configurations. Such collisions have a clear direct character and further suggest that the distribution of low impact parameters contributes to the widths of the rotational distributions, an important probe of the potential energy surface. Such trajectories are truly diagnostic of the transition from collision complex mediated dynamics to direct, impulsive collisions.

Conclusions

The work we have reported here represents one of the most detailed dynamical studies of a simple ion–molecule reaction presented to date. Product angular distributions indicate that the strong attractive potential of the approaching reagents plays a dominant role in the dynamics by controlling energy partitioning of the transient O^-·HF complex. Nevertheless, vibrational product state distributions are in clear disagreement with Phase Space theory, in that more OH is formed in $v' = 1$ and less in $v' = 0$, than predicted by theory. The product kinetic energy distributions for single vibrational states have been analyzed for the OH rotational energy distributions. The results show that OH is formed with $J' \sim 12$–$15\hbar$, roughly independent of vibrational state. The widths of the rotational state distributions undergo a marked broadening at the higher collision energy for low impact parameter collisions, suggesting that such collisions are direct, and that a distribution of bent geometries on the low energy repulsive wall of the surface determines the partitioning of reagent translation into product translation and rotation. Such a picture is consistent with the onset of induced repulsive energy release as collisions sample the low energy repulsive wall.

The data presented for this reaction are comparable in detail to those for the $F + H_2$ reaction (29). The extensive energy dependent internal energy distributions as well as state-specific angular distributions will provide critical tests for *ab initio* potential energy surfaces as well as dynamics calculated on such surfaces. We hope that this system will become a benchmark for low energy proton transfer systems.

Received July 20, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

LIFENG CHEN, CHRISTA L. COLYER, MUTHONI G. KAMAU, JAN C. MYLAND, KEITH B. OLDHAM, and PETER G. SYMONS. Can. J. Chem. **72**, 836 (1994).

An aqueous solution containing supporting electrolyte and a small concentration of an electroactive analyte is allowed to flow, under a gravitational head, through a polarized platinum tube. The tube is narrow enough that, during their few seconds of residence time within the tube, virtually all the analyte molecules are able to diffuse to the tube wall and be electrolytically destroyed. The analyte concentration is accurately calculable, when the applied voltage and head are optimized, from the measured flow rate of the solution and the steady-state electric current, the latter being background-corrected by subtracting the current under no-flow conditions. Though the detailed theory is complicated, the principles of the method and its experimental realization are straightforward.

LIFENG CHEN, CHRISTA L. COLYER, MUTHONI G. KAMAU, JAN C. MYLAND, KEITH B. OLDHAM et PETER G. SYMONS. Can. J. Chem. **72**, 836 (1994).

On permet à une solution aqueuse contenant un électrolyte de support et une faible concentration d'un produit à analyser électroactif de s'écouler, par gravitation, à travers un tube de platine polarisé. Le tube est suffisamment étroit pour que, durant les quelques secondes où elles sont présentes dans le tube, pratiquement toutes les molécules du produit à analyser sont capables de diffuser vers la paroi du tube et d'être détruites électrolytiquement. Quand on optimise le voltage appliqué et la gravitation, on peut calculer avec précision la concentration du produit à analyser à partir de la mesure de la vitesse d'écoulement de la solution et du courant électrique à l'état stationnaire; on corrige ce dernier pour le bruit de fond en soustrayant le courant observé lorsqu'il n'y a pas d'écoulement. Même si la théorie détaillée est complexe, les principes de la méthode et sa réalisation expérimentale sont simples.

[Traduit par la rédaction]

Introduction

In analytical coulometry the analyte is quantitatively removed from solution by exhaustive electrolysis. The original analyte concentration c^b is then calculated by the formula

$$[1] \qquad c^b = \frac{Q}{nFV}$$

from two measured quantities (the total electric charge Q and the sample volume V) and two known constants (Faraday's constant F and the number n of electrons involved in the electrode reaction). Coulometry with the potential controlled electronically was introduced by Hickling (1) in 1942; by 1975, a review (2) of this topic cited almost 700 references. Since that time coulometry continues to hold its place in the repertoire of electroanalytical techniques, though rival amperometric methods have stolen most of the limelight.

Even when diffusion is augmented by convective transport, exhaustive electrolysis is a slow process. Because the electrolysis time increases with the cell volume, researchers have striven to reduce V, leading to such developments as thin-layer coulometry (3). A difficulty that is then encountered is in delineating the boundary of the electrolysis zone and in measuring its volume accurately. These obstacles are overcome by allowing the analyte solution to flow slowly and steadily through the cell: the electrolysis zone boundary is no longer important, and the measurement of a small volume is replaced by the easier task of measuring a slow flow rate (dV/dt). The analyte concentration is now calculable from the steady-state current I by the formula

$$[2] \qquad c^b = \frac{I}{nF(dV/dt)} = \frac{I}{nFf}$$

which may be obtained from eq. [1] by differentiation. Henceforth we shall use f, instead of dV/dt, to denote the constant flow rate. Equation [2] provides the basis of flowing coulometry. Note that, even though the measured electrical variable is now the *current*, the technique is appropriately named "flowing *coulo*metry" (4) because its principles are closer to those of classical coulometry than they are to standard amperometric methods. Flowing coulometry has been practiced for many years, a review (5) of the technique appearing as early as 1966.

In this article we describe experiments in which, driven by a gravitational head, a solution of an electroactive analyte flows through a narrow cylindrical metal tube, which serves to define the solution's flow rate. During its few seconds of residence time within the tube, effectively *all* the analyte is able to diffuse to the tube's inner wall, where it is oxidized or reduced. Because of the inherent slowness of diffusion, this rapid removal of a solute by electrolysis is possible only in the *micro*bore metal tubing that has recently become available commercially. Studies of electrochemical processes within platinum and gold tubes of considerably wider bores were pioneered by Blaedel and co-workers (6) a quarter of a century ago, and have continued in this area (7).

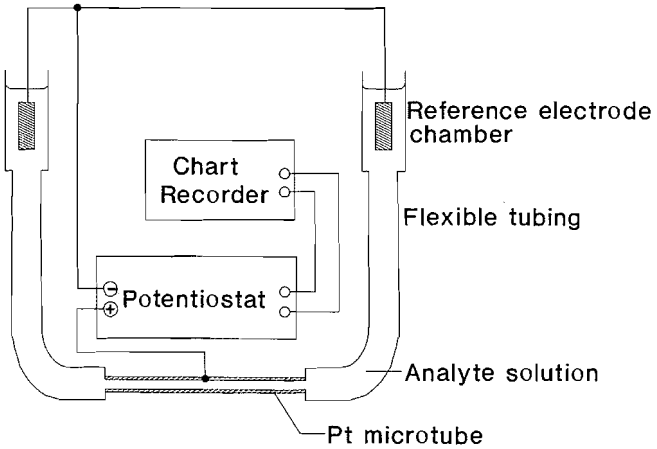

FIG. 1. Diagram showing the essential features of the microtube flowing coulometry apparatus.

A simplified diagram of our apparatus is shown in Fig. 1. Solution containing the analyte $[Fe(CN)_6]^{4-}$ (aq) is allowed to flow through a platinum microtube under an adjustable gravitational head. The tube functions as an anode and two commoned cathodes are mounted in the inlet and outlet chambers. With a suitable potential applied across the cell, the steady-state current is measured both with flow (I_f) and without (I_{nf}). The latter measurement is treated as a nonfaradaic "background", the difference $I_f - I_{nf}$ replacing I in eq. [2]. Accordingly, the analyte concentration can be calculated from

$$[3] \qquad c^b = \frac{I_f - I_{nf}}{nFf}$$

the flow rate f being measured in a separate experiment under identical conditions.

Theory

No-flow case

First, we address the question of how rapidly diffusion to the wall can remove an electroactive solute from the interior of a tube *in the absence of flow*. It is this process that governs the decay of the faradaic current in the non-flowing phase. In a cylindrical coordinate system, with r denoting radial distance from the tube's axis, diffusion is governed by Fick's second law in the form (8)

$$[4] \qquad \frac{\partial}{\partial t} c(r, t) = D\left(\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r}\right) c(r, t)$$

Here D is the diffusivity (diffusion coefficient) of the electroactive species and c is its concentration, which is a function of position r and time t. A solution to eq. [4] is sought subject to the condition that the concentration equals its original (bulk) value c^b initially:

$$[5] \qquad c(r, 0) = c^b$$

and the two boundary conditions

$$[6] \qquad c(R, t > 0) = 0$$

where R is the inner radius of the tube, and

$$[7] \qquad \frac{\partial c}{\partial r}(0, t) = 0$$

TABLE 1. The residual analyte fraction as a function of time. τ equals Dt/R^2 and ε is equal to $\exp(-5.78\tau)$

1	0.0021
2	7×10^{-6}
Large	$\varepsilon/1.446$
∞	0

Equation [7] is a consequence of the cylindrical symmetry, while eq. [6] applies if concentration polarization is total, i.e., if the potential applied to the tube is sufficiently large that the analyte is immediately destroyed on reaching the wall.

The solution to the mathematical problem posed by eqs. [4]–[7] is addressed in Appendix A. Our present interest is in the rate at which the number $N(t)$ of moles of solute within a cross section of the tube decreases with time. $N(t)$ has the mol m^{-1} unit and its initial value is $\pi c^b R^2$.

As discussed in the appendix, the amount remaining after time t is given by the equivalent expressions

$$[8] \qquad \frac{N(t)}{\pi c^b R^2} = \begin{cases} 1 - 4\sqrt{\dfrac{\tau}{\pi}} + \tau + \sqrt{\dfrac{\tau^3}{9\pi}} + \dfrac{\tau^2}{8} + \cdots \\ \dfrac{\exp(-5.783\tau)}{1.446} + \dfrac{\exp(-30.47\tau)}{7.618} + \cdots \end{cases}$$

where τ symbolizes Dt/R^2. This ratio is just the fraction of the original analyte that remains after time t. Table 1 lists some values of this quantity, calculated with the aid of one or other of the series in eq. [8], as a function of the dimensionless parameter Dt/R^2. Note that half the analyte has disappeared by the time 0.0630 R^2/D, and that 99% has been removed by 0.733 R^2/D. The latter characteristic time will be denoted t_{99}:

$$[9] \qquad t_{99} = 0.733\frac{R^2}{D} \approx (1.5 \times 10^9 \text{ s m}^{-2})R^2$$

The final expression in eq. [9] assumes a diffusivity of 5×10^{-10} m^2 s^{-1}, which is a typical value for the hexacyanoferrate(II) ion in a variety of aqueous solutions (9–12). Using the same value of D, Table 2 lists the 99%-removal times for tubes of various radii. Notice that, for a tube of 50 μm internal radius, as used in our experiments, depletion is predicted to be virtually complete in 4 s.

Electric current for the no-flow case

Here we address the question of the magnitude of the current

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

TABLE 2. Times required to remove 99% of an analyte ($D = 5 \times 10^{-10}$ m^2 s^{-1}) from a static solution by electrolysis at the wall of a cylindrical tube of radius R

R	t_{99}
10 μm	0.15 s
20 μm	0.6 s
50 μm	4 s

0.20 mm	1.0 min
0.50 mm	6 min
1.0 mm	24 min

that flows after a microtube, originally containing a solution with an electroactive analyte concentration c^b, is held at a potential sufficient to cause total concentration polarization at the inner surface of the tube. Let $I(t)$ denote this current at a time t after polarization and $Q(t)$ be the corresponding charge. The latter is related by Faraday's law to the total decrease in the amount of analyte:

$$[10] \qquad \int_0^t I(t)\,dt = Q(t) = nF[\pi c^b R^2 - N(t)]Z$$

where Z is the length of the tubular electrode. An expression for this quantity, namely

$$[11] \qquad \frac{Q(t)}{\pi nFc^bR^2Z} = \begin{cases} 4\sqrt{\dfrac{\tau}{\pi}} - \tau - \sqrt{\dfrac{\tau^3}{9\pi}} - \dfrac{\tau^2}{8} - \cdots \\ 1 - \dfrac{\exp(-5.783\tau)}{1.446} - \dfrac{\exp(-30.47\tau)}{7.618} \\ \qquad\qquad - \cdots \end{cases}$$

follows immediately from eqs. [8] and [10].

Differentiation of eq. [11] with respect to t produces the two equivalent expressions

$$[12] \qquad \frac{I(t)}{\pi nFc^bDZ} = \begin{cases} \dfrac{2}{\sqrt{\pi\tau}} - 1 - \sqrt{\dfrac{\tau}{4\pi}} - \dfrac{\tau}{4} - \dfrac{25}{48}\sqrt{\dfrac{\tau^3}{\pi}} \\ \qquad\qquad - \cdots \\ 4\exp(-5.783\tau) + 4\exp(-30.47\tau) \\ \qquad +4\exp(-74.89\tau) + \cdots \end{cases}$$

for the current where, as before, $\tau = Dt/R^2$. Table 3 lists values of the normalized $I(t)$ and $Q(t)$ calculated with the aid of the last two equations.

Flowing solution

When we turn to the case in which the solution flows through the tube, the general problem enters three dimensions with the introduction of an axial z direction. We choose a z axis such that $0 < z \leq Z$, $0 \leq r < R$ corresponds to space within the hollow cylindrical electrode occupied by solution, as illustrated in Fig. 2, whereas $z < 0$, $0 \leq r < R$ corresponds to undepleted solution in a coaxial entry tube that is a geometric continuation of the hollow electrode.

Let $v_z(r)$ be the velocity of flow in the z direction, being independent of z and t but a function r such that

$$[13] \qquad 2\pi \int_0^R r v_z(r)\,dr = f$$

TABLE 3. Normalized charge $Q(t)$ and its derivative $I(t)$ at selected values of the parameter τ, which equals Dt/R^2. ε is again equal to $\exp(-5.78\tau)$

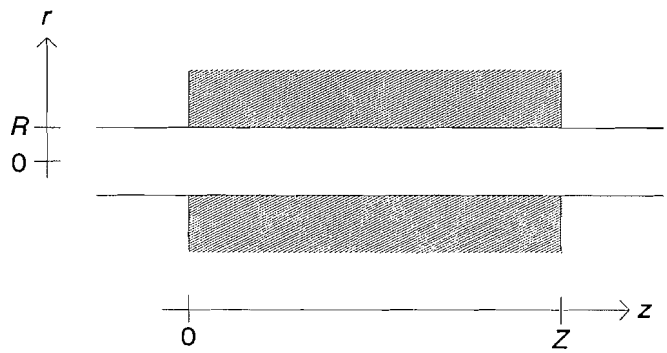

FIG. 2. Schematic diagram showing coordinate system of the microtube.

Then eq. [4] becomes modified to

$$[14] \qquad \frac{\partial}{\partial t}c(r, z, t) = D\left(\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{\partial^2}{\partial z^2}\right)c(r, z, t) - v_z(r)\frac{\partial}{\partial z}c(r, z, t)$$

by the introduction of terms representing diffusion and convection in the z dimension.

Because our interest is confined to the steady state, the left-hand term in eq. [14] may be set to zero. We also plan to ignore the $\partial^2 c/\partial z^2$ term. This is easily justified in the context of the parameters adopted in our experiments because the Z dimension of the tube exceeds the R dimension by a factor of 2000. Concentration gradients in the z dimension will therefore be minuscule in relation to $\partial c/\partial r$ values. With these simplifications eq. [14] may be rearranged to

$$[15] \qquad \frac{\partial}{\partial z}c(r, z) = \frac{D}{v_z(r)}\left(\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r}\right)c(r, z)$$

A solution to this differential equation must also obey the

For personal use only.

prevailing boundary conditions. Since fresh solution enters the electrode tube at $z = 0$ then

$$[16] \qquad c(r, 0) = c^{b}$$

If concentration polarization is total then

$$[17] \qquad c(R, z > 0) = 0$$

and due to the cylindrical symmetry of the tube

$$[18] \qquad \frac{\partial c}{\partial r}(0, z) = 0$$

The similarity of these three boundary conditions to those in eqs. [5]–[7] for the no-flow problem is evident.

Electric current in steady-state flow

The prime measurement in microtube flowing coulometry is the steady-state current I that flows after the dissipation of the transient behaviour, which occurs when the flow first starts. We need to be able to predict what this current should be for a tube of any dimensions R, Z and for any flow rate f. There are (at least) three possible approaches to the calculation of the current:

(*a*) From the flux of analyte at the walls of the tube, via the equation

$$[19] \qquad \frac{I}{nF} = 2\pi RD \int_0^Z \left[\frac{\partial}{\partial r} c(r, z)\right]_{r=R} \mathrm{d}z$$

This is the standard method used by electrochemists to calculate voltammetric currents.

(*b*) From the equation

$$[20] \qquad \frac{I}{nF} = -2\pi \int_0^Z \int_0^R r v_z(r) \frac{\partial}{\partial z} c(r, z)\, \mathrm{d}r\, \mathrm{d}z$$

which we derive by the following argument. Consider the element of solution between the planes z and $z + \mathrm{d}z$. Analyte enters this element at a rate (mol s^{-1}) given by

$$[21] \qquad 2\pi \int_0^R r v_z(r) c(r, z)\, \mathrm{d}r$$

and leaves at a rate given by a similar equation in which $c(r, z+\mathrm{d}z)$ replaces $c(r, z)$. The difference between these two rates, which again may be expressed analogously to eq. [21] but with $-(\partial/\partial z)c(r, z)\mathrm{d}z$ replacing $c(r, z)$, represents the rate at which analyte is lost by electrolysis at the wall segment of length $\mathrm{d}z$. Equation [20] then follows by z-integration.

(*c*) By ignoring the distribution of analyte in the body of the tube and employing the equation

$$[22] \qquad \frac{I}{nF} = c^{b} f - 2\pi \int_0^R r v_z(r) c(r, Z)\, \mathrm{d}r$$

The two right-hand terms are the rate of entry (mol s^{-1}) of analyte into the electrode tube across the $z = 0$ plane and its rate of exit across the $z = Z$ plane.

Though they appear very distinct, the three methods are equivalent. Nevertheless, from a computational viewpoint, one may be much easier to implement, in certain circumstances, than the others.

Uniform flow

In this section we assume that the solution flows uniformly down the tube, so that the flow velocity is independent of the radial position. In that event

$$[23] \qquad v_z(r) = v_z = \frac{f}{\pi R^2}$$

where f is the volume flow rate. The differential equation [15] then becomes

$$[24] \qquad \frac{\partial}{\partial z} c(r, z) = \frac{R^2}{K}\left(\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r}\right) c(r, z)$$

where K is a characteristic length equal to $f/\pi D$. Comparison with eq. [4] shows this problem to be strictly equivalent to the no-flow problem, the time dimension in the static case being replaced by the distance dimension z in the steady-state uniform-flow problem. Because z is measured from the inlet end of the tube, it is related to t in the no-flow case by the equivalence

$$[25] \qquad z = \frac{KD}{R^2} t = \frac{f}{\pi R^2} t$$

Hence, by analogy with expressions [8],

$$[26] \qquad \frac{N(z)}{\pi c^{b} R^2} = \begin{cases} 1 - 4\sqrt{\dfrac{\zeta}{\pi}} + \zeta + \sqrt{\dfrac{\zeta^3}{9\pi}} + \dfrac{\zeta^2}{8} + \cdots \\ \dfrac{\exp(-5.783\zeta)}{1.446} + \dfrac{\exp(-30.47\zeta)}{7.618} + \cdots \end{cases}$$

where $\zeta = z/K$ and is equivalent to τ. The significance of $N(z)$ remains as before: it is the total amount of the analyte in a cross section of the tube. It can be defined by

$$[27] \qquad N(z) = 2\pi \int_0^R r c(r, z)\mathrm{d}r$$

and has the mol m^{-1} unit.

To find the current, we shall adopt method (*b*) of the previous section. Because we are treating $v_z(r)$ as independent of r, the inner integral in eq. [20] becomes

$$[28] \qquad -2\pi v_z \int_0^R r \frac{\partial}{\partial z} c(r, z)\, \mathrm{d}r = -v_z \frac{\mathrm{d}}{\mathrm{d}z} N(z)$$

in light of definition [27]. Accordingly, making reference again to eq. [20], we find the simple expression

$$[29] \qquad \frac{I(Z)}{nF} = -v_z \int_{z=0}^{z=Z} \mathrm{d}N = v_z[\pi c^{b} R^2 - N(Z)] = f c^{b}\left[1 - \frac{N(Z)}{\pi c^{b} R^2}\right]$$

so that, when the expansions [26] are used, the result

$$[30] \qquad \frac{I(Z)}{nFfc^{b}} = \begin{cases} 4\sqrt{\dfrac{Z}{\pi K}} - \dfrac{Z}{K} - \sqrt{\dfrac{Z^3}{9\pi K^3}} - \dfrac{Z^2}{8K^2} - \cdots \\ 1 - \dfrac{\exp(-5.783Z/K)}{1.446} - \dfrac{\exp(-30.47Z/K)}{7.618} - \cdots \end{cases}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

emerges for the current. Notice, by comparison with eq. [11], that the *current* in the uniform-flow case is the analogue of the *charge* in the no-flow experiment.

The length of tube needed to capture 99% of the analyte is easily found by analogy with eq. [9], as

$$[31] \qquad Z_{99} = 0.733\,K \approx (5 \times 10^8\ \mathrm{s\ m^{-2}})f$$

if the flow is regarded as uniform. For example, the 10 cm length of the tube used in our experiments is predicted, according to this model, to capture at least 99% of the analyte provided that the uniform-flow rate does not exceed 2×10^{-10} m^3 s^{-1}, or 0.2 μL s^{-1}.

Complete solution for uniform flow

Another interpretation of the quantity $N(z)$ is that $N(z)/\pi R^2$ represents the average concentration

$$[32] \qquad c_{\mathrm{avg}}(z) = \frac{N(z)}{\pi R^2} = \frac{2}{R^2}\int_0^R rc(r, z)\,\mathrm{d}r$$

of the analyte at the plane $z = z$. As we have seen, this information is adequate to calculate the salient experiment parameter, the current. However, it is also of interest to determine how the concentration varies as a function of r.

To address this question, we return to eq. [24] and solve it, along with its attendant boundary conditions [16]–[18], by the method of "separation of variables." Details of the solution have been relegated to Appendix B and here we present only the final result:

$$[33] \qquad c(r, z) = 2c^{\mathrm{b}}\sum_{k=1}^{\infty}\frac{\mathrm{J}_0\left(\frac{j_{0,k}r}{R}\right)\exp\left(-\frac{j_{0,k}^2 z}{K}\right)}{j_{0,k}\mathrm{J}_1(j_{0,k})}$$

where $\mathrm{J}_0(\ )$ and $\mathrm{J}_1(\ )$ are Bessel functions and $j_{0,k}$ denotes the kth zero of J_0.

It is quite easy to demonstrate that, substituted into eq. [19], this complete solution leads via method (*a*) to the same current expressions as in eq. [30] by method (*b*). However, conclusions may be reached from eq. [33] that were inaccessible by route (*b*). For example, we can argue that when z is large enough, only the $k = 1$ term contributes significantly to the summation in eq. [33] and then the concentration profile in the tube is that of a zeroth-order Bessel function, namely:

$$[34] \qquad c(r, \text{large } z) = 1.602\,c^{\mathrm{b}}\mathrm{J}_0\left(\frac{2.405r}{R}\right)\exp\left(-\frac{5.783z}{K}\right)$$

This approximation is certainly valid at Z_{99}; in fact it is useful beyond about Z_{50}, the plane at which half the analyte has been removed.

Poiseuille flow

Though it has provided an easily tractable model, the assumption of uniform flow is not valid for a gravitational head, though it is applicable when electroosmosis provides the driving force. In the cylindrical tube of our experiments the flow profile is not flat with an r-independent axial velocity v_z; instead, once a streamlined flow regime is established, the local velocity is dependent parabolically on the radial coordinate

$$[35] \qquad v_z(r) = \frac{2(R^2 - r^2)}{\pi R^4}f$$

This means that the solution moves more slowly than average in the annular region $(R/\sqrt{2}) < r \leq R$ and faster than average in the central core $0 \leq r < (R/\sqrt{2})$. As a result, the concentration profiles become skewed compared with those in the uniform-flow case, and capture at the wall is less efficient.

When eq. [35] replaces eq. [23], the differential equation to be solved becomes

$$[36] \qquad \frac{\partial}{\partial z}c(r, z) = \frac{R^2}{2K(1 - r^2/R^2)}\left(\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r}\right)c(r, z)$$

instead of eq. [24]. The boundary conditions [16]–[18] remain unchanged. This set of equations may be solved by a procedure, described in Appendix C, which closely parallels that used in the uniform-flow problem. The solution, however, is much more complicated. It is

$$[37] \qquad c(r, z) = c^{\mathrm{b}}\sum_{k=1}^{\infty}A_k\mathrm{E}_k\left(\frac{r}{R}\right)\exp\left(-\frac{2(2\nu_k + 1)^2 z}{K}\right)$$

where $\mathrm{E}_k(\rho)$ denotes the Graetz function (ref. 13, p. 204), which we have defined by

$$[38] \qquad \mathrm{E}_k(\rho) = \mathrm{L}_{\nu_k}((4\nu_k + 2)\rho^2)\exp(-(2\nu_k + 1)\rho^2)$$

ν_k is the kth zero of the Graetz function which satisfies the equality $\mathrm{L}_{\nu_k}(4\nu_k + 2) = 0$, where $\mathrm{L}_{\nu_k}(\ )$ is the Laguerre function. The first four values of ν_k are listed in Appendix C. The coefficients A_k are given by the ratio of two integrals

$$[39] \qquad A_k = \frac{\int_0^1 \rho(1 - \rho^2)\mathrm{E}_k(\rho)\,\mathrm{d}\rho}{\int_0^1 \rho(1 - \rho^2)\mathrm{E}_k^2(\rho)\,\mathrm{d}\rho}$$

where ρ is used to denote the r/R ratio. Values of $A_1, \ldots, A_4$ are listed in Appendix C.

As with the uniform-flow problem, the exponential terms in eq. [37] ensure such rapid convergence for large Z that only the $k = 1$ summand is needed, so that

$$[40] \qquad c(r, \text{large } Z) = c^{\mathrm{b}}A_1\mathrm{E}_1\left(\frac{r}{R}\right)\exp\left(-\frac{2(2\nu_1 + 1)^2 Z}{K}\right)$$

We plan to use method (*c*) to calculate the current and, because our experimental interest is in using tubes long enough that almost all the analyte is captured, Z will be restricted to values large enough that eq. [40] is adequate. The current, then, is given by

$$[41] \qquad \frac{I(Z)}{nF} = c^{\mathrm{b}}f - 4c^{\mathrm{b}}f \times \exp\left(-\frac{2(2\nu_1 + 1)^2 Z}{K}\right)A_1\int_0^1 \rho(1 - \rho^2)\mathrm{E}_1(\rho)\,\mathrm{d}\rho$$

where use has been made of eqs [22], [35], and [40]. Notice that the integral in this equation is identical with the numeratorial integral in the $k = 1$ version of eq. [39]. If follows that

$$[42] \qquad \frac{I(Z)}{nFfc^{\mathrm{b}}} = 1 - 4\frac{\Lambda^2}{\Omega}\exp\left(-\frac{2(2\nu_1 + 1)^2 Z}{K}\right)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

where Λ and Ω are the definite integrals

$$[43] \qquad \Lambda = \int_0^1 \rho(1-\rho^2)E_1(\rho)\,d\rho = 0.1387$$

and

$$[44] \qquad \Omega = \int_0^1 \rho(1-\rho^2)E_1^2(\rho)\,d\rho = 0.09393$$

that we have evaluated numerically (ref. 14, Sect. A7) and found to have the values cited.

Finally, therefore, we can calculate the current under Poiseuille flow from the numerical equation

$$[45] \qquad \frac{I(Z)}{nFfc^b} = 1 - 0.8191 \exp\left(-\frac{3.657Z}{K}\right)$$

provided Z exceeds $0.14K$. If this is not the case, more than one exponential term must be included, the first two being

$$[46] \qquad \frac{I(Z)}{nFfc^b} = 1 - 0.8191 \exp\left(-\frac{3.657Z}{K}\right) - 0.09753 \exp\left(-\frac{22.30Z}{K}\right) - \cdots$$

Note the similarity of this result to the second alternative in eq. [30].

The length of tube needed to capture 99% of the analyte is easily found by making use of eq. [45]. 99% capture corresponds to only 1% of the analyte exiting the tube and thus the second right-hand terms in eqs. [41] and [45] must be equal to 0.01. These terms have this value at

$$[47] \qquad Z_{99} = 1.205K \approx (8 \times 10^8 \text{ s m}^{-2})f$$

To ensure that virtually all of the analyte will suffer electrolysis during its passage through the tube, and that eq. [2] will be valid, Z must be greater than Z_{99}. Notice the surprising result that expression [47] does not involve the tube radius.

As is evident in eqs. [31] and [47], the planar and Poiseuille flow regimes give different results for the calculation of Z_{99} or the flow rate. By assuming Poiseuille flow, the tube must be longer or the flow rate slower by a factor of 1.64 than that predicted by planar flow. Table 4 lists values of the parameter $\pi DZ/f$ needed to capture a certain percentage of the analyte for each flow profile. The ratio of this parameter for Poiseuille and planar flow decreases as the percentage captured increases.

Flow rate

Equation [47] may be interpreted as prescribing a maximum flow rate, which we may also regard as the optimal flow rate

$$[48] \qquad f_{opt} = \frac{\pi DZ_{99}}{1.205}$$

because it makes the most efficient use of the tube as an electrode. With the values $D = 5 \times 10^{-10}$ m^2 s^{-1} and $Z = 0.100$ m appropriate to our experiments, an optimal flow rate of 1.3×10^{-10} m^3 s^{-1} is predicted. Flow rates that are greater than this optimal value permit unelectrolyzed analyte to pass through the tube, while lower flow rates leave a portion of the wall area unused, with the consequential penalty of unnecessarily large ohmic polarizations and background currents.

TABLE 4. Values for the ratio $\pi DZ/f$ needed to capture a percentage of the analyte for both the planar and Poiseuille flows

Percent captured	$\left(\frac{\pi DZ}{f}\right)_{plr}$	$\left(\frac{\pi DZ}{f}\right)_{Poi}$	Ratio of Poiseuille to planar
50.0	0.0629	0.138	2.19
80.0	0.215	0.386	1.80
90.0	0.334	0.575	1.72
95.0	0.454	0.765	1.69
99.0	0.733	1.205	1.64
99.9	1.131	1.834	1.62
100	∞	∞	1.58

However, as the bulk concentration c^b increases, so does the current density and ohmic overvoltage. To counteract the lack of total concentration polarization may then require a flow rate slower than f_{opt}.

Poiseuille's law relates the flow rate by the equation

$$[49] \qquad f = \frac{\pi R^4 dgh}{8\eta Z}$$

to the gravitational head h that drives the solution through the tube. Here g is the acceleration (9.806 m s^{-2}) caused by gravity, while d and η are, respectively, the density and viscosity of the solution. Using values (997.1 kg m^{-3} and 8.904×10^{-4} kg m^{-1} s^{-1}) of d and η appropriate to pure water at 25°C, we calculate from eqs. [48] and [49] that the optimal head is

$$[50] \qquad h_{opt} = (6.05 \times 10^{-7} \text{ m s}) \frac{Z^2 D}{R^4}$$

for aqueous solutions whose density and viscosity are not significantly different from those of the solvent. Experimentally convenient tube lengths lie in the range 20–100 mm. Table 5, based on eq. [50], lists the optimal heads for this range of lengths and an analyte of diffusivity 5×10^{-10} m^2 s^{-1}. Notice that it is only for a tube of inner radius in the vicinity of 50 μm that an optimal gravitational head exists which is both practically attainable and accurately measurable. It was these considerations, as well as the cost and commercial availability of platinum microtube, that dictated our choice (100 mm length and 50 μm internal radius) of experimental tube dimensions. Of course, forces other than gravitational could be used to drive the solution through the tube, but gravity is simple and reliable.

Experimental

The microtube and other apparatus

A platinum microtube was supplied by Goodfellow (Cambridge, United Kingdom), with nominal dimensions of 100 mm length, 0.40 mm outside diameter, and 0.15 mm wall thickness. Flow rates of water through the tube were measured to be in excess of the predictions of Poiseuille's equation, possibly because the inner radius is larger than the nominal 50 μm. An 8% tolerance in the tube diameter would explain our findings.

To protect the fragile microtube, it was mounted within a stainless-steel support tube by means of Teflon ferrules. Detail of one end of the assembly is shown in Fig. 3; the other end is identical. After assembly, electrical contact to the microtube was achieved by placing small pieces of Wood's metal and a copper wire into a hole previously drilled through the wall of the stainless-steel tube; after heating with

TABLE 5. Optimal heads calculated for solutions flowing through tubes of the stated radii and lengths 20–100 mm

R	h_{opt}
10 μm	12–302 m
20 μm	0.76–19 m
50 μm	19–484 mm
0.10 mm	1.2–30 mm
0.20 mm	0.075–1.9 mm
0.50 mm	1.9–48 μm
1.0 mm	0.12–3.0 μm

a hot-air gun, the fusible metal formed a conducting bond between the copper wire and the two tubes. When not in use, the microtube was stored with its bore filled with distilled water.

The mounted microtube was positioned horizontally and connected by flexible Tygon tubing to two chambers. Each chamber was adapted from the plastic barrel of a graduated 1 cm^3 disposable hypodermic syringe, whereby accurate flow-rate measurements could be made. In the flowing coulometric studies, these chambers also accommodated the reference electrodes, which were constructed from porous silver foil, previously anodized to acquire a coating of AgCl or Ag_2SO_4.

The entire apparatus has total bilateral symmetry about the midplane of the microtube. To achieve flow, one of the reference chambers was raised an appropriate distance above the other, the head being accurately measured.

Solutions

The reaction chosen for study was the oxidation of the hexacyanoferrate(II) ion

$$[51] \qquad [Fe(CN)_6]^{4-}(aq) \rightarrow e^- + [Fe(CN)_6]^{3-}(aq)$$

in aqueous solution. An oxidation was chosen in preference to a reduction to avoid interference from, and the necessity to remove, dissolved oxygen. Solutions of known concentrations in the range 0.025–10.00 mM were prepared daily from weighted quantities of $K_4Fe(CN)_6 \cdot 3H_2O$ (BDH, Toronto) and stock solutions of supporting electrolyte.

Four different supporting electrolytes were employed: (*a*) 2.50 M KCl (BDH, Toronto); (*b*) 2.00 M KNO_3 (Baker, Phillipsburg, N.J.) plus 0.50 M KCl; (*c*) 1.80 M K_2SO_4 (BDH, Toronto); and (*d*) 1.00 M H_2SO_4 (Caledon, Georgetown). All reagents were analytical grade and were used as received. Similar results were obtained for all four solutions, with (*d*) giving a wider range of useful voltages (and therefore being used more often) than the other three, presumably because of its higher conductivity. However, the hexacyanoferrate(II) ion underwent a slow decomposition in the acidic medium (*d*), as evidenced by the buildup of a pale-blue colouration, so that fresh solutions needed to be prepared more frequently with this particular supporting electrolyte.

Solutions were not degassed, though this procedure might have eliminated the occasional anomalous behaviour that we attribute to bubble formation within the microtube. Experiments were performed at an ambient temperature of 23 ± 2°C.

Procedure

The levels in the two chambers were carefully adjusted to be equal and the system was left for a few minutes to reach a no-flow condition before any electrical signal was applied.

The simple electrical circuit is illustrated in Fig. 1. Because separate reference and counter electrodes would have been pointless, the potentiostat (Pine Instruments model RDE3) was operated in a two-electrode mode, generating a preset constant potential difference ΔE that was applied to the microtube with respect to the twin silver/silver salt electrodes. The separate currents flowing from the two reference electrodes were not monitored; instead the total current was measured and displayed as a function of time on an XY-chart recorder.

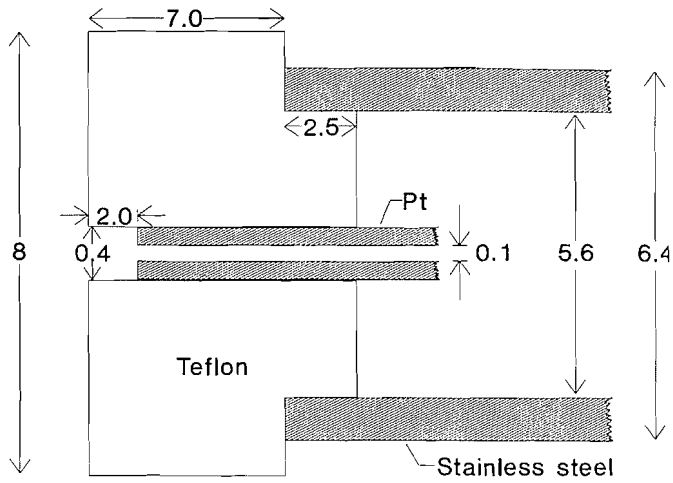

FIG. 3. Detail, not to scale, of one end of the microtube mount. All dimensions are in millimetres.

At every value of ΔE applied, the tube was "conditioned" before measuring the steady-state current under flow or no-flow conditions. This process, believed to involve the equilibration of the oxide layer, required the potential to be applied for some minutes to the tube filled with non-flowing analyte solution. After conditioning, the tube was flushed with fresh analyte solution, by gravitational flow, and the chambers returned to their original, levelled positions before commencing the experiment proper.

The current during the phase of the experiment with levelled chambers, initially very large, declined steeply and after several minutes acquired a constant no-flow value I_{nf}. This steady-state condition was allowed to persist for a further 60 s, to allow an accurate determination of I_{nf}.

One of the chambers was then raised to a predetermined level, so that flow suddenly commenced. As the exhausted solution within the tube was replaced by new analyte-containing solution, the current increased, but it eventually settled to a new constant value I_f, as a flowing steady-state regime became established in the tube. The I_f current was carefully measured from the chart record and the quantity $(I_f - I_{nf})/nFf$ was then evaluated; this, according to eq. [3], should be equal to the bulk analyte concentration.

Results and discussion

In our procedure, the I_{nf} current is measured under conditions of no-flow and after an interval so long that all the hexacyanoferrate(II) ion initially present has had ample time to reach the wall and be oxidized. This current therefore contains no component arising from reaction [51]; it is solely "background" current arising from imperfectly understood steady-state processes occurring at the platinum/solution interface. Because there is no change in applied potential between the measurement of the I_{nf} and I_f currents, it is believed that the background current remains virtually unchanged when flow is commenced. Therefore the subtraction $I_f - I_{nf}$ is designed to correct for the background. If the subtractive correction is efficient, then eq. [3] will hold subject to two provisos: that the applied voltage ΔE is large enough, and the flow rate small enough, to ensure complete depletion. Figure 4 shows a typical current-versus-time trace, in which the two measured currents are identified.

Using a solution of known composition and standard flow rate, a typical series of experiments consisted of repeating the procedure described above with a steadily increasing ΔE. Table 6 presents values of the quantity $(I_f - I_{nf})/nFf$ calculated for many experimental series, with $[Fe(CN)_6]^{4-}$ concentra-

[a]Each table entry represents the average of at least three replications. The relative standard deviation associated with each entry averages 1.2% and never exceeds 3.7%.

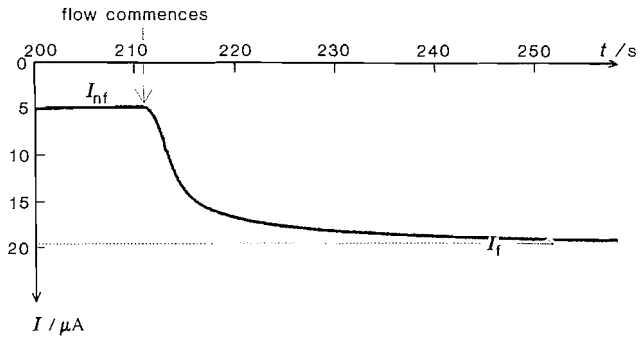

FIG. 4. Typical chart record, showing a no-flow current of 5 μA and a flow current of 19.5 μA. Experimental conditions: 2.00 mM $Fe(CN)_6^{4-}$ in 1.00 M H_2SO_4; ΔE = 1000 mV; f = 7.31 × 10^{-11} m^3 s^{-1}.

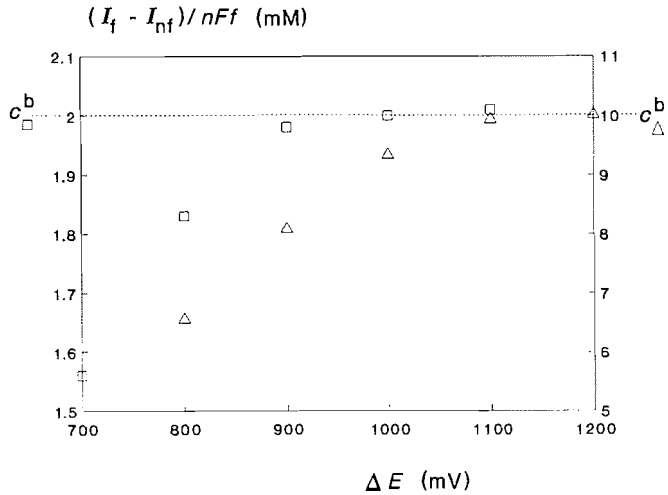

FIG. 5. Experimentally determined values of $(I_f - I_{nf})/nFf$ as a function of applied potential difference for a 2.00 mM (□) and a 10.00 mM (△) $[Fe(CN)_6]^4$ solution prepared in 1.00 M H_2SO_4, with flow rates of 7.31 × 10^{-11} and 3.54 × 10^{-11} m^3 s^{-1}, respectively.

tions ranging from 0.025 to 10.00 mM (in 1.00 M H_2SO_4) and solution flow rates ranging from 3.54 × 10^{-11} to 1.40 × 10^{-10} m^3 s^{-1}. The experimental series for the 2.00 mM and 10.00 mM table entries are illustrated in Fig. 5.

From the table it is evident that there was incomplete "capture" of the hexacyanoferrate(II) ion at applied potentials of less than 700 mV, regardless of bulk concentration or solution flow rate. At the lowest analyte concentrations, complete capture proved possible with a flow rate of 1.40 × 10^{-10} m^3 s^{-1} or less, which is in excellent agreement with the theoretical optimal flow rate of 1.3 × 10^{-10} m^3 s^{-1}. At higher concentrations, however, lower flow rates and (or) higher cell voltages were needed. We interpret this effect as arising from ohmic drop within the solution (15). Calculations that will be published elsewhere show that the currents flowing through the tube at the highest concentrations lead to *IR* products on the order of volts, effectively shutting off the central region of the tube. The tube acts as if it were shorter and, in consequence, slower flow rates are needed.

In Fig. 5, for example, applied potentials in the range of 900–1100 mV with a flow rate of 7.31 × 10^{-11} m^3 s^{-1} gave $(I_f - I_{nf})/nFf$ values within 1% of the true analyte concentration for a 2.00 mM $[Fe(CN)_6]^{4-}$ solution. However, for a solution five times more concentrated, a slower flow rate (3.54 × 10^{-11} m^3 s^{-1}) and higher potential range (1100–1200 mV) were required to obtain $(I_f - I_{nf})/nFf$ values within 1% of the true bulk concentration.

The principles upon which microtube flowing coulometry rest are simple and elegant. Once the microtube is mounted, the apparatus is uncomplicated and easy to use. The only measurements needed are of electric current and volume flow rate and, since these are made in the steady state, high accuracy is attainable. Though the detailed theory of the method is elaborate, the success of analysis by microtube flowing coulometry is independent of these theoretical details.

There are, however, a number of drawbacks to the technique. Sensitivity is limited by the background current, though we have made successful measurements down to the submillimolar level. The possibility of reducing background currents by using a gold microtube in experiments similar to those cited herein remains to be investigated. Studies have not been made with mixtures of electroactive species but, because of the need to apply extra voltage to overcome the considerable position-dependent ohmic polarization, it is unlikely that the method will display noteworthy selectivity. Yet another disadvantage is the need to work with solutions that confer high conductivity.

Appendix A

The initial condition [5] is incorporated when eq. [4] is Laplace transformed to the second-order differential equation

$$[A1] \qquad \frac{d^2\bar{c}}{dr^2} + \frac{1}{r}\frac{d\bar{c}}{dr} = \frac{s\bar{c}}{D} - \frac{c^b}{D}$$

of which the general solution (ref. 16, p. 339) is

$$[A2] \qquad \bar{c}(r, s) = \frac{c^b}{s} + A(s)I_0\left(r\sqrt{\frac{s}{D}}\right) + B(s)K_0\left(r\sqrt{\frac{s}{D}}\right)$$

where $I_0(\ )$ and $K_0(\ )$ are the zeroth-order instances of the hyperbolic Bessel and the Basset functions (ref. 14, Chaps. 49 and 51) respectively. Arbitrary functions of the Laplace variable s are represented by the coefficients $A(s)$ and $B(s)$; the forms adopted by these coefficients for the present problem may be deduced from the boundary conditions [6] and [7]. One finds $A(s) = -c^b/[sI_0(R\sqrt{s/D})]$ and $B(s) = 0$ and accordingly

$$[A3] \qquad \bar{c}(r, s) = \frac{c^b}{s}\left[1 - \frac{I_0\left(r\sqrt{\frac{s}{D}}\right)}{I_0\left(R\sqrt{\frac{s}{D}}\right)}\right]$$

The total amount of solute in a cross section of the tube is

$$[A4] \qquad N(t) = 2\pi\int_0^R rc(r, t)\,dr$$

and, by the integration (ref. 14, formula 49:10:7) of expression [A3] with respect to r, the transform of this quantity is found to be

$$[A5] \qquad \bar{N}(s) = 2\pi\int_0^R r\bar{c}(r, s)\,dr = \frac{\pi c^b R^4}{D}\left[\frac{1}{\sigma} - \frac{2I_1(\sqrt{\sigma})}{\sqrt{\sigma^3}\,I_0(\sqrt{\sigma})}\right]$$

where σ is used as an abbreviation for R^2s/D and $I_1(\ )$ denotes the first-order hyperbolic Bessel function (ref. 14, Chap. 49).

Though equation [A5] cannot be inverted to a closed algebraic form, expansions are possible that permit two expressions for $N(t)$ to be found, at least one of which is valid at any instant. By using asymptotic expansions (ref. 14, formulas 49:6:4 and 49:6:5) of the hyperbolic Bessel functions in eq. [A5], and performing a synthetic division, one finds

$$[A6] \qquad \frac{D\bar{N}(s)}{\pi c^b R^4} = \frac{1}{\sigma} - \frac{2}{\sqrt{\sigma^3}} + \frac{1}{\sigma^2} + \frac{1}{4\sqrt{\sigma^5}} + \frac{1}{4\sigma^3} + \frac{25}{64\sqrt{\sigma^7}} + \cdots$$

which inverts to

$$[A7] \qquad \frac{N(t)}{\pi c^b R^2} = 1 - 4\sqrt{\frac{\tau}{\pi}} + \tau + \sqrt{\frac{\tau^3}{9\pi}} + \frac{\tau^2}{8} + \frac{5}{24}\sqrt{\frac{\tau^5}{\pi}} + \cdots$$

where $\tau = Dt/R^2$. Because the series on which it is based are only asymptotically convergent, eq. [A7] is strictly valid only in the $t \longrightarrow 0$ limit; nonetheless, it may be used to generate accurate numerical values provided that t is not too large.

Alternatively, one may exploit an infinite product expansion of the zeroth-order hyperbolic Bessel function by writing

$$[A8] \qquad \frac{I_1(\sqrt{\sigma})}{2\sqrt{\sigma}I_0(\sqrt{\sigma})} = \frac{d[\ln I_0(\sqrt{\sigma})]}{d\sigma} = \left(\frac{d}{d\sigma}\right) \ln \prod_{k=1}^{\infty} \left[1 + \frac{\sigma}{j_{0,k}^2}\right]$$

Here $j_{0,k}$ denotes the kth zero of the zeroth-order Bessel function (ref. 14, Sect. 52:9), of which the first few values are $j_{0,1} = 2.4048$, $j_{0,2} = 5.5201$, $j_{0,3} = 8.6537$, $j_{0,4} = 11.7915$. Thereby, eq. [A5] can be converted to

$$[A9] \qquad \frac{D\bar{N}(s)}{\pi c^b R^4} = \left(\frac{1}{\sigma}\right)\left[1 - \sum_{k=1}^{\infty} \frac{4}{\sigma + j_{0,k}^2}\right] = \sum_{k=1}^{\infty} \frac{4}{j_{0,k}^2(\sigma + j_{0,k}^2)}$$

in which the second equality holds because $\Sigma(1/j_{0,k}^2) = 1/4$. Inversion to

$$[A10] \qquad \frac{N(t)}{\pi c^b R^2} = 4\sum_{k=1}^{\infty} \frac{\exp(-j_{0,k}^2\tau)}{j_{0,k}^2}$$

is now readily achieved. Except when τ is very small, this series converges very rapidly. In fact, one term is often adequate.

Equations [A7] and [A10] lead directly to eq. [8] of the main text.

Appendix B

Define $\rho = r/R$ and $\zeta = z/K$, so that eq. [24] becomes

$$[B1] \qquad \frac{\partial}{\partial\zeta} c(\rho, \zeta) = \left(\frac{\partial^2}{\partial\rho^2} + \frac{1}{\rho}\frac{\partial}{\partial\rho}\right) c(\rho, \zeta)$$

and the boundary conditions [16]–[18] become

$$[B2] \qquad c(\rho, 0) = c^b$$

$$[B3] \qquad c(1, \zeta) = 0$$

and

$$[B4] \qquad \frac{\partial c}{\partial\rho}(0, \zeta) = 0$$

A solution of the form

$$[B5] \qquad c(\rho, \zeta) = c^b \sum_{k=1}^{\infty} A_k G_k(\rho) H_k(\zeta)$$

is assumed where each unknown function $G_k(\rho)$ is independent of ζ and is defined such that

$$[B6] \qquad G_k(0) = 1$$

and similarly each $H_k(\zeta)$ function is independent of ρ and satisfies

$$[B7] \qquad H_k(0) = 1$$

If [B5] satisfies [B1], then so does any constant multiplied by each summand. Hence $G_k(\rho)H_k(\zeta)$ satisfies [B1] and when this is substituted for $c(\rho, \zeta)$ one finds

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

$$[B8] \quad \frac{1}{H_k(\zeta)}\frac{d}{d\zeta}H_k(\zeta) = \frac{1}{G_k(\rho)}\left[\frac{d^2}{d\rho^2} + \frac{1}{\rho}\frac{d}{d\rho}\right]G_k(\rho) = -\lambda_k^2$$

The third equality stems from the fact that since the left-hand side is independent of ρ and the right-hand side is independent of ζ, they must each equal the same constant, $-\lambda_k^2$. Thus

$$[B9] \quad \frac{d}{d\zeta}H_k(\zeta) = -\lambda_k^2 H_k(\zeta)$$

so that

$$[B10] \quad H_k(\zeta) = (\text{const})\exp(-\lambda_k^2\zeta)$$

but, because of [*B*7], the constant must be unity. Therefore

$$[B11] \quad H_k(\zeta) = \exp(-\lambda_k^2\zeta)$$

The right-hand side of [*B*8] leads to

$$[B12] \quad \frac{d^2G_k(\rho)}{d\rho^2} + \frac{1}{\rho}\frac{dG_k(\rho)}{d\rho} + \lambda_k^2 G_k(\rho) = 0$$

which is an example of Bessel's equation (ref. 16, p. 338) whose solution is of the form

$$[B13] \quad G_k(\rho) = UJ_0(\lambda_k\rho) + VY_0(\lambda_k\rho)$$

where $J_0(\ )$ and $Y_0(\ )$ are zeroth-order Bessel and Neumann functions and U and V are constants. However, because $J_0(0) = 1$ and $Y_0(0) = \infty$, we must choose $U = 1$ and $V = 0$ to satisfy [*B*6]. Hence:

$$[B14] \quad G_k(\rho)H_k(\zeta) = J_0(\lambda_k\rho)\exp(-\lambda_k^2\zeta)$$

To satisfy boundary condition [*B*3]

$$[B15] \quad J_0(\lambda_k)\exp(-\lambda_k^2\zeta) = 0$$

requires that λ_k be one of the zeros of the zeroth-order Bessel function. If λ_k is the kth zero then $\lambda_1 = j_{0,1}$, $\lambda_2 = j_{0,2}$, etc. as given in Appendix A.

G_k and H_k are now identified but A_k must still be found. Substitution of condition [*B*2] into [*B*5] gives

$$[B16] \quad 1 = \sum_{k=1}^{\infty} A_k G_k(\rho) = \sum_{k=1}^{\infty} A_k J_0(j_{0,k}\rho)$$

Multiplying each side of [*B*16] by $\rho J_0(j_{0,K}\rho)$ where $j_{0,K}$ is one particular value of the $j_{0,k}$'s and integrating from 0 to 1 gives

$$[B17] \quad \int_0^1 \rho J_0(j_{0,K}\rho)\,d\rho = \sum_{k=1}^{\infty} A_k \int_0^1 \rho J_0(j_{0,K}\rho)J_0(j_{0,k}\rho)d\rho$$

Due to the orthogonality of Bessel functions (ref. 14, Sect. 52:14) the right-hand integral is zero except when $k = K$, in which case we have

$$[B18] \quad \int_0^1 \rho J_0^2(j_{0,K}\rho)d\rho = \frac{1}{2}J_1^2(j_{0,K})$$

Moreover the left-hand integral evaluates to $[J_1(j_{0,K})]/j_{0,K}$. Therefore

$$[B19] \quad A_K = \frac{2}{j_{0,K}J_1(j_{0,K})}$$

which gives values of $A_1 = 1.602$, $A_2 = -1.065$, $A_3 = 0.851$, etc. The final expression for the concentration is thus

$$[B20] \quad c(\rho, \zeta) = 2c^b \sum_{k=1}^{\infty} \frac{J_0(j_{0,k}\rho)\exp(-j_{0,k}^2\zeta)}{j_{0,k}J_1(j_{0,k})}$$

Appendix C

Following a procedure that parallels that in Appendix B, a solution identical in form to [*B*5] is assumed to be a solution to the Poiseuille flow problem governed by the differential equation

$$[C1] \qquad \frac{\partial}{\partial\zeta}c(\rho,\zeta)=\frac{1}{2(1-\rho^2)}\left(\frac{\partial^2}{\partial\rho^2}+\frac{1}{\rho}\frac{\partial}{\partial\rho}\right)c(\rho,\zeta)$$

After the variables are separated, the dual equations are

$$[C2] \qquad \frac{2}{H_k(\zeta)}\frac{d}{d\zeta}H_k(\zeta)=\frac{1}{(1-\rho^2)G_k(\rho)}\left[\frac{d^2}{d\rho^2}+\frac{1}{\rho}\frac{d}{d\rho}\right]G_k(\rho)$$

This time it is more convenient to let the separation constant be $-(4\nu_k+2)^2$, rather than $-\lambda_k^2$. The ζ-dependent function is found to be

$$[C3] \qquad H_k(\zeta)=\exp(-2(2\nu_k+1)^2\zeta)$$

while the ρ-dependent function must satisfy the differential equation

$$[C4] \qquad \frac{d^2G_k(\rho)}{d\rho^2}+\frac{1}{\rho}\frac{dG_k(\rho)}{d\rho}+(4\nu_k+2)^2(1-\rho^2)G_k(\rho)=0$$

A change of independent variable from ρ to $\Upsilon=(4\nu_k+2)\rho^2$ and of dependent variable from $G_k(\rho)$ to $S_k(\Upsilon)=G_k(\rho)\exp(\Upsilon/2)$ converts [*C*4] into

$$[C5] \qquad \Upsilon\frac{d^2S_k(\Upsilon)}{d\Upsilon^2}+(1-\Upsilon)\frac{dS_k(\Upsilon)}{d\Upsilon}+\nu_kS_k(\Upsilon)=0$$

which is a form of Laguerre's equation (ref. 16, p. 330).

Equation [*C*5] is solved by the Laguerre function (ref. 14, Sect. 23:14) of degree ν_k and we therefore postulate that the appropriate solution to [*C*5] is

$$[C6] \qquad S_k(\Upsilon)=(\text{constant})\,L_{\nu_k}(\Upsilon)$$

or equivalently

$$[C7] \qquad G_k(\rho)=(\text{constant})\exp(-(2\nu_k+1)\rho^2)L_{\nu_k}((4\nu_k+2)\rho^2)$$

Because Laguerre functions of zero argument equal unity, the "constant" must itself be unity in order that condition [*B*6] be satisfied.

Therefore, putting the two functions together

$$[C8] \qquad G_k(\rho)H_k(\zeta)=L_{\nu_k}((4\nu_k+2)\rho^2)\exp(-(2\nu_k+1)\rho^2-2(2\nu_k+1)^2\zeta)$$

Boundary condition [*B*3] demands that

$$[C9] \qquad 0=L_{\nu_k}(4\nu_k+2)\exp(-(2\nu_k+1)-2(2\nu_k+1)^2\zeta)$$

Since ζ is a variable, this condition can only be met by certain specific values of ν_k for which $L_{\nu_k}(4\nu_k+2)=0$. The first such zero occurs close to 0.1761; the second, third, and fourth are $\nu_2\approx 1.1698$, $\nu_3\approx 2.1683$, and $\nu_4\approx 3.1678$, etc. As k increases the values approach $\nu_k=k-5/6$. Accurate values of these special orders are not available in the literature and $\nu_1, \nu_2, \ldots \nu_{20}$ were therefore calculated from the hypergeometric representation of the Laguerre function (ref. 14, Sect. 18:14). These values agree with less precise results published elsewhere (17, 18, 13).

G_k and H_k are now identified and again it only remains to find the A_k's. The first equality in [*B*16] holds so that

$$[C10] \qquad 1=\sum_{k=1}^{\infty}A_kL_{\nu_k}((4\nu_k+2)\rho^2)\exp(-(2\nu_k+1)\rho^2)$$

$$=\sum_{k=1}^{\infty}A_kE_k(\rho)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

where we use $E_k(\rho)$ as a convenient abbreviation. The orthogonality procedure may again be used. The $E_k(\rho)$ functions are mutually orthogonal on the interval 0 to 1 with a weighting factor of $\rho(1-\rho^2)$ (ref. 13, p. 200). Therefore, on multiplying both sides of [C10] by $\rho(1-\rho^2)E_K(\rho)$ one obtains

$$[C11] \quad \int_0^1 \rho(1-\rho^2)E_K(\rho)\,d\rho = \sum_{k=1}^{\infty} A_k \int_0^1 \rho(1-\rho^2)E_K(\rho)E_k(\rho)\,d\rho$$

$$= A_K \int_0^1 \rho(1-\rho^2)E_K^2(\rho)\,d\rho$$

after integration. The left-hand integral has been found to evaluate to

$$[C12] \quad \int_0^1 \rho(1-\rho^2)E_K(\rho)\,d\rho = \frac{2\nu_K L_{\nu_K-1}(4\nu_K+2)\exp(-\lambda_K/2)}{4\nu_K+2}$$

but since the right-hand integral has to be evaluated numerically, both integrals were so evaluated and gave for the first four values of A_k: $A_1 = 1.476$, $A_2 = -0.8061$, $A_3 = 0.5888$, and $A_4 = -0.4759$.

Appendix D: glossary of symbols

A_k	summation constant
$A(s)$, $B(s)$	arbitrary functions of the Laplace variable (mol m^{-3} s)
c	local analyte concentration (mol m^{-3})
c^b	original (bulk) analyte concentration (mol m^{-3})
$c_{avg}(z)$	average concentration at the plane $z = z$ (mol m^{-3})
d	density of solution (kg m^{-3})
D	analyte diffusivity (m^2 s^{-1})
$E_k(\rho)$	the kth Graetz function
F	Faraday's constant (96485 C mol^{-1})
f	flow rate (m^3 s^{-1})
f_{opt}	optimal flow rate (m^3 s^{-1})
$G_k(\rho)$	kth undimensionalized function of the radial coordinate
g	gravitational acceleration (m s^{-2})
$H_k(\zeta)$	kth undimensionalized function of the axial coordinate
h	hydrostatic head (m)
h_{opt}	optimal hydrostatic head (m)
I	electric current (A)
I_{nf}, I_f	experimental steady-state no-flow and flow currents (A)
$I_0(\ )$, $I_1(\ )$	hyperbolic Bessel functions of zeroth, first order
$J_0(\ )$, $J_1(\ )$	Bessel functions of zeroth, first order
$j_{0,k}$	kth zero of the zeroth-order Bessel function
$K_0(\ )$	zeroth-order Basset function
K	characteristic length equal to $f/\pi D$ (m)
k	summation or product index
$L_{\nu_k}(\ )$	Laguerre function of degree ν_k
$N(t)$	amount of analyte in a cross section of the tube at time t (mol m^{-1})
$N(z)$	amount of analyte in a cross section of the tube at position z (mol m^{-1})
n	number of electrons involved in the electrode reaction
Q	total charge (C)
R	inner radius of microtube (m)
r	radial coordinate (m)
$S_k(\rho)$	kth undimensionalized function of the radial coordinate
s	Laplace variable (s^{-1})
t	time (s)
t_{99}	time at which 99% of the analyte has been consumed (s)
U, V	arbitrary constants of integration
V	sample volume (m^3)
$v_z(r)$	flow velocity (m s^{-1})
$Y_0(\ )$	zeroth-order Neumann function
Z	tube length (m)
Z_{99}, Z_{50}	tube lengths needed to consume 99% or 50% of the analyte (m)
z	axial coordinate (m)
ΔE	applied potential difference (V)

Multiple potential surfaces and movable energy barriers in the chemiluminescent reaction Mn + $SnCl_4$

DALE L. HERBERTSON,[1] DAVID A. NEWNHAM,[2] AND MARTIN R. LEVY[3]

Department of Chemical and Life Sciences, University of Northumbria at Newcastle, Ellison Building, Ellison Place, Newcastle upon Tyne NE1 8ST, U.K.

Received July 5, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

DALE L. HERBERTSON, DAVID A. NEWNHAM, and MARTIN R. LEVY. Can. J. Chem. **72**, 850 (1994).

A laser-ablated pulsed beam of Mn atoms, in various long-lived states, has been employed to determine excitation functions for the reactions Mn + $SnCl_4$ → MnCl* ("blue," "green," "red") + $SnCl_3$. The data all show a sharp rise at low energies, followed by an equally rapid fall, but they differ in the initial thresholds and the rate at which $\sigma(E_T)$ approaches zero. Analysis in terms of a multiple line-of-centres model (Levy, Res. Chem. Kinet. **1**, 163 (1993)) indicates that each excitation function is unique, and is due to reaction of only one Mn reagent state — most probably the first metastable state, a^6D_J. This suggests a strong symmetry control in the entrance channel of the reaction, at least; that is, the Mn atom approaches along the C_3 axis of $SnCl_4$, so that the symmetry corresponding to the spatial configuration of the odd *d* electron is retained. In two cases, "blue" and "red," if not all, the luminescing MnCl* state seems to be produced on a surface that does not directly correlate with the reagents. As collision energy increases in each case, the reaction transition state seems to shift *forward* into the entrance valley, a result attributed to restricted access to the exit valley.

DALE L. HERBERTSON, DAVID A. NEWNHAM et MARTIN R. LEVY. Can. J. Chem. **72**, 850 (1994).

On a utilisé un faisceau pulsé d'atomes de Mn, obtenus par ablation au laser et présents dans divers états de longue durée, pour déterminer les fonctions d'excitation de la réaction Mn + $SnCl_4$ → MnCl* («bleu», «vert» ou «rouge») + $SnCl_3$. Les données indiquent toutes une augmentation importante des basses énergies suivie par une baisse aussi rapide; elles diffèrent toutefois par leurs seuils initiaux et par la vitesse à laquelle $\sigma(E_T)$ approche de zéro. Une analyse en fonction du modèle à plusieurs raies centrales (Levy, Res. Chem. Kinet. **1**, 163 (1993)) indique que chaque fonction d'excitation est unique et qu'elle est causée par la réaction d'un seul état réactif du Mn, probablement le premier état métastable, a^6D_J. Ceci suggère la présence d'un contrôle important par la symétrie dans le canal d'entrée de le réaction, au moins que l'atome de Mn approche par l'axe C_3 du $SnCl_4$, de façon à ce que la symétrie correspondant à la configuration spaciale de l'électron *d* célibataire est maintenue. Dans au moins deux cas, «bleu» et «rouge», l'état MnCl* luminescent semble être produit sur une surface qui n'est pas en corrélation directe avec les réactifs. Lorsque l'énergie de collision augmente dans chaque cas, l'état de transition de la réaction semble se déplacer vers *l'avant*, dans la vallée d'entrée; ce résultat est attribué à un accès limité à la vallée de sortie.

[Traduit par la rédaction]

Introduction

Among the many contributions of John Polanyi to reaction dynamics, a classic series of papers (1–8) deals with the consequences of different energy barrier locations. By performing trajectory calculations on model thermoneutral surfaces, he and his colleagues have shown that the position of the *crest* of the barrier plays a significant role. Thus, if the crest lies in the entrance valley ("surface I"), translational energy in excess of the barrier leads to reaction, while vibration does not, whereas the opposite holds if the crest is in the exit valley ("surface II"). This behaviour is readily understood in terms of the motion of a sliding mass along the reaction coordinate: for surface I, linear momentum along the approach direction R_{AB} is needed to overcome the barrier, while, for surface II, momentum along the product distance R_{BC} (i.e., reagent vibration) helps the system to turn the corner and to surmount the barrier. However, for a given basic surface, the results are modified to a certain extent by mass effects: thus the combination **L** + **HH** (**L** = light atom, **H** = heavy atom) effectively skews and scales the surface so that the barrier shifts to a later position, accentuating the behaviour on I while moderating that on II, whereas **H** + **HL** shows the opposite behaviour since the barrier is effectively shifted further forward.

Calculations on exothermic reactions (with much lower barriers) show that both excess translation and vibration enhance reaction, but the translation is much more effective (9). On the other hand, endothermic reactions (with higher barriers) are predicted generally to require vibrational excitation (10) (this would be expected from microscopic reversibility if the corresponding exothermic reaction disposed its energy into vibration). It has been concluded (10) that substantially exothermic reactions have the crest of the barrier along R_{AB}, while substantially endothermic reactions have the crest along R_{BC}.

Later papers of the series (6–8) have nonetheless shown that substantially endothermic reactions do require a minimum reagent translational energy in addition to the vibrational energy. This lower limit corresponds to the magnitude of the repulsive energy release in the reverse, exothermic direction, and therefore provides a measure of the energy required to overcome that part of the barrier that lies along the endothermic coordinate of approach. This result has been confirmed by calculations on surfaces with "sudden" and "gradual" rises to the crest. The greater availability of translational energy for barrier crossing on gradual surfaces seems to correlate not only with a greater fraction of the barrier along the endothermic coordinate of approach, but also with a more gradual curvature of the repulsive wall of the potential at short internuclear distances.

While a number of experimental studies, e.g., K + HCl, HF (v = 0,1) (11) and Ba + N_2O (n_2 = 0,1) (12–14) have addressed

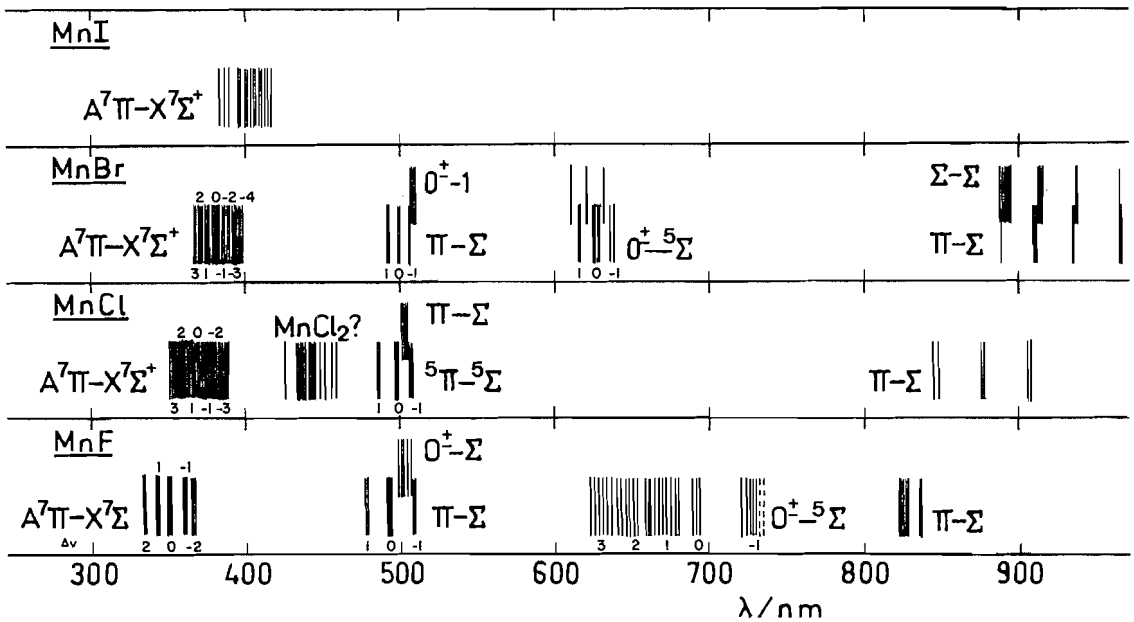

FIG. 1. Schematic representation of the known electronic spectroscopy of the Mn monohalides (28–31). The bands marked $MnCl_2$? have been reported only once, by Mesnage in 1930 (29), and he suggested that they might not be due to MnCl. The possible attribution to $MnCl_2$ is due to Pearse and Gaydon (31).

the relative role of translational and vibrational energy in promoting reaction, the foregoing conclusions about the disposition of barrier crests on substantially exothermic and endothermic potential surfaces do not seem to have received any critical examination. In particular, while the conclusions may well be appropriate for single potential surfaces, it is not clear that they can apply when multiple surfaces interact, for example, in reactions that are substantially exothermic to ground state products but endothermic to formation of electronically excited species. Likewise, relatively little attention has been given to determining either the position of the barrier crest relative to the repulsive wall, or the degree of curvature in the threshold region. However, following a recent survey and reinterpretation, by one of us (15), of a large number of translational excitation functions for chemical reactions, it is becoming clear that such information is already available, albeit in somewhat crude form. In addition, there appears to be a whole class of reactions for which the position of the barrier crest effectively sampled by trajectories is not fixed, but shifts *forward* into the entrance valley as collision energy increases. The present paper shows how the chemiluminescent reactions of Mn atoms with $SnCl_4$ fall into the latter category.

Over the past years, considerable effort at this laboratory has been directed towards the investigation of chemiluminescent reactions of Mn atoms in various long-lived states. Laser ablation of a solid metal target has been employed to generate a pulsed beam of Mn atoms, and thereby to measure the collision energy dependences of the following processes:

$$Mn + N_2O, O_2, NO_2, CO_2, SO_2 \rightarrow MnO^*(A^6\Sigma^+)$$

(refs. 16, 17)

$$Mn + D_2 \rightarrow MnD^*(d^5\Pi) \text{ (ref. 18)}$$

$$Mn + CH_4, C_2H_2, C_2H_4, C_2H_6, C_3H_6, 1\text{-}C_4H_8,$$
$$1\text{-}C_4H_{10}, c\text{-}C_5H_{12} \rightarrow MnH^*(A^7\Pi, d^5\Pi) \text{ (ref. 19)}$$

In all these cases, analysis of the excitation functions in terms of microcanonical transition state theory (MTST) (20) indicates that chemiluminescence derives from only a very small number of metal atom states, most commonly the first excited state, a^6D_J, although ground-state a^6S atoms appear to responsible in $Mn + N_2O$ (16), while very highly excited states seem to be the active species with D_2 and the smallest hydrocarbons.

The extension of such studies to reactions with halogen-containing molecules is a logical next step. By analogy with alkali (21–26) and alkaline earth (27) atom reactions, $Mn + SnCl_4$ would appear to be a useful starting point for such investigations. However, two problems arise: firstly, many of the manganese monohalide bands are not well characterized, and, secondly, the exoergicity of the fully ground state reaction

$$[1] \quad Mn + SnCl_4 \rightarrow MnCl + SnCl_3$$

is not known, as the $SnCl_3$—Cl bond strength has not been determined.

Figure 1 shows schematically the state of published Mn monohalide electronic spectroscopy, which dates from the 1960s at the latest (28–31). Several band systems are known for each molecule, from the ultraviolet to the infrared, although some seem to be absent or even questionable. By comparison with MnH (32–34), septuplet and several quintet band systems are to be anticipated but, of those shown in the figure, only the UV system has been definitely assigned, as $A^7\Pi \rightarrow X^7\Sigma^+$ (a far UV system not shown on the figure, and designated $B^7\Sigma^+ \rightarrow X^7\Sigma^+$, has also been detected for MnF and MnCl). For the rest, analysis of the vibrational (and in some cases rotational) structure has allowed a number of vibrational constants, ν_{00} values (Table 1) and probable term symbols of the participating state pairs to be deduced, but neither the exact identify of the *lower* state of the transition, nor its excitation energy, is known. If, however, these band systems can be detected from the reaction $Mn + SnCl_4$, and the translational thresholds determined, then upper limits can be placed on the excitations, providing the Mn

TABLE 2. Gaseous enthalpies of formation (kJ mol^{-1}) at 298 K (37) (A = Si, Ge, Sn, Cl)

Element	ACl_4	ACl_3	ACl_2	A
Si	−664.8	−393.1	−168.6	+450.0
Ge	−495.8	−320.8	−171.0	+374.0
Sn	−471.5	?	−197.9	+301.5
Cl	—	—	—	+121.9

reagent states and the ground-state reaction exothermicity are known.

In the previous work on K, Rb, Cs + $SnCl_4$, Wilson, Riley and Herschbach (21, 22) assumed an $SnCl_3$—Cl bond energy of ~315 kJ mol^{-1}, i.e, one quarter of the enthalpy of atomization of $SnCl_4$ (35). By contrast, Behrens et al. (26), in studying the Li reaction, used the significantly lower value of ~230 kJ mol^{-1}, recommended by Oldershaw and Robinson (36) following flash photolysis studies of $SnCl_4$ decomposition. For the present purposes, this disagreement is simply too broad. However, a new (and arguably more reliable) estimate of the $SnCl_3$—Cl bond energy can be obtained by considering the enthalpy changes for the processes

[2] $ACl_4(g) \rightarrow ACl_3(g) + Cl(g)$

[3] $\frac{1}{2}ACl_4(g) \rightarrow \frac{1}{2}ACl_2(g) + Cl(g)$

[4] $\frac{1}{4}ACl_4(g) \rightarrow \frac{1}{4}A(g) + Cl(g)$

where A = Si, Ge, or Sn. Enthalpies of formation (at 298 K) have now been obtained (37) for all the relevant species except $SnCl_3$, and are listed in Table 2, while Fig. 2 shows the result of plotting the data for reactions [2] and [3] against those for reaction [4]. It can be seen that, as the central atom gets heavier, not only do the enthalpy changes for eqs. [2]–[4] decrease, but the gap between the values for eqs. [2] and [3] also falls. Extrapolation of the ΔH_2 data suggests a value for Sn ~263 kJ mol^{-1}, i.e., very close to that for ΔH_3, and, with one proviso that will be discussed below, this can be taken as the effective $SnCl_3$—Cl bond energy. The extrapolation is crude, but it seems unlikely from the trends that the missing ΔH_2 value should be any more than 5 kJ mol^{-1} higher than this. In fact, in deriving their value

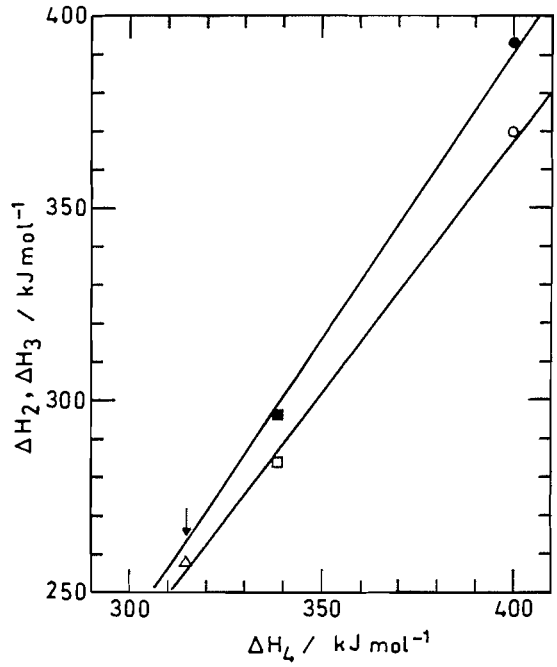

FIG. 2. Estimate of $D(SnCl_3$—Cl) by plotting enthalpy changes for reaction (2), $ACl_4 \rightarrow ACl_3$ + Cl (solid symbols), and reaction [3], $\frac{1}{2}ACl_4 \rightarrow \frac{1}{2}ACl_2$ + Cl (hollow symbols), against reaction [4], $\frac{1}{4}ACl_4 \rightarrow \frac{1}{4}A$ + Cl, for A = Si(●, ○), Ge(■, □), Sn(Δ). The ΔH values plotted were calculated from enthalpies of formation given in Table 2 (37). The tip of the arrow represents the preferred ΔH_3 value deduced for A = Sn.

TABLE 3. Mn state excitations (39) (with spin-orbit splitting)

State	E_i/kJ mol^{-1}
a^6S	0
a^6D_J	207 ± 4
z^8P_J	222 ± 2
a^4D_J	281 ± 2

for $D(SnCl_3$—Cl), Oldershaw and Robinson (37) *assumed* that it would be approximately equal to $D(SnCl_3$—Cl); the higher value here stems entirely from the enthalpy of atomization of $SnCl_2$ being less than deduced by Oldershaw and Robinson.

Using this derived value, and the known MnCl bond energy of 357 kJ mol^{-1} (38), we calculate ΔD_0 ~ 94 kJ mol^{-1} for reaction [1]. For ground state atoms, this is clearly insufficient to excite any of the MnCl band systems in Fig. 1 and Table 1, unless translational energy is supplied. However, some of the band systems might be produced without a translational threshold, if their lower states are not themselves highly excited, and if metastable Mn atoms are the reagents. The excitation energies of the lowest Mn metastable states are listed in Table 3 (39).

Experimental

A full description of the apparatus has been given previously (16, 17). Briefly, a pulsed beam of Mn atoms and ions, of wide velocity range and comprising various long-lived electronic states (including the ground state), is produced by focusing the Q-switched output (~10 ns) of a Nd:YAG laser at 1.064 μm directly onto a solid metal target in vacuo. The beam is collimated by a small aperture in the focusing mir-

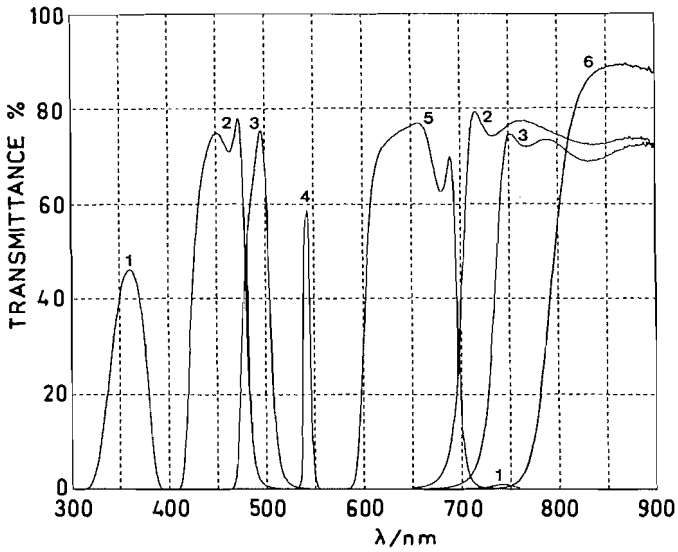

FIG. 3. Transmission curves of the various filters used: 1, 320–390 nm (ultraviolet); 2, 418–490 nm (blue); 3, 470–510 nm (green); 4, 540 nm narrow band (for Mn beam emission); 5, 590–690 nm (red); 6, >750 nm (infrared).

ror, stripped of ions by a d.c. electric field, and passed into a separate vacuum chamber containing a low pressure of $SnCl_4$ reactant gas. Here the beam is monitored, after a 282-mm flight path from the target, by emission at ~540 nm from the metastable $Mn^*(z^8P_J)$ states, whose radiative lifetimes, ~82 and ~122 μs (16), are of a similar order to the flight times. A beamsplitter and an appropriate broadband filter allow simultaneous detection of chemiluminescence at the same point. Signals from the two monitoring photomultipliers are amplified, acquired alternately into the two channels of a transient digitizer, and then averaged over 255 laser shots each to generate time profiles $I(t)$, $I_r(t)$ for beam emission and chemiluminescence, respectively. In these experiments, data have been obtained at both 5 MHz and 2 MHz digitizing rates, the latter allowing measurement (over 1024 channels maximum) to much longer flight times, i.e., to much lower collision energies.

The transmission curves of the various filters employed are displayed in Fig. 3. OX1 ("Chance's glass") and 750 nm cut-on filters, respectively, were used in the (unsuccessful) attempts to detect emission in the MnCl $A^7\Sigma^+ \rightarrow X^7\Sigma^+$ ("ultraviolet") and infrared Π–Σ band systems; in the other cases, combinations of short-pass and cut-on filters were necessary. To simplify the following discussion, we label these remaining band systems by the colours of the filter combinations used: "blue" (418–490 nm), "green" (470–510 nm), and "red" (590–690 nm). As shown in the figure, the blue and green filter transmissions overlap, but exchange of cut-on filters showed that no significant chemiluminescence occurred in the 470–490 nm region. The emissions that were detected are therefore more correctly described as concentrated in the 418–470 and 490–510 nm regions, respectively. The additional transmission of these filter combinations in the far red and infrared parts of the spectrum likewise caused no problem: as remarked above, no infrared chemiluminescence was detected, and while red emission was found, none could been seen through the blue and green filters when the short wavelength transmission was blocked out.

Figure 4 shows typical beam and chemiluminescence time profiles, obtained at the 5 MHz digitizing rate. As before (16, 17), such data were transformed to relative cross section σ by taking ratios point by point, and correcting for the different detection efficiencies and the radiative decay of the emitting Mn^* ($z^8P_{7/2,5/2}$) substates:

$$[5] \quad \sigma(t) \propto (I_r(t)\Gamma(t)t)/I(t)$$

Here $\Gamma(t)$ is the weighted exponential decay factor of the emitting J-substates (described in ref. 16), and the factor t enters because the beam signal represents number density rather than flux. This procedure

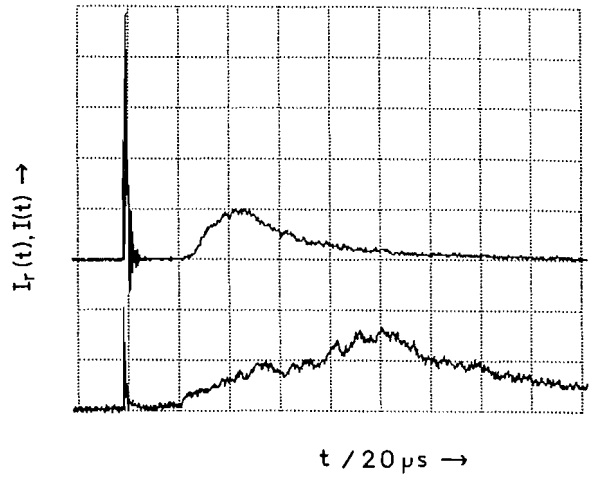

FIG. 4. Typical time profiles of $Mn(z^8P_J \rightarrow a^6S)$ beam emission (upper) and Mn + $SnCl_4$ blue luminescence (lower), each averaged over 255 laser shots. Vertical sensitivity is respectively 10 and 5 mV/division, with fullscale resolution 128 point. Horizontal resolution is 1024 point, the start of the initial spike in both traces indicating the time zero.

assumes that all Mn states start with the same velocity distribution, a reasonable assumption in view of the ~80 000 K temperature of the laser-produced Mn plasma (16). Leaving aside for the moment the spread of $SnCl_4$ collision velocities in this beam-gas configuration, the *nominal* collision velocity is equal to x/t, where x is the distance (282 mm) from the target; and the *nominal* collision energy E_T^0 is given by

$$[6] \quad E_T^0 = \tfrac{1}{2}\mu(x/t)^2$$

Equations [5] and [6] can thus be used to generate relative chemiluminescence cross sections $\sigma(E_T^0)$. However, from an individual pair of data traces such as those in Fig. 4, the overall noise in σ is generally quite large, due to the small magnitude and erratic nature of the primary signals, particularly at long delay times. The excitation functions that are presented below are therefore the result of adding together relative cross sections derived from a substantial number of pairs of data traces. In addition, the Doppler broadening at each nominal collision energy E_T^0 means that $\sigma(E_T^0)$ differs somewhat from the *true* excitation function $\sigma(E_T)$, particularly in the threshold region $E_T \approx E_0$. However, as demonstrated previously (17), this deviation can be rigorously accounted for in the data analysis.

As before, the solid Mn target was electrolytic quality. $SnCl_4$ (BDH) was degassed at liquid nitrogen temperature before admission to the reaction chamber. Typical pressures measured by the Penning gauge were ~$(1–2) \times 10^{-3}$ Torr (0.13–0.27 Pa) but, as the gauge was calibrated only for nitrogen, the true pressure may have been as much as a factor of 10 less. At the highest pressures, some attenuation of the beam was evident, but since both beam and luminescence were detected at the same point, this was assumed to be unimportant.

Results and analysis

As remarked above, no emission could be detected in the ultraviolet or infrared band systems, but signal was indeed found in the blue, green, and red filter regions. In addition, and in common with many other collision partners (16, 18, 19, 40–42), $SnCl_4$ was observed to give rise to $Mn^*(z^6P \rightarrow a^6S)$ collision-induced emission at ~403 nm; however, discussion of that process will be reserved to a subsequent paper (41).

Figure 5 shows excitation functions $\sigma(E_T^0)$ for emissions in the blue, green, and red spectral regions, derived from time profiles recorded, at 0.2 μs digitizing intervals, to 180 μs maximum delay time (i.e., minimum energy $E_T^0 \sim 56$ kJ mol^{-1}). To

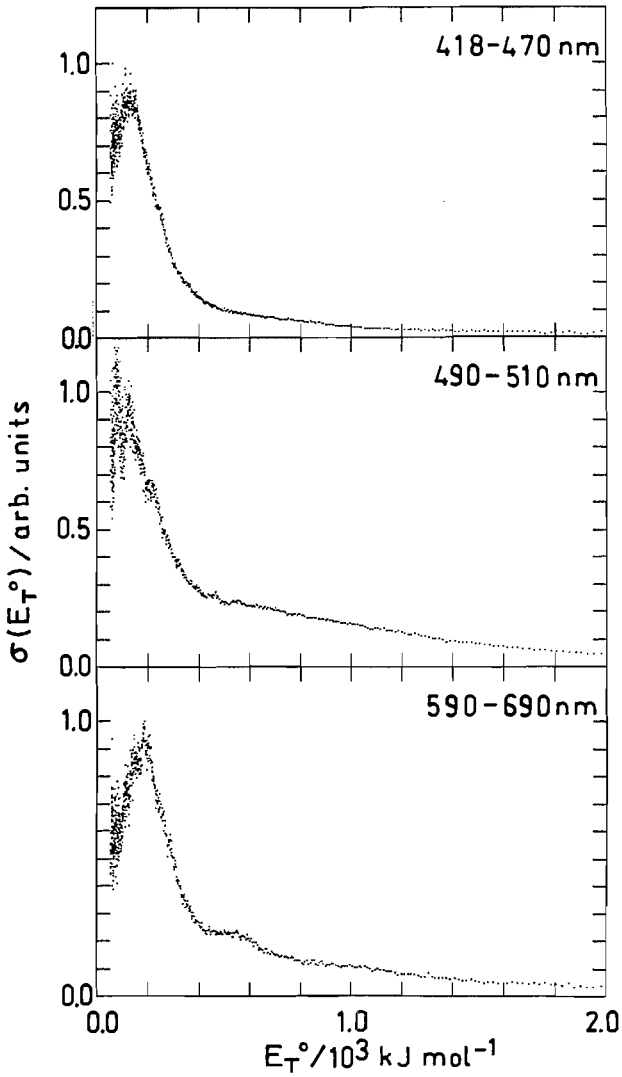

FIG. 5. Excitation functions, $\sigma(E_T^0)$, for production of emission in the wavelength regions indicated, in collisions of Mn atoms with $SnCl_4$. Point-to-point resolution corresponds to 0.2 μs delay, and the data therefore start at only $E_T^0 \sim 56$ kJ mol^{-1} . The excitation functions are arbitrarily normalized to unity at their maximum.

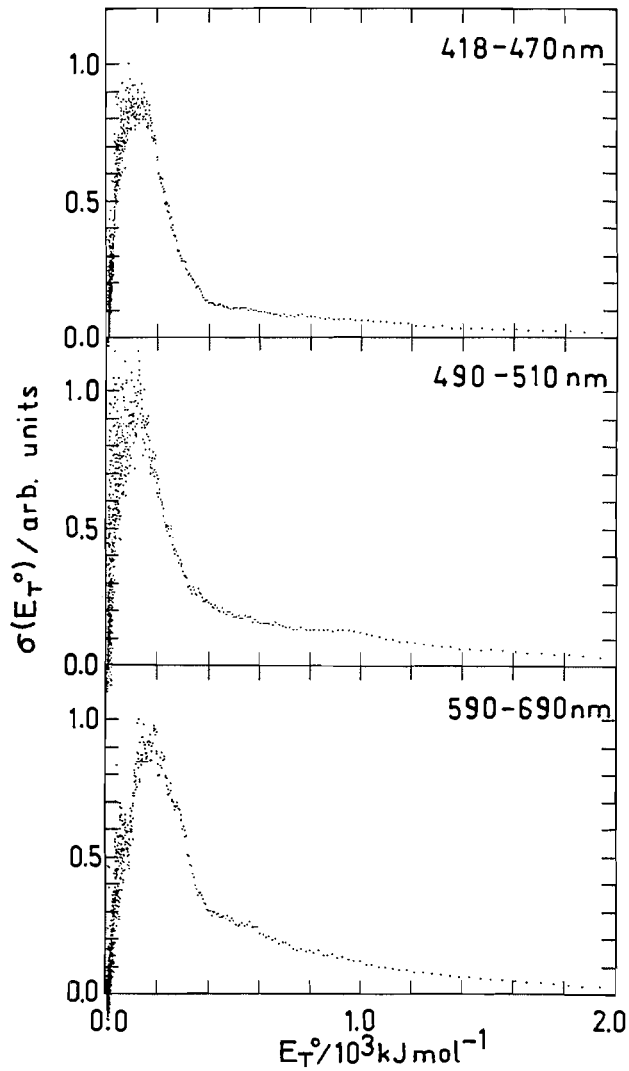

FIG. 6. Same as in Fig. 5, but recorded at 0.5 μs resolution. The data now extend down to $E_T^0 \sim 9$ kJ mol^{-1}.

generate these, some 9200, 45 000, and 17 000 laser shots were required, respectively. Absolute comparison of the peak cross sections is unfortunately not straightforward, as the scattering gas pressure could not be held constant over the large number of runs (of 255 shots per channel) required to generate data of satisfactory quality. However, a crude comparison at 102.4 μs delay (~172 kJ mol^{-1}, close to the peak cross section), taking into account the varying quantum efficiency of the photomultiplier, yielded relative intensities of ~1.0:1.5:5.0 for the green, red, and blue emissions, respectively. That the blue signal is by far the largest is clear from the different numbers of shots required, and from the different signal-to-noise ratios still remaining, in Fig. 5.

The excitation functions all show the same basic form, rising rapidly to a peak in the range ~150–200 kJ mol^{-1}, and falling off rapidly thereafter. There are differences, however, in the rate at which the cross sections approach zero as E_T^0 increases: in particular, the fall-off starts latest for the red signal, and both the green and red excitation functions seem to show a pronounced shoulder. However, as all three show significant noise at low energies (i.e., long times) and thresholds below the minimum energy achieved, the behaviour up to and including the peak cross section remains somewhat ambiguous.

To resolve this issue, the experiments were repeated at 0.5 μs digitizing intervals. This was not adopted as a routine measure since the laser focussing conditions necessary to sustain the Mn beam at significant magnitudes in the range ~200–500 μs could only be achieved, and then fleetingly, for a fresh mirror and Mn target combination. However, after strenuous efforts, it was possible to accumulate data of satisfactory quality over some 9200 laser shots in each spectral region. The results, displayed in Fig. 6, are in general noisier than those of Fig. 5, in part because of the smaller number of laser shots, but also because of the reduced chance of capturing individual photons at the slower digitizing rate. Nonetheless, the data do now extend to detectable thresholds and, within the noise, the measured excitation functions achieved at the different digitizing rates agree quite well. For the green emission, the shoulder/peak ratio is somewhat smaller than at 0.2 μs, but this discrepancy must be regarded as a consequence of the substantial difference in the number of laser shots employed (~9200 instead of ~45 000).

In past work from this laboratory (17, 18, 40), the initial rise part of such excitation functions has been analysed in terms of the microcanonical transition state theory (MTST) approach of González Ureña (20):

$$[7] \quad \sigma(E_T) = \sigma_0(E_T - E_0)^n/E_T$$

where E_0 is the threshold, and n is a small number representing the active modes at the critical transition state. In principle, the analysis involves transforming eq. [7] to the yield function form

$$[8] \quad Y(E_T) = \sigma(E_T)E_T = \sigma_0(E_T - E_0)^n$$

and plotting $Y^{1/n}$ against E_T for different values of n until the best linearity is achieved. In practice, however, as noted above, the beam-gas configuration measures an effective cross section $\sigma(E_T^0)$ at *nominal* collision energy E_T^0, with collision energy spread introducing a degree of threshold curvature in the linear $Y^{1/n}$ plot. Nonetheless, the curvature can be modeled analytically for integral values of n (17). By this means it was found that, in the reactions $Mn^*(a^6D_J) + O_2$, NO_2, CO_2, SO_2 (17), n = 2–3 at relatively low energies, but $n = 1$ at higher energies. This indicates a potential well before the exit transition state, but one whose influence on the transition state dynamics diminishes as collision energy increases.

In the present case, yield functions $Y(E_T^0)$ for the threshold regions of the three different emissions, i.e, calculated from the cross sections of Fig. 6, are displayed in Fig. 7. The initial linear behaviour is quite clear, showing that the data follow the line-of-centres form ($n = 1$), from thresholds of 10 ± 2, 15 ± 2, and 22 ± 1 kJ mol^{-1}, respectively. Despite the noise on the cross-section data, the yield function plots define the thresholds extremely tightly, especially when the requirement to fit the threshold curvature (see below, Fig. 10) as well as the linear part is taken into account. Not only does the conversion to yield function reduce the relative noise, but the reduced energy interval at long delay times means that the functionality becomes better defined as E_T^0 decreases towards E_0. The error limits given here indicate *absolute* possible maximum and minimum values for each threshold, pushed to the limit of consistency with the data. Although the blue and green thresholds are relatively close, it has not proved possible to reconcile them satisfactorily with any single intermediate value.

The significant higher energy differences in Fig. 7 lend support to the observation of different thresholds. The green plot is linear up to ~140 kJ mol^{-1}, the red emission shows a second threshold at ~105 kJ mol^{-1}, whereas the blue plot displays a "step," with a sharp upward break near 30 kJ mol^{-1}, followed by a *linear* fall-off from ~40 kJ mol^{-1}. While the red break at ~105 kJ mol^{-1} also appears on the 0.2 μs yield function (not shown), the step in the blue emission is at such low energies that it is not even hinted at in the 0.2 μs data. The reality of this feature was confirmed by adding separately 3 groups of 6 files, instead of the 18 previously summed together; although the noise is higher, the step clearly appears in each group.

Space considerations limit our presentation of the yield functions to the threshold region only. However, at energies beyond the range of Fig. 7, all plots display a sharp downward break, while further, opposite, slope changes occur at higher energies still. This, together with the peculiar behaviour of the blue data at E_T^0 ~ 30–40 kJ mol^{-1}, has prompted the question of what may be responsible, and whether in general there is a suitable

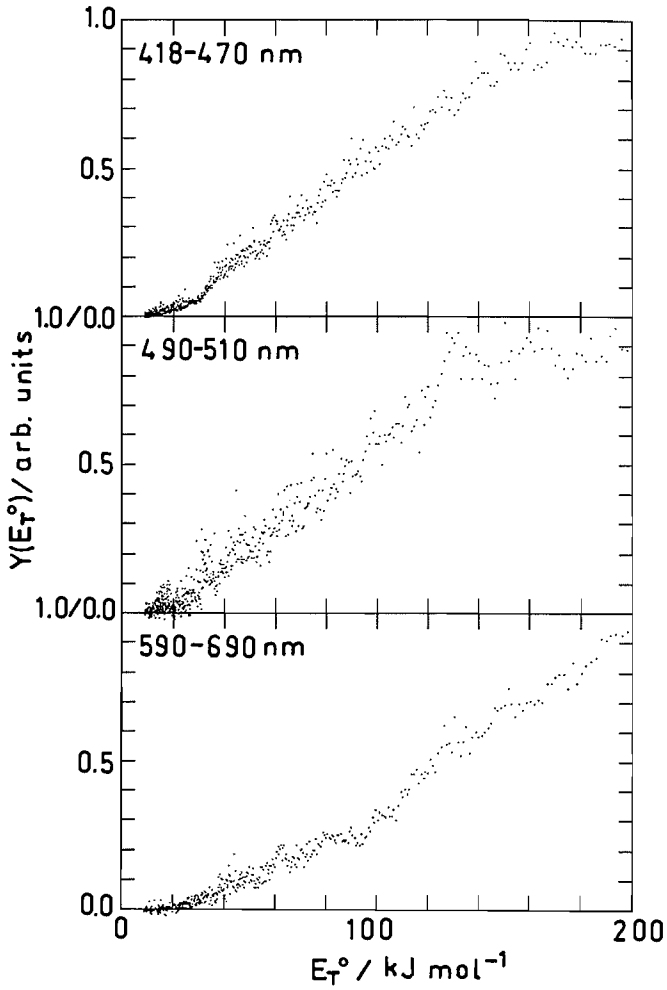

FIG. 7. Yield functions $Y(E_T^0)$ for the threshold region, calculated from the data of Fig. 6 (again arbitrary normalization).

functional form that may be employed to analyse the fall-off for each of these excitation functions. In fact, such a procedure has recently been proposed by one of us (15). It takes the form

$$[9] \quad \sigma(E_T) \sim \Sigma\sigma_k(1 - E_k/E_T)$$

where $k = 0, 1, 2,...$ and σ_k ($k > 0$) may be negative. Each term in the series only contributes from its threshold E_k, and the asymptotic sign allows for initial $n > 1$ behaviour by each individual component. This result has proved highly successful in analysing a large number of excitation functions in the scientific literature, revealing two major classes of fall-off from an initial rise (15).

In "simple" cases, generally only two terms contribute, with $|\sigma_1| \leq \sigma_0$; eq. [9] may then be written, for $E_T > E_1$, as

$$[10] \quad \sigma(E_T) \sim \pi P_0 R_0^2(1 - E_0/E_T) - \pi P_0 P_1 R_1^2(1 - E_1/E_T)$$

Here, as illustrated in Fig. 8, the first term represents reaction, with probability P_0 and line-of-centres energy $\geq E_0$, at internuclear distance R_0, while the second represents *recrossing*, with probability P_1, as the system penetrates with line-of-centres energy $\geq E_1$ to internuclear distance R_1, and is reflected from the repulsive wall of the potential. Since $P_1 \leq 1$, and recrossing

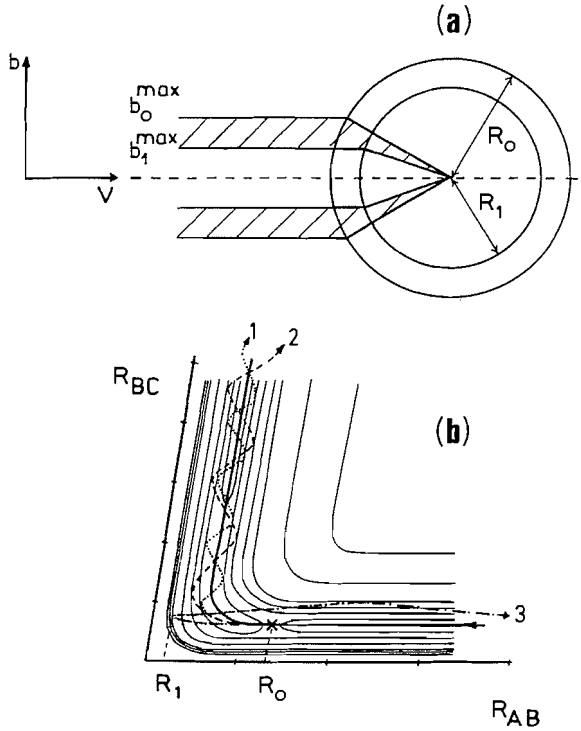

FIG. 8. (*a*) Simple excitation function fall-off model (15). R_0, R_1 are the line-of-centres internuclear distances at which, respectively, reaction and depletion occur; b_0^{max}, b_1^{max} are the respective maximum impact parameters for the two processes at a given relative velocity *V*. (*b*) Schematic of A + BC → AB + C potential surface shape and dynamics consistent with this model. The bold line indicates the minimum energy path, with saddle point × at R_0, while trajectories 1, 2, and 3 have increasing energy in excess of the barrier. Recrossing occurs when trajectories can penetrate as far the repulsive wall of the potential at R_1.

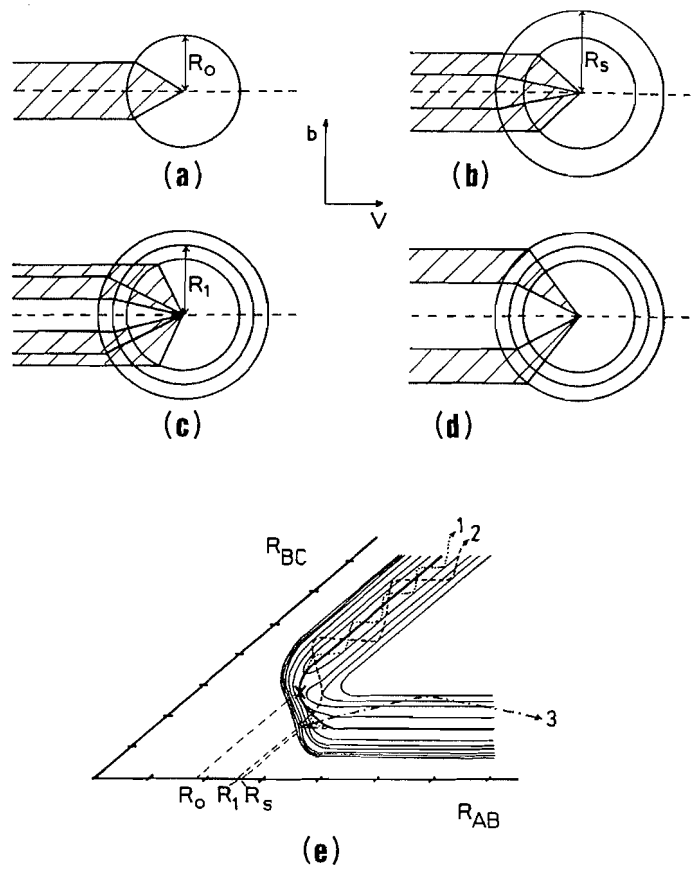

FIG. 9. Complex excitation function fall-off model (15). (*a*) At low collision energy, reaction only occurs at R_0. (*b*) As E_T increases, the transition state for reaction shifts *forward* to R_s at low impact parameters, but the overall cross section is not affected. (*c*) At higher energies, depletion starts at R_1. (*d*) At higher energies still, σ starts to rise again, as reaction at R_s can now occur at impact parameters greater than R_0. (*e*) Schematic of potential surface features consistent with the above behaviour: as before, the bold line represents the minimum energy path; 1, 2, and 3 are trajectories with progressively higher collision energy; and × is the saddle point.

requires that $R_1 \leq R_0$, the relative slopes σ_0 and $(\sigma_0 + \sigma_1)$ of the bilinear yield plot may then be analysed, to give $P_1 \geq |\sigma_1/\sigma_0|$, or $R_1/R_0 \geq |\sigma_1/\sigma_0|^{1/2}$. Among others, the reactions K + C_2H_5Br (43), Sr + HF (44), and Xe*($^3P_{2,0}$) + HCl (45) fall into this category.

A number of reactions, however, follow more complex behaviour. In essence, this is characterized by a three-term series (at least),

$$[11] \quad \sigma(E_T) \sim \sigma_0(1 - E_0/E_T) + \sigma_1(1 - E_1/E_T) + \sigma_2(1 - E_2/E_T)$$

with each term again only contributing above its threshold. As before, $\sigma_1 < 0$; but in this case $|\sigma_1/\sigma_0| > 1.0$, implying recrossing occurs at greater internuclear distances than reaction! The third, positive, term is, however, significant, suggesting that above E_2 the equation should really be written as

$$[12] \quad \sigma(E_T) \sim \sigma_s(1 - E_s/E_T) + \sigma_1(1 - E_1/E_T)$$

where $\sigma_s = (\sigma_0 + \sigma_2)$ and $E_s = (\sigma_0 E_0 + \sigma_2 E_2)/(\sigma_0 + \sigma_2)$. As shown in Fig. 9, the rapid depletion is then understood in terms of the reaction transition state having already *shifted forward*, from R_0 to a distance R_s, at line-of-centres energy E_s. This shift, however, can only lead to an increase in $\sigma(E_T)$ once $\sigma_s(E_T - E_s) > \sigma_0(E_T - E_0)$, i.e., $E_T > E_2$. Such an interpretation can of course only be valid if the calculated value of $E_s < E_1$, but this does indeed appear to be the case for such reactions as Ba + $N_2O(n_2 = 1)$ (13, 14) and K + CH_3I (46–48). Relative internuclear distances R_s/R_0 and R_1/R_0 have thereby been deduced from the multilinear yield functions found in those reactions (15). The shift has been identified with a restricted access to the exit valley, so that, as collision energy increases, trajectories "cut" the corner and effectively sample an earlier barrier. Such a situation might occur if R_{BC} needs to stretch a little before reaction takes place, and if there is insufficient time for this to occur at elevated collision energies. At higher energies still, there will be even less time, so access to the exit valley is completely blocked off, and depletion occurs at internuclear distances of $\sim R_s$.

In the present cases, the shapes of the excitation and yield functions suggest that the reactions fall for the most part into the second category, although, as noted, the blue emission shows an "early" fall-off that is more reminiscent of the "simple" depletion behaviour. There is, however, an additional complication in that, in principle, several Mn states could generate the observed luminescence, giving rise to several independent production and depletion thresholds. We reserve discussion of this issue to the next section, and concentrate here on determining whether the excitation functions can be modelled and, if so, the parameters of the fit.

TABLE 4. Parameters of the analysis (energies E_k in kJ mol^{-1})

Emission	k	0	1	2	3	4
Blue	σ_k	0.44 ± 0.07	3.40 ± 1.18	−(2.88 ± 1.26)	−(1.37 ± 0.018)	0.337 ± 0.018
	E_k	10 ± 2	36 ± 2	40 ± 1	158 ± 3	393 ∓ 13
Green	σ_k	0.83 ± 0.035	−(0.925 ± 0.025)	0.165 ± 0.005	−(0.123 ± 0.004)	
	E_k	15 ± 2	150 ∓ 5	390 ± 10	955 ∓ 15	
Red	σ_k	0.81 ± 0.03	0.47 ∓ 0.03	−(1.73 ± 0.03)	0.61 ± 0.03	−(0.205 ± 0.005)
	E_k	22 ± 1	100 ± 5	200 ± 5	400 ∓ 10	535 ± 15

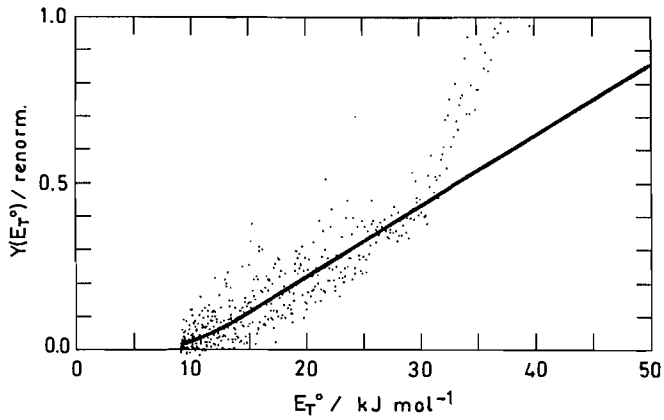

FIG. 10. Magnification of the blue yield function in Fig. 7, showing the line-of-centres "best fit" to the initial rise. The renormalized linear scale corresponds to an expansion factor of ~7.5. The derived initial threshold is ~10 kJ mol^{-1}, but collision energy spread in the beam-gas configuration leads to the curvature shown. Likewise, the true threshold corresponding to the break at ~30 kJ mol^{-1} is in fact ~36 kJ mol^{-1}.

The procedure that has been adopted is essentially an iterative one: first, as shown in Fig. 10, the threshold energy dependence of $Y(E_T^0)$ is fitted to a line-of-centres form, modified by collision energy spread; next, depending on whether $Y(E_T^0)$ shows an upward or downward break from this behaviour, a new yield function is generated by respectively subtracting, or subtracting *from*, the extrapolated form of the fitting; and then the process starts again. In this way, each section of the plot is fitted in turn. However, because the 0.5 μs data are of inferior quality at higher energies, they have only been used to determine the threshold behaviour, and these results have then been employed as starting points for the 0.2 μs analysis.

The σ_k, E_k parameters derived from this procedure are displayed in Table 4. The numbers of pairs in each case, 5 for the blue and red data, and 4 for the green, match the numbers of different slope regions of the yield plots. With the exception of the step in the blue data, all of these slope regions extend over a considerable collision energy range, and, indeed, no satisfactory fitting could be obtained in any of the excitation functions with a smaller number of parameter pairs. The uncertainties given in the table were obtained from repeated trials of the procedure, starting with the maximum and minimum possible E_0 values already given above. The direction of the ± or ∓ signs in the table generally indicates the correlations between successive terms, i.e., a "high" estimate of σ_k will tend to be compensated by a corresponding "low" estimate (or "high" negative estimate) or σ_{k+1}. However, for the blue excitation function the step at ~36 kJ mol^{-1} is so sharp, and the resulting threshold curvature so substantial, that the correlation between the $k = 0$ and $k = 1$ terms is small and, if anything, in the opposite direction. The substantial uncertainty in σ_1 (and hence in σ_2) in this system derives principally from the sharpness and short range of the step; but since the sum $(\sigma_0 + \sigma_1 + \sigma_2)$ is well defined from the yield plot, the uncertainties on the higher terms are much smaller.

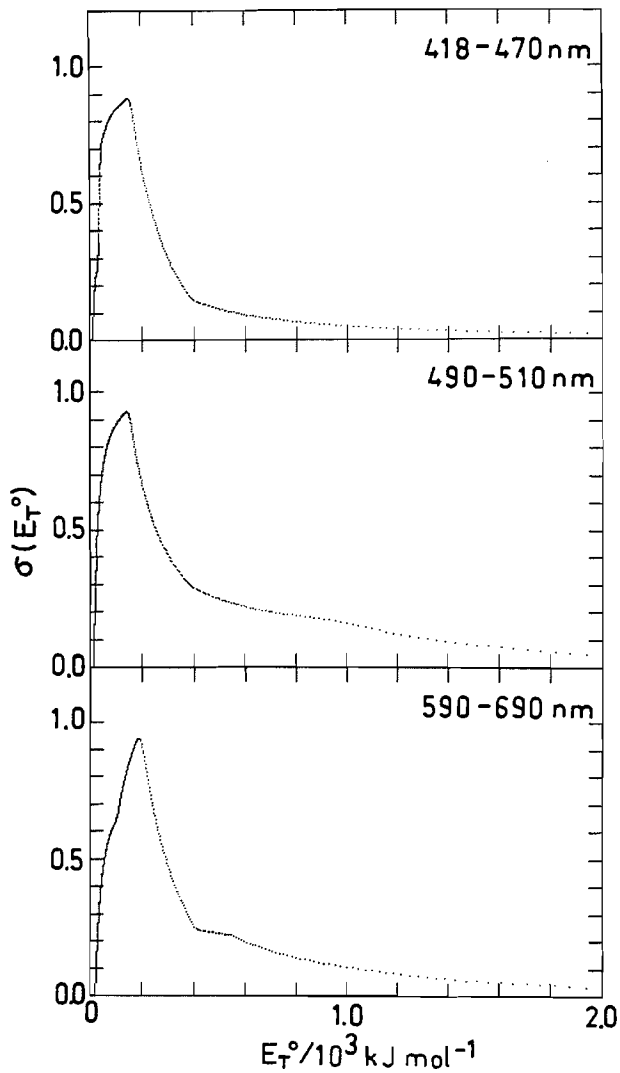

FIG. 11. "Best-fit" excitation functions derived from the parameters given in Table 3, and including the effect of collision energy spread. As with the original data, the separation between data points decreases as collision energy decreases. The apparent steps at low collision energy are merely artefacts of the printer resolution.

The shapes of the "best" excitation function fits (calculated at the E_T^0 value of each data point in Fig. 6) are shown in Fig. 11.

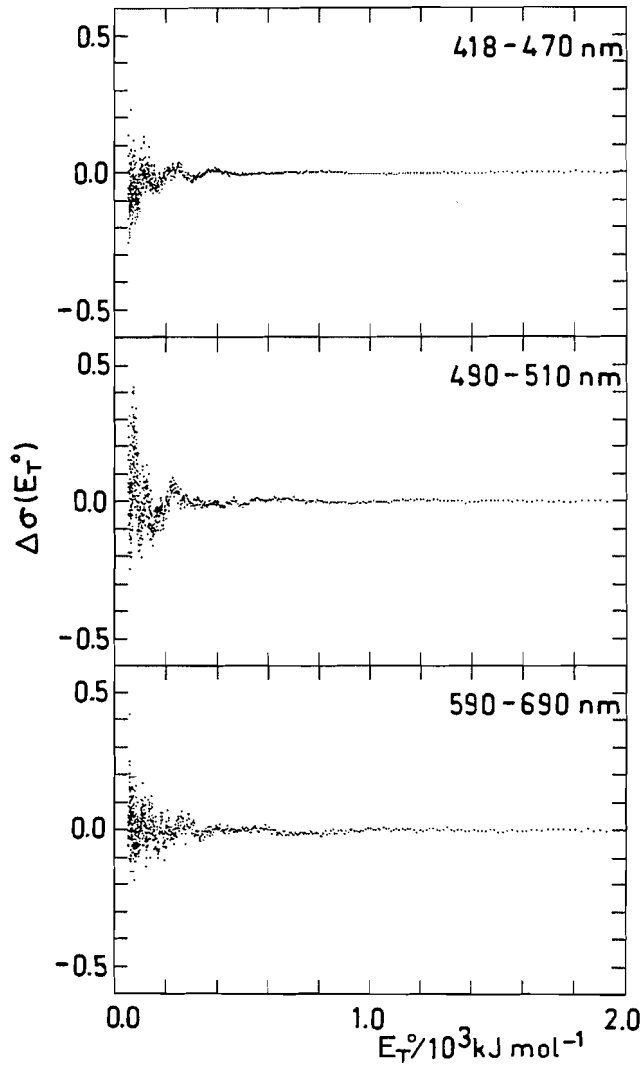

FIG. 12. Residual plots $\Delta\sigma(E_T^0)$ of the deviations between the experimental excitation functions in Fig. 5, and the derived model functions in Fig. 11, to the same scale.

It was not sensible to include such fits in Figs. 5 or 6, since the individual data points are very close together, and most would disappear under the fit. However, to show the quality of agreement, Fig. 12 displays the residual plots representing the difference between the data of Fig. 5 and the calculated excitation functions. Clearly the average deviation is virtually zero across the whole collision energy range. The noise at low energy reflects the noise on the original excitation functions, which are at their largest in that energy range.

Discussion

1. Product and reagent state excitations

The first point to be made about the measured excitation functions is that each is unique. Although the data in Fig. 5 (and Fig. 6) appear superficially similar, the parameters in Table 4 make the differences clear. It is true that there appear to be some correspondences in blue and green E_k values in Table 4, i.e., (10,15), (158,150), and (393,380); but the relative magnitudes of the corresponding σ_k values are quite different: ~0.65 (at E_0 = 12–13), ~1.4, and ~2.2, respectively. Besides, it is important not to take a subset of the parameters in isolation. In terms of the multiple line-of-centres/movable barriers approach outlined above, the sum $\Sigma\ \sigma_k$ can be expected to take values between significantly positive and slightly negative, depending on the degree of depletion and the relative positions of the barriers (e.g., R_1 could even slightly exceed R_s in Fig. 9). For each complete excitation function, we find that $\Sigma\ \sigma_k$ is indeed ~0, but, for the blue data, $(\sigma_0 + \sigma_3 + \sigma_4) \sim -0.54$, which is excessively negative. The correspondences in E_k values between the blue and green data must therefore be regarded as reflecting similarities, rather than *identities*, between the potential surfaces involved.

The uniqueness of the excitation functions, and the correspondence of emission regions with the known MnX spectroscopy, means that the emitters in all cases are almost certainly MnCl* molecules, in *different* electronically excited states. In confirmation of this conclusion, we and other workers have found some or all of the same emissions, again with different excitation functions, in collisions of Mn atoms with $SiCl_4$, CF_4, SF_6, Br_2, ICl, $GeCl_4$, $TiCl_4$, S_2Cl_2, and SO_2Cl_2 (41, 42). MnX_2* (or MnXY*) cannot entirely be eliminated as the blue emitting species, but it seems unlikely that such a product would be detected from so many reactions (in fact, from all except Mn + $GeCl_4$ (42).

Each excitation function also appears to result from reaction of only a single Mn electronic state. As noted above, an upward break in the yield function could represent the observed onset of either a new process (e.g., a shift forward in the transition state location, or an increase in reaction probability) or the contribution of a less excited Mn state to the chemiluminescence, but the magnitude of the fall-off in each case is so large that the latter must be eliminated. It is highly unlikely that chemiluminescent reaction from two different Mn states should start to be depleted from the same threshold energy.

Given that only one Mn state contributes in each case, it is instructive to consider what that might be. Analogously to the reactions with oxygen-containing molecules (17), the threshold E_0 for chemiluminescence is given by

$$[13]\quad E_0 = D_0(SnCl_3\text{—}Cl) - \bar{E}_{v,r}(SnCl_4) - E_i(Mn^*) - D_0(MnCl^*) + E_i(MnCl^*) + E_b$$

where $\bar{E}_{v,r}$ = the average vibration-rotation energy in $SnCl_4$, E_i = electronic excitation, and E_b = the excess barrier over the endothermicity for reaction. As noted in the Introduction, $D_0(SnCl_3\text{—}Cl)$ is not well known, and, in fact, the value estimated above, ~263 kJ mol^{-1}, is strictly an enthalpy change, determined at 298 K rather than at absolute zero. However, since the excitation functions all follow n = 1 MTST functionality, i.e., two-body behaviour, we can assume that the bulk of the $SnCl_4$ vibration-rotation energy at 298 K does not contribute to overcoming any barrier, but is retained in the $SnCl_3$ product. Thus, by restricting the partitioning of E_b only to product translation or to MnCl* vibrational excitation, we can ignore $\bar{E}_{v,r}(SnCl_4)$, and assume $D_0(SnCl_3\text{—}Cl) \sim 263$ kJ mol^{-1}. Equation [13] then becomes

$$[14]\quad E_0 \geq E_i(MnCl^*) - E_i(Mn^*) - 94\ \text{kJ mol}^{-1}$$

A lower limit to $E_i(MnCl^*)$ is given by $h\nu_{00}$ in each case: ~266 kJ mol^{-1} for the blue emission (assuming λ_{00} = 450 nm); ~240 kJ mol^{-1} for the green bands (Table 1 (28)); and, by analogy with MnF (Table 1 (28)), ~173 kJ mol^{-1} for the red bands.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

Substitution of $E_0 = 10$, 15, and 22 kJ mol^{-1}, as appropriate, into eq. [14] then shows that $E_i(Mn^*) \geq 162$, 131, and 57 kJ mol^{-1}, respectively.

Clearly, from Table 3, ground-state Mn atoms cannot be responsible for any of the observed reactions but, in the absence of further information, any of the metastable states listed could be. In any case, since a^6D_J atoms were found to be the most active species in the Mn + O_2, NO_2, CO_2, SO_2 chemiluminescent reactions (17), it would be very surprising if they did not play a role here. On the other hand, participation from z^8P_J atoms should be disfavoured since, as discussed below, the MnCl* emitters are likely to be quintet states, or components thereof, whose production from Mn*(z^8P_J) + $SnCl_4$ would violate spin conservation. That process could happen if the reaction proceeded via a potential well, so that the octet $MnClSnCl_3$ intermediate had a lifetime long enough to cross over to a sextet surface; but the excitation functions suggest that such a feature is absent, since they display $n = 1$ MTST functionality and since (as discussed below) the transition state at low collision energies lies at relatively short internuclear distances, i.e., towards the exit channel.

On the other hand, a contribution from Mn*(a^4D_J) atoms cannot a priori be excluded, since they were implicated in Mn + O_2, CO_2, SO_2 (though *not* Mn + NO_2) (17) and since production of excited quintet states of MnCl* would certainly be spin-allowed. However, as remarked above, the present data can only be understood in terms of a single reagent state in each case. If that state were a^4D_J, then one would expect production of at least some of the MnCl* band systems to be *exoergic*, opening up the possibility of negative thresholds. Among all the many chemiluminescent Mn atoms so far studied, whether with oxygen (16, 17), hydrogen- (18, 19) or halogen- (41, 42) containing molecules, the only one observed to have a negative threshold is Mn + NO_2, and there a^6D_J atoms alone were deduced to be the reagent species, with $n \sim 2.5$ functionality (17). Quite highly excited Mn states do seem to be involved in some of the MnH-producing reactions, but in all these cases the processes remain endoergic, displaying significant thresholds. Thus, although we cannot completely exclude a^4D_J atoms (or, for that matter, higher metastable states) in the present reaction, it seems highly likely that the sole progenitors of all three MnCl* band systems observed here are Mn*(a^6D_J) atoms.

If that is indeed the case, then the absence of any contribution from z^8P_J or a^4D_J is something of a problem, especially as z^8P_J atoms should (as shown below, Fig. 14) correlate with MnCl*($A^7\Pi$), which is not observed here. However, while MnX*($A^7\Pi \rightarrow X^7\Sigma$) luminescence has been observed in Mn + SF_6 (41), SO_2Cl_2 (42), and $TiCl_4$ (42), and z^8P_J atoms may well be the reagent, such emission is a relatively rare occurrence, and it may well be that in most cases ground-state products are preferred. As for a^4D_J atoms, collision-induced dissociation is possible, since the electronic excitation exceeds the (derived) $SnCl_3$—Cl bond energy.

If the a^6D_J state is accepted as the reagent species, then eq. [14] can be used to obtain *upper limits* to the excitation of the emitting MnCl* product states. Inserting $E_i(Mn^*) = 207$ kJ mol^{-1}, from Table 3, leads to $E_i(MnCl^*) < 311$, 316, and 323 kJ mol^{-1} for the *upper* states of the blue, green, and red emissions, respectively. By subtracting $h\nu_{00}$ from these energies, we then obtain $E_i(MnCl^*) < 45$, 76, and 150 kJ mol^{-1} for the respective excitations of the *lower* states of the transitions. Clearly these values would be modified if a more accurate estimate of $D_0(SnCl_3$—Cl) could be obtained, or if a more excited Mn metastable state turns out to be the active species. However, it is noteworthy that these upper excitations are all comparable to that of the $A^7\Pi$ state, 323 kJ mol^{-1} (28). This tallies with the Mn + SF_6 (41), SO_2Cl_2 (42), and $TiCl_4$ (42) results, where the thresholds for MnX*($A^7\Pi$) production suggest that it lies above the blue, green, and red emitting states. Of course, the true excitations may be well below 323 kJ mol^{-1}, since production of each emitting state may involve a different value of the excess barrier E_b.

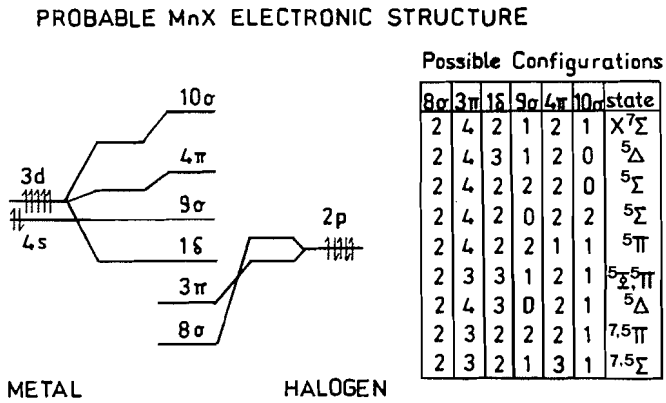
2. Chemiluminescence mechanism

Before considering the processes leading to chemiluminescence, it is necessary to discuss the possible identities of the red, green, and blue states, whose maximum excitations we have just deduced. While the MnCl blue system is something of an enigma, the likely term symbols of the green and red emitting states can be inferred from the analysis by Hayes (28), which has already been summarized in Fig. 1 and Table 1. Although Hayes did not find any red band system for MnCl, his observation of comparable systems for MnF and MnBr strongly suggests that the red emission found here should have the same character, viz. $0^{\pm}$–$^5\Sigma$. The MnF and MnBr spectra do not indicate which of these terms is the upper level of the transition, but $0\pm$ must be preferred since such case (*c*) coupling would be much more likely at higher excitations (28). The upper limit of 323 kJ mol^{-1} determined above for the red emitting state would tend to be consistent with this conclusion.

Hayes found two band systems in the green part of the spectrum, both Π–Σ in character. One, which spans the range 485.0–508.2 nm, is almost certainly $^5\Pi$–$^5\Sigma$; while the other also has "a multiplicity of at least five" (28). Since the vibrational constants ω_e', ω_e'' for each are quite different, it seems unlikely that they are separate components of the same system. It has not been possible to separate the bands in the present experiments, but it is clear that only a single green system is produced; whichever it is, it must be $^5\Pi$–$^5\Sigma$ in character.

Further insight into the likely states involved might be gained by comparison with MnH (32–34), which displays band systems near 416, 450, 480, 566, 847, 939, and 1060 nm. The 566 nm system has been assigned to the $A^7\Pi$–$X^7\Sigma^+$ transition; but the $a^5\Sigma^+$ state lies only ~20 kJ mol^{-1} above the ground state (49, 50), and it has now been shown (33, 34) that the 480, 847, and 1060 systems are due to the $d^5\Pi$–$a^5\Sigma^+$, $c^5\Sigma^+$–$a^5\Sigma^+$, and $b^5\Pi_i$–$a^5\Sigma^+$ transitions, respectively. Similar transitions in MnX would not be unreasonable, although, from the $A^7\Pi$–$X^7\Sigma^+$ comparison, they might well be shifted to shorter wavelengths. In that case we would expect some of the band systems, at least, to have the same ω_e'' values. Unfortunately, Hayes' data (28), albeit incomplete, do not support this. The only coincidences that might be present are between ω_e'' for the higher energy green $^5\Pi$–$^5\Sigma$ bands, and ω_e' for one of the infrared systems (Π–Σ for MnCl, Σ–Σ for MnBr).

Strictly, however, we ought to compare MnX to the isoelectronic FeO. The molecular orbital diagram, after Merer (51), is shown in Fig. 13. In MnX, the ground state is formally ...$8\sigma^2 3\pi^4 1\delta^2 9\sigma^1 4\pi^2 10\sigma^1$, $^7\Sigma^+$, which corresponds to one electron in each of the orbitals that carries over from the metal atom *d* orbitals. The 10σ orbital, however, is strongly antibonding, and low-lying quintet states result from pairing the electron into the 1δ, 9σ, or 4π orbitals. For these excited states, the molecule may therefore be regarded as Mn^{+*}(...$3d^6$, a^5D_J) X^-, the differ-



8σ	3π	1δ	9σ	4π	10σ	state

2	3	2	2	2	1	$^{7,5}\Pi$
2	3	2	1	3	1	$^{7,5}\Sigma$

FIG. 13. Probable MnX electronic structure, after Merer (51) (for the isoelectronic FeO). The halogen atomic orbitals, and the molecular orbital numbering, strictly refer to X = F (or O); however, no substantial differences in comparable molecular orbital energies are anticipated for X = Cl, Br, I.

ent possible locations of the odd *d* electron determining the term symbol. In FeO, the ground state is in fact the $\Omega = 4$ component of the $^5\Delta_i$ multiplet, $..8\sigma^2 3\pi^4 1\delta^3 9\sigma^1 4\pi^2$, ~2 kJ mol^{-1} below the $a^7\Sigma^+$ state, and ~48 kJ mol^{-1} below the $A^5\Sigma^+$ state ($...8\sigma^2 3\pi^4 1\delta^2 9\sigma^2 4\pi^2$) (51). By analogy, therefore, MnX should also possess a low-lying $^5\Delta$ state, as well as $^5\Sigma^+$.

The diagram also illustrates another important expectation for MnX, the possibility of "charge-transfer" configurations, in which an electron is displaced from an orbital predominantly located on X (or O), into one of the partially filled *d*-type orbitals located on the metal. Indeed, FeO (51) shows a $C^5\Pi/B^5\Phi$ charge-transfer complex, with configuration $...8\sigma^2 3\pi^3 9\sigma^1 1\delta^3 4\pi^2 10\sigma^1$, 118–129 kJ mol^{-1} above the ground state; and a strong, highly irregular orange emission, which may also be a charge-transfer system. (The FeO $D^5\Delta$ multiplet, however, at ~214–222 kJ mol^{-1}, seems to involve the non-charge-transfer configuration $...8\sigma^2 3\pi^4 1\delta^3 4\pi^2 10\sigma^1$.) Because of the strength of the MnCl blue emission here, and the lack of structure found by Mesnage (29), it is tempting to speculate that it too might involve a transition from a charge-transfer upper state to a $^5\Delta$ lower state. Certainly, as indicated above, both the blue and green emission bands have quite low-lying lower states, and if the green lower state, at ≤76 kJ mol^{-1}, is $^5\Sigma$, then it would not be unreasonable for the blue lower state, at ≤45 kJ mol^{-1}, to be $^5\Delta$. As already remarked, these excitations might well be even lower if chemiluminescence production involves excess barriers.

Whatever the specific upper and lower term symbols in each band system, it is clear that there must be a considerable number of excited MnCl states at accessible energies — so many, in fact, that Mn*(a^6D_J) atoms are unlikely to correlate directly with most of the upper states of the emission bands detected. Production of chemiluminescence must therefore involve mixing between potential surfaces or between vibrational manifolds of the MnCl product. Since, in principle, a multitude of such mixings may be occurring, a full understanding of the reaction requires knowledge not only of the identities of the various "dark" and luminescent product channels, but of the branching ratios and their dependence on the individual substates of the Mn*(a^6D_J) multiplet.

For chemiluminescence, however, the uniqueness of the excitation functions presented here shows that the mixing must be

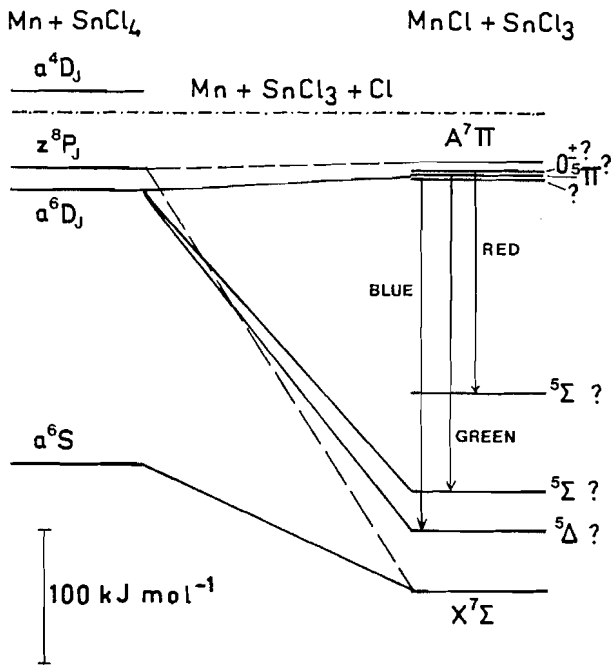

FIG. 14. Possible form of the electronic state correlation diagram for Mn + $SnCl_4$, consistent with the results obtained. The diagram is likely to be incomplete, owing to the fragmentary knowledge of the electronic spectroscopy of both MnCl and $SnCl_3$.

highly selective, i.e, the effective potential surface that leads to each observed emission must be quite distinct. Given the similarity in initial thresholds, and the likely overlap between the vibrational manifolds of the blue, green, and red states, this selectivity suggests some degree of symmetry control. From Fig.13, that would appear to require conservation of *d* electron configuration in the entrance channel, i.e., between Mn*(a^6D_J) + $SnCl_4$ and Mn^{+}*(a^6D_J) + $SnCl_4^-$, the first step to production of electronically excited Mn^+Cl^-. This can only occur if chemiluminescence results from reaction along the C_3 axis: Mn approach along any other direction would mix spatially de- generate *d* orbital configurations with the odd electron in different locations, thereby promoting more than one product state. As the reactive collision evolves, the initial configuration could be lost by mixing between different potential surfaces, but, in view of the selectivity observed, it seems most likely that the mixing will be restricted to surfaces (or vibrational manifolds) that retain the *symmetry* corresponding to the initial configuration, i.e., Σ–Σ, Π–Π, Δ–Δ, or components thereof.

The overall conclusions on energetics and state correlations are schematically summarized in Fig. 14. The term symbols of the different emitting states have been tentatively assigned, on the basis of Hayes' results, but these must be regarded as speculative, since the present work has not addressed the detailed spectroscopy. In any case, the diagram cannot be the complete picture, as no excited electronic states of $SnCl_3$ are represented and as the infrared MnCl band system has been omitted; indeed, investigations of a number of other reactions (41, 42) suggest that the infrared system connects two of the lowest-lying MnCl states. Nonetheless, Fig. 14 does at least provide a possible framework for rationalizing the current observations. It suggests, as discussed below, that the green emission ($^5\Pi? \rightarrow {}^5\Sigma?$) is produced on a surface that directly correlates with Mn*(a^6D_J) + $SnCl_4$, but conversely, that the blue and red emissions will

only result from mixing with surfaces leading to lower lying $^5\Sigma$ or $^5\Delta$ states.

3. Transition states and potential surface shapes

One of the most remarkable features of the present results is the degree to which the multiple line-of-centres model is able to fit the data. Originally developed (15) as an approximate approach to rationalizing data from reactions taking place on single potential surfaces, the model has now demonstrated its applicability to situations where many surface interactions are anticipated. This cuts across the accepted wisdom that the velocity dependence of surface crossing is significant in determining the collision-energy dependence of the cross section. The results show that, in the present cases, such dependence is predominantly discontinuous, i.e, at given line-of-centres energies, the transition state location shifts, or the efficiency of crossing changes, or a competing process begins. The yield functions would show significant curvature if the efficiency of surface crossing depended continuously on velocity.

Following the procedure outlined above, in relation to eqs. [9]–[12], we can interpret the parameters in Table 4 to derive energies and relative internuclear distances of the various critical transition states. We pursue this here with some detail not only to illustrate the possible dynamics consistent with the data, but also to prevent misconceptions and pitfalls in future applications of the procedure. Care is required since any error in determining one pair of parameters generates a comparable but opposite error in the next pair in the series. However, as stated above, subsequent pairs of parameters may well have higher precision: e.g., in the green excitation function the large uncertainty in σ_1 generates an opposite uncertainty in σ_2; but $(\sigma_0 + \sigma_1 + \sigma_2)$, and thus σ_3, are quite well defined. It turns out that most of the derived internuclear distance ratios are fairly insensitive to the uncertainties in the values of the parameters given in Table 4.

All three excitation functions seem to involve, at some energy, a shift forward in the transition state location. The green data reveal this most straightforwardly. From the parameters derived, it seems that the shift occurs at $E_s \simeq 77$ kJ mol^{-1}, and that $R_s/R_0 \simeq 1.09$. Depletion then begins at $E_1 \simeq 150$ kJ mol^{-1}, and $R_1/R_0 \simeq 1.06$; but the internuclear distance at which this takes place also shifts forward, to $R_d/R_0 \simeq 1.12$, at $E_d \simeq 245$ kJ mol^{-1}. In fact, E_s and E_d are strictly upper limits; the true thresholds could be significantly lower if the shift is also accompanied by an initial difference in functionality, i.e., $n > 1$ in eq. [7].

The red excitation function is more complex in that σ_1 is positive. As noted above, this must correspond to some new process — an increase in reaction probability, due to the opening up of a new path, and (or) a shift in the transition state location. If the latter is exclusively the case, then the parameters in Table 4 imply that the shift, to $R_s/R_0 \simeq 1.26$, occurs at $E_s \simeq 51$ kJ mol^{-1}, and is followed by a further shift, to $R_{s'}/R_0 \simeq 1.53$, at $E_{s'} \simeq 163$ kJ mol^{-1}. Depletion likewise begins at $E_2 \simeq 195$ kJ mol^{-1}, and $R_2/R_0 \simeq 1.46$, and shifts forward to $R_d/R_0 \simeq 1.55$ at $E_d \simeq 231$ kJ mol^{-1}. These seem excessively large changes.

On the other hand, if the rise at ~100 kJ mol^{-1} is caused by the opening up of a new path, then the subsequent rapid fall (σ_2) and secondary rise (σ_3) indicate that it must at least have the same entrance channel as the original path. In the extreme case of an increase in reaction probability *at the same internuclear distance*, then the excitation function in the range $E_T \sim$ 100–195 kJ mol^{-1} should be written as

$$[15a] \quad \sigma(E_T) = \pi(P_0 R_0^2(1 - 22/E_T) + \pi(P_1 - P_0)R_0^2(1 - 100/E_T)$$

$$[15b] \quad = \pi(P_1 R_0^2(1 - 100/E_T) + \pi(P_0 R_0^2(78/E_T)$$

where $P_0 < P_1 \leq 1.0$. In terms of Figs. 8 and 9, reaction can now be visualized as occurring with probability P_1 at low impact parameters, and with probability P_0 at high impact parameters. From Table 4, there will then still be a forward shift in transition state location at $E_s \simeq 164$ kJ mol^{-1}, but now to $R_s/R_0 \simeq 1.22$, a similar value to that found for the green data. The relative internuclear distances for depletion are now $R_2/R_0 \simeq 1.16$ and $R_d/R_0 \simeq 1.23$.

Such behaviour does, however, have consequences for the subsequent detail of the excitation and yield functions. Instead of a single break at $E_T = E_3$, there should be a first upward break when

$$[16] \quad \pi R_s^2(E_T - 164) = \pi R_0^2(E_T - 100)$$

i.e., when reaction at R_s with probability P_1 starts to overtake reaction at R_0 with probability P_0; and then a second, but much smaller, upward break should occur when

$$[17] \quad \pi R_s^2(E_T - 164) = \pi R_0^2(E_T - 22)$$

i.e., when reaction at R_0 is completely overtaken. These collision energies turn out to be ~290 and ~460 kJ mol^{-1}, respectively. There is no clear evidence for such thresholds, whether from the excitation function, from the extrapolated yield plot (not shown), or from the residual plot in Fig. 12. However, as collision energy spread would broaden the threshold behaviour, it is conceivable that the changes may lie within the noise on the data.

It seems more likely, however, that any increase in reaction probability should also be accompanied by a shift inwards in the transition state location — i.e, the system has sufficient line-of-centres energy to penetrate to, say, an avoided crossing that allows a greater probability of reaching the exit valley. Equation [15*a*] should then be written

$$[18] \quad \sigma(E_T) = \pi P_0 R_0^2(1 - 22/E_T) + \pi(P_1 - P_0)R_1^2(1 - 100/E_T)$$

where $R_1 < R_0$. From σ_0 and σ_1 we then get $(P_1/P_0 - 1)(R_1^2/R_0^2) \simeq 0.58$, i.e., $P_1/P_0 < 1.58$. In this case, the yield function should still show two upward breaks at higher collision energy, but, depending on the relative magnitudes of P_0, P_1 and R_0, R_1, R_s, these two could again be indistinguishable (within the noise) from the single break found in the analysis.

This last possibility might well apply if, as suggested above, reaction takes place on a potential surface that does not directly correlate with the emitting MnCl* state. At low collision energies, chemiluminescence would then only occur as a result of exit channel interactions or overlap of vibrational manifolds between the directly produced, and the observed, states. At a given collision energy, the mixing — whether in the potential surfaces or in the MnCl product — would become more efficient; and then, at higher energies still, there would be the shift forward in the transition state location, due to restricted access to the exit valley, as found for the green emission. If that is indeed the case, then the rela-

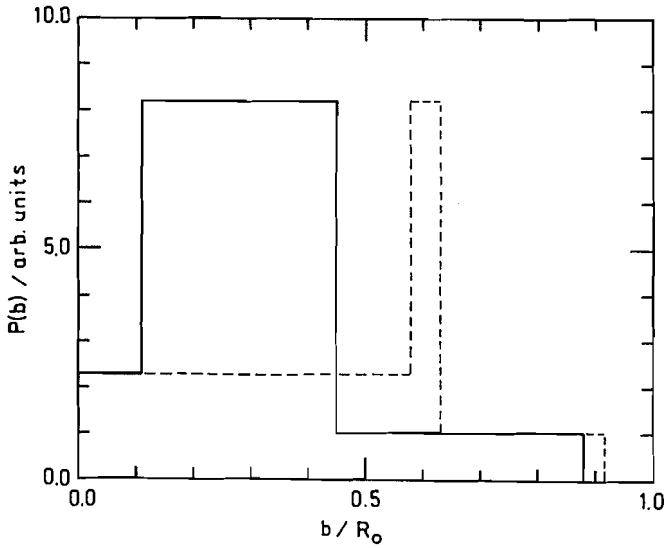

FIG. 15. Derived shape of the opacity function for production of blue MnCl chemiluminescence, calculated for $E_T = 45$ kJ mol^{-1} (solid line) and $E_T = 60$ kJ mol^{-1} (dashed line). The horizontal axis is normalized to unity at $b = R_0$, the internuclear distance corresponding to the transition state on the potential surface.

tive simplicity of the green excitation function suggests that, as illustrated in Fig. 14, it perhaps reflects reaction on a potential surface that correlates directly with the MnCl* emitting state.

The blue yield function is the most complex of all three in Fig. 7. The rise and fall-off in the narrow energy range $E_T \sim$ 36–40 kJ mol^{-1} is so sharp that an experimental artefact was originally suspected; however, since the behaviour appears on each of the data subsets, it must be considered genuine. In view of this, the further rapid depletion from ~158 kJ mol^{-1}, and the subsequent rise from ~393 kJ mol^{-1}, also present a problem: the former implies that the transition state for reaction has shifted forward, but the latter functionality, added to the other positive terms, suggests $E_s \sim$ 60–80 kJ mol^{-1}, i.e., above the ~40 kJ mol^{-1} initial threshold for depletion!

This conundrum can, however, be resolved if we consider that the changes between ~36 and ~40 kJ mol^{-1} correspond to first an increase, then a decrease, in reaction probability with increasing line-of-centres energy. Very crudely, P can then be regarded as taking relative values $\sim\sigma_0$:$(\sigma_0 + \sigma_1)$:$(\sigma_0 + \sigma_1 + \sigma_2)$, i.e., ~1.0:(8.5 ± 1.5):(2.3 ± 0.3), from thresholds ~10, 36, and 40 kJ mol^{-1}, respectively. As E_T increases, $P(b)$ will then assume, equally crudely, the form illustrated in Fig. 15, becoming finally a step with a "spike" superimposed on it. If P remains at the final, low-impact parameter, value when the reaction transition state shifts forward, then, as in Fig. 9, the effect on $\sigma(E_T)$ will not immediately be obvious. At higher energies there should, as discussed for the red emission, be some changes in the slopes of the excitation and yield function plots when reaction at R_s overtakes both the spike and the lower reactivity beyond it; but, because the initial thresholds are in such a narrow energy range, such behaviour could easily be lost in the noise and collision energy spread, and be indistinguishable from the rise threshold at ~393 kJ mol^{-1}.

On this basis, we can write, for the excitation function in the range 40–158 kJ mol^{-1}, the effective single expression

$$[19a]\quad \sigma(E_T) = (0.44 \pm 0.07)\{1 - (10 \pm 2)/E_T\} + (3.40 \pm 1.18)\{1 - (36 \pm 2)/E_T\} - (2.88 \pm 1.26)\{1 - (40 \pm 1)/E_T\}$$

$$[19b]\quad = (0.96 \pm 0.015)\{1 - (12.5 \pm 1.6)/E_T\},$$

the low overall uncertainties in eq. [19*b*] resulting from direct modelling of the yield function in the range $E_T^0 \sim$ 40–100 kJ mol^{-1}. Combination with the $k = 4$ rise term then leads to the conclusion that $R_s/R_0 = 1.16 \pm 0.02$ at $E_s \simeq 111$ kJ mol^{-1}, a similar shift to that deduced for the green and red emissions. The relative internuclear distance for depletion at ~158 kJ mol^{-1} is then $R_d/R_0 = 1.17 \pm 0.02$, again of the same order.

The unusual form of $P(b)$ displayed in Fig. 15 begs the question of whether it is at all physically reasonable. Such a rapid change in reaction probability with impact parameter, or collision energy, is in fact characteristic of a sharp "resonance," of the sort that has been much discussed, from the theoretical standpoint, for H-atom transfer reactions (52). However, the present reaction deals with Cl-atom transfer, and the resonances that are found in 3-dimensional quantal calculations are much narrower than the present spike, and in any case predicted to be washed out by the averaging over all partial waves leading to reaction (52).

One recent experimental result does, however, show that data of the type presented here may not be that unusual. In a high-resolution measurement of the reaction Ca*($^1D_2$) + HCl → CaCl*(A, B) + H, González Ureña and co-workers (53) have found three clear, but progressively diminishing, steps in $\sigma(E_T)$ in the range E_T = 18.5–23.5 kJ mol^{-1}. The authors suggest that the steps are associated with the opening up of internal transition states, corresponding to bending motion, that become available as total energy increases.

It is not the function of the present paper to comment on the Ca*($^1D_2$) + HCl results. However, here there is no definitive evidence for more than one step, although such behaviour might well be hidden by the noise, especially if the second, third, etc. steps are much smaller than the first. In addition, whatever the number of steps, transition state bending motion is unlikely to be the cause in such a large system as Mn + $SnCl_4$. A possible explanation, which is consistent with the deduction above that reagents and observed products are unlikely to correlate directly, is that there is a narrow range of collision energies where there is strong mixing between the potential surface initially sampled, and that leading directly to blue chemiluminescence. Ultimately, as with the red excitation function, the increase in reaction probability is relatively modest; but what is different here is the high efficiency of mixing in a narrow energy range. The situation parallels the sort of predissociation observed in electronic spectroscopy, where a dissociative potential curve mixes with the bound curve of the upper electronic state of the transition. Here, however, the mixing leads to an enhanced access to the blue MnCl product, not to dissociation.

Whatever the exact route from reactants to products, it is clear that the effective potential surfaces for these chemiluminescent reactions differ significantly from those for ground-state alkali and alkaline earth atoms with $SnCl_4$ (21–27). In the latter cases, angular scattering measurements suggest that reaction proceeds on a surface with a significant potential well, corresponding to a stable $M^+SnCl_4^-$ intermediate; but here the

interactions appear to be completely repulsive, with no indications of a well before the exit transition state (i.e., $n = 1$ in eq. [7] always). This result is at first surprising, considering that $Mn^*(a^6D_J)$ atoms should have an ionization potential of 7.43 – 2.15 = 5.28 eV, i.e., comparable to that of $Na(3^2S)$ and $Ba(6^1S)$. However, this corresponds to the process $...3d^64s^1 \rightarrow ...3d^54s^1(Mn^+, a^5S)$, whereas the discussion above has suggested that, for chemiluminescence, the *d*-orbital configuration is initially sustained. In fact, the excitation energy of the $...3d^6$, a^5D_J state of Mn^+ is 1.8 eV (174.5 kJ mol^{-1}) (54), so the ionization potential that we need to take is 7.08 eV. Even allowing for a significant $SnCl_4$ electron affinity, it is clear that the $Mn^*(a^6D_J) + SnCl_4$ and $Mn^{+*}(a^5D_J) + SnCl_4^-$ potentials will cross only at very short internuclear distances, i.e., the interaction is likely to be quite repulsive. Indeed, while the red and blue emissions seem to arise from mixing between potential surfaces or product state manifolds, it is quite conceivable that the thresholds we are observing are true activation barriers, even for those lower-lying product states. If in addition there is a significant stretching of the Sn—Cl equilibrium bond length on electron transfer, as might be expected, then we can see that restricted access to the exit channel might well also arise, as suggest above.

Conclusions

Our analysis of the shapes of the excitation functions for the chemiluminescent Mn + $SnCl_4$ reaction provides us with interesting insights into the potential surfaces involved, and their interactions. In all cases it appears that $Mn^*(a^6D_J)$ atoms are the reagents, but the uniqueness of each excitation function suggests that there is a strong symmetry control. This means that, in the entrance channel at least, the symmetry corresponding to the spatial configuration of the odd *d* electron must be retained, and chemiluminescence result from approach of the Mn atom along the C_3 axis of $SnCl_4$.

In two cases, red and blue, if not all, the luminescing MnCl* state appears to be produced on a surface that does not correlate directly with the reagents. This result is consistent with predictions based on the known, but fragmentary, MnX spectroscopy, and comparison with MnH and FeO, which suggests a large number of relatively low-lying states. At the lowest energies, the red and blue luminescences most probably derive from mixing of vibrational manifolds of MnCl* *states* of the same symmetry, whereas, at higher energies, the mixing appears to be between *surfaces* with Mn^+ configurations of the same symmetry.

In all cases the transition state for reaction seems to shift forward, into the approach coordinate, with increasing collision energy. In the simplest terms, we might consider that this is a case of the barrier crest moving from the exit valley to the entrance valley. However, the notion of barrier crest requires some care when dealing with interacting potential surfaces. At low energies the crest for production of the red and blue emissions, at least, may simply correspond to the threshold for the onset of exit channel mixing. At higher energies, the mixing appears to be between potential surfaces; and since there is no evidence for a well before the transition state, the interaction is likely to occur within the repulsive wall of both potentials. In this circumstance, the barrier crest cannot be represented simply as a saddle point on a contour plot of potential energies, especially as trajectories may double back on themselves once they have made the transition between the surfaces. Even when, at higher energies still, the transition state shifts forward, the concept of barrier crest remains problematic, as the effective barrier no longer lies on the minimum energy path. In both these circumstances, the dynamics are likely to be quite different from those on the relatively simple potential surfaces employed in John Polanyi's pioneering trajectory studies. In particular, there should be changes in the observed dynamics when the transition state shifts or when depletion begins. It would therefore be intriguing to disperse the chemiluminescence from the Mn + $SnCl_4$ reaction, and determine the MnCl* vibrational distributions as a function of collision energy.

Received July 5, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

S. Uma and Puspendu Kumar Das. Can. J. Chem. **72**, 865 (1994).

The relative quantum yields, ϕ^*, for the production of $I^*(^2P_{1/2})$ at 266, 280, and ~305 nm are reported for a series of primary alkyl iodides using the technique of two-photon laser-induced fluorescence for the detection of $I(^2P_{3/2})$ and $I^*(^2P_{1/2})$ atoms. Results are analyzed by invoking the impulsive energy disposal model, which summarizes the dynamics of dissociation as a single parameter. Comparison of our data with those calculated by a more sophisticated time-dependent quantum mechanical model is also made. Near the red edge of the alkyl iodide *A* band, absorption contribution from the $^3Q_1$ state is important and the dynamics near the $^3Q_0$–$^1Q_1$ curve-crossing region seem to be influenced by the kinematics of the dissociation process.

S. Uma et Puspendu Kumar Das. Can. J. Chem. **72**, 865 (1994).

On a déterminé les rendements quantiques relatifs, ϕ^*, pour la production de $I^*(^2P_{1/2})$ à 266, 280 et environ 305 nm, pour une série d'iodures d'alkyles primaires; pour ce faire, on a utilisé la technique de fluorescence à deux photons induite au laser pour la détection des atomes de $I(^2P_{3/2})$ et de $I^*(^2P_{1/2})$. On a analysé les résultats en invoquant le modèle de disposition de l'énergie impulsive qui résume les dynamiques de dissociation en un seul paramètre. On a effectué une comparaison de nos résultats avec ceux calculés à l'aide d'un modèle plus sophistiqué de mécanique quantique dépendant du temps. Au niveau de la limite du rouge de l'absorption de la bande *A* de l'iodure d'alkyle, la contribution de l'état $^3Q_1$ est importante et la dynamique près de la région du croisement de la courbe $^3Q_0$–$^1Q_1$ semble être influencée par la cinématique du processus de dissociation.

[Traduit par la rédaction]

Introduction

Photodissociation dynamics of simple alkyl iodides in the *A* band arising from $n \rightarrow \sigma^*$ ($X \rightarrow A$) transition has been of interest over the last two decades. This is mainly because alkyl iodides offer an unique opportunity to understand key factors such as radical size (CH_3, C_2H_5, C_3H_7, etc.), substitution (CH_3, CF_3, etc.), and structure (primary, secondary, and tertiary) that affect their photodissociation dynamics. Subsequent to the measurement of magnetic circular dichroism (MCD) spectra of CH_3I by Gedanken and Rowe (1), several groups (2–16) came up with a variety of techniques to investigate the dynamics of alkyl iodide photodissociation. Riley and Wilson (2) and Dzvonik et al. (3) simultaneously carried out photodissociation experiments on CH_3I using the time-of-flight (TOF) technique. From the results, they concluded that at 260 nm the transition dipole is predominantly parallel to the C—I bond ($^3Q_0 \leftarrow {}^1A_1$) and the dissociation leads to $I(^2P_{1/2})$ (will be called I* from now) and $CH_3^{\cdot}$ radicals as major products. Later Sparks et al. (4) carried out another TOF experiment on CH_3I at 266 nm; they extracted the ν_2 (umbrella mode of CH_3) vibrational distribution of CH_3 fragments from the spectrum and found that it peaked at $v = 2$. Hermann and Leone (5) measured the infrared emission from CH_3 radicals produced from CH_3I at 248 and 266 nm. Their results at 266 nm agreed well with those of Sparks et al. (4). At 248 nm the vibrational distribution was again found to peak at $v = 2$, which differed from the theoretical results of Shapiro and Bersohn (6) who had predicted the product distribution maximum at $v = 4$ at that wavelength. In 1984, a new TOF experiment on methyl iodide at 248 nm was carried out by van Veen et al. (7). They found two peaks in the spectrum corresponding to $I(^2P_{3/2})$ (will be called I from now) and I* products and both the convoluted vibrational distributions peaked at $v = 2$. Brewer et al. (8) measured the quantum yield of I* production for a series of alkyl iodides at 248 nm using a two-photon laser-induced fluorescence (TPLIF) detection scheme for both I and I* atoms. Photofragmentation of CH_3I at 248 nm was studied by Barry and Gorry (9); they observed the ν_2 vibrational distribution to peak at $v = 2$ for the I* channel, and to extend up to $v = 8$ for the I channel. Using the TPLIF technique, Godwin et al. (10) measured the quantum yield for production of I and I* for a series of alkyl iodides at 248 nm. They observed that the I* yield or the dynamics of I* production varies with the alkyl radical size, substitutions on α- and β-carbon atoms, and structure. Using a diode laser to probe the dissociation dynamics of CH_3I at 266 nm, Hess et al. (11) measured the I* quantum yield as 0.73 ± 0.04. At 229.4 nm Penn et al. (12) also found that I* is the major product from CH_3I. In 1989 Ogorzalek Loo et al. (13) looked again at the vibrational distribution of CH_3 at 266 nm using the multiphoton ionization technique for detecting CH_3 fragments in their vibrational states. They predicted that $v = 0$ is the most populated umbrella vibration in CH_3 fragments, in disagreement with the results obtained by Sparks et al. (4). The authors (13) ascribed the difference to contamination by vibrationally excited CH_3I in the latter experiment. The I* yield increases with increasing vibrational excitation in the methyl fragment and the estimated net yield is 0.56, which is lower than the value measured by other direct techniques.

In this work we report ϕ^*, the relative quantum yield for I* production (i.e., $\phi^* = [I^*]/([I] + [I^*])$), for a series of simple alkyl iodides at three different dissociation wavelengths: 266, 280, and ≃305 nm. The resulting atomic fragments $I(^2P_{3/2})$ and $I^*(^2P_{1/2})$ have been probed directly using the TPLIF technique (8). At ≃305 nm I and I* atoms were produced by the same pulse that was used for probing. From now on the experiments at 266 and 280 nm wavelengths will be referred to as pump–probe experiments and that at ≃305 nm as a single laser experiment. We discuss our results in the light of a classical Landau–Zener model and compare them with recent theoretical and experimental results obtained by other groups.

TABLE 1. Relative quantum yield (ϕ^*) of I* production at different dissociation wavelengths

Molecule	ϕ^* ≃305 nm	ϕ^* 280 nm	ϕ^* 266 nm
Methyl iodide	0.43 ± 0.01	0.69 ± 0.02	0.79 ± 0.02
Ethyl iodide	0.39 ± 0.02	0.60 ± 0.02	0.73 ± 0.02
n-Propyl iodide	0.35 ± 0.02	0.56 ± 0.02	0.66 ± 0.02
n-Butyl iodide	0.30 ± 0.02	0.50 ± 0.03	0.64 ± 0.03
Isobutyl iodide	0.35 ± 0.02	0.56 ± 0.03	0.71 ± 0.01

Experimental setup

The apparatus used in our experiments has been described in detail elsewhere (17). Briefly, a sample gas is contained at 50–70 mTorr (1 Torr = 133.3 Pa) in a stainless steel cell that is pumped continuously by a diffusion pump and the pressure monitored by an MKS Baratron gauge (model 122A). The pump and the probe lasers are crossed perpendicular inside the chamber and the signal is detected at the third perpendicular direction. The fourth harmonic of a Nd-YAG laser (DCR-3G, Spectra Physics) was used for dissociation at 266 nm (≃19 mJ/pulse) whereas the second harmonic of a Nd:YAG pumped dye laser was employed for the photolysis experiments at 280 nm (≃5 mJ/pulse). A typical delay of 400 ns between the pump and the probe lasers was maintained to avoid collisional relaxation of the nascent fragments. The resulting iodine atoms were detected by the technique of TPLIF using another doubled dye laser ("probe" laser) output (≃0.5 mJ/pulse). In the case of ≃305 nm dissociation, the probe laser alone was used but with tight focussing by a 5-in. focal length Suprasil lens at the center of the cell. The VUV fluorescence was detected through a MgF_2 window by a solar blind PMT (Thorn EMI, model 9423B). The space between the window and the PMT was continuously flushed with dry nitrogen. The signal was amplified (×25) by a preamplifier (SRS 440) and averaged in a gated boxcar averager (SRS 250), the output of which was fed to a strip-chart recorder for display. The alkyl iodides were obtained commercially or prepared by standard procedures. All the iodides were decolorized with 10% sodium bisulfite solution, dried on anhydrous $MgSO_4$, and fractionally distilled prior to each experiment.

Results

The VUV emission spectra were recorded by scanning the probe laser across the two-photon absorption lines of I (304.7 nm) and I* (306.7 nm). Typical TPLIF spectra of I* and I are shown in Fig. 1. The relative quantum yield, ϕ^*, was determined directly from the spectra. Here we took the experimental signal intensities S and S^* as being directly proportional to [I] and [I*], respectively. Since our ϕ^* value of 0.79 for CH_3I at 266 nm agrees very well with the same (0.76) found by Riley and Wilson (2) by photofragment spectroscopy, no calibration was done to our raw data.

The quantum yields for I* production obtained at three different wavelengths are listed in Table 1. For the pump–probe experiments, the signal varies linearly with the pump laser power (Fig. 2*a*). For all pump–probe experiments care was taken to reduce the probe-alone contribution to ≤2%. In the single laser experiment the very small difference in the absorption coefficients at 304.7 and 306.7nm is neglected. A power dependence study shows that three photons are involved in the process (Fig. 2*b*), implying that one photon is utilized for the dissociation and two subsequent photons for probing the iodine fragments.

Discussion

The *A* band in the absorption of alkyl iodides arising from a

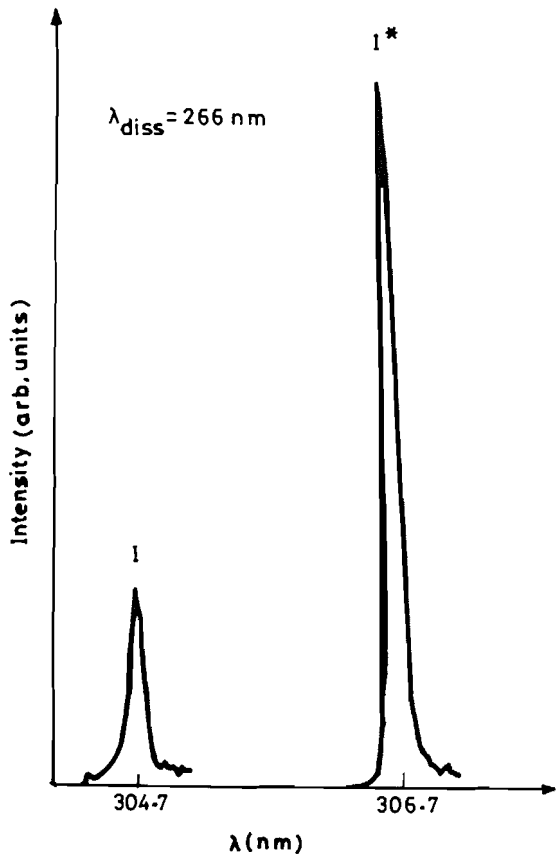

FIG. 1. Typical TPLIF spectra of I and I* from CH_3I dissociation at 266 nm.

$n \rightarrow \sigma^*$ transition is strongly localized on the C—I bond. Gedanken and Rowe (1) resolved that *A* band using MCD. The three possible transitions are labelled according to Mulliken (18) as $^1Q_1 \leftarrow N$, $^3Q_1 \leftarrow N$, and $^3Q_0 \leftarrow N$. The first two transitions are perpendicular transitions leading to the formation of I, whereas the third is a parallel transition that leads to I*. Figure 3 displays a schematic one-dimensional potential energy diagram showing all these states. The electronic transition at 266 and 280 nm is mainly to the $^3Q_0$ state but a significant amount of I atoms (Table 1) are produced by a curve-crossing mechanism from $^3Q_0$ to $^1Q_1$. At these wavelengths no significant contribution is made by the $^3Q_1$ state, as pointed out by Gedanken and Rowe (1). The energy disposal at these two wavelengths may be best described by a simple classical model suggested by Godwin et al. (10). In their model the I* quantum yield is described by the probability of staying on the initial $^3Q_0$ state as,

$$[1] \quad \phi^* = \exp(-2\pi V_{12}^2/\hbar|\Delta F|v) = \exp(-\zeta/v)$$

where V_{12} is the coupling term between the $^3Q_0$ and $^1Q_1$ states, ΔF is the difference in their gradients at the crossing point, and v is the velocity through the crossing point. Further, they grouped the unknowns V_{12} and ΔF into one parameter to determine if it remains the same for a series of related alkanes. Hence the problem is simplified to the extent of finding the velocity at the crossing point. For this the translational energy (E_t) at the asymptotic limits is calculated using a quasidiatomic model and is given by

$$[2] \quad E_t = (\mu_{CI}/\mu_{RI})E_{avl}$$

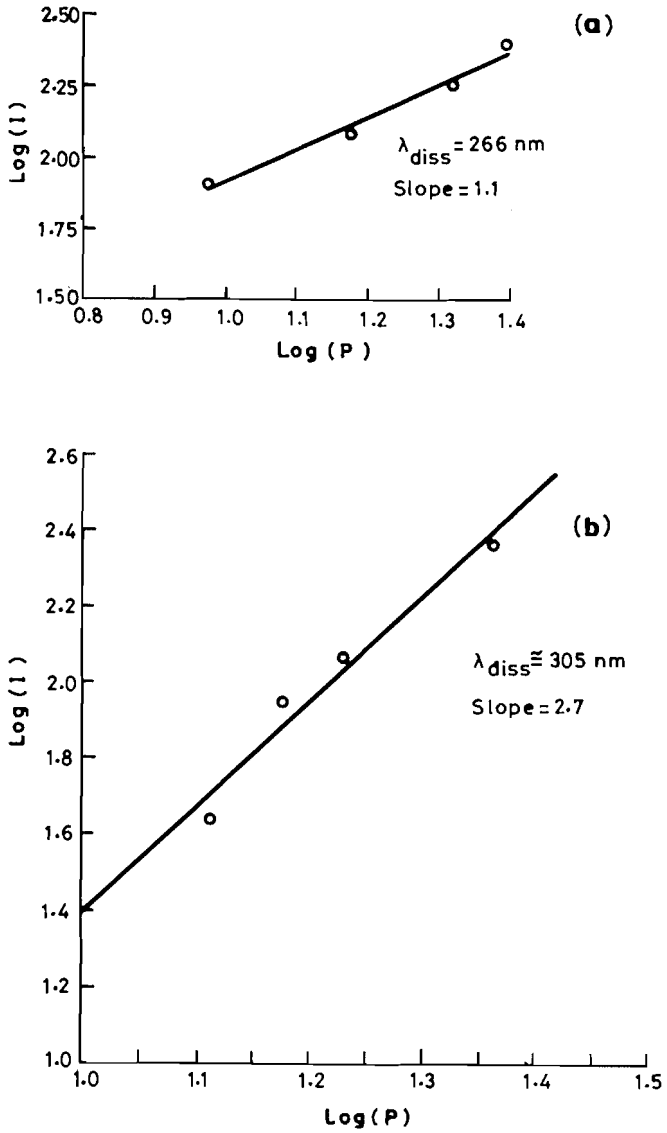

FIG. 2. (*a*) A log–log plot of the pump laser (266 nm) power and the iodine atom signal intensity for the pump–probe experiment. (*b*) A log–log plot of the probe laser power and the iodine atom signal intensity for the single laser experiment. The slope gives the laser power dependence of the signal in each case.

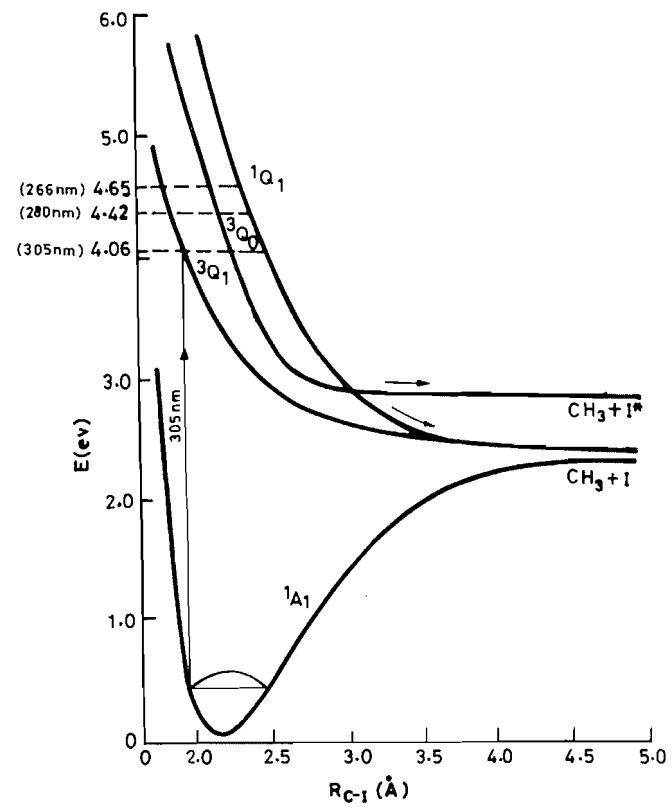

FIG. 3. Schematic potential energy surfaces for the alkyl iodides showing only the important states.

where μ_{CI} is the reduced mass of C and I, μ_{RI} the reduced mass of the radicals R and I, and E_{avl} is the available energy, which is $h\nu - D_0^0 - E_{so}$ with ν being the excitation frequency, D_0^0 the dissociation energy of the C—I bond at 0 K, and E_{so} is the iodine spin-orbit excitation energy. Now E_t must be linearly related to the translational energy at the crossing point and the proportionality constant, if any, may again be absorbed within the parameter ζ. Thus the final expression for ϕ^* becomes,

$$[3] \quad \phi^* = \exp\left[-\mu_{RI}\zeta/(2\,\mu_{CI}\,E_{avl})^{1/2}\right]$$

We have used this model at 266 and 280 nm and find reasonable fits to the experimental points with ζ being 670 m/s and 970 m/s, respectively (Figs. 4*a* and 4*b*). It is worth noting that although a single parameter describes the dynamics on the upper potential energy surfaces, most of the actual information (i.e., the coupling between the potential energy surfaces and the C—I bond length at the crossing point) is actually hidden in this parameter, as pointed out by Lao et al. (14). However, a detailed model to describe the dynamics will be complicated and computationally demanding. Also the predictive power of all such calculations will rely on the accuracy of the potential energy surfaces used. The quantum yield of I* at ~305 nm was not treated in this manner since at this wavelength I is the major product, which cannot be explained on the basis of the initial excitation to the $^3Q_0$ state. But if we look carefully at the different components of the *A* band, this is not at all surprising. Similar to the mechanism proposed by Hwang and El-Sayed (19, 20) in the case of CF_3I dissociation, at this wavelength the initial absorption in alkyl iodides is not mainly confined to the $^3Q_0$ state. The low-energy $^3Q_1$ state carries a significant transition strength (since the total absorption cross section at this wavelength is very small) and produces mainly the ground state I product through a direct dissociation mechanism. Therefore, production of I atoms at this wavelength may be attributed to the direct dissociation from the $^3Q_1$ state as well as curve crossing between the $^3Q_0$ and $^1Q_1$ states. However, it is clear from Table 1 that the extent of these two mechanisms varies as one goes from methyl to isobutyl iodide.

The trend reversal in the ϕ^* values in going from *n*-butyl iodide to isobutyl iodide may be explained qualitatively by considering the increased inductive and hyperconjugative effects in the latter. Since the excitation is localized on the C—I bond, the electronic charge distribution around this bond is likely to affect the dynamical outcome. V_{12} is unlikely to change in the family of primary alkyl iodides since it is directly proportional to the iodine spin-orbit splitting. But depending on the net charge on the β-carbon atom, the internuclear distance where the crossing occurs may be altered. Our results indicate a higher curve-crossing probability (i.e., lower I* yield) for *n*-butyl iodide than

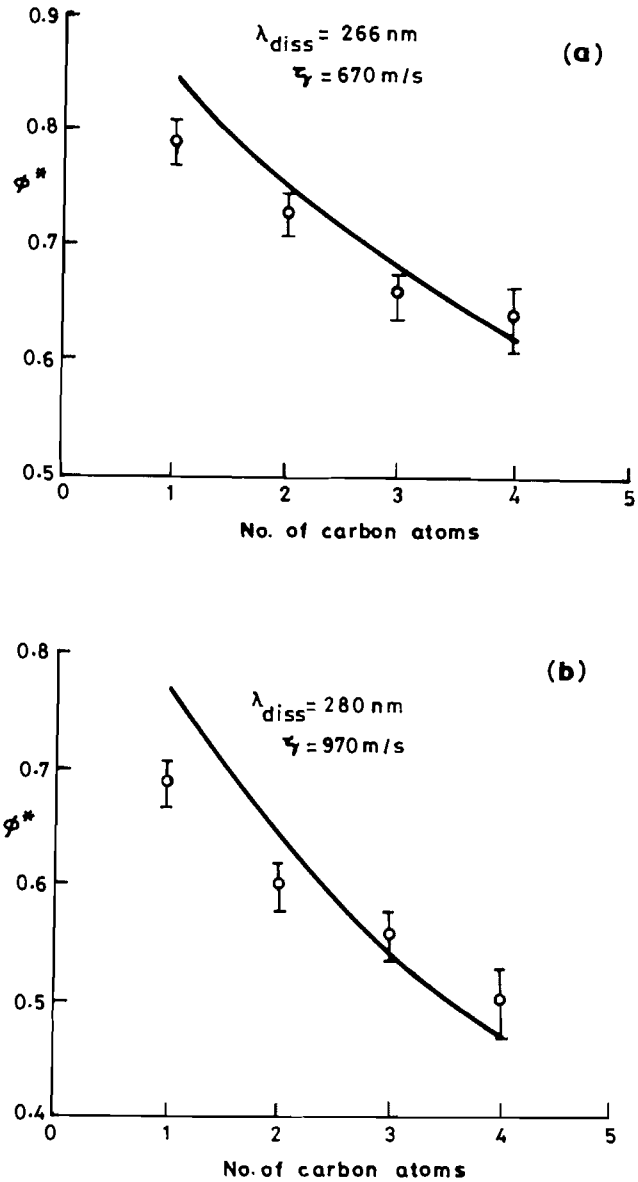

FIG. 4. I* quantum yields at (*a*) 266 nm, and (*b*) 280 nm as a function of number of carbon atoms in the alkyl radical. Solid lines are fits obtained from eq. [3] with ζ values shown on the respective curves.

for isobutyl iodide assuming similar crossing velocities for both.

Recently Guo and Schatz (21–23) carried out three-dimensional quantum mechanical calculations based on the fast Fourier transform method developed by Kosloff and Kosloff (24). Using the potential energy functions and the nonadiabatic coupling between the $^3Q_0$ and $^1Q_1$ states from Yabushita and Morokuma (25), they predicted the I* quantum yield as a function of dissociation wavelength. We have compared our experimental I* yields from CH_3I with Guo's (23) calculations (Fig. 5) and find that the trend is better reproduced when initial excitation is only to the $^3Q_0$ state. However, in his calculation the internal energy distribution in the methyl fragments is better reproduced when excitation to both $^3Q_0$ and $^1Q_1$ states is considered. We find that around 266 nm (near the absorption maxima of the *A* band) the I* yield reaches a maximum and drops much faster at longer wavelengths. The formation of I dominates at ≃305 nm, which is in apparent contradiction to the calculated results (23),

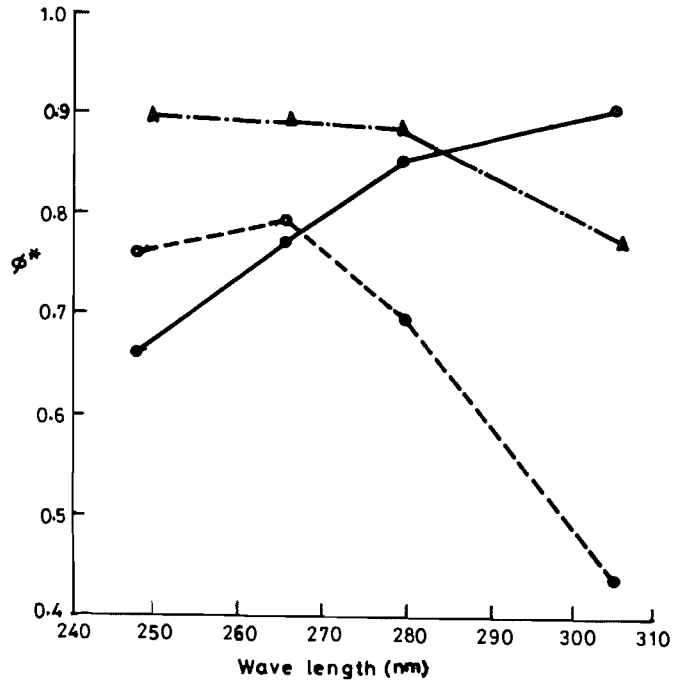

FIG. 5. Comparison of ϕ^* obtained from a full three-dimensional quantum mechanical calculation (adapted from ref. 23) with initial excitation to the $^3Q_0$ state (dot-dash line), with initial excitation to both $^3Q_0$ and $^1Q_1$ states (solid line), and experiments (dotted line). The experimental ϕ^* values at 248 nm are taken from ref. 8.

which predict a much higher I* yield at that wavelength. This discrepancy may be attributed to the fact that the contribution of the $^3Q_1$ state, which is important above 300 nm, has not been included in the above model. Insofar as the effects of substitution, size, and structure on the dynamics of primary alkyl iodide series in the ultraviolet are concerned, treatment by a full three-dimensional sophisticated model would be difficult and a semiclassical model with an accurate potential energy function might be an easier alternative to obtain a good dynamical picture for these molecules.

Conclusion

From the determination of the I* yields at ≃305-, 280-, and 266-nm dissociation of a series of alkyl iodides, it appears that the iodine atom in the spin-orbit excited state is the major product over the *A* band of alkyl iodides except near the red wing. Substantial contribution from the low-energy transition, $^3Q_1 \leftarrow N$, cannot be *undermined* at ≃300 nm absorption. Also, substitutions at the α- as well as the β-carbon atoms will alter the dynamics at the upper potential energy surfaces slightly.

Although a classical impulsive model is useful in describing the dynamics in one dimension, most of the details are lost in such a treatment. An appropriate full three-dimensional quantum mechanical model that contains contributions from all three excited states (i.e., $^1Q_1$, $^3Q_0$, and $^3Q_1$) may better explain the photodissociation dynamics in these molecules. What are more difficult to understand are the effects of substitution, size, and structure of the alkyl radicals on the coupling between the $^3Q_0$ and $^1Q_1$ states and the C—I distance where these two states cross. We hope that future work in this direction will better answer some of these questions.

The MAPDESS, a multi-angle-detector electron scattering spectrometer, has been adapted to electron ejection measurements. A study of autoionization from Rydberg states has been carried out for the neutral linear molecule CO_2 in the continuum region 15–19 eV by low-energy electron impact. Observations have been made of structure due to excitation of these states by slow electron scattering and their decay by ejection of electrons. A multi-angle parallel detection technique has been used and this has enabled some CO_2 autoionizing states resulting from non-dipole transitions to be observed clearly. The major features appearing in the ejected electron spectra of CO_2 have tentatively been classified and (or) assigned in terms of autoionization to the ground ionic state ***X***, from highly excited electronic states corresponding to the "Tanaka progression I" and "Tanaka–Ogawa" Rydberg series converging to the ionic ***A*** state, as well as from the Henning "sharp" and "diffuse" series, along with the forbidden $np\sigma_u$ series, converging to the ***B*** state. In addition to the features already known, new features have been observed, and they seem to be rather sensitive to electron impact energies employed. Strong relative intensity variations are observed at the different impact energies, and marked angular effects are also found in the ejected electron spectra.

Le MAPDESS, un spectromètre à détection multiple conçu pour la diffusion différentielle d'électrons, a été utilisé pour des mesures d'électrons éjectés par impact d'électrons. Nous avons réalisé une étude de l'autoionisation de la molécule linéaire CO_2 impliquant les états de Rydberg situés dans la région 15–19 eV. Les spectres obtenus reflètent l'excitation de ces états par collisions d'électrons lents et leur désexcitation par l'éjection d'électrons. Grâce à la technique utilisée impliquant des électrons projectiles lents et la détection en parallèle à angles multiples, il est possible d'observer certains états autoionisants résultant de transitions non dipolaires. Les principales singularités se manifestant dans les spectres d'électrons éjectés font l'objet de classements et d'attributions en termes de l'autoionization vers l'état fondamental ***X*** de l'ion, à partir des états correspondant à la progression I de Tanaka et des séries de Rydberg de Tanaka–Ogawa convergeant vers l'état ***A*** de l'ion, ainsi que des séries «sharp» et «diffuse» de Henning et de la série interdite $np\sigma_u$ convergeant vers l'état ***B***. De nouvelles singularités particulièrement sensibles à l'énergie d'impact sont observées. Suivant l'énergie d'impact, de grandes variations relatives d'intensité sont observées et des effets très marqués de dépendance angulaire se manifestent dans les spectres d'électrons éjectés.

1. Introduction

The ubiquitous carbon dioxide molecule has historically attracted substantial attention in molecular physics and life sciences because of its abundance and importance in planetary atmospheres and living systems. In particular, spectroscopists and theorists have long been interested in CO_2 as a prototype for photon/electron–molecule collision studies in linear triatomic molecules. Today, CO_2 has in many ways become the paradigm of a single polyatomic molecule in molecular spectroscopy.

The valence electronic structure of CO_2, in the energy region 7–20 eV, has been the subject of considerable experimental investigation by various techniques, such as photon absorption (1–4), photoelectron spectroscopy (5–7), photoionization efficiency spectroscopy (8–10), and electron impact spectroscopy (11–15). Both photoionization (8) and electron energy loss (15) spectra of CO_2 have revealed rich autoionization structures in the first 8 eV above the lowest ionization onset. Some of the structures have been identified as highly excited Rydberg states (4, 15, 16) (e.g., "Henning diffuse" and "sharp" series converging to $B^2\Sigma_u^+$, $v = 0$, ionic state of CO_2^+ (1, 2)), whereas the origin of others remains a mystery. There is now tangible evidence that autoionization can make a major contribution to the ionization cross section for molecules, especially at low energies just above the ionization energy (10). This is particularly remarkable in the near threshold region of the total photoabsorption and photoionization cross sections for diatomic and small polyatomic molecules. For the former, the autoionization processes can in practice dominate the total ionization picture (17, 18).

Although the autoionizing states of CO_2 in the energy region of 15–19 eV have been obtained by various means (2, 3, 8, 12, 18) and studied carefully by optical (6, 19) and electron impact (15) excitation, it is still fair to state that some of the autoionizing features unveiled by those electron spectroscopies mentioned above have not yet been assigned firmly. Against this background of experimental activity, it is worthwhile to reexamine this energy sector using a different approach, such as ejected electron spectroscopy, in which the ejected electrons of autoionization are energy analyzed directly. This complementary information may help to clarify the previous investigations and the mechanism of autoionizing processes in CO_2. It is this consideration as well as a long-standing interest in low-energy electron impact spectroscopy of linear triatomic molecules that has motivated the present study.

Despite a substantial amount of work on CO_2 by means of various spectroscopies for more than half a century, no ejected electron spectroscopy of CO_2 has, to our knowledge, been reported thus far. This may partially reflect the fact that measurements on the electron ejection of autoionizing states arising from photon or electron impact are in general beset by many intrinsic difficulties, and the resulting spectral data are normally rather rich and complicated, and consequently difficult to interpret (20). We recently employed a technique of detecting the

ejected electrons induced by low-energy (20–55 eV) electron excitation with an energy resolution of about 30 meV, and would like to report some of our observations of autoionizing transitions in CO_2. The advantage of ejected electron measurements is that the spectral structure can be ascribed directly to autoionization. In other words, if the initial Rydberg states in the two-step process are already identified, then the kinetic energies of ejected electrons directly determine the final ionic states. In addition, the energy and angular distributions of ejected electrons may yield some information on the decay modes, branching ratios, and the symmetry of the autoionizing states. The use of the low-energy electron scattering method often opens more transition paths than photoabsorption owing to the considerable relaxation of selection rules and therefore enables us to investigate some autoionizing states that are inaccessible by photon excitation, as was demonstrated clearly in some electron excitation studies of CO_2 (13, 15).

The four outermost occupied molecular orbitals (MOs) of CO_2 in its $D_{\infty h}$ ground state configuration are ... $(4\sigma_g)^2(3\sigma_u)^2(1\pi_u)^4(1\pi_g)^4$, with their ionization energies (E_I) decreasing from $4\sigma_g$ to $1\pi_g$. It is known that the $4\sigma_g$, $3\sigma_u$, and $1\pi_g$ MOs are relatively nonbonding and they display only rather narrow peaks in the photoelectron spectrum (5, 7). The $1\pi_u$ is, however, a strong bonding orbital in the valence region and gives rise to a broad photoelectron band that embraces at least seven vibrational levels. The latest photoelectron spectroscopy data (7) provide the $X^2\Pi_g$ ground ionic state ($\Omega_{3/2}$) with an E_I of 13.778 eV, 19.5 meV lower than its spin-orbit partner ($\Omega_{1/2}$); $A^2\Pi_u$ ($\Omega_{3/2}$) with an E_I at 17.314 eV, just 11.9 meV apart from its $\Omega_{1/2}$; $B^2\Sigma_u^+$ at 18.077 eV and $C^2\Sigma_g^+$ 19.394 eV. Rydberg series leading to each of these limits have been observed, among which are the "Tanaka progressions I/II," "Tanaka–Ogawa," and "Lindholm" series converging to the ionic state A (2–4, 6, 8); the two Henning series mentioned earlier and a forbidden $np\sigma_u$ series converging to the B state (1, 2, 15); two absorption (one is much stronger than the other) and an emission series converging to the C state (2). Molecular spectroscopy of CO_2 indicates that both $A^2\Pi_u$ and $B^2\Sigma_u^+$ states are strongly perturbed as a result of Renner–Teller, spin-orbit, and vibronic interactions, while the $C^2\Sigma_g^+$ is highly unstable and may rapidly undergo predissociation (21, 22). Quite noticeably, the excitation spectrum beyond the first threshold is characterized by deep autoionization structures (6, 15, 18). As far as is currently known, this autoionization is of the electronic type, and originates largely from autoionizing Rydberg states, such as autoionization of the Tanaka–Ogawa and two Henning series to the ground ionic state X in its (000) and (100) vibrational levels (18, 19).

