34	0,86 t	13,92 (CH_3)
35	7,18 d	151,89 (CH)
36	5,04 dq	77,88 (CH)
37	1,42 d	18,84 (CH_3)

[a]Constantes de couplage: J_{3a-3b} = 15 Hz; $J_{3a-4\ trans}$ = 8 Hz; $J_{3b-4\ cis}$ = 3 Hz; $J_{3a,b-35}$ = 1 Hz; J_{35-36} = 1,5 Hz; J_{36-37} = 7,5 Hz.
[b]Ces déplacements chimiques (^{13}C RMN) peuvent être inversés.

L'existence d'un système oléfinique, en plus de l'insaturation de la lactone, est confirmée par la préparation des dérivés tétrahydrogénés **1***b* et **1***c* obtenus par hydrogénation catalytique (14) du sénégalène **1** et du tétraacétyl-sénégalène **1***a*. En effet on observe, d'une part la disparition des signaux correspondants aux doubles liaisons sur les spectres RMN ^1H et ^{13}C de **1***b* et **1***c*, d'autre part l'obtention des pics moléculaires augmentés de quatre uma sur le SMIC. De plus, les fragments obtenus sur le SM FAB-Li (15, 16) du sénégalène **1** et du tétrahydro-sénégalène **1***b*, correspondant au pic moléculaire $[M + Li]^+$ (**1** : *m/z* 629; **1***b* : *m/z* 633), aux pics dus à la coupure C-3/C-4 (**1** : *m/z* 517; **1***b* : *m/z* 519) et à la coupure sur le noyau THF (**1** : *m/z* 375 et 245; **1***b* : *m/z* 377 et 247), sont en faveur d'une structure mono-THF, avec un système diol entre la γ-lactone et le THF, et

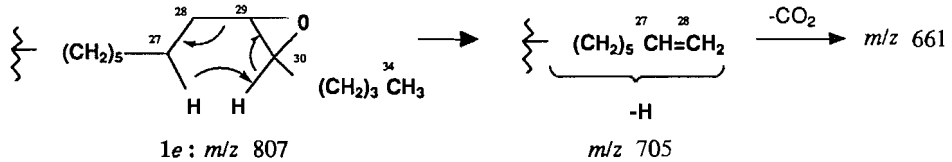
[ ] : Fragments de faible intensité.
[a]SMFAB : *m*-NBA + LiCl.

FIG. 1. Fragmentations de **1**, **1***a*, **1***b* et **1***c* en spectrométrie de masse.



1*e* : *m/z* 807 *m/z* 705

FIG. 2. Fragments de **1***e* en SM.

un système oléfinique entre le THF et le CH_3 terminal (voir figure 1, fragments l_1, l_2 et l_3).

La position de la double liaison sur la chaîne entre le système THF (C_{17}/C_{20}) et le méthyle terminal (CH_3-34) est confirmée, sur le SM de **1***b* et **1***c*, par l'obtention des fragments lactoniques augmentés uniquement de deux uma tandis que la masse moléculaire est quant à elle augmentée de quatre. Une fragmentation entre les carbones 27 et 28 et une autre entre les carbones 31 et 32 (**1** : *m/z* 525 et *m/z* 579; **1***a* : *m/z* 693 et *m/z* 747), permettent de placer la double liaison en 29–30. Ces fragments ne sont pas observés sur les spectres de masse des dérivés tétrahydrogénés **1***b* et **1***c* (voir figure 1).

La préparation de l'époxyde du tétraacétyl-sénégalène (**1***e*) confirme la présence de la double liaison ainsi que sa position en 29–30 sur la chaîne (17). Le pic moléculaire de **1***e* est augmenté de 16 uma $[MH]^+$ *m/z* 807 sur le SMIC. Des fragments caractéristiques de coupure au niveau de l'époxyde sont observés (voir figure 2); le fragment à *m/z* 705 peut être expliqué par un mécanisme similaire à celui proposé (18, 19).

La configuration relative de **1**, au niveau du système THF α-hydroxylé (C-20/C-21 : *thréo*) et diol (C-12/C-13 : *thréo*), est proposée en fonction des déplacements chimiques en RMN ^{13}C des carbones concernés par rapport aux acétogénines mono-THF de configurations relatives connues : solamine et corossolone (10, 20, 21), gigantetrocine et gigantriocine (11) et densicomacines 1 et 2 (13).

Le sénégalène constitue donc le quatrième exemple décrit d'acétogénine possédant une double liaison sur la chaîne aliphatique. Contrairement à la giganenine (22) qui possède cette double liaison du côté lactonique, chez le sénégalène la double liaison est située entre le THF et le méthyle terminal comme dans la gigantetronenine et la gigantrionenine (23). Toutefois il diffère très largement de ces dernières par la position des différentes fonctions et surtout du groupement diol sur la chaîne entre le THF et la lactone.

TABLEAU 2. Cytotoxicité du sénégalène et de ses dérivés sur lignées cellulaires (CE_{50} μg/mL)

Produit	KB	VERO
Sénégalène **1**	$1{,}5 \times 10^{-4}$	2×10^{-1}
Tétraacétyl-sénégalène **1***a*	$3{,}5 \times 10^{-3}$	8×10^{-2}
Tétrahydro-sénégalène **1***b*	$1{,}6 \times 10^{-2}$	0,25
Époxy-tétraacétyl-sénégalène **1***e*	$1{,}4 \times 10^{-2}$	0,6
Vinblastine	10^{-3}	>3

La cytotoxicité du sénégalène et de ses dérivés, étudiée sur lignées cellulaires KB et VERO, est rapportée dans le tableau 2. Le sénégalène **1** ($CE_{50} = 1{,}5 \times 10^{-4}$ μg/mL) présente une activité importante sur cellules KB. La réduction des doubles liaisons diminue fortement cette activité ($CE_{50} = 1{,}6 \times 10^{-2}$ μg/mL). L'acétylation des hydroxyles (**1***a* : $CE_{50} = 3{,}5 \times 10^{-3}$ μg/mL) ou l'époxydation de la double liaison oléfinique (**1***e* : $CE_{50} = 1{,}4 \times 10^{-2}$ μg/mL) diminue également l'activité. La CE_{50} du sénégalène est sensiblement plus élevée sur KB que celle de la vinblastine utilisée comme témoin.

Partie expérimentale

Méthodes générales

Les pouvoirs rotatoires ont été mesurés à l'aide d'un polarimètre Schmidt–Haensch type Polartronic I. Les spectres ont été enregistrés sur les appareils suivants: UV, Unicam Sp 1800; IR, Perkin–Elmer type 257; RMN ^1H et ^{13}C, Bruker AC-200 à 200 MHz (^1H) et à 50 MHz (^{13}C); SMIC et SMIE, Nermag–Sidar; SMFAB, Kratos MS-80. Les chromatographies sur colonne ont été réalisées sur Kieselgel 60 (Merck 9385) ou 60 H (Merck 7736), les chromatographies analytiques sur couche mince (CCM) sur DC Alufolien Kieselgel 60 F 254 (Merck 5554).

Matériel végétal

Les graines d'*Annona senegalensis* ont été récoltées en Juillet 1990 en Casamance (Sénégal); un échantillon d'herbier est déposé sous la référence AL 282 à la Faculté mixte de Médecine et de Pharmacie de Dakar.

Extraction et isolement des acétogénines

L'extraction et le fractionnement des graines d'*Annona senegalensis* ont été guidés par le test sur larves de crevettes d'*Artemia salina* (Brine Shrimp). Les graines séchées et broyées (2,3 kg) sont traitées par le méthanol. Après évaporation, on obtient un résidu de 155,3 g qui a été ensuite repris par le méthanol à chaud. Le fractionnement est effectué dans un premier temps par partage liquide–liquide entre l'extrait méthanolique (A) (additionné de 5% d'eau) et l'hexane. La solution hydrométhanolique est réextraite ensuite par le dichlorométhane. La phase organique (B) (56,2 g) a été fractionnée par chromatographie flash (éluant : CH_2Cl_2/AcOEt/MeOH 10 : 9,5 : 0,5) pour donner cinq acétogénines : le sénégalène **1**, la molvizarine **2**, l'asimicine **3**, la rolliniastatine-2 **4** et la squamocine **5**.

Sénégalène ***1***. $C_{37}H_{66}O_7$; M = 622; $[\alpha]_D$ +16 (*c* 0,21, $CHCl_3$). IR, ν_{max} cm^{-1} (film): 3350, 2840, 1750, 1450, 1310, 1050, 748; HRSMIC, $[MH]^+$ = 623,4908 (calculé pour $C_{37}H_{67}O_7$ = 623,4887); SMIC (NH_3), *m/z*: 640 $[M + NH_4]^+$, 623 (100%) $[MH]^+$, 605 $[MH - H_2O]^+$, 587 $[MH - 2H_2O]^+$, 569 $[MH - 3H_2O]^+$, 551 $[MH - 4H_2O]^+$ (figure 1); RMN ^1H et ^{13}C : voir tableau 1.

Tétraacétyl-sénégalène ***1***a

Par traitement de **1** (10 mg) avec anhydride acétique – pyridine (2 : 1, température ambiante, 1 nuit), le produit **1***a* (huileux) est obtenu quantitativement. $C_{45}H_{74}O_{11}$; RMN ^1H ($CDCl_3$), δ : 0,87 (3H, t, CH_3-34), 1,17–1,70 (34H, m, H-5 à 11, H-22 à 28 et H-31 à 33), 1,40 (3H, d, CH_3-37), 1,56–1,96 (10H, 2m, H-14 à 16 et H-18, 19), 2,02 (3H, s, $OCOCH_3$-4), 2,09 (9H, s, $OCOCH_3$-12, 13, 21), 2,53 (2H, m, H-3), 3,82 et 3,95 (2H, 2m, H-17, 20), 4,82 (3H, m, H-12, 13, 21), 5,0 (1H, dq, H-36), 5,08 (1H, m, H-4), 5,32 (2H, td, H-29, 30), 7,06 (1H, d, H-35). SMFAB (NBA + EtOH), *m/z* : 790 $[M + Na]^+$, 731 $[M - AcOH]^+$, 671 $[M - 2AcOH]^+$, 611 $[M - 3AcOH]^+$, 551 $[M - 4AcOH]^+$ (figure 1).

2,35,29,30-Tétrahydro-sénégalène ***1***b

Par réduction catalytique de **1** en solution méthanolique (5 mg), par H_2 et 10% Pd/C à température ambiante et sous pression atmosphérique pendant 2 h, le produit **1***b* est obtenu quantitativement. $C_{37}H_{70}O_7$; SMIC (NH_3), *m/z* : 644 $[M + NH_4]^+$, 627 (100%) $[MH]^+$, 609 $[M - H_2O]^+$, 591 $[M - 2H_2O]^+$, 573 $[M - 3H_2O]^+$, 555 $[M - 4H_2O]^+$ (figure 1).

2,35,29,30-Tétrahydro-tétraacétyl-sénégalène ***1***c

Par réduction catalytique de **1***a* en solution méthanolique (5 mg), par H_2 et 10% Pd/C à température ambiante et sous pression atmosphérique pendant 2 h, le produit **1***c* est obtenu quantitativement. $C_{45}H_{78}O_{11}$; SMIC (NH_3), *m/z* : 812 $[M + NH_4]^+$, 795 (100%) $[MH]^+$, 735 $[M - AcOH]^+$, 675 $[M - 2AcOH]^+$, 615 $[M - 3AcOH]^+$, 555 $[M - 4AcOH]^+$ (figure 1).

12,13-Acétonide-sénégalène ***1***d

Le produit, **1** (36,2 mg), est traité avec 2,2-diméthoxypropane (9,1 mg), acide *p*-toluènesulfonique (traces) et benzène (1 mL) sous reflux pendant 1 h. Après 1 h d'agitation 0,2 mg de K_2CO_3 sont rajoutés à froid. L'agitation est prolongée pendant 4 h. Le produit de réaction, **1***d*, est ensuite réextrait par l'éther et lavé d'abord par une solution de NaCl saturée et ensuite par H_2O. Le rendement est de 80%. $C_{40}H_{70}O_7$; SMIC (NH_3), *m/z* : 680 $[M + NH_4]^+$, 663 $[MH]^+$, 644 $[M - H_2O]^+$, 626 $[M - 2H_2O]^+$, 605 $[MH - 58]^+$.

29,30-Epoxy-tétraacétyl-sénégalène ***1***e

Le produit, **1***a* (98 mg), est traité avec *m*-CPBA (73,5 mg) et chloroforme (12 mL) pendant 8 h à température ambiante. Le produit de réaction, **1***e*, est lavé d'abord par une solution de 1% de $NaHCO_3$ et ensuite par H_2O et purifié sur colonne de silice. $C_{45}H_{78}O_{12}$; SMIC (NH_3), *m/z* : 824 $[M + NH_4]^+$, 807 $[MH]^+$, 746 $[M - AcOH]^+$, 686 $[M - 2AcOH]^+$, 626 $[M - 3AcOH]^+$, 566 $[M - 4AcOH]^+$ (figure 2).

Molvizarine ***2***. $C_{37}H_{66}O_7$; M = 622; $[\alpha]_D$ +10 (*c* 0,20, $CHCl_3$). Identifiée par analyse des données spectrales, SM, ^1H et ^{13}C RMN (6), et comparaison à un échantillon authentique (*co*-CCM).

Asimicine ***3***. $C_{37}H_{66}O_7$; M = 622; $[\alpha]_D$ +11 (*c* 0,22, $CHCl_3$). Identifiée par analyse des données spectrales, SM, ^1H et ^{13}C RMN, comparaison aux données de la littérature (1) et à un échantillon authentique (*co*-CCM).

Rolliniastatine-2 ***4*** *(= bullatacine).* $C_{37}H_{66}O_7$; M = 622; $[\alpha]_D$ +15 (*c* 0,27, $CHCl_3$) (litt. (8) $[\alpha]_D$ +5,3 (*c* 0,23, $CHCl_3$)); (litt. bullatacin (1) $[\alpha]_{578}$ +14,7 (*c* 0,004, $CHCl_3$)). Identifiée par analyse des données spectrales, SM, ^1H et ^{13}C RMN, et comparaison à un échantillon authentique (*co*-CCM).

Squamocine ***5***. $C_{37}H_{66}O_7$; M = 622; $[\alpha]_D$ +14 (*c* 0,2, $CHCl_3$) (litt. (1) $[\alpha]_D$ +15 (*c* 1,7, MeOH)). Identifiée par analyse des données spectrales, SM, ^1H et ^{13}C RMN, comparaison aux données de la littérature et à un échantillon authentique (*co*-CCM).

The oscillatory Belousov–Zhabotinsky reaction with flavones in batch systems using aqueous–DMF mixed medium

G. MAYA, P.V. LALITHA, AND R. RAMASWAMY

Department of Chemistry, Indian Institute of Technology, Madras – 600 036, India

Received May 25, 1993[1]

G. MAYA, P.V. LALITHA, and R. RAMASWAMY. Can. J. Chem. **72**, 1537 (1994).

Oscillatory systems of the Belousov–Zhabotinsky type with flavones as substrates are described for the first time. Since quercetin and morin are water insoluble, a mixed medium containing DMF and water was used with one of the three catalysts Ce(III), ferroin, or Mn(II). The oscillatory behaviour of a water-soluble substrate (gallic acid) was studied in nine different aqueous–organic mixed media as well as in pure aqueous medium in the bromate–Ce(III) system. The results obtained from a catalyzed system with quercetin or morin as the substrate in an aqueous–organic mixed medium are in agreement with the accepted (FKN) mechanism for an aqueous system.

G. MAYA, P.V. LALITHA et R. RAMASWAMY. Can. J. Chem. **72**, 1537 (1994).

On décrit pour la première fois des systèmes oscillatoires du type Belousov-Zhabotinsky impliquant des flavones comme substrats. La quercétine et la morine étant insoluble dans l'eau, on a utilisé un milieu mixte contenant du DMF et de l'eau avec un des trois catalyseurs suivants: le Ce(III), la ferroïne ou le Mn(II). On a étudié le caractère oscillatoire d'un substrat soluble dans l'eau (l'acide gallique) dans neufs milieux mixtes (eau/solvants organiques) ainsi que dans de l'eau pure dans le système bromate/Ce(III). Les résultats obtenus dans le système catalysé avec la quercétine ou la morine comme substrats, dans un milieu mixte organique aqueux, sont conformes au mécanisme accepté (FKN) du système aqueux.

Introduction

The Belousov–Zhabotinsky (1, 2) oscillatory reaction has attracted the attention of researchers for many years because of their challenging chemistry and their wealth of dynamic behaviour. A number of substrates have been used in this system with different catalysts (3–9). The mechanistic aspects have been presented in detail as the Field–Koros–Noyes (FKN) mechanism (10–12). A systematic study of the aromatic bromate oscillators has been rendered difficult by the poor solubility of many organic compounds and the bromo derivatives in pure aqueous medium. This difficulty has been overcome by employing aqueous–organic mixed media, containing a small percentage of organic solvent in oscillatory systems (13–18). This paper reports on the study of oscillatory behaviour of gallic acid in the Ce(III)-catalysed system in nine different aqueous–organic mixed media. The oscillatory behaviour of two flavones, namely, quercetin and morin, is reported for the first time using three different BZ catalysts (Ce(III), Mn(II), and ferroin).

Experimental

The experimental procedure is the same as that reported elsewhere (14, 15).

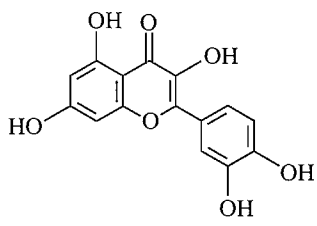
Results and discussion

(A) Gallic acid as substrate

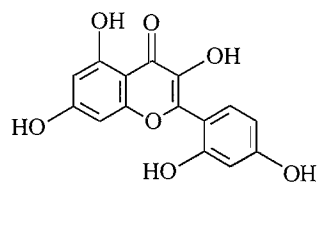
Nine different organic solvents (Table 1) in the form of aqueous–organic mixed media were tested for their suitability for the investigation using gallic acid as a substrate. The reasons for choosing gallic acid as a substrate are as follows: (*i*) It exhibits dynamic behaviour in pure aqueous medium over a wide range of concentration conditions in the B–Z systems (Mn(II), Ce(III), ferroin, and uncatalyzed) (19–21). (*ii*) Since it is water soluble, the study would enable a comparison of its dynamic behaviour in different mixed media as well as in pure aqueous medium. In fact, aqueous–organic media have been used successfully in the ferroin-catalyzed as well as the uncatalyzed bromate systems with gallic acid as substrate (15, 16).

In this study using gallic acid, the system contains 5%(v) of the organic solvent (Table 1). The oscillatory characteristics are presented in Table 1. In the following seven media, namely, water, dimethylformamide (DMF), acetonitrile (AN), tetrahydrofuran (THF), *N*-methyl 2-pyrolidone (N-mp), 1,4-dioxan, and benzene, there are initially two to three large amplitude oscillations (~400 mV) with the initial potential reaching as low as 0.25 V (vs. SCE) followed by six to seven small amplitude (~150 mV) oscillations with peak potentials close to 1.15 V (vs. SCE). The latter oscillations in the high potential region are characteristic of periodic changes in [Ce(IV)]/[Ce(III)] and the large amplitude oscillations characterize changes in $[Br_2]$/$[Br^-]$. Gallic acid exhibits similar oscillatory behaviour in seven of the media employed in the Ce(III) system as presented in Table 1. However, in the mixed media involving 5%(v) of dimethyl sulphoxide (DMSO), CCl_4, or methanol, there are no oscillations. This study shows that the mixed media involving 5%(v) DMF, AN, THF, dioxan, N-mp, or benzene are as good as the aqueous medium and this would facilitate investigations of the structurally related water insoluble substrates in the bromate–Ce(III) system.

The present work also reports for the first time the oscillatory behaviour of two flavones (quercetin and morin) in 20%(v) DMF. The structure of quercetin and morin are given below:



quercetin



morin

The concentration ranges used and the oscillatory parameters are listed in Tables 2 and 3. The oscillatory characteristics at a typical concentration condition are also presented for comparison. These systems exhibit dynamic behaviour only over a nar-

row range of the concentrations of the constituents, presumably due to the moderate reactivity of these flavones towards bromination. This can be attributed to the fused ring structure of flavones.

B. Ce(III) system: quercetin/morin as the substrate

At high concentrations of substrate and low concentrations of H_2SO_4, Ce(III), or $KBrO_3$, the system exhibits two types of oscillations. Initially there are large amplitude oscillations indicative of Br_2/Br^- oscillations (~0.44–0.85 V) (22) followed by small amplitude oscillations in [Ce(IV)]/[Ce(III)] as evident from the potential range (~0.8–0.9 V) (17, 18). Similarly, at low substrate concentration and high concentrations of H_2SO_4, Ce(III), or $KBrO_3$, the system exhibits oscillations in [Ce(IV)]/[Ce(III)] as sensed by the platinum indicator electrode (~0.75–0.95 V). These characteristics are similar for quercetin and morin as the substrates. Typical oscillatory profiles for quercetin and morin in the Ce(III) system are shown in Fig. 1. In the case of quercetin system, the oscillations are characterized by small amplitude (0.80–0.89 V vs. SCE) indicative of Ce(IV)/Ce(III) oscillations, whereas morin exhibits high amplitude oscillations (0.66–0.90 V) initially, due to the mixed control of potential by both Br_2/Br^- and Ce(IV)/Ce(III) couples followed by small amplitude oscillations (0.81–0.93 V).

The mechanism of the catalyzed bromate system in mixed media is found to be the same as that in pure aqueous medium, even though the oscillatory characteristics are altered in the presence of an organic solvent (15). As these substrates are not water soluble, a comparison of the oscillatory behaviour in mixed medium and pure aqueous medium could not be made. In the FKN mechanism for the catalyzed bromate system, an important step is the oxidation of catalyst metal ion.

[A] $BrO_2^{\cdot} + M^{n+} + H^+ \rightleftharpoons HBrO_2 + M^{(n+1)+}$

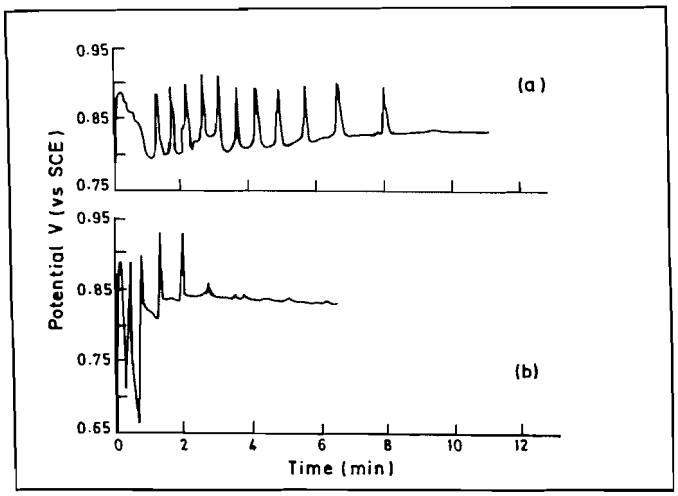

FIG. 1. Oscillatory behaviour of flavone–H_2SO_4–Ce(III)–$KBrO_3$ systems in DMF (20%v) – water mixed medium at 30 ± 0.1°C. Concentration conditions: [substrate]: 0.004 M; [H_2SO_4]: 1 M; [Ce(III)]: 0.001 M; [$KBrO_3$]: 0.1 M. (*a*) Quercetin, (*b*) morin.

The change in the concentration of the constituents alters the oscillatory parameters, as a result of which the rate of the reaction [A] is enhanced or decreased.

C. Ferroin-catalyzed system: quercetin/morin as the substrate

The B–Z system containing quercetin or morin as substrate exhibits large amplitude oscillations when the system contains a high concentration of substrate or low concentrations of H_2SO_4, ferroin, or $KBrO_3$. On the other hand, there are two types of oscillations, characterized by large amplitude (Br_2/Br^-) and small amplitude (ferrin/ferroin, in the high potential region), at low concentration of the substrate or high concentration of H_2SO_4, ferroin, or potassium bromate. The indicator electrode is responsive to the redox couple present depending on the concentrations of the redox couples and the exchange current density values. It is interesting to note that in spite of the higher exchange current density of Pt/ferrin, ferroin ($\sim 10^{-3}$ A cm^{-2}) compared to Pt/Br_2, Br^- ($\sim 10^{-5}$ A cm^{-2}), the systems are characterised by mixed control of potential (of the indicator electrode) under certain concentration conditions. The high amplitude oscillations are caused by a certain initial high concentration of bromine and substrate and a subsequent low concentration of bromine caused by fast bromination. As the reaction proceeds, the concentration of substrate and bromine decreases, now the indicator electrode responds to the $M^{(n+1)+}/M^{n+}$ potential as the [Br_2] is so low that it would no longer control the potential of the Pt electrode (17). Typical oscillatory profiles in the ferroin-catalyzed system with quercetin and morin as substrates are presented in Fig. 2. Here also, the oscillations with quercetin are predominantly ferrin/ferroin controlled, (~0.83–0.89 V) whereas with morin, they are mostly mixed controlled (~0.64–0.92 V). An increase of sustrate concentration increases the time per oscillation, whereas increase in the concentrations of H_2SO_4 or $KBrO_3$ tends to decrease the time per oscillation. The time per oscillation and induction time in quercetin–catalyst–bromate systems are higher than those in morin–catalyst–bromate systems. These observations suggest that morin is more reactive towards bromination compared to quercetin, under the conditions employed.

Conclusions

A critical examination of the oscillatory characteristics — time per oscillation (t) and the value of base and peak potentials, allow us to draw the following conclusions for a catalyzed bromate–flavone system involving one of the three metal ions (Ce(III), Mn(II), or ferroin).

The redox reaction involving metal ion catalyst is favoured by a high concentration of potassium bromate, H^+, or catalyst and a low concentration of substrate. The steps leading to bro-

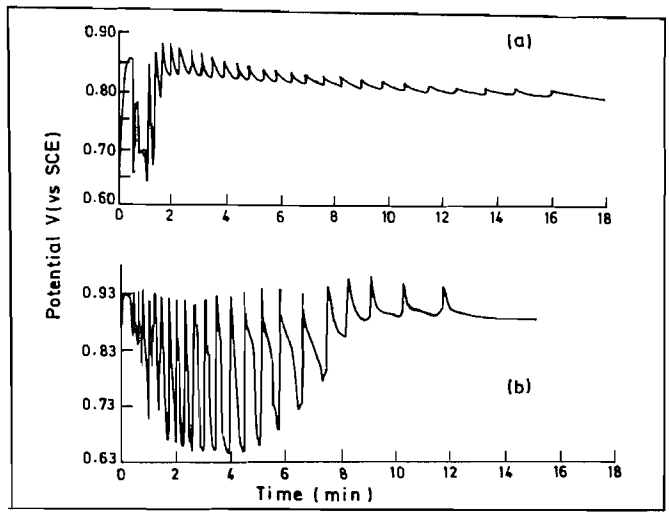

FIG. 2. Oscillatory behaviour of flavone–H_2SO_4–ferroin–$KBrO_3$ systems in DMF (20%v) – water mixed medium at 30 ± 0.1°C. Concentration conditions: [substrate]: 0.015 M; [H_2SO_4]: 1 M; [ferroin]: 0.001 M; [$KBrO_3$]: 0.1 M. (*a*) Quercetin, (*b*) morin.

mine consumption and bromine formation are favoured by a low concentration of potassium bromate, H^+, or catalyst and high concentration of the substrate. Such conclusion can be substantiated by considering the steps involved in the generally accepted (FKN) mechanism for the B–Z reaction.

[1] $BrO_3^- + HBrO_2 + H^+ \rightarrow 2\ BrO_2\cdot + H_2O$

[2] $BrO_2\cdot + M^{n+} + H^+ \rightarrow M^{(n+1)+} + HBrO_2$

[3] $BrO_2\cdot + R{-}H \rightarrow R\cdot + HBrO_2$

The common autocatalytic step [1] is favoured by a high concentration of BrO_3^-. This would be followed by either step [2] or step [3]. A high concentration of $BrO_2\cdot$ (bromate), H^+, or M^{n+} would favour the step involving the redox reaction of the metal ion. Alternatively step [3] would be favoured by a high concentration of the substrate or a low concentration of the metal ion. These observations establish the validity of the generally accepted mechanism of the oscillatory systems in aqueous media to those in aqueous organic mixed media as well.

Transposition en série tricyclique — synthèse et réactivité de bis-triméthylsilyl-bicyclo[*n*,1,0]2-alcène antioxydes

MARIE-CATHERINE GRELIER-MARLY ET MICHELINE GRIGNON-DUBOIS[1]

Laboratoire de chimie organique et organométallique, Université Bordeaux I, 351, Cours de la Libération, 33405 Talence-Cédex, France

Reçu le 17 juin 1993

MARIE-CATHERINE GRELIER-MARLY et MICHELINE GRIGNON-DUBOIS. Can. J. Chem. **72**, 1541 (1994).

Les bis-triméthylsilyl-bicyclo[*n*,1,0]2-alcène antioxydes ($n = 4$ et 6) ont été synthétisés en trois étapes (dichlorocyclopropanation, silylation et époxydation) à partir des cyclo-1,3-diènes correspondants. Leur isomérisation en présence de divers acides de Lewis a été étudiée et comparée aux résultats décrits en série carbonée. Contrairement au 2-carène oxyde qui conduisait exclusivement à la rupture de la liaison C2—O, nous assistons ici essentiellement à celle de la liaison C3—O. Elle s'accompagne de l'ouverture disrotatoire du cyclopropane qui procède par un mécanisme différent selon la valeur de *n*, conduisant ainsi majoritairement au 7,8-bis-triméthylsilyl-9-hydroxy-bicyclo[4,3,0]non-6-ène quand $n = 6$ et au 2,2′-bis-triméthylsilyl-cyclohex-3-ène carboxaldéhyde quand $n = 4$.

MARIE-CATHERINE GRELIER-MARLY and MICHELINE GRIGNON-DUBOIS. Can. J. Chem. **72**, 1541 (1994).

The bis-trimethylsilyl-bicyclo[*n*,1,0]2-alkene antioxides ($n = 4$ and 6) have been synthesized from their 1,3-diene precursors by a three-step process (dichlorocyclopropanation, silylation, and epoxidation). Their rearrangement in the presence of solid and liquid Lewis acids was studied, and compared with the previously described reactivity of 2-carene oxide. With these silylated epoxides, the breaking of the C3—O bond is favoured while C2—O bond breaking had previously been observed with 2-carene oxide. All the resulting products were the three-membered ring-opened ones, but the opening mechanism differs according to the value of *n*, leading mainly to 7,8-bis-trimethylsilyl-9-hydroxy-bicyclo[4,3,0]non-6-ene when $n = 6$ and 2,2′-bis-trimethylsilyl-cyclohex-3-ene carboxaldehyde when $n = 4$.

La transposition du 2,3-époxynorcarane en présence d'acides est connue pour conduire à des menthénol ou menthénones résultant de l'ouverture des deux cycles à trois chaînons sans réarrangement du cycle à 6 chaînons (1). Ayant montré par ailleurs que la substitution du cyclopropane par un ou deux groupes silyles modifie sa réactivité (2*a*), nous avons envisagé le cas du bis-triméthylsilyl-bicyclo[4,1,0]2-heptène antioxyde afin d'examiner l'influence du silicium sur le réarrangement de ces squelettes. L'étude des triméthylsilylbicyclo[*n*,1,0]alcanes et alcènes nous avait permis de mettre en évidence l'importance de la taille du grand cycle dans la réactivité électrophile de ces composés (2*b*, 2*c*). Nous avons donc également envisagé le cas du bis-triméthylsilyl-bicyclo[6,1,0]2-nonène antioxyde.

Résultats et discussion

Les bis-triméthylsilyl-bicyclo[*n*,1,0]2-alcène oxydes sont obtenus quantitativement par action de l'acide métachloroperbenzoïque (3) sur les bicyclo[*n*,1,0]alcènes siliciés **1** et **2**, dont nous avions précédemment proposé une voie de synthèse en deux étapes à partir des cyclo-1,3-diènes (2*c*) (schéma 1). Dans les deux cas, nous isolons un seul stéréoisomère. Le fait que Clark et al. (1*a*) et Coates et coll. (1*c*) n'obtenaient que l'isomère *trans* lors de l'époxydation du 2,3-carène ou des bromonorcarènes suggère qu'il en est de même en série siliciée. Cependant, l'éventualité d'une interaction $(p–d)\pi$ entre l'oxygène et le silicium (4), qui pourrait stabiliser l'isomère *cis* par rapport au *trans*, doit être envisagée. L'analyse du spectre de RMN ^{1}H (250 MHz) ne permet pas de déterminer sans ambiguïté la stéréochimie du composé **3**, les signaux des protons H1 et H2 n'étant pas différenciés. Dans le cas du composé **4**, ce couplage est nul. Une étude conformationnelle des deux isomères a été effectuée par mécanique moléculaire.[2] Les valeurs suivantes, mesurées pour l'angle dièdre H1-C-C-H2, montrent qu'il serait hasardeux de déduire la stéréochimie à partir du seul couplage $^3J(H_1, H_2)$:

3 *trans* : 26° ^3J = 6.7 Hz; **3** *cis* : 50° ^3J = 4,8 Hz

4 *trans* : 103° ^3J = 1 Hz; **4** *cis* : 78° ^3J = 0,6 Hz

Par contre, la proximité de l'oxygène et du silicium *endo* dans les isomères *cis*, devrait avoir des conséquences sur les caractéristiques RMN de ce dernier. Nous nous sommes donc tourné vers la RMN du ^{29}Si dont nous avions démontré l'intérêt dans le domaine de l'analyse structurale des dérivés organosiliciés (6). Les déplacements chimiques et les constantes de couplage ^{29}Si,^{1}H des composés **3** et **4** ont été mesurés et comparés aux valeurs précédemment rapportées pour les bicycloalcanes et alcènes correspondants (6*a*–*c*). L'utilisation de séquence SPT (6) a permis l'attribution des signaux $SiMe_3$ dans le spectre proton. Nous avons ainsi pu corréler les déplacements chimiques ^{1}H et ^{29}Si des groupes silyles de tous ces composés ainsi que les déplacements chimiques du ^{13}C, à partir des spectres COSY (^{1}H, ^{13}C). L'ensemble de ces résultats est rassemblé dans le tableau 1. La similitude des valeurs observées dans toute cette série montre qu'il n'y a pas d'interaction entre l'oxygène et le silicium *endo*, ce qui est en faveur d'une géométrie *trans*. Les effets stériques des groupes triméthylsilyles contrôlent donc la stéréochimie de la réaction.

Réactivité des époxydes 3 et 4

1. Cas du 9,9′ bis-triméthylsilyl-bicyclo[6,1,0]2-alcène antioxyde, 4

Le composé **4** a été soumis à toute une gamme d'acides solides et liquides, tous réputés conduire à l'ouverture de la fonction époxyde : BF_3/Et_2O (7), Al_2O_3 (1*c*, 7, 8), SiO_2 (7, 9), $FeCl_3/SiO_2$ (9), et ZnI_2 (10). À l'exception de SiO_2 qui laisse le composé **4** inchangé, on constate que la réaction n'est jamais univoque et conduit au mélange des dérivés **5–7** où **5** est toujours majoritaire (schéma 2; tableau 2); la meilleure sélectivité est obtenue avec ZnI_2, qui permet d'isoler **5** avec 78% de rende-

ment. Les spectres IR et de RMN (^{1}H et ^{13}C) montrent qu'il s'agit d'un alcool disilicié constitué d'un seul isomère; la formule brute $C_{15}H_{30}Si_2O$ a pu être confirmée par une détermination de la masse exacte (M = 282,182) en spectométrie de masse. Ces données physico-chimiques, pas plus qu'une étude de RMN 2D (COSY), ne nous ont permis de choisir parmi les trois formules **A–C**, toutes théoriquement possibles (cf. schéma 3). En effet, selon que l'ouverture de l'époxyde va s'effectuer par scission de la liaison C2—O ou C3—O, on devrait obtenir un squelette bicyclo[5,2,0]- ou [4,3,0]nonène, résultat respectivement du réarrangement du carbocation cyclopropylcarbinyle ou homocyclopropylcarbinyle. Notons cependant que les valeurs des couplages ^{1}J (^{13}C,^{1}H) des CH_2 et des CH (cf. tableau 3) seraient plutôt en faveur d'un bicycle «6+5» et donc de **B** ou de **C**, sans pour autant permettre de rejeter totalement **A**.

L'identification de **5** a été rendue possible grâce à la RMN du ^{29}Si : en effet, les déplacements chimiques du ^{29}Si observés (7,13 et −14,86 ppm) montrent que, seul, un des siliciums est en position vinylique (−14,86 ppm), ce qui nous permet de rejeter définitivement les structures **A** et **C**. Les couplages ^{29}Si,^{1}H mesurés pour ce signal (cf. partie expérimentale) sont en accord avec la structure proposée. En ce qui concerne le deuxième silicium (7,13 ppm), la complexité du spectre non découplé suggère qu'il est porté par un CH cyclique et est tout à

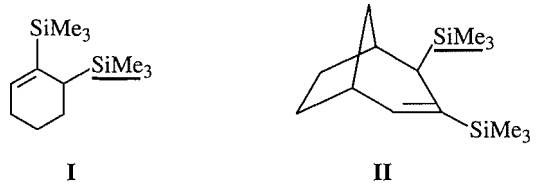
fait comparable à celle observée avec des structures telles que I et II :[3]



I II

Le composé **5** est constitué d'un seul isomère. La comparaison des constantes de couplage mesurées ^3J (H8, H9) ≤ 1 Hz et ^3J (H9, H1) ≤ 1 Hz aux valeurs calculées (5) pour chacun des isomères possibles (*trans* : ^3J (H8, H9) = 0,5 Hz et ^3J (H9, H1) = 1Hz; *cis* : ^3J (H8, H9) = 8 Hz et ^3J (H1, H9) = 8,7 Hz) permet de retenir pour le composé **5** la structure où les protons sont tous en *trans* avec le silicium Si-8 en axial. Ce résultat est en accord avec les données de la littérature (11) concernant la plus grande stabilité de ce type de géométrie.

L'action de l'hexaméthyldisilazane sur **5** conduit à **8** (rdt. 75%). L'examen des spectres de RMN ^1H et ^{13}C montre que l'on n'a pas modifié le squelette et il apparait dans la zone des $SiMe_3$, un signal supplémentaire dû au groupe siloxy. En RMN du ^{29}Si, les signaux des deux siliciums préexistants ne sont pas

$SiMe_3$	−2,30	−0,98	119,2

modifiés par cette réaction. Le déplacement chimique et les couplages observés pour le signal supplémentaire (cf. partie expérimentale) sont tout-à-fait caractéristiques d'un groupement O-$SiMe_3$ porté par un CH cyclique.

Le mécanisme rapporté dans la figure 1 fait intervenir l'ouverture de l'époxyde par scission de la liaison C3—O avec stabilisation de la charge résultante par ouverture disrotatoire du cyclopropane. Le carbocation **A** ainsi formé est stabilisé par la présence des deux groupes triméthylsilyles en position β (12). Le composé **5** résulte de la migration de l'un d'eux, suivie de la perte du proton «tête-de-pont». Sa stéréochimie *trans* implique que c'est le groupe silyle initialement en position *endo* qui effectue cette migration (fig. 2). Le composé **6** résulterait de la stabilisation de **A** par perte du même groupe silyle. La superposition des signaux dans le spectre de RMN ^1H ne nous a pas permis de confirmer la stéréochimie de la jonction de cycle, prévue *cis* par le mécanisme proposée (fig. 2). Notons que les migrations de groupe triméthylsilyle ont été observées par ailleurs dans d'autres séries (12*c*, 13).

Quel que soit l'acide de Lewis utilisé, on isole en outre un sous-produit (rdt. 0–9%) dont les caractéristiques spectrales sont compatibles avec celles du 9-triméthylsilyl-bicyclo[6,1,0]-non-3-ène.

2. Cas du 6,6′ bis-triméthylsilyl-bicyclo[4,1,0]2-alcène antioxyde, 3

L'époxyde **3** a été mis a réagir avec ZnI_2 (réactif le plus sélectif dans le cas de **4**) et SiO_2. La réaction est totale et on isole trois produits originaux disiliciés, **9–11** (schéma 4).

(*i*) **9**, produit majoritaire de la réaction, est un liquide incolore constitué d'un seul isomère, présentant en IR les bandes d'absorption caractéristiques d'un aldéhyde non conjugué (2840 et 1720 cm^{-1}), d'une double liaison (1640 cm^{-1}) et du groupe $SiMe_3$ (1250 et 840 cm^{-1}). L'analyse des spectres de RMN ^{13}C et ^1H nous a permis de l'identifier au 2,2′-bis-triméthylsilyl-cyclo-3-hexène carboxaldéhyde.

(*ii*) La formule de **10** a été établie sur la base des données IR et RMN ^{13}C et ^1H. On note en particulier sur le spectre de RMN ^{13}C, la présence de deux CH cyclopropaniques ayant des déplacements chimiques voisins et de deux CH_2 liés à un carbone sp^2. Ces arguments permettent de rejeter l'éventualité d'un carbonyle en position 1.

(*iii*) Les données structurales relatives à **11** montrent qu'il s'agit d'une cyclohepténone non conjuguée *gem*-disiliciée. La présence dans le spectre de RMN ^1H d'un singulet d'intégration 2H, compatible avec un groupe CH_2 lié à un carbonyle, et l'analyse des couplages des protons éthyléniques, qui montre que les deux groupes silyles sont en position allylique, nous a

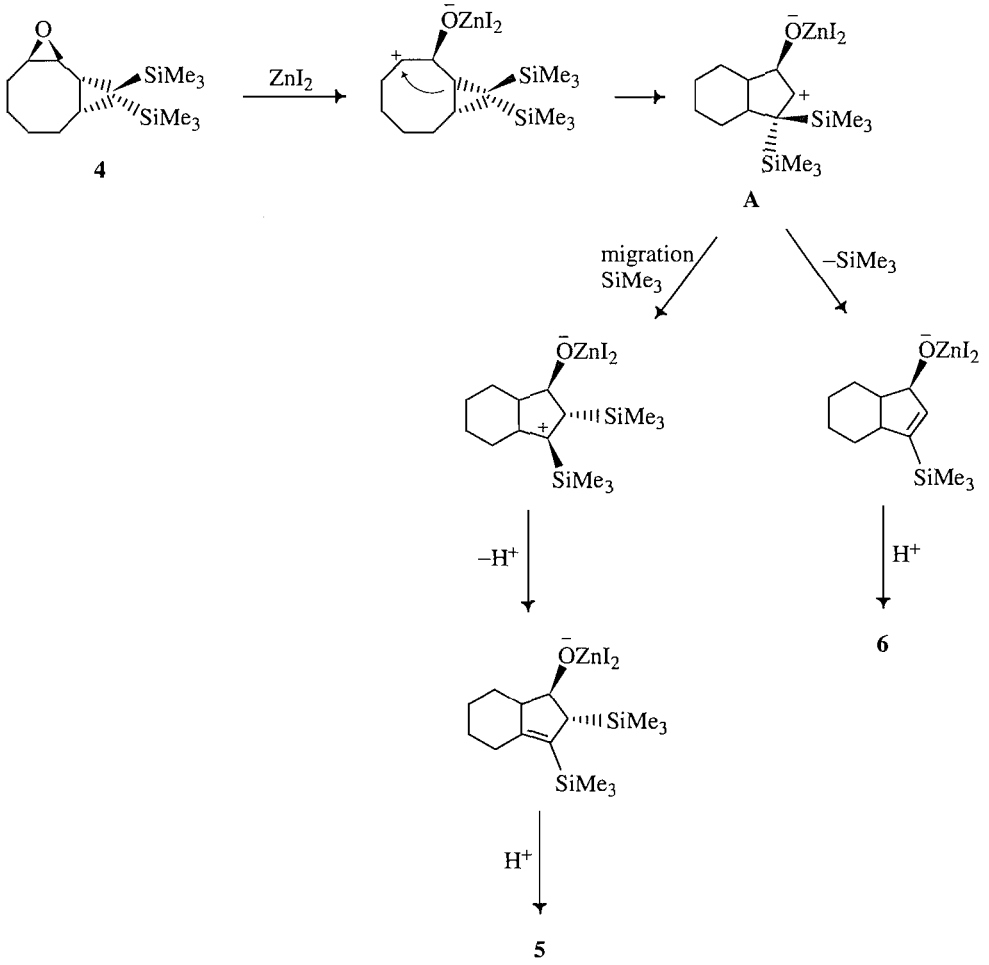

FIGURE 1

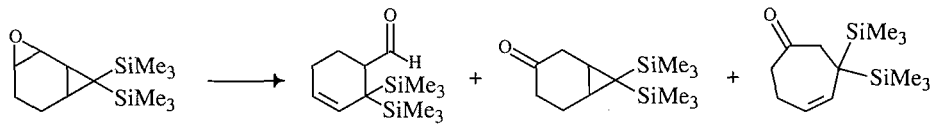

ZnI_2	rdt. :	63%	12%	18%
SiO_2	rdt. :	66%	27%	—

SCHÉMA 4

permis de l'identifier à la 1,1′-bis-triméthylsilyl-cyclohept-2-ène-6-one.

Le mécanisme décrit dans la figure 3 rend compte de ces résultats. Les composés **9** et **11**, qui constituent de 66 à 81% du mélange, résultent d'une ouverture de l'époxyde par scission de la liaison C3—O. Comme précédemment, l'ouverture disrotatoire du cyclopropane conduit à un carbocation β-disilicié (**A**), mais la régiochimie de cette ouverture est différente de celle observée avec le composé **4**, montrant l'influence de la taille du grand cycle (fig. 2). La stabilisation de **A** s'effectue par perte d'un proton. L'ouverture du cyclopropylalcoolate qui en résulte rend compte de l'obtention de **9** et **11**. La formation de bicyclo[3,2,0]hepténol, normalement attendu à partir du carbocation **B**, n'est pas observée. Notons que bien que stériquement contraint, l'obtention de ce type de squelette est envisageable, puisque il a été isolé par Coates et coll. (1*c*) par action du butyllithium sur l'*exo*-7-bromo-bicyclo[4,1,0]2-heptène antioxyde; le mécanisme faisait dans ce cas intervenir une ouverture conrotatoire de l'anion cyclopropanique via l'ouverture de l'époxyde par scission de la liaison C2—O. Seul le composé **10**, dont le rendement varie avec le réactif (tableau 2), résulte de la scission de la liaison C2—O, qui est comme précédemment défavorisée alors qu'elle intervient exclusivement à partir du 2,3-époxycarane.

Conclusion

Ce travail montre que la présence de groupes silyles sur le noyau cyclopropanique modifie la réactivité des bicyclo[*n*,1,0]alcène antioxydes. Contrairement à ce qui avait été observé avec les dérivés du norcaranes, l'ouverture de l'époxyde s'effectue majoritairement par scission de la liaison C3—O suivie d'une ouverture disrotatoire du cyclopropane, favorisée ici par la formation de carbocations β-disiliciés. La régiochimie de cette ouverture est liée à la taille du grand cycle

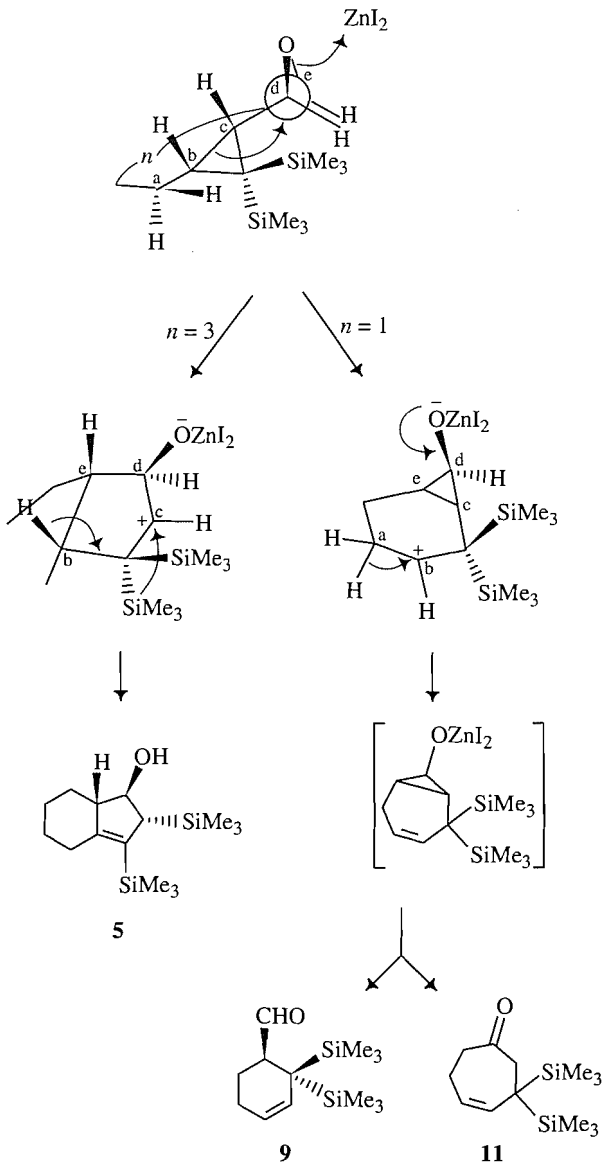

FIGURE 2

et doit traduire, tant la tension du système bicyclique formé, que la géométrie des carbocations intermédiaires dont dépend le recouvrement des orbitales impliquées dans la transposition du squelette. Ainsi, avec $n = 6$, on isole majoritairement des bicycles de type [4,3,0] plus stables que les [6,1,0] (14). Avec $n = 4$, la tension des bicycles [4,1,0] est comparable à celle des bicycles [3,2,0] (14*b*) et les facteurs géométriques doivent jouer ici un rôle important. Cependant, seule une étude conformationnelle des intermédiaires de réaction permettrait de dégager les facteurs prépondérants. Sur le plan synthétique, nous avons pu accéder à des composés originaux (alcool, aldéhyde, cétone) hautement fonctionnalisés qui pourraient constituer d'intéressants intermédiaires de synthèse.