The autoionizing Rydberg states of a molecule may be thought of as an excited ionic core plus an excited electron in a Rydberg-like orbital. Electronic autoionization takes place between this Rydberg state and the ionization continuum of a lower electronic state of the ion, and hence belongs to a process of pure Coulomb interaction. It has been recognized, in addition to radiation decay, as another major de-excitation channel of a highly electronic excited state. This de-excitation is usually fast and efficient, since typical autoionization lifetimes are only $10^{-15} - 10^{-13}$ s. The occurrence of electronic autoionization favours Rydberg states of low n^*, because the higher Rydberg states have a smaller probability of being initially formed by absorption, and hence a smaller probability of subsequently autoionizing (10). There are also selection rules for autoionization of this sort, namely, $\Delta J = 0$, $\Delta L = 0$, and $\Delta S = 0$ for LS coupling and no parity change. In other words, two electrostatically interacting states must have identical symmetry (23). However, this does not necessarily mean that autoionizing transitions have been restricted to a small group of electronic excited states because of these selection rules. On the contrary, a great number of the total final states, molecular ion plus electron of ejection, may meet the symmetry demand of the initial autoionizing Rydberg state. This is due to the fact that the departing electron, such as photoelectrons, can carry practically any kind of symmetry and angular momentum away from the ion. Obviously, studying the symmetry of the outgoing electrons may result in determining the symmetry character of the Rydberg series if one knows the symmetry of the ion that the ejected Rydberg electron has just left behind. This is one reason why tremendous effort, both experimental and theoretical, has been made for years in studying the angular distributions of electrons of emission.

Using a newly constructed multi-angle parallel detection electron spectrometer, we also measured the angular distributions of ejected electrons for CO_2 autoionization, and present here some results that show that the intensities and shapes of autoionization lines vary at different ejection angles and are quite sensitive to incident electron energies as well. These data might potentially be of significance in helping to classify the energy level structure in the autoionizing region of CO_2 and (or) to determine the quantum numbers specifying Rydberg states. In addition, some new features not seen in previous experiments of low-energy electron impact excitation (15) were obtained and they appear to be favoured by low-energy-induced electron ejection. Therefore, the present results complement those of the other researchers mentioned above.

2. Experimental

The experiment was performed with a multi-angle parallel detection electron scattering spectrometer (MAPDESS for short) recently constructed in this laboratory. A schematic side view of this MAPDESS is displayed in Fig. 1; its major features have been discussed in detail elsewhere (24). For a better understanding of the present measurements, the following gives a brief account of this novel electrostatic electron spectrometer.

A well-defined electron beam, formed in the electron gun chamber and energy-selected by the monochromator of a standard 127° cylindrical deflector, is directed towards the collision center by the double-zoom lenses, deflectors, and an electron collimator, to cross at 90° with a beam of a gaseous target emanating from a narrow gas-inlet capillary. After collision, the scattered electrons of selected energy will, with the guidance of an annular lens, pass through the hemispherical analyzer and finally reach the channel electron multipliers.

The energy analyzer, the main piece of the MAPDESS, is a truncated spherical mirror that is symmetric with respect to the scattering center. Its ring-shaped exit is coupled to 19 channel multipliers, thus allowing parallel multichannel detection. Therefore, this spectrometer can directly give the angular distribution of an energy-resolved scattering event at 19 different angles separated by 8°, from 18° to 162°, with respect to the incident electron beam. With an angular resolution of ~3°, the overall energy resolution can be 25 meV, obtained with a monochromated beam in electron energy loss measurements at the analyzer pass energy of 7 eV.

Since the early work of Comer and Read in 1972 (25), refinements of the techniques involving detection of the ejected electrons have been made (26). The kinetic energy of the electron ejected from an autoionizing state, unlike the energies of inelastically scattered electrons, is independent of the incident electron energy (provided that the post-collision interaction is negligible here). This signifies that the

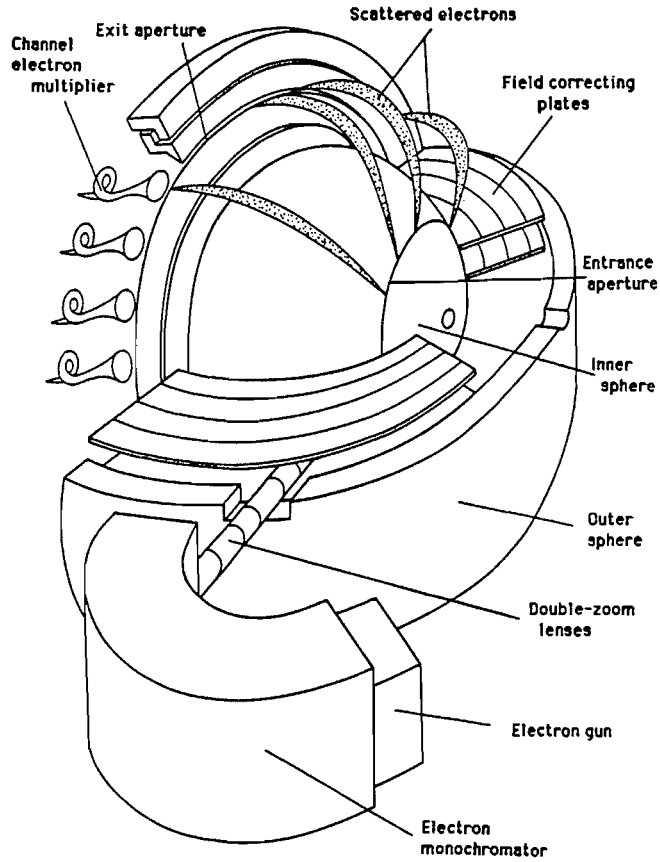

FIG. 1. Schematic three-dimensional view of the MAPDESS.

incident electron beam can be formed from a high-intensity gun, instead of a monochromator, and used directly, as good energy resolution is required solely in the analyzer. This is exactly the case in the present experiment. In fact, the monochromator in Fig. 1 was dismounted for our measurements for the ejection spectra. The energy resolution in this case was approximately 30 meV for the ejection experiment, slightly lower than before. This was already insufficient to observe directly the spin-orbit splitting of the CO_2^+ $X^2\Pi_g$ state, which is only about 19.5 meV (7).

As discussed previously (26), there are two basic modes of measuring an ejected electron spectrum, i.e., either at constant incident energy, measuring the electron yield as a function of energy loss (mode I), or a constant energy loss, measuring the yield as a function of ejection energy (mode II). For clarity, let us review briefly some main points of the early description (26). If the analyzer of an unmonochromated spectrometer receives electrons of various kinetic energies E_k from the collision center at a constant incident energy E_i (mode I), an energy loss spectrum may be obtained by sweeping E_l (sweeping the potential applied to the analyzer V_l in reality, since $E_l = eV_l$) and consequently E_k through the relation

$$[1] \quad E_l = E_i - E_k$$

In the case of autoionization, the kinetic energy of an ejected electron is given by

$$[2] \quad E_{ej} = E^* - E_I$$

where E^* is the energy of an excited Rydberg state. To detect the ejected electrons, one must have $E_{ej} = E_k$, which yields

$$[3] \quad E_l = E_I + E_{ex}$$

where E_{ex} ($= E_i - E^*$) denotes the excess energy of the incident electron relative to the Rydberg state. Thus, through these relations, one may find that mode I can also be used to detect the ejected electrons. On the other hand, by operating the gun and analyzer in the constant energy loss mode (mode II), in which only the incident electron energy is swept, with E_l being kept constant, it is possible to separate the ejected electron spectra from the simpler energy loss spectra. Mode II was utilized in the present work to avoid the possibility of energy loss structure appearing in the ejection spectrum. According to the above equations, one may determine the ejection energy scale by calibrating the incident energy and the energy loss. In this study, however, the energy loss scale was determined by the cutoff feature of the zero kinetic energy in the energy loss spectrum. The fine adjustment of the calibration was achieved by careful alignment of a prominent spectral peak with a spectroscopically well-known excitation line.

The main vacuum chamber containing the spectrometer has a background pressure of about 8×10^{-8} Torr (1 Torr = 133.3 Pa) using an efficient turbo-molecular pumping system. The spectra were recorded at sample pressures of the order of only 5×10^{-6} Torr. This improves the stability of the electron optics and of the instrument. The pressure in the collision region, however, was two orders of magnitude higher owing to the directed nature of the gas inlet jet. The CO_2 sample used was purchased commercially from Liquid Air, with a stated minimum purity of 99.98%, and therefore was taken directly from the lecture bottle without further purification.

3. Results and discussion

3.1 Ejected electron spectra

The three electron ejection spectra of CO_2, exhibiting the systematic change in intensity of features under different experimental conditions, are depicted in Fig. 2. They are representative of the many spectra that were recorded under various incident electron energies (20–55 eV). As explained in the experimental section, these spectra were taken under conditions of the constant energy-loss mode (mode II), which gives a range of incident energies for each spectrum in Fig. 2 from the top to the bottom as follows:

(1) $E_i = 25.0 \rightarrow 29.0$ eV $\quad E_l = 25.0$ eV
(2) $E_i = 30.0 \rightarrow 34.0$ eV $\quad E_l = 30.1$ eV
(3) $E_i = 50.9 \rightarrow 54.9$ eV $\quad E_l = 51.3$ eV

Each spectrum presented here is in fact the sum of 19 spectra recorded simultaneously at every 8° between 18° and 162°. This is somehow parallel to the photoelectron partial cross section for various molecular orbitals in the absorption spectrum that is obtained by integrating angle-resolved differential cross sections over all accessible angles. The strong varying ionization continuum (combined with low-energy electron background) present in the original data has, for clarity, been subtracted following the procedure proposed by Carbonneau et al. (27). Yet, this causes valleys between the peaks to appear as dips in our spectra, which have no real physical significance. The yield of ejected electrons is plotted in arbitrary units of electrons versus ejection kinetic energy, which covers the range from 0.7 eV up to a kinetic energy of 4.7 eV, the energy sector that falls into the region where autoionizing transitions in CO_2 occur most actively amongst the electronic states.

It has been found that the electron ejection features in Fig. 2, which correspond directly to autoionization, are remarkably similar to those appearing in some electron energy loss spectra of CO_2 that were obtained in this laboratory (15, 28), as can be seen in Fig. 3. Here, an ejected electron spectrum summed over all angles was plotted in the inset in order to compare directly with the energy loss spectra recorded in the constant incident

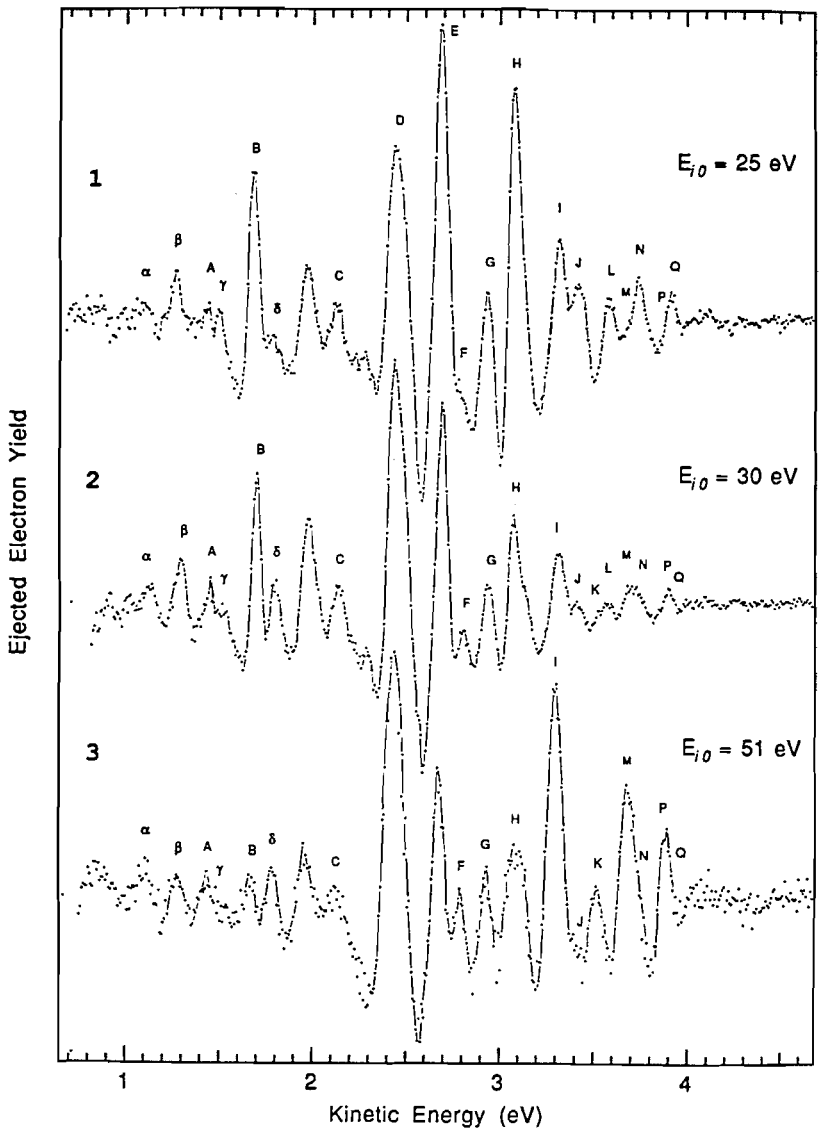

FIG. 2. Ejected electron spectra of CO_2 recorded at various incident electron energies (E_i) and excess energies (E_{ex}), where the incident energy was ramped up to 4 eV above the initial E_{i0} while keeping the energy loss fixed (see the text for details). Each spectrum is in fact the sum of 19 angle-resolved spectra recorded in parallel at every 8° between 18° and 162°. The analyzer energy resolution is approximately 30 meV. Features designated by letters correspond to those observed in the electron energy loss spectra in Fig. 3. Several features labelled by Greek letters are not present in the energy-loss spectra.

energy mode (mode I) for the region showing prominent autoionizing bands. The inset spectrum, which was acquired by scanning the incident energy (mode II) from 40.0 eV to 42.0 eV while fixing the energy loss at 40.0 eV, has seemingly been resolved slightly better than its energy loss counterpart of about 30 meV stated resolution. Figure 3 illustrates one attractive characteristic of ejected electron spectroscopy. The nice and consistent correlation of the features between the ejection spectrum and the energy loss spectrum leaves no doubt that the two techniques are describing the same autoionization zone in CO_2; otherwise, the features would not appear at the same relative position on both spectra. Thus, the same labelling system of features in the energy loss spectrum was adopted to the ejection spectra in Fig. 2 to facilitate the following spectral analysis.

3.2 Energy, intensity, and shape

Although Figs. 2 and 3 show that each of the autoionizing Rydberg series appearing in the excitation spectrum may find its counterpart in the ejection spectrum, this does not make it much easier to unambiguously determine the spectral features observed in ejection. This is because ejection spectroscopy provides us merely with the energy difference between an initial autoionizing state and a final ionic state (see eq. [2]), i.e., the kinetic energy of ejection is known, whereas the two states are not. Unless one of the two coupled states is certain, no decisive assignment can be given in general. Even if an assignment is made, it may not be the unique one, since several possible transitions may sometimes produce the same or very similar ejection energy, which closely matches the energy of the feature determined. Thus, the observation of ejected electrons does cause one complication that is not present in photon or electron excitation experiments, that is, the possible occurrence of one single line in the ejection spectrum corresponding to several autoionizing transitions. This undoubtedly gives rise to some uncertainty in the assignments. Therefore, some of the assignments given have only suggestive significance.

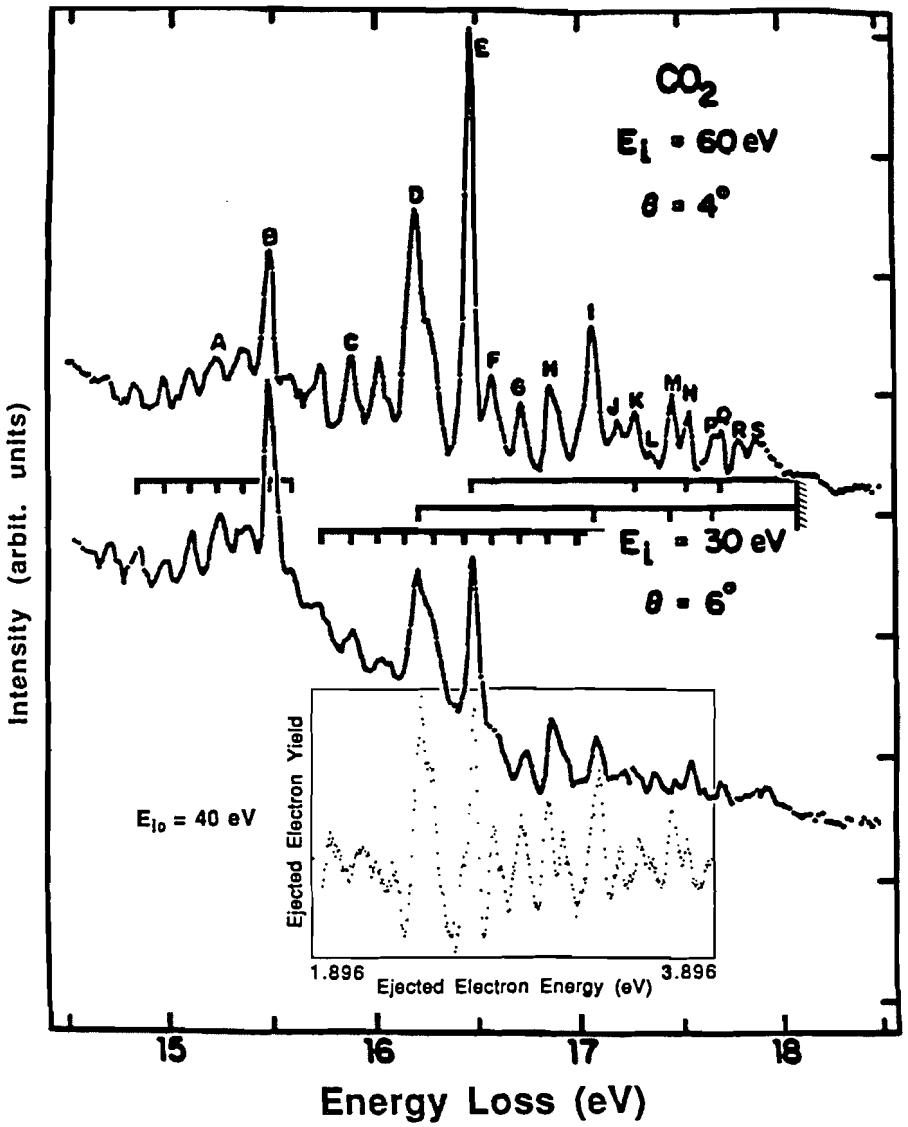

FIG. 3. Electron energy-loss spectra of CO_2 in the energy region 14.5–18.5 eV (taken from ref. 15). The spectra were recorded in the constant incident energy mode at scattering angles of 4° and 6°, and the overall energy resolution of the spectrometer was around 30 meV. The inset presented here is an integrated ejected electron spectrum to illustrate the spectral similarity between absorption and emission. The ejection spectrum was obtained by scanning the incident energy between 40 and 42 eV.

The kinetic energies and proposed assignments of the major spectral features in the ejected electron spectra of CO_2 are listed in Table 1. Since many autoionizing lines are closely spaced or even overlapped in this region and their intensities vary with the incident energy, which makes it sometimes difficult to accurately determine the energy position of features from a single spectrum, Table 1 includes only the features labelled in Fig. 2 as well as those whose positions can be recognized in the different spectra and (or) with reasonable certainty. The tabulated assignments are based, in addition to the previous results of excitation or ionization studies, chiefly on the energy match between the measured kinetic energy and the energy difference between the neutral Rydberg state and the final ionic state. In a few cases, assignments are made in such a way that they are reasonable in the sense that the corresponding autoionizing transitions are in accord with our spectroscopical "intuition" as well as spectroscopically reasonable population analysis results. The autoionizing lines observed in the present study can be identified as members of different Rydberg series, and six Rydberg series have been considered to be present in our ejected electron spectra. Each of these series will be discussed as follows.

3.2.1. Tanaka progression I

This series was identified initially by Henning (1) and was also observed as one of two weak ultraviolet absorption bands by Tanaka et al. (2), who called it the first progression but gave no explanation of it. Lindholm (4) assigned it to the first member of a forbidden Rydberg series ($np\sigma_u\ ^1\Pi_g$) converging to the $A^2\Pi_u$ ionic state of CO_2^+, whose higher members remain unknown up to the present time. In the ejected electron spectra of Fig. 2, this series appears in the low kinetic energy region, starting at the feature α and ending up around the δ. Apparently, the progression looks clearer and sharper under conditions of lower incident electron energies (see spectra 1 and 2), especially at peaks β and B, suggesting their character as optically forbidden transitions. This is consistent with the electron excitation results of Hubin-Franskin et al. (15), who observed, in addition to the impact-energy dependence, the strong angular

[h]Unless indicated by $\Omega_{1/2}$, the final state of autoionization means the ground state $X^2\prod(\Omega = 3/2)$ of CO_2. This is also applicable to the $A^2\prod_g$ ionic state. CO_2 has three fundamental modes of vibration: the symmetric-stretch mode (1, 0, 0); the bending mode (0, 1, 0); and the asymmetric-stretch mode (0, 0, 1). (v_1, v_2, v_3) indicates the vibrational level of the molecular ion.

dependence of this series, indicating a sort of u–u symmetry-forbidden excitation. In terms of the energy shift and the band-shape change in their threshold excitation, Hubin-Franskin et al. even considered the possibility of excitation of a triplet state $^3\Pi_g$ for this first member ($3p\sigma_u$) of the series. In the ejection spectra, the intensity and line shape of peaks β and B vary more noticeably with incident energy, and they have been attributed to the involvement of more than one line under the peak, as indicated in Table 1.

It should be pointed out that some of the features (e.g., γ) have been assigned to electronic autoionization occurring between the $3p\sigma_u$ Rydberg state converging to the v'th vibrational level of the $A^2\Pi_u$ state and the continuum of the $X^2\Pi_g$ state in its v''th vibrational level, since there is no restriction in this regard (23) (although the vibrational intensity distribution in the final ionic states may follow the pattern predicted by the Smith (29) model, which shows that if autoionization dominates the photoionization process in small molecules, such as O_2, the distribution depends only upon Franck–Condon factors connecting the autoionizing Rydberg and final ionic states). However, the considered vibrational levels of the $X^2\Pi_g$ state are only those that have exhibited a reasonable intensity in the CO_2 photoelectron spectrum (5, 7) to be in accord with their probability of being populated. Though less than 1 eV, this energy region has been considered to be very complicated. Baer and Guyon (6) had to propose the excitation to two, rather than one, electronic states in this region to fit the rich structure displayed in their threshold photoelectron spectrum. Interestingly, among the two series they proposed, only the one they believed to originate from the vibrational development of the excited $X^2\Pi_g$ ionic state (i.e., resonance autoionization with ejection of low-energy electrons) is in agreement with our data. Besides the features already studied by electron excitation (15), a few new ones were observed here, and they are given in Table 1.

3.2.2. Tanaka–Ogawa series

This is an optically allowed Rydberg series and each member of the series is composed of a long and strong vibrational progression with a maximum intensity around $v' = 3$ owing to excitation of the symmetric-stretching mode in CO_2. Discovered by Tanaka–Ogawa, the series was classified by Fridh et al. (16) as the $ns\sigma_g$ Rydberg series with quantum defect of 1.18, converging to the $A^2\Pi_u$ ionic state. Because of the profound ν_1 vibrational development of the $A^2\Pi_u$ state itself, stemming from the remarkable change of molecular geometry in ionization of the neutral ground state to the A ionic state, many high-level Rydberg members have already reached deep inside the $A^2\Pi_u$ continuum. The series may therefore be expected to appear as a major progression of Rydberg bands extending through the entire ejection spectrum beyond 1.9 eV. However, the higher n^* Rydberg levels are less likely to be observed in the ejection spectrum here because of insufficient energy resolution. The first Rydberg member to appear in our spectra is a relatively intense peak just below peak C (see Fig. 2). It, along with peak C, has a rather stable shape in the incident energy range under investigation. Yet the peak next to C on the higher energy side has an unusual low intensity compared to the energy-loss spectrum presented in the top of Fig. 2. Although the $v' = 3$ level of the $4s\sigma_g$ Rydberg state, which is supposed to have the highest intensity in the progression, seems to be overshadowed by the illustrious peak D of the Henning series, two other vibrational levels of this state between peaks D and E give rise to a strong appearance (as a visible shoulder) in the inset of Fig. 3.

The remaining members of this series are labelled by the letters F, G, H, J, K, M, and Q; among them, features G and J are the relatively pure Tanaka–Ogawa Rydberg states and somehow show a weak dependence of the series on the incident energy in this region. The dramatic change in intensity of peak H is believed to be associated with another Rydberg series, to be discussed below. Finally, on account of the spin-orbit coupling, each series is in fact made up of two bands that coverage towards the $\Omega = 3/2$ and $\Omega = 1/2$ ionization limits of the $A^2\Pi_u$ state. In a few cases, the members of the series converging to the $\Omega = 1/2$ limit have been considered in our assignments, since they can apparently give a better energy match to the kinetic energy of an autoionizing line, as has been shown in Table 1. Again, several weak features have been identified and their possible corresponding autoionizing transitions are listed in the table.

There also exists another fairly weak but visible (in photoabsorption (3) and photoion yield spectra (8)) progression (5 levels) in parallel with the $n = 4$ member of the Tanaka–Ogawa Rydberg series. This "additional progression" of Tanaka and Ogawa (3), emerging at 15.80 eV, has been considered as the first member ($n = 3$) of a Rydberg series of $nd\delta_g$ excitation by Lindholm (4), based on its quantum defect being about 0.00. Although the series, referred to often today as the Lindholm Rydberg series, has tentatively been extended by McCulloh (8) to the $n = 4$ progression (merely 2 levels at best, however), its other members have remained undefined until now. Because of limitations in the energy resolution, the Lindholm progression is not resolved by our spectrometer and, consequently, the series has been left out altogether. However, it should be borne in mind that, since the Lindholm series occurs closely in parallel with the Tanaka–Ogawa series in the energy region of 15.8–16.9 eV, it may play a role in shaping the autoionization peaks appearing in this region.

3.2.3. Optically forbidden series R_B

This series was first observed by Cvejanovic et al. (14) and was extended to a higher energy area by Hubin-Franskin et al. (15). Three Rydberg states of the series, which are indicated by the letters B, H, and L in Fig. 3, have been determined so far by the low-energy electron impact technique. The differential cross sections of these three states intensify at lower incident electron energies, and vary with the scattering angles, strongly signifying the occurrence of a symmetry-forbidden transition. With a quantum defect of 0.70, the series has been assigned to the $np\lambda_u$ Rydberg series, possibly by symmetry σ_u, converging to the $B^2\Sigma_u^+$ ionic state (15). The forbidden character of this series is also manifested in our ejected electron spectra of Fig. 2. Throughout the three spectra of different incident energies, the peak intensity of the series changes spectacularly, from a pronounced peak (B and H in spectrum 1) to a weak feature (B in spectrum 3) or to a featureless background (L in spectrum 3). The striking intensity enhancement of peaks B and H in spectrum 1 has been attributed to the enhanced population of the initial autoionizing levels using the low-energy electron impact. The exceptional height of peak H may suggest the participation of some other states adjacent to H, such as Rydberg states of the Tanaka–Ogawa (or perhaps plus the Lindholm) series, which apparently also gain some intensity in this energy region, as mentioned earlier. Another piece of evidence supporting this

For personal use only.

idea comes from the inset ejection spectrum in Fig. 3. The spectrum reveals that at the present resolution there exist at least two lines under the envelope of peak H. The line of higher energy has a kinetic energy of 3.150 eV, and there is no other reasonable autoionizing transition that could produce an electron ejection energy of such a value. We have no adequate explanation for this at the moment. It is possible that the 3.150 eV peak is the real line that belongs to the $np\sigma_u$ forbidden series, while the peak on the low-energy side of it (3.086 eV) may be the 5th Rydberg member of the Tanaka–Ogawa $ns\sigma_g$ series converging to the $v' = 3$ vibrational level of the $A^2\Pi_u$ state, judging from its distance to peak G, which is approximately equal to the separation between peaks G and F, as well as from its height, which is the highest in the vibrational development, being in harmony with the photon absorption observation (3).

3.2.4. Henning diffuse series

This series, together with the Henning sharp one to be discussed later, is the oldest Rydberg absorption series discovered in CO_2 by Henning (1). Based on the quantum defect of ~0.31, obtained by the photoabsorption studies of Tanaka et al. (2) and Tanaka and Ogawa (3), the diffuse series was designated initially by Lindholm (4) as an $nd\sigma_g$ Rydberg series, converging to the $B^2\Sigma_u^+$ ionic state. But it was revised later to an $ns\sigma_g$ excitation, upon assuming the quantum defect to be 1.31 rather than 0.31 (16). However, the electron impact work performed in this laboratory (28) shows that the quantum defect of this series is just about 0.30, in rather good agreement with the result of Tanaka and Ogawa (3). Therefore, the former designation ($nd\sigma_g$) is, in our view, preferable on every ground.

The Henning diffuse Rydberg series gives rise to an intense as well as broad autoionization structure in the photoabsorption (6, 18, 19) and electron excitation (15) spectra, at least for the low-energy members. This structure, consisting of the features D, I, M, and P, can also be seen readily in the ejected electron spectra of Figs. 2 and 3, as it dominates each of the spectra. The peak intensity of the series, too, does vary with incident electron energies, but it is enhanced at high incident energy, consistent with the typical behaviour of symmetry-allowed transitions. This effect is particularly noticeable in spectrum 3, where all members of the series gain substantial intensities and virtually overtake their counterparts in the Henning sharp series (features E, N, and Q), and even more, peak I has become more intense than E. This is in sharp contrast to the situation in the electron energy loss spectra (15) (see also Fig. 3), where the cross section of peak E always appears to be larger than that of D and this has led to the conclusion (19) that the Henning sharp Rydberg state represented by peak E is involved in other electronic configurations. We consider that the intensity increase in the Henning diffuse Rydberg series may be associated with the enhanced relative cross section of the initial autoionizing levels at higher impact energies and the coupling between these initial neutral states and the final ionic state. It is possible also that there occurs an increased contribution from other Rydberg series, such as the Tanaka–Ogawa Rydberg series, or perhaps the Lindholm series (4), which runs closely with the Henning series throughout this energy region, since the bands of different n and v values gradually become quite close in energy and even overlap as n increases.

3.2.5. Henning sharp series

Its quantum defect, also determined by Tanaka et al. (2) and Tanaka and Ogawa (3), is approximately 0.93. This number agrees well with the typical quantum defects of $\sigma \rightarrow ns\sigma$ transitions in some small molecules, and hence has led Lindholm (4) to classify the sharp series as an $ns\sigma_g$ excitation series, converging to the same limit as the diffuse series. The classification was reviewed later, however, because the first 3*s* member (near 84.0 nm) was not present in McCulloh's photoion yield spectrum (8). The final designation was then $nd\pi_g$, after the quantum defect was chosen to be almost zero (16). It is interesting to note here that the electron energy loss spectra of CO_2 also provide the sharp series with the quantum defect of 1.05 (28) and, as a result, the series has tentatively been assigned to the $ns\sigma_g$ Rydberg series (15, 28). This is in excellent accord with the result from the fluorescence polarization work by Poliakoff et al. (30), which shows that, like the diffuse series, the sharp one also possesses $^1\Sigma_u^+$ electronic character. On the basis of additional supporting material from the theoretical calculations of Dittman et al. (31), Dehmer (32) suggested that it might be necessary to revise the $nd\pi_g$ designation of Fridh et al. (16). As for the missing 3*s* member, we consider that the 14.682 eV (84.45 nm) peak in our energy loss spectra (15, 28) (see also the first feature in Fig. 3) may be related to this $n = 3$ member. Though anomalously weak in intensity, the peak is not unlikely to be the first member of the sharp series, as this series might have its intensity maximum at $n = 6$ (33). Thus there is meagre evidence to favour the classification of the Henning sharp series as the $nd\pi_g$ excitation.

The $n = 4$ member of the Henning sharp series has in most cases been an outstanding feature in photoabsorption as well as photoionization (6, 8, 18). As can also be seen from the top electron energy loss spectrum in Fig. 3, there, it is peak E that dominates the spectrum and is followed by the other members of the series: the features K, N, and Q. Like peak D of the diffuse series, peak E can also be made to shrink markedly into a background-like feature in the electron energy-loss spectrum under dipole-forbidden conditions (15, 28). Yet this is seemingly not quite the case in the ejected electron spectra. We have observed that the peak intensity associated with peaks E, N, and Q of the sharp series is, instead of shrinking, enhanced as the incident electron energy decreases (see Fig. 2). Such behaviour appears to parallel that observed for optically forbidden transitions in the electron energy loss spectra. This is quite different from the situation we have just met in the Henning diffuse series, implying strongly that these two Henning series bear a different type of substructure and symmetry in nature. A further piece of supporting evidence comes from Fig. 4, which presents the angular distributions of the ejected electrons. In Fig. 4, we see that the autoionizing transition probability of the sharp- series peak E evidently prefers the large ejection angles, which is totally opposite to that of the diffuse-series peak D. We have not been able to carry out a detailed analysis of such remarkable behaviour in intensity at this point. However, the dissimilarity of the two intensity distributions plausibly reflects differences of configurational interaction between these two Henning series and the final $X^2\Pi_g$ continuum states. It has been suggested that the peak E of extraordinary intensity cannot be a pure Rydberg state and contains instead a considerable contribution from unresolved bands related to its neighbouring states (6, 19). The $n = 5$ member of the Tanaka–Ogawa Rydberg series (and perhaps the Lindholm progression as well), with its vibrational levels surrounding peak E, could be a reasonable candidate for such a

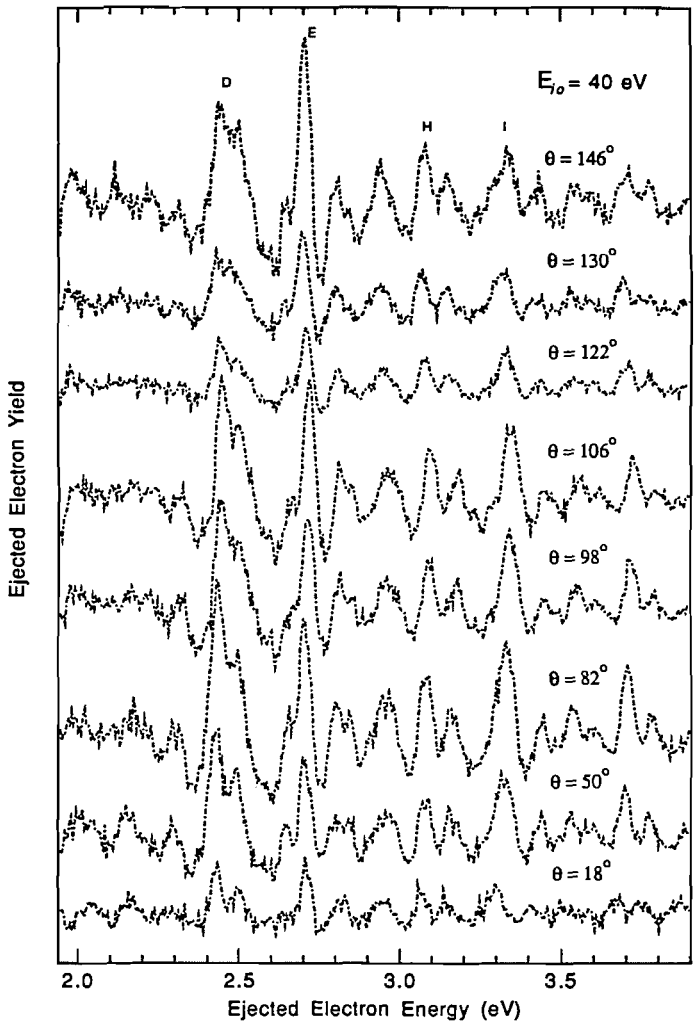

FIG. 4. Ejected electron spectra of CO_2, the sum of which gives rise to the inset presented in Fig. 3, showing the angular behaviour of ejection. For clarity, only 8 representatives are sampled here of the 19 spectra obtained simultaneously by the spectrometer in the constant incident energy mode, as specified in Fig. 3. Each spectrum is plotted to actual height relative to the other spectra to illustrate the probability of autoionizing transitions at different ejection angles.

neighbouring state. Close inspection of spectrum 1 in this region shows that there may exist some strong interaction between the E Rydberg state and the vibrational levels (e.g., the feature F) of the 5th Tanaka–Ogawa series. This could be correlated to the "complex resonance" phenomenon observed in the diatomic molecule N_2 (34, 35).

One more point that should be singled out for recognition is that, unlike the other members of the same series, the $n = 5$ member of the Henning sharp series (feature K) behaves in rather different fashion in Fig. 2. It peaks in spectrum 3 but vanishes in spectrum 1. Again, this behaviour may have something to do with the Tanaka–Ogawa series. In spectrum 1, we assume that the 5th Rydberg state might interact strongly with the high-lying members of the Tanaka–Ogawa series and its electronic character has been distributed over many surrounding levels, resulting in its disappearance from the spectrum. Lacking such interaction, the 5th state emerges as an isolated peak in spectrum 3. It is clear that further careful study will be needed before these phenomena present in our spectra can fully be understood, and other related data, experimental as well as theoretical, will be helpful in this regard.

3.2.6. Rydberg nf_n *series*

This series, along with the other two, was initially observed by Tanaka et al. (2) as a weak absorption Rydberg series that converges to the ionization limit of the $C^2\Sigma_g^+$ ionic state. It was once interpreted by Lindholm (4) as a series of forbidden transitions to $nd\pi_g$ Rydberg states, but such an assignment was criticized by McCulloh (8) because of the absence of the $n = 3$ member (≈69.4 nm) in his photoionization efficiency spectrum. It was then reassigned by Fridh et al. (16) to an allowed nf_u excitation series. However, more recent work of Baer and Guyon (6) claims that an extra sharp autoionization feature of 17.936 eV (69.125 nm) revealed by threshold photoelectron spectroscopy may be associated with the missing $n = 3$ member, and an electron energy loss spectrum recorded in this laboratory (28) shows also that this member appears at 17.886 eV (69.320 nm). This *weak* absorption series has a strong showing in the low energy electron excitation measurements, and its relative cross section is even larger than that of the other absorption series (the third Rydberg series in this region is just an emission series). With the determined quantum defect $\delta = 0.02$, the weak series has been considered as excitation to either $nd\pi_g$ or nf_u Rydberg states (28). Based upon their work of partial photoionization cross section on these three series converging to the $C^2\Sigma_g^+$ state, Hubin-Franskin et al. (19) indicated that the three series autoionize only to the lower ***B*** and ***X*** ionic states. Therefore, we consider that three weak features at the ends of our ejected electron spectra may originate from this sort of autoionization, based mostly upon the transition energies being able to match well the observed kinetic energies. Their assignments are given in Table 1. Considering the nature of the weak absorption as well as the competition from possible predissociation (8, 21, 22), the weak intensity displayed by these autoionizing transitions is fairly understandable.

3.3 Angular behaviour of ejection

The inset ejection spectrum in Fig. 3 is actually the sum of 19 angle-resolved ejected electron spectra that were measured in parallel by the MAPDESS at 19 different angles separated by 8° and ranging from 18° to 162° with respect to the incident electron beam. It represents only the energy distribution of the electrons and a somewhat crude integral behaviour of electrons ejected from various autoionizing states, irrespective of the angle at which the emitted electrons were detected. Therefore, much information about the symmetry about the ejected electrons and (or) the two interacting states in autoionization has been ignored. Eight representative components of the inset spectrum are sampled in Fig. 4 to demonstrate the angular distribution of ejected electrons among the various autoionizing states. Without any normalization and (or) correction of the detector efficiency, each spectrum is plotted to actual height relative to the other spectra to illustrate the probability of autoionizing transitions at different ejection angles. A glance at Fig. 4 shows the drastic change in intensity of some major autoionizing lines as the angle increases: lines D and E, for instance, whose intensities have been virtually inverted, suggesting that the Henning series they represent, respectively, have different electronic character in origin. In terms of a relatively rough estimate, the Henning diffuse series reaches its maximum intensity around 80° at the initial incident energy of 40 eV, whereas the Henning sharp

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

series has its best at 146°. This would have been seen more clearly by plotting the ejected electron yield versus the ejection angle in polar coordinates. In fact, with the 19 points obtained at every incident energy the angular dependence of ejected electrons could be mapped out in a polar plot for each autoionizing state to show its angular behaviour in emission, if the angular dependence of the detector efficiency was properly calibrated. The results should be informative and helpful in determining the wave type and symmetry of the outgoing electrons.

It is obvious from Fig. 4 that the ejected electrons are not isotropically distributed. In general, the electrons leave the randomly oriented, excited CO_2 molecule preferentially in certain directions, and precisely, they favour relatively large angles. We have found the maxima in ejected electron intensity between 80° and 110° with respect to the incident electron beam direction, and low electron yield in the forward angles for every single incident energy measurement. The ejection yield at 146° is always prominently large compared to its neighbours, but the yield is, without exception, extremely low at the three angles of 34°, 58° and 162°. Interestingly, the angle 58° is merely a few degrees away from the so-called magic angle (54.74°), at which the measured photoelectron current is directly proportional to the integrated cross section, regardless of the incident photon polarization and the photoelectron angular distribution. This may serve as a simple example of showing that the behaviour of ejected electrons in autoionization differs in many aspects from that of photoelectrons in direct ionization. However, the significant effect of autoionization on the photoelectron angular asymmetry parameter β has been noted in the study of photoelectron angular distributions in CO_2 (36, 37).

4. Summary

Using a gas-phase electron scattering spectrometer capable of the multiangle parallel detection of electrons departing from the collision center, we have, with the incident electron energy varying from 20 to 55 eV and the angular range between 18° and 162°, measured the energy and angular distributions of electrons ejected from CO_2 autoionizing Rydberg states lying in the continuum region 15–19 eV. The results show that the ejected electrons arising from diverse autoionizing states are quite sensitive to the low incident electron energies utilized and their yields have strong angular dependence. A careful examination of the ejected electron spectra recorded has led to the identification of some new features not present in the electron energy loss spectra and they have tentatively been assigned. Of all the Rydberg series observed, two of the most prominent are the Henning diffuse and sharp series. It was found that they exhibit remarkably different responses to the alteration of the incident energy and the angle. The different geometries of the Rydberg states and a different mechanism of coupling to the $X^2\Pi_g$ ground ionic state have been considered responsible for such behaviour. We have also noted that there apparently exists fairly strong interaction between the Tanaka–Ogawa Rydberg series and the Henning series, which may result in the change of autoionizing lines in intensity and shape. The present study should provide new and valuable information on the molecular spectroscopy and the dynamic interaction associated with the electron–molecule collision of CO_2.

Structural and substituent effects on the ketene infrared stretching frequency

MICHAEL A. MCALLISTER AND THOMAS T. TIDWELL
Department of Chemistry, University of Toronto, Toronto, ON M5S 1A1, Canada

Received July 18, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

MICHAEL A. MCALLISTER and THOMAS T. TIDWELL. Can. J. Chem. **72**, 882 (1994).

The frequencies and intensities of the ketene asymmetric stretching vibration near 2100 cm^{-1} for a series of substituted ketenes and fulvenones have been calculated using *ab initio* molecular orbital methods. Comparisons of the calculated values with experimentally determined results show reasonably good agreement in most cases, with a typical deviation of ± 10 cm^{-1} between the measured and calculated values. A test of a correlation proposed by Gano and Jacob (Spectrochim. Acta, **43***A*, 1023 (1987)) of the frequencies with substituent field and resonance parameters F and R shows a modest correlation coefficient of 0.86, with no significant dependence on R. These results are consistent with enhancements of ketene infrared absorption frequencies by interaction of substituents with the negative charge density at C_β of ketenes, as indicated by the resonance structure $R\bar{C}H—C{\equiv}O^+$. The calculated intensities I (km/mol) for non-π acceptor substituents are correlated with the group electronegativities X by the relationship $I = 1841.6 - 305.7X$ ($r = 0.94$). The π-acceptor substituents show exaltations of the intensities, and the results are interpreted as showing an enhancement of intensities by electropositive substituents increasing the normal ketene dipole directed towards oxygen, and an opposite effect by π-acceptor substituents delocalizing the negative charge at C_β.

MICHAEL A. MCALLISTER et THOMAS T. TIDWELL. Can. J. Chem. **72**, 882 (1994).

Utilisant des méthodes *ab initio* d'orbitales moléculaires, on a calculé les fréquences et les intensités de la vibration d'élongation asymétrique du cétène près de 2100 cm^{-1} d'une série de cétènes et de fulvénones substitués. Des comparaisons des valeurs calculées avec les valeurs obtenues expérimentalement présentent une bonne corrélation dans la plupart des cas; la déviation typique entre les valeurs calculées et expérimentales est de 10 cm^{-1}. Une évaluation d'une corrélation proposée par Gano et Jacob (Spectrochim, Acta, **43***A*, 1023 (1993)) entre les fréquences et les paramètres F (champ du substituant) et R (résonance) présente un modeste coefficient de corrélation (0,86) et aucune dépendance significative sur R. Ces résultats sont en accord avec les augmentations des fréquences d'absorption des cétènes en infrarouge lorsqui'ils sont soumis à l'influence de substituants portant une densité de charge négative sur le C_β, tel que représenté par la structure de résonance $R\bar{C}HC{\equiv}O^+$. On a établi une corrélation entre les intensités calculées, I (km/mol), pour les substituants accepteurs non-π et les électronégativités de groupe, X; la relation est $I = 1841{,}6 - 305{,}7X$ ($r = 0{,}94$). Les substituants accepteurs-π présentent des augmentations des intensités et on interprète les résultats comme une preuve d'une augmentation des intensités par les substituants électropositifs dû à une augmentation du dipôle normal du cétène dirigé vers l'oxygène et d'un effet opposé par les substituants accepteurs-π qui délocalisent la charge négative sur le C_β.

[Traduit par la rédaction]

Introduction

The characteristic carbonyl stretching frequency in the infrared spectra of ketenes near 2100 cm^{-1} is frequently utilized for the detection of these elusive intermediates (1), and is especially useful because the measurements can be made under a wide variety of conditions necessary for observing the ketenes ranging from the gas phase to matrix isolated samples at low temperatures. Analysis of the infrared spectra and assignment of the principal bands has been carried out for ketene itself (2), and for some haloketenes (3*a*–*d*) and silylketenes (3*e*). *Ab initio* calculations at the MP2 level (2*c*) give good agreement with the experimental IR spectrum of ketene.

Despite the frequent use of IR in ketene detection this technique has seldom been used in ketene identification. One reason for this is that ketenes defy systematic experimental study, because the representative types of ketenes have widely different properties, so that different techniques and conditions are needed for the preparation of different ketenes, and the measurements must often be made *in situ*. Moreover, it is not only often difficult to prepare these transient species and measure their spectra, but the absorption frequencies are highly medium dependent, so that to be useful, data sets must be obtained under the same conditions. For example, Moore and Pimental (2*b*) found the C═O stretch of ketene occurs at 2151, 2142, and 2133 cm^{-1} in the gas phase, an Ar matrix, and the solid, respectively, and values for $CCl_2{=}C{=}O$ of 2160, and 2155 have been found in the gas phase and Ar matrix (3*b*, *d*).

Because of the paucity of consistent data there has not been much progress in the investigation of the effect of substituents on the ketene carbonyl stretching frequencies. This is in contrast to the situation with ketones, where large sets of data are available, and there have been detailed correlation analysis of the effects of substituents on stretching frequencies in both aliphatic and aromatic compounds (4).

Gano and Jacob (5*a*) recently addressed the question of substituent effects on ketene stretching frequencies, and analyzed data for a set of four symmetrically disubstituted ketenes $R_2C{=}C{=}O$ (R = H, Cl, CN, and CH_3) for which stretching frequencies were measured in argon matrices, together with a value estimated for R = CF_3 in the matrix, based on gas phase data. These data were correlated using Hammett-type substituent parameters, specifically the field effect parameter F and the resonance effect parameter R, as originally derived by Swain and Lupton (6), by eq. [1].

$$[1] \quad \nu(cm^{-1}) = 24F + 30R + 2142$$

This limited data set gave a rather good correlation, and this was used to predict stretching frequencies for a number of other ketenes. However, so far it appears that none of these predictions has been checked experimentally. The correlation suggests that the C═O stretching frequency is increased both by inductive and resonance electron withdrawal by the substituents, and this is consistent with the expectation that the resonance con-

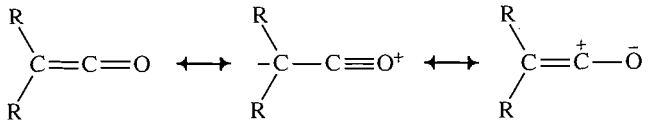
tributor **1***A* of ketenes would be favored by electron acceptors, and would lead to higher frequencies (5*a*). The normal polarity of ketenes is as shown in **1***B*, as shown by the dipole moments, which are enhanced by electropositive groups R, and reduced by electronegative or π-acceptor groups (10a).



1 **1***A* **1***B*

Other data in support of the hypothesis that stabilization of the resonance structure **1***A* by electron-withdrawing substituents leads to increased infrared stretching frequencies are the reported values in 1,2-dichloroethane of diarylketenes $(4\text{-}XC_6H_4)_2C{=}C{=}O$ of 2096, 2100, and 2109 cm^{-1} for X = MeO, H, and O_2N, respectively (5*b*). The increase in the frequency as the acceptor power increases from MeO to H to O_2N is small, but is in the order expected.

The Swain–Lupton treatment of substituent effects has been criticized (7), but an authoritative recent survey of Hammett substituent parameters (8) utilizes modified values of these constants as consistent with current understanding of the field, and reports values for 530 substituents. However, the lack of sufficient ketene data restricts a thorough test of eq. [1].

The question of the effect of substituents on the intensities of infrared vibrations has also been widely studied, particularly for aromatic ring vibrations (4*a*, 9*a*,*b*), and also for the frequencies of carbonyl groups, alkenes, nitriles, and C—H bonds (4*a*, 9*c*–*e*). However, the relationship between infrared frequencies and intensities has been little explored, and there have been measurements of ketene intensities (3*a*), but no systematic study.

The use of *ab initio* molecular orbital calculations provides an attractive alternative approach to the problem of substituent effects on ketene infrared frequencies and intensities. We have previously applied this method to the calculation of the structure and energies of a large number of ketenes (10*a*–*c*) and have found that the stabilizing effect of substituents on ketenes can be correlated by the substituent group electronegativities (10*d*).

These studies have now been extended to the calculation of the infrared stretching frequencies of a large number of ketenes, including mono- and disubstituted species, and some fulvenones and cycloalkylideneketenes (10*b*) for which frequencies have been determined experimentally. An advantage of this approach is that a large number of ketenes of diverse structural types can be considered, and the calculated values all apply to the same medium, namely the gas phase. The validity of the calculations can be tested by comparison to experimental values, for which a reasonable number of gas phase values are available, and the intensities of the absorptions can also be calculated.

Computational methods

Ab initio molecular orbital calculations were carried out for a variety of ketenes using the GAUSSIAN 90 and GAUSSIAN 92 (11*a*) series of programs on Hewlett-Packard 9000-750 and IBM RS/6000-530 minicomputers. All geometries were gradient optimized using the split-valence 6-31G* basis set (11*b*,*c*). There were no geometrical constraints during the optimization, except in the case of fulvenones, for which the ring systems were constrained to planarity. The orders (number of negative diagonal elements of the Hessian matrix) of all critical points were determined at the HF/6-31G* level by analytical differential of the restricted Hartree–Fock wave function and were found to be zero in all cases except for difluorotrifulvenone, divinylketene, heptafulvenone, and trimethyleneketene, which all have order 1 (one). Geometries optimized at MP2/6-31G* were also order checked at that level of theory. The frozen core approximation was not used.

Results and discussion

As a test of the reliability of the calculations, in Table 1 are listed the calculated frequencies for disubstituted and monosubstituted ketenes for which comparative experimental data are available (12, 13), or for which frequencies were predicted by Gano and Jacob (5*a*). Also included for comparison are frequencies calculated by molecular mechanics (MM3) (5*c*). In Table 2 are listed the frequencies calculated at the HF/6-31G* level for 27 monosubstituted ketenes, as well as their calculated intensities. For 19 of these the frequencies for geometries optimized at the MP2/6-31G* level are also given. In Table 3 are listed calculated experimental frequencies for fulvenones, cycloalkylideneketenes, and model compounds.

Comparison of the calculated frequencies for distributed ketenes to the available experimental values (Table 1) show that for ketenes $M_2C{=}C{=}O$ (M = H, Cl, CN, and Me) there is rather good agreement, with the largest deviation (17 cm^{-1}) for M = Cl. However, for M = F and M = NH_2 the deviations of the *ab initio* calculated frequencies from those calculated from their correlation by Gano and Jacob (5*a*) are large (73 and 54 cm^{-1}, respectively). The two methods are not in agreement for these ketenes, and while the *ab initio* methods give satisfactory agreement for the available experimental data for both monosubstituted (*vide infra*) and disubstituted ketenes, until experimental data become available it cannot be determined which method has the best predictive value for these two cases.

There are nine monosubstituted ketenes for which comparisons of the calculated frequencies with gas phase experimental frequencies can be made, and one other for which a solution measurement is available (Table 1). The differences range from 0 to 30.7 cm^{-1}, with an average deviation of 13 cm^{-1}.

There are five examples in Table 1 for which comparisons are available with frequencies calculated by MM3 molecular mechanics calculated values (5*c*), and for all but $Me_2C{=}C{=}O$ these agree to within 12 cm^{-1}. However, the MM3 parameters were adjusted to fit values derived from *ab initio* MP2/4-31G** calculations, except for $Me_2C{=}C{=}O$, and so the agreement is not unexpected.

In Table 3 there are three conjugated fulvenone examples in which the calculated and experimental values can be compared, and in all cases the agreement is excellent. Thus for pentafulvenone two bands are observed experimentally due to matrix effects (12*a*), at 2130 and 2133 cm^{-1}, while the calculated position is 2125 cm^{-1}. For heptafulvenone the calculated and experimental values are both 2103 cm^{-1}, although independent experimental structure proof of the identity of the species giving the absorption at 2103 cm^{-1} is lacking (12*d*). The theoretical and experimental (in a matrix) frequencies determined by others (12*e*) for the thiafulvenone ylide **4** give excellent agreement.

Dimethyleneketene (**2**) (12*b*,*c*) and trimethyleneketene (**3**) (12*c*) each show two bands experimentally, with a 10 cm^{-1} dif-

ference between independent measurements for **2** (Table 3). These are matrix values and it has also been observed that matrix values change with temperature, and so it is difficult to select a standard basis for comparison. The theoretically determined values are within 18 and 7 cm^{-1} for the highest of the experimental values.

In total 17 comparisons between experimental and calculated IR frequencies are available, with an average deviation of 12.9 cm^{-1}. It may be concluded that the *ab initio* calculated values are of significant predictive value for the determination of ketene frequencies within these limits, and can be utilized for the examination of the origin of substituent effects on the frequencies.

Correlation of the frequencies calculated at the HF/6-31G* level with the field and resonance parameters of the substituents (8) is given by eq. [2], with a correlation coefficient $r = 0.87$. The coefficient of the resonance term is indistinguishable from zero within the precision of the correlation, and field effects alone give an equally good correlation, eq. [3] ($r = 0.86$), as shown in Fig. 1. For the smaller set of substituents for which frequencies were obtained for MP2/6-31G* optimized geometries (Table 2) the correlation of the frequencies with the field effect parameter was much poorer.

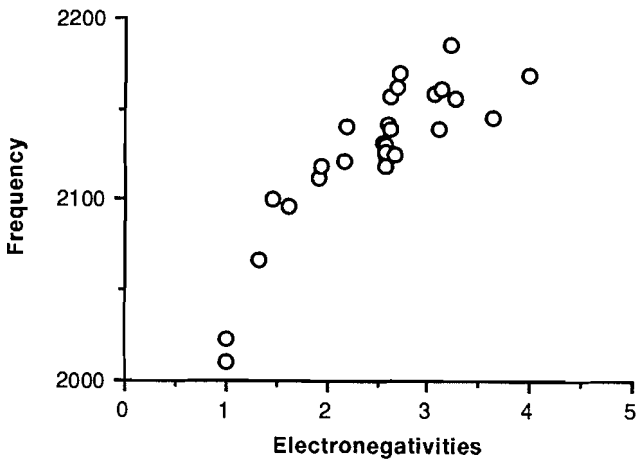

FIG. 2. Plot of ketene HF/6-31G* calculated stretching frequencies (cm^{-1}) versus group electronegativities X.

MgH, BH_2, and AlH_2, for which F and R parameters are not available. A definite trend is seen, but there is no useful linear correlation.

A good correlation is found between the infrared intensities **I** and group electronegativities for the first 17 entries in Table 2, which are generally non-π acceptor substituents. For the HF/6-31G* level calculations the correlation is I (kcal/mol) = 1841.6 − 305.7X, r = 0.94 (Fig. 3), while at the MP2/6-31G* level, for 15 substituents, the correlation is I (kcal/mol) = 1128.3 − 240.8X, r = 0.985. It was not practical to carry out calculations at the higher level for many additional substituents. This enhancement of the IR intensity by electropositive substituents may be attributed to the interaction of the substituent with the asymmetrical vibration of the C=C=O moiety. This vibration, depicted as **2***A* and **2***B*, causes a large change in the dipole moment during the vibration, and this gives rise to the strong ketene band (4*a*). The normal dipole moment of ketones is toward the negatively charged oxygen as represented by resonance structure **1***B*, which corresponds to the vibrational structure **2***B*, and electropositive substituents would augment this interaction.

2*A* **2***B*

Inclusion of the latter 10 substituents in Table 2 in the plot of intensity versus electronegativity results in positive deviations of the calculated intensities from the defined correlation, as shown by closed circles on Fig. 3. These substituents (NO_2, NO, NC, CN, HC≡C, CH_2=CH, CH_2=C=CH, CO_2H, CHO, and Ph) can act as π acceptors, which can interact strongly with the vibrational structure **2***A*, which has enhanced

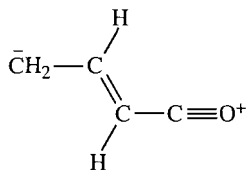
C—C single bond character, and a polarity corresponding to **1***A*, with positive charge on oxygen and negative charge on C_β. The π acceptor group could delocalize this negative charge as in the structure **3** for vinylketene, which has been proposed (13*c*) as leading to the low observed dipole moment of this ketene. Such an interaction could enhance the dipole moment change during the vibration, and thereby increase the intensity.



3

Thus the ketene vibrational intensities are enhanced by both electropositive and by π-acceptor substituents, and the same effects have been proposed to stabilize ketenes (10*a*). There is no strong correlation of the infrared intensities and frequencies, and as noted above the field effect of the substituents appears to be a major contributor to the latter. There is also no correspondence between the *ab initio* calculated intensities and similarly calculated dipole moments, which have been reported previously (10*a*), as the former are determined by the changes in dipole moment during the vibration (4*a*).

In conclusion *ab initio* calculated frequencies for the characteristic vibrations of both monosubstituted and disubstituted ketenes give reasonable predictions of the experimental values. A test of a reported correlation of ketene frequencies with substituent field and resonance parameters shows that field parameters alone are sufficient for the correlation, which is however of limited predictive value. There is a good correlation of calculated intensities with substituent group electronegativities, and there is a further effect of enhancement of the intensities by π acceptor groups.

The reaction $O(^1D)$ + HBr has been investigated by the crossed molecular beams and infrared chemiluminescence methods in an effort to characterize the dynamics of both possible reactive channels. The angular and velocity distribution of the BrO product from the $O(^1D)$ + HBr → BrO + H pathway have been obtained in crossed beam experiments at collision energies, E_c, of 5.0 and 14.0 kcal/mol. The product center-of-mass angular distribution is found to be almost backward–forward symmetric at both E_c, with backward scattering being slightly favored, from which it is deduced that two processes contribute to this channel: a dominant one occurring via formation of a long-lived complex, following $O(^1D)$ insertion, and another one occurring via direct abstraction of the halogen atom and giving rise to a rebound dynamics. The large fraction (≈50%) of available energy released into translation indicates the existence of a potential barrier for H-displacement in the exit channel. From energy and angular momentum conservation arguments, it is inferred that BrO is formed rotationally very hot in the lowest vibrational levels of both $^2\Pi_{3/2}$ and $^2\Pi_{1/2}$ electronic states. The initial vibrational distribution of the OH product from the $O(^1D)$ + HBr → OH + Br channel has been measured using fast time-resolved Fourier transform spectroscopy. The vibrational distribution is strongly inverted, from which it is deduced that the HOBr intermediate dissociates very rapidly, before energy randomization occurs. A lower limit to the branching ratio of the relative cross sections for the BrO + H and OH + Br channels is derived ($\sigma(BrO + H)/\sigma(OH + Br) \geq 0.16 \pm 0.07$) and compared to recent bulk work. The dynamical results for the overall reaction are discussed with reference to the relevant singlet and triplet potential energy surfaces and possible molecular configurations involved. Comparison with the dynamics of the ground state reaction $O(^3P)$ + HBr → OH + Br is carried out also, to examine the effect of electronic excitation on the dynamics of the reactions of atomic oxygen with hydrogen halides.

Dans le but de caractériser les dynamiques des deux vois réactionnelles possibles, on a étudier la réaction $O(^1D)$ + HBr par des méthodes de faisceaux moléculaires croisés et de chimiluminescence infrarouge. On a obtenu les distributions angulaires et de la vélocité du produit BrO provenant de la voie $O(^1D)$ + HBr → BrO + H à l'aide des expériences de faisceaux croisées, à des énergies de collision, E_c, de 5,0 et 14,0 kcal/mol. On a trouvé qu'aux deux E_c la distribution du masse du produit est pratiquement symétrique pour les deux directions même si la diffusion vers l'avant est légèrement favorisée; on en déduit que les deux processus contribuent à cette voie: un processus dominant qui se produit par la formation d'un complexe de longue durée après l'insertion du $O(^1D)$ et un autre qui se produit par un enlèvement direct de l'atome d'halogène et qui donne lieu à une dynamique de rebondissement. La plus grande partie de l'énergie disponible (environ 50%) est transmise sous forme de translation et ceci suggère l'existence d'une barrière de potentiel pour le déplacement du H dans la voie de sortie. Sur la base d'arguments relatifs à la conservation de l'énergie et du moment angulaire, on en déduit que le BrO se forme rotationnellement très chaud dans le états de vibration les plus bas des états électroniques $^2\Pi_{3/2}$ et $^2\Pi_{1/2}$. On a mesuré la distribution vibrationnelle initiale du OH produit par la voie $O(^1D)$ + HBr → OH + Br en faisant appel à de la spectroscopie par transformation de Fourier rapide et résolue en fonction du temps. La distribution vibrationnelle est fortement inversée et, sur cette base, on déduit que l'intermédiaire HOBr se dissocie très rapidement, avant qu'une distribution au hasard ne se produise. On a déduit une limite inférieure pour le rapport des branchements des sections droites relatives des voies BrO + H et OH + Br ($\sigma(BrO + H)/\sigma(OH + Br) \geq 0{,}16 \pm 0{,}07$) et on l'a comparée à celle obtenue au cours d'un travail récent. On discute des résultats dynamiques de la réaction globale en faisant référence aux surfaces d'énergie potentielle singulet et triplet appropriées et aux configurations moléculaires qui pourraient être impliquées. Afin de pouvoir examiner l'effet de l'excitation électronique sur la dynamique des réactions de l'oxygène atomique avec les halogénures d'hydrogène, on a aussi effectué une comparaison avec la dynamique de la réaction de l'état fondamental $O(^3P)$ + HBr → OH + Br.

[Traduit par la rédaction]

Introduction

The reactions of atomic oxygen, both in the ground state $O(^3P)$ and the first electronically excited state $O(^1D)$, with hydrogen halides are of interest in determining the impact of halogen compounds on the chemistry of the stratosphere, particulary with regard to the ozone layer. Also, these reactions occur in the combustion chemistry of halogenated compounds, for example in their use as fire extinguishers. From a fundamental point of view, they comprise a class of three-atom reactions which are amenable to detailed experimental and theoretical investigation. While rate constants as a function of temperature have been measured for the series of the $O(^3P)$ + HX (X = Cl, Br, I) reactions (1–5), only the room temperature rate constants have been determined for the reactions $O(^1D)$ + HCl, HBr, and HF (6, 7). Upon electronic excitation, the rate constant at room temperature increases by six and four orders of magnitude for HCl and HBr, respectively. The reactions of $O(^1D)$ with most compounds occur with near gas kinetic frequency, including those with halogenated molecules (8, 9). This is due to the fact that $O(^1D)$ reactions take place on singlet potential energy sur-

faces with virtually zero activation energy, in contrast to $O(^3P)$ reactions which proceed on triplet surfaces with significant activation energies.

While the microscopic dynamics of $O(^3P)$ reactions with simple molecules have been investigated for a number of years, studies on the reactions $O(^3P)$ + HX (X = Cl, Br) have been reported only recently by Zare and co-workers (10, 11). In the series $O(^1D)$ + HX, only studies on the reaction dynamics with HCl have been reported (12–15). The reactions $O(^3P, ^1D)$ + HCl have also received significant theoretical attention (16*a–c*). No dynamical information is available on the next reaction of the series, namely $O(^1D)$ + HBr.

Dynamical studies of $O(^1D)$ reactions with simple molecules address the important issue of the role of electronic excitation on reaction dynamics. While there has been a long-standing interest in the collisional removal rates of electronically excited atoms (17), only recently has the effect of atomic electronic excitation on the dynamics of A + BC reactions been tackled in crossed beams, using laser excitation of alkali and alkali-earth atoms, in a series of elegant crossed beam experiments by Lee and co-workers (18) and other researchers (19). There has been less work on this effect for non-metal atoms in A + BC reactions. A direct comparative study for the reaction $O(^3P, ^1D)$ + H_2S using crossed beams has been reported recently (20, 21). In this context, new dynamical studies of $O(^1D)$ reactions alone can provide the basis for indirect comparisons for those cases where dynamical studies involving $O(^3P)$ are already available. This is the case of the reaction between atomic oxygen and hydrogen bromide to be examined in the present report.

Bromine contributes significantly to the loss of stratospheric ozone. It is believed to account for nearly one third of the yearly Antarctic ozone loss in the austral spring (22) and for a sizeable fraction of the mid-latitude ozone decline over the last decade (23). The reason for the high contribution of bromine in spite of its much lower (about 1/100) concentration with respect to chlorine is that it is predominantly in "active" forms (compounds which react with ozone directly) in the stratosphere whereas Cl is often in the form of inactive, or "reservoir" compounds. For example, reactions with H_2 and CH_4 which convert active Br into HBr are endoergic, and reservoir molecules such as HBr and $BrONO_2$ are much less stable than the corresponding Cl-containing molecules. Current atmospheric models suggest that the dominant form of bromine in the stratosphere is BrO, a form catalytically active towards ozone destruction. Formation of BrO is a likely pathway in the reactions of $O(^1D)$ with bromocarbons, following direct abstractions or insertion (24). These reactions are faster than the analogous ones with chlorocarbons. BrO formation can arise from the reaction of $O(^1D)$ with HBr also, where the HBr comes from UV photoelimination processes involving hydrobromocarbons.

The reaction of $O(^1D)$ with HBr can be considered prototypical of the reactions of $O(^1D)$ with brominated compounds. The reaction can proceed via two competing pathways:

$$O(^1D) + HBr \rightarrow \begin{cases} \rightarrow OH + Br & \Delta H_0^0 = -60.5 \text{ kcal/mol} \quad [1a] \\ \rightarrow BrO + H & \Delta H_0^0 = -14.0 \text{ kcal/mol} \quad [1b] \end{cases}$$

Also, there is a physical quenching channel:

$$O(^1D) + HBr \rightarrow O(^3P) + HBr \qquad \Delta H_0^0 = -45.4 \text{ kcal/mol} \quad [1c]$$

All products of reaction [1] are catalytically active species in ozone chemistry. A single occurrence of this reaction can initiate the two catalytic cycles (25):

$$\begin{aligned} OH + O_3 &\rightarrow HO_2 + O_2 \\ HO_2 + O &\rightarrow OH + O_2 \\ \hline \textit{net}: \; O_3 + O &\rightarrow 2O_2 \end{aligned}$$

and

$$\begin{aligned} Br + O_3 &\rightarrow BrO + O_2 \\ BrO + O &\rightarrow Br + O_2 \\ \hline \textit{net}: \; O_3 + O &\rightarrow 2O_2 \end{aligned}$$

each of which removes a molecule of ozone and regenerates the reagent radical on each occurrence of the cycle. Furthermore, BrO from reaction [1*b*] can disproportionate (26):

$$BrO + BrO \rightarrow BrO_2 + Br$$

$$BrO + BrO \rightarrow Br_2 + O_2$$

where the unstable BrO_2 species decomposes to Br + O_2 and Br_2 is readily photolyzed to atomic bromine. Therefore, both reactions convert BrO to Br, which starts the catalytic cycle again. Bromine atoms are also regenerated from the very rapid reaction with NO (26):

$$BrO + NO \rightarrow Br + NO_2$$

The bromine–chlorine radical coupling reaction

$$BrO + ClO \rightarrow Br + ClO_2$$

is also important in the stratospheric budget of halogenated species (27). Finally, H-atoms from reaction [1*b*] can react rapidly with ozone (28):

$$H + O_3 \rightarrow OH + O_2$$

creating catalytically active OH.

A recent kinetic study (7) has established that the total rate constant for $O(^1D)$ removal by HBr is very large ($k_{298} = 1.48 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}) and has estimated the branching ratio for reaction [1*a*] and [1*b*] to be $k(1b)/k(1a) \leq 0.05$. The finding that the H-displacement pathway is a minor channel in the reaction of $O(^1D)$ with HBr is somewhat surprising since the analogous reaction with HCl was found to proceed with a similar rate, but the corresponding of channel [1*b*] was estimated (7, 15) to account for about one third of the overall reaction.

Once the total rate constant is established, it becomes important to determine the branching ratio among the possible reaction pathways and the detailed dynamics of the overall reaction. Knowledge of the energy partitioning behavior of the possible reaction channels is important, because the fate of the products in subsequent reactions depends to a large extent upon their state of excitation. For instance, vibrationally excited hydroxyl radicals can undergo reactions with ozone which are not energetically accessible to ground state OH:

$$OH\,(v = 3) + O_3 \rightarrow OH(v = O) + O(^3P) + O_2$$

and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

$$OH\ (v = 1) + O_3 \rightarrow H + 2O_2$$

Finally, the electronic to vibrational energy transfer occurring in the physical quenching channel creates vibrationally excited HBr which can undergo subsequent reactions as well.

This analysis indicates that a dynamical study of reaction [1] may be very useful from both practical and fundamental points of view.

In this work, we report the results of the first direct dynamical investigation of reaction [1]. We employ two sophisticated complementary experimental techniques: the fast time-resolved Fourier-transform infrared chemiluminescence method is used to unravel the dynamics of the H-abstraction channel [1*a*] leading to OH formation, while the crossed molecular beams scattering method with mass spectrometric detection is used to characterize the dynamics of the H-displacement channel [1*b*], which leads to the formation of BrO. The latter also provides an estimate of the lower limit for the ratio of the cross sections for branching into channels [1*b*] and [1*a*]. We found it essential to use both of these powerful and complementary techniques to obtain a complete picture of the reaction dynamics of $O(^1D)$ with HBr. In this context, we note that the combination of molecular beams and low pressure infrared chemiluminescence techniques has provided much of the basis for our present understanding of molecular reaction dynamics. This was recognized by the award of the 1986 Nobel prize for chemistry to D.R. Herschbach, Y.T. Lee, and J.C. Polanyi. Professors Herschbach and Lee pioneered molecular beams methods, and Professor Polanyi developed infrared chemiluminescence for this purpose. It is our pleasure to dedicate this paper to Professor Polanyi on the occasion of his sixty-fifth birthday.

The paper is organized as follows: in Section II we will describe the configuration of the spectroscopic and scattering experiments. The results will be presented in Section III and the discussion will follow in Section IV.

II. Experimental

A. The crossed molecular beams experiment

The scattering experiments were carried out on the universal crossed molecular beam apparatus of Perugia, which is an implementation for reactive scattering studies of the high-resolution machine previously used for measuring elastic and total (elastic + inelastic) differential cross section for atom–atom and atom–molecule collisions (29). The apparatus has been described in detail elsewhere (21, 29), and only a brief description necessary to understand the present experiments is given here. Two well-collimated supersonic beams of the reactants, after two stages of differential pumping, are crossed at 90° under single-collision conditions in a large scattering chamber maintained below 5×10^{-7} mbar. The reaction products are detected by an electron bombardment ionization quadrupole mass-spectrometer which can rotate in the plane of the two beams around their intersection axis (i.e., around the collision region). The ionizer is mounted on a liquid nitrogen cooled OFHC copper chamber, which is kept in the 10^{-11} mbar region by extensive ion-, turbo-, and cryo-pumping and represents the innermost region of a triply differentially pumped ultra-high-vacuum rotatable chamber.

The seeded supersonic atomic oxygen beams, containing $O(^1D)$ and ground-state $O(^3P)$, were generated by a high-pressure, radio-frequency (rf) discharge nozzle source similar in design to that described by Sibener et al. (30) and which has been optimized for $O(^1D)$ production (15, 20, 21). Two $O(^1D)$ beams with different translational energies were produced in order to vary the relative collision energy of the experiment. By discharging 350 mbar of a 5% O_2 in helium gas mixture through a 230 μm diameter quartz nozzle at 250 W of rf power, a beam with peak velocity of 2962 m/s and speed ratio of 6.4 was obtained. By discharging 350 mbar of a 5% O_2 in neon gas mixture through a 260 μm diameter quartz nozzle at 290 W of rf power a beam with peak velocity of 1715 m/s and speed ratio of 5.8 was produced. The angular divergence is 2.3° in both cases. Using the fast and slow beams of $O(^1D)$, relative collision energies, E_c, of 14.0 and 5.0 kcal/mol, respectively, were obtained (see below). Due to very efficient coupling of the rf power to the plasma, high degrees of molecular dissociation are achieved (>80% and >90% with the helium and neon mixture, respectively). The oxygen beams contain a very large fraction of ground-state $O(^3P)$, but this species does not interfere as the collision energies of our experiments are not sufficient to overcome the strong endoergicity of the reaction $O(^3P) + HBr \rightarrow BrO + H$ (ΔH = 31.4 kcal/mol).

Supersonic beams of HBr were generated by expanding pure HBr at a stagnation pressure of 1 bar through a 100 μm diameter stainless-{2}steel nozzle kept at about 510 K to prevent significant cluster formation. For the experiment at E_c = 14.0 kcal/mol the peak velocity was 616 m/s, while slightly different experimental conditions gave a peak velocity of 599 m/s for the experiment at E_c = 5.0 kcal/mol. Speed ratios were about 9 and the angular divergence 2.9° in both cases. Because of the significant rotational cooling during supersonic expansion (a rotational temperature of about 25 K is estimated assuming equilibrium between translational and rotational degrees of freedom), the HBr molecules in the beam are expected to be in the lowest few rotational states of the ground vibrational level and therefore the internal energy of the molecular reactant contributes negligibly (<0.2 kcal/mol) to the total available energy.

Angular distributions of products of reaction [1*b*] were obtained by taking at least 5 scans of 100 s counts at each angle. The HBr beam was modulated at 160 Hz by a tuning-fork chopper for background subtraction. Velocity analysis of the beams was carried out by conventional "single-shot" time-of-flight (TOF) techniques, using a high-speed multichannel scaler and a CAMAC data acquisition system controlled by a personal computer.

Velocity distributions of products were obtained at 13 different angles at E_c = 14.0 kcal/mol and at five different angles at E_c = 5.0 kcal/mol using the cross-correlation TOF technique (31) with four 127-bit pseudorandom sequences. High-time resolution was achieved by spinning the TOF disk, located at the entrance of the detector, at 393.7 Hz corresponding to a dwell time of 5 μs/channel. The flight length was 23.6 cm. Counting times varied from 30 to 120 min depending upon the signal intensity.

B. The time-resolved infrared chemiluminescence experiment

The internal energy distributions in the products of reaction [1*a*] were obtained by measuring their vibrationally- and rotationally-resolved infrared chemiluminescence emission spectra under conditions in which negligible collisional thermalization of these distributions had occurred. In addition, subsequent collisional energy transfer processes were also observed. Both of these results were obtained using fast time-resolved Fourier transform spectroscopy (FTRFTS) with a conventional low pressure infrared chemiluminescence apparatus.

The infrared chemiluminescence apparatus consists of a 25 cm diameter cylindrical stainless steel reaction chamber equipped with two sets of multipass mirrors on axes which are both perpendicular to the axis of the chamber. One set of mirrors passes light from a KrF excimer laser back and forth four times through the reaction zone at the centre of the chamber. The other set collects the emission from the reaction products and focuses it into a Michelson interferometer. The chamber is evacuated through a 38 cm diameter cryobaffle and a 30 cm diameter gate valve by a 5000 L/s diffusion pump. The gate valve is adjusted to maintain the desired pressure (approximately 3×10^{-2} mbar) during the experiments. A dry-ice-cooled copper baffle is also located inside the reaction zone to improve cryopumping and reduce both the thermal and optical background created by the excimer laser light.

Ozone and HBr enter the chamber from the top, are mixed thoroughly by a Teflon baffle just inside the inlet, and flow downward

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

between the multipass mirrors. The ozone is photodissociated by the 248 nm light from the KrF excimer laser, a modified Lumonics model TE-860-4 laser, which produced about 20 mJ/pulse at 330 Hz, the repetition rate required by the experiment.

The photodissociation forms $O(^1D)$ (90%) and $O(^3P)$ (10%) with relative translational energies of about 10 and 37 kcal/mol, respectively (32), in the frame of reference of the HBr collision. As mentioned earlier, the activation energy for the reaction of HBr with $O(^1D)$ is nearly zero, and that of the $O(^3P)$ reaction is about 3 kcal/mol (2–4). In principle, therefore, we cannot rule out the possibility that both electronic states of oxygen created in the photolysis contribute to the *initial* OH product observed in these experiments. We note in passing that this potential interference is possible with *all* experiments which use photodissociation of O_3 to generate $O(^1D)$, unless a very large excess of buffer gas be used to thermalize the translationally hot reagents. If buffer gas is used, however, the results could be compromised by partial thermalization of the reaction products by the buffer gas. To our knowledge, there is no clear experimental resolution to these conflicting effects of adding buffer gas for reagent thermalization.

The interfering reaction with $O(^3P)$ would have to occur at its first collision after the photolysis, because most of the excess translational energy would be lost on the first collision. The presence of translationally hot $O(^3P)$, however, may not be important to the results reported here, for several reasons: first, it is a minor constituent (<10%) of the photodissociation products. Second, the reactive cross sections of processes such as this decrease at the extremely high relative translational energy of the $O(^3P)$ atom (33, 34) and finally, increased reagent translational energy causes reduced product vibrational excitation in reactions such as this (35). This latter effect, in the case of the reaction reported here, causes the OH from the $O(^3P)$ reaction to be created predominantly in the lowest vibrational levels. In contrast to this, the results which we shall describe in the later sections, show that the OH is actually created in very high vibrational levels, consistent with the distribution expected from the $O(^1D)$ reaction.

The partial pressures of each of the O_3 and HBr were maintained at about 0.01 mbar, so the average gas kinetic collision time of the OH with the background gases during the experiments was about 4 μs. The first spectrum was recorded at a time delay of 20 μs *before* the photolysis laser pulse. Thereafter, spectra were recorded at 40 μs intervals until 540 μs after the photolysis pulse. The first measurement which contained signal from the reaction, therefore, was recorded 20 μs, or about 5 gas kinetic collisions, after the initiation of the reaction, and subsequent measurements were spaced at intervals of about 10 gas kinetic collisions.

The time-resolved Fourier transform apparatus used in these experiments was described previously (36). The algorithm, based on continuous-scan Fourier transform spectroscopy, was compared with other similar methods in a previous publication (37). The particular data acquisition configuration used in these experiments was a CAMAC-based PDP 11/83 processor with a LeCroy model 8818 transient digitizer. This was a prototype instrument; it was replaced recently by a VME-based system (38) which uses hardware built in our laboratory, and a Motorola 68040 processor.

The data acquisition system which we developed for our implementation of FTRFTS operates with any commercial continuous-scan Michelson interferometer. For the experiments reported here, we used the interferometer from a Nicolet 7199 FTS instrument, which had been slightly modified for this application. The data acquisition system produces time-resolved spectra by triggering the excitation source (the KrF laser in the present case) at a precisely-measured time with respect to the zero crossing of the He/Ne laser, then triggering the A/D which samples the infrared interferogram at several (precisely-measured) times which are delayed with respect to the time at which the excitation source is triggered. In our implementation, a single scan of the interferometer collects all of the time-delayed interferograms; it is not necessary to interleave data points collected during different interferometer scans into the same interferogram. This point is important in experiments which have systematic noise or instabilities, because the latter can create spectroscopic artifacts if used with the interleaving or "stroboscopic" method. This point is discussed in more detail in ref. 37.

III. Results and analysis

The two experimental techniques employed for the present studies are not equally sensitive for detecting the products of the two possible reactive pathways. The crossed molecular beams technique is more suitable for investigating the H-displacement channel, while the infrared chemiluminescence method is very sensitive to the H-abstraction channel leading to OH product. Under the experimental conditions of the scattering study we were able to observe only the BrO product from reaction [1*b*], while the signal from the kinematically unfavored OH, produced in the reaction channel [1*a*], was <0.01 of the signal from BrO measured at $m/e = 95$. On the basis of linear momentum conservation, in fact, the light OH from the strongly exothermic channel [1*a*] will travel very fast and will be spatially distributed in a very broad laboratory range, while the very heavy BrO from the significantly less exothermic channel [1*b*] will have a much lower center-of-mass (c.m.) velocity and will be confined in a narrow lab angular range around the c.m. This leads to a strong enhancement of the BrO number density in the lab frame with respect to that of OH. From our failure to detect the OH only a lower limit for the ratio of the relative cross sections for the two reaction channels could be estimated (see below). Instead, the OH channel can be easily examined by using spectroscopic techniques such as chemiluminescence emission, which is most sensitive to vibrationally excited species having high Einstein transition probabilities, such as diatomic hydrides. This technique, when coupled with the sensitivity and high resolving power of Fourier transform spectroscopy, can detect less than 10^{10} emitters/(quantum state cm^3) in the infrared.

A. The reactive scattering results: center-of-mass angular and energy distributions of the BrO product

The angular distributions of the BrO product, detected at $m/e = 95$, for the collision energies of 14.0 and 5.0 kcal/mol are shown in Fig. 1. The error bars are of the order of the size of the dots. Product counting rates were 1500 c/s and 500 c/s at the high and low E_c, respectively, with signal-to-noise above 100 using 100 s counting times. The solid lines in Fig. 1 show the calculated best-fit (see below). The product time-of-flight distributions of the two energies are reported in Figs. 2 and 3 together with the results of the best-fit calculations (see below). The TOF distributions have been normalized to the relative intensities at each angle. The angular distributions show some structure around the c.m., with a shoulder at angles $> \Theta_{c.m.}$ higher than at angles $< \Theta_{c.m.}$. The TOF spectra at the highest E_c display also some bimodality at angles close to the center-of-mass. This fact and the fairly large width of the lab angular distributions suggest that the product translational energy distribution peaks away from zero and that the fraction of available energy released in translation is large.

Data at both energies were analyzed by using a forward convolution trial-and-error fitting technique in which the c.m. angular and energy distributions are input as trial functions (39, 40). The corresponding laboratory angular and TOF distributions are then calculated and compared to the experimental data. The experimental resolution broadening, due to the TOF disk and detector slit sizes, disk velocity, and ionizer length, and spread in beam velocities and angular divergences, is taken into account. The original trial function is adjusted and the process

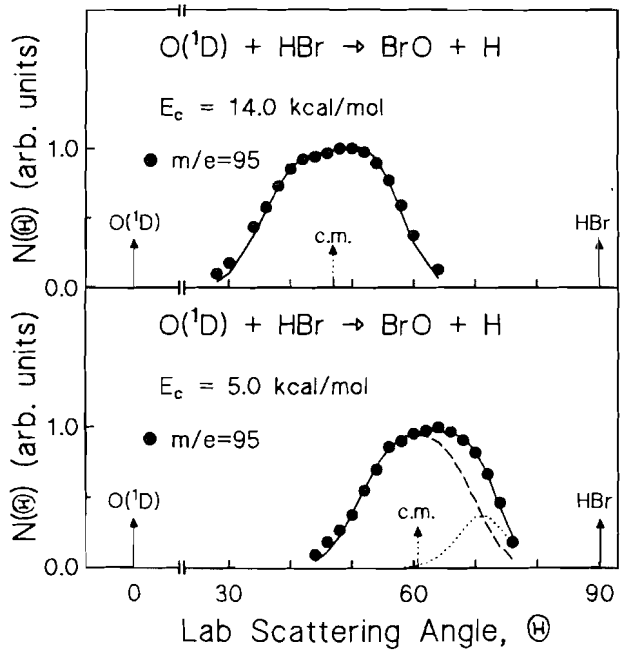

FIG. 1. Laboratory angular distribution of the BrO product from the $O(^1D)$ + HBr reaction at two different collision energies, E_c. Solid lines: calculation with best-fit c.m. translational energy and angular distributions of Fig. 4. In the lower panel, dashed and dotted lines represent the contribution of the long-lived complex mechanism and the rebound mechanism, respectively (see text).

repeated until a satisfactory fit is obtained to both the TOF spectra and the angular distributions. The energy dependence of the reaction cross section has been taken into account in the data analysis. For a reaction without threshold and dominated by long-range forces in the entrance channel, the centrifugal barrier model (41) predicts a decrease of the cross section with the relative collision energy and, therefore, an $E^{-1/3}$ dependence has been used.

The c.m. product flux distribution is assumed to be separable into the product of a translational energy and angular part:

$$I_{c.m.}(\theta, E') = T(\theta) \times P(E')$$

Data at the highest E_c could be fitted in this way. The best fit calculations to the experimental angular and TOF distributions are shown as solid lines in Figs. 1 and 2, respectively. Figure 4 shows the resultant c.m. angular distribution, $T(\theta)$, and translational energy distribution, $P(E'_T)$. The final result of the data fitting analysis is a c.m. contour map of product flux as a function of angle and product recoil energy (40). After a straightforward transformation to convert the flux distribution from an energy space to a velocity space, the c.m. contour map $I_{c.m.}(\theta, u)$, where u is the c.m. product velocity, is represented in polar form in Fig. 5, where a 3-D perspective is also given. The $P(E'_T)$ distribution is very broad and peaks at about 18 kcal/mol, beyond the exothermicity, extending up to the limits of energy conservation (see Fig. 4*b*). The average product translational energy

$$\langle E'_T \rangle = \sum P(E'_T)E'_T / \sum P(E'_T)$$

is about 49% of the total available energy, E_{tot}, which, under the present experimental conditions, is the sum of the relative collision energy and the reaction exoergicity.

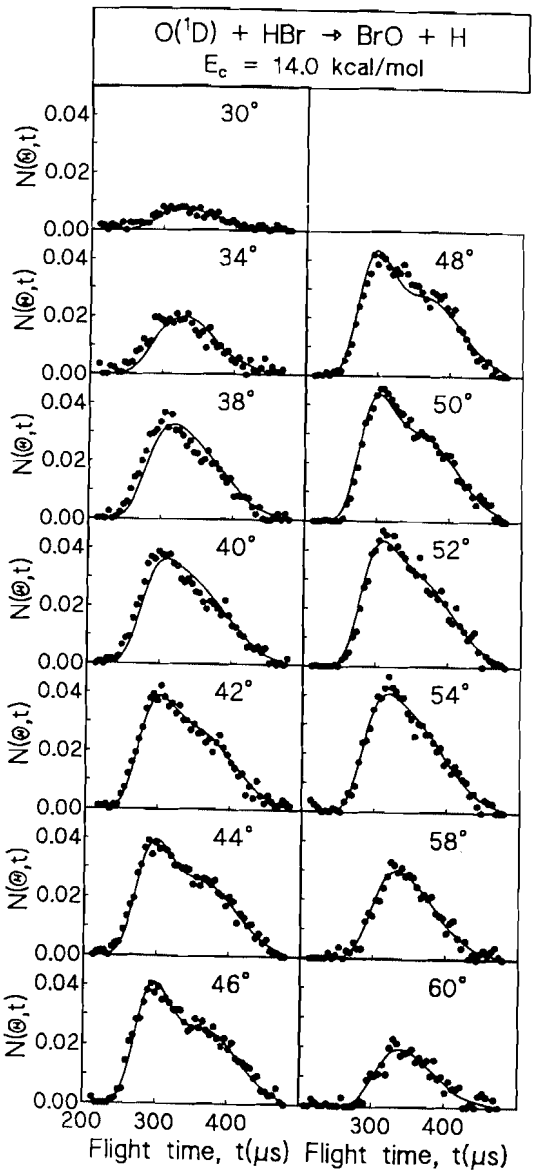

FIG. 2. Time-of-flight spectra of the BrO product at the indicated laboratory angles for the collision energy of 14.0 kcal/mol. The time scale is absolute, the ion flight time and electronic offsets having been taken into account. The distributions are normalized to the relative intensities at each angle. Solid lines: calculation with best-fit c.m. translational energy and angular distributions of Fig. 4.

The transformation of the c.m. flux $I_{c.m.}(\theta, u)$ to laboratory number density $N(\Theta)$ is given by (40):

$$N(\Theta) = (v/u^2)I_{c.m.}(\theta, u)$$

The effect of the Jacobian v/u^2 for the coordinate transformation is seen in the strong enhancement of the low energy product. While the product flux actually peaks fairly well removed from the c.m. vector on the relative velocity axis (see Fig. 5), the observed lab signal, which is proportional to $N(\Theta)$ does not show a pronounced dip around the c.m. The c.m. angular distribution is not backward–forward symmetric, as one would expect if the reaction were proceeding through a long-lived complex, i.e., a complex with a lifetime of several rotational periods (42). A slightly favored backward scattering (with re-

spect to the O atom direction) is noted, well outside the uncertainty. A symmetric $T(\theta)$ would give a calculated symmetric lab angular distribution, while experimentally there is more intensity in the backward direction. This is similar to what was found in the homologous reaction of $O(^1D)$ with HCl (15), where the $T(\theta)$ was interpreted as arising from the superposition of a dominant backward–forward component, following the decomposition of a persistent complex, with a backward component due to a direct rebound interaction. The peaking at the poles ($\theta = 0°$ and 180°) with respect to $\theta = 90°$ provides information about the disposal of the total angular momentum into product rotation (42). In the present case a very weak polarization is found (see Fig. 4(*a*)), weaker than in the case of $O(^1D)$ + HCl. As it will be discussed below, this is consistent with the expected trend of the product rotational excitation.

The data at the lowest E_c could not be fitted quantitatively with single uncoupled c.m. angular and translational energy distributions, although it was possible to reproduce all the qualitative features. In particular, it was not possible to fit the intensity of the angular distribution at angles larger than $\Theta_{c.m.}$. The data could only be fitted by invoking two different reaction micromechanisms, the same two micromechanisms which we believe to be involved at the higher energy: a dominant one involving formation of a long-lived complex with fairly high translational energy release, and a second, backward scattered mechanism with a very high translational energy release. Direct backward scattering attributable to steric effects and accompanied by strong repulsion in the exit channel has been observed in bimolecular reactions (43). The c.m. flux in energy space was parametrized according to:

$$[2] \quad I_{c.m.}(\theta, E') = T_1(\theta) \times P_1(E') + \alpha \times T_2(\theta) \times P_2(E')$$

where the parameter α weights the contribution of the backward component. The best fit to the data at E_c = 5.0 kcal/mol is shown in Figs. 1 and 3 as a continuous line; the two separate contributions from the two micromechanisms are indicated by the dashed and dotted lines. The corresponding best-fit c.m. functions are depicted in Fig. 6. The component corresponding to direct backward scattering accounts for 15% ($\alpha = 0.15 \pm 0.03$) of the overall H-displacement channel, and leads to a larger translational energy release than the micromechanism corresponding to the decay of a long-lived HOBr complex. Within the uncertainty of our determination, the symmetric $T(\theta)$ is isotropic, suggesting a high degree of rotational excitation. The $P(E'_T)$ distributions of the two micromechanisms indicate that at low E_c as well, a large fraction of the total available energy is channeled into translation. The average product translational energy, $\langle E'_T \rangle$, is 48% of the total available energy for the mechanism associated with the formation of a long-lived complex and 77% for the direct rebound mechanism.

A fit attempting to disentangle the contribution of the two possible processes was also carried out at E_c = 14.0 kcal/mol. Using c.m. angular distributions which are similar, and of comparable relative weight, to those found for the low E_c case, it was possible to reach a slightly better fit than that obtained using the single components of Fig. 4. The two resulting $P(E'_T)$

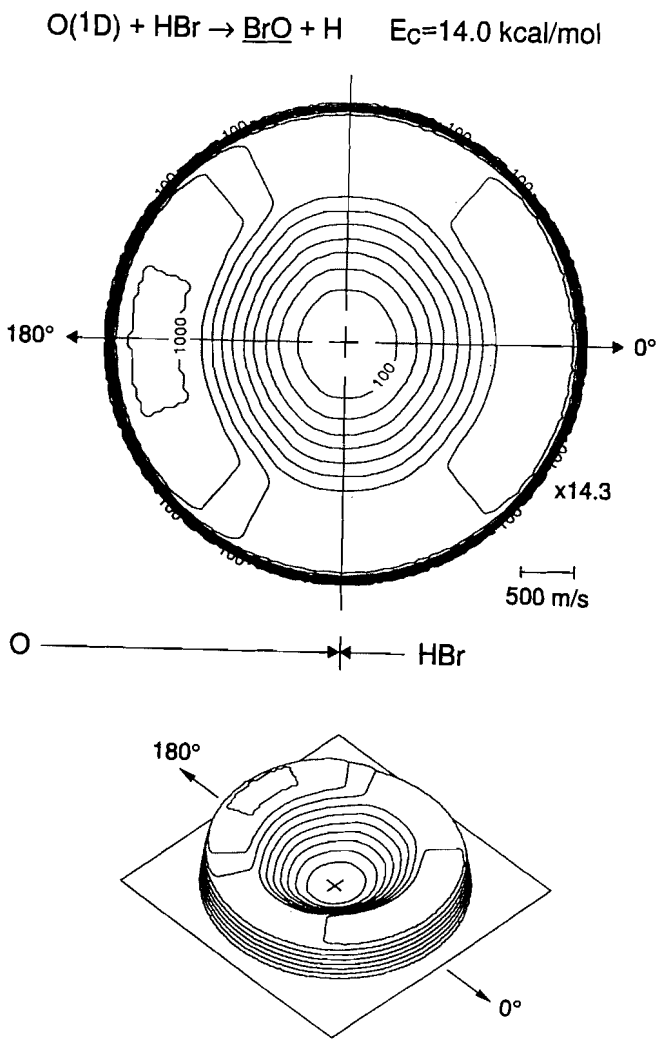

FIG. 5. Top: center-of-mass polar flux (velocity-angle) contour maps of BrO product at a relative collision energy of 14.0 kcal/mol. Bottom: three-dimensional representation of reactive flux intensity at E_c = 14.0 kcal/mol.

distributions, however, were actually overlapping each other. Because of this, we did not feel that an analysis in terms of two components was warranted.

B. The infrared-chemiluminescence results: energy partitioning in the BR + OH channel

A selection of the time-dependent emission spectra recorded using the FTRFTS system is shown in Fig. 7. All of the lines in these spectra can be assigned to the fundamental bands of either OH or HBr. The emission from about 2700 to about 3500 cm^{-1} is from OH, while that from 2350 to 2600 cm^{-1} is from HBr. The spectral resolution is about 0.4 cm^{-1}, which is high enough to resolve all vib-rotational lines in the spectra of OH and HBr, as well as the OH spin doublets and some of the OH lambda doublets. The populations of all vib-rotational states were calculated from the intensities of the corresponding emission lines, using known OH Einstein transition probabilities (44). The zero of the experiment's timescale is defined by the KrF laser pulse which creates the $O(^1D)$; time increases from the bottom of the figure to the top. The bottom spectrum was recorded at 20 μs (about five gas kinetic collisions) after the KrF laser, and the remaining spectra in the figure were recorded at 60 μs (15 collisions), 100 μs (25 collisions), 140 μs (35 collisions), 180 μs (45 collisions), and 220 μs (55 collisions) after time = 0. The OH spectra recorded at the earliest times have their greatest populations in the highest vibrational levels, indicating that the reaction creates OH with a strongly inverted vibrational distribution. We found (14) the same shape for the vibrational distribution of the $O(^1D)$ + HCl reaction, a result which was confirmed in later LIF measurements (13). Both the OH emission intensity and its average vibrational excitation decay smoothly after the first observation until the emission ceases to be observable at 300 μs. This temporal behaviour indicates that OH is a primary reaction product. In contrast to this, the HBr emission intensity is nearly zero in the earliest spectrum, but rises smoothly and slowly at the same time when the OH intensity is falling. This contrasting temporal behaviour shows that the OH and HBr arise from two different processes. All species which are produced directly in the $O(^1D)$ + HBr reaction are present in the earliest observation. This includes all of the OH and a very small amount of vibrationally excited HBr produced in the physical quenching of $O(^1D)$, which has been reported to occur in 20% of the $O(^1D)$ + HBr collisions (7). We observed HCl emission from the analogous process in our study of the $O(^1D)$ + HCl system, and were able to determine the branching ratio directly in that case. We found that the HCl is created with a strongly inverted vibrational distribution by this physical quenching process. In the present study, however, there was no evidence of HBr($v' > 1$) emission in the earliest spectrum. As a consequence, we were not able to determine the branching ratio or the HBr internal energy distribution. The only HBr emission

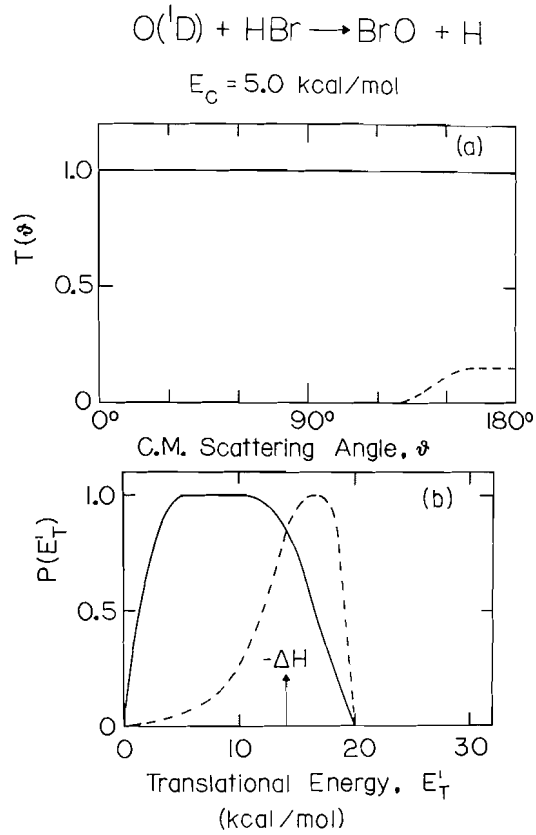

FIG. 6. As in Fig. 4, but at E_c = 5.0 kcal/mol. Solid lines: c.m. functions for the mechanisms via long-lived complex. Dashed lines: c.m. functions for the direct rebound mechanism. The c.m. angular distributions (*a*) for the two different mechanisms are in the same scale.

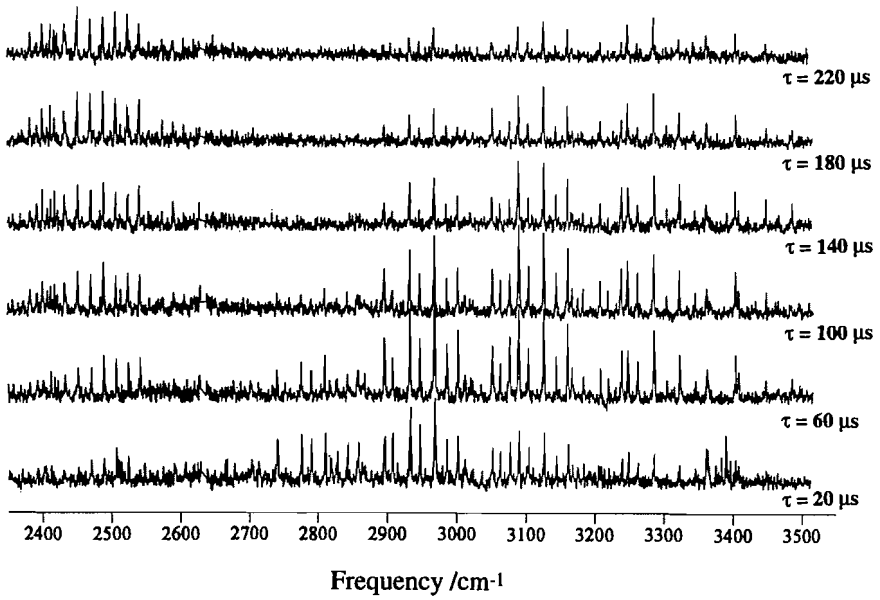

FIG. 7. Time-resolved spectra of the OH product from the $O(^1D)$ + HBr reaction recorded at 40 μs intervals, beginning at 20 μs (bottom) and continuing to 220 μs (top) after the creation of the $O(^1D)$.

For personal use only.

evident in the first spectrum is five transitions of the HBr($v' = 1 \rightarrow 0$) band. The intensity of this emission increases continuously in later spectra. The HBr($v' = 1$), however, is not created in the physical quenching reaction. It is the result of a secondary V–V process between the vibrationally excited OH, created in the reaction, and the remaining HBr($v = 0$) which did not participate in the original reaction:

$$OH(v) + HBr(v = 0) \rightarrow OH(v' < v) + HBr(v = 1)$$

We have also seen this behaviour in the case of the $O(^1D)$/HCl experiments. In both cases, the V–V process is exothermic — the vibrational spacing of OH ($\omega_e = 3738\ cm^{-1}$) is larger than either that of HCl ($\omega_e = 2990\ cm^{-1}$) or HBr ($\omega_e = 2649\ cm^{-1}$) — and it is also quite fast. Since we have no direct measurements of the reagent concentrations, we cannot extract quantitative information about the kinetics of this energy transfer. It is possible to estimate the order of magnitude of the rate constant, however, based on estimated concentrations and the rate of rise of the HBr emission. We estimate the total concentration of vibrationally excited OH to be on the order of 10^{-5} mbar; we know that the concentration of HBr($v = 0$) is about 10^{-2} mbar, and from the rate of increase of the HBr($v = 1$) emission, we estimate that the rate constant for this process must be of the order of $10^6\ mbar^{-1}\ s^{-1}$.

Assignment of the spectra shows that the OH vibrational levels are very highly excited, and show strong population inversion, with population almost to the energetic limit. Because of the large spin–orbit splitting of the Br atom, about 3678 cm^{-1}, the energetic limit on the OH excitation depends on the electronic state of the Br atom. For the OH created in conjunction with the $Br(^2P_{1/2})$ excited state, this limit is OH($v' = 6$), while for that created with the $Br(^2P_{3/2})$ ground state, it is OH($v' = 8$). In contrast, the OH spin–orbit splitting is very small; the $OH(^2\Pi_{1/2})$ excited state is only about 123 cm^{-1} above the $OH(^2\Pi_{3/2})$ ground state.

Examination of the spectra shows that the highest vibrational level which we observe in the $OH(^2\Pi_{1/2}; v')$ manifold is ($v' = 6$). The highest level observed in the $OH(^2\Pi_{3/2})$ ground state manifold, however, is ($v' = 5$). The fact that the excited spin–orbit state has higher vibrational excitation than the ground spin–orbit state is somewhat unusual. It may, however, give information about the preferred reaction pathway, and we shall return to this point later, in the Discussion section.

The OH rotational distributions recorded in our earliest-time spectrum showed slight suprathermal excitation. We believe, however, that these are not the true initial rotational distributions, because rapid rotational energy transfer had probably modified the rotational populations substantially, even at the time of the first spectrum (which corresponds to five gas kinetic collisions). Based on the behaviour we have observed (14, 45, 46) in other experiments involving vibrationally excited OH in collisions with molecules like O_3 and HCl, we estimate that the OH rotational degree of freedom would be partially thermalized after five gas kinetic collisions, and completely thermalized at the second observation, which corresponds to about fifteen collisions.

In this experiment, OH vibrational energy transfer is very much slower than its rotational deactivation, and we believe that virtually no vibrational deactivation had occurred at the time of the initial observation. Vibrational deactivation does occur, however, during our observation time. The data show that the total vibrational inversion is lost after about 250 μs (50–60 gas kinetic collisions). Furthermore, the gases are continuously being pumped through the observation zone, so the OH emission signal becomes too weak to see shortly after this time, at about 300 μs.

The temporal behaviour of the OH vibrational populations is shown in Fig. 8. Each vibrational population is the sum of the rotational populations for that vibrational level. As indicated earlier, we believe that the initial vibrational distribution is that shown for the first time delay. The distribution is collisionally deactivated thereafter in a way which is characteristic of this kind of process. In this vibrational deactivation pattern, which we saw also in the $O(^1D)$ + HCl reaction, the highest vibrational level created by the reaction decreases with time monotonically

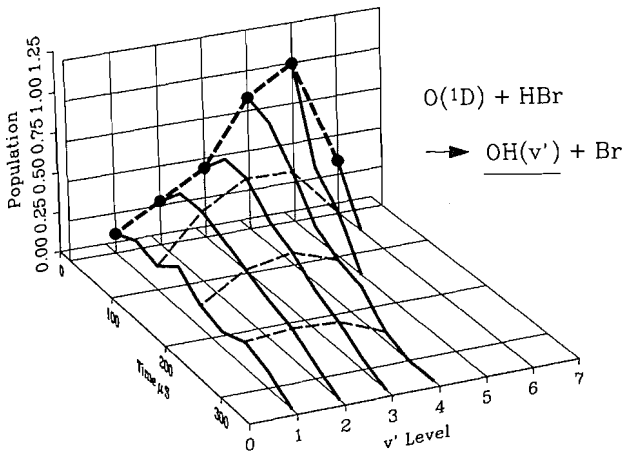

FIG. 8. The evolution of the OH vibrational distribution with time. The initial distribution (recorded at 20 μs) is shown as dots connected by a heavy dashed line. Dashed lines also connect subsequent distributions spaced at 80 μs intervals.

and more rapidly than the lower levels. The populations of the lower levels first increase, then decrease with time. The rates of increase and decrease are fastest for the higher levels and become slower as the vibrational level decreases. Superimposed on this process is a monotonic decrease in the populations of all levels, due to their removal from the observation zone. This overall behaviour constitutes a vibrational "cascading" process in which the predominant collisional deactivation is $\Delta v = -1$. In this process, the initial increase in the vibrational population of each intermediate vibrational level (v) predominantly arises from deactivation of the level immediately above it ($v + 1$), which has a larger population due to the initial population inversion. The population buildup in level (v), in turn, increases the rate of population of the level below it, until the increase with time of the latter is faster than its decrease due to all other processes.

As a consequence of this set of circumstances, the rise and decay of the lower levels is slower than the corresponding processes for the higher levels because the lower levels are fed from an increasingly larger pool of higher levels, and more deactivation steps are involved in their population as the vibrational quantum number decreases. We have modelled the behaviour of such a "cascade" deactivation process for OH collisional relaxation in the products of the reaction $O(^1D) + H_2S \rightarrow OH(v) + HS$. We achieved a reasonable fit using only $\Delta v = -1$ processes (46).

C. The branching ratio $\sigma(BrO + H)/\sigma(OH + Br)$

The mass spectrometric detection of the product OH from channel [1*a*] is, in crossed beams, kinematically very unfavored, since in the c.m. frame, the following relationship holds:

$$u_{OH} = -(m_{Br}/m_{OH})u_{Br}$$

where u is the c.m. velocity and m the mass, and therefore OH will be scattered in a very wide lab angular range. Kinematically it is more favorable to detect the Br atom than the OH counterpart; but, unfortunately, Br^+ produced from dissociative ionization, under electron impact in the detector, of elastically scattered HBr represents a severe complication. We have estimated upper limits for the signal at $m/e = 17$ (OH) and $m/e = 79$ (Br) with respect to the signal at $m/e = 95$ (BrO) by performing TOF measurements at the c.m. angle and have obtained that $(m/e = 17)/(m/e = 95) \leq 0.01$ and $(m/e = 79)/(m/e = 95) \leq 0.05$. Since the absolute intensities of the reactant beams, the exact size of the collision volume, and the detection efficiency are not known, absolute reaction cross sections cannot be derived directly in the present experiment. These parameters, however, do not change during the course of an experiment, and therefore the branching ratio between the two reaction channels can be calculated from the ratio of the relative cross sections, corrected for the ionization cross sections of the products, and their fragmentation patterns and relative transmission through the quadrupole mass filter. The branching ratio, defined as the ratio of the total reaction cross section, $\sigma(ClO + H)$ and $\sigma(OH + Br)$ for channels [1*b*] and [1*a*] is obtained as follows (see also ref. 47):

$$\frac{\sigma(BrO + H)}{\sigma(OH + Br)} = \frac{\sigma^0(BrO + H)}{\sigma^0(OH + Br)} \cdot \frac{\sigma^{ion}(OH)}{\sigma^{ion}(BrO)}$$

where $\sigma^0(BrO + H)$ and $\sigma^0(OH + Br)$ are the apparent cross sections derived from the signal at m/e 95 and 17 and from the ratio of the integrals of the angular and translational energy distributions in the c.m. frame, in which the masses of the different products are taken into account.

A slightly forward-peaked c.m. angular distribution, as obtained from classical trajectory studies (16*b*) for the related $O(^1D) + HCl$ reaction, was assumed for the OH channel and a translational energy distribution, reflecting the degree of internal excitation measured in the infrared-chemiluminescence experiments (see above), was used. The ionization cross sections of OH and BrO, $\sigma^{ion}(OH)$ and $\sigma^{ion}(BrO)$, are approximated using the method of Fitch and Sauter (48) based on polarizability values. The fragmentation pattern under 100 eV electron bombardment was assumed to be the same for the two diatomic species. The transmission of the quadrupole mass filter has been determined to be constant in the range of masses under consideration. The ratio between the cross sections σ for formation of BrO and OH was then calculated to be $\sigma(BrO + H)/\sigma(OH + Br) \geq 0.05$ using the upper limit of the OH/BrO ratio and $\sigma(BrO + H)/\sigma(OH + Br) \geq 0.16 \pm 0.07$ using that of the Br/BrO ratio. The latter value is more reliable, because of the higher sensitivity to the heavier Br atom than to OH. The estimated uncertainty reflects the uncertainty in the c.m. functions (especially $T(\theta)$) assumed for the OH + Br channel, in the ratio of the ionization cross sections and in the fragmentation ratios. For the $O(^1D) + HCl$ reaction (15) it was found $\sigma(ClO + H)/\sigma(OH + Cl) \geq 0.34 \pm 0.10$. However, we note that, under the same experimental conditions, the signal at the BrO mass was 2.5 times larger than the signal at the ClO mass, and even accounting for the 30% larger ionization cross sections of BrO, this leads us to conclude that the cross sections for the channel XO + H are comparable for X = Cl and X = Br. The results for X = Br are in contrast to recent bulk estimates (7), while they were in agreement for X = Cl.

IV. Discussion

In Fig. 9 we show the energy level and correlation diagram which are relevant to the following discussion. The energy levels are only known for the reagents, products, and the ground state of HOBr. No experimental or theoretical information is available for the excited states of the two isomeric forms, HOBr and HBrO, and not even for the ground state of HBrO; in the diagram, therefore, these states have been indicated with

For personal use only.

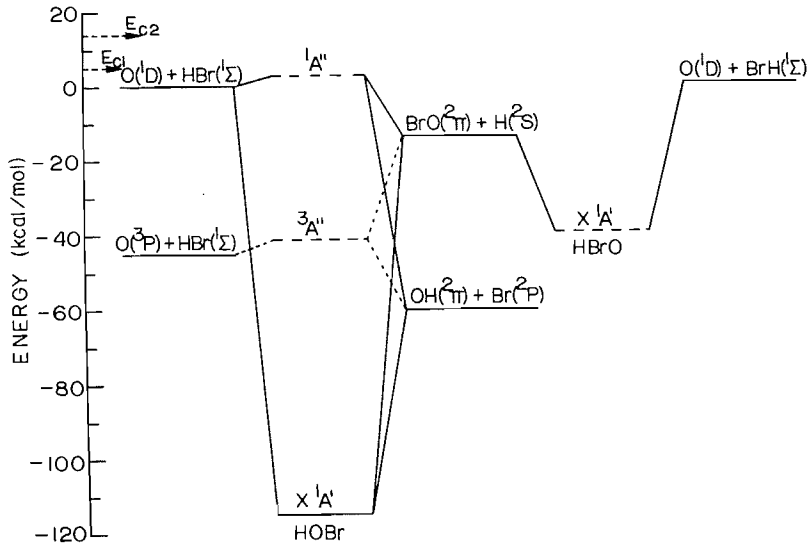

FIG. 9. The energy level and correlation diagram for the $O(^3P,^1D)$ + HBr system. The energies of the HOBr $^3A'$ and $^1A''$ states and of the HBrO X^1A' state (indicated with dashed lines) are not known: the energy of $^3A''$ has been put equal to the activation barrier for the triplet reaction and the others have been drawn by analogy with the related $O(^1D)$ + HCl system (see ref. 15). E_{c1} and E_{c2} indicate the experimental relative collision energies of the scattering study.

dashed lines by analogy with the homologous O + HCl system, for which SCF-CI calculations have been carried out by Bruna et al. (16*a*). Of the two lowest excited singlet states of HOBr, $^1A''$ and $^1A'$, we have assumed that only the $^1A''$ state (represented in the figure) is accessible at the experimental energies and only the ground state of the HBrO isomer may be energetically involved, in analogy with O + HCl (see ref. 15). In Fig. 9, E_{c1} and E_{c2} represent the relative translational energies of the reagents in the low E_c and high E_c scattering experiments, respectively; in the infrared chemiluminescence experiment the maximum energy accessible to the products is about 10 kcal/mol, which is near the average of E_{c1} and E_{c2}. The reaction involving ground state oxygen is also portrayed in Fig. 9, where the triplet ground state surface, $^3A''$, has been located on the energy scale at the value of the experimental activation barrier (about 3.4 kcal/mol) of the $O(^3P)$ + HBr reaction (2–4).

For a detailed discussion of the product energy partitioning it will also be useful to refer to Fig. 10, where the fine structure levels of the products are specified. As can be seen, the electronically adiabatic correlations in the $O(^3P,^1D)$ + HBr system are relatively complex. For the ground state reaction three spin–orbit states of the reagent $O(^3P_{2,1,0})$ are coupled to two $^2P_{3/2,1/2}$ states of the Br atom and two $^2\Pi_{3/2,1/2}$ states of OH. However, assuming linear geometry ($C_{\infty V}$) and with Ω (the projection of the total electronic angular momentum along the internuclear axis), the good quantum number, being conserved, the $^3A''$ ground state triplet surface ($^3\Pi_{2,1,0+,0-}$ in the $C_{\infty V}$ geometry) adiabatically correlates only with the $OH(^2\Pi_{3/2,1/2}) + Br(^2P_{3/2})$ manifold (49, 50). For the excited state reaction, the reagent $O(^1D_2)$ is coupled to two $^2\Pi_{3/2,1/2}$ states of BrO for the H-displacement channel and to two $^2P_{3/2,1/2}$ states of Br and two $^2\Pi_{3/2,1/2}$ states of OH for the H abstraction channel. However, again the X^1A' ($^1\Sigma^+$ in the $C_{\infty V}$ geometry) ground state singlet surface correlates adiabatically only with $OH(^2\Pi_{3/2}) + Br(^2P_{3/2})$ and with $BrO(^2\Pi_{1/2}) + H(^2S_{1/2})$, while the first excited singlet $^1A''$ state ($^1\Pi_1$ in the $C_{\infty V}$ geometry) correlates adiabatically with $OH(^2\Pi_{1/2}) + Br(^2P_{3/2})$ and $BrO(^2\Pi_{3/2}) + H(^2S_{1/2})$ (see ref. 49). Because of the several curve crossings which occur, one may reasonably expect that the product state partitioning is controlled by nonadiabatic couplings in the entrance and/or exit channel regions of the potential energy hypersurface. If the OH forming reaction channel was to proceed adiabatically, no excited $Br(^2P_{1/2})$ should be formed. Unfortunately, this is not probed in our experiments. We note, however, that very recent work by Matsumi et al. (49) on the homologous $O(^1D)$ + HCl reaction found a fine structure branching ratio of product chlorine atoms $Cl(^2P_{1/2})/Cl(^2P_{3/2})$ of 0.20 at a collision energy of 7.6 kcal/mol. Some $Br(^2P_{1/2})$ may well be formed also in the reaction with HBr, although the significantly larger (about 4 times) spin–orbit splitting of Br with respect to Cl suggests a weaker nonadiabatic interaction and consequently a smaller fine structure branching ratio. We note that formation of spin–orbit excited $Br(^2P_{1/2})$ in the amount of about 6% was inferred in a study of the $O(^3P)$ + HBr reaction (10). Nonadiabatic effects should instead be larger in the ground state manifold $OH(^2\Pi_{3/2,1/2}) + Br(^2P_{3/2})$, where the OH fine structure splitting is relatively very small (123 cm^{-1}). Indeed, the spin–orbit levels of OH are populated nearly statistically in the $O(^1D)$ + HCl reaction (13, 14). The same has been found for the $O(^3P)$ + HBr reaction (10) and it is reasonable to expect a similar results for the $O(^1D)$ + HBr reaction as well. The present chemiluminescence study indicates a nearly statistical $OH(^2\Pi_{1/2})/OH(^2\Pi_{3/2})$ ratio (see below).

A. $O(^1D) + HBr \rightarrow OH + Br$

The predominant mode of energy release in this channel is into vibration in the OH product. The observed OH vibrational distribution is strongly inverted, peaking in OH($v' = 5$). The normalized OH vibrational distribution is $P_{OH}(v' = 1{:}2{:}3{:}4{:}5{:}6) = 0.04{:}0.10{:}0.14{:}0.28{:}0.32{:}0.12$. The uncertainty in the normalized population of each level is about ± 0.02. Assuming a negligible population in OH($v' = 0$), which seems justified by the shape of the observed distribution, this indicates that the reaction releases 56% of the available reagent energy into vibration in this channel. In this calculation, the total available energy is taken to be the exoergicity of the reaction forming all products

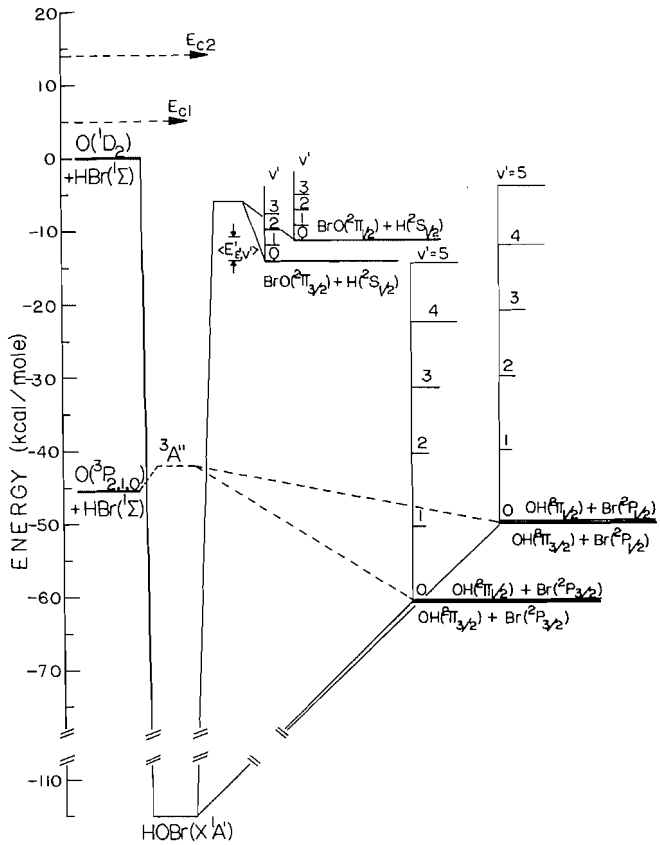

FIG. 10. Detailed energy level and correlation diagram for the $O(^3P,^1D)$ + HBr system: the fine structure states of the products are indicated. $\langle E_{\epsilon',v'} \rangle$ indicates the average fraction of total available energy which is estimated (see Discussion section B.1) to be released into electronic and vibrational degrees of freedom for the scattering experiment at E_{c1} = 5.0 kcal/mol.

in their ground states, 60.5 kcal/mol, plus the relative translational energy in the $O(^1D)$ + HBr collision, about 10 kcal/mol. We note that the entire population of the OH(v' = 6) level is due to the $OH(^2\Pi_{1/2})$ component. Within the signal-to-noise ratio of our measurements, we observe no population for the $OH(^2\Pi_{3/2}$; v' = 6) state. We shall comment on this result later in this section.

This energy partitioning pattern is similar to that found for other similar reactions of $O(^1D)$. The reactions with H_2, CH_4, H_2S, and HCl all produce OH with substantial vibrational excitation (14, 45, 46, 51, 52). In particular, the OH vibrational distribution created by the reaction with HCl is virtually the same as that observed for the HBr reaction. These reactions all share several similarities. They all involve the transfer of a hydrogen atom to $O(^1D)$, from third bodies which have a range of masses, over potential energy surfaces which all have very similar shapes. One of the most important features shared by the potential energy surfaces for all of these reactions is a relatively deep minimum corresponding to a strongly-bound intermediate having the general form H—O—R. (In the present case, although the energy of the other possible bound intermediate, HBrO, is not known, it is unlikely to be as stable as HOBr.) The mass combinations of these reactions also appear to have an influence on the dynamics. The primary effect in this regard is the transfer of a light atom between two heavier entities. In our previous work (14) on the $O(^1D)$ + HCl reaction, we argued that the timescale of the interaction is governed by the relatively slow motion of the heavier atoms, while the motion of the H atom is much faster. The relative masses of the R fragments also appear to be important. We find, for example, that the OH vibrational excitation created by the $O(^1D)$ reactions with HCl, H_2S, and HBr is very much larger than it is for the reactions with H_2 and CH_4. The H_2S reaction channels 60% of the available energy into OH vibration (46); the percentages for the HCl and HBr reactions are 67% and 56% respectively (14, this work). The reactions with H_2 and CH_4 channel only about 40–45% of the energy into OH vibration (45, 51, 52). In the CH_4 reaction, it has been suggested (52) that the additional degrees of freedom play a role in the low vibrational excitation, by introducing a component of energy randomization, which competes with the dissociation. This process was suggested to be responsible for bimodality which was observed in the energy distribution of that reaction. In the case of the HBr reaction, of course, no bimodality in the energy distribution was observed.

The highly specific energy disposal into OH vibration exhibited by the reactions involving the heavy R fragments implies that these occur on a very short timescale — much shorter than the time required for statistical energy partitioning among the product modes. In this sense, we consider these reactions to have direct dynamics. By this, we do not mean to imply that the geometry of the collision is necessarily collinear or that the H atom is transferred at a large distance without significant interaction between the $O(^1D)$ and the other heavy entity. It does imply, however, that the timescale of the interaction must be very short.

We observe nearly statistical population of the spin–orbit states for the lowest five OH vibrational levels created in the $O(^1D)$ + HBr reaction. (By statistical, we mean that the population is proportional to the spin degeneracy, $2J + 1$; we neglect the energy contribution, which is small by comparison with the exoergicity of the reaction.) Averaged over the vibrational levels OH(v' = 1–5), the ratio of the spin–orbit populations which we observe is $OH(^2\Pi_{3/2})/OH(^2\Pi_{1/2}) = 2.2 \pm 0.2$. We found a similar result in the $O(^1D)$ + HCl reaction (14).

In contrast to the lower vibrational levels, we find that the highest observed vibrational level, OH(v'= 6), has a greater population for the $OH(^2\Pi_{1/2})$ excited spin–orbit state, than for the $OH(^2\Pi_{3/2})$ ground state. This is an unusual result. Park et al. (13) determined sublevel populations for the $O(^1D)$ + HCl reaction. They reported a propensity for production of the OH $\Pi(A')$ sublevel; the ratio $\Pi(A')/\Pi(A'') = 2.0$. The $\Pi(A')$ sublevel correlates with the $HOCl(^1A')$ intermediate, indicating that the $(^1A'')$ intermediate does not participate much in the reaction. In the $O(^1D)$ + HX reactions, the $HOX(^1A')$ intermediate correlates adiabatically only with the $OH(^2\Pi_{3/2})$ state while the $OH(^2\Pi_{1/2})$ state correlates with the higher energy $HOX(^1A'')$ intermediate (49). Our result, therefore, indicates that the OH(v' = 6) level results predominantly from reaction via the higher energy $HOBr(^1A'')$ intermediate.

This result is dynamically reasonable in view of the fact that the interaction via the $HOBr(^1A'')$ state is predominantly repulsive. It does not have the potential energy minimum of the $(^1A')$ ground state (see Fig. 9). Reaction on the upper state, therefore, should be more impulsive and have a shorter duration than that on the ground state. This, in turn, could create higher vibrational excitation in the diatomic product. The effect of the higher vibrational excitation on the probability of curve crossing, and hence the reason for the lack of $OH(^2\Pi_{3/2}$; v' = 6) in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

products, cannot be determined without a more detailed knowledge of the shapes of the potential surfaces involved. The information available to us presently, however, indicates that reaction via the lower ($^1A'$) intermediate creates less OH vibrational excitation than reaction on the excited state surface.

B. $O(^1D) + HBr \rightarrow BrO + H$

The derived angular and translational energy distributions of the BrO product in the c.m. frame allow an evaluation of the dynamical influence of the potential energy surface as well as the kinematic constraints for this reaction channel.

1. Product energy distributions

A dominant feature of this reaction channel is the large fraction of available energy released into translation. The $P(E'_T)$ distributions shown in Figs. 4*b* and 6*b* indicate that for both collision energies the average product translational energy is about 50% of E_{tot} and even larger for the range of reactive collisions associated with the rebound dynamics. Classical trajectory studies on model surfaces for the **H + HL → HH + L** (**H** — Heavy; **L** — Light) mass combination have shown that the presence of a late barrier to reaction results in large amounts of energy in translation (53). The presence of a barrier in the exit channel is reported in *ab initio* SCF-CI calculations (16*a*) for the dissociation of HOCl/HClO into ClO + H, both in the ground state (X^1A') potential of HClO and the first excited state ($^1A''$) potentials of HOCl and HClO. It is reasonable to expect the presence of these features also in the strictly related HOBr/HBrO system.

The remaining 50% of available energy will be in internal degrees of freedom (electronic, vibrational, and rotational) and, on the basis of the conservation of the total angular momentum (42), it is expected to be mostly in product rotational excitation. In fact, for the specific mass combination, as a consequence of the much smaller reduced mass of the products (0.990 amu) with respect to that of the reagents (13.37 amu), $\boldsymbol{L} \gg \boldsymbol{L}'$, where $\boldsymbol{L}$ and $\boldsymbol{L}'$ are the initial and final orbital angular momenta, and the final rotational angular momentum, $\boldsymbol{j}'$, is about equal to $\boldsymbol{L}$, since the initial $\boldsymbol{j}$ is very small with respect to $\boldsymbol{L}$ in view of the fact that the HBr reagent molecules are formed in a supersonic expansion, where considerable rotational cooling occurs. As a consequence, $\boldsymbol{L}$ and $\boldsymbol{L}'$ are not expected to be correlated, which determines the observed isotropic shape of the c.m. angular distribution. We recall that for a reaction which proceeds through the formation of a long-lived complex, one will observe a symmetric c.m. angular distribution sharply polarized at $\theta = 0°$ and $\theta = 180°$ if $\boldsymbol{L}$ and $\boldsymbol{L}'$ are parallel or antiparallel; this situation occurs only when the product molecules are not rotationally excited or when M' (the projection of the total angular momentum $\boldsymbol{J}$ along the final recoil velocity v') is null (42). When part of the total $\boldsymbol{J}$ is removed as $\boldsymbol{j}'$ (i.e,, when rotation excitation of the product molecules occurs) and M' is not null, $\boldsymbol{L}$ and $\boldsymbol{L}'$ are weakly correlated and the sharp polarization of $T(\theta)$ at the poles is lost, while the backward–forward symmetry is maintained. In general, when no geometric constraints are present in the collision complex, there will be a distribution of M' and, therefore, dissociation of a complex leading to highly excited products will lead to an isotropic, or nearly isotropic, $T(\theta)$. This appears to be the case observed here (see Figs. 4–6). For the collision energy E_c = 5.0 kcal/mol, very little energy remains for electronic and vibrational excitation, since ≈50% is released in translation and high rotational excitation also occurs. Assuming $j' = L$, one calculates an average product rotational energy, $\langle E'_R \rangle$, of 6.3 kcal/mol. The spin–orbit splitting of $BrO(^2\Pi_{3/2,1/2})$ is 2.8 kcal/mol and the vibrational spacing about 2.1 kcal/mol (54). This suggest that BrO can mainly be formed in the lowest few vibrational levels of the ground $^2\Pi_{3/2}$ electronic state, or in the ground vibrational level of the ground $^2\Pi_{3/2}$ and first electronically excited $^2\Pi_{1/2}$ states (see Fig. 10). Unfortunately, the present experiment does not probe the relative population of the fine structure levels of $BrO(^2\Pi)$. Considering the relatively small spin–orbit splitting of $BrO(^2\Pi)$, which is comparable to that in atomic chlorine, we may reasonably expect that extensive nonadiabatic coupling occurs and that both fine structure components of BrO are populated in the reaction. For E_c = 14.0 kcal/mol similar arguments apply, but now a little more energy will be available for more vibrational excitation of the products.

2. Angular distributions

The $T(\theta)$ in Figs. 4(*a*) and 6(*a*) contain a significant amount of information. At E_c = 5.0 kcal/mol the dominant $T(\theta)$ is symmetric about 90°. Though this symmetry in principle is possible in a direct interaction, it is very likely the result of the formation of a H—O—Br complex with a lifetime longer than its rotational period. At this relatively low E_c, this is not surprising due to the known complex stability of about 115 kcal/mol with respect to the $O(^1D)$ and HBr reactants (ref. 55*a*, the heat of formation of HOBr (ΔH_f^0 = 19 ± 2 kcal/mol) is taken from ref. 55*b*, and that of BrO (ΔH_f^0 = 32 ± 0.6 kcal/mol) from ref 55*c*). The isotropy of the $T(\theta)$ has been rationalized in terms of angular momentum disposal, which leads to highly rotationally excited products and an isotropic distribution of $\boldsymbol{L}'$ (see previous section). The lack of correlation between $\boldsymbol{L}$ and $\boldsymbol{L}'$ is not surprising in this case since the large reactive cross section indicates no geometric constraint in the entrance channel. A small, but significant, portion of reactive collisions lead, at E_c = 5.0 kcal/mol, to backward scattering with a very high degree of product translational excitation. The corresponding $T(\theta)$ is completely confined in the backward hemisphere and peaks at $\theta = 180°$ (see dotted line in Fig. 6(*a*)) and the average fraction of available energy released in translation is very large (about 77%); this implies that collinear, or nearly collinear, encounters at small impact parameters are taking place and leading to the formation of products after passing through a high exit barrier. In this picture the oxygen atom approaches collinearly (or within a narrow cone of acceptance) from the halogen atom side and the configuration involved is O—Br—H (see Fig. 9). It should be noted that trajectory studies (53, 56) on a late barrier surface, for all mass combinations, show a tendency toward backward scattering, in agreement with our observation. From the above, it can be argued that at E_c = 5.0 kcal/mol the reaction takes place by a direct mechanism for very small impact parameters within a narrow angle of orientations and by an insertion mechanism leading to the formation of a long-lived complex for all other impact parameters and orientations. The latter is the dominant micromechanism and is likely to involve the ground state potential energy surface X^1A' of HOBr, although also the X^1A' surface of HBrO cannot be ruled out. The rebound micromechanism is expected to involve the ground X^1A' surface of HBrO (see Fig. 9).

The results obtained at the higher E_c = 14.0 kcal/mol corroborate the above interpretation. In fact, both the $P(E'_T)$ and $T(\theta)$ distributions shown in Fig. 4 can be seen as the superposition of two distributions which can be associated with the same micro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

mechanisms operative at E_c = 5.0 kcal/mol. The $T(\theta)$ is almost backward–forward symmetric, but with more intensity in the backward direction. The $P(E'_T)$ appears to be the envelope of the two $P(E'_T)$ reported in Fig. 6(*b*). As already mentioned, an analysis of the data at this higher E_c in terms of two micromechanisms required the parameter α in eq. [2] to be also 0.15, as at the lower E_c. This seems to suggest that the relative contribution of the two micromechanisms does not vary with E_c, at least in the investigated range. The steric requirement appears to be the dominant factor: when $O(^1D)$ approaches within a narrow cone on the halogen side at small impact parameters, a direct rebound mechanism is operative; for all other orientations and range of impact parameters the reactants are driven into the deep $HOBr(X^1A')$ well following $O(^1D)$ insertion into the H—Br bond and giving rise to the formation of a long-lived collision complex which can undergo H—OBr bond fission because of the high energy content.

The very different dynamics observed for the OH- and BrO-forming channels may be ascribed to the different role played by the different singlet surfaces and the different configurations of the reaction intermediate. A more efficient trapping into the deep potential well of the singlet intermediate seems to be the explanation for the formation of a long-lived complex in the H-displacement process (reaction [1*b*]; this is favored by the significantly lower exoergicity with respect to the H-abstraction process and by the presence of a potential barrier in the exit channel (see Fig. 10).

No clear indication about a possible role of singlet–triplet surface crossing has been obtained in this study. While this will be responsible for the physical quenching of $O(^1D)$ to $O(^3P)$ by HBr, we can only speculate that it may also be involved in the OH-forming channel, as the observation that the OH internal energy distribution from the excited state reaction resembles that of the ground state reaction would suggest (see below). In this regard, recent work by Wategaonkar and Setser (57) on the H + OCl reaction, using infrared chemiluminescence in a fast flow reactor, should be noted. These authors measured the branching to OH + Cl and HCl + $O(^3P)$ with both sets of products being accessed from a bound singlet intermediate. The formation of the $O(^3P)$ + HCl was related to a singlet–triplet surface crossing in the exit channel of the HClO configuration.

A full dynamic description of $O(^1D)$ reactions, which have the characteristics of releasing a very large amount of energy into a strongly bound intermediate, needs to take into account the stability of the singlet intermediate and of its possible isomers, the exoergicity of the process, the multiplicity of the electronic state of the product and the mass combination of the reagents. The present experimental results should facilitate attempts to model the dynamics of the $O(^1D)$ + HX reactions using realistic potential energy surfaces.

C. Comparison with $O(^3P)$ + HBr → OH + Br

The reaction of ground state oxygen with HBr is known to be about four orders of magnitude slower than the reaction of electronically excited oxygen, with the room temperature rate constant being $k_{298} = 3.4 \times 10^{-14}$ cm^{-3} molecule^{-1} s^{-1} and the activation energy of about 3.4 kcal/mol (2–4). In Figs. 9 and 10 the energy level and correlation diagram are also shown for $O(^3P)$. An early ESR flow-tube study found that the OH product vibrational distribution was very strongly inverted (58). More recently, a very detailed dynamical study was performed by Zare and co-workers (10) and a quantitative measure of the product internal energy disposal was provided. It was found that on the average, for collision energies up to 6 kcal/mol, about 75% of the available energy appears as internal (vibrational + rotational) excitation of the OH product, with very strong vibrational and rotational inversion. The OH(v = 0, 1, 2) states were found to be populated in the ratio of (0:9:1) and the dominant product channels are those rotational levels in OH(v = 1) and OH(v = 2) approximately thermoneutral with respect to the reagents. In order to explain an anomaly in the OH(v = 1) rotational distribution it was proposed that 6% of the outcome of the reaction involved the excited state $Br(^2P_{1/2})$ + $OH(^2\Pi)$ channel (see Fig. 10). The results were rationalized in terms of a direct abstraction mechanism and supported by classical trajectory calculations, which for the $O(^3P)$ + HBr mass combination (**H** + **LH′** → **HL** + **H′**) predict that a large fraction of the kinetic energy available will appear as internal excitation. This is the result of kinematic influences of the PES. The trajectory calculations have shown, in fact, that vibrational excitation arises because of the so-called "corner-cutting" trajectories where the dynamics are dominated by the rapid motion of the light H-atom relative to the heavy atoms. It should be noted, however, that these trajectory studies make use of a single PES, and nonadiabatic effects are therefore neglected. It was concluded (10) that the rotational excitation of the OH product derives from the repulsive interaction in the breaking of the OH—Br (Light—Heavy) bond. The transition state geometry is quite bent and this imparts a large torque on the departing OH moiety with efficient conversion of the repulsive energy into product rotation.

The similarity of the OH energy distribution from the reaction: $O(^1D)$ + HBr → OH + Br to that of the $O(^3P)$ reaction suggests the possibility that some $O(^1D)$/HBr collisions which begin on the $^1A'$ surface may switch to the $^3A''$ surface in the entrance channel and finish the reaction on the triplet surface. This spin–orbit crossing is an intriguing possibility which has been puzzling dynamicists for some time. It is known that the physical quenching of $O(^1D)$ to $O(^3P)$ by HBr, which accounts for about 20% of all $O(^1D)$ + HBr collisions at room temperature (7), involves a singlet–triplet crossing. So far, however, there is no direct evidence that this surface crossing also forms OH in $O(^1D)$ reactions with any species. The most commonly accepted mechanism for this is the insertion of $O(^1D)$ into the H—Br bond on the $^1A'$ surface to form a vibrationally hot HOBr complex, which fragments very rapidly within a few bending vibrations into OH + Br. This insertion mechanism is consistent with the observation of the stabilized complex in the $O(^1D)$ + HX (X = Cl, Br), reactions, when these occur in an argon matrix (59). We note parenthetically that the observation of high rotational excitation in the products of the gas phase reaction, to which we have referred earlier, does not contradict the insertion mechanism because Monte Carlo simulations of the $O(^1D)$ + HCl reaction using a statistical model suggest (60) that the high OH rotational excitation arises from angular momentum constraints and has no unique dynamical origin.

It has been noted that the energy partitioning of both the ground state and excited state reactions resembles that of the direct abstraction reaction of F with HBr (34, 61). The observation, however, of a marked propensity for production of the $\Pi(A')$ λ component in the OH product of the $O(^1D)$ + HCl reaction (13) implies that the half-filled π orbital of OH lies preferentially oriented in its rotational plane and remains in the plane of the dissociating triatomic complex. This fact led to the con-

clusion that only the ground $HOCl(X^1A')$ state is involved in the reaction (13). This finding suggests that a possible role of the $^3A''$ state in the reaction with HBr is precluded as well, since the overall dynamics does not seem to change appreciably when HCl is replaced by HBr.

A clarification of the possible role of single–triplet surface crossings and of the similarity with the F + HX reactions has to await the results of dynamical calculations on reliable potential energy surfaces. Finally, it should be noted that the $O(^3P, ^1D)$ + HX systems are good candidates for studies investigating the role of multiple potential surfaces and nonadiabatic effects on chemical reaction dynamics.

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

GEORGE C. SCHATZ, D. SOKOLOVSKI, and J.N.L. CONNOR. Can. J. Chem. **72**, 903 (1994).

We present accurate quantum results for the Cl + HCl → ClH + Cl reaction using a coupled channel hyperspherical coordinate method (denoted CCH). A semiempirical extended London–Eyring–Polanyi–Sato potential energy surface is employed. In our calculations, the body-fixed z projection quantum number Ω in the rotational basis set has been truncated at $\Omega_{max} = 2$, since this is sufficient to give converged results near to, and above, the reaction threshold (total energies E in the range 0.40–0.60 eV). We compare our results with earlier work using the centrifugal sudden hyperspherical (CSH) method, in which only $\Omega = 0$ is included in the basis; other features of the calculations are identical. At $E = 0.40$ eV, where reactivity is low, the CCH($\Omega_{max} = 2$) and CSH($\Omega = 0$) degeneracy averaged reaction probabilities, integral cross sections and product rotational distributions are mostly in excellent agreement. This agreement deteriorates with increasing E, such that at $E = 0.60$ eV, the CCH($\Omega_{max} = 2$) cumulative reaction probability is approximately twice its CSH($\Omega = 0$) counterpart. Even at $E = 0.40$ eV there are some important differences between CCH($\Omega_{max} = 2$) and CSH($\Omega = 0$) concerning m_j-resolved reaction probabilities. In addition, there are differences in the relative contributions of "tight bend" and "nearly free-rotor" mechanisms to the reaction probabilities and product rotational distributions, with the "nearly free-rotor" mechanism dominant in all cases.

GEORGE C. SCHATZ, D. SOKOLOVSKI et J.N.L. CONNOR. Can. J. Chem. **72**, 903 (1994).

On présente des résultats quantiques précis obtenus pour la réaction Cl + HCl → ClH + Cl en faisant appel à une méthode de coordonnées hypersphériques à canal couplé (dénotée CCH). On emploie une surface d'énergie potentielle semi-empirique de London–Eyring–Polanyi–Sato étendue. Dans nos calculs, le nombre quantique Ω de la projection z du corps fixé dans l'ensemble rotationnel de base a été tronqué au niveau de $\Omega_{max} = 2$ parce que ce niveau est suffisant pour obtenir des résultats convergents au niveau du, et au-dessus du, niveau limite de la réaction (énergies totales, E, allant de 0,40 à 0,60 eV). On compare nos résultats avec ceux d'un travail antérieur en utilisant la méthode centrifuge devant soudainement hypersphérique (CSH) dans laquelle on n'inclut que $\Omega = 0$ dans la base alors que les autres caractéristiques des calculs sont identiques. Au niveau de $E = 0{,}40$ eV où la réactivité est faible, les méthodes CCH($\Omega_{max} = 2$) et CSH($\Omega = 0$) sont en excellent accord pour prédire les probabilités moyennes de réactions causées par une dégénérescence, les sections droites intégrales et les distributions rotationnelles du produit. L'accord devient moins bon lorsqu'on augmente la valeur de E; par exemple, lorsque $E = 0{,}60$, la probabilité réactionnelle cumulative selon CCH($\Omega_{max} = 2$) est environ deux fois plus grande que celle prédite par la méthode CSH($\Omega = 0$). Même au niveau de $E = 0{,}40$, il existe quelques différences importantes entres les méthodes CCH($\Omega_{max} = 2$) et CSH($\Omega = 0$) concernant les probabilités réactionnelles résolues selon m_j. De plus, il existe des différences dans les contributions relatives des mécanismes "courbure serrée" et "rotor pratiquement libre" aux probabilités réactionnelles et aux distributions rotationnelles des produits; le mécanisme à "rotor pratiquement libre" est dominant dans tous les cas.

[Traduit par la rédaction]

I. Introduction

The reaction

$$Cl + HCl \rightarrow ClH + Cl$$

is a prototype for heavy–light–heavy (**HLH**) atom-exchange reactions, an area of research pioneered by John Polanyi. As such, the Cl + HCl reaction has been the subject of numerous theoretical investigations, including studies of its potential energy surface (reviewed in refs. 1, 2), quasiclassical trajectory calculations (reviewed in ref. 3), and quantum dynamics computations (reviewed in refs. 4, 5). There have also been experimental measurements, in particular of thermal rate coefficients (reviewed in ref. 6)[2] and of transition state photodetachment spectra (reviewed in ref. 7).

Interest in the quantum dynamics of Cl + HCl has evolved through a number of stages. The early collinear calculations of Bondi et al. (8) computed accurate reaction probabilities and studied the diagonally corrected vibrationally adiabatic hyperspherical (DIVAH) approximation (8). Then various three dimensional quantum approximations were developed and applied, such as the centrifugal sudden distorted wave (CSDW) method (9). In recent years, a significant amount of work has used the centrifugal sudden hyperspherical (CSH) technique (ref. 10, reviewed in ref. 5). In this technique, the Schrödinger equation is first solved exactly for the case where the total angular momentum quantum number is zero ($J = 0$) using a coupled channel (CC) method, and then the CS approximation is used to generate results for $J > 0$, so that partial wave sums can be evaluated. In the CSH method, Ω, the quantum number for the body-fixed z projection of the total angular momentum, is fixed for each coupled-channel calculation, and

then summed over in order to calculate cross sections and rate coefficients.

For a reaction with a minimum barrier height in the collinear geometry, it is the $\Omega = 0$ state which has the largest reaction probability at energies close to the threshold for reaction. Most CSH calculations have therefore been restricted to $\Omega = 0$, with adiabatic bend and related approximations used to perform the sum over Ω (11). Note that many of the commonly used semiempirical potential energy surfaces for Cl + HCl also possess collinear saddle points, although *ab initio* calculations show that the saddle point configuration is bent (6, 12).

In this paper, we present the first results of coupled channel hyperspherical (CCH) calculations for Cl + HCl in which states with different values of Ω are allowed to couple. Although the rotational basis set we use does not include all possible Ω's (the maximum value for Ω is $\Omega_{max} = 2$), the results should be almost converged at the energies we have studied. Of course, convergence with respect to other features of the vibration/rotation basis set has already been demonstrated in our CSH($\Omega = 0$) calculations (5, 10), so the present results should be free of basis set truncation errors.

The main impediment in the present calculations has been computational. For each J, the size of the coupled-channel basis set grows significantly in going from a CSH($\Omega = 0$) to a CCH($\Omega_{max} = 2$) calculation (from 80 states for CSH($\Omega = 0$) to a maximum of 364 states for CCH($\Omega_{max} = 2$) at $E = 0.60$ eV). In addition, a large number of partial waves must be included (up to $J_{max} = 140$ in the present applications). There are also significant disk storage needs (~1 GByte) associated with the intermediate files used during the calculations. Memory is also required to store the scattering information for later analysis (~0.3 GBytes). Our calculations would not be feasible without the Ω_{max} truncation of the allowed values of Ω in the rotational basis set, since the maximum allowed value for Ω is much larger than $\Omega_{max} = 2$.

This Ω_{max} truncation approach has previously been used by Launay et al. in studies of the H + H_2, F + H_2, He + H_2^+, and Cl + H_2 reactions (13). Our application is similar, except that we use Delves' hyperspherical coordinates (14) and a body-fixed representation in which the quantization axis is taken along the atom–diatom Jacobi vector in each arrangement channel. In this approach, Ω-coupling arises in two ways (15): (*a*) from the centrifugal operator for each arrangement channel, and (*b*) from the transformation of coordinates between the reagent and product arrangement channels. For Cl + HCl, the coupling present in the centrifugal operator is generally weak because different Ω's correspond to different bending states of the ClH-Cl saddle point complex, which are approximately separated by the 0.07 eV (600 cm^{-1}) saddle point harmonic bending energy. In contrast, the coupling that arises from the coordinate transformation can be weak or strong, depending on the angle between the reagent and product Jacobi vectors and on the value of J. For Cl + HCl, we are aided by the fact that the **HLH** mass combination and the potential energy surface greatly favor reaction through geometries where the reagent and product helicity axes are approximately antiparallel, i.e., the reagent atom–diatom Jacobi vector is approximately antiparallel to the corresponding product Jacobi vector because the center-of-mass of the **HL** diatom lies close to the **H** atom. If these two vectors were exactly antiparallel, as occurs for the collinear configuration, the coupling would vanish for all J, which makes it likely that the coupling is weak for the real system.

TABLE 1. CCH partial wave cumulative reaction probability $P^J(E)$ as a function of Ω_{max} for $J = 10$ using a small basis in each arrangement channel, $v = 0$ and $j = 0$–3

	$P^J(E)$

2	0.0855	0.0023	1.0329	0.0357
3	0.0855	0.0023	1.0329	0.0357

Section II presents some computational details of our CCH calculations. Section III contains our results, including the J dependence of cumulative and state selected reaction probabilities, the energy dependence of integral cross reactions and probabilities, and product rotational distributions. Our conclusions are in Section IV.

II. Calculations

The potential surface used in all our calculations is the semiempirical extended LEPS (London–Eyring–Polanyi–Sato) function developed by Bondi et al. (8). This BCMR surface has been used in many earlier studies (1–5, 8–11, 16, 17), and a recent comparison with large scale accurate *ab initio* calculations (12) indicates that it is fairly realistic even though it has a collinear saddle point. In addition, thermal rate coefficients calculated by the CSH($\Omega = 0$) method for the BCMR surface are in good agreement with experiment (5, 11).

The CCH method employed for the dynamics calculations has been described in detail previously (10, 17, 18) with the exception of the truncated Ω_{max} procedure. The CCH method expands the wavefunction in a set of vibration–rotation basis functions, defined in terms of Delves' hyperspherical coordinates for each of the two arrangement channels, i.e., reagents and products. The variable describing rotational motion in Delves' coordinates is just the usual Jacobi angle, so a free diatomic rotor basis is used, labelled by the quantum numbers j and Ω. Here Ω is the projection quantum number along the body-fixed z axis for both the total angular momentum quantum number J and the rotational angular quantum number momentum j, which means that the constant $|\Omega| \leq \min(j, J)$ applies in the absence of truncation. In the truncated version, the constraint is modified to $|\Omega| \leq \min(j, J, \Omega_{max})$ where $\Omega_{max} \geq 0$ is chosen large enough to converge the reaction probabilities, as will be illustrated below. The vibrational part of the basis set is defined using numerically determined solutions of a reference potential which changes with hyperradius such that it merges with the isolated diatomic potential at long range.

Table 1 shows the convergence of the CCH partial wave cumulative reaction probability, $P^J(E)$ with Ω_{max} for $J = 10$ at $E = 0.40$ and 0.50 eV, using a relatively small basis ($v = 0$, $j = 0$–3 for each arrangement channel) where it is possible to include all Ω's (denoted $\Omega_{max} = 3$). $P^J(E)$ is the sum over all open reagent and product states of the state-to-state reaction probability, and E is the total energy relative to the minimum of the Cl + HCl potential. At $E = 0.40$ eV, which is just at the threshold for reaction, $P^J(E)$ for $\Omega_{max} = 0$ is already within 3% of the full CCH value for even parity, while $\Omega_{max} = 1$ gives essentially exact results. At $E = 0.50$ eV, the partial

[a] J = 0(1)100 at E = 0.40 eV, J = 0(5)100 at E = 0.45 eV, and J = 0(5)110 at E = 0.50 eV.

wave cumulative reaction probability is much larger, but the $\Omega_{max} = 0$ result is in error by only 4% and $\Omega_{max} = 2$ is fully converged.

In the more extensive calculations reported in the next section, we used a basis consisting of three vibrations, with j_{max} = 19, 13, and 5 for v = 0, 1, and 2, respectively. For $J = 0$ this results in 40 states for each of the two arrangement channels, giving a total of 80 states. This is the same basis set that we used in our previous CSH($\Omega = 0$) calculations (5, 10). For the CCH calculations with $\Omega_{max} = 2$, for $J \geq 2$, the basis set contains 222 and 142 functions for the two parity components. The calculations were performed for J = 0(1)3, 10(10)60, 80(20)140 at E = 0.40 (0.05) 0.60 eV. Linear interpolation of the reaction probabilities was employed to evaluate partial wave sums. We tested this procedure by using our earlier CSH($\Omega = 0$) reaction probabilities to calculate cross sections on two grids: (a) the same coarse grid employed in the CCH($\Omega_{max} = 2$) calculations, and (b) a finer grid consisting of every J for E = 0.40 eV and every 5th J for other energies. Comparison of the two sets of cross sections generally indicates convergence to within 14% (see Table 2). Unfortunately, it is difficult to calculate accurate scattering matrix elements and hence differential cross sections by this interpolation method, so we will not consider angular distributions in this paper. Note also that the energy range E = 0.40–0.60 eV does not include the transition state resonance analyzed in ref. 10.

III. Results

A. Definitions

The reaction probability P is labelled by the total angular momentum quantum number J and by the initial and final quantum numbers (v, j, m_j) and (v', j', m_j') respectively, where m_j is the reagent P-helicity quantum number, which initially is identical to $-\Omega$, and m_j' is the corresponding product quantum number, identical to Ω' (15). The integral reactive cross section Q is labelled by these same initial and final state quantum numbers. Q and P are related by the partial wave sum:

$$Q_{vjm_j \to v'j'm_j'}(E) = \frac{\pi}{k_{vj}^2} \sum_{J=0}^{\infty} (2J+1) P^J_{vjmj \to v'j'm_j'}(E)$$

where k_{vj} is the initial translational wavenumber. Degeneracy averaged cross sections are then defined by

$$Q_{vj \to v'j'}(E) = \frac{1}{2j+1} \sum_{m_j=-j}^{j} \sum_{m_j'=-j'}^{j'} Q_{vjmj \to v'j'm_j'}(E)$$

together with the cross section summed over final states

$$Q_{vj}(E) = \sum_{v'j'} Q_{vj \to v'j'}(E)$$

We will also consider the reaction probability summed over final states

$$P^J_{vjm_j}(E) = \sum_{v'j'm_j'} P^{J'}_{vjm_j \to v'j'm_j'}(E)$$

and its degeneracy average

$$P^J_{vj}(E) = \frac{1}{2j+1} \sum_{m_j} P^J_{vjm_j}(E)$$

as well as the partial wave cumulative reaction probability $P^J(E)$ given by

$$P^J(E) = \sum_{vjm_j} \sum_{v'j'm_j'} P^J_{vjm_j \to v'j'm_j'}(E)$$

where the summations are over all open initial and final rovibrational states. The sum over partial waves of $P^J(E)$ is the cumulative reaction probability $P(E)$, so that,

$$P(E) = \sum_{J=0}^{\infty} (2J+1) P^J(E)$$

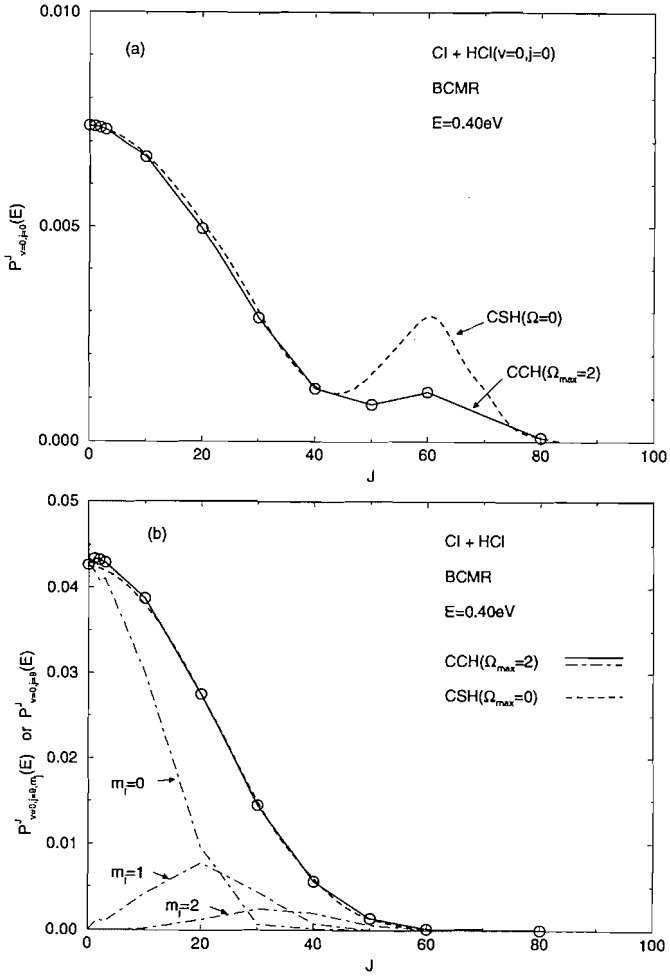

FIG. 1. Reaction probability versus J at $E = 0.40$ eV: (*a*) $P^J_{00}(E)$ with CCH($\Omega_{max} = 2$) (circles and solid curve) and CSH($\Omega = 0$) (dashes), (*b*) $P^J_{09}(E)$ with CCH($\Omega_{max} = 2$) (circles and solid curve) and CSH($\Omega = 0$) (dashes). Also shown are $P^J_{09m_j}(E)$ for CCH($\Omega_{max} = 2$) with $m_j = 0$, 1, 2 (dash–dot). Note that $P^J_{09-m_j}(E) = P^J_{09m_j}(E)$.

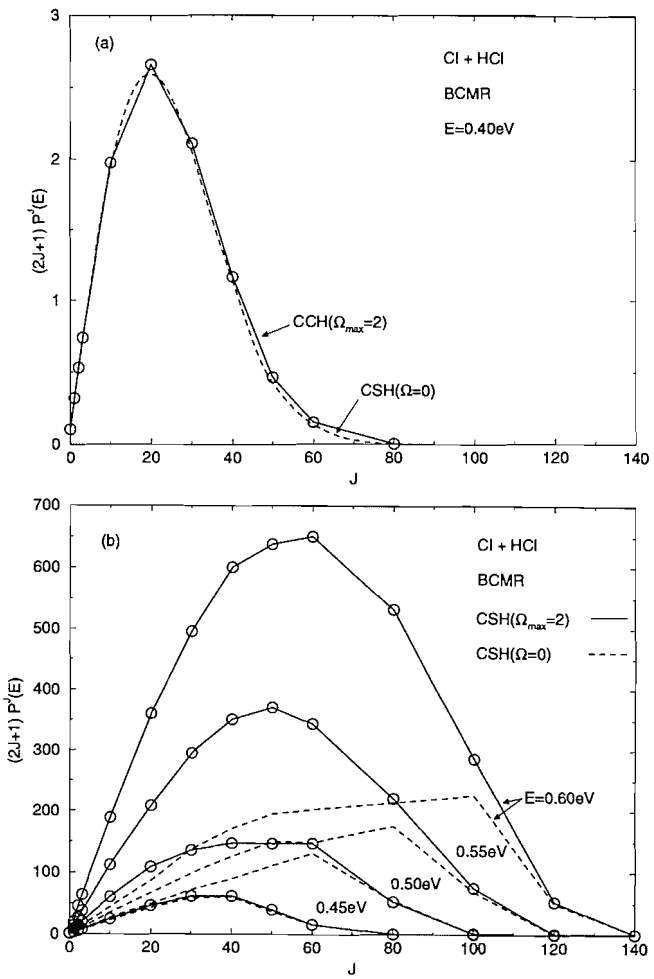

FIG. 2. $(2J + 1)P^J(E)$ versus J, showing CCH($\Omega_{max} = 2$) (circles and solid curves) and CSH($\Omega = 0$) (dashes). The energies are (*a*) $E = 0.40$ eV and (*b*) $E = 0.45$, 0.50, 0.55, and 0.60 eV.

The cumulative reaction probability is important for the reaction dynamics, because thermal rate coefficients may be obtained from a Boltzmann average of $P(E)$; however, we will not calculate thermal rate coefficients here, because the energy range over which CCH($\Omega_{max} = 2$) cross sections have been obtained is too limited for an accurate evaluation of the Boltzmann average.

B. J dependence of reaction probabilities

Figure 1 shows the J dependence of five CCH($\Omega_{max} = 2$) reaction probabilities at $E = 0.40$ eV. In Fig. 1*a* we plot $P^J_{vj}(E)$ vs. J for $v = 0, j = 0$, while in Fig. 1*b* are drawn $P^J_{vjm_j}(E)$ vs. J for $v = 0, j = 9, m_j = 0, 1, 2$ together with the degeneracy averaged reaction probability $P^J_{vj}(E)$ for $v = 0, j = 9$. Note that $P^J_{vj-m_j}(E) = P^J_{vjm_j}(E)$. Figure 2 shows $(2J + 1)P^J(E)$ vs. J at $E = 0.40$ eV (Fig. 2*a*) and at $E = 0.45$, 0.50, 0.55, 0.60 eV (Fig. 2*b*). We also plot the corresponding CSH($\Omega = 0$) probabilities in Figs. 1 and 2.

The most important result in Figs. 1 and 2 is that the CCH($\Omega_{max} = 2$) and CSH($\Omega = 0$) degeneracy averaged and cumulative reaction probabilities are in good agreement for nearly all J at $E = 0.40$ and 0.45 eV. At higher E, the CCH($\Omega_{max} = 2$) probabilities grow larger than CSH($\Omega = 0$) until at $E = 0.60$ eV the ratio CCH($\Omega_{max} = 2$)/CSH($\Omega = 0$) is 2–3 for $J = 30$–90 in Fig. 2*b*. At $E = 0.40$ eV, Fig. 1*b* indicates excellent agreement between the $v = 0, j = 9$ degeneracy averaged probabilities, even though values of $m_j \neq 0$ make a significant contribution to the CCH($\Omega_{max} = 2$) sum over m_j. The $v = 0, j = 0$ probabilities in Fig. 1*a* also agree closely, apart from the peak near $J = 60$ which is much larger for CSH($\Omega = 0$).

The $J = 60$ peak in Fig. 1*a* has previously (5) been connected with a minor part of the reaction mechanism on the BCMR potential surface in which relatively low rotor j states of the reagents react through a nearly collinear transition state, to produce low rotor j' states in the products. This "tight bend" mechanism is distinct from the dominant reaction pathway which involves nearly free rotational motion up to, and down from, the saddle point. This second "nearly-free rotor" mechanism favors reaction from high rotor j states (3, 16), and is thus the only significant mechanism involved in Fig. 1*b* where $j = 9$. However, in Fig. 1*a*, where $j = 0$, the first mechanism controls the high J peak, and we see that this is less pronounced in the CCH($\Omega_{max} = 2$) curve. A simple explanation for this result is that in a CCH calculation, it is possible to make transitions out of $\Omega = 0$ initial states (which dominate the reactivity in either mechanism) to $\Omega' \neq 0$ states, as the reaction occurs. This forces the reaction to follow noncollinear

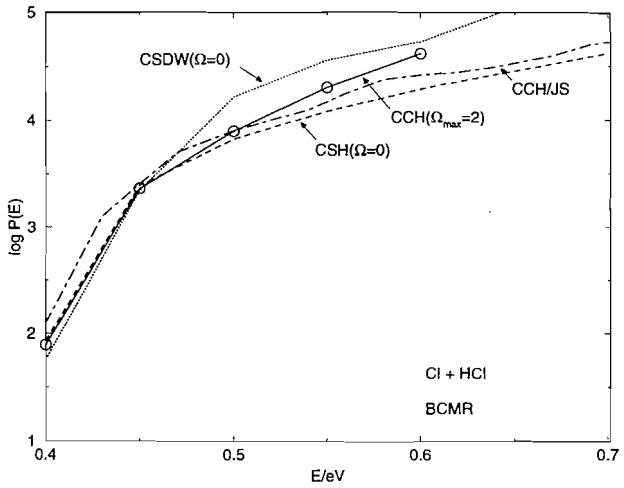

FIG. 3. log $P(E)$ versus E, showing CCH($\Omega_{max} = 2$) (circles and solid curve), CCH/JS (dash dot), CSH($\Omega = 0$) (dashes) and CSDW($\Omega = 0$) (dots).

geometries, because there is a centrifugal potential for $\Omega' \neq 0$ which makes the collinear geometry less accessible. Since the "tight bend" mechanism requires nearly collinear geometries, one thus expects it to be less important in a CCH calculation than in CSH($\Omega = 0$).

Note that the "tight bend" mechanism makes no significant contribution to the J dependence of $(2J+1)P^J(E)$ in Fig. 2, and as a result, the CCH($\Omega_{max} = 2$) and CSH($\Omega = 0$) curves are in good agreement at $E = 0.40$ eV. At higher E, the contributions of $\Omega \neq 0$ and $\Omega' \neq 0$ become important as is evident from Fig. 2*b*, and the CCH($\Omega_{max} = 2$) and CSH($\Omega = 0$) curves are close only in the $J = 0$ and large J limits.

C. Energy dependence of cross sections and probabilities

Table 2 shows the cumulative reaction probability $P(E)$ at the five energies we have done calculations, together with three other quantities: (*1*) the reactive section $Q_{0\hat{j}}(E)$ summed over final states for the reagent state $v = 0$ and $j = \hat{j}_0$, (*2*) $\hat{j}_0$, which is the value of j that has the largest $v = 0$ cross section, and (*3*) $\langle j' \rangle_{0\hat{j}}$, the average product rotational quantum number associated with reagent state $v = 0$, $j = \hat{j}_0$. The entries in this table labelled (*a*) and (*b*) show CCH ($\Omega_{max} = 2$) and CSH($\Omega = 0$) results using the same coarse grid of partial waves. Entry (*c*) reports CSH($\Omega = 0$) results calculated from the finer partial wave grids that were used in our earlier work (5). Figure 3 shows $P(E)$ vs. E for the CCH($\Omega_{max} = 2$) and CSH($\Omega = 0$) calculations, as well as for two other approximations (5), namely (*a*) CCH/JS, a J-shifted $\Omega = 0$ calculation (11) in which only CCH($J = 0$) calculations are done, and (*b*) CSDW($\Omega = 0$), centrifugal sudden distorted wave (9, 16) calculations.

There are three significant conclusions to be drawn from Table 2 and Fig. 3, namely: (*1*) The two sets of CSH($\Omega = 0$) results for $P(E)$ and $Q_{0\hat{j}}(E)$ (i.e., from the finer and coarser partial wave grids) are in good agreement, differing by 4% at $E = 0.40$ eV and 14% at $E = 0.60$ eV. This indicates the accuracy to be expected for the CCH($\Omega_{max} = 2$) results due to the linear interpolation of the partial waves. (*2*) At $E = 0.40$ and 0.45 eV, the CCH($\Omega_{max} = 2$) and CSH($\Omega = 0$) $P(E)$ are in close agreement (6% at $E = 0.40$ eV and 4% at $E = 0.45$ eV). This is the expected result at low E, where only the $\Omega = 0$ ground bending state of the saddle

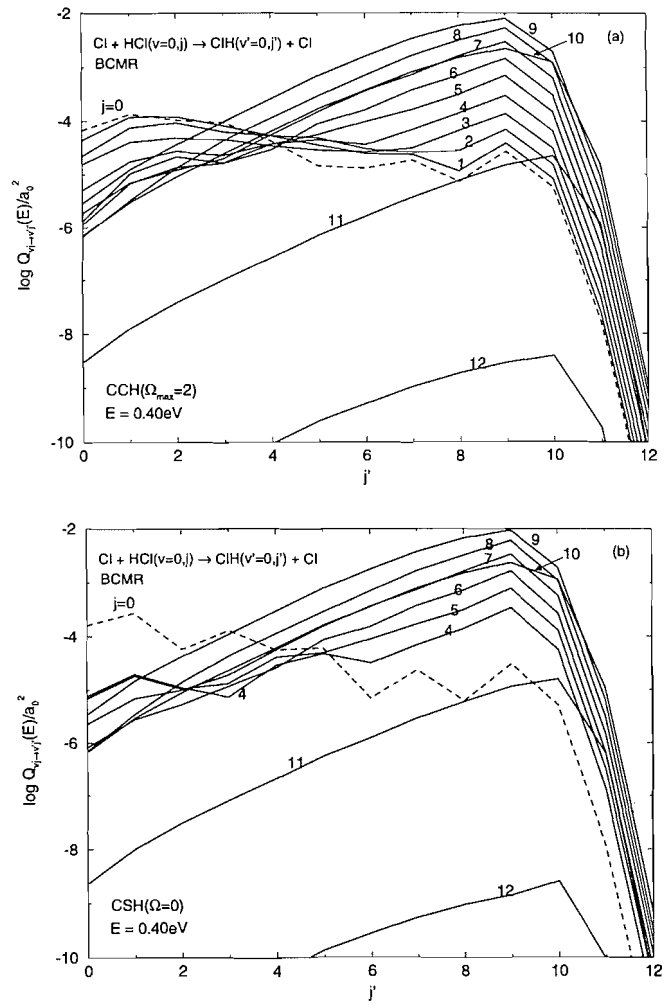

FIG. 4. log $Q_{vj \to v'j'}(E)$ versus j' at $E = 0.40$ eV for $v = v' = 0$ and j in the range between 0 and 12: (*a*) CCH($\Omega_{max} = 2$) results, with the $j = 0$ result displayed using a dashed curve; (*b*) CSH($\Omega = 0$) results, with $j = 1$–3 omitted for clarity of presentation and a dashed curve used for $j = 0$.

point complex contributes to tunnelling through the barrier. At higher E, the CCH($\Omega_{max} = 2$) and CSH($\Omega = 0$) $P(E)$ diverge, differing by a factor of 2.4 at $E = 0.60$ eV. This presumably reflects the contribution of excited bending states to the reaction probabilities. (*3*) Of the three approximate $P(E)$ shown in Fig. 3, it is the CSH($\Omega = 0$) $P(E)$ that agrees best with CCH($\Omega_{max} = 2$) at low E. At higher E, none of the approximate theories include states with $\Omega \neq 0$, so agreement is not expected. Note that CSDW($\Omega = 0$) predicts an even higher $P(E)$ than CCH($\Omega_{max} = 2$), but this is probably due to the breakdown of first order perturbation theory, rather than omission of states with $|\Omega| > 0$.

D. Product rotational energy distributions

Figure 4 shows the logarithm of the state-to-state integral cross section log $Q_{vj \to v'j'}(E)$ versus j' at $E = 0.40$ eV for $v = v' = 0$. The CCH($\Omega_{max} = 2$) cross sections are plotted in Fig. 4*a*, and the CSH($\Omega = 0$) results in Fig. 4*b*. All energetically open rotational states ($j = 0$–12 and $j' = 0$–12) have been included. We note that in both plots, the dominant behavior in the rotational distributions (seen for $j = 5$–12) is an approximately exponential increase up to a maximum at $j' = 9$ or 10, followed by an exponential decrease for $j' > 10$.

As a result, the average value of j', denoted by $\langle j' \rangle_{0\hat{j}}$ for $j = \hat{j}_0$ in Table 2, is close to the peak value of j'.

For $j = 0$–4, the rotational distributions also have a peak or shoulder at low j', in addition to the $j' = 9$ peak. This behavior is seen in both CCH($\Omega_{max} = 2$) and CSH($\Omega = 0$), although the CSH($\Omega = 0$) cross sections also oscillate with j', somewhat obscuring the overall trend. (We have omitted the $j = 1$–3 curves from the CSH($\Omega = 0$) plot because of overlapping oscillations.) In ref. 5, we discussed the low j' peak in the CSH($\Omega = 0$) results, arguing that it may be due to the "tight bend" reaction mechanism discussed earlier, since one expects this mechanism to be more important for low j and j'. Figure 4*a* shows that this same mechanism is present in the CCH($\Omega_{max} = 2$) cross sections, though reduced in magnitude. In ref. 5 we noted that the oscillations in the $j = 0$ curve in Fig. 4*b* could be the result of numerical artifacts. However, an alternative explanation is that they are due to interference between the "tight bend" and "nearly-free rotor" reaction mechanisms discussed previously. If so, then one would expect a smaller interference in the CCH($\Omega_{max} = 2$) results in Fig. 4*a* (as observed) because scattering into channels with $|\Omega| > 0$ or $|\Omega'| > 0$ is more important in one mechanism than in the other.

IV. Conclusions

We have presented CCH($\Omega_{max} = 2$) cumulative and state selected reaction probabilities, integral cross sections, and product rotational distributions for the Cl + HCl reaction on the BCMR potential surface, and comparisons with the CSH($\Omega = 0$), CSDW($\Omega = 0$), and CCH/JS approximations. Our calculations allow an assessment of the accuracy of this earlier work. Much of what we have seen in the new results had been anticipated in the earlier work, in particular, that the cross sections near the reaction threshold are well approximated by CSH($\Omega = 0$). However, as E increases, the CCH($\Omega_{max} = 2$) cross sections increase more rapidly than do CSH($\Omega = 0$). This can be rationalized using the adiabatic bend approximation, but note that even at $E = 0.40$ eV, states with $|\Omega| > 0$ and $|\Omega'| > 0$ make a significant contribution to the CCH($\Omega_{max} = 2$) m_j-resolved cross sections (see Fig. 1*b*). The good agreement between CSH($\Omega = 0$) and CCH($\Omega_{max} = 2$) for degeneracy averaged quantities in this case suggests that Ω does not have to be conserved in order for CSH($\Omega = 0$) to be accurate. What remains to be seen is whether inclusion of states with $|\Omega| > 0$ in CSH will give accurate results at higher E, where the CSH($\Omega = 0$) results are inaccurate.

Hybridization properties of oligoarabinonucleotides

PAUL APOSTOLOS GIANNARIS AND MASAD JOSÉ DAMHA[1]

Department of Chemistry, McGill University, Montreal, QC H3A 2K6, Canada

Received September 8, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

PAUL APOSTOLOS GIANNARIS and MASAD JOSÉ DAMHA. Can. J. Chem. **72**, 909 (1994).

3′-Phosphoramidite derivatives of arabinocytidine, arabinoadenosine, and arabinouridine were prepared and used for the solid-phase synthesis of oligoarabinonucleotides (arabinonucleic acid, or ANA). Thermal denaturation analysis and gel mobility shift assays were used to investigate the interaction between ANA and complementary DNA and RNA. In general, the ANA/DNA and ANA/RNA complexes exhibited melting temperatures comparable to those of the corresponding DNA/DNA and DNA/RNA complexes. Thus the inversion of stereochemistry at the C2′ of ribonucleotides does not have a negative effect on interaction with natural sequences. In fact, in complexes with poly dT, oligoarabinoadenylates displayed greater hybridization affinity than oligoriboadenylates. In summary, we observed that (*i*) ara(Ap)$_7$A interacted favourably with poly rU and poly dT; (*ii*) ara(Cp)$_7$C formed a stable complex with poly rG; (*iii*) ara(Up)$_7$U did not bind with complementary poly rA; and (*iv*) the mixed oligoarabinonucleotide ara(UCU UCC CUC UCC C) formed complexes with complementary DNA and RNA. Hybridization was observed between the phosphorothioatelinked arabinoadenylate ara(Aps)$_7$A and poly rU and poly dT; however, this binding was weaker than that between the phosphorothioate-linked deoxyriboadenylate d(Aps)$_7$A and poly rU and poly dT. Both ara(Aps)$_7$A and its deoxy analog d(Aps)$_7$A displayed significant and similar resistance to digestion by snake venom phosphodiesterase.

PAUL APOSTOLOS GIANNARIS et MASAD JOSÉ DAMHA. Can. J. Chem. **72**, 909 (1994).

On a effectué la synthèse des dérivés 3′-phosphoramidite de l'arabinocytidine, de l'arabinoadénosine et de l'arabinouridine et on les a utilisés pour la synthèse en phase solide d'oligoarabinonucléotides (acide arabinonucléique, AAN). On a utilisé une analyse de dénaturation thermique et des essais de déplacements par mobilité sur gel pour étudier les interactions entre l'AAN et des ADN et ARN complémentaires. En général, les complexes AAN/ADN et AAN/ARN présentent des températures de fusion semblables à celles des complexes correspondants ADN/ADN et ADN/ARN. L'inversion de stéréochimie au niveau C2′ des ribonucléotides n'a donc pas d'effet négatif sur l'interaction avec les séquences naturelles. En fait, dans les complexes contenant des poly dT, les oligoarabinoadénylates présentent une affinité d'hybridation plus grande que celle des oligoriboadénylates. En résumé, on a observé que (*i*) l'ara(Ap)$_7$ interagit favorablement avec les poly rU et poly dT; (*ii*) que l'ara(Cp)$_7$C forme un complexe stable avec le poly rG; (*iii*) que l'ara(Up)$_7$U ne se lie pas avec le poly rA complémentaire et (*iv*) que l'oligoarabinonucléotide mixte ara(UCU UCC CUC UCC C) forme des complexes avec les ADN et ARN complémentaires. On a observé une hybridation entre l'arabinoadénylate ara(Aps)$_7$A lié au phosphorothioate et les poly rU et poly dT; toutefois, cette interaction est plus faible que celle entre le désoxyriboadénylate d(Aps)$_7$A lié au phosphorothioate et les poly rU et poly dT. L'ara(Aps)$_7$ ainsi que son analogue désoxy, d(Aps)$_7$A, présentent tous les deux une résistance importante et semblable à la digestion par la phosphodiestéase du venin de serpent.

[Traduit par la rédaction]

Introduction

The antisense approach to gene regulation requires oligonucleotides that exhibit stability against degradation by cellular enzymes and the ability to hybridize complementary DNA or RNA targets with good affinity and specificity. Short oligodeoxyribonucleotides can function as antisense oligomers (1) although their utility is limited by nucleolytic degradation in vivo (2). Various modified oligomers including those bearing modified phosphodiester linkages (3), non-phosphate linkages (4), and 2′,5′- rather than 3′-5′-phosphodiester linkages (5) have been designed in an attempt to increase nuclease resistance without severely hindering the ability to hybridize target DNA or RNA (for reviews of this area, see ref. 6). In addition, oligomers incorporating modified nucleoside units including α-nucleosides (7), L-deoxyribo and L-ribonucleosides (8, 9), glyceronucleosides (10), 4′-thionucleosides (11), carbocyclic nucleosides (12), and 2′-O-alkyl nucleosides (13) have also been explored as possible antisense agents.

Oligonucleotides containing the sugar D-arabinose (arabinonucleic acids, or ANA) (Scheme 1) have not been investigated as antisense agents, except for one reported example of an oligomer of 1-α-D-arabinofuranosyl thymidine (14). This may be due in part to the inherent difficulties in ANA synthesis, which, as in RNA synthesis (15), necessitates the differential chemical protection of the 2′ and 3′ hydroxyl groups. In the original work by Wechter, oligoarabinonucleotide synthesis was carried out without 2′-OH protection, resulting in mixtures of 2′,5′- and 3′,5′-linked nucleotides (16). There had been two other major strategies in the synthesis of 3′,5′-linked arabinonucleotides. The first and most widely used strategy makes use of 5′,2′-O-protected arabinonucleotides as precursors, which upon phosphorylation of the remaining 3′-hydroxyl function affords a suitable building block for the synthesis of arabinonucleotides (17–19). The problem with this approach is that of selective protection of the 2′-hydroxyl function, a very difficult requirement because of its orientation towards the hindered β face of the sugar. In practice, this is accomplished by first masking the 5′- and 3′-OH groups with a disiloxane bridging group, then protecting the 2′-hydroxyl, and finally deblocking the disiloxane function so that 5′-trityl and 3′-phosphate moieties can be introduced (17, 18). The second strategy is limited to pyrimidine arabinonucleotides, as they require formation of O^2-2′-anhy-

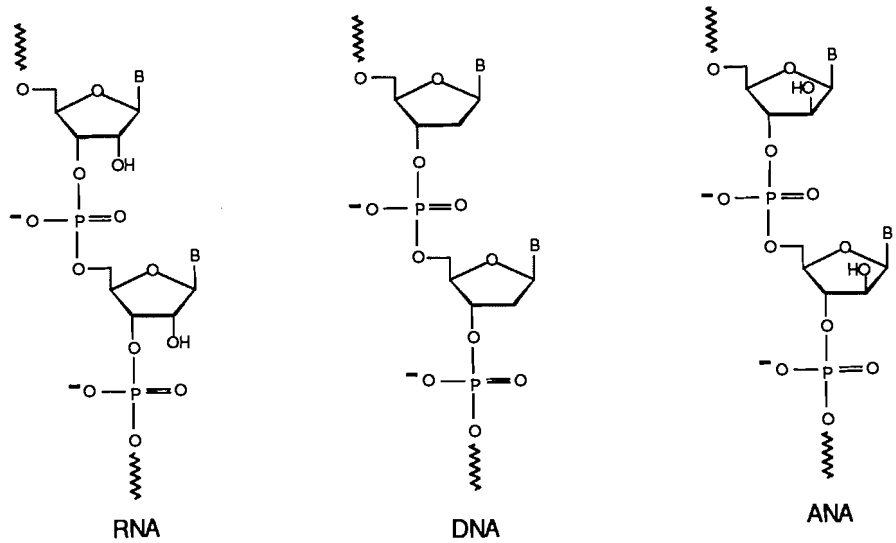

SCHEME 1

dronucleoside synthons, and this strategy is therefore rarely used (20). We thought that the best way to deal with the 2′-OH group was to block it only *after* the desired moieties of 5′- and 3′-positions had been introduced. This was readily achieved by sequential and regioselective tritylation (at 5′), phosphoramidation (at 3′), and acetylation (at 2′) of arabinonucleosides. The resulting 5′-tritylated arabinonucleoside 2′-*O*-acetyl-3′-*O*-phosphoramidites proved to be very useful synthons for the solid-phase synthesis of short arabinoadenylates and uridylates (21). Pfleiderer and co-workers have also made useful advances in using solid-phase phosphoramidite chemistry to make an all-β-D-arabinose "transfer ANA" molecule (22).

Arabinonucleosides have found application as antiviral (23) and antitumor (24) agents and, in particular, arabinofuranosyl cytosine (araC) has been found to be very effective in the treatment of leukemia (25). Although very little is known about the mechanism of action, its activity appears to be associated with its misincorporation into DNA (26). Mikita and Beardsley reported that the presence of araC at the 3′-terminus of a DNA primer strand results in a reduction in the rate of addition of the next nucleotide unit in vitro (27). Similarly, a single internucleotide araC insertion into an oligomer serving as the template strand hindered the function of certain polymerases, affecting, as a result, the process of replication in vitro (27). Whether these observations reflect differences in the structure of the complexes formed by normal DNA and those formed by oligomers containing araC is not clear. X-ray diffraction analysis of the self-complementary DNA oligomer d(CCAGGCaraCTGG) demonstrated that this oligomer forms a duplex with B-DNA conformation with only small conformational perturbations (28). However, molecular modeling studies have indicated that serious steric clashes may occur between the 2′-OH and neighboring atoms when araC is placed into the RNA strand of a DNA/RNA duplex (27). Altona and co-workers prepared self-complementary d(CGaraCTAGCG) to investigate the structural implications of an araC insertion into DNA by NMR analysis (29–31). They discovered that under certain conditions this oligomer exclusively adopts a hairpin structure whereas the unmodified DNA adopts a B-BNA type duplex. AraC incorporation into an alternating dC-dG sequence d(CGaraCGCG) has been shown to facilitate the B to Z conversion (32). Very little is known about the thermal stability of DNA chimeras containing 1-β-D-arabinonucleosides. A self-complementary DNA oligomer containing a single araC insert exhibited a somewhat lower melting temperature (T_m) (2°C/araC substitution) than the unmodified DNA (18) and no interaction was observed between a short oligomer of araU and poly rA (20*a*). In this work we prepared a series of 1-β-D-arabinonucleic acids and show, for the first time, that these oligomers can form stable complexes with complementary single-stranded DNA and RNA.

Results and discussion

Preparation of N^4*-benzoyl-5′-O-monomethoxytritylarabinocytidine-2′-O-acetyl-3′-O-N,N-diisopropyl-β-cyanoethylphosphoramidite* **5**

The title compound was prepared in good yield by acetylation of the 2′-OH *after* protection of the 4-amino and 5′- and 3′-hydroxyl groups (Scheme 2). Thus, 1-β-D-arabinofuranosylcytosine was first protected at the 5′-OH (monomethoxytrityl) and N^4 (benzoyl) positions, affording **3** in 60% combined yield. The protected arabinocytidine **3** was then phosphitylated with *N,N*-diisopropyl-β-cyanoethylphosphonamidic chloride, resulting in mainly **4** (77% yield). The free 2′-OH of **3** also reacted with the phophitylating reagent, although to a much lesser extent as indicated by additional very faint spots in the TLC plate. Compound **4** was produced as a pair of diastereoisomers that could be easily separated by silica gel column chromatography. The position of the phosphoramidite moiety on **4** was established by ^{13}C NMR. The spectrum clearly shows that the C4′, C3′, and C2′ resonances are coupled to phosphorus whereas that of C1′ is not, the two-bond $J(^{13}C3'–^{31}P)$ value being the greatest (Fig. 1). Furthermore, the greatest downfield shift in ^{13}C resonance of the arabinose sugar of **4** relative to the unphosphitylated derivative **3** was observed for C3′, identifying it as the carbon where the phosphoramidite moiety is attached. Subsequent 2′-O-acetylation of one diastereoisomer of **4** afforded the key activated monomer **5** in 87% yield.

Compound **5** was also obtained in a separate synthesis from ribocytidine. The key step in this approach was the inversion of the C2′-OH by strong heating with diphenyl carbonate – water in DMF (33) (Scheme 3). Under the reaction conditions, the initial 2′,3′-cyclic carbonate intermediate **7** reacts intramolecularly, forming 2,2′-cycloanhydride **8** which is subsequently

opened, producing a mixture of arabinocytidine and the starting material in a ratio of 9:1 (TLC, ethanol–water 1:1). These 2′ epimers could not be separated at this stage. They were, however, fully separated by silica gel chromatography after partial protection of the sugar (5′-MMT) and base (4-NH-Bz) moieties. Subsequent phosphitylation and acetylation of **3** afforded **5** in 65% combined yield.

Synthesis and characterization of oligoarabinonucleotides

Oligoarabinonucleotides were synthesized with an Applied Biosystems DNA/RNA synthesizer (model 381A) using amidite **5**, and analogous araU and araA 3′-*O*-(cyanoethyl)phosphoramidites (20). Oligomers were prepared on a 1.0 μmol scale employing "trityl on" synthesis cycle (60 s coupling time) and long-chain alkylamine controlled-pore glass (LCAA-CPG)

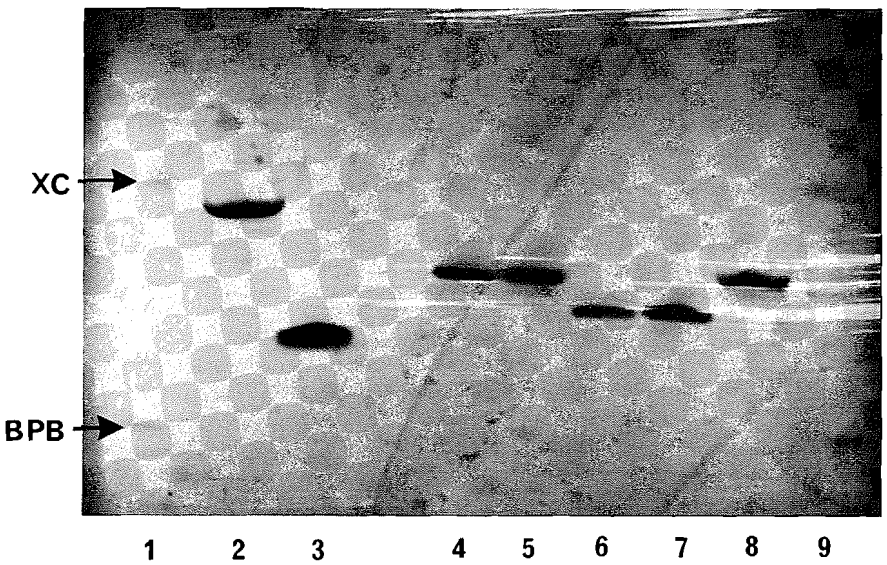

FIG. 2. Polyacrylamide gel electrophoresis (16%, denaturing) of oligoarabinonucleotides. Lanes: (1) xylene cyanol and bromophenol blue; (2) $d(Tp)_{14}T$; (3) $d(Tp)_4T$; (4) crude $ara(Cp)_9C$; (5) pure $ara(Cp)_9C$; (6) crude $ara(Cp)_7C$; (7) pure $ara(Cp)_7C$; (8) $ara(Cp)_9C$ treated with 0.1 N KOH for 24 h; (9) xylene cyanol and bromophenol blue.

bearing 3′-terminal arabinonucleosides. The coupling efficiency was routinely greater than 98% as monitored by the release of the MMT cation. RNA (34) and DNA (35) oligomers were prepared by standard means. Deprotection of sugar and phosphate moieties with concomitant release of oligomers from the glass support was accomplished by a single ammonia treatment (29% NH_4OH, 55°C, 8 h). The terminal trityl group was cleaved with trifluoroacetic acid during purification with a reversed phase OPC® cartridge (Applied Biosystem), and in the case of araC oligomers it was removed prior to purification by polyacrylamide gel electrophoresis (PAGE). Purity of ANA oligomers was verified by analytical gel electrophoresis and was determined to be greater than 95% (Fig. 2). No other bands that would indicate poor monomer coupling or branch formation were detected (21). The ANA, DNA, and RNA sequences prepared for this study are shown in Table 1.

The integrity of the oligoarabinonucleotides was established by chemical and enzymatic degradation with subsequent analysis of the nucleotide–nucleoside mixtures by polyacrylamide gel electrophoresis (PAGE). Oligoarabinonucleotides are expected to be resistant to base conditions since the *trans* relationship of the 2′-OH with respect to the 3′,5′-phosphodiester linkage prevents participation of the 2′-OH in intranucleotide cleavage. This stability has been previously observed for 3′,5′-linked dinu-

[a]Equimolar mixtures on a per base basis were used. T_m's are ±0.5°C. Buffer: 10 mM sodium phosphate with [NaCl] as indicated. —, not observed. Hyperchromicity values (%H) are presented in parentheses relative to the initial temperature reading.

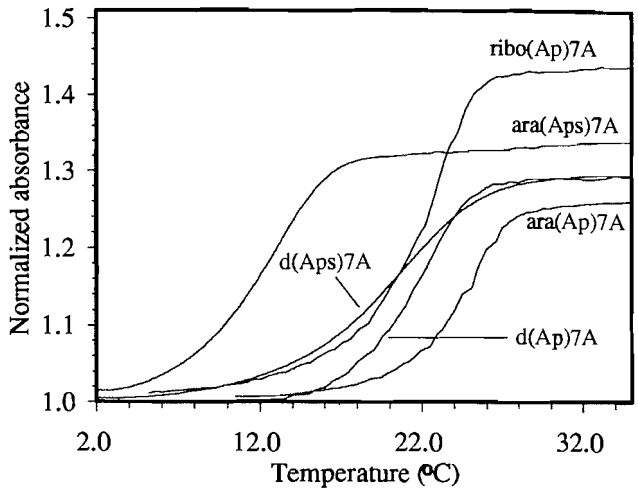

FIG. 3. Thermal denaturations of poly rU:oligomer complexes. Equimolar mixtures (per residue basis) of poly rU and each oligomer indicated below were prepared and denatured in 100 mM NaCl, 10 mM Na_2HPO_4, pH 7.0. Thermal denaturation curves for the mixtures of poly rU with phosphodiester-linked oligomers r(Ap)$_7$A, d(Ap)$_7$A, and ara(Ap)$_7$A as well as phosphorothioate-linked oligomers ara(Aps)$_7$A and d(Aps)$_7$A are shown normalized to their respective first temperature reading. T_m and %H values for these melts are tabulated in Table 2.

cleoside monophosphates of arabinocytidine (16), arabinouridine and arabinoadenosine (21), as well as for the trinucleotide ara-(ApApA) (17). The oligoarabinonucleotides prepared in this study were also found to be completely stable to treatment with 0.1 N KOH for 24 h (Fig. 2, compare lanes 2 and 4 with 7), whereas the corresponding oligoribonucleotides were completely degraded under these conditions (data not shown).

The arabinonucleotides displayed some stability against cleavage by snake venom phosphodiesterase (SVPDE). For example, only 5–10% hydrolysis of ara(Ap)$_7$A, ara(Cp)$_7$C, and ara(Up)$_7$U was detected during incubation of these oligomers with SVPDE at 37°C for 45 min, whereas oligoribonucleotides were completely degraded within 5 min under the same conditions (PAGE). The oligoarabinonucleotides, however, did not exhibit any significant stability, relative to ribonucleotides, when incubated with other nucleases. For example, treatment with the endonucleases Nuclease P1 and Ribonuclease S1, or the 5′-exonuclease calf spleen phosphodiesterase, resulted in degradation of both ara and ribo oligomers within 45 min at 37°C. Digestion with spleen phosphodiesterase served also to establish a 3′,5′-phosphodiester connectivity within the oligoarabinonucleotides, since 2′,5′-linked arabinonucleotides (16) and 2′-5′-linked oligoribonucleotides (5, 16) are not hydrolyzed by this enzyme.

The phosphorothioate-linked oligomers ara(Aps)$_7$A and d(Aps)$_7$A were characterized by incubation with SVPDE at 37°C for 16 h followed by analysis of the digest by HPLC. Under these conditions, less than 20% of ara(Aps)$_7$A and d(Aps)$_7$A was degraded whereas phosphodiester-linked d(Ap)$_7$A was completely degraded within 10 min. The increased stability of the phosphorothioate-linked oligomers d(Aps)$_7$A and ara(Aps)$_7$A, relative to d(Ap)$_7$A, is consistent with related work that shows that phosphorothioate-linked DNA (36) and phosphorothioate linked RNA (37) are more resistant to nuclease activity than normal DNA and RNA strands.

Interaction of oligoarabinonucleotides with complementary DNA and RNA

In the presence of poly dT and 100 mM NaCl, the oligoarabinoadenylate ara(Ap)$_7$A exhibits a melting temperature approximately equal to, or significantly higher than, the corresponding natural oligomers d(Ap)$_7$A and r(Ap)$_7$A (Table 2, Fig. 3). In addition, at 100 mM NaCl, the T_m of the complex formed between ara(Ap)$_7$A and poly rU was marginally higher than those values observed for the complexes d(Ap)$_7$A):(poly rU) and r(Ap)$_7$A):(poly rU) (Table 2, Fig. 3). The stoichiometry of complexes of ara(Ap)$_7$A and r(Ap)$_7$A with poly rU was determined in each case to be 2U:1A (triplex) from UV mixing curves (1 M NaCl at 20°C) (38).[2] All these results suggest that *the inversion of stereochemistry at the C2′ of ribonucleotides usually does not have a strong positive or negative effect on interaction with natural sequences, and that the 2′-OH group of ANA does not usually hinder the formation of ANA/DNA and ANA/RNA complexes.* In fact, the significantly higher T_m observed for complexes ara(Ap)$_7$A:poly dT and ara(Ap)$_7$A:poly rU relative to complexes r(Ap)$_7$A:poly dT and r(Ap)$_7$A:poly rU indicates that the 2′-OH of ANA exerts, in this case, a stabilizing effect.[3] Oligoribonucleotides containing modifications at the 2′-position, including 2′-*O*-methyl (13, 39), 2′-fluoro (40), 2′-*O*-allyl (41), 2′-*O*-ethyl (42), and 2′-*O*-propyl (42), generally exhibit higher T_m than their respective unmodified oligomers in the interaction with complementary RNA. This being the case, it would be of interest to determine whether the stabilizing effect exerted by 2′-substituents in ribonucleotides will also be evident for 2′-O-modified arabinonucleotides.

To study the effect of base sequence on complex stability, the interaction of oligoarabinonucleotide ara(5′-CCC UCU CCC UUC U-3′) (abbreviated ara(U/C)-13-mer) with complementary RNA (r(A/G)-13-mer) and DNA (d(A/G)-13-mer) was

[2]1Py:1Pu mixtures were used in the hybridization assays of ara(Ap)$_7$A and poly dT and polyrU. We later determined that poly rU interacts with ara(Ap)$_7$A with a 2U:1A stoichiometry. We have also observed that mixtures of 1Py:1Pu and 2Py:1Pu (Pu = adenylates and Py = poly rU) give the same T_m values within experimental error.

[3]We make this statement with caution since ΔT_m may not reflect $\Delta\Delta G^0$.

[a] T_m are ±0.5°C for melts with poly rG, and ±1.0°C for all other melts (due to broad transitions). Hyperchromicity values (%H) are presented in parentheses relative to the absorbance reading at 20°C. Buffer: 10 mM sodium phosphate pH 7 with [CsCl] or [NaCl] as indicated. Equimolar mixtures (2.5 μmol in each strand) were used.

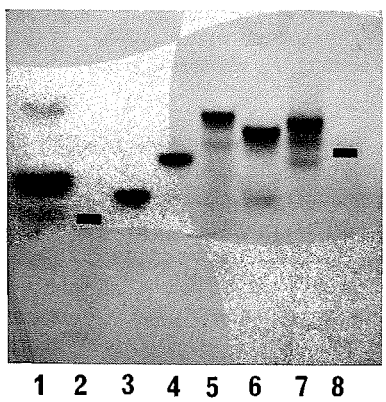

FIG. 4. Mobility shift assay of ara(U/C)-13-mer complex with RNA on non-denaturing PAGE (24%). Mixtures of approximate equimolar strand concentrations (2.0 μmol in each strand) in lanes 5–7. Single strands (ss) are shown in lanes 2–4, and 8. Lanes: (1) xylene cyanol and bromophenol blue; (2) ss r(U/C)-13mer; (3) ss d(T/C)-13-mer; (4) ss ara(U/C)-13-mer; (5) (r(U/C)-13-mer):(r(A/G)-13-mer); (6) (d(T/C)-13-mer):(r(A/G)-13-mer); (7) (ara(U/C)-13-mer):(r(A/G)-13-mer); (8) ss r(A/G)-13-mer. The mobility of the bands in lanes 2 and 8 have been highlighted for clarity. T_m values for these complexes are listed in Table 3.

investigated by UV thermal denaturation analysis (Table 3). All of the complexes listed in Table 3 showed similar broad cooperative transitions at 260 nm indicative of complex formation while the single strands, run on their own, exhibited only linear increases in absorbance.[4] In 200 mM NaCl, the ANA/RNA complex ara(U/C)-13-mer):(r(A/G)-13-mer) exhibited a T_m of 53°C, while the melting temperatures of the analogous RNA/RNA (T_m = 75°C) and DNA/RNA (T_m = 64°C) complexes were significantly higher. A mobility shift PAGE assay was used to confirm the formation of these complexes. Figure 4 clearly

[4] The only exception is r(A/G)-13-mer, which self-associates (ref. 5). The self-association of this oligomer can be largely eliminated by heating the sample to 90°C for 30 min before measurements. Longer heating times are not recommended as this may result in significant degradation.

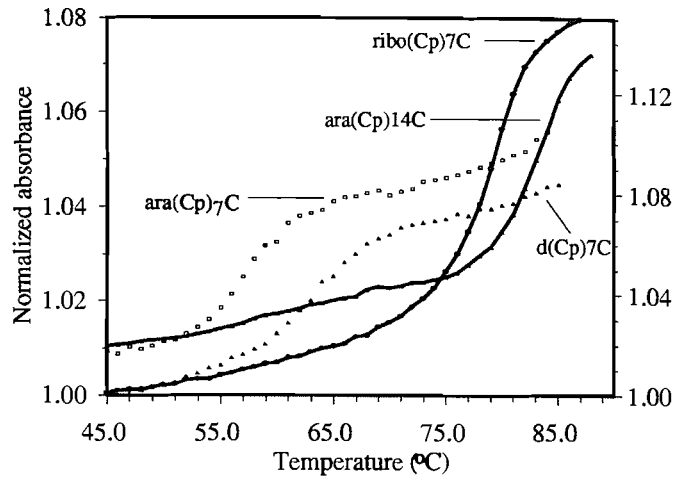

FIG. 5. Thermal denaturations for (oligomer):(poly rG) complexes in 200 mM NaCl, 10 mM Na_2HPO_4, pH 7.0. Curves for the interaction of r(Ap)$_7$A, d(Cp)$_7$C, ara(Cp)$_7$C, and ara(Cp)$_{14}$C are shown normalized to their respective absorbance readings at 20°C. Curves for complexes (poly rG):(ara(Cp)$_7$C) and (poly rG):(ara(Cp)$_{14}$C) are offset for clarity and the curve for (poly rG):(r(Cp)$_7$C) is plotted using the *y*-axis on the right part of the graph. T_m and %H values are tabulated in Table 3.

shows that an equimolar mixture of ara(U/C)-13-mer and r(A/G)-13-mer resulted in the formation of a new band migrating much more slowly than the component single strands (compare lane 7 to 4, and 8) and with very similar mobility to the slow bands in lanes 5 and 6, which represent the complexes (r(U/C)-13-mer):(r(A/G)-13-mer) and (d(A/G)-13-mer):(r(A/G)-13-mer). Hybridization was observed between ara(U/C)-13-mer and d(A/G)-13-mer (T_m = 18°C), although this was significantly weaker than that observed between r(U/C)-13-mer with d(A/G)-13-mer (T_m = 53°C).

Oligoarabinonucleotide ara(Cp)$_7$C forms a stable complex with poly rG in 200 mM NaCl, exhibiting a T_m of 57.0°C. This represents a reduction in T_m of 20° and 7.5° relative to, respectively, the control complexes (r(Cp)$_7$C):(poly rG) and (d(Cp)$_7$C):(poly rG) (Table 3, Fig. 5). The hyperchromic effect observed for (ara(Cp)$_7$C):(poly rG) (5 %H) was similar to that of (d(Cp)$_7$C):(poly rG) (5 %H) and significantly lower than that for the interaction between r(Cp)$_7$C with poly rG (15 %H). This observation may indicate that base stacking in (ara(Cp)$_7$C):(poly rG) is more closely related to that in (d(Cp)$_7$C):(poly rG) than in (r(Cp)$_7$C):(poly rG). As expected, a mixture of poly rG and a longer araC oligomer, namely ara(Cp)$_{14}$C, exhibited a higher T_m and %H relative to ara(Cp)$_7$C, confirming the interaction between araC and riboG residues.

In contrast to our previous finding that ara(Ap)$_7$A forms stable complexes with complementary RNA and DNA, we were unable to detect the formation of a complex between ara(Up)$_7$U and poly rA. There was no cooperative transition at 260 nm upon heating a mixture of ara(Up)$_7$U and poly rA (1 M NaCl), whereas under similar conditions we observed transitions for the melting of (r(Up)$_7$U):(poly rA) and (d(Tp)$_7$T):(poly rA) (Table 2). This observation is consistent with the work of Provenzale and Nagyvary, who showed that short oligomers of araU did not bind with poly rA under conditions where poly rU/poly rA formed (20*a*). It is possible that ara(Up)$_7$U binds to poly rA but the T_m value of the complex is too low to be detected.

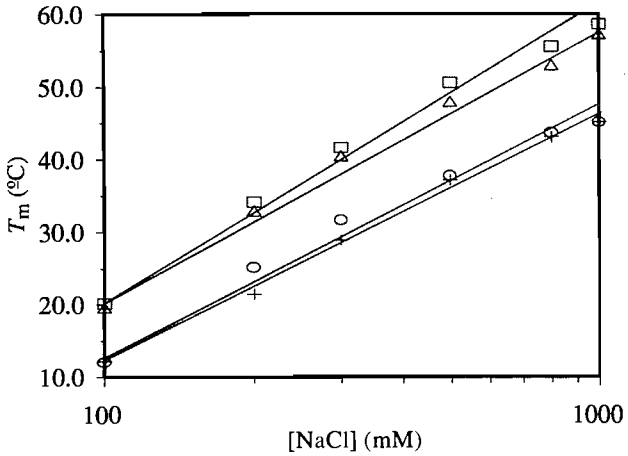

FIG. 6. Effect of increasing [NaCl] concentration on T_m for the complexes of phosphorothioate-linked oligoadenylates with poly dT and poly rU. Log [NaCl] versus T_m curves for the complexes (□) (poly dT):(d(Aps)$_7$A); (△) (poly rU):(d(Aps)$_7$A); (○) (poly rU):(ara(Aps)$_7$A); (+) (poly dT):(ara(Aps)$_7$A).

Interaction of the phosphorothioate ara(Aps)$_7$A with poly dT and poly rU

Replacement of the normal internucleotide linkage in ara(Ap)$_7$A with phosphorothioate linkages had a destabilizing effect on the complexes formed with poly rU and poly dT. For example, in 100 mM NaCl, the T_m of the complex (ara(Aps)$_7$A):(poly rU) was 12.4°C lower than that of the "all"-phosphodiester complex (ara(Ap)$_7$A):(poly rU) (Table 2). Similarly, ara(Aps)$_7$A gave a depressed T_m value when annealed to poly dT. It is clear from Fig. 4 and the data presented in Table 2 that the destabilizing effect resulting from phosphorothioate substitution in ara(Ap)$_7$A is significantly greater than in d(Ap)$_7$A. This destabilization was observed over a large range of ionic conditions (100 mM – 1 M NaCl) as illustrated in the plots of T_m vs. log [NaCl] (Fig. 6). Despite their enhanced nuclease stability, the weak hybridization affinity of phosphorothioate oligoarabinonucleotides may limit their use as antisense agents or as probes. However, we point out that the stability of complexes formed by phosphorothioate oligodeoxynucleotides is known to be sequence dependent.[5,6] Thus, to fully assess the binding potential of phosphorothioate ANA, oligomers of mixed base composition need to be investigated.

Conclusions

ANA oligomers can readily be prepared by the conventional solid-phase methodology employing phosphoramidite chemistry. Oligoarabinonucleotides were found to hybridize with complementary RNA and DNA exhibiting T_m's comparable to, and in some cases greater than, the corresponding unmodified oligomers. Although the ANA oligomers were susceptible to cleavage by certain nucleases, their stability under cellular conditions remains to be determined. Phosphorothioate-linked oligoarabinoadenylates exhibit characteristics normally observed for phosphorothioate DNA and RNA oligomers, for instance, significant stability against SVPDE cleavage and, in the case of ara(Aps)$_7$A, reduced T_m's when hybridized to complementary ssDNA and RNA relative to the unmodified ara(Ap)$_7$A. Our findings that ANA can form stable complexes with both ssDNA and RNA are very encouraging for those hoping to use sugar-modified antisense oligonucleotides as antisense agents or as probes. We are currently evaluating the effect of mixed base composition and 2′-modification (e.g., alkylation) on the ability of ANA to complex with both single- and double-stranded DNA and RNA.

[5]Generally, incorporation of phosphorothioate linkages at the 5′-side of a purine residue results in less destabilization of duplexes relative to when they are placed at the 5′-side of pyrimidines; this is particularly true in phosphorothioate d(AT) and d(GC) systems (43).

[6]Phosphorothiate substitution within (dTpT) is more destabilizing than substitution within (dCpC) oligomers (44).

Experimental

General procedures, chemicals, and reagents

THF was distilled from sodium benzophenone ketyl. Dimethylformamide (DMF), pyridine, and *N,N*-diisopropylethylamine were dried by stirring over CaH_2 followed by distillation under reduced pressure, and were stored over activated 4Å molecular sieves. Dichloromethane was distilled from P_2O_5. Acetonitrile was stirred in P_2O_5 and distilled from calcium hydride. Acetic anhydride was distilled and stored over magnesium turnings. Silylated ribonucleoside 3′-(cyanoethyl)phophoramidites were obtained from Dalton Chemical Laboratories, Inc. (Toronto, Ont.). DNA cyanoethyl phosphoramidite monomers, long-chain alkylamine controlled-pore glass (LCAA-CPG) bearing deoxyribonucleosides, tetraethylthiuram disulfide (TETD), and all other ancillary reagents for DNA/RNA/ANA synthesis were obtained from Applied Biosystems (Toronto, Ont.). LCAA-CPG bearing ribonucleosides or arabinonucleosides were prepared as previously described (45). *N*^{6}-benzoyl-5′-*O*-monomethoxytritylarabinoadenosinesine-2′-*O*-acetyl-3′-*O*-*N,N*-diisopropyl-β-cyanoethylphosphoramidite and 5′-*O*- monomethoxytrityllarabinouridine-2′-*O*-acetyl-3′-*O*-*N,N*-diisopropyl-β-cyanoethylphosphoramidites used in ANA synthesis were prepared according to Damha et al. (21). Cytidine, arabinocytidine, poly dT, poly rU, poly rG, and poly rA were used as obtained from Sigma Chemical Co (St. Louis, Mo.). Polyacrylamide gel electrophoresis reagents were obtained from Bio-Rad (Toronto, Ont.). HPLC grade solvents were purchased from Caledon (Toronto).

Preparation of N^4*-benzoyl-5′-*O*-monomethoxytritylarabinocytosine-2′-*O*-acetyl-3′-*O-N,N*-diisopropyl-β-cyanoethylphosphoramidite* ***5***

1. From 1-β-D-arabinofuranosylcytosine ***1***

Synthesis of 5′-O-monomethoxytritylarabinocytidine ***2***. Arabinocytidine **1** (18.0 mmol, 4.4 g) was coevaporated with pyridine (3 × 10 mL) and dissolved in dry pyridine (20 mL). Monomethoxytrityl chloride (19.8 mmol, 6.1 g) was added and the solution stirred at room temperature for 10 h, at which time a further 800 mg (0.1 equiv.) of monomethoxytrityl chloride was added and the mixture was allowed to stir for an additional 12 h. The mixture was evaporated to near dryness, dissolved in dichloromethane, and washed first with a solution of 5% sodium bicarbonate (100 mL) followed by brine (100 mL). The organic layer was dried over sodium sulfate and coevaporated with a solution of 10% dichloromethane in toluene (2 × 50 mL) to remove residual pyridine. This crude mixture was purified by silica gel chromatography by elution with dichloromethane–ethanol 85:15, affording 7.0 g (79% yield) of pure **2**. TLC (CH_2Cl_2/EtOH, 8:2) R_f 0.42; ($CHCl_3$/EtOH, 7:3) R_f 0.67. UV (95% EtOH/H_2O) λ_{max}: 230, 275 nm; λ_{min}: 224, 252 nm. ^{1}H NMR (acetone-d_6, 500 MHz) δ: 7.2–7.5 (m, 14, aryl trityl), 6.24 (d, 1, $J_{H1'-H2'}$ = 3.91 Hz, H1′), 4.34 (t, 1, H2′), 4.18 (t, 1, H3′), 4.07 (m, 1, H4′), 3.79 (s, 3, OCH_3), 3.45 (m, 2, H5′), 3.41 (m, 2, H5″).

N^4*-Benzoyl-5′-*O*-monomethoxytritylarabinocytidine* ***3***. Monomethoxytritylarabinocytidine **2** (10.9 mmol, 5.65 g) was coevaporated with pyridine (2 × 30 mL) and dissolved in pyridine (40 mL). Trimethylchlorosilane (54.8 mmol, 6.9 mL) was added to the solution over a period of 5 min and the mixture was stirred at ambient temperature (30 min) until all the starting material had reacted (TLC: dichlo-

romethane/ethanol 8:2). Benzoyl chloride (54.9 mmol, 6.4 mL) was added via syringe over a 5 min period. TLC analysis (dichloromethane/ethanol 8:2), 2 h later, indicated that less than 5% of non-benzoylated trisilylated product (R_f 0.76) remained. The reaction flask was immersed in an ice bath and water (5 mL) was added, followed by a solution of 29% ammonia (5 mL) 10 min later. After 15 min of stirring, the "thick" mixture was evaporated to near dryness, dissolved in dichloromethane (30 mL), and washed with water (30 mL). The organic layer was dried over sodium sulfate and the solvent was evaporated. The brown gum was coevaporated with toluene (2 × 30 mL) and purified twice by silica gel chromatography by elution with 5% ethanol–dichloromethane, affording 4.9 g (73% yield) of pure **3**. TLC: (CH_2Cl_2/EtOH 9:1) R_f 0.33; (EtOAc/EtOH, 9:1) R_f 0.63; (EtOAc) R_f = 0.13. UV (95% EtOH/H_2O, nm) λ_{max}: 230, 257, 307; λ_{min}: 224, 245, 286. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 3.73 (s, 3, OCH_3), 3.45 (m, 2, H5′), 4.04 (m, 1, H4′), 4.31 (t, 1, H3′), 4.61 (t, 1, H2′), 6.21 (d, 1, $J_{H1'-H2'}$ = 4.85 Hz, H1′), 7.0–7.5 (m, 14, aryl trityl), 7.4–7.7 (m, 5, aryl benzoyl). MS (FAB-NBA) *m/e*: 620 (MH^+, 5.3%), 273 ($MMTr^+$, 100%), 228 (6.0%), 216 (HCy^{Bz} + H^+, 31.0%).

N^4-*Benzoyl-5′-O-monomethoxytritylarabinocytidine-3′-O-N,N-diiso-propyl*-β-cyanoethylphosphoramidite **4**. To a dry hypovial under argon was aded dry THF (30 mL), dry diisopropylethylamine (35.5 mmol, 6.2 mL), and the nucleoside derivative **3** (4.5 mmol, 8.8 g). *N,N*-Diisopropyl-β-cyanoethylphosphonamidic chloride (9.8 mmol, 2.2 mL) was added dropwise over 20 min. At the 90 min mark, ethyl acetate (prewashed with a solution of 5% sodium bicarbonate) (100 mL) was added and the mixture transferred to a separator funnel where it was washed with brine (4 × 100 mL) and dried over sodium sulfate. Removal of the solvent afforded 1.15 g of a white crystalline foam. TLC analysis (TLC: EtOAc/CH_2Cl_2/Et_3N 48:48:4) indicated a >95% completed reaction. The crude product was purified by silica gel chromatography by elution with CH_2Cl_2/hexanes/triethylamine 50:45:5, yielding both diastereoisomers of compound **4** in 77% combined yield. Physical properties of fast diastereoisomers: TLC (EtOAc/CH_2Cl_2/Et_3N, 48:48:4) R_f 0.62. ^{1}H NMR ($CDCl_3$, 100 MHz) δ: 8.12 (d, 1, H6, J_{H6-H5} = 2.4 Hz), 7.3–7.5 (H5, overlap with trityl), 6.14 (d, 1, $J_{H1'-H2'}$ = 4.98 Hz, H1′), 4.53 (2 × dd, 1, H2′, $J_{H2'-H3'} \cong J_{H1'-H2'}$ = 3.4 Hz), 4.29–4.34 (2 × dd, 1, H3′, $J_{H2'-H3'} \cong J_{H3'-H4'}$ = 3.9 Hz), 4.13–4.16 (m, 1, H4′), 3.4 (m, 2, H5′, H5″), 3.75 (s, 3, OCH_3), 1.17 (d, 6, i-Pr), 1.10 (d, 6, i-Pr). ^{13}C NMR ($CDCl_3$, 100 MHz) δ: 143.65 (s, C6), 113.2 (s, C5), 87.21 (s, C1′), 83.23 (d, C4′), 77.88 (d, C3′), 75.17 (d, C2′), 62.59 (s, C5′). ^{31}P NMR ($CDCl_3$, 80 MHz) δ: 150.60. Physical properties of slow diastereoisomer: TLC (EtOAc/CH_2Cl_2/Et_3N, 48:48:4) 0.48. ^{1}H NMR ($CDCl_3$, 100 MHz) δ: 8.10 (d, 1, H6, J_{H6-H5} = 2.3 Hz), 7.3–7.5 (H5, overlap with trityl), 6.25 (d, 1, $J_{H1'-H2'}$ = 4.03 Hz, H1′), 4.57 (2 × dd, 1, H2′, $J_{H2'-H3'} \cong J_{H1'-H2'}$ = 2.9 Hz), 4.30 (2 × dd, 1, H3′, $J_{H2'-H3'} \cong J_{H3'-H4'}$ = 3.5 Hz), 4.15 (m, 1, H4′), 3.4 (m, 2, H5′, H5″), 3.78 (s, 3, OCH_3), 1.13 (d, 6, i-Pr). ^{13}C NMR ($CDCl_3$, 100 MHz) δ: 86.98 (s, C1′), 83.42 (d, C4′), 78.95 (d, C3′), 74.79 (d, C2′), 62.90 (s, C5′). ^{31}P NMR ($CDCl_3$, 80 MHz) δ: 150.80. MS (FAB-NBA) *m/e*: 820 (MH^+, 6.9%), 602 ([MH^+ − $CNCH_2CH_2OP(OH)$(i-Pr)$_2$], 17.9%), 273 ($MMTr^+$, 100%), 216 (HCy^{Bz} − H^+, 33.9%), 201 ($CNCH_2CH_2OP$(i-Pr)$_2^+$, 46.3%).

N^4-*Benzoyl-5′-O-monomethoxytritylarabinocytosine-2′-O-acetyl-3′-O-N,N-diisopropyl*-β-cyanoethylphosphoramidine **5**. To a dry hypovial containing the slow diastereoisomer of **4** (1.1 mmol, 900 mg) and dimethylaminopyridine (0.4 mmol, 53 mg) were added dry THF (5 mL) and diisopropylethylamine (8.7 mmol, 1.5 mL). Acetic anhydride (4.4 mmol, 450 μL) was added over 1 min and the solution was stirred for 45 min since TLC analysis ((CH_2Cl_2/EtOAc/Et_3N, 1:1) R_f 0.63) indicated that all of the starting material had reacted. Ethyl acetate (prewashed with a solution of 5% sodium bicarbonate) (25 mL) was added and the mixture transferred to a separator funnel where it was washed with brine (5 × 100 mL) and dried over sodium sulfate. Removal of the solvent produced **5** as a white crystalline foam in 87% yield. TLC (EtOAc/CH_2Cl_2/Et_3N, 48:48:4) R_f 0.63. ^{1}H NMR ($CDCl_3$, 400 MHz) δ: 7.96 (d, 1, H6, J_{H6-H5} = 2.4 Hz), 7.3–7.5 (H5, overlap with trityl), 6.33 (d, 1, H1′, $J_{H1'-H2'}$ = 4.21 Hz), 5.45 (2 × dd, 1, H2′, $J_{H2'-H3'} \cong J_{H1'-H2'}$ = 3.2 Hz), 4.40 (2 × dd, 1, H3′, $J_{H2'-H3'} \cong J_{H3'-H4'}$ = 3.2 Hz), 4.25 (m, 1, H4′), 3.70 (s, 3, OCH_3), 3.42 (2 × dd, 1, H5″, $J_{H5'-H5''}$ = 10.2 Hz, $J_{5''-H4'}$ = 4.4 Hz), 3.36 (2 × dd, 1, H5′, $J_{H5'-H5''}$ = 10.2 Hz, $J_{H5'-H4'}$ = 5.6 Hz), 1.74 (s, 3, $COCH_3$). ^{31}P NMR ($CDCl_3$, 80 MHz) δ: 151.26. MS (FAB-NBA) *m/e*: 862 (MH^+, 1.6%), 644 ([MH^+ − $CNCH_2CH_2OP(OH)$(i-Pr)$_2$], 4.3%), 273 ($MMTr^+$, 100%), 216 (HCy^{Bz} + H^+, 14.5%), 201 ($CNCH_2CH_2OP$(i-Pr)$_2^+$, 14.0%).

2. *From cytidine*

A stirred mixture of cytidine (48.7 mmol, 11.8 g), diphenyl carbonate (73.4 mmol, 13.3 g), dimethylformamide (20 mL), and water (50 mmol, 0.9 mL) was heated at 150°C for 15 min and the resulting dark solution was poured, with stirring, into 120 mL of ether. The gummy yellow precipitate formed was washed with cold ether (3 × 50 mL). Two new compounds with a relative intensity of 9:1 were evident by TLC (isopropyl/ammonia/water, 55:35:10, R_f 0.66 and 0.56). This crude mixture was coevaporated (3 × 30 mL) and dissolved in dry pyridine (20 mL). Monomethoxytrityl chloride (31.2 mmol, 9.6 g) (1.3 equivalents based on 50% yield of **2**) was added and the solution stirred for 19 h at room temperature. Analysis by TLC showed the formation of two compounds (CH_2Cl_2/EtOH, 8:2, R_f 0.49 and 0.33) with a relative intensity of 1:9, respectively. The mixture was evaporated to near dryness, dissolved in dichloromethane, washed first with a solution of 5% sodium bicarbonate (100 mL) followed by brine (100 mL), and dried over sodium sulfate. Approximately one half of this mixture (5.8 mmol, 3.0 g), was coevaporated (2 × 30 mL) and dissolved in pyridine (40 mL). Trimethylchlorosilane (29.0 mmol, 3.6 mL) was added and the solution was stirred at ambient temperature for 20 min, at which time benzoyl chloride (29.5 mmol, 3.45 mL) was introduced via syringe. TLC analysis (CH_2Cl_2/EtOH 9:1), 2 h later, indicated that less than 5% of the starting material remained. The mixture was then cooled by immersing in an ice bath; water (5 mL) was added, followed 10 min later by a solution of 29% ammonia (5 mL). After 15 min of stirring, the "thick" mixture was evaporated to near dryness, dissolved in dichloromethane (30 mL), and washed with water (30 mL). The organic layer was dried over sodium sulfate and the solvent evaporated. The brown gum was coevaporated with toluene (2 × 30 mL) and purified twice by silica gel chromatography, eluting first with dichloromethane (750 mL) followed by 5% EtOH/CH_2Cl_2, and affording pure **3** in 26% yield from cytidine. Preparation of **5** from this point on was as described in the previous section.

Solid-phase synthesis and purification of oligonucleotides

Oligoribonucleotides were prepared and purified as previously described (34). DNA oligomers were prepared and purified by the "trityl on" method (35). ANA oligomers were prepared on a 1.0 μmol scale employing "trityl on" synthesis cycle (60 s coupling time). Deprotection of sugar and phosphate moieties with concomitant release of oligomers from the glass support was accomplished by a single ammonia treatment (55°C, 8 h). The terminal trityl group was cleaved with trifluoroacetic acid during purification with reversed phase OPC® cartridges (Applied Biosystems). Oligoarabinocytidines were purified by polyacrylamide gel electrophoresis (PAGE). Phosphorothioate-linked DNA and ANA were prepared using tetraethylthiuram disulfide (TETD) as the sulfurizing reagent. After each coupling the glass beads were exposed to TETD (instead of iodine–water) for 10 min and then washed *extensively* with dry acetonitrile. Phosphorothioate oligomers were deblocked and purified as for the normal (phosphate) sequences.

Polyacrylamide mobility shift assays

Experiments were carried out as previously described (5).

Enzyme resistance assay

Incubations of oligomers with nucleases and analysis of the digests by PAGE were carried out as described (21). Analysis of the SVPDE digests of ara(Aps)$_7$A and d(Aps)$_7$A by HPLC was carried out on a Waters instrument equipped with dual 501 pumps, a 480 UV detector, and a 740 Data module. A Whatman Patrisil ODS-2 (10 μm, 4.6 × 250 mm) column was used with a linear elution gradient 0–50% over 30 min (solvent A: 20 mM KH_2PO_4 pH 5.5; solvent B: methanol).

Melting temperature (T_m) measurements

Thermal denaturations were performed on a Varian–Cary 1 UV spectrophotometer equipped with a Peltier thermal unit. Equimolar mixtures (2.5 μmol in each strand) of complementary oligomers were allowed to equilibrate at 40°C for 20 min, followed by slow cooling (over 20–30 min) to the start temperature prior to starting (runs involving poly rG or poly rA were heated to 80°C for 20–30 min). Thermal denaturation curves were recorded at 1 min intervals at 260 nm while the temperature was ramped at a rate of 0.5°C/min. The curves were analyzed by the first derivative method to obtain T_m values. Hyperchromicity (*%H*) is reported with respect to the initial absorbance in each curve. T_m versus log NaCl data was obtained as follows: first denaturation was run in 100 mM NaCl; upon completion, the sample was cooled slowly to 40°C; an appropriate amount of NaCl crystals was added to increase the salt concentration to the next level, samples were then cooled to the start temperature, and denatured again. This process was repeated for all salt concentrations. No correction for volume was made. Stoichiometry was determined by the method of continuous variation (38) as previously described (5).

To characterize the dynamics of halogen centre reactions, we have investigated the H + ICl system. In particular, we have focused our attention on the importance of indirect atom–diatom reactivity in determining the macroscopic and microscopic branching of a reaction. An analysis of opacity functions and trajectory plots evaluated for different collision angles and isotopic variants evidenced the occurrence of cooperative reactive mechanisms in which an atom of the target diatom favours reaction with the other end of the molecule. Two limiting cooperative mechanisms were singled out and associated with different ranges of the impact parameter. A generalization of these findings to heavier systems has been performed by considering the ^{39}H + ICl reaction. Calculated properties of the model were found to agree with values measured for the K + ICl reaction.

Dans le but de caractériser la dynamique des réactions de centres halogénés, on a étudié le système H + ICl. On a focalisé notre attention sur l'importance de la réactivité indirecte atome–diatome dans la détermination des branches macroscopique et microscopique d'une réaction. Une analyse des fonctions d'opacité et des courbes des trajectoires évaluées pour différents angles de collision et diverses variations isotopiques mettent en évidence la mécanismes de réaction coopérative dans lesquels un atome d'un diatome cible favorise la réaction avec l'autre extrémité de la molécule. On a singularisé deux mécanismes coopératifs limites et on les a associés à divers sections différentes du paramètre d'impact. On a réalisé une généralisation de ces résultats à des systèmes plus lourds en considérant la réaction ^{39}H + ICl. On a trouvé que les propriétés calculées pour le modèle sont en accord avec les valeurs mesurées pour la réaction K + ICl.

[Traduit par la rédaction]

1. Introduction

The rationalization of the dynamics of halogenic centre reactions is of particular interest because indirect paths to reaction (1) (defined as reactive paths leading to a final product partner differing from the atom to which the attack was initially directed) can be singled out. In principle, indirect reactive mechanisms can occur for various kinds of reactions including those collinearly dominated at low collision energy (2). In particular, however, indirect paths to products were found to play an important role for some reactions involving halogenic diatomic targets such as the F + I_2 (3, 4) and F + ICl (5, 6) reactions.

The Potential Energy Surface (PES) of the F + I_2 reaction exoergic and has two wells associated with colinear intermediates: an early (FII) and a late (IFI) one. A peculiar property of the F + I_2 reaction is that the opacity function has been found not to show the usual stepwise shape common to several exoergic reactive processes. The opacity function is, in fact, negligible at small impact parameters (b), it increases with b to reach a maximum at around b = 3 Å, and then it falls quite rapidly. These characteristics were rationalized in terms of a migration of the attacking atom F from the iodine of the first attack to the next one at large values of the impact parameter b. Such a mechanism was found to lead to a larger rotational and a smaller vibrational product excitation (compared with "non-migratory" ones) though the overall product internal energy is about the same.

The heteronuclear nature of the target molecule in the F + ICl reaction offers a means for linking indirect attacks to macroscopic branching (i.e., the yield ratio between different products). In particular, in ref. 6 it was pointed out that the migration of F between I and Cl plays an important role in determining the branching ratio and that the products have more translation and less vibration than those of non-migratory collisions.

A suitable prototype for this type of reactions is H + ICl. Because of the light mass of the impinging atom. H + ICl reactive collisions explore in detail the potential energy surface around the target molecule and, as a result, they allow an exhaustive description of possible paths to reaction. In particular, it is possible to distinguish microscopic branching (alternative reaction paths giving the same product with different energetic properties) from macroscopic branching (alternative reaction paths giving different products) and find out their contribution to reactivity.

An experimental (7) and a theoretical (8) study of this reaction was carried out by Polanyi and co-workers. In an attempt to generalize their conclusions to similar systems we have performed an extended classical trajectory study of the H + ICl reaction and its isotopic variant with the hydrogen artificial

heavy isotope ^{39}H. This reaction has been considered as a model for K + ICl for which angular and time-of-flight distributions have been obtained for both KI and KCl products (9, 10).

The paper is organized as follows: Calculated reactive properties of the H + ICl reaction are reported in Sect. 2 by paying special attention to the competition between alternative paths to reaction. In Sect. 3 a first rationalization of the results is carried out by analysing the opacity functions. In Sect. 4 a graphical analysis of the reactive trajectories is performed to classify the different types of migratory trajectories. In Sect. 5 analogies between K + ICl and H + ICl are investigated by discussing the ^{39}H + ICl reaction and comparing calculated quantities with experimental data.

2. Competing paths for the H + ICl reaction

As already mentioned, the H + ICl system was first investigated by Polanyi and Skrlac (7). They not only measured macroscopic branching by detecting both the HI and the HCl product, but they also found evidence for microscopic branching by obtaining bimodal distributions for the HCl product. These experimental findings were rationalized by carrying out quasiclassical trajectory calculations on a LEPS PES (8).

To understand in more detail the reactive dynamics of this system, we carried out trajectory calculations at both a translational temperature of 300 K and a collision energy of 2 kcal/mol. Differences in the calculated cross sections were found (11) to be related to the contrasting energy dependence of the collinear reactive probability for the following two processes:

[1] $H + ICl \rightarrow HCl + I$

[2] $H + ICl \rightarrow HI + Cl$

In fact, when H approaches ICl collinearly from the Cl side ($\Phi_I = 0°$. Φ_I is defined as the angle formed by the HI and ICl bonds that, thanks to the large mass of I, coincides with the one formed by the atom diatom displacement and the ICl bond), reaction to form HCl occurs by surmounting an early barrier of about 1.6 kcal/mol. (See the lower panel of Fig. 1 where the LEPS PES used has been plotted as a function of the Bond Order coordinates (12).) Collinear approaches of the H atom from the I side ($\Phi_I = 180°$) are shown in the upper panel of Fig. 1. These collisions do not go through a reaction barrier and are driven by a long-range attractive tail. A small well (associated with the formation of the HICl intermediate) occurs in the exit channel before the asymptote of the HI product channel is reached. This channel is 32.6 kcal/mol less exoergic than that leading to the formation of the HCl product. Accordingly, the collinear reactive probability for process [1] is zero at low collision energy and rises steeply to unity at threshold to decrease again at much higher collision energy. By contrast, the collinear reactive probability for process [2] shows no appreciable threshold and decreases with the collision energy.

However, on releasing the constraint of reacting along a line, the reactive outcome may differ (13). To investigate this aspect in detail, the calculations were repeated for a wide range of initial conditions. In Figs. 2 and 3 quasiclassical cross sections are shown for processes [1] and [2], respectively, calculated at $\Phi_I = 180°$, 135°, 90°, 45°, and 0° and E_c from 0.5 to 6 kcal/mol. For all the calculations the reactant ICl molecule was set at the ground rovibrational state ($v = j = 0$).

The short-dashed line of Fig. 2 is a plot of the reactive cross section calculated for process [1] when H attacks from the Cl side starting with a collinear HClI geometry ($\Phi_I = 0°$) and the value of the impact parameter b is chosen randomly (i.e., the velocity vector is not constrained along the line connecting the three atoms). As expected, the calculated cross section when plotted as a function of the collision energy has the typical shape of that of barrier-controlled reactions: there is no reactivity at low translational energy while, once past the threshold (whose location is usually closely related to the vibrationally adiabatic barrier) the reactive cross section rises significantly. When the angle Φ_I increases, the repulsive contribution to the potential associated with Cl is compensated by the long-range attractive tail associated with I. As a result, at low translation energies, H attacks slide sideways towards Cl, lowering or even eliminating threshold effects (cross sections calculated at $\Phi_I = 45°$, 90°, and 135° are also shown in Fig. 2 as dashed-dotted, dotted, and long-dashed curves, respectively). This is still true for $\Phi_I = 180°$ (solid curve) collisions for which the below-the-threshold value of the cross section is particularly large even if attacks to Cl occur from the opposite (I) side. Such a cooperative (intracatalytic) effect of I in enhancing the reaction of H with Cl, when low translation energy collisions take place from the I side, implies also that the impinging H atom has a lower chance of reacting with Cl at higher collision energy. In this case, in fact, the additional momentum induced by the I attractive tail reduces the interaction time between H and Cl (as will be seen in more detail for process [2]).

Plots of the cross section for process [2] are given in Fig. 3. In this case, almost all curves have the same decreasing trend with collision energy owing to the fact that a larger translational energy reduces the interaction time between H and I. This is in line with what has been found for collinear collisions taking place from the I side. However, at a given translational energy, attacks slightly more displaced towards the Cl end ($\Phi_I = 135°$ and 90°, given as long-dashed and dotted curves) are more reactive than those taking place at $\Phi_I = 180°$ (solid line) because the impinging atom is partially slowed down by the repulsive nature of the potential on the Cl side (an intracatalytic effect of Cl). Yet, when a trajectory passes too close to Cl (as for $\Phi_I = 45°$ and 0°; dashed-dotted and short-dashed lines, respectively), the repulsive effect becomes dominant, especially at low translational energies, and repels the incoming atom. As a matter of fact, reaction with I taking place from the opposite side ($\Phi_I = 0°$; short-dashed line) leads to a threshold effect as for barrier-controlled reactions.

3. Opacity functions and migratory trajectories

As for F + I_2 and F + ICl, the reactive behaviour of H + ICl could be rationalized in terms of migratory trajectories (i.e., by assuming that the reaction occurs via the formation of a temporary intermediate in which H binds to an atom of the target molecule different from the final product partner). A clear fingerprint of a migratory mechanism is believed to be the anomalous (inverted as a function of b) shape of the opacity function (4, 6). Yet the opacity functions calculated for H + ICl at collision energies typical of the experiment do not show a definite inverted shape, implying that, for this reaction, migration is not the dominant reactive mechanism.

To investigate this feature in more detail, we calculated fixed angle opacity functions. A synoptic view of the opacity functions of process [1] (dotted line) and process [2] (solid line) calculated at $\Phi_I = 180°$, 135°, 90°, 45°, and 0° (from the left to the

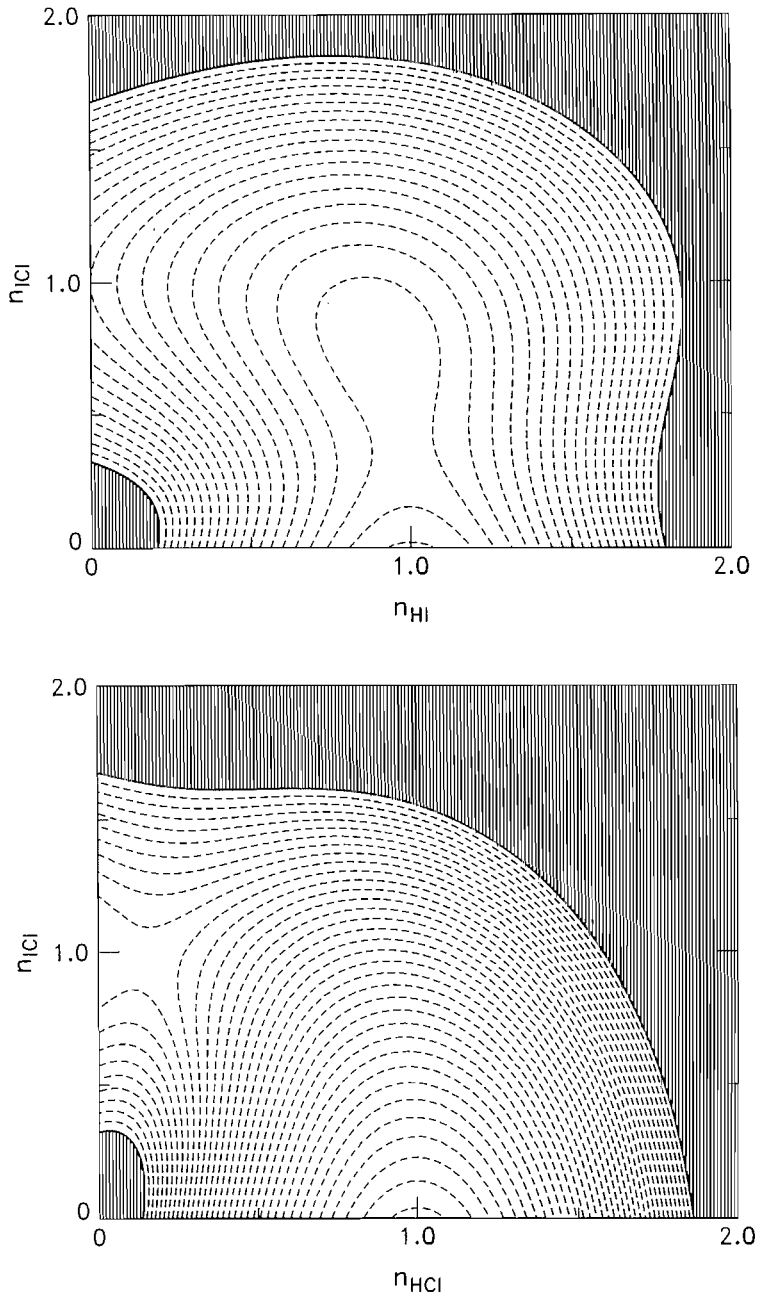

FIG. 1. Isoenergetic contours of the H + ICl potential energy surface used for the calculations plotted as a function of the n_{HI} and n_{ICl} bond order variables and $\Phi_I = 180°$ (upper panel) and as a function of the n_{HCl} and n_{ICl} bond order variables and $\Phi_{Cl} = 180°$ (lower panel). Energy cuts have been taken every 0.23 kcal/mol.

right-hand side panels) and E_e = 1, 2, 3, 4, 5, 6 kcal/mol (from the bottom panel up) is given in Fig. 4. The zero opacity function calculated at $\Phi_I = 0°$ and E_c = 1 kcal/mol (right panel of the bottom row) indicates that at low collision energy the barrier to reaction located on the Cl side prevents H from reaching the product valley of both processes [1] and [2], leading, as a consequence, to a threshold effect. By contrast, for higher Φ_I values (i.e., when attacks pass closer to I) reaction can take place even at such low (smaller than the collinear HClI barrier) energy thanks to the different (attractive instead of repulsive) nature of the potential energy path to reaction. The attractive nature of the reaction path at $\Phi_I = 0°$ manifests itself in a "non-negligible" reactive probability centred on large b values (left panel) due to less direct reaction mechanisms. In this case, in fact, direct attacks with small b are unproductive because they are made too fast by the attractive tail of the potential. For intermediate Φ_I values, when moving right from $\Phi_I = 180°$ to lower Φ_I values, smaller impact parameters increasingly contribute to the opacity function, indicating that for both processes [1] and [2] more direct encounters, with small values of b, become reactive.

When translational energy becomes larger than the barrier to reaction, (see for example the second row from the bottom where opacity functions calculated at E_c = 2 kcal/mol are shown), collisions occurring at $\Phi_I = 0°$ (Cl side) also have enough energy to access the HCl product valley. Accordingly, the related opacity function has the usual stepwise shape typical of direct, barrier-controlled reactions (i.e., it is unity until the

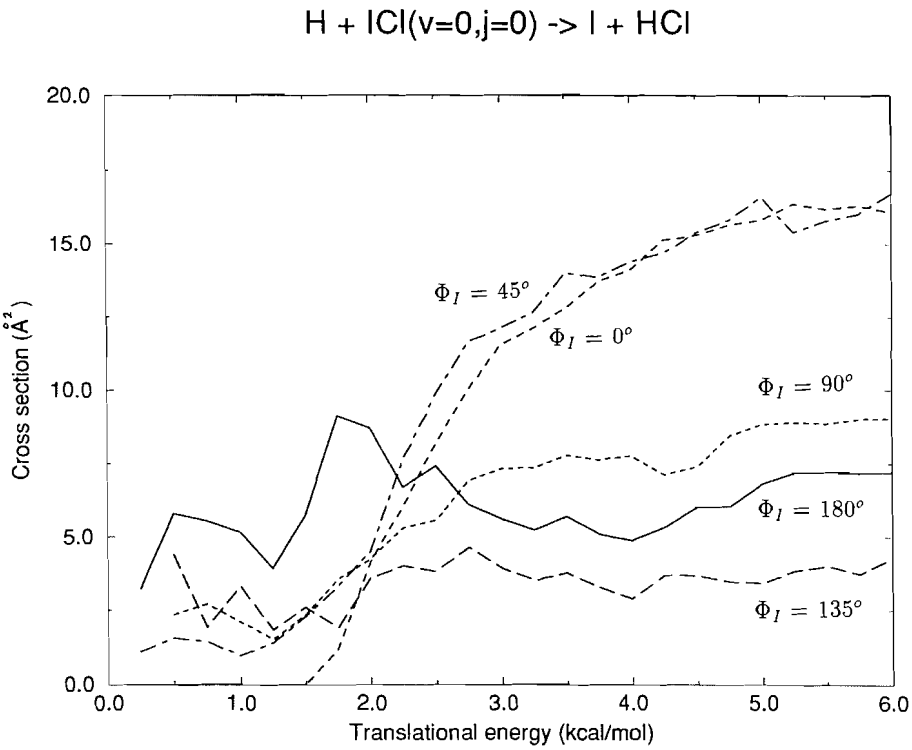

FIG. 2. Fixed Φ_I reactive cross section for the H + ICl → HCl + I process calculated at Φ_I = 0°, 45°, 90°, 135°, and 180° (short-dashed, dashed-dotted, dotted, long-dashed, and solid lines, respectively) plotted as a function of the collision energy.

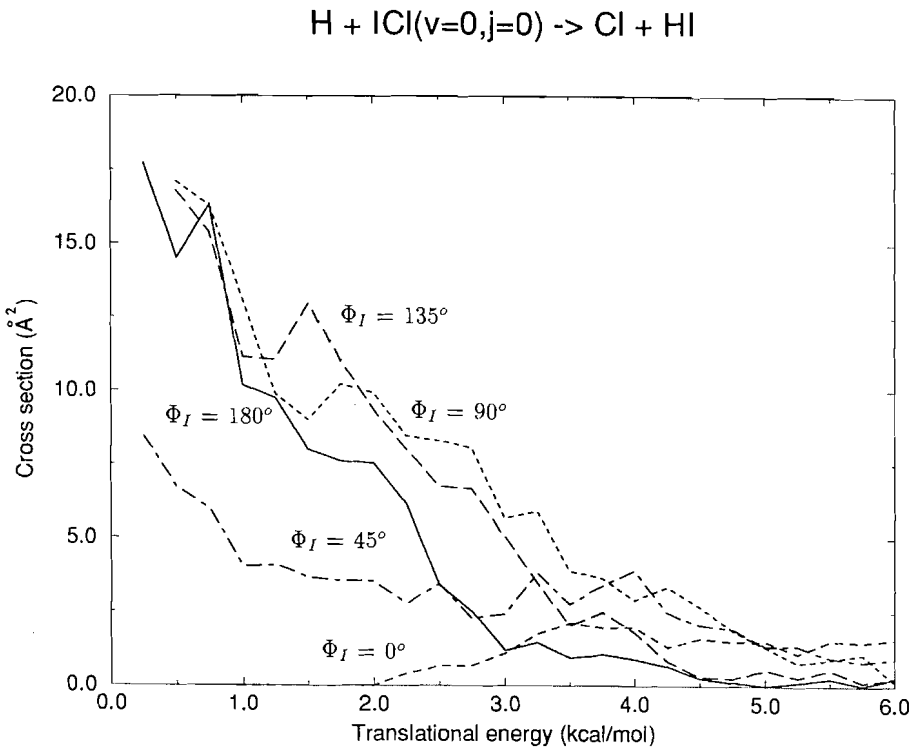

FIG. 3. As in Fig. 2 for the H + ICl → HI + Cl process.

energy component along the line of centres is sufficient to overtake the barrier relative to the corresponding collision angle (14). Again, when Φ_I = 180°, most of the reactivity is indirect and takes place at large b values. Only when moving to smaller Φ_I values do smaller impact parameters contribute to reactivity. Though this is true for both processes [1] and [2], it is the formation of HI that makes the best use of the availability for reaction of a broader range of impact parameters.

When the collision energy rises to 3 kcal/mol (see the third row of the figure) direct (Φ_I = 0°) reactivity with Cl (right

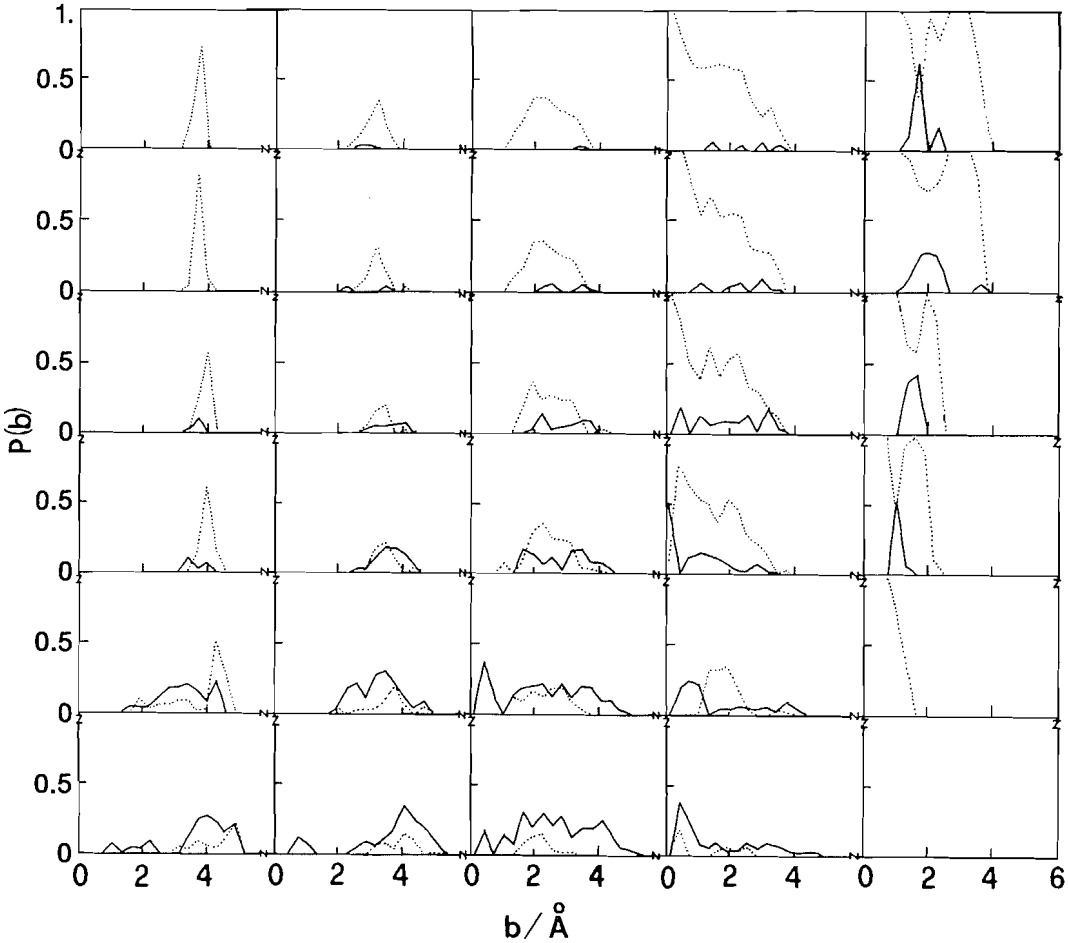

FIG. 4. Opacity functions for process [1] (dotted line) and process [2] (solid line) calculated at $\Phi_I = 180°, 135°, 90°, 45°, 0°$ (from the left to the right panel) and $E_c = 1, 2, 3, 4, 5, 6$ kcal/mol (from the lowest to the highest panel) plotted as a function of b.

panel) benefits from a larger availability of collision energy that is highly efficient in promoting this type of reactive mechanism. As a result, the opacity function extends to larger b values. However, there is a limited small interval of b values for which reactivity of process [1] drastically decreases in favour of that of process [2], which suddenly switches on. In other words, the opacity function plot indicates that there are particular combinations of b and E_c for which reactive attacks on Cl transform into reaction with I, implying a clear migration of H from Cl to I.

Such a situation is not confined to $E_c = 3$ kcal/mol. In fact, the same property is shown by opacity functions calculated at $\Phi_I = 0°$ for $E_c = 4$, 5, and 6 kcal/mol (respectively, the right panel of the three upper rows of the figure). The increase of the collision energy cuts out the contribution to reactivity of process [2] while that of process [1] increases thanks to direct reactivity (small impact parameters) at small Φ_I values and indirect reactivity (large impact parameters) at large Φ_I values.

In conclusion, the analysis of the opacity function suggests that there are clear cooperative (intracatalytic) effects through which an atom of the interhalogenic molecule helps its diatomic partner to react with H. The analysis has also singled out two extreme cases of cooperative mechanisms: One takes place mainly at moderate b values and requires (in a sequence) a close interaction between the incoming atom and both ends of the target molecule. The other takes place at large b values and is associated with a longer range interaction with the target molecule.

4. A graphical analysis of migratory trajectories

To get a better understanding of the dynamical characteristics of cooperative mechanisms, we undertook a graphical analysis of the reactive trajectories. The analysis was restricted to $\Phi_I = 0°$ and 180°, for which the two opposite prototypical cooperative mechanisms were singled out when inspecting the calculated opacity functions. At given values of E_c and Φ_I, the impact parameter was gradually increased from zero to quite large values. This allowed us to investigate the effect of making the velocity vector increasingly point away from the line of centres. Because of the choice of dealing only with initially "non-rotating" reactant molecules, it has been possible to represent the trajectories using daisy plots.

Daisy plots of five typical trajectories calculated at small, medium, and large values of b are shown in Figs. 5–9.

Small impact parameter reactive encounters are direct (i.e., H heads directly onto the atom to which, eventually, it will finally bind, while the other atom is gradually released from the opposite side). An example of this type of direct reactive encounters is given in Fig. 5 for process [1], i.e., for H reacting with Cl after attacking on the Cl side ($\Phi_I = 0°$). As shown by the figure, when the H atom (circles) comes close to Cl (squares) with enough collision energy to overtake the barrier to reaction, it links to the chlorine atom to form a stable HCl bond. Because of the negligible value of the impact parameter, HCl rotates very slowly while it moves away from the triatomic centre of mass (that for H + ICl essentially coincides with the atom I). As result, when

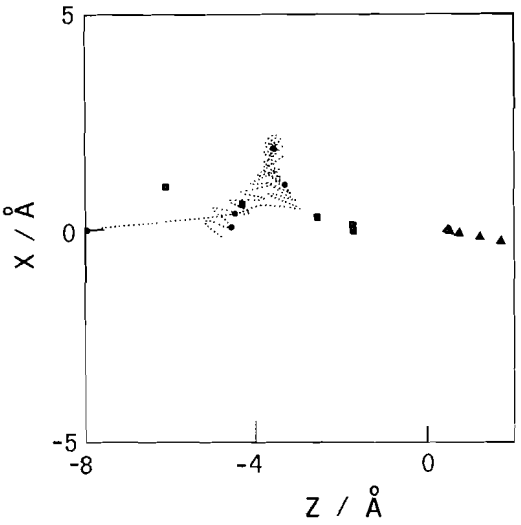

FIG. 5. Daisy plot for a trajectory of the H + ICl → HCl + I process having a small impact parameter.

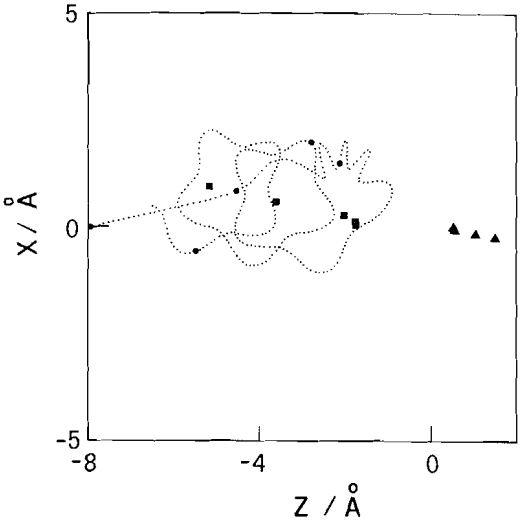

FIG. 6. As in Fig. 5 for a trajectory with moderate impact parameter.

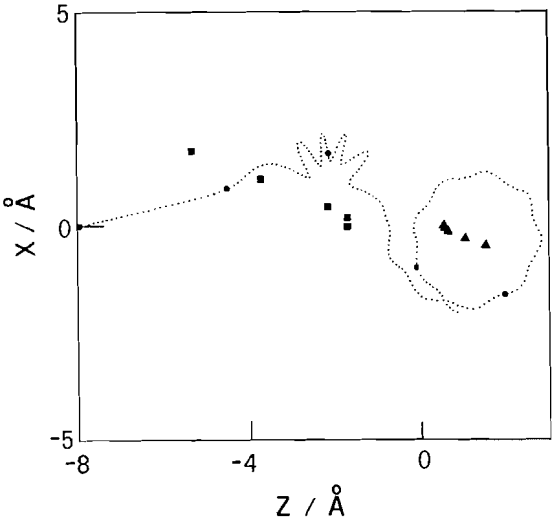

FIG. 7. As in Fig. 6 for a trajectory of the H + ICl → HI + Cl (BRB) process.

H ends up facing I (triangles), the internuclear distance has become so large that the interaction is negligible. A similar situation can occur for attacks taking place from the I side. In this case, however, there is no barrier to reaction. Therefore, the attractive tail of the potential can accelerate the impinging atom so much that the interaction time becomes too short to lead to reaction. Yet, when these small impact parameter collisions succeed in reaching the product valley, the rotation is again so slow that, by the time H ends up facing Cl, this atom has already moved far enough to make the interaction negligible.

At moderate impact parameters, the insertion dynamics becomes much richer and the energy flow increasingly involves rotations. As a matter of fact, when the atom attacks from the Cl side with a moderate impact parameter and enough energy to overtake the reaction barrier, it binds to Cl, leading to a significant rotational component in HCl. As a result, the H atom, after oscillating a few times around Cl, ends up facing the I atom when the internuclear distance is still short enough to lead to a strong interaction. This may generate two possible reactive outcomes: (*a*) the interaction with I pulls ahead the H atom into a faster HCl rotation (see Fig. 6); (*b*) the interaction with I strips out the H atom to form rotationally excited HI (see Fig. 7).

Both cases lead to rotationally excited products as a result of the conversion of the reactant orbiting motion into the product rotational motion. However, while in the first case there is a direct transfer of the reactant orbiting motion into the product rotational motion, in the second case a pure Bind–Release–Bind (BRB) migratory mechanism takes place. Such a mechanism offers a clear rationale for the complementarity shown by the $\Phi_I = 0°$ opacity functions for processes [1] and [2] (see the higher energy right panels of Fig. 4) at moderate *b* values. We also found evidence for a BRB migratory mechanism when the attack takes place from the I side. However, the effect was not unambiguous, not only because the whole process is disfavoured by the lower reactivity of process [2] at high energy but also because of cooperative effects taking place at larger impact parameter (and, therefore, more significantly contributing to the cross section).

The contribution of cooperative mechanisms other than BRB is also evidenced by the graphical study of the trajectories. In this case, the long-range attractive tail of the potential (due to the I atom) balances the escape component of the velocity of the impinging H atom. This kind of orbiting capture prevents H from missing the target and makes it available for a closer interaction with the target diatom. At this point, H can react either with Cl or I according to the particular combination of momenta characterizing that point of the collision. Illustrative cases of the two alternative reactive possibilities for this type of Orbit-And-Bind (OAB) mechanism are given in Figs. 8 and 9 for processes [1] and [2], respectively. In the first case, the orbiting results in H binding to the opposite Cl atom while in the second case H binds to I after bouncing back (twice) from Cl.

5. A model for the K + ICl reaction

To investigate the possibility of generalizing the above findings to heavier systems we made the mass of the H atom 39 times heavier (i.e., we considered the artificial hydrogen isotope ^{39}H). In other words, we took the $^{39}H + ICl \rightarrow {}^{39}HCl + I$ (process [3]) and $^{39}H + ICl \rightarrow {}^{39}HI + Cl$ (process [4]) reactions as a model for K + ICl → KCl + I (process [5]) and K + ICl → KI + Cl (process [6]), respectively. Such a choice was motivated

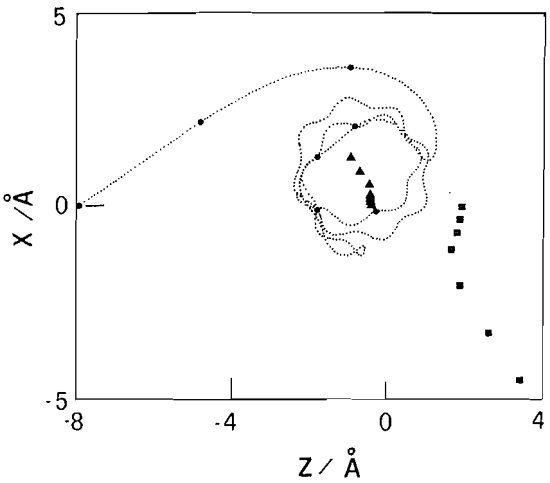

FIG. 8. As in Fig. 6 for a OAB trajectory (large impact parameter).

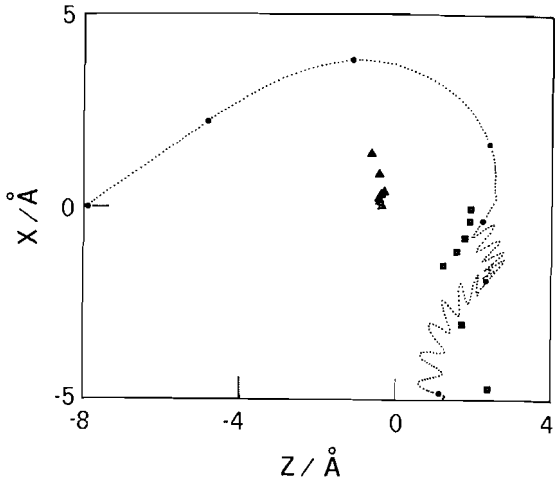

FIG. 9. As in Fig. 7 for a OAB trajectory (large impact parameter).

by the availability of recent crossed molecular beam data (9).

The collision angle Φ_I was either selected randomly or fixed to a given value according to the experimental quantity being considered. The remaining initial conditions were taken, as usual, from a pseudorandom selection with the exception of those fixed by the experiment. In particular, rotational and vibrational energies were selected to give rotational and vibrational temperatures of 14 and 300 K, respectively, while the collision energy was set at 38 kcal/mol. Under these experimental conditions the measured branching ratio between processes [5] and [6] is 4:1. The experiment also finds that product energy distributions are bimodal and migratory mechanisms are so important that *"KCl is formed favourably when the K atom approaches the molecule from the I end and vice versa the formation of KI is enhanced when K hits the Cl end."*

Though the adopted model is rather crude (it completely neglects the differences between the electronic structures of KICl and HICl) our calculations are in satisfactory agreement with measured data. At E_c = 38 kcal/mol, in fact, the calculated value for the branching ratio is about 3:1, only slightly less favourable to the formation of KCl than the experiment. Another favourable comparison of the calculations with the experiment is the energy dependence of the branching ratio. The experiment[2] indicates that the branching ratio increases with energy. The calculations reproduce this finding. In more detail, the trajectory calculations find that, while the cross section of process [3] increases with energy, that of process [4] decreases with energy and, therefore, they cooperate in increasing the branching ratio when energy increases. Such behaviour leads, at low collision energy, to an inversion of the branching ratio.

Again, to understand in more detail the effect of the collision energy on the efficiency of the different processes, we calculated cross sections at fixed angles and at different values of the collision energy. The values of these cross sections are plotted in Figs. 10 and 11 for collision energies ranging from 0 to 6 kcal/mol. The two figures show that by increasing the mass of the impinging atom most of the low-energy structure obtained for H + ICl disappears. The reactive cross section has the expected decreasing trend of reactions without barriers when the product is KI while it has the more familiar post-threshold rise with energy when the product is KCl. An interesting feature of the trajectory results is that, despite the fact that the K atom is heavy, there is a significant contribution of migratory mechanisms to reactivity as can be seen from Figs. 9 and 10. The calculations agree with the experiment also in finding that product energy distributions are bimodal for both processes [3] and [4].

However, there is a key point that the calculations seem unable to reproduce. As already mentioned, oriented beam measurements find that the system systematically favours the reactivity with the opposite end of the reactant molecule. On the contrary, as in the case of the H + ICl reaction, our calculations indicate that, though migratory mechanisms are very important in building up the reactivity of K + ICl, the largest contribution to the reactivity comes from the formation of the product with the ICl end facing the side of the attacking K. Further calculations are in progress to find out possible causes for the discrepancy and to extend the investigation to more complex interhalogenic targets, such as halons.

6. Concluding remarks

By carrying out quasiclassical trajectory calculations for the H + ICl reaction over an extended range of collision energies, it has been possible to rationalize the reactive behaviour of halogenic reaction centres and reproduce experimental findings. In particular, we have been able to calculate the energy dependence of the reactive cross section and find a rationale for the observed branching ratio. Reactive probabilities calculated at different values of the angle of approach have allowed an analysis of the dependence of the efficiency of the competing reactive mechanisms as a function of the impact parameter. The impact parameter was found to play a key role not only in discriminating direct form indirect processes but also in determining the dynamics of the cooperative reactive attacks.

In more detail, by carrying out a graphical analysis of the trajectories it has been found that, at moderate impact parameter, cooperative mechanisms take place via a binding of the impinging atom to the closest end of the diatom. This mechanism produces enough rotational energy to bring the impinging atom in close contact with the other end of the diatomic molecule before the formed molecule is able to escape. As a result of such a close interaction, the formed diatom can either exit highly rotationally excited or rupture to form a new (different) bond. How-

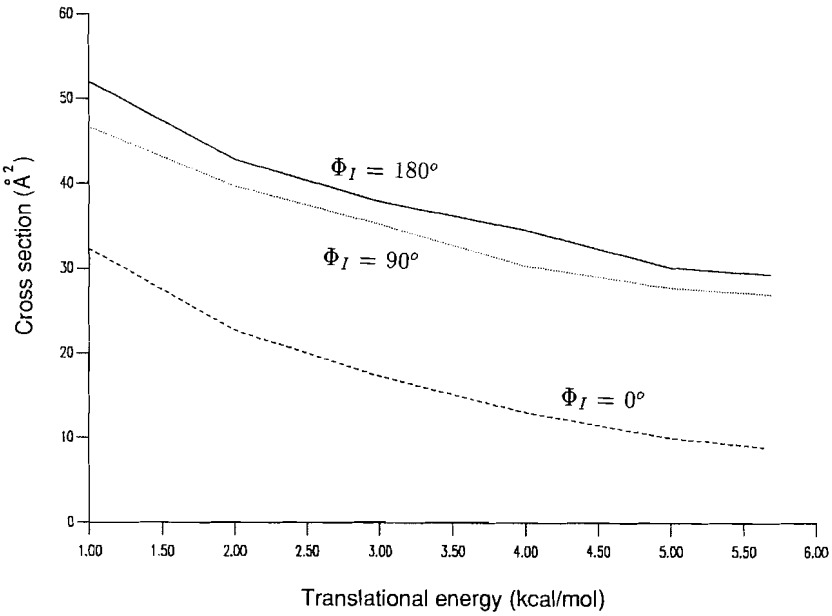

FIG. 11. As in Fig. 10 for the $^{39}H + ICl \rightarrow {}^{39}HI + Cl$ process.

ever, in this case too, the product molecule is formed in a highly excited rotational state.

By contrast, at large b values the cooperative mechanism takes place through an orbiting-like capture of the impinging atom and subsequent formation of a bond with either reaction partner.

We have also investigated the possibility of extending our findings to heavier attacking atoms by modeling the K + ICl reaction as an isotopic variant of the H + ICl reaction. For this system it was found that the lower mobility of the K atom does not prevent migratory mechanisms from occurring. It was also found that the heavier mass of the impinging atom causes the calculated cross section to have a smooth energy dependence and leads to agreement with the measured branching ratio. In addition, calculations were able to predict a bimodal translational energy distribution. On the contrary, though rationalizing the importance of cooperative reactivity, these calculations were unable to agree with the experimentally observed preference of the impinging atom to react with the opposite end of the target molecule.

Quantum chemical shape: new density domain relations for the topology of molecular bodies, functional groups, and chemical bonding

PAUL G. MEZEY

Mathematical Chemistry Research Unit, Department of Chemistry and Department of Mathematics and Statistics, University of Saskatchewan, SK, S7N 0W0 Canada

Received November 5, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

PAUL G. MEZEY. Can. J. Chem. **72**, 928 (1994).

A density domain (DD) is the formal body enclosed by a molecular isodensity contour (MIDCO) surface. Individual nuclear neighborhoods and various formal molecular fragments can be regarded as fuzzy moieties of electron densities, dominated by one or several nuclei. Such a fuzzy fragment involves a whole range of density values, hence it cannot be described by a single MIDCO, but it can be represented by a sequence of density domains. Within the chemically important range of density values, there are only a *finite number of topologically different bodies of density domains*. In the Density Domain Approach, chemical bonding is described by the interfacing and mutual interpenetration of local fuzzy charge density clouds. The bonding between fragments of a molecule is characterized by a finite sequence of density domains within a wide range of density values and by the correponding sequence of topological patterns of the mutual interpenetration of these fragments. In earlier works, the DD approach was advocated as an alternative to the conventional "skeletal model" of chemical bonding. The classically motivated line diagrams as representatives of bonding are replaced by the pattern of interpenetration of fuzzy fragment bodies at various density thresholds. In this study, novel DD relations are described, suitable for a quantum chemical characterization of functional groups, the local shape properties of such groups, and their contributions to global molecular shape.

PAUL G. MEZEY. Can. J. Chem. **72**, 928 (1994).

Un domaine de densité (DD) est l'ensemble formel entouré par une surface de contour d'isodensité moléculaire (MIDCO). On peut considérer que les environnements moléculaires individuels et divers fragments moléculaires formels sont des portions diffuses des densités électroniques, dominées par un ou plusieurs noyaux. Un tel fragment diffus implique un ensemble de valeurs de densité et on ne peut donc le décrire par une seule MIDCO; il peut toutefois être représenté par une séquence de domaines de densité. Dans le domaine chimiquement important des valeurs de densité, il n'existe qu'un *nombre fini de corps topologiquement différents de domaines de densité*. Dans l'approche du domaine de densité, on décrit la liaison chimique par l'interface et l'interpénétration mutuelle de nuages locaux de densité de charge diffuse. On caractérise la liaison entre les fragments d'une molécule par une séquence finie de domaines de densité ayant un grand éventail de valeurs de densité et par la séquence correspondante de patrons topologiques d'interpénétration mutuelle de ces fragments. Dans des travaux antérieurs, l'approche du DD avait été proposée comme une alternative au «modèle du squelette» conventionnel de la liaison chimique. On remplace les diagrammes linéaires proposés d'une façon classique pour représenter les liaisons par le patron d'interpénétration des corps de fragments diffus, à diverses limites de densité. Dans ce travail, on décrit de nouvelles relations de DD appropriées pour une caractérisation, par chimie quantique, des groupes fonctionnels, des propriétés locales des formes de tels groupes et de leurs contributions à la forme moléculaire globale.

[Traduit par la rédaction]

1. Introduction

Reaction topology (1) and molecular topology (2) are the two main branches of a research program aimed at a topological reformulation of the fundamentally classical, geometrical, models of chemistry. The basic principle of the topology program is the notion that on the molecular level, where quantum mechanics plays a prominent role, geometrical concepts are no longer the ideal tools, and topology, a generalization of geometry, provides better models of reality. Most of our traditional chemical concepts have evolved within a classical mechanical framework, based on macroscopic geometrical analogies. The spectacular development of quantum chemistry has made most of its impact in areas of chemistry where classical models are reliable enough for the interpretation of results, such as the calculation of three-dimensional structural diagrams, theoretical bond lengths, and bond angles. These very concepts, however, have inherent limitations. It is well accepted that the concept of precise electronic positions within a molecule has no utility; however, the concept of precise nuclear positions within a molecule is still in use as a practical but ultimately misleading classical approximation. In the strict sense, the Heisenberg uncertainty relation applies to electrons as well as to nuclei, and neither electronic position nor nuclear position within a molecule is meaningful in a quantum mechanical model. Conventionally, precise bond lengths and bond angles rely on a formal determination of nuclear positions, hence none of the formal structural parameters of bond lengths and bond angles is fully compatible within quantum mechanics. It is, however, not easy to escape from the conventional "skeletal" image of a chemical bond as a line between nuclear positions where the bond length is the distance between two nuclei. In fact, it is still a common practice in chemistry to search for classical interpretations and to equate understanding with finding some macroscopic classical analogy. Such analogies have only limited value and can become rather misleading, since many important properties of molecules and reactions, such as quantized molecular vibrations and the contribution of tunneling to the propagation of reactions through energy barriers, are not directly observable in the more familiar macroscopic phenomena. For the understanding of these properties, the conventional "skeletal" image of chemical bonding is more an impediment than a help. By contrast, more of the fundamental aspects of bonding within formal "bodies" of molecules can be described by molecular isodensity contour (MIDCO) surfaces. However, a single MIDCO surface, another geometrical construction, is insufficient by itself to reflect all the essential details of the electron distribution. Therefore,

the fuzzy density domains are characterized not by individual MIDCOs but by *topological equivalence classes* of MIDCOs. This offers an alternative approach for the description of bonding within molecular "bodies," where the conflict with quantum mechanics is avoided (2).

Topological theories and models have an increasingly important role in studies of molecular shape and similarity (3). Besides their role in reformulating some of the basic notions, the topological analysis, quantification, and numerical evaluation of molecular shape similarity have important practical applications, for example, in modern drug design and molecular engineering (4–6). In this report some topological rules influencing the patterns of density domains will be discussed.

2. Molecular isodensity contours (MIDCOs)

For simplicity, we shall first consider the semiclassical models of a formal, static, nuclear arrangement for each molecule. For a given electronic state, the nuclear arrangement K has a dominant influence on the shape of the formal body of molecular electron distribution $\rho(\boldsymbol{r})$. The molecular charge density function $\rho(\boldsymbol{r})$ can be determined experimentally from X-ray diffraction experiments (7, 8), and can be calculated by quantum chemical methods, for example, by the standard quantum chemistry programs (9) or by approximate methods designed for large molecules (10).

We shall regard electron distributions as functions $\rho(\boldsymbol{r}, K)$ of the nuclear arrangement K. It is common to regard the set of all possible nuclear arrangements K of a given stoichiometry as a formal nuclear configuration space. This space is provided with a proper distance function $d(K, K')$ for any two nuclear arrangements K and K', turning the configuration space into a metric space M. Note, however, that the nuclear configuration space M is not a vector space and cannot be turned into one (1).

The molecular potential energy (of a specified electronic state), as a function of the nuclear arrangements K, is a hypersurface $E(K)$ over this space M (1). Chemical species can be associated with various open sets (catchment regions) of the given energy hypersurface, a model that relaxes the classical constraints of rigid nuclear geometry and avoids the conflict with the Heisenberg uncertainty relation (1). Similarly, the 3D electronic density of a specified electronic state can be regarded as a function $\rho(\boldsymbol{r}, K)$ defined over the nuclear configuration space M, and molecular shape can be associated with an entire family of $\rho(\boldsymbol{r}, K)$ charge density distributions occurring within a catchment region (2).

A *molecular isodensity contour surface*, MIDCO, of nuclear configuration K and density threshold a is denoted by $G(a, K)$, and is defined as

$$[1] \quad G(a, K) = \{\boldsymbol{r}: \rho(\boldsymbol{r}, K) = a\}$$

that is, as the collection of all points of the 3D space where the electronic density is equal to the constant a. If a single, formal nuclear configuration K is considered, and if this is evident from the context, then symbol K can be suppressed in the notation, and one may simply write

$$[2] \quad G(a) = \{\boldsymbol{r}: \rho(\boldsymbol{r}) = a\}$$

The electronic density $\rho(\boldsymbol{r})$ is a continuos function; consequently, the set of all points $\boldsymbol{r}$ fulfilling eq. [2] does form a continuous surface.

In the strict sense, the electronic charge density function $\rho(\boldsymbol{r})$ becomes zero only at infinite distance from the nuclei of the molecule. However, $\rho(\boldsymbol{r})$ converges rapidly to zero already at short distances, becoming negligible at about 8–10 Å from the nearest nucleus. The electronic density is approximately localized within a close neighborhood of the nuclei. It is justified to regard only those regions of the 3D space as "belonging" to the molecule of nuclear configuration K, where the electronic density $\rho(\boldsymbol{r})$ is larger than some small threshold. By taking a sufficiently small threshold value a, an approximate *molecular body* can be defined as the collection $F(a, K)$ of all those points $\boldsymbol{r}$ of the 3D space where the electronic density is greater than the threshold a,

$$[3] \quad F(a, K) = \{\boldsymbol{r}: \rho(\boldsymbol{r}, K) > a\}$$

Using the conventional mathematical terminology, these points $\boldsymbol{r}$ are said to form a *level set* $F(a, K)$, with respect to the threshold level a. Note that *negative* charge means a *positive* value for the density function $\rho(\boldsymbol{r}, K)$. Again, if the formal nuclear configuration K is evident from the context, then symbol K can be suppressed, and one may write

$$[4] \quad F(a) = \{\boldsymbol{r}: \rho(\boldsymbol{r}) > a\}$$

According to definitions [3] and [4], those points $\boldsymbol{r}$ of the 3D space where the value of the electronic density function is equal to the threshold,

$$[5] \quad \rho(\boldsymbol{r}) = a$$

do not belong to the level set $F(a)$. One may adopt alternative definitions and include all points $\boldsymbol{r}$ of the 3D space where eq. [5] holds. Such domains of the 3D space, including *all the points and all the boundary points* of the level sets $F(a)$, are, of course, closely related to the level sets $F(a)$ themselves and are of special importance. These domains, providing a natural representation of chemical bonding in molecules, are the *density domains* (2, 11), denoted by $DD(a)$, or by $DD(a, K)$, if the nuclear configuration K is also specified. These density domains are defined as

$$[6] \quad DD(a, K) = \{\boldsymbol{r}: \rho(\boldsymbol{r}, K) \geq a\}$$

or, if the formal nuclear configuration K is evident from the context, then symbol K can be suppressed, and one may write

$$[7] \quad DD(a) = \{\boldsymbol{r}: \rho(\boldsymbol{r}) \geq a\}$$

If molecular charge densities were macroscopic clouds of various densities, then a density domain $DD(a)$ could be visualized as the object seen if one's eyes were adjusted to notice only densities equal to or higher than the threshold a. By readjusting one's eyes, density domains of lower and lower threshold values could be seen.

The shape and size of a level set $F(a, K)$ depend on the choice of the threshold value a. Instead of selecting an arbitrary value for a, it is more meaningful to consider a whole *range* of possible a values for the electronic density level sets $F(a, K)$ and for the related MIDCOs $G(a, K)$ and density domains $DD(a, K)$. It is not necessary to consider very high a values, occurring only in the vicinity of heavy nuclei. Also, by taking a small but non-

For personal use only.

zero lower limit for the a values, one can avoid considering level sets where a single, common envelope surface encloses two, essentially independent, molecules of large but finite distance from one another.

As one of their important applications, MIDCOs are used in molecular similarity analysis. The resulting techniques of precise, nonvisual, algorithmic description of molecular shape and numerical evaluation of molecular similarity are based on the general GSTE principle of treating Geometrical Similarity as Topological Equivalence (2, 12–14). Most computer implementations of the GSTE principle are based on the Shape Group Methods (SGM) (15–18): these are algebraic–topological shape analysis techniques using the homology groups of molecular surfaces truncated according to some local curvature criterion. The GSHAPE 90 computer program (19), based on the shape groups, uses *ab initio* or semiempirical electron densities as input, and performs nonvisual shape analysis and similarity evaluation of molecular sequences. The GSTE principle has also been the basis of other topological methods, where families of alternative geometrical models with equivalent topological features are used for characterization (2, 12–14). Various combinations of geometrical and topological techniques provide numerical measures of molecular shape similarity (2, 12–14).

3. The "Late–Early Rule" of the density domain approach (DDA) to chemical bonding

The conventional formal chemical bonds of a molecule are usually modeled by lines interconnecting the nuclei and represent only a molecular skeleton. However, a bond skeleton cannot fully describe the molecular body and the shape of the molecule. In reality, a molecule is a three-dimensional object held together by the fuzzy body of the electron charge distribution. Chemical bonding is not constrained to a set of lines or narrow bonding channels in space; actual chemical bonding involves a broad interfacing of molecular fragments. A more detailed description of chemical bonding must take into account the 3D fuzzy electron distribution of the molecular body. The family of all topologically distinct density domains are objects that describe in detail the actual buildup of electronic densities within molecules. Furthermore, if the shape analysis is extended to the individual density domains, then additional fine details of electron densities can be distinguished.

Density domains $DD(a, K)$, level sets $F(a, K)$, and MIDCOs $G(a, K)$ are related in a simple way:

$$[8] \quad DD(a, K) = F(a, K) \cup G(a, K)$$

A density domain $DD(a, K)$ can be regarded as a formal *molecular body at an electronic density threshold* a *and nuclear configuration* K. In general, such a $DD(a, K)$ body may be a single piece or it may be a collection of several disconnected pieces $DD_i(a, K)$, called the *maximum connected components* of $DD(a, K)$:

$$[9] \quad DD(a, K) = \bigcup_i DD_i(a, K)$$

Of course, if the body $DD(a, K)$ has a single piece, then $DD(a, K)$ is the same as its single maximum connected component $DD_1(a, K)$,

$$[10] \quad DD(a) = DD_1(a)$$

According to the precise terminology, the $DD_i(a, K)$ maximum components of the $DD(a, K)$ body are the density domains of the molecule at density threshold value a. Conventionally, the term "domain" should be applied only to a single maximum component. However, for simplicity, the term "density domain" is also used for the union in eq. [9].

A MIDCO $G(a, K)$ is also the union of its maximum connected components $G_i(a, K)$:

$$[11] \quad G(a, K) = \bigcup_i G_i(a, K)$$

For any fixed density threshold a, the patterns of the $DD_i(a, K)$ density domains and the patterns of their respective boundary surfaces, the MIDCOs $G_i(a, K)$, provide the same shape information.

In general, one may study the electron density buildup in a molecule by taking an initial high-density threshold a_{max} and gradually decreasing this threshold to a small enough value a such that all the nuclei of the molecule are enclosed by a single MIDCO $G(a)$.

If the nuclear configuration K is fixed and obvious from the context, it can be omitted from the notation. It is useful, however, to indicate the nuclei enclosed by each maximum connected component, that is, by each density domain $DD_i(a)$. If the nuclei A, B, etc., are enclosed within a density domain $DD_i(a_j)$ at a threshold a_j, then the detailed notation $DD_i(a_j, A, B, \ldots)$ can be used.

For example, consider a semiclassical model and the three topologically distinguishable sets of density domains of the equilibrium nuclear arrangement of the methane molecule. At a high density threshold a_1 there is electronic density only near the carbon nucleus, hence there is only a single density domain; at this density threshold a_1 the set of density domains has a single element,

$$[12] \quad \{DD_1(a_1, C)\}$$

At a medium-density threshold a_2, electronic density appears simultaneously about the four hydrogen nuclei (as follows from symmetry), and there are five separate density domains. That is, the set of density domains has five elements,

$$[13] \quad \{DD_1(a_2, C), DD_2(a_2, H), DD_3(a_2, H), DD_4(a_2, H), DD_5(a_2, H)\}$$

At a low enough threshold a_3, the methane molecule has a single density domain that contains all five nuclei C, H, H, H, and H. At this density threshold a_3 the set of density domains has a single element,

$$[14] \quad \{DD_1(a_3, C, H, H, H, H)\}$$

For a detailed illustration, we shall use the ethanol molecule at a nuclear configuration K approximating its equilibrium nuclear geometry, and the electronic density results obtained in a study on the relations between acidity and molecular shape near protonic moieties (20). A sequence of topologically different sets of density domains of the ethanol molecule, CH_3CH_2OH, is shown in Figs. 1–3, as calculated using a 6-31G* basis set, the GAUSSIAN 90 [9] *ab initio*, and the GSHAPE 90 (19) molecular shape analysis programs. Some of the extreme high-density domains are not shown in these figures:

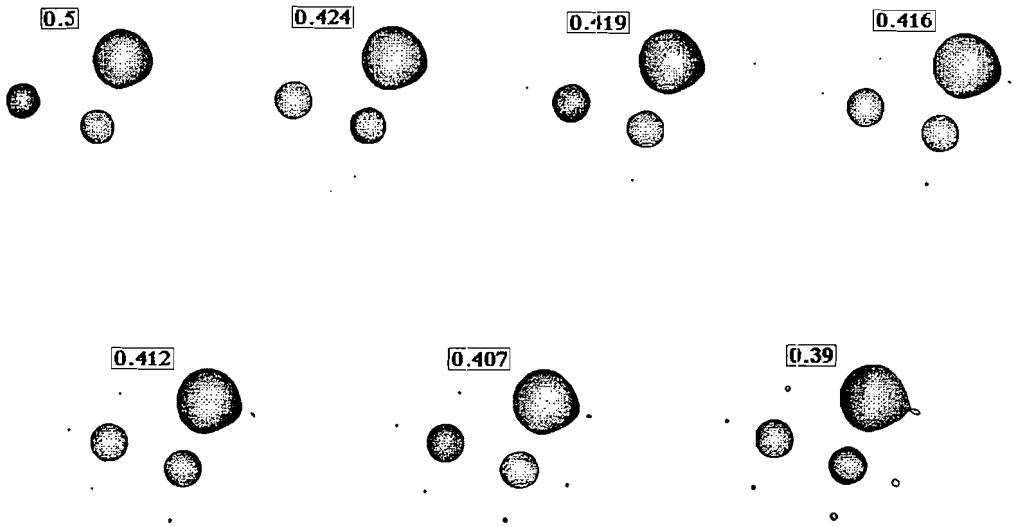

FIG. 1. The topologically different high-threshold density domains of the ethanol molecule CH_3CH_2OH, calculated using a 6-31G* basis set, the GAUSSIAN 90 (9) *ab initio*, and the GSHAPE 90 (19) molecular shape analysis programs.

the density domain $DD_1(a_1, O)$ of the oxygen atom that appears first at a high-density threshold and the next topologically distinct $DD(a)$ pattern of the pair of methyl carbon and oxygen atoms $DD_1(a_2, C)$, $DD_2(a_2, O)$ are not shown in these figures.

The first $DD(a)$ pattern shown in Fig. 1 is the set of the three density domains of the heavy nuclei, that is, the family

$$[15] \quad \{DD_1(a_1, C), DD_2(a_1, C), DD_3(a_1, O)\}$$

where the threshold parameter is $a_1 = 0.5$ au. The density domain $DD_3(a_1, O)$ of the oxygen atom is the bulkiest, reflecting an accumulation of electronic density due to the largest nuclear charge and the highest electronegativity of oxygen among these atoms. This pattern is followed by others showing the sequential appearance of the various hydrogen density domains. According to the calculations, at the $a_j = 0.407$ threshold density all nuclear neighborhoods are present as density domains, and one obtains the family

$$[16] \quad \{DD_1(a_j, H), DD_2(a_j, H), DD_3(a_j, H), DD_4(a_j, H), DD_5(a_j, H), DD_6(a_j, H), DD_7(a_j, C), DD_8(a_j, C), DD_9(a_j, O)\}$$

The last pattern on this figure shows the first merger of density domains in the above sequence of gradually decreasing thresholds. This merger occurs at the threshold value of $a_j = 0.390$, where the density domain of the OH proton links up with that of the oxygen atom. The following family of density domains is obtained:

$$[17] \quad DD_1(a_j, H), DD_2(a_j, H), DD_3(a_j, H), DD_4(a_j, H), DD_5(a_j, H), DD_6(a_j, C), DD_7(a_j, C), DD_8(a_j, O, H)$$

These domains collectively represent the formal ("dismembered") molecular body $DD(a_j)$ at the density threshold $a_j = 0.390$.

This pattern is our first example for the formation of a density domain of a typical *functional group*, the OH group. The corresponding density domain $DD_8(0.390, O, H)$ serves as a density-based justification for assigning a separate identity to the OH functional group and for regarding it as a chemical entity. For the OH group there exists a whole range $[a', a'']$ of density threshold values within which the O and H nuclei are surrounded by MIDCOs, separating them from all the other nuclei of the ethanol molecule. This criterion, the existence of a MIDCO that separates a family a nuclei from all other nuclei of a molecule, has been used for the identification and a detailed characterization of the functional groups of chemistry (11).

Not every actual density domain $DD_i(a_j)$ and the nuclei enclosed by it can be transferred from one molecule to another without altering the topology of the density domain. Nevertheless, the DD approach provides a physically motivated criterion for what molecular moiety, at the given density threshold a, can be regarded to have a well-defined identity. This justifies a generalization of the usual chemical concept of functional groups. According to this generalized concept, a collection of all nuclei within a density domain $DD_i(a_j)$, together with the density domain itself, can be regarded as a functional group of the molecule at the density threshold a_j.

This approach can be regarded as a physically motivated choice (11) within the general scheme (21) for the identification and analysis of functional groups of various molecular arrangements within the nuclear configuration space M. If a MIDCO separates a group of nuclei from the rest of the nuclei of the molecule, this indicates a chemical linkage among the local charge densities surrounding these given nuclei that is more prominent than the linkage between this group and the rest of the molecule. This is a property expected from most functional groups of chemistry. Nevertheless, the Density Domain concept of functional group does not necessarily coincide in each case with the concept conventionally used by chemists. Furthermore, the calculated Density Domains are dependent on the level of quantum chemical methods used. Consequently, in the analysis of calculated functional groups, the quality of the calculated charge density (e.g., basis set specification, such as 6-31G*) should also be indicated, especially for density domains at the high threshold ranges.

In the process of generating density domains of gradually decreasing threshold a, the most acidic proton of the ethanol

molecule loses its separate density domain first. This is the merger of the highest density threshold. The minimal electronic charge density is of the highest value between this proton and another nucleus (the oxygen nucleus) of the molecule. This is only in an apparent conflict with the fact that, as the most acidic proton of the molecule, this is the proton most easily donated to proton acceptors. The explanation of this apparently counterintuitive pattern is explained by the high electronegativity and the resulting, more extensive, high-density domain about the oxygen nucleus. The high electron density cloud about the oxygen engulfs this particular proton, resulting in the highest density threshold "bridgehead" between a proton and another nucleus of this molecule.

This observation can be combined with another: the density domain of the OH proton appears relatively late in the process of gradually decreasing the density threshold. Of course, this fact can also be justified by the high electronegativity of oxygen: the electron density is "siphoned away" by the oxygen; consequently, the nearby proton has a chance for the formation of a density domain only at a lower level of density.

The above two observations represent a rather general trend. Consider a molecule with a set of identical nuclei A and, for simplicity, assume that A is single valenced in the classical sense. Hydrogen nuclei are typical examples. The density domain of a nucleus A that appears late (that is, at a low-density threshold) is likely to join a neighboring density domain early (at a density threshold higher than the DDs of most of the other nuclei of type A). We may state this observed trend as a formal rule. This trend, called the "Late–Early Rule," can be stated as follows.

The Late–Early Rule:

If the threshold density is gradually decreased in a density domain analysis of a given molecule, then the order of joining of various individual density domains of a given atom type A to neighboring density domains tends to be the reversed order of their appearance.

This Late–Early Rule is justified by electronegativity considerations: a higher electronegativity neighbor of A is likely to delay the appearance of the density domain of A to a lower density threshold, and also likely to have a more extensive charge density cloud about it; hence an early joining of the density domains of the neighbor and A is likely. In effect, this density domain exists in a narrower threshold interval that is contained within the corresponding intervals of other density domains containing the same nucleus type A.

One may state this trend using the expected inclusion relations of the electron density threshold intervals where the density domains exist as separate entities. Order the nuclei of type A according to the order of increasing effective electronegativity of the neighbor nuclei involved in the *first* merger of the density domains of nuclei of type A:

$$[18] \quad A^{(k)},\ k = 1, 2, \ldots q$$

Accordingly, the effective electronegativity of nucleus $B^{(1)}$, that is, the first nucleus to share its density domain with that of $A^{(1)}$, is the lowest, whereas the effective electronegativity of nucleus $B^{(q)}$, that is, the first nucleus to share its density domain with that of $A^{(q)}$, is the highest.

Denote by (a_k, a'_k) the interval of density thresholds where a separate density domain exists for nucleus $A^{(k)}$. Then the trend expressed by the Late–Early Rule is equivalent to the following, ideal, sequence of inclusion relations:

$$[19] \quad (a_1, a'_1) \supset (a_2, a'_2) \supset (a_3, a'_3) \supset \ldots \supset (a_k, a'_k) \ldots \supset (a_q, a'_q)$$

The above inclusion relations of the Late–Early Rule are not always followed in a strict sense; however, it is the expected trend. In some examples the extreme case of the Late–Early Rule applies: the density domain of $A^{(q)}$ of a neighbor $B^{(q)}$ of highest electronegativity exists in the narrowest threshold interval, contained within the corresponding intervals of all other density domains of the same nucleus type A. That is, the last domain that appears is the first to join a neighbor. A special case of the Late–Early Rule, as applied to protonic density domains, has been called the Last–First Rule (2). The Late–Early Rule, introduced above, is a generalization of the Last–First Rule.

4. There is no methyl group in the ethanol molecule (according to the density domain functional group criterion)

In Fig. 2 additional mergers of density domains are displayed

For personal use only.

as the density threshold is further reduced. The next two topologically distinct set of density domains are represented by the threshold values of $a_j = 0.303$ and $a_{j'} = 0.293$, corresponding to the two-step merger of methylenic carbon and the two methylenic hydrogen density domains. The resulting two families are the set of seven density domains

[20] $\{DD_1(a_j, H), DD_2(a_j, H), DD_3(a_j, H), DD_4(a_j, H), DD_5(a_j, C), DD_6(a_j, C, H), DD_7(a_j, O, H)\}$

and the set of the six density domains,

[21] $\{DD_1(a_{j'}, H), DD_2(a_{j'}, H), DD_3(a_{j'}, H), DD_4(a_{j'}, C), DD_5(a_{j'}, C, H, H), DD_6(a_{j'}, O, H)\}$

respectively.

The $DD(a_{j'})$ pattern at $a_{j'} = 0.293$ shows the presence of a methylenic (CH_2) functional group, represented by the density domain $DD_5(a_{j'}, C, H, H)$, occurring simultaneously with the hydroxyl group, represented by $DD_6(a_{j'}, O, H)$. Both of these groups have separate chemical identity *within* the ethanol molecule if one accepts the density domain criterion, since there exists a MIDCO that separates the carbon and the two hydrogen nuclei from all other nuclei of the ethanol molecule, and the same holds for the nuclei of the OH moiety. This justifies regarding both the methylene and hydroxyl groups as functional groups within the ethanol molecule. The terminal CH_3 moiety is still disconnected at this density threshold value of $a_{j'} = 0.293$.

The next topologically significant change is the merger of the carbon density domain of the CH_3 moiety (formal methyl group) with one of the corresponding hydrogen density domains. One obtains the density domain family

[22] $\{DD_1(a_j, H), DD_2(a_j, H), DD_3(a_j, C, H), DD_4(a_j, C, H, H), DD_5(a_j, O, H)\}$

as shown by the $DD(a_j)$ body at the threshold $a_j = 0.292$.

The next topological change is of special interest: the merger between the $DD_3(a_j, C, H)$ and $DD_4(a_j, C, H, H)$ domains of the previous density threshold. This merger results in a new family of density domains at the threshold $a = 0.291$:

[23] $\{DD_1(a, H), DD_2(a, H), DD_3(a, C, H, C, H, H), DD_4(a, O, H)\}$

The density domain $DD_3(a, C, H, C, H, H)$ of this family is of special significance: its occurrence clearly shows that the terminal CH_3 moiety (formal methyl group) cannot have a separate density domain. In the given nuclear configuration of the ethanol molecule (and also within an entire topological range of the nuclear configuration space) there exists no MIDCO surface separating the nuclei of the terminal CH_3 moiety from all other nuclei of the molecule.

We may rephrase this observation: *according to the given 6-31G* level of quantum chemical calculations, the methyl group does not appear as a formal functional group of separate identity within the ethanol molecule.* As a density domain functional group, there is no methyl group in the ethanol molecule. This result is in good agreement with chemical practice: few organic chemists would attempt to use ethanol as a methylating agent, that is, as a source of methyl group for incorporation into another molecule to be synthesized.

The next topological change is shown at the threshold value of $a = 0.284$ au. The family of density domains obtained is

[24] $\{DD_1(a, H), DD_2(a, C, H, H, C, H, H), DD_3(a, O, H)\}$

where the pattern of $DD_2(a, C, H, H, C, H, H)$ is of special interest: its shape indicates a "trans disconnected" arrangement. The hydrogen density domain $DD_1(a, H)$ with a dihedral angle near 180° with the density domain $DD_3(a, O, H)$ of the OH functional group has the lowest electron density, indicating differences of formal acidities of the terminal H atoms. These results are similar to those derived from overtone spectra on the nonequivalence of CH bonds (22–28).

The $DD_1(0.284, H)$ density domain joins $DD_2(0.284, C, H, H, C, H, H)$ if the threshold is lowered to $a = 0.282$. The new DD family making up the molecular body DD(0.282) consists of only two density domains,

[25] $\{DD_1(0.282, C, H, H, H, C, H, H), DD_2(0.282, O, H)\}$

The existence of the new density domain $DD_1(0.282, C, H, H, H, C, H, H)$ indicates that the ethyl group is a density domain functional group of the ethanol molecule. The density domains $DD_1(0.282, C, H, H, H, C, H, H)$ and DD_2 (0.282, O, H) of the ethyl functional group and the hydroxyl functional group, respectively, have separate identities at this density threshold value. The presence of the ethyl and the hydroxyl groups in the ethanol molecule is well reflected in the conventional name of the molecule: ethyl alcohol.

Figure 3 shows the next important topological change: the merger of the ethyl and hydroxyl density domains, shown at a threshold value of $a = 0.265$. The family DD(0.265) of density domains has only a single member,

[26] $\{DD_1(0.265, C, H, H, H, C, H, H, O, H)\}$

This last topological change concludes the *bonding sequence* as specified by the topological sequence of gradually interconnected families of density domains. This bonding sequence provides a detailed three-dimensional description of bonding in the ethanol molecule.

At this and any lower density threshold, the nuclei of the molecule are enclosed by a single density contour. In particular, no fragmentation of density domains of the ethanol molecule can occur at lower thresholds. However, further important shape changes occur at lower threshold values; some of the typical shapes are shown for the threshold interval ranging from $a = 0.200$ to $a = 0.004$, leading to an eventual spherical shape at very low densities.

All the different shapes below the $a = 0.265$ threshold represent the same topological molecular body of a single density domain,

[27] $DD(a) = DD_1(a)$

These bodies correspond to a topological ball.

5. A classification of density domains

In each molecule, the bonding pattern shows some characteristic density ranges where typical shape features occur. Never-

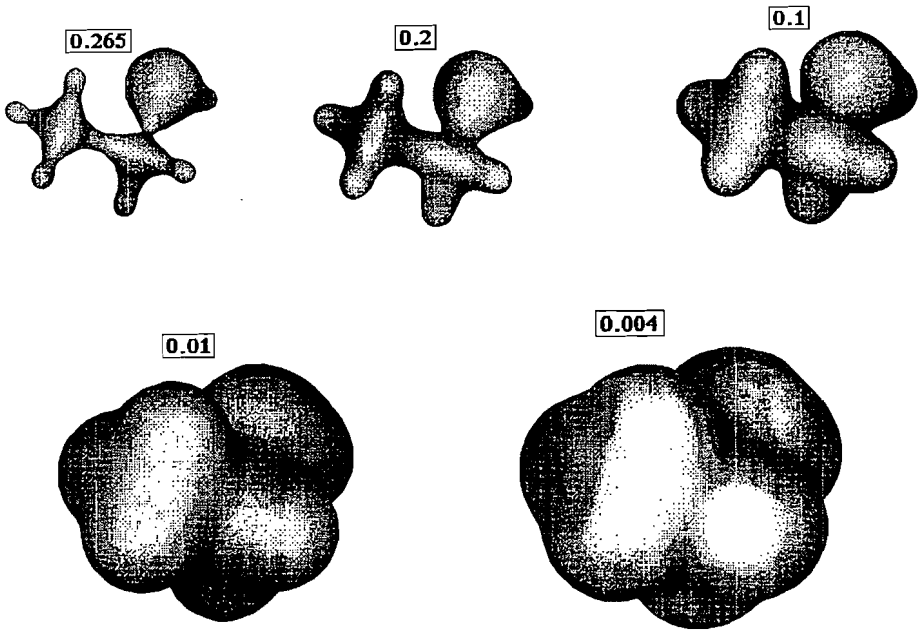

FIG. 3. The topologically different low-threshold density domains of the ethanol molecule CH_3CH_2OH, calculated using a 6-31G* basis set, the GAUSSIAN 90 (9) *ab initio*, and the GSHAPE 90 (19) molecular shape analysis programs.

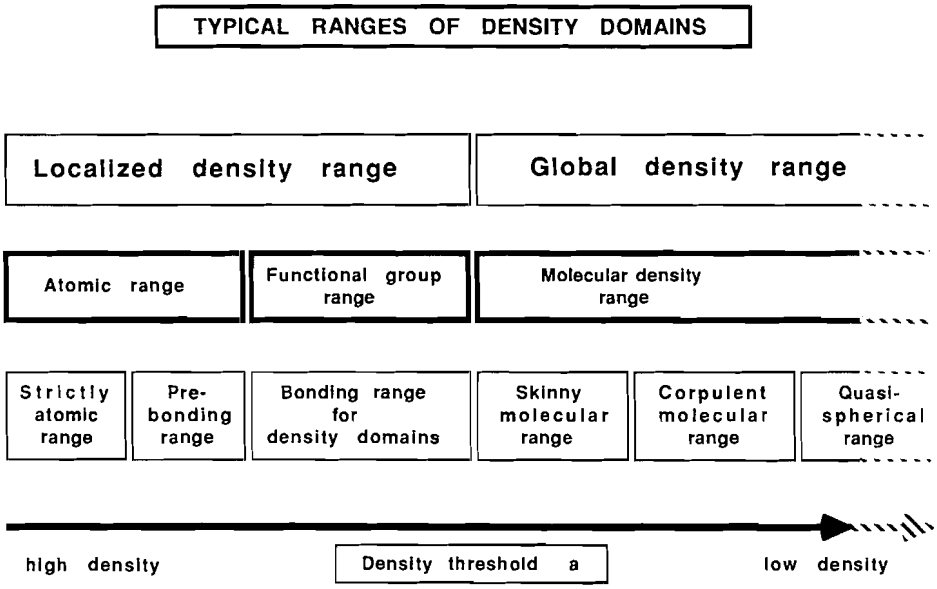

FIG. 4. A classification of types of density domains according to the ranges of the electron density threshold *a*.

theless, there are some important general trends in the entire range of possible density threshold values, valid for all molecules (2). These trends provide a classification of density domains according to various ranges of the density threshold parameter *a*, as illustrated in Fig. 4.

We shall consider a gradual decrease of the density threshold *a*, starting with a high value (2). Within the high-density range of the threshold *a*, only individual nuclear neighborhoods appear as disconnected density domains, that is, there is precisely one nucleus within each density domain that appears. The density range where this holds can be referred to as the *atomic range*. In a lower density range some nuclear neighborhoods join to form density domains containing two or more nuclei, but not all nuclei of the molecule are contained in a common density domain. In this density range one finds the various functional groups as individual entities; hence this range is called the *functional group range*. In this range the bonding pattern (interconnection pattern) of the density domains is revealed; consequently, this range is also called the *bonding range for density domains*. In a lower density range the essential molecular pattern of bonding is established, and all nuclei of the molecule are found within a common density domain. This range is called the *molecular density range*.

The atomic range is subdivided into two subranges. In the *strictly atomic range* all the atomic density domains are convex, whereas in the *prebonding range* at least one density domain is no longer convex, as it "reaches out" to join a neighboring density domain.

The molecular density range also contains some subranges. At the high threshold values within the molecular range, the

For personal use only.

density domains often have some local "neck" regions: there is at least one topological belt or some other multiply connected set on the surface of the density domain along which the surface is not locally convex. Within this density subrange the molecular body is "skinny," and this range is referred to as the *skinny molecular range*. At lower densities no such neck regions occur, but one usually finds at least one local nonconvex region along the surface of the density domain. If this occurs, then the corresponding subrange is called the *corpulent molecular range*. At very low densities the density domains of all molecules (even those of long-chain molecules) are convex. The corresponding range is called the *quasi-spherical molecular range*.

The atomic and the functional group ranges together can be regarded as the *localized range*, and the molecular density range can be regarded as the *global density range*.

The example of the ethanol molecule shown in Figs. 1–3 illustrates the above classification scheme.

Summary

Following an introduction to the concepts, notations, and methods of Density Domain analysis of chemical bonding, a new rule, the Late–Early Rule, has been suggested for the distribution and persistence of density domains within various intervals of density thresholds of molecules. The observations have plausible explanations based on simple electronegativity arguments. Application of Density Domain analysis to the ethanol molecule indicates that no separate electron density envelope exists for the formal terminal methyl group; by this criterion, the electron density distribution does not justify regarding the terminal CH_3 moiety as a formal functional group.

Whereas the emphasis in this study has been on global topological properties of formal molecular bodies, alternative methods are available for detailed shape analysis. The shape changes of each density domain can be described in detail by considering local curvature variations and subdividing the surfaces according to various curvature domains. An algebraic characterization of these shapes can be given (2), using the Shape Group Method (SGM), introduced earlier (15, 16). A detailed shape analysis of individual molecular orbitals, as compared to the density domains, is expected to provide information on reactivity of molecules. This approach, using the *most delocalized orbital representations* (29), will be the subject of a forthcoming study.

The meaning of "adiabatic"

KEITH J. LAIDLER
Department of Chemistry, University of Ottawa, Ottawa, ON K1N 6N5, Canada

Received May 20, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

KEITH J. LAIDLER. Can. J. Chem. **72**, 936 (1994).

In chemical kinetics the word "adiabatic" has come to refer to a process in which there is no change of quantum state, a meaning that has no connection with the thermodynamic meaning or with the etymology of the word. This usage is traced to early discussions of *reversible adiabatic* processes in classical and quantum mechanics, processes that came to be referred to simply as adiabatic.

KEITH J. LAIDLER. Can. J. Chem. **72**, 936 (1994).

En cinétique chimique, le mot «adiabatique» se réfère aujourd'hui à un processus dans lequel il n'y a pas de changement d'état quantique, une signification qui n'a aucune relation avec le sens thermodynamique ou avec l'étymologie du mot. On peut retracer l'origine de ce nouvel usage dans les premières discussions des processus *adiabatiques réversibles* de la mécanique classique ou quantique auxquels on a fini par se référer simplement adiabatiques.

Introduction

In chemical kinetics the word "adiabatic" has long been used to refer to a chemical reaction in which the products remain in the same quantum state as the reactants. This usage has created some puzzlement as it does not seem to have, and indeed does not in fact have, any connection with the etymology of the word adiabatic, or with the appropriate use of the word in thermodynamics. The word adiabatic means "not passing through," and in thermodynamics refers to a condition imposed on a system, a condition that prevents any passage of heat into or out of the system. In its kinetic usage the word relates not to a condition imposed on the system, but rather to an inherent property of a chemical process, namely its tendency under certain conditions to occur without any change in quantum states.

A consideration of how the kinetic meaning of adiabatic developed is of some interest in the history of science, and is also instructive in leading to a better understanding of some of the fundamental principles of statistical mechanics and quantum mechanics. The trail begins with a paper (1) published in 1866 by Ludwig Boltzmann, in which he mistakenly claimed to have derived the second law of thermodynamics on the basis of classical mechanics. Within a few years, thanks to his study of Clerk Maxwell's papers, he had realized that his argument was invalid, and that the second law must be explained along statistical lines. In his 1868 paper, however, he had considered a reversible adiabatic process, and it is from that argument that the winding and sometimes indistinguishable trail eventually led, through several false turns, to the inappropriate use of the word adiabatic in modern kinetics.

"Adiabatic" as used in thermodynamics

The word adiabatic was first used in 1858 by W.J.M. Rankine (2), and it derives from the Greek prefix α- (a-), not, δια (dia), through, and βαινιν (bainen), to pass. Although it was Rankine who first used the word, the *concept* of an adiabatic process, in which no heat enters or leaves the system, is stated clearly in Carnot's famous memoir (3) of 1824, and in Clapeyron's mathematical treatment of Carnot's cycle (4), which involves two isothermal and two adiabatic steps.

"Adiabaticity" in classical mechanics

Boltzmann was 22 years old in 1866 when he wrote his paper entitled "On the mechanical meaning of the second law of thermodynamics" (1). In it he claimed to have given a "purely analytical, completely general, proof of the second law of thermodynamics." By 1868 he had realized that his arguments were ill-conceived, and in that year he published a paper of great importance (5), which initiated his pioneering contributions to statistical mechanics. This contribution owed much to an important paper by Clerk Maxwell (6) on the distribution of speeds in gases. Others, however, notably Rudolf Clausius (7, 8) and Coloman (or Kálmán) Szily von Nagy-Szigeth (9–11), continued to maintain the view that the second law can be proved on the basis of mechanics.

Although Boltzmann's 1866 paper was invalid, it did involve a principle that was later helpful in leading to an understanding of the quantum theory. Boltzmann considered a somewhat artificial model for a gas in which the molecules undergo a periodic motion of frequency ν. He then proved that if the gas were subjected to a *reversible adiabatic change* the ratio of the energy E to the frequency ν would remain constant. In their later papers Clausius and Szily also considered reversible adiabatic changes, agreeing with Boltzmann's conclusion that E/ν remains constant. It was at about that time that the word *action* began to be applied to the quantity E/ν.

Subsequently a number of other workers stressed this invariance of E/ν. In 1902, for example, Lord Rayleigh, in a treatment (12) of the pressure of radiation, considered a simple pendulum consisting of a bob and a string. By means of a small ring round the string its length could be altered, and as the string becomes shorter the frequency of the pendulum increases. Rayleigh proved that if the ring is lowered extremely slowly (i.e., the process is carried out reversibly) work is done on the system and the energy of the pendulum increases in exact proportion to the frequency; in other words the action, E/ν, remains constant. If, on the other hand, the ring is lowered rapidly just at the moment that the string is vertical, no work is done; the frequency increases but the energy remains constant, so that the action is no longer unchanged. Other treatments of the same principle in relation to other situations were given by Andrade (13), Morton (14), and Bhatnagar and Kothari (15).

"Adiabatic invariance" in quantum theory

Paul Ehrenfest was particularly effective in his writings on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

the fundamentals of mechanics (16–19), and he laid special emphasis on this constancy of E/ν, in both classical and quantum mechanics. In one paper (16*a*), published in 1911, he extended the principle of invariance of E/ν in classical systems, for processes that are extremely slow, to apply to motions other than harmonic motions, to which the principle had previously been restricted. He also extended the argument to quantized systems, showing that when the parameters of a system in a particular quantum state are changed slowly, the system remains in the same quantum state. In this same paper he proved rigorously that, since E/ν is the only property that remains constant if one brings about a very slow change in the system, this is the only property that can be quantized. It should be remarked that although as a matter of convenience we speak of the quantization of energy — and this terminology has been sanctioned by Einstein and Planck among many others — it is, strictly speaking, the action (E/ν) that is quantized. Planck in fact referred to his constant h (= E/ν) as the *elementary quantum of action.*

Ehrenfest's analysis in this 1911 paper (16) threw light on a difficulty that was troubling many of the leading physicists of the time. The laws of classical mechanics had been well worked out to deal with energy transfers that occur when molecules collide. What, however, would be the situation if energies are quantized? This matter was brought up at the First Solvay Congress, held in Brussels at the end of October, 1911, only a couple of weeks after Ehrenfest's paper appeared. H.A. Lorenz, then professor at Leiden and in the following year to be succeeded there by Ehrenfest himself, posed a simple question of fundamental importance. He imagined a pendulum oscillating in a particular quantum state, and asked what would happen to the quantized state if the string were shortened. Ehrenfest had not been invited to attend the Congress but, according to the report of the Congress, Einstein immediately and unhesitatingly answered that *if the length were changed infinitely slowly,* the energy would remain equal to $h\nu$. It is known that Einstein had by that time read Ehrenfest's paper (16*a*),[1] and he was probably also familiar with Rayleigh's treatment of the classical problem.

Although the emphasis had always been on the *slowness* of the processes, it was shortly after this meeting that the constancy of E/ν began to be referred to as "adiabatic invariance." This expression was apparently first used in print by Einstein in a paper (20) that appeared in 1914. This usage by Einstein is acknowledged in papers by Ehrenfest (19) which appeared in 1916. The English version of these papers, which appeared in the *Philosophical Magazine*, was entitled "Adiabatic invariants and the theory of quanta," and on page 502 appears the following significant passage:

> "By changing the parameters ... in an infinitely slow way, a given motion $\beta(a)$ may be transformed into another motion $\beta(a')$. This special type of influencing upon the system may be called "*a reversible adiabatic affection*", the motion $\beta(a)$ and $\beta(a')$ being *adiabatically related to each other* [his italics]"

Much the same is said in the Dutch versions of the paper. The key word "reversible" disappeared in the second part of this sentence, and was also omitted in latter discussions of the problem. In some of these later treatments one meets anomalous phrases like "...if a process occurs adiabatically, i.e., very slowly...". The emphasis should, of course, be on the reversibility and not on the adiabaticity; the same effect would be obtained if the process were reversible and *isothermal.* The important point, as stressed by Einstein at the Solvay Congress, is that processes must be *slow* in order for quantum states to be preserved. In spite of this, the inappropriate word adiabatic came to be used.

[1]Reference 16*a* appeared in October, 1911, and the fact that Einstein had read it before the Solvay Congress, which occurred at the end of October, is known from the fact that he referred to it in a letter to his friend M. Besso dated 21st October, 1911.

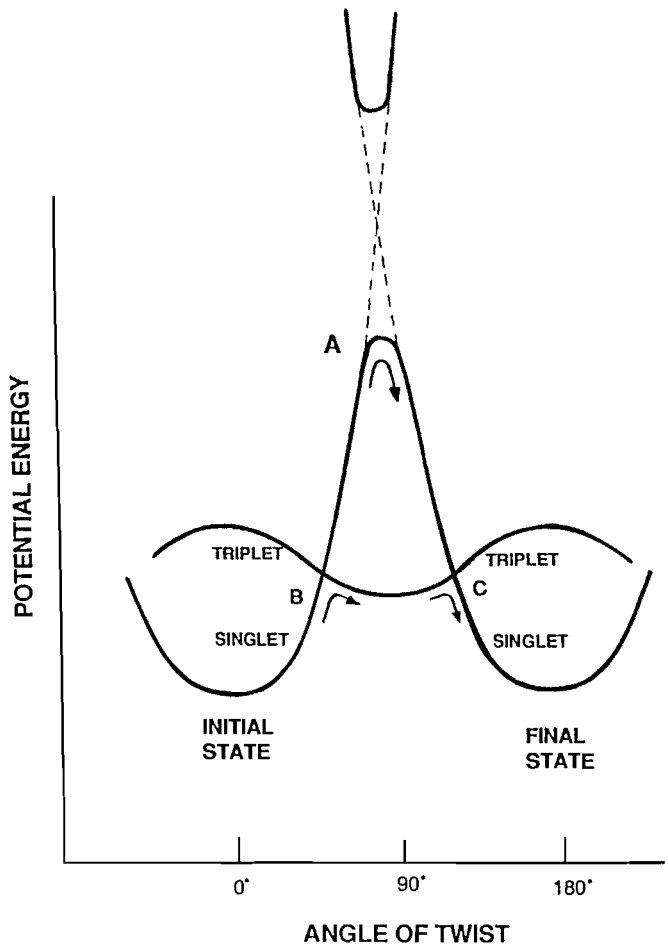

FIG. 1. Schematic potential-energy diagram for the *cis–trans* isomerization of a substituted ethylene.

"Adiabaticity" in chemical kinetics

The modern use of the word adiabatic in chemical kinetics is consistent with the usage introduced by Einstein and Ehrenfest. The first use in kinetics appears to have been by Fritz London (21) in 1928, in connection with his approximate quantum-mechanical expression for the energy of the H...H...H complex, an intermediate in the H + H_2 reaction. In discussing this problem London suggested that many chemical reactions proceed "adiabatically," by which he meant that there is no abrupt jump from one quantum state to another.

Reactions that are not adiabatic in this sense are referred to as diabatic or nonadiabatic. Examples of nonadiabatic reactions are the *cis–trans* isomerizations of certain substituted ethylenes. Figure 1 shows a schematic potential-energy profile (22) for such a system, the energy being plotted against the angle of twist about the double bond. There is a triplet excited state having a minimum corresponding to a twist of 90° so that there are two alternative reaction paths. The system may remain in a singlet state throughout and proceed via point A, where there is a crossing of two singlet states; this process is referred to as adi-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

abatic. Alternatively, the system may cross to the triplet state at B and cross to the singlet state at C; this is the non-adiabatic process. The adiabatic process has a higher activation energy than the non-adiabatic process, but has a normal pre-exponential factor, since there is little restriction to passing from a singlet state to another singlet state. The non-adiabatic process has a lower activation energy but a lower pre-exponential factor because of the difficulty in crossing from a singlet to a triplet state. The evidence for the *cis-trans* isomerizations is that the pre-exponential factors are abnormally low by a factor of about 10^{-3}: this factor, referred to as the *transmission coefficient* for the reaction, reflects the low probability of transition between singlet and triplet states.

Systems approaching B in Fig. 1 do so at various speeds. According to the principles enunciated by Ehrenfest and Einstein, systems moving very slowly will inevitably remain in the triplet state, but these will have insufficient energy to reach C and will therefore not undergo isomerization. Systems moving more rapidly will have a significant possibility of jumping into the triplet state where they will probably undergo a number of vibrations before passing into the product state. The details are obviously a matter of great complexity.

The word adiabatic has also been used in kinetics in a more specialized sense: a reaction in which the system remains in the same vibrational state has been said to be "vibrationally adiabatic." In conventional transition-state theory (23, 24) the initial and activated states are treated quantum mechanically, but the passage over the col is treated classically. Also, in the earlier dynamical treatments of the motion of systems over potential-energy surfaces, the initial states are quantized but the actual motion follows classical laws (25), so that the products do not appear in their appropriate quantum states. Some attempts have been made to develop extensions of conventional transition-state theory in which the motions are constrained to remain in quantum states (26, 27), and these have been referred to as adiabatic transition-state treatments. In a number of publications Polanyi and co-workers have dealt with the theory (28) of this type of adiabaticity and have provided examples (29). Other treatments consistent with this type of adiabaticity have been put forward by Garrett and Truhlar (30), and by Quack and Tröe (31, 32) who have proposed an "adiabatic channel model," which is a detailed version of adiabatic transition-state theory.

The word adiabatic in its kinetic sense also appears in Marcus's theory of unimolecular gas reactions (33, 34), often referred to as Rice–Ramsperger–Kassel–Marcus (RRKM) theory. Certain types of energy residing in a molecule are regarded as inactive or adiabatic; what is meant is that energy of this type remains in the same quantum state during reaction and therefore makes no contribution to the rearrangement of bonds that occurs during reaction. The zero-point energy is adiabatic in this sense, as is the energy of overall translation and rotation, since this energy is preserved when the energized molecule becomes an activated complex. Other energies, such as some vibrational energies, are said in RRKM theory to be active or non-adiabatic.

Discussion

It is evident that besides being used in kinetics in a sense that is different from the thermodynamic sense, the words adiabatic, diabatic, and non-adiabatic are used in different ways by different writers on kinetics. It is obviously of the greatest importance that whenever the words are used in kinetics they should be clearly defined. It should also be noted that the words are often used not to describe the way in which a reaction is believed to proceed, but rather the approximation that is being used in the theoretical treatment of the reaction.

Conical intersections in C_s, C_{2v}, and linear configurations for the $^1A'$ states of the H_2Cl^+ molecule are investigated with the help of a 10 × 10 model Hamiltonian matrix in a valence-bond basis. The line of intersection (*linea*) between states 2 and 3 is traced from one end point, an intersection between two states of $^1B_2$ symmetry in a C_{2v} configuration, to the other end point, an intersection between two $^1\Sigma^+$ states in a linear H—H—Cl configuration. The *linea* consists of 5 branches having symmetries C_s, C_s, $C_{\infty v}$, C_{2v}, and C_s. A *linea* between states 3 and 4 starting at a crossing of $^1\Sigma^+$ and $^1\Pi$ states in a linear $C_{\infty v}$ configuration consists of three branches (C_s, C_{2v}, C_s) leading to the asymptotic region Cl + H_2. The starting point of linea 3/4 is connected to the asymptotic region H + HCl via a *linea* in the linear configuration. *Lineae* of C_s symmetry could be found by examining the eigenvalues of the Hessian matrix of second derivatives along a line of intersection in a higher symmetry (C_{2v} or linear), a useful method for locating accidental intersections that lends itself readily to *ab initio* calculations. The existence of the *lineae* could be related to physical properties of the molecule, such as the dipole moment, indicating that the model Hamiltonian does reflect the true physical behaviour.

Faisant appel à un hamiltonien matriciel modèle de 10 × 10, dans une base de liaison de valence, on a examiné les intersections coniques des configurations C_s, C_{2v} et linéaires des états $^1A'$ de la molécule de H_2Cl^+. La ligne d'intersection (*linea*) entre les états 2 et 3 est tracée à partir d'un point terminal, une intersection entre deux états de symétrie $^1B_2$ de configuration C_{2v} vers un autre point terminal, une intersection entre deux états $^1\Sigma^+$ dans une configuration linéaire H—H—Cl. La *linea* comporte cinq branches de symétries C_s, C_s, $C_{\infty v}$, C_{2v}, et C_s. Une *linea* entre les états 3 et 4, qui commence à un croisement des états $^1\Sigma^+$ et $^1\Pi$ dans une configuration linéaire $C_{\infty v}$, comporte trois branches (C_s, C_{2v} et C_s) et elle conduit à la région asymptotique Cl + H_2. Le pont de départ de la *linea* 3/4 est relié à la région asymptotique H + HCl par le biais d'une *linea* de configuration linéaire. On peut trouver des *lineae* de symétrie C_s en examinant les valeurs propres de la matrice hessiane des deuxièmes dérivés le long d'une ligne d'intersection dans une symétrie plus élevée (C_{2v} ou linéaire); il s'agit d'une méthode utile pour localiser des intersections accidentelles qui se prêtent facilement à des calculs *ab initio*. On peut relier l'existence de *linea* aux propriétés physiques de la molécule, comme le moment dipolaire; ceci indique que l'hamiltonien modèle est un reflet du comportement physique réel.

[Traduit par la rédaction]

Introduction

In this paper we use a diatomics-in-molecules (DIM) model Hamiltonian matrix to map some of the lines of accidental conical intersections in the $^1A'$ states of H_2Cl^+. By accidental, we mean intersections of states from the *same* irreducible representation of the symmetry group of the molecule. The classic paper by Longuet-Higgins in 1975 (1) appears to be definitive as to the existence of such intersections and their dimensionality. Since then, these intersections have become well established both from the theoretical and computational perspectives (2–12) and have important implications for the theory of reaction dynamics (13–22). Within a specified area, the *existence* of a conical intersection can be demonstrated without actually *locating* it, if one exploits the geometric phase factor (Berry's phase): the eigenvectors of the intersecting states change their signs on being transported in a closed curve around the point of intersection (23–28). This also serves to verify that a located point is in fact a bona fide intersection, for there are always numerical limitations preventing one's finding the *exact* intersection. This procedure, applied some time ago (29), was recently used to verify the existence of a conical intersection for high level *ab initio* MCSCF wave functions (2, 3). The first work to locate a conical intersection using large-scale CI wave functions was recently reported (5), in which it is shown that calculation of the Hessian matrix of second derivatives (5, 30) together with the use of Lagrange multipliers (31, 32) permits one to follow the line of intersection very well.

We have used a modification of the Hessian matrix technique to follow some of the lines of accidental intersections, which we shall refer to here as *lineae*, over as much of their entire lengths as possible. Although the DIM valence bond model is simplistic compared with the recent *ab initio* work, it has the advantage of being applicable over the whole of the configuration space of the molecule, allowing us to follow the *lineae* out to large internuclear separations and thus enabling us to map the behaviour of the *lineae* over most of the regions of interest. Our interest (33) in the H_2Cl^+ molecule-ion stems from a study (34) of the ion–molecule reactions:

[1] $$H^+ + HCl \rightarrow H + HCl^+(X\ ^2\Pi)$$

[2] $$H^+ + HCl \rightarrow H + HCl^+(A\ ^2\Sigma^+)$$

The reagents in these reactions correspond to the second $^1A'$

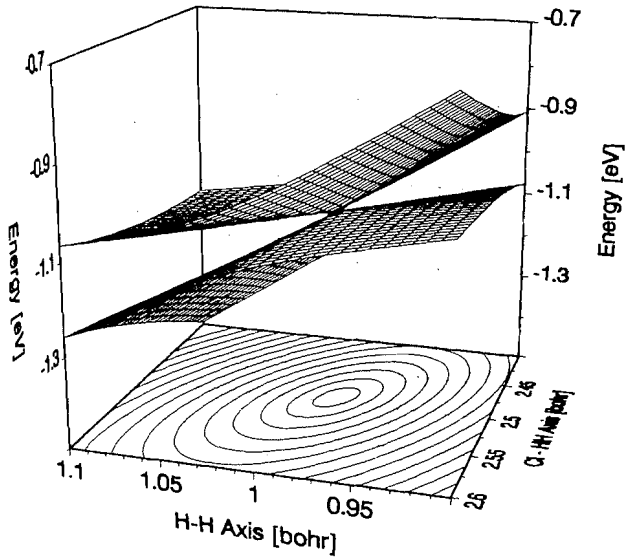

FIG. 1. Conical intersection for potential energy surfaces 2 and 3. r(H—H) = 6 bohr. The position of the Cl atom is referred to a coordinate system with origin in the HH bond midpoint. The energy of each surface is shown by the two cross-hatched sheets, the energy difference by the projections onto the plane.

eigenstate of the H_2Cl^+ molecule; the products correspond to the first and third $^1A'$ eigenstates, respectively. Both reaction paths may proceed via non-adiabatic mechanisms in regions of avoided crossings. In the reaction leading to the *excited* state products, H + $HCl^+(A\ ^2\Sigma^+)$, the avoided crossing region happens to be associated with an accidental conical intersection between the second and third eigenstates in C_s geometrical configurations. This was discovered when the contours for the *difference* in energy between the second and third eigenvalues were plotted for a fixed distance of the H_2 molecule, as in Fig. 1, which shows the two surfaces and the contour map of the energy difference between them. The H_2 bond distance, r(H—H), is held fixed at 6 bohr (1 bohr = 52.9 pm); the direction of the H_2 bond serves to define one of the axes of the plane. The other axis is the line perpendicular to the bond midpoint in the plane of the molecule. The projected contours are characteristic of a conical intersection, the existence of which was verified by computing the change in the geometric phase of the eigenvectors on circumscribing the intersection point.

The work presented here is a continuation of an earlier investigation on conical intersections in the H_2Cl^+ molecule-ion (35), where we only succeeded in calculating a small segment of the *linea* corresponding to the intersection mentioned above, a segment of a second *linea* for eigenvalues 2 and 3, and a third one for states 3 and 4. The existence of these *lineae* in the strong interaction region of the potential energy surface was tentatively related to the crossing of the diatomic curves of the $HCl(X\ ^1\Sigma^+)$ and $HCl^+(A\ ^2\Sigma^+)$ states in the asymptotic region H + HCl, and this in turn was shown to have some relationship to the charge distribution in the molecule. These ideas are reinforced by the present study. In addition, we are now able to follow the *lineae* along their entire lengths and can conclude that they terminate in a united-atom limit, in an asymptotic region, or in a point of higher symmetry. We show that the two segments of the 2/3 *lineae* of the previous work are actually part of a single extended *linea* which is made up of C_s, C_{2v}, and linear parts. The local behaviour of the *lineae* can be related to the crossings that occur in the various diatomic curves in the asymptotic regions corresponding to the separation of one of the atoms from the rest of the molecule. We demonstrate how a C_s *linea* might be located by following *lineae* in higher symmetries.

Computations

The model Hamiltonian

The model Hamiltonian (10 basis functions from 6 valence-bond (VB) structures) is described in earlier work (33) on the first three eigenstates of the H_2Cl^+ molecule-ion; information of relevance to the conical intersections appears in a later paper (35). The basis functions are obtained from spin-coupled direct products of the following set of atomic basis functions: Cl^-, $Cl^+(^3P_g)$, $Cl^+(^1D_g)$, $Cl^+(^1S_g)$, $Cl^+(^2P_u)$, H^+, and $H(^2S_g)$. These suffice to represent the $^1A'$ states of the triatomic molecule and they allow for charge transfer (ionicity) in H_2Cl^+ and in the HCl and HCl^+ fragments. The Hamiltonian matrix elements are evaluated in the diatomics-in-molecules (DIM) approximation: each matrix element is expressed in terms of the atomic and diatomic fragment matrices in the same basis, making use of the rotation matrices associated with the atomic basis functions. The first derivatives of the matrix elements are obtained analytically; the second derivatives are obtained from these numerically.

Since the potential energy surfaces have been described in detail (33), we shall not discuss them here. It should be noted that the DIM model was developed for the region of strong interaction between all three atoms — the behaviour at extremely short range (corresponding to much higher energy) is rather arbitrary. At very long range, the surfaces all approach their correct asymptotic limits but there are some spurious crossings in the diatomic curves, at least for the $H_2^+(X\ ^2\Sigma_g^+)$ and $H_2^+(^2\Sigma_u^+)$ fragments. Crossings in the HCl interactions at ≈7.5 bohr may also be spurious. The crossing of states 2 and 3 for r(H—Cl) = 4.2685 bohr is, however, a real phenomenon, and plays an important role in determining the loci of the *lineae*.

Finding the intersections

The previous work was plagued by numerical difficulties, which prevented us from finding the complete *lineae*. We see now that this was due mainly to our taking one of the internuclear distances, r(H—H), as the parameter describing the *linea* in 3-space, a method similar to that used by Manaa and Yarkony (30, 5). While this is a perfectly good procedure over part of the *linea*, it breaks down in regions where the *linea* is nearly perpendicular to the r(H—H) coordinate, since the plane in which the local search for the intersection is carried out is then nearly identical with the plane containing the *linea*. This is illustrated in Fig. 2. The *linea* cuts the base plane in two points, making it difficult not only to determine the exact point of intersection but also to calculate the geometric phase factor for verification: as the points coalesce, the line circumscribing the point may accidentally include *both* intersection points, leading to a zero phase factor. To remedy this deficiency, we now take the distance *along* the *linea* as the parameter, or progress variable, a procedure that guarantees that the search for the intersection will be carried out in a plane nearly perpendicular to the *linea*, as it should be. Accordingly, each line of intersection, or *linea*, is defined parametrically in

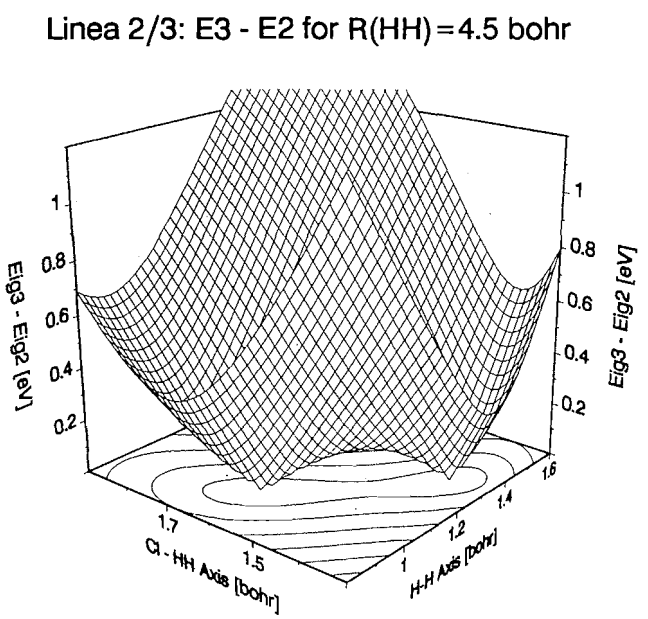

FIG. 2. Energy difference between states 2 and 3 in a region where the *linea* is nearly parallel to the base plane; the projections of this difference are shown as contours in the base plane. The coordinate system is as in Fig. 1 with r(H—H) = 4.5 bohr.

a space of "body-fixed" coordinate, $(u(\lambda), v(\lambda), w(\lambda))$ in terms of the progress variable, λ. The Cartesian coordinates (with respect to a fixed origin in space) for the atoms 1 (H), 2 (H), and 3 (Cl) are given in terms of the body-fixed coordinates as (0, 0, 0), (0, 0, w), and (u, 0, v). The two internuclear distances r(H—Cl) (denoted by r_a and r_b) and the distance r(H—H) (denoted by r_{ab}) are related to these coordinates by

$$[3] \qquad r_a = \sqrt{u^2 + (v - w)^2}$$

$$[4] \qquad r_b = \sqrt{u^2 + v^2}$$

$$[5] \qquad r_{ab} = w$$

To find the point of conical intersection of two eigenstates, E_1 and E_2, one starts with a point lying as close as possible to the *linea*. From such an approximate starting point, the position of the intersection can be found by searching in the plane perpendicular to the direction of the *linea* for the minimum in the *square* of the difference in energy, $S = (E_2 - E_1)^2$, an analytic function. Having found an exact point on the *linea*, successive points in the positive and negative sense of the *linea* direction can be found in a stepwise fashion until the endpoints of the *linea* are reached.

Crucial to this strategy is finding the *linea* direction. This is estimated by computing the Hessian matrix, D, of the second partial derivatives of the function S with respect to the body-fixed coordinates (u, v, w):

$$[6] \qquad D_{ij} = \left(\frac{\partial^2 S}{\partial \eta_i \partial \eta_j}\right)$$

where η_i is one of u, v, w. The matrix D is diagonalized to obtain the eigenvalues, e, and the eigenvectors, c: $Dc = ce$. Since the function S is identically zero at all points on the *linea*, the first and second derivatives are also zero along the direction of the *linea*, which implies that at least one of the eigenvalues of the Hessian matrix will be zero. The eigenvector corresponding to this eigenvalue, the column vector c_1, is then the direction of the *linea* at the point. The other two eigenvectors, c_2 and c_3, provide unit vectors perpendicular to the *linea*. In terms of the row vector (1, 1, 1) in (u, v, w) space, three local unit vectors spanning configuration space can be defined as

$$[7] \qquad \hat{I} = (1, 1, 1)c_1$$

$$[8] \qquad \hat{J} = (1, 1, 1)c_2$$

$$[9] \qquad \hat{K} = (1, 1, 1)c_3$$

The c_i are arranged in increasing order of the absolute values of their corresponding eigenvalues. Points in the neighbourhood of a given point, $Q \equiv (u, v, w)$, are defined in terms of three "Hessian variables" (λ, h_1, h_2):

$$[10] \qquad Q' = Q + \lambda\hat{I} + h_1\hat{J} + h_2\hat{K}$$

The eigenvalues of the Hamiltonian, E_1 and E_2, are considered to be functions of the Hessian variables. The strategy for propagating the *linea* from a point Q_0 to a neighbouring point Q_λ consists of the following steps:

1. Estimate the position of the next point on the *linea* by going a small step λ in the *linea* direction: $Q'_\lambda = Q_0 + \lambda\hat{I}$. ($\lambda$ is the "progress variable", or parameter of the *linea*.)

2. From the approximate point, Q'_λ, find the exact point, Q_λ, by minimizing the function $S(\lambda; h_1, h_2)$ with respect to the two "Hessian variables" h_1, h_2, holding λ fixed. h_1 and h_2 span the space perpendicular to the direction of the *linea*.

3. At the exact point Q_λ, find the new unit vectors $\hat{I}$, $\hat{J}$, $\hat{K}$ by diagonalizing the Hessian matrix at that point.

Step 2, minimizing the function S, may be unsuccessful, especially at large internuclear distances, where whole groups of eigenvalues are nearly degenerate, and at points where the wave functions corresponding to the two intersecting states change their character abruptly, causing the *linea* to execute a sharp turn in configuration space. In this case, step 2 must be repeated with smaller values of the progress variable, λ, until the *linea* is out of the difficult region. Even then, failure of the method can still occur if two nearly parallel *lineae* approach each other, for then there are two zeros of the function S that lie very close to each other. Special numerical methods would then be needed. This procedure worked very well for most cases investigated here, allowing determination of the point of intersection to within a relative error in the energy of better than 10^{-9}. It is more efficient and much more reliable than the methods used in our previous work (35), the chief reason being that the *linea* is defined in terms of a progress variable along a locally determined direction, rather than along some arbitrary global coordinate, although the latter method can be successful over much of the *linea* (30). All of the intersections were verified by computing the geometric phase factor on transporting the eigenvector of the lower state around the intersection in the plane spanned by the Hessian variables. (Note that the *lineae* must either be closed curves or must extend to infinity in order that it be unambiguous whether a given closed curve encircles a *linea* or not. All of the curves discussed here do in fact satisfy this condition.)

A special difficulty arises when there is near degeneracy of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

the lowest Hessian eigenvalue with some of the others. This occurs, for example, when two *lineae* meet each other (e.g., when a *linea* of C_s symmetry meets a *linea* of higher symmetry). In such a case, it is necessary to form a linear combination of the corresponding Hessian eigenvectors so as to project out the unwanted direction. For a *linea* of C_s symmetry, it is convenient to define a *local direction*, $\hat{t}$, which is the direction connecting the two most recently determined points on the *linea*. The matrix of the projector onto $\hat{t}$ is then

$$[11] \qquad P_t = \begin{pmatrix} t_1^2 & t_1 t_2 \\ t_1 t_2 & t_2^2 \end{pmatrix}$$

where $t_i = \hat{t} \cdot c_i$. The desired direction of the *linea* is then obtained from

$$[12] \qquad \hat{l} = (1, 1, 1)(c_1, c_2)p$$

where p is the (column) eigenvector of P_t corresponding to the largest eigenvalue.

For a *linea* in C_{2v} configuration space, a slightly modified procedure is needed: symmetry coordinates are defined as

$$[13] \qquad X = u$$

$$[14] \qquad Y = (2w + v)/\sqrt{5}$$

$$[15] \qquad Z = (w - 2v)/\sqrt{5}$$

Two of these, X and Y, span the C_{2v} space when $Z = 0$, so that if $\hat{t}$ be taken as the unit vector $\hat{Z}$ and the eigenvector p be taken to correspond to the *smallest* eigenvalue of the projector, then eq. [12] eliminates the non-C_{2v} component from the estimated *linea* direction. A similar procedure obtains for a *linea* in linear configurations: the nonlinear component, X, must be projected out. In following a C_s *linea* in regions where it approaches close to a *linea* of higher symmetry, the desired direction is that which has the highest projection onto the component perpendicular to the higher symmetry: $\hat{t} = Z$ for approach to C_{2v} and $\hat{t} = X$ for approach to the linear configuration.

This method of handling degeneracies turns the difficulties experienced earlier (35) to an advantage: not only does it allow a determination of a specified *linea* even when it is in the neighbourhood of *lineae* of differing symmetry, but it can also be used as a diagnostic for the presence of C_s *lineae*, which are normally quite difficult to find. This is illustrated in Fig. 3, which shows the logarithm of the Hessian eigenvalues along C_{2v} branches of *lineae* 2/3 and 3/4. The lowest eigenvalue should, of course, be zero, as explained above. The second eigenvalue is degenerate with the first at the positions marked with C_s. (Note that the C_{2v} branch of *linea* 3/4 is a closed curve.) Hence, it is possible to locate a line of conical intersection in C_s configurations by investigating the behaviour of the Hessian eigenvalues along lines of intersection in higher symmetry. The latter lines can often be determined very easily from contour diagrams of the energy difference between states belonging to different irreducible representations. This procedure lends itself readily to *ab initio* calculations. The two spikes marked "mini C_s" show places where a C_s *linea* makes a small loop away from the C_{2v} symmetry and then returns. We have not investigated this feature further; we mention it only to illustrate the sensitivity of the method for locating *lineae* of accidental intersections.

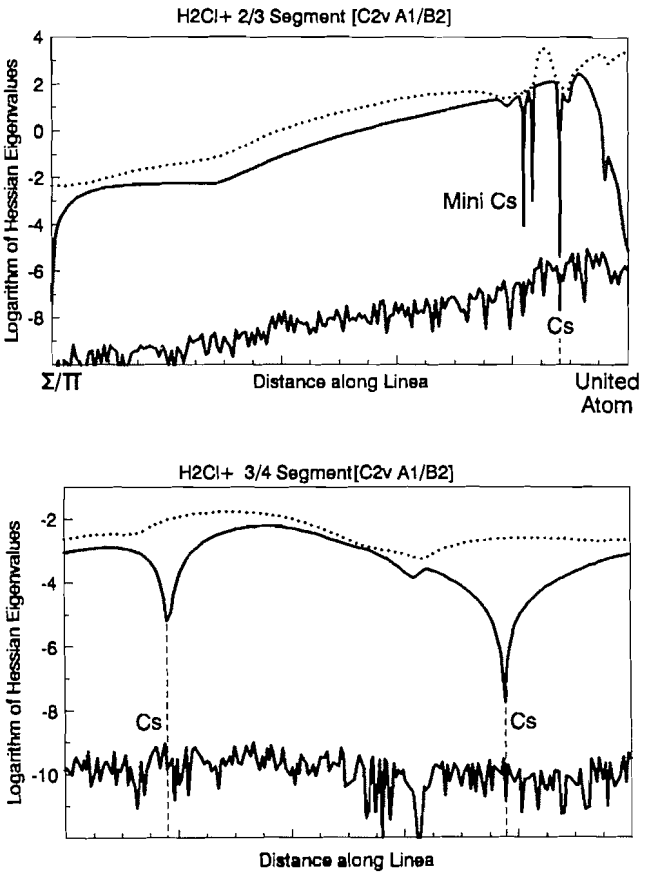

FIG. 3. Logarithm of the 3 Hessian eigenvalues along the C_{2v} branches of *linea* 2/3 (top) and *linea* 3/4 (bottom). The abscissae are in arbitrary units and run over the whole length of the C_{2v} branches shown in Figs. 4 and 6. The positions where the C_{2v} *lineae* intersect with the C_s *linea* are indicated by "C_s". The 3/4 branch is a closed loop: see the projection in Fig. 6.

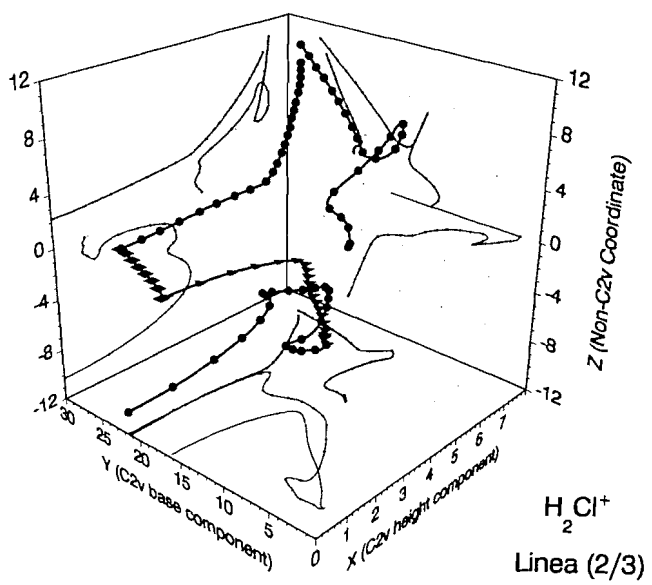

FIG. 4. *Linea* 2/3 referred to C_{2v} symmetry coordinates. The C_s branches are marked with circles, the C_{2v} branch (in the plane $Z = 0$) with triangles, and the linear branch (in the plane $X = 0$) with squares. The C_s projections onto the planes are marked with circles, the other projections are unmarked.

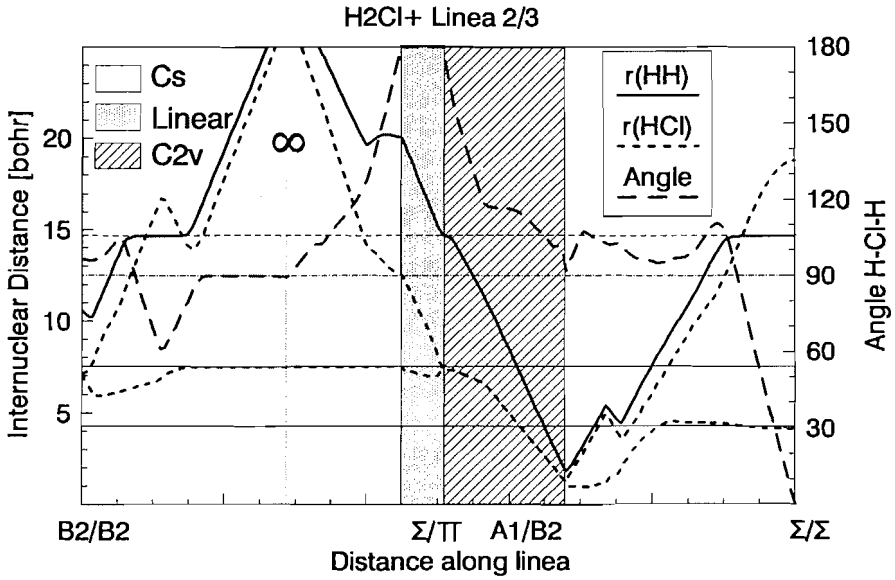

FIG. 5. *Linea* 2/3. Internuclear distances (HH solid lines, HCl short dashed lines) and the H—Cl—H angle (long dashes) as a function of the distance (in arbitrary units) along the *linea*. The C_{2v} and linear regions are emphasized by means of the hatched and dotted backgrounds, respectively. The special points (r(H—Cl) = 4.269 and 7.5185 bohr; r(H—H) = 14.672 bohr) are indicated by thin horizontal lines, solid for HCl, dashed for HH. At the vertical line marked with ∞, the first and second C_s branches approach the asymptotic region H + HCl.

Results

In this work, we are mainly interested in the *lineae* of C_s symmetry. Nevertheless, it is necessary to consider *lineae* of higher symmetry as well, for we have found that the C_s variety proceed until they arrive at one of four types of end point: (*i*) the point at infinity (i.e., one of the asymptotic regions of the potential energy surface, (*ii*) a united atom limit — one, two, or three of the internuclear distances approach zero, (*iii*) a C_{2v} configuration, or (*iv*) a linear configuration. The *lineae* are therefore either closed curves or extend to infinity. In cases (*iii*) and (*iv*) there are two possibilities depending on whether the two intersecting states belong to the same irreducible representation of the higher symmetry state or not. If they do, the C_s *linea* terminates, since in general there cannot be a *line* of intersection in a collinear or C_{2v} subspace (the non-crossing rule!), so that the terminating point is indeed an endpoint. Otherwise, it is usual for the endpoint of the C_s *linea* to lie on a line of intersection in the higher symmetry subspace. This makes it possible for two C_s *lineae* to be connected via higher symmetry *lineae*.

In Fig. 4 the intersection between states 2 and 3, *linea* 2/3, is displayed as a line in 3-space referred to the C_{2v} symmetry coordinates (X, Y, Z) (see eqs. [14] and [15]). This coordinate system is advantageous because the symmetry of each branch of the *linea* is immediately evident: linear configurations must lie in the YZ plane, $X = 0$, and C_{2v} configurations in the XY plane, $Z = 0$. The five branches of the *linea* are represented by thick lines with symbols on them: circles for C_s, triangles for C_{2v}, and squares for linear symmetry. The projections of the C_s branches on each of the three coordinate planes are also shown, as well as two of the projections of the C_{2v} branch (the third projection is just a line in the on the X-axis since the whole curve lies in the XY plane). The internuclear distances and the H—Cl—H angle along *linea* 2/3 are displayed in the companion diagram, Fig. 5. This *linea* starts at an isolated C_{2v} point, where the intersection is between two states of $^1B_2$ symmetry. It follows a C_s branch to the point at infinity corresponding to the asymptotic region H + HCl with angle H—Cl—H = 90° and r(H—Cl) ≈ 7.517 bohr, a distance very close to, but less than, the crossing between two states in the isolated HCl molecule, r(H—Cl) = 7.5185 bohr. At infinity, this branch meets another one with r(H—Cl) = 7.520 bohr (slightly greater than the asymptotic crossing distance), also of C_s symmetry, which proceeds towards the YZ plane to a point of intersection between $^1\Sigma^+$ and $^1\Pi$ states in the linear configuration H—Cl—H. The collinear branch is part of a *linea* that connects a point at infinity, again having r(H—Cl) ≈ 7.517 bohr, with the $D_{\infty h}$ point having r(H—Cl) = 7.386 bohr. The latter point is also the endpoint of a C_{2v} *linea*, which goes to a united atom limit, r(H—H) → 0, r(H—Cl) → 1.524 bohr. Just before reaching this limit, the C_{2v} branch meets another C_s branch at the point r(H—H) = 1.859 bohr, r(H—Cl) = 1.292 bohr. The final branch proceeds to negative values of Z, eventually terminating in a collinear H—H—Cl configuration where there is an intersection of two $^1\Sigma^+$ states for r(H—H) = 14.672 bohr, r(H—Cl) = 4.142 bohr. These values lie very close to curve crossings in the isolated molecules H_2 and HCl: 14.672 and 4.2685 bohr, respectively. The curve crossings in the isolated molecules, collected in Table 1, are indicated by thin horizontal lines in Fig. 5.

TABLE 1. Crossing points in the diatomic curves

Molecule	State indices	Crossing (bohr)	Description of states	
HCl	2/3	4.2685	$HCl^+(A\ ^2\Sigma^+)$	$HCl(X\ ^1\Sigma^+)$
HCl	2/3	7.5185	$HCl^+(A\ ^2\Sigma^+)$	$HCl^+(^2\Pi)$
HCl	3/4	7.4067	$HCl(X\ ^1\Sigma^+)$	$HCl^+(^2\Pi)$
HCl	4/5	7.328	$HCl(^1\Pi)$	$HCl^+(^2\Pi)$
H_2	3/4	14.6704	$H_2^+(X\ ^2\Sigma_g^+)$	$H_2^+(^2\Sigma_u^+)$

Conical intersections between states 3 and 4 are presented in Fig. 6 and its companion Fig. 7. This *linea* consists of three branches. It starts in a linear configuration H—Cl—H with r(H—H) = 12.57 bohr and r(H—Cl) = 5.63 bohr. From there it goes via a C_s *linea* to a C_{2v} point with r(H—H) =

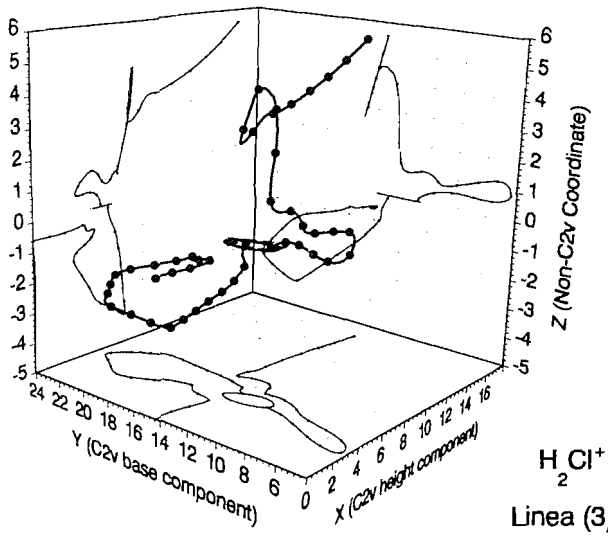

FIG. 6. *Linea* 3/4 referred to C_{2v} symmetry coordinates. The C_s branches are marked with circles, the C_{2v} branch (in the plane $Z = 0$) with triangles. The linear branches (in the plane $X = 0$) leading to the asymptotic region H + HCl are not shown. The C_s projections onto the planes are marked with circles, the other projections are unmarked.

11.63 bohr and r(H—Cl) = 7.85 bohr. The latter lies on a C_{2v} *linea* that is the closed curve for which the Hessian eigenvalues of Fig. 3 were computed. A second C_s branch leaves this curve at the point r(H—H) = 9.73 bohr and r(H—Cl) = 6.79 bohr, and proceeds to the point at infinity corresponding to Cl + H_2 with r(H—H) = 14.672 bohr. One could perhaps allow the existence of a fourth branch going from the starting linear configuration alone a linear line of $^1\Sigma^+$–$^1\Pi$ intersections in two directions, one leading to the point of infinity with r(H—Cl) = 7.43 bohr and the other to the point at infinity with r(H—Cl) = 0.89 bohr, both values of r(H—Cl) corresponding to crossings in the isolated molecule. To avoid clutter, this branch is not shown in the diagrams. Information about the branches of the *lineae* is collected in Table 2.

A few calculations were carried out with a second model Hamiltonian differing from the first only in the $H_2^+(X\ ^2\Sigma_g^+)$ and $H_2^+(^2\Sigma_u^+)$ long-range interactions. The main model has a spurious crossing of these curves at r(H—H) = 14.672 bohr, as shown in Table 1. In the second model, this crossing was removed, altering the locus of the *lineae* at long range (see C_s-b in Table 2). This was done in order to confirm the notion that the accidental crossings in the diatomic curves are intimately bound up with the existence and behaviour of the accidental intersections at finite distances.

Discussion

Using the eigenvalues of the Hessian matrix as a tool for determining the direction(s) of *lineae* near a given point, we have succeeded in tracing out the lines of intersections (2/3) and (3/4) in their entirety. The *lineae* reported in the previous work have been verified and extended and we have shown that they are segments of the *lineae* reported here (with minor differences owing to a slightly different numerical representation of the long-range interactions). In addition, a connecting C_s segment was found by inspecting the Hessian eigenvalues along the *lineae* of higher symmetry, demonstrating that such a method may be of use in searching for C_s *lineae* in other systems.

The shape of the *lineae* is not at all smooth: the figures show that the internuclear distances can change abruptly as a function of the distance along the *linea*. Closer inspection reveals that there are certain "special" values of the distances at which this occurs. In fact, these special values lie very close to points of intersection of the diatomic curves in the asymptotic region. The most important of these are collected in Table 1: at r(H—Cl) = 4.2685 bohr, there is a crossing between the HCl($X\ ^1\Sigma^+$) and HCl$^+$($A\ ^2\Sigma^+$) states; at r(H—Cl) = 7.4067 bohr and r(H—Cl) = 7.5185 bohr there are crossings of the HCl$^+$($^2\Pi$) state with the HCl($X\ ^1\Sigma^+$) and HCl$^+$($A\ ^2\Sigma^+$) states, respectively; at r(H—H) = 14.672 bohr, the $H_2^+(^2\Sigma_u^+)$ state crosses with the $H_2^+(X\ ^2\Sigma_g^+)$ state (a spurious crossing due to inaccuracies in the diatomic input). These crossings play an important role in governing the shape of the various *lineae* because, in the neighbourhood of these points, the character of the adiabatic states changes abruptly. Now the line of intersection is usually associated with some property of the molecule (e.g., the charge distribution), which in turn depends upon the weights of the valence-bond structures in the wave function, and these change abruptly in the region of the crossings. This results in the *linea* undergoing a sharp change in direction in order to stay in a region that preserves the character of the wave function. For example, in Fig. 7, in the region where the progress variable leaves the C_{2v} area heading toward ∞, the lower r(H—Cl) distance increases steadily until it arrives in the neighbourhood of the value 7.39, where, as seen from Table 1, there are several successive crossings because the HCl$^+$($^2\Pi$) state intrudes upon the scene. At values of r(H—Cl) < 7.386, the dominant valence-bond structures in states 3 and 4 of the polyatomic molecule involve the HCl($X\ ^1\Sigma^+$) and HCl($^1\Pi$) states of the diatomic HCl whereas, at larger values, it is the HCl($X\ ^1\Sigma^+$) and HCl$^+$($^2\Pi$) states. At 7.4067 bohr, the latter two states merely change their order but then, at r(H—Cl) = 7.5185 bohr, the wave function would shift to involve the HCl($X\ ^1\Sigma^+$) and HCl$^+$($A\ ^2\Sigma^+$) states. To avoid this, the progress of the smaller HCl distance is arrested temporarily until the H_2 distance increases to a crossing region between the $H_2^+(X\ ^2\Sigma_g^+)$ and $H_2^+(^2\Sigma_u^+)$ states, where the increase in r(H—H) is arrested, allowing r(H—Cl) to increase again. The crossing in the H_2^+ molecule is spurious in our model; if we remove this crossing, then the increase in r(H—H) is not arrested and r(H—Cl) remains at a value of 7.5 bohr. Similar behaviour is seen for *linea* 2/3 in Fig. 5, but for r(H—Cl) $\approx$ 4.265 bohr. This behaviour is very suggestive of an influence of some sort of symmetry associated with the *linea* itself but we have not been able to identify it as yet. Further study utilizing a simpler model would perhaps clarify the behaviour of the intersections.

The use of model potential energy surfaces, in particular the LEPS model, in the study of chemical dynamics has been extremely useful in uncovering the salient features of many systems and has formed the basis for very widely applicable generalizations such as Polanyi's rules. We are therefore hopeful that this work also may be useful in understanding the overall behaviour of accidental conical intersections. Our results are based on a fairly accurate semi-empirical model that gives a very good representation of the shape of the surfaces and the regions of crossing of the first three surfaces in the strong bonding region: the results at very short range and very long range (e.g., >8 bohr) are not reliable, so the *exact* loci of the *lineae* are certainly questionable. Nevertheless, the nature of the accidental intersections and the fact of their existence is, in our opinion, reliable. The main features appear to be robust in the intermediate range. We do not believe

Linea	Branch	First endpoint		Second endpoint	
2/3	C_s	H—Cl—H $C_{2v}(^1B_2/^1B_2)$	r(H—H) = 10.58 r(H—Cl) = 7.10	H + ClH r(H—Cl) = 7.517	Angle H—Cl—H = 90°
2/3	C_s	H—Cl—H $C_{\infty v}(^1\Sigma^+/^1\Pi)$	r(H—H) = 20.08 r(H—Cl) = 7.512	H + ClH r(H—Cl) = 7.520	Angle H—Cl—H = 90°
2/3	$C_{\infty v}$	HCl + H $C_{\infty v}(^1\Sigma^+/^1\Pi)$	r(H—Cl) = 7.517	H—Cl—H $D_{\infty h}(^1\Sigma^+/^1\Pi)$	r(H—H) = 14.772 r(H—Cl) = 7.386
2/3	C_{2v}	r(H—H) → 0 $C_{2v}(^1A_1/^1B_2)$	r(H—Cl) = 1.524	H—Cl—H $D_{\infty v}(^1\Sigma^+/^1\Pi)$	r(H—H) = 14.772 r(H—Cl) = 7.386
2/3	C_s	H—Cl—H $C_{2v}(^1A_1/^1B_2)$	r(H—H) = 1.859 r(H—Cl) = 1.292	H—H—Cl $C_{\infty v}(^1\Sigma^+/^1\Sigma_+)$	r(H—H) = 14.672 r(H—Cl) = 4.142
3/4	C_s	H—Cl—H $C_{2v}(^1A_1/^1B_2)$	r(H—H) = 11.628 r(H—Cl) = 7.848	H—CL—H $C_{\infty v}(^1\Sigma^+/^1\Pi)$	r(H—H) = 12.566 r(H—Cl) = 5.630
3/4	C_{2v}	H—Cl—H $C_{2v}(^1A_1/^1B_2)$	Closed loop		
3/4	C_s	H—Cl—H $C_{2v}(^1A_1/^1B_2)$	r(H—H) = 9.733 r(H—Cl) = 6.789	Cl + H_2	r(H—H) = 14.672
3/4	C_s-b	H—Cl—H $C_{2v}(^1A_1/^1B_2)$	r(H—H) = 9.733 r(H—Cl) = 6.789	H—Cl—H $C_{2v}(^1A_1/^1B_2)$	r(H—H) = 11.423 r(H—Cl) = 7.844

that the C_s *linea* result solely from neglect of terms in the Hamiltonian. The intersections occur for very good physical reasons and are evidently related to the crossing of diatomic curves in the asymptotic region. Note that such crossings do not of themselves imply the existence of conical intersections at finite distances and they are not necessarily connected with them by a *linea*; for that, it is necessary that the direction of the *linea*, as determined by the Hessian eigenvectors, lead from the point at infinity to finite configurations. This is not the case in a molecule such as H_3^+, even though the first two states cross in the same manner as the second and third states of H_2Cl^+. The reason is simply that, at large distances, the interaction is such that the Hessian eigenvector with the lowest eigenvalue is tangential to a large circle drawn around the H_2 molecule. In H_2Cl^+, there is a dipole moment in the HCl molecule and charge transfer in HCl^+. It is then clear that for the configuration H^+ + HCl, the proton can approach the HCl molecule perpendicular to the bond axis in such a way that there is no net ionic interaction (at large distances the covalent interaction is negligible); the approach of an H atom to HCl^+ entails very little interaction at large distances, so that the difference in energy between the two states corresponding to these valence-bond structures can be kept equal to the value at infinity. But the latter is zero if there is a curve crossing! This is precisely the explanation for the behaviour of *linea* 3/4 in the left part of Fig. 7. Thus, the conical intersections observed here are the result of the physical aspects of the model and not of the simplifications that have gone into it, whereby the latter undoubtedly also play a role in determining the exact topology of the *lineae*.

In summary, by using a model Hamiltonian, we have been able to study some of the accidental conical intersections in the H_2Cl^+ molecule in fair detail and have shown their connection with symmetry-allowed intersections and with the behaviour of diatomic interaction potentials. Such model calculations ought to be an aid in finding the location of these intersections with

For personal use only.

more precise methods. In particular, searching for degeneracy in the Hessian matrix eigenvalues along lines of symmetry-allowed intersections provides a powerful way of uncovering the whereabouts of accidental intersections if they exist at all in the molecule under investigation. The methods here could also be extended to molecules of more than three atoms, where the existence of accidental degeneracies is even more probable.

The elementary reaction dynamics of methyl iodide in two Rydberg states leading to an iodine and a methyl radical occur on the femtosecond time scale (M.H. Janssen, M. Dantus, H. Guo, and A.H. Zewail. Chem. Phys. Lett. **214**, 281 (1993)). In this article, we consider the dynamics of this elementary process which involves both the Rydberg and valence states. Direct comparisons are made between theory and experiment with special focus on the following observations: large isotope effects, mode dependence of the predissociation rates, and coherence effects. The quantal molecular dynamics in two-dimensions show that the initial wave packet motion occurs along a vibrational mode involving the light atoms accompanied by transitions from the Rydberg state to the repulsive state; subsequent dynamics on the dissociative state lead to the C—I bond cleavage. The theoretical calculations also give the decay behavior of the Rydberg states with lifetimes in agreement with those observed in the femtosecond experiments. Moreover, the large isotope effect in observed predissociation rates of CH_3I and CD_3I has been successfully reproduced by the same model. The two-dimensional dynamics underscore the shortcomings of a one-dimensional picture in which the C—I serves as the sole reaction coordinate. The model presented here offers a viable mechanism for the dynamics of these Rydberg states.

HUA GUO et AHMED H. ZEWAIL. Can. J. Chem. **72**, 947 (1994).

La dynamique de la réaction élémentaire de l'iodure de méthyle dans les deux états de Rydberg conduit à des radicaux iode et méthyle dans un temps de l'ordre de la femtoseconde (M.H. Janssen, M. Dantus, H. Guo et A.H. Zewail. Chem. Phys. Lett. **214**, 281 (1993)). Nous considérons dans cet article la dynamique de ce processus élémentaire qui implique à la fois les états de Rydberg et la valence. On a comparé directement la théorie et l'expérimentation en mettant l'accent spécialement sur les observations suivantes: un large effet isotopique, l'influence du mode sur la vitesse de prédissociation et les effets de cohérence. La dynamique moléculaire quantique en deux dimensions montre que le mouvement du paquet d'ondes initial se produit le long d'un mode vibrationnel impliquant les atomes légers accompagné des transitions à partir des états de Rydberg jusqu'à l'état de répulsion; les dynamiques subséquentes relatives à l'état de dissociation conduisent au clivage de la liaison C—I. Les calculs théoriques donnent également la dégradation des états de Rydberg avec des temps de vie correspondant à ceux observés dans les expériences de l'ordre de la femtoseconde. De plus, le même modèle a permis de reproduire avec succès, le large effet isotopique dans les vitesses de prédissociation observées du CH_3I et du CD_3I. La dynamique bi-dimensionnelle met en évidence les défauts d'une image monodimensionnelle dans laquelle la liaison C—I représente la seule coordonnée de la réaction. Les modèles présentés offrent un mécanisme viable pour la dynamique de ces états de Rydberg.

[Traduit par la rédaction]

1. Introduction

The elementary processes of dissociation in methyl iodide (CH_3I) and its deuterated isotope (CD_3I) have been the subject of intensive investigations, both experimentally and theoretically. Most studies, guided by the theoretical analysis of Mulliken and Teller (1), were concerned (2–32) with the first absorption band which is structureless from 350 to 190 nm with a peak at 260 nm (2). This so-called A band arises from an electronic transition from a non-bonding $5p\pi$ orbital to a C—I antibonding σ orbital ($n \rightarrow \sigma^*$). Due to the strong spin–orbit coupling of iodine, five electronic states are formed in this manifold. They are, according to Mulliken (1), $^1Q_1(\Pi)$, $^3Q_2(\Delta)$, $^3Q_1(^3\Pi)$, $^3Q_{0+}(^3\Sigma^+)$, and $^3Q_{0-}(^3\Sigma^-)$. Since all the five states are repulsive in the C—I coordinate, the absorption of photon results in prompt fragmentation of methyl iodide. Both real-time measurements (3) and photofragment anisotropy analyses (4) have shown that the dissociation time in the A band is of the order of 100 fs.

The dissociation products from the *A* state excitation include both the ground and excited spin–orbit states of the iodine atom and methyl radical in its ground electronic state (5–8). the ro-vibrational state distributions of the methyl radical have been determined using various experimental techniques. It has been shown that the majority of dissociation energy is channeled into the translational recoil of the fragments and a relatively small portion of the excess energy is disposed into the umbrella bending (ν_5) of the methyl fragment (9–16) and its rotation about the axis perpendicular to the C_3 axis (14, 17, 18). Resonance Raman studies of the dissociation process have demonstrated the involvement of various vibrational modes in the process of fragmentation (19–23).

The dissociation from the A band is reasonably well understood theoretically. *Ab initio* potential energy surfaces have been calculated for the A band states (24, 25). It has been suggested (26) that the dissociation dynamics of CH_3I can be modeled by a collinear triatomic model where the umbrella bend of the CH_3 moiety can be approximated by a stretch between C and H_3. This approximation seems to be adequate for simulating most experimentally observed data. Both quantal (26–29) and classical (30–32) dynamical studies based on this model have been reported and the agreement between the two is generally very promising. Very recently, one of us (33) has reported a three-dimensional quantal study of the dissociation of methyl iodide in the A band, using the *ab initio* potential energy surfaces calculated by Morokuma and co-workers (25). Both the rotational and vibrational distributions of the methyl fragments as well as the I^* yield are in good agreement with latest experimental data (14–18).

In this work, we focus on the dissociation dynamics of several Rydberg states which have higher absorption bands. Despite the vast literature on the A band dissociation, there is little known about the Rydberg states. The Rydberg character of the series can be largely attributed to transitions from a $5p$ orbital to a higher atomic Rydberg orbital, such as $6s$ or $6p$, of the iodine atom (1). The Rydberg series starts at 200 and 184 nm with two distinct bands, known as the B and C bands (34, 35). Both absorption bands are the result of an excitation of a non-bonding $5p\pi$ electron to the first Rydberg orbital ($6s$) of the iodine atom. The strong spin–orbit coupling at the iodine atom causes the splitting of the ion core into $^2E_{1/2}$ and $^2E_{3/2}$ in C_{3v} or $^2\Pi_{1/2}$ or $^2\Pi_{3/2}$ in $C_{\infty v}$, and interactions between the core and Rydberg electron yield five electronic states in two groups separated by approximately 5000 cm^{-1} (1). The B band is derived from the two lower states with a $^2E_{3/2}$ ion core, and the other three states (two are near degenerate) with a $^2E_{1/2}$ ion core are responsible for the C band. Traditionally (36), these states are named as the [1], [2], [3], and [4] states of the $6s$ transition. Similar arguments apply to higher Rydberg absorption bands which are originated from excitations of a non-bonding $5p\pi$ electron to higher Rydberg orbitals of iodine, such as $6p$ and $7s$, etc. In general, each Rydberg manifold splits into two bands characterized by the $^2E_{3/2}$ and $^2E_{1/2}$ ion cores with two distinguishable states for each band. Similar rules apply to the CH_3I^+ ion which can be loosely considered as a Rydberg state with the Rydberg electron infinitely far from the ion core.

The absorption spectra of these Rydberg states have been recorded by several groups (36–44). Felps et al. (36) have measured the one-photon absorption spectra of the B and C bands and extracted frequencies of various modes from the spectra. Resonance enhanced multiphoton ionization (REMPI) and other methods have also been employed to obtain the absorption spectra of methyl iodide (37–43). In particular, Vaida et al. (39–41) have examined the absorption of CH_3I and its clusters with a special interest on the effect of the cluster induced potential shift on the predissociation (42).

The higher $5p\pi \rightarrow 6p$ transitions near 170 and 150 nm have been investigated by Gedanken et al. (44) using (2 + 1) REMPI and by Tsukiyama et al. (45) using fluorescence spectroscopy. Similar to the $5p\pi \rightarrow 6s$ transitions, two bands with a separation of 5000 cm^{-1} were observed. The assignment of the vibronic transitions in this region was made by Gedanken et al. (44). In a recent study by Dobber et al. (46), who used both picosecond and nanosecond REMPI spectroscopy coupled with photoelectron spectroscopy (PES), a comprehensive analysis has led to the reassignment of the $6p$ and $7s$ Rydberg manifolds. These authors (46) were able to identify the feature near 311 nm (155.5 nm in two photons) as the band origin of the $5p\pi \rightarrow 7s$ transition, instead of the ν_6 overtone of the $5p\pi \rightarrow 6p$ transition assigned previously (44).

From the above studies, it has been realized that the transitions from the ground state to various Rydberg states are rather vertical. The vibrational progressions are short and the band origins usually represent the strongest transitions. This is because the Rydberg excitation (including the ionization) from a non-bonding orbital ($5p\pi$) does not significantly alter the molecular geometry of the molecule (or ion). As a result, the vibrational frequencies as well as the equilibrium geometry of various Rydberg states are very similar to those of the ground electronic state (37, 38, 44, 46, 47). All the Rydberg features of methyl iodide are significantly broadened. The broadening is associated with the predissociation of these Rydberg states since the line width is less than the vibrational spacing.

The rates of predissociation have been deduced for the first two Rydberg states (the B and C bands) using various techniques. An early photofragment anisotropy analysis at 193 nm (48) estimated that the lifetime of CH_3I is approximately 150 fs. Ziegler and co-workers (49) have deduced the lifetimes of the B (50–52) and C (53) Rydberg states by monitoring the depolarization ratio of Raman scattering, in which the average rotation of the molecule is utilized as an effective clock. The lifetimes of the B and/or C Rydberg states obtained by these authors range from 10^2 to 10^3 fs and the lifetime data exhibit strong isotopic and mode selectivities (51). For instance, it was found (51) that the lifetime of CD_3I is a factor of two longer than that of CH_3I. Recently, information on lifetimes was also obtained from the direct measurement of the absorption profile, as reported by Syage (43).

Large discrepancies were found among reported lifetimes in the *B* and *C* states. For example, Sapers and Donaldson (38) reported a much faster predissociation rate for the first ν_3 (C—I stretch) overtone in the B band than the band origin. This conclusion was advanced to explain the observation that the ν_3 feature is present in the dimer but disappears in the monomer. Wang and Ziegler (51), from the Raman analysis of the same system, concluded that the decay rate of the first ν_3 overtone is much slower than both the band origin and the second ν_3 overtone. A simple Franck–Condon model was proposed by these authors to rationalize the experimental findings (51). Both results (38, 51), although in opposite directions, pointed to strong mode specificity in the predissociation of methyl iodide Rydberg states. The latest study on the same system (43), however, reported very weak mode-specific predissociation rates for the band origin and the first ν_3 overtone.

Theoretically, the predissociation of Rydberg states of methyl iodide have been studied by several groups. Donaldson et al. (54) reported classical trajectory studies on the predissociation in the B band. These authors utilized empirical potential energy surfaces to investigate the dissociation dynamics and the influence of the cluster on the curve crossing process. Wang and Ziegler (51) proposed a simple Franck–Condon model to interpret their findings of slow predissociation rate of the ν_3 overtone (see above). These studies have not addressed the femtosecond quantum dynamics and, in particular, the large isotope and coherence effects in the predissociation.

Real-time studies of the Rydberg state dynamics of methyl iodide in a molecular beam have been reported using femtosecond transition-state spectroscopy (FTS) (55). In these studies (56, 57), a molecular beam of methyl iodide was excited by a femtosecond (fs) pulse near the $6p$–$7s$ manifold (by two photons) and subsequently ionized by another fs pulse. The resulting parent (CH_3I^+) or fragment ions (CH_3^+ and I^+) were detected in a time-of-flight mass spectrometer. The ionization pulse was delayed from the excitation pulse so that the dynamics of the Rydberg state could be probed with femtosecond resolution. The transients show that the decay of the Rydberg states is on the femtosecond time scale. For example, the $6p[4]$ band origin was found to decay with a lifetime of 178 fs (56, 57). The experiment also shows that there is a strong isotope effect; the lifetime of CD_3I is at least two times longer than that of the CH_3I. Mode specificity in predissociation dynamics was found to be weak in the energy range studied, as the first ν_3 overtone decays only slightly faster than the band origin (57).

To examine the predissociation dynamics on the femtosecond time scale, we have initiated quantum mechanical studies of these Rydberg states in one and two dimensions (57, 58). Classical mechanics and one-dimensional models are not adequate for reasons discussed below. Our preliminary results in two dimensions show that the large isotope effect in the predissociation of the Rydberg states can be attributed to the involvement of the C—H_3 stretch in the dissociation pathway. The experimentally measured transients for the band origin of the $5p\pi \rightarrow 6p[4]$ transitions were nicely reproduced for both CH_3I and its deuterated isotope CD_3I.

In this contribution, we provide a full account of this two-dimensional quantum mechanical model, focusing on the acute isotope effect in dynamics, mode selectivity, and coherence effects. We discuss the nature of the Rydberg-valence state coupling and the non-adiabatic transition dynamics along the reaction coordinate. This paper is organized as follows. In Section II, a brief description of the experimental results is given. In Section III, we discuss the rationale for the newly developed empirical potential energy surfaces for both the Rydberg and dissociative states, and the time-dependent quantum mechanical method used in our calculations. In Section IV, the results from the calculation are presented. The implication of the results and general features of the Rydberg dynamics are discussed in the Section IV.

II. Experimental

As mentioned earlier and detailed elsewhere (56, 57), the Rydberg levels of CH_3I and CD_3I were selectively excited via a femtosecond coherent two-photon absorption. The dynamics of the Rydberg states were then probed by a temporally delayed pulse which ionizes the parent molecule to its ions. This femtosecond pump–probe scheme (with mass resolution) is different from previous REMPI studies using nanosecond or picosecond lasers (44–46). It is well known that the A band states, which serve as the intermediate states for the two-photon excitation ladder, are strongly dissociative with a lifetime of ~100 fs (3–5). Therefore, unless the pulse duration is comparable with or shorter than the dissociation time of the A states, the two-photon transition will be overwhelmed by the one-photon dissociation in lower A band. This phenomenon is clearly illustrated in the nanosecond REMPI studies of methyl iodide (44, 46) where the spectra are contaminated by sharp transitions of the iodine atoms produced from the A band fragmentation. Such a behavior is avoided in the REMPI using femtosecond pulses.

Femtosecond transients were taken at several pump wavelengths (57). Here, we concentrate on three of them, i.e., transitions to the band origin and first ν_3 overtone of the $6p[4]^2E_{1/2}$ Rydberg state and to the band origin of the $7s[1]^2E_{3/2}$ Rydberg state. The three transitions have two-photon excitation energies of 63 493 cm^{-1} (λ_{pump} = 315 nm), 63 958 cm^{-1} (λ_{pump} = 312.5 nm) and 64 230 cm^{-1} (λ_{pump} = 311.5 nm), respectively. The ionization laser has a wavelength of 618 nm. Figure 1 presents the absorption spectrum of methyl iodide (CD_3I) in this spectral region with the assignments by Dobber et al. (46). Two types of pump pulses with different bandwidths were used in the experiment (57). Their excitation bandwidths are 1.5 and 3.5 nm at ~320 nm, respectively. With the broad bandwidth pump pulse, it is possible to excite two vibronic bands coherently, which may lead to interesting dynamics (57), as discussed below.