Partie expérimentale

Caractéristiques physico-chimiques des produits obtenus

Les analyses centésimales ont été effectuées au service central d'analyse du CNRS (F-69390 Vernaison). Les spectres de masse (SM) ont été enregistrés sur un appareil VG micromass 16 F (70 eV) et les spectres IR sur un spectromètre Perkin–Elmer 1420; tous les dérivés siliciés isolés présentent en IR des bandes de très forte intensité à 1250 et 850 cm^{-1} caractéristiques des groupes $SiMe_3$ et qui peuvent masquer le reste du spectre. Les spectres de RMN ont été enregistrés sur un appareil Bruker AC 250 fonctionnant à 250 MHz dans le cas du proton et 62.9 MHz pour le ^{13}C (solvant, $CDCl_3$; C_6H_{12} ref. int. à 1,4 ppm (^1H) ou 27,08 ppm (^{13}C)) et AC 200 fonctionnant à 39,763 MHz dans le cas du ^{29}Si (spectres enregistrés dans un mélange C_6D_6/CCl_4 50 : 50). Les déplacements chimiques du silicium sont déterminés par la technique INEPT refocalisé (15). Les constantes de couplage $^{29}Si,^1H$ sont extraites des spectres SPT (16) et INEPT découplés des protons du groupe $SiMe_3$ (17) et confirmées par simulation sur un Microvax 3100 de Digital à l'aide du programme informatique précédemment décrit (6*d*).

Les composés **1–2** ont été synthétisés par addition de dichlorocarbène respectivement sur les cyclohexadiène- et cyclooctadiène-1,3 suivie d'une silylation et sont identiques aux échantillons précédemment décrits (2*c*).

Réaction d'époxydation

La réaction est conduite sous atmosphère d'argon. Dans un ballon de Grignard de 250 mL, muni d'une agitation mécanique efficace, d'une ampoule à brome et d'un réfrigérant ascendant relié à une colonne de chlorure de calcium, on ajoute goutte à goutte 0,03 mol de substrat à une solution de 150 mL d'éther anhydre et 0,035 mol (1,2 équiv.) d'acide métachloroperbenzoïque (pureté : 50–60%). L'agitation est poursuivie pendant 48 h, puis le solvant est évaporé et le résidu repris au pentane. L'acide métachlorobenzoïque formé est éliminé par filtration. Cette opération est répétée deux fois. Les traces d'acide résiduelles sont ensuite éliminées par lavage avec une solution saturée de Na_2CO_3, puis à l'eau jusqu'à neutralité. La phase organique est séchée sur sulfate de sodium et le solvant évaporé. La pureté du produit ainsi obtenu est supérieure à 99%.

7,7′-Bis-triméthylsilyl-bicyclo[4,1,0]2-heptène antioxyde (3) : 7,6 g, rdt. 99%. IR (film KBr, cm^{-1}) : 2995, 2950, 2900, 1442, 1415, 1265, 1255, 1105, 1070, 1005, 985, 965, 900, 865, 840, 785, 755, 680, 645, 620, 540, 490, 425, 350. SM *m/e* (%) : 182 (2,5), 181 (18,1), 151 (6,5), 147 (18,1), 133 (7,1), 91 (11,8), 75 (13,9), 74 (14,8), 73 (100), 59 (13,5), 45 (21,1), 43 (9,1). Anal. calc. pour $C_{13}H_{26}OSi_2$: C 61,34, H 10,30, O 6,29; trouvée : C 61,61, H 10,23, O 6,32.

9,9′-Bis-triméthylsilyl-bicyclo[6,1,0]2-nonène antioxyde (4) : 8,4 g, rdt. 99%. IR (film KBr, cm^{-1}) : 3000, 2995, 2920, 2860, 1455, 1435, 1265, 1255, 1050, 980, 958, 938, 882, 872, 842, 830, 770, 758, 690, 680, 620, 482, 440, 355. RMN ^1H ($CDCl_3$, 250 MHz) δ ppm : −0,07 (s, 9H, $SiMe_3$), 0,11 (s, 9H, $SiMe_3$), 0,8 (m, 1H, H-8, $J_{8,1}$ 11,2 Hz), 1,0–1,4 (m, 5H), 1,8 (m, 2H), 2,0–2,2 (m, 2H), 2,9 (dt, 1H, H-3, $J_{3,2}$ 3,5 Hz, $J_{3,4}$ 8,5 Hz), 3,1 (dd, 1H, H-2, $J_{1,2}$ 0,5 Hz, $J_{2,3}$ 3,5 Hz). RMN ^{13}C ($CDCl_3$, 62,86 MHz) δ ppm, $SiMe_3$: −0,94, 3,69; CH_2 : 22,5 27,5, 28,5, 30,0; CH : 23,9, 27,5, 54,6, 58,4; C : 4,3. RMN ^{29}Si (cf. tableau 1). SM *m/e* (%) : 282 (0,5), 209 (8,2), 147 (10,3), 75 (14,6), 73 (100), 59 (8,4), 45 (11,2). Anal. calc. pour $C_{15}H_{30}OSi_2$: C 63,76, H 10,70, O 5,66; trouvée : C 63,21, H 10,52, O 5,38.

*Transposition des époxydes **3** et **4***

Par l'alumine activée

À une solution de 2 g d'époxyde dans 30 mL de cyclohexane séché sur tamis moléculaire (4 Å), on ajoute 25 g d'alumine neutre activée (grade I : 0% d'eau) et on agite pendant 24 h. Après filtration, l'alumine est lavée avec un mélange éther–méthanol (1 : 1; v/v). Le solvant est évaporé sous vide et le résidu est analysé par chromatographie en phase gazeuse (CPG). La purification des produits se fait par chromatographie liquide basse pression (SiO_2 : 230–400 mesh, éluant : cyclohexane–éther 8 : 2).

Par l'éthérate de trifluorure de bore

À 5 mmol d'époxyde mis en solution dans 90 mL de benzène anhy-

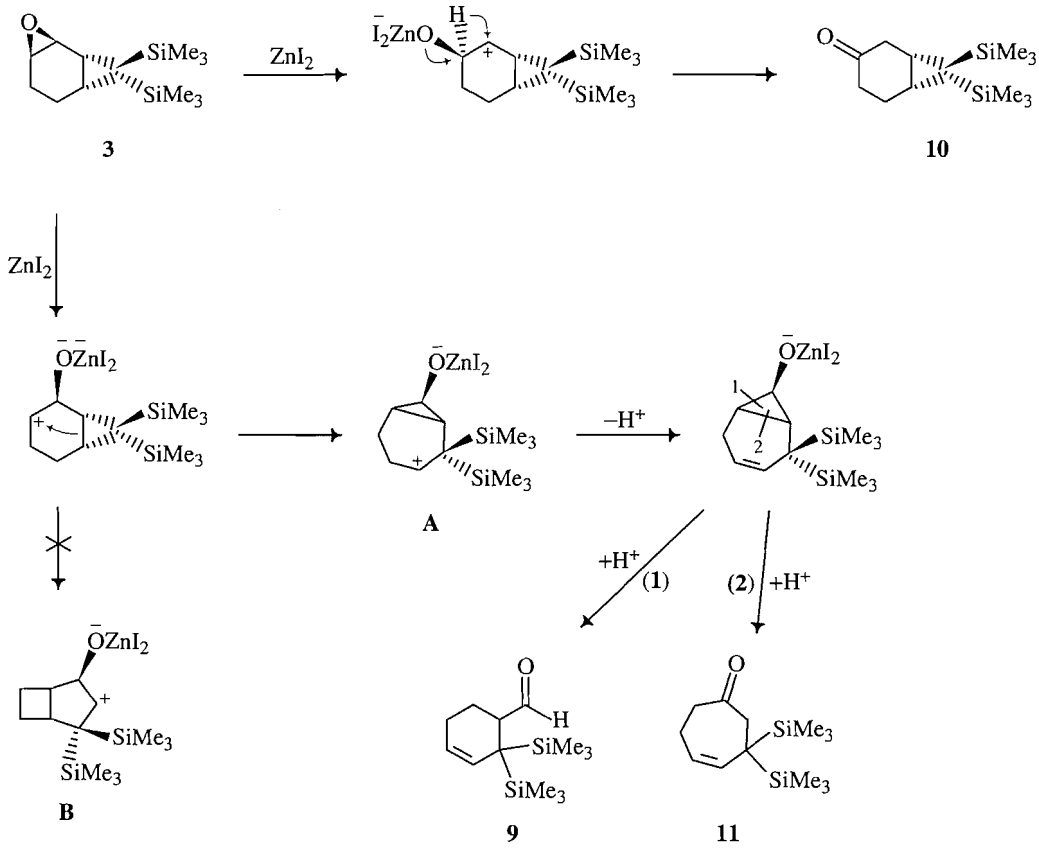

FIGURE 3

dre et maintenu à température ambiante, on ajoute 1,3 équivalents d'éthérate de trifluorure de bore (BF_3/Et_2O) fraîchement distillé sur hydrure de calcium. La manipulation s'effectue sous atmosphère inerte. L'agitation est maintenue pendant 15 min. L'hydrolyse est effectuée par addition d'eau au milieu réactionnel. Après extraction à l'éther de la phase aqueuse, la phase organique est lavée à l'eau jusqu'à neutralité et séchée sur sulfate de sodium anhydre. Après évaporation du solvant, le résidu est purifié comme précédemment.

Par le complexe $FeCl_3$–SiO_2

Le complexe $FeCl_3$–SiO_2 est préparé en mélangeant 50 g de silice (granulométrie 70–230 mesh) avec 4 g de chlorure de fer selon la référence 9. L'ensemble est vigoureusement agité pendant 24 h afin d'obtenir une adsorption homogène. On isole ainsi une poudre vert-jaune qui est utilisé sans purification. Dans un ballon de 50 mL équipé d'une agitation magnétique efficace, on place 2 mmol d'époxyde et 2,4 g de complexe $FeCl_3$ anhydre. On maintient l'agitation à température ambiante jusqu'à obtention d'une poudre brune que l'on extrait à l'éther. Le solvant évaporé, le mélange réactionnel est purifié comme précédemment.

Par l'iodure de zinc

L'iodure de zinc anhydre (2 mmol, 6,4 g) est dissout dans un minimum d'éther anhydre, puis introduit dans un Grignard à trois tubulures muni d'une agitation magnétique efficace, d'une ampoule à brome et d'un réfrigérant ascendant relié à une colonne de chlorure de calcium. On rajoute 90 mL de benzène anhydre et on distille l'éther à pression atmosphérique afin d'obtenir une suspension. Puis, on additionne goutte à goutte 5 mmol d'époxyde dilué dans 30 mL de benzène sec. Le mélange est porté à reflux pendant 8 h. L'avancement de la réaction est suivi grâce au changement de coloration du milieu réactionnel : rose avant et pendant l'addition, jaune en fin de réaction. La solution est alors filtrée, lavée à l'eau, séchée sur sulfate de sodium et le solvant est évaporé. La purification est effectuée comme précédemment.

7,8-Bis-triméthylsilyl-9-hydroxy-bicyclo[4,3,0]non-6-ène (**5**) : rdt. 71% avec ZnI_2. IR (film NaCl, cm^{-1}) : 3460, 2950, 2920, 2860, 1600, 1450, 1250, 850, 830, 750, 680. RMN ^1H ($CDCl_3$, 250 MHz) δ ppm : −0,13 (s, 9H, $SiMe_3$), −0,23 (s, 9H, $SiMe_3$), 1,3 (m, 3H, CH_2 et OH), 1,6 (m, 3H), 1,9 (s él, 1H, H-8), 2,0–2,3 (m, 3H), 2,9 (s él, 1H, H-1), 3,8 (s él, 1H, H-9). Received August 10, 1993

WEIDE LUO, ELENA ATRAZHEVA, NANCY FREGEAU, WILLIAM H. GMEINER, and J. WILLIAM LOWN. Can. J. Chem. **72**, 1548 (1994).

The synthesis, diastereomeric separation, and characterization are described for a series of novel *O*-(2,2,2-trifluoroethyl)-3′,5′-dinucleoside phosphates, required for incorporation into antisense probes in the magnetic resonance imaging investigation of biodistribution. Preliminary assignment of the absolute configuration of the *R*p and *S*p diastereomers is made on the basis of ^{31}P NMR spectra.

WEIDE LUO, ELENA ATRAZHEVA, NANCY FREGEAU, WILLIAM H. GMEINER et J. WILLIAM LOWN. Can. J. Chem. **72**, 1548 (1994).

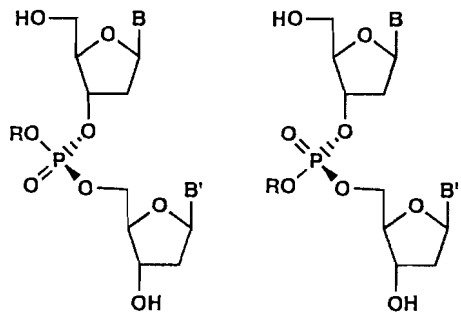
On décrit la synthèse, la séparation des diastéréoisomères et la caractérisation d'une série de nouveaux phosphates de *O*-(2,2,2-trifluoroéthyl)-3′,5′-dinucléosides requis pour l'incorporation dans des sondes pour une étude MRI de biodistribution. Faisant appel à la RMN du ^{31}P, on fait une attribution préliminaire de la configuration absolue des diastéréoisomères *R*p et *S*p.
[Traduit par la Rédaction]

Introduction

Synthetic oligonucleotides that have backbone modifications are useful as model compounds for studying DNA structure and dynamics (1, 2), and as probes for elucidating specific interactions of DNA with proteins and enzymes (3–5). Phosphoric triesters have long been studied as models of these modifications. The phosphoric triester linkage in oligonucleotides can be constructed by oxidative substitution of dinucleoside H-phosphonates with an alcohol (6), transesterification of dinucleoside phosphoric triesters (7), or alkylation of dinucleoside phosphoric diesters. As an example of the latter, two *O*-alkyl-5,5′-dinucleoside phosphates have been synthesized as potential anti-AIDS reagents (8).

The phosphoric triester linkage possesses a chiral centre at the phosphorus atom. The absolute configuration can be defined in the manner of Cahn et al. (9), by inspection of the four groups about the phosphorus atom. The *R*p and *S*p isomers of dinucleoside monophosphate methyl, ethyl, or trifluoroethyl triesters, so defined, are shown in Fig. 1. The stereochemistry of alkylated DNA phosphate groups has been shown to be of biochemical significance (10, 11). Stereochemistry is also clearly important when such modified DNAs are used as probes in structural studies or for antisense applications. Because dinucleoside monophosphate alkyl triesters are almost always produced as a mixture of diastereomers by various preparative methods, the separation of the diastereomers is required. This has often proved to be difficult.

We require certain trifluoroethyl phosphate triester derivatives of nucleosides to extend our studies on the application of ^{19}F NMR in magnetic resonance imaging (MRI) determination of biodistribution of antisense probes (12). In this paper, we present the synthesis of dinucleoside monophosphate 2,2,2-trifluoroethyl triesters, including dinucleotides of TT, TC, TA, CA, AT, and AA, by the phosphite-triester method and separation of the *S*p and *R*p diastereomers. Their absolute configurations were tentatively assigned by comparison of chemical shifts of ^{31}P NMR signals between diastereomers.



R = Me, Et *R*p *S*p
R = CH_2CF_3 *S*p *R*p

FIG. 1. Designation of *R*p and *S*p configurations of diastereomeric *O*-(2,2,2-trifluoroethyl)-3′,5′-inucleoside phosphates and the related methyl and ethyl derivatives.

Results and discussion

To avoid the difficulty of separation of diastereomeric mixtures of phosphoric triesters, we initially carried out the synthetic route as outlined in Scheme 1, in which the key intermediates, dinucleoside H-phosphonates **1**, were subjected to separation of P-diastereomers by flash chromatography on silica gel (13). The next steps to the target molecules (**4**) (sulfurization, alkylation of dinucleoside phosphothioates **2** with 2,2,2-trifluoroethyl iodide, and the oxidation of the resulting phosphoric thiotriesters **3** with *m*-chloroperbenzoic acid) were expected to be stereospecific (14). In the event, our attempts to generate *O*-(2,2,2-trifluoroethyl)dinucleoside phosphothioates **3** from compounds **2** by alkylation in the presence of bases such as pyridine, triethylamine, DABCO, and *N*,*N*-diisopropylethylamine were unsuccessful. The reason for the failure of alkylation is not clear. However, it is possible owing to the lower nucleophilicity of 2,2,2-trifluoroethyl iodide.

The synthesis of the dinucleotides by the phosphite-triester method, which has been applied in DNA solid-phase synthesis, proceeded in two steps: the preparation of deoxyribonucleoside-3′-*O*-(*N*,*N*-di-*iso*-propylamino)phosphoramidites (**5**, **6**, and **7**) and their coupling reactions with 3′-*O*-protected deoxyri-

bonucleosides under the catalysis of tetrazole followed by oxidation with iodine solution, as outlined in Scheme 2.

The phosphitylating reagent (**8**) was prepared in a similar manner as described for chloro-*N,N*-diisopropylamino methoxyphosphine (15). Phosphorus trichloride was allowed to react with 1 equivalent of 2,2,2-trifluoroethanol at low temperature for 5 h. The crude product of the reaction contained unreacted phosphorus trichloride, 2,2,2-trifluoroethyl phosphodichloridite (**9**), di-2,2,2-trifluoroethyl phosphochloridite, and tri(2,2,2-trifluoroethoxy)phosphine, which could be detected by their ^{31}P NMR signals (δ 219.0, 180.8, 166.0, and 139.3, respectively). The desired product **9** was isolated from the mixture by two successive fractional distillations in a yield of 31%. The purity of the compound obtained was proven by its ^{31}P NMR spectrum, in which only one signal at δ 180.8 was observed. The compound **8** was then prepared by the reaction of **9** with 2 equivalents of diisopropylamine in a solution of dichloromethane at low temperature in a yield of 70%. This reagent is extremely sensitive to moisture and air, but can be stored at −30°C for ex-tended periods (at least 2 months) under an argon atmosphere.

The 5′-protected nucleosides (**10**, **11**, and **12**) were prepared by reported methods (15). The syntheses of **5**, **6**, and **7** from **10**, **11**, and **12** with phosphitylating agent **8**, according to the procedure for their methyl analogues described by McBride and Caruthers (16), proceeded normally with yields of 94, 87, and 80%, respectively. Each of the products was an approximately 1:1 mixture of the *S*p and *R*p diastereomers, as indicated by ^{31}P NMR and ^{19}F NMR analyses.

Compounds **5** and **7** were initially used to couple directly to unprotected thymidine under the catalysis of tetrazole. After treatment with the oxidizing reagent *tert*-butyl hydrogen peroxide, dinucleotides **13** and **14** were obtained in yields of 42 and 31%, respectively. To improve the yield, we considered that protection on the 3′-hydroxy group in the deoxyribonucleoside might be beneficial. *tert*-Butyldimethylsilyl was the group of choice as the blocking functionality in this case. Compounds **15**, **16**, and **17** (17) were synthesized from **10**, **11**, and **12** by silylation with *tert*-butyldimethylsilyl chloride under the catalytic action of imidazole, followed by treatment with zinc bromide in dichloromethane to remove the 5′-dimethoxytrityl group (15). The coupling reaction of **5** and **17** (1:1 equiv.) with tetrazole as a catalyst was carried out at room temperature in acetonitrile for 4 h. The resulting dinucleoside phosphite triester was oxidized without isolation by a 0.1 M solution of iodine in a mixture of tetrahydrofuran, 2,6-lutidine, and water (40:10:1 by volume). The desired product **18** was obtained in 91% yield as a 1:1 mixture of diastereomers. By following a similar procedure, dinucleotides **19**, **20**, **21**, and **22** were also successfully prepared from appropriate nucleosides in good yields (85, 77, 93, and 77%, respectively). Removal of the silyl protecting group in each of the dinucleosides was achieved by treatment of the silyl ethers **18**, **19**, **20**, and **21** with tetrabutylammonium fluoride in tetrahydrofuran, affording compounds **25**, **13**, **23**, and **24**, respectively, in good yields.

The separations of the diastereomers, however, proved to be difficult. In the TLC analysis for these dinucleotides, only two of the compounds, **13** and **20**, showed detectable differences in R_f values between the diastereomers when the TLC plates were developed by a mixture of acetic acid and ethyl acetate (4:96, v/v). Therefore, the diastereomeric mixtures of **13** and **20** were separated by flash chromatography on silica gel eluted with the same solvent system to afford fast-moving diastereomers **13***a* and **20***a* and then the slowmoving **13***b* and **20***b* with good recovery yields (70–80 or 30–40% of each diastereomer). Other diastereomeric mixtures of dinucleotides, such as **14**, **19**, **22**, **24**, and **25**, were partially separated by flash chromatography on silica gel eluted with a gradually increasing proportion of methanol in chloroform solution. The optimum concentrations of

AA	**22**	0.5–0.75% B	−2.20/−2.44	$CDCl_3$
TC	**24**	2–4.5% B	−1.34/−1.37	Py-d_5
TA	**25**	2–4.5% B	−1.67/−1.78	Py-d_5

NOTE: Solvent B, methanol in chloroform; solvent C, 4% acetic acid in ethyl acetate.

methanol for separation of the individual diastereomeric mixtures, as well as ^{31}P NMR data of the separated diastereomers, are listed in Table 1. The separations of each pair of diastereomers were followed by ^{31}P NMR analysis. As an example, the ^{31}P NMR spectra of separated diastereomers **22***a* and **22***b* are shown in Fig. 2. Each diastereomer in each pair showed very similar ^{1}H NMR spectra. The largest differences in chemical shift were usually observed for the base aromatic protons as shown in Fig. 3.

Potter and co-workers (18–20) have examined ^{31}P NMR spectra for a variety of dinucleoside methyl phosphotriesters of known configuration, and in all cases it was observed that the *S*p isomer resonates at lower field than the *R*p isomer. Similarly, Summers et al. (21) and Weinfeld et al. (7) found the signal from the *S*p isomer of ethylated internucleotide phosphate at a lower field than the equivalent signal from the *R*p isomer. Although dinucleoside 2,2,2-trifluoroethyl phosphotriesters have not been reported hitherto, ^{31}P NMR is our method of

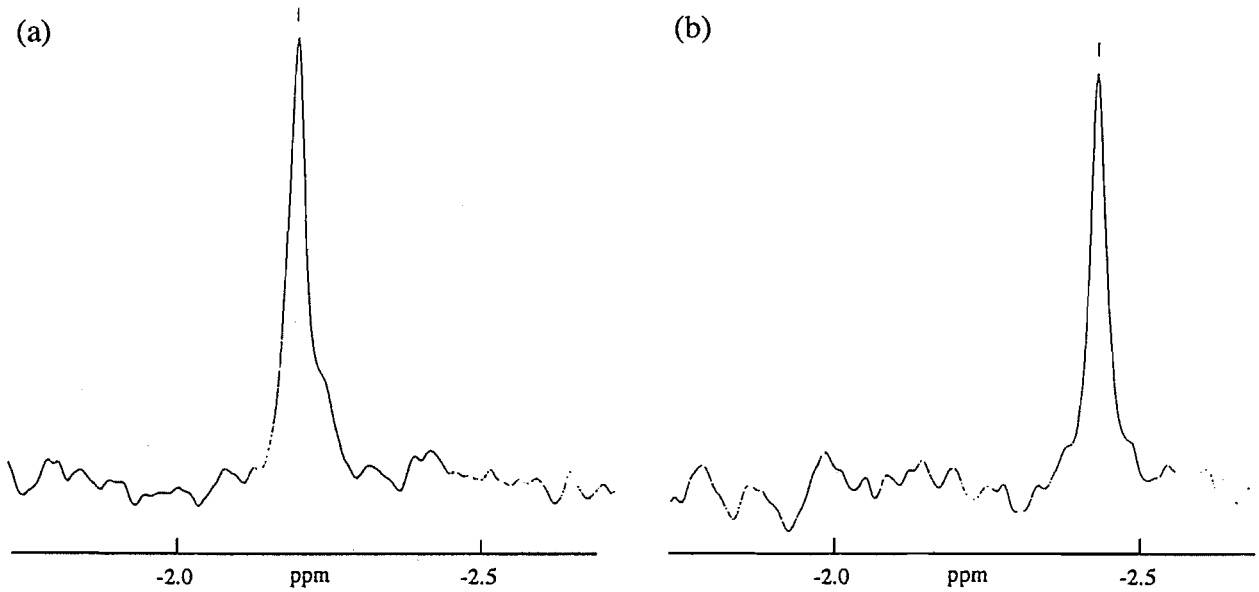

FIG. 2. ^{31}P NMR spectra of separated diastereomers **22***a* (*a*) and **22***b* (*b*).

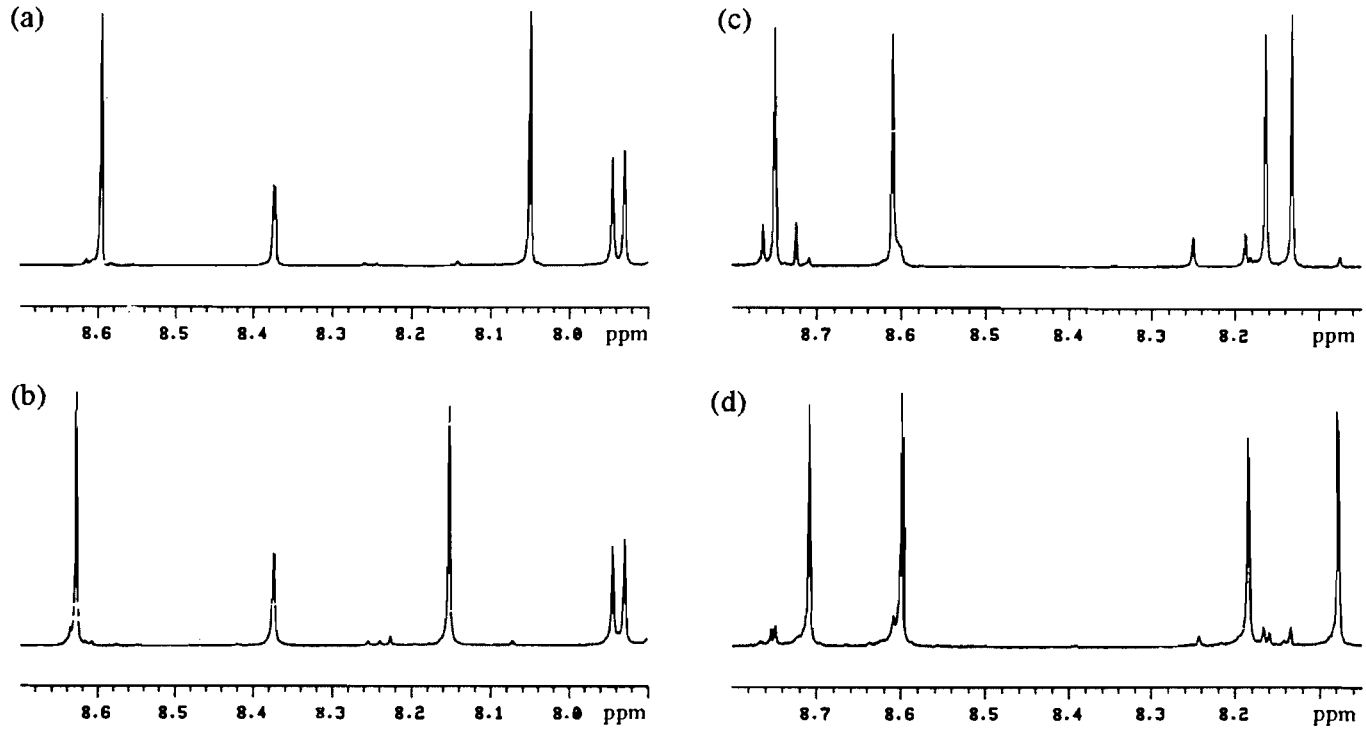

FIG. 3. Comparison of the ^1H NMR spectra of the base aromatic protons of **20***a* (*a*) and **20***b* (*b*) in $CDCl_3$–Py-d_5 (5:1), and **22***a* (*c*) and **22***b* (*d*) in $CDCl_3$.

choice for an initial examination of the absolute configuration about the phosphorus chiral centre. Considering that the weighting order of the four groups about the phosphorus atom in dinucleoside 2,2,2-trifluoroethyl phosphotriesters is different from that in the methyl or ethyl analogues, the faster moving isomers, from which the ^{31}P signal appears at lower field, are tentatively assigned as *R*p isomers and the slower moving isomers are assigned as *S*p. Studies directed towards a more definitive assignment of phosphorus configuration and towards the incorporation of diastereomeric *O*-(2,2,2-trifluoroethyl)-3′,5′-dinucleoside phosphates into specific antisense probes for MRI experiments are ongoing and will be reported in due course.

Experimental

General methods

NMR spectra were recorded on Bruker WH-200 or WH-400 spectrometers. ^1H, ^{19}F, and ^{31}P spectra were referenced to internal tetramethylsilane, external 50% trichlorofluoromethane in deuterium chloroform, and external 85% phosphoric acid in deuterium oxide, respectively. High-resolution mass spectra (HREIMS) and fast-atom bombardment mass spectra (FABMS) were recorded using A.E.I. model MS50 or MS9 mass spectrometers.

Acetonitrile and dichloromethane were distilled from phosphorus pentoxide, chloroform from anhydrous sodium carbonate, and pyridine from potassium hydroxide, toluene-4-sulfonyl chloride, or calcium hydride. Flash chromatography was performed with silica gel, 230–400 mesh ASTM. Merck silica gel plates (60 F_{254}) were used for analytical TLC, and the spots were examined with UV light and 1 N hydrochloric acid spray. Solvent systems for TLC development were as follows: A, Et_3N–EtOAc–CH_2Cl_2 (10:45:45); B, CH_3OH–$CHCl_3$ (1:9); C, AcOH–EtOAc (4:96). The concentrations of all solvent systems were determined by volume.

*2,2,2-Trifluoroethyl phosphodichloridite (**9**)*

2,2,2-Trifluoroethanol (97.3 g, 70 mL, 0.97 mol) contained in a pressure-equalizing dropping funnel was added dropwise over 2 h into magnetically stirred phosphorus trichloride (136.9 g, 87 mL, 1.00 mol) at −20°C, contained in a 250-mL three-necked flask vented via an air condenser equipped with a calcium chloride drying tube. During the addition, the temperature of the Dry Ice – acetone bath was maintained between −20 and −15°C. After the addition was completed, the temperature was allowed to increase to −5°C and maintained for 4 h. Then the bath was removed, and the mixture was allowed to warm up to room temperature with stirring (1 h) and set aside overnight in a fume hood to degas. The homogeneous liquid was fractionated by distillation at atmospheric pressure using a Vigreux column (300–400 mm long). The fraction boiling from 85 to 110°C was refractionated. The pure product (bp 94°C/700 Torr, 64 g, 0.30 mol) was obtained in 31% yield. ^{1}H NMR ($CDCl_3$) δ: 4.45 (dq, J = 8, 7.5 Hz); ^{31}P NMR ($CDCl_3$) δ: 180.84.

*Chloro-*N,N*-diisopropylamino-(2,2,2-trifluoroethoxy)phosphine (**8**)*

Under an argon atmosphere, a solution of diisopropylamine (17.83 g, 0.176 mol) in dichloromethane (40 mL), contained in a 100-mL addition funnel equipped with a calcium chloride drying tube, was added to a magnetically stirred solution of **9** (17.74 g, 0.088 mol) in dichloromethane (50 mL) in a 250-mL three-necked flask at −20°C. During the addition, the temperature of the Dry Ice – acetone bath was maintained between −20 and −10°C. Then the mixture was allowed to warm up slowly to room temperature over 3 h. The white precipitate of diisopropylamine hydrochloride was removed rapidly by vacuum filtration. The filtrate was concentrated by distillation at atmospheric pressure. The residue was fractionated under reduced pressure and the product (**8**, bp 73°C/11 Torr, 16.35 g, 0.0616 mol) was obtained in 70% yield. ^{1}H NMR ($CDCl_3$) δ: 4.04 (dq, 2H, J = 8, 8 Hz, CH_2), 3.74 (dh, 2H, J = 12, 7 Hz, CH), 1.5 (m, 12H, CH_3); ^{31}P NMR ($CDCl_3$) δ: 180.00; ^{19}F NMR ($CDCl_3$) δ: −75.25 (dq, J = 7, 8 Hz); HREIMS *m/e*: 267.0576, 265.0608 ($C_{H816}{}^{37}ClF_3NOP$ and $C_{H816}{}^{35}ClF_3NOP$, 5.19 and 11.41).

*General procedure for preparation of deoxyribonucleoside-3′-*O*-(*N,N*-diisopropylamino)-(2,2,2-trifluoroethyl)phosphoramidites*

Under an argon atmosphere, phosphitylating reagent **8** (1.65 mL, 1.99 g, 7.5 mmol) was injected over 10 s into a magnetically stirred solution of 5′-dimethoxytrityldeoxyribonucleoside **10**, **11**, or **12** (5.0 mmol) and diisopropylethylamine (2.58 g, 2.91 mL, 20.0 mmol) in dichloromethane (15 mL) at room temperature. The mixture was stirred for 20 min, ethanol (0.5 mL) was then added, and the mixture was stirred for 5 min to quench excess phosphitylating reagent. The reaction mixture was transferred to a 250-mL separatory funnel, diluted with a mixture of triethylamine and ethyl acetate (1:20, 100 mL), and washed with 10% aqueous sodium carbonate (2 × 60 mL) and then with saturated aqueous sodium chloride (60 mL). The organic phase was dried over anhydrous sodium sulfate, filtered, and evaporated to a foam under reduced pressure. The crude product was purified by flash chromatography using a mixture of triethylamine, ethyl acetate, dichloromethane, and petroleum ether in the ratio of 1:10:10:20 as eluent. The desired product was obtained in the yield of 80–95%.

*(R*p*,S*p*)-5′-*O*-(4,4′-Dimethoxytrityl)thymidine-3′-*O*-(*N,N*-diisopropylamino)-(2,2,2-trifluoroethyl)phosphoramidites (**5**)*

From **10** (5.0 mmol), **5** (3.64 g, 4.70 mmol) was isolated in 94% yield. TLC (silica gel, solvent A) R_f 0.80; ^{1}H NMR ($CDCl_3$) δ: 8.10 (bs, 1H, NH), 7.67 and 7.58 (s, 1H, H6), 7.4–7.2 (m, 9H, ArH), 6.83 (d, 4H, J = 8 Hz, ArH), 6.40 (m, 1H, H1′), 4.66 (m, 1H, H3′), 4.20 and 4.14 (m, 1H, H4′), 3.98 (m, 2H, CF_3CH_2), 3.80 (s, 6H, CH_3O), 3.60 (m, 2H, $CH(CH_3)_2$), 3.50 and 3.33 (m, 1H each, H5′ and H5″), 2.50 and 2.33 (m, 2H, H2′ and H2″), 1.40 and 1.42 (s, 3H, 5-CH_3), 1.20 (m, 12H, $CH(CH_3)_2$); ^{31}P NMR ($CDCl_3$) δ: 152.89 and 152.62 (1:1, q, J = 6 Hz); ^{19}F NMR ($CDCl_3$) δ: −75.10 and −75.28 (1:1, dt, J = 6, 9 Hz); FABMS *m/e*: 774 ($M + H^+$).

*(R*p*,S*p*)-N^4-Benzoyl-5′-(4,4′-dimethoxytrityl)-2′-deoxycytidine-3′-*O*-(N,N-diisopropylamino)-(2,2,2-trifluoroethyl)phosphoramidites (**6**)*

From **11** (5.0 mmol), **6** (3.75 g, 4.35 mmol) was isolated in 87% yield. TLC (silica gel, solvent A) R_f 0.75; ^{1}H NMR ($CDCl_3$) δ: 9.10 (bs, 1H, NH), 8.35 and 8.30 (d, 1H, J = 7 Hz, H6), 7.90 (d, 2H, J = 8 Hz, BzH), 7.62 (t, 1H, J = 8 Hz, BzH), 7.52 (t, 2H, J = 8 Hz, BzH), 7.42 (d, 1H, J = 7 Hz, H5), 7.3 (m, 9H, ArH), 6.88 (d, 4H, J = 8 Hz, ArH), 6.32 and 6.30 (dd, 1H, J = 6, 6 Hz, H1′), 4.66 (m, 1H, H3′), 4.28 and 4.24 (m, 1H, H4′), 3.97 and 3.87 (ddq, 1H each, J = 12, 8, 8 Hz, CF_3CH_2), 3.81 (s, 6H, CH_3O), 3.63 (m, 2H, $CH(CH_3)_2$), 3.50 and 3.43 (m, 1H each, H5′ and H5″), 2.80 and 2.33 (m, 2H, H2′ and H2″), 1.20 (m, 12H, $CH(CH_3)_2$); ^{31}P NMR ($CDCl_3$) δ: 153.07 and 152.66 (1:1, q, J = 6 Hz); ^{19}F NMR ($CDCl_3$) δ: −75.05 and −75.04 (1:1, dt, J = 6, 9 Hz); FABMS *m/e*: 863 ($M + H^+$).

*(R*p*,S*p*)-N^6-Benzoyl-5′-(4,4′-dimethoxytrityl)-2′-deoxyadenosine-3′-*O*-(N,N-diisopropylamino)-(2,2,2-trifluoroethyl)-phosphoramidites (**7**)*

From **12** (5.0 mmol), **7** (4.0 mmol) was isolated in 80% yield. TLC (silica gel, solvent A) R_f 0.80; ^{1}H NMR ($CDCl_3$) δ: 9.10 (bs, 1H, NH), 8.70 (s, 1H, H2), 8.20 and 8.15 (s, 1H, H8), 8.00 (d, 2H, J = 8 Hz, BzH), 7.65 (t, 1H, J = 8 Hz, BzH), 7.50 (t, 2H, J = 8 Hz, BzH), 7.4–7.2 (m, 9H, ArH), 6.75 (d, 4H, J = 8 Hz, ArH), 6.48 (m, 1H, H1′), 4.77 (m, 1H, H3′), 4.28 and 4.32 (m, 1H, H4′), 3.82 and 3.80 (dq, 1H each, J = 9, 9 Hz, CF_3CH_2), 3.74 (s, 6H, CH_3O), 3.60 (m, 2H, $CH(CH_3)_2$), 3.40 and 3.31 (m, 1H each, H5′ and H5″), 2.92 and 2.66 (m, 2H, H2′ and H2″), 1.20 (m, 12 H, $CH(CH_3)_2$); ^{31}P NMR ($CDCl_3$) δ: 152.90 and 152.70 (1:1, q, J = 6 Hz); ^{19}F NMR ($CDCl_3$) δ: −75.07 and −75.08 (1:1, dt, J = 6, 9 Hz); FABMS *m/e*: 909 and 807 ($M + Na^+$ and $M + H^+$).

*(R*p*,S*p*)-5′-*O*-(4,4′-Dimethoxytrityl)thymidylyl-3′,5′-N^6-benzoyl-3′-*O*-[(1,1-dimethylethyl)dimethylsilyl]-2′-deoxyadenosine (2,2,2-trifluoroethyl)phosphates (**18**)*

Under an argon atmosphere, phosphoramidite **5** (1.70 g, 2.2 mmol) and tetrazole (0.28 g, 4.06 mmol) were added to a magnetically stirred solution of **17** (0.938 g, 2.00 mmol) in acetonitrile (50 mL). The mixture was stirred at room temperature for 4 h and then 0.10 M iodine solution in a mixture of tetrahydrofuran, 2,6-lutidine, and water (40:10:1 by volume, 22 mL) was added. The mixture was stirred for 10 min and then transferred to a 250-mL separatory funnel and diluted with ethyl acetate (100 mL). The liquid was washed with saturated aqueous sodium bicarbonate (2 × 60 mL) and then with saturated aqueous sodium chloride (60 mL). The aqueous phases were extracted with ethyl acetate (2 × 50 mL). The organic phases were combined, dried over anhydrous sodium sulfate, filtered, and concentrated under reduced pressure to a foam (2.76 g). The crude residue was subjected to flash chromatography with 3% solution of methanol in chloroform as eluent, giving dinucleotides **18** as a 1:1 mixture of two diastereomers (2.11 g, 1.82 mmol, 91% yield). TLC (silica gel, solvent B) R_f 0.52; ^{1}H NMR ($CDCl_3$) δ: 9.10 (bs, 1H, NH), 8.75 and 8.44 (m, 1H each, H2 and H8), 8.22 and 8.20 (s, 1H, H6), 8.00 (m, 2H, BzH), 7.60 (m, 1H, BzH), 7.50 (m, 2H, BzH), 7.36–7.20 (m, 9H, ArH), 6.82 (m, 4H, ArH), 6.52 (dd, 0.5H, H1′), 6.45 and 6.43 (m, 1.5H, H1′), 5.12 (m, 1H, H3′), 4.70 (m, 1H, H3′), 4.4–4.1 (m, 6H, H4′, H4′, CF_3CH_2, H5′, and H5″), 3.77 (s, 6 H, CH_3O), 3.47 and 3.33 (m, 1H each, H5′ and H5″), 2.91, 2.57, 2.49, and 2.38 (m, 1H each, H2′ and H2″), 1.37 and 1.35 (s, 3H, 5-CH_3), 0.91 and 0.92 (s, 9H, $C(CH_3)_3$), 0.12 (s, 6H,

For personal use only.

$Si(CH_3)_2$); ^{31}P NMR ($CDCl_3$) δ: −1.90 and −2.42 (1:1); ^{19}F NMR ($CDCl_3$) δ: −75.27 and −75.37 (1:1, t, J = 8 Hz); FABMS *m/e*: 1180 and 1158 (M + Na^+ and M + H^+).

*(Rp,Sp)-5′-O-(4,4′-Dimethoxytrityl)thymidylyl-3′,5′-N^6-benzoyl-2′-deoxyadenosine (2,2,2-trifluoroethyl)phosphates (**25***a* and **25***b*)*

To a solution of **18** (310 mg, 0.272 mmol) in tetrahydrofuran (5 mL) was added 1 M tetrabutylammonium fluoride solution in tetrahydrofuran (containing 5% water, 1 mL). The mixture was stirred at room temperature for 20 min and then concentrated under reduced pressure. The residue was subjected to flash chromatography on silica gel with 0–6% methanol in chloroform. Products **25***a* and **25***b* (260 mg, 0.249 mmol) were obtained in 92% yield as a 1:1 mixture of two diastereomers: ^{31}P NMR (Py-d_5) δ: −1.67 and −1.78; FABMS *m/e*: 1066 and 1044 (M + Na^+ and M + H^+). The isomers were partially separated by further flash chromatography on silica gel, eluted with 2–4.5% methanol in chloroform. The percentage of methanol was increased at the rate of 0.25%/200 mL. With TLC analysis, compounds **25***a* and **25***b* were distributed in 30 of 60 eluted fractions. The first 5 fractions afforded 90% pure isomer **25***a* (25 mg). TLC (silica gel, solvent B) R_f 0.30; ^1H NMR (Py-d_5) δ: 13.3 and 12.3 (bs, 1H each, NH), 8.97 and 8.89 (s, 1H each, H2 and H8), 8.54 (s, 1H, H6), 8.28 (d, 2H, BzH), 7.68 (m, 3H, BzH), 7.55–7.36 (m, 8H, ArH), 7.27 (t, 1H, J = 8 Hz, ArH), 7.00 (d, 4H, J = 8 Hz, ArH), 6.90–6.80 (m, 2H, H1′), 5.60 (m, 1H, H3′), 5.10 (m, 1H, H3′), 4.82 (m, 2H, CF_3CH_2), 4.70 (m, 2H, H5′ and H5″), 4.64 (m, 1H, H4′), 4.56 (m, 1H, H4′), 3.67 (s, 6H, CH_3O), 3.63 (m, 2H, H5′ and H5″), 3.17 (ddd, 1H, J = 13, 6.5, 6.5 Hz, H2′ or H2″), 2.87 (m, 1H, H2′ or H2″), 2.75 (m, 2H, H2′ and H2″), 1.70 (s, 3H, 5-CH_3); ^{31}P NMR (Py-d_5) δ: −1.67; ^{19}F NMR (Py-d_5) δ: −75.01 (t, J = 8 Hz). The last 5 fractions gave the other isomer (**25***b*, 92% pure, 20 mg). TLC (silica gel, solvent B) R_f 0.30; ^1H NMR (Py-d_5) δ: 13.3 and 12.3 (bs, 1H each, NH), 8.96 and 8.84 (s, 1H each, H2 and H8), 8.54 (s, 1H, H6), 8.30 (d, 2H, BzH), 7.68 (m, 3H, BzH), 7.55–7.36 (m, 8H, ArH), 7.27 (t, 1H, J = 8 Hz, ArH), 7.00 (d, 4H, J = 8 Hz, ArH), 6.90–6.80 (m, 2H, H1′), 5.60 (m, 1H, H3′), 5.10 (m, 1H, H3′), 4.79 (m, 2H, CF_3CH_2), 4.72 (m, 2H, H5′ and H5″), 4.65 (m, 1H, H4′), 4.54 (m, 1H, H4′), 3.67 (s, 6H, CH_3O), 3.63 (m, 2H, H5′ and H5″), 3.19 (ddd, 1H, J = 13, 6.5, 6.5 Hz, H2′), 2.87 (m, 1H, H2′ or H2″), 2.75 (m, 2H, H2′ or H2″), 1.70 (s, 3H, 5-CH_3); ^{31}P NMR (Py-d_5) δ: −1.78; ^{19}F NMR (Py-d_5) δ: −75.00 (t, J = 8 Hz). From other fractions, the diastereomeric mixture of **25***a* and **25***b* (182 mg) was recovered.

*(Rp,Sp)-5′-O-(4,4′-Dimethoxytrityl)thymidylyl-3′,5′-3′-O-[(1,1-dimethylethyl)dimethylsilyl]thymidine 2,2,2-trifluoroethyl)-phosphates (**19**a and **19**b)*

Using a similar procedure as for **18**, from **5** (2.38 g, 3.08 mmol) and **15** (0.98 g, 2.75 mmol), **19** (2.31 g, 2.21 mmol, 80% yield) was obtained as a 1:1 mixture of two diastereomers, which were partially separated in the manner as described for **25***a* and **25***b* with 1–3% methanol in chloroform as eluent. Compound **19***a*: TLC (silica gel, solvent B) R_f 0.50; ^1H NMR ($CDCl_3$) δ: 9.10 (bs, 2H, NH), 7.50 (m, 1H, H6), 7.40–7.10 (m, 10H, H6 and ArH), 6.83 (d, 4H, J = 8 Hz, ArH), 6.18 (m, 2H, H1′), 5.15 (m, 1H, H3′), 4.4–4.1 (m, 5H, H3′, CF_3CH_2, H5′, and H5″), 3.95 (m, 2H, H4′), 3.75 (s, 6H, CH_3O), 3.52 and 3.40 (m, 1H each, H5′ and H5″), 2.60, 2.50, 2.40 and 2.20 (m, 1H each, H2′ and H2″), 1.85 and 1.45 (d, 3H each, J = 1 Hz, 5-CH_3), 0.90 (s, 9H, $C(CH_3)_3$), 0.05 (s, 6H, $Si(CH_3)_2$); ^{31}P NMR ($CDCl_3$) δ: −2.26; ^{19}F NMR ($CDCl_3$) δ: −75.24 (t, J = 8 Hz); FABMS *m/e*: 1067 (M + Na^+). Compound **19***b*: TLC (silica gel, solvent B) R_f 0.50; ^1H NMR ($CDCl_3$) δ: 9.10 (bs, 2H, NH), 7.50 (m, 1H, H6), 7.40–7.10 (m, 10H, H6 and ArH), 6.82 (d, 4H, J = 8 Hz, ArH), 6.43 (dd, 1H, J = 9, 5 Hz, H1′), 6.16 (t, 1H, J = 7 Hz, H1′), 5.15 (m, 1H, H3′), 4.4–4.1 (m, 5H, H3′, CF_3CH_2, H5′, and H5″), 3.95 (m, 2H, H4′), 3.75 (s, 6H, CH_3O), 3.52 and 3.35 (m, 1H each, H5′ and H5″), 2.60, 2.50, 2.40, and 2.20 (m, 1H each, H2′ and H2″), 1.85 and 1.40 (d, 3H each, J = 1 Hz, 5-CH_3), 0.90 (s, 9H, $C(CH_3)_3$), 0.05 (s, 6H, $Si(CH_3)_2$); ^{31}P NMR ($CDCl_3$) δ: −2.26; ^{19}F NMR ($CDCl_3$) δ: −75.24 (t, J = 8 Hz); FABMS *m/e*: 1067 (M + Na^+).

*(Rp,Sp)-5′-O-(4,4′-Dimethoxytrityl)thymidylyl-3′,5′-thymidine (2,2,2-trifluoroethyl)phosphates (**13**a and **13**b)*

Desilylation method

Using the desilylation procedure described for **18**, **19** (0.47 g, 0.45 mmol) gave an 85% yield of a 1:1 diastereomeric mixture of **13***a* and **13***b* (0.36 g, 0.38 mmol). The mixture was separated by flash chromatography on silica gel, eluted with 4% acetic acid in ethyl acetate, giving 18% of **13***a*, 13% of diastereomeric mixture, and 20% of **13***b*. Compound **13***a*: TLC (silica gel, solvent B) R_f 0.27 and TLC (silica gel, solvent C) R_f 0.29; ^1H NMR (Py-d_5) δ: 13.25 (bs, 2H, NH), 7.75–7.24 (m, 11H, H6 and ArH), 7.02 (d, 4H, J = 9 Hz, ArH), 6.83 (m, 2H, H1′), 5.70 (m, 1H, H3′), 4.92 (p, 2H, CF_3CH_2), 4.80 (m, 1H, H3′), 4.65 (m, 3H, H4′, H5′, and H5″), 4.45 (m, 1H, H4′), 3.75 (s, 6H, CH_3O), 3.67 (m, 2H, H5′ and H5″), 2.86 and 2.54 (m, 2H each, H2′ and H2″), 2.05 and 1.70 (d, 3H each, J = 1 Hz, 5-CH_3); ^{31}P NMR (Py-d_5) δ: −1.46; ^{19}F NMR (Py-d_5) δ: −74.99 (t, J = 8 Hz); FABMS *m/e*: 953 (M + Na^+). Compound **13***b*: TLC (silica gel, solvent B) R_f 0.27 and TLC (silica gel, solvent C) R_f 0.20; ^1H NMR (Py-d_5) δ: 13.2 (bs, 2H, NH), 7.7–7.2 (m, 11H, H6 and ArH), 7.00 (d, 4H, J = 9 Hz, ArH), 6.90–6.78 (m, 2H, H1′), 5.70 (m, 1H, H3′), 4.85 (m, 3H, H3′ and CF_3CH_2), 4.70–4.45 (m, 4H, H4′, H5′, and H5″), 3.7 (s, 6H, CH_3O), 3.67 (m, 2H, H5′ and H5″), 2.91 and 2.62 (m, 2H each, H2′ and H2″), 2.05 and 1.67 (d, 3H each, J = 1 Hz, 5-CH_3); ^{31}P NMR (Py-d_5) δ: −1.60; ^{19}F NMR (Py-d_5) δ: −74.98 (t, J = 8 Hz); FABMS *m/e*: 953 (M + Na^+).

Direct method

Thymidine (245 mg, 1.00 mmol) was dried by coevaporation with acetonitrile and pyridine (5:1, 2 × 5 mL) under reduced pressure. Under an argon atmosphere, the thymidine was dissolved in pyridine (3 mL) and a solution of **5** (512 mg, 0.661 mmol) in acetonitrile (10 mL), which was saturated with tetrazole, was added by syringe. The mixture was stirred at room temperature overnight. *tert*-Butyl hydrogen peroxide solution in 2,2,4-trimethylpentane (3 M, 0.33 mL) was added. After stirring for 10 min, the mixture was poured into aqueous saturated sodium chloride (30 mL) and extracted with chloroform (2 × 40 mL). The extracts were combined, dried over anhydrous sodium sulfate, filtered, and concentrated under reduced pressure. The residue was subjected to flash chromatography on silica gel. Elution with 6% methanol in chloroform gave products **13***a* and **13***b* as a 1:1 diastereomeric mixture (258 mg, 0.278 mmol, 42% yield).

*(Rp,Sp)-N^6-Benzoyl-5′-(4,4′-dimethoxytrityl)-2′-deoxyadenoylyl-3′,5′-thymidine (2,2,2-trifluoroethyl)phosphates (**14**a and **14**b)*

Using a similar procedure as described for **13** (direct method) from **7** (886 mg, 1.0 mmol) and thymidine (290 mg, 1.2 mmol), **14** (318 mg, 0.31 mmol, 31% yield) was obtained as a 1:1 mixture of diastereomers. The mixture was partially separated in the manner as described for **25**, giving **14***a* and **14***b*. Compound **14***a*: TLC (silica gel, solvent B) R_f 0.32; ^1H NMR (CD_3OD) δ: 13.3 and 10.3 (bs, 1H each, NH), 8.57 (s, 1H, H2), 8.46 (s, 1H, H8), 8.07 (d, 2H, J = 8 Hz, BzH), 7.65 (d, 1H, J = 8 Hz, BzH), 7.55 (t, 2H, J = 8 Hz, BzH), 7.42 (q, 1H, J = 1 Hz, H6), 7.37–7.12 (m, 7H, ArH), 6.78 (d, 4H, J = 8 Hz, ArH), 6.53 and 6.21 (t, 1H each, J = 6.5 Hz, H1′), 5.48 (m, 1H, H3′), 4.63 (dq, 2H, J = 8, 8 Hz, CF_3CH_2), 4.48–4.33 (m, 4H, H3′, H5′, H5″, and H4′), 4.05 (m, 1H, H4′), 3.73 (s, 6H, CH_3O), 3.40 (m, 2H, H5′ and H5″), 2.90–2.80 and 2.28–2.23 (m, 2H each, H2′ and H2″), 1.81 (s, 3H, 5-CH_3); ^{31}P NMR (CD_3OD) δ: −2.71; ^{19}F NMR (CD_3OD) δ: −76.88 (t, J = 8 Hz); FABMS *m/e*: 1066 (M + Na^+). Compound **14***b*: TLC (silica gel, solvent B) R_f 0.32; ^1H NMR (CD_3OD) δ: 13.3 and 10.3 (bs, 1H each, NH), 8.56 (s, 1H, H2), 8.43 (s, 1H, H8), 8.07 (d, 2H, J = 8 Hz, BzH), 7.65 (d, 1H, J = 8 Hz, BzH), 7.55 (t, 2H, J = 8 Hz, BzH), 7.47 (q, 1H, J = 1 Hz, H6), 7.37–7.12 (m, 7H, ArH), 6.75 (d, 4H, J = 8 Hz, ArH), 6.52 and 6.20 (t, 1H each, J = 6.5 Hz, H1′), 5.42 (m, 1H, H3′), 4.59 (dq, 2H, J = 8, 8 Hz, CF_3CH_2), 4.48–4.33 (m, 4H, H3′, H5′, H5″, and H4′), 4.05 (m, 1H, H4′), 3.73 (s, 6H, CH_3O), 3.40 (m, 2H, H5′ and H5″), 2.90–2.80 and 2.28–2.23 (m, 2H each, H2′ and H2″), 1.80 (s, 3H, 5-CH_3); ^{31}P NMR (CD_3OD) δ: −2.87; ^{19}F NMR (CD_3OD) δ: −76.85 (t, J = 8 Hz); FABMS *m/e*: 1066 (M + Na^+).

*(Rp,Sp)-N^4-Benzoyl-5′-(4,4′-dimethoxytrityl)-2′-deoxycytidylyl-3′,5′-N^6-benzoyl-3′-O-[(1,1dimethylethyl)dimethylsilyl]-2′-deoxyadenosine (2,2,2-trifluoroethyl)phosphates (**20**a and **20**b)*

Using a similar procedure as described for **18**, from **6** (2.62 g, 3.04 mmol) and **17** (1.23 g, 2.62 mmol), **20** (2.52 g, 2.02 mmol, 77% yield) was obtained as a 1:1 mixture of two diastereomers. The mixture (500 mg) was separated by flash chromatography on silica gel, eluted with 4% acetic acid in ethyl acetate, giving **20***a* (180 mg, 36%) and **20***b* (216 mg, 43%). Compound **20***a*: TLC (silica gel, solvent B) R_f 0.61 and TLC (silica gel, solvent C) R_f 0.32; ^{1}H NMR ($CDCl_3$) δ: 9.25 (bs, 1H, NH), 8.67 and 8.24 (s, 1H each, H2 and H8), 8.10 (d, 1H, J = 7.5 Hz, H6), 8.05 and 7.93 (dd, 2H each, J = 8, 1 Hz, BzH), 7.55 and 7.50 (td, 1H each, J = 8, 1 Hz, BzH), 7.45 and 7.42 (t, 2H each, BzH), 7.36–7.19 (m, 10H, ArH and H5), 6.95 (dd, 4H, J = 8, 1 Hz, ArH), 6.46 and 6.31 (t, 1H each, J = 7.5 Hz, H1′), 5.11 (m, 1H, H3′), 4.71 (ddd, 1H, J = 6, 4.5, 4.5 Hz, H3′), 4.43–4.24 and 4.16 (m, 6H, H4′, CF_3CH_2, H5′, and H5″), 3.72 (s, 6H, CH_3O), 3.44 (m, 2H, H5′ and H5″), 2.99–2.91 (m, 2H, H2′ and (or) H2″), 2.46 (ddd, 1H, J = 14, 5.5, 4.5 Hz, H2′ or H2″), 2.36 (m, 1H, H2′ or H2″), 0.93 (s, 9H, $C(CH_3)_3$), 0.15 (s, 6H, $Si(CH_3)_2$); ^{31}P NMR ($CDCl_3$) δ: −2.28; ^{19}F NMR ($CDCl_3$) δ: −75.23 (t, J = 8 Hz); FABMS *m/e*: 1269 (M + Na^+). Compound **20***b*: TLC (silica gel, solvent B) R_f 0.61 and TLC (silica gel, solvent C) R_f 0.22; ^{1}H NMR ($CDCl_3$) δ: 9.25 (bs, 1H, NH), 8.78 and 8.30 (s, 1H each, H2 and H8), 8.10 (d, 1H, J = 7.5 Hz, H6), 8.00 and 7.90 (dd, 2H each, J = 8, 1 Hz, BzH), 7.50 and 7.46 (td, 1H each, J = 8, 1 Hz, BzH), 7.40 and 7.36 (t, 2H each, BzH), 7.34–7.16 (m, 10H, ArH and H5), 6.81 (dd, 4H, J = 8, 1 Hz, ArH), 6.45 and 6.28 (t, 1H each, J = 7.5 Hz, H1′), 5.13 (m, 1H, H3′), 4.73 (ddd, 1H, J = 6, 4.5, 4.5 Hz, H3′), 4.39–4.18 and 4.16 (m, 6 H, H4′, CF_3CH_2, H5′, and H5″), 3.68 (s, 6H, CH_3O), 3.42 and 5.38 (dd, 1H each, J = 11, 3.5 Hz, H5′ and H5″), 2.96 (ddd, 1H, J = 13, 6.5, 6.5 Hz, H2′ or H2″), 2.91 (ddd, 1H, J = 14, 5.5, 2.5 Hz, H2′ or H2″), 2.43 (ddd, 1H, J = 14, 5.5, 4.5 Hz, H2′ or H2″), 2.32 (m, 1H, H2′ or H2″), 0.90 (s, 9H, $C(CH_3)_3$), 0.10 (s, 6H, $Si(CH_3)_2$); ^{31}P NMR ($CDCl_3$) δ: −2.35; ^{19}F NMR ($CDCl_3$) δ: −75.29 (t, J = 8 Hz); FABMS *m/e*: 1269 (M + Na^+).

*(Rp,Sp)-N^4-Benzoyl-5′-(4,4′-dimethoxytrityl)-2′-deoxycytidylyl-3′,5′-N^6-benzoyl-2′-deoxyadenosine (2,2,2-trifluoroethyl)phosphates (**23**a and **23**b)*

Using the desilylation procedure described for **18**, **20***a* (70 mg, 0.056 mmol) gave **23***a* (30 mg, 0.027 mmol, 48% yield). TLC (silica gel, solvent B) R_f 0.30 and TLC (silica gel, solvent C) R_f 0.35; ^{1}H NMR (Py-d_5) δ: 13.5 and 12.3 (bs, 1H each, NH), 8.71 and 8.52 (s, 1H each, H2 and H8), 8.09 (d, 1H, J = 7.5 Hz, H6), 8.05 and 7.94 (dd, 2H each, J = 8, 1 Hz, BzH), 7.41–7.03 (m, 16H, ArH and H5), 6.75 (dd, 4H, J = 8, 1 Hz, ArH), 6.50 and 6.30 (t, 1H each, J = 6.5 Hz, H1′), 5.27 (m, 1H, H3′), 4.87 (m, 1H, H3′), 4.55–4.35 (m, 6H, H4′, CF_3CH_2, H5′, and H5″), 3.49 (s, 6H, CH_3O), 3.41 (m, 2H, H5′ and H5″), 2.97 (ddd, 1H, J = 14, 6.5, 6 Hz, H2′ or H2″), 2.92 (ddd, 1H, J = 14, 6.5, 2.5 Hz, H2′ or H2″), 2.53 (ddd, 1H, J = 14, 6.5, 4.5 Hz, H2′ or H2″), 2.43 (ddd, 1H, J = 14, 6.5, 7 Hz, H2′ or H2″); ^{31}P NMR (Py-d_5) δ: −1.76; ^{19}F NMR (Py-d_5) δ: −75.39 (t, J = 8 Hz); FABMS *m/e*: 1155 (M + Na^+).

Using the desilylation procedure described for **18**, **20***b* (200 mg, 0.161 mmol) gave 47% yield of **23***b* (85 mg, 0.075 mmol). TLC (silica gel, solvent B) R_f 0.30 and TLC (silica gel, solvent C) R_f 0.35; ^{1}H NMR (Py-d_5) δ: 13.5 and 12.3 (bs, 1H each, NH), 8.73 and 8.57 (s, 1H each, H2 and H8), 8.09 (d, 1H, J = 7.5 Hz, H6), 8.05 and 7.94 (dd, 2H each, J = 8, 1 Hz, BzH), 7.41–7.03 (m, 16H, ArH and H5), 6.75 (dd, 4H, J = 8, 1 Hz, ArH), 6.60 and 6.39 (t, 1H each, J = 6.5 Hz, H1′), 5.27 (m, 1H, H3′), 4.87 (m, 1 H, H3′), 4.55–4.35 (m, 6H, H4′, CF_3CH_2, H5′, and H5″), 3.49 (s, 6H, CH_3O), 3.41 (m, 2H, H5′ and H5″), 2.97 (ddd, 1H, J = 14, 6.5, 6 Hz, H2′ or H2″), 2.92 (ddd, 1H, J = 14, 6.5, 2.5 Hz, H2′ or H2″), 2.53 (ddd, 1H, J = 14, 6.5, 4.5 Hz, H2′ or H2″), 2.43 (ddd, 1H, J = 14, 6.5, 7 Hz, H2′ or H2″); ^{31}P NMR (Py-d_5) δ: −1.86; ^{19}F NMR (Py-d_5) δ: −75.36 (t, J = 8 Hz); FABMS *m/e*: 1155 (M + Na^+).

*(Rp,Sp)-5′-O-(4,4′-Dimethoxytrityl)thymidylyl-3′,5′-N^4-benzoyl-3′-O-[(1,1-dimethylethyl)-dimethylsilyl]-2′-deoxycytidine (2,2,2-trifluoroethyl)phosphates (**21**a and **21**b)*

Using a similar procedure as described for **18**, from **5** (722 mg, 0.94 mmol) and **16** (380 mg, 0.85 mmol), **21** (900 mg, 0.794 mmol, 93% yield) was obtained as a 1:1 mixture of two diastereomers. TLC (silica gel, solvent B) R_f 0.57; ^{1}H NMR ($CDCl_3$) δ: 8.75 and 8.72 (bs, 1H, NH), 8.62 (m, 2H, NH and TH6), 8.03 and 7.99 (d, 1H, J = 8 Hz, C-H6), 7.82 and 7.89 (d, 1H, J = 8 Hz, H5), 7.86 (d, 2H, J = 8 Hz, BzH), 7.70 (t, 1H, J = 8 Hz, BzH), 7.61 (t, 2H, J = 8 Hz, BzH), 7.55 (m, 3H, ArH), 7.30 (m, 6H, ArH), 6.83 (m, 4H, ArH), 6.43 and 6.41 (t, 1H, J = 5.5 Hz, H1′), 6.21 (m, 1H, H1′), 5.16 (m, 1H, H3′), 4.50–1.40 (m, 7H, H3′, H4′, CF_3CH_2, H5′, and H5″), 3.78 (s, 6H, CH_3O), 3.54 and 3.39 (m, 2H, H5′ and H5″), 2.70–2.30 and 2.19 (m, 4H, H2′ and H2″), 1.42 and 1.41 (s, 3H, 5-CH_3), 0.88 and 0.89 (s, 9H, $C(CH_3)_3$), 0.08 and 0.07 (s, 6H, $Si(CH_3)_2$); ^{31}P NMR ($CDCl_3$) δ: −1.93 and −1.97 (1:1); ^{19}F NMR ($CDCl_3$) δ: −75.18 and −75.29 (1:1, t, J = 8 Hz); FABMS *m/e*: 1156 (M + Na^+).

*(Rp,Sp)-5′-O-(4,4′-Dimethoxytrityl)thymidylyl-3′,5′-N^4-benzoyl-2′-deoxycytidine (2,2,2-trifluoroethyl)phosphates (**24**a and **24**b)*

Using the desilylation procedure described for **18**, **21** (480 mg, 0.420 mmol) gave 79% yield of a 1:1 diastereomeric mixture (**24***a* and **24***b*, 340 mg, 0.334 mmol), which was partially separated in the same manner as described for **25**, giving **24***a* and **24***b*. Compound **24***a*: TLC (silica gel, solvent B) R_f 0.33; ^{1}H NMR (Py-d_5) δ: 13.3 and 12.3 (bs, 1H each, NH), 8.40 (d, 1H, J = 8 Hz, C-H6), 8.20 (s, 1H, T-H6), 8.20 (d, 2H, J = 8 Hz, BzH), 7.78 (d, 1H, J = 8 Hz, BzH), 7.73 (t, 2H, J = 8 Hz, BzH), 7.72 (d, 1H, J = 8 Hz, H5), 7.61 (t, 2H, J = 8 Hz, BzH), 7.56–7.30 (m, 9H, ArH), 7.01 (d, 4H, J = 8 Hz, ArH), 6.90 and 6.80 (t, 1H each, J = 6 Hz, H1′), 5.72 (m, 1H, H3′), 4.98 (m, 2H, CF_3CH_2), 4.83 (m, 1H, H3′), 4.72 (m, 2H, H5′ and H5″), 4.68 and 4.60 (m, 1H each, H4′), 3.69 (s, 6H, CH_3O), 3.62 (m, 2H, H5′ and H5″), 2.98–2.80 (m, 3H, H2′ and H2″), 2.56 (ddd, 1H, J = 14, 7, 6 Hz, H2′ or H2″), 1.70 (s, 3H, 5-CH_3); ^{31}P NMR (Py-d_5) δ: −1.34; ^{19}F NMR (Py-d_5) δ: −74.87 (t, J = 8 Hz); FABMS *m/e*: 1042 (M + Na^+). Compound **24***b*: TLC (silica gel, solvent B) R_f 0.33; ^{1}H NMR (Py-d_5) δ: 13.3 and 12.3 (bs, 1H each, NH), 8.47 (d, 1H, J = 8 Hz, C-H6), 8.20 (s, 1H, T-H6), 8.20 (d, 2H, J = 8 Hz, BzH), 7.78 (d, 1H, J = 8 Hz, BzH), 7.73 (t, 2H, J = 8 Hz, BzH), 7.72 (d, 1H, J = 8 Hz, H5), 7.61 (t, 2H, J = 8 Hz, BzH), 7.56–7.30 (m, 9H, ArH), 7.01 (d, 4H, J = 8 Hz, ArH), 6.90 and 6.80 (t, 1H each, J = 6 Hz, H1′), 5.72 (m, 1H, H3′), 4.98 (m, 2H, CF_3CH_2), 4.84 (m, 1H, H3′), 4.76 (m, 2H, H5′ and H5″), 4.63 (m, 2H, H4′), 3.69 (s, 6H, CH_3O), 3.62 (m, 2H, H5′ and H5″), 2.98–2.80 (m, 3H, H2′ and H2″), 2.59 (ddd, 1H, J = 14, 7, 6 Hz, H2′ or H2″), 1.70 (s, 3H, 5-CH_3); ^{31}P NMR (Py-d_5) δ: −1.37; ^{19}F NMR (Py-d_5) δ: −74.88 (t, J = 8 Hz); FABMS *m/e*: 1042 (M + Na^+).

*(Rp,Sp)-N^6-Benzoyl-5′-(4,4′-dimethoxytrityl)-2′-deoxyadenoylyl-3′,5′-N^6-benzoyl-3′-O-[(1,1-dimethylethyl)dimethylsilyl]-2′-deoxyadenosine (2,2,2-trifluoroethyl)phosphates (**22**a and **22**b)*

Using a similar procedure as described for **18**, from **7** (443 mg, 0.50 mmol) and **17** (233 mg, 0.50 mmol), **22** (479 mg, 0.377 mmol, 77% yield) was obtained as a 1:1 mixture of two diastereomers, which was partially separated in a similar manner as used for **25** with 0.5–0.75% methanol in chloroform as eluent, giving **22***a* and **22***b*. Compound **22***a*: TLC (silica gel, solvent B) R_f 0.43; ^{1}H NMR ($CDCl_3$) δ: 13.3 and 12.3 (bs, 2H, NH), 8.73, 8.60, 8.17 and 8.13 (s, 1H each, H2 and H8), 8.00 and 7.95 (d, 2H each, J = 8 Hz, BzH), 7.68 (t, 1H, J = 8 Hz, BzH), 7.60–7.13 (m, 14H, ArH), 6.75 (d, 4H, J = 8 Hz, ArH), 6.45 (dd, 1H, J = 9, 6 Hz, H1′), 6.43 (t, 1H, J = 6.5 Hz, H1′), 5.24 (m, 1H, H3′), 4.71 (m, 1H, H3′), 4.42–4.20 and 4.17 (m, 6H, H4′, CF_3CH_2, H5′, and H5″), 3.72 (s, 6H, CH_3O), 3.40 and 3.36 (dd, 1H each, J = 10, 4 Hz, H5′ and H5″), 3.12, 2.92, 2.48, and 2.73 (m, 1H each, H2′ and H2″), 0.92 (s, 9H, $C(CH_3)_3$), 0.12 (s, 6H, $Si(CH_3)_2$); ^{31}P NMR ($CDCl_3$) δ: −2.20; ^{19}F NMR ($CDCl_3$) δ: −75.23 (t, J = 8 Hz); FABMS *m/z*: 1293 (M + Na^+). Compound **22***b*: TLC (silica gel, solvent B) R_f 0.43; ^{1}H NMR ($CDCl_3$) δ: 13.3 and 12.3 (bs, 2H, NH), 8.70, 8.59, 8.19 and 8.09 (s, 1H each, H2 and H8), 8.00 and 7.95 (d, 2H each, J = 8 Hz, BzH), 7.68 (t, 1H, J = 8 Hz, BzH), 7.60–7.13 (m, 14H, ArH), 6.75 (d, 4H, J = 8 Hz, ArH), 6.41 (dd, 1H, J = 9, 6 Hz, H1′), 6.44 (t, 1H, J = 6.5 Hz, H1′), 5.24 (m, 1H, H3′), 4.71 (m, 1H, H3′), 4.42–4.20 and 4.17 (m, 6H, H4′, CF_3CH_2, H5′, and H5″), 3.74 (s, 6H, CH_3O), 3.40 and 3.36 (dd,

1H each, J = 10, 4 Hz, H5′ and H5″), 3.06, 2.95, 2.48, and 2.48 (m, 1H each, H2′ and H2″), 0.92 (s, 9H, $C(CH_3)_3$), 0.12 (s, 6H, $Si(CH_3)_2$); ^{31}P NMR ($CDCl_3$) δ: −2.44; ^{19}F NMR ($CDCl_3$) δ: −75.29 (t, J = 8 Hz); FABMS *m/e*: 1293 ($M + Na^+$).

The photochemistry of 8-methyl-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene

CHRISTOPHER OWEN BENDER,[1] DONALD LAVERNE BENGTSON, DOUGLAS DOLMAN, AND RYAN TODD MCKAY

Department of Chemistry, University of Lethbridge, Lethbridge, AB T1K 3M4, Canada

Received November 26, 1993

CHRISTOPHER OWEN BENDER, DONALD LAVERNE BENGTSON, DOUGLAS DOLMAN, and RYAN TODD MCKAY. Can. J. Chem. **72**, 1556 (1994).

8-Methyl-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (**20**) was prepared by Shapiro reaction from 8-methyl-2,3-benzobicyclo[4.2.0]octa-2,7-dien-4-one (**19**). Triene **20** was found to be thermally and photochemically reactive. 6-Methylbenzocyclooctatetraene (i.e., 6-methyl COT **21**) was the unique product formed when solutions of **20** were heated at 150°C for 10 h. The direct irradiation of triene **20** gave 6-methylbenzosemibullvalene (i.e., SB **22**, 46%, Φ = 0.073), 5-methyl-7,8-benzotetracyclo[3.3.0^{2,4}.0^{3,6}]oct-7-ene (**23**, 35%, Φ = 0.062), 6-methyl COT **21** (4%, Φ = 0.008), 7-methyl COT **24** (1%, Φ = 0.002), and naphthalene (3%, Φ = 0.006). Sensitized irradiations of **20** gave SB **22** (45%, Φ = 0.022), 6-methyl COT **21** (2%, Φ = 0.001), and naphthalene (4%, Φ = 0.002). Studies with deuterium-labelled triene (**20***a*) indicated that the semibullvalene **22** was produced from both S_1 and T_1 excited states of **20** by Zimmerman di-π-methane rearrangement.

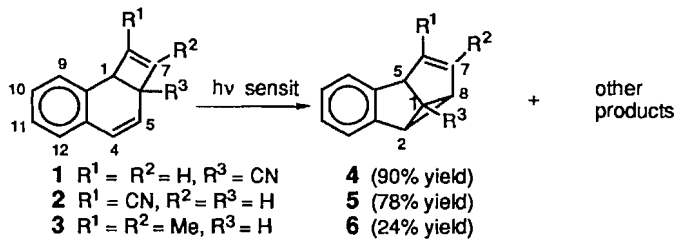
CHRISTOPHER OWEN BENDER, DONALD LAVERNE BENGTSON, DOUGLAS DOLMAN et RYAN TODD MCKAY. Can. J. Chem. **72**, 1556 (1994).

On a préparé le 8-méthyl-2,3-benzobicyclo[4.2.0]octa-2,4,7-triène (**20**) par la réaction de Shapiro effectuée à l'aide de la 8-méthyl-2,3-benzobicyclo[4.2.0]octa-2,7-dièn-4-one (**19**). On a trouvé que le triène **20** est réactif tant thermiquement que photochimiquement. Le 6-méthylbenzocyclooctatétraène (soit, le 6-méthyl COT, **21**) est l'unique produit formé lorsqu'on chauffe des solutions du composé **20** à 150°C pendant 10 h. L'irradiation directe du triène **20** conduit au 6-méthylbenzosemibullvalène (soit le SB **22**, 46%, Φ = 0,073), au 5-méthyl-7,8-benzotétracyclo[3.3.0^{2,4}.0^{3,6}]oct-7-ène (**23**, 35%, Φ = 0,062), le 6-méthyl COT **21** (4%, Φ = 0,008), le 7-méthyl COT **24** (1%, Φ = 0,002) et le naphtalène (3%, Φ = 0,006). Des irradiations sensibilisées du composé **20** conduisent au composé SB **22** (45%, Φ = 0,022), au 6-méthyl COT **21** (2%, Φ = 0,001) et au naphtalène (4%, Φ = 0,002). Des études avec du triène marqué au deutérium (**20***a*) indiquent que le semibullvalène **22** se forme aussi bien à partir des états excités S_1 et T_1 du produit **20**, par le biais d'une transposition di-π-méthane de Zimmerman.

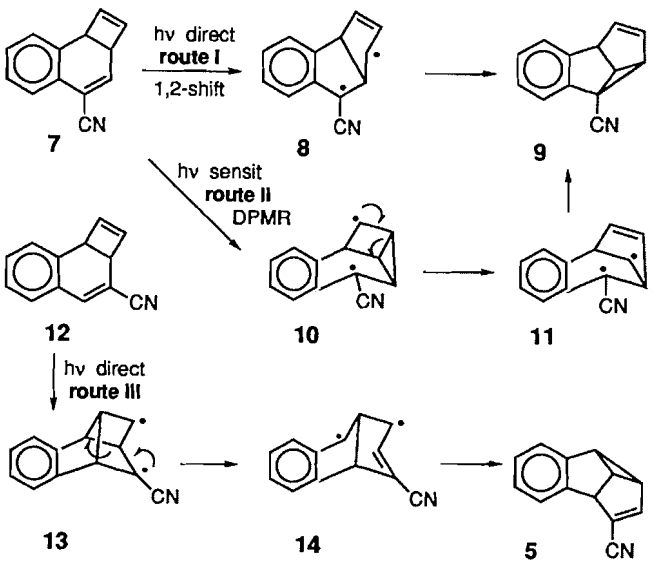
[Traduit par la Rédaction]

Introduction

The synthesis of polyquinanes continues to be an area of interest (1) due to the biological and therapeutic activity exhibited by numerous members of this class of compound. Effective routes to a variety of these cyclopentanoids have been elaborated using semibullvalene (SB) derivatives as starting materials (2), and this in turn has made the development of additional methods of SB synthesis an attractive undertaking. Recently, we (3–8) and others (9) have observed that SBs can be generated from the sensitized and (or) direct irradiation of 2,3-benzobicyclo[4.2.0]octa-2,4,7-trienes; for example, trienes **1–3** give SBs **4–6** (6–8) (Scheme 1). Intriguingly, the SBs are not produced by a single mechanistic pathway. The results of deuterium-labelling experiments have shown that at least three routes can be used to generate the SB product, and in some cases their mode of formation has been shown to be multiplicity dependent, e.g., triene **7** gives SB **9** via a 1,2-shift mechanism (route i, Scheme 2) from S_1, but utilizes a Zimmerman di-π-methane rearrangement (DPM rearrangement) to provide the same semibullvalene from T_1 (route ii, Scheme 2 (3)). The third, and least observed, route involves initial bridging between the distal carbons (i.e., C-4 and C-8) of the vinyl groups. This mechanism was invoked to explain the formation of the SB **5** from the triene **12** (route iii, Scheme 2 (5)).



SCHEME 1



SCHEME 2

Those triene derivatives that have been examined to date contain π-conjugating groups (e.g., CN (3–7), CO_2R (9), Ph (10)), with the single exception of the 7,8-dimethyl derivative **3** (8); only SB **6** and naphthalene were detected, in meager yields, as photoproducts from the direct or sensitized irradiation of triene **3**. To explore further the factors that control the excited-state

reactivity of simple alkyl-substituted trienes, we have studied, and now report on, the photochemistry of the monomethyl compound **20**.

Results

The preparation of 8-methyl-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (**20**), which starts with the addition of benzyne to *o*-methylanisole, is outlined in Scheme 3. The first four steps in the synthetic sequence follow those used in the reported preparation of the 7,8-dimethyl triene **3** (8). Although the ketone **18** could be converted to the COT **21** via the Shapiro reaction, it was found that the subsequent photo-conversion of **21** to the desired triene **20** was excessively slow (e.g., the production of ca. 1 mg of **20** per hour of irradiation). A more efficient route was to photoclose the ketone **18** to the bicyclo[4.2.0] system **19**, which was then transformed to the desired triene **20** by the Shapiro reaction. Additionally, in the photochemical step (**18** → **19**) it was found to be advantageous to carry out the irradiation in the presence of piperylene to quench the triplet-state activity of ketone **19**, and thus limit the formation of secondary products that otherwise occur.

The structural assignment of triene **20** was based on comparison of its NMR spectral data with those of the known 7,8-dimethyl analogue **3**; the chemical shifts of corresponding protons were within δ 0.15, and coupling constants between corresponding protons were identical (8). Supporting evidence for structure **20** was obtained from its thermal reactivity. Like

[a]Coupling constants for **22** are $J_{1,2} = J_{1,5} = J_{1,8} = J_{2,8} = 6.5$, and $J_{7,8} = 2.5$ Hz; corresponding coupling constants for **6** and **25** are within 0.5 Hz.
[b]Run in $CDCl_3$.
[c]Run in CCl_4.

many other derivatives of the triene system (3–7), **20** is smoothly converted to COT product on heating (→**21**). The arrangement is noticeable on GC columns at temperatures >110°C, and is essentially quantitative when solutions of **20** are maintained at ca. 150°C for 10 h.

The triene is also photochemically reactive, and the semibullvalene 6-methylbenzotricyclo[3.3.0.0^{2,8}]octa-3,6-diene (**22**) was formed as the major product under both direct (λ ≥ 295 nm) and sensitized (λ ≥ 320 nm; dimethylaminobenzophenone) irradiation conditions. The structures, analytical yields (based on consumed substrate; GC analysis), and quantum yields (Φ's) of all the photoproducts are given in Scheme 4.

The characterizations of the photoproducts rest on spectral data. In the case of the SB **22**, the proton NMR spectrum showed chemical shifts and coupling constants that are typical for the rigid benzosemibullvalene skeleton. Table 1 compares the proton chemical shifts of **22** with those of related SBs: the 6,7-dimethyl derivative **6** (8), and the unsubstituted parent compound (**25**, Scheme 5) (11).

For 5-methyl-7,8-benzotetracyclo[3.3.0^{2,4}.0^{3,6}]oct-7-ene (**23**), the C_s symmetry of the molecule was revealed by the ^{13}C NMR spectrum, which showed only eight lines; the chemical shifts of the aliphatic ring and methyl carbons (δ 55.2 C-1(6), δ 20.1 C-2(3), δ 26.9 C-4, δ 67.0 C-5, and δ 15.5 CH_3) correlate well with those reported (21) for the corresponding 5-methyl alkene analogue (**26**, Scheme 5) (δ 54.7 C-1(6), δ 20.3 C-2(3), δ 24.0 C-4, δ 65.2 C-5, and δ 14.3 CH_3). Additionally, in the ^{1}H NMR spectrum, the signals due to the non-aromatic ring protons (δ 3.59 H-1(6), δ 2.05 H-2(3), and δ 2.69 H-4) appear as an AA″MX′X spin system as they do in the analogue **26** (δ 3.14 H-1(6), δ 1.98 H-2(3), and δ 2.41 H-4); in both compounds, H-4 occurs as a triplet, with $J_{4,2} = J_{4,3} = 3.5$ Hz (12).

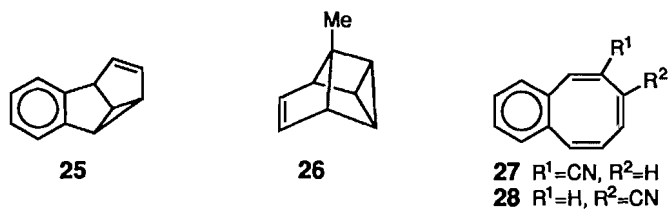
[a]Run in $CDCl_3$ solvent. Coupling constants for **21** and **24**, where applicable, are $J_{5,6} = J_{9,10} = 11.5$, and $J_{8,9} = 2.5$ Hz. For **27** and **28**, $J_{9,10} = 11.5$, and $J_{8,9} = 4$ Hz.



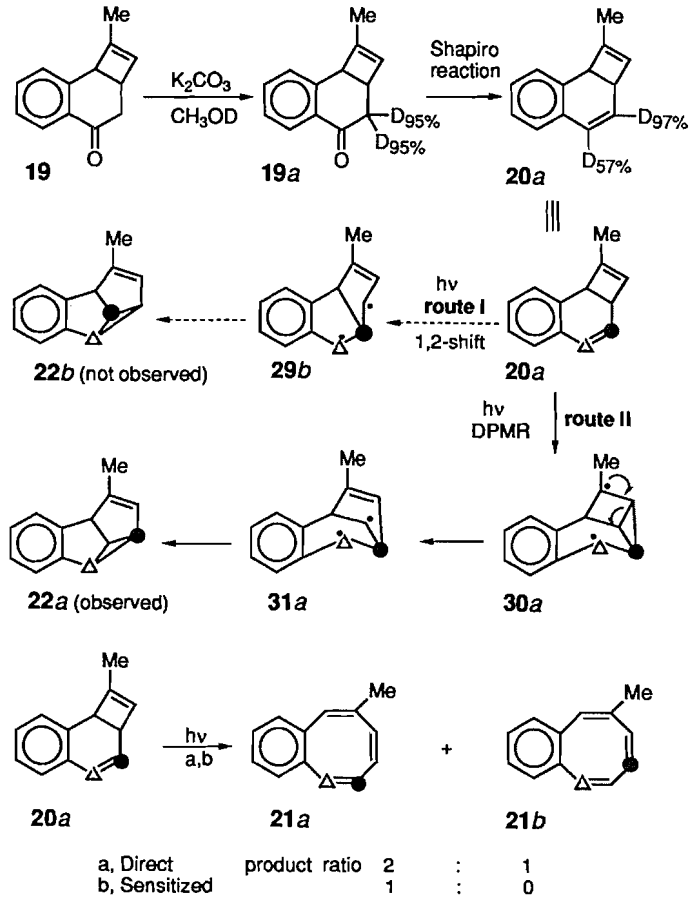
SCHEME 5

The structures given to the COTs **21** and **24** were based on comparison of their proton NMR spectra with those of the known cyano-substituted COTs **27** and **28** (Scheme 5) (13); the spectral details are displayed in Table 2. The chemical shifts and coupling constants for corresponding protons are closely similar, except for the proton *cis*-vinyl to the substituent (i.e., H-5 in **21**, and H-8 in **24**). As expected, these protons in the methyl derivatives show upfield chemical shifts (δ 0.88 for H-5 in **21**, and δ 1.05 for H-8 in **24**) that are consistent with the reported substituent constant differences of minus δ 1.04 for olefinic protons *cis* to methyl (−0.26) and cyano (+0.78) groups (14). A final point with respect to the NMR spectrum of **21** is that the signal positions for H-7 and H-8 are essentially coincidental at 400 MHz. The addition of the alkene-complexing agent AgFOD, however, permitted resolution of these signals at 250 MHz (note Experimental for details).

Subsequent to the structural assignments, control experiments were performed on the photoproducts individually to ascertain if any photo-interconversion could have occurred under the direct or sensitized conditions used during the irradiations of triene **20**. In each case the substrates proved to be very stable, and only from the direct irradiation ($\lambda \geq 295$ nm) of COT **21** was a photorearrangement noted; a trace amount of triene **20** was slowly formed, according to GC analysis.

Mechanistic considerations

As noted in the Introduction, previous studies with several of the cyano-substituted derivatives of the triene system had revealed that the semibullvalene product can be formed by three different mechanistic routes. It was therefore pertinent to investigate the situation with triene **20**, since here both the 1,2-shift mechanism and the Zimmerman DPM rearrangement could account for the production of SB **22**; the operation of the third mechanism (route iii, Scheme 2) can be ruled out since this would have led to 2-methylbenzosemibullvalene, a product not observed in this study. These two options, which are shown in Scheme 6 as route i and route ii, respectively, are skeletally different. It was therefore possible to determine the extent to which they participated in the semibullvalene formation by examination of the deuterium distributions in the SB produced from the labelled triene material **20***a*.



SCHEME 6

The doubly deuterated triene **20***a* (ca. 57%-d_1 at C-4, and 97%-d_1 at C-5) was prepared from the labelled ketone **19***a* via the Shapiro reaction, as outlined in Scheme 6. The occurrence of the additional deuterium at C-4 of the triene is not exceptional. Similar partial deuterium incorporations at this site (i.e., on the carbon of the original carbonyl) have been reported using the tosylhydrazone–alkyllithium procedure, and a mechanistic rationalization has been proposed by Shapiro and Hornaman (15). Importantly, the major label at C-5 in **20***a* was ideally

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

located to distinguish between the mechanisms depicted in Scheme 6 as routes i and ii. The SB product isolated from either the direct or the sensitized irradiation of triene **20***a* contained identical deuterium distributions, as determined by proton NMR analyses. In each case the labels were located at C-2 and C-8, in agreement with the structure designated as **22***a*. Thus, the 1,2-shift pathway (i.e., route i, Scheme 6) does not function in the formation of SB **22** from triene **20**.

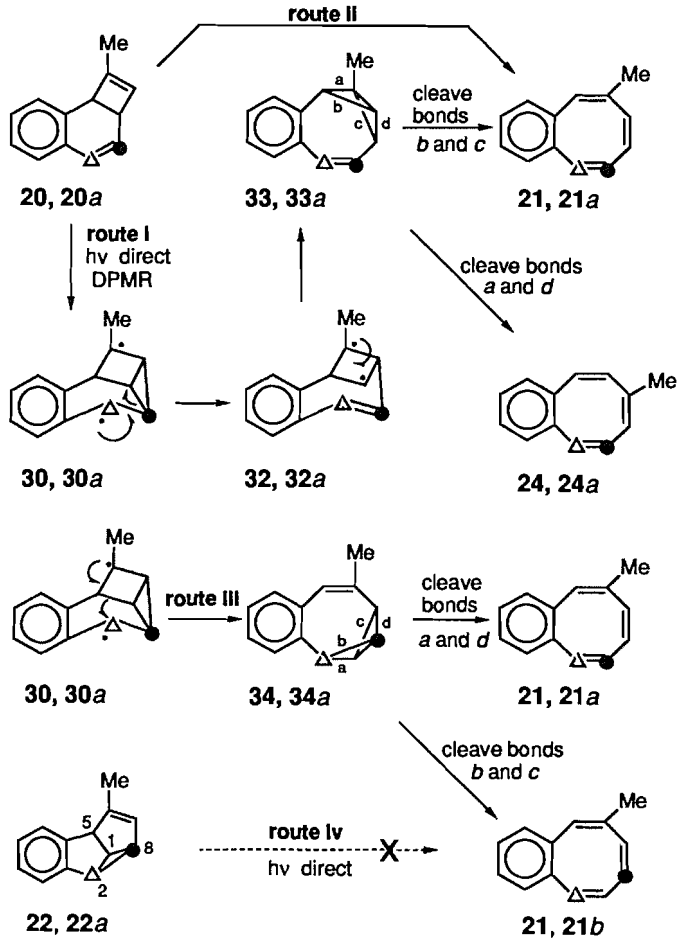
An additional interesting result from the labelling studies was the finding that the deuterium distributions in the labelled COT **21** material isolated from the direct irradiation of **20***a* were not the same as those from sensitization (note: the deuterium distributions found in the labelled tetracycle **23** and COT **24** are unexceptional, and are given in the Experimental). The labels in the COT **21** from sensitized runs were attached to C-10 (55%) and C-9 (97%), corresponding to an electrocyclic $2\sigma_s + 2\pi_s$ ring opening of **20***a* to give COT **21***a* (Scheme 6). Those from the direct irradiation were located at C-10 (57%), at C-9 (65%), and at C-8 (36%), and accord largely with the presence of a 2:1 mixture of label isomers represented by structures **21***a* and **21***b*, respectively (note Scheme 6). Mechanistically, we are unable to account for the formation of COT **24***a* and the label isomers **21***a* and **21***b* from the direct irradiation of triene **20***a* in terms of a single mechanism (vide infra).

Discussion

The assignments of excited-state multiplicities responsible for the numerous products encountered in the photochemistry of triene **20** were straightforward. The tetracycle **23** and COT **24** were assumed to be uniquely singlet derived since they are formed only upon direct irradiations. By contrast, the remaining three compounds, viz, SB **22**, COT **21**, and naphthalene, are produced from both S_1 and T_1, depending upon the mode of excitation employed. They are T_1 derived when generated from sensitization, and are mostly (70–100%) from S_1 when direct irradiation is used. This latter conclusion follows from the observation that the quantum yields (summarized in Scheme 4) for the photoproducts from the direct irradiation of triene **20** are at least three times greater than those from the sensitized runs. Application of the bracketing expression $\Phi^{dir} - \Phi^{sens} \leq {}^1\Phi \leq \Phi^{dir}$ (16) then suggests that *at least* 70% of SB **22**, COT **21**, and naphthalene from direct irradiation must be from S_1.

This latter interpretation is reasonable only if energy transfer to T_1 of triene **20** is efficient in the sensitized irradiations. To ensure that this condition was met, sensitization experiments with different sensitizers were performed: *p*-dimethylaminobenzophenone (E_T 62 kcal/mol), thioxanthone (E_T 65.5 kcal/mol), and benzophenone (E_T 69 kcal/mol). In all cases the quantum yields were the same, within experimental error. Furthermore, in the case of benzophenone sensitization, the photoreduction of the sensitizer was effectively quenched in the presence of the triene, and thus it seems reasonable to infer that triplet energy transfer to **20** was indeed efficient.

The finding that SB **22** can be produced from both S_1 and T_1 is significant. The deuterium-labelling studies are consistent with the operation of a DPM rearrangement in each case, and although such a transformation from the triplet excited state is normal in rigid molecules, it is rare that S_1 undergoes the same major process. A further example of this uncommon situation involving a DPM rearrangement from both S_1 and T_1 was noted previously for the 8-cyano triene **2** (6). It is possible that the reaction synchronicity differs in the singlet and triplet excited states of these compounds. Interestingly, Robb and co-workers



SCHEME 7

obtained results from a theoretical approach that suggest some or all the steps in the traditional Zimmerman mechanism may merge into one step for singlet DPMRs, and the reaction may become concerted (17). On the other hand, for the triplet reaction in constrained systems, Zimmerman recently reported further experimental and theoretical work in support of the stepwise mechanism (18).

We note that the formation of SB **22** is especially favorable when generated from T_1. This finding is attributed to the stabilization of the radical centres of intermediate **30** by the methyl group and aromatic ring, and falls in line with the generalization that electron-stabilizing groups at the distal carbons of the di-π-methane moiety promote the Zimmerman rearrangement (19).

Lastly with respect to the DPMR, the formation of COT **24** and part of COT **21** in the direct irradiation of triene **20** can also be interpreted in terms of a singlet-derived Zimmerman rearrangement. Here, it is suggested that the DPM mechanism involves closure to an alternative vinylcyclopropane, shown as octavalene **33** (Scheme 7, route i), which then undergoes thermal reorganization to the COTs. A similar rationale was invoked to account for the formation of the cyano-COTs **27** and **28** from the direct photolysis of triene **2** (6), and independently generated 1,3-cyclobutanediyls like the proposed intermediate **32** are reported to give bicyclobutanes by bonding at the radical centres (20). An additional route from **20** to COT **21** (but not to

SCHEME 8

COT **24**) may also be via $2\sigma_s + 2\pi_s$ electrocyclic opening (21) of the cyclobutene ring of the triene (note Scheme 7, route ii). Unfortunately, the labelling pattern used in this study does not permit us to discern to what extent this pathway is used in direct irradiations. However, operation of route ii (Scheme 7), and not route i, does account for the formation of COT **21** and the absence of COT **24** from sensitization irradiation of triene **20**.