The transients measured using narrow bandwidth pump pulses can be fitted to single exponential functions, from which the lifetime of the Rydberg state can be obtained. Table 1 lists the lifetimes of individual Rydberg states for both CH_3I and CD_3I. It is clear that no mode selectivity in the lifetime of the $6p[4]^2E_{1/2}$ state is weak in the energy range studied. The lifetime of the band origin (178 fs) is only slightly longer than that of the first ν_3 overtone (141 fs) of $6p[4]^2E_{1/2}$ Rydberg state. The FTS measurements have also been made for the deuterated methyl iodide. It was found that the decay time of CD_3I is generally a factor of two or more slower than that of CH_3I, as shown in Fig. 2*a*.

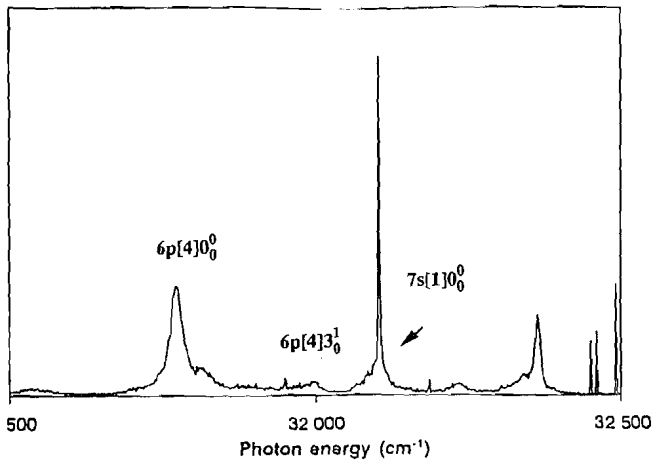

FIG. 1. Experimental Rydberg state absorption spectrum of the CD_3I near 64 000 cm^{-1} (adopted from Dobber et al. (46)). Note that the sharp feature near 32 100 cm^{-1} is due to an atomic iodine transition and is irrelevant to the molecular Rydberg absorption.

TABLE 1. Experimental lifetimes of Rydberg levels

λ^a (nm)	Level[b]	Lifetimes (fs) CH_3I	Lifetimes (fs) CD_3I
315.0/b	$6p[4]0_0^0$	178	333
314.7/n	$6p[4]0_0^0$	183	—
312.7/n	$6p[4]3_0^1$	141	—
312.0/b	$\{6p[4]3_0^1 + 7s[1]0_0^0\}$	141	414
311.3/n	$7s[1]0_0^0$	115	—

[a]Letters n and b denote narrow and broad bandwidths of the pump pulses, respectively.

[b]The vibrational modes of CH_3I are defined as follows (34): the symmetric C—H_3 stretch (ν_1), the umbrella C—H_3 bend (ν_2), the C—I stretch (ν_3), the antisymmetric C—H_3 stretch (ν_4), the CH_3 deformation (ν_5), and the I—C—H_3 bend (ν_6).

The broadening of the pump pulse bandwidth does not significantly alter the lifetime of the band origin of the $6p[4]^2E_{1/2}$ Rydberg state (57). When the broad bandwidth pulse was tuned to 311 nm, however, the experimental transient could not be fitted to a single exponential (see Fig. 2*b*). It seems that the transient contains a double peak structure or a damped oscillatory structure with a frequency of 7×10^{12} Hz (Δt = 140 fs) at the initial stage of the dynamics. A similar effect has been found for the same Rydberg feature of the deuterated methyl iodide. It should be noted that the broad bandwidth pulse covers coherently both the first ν_3 overtone of the $6p[4]^2E_{1/2}$ state and the band origin of the $7s[1]^2E_{3/2}$ state, which have an energy separation of 240 cm^{-1} (see Fig. 1). This point will be discussed in more detail later when we discuss the coherence effect.

III. Theoretical model

A one-dimensional model was recently proposed to simulate the observed femtosecond dynamics of methyl iodide Rydberg predissociation (58). In this model, only the C—I coordinate was considered and the predissociation dynamics were modeled by non-adiabatic transitions from the Rydberg state to a dissociative state using a quantum mechanical method. The results indeed showed a slightly slower predissociation rate for the deuterated methyl iodide than that of CH_3I, but the cal-

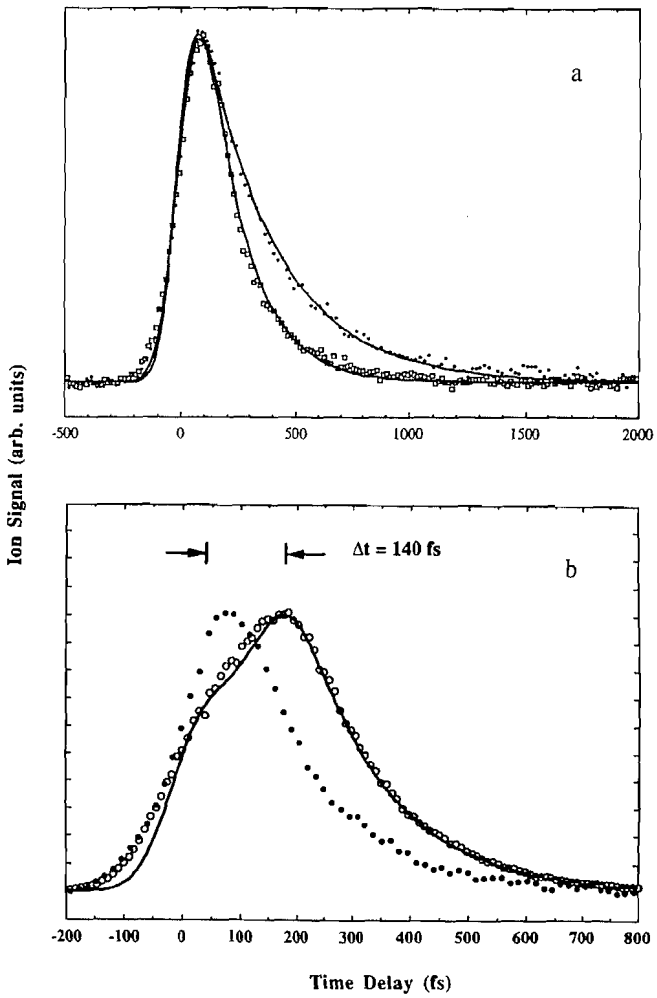

FIG. 2. Femtosecond transients obtained (*a*) for 315 nm two photon excitation for CH_3I (open square) and CD_3I (filled circles) (adopted from Dantus et al. (56)), and (*b*) for 312 nm two-photon excitation of CH_3I (adopted from Janssen et al. (57)). A transient has been superimposed (filled circles) in (*b*) to highlight the large difference in shape occurring when the $6p[4]\ 3_0^1$ and $7s[1]\ 0_0^0$ modes are overlapped by the excitation-laser bandwidth (see text).

culated isotope effect was significantly smaller than the ratio found experimentally. The implication is that the C—I mode may not be the major contributor of the initial predissociation reaction pathway. This can be readily understood in terms of the ratio of the reduced masses of the deuterated and hydrogenated methyl iodide species, which is 1.18. The significant isotope effect indicates the involvement of modes other than the dissociating C—I coordinate. One possibility is that the molecule dissociates through a barrier involving light atom (H or D) tunneling. An overall slowdown of the deuterated predissociation dynamics is hence expected because the tunneling probability decreases exponentially with mass.

We in this work propose a new predissociation mechanism for the CH_3I Rydberg states by including another nuclear mode. Our choice of the additional mode is the ν_1 vibration, i.e., the symmetries C—H_3 stretch (58). The reduced mass of the C—H_3 mode is 1.67 times smaller than that of C—D_3, which may result in a large isotope effect. It should be pointed out that the choice of the ν_1 mode is to some extent arbitrary because the dissociation may well involve one or many other modes that have large mass differences, such as the antisymmetric C—H_3 stretch (ν_4) or umbrella bend (ν_5) modes, etc. Our purpose here is to illustrate the importance of the multidimensional effect on the predissociation dynamics. There is some evidence indicating the involvement of the ν_1 mode in the predissociation. For example, resonance Raman measurements (50–53) on lower B and C Rydberg states concluded that the excitation in the C—H_3 symmetric stretch leads to much faster decay rates for both CH_3I and CD_3I. Photofragmentation experiments (48, 60) also found significant excitation of the fragment C—H vibration and even cleavage of a C—H bond during the dissociation for photon wavelengths shorter than 170 nm. In the next subsection we will develop empirical potential energy surfaces for both the Rydberg and dissociative states for the CH_3I system based on these arguments. The dynamical calculations on these potential energy surfaces will be detailed in the second subsection.

A. Potential energy surfaces

The existing *ab initio* calculations of methyl iodide potential energy surfaces (24, 25) are mainly concerned with the low-lying A manifold and the ground electronic state. Information on the Rydberg potential energy surfaces is mostly from spectroscopic data. It is well known from absorption studies that the potential energy surfaces of the Rydberg states are very similar to that of the ground state. The normal frequencies of the Rydberg states are found to be comparable with those on the ground state (36, 44, 46). The similarities between the ground and Rydberg states of methyl iodide indicate that the Rydberg transitions have little impact on the molecular parameters of the CH_3I ion core. Such a phenomenon is due to the fact that the Rydberg transition is from a non-bonding orbital ($5p\pi$) to an atomic orbital (6*s*, 6*p*, or 7*s* etc.).

Throughout this work, we will limit ourselves to a two-dimensional model which involves both the C—I (ν_3) and C—H_3 (ν_1) vibrational modes. Empirical potential energy surfaces are developed to possess certain important features which will result in an accurate reproduction of experimental findings. For instance, the intersection between the Rydberg state and the repulsive state (i.e. the seam) is arranged in such a way that the isotope effect in the predissociation can be correctly represented. We have manipulated the potentials so that the seam is perpendicular to the C—H_3 coordinate in the Franck–Condon region, rather than to the C—I dissociation mode as assumed in the one-dimensional calculations (58). Thus, the dissociation is more likely to proceed along the C—H_3 coordinate at the beginning of the dissociation. Subsequent dissociation will then lead to the C—I bond cleavage. The resulting reaction pathway therefore involves both the C—I and C—H_3 modes and the dissociation should show a much larger isotope effect due to the significantly larger differences in both the reduced mass and zero point energy during the initial pr dissociation dynamics. The nature of similar reaction path been addressed recently in the work of Nikitin and co-wor (59).

For the sake of simplicity, the potential energy surfa the ground state, the Rydberg state and the repulsive s all written as sums of two one-dimensional potentials. aration of modes in the model potential energy surfa not affect the dynamics because the potentials are relative to each other. The ground electronic st energy surface consists of a Morse function in ordinate (R) and a quadratic potential for C— (*r*):

TABLE 2. Parameters of potential energy surfaces (atomic units[a])

Parameter	Value	Parameter	Value	Parameter	Value	Parameter	Value	Parameter	Value
D_1	0.08741	R_{01}	4.1688	r_{01}	2.0503	α_1	0.9150	ϵ_1	-0.2893
D_2	0.07153	R_{02}	4.2576	r_{02}	2.0503	α_2	0.8295	ϵ_2	0.0000
D_3	18.3673	R_{03}	0.0	r_{03}	2.5503	α_3	1.30	ϵ_3	-0.1044
						α_{23}	0.50		
D_{23}	0.028					$k_{01} = k_{02} = k_{03} = 0.8066$			

[a]1.0 Å = 1.8898 au (Bohr), 1.0 eV = 0.03675 au (Hartree).

$$[1] \qquad V_1 = D_1\{1 - \exp[-\alpha_1(R - R_{01})]\}^2 + \tfrac{1}{2}k_1(r - r_{01})^2 + \epsilon_1$$

Similar form of potential energy function is given for the Rydberg state:

$$[2] \qquad V_2 = D_2\{1 - \exp[-\alpha_2(R - R_{02})]\}^2 + \tfrac{1}{2}k_2(r - r_{02})^2 + \epsilon_2$$

The Morse potential of the Rydberg state is slightly different from that of the ground state, reflecting changes in molecular parameters. The C—H_3 potential, on other hand, is chosen to be identical to that of the ground state. The selection of the potential parameters is consistent with the absorption spectrum of Rydberg states of methyl iodide (44, 46), as shown below.

There is little known about the nature of the dissociative state which interacts with the Rydberg state. This dissociative state is "optically dark" and information from *ab initio* calculations is sketchy. There are some suggestions that it may be one of the five A band states (57). For the zeroth order, we assume that it is repulsive in the C—I coordinate and bound in the C—H_3 coordinate. An exponential function is used for the C—I mode and a harmonic oscillator potential is adopted for the C—H_3 mode:

$$[3] \qquad V_3 = D_3 \exp[-\alpha_3(R - R_{03})] + \tfrac{1}{2}k_3(r - r_{03})^2 + \epsilon_3$$

The C—H_3 potential in eq. [3] has the same force constant as the ground state, but is shifted from the ground state C—H_3 equilibrium geometry. Such a shift enables the dissociative state to form an intersection with the Rydberg state in the direction perpendicular to the C—H_3 coordinate. As discussed earlier, the location of the intersection is vital in simulating the experimentally observed isotope effect. As shown in the one-dimensional calculations (58), the alternative would be an intersection perpendicular to the C—I coordinate, which would only produce a limited isotope effect. It should be pointed out that this potential energy surface is not expected to give the correct asymptotic properties of the CH_3 fragment. However, this deficiency would have little effect on the Rydberg dynamics which occurs at relatively small C—I distances.

The parameters of all the three potential energy surfaces are given in Table 2. The potential energy surfaces of both the bound Rydberg and dissociative states are plotted in Fig. 3. The intersection between the two potential energy surfaces is nearly perpendicular to the C—H_3 coordinate, as shown in the figure. Three dimensional view of the lower adiabatic potential energy surface is also given in Fig. 3*b*.

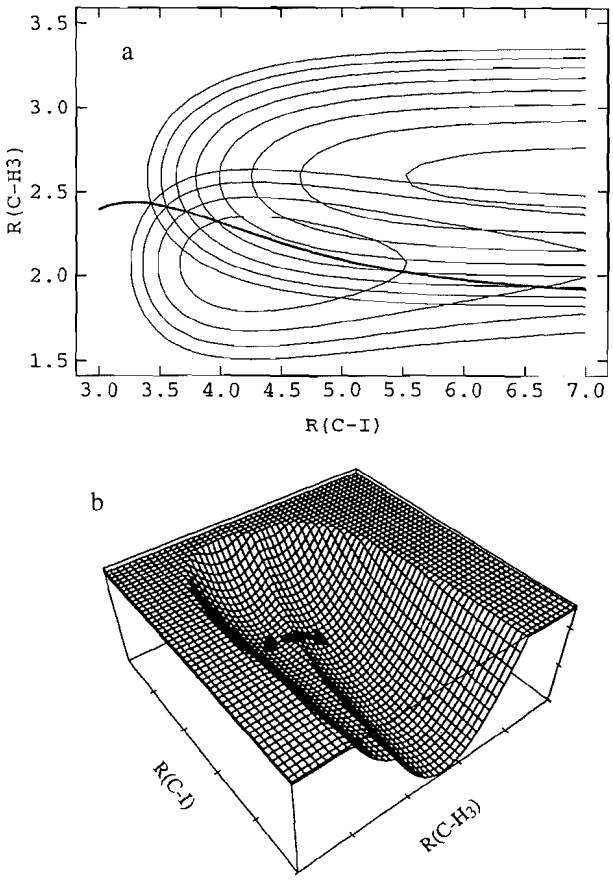

FIG. 3. (*a*) Diabatic potential energy surfaces of the $6p[4]^2E_{1/2}$ Rydberg state and the dissociative state. The intersection (seam) of the two potential energy surfaces is also given with a heavy black line. The energy interval of the contours is 0.03 au. (*b*) Three dimensional view of the lower adiabatic potential energy surface. The C—I and C—H_3 coordinates are from (3.0, 1.0) to (6.0, 4.0) au. The Franck–Condon region is showed by the black spot and the minimal energy path is indicated by the arrow.

B. Time-dependent quantum mechanical theory

Theoretical studies of the femtosecond dynamics have been reported by many groups (see, e.g., refs. 61–71). In this work, we employ a time-dependent quantum mechanical description of such a process. The nuclear Hamiltonian of the methyl iodide Rydberg system including the light–molecular interaction is given in a diabatic representation (58):

$$[4] \qquad \mathbf{H} = \begin{bmatrix} \mathbf{h}_{11} & \mathbf{h}_{12} & \mathbf{0} & \mathbf{0} \\ \mathbf{h}_{12}^* & \mathbf{h}_{22} & \mathbf{h}_{23} & \mathbf{h}_{24} \\ \mathbf{0} & \mathbf{h}_{23}^* & \mathbf{h}_{33} & \mathbf{0} \\ \mathbf{0} & \mathbf{h}_{24}^* & \mathbf{0} & \mathbf{h}_{44} \end{bmatrix}$$

For personal use only.

where the asterisk denotes complex conjugate. There are at least four states involved in the pump-probe experiment (57). An additional state is needed when the electronic coherence effect is studied. The ground electronic state (state 1) is coupled radiatively ($\mathbf{h}_{12}$) with the Rydberg state (state 2). The non-adiabatic or radiationless interaction ($\mathbf{h}_{23}$) between the Rydberg state and the dissociative state (state 3) is responsible for the predissociation. The dynamics on the Rydberg state are probed by a delayed pulse ($\mathbf{h}_{24}$) which promotes the molecule to the ion state (state 4). The diagonal terms in the Hamiltonian matrix consist of the kinetic and potential energy operators:

$$[5] \qquad \mathbf{h}_{ii} = \frac{\mathbf{p}_R^2}{2\mu_R} + \frac{\mathbf{p}_r^2}{2\mu_r} + V_i(R, r)$$

where V_i are the diabatic potential energy surfaces defined in the last subsection; μ_R and μ_r are appropriate reduced masses for the two coordinates. The overall rotation of the parent molecule is not included in our model since the dissociation time of the Rydberg states is much shorter than the rotational period. Other degrees of freedom of methyl iodide are also assumed to be separable from the reaction coordinates and not considered here. The off-diagonal matrix terms representing the non-adiabatic coupling are given by the coupling potential:

$$[6] \qquad \mathbf{h}_{23} = V_{23} = D_{23} \exp[-\alpha_{23}R]$$

The potential parameters for the non-adiabatic coupling are given in Table 2.

Within the dipole and classical electromagnetic field approximations (63, 67, 72), the light-molecular interactions are given by

$$[7] \qquad \begin{aligned} \mathbf{h}_{12} &= A_{12}(t) \exp(i\omega_{12}t) \\ \mathbf{h}_{24} &= A_{24}(t-\tau) \exp(i\omega_{24}t) \end{aligned}$$

where ω_{12} and ω_{24} are the photon frequencies of the pump and probe pulses, respectively. τ denotes the time delay between the pump and probe pulses. The pre-exponential factor $A(t)$ consists of the appropriate transition dipole moment and the temporal shape of the pulse. The transition dipole moments are assumed to be constants of the nuclear coordinates (Condon approximation) because of the lack of information on their coordinate dependence. The laser pulses are assumed to have a Gaussian functional form (63):

$$[8] \qquad A(t-t_0) = A_0 \exp[-\beta(t-t_0)^2/2]$$

Where β determines the temporal width of the pulse and t_0 determines the time of the pulse.

The overall dynamics of the pump-probe process can be obtained by solving the time-dependent Schrödinger equation (atomic units are used hereafter) (58, 63, 67)]:

$$[9] \qquad i\frac{\partial}{\partial t}\begin{bmatrix}\varphi_1\\ \varphi_2\\ \varphi_3\\ \varphi_4\end{bmatrix} = \begin{bmatrix}\mathbf{h}_{11} & \mathbf{h}_{12} & \mathbf{0} & \mathbf{0}\\ \mathbf{h}_{12}^* & \mathbf{h}_{22} & \mathbf{h}_{23} & \mathbf{h}_{24}\\ \mathbf{0} & \mathbf{h}_{23}^* & \mathbf{h}_{33} & \mathbf{0}\\ \mathbf{0} & \mathbf{h}_{24}^* & \mathbf{0} & \mathbf{h}_{44}\end{bmatrix}\begin{bmatrix}\varphi_1\\ \varphi_2\\ \varphi_3\\ \varphi_4\end{bmatrix}$$

where φ_i are the nuclear wavefunctions on individual electronic states. Initially, only the ground state is populated and wavefunctions on all other states are assumed to be zero. The highly oscillatory phase factor in the radiative coupling (i.e., $\exp(i\omega t)$) can be absorbed into the wavefunction. The effect of this operation is to raise the ground state potential by the amount ω_{12} and lower the ion state potential by ω_{24} (63). Therefore, the radiative coupling can be effectively regarded as a time-dependent non-adiabatic coupling. Such a treatment not only avoids oscillations introduced by the field, which may substantially increase the number of temporal steps in numerical integration, but also simplifies the Schrödinger equation dramatically.

It is instructive to rewrite the Schrödinger equation in the integral form. For the Rydberg state, for example, its temporal evolution can be described by:

$$[10] \qquad \begin{aligned} \varphi_2(t) &= -i\int_{-\infty}^{t} dt' e^{[-i\mathbf{h}_{22}(t-t')]}[\mathbf{h}_{12}\varphi_1(t') \\ &\quad + \mathbf{h}_{23}\varphi_3(t') + \mathbf{h}_{24}\varphi_4(t')] \\ &= -i\int_{-\infty}^{t} dt' e^{[-i\mathbf{h}_{22}(t-t')]}[A_{12}(t')\varphi_1(t') \\ &\quad + V_{23}\varphi_3(t') + A_{24}(t'-\tau)\varphi_4(t')] \end{aligned}$$

The population of the Rydberg state as initial $t \rightarrow -\infty$ is zero. The first term in the integrand represents the transfer of population from the ground state to the Rydberg state while the pump pulse is switched on. Population is subsequently lost to the dissociative state via the non-adiabatic coupling V_{23}. When the probe pulse is switched on at time τ, some population is transferred to the ion state, which is represented by the third term. If the laser field is considered to be weak, a perturbative approach can be adopted (65, 69, 72). Under such circumstances, the ground state can be, to the first order, approximated by a stationary state and the population transferred back from the Rydberg state is negligible.

The experimentally measured ion transient signal is considered to be proportional to the asymptotic population of the ion state at different delay times. In our calculations, however, we have imposed an approximation that the ionization photon is on resonance with the energy gap between the Rydberg state and the ion state. Therefore, the ion state population at various delay times (the transient) is directly proportional to the temporal population on the Rydberg state except for a numerical factor representing the pulse shape (69). Photo-induced ionization processes are often considered as a Franck–Condon event. Since the electron ejected by the photon may carry different kinetic energies, even with the same ionization photon wavelength, its treatment requires special care (73, 74). Limited test calculations with all four states have been carried out and the transients obtained are almost identical to the temporal population of the Rydberg state. Another approximation in our calculations is the treatment of the pump pulse. We have assumed that the Rydberg state is prepared by a single photon whereas two coherent photons were used in the experiment to reach the Rydberg state. This simplification should not significantly affect the calculated results, other than the usual change in the pulse width and coherence width with multiphoton processes.

The numerical solution of the time-dependent Schrödinger equation was carried out on a two-dimensional grid. The temporal propagation of the coupled differential equations was accompanied by using a short iterative Lanczos (SIL) method (75). In the SIL method, a N-dimensional Krylov subspace

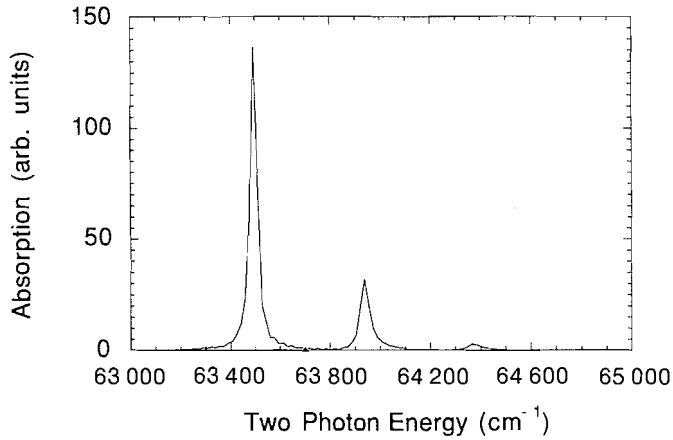

FIG. 4. Calculated absorption spectrum of the $6p[4]^2E_{1/2}$ Rydberg state of CH_3I using the model potential energy surfaces. The spectrum shows the strongest absorption is at the band origin and the ν_3 progression is weak.

spanned by $\mathbf{H}^N\Psi$ is constructed by the Lanczos recursion scheme. The propagator is then obtained from the eigenvalues and diagonalization matrix of effective Hamiltonian matrix in the subspace. It has been shown (75) to be efficient in dealing with both the time-dependent and time-independent Hamiltonians.

The evaluation of $\mathbf{H}\Psi$ was carried out in two steps. The action of the potential energy operator on the wavefunction can be readily obtained by multiplying the two at each grid point. The action of the kinetic energy operator was calculated in momentum space where the kinetic energy operator is diagonal. The wavefunction transformation between coordinate and momentum representations was carried out by using a fast Fourier transform (FFT) method (76). In order to avoid reflection on the edges of the grid, a damping scheme (77) was used at large R to eliminate the wave packet on the dissociative state. Since we are interested in the population decay on the bound Rydberg state, the damping at large C—I distances would not affect our simulation.

IV. Results and discussion

We used in the calculations a grid of 256 × 32 (R, r) points covering a rectangular region from (3.5, 1.0) to (7.5, 4.0) bohr. The temporal interval is 0.5 fs with an eight-dimensional Krylov space for the SIL propagator. The starting point of the propagation is −300 fs and the pump pulse is centered at 0 fs. The laser pulse was chosen to have an 80 fs temporal width (FWHM). The laser field strength was arbitrarily chosen to simulate a weak field scenario. Convergence tests have been conducted with respect to the sizes of both spatial and temporal grids.

A. Absorption, isotope effect, and mode selectivity

Figure 4 is the calculated absorption spectrum of the $6p[4]^2E_{1/2}$ Rydberg state of CH_3I. The spectrum was calculated from the Fourier transform of the autocorrelation function of the Rydberg state with a delta-function excitation pulse (78, 79). The energy resolution of the spectrum is approximately 17 cm^{-1} which corresponds to 2 ps of propagation. The calculated spectrum shows an intensive absorption near 63 500 cm^{-1} and two much weaker overtone excitations near 63 950 and 64 400 cm^{-1}, respectively, in good agreement with experiment (44, 46). Note that the equilibrium geometry

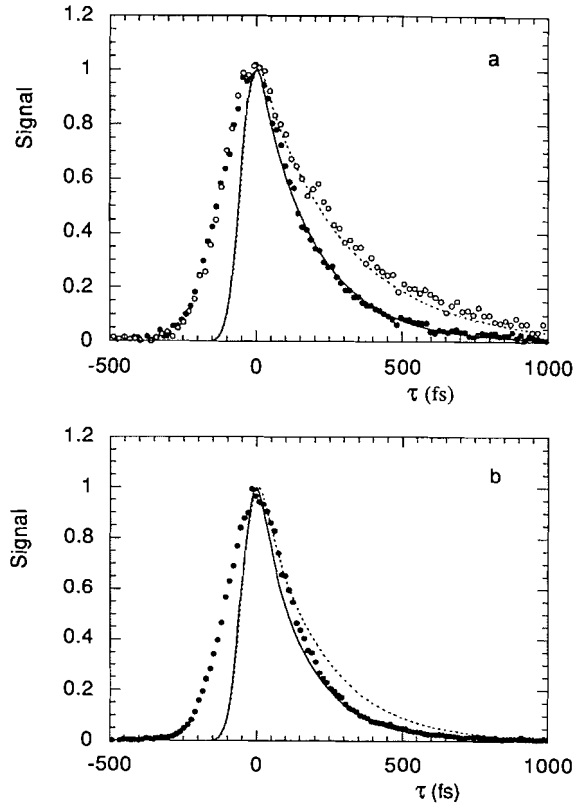

FIG. 5. Calculated femtosecond transient of the $6p[4]\ 0_0^0$ (*a*) and $6p[4]\ 3_0^1$ (*b*) Rydberg levels for both CH_3I (solid line) and CD_3I (dashed line). The experimental data (filled and open circles for CH_3I and CD_3I, respectively) are also given.

of the Rydberg state is shifted to a larger R relative to that of the ground state. The difference in the equilibrium geometry of the two states changes the Franck–Condon overlap and results in a weak progression in ν_3. No progression in the ν_1 mode is observed because the Rydberg state has the same C—H_3 potential as the ground state.

The transients of the first two vibrational levels of the $6p[4]^2E_{1/2}$ Rydberg state for both CH_3I and CD_3I are given in Fig. 5 together with corresponding experimental data. All the curves are normalized to unity and the zero time is arbitrarily chosen. The top panel is for the band origin of the $6p[4]^2E_{1/2}$ Rydberg state. The calculated decay curves not only fit the experimental transients, they also correctly reproduce the isotope effect observed in the experiment. The agreement between the two-dimensional model calculations and the experiments of CD_3I is particularly encouraging since our potential parameters were only adjusted to fit the CH_3I transient. Comparison with previous one-dimensional calculations (58) strongly supports the argument that the significant isotope effect is due to the involvement of tunneling of the light atoms during predissociation. The lower panel in Fig. 5 gives the transients of the first overtone of the ν_3 mode on the $6p[4]^2E_{1/2}$ Rydberg state. Experimental data are only available for the CH_3I species. The agreement again is rather satisfactory. The calculated results support the experimental observation that the ν_3 vibrational overtone predissociates slightly faster than the band origin.

Figure 6 shows a cut of the potential energy surfaces along the C—H_3 coordinate at the groundstate equilibrium C—I distance. The CH_3I low-lying vibrational levels of both the $6p[4]^2E_{1/2}$ and $7s[1]^2E_{3/2}$ Rydberg states also plotted in the

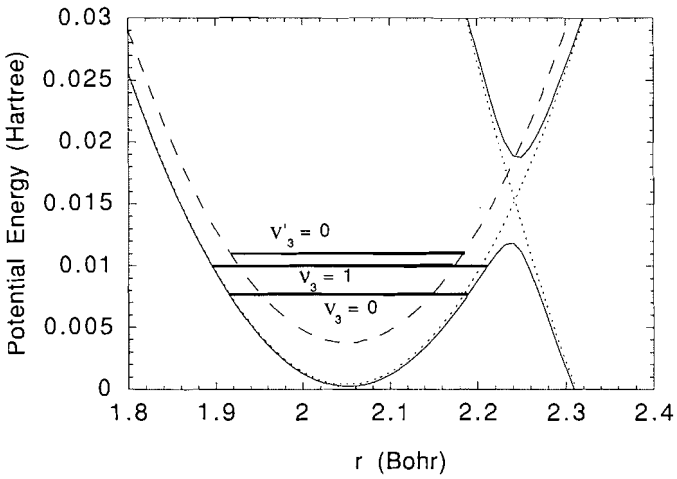

FIG. 6. Potential energy surface cuts in the C—H_3 coordinate at the ground state C—I equilibrium geometry. The dotted (the $6p[4]$ Rydberg and dissociative states) and dashed (the $7s[1]$ Rydberg state) lines are diabatic surfaces. The solid lines represent adiabatic surfaces formed between the $6p[4]$ Rydberg and dissociative states. Vibrational levels on the two Rydberg states are also given. Both the isotope effect and mode selectivity can be explained in the adiabatic picture (see text).

figure. The $6p[4]^2E_{1/2}$ Rydberg state intersects with the dissociative state at $r = 2.25$ au and they form two adiabatic surfaces due to the non-adiabatic coupling between the two states. It was found from our calculations that the coupling is significant so that the transition from the Rydberg state to the dissociative state is best described in the adiabatic representation. At the intersection, as shown in Fig. 6, the coupling is approximately 700 cm^{-1}. In order to reach the dissociation channel, the system has to tunnel through a barrier formed by the lower adiabatic surface. Since the deuterated methyl iodide has a much larger reduced mass in the r coordinate, it is more difficult to penetrate the barrier to dissociate. Furthermore, the CD_3I vibrational levels (not shown in the figure) are lower than their CH_3I counterparts because of the smaller zero point energy. The width of the barrier at these levels is thus relatively broader. Both factors contribute to the overall slowdown of the CD_3I predissociation.

The accelerated predissociation rate for the first ν_3 overtone can also be interpreted using the picture of Fig. 6. It can be clearly seen from the figure that the vibrational level for the first ν_3 overtone is much closer to the top of the barrier so that it is much easier to penetrate the barrier and dissociate. However, the increase in predissociation rate is small because the averaged kinetic energy is largely in the C—I direction.

B. Wave packet dynamics

As we indicated earlier in this paper, the model potential energy surfaces were developed in such a way that the predissociation proceeds initially along the C—H_3 coordinate and then leads to CH_3 and I. Indeed, the wave packet dynamics clearly show these characteristics of the potential energy surfaces. Snapshots of the decaying wave packet of CH_3I at 0, 10, 20, and 30 fs are plotted in Fig. 7. The lower *adiabatic* potential energy surface is also given in the background (heavy contours). In order to show the immediate propagation at short times, we used a delta function pulse for the excitation of the wave packet from the ground state. The wave packet shown in Fig. 7 is a sum of the wave packet modules on both the Rydberg and dissociative states. The wave packet is initially prepared on the Rydberg state, in the small well on the adiabatic surface (Fig. 7*a*).

In the first ten femtoseconds, the movement of the wave packet is mostly along the CH_3 coordinate (Fig. 7*b*) because the barrier to direct C—I bond cleavage is very high. The wave packet therefore chooses to make non-adiabatic transitions from the Rydberg state to the dissociative state along the C—H_3 coordinate. The part of the wave packet that escapes from the shallow well immediately experiences strong forces in both the C—H_3 and C—I directions. As a result, the wave packet starts to oscillate in the C—H_3 direction and accelerate down hill towards the dissociation of the C—I bond (Fig. 7*c* and *d*). These transitions are responsible for the decay of the Rydberg population shown in Fig. 5. It was found that there is no population recurrence in the Rydberg state and the decay can be readily fitted by an exponential function. The wave packet at large C—I distances is damped in the calculation since we are only interested in the dynamics of the parent CH_3I Rydberg state.

The oscillation in the C—H_3 coordinate will eventually lead to the excitation of the CH_3 fragment and such a motion is the analog of transition-state resonances (80). In the extreme cases, the excitation can result in the C—H bond cleavage. Although the asymptotic CH_3 internal energy is not of interest in this study, the strong oscillation in the C—H_3 mode is consistent with experimental observations of large vibrational excitation of the CH_3 fragment (48, 60).

C. Coherence effects

Finally, we would like to discuss the possible existence of coherence in the sufficiently broad bandwidth excitation near 312 nm (57). As shown in Fig. 2, the transient at 312 nm seems to have two peaks with a shift or an "oscillation period" of 140 fs. This frequency coincides with the energy difference between the $\nu_3 = 1$ vibrational level on the $6p[4]^2E_{1/2}$ Rydberg state and the $\nu_3 = 0$ level on the $7s[1]^2E_{3/2}$ Rydberg state. Since both vibrational levels could be coherently excited by a single pulse, there is a possibility that they may retain the coherence for some time provided that these two states are properly coupled. In this section, we will attempt to model coherence effects using wave packet dynamics.

The key in preparing a wave packet is to coherently excite more than one quantum state. In other words, these quantum states have to be excited by photons with the same phase. This was not possible experimentally until the introduction of the femtosecond lasers since only on this time scale a coherent nuclear wave packet could be formed at a given nuclear geometry (55). On a given potential, coherence can be manifested in a number of ways. For example, it has been shown in the case of I_2 (81) that a coherent wave packet can be prepared on an excited state by a femtosecond pulse and probed by another femtosecond pulse at a delayed time via either fluorescence (81) or ionization (56). The wave packet oscillates between the two turning points of the potential energy curve and its motion can be described by classical (82) and quantum (83) mechanics. The wave packet is a coherent superposition of adjacent vibrational eigenstates, and since each vibrational state has different energy, interferences among these states lead to time-dependent motion of the packet. The wave packet dephases gradually due to the anharmonicity of the potential. The time period for the wave packet to return to the original internuclear separation is determined by the energy differences

between adjacent levels. This type of coherence is universal to all processes involving elementary nuclear motions on various types of potentials (55).

Coherence can also exist between two states with different electronic characters provided they are appropriately coupled. In the case of methyl iodide, the band origin of the $7s[1]^2E_{3/2}$ state is only 240 cm^{-1} higher than the first ν_3 overtone on the $6p[4]^2E_{1/2}$ state. This can be seen from Fig. 6 where the vibrational levels are plotted with the potential energy surfaces of the $7s$ (dashed line) and $6p$ (dotted line) states. We have carried out calculations with two phase-locked ($\Delta\phi = 0$) femtosecond pulses tuned respectively to the two vibrational levels on the two Rydberg states. The transition dipole moment of the $7s[1]$ state was assumed to be a factor of two smaller than that of the $6p[4]$ state, in accordance with the experimental absorption spectrum (44, 46). Appropriate modifications of the Schrödinger equation were needed to include an extra state and two pump pulses. Although the two Rydberg states are not directly coupled, both of them are coupled with the dissociative state. Because of the energy difference between the two levels, interferences may arise and cause oscillations or quantum beats in the populations of the Rydberg states, which is reminiscence of the vibrational coherence in I_2. The calculated populations of both Rydberg levels are plotted with respect to time for both CH_3I (Fig. 8*a*) and CD_3I (Fig. 8*b*). It can be clearly seen that there is an oscillation with a frequency of approximately 140 fs throughout the decay of both CH_3I and CD_3I. Our calculated results give a reasonable account on the oscillatory feature observed in experiment although they are unable to offer a quantitative agreement, particularly at longer times. The disappearance of the oscillation in the later part of the dissociation is probably due to dephasing in a larger dimensional space which is not considered here.

One approximation we made in the calculations was to neglect the ionization pulse. Our rationale is based on the lack of knowledge of the ion state and the Franck–Condon nature of an ionization process. It should be pointed out that the oscillatory structure may also be attributed to the ionization process. Two ionization pathways exist during the probe process. One pathway is via the $6p[4]$ state while the other is via the $7s[1]$ state. Since the two Rydberg levels are prepared coherently by the pump pulse, the total ion signal is a square of the amplitude sum for the two pathways. Interferences will be important if the two pathways have comparable amplitudes. Furthermore, the energy difference of 240 cm^{-1} between the two Rydberg levels may survive the ionization and leads to the oscillations in the ion population in the first hundred femtoseconds (84, 85). The role played by the ionization in femtosecond pump-probe experiments certainly needs a more detailed analysis. It would be interesting to experimentally resolve the phase shift as the system executes the motion between the two states, in analogy with the experiment on iodine (86) and with the experiments on phase-shifted quantum beats for IVR studies (87).

FIG. 7. Snapshots of wave packet at 0 (*a*), 10 (*b*), 20 (*c*), and 30 (*d*) fs after a delta-function pulse excitation to the $6p[4]$ state. The heavy contours are the adiabatic potential energy surface formed by the Rydberg and repulsive states. The dissociation proceeds first along the C—H_3 vibrational coordinate and then to the C—I dissociation coordinate.

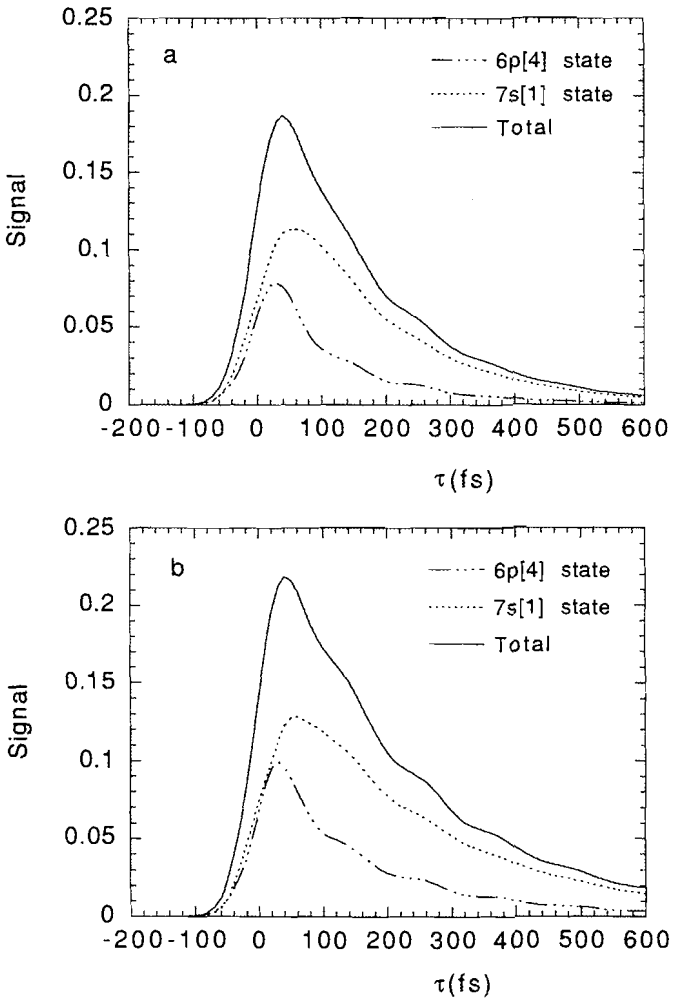

FIG. 8. Calculated transients for the broad bandwidth pulse excitation at 312 nm. Both the $6p[4]$ 3_0^1 and $7s[1]$ 0_0^0 Rydberg levels are excited coherently by the pulse. Oscillations with approximately 140 fs can be seen for both CH_3I (upper panel) and CD_3I (lower panel). The solid lines represent the total ion signal which is a sum of the signals from the two Rydberg states.

V. Conclusion

In summary, the femtosecond dynamics of Rydberg states, associated with the process of bond breakage in methyl iodide, involves more than one nuclear degree of freedom. This conclusion is based on experimental evidence of large isotope effects in the dissociation rate, which is indicative of the involvement of light atom tunneling in the dissociation. A two-dimensional model of the Rydberg predissociation dynamics of both methyl iodide and its deuterated isotope is advanced to account for the isotope effect, mode selectivity and coherence effects.

The two degrees of freedom involved in the model calculations are the C—I and C—H_3 coordinates. It is found that the predissociation of a methyl iodide Rydberg state involves non-adiabatic transitions to a dissociative state. Because the intersection between the Rydberg and dissociative states is perpendicular to the C—H_3 coordinate, the wave packet is forced to tunnel through the adiabatic barrier formed by the intersection and then dissociates. Since the predissociation involves tunneling of light atoms, a classical treatment of the dynamics becomes inappropriate. The calculations successfully reproduce the experimental observations and emphasize the importance of multidimensionality of the reaction pathway and the involvement of hydrogen (deuterium) atoms during the bond cleavage. We have also addressed the coherence effect induced by a broad bandwidth pump pulse. Although the model gives all the major features of the experimental results, it should be realized that the actual dynamics may involve many degrees of freedom. However, the present description may be sufficient for describing the elementary Rydberg state dynamics on the femtosecond scale.

For the future work, it would be advantageous to carry out *ab initio* calculations of the potential energy surfaces of the Rydberg and dissociative states of methyl iodide, which may help us to quantify the effect of the multidimensionality on the wave packet dynamics and on the non-adiabatic coupling. It would also be desirable to investigate the dynamics in the lower B and C bands in real-time in order to resolve some apparent controversies. Studies on this and other systems should be important to a broad class of Rydberg state dynamics, especially that the femtosecond time and mass resolutions make it possible to selectively isolate the elemental steps before long time events become operative.

Acknowledgments

This article is dedicated to John C. Polanyi, a colleague and friend, whose visionary and insightful work continues to inspire researchers in a number of areas covering science and humanity; it has certainly influenced the contribution reported here.

Extensive control over relative product yields is shown to result from weak laser photodissociation in a two-color coherent control scenario. Photodissociation takes place from a superposition state prepared by stimulated emission pumping. The method allows for control in the presence of laser phase jumps by using four-wave mixing to prepare the required laser frequencies. The near UV photodissociation of Na_2, resulting in the Na(3*s*) + Na(4*s*) and the Na(3*s*) + Na(3*d*) products, is used to illustrate the method.

JEFFREY DODS, PAUL BRUMER et MOSHE SHAPIRO. Can. J. Chem. **72**, 958 (1994).

On démontre que les rendements relatifs en produit peuvent être fortement contrôlés par une photodissociation faible au laser dans un scénario de contrôle cohérent en deux couleurs. La photodissociation se produit par un état de superposition préparé par un pompage stimulé d'émission. La méthode permet de réaliser un contrôle en présence de sauts de phase du laser en utilisant un mélange de quatre ondes pour préparer les fréquences laser requises. Pour illustrer la méthode, on utilise la photodissociation dans le proche UV du Na_2 qui conduit aux produits Na(3*s*) + Na(4*s*) et Na(3*s*) +Na(3*d*).

[Traduit par la rédaction]

1. Introduction

The past few decades have seen enormous progress in our understanding of the detailed dynamics of chemical reactions, and J.C. Polanyi's pioneering leadership in this area is widely acclaimed. This knowledge base has allowed recent progress (1, 2) towards an essential goal of practical chemistry, control over chemical reactions. Our technique of coherent radiative control (1) affords a method of controlling molecular dynamics by exploiting quantum interference phenomena. For example, in photodissociation of a molecule at energy E where a number of products are present, control over relative product yield can be achieved by introducing two or more simultaneous excitation routes. Varying the intensity and relative phases of the lasers used to excite the molecule allows one to directly alter the interference between these routes and hence to directly alter the reaction yield.

Thus far we have devised a number of scenarios that rely upon this interference principle and that utilize either CW or pulsed laser excitation sources. Here we introduce a specific scenario, which embellishes our first control scheme (3) and which allows us to bypass deleterious incoherence effects due to laser jitter.[2] Briefly, the scheme involves two steps: preparation of a molecular superposition state by stimulated emission pumping (SEP), followed by photodissociation after a suitable time delay. If the frequencies used are prepared by an appropriate nonlinear mixing scheme then we show that the method is insensitive to any laser jitter inherent in the light sources. In the next section we give a more detailed overview of the control scheme. Subsequent sections describe the details of the method and give applications to the photodissociation of Na_2.

2. One photon vs. one photon coherent control

2.1 Overview

The first coherent control scenario (3) considered the photodissociation, at energy E, of a molecule in a superposition of two bound states $|E_1\rangle$ and $|E_2\rangle$. The ratio of dissociation products could be varied by altering the relative phase and intensity of two coherent sources, of frequencies $(E - E_i)/\hbar\,(i = 1, 2)$. In addition, we demonstrated, through a quantitative study of products in methyl iodide dissociation, that the range of product control can be extensive. A subsequent study of the utility of this scenario in the presence of collisions (5) showed that control survived over a reasonable temperature range.

In this paper we demonstrate that by preparing the initial state in a specific fashion we are able to construct an experimental scheme that is readily implemented and that minimizes deleterious effects due to laser jitter. In addition, the method allows for the preparation of superposition states where $(E_2 - E_1)$ can be large, aiding in the supression of uncontrollable competitive photodissociation routes.

Briefly, we propose to use a frequency ω_0 to pump two dye lasers at frequencies ω_1 and ω_2. The quantity $\hbar\,(\omega_1 - \omega_2)$ is chosen equal to $(E_j - E_i)$, the energy difference between $|E_j\rangle$ and $|E_i\rangle$, two vib-rotational levels on the ground electronic surface. The molecule (see Fig. 1) is then irradiated with ω_1 and ω_2 light for a fixed time period, resulting in preparation of the superposition state via stimulated emission pumping (6). After some selected time delay the molecule is photodissociated with two frequencies $(\omega_0 + \omega_1)$ and $(\omega_0 + \omega_2)$ prepared by mixing the ω_1 and ω_2 beams with ω_0 in a nonlinear crystal. Simultaneous excitation to energy E results, with interference effects controlled by the relative intensity and phases of the two routes. Phase jitter effects are eliminated and uncontrollable satellite contributions can be minimized, as discussed below.

2.2 Superposition preparation

Consider the molecule, defined by Hamiltonian H_m with eigenstates $|E_j\rangle$ of energy E_j, which is subject to the time-dependent perturbation $V(t)$. The standard solution (7) is given by the wavefunction $|\psi(t)\rangle$:

[1]Author to whom correspondence may be addressed.

[2]For an alternate two-photon vs. two-photon control scheme for overcoming interference loss due to phase jumps and thermal effects see ref. 4.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

[1] $$|\psi(t)\rangle = \sum_j a_j(t)|E_j\rangle \exp(-iE_jt/\hbar)$$

where

[2] $$a_j(t) \equiv \langle E_j|\psi^{\mathrm{I}}(t)\rangle = \langle E_j|\mathbf{T}\exp\left(-\frac{i}{\hbar}\int_{t_0}^{t} V^{\mathrm{I}}(t')\mathrm{d}t'\right)|\psi(t_0)\rangle$$

Here $\mathbf{T}$ is the time-ordering operator and $V^{\mathrm{I}}(t)$ and $|\psi^{\mathrm{I}}(t)\rangle$ denote the perturbation and wavefunction in the interaction representation. That is

[3] $$|\psi(t)\rangle = \exp(-iH_{\mathrm{m}}t/\hbar)|\psi^{\mathrm{I}}(t)\rangle$$

and

$$V^{\mathrm{I}}(t) = \exp(iH_{\mathrm{m}}t/\hbar)V(t)\exp(-iH_{\mathrm{m}}t/\hbar)$$

In the case of SEP preparation, $V(t)$ describes the influence of two laser fields with frequencies ω_1 and ω_2, and amplitudes ϵ_1, ϵ_2, i.e.,

[4] $$V(t) = -d_{\epsilon_1}\epsilon_1(\omega_1)\cos(\omega_1t + \phi_1) - d_{\epsilon_2}\epsilon_2(\omega_2)\cos(\omega_2t + \phi_2)$$

Here the d_{ϵ_i} is the component of the transition dipole moment operator along the direction of the ith linearly polarized electric field. Expanding the exponential function in eq. [2] in a power series, truncating after the third term, and assuming the initial state $|\psi(t_0)\rangle$ to be the ith vibration–rotation level of the ground electronic state with no population in states $|E_j\rangle \neq |E_i\rangle$, allows us to rewrite eq. [2] as

[5] $$a_j(t) = \langle E_j|1 - \frac{i}{\hbar}\int_{t_0}^{t} V^{\mathrm{I}}(t')\mathrm{d}t' - \frac{1}{2\hbar^2}\int_{t_0}^{t}V^{\mathrm{I}}(t')\mathrm{d}t'\int_{t_0}^{t'}V^{\mathrm{I}}(t'')\mathrm{d}t''|E_i\rangle$$

Both the first and second matrix elements are zero, the first by orthogonality and the second (the first-order, one-photon transition) because the transition between $|E_i\rangle$ and $|E_j\rangle$, which belong to the same electronic surface, is assumed dipole forbidden.

To evaluate the third term we insert complete sets of states between the integrals. We can limit consideration to a particular vibration–rotation level of an intermediate electronic state (denoted $|E_{\mathrm{N}}\rangle$) if ω_1 and ω_2 are tuned to resonance. Choosing ω_1 resonant with the $E_i \longrightarrow E_{\mathrm{N}}$ transition and ω_2 with the stimulated $E_{\mathrm{N}} \longrightarrow E_j$ emission, we can rewrite eq. [2] as

[6] $$a_j(t) = -\frac{1}{2\hbar^2}\int_{t_0}^{t}\mathrm{d}t'\exp\big(i(E_j - E_{\mathrm{N}})t'/\hbar\big)\langle E_j|V(t')|E_{\mathrm{N}}\rangle\int_{t_0}^{t'}\mathrm{d}t''\exp\big(i(E_{\mathrm{N}} - E_i)t''/\hbar\big)\langle E_{\mathrm{N}}|V(t'')|E_i\rangle$$

Substituting the explicit form of $V(t)$ we obtain, in the rotating wave approximation (i.e., retaining absorption of $|E_i\rangle$ to $|E_{\mathrm{N}}\rangle$ and emission from $|E_{\mathrm{N}}\rangle$ to $|E_j\rangle$), that

[7] $$a_j(t) = \frac{1}{4\hbar^2}\int_{t_0}^{t}\mathrm{d}t'\exp\big(i(E_j - E_{\mathrm{N}} + \hbar\omega_2)t'/\hbar + i\phi_2\big) \times\epsilon_2(\omega_2)\langle E_j|d_{\epsilon_2}|E_{\mathrm{N}}\rangle\int_{t_0}^{t'}\mathrm{d}t''\exp(i(E_{\mathrm{N}} - E_i - \hbar\omega_1)t''/\hbar - i\phi_1)\epsilon_1(\omega_1)\langle E_{\mathrm{N}}|d_{\epsilon_1}|E_i\rangle$$

Evaluating the integrals gives

[8] $$a_j(t) = \frac{1}{8\hbar^2}(t - t_0)^2\epsilon_1(\omega_1)\epsilon_2(\omega_2)\langle E_j|d_{\epsilon_2}|E_{\mathrm{N}}\rangle\langle E_{\mathrm{N}}|d_{\epsilon_1}|E_i\rangle\exp(i(\phi_2 - \phi_1))$$

[9] $$\equiv a_j^{\mathrm{p}}\exp(i(\phi_2 - \phi_1 + \beta_{ij}))$$

where a_j^{p} denotes the absolute magnitude of the post-preparation coefficient of state $|E_i\rangle$ and β_{ij} is the phase of $\langle E_j|d_{\epsilon_2}|E_{\mathrm{N}}\rangle\langle E_{\mathrm{N}}|d_{\epsilon_1}|E_i\rangle$. Equation [1] therefore acquires the explicit form

[10] $$|\psi(t)\rangle = |E_i\rangle\exp(-iE_it/\hbar) + a_j^{\mathrm{p}}\exp(i(\phi_2 - \phi_1 + \beta_{ij} - E_jt/\hbar))|E_j\rangle$$

Equation [10] neglects the term in $|E_{\mathrm{N}}\rangle$, which is justified if, as below, subsequent photodissociation from $|E_{\mathrm{N}}\rangle$ is negligible due to poor Franck–Condon factors.

It is convenient to begin the photodissociation at time zero. To allow this we shift the zero of time by starting the SEP preparation step at time $-(T + \tau_{\mathrm{p}})$ and terminating it at time $-T$. The molecular state at the time the SEP preparation is completed ($t = -T$) is then

[11] $$|\psi(-T)\rangle = |E_i\rangle + a_j^{\mathrm{p}}\exp(i(\phi_2 - \phi_1 + \beta_{ij}))|E_j\rangle$$

and the state at a time just before the turn on of the photodissociation laser is

[12] $$|\psi(0)\rangle = |E_i\rangle\exp(-iE_iT/\hbar) + a_j^{\mathrm{p}}\exp(i(\phi_2 - \phi_1 + \beta_{ij}))|E_j\rangle\exp(-iE_jT/\hbar)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

Thus the final outcome of the molecular preparation step leaves the molecule in a superposition of bound states with phases dictated by relative laser phase and time delay before the photodissociation pulse. Note also that the molecular state has acquired the relative laser phase $(\phi_2 - \phi_1)$, with positive phase contribution ϕ_2 from emission and negative, $-\phi_1$, from absorption. Below we will see that the form of these phases is crucial to the coherent control scheme.

2.3 Photodissociation of the superposition state

Consider now photodissociation of the prepared superposition state of eq. [12] by two CW lasers of frequency $\omega_{E_i} = (E - E_i)/\hbar$ and $\omega_{E_j} = (E - E_j)/\hbar$ (or by pulses containing these frequencies):

$$[13] \qquad \epsilon(t) = \epsilon_4(\omega_{E_i}) \cos(\omega_{E_i} t + \phi_4) + \epsilon_3(\omega_{E_j}) \cos(\omega_{E_j} t + \phi_3)$$

To obtain the photodissociation amplitudes $b(Enq|t \rightarrow \infty)$ we expand the wavefunction as

$$[14] \qquad |\psi(t)\rangle = \sum_i c_i(t)|E_i\rangle \exp\left(-\frac{i}{\hbar} E_i t\right) + \sum_{nq} \int \mathrm{d}E' b(E'nq|t)|E'nq^-\rangle \exp\left(-\frac{i}{\hbar} E' t\right)$$

and solve for $b(Enq|t)$. Here $|Enq^-\rangle$ are incoming scattering wave functions which asymptotically go to products at energy E in arrangement channel q and internal quantum numbers n; in diatomics, n is simply the scattering angle vector $\hat{\mathbf{k}}$. Assuming the fields are sufficiently weak we have $c_i(t) = a_i^0$ at all times and, at long times, (3):

$$[15] \qquad \left(\frac{\hbar}{i\pi}\right) b(Enq|t \rightarrow \infty) = \epsilon_4(\omega_{E_i})\langle Enq^-|d_{\epsilon_4}|E_i\rangle \exp(-i(\phi_{\omega_{E_i}} + E_i T/\hbar)) + a_j^0 \epsilon_3(\omega_{E_j})\langle Enq^-|d_{\epsilon_3}|E_j\rangle \exp(i(\phi_2 - \phi_1 + \beta_{ij} - \phi_{\omega_{E_j}} - E_j T/\hbar))$$

with $E = E_i + \hbar\omega_{E_i} = E_j + \hbar\omega_{E_j}$. The probability of forming product in product channel q at energy E is given by $P(q;E) = \lim_{t\rightarrow\infty} \sum_n |b(Enq|t)|^2$. This assumes a convenient form if we introduce the notation

$$[16] \qquad d_{44}^q = \int \mathrm{d}\hat{\mathbf{k}} |\langle Enq^-|d_{\epsilon_4}|E_i\rangle|^2$$

$$[17] \qquad d_{33}^q = \int \mathrm{d}\hat{\mathbf{k}} |\langle Enq^-|d_{\epsilon_3}|E_j\rangle|^2$$

$$[18] \qquad d_{34}^q = |d_{34}^q| \exp(i\alpha_{34}^q) = \int \mathrm{d}\hat{\mathbf{k}} \langle E_j|d_{\epsilon_3}|Enq^-\rangle\langle Enq^-|d_{\epsilon_4}|E_i\rangle$$

Expanding the square in $|b(Enq|t)|^2$ allows us to write the yield $R(q;E)$ to observe products in channel q, with energy E as

$$[19] \qquad R(q;E) = \frac{P(q;E)}{P(q;E) + P(q';E)}$$

with

$$[20] \qquad P(q;E) \propto d_{44}^q + x^2 d_{33}^q + 2x|d_{34}^q| \cos(\Phi + \beta_{ij} + \alpha_{34}^q)$$

Here we have left out proportionality factors irrelevant to R and have introduced the notation:

$$[21] \qquad \Phi = \phi_{\omega_{E_i}} - \phi_{\omega_{E_j}} + \phi_2 - \phi_1 + (E_i - E_j)T/\hbar$$

$$[22] \qquad x = \frac{a_j^0 \epsilon_3(\omega_{E_j})}{\epsilon_4(\omega_{E_i})}$$

Equation [20] comprises three terms, direct photodissociation of levels $|E_i\rangle$ and $|E_j\rangle$ plus an interference term between these routes. It is evident from eq. [20] that changing either x or Φ will result in a variation in the probability $P(q;E)$. Both variables comprise experimentally controllable parameters including the relative phases and intensities of the excitation sources in both steps, as well as the time delay T between preparation and dissociation. Varying these control parameters in the laboratory allows direct control over the interference term and hence over the product distribution.

Additional photodissociation at energies other than E, the so-called satellite contributions, also occur. These correspond to the photodissociation of $|E_i\rangle$ by absorption of ω_{E_j} to energy $E + E_i - E_j$ and the photodissociation of $|E_j\rangle$ by absorption of ω_{E_i} to energy $E + E_j - E_i$. Since there is only one pathway to each of these energies, they correspond to uncontrolled photodissociation pathways. However, this scenario allows large $(E_i - E_j)$ so that these absorptions may be placed outside of the continuum absorption range.

2.4 Countering phase incoherence

Relying on independent lasers for state creation and subsequent photodissociation has serious disadvantages. Specifically, if the four relative laser phases within Φ are unstable or uncorrelated then phase fluctuations during the interaction of the molecule with four independent lasers can lead to extensive phase averaging. Such phase averaging destroys the coherence vital to coherent control. However, a simple experimental scenario resolves this problem. In particular, consider using a single CW laser of frequency ω_0 to pump two dye lasers at frequencies ω_1 and ω_2. The associated laser phases are denoted ϕ_0, ϕ_1, and ϕ_2. The three frequencies are chosen such that $(\omega_0 + \omega_1) = \omega_{E_i}$, $(\omega_0 + \omega_2) = \omega_{E_j}$. If ω_1 and ω_0, as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

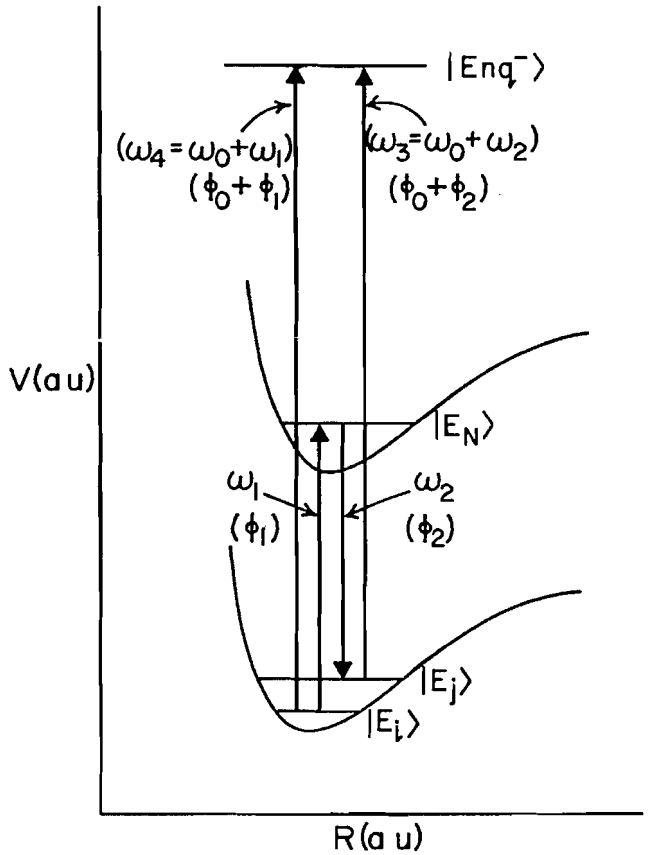

FIG. 1. Schematic of the coherent control scenario. The phase of route one (excitation by $\omega_0 + \omega_1$) imparts to the continuum state $\phi_0+\phi_1$. Similarly, the phase imparted in route two (ω_1, ω_2) preparation followed by $\omega_0+\omega_2$ dissociation equals $(\phi_1-\phi_2+\phi_0+\phi_2) = (\phi_0+\phi_1)$.

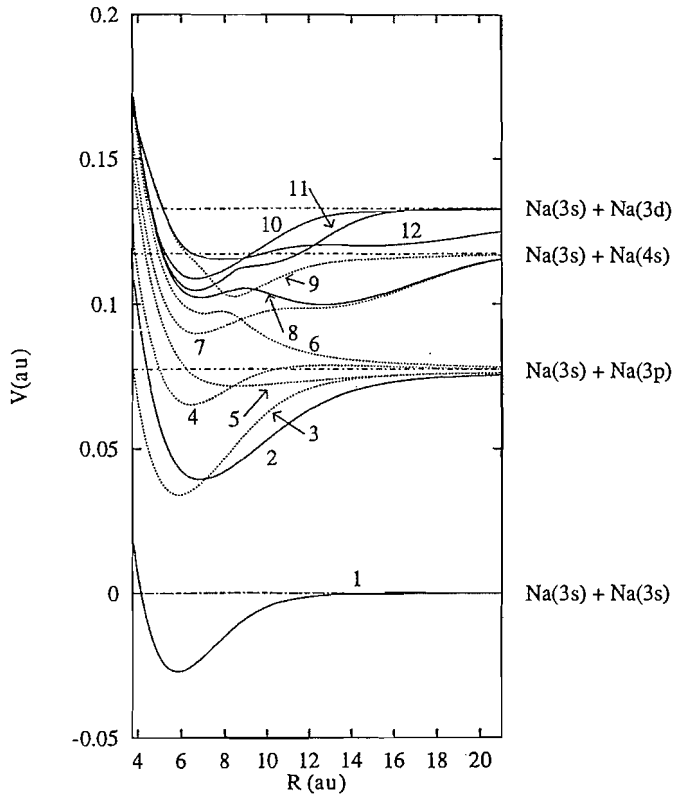

FIG. 2. The most relevant Na_2 potential curves are shown: $(1)^1\Sigma_g$, $(2)^1\Sigma_u$, $(3)^3\Pi_u$, $(4)^1\Pi_u$, $(5)^1\Pi_g$, $(6)^3\Sigma_u$, $(7)^1\Sigma_g$, $(8)^1\Sigma_u$, $(9)^3\Sigma_u$, $(10)^1\Pi_u$, $(11)^3\Pi_u$, $(12)^1\Sigma_u$, Additional states included in the computation but omitted here for clarity are as follows: one $^1\Sigma_g$, two $^3\Sigma_g$, and one $^3\Pi_g$, which are asymptotic to the Na(3*s*) + Na(3*p*) product, and one $^3\Sigma_g$ state that is asymptotic to the Na(3*s*) + Na(4*s*) product.

well as ω_2 and ω_0, are mixed in a nonlinear crystal then the created frequencies $(\omega_0+\omega_1) = \omega_{E_i}$ and $(\omega_0+\omega_2) = \omega_{E_j}$ have phases $\phi_0+\phi_1$ and $\phi_0+\phi_2$, respectively.

With this mode of frequency preparation the phase Φ assumes the form:

$$[23] \quad \Phi = \phi_{\omega_{E_i}} - (\phi_1 - \phi_2 + \phi_{\omega_{E_j}}) + (E_i - E_j)T/\hbar$$

$$[24] \quad = (\phi_0 + \phi_1) - (\phi_1 - \phi_2 + \phi_0 + \phi_2) + (E_i - E_j)T/\hbar$$

$$[25] \quad = (E_i - E_j)T/\hbar$$

Thus the phase difference between the two routes is independent of the laser phases and, in particular, independent of the fluctuations in the laser sources.

An enlightening qualitative picture of the phases associated with the two excitation routes to dissociation is shown in Fig. 1. Route one to dissociation is excitation from level $|E_i\rangle$ via $\epsilon_4(\omega_{E_i})$; the created state acquires the phases $[-(\phi_0 + \phi_1)]$. Route two is a three-photon route, from $|E_i\rangle$ to $|E_N\rangle$ to $|E_j\rangle$ to the continuum. Phase accumulated along this route is $[-\phi_1 + \phi_2 - (\phi_0 + \phi_2)] = [-(\phi_0 + \phi_1)]$. Hence both excitation routes result in the same accumulated phase and the phase difference between them cancels.

Laboratory control over the phase then corresponds to varying T or, if preferred, deliberately introducing an additional phase delay between the two routes. We therefore extend the definition of Φ to include any experimentally introduced additional phase delay.

3. Results

Although this control scheme is applicable to a wide range of molecules, it is convenient to choose a particular system, e.g., Na_2, to demonstrate the method. We first consider some photodissociation amplitudes characteristic of the energy range of interest. Appendix A provides additional details on the nature of these calculations; below we will discuss only the qualitative results of the photodissociation and the coherent control of products Na(3*s*) + Na(4*s*) vs. Na(3*s*) + Na(3*d*).

3.1 Na_2 photodissociation

A total of 17 Na_2 electronic states (8) were included in the computation. The 12 curves contributing most significantly are shown in Fig. 2, with the remainder omitted for clarity of presentation. Those which are dipole coupled to the ground state (9), and which are in the energy range of interest, are shown using solid lines. Since the ground state of Na_2 is a $^1\Sigma_g$, only singlets of ungerade symmetry are dipole coupled to this state. A small spin-orbit coupling does mix singlet states with triplets; only one triplet state need concern us in this study, the $^3\Pi_u$ curve numbered 11. Also shown are typical frequencies used to apply the coherent control scenario discussed above to this system. The low-lying potentials leading to the Na(3*s*) + Na(3*p*) and Na(3*s*) + Na(3*s*) have negligible Franck–Condon factors for the photodissociation energies of interest, but are necessary for the computation of the SEP preparation step.

For personal use only.

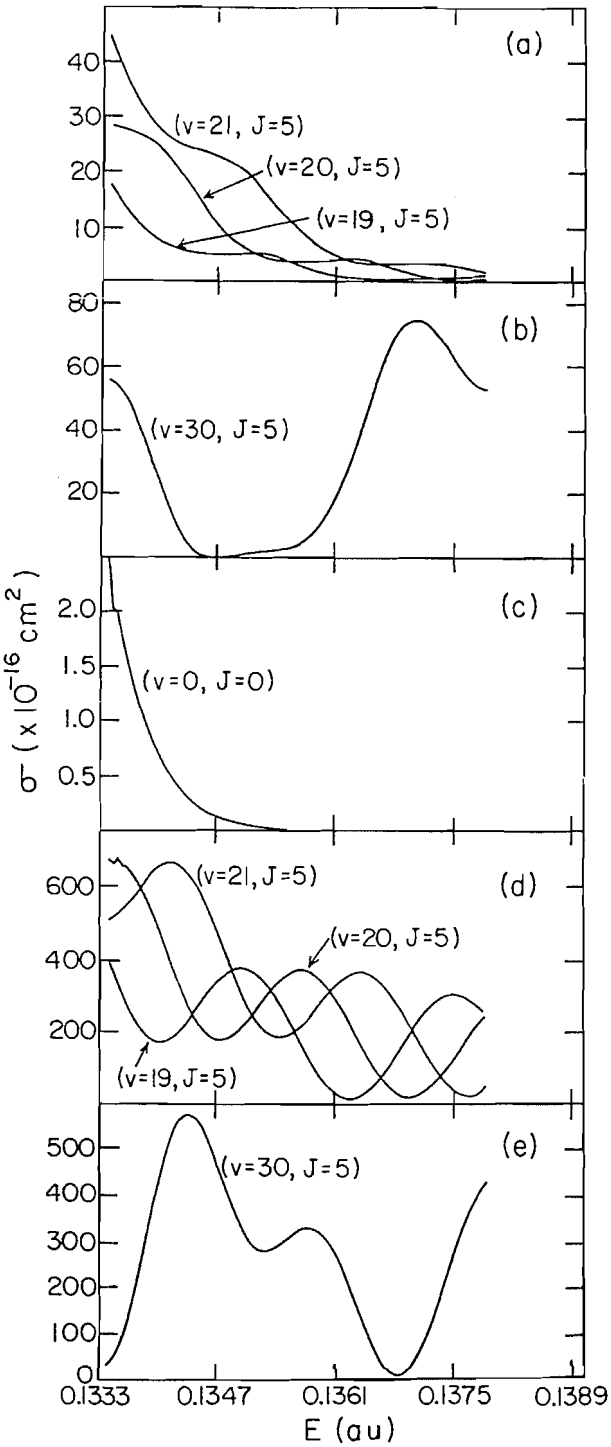

FIG. 3. Photodissociation cross sections into Na(3*s*) + Na(4*s*) from $J = 5$, (*a*) $v = 19, 20, 21$; (*b*) $v = 30$. Photodissociation cross sections into Na(3*s*) + Na(3*d*) vs. photon energy from Na_2; (*c*) into $v = 0$, $J = 0$; (*d*) $J = 5$, $v = 19, 20$, and 21; and (*e*) $v = 30$.

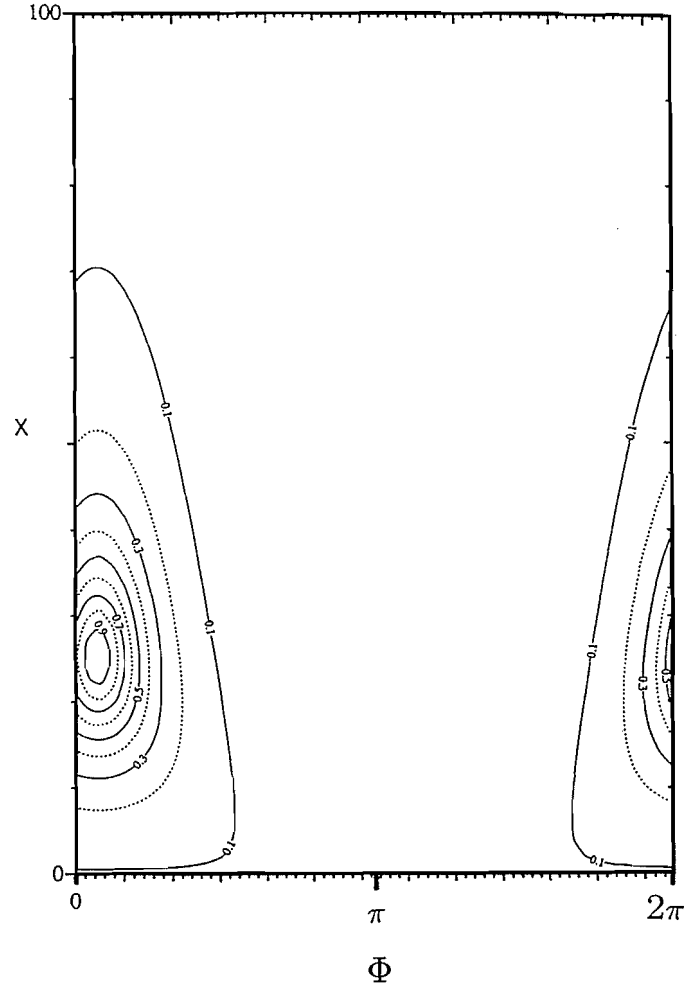

FIG. 4. Contours of constant $R(4s; E)$. The ordinate is the parameter x and the abscissa is the relative phase Φ. The control map is for the initial superposition of $v = 24$, $J = 0$ with $v' = 27$, $J = 0$.

Our computations show that the Na_2 photodissociation cross section to the Na(3*s*) + Na(4*s*) channel is extremely small for vibrational states $v = 0$ to $v = 15$. This is due to the large bond length of the ground $(1)^1\Sigma_g$ state of Na_2, resulting in a small overlap between the $v = 0$ to $v = 15$ levels and the state $[(8)^1\Sigma_u]$ leading to the Na(3*s*) + Na(4*s*) products. This low cross section is in contrast with the Na(3*s*) + Na(3*d*) channel cross section, which has a detectable magnitude starting with photodissociation of the Na_2 $v = 0$ state due to adequate overlap with the $(12)^1\Sigma_u$ state. The cross section for both channels increases as v increases. Figure 3 shows selected Na_2 photodissociation cross sections.

Figure 3*a* shows typical cross sections to the Na(3*s*) + Na(4*s*) product channel. Adjacent bound states are seen to give similar cross sections. For $v = 19$ to $v = 21$, the decrease in cross section as photolysis energy increases is due to diminishing Franck–Condon factors on the repulsive wall of the excited surfaces. But $v = 30$ (Fig. 3*b*) has a different structure because the turning point of the bound state is outside the turning point of the excited state repulsive wall. A minimum is seen at about 0.1347 au of photon energy, followed by a peak at 0.1370 au.

Sample results for the Na(3*s*) + Na(3*d*) channel are shown in Figs. 3*c*–*e*. The vibrationless level of the $(1)^1\Sigma_g$ state of Na_2 has a Na(3*s*) + Na(3*d*) channel cross section that decays rapidly (Fig. 3*c*). By $v = 10$ the cross section develops clear oscillations, but by $v = 30$ (Fig. 3*e*) the oscillatory structure is no longer clear because there is significant interference from the Franck–Condon factors of the two strongly participating singlet states, the $(12)^1\Sigma_u$ and the $(10)^1\Pi_u$ states. This is in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12

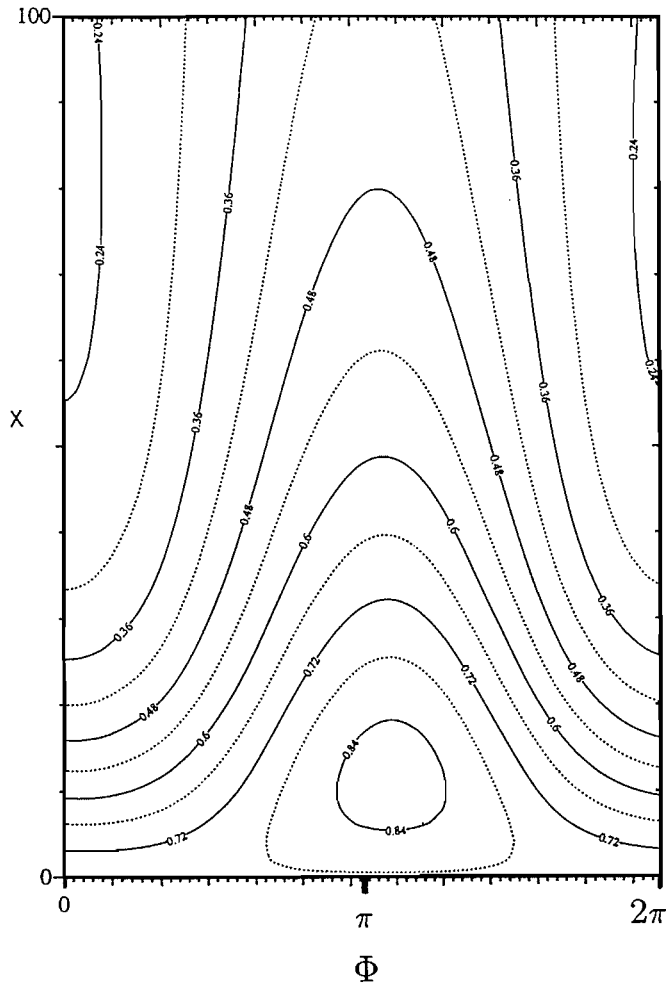

FIG. 5. As in Fig. 4 but with $J = 5$.

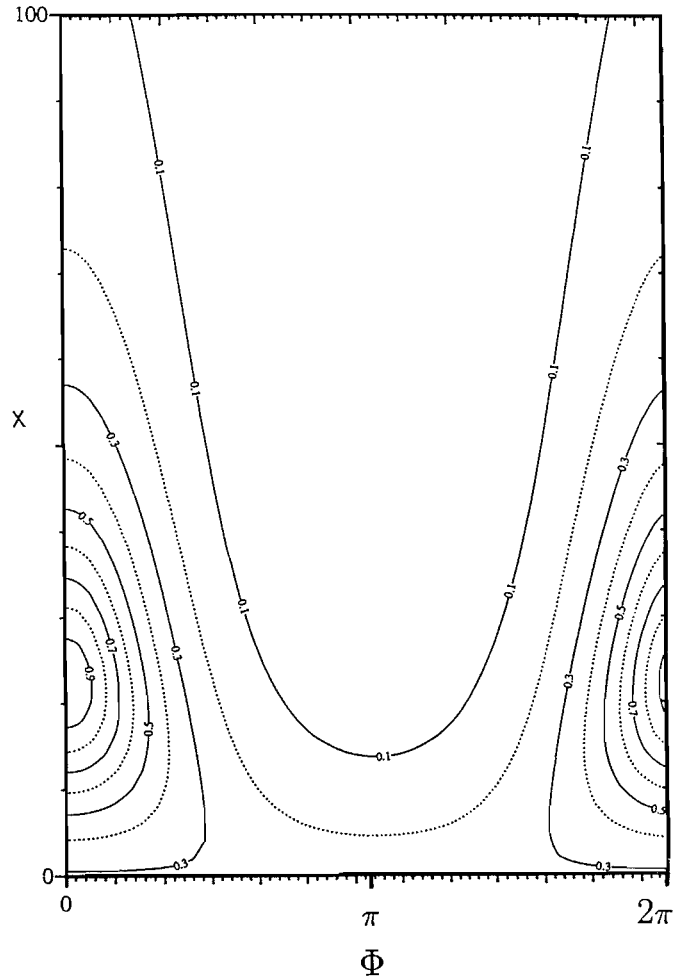

FIG. 6. As in Fig. 4 but with $J = 10$.

contrast with the results in Fig. 3*d* where the oscillatory structure is clear and where only one excited state, the $(12)^1\Sigma_u$, dominates the photodissociation. This state has a distinctly different location of its inner repulsive wall in the region of the Na(3*s*) + Na(3*d*) channel threshold.

3.2 Coherent control of Na_2

Here we consider control over the fractional yield of the $q \equiv$ Na(3*s*) + Na(4*s*) vs. the $q' \equiv$ Na(3*s*) + Na(3*d*) channels. The vanishingly small cross section to produce Na(3*s*) + Na(4*s*) for lower vibrational states prevents us from using low vibrational states for coherent control purposes. Below we describe control starting with the higher vibrational states ($v \geq 24$), which, if desired, can be experimentally created by the SEP pumping or by adiabatic passage techniques (10). We will use the availability of such techniques to our advantage by assuming that control can begin with the molecule in a high vibrational level of the ground electronic state.

Assume, for example, that we can begin the control experiment with the molecule in $v = 24$ and J_i, $M_i = 0$, where the latter denotes the angular momentum of the *i*th state and its *z*-projection. A survey (11) of Franck–Condon factors between this state and vib-rotational states of the $(2)^1\Sigma_u$ state shows that a superposition state comprising the $(v = 24, J = 0)$, and $(v = 27, J = 0)$ states could be conveniently formed via an $|E_N\rangle$ state with $v = 14$, $J = 1$. This corresponds to the choice $\hbar\omega_1 = 12\,883$ cm^{-1} and $\hbar\omega_2 = 12\,538$ cm^{-1}. Control results at $E = 29\,672$ cm^{-1} are shown in Fig. 4 where we plot $R(4s;E)$, the fractional yield of 4*s* as a function of the control parameters *x* and Φ. The figure shows contours of constant $R(4s;E)$ and indicates that the branching ratio can be varied between 10 and 90% by varying *x* and Φ. The maximum Na(4*s*) yield is at $\Phi \sim 0.2\pi$ radians and the amplitude factor $x \sim 25$.

Figures 5 and 6 show results for initial states with higher rotational quantum numbers for which *M* averaging has been performed. Figure 5 shows results for the superpositions $(v = 24, J = 5)$, and $(v = 27, J = 5)$ at the slightly higher energy $E = 30\,046$ cm^{-1}. Control of the Na(4*s*) yield has been somewhat reduced (ranging from 0.24 to 0.84) relative to the case shown in Fig. 4. This is accompanied by a shift in the maximum in the Na(4*s*) yield to $\Phi \sim 3.5\pi$ radians and $x \sim 10$. The $J_i = J_j = 10$ case (Fig. 6) shows very similar results to the $J_i = J_j = 0$ situation, with the range of control of 0.1–0.9 now restored.

As an example of the observed behavior of other combinations of bound state pairs, consider the case where the molecule is in the $v = 27$, $J = 0$ plus $v = 31$, $J = 0$ state, pumped via the intermediate $v = 21$, $|E_N\rangle$ state. This corresponds to using $\hbar\omega_1 = 13\,268$ cm^{-1} and $\hbar\omega_2 = 12\,837$ cm^{-1}. The resultant $R(4s;E)$ control map at $E = 29\,607$ cm^{-1}

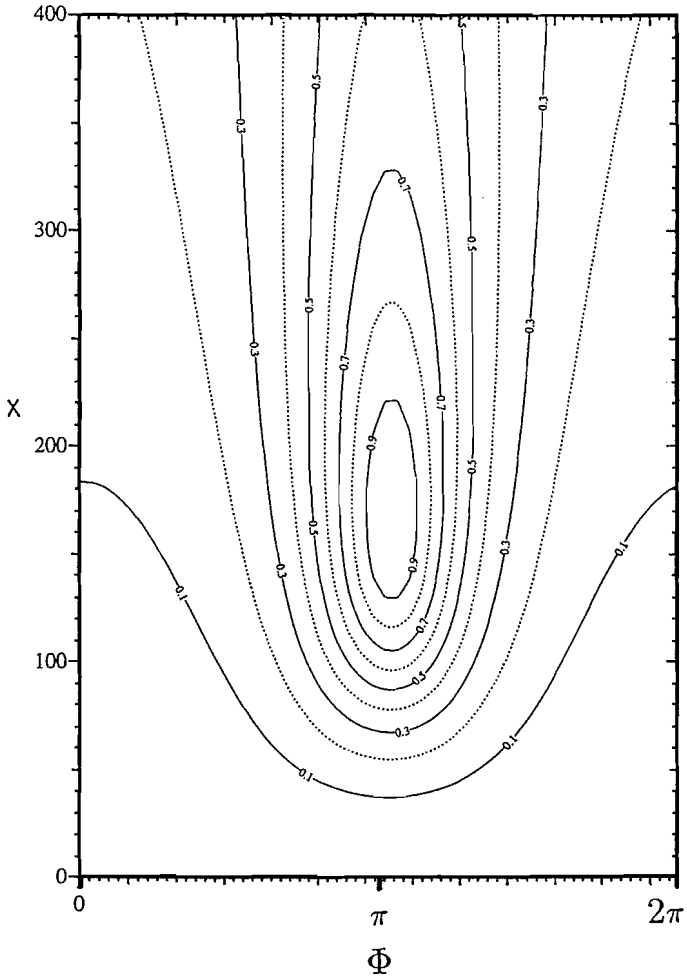

FIG. 7. As in Fig. 4 but with $v = 27$, and $v = 31$.

is shown in Fig. 7. The observed range of control is large, with the maximum in the Na(4*s*) yield appearing at very large x. This is a consequence of the relatively small Franck–Condon factor between the intermediate state and $v = 31$. That is, if one of the excitation paths has a much weaker cross section, the electric field carrying that component to the continuum must be increased to compensate, resulting in large x.

4. Conclusion

We have proposed a SEP one photon vs. one photon coherent control scheme with a number of experimental advantages. Specifically, the scenario allows minimization of effects due to laser jitter and reduction of effects due to uncontrolled satellites. The scenario shows the possibility of a wide range of control, as demonstrated in computations on electronic branching in the photodissociation of Na_2.

5. Appendix: Computational details

The bound–bound matrix elements, $\langle E_j|d|E_N\rangle\langle E_N|d|E_i\rangle$ that appear in $P(q;E)$ are calculated using uniform semiclassical wave functions.

To solve for the photodissociation amplitude, a considerable amount of manipulation is required. Here we only state the relevant results of the formulation (12, 13).

The amplitude $\langle Enq^-|d|E_i\rangle$ is obtained in accord with the method of Levy and Shapiro (12). Specifically we expand in partial waves

$$[A1] \quad \langle Enq^-|d|E_i\rangle \equiv \langle Enq^-|d|E_i, J_i, M_i\rangle$$

$$= \frac{\sqrt{2\mu k_n}}{h} \sum_{J,p,\lambda\geq 0} \begin{pmatrix} J & 1 & J_i \\ -M_i & 0 & M_i \end{pmatrix} \sqrt{2J+1}\, \mathcal{D}^{J,p}_{\lambda,M_i}(\phi_k, \theta_k, 0)\mathrm{t}(EJp\lambda q|E_iJ_i)$$

where $\hat{\mathbf{k}} = (\phi_k, \theta_k)$ is the direction of the recoiling fragments and λ is the magnitude of the electronic angular momentum about the internuclear axis. The $\mathcal{D}^{J,p}_{\lambda,M_i}$ are the parity-adapted rotation matrices defined, with parity $p = \pm 1$ as:

$$[A2] \quad \mathcal{D}^{J,p}_{\lambda,M_i} = t_\lambda[\mathcal{D}^{J}_{\lambda,M_i} + p\mathcal{D}^{J}_{-\lambda,M_i}]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

where $t_\lambda = \sqrt{\frac{1}{2}}$ for $\lambda \neq 0$ and $t_\lambda = \frac{1}{2}$ for $\lambda = 0$. The quantity $\mathbf{t}$ is the reduced matrix element for photodissociation.

$$[A3] \quad \mathbf{t}(EJp\lambda q|E_iJ_i) = (-1)^\lambda t_\lambda \sqrt{(2J+1)(2J_i+1)} \begin{pmatrix} J & 1 & J_i \\ -\lambda & \lambda & 0 \end{pmatrix} (1 + p(-1)^{J+1+J_i}) \times \sum_\xi \int \mathrm{d}\, R\Phi_\xi^{*(J,p-)}(R)(\xi|d|g)\Phi_{E_i}^{J_i}(R)$$

Here the sum over ξ is over all the electronic states that correlate with the same final channel. The $(\xi|d(R)|g)$ matrix element is the electronic transition dipole moment between the ground state and the ξth state. The quantity $\Phi_\xi^{(J,p-)}(R)$ is the radial nuclear scattering wave function in electronic state's ξ and $\Phi_{E_i}^{J_i}(R)$ is the radial nuclear bound wavefunction with energy E_i.

The $\mathbf{t}$ matrix element is computed using the artificial channel method (14).

To calculate the probability $P(q; E)$ requires repeated use of this explicit form. For example, to calculate the first term d_{44}^q, we expand the $\mathcal{D}_{\lambda,M_i}^{J,p}$ and perform the integration over the scattering angle $\hat{\mathbf{k}}$ to arrive at:

$$[AA4] \quad d_{44}^q = \frac{8\pi\mu k_n}{\hbar^2} \sum_{J,p,\lambda\geq 0} \begin{pmatrix} J & 1 & J_i \\ -M_i & 0 & M_i \end{pmatrix}^2 |\mathbf{t}(EJp\lambda nq|E_iJ_i)|^2$$

Similarly, the other terms in $P(q; E)$ are given by:

$$[AA5] \quad d_{33}^q = \frac{8\pi\mu k_n}{\hbar^2} \sum_{J,p,\lambda\geq 0} \begin{pmatrix} J & 1 & J_j \\ -M_j & 0 & M_j \end{pmatrix}^2 |\mathbf{t}(EJp\lambda q|E_jJ_j)|^2$$

and

$$[AA6] \quad d_{34}^q = \frac{8\pi\mu k_n}{\hbar^2} \sum_{J,p,\lambda\geq 0} \begin{pmatrix} J & 1 & J_i \\ -M_i & 0 & M_i \end{pmatrix} \begin{pmatrix} J & 1 & J_j \\ -M_j & 0 & M_j \end{pmatrix} \mathbf{t}(EJp\lambda q|E_iJ_i)\mathbf{t}^*(EJp\lambda q|E_jJ_j)$$

In general, the sums over J extend over $J_i - 1$, J_i, $J_i + 1$ except for the $J_i = 0$ case for which there is only the $J = 1$ term.

Fragmentation in a quadrupole ion trap of each of two isomeric molecular ions, obtained from 4-nitro-*o*-xylene and 4-nitro-*m*-xylene, has been investigated. It is demonstrated that the degree of fragmentation may be controlled by prolongation of both the duration for which the working point of the mass-selected species is held in the vicinity of a stability boundary and a prior collisional cooling period. The extent of fragmentation has been found to increase as the working point is held near the $\beta_z = 0$ stability boundary while the relative abundances of fragment ions can be varied with the duration of the collisional cooling period. Under appropriate conditions for 4-nitro-*o*-xylene, >94% of the isolated ions can be fragmented; <5% of the ions are lost from the ion trap while 1% remain intact. As 99% of the charge of the fragmented ions is retained in the ion trap, the overall optimum efficiency of boundary-activated dissociation is >93%; the corresponding efficiency for 4-nitro-*m*-xylene is 74%. 50% of the selected ions can be fragmented in ≤3 ms. The results are compared with collision-activated dissociation studies carried out with a triple stage quadrupole–hexapole–quadrupole instrument. This technique of boundary-activated dissociation provides a general procedure which does not require careful tuning of the instrument as is required for the more commonly-used technique of resonance excitation.

On a étudié la fragmentation de deux ions moléculaires, obtenus à partir des 4-nitro-*o*-xylène et 4-nitro-*m*-xylène, dans un piège à ions quadripolaires. On a démontré que le degré de fragmentation peut être contrôlé par une prolongation à la fois de la période préalable de refroidissement collisionnel et de la durée pour laquelle le point de travail des espèces de masse choisie est maintenue dans les environs d'une frontière de stabilité. On a trouvé que le degré de fragmentation augmente lorsque le point de travail est maintenu près de la frontière de stabilité $\beta_z = 0$ alors que les abondances relatives des ions fragments peuvent être amenées à varier avec la durée de la période de refroidissement collisionnel. Pour le 4-nitro-*o*-xylène dans des conditions appropriées, >94% des ions isolés peuvent être fragmentés; <5% des ions sont perdus du piège à ions et 1% demeure intact. Comme 99% de la charge des ions fragmentés sont retenus dans le piège à ions, l'efficacité optimale globale de la dissociation activée par la frontière est >93%; l'efficacité correspondante pour le 4-nitro-*m*-xylène est de 74%. Près de 50% des ions choisis peuvent être fragmentés en ≤3 ms. On compare ces résultats avec ceux d'études de dissociations activées par des collisions et effectuées à l'aide d'une appareil à trois stades quadripolaire–hexapolaire–quadripolaire. Cette technique de la dissociation activée par la frontière fournit une méthode générale qui ne requiert pas un ajustement aussi rigoureux que celui exigé pour la technique habituelle de l'excitation par résonance.

[Traduit par la rédaction]

Introduction

The quadrupole ion trap has been shown to be highly effective for performing tandem mass spectrometry (MS/MS) experiments (1, 2). An essential element of tandem mass spectrometry is the quiescent period when the amplitude of the RF drive potential is held constant, following a process of mass-selection, and the isolated reactant ion species is allowed to undergo unimolecular and/or bimolecular reactions which, in the widest sense, will include cluster formation, photo-dissociation (3, 4), collisions with surfaces (5), pulsed axial activation (6), and resonance excitation. The vast majority of ion trap MS/MS data has been obtained with an auxiliary RF potential, or "tickle" (7) voltage, applied across the end-cap electrodes and oscillating at a frequency resonant with a component of the secular motion of a chosen and isolated ion species. However, the "tickle" frequency must be carefully tuned to the secular frequency of the ion if high fragmentation efficiencies are to be obtained and this tuning procedure is experimentally difficult for transient species, such as those eluting from a chromatographic inlet. A general procedure for ion activation which does not require such careful tuning would, therefore, be useful for ion trap tandem mass spectrometry.

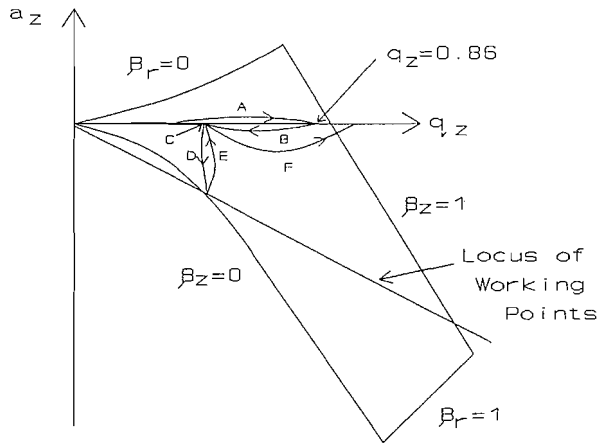

FIG. 1. Stability diagram in a_z, q_z space for the quadrupole ion trap showing the four boundaries at which $\beta_z = 0$ and 1, and $\beta_r = 0$ and 1. The movement of the working point of a chosen ion species is described by the path ABCDEF. Ion ejection was carried out at q_z = 0.86, as shown. The locus of all working points during boundary-activated dissociation is shown also.

Two such ion activation methods which employ DC pulses rather than resonance excitation have been reported recently. When short-duration, fast-rising DC pulses of amplitude ca. 350 V are applied to both end-cap electrodes, ions impinge upon the end-cap electrodes and interact with the surfaces (5). For example, in the dissociation of the pyrene molecular ion, *m/z* 202, the fragment ion of *m/z* 122 was observed; while the relative abundance of this fragment was but 0.2%, observation of this fragment is significant in that its appearance energy is some 17 eV. A related method of pulsed axial activation has been reported from the same laboratory (6); here, ion activation was observed using fast DC pulses applied to one end-cap electrode only. The amount of internal energy deposited, which can be controlled directly by variation of the amplitude of the pulse, has been estimated to exceed 10 eV in the dissociation of the *n*-butylbenzene molecular ion and 13 eV for dissociation of $W(CO)_6^{+\cdot}$ to W^+. Dissociation efficiencies ranged from 50% at low internal energy deposition to 5% at maximum internal energy deposition. In the high internal energy regime, collisions with an electrode surface may occur.

A further ion activation–method proposed in 1991 (8) has attracted considerable attention (9–13). This method is based on the interaction of mass-selected ions with the high fields derived from the RF drive potential; this interaction causes acceleration of the ion which is dissociated following activation in collisions with the buffer gas. The interaction of the ions with the high fields is brought about experimentally by choosing values of the stability parameters (1) a_z and q_z such that the working point of the ion species is located close to the boundary of the stability diagram (Fig. 1); it is for this reason that this method has been described as "boundary activation", or "boundary-activated dissociation" (BAD). BAD is, therefore, a mass-selective collisional process which does not require the careful tuning of a tickle voltage. Curcuroto et al. (11) found that internal energy deposition at a boundary exceeded that observed by tickling, yet Creaser and O'Neill (13) found that energy deposition in BAD was generally lower than that for optimized CAD.

The positioning of the working point of a given ion species close to a boundary of the stability diagram has implications for the trajectory stability of other ion species stored simultaneously in the ion trap. Let us recall that, under all operating conditions of the ion trap, the locus of working points of stored ions is a straight line passing through the origin of the stability diagram in a_z, q_z space. When the working point of a given ion species is moved to the $\beta_z = 1$ boundary the trajectories of ions having lower mass/charge, *m/z*, ratios become unstable and such ions are lost from the trap. When the working point of the same ion species is moved subsequently close to the $\beta_z = 0$ boundary, the trajectories of ions having higher *m/z* ratios become unstable and these ions are lost from the trap leaving the given ion species isolated in the ion trap. When the working point is held in the vicinity of the $\beta_z = 0$ boundary for some milliseconds, the isolated ion species undergoes BAD following activating collisions with helium buffer gas; fragment ions are formed which can be detected during a normal analytical scan of the instrument, and the locus of the working points (during BAD) of all ion species is shown in Fig. 1. Thus ion isolation carried out in two consecutive steps, as described above, can be followed immediately by a non-resonant excitation process leading to fragmentation of the isolated ion species.

In simulation studies (14) of consecutive ion isolation (15), it was found that a period of collisional cooling of a given ion species, prior to moving the working point close to the $\beta_z = 0$ boundary, had a profound effect on the amount of energy that an ion could absorb from the RF field without the ion being lost in a collision with an electrode. Consequently, it was hypothesized that the fragmentation pattern obtained by BAD would be affected by a period of collisional cooling also. This hypothesis was tested experimentally using 2,6-dimethyl-9-methoxy-4*H*-pyrrole[3,2,1,-*ij*]quinoline-4-one, synthesized and purified as described elsewhere (16). This compound was selected on the basis of the availability of a large amount of mass spectrometric data (11, 17); in retrospect, it was not the best choice as the activation energies of the fragmentation channels are not known. However, at that time, the marked effects of variation of cooling time prior to BAD were not known also. Upon BAD, at a helium buffer gas pressure of ca. 1×10^{-3} Torr, four fragment ion species were observed, two of which had not been observed with tickle excitation (18, 19). Furthermore, when the cooling period was varied from 0–450 μs, the fragment ion relative abundances varied in a fashion reminiscent of that exhibited in an energy-breakdown curve.

We report here a study of the effects of variation of the duration of each of collision cooling and boundary-activated dissociation on the mass-selected isomeric molecular ions of 4-nitro-*o*-xylene and 4-nitro-*m*-xylene, together with a comparison of collision-activated dissociation (CAD) carried out with a triple stage (QhQ) instrument comprised of two quadrupole mass filters with an intervening hexapole collision cell. Again, the choice of compound was not the best, but an inter-laboratory study is now underway of five compounds selected on the basis of known thermochemistry.

Experimental

The ion trap experiments were carried out with a modified Varian Saturn I Ion Trap Detector operated with dipolar resonance ejection at a fixed frequency of 416.5 kHz to give mass-selective ejection at q_z = 0.86 during the analytical scan. The modified Saturn I instrument was controlled by a data acquisition programme which had been written in a combination of C and assembler. Scan functions, which describe the temporal variations of electrode potentials during each experiment, were customized to perform CAD experiments utilizing BAD with or

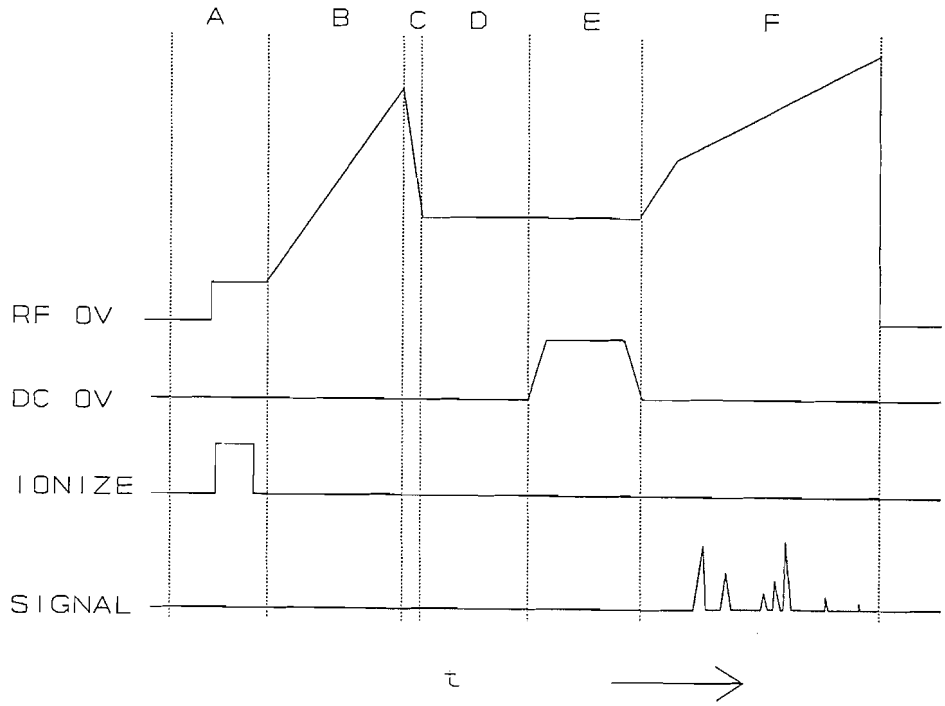

FIG. 2. The scan function for ion isolation and boundary-activated dissociation. The segments are described in the text.

without a period of collisional cooling; a typical scan function for a consecutive isolation/BAD experiment is shown in Fig. 2. The corresponding effect on the working point of the chosen ion species is shown in Fig. 1: here, the initial RF ramp (A) moved the working point of the chosen ion species close to $q_z = 0.86$ whereupon all lower mass ions were ejected; the RF amplitude was ramped down (B) to place the chosen ion's working point at C where a cooling period could be incorporated into the scan function; a DC pulse was applied (D) to move the working point to the vicinity of the $\beta_z = 0$ boundary; at the end of the DC plateau duration, the DC pulse was removed (E) and was followed by an analytical scan (F).

The ion trap was operated in pulsed mode, that is, ionization was effected with a pulse of 70 eV electrons (segment A in Fig. 2), after which the RF level was increased to eject ions of low *m/z* values at $q_z = 0.86$ using axial modulation (segment B). The q_z value of the chosen ion species was established by ramping the RF level to the appropriate value (segment C). Segment D represents a collisional cooling period of variable duration, which was followed by a DC ramp (segment E) to move the working point of the chosen ion species to the vicinity of the $\beta_z = 0$ boundary and to eject ions of higher *m/z* values. The DC level was maintained for a variable period, then reduced to zero and followed by a mass-instability scan of the RF voltage. Collision-activated dissociation mass spectra were obtained by co-adding 500 microscans. The absolute partial pressures of 4-nitro-*o*-xylene (m.p. 30–31°C) and 4-nitro-*m*- xylene (m.p. 9°C) in the ion trap were not known. Concentrations of these compounds were adjusted by varying the temperature of the inlet system to obtain an ion count of ca. 20 000 ions with an ionization period of 1000 μs. The helium pressure in the manifold measured with a Bayard–Alpert ionization gauge corrected for helium sensitivity was ca. 0.1×10^{-3} Torr; the helium pressure in the ion trap is ca. ten times that in the manifold. Under these conditions, collisions of ions with helium atoms are much more frequent than with parent molecules.

The QhQ instrument was a VG Quattro (Fisons Instruments, Altringham, England). Ions were formed by 70 eV electron ionization, selected by a first quadrupole, dissociated in the middle hexapole collision cell and analyzed by a second quadrupole. The collision gas was argon and the energy of the incident ion beam was determined by the potential difference between the ion source and the collision cell. Collision-activated dissociation mass spectra was obtained by multichannel accumulation of data from ca. 20–30 scans.

Results and discussion

4-Nitro-o-xylene

The fragmentation scheme for the molecular ion of 4-nitro-*o*-xylene is given in eq. [1]

$$\begin{aligned} C_6H_3(CH_3)_2NO_2^{+\cdot} &\rightarrow 121^+ + NO^{\cdot} \qquad (ortho) \\ &\rightarrow 106^{+\cdot} + NO^{\cdot} + CH_3^{\cdot} \\ &\rightarrow 105^+ + NO_2^{\cdot} \\ &\rightarrow 93^+ + NO^{\cdot} + CO \\ &\rightarrow 91^+ + NO^{\cdot} + CH_2O \end{aligned} \qquad [1]$$

In Table 1 are shown the results of a number of experiments in which following ejection of ions of lower *m/z* ratio the working point for the molecular ion of 4-nitro-*o*-xylene, *m/z* 151, was moved from the q_z axis to the vicinity of the $\beta_z = 0$ boundary and then returned to the q_z axis, at a constant value of $q_z = 0.3$. The abundances were reproducible to within 1% of abundances in excess of 20%, and up to 5% for lower abundances. Throughout this work, reference is made to the base condition wherein there was no cooling period and the DC plateau duration was zero. However, the imposition and removal of a positive DC pulse takes a finite time which is estimated as ca. 1 ms. As the duration of this "zero" DC plateau is not known precisely, all stated values of DC plateau duration refer to the additional duration of the DC plateau. Following the "zero" plateau duration, it was observed during the subsequent analytical scan that 95.2% of the total ion signal was due to the molecular ion and the remainder was due to four fragment ion species, *m/z* 121, 105, 93, and 91. The amplitude of the DC pulse was selected such that the total ion signal was not significantly less (>95%) than the signal due to the molecular ion in the absence of the DC pulse, yet traces of fragment ions could be detected.

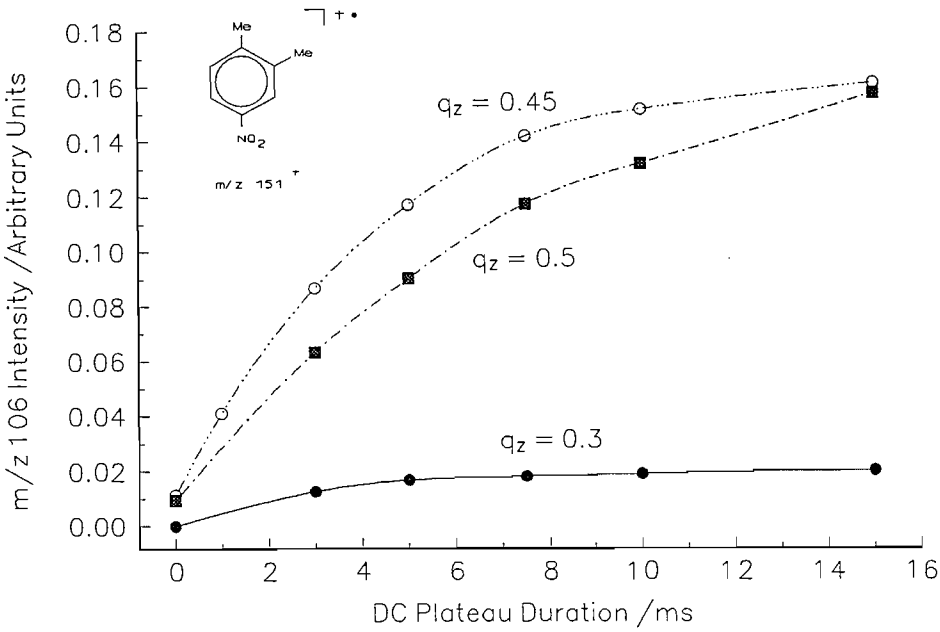

FIG. 3. Boundary-activated dissociation; variation of the degree of fragmentation of $M^{+\cdot}$ of 4-nitro-*o*-xylene to *m/z* 106 with DC plateau duration (in excess of "zero" duration) for three values of q_z:

These conditions were appropriate for the removal of (hypothetical) ions of higher *m/z* ratio; the total ion signal was used as a basis for comparison with those obtained with a finite pre-cooling and/or a plateau duration. As the DC plateau duration was increased to 15 ms, the relative abundance of the molecular ion fell dramatically (to 1.4%); approximately half of the molecular ions were lost from the ion trap, while half were dissociated among all of the previously-observed dissociation channels together with a new channel to form *m/z* 106. The dominant dissociative channel showed the loss of NO˙ to form *m/z* 121. According to Beynon et al. (20), *m/z* 151 dissociates via two competitive unimolecular mechanisms with similar activation energies. One channel leads to *m/z* 121 with a resonance-stabilized aryloxy cation structure while the other channel proceeds through a three-membered epoxide intermediate resulting in relatively unstable *m/z* 121 ions. When the experiment was repeated with a cooling period of 50 ms, each of the original dissociative channel products showed slight decreases in relative abundance, the overall ion signal was lowered, yet the molecular ion abundance and that of *m/z* 106 increased somewhat. These results indicate that formation of *m/z* 106 is favoured under these conditions but the retention of other fragment ions is impaired. This trend is continued when the cooling period is increased to 100 ms.

The entire series of experiments was repeated at $q_z = 0.45$. At zero cooling and "zero" DC plateau duration, the mass spectrum was not dissimilar from that obtained earlier. A trace of fragment ion *m/z* 106 was observed here, while no signal was detected for *m/z* 91. Again upon allowing a plateau duration of 15 ms, the relative abundance of the molecular ion fell dramatically to 0.7% but, under these conditions, there was high retention of ions within the trap in that 99.2% of the original total ion abundance was retained. Once more, the principal fragment ion species was *m/z* 121 (73.8%); the other species detected were *m/z* 106, 105, 93, and 91. Upon the addition of cooling periods of 50 and 100 ms, the system reacted in a very interesting manner. The total ion abundance fell only slightly to 97.6% at the longer cooling time, showing that evaporative ion losses are minimal at the higher value of $q_z = 0.45$. Fragment ion species of *m/z* 121, 105, and 93 declined in relative abundance while those of *m/z* 106 and 91 increased. These results, wherein ions with lower *m/z* ratios are observed with greater abundance at the expense of ions of higher *m/z* ratios, suggested that fragmentation reaction channels of relatively high activation energies become more competitive with those of lower activation energies as the cooling period is increased. The more an ion is cooled, the greater is the internal energy which may be acquired subsequently by the ion so that, upon unimolecular fragmentation, fragmentation channels of greater activation energy are accessed.

The effect of DC plateau duration on the fragmentation of the

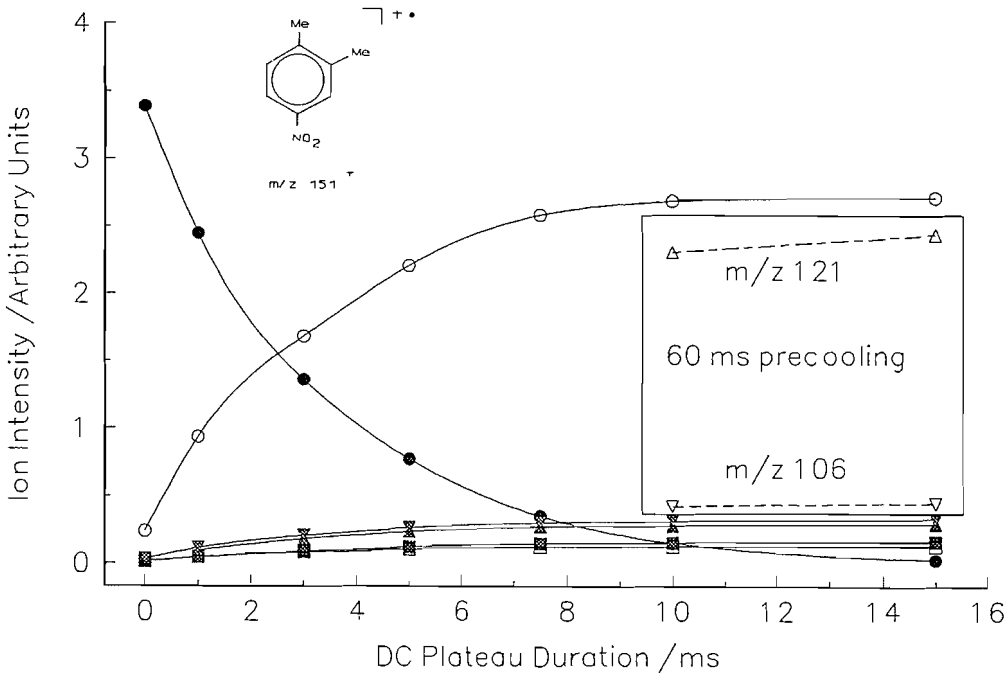

FIG. 4. Boundary-activated dissociation; variation of fragmentation of $M^{+\cdot}$ of 4-nitro-*o*-xylene and formation of fragment ions with DC plateau duration (in excess of "zero" duration) at $q_z = 0.45$. The effects of a cooling period of 60 ms on the relative abundances of *m/z* 121 and *m/z* 106 are shown in the inset. Total ion retention at the end of 15 ms of DC plateau is 97%.

molecular ion of 4-nitro-*o*-xylene to *m/z* 106 by loss of NO˙ and CH_3˙ is shown in Fig. 3 for three values of q_z. The results obtained at $q_z = 0.3$ show that the maximum yield of *m/z* 106 is reached after some 7.5 ms, at this point virtually all of the molecular ions either had been dissociated or ejected from the trap. At $q_z = 0.45$, fragmentation to *m/z* 106 continues throughout the observation time of 15 ms at which point virtually all of the molecular ions had been dissociated; there was no ion loss under these conditions. Note that the intensities of *m/z* 106 for 15 ms of DC plateau duration at $q_z = 0.3$ and $q_z = 0.45$ correspond to the appropriate abundances shown in Tables 1 and 2, respectively. At $q_z = 0.5$, the final degree of fragmentation to *m/z* 106 is similar to that obtained at $q_z = 0.45$. Although the field which the molecular ion experiences is greater at the higher value of q_z, the initial rate of fragmentation at $q_z = 0.5$ is lower than that at $q_z = 0.45$; a probable explanation for this observation is that the proximity of the working point to the $\beta_z = 0$ boundary differed slightly in these two experiments.

The influence of DC plateau duration on the abundances of the 4-nitro-*o*-xylene molecular ion and fragment ions at $q_z = 0.45$ is shown in Fig. 4. This value for q_z was chosen to maximize both fragmentation and the mass range of daughter ions which could be stored. Total ion retention at the end of 15 ms of DC plateau is 97%. Also shown here is the effect of 60 ms of cooling. The principal dissociative channel enhanced by cooling is that in which *m/z* 106 is formed (by loss of NO˙ + CH_3˙), and at the expense of *m/z* 121 (formed by loss of NO˙).

In Fig. 5 it is seen that the relative abundance of the *m/z* 106 ion increases linearly with the duration of both DC plateau and cooling period. The possibility of a direct relationship between *m/z* 121 and *m/z* 106 arose as it had been observed in earlier work that *m/z* 502, as produced by electron impact from perfluorotri-*n*-butylamine, exists in a long-lived metastable state and, when isolated in the ion trap, undergoes unimolecular fragmentation without additional excitation. However, when *m/z* 121 was isolated and subjected to BAD for 20 ms, the only signals observed were those due to *m/z* 93 and 91, of approximately equal intensity, and presumably through losses of CO and CH_2O, respectively. By chance, here was a situation wherein an excited ion dissociated via two reaction channels with equal weighting without the benefit of a cooling period. Thus an opportunity was afforded for examining the effects, if any, of cooling mass-selected ions which upon 20 ms of BAD showed similar rate constants for two quite dissimilar rearrangement reactions. The effects of up to 100 ms of cooling mass-selected *m/z* 121 ions on the ratio of the product ions, *m/z* 91 and *m/z* 93,

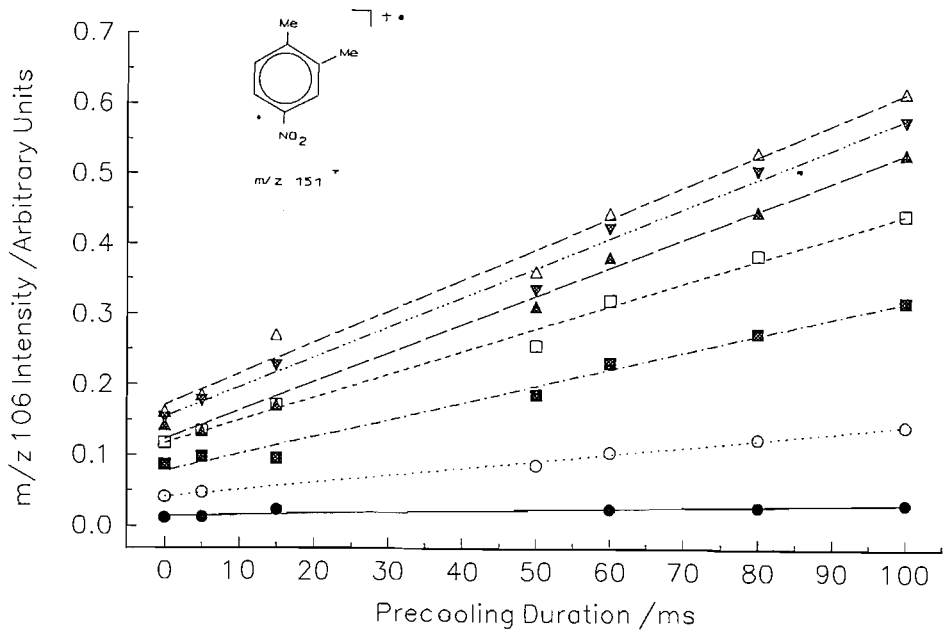

FIG. 5. Boundary-activated dissociation at $q_z = 0.45$; variation of the relative abundance of the *m/z* 106 fragment ion produced from $M^{+\cdot}$ of 4-nitro-*o*-xylene with the duration of a cooling period. Data are shown for each of seven DC plateau durations, as follows: ●, "zero" plateau duration; ○, 5 ms; ■, 15 ms; □, 50 ms; ▲, 60 ms; ▼, 80 ms; △, 100 ms.

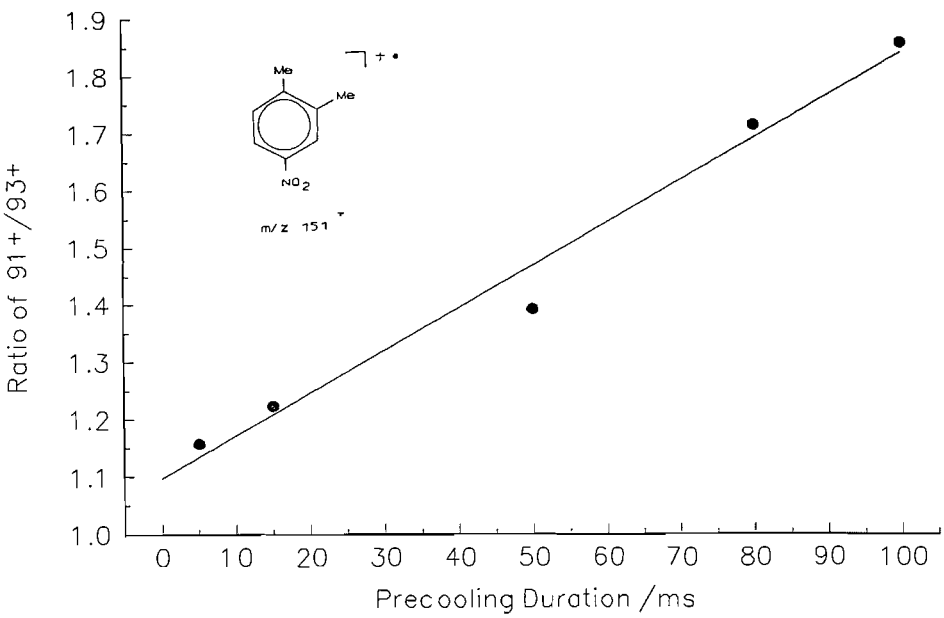

FIG. 6. Boundary-activated dissociation of *m/z* 121 from 4-nitro-*o*-xylene; variation of the intensity ratio of the product ions, *m/z* 91 and 93, with the duration of a cooling period.

are shown in Fig. 6. The signal intensity ratio for *m/z* 91 and *m/z* 93 increased as the cooling period was extended, so that, after 100 ms of cooling the abundance ratio *m/z* 91/*m/z* 93 was double that in the absence of cooling. Thus, on the basis of our understanding of the results to date, it would appear that the activation energy for the formation of *m/z* 91 exceeds that for formation of *m/z* 93. This hypothesis was confirmed by the dissociation of *m/z* 121 in a triple stage quadrupole instrument: here, at each of two collision energies, the signal intensity of *m/z* 91 was less than that of *m/z* 93; the abundance ratio *m/z* 91/*m/z* 93 was 1:7 at a collision energy of 10 eV and 1:4 at 100 eV.

Parenthetically, once appropriate values for q_z (0.45) and the DC pulse amplitude (95 V) had been chosen, tandem mass spectrometry was performed facilely up to $(MS)^5$ using the existing software.

4-Nitro-m-*xylene*

Fragmentation of the 4-nitro-*m*-xylene molecular ion differs significantly from that of the *ortho* isomer, as is shown in eq. [2]

$$\text{[2]}\quad \begin{aligned} C_6H_3(CH_3)_2NO_2^{+\cdot} &\rightarrow 135^{+\cdot} + O \qquad (\textit{meta}) \\ &\rightarrow 134^{+} + OH^{\cdot} \\ &\rightarrow 106^{+\cdot} + NO^{\cdot} + CH_3^{\cdot} \\ &\rightarrow 105^{+} + NO_2^{\cdot} \end{aligned}$$

The above series of experiments was repeated with the molecular ion of 4-nitro-*m*-xylene at both $q_z = 0.3$ and 0.45; the results are shown in Tables 3 and 4, respectively. At $q_z = 0.3$ and with zero cooling and "zero" DC plateau, the results obtained were similar to those for 4-nitro-*o*-xylene, except that the fragments were different; in place of *m/z* 121, 93, and 91, ions of *m/z* 135 and 134 were observed. Upon introducing a plateau duration of 15 ms, 75% of the ions were lost from the trap, the relative abundance of the molecular ion fell to 0.9% but that of each of the four fragment ion species was increased. When a cooling period of 50 ms was introduced, the relative abundances of all of the ion species were increased slightly, and the total ion signal increased accordingly.

The results shown in Table 3 indicate that, with finite plateau duration and cooling period, only half the number of fragment ions from the *meta* isomer remain in the trap compared with those of the *ortho* isomer at $q_z = 0.3$. As the experimental conditions were the same for each isomer, then the degrees of internal energy enhancement must have been comparable for the isomeric molecular ions, thus a lowered retention of ions indicates that evaporation of *meta* isomer molecular ions exceeds fragmentation and that the activation energies of the dissociative reaction channels are greater than those for the *ortho* isomer.

The results shown in Table 4 were obtained for the *meta* isomer at $q_z = 0.45$. Under zero cooling and DC plateau conditions, some 16.1% of the molecular ion dissociated to form the four fragment ion species. When the DC plateau duration was extended to 50 ms, the molecular ion was almost fully dissociated; the major fragmentation channels were those which led to the formation of *m/z* 105 and 106 in the abundance ratio 5:2. The insertion into the scan function of cooling periods of 50 and 80 ms duration had virtually no effect on the relative ion abundances.

From these results, the duration (15 ms) of the DC plateau is sufficient to bring about almost complete dissociation of the molecular ion. The influence of a cooling period here is small, at best; at $q_z = 0.3$, the relative abundances of all fragment ions were enhanced a little with a cooling period of 50 ms, while at $q_z = 0.45$, only the *m/z* 134 fragment ion relative abundance was enhanced. The total ion retention at $q_z = 0.45$ may be low due to formation of *m/z* 77 fragment ions which would not be detected under these conditions (*vide infra*); however, at $q_z = 0.3$, where such ions would have been detected, none were observed.

Variation of the relative abundances of the 4-nitro-*m*-xylene molecular ion and fragment ions with DC plateau duration at $q_z = 0.45$ and with 15 ms of cooling is shown in Fig. 7. Once more, the rapid decrease in molecular ion relative abundance continues smoothly throughout the period of observation. As dissociation of the molecular ion is virtually complete after 10 ms at the DC plateau with 69% ion retention, clearly BAD is compatible with the requirements for rapid ion dissociation on

the gas chromatographic time-scale, as reported earlier by Creaser and O'Neill (13). A DC plateau duration of only 2.7 ms is required for 50% dissociation; the corresponding time in Fig. 4 is 2.2 ms. The dominant fragment ion species is *m/z* 105 formed by loss of $NO_2^{\cdot}$.

The mechanism for BAD involves the action of the RF trapping field on the selected ion species when its working point is moved to the vicinity of the $\beta_z = 0$ stability boundary. The ions are both accelerated by the field and moved axially away from the centre of the ion trap whereupon they experience multiple collisions with helium buffer gas, acquire internal energy in these collisions and, in the limit, either dissociate due to their internal energy or escape from the trapping field once their kinetic energy exceeds the trapping potential. The proximity of the mass-selected ion working point to the $\beta_z = 0$ boundary, which is determined by the magnitude of the DC voltage applied to the ring electrode (at a given q_z) determines, in turn, both the degree of ion loss and the rate of ion dissociation. The magnitude of the DC voltage was chosen such that <5% of the total charge was lost when the DC voltage was applied and removed immediately, that is, with zero plateau time. Upon extending the plateau time under ideal conditions (see Table 2), more than 99% of mass-selected ions are lost either by dissociation (with 98.5% retention of fragment ions) or by ejection (0.8%) from the trap. Thus the optimum BAD efficiency (defined as the sum of the fragment ion signal intensities divided by the initial mass-selected ion signal intensity) for 4-nitro-*o*-xylene is >93%. For 4-nitro-*m*-xylene, the efficiency is >74%. Creaser and O'Neill (13), using a plateau time of 50 ms, reported a fragmentation efficiency (defined as the sum of the product ions divided by the sum of the product ions plus the residual precursor ions) of 99.2% for diethylbenzene and 8.9% for benzothiophene. Despite the low fragmentation efficiency for benzothiophene, the product ions permitted the presence of benzothiophene in a complex diesel matrix to be confirmed.

The locus of the working points of the fragment ions is a line passing through the origin of the stability diagram and the working point (near the $\beta_z = 0$ boundary) of the selected ion species. Thus the fragment ions' working points all lie at higher q_z and lower a_z values; yet these ions do not experience the high RF field experienced by the selected ion species, rather they appear to be focused collisionally towards the centre of the trap from which they are detected with high efficiency.

When BAD is carried out at $q_z = 0.45$, the mass range of daughter ions which may be trapped is limited by the intersection of the locus of working points with the $\beta_z = 1$ boundary which occurs at $q_z \approx 1.1$. Thus for the example of a mass-selected ion of *m/z* 151 subjected to BAD at $q_z = 0.45$, the mass range of daughter ions which may be trapped extends to *m/z* 62. Ions of lower *m/z* ratio are lost from the trap. In order to analyze, or detect, all of the ions stored, it is necessary to reduce the DC and RF voltages incrementally so as to maintain the working point of *m/z* 62 ions within the stability diagram. In the work described here, the daughter ion mass range is limited by two factors: firstly, the DC voltage was reduced in one step (thus placing all of the working points on the q_z axis) and, secondly, the analytical scan was carried out with axial modulation (that is, resonant ejection) at $q_z = 0.86$. Note that, in practice, resonant mass-selective instability occurs at $q_z = 0.9014$, rather than the intersection of the q_z axis and the $\beta_z = 1$ boundary for which the theoretical value of $q_z = 0.908$. Thus the daughter ion mass range in the experiments described above with BAD of *m/z* 151 at $q_z = 0.45$ extended to *m/z* 79 only.

The mechanism proposed for the cooling effect is based on the earlier simulation study (14) and the experimental observations. When ions have undergone a process of isolation, either by the concurrent or consecutive process, their trajectories fill a volume of several cubic millimeters near the centre of the trap. As their working point approaches the $\beta_z = 0$ boundary for the BAD, there is a competition between internal energy increase which will lead to dissociation and kinetic energy increase which will lead to ion loss. The moderating effects of ion/buffer gas collisions are negligible under BAD conditions. In an extreme case, when an ion is accelerated by the field and suffers few if any collisions it can acquire sufficient kinetic energy that its trajectory exceeds the physical limits of the trap so that it strikes an electrode and is lost. Clearly, the lower the trapping potential (at low q_z values) the greater will be the number of ions which are lost this way. When the volume filled by ion trajectories is reduced by momentum-dissipating collisions with buffer gas while the working point is maintained on the q_z axis, ion kinetic energies are lowered and the ions reside closer to the bottom of the trapping pseudo-potential well. When the working point is moved subsequently to the boundary, the accelerations experienced by the ions tightly focused near the centre of the trap are much reduced because the RF trapping field is smaller near the centre of the trap. As the ions are moved gradually from the trap centre and gain kinetic energy, collisions with buffer gas atoms lead to an accumulation of internal energy, but now the competition between acquisition of internal energy and kinetic energy is in favour of the former as ions suffer more collisions at low kinetic energy. Thus ion internal energy increases under conditions which are not conducive to acceleration to kinetic energies sufficiently great that ion trajectories exceed the physical limits of the trap. This mechanism is shown schematically in Fig. 8. In Fig. 8(*a*) are shown five Maxwell–Boltzmann-type (assumed) distributions of ion kinetic energies; the ordinate is the energy scale. The solid line corresponds to the distribution of nascent ions formed by electron impact. In Fig. 8(*b*), a trapping potential well in the axial dimension is shown on the same arbitrary energy scale. As the ions are subjected to a cooling period, their Maxwell–Boltzmann-type distributions of ion kinetic energies move towards the foot of the diagram so that the ions reside closer to the bottom of the potential well.

Thus far, the cooling period has been treated simply as one in which ion momentum is lost but it is equally possible that, during this period of kinetic cooling, ion internal energy increases just as it appears to do during the initial stages of BAD.

If we assume an activation energy of 5 eV and a collision rate with helium of 20 000 s^{-1}, then the average internal energy increment per collision during excitation may be calculated. Some 50% of selected ions can be dissociated by BAD in 2.6 ms; during that time, an ion experiences, on the average, 52 collisions thus the average internal energy increment is 0.1 eV. The transfer of 0.1 eV requires an ion kinetic energy of at least 4 eV, based on target and projectile masses of 4 u and 151 u, respectively. An ion kinetic energy of 4 eV is not unduly large and, as simulation studies (14) have shown that ions can acquire of the order of 100 eV while their working point is close to a boundary of the stability diagram, this ion kinetic energy requirement may even be increased several-fold. However, this model requires that the average net increase, per collision, in ion inter-

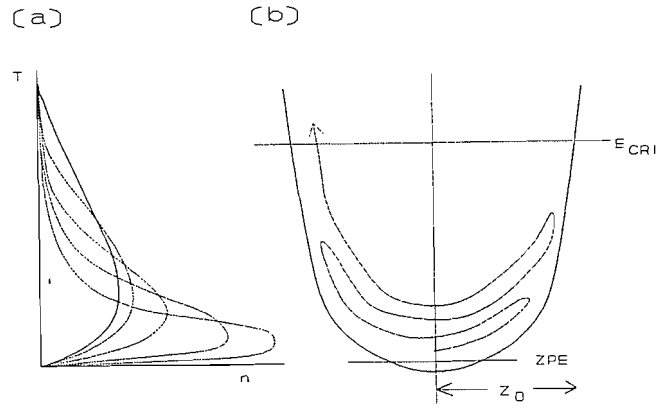

FIG. 8. Schematic representation of collisional cooling. (*a*), five Maxwell–Boltzmann-type (assumed) distributions of ion kinetic energies; the ordinate is the energy scale. The solid line corresponds to the distribution of nascent ions formed by electron impact; dashed lines represent successively cooler distributions (as the maximum in each curve moves to lower energies) brought about by collisions with buffer gas atoms. (*b*), a trapping potential well in the axial dimension shown on the same arbitrary energy scale. As ions are cooled, they reside closer to the bottom of the potential well.

nal energy due to ion activation and ion de-activation during BAD is 0.1 eV.

In summary, it is proposed that during the cooling period ion kinetic energy and axial (and radial) excursions of ions from the trap centre are reduced, as has been shown by simulation (14). Also during the cooling period, when an ion undergoes momentum-dissipating and focusing collisions with helium buffer gas, ion internal energy may be enhanced moderately. Prolongation of the cooling period without the intercession of BAD failed to produce ion fragmentation. Thus, unlike BAD, cooling alone is insufficient to bring about dissociation in the ions studied to date. Upon BAD, the effect of helium buffer gas is to expand ion axial excursions (though from much reduced values compared with those for ions which had not been cooled). As ion excursions from the trap centre increase, ion motion is influenced strongly by the RF trapping field so that ion kinetic energy increases. In turn, ion internal energy increases rapidly so as to access, or access more readily, reaction channels with higher energies of activation. In combination with BAD, cooling can enhance access to reaction channels.

Comparison with results from a QhQ instrument

An attempt has been made to compare the fragmentation patterns of 4-nitro-*o*-xylene and 4-nitro-*m*-xylene obtained with the ion trap under conditions of BAD with cooling with those obtained with a QhQ instrument. Two types of mass spectra were obtained with the QhQ. Firstly, 70 eV electron impact mass spectra were obtained: the mass spectra of the two isomers differ substantially as can be seen from Table 5; the molecular ion is the base peak for the *ortho* isomer, whereas the base peak for the *meta* isomer is *m/z* 77. Secondly, collision-activated dissociation mass spectra were obtained for the molecular ion of each isomer using argon as the collision gas. The collision energy of the mass-selected molecular ions was varied over the range 10–100 eV and, for one isomer, the effects of an increase in the collision gas pressure were investigated. The relative fragment ion abundances of the QhQ daughter ion mass spectra, electron impact mass spectrum and ion trap daughter ion mass spectrum for the *ortho* and *meta* isomers are shown in Tables 6 and 7, respectively.

From a comparison of the data shown in Tables 6 and 7, the patterns of fragment ion relative abundances obtained with the ion trap show some degree of similarity with both EI mass spectra and with daughter ion mass spectra obtained at collision energies of 100 eV, in general agreement with an earlier comparison (18). Yet these comparisons are far from satisfactory if the intent is to use the QhQ data in order to assign a crude "collision energy" to the ion trap data. In Table 6, a major fragment ion in the ion trap is *m/z* 106 which is not observed at all in the QhQ daughter ion spectra; while this species is observed in the QhQ EI mass spectrum, its relative abundance can be accounted for entirely as the ^{13}C-containing analogue of *m/z* 105. Furthermore, *m/z* 103 is not observed at all in the ion trap yet it is almost invariably observed in QhQ spectra.

A major difference between the mass spectra obtained with the QhQ and those obtained with the ion trap, as shown in Tables 6 and 7, is the relative abundance of the mass-selected ion undergoing dissociation after completion of the dissociation processes. For example, at collision gas pressures of 0.30, 0.75, 1.0, and 1.8 mTorr, the fractional survival of mass-selected *m/z* 151 ions was 0.78, 0.50, 0.37, and 0.18, respectively; these results were obtained with a collision energy of 100 eV. In the ion trap, where the pressure of collision gas is ca. 0.2 mTorr, the mass-selected ion is almost fully dissociated. Clearly, the mass-selected ions experience very different conditions: in the QhQ, ions are accelerated initially then suffer a single collision (or very few) with the target gas in which part of the ion kinetic energy is converted to internal energy whereupon the ion eventually undergoes unimolecular dissociation; in the ion trap, the kinetic energization process is interspersed with many collisional events by which ion internal energy is accumulated incrementally. It is then not entirely unexpected that the fragmentation patterns obtained from such widely-differing pro-

cesses are so different. Not only do the patterns of relative abundances differ but, in some cases, the same ion species are not observed in both methods, yet all of the fragment ion species observed are observed in the EI mass spectra.

Conclusions

Boundary-activated dissociation can afford a highly efficient and rapid method for dissociation of mass-selected ions of the compounds examined with, under appropriate conditions, almost total retention of daughter ion fragments. A DC plateau duration of some 10–15 ms is sufficient to cause the fragmentation of ≥90% of the isolated ion species. BAD can be applied facilely to successive generations of ions. The addition of a cooling period appears to bring about significant changes in the fragmentation patterns which are more marked for the *ortho* isomer molecular ion than for that from the *meta* isomer. These changes invariably show enhanced signal relative abundances for ions of lower *m/z* ratio and suggest that channels having higher activation energies are accessed in this manner. A change in the BAD abundance ratio of grand-daughter ions from an isolated daughter ion species was observed to be dependent upon the duration of a cooling period.

We report time-of-flight measurements of the H atom fragments arising in the photodissociation of phosphine at three near ultraviolet excitation wavelengths — 218.2 nm, 221.6 nm, and 228.0 nm. For these wavelengths, energetic considerations dictate that ground state $PH_2(\tilde{X})$ fragments must be the partner product of the primary photolysis event. The measured H atom kinetic energy distributions indicate that internal excitation of these partner fragments accounts for the major part ($\geqslant$62%) of the available energy, in excess of that required to break the H—PH_2 bond, provided by the photon. Inspection of the poorly resolved structure evident near the peak of the H atom kinetic energy distribution suggests the presence of substantial bending excitation and *a*-axis rotational excitation in the PH_2 partner fragment. The H atom kinetic energy distribution also shows clear evidence of atoms arising from secondary photolysis of the primary $PH_2(\tilde{X})$ fragments. This secondary photo-dissociation is observed to show a marked anisotropy, consistent with a perpendicular photo-excitation of the $PH_2(\tilde{X})$ fragment. Arguments are presented which indicate that the secondary photolysis leads both to the formation of PH(X) fragments, carrying high levels of rotational excitation, and to the three-body atomisation process.

IAN R. LAMBERT, GREGORY P. MORLEY, DAVID H. MORDAUNT, MICHAEL N.R. ASHFOLD et RICHARD N. DIXON. Can. J. Chem. **72**, 977 (1994).

On a effectué des mesures en temps de vol des atomes d'hydrogène, sous la forme de fragments provenant de la photodissociation de la phosphine à trois longueurs d'onde d'excitation — 218,2, 221,6 et 228,0 nm — proches de l'ultraviolet. Pour ces longueurs d'onde, des considérations énergétiques dictent que les fragments $PH_2(\tilde{X})$ de l'état fondamental doivent être les produits partenaires de la photolyse primaire. Les distributions de l'énergie cinétique mesurées pour les atomes d'hydrogène indiquent que l'excitation interne de ces fragments partenaires tient compte de la plus grande partie ($\geqslant$62%) de l'énergie disponible à partir du photon, ce qui est supérieur à l'énergie requise pour briser la liaison H—PH_2. Un examen minutieux de la structure mal résolue présente près du pic de la distribution de l'énergie cinétique des atomes d'hydrogène suggère la présence d'une excitation importante de déformation et d'une excitation rotationnelle le long de l'axe *a* du fragment partenaire PH_2. La distribution de l'énergie cinétique des atomes d'hydrogène montre des preuves de la présence d'atomes provenant d'une photolyse secondaire des fragments $PH_2(\tilde{X})$ primaires. L'observation de cette photodissociation secondaire démontre la présence d'une anisotropie marquée qui est en accord avec une photoexcitation du fragment $PH_2(\tilde{X})$. On présente des arguments indiquant que la photolyse secondaire conduit à la formation de fragments PH(X) portant des niveaux élevés d'excitation rotationnelle ainsi qu'au processus d'atomisation à trois corps.

[Traduit par la rédaction]

Introduction

The ultraviolet (UV) and vacuum ultraviolet (VUV) photochemistry of phosphine is of interest for several reasons. From a commercial viewpoint, PH_3 is an important component in the growth of InP, GaP, terniary and quarternary semiconductors by metalorganic chemical vapour deposition (MOCVD) methods (1, 2). Reports have appeared suggesting that such microelectronic device fabrication processes may be enhanced by the presence of UV laser radiation (3). An understanding of phosphine photochemistry is also important, given that PH_3 is a significant constituent of the reducing atmospheres of some of the outer planets, notably Jupiter and Saturn (4–7). Finally, at the most fundamental level, it is of interest to look for parallels between the primary photochemistry of PH_3 and that of its far more extensively studied first row homologue, ammonia.

The electronic absorption spectra of PH_3 and NH_3 show many similarities. In both cases the longest wavelength ($\tilde{A}$–$\tilde{X}$) absorption feature is associated with electronic promotion from the highest occupied lone pair orbital (of a_2'' symmetry in the planar D_{3h} limit) to an excited orbital that is reasonably approximated as an *ns* Rydberg orbital (n = 3 and 4, respectively, in the case of NH_3 and PH_3) in the vertical Franck–Condon region. In NH_3, this excitation is accompanied by a planar ← pyramidal change in the equilibrium geometry of the nuclear framework. Analysis of the first band in the photoelectron spectrum of PH_3, however, indicates that the equilibrium configuration of the ground state of the PH_3^+ ion is slightly nonplanar, with an angle of ~15° between any one P—H bond and the plane defined by the remaining PH_2 moiety (8). *Ab initio* calculations (9) suggest a similar non-planarity for the first excited $\tilde{A}^1A_1$ (C_{3v}) state of PH_3. In both molecules, elongation of one N—H (P—H) bond causes the excited *ns* orbital to acquire substantial antibonding valence character and, ultimately, to evolve to the 1*s* orbital of the atomic hydrogen fragment. *Ab initio* calculations of the potential energy surface for the first excited singlet electronic state of NH_3 — the $\tilde{A}^1A_2''$ state — reveal a small potential energy barrier in the H_2N---H dissociation coordinate, the magnitude of which increases with bending away from planarity (10–12). Because of this barrier, the pure bending vibrational levels of the $\tilde{A}^1A_2''$ state of ammonia are quasi-bound and the $NH_3(\tilde{A}^1A_2'' \leftarrow \tilde{X}^1A_1')$ absorption spectrum shows a progression of predissociation broadened vibronic bands involving excitation of ν_2' (the excited state out-of-plane bending mode) (11, 13–16).

The corresponding $\tilde{A}$–$\tilde{X}$ transition in PH_3 appears as a broad continuous absorption, centred around 180 nm but extending to

wavelengths ~230 nm (17–21). This lack of any discernable vibronic structure is consistent with the *ab initio* calculations of Müller et al. (9), which show only a small barrier (less than the zero-point energy associated with a P—H stretching vibration) in the H_2P---H exit channel of the $\tilde{A}^1A_1$ state potential. The corresponding first excited triplet state of PH_3 (the $\tilde{a}^3A_1$ state) is also predicted (9) to be unbound with respect to the ground state products H + $PH_2(\tilde{X})$ — a result consistent with the diffuse appearance of the $\tilde{a}^3A_1 \leftarrow \tilde{X}^1A_1$ transition in the electron energy loss spectrum of PH_3 (22). Several of the higher excited states of PH_3 are sufficiently resistant to predissociation that they show resolved vibronic (but not rotational) structure (18, 20, 23). This structure has been explained in terms of a number of overlapping progressions, involving excitation of the ν_2 mode as expected on Franck–Condon grounds, but the lack of rotational resolution has hampered definitive symmetry assignments for these (presumed) Rydberg excited states.

The photochemistry of NH_3 following excitation to its $\tilde{A}^1A_2''$ state has been much studied. The ensuing dissociation dynamics, and thus the ultimate energy disposal, has been shown to be greatly influenced by the presence of a conical intersection, in the H_2N---H dissociation coordinate at extended C_{2v} geometries, between the parent ground ($\tilde{X}$) and first excited ($\tilde{A}$) state surfaces. Early studies of NH_3 photolysis following excitation within its $\tilde{A}$–$\tilde{X}$ absorption system showed the resulting H atoms to be translationally "cool" (24), and the accompanying $NH_2(\tilde{X})$ fragments to be highly internally excited — as evidenced by the (at the time) unintelligibly complex appearance of the resulting $NH_2(\tilde{A}$–$\tilde{X})$ laser induced fluorescence (LIF) spectrum (25). Such conclusions were reiterated in a more recent study of the Doppler lineshape of the resulting H atom photofragments (26). However, any quantitative understanding of the energy disposal in this dissociation, and its specific dependence on parent quantum state, had to await the development of the technique of H atom photofragment translational spectroscopy by Welge and co-workers (27–32). The time-of-flight (TOF) spectra of the H atoms resulting from photodissociation of NH_3 following excitation to each of a number of vibronic levels of the $\tilde{A}^1A_2''$ state showed well resolved struture. Analysis of this structure revealed a strong propensity for the partner $NH_2(\tilde{X})$ fragments to be formed with little vibrational excitation, but with large amounts of rotational excitation, specifically concentrated about the *a*-inertial axis (28–30). Such product rotational energy disposal can be directly correlated to the effects of the conical intersection, in the H_2N---H dissociation channel, through which the dissociating $NH_3(\tilde{A})$ molecules must pass in order to reach the H + NH_2 asymptote (28–30, 33). Finally, given detailed knowledge of the identities and energies of these high angular momentum states of the $NH_2(\tilde{X})$ products it has since proved possible to assign their LIF excitation spectra and thereby deduce improved bending potential energy functions for both the ground $\tilde{X}^2B_1$ and first excited $\tilde{A}^2A_1$ states of the NH_2 radical (34).

No such high resolution studies of the primary photochemistry of PH_3 have been reported. Given $D_0(H_2P—H) = 28\,850 \pm 150\ cm^{-1}$ (35), we can deduce the following threshold wavelengths for forming ground and excited state PH_2 fragments in the photodissociation of PH_3:

[1] $PH_3 + h\nu \rightarrow PH_2(\tilde{X}^2B_1) + H \qquad \lambda \leq 347$ nm

[2] $\qquad\qquad PH_2(\tilde{A}^2A_1) + H \qquad \lambda \leq 212$ nm

In addition, the following PH forming fragmentation channels also satisfy the requirements of spin and energy conservation following excitation within the $\tilde{A}$–$\tilde{X}$ absorption band of PH_3 (36):

[3] $PH_3 + h\nu \rightarrow PH(a^1\Delta) + H_2 \qquad \lambda \leq 404$ nm

[4] $\qquad\qquad PH(b^1\Sigma^+) + H_2 \qquad \lambda \leq 316$ nm

[5] $\qquad\qquad PH(X^3\Sigma^-) + H + H \qquad \lambda \leq 187$ nm

[6] $\qquad\qquad PH(c^1\Pi) + H_2 \qquad \lambda \leq 181$ nm

We recognise that the quoted wavelength thresholds for the H_2 elimination pathways (which correspond to the thermodynamic thresholds) are likely to be too long, since these processes almost certainly have an associated activation barrier. Indeed, there is by now reasonable consensus that dissociation [1] is the dominant primary process following excitation within the parent $\tilde{A}$–$\tilde{X}$ absorption band. Kley and Welge (37) observed transient absorptions due to both PH_2 and PH radicals in their respective ground states (but none due to PH fragments in their metastable $a^1\Delta$ electronic state) following broadband flash photolysis using wavelengths longer than 195 nm. Their observation that the strengths of these absorptions grew with time delay and with increasing pressure of added inert gas led to the suggestion that the nascent PH_2 and PH fragments were formed with considerable internal (or, possibly, electronic) excitation. Di Stefano et al. (38, 39) have reported measurements of the spontaneous fluorescence from electronically excited $PH_2(\tilde{A})$ and PH(*b*) fragments as a function of parent excitation wavelength, thereby obtaining fluorescence excitation spectra for these two photofragments. No emission from PH(*b*) fragments was identified for excitation wavelengths longer than ~147 nm (39), thereby indicating negligible rôle for dissociation channel [4] at the excitation wavelengths employed in the present study. $PH_2(\tilde{A}$–$\tilde{X})$ photofragment fluorescence has been detected following PH_3 photolysis at wavelengths as long as 208 nm (38). This particular fluoresence excitation spectrum provides a fairly faithful replication of the parent PH_3 absorption spectrum at energies up to the first ionisation limit (125.6 nm (35)) but the estimated quantum yield for dissociation [2] was never greater than ~2%. Two later studies have attempted to shed further light on the detailed energy disposal within the nascent PH_2 fragments following PH_3 photolysis at the ArF laser wavelength, 193.3 nm. In the first of these Sam and Yardley (40) observed fluorescence from electronically excited $PH_2(\tilde{A})$ and PH(*A*) photoproducts. The latter were deduced to arise from a two-photon excitation process which, by analogy with ammonia (41), we can surmise involves the initial formation of highly internally excited $PH_2(\tilde{X})$ fragments which themselves undergo secondary photolysis. Most recently, Wittig and co-workers (42) reinvestigated this photo-dissociation process using the technique of velocity aligned Doppler spectroscopy (VADS). Analysis of the VADS lineshapes of the resulting H atom photofragments confirmed that most of the available energy was partitioned into (unspecified) internal excitation of the $PH_2(\tilde{X})$ partner ($\langle E_{int} \rangle \sim 14\,000\ cm^{-1}$). The deduced shape of the $PH_2(\tilde{X})$ fragment internal energy distribution was seen to be in good accord with that predicted by a simple density of states (prior) calculation, leading these authors to suggest that statistical factors may play an important role in this dissociation (42).

Here we report the first application of the technique of H

atom photofragment translational spectroscopy to the near UV photo-dissociation of a jet-cooled sample of PH_3. We have specifically chosen to study this photolysis at wavelengths (218–228 nm) in the low energy tail of the $PH_3(\tilde{A}–\tilde{X})$ electronic absorption-wavelengths for which, by analogy with ammonia, we might expect the simplest pattern of fragment internal energy disposal. Dissociation channels [1], [3], and [4] are the only energetically-allowed processes following one photon absorption at these wavelengths. Of these, only channel [1] will yield the H atoms to which our experiment is sensitive but, as summarised above, the quantum yields for processes [3] and [4] are believed to be minimal at these energies. Our results confirm the importance of the primary dissociation channel [1], yielding $PH_2(\tilde{X})$ fragments with very high levels of internal excitation. Even with the high intrinsic resolution of our present experiment the total fragment kinetic energy spectrum is essentially continuous, although some partially resolved structure is evident at the highest PH_2 internal energies. Partly by analogy with previous studies of the near UV photolysis of NH_3, we attribute this structure to selective formation of fragments with high levels of *a*-axis rotational angular momentum. The total fragment kinetic energy spectrum also shows clear evidence of H atoms arising from secondary photolysis of the primary $PH_2(\tilde{X})$ fragments; the partner PH fragments are deduced to be formed via a perpendicular photoexcitation, with an anisotropic distribution of recoil velocities and with large amounts of internal (presumably rotational) energy.

Experimental

The photofragment translational spectrometer and the laser systems used to effect the photodissociation and to "tag" the resulting atomic H photofragments have been described previously (43–45); only key features will be summarised here. A skimmed pulsed supersonic beam of PH_3 (BOC, Electra II grade, stated purity 99.999%) seeded in argon (5% mixing ratio, total stagnation pressure of ~1 bar) is crossed at 90° by the output of the various pulsed laser systems used to effect the photolysis and to "tag" the nascent H atom photoproducts. The recoil kinetic energy distribution of these tagged atoms is determined by measuring their collision free times-of-flight (TOF) to a detector (a Johnston multiplier, type MM1-SG) positioned along the third orthogonal axis with its front face 425.7 mm distant from the interaction region.

The experiment employs three pulsed laser systems. Near UV photolysis was brought about using an Nd–YAG pumped dye laser system (JK Lasers HY-750 plus Quanta-Ray PDL-2) operating at selected wavelengths in the range 545–585 nm. This dye laser output was frequency doubled and then mixed with the residual 1064 nm fundamental radiation of the Nd–YAG laser to yield radiation at 218.2 nm (45 826 cm^{-1}), 221.6 nm (45 112 cm^{-1}), and 228.0 nm (43 855 cm^{-1}), respectively. The resulting near UV radiation was directed through a polarisation rotator (Newport RFU $\frac{1}{2}$ Fresnel rhomb) and then focussed (75 cm f.l. lens) so as to intercept the output of the pulsed molecular beam in the centre of the interaction region. "Tagging" the H photofragments involves promoting them, via a double resonant excitation, to high Rydberg states (principal quantum number $n \sim 70$) lying just below the ionization threshold. In our experiment this is achieved using one Nd–YAG pump laser (Continuum YG 682-10) and two dye lasers. The first of these is employed to generate the Lyman-*a* radiation (corresponding wavenumber 82 259 cm^{-1}) required in order to excite the H ($2p \leftarrow 1s$) transition. The dye laser itself operates at ~554.9 nm, its output is mixed with the residual 1064 nm fundamental output of the Nd–YAG laser in a KDP crystal, and the resulting near UV radiation (at ~364.6 nm) is then frequency tripled, in krypton, to produce the required radiation at 121.6 nm. The second dye laser (Spectron SL4000G) operates with the dye LDS 720 to produce light at ~730 nm. This is frequency doubled (in a DCDA crystal) to yield the UV radiation required to further promote the H ($n = 2$) atoms to levels close to the ionisation limit. The UV and VUV beams are focussed into the interaction region (crossing angle ~6°) so as to spatially and temporally overlap the focussed output of the photolysis laser. Rydberg atoms excited in this way "fly" from the interaction volume; those that happen to recoil along the TOF axis are field ionised immediately prior to striking the Johnston multiplier. A pair of suitably biased annual electrodes (providing a field strength ~2 V mm^{-1}) positioned on either side of the interaction region ensure that any ions formed by the initial laser excitations are extracted at source and thus do not contribute to the measured TOF spectrum. The output from the multiplier is amplified and sent to one channel of a digital storage oscilloscope (LeCroy 9450, 350 MHz bandwidth) for visual display. The signal is also transferred on a shot by shot basis, via a parallel interface, to an IBM PS/2 for accumulation and subsequent data processing.

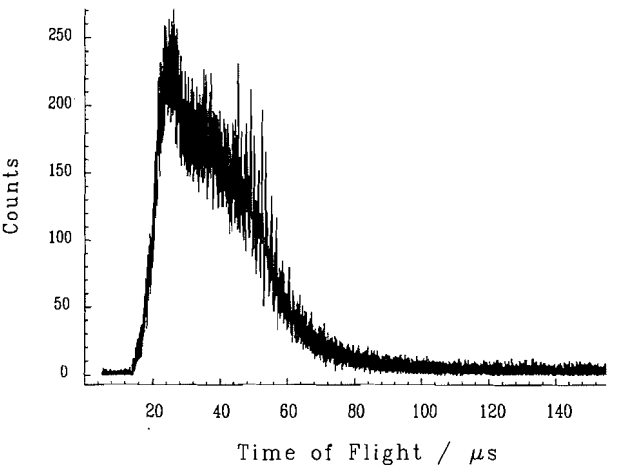

FIG. 1. H Rydberg atom TOF spectrum resulting from photolysis of a jet-cooled sample of PH_3 using 218.2 nm laser radiation, linearly polarised with ϵ_{phot} aligned parallel to the TOF axis.

Results

Figure 1 shows an H Rydberg atom TOF spectrum resulting from photolysis of a jet-cooled PH_3 sample using 218.2 nm radiation, linearly polarised with its electric vector (ϵ_{phot}) aligned parallel to the TOF axis. Figure 2*a* shows the same data, transformed to a plot of total fragment kinetic energy using the conversion

$$[7] \quad E_{kin,total} = E_{kin,H} + E_{kin,PH_2} = \frac{1}{2} m_H \left[1 + \frac{m_H}{m_{PH_2}}\right] \left(\frac{d}{t_H}\right)^2$$

where t_H is the measured H atom TOF and d is the flight distance (425.7 mm). Also indicated on this spectrum (by the arrow) is the maximum fragment kinetic energy (~17 000 cm^{-1}) that is allowed by energy conservation assuming that the observed H atoms arise solely from dissociation channel [1]. Even a cursory inspection of Fig. 2*a* is sufficient to reveal that some H atoms are formed with kinetic energies that exceed this presupposed maximum. The partially resolved structure evident around the maximum of this distribution is shown on an expanded scale in the inset.

The corresponding spectrum recorded with ϵ_{phot} aligned perpendicular to the TOF axis is shown in Fig. 2*b*. It shows the same partially resolved fine structure near the distribution maximum and, once again, the formation of some H atoms with kinetic energies in excess of what is possible simply from 218.2 nm photolysis of PH_3 via primary dissociation pathway [1]. Even more noteworthy, however, is the secondary maxi-

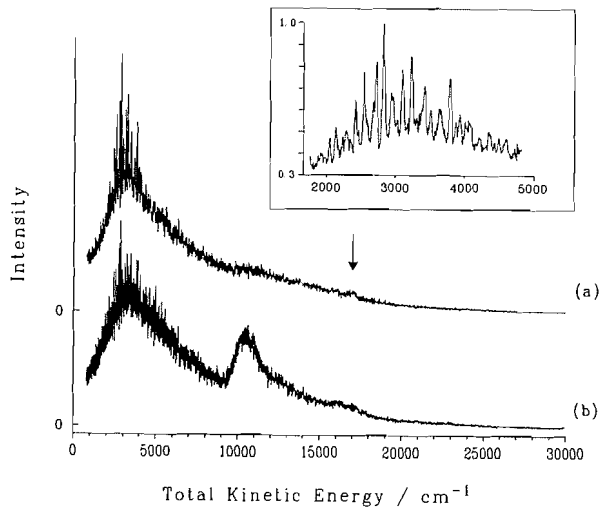

FIG. 2. Total kinetic energy spectrum of the fragments resulting from photolysis of a jet-cooled sample of PH_3 at 218.2 nm with ϵ_{phot} aligned (*a*) parallel and (*b*) perpendicular to the TOF axis. The incompletely resolved structure around the peak of (*a*) is displayed again, in the inset, with an offset baseline and on a four times expanded energy scale. The kinetic energy scales on these spectra are appropriate for the case of an H atom recoiling from a PH_2 fragment, as defined in eq. [7].

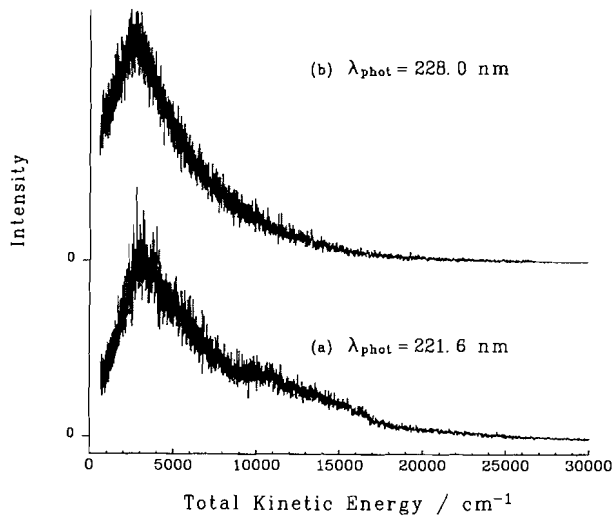

FIG. 3. Total kinetic energy spectrum of the fragments resulting from photolysis of PH_3 at (*a*) 221.6 nm and (*b*) 228.0 nm. In both cases ϵ_{phot} was aligned parallel to the TOF axis. The horizontal scale is appropriate for the case of an H atom recoiling from a PH_2 fragment, as defined in eq. [7].

mum in this kinetic energy distribution, peaking at $E_{kin} \sim 10\,000$ cm^{-1}. The relative importance of this secondary maximum was observed to increase as the energy of the UV photolysis laser was increased. The total fragment kinetic energy spectra obtained at both of the longer excitation wavelengths investigated (221.6 and 228.0 nm) were found to be of generally similar profile; see Fig. 3. Checks were made to ensure that the fastest atoms did not derive from PH_3 photolysis by the Lyman-α probe radiation. Certainly, at our highest Lyman-α intensities we were able to detect an abundance of H atoms resulting from 121.6 nm photodissociation of PH_3, the TOF spectrum of which was dominated by "slow" atoms and had an overall shape not dissimilar to that obtained using the near UV wavelengths (e.g. Fig. 1). Converting this TOF spectrum to a spectrum of total fragment kinetic energy is complicated by the multiplicity of H atom forming dissociation channels that are energetically possible using a 121.6 nm photon; even the four body atomisation process is exoergic by ~2800 cm^{-1} at this wavelength! However, TOF spectra such as that shown in Fig. 1 were recorded under conditions where the VUV photon flux had been reduced to the point where the H atom TOF signal resulting solely from Lyman-α dissociation of PH_3 was negligible. (This is most simply achieved by increasing the pressure of krypton in the tripling cell, and thereby degrading the third harmonic generation efficiency.)

As we show below, both the angular dependent secondary peak in the total fragment kinetic energy spectrum, and the yield of H atoms with kinetic energies greater than can be derived simply from the one photon dissociation of PH_3 at 218.2 nm, can be most easily explained in terms of secondary photolysis of the nascent $PH_2(\tilde{X})$ fragments. Such a suggestion is not entirely original (40, 42). It is also reminiscent of the photochemistry reported recently for the SH/SD(X) fragments resulting from near UV photodissociation of H_2S and D_2S (45, 46).

Discussion

The primary photolysis: $PH_3 \rightarrow PH_2(\tilde{X}) + H$

H atoms attributable to secondary photolysis are most evident in spectra recorded with ϵ_{phot} perpendicular to the TOF axis so, in order to focus on the primary step, we first concentrate attention on spectra such as those shown in Figs. 2*a* and 3 which were derived from experiments in which ϵ_{phot} was aligned parallel to the TOF axis. Quantifying the observed energy disposal is complicated by any underlying H atom signal resulting from secondary photolysis and by the fact that our measured distributions do not extend down to zero kinetic energy. Nonetheless we are able to make a reasonable estimate of the "centre of gravity" of the distribution of H atoms with kinetic energies less than the 17 000 cm^{-1} maximum permitted, by energy conservation, from the primary photolysis step. Thus we can estimate that internal excitation of the nascent PH_2 fragments accounts for at least 62% of the available energy (i.e. the energy provided by the photolysis photon in excess of that required to break the H—PH_2 bond). The general form of this distribution is pleasingly similar to that deduced by Wittig and co-workers (42) from analysis of the VADS lineshapes of the H atoms resulting from photolysis of a room temperature sample of phosphine at 193.3 nm. The observation that the form of this earlier distribution was in reasonable accord with that predicted using a prior calculation (i.e. with a model which assumes that the probability for dissociating to yield a PH_2 fragment with a particular internal energy is dependent upon the PH_2 vibrational state density at that particular energy) led these authors to enquire whether this photodissociation process should be viewed as an example of a "statistical" fragmentation (42). Such a process would be somewhat surprising given the demonstrable role of dynamics in establishing the product energy disposal in the corresponding photofragmentation of NH_3 (28–30). The present results, particularly the partially resolved structure around the maximum in the total kinetic energy spectrum, suggest that such is not the case.

Fragmentation channel [2] would be an endoergic process at the excitation wavelengths used in the present experiment. It thus follows that the fine structure apparent in the total kinetic energy spectrum must be associated with the formation of

ground state PH_2 fragments in a very specific subset of the total density of rovibrational eigenstates existing at internal energies $\sim$14 000 cm^{-1}. However, definitive assignment of this structure is hampered by the lack of spectroscopic data concerning high rovibrational levels of the ground electronic state of PH_2. Spectroscopy involving thermalised PH_2 samples (47–49), supplemented by *ab initio* theory (50), has yielded the following vibrational and rotational parameters for the $\tilde{X}\,^2B_1$ state of PH_2:

$$\nu_1 = 2330\ cm^{-1} \qquad A_0 = 9.132\ cm^{-1}$$

$$\nu_2 = 1102\ cm^{-1} \qquad B_0 = 8.084\ cm^{-1}$$

$$\nu_3 = 2495\ cm^{-1} \qquad C_0 = 4.215\ cm^{-1}$$

but the rotational analyses are based on transitions involving levels with $N \leqslant 9$ and $K_a \leqslant 8$ only (49).

To proceed further with the assignment we again compare and contrast this fragmentation process with that for ammonia. Photodissociation of NH_3 following excitation at the long wavelength end of its $\tilde{A}$–$\tilde{X}$ transition yields $NH_2(\tilde{X})$ fragments, primarily in their vibrationless level and in the specific subset of rotational states that have $N \sim K_a$. The observed propensity for *a*-axis rotational excitation of the molecular fragment has been rationalised in terms of the Franck–Condon excitation of out-of-plane bending motion in the parent molecule, amplified by the presence of the deep conical intersection between the $\tilde{A}$ and $\tilde{X}$ states of the parent at planar configurations in the H---NH_2 exit channel, through which the dissociating molecule must pass in order to yield ground state fragments (28–30). The physics of PH_3 dissociation following excitation to its $\tilde{A}\,^1A_1$ state must show many parallels. As in NH_3, the dominant forces acting on the nuclei following electronic excitation will tend to promote out-of-plane motion and simultaneous elongation of one P—H bond. Dissociation to the ground state H + $PH_2(\tilde{X})$ products will require the molecule to pass through a near planar geometry as it traverses the region of the conical intersection in the exit channel. Given this scenario, specific excitation of *a*-axis rotational motion in the resulting $PH_2(\tilde{X})$ fragments would seem to be inevitable. However, a comparison between the geometries of the ground ($\tilde{X}$) and excited ($\tilde{A}$) states of ammonia and phosphine and of the resulting ground state NH_2 and PH_2 fragments indicates that we should also expect substantially more bending excitation in the $PH_2(\tilde{X})$ products. Such has been proposed previously (40, 42), and is based on a consideration of the much greater change in the equilibrium bond angle of the surviving PH_2 moiety as the PH_3 molecule evolves from its excited $\tilde{A}$ state ($\hat{HPH} \sim 114°$ (9)) to the ground state product ($\hat{HPH} \sim 92°$ (47–49)).

Rigorous confirmation of this proposed energy disposal would require knowledge of the eigenvalues of the rotational levels with $N \sim K_a$ for the various ν_2 bending vibrational levels of $PH_2(\tilde{X})$. Such data are not yet available, but can be estimated given a realistic model for the PH_2 ground state bending potential function. This we have attempted to do, treating PH_2 as a "semi-rigid" bender (51) and including the strong Renner–Teller interaction between its $\tilde{A}$ and $\tilde{X}$ states for $K_a > 0$. In this method the centrifugal energy and the Renner–Teller interaction terms for each value of K_a are added to the Born–Oppenheimer potential energy functions to yield a single effective Hamiltonian for the bending motion in the $\tilde{A}$ and $\tilde{X}$ states. The eigenvalues of this Hamiltonian are the substate origins $G(\nu_2, K_a)$ for the two states, to which can be added the complete manifold of rotational energy levels derived using the usual perturbation theory approach. We used this Hamiltonian as formulated by Duxbury and Dixon (51), together with a potential energy function derived by least squares fitting to existing term values for levels of the $\tilde{A}$ and $\tilde{X}$ states of PH_2 (47–49), to calculate term values for all ground state levels with $N = K_a$, $\nu_2 \leq 7$ and total energy less than that of the first excited $\tilde{A}^2A_1$ state (i.e. $E_{int} \leqslant$ 18 000 cm^{-1}). Unfortunately, these calculations do not provide any single, unambiguous interpretation of the fine structure peaks evident at internal energies $\sim$14 000 cm^{-1} in Fig. 2. This is not particularly surprising given the paucity of spectroscopic data available for fitting the ground state potential function. What is encouraging, however, is the fact that several pairs and sequences of peaks are observed with separations similar to the predicted eigenvalue spacings, thus lending support to our expectation that the observed fine structure will ultimately prove to be explicable in terms of a number of overlapping progressions of levels with $N \sim K_a$.

Secondary photolysis

From kinetic energy spectra such as that shown in Fig. 2*a* we conclude that the primary photolysis of PH_3 at 218.2 nm results in $PH_2(\tilde{X})$ fragments with internal energies spanning the entire range from zero up to the maximum available energy ($\sim$17 000 cm^{-1}), peaking at $E_{int} \sim$ 14 000 cm^{-1}. This distribution is shown schematically in Fig. 4*a*. How should we picture the secondary photolysis of these $PH_2(\tilde{X})$ fragments? Given the angular anisotropy of the resulting H atom photofragments we must conclude that the dissociation occurs on a timescale that is fast compared to the timescale for rotation. Notwithstanding the large amount of internal excitation within the primary fragments, our observation that the maximum yield of secondary H atoms occurs when ϵ_{phot} is orthogonal to the TOF axis is most readily explained by assuming a perpendicular (i.e. $^2A_1 \leftarrow \tilde{X}^2B_1$) excitation in the PH_2 fragment. There is no available experimental information concerning the higher excited electronic states of the PH_2 radical but, given the close similarity between the first ionisation potentials of PH_2 and PH_3 (35), it is reasonable to suppose that the first Rydberg absorption of PH_2 (i.e. the $^2A_1 \leftarrow \tilde{X}\,^2B_1$ transition associated with the $4sa_1 \leftarrow 2b_1$ electron promotion) will fall in the same wavelength range as the $\tilde{A}$–$\tilde{X}$ transition of PH_3. As with other hydride molecules we might also anticipate that this first nominal "Rydberg" state of PH_2 actually has substantial antibonding valence character (19). The one reported *ab initio* calculation for this second $^2A_1$ excited state of PH_2 suggests that such a picture may be overly simplistic. Specifically, Gu et al. (52) have calculated the form of the bending potential for the 2^2A_1 state (with both bonds held fixed at their ground state separation, $R_{P—H}$ = 0.1418 nm) and found it to have a linear equilibrium configuration, at which geometry the wavefunction shows minimal Rydberg character. However, the reported bending potential curve (52) is not just a simple parabolic function; rather it shows a point of inflection at $\hat{HPH} \sim 120°$ suggestive of an avoided crossing between bent (largely Rydberg) and linear (predominantly valence) diabatic functions of $^2A_1$ symmetry. Only future, more extensive, calculations will reveal to what extent, if at all, this result is conditioned by the somewhat restricted basis set employed.

We now turn to consider the possible products of the secondary photodissociation. Figure 4*b* shows the population distribution of the nascent $PH_2(\tilde{X})$ fragments raised in energy by

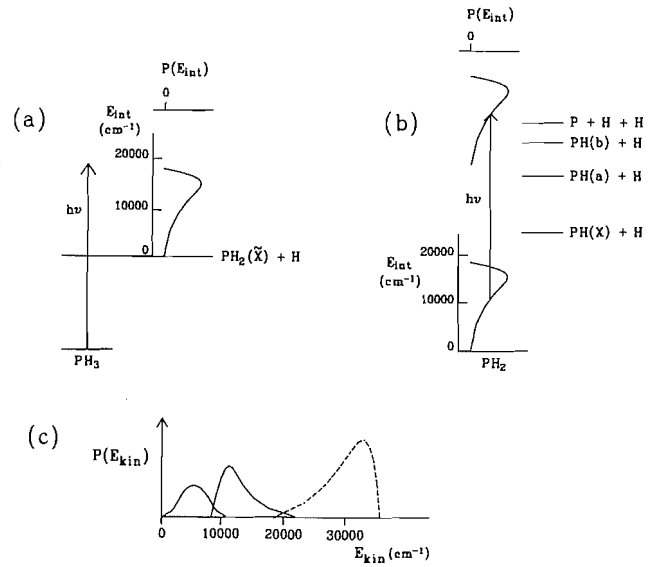

FIG. 4. Schematic illustration of various possible forms of the kinetic energy distribution of the H atoms resulting from secondary photolysis of the $PH_2(\tilde{X})$ fragments arising in the near UV photodissociation of PH_3. (*a*) depicts the general form of the experimentally observed internal distribution, $P(E_{int})$, of the primary $PH_2(\tilde{X})$ fragments. (*b*) shows the energy of this distribution of PH_2 fragments *after absorption of a near UV photolysis photon*, relative to the various H + PH dissociation thresholds. This clearly shows that *if* the major dissociation pathway were to yield internally cold ground state PH fragments then the partner H atoms would of necessity possess a highly excited, inverted kinetic energy distribution (dashed curve in (*c*)). In actuality, we deduce the kinetic energy distribution of these secondary H atoms to be of the form shown by the solid curves in (*c*), which we interpret in terms of the sum of two distinct contributions derived from dissociation pathways yielding (*i*) very highly rotationally excited PH(X) fragments and (*ii*) three atomic fragments — see text for further details.

absorption of one UV photolysis photon. Were we to assume that this photo-excitation (and the subsequent dissociation) occurs with an efficiency that is independent of the degree of internal excitation in the nascent PH_2 fragment and that the dissociation results in the formation of just *ground* state PH fragments *with little internal excitation* then, given D_0(H—PH) = 25 950 ± 700 cm^{-1} (35), we would expect the H atom photoproducts resulting from 218.2 nm photolysis of the $PH_2(\tilde{X})$ fragments to have a kinetic energy distribution that was a mirror image of that arising from the primary dissociation, i.e. a distribution which starts at $E_{kin} \sim 20\,000$ cm^{-1} and peaks at kinetic energies around 34 000 cm^{-1} (i.e. as shown by the dashed curve in Fig. 4*c*). The distribution of secondary fragments we observe is very different: it contains some fast fragments, but peaks at kinetic energies ~10 000 cm^{-1} and then falls off at still lower kinetic energies.

The following H atom forming decomposition pathways are available to a $PH_2(\tilde{X})$ fragment *in its zero-point level* following absorption of a 218.2 nm photon:

[8] $PH_2(\tilde{X}) + h\nu(218.2\text{ nm}) \rightarrow PH(X^3\Sigma^-) + H \quad KE \leqslant 19\,900\text{ cm}^{-1}$

[9] $\rightarrow PH(a^1\Delta) + H \quad KE \leqslant 12\,200\text{ cm}^{-1}$

[10] $\rightarrow PH(b^1\Sigma^+) + H \quad KE \leqslant 4\,700\text{ cm}^{-1}$

However, we know that the nascent $PH_2(\tilde{X})$ fragments formed in the primary photolysis step actually have a most probable kinetic energy of ~14 000 cm^{-1} and a maximum kinetic energy ~17 000 cm^{-1}. If some or all of this internal excitation of the PH_2 fragments can be partitioned into recoil of the secondary photodissociation products then the maximum kinetic energies quoted above need to be increased accordingly. In addition, further decomposition pathways become energetically allowed if we include the PH_2 internal excitation in the overall energy balance, e.g.:

$PH_2(\tilde{X}, E_{int} = 14\,000\text{ cm}^{-1}) + h\nu(218.2\text{ nm})$

[11] $\rightarrow PH(A^3\Pi) + H \quad KE \leqslant 4\,300\text{ cm}^{-1}$

[12] $\rightarrow P(^4S) + H + H \quad KE \sim 9\,200\text{ cm}^{-1}$

The present data do not allow unambiguous identification of the products of the secondary photolysis, but the following interpretation appears to be consistent with most of the available observations. We propose that dissociation of the highly internally excited $PH_2(\tilde{X})$ fragments yields PH fragments predominantly, if not exclusively, in their ground electronic state and carrying very high levels of internal (principally rotational) excitation. Extensive vibrational excitation of the PH product is considered less likely given the similar P—H bond lengths in PH_2 and PH. Product rotation, however, can be envisaged arising as a carry over both of the *a*-axis rotational motion and large amplitude bending in the photo-excited PH_2 molecule. The three-body fragmentation [2] represents the ultimate of this mode of dissociation, in which the centrifugal forces acting in the photo-excited PH_2 fragment are sufficient to induce rupture of both P—H bonds; the most probable partitioning of the surplus energy in such a three-body dissociation would have the two H atoms each recoiling with roughly half of the available energy.

Such an interpretation is consistent with the observed kinetic energy distribution of the secondary photolysis products. It accounts for the way in which the secondary H atom yield increases with decreasing kinetic energy up to the point where the PH(X) partner is itself unstable. At this threshold the experimental spectrum shows a discontinuity in the H atom yield. This, too, is reasonable since the simultaneous three body dissociation (12) is not restricted to follow one or other of the H---PH exit valleys on the excited state potential, and will tend to favour an equitable sharing of the available energy between the two recoiling H atoms. Dissociations proceeding via [12] are thus presumed to contribute to the broad underlying maximum centred at $E_{kin} \sim 5000$ cm^{-1}. (Such a model of the secondary dissociation process is reminiscent of that occurring in H_2S and D_2S following excitation to the $\tilde{B}^1A_1$ surface (31, 45).) The solid curves in Fig. 4*c* illustrate the expected forms of the distributions arising from these two secondary decomposition pathways. Experimentally, of course, we will measure the sum of the two, superimposed upon the kinetic energy spectrum of the H atoms arising from the primary photolysis of the PH_3 parent molecules. Our interpretation is consistent with the early observation of Kley and Welge (37), that absorption due to ground state PH(X) fragments arising in the near UV flash photolysis of PH_3 increases with increasing pressure and/or time delay; such would be expected as the highly internally excited PH(X) fragments are collisionally relaxed. Lastly, we note that our exclusion of any major role for dissociation pathways [9] and [10] (a conclusion based largely on the fact that the $a^1\Delta$ and

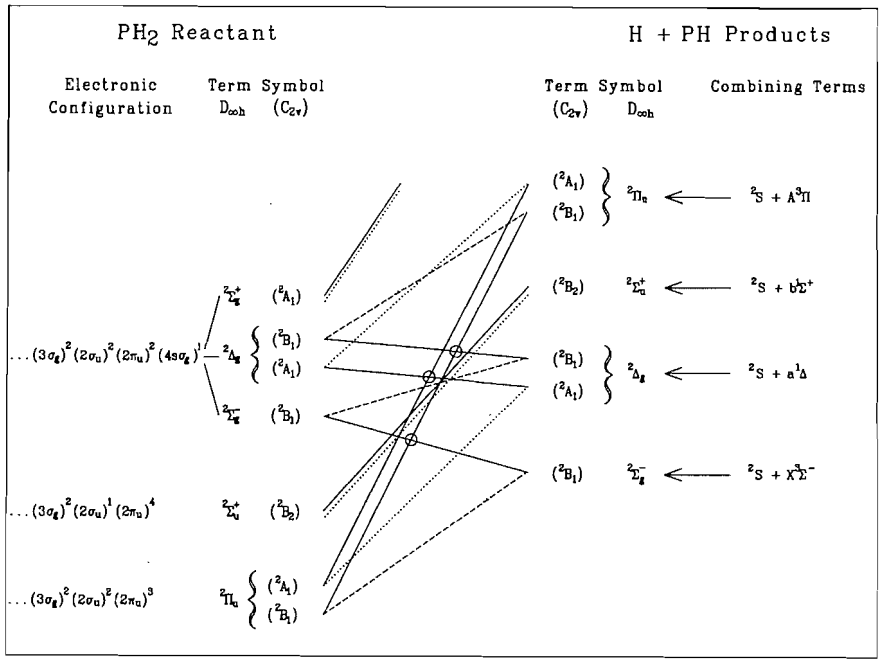

FIG. 5. Correlation diagram linking electronic states of PH_2 with those of the H + PH fragments. The states are defined in the linear and bent C_{2v} limits. Correlations in the linear limit are shown by the solid tie lines (—), the circles indicate regions of avoided crossing in the C_{2v} limit, whilst the dashed lines (... and --- for A' and A'' states, respectively) show the correlations appropriate to the lower (C_s) symmetry prevailing during the $PH_2 \rightarrow PH + H$ dissociation process.

$b^1\Sigma^+$ excited states of PH both correlate to excited states of the phosphorus atom and are thus less obviously able to account for the observed discontinuity in the H atom kinetic energy spectrum) is consistent with the fact that there have been no reports of absorption associated with PH(a) fragments following PH_3 photolysis in the near ultraviolet (37), nor of fluorescence from PH(b) photofragments following PH_3 photolysis at 193.3 nm (40).

Finally, we should give brief consideration to possible mechanisms for the secondary photodissociation process. Figure 5 shows a correlation diagram linking electronic states of PH_2 and the H + PH products resulting from simple P—H bond fission in the linear, bent (C_{2v}) and asymmetric bent (C_s) limits. In no case does the photoprepared 2^2A_1 state of PH_2 (pictured here as one component of the 4s Rydberg state having $^2\Delta_g$ symmetry in the linear limit) correlate diabatically with the ground state products. In the linear limit the natural correlation appears to be with the low lying metastable $a^1\Delta$ state of the PH product, whilst in the point group of lowest symmetry (C_s) the 2^2A_1 state correlates with the $A^3\Pi$ excited state of PH; i.e. product channel [11], which at the present excitation wavelengths is exoergic only for the most internally excited PH_2 fragments. Clearly, any mechanism advanced to explain fragmentation to *ground* state products must provide a means of coupling between A' and A'' surfaces. Renner–Teller (electronic Coriolis) and spin–orbit coupling are two such mechanisms. Both would be capable of mixing the $^2A_1$ and $^2B_1$ components of the $^2\Delta_g$ state, particularly at geometries where the two states are near degenerate; i.e. at or close to the linear configuration. In the present case, however, the PH_2 primary products are believed to be formed with high levels of a-axis rotational excitation. Such excitation must inevitably cause strong centrifugal distortion away from the a-axis (34) with the result that the photoexcited PH_2 fragments will never have the opportunity to sample near linear configurations. However, given these high levels of a-axis rotation in the PH_2 fragment and the corresponding magnitude of the effective coupling operator $2AKL_z$, electronic Coriolis mixing is still expected to be important wherever there is an accidental degeneracy. Further, Λ will be a poor quantum number for PH_2 at these strongly bent geometries. Thus it is unlikely that such mixings will occur only between levels of the $^2A_1$ and $^2B_1$ Renner–Teller components of the $^2\Delta_g$ state. Rather we expect similar mixing whenever there is an accidental degeneracy between levels of the photo-excited $^2A_1(^2A')$ state of PH_2 and those belonging to neighbouring states of $^2B_1(^2A'')$ symmetry. Provided K(K_a) is high, therefore, we anticipate that population transfer to the ground state surface will be a facile process — as indeed our interpretation of the H atom kinetic energy spectrum and, particularly, the deduced recoil anisotropy shows it to be.

Conclusions

In this paper we present time-of-flight spectra for the H atom fragments arising following excitation of jet-cooled PH_3 molecules in the long wavelength tail of its near ultraviolet $\tilde{A}$–$\tilde{X}$ absorption system. Energy conservation requires that the partner molecular fragments arising in the primary photolysis step are, of necessity, PH_2 fragments in their electronic ground state. The measured H atom kinetic energy distributions are broad, and show only poorly resolved structure. Nonetheless they suffice to indicate that the $PH_2(\tilde{X})$ fragments carry substantial internal excitation — at least 62% of the available energy. Analogy with ammonia — the photochemistry of which has been studied in much greater detail — suggests that bending vibrational motion and a-axis rotation are both important contributors to this internal excitation.

The H atom translational energy spectra also show clear evidence of H atoms arising from secondary photodissociation of the primary $PH_2(\tilde{X})$ fragments. These secondary photoproducts show a marked anisotropy, the angular dependence of which can be understood if the photo-excitation of the PH_2 moiety is

assumed to involve a perpendicular transition. The kinetic energy spectrum of the secondary H atoms indicates that, following photo-excitation, the primary PH_2 fragments dissociate both by single P—H bond cleavage — yielding an H atom together with a highly rotationally excited ground state $PH(X)$ fragment — and via a three-body fragmentation process, forming H + H + $P(^4S)$ atoms. Electronic Coriolis mixing is advanced as the most likely mechanism for coupling the photo-excited PH_2 fragments with these ground state product channels.

Acknowledgements

Once again it is a pleasure to acknowledge the generous help and inspiration of Professor K.H. Welge, Dr. L. Schnieder and their colleagues at Universität Bielefeld. We are also grateful to SERC — for equipment grants, for a post-doctoral fellowship (to I.R.L.) and research studentships (to G.P.M. and D.H.M.), and to the Laser Support Facility at the SERC Rutherford Laboratory for the loan of the photolysis laser system.

"Exact" quantum close coupled (CC) and infinite-order sudden approximation (IOSA) calculations have been carried out for the Ar + HF system on an accurate potential energy surface. The differential cross sections from the IOSA calculations show marked differences from the CC results. We find that the energy sudden component of the IOSA breaks down in a different manner for small and large impact parameters, significantly shifting and distorting the state-to-state differential cross sections. We also find that the centrifugal sudden approximation alone reproduces all features of the full semiclassical calculations quite faithfully. Through the use of several rotational sudden approximations, including a semiclassical version of the IOSA, we identify how the differences between the CC and IOSA results arise.

JAMES J.C. BARRETT, HOWARD R. MAYNE, MARK KEIL et LESLIE J. RAWLUK. Can. J. Chem. **72**, 985 (1994).

On a effectué des calculs quantiques en couplage fermé « exact » (CC) et dans l'approximation soudaine d'ordre infini (IOSA) pour le système Ar + HF, sur une surface d'énergie potentielle précise. Les sections droites différentielles obtenues par les calculs IOSA présentent des différences importantes par rapport à celles obtenus par CC. On a trouvé que la composante énergétique soudaine de l'approximation IOSA se répartit d'une façon différente suivant les paramètres d'impact petits ou grands et qu'il en résulte un déplacement et une distorsion des sections droites différentielles d'un état à un autre. On a aussi trouvé que l'approximation centrifuge soudaine permet de reproduire fidèlement, toute seule, toutes les caractéristiques des calculs semiclassiques complets. Utilisant plusieurs approximations rotationnelles soudaines, y compris une version semiclassique de IOSA, on a pu identifier l'origine des différences entre les méthodes CC et IOSA.