A further pathway to COT **21** must also function in the direct irradiation of triene **20**, since neither route i nor route ii (Scheme 7) can account for the label distribution observed in the deuterated product COT **21***b* (Scheme 6). One initially attractive mechanistic explanation for the low deuterium content at C-9 in the labelled COT **21**, and one that has literature precedent in analogous compounds (11, 13), was based on the secondary photochemical conversion of the primary SB **22** product to the COT, via cleavage of bonds C1—C5 and C2—C8 (Scheme 7, route iv). This possibility was discounted, however, by the finding that the semibullvalene was stable (GC showed no COT production) to the conditions used in the direct irradiation (Pyrex-filtered light) of triene **20**. A possible mechanism (route iii, Scheme 7) that can account for the formation of COT **21***b* (and in part **21***a*) is via the thermal isomerization of the octavalene intermediate **34***a* (cf. the fate of octavalene **33***a*, vide supra). In view of the low yield of COT **21**, and the fact that the involvement of intermediates has not been excluded, further speculation regarding additional pathways to COT **21** is deferred.

An unexpected product from the direct photolysis of **20** was the tetracycle **23**. Until now, intramolecular $2\pi + 2\pi$ photoclosures in bicyclo[4.2.0]octatrienes have been found only in compounds containing π-conjugating substituents at one or both sp^2 carbons of the cyclobutene ring, e.g., note compounds **2** (6), **35** (7), **36** (10), **41** (22), and **42** (23) in Scheme 8. By contrast, compounds **1** (7), **3** (8), **7** (3), **12** (5), **37** (4), and **43** (24) do not photoclose. Failure to undergo the cycloaddition was attributed to the lack of sufficient donor–acceptor interaction between the potential $2\pi + 2\pi$ partners (7). However, the present results

[a]Ground state geometries were obtained from MNDO calculations, and changes in interaction energies were calculated by the CNDO/S-CI method (31). Negative values are interpreted as attractive "forces" tending to bring atoms together, while positive values are repulsive. Calculations on the full molecules were performed; only selected values are given here.

show that this is not the feature that controls the reaction in bicyclo[4.2.0]octatrienes, since the "donor–acceptor" properties of model olefins representing the individual addends in **20** are essentially the same as those in the non-photoclosing dimethyl triene **3**. For example, in both trienes the "donor" portion is common (styrene, IP_V = 8.43 eV (25)), and the electron affinities of models for the "acceptor" vinyl groups are nearly identical (cf. EA_V = 2.27 eV (26) for the tetramethylethylene moiety in **3**, versus an EA_V = 2.24 eV (26) for the trimethylethylene moiety in **20**).

In an attempt to explain the deviation in behaviour of the two alkylated trienes, we turned to a theoretical approach that had successfully predicted the $2\pi + 2\pi$ products encountered in the photochemistry of benzobarrelene derivatives (13). However, this approach, which is based upon CNDO/2-CI calculations of the changes in atom–atom interaction energies for the lowest singlets of the trienes, did not prove useful in the present case. Inspection of Table 3 (see Experimental section: Calculations) does not reveal any significant divergence of the initial distributions of electronic excitation in **3**, compared to **20**, that would account for the observed variation in their photoclosure reactivities. In particular, the calculations predict that bonding between C-4 and C-8 and between C-5 and C-7 should be favorable in both compounds (−0.15 eV and −0.56 eV for **3**; and −0.11 eV and −0.46 eV for **20**).

Finally, we note that despite the difference in the stereoelectronic nature of a methyl substituent versus a cyano substituent, the photochemistry of triene **20** resembles that of **2** much more closely than that of the dimethyl derivative **3**. Further studies of the photochemistry of other methyl triene derivatives, as well as that of the unsubstituted parent, are in progress.

Experimental

Instrumentation and materials

The NMR spectra were recorded on either Bruker 250- or 400-MHz instruments, with TMS as internal standard. The chemical shifts are in δ units and the coupling constants (*J*) in Hz. The abbreviations br, s, d, t, q, and m refer to broad, singlet, doublet, triplet, quartet, and multiplet, respectively. The GC/MS was recorded on an HP 5890 (GC)/5970 (MS) instrument fitted with a DB-5 (J & W Scientific) fused silica capillary column, 15 m × 0.25 μm. The IR spectra were recorded on a Bomem MB 102 FT spectrometer. The UV spectra were measured on a Varian DMS 100S spectrometer; maxima are given in nm, with λ_{max} values in parentheses; sh = shoulder. Melting points are uncorrected. Elemental analyses were performed by Galbraith Labs, Inc., Knoxville, Tenn. Column chromatography was carried out on Silica Gel 60 (Merck; 230–400 mesh) mixed with Sylvania 2282 phosphor and slurry packed into quartz columns permitting monitoring by a hand UV lamp, or on Lobar columns (Merck; size B, LiChroprep Si 60), or on silica gel/$AgNO_3$ columns (10:1, by weight). The GC analyses were made on a Varian 3700 instrument (FID), coupled to a Varian CDS 111 computing integrator, and fitted with an SE-30 fused silica capillary column 30 m × 0.32 mm. Cyclohexane solvent for quantum yields was prepared by scrubbing with 20% fuming sulfuric acid, followed by washing with 10% aqueous sodium hydroxide, drying ($MgSO_4$), and finally distilling from calcium hydride. The sensitizers *p*-dimethylaminobenzophenone, thioxanthone, and benzophenone were recrystallized (after sublimation) prior to use.

General procedures for preparative photolyses

The apparatus consisted of a 450-W Hanovia medium pressure mercury arc surrounded by a water-cooled quartz immersion well. Unless otherwise stated, the light was filtered through either a cyclindrical sleeve of Pyrex or Corex glass. Three types of sample cell were used. Cell A (250-mL sample volume) consisted of a cylindrical well, which surrounded the aqueous filter jacket. Cell A was fitted with gas inlet and exit ports, and sample solutions were magnetically stirred, and purged with argon prior to, and during, irradiations. Cell B (35-mL sample volume) and Cell C (3.5 mL) were a quartz test-tube-like vessel and a quartz cuvette, respectively; sample solutions contained therein were deoxygenated by flushing with argon and sealed under a positive pressure; the solutions were magnetically stirred throughout the course of the irradiations.

*2-Methyl-1-methoxy-4-hydro-1,4-ethenonaphthalene (**15**)*

A mixture of benzene diazonium carboxylate, prepared, as previously described (13), from 10.5 g (76.8 mmol) of anthranilic acid, and 500 mL of 2-methylanisole was stirred at 45–60°C overnight, and then concentrated on a rotovap. The residue was dissolved in toluene (50 mL), diluted with 500 mL of hexane, filtered, and the filtrate concentrated. The residue was then short-path distilled (90°C/0.1 Torr; 1 Torr = 133.3 Pa) and the distillate was chromatographed on Silica Gel 60 (0.9 cm × 30 cm) with 2% ether – hexane. The main band was concentrated and the residue was rechromatographed on a Lobar silica gel column with 5% ether – hexane. Concentration of the third band gave 470.5 mg (4.5%) of colourless barrelene (**15**), mp 43–45°C (from ethanol); UV (hexane): 277 (760), 270 (780), 263 (640), 255 sh (640), and 234 sh (1160); ^{1}H NMR (250 MHz; $CDCl_3$): 7.29–7.41 (m, 1H, aromatic), 6.80–6.97 (m, 5H, 3 aromatics, H-5 and H-6), 6.27 (sym m, 1H, H-3), 4.61 (dt, 1H, H-4, $J_{4,3} = J_{4,5} = 6$, $J_{4,6} = 1.5$), 3.78 (s, 3H, methoxyl), and 1.83 (d, 3H, methyl, $J_{Me,3} = 1.5$); ^{13}C NMR (62.9 MHz; $CDCl_3$): 14.7, 47.5, 55.1, 90.8, 119.2, 121.4, 123.0, 123.5, 131.5, 137.2, 138.4, 146.2, 147.7, and 151.5. Anal. calcd. for $C_{14}H_{14}O$: C 84.81, H 7.12; found: C 84.78, H 7.09.

*Sensitized photolysis of barrelene **15***

A 250 mL solution of cyclohexane containing 986.9 mg (5.0 mmol) of barrelene **15** and 15 mL of acetone sensitizer was photolyzed with Pyrex-filtered light for 2 h. The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (0.9 cm × 20 cm) with 4% ethyl acetate – hexane solvent. The main band was rechromatographed on a silica gel/$AgNO_3$ column with 1.5% ethyl acetate – hexane solvent. The first band contained 179.9 mg (18%) of 5-methoxy-6-methylbenzotricyclo[3.3.0.0^{2,8}]octa-3,6-diene as a colourless solid, mp 85–87°C; UV (hexane): 282 (760), 274 (870), 268 sh (700), and 232 (5 270); ^{1}H NMR (250 MHz; $CDCl_3$): 7.13–7.32 (m, 4H, aromatics), 4.88 (m, 1H, H-7), 3.43 (t, 1H, H-1, $J_{1,2} = J_{1,8} = 6.5$), 3.32 (s, 3H, methoxyl), 3.10 (t, 1H, H-2, $J_{2,1} = J_{2,8} = 6.5$), 2.71 (dt, 1H, H-8, $J_{8,1} = J_{8,2} = 6.5 = J_{8,7} = 2.5$), and 1.66 (d, 3H, methyl, $J_{Me,1} = 1.2$); ^{13}C NMR (62.9 MHz; $CDCl_3$): 10.6 (methyl), 37.4 (C2), 37.7 (C8), 51.2 (C1), 52.9 (methoxyl), 99.1, 117.5 (C7), 119.3, 125.2, 125.3, 127.3, 136.4, 145.2, and 147.5; assignments as determined by Hetcorr experiments. Mass spectrum showed molecular ion at *m/e* = 198.1046 (94%); $C_{14}H_{14}O$ requires 198.1045. Anal. found: C 85.20, H 7.10.

The second band gave 330.7 mg (34%) of 5-methoxy-1-methylbenzotricyclo[3.3.0.0^{2,8}]octa-3,6-diene (SB **16**) as a colourless liquid, after short-path distillation at 80°C/0.1 Torr; UV (hexane): 282.5 (820), 275 (920), 269 sh (710), and 230 (2 430); ^{1}H NMR (250 MHz; $CDCl_3$): 7.12–7.29 (m, 4H, aromatics), 5.65 (d, 1H, H-6, $J_{6,7} = 5$), 5.15 (dd, 1H, H-7, $J_{7,6} = 5$, $J_{7,8} = 2.5$), 3.50 (s, 3H, methoxyl), 3.04 (d, 1H, H-2, $J_{2,8} = 6.5$), 2.71 (dd, 1H, H-8, $J_{8,7} = 2.5$, $J_{8,2} = 6.5$), and 1.43 (s, 3H, methyl); ^{13}C NMR (62.9 MHz; $CDCl_3$): 14.3 (methyl), 44.5 (C2), 46.8 (C8), 54.8 (methoxyl), 61.2, 98.5, 120.2 (C7), 120.7, 125.1, 125.44, 127.3, 135.1 (C6), 135.9, and 148.7; assignments as determined by Hetcorr experiments. Mass spectrum showed molecular ion at *m/e* = 198.1051 (100%); $C_{14}H_{14}O$ requires 198.1045. Anal. found: C 84.63, H 7.03. The third band gave 169.3 mg (17%) of recovered barrelene.

*Gas phase thermolysis of SB **16**, and conversion of COT **17** to ketone **18***

Over a 1.5 h period 592.6 mg (3.0 mmol) of SB **16** was distilled into a Pyrex tube (2 cm × 30 cm) packed with glass beads (0.5 cm diameter) maintained at ca. 460°C. The pressure was kept at 6 Torr by the passage of argon. The thermolysis product, mostly COT **17**, collected in an ice-cooled U-trap, was not purified, but was treated directly with 8 mL of 80% aqueous acetic acid. The solution was stirred at room temperature overnight, then treated with 200 mL of 15% aqueous $KHCO_3$, and extracted with 200 mL hexane. The extract was washed (2 × 50 mL water), dried (Na_2SO_4), concentrated, and chromatographed on Silica Gel 60 (0.9 cm × 7 cm) with 5% ether – hexane solvent. The main band was rechromatographed on a Lobar column (3% ethyl acetate – hexane). The first fraction gave 292.3 mg (53%) of ketone **18**, mp 46–48°C (from hexane); IR (Nujol): 1685 (C=O) cm^{-1}; UV (hexane): 366 sh (220), 351 sh (660), 336 sh (1140), 312 sh (3080), 305 (3270), 234 (27300); ^{1}H NMR (250 MHz; $CDCl_3$): 8.35 (dd, 1H, H-4, $J = 7.7$, $J = 1.7$), 7.46–7.52 (m, 1H, aromatic), 7.26–7.34 (m, 2H, 2 aromatics), 6.71 (br s, 1H, H-10), 6.15 (d, 1H, H-8, $J_{8,7} = 10$), 5.76 (dt, 1H, H-7, $J_{7,8} = 10$, $J_{7,6} = J_{7,6'} = 8$), 3.43 (d, 2H, H-6 and H-6′, $J_{6,7} = J_{6,7'} = 8$), and 2.08 (d, 3H, methyl, $J_{Me,10} = 1.1$); ^{13}C NMR (62.9 MHz; $CDCl_3$): 24.7 (methyl), 44.3 (CH_2), 126.37 (C7), 126.40, 128.8 (C10), 130.6 (C4), 132.0, 132.9 (C8), 133.3, 136.0, 136.8, 138.1, 195.0 (C=O); assignments as determined by Hetcorr experiments. Mass spectrum showed molecular ion at *m/e* = 184.0886 (94%), 169 (100%), $C_{13}H_{12}O$ requires 184.0888. Anal. calcd. for $C_{13}H_{12}O$: C 84.75, H 6.57; found: C 84.73, H 6.74.

*Cyclohexanone **19** from irradiation of ketone **18***

A 250 mL solution of cyclohexane containing 474.4 mg (2.40 mmol) of ketone **18** and 40 mL of piperylene quencher was photolyzed with Pyrex-filtered light for 15 min in Cell A. The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (0.9 cm × 10 cm) with 100 mL of 5% ethyl acetate – hexane solvent. The main band was rechromatographed on a Lobar column with 2.5% ethyl acetate – hexane solvent. The first band gave 64.5 mg (14%) of recovered ketone **18**; the second band contained 386.2 mg (81%) of colourless cyclohexanone **19**, mp 47–48°C (from hexane); IR (Njuol): 1663 (C=O) cm^{-1}; UV (cyclohexane): 328 (85), 289 (1350); ^{1}H NMR (250 MHz; $CDCl_3$): 7.87 (dd, 1H, aromatic, $J = 1.5$, $J = 7.5$), 7.52 (dt,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

1H, aromatic, J = 1.5, J = 7.5), 7.25–7.34 (m, 2H, 2 aromatics), 5.80 (m, 1H, H-7), 3.88 (br d, 1H, H-1, $J_{1,6}$ = 4.0), 3.51 (sym m, 1H, H-6,), 2.84 (dd, 1H, H-5′, $J_{5',5}$ = 16, $J_{5',6}$ = 2.0), 2.72 (dd, 1H, H-5, $J_{5,5'}$ = 16, $J_{5,6}$ = 7.5), and 1.50 (sym m, 3H, methyl); ^{13}C NMR (62.9 MHz; $CDCl_3$): 14.0 (methyl), 35.1 (C6), 41.3 (CH_2), 46.4 (C1), 126.3, 127.4, 128.7, 130.7 (C7), 133.1, 144.1, 154.0, 196.7 (C=O), one carbon missing; assignments as determined by Hetcorr experiments. Mass spectrum showed molecular ion at *m/e* = 184.0886 (63%), 115 (100%); $C_{13}H_{12}O$ requires 184.0888. Anal. found: C 84.75, H 6.57.

*Triene **20** from cyclohexanone **19** via the Shapiro reaction (27)*

A solution of 66 mg (0.36 mmol) of cyclohexanone **19**, 66 mg (0.36 mmol) of *p*-toluenesulfonylhydrazide, and 0.1 mL of acetic acid in 1 mL of methanol was refluxed for 30 min, left to stand at room temperature overnight, and then cooled to −12°C for 12 h. The resulting crystals were filtered and dried in vacuo to give 102 mg (81%) of the tosylhydrazone as white crystals, mp 185–187°C (dec.). A solution of 0.5 mL (0.7 mmol) of 1.4 M methyllithium in ether was slowly added (2 min) to a stirred, ice-cooled slurry of 102 mg (0.29 mmol) of the tosylhydrazone in 2 mL of dry ether, under a nitrogen atmosphere. The resulting orange solution was stirred at room temperature for 1.25 h, refluxed for 10 min, cooled, and then made slightly acidic by the addition of aqueous ammonium chloride solution. The ether layer was washed with water, dried ($MgSO_4$), concentrated, and the residue chromatographed on Silica Gel 60 (0.9 cm × 10 cm) with hexane solvent. The main band gave 48.7 mg (88%) of triene **20** as a colourless oil (>99% pure by GC); UV (cyclohexane): 302 (1110), 295 sh (2300), 290 sh (2900), 282 (4750), and 271 (5120); ^{1}H NMR (400 MHz; $CDCl_3$): 7.08–7.26 (m, 2H, aromatics), 6.99–7.04 (m, 2H, aromatics), 6.22 (d, 1H, H-4, $J_{4,5}$ = 10), 5.90 (dd, 1H, H-5, $J_{5,4}$ = 10, $J_{5,6}$ = 4.5), 5.84 (br s, 1H, H-7), 3.91 (d, 1H, H-1, $J_{1,6}$ = 4.5), 3.48 (br s, 1H, H-6), and 1.65 (br s, 3H, methyl); spin decoupling experiments: irradiation of H-5 collapsed H-4 to an s; irradiation of H-7 modified the methyl signal, irradiation of H-1 modified H-6 and the methyl signal; irradiation of H-6 collapsed H-5 to a d ($J_{5,4}$ = 10) and H-1 to an s; irradiation of the methyl signal sharpened H-7 and H-1, and collapsed H-6 to a t ($J_{6,1}$ = $J_{6,5}$ = 4.5); ^{13}C NMR (62.9 MHz; $CDCl_3$): 14.3 (methyl), 39.7 (C6), 45.6(C1), 125.4 (C4), 126.5, 127.4, 127.8, 128.0, 129.5 (C5), 132.1 (C7), 134.7, 149.0, one carbon missing; assignments as determined by Hetcorr experiments. Mass spectrum showed molecular ion at *m/e* = 168.0936 (70%), 128 (100%; M^+ − propyne); $C_{13}H_{12}$ requires 168.0939. Anal. calcd. for $C_{13}H_{12}$: C 92.81, H 7.19; found: C 93.01, H 7.31.

*Thermolysis of triene **20***

A solution of 6.1 mg (0.036 mmol) of **20** in 1 mL of *n*-nonane was refluxed (ca. 150°C) for 5 h. The thermolysis product was chromatographed on Silica Gel 60 (0.9 cm × 10 cm; cyclohexane). Short-path distillation (60°C/0.1 Torr) of the main band gave 5.5 mg (90%) of COT **21**; UV (cyclohexane): 269 sh (1200) and 234 (22 500); ^{1}H NMR (400 MHz; $CDCl_3$): 7.16–7.24 (m, 2H, aromatics), 6.95–6.96 (m, 2H, aromatics), 6.57 (d, 1H, H-10, $J_{10,9}$ = 11.5), 6.34 (br s, 1H, H-5), 6.04 (dd, 1H, H-9, $J_{9,8}$ = 2.5, $J_{9,10}$ = 11.5), 5.82 (m, 2H, H-7 and H-8), and 1.88 (m, 3H, methyl); spin decoupling experiments: irradiation of the methyl signal sharpened H-5; irradiation of the H-7, H-8 multiplet collapsed H-9 to a d ($J_{9,10}$ = 11.5); irradiation of H-9 collapsed H-10 to an s, and modified the H-7, H-8 multiplet; irradiation of H-5 collapsed the methyl signal to an s; irradiation of H-10 collapsed H-9 to a br s; ^{13}C NMR (62.9 MHz; $CDCl_3$): 24.0 (methyl), 126.4, 126.9, 128.5, 129.0, 129.2, 129.6, 131.3, 133.7, 134.2, 138.0, 139.1, and 139.3; a solution containing 0.1 M **21** and 0.2 M Ag FOD (Aldrich) gave ^{1}H NMR (250 MHz; $CDCl_3$): 7.17–7.27 (m, 2H, aromatics), 6.95–7.20 (m, 2H, aromatics), 6.75 (d, 1H, H-10, $J_{10,9}$ = 11.5), 6.50 (br s, 1H, H-5), 6.24 (dd, 1H, H-9, $J_{9,8}$ = 2.5, $J_{9,10}$ = 11.5), 5.98 (d, 1H, H-7, $J_{7,8}$ = 11.5), 5.92 (dd, 1H, H-8, $J_{8,7}$ = 11.5, $J_{8,9}$ = 2.5), and 1.96 (d, 3H, methyl, $J_{Me,5}$ = 1.3). Mass spectrum showed molecular ion at *m/e* = 168.0936 (100%).

*Direct irradiation of triene **20***

A solution of 64.2 mg (0.38 mmol) of **20** and 43.2 mg of undecane (GC standard) in 250 mL of cyclohexane was irradiated (Pyrex filter) for 2.5 h in Cell A (78% conversion by GC). The photolysate composition analysed (as determined by GC peak areas calibrated (peak area versus mass) for the undecane internal standard against individual photolysate components) for 1.37 mg (2%) of naphthalene, 17.4 mg (27%) of pentacyclic **23**, 2.3 mg (3.5%) of COT **21**, ca. 0.6 mg (1%) of COT **24**, 13.9 mg (22%) of triene **20**, and 22.9 mg (36%) of SB **22**. The photolysate was concentrated and chromatographed on Silica Gel 60 (0.9 cm × 10 cm; 100 mL hexane) to remove polymeric materials. The eluate was concentrated and chromatographed on a Lobar column with hexane solvent. The first band contained a trace of naphthalene (identified by GC and TLC comparison with an authentic sample). The second band gave 15.2 mg (24%) of colourless pentacyclic **23**, after short-path distillation (60°C/0.1 Torr); UV (hexane): 274 (965), 267 (865), 265 sh (750), 261 (610), and 255 sh (410); ^{1}H NMR (400 MHz; $CDCl_3$): 7.13–7.19 (m, 2H, aromatics), 7.10–7.13 (m, 2H, aromatics), 3.59 (br s, 2H, H-1 and H-6), 2.69 (t, 1H, H-4, $J_{4,2}$ = $J_{4,3}$ = 3.5), 2.04–2.06 (m, 2H, H-2 and H-3), and 0.90 (s, 3H, methyl); spin decoupling experiments: irradiation of H-1(6) collapsed H-2(3) to a d ($J_{4,2(3)}$ = 3.5); irradiation of H-2(3) sharpened H-1(6), and collapsed H-4 to an s; irradiation of H-4 collapsed H-2(3) to an s. ^{13}C NMR (62.9 MHz; $CDCl_3$): 15.5, 20.1, 26.9, 55.2, 67.0, 122.1, 125.8, and 146.9. Mass spectrum showed molecular ion at *m/e* = 168.0934 (52%), 128 (100%); $C_{13}H_{12}$ requires 168.0939.

The third band gave 11.7 mg (18%) of recovered triene **20**. The fifth band gave 19.8 mg (31%) of SB **22**, mp 53–54.5°C, after crystallization from ethanol; UV (hexane): 283 (820), 275 (1000), and 269 sh (920); ^{1}H NMR (400 MHz; $CDCl_3$): 7.33 (d, 1H, aromatic, J = 7), 7.06–7.16 (m, 2H, aromatics), 7.01 (d, 1H, aromatic, J = 7), 4.86 (br s, 1H, H-7), 3.60 (d, 1H, H-5, $J_{5,1}$ = 6.25), 3.33 (q, 1H, H-1, $J_{1,2}$ = $J_{1,5}$ = $J_{1,8}$ = 6.5), 2.96 (t, 1H, H-2, $J_{2,1}$ = $J_{2,8}$ = 6.5), 2.58 (dt, 1H, H-8, $J_{8,1}$ = 6.5, $J_{8,7}$ = 2.5), and 1.72 (s, 3H, methyl); spin decoupling experiments: irradiation of the methyl collapsed H-7 to a d ($J_{7,8}$ = 2.5); irradiation of H-8 collapsed H-2 to a d ($J_{2,1}$ = 6.3); irradiation of H-2 collapsed H-8 to an unresolved dd, and H-1 to a t ($J_{1,5}$ = $J_{1,8}$ = 6.2); irradiation of H-1 collapsed H-8 to an unresolved d, H-2 to a d ($J_{2,8}$ = 7), and collapsed H-5 to an s; irradiation of H-5 collapsed H-1 to a t ($J_{1,2}$ = $J_{1,8}$ = 6.5); irradiation of H-7 collapsed H-8 to a t ($J_{8,1}$ = $J_{8,2}$ = 6.5) and sharpened the methyl signal. ^{13}C NMR (62.9 MHz; $CDCl_3$): 13.9, 37.3, 38.2, 49.2, 57.4, 116.7, 120.5, 125.0, 125.3, 126.1, 138.7, 146.4, and 149.9. Mass spectrum showed molecular ion at *m/e* = 168.0935 (100%); $C_{13}H_{12}$ requires 168.0939.

The fourth band contained a mixture of the COTs **21** and **24**. These were separated on a silica gel/$AgNO_3$ column with hexane solvent. The first band contained ca. 1.5 mg (2%) of COT **21** (identified by NMR and GC comparison with an authentic sample, vide supra). The second band contained ca. 0.5 mg (1%) of COT **24** of GC purity >98%; ^{1}H NMR (400 MHz; $CDCl_3$): 7.17–7.20 (m, 2H, aromatics), 6.96–6.98 (m, 2H, aromatics), 6.49 (d, 2H, H-5 and H-10, $J_{5,6}$ = $J_{10,9}$ = 11.5), 5.98–6.00 (br d, 1H, H-9, $J_{9,10}$ = 11.5), 5.96 (d, 1H, H-6, $J_{6,5}$ = 11.5), 5.62 (br s, 1H, H-8), and 1.76 (br s, 3H, methyl); mass spectrum from GC/MS showed molecular ion at *m/e* = 168.1 (75%), 153.1 (100%).

*Sensitized irradiation of triene **20***

A solution of 32.2 mg (0.19 mmol) of **20**, 10.0 mg of undecane (GC standard), and 31.2 mg (0.14 mmol) of *p*-dimethylaminobenzophenone in 40 mL of cyclohexane was irradiated for 30 min in Cell B, with light filtered through a WG 360 glass (Schott) filter (53% conversion by GC). The photolysate composition analysed (as determined by GC peak areas calibrated (peak area versus mass) for the undecane internal standard against the individual photolysate components) for ca. 0.5 mg (2%) of naphthalene, ca. 0.2 mg (0.5%) of COT **21**, 15.2 mg (47%) of triene **20**, and 7.5 mg (23%) of SB **22**. The photolysate was concentrated and chromatographed on Silica Gel 60 (0.9 cm × 10 cm; 100 mL hexane) to remove polymeric materials and sensitizer. The eluate was concentrated and chromatographed on a Lobar column with hexane solvent. The first band contained a trace of naphthalene (identified by GC and TLC comparison with an authentic sample). The second band gave a trace of COT **21** (identified by NMR and GC

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

comparison with an authentic sample). The third band gave 13.8 mg (43%) of recovered triene **20**, and the final band gave 7.3 mg (23%) of SB **22** (GC purity > 99%).

*Labelled cyclohexanone **10**a*

To a solution of 458.7 mg (2.49 mmol) of cyclohexanone **19** in 47 g of methanol-d_1 was added 20 mg of potassium carbonate. The solution was stirred at room temperature for 48 h. The solvent was removed under vacuum (oil pump) and the residue was taken up in hexane (15 mL) and washed with D_2O (2 mL). The hexane solution was concentrated and chromatographed on SG 60 (0.9 cm × 3 cm) with 5% ethyl acetate – hexane. The main band gave 445.3 (97%) of deuterated cyclohexanone **19***a* (95%-d_2 labelled at C-5), mp 47–48°C; ^{1}H NMR (250 MHz; $CDCl_3$): 7.87 (dd, 1.00H, aromatic, J = 1.5, J = 7.5), 7.52 (dt, 1.02H, aromatic, J = 1.5, J = 7.5), 7.25–7.34 (m, 2.07H, 2 aromatics and residual $CHCl_3$), 5.80 (m, 1.00H, H-7), 3.88 (br s, 1.01H, H-1), 3.51 (br s, 1.00H, H-6), 2.72 and 2.84 (m and m, 0.05H, H-5′ and H-5), and 1.50 (sym m, 3.09H, methyl).

*Labelled triene **20**a from cyclohexanone **19**a via the Shapiro reaction*

A solution of 445.3 mg (2.39 mmol) of deuterated cyclohexanone **19***a* (95%-d_2 at C-5), 457.1 mg (2.49 mmol) of *p*-toluenesulfonylhydrazide, and 0.3 mL of acetic acid-d_1 in 3 mL of methanol-d_1 was left to stand at room temperature for 18 h, and then cooled to −12°C for 12 h. The resulting crystals were filtered and dried in vacuo to give 597.5 mg (82%) of labelled tosylhydrazone as white crystals, mp 185–187°C (dec.). The procedure described above for the preparation of triene **20** was used to convert 201.9 mg (0.57 mmol) of the labelled tosylhydrazone to 115.6 mg (96%) of labelled triene **20***a* (GC purity >99%); ^{1}H NMR (250 MHz; $CDCl_3$): 6.97–7.14 (m, 2.20H, 2 aromatics and residual $CHCl_3$), 6.89–6.97 (m, 2.00H, aromatics), 6.13 (s, 0.43H, H-4), 5.81 (dd, 0.03H, H-5, $J_{5,4}$ = 10, $J_{5,6}$ = 4.5), 5.76 (br s, 1.00H, H-7), 3.82 (d, 1.00H, H-1, $J_{1,6}$ = 4.5), 3.39 (br s, 1.00H, H-6), and 1.56 (br s, 3.05H, methyl), i.e., triene **20***a* is 97%-d_1 labelled at C-5 and 57%-d_1 labelled at C-4.

*Thermolysis of labelled triene **20**a*

A solution of 8.2 mg (0.049 mmol) of **20***a* in 1 mL of *n*-nonane was refluxed (ca. 150°C) for 16 h. The thermolysis product was chromatographed on Silica Gel 60 (0.9 cm × 10 cm; hexane). Short-path distillation (60°C/0.1 Torr) of the main band gave 7.6 mg (93%) of COT **21***a*; ^{1}H NMR (250 MHz; $CDCl_3$): 7.12–7.23 (m, 2.05H, aromatics), 6.92–7.00 (m, 2.00H, aromatics), 6.57 (br s, 0.42H, H-10), 6.34 (br s, 1.00H, H-5), 6.04 (m, 0.02H, H-9), 5.82 (m, 2.02H, H-7 and H-8), and 1.88 (d, 3.14H, methyl, $J_{Me,5}$ = 1.5).

*Direct irradiation of labelled triene **20**a*

A solution of 112.0 mg (0.67 mmol) of **20***a* and 14.2 mg of undecane (GC standard) in 250 mL of cyclohexane was irradiated (Pyrex filter) for 3.3 h in Cell A (79% conversion by GC). The photolysate was worked up as in the case of the direct irradiation of unlabelled triene **20** to give ca. 1.0 mg (1%) of naphthalene, and 11.2 mg (17%) of pentacyclic **23**-$d_{1.5}$, ^{1}H NMR (250 MHz; $CDCl_3$): 7.09–7.20 (m, 4.21H, 4 aromatics + residual $CHCl_3$), 3.58 (s, 1.45H, H-6 and residual H-1), 2.67 (d, 1.00H, H-4, $J_{4,3}$ = 3.5), 2.05 (br s, 1.02H, H-2, and H-3), and 0.90 (s, 3.40H, methyl); 17.9 mg (16%) of recovered triene **20***a*, ^{1}H NMR (250 MHz; $CDCl_3$): 7.08–7.17 (m, 2.06H, 2 aromatics), 6.98–7.00 (m, 2.00H, aromatics), 6.14 (s, 0.42H, H-4), 5.90 (dd, 0.03H, H-5, $J_{5,4}$ = 10, $J_{5,6}$ = 4.5), 5.84 (br s, 0.99H, H-7), 3.91 (d, 1.00H, H-1, $J_{1,6}$ = 4.5), 3.48 (br s, 1.00H, H-6), and 1.64 (br s, 3.15H, methyl); 29.2 mg (26%) of SB **22***a*, ^{1}H NMR (250 MHz; $CDCl_3$): 7.34 (d, 1.00H, aromatic, J = 7), 7.01–7.17 (m, 3.05H, aromatics), 4.86 (br s, 0.97H, H-7), 3.60 (d, 1.00H, H-5, $J_{5,1}$ = 6.25), 3.33 (t, 0.97H, H-1, $J_{1,2} = J_{1,5}$ = 6.5), 2.96 (d, 0.45H, H-2, $J_{2,1}$ = 6.5), 2.58 (m, 0.03H, H-8), and 1.72 (s, 3.06H, methyl); 2.5 mg (2%) of labelled COT **21**; a solution containing 0.02 M COT and 0.2 M Ag FOD (Aldrich) gave ^{1}H NMR (250 MHz; $CDCl_3$): 7.15–7.27 (m, 2.92H, 2 aromatics plus residual $CHCl_3$), 6.93–7.10 (m, 2.00H, aromatics), 6.65–6.71 (m, 0.43H, H-10, $J_{10,9}$ = 11.5), 6.45 (br s, 0.97H, H-5), 6.14–6.19 (m, 0.35H, H-9), 5.92 (d, broad larger limb, 0.98H, H-7, $J_{7,8}$ = 11.5) and 5.88 (d, 0.74H, H-8, $J_{8,7}$ = 11.5), and 1.92 (d, 3H, methyl, $J_{Me,5}$ = 1.2); and 1.2 mg (1%) of COT **24***a*, ^{1}H NMR (250 MHz; $CDCl_3$): 7.18–7.22 (m, 2.11H, aromatics), 6.94–6.99 (m, 2.00H, aromatics), 6.49 (d and br s, 1.48H, H-5 and H-10, $J_{5,6}$ = 11.5), 5.92 (d, 1.02H, H-6 and residual H-9, $J_{9,10}$ = 11.5), 5.62 (br s, 1.00H, H-8), and 1.76 (s, 3.43H, methyl).

*Sensitized irradiation of triene **20**a*

A solution of 45.4 mg (0.27 mmol) of **20***a*, 13.3 mg of undecane (GC standard), and 45.4 mg (0.20 mmol) of *p*-dimethylaminobenzophenone in 40 mL of cyclohexane was irradiated for 40 min in Cell B, with light filtered through a WG 360 glass (Schott) filter (57% conversion by GC). The photolysate was worked up as in the case of the sensitized irradiation of unlabelled triene **11** to give a trace of naphthalene; 13.4 mg (30%) of recovered triene **20***a*, ^{1}H NMR (250 MHz; $CDCl_3$): 7.07–7.17 (m, 2.00H, 2 aromatics), 6.96–7.06 (m, 2.00H, aromatics), 6.22 (s, 0.42H, H-4), 5.90 (dd, 0.02H, H-5, $J_{5,4}$ = 10, $J_{5,6}$ = 4.5), 5.84 (br s, 0.97H, H-7), 3.91 (d, 0.98H, H-1, $J_{1,6}$ = 4.5), 3.48 (br s, 1.00H, H-6), and 1.64 (br s, 3.07H, methyl); a trace of COT **21***a*, ^{1}H NMR (250 MHz; $CDCl_3$): 7.14–7.21 (m, 1.96H, aromatics), 6.94–6.98 (m, 2.00H, aromatics), 6.57 (br s, 0.45H, H-10), 6.34, (br s, 0.99H, H-5), 6.04 (m, 0.03H, H-9), 5.83 (m, 1.98H, H-7 and H-8), and 1.88 (d, 3.29H, methyl, $J_{Me,5}$ = 1.5); and 7.3 mg (16%) of SB **22***a*, ^{1}H NMR (250 MHz; $CDCl_3$): 7.34 (d, 1.00H, aromatic, J = 7), 7.01–7.17 (m, 3.15H, aromatics), 4.86 (br s, 0.98H, H-7), 3.60 (d, 1.00H, H-5, $J_{5,1}$ = 6.25), 3.33 (t, 1.00H, H-1, $J_{1,2} = J_{1,5}$ = 6.5), 2.96 (d, 0.45H, H-2, $J_{2,1}$ = 6.5), 2.58 (m, 0.02H, H-8), and 1.72 (s, 3.06H, methyl).

Quantum yield determinations

Quantum yield measurements were performed on an apparatus previously described (28), which includes an optical bench arranged for beam splitting into a ferrioxalate actinometer (29). Cyclohexane solutions (3.5 mL) of reactants (ca. (4.5–6.5) × 10^{-3} M) and sensitizer, if any (*p*-dimethylaminobenzophenone, 5.0 × 10^{-3} M; benzophenone, 8.2 × 10^{-2} M; and thioxanthone, 1.2 × 10^{-3} M), were deoxygenated prior to irradiation by flushing with argon. A positive pressure of argon was maintained over the stirred solutions throughout the course of the irradiations. The quantum yields (Φ's) were obtained from several runs extrapolated to zero conversion. Product analyses were determined by GC (internal tetradecane standard). For the direct irradiation of triene **20**, light of wavelength 280 nm was used. For sensitized runs the sensitizers absorbed >95% of the incident light (366 nm) employed.

Calculations

The CNDO semi-empirical molecular orbital calculations were performed on the full molecules, as previously described (13), except that the ground state geometries were determined using the MNDO approximation (30), since optimization via the CNDO approach led to collapse of the bridgehead C5—C6—C7 angle of triene **20**. The version of MNDO used was contained in the HyperChem package of programs.[2] The vertical excitation energies were obtained by configuration interaction (60 states) with the CNDO/S parametization (31), using a modified version of the program QCPE no. 315, originally written by Del Bene and Jaffé (31, 32). The CI expansion coefficients were employed to partition the excitation energy into single atom and atom–atom interaction energies (13); the latter energies are listed in Table 3. We interpret negative values to indicate "forces" that tend to bring atoms together, while positive values cause the atoms to move further apart. Inspection of Table 3 shows that the entries for compound **3** are mostly very similar to those for **20**; only for the 1–2 atom–atom interaction energies are there significant differences between the two trienes, and for which we are unwilling to identify a mechanistic consequence.

Irradiation of *ortho*-benzylbenzophenone leads to the formation of two (*E,E* and *Z,E*) out of the possible four photoenols. Laser flash photolysis studies show that the process involves the intermediacy of a short-lived biradical ($\tau \sim 50$ ns in methanol) that decays concurrently with the formation of the photoenols. The *Z,E* enol is very short lived and decays by an allowed 1,5-hydrogen shift to regenerate the starting material; its lifetime is <30 ns, 280 ns, 1.4 μs, and 90 ns, in benzene, acetonitrile, methanol, and trifluoroethanol, respectively. The *Z,E* enol is stabilized in hydroxylic solvents, although the acidity of trifluoroethanol seems to promote reketonization. *E,E* Enol lifetimes range from 80 μs (trifluoroethanol) to 470 μs (benzene) and its decay involves cyclization leading to 10-phenylanthrone following oxidation of the appropriate dihydroanthracene formed initially.

J.C. NETTO-FERREIRA, V. WINTGENS et J.C. SCAIANO. Can. J. Chem. **72**, 1565 (1994).

L'irradiation de l'*ortho*-benzylbenzophénone conduit à la formation de deux (*E,E* et *Z,E*) des quatre photoénols possibles. Des études de photolyse éclair au laser montrent que le processus implique un biradical de courte vie ($\tau \sim 50$ ns, dans le méthanol) comme intermédiaire qui se décomposé concurremment avec la formation de photoénols. La durée de vie de l'énol *Z,E* est très courte et il se décompose par un déplacement 1,5 d'hydrogène pour régénérer le produit de départ; son temps de vie est respectivement de <30 ns, 280 ns, 1,4 μs et 90 ns dans le benzène, l'acétonitrile, le méthanol et le trifluoroéthanol. L'énol *Z,E* est stabilisé dans les solvants hydroxylés, même si l'acidité du trifluoroéthanol semble favoriser une recétonisation. Les temps de vie de l'énol *E,E* varient de 80 μs (trifluoroéthanol) à 470 μs (benzène) et sa décomposition implique une cyclisation conduisant à la 10-phénylanthrone après une oxydation du dihydroanthracène approprié qui se forme initialement.

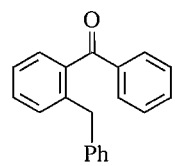
[Traduit par la Rédaction]

Introduction

Aromatic ketones containing alkyl substituents in the *ortho* position give upon excitation a mixture of isomeric enols showing similar spectroscopic properties but very different kinetic behaviour. Triplet excited states and a rotationally equilibrated 1,4-biradical are the precursors for these photoenols (1–4).

In most cases the photoenols decay by a thermally allowed 1,5-hydrogen shift, regenerating the starting ketone. However, there are a few examples in which photoenol decay results in product formation. For example, photolysis of 2-substituted *ortho*-ethylbenzophenones gives *ortho*-vinylbenzophenone by elimination of the 2-substituent (5). Suitably substituted aromatic ketones can form the corresponding benzocyclobutenols in fairly high quantum yields, suggesting that intramolecular [2+2] cycloaddition may be a more common process in photoenol chemistry than had been previously assumed (6–9). Other examples include chloride elimination from α-chloro acetophenones with the concomitant formation of 1-indanones (10–12), the formation of 3-phenylphthalide from the photolysis of *ortho*-benzoylbenzaldehyde (13), and, finally, the synthesis of 2-hydroxy-2-alkyl(or aryl)-1-indanones from *ortho*-alkyl substituted aromatic α-diketones (14–18).[2]

In this paper we show results obtained by laser flash photolysis and product studies on the photoenols in different solvents, generated by irradiation of *ortho*-benzylbenzophenone (**1**).



1

Previous studies on this ketone showing some of the possible intermediates involved in the dynamics of product formation from **1** have already been reported (19–21); however, a complete understanding of these processes is not yet available. Our goal was to provide such an understanding through the characterization of intermediates and products resulting from the photochemistry of *ortho*-benzylbenzophenone **1**.

Experimental part

Materials

The solvents employed were Spectrograde or Gold Label and were used as received. Dimethyl ketomalonate, dimethyl acetylenedicarboxylate, and maleic anhydride (all from Aldrich) were used as received. 1,3-Cyclohexadiene (Aldrich) was bulb-to-bulb distilled shortly before use.

ortho-Benzylbenzophenone (**1**) was synthesized in a three-step reaction. 2-Bromobenzhydrol was prepared by a Grignard reaction between phenylmagnesium bromide and 2-bromobenzaldehyde. The alcohol was then refluxed in the presence of iodine and red phosphorus

using an acetic acid – water mixture as the solvent. The 2-bromodiphenylmethane obtained in this reaction was purified by fractional distillation under reduced pressure, following the same procedure described for the chlorine derivative (22). A Grignard reagent was prepared using this bromo derivative to which benzonitrile was added, with the resulting mixture being left under reflux for 8 h (a procedure similar to that described for the synthesis of 2-benzylphenyl-2-pyridylketone (23). After acid hydrolysis, **1** was extracted with ethyl ether from the crude mixture, and purified by preparative thin-layer chromatography in a Chromatotron apparatus (silica gel, 1.5% ethyl acetate – hexane), yielding pale yellow crystals, mp 50–51°C (lit. (22) mp 50–52°C).

General techniques

UV–visible spectra were recorded with a Hewlett–Packard 8451-A diode array spectrometer.

GC analyses were carried out on a Perkin–Elmer model 8320 capillary gas chromatograph employing a 12-m J&W bonded-phase vitreous silica BP1 silicone column. GC–MS analyses were performed on a Hewlett–Packard model 5995 instrument.

Melting points were determined in a Mel-Temp apparatus and were not corrected.

Product studies

Typical samples were 1 mL, containing 0.03 M of **1** in benzene or in trifluoroethanol. The samples were contained in Pyrex tubes and were deaerated by bubbling with oxygen-free nitrogen. The irradiations were carried out in a "merry-go-round" apparatus with nine RPR-3000 lamps. The products were analysed by GC and GC–MS.

Laser flash photolysis

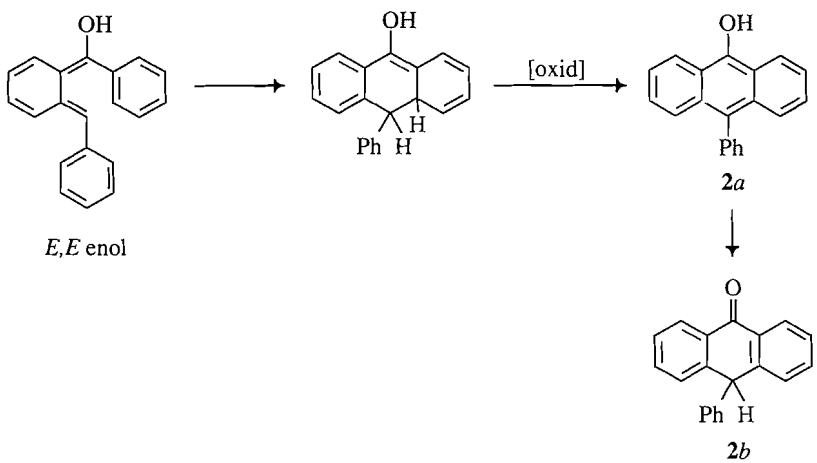
Samples were contained in 7×7 mm^2 cells made of Suprasil quartz tubing and were deaerated by bubbling with oxygen-free nitrogen. The samples were irradiated with the pulses (308 nm, ≈5 ns, ≤20 mJ/pulse) from a Lumonics EX-510 excimer laser. Our detection system incorporates a monochromator–photomultiplier combination; the signals from the RCA-4840 photomultiplier were captured by a Tektronix 2440 transient digitizer, and were then transferred to a MacIntosh IIci computer that controlled the system and provided suitable storage and processing facilitioes through the use of a home-developed program using LabVIEW-2.2 software. Further details on similar laser systems have been reported elsewhere (24, 25).

Results

Product studies

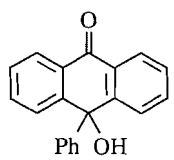
Irradiation of *ortho*-benzylbenzophenone (**1**) in benzene at 300 nm leads to the formation of at least four products as analysed by GC–MS. The main product has a molecular weight of 270 and was attributed to 10-phenylanthrone (**2***b*), the keto form of 10-phenyl-9-anthranol (**2***a*). This product can be easily formed by an intramolecular cyclization from the corresponding *E,E* enol formed from **1** (vide infra), through the intermediacy of the properly substituted dihydroanthracene. Further oxidation of this intermediate leads to **2**.

While the irradiation was conducted with deaerated samples, they may still have contained some traces of oxygen, or be exposed to it during post-irradiation handling. Thus, oxygen



E,E enol

insertion in **2** can explain the formation of 10-hydroxy-10-phenyl-anthrone (26) (**3**), (mol. wt. 286), the other identified product obtained upon irradiation of **1**. The two other peaks present in the GC trace and accounting for ca. 20% of products could not be identified.



3

A mixture of the same products was obtained when **1** was photolyzed in trifluoroethanol.

Laser flash photolysis

Laser flash photolysis of *ortho*-benzylbenzophenone (**1**) in deaerated benzene leads to a transient spectrum with maxima at 340 and 440 nm (Fig. 1). The clean first-order decay associated with these two mixima (see insert in Fig. 1) leads us to conclude that it cannot be associated with a mixture of transients. The lifetime measured for this species is ca. 470 μs. Triplet quenchers such as 1,3-cyclohexadiene have no effect on this transient lifetime. On the other hand, the very efficient dienophile, dimethyl ketomalonate, quenches this transient with a rate constant of 3×10^4 M^{-1} s^{-1}. We were not able to observe any quenching by using either maleic anhydride or dimethyl acetylenedicarboxylate as quenchers. Based on these data, the transient responsible for the decay initially observed was tentatively identified as one of the four possible photoenols derived from **1**, i.e., the *E,E* enol **4** (vide infra).