I. Introduction

One of the first attempts to systematize rate constants for state-to-state rotational relaxation was made by Polanyi and Woodall over two decades ago (1), as a by-product of measuring state-resolved populations in chemiluminescent reactions producing hydrogen halide products. The early success of their "exponential gap" scaling rule lay in its ability to correlate rate constants for a wide variety of systems. More detailed measurements however, especially differential cross sections, could not be explained by a two-parameter empirical model. Instead, these more detailed studies began to reveal the dynamical role of the potential energy surface for rotational energy transfer.

In the last decade, scattering studies have been joined by high-resolution spectroscopic studies on weakly-bound van der Waals molecules. Whenever accessible, experimental high resolution spectroscopy has always provided the most accurate source of information on intermolecular forces, including those for van der Waals molecules (2). In particular, accurate potential energy surfaces have been obtained using these techniques for weakly-bound rare gas + hydrogen halide systems (3, 4). However, such measurements are sensitive primarily to those parts of the potential capable of supporting bound states. Repulsive regions of the potential surface can only be obtained by rather extensive extrapolations of the spectroscopic information. In contrast, state-to-state scattering experiments, especially differential cross sections (DCS), probe the repulsive wall of the potential directly (5, 6). Such experiments can help characterize the potential for purely repulsive or very weakly attractive systems (6).

It is clear from the above that scattering measurements and spectroscopy tend to provide complementary information on the potential. Spectroscopic data for the Ar+HF system have been used by Hutson (3) to obtain a potential of excellent quality (7) in the attractive region, hereafter referred to as the "Hutson H6" potential. Scattering data, in the form of final state selected DCS from crossed molecular beam experiments on Ar+HF, have also recently been obtained (8). In order to analyze these experiments, "exact" quantum mechanical close-coupled (CC) inelastic scattering calculations have been carried out (9) using the Hutson H6 potential energy surface (3). When the results were transformed to the laboratory scattering frame, and averaged over the experimental conditions, the agreement was found to be quite good for the low final rotational states, $j' \leq 2$. The comparison of the CC results with the experimental DCS for the higher rotational states was poor (9). This is not surprising, since large Δj transitions are due primarily to collisions which sample the repulsive wall of the potential (10, 11), and this is the portion of the potential not directly probed by the spectroscopic studies. Again it is clear that spectroscopic and scattering results are best combined to determine attractive and repulsive regions of the potential surface.

Nevertheless, scattering results are not necessarily insensi-

tive to the attractive portions of the potential. In the earlier study (9), we conducted calculations to determine the sensitivity of the scattering to various features of the potential. It was found that the state-to-state DCS, particularly for the $j = 0 \rightarrow j' = 0$ and $j = 0 \rightarrow j' = 1$ transitions, displayed novel features with interference characteristics of quantum mechanical origin (9). Using the CC method, it was shown that these DCS were very sensitive to changes in both the attractive well and the repulsive wall. Further work on this system using a semiclassical approach (12) showed in more detail how the attractive and repulsive regions of the potential strike a particular balance in producing the novel features observed in the CC calculations, features that are entirely absent from the fully classical results.

For predominantly repulsive systems, the theoretical technique most successful in extracting information on the potential energy surface has been the infinite order sudden approximation (IOSA) (13, 14). This approximation has also been invaluable in obtaining a physical understanding of rotational excitation due to scattering from a hard anisotropic core (11, 15). The success of the IOSA in fitting repulsive potentials is due to the following: the method is computationally fast; and, in conjunction with an additional semiclassical approximation (11, 16), it links the local surface topography with the dynamics. Unfortunately, it is likely that the IOSA performance is poorest for precisely those rare gas + hydrogen halide (HX) van der Waals systems best characterized spectroscopically. Not only is the energy sudden criterion violated by the large HX rotational spacings, but the centrifugal sudden criterion is also rendered suspect the by attractiveness of the potential energy surface. In view of the IOSA's difficulties, the unambiguous, global determination of a strongly attractive, anisotropic potential surface, such as that for Ar+HF scattering, poses a theoretical challenge.

Accordingly, calculations on the Hutson H6 Ar+HF potential were carried out using the IOSA and compared with CC data (9). The results were disappointingly poor, at least quantitatively, in the sense that they failed to reproduce the "exact" CC results at the state resolved level, thus prohibiting the use of the IOSA in systematically improving even the repulsive region of the potential. Since the IOSA is such a frequently used tool in the analysis of rotationally inelastic scattering (11) it would be beneficial to better understand these discrepancies between the IOSA and CC results. In particular, we use previously developed semiclassical methods (12, 17) herein to understand the origins of these deviations. There have previously been a few systematic studies of decoupling approximations within a time-dependent framework (17–19). Perhaps the most comprehensive such work was that on the classical limit of decoupling (20).

In section II, we present the computational methods employed in this study. In particular, we detail the semiclassical method together with the decoupling and sudden approximations used. In section III, we compare the semiclassical CC and IOSA results. We further relate features in the CC and IOSA DCS to oscillations in the semiclassical opacity functions. This leads us to introduce a two-state model of the semiclassical method. This simplification elucidates shortcomings of the IOSA occurring even for low impact parameters (i.e. repulsive collisions). Finally, we examine the time-dependent evolution of the system to explain the failure of the IOSA for high impact parameters. Concluding remarks are made in section IV.

II. Calculations

IIA. Time-independent methods

The time-independent close-coupled (CC) calculations using the HIBRIDON package of molecular scattering programs have been described elsewhere in detail (9, 21). The infinite order sudden approximation (IOSA) calculations are carried out using the standard l-initial convention (13, 14).

IIB. Time-dependent methods

The time-dependent methods employed here are less standard than the time-independent methods. We therefore describe the time-dependent semiclassical (or classical path) method in some detail. In addition, we give explicit formulations for a hierarchy of approximations leading ultimately to the semiclassical version of the IOSA. The methods have been reviewed previously (17, 19, 22).

In the semiclassical approximation for rotationally inelastic collisions (23) we take advantage of the mass discrepancy between the translational and internal coordinates of the collision system. In this case we are scattering a hydrogenic diatom (HF) from a heavy rare gas atom (Ar). In this problem the translational reduced mass, given by

$$[1] \qquad M = \frac{m_{\mathrm{Ar}}(m_{\mathrm{F}} + m_{\mathrm{H}})}{m_{\mathrm{Ar}} + m_{\mathrm{F}} + m_{\mathrm{H}}}$$

is large. Therefore, the relative motion can reasonably be treated classically. Conversely the rotational degrees of freedom of the hydrogenic HF must be treated quantum mechanically to give accurate dynamics.

The motion for the translational coordinate is governed by Hamilton's equations of motion. In Cartesian coordinates these are given by

$$[2] \qquad \dot{\mathbf{R}} = \frac{\partial H_{\mathrm{cl}}}{\partial \mathbf{P}}; \quad \dot{\mathbf{P}} = -\frac{\partial H_{\mathrm{cl}}}{\partial \mathbf{R}}$$

where $\mathbf{R}$ is the displacement of the atom from the diatom center of mass, and $\mathbf{P}$ is its conjugate momentum. The classical Hamiltonian for the translational motion is given by

$$[3] \qquad H_{\mathrm{cl}} = \frac{P^2}{2M} + \langle V(\mathbf{R}) \rangle$$

where $\langle V(\mathbf{R}) \rangle$ is an appropriate average of the potential energy over the internal coordinates (24).

Propagation of the rotational degrees of freedom is achieved by solving the time-dependent Schrödinger equation for the internal state wave function (25)

$$[4] \qquad i\hbar \frac{\mathrm{d}|\Psi(t)\rangle}{\mathrm{d}t} = \hat{H}_{\mathrm{q}}|\Psi(t)\rangle$$

where $\hat{H}_{\mathrm{q}}$ is the quantum Hamiltonian for a rigid rotor in a time-dependent external field, $\hat{V}(t)$. The time dependence of $\hat{H}_{\mathrm{q}}$ arises from the external field as

$$[5] \qquad \hat{H}_{\mathrm{q}} = \hat{H}_0 + \hat{V}(t)$$

where $\hat{H}_0$ is the zeroth order Hamiltonian for an unperturbed rigid rotor. We expand the wave function for the system in an appropriate basis set (i.e. the eigenstates of $\hat{H}_0$, the spherical harmonics) so that

$$[6] \qquad |\Psi(t)\rangle = \sum_l c_l(t)|l\rangle \exp(-iE_l t/\hbar)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

with $c_l(t)$ being the time-dependent expansion coefficient for the lth rotational state, $|jm\rangle$, and E_l is the energy associated with the j rotational level of the lth state. The time-dependent quantum equations of motion are then given by

$$[7] \qquad i\hbar\,\dot{c}_k = \sum_l c_l V_{kl}(t) \exp(i\omega_{kl}t)$$

where

$$[8] \qquad V_{kl}(t) = \langle k|\hat{V}(t)|l\rangle$$

and

$$[9] \qquad \omega_{kl} = \frac{E_k - E_l}{\hbar}$$

We shall refer to eq. [7] as being the "full" semiclassical treatment, or simply "SC". The integral in eq. [8] is given by

$$[10] \qquad V_{kl}(t) = \int d\hat{\mathbf{r}} Y^*_{j'm'}(\hat{\mathbf{r}})\hat{V}(\mathbf{R}(t), \hat{\mathbf{r}})Y_{jm}(\hat{\mathbf{r}})$$

where $\mathbf{R}(t)$ is the atom–diatom displacement vector as a function of time from the classical part of the calculation and $\hat{\mathbf{r}}$ is the diatom bond unit vector. The classical and quantum degrees of freedom are propagated simultaneously.

The potential energy operator, $\hat{V}$, taken as the interaction potential, $V(R, \gamma)$, is a function of R and γ only. R is the length of the vector $\mathbf{R}(t)$ and γ is the angle between $\hat{\mathbf{r}}$ and $\mathbf{R}(t)$. In the classical trajectory, $\mathbf{R}$ is described in space-fixed coordinates (26). In this study $V(R, \gamma)$ is taken as the Hutson H6 potential for Ar+HF ($v = 0$) (3). This potential is selected over several other surfaces (27) because it has been shown in previous work (9) to best reproduce scattering features experimentally observed in rotationally resolved differential cross sections (8). It has also been very useful in extending further spectroscopic studies (28).

The time-dependent probability of finding the system in some rotational state, k, is given by

$$[11] \qquad P_k(t) = |c_k(t)|^2$$

The final probability is taken as $t \rightarrow \infty$. In our semiclassical treatment a trajectory is started at some impact parameter, b, and run until the final rotational state probability is constant to three decimal places. Since we are not concerned with resolving the m-sublevels, the quantum opacity function for a given final rotational level, $P_{j'}(b)$, is given as the sum

$$[12] \qquad P_{j'}(b) = \sum_{m'=-j'}^{j'} |c_{j'm'}|^2$$

The scattering angle, θ, for a trajectory is given as the angle between the initial and final classical relative momentum vectors, $\mathbf{P}$ and $\mathbf{P}'$, respectively. The classical deflection function, $\theta(b)$, is obtained from a set of trajectories calculated for an elastic collision between the Ar and HF. The $\langle V(R)\rangle$ used in the classical trajectory calculation is taken as the spherical average of the H6 potential. It has been suggested that an "Ehrenfest" average of the potential (22, 23), given by

$$[13] \qquad \langle V(R(t))\rangle = \langle \Psi(t)|V(\mathbf{R}(t), \hat{\mathbf{r}})|\Psi(t)\rangle$$

be used in the classical trajectory. We have employed this method in our calculations and find that using the spherical average of the potential shows no significant difference between the deflection or opacity functions from an Ehrenfest average calculation, but with a substantial savings in computational time.

From the quantum opacity function for elastic and inelastic transitions and the classical deflection function for the scattering angle, we calculate the DCS using

$$[14] \qquad \frac{d\sigma_{j'}(\theta)}{d\bar{\omega}} = \frac{1}{\sin\theta} \sum_i b_i P_{j'}(b_i) \left|\frac{d\theta}{db}\right|^{-1}_i$$

where b_i is the impact parameter leading to the particular scattering angle, θ. In the sum over i, there is one trajectory for $\theta > |\theta_r|$, whereas three trajectories contribute for $\theta \leq |\theta_r|$, where θ_r is the classical rainbow angle (29). The problems associated with using this classical definition of the DCS are well known (30); however, we find this method to be sufficient in our application.

The first of the approximations to the full SC dynamics that we introduce is the "energy sudden" approximation (31, 32). This approximation is based on the assumption that all rotational energy levels are degenerate, i.e. $E_k = E_l$. In this case, $\omega_{kl} = 0$ and eq. [7] reduces to

$$[15] \qquad i\hbar\,\dot{c}_k = \sum_l c_l V_{kl}(t)$$

We will refer to this as the semiclassical energy-sudden approximation (SC-ES). While this approximation does not lead to a significant savings in computational time, we will see in the following section that the SC-ES does allow for the investigation of the exact nature of any differences between the IOSA and a fully coupled calculation of the scattering dynamics.

In order to implement the decoupling approximations, we introduce body-fixed (BF) coordinates (33), in which the BF vector, $\hat{\mathbf{z}}$, is chosen to lie along the internuclear separation vector, $\mathbf{R}$. In this case, the time-dependent equations of motion are given by

$$[16] \qquad i\hbar\,\dot{c}_{j'm}(t) = \sum_j c_{jm}(t)\langle j'm|V(t)|jm\rangle \exp(i\omega_{j'j}t)$$

(Note that due to the axial symmetry of the potential, only $\Delta m = 0$ transitions are allowed.) Because of the similarity of this method to the time-independent coupled-states approximation (34), we shall denote the results from eq. [16] as the semiclassical coupled-states (SC-CS) approximation. Essentially, the approximation involved in going from the full semiclassical theory to the SC-CS approximation, in which the m-sublevels are decoupled, is equivalent to the "centrifugal sudden" approximation (13, 35).

The final approximation required to produce a coupling scheme in the time-dependent, semiclassical regime equivalent to the IOSA is to incorporate the energy sudden approximation into eq. [16]. Thus, the time-dependent equivalent of the IOSA is given by

$$[17] \qquad i\hbar\,\dot{c}_{j'm}(t) = \sum_j c_{jm}(t)\langle j'm|V(t)|jm\rangle$$

We shall refer to this result as the SC-IOS approximation. In all

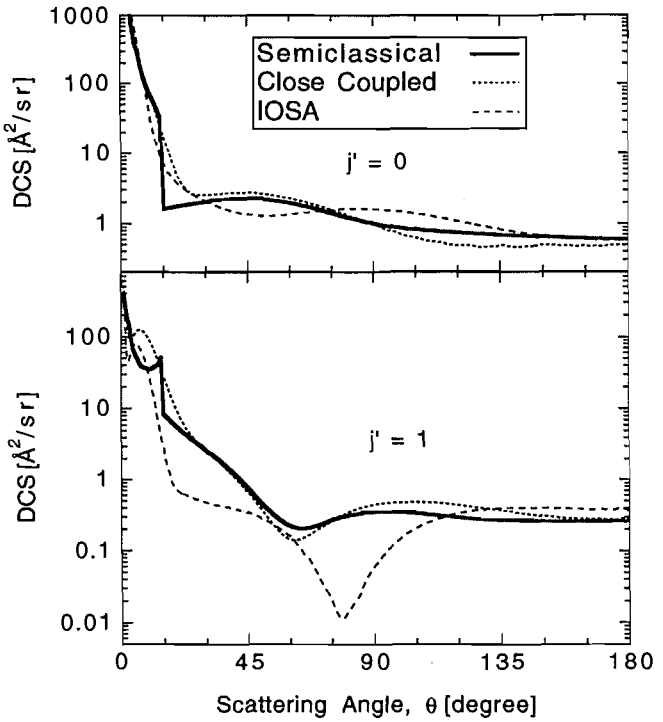

FIG. 1. Differential cross sections for Ar+HF ($j = 0$) $\longrightarrow$ Ar + HF ($j' = 0, 1$) calculated using the full semiclassical, quantum CC and IOSA formalisms. Relative collision energy, $E_{coll} = 135$ meV. Note that the CC and IOSA results have been smoothed using a 2° angular averaging function to suppress high frequency oscillations.

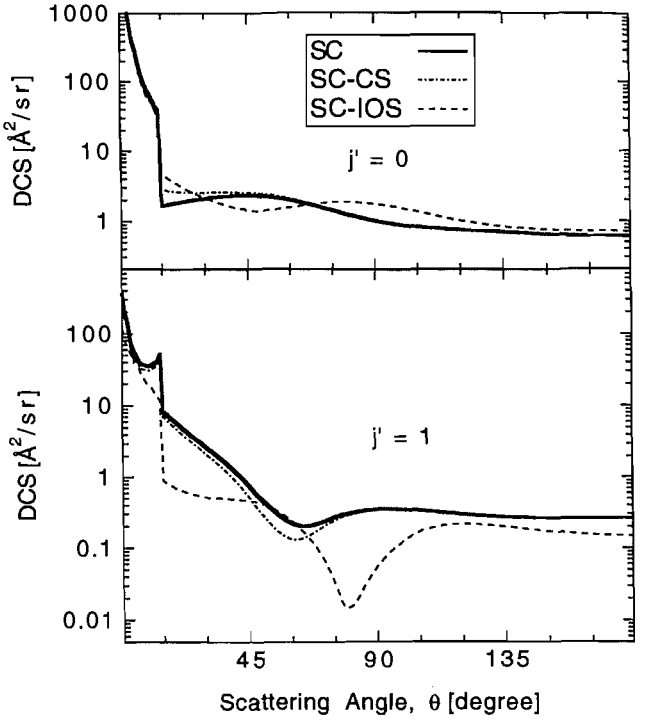

FIG. 2. Differential cross sections calculated using the full semiclassical method and indicated approximations. Collision energy and initial rotational state are in Fig. 1.

of the semiclassical methods the time-dependent equations are solved using a standard fourth-order Runge–Kutta integrator. We concentrate our efforts in this paper on the transitions out of an initial state $|j = 0, m = 0\rangle$ at a single collision energy of 135 meV, the nominal collision energy of the scattering experiment (8, 9). In all cases, a 2° angular averaging is imposed upon the calculated results to obviate features as yet inaccessible to these experiments.

III. Results and discussion

The DCS calculated using the "exact" CC, IOSA, and full semiclassical methods at a collision energy of 135 meV are shown in Fig. 1. The most notable features of the CC DCS have been discussed elsewhere (9, 12). To summarize: (*1*) the rainbow, expected at 7°, in the elastic $0 \longrightarrow 0$ DCS is suppressed whereas this feature is present in the $0 \longrightarrow 1$ DCS; (2) there is a broad shoulder in the $0 \longrightarrow 0$ DCS at $\theta \sim 40$–$70°$ with a concomitant dip in the $\theta \longrightarrow 1$ DCS centered near $\theta \sim 60°$. It has been shown (9) that these features have a quantum mechanical origin. Away from the rainbow angle, there is good agreement between the semiclassical DCS and the CC results indicating that the full semiclassical model provides an reasonable description of the collision dynamics (12).

The IOSA DCS shows features qualitatively similar to those in the CC DCS. For instance, the rainbow in the $0 \longrightarrow 0$ DCS is suppressed in this approximation, whereas the $0 \longrightarrow 1$ DCS does show a rainbow. In addition, there is a shoulder in the $0 \longrightarrow 0$ DCS, but in the IOSA the feature has shifted out to scattering angles near $\theta \sim 90°$. The accompanying dip in the $0 \longrightarrow 1$ DCS is also shifted to the same region.

In Fig. 2 we compare the full semiclassical calculations of the DCS with those using the SC-CS and the SC-IOS approximations. It is seen that the full and CS semiclassical results are in very good agreement, so that the SC-CS approximation reproduces the CC DCS rather well for this case. In contrast, the SC-IOS differs markedly from the SC results. The shoulder/dip features in the SC-IOS DCS are shifted to higher scattering angles. In fact, the SC-IOS greatly resembles the results from the time-independent IOSA calculation. To emphasize the similarity, we compare the DCS from the IOSA with those from the SC-IOS treatment in Fig. 3. The agreement is very good, with the exception of an indication of the rainbow in the SC-IOS elastic DCS. (In the rainbow region, a "primitive" semiclassical approximation like eq. [14] is expected to fail catastrophically (36)).

We now examine the collision dynamics within each of the approximations more closely. We take advantage of the time-dependent semiclassical framework, in which we can examine the contributions from individual impact parameters and the role of the potential as the trajectory evolves in time. We use these attributes to analyze the discrepancies between the fully-coupled SC and the SC-IOS calculations and relate these back to the differences between the quantum CC and IOSA results.

We first examine opacity functions from the full SC calculation and from each of the more approximate methods, shown in Figs. 4*a*–*d*. The opacity functions for the full SC (Fig. 4*a*) and the SC-CS (Fig. 4*b*) are almost identical, with the most marked difference being a somewhat smaller $P_l(b)$ near the maximum at $b = 7$ bohr in the SC-CS. This translates into an excellent agreement between the full SC and SC-CS DCS of Fig. 2. Comparing the opacity functions from the SC-ES (Fig. 4*c*) and SC-IOS (Fig. 4*d*) with Fig. 4*a*, we immediately see a dramatic difference attributable to the ES approximation.

The most obvious difference between the SC-ES and the full SC opacity functions is in the impact parameter region, $5.5 < b < 8.0$ bohr. However, a far more noticeable effect on

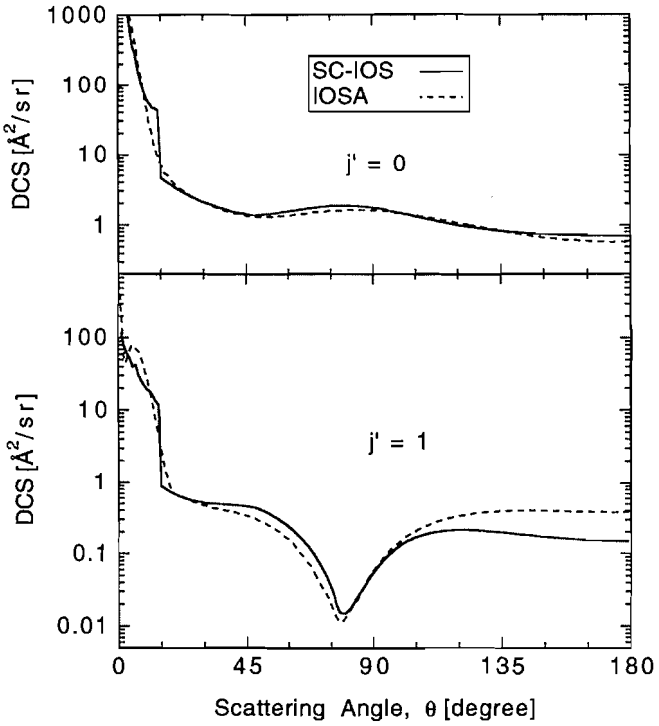

FIG. 3. Comparison of DCS from the time-independent quantum IOSA and the semiclassical IOS approximations.

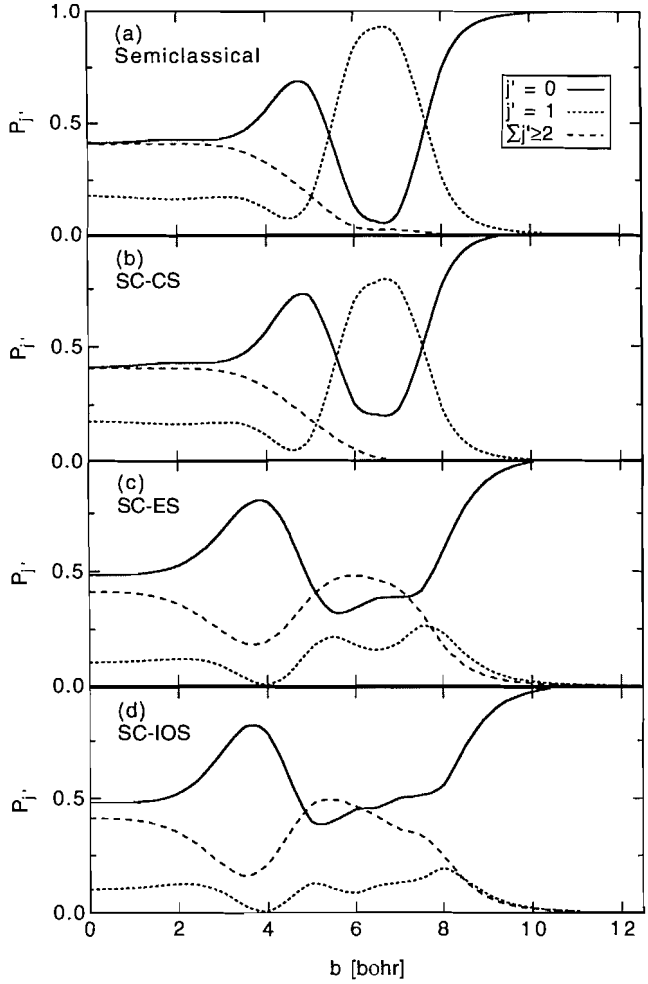

FIG. 4. Opacity functions for Ar+HF ($j = 0$) $\longrightarrow$ Ar + HF (j') from: (*a*) the full semiclassical method; (*b*) SC-CS; (*c*) SC-ES; and (*d*) SC-IOS. The summation refers to the total transition probability into rotational states $j' \geq 2$.

the observed DCS comes from the more subtle difference in the range, $3.5 < b < 5.5$ bohr, as we shall explain below. In this region, the peak and dip seen, respectively, in the $P_0(b)$ and $P_1(b)$ functions are shifted to a slightly lower b in the SC-ES (and SC-IOS) opacity functions. To highlight this shift we plot, in Fig. 5, the opacity functions for $j' = 0$ only. We also show the deflection function in this plot to indicate the scattering angles at which the features in the opacity functions manifest themselves in the DCS. The DCS is obtained from the opacity and deflection functions using eq. [14]. It is clear that a maximum in the opacity function, in the region where $\theta(b)$ is single valued, will account for a peak or "shoulder" in the DCS. (Scattering angles less than the rainbow angle, θ_r, result from impact parameters $b > 6$ bohr. In this region the effect of changes in the $P_{j'}(b)$ on the DCS is less obvious since three impact parameters contribute to the DCS.) From Fig. 5 we recognize that the shift of the $P_0(b)$ peak to lower impact parameter will cause the "shoulder" feature in the $j' = 0$ DCS to shift out to higher scattering angles. The shift in the $P_0(b)$ peak from $b = 4.5$ bohr to $b = 4.0$ bohr is responsible for the shift of the shoulder in the $0 \longrightarrow 0$ DCS in the IOSA of Fig. 1. Note that, although the $P_0(b)$ has a larger value in the SC-IOS, it occurs at a lower b value. This reduced b-weighting (see eq. [14]) compensates for the increased peak height and the shoulders are seen to have comparable intensities.

Complementary arguments are used to explain the more dramatic dip in the $0 \longrightarrow 1$ DCS observed between the CC and the IOSA. In Fig. 6 we plot the opacity functions for $j' = 1$ from each of the SC approximations. As with the peak in $P_0(b)$, the dip in $P_1(b)$ is shifted to lower impact parameters in the SC-IOS as compared to the dip in the full SC opacity function. We can also see in Fig. 6 that the dip in the SC-IOS $P_1(b)$ is deeper than in the SC model. The combination of these two features — the shift to lower impact parameter and the smaller $P_1(b)$ — result in the deep hole observed for the $0 \longrightarrow 1$ IOSA DCS in Fig. 1.

We have now established a connection between the opacity functions calculated from the various SC approximations and the features observed in the CC and IOSA DCS. We now go on to discuss the origins of the differences observed in the opacity functions calculated using the SC and SC-ES methods. Looking at Figs. 5 and 6 we see that there are two distinct regions in the opacity functions. In the low impact parameter region, $b < 5.5$ bohr, the SC and SC-ES results are qualitatively similar. However, in the high impact parameter region, $b > 5.5$ bohr, the opacity functions differ quite dramatically. We take this impact parameter, $b = 5.5$ bohr, as the division point for our discussion because of the qualitative difference between the opacity functions in these regions.

Further investigation of the dynamics reveals that a qualitative change in the coupling potential, $V_{kl}(t)$, occurs in the region of the dividing point, $b = 5.5$ bohr. This is illustrated for $V_{00}(t)$ and $V_{01}(t)$ in Fig. 7. The $V_{kl}(t)$ changes from a function which has attractive and repulsive portions to one which is solely attractive. We discuss the scattering dynamics in these two impact parameter regions in the sections below.

IIIA. Low impact parameter region

As stated above, the shift in the shoulder/hole feature to

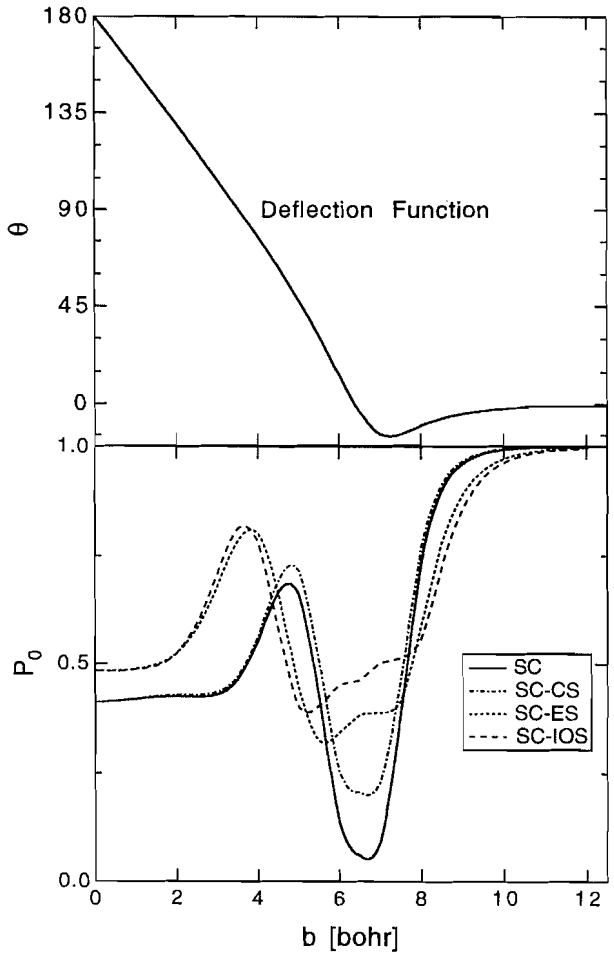

FIG. 5. Upper panel: Classical deflection function for elastic Ar+HF ($0 \rightarrow 0$) collision on the Hutson H6 ($v = 0$) surface, used in calculating each of the semiclassical DCS. Lower panel: Comparison of the $j' = 0$ opacity functions from each of the semiclassical approximations.

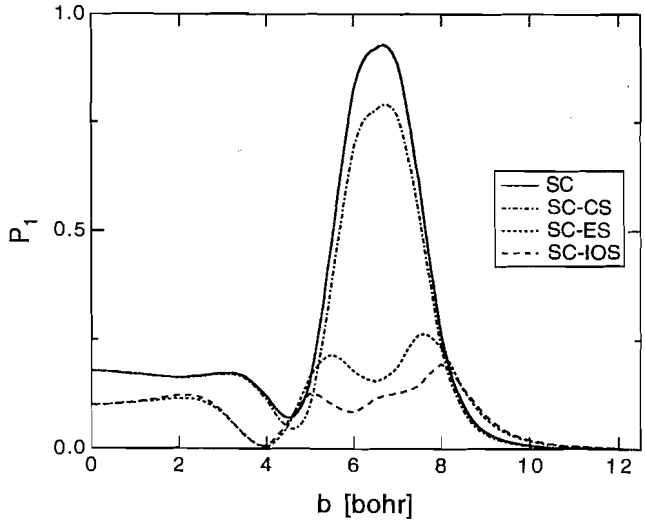

FIG. 6. Comparison of the opacity functions for Ar+HF ($j = 0$) $\rightarrow$ Ar + HF ($j' = 1$) from each of the semiclassical approximations.

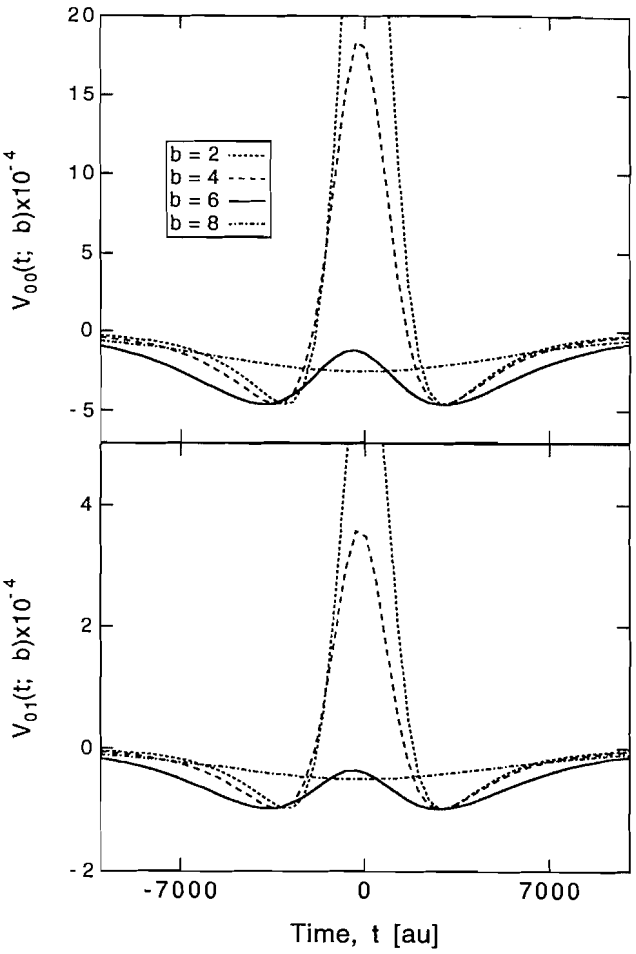

FIG. 7. Time-dependent coupling potentials at several impact parameters, b. The upper panel shows $\langle 00|V(t)|00\rangle$, denoted $V_{00}(t; b)$. The lower panel shows $\langle 00|V(t)|10\rangle$, denoted $V_{01}(t; b)$.

higher scattering angles in the IOSA is caused by a related shift of the peak in the $P_0(b)$ to lower impact parameters in the SC-IOS calculations. In a previous publication Barrett et al. (12) employed a "two-state model" to suggest that the shoulder/hole feature in the $j' = 0$ and 1 DCS was due to a balance between the repulsive and attractive parts of the potential energy surface. A two-state model was justified in the previous study by noting that: (*1*) There is a strong coupling between the $j = 0$ and $j = 1$ states, denoted by the near mirror imaging of the $P_0(b)$ in the $P_1(b)$; that is, as the $P_0(b)$ increases or decreases, the $P_1(b)$ displays a complementary decrease or increase; (*2*) The transition probabilities for the system are dominated by the transitions $0 \rightarrow 0$ and $0 \rightarrow 1$; these two final states comprise 70% or more of the total transition probability at all impact parameters.

The equations of motion for the two-state model, within the SC-CS approximation, are given by

$$[18a] \quad i\hbar\,\dot{c}_0(t) = c_0(t)V_{00}(t) + c_1(t)V_{01}(t)\exp(i\omega_{01}t)$$

$$[18b] \quad i\hbar\,\dot{c}_1(t) = c_0(t)V_{01}(t)\exp(i\omega_{10}t) + c_1(t)V_{11}(t)$$

Note that $V_{10}(t) = V_{01}(t)$. By recognizing (12) that the $V_{00}(t)$ and $V_{11}(t)$ are very similar during the course of the time evolution and by further recognizing (12) that the $V_{01}(t)$ has roughly

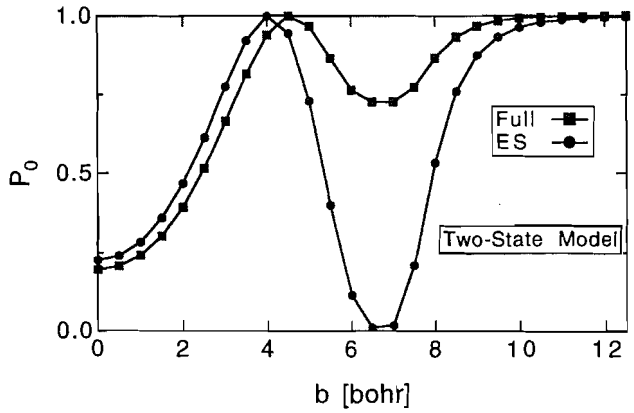

FIG. 8. Opacity functions from a two-state model of the Ar+HF collision dynamics. "Full" indicates use of eqs. [20]; "ES" indicates use of eqs. [21].

the same functional form as $V_{00}(t)$, but with a smaller magnitude, we make the following simplifications to eqs. [18]: (*1*) We substitute $V_{00}(t)$ for $V_{11}(t)$; (*2*) We employ a parameter to determine the coupling between the 0 and 1 states. In doing this we replace $V_{01}(t)$ with $\epsilon V_{00}(t)$, where ϵ is the coupling parameter less than 1. Using these simplifications in eqs. [18] we obtain

$$[19a] \quad i\hbar\,\dot{c}_0(t) = V_{00}(t)\big(c_0(t) + \epsilon c_1(t)\exp(i\omega_{01}t)\big)$$

$$[19b] \quad i\hbar\,\dot{c}_1(t) = V_{00}(t)\big(\epsilon c_0(t)\exp(i\omega_{10}t) + c_1(t)\big)$$

as the basic equations for the fully coupled two-state model. As in a previous work (12) we use, as a reasonable estimate to the true coupling potential, and ϵ value of 0.2 to analyze the scattering dynamics of the fully coupled system.

We may further simplify the two-state model by incorporating the ES approximation into eqs. [19] to obtain

$$[20a] \quad i\hbar\,\dot{c}_0(t) = V_{00}(t)\big(c_0(t) + \epsilon c_1(t)\big)$$

$$[20b] \quad i\hbar\,\dot{c}_1(t) = V_{00}(t)\big(\epsilon c_0(t) + c_1(t)\big)$$

as the "energy sudden" two-state model. We now use the simplified two-state models of eqs. [19] and [20] to explore the effects of the ES approximation on the scattering dynamics. In Fig. 8 we plot the opacity function for $j' = 0$ from the two-state model with and without the ES approximation. It is evident that the $P_0(b)$ are similar up to $b \sim 5.0$ bohr. The only significant difference is a slight shift of the energy sudden curve to lower impact parameters. Qualitatively, this is just what is observed in Fig. 5: both methods which employ the energy sudden approximation have their first maximum in $P_0(b)$ at lower b values than those calculations which have non-zero energy spacings. This shift to lower b in that impact parameter region where the scattering is sideways is just what is required to shift the shoulder in the $0 \rightarrow 0$ DCS to higher scattering angles, as was observed in the IOSA of Fig. 1. Thus the two-state model reproduces this trend very well. We analyze this shift further below.

One advantage of the two-state model is that it is simple to analyse. In particular, there are only two state coefficients to consider, $c_0(t)$ and $c_1(t)$, and the scattering dynamics reduce to

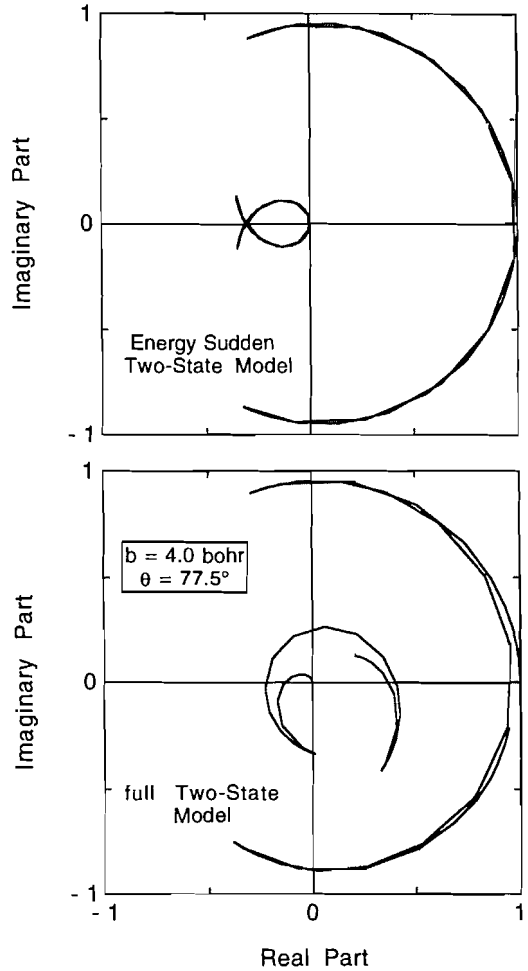

FIG. 9. Time evolution of the expansion coefficients c_0 and c_1 from the full (lower panel) and ES (lower panel) two state models at impact parameter, $b = 4.0$ bohr. Initially, $c_0 = (1, 0)$, $c_1 = (0, 0)$. Thus the outer curve describes the evolution of c_0, the inner curve c_1. The V_{00} potential controlling the dynamics is shown in Fig. 7. The initial sense of motion is counter-clockwise. At $t = -2400$ au, V_{00} changes sign, as does the sense of motion. The next reversal occurs at $t = 2400$ au.

the time-evolution of these two states. We plot trajectories of these coefficients in Fig. 9. The upper panel shows the time-evolution of the system using the energy sudden formulation (eqs. [20]); the lower panel shows the evolution of the full two-state model (eqs. [19]). In order to explain the motion in these plots we note that for $\epsilon = 0$ (i.e. no coupling between the states) the equations of motion are

$$[21] \quad \dot{c}_i = \frac{-ic_iV_{00}}{\hbar} \qquad (i = 0,\ 1)$$

By writing $c_i = |c_i|\exp(i\phi_i)$, where $\phi_i = \arg(c_i)$, substituting into eq. [21], and equating the real and imaginary parts we obtain:

$$[22] \quad \frac{\mathrm{d}}{\mathrm{d}t}|c_i| = 0; \qquad \frac{\mathrm{d}}{\mathrm{d}t}\phi_i = \frac{-V_{00}}{\hbar}$$

Thus motion in this case is pure rotation in the complex plane. A negative coupling potential leads to counter-clockwise rotation in the complex plane; a positive V_{00} gives clockwise

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

rotation. Furthermore, for the $\epsilon = 0$ case, the equations may be solved explicitly to give

$$[23] \qquad c_i(t) = c_i(-\infty) \exp\left(-i \int_{-\infty}^{t} \mathrm{d}t' V_{00}(t')/\hbar\right)$$

as the time-evolution for the states. The integral in eq. [23] is known as the action integral (17, 22).

We consider next the effect of c_j ($j \neq i$) on c_i when c_i is negligible. In this case we have

$$[24] \qquad i\hbar\, \dot{c}_i(t) = c_j(t)\epsilon V_{00}(t) \exp(\pm i\omega_{01}t)$$

where the +(−) applies to $i = 0(1)$. An alternative expression for eq. [24] gives the change in c_i, δc_i, as

$$\begin{aligned}[25] \delta c_i(t) = \dot{c}_i(t)\delta t &= (\delta t \hbar^{-1} \epsilon V_{00}(t)|c_j(t)|) \\ &\quad \times \exp\left[i\left(\phi_j - \frac{\pi}{2} \pm \omega_{01}t\right)\right] \\ &= \{\delta t \hbar^{-1}\epsilon |V_{00}(t)||c_j(t)|\} \\ &\quad \times \exp\left[i\left(\phi_j - \mathrm{sign}\,(V_{00}(t))\frac{\pi}{2} \pm \omega_{01}t\right)\right]\end{aligned}$$

The term within the braces { } is always positive. Thus, when ω_{01} is zero (i.e. in the ES approximation), the change in c_i due to a nonzero c_j is a complex number rotated $\pi/2$ from c_j on the clockwise or counter-clockwise side depending on the sign of V_{00}.

The two-state model was utilized in an earlier study (12) to explain the presence of the shoulder in the $0 \rightarrow 0$ DCS. We briefly reiterate some of our earlier findings to explain the difference between the two-state model with and without the ES approximation. Referring to the upper panel in Fig. 9, we see that the $c_0(t)$ returns to its initial value of (1, 0) twice during the collision. In fact, it is clear that the net action for this trajectory is almost exactly zero. That is, at this impact parameter the attractive and repulsive parts of the potential exactly balance each other on the incoming and outgoing portions of the classical path. We can see that initially $c_0(t)$ rotates in a counter-clockwise sense until the repulsive part of the potential is reached. At this point the potential becomes positive and $c_0(t)$ retraces its initial path. Note that during this trajectory, the c_1 term always remains small and the evolution of the states is essentially governed by the simplification given in eq. [21]. The rotation of $c_0(t)$ continues to a point conjugate to the position where the repulsive part of the potential was entered. As the trajectory goes back into the attractive part of the potential, and V_{00} goes negative, the cycle is completed by $c_0(t)$ retracing its path once more back to a point near (1, 0). It is this balancing between the attractive and repulsive parts of the potential — which leads to the zero action — that is responsible for the quantum feature seen near $\theta = 40$–$70°$ in the CC DCS in Fig. 1.

Now examine the lower panel in Fig. 9. The motion begines as in the two-state energy sudden case. However, instead of the change in c_1 being directed along a vector $\pi/2$ to the direction of c_0, the motion is pushed further in the counter-clockwise direction due to the presence of the ω_{01} term. This motion is exemplified by eq. [25]. When the potential becomes positive, instead of retracing itself, as with the ES model, the c_1 in the full model is pulled out further. That is, the rotation rate in the clockwise direction is slowed by the non-zero ω_{01}. As the particles separate on the outgoing path of the trajectory, the c_1 is again pulled in the counter-clockwise direction and spirals toward the origin. The trajectory once more produces a nearly null action; however, the inclusion of the non-zero frequency, ω_{01}, has slightly shifted the phase of the coefficients. Thus the overall trend of the $c_i(t)$ motion is similar in the two models, but the asymptotic values of the c_i are slightly shifted. This accounts for the shift of the shoulder/hole feature observed in the CC and IOSA DCS.

IIIB. High impact parameter region

We now discuss the scattering dynamics in the impact parameter range, $5.5 < b < 8.0$ bohr. Because this impact parameter range lies in the rainbow scattering region, changes in the opacity functions have a less obvious effect on the shape of the DCS, but have a large effect on the integral cross section. This region also shows the greatest difference between the opacity functions of the full SC calculation and the SC-IOS, and understanding this difference is important to identifying any shortcomings in the IOS approximation.

At the higher impact parameters ($b > 5.5$ bohr) the potential is attractive during the full time-evolution of the system. That is, the trajectory never encounters the repulsive part of the potential. Examination of Fig. 8 shows that the two-state model does not reporduce the trends in the opacity functions of the SC or SC-IOS. This is very intriguing because in this impact parameter range the asymptotic values of the expansion coefficients, (that is, the opacity functions of Fig. 4*a*) show that >90% of the total probability is in the $j' = 0$ and 1 rotational states if the full dynamics are employed. In addition, Fig. 4*d* reveals that for the SC-IOS ~50% of the final state probability is in $j' \geq 2$. In light of this, we see that the two-state model is inappropriate for an understanding of the energy sudden dynamics in this impact parameter region. Accordingly, we set it aside and return to the multi-state methods.

Examination of Figs 4*a* and 4*b* shows that at impact parameters greater than 5.5 bohr, transitions to the higher rotational states (i.e. $j' \geq 2$) do not occur when ω_{kl} is non-zero. This is due to the energetic separation of the states which manifests itself through the $\exp(i\omega_{kl}t)$ term, which is included in the full SC and in the SC-CS. The effect of the frequency term is most easily seen, perhaps, if one considers the first order perturbation theory limit (37) of the time-dependent scattering:

$$[26] \qquad P_{j'} = \left| \int_{-\infty}^{\infty} \mathrm{d}t V_{0j'}(t) \exp(i\omega_{0j'}t) \right|^2 \hbar^{-2}$$

This has the form of the Fourier transform of the interaction potential. In general, for simple $V_{0j'}(t)$, this term will decrease as $\omega_{0j'}$ increases; that is, the low frequency terms will dominate. Since in the impact parameter region of interest here — high b — $V_{0j'}(t) < 0$ for all time, this is expected to hold. Clearly, the sudden approximation of setting $\omega_{0j'}$ to zero removes this frequency dependence, and the probabilities of all transitions become solely a function of the action integral for the $0 \rightarrow j'$ transition.

Figures 4*c* and 4*d* show that a substantial component of the total transition probability is in $j' \geq 2$ for the SC-ES and SC-IOS approximations. We also see from Fig. 4 that the major differences between the SC and the SC-IOS in the high impact parameter region result from making the ES approximation. Because of this, we focus on the differences between the full SC and SC-ES methods.

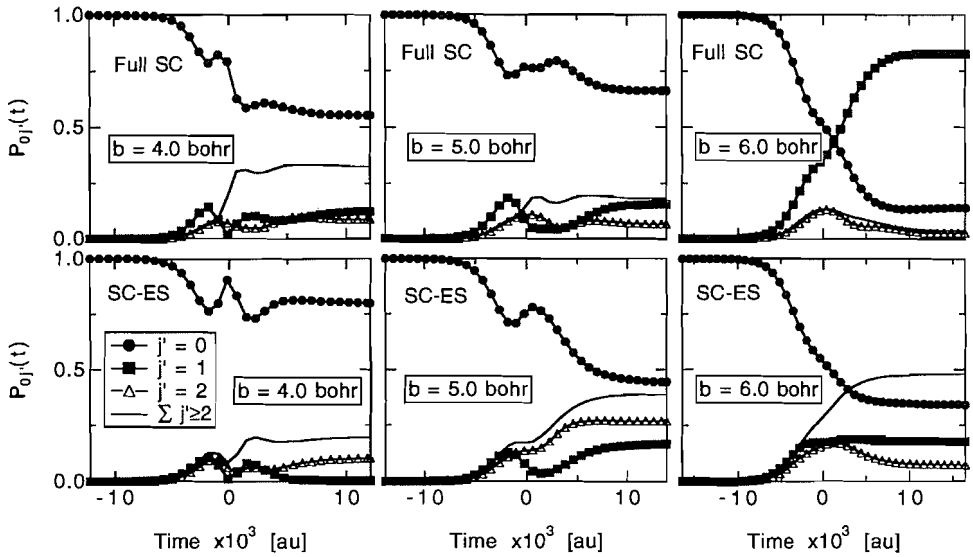

FIG. 10. Time evolution of rotational state probability from the full SC and the SC-ES models. In both cases the summation refers to the total probability for rotational states, $j' \geq 2$. Note different time scales for each impact parameter.

In Fig. 10 we plot the rotational state probability as a function of time, $P_{j'}(t)$, for the SC and SC-ES models at several impact parameters. At the lower impact parameters the time-dependent probability for $j' = 0$ and $j' = 1$ are quite similar in both models, as expected from our previous analysis. The summed probabilities into rotational states $j' \geq 2$ are also similar; however, the SC-ES overestimates the probability into $j' = 2$. As we move to higher impact parameters (e.g. $b = 5.0$ bohr), again the $j' = 0$ and 1 probabilities are similar in the two methods, but it is now becoming clear that the SC-ES is greatly overestimating the transition probability into the higher rotational states.

By $b = 6$ bohr, the dynamics exhibited by the SC and the SC-ES are quite different. The reason for this should be clear from the above discussion. In this impact parameter interval, the interaction potentials (see Fig. 7) are purely non-positive. Thus, the "sudden" action can accumulate monotonically along the trajectory. This is not necessarily the case for all $V_{0j'}$, but it certainly explains the generally poor performance of the SC-ES in this region. For instance, in the SC method the $P_1(t)$ increases steadily from its initial value of zero to become the dominant transition. In the SC-ES the $P_1(t)$ increases on the incoming part of the trajectory, as in the full SC method, however the $P_1(t)$ reaches its asymptotic value by the mid-point of the trajectory. In both methods the $P_2(t)$ increases steadily and reaches a maximum near the turning point of the trajectory, then falls off to $P_2(t) < 0.1$. The difference between the methods is that in the full SC the $P_2(t)$ (along with the continued decrease in $P_0(t)$) relinquishes much of the flux to $P_1(t)$. In the SC-ES, however, because of the removal of the exp $(i\omega_{kl}t)$ term the states $j' > 2$ begin to dominate the total transition probability.

This is the impact parameter region where the IOS approximation performs most poorly. By overestimating the transition probability into the higher rotational states, the IOS approximation no longer provides an adequate representation of the true collision dynamics. It is generally accepted that the IOSA is poor when the scattering is dominated by a strongly attractive potential (11). Our time-dependent pictures provides a rather striking illustration of this.

Conclusions

In this paper we have explored the collision dynamics for Ar+HF using several computational approaches. We presented time-independent quantum mechanical CC and IOSA results calculated on the Hutson H6 potential for the Ar+HF ($v = 0$) system at a collision energy of 135meV out of an initial rotational state, $|j = 0, m = 0\rangle$. The differential cross sections obtained using the IOSA differ markedly from the CC differential cross sections. The origin of this discrepancy was investigated using several time-dependent semiclassical methods. With this approach, the effect of each of the decoupling approximations on the dynamics was explored. The intuitive advantage of the time-dependent methods over the time-independent methods, is that the local (rather than the global) effects of the potential on the scattering dynamics can be observed.

From this work it was found that the biggest deviation of the IOSA from the "exact" CC calculations is due to the inclusion of the energy sudden approximation. Further, it was found that the energy sudden approximation "failed" differently for different impact parameter regions. For $b < 5.5$ bohr, in which the repulsive part of the potential is sampled and backwards and sideways scattering dominate, the opacity functions obtained from the SC-IOS are qualitatively similar to those obtained using the fully coupled SC method. While this qualitative agreement is encouraging, the quantitative differences are sufficiently great to shift features in the DCS by as much as 30°.

An analysis of the time dependence of the dynamics in this low impact parameter region was facilitated by the use of a two-state model calculation. The model data agreed well with the SC calculations, and revealed the same trends on the inclusion of the ES approximation. The model revealed that at one impact parameter in this range the net action along the classical trajectory will be zero. In the model with the energy sudden approximation included it was found that the zero action trajectory leads to a transition probability for $0 \rightarrow 0$ of essentially unity — necessarily a maximum. With the ES approximation absent, the trend is similar but the maximum shifts slightly to higher impact parameters.

In the impact parameter range $b > 5.5$ bohr, the SC-ES

method performs badly when compared to the full SC. The two-state model is no longer appropriate in this region to study the sudden approximation, since it is clear that the energy sudden approximation allows access to higher product rotational states than occur in the full calculation. At these higher impact parameters, the trajectory experiences exclusively an attractive potential. It is the presence of the attractive potential and the energy sudden approximation that artificially couples the system to high j' states in the IOSA; this does not occur to as great an extent for a replusive encounter.

Finally, we make some remarks on the universality of our findings. As its name implies, the accuracy of the "sudden" approximation depends on the time scales involved during the collision. At the collision energy used here, the collision time is on the order of 2×10^4 au. This is comparable with the classical rotational period for an HF molecule in its $j = 1$ state, 3.354×10^4 au. Therefore, for the system at hand, the IOSA is unlikely to be accurate, even for the $j = 0 \rightarrow j' = 1$ transition, at collision energies less than 1 eV. Similarly, one would expect the sudden approximation to perform better in calculations with lighter rare gas atoms, but worse with heavier ones. Our findings here and previously (9) indicate that the IOSA is unlikely to prove a useful tool in improving potential surfaces for rare gas+hydrogen halide scattering for the experimental conditions presently accessible.

Dedication and acknowledgements

It is a pleasure to dedicate this paper to Professor John C. Polanyi on the occasion of his 65th birthday. We (H.R.M. and M.K.) first became interested in the problem of rotational energy transfer while enjoying post-doctoral fellowships in Professor Polanyi's group. We had earlier contributed to experiments showing anomalously large $j = 0 \rightarrow j' = 1$ integral cross sections for collisions of HF with several rare gases. Such integral cross sections were first measured in Professor Polanyi's laboratories a decade ago (38).

In addition to acknowledging Professor Polanyi's sponsorship of our earlier work, we would like to thank a number of our contemporaries at Toronto, all of whom worked on the "yellow machine" or *inside* the "red machine": Jack Barnes, Ray Kutina, Kenji Honma, Dan Thomas and Dave Wrigley.

Acknowledgment is made to the donors of the Petroleum Research administered by the American Chemical Society, for support to H.R.M. of this research. M.K. also wishes to thank the donors of the Petroleum Research administered by the American Chemical Society for support of this research.

Transition state spectroscopy with electrons as studied by 3D-trajectory calculations of the reaction $He^+ + Br_2^- \rightarrow He^+Br^- + Br$

HARALD MORGNER[1] AND HUBERT SEIBERLE[2]

Fakultät für Physik der Universität Freiburg, Hermann-Herder-Str.3, D-79104 Freiburg, Germany

Received September 8, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

HARALD MORGNER and HUBERT SEIBERLE. Can. J. Chem. **72**, 995 (1994).

We investigate electron emission from the interaction of metastable helium He($1s2s$; 2^3S) with Br_2 molecules. A small part of the electron energy spectrum is due to direct Penning ionization, giving rise to spectral features familiar from photoionization of Br_2. However, the dominant contribution to electron emission originates from a collision complex that can be described as ion pair state He^+–Br_2^-. In analogy to a collision between the alkali atom Li($2s$) and Br_2, which leads via Li^+–Br_2^- to salt formation LiBr + Br, this system can be viewed as undergoing a chemical reaction to He^+Br^- Br. Of course, no stable products He^+Br^- can be produced in this way since the large recombination energy of He^+ causes autoionization to He + Br^+ + e^-. On the other hand, this situation is ideal if one wishes to study spectroscopically the transition state of a chemical reaction, in our case the development of the system from He($1s2s$) + Br_2 to (He^+Br^-) + Br. Neither of the separate reaction partners is able to emit electrons. During the encounter the lifetime against autoionization is so short that decay into the ionized channel cannot occur long after the chemical reaction is complete. Thus, electron emission is confined to the lifetime of the reaction complex. Accordingly, the electron energy spectrum contains information exclusively on the transition state with no blending by emission from educts or products as could be the case in optical spectroscopy. As a case study we carry out 3D-trajectory calculations on the collision complex He^+–Br_2^-, monitoring the energy distribution of emitted electrons throughout the lifetime of the complex. We find that the electron energy spectrum varies strongly from the initial to the final stages of the ongoing chemical reaction.

HARALD MORGNER et HUBERT SEIBERLE. Can. J. Chem. **72**, 995 (1994).

On a étudié l'émission électronique provenant de l'interaction de l'hélium métastable, He($1s2s$; 2^3S) avec les molécules de Br_2. Une faible partie du spectre d'énergie électronique est dû à l'ionisation de directe de Penning qui donne lieu aux caractéristiques spectrales bien connues de la photoionistion du Br_2. Toutefois, la contribution la plus importante á l'émission d'électrons tire son origine d'un complexe de collision que l'on peut décrire comme un état de paire d'ions He^+–Br_2^-. Par analogie avec la collision entre un atome du métal alcalin Li($2s$) avec le Br_2 qui conduit à la formation de sel, LiBr + Br, par le biais du Li^+–Br_2^-, on peut considérer que ce système subit une réaction chimique conduisant au He^+Br^- Br. On ne peut toutefois pas obtenir de produit He^+Br^- stable de cette façon puisque la grande énergie de recombinaison du He^+ provoque son autoionisation en He + Br^+ + e^-. Par ailleurs, cette situation est idéale pour quelqu'un quiv veut étudier l'état de transition d'une réaction chimique d'une façon spectroscopique, dans notre cas la réaction allant de He($1s2s$) + Br_2 à (He^+Br^-) + Br. Aucun des partenaires de chacune des deux réactions séparées n'émet d'électrons. Au cours de la rencontre, le temps de vie en fonction de l'autoionisation est tellement faible que la dcroissance par la voie ionisée ne peut pas se produire longtemps aprs que la réaction chimique se soit complétée. L'émission d'électrons est donc limitée au temps de vie du complexe réactionnel. Il en découle que le spectre d'énergie électronique ne contient que de l'information relative à l'état de transition, sans mélange avec des émissions d'éduits ou de produits comme c'est le cas en spectroscopie optique. À titre d'exemple, on a effectué des calculs de la trajectoire tridimensionnelle du complexe de collision He^+–Br_2^- en examinant la distribution d'énergie des électrons émis pendant toute la duré de vie du complexe. On a trouvé que le spectre d'énergie électronique varie fortement de l'étape initiale à l'étape finale de la réaction chimique qui se produit.

[Traduit par la rédaction]

1. Introduction

It certainly has always been, and still is, a challenge for the spectroscopist to observe a chemical reaction not via the ready products but by monitoring information from the collision complex itself, i.e., from the ongoing reaction. If attempted by optical spectroscopy the odds seem to be strongly against such an enterprise: the lifetime against photon emission ($\sim 10^{-8}$ s) is orders of magnitude larger than the typical duration of a collision ($\sim 10^{-13}$–10^{-12} s) with the consequence that low signal, large background, and blending by emission from educts or products represent a severe problem. In spite of these difficulties, John Polanyi has for many years pursued this goal (1–3) and inspired others, both experimentalists (4) and theorists (5).

It has been proposed by Polanyi to designate the object of this type of spectroscopy as the "transition state" (1) and to understand by this term not one point in the space of nuclear motion but "the range of configurations encountered en route from reactant to product." Since one of us (H.M.) learned about the idea of "transition state spectroscopy" in 1984 (6), we began to interpret experimental data on Penning electron spectroscopy with this goal in mind (7, 8) and thus gave a new direction to an already existing activity (9). There is, of course, no general relationship between Penning electron spectroscopy and chemical reactions. However, for selected cases the link is rather direct. As an example, we discuss the process

$$[1] \qquad Li + Br_2 \rightarrow (Li^+ + Br_2^-) \rightarrow LiBr + Br$$

which can be considered a prototype chemical reaction. The intermediate collision complex, denoted here as ion pair state, would be the object of our curiosity in the context of transition state spectroscopy. Essentially the same situation can occur as a consequence of the encounter of metastable helium $He^*(1s2s)$ with a halogen molecule

[2a] $He^*(1s2s) + Br_2 \rightarrow He + Br_2^+ + e^-$

[2b] $\rightarrow (He^+ + Br_2^-) \rightarrow He + Br + Br^+ + e^-$

A third type of process, namely excitation transfer with subsequent autoionization of the superexcited target molecule, is known for $He^* + Cl_2$ (7, 9, 10) but apparently is insignificant for $He^* + Br_2$ (8).

In the processes [2a] and [2b], the metastable atom plays a twofold role. Firstly, it carries a fairly large amount of excitation energy (~20 eV), which can lead in a direct Penning process to ionization of the target molecule, reaction [2a]. The resulting electron energy spectrum is essentially the same as that obtained in photoionization. Secondly, He^* is an atom with a 2s valence electron and thus a species that undergoes chemical reactions as readily as $Li(1s^22s)$. This latter feature is the basis of our approach. As in reaction [1], the transition from the covalent to the ion pair state is possible. It is even, by far, the dominant process and it is known that reaction [2a] is enabled only by symmetry conservation that prohibits ion pair formation in the isosceles triangle conformation of the nuclei (10). The collision complex $He^+ + Br_2^-$ will develop in time to (He^+Br^-) and Br, just as in process [1]. The important, and for our purpose crucial, aspect is, however, that the recombination energy of He^+ (24.587 eV) is so large that the collision complex lies in the autoionization continuum throughout its time evolution. Consequently, electrons will be emitted from this transition state system.

Since the lifetime against autoionization can be as short as 10^{-16} s, the probability for electron emission during the lifetime of the collision complex is almost unity. This is indeed a very different situation compared to photon emission spectroscopy. Together with the fact that the separated reaction partners He^* and Br_2 are not able to autoionize, this confines the emission of electrons to the lifetime of the collision complex, an ideal situation for the purpose of transition state spectroscopy.

As is usual in this field, calculations that model the dynamics of the system are needed in order to retrieve the information from the experimental data. We carry out trajectory calculations for the three-body system $He^+ + Br_2^-$ using a potential surface constructed in the framework of "diatoms in molecules." The electronic transition probability is described by analytical functions, the parameters of which had to be determined. The extent of agreement between measured and calculated electron energy spectra serves as an indication that the dynamics of the nuclear motion in the collision complex as well as its decay via ionization is properly described in the calculations. The progress of the present study over a preceding study (8) on $He^* + Br_2$ can be indicated by considering several aspects:

1. In ref. 8 we described the potential surface of the collision complex $(He^+ + Br_2^-)$ by only two coordinates, namely, the separation between He and the center of mass of Br_2 and the distance between the bromine atoms. Thus, the chemical reaction proper cannot be accounted for without changing the meaning of the coordinates in the course of the time evolution of the complex (7).

2. The fact that the transition $He^* + Br_2 \rightarrow He^+ + Br_2^-$ is symmetry forbidden if He^* is in the middle plane of the Br atoms is fully accounted for in our model. This restricts the starting conformations for the time evolution of the complex $(He^+ + Br_2^-)$.

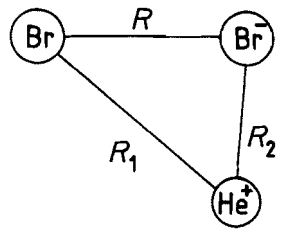

FIG. 1. Coordinate system for the description of the He^+–Br_2^- potential surface. The z-axis coincides with the Br—Br internuclear axis. He^+ lies in the (x, z) plane, which renders the nuclear y-coordinates identically zero. Both angles β_i are measured against the positive direction of the z-axis. For the orientation of the corresponding orbitals at sites 1 and 2 we have chosen the convention that they are identical except for a translation along the z-axis by the distance R.

3. The electron energy spectrum depends not only on the energy of the collision complex but, as well, on the energy of the ionized system after electron emission. Here, we have introduced a more realistic description by incorporating the complete set of Br_2^+ potential curves.

We find the interesting result that the spectrum of emitted electrons varies drastically in the course of the chemical reaction going on. Secondly, we observe a distinct correlation between the motion of He^+ and the relative motion of the two Br nuclei even if we average over all trajectories taken into account.

This paper is organized as follows: in Sect. 2, the potential surfaces and the electronic transitions are discussed and their description within this paper are given. The algorithm for the trajectory calculations and the hierarchy of electronic transitions are treated in the subsequent section. In the last section we present as our main result the link between the shape of the electron energy spectrum and the dynamics of the system $He^+ + Br_2^-$.

2. Potential surfaces and transition probabilities

2.a. He^+–Br_2^- potential surface

The potential surface of the triatomic system $He^+(^2S)$, $Br(^2P)$, and $Br^-(^1S_0)$ is described by a perturbation method within the concept of "diatoms in molecules." Spin is neglected in the treatment. Figure 1 explains the coordinate system. We distinguish two sites for bromine atoms. The total state of the triatomic is described as the superposition of two states that are defined by assigning the full excess charge of Br_2^- to only one bromine atom. State 1 is defined by having the neutral bromine at site 1 and $Br^-(^1S_0)$ at site 2. State 2 is defined by the reverse positions of Br and Br^-. We have to consider three pairs of atoms. We start with the potentials of Br_2^-. From ref. 11 we take the potentials of the ground state $^2\Sigma_u^+$ and three excited states which have, in increasing energetic order, the symmetries $^2\Pi_g$, $^2\Pi_u$, and $^2\Sigma_g^+$. We interpret the difference between gerade and ungerade states as being caused by symmetric splitting of an unperturbed state due to an exchange matrix element $V_{12}(R)$ and get

$$
\begin{aligned}
V(\Sigma_u^+|R) &= V^{\Sigma}(R) + V_{12}^{\Sigma}(R) \\
V(\Sigma_g^+|R) &= V^{\Sigma}(R) - V_{12}^{\Sigma}(R) \\
V(\Pi_g|R) &= V^{\Pi}(R) - V_{12}^{\Pi}(R) \\
V(\Pi_u|R) &= V^{\Pi}(R) + V_{12}^{\Pi}(R)
\end{aligned}
\qquad [3]
$$

TABLE 1. Information on LiBr (12) and parameters for the He^+–Br^- interaction potential $U(R_i)$. The zero of $U(R_i)$ corresponds to $He^+ + Br^-$ at infinite separation

LiBr	D_e[LiBr → Li + Br]	=	4.335 eV
	D_e[LiBr → $Li^+ + Br^-$]	=	6.363 eV
	R_e	=	$4.1 a_0$
	ω_e	=	563.1 cm^{-1}

He^+Br^-

$$U(R_i) = \begin{cases} D(e^{2y} - 2e^{y}) \\ \quad \text{with } y = \beta(1 - R_i/R_e) & R_i < R_s \\ -\dfrac{27.211}{R_i} - \dfrac{1}{2}\dfrac{\alpha}{R_i^4} & R_i \geq R_s \end{cases}$$

with

D = 6.363 eV
R_e = 4.1 a_0
β = 1.624
α = 502.4 a_0^3
R_s = 5.3267 a_0

The signs follow from our convention that the orientation of corresponding orbitals at sites 1 and 2 is identical, which means that the orbitals can be transformed into each other by a mere translation along the internuclear axis. It follows that $V_{12}^{\Sigma}(R) < 0$ and $V_{12}^{\Pi}(R) > 0$.

The interaction between $He^+(^2S)$ and $Br^-(^1S_0)$ is spherically symmetric. The potential is described at long range by the Coulomb potential plus an induction term arising from the polarizability of Br^-. At shorter distances we make use of information on the ground state of LiBr. From ref. 12 we obtain the equilibrium distance r_e, the potential well depth with respect to dissociation into neutrals D_e[Li + Br], and the energy of the vibrational quantum ω_e = 563.1 cm^{-1}. Combining the quoted information allows us to give a substantial estimate of the He^+–Br^- potential at all relevant separations. Numerical values are found in Table 1. Below, this potential is denoted by $U(R_i)$ where i refers to the site of the negative ion Br^-.

To zeroth order we neglect the influence of He^+ on the neutral Br atom. There is, however, the possibility that the presence of He^+ causes mixing of the Br_2^- states that have pure Π or Σ symmetry with respect to the Br–Br^- axis. Thus, the presence of He^+ influences the Br_2^- subsystem in two respects: the degree to which the He^+ polarizes the Br_2^- by dragging the excess negative charge to the bromine at the site closer to He^+, and the extent to which the Π states of Br_2^- contribute. This latter information should in principle have impact on the ionization process. We lack, however, sufficiently detailed knowledge on the ionization process to exploit this information (cf. Sect. 2.*d*). Further, we found that the degree of polarization of Br_2^- as mentioned above is well described by using only the $Br_2^-(^2\Sigma_u, {}^2\Sigma_g)$ states as basis states. This reduces the energy matrix of He^+–Br_2^- to a 2 × 2 matrix

$$[4] \qquad \begin{bmatrix} V^{\Sigma}(R) + U(R_2) & V_{12}^{\Sigma}(R) \\ V_{12}^{\Sigma}(R) & V^{\Sigma}(R) + U(R_1) \end{bmatrix}$$

The results reported below were obtained with this simplified matrix. It can be diagonalized analytically and thus saves a fair amount of computer time.

The lowest eigenvalue of this matrix is employed as the He^+–Br_2^- potential surface

$$[5] \qquad V(R_1, R, R_2) = V^{\Sigma}(R) + \frac{U(R_1) + U(R_2)}{2} - \{0.25(U(R_1) - U(R_2))^2 + V_{12}^{\Sigma}(R)\}^{1/2}$$

The related eigenvector is (a_1, a_2) with

$$[6] \qquad a_1 = \left\{ \left(\frac{V^{\Sigma}(R) + U(R_2) - V(R_1, R, R_2)}{V_{12}^{\Sigma}(R)} \right)^2 + 1 \right\}^{-1/2}$$

$$a_2 = a_1 \frac{V(R_1, R, R_2) - V^{\Sigma}(R) - U(R_2)}{V_{12}^{\Sigma}(R)}$$

a_i is the amplitude of the state describing the situation with the neutral Br atom at site i and the negative ion Br^- at the opposite site.

2.b. Transition $He^* + Br_2 \rightarrow He^+ + Br_2^-$

Within the concept of "diatoms in molecules" we consider explicitly the electron transition between two atoms He^*+Br → $He^+ + Br^-$. We describe the transition matrix element as (13)

$$V_{c \rightarrow i}(R_i) = DR_i \exp(-R_i C_{inv})$$

with

$$C_{inv} = \left(\frac{IP[He^*]}{2} \right)^{1/2} + \left(\frac{EA[Br]}{2} \right)^{1/2}$$

$$D = IP[He^*] \cdot EA[Br]\ C_{inv}$$

$$IP[He^*] = 0.175 \text{ au}$$

$$EA[Br] = 0.124 \text{ au}$$

The total electronic transition matrix element is then

$$[7] \qquad V_{c \rightarrow i}(R_1, R, R_2) = \sum_{i=1}^{2} V_{c \rightarrow i}(R_i) a_i \cos \beta_i$$

with a_i being the component of the eigenvector of $He^+ + Br_2^-$ defined above. For the case in which He forms an isosceles triangle with the two bromine atoms, our above-defined convention leads to $a_1 = a_2$ and $\cos \beta_1 = -\cos \beta_2$. Thus, the definition of $V_{c \rightarrow i}(R_1, R, R_2)$ prohibits covalent to ion pair transitions in the isosceles conformation of the nuclei as required by symmetry arguments (10).

The transition rate is obtained as

$$[8] \qquad W_{c \rightarrow i}(R_1, R, R_2) = 2\pi \rho(R) \frac{V_{c \rightarrow i}^2(R_1, R, R_2)}{\hbar}$$

The weighting factor $\rho(R)$ is the normalized probability function for finding the $Br_2(v = 0)$ molecule at internuclear separation R.

2.c. Br_2^+ potential curves

In the final state of the collision complex, i.e., after the emission of an electron, we have the system He + Br + Br^+. We simplify the treatment by neglecting the interaction of the bromine atoms with the ground state rare gas He for all nuclear conformations. Thus, the final state is fully described by the molecular states of Br_2^+. In a previous publication (8) we

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

collected information on those states of Br_2^+ that are accessible by photoionization, i.e., by a one-electron process, from the ground state. In the present study, however, we have to consider ionization via an intrinsic two-electron process from the negative ion Br_2^- state.

Consequently, we must be aware that no propensity rule such as Koopman's theorem favours ionization into the known $Br_2^+(X, A, B, C)$ states, but that in principle all possible molecular states of Br_2^+ could be populated. Hence we have tried to estimate the Br_2^+ states in such a way that the energy positions of all states are represented more realistically than by only the four states X, A, B, C. On the other hand, we tried to avoid unnecessary speculations. We make use of a simple perturbation ansatz for the molecular states, spin not being taken into account.

For the Br^+ atom with its two-hole orbitals labelled a and b we define the set of states

$$|lm; l_a m_a l_b m_b\rangle = C(l_a l_b l; m_a m_b m)|l_a m_a\rangle|l_b m_b\rangle$$

with C( ) denoting the Clebsch–Gordon coefficients.

The states of the neutral atom Br(P) we denote by the set $|l_c m_c\rangle$. Projection quantum numbers are meant with reference to the Br–Br axis. The angular momenta l_a, l_b, l_c are unity since they refer to atomic p-hole orbitals. The tensor product of both sets is used as basis for Br_2^+.

The electrostatic interactions between the three-hole orbitals are treated pairwise. The interatomic interactions a, c and b, c are described by the operators O_{ac} and O_{bc}. To keep the number of parameters small we employ only the diagonal elements

$$[9] \qquad O_{m_a m_c} = \langle m_a' m_c'|O_{ac}|m_a m_c\rangle \delta_{m_a,m_a'} \delta_{m_c,m_c'}$$

and likewise for the operator O_{bc}. If O_{ac} were the Coulomb operator it would follow from ref. 14 that O_{mamc} depends on the absolute values $|m_a|$ and $|m_c|$ only. By assuming the same property for the operator O_{ac} we reduce the number of unknown matrix elements of O_{ac} and O_{bc} to three: O_{00}, O_{10}, O_{11}. The matrix element of interatomic interaction $O = O_{ac} + O_{bc}$ is then in the above chosen basis.

$$[10] \qquad \langle l'm'm_a'; m_c'|O_{ac} + O_{bc}|lmm_a; m_c\rangle$$
$$= C(11l'; m_a m - m_a m) C(11l; m_a m - m_a m) \{O_{|m_a|,|m_c|} + O_{|m-m_a|,|m_c|}\}$$

Note that this matrix is not diagonal in l, which has the values 1, 2, 0 for the three states of the bromine ion $Br^+(^3P, {}^1D, {}^1S)$.

The operator that controls the interaction between the hole orbitals within the ion Br^+ is diagonal in l, independent of m, and does not act on the neutral Br atom. Thus, we can write its matrix elements as

$$[11] \qquad \langle l'm'm_a'; m_c'|A|lmm_a; m_c\rangle = \langle l|A|l\rangle \delta_{l,l'}, \delta_{m,m'}, \delta_{m_a,m_a'} \delta_{m_c,m_c'}$$

Following ref. 14 this can be parametrized as

$$\langle l|A|l\rangle = \begin{cases} -5F_2 & (l = 1) \\ 1F_2 & (l = 2) \\ 10F_2 & (l = 0) \end{cases}$$

with $F_2 = 0.207$ eV.

The gerade–ungerade splitting is described by the exchange operator V^{ex}, which we conceive to consist of three summands that act on either of the three-hole states. The matrix elements of this operator are

$$[12] \qquad \langle lmm_a; m_c|V^{ex}|lmm_a; m_c\rangle$$
$$= C(11l; m_a m - m_a m)^2 \{\langle m_a|V_a^{ex}|m_a\rangle + \langle m - m_a|V_b^{ex}|m - m_a\rangle + \langle m_c|V_c^{ex}|m_c\rangle\}$$
$$= C(11l; m_a m - m_a m)^2 \{V_{|m_a|}^{ex} + V_{|m-m_a|}^{ex} + V_{|m_c|}^{ex}\}$$

In the above equation the bra vectors refer to a situation where Br and Br^+ have exchanged their position compared to the meaning of the ket vectors.

$V_1^{ex}(R)$, i.e., the g–u splitting of the π-orbitals, can be calculated from the energy separation between the known Br_2^+ potentials $V(X^2\Pi_g)$ and $V(A^2\Pi_u)$ via

$$V_1^{ex}(R) = \tfrac{1}{2}[V(A^2\Pi_u|R) - V(X^2\Pi_g|R)]$$

This is justified by the fact that both Br_2^+ states can be considered as being created from their parent state $Br_2(X^1\Sigma_g)$ by a one-electron process. Removal of a $2\pi_g$ electron leads to the $X^2\Pi_g$ state and a $(2\pi_u)^{-1}$ hole forms Br_2^+ in the $A^2\Pi_u$ state.

Lack of information on Σ_u states of Br_2^+ prohibits a similar approach for the g–u splitting of the σ-orbitals. To help this situation we make use of a rule of thumb that holds roughly for many molecules tested during the preparation of a paper on molecular rare gas ions (15), even though it was not used in ref. 15. This rule states that the ratio of exchange matrix elements of p-orbitals in σ-symmetry and in π-symmetry can be roughly equated to the internuclear separation in atomic units.

$$\frac{V_0^{ex}}{V_1^{ex}} = -\frac{R}{a_0}$$

with R in atomic units. The minus sign results from our convention that like orbitals at each atom are defined as being identical except for translation.

We count four unknown parameters that we have introduced in the above treatment:

$$O_{00}(R),\ O_{10}(R),\ O_{11}(R), \text{ and } V_1^{ex}(R)$$

On the other hand we can employ as known quantities the potential curves of the four spinless Br_2^+ states

$$V(X^2\Pi_g|R),\ V(A^2\Pi_u|R),\ V(B^2\Sigma_g|R), \text{ and } V(C^2\Sigma_g|R)$$

Information, including analytical expressions for these potential curves, has been collected in ref. 8. As pointed out before, V_1^{ex} can be determined in a straightforward way from the difference between the $A^2\Pi_u$ and $X^2\Pi_g$ potentials. The other three quantities have to be determined by evaluation of three coupled linear equations.

We are now in the position to compute all Br_2^+ states dissociating to Br(^2P) and $Br^+(^3P, {}^1D, {}^1S)$. Inclusion of spin could be done in a straightforward way (14) but has been omitted since spin is not taken into account in our treatment of the ionization process. The calculated potential curves are displayed

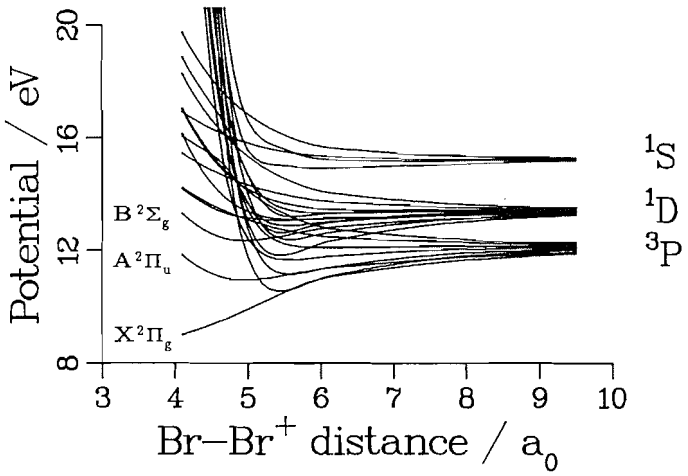

FIG. 2. Potential curves of the Br_2^+ states. Calculated without spin using the parametrization discussed in the text. The equilibrium separation for the lowest $Br_2^+(X^2\pi_g)$ state is $r_e = 4.145a_0$. For our trajectory calculations only distances larger than the equilibrium separation of the neutral Br_2 ($r_e = 4.311a_0$) are relevant. The calculation is not meant to predict individual unknown states of Br_2^+ but to give a reasonable estimate of the range of energies spanned by Br_2^+ as a function of internuclear separation R.

in Fig. 2. The states $X^2\Pi_g$, $A^2\Pi_u$, and $B^2\Sigma_g$ are indicated. The potential curve of $C^2\Sigma_g$ is buried under a wealth of other states.

We would like to emphasize that this calculation is not meant to predict individual states of Br_2^+ but rather to give a reasonable estimate of the range of energies spanned by the Br_2^+ states as a function of internuclear separation.

2.d. Transition $He^+ + Br + Br^- \rightarrow He + Br + Br^+ + e^-$

Because of the large recombination energy of He^+, the system $He^+ + Br + Br^-$ lies in the ionization continuum of $He + Br + Br^+ + e^-$. The rate for electron emission

$$W(R_1, R, R_2) = 1/\hbar\,\Gamma(R_1, R, R_2)$$

in connection with the dynamics of nuclear motion governs the probability that a conformation (R_1, R, R_2) contributes to the observed electron energy spectrum.

Again, we rely on the concept of "diatoms in molecules" in parametrizing the autoionization width $\Gamma(R_1, R, R_2)$. For ionization to take place, two electrons have to move: one electron tunnels from bromide into the 1*s* hole of He^+. The excess energy is transferred to a second bromine electron, which is emitted. We assume the first electron to originate from Br^- rather than from Br. This is plausible for two reasons: firstly, the 4*p* orbitals of the negative ion are far more extended than those at the neutral ion; secondly, the bromine atom closest to He^+ will always have the larger fraction of the negative charge due to polarization, thus rendering the influence of the system $He^+ + Br$ less significant than that of the $He^+ + Br^-$. Further, we assume that the emitted electron starts from the same bromine atom as the first one. This is certainly true during the later stages of the reaction when the distance between the two bromine atoms has reached large values, but we employ this concept for all nuclear conformations. It follows that the autoionization width of the whole complex $He^+ + Br + Br^-$ can be built up from the properties of the diatomic system

$$He^+ + Br^- \rightarrow He + Br^+(^3P, {}^1D, {}^1S) + e^-$$

Even though this is a two-electron process, we use the analytical form from ref. 13 for the electronic matrix element

$$H_{el}(l|R_j) = \begin{cases} D_P \cdot R_j \exp(-R_j/C_P) & \text{for } Br^+(^3P), \\ & \text{i.e., } l = 1 \\ D_D \cdot R_j \exp(-R_j/C_D) & \text{for } Br^+(^1D, {}^1S), \\ & \text{i.e., } l = 2, 0 \end{cases}$$

The four parameters D_P, C_P, D_D, and C_D are varied in the course of the calculation to fit the experimental electron energy spectrum. We found that the population of the final states $Br^+(P)$ and $Br^+(D)$ have to be described by different sets of parameters. The state $Br^+(^1S)$ is of lesser importance, since at larger Br–Br distance it is too high in energy to allow electron emission and at smaller Br–Br separations its effect is diluted in the many molecular Br_2^+ states. Population of $Br^+(S)$ is satisfactorily described by the parameters chosen for $Br^+(D)$. In this model, the autoionization width is written as

$$\Gamma(R_1, R, R_2) = \sum_I \Gamma(I|R_1, R, R_3)$$

with the partial widths being expressed as

$$[13] \qquad \Gamma(I|R_1, R, R_2) = \sum c_{I,l}{}^2 (a_1{}^2 H_{el}{}^2(l, R_2) + a_2{}^2 H_{el}(l, R_1))^2$$

The index I refers to the Br_2^+ states discussed above and the coefficients $c_{I,l}$ are the weighting factors of the ionic states $Br^+(l = 1, 2, 0)$. The coefficients a_i are familiar from the definition of the $He^+ + Br + Br^-$ potential surface and depend on all three nuclear distances R_1, R, R_2. The incoherent summing over the two contributions of the wavefunction of $He^+ + Br + Br^-$ has been employed since the lack of information about the angular distribution of the emitted electrons does not allow us to consider symmetry restrictions in the electron emission process without introducing further parameters. Because there is neither a basis to determine these parameters nor the need to take care of electron angular distributions we have chosen the form of eq. [13] to describe the ionization probability. Unfortunately, the numerical values of the four parameters D_P, D_D, C_P, C_D cannot be supplied. In the seven years that elapsed between carrying out the calculations and writing this paper, these values were lost and a new determination would require repeating the extended calculations. We would like to state, however, that the implicit effect of these parameters is clearly visible in the results presented: the relative weight of events taking place in early and late stages of the development of the collision complex reflects the prefactors D_P and D_D, and the spatial distribution for the ionization events to take place is intricately connected to the characteristic distances C_P and C_D.

3. Trajectory calculations

The calculations are carried out for the collision energy between He^* and Br_2 of $E_{coll} = 70$ meV, which represents the mean value that we use for comparison in the experiment.

In the laboratory frame we define a coordinate system in the following way: a plane is defined by the center of mass of the Br_2 molecule and the initial position and initial velocity of the projectile He^*. The *z*-axis goes through the center of mass of Br_2 and is parallel to the He^* velocity. The initial

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

distance between He* and the target center of mass is $13a_0$, which is sufficiently large to exclude reactions. As a first step a random number generator selects the orientation of the axis of the target molecule by two angles, one with respect to the z-axis and one with reference to the plane defined above. Further, the impact parameter of He* with respect to the Br_2 center of mass is chosen from the interval $0 < b \leq b_{max}$ such that the values of b^2 are randomly distributed. The maximum impact parameter is set to $b_{max} = 11a_0$ since crossing into the ion pair state $He^+ + Br_2^-$ is insignificant beyond this value. Note that this coordinate system differs from the one used to define the electronic properties. Evaluation of potential energies and transition amplitudes in the trajectory calculations require a coordinate transformation.

The nuclear motion of the system He^*+Br_2 is then described by a straight trajectory of He* with Br_2 remaining fixed in space. This simplified treatment of molecular dynamics is justified by the fact that it is applied only for large projectile–target separations. However, along this trajectory the coupling to the ion pair configuration

$$He^* + Br_2 \rightarrow He^+ + Br_2^-$$

as expressed in Sect. 2.*b* is monitored. If the integrated transition probability exceeds 10%, the motion in the $He^* + Br_2$ channel is interrupted and a new trajectory is started in the potential surface of the system $He^+ + Br_2^-$, as discussed in Sect. 2.*a*. Nuclear motion is then propagated by means of the Gear integrator (16). We employ the code used by Gerlich et al. (17). We had to add, of course, the subroutines that handle decay into final states $He+Br_2^+ + e^-$. This is a straightforward task that has been done before (7–9). During every time step ($\Delta t = 0.25 \times 10^{-14}$ s) the transition probabilities in the Br_2^+ states as defined in Sect. 2.*c* are evaluated according to Sect. 2.*d* and the corresponding contributions to the electron energy spectrum stored. If the total ionization probability along the trajectory has risen above 0.95 the trajectory is stopped.

Then the program switches back into the system $He^* + Br_2$ and continues the interrupted trajectory until again a 10% probability for transition into the ion pair state $He^+ + Br_2^-$ is accumulated, and so forth until the survival probability in the $He^* + Br_2$ trajectory is below 0.05.

4. Results

In Fig. 3*a* we show the experimental electron energy spectrum that results from the reaction of $He^*(2^3S)$ with Br_2 (18). We reproduce here only the range of electron energies up to 6.2 eV since the features at larger energies are due to direct Penning ionization into the $Br_2^+(X, A)$ states. As discussed above, this process [2*a*] has no bearing on the question of transition state spectroscopy. The population of $Br_2^+(B^2\Sigma_g^+)$ via process [2*a*] could, in principle, show up in the spectrum. Its energy position is given by the difference between the excitation energy of $He(2^3S)$ and the vertical ionization potential of the $B^2\Sigma_g^+$ state as $19.8 - 14.6 = 5.2$ eV. Comparison with the HeI photoelectron spectrum reveals, however, that such a conbution must be extremely small (18). Thus, we can consider the spectrum in Fig. 3*a* as being caused by electron emission from the reaction complex $He^+ + Br_2^-$. Figure 3*b* displays, for comparison, our calculated spectrum. Even though the agreement is not perfect within the very small experimental error, the similarity is such that the essential features of the dynamics of the system are apparently reproduced in the calculation. The

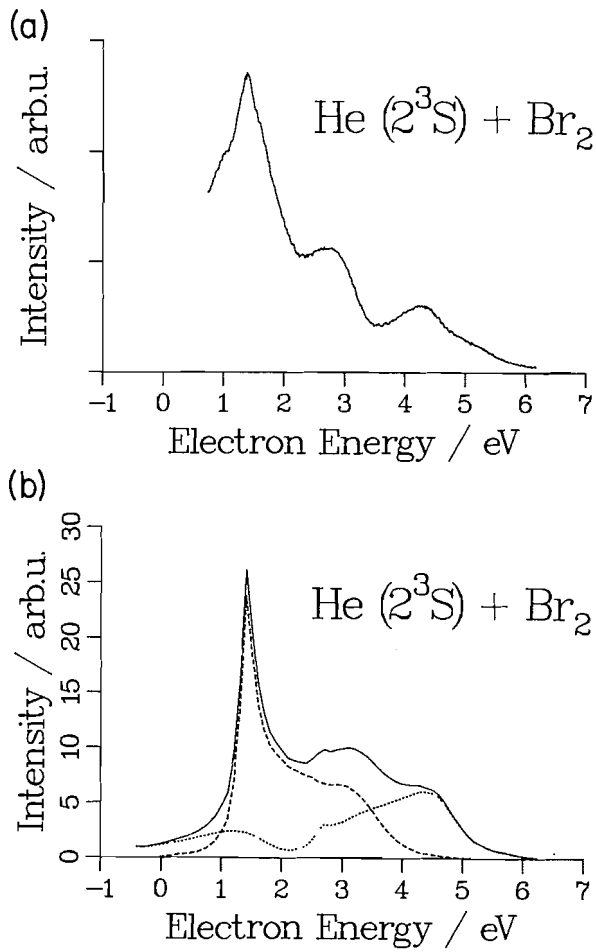

FIG. 3. (*a*) Experimental electron energy spectrum from the reaction of $He(2^3S)$ with Br_2, adopted from ref. 18. Only the energy range below 6.2 eV, which originates from the collision complex He^+–Br_2^-, is shown, i.e., after the covalent to ion pair transition $He^* + Br_2 \rightarrow He^+$–$Br_2^-$ has taken place. Further discussion is in the text. (*b*) Calculated spectrum. Best fit with respect to the parameters of the autoionization width as defined in Sect. 2.*d*. The contributions related to $Br^+(P, D)$ are shown separately. Dotted line: $Br^+(P)$; broken line $Br^+(D)$. Further explanation is in the text.

respective contributions of the spectrum that can be related to the population of $Br^+(P)$ and $Br^+(D)$ states are indicated. In the nomenclature of Sect. 2.*c* this means that the populations of basis states containing $|l = 1, m\rangle$ and $|l = 2, m\rangle$ are separately stored in the calculation. As mentioned in Sect. 2.*d*, the states containing $|l = 0\rangle$ hardly play a role. Some energy considerations allow us to illustrate the gross features of Fig. 3*b*. If we use $He + Br_2(v = 0)$ as zero of the energy scale, the system He^*+Br_2 starts with an electronic energy of 19.819 eV, which is the excitation energy of $He^*(2^3S)$. Since dissociation of Br_2 requires $D_2[Br_2] = 1.99$ eV (8), the subsystem He^+Br^- can be formed with a maximum energy of 17.83 eV in the course of the process $He^* + Br_2 \rightarrow He^+Br_2^- \rightarrow He^+Br^- + Br$ in the limit of small relative kinetic energy between He* and Br_2. On the other hand, the minimum value of the He^+Br^- potential (cf. Table 1) can be computed from the atomic energy values IP[He*] = 4.768 eV and EA[Br] = 3.364 eV (8) to be 14.86 eV. Accordingly, the autoionization of the subsystem He^+Br^- into a given state $He + Br^+(P, D, S)$ should have an electron energy spread of $17.83 - 14.86 = 2.97$ eV. Population of the $Br^+(^1D)$ state (IP = 13.34 eV) should lead

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

to electron energies between 1.52 and 4.49 eV. The respective boundaries for the $Br^+(^3P)$ state are 2.77 and 5.74 eV. Inspection of Fig. 3*b* shows that the major features of the calculated spectra lie in the quoted energy regimes. However, some parts of the spectra are distinctly outside the given bounds. In particular, the prominent peak at ~1.4 eV electron energy, which is associated with formation of the $Br^+(^1D)$ state, is just below the lower bound of 1.52 eV. This indicates that the autoionization of the subsystem He^+Br^- is not a sufficient description of the process and that the binding energy between all three atoms plays a role: if the binding energy is smaller in the final state than in the neutral precursor, the energy of the emitted electron is smaller than the quoted lower bound and vice versa.

The attempt to visualize the nuclear motion is shown in Fig. 4 in a manner used before in ref. 19. The trajectories chosen lie in one plane and the coordinates of the three nuclei are given within this plane for several time steps. The trajectories are followed from the instant when transition from the covalent $He^* + Br_2$ into the ion pair state has occurred until the total probability for electron emission exceeds 0.95. The starting positions of the nuclei are denoted by an octagon. At every 15th time step other symbols indicate the acquired nuclear positions. This is meant to give an impression of the simultaneous motion of the three particles. It can be observed that the two bromine nuclei separate monotonically in time whereas the helium ion oscillates with a large amplitude. The mass ratio between He and Br keeps the corresponding oscillations of the nearest Br atom on a very small, but visible, amplitude. We observe that at, or shortly after, the third close encounter between helium and either of the bromine atoms the trajectory is stopped, which indicates that its survival probability is below 5%. At this instant, we find that the separation between the halide nuclei has become rather large and, further, that it is clearly decided to which of the Br atoms the helium has formed a bond. In other words the chemical reaction

$$He^+ + Br_2^- \rightarrow He^+Br^- + Br$$

is visibly completed. This shows that the process of electron emission is fast enough to be confined to the transition state but slow enough to go on until the characteristic features of the exit channel can clearly be identified. In Fig. 4*a* we have a situation where the He^+ attack occurs at the same Br atom with which a bond is formed later on. A different type of trajectory is depicted in Fig. 4*b*. Here the light projectile switches after the first encounter to the other bromine atom, to stay there until the bond is stabilized. The difference between these pathways has been observed before (20) in the analysis of the reaction of hydrogen atoms with heteronuclear halogen molecules and has been given the name "microscopic branching." Its occurrence was found to show up in a bimodal distribution of rotational states of the hydrogen halides formed in the reaction. This, of course, is not the realm of "transition state spectroscopy" but rather the spectroscopy of reaction products. In our case, identification of microscopic branching is made difficult by the fact that the target molecule is homonuclear. The trajectories in Fig. 4, however, show features familiar from ref. 20. The rotational excitation is clearly larger in Fig. 4*b*, i.e., after the helium has switched sites. This should enhance the centrifugal forces and, indeed, the minimum distance between He and Br during the second and third encounters in Fig. 4*b* is larger ($3.24a_0$) than in the first close encounter in Fig. 4*b* and in all three encounters in Fig. 4*a* ($2.97a_0$). Since the electron energy

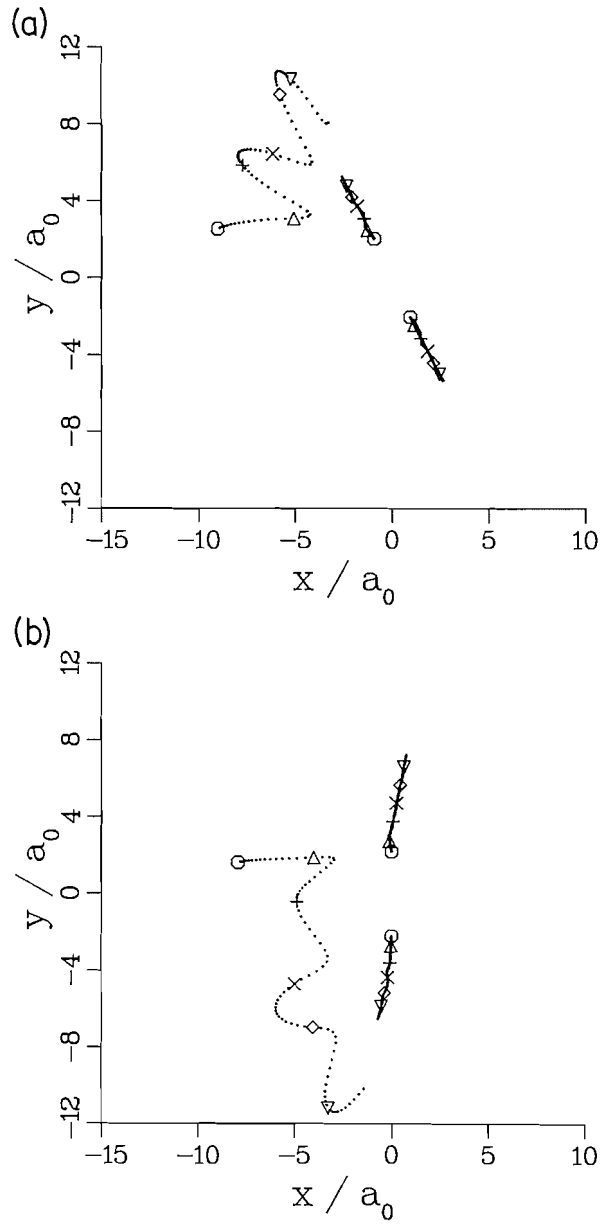

FIG. 4. Trajectories of the He^+–Br_2^- complex. The octagons indicate the positions of He and the two Br atoms right after electron transfer from He^* to Br_2. Time evolution of the system is visualized by dots for every time step. Same symbols for the nuclear positions refer to the same time. (*a*) Example of a trajectory where He^+ stays near the bromine first encountered; (*b*) example of a trajectory where He^+ switches to the other Br atom after first encounter.

depends strongly on the internuclear separation, it is to be expected that the effect should be observable experimentally. To study the problem more carefully in a calculation like ours, one had to store the electron energy spectra for both types of trajectories separately. Unfortunately, we neglected to do so, not being aware of the question at the time the calculations were carried out. It is interesting to note in this context that electron energy spectra from reactions of He^* with heteronuclear halogen molecules (18) can be understood as linear combinations of the spectra from the respective homonuclear halogens only as concerns the gross features. A careful inspection of the spectra shows (18) that the different details of the reaction dynamics have a district influence of the experimental data.

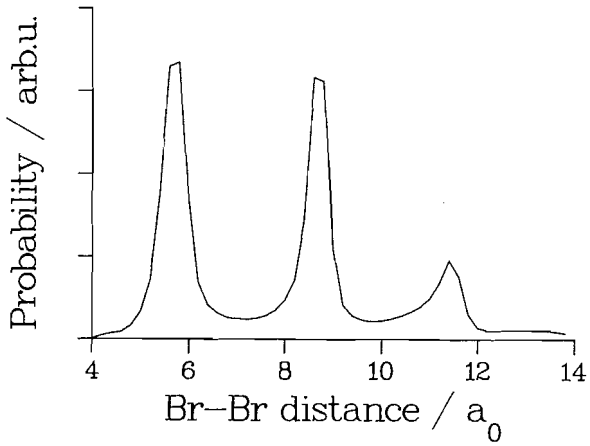

FIG. 5. Ionization probability as function of Br–Br separation. Averaged over all trajectories. The maxima of the ionization probability arise from the first, second, and third close encounters of the He^+ ion with either of the Br atoms. Since the Br–Br separation varies monotonically with time the ionization probability would exhibit the maxima as well if plotted as function of time.

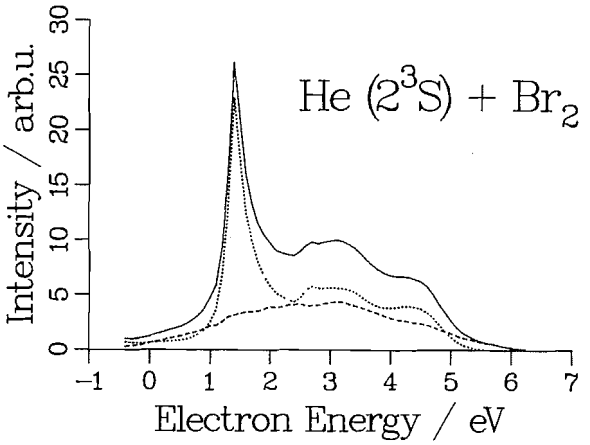

FIG. 6. Electron energy spectrum composed from the contributions during the first encounter (dashed line) and the second and third encounters (dotted line).

The fact that the autoionization width Γ (cf. Sect. 2.*d*) increases with decreasing distance between helium and either of the bromine atoms results in enhanced electron emission during close encounters. Thus, one expects a cyclic ionization activity as a function of time for a given trajectory. We found, however, that even if we average over all trajectories with initial conditions as described in Sect. 2 we have a surprisingly well-structured behaviour. In Fig. 5 we have plotted the ionization probability averaged over all trajectories as a function of Br–Br separation. The latter varies monotonically with time as seen in Figs. 4*a* and *b*. This finding allows us to plot separately the electron energy distributions that originate from different encounters. In Fig. 6 we show how the calculated electron energy spectrum is composed of the contribution from the first encounter and the contributions from the second and third encounters, the latter ones being very similar. The first encounter can be conceived as reaction between the projectile helium and a molecular target. At the corresponding Br–Br distance of $\sim 5.8a_0$ the Br_2^+ states (cf. Fig. 2) represent a broad and rather evenly populated energy band, giving rise to an unstructured electron energy distribution. On the other

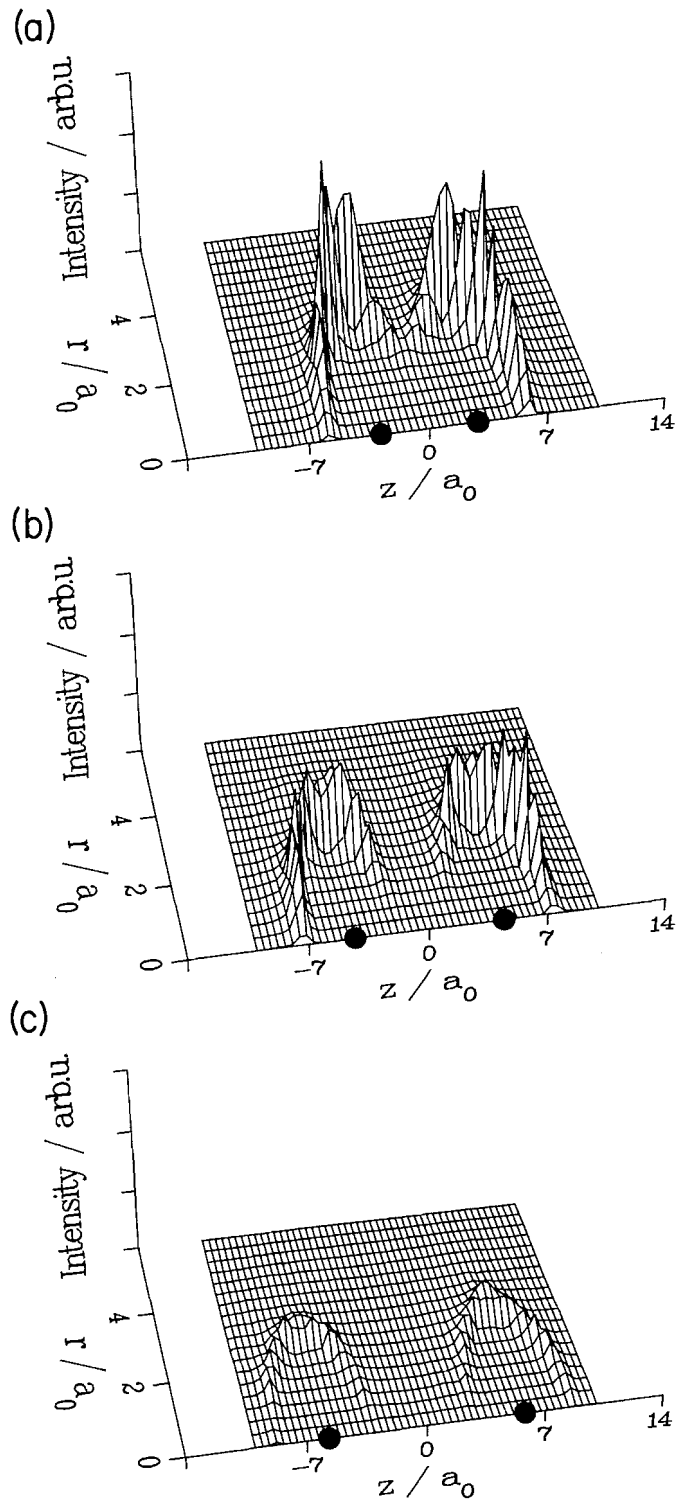

FIG. 7. Ionization probability as a function of He^+ position. The He^+ position is given in a system of cylindrical coordinates. Its z-axis coincides with the Br–Br axis. r measures the separation between He^+ and the z-axis. (*a*) First encounter; (*b*) second encounter; (*c*) third encounter. For further explanation, see text.

hand, the following encounters occur with the second Br atom being at a distance of almost $9a_0$ or more. Here, electron emission occurs with a much narrower distribution of final states. Accordingly, the electron energy distribution is distinctly more structured and contains the peak at ~1.4 eV electron energy that is characteristic for the halogen species involved (18). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

main process leading to this peak is ionization into the $Br^+(^1D)$ state, as can be seen in Fig. 3*b*. The large Br–Br separation suggests understanding this feature as being essentially due to autoionization of the subsystem He^+Br^-. The limits of this concept have already been pointed out in the discussion of Fig. 3*b*. Nonetheless, this concept provides the framework to explain why formation of the $Br^+(^1D)$ state, but not of $Br^+(^3P)$, is associated with a sharp peak: ionization into the $Br^+(^1D)$ state takes place with large probability at separations near the minimum of the He^+–Br^- potential curve $U(R_i)$ whereas the population of the $Br^+(^3P)$ state is confined to smaller He^+–Br^- separations. This is caused by a different R_i dependence of the corresponding electronic matrix elements, discussed in Sect. 2.*d*. In terms of the parameters given in Sect. 2.*d* this means that $C_P < C_D$.

As a result of the analysis we note that the electron energy spectrum varies drastically between the initial and final stages of the observed chemical reaction

$$He^+ + Br_2^- \rightarrow He^+Br^- + Br$$

Thus, this type of spectroscopy has the potential for direct observation of the time evolution of the "transition state."

To make visible which parts of the nuclear conformation space are probed by electron emission, we display the ionization probability as a function of the He^+ position. Figures 7*a*, *b*, *c* refer to the first, second, and third encounters, respectively. Again we can observe how the target behaviour varies from that of a molecular entity to that of two individual atoms. The low ionization activity at $z = 0$ in Fig. 7*a* is a result of the geometrical constraint on covalent to ion pair transition mentioned in Sect. 2.*b*.

1993 Syntex Award Lecture
Photomedicine and photodynamic therapy[1]

DAVID DOLPHIN[2]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, BC V6T 1Z1, Canada

Received June 4, 1993

DAVID DOLPHIN. Can. J. Chem. **72**, 1005 (1994).

Photodynamic therapy (PDT) involves the treatment of diseased tissue and cells using a photosensitizer and visible light. Such photomedical treatments have been known since the time of the ancient Egyptians but it was only just this year that this therapeutic modality was made available to modern medicine with the approval, in Canada, of Photofrin® for the treatment of bladder cancer. This paper reviews PDT with an emphasis on drug development, particulary for the second generation drugs, especially BPDMA (benzoporphyrin derivative-mono acid), which is now in human clinical trials.

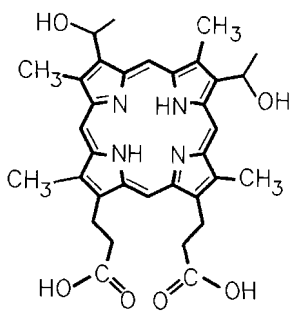
DAVID DOLPHIN. Can. J. Chem. **72**, 1005 (1994).

La thérapie photodynamique (TPD) implique le traitement des tissus et des cellules malades en utilisant un photosensibilisateur et la lumière visible. De tels traitements photomédicaux sont connus depuis le temps des anciens Egyptiens, mais la médecine moderne n'a eu accès à cette modalité thérapeutique que cette année seulement avec l'approbation, au Canada, de la Photofine® pour le traitement du cancer de la vessie. Cet article revoit la TPD en mettant l'emphase sur la mise au point des médicaments, particulièrement pour la deuxième génération de médicaments et spécialement la BPDMA (le dérivé mono-acide de la benzophorphyrine) qui est à l'essai clinique chez les humains.

[Traduit par la Rédaction]

Photomedicine has been practiced since at least the time of the ancient Egyptians (1). Psoralins from orally ingested plants accumulated in the skin and when activated by sunlight brought about repigmentation of the skin. This 4000-year-old treatment for vitilago is still used today with psoralins and UV exposure and represents the best known treatment even though it has only limited success. Indeed, a number of skin diseases, including acne, eczema, herpes simplex, and psoriasis, have been treated in a similar manner.

Niels Finsen won the Nobel Prize in Medicine in 1903 for his treatment of cutaneous tuberculosis by UV radiation. However, the most promising areas of photomedicine are those that use a photosensitizer. Indeed, it was believed in the 19th century that all efficacious drugs were colored and while this belief led to the discovery of the sulfa drugs (Prontosil is an azo dye) it was not until the beginning of the 20th century that the medicinal properties of photosensitizers were explored. Raab (2) in 1900 showed that acridine dyes and light effectively killed *Paramecia*. In 1925 Policard (3) examined the ability of porphyrins, including hematoporphyrin (**1**), to produce a phototoxic effect.



1

Mayer-Betz injected himself with 200 mg of hematoporphyrin (4) and suffered no ill effects until he exposed himself to sunlight, whereupon he suffered extreme swelling and remained photosensitive for several months. Similar accumulation of porphyrins in the skin of porphyric patients may cause severe skin necrosis upon exposure to strong light (5). Auler and Banzer in 1946 (6) showed that hematoporphyrin accumulated in cancerous tissues and, since it exhibits strong fluorescence, its localization into neoplastic and rapidly dividing tissue could be quantitatively assessed (7).

Hematoporphyrin derivative HpD was first prepared by Schwartz and co-workers and its potential as a radiosensitizer was examined (8), but in 1964 Lipson et al. showed that HpD preferentially accumulated in cancerous tissue rather than in the surrounding healthy tissue (9–11). Interest in photomedicine and particulary photodynamic therapy (PDT) was rekindled when Dougherty (12) showed that HpD could be purified by gel exclusion chromatography, which removed monomeric porphyrins. The remaining oligomeric material is known as Photofrin® (**2**) and Quadra Logic Technologies, Vancouver (QLT), in partnership with Lederle Laboratories have just received a notice of Compliance from the Canadian Health Protection Branch for the use of Photofrin® in the treatment of superficial bladder cancer.

Photodynamic therapy (PDT) requires that the photoactive agent first absorb a photon of a specific wavelength and in general the action spectra correlate well with the absorption spectra. As can be seen from the modified Yablonski diagram in Fig. 1, the first excited singlet state (S_1) can fluoresce or this excited state can participate in an electron transfer process with a biological substrate, resulting in the photobleaching of the photosensitizer and modification (destruction/inactivation) of the substrate. This is known as a Type I photoprocess (13). PUVA (psoralin, 8-methoxypsoralin, plus UV radiation using UVA) relies on this photochemistry where the psoralin is believed to undergo photoaddition to thymidine bases of DNA (14). In addition to being the most widely used treatment of psoriasis, PUVA also gives rise to cutaneous cancers (15). Photosynthesis using reduced porphyrins (chlorophylls, bacteriochlorophylls) makes use of a Type I process but the initially oxidized "porphyrin", at the reaction center, is reduced by another porphyrin

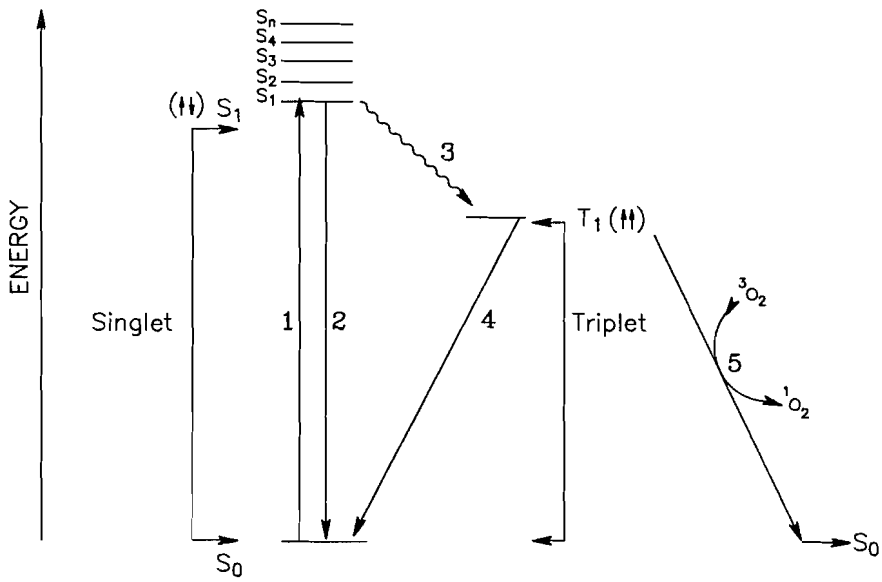
PHOTOFRIN® (Profimer Sodium) **(2)**



1 – Absorption – Depends upon extinction coefficient and wavelength
2 – Fluorescence – Lifetime depends on molecular interactions
3 – Intersystem crossing
4 – Phosphorescence
5 – Conversion of triplet oxygen $^3O_2$ to singlet oxygen $^1O_2$

FIG. 1. Modified Yablonski diagram.

(cytochrome) such that no net destruction of the photoactive species occurs.

A second, and far more interesting, photochemical process known as a Type II photoprocess results in the conversion of stable triplet oxygen ($^3O_2$) to the short-lived but highly reactive (toxic) singlet oxygen ($^1O_2$). This reaction occurs, as shown in Fig. 1, when the S_1 state of the photosensitizer undergoes intersystem crossing to its first excited triplet state (T_1) followed by a triplet–triplet reaction with $^3O_2$ to regenerate the photosensitizer in its ground state and singlet oxygen.

Singlet oxygen has a lifetime of ~6 μs in water and a little longer in lipid and cell membranes, which means that it cannot diffuse more than a single cell length. Singlet oxygen is a powerful, fairly indiscriminant, oxidant that reacts with a variety of biological molecules and assemblies. As shown in Fig. 2, oxygen atom transfer can result in the oxidation of both carbon and sulfur and in the formation of hydroperoxides from a variety of substrates including cholesterol and phosopholipids. The site of the greatest accumulation of the phototoxin may not define the site of cell death since, while a single oxidation of an amino acid in a protein may results in the shutdown of critical biological process (16–18), greater destruction of less critical sites may be required for cell death. Be that as it may, Oleinick and colleagues (19) have shown that, in vitro, cells die by apoptosis[3]

[3]Apoptosis is programmed cell death involving endonucleosis and chromatin condensation.

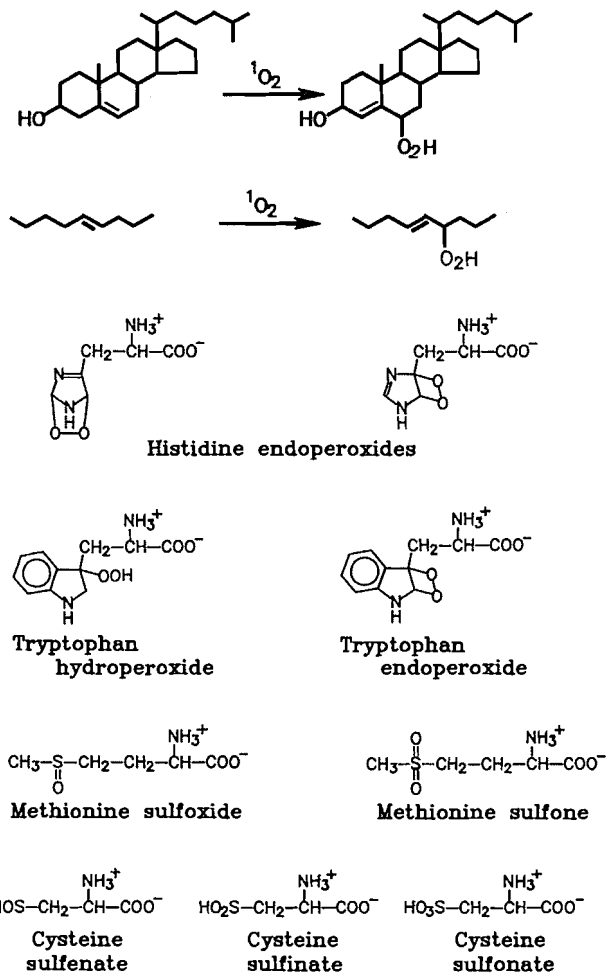

FIG. 2. Typical examples of the reactions of singlet oxygen with biomolecules.

after PDT. A dramatic example of cell membrane damage is shown in Fig. 3. This damage was observed (20) using BPDMA, which is discussed below.

Since most photosensitizers currently in clinical trials for PDT (21) have quantum yields for singlet oxygen production of ~0.5 or higher, considerable amounts of singlet oxygen can be produced when the photosensitizer is illuminated with light of the appropriate wavelength. The penetration of light through tissue is attenuated by a number of factors but absorption and scattering are the most important in limiting the penetration depth for effective treatment. Heme proteins account for most of the absorption of light in the visible region. Since this drops off rapidly beyond 550 nm, the effective depth of penetration doubles in going from 550 to 630 nm (where Photofrin® is activated) and doubles again in going to 700 nm. However, beyond 700 nm only an additional 10% increase in penetration is achieved by moving into the infrared (Fig. 4). The clinical activation of Photofrin® at 630 nm was chosen since it has an absorption band there (albeit weak) that is stronger than the absorption of oxyhemoglobin at that wavelength (Fig. 5).

Porphyrins (**3**) (Fig. 6) are 18π-electron aromatic macrocycles that exhibit characteristics optical spectra with a very strong π–π* transition around 400 nm (known as the Soret band) and four Q-bands in the visible region. As can be seen in Fig. 6, two of the peripheral double bonds, in opposite pyrrolic rings, are crossed conjugated and are not required to maintain aromaticity. Thus reduction of one or both of these cross-conjugated double bonds (to give chlorins (**4**) and bacteriochlorins (**5**) maintains aromaticity but the change in symmetry results in bathochemically shifted Q-bands with high extinction coefficients (Fig. 6). Nature uses these optical properties of the reduced porphyrins to harvest solar energy via photosynthesis with chlorophylls and bacteriochlorophylls as both antennae and reaction center pigments. The long-wavelength absorptions of these chromophores naturally led to explorations of their use as phototoxins in PDT where they have exhibited some interesting properties (22, 23). Nevertheless, the complexity of these natural pigments and the considerable problems in their isolation, separation, and purification add to the difficulties in their development for clinical use. Moreover, chlorins and bacteriochlorins, by virtue of their di- and tetrahydro reduction states, can be readily oxidized back to the parent porphyrin accompanied by the loss of their long-wavelength absorption bands. This potential lack of stability has led us to examine other ways of producing stable chlorin-like chromophores.

Protoporphyrin IX as its iron complex (heme) is the prosthetic group of heme proteins and is thus readily available from a number of animal sources. As a result of the cross-conjugated nature of the peripheral double bonds it seemed likely that one of these double bonds and a conjugated vinyl group of protoporphyrin IX might act as a diene in a Diels–Alder reaction (24).

When protoporphyrin IX dimethyl ester (**6**) is treated with a strong dienophile such as tetracyanoethylene, both 2 + 2 and 2 + 4 cycloadditions take place on either or both rings A and B (Scheme 1) (24). Acetylene dicarboxylic ester, on the other hand, brings about a Diels–Alder reaction at either ring A or B but we have not seen reaction at both rings (25). The initially formed cycloadducts (**7,8**) are 1,4-cyclohexadienes having strong absorptions at 666 nm consistent with their chlorin-like chromophores (Fig. 7). Treatment of the 1,4-diene with triethylamine tautomerizes it to the 1,3-diene (**9**). This conjugated chlorin absorbs at 686 nm and turns out to be a kinetically controlled product having a cis arrangement of the angular methyl and methoxycarbonyl groups. Treatment of this *cis*-1,3-diene or the original 1,4–dienes with 1,5–diazobicyclo[5.4.0]undec-5-ene (DBU) generates the thermodynamically more stable *trans* product (**11**). X-ray crystallography confirms the structure and stereochemical assignments made from previous NMR studies (Fig 8) (26). The *cis* and *trans* isomers both exhibit strong absorption around ~690 nm (Fig. 7). Prolonged treatment of the 1,3-dienes with TEA eliminates the angular methyl group and generates the benzoporphyrin (**10**), which has a characteristic porphyrin spectrum (Fig. 7).

Hydrolysis of the dimethyl ester in concentrated HCl leaves the ester groups on the exocyclic ring intact owing to steric hindrance experienced by the group close to the angular methyl and the conjugation of the other. The propionic esters do hydrolyze to give a mixture of the diacid (**14**) and the two regioisomeric monacid monoesters (**12, 13**). Cytotoxicity studies using the diacid showed that it was 10–70 times more cytotoxic than hematoporphyrin against a variety of normal and malignant cell lines (27). Surprisingly, a comparison of the phototoxicity of the monoacids showed that they were five times more cytotoxic than the corresponding diacids (28) for both the ring A and ring B analogs (Fig. 9). We choose to proceed towards clinical trials using the two regioisomeric monoacids of the ring A analog (**12** and **13**) that we call BPDMA (benzoporphyrin derivative ring

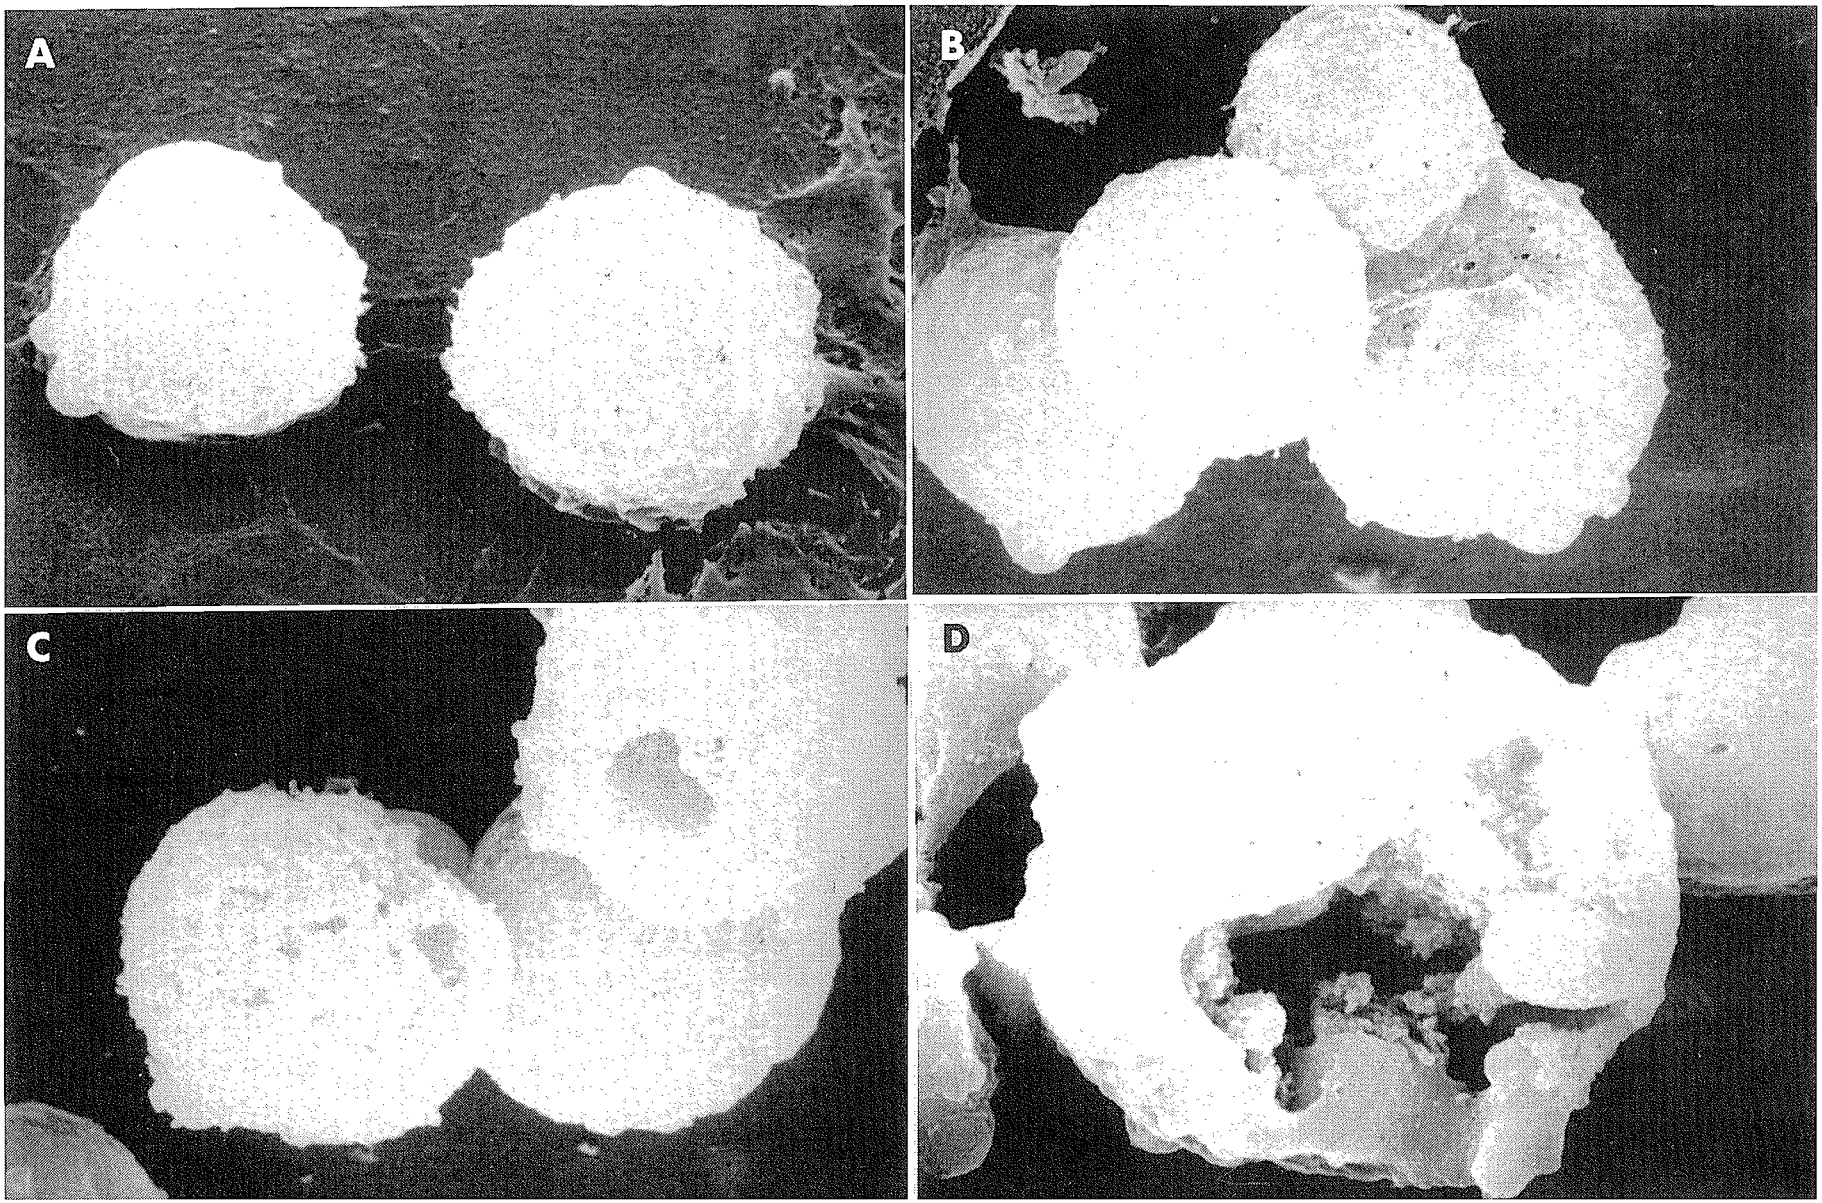

FIG. 3. Feline T cells were treated with 2 μg/mL of BPDMA and light. A: uninfected cells and light show no damage; B, infected (with FelV) cells after early treatment with light show small holes in the membrane, as light treatment continues, the holes increase in size (C) until the membrane eventually appears to be completely destroyed (D). Reprinted by permission form Blood Cells (20).

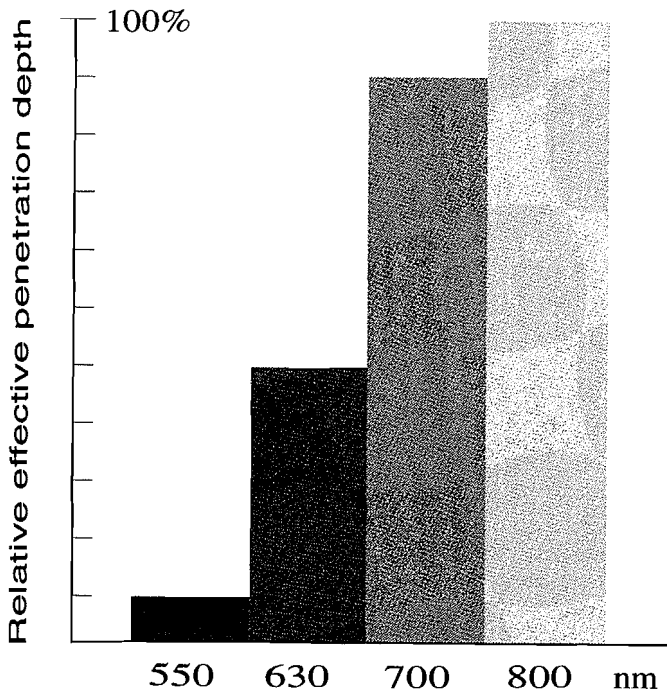

FIG. 4. Relative depth of penetration, in muscle, of light of various wavelengths.

A mono acid), whose optical spectrum (Fig. 10) shows a maximum absorption at the wavelength (~690 nm) where blood has a minimum absorption.

While BPDMA does not show specific affinity for tumors, it exhibits significantly higher concentrations in tumors than in the surrounding healthy tissues (29). BPDMA localized in tumors better than in other tissues except liver, kidney, and

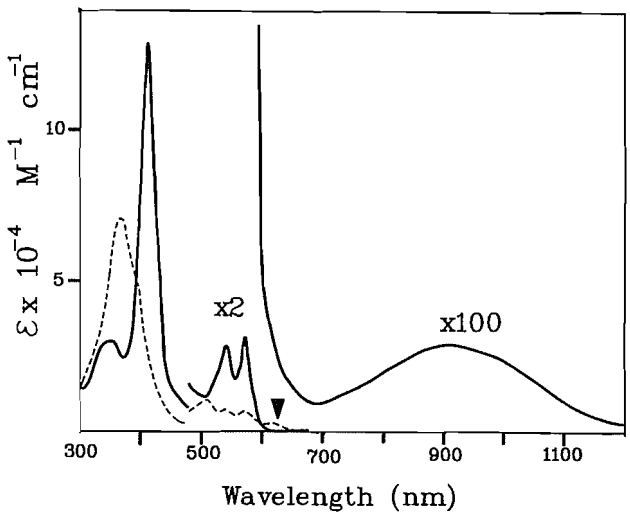

FIG. 5. Optical spectra of oxyhemoglobin (——) and Photofrin® (- - - -).

spleen. BPDMA is a chemically stable powerful phototoxin (its quantum yield for singlet oxygen is 0.46 (30)); however, before proceeding with the extremely expensive and time- consuming preclinical studies needed before a health board will issue an IND (investigation of a new drug), which allows the undertaking of human clinical trials, one is well advised to examine the extent of prolonged skin photosensitivity.

Photofrin® causes skin photosensitivity in patients for 4–6 weeks after treatment. This is a minor side effect compared to those experienced with chemotherapy or radiation therapy; nevertheless, a successful second generation phototoxin for PDT must exhibit dramatically reduced skin photosensitivity compared to Photofrin®. As can be seen from Fig. 11, compounds **12**, **13**, and **14** all showed rapidly decreasing skin photo-

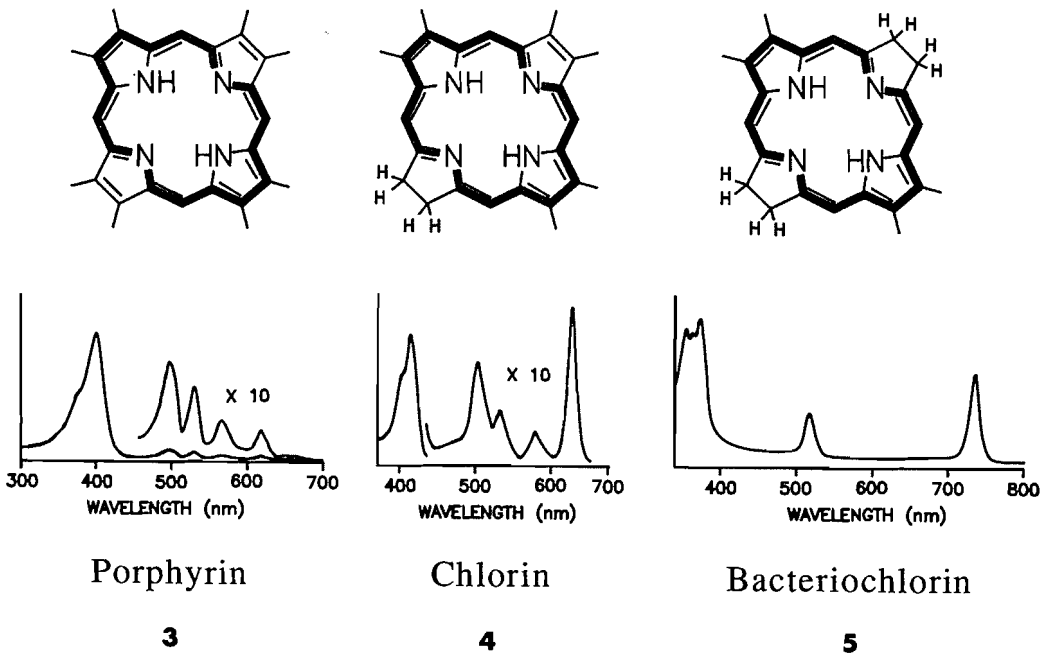

FIG. 6. Structures of the porphyrin (**3**), chlorin (**4**), and bacteriochlorin (**5**) macrocycles. The cross-conjugated double bonds in **3** can be reduced, leaving the dihydro (**4**) and tetrahydro (**5**) analogs aromatic. Increasing reductions result in an increasing bathochromic shift of the lowest energy absorption band.

sensitivity compared to Photofrin®, and after 72 skin photosensitivity had almost returned to normal with the monoacids. At this stage we were anxious to see if this minimal skin photosensitivity would also be seen with humans.

BPDMA is virtually insoluble in water and it has been formulated in unilamellar liposomes to make it water soluble. There is evidence to suggest that tumor selectivity with hydrophobic photosensitizers may be mediated by plasma proteins, especially low-density lipoproteins (LDL) (31–33). BPDMA associates predominantly with LDL (34) and, when preassociated with LDL improved delivery to tumors in a mouse tumor model was seen (35). The unilamellar liposomes rapidly deliver the BPDMA to the lipoprotein fraction when placed in serum, and PDT in a mouse tumor model showed that the liposomally formulated material accumulated more rapidly when delivered in this fashion than when injected in DMSO/PBS (36).

As long as a phototoxin preferentially accumulates in diseased tissue, or in a pathogen, then differential damage occurs when the system is illuminated. Under such conditions an appropriate drug dose – light energy combination can be found whereby the diseased tissue or pathogen can be destroyed without causing irreversible damage to healthy tissues. Photobleaching (37), a type I photoprocess that occurs more readily in vivo than in pure organic or aqueous solvents, may assist in minimizing damage to healthy tissue if photobleaching of low concentrations of the phototoxin in healthy tissue is complete

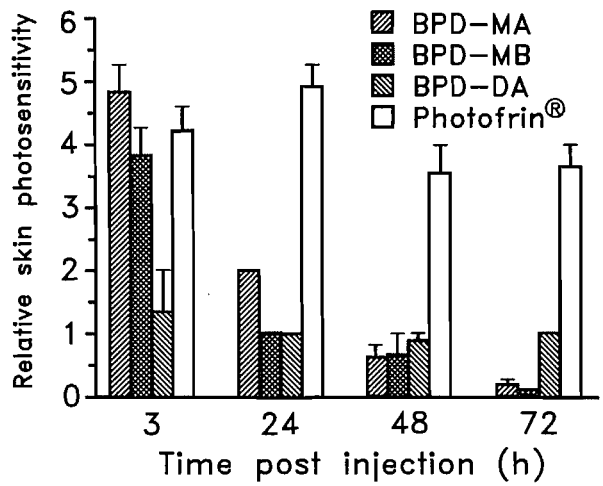

FIG. 11. Skin photosensitivity in mice following i.v. injection of the photosensitizers (4 mg/kg) and exposure to white light (95 J/cm^2). Severe damage resulting in eschar formation was scored as 5 (47). Compounds are described in Fig. 9.

before irreversible damage can take place. Photofrin® and BPDMA photobleach at similar rates.[4]

While we are just beginning to understand the mechanisms by which phototoxins biodistribute, few structure–activity relationships are known. Nevertheless, BPDMA has a great propensity to accumulate in diseased cells and in the neovasculature of hypoproliferic tissues. Measurements of biodistribution are aided by the strong fluorescence at 690 nm shown by BPDMA (Fig. 12). Fluorescence-activated cell-sorting (FACS) analysis following excitation in the UV at 420 nm showed dramatic differences between several leukemic cell lines, leukemic clinical isolates, and normal bone marrow cells incubated with BPDMA (38). Indeed BPDMA shows great potential for the ex-vivo purging of residual tumor cells in autologous bone marrow grafts. A four-log elimination of tumor cells occurred after a 1-h incubation with 75 ng/mL BPDMA followed by exposure to white light; at the same time pluripotent stems, the progenitors for all hemopoietic cells, survived the purging regime (39). Human clinical trial using BPDMA to purge leukemic autolysis grafts will begin this year under the direction of QLT.

Numerous viruses, pathogenic to humans, contain an outer hydrophobic membrane (envelope). Included amongst these viruses are cytomegatovirus (CMV), herpes simplex virus (HSV), several of the hepatitis viruses, and retroviruses such as the human T cell leukemic virus (HTLV) and human immunodeficiency virus (HIV). These, and other viruses, may be transmitted in transfused blood but it has been shown, using

vesicular stomatitis virus (VSV) and feline leukemia virus (FeLV) as models, that BPDMA and light were effective in eliminating both cell-free virus and virally infected cells while at the same time leaving the red cells apparently undamaged (20, 40). Further studies have shown that BPDMA is effective for the elimination of both free and virally infected leukocytes in whole blood from virally infected humans under conditions that appeared to spare both the red cells and uninfected leukocytes (41). On the basis of these results and other preclinical studies, QLT plan to initiate clinical trials for the extracorporeal treatment of HIV-infected patients. The benefits of reducing the viral load must await the results of the clinical trials. In addition to reducing the viremia, other immunologic effects may be found as were observed after PDT with Photofrin®. Immunosuppression, as indicated by sensitivity to dinitrofluorobenzene (42), was observed in mice after PDT and an increase in chronic inflammatory cells was observed in patients after treatment for bladder cancer using Photofrin®. Moreover, the release of cytokines such as interleukin-1b and -2 and the release of tumor necrosis factor by macrophages (43, 44) and of thromoxane (45) have all been observed shortly after PDT.

While several second generation drugs are in clinical trials (21), the most advanced and most promising is BPDMA, which is being used on a number of cutaneous cancers including basal cell carcinoma, metastatic breast and gastrointestinal carcinomas, and metastatic amelanotic melanoma as well as for the treatment of psoriasis. At the present time the drug is infused in doses ranging from 1.5 to 5.0 mg/kg and light doses, administered 3 h later, have ranged from 25 to 150 J/cm^2. More than 70 cutaneous tumors have been treated and followed for several months after treatment. Complete responses were observed for the higher drug and light doses, and overall tumor responses of greater than 60% has been recorded (46). These exciting and promising results are being paralleled in the treatment of psoriasis where only a few patients have so far been treated.

We noted above that any successful second generation photosensitizer must exhibit minimally prolonged skin photosensitivity if it is to be successful in the clinic. The pharmacokinetic profile for BPDMA in human serum concentrations is shown in Fig. 13 where rapid clearance from the system is clearly observed. This decrease in serum levels is paralleled by a lowering of skin photosensitivity with time. A major purpose of the first phase of the clinical trial was a measurement of skin photosensitivity, and extensive studies using UVA and visible light from a solar simulator (using a filtered xenon arc lamp) have been carried out (46). Marked skin photosensitivity was observed shortly after treatment but photosensitivity shows a logarithmic decrease with time and it is expected that skin photosensitivity will return to normal (pre-BPDMA infusion) within 1–2 days at the expected clinical dose of BPDMA.

BPDMA thus seems to be meeting all of the necessary and hoped-for requirements of a successful second generation photosensitizing drug and, as the only non-mutagenic, non-carcinogenic, non-(dark) toxic anti-cancer drug known, we anticipate its use in a variety of clinical situations.

1992 Lemieux Award Lecture
Studies related to the penicillin receptor[1]

SAUL WOLFE[2]
Department of Chemistry, Simon Fraser University, Burnaby, BC V5A 1S6, Canada

Received June 3, 1993

SAUL WOLFE. Can. J. Chem. **72**, 1014 (1994).

The relative antibacterial activities of penicillins and cephalosporins are discussed in terms of their differing abilities to complex to and react with penicillin-binding proteins. The insights gained from such an analysis are being used to attempt the design of new kinds of structures targeted to the penicillin receptor. Details of such design, and examples of several new classes of compounds suggested by this work, are described. Some of these compounds exhibit interesting antibacterial activity.

SAUL WOLFE. Can. J. Chem. **72**, 1014 (1994).

On discute des activités antibactériennes relatives des pénicillines et des céphalosporines en fonction de leurs facilités relatives de se complexer à et de réagir avec les protéines qui lient les pénicillines. On utilise les connaissances acquises par une telle analyse pour essayer d'imaginer de nouvelles sortes de structures pouvant s'associer au récepteur de la pénicilline. On décrit les détails d'un tel développement et on présente des exemples de nouvelles classes de composés qui ont été suggérées par ce travail. Un certain nombre de ces composés présentent une activité antibactérienne intéressante.

[Traduit par la Rédaction]

An introduction to "Sugar Ray"

I first met Professor Lemieux in Ottawa in the spring of 1955, in a "temporary" womens' barrack that had been built for the Second World War. The barrack had been converted to the chemistry building of the University of Ottawa by two carpenters named Lemieux and Anet, with the assistance of the Oblate Fathers of the University. Three months later I returned to Ottawa, with a Master's degree from the University of Toronto, as the Department's (and Lemieux's) first Ph.D. student. It is difficult to convey to today's colleagues and students the conditions under which organic chemistry students were required to work in Toronto at that time; but as a result of my experience in that environment, I was apprehensive about how I was expected to behave in the presence of my supervisor, and how I should address him. When I sought advice on this matter, it was suggested that I should refer to Professor Lemieux as "Sugar Ray".

The last time I related this story in public, I attributed the advice to Frank Anet, whom I was introducing at one of the frequent Lemieux symposia. Frank was dumbfounded, insisted that he would not have used such a description, and that this sobriquet would never have occurred to him. In any event, he argued, scientific precision would have been better served at that time by the name "Maltose Ray" or Sucrose Ray".

I have many people to thank for the Lemieux Award, including the individuals who, without my knowledge, nominated and selected me. But the person who has to accept the greatest responsibility is Professor Lemieux himself. He is the father of my career. What I learned from him is that research can be exciting and great fun, if one works hard, is prepared to take some risks, and always treats the work seriously, but never oneself. He encouraged me to have ideas, and he taught me how to develop ideas and to devise ways to test them. In view of his lifelong influence upon every aspect of what I do, I would like to take this opportunity to urge those referees of my papers and grant applications, or those members of audiences who are outraged by my work, to consider directing their outrage in future to Lemieux and not to me.

Amel Menotti and Bristol Laboratories

After he completed his PhD in 1946, Professor Lemieux joined Wolfrom's group at Ohio State as a Bristol Laboratories Fellow. This Fellowship had been created by Dr. Amel Menotti, who was then, and for many years afterwards, Vice President and Scientific Director of Bristol. Ten years later, when the antibiotic kanamycin was discovered in Umezawa's laboratory in Japan, as a result of research also supported by Bristol (1), Lemieux was asked to help with the elucidation of its structure. The student who worked on the structure of kanosamine was Ning-Jo Chü (2), with whom I was at that time sharing an apartment.

I learned about Bristol Laboratories from Paul Chü and, in 1959, when I could not find work in Canada, I wrote to Bristol. On Professor Lemieux's recommendation, Dr. Menotti offered me a position. 6-Aminopenicillanic acid (6-APA) (**1**), the nucleus of penicillin (**2**), had just become available as a result of research at Beecham Laboratories (3), and Beecham and Bristol were collaborating on the synthesis and evaluation of the many new semisynthetic penicillins that were now accessible via chemical acylation of the amino group of 6-APA. The nucleus itself has no antibacterial activity, but every semisynthetic penicillin is biologically active, the magnitude and nature of the activity depending on the nature of R.

Diastereomeric penicillins

By the summer of 1960, a first set of lead structures had been identified, and these compounds were undergoing development. Among them were three (**3***b*, **3***c*, and **4***b*) in which the side-chain carboxylic acid had a stereogenic centre at the α-carbon. In each case, when the penicillins were prepared from the resolved acids, one of the diastereomers was found to be 5 to 10 times more active than the other against a range of organisms. In the case of α-aminopenicillin G (**3***b*), which later became known as ampicillin, and α-hydroxypenicillin G (**3***c*), the side-chain acid having the *R*-configuration gave the more active penicillin, but with α-methylpenicillin V (**4***b*), which later became known as phenethicillin, the *S*-acid offorded the more active penicillin.

[1]This work was presented as the Lemieux Award Lecture at the 75th Annual Conference of the Canadian Society for Chemistry, Edmonton, June 1, 1992.

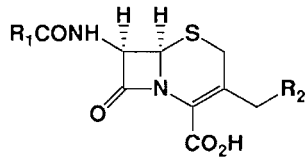
More active Less active

5



6

When Joe Lein, Alex Gourevitch, and I examined the structures of these compounds, we found that, despite the differences in absolute configuration, in each case the side chain acid that led to the more active penicillin had the small, medium, and large substituents arranged in a clockwise sense when these were viewed along the C_α-COOH bond (**5**). Our 1961 paper reporting this observation was my first publication in the field. (4), but the questions that it raised, and my attempts to pursue these questions, have occupied my attention continuously since that time.

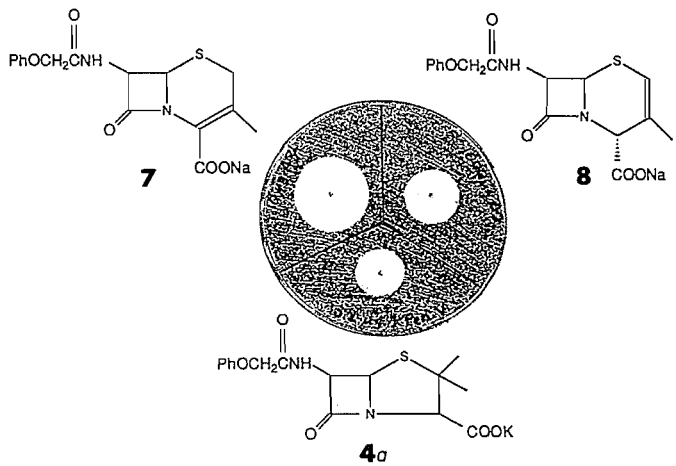
The earliest work on semisynthetic penicillins coincided with Abraham and Newton's completion of the structure proof of Cephalosporin C (**6**; R^1 = δ-D-α-aminoadipyl; R^2 = OAc) (5). It is evident, upon examination of **2** and **6**, that penicillins and cephalosporins have a number of structural and stereochemical features in common. They also have the same mechanism of action (6), and they are formed in nature from the same amino acid and peptide precursors (7). Although the original data base for the small–medium–large effect in the side chains of penicillins was three, numerous others have been added since (8), with no exceptions, and the effect is also seen in the side chains of cephalosporins (9).

Lock and key interactions

In 1894, Emil Fisher wrote that, for a chemical reaction to take place between an enzyme and its substrate, these must fit together like a lock and a key (10). I believe that I first learned of this idea in Lemieux's graduate course in carbohydrate chemistry. One way to apply the concept to the action of an enzyme, or the interaction of a drug with its receptor, is to think of the opening of a lock as a two-stage process: in the first stage, the key fits into the lock; in the second, the key turns and opens the lock. As I will explain later, I now find it useful to treat the first stage as analogous to the formation of an enzyme–substrate complex (eq. [1]), that is, the "fit" of a drug to its receptor, and the second stage as related to k_{cat}, that is, the "reactivity" of a drug with its receptor. Understanding a lock and key relationship therefore requires an understanding of both fit and reactivity.

$$[1]\quad E + S \rightleftharpoons ES \xrightarrow{k_{cat}} P$$

"fit" *"reactivity"*



7 **8** **4***a*

FIG. 1. Zones of inhibition, versus a sensitive strain of *S. aureus*, using the potassium salt of penicillin V (**4***a*), the sodium salt of desacetoxycephalosporin V (**7**), and the sodium salt of Δ^2-desacetoxycephalosporin V (**8**). The amounts of material on this plate are: **4***a*, 0.1 μg; 7, 5 μg; **8**, 500 μg.

Figure 1 shows zones of inhibition for penicillin V (**4***a*), desacetoxycephalosporin V (**7**), and the Δ^2-isomer of desacetoxycephalosporin V (**8**), against a strain of *Staphylococcus aureus* isolated at Vancouver General Hospital. The relative amounts of material required to achieve the same inhibition are **4***a*: 1; **7**: 50; **8**: 5000. Is the Δ^3-cephalosporin less active than the penicillin because it has a poorer fit or because it is inherently less reactive? If an imperfect substrate exhibits a poorer fit, how is its reactivity affected? It has been argued (11*a*, 11*b*, 11*c*) that "reacting molecules have to be in a particular position relative to each other in order to undergo reaction and that they bind to the active site of (an) enzyme in this favourable mutual orientation" (11*d*). Does this view imply that there is a *perfect* substrate for which the *optimum* "particular positions" achieved by the reacting atoms of an enzyme–substrate complex can be determined? What are the kinetic consequences of deviations from these positions?

The early work of Eschenmoser and co-workers (11*e*), King and McGarrity (11*f*), and Lok and Coward (11*g*), and more recent work by Beak (11*h*) on endocyclic methyl transfer (e.g.,

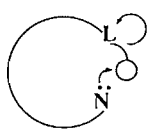
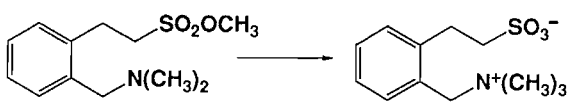
[a]Data from ref. 12.

9), provides helpful insights on this point. When the length of the chain separating N and L is too short, the geometrical requirements of an intramolecular S_N2 reaction cannot be achieved, and only intermolecular methyl transfer is then observed. King found that there is an intramolecular component in the case of **10**, but not in the case of **11**, and was able to estimate that endocyclic methyl transfer is at least 200 times slower in the latter case.



9



10

11

At the molecular level the catalytic efficiency of an enzyme is given by the ratio k_2/K_m, where $K_m = (k_{-1} + k_2)/k_1$. For the process summarized in Scheme 1, the units of k_2/K_m are M^{-1} s^{-1}, which corresponds to a second order rate constant. As will be seen later, this scheme describes the initial stages of the reactions of penicillins and cephalosporins with penicillin-binding proteins (PBP's); the chemical reaction measured by k_2 is the acylation of the hydroxyl group of a serine residue by the β-lactam ring. As summarized in Table 1, for an exocellular PBP from *Streptomyces* R61, which has been studied in some detail (12), the catalytic efficiencies towards 6-APA, cephaloglycine, and penicillin G are 0.2, 22, and 13 000. The corresponding second-order rate constants for nonenzymatic hydrolysis by OH^- are 0.15, 0.90, and 0.50. There is no correlation between the trends in the enzymatic and nonenzymatic rate constants, but this could simply mean that hydrolysis by OH^- does not properly simulate the chemical reaction measured by k_2. The trends in k_2 and K_m are somewhat more revealing, and one might conclude that it is rather important to understand the mechanism of the acylation step.

None of this was known in 1960. At that time we thought that the bicyclic nucleus of a penicillin or cephalosporin provided the fit, and that the side chain was needed to turn on the activity. But if every side chain turns on activity, how can the *configuration* in the side chain affect activity by an order of magnitude? What are the conformations of diastereomeric penicillins? How are epimers distinguished by the penicillin receptor? What is this receptor? Would answers to such questions lead to the design of novel structural types that would mimic the action of penicillin? Figure 2 shows zones of inhibition against *Escherichia coli* exhibited by penicillin V and one such compound. The structure of this compound and the reasoning that led to its synthesis will be presented later.

It was my good luck that Dr. Menotti believed in taking risks. He took a personal interest in the questions that I was asking in 1960, and decided to give me the freedom to pursue them on a

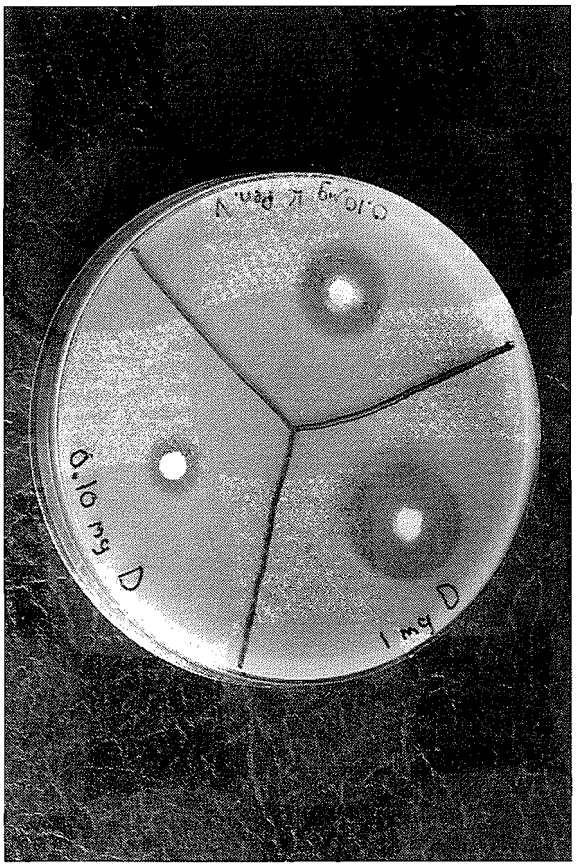

FIG. 2. Zones of inhibition, versus a sensitive strain of *S. aureus,* using 0.1 μg of penicillin V, and 0.1 and 1.0 mg of **20** (see text).

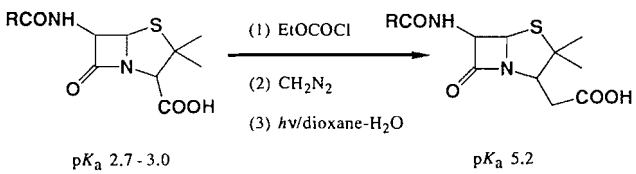

SCHEME 2

full-time basis. He also asked Joe Lein, Irv Hooper, and Merle Pindell, the heads of the microbiology, biochemistry, and pharmacology groups, to help me read the literature of their disciplines.

Moving to Queen's. Sulfur-free penicillin derivatives

He then did much more. When Bob McIntosh persuaded me to move to Queen's in 1961, Bristol offered the University a substantial unrestricted gift to equip my laboratory, and Dr. Menotti personally travelled to Kingston to persuade John Deutsch to allow Bristol to fund my work directly. This funding continued for more than 10 years, until Dr. Menotti's retirement.

From discussions with Merle Pindell I learned that optimum absorption and blood levels are found for carboxylic acids when these have pK_a's above 5. Penicillins have pK_a's between 2.7 and 3.0. We thought that the pK_a would be raised if the carboxyl group were moved away from the thiazolidine ring. Photochemical Arndt–Eistert homologation successfully gave homopenicillin G and homopenicillin V (Scheme 2), both of which were obtained crystalline as their potassium salts. Both had pK_a's of 5.2. Although, in each case the in vitro activity was

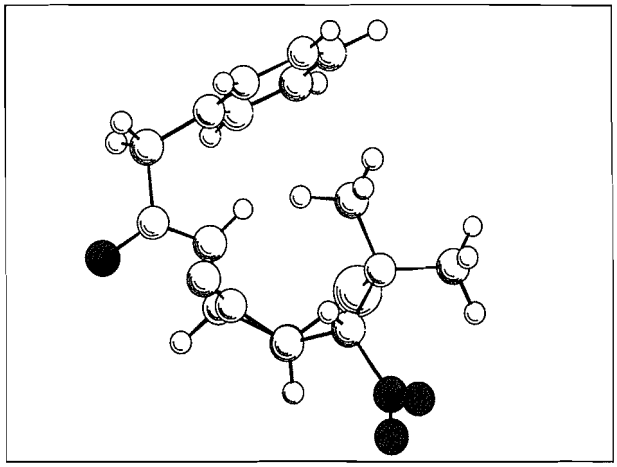

FIG. 3. Crystal structure of penicillin G. The carboxyl group and the carbonyl oxygen of the amide side chain occupy the convex face of the bicyclic system (shaded). The aromatic side chain is on the concave face of the molecule.

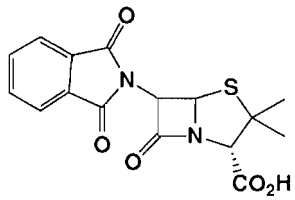
less than 1% of that of the parent penicillin, high or prolonged blood levels could lead to much better activity in vivo. Merle Pindell's group therefore proceeded to in vivo trials. All members of a control group of animals survived treatment with homopenicillins, but all of the infected animals died.[3]

It was already known that a free carboxyl group is essential for in vitro activity of penicillins. Indeed, by 1961, all of the obvious changes around the periphery of the bicyclic nucleus had been carried out, always with loss of activity. In addition, Sheehan's total synthesis (13) and the later work of Vanderhaeghe and coworkers (14) had shown that, of the eight stereoisomers of penicillin, only the natural isomer is active. From our experiments with homopenicillins we now knew that, if the carboxyl group engages in binding to a penicillin receptor, this group must be positioned precisely with respect to at least one other binding site in the molecule.

Although we did not realize it at the time, there was evidence regarding the nature of the second binding site. Phthalimidopenicillin (**12**), which lacks an N-H in the side chain, is at least 300 times less active than penicillin G, and it could not be excluded that the observed activity arises from hydrolysis to the phthalamic acid, which does occur at pH 7.5 (15).



12

Figure 3 shows the crystal structure of penicillin G (16). In the crystal structures of all penicillins and cephalosporins, the carboxyl group and the amide oxygen of the side chain occupy the convex face of the bicyclic system; the amide N-H is on the concave face. Since the solution conformation was not known, we supposed that it is the same as the crystal structure, and that the exposed amide oxygen complexes to the penicillin receptor.

R.U. Lemieux

July 6, 1960.

The nuclear magnetic resonance spectra for 6-aminopenicillanic acid and eleven of its N-acyl derivatives are reproduced in figure 1. The spectra were measured in heavy water, 20-30% solution, using a high resolution Varian spectrometer operating at 60 Mc/s. The chemical shifts were established using the side-band technique and are reproducible to better than 1%. All chemical shifts are from the signal arising from the H_2O signal.

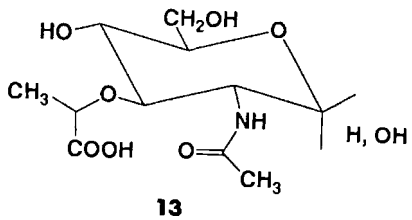
FIG. 4. Extract from a report written by R.U. Lemieux in 1960.

This is consistent with the requirement that, for antibacterial activity to be achieved, an acyl group must be attached to the amino group of 6-APA. In the phthalimido compound, the N-H is replaced by a carbonyl carbon, and both carbonyl carbons are attached to a benzene ring. We thought that the steric hindrance thus created on the concave face of the molecule would result in rotation about the C6—N bond, and cause the complexing oxygen to move away from its optimum position.

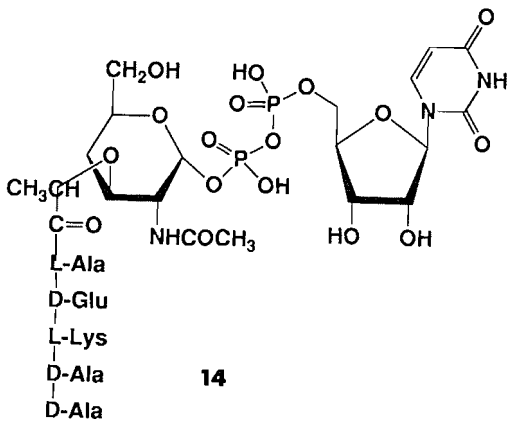
We used the same reasoning 5 years later when Leigh, at ICI Laboratories, reported that *N*-methylpenicillin V is 1000 times less active than penicillin V (17). However, it must also be recognized that the conversion of penicillin V to *N*-methylpenicillin V and the conversion of 6-APA to phthalimidopenicillin lead to compounds that no longer have an *N-H* in the side chain. The possibility that it is the amide *hydrogen*, and not the carbonyl *oxygen*, which interacts with the penicillin receptor did not occur to me for more than 25 years. This idea will be pursued later, but we may note here that an important difference between 6-APA and an *N*-acylated 6-APA derivative is that the amino nitrogen of 6-APA is a hydrogen-bond acceptor, but the amide N—H of a penicillin is a hydrogen-bond donor.

Another relevant result from this early period was provided by Professor Lemieux. During the winter of 1956–1957, we had heard a lecture by Harold Bernstein on the subject of the nmr spectrum of phenanthrene. He had found, using compounds that Leonard Leitch had labelled with deuterium, that the 4,5-hydrogens are shifted downfield by 1 ppm; and in that lecture what became known as the ring current effect was discussed for the first time. By 1960 this effect was sufficiently well established that we thought we might be able to learn how the benzene rings were oriented in the ampicillin (**3***b*) and phenethicillin (**4***b*) diastereomers by examination of the chemical shifts of the methyl groups. We did not yet have an nmr spectrometer at Bristol, but Professor Lemieux did, in Ottawa. Figure 4 is the introduction to his report, reproduced here to illustrate how spectra were obtained at that time. We were able to supply the *R* and *S* isomers of α-methylpenicillin V; each isomer exhibited nonequivalent methyl groups in the thiazolidine ring, but the chemical shifts of these methyl groups were the same in both isomers. A few months later we obtained our own spectrometer, and were able to examine the spectra of the isomers of α-amino and α-hydroxypenicillin G. They also showed no difference in the chemical shifts of the methyl groups. I did not return to this matter for 25 years.

From Joe Lein and Irv Hooper I learned that penicillin acts on growing bacteria by inhibiting the formation of their cell walls, that all bacterial cell walls contain *N*-acetylmuramic acid (**13**) (18), and that penicillin-treated cells of *S. aureus* had been found by Park (19) to accumulate a number of uridine nucleotides, e.g., **14**, in which a short peptide chain is attached to the carboxyl group of the *N*-acetylmuramic acid. The pK_a of *N*-acetylmuramic acid is 2.6, almost the same as that of penicillin.



13



14

Since *N*-acetylmuramic acid had been found only in bacterial cells and in certain rickettsiae, and penicillin is toxic to bacterial cells and the same rickettsiae, our first idea was that penicillin is a structural analog of *N*-acetylmuramic acid, and blocks its incorporation into the cell wall. Figure 5, which dates from 1960, shows the model that was proposed following inspection of molecular models. In this figure the bold lines denote the matching parts of the two molecules. In terms of this model, the fusion of a second ring to the β-lactam achieves conformational constraint, but the presence of sulfur in this second ring would not be essential for this constraint. The β-lactam ring is thereby positioned properly with respect to, and acylates a functional group at, the active site.

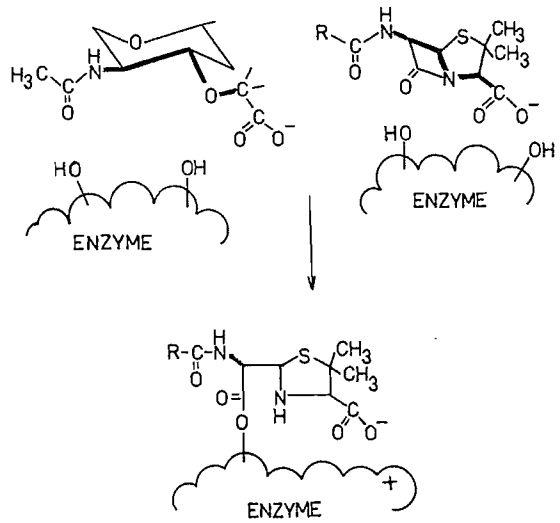

FIG. 5. An early model purporting to demonstrate a structural relation between *N*-acetylmuramic acid and penicillin as a basis for the action of the antibiotic.

One of the predictions of this model is that replacement of the sulfur atom of penicillin by other atoms, e.g., oxygen, carbon, nitrogen, selenium, should not lead to loss of activity. This was the project I took to Queen's. The first Bristol postdoctoral fellow was Dick Stoodley, who had just completed a Ph.D. in carbohydrate chemistry with J.K.N. Jones. Six months after he began, I showed him a paper that had just appeared in Nature, with the title "A Structural Similarity Between *N*-Acetylmuramic Acid and Penicillin as a Basis for Antibiotic Action" (20). Collins and Richmond, at the National Institute for Medical Research, at Mill Hill, had independently reached, and published, the hypothesis on which my entire synthetic programme was based.

My recollection is that Stoodley was crushed, but I was excited: Mill Hill was a major laboratory, and many of Alexander Fleming's contemporaries worked there. My ideas might, therefore, not be entirely without value. I wrote to John Collins, and was informed that they were not pursuing a synthetic programme based on their model. He later spent several months in Kingston, and invited me to London and then Edinburgh, where he introduced me to Henry Arnstein, Dorothy Hodgkin, Mark Richmond, and Richard Ambler, who was the first to determine the sequence of a penicillin-recognizing enzyme.

The work on sulfur-free penicillin derivatives continued for more than 10 years before any of it was published. We could do this for two reasons: through Dr. Menotti, the support from Bristol was assured; and, so far as I knew, no other laboratory in the world was engaged in similar chemistry. The conversion of a penicillin into a 1-oxacephem was reported at the Quebec CIC Conference in 1972, and followed up with six papers during the next 2 years (21).

Unfortunately for me, Saul was a King of Israel, but Moses was a prophet and, unlike Moses Gomberg (Fig. 6), I was unable to reserve this field for myself (22). By the time of the IUPAC natural products meeting in Ottawa in 1974, I was able to show a slide listing over 40 laboratories now working on nuclear-modified penicillins. Soon afterwards (Fig. 7), Woodward's synthesis of penems (23), and the discovery of thienamycin (24), clavulanic acid (25), the nocardicins (26), and the monobactams (27) attracted many more workers to the field.

One of these groups was directed by Wataru Nagata at the

BY M. GOMBERG.

[PRELIMINARY PAPER.]

SOME time ago I published a method of preparing tetraphenylmethane. The yield was rather small and I was obliged to study the solubilities, composition, molecular weight, and the nitro derivative on about 0.5 gram of the hydrocarbon. The stereochemical interest attached to this compound has induced me to take up the subject once more, in the hope of obtaining larger yields. I have, therefore, gone over most of the methods which have been tried by others for the preparation of tetraphenylmethane. My results, while differing in detail from those published by others, agree in the main,—the hydrocarbon could not be obtained by the usual reactions. One of the main proofs advanced by me for the constitution of tetraphenylmethane was that it furnished a tetranitro derivative which gave no colored salts with alcoholic potash, while most of the less phenylated methanes do respond to this test. To prove whether

This work will be continued and I wish to reserve the field for myself.

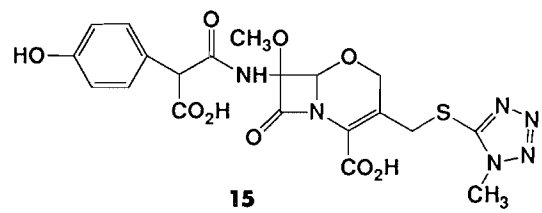
Shionogi Pharmaceutical Company, in Osaka. During a period of 5 years they synthesized many oxacephems, and discovered and developed an industrial synthesis of the compound now known as latamoxef (**15**), which has been in clinical use since about 1980 (28). In 1979, Dr. Nagata invited me to meet with Shionogi's oxacephem team. There were so many people in the room that I knew it was time to leave this field.



15

Penicillin-recognizing enzymes

However, I had also known for some time that the *N*-acetylmuramic acid hypothesis, on which our oxacephem work was founded, is not correct. The early research of Park has been continued to the present day, mainly by Park's co-worker Strominger (29), by Strominger's co-worker Ghuysen (30), and by Ghuysen's collaborator Frère (31). Strominger showed, in the early 1960's, that the incorporation of the *N*-acetylmuramic acid pentapeptide into cell walls leads to a linear polymer containing alternating units of the muramyl peptide and *N*- acetylglucosamine, and that this reaction is not blocked by penicillin (32). Later work revealed that the wall consists of a cross-linked polymer in which the terminal D-alanine is lost and the penultimate D-alanine is linked to the terminal amino group of lysine, through a pentaglycine bridge. The key observation was made by Tipper and Strominger in 1965 (33), namely, that it is this final, cross-linking, step that is blocked by penicillins and cephalosporins. These workers therefore suggested that penicillin is a structural analog of *N*-acyl-D-ala-D-ala. This hypothesis remains valid today.

Figure 8 is taken from the 1966 thesis of my student Syed

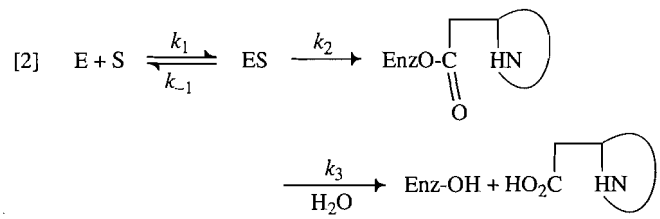
Hasan. It shows the skeleton of *N*-acyl-D-ala-D-ala in the conformation proposed by Strominger, and in the one that we preferred at that time, superimposed on the skeleton of penicillin. Since the sulfur atom is not essential to the analogy in either proposal, our synthetic objectives remained valid.

All penicillin-recognizing enzymes are serine proteases, which differ in their kinetic behaviour and, to some extent, in their constitutions. Whether a β-lactam compound acylates and thereby inactivates the enzyme, or is hydrolyzed and thereby is itself inactivated, depends on the relative magnitudes of k_2 and k_3 of eq. [2]. When $k_2 \gg k_3$, the enzyme is termed a penicillin-binding protein, as noted earlier; when $k_2 \approx k_3$, the enzyme is a β-lactamase. Table 2 illustrates, for penicillin G, the kinetic differences between the two types of enzyme (34).



All penicillin-recognizing enzymes contain the sequence Ser-X-X-Lys at the active site (35). Several β-lactamases and one PBP, from *Streptomyces* R61, have been crystallized (36). The β-lactamases have a second lysine residue, and also arginine and glutamate in the vicinity of the active site. The roles of these residues in the formation of the initial complex and in the hydrolysis of the acyl enzyme are currently under intensive study in a number of laboratories, using site-directed mutagenesis and X-ray crystallography (37). The β-lactamases also have up to five water molecules in the vicinity of the active site.

In the PBP from *Streptomyces* R61 the serine and lysine side chains of the Ser-X-X-Lys tetrad are on the same side of the molecule, and Ghuysen and Frère have suggested, based on pH-dependence experiments (38), that the terminal amino group of this lysine residue is charge-paired to the carboxyl group of the antibiotic.

The action of the trypsin serine proteases involves a charge relay mechanism (39), in which close contact between the carboxyl group of aspartic acid, the imidazole ring of histidine, and the hydroxyl group of the active site serine act to deprotonate this hydroxyl group, which then adds to the carbonyl group of the substrate. The resulting charged tetrahedral intermediate is stabilized by hydrogen bonding in the so-called oxyanion hole (40).

An Asp-His-Ser catalytic triad is not seen in the PBP crystal structure. There is a histidine residue whose imidazole ring is ca. 5 Å away from the serine hydroxyl group (41), and mutagenesis and pH-dependence studies suggest that this residue facilitates the positioning of the antibiotic in the active site (42).

These findings may mean that the hydrogen atom of the serine hydroxyl group is involved directly in the chemical reaction.

Theoretical studies

As a result of observations by Erwin Buncel (43) and the work of Arvi Rauk, one of my first students (44), we decided in 1964 to try to learn how to carry out and interpret ab initio molecular orbital calculations, with Imre Csizmadia as our mentor. Between 1964 and 1980, Rauk's pioneering work on sulfur-containing carbanions was continued and extended by a series of outstanding students: Luis Tel, Mike Whangbo, Berny Schlegel, Dave Mitchell, and Albert Stolow (45).

During the same period, numerous papers appeared in the literature describing molecular orbital calculations on simple β-lactam compounds and, in some cases, reactions of β-lactam compounds with hydride ion. However, I did not believe that knowledge of the angles at a β-lactam nitrogen atom, or the bond order between this atom and the adjacent carbonyl group, or the charge at the carbonyl group, or the arbitrary positioning of an arbitrary nucleophile with respect to this group, had any relevance to how penicillin binds to and reacts with its receptor, if this receptor were not also taken into account in the analysis. However, it was not possible to contemplate molecular orbital calculations on a protein receptor. Molecular mechanics programmes for peptides were available, but in the early 1980's these seemed to consist of black boxes with no published documentation of the algorithms employed, or the origins of parameters. Allinger's MM2 programme was fully documented (46), but was restricted to 100 atoms, and there were no parameters for peptides or β-lactam antibiotics. Scheraga's fully documented ECEPP programme (47) produced peptide structures and coordinates, but ultimately was limited by its use of fixed bond lengths and bond angles.

I thought that the problem was intractable, until Mario Pinto wondered whether one could use ab initio calculations to obtain unknown force constants, and torsional and electrostatic parameters for MM2. This would produce a "Scaled Quantum Mechanical Force Field" (48). At the time we decided to pursue this idea, CHARMM (49), AMBER (50), and MACROMODEL (51) had not yet appeared in the literature, and Allinger's peptide parameters had not yet been published (52).

Eventually we greatly expanded the dimensions of MM2 (53), and determined and tested MM2 parameters for peptides (53), penicillins (54), and cephalosporins (55), as well as the new structures described later. For small molecules, a rather complete conformational analysis is feasible, using the dihedral driver of MM2, but this strategy is impractical for a peptide. The conceptual breakthrough was made by Stephen Bruder and Kiyull Yang, who devised a random number strategy that screens hundreds of thousands of torsional isomers, using ECEPP, minimizes several hundred low-energy structures of this set, and then automatically converts these to the MM2 format for final minimization of all bond lengths, bond angles, and dihedral angles (56).

All of the results that will now be described have been obtained using the bulk dielectric constant to treat the solvent. Most workers, including Professor Lemieux (57), regard this as an unacceptable assumption. However, our decision to proceed in this manner, at least for the present, was based on the data seen in Table 3, which refer to the solvent dependence of the conformations of the alanyl dipeptide, and are in agreement with experiment.

Figure 9 shows *A*, the crystal structure of penicillin G, after minimization with a dielectric constant of 78.5, and also a conformation (*B*) calculated to be 3 kcal/mol lower in energy than the crystal structure. Also shown are *C*, the calculated conformations of *N*-methylpenicillin G, *D*, the ampicillin epimer having the D (more active) and *E*, the epimer having the L (less active) configuration in the side chain (58). The most significant difference between *A* and *B* is the orientation of the amide bond of the side chain: in the optimized structure the N-H moves to the convex face, and the C=O to the concave face of the molecule.

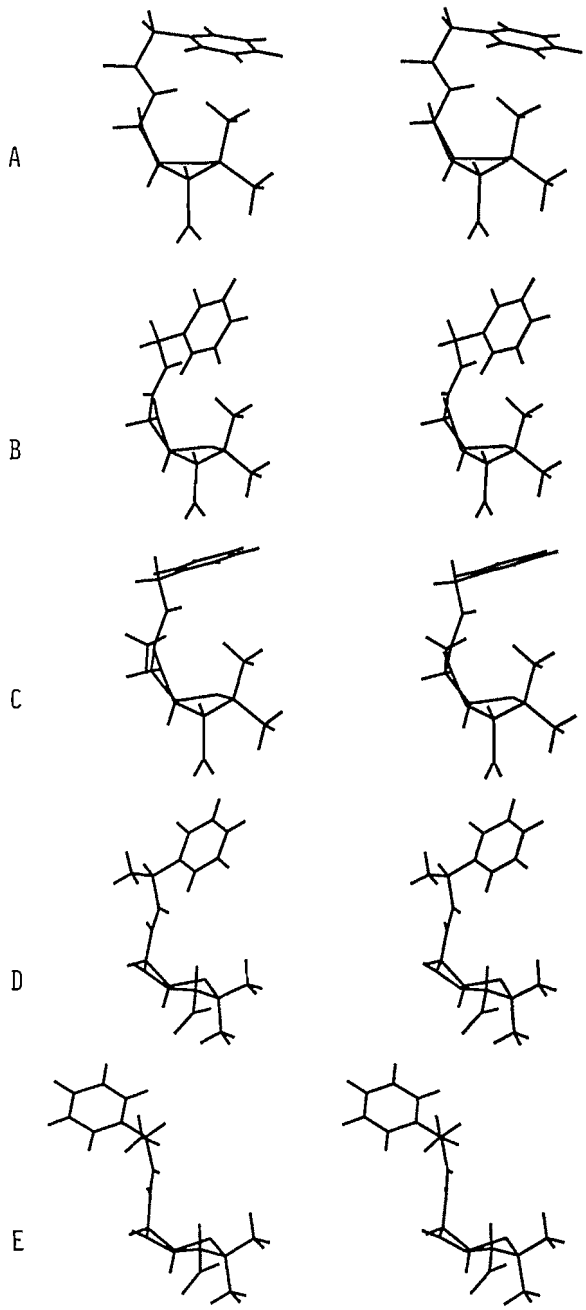

FIG. 9. Stereoscopic views along the N4—C5 bond. FIG. 10. A computer-generated model of the active site of a penicillin-binding protein having the sequence val-gly-ser-val-thr-lys. The model shows close contact, on the concave face, between the serine hydroxyl, the lysine amino, and an end group (shaded).

tational observation was that, in *N*-methylpenicillin G (*C*), the methyl group occupies the same position as the N-H of penicillin G; but the latter is an active compound, and *N*-methylpenicillins are inactive as antibacterial agents (17). Eventually we concluded that the convex face of penicillin must be binding to its receptor, and that the carboxyl group and the amide N-H are engaged in primary binding to this receptor.

To obtain a model of a penicillin receptor, we selected the sequence around the active site of *Streptomyces* R61, i.e., Ac-Val-Gly-Ser-Val-Thr-Lys-NHMe, for examination by the Bruder–Yang strategy (56).We assumed that we were seeking a low-energy conformation in which the terminal amino group of lysine is 6–8 Å from the serine hydroxyl oxygen. Following a preliminary search of 200 000 structures and examination of 50 low-energy structures we found the conformation shown in Fig. 10. The serine oxygen – lysine nitrogen distance in this structure is 8.5 Å. These reactive sites are on the concave face of the structure, which also includes an amide carbonyl group. It now seemed reasonable to try to form a supermolecule in which the amide N-H of penicillin G was hydrogen-bonded to the amide C=O of the receptor model, and the carboxyl group of the antibiotic was hydrogen-bonded to the terminal amino group of the lysine residue. Kiyull Yang wrote a computer programme that creates a supermolecule by specification of two intermolecular hydrogen bonds, minimizes the energy of this supermolecule

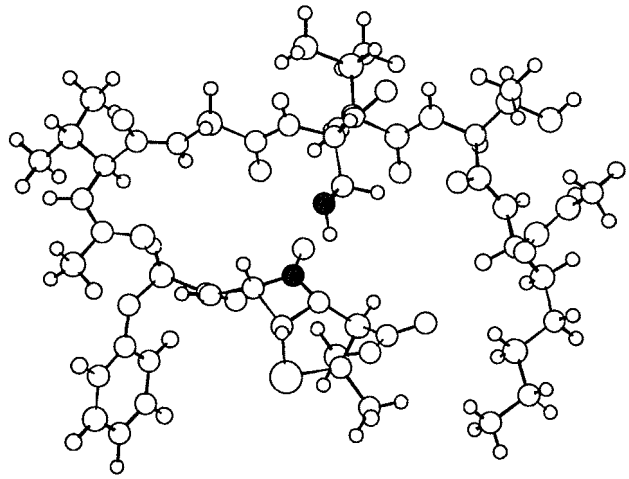

FIG. 11. Docking of penicillin V to the active site model of Fig. 10. Formation of hydrogen bonds between CO_2^- and NH_3^+, and between amide N-H and valine C=O, results in close contact between the serine hydroxyl group of the receptor and the convex face of the β-lactam ring of the antibiotic. The serine oxygen and β-lactam carbonyl carbon are shaded.

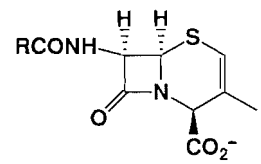
and the two hydrogen-bonding distances, and creates the input file for a full MM2 minimization (58).

In the case of the global minimum of penicillin G, this procedure led to the structure shown in Fig. 11, in which the serine oxygen is positioned on the convex face of penicillin, 3.8 Å from the carbon atom to which it will become bonded. Significantly, the higher energy crystal conformation of penicillin G produces a lower energy complex (Fig. 12), in which the serine hydroxyl group is also on the convex face of the molecule, and again positioned over the β-lactam ring. We believe that, had only the crystal structure been available to us, we would have expected the amide N-H to be buried in the interior of the molecule, and would not have examined its participation in the complexation.

Figure 13 shows **7**, **8**, and **16**, the 4-epi isomer of **8**, docked to the model of the penicillin receptor (55). In each case we observe the same kind of relationship between the serine hydroxyl group and the convex face of the antibiotic.



16

When we published the structures of some of these computer-generated complexes in 1988 (58), there was already in the literature a 1983 structure (Fig. 14), based on the experimental crystal structure of the *Streptomyces* R61 enzyme (59). In this 1983 structure, the serine hydroxyl group is clearly seen to be positioned on the *concave face* of the bicyclic system. Subsequently, however, Kelly and Knox (60) proposed a rather different structure for the cephalosporin complex (Fig. 15). A close relationship between the carboxyl group of the antibiotic and the terminal amino group of the lysine residue of the Ser-X-X-Lys tetrad can now be seen and, significantly, the hydroxyl oxygen of the active site serine *occupies the convex face of the molecule*, as in all of our theoretical structures.

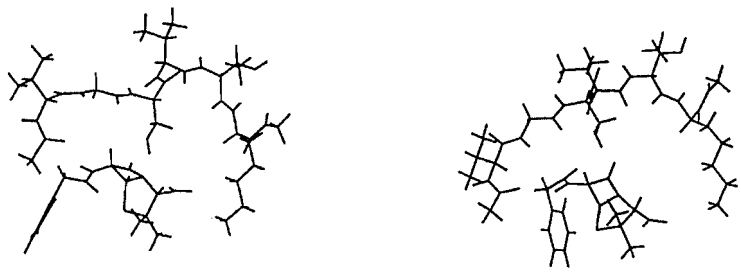


FIG. 12. Docking of the crystal structure of penicillin G and also of the minimized structure of penicillin G to the active site model of Fig. 10, using the protocol of Fig. 11. The higher energy crystal structure forms a lower energy complex.