The transient spectrum in deaerated acetonitrile is quite similar to that recorded in benzene. However, in this case two decay components are clearly observed. The shorter lived transient ($\tau = 280$ ns) was attributed to the *Z,E* enol **5**, with its faster deac-

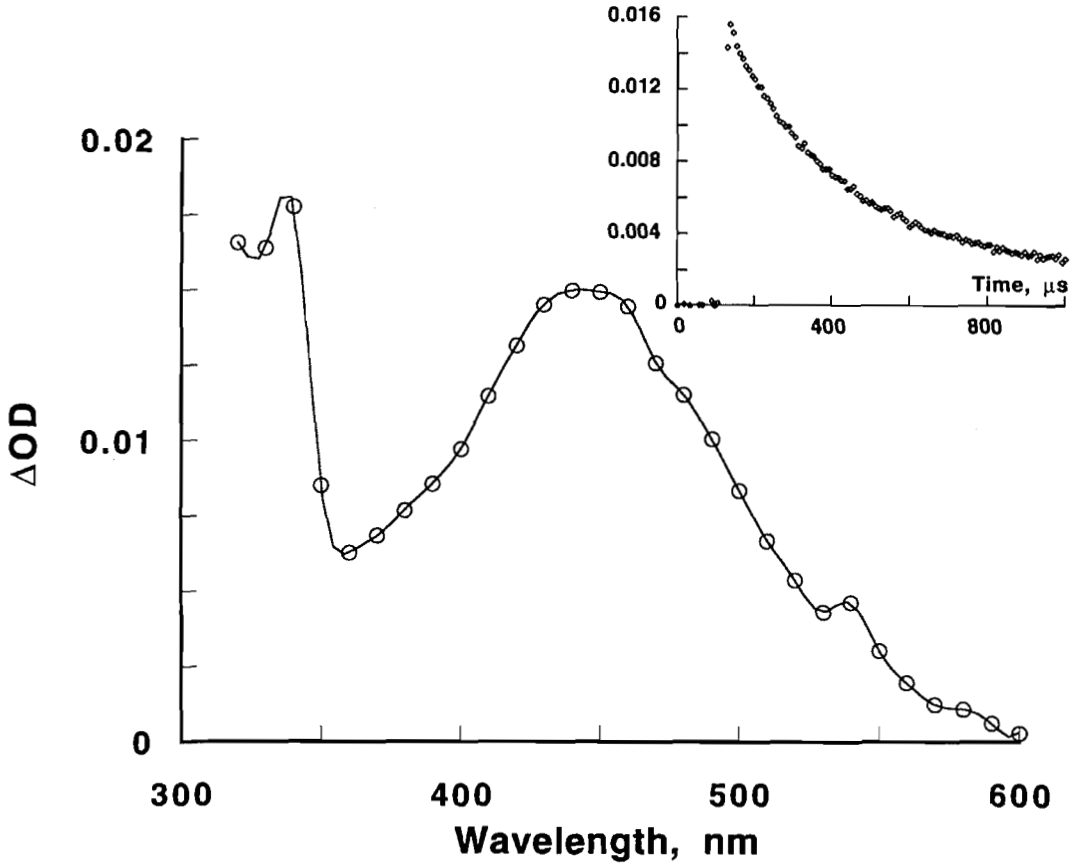

FIG. 1. Enol absorption spectrum obtained on 308 nm excitation of *ortho*-benzylbenzophenone (**1**) in benzene, and (insert) decay of the photoenol.

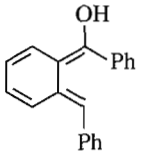
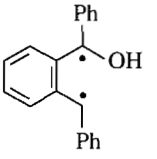
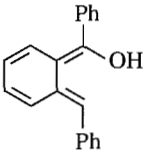


4 (*E,E* enol)



6

tivation rate constant being due to the allowed 1,5-hydrogen shift reketonization process. For the *E,E* enol we measured a lifetime of 190 μs.



5 (*Z,E* enol)

At 330 nm we could also observe a very short-lived transient ($\tau \sim 20$ ns), readily quenched by oxygen but not by 1,3-cyclohexadiene. Concomitantly, a growth was noticed at 440 nm (the photoenol region) on the same time scale, following the same kinetics as those observed for the decay at 330 nm. This short-lived transient was attributed to biradical **6**, the expected precursor of the enols.

Just as in the case of benzene and acetonitrile, the spectrum recorded in methanol on a 50 μs time scale shows two bands with maxima at 320 and 440 nm (Fig. 2). A slight shift to the red could be observed when the spectrum was recorded 50 μs after the laser pulse, compared to the one recorded at 1 μs. The decay is clearly biexponential, from which we measured lifetimes of 1.4 and 150 μs, with both decays being insensitive to the presence of oxygen. Again, a short-lived transient was observed

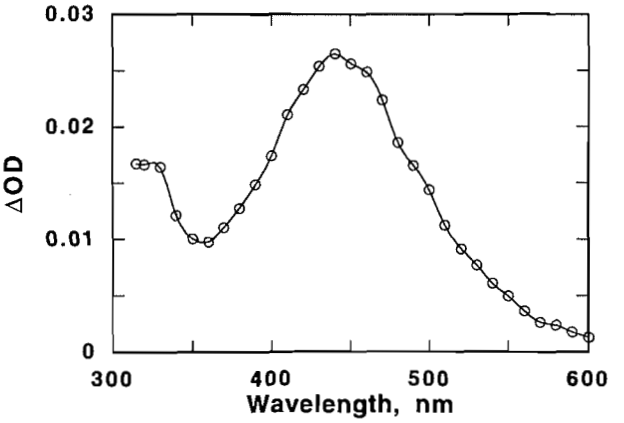


FIG. 2. Enols absorption spectra obtained on 308 nm excitation of *ortho*-benzylbenzophenone (**1**) in methanol on a 50 μs time scale.

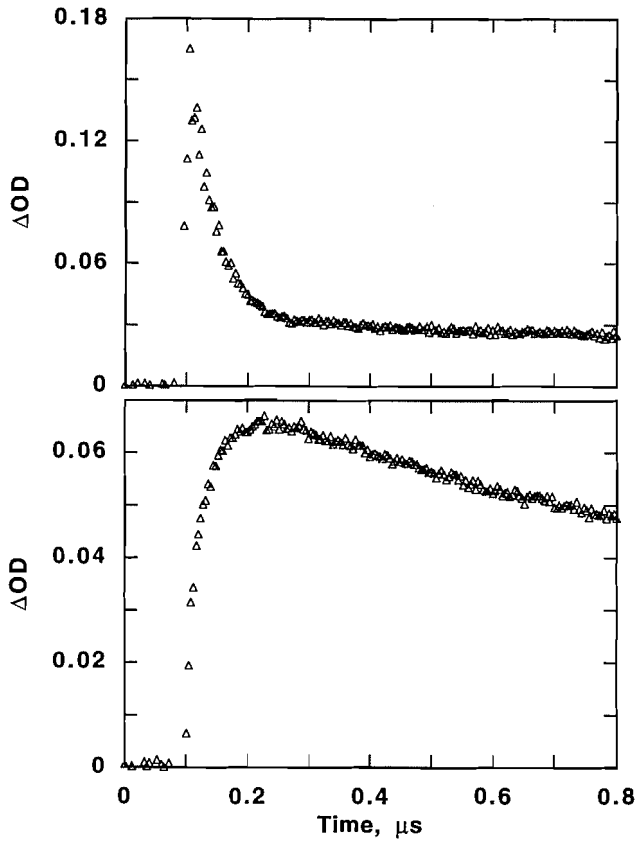

FIG. 3. Top: Decay of absorption at 330 nm due to biradical **6** generated from *ortho*-benzylbenzophenone (**1**) upon 308 nm excitation in methanol. Bottom: growth at 440 nm for the enol mixture generated as above.

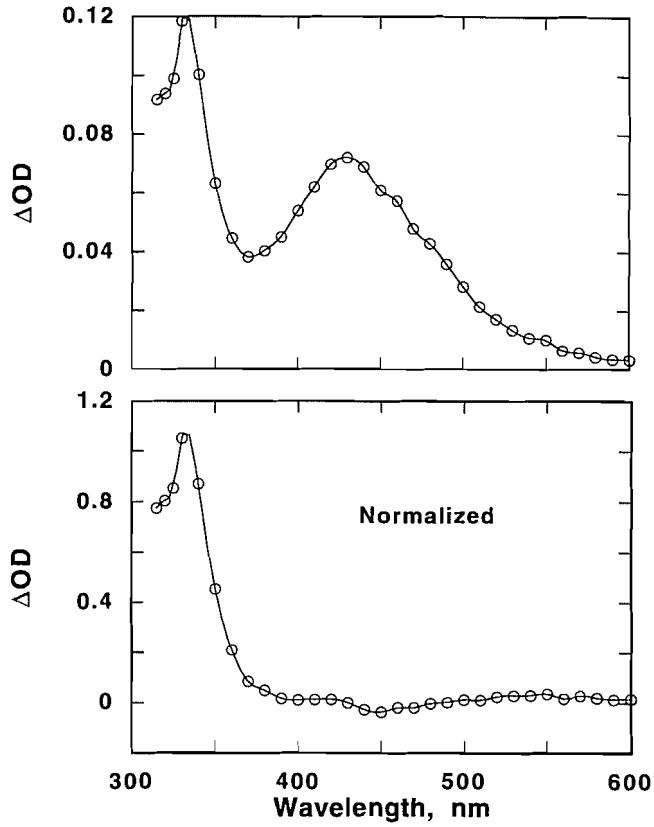

FIG. 4. Top: Enols absorption spectra obtained on excitation of *ortho*-benzylbenzophenone (**1**) in methanol on 1 μs time scale. Bottom: Difference spectrum from the subtraction of the spectrum in Fig. 2 from that in Fig. 4, top.

when the decay was monitored at 330 nm (Fig. 3, top), showing the same kinetics as the growth observed at 440 nm on the 100 ns time scale (Fig. 3, bottom).

When the spectrum in methanol was recorded on a 1 μs time scale, a very sharp and intense band with maximum absorption at 320 nm could be noticed in addition to the already reported photoenol absorptions at 320 and 440 nm (Fig. 4, top). Subtracting the spectrum at 50 μs decay (due to photoenols **4** and **5**) from the one recorded on this short time scale, corresponding to the biradical plus photoenols mixture, we obtain only one maximum at 330 nm, which can be assigned to biradical **6** (Fig. 4, bottom).

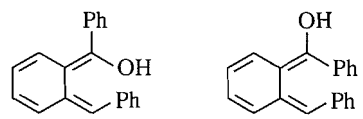
From the spectroscopic and kinetic points of view, there is great similarity between the data obtained in the previous solvents and in trifluoroethanol, the last solvent used in this work. For example, in this solvent we were able to observe the decay related to biradical **6** (τ = 30 ns, λ_{max} = 320 nm) and the enol growth at 430 nm. At this wavelength we observe a two- component decay from which we obtain lifetimes of 90 ns (*Z,E* enol) and 80 μs (*E,E* enol).

Table 1 summarizes the data obtained in these experiments.

Discussion

Upon irradiation, *ortho*-benzylbenzophenone (**1**) can give a mixture of four possible photoenols: the already mentioned **4** (*E,E* enol) and **5** (*Z,E* enol), as well as **7** (*Z,Z* enol) and **8** (*E,Z* enol).

It is clear that **7** and, in particular, **8** show considerable steric



7 (*Z,Z* enol) **8** (*E,Z* enol)

congestion and, in principle, their involvement in product formation from **1** should not be expected. In fact, quenching experiments under steady-state conditions performed by Pfau et al. (21), using selected dienophiles and benzene as solvent, show conclusively that **4** was the only photoenol formed. These data are in full agreement with results obtained in this work for the same solvent. We note that **5** is probably formed in nonpolar solvents such as benzene. However, its lifetime is probably too short for **5** to be either detected spectroscopically, or trapped in preparative work.

It is well known that an increase in solvent polarity leads to an enhancement in photoenol lifetime, which is more effective in hydroxylic solvents (2–4). In these cases the hydrogen bonds formed between the hydroxylic protons of the enol and the solvent are responsible for a considerable slowdown of the reketonization process. Thus, we rationalize our results as a consequence of changes in hydrogen bonding in the various solvents employed. An inspection of Table 1 shows that there was a substantial increase in the *Z,E* enol lifetime on going from benzene to methanol. Thus, this species can become an observable transient under laser flash photolysis conditions. The shortening in the lifetime of **5** in trifluoroethanol can be easily

TABLE 1. Spectroscopic and kinetic data for the transients observed upon laser flash photolysis of **1** in several solvents

	Lifetime (μs)			Maximum absorption (nm)

explained by assuming that either its acidity or traces of organic acids can catalyze the reversion of this photoenol to the corresponding ketone (20, 27).

Photodecomposition of *ortho*-benzylbenzophenone yields a photoenol mixture from which several products can be formed. The immediate precursor of these enols is the biradical **6**. Since it was not possible to resolve the biradical formation in any of the solvents used, it is safe to assume that its precursor, i.e., the triplet state for **1**, has a lifetime of less than 20 ns.

The chemistry of thujone. XVII.[1] The synthesis of ambergris fragrances and related analogues

JAMES P. KUTNEY[2] AND YONG-HUANG CHEN

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, BC V6T 1Z1, Canada

Received August 11, 1993

JAMES P. KUTNEY and YONG-HUANG CHEN. Can. J. Chem. **72**, 1570 (1994).

A strategy to utilize the thujone-derived enone **1** for the development of a synthetic route to ambergris fragrances is presented. Thujone (**8**) is transformed to the tricyclic enone **9**, via the Robinson annulation reaction, and the latter is then elaborated to the *cis*-fused tricyclic intermediates **10**, **11**, and **12**. Extrusion of the isopropyl side chain in **12** is achieved through an initial ozonation reaction and the resulting ketone **14** is then treated with *m*-CPBA to afford **16**. Cyclopropyl ring opening in **16** is performed via initial saponification to the alcohol **17** and the latter is then reacted with $FeCl_3$ and sodium acetate to enone **1**. The necessary elaboration of a tetrahydrofuran ring attached to ring B of **1** is achieved through reaction of **1** with vinylmagnesium bromide, alkylation, hydroboration, and final acid-catalyzed ring closure of the 1,5-diol **4**. The route affords the opportunity of synthesizing a variety of analogues within the Ambrox series.

JAMES P. KUTNEY et YONG-HUANG CHEN. Can. J. Chem. **72**, 1570 (1994).

On propose une stratégie dans le but d'utiliser l'énone **1** dérivée de la thujone pour le développement d'une voie de synthèse des essences de l'Ambregris. On transforme la thujone (**8**) en énone tricyclique **9** par le biais d'une réaction d'annélation de Robinson et, par la suite, cette dernière cétone est transformée en intermédiaires tricycliques **10**, **11** et **12** à fusion *cis*. L'extrusion de la chaîne latérale isopropyle du composé **12** est réalisée à l'aide d'une réaction d'ozonolyse initiale, suivie par la traitement de la cétone **14** qui en résulte avec de l'acide *m*-CPBA pour obtenir le produit **16**. On effectue l'ouverture du cyclopropyle du composé **16** en procédant au départ à une saponification en alcool **17** et en soumettant ensuite ce composé à une réaction avec du $FeCl_3$ et de l'acétate de sodium pour obtenir l'énone **1**. On procède à l'élaboration du noyau tétrahydrofurane attaché au cycle B du composé **1** en soumettant ce produit à une réaction avec le bromure de vinylmagnésium, puis à une alkylation, à une hydroboration et finalement à une ouverture de cycle acidocatalysée conduisant au 1,5-diol, **4**. Cette voie offre la possibilité de synthétiser une variété d'analogues de la série de l'Ambrox.

[Traduit par la Rédaction]

Ambergris and ambergris fragrances represent a most valuable family of perfumes. Their outstanding fragrances accounts for man's familiarity with this substance over many years (2, 3). One of the classics of amber chemicals, (–)-Ambrox (**2**), in a mixture with (+)-iso-Ambrox (**3**) and in the form of the base Fixateur 404 (trade name of Firmenich) has been available in the perfumery industry for more than 30 years. Extensive studies correlating structure with smell have also been described (3). (–)-Ambrox (**2**), present in trace amounts in whale secretions, is prepared commercially from sclareol, a natural product isolated from clary sage. As future requirements within the ambergris family will depend increasingly on synthetic materials, it was therefore in our interest to develop a versatile route to this family of compounds from thujone (**8**), a readily available waste by-product in the B.C. forest industry.

The retrosynthetic analysis that was considered for the possible elaboration of a versatile route to **2** and **3** and (or) their related analogues is summarized in Scheme 1. The *cis*-fused enone **1** was a promising starting material: the convex β face and the steric hindrance from the axial methyl at C4 in ring A of the major conformer (nonsteroidal) should ensure a favorable conjugate addition (e.g., by a vinyl anion equivalent) from the β face of the ring B segment thereby generating a chiral center at C9 with the same configuration as that in (–)-Ambrox (**2**). The conjugate addition might also provide an excellent opportunity to stereoselectively introduce a methyl group at C8, by trapping the enolate produced in the addition reaction with appropriate methylating reagents, for example, iodomethane. The *cis*-fused γ,δ-enone **6**, thus obtained, would subsequently be converted to its epimer, the *trans*-fused γ,δ-enone **5**.

We also envisaged that the furan ring C of (–)-Ambrox (**2**) or (+)-iso-Ambrox (**3**) may be formed by an acid-catalyzed cyclization of the *trans*-fused 1,5-diol **4**, which would be prepared by stereoselective reduction of **5** and subsequent hydroboration. Conformational analysis of **4** reveals that an axial orientation of the secondary hydroxyl group at C7, as shown, would be necessary to ensure a facile migration of the axial hydride from the vicinal tertiary carbon (C8). Alternatively, an equatorial orientation of this secondary hydroxyl group as shown in **7** would probably lead to some skeletal rearrangement.

To evaluate the feasibility of the above strategy, the synthesis of **1** became our initial consideration. The successful synthetic route from thujone (**8**) is summarized in Schemes 2 and 3. The readily available enone **9**, obtained in earlier studies (5), was catalytically reduced to the *cis*-fused ketone **10** in essentially quantitative yield, and the latter upon methylation to **11** and Wolff–Kishner removal of the carbonyl group in **11**, affords **12**.

The desired removal of the isopropyl side chain could be achieved via initial application of a previously developed ozonation reaction (6). Ozonation of **12** at low temperature provides a reaction mixture containing the tertiary alcohol **13** (42% yield) and the ketone **14** (27%). Although separation and characterization of these compounds was completed (see Experimental), the desired ketone **14** could be obtained in 62% overall yield from **12** by further manipulation of the reaction mixture obtained directly from the ozonation of **12**. Treatment of this mixture with pyridinium tosylate affords facile dehydration of **13** to the vinylcyclopropane analogue **15** and the resulting mixture is treated successively with potassium permangate and lead tetraacetate. Alternatively, the pure alcohol **13**, separated from **14**, is dehydrated to **15** (91% yield) and the latter ozonized to **14**.

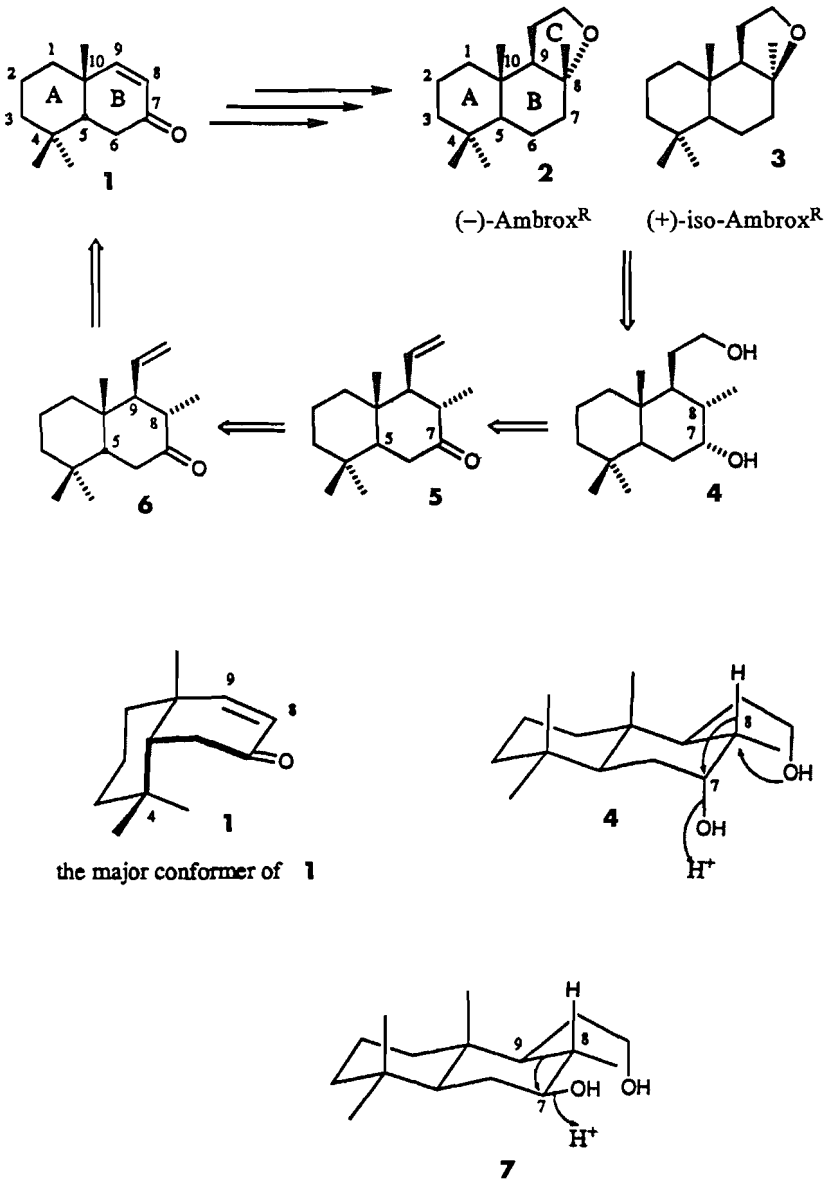

SCHEME 1. Summary of overall strategy for synthesis of ambergris fragrances from thujone-derived synthons.

It should be noted that the ketone **14** can be prepared from **9** in an overall yield of 27% by performing the sequence 9 → → → **14** without purification of intermediates.

Elaboration of **14** to the desired enone **1** followed the sequence summarized in Scheme 3. It was perceived that a Baeyer–Villiger reaction would cleave the side chain of **14** in a regioselective manner to afford **16**, in view of a previous study (7–9) involving the preferential insertion of oxygen into the cyclopropyl side chain of methyl cyclopropyl ketone. For this purpose, stirring **14** in methylene chloride with *m*-CPBA at room temperature for 2 days gave **16** in 79% yield based on the recovery of starting material (46% yield). An optimization of the reaction was carried out according to Table 1. *p*-Toluenesulfonic acid had little catalytic effect on the *m*-CPBA oxidation reaction. Under refluxing conditions, the reaction appeared to accelerate at the beginning but slowed down quickly after a few hours and started to afford some unidentified by-products. When the concentration of the substrate was increased to 0.82 M, the reaction was quite complete after refluxing in methylene chloride for 12 h and the yield of **16** was 82%. Although the use of trifluoroperacetic acid (7) improved the yield to as high as 94%, the reaction was not easily reproducible. This was probably due to the instability of trifluoroperacetic acid. Therefore, the preferred procedure for the preparation of **16** was to employ a high concentration of substance **14** with *m*-CPBA as the oxidizing agent in refluxing methylene chloride.

The mass spectrum of acetate **16** showed the molecular ion peak at *m/z* 236. The IR spectrum had a carbonyl absorption at 1735 cm^{-1} while the ^{1}H NMR spectrum displayed four methyl singlets at δ 0.80, 0.97, 1.05, and 2.10 ppm. The methyl singlet at δ 2.10 ppm was obviously due to the acetate group, which unambiguously demonstrated the insertion of oxygen into the position between the quaternary cyclopropyl carbon (C7) and the carbonyl carbon.

Regioselective ring opening of alkyl-substituted cyclopropanols by ferric chloride has been studied extensively by DePuy and van Lanen (10). From these studies it is clear that the more substituted C—C bond is preferentially cleaved.

Saponification of **16** was carried out in dilute potassium hydroxide – ethanol solution for 30 min. The rather polar **17**

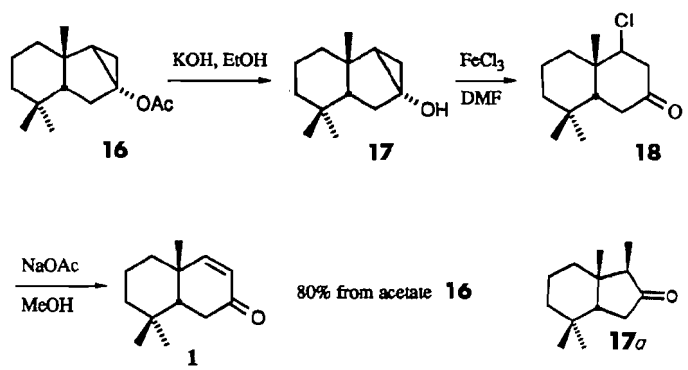


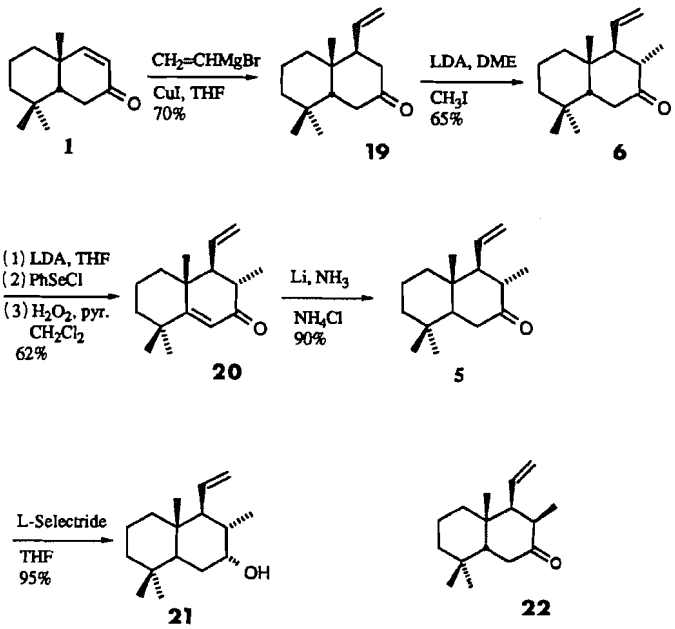
SCHEME 3. Conversion of tricyclic acetate **16** to enone **1**.

was obtained in almost quantitative yield provided the reaction mixture was worked up immediately, since **17** is unstable and undergoes facile conversion to the undesirable cyclopentanone analogue **17***a*.

The lability of cyclopropanol **17** dictated its immediate application to the next reaction. The mixture of anhydrous ferric chloride and **17** in anhydrous *N,N*-dimethylformamide was agitated under nitrogen at room temperature for 24 h. The major product **18** was isolated, in addition to a small amount of **17***a*, as evidenced from its spectral data (see Experimental).

The β-chloroketone **18** had its mass spectrum showing molecular ion peaks at *m/z* 230 (0.2%) and 228 (0.6%) corresponding to formulas $C_{13}H_{21}O^{37}Cl$ and $C_{13}H_{21}O^{35}Cl$, and other characteristic spectral data (see Experimental). The orientation of the chlorine function in **18** was uncertain.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.



SCHEME 4. Conversion of enone **1** to bicyclic alcohol **21**.

The β-chloroketone **18** underwent elimination of hydrogen chloride to give enone **1** easily even without addition of any base. Consequently, the crude product from the above ring-cleavage reaction was treated with sodium acetate in refluxing methanol for a few hours. The overall yield of **1** from acetate **16** was 80%, equivalent to a 93% yield for each step. The ketone **1** was a white solid with mp 64–66°C (lit. (11) mp 68°C).

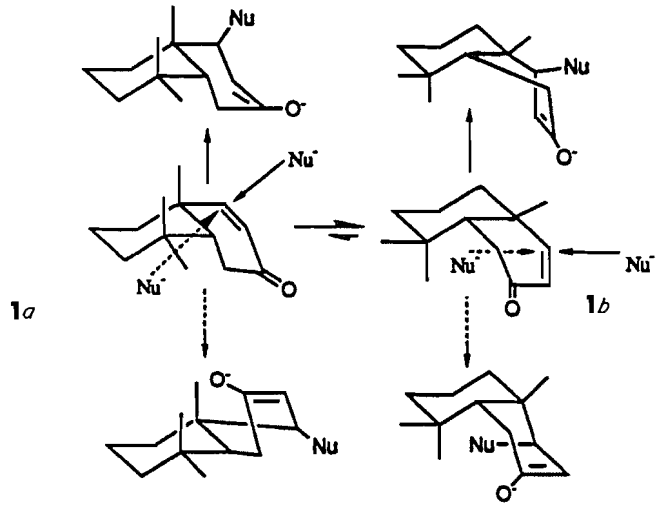
As noted earlier, the racemate of **1** was prepared previously by an interesting photochemical epimerization (11).

To complete the synthesis of (–)-Ambrox (**2**), as outlined in Schemes 4 and 5, a diastereoselective conjugate addition to enone **1** from the β face of the molecule was essential. Conjugate addition to enones by organocopper reagents has been widely employed in organic synthesis, as indicated in several reviews (12, 13). Diastereoselective addition is generally established with the incoming group approaching in a manner perpendicular to the enone plane in order to allow maximum orbital overlap during the progress of the reaction. This stereoelectronic requirement clearly demands a careful conformational analysis of the enone in order to determine the facial preference of the conjugate addition. Such an analysis of enone **1**, as shown in **1***a* and **1***b*, suggested that the desired conversion of **1** to **19** (Scheme 4) could be expected.

Experimentally, conjugate addition of **1** with 2.0 equivalents of vinylmagnesium bromide and a catalytic amount of cuprous iodide in dimethyl sulfide:THF (1:5, v/v) solution gave the β-face addition product **19** in 70% yield, the stereochemistry of which was confirmed by the ^{1}H NMR spectrum of the subsequent methylation product **6** (see later). The absence of dimethyl sulfide (14) or the use of cuprous bromide as catalyst led to decrease in yields, likely due to the formation of competing 1,2-addition by-products. Some polar by-products were often observed in the reaction.

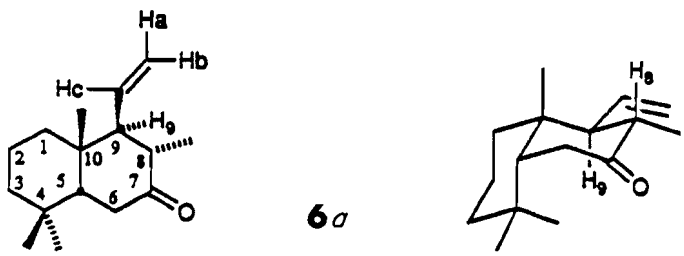
The alkylation of **19** to **6** involved a detailed study, to establish optimum conditions and information about the stereochemistry of methylation.

After the enone **19** was treated with LDA in dimethoxyethane



(DME) (15), initially at –78°C for 30 min, the mixture was warmed to approximately 45°C. Iodomethane (5.0 equiv.) was added rapidly to the mixture. Compound **6** together with its minor epimer **22** (6:1) was isolated in 60–70% yield. Since these two epimers were not separable, a basic treatment with potassium hydroxide in methanol was performed to convert the epimeric mixture into the more stable compound **6** (97% pure by GC). When THF was used as the solvent for the methylation reaction, a very large recovery (>60%) of starting material was observed, presumably because the sluggishness of the methylation reaction led to a quick equilibration of the initially generated enolate with the methylation products through proton exchange (16). It should be noted that the deprotonation in ring B of **19** was regioselective and the alternative deprotonation at C6 was not observed.

The mass spectrum of **6** revealed the molecular ion peak at *m/z* 234. Its IR spectrum indicated a carbonyl stretching absorption at 1700 cm^{-1}, and a carbon–carbon double bond stretching absorption at 1630 cm^{-1}. Its ^{1}H NMR spectrum, in $CDCl_3$, displayed three methyl singlets at δ 0.82, 0.94, and 1.14 ppm and one methyl doublet (J = 6 Hz) at δ 1.04 ppm. Also present was a one-proton multiplet at δ 2.30 ppm, a complex three-proton multiplet at δ 2.40–2.70 ppm, corresponding to the allylic proton at C9, and three protons α to the carbonyl group. The olefinic signal at δ 5.01 ppm appeared as a doublet of doublets of doublets (J = 17.0, 1.8, and 0.5 Hz). This signal was assigned to Hb (see **6***a*) since the resonance of Hb was expected to have a



large J value (15–20 Hz), due to coupling with Hc, which was *trans* to Hb, and two small J values due to coupling with Ha and H9. Thus, the three J values were tentatively assigned as J (Hb,Hc) = 17.0 Hz, J (Ha,Hb) = 1.8 Hz, J (Hb,H9) = 0.5 Hz). The olefinic proton signal at δ 5.14 ppm appeared as a doublet of doublets (J = 10.2 and 1.8 Hz). This signal was assigned to Ha since the resonance of Ha should have a J value at 8–12 Hz, due to coupling with Hc, which was *cis* to Ha, and a small J

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12

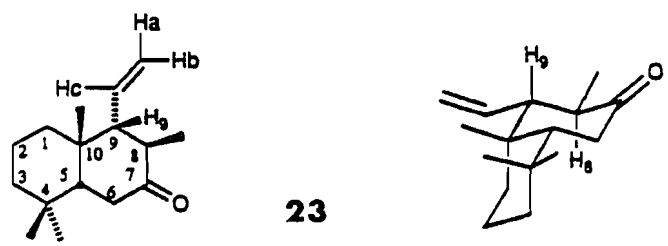
Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

value of 1.8 Hz due to coupling with Hb. On this basis, J (Ha,Hc) = 10.2 Hz. The olefinic proton signal at δ 5.55 appeared as a doublet of triplets (J = 17.0 and 10.2 Hz). It was assigned to Hc since the resonance of Hc was expected to appear at lower field and should show J values of 17.0 and 10.2 Hz, thereby revealing J (Hc,H9) = J (Ha,Hc) = 10.2 Hz. The large coupling constant between Hc and H9 (J = 10.2 Hz) indicated a near coplanarity of the C9—H9 and C11—Hc bonds. In the nonsteroid-like conformer **6***a*, the vinyl side chain is drawn as shown in order to portray this situation and to indicate minimal interactions with neighboring groups, as revealed from molecular models.

The epimer **22**, generated as a minor product together with **6** during the methylation of **19**, was not characterized by spectroscopy since its separation from **6** was very difficult. However, a partially enriched sample (50% by GC) obtained from the methylation in THF was converted into **6** (97% pure by GC) by treatment of the mixture with a dilute KOH–methanol solution. The existence of **22** was then indirectly confirmed.

To confirm the stereoselectivity of the conjugate addition reaction and the regioselectivity of the methylation reaction, a detailed ^{1}H NMR spectral analysis of **6** was conducted. The ^{1}H NMR spectrum in deuterated benzene afforded a clear resolution of the four proton signals at δ 2.20–2.70 ppm previously observed in the spectrum taken in deuterated chloroform. Decoupling by irradiation at δ 5.75 ppm (Hc signal, see **6***a*) caused a one-proton triplet (J = 10.2 Hz) at δ 2.42 ppm to collapse into a doublet (J = 10.2 Hz) in addition to the collapsing of the Ha signal at δ 4.94 ppm and Hb at δ 4.82 ppm into two broad singlets. Therefore, the triplet signal at δ 2.42 ppm was clearly due to the allylic proton (H9), which apparently coupled only with Hc and one neighbouring axial proton (J = 10.2 Hz). Thus, the methylation of **19** must have taken place at C8 rather than at C6. The methylation at C6 would have produced an isomer that should have a more complex signal (doublet of doublets or triplet) for the allylic proton (H9) if irradiation at the Hc signal had occurred. The only methyl doublet signal in the $CDCl_3$ spectrum that appeared at δ 1.15 (J = 5.1 Hz) was assigned to the methyl group at C8. A one-proton multiplet, consisting of six lines of equal spacing (5.1 Hz) and an intensity ratio 1:3:4:4:3:1, appeared at δ 1.90 ppm in the C_6D_6 spectrum and at δ 2.28 ppm in $CDCl_3$, respectively. The splitting pattern of this signal was indeed a doublet of quartets with J = 10.2 Hz for the doublet coupling and J = 5.1 Hz for the quartet coupling. Thus, this signal was assigned to the α methine proton at C8.

In fact, the structure **23**, which had reverse configurations at



23

C8 and C9 with regard to **6**, could also account for the result of decoupling experiments, especially the large coupling constant between Hc and H1 (J (Hc,H1) = 10.2 Hz) due to the diaxial orientation of these two protons. Therefore, to eliminate further doubt about the stereochemistry of **6**, NOE difference experiments were carried out. Unfortunately, this study did not provide unambiguous evidence due to the close proximity of signals in the aliphatic proton region in both $CDCl_3$ and C_6D_6 spectra. As a result, the interpretation of NOE difference experiments was very difficult. However, important evidence was later obtained from *trans* isomer **5**, the epimer of **6** (see later).

To obtain **6** more effectively, we had tried to carry out an "one-pot" reaction by quenching the enolate generated in the conjugate addition with iodomethane. The one-pot operation would eliminate intermediate isolation and could be an efficient way to ensure the desired regioselective methylation (17, 18). However, the one-pot process proved to be very sluggish and produced mostly by-products, in addition to **6** (10%) and **19** (10%). Attempts to improve the reaction, by changing solvents (Et_2O, THF, DME), temperature, and using HMPA as additive, failed. Since the conjugate addition proceeded well to produce **19** in good yield, the methylation step must be responsible for the sluggishness of this one-pot operation. In view of the apparent sluggishness of the methylation reaction, under the experimental conditions, competitive proton exchange between the initially formed enolate from the conjugate addition reaction and the methylation product **6** could occur. The enolate of **6**, thus generated, would then be further methylated. O-Methylation of enolates might be also responsible for the lack of reasonable yields of **6**.

The stereochemical conversion of the A/B *cis* fusion in **6** to the desired A/B *trans* fusion in **5** was realized through a two-step sequence as shown in Scheme 4. Slow addition of **6**, dissolved in THF solution, to a LDA–THF solution at –78°C under nitrogen was followed by rapid injection of a phenylselenenyl chloride – THF mixture. After stirring 1 h at room temperature and removal of solvent, methylene chloride, pyridine, and hydrogen peroxide were added, and the resulting mixture was stirred overnight. Dienone **20** was then isolated in 62% yield (based on a 25% recovery of starting material). The mass spectrum of **20** indicated a molecular ion peak at m/z 232. The UV spectrum, with absorptions at 242 nm and 383 nm, and the IR spectrum, with an intense conjugated carbonyl stretching absorption at 1660 cm^{-1}, substantiated the desired enone chromophore. The ^{1}H NMR spectrum revealed a methyl doublet (J = 5.1 Hz) at δ 1.07 ppm and three methyl singlets at δ 1.17, 1.22, and 1.25 ppm. A triplet (J = 10.2 Hz) at δ 2.12 ppm and a multiplet at δ 2.40 ppm, consisting of six equally spaced (5.1 Hz) lines that had an intensity ratio 1:3:4:4:3:1, were assigned to the allylic proton at C9 and the methine proton at C8 (dq, J = 10.2 and 5.1 Hz). Four olefinic protons at δ 5.05 (dd, J = 17.0 and 1.8 Hz), 5.18 (dd, J = 10.2 and 1.8 Hz), 5.64 (dt, J = 17.0 and 10.1 Hz), and 6.00 (s) ppm were attributed to the three vinyl protons and H6, respectively.

To reduce the large recovery of starting material and improve the yield of dehydrogenation, different conditions were applied (19). One-pot elimination of the phenylselenide oxide by direct H_2O_2 (30%) addition to the phenylselenide prepared in THF or DME led to an even greater recovery of starting material (50%) and a lower yield of **20** (50% based on recovery). Another one-pot elimination of phenylselenide oxide, by transferring the phenylselenide into a sodium periodate solution in methanol–H_2O (1:1) mixture, resulted in the formation of a new compound of unknown structure (25% based on recovery) in addition to **20** (40% based on recovery) and the recovered starting material (25%).

TLC monitoring of the reaction showed that only a small quantity of starting material **6** was left after the introduction of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

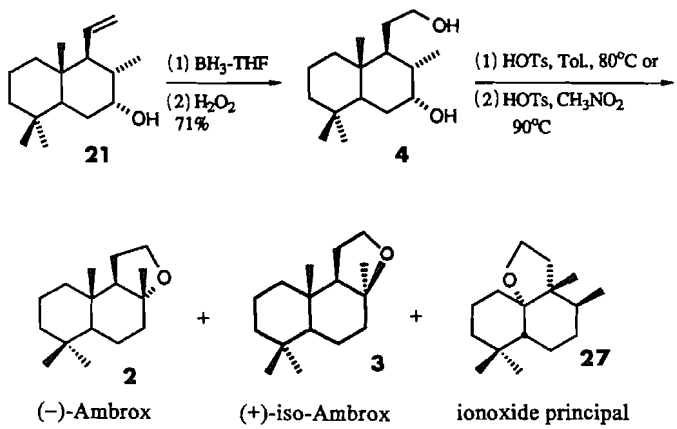
phenylselenenyl chloride, and the newly generated phenylselenides appeared as two UV-active spots (TLC) of apparently different intensities. Attempts to separate these two compounds by silica gel chromatography failed, as only the starting material **6** was isolated. Apparently, the selenides were very labile. In fact, even leaving the phenylselenides in THF–H_2O mixture overnight regenerated the starting material **6** as exclusive product.

It was expected that the phenylselenylation of **6** would produce two diastereomers resulting from the attacks on the α and β faces of the enolates of **6**. The results obtained reveal that the β attack, to afford the axial orientation of the selenyl unit, was the dominant course of the reaction.

The stereochemistry of Birch reduction of octalones has been well studied (20) and theories to rationalize the data have been put forth (21, 22). It was therefore expected that the reduction of **20** should proceed to afford **5**. Treatment of **20** in anhydrous ether:ammonia (1:2), employing a slight excess of lithium for 1 h and quenching the resulting mixture by ammonium chloride, afforded **5** in 90% yield. The mass spectrum of **5** showed its molecular ion peak at *m/z* 234 while the IR spectrum indicated the carbonyl stretching absorption at 1706 cm^{-1}. The ^1H NMR spectrum, in $CDCl_3$, displayed three methyl singlets at δ 0.88, 0.90, and 1.09 ppm, a methyl doublet (J = 6.0 Hz) at δ 0.93 ppm, a four-proton multiplet at δ 2.00–2.50 ppm, and three olefinic protons at δ 4.98 ppm (dd, J = 16.8 and 1.6 Hz), 5.12 ppm (dd, J = 10.0 and 1.6 Hz), and 5.56 ppm (dt, J = 16.8 and 10.0 Hz). As in the case of **6**, these olefinic signals were assigned to the three vinyl protons. The large coupling constant (J = 12.0 Hz) between the H9 and H8 signals were again observed from the H9 signals (δ 1.96 ppm, t, J = 12.0 Hz) in the ^1H NMR spectrum (C_6D_6), which proved beyond any doubt that the vinyl side chain and the methyl group at C8 in **5** were both oriented in an equatorial manner.

As stated earlier (Scheme 1), an axial secondary hydroxyl group at C7 in diol **4** was required for the cyclization to occur in a desired manner. To this end, enone **5** was treated with L-Selectride in THF at –78°C, and the axial alcohol **21** was isolated in nearly quantitative yield. The mass spectrum indicated the molecular ion peak at *m/z* 236 and a fragment ion at *m/z* 218 due to the loss of a water molecule. The IR spectrum showed a broad intense hydroxyl stretching absorption near 3450 cm^{-1} and a carbon–carbon double bond stretching absorption at 1630 cm^{-1}. The ^1H NMR spectrum revealed a quartet (J = 3.0 Hz) at δ 3.92 ppm corresponding to the C7 proton adjacent to the axial hydroxyl group and three one-proton multiplets at δ 4.94 (dd, J = 17.2 and 2.4 Hz), 5.02 (dd, J = 10.4 and 2.4 Hz), and 5.52 (dt, J = 17.2 and 10.4 Hz) ppm. The fact that the C7 proton appeared as a quartet at δ 3.92 ppm with a small coupling constant (J = 3.0 Hz) confirmed its equatorial orientation.

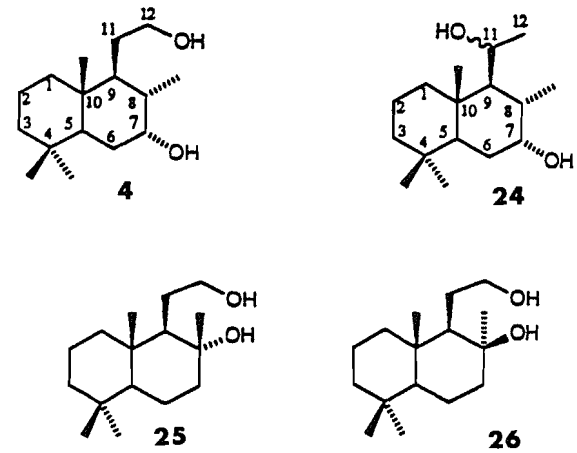
The hydroboration of **21**, with borane in THF, followed by basic hydrogen peroxide work-up, produced mainly the 1,5-diol **4** (70%) (Scheme 5) in addition to a minor 1,4-diol **24** (10%). Diol **4** had its mass spectrum showing the molecular ion peak at *m/z* 254 and two fragment ions at *m/z* 236 and 218 corresponding to loss of one and two water molecules from the parent molecular ion. The ^1H NMR spectrum revealed two overlapping methyl singlets at δ 0.82 ppm, one methyl singlet at δ 0.85 ppm, a methyl doublet at δ 0.98 (J = 6.0 Hz), a one-proton multiplet (dt, J = 7.2 and 9.6 Hz) at δ 3.50, a one-proton multiplet at δ 3.62 ppm (J = 5.6 and 9.6 Hz), and a quartet (J = 3.0 Hz) at δ 3.85 ppm corresponding to the C7 hydrogen. The two one-proton multiplets at δ 3.50 and 3.62 ppm were due to the C6 methylene group.



SCHEME 5. Conversion of bicyclic alcohol **21** to ambergris fragrances.

The minor product **24** appeared to be a mixture of two diastereomers with a ratio of 4:1, as indicated in the ^1H NMR spectrum. These two diastereomers were difficult to separate by column chromatography. The mass spectrum of the mixture revealed a molecular ion peak at *m/z* 254, while the IR spectrum showed an intense hydroxyl absorption at 3400 cm^{-1}. In the ^1H NMR spectrum, the minor diastereomer had a broad singlet at δ 3.77 ppm corresponding to H7 and a quartet (J = 8.0 Hz) at δ 4.12 ppm corresponding to the proton at C11 while the major isomer had a broad singlet at δ 3.87 ppm corresponding to H7 and a quartet (J = 8.0 Hz) at δ 4.21 ppm corresponding to the proton at C11 in the ^1H NMR spectrum. Further assignment of the stereochemistry at C11 to these two diastereomers was not possible based on the above obtained data.

Finally, for preparative purposes, the conversion of ketone **5** to diol **4** (Schemes 4 and 5) can be accomplished as a one-pot operation in an overall yield of 65%.

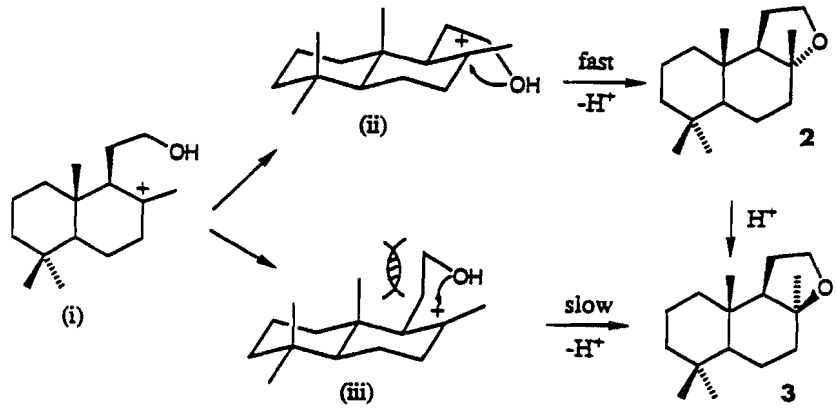


As summarized in the reviews noted earlier (2–4), most of the synthetic sequences to natural or racemic Ambrox involved a cyclization of a 1,4-difunctional (at C8 and C12) intermediate to form the tetrahydrofuran ring. Cyclizations of the 1,4-diol **25** by β-naphthalenensulfonic acid in toluene (23–26) or *p*-toluenesulfonyl chloride in pyridine (27, 28) and the epimeric 1,4-diol **26** by *p*-toluenesulfonic acid in nitromethane (29) are of more direct relevance to our designed cyclization of diol **4**.

TABLE 2. Cyclization of the 1,5-diol **4**

Conditions	Composition of dehydration products, %				
	2	**3**	**27**	**28**	Hydrocarbons
HOTs (2.0 equiv.), CH_3NO_2 80°C, 2 h	31	30	—	15	22
HOTs (2.0 equiv.), toluene 80°C, 2 h	48	10	—	15	8
HOTs (6.0 equiv.), CH_3NO_2 100°C, 0.5 h	—	19	34	—	41

It is assumed (29) that these cyclization reactions catalyzed by acids proceed through a tertiary carbocation (i) which is formed by elimination of the tertiary hydroxyl group in **25** or **26**. The α-face attack by the primary hydroxyl is kinetically preferred to the β-face attack because the latter would be subjected to steric hindrance from the angular methyl group in the transition state (iii). Thus, (–)-Ambrox (**2**) is preferentially produced through a lower energy transition state (ii). However, (+)-iso- Ambrox (**3**) resulting from the β-face attack will become the major product under prolonged treatment and can actually be obtained from **2** under the same condition (23–26).



The final steps in the sequence, as summarized in the overall strategy shown in Scheme 1, involved the acid-catalyzed cyclization of the 1,5-diol **4** to afford the tetrahydrofuran ring system present in **2** and **3**. To this end, an extensive study directed at the cyclization of **4** to the target compounds was undertaken. A summary of the results is provided in Table 2.

Treatment of **4** with *p*-toluenesulfonic acid (2.0 equiv.) in nitromethane at 80°C for 2 h gave (–)-Ambrox (**2**, 31%), (+)-iso-Ambrox (**3**, 30%), a mixture of alcohols (**28**, 15%), and a mixture of hydrocarbons. The yield of **2** was improved to 48% using toluene as the solvent. All spectroscopic data of **2** and **3** were consistent with those recorded in the literature (30).

The mixture of alcohols labelled as **28** in Table 2 contained several compounds, as shown in the gas chromatogram and the complex ^{1}H NMR spectrum. This mixture could not be further purified in spite of extensive chromatographic studies. It displayed a hydroxyl stretching absorption at 3450 cm^{-1} in the IR spectrum and a molecular ion peak at *m/z* 220 in the mass spectrum. Although further characterization data were not obtained due to the difficulties associated with purification, it is assumed that the mixture represents alkenes (see **28***a* and **28***b*) in which one molecule of water had been lost from diol **4**. In view of the subsequent isolation of **27**, the principal component of "ionoxide" previously reported by Vlad et al. (31), it is speculated that such alkenes could be intermediates in a plausible mechanistic pathway from either diol **4** or (+)-iso-Ambrox (**3**) to **27** (Scheme 6). However, direct evidence for this proposal is unavailable from our studies.

The nonpolar hydrocarbon mixture, obtained in the first eluted fractions in column chromatography, contained several compounds, as revealed from the gas chromatograph. Here, again, attempts at purification failed. The IR spectrum indicated no hydroxyl stretching absorption while the mass spectrum showed an ion peak at *m/z* 218. Thus, this mixture appears to consist of a dehydrated product of diol. The ^{1}H NMR spectrum displayed poorly resolved aliphatic proton signals at δ 0.60–2.65 ppm and olefinic proton signals at δ 5.00–5.60 ppm.

In conclusion, we have succeeded in synthesizing (–)-Ambrox (**2**) from the thujone-derived enone **1** in seven steps and in an overall yield of 9.5%. Moreover, a novel synthesis of **27**, the principal component of "ionoxide," was discovered. It is claimed (31) that ionoxide possesses a very distinct musk–ambergris odor and a high rating as a perfume. The successful strategy should be applicable to the synthesis of other ambergris fragrances, and such studies are presently underway.

Two recent publications concerning the synthesis of racemic Ambrox^R are noted (32, 33).

Experimental

In general, solvents (ACS grade) were used for chromatography without further purification. Petroleum ether refers to the fraction boiling in the range 30–60°C. Anhydrous diethyl ether, tetrahydrofuran,

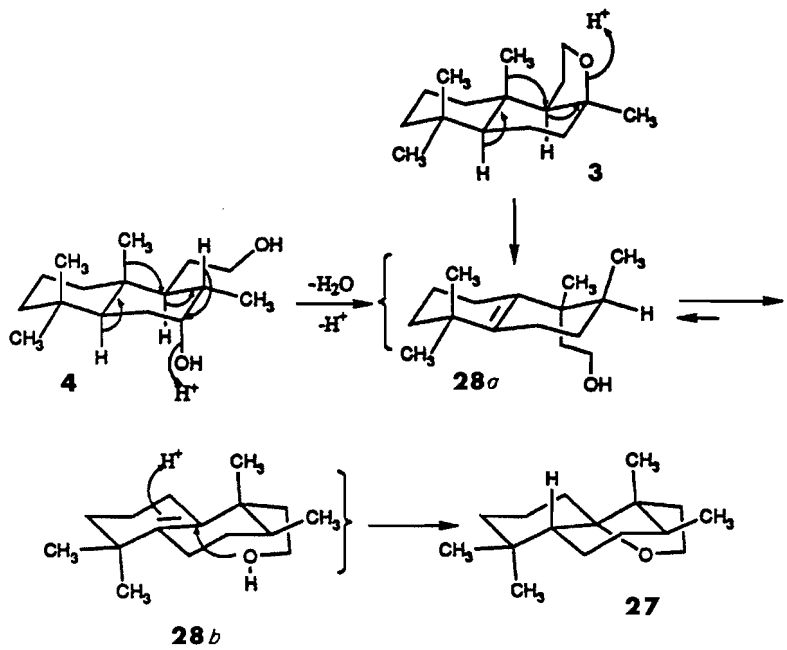

SCHEME 6. Proposed mechanism for the formation of **27** from postulated intermediates **28**.

and benzene were prepared by distillation from a mixture containing sodium and benzophenone. Anhydrous methylene chloride, chloroform, and *n*-pentane were prepared by distillation from phosphorus pentoxide. Anhydrous diisopropylamine, HMPA, DMF, and DMSO were prepared by distillation from calcium hydride and stored in the presence of molecular sieves under nitrogen. Anhydrous methanol and ethanol were distilled from magnesium. *n*-Butyllithium, LDA, and vinylmagnesium bromide solutions were standardized by titration against *sec*-butanol in benzene using 1,10-phenanthroline as indicator under nitrogen. Borane in THF and L-Selectride were standardized by measuring hydrogen released from their reaction with 1:1 glycerol:water solution. Thujone was obtained by distillation of Western red cedar leaf oil, which was generously donated by Intrinsic Research and Development Incorporated.

Unless stated otherwise, all reactions were carried out under a positive pressure of dry nitrogen. Reactions at –78, –40, –25, and 0°C were performed with Dry Ice/acetone, Dry Ice/acetonitrile, Dry Ice/carbon tetrachloride, and ice/water cooling baths respectively.

Reactions were monitored by thin-layer chromatography (TLC) and (or) gas chromatography (GC). Analytical TLC was carried out on aluminum-backed silica gel plates (Merck Silica Gel 60 F_{254}). Visualization was realized by ultraviolet light and (or) by heating after spraying with 10% ammonium molybdate in 10% sulfuric acid. Gas chromatography was performed on a Hewlett-Packard 5890A gas chromatograph, using a flame ionization detector and a 14.5 m × 0.252 mm fused silica capillary column coated with cyanopropylphenyl silicone gum (DB 1701). Unless otherwise stated, all reaction products were purified by flash chromatography using silica gel (230–400 mesh) supplied by E. Merck Co. with air pressure to obtain a suitable flow. Unless otherwise stated, the eluting solvents were ethyl acetate:hexanes mixtures. Hexanes is a commercial mixture containing predominantly *n*-hexane and methylcyclopentane.

Melting points were measured using a Kofler block melting point apparatus and are uncorrected. Optical rotations were recorded on a Perkin–Elmer 141 automatic polarimeter in chloroform solution using a quartz cell of 10 cm path length with the concentration (in g/100 mL) given in parentheses. The ultraviolet spectra were recorded on Cary 15 or Perkin–Elmer Lambda 4B UV/VIS spectrometers using quartz cells of 1 cm path length. The infrared spectra were recorded on Perkin–Elmer 710, 710B, and 1710 spectrometers in chloroform solution using NaCl cells of 0.1 mm path length or as thin film using NaCl plates. The ^{1}H NMR spectra were obtained from Bruker WH-400, AE-200, or Varian XL-300 spectrometers with deuteriochloroform as solvent and the chemical shifts are reported in the delta (δ) scale in ppm relative to tetramethylsilane. The ^{13}C spectra were taken on Bruker AE-200 or XL-300 spectrometers and chemical shifts are reported in the delta (δ) scale in ppm relative to tetramethylsilane. The low- and high-resolution mass spectra were recorded on AEI-MS 902 or Kratos-MS-50 spectrometers using the electron impact ionization method while the chemical ionization mass spectra were recorded on a Delsi Nermag R10-1 OC spectrometer using ammonia as carrier gas. CD spectra were recorded on a Jasco J-20 automatic recording spectropolarimeter. Elemental analyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia.

All compounds in the Experimental section are named in accordance with IUPAC and Chemical Abstract rules. Names for compounds of the tricyclo[4.4.0.0]decane skeleton (i.e., the cycloprop[α]indene skeleton) are also included to facilitate comparison with other similar compounds previously prepared and named by our group. However, the numbering system employed in the Discussion follows the normal conventions of terpenoid and steroid literature in order to have convenient comparison with natural products and with related analogues.

*Catalytic hydrogenation: enone **9** to ketone **10***

*[1aS-(1aα,1bβ,5α,5aβ,6aα)] 1a,1b,2,3,5,5a,6,6a-Octahydro-1b,5-dimethyl-6a-(1-methylethyl)cycloprop[α]inden-4(1H)-one (**10**) or [1R,2S,6S,7S,9R] 2,6-dimethyl-9-(1-methylethyl)tricyclo[4.4.0.0^{7,9}]decan-3-one (**10**)*

Enone **9** (62 g, 282 mmol) prepared via the previously published procedure (5) was dissolved in ethanol (500 mL), and 10% palladium–carbon catalyst (1.50 g) was added. The mixture was vigorously stirred under 1 atm (101.3 kPa) H_2 for 8 h and filtered through a thick Celite cake. Evaporation of ethanol gave **10** as a colorless oil (62 g, 99%).

The physical properties of **10** are as follows: $[\alpha]_D^{25}$ +61.5 (*c* 1.00, $CHCl_3$). IR (film) ν_{max} : 3050 (C—H stretching of the cyclopropyl group), 1710 (C=O stretching) cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.20 (1H, *J* = 4.8 and 8.0 Hz), 0.42 (1H, t, *J* = 4.8 Hz), 0.85 (3H, d, *J* = 6.8 Hz), 0.87–1.00 (7H, including 0.91 (3H, d, *J* = 6.8 Hz) and 0.94 (3H, d, *J* = 7.2 Hz)), 1.10–1.40 (5H, m, including 1.24 (3H, s)), 1.45–1.90 (4H, m), 2.15 (1H, m), 2.42 (1H, m), 2.58 (1H, m). MS *m/z*: 220

*Methylation: ketone **10** to ketone **11***

*[1aS-(1aα,1bβ,5aβ,6aα)] 1a,1b,2,3,5,5a,6,6a-Octahydro-1b,5,5-trimethyl-6a-(1-methylethyl)cycloprop[α]inden-4(1H)-one (**11**) or [1S,6R,7S,9S] 2,2,6- trimethyl-9-(1-methylethyl)tricyclo[4.4.0.0^{7,9}]decan-3-one (**11**)*

To the solution of ketone **10** (62 g, 0.282 mol) in anhydrous *tert*-butanol (700 mL), potassium *tert*butoxide (130.5 g, 1.07 mol) was added slowly under nitrogen. Iodomethane (66.6 mL, 1.07 mol) was added in a dropwise manner with stirring to ensure a gentle reflux. Upon completion of addition, refluxing was continued for 30 min. The mixture was cooled, quenched with water (700 mL), and extracted with petroleum ether (3 × 500 mL). Evaporation of solvent gave an oil, which was chromatographed to provide the methylated ketone **11** (55.1 g, 84%).

The physical properties of **11** are as follows: $[\alpha]_D^{25}$ +14.0 (*c* 1.0, $CHCl_3$). IR ν_{max} (film): 3060, 1700 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.18 (1H, dd, *J* = 4.0 and 8.0 Hz), 0.40 (1H, t, *J* = 4.0 Hz), 0.80–0.88 (4H, m, including 0.85 (3H, d, *J* = 7.2 Hz)), 0.90 (3H, d, *J* = 7.2 Hz), 0.97 (3H, s), 1.22 (3H, s), 1.25–1.50 (6H, m, including 1.32 (3H, s)), 1.65–1.90 (3H, m), 215 (1H, td, *J* = 4.4 and 15.2 Hz), 2.70 (1H, m). MS *m/z*: 234 (M, 56%), 219 (14%), 201 (22%), 191 (30%), 173 (51%), 43 (100%). High-resolution mass measurement: calcd. for $C_{16}H_{26}O$: 234.1983; found: 234.1986.

*Wolff–Kishner–Huang–Minlon reaction: ketone **11** to alkane **12***

*[1aS-(1aα,1bβ,5aβ,6aα)]Decahydro-1b,5,5-trimethyl-6a-(1-methylethyl)cycloprop[α]indene (**12**), or [1R,6S,7S,9R] 9-(1-methylethyl)-2,2,6-trimethyltricyclo[4.4.0.0^{7,9}]decane (**12**)*

Ketone **11** (42.0 g, 180 mmol) in diethylene glycol (300 mL) was treated with potassium hydroxide (37 g, 528 mmol) and hydrazine monohydrate (26.8 mL, 552 mmol). The mixture was heated at 100°C for 1.5 h under nitrogen. The temperature was then raised to 220°C to remove water and excess hydrazine. Refluxing was continued at 210°C for 4 h. The mixture was cooled, diluted with water (1 L), and extracted with petroleum ether (3 × 600 mL). Evaporation of the solvent gave a brown oil, which was rapidly chromatographed using petroleum ether as eluting solvent to afford **12** as a colourless oil (24.50 g, 62%).

The physical properties of **12** are as follows: $[\alpha]_D^{25}$ +42.5 (*c* 1.00, $CHCl_3$). IR ν_{max} (film): 3060 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.04 (1H, dd, *J* = 4.6 and 8.4 Hz), 0.40 (1H, t, *J* = 4.6 Hz), 0.72–0.82 (4H, including 0.78 (3H, s)), 0.82–1.65 (22H, including 0.88 (3H, d, *J* = 7.2 Hz), 0.95 (3H, d, *J* = 7.2 Hz), 0.98 (3H, s), and 1.07 (3H, s)). MS *m/z*: 220 (M^+, 3%), 205 (10%), 177 (46%), 109 (100%). High-resolution mass measurement: calcd. for $C_{16}H_{28}$: 220.2191; found: 220.2198.

*Ozonolysis: alkane **12** to alcohol **13** and ketone **14***

*[1aR](1aα,2aβ,5aβ,6aα)] Decahydro-α-hydroxy-α,α,1b,5,5-penta-methylcycloprop[α]inden-6a-methanol (**13**) or [1R,6S,7R,9S] 9-(1-hydroxyl-1-methylethyl)-2,2,6- trimethyltricyclo [4.4.0.0^{7,9}]decane (**13**) and [1aR-(1aα,2aβ,5aβ,6aα)] 6a-acetyl-decahydro-1b,5,5-trimethylcycloprop[α]indene (**14**) or [1R,6S,7R,9S] 9-acetyl-2,2,6-trimethyltricyclo[4.4.0.0^{7,9}]-decan-3-one (14)*

Compound **12** (4.50 g, 20.4 mmol) in ethyl acetate (500 mL) was cooled to –40°C. A stream of ozone in oxygen (90 V, flow rate 9.1 mL/s) was passed for 6.5 h. The oxygen flow was allowed to pass through the solution until the blue colour disappeared. Dimethyl sulfide (1.0 mL) was added and the stirred mixture was warmed slowly to room temperature. After washing with water and saturated sodium bicarbonate solution, the mixture was dried over magnesium sulfate. Solvent evaporation gave an oil, which was chromatographed to afford compounds **13** (2.01 g, 42%) and **14** (1.23 g, 27%) in a total yield of 69%.

The physical properties of **13** are as follows: $[\alpha]_D^{25}$ +49.2 (*c* 1.00, $CHCl_3$). IR ν_{max} (film): 3400 (O—H stretching), 3060 (C—H stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.40–0.55 (2H, m), 0.72 (3H, s), 0.80–1.90 (23H, including 0.92 (3H, s), 1.05 (3H, s), 1.10 (3H, s), and 1.19 (3H, s)). MS *m/z*: 236 (M^+, 1%), 218 (36%), 203 (27%), 178 (41%), 163 (60%), 59 (100%). High-resolution mass measurement: calcd. for $C_{16}H_{28}O$: 236.2140; found: 236.2140. The physical properties of **14** are as follows: $[\alpha]_D^{25}$ +82 (*c* 0.24, $CHCl_3$). IR ν_{max} (film): 1675 (C=O stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.83 (3H, s), 1.00 (3H, s), 1.05 (1H, m), 1.10–1.70 (12H, m, including 1.15 (3H, s)), 1.80 (1H, dd, *J* = 4.0 and 12.0 Hz), 2.00 (3H, s), 2.20 (1H, t, *J* = 12.0 Hz). MS *m/z*: 220 (M^+, 34%), 205 (16%), 177 (17%), 109 (34%), 43 (100%). High resolution mass measurement: calcd. for $C_{15}H_{24}O$: 220.1827; found: 220.1825.

*Dehydration: alcohol **13** to alkene **15***

*[1aR-(1aα,1bβ,5aβ,6aα)] Decahydro-1b,5,5-trimethyl-6a-(1-methylethenyl)cycloprop[α]indene (**15**) or [1R,6S,7R,9S] 9-(1-methylethenyl)-2,2,6-trimethyltricyclo[4.4.0.0^{7,9}]decane (**15**)*

To the alcohol **13** (171 mg, 0.724 mmol) in benzene (15.0 mL) solution, pyridinium tosylate (28 mg, 0.11 mmol, 0.15 equiv.) was added. The mixture was refluxed, utilizing a Dean–Stark apparatus, for 15 min. After the reaction mixture was washed with saturated sodium bicarbonate solution (10 mL), the organic layer was separated and concentrated in vacuo. Column chromatography by ethyl acetate:hexanes mixture (8:1, v/v) gave the vinyl cyclopropane **15** (127 mg, 91%) and the starting alcohol **13** (20.0 mg, 12%).

The physical properties of **15** are as follows: $[\alpha]_D^{25}$ +87.9 (*c* 1.09, $CHCl_3$). IR ν_{max} (film): 3075, 1650 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.52 (1H, dd, *J* = 4.8 and 8.8 Hz), 0.68 (1H, t, *J* = 4.8 Hz), 0.81 (3H, s), 1.00 (3H, s), 1.02–1.58 (11H, m, including 1.13 (3H, s)), 1.65 (3H, s), 1.70–1.92 (2H, m), 4.65–4.85 (2H, 2 br s). MS *m/z*: 218 (M^+, 27%), 203 (23%), 189 (4%), 175 (21%), 147 (31%), 147 (51%), 109 (100%). High-resolution mass measurement: calcd. for $C_{16}H_{26}$: 218.2035; found: 218.2030.

*Ozonolysis: alkene **15** to ketone **14***

Method A

To a solution of the vinyl cyclopropane **15** (200 mg, 0.917 mmol) in a solvent mixture of *tert*-BuOH:water (9.0 mL, 2:1, v/v), potassium permanganate (436 mg, 2.76 mmol) was added at room temperature. The resulting dark purple solution was stirred first at room temperature for 40 min, and then at 40°C for 10 min. The mixture was then diluted with water (20 mL) and extracted with ethyl acetate (2 × 25 mL). The combined extract was washed with brine (10 mL) and concentrated in vacuo. The oil obtained above was then dissolved in methanol (10 mL) and treated with $Pb(OAc)_4$ (313 mg, 0.706 mmol) for 1 h at room temperature. After concentration in vacuo, the crude product was column chromatographed using ethyl acetate:hexanes mixture (1:8, v/v) to give the starting vinyl cyclopropane **15** (4.1 mg, 2%) and ketone **14** (180 mg, 91%, based on recovery).

Method B

A stream of ozone was passed through a solution of the vinyl cyclopropane **15** (117 mg, 0.536 mmol) in methylene chloride (5.0 mL) at –40°C for 30 min. After addition of dimethyl sulfide (2 mL), the mixture was warmed slowly and then stirred at room temperature for 2 days. Concentration of the reaction mixture in vacuo gave a crude product that was chromatographed with ethyl acetate:hexanes mixture (1:8, v/v) to provide ketone **14** (73 mg, 62%).

*Baeyer–Villiger reaction: ketone **14** to acetate **16***

*[1aR-(1aα,1bβ,5aβ,6aα)] Decahydro-1b,5,5-trimethylcycloprop[α]inden-6a-yl acetate (**16**) or [1R,6S,7R,9S) 9-acetoxy-2,2,6-trimethyltricylo[4.4.0.0^{7,9}]decane (**16**)*

To the solution of ketone **14** (1.80 g, 8.18 mmol) in methylene chloride (10 mL) was added *m*-CPBA (4.45 g, 80–85% pure, 2.1 mmol, 2.5 equiv.). The above mixture was refluxed for 12 h during which time a milky thick slurry was observed. After cooling to room temperature, methylene chloride (50 mL) was added and the mixture was washed

For personal use only.

rapidly with 10% brine solution (50 mL). The organic layer was separated, washed with brine solution (20 mL), dried with magnesium sulfate, and concentrated in vacuo. Column chromatography of the crude product using ethyl acetate:hexanes mixture (1:8 v/v) gave acetate **16** (1.50 g, 82% based on starting material recovery) and starting ketone **14** (0.09 g).

The physical properties of **16** are as follows: $[\alpha]_D^{25}$ +36.7 (*c* 1.0, $CHCl_3$). IR ν_{max} (film): 3050 (C—H stretching), 1735 (C=O stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.70 (1H, m), 0.80 (3H, s), 0.90–1.02 (4H, m, including 0.97 (3H, s)), 1.05 (3H, s), 1.10–1.70 (8H, m), 1.90–2.10 (4H, including 2.10 (3H, s)), 2.23 (1H, dd, *J* = 8.0 and 12.0 Hz). MS *m/z*: 236 (M^+, 1%), 221 (19%), 194 (21%), 179 (22%), 109 (100%). High-resolution mass measurement: calcd. for $C_{15}H_{24}O_2$: 236.1776; found: 236.1774.

*Saponification: acetate **16** to cyclopropanol **17***

*[1aR-(1aα,1bβ,5aβ,6aα)] Decahydro-1b,5,5-trimethylcyclopro[α]inden-6a-ol (**17**) or [1R,6S,7R,9S] 2,2,6-trimethyltricyclo[4.4.0.0^{7,9}]decan-9-ol (**17**)*

Acetate **16** (589 mg, 2.50 mmol) was dissolved in ethanol (20 mL) at room temperature. To this solution was added powdered potassium hydroxide (230 mg, 3.28 mmol) under nitrogen. The resulting mixture was stirred for 30 min, diluted with water (20 mL), and extracted with methylene chloride (2 × 20 mL). The methylene chloride solution was dried over magnesium sulfate, and concentrated to provide alcohol **17** as an oil (490 mg, 100%).

The physical properties of **17** are as follows: $[\alpha]_D^{25}$ +34.5 (*c* 1.00, $CHCl_3$). IR ν_{max} (film): 3050–3650 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.80 (3H, s), 0.96 (3H, s), 1.01 (3H, s), 1.98 (2H, m). MS *m/z*: 194 (M^+, 3%), 179 (5%), 124 (29%), 109 (100%), 81 (23%). High-resolution mass measurement: calcd. for $C_{13}H_{22}O$: 194.1672; found: 194.1665.

*Cyclopropane ring opening reaction by $FeCl_3$: cyclopropanol **17** to β-chloroketone **18***

*[4aS-(4aα,8aα)] 4-Chloro-3,4,4a,5,6,7,8,8a-octahydro-4a,8,8-trimethylnaphthalen-2(1H)-one (**18**)*

The alcohol **17** (490 mg, 2.53 mmol) obtained from the above reaction was dissolved in anhydrous DMF (12.5 mL) under nitrogen and cooled to 0°C. Anhydrous ferric chloride (1.03 g, 6.35 mml) was then added to this solution. After stirring for 1 h, the resulting brown mixture was warmed to room temperature and stirring continued for 24 h. Addition of 1 M hydrochloric acid (20 mL) to the mixture was followed by extraction with diethyl ether (2 × 20 mL). After drying over magnesium sulfate and solvent removal, the crude product containing **18** was subjected to dehydrochlorination without further separation.

The physical properties of **18** are as follows: IR ν_{max} (film): 1720 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.76 (3H, s), 0.90 (3H, s), 1.25 (3H, s), 2.10–3.00 (4H, m), 4.70 (1H, dd, *J* = 6.0 and 12.0 Hz). MS *m/z*: 228/230 (M^+, 0.6%/0.2%), 206 (1%), 193 (8%), 43 (100%). High-resolution mass measurement: calcd. for $C_{13}H_{21}O_{37}Cl$: 230.1251; found: 230.1223; calcd. for $C_{13}H_{21}O_{35}Cl$: 228.1281; found: 228.1276.

*Dehydrochlorination: β-chloroketone **18** to enone **1***

*[4aR-(4aα,8α)] 4a,5,6,7,8,8a-Hexahydro-4a,8,8-trimethylnaphthalen-2(1H)-one (**1**)*

The above crude product containing β-chloroketone **18** was dissolved in a saturated sodium acetate – methanol solution (10 mL). This mixture was refluxed for 3 h and concentrated in vacuo. Purification by column chromatography with ethyl acetate:hexanes (2:8) gave enone **1** (384 mg, overall 80% from acetate **16**).

The physical properties of **1** are as follows: Mp 64–66°C. $[\alpha]_D^{25}$ +47.6 (*c* 1.00, $CHCl_3$). UV (MeOH, *c* 20.0 mg/L) λ_{max}:235 nm (log ε = 3.842). IR ν_{max} (film): 1664 (C=O stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.77 (3H, s), 0.96 (3H, s), 1.22 (3h, s), 1.22 (3H, s), 1.27–1.75 (7H, m), 2.50–2.80 (2H, m), 5.95 (1H, d, *J* = 9.6 Hz), 6.27 (1H, d, *J* = 9.6 Hz). MS *m/z*: 192 (M^+, 13%), 150 (45%), 69 (100%). High-resolution mass measurement: calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1518. Anal. calcd for $C_{13}H_{20}O$: C 81.20, H 10.50; found: C 81.13, H 10.48.

*Conjugate addition: α,β-enone **1** to cis-fused γ,δ-enone **19***

*[4R-(4aα,4aα,8aα)] 4-Ethenyl-3,4,4a,5,6,7,8,8a-octahydro-4a,8,8-trimethylnaphthalen-2(1H)-one (**19**)*

To a solution of enone **1** (718 mg, 3.74 mmol) in anhydrous THF (20 mL), cuprous iodide (112 mg, 0.59 mmol, 0.15 equiv.) and dimethyl sulfide (5 mL) were introduced under a nitrogen atmosphere. This mixture was cooled to 0°C and 0.66 M vinylmagnesium bromide in THF solution (8.2 mL, 5.41 mmol, 1.4 equiv.) was added in a dropwise manner over a period of 1 h. After the mixture was warmed to room temperature and stirred for another hour, saturated brine solution (20 mL) was introduced to quench the excess vinylmagnesium bromide. The organic layer was separated; the aqueous layer was extracted with diethyl ether (10 mL). The combined organic solution was dried over magnesium sulfate and concentrated in vacuo to give a crude oil, which was then chromatographed to provide enone **19** in 70% yield (576 mg).

The physical properties of **19** are as follows: $[\alpha]_D^{25}$ +22.2 (*c* 1.00, $CHCl_3$). IR ν_{max} (film): 1710 (C=O stretch), 1635 (C=C stretch) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.80–1.70 (14H, including 0.90 (3H, s), 0.95 (3H, s), and 1.09 (3H, s)), 1.90 (1H, m), 2.25–3.10 (5H, m), 4.95–5.15 (2H, m), 5.70 (1H, m). MS *m/z*: 220 (M^+, 16%), 205 (4%), 123 (68%), 43 (100%). High-resolution mass measurement: calcd. for $C_{15}H_{24}O$: 220.1828; found: 220.1831.

*Methylation by LDA and iodomethane: cis-fused γ,δ-enone **19** to cis-fused γ,δ-enone **6***

*[3S-(3α,4β,4aβ,8aβ)] 4-Ethenyl-3,4,4a,5,6,7,8,8a-octahydro-3,4a,8,8-tetramethylnaphthalen-2(1H)-one (**6**)*

A solution of LDA in *n*-pentane (0.68 M, 2.6 mL, 1.77 mmol) was concentrated to remove *n*-pentane. The resulting white viscous mixture was cooled to –40°C, and anhydrous dimethoxyethane (1 mL) was then added under nitrogen. Enone **19** (350 mg, 1.59 mmol) in dimethoxyethane (3.5 mL) was introduced to the LDA solution in a dropwise manner over a period of 1 h. This enolate solution was warmed rapidly to 50°C and freshly distilled iodomethane (0.40 mL, 6.42 mmol) was added rapidly. The resulting turbid yellowish mixture was stirred at 50°C for 30 min and quenched with a solution of potassium hydroxide (100 mg) in methanol (10 mL). After stirring for 30 min, the reaction mixture was concentrated in vacuo to give the crude product, which was chromatographed with ethyl acetate:hexanes (1:8, v/v) to afford **6** (207 mg, 65% based on recovery of **19**) and the starting enone **19** (53 mg, 15%).

The physical properties of **6** are as follows: $[\alpha]_D^{25}$ +29.3 (*c* 1.00, $CHCl_3$). IR ν_{max} (film): 1700 (C=O stretching), 1630 (C=C stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.70–1.60 (18H, m, including 0.82 (3H, s), 0.94 (3H, s), and 1.04 (3H, d, *J* = 6.4 Hz), 1.14 (3H, s)), 1.90 (1H, m), 2.30 (1H, m), 2.45–2.70 (3H, m), 4.95–5.20 (2H, m), 5.55 (1H, m). MS *m/z*: 234 (M^+, 2%), 219 (1%), 167 (36%), 149 (100%).

*Dehydrogenation by $PhSeCl/H_2O_2$: cis-fused γ,δ-enone **6** to dienone **20***

*[3S-(3α,4β,4aβ,8aβ)] 4-Ethenyl-4,4a,5,6,7,8-hexahydro-3,4a,8,8-tetramethylnapthalen-2(3H)-one (**20**)*

A solution of LDA in *n*-pentane (0.50 M, 2.30 mL, 1.15 mmol) was concentrated in vacuo to remove *n*-pentane. The viscous mixture was cooled to –40°C and anhydrous THF (1 mL) was then added under nitrogen. The solution of **6** (250 mg, 1.07 mmol) in anhydrous THF (3 mL) was added in a dropwise manner with stirring over a 45 min period. The resulting mixture was warmed to room temperature and phenylselenyl chloride (212 mg, 1.10 mmol) was introduced. Stirring at room temperature was continued for 1.5 h before addition of pyridine (0.5 mL), methylene chloride (5 mL), and hydrogen peroxide (0.5 mL of 30% H_2O_2 in 3 mL of water). The two-phase mixture was stirred at room temperature for 5 h and separated. The aqueous layer was extracted with methylene chloride (5 mL). The combined organic layers were dried over magnesium sulfate and concentrated in vacuo to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by ESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

yield a crude product. Purification by column chromatography with ethyl acetate:hexanes (1:8, v/v) afforded dienone **20** (134 mg, 62% based on recovery of starting material) and the starting material **6** (31 mg).

The physical properties of **20** are as follows: $[\alpha]_D^{25}$ –4.2 (*c* 1.00, $CHCl_3$). UV (MeOH, *c* 40.0 mg/L) λ_{max}: 242 nm ($\log \epsilon = 3.96$). IR ν_{max} (film): 1665 (C=O stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.80–1.90 (18H, m, including 1.07 (3H, d, J = 5.1 Hz), 1.17 (3H, s), 1.22 (3H, s), and 1.25 (3H, s)), 2.12 (1H, t, J = 10.2 Hz), 2.40 (1H, m), 5.00–5.25 (2H, m), 5.69 (1H, m), 6.00 (1H, s). MS *m/z*: 232 (M^+, 21%), 217 (17%), 189 (3%), 178 (8%), 164 (100%), 149 (49%), 121 (15%). High-resolution mass measurement: calcd. for $C_{16}H_{24}O$: 232.1827; found: 232.1829.

*Birch reduction: dienone **20** to* trans*-fused* γ,δ*-enone **5***

*[3S-(3α,4β,4aβ,8aα) 4-Ethenyl-3,4,4a,5,6,7,8,8a-octahydro-3,4a,8,8-tetramethylnaphthalen-2(1*H*)-one (**5**)*

To a solution of dienone **20** (300 mg, 1.29 mmol) in anhydrous THF (2 mL), anhydrous ammonia (4 mL) was distilled from sodium under a nitrogen atmosphere. Small pieces of lithium were added slowly over a 30 min period until a persistent dark blue color remained. After stirring for 1 h at –33°C, ammonium chloride powder was introduced to quench excess lithium. Evaporation of ammonia and THF gave a yellowish oil, which was chromatographed to afford the *trans*-fused decalone **5** (268 mg, 90%).

The physical properties of **5** are as follows: $[\alpha]_D^{25}$ –8.38 (*c* 2.40, $CHCl_3$). IR ν_{max} (film): 1706 (C=O stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.75–1.80 (19H, m, including 0.88 (3H, s), 0.90 (3H, s), 0.97 (3H, d, J = 6.0 Hz), and 1.09 (3H, s)), 2.00–2.50 (4H, m), 4.98 (1H, dd, J = 1.6 and 16.8 Hz), 5.12 (1H, dd, J = 1.6 and 10.0 Hz), 5.56 (1H, dt, J = 10.0 and 16.8 Hz). MS *m/z*: 234 (M^+, 34%), 219 (9%), 203 (0.3%), 137 (11%), 123 (100%), 109 (19%). High-resolution mass measurement: calcd. for $C_{16}H_{26}O$: 236.2140; found: 236.2097.

Reduction by L-Selectride: trans*-fused* γ,δ*-enone **5** to alcohol **21***

*[2R-(2α,3α,4β,4aβ,8aα)] 4-Ethenyl-decahydro-3,4a,8,8-tetramethylnapthalen-2-ol (**21**)*

The *trans*-fused ketone **5** (250 mg, 1.07 mmol) in anhydrous THF (2 mL) was added in a dropwise manner to L-Selectride (0.72 M, 3.0 mL, THF), at –78°C for 30 min. The solution was stirred for 1.5 h, warmed to 0°C, and stirred for an additional hour. Aqueous sodium hydroxide solution (3.0 mL, 3M) and aqueous 30% hydrogen peroxide (3 mL) were then introduced. The resulting mixture was stirred for 30 min, saturated with potassium carbonate, and separated. The aqueous layer was further extracted with diethyl ether (2 × 10 mL). The organic solutions were combined and concentrated in vacuo. Purification by column chromatography with ethyl acetate:hexanes (2:8, v/v) gave alcohol **21** (240 mg, 95%).

The physical properties of **21** are as follows: $[\alpha]_D^{25}$ –40.9 (c 1.00, $CHCl_3$). IR ν_{max} (film): 3450 (O—H stretching), 1630 (C=O stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.70–1.85 (24H, m), 3.92 (1H, q, J = 3.0 Hz), 4.94 (1H, dd, J = 2.4 and 17.2 Hz), 5.02 (1H, dd, J = 2.4 and 10.4 Hz), 5.52 (1H, td, J = 10.4 and 17.2 Hz). MS *m/z*: 236 (M^+, 2%), 218 (2%), 203 (5%), 123 (100%). High-resolution mass measurement: calcd. for $C_{16}H_{28}O$: 236.1240; found: 236.2136. *Cyclization: 1,5-diol **4** to **2**, **3**, and **27***

*[3aR-(3aα,5aβ,9aα,9bβ)] Dodecahydro-3a,6,6,9a-tetramethyl-1*H*-naphtho[2,1-*b*]furan (**2**). [3aS-(3aα,5aα,9aβ,9bα)] Dodecahydro-3a,6,6,9a-tetramethyl-1*H*-naphtho[2,1-*b*]furan (**3**). [3aR-(3aα,4α,6aα,10aS*)] Dodecahydro-3a,4,7,7-tetramethyl-2*H*-naphtho[8a,1-*b*]furan (**27**)*

Procedure no. 1

Diol **4** (20 mg, 0.079 mmol) in anhydrous toluene (2 mL) was treated with *p*-toluenesulfonic acid (27 mg, 0.16 mmol, 2.0 equiv.) under a nitrogen atmosphere. This solution was then heated at 80°C for 2 h. The resulting mixture was transferred by the use of diethyl ether (10 mL) to a separatory funnel, washed with saturated sodium carbonate solution, dried over magnesium sulfate, and concentrated in vacuo. Column chromatography with hexanes, ethyl acetate:hexanes (1:50, v/v), ethyl acetate:hexanes (1:20, v/v), and ethyl acetate:hexanes (1:8, v/v) consecutively gave a mixture of hydrocarbons (1.4 mg, 8%), (+)-iso-Ambrox (**3**) (1.9 mg, 10%), and (–)-Ambrox (**2**) (8.9 mg, 48%).

Procedure no. 2

Diol **4** (20 mg, 0.079 mmol) in nitromethane (2 mL) was treated with *p*-toluenesulfonic acid (81 mg, 0.47 mmol, 6.0 equiv.) under a nitrogen atmosphere. The solution was then heated at 100°C for 30 min. After a work-up similar to that in procedure no. 1, the crude product was chromatographed with hexanes and ethyl acetate:hexanes (1:50, v/v) to give a mixture of hydrocarbons (7.0 mg, 41%), the ionoxide principal **27** (6.4 mg, 34%), and (+)-iso-Ambrox (**3**) (3.5 mg, 19%).

The physical properties of **2** are as follows: mp 74–76°C. $[\alpha]_D^{25}$ –25.1 (*c* 1.00, $CHCl_3$). IR ($CHCl_3$) ν_{max}: 1450, 1385, 995, 970 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.83 (3H, s), 0.84 (3H, s), 0.88 (3H, s), 1.09 (3H, s), 3.83 (1H, q, J = 8 Hz), 3.92 (1H, m). MS *m/z*: 236 (M^+, 3%), 221 (100%), 205 (7%), 177 (4%), 137 (40%), 97 (38%), 84 (24%), 81 (20%), 69 (20%), 59 (23%), 55 (19%), 43 (21%). High-resolution mass measurement: calcd. for $C_{16}H_{28}O$: 236.2140; found: 236.2139. For comparison, the reported literature values for **2** (30) are mp 77–75.5°C. $[\alpha]_D^{20}$ –24.7 (*c* 1.0, $CHCl_3$). The IR, ^1H NMR, and mass spectroscopic data are also identical with those presented above.

The physical properties of **3** are as follows: mp 57–59°C. $[\alpha]_D^{25}$ +7.4 (*c* 1.00, $CDCl_3$). IR ($CHCl_3$) ν_{max}: 1440, 1390, 1010, 980 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.86 (3H, s), 0.89 (3H, s), 0.90 (3H, s), 1.06 (3H, s), 3.70 (q, J = 8 Hz), 3.80 (1H, dt, J = 3 and 8 Hz). MS *m/z*: 236 (M^+, 0.0%), 221 ($M^+ - CH_3$, 100%), 177 (2%), 137 (21%), 109 (8%), 97 (33%), 84 (32%), 69 (22%), 55 (34%), 47 (8%), 43 (50%). High-resolution mass measurement: calcd. for $C_{15}H_{25}O$ ($M^+ - CH_3$): 221.1905; found: 221.1906. Chemical ionization MS using methane as carrier gas: 251 ($M + CH_5^+$), 237 ($M + H^+$). For comparison, the reported literature values for **3** (30) are Mp 60–60.5°C. $[\alpha]_D^{25}$ +7.5 (*c* 1.00, $CHCl_3$). The IR, ^1H NMR, and mass spectroscopic data are also identical with those presented above.

The physical properties of **27** are as follows: $[\alpha]_D^{25}$ +37.1 (*c* 1.00, $CHCl_3$). IR (film) ν_{max}: 1380, 1370, 1030, 1045 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.81 (3H), 0.83 (3H, d, J = 6 Hz), 0.87 (3H, s), 0.94

(3H, s), 3.70 (1H, dt, J = 2 and 9 Hz), 3.81 (1H, q, J = 9 Hz). MS m/z: 236 (M^+, 10%), 221 (5%), 194 (15%), 193 (100%). High-resolution mass measurement: calcd. for $C_{16}H_{28}O$: 236.2140; found: 236.2142.

Sulfur bonding in cyclic $P_2S_2N_4$ systems: a density functional comparison of 1,1,5,5-tetramethylbicyclo[3.3.0]-1,5-diphospha-3,7-dithia-2,4,6,8-tetrazocine with the 1,1,3,5,5-pentamethyl-1,5-diphospha-3,7-dithia-2,4,6,8-tetrazocine anion

HEIKO JACOBSEN, TOM ZIEGLER, TRISTRAM CHIVERS, and RAINER VOLLMERHAUS. Can. J. Chem. **72**, 1582 (1994).

The electronic structure and the bonding of the title compounds have been investigated using density functional theory within the local density approximation, adding nonlocal corrections to exchange and correlation energy. The cross-ring sulfur–sulfur bond energy in 1,1,5,5-tetramethylbicyclo[3.3.0]-1,5-diphospha-3,7-dithia-2,4,6,8-tetrazocine was estimated to be about 133 kJ/mol. The HOMO of the 1,1,3,5,5-pentamethyl-1,5-diphospha-3,7-dithia-2,4,6,8-tetrazocine anion is mainly localized at the site of the unmethylated sulfur atom and is antibonding with respect to the sulfur–carbon bond of the methylated sulfur atom, which has a relatively weak estimated bond strength of 218 kJ/mol.

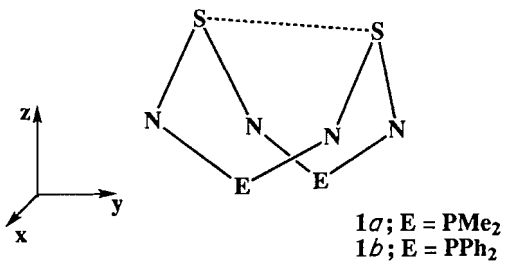
HEIKO JACOBSEN, TOM ZIEGLER, TRISTRAM CHIVERS et RAINER VOLLMERHAUS. Can. J. Chem. **72**, 1582 (1994).

Faisant appel à la théorie de la densité fonctionnelle dans le cadre de l'approximation de la densité locale, tout en ajoutant des corrections non locales pour les énergies d'échange et de corrélation, on a étudié la structure électronique et les liaisons des composés mentionnés dans le titre. On a évalué que l'énergie de la liaison soufre–soufre à travers le cycle du 1,1,5,5-tétraméthylbicyclo[3.3.0]-1,5-diphospha-3,7-dithia-2,4,6,8-tétrazocine est d'environ 133 kJ/mol. L'orbital moléculaire OH de l'anion 1,1,5,5-tétraméthylbicyclo[3.3.0]-1,5-diphospha-3,7-dithia-2,4,6,8-tétrazocine est principalement délocalisé au niveau de l'atome de soufre qui n'est pas méthylé et elle est antiliante par rapport à la liaison soufre–carbone de l'atome de soufre méthylé dont la force de liaison évaluée, 218 kJ/mol, est relativement faible.

[Traduit par la Rédaction]

Introduction

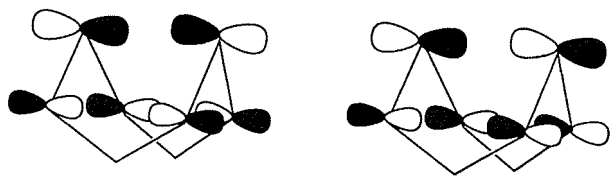
The first eight-membered $P_2S_2N_4$ system containing a sulfur–sulfur bond was described by Chivers and co-workers (1) in 1982. 1,1,5,5-Tetramethylbicyclo[3.3.0]-1,5-diphospha- 3,7-dithia-2,4,6,8-tetrazocine, 1,5-$Me_4P_2S_2N_4$ (**1***a*), possesses a puckered bicyclic structure with a short sulfur–sulfur contact of 2.55 Å (see Scheme 1). Subsequently, the structure of the tetraphenyl derivative 1,5-$Ph_4P_2S_2N_4$ (**1***b*) was reported (2). This molecule also exhibits a cradle configuration with an S—S bond length of 2.53 Å. These S—S bond lengths are comparable with the value for the parent compound S_4N_4 (d_{S-S} = 2.58 Å) (3).



1*a*; E = PMe_2
1*b*; E = PPh_2

SCHEME 1

The bonding in cyclic 1,5-$P_2S_2N_4$ systems has been investigated by Hückel-MO theory (1, 2). It has been shown that the formation of a sulfur–sulfur σ bond is the driving and stabilizing force on going from a planar 10π-electron system to the puckered structure having two allyl-like 4π-electron systems (1). Oakley and co-workers have demonstrated that the frontier orbitals in dithiatetrazocines represent bonding and antibonding sulfur–sulfur σ and σ* orbitals for the HOMO and the LUMO, respectively (4). Although it is appealing to equate these orbitals with the σ and σ* orbitals of a disulfide linkage, the phase properties and one-electron energies of the σ/σ* orbitals in dithiatetrazocines suggest a direct isolobal analogy with the π/π* levels of an electron-deficient olefin (4). This concept can easily be transferred to the 1,5-$P_2S_2N_4$ systems; the HOMO **I***a* and the LUMO **I***b* are depicted in Scheme 2.



I*a* **I***b*

SCHEME 2

As a test of the analogy mentioned above, the platinum complex Pt(η^2-S,S′-1,5-$Ph_4P_2S_2N_4$)$(PPh_3)_2$ has been prepared as an analogue of the classical η^2-alkene complexes Pt(C_2R_4)-$(PPh_3)_2$ (5). A density functional analysis revealed that the heterocyclic ligand coordinated to the metal shows both donation from σ(S—S), **I***a*, as well as back-donation into σ*(S—S), **I***b*. The back-donation and the overall bond strength for the $P_2S_2N_4$ ligand falls between that of the electron-deficient alkene $C_2(CN)_4$ and that of the more electron-rich alkene C_2H_4 (5).

Recently, Chivers et al. prepared the eight-membered anionic system 1,1,3,5,5-pentaphenyl-1,5-diphospha-3,7-dithia-2,4,6,8-tetrazocine (**2***a*) as the lithium derivative (6). This system, in which one of the sulfur centers has been phenylated, adopts a boat configuration with an almost planar arrangement of the two NPN units and an S—S distance of 3.31 Å. The geometry of this ion is shown schematically in Scheme 3. The

SCHEME 3

lithium atom is bonded to two nitrogens on the opposite side of the ring from the site of nucleophilic attack (6).[2]

This finding prompted us to reinvestigate the bonding in cyclic 1,5-$P_2S_2N_4$ systems using approximate density functional theory (DFT). In particular, we wanted to determine (*a*) the fate of the σ(S—S) and σ*(S—S) orbitals under nucleophilic attack, (*b*) the charge distribution in the anionic system **2**, and (*c*) a rough estimate of the thermodynamics of this process. We also included a calculation involving a coordinated lithium cation, as found in the crystal structure analysis.

Computational details

Single point calculations were performed for 1,5-$Me_4P_2S_2N_4$ (**1***a*) and for the hypothetical structures $Me_5P_2S_2N_4^-$ (**2***b*) and Li[$Me_5P_2S_2N_4$] (**3**), utilizing the AMOL program package developed by Baerends et al. (7) and vectorized by Ravenek (8). The applied basis set was of double ζ quality, augmented by one polarization function. Electron correlation was treated at the LDA/NL level of theory. The application of DFT to molecular structures and energetics has been reviewed recently (9). We refer the reader to this work for further references and a more detailed description of the method.

The structure of **1***a* was taken from the X-ray data (1), and symmetrized according to C_{2v} symmetry. The geometries for **2***b* and **3** were also based on the X-ray data for the lithium derivative of **2***a* (6). For the sake of computational ease, phenyl groups have been replaced by methyl groups, and a C_s symmetry has been adopted. For the geometric arrangements, we refer to refs. 1 and 6.