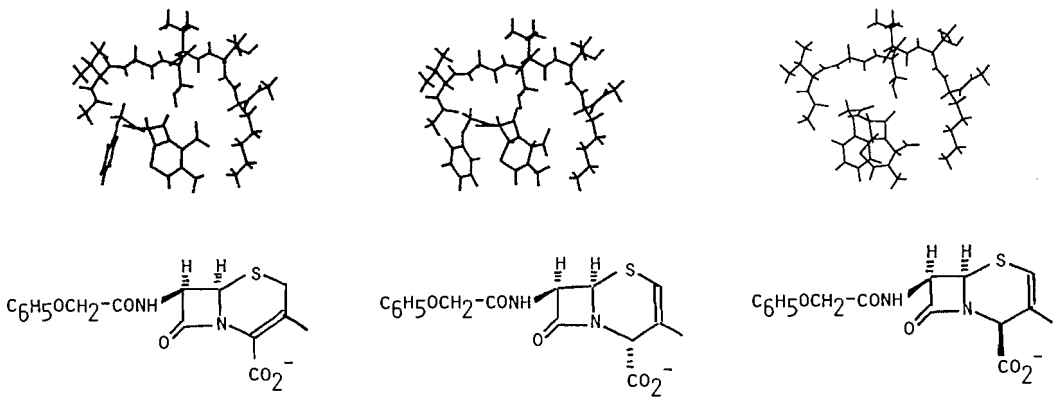

FIG. 13. Docking of the cephems **7**, **8**, and **16** to the active-site model of Fig. 10, as in Fig. 11, showing the similar relationship in each case between the serine hydroxyl group of the receptor and the convex face of the antibiotic.

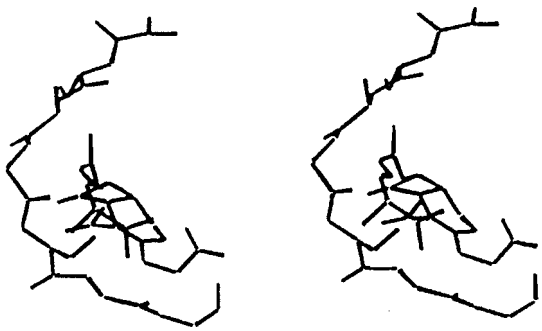

FIG. 14. A 1983 proposal, based on an experimental crystal structure, showing the hydroxyl group of serine attacking the concave face of a cephalosporin (from ref. 59).

Neutral alcoholysis of β-lactam compounds: the role of water

How is the C-O-H group acylated by the N-C=O moiety of a β-lactam ring when these are oriented with respect to each other as depicted in Fig. 16? Although the O..C=O angle is correct (61), the geometry of Fig. 16 is not consistent with a mechanism involving an initial addition to the carbonyl group to form a tetrahedral intermediate; such a mechanism would require attack by O-C from the direction *anti* to C=O, and not *syn* as seen in the figure. In fact, the acylation mechanism suggested by Fig. 16 is an unprecedented one, in which C—O and N—H bond formation are concerted with the cleavage of the β-lactam bond.

It is known, from the work of Michael Page (62), that the chemical hydrolysis of penicillin G exhibits the pH dependence shown in Fig. 17. In the acid region, there is rate-determining protonation of the β-lactam nitrogen, from the convex face of the molecule; in the alkaline region, nucleophilic addition of HO^- to the carbonyl group is rate determining. There are no experimental data for the biologically relevant region pH 6–8, and, with Fig. 16 in mind, we decided to search for a neutral mechanism in which the two reactions merge.

Figure 18 shows transition structures, fully optimized by ab initio calculations at the 3-21G level (63), for the reaction of methanol with *N*-methylazetidinone via the unprecedented pathway involving *N*-protonation, and also via an *O*-protonated pathway, which leads to the tetrahedral intermediate. Each of these structures possesses one and only one imaginary frequency, and represents a genuine transition state. An *N*-protonated process therefore exists, at least at this computational level. More importantly, on the basis of one-point calculations at the correlated MP2/6-31G* level, the *N*-protonated transition structure is 7.84 kcal/mol lower in energy than its *O*-protonated isomer!

Figure 19 shows the fully optimized 3-21G* transition structures for the reaction of the bicyclic penam (thiazolidine-β-lactam) nucleus with methanol via the *N*-protonated pathway, an *O*-protonated pathway from the convex face, and

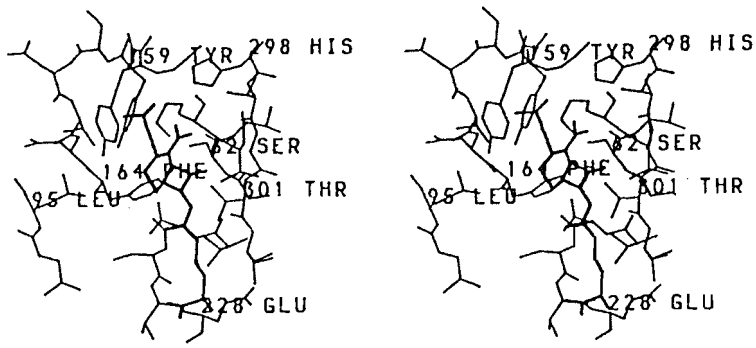

FIG. 15. A 1989 proposal, based on the same crystal structure as Fig. 14, but now showing the hydroxyl group of serine attacking the convex face of a cephalosporin (from ref. 60).

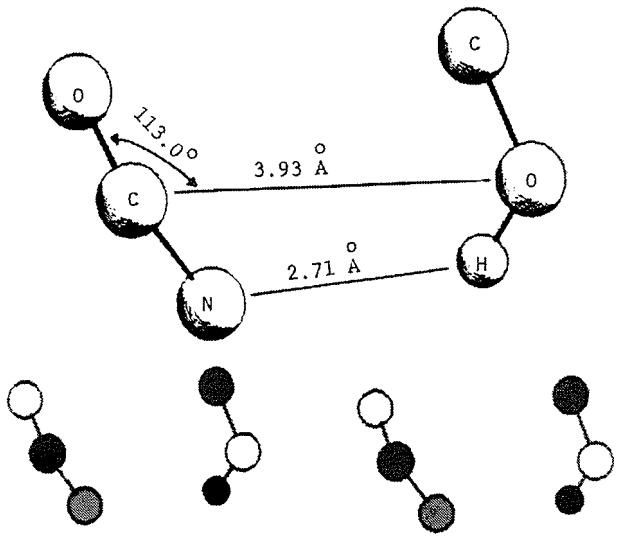

FIG. 16. A closeup view of the relationship between the serine C-O-H and β-lactam N–C=O in the calculated complex between penicillin G and the receptor model of Fig. 10 (from ref. 58).

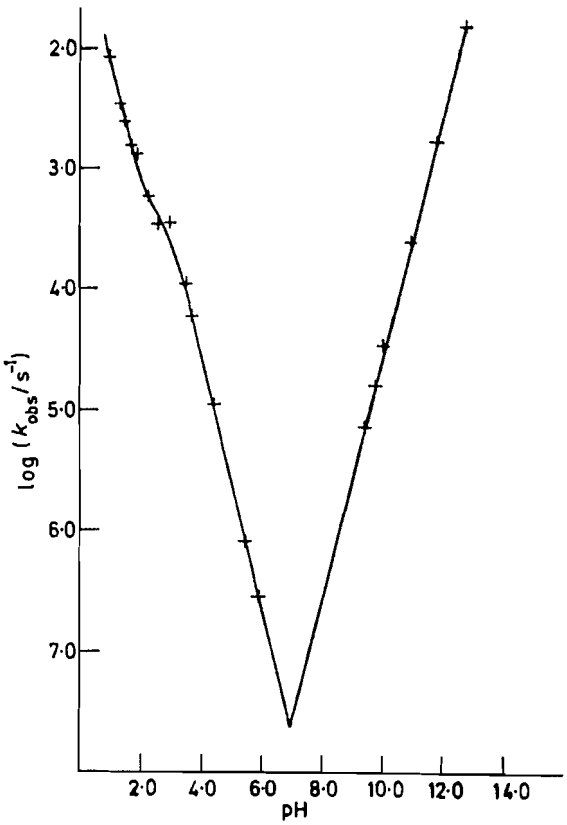

FIG. 17. pH dependence of the chemical hydrolysis of penicillin G (from ref. 62).

an *O*-protonated pathway from the concave face (63). Again, on the basis of the one-point MP2/6-31G* energies, the *N*-protonated pathway is preferred over either *O*-protonated pathway by almost 8 kcal/mol; in the *O*-protonated pathway, attack from the convex face is 2 kcal/mol lower in energy than attack from the concave face. The different orientations of the methyl group in the *O*-protonated and *N*-protonated mechanisms should also be noted.

It would be proper to object at this stage that these computational results are irrelevant, because they refer to the gas phase, in which the four-centred processes seen in Figs. 18 and 19 are enforced by the absence of water. However, the chemical reactions of β-lactam compounds with penicillin-recognizing enzymes also take place in an environment that is almost solvent free. Although the water content at the active site of the PBP is not known to us, as noted earlier β-lactamases contain at least one water molecule in this region. Accordingly, we decided to examine the effect of one water molecule on the different reactions of methanol with β-lactam compounds.

Figure 20 shows 3-21G transition structures for the reaction of methanol with *N*-methylazetidinone, with the addition of one water molecule (63). The significant results are that the *N*-protonated pathway is preferred by over 9 kcal/mol, and that the water molecule has a substantial catalytic effect on both reactions, over 10 kcal/mol.

These are very difficult structures to determine at this computational level, and we believed that it was not feasible to go further. However, for reasons that will soon be clear, it became necessary to examine the catalytic effect of water on the reaction of methanol with a C3-carboxypenam (63). The structures shown in Fig. 21 required more than 6 months to find, and are fully optimized at 3-21G*. The *N*-protonated pathway proceeds via a termolecular complex, which precedes the transition state along the reaction coordinate. The transition structure resembles the one for *N*-methylazetidinone.

We were surprised to find that the C···O distance in the termolecular complex is 3.8 Å, the same as in the molecular mechanics structures seen earlier. Accordingly, Dr. Yang modified the molecular mechanics docking programme to allow a water molecule to be included at the active site. In the case of penicillin V, this led to the structure shown in Fig. 22 which, in truncated form, is shown, together with the ab initio structure,

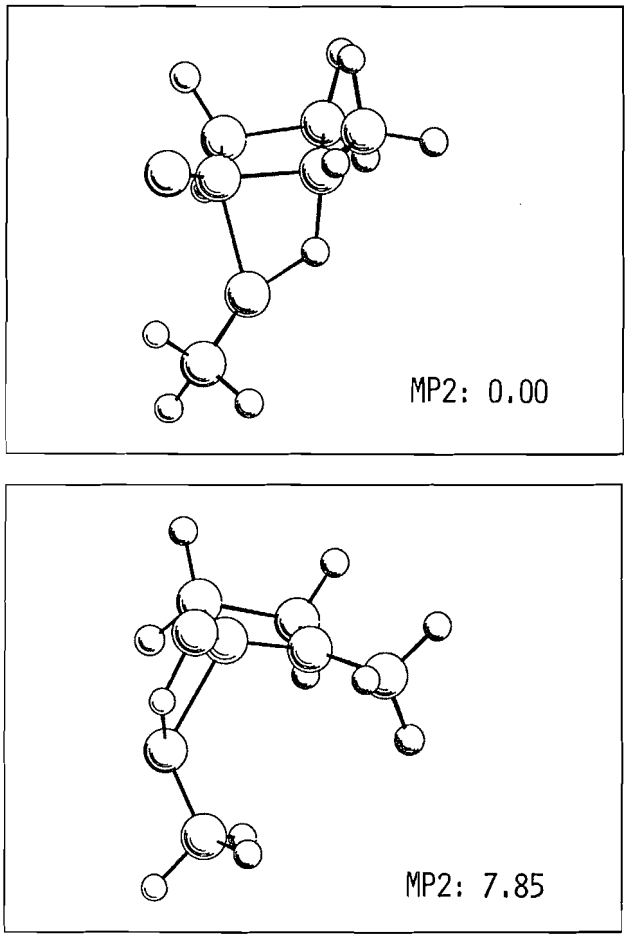

FIG. 18. Transition structures for the reaction of methanol with *N*-methylazetidinone via *N*-protonated (top) and *O*-protonated pathways (bottom). The structures are optimized at 3-21G; the relative energies are obtained at MP2/6-31G*//3-21G.

in Fig. 23. The two structures are obtained in entirely different ways, and we believe Fig. 23 suggests that the function of the enzyme is to orient the reacting molecules on the proper reaction coordinate for the most favourable chemical reaction. We also believe that this conclusion is consistent with the views expressed earlier (11).

Combining "fit" with "reactivity." Semiempirical calculations

We now wish to understand how differences in the fit to, and reactivity with, a penicillin-binding protein produces differences in antibacterial activity. We propose to compare the fits using the root-mean-square differences in the positions of the N-C=O and C-O-H atoms of different complexes, relative to their positions in a standard substrate. Reactivities could be compared if activation energies for the neutral alcoholysis of the β-lactam ring could be computed as a function of extensive structural variation of the system.

Ab initio calculations would not be practical in the latter case. Semiempirical computations would be feasible, but the results would have to be compatible with the three ab initio benchmarks determined above, viz., (*i*), in four-centred reactions of methanol with the β-lactam ring system, the *N*-protonated pathway is preferred over the *O*-protonated pathway; (ii) *O*-protonated attack from the convex face of a bicyclic system is

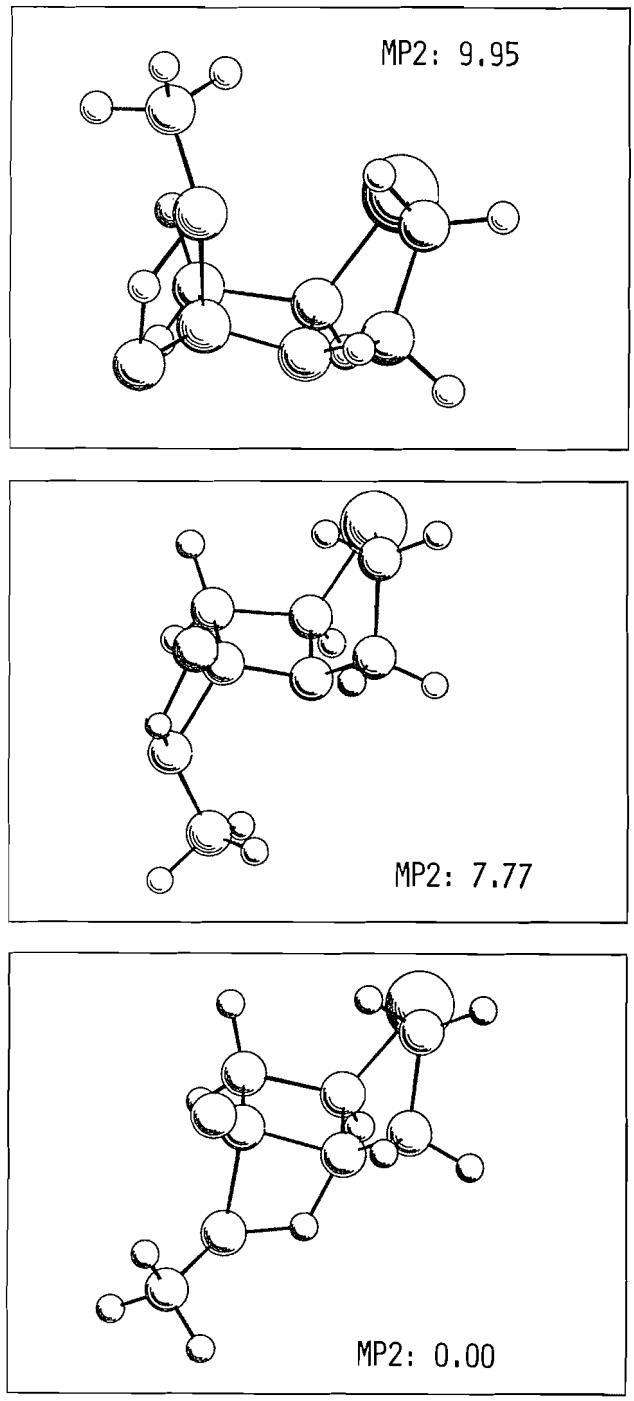

FIG. 19. Transition structures for the reaction of methanol with the penam ring system via *N*-protonated (bottom), *exo*-*O*-protonated (centre), and *endo*-*O*-protonated pathways (top). The structures are optimized at 3-21G*; the relative energies are obtained at MP2/6-31G*// 3-21G*.

preferred over attack from the concave face; (*iii*) in reactions that include water, the water has a catalytic effect.

As shown in Table 4 (55), of the several semiempirical possibilities, namely, AM1, MNDO, MNDO/M, PM3, and MINDO/3, only MINDO/3 reproduces the ab initio trends for the four-centred reactions. Accordingly, MINDO/3 was used for a systematic study of structure–reactivity relationships. Each line of Fig. 24 compares the relative reactivities of a series of related structures, expressed as $\Delta\Delta E^{\ddagger}$, to the parent penam

TABLE 4. Relative energies of four-centred transition structures for the reaction of methanol with a fused β-lactam-thiazolidine (kcal/mol)

Reaction	MP2/6-31G*//3-21G*	MINDO/3	MNDO	AM1	MNDO/M	PM3
N-attack	0.00	0.00	7.38	10.84	10.39	11.19
O-attack (convex)	7.77	4.80	0.00	0.00	0.00	0.00
O-attack (concave)	9.95	5.54	6.62	5.19	6.43	3.90

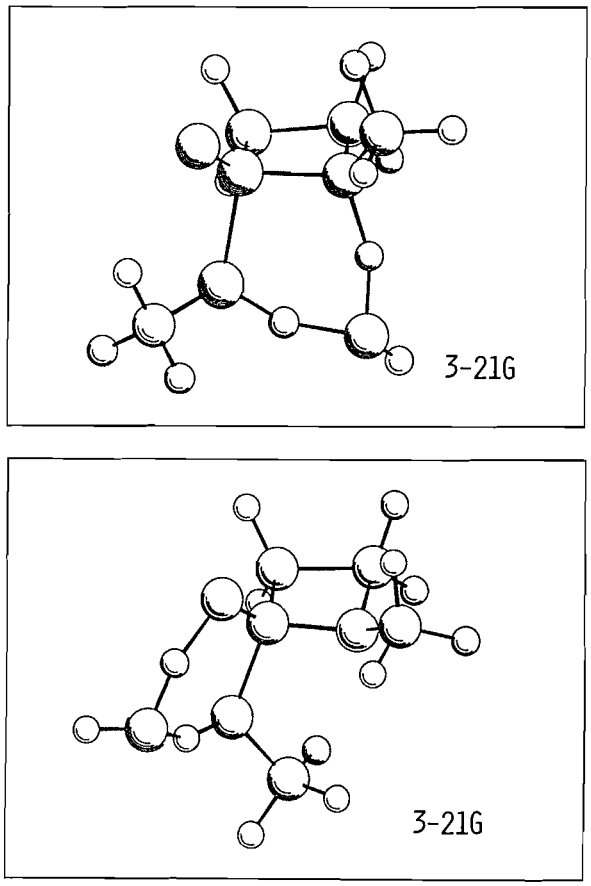

FIG. 20. Effect of water on the reaction of methanol with *N*-methylazetidinone by the *N*-protonated (top) and *O*-protonated pathways (bottom). The catalytic effect of the water molecule is 10 kcal/mol.

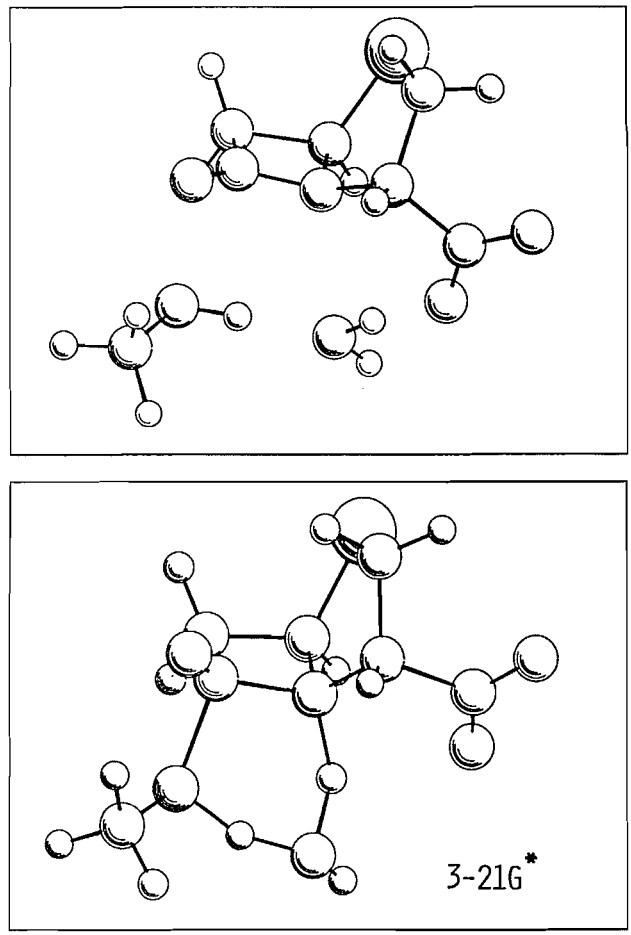

FIG. 21. Reactant complex and transition structure computed at 3-21G* for the attack of methanol upon 3α-carboxypenam, with catalysis by one water molecule.

ring system. Line 3 suggests that the attachment of a carboxyl group on the convex face, corresponding to the natural penicillin configuration, increases the reactivity, but the epimer is less reactive. Line 2 suggests that the Δ^3-cephem nucleus is inherently less reactive than the penicillin nucleus; isomerization of the double bond decreases the reactivity further. Attachment of the methyl groups decreases the reactivity, unless an α-carboxyl group is also present (line 4). The reactivities of the nucleus alone and of a fully functionalized penicillin are almost the same (line 5).

Turning to the effect of water, we found that only AM1 correctly predicts catalysis. All other semiempirical procedures predict inhibition. Accordingly, using AM1, we began to extend the data of Fig. 24 to include the effect of water (Fig. 25). The trends in lines 1 and 2 of Fig. 24 and 25 are the same. However, with the carboxypenams (line 3), the AM1 mechanism changes.[4]

Proceeding from the separated reactants, there are now two intermediates, two transition structures, and the hydrolyzed product. The first intermediate is the termolecular complex (Fig. 26). Although, superficially, the AM1 and ab initio complexes seem to resemble one another, they differ in an important way, because of a known artifact of AM1: with AM1, water molecules incorrectly tend to form bifurcated hydrogen bonds (64). Because of the bifurcated water–carboxylate geometry in the AM1 complex, what ensues resembles a proton shuttle triggered by the carboxylate anion (Fig. 27). One proton moves

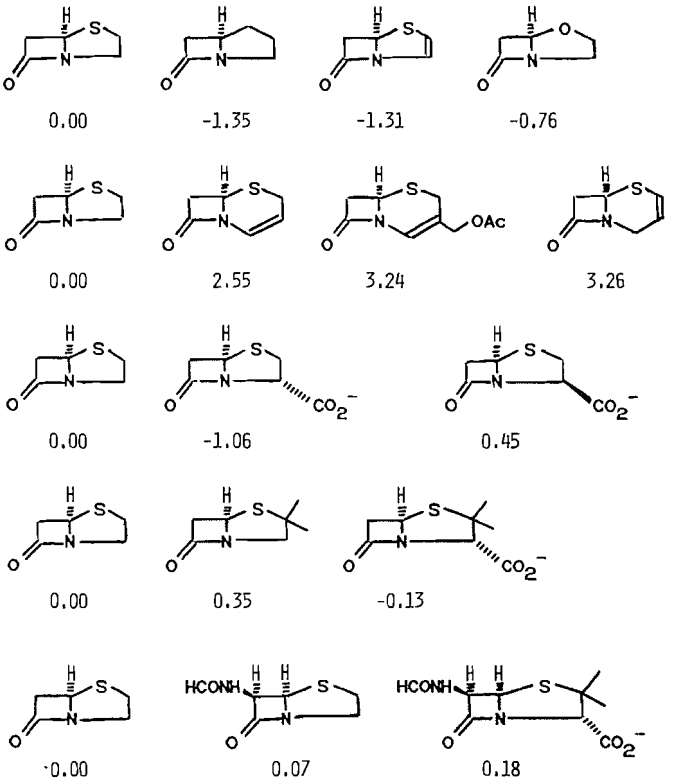

FIG. 24. Calculated MINDO/3 activation energies, relative to the penam skeleton, for the reaction of methanol with various β-lactam compounds via an *N*-protonated pathway.

TABLE 5. Calculated fits[a] and reactivities[b] relative to penicillin V (**4***a*) for the interaction of Δ^3-cephem V (**7**), 4α-Δ^2-cephem V (**8**), and 4α-Δ^2-cephem V (**16**) with the penicillin receptor model (Fig. 10)

Compound	$\Delta\Delta E^{\ddagger}$ (kcal/mol)	RMS (Å)
4*a*	0.00	0.000
7	2.81	0.103
8	1.94	0.684
16	4.65	0.252

[a]Refers to the root-mean-square deviation of the coordinates of the serine C-O-H and the β-lactam N—C=O in the complexes, from those of penicillin V.
[b]Refers to MINDO/3 calculations of the reactions of methanol with 3α-carboxypenam in the case of **4***a*, Δ^3-cephem-4-carboxylate in the case of **7**, 4α-Δ^2-cephemcarboxylate in the case of **8** and 4β-Δ^2-cephemcarboxylate in the case of **16**.

from water to the carboxylate anion, a second proton moves from methanol to water, and the methoxide ion adds to the carbonyl group to form a tetrahedral intermediate; the formation of this intermediate is rate determining. In the product-determining step, a proton is transferred from the carboxyl group to nitrogen, and a new bifurcated hydrogen bond is created.

Although the mechanism depicted in Fig. 27 seems interesting, the ab initio calculations described earlier show that a multistep mechanism does not occur. These findings reemphasize that semiempirical calculations on complex chemical processes must be interpreted with caution.

Table 5 summarizes the "fits" and "reactivities" exhibited by a Δ^3-cephem, a 4α-Δ^2-cephem, and a 4β-Δ^2-cephem, each carrying the penicillin V side chain, compared to penicillin V itself (55). The reactivities are based on MINDO/3 calculations of the four-centred processes.

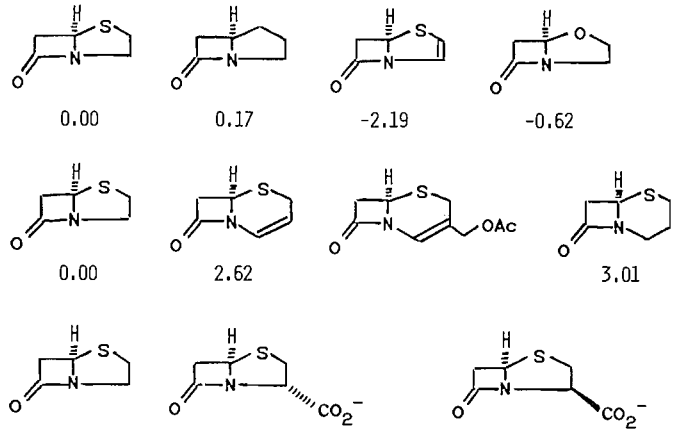

FIG. 25. Calculated AM1 activation energies, relative to the penam skeleton, for the reaction of methanol with various β-lactam compounds via an *N*-protonated pathway, with catalysis by one water molecule.

As mentioned earlier, the Δ^3-cephem is 50 times less active, and the 4α-Δ^2-cephem, which equilibrates with the Δ^3-cephem in solution, is 5000 times less active that the penicillin.The 4β epimer had been predicted by Noal Cohen to be active (65), but a compound of this type proved to be inactive when synthesized at Ciba–Geigy (66). According to Table 5, the Δ^3-cephem has a slightly different fit than the penicillin, and it is inherently less reactive. With a carboxyl group on the convex face of the molecule, the 4α-Δ^2-cephem is more reactive than the Δ^3-cephem, but it has a significantly poorer fit. In the 4β epimer, the fit is greatly improved, at the expense of an inherent decrease in reactivity.

Targeting the penicillin receptor

We believed that this kind of analysis provided, for the first time, sufficient insight into what is happening at the penicillin receptor to allow the design of new kinds of compounds having structures and reactivities targeted to this receptor. As depicted in Fig. 28, the target should have functional groups able to hydrogen-bond to the amino and carbonyl groups of the receptor model. Positioned between these two groups, and oriented properly in relation to them, the target structure should contain a functional group that will fit to the hydroxyl group of serine, and exhibit a four-centred relationship with this group.

On the basis of MINDO/3 calculations of four-centred methanolysis mechanisms, cyclic imines appeared to be significantly more reactive than β-lactams, and their reactivity could be varied by variation of the size of the ring and the nature of any additional substituents (67). Accordingly, we wished to synthesize a molecule possessing a cyclic C=N group, to react with the hydroxyl group of serine, a carboxyl group able to complex to the amino group of lysine, and a hydroxyl group positioned to hydrogen-bond to the carbonyl oxygen of the receptor model. Since the distances between these groups, and also the dihedral angles about the bonds separating them, were known from, eg. Fig. 11–13, potential candidates could be screened initially by inspection of molecular models. For promising structures, MM2 parameters were determined, and the compounds were calculated and docked to the model of the penicillin receptor.

The strategy led to **17** as a candidate for synthesis (67). However, model experiments soon revealed that **18** could, in principle, adopt any of three tautomeric structures: the imine **18***a*; the endocyclic enamine **18c**; or the exocyclic enamine **18***b*.Only enamine **18***c* could be detected by nmr in all solvents examined. Therefore it was necessary to block the formation of this tautomer. When this was accomplished by the introduction of methyl groups at C2, two tautomeric structures (e.g., **19***a* and **19b**) remained possible. Although the position of equilibrium between **19***a* and **19***b* was solvent dependent, the side chain of **19***b* is seen to be a masked aldehyde and, when **19***a* was generated from its silylated derivative, the compound proved to be highly unstable.

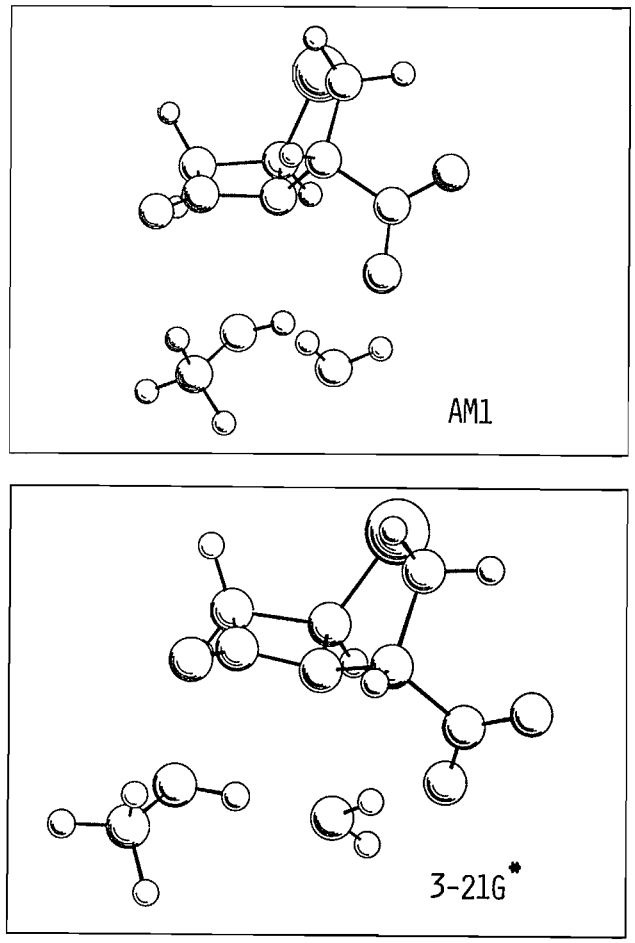

FIG. 26. Primary complex for the reaction of methanol with 3α-carboxypenam, catalyzed by one water molecule, as calculated by AM1 (top) and ab initio 3-21G* (bottom). The AM1 structure has bifurcated hydrogen bonds between the water molecule and a carboxylate oxygen.

Accordingly it became necessary to move the hydroxyl group one position further away from the nucleus. The resulting structure (**20**), for which Fig. 29 represents one conformation of the 3*S*, 8*R* isomer complexed to the model of the penicillin receptor, seemed to exhibit an acceptable fit.

The first synthesis of **20** began with the homoallylic alcohol **21** and D-serine. The alcohol was converted to the mercaptoketone **22** by successive silylation, permanganate oxidation, mesylation, and sulfuration. The amino acid was converted to the D-β-lactone **23** by the method of Vederas and co-workers (68). Condensation of **22**, as its lithium salt, with **23**, followed by deprotection with formic acid, then yielded 3*S*-**20** as a mixture of epimers at C8. As seen in Figs. 1 and 2, this material exhibited antibacterial activity versus *S. aureus* comparable to that of the Δ^2-cephem **8.**

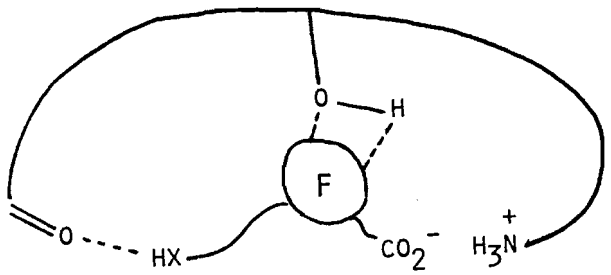

FIG. 28. Requirements for the design of a compound targeted to the penicillin receptor (see text).

Significantly, when the synthesis was repeated starting with L-serine, to yield 3*R*-**20** as a mixture of epimers at C8, this material was found to be inactive at the concentration employed in Fig. 2. This suggests that the activity observed in the 3*S* series is probably not the result of a generalized bactericidal effect of structure **20**, but, rather, is associated with a more specific "fit" to a receptor by the isomers having the 3*S* configuration

In subsequent work (69), sterospecific syntheses of the four stereoisomers of **20** were devised, and the activity of the 3*S* series and lack of activity in the 3*R* series were confirmed. The side-chain epimers were found to have comparable activity.

Although the activities of these first examples of designed antibacterial agents were low, we were encouraged by the fact that the activities of Δ^2-cephems are also low, but only one structural change is needed to convert the latter into the clinically important Δ^3-cephems. Therefore, the syntheses of 3*S*-**20** were scaled up to provide sufficient material for more detailed microbiological and toxicological studies. However, we now found that we could not crystallize the compounds. During these crystallization attempts, the nmr spectra became progressively more complex, *but the antibacterial activity remained.*

This situation was clarified by HPLC, which revealed that the degraded material consists of at least five components, each of which is active, and rapidly reequilibrates with the others. The major component was found to have structure **20** (67).

These complications led us to consider the general structure **24**, which can be regarded as a variant of **20** in which the labile aldol side chain is replaced by an aromatic ring or, as an alternative, a structure such as **25**. The latter compounds are accessible in one step, reaction of an aryl nitrile with cysteine (70), and Fig. 30 suggests that an ortho hydroxyl group would provide an acceptable fit to the receptor model. In Fig. 30, which refers to the L isomer of 2-(*o*-hydroxyphenyl)-thiazoline-4-carboxylic acid, the attack of the serine can be seen to be *syn* to the carboxyl group, as in penicillins and cephalosporins. In the case of the D isomer (not shown), the serine attack is *anti* to the carboxyl group. We found thiazolines having the general structure **25** to be stable for several days in water solvent, and antibacterial activity was observed with both enantiomers. The activity of the D isomer was comparable to that of 3*S*-**20**, but the L isomer appeared to be significantly more active.

We do not yet know the mechanisms of action of **20** and **25**, and will have to be prepared for the possibility that the reasoning which led to the syntheses of these compounds is flawed. However, the hypothesis depicted in Fig. 5 was also flawed, but this led to sulfur-free penicillins, and resulted in the discovery of the oxacephems. If, with the aid of the current theoretical model, we discovered (or rediscovered (71)) a useful lead structure, the model will have served its purpose. Thus, after our theoretical and experimental work on the isomers of **25** was complete, we learned that the L isomer is a known compound, dihydroeruginoic acid, which has been patented as a medicinal agent against Gram positive fungi, moulds, and newcastle disease virus (71).

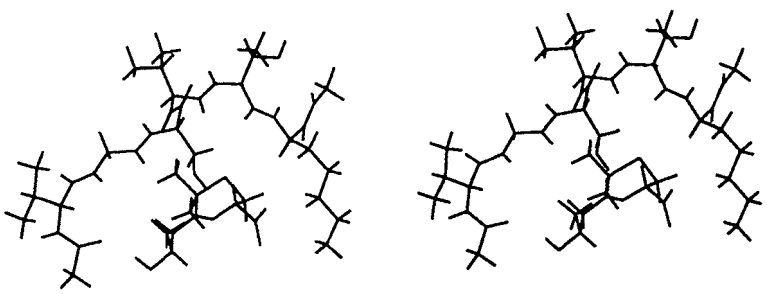

FIG. 29. Stereoscopic view of **20** complexed to the receptor model. The hydroxyl group of serine is positioned over the C=N of **20**.

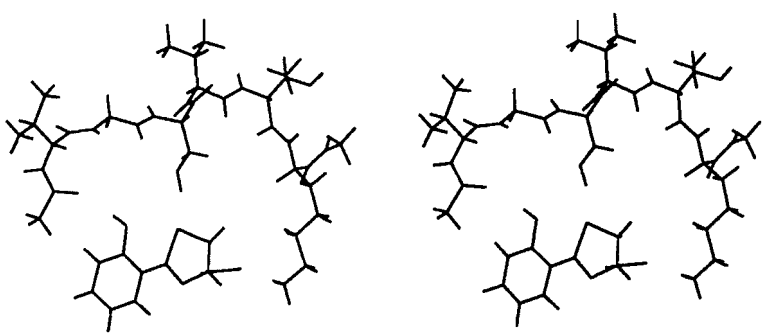

FIG. 30. Stereoscopic view of L-**25** complexed to the receptor model, which suggests that an *ortho* hydroxyl group in the aromatic ring provides an acceptable fit.

Acknowledgments

The work reported here has been funded at various times by Bristol Laboratories, National Research Council (NRC) and Natural Sciences and Engineering Research Council (NSERC) Operating and Equipment Grants, the Atkinson Foundation of Toronto, the Killam Foundation, Robert Bender, Queen's University, and Simon Fraser University.

I sincerely thank all of the colleagues and co-workers, named in the text and in the references, who contributed to the development of these ideas during a period of 33 years.

I thank Bob McIntosh, Don Heyding, Duncan Sinclair, and the staff of the Office of Research Services at Queen's University for their many years of friendship and support.

I am particularly indebted to Cam Oehlschlager. In 1990 he persuaded his colleagues in the Chemistry Department and the senior administrators of Simon Fraser University that I was still capable of useful research. He then built for me a beautiful office and laboratory, provided me with a computer 30 times more powerful than the one I had been using, and placed me among an exciting and dedicated group of young organic, inorganic, polymer, and biochemistry faculty, with whom I have been able to interact extensively. Much of the recent work I have described was carried out in the intensive research environment that can now be found at SFU.

The docking of penicillins to a computer model of the active site of the penicillin-binding protein of *Streptomyces* R61 produces structures that exhibit a four-centred interaction between the O-H of a serine residue and the (O)C-N of the β-lactam ring. If such a structure is a stationary point on the reaction coordinate for the acylation of the serine OH by the β-lactam carbonyl group, the acylation mechanism would appear to consist of O—C and H—N bond formation, concerted with the cleavage of the C—N bond. The existence of this "N-protonation" mechanism, and the energetics of this mechanism in comparison to the usual "O-protonation" pathway in which proton transfer to oxygen and addition to the carbonyl group *precede* C—N bond fission, have been examined by ab initio MO calculations on the neutral hydrolysis and methanolysis of *N*-methylazetidinone, penam, and penam-3α-carboxylate. The geometries of reactants and transition structures have been optimized fully at the 3-21G or 3-21G* levels, the existence of transition structures has been confirmed by vibrational analysis, thermochemical data have been computed, and the one-point energies of all structures have been determined at the MP2/6-31G* level. The N-protonation mechanism is found to exist with all substrates, and to be preferred over the O-protonation mechanism by over 5 kcal/mol. The activation energies are 5 kcal/mol lower in the bicyclic penam than in the monocyclic *N*-methylazetidinone, and attack from the convex face is preferred over attack from the concave face. The introduction of a 3α-carboxylate group, as in penicillin itself, results in an additional 5 kcal/mol decrease in activation energy. The origins of these trends are discussed. Since the active sites of some penicillin-recognizing enzymes contain at least one water molecule, catalysis of the foregoing reactions by one water molecule has also been examined. The catalysis amounts to over 10 kcal/mol in both the N- and O-protonation mechanisms, and the preference for the N-protonation mechanism is maintained. It is concluded that penicillin complexes to its receptor in such a manner as to allow acylation of the active site serine residue to proceed via the energetically most favourable mechanism.

SAUL WOLFE, CHAN-KYUNG KIM et KIYULL YANG. Can. J. Chem. **72**, 1033 (1994).

L'arrimage de pénicillines au modèle sur ordinateur du site actif de la protéine de liaison de la pénicilline du *Streptomyces* R61 fournit des structures qui présentent une interaction à quatre centres entre le O-H de la sérine et le (O)C-N du noyau β-lactame. Si une telle structure est un point stationnaire sur les coordonnées réactionnelles de l'acylation du OH de la sérine par le groupe carbonyle du β-lactame, il semblerait que le mécanisme d'acylation comporterait la formation de liaisons O—C et H—N concertée avec un clivage de la liaison C—N. L'existence de ce mécanisme de «N-protonation» et les énergies impliquées dans ce mécanisme, par comparaison avec la voie usuelle de «O-protonation» dans laquelle le transfert d'un proton à l'oxygène et l'addition sur le group carbonyles *précèdent* la fission de la liaison C—N, ont été étudiées par des calculs d'OM ab initio pour l'hydrolyse neutre et pour la méthanolyse de la *N*-méthylazétidinone, du péname et du péname-3α-carboxylate. On a pleinement optimisé les géométries de réactifs et des structures de transition aux niveaux 3-21G ou 3-21G*, on a confirmé l'existence de structures de transition par une analyse vibrationnelle, on a calculé les données thermochimiques et on a déterminé les énergies ponctuelles de toutes les structures au niveau MP2/6-31G*. On a trouvé que le mécanisme de N-protonation existe pour tous les substrats et qu'il est préféré au mécanisme par O-protonation par plus de 5 kcal/mol. Les énergies d'activation sont 5 kcal/mol plus faible dans le péname bicyclique que dans la N-méthylazétidinone monocyclique et que l'attaque par la face convexe est préférée à l'attaque par la face concave. L'introduction d'un groupe carboxylique en position 3α, comme il en existe un dans la pénicilline elle-même, réduit encore une fois l'énergie d'activation par un autre 5 kcal/mol. On discute des origines de ces tendances. Puisque les sites actifs de certains enzymes qui reconnaissent les pénicillines contiennent au moins une molécule d'eau, on a aussi examiné la catalyse par une molécule d'eau des réactions mentionnées plus haut. La catalyse par l'eau des mécanismes de N- et de O-protonation correspond à 10 kcal/mol et la préférence pour le mécanisme par N-protonation est maintenu. On en conclut que la pénicilline se complexe à son récepteur d'une façon telle que l'acylation du site actif de la sérine pourra se faire par le mécanisme énergétiquement le plus favorable.

[Traduit par la Rédaction]

Introduction

β-Lactam antibiotics function by covalent bonding to the active site serine residue of one or more of a group of enzymes termed penicillin-binding proteins (PBP's) (1). These enzymes serve to complete bacterial cell wall synthesis by a cross-linking of peptidoglycan chains, and they are essential to the cells (2).

The simplest kinetic description of the reaction between a PBP and a β-lactam antibiotic is given in eq. [1], where **1** is a generalized structure. Since the PBP is regenerated in the deacylation step, useful antibacterial activity is considered (3) to require $k_3/K \geq 1000\ M^{-1}\ s^{-1}$, and $k_4 \leq 1 \times 10^{-4}\ s^{-1}$.

Using the serine- and lysine-containing active site hexapeptide of a D-alanyl carboxypeptidase-transpeptidase of *Streptomyces* R61 (4) as a model of a PBP, and a test series of nine penicillins (**2**), ranging from the highly active penicillin G (R = $PhCH_2$, R′ = H) to the biologically inactive 6α-methylpenicillin G (R = $PhCH_2$, R′ = Me), we have studied the complexation step of eq. [1] (5). In each case, the assumptions that the lock and key

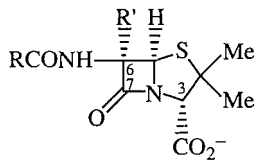
(6) interactions take place on the convex face of penicillin, and involve hydrogen bonding to the C3-carboxyl group and the side chain N-H, lead to a close contact in the complex between the hydroxyl oxygen of the serine and C7 of the penicillin (Fig. 1 (5)). The same relationship between the serine hydroxyl group and the β-lactam ring is seen in complexes formed from the experimental crystal structure of the *Streptomyces* R61 enzyme (7). The O—C7 distances and O—C7=O angles of Fig. 1 are appropriate for the attack of a nucleophile upon a carbonyl group (8), and variations in these parameters can be correlated qualitatively with variations in antibacterial activity.



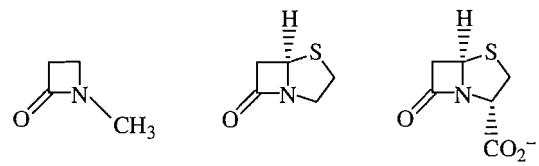
2

As a first step in the possible extension of these qualitative observations to more quantitative structure–activity predictions, we sought an understanding of the mechanism of the acylation step, and the nature of its transition structure. The PBP of *Streptomyces* R61 is an atypical serine peptidase, because a histidine residue does not appear to participate in the acyl transfer (9). This could mean that the hydroxyl hydrogen is involved directly in the reaction. For example, if the four-centred relationship between O-H of serine and C7-N of the β-lactam ring that is seen in Fig. 1 represents the geometry of a stationary point on a reaction coordinate, the indicated reaction should be C7—O bond formation and H → N proton transfer, concerted with the cleavage of the β-lactam bond. The existence of such a mechanism in the neutral hydrolysis of formamide has been discussed recently (10).

The geometry of Fig. 1 is reminiscent of that found in *gas phase* additions of alcohols to carbonyl groups (11), in which a cyclic process is enforced by the absence of solvent. There are significant differences, however: the process suggested by Fig. 1 involves proton transfer to *nitrogen*, not oxygen; also, the bond lengths of Fig. 1 (C—O = 3.6–4.4 Å; N—H = 2.7–4.3 Å (5)) are much longer than the C—O and O—H bond lengths (1.67–1.69 Å and 1.41–1.45 Å, respectively) in the four-centred transition states of the addition of alcohols to aldehydes (11*a*). As will be seen later, the longer bond lengths of Fig. 1 are compatible with the presence of a catalytic water molecule in the complex.

The hydrolysis and alcoholysis of β-lactam compounds have received much experimental (12) and theoretical (13) attention. In water solvent above pH 8, the rate-determining step in the hydrolysis of penicillin G is addition to the carbonyl group to form a tetrahedral intermediate; below pH 6, there is rate-determining proton transfer to the β-lactam nitrogen, from the convex face of the molecule (14). Hydrolysis is extremely slow in the (biologically relevant) pH range 6–8 (15), and the possible existence of a molecular mechanism in this region is not established. Likewise, all previous theoretical studies of β-lactam hydrolysis or alcoholysis have focused on anionic addition to the β-lactam carbonyl group.

Using ab initio molecular orbital (MO) theory, with full geometry optimization and vibrational characterization of all reactant and transition structures at the 3-21G or 3-21G* levels (16), followed by single point MP2/6-31G* calculations of the energies of these structures (17), we have now examined the neutral hydrolysis and methanolysis of monocyclic and bicyclic azetidinones. In the initial stage of the work the objectives were to determine whether ab initio MO theory supports the existence of four-centred transition structures in the reactions of *N*-methylazetidinone (**3**), penam (**4**), and penam-3α-carboxylate (**5**), and which four-centred structure (N-protonated, O-protonated, *exo*-attack, *endo*-attack) is energetically preferred.



3 4 5

These calculations describe gas phase reactions, and some authors (10*b*, 11*b*) suggest that this is a valid way to treat the hydrophobic environment at the active site of an enzyme. However, we have noted recently (18) that the magnitude of the secondary kinetic isotope effect in an enzymatic methyl transfer reaction is not compatible with the desolvation argument.

Although the crystal structure of the *Streptomyces* R61 PBP has been discussed extensively (4, 7), the water content of its active site is not known. This information is, however, available for two related penicillin-recognizing enzymes, β-lactamases from *S. aureus* (19) and from *B. licheniformis* (20). The two structures (P3BLM and P4BLM, respectively) were retrieved from the Brookhaven Protein Data Bank, and the number of water molecules in the vicinity of the active site Ser70 hydroxyl oxygen was determined. In the case of the *S. aureus* enzyme (P3BLM), there were 3 water molecules ca. 3 Å, 4 water molecules 4–5 Å, and 16 water molecules 5–10 Å from the serine hydroxyl oxygen. In the *B. licheniformis* structure, there were 2 water molecules ca. 2–3 Å, 2 water molecules 4–5 Å, and 12 water molecules 5–10 Å from the serine hydroxyl oxygen. The closest contacts in the two cases are shown in Fig. 2.

Accordingly, in the second stage of the work, the effect of one water molecule on the N- and O-protonated pathways was examined, using **3** and **5** as substrates.

Calculations were performed using GAUSSIAN 86 (21), GAUSSIAN 90 (22), or GAUSSIAN 92 (23). Thermochemical quantities ($\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta G^{\ddagger}$) were calculated by standard procedures (24), from the output of these programmes.

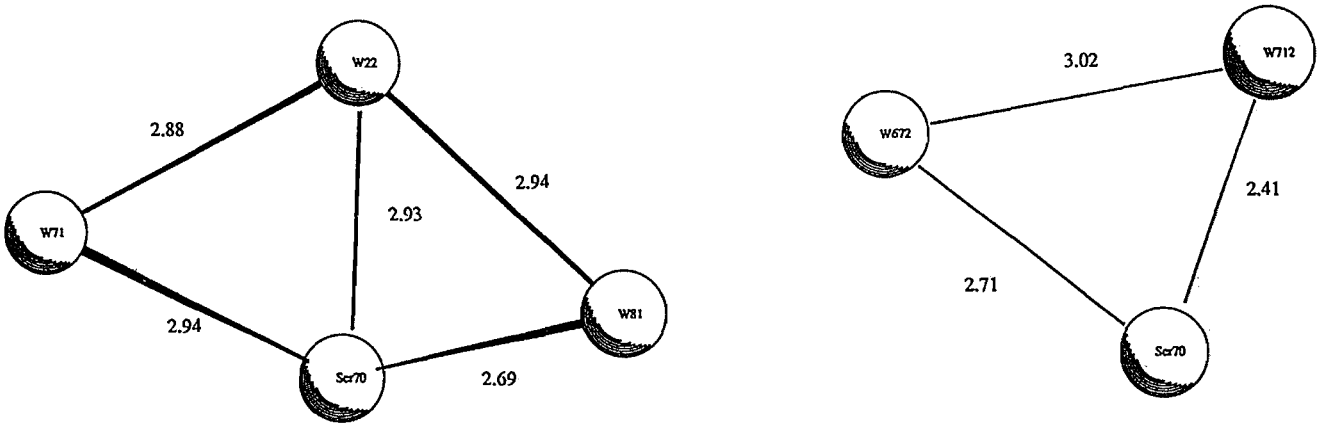
Inset: a closeup view of the relationship in the complex between the C-O-H of the serine residue of the peptide, and the N-C═O of the β-lactam ring.



S. aureus *B. licheniformis*

FIG. 2. Left: the γ oxygen atom of the active site serine residue in the crystal structure of a β-lactamase from *S. aureus*, and the positions of the oxygen atoms of the three closest water molecules. Right: the γ oxygen of the active site serine residue in the crystal structure of a β-lactamase from *B. licheniformis*, and the positions of the oxygen atoms of the two closest water molecules. Distances are in ångstroms.

6-31G*//3-21G (3-21G*) energies of **3**, **4**, **5**, H_2O, CH_3OH, the hydrogen-bonded complexes between **3**, **4**, **5** and water or methanol, and the N-protonated and O-protonated four-centred transition structures. Table 2 collects the energy differences calculated from these data.

With the monocyclic *N*-methylazetidinone **3** as the substrate, the N-protonation mechanism is favoured by at least 5 kcal mol^{-1} in the reaction with water, and also in the reaction with methanol. This preference does not depend on how the activation energy is expressed (electronic energy ($\Delta E^{\ddagger}$), enthalpy ($\Delta H^{\ddagger}$), or free energy ($\Delta G^{\ddagger}$)), or on how the activation energy is measured (from the separated reactants, or from the hydrogen-bonded complexes). The $\Delta E^{\ddagger}$ and $\Delta H^{\ddagger}$ are higher when calculated from the hydrogen-bonded complexes, because these are stabilized relative to the separated reactants. However, there is a compensating entropic effect, because the pre-association of reactants in these complexes significantly reduces the unfavorable entropies of activation of these cyclic

[c]Refers to attack of methanol from the convex face of the molecule.
[d]Refers to attack of methanol from the concave face of the molecule.

processes. Consequently the free energies of activation are virtually the same, whether these are based on the separated reactants, or on the complexes.

The preference for the N-protonation mechanism is maintained with the bicyclic compound **4** as the substrate but, compared to **3**, the activation energies of both mechanisms are lower by ca. 5 kcal/mol^{-1}. An additional 5 kcal/mol^{-1} reduction in activation energy is seen with **5**, which has the 3α-carboxylate group of penicillin. In the case of the O-protonation mechanism, attack from the convex face of **4** is preferred by at least 2 kcal/mol^{-1} over attack from the concave face. The energy differences just discussed are necessary benchmarks for the evaluation of any semiempirical molecular orbital treatment of these reactions (25).

Geometries

Figure 3 shows **3** and the N- and O-protonated transition structures for the reactions of **3** with water and with methanol.

Centre right: O-protonation transition structure for the hydrolysis of **3**. Lower left: N-protonation transition structure for the methanolysis of **3**. Lower right: O-protonation transition structure for the methanolysis of **3**.

Figure 4 shows **4** and the transition structures for the N- and O-protonated reactions of **4** with methanol. Figure 5 shows **5** and the transition structure for the N-protonation reaction **5** with methanol.[4] The imaginary frequencies of the various transition structures are included in Figs. 3–5.

There is no obvious relationship between the N—C and C═O β-lactam bond lengths and the relative reactivities of **3–5**. The N—C and C═O bond lengths calculated for the bicyclic **5** (1.377 and 1.205 Å, respectively) are very close to those found in penicillin crystal structures (1.380 and 1.210 Å, respectively (26)), and not very different from those calculated for the monocyclic **3**. In **4**, the N—C bond is longer (1.405 Å) and the C═O bond is shorter (1.195 Å).

A relationship between the planarity of a β-lactam nitrogen and the ease of hydrolysis of the ring was first discussed by

[4]Full details of the geometries of all structures calculated in this work are available as Supplementary Data, and may be purchased from the Depository of Unpublished Data, Documentary Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

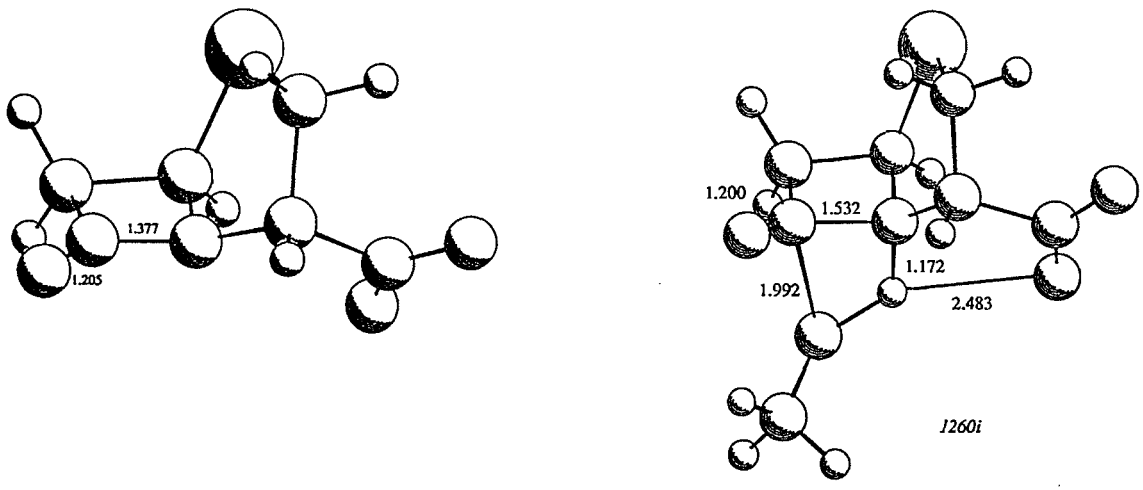

FIG. 5. Left: calculated structure of penam-3α-carboxylate (**5**). Right: N-protonation transition structure for the methanolysis of **5**.

Woodward (27). Subsequent workers sought relationships between the planarity at this centre, as measured by the sum of the angles at nitrogen, and the antibacterial activity of a β-lactam antibiotic (28). In **3–5**, the sum of the angles at the β-lactam nitrogen atoms are 360.0°, 336.1°, and 344.6°, respectively. The value for **4** is the same as that found in the crystal structure of penicillin G (335.8° (5)). The greater reactivity of **4** over **3** calculated in this work is consistent with the nonplanarity argument, but the enhanced reactivity of **5** over **4** implies that other effects are also operative.

Examination of O···C (i) and H···N (ii) bond formation, and β-lactam bond cleavage (iii) in the N-protonation transition structures for the methanolyses of **3** and **4** suggests that (i) and (iii) are more advanced with the more reactive (and more pyramidal at nitrogen) substrate **4**, and (ii) is more advanced in the planar (at nitrogen) substrate **3**. In the N-protonation transition

structure of the most reactive substrate **5**, the proton transfer to nitrogen is nearly complete; in addition, there is a significant change in the magnitude of the imaginary frequency. Figure 6 displays the vibrations associated with this imaginary frequency, using the programme XMol (29). From left to right these depict an inversion motion of the β-lactam nitrogen, proton transfer, continued inversion at nitrogen with strengthening of the nascent N—H bond, and a further nitrogen movement with cleavage of the N—C bond and C—O bond formation. All of these effects seem to be the result of an attractive interaction, on the convex face of the molecule, between the carboxylate anion and the proton-in-flight.

The differences in (i) and (ii) in the N-protonation and O-protonation mechanisms do not seem to be sufficient to explain the energetic preference for the former reaction. However, it is evident from Fig. 3 that the two mechanisms lead to different positions of the R group of the R-O-H moiety with respect to the methyl group of *N*-methylazetidinone: in the O-protonation mechanism there is a 1,3-eclipsing interaction between R and Me. In the O-protonation mechanism from the convex face of **4** there is close contact between the methyl group of methanol and C4 of the thiazolidine ring.

Catalysis by water of the hydrolysis and methanolysis of 3 and 5

Table 3 summarizes the 3-21G (3-21G*) and MP2/6-31G*// 3-21G (3-21G*) energies of the termolecular complexes (C) and transition structures (≠) that are formed by the N-protonation and O-protonation mechanisms of water-catalyzed hydrolysis and methanolysis of **3**, and methanolysis of **5**. The energy differences calculated from these data, and from the appropriate data of Table 1, are collected in Table 4. The termolecular complexes and transition structures formed in the different mechanisms are shown in Figs. 7–12.

From the $\Delta E^{\neq}$ and $\Delta H^{\neq}$ calculated at 3-21G (3-21G*), one might conclude from Table 4 that the ternary complexes are stabilized relative to the separated reactants by ca. 20 kcal/mol^{-1} in the N-protonation mechanism and ca. 25 kcal mol^{-1} in the O-protonation mechanism. However, these large stabilization energies are the result of the incomplete description of the separated reactants that is achieved when a relatively small basis set such as 3-21G or 3-21G* is used. This is termed basis set superposition error (BSSE) (30), which has been discussed extensively in connection with calculations on water clusters (31). The BSSE leads to energies of separated reactants that are artificially too high, causing $\Delta E^{\neq}$ and $\Delta H^{\neq}$ to be too low or even negative, when these are calculated from the separated reactants.

Because of the BSSE, it is more reliable to compare absolute energies of isomeric transition structures, especially when these are obtained at the MP2/6-31G* level. In a recent study of the hydration of formaldehyde actively catalyzed by one, two, and three molecules of water (32), very similar activation energies were computed at MP2/6-31G*//MP2-6-31G* and MP2/ 6-31G*//3-21G, because the geometries calculated at 3-21G and at MP2/6-31G* are not very different.

An alternative way to deal with the BSSE problem is to compute all stationary points of a reaction with the same basis set. This is the situation when the activation energies are calculated

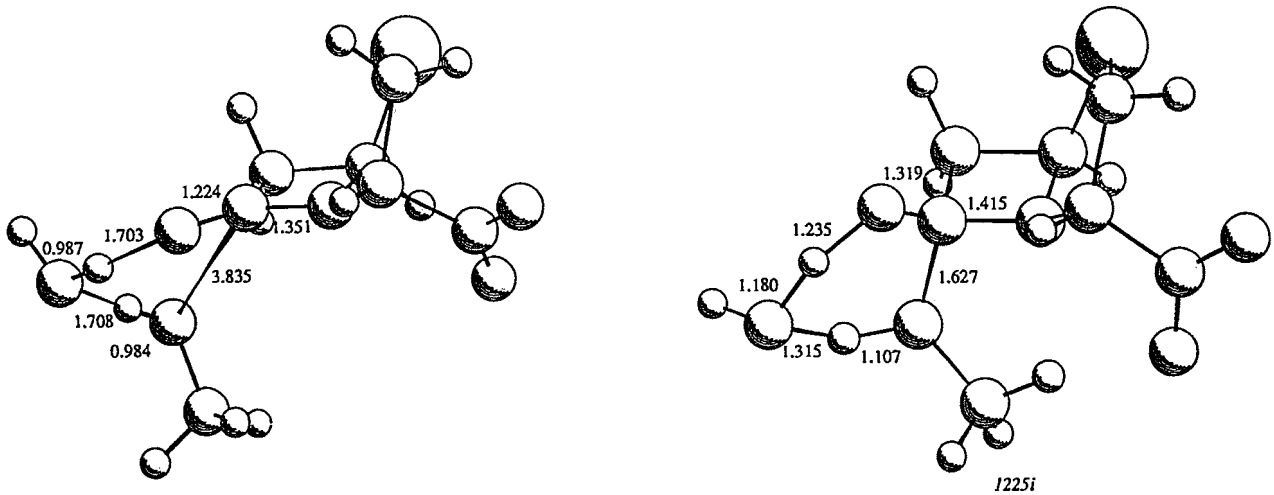

FIG. 12. Calculated reactant complex (left) and transition structure (right) for the methanolysis of **5** by the O-protonation mechanism, with catalysis by one water molecule.

from the ternary complexes, and for these entries of Table 4 it can be seen that the numbers in the first and last columns of Table 4 are not very different.

Unfortunately, as can be seen in Fig. 11, the water molecule of the termolecular complex of **5** with methanol and water is calculated to be hydrogen bonded to the carboxylate anion, and not to the β-lactam nitrogen. The energy of this complex is therefore much too low, leading to an artificially high 3-21G* N-protonation barrier. In this case the only reliable $\Delta E^{\ddagger}$ are those calculated from the separated reactants.

With this qualification, it is clear from the last column of Table 4 that the preference for the N-protonation mechanism is 2–4 kcal mol^{-1} when calculated from the separated reactants, and 7–8 kcal mol^{-1} when calculated from the complexes.

It is also clear than one water molecule has a pronounced catalytic effect, *amounting to at least 10 kcal* mol^{-1}, on the neutral hydrolysis and methanolysis of azetidinones.[5]

A most interesting feature of the geometries shown in Figs. 7 and 9 is the ca. 3.9 Å O···C=O distance in the hydrogen-bonded complexes. This is reminiscent of the 4.1 Å O···C=O distance seen in Fig. 1, and the 3.6–4.4 Å range of values mentioned in the Introduction (5) for the distance, in the docked complexes, between the hydroxyl oxygen of serine and the carbon atom of the β-lactam carbonyl group.

This observation suggests that the O—H/C(O)—N distances in the "enzyme"–substrate complexes are longer than those of four-centred transition structures in order to allow a water molecule to be accommodated. The addition of this water molecule would then create a Ser-O-H/H-O-H/N-C=O geometry that is identical to the geometry of the stationary point of the chemical reaction.

These findings raise many questions. For example, (*i*) can an enzyme exert its catalytic effect by causing a termolecular reactant complex to be assembled in the proper geometry, thereby reducing the unfavorable entropy of activation associated with a termolecular reaction? (*ii*) does the "fit" of a substrate to an enzyme cause reacting groups to be organized into a geometry that can be computed ab initio? (*iii*) is the kinetic behaviour of different substrates of an enzyme determined by the degree to which the reactive site geometries of their enzyme–substrate complexes can attain the geometry of the calculated "perfect fit"? (*iv*) can an understanding of "fit" be used in drug design?

Answers to these questions are currently being sought (32, 33). Regardless of the eventual conclusions of those studies, the principal results of the present work are the conclusions that penicillin complexes with its receptor in such a way as to allow the most favourable mechanism for acylation of the active site serine to be attained, and that this mechanism can consist of a one-step water-catalyzed cleavage of the β-lactam bond, with proton transfer to nitrogen.

[5]NOTE ADDED IN PROOF: We have now found that a *second* water molecule has a small inhibitory effect.

The semiempirical molecular orbital procedures MINDO/3, MNDO, MNDO/M, AM1, and PM3 have been used to examine possible mechanisms and modes of attack of methanol on penam, the bicyclic ring system of penicillin. These mechanisms include a one-step process in which C—O bond formation from the convex face of the molecule and proton transfer to the β-lactam nitrogen are concerted with the cleavage of the N—C(O) bond (the N-protonated pathway), and two O-protonated pathways, viz., addition to the β-lactam carbonyl group from the convex face and from the concave face of the bicyclic ring system. Only MINDO/3 reproduces the ab initio MP2/6-31G*//3-21G* trends, that the N-protonated pathway is energetically preferred over either O-protonated pathway, and, in the latter, attack from the convex face is slightly preferred over attack from the concave face. MINDO/3 has, therefore, been used for a systematic examination of the reactions of many substituted and unsubstituted β-lactam-containing ring systems with methanol. The N-protonated structure created by attack of the alcohol from the convex face of the molecule is always preferred, and structure–reactivity relationships are observed that parallel structure–activity relationships of β-lactam antibiotics. MINDO/3 has also been used to compute a scaled quantum mechanical force field for Δ^2- and Δ^3-cephems. This has allowed parameters to be proposed for Δ^2- and Δ^3-cephems in the force field of Allinger's MMP2(85) programme that complement earlier parameterizations of the program for penicillins and peptides. The availability of these parameters has led to the development of a protocol for the analysis of the differences in the antibacterial activities of penicillins and cephalosporins. The analysis is based on a combination of "fit" and "reactivity" at the site of action. Fit is determined from the geometry that results when the β-lactam compound is complexed to a hexapeptide model of the penicillin receptor, in particular, the four-centred interaction between C-O-H of the active site serine residue and (O)C-N of the azetidinone ring. Reactivity is derived from MINDO/3 calculations of $\Delta E^{\neq}$ for the reaction of methanol with the different ring systems via the N-protonated pathway. Δ^3-Cephalosporins are suggested to be inherently less active than penicillins because they are inherently less *reactive*. Δ^2-Cephalosporins containing a 4α-oriented carboxyl group are much less active than Δ^3-cephalosporins because they have a much poorer *fit*. The 4β epimers of these Δ^2-cephalosporins are much less active than Δ^3-cephalosporins because they are much less *reactive*.

SAUL WOLFE et TOVA HOZ. Can. J. Chem. **72**, 1044 (1994).

On a utilisé les méthodes de calculs d'orbitales moléculaires semiempiriques MINDO/3, MNDO, MNDO/M, AM1 et PM3 pour étudier les mécanismes possibles et les modes d'attaque du méthanol sur le péname, le système bicyclique de la pénicilline. Ces mécanismes incluent le processus en une étape au cours duquel la formation d'une liaison C—O à partir de la face convexe de la molécule et le transfert de proton à l'azote du β-lactame se font d'une façon concertée avec le clivage de la liaison N—C(O) (la voie N-protonée) ainsi que deux voies O-protonées, à savoir l'addition au groupe carbonyle du β-lactame à partir de le face convexe ou de la face concave du système bicyclique. Seuls les calculs MINDO/3 ont permis de reproduire les tendances des calculs ab initio MP2/6-31G*//3-21G* selon lesquels la voie N-protonée est d'une point de vue énergétique préférée aux deux voies O-protonées et, dans ces derniers cas, l'attaque par la face convexe est légèrement préférée à une attaque par la face concave. On a donc utilisé les calculs MINDO/3 pour examiner d'une façon systématique les réactions du méthanol avec plusieurs systèmes cycliques de β-lactames substitués et non substitués. La structure N-protonée créée par l'attaque de l'alcool sur la face convexe de la molécule est toujours privilégiée et on a observé des relations structure–activité qui sont parallèles aux relations structure–activité d'antibiotiques de β-lactames. On a aussi utilisé des calculs MINDO/3 pour calculer un champ de force de mécanique quantique pour les Δ^2- et Δ^3-céphèmes. On a ainsi pu proposer des paramètres pour les Δ^2- et Δ^3-céphèmes dans le champ de force du programme MMP2(85) d'Allinger qui sert de complément aux paramétrisations antérieures du programme pour les pénicillines et les peptides. La disponibilité de ces paramètres a conduit au développement d'un protocole pour l'analyse des différences dans les activités antibactériennes des pénicillines et des céphalosporines. L'analyse est basée sur une combinaison d'«ajustement» et de «réactivité» au site de l'action. L'ajustment est déterminé à partir des géométries qui sont obtenues lorsque le composé β-lactame se complexe à un hexapeptide modèle du récepteur de la pénicilline, en particulier, l'interaction à quatre centres entre le C-O-H de la sérine du site actif et le (O)C-N du noyau de l'azétidinone. La réactivité est déterminée par des calculs MINDO/3 du $\Delta E^{\neq}$ pour la réaction du méthanol avec divers systèmes cycliques par le biais de la voie N-protonée. Il est suggéré que les Δ^3-céphalosporines sont d'une façon inhérente moins actives que les pénicillines parce qu'elles sont d'une façon inhérente moins *réactives*. Les Δ^2-céphalosporines contenant un groupe carboxyle orienté en 4α sont beaucoup moins actives que les Δ^3-céphalosporines parce qu'elles s'*ajustent* beaucoup plus mal. Les épimères 4β de ces Δ^2-céphalosporines sont moins actifs que les Δ^3-céphalosporines parce qu'ils sont beaucoup moins *réactifs*.

TABLE 1. Relative energies (kcal/mol) of four-centred transition structures[a] in the reaction of methanol with penam, a fused β-lactam thiazolidine compound

Reaction	MP2/6-31G*//3-21G*	MINDO/3	MNDO	MNDO/M	AM1	PM3
N-Attack	0.00	0.00	7.38	10.39	10.84	11.19
O-Attack (convex)	7.77	4.80	0.00	0.00	0.00	0.00
O-Attack (concave)	9.95	5.54	6.62	6.43	5.19	3.90

[a]All transition structures have been characterized by vibrational analysis, and exhibit one imaginary frequency.

Introduction

Cephalosporins (**1**) are related to penicillins (**2**) structurally (1), biosynthetically (2), and in their mechanism of action (3). This mechanism includes complexation of the antibiotic to the active site of a penicillin binding protein (PBP) (4) (Step 1), followed by acylation of a serine hydroxyl group of this enzyme by the β-lactam carbonyl group (5) (Step 2).

We have recently studied Step 1 (6) for a series of penicillins, using a computer-derived model of the active site hexapeptide (Ac-Val[1]-Gly[2]-Ser[3]-Val[4]-Thr[5]-Lys[6]-NHMe) of a PBP from *Streptomyces* R61 (7). Examination of the geometry of the interaction between the serine O-H and the β-lactam N-C(O) in these complexes led to the suggestion that Step 2 may involve protonation of the β-lactam nitrogen concerted with C7—O bond formation. Support has now been obtained for the existence and, indeed, energetic preference for this mechanism (8) in the gas phase, and also in the presence of a catalytic water molecule (9).

These findings lead to the idea that the differing antibacterial activities exhibited by different β-lactam-containing ring systems are determined, inter alia, by their different "fits" to the PBP (Step 1), and their different intrinsic "reactivities" towards alcoholysis via an N-protonated transition structure (Step 2). The present work is concerned with an examination of the "fits" and "reactivities" associated with the penicillin, Δ^2-cephalosporin, and Δ^3-cephalosporin classes of β-lactam compounds bearing the common side chain R = $PhOCH_2CONH$ of penicillin V.

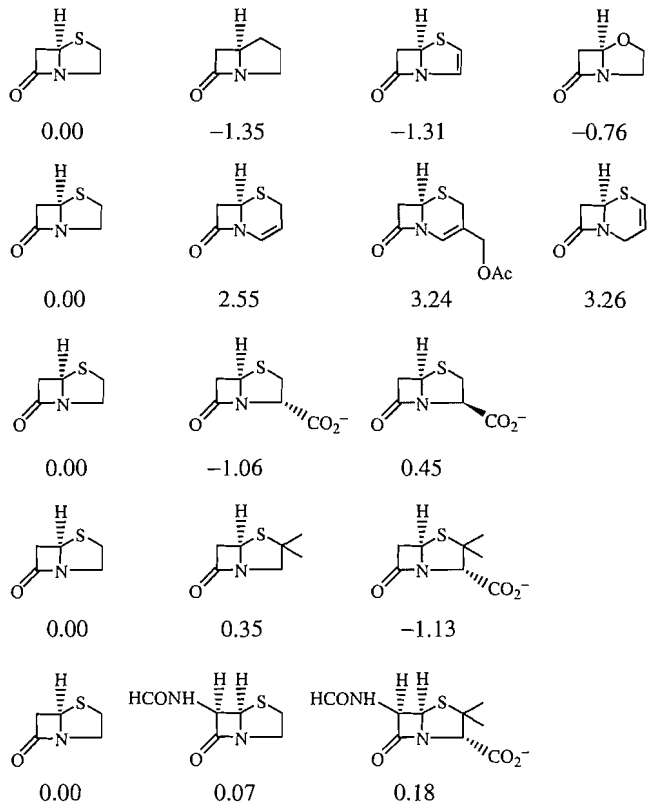
Cephalosporins undergo a facile $\Delta^3 \rightleftarrows \Delta^2$ isomerization, to give equilibrium mixtures in which the *biologically inactive* Δ^2 isomer (**3**) predominates (10). Several kinds of explanations have been advanced to account for this loss of activity (11). The majority of the earlier proposals had focused on the apparent stability of Δ^2-cephems towards *basic* hydrolysis (11*a*), but in an important contribution, Cohen (11*b*) argued that the problem resides in the fit of such compounds to the penicillin receptor, and that an improved fit might be achieved by 4-*epi*-Δ^2-cephems (**4**). However, compounds of this type have since been found also to be inactive (12).

Results and discussion

A semiempirical molecular orbital treatment of "reactivity"

As a measure of the different "reactivities" of different β-lactam containing ring systems, we wished to compute $\Delta E^{\ddagger}$ for the four-centred reaction of methanol with the N-C(O) groups of these compounds. Because of the large number of $\Delta E^{\ddagger}$ computations that were required, ab initio methods were not feasible, and a semiempirical approach was sought from among MINDO/3 (13), MNDO (14), MNDO/M (15), AM1 (16), and PM3 (17). The decision regarding which of these would be most reliable was based on the ab initio benchmark of ref. 9: at the MP2/6-31G*//3-21G* level, transition structure **5**, which involves attack from the convex face of the molecule and proton transfer to the β-lactam nitrogen, is 7.77 kcal/mol more stable than transition structure **6**, which involves attack from the convex face of the molecule and proton transfer to the carbonyl oxygen; **6** is, in turn, 2.18 kcal/mol more stable than transition structure **7**, in which addition to the carbonyl group takes place from the concave face of the molecule. As can be seen in Table 1, only MINDO/3 captures the ab initio trends.

TABLE 2. Calculated $\Delta\Delta E^{\ddagger}$ (kcal/mol, MINDO/3) relative to penam for the methanolyses of β-lactam compounds via N-protonated transition structures[a]



[a]See footnote *a* of Table 1.

Structure–activity and structure–"reactivity" relationships

Table 2 summarizes the calculated activation energies ($\Delta\Delta E^{\ddagger}$, MINDO/3, kcal/mol relative to penam) for the methanolyses of a number of bicyclic azetidinones. Each row of Table 2 examines the effect of a different kind of structural change on the $\Delta E^{\ddagger}$ of penam, the parent compound. The data are discussed row by row:

1. The relative reactivities are carbapenam > penem > oxap-

TABLE 3. Calculated $\Delta\Delta E^{\ddagger}$ (kcal/mol, MINDO/3) relative to **8** for the methanolyses of carboxy-substituted cephalosporins via a four-centred N-protonated transition structure[a]

Substrate	$\Delta\Delta E^{\ddagger}$
8	0.00
9	1.94
10	2.81
11	4.65
12	2.08
13	3.50
14	8.04
15	8.33

[a]See footnote *a* of Table 1.

enam > penam. Oxapenicillins (18) and penems (19) having the C3 and C6 substituents of penicillins are known to have antibacterial activity; although the carbapenam ring system is known (20), carbapenicillins have not yet been reported.

2. In the comparison of the penam and cephem ring systems, the relative reactivities are penam >> Δ^3-cephem > Δ^2-cephem, acetoxymethyl-Δ^3-cephem. With a common acylamino side chain, penicillins are an order of magnitude more active than acetoxymethyl-Δ^3-cephalosporins and the latter are, in general, an order of magnitude more active than 3-methyl-Δ^3-cephems (21); as already mentioned, Δ^2-cephems are inactive.

3. Introduction of the C3α-carboxyl group enhances the reactivity. We suggest that the carboxyl group assists the methanolysis through hydrogen bonding, because epimerization (C3β) decreases the reactivity significantly.

4. Introduction of C2-methyl substituents decreases the reactivity, unless a C3α-carboxyl group is present.

5. The 6β-acylamino substituent has almost no effect on the reactivity. Consequently, the chemical reactivity of a penicillin differs only slightly from that of the parent penam.

Figure 1 shows stereoscopic views of three isomeric transition structures for the methanolysis of the β-lactam ring of formylpenicillin. A is the N-protonated transition structure; B is the O-protonated transition structure for attack from the convex face; C is the O-protonated transition structure for attack for the concave face. The relative energies of the structures are A: 0.00 kcal/mol; B, 7.36 kcal/mol; C, 9.73 kcal/mol.[4]

The trend seen on line 3 of Table 1 is also present in 4α-carboxy and 4β-carboxy-Δ^2-cephems. Table 3 gives $\Delta E^{\ddagger}$ relative to 2,2-dimethyl-3α-carboxypenam (**8**) for the methanolysis of the β-lactam rings of cephems via N-protonated transition structures. The relative reactivities are: penam (**8**) > Δ^2-cephem (**9**) > Δ^3-cephem (**10**) > 4-*epi*-Δ^2-cephem (**11**). The stereoisomers **9** and **11** exhibit a 2.71 kcal/mol difference in $\Delta E^{\ddagger}$. If this difference reflects the hydrogen-bonding assistance provided for attack from the convex face of the molecule by an α-oriented carboxylate group, the reactivity of **11** might be improved by the introduction of a new hydrogen-bonding donor atom onto this convex face. Possible sites for such a substituent include 4α and 7α (see **9** for numbering), and Table 3 includes the results obtained for the 7α-methoxy (**12**), 4α-carboxy (**13**), 7α-fluoro (**14**), and 4α-methoxy (**15**) compounds. Depending on their "fits", the "reactivities" calculated for **12** and **13** could make acylamino-substituted derivatives of these compounds interesting.

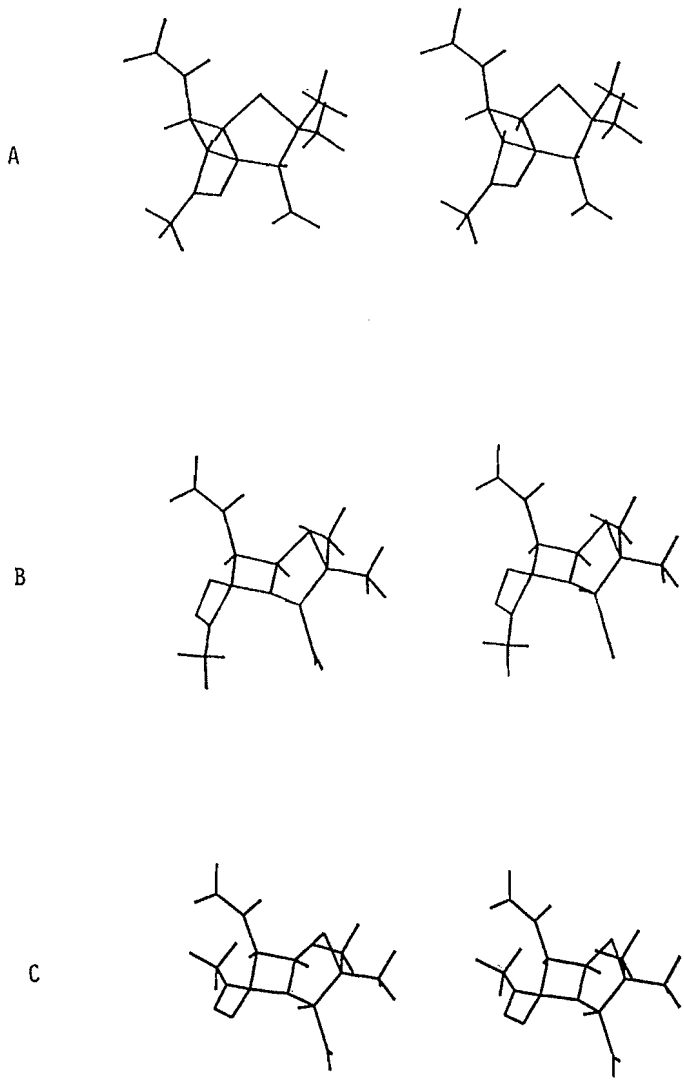

FIG. 1. (*a*) N-protonated transition structure for the methanolysis of N-formylpenicillin; (*b*) O-protonated transition structure for the methanolysis of N-formylpenicillin from the convex face; (*c*) O-protonated transition structure for the methanolysis of N-formylpenicillin from the concave face. All structures have been optimized fully using MINDO/3.

Ceparam, a parameterization of cephalosporins for MMP2(85)

A prerequisite to the treatment of the "fit" of cephalosporins to our hexapeptide model of the penicillin receptor is the establishment of parameters for the molecular mechanics force field of MMP2(85) (22), comparable in quality to MMPEN (23), the parameterization of this force field for penicillins. In the case of MMPEN, torsional and electrostatic parameters were determined computationally (24, 25), van der Waals parameters were taken from MMP2(85), and stretching and bending parameters were available from crystallographic data and the experimental force fields of 2-azetidinone and thiazolidine. An analogous strategy was envisaged for cephalosporins, but the paucity of crystallographic information and absence of vibra-

[4]All of the primary data (geometries, parameters) of this article are available as supplementary data, and may be purchased from the Depository of Unpublished Data, Documentary Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

tional data for dihydrothiazines necessitated a scaled quantum mechanical (SQM) (26) approach to obtain the stretching and bending parameters.

Using MINDO/3, the internal coordinates of the optimized geometries of 3-methyl-Δ^2- and 3-methyl-Δ^3-cephem were distorted one at a time (27)[5] in both positive and negative directions by 0.01 Å for bond stretching, and 1.0° for angle bending, while the rest of the molecule was allowed to relax, and the force constants were calculated numerically. Scaling factors were determined by inspection of calculated and experimental results for cyclohexene (28), cyclobutane (29), azetidine (30), 2-azetidinone (31), thiazolidine (32), propene (33), 1-propenethiol (34), and allylamine (35), and are included with the supplementary data.[4]

As a preliminary test of the SQM computational strategy, the stretching and bending parameters of the penicillin nucleus were calculated, using MINDO/3. Introduction of these parameters into MMPEN (23) in place of the previous experimentally derived parameters (31, 32) allowed the crystal structure of penicillin G to be reproduced exactly.

Completion of the parameterization then followed established procedures (23). The final refinements of the torsional parameters were performed by trial and error, until the rms

Stereoscopic view of the complex formed from **22**.

deviations from the experimental crystal structures of **16** (36) and **17** (37) were less than 0.4 Å in each case.

Fitting penicillin V and cephalosporin V analogs to the receptor model

Figure 2 shows stereoscopic views of the complexes formed between our model of the penicillin receptor (6) and: A, penicillin V (**18**); B, 3-methyl-Δ^3-cephalosporin V (**19**); C, 3-methyl-Δ^2-cephalosporin V (**17**); D, 3-methyl-4-*epi*-Δ^2-cephalosporin V (**20**); E, 3-methyl-4-*epi*-7α-methoxy-Δ^2-cephalosporin V (**21**); F, 3-methyl-4,4-dicarboxy-Δ^2-cephem (**22**). To obtain these complexes (6), hydrogen bonding was assumed between the carboxyl group of the β-lactam compound and the terminal amino group of Lys^6, and between the side-chain N-H and the Val^1 end group, a preliminary minimization was performed using a simplified van der Waals and electrostatic force field, and the Cartesian coordinates of the resulting supermolecule were then employed as input to MMP2(85).

The docking of several conformations of each of the β-lactam compounds was examined and, in each case, the lowest energy complex was achieved from the global minimum of the uncomplexed structure. In the global minima of **17**, **19**, and **20**, the conformations of the dihydrothiazine rings are the same as in the crystal structures, but Ar···S interactions (38) cause compact conformations of the side chains to be preferred, as already noted for penicillins (23).

TABLE 4. Root-mean-square (rms) differences (Å), relative to penicillin V, of the Cartesian coordinates of the O-H atoms of serine and the C(O)-N atoms of the azetidinone ring in complexes of β-lactam compounds with a model of the penicillin receptor (column 2). Activation energies (MINDO/3, kcal/mol, from Table 3), relative to **8**, for the reaction of azetidinones with methanol (column 3). The product of rms × $\Delta\Delta E^{\ddagger}$ (column 4)

Substrate	rms	$\Delta\Delta E^{\ddagger}$	rms × $\Delta\Delta E^{\ddagger}$
18	0.000	0.00	0.00
19	0.103	2.81	0.29
17	0.684	1.94	1.33

Δ^2-cephem **20** to the model of the penicillin receptor is much better than that of the Δ^2-cephem **17**, *as predicted by Cohen* (11*b*). Table 4 also includes $\Delta\Delta E^{\ddagger}$, relative to penicillin, for the various compounds, as well as the *product* rms $\times$ $\Delta\Delta E^{\ddagger}$, which appears to order **17–20** in the order of their antibacterial activities. Based on this quantity, **17** is inactive because of its poorer fit, and **20** is inactive because of its reduced chemical reactivity. Taken together, the "fits" and "reactivities" of **21** and **22** suggest that **21** may be more active, and **22** less active than previously described Δ^2-cephems. Experimental tests of these conclusions, as well as syntheses of novel structures based on the analysis developed herein, are in progress.

β-Lactam compounds act on penicillin-recognizing enzymes via acylation of the hydroxyl group of an active site serine. When the resulting acyl enzyme is kinetically stable, as in the case of a penicillin-binding protein (PBP), the biosynthesis of a bacterial cell wall is inhibited, and death of the organism results. The de novo design of an antibacterial agent targeted to a PBP might be possible if the three-dimensional structural requirements of the equilibrium (i.e., *fit*) and catalytic (i.e. *reactivity*) steps of the aforementioned enzymatic process could be determined. For a model of the active site of a PBP from *Streptomyces* R61, the use of molecular mechanics calculations to treat "fit," and ab initio molecular orbital calculations to treat "reactivity," leads to the idea that the carboxyl group (G_1) and the amide N-H (G_2) of the antibiotic are hydrogen bonded to a lysine amino group and a valine carbonyl group in the enzyme–substrate complex. These two hydrogen bonds place the serine hydroxyl group on the convex face of the antibiotic, in position for attack on the β-lactam ring by a neutral reaction, catalyzed by water, that involves a direct proton transfer to the β-lactam nitrogen. Molecular orbital calculations of structure–reactivity relations associated with this mechanism suggest that C═N is bioisosteric to the β-lactam N-C(═O), comparable to a β-lactam in its reactivity with an alcohol, and that the product RO(C-N)H is formed essentially irreversibly ($-\Delta E > 10$ kcal/mol). Accordingly, structures containing a G_1 and a G_2 separated by a C═N, and positioned in different ways with respect to this functional group, have been synthesized computationally and examined for their ability to fit to the PBP model. This strategy identified a 2*H*-5,6-dihydro-1,4-thiazine substituted by hydroxyl and carboxyl groups as a target for chemical synthesis. However, exploratory experiments suggested that the C═N of this compound equilibrates with endocyclic and exocyclic enamine tautomers. This required that the C2 position be substituted, and that the hydroxyl group not be attached to the carbon atom adjacent to the C═N. These conditions are met in a 2,2-dimethyl-3-(2-hydroxypropyl)-1,4-thiazine, which also exhibits the necessary fit to the PBP model. Two epimers of this compound have been synthesized, from D- and L-serine. The compound derived from L-serine is not active. The compound derived from D-serine exhibits antibacterial activity, but is unstable, and binding studies with PBP's have not been performed. It is hoped that these studies can be carried out if modification of the lead structure leads to compounds with improved chemical stability.

SAUL WOLFE, HAOLUN JIN, KIYULL YANG, CHAN-KYUNG KIM et ERNEST MCEACHERN. Can. J. Chem. **72**, 1051 (1994).

Les β-lactames agissent sur les enzymes qui reconnaissent la pénicilline par le biais d'une acylation du groupe hydroxyle d'un site actif de la sérine. Lorsque l'enzyme acylé qui en résulte est cinétiquement stable, comme dans le cas d'une pénicilline se liant à une protéine (PBP), la biosynthèse d'une paroi de la cellule bactérienne est inhibée et la mort de l'organisme s'en suit. Le «design» de novo d'un agent antibactérien orientée vers une PBP peut être possible s'il est possible de déterminer les besoins structuraux des étapes d'équilibre (à savoir l'*ajustement*) et catalytique (à savoir la *réactivité*) des processus enzymatiques mentionnés plus haut. Pour un modèle du site actif d'une PBP du *Streptomyces* R61, l'utilisation de calculs de mécanique moléculaire pour examiner l'adjustement et des calculs d'orbitales moléculaires ab initio pour traité de la «réactivité» conduisent à la suggestion que, dans le complexe enzyme–substrat, le groupe carboxyle (G_1) et le groupe amide (G_2) de l'antibiotique sont reliés à un groupe amino de la lysine et à un groupe carbonyle de la valine par des liaisons hydrogènes. Ces deux liaisons hydrogènes placent le groupe hydroxyle de la sérine sur la face convexe de l'antibiotique, dans une position permettant une attaque sur le noyau β-lactame par une réaction neutre, catalysée par l'eau, qui implique un transfert direct de proton à l'azote du β-lactame. Des calculs d'orbitales moléculaires des relations structure–réactivité associées avec ce mécanisme suggèrent que le C═N est bioisostérique avec le β-lactame, N-C(═O), comparable au β-lactame en ce qui a trait à sa réactivité avec un alcool, et que le produit RO(C-N)H se forme d'une façon qui est essentiellement irréversible ($-\Delta E > 10$ kcal/mol). Sur cette base, on a synthétisé par ordinateur des structures contenant les groupes G_1 et G_2 séparés par un C═N et placés dans des positions diverses par rapport à ce groupe fonctionnel et on a examiné leur habilité à s'insérer dans le modèle PBP. Cette stratégie a permis d'identifier une 2*H*-5,6-dihydro-1,4-thiazine substituée par des groupes hydroxyles et carboxyles comme cibles pour une synthèse chimique. Toutefois, des essais préliminaires ont suggéré que le C═N de ce composé serait en équilibre avec les énamines endocycliques et exocycliques tautomères. Cette caractéristique nécessite que la position C2 soit substituée et que le groupe hydroxyle ne soit pas attaché au carbone adjacent du C═N. On rencontre ces conditions dans une 2,2-diméthyl-3-(2-hydroxypropyl)-1,4-thiazine qui présente aussi les qualités requises pour s'insérer dans le modèle PBP. On a synthétisé deux épimères de ce composé à partir des D- et L-sérine. Le composé dérivé de la L-sérine n'est pas actif. Le composé dérivé de la D-sérine présente une activité antibactérienne, mais il est instable et on n'a pas pu effectuer d'études de liaisons avec les PBP. On espère que ces études pourront être effectuées sur des modifications de cette structure qui auraient une meilleure stabilité chimique.

Introduction

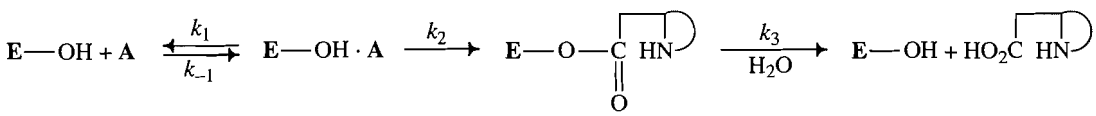
β-Lactam antibiotics interact with their target enzymes in three stages (Scheme 1) (1). In the first stage, the antibiotic (**A**) "fits" reversibly (k_1, k_{-1}) to the enzyme (**E**-OH), to form an enzyme–substrate complex (**E**-OH·**A**). Then OH, the hydroxyl group of a serine residue, "reacts" (k_2), and is acylated by the β-lactam carbonyl group. In the final stage, the acyl-enzyme (**E**-OCOR) is hydrolysed (k_3). This regenerates **E**-OH, and produces an inactive degradation product of the antibiotic.

When $k_3 \ll k_2$, Scheme 1 leads to inactivation of the enzyme, and an enzyme that exhibits these kinetics is termed a penicillin-binding protein (PBP) (2). The inactivation of a PBP comprises a killing mechanism, because these enzymes play an essential role in the biosynthesis of bacterial cell walls. When the biosynthesis is interrupted, the wall is weakened, becomes permeable to water, and the cell swells, bursts, and dies. On the other hand, if k_3 is large in Scheme 1, it is the substrate that is inactivated; an enzyme having this property is termed a β-lactamase (3), and its presence, or its ability to be induced when an organism is challenged by a β-lactam antibiotic, are primarily responsible for bacterial resistance to these antibiotics.

Theoretical considerations: "fit" and "reactivity"

We have recently discussed the abilities of penicillins (**1**) and cephalosporins (**2**) to "fit" to a computer-generated model (Fig. 1) of the peptide Ac-Val[1]-Gly[2]-Ser[3]-Val[4]-Thr[5]-Lys[6]-NHMe (**3**) (4). This peptide contains the residues that surround the active site serine of a PBP from *Streptomyces* R61, which has been studied in some detail (5). Since (*i*) structure–activity and conformation–activity relationships project important roles for the carboxyl group and the amide N-H of a β-lactam antibiotic in its interaction with a PBP (4); (*ii*) pH-dependence studies suggest that the carboxyl group of the antibiotic is charge-paired to the terminal amino group of Lys[6] (5*b*); (*iii*) in **3**, the carbonyl group of Val[1] and the Ser[3] and Lys[6] side chains are in proximity, we "fit" β-lactam antibiotics to **3** with one hydrogen bond from the side-chain N-H to the carbonyl group of Val[1], and a second hydrogen bond from the amino group of Lys[6] to the carboxyl group.

When this docking strategy is used to "fit" the crystal structure of penicillin G (6) to **3**, the complex which results (Fig. 2) has the Ser[3] hydroxyl group positioned on the convex face of the bicyclic molecule, poised for attack on the β-lactam group. The positions of the C-O-H and N-C=O reacting groups of Fig. 2 with respect to one another (C-O approximately *syn* to C=O, and O-H approximately *syn* to N-C on the convex face) are the same as those seen in the most recent modelling of a β-lactam antibiotic into the active site of the *crystal structure* of the *Streptomyces* R61 PBP (7). However, there is a mechanistic problem associated with these structures, because addition to the carbonyl group to form the expected tetrahedral intermediate of β-lactam alcoholysis cannot occur from a geometry in which C-O and C=O are *syn* to one another.



SCHEME 1

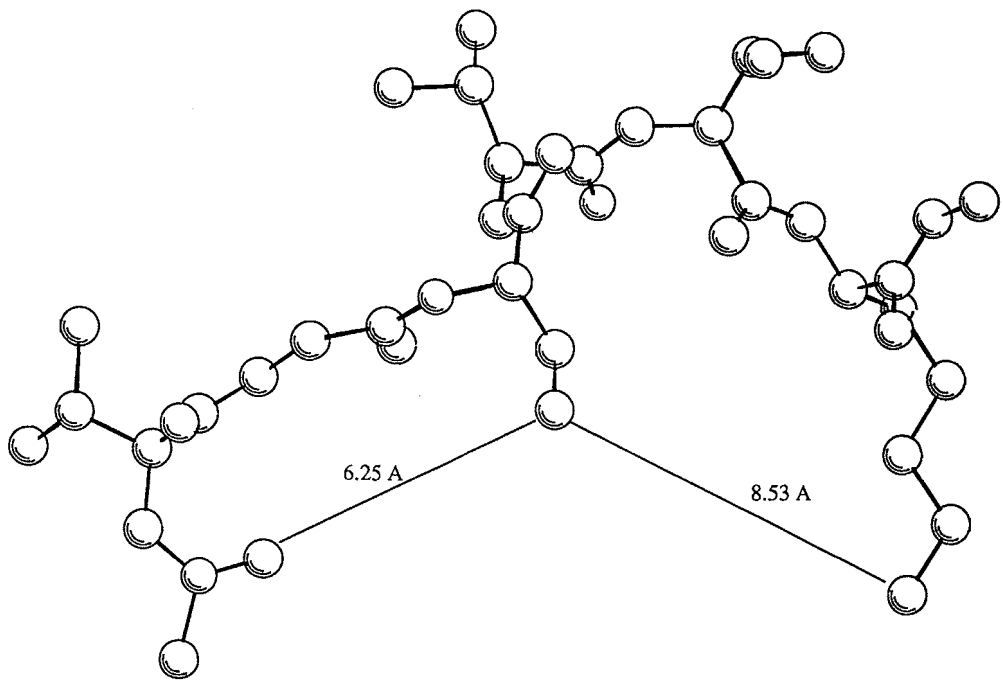


FIG. 1. A computer-generated model of the active site of a penicillin-binding protein having the sequence val-gly-ser-val-thr-lys. The model shows close contact, on the concave face, between the serine hydroxyl, the lysine amino, and a valine carbonyl.

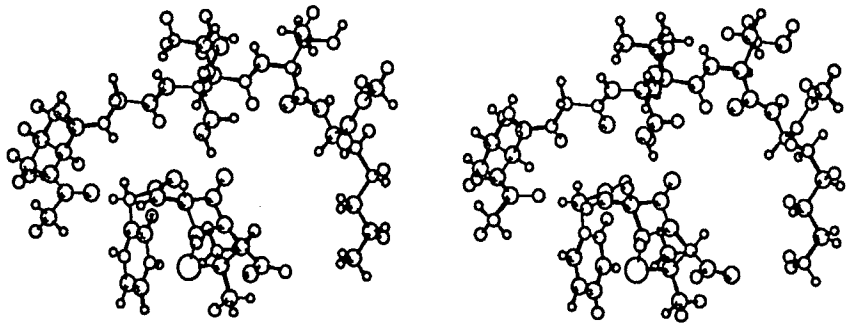

FIG. 2. Docking of the crystal structure of penicillin G to the active site model of Fig. 1. The creation of hydrogen bonds between the carboxyl group of the antibiotic and the amino group of lysine, and between the amide N-H of the antibiotic and the valine carbonyl, results in close contact between the serine hydroxyl group and the convex face of the penicillin.

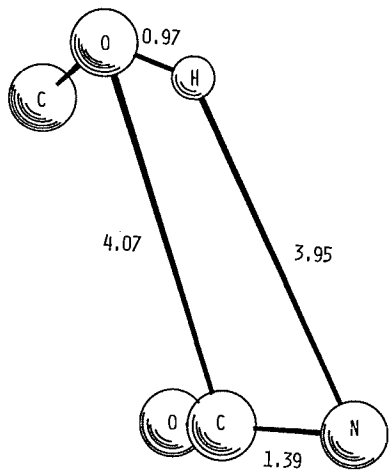

FIG. 3. A closeup view of the C-O-H/N-C=O relationship in Fig. 2.

The nature of the problem is seen more clearly in Fig. 3, a closeup view of the C-O-H/N-C=O relationship in Fig. 2. This arrangement of the reacting groups suggests that the "reactivity" step of Scheme 1, which produces the acyl-enzyme, involves C=O bond formation and proton transfer to nitrogen, *concerted with the fission of the β-lactam bond.* As we report elsewhere (8), ab initio MP2/6-31G*//3-21G* calculations (9) of the neutral hydrolysis and alcoholysis of *N*-methylazetidinone (**4**) and penam (**5**) confirm that a concerted mechanism, with proton transfer to nitrogen, exists, and is 5–10 kcal/mol energetically more favorable than addition to the carbonyl group, with proton transfer to oxygen. In addition, attack on **5** from the convex face is more favourable than attack from the concave face.

What emerges from this theoretical analysis of the first two steps of Scheme 1 is the idea that a β-lactam antibiotic "fits" to a PBP in such a way as to permit acylation of a hydroxyl group via the mechanistically and energetically most favourable chemical "reaction". The realization that the action of the enzyme involves both "fit" and "reactivity" (10) is a variation of Emil Fischer's lock and key analogy (11), in which a key fits into a lock, and then turns to open the lock.

The methanolysis of **4** exhibits significant catalysis by one water molecule (8). In this case, based on 3-21G calculations, the reaction proceeds via a ternary complex (Fig. 4), whose C-OH/N-C=O/H-O-H bond lengths are highlighted in Fig. 5.

If the water molecule is deleted from Fig. 5, what remains resembles Fig. 3. This suggests that the structure of Fig. 3 is

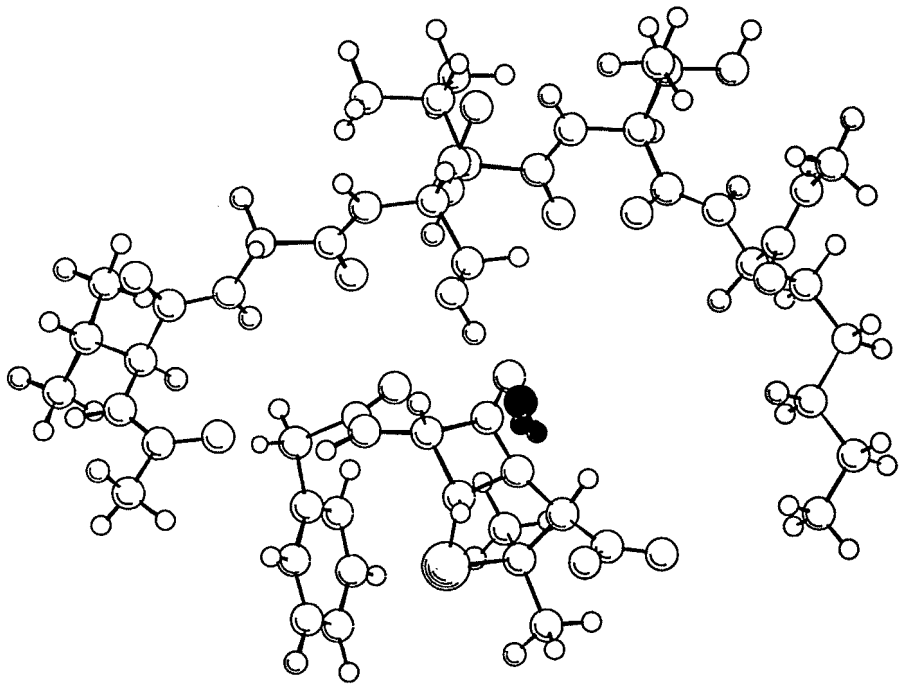

FIG. 6. Addition of one water molecule to the complex of penicillin G with the receptor model. The water molecule is in the centre of the structure.

able to accommodate a water molecule, and that at least one water molecule should also be included in the active site of Fig. 2. This would be consistent with the limited information concerning water in the active sites of β-lactamase crystal structures (12). Based on these considerations, the program developed to obtain the supermolecule of Fig. 2 (4) was modified[6] to allow a third molecule, in this case, water, to be included, with the result shown in Fig. 6 and, in close-up, in Figs. 7 and 8.

It is important to emphasize that the (nearly identical) Figs. 5 and 8 are obtained in very different ways. Figure 5, an ab initio result, is a closeup view of a stationary point on a reaction coordinate; Fig. 8, a molecular mechanics result, is a closeup view of an "enzyme"–water–substrate complex. Because of its ability to assemble the reactants in the proper manner, the "enzyme" has overcome the entropic disadvantage of a termolecular process.

Targeting a PBP

We wish to use the insights gained from the work just described to attempt the de novo design of a molecule that will "fit" to the active site of a PBP in the same manner as penicillin, "react" with the hydroxyl group of the active site serine through a geometry similar to that seen in Figs. 3 or 8, and exhibit antibacterial activity (13). As depicted in Fig. 9, our synthetic objective should possess a carboxyl group or its bioisosteric equivalent (G_1), to interact with the Lys^6 amino group of **3**, and also a hydrogen-bonding donor group X-H (G_2), to interact with the Val^1 carbonyl group of **3**. The distance between G_1 and G_2 can be determined from, e.g., the corresponding distance in the crystal structure of penicillin G.

The formation of the hydrogen bonds to G_1 and G_2 must now cause a functional group 𝔽 to be oriented into a four-centred relationship with respect to the serine hydroxyl group (cf. Fig. 3). A decision concerning the choice of 𝔽 is possible if a functional group can be found that reacts with a hydroxyl group via a four-centred geometry, possibly with catalysis by water, and with an activation energy comparable to that exhibited by a β-lactam. The search for 𝔽 was carried out computationally.

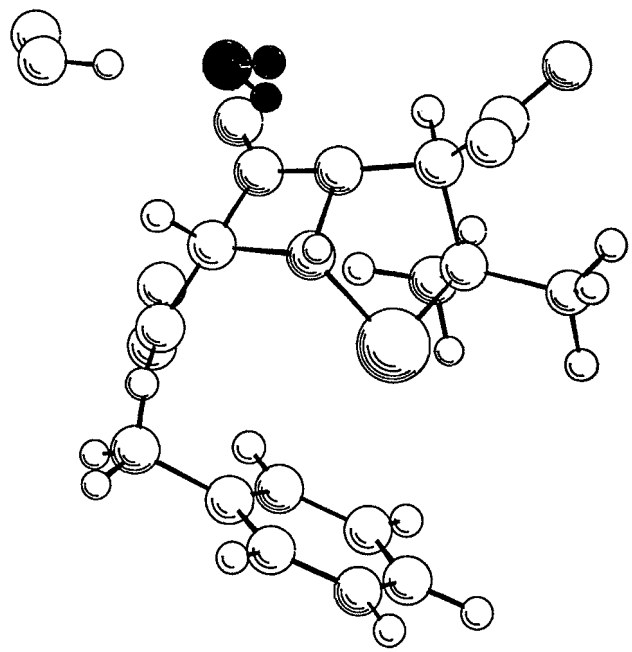

FIG. 7. Truncation of the structure of Fig. 6, showing the C-O-H of serine and the water molecule on the convex face of the penicillin.

Figure 10 is the N-protonated transition structure calculated, using MINDO/3, for the four-centred reaction of 2,2-dimethyl-3α-carboxypenam (**6**) with methanol. The activation energy of this reaction is 49.6 kcal/mol, 7.6 kcal/mol lower than that required for the alternative process of addition to the β-lactam carbonyl group. This trend is typical. As discussed elsewhere (14), MINDO/3, but not MNDO, MNDO/H, AM1,

[6]K. Yang and S. Wolfe. To be published.

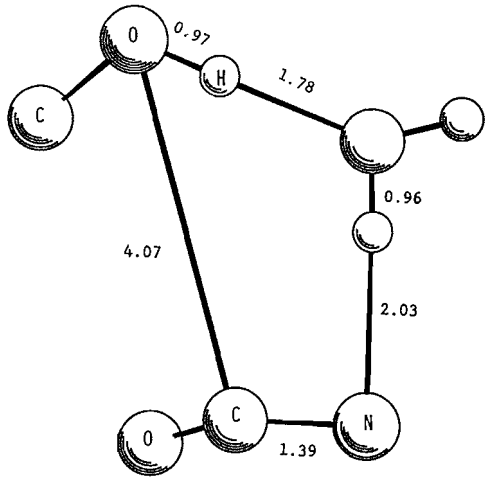

FIG. 8. A closeup view of the C-O-H/N-C=O/H-O-H bond lengths in Figs. 6 and 7.

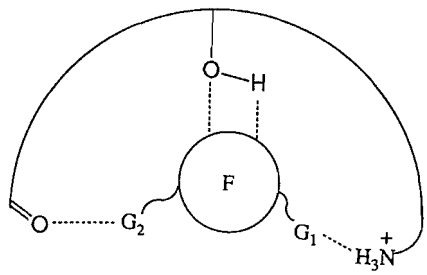

FIG. 9. Targeting the penicillin receptor.

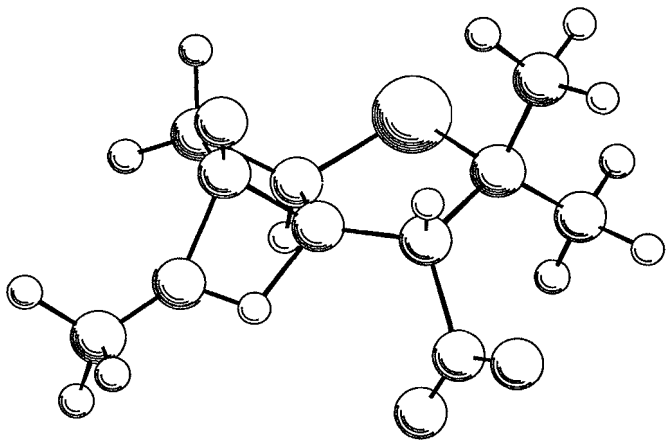

FIG. 10. MINDO/3 transition structure for the methanolysis of 2,2-dimethyl-3α-carboxypenam.

or PM3 reproduces the ab initio findings concerning the relative energies of the N- and O-protonated reaction pathways. In addition, MINDO/3 calculations of the activation energies for the methanolyses of azetidinones provide structure–reactivity trends that parallel the trends in the structure–activity relations of penicillins and cephalosporins (14). Therefore, the MINDO/3 semiempirical procedure was used for a preliminary survey of more general relationships between structure and four-centred reactivity towards methanol.

Table 1 lists the activation energies calculated for the four-centred reactions of methanol with the β-lactam (N-C=O), γ-lactam (N-C=O), β-lactone (O-C=O), γ-lactone

TABLE 1. Calculated activation energies (kcal/mol, MINDO/3), relative to 2,2-dimethyl-4-carboxypenam (6), for the neutral methanolysis of various compounds via a four-centred mechanism

(O-C=O), oxazolidinone (O-N-C=O) (13*f*, 13*g*, 13*h*), and pyrazolidinone (N-N-C=O) (13*d*, 13e) functional groups, relative to the 49.6 kcal/mol calculated for **6**. The designations N, A, and B in Table 1 refer to the site to which the O-H proton of methanol is added. All of the compounds of Table 1 are calculated to be less reactive than **6**.

On the other hand, the data of Table 2 suggest that the imino group (C=N) is inherently more reactive towards methanol than the β-lactam ring of **6**, and that the reactivity of this group can be varied by variation of the ring size and the nature of the substituents.

The reactivities of several cyclic imines with methanol, with and without catalysis by water, were therefore examined more closely, using the 3-21G basis set for ab initio geometry optimizations, followed by one-point calculations of energies at the MP2/6-31G* level. In Fig. 11, A and B are the reactant complex and transition structure for the four-centred reaction with pyrroline, which produces the carbinolamine ether E; C and D are stereoscopic views of the complex and transition structure of the water-catalyzed process.

Table 3 summarizes the calculated reactivities towards methanol of *N*-methylazetidinone, 1-pyrroline, 2-oxazoline, 2-thiazoline, and also *N*-methyloxazolidinone. The first and second columns of Table 3 give the energy differences between separated reactants and transition structures for the uncatalyzed and catalyzed reactions; the third column shows the energy differences between the ternary reactant complexes and the transition structures of the catalyzed reactions.

The enhanced C=N reactivity predicted by the four-centred

MINDO/3 calculations of Table 2 is not reproduced by the four-centred ab initio calculations of Table 3. In the β-lactam N-C=O, the lone pair of N and the π-orbital of C=O are approximately parallel, and the formation of the N—H and C—O bonds of the four-centred structure in a *syn* manner is not inhibited. In N=C, however, the lone pair of N and the

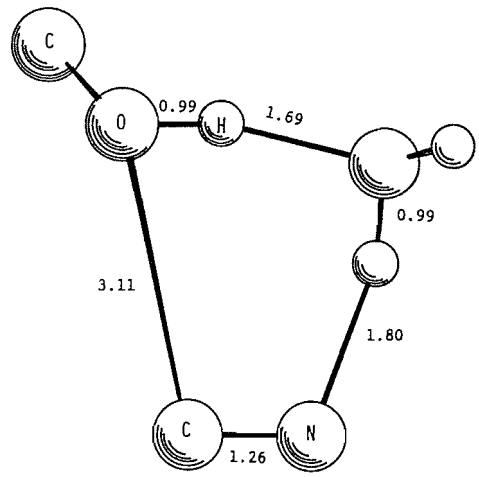

FIG. 12. A closeup view of the C-O-H/C=N/H-O-H bond lengths in the reactant complex C of Fig. 11.

π-orbital of N=C are approximately perpendicular, and *syn* formation of the N—H and C—O bonds is more difficult. This effect is taken into account in the ab initio calculations, but not by MINDO/3 (15). As can be seen in D of Fig. 11, the catalytic water molecule is important, because it allows the H-N-C-O dihedral angle to increase. The trends in the second and third columns of Table 3 are therefore more reliable than the four-centred trends, and suggest that the *bioreactivity* of C=N should be comparable to that of the β-lactam N-C=O. As seen in Fig. 12, the C=N group is also *bioisosteric* to N-C=O; this figure is a closeup view of the C-O-H/C=N/H-O-H bond lengths in C (Fig. 11), and can be compared to Fig. 5.

The final column of Table 3 contains the important result that the formation of a carbinolamine ether is an exoergic process. This means that the capture of a hydroxyl group by an imine function will be effectively irreversible, a necessary requirement for a compound targeted to a penicillin receptor. Furthermore, since the final deacylation step of Scheme 1 has no counterpart in the case of a carbinolamine ether, the incorporation of C=N into a properly designed compound could lead to the inhibition of both PBP's *and* β-lactamases.

It should be emphasized that the role of water could not be examined in the MINDO/3 calculations of Tables 1 and 2, because MINDO/3 does not treat intermolecular hydrogen bonds well, and predicts that water *inhibits* all of these processes (10). In addition, although AM1 correctly predicts catalysis, the use of AM1 for a systematic analysis of the catalyzed reactions fails for other reasons (10). Nevertheless, despite all of these limitations of the semiempirical calculations, these calculations do agree with the ab initio identification of C=N as a candidate for 𝔽.

In this connection, a referee has commented that excessive reliance on the MINDO/3 calculations of Table 1 would not have identified the X-N-C=O functionality of oxazolidinones (X = OR) and pyrazolidinones (X = NR_2) as potential candidates for 𝔽, and the existence of antibacterial agents containing these ring systems and targeted towards penicillin-binding proteins (13*d*, 13*e*, 13*f*, 13*g*, 13*h*) would not have been predicted.

The reason for the failure of MINDO/3 in the case of molecules having adjacent electron pairs (15) is that the neglect of one-centre overlap in the INDO procedure causes N—N (N—O) bonds to be too short and R-N-N (R-N-O) angles to be too large. The molecules then behave as though they have an

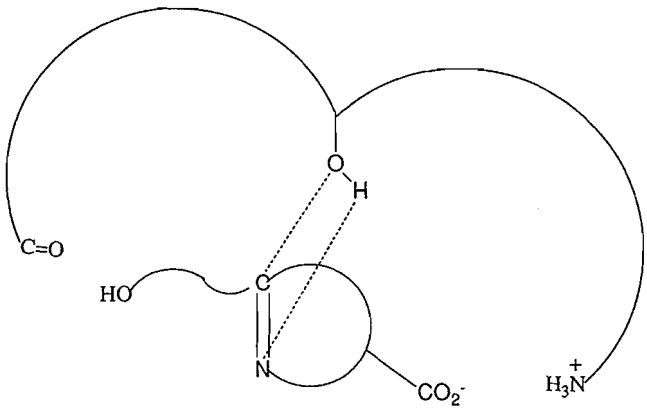

FIG. 13. Updated requirements for the targeting of the penicillin receptor.

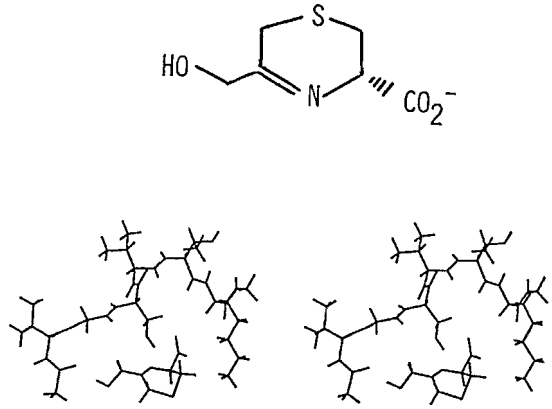

FIG. 14. Stereoscopic view of the initial synthetic target **7**, showing the *S* enantiomer docked to the penicillin receptor model.

electron-withdrawing substituent attached to a planar nitrogen, and proton transfer to this nitrogen becomes more difficult. As seen in the final entry of Table 3, the 6.15 kcal/mol reactivity preference for *N*-methylazetidinone over *N*-methyloxazolidinone that is predicted by MINDO/3 (Table 1) has been reversed at MP2/6-31G*//3-21G, to a 2.83 kcal/mol preference for the reaction of *N*-methyloxazolidinone. Clearly, ab initio calculations should be given priority in future computational studies related to 𝔽.

The identification of C=N as our current candidate for 𝔽 allowed Fig. 9 to be revised to Fig. 13, in which G_1 is CO_2^-, and G_2 is OH, and it was now necessary to create the desired spatial relationship between G_1, C=N, and G_2. This was done, crudely at first, by inspection of molecular models. For example, based on the dihedral angles in penicillin G, a compound having the part structure H-O-C1-C2=N-C3-CO_2^- would require O-C-C=N and C=N-C-C dihedral angles of −155° and +155°, respectively. Structures in which C1 and C3, or C2 and C3 were connected by different sized rings were, therefore, examined; these, in turn, suggested other possibilities.

A more careful conformational analysis of each candidate structure identified in this way was then performed, using MM2 (28). Previously unknown MM2 parameters were found, where necessary, using established procedures (14, 16). The parameters thus determined for the compounds to be discussed below are available as Supplementary Material.[7]

Each candidate was docked to **3** via the two hydrogen bonds already noted, and the relationship between the C=N of the candidate and the O-H of Ser^3 in the resulting complex was examined. This procedure eventually identified a number of targets for synthesis, and a programme directed towards the 2*H*-5,6-dihydro-1,4-thiazine **7** (cf Fig. 14), was initiated. Because it was known (17) that dihydrothiazines exhibit imine–enamine tautomerism (e.g., **8***a–c*), some preliminary experiments were necessary to assess the possible complications resulting from such tautomerism.

Preliminary Synthetic Studies

The reaction of L-cysteine with 1-benzoyloxy-3-chloropropanone (**9**), prepared in three steps from epichlorohydrin (18), produced an unstable product from which, after esterification with diazomethane, only the enamine **10** could be isolated. The same compound was obtained when **9** was reacted with the methyl ester of cysteine. Attempts to shift the double bond of **10** were not successful.

After numerous variations of the above synthesis had been examined, a compound with the gross structure **12***a* was isolated from the reaction of L-cysteine methyl ester with methyl bromoacetoacetate (**11**). However, this compound is a special case, since its ^{1}Hmr spectrum is consistent with the zwitterion structure **12***b* (no side-chain CH_2, but N^+-H at 9.00 and C=C-H at 4.63 ppm).

It was concluded that these 5,6-dihydro-1,4-thiazines prefer the 4H-tautomeric structure **8***b* and that, to avoid this structure, it would be necessary to place substituents at C2. The original objective **7** was, therefore, modified to **13***a*, which is the cyclodehydration product of **14***a*.

Scheme 2 summarizes the synthesis of the fully protected cysteine derivative **14***b*. Bromination of methyl isopropyl ketone afforded **15**, which was oxidized to **16** with lead tetraacetate, and then thiolated to **17** with triethylamine – hydrogen sulfide. Condensation of the lithium salt of **17** with the Vederas lactone **18** (19) proceeded smoothly to yield the acid **14***c*, and thence **14***b*.

Removal of the *tert*-butoxycarbonyl protecting group of **14***b* with anhydrous formic acid (20) led directly to the protected dihydrothiazine **13***b*. That cyclization had taken place in the desired manner was immediately apparent from the observation of ^{1}Hmr coupling, through the C=N double bond, between the exocyclic methylene protons and H5.

Unfortunately, **13***b* was not stable, and decomposed completely within 1 day to acetic acid and the thiazine **19** (Scheme 3). This decomposition may proceed by 1,4-elimination of acetic acid from **13***b*, to form **20**, which tautomerizes to **19**. The alternative tautomerization, from **13***b* to **21**, could not be observed. However, the experiments summarized in Scheme 4 demonstrate that the latter process does occur. Lithium hydroxide hydrolysis of **14***b*, and remethylation, afforded **14***d*, which was silylated to **14***e*. The deprotection of **14***e* with formic acid did not proceed as with **14***b*; instead the product was the exocyclic enamine **22**, and not the dihydrothiazine **13***c*. Treatment of **14***d* with formic acid gave a complex reaction mixture from which no identifiable product could be isolated.

The imine tautomer is sometimes stable

The observations summarized so far seem to be consistent

a: R^1 = OH, R^2 = H
b: R^1 = AcO, R^2 = Me
c: R^1 = TBDPSO, R^2 = Me
d: R^1 = H, R^2 = Me
e: R^1 = H, R^2 = H
f: R^1 = H, R^2 = Na

with prior work (17): in the C2-unsubstituted system the endocyclic enamine is the preferred tautomeric structure; when this structure is blocked by the introduction of methyl groups, the relative stabilities of the imine and exocyclic enamine structures depend upon the nature of R^1 of **13**. This latter point was examined further with the deoxy compound **13***d*, prepared from the bromoketone **15** by thiolation, condensation with **18** as in Scheme 2, methylation, and deprotection with formic acid.

The imine structure **13***d* was readily identified by the 2.0 Hz coupling between H5 and the C3 methyl protons. Only this structure could be observed in pure chloroform solvent, and the compound appeared to be stable for at least several days. In one preparation, however, the chloroform was not pure, and **13***d* underwent complete rearrangement to the enamine tautomer **23***a* in 1 day (N-H at 5.20 Hz; C=CH_2 singlets at 4.59, 4.60 Hz).

A knowledge of the chemical shifts of **23***a* proved useful in the next set of experiments. Hydrolysis of **13***d* to the acid **13***e* was successful, using lithium hydroxide. Only the imine tautomer of the sodium salt **13***f* could be observed in D_2O solvent during a period of 3 days at room temperature. However, during this period, the C3 methyl protons underwent hydrogen–deuterium exchange. The solution of **13***f* was lyophilized at this point, and the compound was redissolved in H_2O. Because of the isotope effect, the original spectrum of **13***f* required 5 days to reappear fully. At no time during these experiments in D_2O and H_2O was any other compound (e.g., **23***b*) observable by nmr.

The simplest explanation of these observations is that the imine–enamine equilibrium **13***f* ⟶ **23***b* lies on the side of the imine tautomer in water, and this leads to the exchange of the methyl protons in a deuterated solvent.

Interaction of theory and synthesis: the 2-hydroxypropyl side chain

It was now clear that the desired ring system could be attained, and the imine tautomer maintained in water solvent. However, it was also clear that the molecule does not tolerate oxygen on the carbon atom adjacent to the C=N double bond. The hydroxyl group of **13***a* would therefore have to be repositioned. Replacement of the hydroxymethyl side chain of **13***a* by

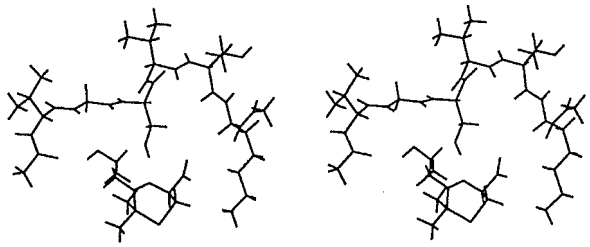

FIG. 15. Stereoscopic view showing one of the conformations of one of the stereoisomers of **26** docked to the penicillin receptor model.

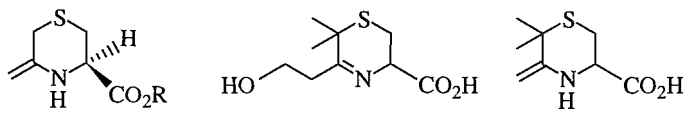
a hydroxyethyl side chain leads to **24**. However, this compound is, formally, the primary product of the reaction of the enamine **25** with formaldehyde, and was feared to be unstable with respect to the reverse of the latter process. The hydroxypropyl side chain (**26**) was, therefore, examined.

Figure 15 is a stereoscopic view of the structure obtained by docking **3** to one of the conformations of the 3**S**,8**R** isomer of **26** (21). This structure is compatible with the formal design requirement depicted in Fig. 13, and the synthesis of **26**, the cyclodehydration product of **27** ($R^1 = R^2 = H$), was undertaken.

Based on the preliminary studies already described, it was expected that **27** would be accessible from the reaction of the mercaptoketone **28** with **18**, and that **28** could be synthesized from the ketol **29**. If an olefin-to-ketol oxidation **30** → **29** could be achieved, the starting materials for the synthesis of **26** would then be 5-methyl-4-hexen-2-ol (**30**, R = H) and serine. Since the racemic bromide **31** was known from the work of Julia et al. (22), the first synthesis of **26** was directed towards the 3**R** and 3**S** isomers, starting with **31** and, respectively, L- and D-serine.

The bromide **31** was converted, via the acetate (**30**, R = OAc) and alcohol (**30**, R = OH), to the *tert*-butyldimethylsilyl (*t*-BDMS) compound (**30**, R = *t*-BDMS). As shown in Scheme 5, the key olefin-to-ketol transformation was accomplished



23

SCHEME 5

using potassium permanganate (23). Although the reaction conditions are rather special, this is a general reaction, which usually proceeds in 70–80% yield.[8]

The silylated ketol **29** (R = *t*-BDMS) was converted to the thiol **28** (R = *t*-BDMS), following activation as the mesylate and, as the lithium salt, **28** reacted with D- and L-**18** to produce the 2**S** and 2**R** isomers of **27** (R^1 = *t*-BDMS, R^2 = *t*-Boc) in over 80% yield.

In addition to **27** (R^1 = *t*-BDMS), the compounds **27** (R^1 = Ac) and **27** (R^1 = *tert*-butyldiphenylsilyl) were also synthesized. The latter two did not undergo clean removal of the *t*-Boc protecting group. Formic acid treatment of the acetate or trifluoroacetic acid treatment of the *tert*-butyldiphenylsilyl ether resulted in concomitant elimination of the C8 substituent of **27**. On the other hand, treatment of **27** (R^1 = *t*-BDMS) with formic acid led to the removal of both protecting groups, and cyclization to **26**.

The 3**R** and 3**S** epimers of **26**, synthesized separately from L- and D-serine, are not particularly stable. Figure 16 is the analytical chromatogram obtained, using an acetonitrile–water gradient with detection at 250 nm, for a sample of the amorphous sodium salt of 3**S**-**26**, after this had been maintained at 0°C for several weeks, or at room temperature for 1 day. The peak labelled D comprises ca. 45% of the mixture, and is also the initial product of the deprotection of **27**; the nmr and high-resolution mass spectra of D confirm structure **26**. Each of the peaks seen in Fig. 16 begins to reappear after several hours when the sodium salt of **26** is dissolved in water. The bioassay of **26** was, therefore, carried out as soon as possible after the isolation of the compound, and always within 1 day.

Bioassay of 26S and 26R: 26S is an antibacterial agent

The bioassay of **26S** and **26R** was carried out at 37°C using

[8]H. Jin and S. Wolfe. To be published. See also ref. 29.

TABLE 4. Inhibition of *S. aureus* by the thiazine **27**[a]

Amount (mg)	Zone of Inhibition (mm)
0.05	6.0
0.10	8.5
1.0	19
1.0	18

[a]Potassium penicillin V (0.10 μg) gives a 13 mm zone of inhibition.

4.0 mm filter discs, loaded with known weights of material, and placed on (*i*) *Sarcina lutea* seeded plates prepared by Mr. Dennis Muncey, Department of Microbiology, Queen's University; (*ii*) *Escherichia coli* seeded plates prepared by Dr. G.J. Delisle, Hotel Dieu Hospital, Kingston; (*iii*) penicillin sensitive *Staphylococcus aureus* plates prepared by Dr. J.A. Smith, Vancouver General Hospital.

The *R* isomer, synthesized from L-serine, did not exhibit activity against any of these organisms, in amounts up to 1000μg. At this level, the *S* isomer showed activity against all of the organisms. Direct comparisons with authentic antibiotics indicated that **26S** has 1/800 the activity of penicillin G versus *S. lutea*, and 1/10 the activity of cephalexin versus *E. coli*. As seen in Table 4, inhibition of *S. aureus* could be observed using 50 μg of **26S.**

Although the activity thus observed with the *S* isomer of **26** is extremely modest in comparison to that of penicillin G, as a lead structure representing the prototype of a designed antibacterial agent, **26S** is already comparable to a Δ^2-cephalosporin (10), which requires only one structural change (Δ^2 to Δ^3 isomerization) to become a useful antibiotic. Furthermore, the much lower activity of the *R* isomer of **26** suggests that **26S** is not a general bactericidal agent, but functions via a three-dimensional fit to a specific receptor. An understanding of the nature of this fit will require bioassay data for each of the four stereoisomers of **26**, and, eventually, kinetic studies of the reactions of these compounds with penicillin-recognizing enzymes. The syntheses and bioassays of the four stereoisomers of **26** are reported in an accompanying paper (21). However, because of its chemical instability, binding studies with **26** are not currently planned, unless systematic modification of the lead structure is unable to improve the stability.

Experimental

General experimental

All syntheses with sulfur-containing compounds were performed under dry nitrogen. Anhydrous magnesium sulfate was used routinely as a drying agent. Melting points were determined on a Fisher–Johns apparatus, and are uncorrected. Solvents were distilled before use and dried, as necessary, by literature procedures. Optical rotations were obtained on Perkin Elmer 141 or Rudolph Automatic polarimeters. Infrared (ir) spectra were recorded on a Perkin–Elmer 599B spectrometer. Nuclear magnetic resonance (nmr) spectra were run at 400 MHz on Bruker WM or Bruker AM spectrometers. High-resolution mass spectra refer to direct inlet EI measurements on a Kratos MS50 Spectrometer.

Analytical thin-layer chromatography was carried out on precoated Merck Silica Gel 60 F-254 plates with aluminium backing. Spots were observed under short-wavelength ultraviolet light, or were visualized with iodine vapour, ninhydrin, or ceric sulfate. Preparative layer chromatography (plc) was performed on Silica gel 60 F-254 precoated 20 × 20 cm plates (layer thickness 2mm) or, alternatively, glass plates were coated with a slurry of Macherey Nagel silica gel G-HR and calcium sulfate. Flash chromatography was carried out with 230–400 mesh Merck silica gel. The high-performance liquid chromatography (HPLC) system consisted of an M600 gradient module, U6K universal sample injector, 486 tunable absorbance detector, 170 sample loader, M746 data module, and fraction collector plus diverter valve, all from Waters. Analytical work was carried out using a 8 × 10 10-μm 125 Å μBondapak column. Preparative work was performed using a 25 × 10 10-μm 125 Å μBondapak column, with a loading of 25 mg per run. Acetonitrile and methanol for HPLC analyses were HPLC grade. Water for HPLC was collected through a Millipore purifier and degassed prior to use.

Elemental analyses are by M.K. Yang on a Carlo Erba model 1106 elemental analyzer at Simon Fraser University.

Theoretical

Ab initio molecular orbital calculations were carried out using GAUSSIAN 86 (24), GAUSSIAN 90 (25), or GAUSSIAN 92 (26). Semiempirical molecular orbital calculations were performed using AMPAC Version 2.1, kindly provided by Professor M.J.S. Dewar, or MOPAC Version 6.0 (27). Molecular mechanics calculations employed an extensively locally modified version of MMP2(85) (28). Docking of two molecules to form an intermolecular complex was accomplished as follows: first, preliminary MM2 calculations were carried out on these molecules to obtain, for predetermined conformations of each, their input data files. Then the numbering of the atoms that had been selected to engage in intermolecular hydrogen bond formation was determined. Next, the energy of the supermolecule created by these hydrogen bonds was minimized to produce an MM2 input file for the supermolecule. The docking of three molecules was carried out in two steps: in the first, the strategy just described was employed to dock two of the three molecules. Then the third molecule was added, using the appropriate numbers to identify the atoms engaging in the hydrogen bonds. Structures are drawn using a locally modified version of CHEMGRAF. We thank Dr. David Watkin, Oxford University, for a copy of the source code of this programme.

*Synthesis of the endocyclic enamine **10***

A solution of epichlorohydrin (10 mL) in water (10 mL) containing *p*-toluenesulfonic acid (50 mg) was refluxed for 9 h, cooled, neutralized by addition of sodium bicarbonate (22 mg), and distilled under reduced pressure. After removal of the water, 2-chloropropane-1,2-diol (9.3 g) was collected at 55°/2 Torr (1 Torr = 133.3 Pa). A solution of this diol (1.1 g, 10 mmol) in methylene chloride (10 mL) was cooled in an ice-bath, and treated successively with triethylamine (2.09 mL, 1.52 g, 15 mmol) and benzoyl chloride (1.16 mL, 1.40 g, 10 mmol). After 1 h, additional methylene chloride (10 mL) was added, and the solution was washed successively with water (2 × 10 mL), 0.1 N hydrochloric acid (2 × 10 mL), saturated sodium bicarbonate (1 × 10 mL), water (1 × 10 mL), and saturated sodium chloride (1 × 10 mL), dried, and evaporated. The crude monobenzoate (1.89 g, 8.8 mmol) was used directly in the next step. It was dissolved in methylene chloride (30 mL), and pyridinium chlorochromate (PCC) (9.5 g) was added in portions. The reaction mixture was stirred at room temperature for 6 h and additional PCC (5.0 g) was then added. Stirring was continued for 30 h. The mixture was then filtered, and after washing with methylene chloride (2 × 10 mL), the combined filtrates were washed successively with 0.5 N hydrochloric acid (2 × 10 mL), saturated sodium bicarbonate (2 × 10 mL), water (1 × 10 mL), and saturated sodium chloride (1 × 10 mL), dried, and evaporated. The residue was chromatographed on 5 g of silica gel. Successive elution with 10, 15, 25, and 50% ethyl acetate – hexane yielded 483 mg of the crystalline chloroketone **9** mp 94°C (lit. (18) mp 94°C).

To a solution of L-cysteine (12.1 mg, 0.1 mmol) in methanol (0.3 mL) were added consecutively triethylamine (28 μL, 0.2 mmol), dimethylformamide (DMF) (0.1 mL), and a solution of **9** (21.3 mg, 0.1 mmol) in DMF (0.2 mL). After 10 min, acetic acid (6 μL) was added, followed by ethereal diazomethane until the yellow colour per-

For personal use only.

sisted. After an additional 10 min, ethyl acetate (5 mL) was added, and the reaction mixture was washed successively with water (2 × 5 mL) and saturated sodium chloride (1 × 5 mL), dried, and concentrated to yield 26 mg of crude product. This was purified by plc (silica gel, methylene chloride:ethyl acetate:acetic acid, 1.2:0.8:0.1, one elution) to give 7 mg, (24%) of **10**, $[\alpha]_D^{25}$ 172 (*c* 5, MeOH); ^{1}Hmr ($CDCl_3$), δ: 8.06 (2H, d, 7 Hz), 7.59 (1H, t, 7 Hz), 7.48 (2H, t, 7 Hz), 6.06 (1H, br, N-H), 5.50 (1H, C═C-H), 4.96 (1H, d, 12 Hz, O-C-H), 4.89 (1H, d, 12 Hz, O-C-H), 4.53 1H, d, 12 Hz, N-C-H), 3.87 (3H, s, ester), 3.35 (1H, d, 12 Hz, S-C-H), 2.31 (1H, t, 12 Hz, S-C-H). Decoupling experiments established that the protons at δ 4.53 and 3.35 are not coupled.

In a second experiment, the methyl ester hydrochloride of L-serine (207 mg, 1.2 mmol), in methanol (2 mL), was cooled in an ice-bath and triethylamine (336 μL, 2.4 mmol) and a solution of **9** (256 mg, 1.2 mmol) in dimethylformamide (3.7 mL) were added. The clear solution was stirred for 35 min, and then concentrated under reduced pressure to remove most of the methanol. Methylene chloride (50 mL) was added, and the resulting solution was washed successively with saturated sodium bicarbonate (2 × 10 mL), water (2 × 10 mL), and saturated sodium chloride (1 × 10 mL), dried, and evaporated. The residue was chromatographed on silica gel (11 g); successive elution with 10, 15, 30, 40, 50, and 60% acetone–hexane afforded, in the latter eluate, 48 mg (14%) of **10**.

*Synthesis of the zwitterionic imine **12**b*

Ketene dimer (1.05 g, 12.5 mmol, purified by distillation at 48–54°C/90 Torr) was dissolved in carbon tetrachloride (8 mL), cooled in an ice-bath, and a solution of bromine (2.0 g, 12.5 mmol, freshly treated with concentrated sulfuric acid), in carbon tetrachloride (5 mL) was added dropwise. Stirring was continued for 5 min, and methanol (0.6 mL, 0.47 g, 14.8 mmol) was then added. After 10 min, the reaction mixture was washed with water until the aqueous washings were neutral (3 × 10 mL), and then successively with saturated sodium bicarbonate (1 × 10 mL), water (1 × 5 mL), and saturated sodium chloride (1 × 5 mL), dried, and concentrated to yield 1.95 g of the bromoacetoacetate **11**.

The methyl ester hydrochloride of L-serine (17.2 mg, 0.1 mmol), in methanol (0.1 mL), was cooled in an ice-bath, and **11** (19.5 mg, 0.1 mmol), in methanol (1.1 mL), was added. The solution was stirred, allowed to warm to room temperature, and, after 30 min, triethylamine (28 μL, 0.2 mmol) was added. After 10 h, the solvent was removed and the residue, in methylene chloride (15 mL), was washed successively with saturated sodium bicarbonate (1 × 5 mL), water (1 × 5 mL), and saturated sodium chloride (1 × 5 mL). The solvent was dried and evaporated, and the product purified by chromatography on a column containing 1.5 g of silica gel. Elution with 20% ethyl acetate–hexane afforded 10 mg (43%) of ***12b***; ^{1}Hmr ($CDCl_3$), δ: 9.00 (1H, br, N^+-H), 4.63 (1H, s, C═C-H), 4.27 (1H, dd, 4, 9 Hz, N-C-H), 3.82 (3H, s), 3.66 (3H, s), 3.36 (1H, d, 14 Hz, S-C-H), 3.29 (1H, dd, 4, 14 Hz, S-C-H), 3.17 (1H, d, 14 Hz, S-C-H), 3.02 (1H, dd, 9, 14 Hz, S-C-H).

*Synthesis of **14**b*

*A. Preparation of the thiol **17***

Methyl isopropyl ketone (15 mL, 140 mmol) was added to a solution of potassium chloride (1.1 g, 14.8 mmol) in water (9.6 mL). The mixture was stirred, warmed to 60°C, and illuminated with a 350-W tungsten lamp mounted beside the flask. Bromine (11.9 g, 74.4 mmol) was then added dropwise. When the colour of the first few drops had disappeared, the heating bath was replaced by a cold water bath, and the 350-W bulb was replaced by a 60-W bulb. Addition of bromine was continued at a rate sufficient to maintain the internal temperature at 40–45°C. When the addition was complete (25 min), the reaction mixture was allowed to stand for 2 h and the organic phase was then separated, washed with water – magnesium oxide, and dried over anhydrous calcium chloride. Fractional distillation afforded 7.0 g (30%) of **15**, bp 82–86°C/145 Torr; ^{1}Hmr ($CDCl_3$), δ: 2.36 (3H, s), 1.77 (6H, s).

The bromoketone **15** (4.65 g, 28 mmol) was dissolved in glacial acetic acid (40 mL), and freshly recrystallized lead tetraacetate (12.5 g, 28.2 mmol) was added. The mixture was heated at 100°C, with stirring, for 2 h and cooled to room temperature. Ethylene glycol (2 mL) was then added to destroy unreacted lead tetraacetate. The reaction mixture was diluted with ether (100 mL), washed successively with 10% sodium carbonate, water, and saturated sodium chloride, dried, and evaporated. The residue was distilled, and the fraction boiling at 57–60°C/120 Torr was further purified by chromatography (silica gel, 5% → 10% → 15% ether–hexane) to give the bromoketoacetate **16** (750 mg, 11%); ^{1}Hmr ($CDCl_3$), δ: 5.16 (2H, s), 2.13 (3H, s), 1.87 (6H, s).

Triethylamine (140 μL) was added to methylene chloride (3 mL). The solution was cooled to −20°C, and gaseous hydrogen sulfide was introduced during 10 min. Then the bromoketoacetate **16** (200 mg), in methylene chloride (1.0 mL), was added dropwise with stirring during 10 min. The yellow solution was diluted with methylene chloride (30 mL), washed successively with 2 N hydrochloric acid, water, and saturated sodium chloride, dried over anhydrous sodium sulfate, and evaporated to yield the mercaptoketoacetate **17** (145 mg, 96%); ^{1}Hmr ($CDCl_3$), δ: 5.16 (2H, s), 2.18 (3H, s), 1.57 (6H, s) 1.55 (1H, s).

*B. Preparation of the β-lactone **18***

To triphenylphosphine (258 mg, 0.98 mmol) in dry tetrahydrofuran (1.0 mL) was added dropwise with stirring at −78°C a solution of dimethylacetylenedicarboxylate (144 mg, 0.99 mmol) in tetrahydrofuran (1.0 mL). The white slurry was maintained at −78°C for 10 min, and a solution of Boc-L-serine (184 mg, 0.90 mmol) in tetrahydrofuran (1.0 mL) was added dropwise. The temperature was maintained at −78°C for 20 min and the reaction mixture was then allowed to warm to room temperature (2 h). The solvent was removed and the residue was chromatographed on silica gel. Elution with 15% → 22% → 30% → 35% ethyl acetate – hexane afforded the β-lactone **L-18**. ^{1}Hmr ($CDCl_3$), δ: 5.29 (1H, br), 4.92 (1H, br), 4.34 (2H, br), 9.07 (9H, s). Anal. calcd. for $C_8H_{13}NO_4$: C 51.33, H 6.99, N 7.48; found: C 51.59, H 7.05, N 7.62.

*C. Reaction of **17** with **18***

To a solution of **17** (79.6 mg, 0.45 mmol) in dry degassed dimethylformamide (1.5 mL) was added dropwise a solution of lithium diisopropylamide (0.8 mmol) in tetrahydrofuran (1.5 mL). The addition was carried out under nitrogen at −60°C. The reaction mixture was allowed to warm to −25°C during 50 min, cooled again to −55°C, and a solution of **18** (56.4 mg, 0.30 mmol) in dry degassed dimethylformamide (0.5 mL) was added dropwise. When the addition was complete, the mixture was warmed to −20°C, stirred for 25 min, and then diluted with ethyl acetate (30 mL) and washed with 0.5 N hydrochloric acid (2 mL). The aqueous layer was extracted with ethyl acetate (2 × 10 mL) and the combined organic extracts were washed with water (2 × 5 mL) and saturated sodium chloride (1 × 5 mL), dried, and evaporated. The oily residue was purified by preparative layer chromatography on a 10 × 20 cm plate coated with silica gel, using methylene chloride:ethyl acetate:acetic acid (1.7:0.3:0.05) as eluant to give ***14c*** (77 mg, 70%); ^{1}Hmr ($CDCl_3$), δ: 5.43 (1H, br), 5.20 (1H, d, 18 Hz), 5.04 (1H, d, 18 Hz), 4.46 (1H, br), 2.97 (1H, br), 2.78, 2.74 (1H, dd, 4.5, 9.0 Hz), 2.17 (3H, s), 1.48 (3H, s), 1.47 (3H, s), 1.44 (9H, s).

The acid ***14c*** (77 mg) was dissolved in methylene chloride (10 mL) and treated at 0°C with an ethereal solution of diazomethane. The solvent was removed and the residue was purified on a 5 × 10 cm silica gel plate using hexane:ethyl acetate (1.4:0.6) as eluant to give the ester ***14b*** (48.2 mg); ^{1}Hmr ($CDCl_3$), δ: 5.32 (1H, br d, N-H), 5.15 (1H, d, 11 Hz, O-C-H), 5.07 (1H, d, 11 Hz, O-C-H), 4.48 (1H, br q, N-C-H), 3.76 (3H, s,ester), 2.91 (1H, dd, 4, 12 Hz, S-C-H), 2.74 (1H, dd, 5.5, 12 Hz, S-C-H), 2.17 (3H, s, Ac), 1.48 (3H, s, C-Me), 1.47 (3H, s, C-Me), 1.44 (9H, s, *t*-Boc).

*Deprotection and cyclization of **14**b. Formation of **13**b and **19***

The methyl ester acetate ***14b*** (3.7 mg) was treated at room temperature with anhydrous formic acid (0.2 mL). After 10 min, the solution was frozen and the solvent removed by lyophilization to give ***13b***;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by ESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

^{1}Hmr ($CDCl_3$), δ: 4.82 (1H, q, 1.8, 14.3 Hz, O-C-H coupled to O-C-H and N-C-H), 4.71 (1H, q, 2.4, 14.3 Hz, O-C-H coupled to O-C-H and N-C-H), 4.56 (1H, td, 1.8, 2.4, 7.8 Hz, N-CH), 3.79 (3H, s, ester), 2.94 (2H, d, 7.8 Hz), 2.14 (3H, s, Ac), 1.36 (6H, s, C-Me). During a period of 24 h, the spectrum of **13***b* gradually disappeared, and the spectra of **19** and acetic acid (2.09 ppm) appeared; ^{1}Hmr of **19** ($CDCl_3$), δ: 7.29 (1H, q, S-C-H coupled to C═C-Me), 3.86 (3H, s, ester), 2.29 (3H, d, N═C-Me), 1.36 (6H, s, C-Me).

*Conversion of **14**b to the exocyclic enamine **22***

The ester **14***b* (46 mg), in tetrahydrofuran (1 mL), was treated at room temperature with 0.25 M lithium hydroxide (0.4 mL). After 25 min an additional 0.4 mL of lithium hydroxide was added. The mixture was stirred for 35 min and then diluted with ethyl acetate (10 mL) and washed with 0.5 N hydrochloric acid (2 × 5 mL). The aqueous layer was extracted with ethyl acetate (2 × 5 mL) and the combined organic extracts were washed with water (1 × 5 mL), followed by saturated sodium chloride (1 × 5 mL), dried, and evaporated. The residue was dissolved in the minimum of methylene chloride, treated with ethereal diazomethane, concentrated, and the residue was purified on a 10 × 20 cm silica gel plate. Elution with hexane:ethyl acetate (1.4:0.6) gave **14***d* (14.4 mg); ^{1}Hmr ($CDCl_3$), δ: 5.22 (1H, br), 4.58 (2H, d), 4.48 (1H, br), 3.75 (3H, s), 3.06 (1H, br), 2.92 (1H, br), 2.74 (1H, dd, 5, 11 Hz), 1.46 (9H, s), 1.44 (6H, s).

To a solution of **14***d* (5 mg, 0.015 mmol) in freshly dried pyridine (0.2 mL) were added successively silver nitrate (3.4 mg, 0.02 mmol) and *tert*-butyldiphenylchlorosilane (6.3 mg, 0.023 mmol). The solution was stirred for 15 min at room temperature. The solvent was then removed and the product was purified by preparative layer chromatography to give **14***e* (5.5 mg); ^{1}Hmr ($CDCl_3$), δ: 7.69 (4H, m), 7.41 (6H, m), 5.07 (1 H, br), 4.70 (2H, s), 4.41 (1H, br), 3.72 (3H, s), 2.70 (1H, dd, 6, 15 Hz), 2.55 (1H, dd, 6, 15 Hz), 1.43 (9H, s), 1.28 (3H, s), 1.26 (3H, s), 1.10 (9H, s).

The silylated ester **14***e* (5 mg) was treated at room temperature with formic acid (0.2 mL). After 33 min the reaction mixture was frozen and the solvent was removed by lyophilization to yield the enamine **22**. ^{1}Hmr ($CDCl_3$), δ: 8.31 (1H, br, N-H), 7.69 (4H, m, Ar), 7.40 (6H, m, Ar), 5.90 (1H, s, C═C-H) 4.65 (1H, br, N-C-H), 3.79 (3H, s, ester), 3.17 (1H, dd, 10, 15 Hz, S-C-H), 3.00 (1H, dd, 3, 15 Hz, S-C-H), 1.49 (3H, s, C-Me), 1.31 (3H, s, C-Me), 1.08 (9H, s, *t*-Bu).

*Synthesis of the deoxythiazine **13**d*

To methylene chloride (3 mL), saturated with hydrogen sulfide, were added successively at −20°C triethylamine (0.33 mL, 0.24 g, 2.36 mmol) and the bromoketone **15** (330 mg, 2.0 mmol). The reaction was complete in 10 min, and the thiol (101 mg) was isolated as described above for **17**, and used directly in the next step.

To the thiol (38 mg, 0.32 mmol), in dimethylformamide (1 mL), was added dropwise at −55°C 1.0 mL of a 0.64 M solution of lithium diisopropylamide in tetrahydrofuran. The temperature was allowed to rise to −20°C during 45 min, then lowered again to −55°C, and **18** (30 mg, 0.16 mmol), in dimethylformamide (0.4 mL), was added. Stirring was continued at −20°C for 25 min, and the reaction mixture was then worked up as described above for **14***c*. The product was purified by plc (silica gel, 0.5 mm thickness, 10 × 20 cm plate, methylene chloride: ethyl acetate:acetic acid 1.7:0.3:0.05, one elution), to give 43.5 mg (89%) of the cysteine derivative Me-CO-C(Me)$_2$-S-CH$_2$-CH(NHBoc)-CO_2H.

This acid (20 mg), in methylene chloride (0.5 mL), was treated with ethereal diazomethane. The reaction was instantaneous. The solvent was removed and the residue purified by plc (silica gel, 10 × 20 cm, hexane – ethyl acetate 1.4:0.6, one elution) to give the methyl ester (18 mg); ^{1}Hmr ($CDCl_3$), δ: 5.19 (1H, d, 4 Hz, N-H), 4.48 (1H, br, N-C-H), 3.73 (3H, s, ester), 2.82 (1H, dd, 5, 16 Hz, S-C-H), 2.73 (1H, dd, 7, 16 Hz), 2.26 (3H, s, Me-CO), 1.41 (9H, s, Boc), 1.39 (6H, s, C-Me).

The methyl ester (14 mg) was dissolved in anhydrous formic acid (0.4 mL) and the solution was maintained at room temperature for 50 min. The solvent was then removed by lyophilization, and the product was purified by plc (alumina, 10 × 20 cm, methylene chloride:ethyl acetate 0.8:1.2, two elutions) to give the thiazine **13***d*; ^{1}Hmr ($CDCl_3$), δ: 4.48 (1H, ddq, 2.0, 5.0, 8.8 Hz, N-C-H coupled to S-C-H, S-C-H, and N═C-Me), 3.81 (3H, s, ester), 2.88 (1H, dd, 5.0, 14.2 Hz, S-C-H), 2.94 (1H, dd, 8.8, 14.2 Hz), 2.10 (1H, d, 2.0 Hz, N═C-Me coupled to N-C-H), 1.52 (3H, s, CMe), 1.47 (3H, s, C-Me).

The thiazine **13***d* was relatively stable. However, one $CDCl_3$ solution underwent isomerization to the enamine **23***a*; ^{1}Hmr, δ: 5.20 (1H, br s, N-H), 4.60 (1H, s, C═C-H), 4.59 (1H, s, C═C-H), 4.51 (1H, m), 3.77 (3H, s, ester), 2.94 (1H, dd, 5.0, 13 Hz), 2.77 (1H, dd, 5.8, 13 Hz), 1.47 (3H, s, C-Me), 1.46 (3H, s, CMe).

*Hydrolysis of **13**d*

The methyl ester (1.3 mg, 0.0055 mmol) was treated at 0°C with methanol (0.2 mL) and 0.5 M lithium hydroxide (80 μL). After 20 min, 1 M sulfuric acid (17.25 μL) was added, the methanol was removed under reduced pressure, and the remaining solvent was removed by lyophilization. For nmr studies the residue was dissolved in 0.6 mL of a solution prepared from 4 mg of sodium bicarbonate and 1.0 mL of D_2O; ^{1}Hmr of **13***f* (D_2O), δ: 4.12 (1H, br), 2.87 (1H, q, 4.9, 14 Hz), 2.78 (1H, q, 7.3, 14 Hz), 1.95(3H, br, exchanges), 1.37 (3H, s), 1.35 (3H, s).

*Synthesis of **26**. Biologically active series*

*A. Synthesis of the bromide **31***

A solution of ethyl 2-methylcyclopropanecarboxylate (5.0 g, 38.9 mmol) in dry ether (5 mL) was added dropwise, with stirring under nitrogen, to the Grignard reagent prepared from magnesium turnings (1.935 g, 0.080 g-atom) and methyl iodide (12.43 g, 87.6 mmol) in dry ether (42 mL). The addition required 30 min; stirring was continued for 2.75 h at room temperature and then for 2 h under reflux. The reaction mixture was cooled in an icebath and saturated ammonium chloride (10 mL) was added, with stirring. The layers were separated and the aqueous layer was extracted with ether (2 × 20 mL). The combined organic phase was dried, evaporated, and the residue distilled at 132–136°C to give the tertiary alcohol product (4.24 g, 95%).

To this alcohol (4.24 g, 37 mmol), cooled in an ice-bath, was added ice-cold 48% hydrobromic acid (15 mL). The mixture was shaken vigorously in the ice-bath for 30 min. The two layers were then separated, the aqueous layer extracted with hexane (2 × 20 mL), and the combined organic phase was washed successively with saturated bicarbonate (2 × 10 mL), water (2 × 10 mL), and saturated sodium chloride (2 × 10 mL), dried over anhydrous sodium sulfate, and evaporated. Distillation afforded 3.72 g (60%) of the bromide **31**, bp 46–54°C/10 Torr; ^{1}Hmr ($CDCl_3$) δ: 5.18 (1H, br t), 4.11 (1H, q), 2.59 (1H, m), 2.51 (1H, m), 1.72 (3H, s), 1.68 (3H, d, 8 Hz), 1.62 (3H, s).

*B. Conversion of **31** to **30** (R = Ac)*

To a solution of the bromide **31** (3.72 g, 21 mmol) in glacial acetic acid (20 mL) was added potassium acetate (3.1 g, 31.6 mmol). The mixture was heated under reflux for 12 h, cooled, and poured into water (30 mL). Extraction with ether (3 × 30 mL), followed by successive washing of the organic phase with saturated sodium carbonate, water, and saturated sodium chloride, drying, and evaporation at room temperature yielded the acetate 2.82 g (85%); ^{1}Hmr ($CDCl_3$), δ: 5.10 (1H, br t), 4.88 (1H, q, 6 Hz), 2.30 (1H, m), 2.19 (1H, m), 2.02 (3H, s), 1.71 (3H, br s), 1.62 (3H, br s), 1.20 (3H, d, 6 Hz).

C. Hydrolysis of the acetate

The acetate (320 mg, 2.05 mmol) was dissolved in methanol (2 mL) and treated dropwise with a 1.5 M solution of potassium hydroxide in methanol (1.38 mL). The reaction mixture was allowed to stand for 6 h and was then neutralized with 1.5 M methanolic hydrogen chloride, and the solvent was removed. The residue was dissolved in methylene chloride, and this solution was washed successively with water and saturated sodium chloride, dried, and evaporated to give the alcohol **30**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

(R = H) (208 mg, 99%); ^{1}Hmr ($CDCl_3$) δ: 5.14 (1H, tq, 1.5, 8 Hz), 3.79 (1H, sextet, 6 Hz), 2.16 (2H, br t, 7.5 Hz), 1.72 (3H, br s), 1.63 (3H, br s), 1.18 (3H, d, 6 Hz).

D. tert-*Butyldimethylsilylation of the alcohol* ***30*** *(R = H)*

The alcohol (312 mg, 2.73 mmol) was dissolved in dimethylformamide (2 mL) and to this solution were added successively *tert*-butyldimethylchlorosilane (535 mg, 3.55 mmol), pyridine (0.29 mL, 284 mg, 3.59 mmol), and silver nitrate (603 mg, 3.55 mmol). The mixture was stirred for 2 h and then filtered. The insoluble material was triturated with ether (20 mL) and the combined organic material was washed successively with saturated sodium bicarbonate, water, and saturated sodium chloride, dried, and evaporated to give the silylated compound **30** (R = *t*-BDMS) (620 mg, 100%); ^{1}Hmr ($CDCl_3$), δ: 5.13 (1H, br t), 3.77 (1H, m), 2.17 (1H, m), 2.08 (1H, m), 1.69 (3H, br s), 1.60 (3H, br s), 1.11 (3H, d, 6.1 Hz), 0.88 (9H, s), 0.05 (3H, s), 0.03 (3H, s).

E. Permanganate oxidation of the silylated alcohol. Preparation of the ketol ***29*** *(R = t-BDMS)*

The olefin **30** (R = *t*-BDMS) (624 mg, 2.73 mmol) was dissolved in acetone (3 mL) and 18-crown-6 (100 mg, 0.27 mmol) and acetic acid (0.16 mL) were added successively followed, dropwise, by a solution of potassium permanganate (603 mg, 3.82 mmol) in water (7.5 mL). The mixture was stirred for 1 h and then diluted with methylene chloride (50 mL). The organic phase was washed successively with 20% sodium bisulfite, 0.5 N hydrochloric acid, saturated sodium bicarbonate, water, and saturated sodium chloride, dried, and evaporated. The residue was subjected to flash chromatography on silica gel (7 g). Elution with 4 → 15% ethyl acetate – hexane gave 479 mg (70%) of **29** (R = *t*-BDMS); ^{1}Hmr ($CDCl_3$), δ: 4.42 (1H, m), 3.95 (1H, s), 2.83 (1H, dd, 7.6, 16.0 Hz), 2.47 (1H, dd, 4.8, 16.0 Hz), 1.34 (3H, s), 1.33 (3H, s), 1.18 (3H, d, 6.1 Hz), 0.84 (9H, s), 0.06 (3H, s), 0.02 (3H, s). Mass spectrum (CI, isobutane, *m/e*): 261 (M + 1). Anal. calcd. for $C_{13}H_{28}O_3Si$: C 59.95, H 10.84; found: C 59.78, H 10.99.

F. Mesylation of ***29*** *(R = t-BDMS)*

To a solution of the ketol (478 mg, 1.83 mmol) in methylene chloride (6 mL) were added successively triethylamine (0.76 mL, 4.0 mmol) and methanesulfonyl chloride (0.24 mL, 3.1 mmol). The reaction mixture was stirred for 5 h at room temperature and then diluted with methylene chloride (80 mL). The solution was washed successively with water, 0.5 N hydrochloric acid, saturated sodium bicarbonate, water, and saturated sodium chloride, dried, and evaporated. Flash chromatography on silica gel (3 g) and elution with 7% → 8% → 9% → 10% ethyl acetate – hexane gave the mesylate Me-CH(O*t*BDMS)-CH_2-CO-CH(Me)$_2$-OSO_2CH_3 (432 mg, 70%); ^{1}Hmr ($CDCl_3$), δ: 4.40 (1H, m), 3.11 (3H, s), 2.94 (1H, dd, 7.5, 17.3 Hz), 2.59 (1H, dd, 4.6, 17.3 Hz), 1.68 (3H, s), 1.63 (3H, s), 1.18 (3H, d, 6.1 Hz), 0.84 (9H, s), 0.07 (3H, s), 0.02 (3H, s).

G. Synthesis of the thiol ***28*** *(R = t-BDMS)*

Methylene chloride (5 mL) was saturated with hydrogen sulfide at −20°C, and triethylamine (0.14 mL, 1 mmol) and a solution of the above mesylate (233 mg, 0.5 mmol) were added successively. The solution was stirred for 10 min at −20°C and for 45 min at −20° to 0°C, and was then diluted with methylene chloride (30 mL), washed successively with 0.5 N hydrochloric acid, water, and saturated sodium chloride, dried, and evaporated to give, after drying at 0.1 Torr, the silylated mercaptan **28** (R = *t*-BDMS) (170 mg, 85%); ^{1}Hmr ($CDCl_3$), δ: 4.37 (1H, m), 2.98 (1H, dd, 5, 11 Hz), 2.63 (1H, dd, 4, 11 Hz), 1.98 (1H, s), 1.49 (3H, s), 1.48 (3H, s), 1.17 (3H, d, 6 Hz), 0.84 (9H, s), 0.05 (3H, s), 0.01 (3H, s). Mass spectrum (CI, *m/e*): 277 (M^+). Anal. calcd. for $C_{13}H_{28}O_2SSi$: C 56.47, H 10.21; found: C 56.25, H 10.07.

H. Coupling of the thiol ***28*** *(R = t-BDMS) with* ***D-18****: 27 (R^1 = t-BDMS, R^2 = Boc)*

Under nitrogen, the mercaptan **28** (100 mg, 0.36 mmol) was dissolved in degassed dimethylformamide (1.0 mL). The solution was cooled to −55°C and treated with 0.46 mL of a solution of lithium diisopropylamide prepared from *n*-butyllithium (0.8 mL of a 1.6 M hexane solution) and diisopropylamide (0.36 mL, 0.259 g, 2.56 mmol) in degassed tetrahydrofuran (0.8 mL). The reaction mixture was stirred at −45°C for 30 min, and a solution of the β-lactone **D-18** (56.8 mg, 0.30 mmol) in degassed dimethylformamide (0.8 mL) was added. The mixture was stirred at −30°C for 20 min, then diluted with methylene chloride (10 mL), and washed with 0.5 N hydrochloric acid. The aqueous layer was extracted with methylene chloride (2 × 5 mL) and the combined organic extracts were washed with water, then saturated sodium chloride, dried, and evaporated. The residue was dried under high vacuum and purified by flash chromatography (silica gel, 4 g; 0% → 8% ethyl acetate – methylene chloride (1% acetic acid)) to give the coupled product **27** (R^1 = *t*-BDMS, R^2 = Boc) having the *S* configuration at C2 in 89% yield; ^{1}Hmr ($CDCl_3$), δ (one isomer): 5.28 (1H, br t), 4.48 (1H, br), 4.32 (1H, m), 2.83, 2.71 (2H, m), 2.71, 2.62 (2H, m), 1.44 (6H, s), 1.16 (3H, d, 6 Hz), 0.85 (9H, s), 0.05 (3H, s), 0.00 (3H, s). The nmr spectrum shows a 1:1 mixture of epimers in the 2-hydroxypropyl side chain. Anal. calcd. for $C_{21}H_{41}NO_6SSi$: C 54.40, H 8.91, N 3.02; found: C 54.16, H 8.72, N 2.96.

I. Formation and characterization of 3S- ***26***

To **27** (R^1 = *t*-BDMS, R^2 = Boc) (22.7 mg, 0.049 mmol) was added formic acid (0.3 mL). The solution was shaken for 20 min at room temperature and the solvent was then removed by lyophilization. The residue was dissolved in a mixture of ether (3 mL) and water (1 mL). The ether phase was extracted with water (1 mL), and the combined aqueous phase was neutralized with 5% sodium bicarbonate and lyophilized to give **26** (5 mg, 40%) as a mixture of epimers in the 2-hydroxypropyl side chain; ir (KBr, cm^{-1}): 3422 (OH), 1696 (C=O), 1636 (C=N); ^{1}Hmr (D_2O), δ: 4.23 (1H, m), 3.80 (1H, m), 3.30 (1H, q), 2.70–2.85 (3H, m), 1.40 (6H, s), 1.15 (3H, d). High-resolution mass spectrum (*m/e*): 231.0924 (M^+), 213.0823 (M − H_2O).

Synthesis of the stereoisomers of a novel antibacterial agent and interpretation of their relative activities in terms of a theoretical model of the penicillin receptor

SAUL WOLFE,[1] CAIJUN ZHANG, BLAIR D. JOHNSTON, AND CHAN-KYUNG KIM
Department of Chemistry, Simon Fraser University, Burnaby, BC V5A 1S6, Canada

Received August 25, 1993

SAUL WOLFE, CAIJUN ZHANG, BLAIR D. JOHNSTON, and CHAN-KYUNG KIM. Can. J. Chem. **72**, 1066 (1994).

2,2-Dimethyl-3-(2′-hydroxypropyl)-5-carboxy-Δ^3-1,4-thiazine (**1**) is a designed antibacterial agent. Based on an analysis of how penicillin complexes to and reacts with a model of a penicillin-binding protein, **1** contains a functional group (C═N) that can react with a serine hydroxyl group of the receptor according to the putative reaction Enz-OH + C═N → Enz-O-C-NH. Compound **1** also contains additional substituents that are designed to position the O-H and C═N groups relative to one another in the enzyme–substrate complex in a geometry that attempts to reproduce the optimum geometry of approach of two such reactants. A most important assumption is that this optimum geometry can be computed ab initio. In a first preparation of **1**, (±)-5-methyl-4-hexene-2-ol (**2**) was converted to the lithium salt of (±)-2-mercapto-2-methyl-5-*tert*-butyldimethylsiloxy-3- hexanone (**7**), which was condensed with the *N*-*tert*-butoxycarbonyl-D- and L-serine-β-lactones (**3**). The synthesis was completed by deprotection with formic acid and cyclization in water. The *R* and *S* enantiomers of **2** have now been obtained, and the absolute configuration of the alcohol established, by reaction of the *R*- and *S*-propylene oxides with an organometallic reagent prepared from β,β-dimethylvinyl bromide. The *R* alcohol has also been secured by lipase-catalyzed transesterification with trifluoroethyl butyrate, and chemical hydrolysis of the trifluoroethyl ester. The *R* and *S* enantiomers of **2** were converted to the *R* and *S* enantiomers of **7**, and these were condensed with the *R* and *S* enantiomers of **3** to yield each of the stereoisomers of the chemically unstable **1** in ca. 95% optically pure form. Antibacterial activity resides in the 5*S*,8*R* and 5*S*,8*S* isomers. These findings are shown to be consistent with the theoretical model. It is hoped that the stability of the lead structure **1** can be improved, to allow binding experiments with penicillin recognizing enzymes to proceed.

SAUL WOLFE, CAIJUN ZHANG, BLAIR D. JOHNSTON et CHAN-KYUNG KIM. Can. J. Chem. **72**, 1066 (1994).

La 2,2-diméthyl-3-(2′-hydroxypropyl)-5-carboxy-Δ^3-1,4-thiazine (**1**) devrait être une agent antibactérien. Sur la base d'une analyse du mécanisme de complexation et de réaction de la pénicilline avec un modèle d'une protéine se liant à la pénicilline, **1** contient un groupe fonctionnel (C═N) qui peut réagir avec un groupe hydroxyle de la sérine du récepteur suivant la réaction Enz-OH + C═N → Enz-O-C-NH. Le composé **1** contient aussi des substituants additionnels choisis pour orienter les groupes O-H et C═N l'un par rapport à l'autre dans le complexe enzyme–substrat dans une géométrie qui essaye de reproduire la géométrie optimale de l'approche de deux tels réactants. Une hypothèse très importante est que cette géométrie optimale peut être calculée ab initio. Dans une première préparation du composé **1**, on a transformé le (±)-5-méthyl-hex-4-èn-2-ol (**2**) en sel de lithium de la (±)-2-mercapto-2-méthyl-5-*tert*-butyldiméthylsiloxyhexan-3-one (**7**) qui a été condensée avec les *N*-*tert*-butoxycarbonyl-D- et L-sérine-β-lactones (**3**). On a complété la synthèse par une déprotection à l'aide d'acide formique et une cyclisation dans l'eau. On a maintenant obtenu les énantiomères *R* et *S* du composé **2** et on a déterminé la configuration absolue de l'alcool par réaction avec les oxydes de propylène *R* et *S* avec un réactif organométallique préparé à partir du bromure de β,β-diméthylvinyle. On a aussi préparé l'alcool *R* par une transestérification catalysée par la lipase avec du butyrate de trifluoroéthyle, suivi d'une hydrolyse chimique de l'ester trifluoroéthyle. On a transformé les énantiomères *R* et *S* du composé **2** en énantiomères *R* et *S* du composé **7** et on a condensé ces derniers avec les *R* et *S* du composé **3** pour obtenir chacun des stéréoisomères du produit **1** (qui est chimiquement instable) sous des formes qui sont environ 95% optiquement pures. On retrouve de l'activité antibactérienne avec les isomères 5*S*,8*R* et 5*S*,8*S*. On montre que ces résultats sont en accord avec le modèle théorique. On espère, dans le but de permettre des études de liaison avec des enzymes qui reconnaissent la pénicilline, qu'il sera possible d'augmenter la stabilité de la structure **1**.

[Traduit par la Rédaction]

Introduction

β-Lactam antibiotics act on their target enzymes (penicillin-binding proteins, PBP's) by acylation of the hydroxyl group of an active site serine residue (1). The reaction is believed to proceed within a complex in which the hydroxyl group and a water molecule are properly positioned for attack on the N—C bond of the β-lactam N-C═O (2). The necessary geometry is achieved by hydrogen bonding of the carboxyl group (G_1) and side-chain N-H (G_2) of the antibiotic to complementary amino and carbonyl groups of the PBP (3).

We have proposed (4) that the N═C bond of an imine is bioisosteric to the N—C bond of the β-lactam group, and comparable to a β-lactam in its bioreactivity towards a hydroxyl group. A compound intended to fit to, and react with, the penicillin receptor in the same manner as penicillin itself might, therefore, contain an imine group properly positioned with respect to a G_1 and a G_2. A reconciliation of these structural requirements with the chemical properties of dihydrothiazines suggested compound **1** as an example of a designed antibacterial agent. As summarized in Scheme 1 (4), the synthesis of **1** was accomplished starting with the racemic alcohol **2**, prepared by a literature route from ethyl 2-methylcyclopropanecarboxylate (5), and the chiral lactones **3**, prepared by a literature route from D- and L-serine (6). The compound having stereostructure **1***a*, derived from D-serine, is an antibacterial agent; the isomer **1***b* is not active.

In the present work, new syntheses of **2** and of its *R* and *S* enantiomers, as well as an enzymatic resolution of **2**, have been carried out, and the strategy of Scheme 1 has then been followed to produce each of the four stereoisomers of **1**. Although these compounds are chemically unstable, the activity of the **1***a*

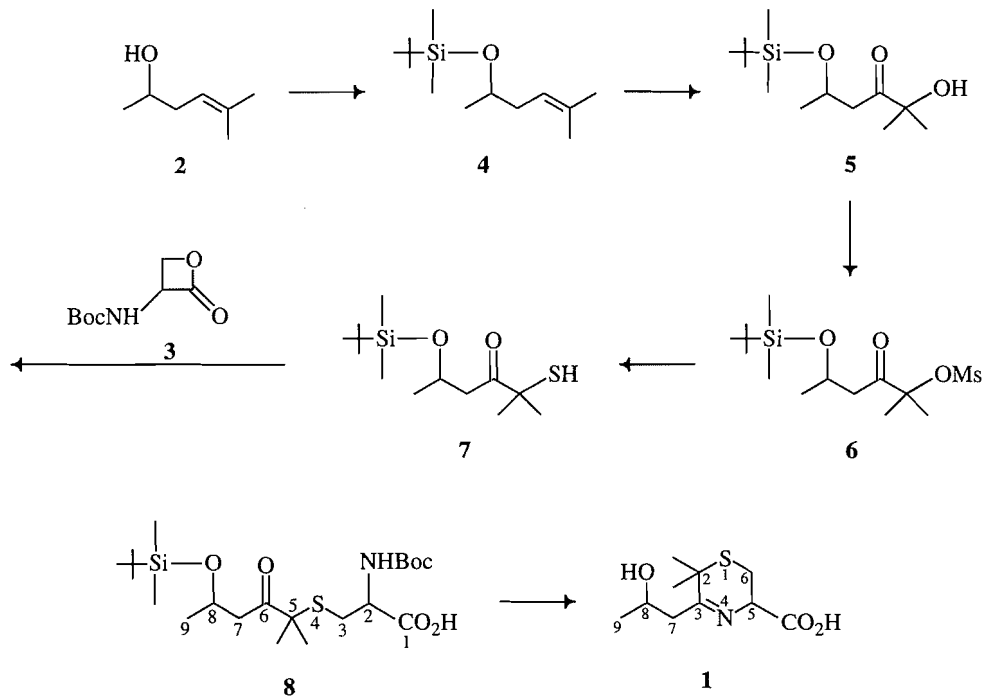


SCHEME 1

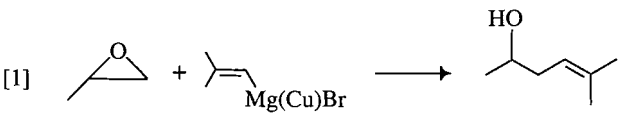
1*a* **1***b*

stereostructure has been confirmed, and it has been found that the hydroxypropyl side-chain epimers have the same activity. Analysis of these observations has led to new insights into the meaning of "fit," as applied to an enzyme–substrate complex, a definition of "fit," and a relationship between a biological property (antibacterial activity) and the "fits" exhibited by different stereoisomers.

Results and discussion

Syntheses

The addition of racemic propylene oxide (**9**) to the organometallic reagent **10**, prepared from β,β-dimethylvinyl bromide (7) by successive treatment with magnesium and then cuprous iodide (8), afforded the racemic alcohol **2** in 80% yield (eq. [1]).

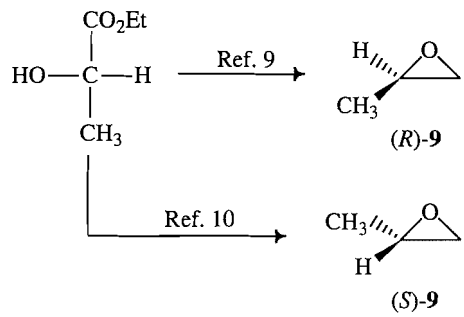


[1]

9 **10** **2**

The *R* and *S* enantiomers of **2** were, therefore, accessible from the *R* and *S* enantiomers of propylene oxide. These were prepared from ethyl L-lactate by (*a*) tosylation, reduction with borane – dimethyl sulfide, and treatment with base to obtain *R*-propylene oxide, $[\alpha]_D^{23}$ +7.32 (*c* 2.5, CH_2Cl_2) (9); or (*b*) reduction with lithium aluminium hydride, reaction with 45% hydrogen bromide in acetic acid, and treatment with base to obtain *S*-propylene oxide, $[\alpha]_D^{20}$ −7.57 (*c* 1.6, CH_2Cl_2) (10) (Scheme 2).

The reaction of the *R*-epoxide with **10** gave *R*-**2**, $[\alpha]_D^{21}$ −11.74 (*c* 3.15, CH_2Cl_2); *p*-nitrobenzoate: $[\alpha]_D^{21}$ −31.5 (*c* 1.3, CH_2Cl_2). The *S*-epoxide reacted analogously to give *S*-**2**, $[\alpha]_D^{21}$ +11.75 (*c* 1.6, CH_2Cl_2); *p*-nitrobenzoate: $[\alpha]_D^{21}$ +31.90 (*c* 0.94, CH_2Cl_2).



SCHEME 2

Alternatively, trifluoroethyl butyrate and the racemic alcohol **2** were stirred in ether with porcine pancreatic lipase (11) until 50% conversion to the *n*-butyl ester of **2** had occurred (Scheme 3). The unreacted alcohol recovered from the kinetic resolution at this stage was the expected (11) *S* enantiomer, $[\alpha]_D^{21}$ +9.2 (*c* 2.1, CH_2Cl_2). Hydrolysis of the *R* ester gave *R*-**2** of high optical purity, $[\alpha]_D^{21}$ −11.95 (*c* 2.0, CH_2Cl_2).

Racemic **2** and the optically active alcohols prepared by the epoxide route and by kinetic resolution were then converted to their Mosher esters (12) by reaction with the acid chloride (13) of *R*-(+)-α-methoxy-α-(trifluoromethyl)-phenylacetic acid (MTPA). Examination of the ^{19}F and ^1Hmr spectra of the various **2**-MTPA esters indicated that optical purities were best determined by integration of the methyl doublets of the Me-CHX- moiety at δ =1.258 (*R* epimer) and 1.326 (*S* epimer) in the ^1Hmr spectrum. Except for the *S* alcohol from the kinetic resolution, all optically active samples of **2** exhibited >97% enantiomeric excess (ee). The syntheses of the stereoisomers of **1** were therefore continued using *S*-**2** from the epoxide route,

TABLE 1. Rotations ($[\alpha]_D$, degrees) of the enantiomers of **2–7** (Scheme 1)[a]

Compound	Isomer	Rotation
2	**R**	−11.74
	S	+11.75
3	**R**	+10.91
	S	−10.81
4	**R**	−5.04
	S	+5.04
5	**R**	−32.0
	S	+32.2
6	**R**	−10.1
	S	+10.6
7	**R**	−33.5
	S	+33.3

[a]All rotations are in CH_2Cl_2.

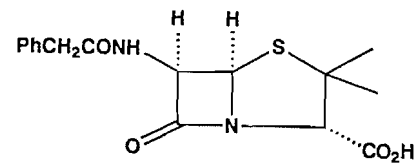
R-**2** from the kinetic resolution, *S*-**3** from L-serine, and *R*-**3** from D-serine.

Table 1 summarizes the rotations of **2–7** in the *R* and *S* series (Scheme 1). Coupling of the lithium salts of *R*- and *S*-**7** with *R*- and *S*-**3** yielded the four stereoisomers of **8**, each of which was obtained in analytically pure form. The structures and rotations of the isomers of **8** are shown in Table 2, which includes the structures and rotations of the four stereoisomers of **1** prepared from **8** by deprotection with formic acid, cyclization in water, and purification by preparative HPLC (4). Each of the isomers of **1** is believed to be ca. 95% stereochemically pure.

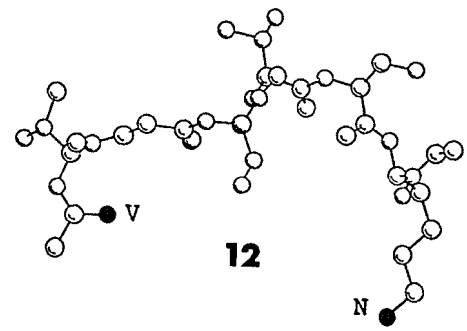
Figure 1 shows the zones of inhibition versus *Staphylococcus aureus* produced by 0.1 μg of penicillin V and by 1.0 mg of each of the isomers of **1**. It is evident that the activity of **1** resides in the isomers having the *S* configuration at C5, as noted earlier in stereostructure **1***a*. The activities of the 5*S*,8*S* and 5*S*,8*R* isomers appear to be the same. The active isomers of **1** have only about 1/1000 the activity of penicillin V, but these activities are already comparable to that of a Δ^2-cephalosporin (2). Although Δ^2-cephalosporins are too weakly active to be useful antibiotics, one structural change, a shift of the nuclear double bond, yields the clinically important Δ^3-cephalosporins. We hope that the lead structure **1** can also be modified to improve its activity and chemical stability. Increased chemical stability will facilitate the planning of binding experiments with penicillin-recognizing enzymes.

Theoretical considerations

The antibacterial activity of a penicillin is the end result of the ability of the compound to reach, and then fit to and acylate, a PBP. As a result of the "fit", the hydroxyl group of the active site serine residue and the N—C bond of the β-lactam N-C=O are so positioned with respect to one another that a catalytic water molecule can complete the structure of the complex in which the acylation reaction occurs. Figure 2 illustrates this point. Structure A (4) is a closeup view of the C-O-H/H-O-H/N-C=O geometry in the complex formed between the crystal structure of penicillin G (**11**), a water molecule, and **12**, a hexapeptide model of the penicillin receptor (3). To form this complex, G_1, the carboxyl group of the antibiotic, was hydrogen bonded to the terminal amino group of a lysine residue of **12**, labelled N, and G_2, the side-chain N-H of the antibiotic, was hydrogen bonded to a carbonyl oxygen of **12**, labelled V. Structure B (4) is a closeup view of the C-O-H/H-O-H/N-C=O geometry in the ab initio (3-21G) complex that proceeds to the transition state of the water-catalyzed methanolysis of *N*-methylazetidinone. There is an obvious resemblance between A and B, and the root-mean-square deviation (rms) between the six atoms of the cyclic portions of the two structures is 0.24 Å. This value (rms = 0.24 Å) can be regarded as a theoretical measure of the *optimum fit* for penicillin.



11



12

If **1** has the same mechanism of action as penicillin (*a point not yet proven experimentally*), the chemical reaction that serves as the analog of acylation by the β-lactam ring is addition of the serine hydroxyl group to the C=N bond. For such a reaction, Fig. 3, the 3-21G reactant complex of the water-catalyzed reaction of methanol with 1-pyrroline (4) is the structure to which the fit to the PBP can be compared. In practice, the "fits" discussed below are based on the four-centred relationship between O-H and C=N (shown, for the 3-21G structure, as an insert in Fig. 3).

Figure 4 shows one of the conformations of the 5*S*,8*S* isomer

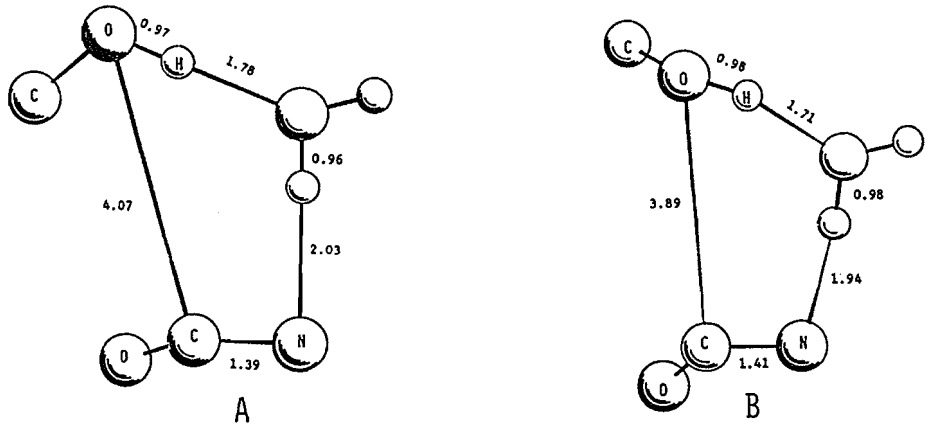

FIG. 2. (A) A closeup view of the C-O-H/H-O-H/N-C=O geometry in the complex of the crystal structure of penicillin G and a water molecule with **12**, Ac-NH-Val-Gly-Ser-Val-Thr-Lys-NHMe. (B) A closeup view of the C-O-H/H-O-H/N-C=O geometry in the stationary point, computed at 3-21G, that is formed when methanol reacts with *N*-methylazetidinone in the presence of one water molecule. The RMS deviation between the two structures is 0.24 Å.

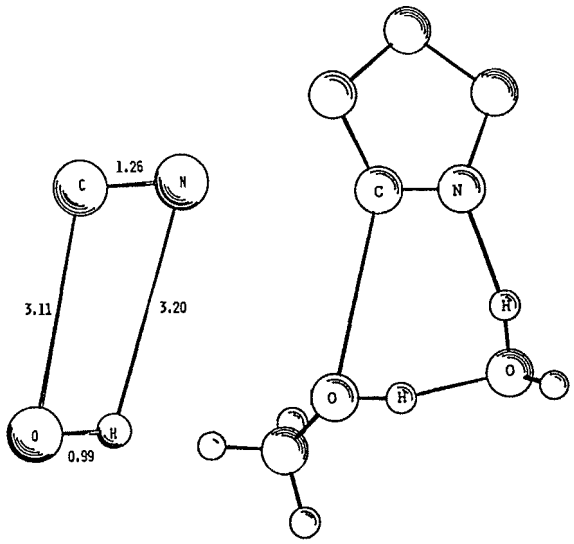

FIG. 3. The stationary point, computed at 3-21G, showing the complex that is formed when methanol reacts with 1-pyrroline in the presence of one water molecule (some hydrogens have been deleted for clarity). Inset: a closeup view of the O-H/C=N geometry in this complex.