Results and discussion

Figure 1 shows a selection of the orbital manifold for 1,5-$Me_4P_2S_2N_4$ (**1**) and $Me_5P_2S_2N_4^-$ (**2***b*). For 1,5-$Me_4P_2S_2N_4$ (**1**), the orbitals $a_1(12)$ and $b_2(8)$ represent the HOMO and LUMO of this system and correspond to the orbitals **I***a* and **I***b*, respectively, shown in Scheme 2. The HOMO–LUMO gap has been calculated to amount to 3.60 eV or 344 nm. The UV–visible spectrum of this compound (measured in CH_2Cl_2) shows one band at 265 nm (1). We note that the calculated HOMO–LUMO transition is of lower energy than the experimentally observed value. This suggests that the observed UV band might correspond to a transition into a higher excited electronic state. A possible transition, which is allowed by symmetry, is the excitation from the HOMO $a_1(12)$ to the LUMO + 1, $a_1(13)$. The $a_1(13)$ orbital lies 4.9 eV above the HOMO, which corresponds to 252 nm. DFT has been used extensively to calculate excitation energies and usually provides results in close agreement with the experimental values (9). Thus, it seems likely that the observed transition for 1,5-$Me_4P_2S_2N_4$ (**1**) is HOMO to LUMO + 1. The calculated intensities for these two different electronic transitions would be necessary for a correct assignment of the UV spectrum. Unfortunately, this feature is presently not available in the AMOL program package.

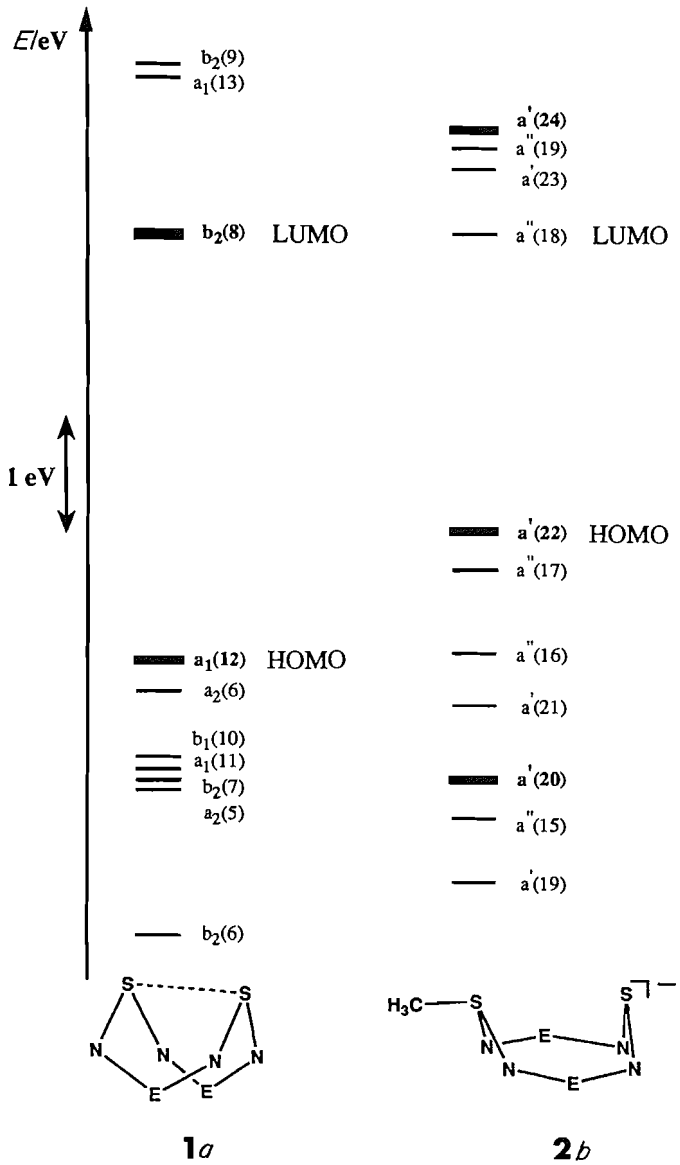

FIG. 1. Partial orbital diagram for 1,5-$Me_4P_2S_2N_4$ and $Me_5P_2S_2N_4^-$. Some important orbitals are outlined in bold.

For the anionic system $Me_5P_2S_2N_4^-$ (**3**), the HOMO–LUMO gap decreases to 2.59 eV or 479 nm. Coordination of a Li^+ cation to form Li[$Me_5P_2S_2N_4$] (**3**) increases this value to 3.08 eV or 402 nm. We thus expect the S-methylated 1,5-$P_2S_2N_4$ anion to absorb light in the blue region of the visible spectrum and to appear yellow to orange in color.

The methylation reaction can be viewed as a nucleophilic attack of a methyl anion at one of the sulfur centers of 1,5-$Me_4P_2S_2N_4$ (**1***a*). The incoming species will attack via the antibonding σ*(S—S) orbital and will induce a cleavage of the sulfur–sulfur bond. This process is shown in Scheme 4. The lone pair of the methyl anion together with the σ(S—S)/σ*(S—S) set of the ring system will form a new set of three

[2]The lithium derivative of **2***a* exists as a centrosymmetric, step-shaped dimer in which each lithium forms a bridge with the nitrogen atoms of the second $P_2S_2N_4$ ring (6).

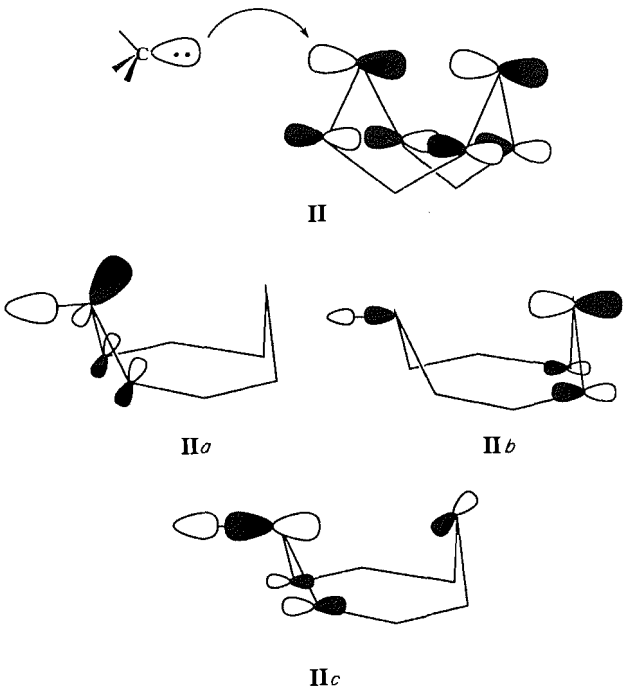

SCHEME 4

orbitals in the S-methylated structure, two of which are doubly occupied. Since all relevant orbitals are symmetric with respect to the preserved mirror plane of the molecule, they will all belong to the a' representation of the C_s point group. This new set of orbitals **II***a*, **II***b*, and **II***c* is illustrated in Scheme 4.

Of these three orbitals, **II***a* is lowest in energy. This orbital is essentially bonding with respect to the methyl group and a ring sulfur atom, and nonbonding with respect to the two-ring sulfur atoms. We can identify this orbital as $a'(20)$ of Fig. 1. The next orbital **II***b* is also an S—S nonbonding orbital, but it is slightly antibonding with respect to the C—S bond. This orbital corresponds to $a'(22)$ and thus represents the HOMO of $Me_5P_2S_2N_4^-$ (**2***b*). Whereas the bonding orbital **II***a* is mainly localized on the methylated site of the ring system, the HOMO **II***b* is mainly limited to the opposite side of the ring. Finally, there is orbital **II***c*, which is antibonding both with respect to the C—S bond as well as the S—S link. Figure 1 shows that this antibonding orbital, $a'(24)$, belongs to the set of unoccupied orbitals, lying about 1 eV in energy above the LUMO.

We now turn to a discussion of the atomic charges, which are displayed in Fig. 2. The calculations for the atomic charges were based on a Mulliken population analysis. These values are good indicators for electronic structure changes, but the absolute numbers should not be taken too seriously. The neutral structure 1,5-$Me_4P_2S_2N_4$ (**1***a*) possesses negative partial charges at the nitrogen atoms as well as positive partial charges at the phosphorus and sulfur atoms, with the charge at P being almost three times as high as the charge at S. This molecule possesses a dipole moment in the $z(y)$ direction,[3] for which the absolute value is calculated to be $\mu_{z(y)} = 5.15$D. On going to the anionic structure $Me_5P_2S_2N_4^-$ (**2***b*), we find the most dramatic

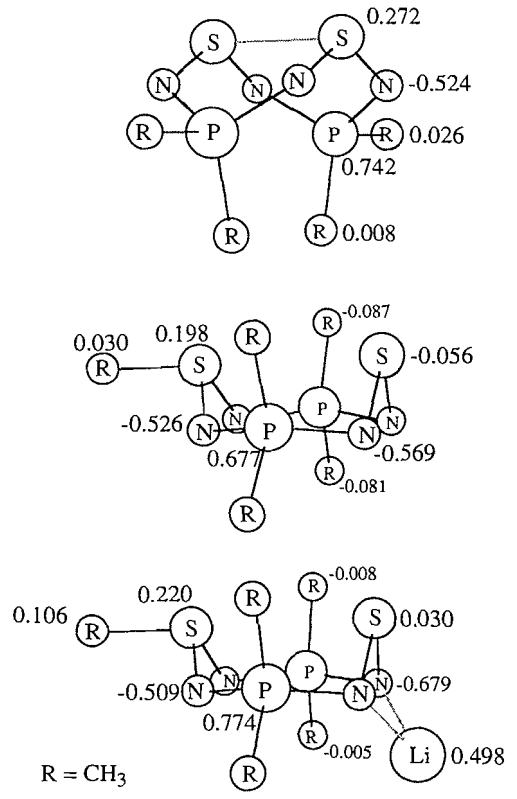

FIG. 2. Atomic charges (in au) for 1,5-$Me_4P_2S_2N_4$, $Me_5P_2S_2N_4^-$, and $Li[Me_5P_2S_2N_4]$.

increase of charge at the sulfur opposite to the site of methylation. Compared to the neutral structure, we calculate an increase of negative charge by 0.328 au. The negative charge on the two nitrogens at the methylation site is 0.043 au smaller than the charge at the N atoms bound to the second S atom. The fact that the HOMO of the anionic system is localized at the site opposite the methylation site is well reflected in the charge distribution. Furthermore, the structures of the known metal complexes of the anions $Ph_4RP_2S_2N_4^-$ (R = alkyl, aryl) are consistent both with the composition of the HOMO and the calculated atomic charges for $Me_5P_2S_2N_4^-$ (**2***b*). These anions have been shown to form η^1-S complexes with Pt(II) or Pd(II) (10) and η^2-N,S complexes with Ti, Zr, or Hf (11). In all cases the metal is attached to the side of the $P_2S_2N_4$ ring opposite to the S—R group. The anion **2***b* possesses a high charge separation in the $x(y)$ direction of the S—S vector. Since phosphorus and nitrogen atoms from almost a planar arrangement, charge separation in the $y(z)$ direction becomes less effective. The coordination of lithium to the ring system leads to a further polarization of charge. The negative charge of the coordinating N atoms increases, whereas for the second pair of N atoms it decreases. Interestingly, the coordination of the metal cation also induces an increase of the atomic charge at the S-methyl group and thus might activate the S—C bond. Consistent with this prediction, we note that S-dealkylation occurs in some reactions of the lithium derivatives $[Li[Ph_4RP_2S_2N_4]]_2$ (R = alkyl).[4]

Finally, we will comment on the thermodynamics of this process. Since we are not working with optimized structures but refer in all cases to the geometries in the crystal, we are provid-

[3]We refer to Schemes 1 and 3 for the coordinate systems. Since the point groups C_{2v} and C_s require a different set of coordinate systems, for a given C_{2v} direction, we refer in parentheses to its C_s counterpart, and vice versa.

[4]T. Chivers, R.W. Hilts, and R. Vollmerhaus. Unpublished results.

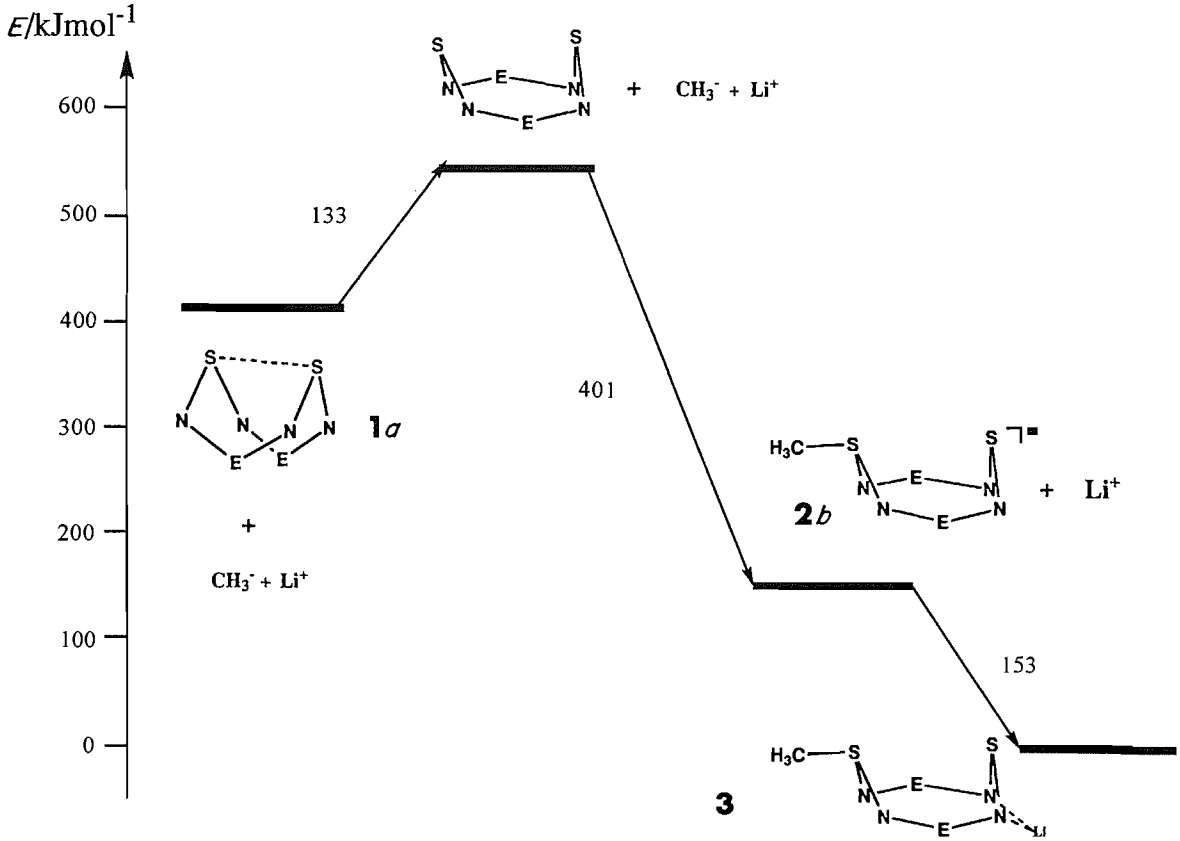

FIG. 3. Total energies for several 1,5-$P_2S_2N_4$ systems relative to $Li[Me_5P_2S_2N_4]$.

ing good estimates rather than accurate numbers for different bonding energies. However, these values provide some insight into the nature of the bonds involved. The total energies for various systems are summarized in Fig. 3. The value for $Li[Me_5P_2S_2N_4]$ (**3**) is set to zero. In the first step, we look at the change in energy when 1,5-$Me_4P_2S_2N_4$ (**1***a*) is distorted in a such a way that the ring now takes on the geometry of the methylated system. This deformation requires an energy of 133 kJ/mol, which we define as the cross-ring S—S bond energy. This energy is about half the energy for an S—S linkage in disulfide structures (HSSH: 276 ± 8 kJ/mol; CH_3SSCH_3: 272.8 ± 3.8 kJ/mol (12)). The cross-ring S—S bond distance is significantly longer than that in disulfides (d_{S-S}(HSSH): 2.058 ± 0.005 Å; $d_{S-S}(CH_3SSCH_3)$: 2.038 Å (13)), which provides one reason for a lower bonding energy. We calculated the change in S—S bonding energy for HSSH on going from the equilibrium structure to an elongated structure with d_{S-S} = 2.55 Å to be 71 kJ/mol. This accounts for only half of the energy difference between the intramolecular S—S bond and that of typical disulfide bonds. This again emphasizes that the cross-ring S—S bond is significantly different from a disulfide linkage. We should point out that our definition of the transannular S—S bond not only describes the S—S bonding interaction but also includes changes in the torsional energy of the cyclic system. We can estimate this contribution to be about 20 kJ/mol. Thus the cross-ring S—S bond strength as defined above provides a reasonable approximation to the S—S bonding interaction.

If we now look at the energy after adding a CH_3^- anion to the distorted ring to form $Me_5P_2S_2N_4^-$ (**2***b*), we gain a total of 401 kJ/mol. This energy decrease stems from two sources, namely, the formation of a C—S bond as well as the more effective stabilization of the electronic charge on the $P_2S_2N_4$ system. The last term can be obtained by the calculated difference in the vertical electron affinities of the two species involved. It amounts to 185 kJ/mol. Therefore, we can estimate the strength of the C—S bond to be about 218 kJ/mol. This value is smaller than typical values for S—C bonds (HS—CH_3: 312.5 ± 4.2 kJ/mol; CH_3S—CH_3: 307.9 ± 3.3 kJ/mol; $C_6H_5CH_2$—SCH_3: 256.9 ± 8 kJ/mol (12)). The S—C destabilizing nature of the HOMO of $Me_5P_2S_2N_4^-$ (**2***b*) is responsible for the somewhat lower S—C bond strength in the methylated ring system.

Photophysical behavior of oligoethylene glycols labeled with naphthalene carboxylate and phosphate esters

SAM LEE AND MITCHELL A. WINNIK[1]

Department of Chemistry and Erindale College, University of Toronto, 80 St. George St., Toronto, ON M5S 1A1, Canada

Received April 21, 1993

SAM LEE and MITCHELL A. WINNIK. Can. J. Chem. **72**, 1587 (1994).

The fluorescence spectra of tri- and tetraethylene glycol esterified with 2-(1-naphthyl)ethyl ethyl phosphate and 2-(1-naphthyl)ethyl 2-(ethoxy)ethyl phosphate were studied in dilute solutions of tetrahydrofuran (THF) and diethyl ether. They were compared with the fluorescence from tri- and tetraethylene glycol esterified with 1-naphthyl acetic acid. These compounds form intramolecular excimers. The extent of excimer formation is not extensive, but the relative amount of excimer emission from these compounds varies with the choice of solvent. Three synthetic intermediates to the phosphates, the 2-(1-naphthyl)ethyl *N*,*N*-diisopropylphosphoramidites of tri- and tetraethylene glycol and of 2-ethoxyethanol, were also examined. These compounds form intramolecular exciplexes. In THF, the relative amount of exciplex emission from the phosphoramidites follows the same trend as the carboxylate esters. In diethyl ether, the trend is different. Rates of fluorescence decay have been measured for these compounds. The results are discussed in terms of how information about the conformational and dynamic behavior of these molecules in solution can be obtained, and how the solvent can influence the relative amounts of excimer or exciplex fluorescence.

SAM LEE et MITCHELL A. WINNIK. Can. J. Chem. **72**, 1587 (1994).

Opérant en solutions diluées de tétrahydrofurane (THF) ou d'éther éthylique, on a étudié les spectres de fluorescence de tri- et tétra-éthylèneglycols estérifiés avec des phosphates de 2-(1-naphtyl)éthyléthyle ou de 2-(1-naphtyl)éthyl 2-(éthoxy)éthyle. On les a comparés avec les spectres de fluorescence de tri- et tétra-éthylèneglycols estérifiés avec de l'acide 1-naphtylacétique. Le degré de formation d'excimères n'est pas élevé, mais l'intensité relative de l'émission provenant des excimères de ces composés varie avec la nature du solvant. On a aussi étudié les trois intermédiaires de synthèse des phosphates, les 2-(1-naphtyl)éthyl *N*,*N*-diisopropylphosphoramidites des tri- et tétra-éthylèneglycols et du 2-éthoxyéthanol. Ces composés forment des excimères intramoléculaires. Dans le THF, l'intensité relative de leur émission suit la tendance observée avec les esters des acides carboxyliques. Dans l'éther éthylique, la tendance est différente. On a mesuré les vitesses de décroissance de la fluorescence de ces composés. On discute les résultats en fonction de la façon par laquelle on peut obtenir des informations relatives au comportement conformationnel et dynamique de ces molécules en solution, et comment le solvant peut influencer l'intensité relative de fluorescence de l'excimère ou de l'exciplexe.

[Traduit par la Rédaction]

Introduction

One of the fundamental aspects of polymer chemistry is the conformation and motion of linear polymer chains in solution. The shape and dynamic behavior of a polymer coil are affected by factors such as chain stiffness, excluded volume, and hydrodynamic interactions. These topics have been studied for many decades (1–3). Within this context, we have had a continuing interest in the cyclization of polymer chains.

The extent of cyclization and dynamics of cyclization can be studied in various ways (4–11). We have recently begun to explore a new approach that involves a series of reactions currently used in solid-phase oligonucleotide synthesis (12, 13). This "phosphite triester" method can, in principle, be used to generate linear polymers that contain two chromophores separated by a fixed number of monomer units and that are symmetrically positioned within the chain. This would permit the motion of the interior segments to be probed as the "backbone-to-backbone" cyclization of the linear chain.

To begin, we investigated the synthesis of model oligomers, based upon triethylene glycol and tetraethylene glycol, and naphthalene as the fluorophore label (14). This allowed us to optimize reaction conditions and to prepare well-characterized intermediates and products. We have also described briefly the steady-state fluorescence properties of these molecules. In this paper, we examine their fluorescence behavior and fluorescence decay kinetics in detail. We compare their properties with naphthalene end-labeled tri- and tetraethylene glycol where the fluorophores are attached via carboxylate ester groups. The results of the fluorescence decay kinetics measurements are, in fact, rather disappointing. The extent of naphthalene excimer formation is sufficiently small that only limited insights are possible. Thus, naphthalene is not really an adequate excimer-forming chromophore for such studies. Ironically, some of our most interesting observations derive from examination of phosphoramidite synthetic intermediates.

Results and discussion

Materials

We have synthesized the bis-phosphates **131**, **232**, **141**, and **242** using a procedure described previously (14). For polymers, pyrene is the common choice for the excimer-forming probe. For these shorter chains, we chose to label these oligomers with naphthalene. The major reason for choosing naphthalene was the ease in purifying and characterizing the reaction intermediates. **131** and **232** are oligoethylene glycols where the two naphthalene probes are separated by three oxyethylene monomer units. The ends of these two labelled glycols are flanked by one and two monomer units, respectively. **141** and **242** both have four oxyethylene monomer units separating the two chromophores. The ends of these two labelled glycols are also flanked by one and two monomer units, respectively. The phosphate **22** served as the model compound for these bis-phosphates.

In the preparation of the bis-phosphates, the bis-phospho-

ramidites **P3** and **P4** were synthetic intermediates. These compounds also exhibit fluorescence behavior that is interesting and informative on their own. As a model compound, the phosphoramidite **P2** was also synthesized.

For a comparative study, **N3N** and **N4N** were also prepared. These two diesters differ from the bis-phosphates in the type of functional group used to attach the naphthalene probe onto triethylene glycol and tetraethylene glycol. They also do not have any additional monomer units flanking the labelled ends. In this system, the ester **N2** served as the model compound.

Bis-phosphate fluorescence

Fluorescence spectra of the four bis-phosphate ester derivatives are shown in Fig. 1 along with that of the model com-

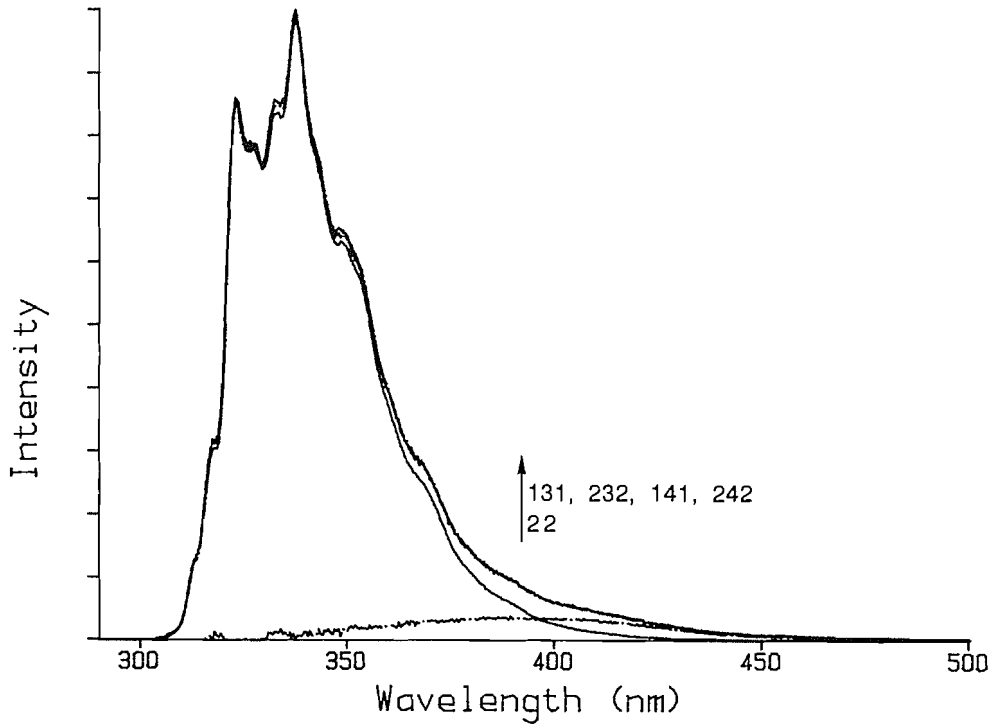

FIG. 1. Normalized fluorescence spectra of the model phosphate (**22**) and the bis-phosphates (**131**, **232**, **141**, and **242**) in diethyl ether at room temperature (labels refer to the solid lines). The excimer band (— · —) was obtained by subtraction of the fluorescence spectrum of **22** from the spectrum of **242**.

pound **22** for dilute solutions of these molecules in diethyl ether. The spectra are similar for solutions in THF (not shown). There is very little excimer emission. The absence of significant excimer emission could be due to very slow cyclization of these molecules or it may be related to the weak tendency of naphthalene to form excimers. We will come back to this point later. Fluorescence decay measurements (Table 1) indicate that the naphthalene decay times are nearly indistinguishable from that of the model compound. One interesting feature is that the bis-phosphates have slightly shorter lifetimes in diethyl ether and, in both solvents, give poorer fits to a single exponential decay profile than the model compound. This effect is so consistent that it suggests that the naphthalenes do interact in the excited state.

Diester fluorescence

Fluorescence spectra of **N3N** and **N4N** in dilute solution in THF are shown in Fig. 2 along with that of the model ester **N2**. Corresponding spectra for these molecules in diethyl ether solution are shown in Fig. 3. There is clear indication in both solvents of a new emission, observed as a long tail extending toward lower energies. When the fluorescence spectrum of the model compound is subtracted from either of the two normalized spectra, a broad, structureless band centered at 400 nm is recovered. This new fluorescence emission comes from the intramolecular excimer. At the concentrations examined ($<10^{-4}$ M), values of the excimer-to-monomer intensity ratio I_E/I_M are independent of concentration. Hence excimer formation is an intramolecular process.

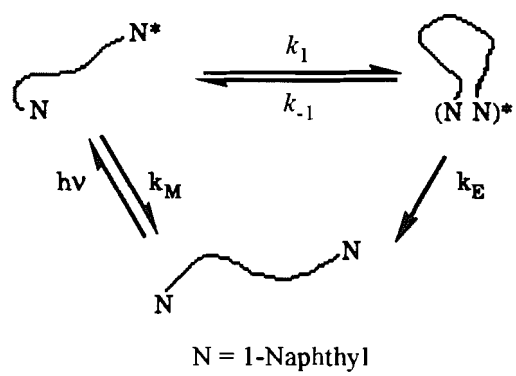
Excitation spectra were examined for both molecules in both solvents. Identical spectra were obtained when the emission was monitored at 450 nm (the excimer band) and when the emission was monitored at 324 nm. If a significant fraction of the naphthalene groups were associated prior to absorption of a photon, one would expect a red shift of the excitation spectrum of the excimer relative to that of the monomer. As a consequence, we conclude that excimers observed in this system arise through diffusion together of naphthalenes subsequent to excitation.

The only surprise in these spectra is that I_E/I_M is *larger* for **N4N** than for **N3N** for samples in diethyl ether. One expects the rate and extent of cyclization to decrease with increasing chain length. We observe this for **N3N** and **N4N** in THF, but not in diethyl ether.

Excimer formation kinetics are normally described by the Birks model, Scheme 1 (15). For weakly bound excimers, of which naphthalene is an example, $k_{-1} \gg k_E$. In this so-called high-temperature limit, Scheme 1 predicts the "monomer" fluorescence intensity ($I_M(t)$) to decay exponentially following δ-pulse excitation:

$$[1] \qquad I_M(t) = a_1 \exp(-\lambda_1 t)$$

$$[2] \qquad \lambda_1 = k_M + k_q$$



N = 1-Naphthyl

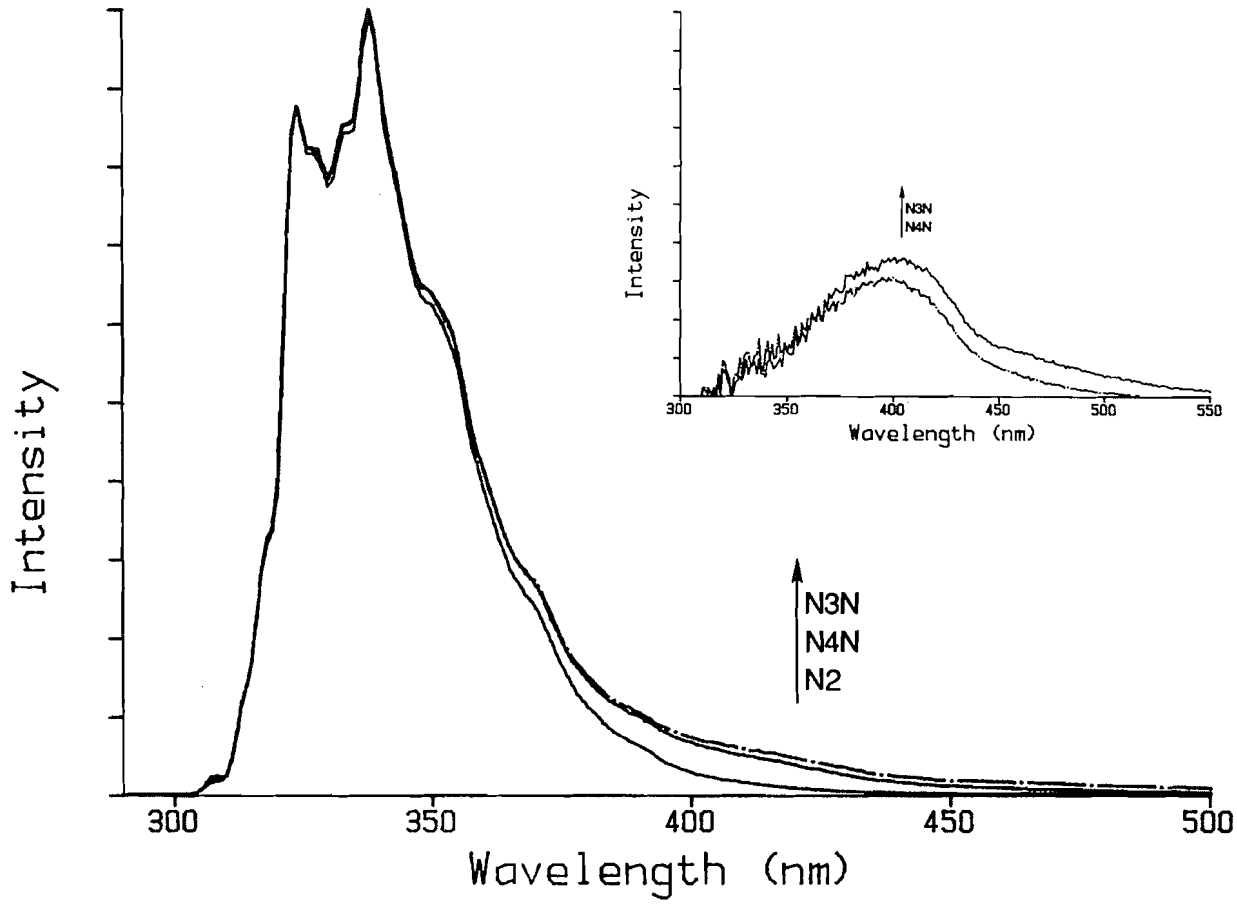

FIG. 2. Normalized fluorescence spectra of the model ester **N2** and the diesters **N3N** and **N4N** in THF at room temperature. Inset: excimer bands obtained by subtraction of the fluorescence spectrum of the model compound from the corresponding diester fluorescence spectra (expansion: ×8).

where $k_q = (k_1/k_{-1})k_E$. Under these circumstances, there is essentially a conformational preequilibrium (with $K = k_1/k_{-1}$) preceding the quenching step k_E, and k_q values can be obtained from $I_M(t)$ if the rate, k_M, is known. The value of these rate constants can be determined from $I_M(t)$ if the rate, k_M, is known. This can be found from an independent measurement using a model compound, where τ_M is its excited state lifetime in dilute solution:

$$[3] \qquad I_M(t) = a_0 \exp(-\lambda_M t); \qquad \lambda_M = k_M = {\tau_M}^{-1}$$

This analysis fails here, but for a reason that is itself quite interesting. This is related to the choice of model compounds. **N2** has a lifetime (50 ns, Table 1) that is significantly shorter than that of 1-methylnaphthalene (75 ns, THF; 80 ns, ether). Thus the ester group, or perhaps the PEO chain, causes some quenching of excited naphthalene. In retrospect, we recall the finding of Monnerie and co-workers that the ether functionality quenches anthracene fluorescence, but we did not anticipate this kind of effect here, where the solvents are also ethers (16). Comparison of the fluorescence lifetime of methylnaphthalene with that of the model phosphate **22** shows that this effect is present here as well.

Under these circumstances, we would normally assume that the quenching effect on the bis-naphthalene derivative is the same as on the model compound, and thus only affects k_M. This may not be true here since the excimer-forming diesters have the same monomer lifetime as the model compound. The one conclusion one can draw here is that the extent of excimer formation must be small.

We can still make comparisons between di-labeled pairs. The quantum efficiencies (Φ) are related to the rate constant in Scheme 1 by the expression

$$[4] \qquad \frac{\Phi_E}{\Phi_M} = \frac{k_{fE}}{k_{fM}}\left(\frac{k_1}{k_{-1} + k_E}\right) \propto \frac{I_E}{I_M}$$

where k_{fE} and k_{fM} are the respective radiative rate constants. These terms do not depend upon chain length. When cyclization does not involve ring strain, then k_{-1} is similarly independent of chain length. Thus, when one wishes to compare intramolecular excimer formation in two samples of different chain length, the expressions

$$[5] \qquad \frac{(I_E/I_M)}{(I_E/I_M)'} = \frac{k_1}{k_1'} \quad \text{or} \quad \frac{(k_1/k_{-1})}{(k_1/k_{-1})'}$$

are particularly useful. By writing (k_1/k_{-1}) we emphasize that a conformational preequilibrium precedes quenching when the system is operating in the high temperature limit. Equation [5] allows us to quantify the enhanced formation of excimer for **N4N** over **N3N** in ether, and for **N3N** over **N4N** in THF. When these esters were examined in other solvents, it became clear that the relative extent of excimer formation is also dependent on the choice of solvent (Table 2).

Bis-phosphoramidite fluorescence

The fluorescence spectra of **P2**, **P3**, and **P4** in THF are presented in Fig. 4. They are compared with the model phosphate **22** by normalizing their 0–0 fluorescence band to that of the phosphate at 323 nm. The phosphoramidites all have an additional tail extending to longer wavelengths which peaks at about 485 nm. This extra emission comes from the intramolecular exciplex formed from the interaction of the excited naphthalene moiety with the phosphoramidite group. While the amount of intramolecular exciplex emission is not extensive, the amount of fluorescence self-quenching in these molecules is substantial. When the total fluorescence intensity from the phosphate **22** is compared with that of the phosphoramidite **P2**, at equal concentrations of the chromophore, the phosphoramidite only exhibits 17% of the total fluorescence emission from **22**.

The lifetimes can be similarly compared. The quantum yield for fluorescence (Φ_f) is related to the radiative rate constant for fluorescence (k_f) and the rate constant for quenching of the excited chromophore by radiationless pathways (Σk_d):

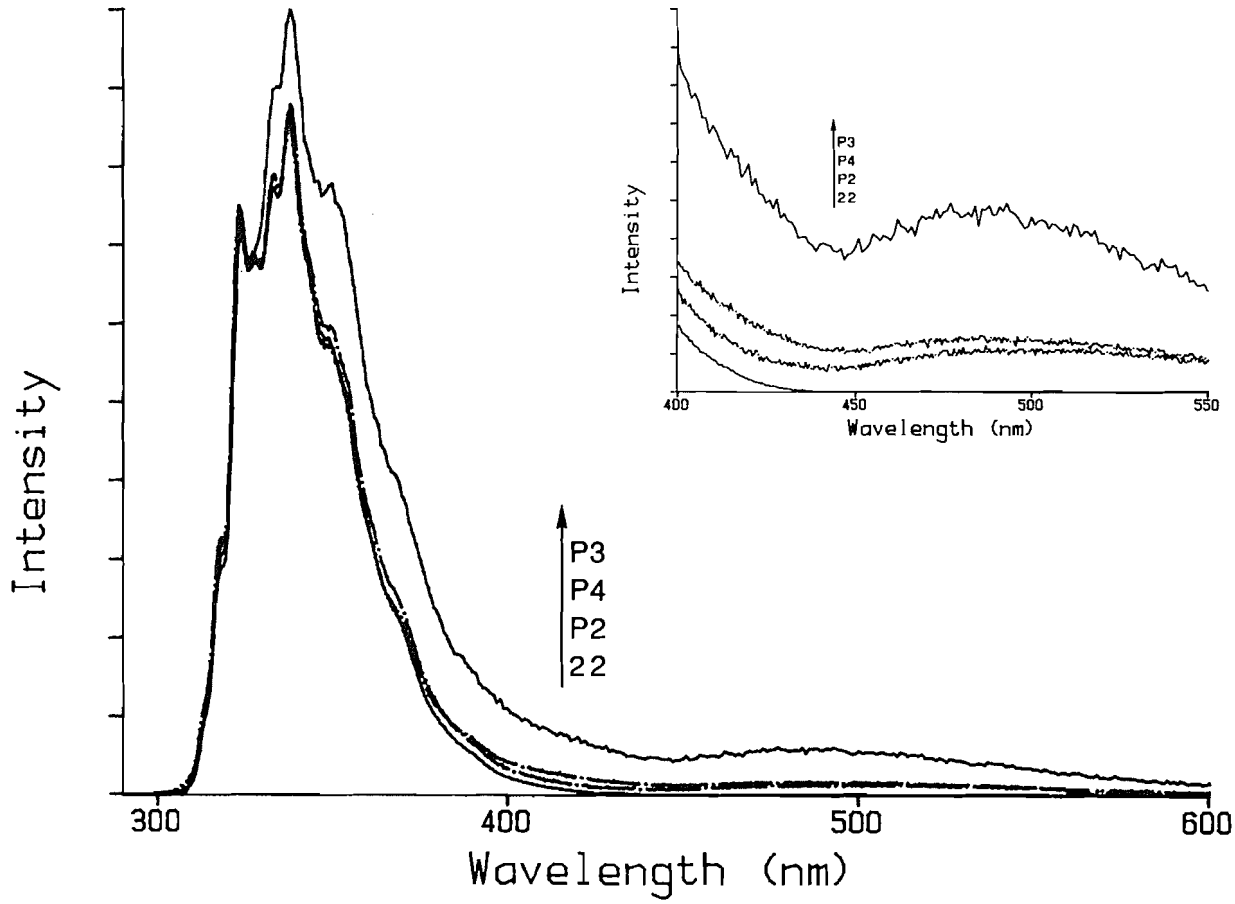

FIG. 4. Normalized fluorescence spectra of the model phosphate (**22**), model phosphoramidite (**P2**), and the bis-phosphoramidites (**P3** and **P4**) in THF at room temperature. Inset: ×8 expansion of the 400–550 nm region.

$$[6] \qquad \Phi_f = \frac{k_f}{k_f + \Sigma k_d}$$

Since the measured lifetime $\tau = 1/(k_f + \Sigma k_d)$, $\Phi_f(\mathbf{P2})/\Phi_f(\mathbf{22})$ (= 0.17) should be equal to $\tau(\mathbf{P2})/\tau(\mathbf{22})$. However, $\tau(\mathbf{P2})/\tau(\mathbf{22})$ = 0.05 (Table 3), indicating that additional mechanisms, apart from exciplex formation, are available to quench **P2** fluorescence that are not present in the model compound **22**.

The bis-phosphoramidites show more exciplex emission than the phosphoramidite **P2** because the excited chromophore can form a complex, either with the "proximal" phosphoramidite group in a way similar to that of the model phosphoramidite **P2**, or with the "distal" phosphoramidite group at the other end of the molecule. Excimer formation is also possible, but the amount is insignificant because the naphthalene excimer is more weakly bound compared with the exciplex. In the case of **P4**, where the phosphoramidite groups are separated by four monomer units, the exciplex emission is greater than in **P2** by only a small amount. The shorter bis-phosphoramidite **P3**, where the phosphoramidite groups are separated by three monomer units, exhibits substantially greater exciplex emission than either **P2** or **P4**.

The fluorescence spectra of the phosphoramidites and the model phosphate were also recorded in diethyl ether (Fig. 5). Subtracting the normalized fluorescence spectrum of the model phosphate from each of the corresponding phosphoramidites yields exciplex fluorescence bands containing two broad peaks: one centered at 360 nm and the other at 485 nm. The band centered at 360 nm might be due to a second, higher energy exciplex. The bis-phosphoramidite **P3** shows the greatest amount of exciplex fluorescence. Interestingly, the bis-phosphoramidite **P4** exhibits less exciplex emission than that of the model phosphoramidite **P2**.

TABLE 3. Fluorescence decay data for the phosphoramidite **P2** in THF and diethyl ether at 22°C

THF[a] τ_i (a_i)[c]	Diethyl ether[b] τ_i (a_i)
62.6 (0.028)	51.8 (0.004)
15.0 (0.031)	15.7 (0.028)
1.00 (0.941)	0.697 (0.968)

[a] χ^2 (chi-square) value in THF = 1.068.
[b] χ^2 (chi-square) value in diethyl ether = 1.057.
[c] Decay data were fit to a sum of three exponentials (λ). a_i is the normalized pre-exponential value for the corresponding lifetimes ($\tau = \lambda^{-1}$).

The excitation spectra of the phosphoramidites in diethyl ether, obtained by monitoring the emission at 323 nm, are identical to the spectra obtained by monitoring the emission at 485 nm. Hence, the naphthalene–phosphoramidite complex does not exist prior to excitation, and exciplex formation is a result of a dynamic process.

The fluorescence decay profile of the phosphoramidites are

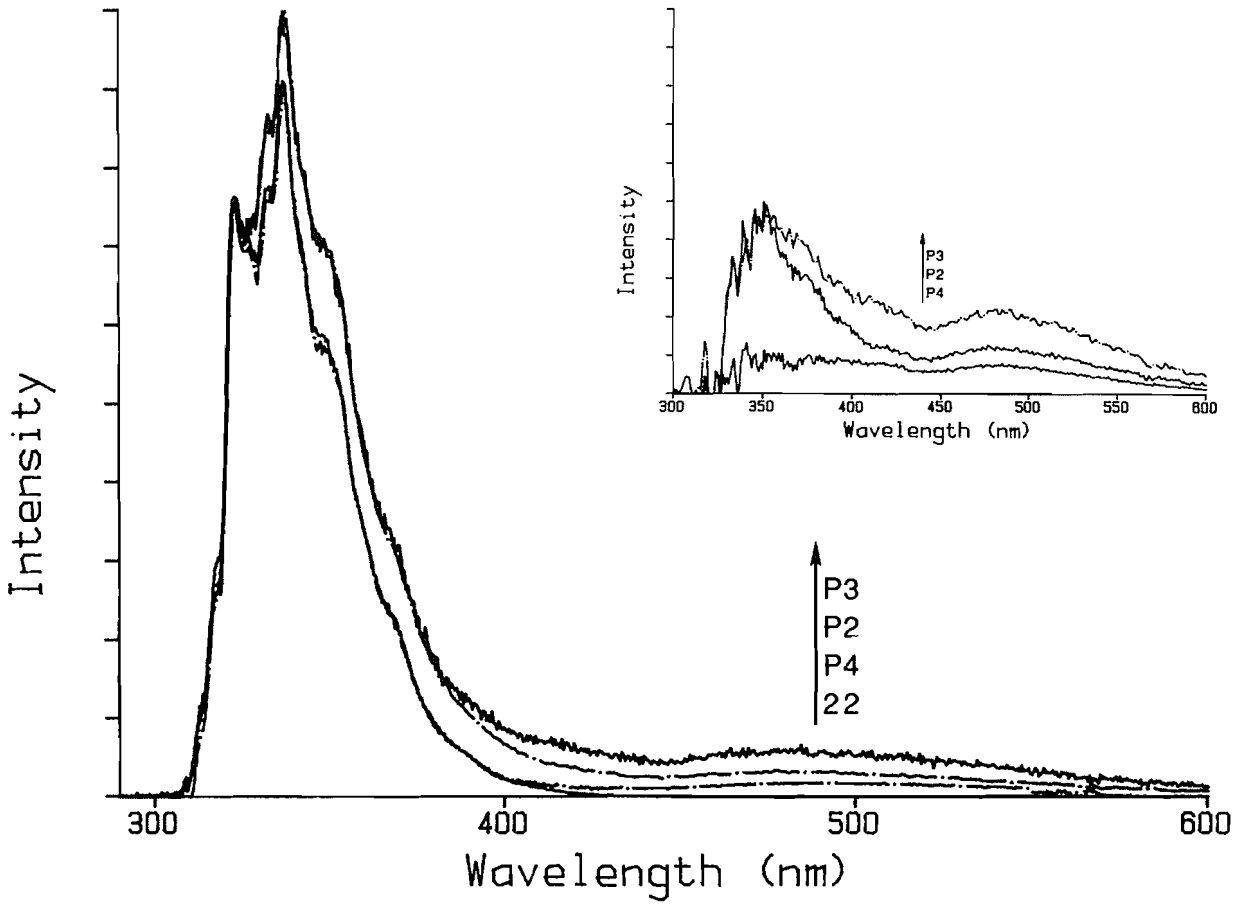

FIG. 5. Normalized fluorescence spectra of the model phosphate (**22**), model phosphoramidite (**P2**), and the bis-phosphoramidites (**P3** and **P4**) in diethyl ether at room temperature. Inset: exciplex bands obtained by subtraction of the model phosphate fluorescence spectrum from the fluorescence spectra of the corresponding phosphoramidites.

strongly nonexponential. For **P2**, three exponential terms are needed to fit the data (Table 3). The quenching kinetics are complex, but one reasonable interpretation of the decay data is that exciplex formation is much faster than exciplex decay. Calculation of the mean decay time $\langle\tau\rangle$ (eq. [7]) from the two (short time) components of the decay sets the timescale for exciplex formation. This value is 1.1 ns in diethyl ether and 1.4 ns in THF. The weak 63 ns component in THF (52 ns in ether) is due to reformation of excited naphthalene from exciplex dissociation. Even incorporating the long third component into the calculation of $\langle\tau\rangle$ increases its value only to 1.3 ns in ether and 3.1 ns in THF.

$$[7] \qquad \langle\tau\rangle = \frac{a_1\tau_1 + a_2\tau_2}{a_1 + a_2}$$

Chain conformation and dynamics

When the chain is short, structural features associated with interactions between neighboring monomer units limit the relative orientations of the chromophores and perturb the nature of their photoreaction. However, there is ample evidence to suggest that these oligomers are sufficiently long to permit all possible orientations of the terminal chromophores to occur (17–19). Our observations thus provide qualitative and semiqualitative information about chain conformation in these tri- and tetraethylene glycol derivatives. In the phosphoramidites, exciplex formation between excited state naphthalene and the proximal phosphoramidite group is very fast. In the longer bis-phosphoramidite **P4** the effect of the distal phosphoramidite group is minimal because the excited naphthalene is, on average, quenched by the proximal phosphoramidite group before it can encounter the phosphoramidite group at the other end of the chain. In the shorter bis-phosphoramidite **P3**, cyclization of the chain ends is much faster, and quenching of the excited naphthalene chromophore by the distal phosphoramidite group is now competitive with quenching by the proximal phosphoramidite group. To compete, the interaction with the distal phosphoramidite group must occur on a timescale of 1–3 ns. This result is consistent with those obtained from doubly end-labelled molecules of similar lengths. The longer pentaethylene glycol, esterified at both ends with naphthalene, has a short-lifetime component of 2 ns in isopentane (19). Bis(1-pyrenylmethyl) dodecanedicarboxylate in 2-methyltetrahydrofuran has a short lifetime component of 5 ns (20): the stiffer hydrocarbon chain and the extra drag arising from the bulky pyrene groups slows the rate of terminal cyclization.