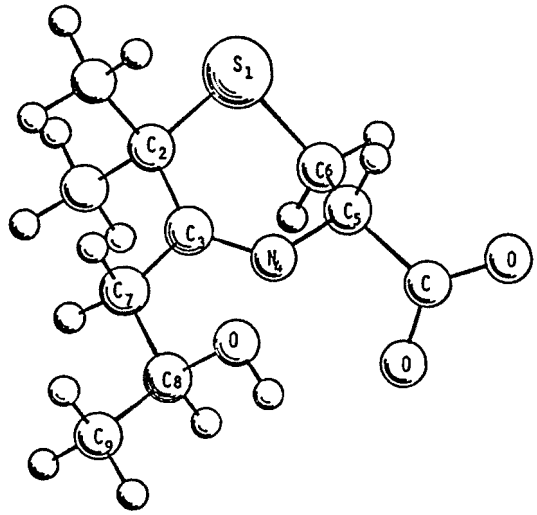

FIG. 4. One of the conformations of the 5*S*,8*S* isomer of **1**. The structure is conformation 2 of Table 3.

tains the analogous data for the *RS/SR* conformations and the *RS* and *SR* complexes. The structure shown in Fig. 4 is conformation 2 of Table 3.

Referring to Table 3, we observe that conformations 1–6 and conformation 8 of the *SS* isomer exhibit better fits to the receptor model than do any of the conformations of the *RR* isomer. In Table 4 we observe that the fit of conformation 3 of the *SR* isomer is better than that of any conformation of the *RS* isomer, and the same as that of conformations 1, 2, and 8 of the *RR* isomer.

With "fit" defined as the deviation between the geometry accessible to the reacting groups in the "enzyme"–substrate complex and the geometry of the stationary point (reactant complex) of the reaction itself, the ordering of these fits is

$$\text{penicillin G} > (5S,8S = 5S,8R) > 5R,8S > 5R,8R$$

This ordering of fits is reminiscent of the ordering of relative antibacterial activities seen in Fig. 1.

There are several practical and mechanistic consequences if binding experiments with penicillin-recognizing enzymes support the connection between theory and experiment that has been developed here. The existence of a quantitative definition of "fit", and also of a relationship between the "fit" exhibited by a candidate structure and its putative antibacterial activity, will narrow the choice of compounds to be selected for synthesis.

As was evident in Fig. 2, our definition of "fit" is based on the geometry of an "enzyme"–substrate complex, not a transition structure. This idea appears to be in conflict with the belief that transition state stabilization is the origin of enzymic catalysis (15). The relationships between ground state and transition state effects (16), and related questions (17), will have to be addressed in the next phase of this research.

Experimental

General

General experimental procedures have been summarized in ref. 4.

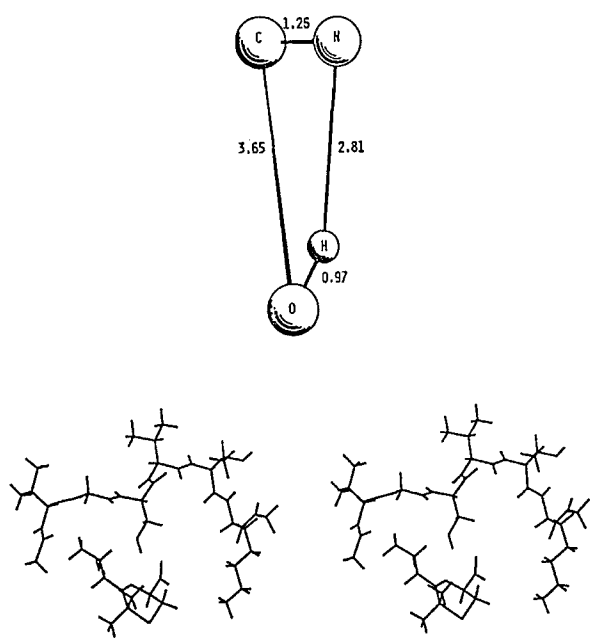

FIG. 5. Stereoscopic view of the complex formed between the structure of Fig. 4 and the model of the penicillin receptor. Inset: a closeup view of the O-H/C=N geometry in this complex. The RMS deviation between the insets of Figs. 3 and 5 is 0.37 Å.

*(S)-Propylene oxide (−)-***9**

This compound was also prepared from ethyl L-lactate (10); $[\alpha]_D^{20}$ −7.57 (*c* 1.58, CH_2Cl_2) (lit. (14) $[\alpha]_D^{20}$ −7.77 (*c* 0.032, $CHCl_3$)); ir (film): 2994.8, 1407.2, 1265.3, 1023.1, 949.8, 828.8 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 1.29 (3H, d, 5.2 Hz, $CHCH_3$), 2.42 (1H, dd, 5.0, 2.7 Hz, CHH), 2.72 (1H, dd, 5.0, 5.0 Hz, CHH), 2.95 (1H, m, $CHCH_3$).

(R)-5-Methyl-4-hexene-2-ol (−)-2

A solution of bromine (150 mL, 465.3 g, 2.9 mol) in methylene chloride (500 mL) was cooled in an ice-bath, stirred, and isobutylene was bubbled in slowly. When the bromine colour disappeared the solvent was removed, and the residue was distilled to give 433.4 g (69%) of 1,2-dibromo-2-methylpropane, bp 46–48°/20 Torr (1 Torr = 133.3 Pa); ^{1}Hmr ($CDCl_3$), δ: 1.87 (6H, s), 4.86 (2H, s). The dibromide (84.0 g, 0.39 mol) was added dropwise over 45 min at 100°C to a solution of potassium hydroxide (30 g, 0.53 mol) in ethylene glycol (100 mL) in a flask set up for distillation. The reaction was terminated when the distillation temperature reached 90°C. The two phases of the distillate were transferred to a separatory funnel with the aid of methylene chloride (5 mL), and the lower phase was separated, dried over anhydrous calcium chloride, and distilled to yield 41.8 g (80%) of β,β-dimethylvinyl bromide (7), bp 90–92°C; ^{1}Hmr ($CDCl_3$), δ: 1.78 (6H, d), 5.87 (1H, m).

Tetrahydrofuran (30 mL) was stirred under nitrogen with magnesium turnings (2.0 g, 82 mg-atom). A crystal of iodine and 0.2 mL of 1,2-dibromoethane were added, the mixture was refluxed until the iodine colour had disappeared, and β,β-dimethylvinyl bromide (5.58 g, 4.2 mL, 41 mmol) in tetrahydrofuran (10 mL) was added drop-

For personal use only.

wise over 30 min. The reaction mixture was refluxed for 3 h, cooled to room temperature, and the supernatant was transferred to a fresh flask. The solution was cooled to −30°C, dry cuprous iodide (0.16 g, 8 mmol) was added in one portion, the mixture was stirred for 15 min, and a solution of (*R*)-propylene oxide (2.0 g, 2.4 mL, 34.4 mmol) in tetrahydrofuran (20 mL) was then added dropwise during 1 h. When the addition was complete, the mixture was warmed to room temperature, stirred for 4 h, and poured onto rapidly stirred saturated ammonium chloride (150 mL). The organic layer was separated and the blue aqueous layer was extracted with ether (3 × 20 mL). The combined organic extract was washed with saturated sodium chloride (2 × 50 mL), dried over anhydrous magnesium sulfate, evaporated, and distilled to give 3.12 g (79%) of a colourless oil, bp 65–70°/20 Torr; $[\alpha]_D^{21}$ −11.74 (*c* 3.15, CH_2Cl_2); ir (film): 3362.0, 2969.5, 2926.8, 1716.0, 1455.8, 1375.9, 1121.8, 1078.3 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 1.18 (3H, d, 6.7 Hz, $CHCH_3$), 1.63 (1H, s, O*H*), 1.63 (3H, s, CCH_3), 1.72 (3H, s, CCH_3), 2.16 (2H, dd, 7.5, 7.5 Hz, $CHCH_2CH$), 3.79 (1H, m, C*H*OH), 5.15 (1H, m, C*H*═C); ms (*m/e*, CI): 114 ($M^+ + 1$), 97 ($M^+ - H_2O$).

(S)-5-Methyl-4-hexene-2-ol (+)-2

This compound was prepared from (*S*)-propylene oxide in 80% yield; $[\alpha]_D^{21}$ +11.75 (*c* 1.6, CH_2Cl_2); ir (film): 3362.0, 2969.5, 2926.8, 1716.0, 1455.8, 1375.9, 1121.8, 1078.3 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 1.18 (3H, d, 6.7 Hz), 1.63 (1H, s), 1.63 (3H, s), 1.72 (3H, s), 2.16 (2H, dd, 7.5, 7.5 Hz), 3.79 (1H, m), 5.15 (1H, m); ms (*m/e*, CI): 114 ($M^+ + 1$), 97 ($M^+ - H_2O$).

Resolution of 5-methyl-4-hexene-2-ol

A mixture of trifluoroethanol (20.6 g, 15.0 mL, 206 mmol), butyric anhydride (31.9 g, 23.0 mL, 202 mmol), and *p*-toluenesulfonic acid monohydrate (0.3 g) was stirred and heated to reflux under nitrogen. When the temperature of the vapour reached 105°C, the reflux condenser was replaced by a distillation head and rapid distillation was performed. The material boiling to 130°C was collected and redistilled through a 20-cm Vigreux column to give a central fraction of trifluoroethyl butyrate, bp 105–115°C, 33.2 g (90%); ir (film): 2972.4, 2881.3, 1762.4, 1713.0, 1413.7, 1282.9, 1169.9, 1102.5 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 1.00 (3H, t, 7.2 Hz, $CH_2CH_2CH_3$), 1.71 (2H, m, $CH_2CH_2CH_3$), 2.43 (2H, t, 7.0 Hz, $CH_2CH_2CH_3$), 4.49 (2H, q, 8.3 Hz, CH_2CF_3); ms (*m/e*): 170 (M^+), 155 ($M^+ - CH_3$).

5-Methyl-4-hexen-2-ol (10.66 g, 93.3 mmol), trifluoroethyl butyrate (18.8 g, 110 mmol), dry ether (55 mL), and Porcine Pancreatic Lipase (E.C. 3.1.1.3, Sigma crude preparation lipase, type 2, no. L-3126, 8.2 g) were stirred in a 250-mL flask protected from moisture. The progress of the reaction was monitored by gas chromatography (GC). When this indicated that 50% of the alcohol had been esterified, the reaction was terminated by filtration. The filtrate was concentrated and the residue distilled to give (*S*)-(+)-5-methyl-4-hexen-2-ol, 4.87 g (46%), bp 65–75°C/17 Torr, and the trifluoroethyl ester of (*R*)-5-methyl-4-hexen-2-ol, 4.07 g (24%), bp 80–95°C/17 Torr. The ester (4.07 g, 21.7 mmol), in 1.0 M methanolic potassium hydroxide (50 mL, 50 mmol), was refluxed for 50 min. The solvent was removed and the residue was triturated with ether (3 × 20 mL). This extract was washed with saturated sodium chloride (2 × 20 mL), dried over anhydrous magnesium sulfate, and evaporated. Distillation afforded 1.5 g (69%) of (*R*)-(−)-5-methyl-4-hexen-2-ol, bp 60–70°C/15 Torr. For (*S*)-(+)-5-methyl-4-hexen-2-ol (ee = 65%): $[\alpha]_D^{21}$ +9.19 (*c* 2.1, CH_2Cl_2); ir (film): 3362.0, 2969.5, 2926.8, 1716.0, 1455.8, 1375.9, 1121.8, 1078.3 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 1.18 (3H, d, 6.7 Hz), 1.63 (1H, s), 1.63 (3H, s), 1.72 (3H, s), 2.16 (2H, dd, 7.5, 7.5 Hz), 3.79 (1H, m), 5.15 (1H, m); ms (*m/e*, CI): 114 ($M^+ + 1$), 97 ($M^+ - H_2O$). For (*R*)-(-)-5-methyl-4-hexane-2-ol (ee = 97%): $[\alpha]_D^{21}$ −11.95 (*c* 2.05, CH_2Cl_2); ir (film): 3362.0, 2969.5 2926.8, 1716.0, 1455.8, 1375.9, 1121.8, 1078.3 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 1.18 (3H, d, 5.7 Hz), 1.63 (1H, s), 1.63 (3H, s), 1.72 (3H, s), 2.16 (2H, dd, 7.5, 7.5 Hz), 3.79 (1H, m), 5.15 (1H, m); ms (*m/e*, relative intensity, CI): 114 ($M^+ + 1$), 97 ($M^+ - H_2O$).

(R)-(−)-5-Methyl-4-hexen-2-ol p-*nitrobenzoate*

p-Nitrobenzoyl chloride (80 mg, 0.47 mmol) was added to a solution of (*R*)-(−)-5-methyl-4-hexen-2-ol (50 mg, 0.44 mmol, from epoxide) in pyridine (2 mL). The solution was stirred at room temperature for 3 h, and then poured into water (5 mL). The aqueous layer was extracted with ether (2 × 5 mL), and this extract was washed successively with 5% sodium bicarbonate (2 × 5 mL) and saturated sodium chloride (2 × 5 mL), dried over anhydrous magnesium sulfate, and evaporated. The syrup was purified by flash chromatography on silica gel (10% ethyl acetate – hexane, 50 mL) to give 80.1 mg (73%) of material, mp 47.0–48.0°C after recrystallization from methanol; $[\alpha]_D^{21}$ −31.5 (*c* 1.30, CH_2Cl_2); ir (film): 3113.8, 2976.1, 1714.8, 1607.7, 1528.6, 1450.6, 1353.5, 1274.4, 1105.8, 1056.1 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 1.36 (3H, d, 6.3 Hz, $CHCH_3$), 1.63 (3H, s, CCH_3), 1.70 (3H, s, CCH_3), 2.34 (1H, m, $CHCH_2CH$), 2.45 (1H, m, $CHCH_2$), 5.16 (1H, m, $OCHCH_3$), 5.16 (1H, m, C*H*═C), 8.19 (2H, m), 8.28 (2H, m); ms (*m/e*, CI): 264 ($M^+ + 1$). Anal. calcd. for $C_{14}H_{17}O_4N$: C 63.86, H 6.51, N 5.32; found: C 64.08, H 6.58, N 5.27.

(S)-(+)-5-Methyl-4-hexen-2-ol p-*nitrobenzoate*

This compound was prepared from (*S*)-(+)-5-methyl-4-hexen-2-ol (50 mg, 0.44 mmol, from epoxide); mp 47.0–48.0°C, $[\alpha]_D^{21}$ +31.90 (*c* 0.94, CH_2Cl_2); ir (film): 3113.8, 2976.1, 1714.8, 1607.7, 1528.6, 1450.6, 1353.5, 1274.4, 1105.8, 1056.1 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 1.36 (3H, d, 6.3 Hz), 1.63 (3H, s), 1.70 (3H, s), 2.34 (1H, m), 2.45 (1H, m), 5.16 (1H, m), 5.16 (1H, m), 8.19 (2H, m), 8.28 (2H, m); ms (*m/e*, CI): 264 ($M^+ + 1$). Anal. calcd. for $C_{14}H_{17}O_4N$: C 63.86, H 6.51, N 5.32; found: C 64.06, H 6.54, N 5.19.

Mosher esters of 5-methyl-4-hexen-2-ol

(R)-5-Methyl-4-hexen-2-ol, (S)-α-methoxy-α-(trifluoromethyl)-phenylacetate

A mixture of 4-dimethylaminopyridine (DMAP, 18 mg, 0.15 mmol) and triethylamine (100 μL) in methylene chloride (0.5 mL) was treated with (*R*)-**2** (17 mg, 0.15 mmol, from epoxide), and 30 μL (40.5 mg, 0.16 mmol) of (+)-MTPA-chloride was added. The solution was stirred at room temperature for 2 h and the reaction was then quenched by addition of 3 drops of water. The mixture was passed through a short plug of silica gel (1.5 cm, 20% ethyl acetate in hexane as eluent) to yield 40.3 mg (82%) of an oil; ^{1}Hmr ($CDCl_3$), δ: 1.258 (3H, d, 6.3 Hz, $CHCH_3$), 1.48 (3H, s, CCH_3), 1.76 (3H, s, CCH_3), 2.17 (1H, m, $CHCHHCH$), 2.42 (1H, m, $CHCHHCH$), 3.55 (3H, s, OCH_3), 3.55 (1H, m, $CHCH_3$), 5.10 (1H, m, C*H*═C), 7.43 (3H, m) 7.53 (2H, m), ee 98%.

(S)-5-Methyl-4-hexen-2-ol, (S)-α-methoxy-α(trifluoromethyl)-phenylacetate

This compound was prepared from (**S**)-**2** (17 mg, 0.15 mmol, from epoxide); ^{1}Hmr ($CDCl_3$), δ: 1.326 (3H, d, 6.3 Hz, $CHCH_3$), 1.53 (3H, s, CCH_3), 1.63 (3H, s, CCH_3), 2.20 (1H, m, $CHCHHCH$), 2.33 (1H, m, $CHCHHCH$), 3.55 (3H, s, OCH_3), 3.56 (1H, m, $CHCH_3$), 5.13 (1H, m, C*H*═C), 7.43 (3H, m), 7.53 (2H, m), ee 97.2%.

*(R)-2-*tert*-Butyldimethylsiloxy-5-methyl-4-hexene (R)-4*

A solution of (*R*)-**2** (2.721 g, 23.83 mmol, $[\alpha]_D^{21}$ −11.95), DBU (0.7 mL, 0.713 g, 4.7 mmol), and triethylamine (3.2 mL, 2.32 g, 24.2 mmol) in methylene chloride (150 mL) was cooled in an ice-bath, and *tert*-butyldimethylsilyl chloride (5.75 g, 38.1 mmol) was added in three portions during 10 min. The reaction mixture was stirred overnight while warming to room temperature, and then poured into 150 mL of water. The aqueous phase was extracted with ether (3 × 30 mL) and the combined organic layers were washed with 0.5 N hydrochloric acid (30 mL), saturated sodium bisulfate (2 × 30 mL) and saturated sodium chloride (2 × 30 mL), dried over anhydrous magnesium sulfate, and evaporated. The residue was distilled to give 3.42 g (62%) of a colourless liquid, bp 61–65°C/0.1 Torr; $[\alpha]_D^{23.5}$ −5.04 (*c* 1.19, CH_2Cl_2); ir (film): 2940, 2915, 2842, 1464, 1455, 1370, 1250, 1130, 1089, 1005, 840, 776 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 0.033 (3H, s, $SiCH_3$), 0.050 (3H, s, $SiCH_3$), 0.88 (9H, s, $SiC(CH_3)_3$), 1.11 (3H, d, 6.1 Hz, $CHCH_3$), 1.692 (3H, s, CCH_3), 1.694 (3H, s, CCH_3), 2.06 (1H,

For personal use only.

m, CHCH*H*CH), 2.16 (1H, m, CHC*H*HCH), 3.77 (1H, m, C*H*CH_3), 5.13 (1H, m, C*H*=C).

*(S)-2-*tert*-Butyldimethylsiloxy-5-methyl-4-hexene (S)-4*

This compound was prepared from (*S*)-**2**, $[\alpha]_D^{21}$ +11.75); bp 62–66°C/0.i Torr; $[\alpha]_D^{22}$ +5.04 (*c* 1.80, CH_2Cl_2); ir (film): 2940, 2915, 2842, 1464, 1455, 1370, 1250, 1130, 1089, 1005, 840,776 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 0.033 (3H, s), 0.050 (3H, s), 0.88 (9H, s), 1.11 (3H, d, 1.6 Hz), 1.692 (3H, s), 1.694 (3H, s), 2.06 (1H, m), 2.16 (1H, m), 3.77 (1H, m), 5.13 (1H, m).

*(R)-2-Hydroxy-2-methyl-5-*tert*-butyldimethylsiloxy-3-hexanone (R)-5*

A mixture of (*R*)-**4** (5.85 g, 25.4 mmol, $[\alpha]_D^{24}$ −5.04), reagent grade acetone (115 mL), water (43 mL), and acetic acid (4.75 mL) was stirred at room temperature, and a solution of potassium permanganate (6.0 g, 38.0 mmol) in water (25 mL) and acetone (93 mL) was added quickly. The reaction mixture was stirred for 1.5 h and then poured onto saturated sodium bisulfite (500 mL). The aqueous phase was extracted with ether (4 × 60 mL), and the combined organic extracts were washed successively with saturated sodium bicarbonate (2 × 50 mL) and saturated sodium chloride (2 × 60 mL), dried over anhydrous magnesium sulfate, and concentrated. The residue was purified by flash chromatography on silica gel (5% and 14% ethyl acetate in hexane) to yield 5.85 g (88%) of a colourless liquid; $[\alpha]_D^{21}$ −32.05 (*c* 1.56, CH_2Cl_2); ir (film): 3480.3, 2957.8, 2857.5, 1711.7, 1472.2, 1375.5, 1255.7, 1136.4, 1078.8, 1004.5, 836.2 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 0.017 (3H, s, SiCH_3), 0.063 (3H, s, SiCH_3), 0.840 (9H, s, SiC(CH_3)$_3$), 1.179 (3H, d, 6.1 Hz, CHCH_3), 1.328 (3H, s, CCH_3), 1.339 (3H, s, CCH_3), 2.474 (1H, dd, 16.0, 4.8 Hz, CHCH*H*CO), 2.834 (1H, dd, 16.0, 7.6 Hz, CHC*H*HCO), 4.39 (1H, m, C*H*CH_3); ms (*m/e*, CI): 261 (M^+ + 1), 243 (M^+ − H_2O), 159. Anal. calcd. for $C_{13}H_{28}O_3Si$: C 59.95, H 10.84; found: C 59.78, H 10.99.

*(S)-2-Hydroxy-2-methyl-5-*tert*-butyldimethylsiloxy-3-hexanone (S)-5*

This compound was obtained in 88% yield from (*S*)-**4** having $[\alpha]_D^{22}$ +5.04: $[\alpha]_D^{23}$ +32.2 (*c* 1.42, CH_2Cl_2); ir (film): 3480.3, 2957.8, 2857.5, 1711.7, 1472.2, 1375.5, 1255.7, 1136.4, 1078.8, 1004.5, 836.2 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 0.017 (3H, s), 0.063 (3H, s), 0.840 (9H, s), 1.179 (3H, d, 6.1 Hz), 1.328 (3H, s), 1.339 (3H, s), 2.474 (1H, dd, 16.0, 4.8 Hz), 2.834 (1H, dd, 16.0, 7.6 Hz), 4.39 (1H, m); ms (*m/e*, CI): 261 (M^+ + 1), 243 (M^+ − H_2O), 159. Anal. calcd. for $C_{13}H_{28}O_3Si$: C 59.95, H 10.84; found: C 60.09, H 10.70.

*(R)-2-Methyl-2-methanesulfonyloxy-5-*tert*-butyldimethylsiloxy-3-hexanone (R)-6*

A mixture of *R*-**5** (1.10 g, 4.2 mmol, $[\alpha]_D^{21}$ −32.1) and triethylamine (1.0 mL, 7.1 mmol) in methylene chloride (150 mL) was stirred in an ice-water bath, and methanesulfonyl chloride (0.5 mL, 6.3 mmol) in methylene chloride (10 mL) was added dropwise. The reaction mixture was stirred at 0–10°C for 5 h and then poured onto water (150 mL). The organic layer was separated and the aqueous layer was extracted with methylene chloride (3 × 50 mL). The combined organic extracts were washed with 0.5 N hydrochloric acid (20 mL), saturated sodium bicarbonate (2 × 60 mL), and saturated sodium chloride (2 × 60 mL), dried over anhydrous magnesium sulfate, and concentrated. The residue was flash chromatographed on silica gel (20% ethyl acetate in hexane) to yield 1.12 g (79%) of a colourless liquid, $[\alpha]_D^{21}$ −10.1 (*c* 3.16, CH_2Cl_2); ir (film): 2957.5, 2856.8, 2360.1, 1706.8, 1471.9, 1373.9, 1255.5, 1138.3, 1079.8, 1006.1 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 0.016 (3H, s, SiCH_3), 0.069 (3H, s, SiCH_3), 0.840 (9H, s, SiC(CH_3)$_3$), 1.184 (3H, d, 6.1 Hz, CHCH_3), 1.633 (3H, s, CCH_3), 1.675 (3H, s, CCH_3), 2.589 (1H, dd, 17.3, 4.6 Hz, CHCH*H*CO), 2.941 (1H, dd, 17.3, 7.5 Hz, CHC*H*HCO), 3.113 (3H, s, OCH_3), 4.40 (1H, m, C*H*CH_3).

*(S)-2-Methyl-2-methanesulfonyloxy-5-*tert*-butyldimethylsiloxy-3-hexanone (S)-6*

This compound was prepared in 78% yield from (*S*)-**5** having $[\alpha]_D^{23}$ +32.2: $[\alpha]_D^{21}$ +10.6 (*c* 1.22, CH_2Cl_2); ir (film): 2957.5, 2856.8, 2360.1, 1706.8, 1471.9, 1373.9, 1255.5, 1138.3, 1079.8, 1006.1 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 0.016 (3H, s), 0.069 (3H, s), 0.840 (9H, s), 1.184 (3H, d, 6.1 Hz), 1.633 (3H, s), 1.675 (3H, s), 2.589 (1H, dd, 17.3, 4.6 Hz), 2.941 (1H, dd, 17.3, 7.5 Hz), 3.113 (3H, s), 4.40 (1H, m).

*(R)-2-Mercapto-2-methyl-5-*tert*-butyldimethylsiloxy-3-hexanone (R)-7*

Triethylamine (4.75 mL) was added to methylene chloride (60 mL). The solution was stirred, cooled to −15°C, and hydrogen sulfide was passed in for 20 min. Then a solution of *R*-**6** (3.93 g, 11.6 mmol, $[\alpha]_D^{23}$ −10.1) in methylene chloride (20 mL) was added dropwise with stirring during 30 min. The reaction mixture was stirred at −15 to 0°C for 5 h with continuous introduction of hydrogen sulfide, and was then poured onto water (100 mL). The organic layer was separated and the aqueous layer was extracted with methylene chloride (3 × 50 mL). The combined organic extract was washed with 0.5 N hydrochloric acid (20 mL), water (2 × 50 mL), and saturated sodium sulfate (2 × 60 mL), dried over anhydrous magnesium sulfate, and concentrated. Chromatography on silica gel (10% ethyl acetate in hexane) yielded 2.58 g (80%) of a colourless liquid; $[\alpha]_D^{21}$ −33.5 (*c* 1.01, CH_2Cl_2); ir (film): 2929.7, 2856.9, 1707.0, 1461.8, 1374.0, 1255.4, 1137.9, 1079.6, 1005.8 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 0.011 (3H, s, SiCH_3), 0.056 (3H, s, SiCH_3), 0.844 (9H, s, SiC(CH_3)$_3$), 1.18 (3H, d, 6.0 Hz, CHCH_3), 1.484 (3H, s, CCH_3), 1.521 (3H, s, CCH_3), 1.98 (1H, s, S*H*), 2.626 (1H, dd, 16.0, 5.2 Hz, CHCH*H*CO), 2.980 (1H, dd, 16.0, 7.2 Hz, CHC*H*HCO), 4.36 (1H, m, C*H*CH_3); ms (*m/e*): 277 (M^+), 245 (M^+ − SH). Anal. calcd. for $C_{13}H_{28}O_2SSi$: C 56.47, H 10.21; found: C 56.34, H 10.28.

*(S)-2-Mercapto-2-methyl-5-*tert*-butyldimethylsiloxy-3-hexanone (S)-7*

This compound was prepared in 78% yield from (*S*)-**6** having $[\alpha]_D^{21}$ +10.6: $[\alpha]_D^{21}$ +33.3 (*c* 1.02, CH_2Cl_2); ir (film): 2929.7, 2856.9, 1707.0, 1461.8, 1374.0, 1255.4, 1137.9, 1079.6, 1005.8 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 0.011 (3H, s), 0.056 (3H, s), 0.844 (9H, s), 1.18 (3H, d, 6.0 Hz), 1.484 (3H, s), 1.521 (3H, s), 1.98 (1H, s), 2.626 (1H, dd, 16.0, 5.2 Hz), 2.980 (1H, dd, 16.0, 7.2 Hz), 4.36 (1H, m); ms (*m/e*): 277 (M^+), 245 (M^+ − SH). Anal. calcd. for $C_{13}H_{28}O_2SSi$: C 56.47, H 10.21; found: C 56.52, H 10.02.

N-tert-*Butoxycarbonyl-*D*-serine-*β*-lactone (R)-3*

A solution of triphenylphosphine (2.006 g, 7.65 mmol) in anhydrous tetrahydrofuran (30 mL) was stirred under nitrogen, cooled to −78°C, and dimethylazodicarboxylate (0.9 mL, 1.19 g, 8.2 mmol) was added dropwise during 10 min. The mixture was stirred for an additional 10 min, and a solution of freshly dried *N-t*-Boc-D-serine (1.20 g, 5.85 mmol) in tetrahydrofuran (30 mL) was added dropwise during 25 min. Stirring was continued at −78°C for 30 min, and for an additional 3 h after the cooling bath had been removed. The solvent was then removed under reduced pressure, and the residue was chromatographed on silica gel (35% ethyl acetate in hexane) to give the product (0.638 g, 58%), mp 117.5–118.5°C; $[\alpha]_D^{21}$ +10.91 (*c* 1.10, CH_2Cl_2); ir (KBr): 3360, 3032, 2978, 1844, 1680, 1534, 1370, 1290 cm^{-1}; ^{1}Hmr (acetone-d_6), δ: 1.40 (9H, s, *t*-Bu), 4.404 (2H, m, CH_2), 4.454 (1H, m, CH), 5.214 (1H, m, NH); ms (*m/e*, CI): 188 (M^+ + 1), 132 (M^+ − *t*-Bu). Anal. calcd. for $C_8H_{13}NO_4$: C 51.33, H 6.99, N 7.48; found: C 51.60, H 6.96, N 7.53.

N-tert-*Butoxycarbonyl-*L*-serine-*β*-lactone (S)-3*

This compound was prepared in 57% yield from *N-t*-Boc-L-serine; mp 117.5–118.5°C (lit. (6) mp 119.5–120.5°C); $[\alpha]_D^{21}$ −10.8 (*c*, 0.93, CH_2Cl_2); $[\alpha]_D^{21}$ −26.4 (*c* 0.53, CH_3CN) (lit. (6) $[\alpha]_D^{22}$ −26.7 (*c* 1, CH_3CN); ir (KBr): 3360, 3032, 2978, 1844, 1680, 1534, 1370, 1290 cm^{-1}; ^{1}Hmr (acetone-d_6), δ: 1.40 (9H, s), 4.404 (2H, m), 4.454 (1H, m), 5.214 (1H, m); ms (*m/e*, CI): 188, 132. Anal. calcd. for $C_8H_{13}NO_4$: C 51.33, H 6.99, N 7.48; found: C 51.59, H 7.05, N 7.62.

*(2R,8R)-2-*tert*-Butoxycarbonylamino-4-thia-5,5-dimethyl-6-oxo-8-*tert*-butyldimethylsiloxynonanoic acid (2R,8R)-8*

A solution of (*R*)-**7** (322 mg, 1.165 mmol, $[\alpha]_D^{21}$ −33.5) in dry tet-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12

rahydrofuran (15 mL) was cooled to −40°C, stirred, and 1 N lithium diisopropylamide (1.20 mL, 1.2 mmol, freshly prepared at −40°C under nitrogen by addition of 1.0 mL of 2.5 M ethereal *n*-butyllithium to 1.5 mL of a 1:2 v:v solution of diisopropylamine in tetrahydrofuran) was added dropwise. Then *N-tert*-butoxycarbonyl-L-serine-β-lactone (*S*-**3**) (224 mg, 1.19 mmol, $[\alpha]_D^{21}$ −10.81) in tetrahydrofuran (10 mL) was added dropwise. The mixture was stirred at −40 to −5°C for 6 h, and was then diluted with methylene chloride (100 mL) and washed with 0.5 N hydrochloric acid (20 mL). The organic layer was separated and the aqueous layer was extracted with methylene chloride (3 × 25 mL). The combined organic extract was washed with water (2 × 25 mL) and with saturated sodium chloride (2 × 30 mL), dried over anhydrous magnesium sulfate, and concentrated. The residue was purified by flash chromatography on silica gel (9% methanol in methylene chloride) and then by preparative layer chromatography (silica gel, thickness 1.0 mm, 20 × 20 cm plate) to give 84 mg (16%) of (2*R*,8*R*)-**8**; $[\alpha]_D^{24}$ −26.9 (*c* 0.45, CH_2Cl_2); ir (film): 2929.7, 2856.9, 1707.0, 1461.8, 1374.0, 1255.4, 1137.9, 1079.6, 1005.8 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 0.005 (3H, s, $SiCH_3$), 0.055 (3H, s, $SiCH_3$), 0.862 (9H, s, $SiC(CH_3)_3$), 1.165 (3H, d, 6.0 Hz, $CHCH_3$), 1.459 (15H, s, $OC(CH_3)_3$ and $C(CH_3)_2$), 2.598 (1H, dd, 5.4 Hz, 16 Hz, CHCH*H*CO), 2.76 (2H, m, SCH_2CH), 2.949 (1H, dd, 7.3 Hz, 16 Hz, CHC*H*HCO), 4.157 (1H, m, SCH_2CH), 4.327 (1H, m, $OCHCH_3$), 5.523 (1H, m, N*H*); ms (*m/e*, relative intensity): 277 (60), 245 (100), 219 (11), 187 (20), 159 (62). Anal. calcd. for $C_{21}H_{41}O_6SSi$: C 54.39, H 8.91, N 3.02; found: C 54.13, H 9.00, N 2.89.

*(2*R,*8*S*)-2-*tert-*Butoxycarbonylamino-4-thia-5,5-dimethyl-6-oxo-8-*tert-*butyldimethylsiloxynonanoic acid (2*R,*8*S*)-8***

This compound was prepared from (*S*)-**7** (0.230 g, 0.832 mmol, $[\alpha]_D^{21}$ +33.3) and *N-tert*-butoxycarbonyl-L-serine-β-lactone (0.197 g, 1.0 mmol, $[\alpha]_D^{21}$ −10.81). The product (51.4 mg, 11%) was purified as described above; $[\alpha]_D^{24}$ +33.9 (*c* 1.12, CH_2Cl_2); ir (film): 2929.7, 2856.9, 1707.0, 1461.8, 1374.0, 1255.4, 1137.9, 1079.6, 1005.8 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 0.007 (3H, s), 0.047 (3H, s), 0.846 (9H, s), 1.161 (3H, d, 6.0 Hz), 1.442 (15H, s), 2.563 (1H, dd, 5.4 Hz, 16.3 Hz), 2.77 (2H, m), 2.905 (1H, dd, 7.3 Hz, 16.3 Hz), 4.332 (1H, m), 4.489 (1H, m), 5.250 (1H, m); ms (*m/e*, relative intensity): 277 (60), 245 (100), 219 (11), 187 (20), 159 (62). Anal. calcd. for $C_{21}H_{41}O_6SSi$: C 54.39, H 8.91, N 3.02; found: C 54.59, H 8.77, N 3.22.

*(2*S,*8*R*)-2-*tert-*Butoxycarbonylamino-4-thia-5,5-dimethyl-6-oxo-8-*tert-*butyldimethylsiloxynonanoic acid (2*S,*8*R*)-8***

This compound was prepared from (*R*)-**7** (0.245 g, 0.9 mmol, $[\alpha]_D^{24}$ −33.0) and *N-tert*-butoxycarbonyl-D-serine-β-lactone (0.198 g, 1.05 mmol, $[\alpha]_D^{21}$ +10.91). The product (94.0 mg, 23%) was purified as described above; $[\alpha]_D^{24}$ −33.0 (*c* 0.46, CH_2Cl_2); ir (film): 2929.7, 2856.9, 1707.0, 1461.8, 1374.0, 1255.4, 1137.9, 1079.6, 1005.8 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 0.003 (3H, s), 0.057 (3H, s), 0.843 (9H, s), 1.162 (3H, d, 6.0 Hz), 1.419 (15H, s), 2.604 (1H, dd, 5.4 Hz, 16.3 Hz), 2.81 (2H, m), 2.947 (1H, dd, 7.3 Hz, 16.3 Hz), 4.110 (1H, m), 4.325 (1H, m), 5.592 (1H, m); ms (*m/e*, relative intensity): 277 (60), 245 (100), 219 (11), 187 (20), 159 (62). Anal. calcd. for $C_{21}H_{41}O_6SSi$: C 54.39, H 8.91, N 3.02; found: C 54.40, H 8.80, N 2.97.

*(2*S,*8*S*)-2-*tert-*Butoxycarbonylamino-4-thia-5,5-dimethyl-6-oxo-8-*tert-*butyldimethylsiloxynonanoic acid (2*S,*8*S*)-8***

This compound was prepared from (*S*)-**7** (0.245 g, 0.9 mmol, $[\alpha]_D^{21}$ +33.3) and *N-tert*-butoxycarbonyl-D-serine-β-lactone (0.200 g, 1.07 mmol, $[\alpha]_D^{21}$ +10.91). The product (60.0 mg, 15%) was purified as described above; $[\alpha]_D^{24}$ +27.2 (*c* 0.81, CH_2Cl_2); ir (film): 2929.7, 2856.9, 1707.0, 1461.8, 1374.0, 1255.4, 1137.9, 1079.6, 1005.8 cm^{-1}; ^{1}Hmr ($CDCl_3$), δ: 0.006 (3H, s), 0.056 (3H, s), 0.843 (9H, s), 1.163 (3H, d, 6.0 Hz), 1.442 (15H, s), 2.602(1H, dd, 5.4 Hz, 16.3 Hz), 2.78 (2H, m), 2.968 (1H, dd, 7.3 Hz, 16.3 Hz), 4.173 (1H, m), 4.312 (1H, m), 5.490 (1H, m); ms (*m/e*, relative intensity): 277 (60), 245 (100), 219 (11), 187 (20), 159 (62). Anal. calcd. for $C_{21}H_{41}O_6SSi$: C 54.39, H 8.91, N 3.02; found: C 54.47, H 8.75, N 3.12.

*(5*R,*8*R*)-2,2-Dimethyl-3-(2′-hydroxypropyl)-5-carboxy-Δ^3-1,4-thiazine (5*R,*8*R*)-1***

The acid (2*R*,8*R*)-**8** (20.0 mg, 0.043 mmol, $[\alpha]_D^{24}$ −26.9) was dissolved in methylene chloride (0.5 mL), and 1.0 mL of 98% formic acid and one drop of 1,3-propanedithiol were added. The solution was stirred at room temperature for 10 h. The solvent was then removed under high vacuum, and the residue was treated with ether (5 mL) and water (5 mL). The ether layer was extracted with water (2 × 5 mL). The combined aqueous extracts were neutralized to pH 8 with 5% sodium bicarbonate and lyophilized to yield 20 mg of white solid. This was dissolved in 4.0 mL of water, and purified by HPLC, using the following conditions: detection at 254 nm; sensitivity 1.0 AUS; injection volume 1.0 mL; flow rate 10.0 mL/min; gradient elution with water–acetonitrile. Collection of the fraction with retention time 9.87 min yielded 2.5 mg (25%) of (5*R*,8*R*)-**1**; $[\alpha]_D^{24}$ −155 (*c* 0.045, 50% acetone–water); ir (film): 3421.7, 2972.4, 1751.5, 1686.1, 1636.7, 1388.2, 1074.3 cm^{-1}; ^{1}Hmr (D_2O), δ: 1.18 (3H, d, 6.2 Hz, $CHCH_3$), 1.39 (6H, s, $C(CH_3)_2$), 2.68 (1H, m, CHCH*H*C=N), 2.84 (2H, m, SCH_2CH), 2.97 (1H, m, CHC*H*HC=N), 4.24 (1H, m, SCH_2CH), 4.53 (1H, m, $CHCH_2C$=N); ms (*m/e*): 231 (M^+).

*(5*S,*8*R*)-2,2-Dimethyl-3-(2′-hydroxypropyl)-5-carboxy-Δ^3-1,4-thiazine (5*S,*8*R*)-1***

This compound was prepared from (2*S*,8*R*)-**8** (20.0 mg, 0.043 mmol, $[\alpha]_D^{24}$ −33.0). The crude product (21.0 mg) was purified by HPLC to yield 3.1 mg (31%) of (5*S*,8*R*)-**1**; $[\alpha]_D^{24}$ −75 (*c* 0.080, 50% acetone–water); ir (film): 3421.7, 2972.4, 1751.5, 1686.1, 1636.7, 1388.2, 1074.3 cm^{-1}; ^{1}Hmr (D_2O), δ: 1.16 (3H, d, 6.2 Hz), 1.45 (6H, s), 2.75 (1H, m), 2.82 (2H, m), 2.93 (1H, m), 4.23 (1H, m), 4.52 (1H, m); ms (*m/e*): 231 (M^+).

*(5*R,*8*S*)-2,2-Dimethyl-3-(2′-hydroxypropyl)-5-carboxy-Δ^3-1,4-thiazine (5*R,*8*S*)-1***

This compound was prepared from (2*R*,8*S*)-**8** (20.0 mg, 0.043 mmol, $[\alpha]_D^{24}$ +33.9). The crude product (20.5 mg) was purified by HPLC to give 3.0 mg (30%) of (5*R*,8*S*)-**1**; $[\alpha]_D^{24}$ +73 (*c* 0.060, 50% acetone–water); ir (film): 3421.7, 2972.4, 1751.5, 1686.1, 1636.7, 1388.2, 1074.3 cm^{-1}; ^{1}Hmr (D_2O), δ: 1.18 (3H, d, 6.0 Hz), 1.45 (6H, s), 2.68 (1H, m), 2.84 (2H, m), 2.97 (1H, m), 4.22 (1H, m), 4.53 (1H, m); ms (*m/e*): 231 (M^+).

*(5*S,*8*S*)-2,2-Dimethyl-3-(2′-hydroxypropyl)-5-carboxy-Δ^3-1,4-thiazine (5*S,*8*S*)-1***

This compound was prepared from (2*S*,8*S*)-**8** (20.0 mg, 0.043 mmol, $[\alpha]_D^{24}$ +27.2). The crude product (19.8 mg) was purified by HPLC to yield 2.4 mg (24%) of (5*S*,8*S*)-**1**; $[\alpha]_D^{24}$ +155 (*c* 0.055, 50% acetone–water); ir (film): 3421.7, 2972.4, 1751.5, 1686.1, 1636.7, 1388.2, 1074.3 cm^{-1}; ^{1}Hmr (D_2O), δ: 1.19 (3H, d, 6.2 Hz), 1.456 (6H, s), 2.68 (1H, m), 2.84 (2H, m), 2.97 (1H, m), 4.22 (1H, m), 4.32 (1H, m); ms (*m/e*): 231 (M^+).

M. IQBAL, M. ASGHAR JAMAL, MAQSOOD AHMED, and BASHIR AHMED. Can. J. Chem. **72**, 1076 (1994).

Partial molar volumes, V^0, of six drugs, mostly anaesthetics, viz., cinchocaine HCl, lidocaine HCl, mepivacaine HCl, procaine HCl, propranolol HCl, tetracaine HCl, in water and ethanol, calculated from precision densities obtained at 35°C from a vibrating tube densitometer, are reported in this work. The data represent the smaller volumes of drug molecules in ethanol than in water. Volume contribution of hydrochloride part were calculated and excluded from V^0 to assess the volume of free base component of the solutes. Volumes of free bases were also found smaller in ethanol, although much closer to those in water. The differences in volumes are interpreted as due to hydrophobicity of solutes. Relative hydrophobicities were estimated from volumes of transfer from aqueous to organic media. Correlation of V^0 with van der Waal volumes are also reported. The hydrophobicity of these compounds is proposed to play a key role in the resulting drug action. Possible mechanism of drug binding with the membrane structure is also discussed.

M. IQBAL, M. ASGHAR JAMAL, MAQSOOD AHMED et BASHIR AHMED. Can. J. Chem. **72**, 1076 (1994).

Utilisant des densités mesurées avec précision à 35°C, à l'aide d'un densimètre à tube vibrant, on a calculé les volumes molaires partiels, V^0, de six drogues, principalement des anesthésiques, à savoir les chlorhydrates de cinchocaïne, de lidocaïne, de mépivacaïne, de procaïne, de propranalol et de tétracaïne, dans l'eau et l'éthanol. Les données représentent des volumes plus faibles des molécules de drogues dans l'éthanol que dans l'eau. On a calculé la contribution au volume de la portion chlorhydrate et, dans le but d'évaluer le volume de la portion de la base libre dans les solutés, on l'a exclue de la valeur de V^0. On a trouvé que les volumes des bases libres sont aussi plus petites dans l'éthanol que dans l'eau, même s'ils sont maintenant plus proches que ceux dans l'eau. On attribue les différences dans les volumes à l'hydrophobicité des solutés. On a évalué les hydrophobicités relatives à partir des volumes de transfert de solutions aqueuses à des solutions organiques. On rapporte aussi une corrélation entre V^0 et les volumes de van der Waal. On suggère que l'hydrophobicité de ces composés joue un rôle important dans l'activité de ces composés comme drogues. On discute aussi du mécanisme possible de fixation de la drogue avec les structures membranaires.

Introduction

Solute–solvent interactions play an important role in a variety of phenomena. In bio-physical chemistry, drug interaction is a subject of intensive studies, involving complex molecular mechanisms. Despite years of investigations, many important drug actions and their mechanisms are not fully understood. Structure activity relationship is one of the most common rationale presented for explaining drug reactions. In cases such as certain hormones, antibiotic and peptide actions, amphiphilicity in molecular structure is considered to be a key factor in the overall drug mechanism (1, 2). Knowledge about mechanism of anaesthesia is also clouded in mystery despite years of intensive studies (3). The role of volume property, however, is considered important in connection with this phenomenon. According to the concept of critical volume of anaesthesia (4, 5), nerve conduction is blocked when drug molecules enter the lipid bilayer and causes expansion in the membrane structure to a critical volume level. The disordering of bilayer structure, resulting from volumetric expansion, causes the disfunctioning of the membrane transport property and the blockage of nerve conduction. An important evidence in favour of this concept is given in terms of the observed reversal of anaesthesia under applied pressure (4).

Since volume is an additive property, gross changes in the volume of a system can be assessed by comparing the volume of the system with those of its components. Moreover, volumetric data often lead to interpretations in terms of molecular interactions within the system. Volumetric data of drugs, lipid bilayers, and membrane proteins can provide clues to the interactions occurring in cellular fluids. Recent literature on the volumetric properties of drugs and other materials of biological importance shows increasing interest by a number of workers in this area of study (6–10).

This work is part of a study of molecular interactions in drug-substrate systems using thermodynamic methods. Partial molar volumes of six drug compounds, mostly anesthetics, are calculated from experimental densities in water and ethanol (aqueous and organic media) at 35°C, using a vibrating tube electronic densitometer. The data are discussed in terms of relative solvation of these compounds in both solvents. Relative hydrophobicity of solutes and aspects of structural features viz-a-viz drug action are also discussed.

Experimental

Materials and method

Drugs used in this study are as follows: (*1*) cinchocaine HCl (Orgamol, Fabrication de Products Chimiques Evionnaz, Suisse, Batch No. 96682); (*2*) lidocaine HCl (from Co. Farmaceutical Milanese, S.p.a. 20151 Milano-viagallarate, Italy); (*3*) mepivaciane HCl (Orgamol, Fabrication de Products Chimiques Evionnaz, Suisse, Batch No. 89012); (*4*) procaine HCl (E. Merck USP lot 7467); (*5*) propranolol HCl (Sigma lot No. 33F-0495); (*6*) Tetracaine

[a] V_w^0 at 25°C = 225.84 cm^3 mol^{-1} from ref. 9.
[b] V_w^0 at 25°C = 245.14 cm^3 mol^{-1} from ref. 9.

HCl (Orgamol, Fabrication de Products Chimiques Evionnaz, Suisse, Batch No. 96573).

Samples were purified by recrystallising from ethanol–water mixtures. Densities of aqueous and ethanolic solutions were measured at 35°C, using a vibrating tube electronic densitometer (11) (Anton Paar DMA 60/602), capable of an accuracy to $\pm 2 \times 10^{-6}$ g cm^{-3}. Calibration of densitometer was done using literature densities of water (12) and 2-propanol (13). Temperature control was maintained by a HETO circulating thermostat which provides an accuracy to better than ±0.01°C. Temperature calibration was done with respect to the triple point of water. Water used in the experimentation was doubly distilled, deionised, and degassed. Absolute ethanol (Merck) was used directly as the organic solvent.

Results and discussion

Apparent molal volumes (ϕ_v cm^3 mol^{-1}) were first calculated using the following equation:

$$[1] \quad \phi_v = \frac{1000(d_0 - d)}{mdd_0} + \frac{M}{d}$$

where d, d_0, m, and M are the densities of solution, solvent, molality, and the relative molar mass of solute, respectively. Apparent molar volume data for these compounds in water were checked for possible changes arising from proton ionisation and disproportionation reactions, etc. (10, 14, 15). The corrections in ϕ_v due to such reactions were found to be within experimental error and are thus ignored.

ϕ_v data were found to vary linearly and were fitted to the following equation using a weighted least squares fit programme.

$$[2] \quad \phi_v + \phi_v^0 + S_v m^x$$

where ϕ_v^0, the first coefficient of fit, is the apparent molal volume at infinite dilution and S_v is the second coefficient of fit. Values of x were taken as 1/2 and 1, for data in water and ethanol, respectively (to take into account the electrolytic character of solutes in water). Errors in the apparent molal volumes ($\delta\phi_v$) were computed and used as weighting parameters in the least squares fit computation of ϕ_v^0 (10, 16). Values of ϕ_v^0 obtained from the fitting procedure were taken to be partial molal volumes, V^0, of the respective compounds, and are shown in Table 1.

It is seen that the volumes of these drugs in water, V_w^0, are higher than those in ethanol, V_e^0, the difference ranging from 10 to 20 cm^3 mol^{-1}. A rough correlation was also found between V^0 and molar mass of these compounds. Values of correlation coefficients were found to be 0.6761 and 0.7085 in water and ethanol, respectively. Studies made in the past on model compounds (polar, non-polar, amphiphilic, etc.) have shown that the volumes of water-soluble compounds are generally smaller in aqueous medium than in nonaqueous medium (17, 18). Present data, however, show an opposite trend implying a behaviour similar to that of water-insoluble (hydrophobic) compounds.

Using the principle of volume additivity, the volume of a hydrochloride salt, V^0(BHCl), can be taken as the sum of the volume of free base, V^0(B), and that of HCl, V^0(HCl).

$$[3] \quad V^0(\text{BHCl}) = V^0(\text{B}) + V^0(\text{HCl})$$

The volume contribution of the free base component, which would be of much greater significance to a pharmacologist, could best be obtained from direct experimentation of free base solutes. We, however, could not obtain experimental data for free bases due to a shortage in materials. Instead, we attempted calculations of V^0(B), using V^0(HCl) data from the literature. One of the methods is to subtract the partial molar volume of pure HCl in the given solvent from V^0(BHCl). In water, at 35°C, we derived this value to be = 17.90 cm^3 mol^{-1} (17). Another method provides more realistic estimates of V^0(HCl) in compounds of similar structure. Recent volumetric data of neurotransmitter drugs in water by Shahidi (9) shows that the value of V^0(HCl) in these cases varies from 11 to 14.5 cm^3 mol^{-1} at 25°C. It is found to be on the low side (11 cm^3 mol^{-1}) when the amino group is at the terminus whereas for molecules with the amino group away from the terminus and within the alkyl chain, the value of V^0(HCl) is found to be ≃14.5 cm^3 mol^{-1}. In our case, since the amino group is away from the terminus and within the alkyl chains, we can choose the higher value with a further increment of 0.5 cm^3 mol^{-1}, on account of the higher temperature of the system (35°C) and an anticipated less hydration (due to more complex structures). Considering the expandability of HCl and the complexity of molecular structure of these solutes, this increment is reasonable in the present calculations. Therefore, using V^0(HCl) = 15.0 cm^3 mol^{-1} in eq. [3], one gets the volumes of free base components in water, V_w^0(B), as shown in Table 2.

In the case of ethanol, there were no data for similar compounds and no other realistic estimates of V^0(HCl), available. We therefore resorted to calculating V^0(B) using partial molar volumes of pure HCl in ethanol. At 25°C, this value is reported to be 3.00 cm^3 mol^{-1} (17). However, we have allowed an incre-

ment of 0.2 cm^3 mol^{-1} when we are applying this to eq. [3] using the above argument. In other words, V^0(HCl) = 3.2 cm^3 mol^{-1} and the volumes of free bases calculated are reported in Table 2 as V_e^0(B).

Tables 1 and 2 show that while V^0(BHCl) values differ by 10 to 20 cm^3 mol^{-1}, the difference in V^0(B) is much smaller (0.2 to 9 cm^3 mol^{-1}). Volumes of transfer from aqueous to ethanolic medium, V_{tr} (= $V_w^0 - V_e^0$), were calculated and found to be positive as shown in Table 1. For mepivacaine and tetracaine, the V_{tr}^0 values fall within the experimental error, implying nearly the same volumes of free base molecules in both solvents. The positive values of V_{tr}^0 for all compounds, however, show a trend in the data that can be discussed in terms of the solvation of these compounds.

Smaller volumes of hydrochloride salts and their free base moieties in ethanol can be interpreted in terms of more intensive solvation of these solutes in ethanol than in aqueous medium. This also implies a hydrophobic character for these compounds despite some of their apparent hydrophilic properties. Although there are certain polar sites such as, —O—, $\equiv N^+-$, etc., present in these molecules (Fig. 1), they also contain alkyl chains, aromatic rings, and other hydrophobic groups. The net character of the molecule resulting from the complex interactions of various sites seems to render the molecule virtually hydrophobic.

Van der Waal volumes, V_v, of these solutes were also calculated from group contributions, using Bondi's data (19). Correlation between V^0 and V_v were obtained using the well known

equation (20) [4]

$$[4] \quad V^0 = aV_v + b$$

a and b for the hydrochloride salts were found to be 1.601 ± 0.033 and −20.754 ± 5.727 in water and 1.657 ± 0.059 and −46.045 ± 9.476 in ethanol. For free bases, these values are a = 1.601 ± 0.032, b = −59.151 ± 6.200 in water and a = 1.657 ± 0.060, b = −73.470 ± 9.342 in ethanol.

The compounds studied in this work are known for their anaesthetic action in terms of specific duration, strength, selectivity of action, side effects, etc. (21–26). Figure 1 shows that an important structural feature of these compounds is the presence of hydrophobic and hydrophilic domains separated by an intervening alkyl chain. The hydrophilic group is generally a tertiary or secondary amine while the major hydrophobic residue is often an aromatic ring. Amino nitrogen of the hydrophilic portion is generally separated from the aromatic segment by a distance of 4 to 6 bonds in the aliphatic chain. This structural feature appears to be a key factor in the anaesthetic action of these drugs, supporting the theory that the anaesthetic is dependent on a structure–activity relationship (27).

The hydrophobicity of these compounds may well play a crucial role in the resulting drug reaction. It can be argued that the hydrophobic force supplements the structure–activity relationship in that these molecules tend to bind in a site-specific manner. The hydrophilic and hydrophobic parts of the drug match with the specific counter sites on the membrane. The hydrophilic part of the drug molecule (—$N^+\tilde{N}$) being anchored to the polar head group of the lipid chain (or at some suitable site on the imbedded protein), pushes the hydrophobic tail into the bilayer grease. The submerging of hydrophobic part into the lipid chain structure then causes a subsequent fluidization of the organised membrane resulting into a volume expansion and hence a blockage of the ion transport.[3]

[3]A complete set of tables of experimental data showing molalities, densities, and ϕ_v values for the compounds studied may be purchased from: the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Activities of dilute NiO in $Na_2O{\cdot}2SiO_2$ by electromotive force measurements[1]

P.J. TUMIDAJSKI

Materials Laboratory, Building M-20, National Research Council of Canada, Ottawa, ON K1A 0R6, Canada

Received July 20, 1993

P.J. TUMIDAJSKI. Can. J. Chem. **72**, 1080 (1994).

The thermodynamic properties of dilute NiO in $Na_2O{\cdot}2SiO_2$ for $X_{NiO} < 0.0125$ have been investigated in the temperature range 1073–1173 K by emf measurements using the electrochemical cell

$$Ni_{(s)}|NiO_{(s)}|ZrO_2\text{–}CaO||Ni_{(s)}|NiO$$

where *NiO* denotes a solution with $Na_2O{\cdot}2SiO_2$. It was found that for $X_{NiO} < 0.003$ the solutions obey Henry's law. The Henrian activity coefficients and the related dilute solution thermodynamic properties based on the solid NiO standard state are reported.

P.J. TUMIDAJSKI. Can. J. Chem. **72**, 1080 (1994).

Utilisant une celle électrochimioque

$$Ni_{(s)}|NiO_{(s)}|ZrO_2\text{–}CaO||Ni_{(s)}|NiO$$

dans laquelle *NiO* indique une solution de $Na_2O{\cdot}2SiO_2$ et faisant appel à des mesures de fem, on a étudié les propriétés thermodynamiques du NiO en solution dilué ($X_{NiO} < 0{,}0125$) dans du $Na_2O{\cdot}2SiO_2$, à des températures allant de 1073 à 1173 K. On a trouvé que, pour $X_{NiO} < 0{,}003$ les solutions obéissent à la loi de Henry. On rapporte les coefficients d'activité de Henry et les propriétés thermodynamiques apparentées des solutions diluées qui sont basées sur l'état de référence du NiO solide.

[Traduit par la Rédaction]

Introduction

Despite the industrial and theoretical significance of NiO slags, there is a paucity of accurate thermodynamic data for these systems. The thermodynamic properties of NiO in calcium and sodium silicates have been studied (1–4). However, the thermodynamic properties of dilute solutions of NiO in silicate slag have not heretofore been reported. It was the purpose of the present study to investigate dilute solutions of NiO ($X_{NiO} < 0.0125$) in $Na_2O{\cdot}2SiO_2$. Dilute solutions are ideally suited for understanding the effects of complex formation in silicates and the relationships between structure and thermodynamic properties. Furthermore, fundamental slag studies aid in the understanding and optimization of industrial pyrometallurgical processes.

Experimental

The electrochemical cell is an oxygen concentration cell described as

$$(RE)\ Ni_{(s)}|NiO_{(s)}|ZrO_2\text{–}CaO||Ni_{(s)}|NiO\ (WE)$$

where *NiO* denotes a solution with $Na_2O{\cdot}2SiO_2$. The cell design is given in Fig. 1. The cell consisted of two independent and isolated half-cell compartments and a solid electrolyte. The solid electrolytes were 46 cm long by 6 mm o.d. tubes with closed ends. The tubes were ZrO_2 stabilized with 5 mol% CaO. The imperviousness of the tubes was checked with a helium leak tester. The only mass transfer through the electrolyte was the electrochemical transfer of oxide anions. The reference electrode (RE) consisted of a spectrographically pure Ni wire immersed in an equimolar mixture of Ni and NiO powders. The working electrode (WE) was a Ni wire which dipped into the slag. The slag was contained in a zirconia crucible. There was minimal evidence of chemical attack of the crucibles and electrolyte tubes after several days of exposure. The entire cell was contained in a 5 cm o.d. quartz tube.

The cell was assembled and heated slowly to 500°C. Vacuum was applied to the WE and RE compartments. After 3 h the glass tubes from the electrode compartments were flame-sealed; then the temperature was increased to 800°C. Eight hours were required for cell voltage to stabilize which indicated that equilibrium was established. The cell response to temperature change was immediate. However, temperature cycling and polarization tests were done to confirm reversibility. For the latter, 1 mA was passed through the cell in each direction using an external d.c. source. In each case, the cell voltage returned to the original value in less than a minute. Runs for each composition lasted 2 days. Temperatures were measured with a Pt versus Pt 13% Rh thermocouple. All voltages were recorded with a high imput impedance $6\frac{1}{2}$ digit digital multimeter (Hewlett-Packard Model 3468B).

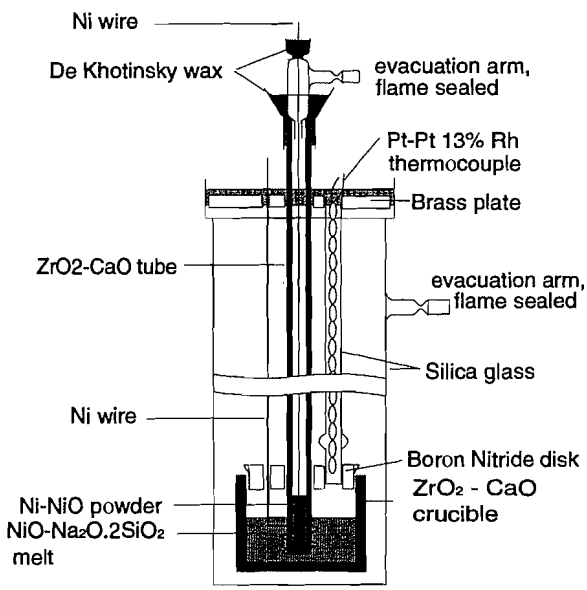

FIG. 1. Experimental electrochemical cell.

The method adopted for the preparation of the slags was to initially make $Na_2O{\cdot}2SiO_2$, and then to melt it with NiO. The $Na_2O{\cdot}2SiO_2$ was produced by melting in a platinum crucible a mixture of Na_2CO_3 and SiO_2. After 48 h, the slag was homogeneous. When the presence

For personal use only.

of CO_2 bubbles was considerable, the slag was ground and remelted. Subsequently, $Na_2O{\cdot}2SiO_2$ and NiO were melted together at 1050°C for 48 h. The ternary slags were homogeneous and slightly purple in color. The intensity of the color varied according to the NiO content. Samples were finely ground and stored in a desiccator. The exact composition of NiO in $Na_2O{\cdot}2SiO_2$ was confirmed by the dimethylglyoxime wet chemical technique.

The chemical reactions for the NiO concentration cell are as follows:

[1*a*] RE: $NiO_{(s)} + 2e^- = Ni_{(s)} + O^{2-}_{RE}$

[1*b*] Transference through ZrO_2–CaO: $O^{2-}_{RE} = O^{2-}_{WE}$

[1*c*] WE: $Ni_{(s)} + O^{2-}_{WE} = NiO + 2e^-$

[1] Overall: $NiO_{(solid,a=1)} = NiO_{solution,a<1)}$

where *NiO* denotes a solution with $Na_2O{\cdot}2SiO_2$. The corresponding Nernst equation is,

$$[2] \quad E_{cell} = -\frac{R\cdot T}{2\cdot F}\ln a_{NiO\ (solid\ standard\ state)} = -\frac{R\cdot T}{2\cdot F}\ln \gamma_{NiO} - \frac{R\cdot T}{2\cdot F}\ln X_{NiO}$$

where E_{cell} is the measured cell voltage at temperature T, R is the universal gas constant, and F is the Faraday constant. A plot of E_{cell} against $\ln X_{NiO}$ should be linear with a slope of $R\cdot T/2\cdot F$.

Results and discussions

Table 1 summarizes the measured cell voltages which have been expressed as least-squares lines of the form $E = A + BT$, where E represents the cell voltage in mV, and T is the thermodynamic temperature in Kelvin. The correlation coefficients in Table 1 indicate that the plots of cell voltage versus temperature are linear. The estimate for the standard deviation of cell potential for the regression of cell potential on temperature is approximately 3 mV for all compositions. Figure 2 is the variation of the cell voltage versus temperature for all the compositions studied. The experimental data are well represented by the linear least squares lines as indicated.

The Nernst plots for 1073, 1173 and 1273 K, as expressed by eq. [2], are given in Fig. 3. The experimental data indicate a two-electron reaction, as expected. Linear regression analysis for the Nernst plots gave correlation coefficients of almost unity for all cases. The linearity of the plots indicates that the dilute solutions of NiO in $Na_2O{\cdot}2SiO_2$ obey Henry's law.

The NiO activities based on the solid standard state, and calculated with eq. [2], are summarized in Table 2 for 1073, 1173, and 1273 K. The NiO activities based on the liquid standard state were not reported because reliable data for the heat of fusion for NiO is unavailable. It can be seen from Table 2 that the NiO activities deviate positively from the ideal behavior (i.e., $a_i = X_i$, for all X_i's). The structural interpretations of the activity deviations is highly speculative when the standard state is the solid and will not be pursued. Also included in Table 2 are the dilute solution properties. The Henrian activity coefficients were calculated with eq. [3].

$$[3] \quad \left.\frac{\partial a_{NiO}}{\partial X_{NiO}}\right|_{X_{NiO}\to 0} = \gamma^0_{henrian}$$

The relationship is depicted graphically for 1173 K in Fig. 4. The activity coefficients follow Henry's law for $X_{NiO} < 0.003$; and for this composition range the solutions can be considered

[a]Based on the solid standard state.

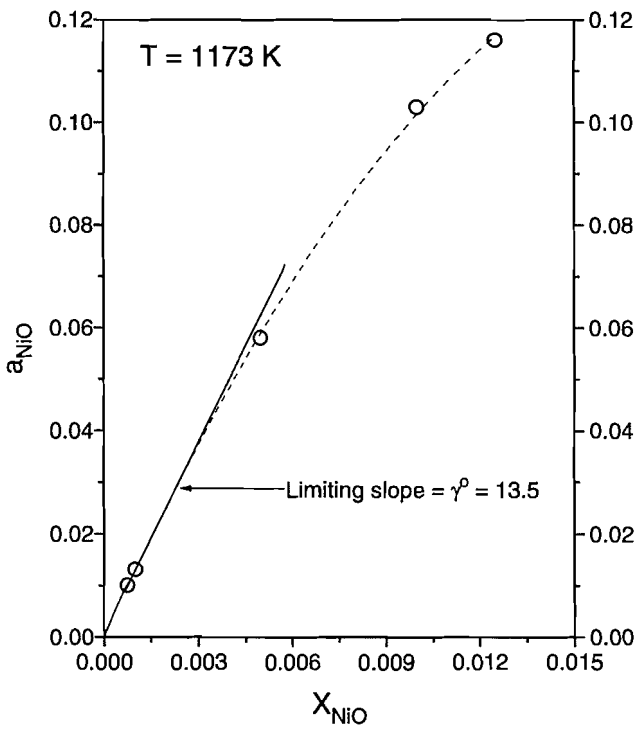

FIG. 4. Concentration dependence of NiO activities at 1173 K, and determination of the Henrian activity coefficient.

to be exactly Henrian (i.e. activity coefficients are compositionally independent and not equal to unity). The uncertainty in the reported activity coefficient values is estimated to be ±5%. The partial enthalpy, entropy, and excess free energy of mixing for NiO based on the solid standard state are also reported in Table 2. The values were calculated according to eq. [4] to eq. [6].

$$[4] \qquad \overline{\Delta H} = \frac{\partial(R \cdot \ln \gamma_{NiO})}{\partial(1/T)}$$

$$[5] \qquad \overline{\Delta H}^{xs} = R \cdot T \cdot \ln \gamma_{NiO}$$

$$[6] \qquad \overline{\Delta S} = -\frac{\partial(R \cdot \ln \gamma_{NiO})}{\partial(T)}$$

The error in the values of enthalpies and excess free energies is approximately ±3 kJ mol^{-1}, while the error for the entropies is ±3 J mol^{-1} K^{-1}. The enthalpies and entropies are considered to be temperature independent over the limited temperature range of the experiments.

Solvent effects on the reactivity of solvated electrons with ions in isobutanol/water mixed solvents

RUZHONG CHEN, YURIS AVOTINSH,[1] AND GORDON R. FREEMAN[2]
Chemistry Department, University of Alberta, Edmonton, AB T6G 2G2, Canada

Received July 20, 1993

RUZHONG CHEN, YURIS AVOTINSH, and GORDON R. FREEMAN. Can. J. Chem. **72**, 1083 (1994).

The effective reaction radii κR_r, where R_r is the reactive encounter radius and κ is the probability of reaction per encounter, for e_s^- with H_s^+, $NH_{4,s}^+$, Ag_s^+, Cu_s^{2+}, and $NO_{3,s}^-$ are all 0.7 ± 0.1 nm in isobutanol containing 10–20 mol% water. The value remains at 0.7 ± 0.1 nm for H_s^+, Ag_s^+, and Cu_s^{2+} in pure isobutanol, and for the two transition metal ions in pure water solvent. The value for $NO_{3,s}^-$ reduces to 0.35 nm in pure isobutanol and pure water solvents, whereas for H_s^+ and $NH_{4,s}^+$ in pure water solvent it is only 0.14 nm and 2.6×10^{-5} nm, respectively. The low reactivity of $NH_{4,s}^+$ with e_s^- in water is attributed to the symmetry of the hydrogen-bonded solvation structure of NH_4^+ in water, and the higher reactivity of H_s^+ ($OH_{3,s}^+$) is attributed to the lower symmetry of its hydrogen-bonded solvation structure. The NH_4^+ and OH_3^+ ions have no low-lying orbital for an electron to occupy, so either reaction occurs by proton transfer to the electron site or the neutral species must decompose. We suggest that the proton transfer or the decomposition of the neutral species is facilitated by an unsymmetrical solvation structure.

Reaction of e_s^- in $Al(ClO_4)_3$ solutions in water is due mainly to H_s^+ from hydrolysis of Al_s^{3+}, and partly to partially hydroxylated aluminum(III) species. Reaction of e_s^- with Al_s^{3+} itself appears to be negligible in water. The reactivity of the solutions of $Al(ClO_4)_3$ in isobutanol-rich solvents is 3–5 times greater than that in water.

In pure C_1 to C_4 1-alcanol solvents the value of $k_2(e_s^- + NO_{3,s}^-)$ increases linearly with the dielectric relaxation time τ_1 of the solvent. In these solvents the probability of permanent capture per encounter increases approximately as the square of the encounter duration.

RUZHONG CHEN, YURIS AVOTINSH et GORDON R. FREEMAN. Can. J. Chem. **72**, 1083 (1994).

On a déterminé que dans de l'isobutanol contenant de 10 à 20% d'eau, les rayons efficaces de réaction, κR_r, où R_r est le rayon de rencontre réactif et κ est la probabilité de réaction par rencontre, des entités e_s^- avec H_s^+, $NH_{4,s}^+$, Ag_s^+, Cu_s^{2+} et $NO_{3,s}^-$ son tous égaux à 0,7 ± 0,1. La valeur demeure 0,7 ± 0,1 nm pour H_s^+, Ag_s^+ et Cu_s^{2+} dans l'isobutanol pur et pour les ions des deux métaux de transition dans l'eau pure. La valeur pour $NO_{3,s}^-$ diminue à 0,35 nm dans l'isobutanol pur et l'eau pure alors que, pour le H_s^+ et le $NH_{4,s}^+$ dans l'eau pure, les valeurs sont respectivement 0,14 nm et $2,6 \times 10^{-5}$ nm. On attribue la faible réactivité du $NH_{4,s}^+$ avec les e_s^- dans l'eau à la symétrie de la structure de solvatation comportant des liaisons hydrogènes du $NH_{4,s}^+$ dans l'eau et on attribue la réactivité plus élevée des H_s^+ ($OH_{3,s}^+$) à la symétrie plus faible de sa structure de solvatation comportant une liaison hydrogène. Les ions NH_4^+ et OH_3^+ n'ont aucune orbitale de bas niveau pour accommoder un électron; la réaction se produit donc par un transfert de proton vers un site d'électron ou les espèces neutres doivent se décomposer. On suggère que le transfert de proton ou la décomposition d'espèces neutres est rendu plus facile par une structure de solvatation qui n'est pas symétrique.

La réaction des e_s^- dans des solutions de $Al(ClO_4)_3$ dans l'eau est principalement due aux H_s^+ provenant de l'hydrolyse des Al_s^{3+} et, en partie, à des espèces d'aluminium(III) partiellement hydroxylées. La réactivité des solutions de $Al(ClO_4)_3$ dans des solvants riches en isobutanol est de trois à cinq fois plus grande que dans l'eau.

Dans des solvants formés d'alcanols purs contenant de un à quatre atomes de carbone, la valeur de $k_2(e_s^- + NO_{3,s}^-)$ augmente d'une façon linéaire avec le temps de relaxation diélectrique, τ_1, du solvant. Dans ces solvants, la probabilité d'une capture permanente par rencontre augmente par un facteur approximativement égal au carré de la durée de rencontre.

[Traduit par la Rédaction]

Introduction

The present article continues the studies of solvated electron reactions with ions in mixed solvents (1), in this case isobutanol/water.

The reactions of solvated electrons (e_s^-) are usually electron transfer reactions (2). Possible exceptions are $e_s^- + ROH \rightarrow H + RO_s^-$ and $e_s^- + ROH_{2,s}^+ \rightarrow H + ROH$ in water and alcohols, where a proton from a solvating —OH or $—OH_2^+$ group might transfer to the site of the electron (3). Proton transfer to the "cavity" of the electron site might avoid the work needed to create a new site for the H atom if the electron were to transfer first, followed by decomposition of the transient ROH^- or ROH_2. The electron and proton are both elementary particles, but the former has a much smaller mass and, other things being equal, would have a larger transfer probability. Protons have larger mobilities than do electrons in water and alcohols, which means that the transport mechanisms are different.

For electron transfer between two species A and B in liquid media one may write

$$[1a] \qquad A_s + B_s \rightleftharpoons [A_s, B_s]$$

$$[1b] \qquad [A_s, B_s] \rightarrow C_s + D_s$$

where the subscript s signifies "solvated". The first step represents the random diffusion of two reactants, which by chance encounter each other and thereby form an [encounter pair], and which might diffuse apart again. The second step represents electron transfer within the encounter pair, which might involve thermal activation of the solvated species A_s and B_s in concert (4, 5).

The overall second order reaction rate constant k_2 may be represented by

$$[2] \qquad \frac{1}{k_2} = \frac{1}{k_{1a}} + \frac{1}{K_{1a}k_{1b}} = \frac{1}{k_d} + \frac{1}{K_{1a}k_r}$$

where $k_d = k_{1a}$ = diffusion controlled upper limit of the reaction rate constant, $K_{1a} = k_{1a}/k_{-1a}$, and $k_r = k_{1b}$ = rate of formation of products from encounter pairs. The value of K_{1a} is typically 10^{-5} m^3/mol.

We analyze large values of k_2 from the viewpoint of the Smoluchowski–Debye model (1, 6):

$$[3] \qquad k_2 \approx k_d = 4\pi N_A(D_A + D_B)R_r f$$

where N_A = Avogadro's constant, D_A and D_B are diffusion coefficients, R_r is the average center-to-center distance between A and B when electron transfer occurs, and f is a factor that accounts for the effect of the coulombic interaction between the reactants on their probability of diffusing to within a distance R_r of each other.

The relative contributions of k_d and k_r to limiting the observed reaction rate are reflected in the ratio k_2/k_d. If $k_2 \approx k_d$, then $K_{1a}k_r \gg k_d$; if $k_2 = 0.5\,k_d$, then $K_{1a}k_r \approx k_d$; if $k_2 \ll k_d$, then $k_2 \approx K_{1a}k_r$. We have introduced the probability κ that reaction occurs during the lifetime of an encounter pair (1). Then,

$$[4] \qquad k_2 = \kappa k_d = 4\pi N_A(D_A + D_B)\kappa R_r f$$

For example, when $\kappa \leq 0.10$, then $K_{1a}k_r \leq k_d/9$. We evaluate solvent effects on k_2/f. Partial information is obtained about the diffusion coefficients of ionic reactants by measuring molar conductances of the reactant electrolyte solutions.

Experimental

Materials

Isobutanol (Aldrich, 99+%, Spectrophotometric Grade, Gold Label) was dried for one week on Davison Molecular Sieves (3 Å), then treated for one day under UHP argon (99.999%, Liquid Carbonic Canada Ltd.) with sodium borohydride (2 g/L) at 330 K. The alcohol was then fractionally distilled under argon, through an 80 × 2.3 cm column packed with glass helices, discarding the first 20% and last 40%. The middle 40% portion was collected and stored in a flask under argon. The water content, measured by Karl–Fisher titration, was 0.05 mol%. The solvated electron half-life after a 100 ns pulse of 340 fJ (2.1 MeV) electrons (4 J/kg) at 298 K was about 10 μs.

Singly distilled water was further purified in a Barnstead Nanopure II ion exchange system. The half-life of solvated electrons after a 100 ns pulse of 340 fJ electrons (4 J/kg) was about 12 μs.

The following chemicals were obtained from Aldrich: lithium nitrate (99.999%, gold label), ammonium nitrate (99.999%), ammonium perchlorate (99.8%), lithium perchlorate (reagent grade), copper(II) perchlorate (98%, reagent grade), and aluminum(III) perchlorate (98%, reagent grade). Silver perchlorate (reagent grade) was from Strem. After opening a bottle, it was stored in a vacuum desiccator that contained P_2O_5.

Perchloric acid (70 wt%, in water) was obtained from Fisher Scientific.

The salts and acid were used as received.

Techniques

Butanol/water mixed solvents were prepared in a 1000 cm^3 volumetric flask, by volume measurements at 298 K.

Solid solutes were weighed into 25 cm^3 volumetric flasks and dissolved in the mixed solvent to get the stock solution. Sample solutions were made by diluting aliquots of stock solution, using syringes or volumetric pipettes. Perchloric acid samples were prepared through several steps of dilution from the 70 wt% solution, and the concentrations were checked with the calibrated pH meter.

Four to six sample solutions with different concentrations were prepared for each solute. The solutions were poured into 10 mm Spectrosil optical cells, deaerated by bubbling with UHP argon, and sealed. All components of the solution were of low volatility, so their concentration changed negligibly during bubbling.

Electrons were produced by pulse radiolysis. The radiation was a 100 ns pulse of 340 fJ (2.1 MeV) electrons, delivering a dose of ~4 Gy(J/kg). The number of pulses per sample was 2 or 3 at each temperature, and the number of temperatures per sample was 4 or 5. A pure solvent sample was part of each series, so the effect of the ~3×10^{-3} mol/m^3 of aldehyde produced during three pulses would not affect the value of k_2 obtained from the slope of the plot of k_{obs} against added solute concentration.

The light source was a 1000 W Xe arc lamp (Optical Radiation Co., model XLN) contained in a lamp housing (Photochemical Research Assoc., model PRA ALH220). A Bausch and Lomb monochromator housing, type 33-86-25, was used with the grating type 33-86-03 (700–1000 nm), and a Corning filter type CS-2-64 (700–1000 nm). The light intensity reaching the detector was controlled by adjusting the slits on the monochromator. The wavelength of the analyzing light was 850 nm with bandwidth 9 nm, to obtain an optimal absorption signal.

The silicon detector (pin photodiode SGD 040) was sensitive over the wavelength range 400–1100 nm. The 3 to 97% response time of the detector, amplifier and transient digitizer (Tektronix R7912) was 6 ns. The signal to noise ratio of the differential amplifier (Tektronix 7A13) was increased by using the 5 MHz filter, which gave a system response time of 96 ns.

The cell holder in the thermostated box was repeatedly rotated full cycles clockwise and counterclockwise between pulse measurements, to obtain a temperature uniformity of ±0.1 K within the box.

The decay half-life of the solvated electron absorption was computed as a function of time after each pulse, and recorded on the absorption trace (1*b*). The first order decay constants were plotted against solute concentration, and second order rate constants obtained from the slope of the line. At high concentrations in butanol the plots were curved due to ionic strength effects, in which case initial slopes were used.

Electrical conductivity measurements were made as described earlier (1*a*).

pH measurements were made with a Fisher Accumet digital pH/ion meter (model 520) with a glass indicating electrode (Fisher No. 13-639-3) and a reference electrode (Fisher No. 13-639-52). The meter was calibrated with two standard buffer solutions at 298 K, SO-B-108 (pH = 7.00 ± 0.01) and SO-B-98B (pH = 4.00 ± 0.01).

Results and discussion

Physical properties

Isobutanol is not miscible with water in the composition range 45.4–97.8 mol% water at 298 K (7). Reaction rate constants were measured in solvents that contained the following mol% water: 0.0, 10.0, 20.0, 35.0, 45.0, 98.0, 100.0. Values of the viscosities of the mixed solvents were obtained from ref. 8, and of the relative permittivities at 298 K from ref. 9.

Rate constants

Arrhenius plots of k_2 for $LiNO_3$, NH_4NO_3, NH_4ClO_4, $AgClO_4$, $HClO_4$, and $Cu(ClO_4)_2$ in the mixed solvents are given in Figs. 1–4. The symbols that represent the different solvent compositions are listed in Table 1.

The precision of k_2 values is 5–10% in pure water solvent and 10–15% in mixed and pure alcohol solvents.

Due to the low solubilities of NH_4ClO_4 and NH_4NO_3 in pure

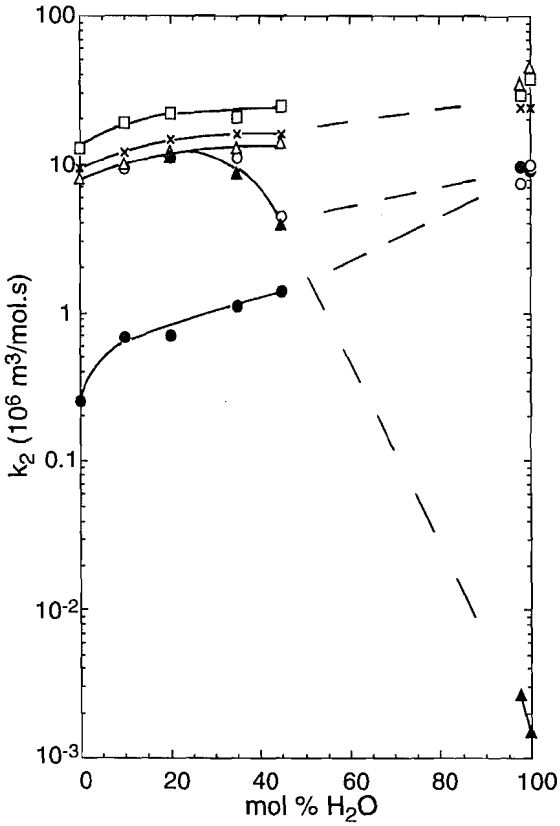

FIG. 5. Solvent composition dependence of k_2 at 298 K in isobutanol/water solvents. ● $LiNO_3$, ○ NH_4NO_3, ▲ NH_4ClO_4, △ $AgClO_4$, × $HClO_4$, □ $Cu(ClO_4)_2$.

[5] $$NH^+_{4,s} \rightleftharpoons NH_3 + H^+_s$$

[6] $$[H^+] = (K_a[NH^+_{4,s}])^{0.5}$$

Values of the dissociation constant K_a of $NH^+_{4,s}$ are only known for pure water solvent (1*a*), but they are a reasonable approximation for the 98 mol% water solvent as well. The values of $k_2(e^-_s + NH^+_{4,s})$ were calculated from the slopes of plots of $(k_{obs} - k_2[H^+_s])$ against the concentration of undissociated $NH^+_{4,s}$, where k_2 is the rate constant for $(e^+_s + H^+_s)$ in the appropriate solvent. The corrections are ~50% at 277 K and ~80% at 328 K; the values of $k_2(e^-_s + NH^+_{4,s})$ are very low in these solvents.

In the alcohol-rich solvents the values of $k_2(e^-_s + NH^+_{4,s})$ are so high that, unless K_a is >10× the value in pure water solvent, the corrections for $k_2[H^+_s]$ are negligible. The values of k_2 in alcohol-rich solvents were taken directly from the slopes of plots of k_{obs} against added $[NH^+_{4,s}]$.

The overall rate constants at 297 K for reaction of e^-_s with $Li^+_s + ClO^-_{4,s}$ are 100 ± 20 m^3/mol.s in water and <40 m^3/mol.s in isobutanol. Thus the rate constants of e^-_s with the ions Li^+_s and $ClO^-_{4,s}$ are negligible by comparison with those with $NO^-_{3,s}$, $NH^+_{4,s}$, H^+_s, Ag^+_s, and Cu^{2+}_s.

Figure 5 displays the solvent composition dependence of k_2 at 298 K for $NO^-_{3,s}$, $NH^+_{4,s}$, H^+_s, Ag^+_s, and Cu^{2+}_s, and for $NH^+_{4,s}$ and $NO^-_{3,s}$ in combination. As found in other mixed solvents (1*a*), the reaction of e^-_s with $NH^+_{4,s}$ is 4 orders of magnitude faster in the alcohol-rich solvent than in pure water solvent. The low reactivity in water is attributed (1*b*) to a symmetric

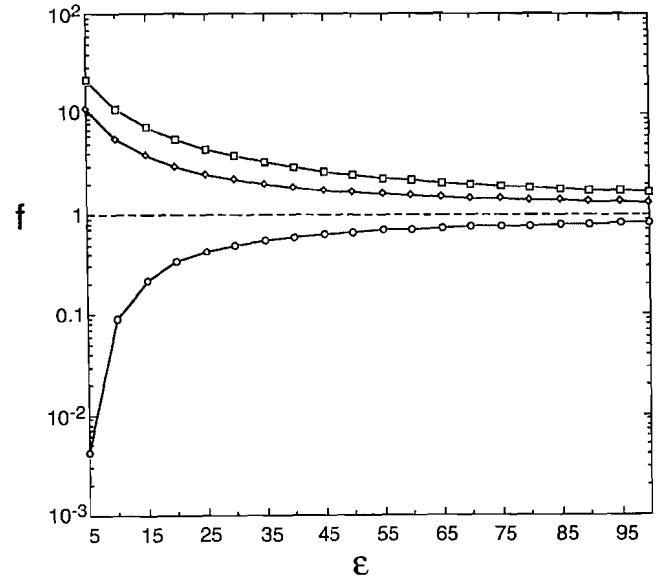

FIG. 6. Dielectric permittivity dependence of the Debye factor f at 298 K. □ $z = +2$ and ◇ $z = +1$, using $R_r = 1.0$ nm; ○ $z = -1$, using $R_r = 1.5$ nm.

structure of NH^+_4 hydrogen bonded into the structure of water, which would tend to spread out the positive charge and reduce the electron affinity of the ion. The reaction might actually happen by proton transfer to the electron site (3). In alcohol, NH^+_4 is unsymmetrically solvated, which evidently facilitates either electron attachment and the subsequent decomposition of $NH_4 \rightarrow H + NH_3$ (1*b*), or approach of the electron site and proton transfer to it.

The observed rate constants for NH_4NO_3 solutions are mainly due to $NO^-_{3,s}$ in the water-rich region and to $NH^+_{4,s}$ in the alcohol-rich region.

The Debye factor f

The coulombic interaction between e^-_s and a reactant of charge $z\xi$ increases their probability of approach to within the distance R_r if z is positive, and decreases it if z is negative (ref. 6; Fig. 6):

[7] $$f = \frac{U(R_r)}{k_B T}\left[\exp\left(\frac{U(R_r)}{k_B T}\right) - 1\right]^{-1}$$

where $U(R_r)$ is the potential energy of interaction between the reactants at center-to-center distance R_r, and k_B is Boltzmann's constant. For the electron and ion,

[8] $$U(R_r) = -\frac{z\xi^2}{4\pi\epsilon_0\epsilon R_r}$$

where ϵ_0 is the permittivity of vacuum, and ϵ is the relative permittivity of the medium between the electron and ion.

The estimated value of f depends on the choice of values of ϵ and R_r. Some authors used the hydrated ion radius for R_r (10), which seems too small for solvated electron reaction with a solvated ion (4). The van der Waals diameter of a water molecule is 0.29 nm (footnote 3). To use the bulk value of ϵ for water one would need at least three water molecules

[3]Reference 11. $r_{vdW} = \left(\frac{3}{4\pi N_A} \cdot \frac{b}{4}\right)^{1/3} = 4.63 \times 10^{-9}\, b^{1/3}$.

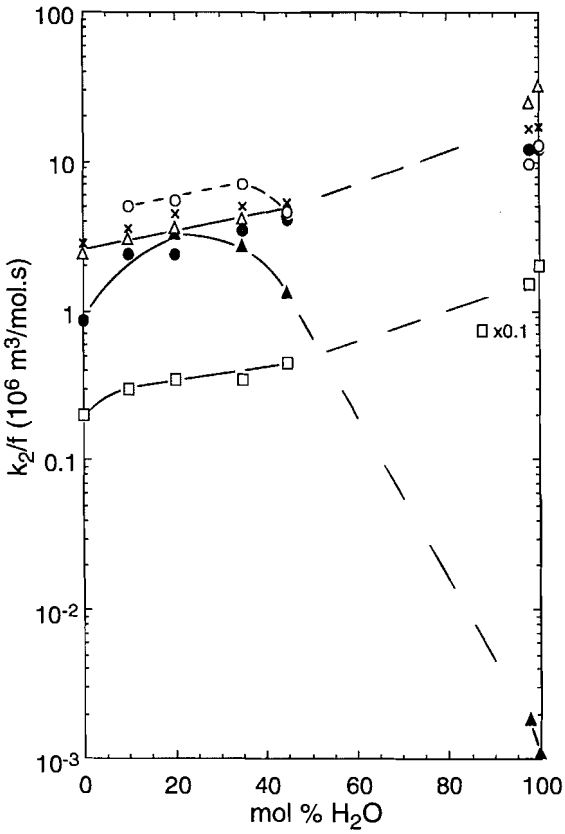

FIG. 7. Solvent composition dependence of k_2/f at 298 K in isobutanol/water solvents. See Table 2 for values of f. Symbols as in Fig. 5. To separate the lines, some values of k_2/f have been multiplied by the factors indicated.

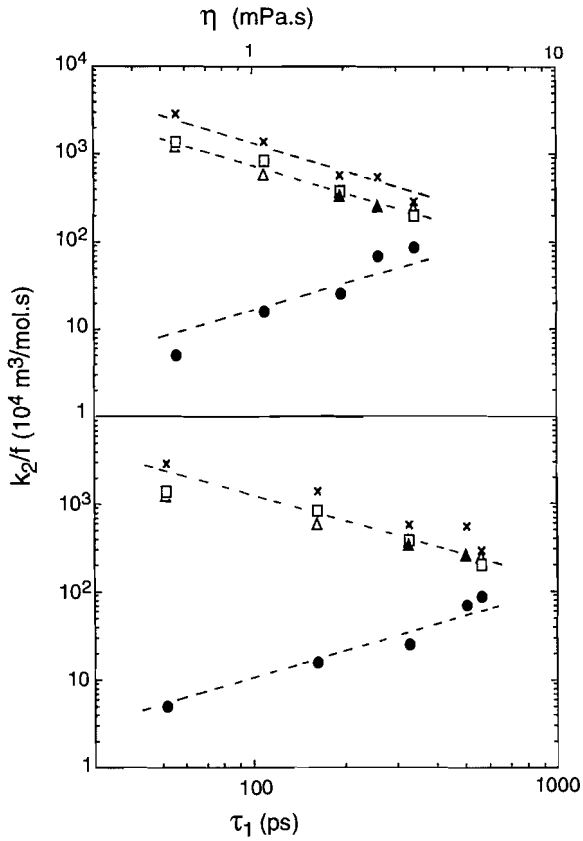

FIG. 8. k_2/f in pure primary C_1–C_4 alcohol solvents at 298 K, as functions of viscosity η and dielectric relaxation time τ_1. Symbols as in Fig. 5. References for k_2: C_1 and C_2 (14); C_3 (1*b*, 15); C_4 (1*a* and present work, data for H^+ in 1-BuOH, unpublished data measured by the authors). Solvent properties: η (12); τ_1 (13). The dashed lines have slopes of 1.0.

between the reactants (one polarized by each reactant, and one relatively free), so $\epsilon = 78$ would require $R_r \geq 0.9$ nm. We took $R_r = 1.0$ nm for reaction of e_s^- with positive ions. The repulsion between a negative ion and an electron makes it somewhat more difficult for them to approach each other closely, so we took $R_r = 1.5$ nm for reaction of e_s^- with anions and used the bulk value of the static dielectric constant of the solvent. Values of f at 298 K are shown as functions of ϵ and z in Fig. 6. Values of f at other temperatures were not calculated because the variation of ϵ with temperature is not known for the mixed solvents.

The solvent composition dependences of k_2/f at 298 K are shown in Fig. 7. When adjusted for the coulombic interactions in this way, the rate constants k_2/f are all similar and increase with increasing water content. Exceptions are the low values for $e_s^- + NO_{3,s}^-$ in pure alcohol solvent and $e_s^- + NH_{4,s}^+$ in water, which are inefficient reactions (1). The points for ammonium nitrate are higher than the rest because both ions are reactants; the overall k_2 was partitioned between $NH_{4,s}^+$ and $NO_{3,s}^-$ using the ratio of ammonium perchlorate and lithium nitrate rate constants, then each part was divided by the appropriate f, and the results added to obtain an overall k_2/f.

Comparisons of k_2/f *in other primary alcohols*

Alcohols that have longer alkyl groups have lower molecular diffusion rates, indicated by the higher shear viscosities η (12), and lower molecular rotation rates, indicated by the longer dielectric relaxation times τ (13). The changes of k_2/f with η and τ for reactions of e_s^- with a number of cations and anions in a series of primary alcohol solvents (1, 14, 15) are shown in Fig. 8.

Reactions of e_s^- with the positive ions (H_s^+, $NH_{4,s}^+$, Ag_s^+, Cu_s^{2+}) display values of k_2/f that vary approximately as η^{-1} and τ^{-1} (Fig. 8). The correlation with η^{-1} and the near equality of the values for the different ions indicates that the reactions in alcohol solvents are essentially diffusion-controlled (16*a*). The somewhat larger rate constants for H_s^+ are due to the proton-hopping mechanism of diffusion (16*b*).

For the e_s^- reaction with $NO_{3,s}^-$ the value of k_2/f increases as η^{+1} (Fig. 8) so the diffusion process [1*a*] is not rate limiting. The duration of an encounter between a pair of reactants increases with increasing η; the multistep reaction that results in the permanent capture of e_s^- by $NO_{3,s}^-$ (1) evidently becomes more probable as the encounter duration increases, in spite of the fact that the rate of new encounters decreases. This indicates that the probability of reaction per encounter increases approximately as the square of the encounter duration.

There is a correlation between the viscosity and the longest dielectric relaxation time τ_1 in alcohols (Fig. 9). The correlation of k_2/f for $(e_s^- + NO_{3,s}^-)$ with τ_1^{+1} is better than that with η^{+1} (Fig. 8), which we do not yet understand. The line through the points in Fig. 9 intersects the η axis, which indicates that the rounder shaped alcohol molecules (methanol) can rotate more freely (small τ) than they can bump past each other (η). This might mean that the duration of an e_s^- encounter with a $NO_{3,s}^-$ is determined by the molecular dipole rotation time.

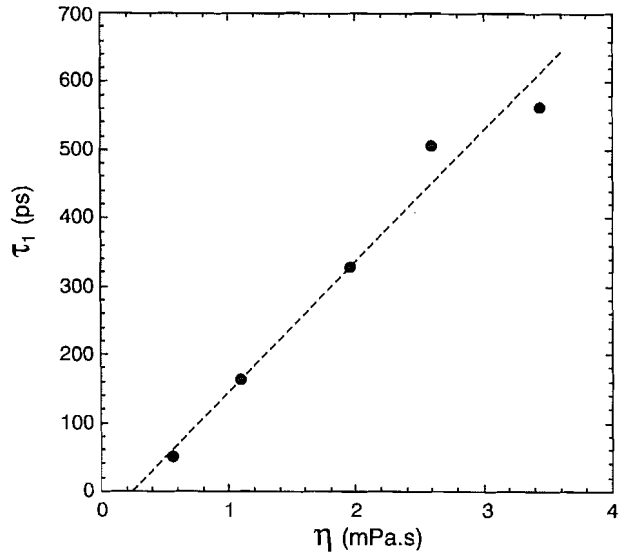

FIG. 9. Dielectric relaxation time τ_1 (13*a*, *b*) of primary C_1–C_4 alcohols at 298 K, as a function of viscosity η (12). The dashed line represents $\tau_1/\text{ps} = 192\ (\eta - 0.24)/\text{mPa s}$.

Dipole reorientation must accompany charge migration in polar solvents, because of the large polarization energy of the solvent molecules around the ion or electron.

Electrical conductivities and effective reaction radii (κR_r)

The diffusion coefficients in eq. [4] are related to the molar electrical conductivities λ ($S \cdot m^2/mol$) of the respective ions (16*b*). However, the conductivities of solvated electrons in the mixed solvents are not known, so the ionic conductivities Λ_0 of the dilute reactant electrolyte solutions are used as an approximation. The ratios of the conductance of e_s^- (17) to that of the various reactant ions (18) in water are known and are roughly assumed to have similar values in the mixed solvents (15):

$$[9] \qquad \lambda(e_s^-) + \lambda(B^z)/z^2 \approx 1.8\Lambda_0/z$$

where z is the number of charges on the reactant in B^z, Λ_0 is the molar conductivity of its electrolyte solutions at low concentration, and the factor 1.8 has an average deviance of ±0.2 for the present solutes in water. By rearranging eq. [4] and making appropriate use of eq. [9] one can obtain (15*b*):

$$[10] \qquad \kappa R_r \approx 1 \times 10^{-16} z k_2/fT\Lambda_0$$

The solvent composition dependences of Λ_0 of the reactant electrolytes at 298 K, and of the approximate values of κR_r at 298 K, are shown in Figs. 10 and 11, respectively. The rate parameters are listed in Table 2. In most cases the concentrations of salts are ≤0.2 mol/m³ for k_2 and Λ measurements, so ion pairing is negligible. The low reactivity of NH_4ClO_4 in water required concentrations up to 100 mol/m³ for measurement of k_2, and the same concentration range was used for Λ measurement; the Debye–Hückel–Onsager equation (16*c*) describes the Λ data, so ion pairing is negligible.

Most of these values of κR_r are relatively insensitive to solvent composition. The greatest exception is for $NH_{4,s}^+$, which is only 10^{-4} times as reactive in water as in isobutanol. The next largest exception is for H_s^+, which is only 0.2 times as reactive in pure water solvent as in the alcohol-rich solvents;

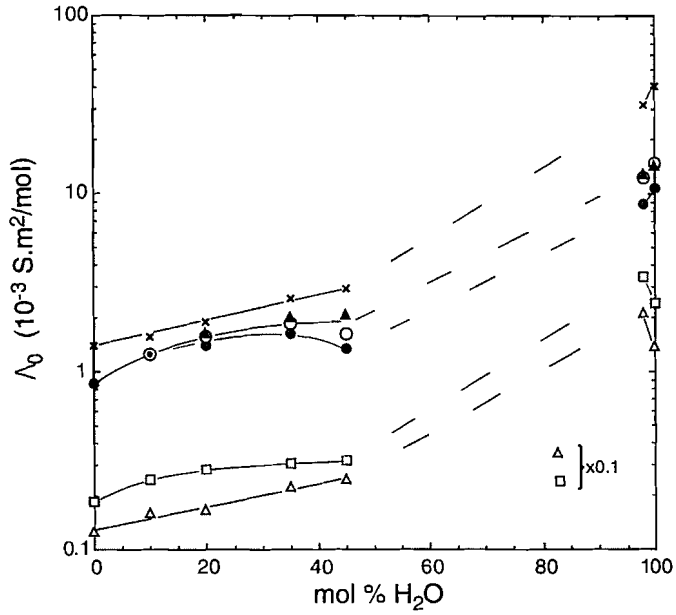

FIG. 10. Solvent composition dependences of the molar conductivities Λ_0 of dilute electrolyte solutions at 298 K in isobutanol/water solvents. Symbols as in Fig. 5. Some values of Λ_0 have been multiplied by the factors indicated.

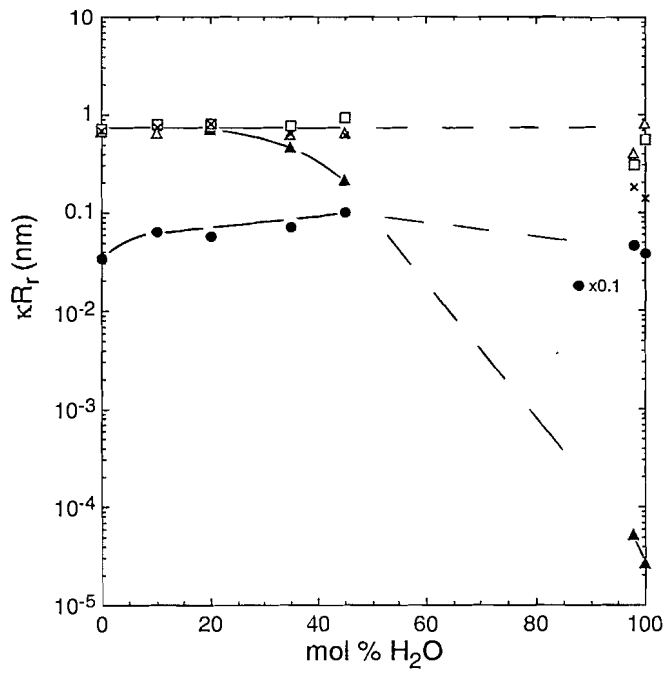

FIG. 11. Solvent composition dependences of κR_r, eq. [10], at 298 K in isobutanol/water solvents. Symbols as in Fig. 5. Some values of κR_r have been multiplied by the factors indicated.

this supports the previous conclusion that reaction of e_s^- with H_s^+ in water is 0.2 times slower than diffusion controlled (19, 20), and that the reaction is diffusion controlled in alcohol.

Activation energies E_2 *and* E_Λ

The Arrhenius temperature coefficients E_2 and E_Λ of reaction and conductance neare 298 K are plotted against solvent composition in Fig. 12. The most remarkable feature is the large increase of E_Λ upon addition of 2 mol% of isobutanol to the aqueous solutions of $AgClO_4$ and $Cu(ClO_4)_2$, as seen on

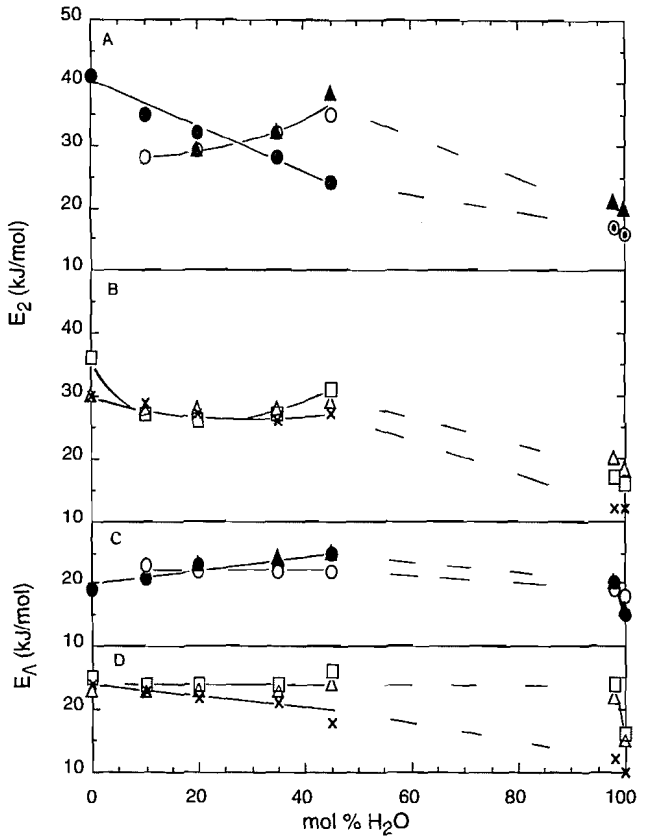

FIG. 12. Solvent composition dependences of the activation energies E_2 of e_s^- reactions, and E_Λ of conductance, near 298 K in isobutanol/water solvents. Symbols as in Fig. 5. *A*, *C*: $LiNO_3$, NH_4NO_3, and NH_4ClO_4. *B*, *D*: $AgClO_4$, $HClO_4$, and $Cu(ClO_4)_2$.

the right-hand side of Fig. 12*D*. This effect is reproducible and corresponds to an increase in conductivity at 298 K (Fig. 10), which contrasts with the decrease of conductivity of the other aqueous solutions when 2 mol% of isobutanol was added (Fig. 10). The decrease of Λ and relatively small increase of E_Λ of the other solutions is due to the increased η upon addition of 2 mol% of alcohol to water (Table 2). The *increase* of Λ and large increase of E_Λ of the $AgClO_4$ and $Cu(ClO_4)_2$ solutions is attributed to an increase of hydrolysis of metal ions, perhaps by complexation of Cu^{2+} and Ag^+ with the alcohol. The increase of Λ with T is reproducible with different heating times. It is not due to oxidation of the alcohol by ClO_4^-, and is worth a separate study. A pH meter would have to be calibrated for each solvent and temperature.

The Arrhenius temperature coefficients of the e_s^- reactions in pure water solvent are 2 ± 2 kJ/mol greater than those of conductance of the electrolyte solutions; this difference is essentially the mean thermal agitation energy $RT = 2.5$ kJ/mol, since conductance is driven by the electric field, whereas diffusion is driven by thermal energy. The values of E_2 in pure water solvent are 3 ± 1 kJ/mol lower than the temperature coefficient of solvated electron diffusion, 20 kJ/mol (17). The exception is $(e_s^- + H_s^+)$, where $E_2 = 12$ kJ/mol equals the temperature coefficient of proton diffusion in water near 298 K (ref. 17; Table 2, $E_\Lambda(H_s^+ + ClO_{4,s}^-) + 2.5$ kJ/mol).

In the alcohol-rich mixed solvents E_2 is ~6 kJ/mol greater than E_Λ for the transition metal ions Ag^+ and Cu^{2+} and the acidic ions H_s^+ and $NH_{4,s}^+$, indicating a need for a slightly greater agitation energy to react. At the miscibility edge of 45 mol% water, $(E_2 - E_\Lambda)$ for the acidic ions increases to ~12 kJ/mol, possibly indicating that e_s^- and the acidic ions are selectively solvated by different components of the solvent, or that they are selectively solvated in the same component but separated by a microstructure of the other component.

The effect of greatest magnitude is the opposite changes of E_2 and E_Λ for the $LiNO_3$ solutions on going from pure isobutanol to the water solubility edge at 45 mol% water (Figs. 12*A* and *C*): E_2 decreases from 41 to 25 kJ/mol while E_Λ increases from 19 to 25 kJ/mol. Thus, $E_2 - E_\Lambda = 22$ kJ/mol in pure isobutanol solvent, but it decreases upon addition of water, reaching zero at the water solubility limit of 45 mol%, and remains at essentially zero in pure water solvent. Electron capture by NO_3^- is clinched by subsequent reaction of the initial NO_3^{2-}; the reaction is evidently a relatively easy protonation by water in pure water solvent, but involves a more difficult reaction of the alcohol in alcohol solvent (1).

A plot of $(E_2 - E_\Lambda)$ against E_Λ for the various solvent compositions breaks the data into alcohol-rich and water-rich regions, which have been demonstrated in greater detail for other alcohols by plots of k_2 against η at 298 K (21, 22). The $(E_2 - E_\Lambda)$ plot is therefore not shown.

Alcohol/water mixed solvents form composite structures, as indicated by their thermodynamic properties (23). Dilute solutions of electrolytes in mixtures near the critical 2-phase composition might have properties characteristic of nanoemulsions. The study of liquids and of liquid solutions for their own sake has reached the beginning of a new cycle of great interest and value to general science.

Effective radii R_d for mutual diffusion

We obtain further insight into eqs. [4] and [10] by considering R_d. The Stokes radius R_d for mutual diffusion of ions i and j in an electrolyte solution is (16*a*)

$$[11] \qquad R_d = \left(\frac{1}{R_{di}} + \frac{1}{R_{dj}}\right)^{-1} = 8.62 \times 10^{-16}/\eta \left(\frac{\lambda_i}{z_i^2} + \frac{\lambda_j}{z_j^2}\right)$$

In our case, $i = e_s^-$ and $j =$ reactant ion. As discussed earlier, values of $\lambda_{e_s^-}$ are not available for the mixed solvents, so we use the approximation $[\lambda_{e_s^-} + (\lambda_j/z_j^2)] \approx 1.8\Lambda_0/z_j$, hence

$$[12] \qquad R_d \approx 5 \times 10^{-16} z_j/\eta\Lambda_0$$

where Λ_0 is the molar conductance of dilute solutions of the electrolyte that contains reactant ion j.

The solvent composition dependences of R_d are shown in Fig. 13. Equation [12] emphasizes the more mobile ion. In water the mobility of e_s^- (17, 24) is greater than that of all the ions we studied except H_s^+; the last has a high mobility due to a solvent-structure-dependent proton hopping mechanism (16*b*). This is why R_d for $HClO_4$ is only 14 pm, while the rest are in the vicinity of 45 pm in pure water solvent.

The apparent decrease of R_d for $AgClO_4$ and $Cu(ClO_4)_2$ from 43 pm in pure water to 20 pm in 98 mol% water (Fig. 13) supports the suggestion that the increase of Λ_0 and E_Λ of these solutions upon addition of 2 mol% of isobutanol to water is caused by complexation of the Ag^+ and Cu^{2+} ions by the alcohol, and acid dissociation of the complex ion: for example,

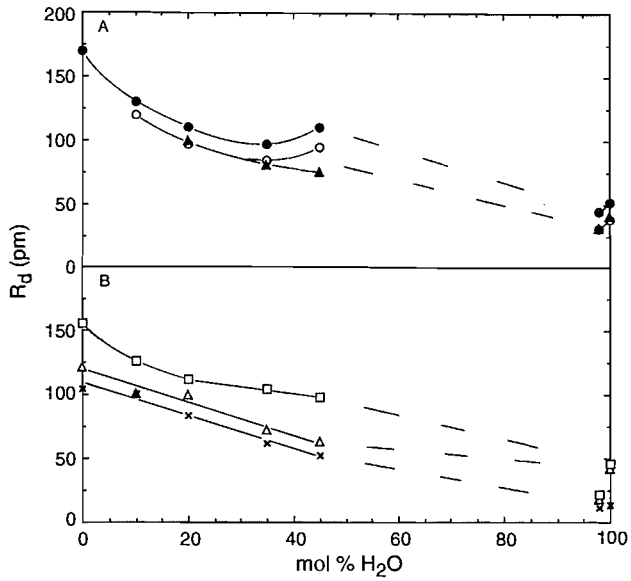

FIG. 13. Solvent composition dependence of R_d, eq. [12], at 298 K in isobutanol/water mixed solvents. Symbols as in Fig. 5. *A*: $LiNO_3$, NH_4NO_3, and NH_4ClO_4. *B*: $AgClO_4$, $HClO_4$, and $Cu(ClO_4)_2$.

[13] $[Ag(ROH)_2]_s^+ \rightleftharpoons [(ROH)AgOR]_s + H_s^+$

This is why the dashed lines do not acknowledge the apparent decrease of R_d in Fig. 13 or of κR_r in Fig. 11 for Ag^+ or Cu^{2+} on going from 100 to 98 mol% water. These ions hydrolyse to a small extent even in pure water solvent (Table 4-1, p. 50 of ref. 25), which was detectable with the pH meter. However, addition of 2 mol% (10 vol.%) of isobutanol to the water or to the dilute salt solutions did not change their indicated pH's appreciably (±0.03 units), possibly due to an effect of the alcohol on the electrode.

The fact that R_d for $H^+ClO_4^-$ is also smaller in pure alcohol and the mixed solvents than R_d for the other electrolytes (Fig. 13), indicates that proton hopping also occurs in those solvents. The ratio $R_d(H^+ClO_4^-)/R_d$ (other salts) ≈ 0.3 in water and is usually ~0.6 in isobutanol, so proton hopping is less efficient in alcohol than in water. However, $Ag^+ClO_4^-$ has an exceptionally high conductance in alcohol solvents (Fig. 13 and ref. 15*b*), which again suggests that reaction [13] occurs.

The larger values of R_d for electrolytes in alcohol than in water are attributed to the larger size of the solvating molecules that attach to the ions.

Reactions of e_s^- in $Al(ClO_4)_3$ solutions

The reaction rate of e_s^- with Al_s^{3+} cannot be measured directly, because Al_s^{3+} hydrolyses extensively (25). The identities of the species present in aluminum salt solutions at different pH's are not well known, because the hydrolysed ions can form charged clusters and polymers (25–28). For example, Rubin and co-workers studied the influence of pH on clustering and coagulation in Al(III) solutions, and concluded that in acidic aqueous solutions the main species in equilibrium are Al_s^{3+}, $AlOH_s^{2+}$, and a polymer $[Al_8(OH)_{20}]_s^{4+}$. However, for the very dilute, natural pH solutions of $Al(ClO_4)_3$ used in our work, we only consider two equilibria (25, 28):

[14] $[(H_2O)_6Al]_s^{3+} \rightleftharpoons [(H_2O)_5AlOH]_s^{2+} + H_s^+,\ K_{14}$

[15] $[(H_2O)_5AlOH]_s^{2+} \rightleftharpoons [(H_2O)_4Al(OH)_2]_s^+ + H_s^+,\ K_{15}$

where K_{14} and K_{15} are the equilibrium constants.

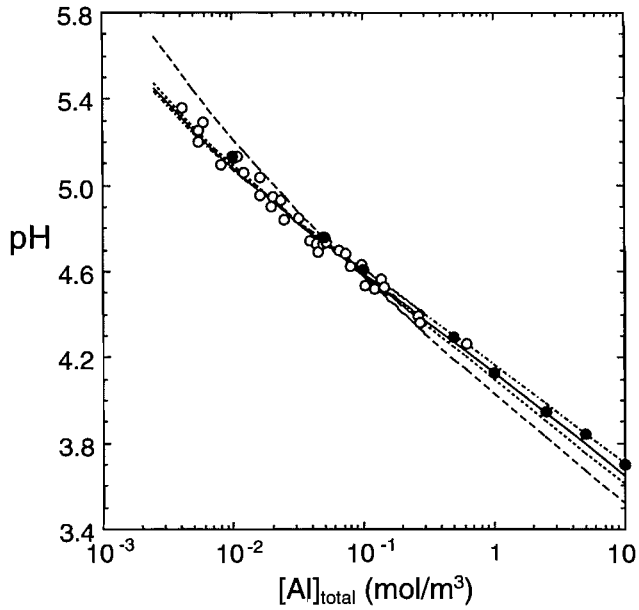

FIG. 14. pH of $Al(ClO_4)_3$ aqueous solutions at 298 K as a function of concentration of aluminum(III) added. ○ present measurements; ● ref. 28. — calculated for reactions [14] and [15], with $K_{15}/K_{14} = 2$ and $K_{14} = 4.7\times10^{-3}$ mol/m^3; - - - $K_{15}/K_{14} = 0$ and $K_{14} = 9.6\times10^{-3}$ mol/m^3; ··· $K_{15}/K_{14} = 1$ and $K_{14} = 6.0\times10^{-3}$ mol/m^3; - · - · - · $K_{15}/K_{14} = 4$ and $K_{14} = 3.5\times10^{-3}$ mol/m^3.

Measured values of pH of aqueous $Al(ClO_4)_3$ solutions at 298 K are plotted against added Al(III) concentration in Fig. 14, along with data from ref. 28. The e_s^- reaction rate constant data were obtained at $Al(ClO_4)_3$ concentrations <0.10 mol/m^3, but pH was also measured at higher concentrations to sort out the hydrolysis equilibria. We attempted to fit the data in Fig. 14 by selecting a value of K_{15}/K_{14} and adjusting the value of K_{14} to give calculated pH values as near as possible to the experimental values. Curves for $K_{15}/K_{14} = 0$, 1, 2, and 4 are shown in Fig. 14, and the corresponding values of K_{14} are given in the legend. The best fit was obtained with $K_{15}/K_{14} = 2$ and $K_{14} = 4.7\times10^{-3}$ mol/m^3, which corresponds to $pK_{14} = 5.33$ and $pK_{15} = 5.03$. The dashed line for $K_{15}/K_{14} = 0$ corresponds to the single stage hydrolysis with $pK = 5.02$ reported earlier (25). Figure 14 confirms that multistep hydrolysis (25–28) is significant even at these low concentrations.

Measured half-lives of e_s^- in these solutions gave the first-order k_{obs} values displayed in Fig. 15. These values were corrected for reaction of e_s^- with H_s^+, using the measured pH values and $k_2(e_s^- + H_s^+) = 2.4\times10^7$ m^{3}mol.s. The net reaction rate with aluminum species is represented by $(k_{obs} - 2.4\times10^7[H_s^+])$; the curve is sublinear (Fig. 15). The net reaction rate also gives sublinear curves when plotted against the equilibrium values of $[Al_s^{3+}]$ or $[HOAl_s^{2+}]$; it gives a superlinear curve when plotted against $[(HO)_2Al_s^+]$. It appears that e_s^- does not react appreciably with Al_s^{3+}, but that it reacts with a partially hydroxylated species with a rate constant $k_2 > 3\times10^6$ m^3/mol.s.

An early report of $k_2(e_s^- + Al_s^{3+}) = 2\times10^6$ m^3/mol.s in water at room temperature, at pH = 6.8 (29*a*), is unclear, because at pH = 6.8 hydrated alumina precipitates. We observed the e_s^- reaction rate in the aluminum perchlorate "solutions" at pH = 6.4 to be the same as that in aqueous $H_2PO_4^-/HPO_4^{2-}$ buffer at that pH. Anbar and Hart might have obtained pH = 6.8 with $H_2PO_4^-/HPO_4^{2-}$ buffer (29*b*) in which case the

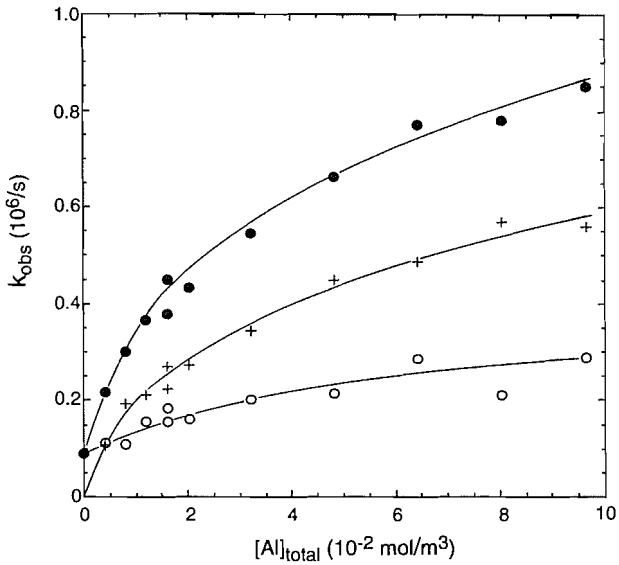

FIG. 15. k_{obs} of e_s^- reactions in $Al(ClO_4)_3$ aqueous solutions as a function of concentration of aluminum(III) added. ●, experimentally measured k_{obs}; +, 2.4×10^7 $[H_s^+]$, with $[H_s^+]$ from pH measurement; ○ ($k_{obs} - 2.4 \times 10^7[H^+]$).

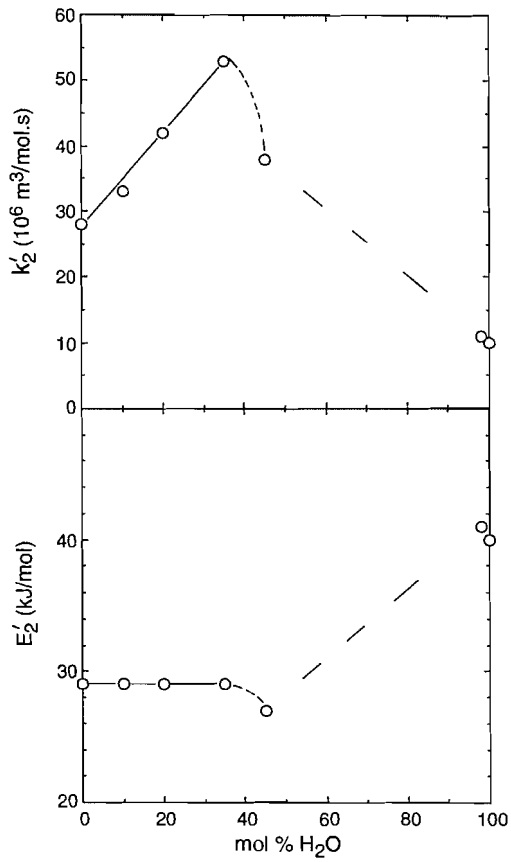

FIG. 16. Solvent composition dependences of rate constants k_2' and Arrhenius temperature coefficients E_2' for reaction of e_s^- in aluminum perchlorate solutions at 298 K. See text.

observed reaction rate could have been due to the $H_2PO_4^-$. We obtained $k_2(e_s^- + H_2PO_4^-) = 1.2 \times 10^4$ m^3/mol.s at $[H_2PO_4^-] = 72$ mol/m^3 and pH = 6.42 at 298 K, whereas Anbar and Hart (29*c*) reported 0.8×10^4 m^3/mol.s at $[H_2PO_4^-] = 100$ mol/m^3 and pH = 7.1 at room temperature.

We could not measure $[H_s^+]$ in the alcoholic solvents. Uncorrected values of k_2' obtained from plots of k_{obs} against added $[Al(ClO_4)_3]$ and the corresponding Arrhenius temperature coefficients E_2' are displayed against solvent composition in Fig. 16. The relatively low values of k_2' and high values of E_2' in pure water and 98 mol% water solvents indicate that the hydrolysis reactions, possibly [14] and [15], have activation energies of about 20 kJ/mol. The higher values of k_2' and lower E_2' in the isobutanol-rich solvents indicate that either the acid dissociation constants of the solvated Al_s^{3+} are higher in these solvents, or that the solvated ions themselves are more reactive with e_s^-.

Reçu le 31 mars 1993

B. MAILLARD, X. LUBEIGT, M-J. BOURGEOIS et E. MONTAUDON. Can. J. Chem. **72**, 1094 (1994).

La décomposition des dérivés peroxydiques δ-insaturés CH_2=$CH(CH_2)_3OY$ (Y = O*t*Bu, $OCMe_2Ph$, OCOEt, $OCMe_2OMe$) dans divers solvants conduit à un hétérocycle et éventuellement un peroxyde adduit. La substitution homolytique intramoléculaire (S_Hi), responsable de la formation du cycle, dépend de la stabilité de la liaison O—Y. Celle-ci est déterminée par analyse calorimétrique différentielle des homologues saturés. Une estimation de la constante de vitesse de la S_Hi à 60°C est donnée pour Y = O*t*Bu, $OCMe_2Ph$.

B. MAILLARD, X. LUBEIGT, M-J. BOURGEOIS, and E. MONTAUDON. Can. J. Chem. **72**, 1094 (1994).

Induced decomposition of δ-unsaturated peroxidic derivatives CH_2=$CH(CH_2)_3OY$ (Y = O*t*Bu, $OCMe_2Ph$, OCOEt, $OCMe_2OMe$) in various solvents yields a heterocycle and, in some cases, a peroxidic adduct. Intramolecular homolytic substitution (S_Hi) leading to the cyclic ether is highly dependent on the thermal stability of the peroxidic linkage. The rate constant was determined at 60°C for Y = O*t*Bu, $OCMe_2Ph$.

Depuis plusieurs années notre recherche s'est développée dans la définition des paramètres gouvernant la décomposition induite des composés peroxydiques insaturés afin de permettre des applications synthétiques de ce type de réaction. Au cours de ce travail, nous avons observé une première fois (1) l'influence de la nature du groupe lié à l'atome d'oxygène sur la compétition existant après addition du radical Z à la double liaison de dérivés peroxydiques de l'acide hex-5-énoïque. Lorsque la réaction est effectuée dans le cyclohexane (ZH = C_6H_{12}), si Y est un groupe *tert*-butoxyle, le seul produit de la réaction est le perester, tandis que si Y est un groupe hex-5-énoyloxyle, seule la δ-lactone est formée (figure 1, $n = 3$).

Par ailleurs au cours de l'étude du mécanisme de décomposition induite du perpent-4-énoate de *tert*-butyle (2) nous avons été amenés à remplacer le groupe *tert*-butoxyle par d'autres (Y = CH_2Ph, OCOR, NR_2) qui paraissaient susceptibles d'être expulsés par attaque intramoléculaire du radical résultant de l'addition du radical Z sur la double liaison (figure 1, $n = 2$). Seuls le perester de *tert*-butyle (Y = O*t*Bu) et le peroxyde de diacyle (Y = OCOR) ont conduit à la formation de la γ-lactone résultant de la substitution homolytique intramoléculaire (S_Hi) du groupe Y.

Cet ensemble de résultats semblait indiquer que la S_Hi se fait d'autant plus facilement que la liaison O—Y est plus faible. Nous avons voulu analyser ce phénomène en étudiant le comportement de différents dérivés peroxydiques, issus de l'hydroperoxyde de pent-5-ényle, qui présentent des stabilités thermiques différentes. En effet, il existe une corrélation entre ce paramètre et la force de la liaison O—Y rompue au cours de l'homolyse. Les modèles choisis pour effectuer cette étude sont les suivants :

CH_2=$CH(CH_2)_3O$—O*t*Bu **1***a* CH_2=$CH(CH_2)_3O$—$OCMe_2Ph$ **1***b*

CH_2=$CH(CH_2)_3O$—OC(O)Et **1***c* CH_2=$CH(CH_2)_3O$—$OCMe_2OMe$ **1***d*

[1]Auteurs à qui adresser toute correspondance.

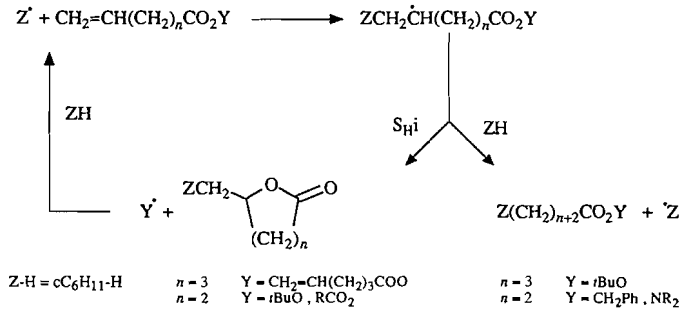

FIG. 1

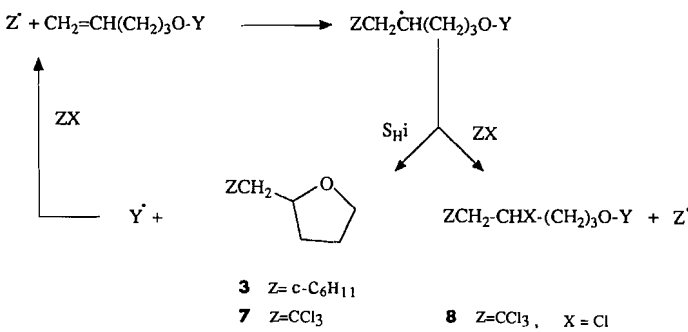

FIG. 2

Dans ces conditions, l'hétérocycle susceptible de se former sera le même dérivé tétrahydrofuranique (figure 2).

1. Définition des conditions de réaction

Les premières études ont été réalisées en utilisant le cyclohexane comme substrat ZH. Le rapport ZH/peroxyde a été fixé à 50/1, comme dans le travail relatif à la stéréochimie de la formation des tétrahydrofurane (3).

L'addition doit être réalisée à une température telle que la perte des composés peroxydiques **1** par thermolyse soit

Can. J. Chem. Downloaded from www.nrcresearchpress.com by ESC ESCOLA DE ENGENHARIA on 09/08/12

TABLEAU 1. Addition radicalaire[a,b] du cyclohexane aux composés peroxydiques **1**

n°	Y	Peroxyde résiduel	**3**	**4**	**5**	**6**	Bilan
1*a*	O*t*Bu	10	70	9	4		93
1*b*	$OCMe_2Ph$	[c]	36	6	4		46
1*c*	OC(O)Et	7	40	8	4	30	89
1*d*	$OCMe_2OMe$	25	44	6	4		79

[a]Rapports molaires solvant/**1**/PDCE : 50/1/0,5; 60°C; 10 h.
[b]Rendements déterminés par CPG par rapport au peroxyde mis en jeu.
[c]**1***b* ne peut pas être mis en évidence dans nos conditions d'analyse.

minimisée, la réaction radicalaire étant déclenchée par la dégradation d'un amorceur annexe. Le choix de ce dernier dépend de la stabilité thermique des composés **1**. Une étude qualitative par DSC des composés saturés correspondants $CH_3(CH_2)_4O$—Y, **2**, en solution 0,1 mol/L dans le phtalate de dibutyle indique que la décomposition débute à 115°C pour **2***a* et **2***b*, 65°C pour **2***c* et 105°C pour **2***d*. Ceci montre que la stabilité de la liaison O—Y augmente dans le sens :

$$\underset{\mathbf{2}c}{\text{O—OCOEt}} < \underset{\mathbf{2}d}{\text{O—OCMe}_2\text{OMe}} < \underset{\mathbf{2}a}{\text{O—O}t\text{Bu}}, \underset{\mathbf{2}b}{\text{O—OCMe}_2\text{Ph}}$$

Nous avons donc choisi d'amorcer les additions radicalaires à 60°C par le perdicarbonate de diéthyle (PDCE). Des essais préliminaires ont montré que les meilleurs rendements en 2-cyclohexylméthyl tétrahydrofurane, **3**, (figure 2, Z—X = cC_6H_{11}—H) sont obtenus pour un rapport molaire PDCE/**1** = 0,5.

En conclusion, les conditions de réaction sont les suivantes : chauffage d'un mélange cyclohexane/**1**/PDCE (rapports molaires 50/1/0,5) à 60°C durant 10 h.

2. Addition de radicaux cyclohexyle

Les produits obtenus au cours des additions radicalaires du cyclohexane aux composés peroxydiques **1** sont présentés dans le tableau 1.

À côté de l'éther cyclique **3** dont la formation est décrite dans la figure 2 (Z = cC_6H_{11}), on identifie dans tous les cas : (*i*) l'éther de cyclohexyle et de pent-4-ényle, issu de l'attaque de la liaison O—O par le radical cyclohexyle (figure 3). Compte-tenu des faibles rendements d'obtention de ce produit, nous n'avons pas cherché les produits du type $C_6H_{11}Y$, qui pourraient se former de la même manière, d'autant plus que, dans les milieux réactionnels, tous les composés présents en quantités importantes ont été identifiés; (*ii*) le carbonate d'éthyle et de (2-tétrahydrofuryl) méthyle, **5**, formé par addition du radical éthoxycarbonyloxyle issu de l'amorceur au dérivé peroxydique **1** (figure 4).

Dans le cas particulier du perpropionate de pent-4-ényle, **1***c*, on observe la présence du 2-propyl tétrahydrofurane, **6**, formé par décomposition induite du perester par le radical éthyle (figure 5). Cette réaction, secondaire ici, peut présenter une excellente voie d'accès à des 2-alkyl tétrahydrofuranes.

La différence de comportement des radicaux éthoxycarbonyloxyle et propionyloxyle s'explique par une plus grande vitesse de décarboxylation de ces derniers (4, 5).

Notons que si le bilan en produits identifiés est compris

FIG. 3

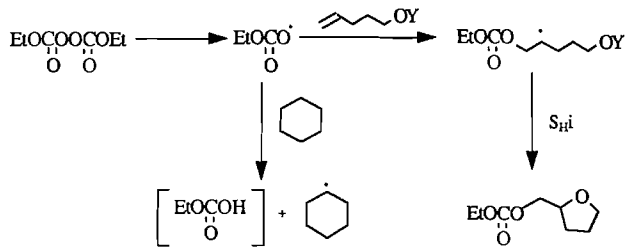

FIG. 4

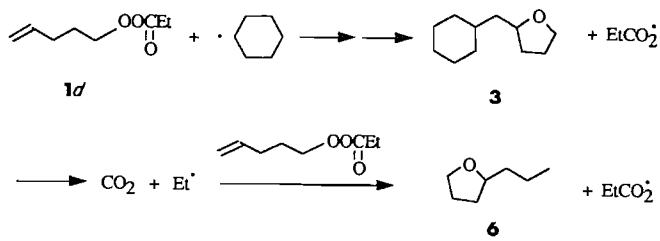

FIG. 5

entre 79 et 93% pour les peroxydes **1***a*, **1***c* et **1***d*, il est loin d'être complet pour le peroxyde **1***b*, même en considérant que le mélange réactionnel peut contenir du peroxyde initial.

Si l'on compare les rapports hétérocycles formés (**3** + **5** + **6**)/composé peroxydique consommé, le classement des aptitudes des divers composés peroxydiques insaturés à conduire à un éther cyclique est :

$$\underset{\mathbf{1}d}{\text{O—OCMe}_2\text{OMe}} < \underset{\mathbf{1}a}{\text{O—O}t\text{Bu}}, \underset{\mathbf{1}c}{\text{O—OCOEt}}$$

le peroxyde **1***b* ne pouvant être classé, puisqu'il n'est pas possible de savoir s'il a été totalement consommé. Il ne semble donc y avoir aucune corrélation entre ce classement et celui de la stabilité des liaisons O—O des composés peroxydiques saturés **2**, précédemment établi.

Cependant, ces conclusions peuvent traduire davantage l'intervention de nombreuses réactions secondaires que l'influence de la nature de la liaison O—O sur la réaction étudiée. C'est pourquoi, une autre méthodologie devra être développée.

3. Addition de radicaux trichlorométhyle

Une définition efficace de l'influence de la force de la liaison O—O sur la facilité de la S_Hi nécessite la recherche de conditions dans lesquelles il pourrait y avoir compétition entre la S_Hi et une réaction de transfert; cette dernière serait utilisée comme réaction étalon.

Le choix du milieu réactionnel pour cette étude doit être basé sur les remarques suivantes : (*i*) le radical Z doit s'additionner efficacement sur la double liaison; (*ii*) le radical Z doit avoir plusieurs sources ZX pour lesquelles la constante de vitesse de transfert de X à un radical alkyle secondaire est connue; ces composés doivent aussi transférer aisément l'atome X aux radicaux Y ou à ceux qui en découlent.

Les dérivés de type CCl_3—X satisfont à ces conditions. L'utilisation d'un précurseur des espèces trichlorométhyle plutôt qu'un autre, voire d'un mélange, permet d'obtenir des proportions relatives d'hétérocycle **7** et de peroxyde adduit **8** variables (figure 2, Z—X = CCl_3—X). En effet, les vitesses d'attaque du radical alkyle secondaire sur le dérivé halogéné devraient varier fortement selon la nature de l'atome X, si l'on se base sur les constantes de vitesse suivantes :

X = H $k_H = 2{,}54 \times 10^2\ M^{-1}\ s^{-1}$ (37°C) pour un radical *tert*-butyle (6)

X = Cl $k_{Cl} = 4{,}9 \times 10^4\ M^{-1}\ s^{-1}$ (37°C) pour un radical *tert*-butyle (6)

X = Cl $k_{Cl} = 1{,}9 \times 10^5\ M^{-1}\ s^{-1}$ (60°C) pour un radical cyclohexyle (7)

X = Br $\frac{k_{Br}}{k_{Cl}} = 1600$ pour un radical cyclohexyle (8)

soit $k_{Br} = 3 \times 10^8\ M^{-1}\ s^{-1}$ (60°C).

Les réactions sont réalisées comme indiqué dans la section 1, à savoir : chauffage à 60°C durant 10 h. Compte tenu de la nature des solvants et afin de piéger l'eau et les acides pouvant se former ou présents initialement, les décompositions sont effectuées, sous agitation, en présence de sulfate et de carbonate de sodium anhydres (9). Les rapports molaires solvant/peroxyde/PDCE/Na_2SO_4/Na_2CO_3 utilisés sont 50/1/0,5/0,1/0,2.

(a) Constantes de vitesse des S_Hi

Dans la mesure où l'hétérocycle **7** et le peroxyde adduit **8** sont stables dans les conditions de réaction et d'analyse, la détermination de leurs proportions relatives, à faible taux de conversion du peroxyde **1**, permet d'accéder à la constante de vitesse de la S_Hi.

En effet compte-tenu de la compétition étudiée (figure 2, Z—X = CCl_3—X), on peut écrire les équations cinétiques :

$$\frac{d[\mathbf{7}]}{dt} = k_{S_Hi}[R^\cdot]$$

$$\frac{d[\mathbf{8}]}{dt} = k_X[R^\cdot][CCl_3X]$$

soit après intégration :

$$\frac{[\mathbf{7}]}{[\mathbf{8}]} = \frac{k_{S_Hi}}{k_X}\,\frac{1}{[CCl_3X]}$$

ou $$k_{S_Hi} = k_X[CCl_3X]\,\frac{[\mathbf{7}]}{[\mathbf{8}]}$$

Peroxyde de tert*-butyle et de pent-4-ényle,* **1***a*

La décomposition de **1***a* dans CCl_4 conduit à un mélange hétérocycle–peroxyde adduit dans lequel l'hétérocycle est très minoritaire. L'utilisation d'un solvant tel que $CHCl_3$, dans lequel le transfert de X (H) est moins rapide, permet de favoriser la formation de ce dernier; mais dans ces conditions le peroxyde adduit n'est pas obtenu. Des réactions ont donc été réalisées, à l'échelle analytique, dans des mélanges $CHCl_3$/CCl_4 utilisés dans les rapports molaires : 90/10; 80/20; 70/30; 60/40; 50/50, contenant respectivement : 1,25; 2,4; 3,55; 4,6; 5,65 moles de CCl_4 par litre. Le peroxyde de *tert*-butyle et de 4,6,6,6-tétrachlorohexyle, **8***a*, et le 2-(2,2,2-trichloroéthyl) tétrahydrofurane, **7**, sont dosés par CPG; la validité du dosage est testée par l'analyse de mélanges synthétiques de mêmes compositions. Les résultats sont rassemblés dans la figure 6.

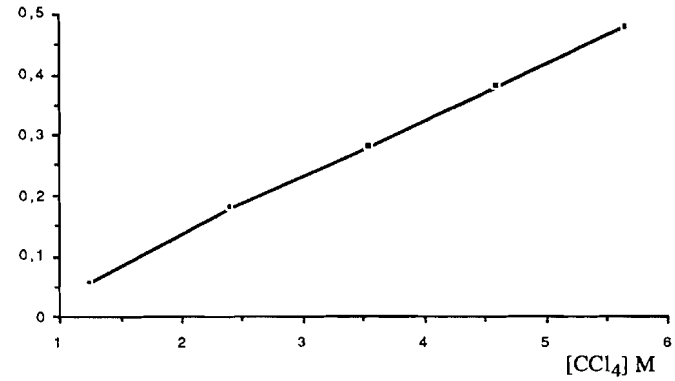

FIG. 6. Effet de la concentration en CCl_4 sur la distribution des produits de réaction.

Compte-tenu de l'équation cinétique précédemment établie, la pente de la droite $[\mathbf{8}a]/[\mathbf{7}] = f([CCl_4])$ représente le rapport k_{Cl}/k_{S_Hi}. Des valeurs expérimentale ($k_{Cl}/k_{S_Hi} = 0{,}08$) et bibliographique (7) ($k_{Cl} = 1{,}9 \times 10^5\ M^{-1}\ s^{-1}$ pour un radical alkyle secondaire à 60°C), on peut déduire : $k_{S_Hi} = 2{,}4 \times 10^6\ s^{-1}$. Notons que les résultats obtenus lors de l'addition de CCl_4 à **1***a* (10) nous avaient conduits à une estimation de l'ordre de $10^6\ s^{-1}$, à 110°C.

Peroxyde de cumyle et de pent-4-ényle, **1**b

Contrairement au cas précédent, la détection en CPG du peroxyde adduit **8***b*, de masse moléculaire plus élevée, est impossible. Une estimation de la constante de vitesse de la S_Hi a alors été réalisée à partir des produits isolés. La décomposition de **1***b* dans CCl_4 conduit, après chromatographie liquide–solide, à 25% d'hétérocycle **7** et 15% de peroxyde de cumyle et de 4,6,6,6-tétrachlorohexyle, **8***b*. Dans l'hypothèse où ces deux composés ont été totalement récupérés, on estime $k_{S_Hi} \sim 3 \times 10^6\ s^{-1}$.

TABLEAU 2. Addition radicalaire[a] de solvants polyhalogénés aux composés peroxydiques **1**

n°	Y	7 Rdt (%)[b]	Solvant CCl_4	Solvant $BrCCl_3$
1*a*	O*t*Bu	<2	99	1
1*b*	$OCMe_2Ph$	<2	99	1
1*c*	OC(O)Et	6	0	100
1*d*	$OCMe_2OMe$	<2	90	10

[a]Rapports molaires solvant/**1**/PDCE/Na_2SO_4/Na_2CO_3 : 50/1/0,5/0,1/0,2; 60°C : 10 h.
[b]Présence décelée par CPG (limite de détection de **7**, ~2%).

Perpropionate de pent-4-ényle, **1***c, et peroxyde de (1-méthoxy-1-méthyl) éthyle et de pent-4-ényle,* **1***d*

Les peroxydes adduits **8***c* et **8***d*, beaucoup plus fragiles que leurs homologues **8***a* et **8***b* (cf. peroxydes saturés dans section 1), n'ayant pu être préparés en raison de leur instabilité, il n'a pas été possible de les identifier lors des décompositions de **1***c* et **1***d*. Par conséquent une estimation de la constante de vitesse de la substitution homolytique ne peut être donnée.

(b) Classement des réactions de S_Hi en fonction des groupes Y

S'il ne nous est pas possible pour tous les composés peroxydiques **1** de déterminer la quantité de peroxyde adduit formé, il devrait être relativement facile de définir à partir de quelles proportions et de quel mélange de solvants précurseurs de radicaux $^{\cdot}CCl_3$ la réaction de S_Hi n'a plus lieu, en suivant la disparition de **7**.

Les réactions ont tout d'abord été effectuées dans le tétrachlorure de carbone afin de situer la réaction de S_Hi relativement au transfert. Dans ce solvant, **7** est identifié dans tous les cas. Afin de favoriser l'étape de transfert, des quantités croissantes de $BrCCl_3$ ont été ajoutées au CCl_4. Les proportions limites des deux solvants halogénés permettant d'éliminer la formation de **7** ont pu être définies (tableau 2).

Les résultats de cette étude montrent que la facilité de la S_Hi évolue donc dans le sens :

$$\underset{\mathbf{1}a}{O\text{—}OtBu},\ \underset{\mathbf{1}b}{O\text{—}OCMe_2Ph},\ <\ \underset{\mathbf{1}d}{O\text{—}OCMe_2OMe}\ <\ \underset{\mathbf{1}c}{O\text{—}OCOEt}$$

Si l'on compare ce classement à celui des stabilités des composés peroxydiques saturés correspondant, on observe une bonne concordance générale. Toutefois, ces résultats doivent être considérés avec une certaine précaution en raison de l'absence de bilans réactionnels au cours des analyses.

Conclusion

Cette étude a permis de montrer que le classement des composés peroxydiques vis à vis de la S_Hi :

$$O\text{—}OtBu,\ O\text{—}OCMe_2Ph,\ <\ O\text{—}OCMe_2OMe\ <\ O\text{—}OCOEt$$

semble suivre l'ordre inverse de stabilité des fonctions peroxydiques :

$$O\text{—}OCOEt\ <\ O\text{—}OCMe_2OMe\ <\ O\text{—}OtBu,\ O\text{—}OCMe_2Ph$$

Une estimation de la constante de vitesse de la S_Hi ($\sim 10^6$ s^{-1} à 60°C) n'a été possible qu'à partir de **1***a* et **1***b*, du fait de l'instabilité des peroxydes adduits susceptibles de se former dans les autres cas.

Partie expérimentale

Techniques analytiques

L'analyse des produits de réaction par chromatographie en phase gazeuse a été effectuée sur les appareils suivants : Intersmat IGC 112 F (ionisation de flamme, gaz vecteur : azote), équipé de colonnes en acier inox de 2 mm de diamètre intérieur : OV 17 (10% sur Chromosorb W HP, 80/100 mesh, longueur 1,5 m), FFAP (10% sur Chromosorb W AW, 80/100 mesh, longueur 2 m) et Carbowax 20 M (5% sur Chromosorb W DMCS, 80/10 mesh, longueur 3 m); Delsi DI 200 (ionisation de flamme, gaz vecteur : azote), équipé de colonnes capillaires en silice fondue : CP Sil 5 CB (longueur 25 m, diamètre intérieur 0,32 mm) et BP 20 (longueur 25 m, diamètre intérieur 0,22 mm). Ces appareils sont associés à un intégrateur Intersmat 1CR-1B donnant les temps de rétention et les surfaces des pics. Les dosages ont été effectués par la méthode de l'étalon interne.

Les spectres RMN ^1H ont été enregistrés sur des appareils Perkin–Elmer R 24B fonctionnant à 60 MHz et Bruker AC 250 fonctionnant à 250 MHz. Tous les composés étudiés sont en solution dans le tétrachlorure de carbone, en présence de TMS ou de benzène comme référence interne. Les spectres RMN ^{13}C ont été enregistrés dans des solutions de chloroforme deutéré sur un appareil Bruker AC 250 fonctionnant à 62,9 MHz.

Les spectres de masse ont été réalisés sur un spectromètre à simple focalisation VG Micromass 16F, couplé avec un chromatographe en phase gazeuse Intersmat IGC 121M.

Techniques réactionnelles

Les réactions sont effectuées par chauffage à 60°C, durant 10 h, de mélanges constitués par le solvant, le composé peroxydique et l'amorceur (perdicarbonate de diéthyle, PDCE) dans les rapports molaires 50/1/0,5. Lorsqu'il s'agit de solvants halogénés, du sulfate et du carbonate de sodium sont ajoutés dans les rapports molaires 0,1/0,2, et le milieu réactionnel est agité magnétiquement. Les conditions propres à chaque expérience sont rappelées dans les tableaux de la partie théorique.

(a) Études analytiques : 2 cm^3 de solution sont introduits dans une ampoule de 10 cm^3. Celle-ci, fermée hermétiquement, est placée sur un agitateur magnétique chauffant équipé d'un bain d'huile thermostaté. Les rendements sont déterminés par CPG directement sur le mélange réactionnel selon la méthode de l'étalon interne.

(b) Études préparatives : 90 cm^3 de solution sont introduits dans un autoclave en acier de 125 cm^3 que l'on place dans une étuve préalablement chauffée à 60°C ou sur un agitateur magnétique chauffant équipé d'un bain d'huile thermostaté. Après élimination du solvant, les hétérocycles sont isolés par distillation (appareil classique ou microfour tubulaire). Les peroxydes adduits sont isolés par chromatographie liquide–solide sur gel de silice. Les structures sont déterminées par les techniques spectroscopiques habituelles.

Matières premières

(a) Amorceur

Le *perdicarbonate de diéthyle* est synthétisé selon la référence 11.

(b) Peroxydes de dialkyle

Ils sont préparés à partir du 5-bromopent-1-ène (12) ou du 1-bromopentane et des hydroperoxydes de *tert*-butyle ou de cumyle selon la référence 13. *Peroxyde de* tert*-butyle et de pent-4-ényle,* **1***a* : décrit dans la référence 10. *Peroxyde de cumyle et de pent-4-ényle,* **1***b* : purifié sur silice; Rdt = 75%; n_D^{20} = 1,4975. RMN ^1H (ppm) : 7,7–6,9, m, 5H (H Ar); 6,2–4,6, m, 3H (CH_2=CH); 3,8, t (J = 8 Hz), 2H (CH_2O); 2,3–1,6, m, 4H (CH_2CH_2); 1,5, s, 6H ($(CH_3)_2C$). *Peroxyde de* tert*-butyle et de pentyle,* **2***a* : décrit dans la référence 13. *Peroxyde de cumyle et de pentyle,* **2***b* : purifié sur silice; Rdt = 65%; n_D^{20} = 1,4868. RMN ^1H (ppm) : 7,6–6,9, m, 5H (H Ar); 3,8, t (J = 8 Hz), 2H (CH_2O); 2,3–0,9, m, 15H (autres H). Litt. (14) $Eb_{0,01}$ = 46–47°C.

For personal use only.

(c) Peresters

Ils sont synthétisés selon la référence 15 à partir du chlorure de propanoyle et des hydroperoxydes correspondants, eux-mêmes préparés selon la référence 16 à partir du pent-4-én-1-ol (17) et du pentanol, via leur mésylate (18). *Perpropionate de pent-4-ényle,* **1***c* : purifié sur silice; Rdt = 58%; n_D^{20} = 1,4300. RMN ^{1}H (ppm) : 6,1–4,7, m, 3H (CH_2=CH); 4,1, t (J = 8 Hz), 2H (CH_2O); 2,6–1,6, m, 6H (autres CH_2); 1,1, t (J = 8 Hz), 3H (CH_3). *Perpropionate de pentyle,* **2***c* : purifié sur silice; Rdt = 63%; n_D^{20} = 1,4158. RMN ^{1}H (ppm) : 4,1, t (J = 8 Hz), 2H (CH_2O); 2,3, q (J = 8 Hz), 2H (CH_2CH_3); 2–0,8, m, 12H (autres H).

(d) Peroxycétals

Ils sont préparés selon la référence 19 à partir de 2-méthoxypropène et des hydroperoxydes correspondants en milieu acide. *Peroxyde de (1-méthoxy-1-méthyl) éthyle et de pent-4-ényle,* **1***d* : Rdt = 60%; n_D^{20} = 1,4275; Eb_5 = 48°C. RMN ^{1}H (ppm) : 6,2–4,7, m, 3H (CH_2=CH); 3,9, t (J = 8 Hz), 2H (CH_2O); 3,1, s, 3H (CH_3O); 2,5–1,3, m, 4H (CH_2CH_2); 1,25, s, 6H (($CH_3)_2C$). *Peroxyde de (1-méthoxy-1-méthyl) éthyle et de pentyle,* **2***d* : Rdt = 48%; n_D^{20} = 1,4116; Eb_{10} = 61°C. RMN ^{1}H (ppm) : 3,9, t (J = 8 Hz), 2H (CH_2O); 3,2, s, 3H (CH_3O); 1,8–0,8, m, 9H (autres H); 1,25, s, 6H (($CH_3)_2C$).

Produits de réactions

2-Cyclohexylméthyl tétrahydrofurane, ***3*** : n_D^{20} = 1,4721; $Eb_{0,35}$ = 77°C (litt. (20) $Eb_{0,1}$ = 45°C). RMN ^{1}H (ppm) : 4,2–3,5, m, 3H (H en α de O); 2,25–1, m, 17H (autres H). Principaux pics du spectre de masse (*m/z*, abondance) : 41 (35); 43 (30); 55 (21); 71 (100).

Ether de cyclohexyle et de pent-4-ényle, ***4*** : un échantillon de référence a été synthétisé selon la référence 21 : Une solution de 0,05 mol de cyclohexanol dans son volume de HMPT est additionnée goutte à goutte à 0,05 mol de NaH recouvert de HMPT. Un fort dégagement gazeux se produit. À la fin de celui-ci, on ajoute 0,05 mol de 5-bromopent-1-ène en solution dans son volume de HMPT, puis le milieu réactionnel est chauffé 3 h à 70°C. Après refroidissement, la solution est versée sur la glace, puis acidifiée avec HCl 10%. La phase organique est extraite à l'éther, lavée à l'eau jusqu'à neutralité puis séchée sur sulfate de sodium anhydre. Après élimination du solvant, l'éther obtenu est purifié par distillation; Rdt = 35%; n_D^{20} = 1,4511; Eb_3 = 104°C. RMN ^{1}H (ppm) : 6,1–4,7, m, 3H (CH_2=CH); 4–3,7, m, 3H (H en α de O); 2,1–1, m, 14H (autres H). Rate constants for cyanate hydrolysis to urea: A Raman study

NANPING WEN AND MURRAY H. BROOKER[1]

Chemistry Department, Memorial University of Newfoundland, St. John's, NF A1B 3X7, Canada

Received September 1, 1992[2]

NANPING WEN and MURRAY H. BROOKER. Can. J. Chem. **72**, 1099 (1994).

Raman spectra of aqueous solutions of potassium cyanate have been obtained at suitable time intervals. It was found that the peaks attributed to cyanate became less intense, while the peaks attributed to urea, carbamate and carbonate, centred at 1003, 1034, and 1065 cm^{-1}, respectively, enhanced greatly with the passage of time. Further Raman spectroscopic studies revealed that the cyanate ion hydrolysed slowly and spontaneously at room temperature. Urea, carbamate, and carbonate were formed even without additional ammonium. Raman intensity measurements were used to monitor species concentrations as a function of time. The results suggested a complicated hydrolysis process: the hydrolysis of cyanate ion to form carbonate and ammonium, a rearrangement type reaction of aqueous cyanate ion with aqueous ammonium to formed urea, and an equilibrium reaction of carbonate and ammonium to form carbamate. The initial hydrolysis of cyanate with pure water was found to be first order with rate constant $k_1 = (2.67 \pm 0.53) \times 10^{-4}$ min^{-1} at 22°C. The reaction of cyanate with aqueous ammonium was found to be second order with rate constant $k_2 = (4.64 \pm 0.93) \times 10^{-4}$ $mol^{-1} \cdot L \cdot min^{-1}$. The equilibrium reaction of carbonate and ammonium to form carbamate was very fast. Urea and carbamate were formed in parallel reactions. It was not possible to convert urea to carbamate or carbamate to urea at room temperature.

NANPING WEN et MURRAY H. BROOKER. Can. J. Chem. **72**, 1099 (1994).

On a déterminé les spectres Raman de solutions aqueuses de cyanate de potassium à divers intervalles de temps. On a trouvé que l'intensité des raies d'absorption attribuées au cyanate diminuent avec le temps alors que celles des raies dues à l'urée, au carbamate et au carbonate, centrées respectivement à 1003, 1034 et 1065 cm^{-1}, augmentent considérablement avec le temps. D'autres études par spectroscopie Raman ont révélé que, à la température ambiante, l'ion cyanate s'hydrolyse lentement et spontanément. Il y a formation d'urée, de carbamate et de carbonate, même sans addition d'ion ammonium supplémentaire. On a utilisé des mesures d'intensité en Raman pour déterminer d'une façon quantitative les concentrations des diverses espèces en fonction du temps. Les résultats suggèrent l'existence d'un processus d'hydrolyse compliqué; l'hydrolyse de l'ion cyanate pour former du carbonate et de l'ammonium, une réaction ressemblant à un réarrangement de l'ion cyanate aqueux avec de l'ammonium aqueux conduisant à de l'urée et une réaction d'équilibre du carbonate et de l'ammonium pour former du carbamate. On a trouvé que l'hydrolyse initiale du cyanate dans l'eau pure est du premier ordre avec une constante de vitesse de $k_1 = (2{,}67 \pm 0{,}53) \times 10^{-4}$ min^{-1}, à 22°C. On a trouvé que la réaction du cyanate avec l'ammonium aqueux est du deuxième ordre, avec une constante de vitesse $k_2 = (4{,}64 \pm 0{,}93) \times 10^{-4}$ $mol^{-1} \cdot L \cdot min^{-1}$. La réaction d'équilibre du carbonate et de l'ammonium pour former du carbamate est très rapide. L'urée et le carbonate se forment par des réactions parallèles. À la température ambiante, il n'a pas été possible de transformer de l'urée en carbamate ou du carbamate en urée.

[Traduit par la Rédaction]

1. Introduction

Wöhler (1) first synthesised urea in 1828 by evaporation to dryness a mixture of aqueous ammonium sulphate and potassium cyanate. It has long been supposed that the ammonium cyanate produced in the metathesis reaction rearranged into urea although the mechanism has been the subject of much debate (2). As part of a comprehensive study (3) of aqueous solutions of small molecules which contain N, C, O, and H the Raman spectrum KOCN has been measured for the aged aqueous phase. A full account of band assignments, Fermi resonance, and hydration of aqueous cyanate has been presented elsewhere (3, 4).

Several previous studies (5, 6) indicated that the spectrum of the potassium cyanate aqueous solution changed with the passage of time. After aqueous cyanate had stood a few days, new peaks were observed. Williams (5) and Cleveland (6) have reported evidence of cyanate hydrolysis and assigned the new peaks to ammonium, carbonate, and bicarbonate ions formed by hydrolysis reactions ([1] and [2]).

[1] $$KOCN + 3H_2O \rightarrow KHCO_3 + NH_4OH$$

[2] $$2KOCN + 4H_2O \rightarrow K_2CO_3 + (NH_4)_2CO_3$$

However, the present study on aged aqueous potassium cyanate revealed the presence of urea, carbamate, and carbonate formed by hydrolysis (reaction [3]). Urea was formed even in the absence of additional ammonium.

[3] $$3OCN^- + 3H_2O \rightarrow H_2NCOO^- + H_2NCONH_2 + CO_3^{2-}$$

There was no evidence to suggest the presence of bicarbonate or ammonium ions in the aged solutions although small quantities of these ions would be expected since aqueous carbamate has been shown to exist in equilibrium with ammonium, carbonate, and bicarbonate (3, 7). Addition of potassium cyanate to aqueous ammonium chloride resulted in a much greater yield in urea.

2. Experimental

The spectroscopic measurements were carried out on a Coderg PHO Raman spectrometer after sample excitation with a INNOVA 70-4 argon ion laser operating at approximately 1300 mW output in the 488.0 nm wavelength line. The usual right angle scattering geometry was employed with the incident light vertically polarized and the scattered light analyzed with polaroid film to give the $I_{\parallel}[x(zz)y]$ and $I_{\perp}[x(zx)y]$ scattering geometries. A quarter-wave plate before the entrance slit served to compensate for the grating polarization preference. Raman wavenumber calibration was achieved with the plasma lines of the laser, but when required a narrow-bandpass interference filter was used to remove the unwanted plasma lines. The spectral slit widths of the double monochromator were set at 2.0 cm^{-1}, which is sufficiently narrow to avoid the need for a slit correction to the band-shape. The Raman scattering light was detected with a PMT cooled to −30°C, integrated with a photon counter and processed with a

home-built box-car averager interfaced to the Memorial University VAX 8800 computer. The scan rate was 50 cm^{-1} min^{-1} and two data points were collected per wavenumber. Spectra were smoothed twice with a Savitsky–Golay three-point smoothing function. Curve resolution of overlapped bands and calculations of band half-width and intensity were achieved with a standard computer fitting program CURVEFIT originally developed by Pitha and Jones (8–10) for infrared spectroscopy and subsequently modified by Brooker and Rice (11) for Raman spectroscopy (BASIC language, VAX/VMS version).

All chemicals were reagent grade used without further purification. Potassium cyanate was obtained from BDH Chemical Ltd. Aqueous solutions were prepared with distilled water. The aqueous solutions of potassium cyanate contained a measured amount of $NaClO_4$ (0.0500 mol·L^{-1}) and the 935 cm^{-1} band of ClO_4^- was used as an internal intensity standard for the quantitative study. Samples were sealed-off in quartz tubing (4 mm in outsider diameter and approximately 15 cm in length) under their own vapour pressure to avoid loss of ammonia and carbon dioxide gases which are decomposition products of carbamic acid. The aqueous samples were routinely centrifuged for 5 min to settle dust particles. The Raman spectra of the fresh aqueous solutions were obtained immediately. Samples were then stored in a lightproof place. Additional Raman studies were made after suitable intervals. No special effort was made to control the temperatures of the samples for such long time periods; however the samples were measured and stored in a room at a well-controlled ambient temperature of 22 ± 0.5°C.

3. Results and discussion

Hydrolysis of cyanate to urea

The Raman spectrum of aqueous potassium cyanate solutions changed considerably with the passage of time (Fig. 1). In the spectrum of a freshly prepared potassium cyanate aqeuous solution intense bands appeared at 1223 and 1310 cm^{-1} due to $2\nu_2$ and ν_1 in Fermi resonance (3, 4). Several hours after the solution was prepared the bands centred at 1223 and 1310 cm^{-1} became less intense, while the new bands appearing at 1003, 1034, and 1065 cm^{-1} greatly increased in intensity with the passage of time. After about 10 days the intensities of the new bands reached a maximum and the bands due to cyanate were no longer detectable. As an aid to the assignments the Raman spectra between 300 and 2300 cm^{-1} of a 2.0 mol·L^{-1} potassium cyanate solution aged in ordinary aqueous solution (curve *a*) and aged in deuterium aqueous solution (curve *b*) were measured (Fig. 2).

Williams (5) and Cleveland (6) suggested that the new bands in the spectrum of potassium cyanate aged in ordinary aqueous solution arose from the carbonate, bicarbonate, and ammonium, which were formed by hydrolysis of potassium cyanate (reactions [1] and [2]). There can be no doubt that the band at 1065 cm^{-1} is due to the $\nu_1(A_1')$, CO_3^{2-} symmetric stretch. However, there was no evidence to suggest the presence of peaks due to bicarbonate or ammonium as suggested by Williams and Cleveland. The characteristic peaks for bicarbonate (12) and ammonium (13) are at 1017, $\nu_5(A')$, the C—OH stretching of bicarbonate ion, and 1450 cm^{-1}, the N—H antisymmetric stretching, $\nu_3(F_2)$, of ammonium ion, respectively. It was possible to identify the urea and carbamate ion as the source of the peaks at 1003 and 1034 cm^{-1} by comparison with spectra of known samples. The urea assignments were confirmed by the presence of bands due to $(ND_2)_2CO$ at 991 and 889 cm^{-1} in the spectrum (Fig. 2) of the sample hydrolysed in D_2O. These assignments were in excellent agreement with the results obtained by Yamaguchi et al. (14) for pure urea-d_4. Although the band due to carbamate-h_2 was identified in the spectrum of the KOCN hydrolysed in H_2O, a comparable band due to carbamate-d_2 was not detected for KOCN dissolved in D_2O. The difference between the present results and those of Cleveland and Williams can be accounted for by the experimental differences in the sample control. In the present work the samples were maintained in sealed tubes which did not allow ammonia gas to escape. An aged sample (sealed) of 2.0 mol·L^{-1} potassium cyanate aqueous solution had a pH value of about 10 when hydrolysis was complete. At this pH there should be a considerable amount of ammonia but because of the presence of carbonate an equilibrium reaction resulted and carbamate was formed. If the solution were exposed to atmosphere the carbamate solution would lose ammonia slowly and would become more acidic.

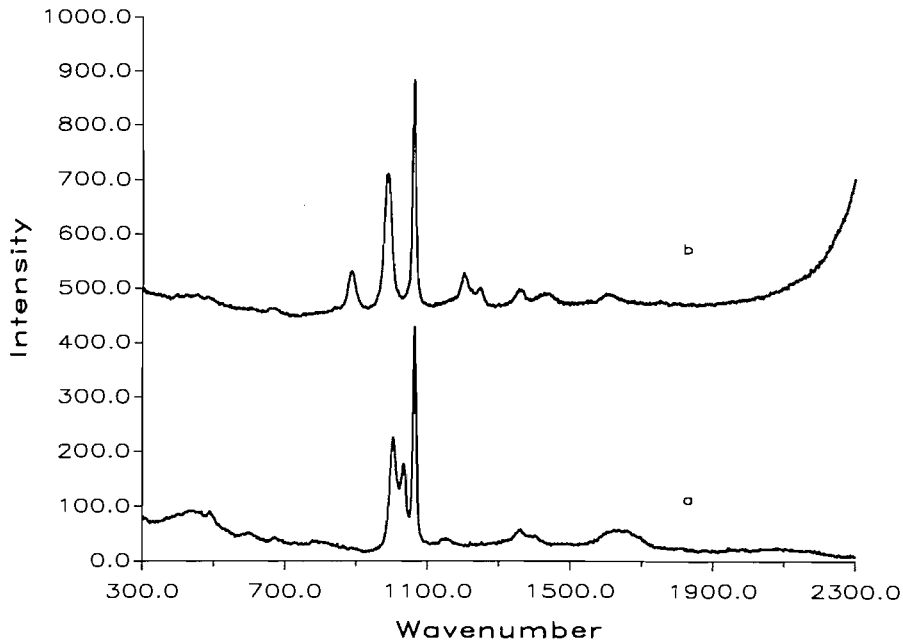

FIG. 2. Raman spectra of (*a*) an aged normal aqueous solution of 2.0 mol·L^{-1} KOCN; (*b*) an aged deuterium aqueous solution of 2.0 mol·L^{-1} KOCN, both at 22°C.

In 1828 Wöhler (1) synthesised urea by adding ammonium sulphate solution to potassium cyanate solution and evaporating the mixture to dryness. Normally, it is assumed that ammonium cyanate was prepared in an ion-pair reaction [4]

[4] $$NH_4^+ + OCN^- \rightarrow NH_4OCN$$

followed by rearrangement of ammonium cyanate to form urea (reaction [5]).

[5] $$NH_4OCN \rightarrow NH_2CONH_2$$

The nature and mechanism of this reaction is not fully understood. The mechanism for the formation of urea in the Wöhler synthesis was the subject of considerable debate in the early period (15–19). It has been shown that both the ionic and the molecular mechanisms conform to the same rate law because of the equilibrium acid–base reactions for ammonium, ammonia, and cyanate, cyanic acid with an overall equilibrium constant, K.

[6] $$NH_4^+ + OCN^- \rightarrow H_2NCONH_2$$

[7] $$\text{Rate} = kC_{NH_4^+}C_{OCN^-}(\gamma_\pm)^2$$

[8] $$NH_3 + HOCN \rightarrow H_2NCONH_2$$

[9] $$\text{Rate} = k'KC_{NH_3}C_{HOCN}(\gamma_\pm)^2$$

In 1961, Frost and Pearson (2) concluded that the two mechanisms were equally supported by the available kinetic evidence and would be indistinguishable through kinetic studies. However, Moelwyn-Hughes (20) did not agree with Frost and Pearson's conclusion and proposed that the ionic mechanism was indicated because of the similarity between the pre-exponential term in the Arrhenius equation for the Wöhler reaction with the same term for the ionic reaction of HCO_3^- protonation; both values are higher by a factor of at least 100 than the value generally found for reactions between neutral molecules in solution.

In the present study Raman spectra of aged aqueous solutions of a mixture 2.0 mol·L^{-1} ammonium chloride with 2.0 mol·L^{-1} potassium cyanate were measured and compared to a 2.0 mol·L^{-1} solution of pure urea (curves *a* and *b* in Fig. 3). The very strong band at 1003 cm^{-1} was due to the $\nu_4(A_1)$, NCN symmetric stretching, of urea (14). The urea has been characterized not only by the 1003 cm^{-1} band but also by the 1158, $\nu_3(A_1)$, NH_2 wagging, 1597, $\nu_2(A_1)$, NH_2 rocking, and 1662 cm^{-1}, $\nu_1(A_1)$, CO stretching, bands of urea (14). The band at 1034 cm^{-1}, of medium intensity and overlapping with the 1003 cm^{-1} band of urea (Fig. 1), was assigned to the ν_5, NH_2 symmetric rock, of H_2NCOO^- (21). Raman investigations of aqueous ammonium carbonate solutions (3, 7) showed that carbamate ion was a major equilibrium species but urea was not formed in this system.

[10] $$CO_3^{2-} + NH_4^+ \rightleftarrows H_2NCOO^- + H_2O$$

The carbamate ion has also been characterized by Raman bands at 563, ν_{12} torsion about the C—N axis, and 1405 cm^{-1}, ν_3 C—N stretching (21). These additional characteristic frequencies of carbamate ion have also been detected in the Raman spectrum of aged aqueous potassium cyanate (Fig. 3*c*).

There was no doubt that the new band at 1065 cm^{-1} with strong intensity (Figs. 1–3) was due to carbonate, as suggested by Williams and Cleveland. The presence of carbonate was clearly indicated by the characteristic peaks at 676 cm^{-1} $\nu_4(E')$, 1065 cm^{-1} $\nu_1(A_1')$, and a weak broad peak at 1380 cm^{-1} $\nu_3(E')$. The frequencies, half-widths, and depolarization ratios for these bands were all identical to those of the pure aqueous sodium carbonate.

It was concluded that the new bands at 1003, 1034, and 1065 cm^{-1} (Figs. 1–3) were due to $\nu_4(A_1)$, NCN symmetric stretching, of urea, ν_5, NH_2 symmetric rock, of carbamate, and $\nu_1(A_1')$, CO symmetric stretching, of carbonate, respectively. Clearly, urea, carbamate, and carbonate were formed

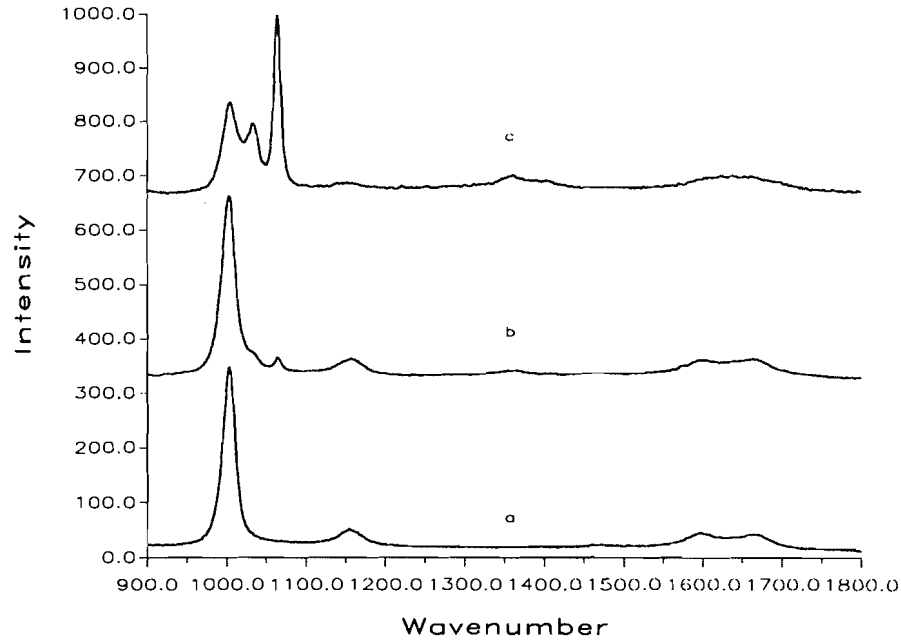

FIG. 3. Raman spectra of (*a*) an 2.0 mol·L^{-1} urea aqueous solution; (*b*) an aged aqueous solution of 2.0 mol·L^{-1} KOCN and 2.0 mol·L^{-1} NH_4Cl; (*c*) an aged aqueous solution of 2.0 mol·L^{-1} KOCN, all at 22°C.

by cyanate hydrolysis (reaction [11]).

[11] $$3OCN^- + 3H_2O \rightarrow H_2NCONH_2 + H_2NCOO^- + CO_3^{2-}$$

The rate of cyanate hydrolysis

The preliminary studies described above revealed that the cyanate ions underwent hydrolysis to form urea, carbamate and carbonate slowly and spontaneously, even without additional ammonium and the reaction took place at room temperature. The possible hydrolysis processes might be as follows:

[12] $$OCN^- + 2H_2O \rightarrow CO_3^{2-} + NH_4^+$$

[13] $$OCN^- + NH_4^+ \rightarrow H_2NCONH_2$$

[14] $$CO_3^{2-} + NH_4^+ \rightleftarrows H_2NCOO^- + H_2O$$

The overall reaction is

[15] $$3OCN^- + 3H_2O \rightarrow H_2NCONH_2 + H_2NCOO^- + CO_3^{2-}$$

In the first reaction, cyanate ion undergoes hydrolysis to produce carbonate and ammonium ions. Since there is a large excess of water in the reaction mixture, the concentration of water remains virtually constant throughout the course of the hydrolysis. Under this condition the change in the amount of water present in the solution has no effect on the rate. Therefore the rate of cyanate ion hydrolysis might be expressed as a first order reaction (eq. [16]).

[16] $$\text{Rate}_I = -\frac{dC_{OCN^-}}{dt} = k_1 C_{OCN^-}$$

where Rate_I is the rate of cyanate ion hydrolysis (eq. [12]). One can show from eq. [16] that

[17] $$\log C_{OCN^-} = -\frac{k_1 t}{2.303} + \log C_{0,OCN^-}$$

where log is the common or base 10 logarithms, C_{0,OCN^-} and C_{OCN^-} are the concentrations of cyanate ion at times $t = 0$ and $t = t$, respectively. Therefore if the reaction is first order a plot of log C_{OCN^-} versus t would give a straight line with a slope of $-k_1/2.303$. The rate constant k_1 can be determined.

Kinetic measurements were carried out for different concentrations of potassium cyanate. The results indicated that the hydrolysis of cyanate ion in pure water (eq. [12]) was very slow (e.g., for a 2.0 mol·L^{-1} KOCN aqueous solution complete reaction took about 10 days at room temperature). From the kinetic measurements it was found that the rate at which cyanate ion hydrolysed in dilute aqueous solution was directly proportional to the cyanate concentration for about the first 4000 min after sample preparation. An example will serve to illustrate the progress of the reaction with time.

The Raman spectrum of a 2.48 mol·L^{-1} KOCN aqueous solution changed with the passage of time (Fig. 1). The use of the 934 cm^{-1} band of ClO_4^- as an internal intensity reference permitted quantitative measurements of the concentration (C) from the integrated band intensities (I) through the relationship $I = JC$, where J is the molar scattering coefficient. It proved convenient to measure the increase in product concentrations: carbonate, carbamate, and bicarbonate because the cyanate bands were weak, broad, and complicated by Fermi resonance. Cyanate concentration measured at each time period are listed in Table 1, where the concentration of the cyanate ion, C_{OCN^-}, for each measurement was obtained by subtracting the concentrations of urea, carbamate, and carbonate from the initial concentration of cyanate ion.

[18] $$C_{OCN^-} = C_{0,OCN^-} - C_{H_2NCONH_2} - C_{H_2NCO_2^-} - C_{CO_3^{2-}}$$

$C_{H_2NCONH_2}$, $C_{H_2NCO_2^-}$, and $C_{CO_3^{2-}}$ were calculated from the relative integrated intensities of the 1003, 1034, and 1065 cm^{-1} bands obtained in each kinetic measurement and the corresponding $J_{H_2NCONH_2}$, $J_{H_2NCO_2^-}$, and $J_{CO_3^{2-}}$ values (0.481, 0.403, and 0.375 L·mol^{-1}) (3). $J_{CO_3^{2-}} = 0.375 \pm 0.019$ and $J_{H_2NCONH_2} = 0.481 \pm 0.024$ L·mol^{-1} were obtained from in-

tensity measurements of the 1065 cm^{-1} band of carbonate (in a series of aqueous sodium carbonate solutions) relative to the 934 cm^{-1} band of the perchlorate internal standard and for the 1003 cm^{-1} band of aqueous urea in an analogous procedure. The value of $J_{H_2NCOO^-} = 0.403 \pm 0.040$ L·mol^{-1} was obtained in a similar manner from intensity measurements of the 1034 cm^{-1} band of carbamate ion in aqueous ammonium carbamate solutions (a correction for the presence of carbonate and bicarbonate was required). The log C_{OCN^-} versus t plot (Fig. 4) gave a straight line with a slope of $-(1.158 \pm 0.231) \times 10^{-4}$ at $t < 4000$ min. The first order rate constant was determined from the slope of the line, $k_1 = (2.67 \pm 0.53) \times 10^{-4}$ min^{-1}. The half-life of the hydrolysis was 2600 (±520) min and was independent of the initial concentration of the cyanate ion.

For the second process, reaction of cyanate ion with ammonium to produce urea (eq. [13]), the rate might be considered as follows

$$[19] \qquad \text{Rate}_2 = -\frac{dC_{OCN^-}}{dt} = k_2 C_{OCN^-} C_{NH_4^+}$$

where Rate$_2$ is the rate of cyanate ion aqueous rearrangement reaction with ammonium (eq. [13]). In this case the initial concentrations of cyanate and ammonium were equal. They remained equal as the reaction proceeds if there were no competing reactions. The integrated rate equation for the second order reaction is then,

$$[20] \qquad \frac{1}{C_{OCN^-}} - \frac{1}{C_{0,OCN^-}} = k_2 t$$

If the reaction is second order the plot of $1/C_{OCN^-}$ versus t will give a straight line with a slope k_2.

To assess the above proposal Raman spectroscopy was used to study the reaction rates for solutions with constant concentration of cyanate and different concentrations of ammonium chloride. In an aqueous solution of cyanate also containing ammonium the hydrolysis reaction was much faster than that in a solution of potassium cyanate in water only (e.g., for a 2.0 mol · L^{-1} KOCN with 2.0 mol · L^{-1} NH_4Cl aqueous solution complete reaction took about 3 days at room temperature). Furthermore, the addition of ammonium to aqueous cyanate resulted in a much greater yield of urea. A second order reaction was indicated by the fact that when the concentration of cyanate was kept constant the rate was directly proportional to the concentration of ammonium. The greater the amount of ammonium, the faster the rate. Clearly, ammonium was one of the reactants and the reaction of cyanate ion with ammonium could be an elementary step.

For example, the Raman spectra measured at different elapsed time for the 2.47 mol·L^{-1} KOCN with 2.47 mol·L^{-1} NH_4Cl aqueous solution at room temperature showed that urea was formed (Fig. 5). The corresponding kinetic data have been listed in Table 2. For the graph of $1/C_{OCN^-}$

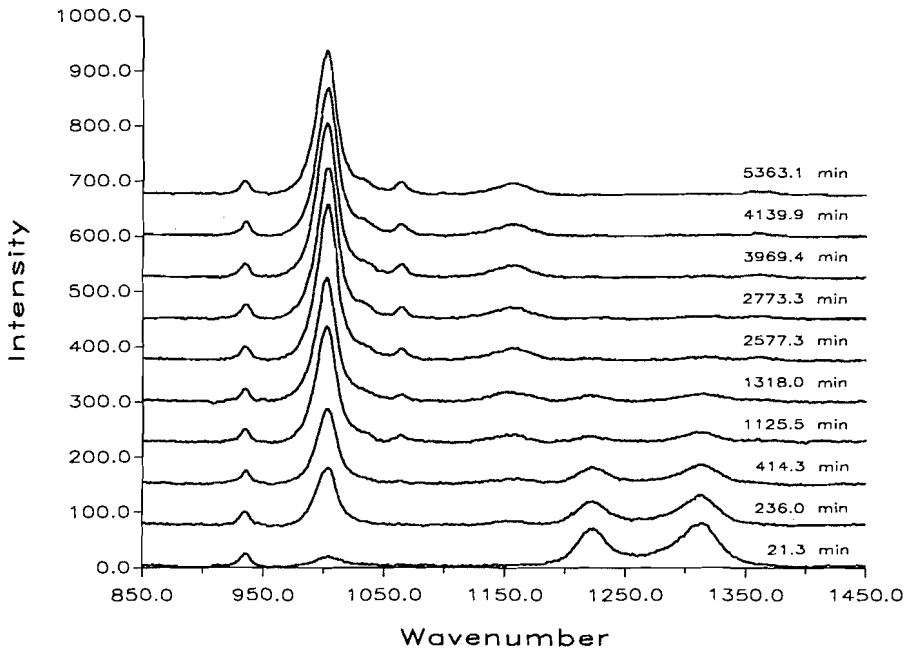

FIG. 5. Raman spectra of a solution of 2.47 mol·L^{-1} KOCN and 2.47 mol·L^{-1} NH_4Cl at 22°C at different times. A 0.0500 mol·L^{-1} $NaClO_4$ has been added as an internal intensity standard.

plotted versus t (Fig. 6) the points lie close to a straight line. These results confirmed that the kinetics were second order. The rate constant was equal to the slope of the line $k_2 = (4.64 \pm 0.93) \times 10^{-4}$ mol^{-1} · L · min^{-1}.

For the third process (eq. [14]), carbonate and ammonium react to produce carbamate.

[21] $$CO_3^{2-} + NH_4^+ \rightleftarrows H_2NCOO^- + H_2O$$

This reaction has been shown to be a fast exchange reaction. The carbonate and ammonium were found to be in equilibrium with carbamate. The equilibrium has been discussed in detail (3, 7). The amount carbonate and ammonium at equilibrium was essentially controlled by the pH. It was found that when the cyanate ion hydrolysis was complete, the aqueous solution had a pH value of about 10. At this pH the major species present are carbonate and carbamate, not bicarbonate.

The characteristic band of bicarbonate has been identified at 1017 cm^{-1}, $\nu_5(A')$ C—OH stretching (12). It was found that there was a small amount of bicarbonate (1017 cm^{-1}) in the early stage of the reaction (the curves at t = 21.6 min in Fig. 1). The presence of bicarbonate at the initial stage of hydrolysis can be explained by the fact that the hydrolysis of potassium cyanate in pure water initially gives a pH value of about 9. At this pH the carbonate ion produced in the first stage of cyanate hydrolysis (eq. [12]) was in equilibrium with bicarbonate. A detectable amount of bicarbonate was found in the early stage of hydrolysis but as NH_4^+ was consumed to produce urea the pH value increased and the equilibrium between the carbonate and bicarbonate shifted to favour the formation of the carbonate.

[22] $$CO_3^{2-} + H_2O \rightleftarrows HCO_3^- + OH^-$$

which then increased the formation of the carbamate.

[23] $$CO_3^{2-} + NH_4^+ \rightleftarrows H_2NCOO^- + H_2O$$

The hydrolysis of a mixture of 2.0 mol·L^{-1} potassium cyanate with 2.0 mol·L^{-1} aqueous ammonia was also studied by Raman measurements. It was found that the rate of cyanate hydrolysis was slower than the rate of cyanate hydrolysis in pure water although more ammonia was added. In this case the principal product was carbonate, not urea. The pH value for a mixture of 2.0 mol·L^{-1} potassium cyanate and 2.0 mol·L^{-1} ammonia was about 12. At this pH value, the concentration of ammonium ion free to react would only be 10^{-3} mol·L^{-1} initially. This small amount of ammonium ion had a negligible influence on the rate of cyanate hydrolysis. The fact that the rate of cyanate hydrolysis in aqueous ammonia was slower than that in pure water or that in ammonium chloride solution indicated that the reaction to produce urea is not just a nucleophilic attack of NH_3 at the C of OCN^-.

The kinetic Raman measurements were also carried out for a 2.0 mol·L^{-1} potassium cynate with additional sodium hy-

droxide (0.050 mol · L^{-1}) aqueous solution. The result indicated that the rate of cyanate hydrolysis in sodium hydroxide solution is much slower than that in pure water. When sodium hydroxide was added, the pH of this solution was about 13. At this high pH, the ammonium/ammonia ratio was 3.6×10^{-4} to 1. The free ammonium ion concentration produced from the first step of cyanate hydrolysis (eq. [12]) was reduced. With this low concentration of ammonium ion, the rate of cyanate rearrangement with ammonium to form urea (eq. [13]) was significantly reduced even when compared to cyanate hydrolysis in pure water.

From an overall view, the hydrolysis of cyanate ion is a complex process which contains a consecutive reaction, a parallel reaction, and a chemical equilibrium system. Careful consideration of cyanate ion hydrolysis in pure water indicated that when the concentration of cyanate ion, C_{OCN^-}, was not too low and the reaction time, t, was not too long (e.g., in the case of $C_{0,OCN^-} = 2$ mol·L^{-1}, $t < 4000$ min), the concentration of NH_4^+ produced by cyanate ion hydrolysis, $OCN^- + H_2O \rightarrow NH_4^+ + CO_3^{2-}$, was relatively low and the consumption of the cyanate ion by reacting with ammonium, $OCN^- + NH_4^+ \rightarrow H_2NCONH_2$, was relatively small. The effect of competition by the parallel reaction, $OCN^- + NH_4^+ \rightarrow H_2NCONH_2$, was not sufficient to cause deviation from first order kinetics. It is important to notice that urea was produced throughout the course of the reaction (Fig. 1). Nevertheless the initial part of log C_{OCN^-} versus t plot for cyanate ion hydrolysis in pure water (Fig. 4) was presented as a straight line. Therefore hydrolysis of the cyanate ion in pure water appears to be a first order reaction with the rate-determining step given by eq. [12]. When the reaction time was greater than 4000 min, $t > 4000$ min, the effect of competition by the parallel reaction, $OCN^- + NH_4^+ \rightarrow H_2NCONH_2$, increased and the concentration of cyanate decreased at a faster rate (Fig. 4).

For hydrolysis of potassium cyanate with additional ammonium chloride the concentration of added NH_4^+ was much higher than the concentration of NH_4^+ produced by cyanate hydrolysis, $OCN^- + H_2O \rightarrow NH_4^+ + CO_3^{2-}$. In addition, the rate constant of cyanate ion hydrolysis in pure water was much slower than the rate constant of the reaction of cyanate ion with ammonium. Since, $k_1 \ll k_2$, the $1/C_{OCN^-}$ versus t plot (Fig. 6) was a straight line.

The rate constants and half-lives for the reactions are presented in Table 3.

4. Conclusion

The rate constants have been determined for two parallel reactions that occur when cyanate undergoes hydrolysis. The initial stages of cyanate hydrolysis generate carbonate, bicarbonate, carbamate, and ammonium ions. The excess cyanate then reacts with ammonium to produce urea. The present studies cannot be directly compared to previous work because the previous work was performed at higher temperatures (because the reaction was so slow for conventional methods) and in open vessels. However, the results are in reasonable agreement with the values calculated from the kinetic parameters obtained at higher temperatures. The present work confirmed that the rate was directly proportional to the concentration of ammonium rather than ammonia and tends to support the ionic mechanism argued by Moelwyn-Hughes. The parallel reaction to produce carbamate has been shown to be important. The present study demonstrated that Raman spectroscopy can be employed to monitor both the reactants and the products associated with cyanate ion hydrolysis.

Interligand interaction in ternary complexes of Zn(II) and Cd(II) with dipeptides and aminoacids[1]

ALEXANDER VARGHESE VAIDYAN AND PABITRA K. BHATTACHARYA

Department of Chemistry, Faculty of Science, M.S. University of Baroda, Baroda 390002, India

Received June 11, 1993

ALEXANDER VARGHESE VAIDYAN and PABITRA K. BHATTACHARYA. Can. J. Chem. **72**, 1107 (1994).

The stability constants of binary and ternary complexes [MA], [MA_2], and [MAL] (where M = Zn(II) on Cd(II); A = glycylglycine, glycyl L-alanine, glycyl L-leucine; L = α-alanine phenylalanine, tyrosine, tryptophan, or L-listidine) in aqueous medium have been determined potentometrically at 25°C and an ionic strength of 0.2 M $NaClO_4$ (0.2 mol dm^{-3}) using a computer system. It is observed that Δ log *K* of MAL complexes has low negative or positive values. Probable reasons have been discussed.

ALEXANDER VARGHESE VAIDYAN et PABITRA K. BHATTACHARYA. Can. J. Chem. **72**, 1107 (1994).

Faisant appel à la potentiométrie, opérant à 25°C, dans un milieu aqueux de force ionique 0,2 M de $NaClO_4$ (0,2 mol dm^{-3}), et utilisant un logiciel d'ordinateur, on a déterminé les constantes de stabilité de complexes binaires et tertiaires [MA], [MA_2] et [MAL] dans lesquels M = Zn(II) ou Cd(II), A = glycylglycine, glycyl-L-alanine ou glycyl-L-leucine et L = α-alanine, phénylalanine, tyrosine, tryptophane ou L-histidine. On a observé que les valeurs du Δ log *K* des complexes MAL sont faibles, avec des signes négatifs ou positifs. On discute des causes de ces résultats.

[Traduit par la Rédaction]

Introduction

It is well known that Zn(II) ion is an integral component of many proteins and is indispensable for their catalytic function and structural stability (1). The biological roles of zinc(II) have been well reviewed (2–6) and seem dominated by its ability to assume distorted four- or five-coordinated structures in enzymes. In biological system, the metal ion is bound to two different ligands at various stages and there are various factors that stabilize these ternary complexes (7). Flexible intramolecular interligand interaction between the non-coordinating groups of the two ligands is the most important factor (8, 9). For the interaction, non-coordinating side groups on the two ligands should be suitably oriented to achieve effective overlap (10, 11). In the case of Zn(II) complexes with tetrahedral geometry, hydrophobic interaction between non-coordinated side groups of two ligands are more pronounced than in square planar Ni(II) or Cu(II) complexes (12), and hence Δ log *K* will be less negative or more positive in Zn(II) complexes than in Cu(II) or Ni(II) complexes.

Complexes of aminoacids and oligopeptides are involved in the exchange and the transport mechanism of trace metal ions in the human body (13). Hence it is worthwhile to study ternary complexes of Zn(II) and Cd(II) involving dipeptides and aminoacids. The MAL complexes, where M = Zn(II) or Cd(II); A = glycyl glycine (gg), glycyl L-alanine (ga), or glycyl L-leucine (gl); and L = α-alanine (ala), phenylalanine (phe), tyrosine (tyr), tryptophan (trp), or L-histidine (hist) have been studied.

Experimental

All the reagents used were of A.R. grade. Potentiometric titrations were carried out in aqueous medium at 25°C and at an ionic strength of 0.2 mol dm^{-3} ($NaClO_4$). The perchlorate solutions of Zn(II) and Cd(II) were prepared and standardized by titration with EDTA solution.

The formation constants for the ternary systems were computed from the titration data in which concentrations of metal, dipeptides (A), and aminoacids (L) were in the ratio 1:1:1, 1:2:2, and 1:3:3. Titrations were done against a standard alkali (ca. 0.2 M NaOH). A summary of the other experimental parameters for the Zn(II) and Cd(II) binary and mixed ligand systems is given below:

out twice to check reproducibility. The refined values of the protonation constants have been used as fixed parameters for the refinement of binary complexes and the values of protonation constants and the binary constants have been used as fixed parameters for the refinements of mixed ligand species. The protonation constants and formation constants of binary and mixed ligand complexes, and their $\Delta \log K$ values are listed in Tables 1 and 2.

Results and discussion

It was reported earlier that in the complex [ZnA], where A = glycylglycine or glycinamide (15), the ligand binds to the metal ion through N-amino and O-peptide donor groups, as in the case of CuA at low pH. For the copper dipeptide system, the formation of CuA_{-H} was also observed at high pH, with coordination from N-amino and deprotonated peptide N (16, 17). However, in the case of Zn(II) dipeptide systems, it has been reported that species ZnA_{-H} is not of much significance (18). In the bis species ZnA_2, the dipeptide coordinates from amino-nitrogen and peptide oxygen. Similarly, we found the presence of the CdA and CdA_2 species with the dipeptide bound to the Cd(II) ion through N-amino and O-peptide groups.

In the binary system containing Zn(II), the equilibrium reaction such as $Zn + A + H_2O \rightleftharpoons ZnA(OH) + H^+$, was assumed to exist and the equilibrium constant

$$K = [ZnA(OH)][H^+]/[Zn^{2+}][H_2O]$$

could be refined. However, it is to be noted that an equilibrium due to deprotonation of peptide nitrogen in the presence of metal ion may exist. This reaction of the dipeptide with the cation, resulting in the formation of ZnA_{-H} and the liberation of proton, is similar to the above equilibrium reaction in which zinc hydroxy species is formed. Thus the formation of ZnA_{-H} species at high pH cannot be ruled out. However, the value of the constant K^M_{MA} for the formation of ZnA calculated without taking into account the formation of ZnA(OH) is very close to the value obtained by taking into account the formation of this species. This is because, as seen in the calculated concentration of the species, the percentage of ZnA(OH) formed in the pH range of calculation is not very significant. In the case of Cd(II) system, taking the formation of CdA(OH) into account does not affect the results, showing that the hydroxy species is not formed. The values of binary constants reported here are comparable with the literature values (18).

The formation of a ternary complex may take place through simultaneous binding of the metal ion with the ligands: $M + A + L \rightleftharpoons MAL$. The constants K^M_{MAL} were calculated and are reported in the Table 2.

In the ternary complexes, an equilibrium, $M^{2+} + A + L + H_2O = MA(OH)L + H^+$ was also considered, but its equilibrium constant could not be refined. Hence, no formation of MA(OH)L was considered in the case of both Zn(II) and Cd(II) ternary complexes. The stability of the ternary complexes has been evaluated in terms of $\Delta \log K$.

$$\Delta \log K = \log K^M_{MAL} - (\log K^M_{MA} + \log K^M_{ML})$$

It can also be represented as

$$\Delta \log K = \log K^M_{MAL} - \log K^M_{ML}$$

$$\Delta \log K = \log K^M_{MAL} - \log K^M_{MA}$$

Deviation in $\Delta \log K$ has been calculated by assuming error

propagation, and shown in Table 2. Δ log K can be described as the difference in the strength of binding of the ligand to the free metal ion and the metal ion already bound to another ligand. The tendency of metal ions to bind with a ligand decreases with increase in the number of ligands because of statistical, electrostatic, and steric factors. Hence, K^{M}_{MAL} should be less than K^{M}_{ML} and Δ log K should be negative. In the case of MAL complexes, where L = α-alanine (ala) or phenylalanine (phe), Δ log K was found to be negative. This can be accounted for by considering the electrostatic repulsion between the aminoacid anion and dipeptide anion. However, it is less negative than what is expected, when one takes into consideration the repulsion between the aminoacid anion and dipeptide anion. This can be due to the intramolecular hydrogen bonding between carboxylate groups of dipeptide and the amino group of the aminoacid (19). Furthermore, it was observed that when L = tryptophan (trp) or tyrosine (tyr), Δ log K is either less negative or positive.

This observation can be explained as follows. The aminoacids are coordinated from the aminocarboxylate end, whereas the indole and hydroxyphenyl group of tryptophan and tyrosine are free. The less negative or positive Δ log K values for the complexes may be due to hydrogen bonding between the indole NH of tryptophan or the hydroxyphenyl OH group of tyrosine and the free carboxylate oxygen of the dipeptides as indicated in the case of copper complexes (17). This results in the equilibrium of the mixed ligand complex formation reaction M + A + L $\rightleftharpoons$ MAL to proceed more to the right, resulting in higher values of log K^{M}_{MAL} and more positive Δ log K. It is, however, observed that the Δ log K values for Zn(II) complexes are less negative than those for the corresponding Cu(II) complexes. This may be attributed to the fact that intramolecular ligand–ligand interaction is enhanced in tetrahedral Zn(II) or Cd(II) complexes, leading to a larger shift of the equilibrium to the right and therefore resulting in less negative or positive Δ log K values. Non-covalent interaction in Zn(II) complexes, dependent on the geometrical coordination requirements of the metal ion, has been suggested by Rizzarelli and co-workers (20–22) and in our earlier investigation (23). It is, however, observed that for the Cd(II) complexes Δ log K values are more negative than those for Zn(II) complexes. This may be because Cd(II) complexes take up an octahedral geometry more easily than Zn(II) complexes, resulting in a smaller amount of H-bonding and a less amount of the CdAL complex formed. H-Bonding interaction in Zn(II) complexes are shown in Fig. 2.

In the case of Zn(II) histidine (L) – dipeptide (A) mixed system, ZnALH and ZnAL species were obtained in addition to the binary species ZnA, ZnL, and ZnLH. In the Cd(II) – histidine (L) – dipeptide (A) system, on the other hand, only [CdAL] species was detected, no [CdALH] formation was observed more-

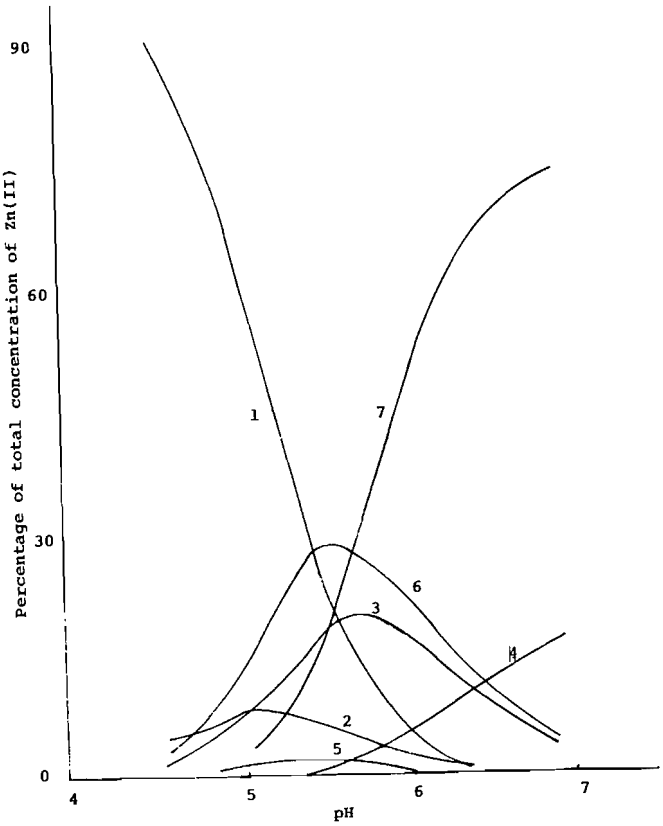

FIG. 1. Distribution of species of Zn–Gly–Gly (A) – Hist (L) – system at M:A:L ratio of 1:2:2: (*1*) free Zn(II), (*2*) ZnLH, (*3*) ZnL, (*4*) ZnL_2, (*5*) ZnA, (*6*) ZnLHA (*7*) ZnAL.

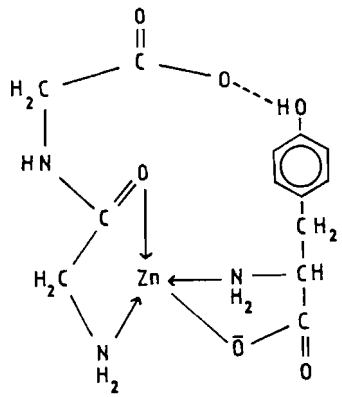

FIG. 2. Proposed structure for [Zn(Gly, Gly) (tyr)].

over, in the binary system, only the formation of CdL has been reported and no CdLH is formed (18).

For the ZnALH species, which is formed at lower pH, coordination of histidine occurs through the amino carboxylate end and the imidazole nitrogen remains protonated. Δ log *K* values for all ZnALH complexes are positive, indicating higher stability. This can be explained by the fact that the protonated histidine is neutral and does not repel the incoming dipeptide anion. Furthermore, there is H-bonding between the free protonated imidazole or histidine and the non-coordinated carboxylate group of the dipeptide (17). These two effects enhance the stability of the ternary species.

In the case of the MLA species where M = Zn(II) or Cd(II), histidine may coordinate through amino nitrogen and imidazole nitrogen, and the carboxylate group is free, as in the copper or nickel system at high pH. The Δ log *K* values for MAL complexes, when L is histidinate, is more positive than when L is α-alanine or phenylalanine. This is because in the MA–histidine system, there is a possibility of double hydrogen bonding. First the free carboxylate group of dipeptide may be involved in hydrogen bonding with the amino group of histidine, as in case of other M-dipeptide – amino acid complexes. Furthermore, the free carboxylate group of histidine can form a hydrogen bond with the amino group of dipeptide. This double hydrogen bonding results in an enhanced stability of the ternary complex and hence Δ log *K* is positive. It is thus observed that using the same solvent in the binary and ternary systems, the relative stabilization of ternary complexes varies depending on the extent of intramolecular interligand interaction between the noncoordinating side groups of the ligands.

Excess enthalpies of some (1-propanol + methyl *tert*-butyl ether + C_6-hydrocarbon) ternary systems at 298.15 K

SHEMIN ZHU, SHUBAO SHEN, GEORGE C. BENSON, AND BENJAMIN C.-Y. LU
Department of Chemical Engineering, University of Ottawa, Ottawa, ON K1N 6N5, Canada
Received July 29, 1993

SHEMIN ZHU, SHUBAO SHEN, GEORGE C. BENSON, and BENJAMIN C.-Y. LU. Can. J. Chem. **72**, 1111 (1994).

Calorimetric measurements of excess enthalpies are reported for the three ternary systems (1-propanol + methyl *tert*-butyl ether + (*n*-hexane, or 2,3-dimethylbutane, or cyclohexane)) at 298.15 K. Smoothing equations, fitted to the results, were used to construct constant enthalpy contours on a Roozeboom diagram for each of the systems.

SHEMIN ZHU, SHUBAO SHEN, GEORGE C. BENSON et BENJAMIN C.-Y. LU. Can. J. Chem. **72**, 1111 (1994).

On a effectué des mesures calorimétriques d'enthalpies en excès pour trois systèmes ternaires (propan-1-ol + oxyde de méthyle et de *tert*-butyle + (*n*-hexane ou 2,3-diméthylbutane ou cyclohexane)) à 298,15 K. On a utilisé des équations atténuées, ajustées aux résultats, pour construire, pour chaque système, des contours d'enthalpie constante sur un diagramme de Roozeboom.

The use of alkanols and ethers as gasoline additives has led to an increased interest in the thermodynamic properties of their mixtures with hydrocarbons. Recently we have been studying the excess thermodynamic properties of ternary systems of the type (alkanol + ether + hydrocarbon) (1, 2). As a continuation of those investigations, we have determined the excess molar enthalpies of three ternary systems of the type (1-propanol + methyl *tert*-butyl ether + a C_6-hydrocarbon) where the C_6-hydrocarbon is *either* *n*-hexane, or 2,3-dimethylbutane, or cyclohexane.

Experimental

Component liquids

Anhydrous 1-propanol (PrOH) and methyl *tert*-butyl ether (MTBE) were obtained from the Aldrich Chemical Co. Pure Grade *n*-hexane (*n*-C_6), 2,3-dimethylbutane (*br*-C_6), and cyclohexane (*c*-C_6) were obtained from the Phillips Chemical Co. All of these materials had stated purities exceeding 99 mol%. Their densities, measured at 298.15 K in an Anton-Paar digital densimeter, were 799.64, 735.56, 655.04, 657.13, and 774.04 kg m^{-3} for PrOH, MTBE, *n*-C_6, *br*-C_6, and *c*-C_6, respectively. These are in reasonable agreement with the values 799.75, 735.3, 654.84, 657.02, and 773.89 kg m^{-3}, compiled by the TRC (3, 4).

Calorimetric measurements

Excess molar enthalpies H_m^E at 298.15 ± 0.005 K were measured in an LKB flow microcalorimeter. Details of the equipment and its operation have been described previously (5, 6). In studying the ternary systems, the excess molar enthalpy $H_{m,1+23}^E$ was measured for several pseudo-binary systems in which component 1 (PrOH) was added to binary mixtures of components 2 (MTBE) and 3 (*n*-C_6, or *br*-C_6, or *c*-C_6) having a fixed mole ratio x_2/x_3. These binaries were prepared by weighing. The excess molar enthalpy $H_{m,123}^E$ of the ternary system is then given by the relation

$$[1] \qquad H_{m,123}^E = H_{m,1+23}^E + (1 - x_1)H_{m,23}^E$$

where $H_{m,23}^E$ is the excess molar enthalpy of the particular (MTBE + C_6-hydrocarbon) binary. Over most of the PrOH mole fraction range, the errors of $H_{m,1+23}^E$ are about 0.5% or 2 J mol^{-1}, whichever is larger. Errors in the mole fractions of the ternary mixtures are estimated to be less than 5×10^{-4}.

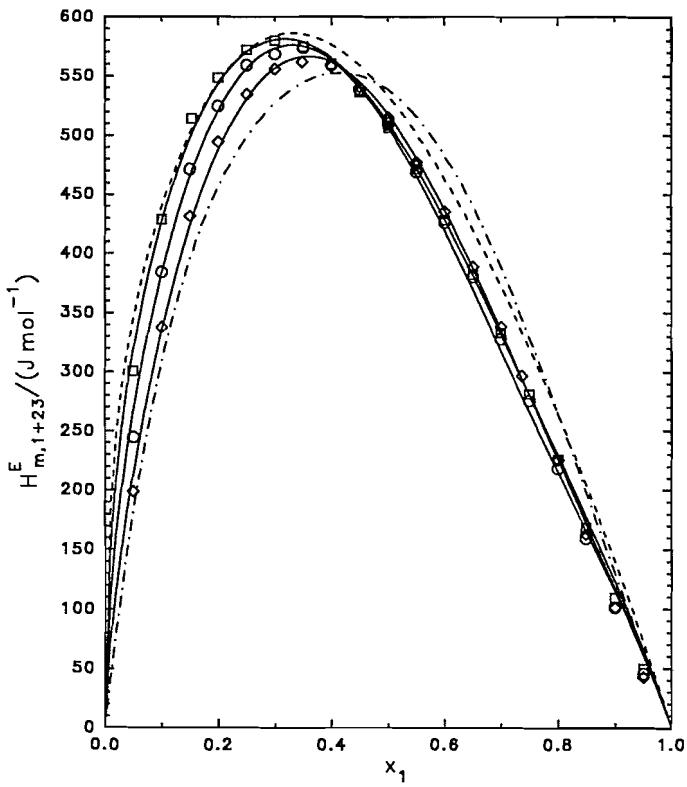

FIG. 1. Excess molar enthalpies $H_{m,1+23}^E$ at 298.15 K for the addition of PrOH to binary mixtures of MTBE and *n*-C_6 to form $x_1C_3H_7OH + x_2(CH_3)_3COCH_3 + x_3CH_3(CH_2)_4CH_3$. Experimental results: □, $x_2/x_3 = 0.3333$; ○, $x_2/x_3 = 0.9992$; ◇, $x_2/x_3 = 3.0000$. Curves: -·-, $x_3 = 0$, from ref. 1; ---, $x_2 = 0$, from ref. 10; —, calculated from eqs. [2] and [3] with $H_{m,T}^E$ from the footnote of Table 1.

Results and discussion

Tables 1–3 summarize the experimental values of $H_{m,1+23}^E$ measured for the three ternary systems. Included in these tables are the corresponding values of $H_{m,123}^E$ calculated from eq. [1], using the smooth representations of $H_{m,23}^E$ reported previously

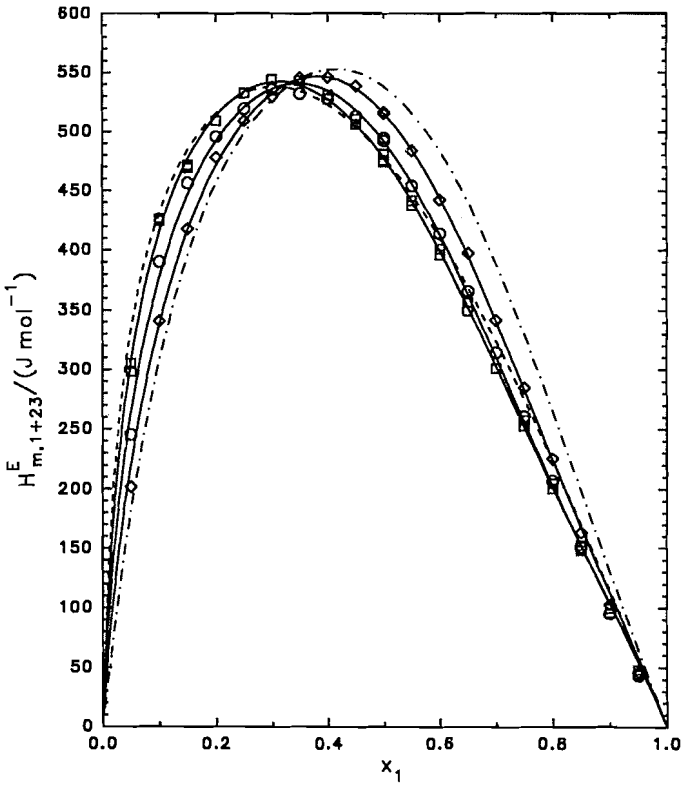

FIG. 2. Excess molar enthalpies $H^E_{m,1+23}$ at 298.15 K for the addition of PrOH to binary mixtures of MTBE and *br*-C_6 to form $x_1C_3H_7OH + x_2(CH_3)_3COCH_3 + x_3(CH_3)_2CHCH(CH_3)_2$. Experimental results: □, $x_2/x_3 = 0.3334$; ○, $x_2/x_3 = 1.0007$; ◇, $x_2/x_3 = 2.9903$. Curves: ---, $x_3 = 0$, from ref. 1; ---, $x_2 = 0$, from ref. 8; —, calculated from eqs. [2] and [3] with $H^E_{m,T}$ from the footnote of Table 2.

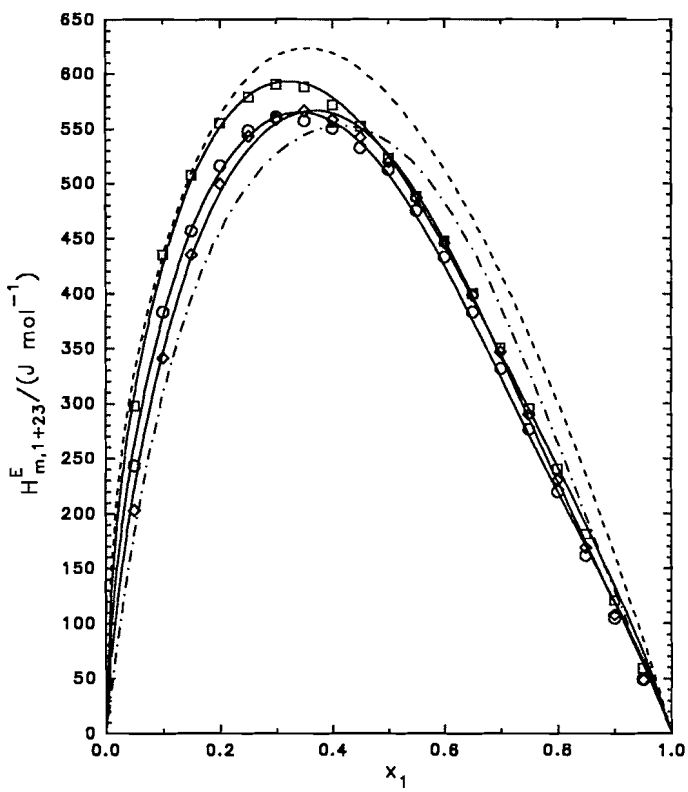

FIG. 3. Excess molar enthalpies $H^E_{m,1+23}$ at 298.15 K for the addition of PrOH to binary mixtures of MTBE and *c*-C_6 to form $x_1C_3H_7OH + x_2(CH_3)_3COCH_3 + x_3C_6H_{12}$. Experimental results: □, $x_2/x_3 = 0.3335$; ○, $x_2/x_3 = 0.9993$; ◇, $x_2/x_3 = 2.9920$. Curves: ---, $x_3 = 0$, from ref. 1; ---, $x_2 = 0$, from ref. 11; —, calculated from eqs. [2] and [3] with $H^E_{m,T}$ from the footnote of Table 3.

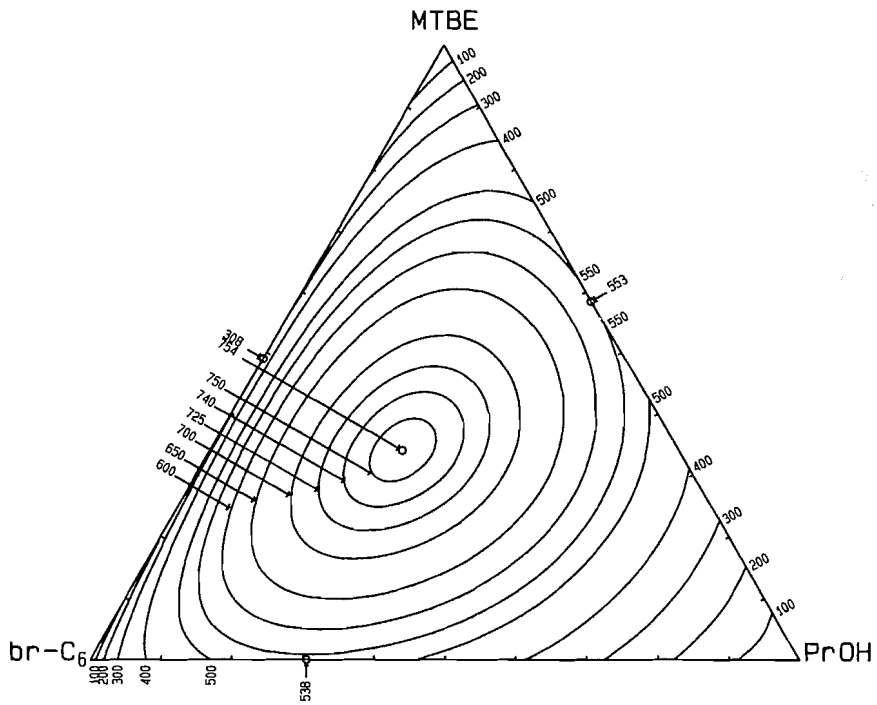

FIG. 4. Contours for constant values of the excess molar enthalpy $H^E_{m,123}/(J\ mol^{-1})$ of the (PrOH + MTBE + *br*-C_6) system at 298.15 K, calculated from eqs. [1]–[3] using $H^E_{m,T}$ from the footnote of Table 2.

for (MTBE + n-C_6) (7), (MTBE + br-C_6) (8), and (MTBE + c-C_6) (9). The $H^E_{m,1+23}$ results are plotted in Figs. 1–3. Also shown for each system are curves for the cases $x_2 = 0$ and $x_3 = 0$, taken from the literature: (PrOH + MTBE) (1), (PrOH + n-C_6) (10), (PrOH + br-C_6) (8), and (PrOH + c-C_6) (11).

As in our previous work (1, 2, 7, 9, 10), the values of $H^E_{m,1+23}$ were represented as a sum of binary terms (12) with an added ternary contribution

$$[2] \qquad H^E_{m,1+23} = \left(\frac{x_2}{1-x_1}\right)H^E_{m,12} + \left(\frac{x_3}{1-x_1}\right)H^E_{m,13} + H^E_{m,T}$$

and following Morris et al. (13), the form

$$[3] \qquad H^E_{m,T} = x_1x_2x_3(c_0 + c_1x_1 + c_2x_2 + c_3{x_1}^2 + c_4x_1x_2 + c_5{x_2}^2 + c_6{x_1}^3 + \cdots)$$

was adopted for the ternary term. For each system, the values of the parameters c_k were determined by the method of least squares, and the results of the analyses are given in the footnotes of Tables 1–3, along with the standard deviations s of the representations. Curves calculated using these representations are shown in Figs. 1–3.

Equations [1]–[3] were used to calculate constant $H^E_{m,123}$ contours on Roozeboom diagrams for each of the systems. These are very similar to each other and to those found for the ethanol systems studied previously (2). The plot for (PrOH + MTBE + br-C_6) in Fig. 4 typifies the behaviour of $H^E_{m,123}$ for the present systems. In all cases, a maximum of $H^E_{m,123}$ occurs near the centroid of the triangle. The locations and values of the maxima (x_1, x_2, $H^E_{m,123}$/(J mol^{-1})) are (0.2683, 0.3438, 836), (0.2713, 0.3397, 754), and (0.2491, 0.3181, 899) for the present n-C_6, br-C_6, and c-C_6 systems, respectively.

Rate constant and activation energy determination for reaction of $e^-_{(aq)}$ and $^{\cdot}OH$ with 2-butanone and propanal[1]

STEPHEN P. MEZYK

AECL Research, Research Chemistry Branch, Whiteshell Laboratories, Pinawa, MB R0E 1L0, Canada

and

Radiation Laboratory, University of Notre Dame, South Bend, IN 46556, U.S.A.

Received September 27, 1993

STEPHEN P. MEZYK. Can. J. Chem. **72**, 1116 (1994).

The techniques of pulse radiolysis and absorption spectroscopy have been used to determine kinetic parameters for $e^-_{(aq)}$ and $^{\cdot}OH$ reaction with 2-butanone and propanal. The temperature dependent rate constants for hydrated electron reaction are given by $\ln k(T) = (28.96 \pm 0.06) - (1970 \pm 20)/T$ (2-butanone, 275–343 K), and $\ln k(T) = (29.2 \pm 0.2) - (2160 \pm 50)/T$ (propanal, 275–310 K), where the given uncertainties are 1σ and only represent precision, and the rate constants are in units of M^{-1} s^{-1}. For hydroxyl radical reaction over the same temperature ranges, $\ln k(T) = (25.32 \pm 0.02) - (1460 \pm 40)/T$ (2-butanone) and $\ln k(T) = (32.73 \pm 0.03) - (3310 \pm 100)/T$ (propanal).

STEPHEN P. MEZYK. Can. J. Chem. **72**, 1116 (1994).

On a utilisé des techniques de radiolyse pulsée et de spectroscopie d'absorption pour déterminer les paramètres cinétiques des réactions de $e^-_{(aq)}$ et de $^{\cdot}OH$ avec la butan-2-one et le propanal. Les constantes de vitesse dépendantes de la température pour la réaction de l'électron hydraté sont données $\ln k(T) = (28{,}96 \pm 0{,}06) - (1970 \pm 20)/T$ (butan-2-one, 275–343 K) et $\ln k(T) = (29{,}2 \pm 0{,}2) - (2160 \pm 50)/T$ (propanal, 275–310 K), pour lesquelles les incertitudes sont données par 1σ et ne représentent que la précision et les constantes de vitesses sont en unités de M^{-1} s^{-1}. Pour la réaction du radical hydroxyle aux mêmes températures, $\ln k(T) = (25{,}32 \pm 0{,}02) - (1460 \pm 40)/T$ (butan-2-one) et $\ln k(T) = (32{,}73 \pm 0{,}03) - (3310 \pm 100)/T$ (propanal).

Introduction

The hazard of radioactive iodine release to the atmosphere, following a nuclear reactor accident, has greatly stimulated the study of the radiation-induced chemistry of iodine-containing species (1). As large quantities of water are also expected to be released in most accidents at water-cooled reactors, a good knowledge of the aqueous chemistry of iodine is necessary for an adequate understanding of its behaviour under these conditions. To date, a large body of information on the mechanisms and rate constants for inorganic iodo-species reaction with a variety of free radicals in solution has been collected (2).

The high radiation fields also expected to be present have been shown to significantly affect the iodine chemistry that occurs (3). Of particular interest are the reactions that lead to the formation of low molecular weight iodoalkanes (4). These species are more volatile, and thus harder to contain than inorganic forms of iodine. Although qualitative demonstration of their formation in irradiated iodide or iodine solutions containing organic impurities has been reported (5–7), there is very little quantitative information on rate constants or mechanisms presently available.

A systematic investigation of this process has recently been initiated, using 2-butanone (MEK) as a prototypical organic impurity (8). The steady state irradiation of MEK solutions has been shown to produce a large number of product species (9). Thus, to ensure a complete understanding of this radiolytic process, the confirmation of proposed mechanistic schemes by computer modelling is required. Such modelling is dependent on accurate rate constant data being available for the aqueous radiolysis species reaction with MEK and its subsequent radiolytic products.

Rate constants for the reaction of water radiolysis intermediates with MEK, and some of its radiolysis products, have not previously been accurately determined. Hence the measurement of kinetic parameters for these compounds has been initiated. This paper reports the experimental determination of the rate constants and activation energies for the reaction of $e^-_{(aq)}$ and $^{\cdot}OH$ with MEK and propionaldehyde (propanal).

Experimental

Solutions of MEK (Aldrich HPLC grade, 99.5%+) and propanal (Aldrich 99%+) were prepared by pipetting the neat liquid into known volumes of Millipore filtered water, which had been fully deoxygenated by bubbling with N_2O or N_2. Some solutions had their pH adjusted to ~5.2 by addition of 10^{-2} M sodium phosphate (monobasic, Anachemica A.C.S. reagent); the rate constants obtained under these conditions were the same as from unbuffered solutions. More acidic solutions were prepared by addition of $HClO_4$ (Baker Analyzed).

The electron pulse radiolysis facilities at the Radiation Laboratory, University of Notre Dame, were used for all these experiments. This system has been described in detail elsewhere (10). The solution flow rate was adjusted so that each irradiation was performed on a fresh sample. Dosimetry was performed using N_2O saturated 10^{-2} M KSCN (Fischer certified) with typical doses of ~600 rads/10 ns pulse.

Experiments at non-ambient temperatures were performed by flowing the room temperature solutions through a short, temperature-controlled condenser tube immediately before irradiation (11). The exact solution temperature was measured by a thermocouple placed directly above the irradiation cell. The temperature stability of this method was found to be better than ±0.5°C.

Results and discussion

Reaction of hydrated electron

The irradiation of N_2-saturated solutions containing 1.0 M *t*-butanol and MEK allows the reaction

$$e^-_{(aq)} + CH_3CH_2COCH_3 \rightarrow CH_3CH_2C(CH_3)O^{\cdot -}$$

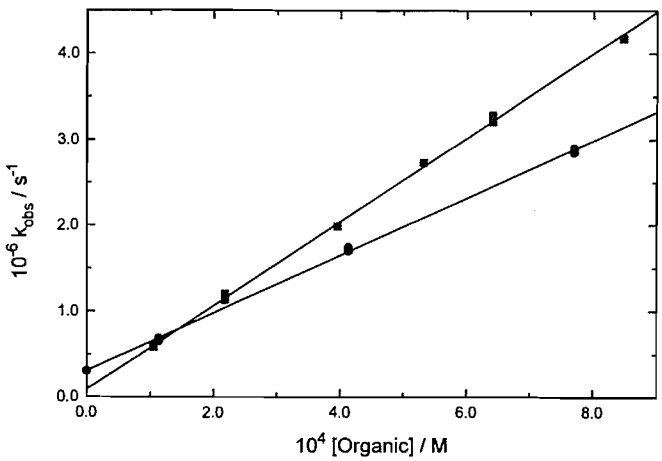

FIG. 1. Rate constant determination for $e^-_{(aq)}$ reaction with MEK (■, 23.0°C) and propanal 23.3 (●, 23.3°C).

to be studied in isolation. The rate constant for this reaction was measured by observing the change in decay of the hydrated electron at 600–650 nm, as a function of the MEK concentration over the range (1–10) × 10^{-4} M. To ensure that monochromator second order effects and solution photolysis were minimized, a Corning 0-54 cut-off filter was placed between the monitoring lamp and the solution.

Typical results from this study are shown in Fig. 1, for a temperature of 23.0°C. A rate constant of $(4.9\pm0.1)\times10^9$ M^{-1} s^{-1} was obtained, significantly slower than the only previous measurement indirectly obtained for room temperature liquid MEK (12) of 1.2×10^{11} M^{-1} s^{-1}.

These experiments were repeated across the temperature range 1.5–70°C, and the individual rate constants obtained are given in Table 1. From the Arrhenius expression,

$$k = Ae^{-E_a/RT}$$

plotted in Fig. 2, the measured activation energy for this reaction is 16.4 ± 0.2 kJ mol^{-1}, with a corresponding pre-exponential factor, $A = (3.8 \pm 0.2) \times 10^{12}$ M^{-1} s^{-1}. These values are in very good agreement to those measured for acetone (13), where an activation energy of 15 kJ mol^{-1} and an A factor of 3.29×10^{12} M^{-1} s^{-1} were obtained over the temperature range 3–47°C.

Similar experiments were conducted for propanal and for this compound, a value of $(3.36\pm0.06)\times10^9$ M^{-1} s^{-1} was obtained at 23.3°C, (Fig. 1), in good agreement with the previous determination of 4.1×10^9 M^{-1} s^{-1} at room temperature (14). By varying the temperature over the range 2–37°C (values given in Table 1), an activation energy of 18.0 ± 0.4 kJ mol^{-1} was obtained (Fig. 2), with an A factor of $(4.8\pm1.0)\times10^{12}$ M^{-1} s^{-1}. The close agreement of the measured Arrhenius parameters for MEK, propanal, and acetone suggests that the hydrated electron reaction mechanism of addition to the oxygen atom (2) is the same for all three compounds.

Reaction of hydroxyl radical

The direct rate constant measurement for the reaction

$$^{\bullet}OH + CH_3CH_2COCH_3 \rightarrow H_2O + CH_3COC^{\bullet}HCH_3$$

was not possible, as the irradiation of N_2O saturated MEK solutions over the pH range 2.0–7.0 produced no change in absorbance over the wavelength range 250–800 nm. Thus this

rate constant was determined by competition kinetics, using SCN^- as the reaction standard. This reaction

$$^{\bullet}OH + SCN^- \rightarrow SCNOH^{\bullet -}$$

was chosen to allow direct comparison to the only previous rate constant determination for hydroxyl radical reaction with MEK (15), and because its temperature dependence has been characterized by the expression (16)

$$[1] \qquad \ln k(T) = (29.6 \pm 0.6) - (1900 \pm 190)/T$$

over the range of this study.

Stock solutions of 1.01×10^{-4} M SCN^- buffered at pH 5.2 were irradiated and the $(SCN)_2^{\bullet -}$ absorption at 472 nm

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

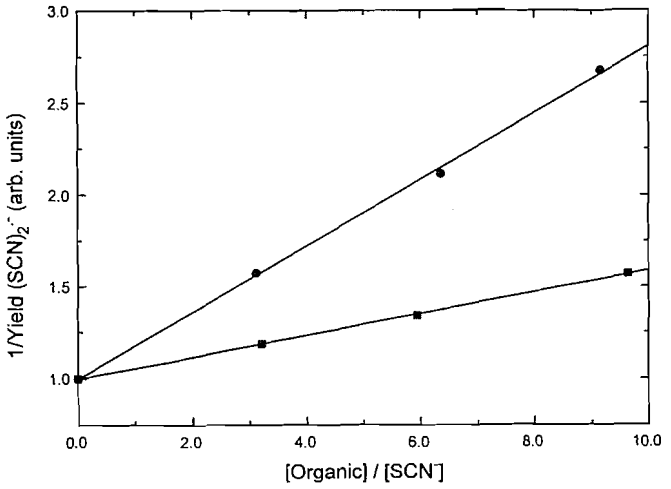

FIG. 3. Competition kinetics determination of the rate constant for reaction of ·OH, with MEK (■, 24.4°C) and propanal (●, 24.6°C), for 1.01×10^{-4} M SCN^- solutions at pH 5.2.

measured. The addition of MEK, over the concentration range $(1–10) \times 10^{-4}$ M, caused the intensity of the peak absorbance to decrease. Assuming that the initial ·OH radical yield is the same in both solutions, the standard competition kinetics equation

$$\frac{1}{[SCN]_2^{\cdot-}} = 1 + \frac{k_{MEK}[MEK]}{k_{SCN^-}[SCN^-]}$$

predicts that a plot of $1/\text{Yield}(SCN)_2^{\cdot-}$ vs. $[MEK]/[SCN^-]$ should give a straight line of slope k_{MEK}/k_{SCN^-}. The values obtained for MEK at 24.4°C are shown in Fig. 3, and an excellent straight line of slope 0.0599 ± 0.0007 was obtained. Based on the calculated rate constant (16) of 1.22×10^{10} M^{-1} s^{-1} for ·OH with SCN^- at this temperature, this corresponds to a rate constant for ·OH reaction with MEK of $(7.34 \pm 0.08) \times 10^8$ M^{-1} s^{-1}. This value is slightly lower than the previously determined rate constant of 9×10^8 M^{-1} s^{-1} (15).

Concern has been raised previously (17) about a potential problem with this procedure in that the formation of $(SCN)_2^{\cdot-}$ involves the intermediate formation of SCN· and $SCNOH^{\cdot-}$ (18–20). If either of these species can oxidise MEK, then less $(SCN)_2^{\cdot-}$ will be formed, leading to an artificially high rate constant for ·OH reaction with MEK.

To determine whether such interfering reactions occurred for MEK, the experimental $(SCN)_2^{\cdot-}$ formation curves obtained at 24.4°C (shown in Fig. 4) were modelled by the following reaction scheme,

$$e^-_{(aq)} + N_2O + H_2O \rightarrow {}^{\cdot}OH + N_2 + {}^-OH \qquad k = 8.9 \times 10^9\ M^{-1}\ s^{-1} \quad (2)$$

$$^{\cdot}OH + SCN^- \rightarrow SCNOH^{\cdot-} \qquad k = 1.22 \times 10^{10}\ M^{-1}\ s^{-1} \quad (16)$$

[2] $SCNOH^{\cdot-} \rightarrow SCN^{\cdot} + {}^-OH \qquad k_2$

[3] $SCN^{\cdot} + SCN^- \rightarrow (SCN)_2^{\cdot-} \qquad k_3$

[4] $(SCN)_2^{\cdot-} \rightarrow SCN^{\cdot} + SCN^- \qquad k_4$

$$^{\cdot}OH + MEK \rightarrow MEK^{\cdot} + {}^-OH \qquad k = 7.34 \times 10^8\ M^{-1}\ s^{-1}$$

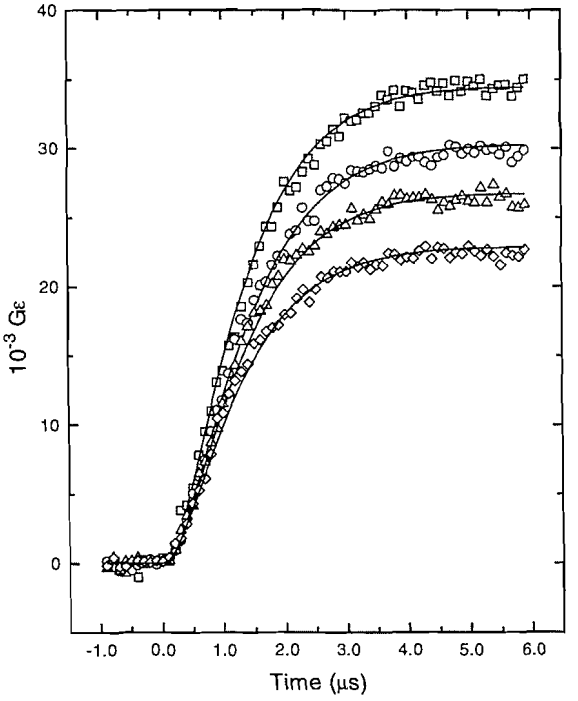

FIG. 4. Comparison of experimental and calculated $(SCN)_2^{\cdot-}$ growth kinetics observed at 472 nm with added MEK concentrations of 0.00 (□), 3.25 (○), 6.01 (△), and 9.71 (◇) $\times 10^{-4}$ M at 24.4°C. Solid lines are calculated based on model described in text.

using the FACSIMILE (21) modelling program. The values of the rate constants, k_2–k_4, and the total yield of $(SCN)_2^{\cdot-}$ were fitted to the experimental data, with average values of $G\epsilon = 34\,500 \pm 200$, $k_2 = (1.57 \pm 0.04) \times 10^9$ s^{-1}, $k_3 = (1.23 \pm 0.07) \times 10^{10}$ M^{-1} s^{-1} and $k_4 = (1.51 \pm 0.05) \times 10^4$ s^{-1} obtained. These rate constants are in general agreement with previously determined values of $>5 \times 10^7$ s^{-1} (19), $\sim 6 \times 10^9$ M^{-1} s^{-1} (16), and $\sim 3 \times 10^4$ s^{-1} (16), respectively (the latter two literature values have extremely large error, and can only be considered correct to their order of magnitude). Using the values of this study, the temporal profiles for the different MEK concentrations were calculated, and these are also shown in Fig. 4. The excellent agreement seen suggests that no additional reactions are occurring in this system.

Additional evidence was obtained by modelling the effects of adding the hypothetical oxidising reactions

[5] $SCNOH^{\cdot-} + MEK \rightarrow MEK^{\cdot} + SCN^- + {}^-OH \qquad k_5$

[6] $SCN^{\cdot} + MEK \rightarrow MEK^{\cdot} + SCN^- \qquad k_6$

[7] $MEK^{\cdot} + SCN^- \rightarrow SCN^{\cdot} + MEK \qquad k_7$

to the original reaction mechanism. These calculated temporal profiles, for a MEK concentration of 9.71×10^{-4} M, are shown in Fig. 5. It was found that including reaction [5], with a reaction rate constant of $k_5 \leq 5.0 \times 10^9$ M^{-1} s^{-1}, had no effect on the $(SCN)_2^{\cdot-}$ growth profile. However, if reaction [6] occurred with the same rate constant, then the yield of $(SCN)_2^{\cdot-}$ was considerably reduced, and the $(SCN)_2^{\cdot-}$ growth rate was far faster. In contrast, the effect of including reaction [7] was to increase the yield, and make the overall growth significantly slower.

Based on these findings, it is believed that there are no

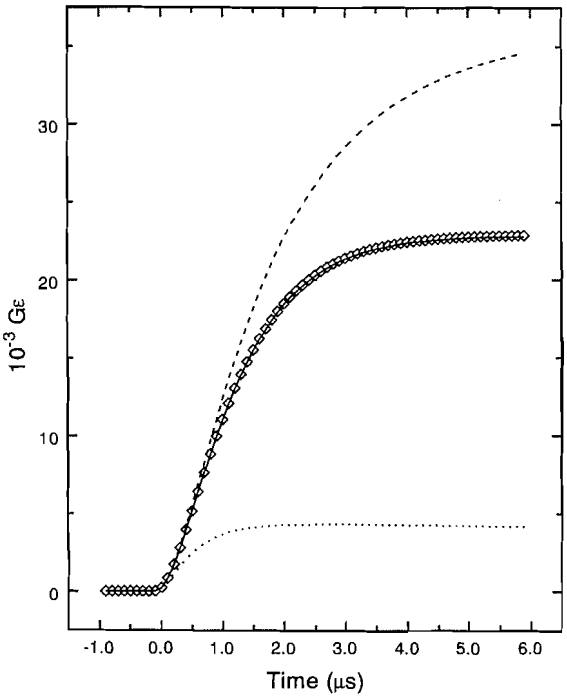

FIG. 5. Calculated $(SCN)_2^{\bullet -}$ growth kinetics for 9.71×10^{-4} M MEK solutions containing no additional oxidation reactions (◇), $SCNOH^{\bullet -}$ oxidation of MEK with $k_5 = 5.0 \times 10^9$ M^{-1} s^{-1} (—); $^{\bullet}SCN$ oxidation of MEK with $k_6 = 5.0 \times 10^9$ M^{-1} s^{-1} (···) and MEK$^{\bullet}$ oxidation of SCN^- with $k_7 = 5.0 \times 10^9$ M^{-1} s^{-1} (- - -).

oxidation reactions from $SCN^{\bullet}$ or $SCNOH^{\bullet -}$ occurring for MEK.

Rate constants for MEK reaction with $^{\bullet}OH$ were obtained at various temperatures (see Table 1) and the calculated Arrhenius plot is also shown in Fig. 2. For this reaction a value of $E_a = 12.2 \pm 0.3$ kJ mol^{-1} was obtained, with an A factor of $(1.00 \pm 0.02) \times 10^{11}$ M^{-1} s^{-1}.

Analogous SCN^- competition experiments were also performed for propanal. The rate constant determined at 24.6°C, $(2.39 \pm 0.06) \times 10^9$ M^{-1} s^{-1} (Fig. 3) is faster than measured for $^{\bullet}OH$ reaction with MEK. The experimental temporal profiles for different propanal concentrations were also modelled at this temperature, and again showed that no extraneous oxidation reactions need to be considered. Rate constant determinations at different temperatures gave the activation energy and pre-exponential factors for propanal as 27.5 ± 0.8 kJ mol^{-1} and $(1.63 \pm 0.05) \times 10^{14}$ M^{-1} s^{-1}, respectively, (individual values shown in Table 1 and Fig. 2).

These higher E_a and A Arrhenius parameters suggest that either a different $^{\bullet}H$ atom is being abstracted from propanal, or that the β carbon C—H bond strength is larger than in MEK. At present, *ab initio* calculations and EPR experiments are being performed to investigate these two possibilities.

Protonation/deprotonation energetics of uracil, thymine, and cytosine in water from e.m.f./spectrophotometric measurements

SONALI GANGULY AND KIRON K. KUNDU[1]
Physical Chemistry Laboratories, Jadavpur University, Calcutta-700 032, India
Received March 19, 1993

SONALI GANGULY and KIRON K. KUNDU. Can. J. Chem. **72**, 1120 (1994).

The protonation/deprotonation constants for uracil (U) (pK_1 and pK_2), thymine (T) (pK_1) and cytosine (C) (pK_1 and pK_2) in water have been determined from emf measurements of Harned–Ehler type cells comprising H_2 and Ag–AgI electrodes at five equidistant temperatures ranging from 15–35°C. The pK_a values were fitted in the temperature equation $pK_a = AT^{-1} + B + CT$ by the method of least squares and the standard free energies (ΔG^0), entropies (ΔS^0), and enthalpies (ΔH^0) of protonation/deprotonation processes in water were evaluated using the values of the coefficients A, B, and C of the respective acids. The second step deprotonation constant for T was determined using precise spectrophotometric method. The results have been duly compared with the existing literature data and are also shown to derive important reflections on the sites of protonation/deprotonation in the light of pK values of some acids and bases of comparable functional groups and especially the entropies of protonation/deprotonation of the key DNA–RNA base molecules.

SONALI GANGULY et KIRON K. KUNDU. Can. J. Chem. **72**, 1120 (1994).

Utilisant des mesures de fém de cellules de type Harned Ehler comportant des électrodes H_2 et Ag–AgI effectuées à cinq températures équidistantes allant de 15 à 35°C, on a déterminé les constantes de protonation/déprotonation de l'uracile (U) (pK_1 et pK_2), de la thymine (T) (pK_1) et de la cytosine (C) (pK_1 et pK_2) dans l'eau. Faisant appel à la méthode des moindres carrés, on a ajusté les valeurs de pK_a dans l'équation de température: $pK_a = AT^{-1} + B + CT$; utilisant les valeurs des coefficients A, B et C, on a aussi évalué les énergies libres (ΔG^0), les entropies (ΔS^0) et les enthalpies (ΔH^0) standards des processus de protonation/déprotonation des acides respectifs dans l'eau. Utilisant une méthode spectrophotométrique précise, on a calculé la deuxième constante de déprotonation de T. On a comparé les résultats avec ceux rapportés dans la littérature et, en se basant sur les valeurs de pK_a de quelques acides et de quelques bases portant des groupes fonctionnels comparables et spécialement sur les valeurs des entropies de protonation/déprotonation de molécules clés des bases ADR–ARN, on peut tirer des indications importantes sur les sites de protonation/déprotonation.

[Traduit par la Rédaction]

Introduction

It is well known that a living organism is an open, self regulating, self reproducing and developing heterogeneous system whose most important functional substances are biopolymers, proteins, and nucleic acids (1). In fact, the latter biopolymers are the principal constituents of chromosomes which are responsible for the key living process, namely "biogenesis" — the basis for self-reproduction, development, and propagation of life itself. Also, it is the nucleic acids which dictate the structure and properties of living cells and organisms in the final analysis and specify the genetic programme of protein synthesis.

The principal chain of nucleic acids consists of alternating phosphoric acid (P) units and a sugar moiety. Attached to each of the sugar unit is one heterocyclic nitrogeneous base and this type of sequence is repeated n times. The nitrogeneous heterocyclic bases are derivatives of pyrimidines and purines. Uracil (U), thymine (T), and cytosine (C) are the principal pyrimidine "bases" present in DNA's and RNA's. Because of the structural features all these heterocyclic nitrogeneous bases display "tautomerism" and variable proton accepting and donating propensity and hence the varied energetics of protonation/deprotonation. Energetics of these important biochemical molecules will help us understand the primary roles of RNA's and DNA's on various biological processes. The structures of U, T, and C are illustrated in Fig. 1.

Literature survey (2, 3) reveals that some of the desired data in water are no doubt available. However, we consider most of these protonation/deprotonation constant data to be lacking in precision. These data either are based on half-neutralization

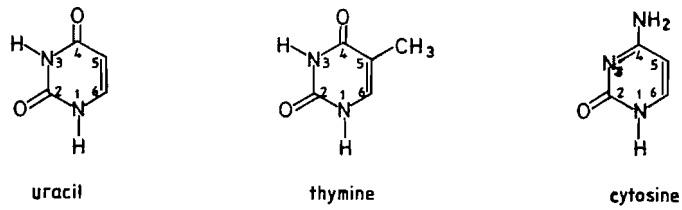

FIG. 1. Structures of uracil, thymine, cytosine.

point (hnp) determination of pH-titration curves using glass (H^+) and aqueous saturated calomel electrodes SCE (W) or hydrogen–calomel electrodes forming cells with liquid junction, or spectrophotometric methods based on isosbestic points using different pH solutions. Moreover, since the experiments were done under a variety of temperature, ionic strength, and solvent conditions, their results are hardly comparable and lack in true thermodynamic precision and physical significance. Furthermore, until now there have been no deprotonation constant and thermodynamic quantities reported for the second step deprotonation constant for T and U, respectively.

This paper reports our findings on protonation/deprotonation constants and related true thermodynamic quantities for U, T, and C as determined by the most precise method by measuring the emf's. We used Harned–Ehler (4) type galvanic cells without liquid junctions comprising Pt, H_2 (g, 1 atm) and Ag–AgI electrodes and buffers of different ionic strengths and did the measurements at five equidistant temperatures ranging from 15–35°C. Notably, preliminary studies with Ag–AgCl electrode exhibited perceptible drifts in emf values with time especially in the case of the free base C containing an amino group possibly because of the formation of Ag^+–amine complex with this compound. The same tendency was however found to be

completely absent in the case of Ag–AgI electrodes due to the lower solubility of AgI as compared to AgCl. Since the effect of hydrolysis was very high in the case of second step deprotonation of T, pK_2 of T cannot be evaluated by emf method and so precise spectrophotometric method was adopted.

The Harned–Ehler type cells used for the determination of various pK_a's and related energetics are [A]–[D].

For $p(K_1)_{H_2A}$ of U, T:

[A] Pt, H_2 (g, 1 atm)/$H_2A(m_1)$, $NaHA(m_2)$, $KI(m_3)$/AgI–Ag

For $p(K_2)_{HA^-}$ of U:

[B] Pt, H_2 (g, 1 atm)/$NaHA(m_1)$, $Na_2A(m_2)$, $KI(m_3)$/AgI–Ag

For $p(K_1)_{H_2A^+}$ of C:

[C] Pt, H_2 (g, 1 atm)/$H_2A^+I^-(m_1)$, $HA(m_2)$, $KI(m_3)$/AgI–Ag

For $p(K_2)_{HA}$ of C:

[D] Pt, H_2 (g, 1 atm)/$HA(m_1)$, $NaA(m_2)$, $KI(m_3)$/AgI–Ag

Experimental

U (grade U-0750), T (grade T-0376), and C (grade C-3506) were all from Sigma and used without further pretreatment. These biochemicals assayed 99% by UV spectroscopy (5, 6). Water was triply distilled and stored in a CO_2-free atmosphere. KI (GR, E Merck) was used after drying at 150°C and then stored in a vacuum desiccator for about 12 h. Stock NaOH (GR, E Merck) solution was prepared and its molality was obtained by alkalimetric titration. For the determination of pK_1 and pK_2 for U, pK_1 for T, and pK_2 for C, cell solutions of different ionic strengths were prepared in well stoppered Jena bottles by mixing appropriate weighed amounts of the "base" under study, KI, NaOH solution, and triply distilled water. For determining pK_1 for C, distilled HI acid (GR, E Merck) was used instead of alkali solution. The method of HI distillation was similar to that as described earlier (*7a*).

For determining the pK_2 of T, buffers containing T and NaOH solution (0.5–5 M) were prepared in a closed chamber fluxed with pure nitrogen to avoid CO_2.

Emf method

The emf's of the cells were measured using a Leeds and Northrup K_4-potentiometer fitted with a moving coil galvanometer (Cambridge Instrument Co.) as the null point detector. Ag–AgI electrodes were of the thermal type and prepared by the method described earlier (*7a*). General experimental procedures including the preparation of H_2(Pt) electrodes and the measurement of emf were similar to those described elsewhere (7). The Ag–AgI electrodes were introduced after 1 h discharge of hydrogen gas through the cells. The equilibrium was attained in 3–4 h. When the emf readings stayed constant to about ±0.1 mV for 1 h, it was assumed that equilibrium had been reached. The readings were first taken at 15°C and then successively at higher temperatures at 5°C intervals. The readings at 25°C when back checked after 35°C agreed to within ±0.3 mV.

Spectrophotometry

A Perkin Elmer Lambda 3A UV/VIS spectrophotometer was used to measure the absorbances of each buffer solution at wavelength = 280 nm (5, 6).

Results

The measured emf's of cells [A]–[D] at different temperatures after due correction to $p_{H_2} = 1$ atm gave the values of E. These E values and the corresponding molalities of KI, H_2A, NaHA for cell [A], KI, NaHA, Na_2A for cell [B], KI, $H_2A^+I^-$, HA for cell [C], and KI, HA, NaA for cell [D] for each of the solvent mixtures are given in Table 1.

The values of pK_1 and pK_2 for U, pK_1 for T, and pK_1 and pK_2 for C were obtained using the functions pK_1' and pK_2' as defined by eqs. [1] to [4].

In the above equations m and γ denote the molality and molal activity coefficients of the species involved. The standard state is so chosen that at infinite dilution in the solvent water γ_i of any species i is equal to unity. The required $(E^0)_{Ag-AgI}$ values in water at different temperatures were known from the literature (7). The involved activity coefficients in water are approximated by the Debye–Hückel limiting law $-\log \gamma_i = S_f z_i^2 (\mu d_0)^{1/2}$ where μ = molal ionic strength of the cell solution, z_i = charge of the species involved and S_f = Debye–Hückel constant. Since pK_1' for C is around 4, pK_1's for U, T and pK_2's for U, C are above 9, due corrections for m_{H^+} (9) and m_{OH^-} (8) have been made, respectively. The pK values at different temperatures were obtained from linear fit of the type $pK' = pK + b\mu$ and their values are listed in Table 2. These pK's were fitted into Harned-Robinson type expression (10)

$$[5] \qquad pK = AT^{-1} + B + CT$$

by the method of least squares. The thermodynamic parameters ΔG^0, ΔS^0, ΔH^0 accompanying the protonation/deprotonation of the acids were evaluated using the following relationships that involve the coefficients of eq. [5]

$$[6] \qquad \Delta G^0 = 2.3026R[A + BT + CT^2]$$

$$[7] \qquad \Delta S^0 = -2.3026R[B + 2CT]$$

[8] $$\Delta H^0 = 2.3026R[A - CT^2]$$

The values of ΔG^0, ΔS^0, and ΔH^0 so obtained and the values of constants A, B, and C are presented in Table 3. The maximum uncertainties in ΔG^0, ΔS^0, and ΔH^0 as calculated by Please's method (11) are ±0.03 kJ mol^{-1}, ±1 J K^{-1} mol^{-1}, and ±0.3 kJ mol^{-1}, respectively.

pK_2 for T at 25°C was obtained from the following relationship

[9] $$H_- = p(K_a)_{HA^-} + \log [C_{A^{2-}}/C_{HA^-}]$$
$$= p(K_a)_{HA^-} + \log [(A - A_a)/(A_b - A)]$$

where H_- is the acidity function of the solution (12*a*), A = absorbance of each buffer solution, A_a = absorbance corresponding to the most acidic form, A_b = absorbance corresponding to the most alkaline form at λ_{max} = 280 nm. At $\log [(A - A_a)/(A_b - A)] = 0$, $p(K_a)_{HA^-} = H_-$. The values of H_- for different strengths of NaOH solutions are taken from the literature (12*b*, 13). The linear plot of H_- against $\log [(A - A_a)/(A_b - A)]$ is shown in Fig. 2. The results are presented in Table 4.

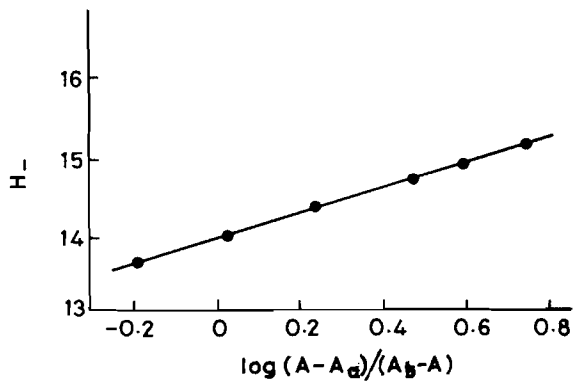

FIG. 2. Variation of H_- with $\log [(A - A_a)/(A_b - A)]$.

Discussion

Ultraviolet and ultrasonic absorption studies (6, 14) indicate that U and T primarily exist in the lactam form in an aqueous solution. However, in the alkaline solution two ionizations were detected: that of the 2-hydroxyl group characterised by pK_1 and that of the 4-hydroxyl group for pK_2. The pK_a values

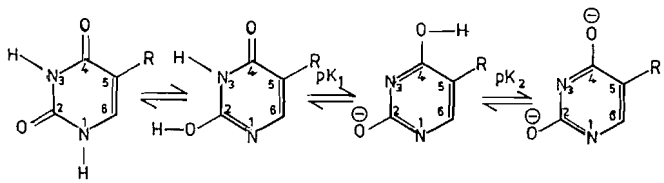
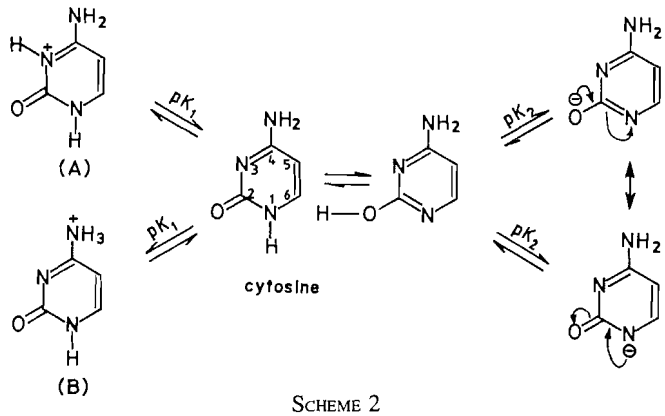
for T are slightly higher which is perhaps due to the presence of —CH_3 group at 5 position. The possible stepwise ionizations involved in the cases of U and T are summarised in Scheme 1.



SCHEME 1

The site of ionization from the protonated form of C(CH^+) is still a subject of controversy. From reports based on n.m.r. data (15, 16), calorimetry (17) and resemblance of enthalpy of ionization (ΔH^0) of CH^+ and protonated pyridine (PyH^+) (ref. 3), some previous workers are of the opinion that (*A*) represents CH^+. On the contrary, potentiometric, spectrophotometric, and ultrasonic studies (14, 18) and similarity of pK_a values of CH^+ and protonated aniline ($PhNH_3^+$) (19) led to suggest that (*B*) (Scheme 2) is the protonated form of C. A perusal of the



SCHEME 2

comparison of the related thermodynamic data of CH^+, PyH^+, and $PhNH_3^+$ at 25°C as given below

	CH^+	PyH^+	$PhNH_3^+$
ΔH^0/kJ mol^{-1}	21.5 (ref. 3)	20.1 (ref. 3)	30.4 (ref. 3)
ΔG^0/kJ mol^{-1}	26.4	30.0 (ref. 20)	26.4 (ref. 20)
$T\Delta S^0$/kJ mol^{-1}	−4.9	−9.9	4.1

seemingly fails to distinguish which of the forms really stanc for CH^+. However, based on ultrasonic absorption studies o proton transfer reaction in acidic range, Zana et al. believe that —NH_2 group of C is the favourable site of protonatior [form (B)]. The possible ionization step considered for CH^+ is depicted in Scheme 2.

Since ultrasonic absorption studies of proton transfer reactions in alkaline range shows no absorption maximum, Zana et al. conclude that C molecule does not contain lactam group. Therefore, as per Scheme 2, the lactim form of C is predominantly involved in yielding the extractable proton in alkaline range.

The observed protonation/deprotonation constants for U, T, and C and the related energetics at 25°C are compared (Table 5) with some literature data based on various methods.

The small negative magnitude of the entropy change accompanying the first step deprotonation of C, ΔS_1^0(C) and the large negative magnitude of ΔS_2^0(C) can be probably explained from the nature of the equilibria involved. Thus in the first step ionization of protonated C which is a charge transfer process:

$$H_2A^+ + H_2O \overset{K_1}{\rightleftharpoons} H_3O^+ + HA$$

ΔS_1^0(C) is given by eq. [10] (refs. 21, 22).

$$[10] \qquad \Delta S_1^0(C) = (\bar{S}^0_{H_3O^+} - \bar{S}^0_{H_2O}) + (\bar{S}^0_{HA} - \bar{S}^0_{H_2A^+})$$

$\bar{S}_i^0$ being the standard entropy per mole of i. In the second step ionization which involves charge separation:

$$HA + H_2O \overset{K_2}{\rightleftharpoons} H_3O^+ + A^-$$

ΔS_2^0(C) in represented by eq. [11]

$$[11] \qquad \Delta S_2^0(C) = (\bar{S}^0_{H_3O^+} - \bar{S}^0_{H_2O}) + (\bar{S}^0_{A^-} - \bar{S}^0_{HA})$$

Since H_3O^+ carrying a charge must be solvated, there is an increase in orderliness and therefore a decrease in entropy relative to H_2O, i.e. $\bar{S}^0_{H_3O^+} < \bar{S}^0_{H_2O}$. For a similar reason $\bar{S}^0_{H_2A^+} < \bar{S}^0_{HA}$ and hence the small negative magnitude of ΔS_1^0(C) as the two terms in parentheses in eq. [10] almost nullify each other. Similarly, in the case of deprotonation of HA, as $\bar{S}^0_{A^-} < \bar{S}^0_{HA}$ and $\bar{S}^0_{H_3O^+} < \bar{S}^0_{H_2O}$ the resulting ΔS_2^0(C) should be large negative as observed.

In the case of U, the dissociation processes involved are $H_2A \overset{K_1}{\rightleftharpoons} H^+ + HA^-$ and $HA^- \overset{K_2}{\rightleftharpoons} H^+ + A^{2-}$ and the corresponding entropy changes are given by eqs. [12] and [13].

$$[12] \qquad \Delta S_1^0(U) = (\bar{S}^0_{H_3O^+} - \bar{S}^0_{H_2O}) + (\bar{S}^0_{HA^-} - \bar{S}^0_{H_2A})$$

and

$$[13] \qquad \Delta S_2^0(U) = (\bar{S}^0_{H_3O^+} - \bar{S}^0_{H_2O}) + (\bar{S}^0_{A^{2-}} - \bar{S}^0_{HA^-})$$

Now, from Born-type electrostatic effect (23) one expects $\Delta S_2^0(U) < \Delta S_1^0(U)$. However, the observed data show just the reverse as $\Delta S_2^0(U) = -57.1$ J K^{-1} mol^{-1} and $\Delta S_1^0(U) = -62.4$ J K^{-1} mol^{-1}. Evidently Born-type electrostatic effect is not the sole contributing factor. In fact, as indicated earlier (24), $\bar{S}^0(i)$ for any species i can be visualized as the sum of several effects, viz.

[14] $$\bar{S}^0(i) = \bar{S}^0_{int}(i) + \bar{S}^0_{cav}(i) + \bar{S}^0_{disp}(i) + \bar{S}^0_{dd}(i)$$

$$\text{or } \bar{S}^0_B(i) + \bar{S}^0_{str}(i)$$

where $\bar{S}^0_{int}(i)$ stands for the entropy due to intrinsic structure of the species, $\bar{S}^0_{cav}(i)$ that associated with the formation of cavity required for accommodation of the species in the solvent, $\bar{S}^0_{disp}(i)$ that for dispersion effect, $\bar{S}^0_{dd}(i)$ due to dipole–dipole interaction in case of non-ionic species and $\bar{S}^0_B$ for Born-type electrostatic effect for ionic species and $\bar{S}^0_{str}(i)$ is that associated with the change in the order–disorder of solvent molecules adjacent to the dissolved species. As the contributions from ion–dipole and ion – induced dipole interactions are bereft of dielectric constants and other temperature dependent terms (23, 25), the entropy contributions for those terms are zero. From eqs. [12] to [14] we can write

[15] $$\Delta S_2^0(U) - \Delta S_1^0(U) = \bar{S}^0(A^{2-}) - 2\bar{S}^0(HA^-) + \bar{S}^0(H_2A)$$

$$= \bar{S}^0_B(A^{2-}) - 2\bar{S}^0_B(HA^-) + \bar{S}^0_{dd}(H_2A) + \Delta S^0_{str}$$

as the intrinsic, cavity, and dispersion terms are likely to be cancelled for the species HA, A^-, and A^{2-}. In eq. [15], ΔS^0_{str} stands for $\bar{S}^0_{str}(A^{2-}) - 2\bar{S}^0_{str}(HA^-) + \bar{S}^0_{str}(H_2A)$. Now, although the Born and dipole–dipole interaction terms are tentatively computable by the relevant expressions (23, 25), it is hardly feasible to account for the difference of $\Delta S_2^0(U) - \Delta S_1^0(U) = 5.3$ J K^{-1} mol^{-1} unless ΔS^0_{str} is realized. This is formidably difficult for these species.

To gain a better insight into the relative solvation behavior of the anions, especially those involved in the first step ionization process, we calculate the enthalpy of formation of A^- ($\Delta H_f^0(A^-)$ and HA^- ($\Delta H_f^0(HA^-)$. In the case of U, T, and C, the following equilibria for the thermodynamics of solute–solvent interaction can be considered:

$$HA\ (solid) \rightleftharpoons HA\ (soln)$$

and

$$H_2A\ (solid) \rightleftharpoons H_2A\ (soln)$$

Enthalpy of ionization, ΔH_{ion}, for the above equilibria can be ascribed as

[16] $$\Delta H_{ion}(HA) = \Delta H^0_{f,soln}(H^+) + \Delta H^0_{f,soln}(A^-) - \Delta H^0_{f,soln}(HA)$$

and

[17] $$\Delta H_{ion}(H_2A) = \Delta H^0_{f,soln}(H^+) + \Delta H^0_{f,soln}(HA^-) - \Delta H^0_{f,soln}(H_2A)$$

Enthalpy of solution, ΔH_{soln}, can be written as

[18] $$\Delta H_{soln}(HA) = \Delta H^0_{f,soln}(HA) - \Delta H^0_{f,solid}(HA)$$

and

[19] $$\Delta H_{soln}(H_2A) = \Delta H^0_{f,soln}(H_2A) - \Delta H^0_{f,solid}(H_2A)$$

Again

$$\Delta H^0_{f,soln}(H^+) = \tfrac{1}{2} D(H_2) + I(H) + \Delta H_{hydr}(H^+)$$

$$= 659.4 \text{ kJ mol}^{-1}.$$

where $D(H_2)$ (ref. 26) stands for the dissociation energy of H_2 molecule, $I(H)$ (ref. 26) that for ionization energy of H atom and $\Delta H_{hydr}(H^+)$ (ref. 25) is the enthalpy change associated with the transfer of H^+ from gaseous state to solution.

Adding eqs. [16] and [18] and substituting the values for

$\Delta H^0_{f,soln}(H^+)$, $\Delta H^0_{f,soln}(HA)$ (27, 28), and $\Delta H_{soln}(HA)$ (29), we get the enthalpy of formation of the anion of C in solution, i.e. $\Delta H^0_{f,soln,C}(A^-) = -832.5$ kJ mol^{-1}. Similarly for U and T, $\Delta H^0_{f,soln,U}(HA^-) = -1019.6$ kJ mol^{-1} and $\Delta H^0_{f,soln,T}(HA^-) = -1062.9$ kJ mol^{-1}.

From the negative magnitude of $\Delta H^0_{f,soln}(A^-$ or $HA^-)$ it is apparent that the heats of formation of the anions A^- and HA^- of the pyrimidine bases in water are, as expected, highly negative. Furthermore, the relative increasing order of $|\Delta H^0_{f,soln,C}(A^-)| < |\Delta H^0_{f,soln,U}(HA^-)| < |\Delta H^0_{f,soln,T}(HA^-)|$ suggests that the anion of T is more solvated in water than the same for U and C. This behavior is also in accordance with what is expected from charge density distribution (30) and the fact that the methyl group of T is slightly more stabilized by water due to the structuring of water molecules about this hydrophobic group.

Thiobenzoates of lead (II) and bismuth (III). The crystal and molecular structures of $(AsPh_4)$ $[Pb(SOCPh)_3]$ and $Pb(SOCPh)_2(S_2CP\{c\text{-}C_6H_{11}\}_3)$[1]

THOMAS R. BURNETT, PHILIP A.W. DEAN,[2] AND JAGADESE J. VITTAL[2]

Received August 10, 1993

THOMAS R. BURNETT, PHILIP A.W. DEAN, and JAGADESE J. VITTAL. Can. J. Chem. **72**, 1127 (1994).

The compounds $M(SOCPh)_n$ (M = Pb, n = 2; M = Bi, n = 3) have been prepared by the reaction of $M(OAc)_n$ or $M(SPh)_n$ with a slight excess of PhCOSH in MeOH. The ligands $PhCOS^-$, $(c\text{-}C_6H_{11})_3PCS_2$ and $(c\text{-}C_6H_{11})_3PO$ solubilize $Pb(SOCPh)_2$ in solvents in which it is otherwise poorly soluble. Neither Ph_3P nor Ph_3P increase the solubility of $Pb(SOCPh)_2$ and none of the above five ligands enhance the solubility of very poorly soluble $Bi(SOCPh)_3$. Solubilization of the Pb(II) compound is due in each case to a 1:1 reaction as shown by the isolation of $(Ph_4As)(SOCPh)_3]$ (**1**) and $Pb(SOCPh)_2(S_2CP\{c\text{-}C_6H_{11}\}_3)$ (**2**), and by a multi-NMR (^{31}P, ^{207}Pb) study of the system Pb(SOCPh) : $(c\text{-}C_6H_{11})_3PO$ (in which unidentified more ligand-rich species are also formed). **1** and **2** have been characterized by multi-nuclear magnetic resonance spectroscopy (^{13}C, ^{31}P, ^{207}Pb, as appropriate) and by single crystal X-ray diffractometry techniques at –50°C. The compound $\mathbf{1}.CH_2Cl_2$ (= **1′**) crystallizes in the triclinic space group $P\bar{1}$ with Z = 2. The crystal data for **1′** are a = 13.395(4), (b) = 16.585(3), c = 11.582(3) Å, α = 88.03(2), β = 112.34(2), γ = 113.00(2)°, V = 2171(1) Å^3, ρ_{calcd} (ρ_{obsd}) = 1.663 (1.65(3)) g cm^{-3}, R_F = 0.038, R_w = 0.035. In the $[Pb(SOCPh)_3]^-$ anion the Pb—S distances are in the range 2.703(3) – 2.763(2) Å. The primary coordination geometry around Pb is trigonal pyramidal (PbS_3 kernel). There are four additional weaker interactions with oxygen atoms, one from each ligand and one a bridging interaction that links the anions in a centrosymmetric dimer. The Pb—O distances are in the range 2.879(6) – 3.298(7) Å. Compound **2** crystallizes in the monoclinic space group, $P2_1/c$ with Z = 4. The crystal data for **2** are, a = 17.039(2), b = 11.834(2), c = 18.965(3) Å, β = 116.44(1)°, V = 3424(1) Å^3, ρ_{calcd} (ρ_{obsd}) = 1.621 (1.61(3)) g cm^{-3}, R_F = 0.034, R_w = 0.029. The $(c\text{-}C_6H_{11})_3PCS_2$ ligand binds in an anisobidentate manner and the primary coordination geometry around Pb in the neutral molecule is trigonal pyramidal, the primary Pb—S distances in the PbS_3 kernel being 2.626(2), 2.755(2), and 2.885(2) Å. The weakly bound sulfur of the $(c\text{-}C_6H_{11})_3PCS_2$ acts as a bridge, again producing a centrosymmetric dimer. In addition to the two weak interactions to sulfur (3.350(2), 3.639(2) Å) there are also two involving the oxygens of the $PhCOS^-$ ligands (2.626(5), 3.002(5) Å).

2 is the first complex containing a ligand of the type R_3PCS_2 bound to a Main Group element.

THOMAS R. BURNETT, PHILIP A.W. DEAN et JAGADESE J. VITTAL. Can. J. Chem. **72**, 1127 (1994).

On a préparé les composés $M(SOCPh)_n$ (M = Pb, n = 2; M = Bi, n = 3) en faisant réagir le $M(OAc)_n$ ou le $M(SPh)_n$ avec un léger excès de PSCOSH dans du MEOH. Les ligands $PhCOS^-$, $(c\text{-}C_6H_{11})_3PCS_2$ et $(c\text{-}C_6H_{11})_3PO$ solubilisent le composé $Pb(SOCPh)_2$ dans des solvants qui ne le dissolvaient que faiblement. Le Ph_3P et le Ph_3P n'augmentent pas la solubilité du $Pb(SOCPh)_2$ et les cinq ligands mentionnés ci-dessus n'améliorent aucunement la solubilité du composé $Bi(SOCPh)_3$ très faiblement soluble. La solubilisation du composé Pb(II) est due, dans chaque cas, à une réaction 1:1 comme le démontrent les diverses études en rmn des noyaux multiples (^{31}p et du $^{207}Pb^{31}$) du système Pb(SOCPh) : $(c\text{-}C_6H_{11})_3PO$ (dans lequel il se forme également des espèces plus riches en ligands que l'on n'a pas identifiées) et également le fait que l'on a pu isoler les composés $(Ph_4As)[Pb(SOCPh)_3]$ (**1**) et $Pb(SOCPh)_2(S_2CP\{c\text{-}C_6H_{11}\}_3)$ (**2**). On a caractérisé les composés **1** et **2** par la spectroscopie de résonnance des noyaux multiples (^{13}C, ^{31}P et du ^{207}Pb selon le cas) et par les techniques de diffraction de rayons x sur un monocristal à –50°C. Le composé $\mathbf{1}.CH_2Cl_2$ (=**1′**) appartient au groupe d'espace triclinique $P\bar{1}$ avec Z = 2, a = 13,395(4), (b) = 16,585(3), (c) = 11,582(3) Å, α = 88,03(2), β = 112,34(2), γ = 113,00(2)°, V = 2171(1) Å^3, $\rho_{calculé}$ ($\rho_{observé}$) = 1,663 (1,65(3)) gcm^{-3}, R_F = 0,038, R_w = 0,035. Dans l'anion $[Pb(SOCPh)_3]^-$ les distances Pb—S se situent dans l'intervalle 2,703(3) – 2,763(2) Å. La géométrie de coordination primaire autour du Pb est trigonale pyramidale (dans le noyau PbS_3). Il y a quatre faibles interactions additionnelles avec les atomes d'oxygène, une à partir de chaque ligand et une autre interaction en position de pont qui lie les anions dans un dimère centrosymétrique. Les distances Pb—O se situent dans l'intervalle de 2,879(6) – 3,298(7) Å. Le composé **2** appartient au groupe d'espace monoclinique $P2_1/c$ avec Z = 4, a = 17,039(2), b = 11,834(2), c = 18,965(3) Å, β = 116,44(1)°, V = 3424(1) Å^3, $\rho_{calculé}$ ($\rho_{observé}$) = 1,621 (1,61(3)) g cm^{-3}, R_F = 0,034, R_w = 0,029. Le ligand $(c\text{-}C_6H_{11})_3PCS_2$ est lié de façon anisobidentate et la géométrie de coordination primaire autour du Pb dans la molécule neutre est trigonale pyramidale, les distances primarires Pb—S dans le noyau PbS_3 étant 2,626(2), 2,755(2) et 2,885(2) Å. La faible liaison soufre du composé $(c\text{-}C_6H_{11})_3PCS_2$ sert de pont, produisant un dimère centrosymétrique. En plus de ces deux faibles interactions dues au soufre (3,350(2), 3,639(2) Å) il y a également deux autres interactions impliquant l'oxygène des ligands de type $PhCOS^-$ (2,626(5), 3,002(5) Å.

Le complexe **2** est le premier à contenir un ligand du type R_3PCS_2 lié à un élément du group principal.

[Traduit par la Rédaction]

Introduction

Monothiocarboxylates are an interesting class of ligands containing both a soft sulfur donor site and a hard oxygen donor site (1, 2). The presence of two types of donor sites can lead to aggregation of soft and hard metal centres. This is shown, for example, in the recently reported (3) structure of trinuclear $[Na(CdSOCPh_3)_2]^-$. In this anion the relatively soft Cd(II) is bound strongly to sulfur atoms while the hard Na(I) is attached to oxygen atoms.

Evidently use of $RCOS^-$ ligands might lead to a variety of unusual bimetallics species. However, extension of this chemistry to include soft Main Group metal centres is hampered by the dearth of information that is available about even the relevant *simple* metal monothiocarboxylates (1, 2). Therefore, as a contribution to this area we describe here the synthesis and some properties of $Pb(SOCPh)_2$ and $Bi(SOCPh)_3$. As part of

this study, we have isolated both ($AsPh_4$) [$Pb(SOCPh)_3$] and $Pb(SOCPh)_2(S_2CPCy_3)$[3] and characterized them by NMR spectroscopy and X-ray structural analysis. Complexes of R_3PCS_2 with transition metals have become well-established over the last two decades (for a recent paper, see ref. 4), but as far as we are aware $Pb(SOCPh)_2(S_2CPCy_3)$ represents the first example of a complex of this type of ligand with a Main Group element.

Experimental

Material and general procedures

All starting materials were of reagent grade and were used as received, except that triphenylphosphine was recrystallized from ethanol. Literature methods were used from the synthesis of $Bi(OAc)_3$ (5), $Bi(SPh)_3$ (6), $Pb(SPh)_2$ (7), $Ph_4As[Pb(SPh)_3]$ (8), and Ph_2S_2(9). $KMnO_4$ oxidation of the phosphine in Me_2CO (10) was used to produce both $OPPh_3$ and $OPCy_3$.

Solvents for use in synthesis or the preparation of NMR samples were dried by standing over 3A molecular sieves. Before use with thiolates or thiobenzoates they were thoroughly deoxygenated with Ar. Syntheses were carried out by Schlenk-type techniques or in an Ar-filled glovebag.

$Pb(SOCPh)_2$

(*A*) To a stirred solution of $Pb(OAc)_2.3H_2O$ (5.17 g, 13.6 mmol) in 30 mL of eythanol thiobenzoic acid (5.5 mL, 46.8 mmol) was added slowly. A thick suspension of yellow precipitate appeared immediately. A small amount of brown contaminant, presumably PbS,[4] formed unless the PhCOSH was added below the surface by syringe. The mixture was stirred for 2 h to ensure complete reaction. The thick suspension was then centrifuged, the supernatant liquid was removed, and the solid was washed three times with cold ethanol, with recentrifugation between washings. In the final cycle the supernatant liquid was colourless. The product was dried under vacuum. Yield: 5.31 g (81.1%). *Anal.* calcd. for $C_{14}H_{10}O_2PbS_2$: C 34.91, H 2.08; found: C 35.01, 35.11; H 1.83, 1.94.

(*B*) To a suspension of $Pb(SPh)_2$ (3.73 g, 8.8 mmol) in ethanol (60 mL) thiobenzoic acid (2.4 mL, 20.3 mmol) was added below the surface using a syringe. The bright yellow suspension became much paler in colour. Thereafter, the procedure was as described in synthesis (*A*). Yield: 4.06 g(95.9%). *Anal.* found: C 34.87 H 1.97. The IR spectrum (Nujol mull) showed that $Pb(SPh)_2$ (ν(C—S) $\approx$ 730 cm^{-1}) was absent.

$Bi(SOCPh)_3$

(*A*) This procedure followed method (*A*) used for $Pb(SOCPh)_2$ except that $Bi(OAc)_3$ was used in place of $Pb(OAc)_2$, and the amount of PhCOSH was a slight excess over the required PhCOSH:Bi ratio of 3:1. Yield of the pale yellow product: 92%. *Anal.* calcd. for $C_{21}H_{15}BiO_3S_3$: C 40.65, H 2.42; found: C 40.16, 39.97; H 2.14, 2.28.

(*B*) This synthesis was similar to synthesis (*B*) used for $Pb(SOCPh)_2$ except that $Pb(SPh)_2$ was replaced by $Bi(SPh)_3$. The amount PhCOSH was adjusted accordingly. Yield: 95%. *Anal.* found: C 40.57, H 2.16. The IR spectrum showed that $Bi(SPh)_3$ (ν(C—S) $\approx$ 730 cm^{-1}) was absent.

$(Ph_4As)[Pb(SOCPh)_3]$ (1)

(*A*) Thiobenzoic acid (0.49 mL, 4.1 mmol) was added to a solution of NaOMe produced by adding sodium metal (0.10 g, 4.3 mmol) to methanol (5 mL). The resulting solution of NaSOCPh was added to a stirred suspension of $Pb(SOCPh)_2$ (1.0 g, 2.1 mmol) in methanol (20 mL), causing dissolution of the lead compound to give a green solution. When a solution of $(AsPh_4)Cl.H_2O$ (0.88 g, 2.1 mmol) in MeOH (30 mL) was added, initially there was precipitation of a yellow solid, but this disappeared quickly in the solution to give, finally, a brown oil and a yellow supernatant solution. The yellow solution was decanted from the oil, and water (ca. 60 mL) was added to it until a trace of pale yellow solid persisted. The mixture was refrigerated and produced pale yellow crystals, which were separated by filtration under Ar and dried in vacuo. The product was recrystallized from Me_2CO:H_2O (3:2 v:v), isolated by filtration, and dried.

The brown oil produced a grey solid when 10 mL of water was added. This solid was dried under vacuum then dissolved in Me_2CO. The solution was filtered using a fine frit. The filtrate was treated in the same way as the yellow supernatant liquid to yield another crop of the pale yellow crystals. Combined yield: 67% (1.39 g). *Anal.* calcd. $C_{45}H_{35}AsO_3PbS3$: C 53.92, H 3.49; found: C 54.02, H 3.38 (crystals from original yellow solution). ^1H NMR ($(CD_3)_2CO$, 293 K): 7.0–7.6, 8.0–8.17 (anion); 7.7–8.0 (cation); Ph_{cation}/Ph_{anion} = 4/3. ^{13}C NMR ($CDCl_3$, 293 K): 143.9 (C_1), 128.9 ($C_{2,6}$ or $C_{3,5}$), 128.3 ($C_{2,6}$ or $C_{3,5}$), 132.0 (C_4), 204.6 (Ph*C*OS) [anion]; 122.1 (C_1), 134.3 ($C_{2,6}$), 131.9 ($C_{3,5}$), 135.4 (C_4) [cation].

(*B*) This procedure was generally similar to that used to synthesize $Ph_4As[Pb(SPh)_3]$ (8). A solution of NaSOCPh in methanol was prepared as in route (*A*), using thiobenzoic acid (1.7 mL, 14.5 mmol) and sodium metal (0.3 g, 13.0 mmol). This solution was added to a stirred solution of $Pb(NO_3)_2$ (1.42 g, 4.3 mmol) in 5 mL of water producing a brown-coloured supernatant liquid and a beige precipitate. A solution of $(AsPh_4)Cl.H_2O$ (1.85 g, 4.4 mmol) in methanol (30 mL) was stirred into the mixture resulting in a faint yellow supernatant liquid and brown precipitate. A 100-mL volume of water was added to this solution producing more brown precipitate and causing the supernatant liquid to become colourless. The precipitate was allowed to settle and the supernatant liquid removed by decantation. The brown solid was washed twice with ethanol and dried under vacuum. Acetone (ca. 30 mL) was added to the solid. Undissolved material was removed with a fine frit and water was added to the filtrate until a yellow precipitate persisted. This solution was refrigerated and pale yellow crystals resulted. When separated by filtration and dried the crystals had a beige colour and when examined under a microscope they were found to contain a mixture of pale yellow crystals and a very fine brown contaminant, presumably PbS. A second recrystallization from a 3:2 acetone:water mixture resulted in crystals with the same contaminant present. The sample was purified using a column of Kieselgel 60 silica gel (18 cm long, 1 cm id).[5] A solution of all of the isolated material in Me_2CO (ca. 20 mL) was passed through the column, followed by a 5-mL wash of acetone. The solvent was removed from the eluate producing an oil. This oil produced pale yellow crystals from an acetone–water solution. Yield: 29.3% (1.26 g). The identity of this material with that produced by method (*A*) was confirmed by ^1H, ^{13}C, and ^{207}Pb NMR.

$Pb(SOCPh)_2(S_2CPCy_3)$ (2)

To a suspension of $Pb(SOCPh)_2$ (0.48 g, 1.0 mmol) in CS_2 (40 mL) was added S_2CPCy_3 (0.36 g, 1.1 mmol), gradually, with continuous stirring. The mixture became deep red in colour as the solids dissolved. The small amount of solid remaining after ca. 20 min was removed using a medium frit. A two-thirds reduction in the volume of the filtrate was achieved under a stream of Ar. The concentrated mixture was refrigerated overnight to promote crystallization. Using a pipette, most of the supernatant liquid was separated from the crystals so produced. Then the red–brown crystals were isolated by filtration, washed with cold CS_2, and dried under a flow of argon. The volume of the separated supernatant liquid was reduced by about one half under an Ar stream and the solution refrigerated again. Once again the crystals produced were separated by filtration, washed, and dried. This procedure was repeated until no more crystalline material was formed. Combined yield: 48% (0.40 g). *Anal.* Calcd. for $C_{33}H_{43}O_2PPbS_4$: C 47.30, H 5.14, S 15.30; found: C 47.11, 47.29; H 4.69, 4.88; S 15.12, 15.21.

NMR spectra

All spectra were measured at ambient probe temperature. The ^1H

[3]Cy = *c*-C_6H_{11}.

[4]We observe that PbS forms when the vapor of PhCOSH comes in contact with $Pb(OAc)_2$/EtOH.

[5]A shorter column would have sufficed.

[a] $R_F = \Sigma(\|F_o\| - F_c\|)/\Sigma|F_o|$; $R_w = [\Sigma w(\|F_o\| - |F_c\|)^2/\Sigma w|F_o|]^{1/2}$ and GoF = $[\Sigma w (\|F_o\| - |F_c\|)^2/(\text{number of reflections} - \text{number of parameters})]^{1/2}$.

NMR spectra were measured using a Varian Gemini-200 or XL-300 spectrometer and referenced using the solvent residual signal ($\delta_H(CD_3)(CHD_2)CO$) = 2.04). The ^{13}C spectra were measured using a broad-banded Varian Gemini-200 or Varian XL300 spectrometer depending upon the probe size to be used (10 mm or 5 mm), and referenced to the solvent signal ($\delta_c(CDCl_3)$ = 77.0). The ^{31}P and ^{207}Pb[6] NMR spectra were obtained with the broad-banded Varian Gemini-200 with and without ^1H-decoupling, respectively, and with no ^2D field/frequency lock (field drift is negligible, <0.04 and <0.02 ppm/day for ^{31}P and ^{207}Pb, respectively). In these cases samples were prepared in 10 mm od NMR tubes with concentrations expressed in terms of mass of solute/volume of solvent. They were referenced by sample interchange with 85% H_3PO_4 and 1.0 *M* $Pb(NO_3)_2$(aq), respectively. For the latter reference δ_{Pb}(1.0 *M* $Pb(NO_3)_2$(aq)) = $\delta_{Pb}(PbMe_4$(toluene)) + 2961 ppm (12); in the text δ_{Pb} are given relative to the $PbMe_4$ standard. The ^{31}P and ^{207}Pb NMR chemical shifts are thought to be reproducible to ±0.1 and ±2 ppm, respectively.

IR spectra

All IR spectra were measured as mulls between KBr windows using a Nicolet 205 FTIR spectrometer.

X-ray structure determination

Crystals of **1** (as the CH_2Cl_2 solvate, **1′** (see below)) suitable for X-ray analysis were obtained by diffusing Et_2O into a solution of **1** in CH_2Cl_2. Suitable crystals of **2** were obtained during the synthesis described above.

The crystals **1′** and **2** were examined by a similar experimental procedure. An overview is given below and crystal data are summarized in Table 1. The crystal densities were measured by the neutral buoyancy method in mixtures of CCl_4 and 1,2-$C_2H_4Br_2$. Crystal **1′** was losing solvent at room temperature and hence measurements were made at −50°C. For comparison, the data collection of crystal **2** was also carried out at −50°C. In both cases data were collected on an Enraf-Nonius CAD4F diffractometer using graphite monochromated Mo Kα radiation (13). Photo and automatic indexing routines, followed by least squares fits of 21 accurately centered reflections gave cell constant and an orientation matrix. Intensity data were recorded in ω mode at variable scan speeds (1.50 to 4.12 deg min^{-1}), and a scan width of 0.70 + 0.35 tan θ with a maximum time per datum of 45 s. Background measurements were made by extending the scan by 25% on each side. Standard reflections were monitored every 120 min of X-ray exposure time. The faces of the data crystals were indexed and the distances among them were measured under a Filar microscope for Gaussian absorption correction which was made using the routine "abso". The data were processed using the NRCVAX crystal structure programs (14) running on a SUN 3/80 workstation. The structure solutions and the refinements were done by full-matrix least-squares techniques on F. The structures were solved using the program SHELXS-86 (15) and subsequent difference Fourier techniques. Anisotropic thermal parameters were assigned to all the atoms except for the phenyl rings and were refined. The hydrogen atoms were placed in ideal positions (C—H = 1.08 Å) and their thermal parameters were taken to be 10% larger than those of the attached carbon atoms.

Crystal 1′

A crystal of suitable size (0.1 × 0.1 × 0.2 × mm) was obtained by cleaving a rod-like crystal along (201) plane. In all 6201 reflections in the 2θ range 0–45° ($-45 \leq h \leq 1, -17 \leq k \leq 17, -12 \leq l \leq 12$) and 32 repetitions of the standards were recorded. The crystal used for data collection has 11 faces. The indices are {0,1,0}, {1,$\bar{1}$,$\bar{1}$}, ($\bar{1}$,1,$\bar{1}$), ($\bar{1}$,$\bar{1}$,1), (1,0,$\bar{1}$), (2,0,1), (0,$\bar{1}$,$\bar{1}$), (0,1,$\bar{1}$), and ($\bar{1}$,2,0). The minimum and maximum transmissions factors are 0.548 and 0.768. The space group $P\bar{1}$ was assumed for the triclinic system. The refinement converged for 196 parameters and 4513 ($I \geq 2.5\sigma(I)$) observations at R_F = 0.038, R_w = 0.035 and Gof = 2.53 using the weighting scheme based on counting statistics. In the final difference Fourier synthesis ranges from 1.66 to −0.84 e Å^{-3}. The top two peaks have the electron density greater than 1.0 e Å^{-3}. The top two peaks have the electron density greater than 1.0 e Å^{-3} and are associated with Pb at distances 1.26 and 1.34 Å respectively. The largest Δ/σ = 0.037.

Crystal 2

A blood-red crystal of suitable size (0.27 × 0.29 × 0.41 mm) was obtained by cleaving a plate along the (100) and (100) planes. The initial orientation matrix and the monoclinic cell were obtained from 25

[6] ^{207}Pb, 22.6% natural abundance, spin, I = 1/2, receptivity relative to ^{13}C, D^C = 11.4 (ref. 11).

reflections using the routines SEARCH and INDEX. The cell reduction program indicated a C-centered orthorhombic cell. The Laue check on a limited number of reflections suggested *mmm* symmetry. On the basis of these observations the intensity data were collected initially in a C-centered orthorhombic cell ($a = 33.985(13)$, $b = 17.047(5)$, $c = 11.838(4)$ Å, $Z = 8$). At the end of the data collection, an inspection of all the absorption corrected data showed that the systematic absences and symmetry-related reflections did not reflect the crystal system or the space group chosen. The data and the cell were transformed to a monoclinic system using the matrix transformation [0,–1,0, 0,0,1, –0.5,0.5,0], and it was found that the crystal belonged to the Laue group *2/m* (based on an observation of symmetry equivalent reflections) with the space group $P2_1/c$ from the systematic absences (16) ($h0l$, $l = 2n + 1$ and $0k0$, $k = 2n + 1$). However, the data collection was completed on the old C-centered orthorhombic cell ($-40 \leq h \leq 1$, $-20 \leq k \leq 20$, $-14 \leq l \leq 14$) in the 2θ range 0–50°. The data were processed, corrected for absorption and finally transformed to the monoclinic cell using the above-mentioned transformation matrix. The new cell data are $a = 17.039(2)$, $b = 11.834(2)$, $c = 18.965(3)$ Å, $\beta = 116.44(1)°$ (centering from 21 high angles in the 2θ range 24.1 to 30.2°), $Z = 4$. All the numbers reported here belong to the monoclinic cell. In all 10163 reflections were recorded, of which 6015 are unique reflections. The crystal used for data collection was seven faces with indices {1,0,0}, {0,1,0}, {$\bar{1}$,0,2}, and ($\bar{1}$,0,1). The minimum and maximum transmission factors are 0.2458 and 0.3445. In the final cycles, the refinement of 287 parameters and 4405 ($I \geq 2.5\sigma(I)$) observations, gave convergence at $R_F = 0.034$, $R_w = 0.029$, and GoF = 3.37 using the weighting scheme based on counting statistics. In the final difference Fourier synthesis ranges 1.00 to –1.26 e Å^{-3}. The top peak was 1.05 Å from Pb. The largest $\Delta/\sigma = 0.065$. The secondary extinction coefficient was refined to 0.636 (17).

The experimental details and crystal data are shown in Table 1, the positional and B_{iso} thermal parameters are given in Tables 2 and 3 for **1′** and **2** respectively. Tables of anisotropic thermal parameters, hydrogen atom positional parameters, selected dihedral and torsional angles have been included in the depository materials.[7]

Elemental analysis

Elemental microanalyses were carried out by Guelph Chemical Laboratories Ltd.

Results and discussion.

$Pb(SOCPh)_2$ and $Bi(SOCPh)_3$

These compounds can be synthesized in excellent yields by the following simple routes (M = Pb, $n = 2$; M = Bi, $n = 3$):

[1] $M(OAc)_n + n\text{PhCOSH} \xrightarrow{\text{MeOH}} M(SOCPh)_n + n\text{HOAc}$

[2] $M(SPh)_n + n\text{PhCOSH} \xrightarrow{\text{MeOH}} M(SOCPh)_n + n\text{PhSH}$

A minor complication is the gas phase reaction between thiobenzoic acid and the slurry of metal acetate or benzenethiolate, but this can be prevented by addition of the acid below the surface of the slurry.

Both salts are insoluble in most common solvents, pointing to polymeric structures. However, they are soluble in DMF. At 294 K the ^{207}Pb NMR spectrum of a saturated solution of $Pb(SOCPh)_2$ in DMF consists of a very broad line ($\Delta_{\nu 1/2} \approx 2000$ Hz) with $\delta_{Pb} \approx 740$. At 213 K, no ^{207}Pb signal was observed for the solution. There is evidently an exchange process and no information can be obtained on the nature of the species present.

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

Addition of donor ligands

The addition of strong donor ligands has been found to solubilize dimeric $Ni_2(SOCPh)_4.EtOH$ (17) and the presumed- polymeric thiobenzoates of Pd(II) and Pt(II) (18). These earlier findings and the solubility of both $Pb(SOCPh)_2$ and $Bi(SOCPh)_3$ in the strong donor solvent (19) DMF, suggested that solubilization of the Pb(II) and Bi(III) salts might be achieved by the addition of appropriate ligands.

None of the ligands $PhCOS^-$, Cy_3PCS_2, Cy_3PO, Ph_3PO, or PPh_3 increased the solubility of $Bi(SOCPh)_3$ in any of the solvents in which it was otherwise insoluble. However, more positive results were obtained for $Pb(SOCPh)_2$ as described next.

(i) $Pb(SOCPh)_2$:$SOCPh^-$

Addition of one mole equivalent of $PhCOS^-$ to $Pb(SOCPh)_2$ in MeOH leads to the formation of $[Pb(SOCPh)_3]^-$ (reaction [3]). The new anion has been isolated in good yield as the $AsPh_4^+$ salt, **1**. Alternatively, **1** may be synthesized from $Pb(NO_3)_2$ and excess $PhCOS^-$ in methanol:water (reaction[4]). In this case the yield is poor. A brown solid, presumably PbS, is formed concurrently and it is tedious to separate this from the $AsPh_4^+$ salt.

$$[3]\quad Pb(SOCPh)_2 + PhCOS^- \xrightarrow{MeOH} [Pb(SOCPh)_3]^-$$

$$[4]\quad Pb^{2+} + 3PhCOS^- \xrightarrow{MeOH:H_2O} [Pb(SOCPh)_3]^-$$

The salt **1** is soluble in Me_2CO, MeCN, CH_2Cl_2, $CHCl_3$, and DMF. The ^{207}Pb NMR chemical shifts (and approximate linewidths[8]) at 294 K and a concentration of 0.025 mol per L of solvent are at 1463 (13 Hz), 1422 (15 Hz), and 1422 (280 Hz) in Me_2CO, MeCN, and DMF, respectively, at 294 K. These indicate the presence of the same species in each solvent, allowing for solvent effect on δ_{Pb}, which are expected to be large. The relatively large value of $\Delta\nu_{1/2}$ found for the DMF solution may indicate exchange broadening caused by the onset of dissociation.

^{207}Pb NMR chemical shifts found for mixtures of $(Ph_4As)[Pb(SPh)_3]$ and excess PhCOSH or $(PhCOS)_2$ show that the $[Pb(SOCPh)_3]^-$ anion is also being formed according to reactions [5] and [6].

$$[5]\quad [Pb(SPh)_3]^- + 3PhCOS \rightarrow [Pb(SOCPh)_3]^- + 3PhSH$$

$$[6]\quad [Pb(SPh)_3]^- + (3/2)\,(PhCOS)_2 \rightarrow [Pb(SOCPh)_3]^- + (3/2)Ph_2S_2$$

For reaction [5] in $CHCl_3$ $\delta_{Pb}(\Delta\nu_{1/2}) = 1414$ (≈140 Hz), while for reaction [6] in Me_2CO, $\delta_{Pb}(\Delta\nu_{1/2}) = 1466$ (≈10 Hz).

The ^{207}Pb resonance of $[Pb(SOCPh)_3]^-$ is considerably more shielded than those found (8, 20) for various anions $[Pb(SR)_3^-]$, e.g. 2868 ppm for $(Ph_4As)[Pb(SPh)_3]^-$ in $CHCl_3$ at 296 K (8). The same phenomenon has been observed (3) for $[Cd(SOCPh)_3]^-$ vs. $[Cd(SR)_3]^-$ and has been taken to indicate a significant interaction of the metal with the oxygen of the $PhCOS^-$ ligand. The structure of $[Pb(SOCPh)_3]^-$, discussed below, shows that there is indeed an interaction with the oxygens in this anion.

(ii) $Pb(SOCPh)_2$:S_2CPCy_3

$Pb(SOCPh)_2$ is poorly soluble in CS_2, but becomes very soluble in the presence of S_2CPCy_3. From these mixtures a red–brown (blood red as larger crystals) 1:1 adduct can be obtained in moderate yield. The solubility of these crystals in CS_2 is much less than that attainable in the initial (presumably supersaturated) solution.

The formation of $Pb(SOCPh)_2(S_2CPCy_3)$ is associated with a deshielding of the ^{31}P NMR signal of S_2CPCy_3: $\delta_P = 23.8$ and $\Delta\delta_P$ (= δ_P(complex) − δ_P(free ligand)) = 9.9 for solutions in CS_2 at 294 K. Clearly binding between the S_2CPCy_3 and the lead center persists in solution. The ^{207}Pb NMR spectrum of the 1:1 adduct in CS_2 gives $\delta_{Pb}(\Delta\nu_{1/2}) = 1288$ (≈220 Hz) for a saturated solution in CS_2 (< 0.025 mol/L of CS_2). It is tempting to conclude from the similar ^{207}Pb NMR chemical shifts of $Pb(SOCPh)_2$ and $[Pb(SOCPh)_3]^-$ that there is a similarity of structure, and X-ray analysis (see below) does reveal a common

[8] The values of $\Delta\nu_{1/2}$ are upper limits, since the values generally increase with time, presumably due to minor temperature fluctuations coupled with a high temperature effect on δ_{Pb}.

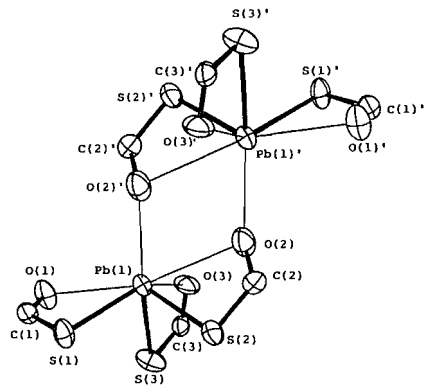

FIG. 2. The dimeric interaction between the anions in **1′**.

PbS_3 primary kernel. Such logic may be simplistic, however, since the ^{207}Pb chemical shift of $Pb(SOCPh)_2(OPCy_3)$ is also similar (see below).

(iii) $Pb(SOCPh)_2$:$PPCy_3$

Addition of $OPCy_3$ (but not the weaker donor $OPPh_3$, or PPh_3 itself) solubilizes $Pb(SOCPh)_2$ in Me_2CO. The lead salt is completely soluble at a 1:1 ratio. A titration using ^{31}P NMR confirms this reactant ratio for $Pb(SOCPh)_2/OPCy_3 \geq 1$.[9] The complex $Pb(SOCPh)_2(OPCy_3)$ is characterized by $\delta_P = 58.2$, deshielded as expected (22) relative to free $OPCy_3$ ($\delta_P = 48.8$), and $\delta_{Pb}(\Delta\nu^{1/2}) = 1335(\approx 890\ Hz^7)$ at 294 K. (These values were measured with $Pb(SOCPh)_2/OPCy_3 \leq 1$ for ^{31}P, and with $Pb(SOCPh)_2/OPCy_3 = 2$ and 0.05 mol of $OPCy_3$ per L of acetone for ^{207}Pb.)

An alternative formulation of the product as $[Pb(OPCy_3)_3][Pb(SOCPh)_3]_2$ is ruled out by δ_{Pb}. For $[Pb(OPCy_3)_3]^{2+}$ $\delta_{Pb} \approx -1142$ (relative to $PbMe_4$(toluene)) for a solution in SO_2(1) at 203 K (22). Combined with $\delta_{Pb}([Pb(SOCPh)_3]^-)$, this leads to $\delta_{Pb} \approx 590$ for $[Pb(OPCy_3)_3][Pb(SOCPh)_3]_2$, assuming fast exchange (only one signal is observed in the ^{207}Pb NMR spectrum). Even allowing for temperature and medium effects on δ_{Pb}, which are expected to be large, this is quite different from the value of δ_{Pb} observed.

Structure of $(AsPh_4)[Pb(SOCPh)_3]$. CH_2Cl_2 (1′)

The crystal structure consists of discrete cations, anions occurring as centrosymmetric dimers, and a molecule of solvent (CH_2Cl_2). The Pb and As are separated by 6.59 Å. The shortest interionic distance of 2.307 Å is H(44)...O(3) [x, $(1 + y)$, $(1 + z)$].

Figure 1 shows a view of the $[Pb(SOCPh)_3]^-$ anion and gives the atomic numbering scheme used. Figure 2 shows the coordination spheres of the lead atoms in the centrosymmetric dimer that the anions form. The Pb...Pb distance in the dimer is 5.509(2) Å. Listed in Table 4 are selected bond distances and angles. Those of the cation and solvent molecule are unexceptional and are not discussed further.

The immediate coordination sphere of each lead atom contains three sulfur atoms and three oxygen atoms from three chelating thiobenzoate ligands. The three Pb—S distances are significantly different and cover the range 2.706(3) – 2.764(3) Å. The shortest Pb—S distance just touches on the range of Pb—S distances found for primary interactions in Pb(II) complexes with simple terminal mono- and di-thiolates (2.554(4) to 2.696(3) Å (8, 23)). However, they all fall into the range that has been established from the shorter Pb—S bonds to the anisobidentate ligands that are found in Pb(II) complexes of dithiocarbamates (24), xanthates (25, 26) and dithiophosphates (27) (2.673(4) to 2.946(3) Å). The S—Pb—S angles are irregular and cover the range 85.02(9)–90.75(8)°. For comparison, S—Pb—S angles for the $Pb(SPh)_3^-$ anion are 90.32(4) – 96.14(5)° in the $AsPh_4^+$ salt (8) and 89.7(1) – 102.7(1)° in the $N^nPr_4^+$ salt (23*a*) and the angles between the three shorter Pb—S distances in $[Pb(S_2COEt)_3]^-$ are 84.38(8)–89.80(9)°(26).

The Pb—O distances are 2.879(6), 2.905(7), and 3.113(6) Å. The longest is associated with the bridging interaction, Pb—O(2)[a], 3.298(7) Å. All four Pb—O distances are less than the sum of the van der Waals radii, 3.5 Å (28). They are, however, significantly longer than those found for the primary bonds in simple carboxylates of Pb(II), for which Pb—O distances to the bidentate ligands fall in the range 2.32(2)–2.74(1) Å (29). Thus the Pb—O distances in the present case represent secondary interactions.

In the $PhCOS^-$ ligands, the C—O distances range from 1.219(11) to 1.235(11) Å, the C—S distances from 1.721(10) to 1.739(9) Å, and the S—C—O angles from 122.1(7) to 123.5(7)°. These values are comparable to those found in $(Me_4N)[Na(CdSOCPh_3)_2]$ (3), $[Ni(SOCPh)_2]_2$.EtOH (30), and $(PhCOS)_2$ (31).

It is possible to consider the coordination geometry around Pb as being based primarily on a pyramidal PbS_3 kernel of the VSEPR type AX_3E. The weaker Pb—O interactions then occur around the region that is occupied by the lone pair electrons, as occurs in the dimer of $[Pb(SOCOEt)_3]^-$ also (26). The geometry of the overall PbS_3O_4 kernel in the dimer of $[Pb(SOCPh)_3]^-$ is remarkably similar to that of the overall SbS_3O_4 kernel found in polymeric $Sb(SOCMe)_3$ (32). Earlier authors (26) have commented that the structures of Pb(II) complexes are "strikingly reminiscent" of their Sb(III) and Bi(III) analogues.

It is important to note that although the Pb—O bonds of $[Pb(SOCPh)_3]^-$ are secondary in the solid state, the ^{207}Pb NMR chemical shift of the anion (as discussed above) suggests that Pb—O bonding remains important for the anion in solution. A reviewer has suggested that a different structure with stronger Pb—O bonding may occur in solution.

[9]At $Pb(SOCPh)_2/OPCy_3 < 1$, δ_P is less shielded than expected for $Pb(SOCPh)_2(OPCy_3)$ and excess $OPCy_3$ undergoing fast exchange. Evidently more than one $OPCy_3$ can coordinate to Pb, but we were unable to identify the ligand-rich species formed. We note that there is evidence for $[Pb(OPPh_3)_n]^{2+}$ ($n > 3$) are known (ref. 21).

[a]Symmetry equivalents ($-x$, $-y$, $-z$).

Structure of $Pb(SOCPh)_2$ (S_2CPCy_3) (2)

The crystal structure of this compound shows that it is essentially molecular. Figure 3 shows a molecule and gives the numbering scheme used. However, the molecules are linked together as dimers through a long interaction, Pb—S(4)[a], 3.639(2) Å, that is just within the sum of the van der Waals radii, 3.80 Å (28). A dimer is shown in Fig 4. Within the dimer, the Pb...PB distance is 5.723 Å. Selected bond distances and angles are given in Table 5.

In the $Pb(SOCPh)_2(S_2CPCy_3)$ molecule, the primary bonding is to three sulfur atoms, one from each ligand. The bonding of the two thiobenzoate ligands differs. One, ligand(1), has a Pb—S distance (2.755(2) Å) that places it within the range of primary Pb—S distances observed for $[Pb(SOCPh)_3]^-$, and a Pb—O distance (2.626(5) Å) significantly shorter than the Pb—O distances observed in the anion. The other ligand(2), has a Pb—S distance (2.626(2) Å) that is shorter than the corresponding distances in the anion, while the Pb—O distance (3.002(5) Å) is within the appropriate range of the anion.

The S_2CPCy_3 ligand is bound in an anisobidentate manner, with Pb—S distances 2.885(2) and 3.350(2) Å. The shorter of these places it within the range of primary Pb—S distances found for dithiocarbamates, xanthates, and dithiophosphates (see above). The longer of the Pb—S distances places it outside the range observed for the weaker bonds of the anisobidentate ligands in these compounds (2.83(4)–3.232(10) Å (24–27)). Still, it is significantly less than the Pb—S(4)[a] bridging distance or the van der Waals distance. The weak bridging interaction of S(4) seems insufficient to account for the discrepancy between Pb—S(3) and Pb—S(4), which we attribute instead to the propensity of Pb(II) to form a pyramidal PbS_3 primary kernel.

The Pb—S(4) interaction, though weak, may be significant.

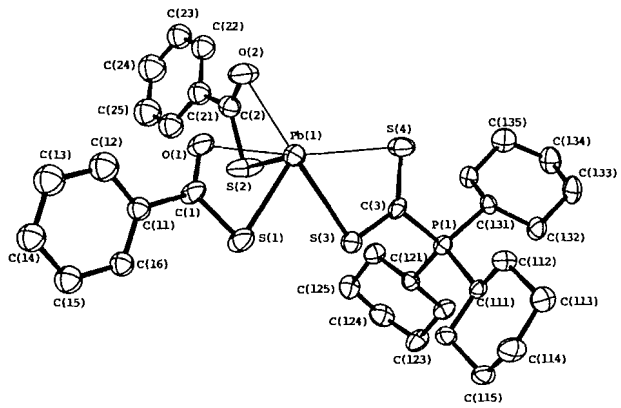

FIG. 3. A view of the $Pb(SOCPh)_2(S_2CPCy_3)$ molecule in **2** and the atom numbering scheme. Atoms are drawn as 50% probability thermal ellipsoids and hydrogen atoms have been omitted for clarity.

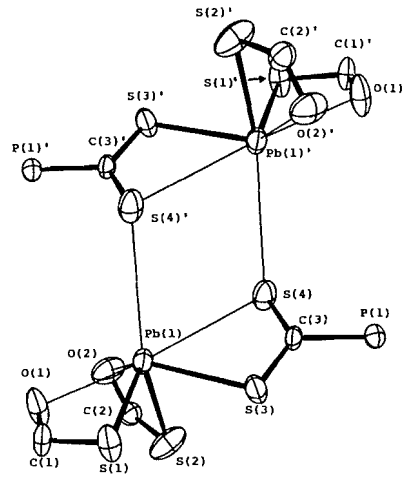

FIG. 4. The dimeric interaction between the molecules in **2**.

The difference between the Pb—S(3) and Pb—S(4) distances is less than the 1.241 Å difference between the two Pt—S distances in *cis*-$[Pt(C_6F_6)_2\{SC(S)PCy_3\}(CO)]$ where the S_2CPCy_3 ligand is considered monodentate (33). Two other structural features suggest a significance for Pb—S(4). First, the difference between the two C—S distances of the S_2CPCy_3 ligand, Δr(C—S), for $(Pb(SOCPh)_2(S_2CPCy_3)$ is smaller than that found in *cis*-$[Pt(C_6F_6)_2\{\eta^1\text{-}SC(S)PCy_3\}(CO)]$ (33), though probably larger than that found in $[Pt(C_6F_5)_2\eta^2\text{-}S_2CPCy_3)]$ (33). Second, the S—C—S angle of the carbodithioate moiety in the lead complex falls between those of the Pd and Pt complexes just mentioned.

Considering the angles subtended at Pb by the sulfurs that are strongly bound, the angle S(1)—Pb—S(2) between the sulfur atoms of the thiobenzoates is 90.34(7)°, larger than the S—Pb—S angles involving a thiobenzoate and S_2CPCy_3 (76.82(6) and 84.72(7)°). The reason for this discrepancy is not clear, but we note that even in $[Pb(S_2COEt)_3]^-$, where all three ligands are identical, there is significant variation in the S—Pb—S angles (84.38(8)–89.80(9)°) (26).

As is the case for $[Pb(SOCPh)_3]^-$ and other structures already discussed, the secondary interactions in $Pb(SOCPh)_2(S_2CPCy_3)$ (with O(1), O(2), S(4), and S(4)^a) take place in the "open" region expected to be occupied by the lone pair on a molecule of the VSEPR type AX_3E.

Each of the four-membered rings Pb,S(1),O(1),C(1), Pb,S(2),O(2),C(2), and Pb,S(3),S(4),C(3) is planar within experimental error. The dihedral angle between the first and last of these planes is particularly small, 10.8(2)°, perhaps due to the approach of the bridging sulfur, S(4)^a.

The complex **2** is the first of a Main Group element with an R_3PCS_2 ligand. However, apart from the features discussed above, the structure of the S_2CPCy_3 ligand in the Pb(II) complex is comparable to those where this ligand acts as a $2e^-$- or $4e^-$-donor to a transition metal (33)[10]. Factors that may contribute to the stability of the S_2CPR_3 ligand in the Pb(II) complex include the relative "softness" (34) of the metal center (reflected here by strong bonding to the S atoms and weak bonding to the O atoms of $PhCOS^-$) and a symbiotic relationship (35) between the S_2CPCy_3 and the S-bound $PhCOS^-$ ligands already present.[11] In any event, there seems no reason to believe that the lead complex is unique. Indeed the absence of R_3PCS_2 complexes of the Main Group elements may simply be due to lack of attention. Accordingly, we plan to explore this area further.

Conclusions.

The compounds $Pb(SOCPh)_2$ and $Bi(SCOPh)_3$ can be prepared by reaction of PhCOSH with the appropriate metal acetate or benzenethiolate. The ligands $PhCOS^-$, Cy_3PCS_2, and Cy_3PO form 1:1 complexes with $Pb(SOCPh)_2$ causing solubilization of the lead compound in solvents in which it is otherwise insoluble. Neither Ph_3P nor Ph_3PO increase the solubility of $Pb(SOCPh)_2$ and none of the five ligands enhance the solubility of very poorly soluble $Bi(SOCPh)_3$.

Single crystal X-ray analyses of (Ph_4As) $[Pb(SCOPh)_3]$ and $Pb(SOCPh)_2(S_2CP\{c\text{-}C_6H_{11}\}_3)$ show that in both cases the primary coordination kernal is PbS_3 with a trigonal pyramidal geometry. The complex with Cy_3PCS_2 is the first for any ligand of the type R_3PCS_2 with a Main group element.

[10]Other bonding modes are known with transition metals (ref. 4).

[11]We note that in complexes of monothiocarbamates, the S atoms tend to occupy mutually adjacent positions, but the reasons for this are not well understood (ref. 2). In the present complex one interligand S...S distance, S(1)...S(3), 3.5056 Å, is less than the sum of the van der Waals radii, 3.6 Å (ref. 28). This relatively short distance may represent an interaction that stabilizes the particular combination of ligands present, albeit weakly

On the mechanism of alkaline hydrogen peroxide oxidation of the lignin model *p*-hydroxyacetophenone

MARTIN B. HOCKING[1] AND JOHN P. CROW[2]

Department of Chemistry, University of Victoria, Victoria, BC V8W 3P6, Canada

Received July 6, 1993

MARTIN B. HOCKING and JOHN P. CROW. Can. J. Chem. **72**, 1137 (1994).

The oxidation of *p*-hydroxyacetophenone by a small excess of alkaline hydrogen peroxide has been found to be an autocatalysed process in which hydroquinone monoacetate and the peracetate ion are generated and consumed at similar rates. The reaction proceeds at a maximum rate when the base concentration is about 0.3 M. A chain-type mechanism that involves peracetate as the oxidizing agent is proposed for the reaction that explains the observed dependence of rate on base concentration. At high pH *o*-hydroxyacetophenone reacts by the same mechanism, whereas *m*-hydroxyacetophenone does not react with hydrogen peroxide under these conditions.

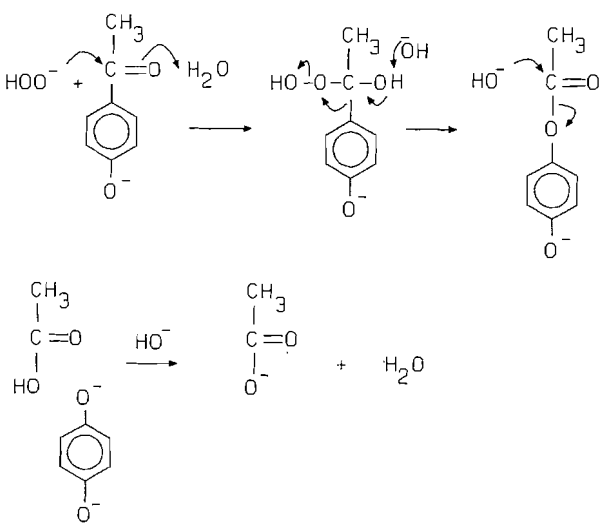
MARTIN B. HOCKING et JOHN P. CROW. Can. J. Chem. **72**, 1137 (1994).

On a trouvé que l'oxydation de la *p*-hydroxyacétophénone par un léger excès de peroxyde d'hydrogène alcalin est un processus autocatalysé dans lequel le monoacétate de l'hydroquinone et l'ion peracétate sont générés et consommés à des vitesses relativement semblables. La réaction se produit avec une vitesse maximale lorsque la concentration de la base est d'environ 0,3 M. On suggère que le mécanisme est de type «en chaîne» et qu'il implique le peracétate comme agent oxydant; ce mécanisme explique la relation entre la vitesse de la réaction et la concentration de la base. À des pH plus élevés, l'*o*-hydroxyacétophénone réagit par le même mécanisme alors que, dans ces conditions, la *m*-hydroxyacétophénone ne réagit pas avec le peroxyde d'hydrogène.

[Traduit par la Rédaction]

Introduction

Aromatic hydroxyketones and other compounds with oxygen atoms *para* to unsaturated groups are of interest relevant to the bleaching of wood pulp, because they contain chromophores similar to those found in lignin (1, 2). Investigation of the oxidation reactions of compounds of this type gives information on the processes that are likely to occur during the bleaching of wood pulp. It has long been accepted that the initial step in the hydrogen peroxide oxidation of an aromatic *o*- or *p*-hydroxyketone under alkaline conditions is the nucleophilic attack of the carbonyl carbon atom of the ketone by the hydroperoxide anion (3, 4). This is followed by a Baeyer–Villiger type rearrangement to give an ester that may react further, depending on conditions (Scheme 1).



SCHEME 1

Hocking (5) showed earlier that the rate of reaction of the lignin model *p*-hydroxyacetophenone (*p*HAP) with a 100-fold excess of aqueous alkaline hydrogen peroxide depended on the concentration of hydrogen peroxide to the power 1.4. Under different conditions they detected and isolated hydroquinone monoacetate (HMA) as an intermediate in the reaction. Normally this ester is hydrolysed during the reaction to the final products hydroquinone and the acetate ion (6). They also noted that concentrations of reactant *p*HAP and product acetate could be monitored by NMR from their methyl resonances since these were sharp, upfield from water and separated by about 0.6 ppm. To try to clarify the role of the intermediate HMA in the mechanism, we have now extended the study of the alkaline peroxide oxidation of hydroxyketones in aqueous solution to situations in which the hydrogen peroxide is in 2–10 times excess, conditions that more closely resemble the stoichiometric to 6 times excess, peroxide to carbonyl content, typically used in the bleaching of wood pulp (7).

Results and discussion

The fractions of the original amount of a 0.29 mmol sample of *p*HAP left during its reaction with 1.44 mmol of hydrogen peroxide in the presence of sodium hydroxide or sodium carbonate in 1.2 mL of aqueous solution at 30°C was determined from the relative peak heights of the proton methyl resonances of the *p*HAP reactant and the acetate product (Scheme 1). Hydroquinone, the aromatic product, did not rapidly undergo significant further reaction under the conditions used. The reaction was predictable and the results were surprisingly consistent from one kinetic run to the next. No evidence of oxygen formation, which could indicate the presence of free radicals, was seen, probably because phenols are effective free radical scavengers.

Figure 1 shows the rate curve for this reaction in the presence of 0.30 mmol of base. Examples of the raw concentration data used to draw the graphs in Figs. 1 and 3 are given in Table 1. In both sodium carbonate and sodium hydroxide solutions the reaction has an induction period, which was very helpful for the monitoring method used, followed by a period when the reac-

[a]Values of (*p*HAP methyl peak height)/(sum of *p*HAP methyl and acetate methyl peak heights) were calculated to three significant figures and are accurate to two figures. Estimated error in fraction data is ±4%.

tion occurs at a relatively constant rate. The rate of reaction was taken to be the slope of the linear portion of the rate curve in milligrams of *p*HAP per second. A series of kinetic runs with various initial concentrations of reactants gave similarly shaped rate curves, although the induction period varied from 1 to 7 min. The rate, which was reproducible to within ±5% for the same set of conditions, depended on the nature of the base used and the initial concentration of reactants. Values of rates obtained are given in Table 2.

The curves plotted in Fig. 2, for the reaction of 0.29 mmol of *p*HAP with 1.44 mmol of hydrogen peroxide in various molar concentrations of aqueous base, show that the rate is invariably greater in sodium carbonate than sodium hydroxide solution, and that there is an optimum base concentration for each base to obtain the maximum rate. Interestingly this parallels the observed behaviour of alkaline hydrogen peroxide in the bleaching of wood pulp, which also shows an optimum base concentration for maximum effectiveness (7, 8).

Sigmoidal-shaped rate curves similar to the ones in Fig. 1 are characteristic of reactions that are autocatalysed and depend on the presence of an intermediate generated during the induction period by the reaction. To determine the nature of the intermediate, the oxidation reactions were repeated in the presence of various additives. Addition of magnesium sulphate, which is commonly used as a stabilizer in pulp bleaching (7), or the reaction products acetate and hydroquinone had little effect on the rate. However, addition to the reaction mixture of either hydroquinone monoacetate or sodium peracetate in amounts of about 0.5 mol% of the hydrogen peroxide concentration eliminated the induction period and increased the rate somewhat.

Figure 3 shows the reactant remaining during the same reactions (0.29 mmol *p*HAP, 1.44 mmol peroxide, and 0.30 mmol NaOH in 1.2 mL solution at 30°C) with and without the presence of 0.0054 mmol of sodium peracetate added at the start of the reaction at the same time as the hydrogen peroxide.

An extension of earlier NMR studies confirmed that HMA and other phenyl esters, such as hydroquinone diacetate and acetyl salicylate, in the presence of alkaline hydrogen peroxide are hydrolysed to phenols and peracetate rather than acetate (6). That peracetate was produced was confirmed by both ^1H and ^{13}C NMR (Table 3). However, peracetate possesses limited stability in the alkaline solutions used. Its slow decay to acetate could be followed by ^1H NMR scans at 5-min intervals; under the conditions used for the kinetic runs, half of a sample of peracetate had decomposed to acetate within 10 min. Hofman et al. have studied the hydrolysis by alkaline hydrogen peroxide of various *N*- and *O*-acetyl esters and found that peracetate, rather than acetate, is the major hydrolysis product (10). Clearly the

[a]Reactant and additive quantities are given in millimoles. *p* = *p*HAP, *o* = *o*HAP.
[b]H = sodium hydroxide, C = sodium carbonate. Quantities are given in millimoles.
[c]Additives: Mg = magnesium sulphate; Hq = hydroquinone; Ac = sodium acetate; HMA = hydroquinone monoacetate; Pa = sodium peracetate; none where none specified.
[d]Rate is the slope of the linear portion of the rate curve, except for the asterisk where the rate is calculated from the slope of 1/(fraction of *p*HAP left) vs. time. est reactions were too fast to allow accurate determination of the rate.
[e]All runs had an induction period, except where noted.
[f]The pH was measured at the start of the reaction for the runs given.

peracetate ion, generated from hydroquinone monoacetate and hydrogen peroxide, is the active oxidizing agent in this autocatalysed reaction. A probable mechanism for the reaction that fits the observed requirements is shown in Scheme 2.

The key sequence of reactions in the mechanism proposed is the nucleophilic attack of peracetate on the carbonyl carbon of *p*HAP, followed by rearrangement of the peroxy adduct to hydroquinone monoacetate. This is hydrolysed by the hydroperoxide anion to hydroquinone and another peracetate ion that continues the oxidation cycle. The peracetate concentration rapidly builds up to a steady state, resulting in the constant rate observed in these reactions.

The reaction went only slightly faster, 0.17 vs. 0.14 mg *p*HAP per second, when the initial amount of hydrogen peroxide was increased to 2.16 mmol in run 16 from 1.44 mmol in run 13. When the initial amount of *p*HAP was increased from 0.29 mmol in run 13 to 0.44 mmol in run 19, the reaction rate increased markedly from 0.14 to 0.23 mg/s. These observations would indicate that step 4 in the mechanism, attack of peracetate on the hydroxyketone, is slower than step 3, hydrolysis of HMA by hydroperoxide anion to peracetate.

The mechanism presented is also supported by the results of the reaction of *p*HAP with an equivalent amount of peracetate in slightly basic solution (run 34 in Table 2). This reaction has no induction period and, with a rate of 2.8 mg/s, was 70 times faster than the rate observed for the oxidation of *p*HAP with hydrogen peroxide. These characteristics meant that the reaction of *p*HAP with peracetate was particularly difficult to follow by the NMR method used and reliable numerical data were hard to obtain, hence information on the rate of the reaction was of doubtful value.

Ogata and Sawaki (11) reported that the oxidation of hydroxyketones by peroxybenzoic acid is a second-order process, so it is likely that the oxidation of *p*HAP by peracetate, a similar process, also follows second-order kinetics. When the reaction between *p*HAP and peracetate in sodium hydroxide

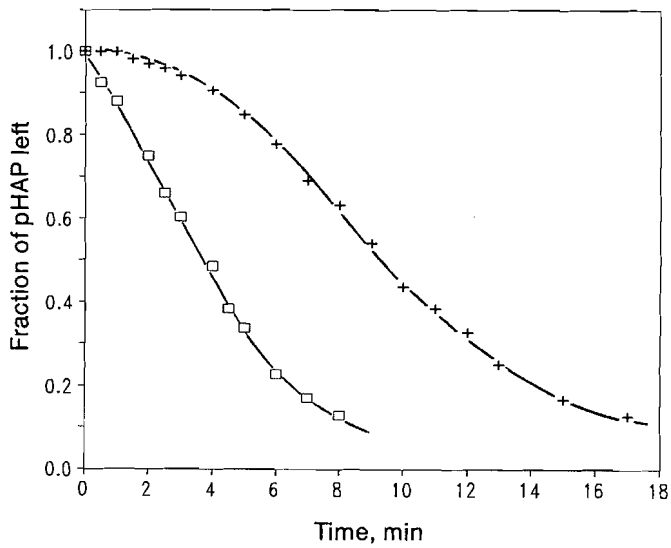

FIG. 3. Fraction of 0.29 mmol of *p*HAP remaining during oxidation by 1.44 mmol hydrogen peroxide in 1.2 mL of solution containing 0.3 mmol of sodium hydroxide at 30°C. +, without other additives, run 3; □, with 5.4 μmol of added peracetate, run 24.

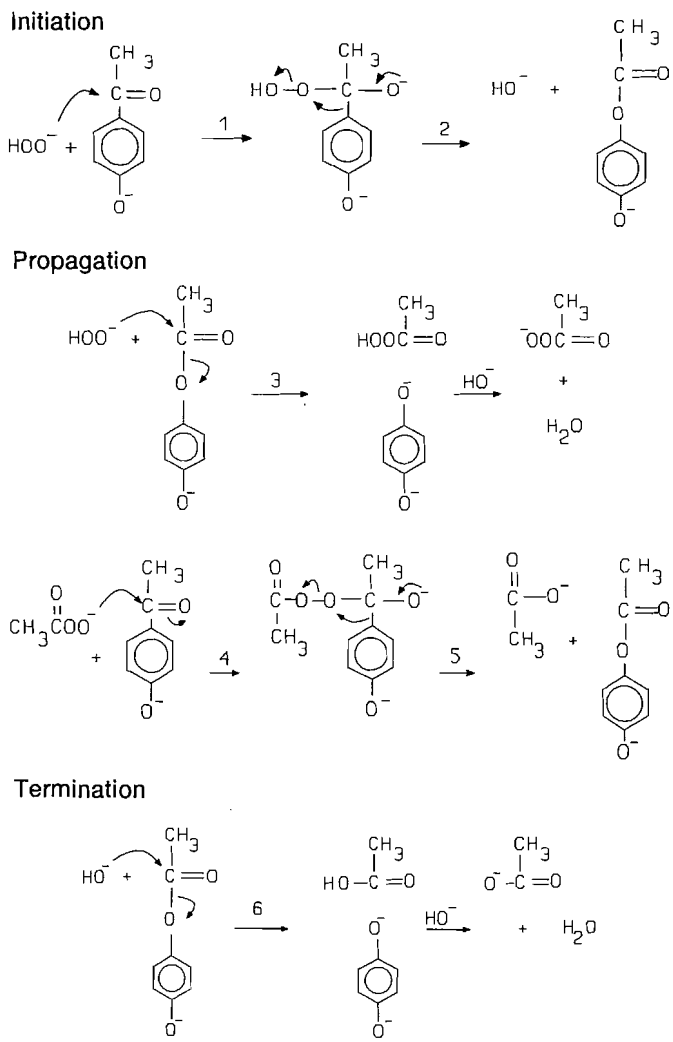

SCHEME 2. Proposed mechanism for the hydrogen peroxide oxidation of *p*HAP which produces and uses peracetate.

solution at pH 8 was scaled up and subsequently extracted with ether, it was possible to obtain crystals of HMA in 10% yield. NMR scans of this reaction mixture prior to extraction showed much larger concentrations of HMA present (by far the largest peak) in addition to hydroquinone and acetate ions, but rapid hydrolysis of the rather labile HMA under the basic conditions used decreased the actual recovery of solid product. High-amplification NMR scans of the reaction mixture of *p*HAP and hydrogen peroxide used earlier in the kinetic runs showed small methyl resonances at the shifts expected for peracetate and HMA, in addition to those of reactant and product. The elimination of the induction period by initial addition of peracetate, the known formation of peracetate from hydrogen peroxide and HMA, and the fast reaction of peracetate and *p*HAP strongly support the proposed mechanism.

Previous studies of the reaction of *o*HAP with alkaline hydrogen peroxide showed that the reaction is fast at low pH, but much slower at pHs over 12 (11, 12). The reaction between 0.3 mmol of *o*HAP and 0.72 mmol of hydrogen peroxide in the presence of 0.9 mmol (0.75 M) of sodium hydroxide in a total volume of 1.2 mL was quite slow and found to have an induction period that was removed when peracetate was added at the start of the reaction. It seems probable that under these conditions the *ortho* isomer also reacts by a mechanism similar to that proposed earlier for the *para* isomer. When the concentration of sodium hydroxide was decreased to 0.5 M (0.6 mmol of NaOH added), this reaction was much faster; it was essentially complete in 90 s (e.g., runs 32 and 30 in Table 2). This was too fast to quantitatively measure by the NMR method used, nor could an induction period be detected under these conditions. Therefore, it is likely that the fast oxidation of *o*HAP proceeds via a different mechanism, one that does not require generation of peracetate, when the base concentration is lower.

*m*HAP, which is much less reactive than the *ortho* and *para* isomers for electronic reasons, did not react with either hydrogen peroxide or peracetate in dilute aqueous sodium hydroxide.

The mechanism proposed for the reaction of *p*HAP with alkaline hydrogen peroxide explains the observed dependence of the rate on base type and concentration. Base is required to ensure significant dissociation of hydrogen peroxide to the hydroperoxide anion required for the cleavage of hydroquinone monoacetate to peracetate and hydroquinone. Hydroxide ions, when present in excess of the amount required to produce the hydroperoxide anion, can hydrolyse HMA to hydroquinone and acetate and so will compete with the hydroperoxide anion for the available HMA, causing a lower steady-state concentration of both HMA and peracetate and hence a slower reaction. Thus, we would expect the rate of ketone oxidation to be greater in aqueous sodium carbonate, which provides sufficient alkalinity without a high concentration of hydroxide ions, than in aqueous sodium hydroxide solution. This explanation would also predict that there should be an optimum base concentration for maximum rate as is observed, rather than a progressive increase of rate with base concentration.

Interpretation of the relevance of these results to the brightening reactions of softwood mechanical pulps is complex (13, 14). As seen with the model compound here, there is an optimum ratio of sodium hydroxide to pulp for any given peroxide:pulp ratio to achieve maximum brightness. However, this is not so much rate related as a factor of residual hydroxide ion concentration (or pH) at the time that the peroxide component of the brightening system used is exhausted. Too high a pH at this stage promotes pulp-darkening reactions.

TABLE 3. Summary of experimentally observed NMR shift data

Substances	^{1}H NMR (ppm)[a]	^{13}C NMR (ppm)[b]
Sodium acetate	1.9	20.2 (CH_3), 176.5 (CO)
Sodium peracetate	2.1	16.7 (CH_3), 172.6 (CO)
Hydroquinone	6.9	(115.6, 149.7)[c]
Hydroquinone monoacetate	2.3, 7.0d (J = 1 Hz)	
HMA + H_2O_2[d]	2.1, 2.3, 6.9, 7.0d (J = 1 Hz)	
HMA + H_2O_2 + Na_2CO_3[e]	2.1, 6.9	16.7, 20.2, 116.2 148.8, 172.6, 176.6
*p*HAP	2.5, 6.7d, 7.7d (J = 10 Hz)	
Runs 3 (high amplitude)	1.9, 2.1, 2.3, 2.5 (CH_3 only)	

[a]All ^{1}H NMR spectra were measured on 10-ppm sweep widths at 30°C on a Perkin Elmer R-32 continuous wave spectrometer at 90 MHz in 2% aqueous solution relative to an external TMS standard in $CDCl_3$. d, doublet.

[b]^{13}C NMR shifts were referenced to TMS, were measured on 188-ppm sweep width in aqueous solution at ambient temperature on a Bruker AMX 360 FT spectrometer at 90.568 MHz locked to an internal D_2O reference, and are nonquantitative. Collection parameters for the sodium acetate and sodium peracetate spectra: acquisition time, 0.623 s; relaxation delay, 0.100 s; recycle time, 0.723 s; from 700 transients. Collection conditions for the oxidation mixture spectrum (footnote *e*) were as follows: acquisition time, 0.819 s; relaxation delay, 0.100 s; recycle time, 0.919 s, for a total of 3300 transients.

[c]From ref. 9; in dimethyl sulphoxide.

[d]21.5 mg HMA in 1 mL of D_2O and 0.2 mL of 7.2 M H_2O_2.

[e]21.5 mg HMA in 1 mL of D_2O and 0.2 mL of 7.2 M H_2O_2, and 0.2 mL of 1 M Na_2CO_3.

It is also difficult to directly translate the promising rate measurements of *p*HAP oxidation in aqueous sodium carbonate to the brightening reactions of mechanical pulps. Decreased brightness gains of 1–1.5 points, but with improved brightness stability, has been reported from tests of partial replacement of sodium hydroxide by sodium carbonate in the peroxide brightening of spruce chemithermomechanical pulp (CTMP) (15). Full replacement of sodium carbonate has also been reported to yield equivalent final brightness with aspen CTMP, while also providing superior peroxide stabilization and consequent higher peroxide residuals (16). Our model compound rate findings confirm the need evident from these results to further explore the benefits to be achieved by optimized conditions for sodium carbonate replacement in the peroxide-based bleaching of wood pulps.

Experimental

Commercial *p*HAP and *m*HAP were purified by recrystallization from toluene and then water before use. Hydroquinone monoacetate was obtained as previously described (5). Commercial peracetic acid (32%) was analyzed for acid equivalence by titration with sodium hydroxide solution, for peroxide concentration by titration with permanganate solution (17), and for total oxidizing ability by addition of potassium iodide and subsequent titration with thiosulphate (18). The concentration of commercial 30% hydrogen peroxide was checked by addition of iodide and then titration with aqueous thiosulphate solution (18). It was diluted with distilled and deionized water to make its concentration 7.2 M before use.

^{1}H NMR spectra and the quantitative work for the kinetic runs were carried out on aqueous solutions at 30°C on a Perkin Elmer R-32 continuous wave spectrometer at 90 MHz. ^{13}C spectra were run at ambient temperature at 90.568 MHz on a Bruker AMX 360 FT NMR spectrometer. Values of pH were measured on a Metrohm 632 pH meter standardized at pH 9.18. Mass spectra were run on a Finnigan 3300 quadrupole GC–MS system spectrometer.

Kinetic experiments

The starting amount of hydroxyketone (usually 40 mg, 0.29 mmol) was dissolved in the required volume of 1.0 M base. The required amount of distilled, deionized water was added so that the final volume after all additions would be 1.2 mL for all kinetic runs. The solution was placed in the spectrometer in a 5-mm NMR tube and allowed to reach 30°C. The required amount (usually 0.2 mL) of 7.2 M hydrogen peroxide solution (1.44 mmol) was added to the sample, timing was started, and the mixture was shaken for 5 s. NMR scans of the methyl peaks in the region of 2.6–1.8 ppm were made every 30 or 60 s as the HAP methyl resonance decreased in size, while that of the acetate increased. In most cases the sum of the two peak heights stayed remarkably constant (about 80 mm) during the run. The fraction of reactant remaining was calculated from the relative peak heights. Previous studies had indicated that the peak height was a reliable measure of the relative amount of substance in solution (5, 12). Occasionally impurities caused decomposition of the peroxide to oxygen, which resulted in a rapid loss of resolution and collapse of the methyl resonances. Additives, when used, were dissolved in the appropriate amount of water and added to the mixture immediately after the hydrogen peroxide solution. To prevent premature decomposition of the peracetic acid, it was diluted and neutralized immediately before use by adding 0.1 mL of it to 10 mL of 0.122 M NaOH solution. One tenth of a millilitre of this diluted solution contained 0.0054 mmol of neutralized peracetate ion.

Preparation of HMA from peracetate and pHAP

*p*HAP (500 mg) was dissolved in 6 mL of 1 M NaOH. To this was added 6 mL of 1 M NaOH containing 1 mL of peracetic acid. The pH was adjusted to 8 by addition of a few more drops of NaOH solution. The mixture was stirred for 15 min at room temperature and then extracted with three 10-mL portions of diethyl ether. The combined extracts were dried with anhydrous sodium sulphate and the ether was evaporated under reduced pressure. The residual oil was pumped on a vacuum line for 1 h. The residue was extracted with two 60-mL portions of hot hexane, which were allowed to cool very slowly (24 h) to −10°C. The yield was very variable, during several repetitions; 45–100 mg of crystalline HMA was obtained, mp 55–58°C (lit. (19) mp 61–63°C). The ^{1}H NMR spectrum was identical to that of authentic material. The chemical ionization mass spectrum showed peaks at 154 (M + 1), 181 (M + 29), and 193 (M + 41).

Adamantyl-1,3,4-oxathiazol-2-one has been prepared for the first time and from it 1-adamantyl nitrile sulphide has been generated. Characterisation data are presented, including the X-Ray crystal structure of the oxathiazolone. (Crystal data for $C_{12}H_{15}NO_2S$: monoclinic, space group $P2_1/c$, a = 11.334(2) Å, b = 7.344(1) Å, c = 14.373(2) Å, β = 107.74(1)°, V = 1139.5(3) Å^3, Z = 4, R = 0.042). The planar heterocyclic ring is similar to structures observed in the gas phase for other oxathiazolone derivatives. The nitrile sulphide was reacted with dimethyl-acetylene dicarboxylate *in situ* to give an isothiazole derivative. The X-Ray crystal structure of 3-adamantyl-4,5-bis(methoxycarbonyl)-isothiazole has been obtained. (Crystal data for $C_{17}H_{21}NO_4S$: monoclinic, space group $P2_1/n$, a = 7.305(4) Å, b = 7.339(4) Å, c = 31.552(4) Å, β = 92.75(3)°, V = 1690(1) Å^3, Z = 4, R = 0.079). A general cycloaddition reaction was discovered between the nitrile sulphides and thiazyl chloride to give 1,2,3,5-dithiadiazolium chlorides. The structure of the new 4-adamantyl-1,2,3,5-dithiadiazolium chloride was confirmed by reduction to the 4-adamantyl-1,2,3,5-dithiadiazolyl for which the X-Ray crystal structure has been determined. (Crystal data for $C_{11}H_{15}N_2S_2$: monoclinic, space group $C2$, a = 10.284(4) Å, b = 8.651(2) Å, c = 13.669(2) Å, β = 112.83(1)°, V = 1120.9(4) Å^3, Z = 4, R = 0.042). The radical adopts a twisted dimer structure in the solid state which is similar to the structures observed for other alkyl derivatives.

JOHN N. BRIDSON, STEVEN B. COPP, MELBOURNE J. SCHRIVER, SHUGUANG ZHU et MICHAEL J. ZAWOROTKO. Can. J. Chem. **72**, 1143 (1994).

On a préparé l'adamantyl-1,3,4-oxathiazol-2-one pour la première fois et on l'a utilisé pour générer la sulfure de 1-adamantyl nitrile. On présente les données ayant servi à sa caractérisation, y compris la structure de l'oxathiazolone déterminée par diffraction des rayons X. Les données cristallines pour $C_{12}H_{15}NO_2S$ sont les suivantes: cristaux monocliniques, groupe d'espace $P2_1/c$, avec a = 11,334(2), b = 7,344(1) et c = 14,373(2) Å, β = 107,74(1)°, V = 1139,5(3) Å^3, Z = 4 et R = 0,042. Le noyau hétérocyclique planaire est semblable à celui observé pour les structures en phase gazeuse pour d'autres dérivés oxathiazolone. Le sulfure de nitrile réagit avec l'acétylènedicarboxylate de diméthyle *in situ* et fournit un dérivé isothiazole. On a détermine la structure du 3-adamantyl-4,5-bis(méthoxycarbonyl)isothiazole par diffraction des rayons X. Les données cristallines pour $C_{17}H_{21}NO_4S$ sont les suivantes: cristaux monocliniques, groupe d'espace $P2_1/n$, avec a = 7,305(4), b = 7,339(4), c = 31,552(4) Å, β = 92,75(3)°, V = 1690(1) Å^3, Z = 4 et R = 0,079. On a découvert une réaction générale de cycloaddition des sulfures de nitrile avec le chlorure de thiazyle qui conduit à des chlorures de 1,2,3,5-dithiadiazolium. On a confirmé la structure du nouveau chlorure de 4-adamantyl-1,2,3,5-dithiadiazolium par réduction en 4-adamantyl-1,2,3,5-dithiadiazolyle dont on a déterminé la structure par diffraction des rayons X. Les données cristallines pour $C_{11}H_{15}N_2S$ sont les suivantes: cristaux monocliniques, groupe d'espace C_2, avec a = 10,282(4), b = 8,651(2), c = 13,669(2) Å, β = 112,83(1)°, V = 1120,9(3) Å^3, Z = 4 et R = 0,042. À l'état solide, le radical adopte une structure dimère déformée semblable à celles des structures observées pour d'autres dérivés alkyles.

[Traduit par la Rédaction]

Introduction

The chemistry of the heavier elements from Groups 15 and 16 has often been dominated by either metathetical or non-specific, low yield reactions. In contrast, the organic chemistry of carbon has provided chemists with a number of general, high yield reactions that can reliably be used in the synthesis of new molecules. These reactions are often controlled by subtle electronic features of the molecules involved and the products of the reactions are usually predictable. The Diels-Alder and 1,3–dipolar cycloaddition reactions are classic examples of these types of synthetically useful processes that dominate organic synthesis. It has generally been thought that the ability of carbon to form π bonds is a phenomenon unique to the first row elements and that the heavy Main Group elements would not participate in similar processes. The recent preparation of a number of molecules that contain stable π bonds to the heavier elements of Groups 15 and 16 (1) suggests that the chemistry of carbon may be a template for the discovery of new areas of Main Group chemistry.

The 1,3-dipole cycloaddition reaction has been used in recent years in the preparation of a number of new heterocyclic systems (2, 3). In these reactions, molecules that incorporate π bonds to the pnictogens and chalcogens have acted as both the dipole and the dipolarophile. Propargyl-allenyl 1,3-dipoles often feature elements of Groups 16 and 17 in the π manifold, however, those that incorporate third and fourth period elements are rare and usually unstable. The nitrile sulphides **1** which are an unstable family of 1,3-dipoles that contain a sulphur–nitrogen π bond have been the subject of several recent reviews (4, 5). They are typically generated *in situ* from precursor oxathiazolone heterocycles **2** in the presence of a dipolarophile to give five-membered ring heterocycles.

The nitrile sulphides have been shown to decompose to the

corresponding nitriles and elemental sulphur. The nitrile oxides (R—C≡N—O), a related family of 1,3-dipoles, can be isolated in the presence of sterically protective groups such as mesityl (—$C_6H_2(Me)_3$) or "super mesityl" (—$C_6H_2(t\text{-butyl})_3$) (4). The extreme steric protection offered by these groups has also been used in Main Group chemistry in the isolation of new π systems. It has been shown, however, that Main Group π systems such as the phosphaalkynes (R—C≡P) can also be stabilised by substitution with saturated alkyl groups (such as *t*-butyl, —C_4H_9) or cage hydrocarbons (such as adamantyl, —$C_{10}H_{15}$) (2). Nitrile sulphides, or the precursor molecules from which they are generated, that would be stabilised by extreme steric protection or substitution with cage hydrocarbons have not been prepared or generated.

In this work we will investigate the possible stabilisation of the nitrile sulphide moiety by substitution with an adamantane group. The preparation and the solid state structure of the adamantyl derivative of the precursor oxathiazolone **2***c* is described and is the first reported crystal structure of any member of this family of heterocycles. The cycloaddition chemistry of this new nitrile sulphide to the carbon–carbon and sulphur–nitrogen triple bonds to give isothiazole **3** and 1,2,3,5-dithiadiazolium **4** derivatives respectively is presented. The solid state structure of the isothiazole adduct **3** between adamantyl nitrile sulphide and dimethyl acetylene dicarboxylate [DMAD] is presented. The structure of the 4-adamantyl-1,2,3,5-dithiadiazolyl radical, generated by the reduction of **4c** is also described.

Experimental

General procedures

Reagents used in synthesis ($C_6H_5C(O)NH_2$, $C_4H_9C(O)Cl$, $C_{10}H_{15}C(O)Cl$, $CH_3CO_2CCCO_2CH_3$ (DMAD), and $(C_6H_5)_3Sb$) were purchased from Aldrich and used as received. The amides $C_4H_9C(O)NH_2$ and $C_{10}H_{15}C(O)NH2$ were prepared from the acid chlorides following standard literature procedures (6). $(NSCl)_3$ was prepared as described in ref. 7. Solvents were refluxed with the appropriate drying agent (C_6H_5Cl (CaH_2), $C_6H_5CH_3$ (Na), CH_2Cl_2 (CaH_2)) and distilled under nitrogen prior to use. Air sensitive compounds were handled under a nitrogen atmosphere. Solids were manipulated in a Vacuum Atmospheres nitrogen-filled glove box. Melting points were determined on a Mel-Temp II melting point apparatus and are uncorrected. Elemental analyses were carried out at Canadian Microanalytical Service Ltd., Delta, British Columbia, Canada. IR spectra were recorded from Nujol mulls on KBr plates using a Mattson Polaris FT-IR instrument. NMR spectra were recorded on a General Electric 300 MHz instrument [^1H, ^{13}C] or on a Bruker AMX400 MB instrument (^{14}N) (at the Atlantic Regional Magnetic Resonance Center). Chemical shifts are reported in ppm (high frequency positive) relative to internal standards (^1H, ^{13}C: TMS) and external standards (^{14}N:CH_3NO_2). Mass spectra were recorded on a VG Micromass 7070HS double focusing spectrometer. Molecular orbital calculations were made using the Hyperchem (version III) suite of semi-empirical programs from Autodesk operating on a 80486 based IBM compatible computer. Molecules were subjected to a full geometry optimisation (Polak-Ribiere conjugate gradient) prior to single point calculation of the molecular orbitals.

Preparation and characterisation data

$C_{10}H_{15}$—$\overline{COC(O)SN}$ 2c

Neat chlorocarbonylsulfenyl chloride, ClC(O)SCl (28.0 g, 221.4 mmol) was added to a mixture of toluene (~150 mL) and adamantyl amide, $C_{10}H_{15}C(O)NH_2$ (20.8 g, 116.0 mmol) under nitrogen to give a clear yellow solution over a white solid. The solution was brought to reflux (at which point the solid dissolved) and maintained at that temperature for three hours. The resulting yellow–brown solution was poured into a crystallizing dish and allowed to evaporate to dryness to give a dark brown crystalline solid (25.6 g) which was transferred to a sublimation apparatus and heated to 90°C [10^{-3} mmHg] for 20 h to give a white sublimed solid (24.8 g) and a non-sublimed brown residue. The white solid was recrystallised from hexanes to give clear, colourless plate shaped crystals of $C_{10}H_{15}$—$\overline{COC(O)SN}$ (16.3 g, 68.7 mmol, 59.2%), mp 79–81°C, IR (cm^{-1}): 1809 (sh), 1766 (s), 1594 (ms), 1236 (m), 1101 (w), 1072 (m), 996 (ms), 907 (ms), 570(w). NMR, ^1H δ: 2.09, 1.96, 1.76 ^{13}C δ(assign.): 174.8 (C=O), 167.3 (C_{het}), 38.9 (CH_2), 38.5 (C_{quat}), 36.1 (CH_2), 27.5 (CH) ^{14}N δ($\Delta v^{1/2}$ Hz) –160 (950). Mass spectrum [IE, 70 eV] *m/e* (%, assign.): 237 (12, $C_{10}H_{15}COC(O)SN$), 193 (1, $C_{10}H_{15}CNS$), 161 (12, $C_{10}H_{15}CN$), 135 (100, $C_{10}H_{15}$), 95 (24), 79 (18), 41 (16). $C_{10}H_{15}$—$\overline{CNSC(CO_2CH_3)C(CO_2CH_3)}$ 3

5-Adamantyl-1,3,4-oxathiazol-2-one, $C_{10}H_{15}$—$\overline{COC(O)SN}$ (2.4 g, 10.0 mmol) was dissolved in chlorobenzene (~25 mL) and added dropwise to a refluxing mixture of chlorobenzene (~25 mL) and DMAD, $CH_3CO_2CCCO_2CH_3$ (1.5 g, 10.7 mmol). The addition was conducted under nitrogen and complete addition required 5 h. The reaction mixture was refluxed for 20 h to give a light brown solution from which an oily yellow brown solid (2.6 g) was recovered by solvent evaporation and exhaustive evacuation. The solid was dissolved in $CHCl_3$ and passed through a column (silica gel, 60 mesh) to give a light–yellow solid (1.9 g) which was transferred to a subli mation apparatus and heated to 50°C [10^{-3} mmHg] for several days. The yellow-white solid (0.94 g) which sublimed to the cold finger was shown to be a mixture of the product **3** and $C_{10}H_{15}$—CN by NMR and mass spectroscopy. The non-sublimed yellow-white solid was shown to be pure isothiazole **3** (0.90 g, 2.68 mmol, 26.8%). The product was recrystallised from $CHCl_3$ to give clear colourless plate shaped crystals of $C_{10}H_{15}$—$\overline{CNSC(CO_2CH_3)C(CO_2CH_3)}$, mp 117.5–118.5°C, IR ($cm^{-1}$): 1739 (s), 1531 (m), 1336 (w), 1271 (ms), 1245 (ms), 1133 (m), 1016 (m), 983 (w), 801 (w), 777 (w). NMR, ^1H δ(#H): 3.97/3.90 (6H, OCH_3), 2.06 (9H), 1.75(6H) ^{13}C δ(assign.): 175.5 (C=O), 166.3 (C=O), 159.5(C_{het}), 154.6(C_{het}),132.8(C_{het}), 53.0/52.8 (OCH_3), 40.8 (CH_2), 40.4 (C_{quat}), 36.4 (CH), 28.4 (CH_2) ^{14}N δ($\Delta v^{1/2}$ Hz) –87 (2500). [a]The number given is the millimolar equivalents of NSCl.

[b]An alternate procedure was used in this preparation. The oxathiazolone was dissolved in C_6H_5Cl (~25 mL) and added dropwise to a refluxing solution of $(NSCl)_3$ in C_6H_5Cl (~75 mL) under nitrogen. The subsequent procedure was as described above.

[c]The product of this reaction was a partial C_6H_5Cl solvate. The elemental analysis is most consistent with a compound of composition C_6H_5—$CN_2S_2^+Cl^-$·$0.2C_6H_5Cl$. The % yield and the elemental analysis are calculated with respect to this partial solvate.

[d]This derivative has not been reported in the literature. $C_{10}H_{15}$—$\overline{CNSSN}^+Cl^-$, mp 260–263°C (decomp.), IR; Nujol mull, KBr plates, cm^{-1}: 1672 (w), 1308 (ms), 1261 (m), 1117 (m), 1102 (m), 1019 (w), 899 (m), 891 (m), 857 (m), 800 (w), 714 (ms). Mass Spectrum [IE, 70 eV] *m/e* (%, assign.): 239 (9, $C_{10}H_{15}$—$CNSSN^+$), 160 (6, $C_{10}H_{14}CN^+$?), 135 (4, $C_{10}H_{15}^+$), 104 (1, $CNSSN^+$), 62 (36), 59 (16), 45 (86), 44 (30), 41 (11), 36 (15), 32 (22, S^+), 28 (100, N_2^+)

mL) under N_2 was prepared in a 10 mm o.d. NMR tube fitted with a J. Young, Teflon in glass valve. The solution was immediately examined at room temperature by ^{14}N NMR spectroscopy. Three resonances were observed at 330 ppm (NSCl), −72 ppm (N_2) and −262 ppm ($(NSCl)_3$, assignments based on ref. 8). The two higher frequency resonances were not large enough to reliably allow concentration analysis by integration. The solution was then heated to reflux (135°C) for 10 min and then cooled to room temperature. The ^{14}N NMR spectrum of this solution contained the same three resonances, however, the NSCl and N_2 resonances were of much greater intensity and approximately equal integration. The resonance due to $(NSCl)_3$ was observed but could not be reliably analyzed by integration. The solution was heated further but massive precipitation of a yellow solid occurred and the solution became murky, consistent with decomposition. It was also observed when the tube was opened that a significant increase in pressure had occurred.

Reaction of R-$\overline{COC(O)SN}$ 2 with NSCl

A solution of the oxathiazolone **2** (~40 mmol) and $(NSCl)_3$ (~50 mmol NSCl) in C_6H_5Cl (~100 mL) was heated at reflux for 20 h under nitrogen. The reaction mixtures were typically observed to pass from an initial clear yellow colour through green and dark brown stages to eventually resolve to a clear orange solution over a yellow–orange solid. The air-sensitive, yellow–orange solid was removed by filtration, ground to a fine powder and transferred to a sublimation apparatus where it was heated to 100°C (10^{-3} mmHg) to attempt to remove solvent of crystallisation and sulphur. The resultant non-sublimed yellow white solids were then identified as 1,2,3,5-dithiadiazolium chlorides by comparison of their infrared spectra with published spectra, mass spectroscopy and elemental analysis. All pertinent experimental data are given in Table 1. The C_6H_5Cl solution containing the soluble products from the original reaction mixture was fractionally distilled to give the solvent and nitrile (R = —C_6H_5) or a red–black viscous liquid from which the nitrile could be removed by sublimation (R = $C_{10}H_{15}$, 20 h, 100°C, 10^{-3} mmHg). The nitriles were identified by comparison of the infrared and NMR spectra with published spectra.

Reaction of $C_{10}H_{15}$—CN with NSCl

A mixture of $C_{10}H_{15}$—CN (1.629 g, 10.10 mmol) and $(NSCl)_3$ (0.862 g, 10.57 mmol NSCl) was dissolved in C_6H_5Cl (~75 mL) and heated to reflux under nitrogen for 20 h. The initial reaction mixture was a clear light yellow colour that went through dark green and opaque black phases until it resolved to a deep red–orange solution. Filtration of the solution did not reveal undissolved solids. The solvent was reduced by distillation to a volume of approximately 10 mL and allowed to remain at r.t. overnight after which a small amount of a colourless crystalline solid was recovered by filtration (0.07 g). The colourless crystalline solid was shown to be pure, unreacted nitrile by IR and NMR spectroscopy. Further reduction in the volume of the solution gave an intractable red–brown tar-like solid.

$C_{10}H_{15}$—$\overline{CNSSN}$, 8

A mixture of $C_{10}H_{15}$—$\overline{CNSSN}^+Cl^-$ (6.355 g, 23.12 mmol) and $(C_6H_5)_3Sb$ (4.99 g, 14.13 mmol] was dissolved in CH_2Cl_2 (~75 mL) under nitrogen. An immediate reaction occurred to give an opaque blue–black solution which was stirred overnight. The solvent was removed by evacuation to give a blue-black solid which was washed with pentane and transferred to a sublimation tube. The solid was heated to 60°C [10^{-3} mmHg] for several days. This sublimation gave a crop of large (>2mm) plate-shaped, purple–black crystals of $C_{10}H_{15}$—$\overline{CNSSN}$ (2.447 g, 10.22 mmol, 44%), mp 78–80°C. IR (cm^{-1}): 1673 (w), 1580 (m), 1306 (w), 1252 (ms), 1177 (w), 998 (w), 722 (ms), 610 (w). Mass spectrum [IE, 70 eV] m/e (%, assign.): 239 (100, $C_{10}H_{15}CNSSN$), 160 (59, $C_{10}H_{14}CN$?), 135 (41, $C_{10}H_{15}$), 104 (12, CNSSN), 93 (24), 79 (36, HSNS ?), 46 (12, NS), 41 (34). Elemental anal., element calcd.(obs.): C 55.19(51.95), H 6.32(6.31), N 11.70(10.76), S 26.79(28.95).

X-ray data collection, solution and refinement

All pertinent crystallographic data are summarised in Table 2. (**2c**) Data were collected at room temperature (17 ± 1°C)on an Enraf-Nonius CAD-4 diffractometer (MoK_α, $\lambda = 0.70930$ Å, graphite monochromator) using the ω scan mode. No significant decay of three standard reflections was observed during data collection. Unit cell parameters were obtained from 24 reflections with 2θ angle in the range of 28.00–40.00 degrees. The choice of space group was based on systematically absent reflections. Data were corrected for Lorentz and polarisation effects. Scattering factors were taken from the International Tables for X-ray Crystallography (9). An empirical absorbtion correction was made based on a series of ψ scans which resulted in minimum and maximum transmission factors of 0.817602 and 0.988848 respectively. Hydrogen atoms were treated as follows: methylene hydrogen atoms were placed in calculated positions with $D_{C\text{-}H}$= 1.08 Å; methyne hydrogen atoms were located via difference Fourier map inspection. Hydrogen atoms were given temperature factors based on the carbon atoms to which they are bonded and fixed

during least squares refinement. All crystallographic calculations were effected with the PC version of NRCVAX (10) implemented on a 80486 based IBM compatible computer. Fractional atomic coordinates and isotropic thermal parameters are given in Table 3 and selected bond distances and angles are given in Table 6. Supplementary material (anisotropic thermal parameters and structure factors) is available.[3]

Data were collected at room temperature (26 ± 1°C) on a Rigaku AFC6S diffractometer (**3**: CuK_α, λ = 1.54178 Å; **8**: MoK_α, λ = 0.70930 Å, graphite monochromator) and a 2KW sealed tube generator. Cell constants and an orientation matrix for the data collection were obtained from a least squares refinement using the setting angles of 20 carefully centered reflections in the range 48.2 < 2θ < 50.6 degrees for **3** and 18 reflections in the range 38.32 < 2θ <49.67 degrees for **8**. The space groups were determined based on the systematic absences, packing considerations and a statistical analysis of intensity distribution. The data were collected using the ω–2θ scan technique to a maximum of 2θ value of 120.2° for **3** and 49.9° for **8**. The intensities of three representative reflections which were measured after every 150 reflections remained constant throughout data collection indicating crystal and electronic stability. The crystal of **8** was cut to size from a larger crystal resulting in a highly irregular shape. An absorption correction, using the program DIFABS (11), was applied to both **3** (which resulted in transmission factors ranging from 0.61 to 1.15) and **8** (which resulted in transmission factors ranging from 0.79 to 1.69). The data were corrected for Lorentz and polarisation effects. The structure was solved by direct methods. The non-hydrogen atoms were refined anisotropically. Neutral atom scattering factors were taken from Cromer and Waber (9). In the structure of **8** the hydrogen atoms were initially placed in calculated positions assuming bond lengths of 0.95 Å, then allowed to refine, with very little result. They were subsequently fixed again and so are included but not refined in the final rounds of least squares calculations. The isotropic thermal parameters of the hydrogen atoms were set 20% greater than the bonded carbons. The structure of **3** collected and solved normally, but a second partial image of the skeleton rotated by 60° appeared in the difference maps. Attempts to locate all the atoms were unsuccessful, but the three atoms bonded to the pivotal carbon atom showed up clearly in both major and minor images (which exist in a ratio of 7:3) permitting placement of the missing atoms in calculated positions. Diagrams and data are given here for the major orientation of the adamantyl group. Details of the minor orientation are provided as supplementary material. The hydrogen atom positions were initially calculated assuming bond lengths of 0.95 Å and isotropic thermal parameters 20% greater than the bonded partner.

The hydrogen atoms were calculated independently and the minor set was copied into a data file already holding the major set. The image of the major orientation is good and well refined with all heavy atoms set anisotropic. All calculations for the structures of **3** and **8** were performed using the TEXSAN crystallographic software package (12) using a VAX 3100 work station. Fractional atomic coordinates and isotropic thermal parameters for **3** and **8** are given in Tables 4 and 5 respectively and selected bond distances and angles are given in Tables 7 and 8 respectively. Supplementary material (anisotropic thermal parameters and structure factors, 60 pages) is available.[3]

Results and discussion

Preparation, characterisation and structure of 5-adamantyl-1,3,4-oxathiazol-2-one, 2c

The generation of nitrile sulphides *in situ* from oxathiazolone heterocycles 2 is a well established reaction (5). If the nitrile sulphide is not trapped by a dipolarophile it will immediately decompose to a nitrile and sulphur. In fact stable, isolable nitrile sulphides have never been prepared. The preparation of the heterocyclic precursor is a general and near quantitative cycloaddition reaction involving the elimination of two equivalents of HCl from the reaction of an amide with chlorocarbonyl sulfenyl chloride. A wide variety of aromatic derivatives and a smaller number of alkyl derivatives of this heterocycle have been prepared via this route, however, the

adamantyl derivative has not been reported. The preparation of 5-adamantyl-1,3,2-oxathiazol-2-one, **2***c*, from adamantyl amide and chlorocarbonyl sulfenyl chloride in hot toluene produced a mixture of products that was largely the desired heterocycle, sulphur and adamantyl nitrile. The two latter products are undoubtedly produced by the decomposition described above. Unfortunately, when the reaction was run for longer periods at a lower temperature (to prevent decomposition) the product that was obtained was contaminated with the amide and was isolated in lower yield. Therefore, the preparation was typically conducted at 100°C in toluene and the product had to be purified by sublimation (to remove tarrish impurities), filtered on a silica gel column and then recrystallised several times to give a pure product. Significant amounts of the heterocyclic product remained in the mother liquors and the non-crystalline crusts removed during the recrystallisation process. The pure crystalline solid was observed to acquire a distinct light violet colour when left exposed to light on the bench. This change in colour did not lead to any changes in the observed physical (mp) or spectroscopic (^{1}H, ^{13}C NMR, and IR) properties.

The identity of this new derivative of the oxathiazolone heterocycle family was established by spectroscopic and ultimately by crystallographic methods. The ^{13}C NMR of derivatives of this heterocyclic family have two characteristic resonances at 174.2 ± 0.6 ppm [C^2, C=O] and 162 ± 5.2 ppm (C^5) (R = —CH_3, —C_4H_9, —$C_{10}H_{15}$, —C_6H_5). The identity of the product is confirmed by the mass spectrum which gives the expected molecular ion and the fragments generated by loss of CO_2, S, and CN in sequence.

The solid state structure of **2***c* is shown in Fig. 1. The oxathiazolone rings are planar and apparently unassociated in the solid state with no significant intermolecular contacts. This is

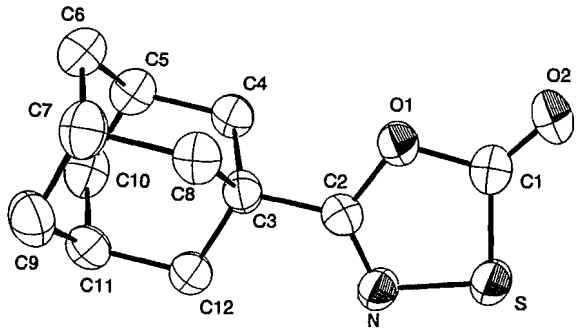

FIG. 1 ORTEP view of $C_{10}H_{15}$—COC(O)SN **2***c*.

the first report of the solid state structure of any derivative of this the oxathiazol-2-one family, however, there have been reports of the gas phase structures of two derivatives (R = H, CH_3) (13). The solid state and gas phase structures are not significantly different ($\Delta \geq 3\sigma$).The result of a bond order analysis based on the Pauling (14) and Nyberg equations (15) is summarised in **5** and is consistent with π bonds which are not significantly delocalised to adjacent atoms. The adamantyl moiety and the bond to the bridgehead carbon are identical to those reported in the literature for other small molecules.

Cycloaddition reaction of adamantyl nitrile sulphide with DMAD

Dimethyl acetylene dicarboxylate (DMAD) is a powerful dipolarophile due to its exceptional stability and excellent electronic properties for participation in cycloaddition reactions (4). Most known nitrile sulphides have been reacted with DMAD and give the expected isothiazole heterocycles in varying yields. This is an important route to an industrially significant family of heterocycles which are used in the pesticide and pharmaceutical industries (16).

The reaction of **2***c* with DMAD in refluxing chlorobenzene produced a mixture of the isothiazole, nitrile, and sulphur with unreacted DMAD. To separate the components of this mixture a process of vacuum drying, filtration and finally sublimation was required. The sublimation must be conducted at low tem peratures, for both the nitrile and the isothiazole readily sublime but the higher molecular mass of the isothiazole product allows recovery a pure compound as a non-sublimed solid that can be recrystallised from a blend of hexanes and chloroform. The separation of the adamantyl nitrile from the product is again a problem that has only partially been solved and a significant fraction of the product remains in the form of a mixture. Column chromatography using a variety of solvent combinations did not give adequate separation of the two species. The identity of the pure product is clearly established by spectroscopy and unequivocally confirmed by X-ray crystallography. The ^{1}H and ^{13}C NMR spectra of isothiazoles and

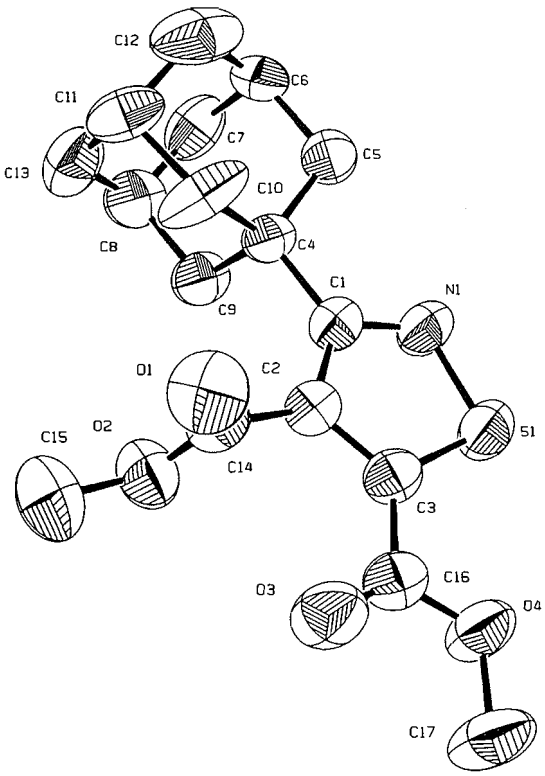

FIG. 2 ORTEP view of $C_{10}H_{15}$—CNSC(C(O)OCH$_3$)C(C(O)OCH$_3$) **3**.

DMAD cycloadducts have been compiled (16) and generally show two resonances in the range 155 ± 11 ppm (this work: 159.5 and 154.6 ppm) and a third resonance in the range 128 ± 18 ppm (this work: 132.0 ppm) for the three endocyclic carbon atoms. The spectra of 3 are also consistent with the DMAD molecule incorporated into the five membered ring [IR: strong carbonyl band at 1739 cm^{-1}, ^{1}H NMR: two OCH$_3$ resonances at 3.97 and 3.90 ppm, ^{13}C NMR: two OCH$_3$ resonances at 53.1 and 52.9 ppm and two C=O resonances at 175.5 and 166.3 ppm). The identity of the product is confirmed by the mass spectrum which gives the expected molecular ion and the fragments generated by loss of Me, OMe, and CO_2Me in sequence.

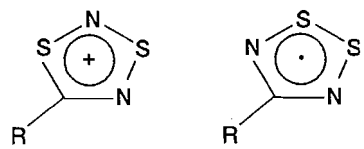
The solid state structure and the unit cell of **2***c* are shown in Figs. 2 and 3, respectively. The isothiazole heterocycles are apparently unassociated in the solid state with no significant intermolecular contacts. Solid state structures that contain DMAD cycloadducts or isothiazole heterocycles have been reported but the structure of the new compound **3** is the first structure of an isothiazole that is a cycloadduct of DMAD or that is substituted by an adamantyl group. The structure (bond lengths, bond angles, and substituent orientation) is consistent with those reported for molecules that contain DMAD, isothiazole or adamantyl moieties. However, the carbon–sulphur bonds (C3—S1: 1.690(4) Å, reported average: 1.720 Å) and the carbon–carbon (C1 and C2: 1.429(6) Å, reported average 1.454 Å) bonds are significantly shorter than the related bonds in previously reported isothiazole structures (16). These observations may be due to the influence of π bond delocalisation to the methyl carboxylate moieties. A bond order analysis of the isothiazole ring is given in **6** and confirms that there is significant π bond delocalisation in the isothiazole ring. Banisters treatment of such π systems (17) indicates that the isothiazole ring is a 6π system (3C (3 πe$^-$) + N (1 πe$^-$) + S (2 πe$^-$)) and is therefore a pseudo Hückel 4*n* + 2 aromatic system.

The general cycloaddition reaction of nitrile sulphides with thiazyl chloride

Thiazyl halides (N≡S—X, X = F, Cl) are well known in sulphur–nitrogen chemistry for their high reactivity and predictable behaviour in cycloaddition reactions (8, 18). A number of methods have been reported for the generation of these species (19). The formal sulphur–nitrogen triple bond in the thiazyl halide molecule has been used in both Diels–Alder and 1,3-dipolar cycloaddition reactions to give heterocyclic products in high yield.

The thiazyl chloride monomer is known to be intimately involved with its trimer $(NSCl)_3$ in solution and it has been reported using ^{14}N NMR spectroscopy that the equilibrium between the monomer and the trimer is strongly dependant on the solvent polarity and temperature (8). We have shown using ^{14}N NMR that the trimer is soluble in chlorobenzene and that at room temperature only trace amounts of the monomer can be detected. At the reflux temperature of chlorobenzene how ever, only trace amounts of the trimer are present and that the equilibrium is effectively shifted entirely in favour of the monomer. Decomposition of the sample at this temperature is rapid, leading to insoluble solids and nitrogen. Therefore, hot solutions of $(NSCl)_3$ in chlorobenzene can be used as a synthetic equivalent to a solution of NSCl but the stability of the solution is low and the *in situ* reaction must occur quickly if significant yields of product are to be expected. Therefore, it was proposed that the *in situ* reaction of NSCl and a nitrile sulphide in refluxing chlorobenzene could give a cycloadduct resulting from the reaction of the 1,3-dipole with the sulphur–nitrogen triple bond. This reaction has not been previously reported.

The general reaction of nitrile sulphides with thiazyl chloride were carried out in refluxing chlorobenzene and the products recovered by filtration and sublimation (to remove solvent and nitrile impurities). The cycloaddition reaction between these two species could give heterocycles of the 1,2,3,5-dithiadiazolium, **4**, or 1,3,2,4-dithiadiazolium, **7**, families. These cations are expected from this reaction because the autoionisation reaction to generate a 6π cationic system as a chloride salt is known to be energetically favourable (17).



7 8

The products recovered from these reactions were shown to be derivatives of the 1,2,3,5-dithiadiazolium cation (4) in reasonable yields (typically ~50%). The salt 4b was recovered as a partial solvate (4b$^+$Cl$^-$·(1/5)C_6H_5Cl) which could not be reduced to a lower solvate by the sublimation procedures used for the other derivatives. Therefore, these reactions represent a new, general route to dithiadiazolium chloride salts. The generation of heterocyclic radicals (1,2,3,5-dithiadiazolyl, **8**) with potentially useful conductivity properties from these salts has been of intense interest to Main Group chemists (20). A number of methods have been reported for their preparation and indeed this family of heterocyclic cations appears to represent a "thermodynamic sink" in heterocyclic carbon–sulphur—

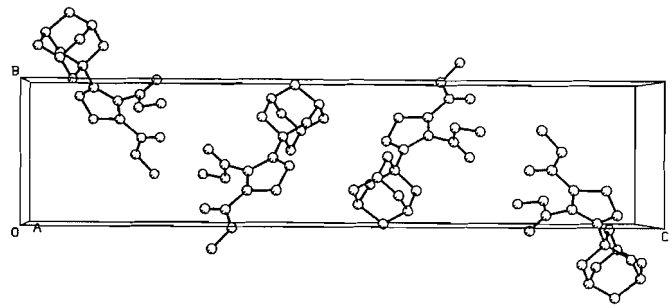

FIG. 3 PLUTO view of the unit cell of $C_{10}H_{15}$—CNSC(C(O)OCH$_3$)C(C(O)OCH$_3$) **3**.

nitrogen chemistry. To demonstrate that the reactions reported here must involve the cycloaddition of the nitrile sulphide, adamantyl nitrile was reacted with $(NSCl)_3$ under the conditions used for these cycloaddition reactions. The reaction did not give a isolable sample of the dithiadiazolium salt **4***c*$^+$Cl$^-$ even though it has been reported that nitriles react with $(NSCl)_3$ to give dithiadiazolium salts under milder reaction conditions (21). This demonstrates that the reaction environment leading to the decomposition of the nitrile sulphide to nitrile and sulphur does not provide for a significant enhancement of the yield of the reaction. Additionally, it was shown that the highest yields are obtained for reactions in which the oxathiazol-2-one precursor is intimately mixed with the thiazyl chloride (Table 1). It has been reported that higher yields of reactions involving nitrile sulphides are observed when the dipole (nitrile sulphide) is slowly added to a dilute solution of a large excess of the dipolarophile (π bond) (5). In these reactions however, the thermal instability of the thiazyl chloride monomer in the reaction environment condemns such a procedure to lower yields. The thermal instability of thiazyl chloride in refluxing chlorobenzene would appear to be the most significant factor in limiting this reaction.

The dithiadiazolium chlorides generated in this work were identified by infrared and mass spectroscopy and elemental analysis. The mass spectra of these species contained peaks assignable to the expected molecular cations and a fragmentation pattern consistent with sequential loss of a S_2N fragment and the substituent from the heterocycle. The infrared and mass spectra of two derivatives (R = C_6H_5 and C_4H_9) have been reported previously. The hitherto unknown adamantyl derivative has spectroscopic and physical properties that are consistent with those of other alkyl derivatives of this family. The insolubility of these salts and their high thermal stability make them difficult to fully characterise, therefore the adamantyl salt 4c was reduced to the new radical 4-adamantyl-1,2,3,5-dithiadiazolyl, **8**. The protocol established by Oakley and co-workers for the reduction and purification of these heterocycles was followed in which the salt was reacted with triphenyl antimony in methylene chloride and the solvent removed to give an opaque black solid which was washed with pentane and then purified by sublimation (22). The large purple–black crystals were identified as the radical **8** by mass spectroscopy, elemental analysis, and X-ray crystallography. The strongest peak in the mass spectrum of this radical is the molecular ion which is likely due to the volatility and stability of this radical.

The solid state structure of **8** is shown in Figure 4 and the contents of the unit cell of **8** is shown in Fig. 5. A bond order analysis of the dithiadiazolyl ring is given in **9** and the π bond

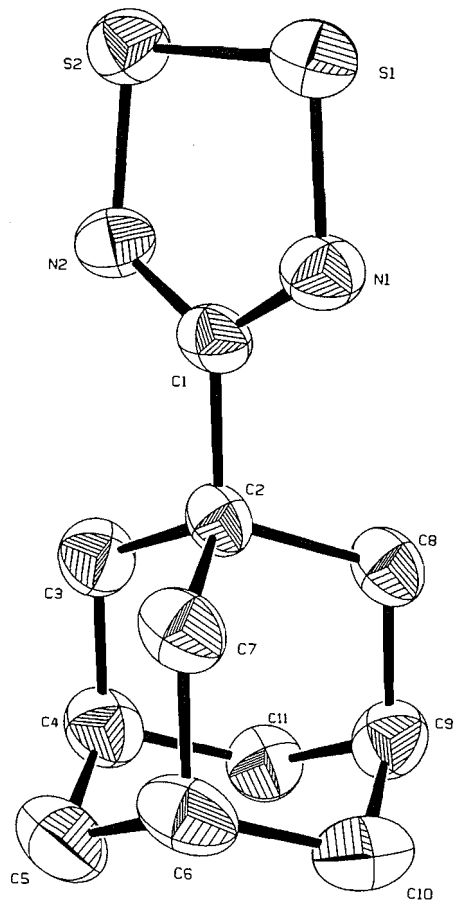

FIG. 4 ORTEP view of $C_{10}H_{15}$-CN_2S_2 **8**.

delocalisation that is expected in the 7π heterocycle is observed. To date, the crystal structures of five mono-functional dithiadiazolyl radical dimers have been reported (R = —CH_3 (23), —CF_3 (24), —$N(CH_3)_2$ (25), —C_6H_5 (26), —*p*-C_6H_5(CN) (27)) and their solid state structures have been recently reviewed (25). The structure of the adamantyl dithiadiazolyl derivative presented here is congruous with the reported structures. The heterocycle is planar and the bond distances and angles within the ring are not significantly different from the mean values reported for this ring system (25).

In this structure the dithiadiazolyl heterocycles are associated into roughly co-planar dimer units in which the rings are rotated approximately 90° from a "*cis*" structure **12** with the most significant intermolecular contacts occurring between the sulphur atoms (S(2)—S(2): 3.036(3) Å). Secondary inter-

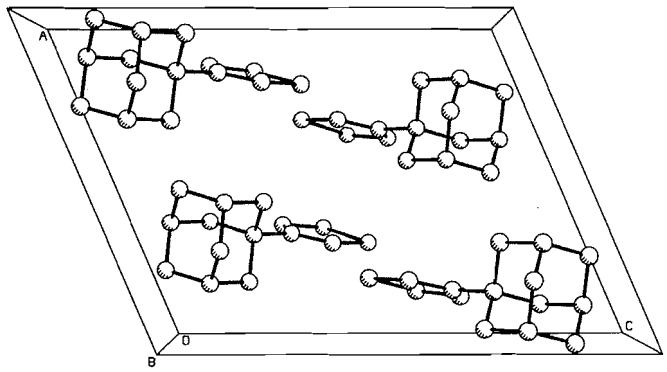

FIG. 5 PLUTO view of the unit cell of $C_{10}H_{15}$—CN_2S_2 **8** showing the orientation of the dimer units.

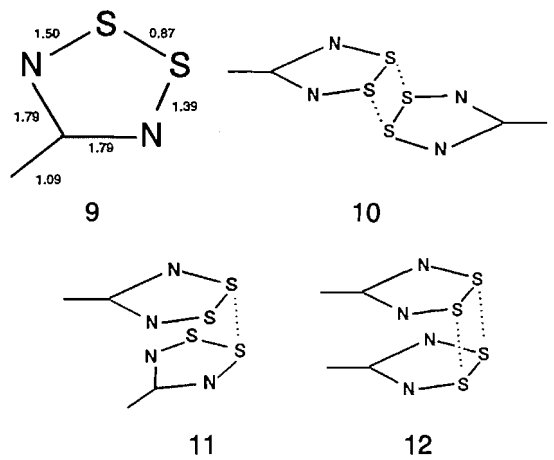
molecular contacts are observed between the sulphur and nitrogen atoms (shortest contact S(2)—N(1): 3.269(4) Å). This essentially co-planar twisted conformation **11** is observed in the methyl, trifluoromethyl, and dimethyl-amino derivatives of this radical family. Theoretical studies have been used to show that the conformation of the dimer can be changed from **10** to **11** to **12** with only small changes in the total energy of the system (24). It has been suggested that the actual orientation



of the dimer may be primarily a result of simple packing forces (20). With this in mind, we proposed that the adamantyl derivative may adopt the *trans* conformation **12** of the dimer to minimise steric interactions between the bulky substituent groups. The *trans* conformation has only been reported for the cyano-phenyl derivative in which secondary interactions involving the sulphur atoms and the cyano group made this the preferred conformation. The structure of **8** is the first of a dithiadiazolyl radical that is substituted with a cage hydrocarbon. It is apparent that the rigidity and steric influence of the large adamantyl moiety has not significantly affected the structure from that observed for smaller alkyl substituents. The preference of alkyl derivatives of this ring system for the twisted dimer structure suggests that the *cis* **10** and *trans* **12** structures observed for the phenyl and cyano-phenyl derivatives, respectively, are the result of electronic differences that involve the delocalisation of charge or π bonding into the substituent. The fact that the twisted conformation **11** was found to be the structure of the adamantyl dimer suggests that this structure may indeed be a minimum between the higher energy dimer conformations **10** and **12**.