We have discussed exciplex emission in the phosphoramidites as though exciplex formation was largely irreversible, corresponding to the low-temperature limit ($k_{-1} \ll k_E$) of Scheme 1. The major evidence for the validity of this point of view is the large extent of monomer quenching caused by the presence of the phosphoramidite group. Thus, the phosphoramidites give us some information about chain dynamics.

The esters, on the other hand, operate in the high-temperature limit, and can provide information only about the probability

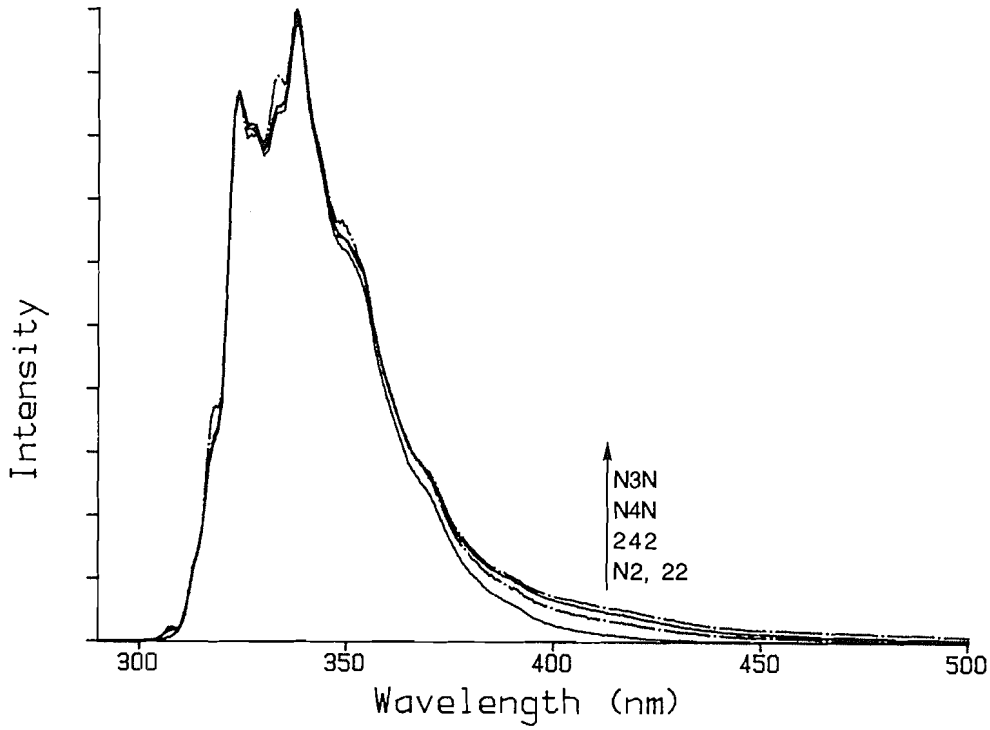

FIG. 6. Normalized fluorescence spectra of the bis-phosphates (represented by **242**), the diesters (**N3N** and **N4N**), and the model compounds (**N2** and **22**) in THF at room temperature.

of the chain ends coming together. Comparing phosphates with carboxylate esters (Fig. 6), we note significantly less excimer from the phosphates, implying the importance of steric effects when the chromophores are not situated at the chain ends. These presumably operate locally and interfere with the N* + N interaction.

Our most interesting observations were the reduced emission of **P4** relative to **P2** in diethyl ether, and the enhanced emission of **N4N** over **N3N** in diethyl ether and cyclohexane. The enhancement could be due either to an unfavourable solvent interaction with the end groups, or to an unfavourable solvent interaction with the oligomeric chain. When the interactions between the chromophores and the solvent are sufficiently unfavourable, some association of the aromatic groups could occur. One documented example of this effect involves pyrene-end-capped polyethylene oxide (PEO, $M_w = 8000$) in aqueous solution (21–24). Hydrophobic attractions between the pyrenes lead to a small proportion of the chains (ca. 6%) with their ends in contact. Another example involves bis-pyrene-1-carboxylate esters of 1,*n*-alkane diols in linear hydrocarbons (25). Excitation spectra in our systems indicate that preassociation of N-groups is unlikely to be important here.

On the other hand, diethyl ether and cyclohexane are non-solvents for PEO. Some vestige of this effect may well be operating on these tri- and tetraethylene glycol derivatives. The dimensions of high molecular weight polymers are very sensitive to solvent quality, although very poor solvents induce phase separation rather than collapse. This might also explain the reduced emission of **P4** compared to **P2** if the oligoethylene glycol chain is collapsed, raising the conformational barriers to exciplex formation. These effects become less important for shorter chains. It is very rare to encounter examples of such solvent effects on oligomers as short as those we examine here.

Experimental

Sample preparation

All solvents were of spectroscopic grade except diethyl ether (ACS). THF and diethyl ether were distilled from lithium aluminum hydride. Benzene and cyclohexane were distilled from sodium. Acetonitrile was distilled from calcium hydride. All compounds were freshly chromatographed before solutions were prepared with them. The concentration of chromophore in all solutions was of the order of 10^{-6}–10^{-5} M. Sample solutions were degassed by vigorously bubbling with argon (Union Carbide, <0.5 ppm, <3 ppm water), presaturated with the solvent, for 20 min.

Fluorescence

All fluorescence measurements were recorded at room temperature. Steady state fluorescence spectra were recorded on a SPEX Fluorolog 2 spectrometer at a right angle geometry using 1 mm excitation and emission slit widths. The excitation wavelength was 282 nm. Emission spectra were corrected for scattering and the wavelength sensitivity of the photomultiplier tube. I_E/I_M ratios were obtained by subtracting the normalized spectrum of the model compound from the diester, and integrating over the result to obtain I_E. I_M were obtained from integration of the spectrum of the model compound.

Fluorescence decay curves were obtained by the single photon counting technique (26). The excitation source was a coaxial flashlamp (Edinburgh Instruments, model 199F) filled with deuterium at a pressure of 100 Torr (1 Torr = 133.3 Pa). The excitation wavelength (282 nm) was selected by a Jobin–Yvon model H-20 monochromator, and that of the fluorescence (323 nm) by a SPEX Minimate model 1760 monochromator. The electronic signals were processed using ordinary Ortec instrumentation. The analyses of the decay curves were performed with the δ-pulse deconvolution method (27) using iterative weighted linear least-squares analysis to find the parameters of the fluorescence decay curves having the best fit. Degassed *p*-terphenyl in cyclohexane was used as the reference for the decay profiles.

Materials

All general procedures and techniques, including the synthesis of the phosphates and phosphoramidites, have been previously described

For personal use only.

(14). The carboxylic acid esters were prepared by DCC coupling of the corresponding acid and alcohol.

2-Ethoxyethyl (1-naphthyl)acetate (N2)

Yield: 60% as a clear, colourless oil; R_f 0.51 (80% diethyl ether – 20% hexane); IR (neat): 780, 1050, 1125, 1170, 1265, 1385, 1450, 1510, 1600, 1735 cm^{-1}; UV (THF), λ_{max} nm (ϵ): 224 (7.09 × 10^4), 272 (5830), 282 (6860), 292 (4770), 314 (305); ^1H NMR (acetone-d_6): 1.07 (t, 3H, $^3J_{HH'}$ = 7.0 Hz, CH_3), 3.38 (q, 2H, $^3J_{HH'}$ = 7.0 Hz, CH_2CH_3), 3.56 (t, 2H, $^3J_{HH'}$ = 4.1 and 5.1 Hz, $COOCH_2CH_2$), 4.13 (s, 2H, $C_{10}H_7CH_2$), 4.19 (t, 2H, $^3J_{HH'}$ = 4.5 and 5.0 Hz, $COOCH_2$), 7.43–8.05 (m, 7H, naphthyl-*H*); ^{13}C NMR (acetone-d_6): 15.47 (CH_3), 39.28 ($C_{10}H_7CH_2$), 64.71 ($COOCH_2$), 66.76 (CH_2CH_3), 68.89 ($COOCH_2CH_2$), 124.87, 126.30, 126.53, 126.98, 128.61, 128.85, 129.41, 132.08, 133.17, 134.81 (naphthyl-*C*), 171.79 (*C*OO); mass spectrum, *m/e* (rel. intensity): 259 (M + 1)$^+$ (19), 258 M$^+$ (57), 186 (49), 168 (60), 141 (100), 115 (42).

Triethylene glycol di-(1-naphthyl)acetate (N3N)

Yield: 72% as a clear, colourless oil; R_f 0.27 (80% diethyl ether – 20% hexane); IR (neat): 780, 960, 1050, 1130, 1265, 1510, 1600, 1740 cm^{-1}; ^1H NMR (acetone-d_6): 3.43 (s, 4H, OCH_2CH_2O), 3.60 (t, 4H, $^3J_{HH'}$ = 4.7 and 4.8 Hz, $COOCH_2CH_2$), 4.12 (s, 4H, $C_{10}H_7CH_2$), 4.19 (t, 4H, $^3J_{HH'}$ = 4.7 and 4.9 Hz, $COOCH_2$), 7.42–8.04 (m, 14H, naphthyl-*H*); ^{13}C NMR (acetone-d_6): 39.27 ($C_{10}H_7CH_2$), 64.69 ($COOCH_2$), 69.59 ($COOCH_2CH_2$), 71.13 (OCH_2CH_2O), 124.89, 126.31, 126.54, 127.02, 128.60, 128.86, 129.40, 132.06, 133.15, 134.79 (naphthyl-*C*), 171.78 (*C*OO); mass spectrum, *m/e* (rel. intensity): 487 (M + 1)$^+$ (15), 486 M$^+$ (28), 213 (25), 168 (100), 141 (93), 115 (28).

Tetraethylene glycol di-(1-naphthyl)acetate (N4N)

Yield: 71% as a clear, colourless oil; R_f 0.15 (80% diethyl ether – 20% hexane); IR (neat): 780, 960, 1050, 1130, 1250, 1450, 1510, 1600, 1730 cm^{-1}; ^1H NMR ($CDCl_3$): 3.43 (m, 8H, $CH_2CH_2OCH_2CH_2$), 3.56 (t, 4H, $^3J_{HH'}$ = 4.7 and 4.8 Hz, $COOCH_2CH_2$), 4.04 (s, 4H, $C_{10}H_7CH_2$), 4.20 (t, 4H, $^3J_{HH'}$ = 4.8 Hz, $COOCH_2$), 7.35–7.97 (m, 14H, naphthyl-*H*); ^{13}C NMR ($CDCl_3$): 38.74 ($C_{10}H_7CH_2$), 63.85 ($COOCH_2$), 68.68 ($COOCH_2CH_2$), 70.17 ($COOCH_2CH_2OCH_2$), 70.20 ($COOCH_2CH_2OCH_2CH_2$) 123.57, 125.21, 125.49, 126.07, 127.75, 127.77, 128.43, 130.24, 131.82, 133.52 (naphthyl-*C*), 171.16 (*C*OO); mass spectrum, *m/e* (rel. intensity): 531 (M + 1)$^+$ (10), 530 M$^+$ (20), 362 (5), 213 (39), 168 (100), 141 (93), 115 (27).

Received December 31, 1993

ALBERT Y. JIN, LISBETH A. BENESCH, and DONALD F. WEAVER. Can. J. Chem. **72**, 1596 (1994).

MM2 force field parameters for phospholipids were developed. These parameters — MM2(Lipid) — were employed in energy-minimization calculations (using crystal structures as starting conformations) on four phospholipids: dimyristoylphosphatidylglycerol, dilauroylphosphatidyl-*N,N*-dimethylamine, 1,2-dilauroyl-*dl*-phosphatidylethanolamine, and deoxylysophosphatidylcholine. After minimization, slight conformational changes were seen in the hydrocarbon chains, while greater change was seen at the head group. The diacylglycerol backbone of the energy-minimized structures exhibited conformations corresponding to experimentally observed conformations. The energy minimization of a randomly and significantly altered geometry of 1,2-dilauroyl-*dl*-phosphatidylethanolamine resulted in a head group conformation that closely agreed with *ab initio* theoretical calculations. The utility of AM1 in molecular mechanics parameterization was demonstrated.

ALBERT Y. JIN, LISBETH A. BENESCH et DONALD F. WEAVER. Can. J. Chem. **72**, 1596 (1994).

On a mis au point des paramètres de champ de force MM2 pour les phospholipides. On a utilisé ces paramètres — MM2(Lipides) — pour faire des calculs de minimisations d'énergie (utilisant des structures cristallines comme conformations de départ) sur quatre phospholipides: dimyristoylphosphatidylglycérol, dilauroylphosphatidyl-*N,N*-diméthylamine, 1,2-dilauroyl-*dl*-phosphatidyléthanolamine et désoxylysophosphatidylcholine. Après minimisation, on a observé de faibles changements conformationnels dans les chaînes hydrocarbonées, alors que l'on a observé des changements plus importants au niveau du groupe de tête. Le squelette diacylglycérol des structures pour lesquelles on a minimisé l'énergie présente des conformations correspondant aux conformations observées expérimentalement. La minimisation énergétique d'une 1,2-dilauroyl-*dl*-phosphatidyléthanolamine dont la structure avait été modifiée d'une façon importante et au hasard a conduit à un groupe de tête qui est en bon accord avec celui obtenu par des caculs théoriques *ab initio*. On démontre l'utilité du AM1 dans la paramétrisation de la mécanique moléculaire.

[Traduit par la Rédaction]

1. Introduction

The past decade has witnessed considerable interest in applying molecular mechanics to conformational optimization calculations for large molecules of biological and pharmaceutical significance. One class of molecules which has received surprisingly little attention are the phospholipids which constitute the major components of biological membranes (1–4). Although the molecular mechanics approach has been applied extensively to peptides, nucleotides, and other biomolecules through force fields such as MM2 (5), CHARMM (6) and AMBER (7), the equivalent treatment of membrane phospholipids is decidedly lacking. Recent experimental work has strongly suggested that molecules such as peptides or drugs, undergo significant conformational changes induced by interactions with the surrounding environment, either aqueous or lipid (8, 9). Moreover, the limitations of vacuum phase conformational calculations on biological molecules further emphasize the need to develop computational simulation methods to model environmental effects in the biological milieu. Therefore, it is imperative that the influence of a phospholipid environment be considered when searching for low energy bioactive conformations of molecules such as intramembrane proteins or drugs. This is particularly relevant in neurochemistry because neurohormones, neurotransmitters, and neuroreceptors all exist in an environment dominated by brain lipids.

As a first step towards achieving realistic neurochemical simulations, the molecular properties of membrane phospholipids must be modelled accurately. Phosphatidylcholines and phosphatidylethanolamines are two lipids which are of particular interest because both are present in large quantities in brain (neuronal) membranes. As such, they constitute a significant portion of the lipid environment of various neuropeptides and drugs (10). For this reason, we have developed an MM2 force field parameterization (MM2(Lipid)) suited to the geometry optimization of phospholipids found in neuronal membranes. (The popularity of the MM2 program precipitated the effort to develop parameters suited to this force field.) These parameters were then used to calculate the energy-minimized structures of four phospholipids. The ability of these parameters to generate experimentally determined geometries was also evaluated.

2. Methods

Although MM2 has been optimized for many classes of molecules, this important force field is unable to treat neuronal phospholipids. A set of computational procedures, as outlined by Hopfinger and Pearlstein (11), in conjunction with X-ray crystallographic data, *ab initio* molecular orbital calculations and semi-empirical molecular orbital calculations were used to generate an appropriate set of atom types and parameters. New parameters pertaining to the phosphate head group are shown in Table 1.

2.1 Atom types

The basis of any force field is the allocation of atom type; that

TABLE 1. MM2(Lipid) parameters for lipid phosphate headgroups

(*a*) Bond stretching parameters

Bond	l_0(Å)	k_s(mdyn/Å)
6–60	1.580	2.046
47–60	1.477	7.759

(*b*) Bond angle bending parameters

Bond angle	θ_0(degrees)	k_θ(mdyn Å/rad^2)
1–6–60	118.3	0.412
6–60–6	105.0	0.315
6–60–47	116.42	0.377
47–60–47	115.58	0.384

(*c*) Torsional parameters

Torsional angle	V_1 (kcal/mol)	V_2 (kcal/mol)	V_3 (kcal/mol)
1–1–6–60	38.466	−25.305	10.630
1–6–60–47	−5.900	−1.000	0.000
1–6–60–6	5.900	−2.500	0.250
5–1–6–60	0.000	0.000	−0.500

(*d*) Van der Waals' parameters

Atom type	r(Å)	ε(kcal/mol)
47 (O)	1.68	0.050
60 (P)	2.02	0.168

(*e*) Electrostatic parameters

Bond	Bond dipole moment (Debyes)
6–60	8.91
47–60	9.42

is, the selection of atoms which are sufficiently alike in a chemical and physical sense to be treated identically in the molecular mechanical refinement. The Born–Oppenheimer approximation states that the Schrödinger equation can be separated into a part that describes the motion of electrons and a part that describes the motion of nuclei, and that these can be treated independently. In molecular mechanics, which treats electrons in a classical electrostatic manner, nuclear positioning is dominant and a wide range of atom types per element is necessary. MM2(Lipid) employs eleven atom types for its description of neuronal lipids. Although the treatment of sp^3 atom types is straightforward, a variety of sp^2 atom types are necessary to ensure geometrical precision. The number of atom types employed in MM2(Lipid) represents the minimum number required for an accurate representation, while endeavouring to avoid the problems associated with excessive (and thus cumbersome) parameterization.

The MM2 atom types that were employed are shown in the lipids illustrated in Fig. 1.

2.2 Bond length and bond angle parameters

During the solvation of peptides and drugs by membrane lipids, lipid molecules may undergo significant geometrical alteration; accordingly, bond length and bond angle parameters must be carefully selected.

For the lipid tail, the C—C and C—H bond lengths were taken from the MM2(91) parameter set. The k_s stretching force constants were taken from the molecular mechanics literature. For example, the C—C (type 1–1) stretching constant is given as 4.40, 4.40, 4.40 and 4.48 mdyn/Å by Allinger (12), Schleyer and co-workers (13), Ermer and Lifson (14), and Boyd and co-workers (15), respectively; the C—H (type 1–5) stretching constant is given as 4.60, 3.85, 4.60, 4.54 and 4.70 mdyn/Å by Allinger (12), Fitzwater and Bartell (16), Schleyer and co-workers (13), Ermer and Lifson (14), and Boyd and co-workers (15), respectively. In view of this, MM2(Lipid) uses values of 4.40 and 4.60 mdyn/Å for 1–1 and 1–5 bond types.

Vibrational spectroscopy studies demonstrate that bond angles exhibit greater variability than bond lengths and thus are of greater import for precise geometrical and conformational analysis. For the lipid tail, the C—C—C, C—C—H, and H—C—H equilibrium values were obtained from the MM2(91) parameter set. The k_θ angle bending parameters were adapted from the molecular mechanics literature. For example, the C—C—C (type 1–1–1) bending constant is given as 0.450, 0.629, 0.570, 0.647, and 0.800 mdyn/deg by Allinger (12), Fitz-

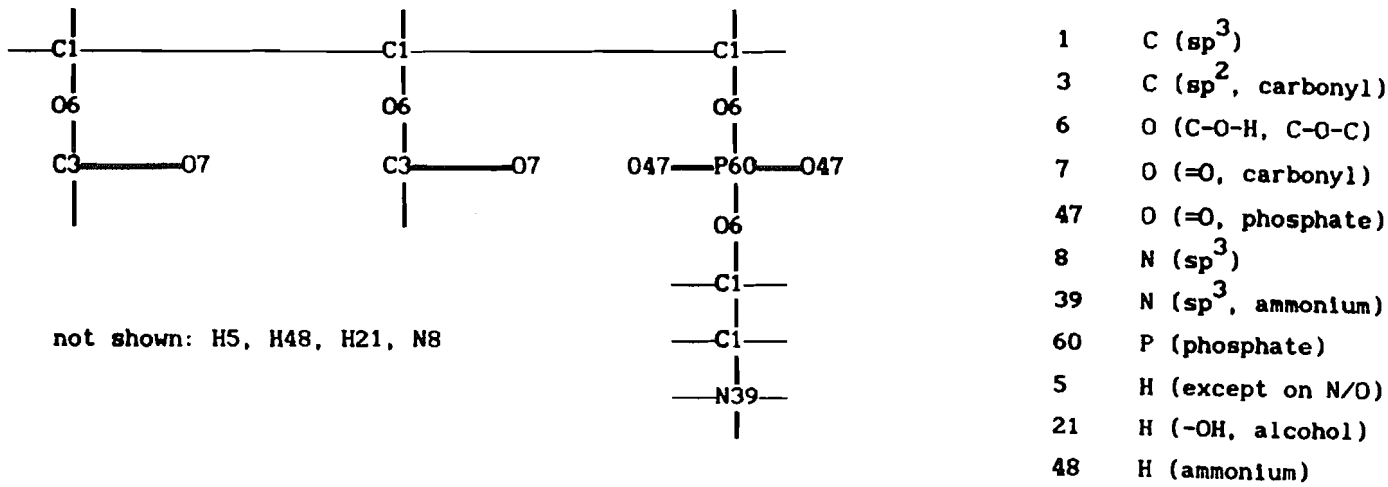

FIG. 1. MM2 (Lipid) atom types.

water and Bartell (16), Schleyer and co-workers (13), Ermer and Lifson (14), and Boyd and co-workers (15), respectively; the C—C—H (type 1–1–5) bending constant is given as 0.360, 0.322, 0.400, 0.521, and 0.608 mdyn/deg by Allinger (12), Fitzwater and Bartell (16), Schleyer and co-workers (13), Ermer and Lifson (14), and Boyd and co-workers (15), respectively; the H—C—H (type 5–1–5) bending constant is given as 0.320, 0.350, 0.330, 0.549, and 0.508 mdyn/deg by Allinger (12), Fitzwater and Bartell (16), Schleyer and co-workers (13), Ermer and Lifson (14), and Boyd and co-workers (15), respectively. Accordingly, the MM2(Lipid) parameterization uses values of 0.450, 0.360, and 0.320 mdyn/deg for the 1–1–1, 1–1–5, and 5–1–5 bond angle types.

For the phosphate head group, equilibrium values for bond lengths and bond angles were taken from *ab initio* molecular orbital calculations on dimethyl phosphonate and phosphoric acid, as reported by Van Wazer and Ewig (17, 18). In accord with Hopfinger and Pearlstein (11), the k_s and k_θ force constants were determined by calculating the energy of the model compound dimethyl phosphate at various values of a given bond length or bond angle; energies were calculated using AM1 semi-empirical molecular orbital calculations. These energies were then plotted as a function of the given structural parameter and the data was fit, using a least-squares fitting routine, to the truncated Taylor series expansion used in the MM2 force field. Taking into account the difference in force constants used in the MM2 force field and those determined through quantum chemical techniques, scaling factors, as determined by Leonard and Ashman (19), were then applied to the calculated force constants.

2.3 Torsional angle parameters

The explicit incorporation of torsional terms is necessary for the consideration of atom pairs which are separated by a chain of three bonds.

Parameters for the lipid tail (C—C—C—C, C—C—C—H, and H—C—C—H) were taken from MM2(91). Thus, for the group C—CH_2—CH_2—C, the barrier to rotation is determined by the sum of the V_1, V_2, and V_3 terms for one C—C—C—C angle, four C—C—C—H angles, and four H—C—C—H angles. For the phosphate head group, rotational barriers were determined by plotting the conformational energy (calculated using the AM1 Hamiltonian (20)) of either dimethyl phosphate or diethyl phosphate as a function of a given torsional angle. Although the positions of the maxima and minima were well-determined by AM1 (in comparison to *ab initio* values), the barrier heights were excessively large and were set to reflect values from *ab initio* molecular orbital calculations reported in the literature (17, 21, 22). For example, for the torsional angle P—O—C—H, the AM1 result indicates maxima at 60°, 180°, and 300°, with an average barrier height of 1.1 kcal/mol. The 4-31G* basis set *ab initio* molecular orbital result predicts maxima at the same locations but rotational barriers of only 0.5 kcal/mol (17). Therefore, the V_1, V_2, and V_3 terms for P—O—C—H were set to yield a rotational barrier of 0.5 kcal/mol at 60°, 180°, and 300°.

2.4 Van der Waals' parameters

The sum of the attractive and repulsive energies constitutes the van der Waals' interaction potential between a pair of non-bonded atoms. For neutral, non-polar molecules, the general forms of this interaction are the Lennard–Jones and Buckingham potentials; the Hill potential employed in MM2(Lipid) is a specific example of the Buckingham potential. Hill demonstrated that this potential energy function provides a good description for simple molecules (23). Using the Hill potential, atoms are regarded as distensible spheres of radius r_0 and "hardness" ϵ.

The van der Waals' radii for P and O (sp^2, phosphate) were initially taken from experimental values (24). However, there is a consistent difference between established molecular mechanics values and experimental values; accordingly, an empirically derived scaling factor of 1.12 was applied. Thus, the van der Waals' radius for P was 1.12×1.800 Å = 2.02 Å. Similarly, the van der Waals' radius for O (sp^2, phosphate) was 1.68 Å.

The van der Waals' parameters for the remaining atom types were adopted from the MM2(91) parameter set.

2.5 Electrostatic parameters

Since the accurate conformational analysis of large biomolecules, like lipids, requires the inclusion of non-bonded interactions, the evaluation of electrostatic interactions are of utmost importance. In classical electrostatic theory, the interaction energy between diffuse charge clouds is calculated by a series expansion. For interactions between point charges, the dipole–dipole interaction energy is the leading term and can be calcu-

lated by the Jeans' function (25). Thus there are two possible approaches for the treatment of electrostatic interactions: the point charge model, in which the charges are treated as geometric points placed at the atomic nuclei; and, the dipole model, in which bond moments are assigned to every bond in the molecule. Allinger has concluded that the two treatments are essentially equivalent (26). Since MM2(Lipid) employs the dipole model, it was necessary to assign bond moments to all possible bonds in each lipid.

For the bond types 47–60 and 6–60, bond moments, BM, were calculated from the equation:

$$BM = (2.385)l_0(Q_1 - Q_2); (Q_1 \geq Q_2)$$

where, for atoms 1 and 2, Q_1 and Q_2 are the charge densities, l_0 is the bond length, and the factor 2.385 converts BM to Debye units (when l_0 is in Å and the charge densities are in electron units) (11). The charge densities of P, O(sp^3), and O(sp^2, phosphate) were obtained from an electrostatic potential method (CHELP) (27). The bond moments for 47–60 and 6–60 are (in Debyes), 9.42 and 8.91, respectively.

2.6 Computational methods

All computational tasks were accomplished on an IBM RS/6000 550 RISC computer operating under AIX. MM2 force field calculations were performed using the MM2(91) program (5). Parameterization of the MM2(Lipid) force field was effected using both semi-empirical and *ab initio* molecular orbital calculations. Semi-empirical molecular orbital calculations were executed using the AM1 Hamiltonian (20) as implemented in the MOPAC 5.1 program. The PRECISE option was used as SCF convergence criteria. Geometry optimization was performed using the PULAY optimization procedure within MOPAC. Root-mean-square fitting to crystal structures was performed using the COMP function of the KGNGRAF graphics program distributed with the MOTECC-90 family of programs (28). DREIDING force field calculations were performed using the program BIOGRAF (version 3.0), from Biodesign, Inc. (29).

3. Results

Four lipids with known crystal structures were chosen to evaluate the MM2(Lipid) parameters: dimyristoylphosphatidylglycerol (lipid1) (30), dilauroylphosphatidyl-*N*,*N*-dimethylethanolamine (lipid2) (31), 1,2-dilauroyl-*dl*-phosphatidylethanolamine (lipid3) (32), and deoxylysophosphatidylcholine (lipid4) (33). For each lipid, the energy-minimized structure was determined using the crystal structure as the starting conformation. The conformational energy of both the crystal structures and the energy-minimized structures, as well as the root-mean-square fit, is shown in Table 2. Figure 2 shows the energy-minimized structure of lipid1. Initial and final values for the bond lengths, bond angles, and torsional angles of lipid1 are shown in Tables 3, 4, and 5. (Lipid1 atom numbering is shown in Fig. 3).

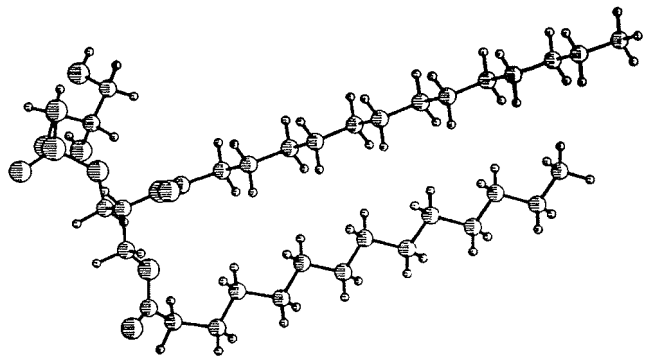

FIG. 2. Energy-minimized structure of lipid1.

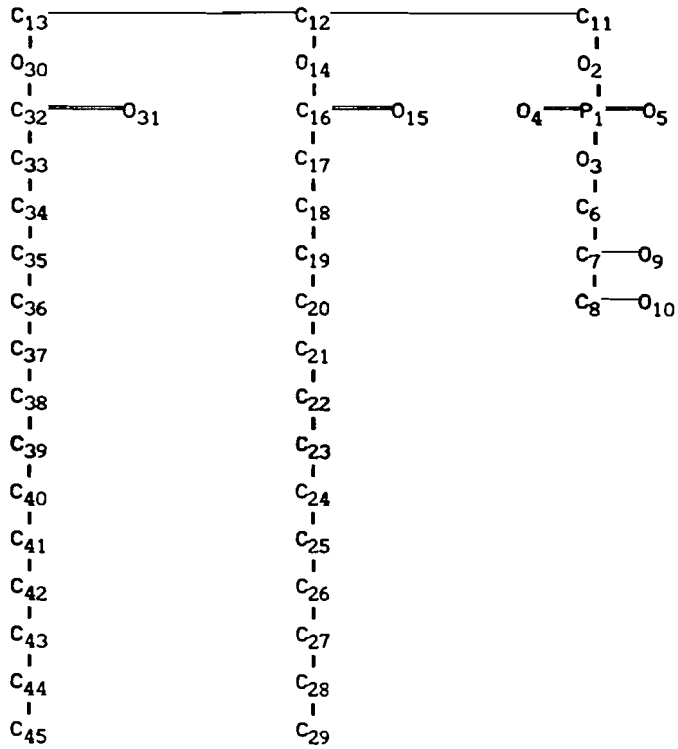

FIG. 3. Atom numbering for lipid1.

3.1 Head group conformation

After the energy minimization of each lipid, the most significant conformational changes occurred at the head group. These changes are due to the removal of hydrogen-bonding and ionic interactions that are present in the crystal lattice. For example,

the 60–47 (P—O) and the 60–6 (P—O) bond lengths changed by approximately 0.092 Å and 0.128 Å, respectively. Overall, changes in bond length, bond angle, and torsional angle at the phosphate head group did not result in conformations that were significantly different from the known crystal structure.

3.2 Diacylglycerol backbone conformation

The conformations of the glycerol backbone of lipid1, lipid2, and lipid3 were in agreement with two experimentally observed conformations shown in Figs. 4*a* and 4*b* (34). Both lipid1 and lipid2 achieved the conformation shown in Fig. 4*a* while lipid3 attained the conformation shown in Fig. 4*b*. It has been postulated by Hauser et al. that these conformations allow optimal van der Waals' and hydrophobic interactions between the fatty acyl chains (34).

3.3 Hydrocarbon chain conformation

For lipid1, lipid2, and lipid3 the conformation of the hydro-

carbon chains remained essentially unaltered after energy minimization. The larger RMS fit for lipid4, however, can be attributed to a distortion of the hydrocarbon chain at the acyl ester group in the crystal structure (33). As noted by Hauser et al., "it cannot be definitely concluded whether this irregularity reflects a statistical disorder of the chains only or is also due to some accommodation problems of the carboxyl ester group and of the methyl chain end" (33). In the energy-minimized structure, this irregularity was significantly alleviated.

3.4 Energy minimization of an unfavourable conformation

Commencing a minimization using the X-ray structure as a starting conformation does not adequately challenge the utility of a force field energy refinement process. To further evaluate the MM2(Lipid) parameters, the crystal structure geometry of lipid3 was randomly and significantly altered to yield an unfavourable conformation and then minimized. In the resulting energy minimized structure, shown in Fig. 5, the polar head group has undergone a conformational change due to an apparent interaction between the ammonium and the phosphate moieties. This interaction is similar to that observed in *ab initio* molecular orbital calculations performed on the phosphorylethanolamine group (35). The initial steric energy of the altered lipid3 geometry was 5831.2 kcal/mol and the final steric energy of the minimized structure was 26.6 kcal/mol. The root-mean-square fit between the crystal structure and the minimized structure was 0.877 Å.

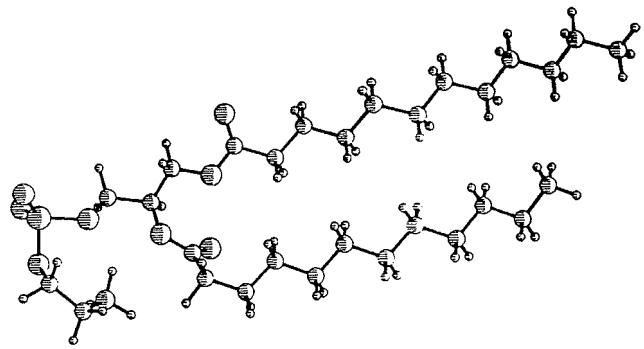

FIG. 5. Energy-minimized structure of lipid3 (from an unfavourable initial conformation).

4. Discussion

4.1 Force field parameterization

The strength of the molecular mechanics method lies in its ability to predict reasonably accurate structures and energies of a diverse range of large molecules. However, this can be realized only upon validation of both the potential energy functions and the parameters that are incorporated into these functions. Unfortunately, it is unreasonable to expect that every required parameter will be included in any given molecular mechanics program. Therefore, the user is often obliged to supply missing parameters. Regrettably, most reports of molecular mechanics parameterization are vague.

4.1.1 General approach to the parameterization process

Force field parameterization can be approached in a number of ways. Very often, the techniques that are employed will involve both logical and intuitive processes; as Allinger has described, "there is an art and a science to molecular mechanics parameterization" (26). In some cases, parameters can be obtained through the application of least-squares methods to an appropriate data set. On the other hand, it is also not uncommon to obtain parameters through what is euphemistically referred to as "judicious selection". In the final analysis, the vindication of any parameterization method lies in the validity of the subsequent calculations.

Although the current trend in force field parameterization is to employ more rigorous *ab initio* molecular orbital calculations, there is some question concerning the applicability of parameters derived by these methods. As Alemán and Orozco have observed (36), even when the *ab initio* wavefunction is evaluated at the restricted Hartree–Fock level and less rigorous low level basis sets are used, the size of the model compound

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

must still be quite small. Therefore, there is the possibility that parameters derived from such a specific molecular environment may not necessarily be applicable to large molecule problems. However, it is well within the ability of current semi-empirical molecular orbital methods to obtain force field parameters from calculations based on more reasonably sized model compounds. Hopfinger has suggested the utility of MNDO calculations during molecular mechanics parameterization (11). More recently, Alemán and Orozco have suggested that the AM1 Hamiltonian is remarkably capable of reproducing parameters that are used by a variety of force fields, particularly MM2 (36). In studies on dihydropyridines, Bikker and Weaver have also found that because of the parameterization of AM1 and the employment of up to four Gaussian functions to correct the nuclear core repulsion term, the behaviour of the atom pairs N—O, C—O, C—N, C—H, and N—H are better evaluated by AM1 than by either MNDO or PM3 (37). For the parameterization of MM2(Lipid), the AM1 Hamiltonian was well-suited to the task of generating data sets from which bond length and bond angle parameters could be determined. Also, the use of AM1 was of great value in the evaluation of the torsional angle parameters.

4.1.2 Bond length and bond angle parameters

Generally, the preferred route by which these parameters are evaluated employ *ab initio* molecular orbital methods. However, it was found that for the model compounds dimethyl phosphate and diethyl phosphate, AM1 calculations yielded bond lengths and bond angles that were similar to both experimental values and *ab initio* theoretical results reported in the literature. For example, in diethyl phosphate, the average C—O bond length obtained through AM1 was 1.42 Å. This is quite similar to the experimental C—O bond length of 1.43 ± 0.01 Å (38). Van Wazer and Ewig have also reported similar values based on calculations of methyl phosphinate, dimethyl phosphonate, and trimethyl phosphate at the STO-3G*, 3-21G*, and 4-31G* *ab initio* level (18). Bond angles from AM1 also agreed well with *ab initio* results. For example, the average H—C—O bond angle calculated by AM1 for dimethyl phosphate was 109.433°. This is similar to the average H—C—O angle calculated for dimethyl phosphonate at the STO-3G* level (110.208°) (18). Hence, it was clear that there was no compromise in accuracy in choosing the faster semi-empirical route over a more computationally intensive *ab initio* approach.

4.1.3 Torsional parameters

The development of torsional parameters is generally one of the more difficult tasks that is encountered in parameterization. Often, there is little or no experimental data available and it is not always possible to devise and execute experiments aimed at determining the full potential function. In the approach taken in the parameterization of MM2(Lipid), semi-empirical calculations were used in conjunction with *ab initio* results to determine rotational barriers. The performance of AM1 was found to be quite acceptable in this respect. As mentioned above, the locations of maxima and minima for torsional rotational barriers involving phosphorus atoms were well-determined by AM1. However, the barrier heights were significantly exaggerated using the AM1 method. Accordingly, the barrier heights in MM2(Lipid) were adjusted to agree with *ab initio* values (17, 21, 22). (Alternatively, rotational barrier heights could have been evaluated by performing *ab initio* point calculations at the extrema determined by AM1.) This approach, while retaining a high degree of accuracy, has the added benefit of being much faster than an *ab initio* calculation of the full torsional potential function. It should be noted that the indiscriminate use of other semi-empirical methods could be problematic since various Hamiltonians treat different dihedral angles with varying success. For example, both PM3 and MNDO may yield misleading representations of some torsional angles, such as those of conjugate bonds or ester functionalities (36, 37).

4.1.4 Van der Waals' parameters

In developing MM2(Lipid), the determination of accurate van der Waals' radii was to a great extent confounded by the lack of a standard definition. For example, from the crystallographic point of view, the sum of the van der Waals' radii can be considered to be the distance of closest approach between two non-bonded atoms in a solid (24). However, Allinger has pointed out that this differs substantially from the molecular mechanics definition (26), in which the sum of the van der Waals' radii is the distance at which the van der Waals' potential for two non-bonded atoms is at a minimum. The actual measurement of van der Waals' radii has also been subjected to a variety of treatments. Francl et al. have obtained atomic radii for a series of molecules by fitting calculated total electron densities using spheres of adjustable radii centered on the nuclei (39). Alternatively, Bader has proposed a method of partitioning the total molecular charge distribution between the nuclei in a molecule by using bond critical points (40). In Bader's theory of molecular structure, a reasonable approximation of a van der Waals' radius could be obtained by taking the distance from the nucleus to the 0.002-au contour (1.000 au = 6.748 e/Å^3); this distance is termed the non-bonded radius (41). A brief comparison of the different methods revealed significant differences. For example, the non-bonded radius for carbon determined via Bader's methodology was 1.65 Å (40), whereas that determined by Francl was 1.893 ± 0.050 Å (39). The experimental carbon van der Waals' radius as determined crystallographically by Bondi was 1.70 Å (24). In molecular mechanics force fields, the typical carbon van der Waals' radius is 1.90–1.94 Å; this empirically derived and significantly larger radius is necessary to ensure the adequacy of molecular mechanics in reproducing experimental conformations.

By convention, in the parameterization of molecular mechanics force fields, it is customary to use experimental van der Waals' radii with an appropriate empirical scaling factor. Accordingly, in parameterizing MM2(Lipid) for phosphorus and oxygen, the experimental radii reported by Bondi were used. Because the van der Waals' radii elucidated through crystallographic means are generally smaller than the radii used in molecular mechanics, a scaling factor of 1.12 was applied to these experimental values to obtain van der Waals' radii appropriate for the MM2 force field.

4.1.5 Electrostatic parameters

For MM2(Lipid), it was necessary to develop electrostatic parameters for non-bonded interactions. Schaumberger and Kohler have used a number of approaches to calculate charge densities for phosphorylcholine and its derivatives (27). For example, in Mulliken population analysis, charges can be derived by summing the Mulliken populations of all orbitals on each atom (42). However, because the overlap populations are distributed evenly among the overlapping orbitals in this approach, unrealistic charge distributions may result. To a cer-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

tain extent, this problem may be overcome through natural population analysis (43, 44). Through this method, transformations are used to redistribute overlap populations into orthonormal atomic orbitals with a maximal occupation number. Alternatively, the "CHELP" (charges from electrostatic potentials) procedure, developed by Chirlian and Francl (45), offers a completely different approach. In this method, charge is distributed between the atoms in a molecule such that at several thousand points, the resulting potential is fitted to the electrostatic potential arising from the wavefunction of the molecule. For phosphorylcholine and its derivatives, the dipole moments calculated from the CHELP charges correspond closely with the dipole moments calculated from the wavefunction directly. Thus, in the parameterization of MM2(Lipid), CHELP charges were used to calculate the bond dipole moments for bond types 6–60 and 47–60.

4.2 Comparison to the DREIDING force field

The MM2(Lipid) force field parameterization represents a significant advance over current force fields in its ability to deal with phospholipids. For example, the AMBER force field in molecular modelling packages such as BIOGRAF has been parameterized for phosphorus in nucleotides but not lipids (7). In contrast, the DREIDING force field has been parameterized for a wide variety of molecules (29). However, these parameters are often too generic. For example, the harmonic bond stretching constants for the P(sp^3)—O(sp^3), P(sp^3)—O(sp^2) and P(sp^3)—OH bonds are each 700 kcal/mol. Consequently, in special situations, there may be some compromise in the validity of conformational calculations. For comparison purposes, the structure of lipid3 was energy-minimized starting from its crystal structure using the DREIDING force field. The final structure was accompanied by a decrease in steric energy from 589.2 to 81.4 kcal/mol and the root-mean-square fit to the crystal structure was 0.98 Å. Energy minimization of a distorted lipid3 geometry resulted in a structure with a steric energy of 87.0 kcal/mol and a root-mean-square fit of 1.82 Å to the crystal structure. In this conformation, the headgroup was oriented almost perpendicular to the plane of the two fatty acyl chains and consequently, a lipid bilayer would be difficult to achieve. However, the DREIDING force field predicts that this conformation is accessible as it is only slightly higher in energy than that minimized from the crystal structure. In contrast, using the MM2(Lipid) force field, this conformation had a steric energy of 49.3 kcal/mol, which is almost 30 kcal/mol higher in energy than the conformation obtained from minimization of the crystal structure using the MM2(Lipid) force field. Thus, in this case, the MM2(Lipid) force field accurately predicts that this conformation is unfavourable.

4.3 The need for molecular mechanics parameters for lipids

The biological activity of many compounds is significantly dependent upon their *in vivo* conformation. Since the biological activity of many drugs is a manifestation of an interaction with a membrane-bound receptor protein, both drug and receptor conformation are dependent on not only an aqueous environment, but also a lipid environment. For example, both lipid–peptide and lipid–protein interactions can be profoundly responsible for the efficacy of peptide antibiotics and membrane protein function. The ability of both gramicidin A and valinomycin to alter specific ion fluxes is dependent on hydrophobic interactions with lipid membranes (46). Intrinsic membrane proteins, such as rhodopsin, also rely on the presence of lipid. Dissociation of such proteins from a membrane environment inevitably results in a loss of function, as well as a loss of both secondary and tertiary structure (47). Currently, many experimental methods are available to investigate interactions with lipids: fluorescence spectroscopy, differential scanning calorimetry, electron spin resonance and nuclear magnetic resonance. The particular utility of a molecular mechanics approach lies in its ability to provide a detailed conformational and thermodynamic description of both the molecule of interest and its environment. The failure of current molecular mechanics programs to accurately model lipid molecules detracts from the significance of conformational investigations on compounds of pharmaceutical interest. The MM2(Lipid) parameters have been successfully applied in the geometry optimization of four lipids, indicating that their usage will both greatly assist in conformational investigations and enhance the validity of a simulated membrane environment.

5. Conclusions

The results of the energy minimization calculations show that the MM2(Lipid) force field accurately predicts the conformation of phospholipids. When crystal structures were used as starting points for energy minimization, only small conformational changes were observed in the hydrocarbon chains and in the phosphate head group. After minimization, the diacylglycerol backbone achieved one of two stable conformations that have been observed experimentally (34).

AM1 was well-suited to the parameterization of MM2(Lipid). As a molecular mechanics parameterization tool, AM1 is particularly useful for three reasons: it is capable of performing calculations on reasonably sized compounds; it is computationally less demanding than *ab initio* molecular orbital methods; and, most importantly, it is capable of determining molecular mechanics parameters with a high degree of precision. However, in determining torsional angle parameters, AM1 values provide excessively high barriers to rotation.

A binuclear bis{bis(dimethylphosphino)methane}disilver(I) complex with weakly bonded hexafluoroacetylacetonato ligands

ZHENG YUAN, NEIL H. DRYDEN, JAGADESE J. VITTAL, AND RICHARD J. PUDDEPHATT[1]

Department of Chemistry, University of Western Ontario, London, ON N6A 5B7 Canada

Received December 9, 1993

ZHENG YUAN, NEIL H. DRYDEN, JAGADESE J. VITTAL, and RICHARD J. PUDDEPHATT. Can. J. Chem. **72**, 1605 (1994).

The new complex $[Ag_2(hfac)_2(\mu\text{-dmpm})_2]$ (hfac = hexafluoroacetylacetonato, dmpm = $Me_2PCH_2PMe_2$) has been prepared and characterized both spectroscopically and by an X-ray structure determination (orthorhombic, *Pbca* (No. 61), $a = 9.960(2)$, $b = 14.694(3)$, $c = 22.548(3)$ Å, $Z = 4$, $R = 0.0495$, $R_w = 0.0532$). The data indicate that the $hfac^-$ ligands have mostly ionic character and it is suggested that this may be responsible for the low volatility of complexes $[Ag(hfac)L_n]$ compared to $[Cu(hfac)L_n]$; these complexes are of interest as precursors for chemical vapour deposition of silver.

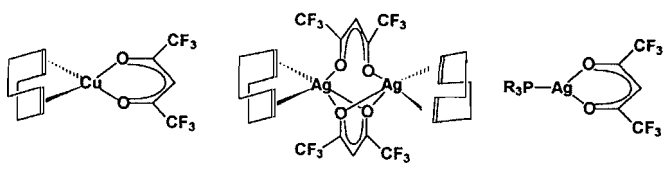
ZHENG YUAN, NEIL H. DRYDEN, JAGADESE J. VITTAL et RICHARD J. PUDDEPHATT. Can. J. Chem. **72**, 1605 (1994).

On a préparé le nouveau complexe $[Ag_2(hfac)_2(\mu\text{-dmpm})_2]$ (hfac = hexafluoroacétylacétonato, dmpm = $Me_2PCH_2PMe_2$) et on l'a caractérisé tant par spectroscopie que par diffraction des rayons x (cristaux orthorhombiques, *Pbca* (No. 61), $a = 9{,}960(2)$, $b = 14{,}694(3)$ et $c = 22{,}548(3)$ Å, $Z = 4$, $R = 0{,}0495$, $R_w = 0{,}0532$). Les données indiquent que les coordinats $hfac^-$ possèdent principalement un caractère ionique et ils suggèrent que cette propriété peut être responsable pour la faible volatilité des complexes $[Ag(hfac)_n]$ par comparaison avec les complexes $[Cu(hfac)_n]$; ces complexes présentent de l'intérêt comme précurseurs pour le dépôt de la vapeur chimique de l'argent.

[Traduit par la rédaction]

Introduction

There has been recent interest in new methods of formation of silver films, which have potential applications as components of high-temperature superconducting materials (1), as contacts in microelectronic devices if problems of diffusion can be overcome (2), and as biocides in biomaterials used in appliances such as catheters (3). However, the formation of silver films by chemical vapour deposition (CVD) has proved to be difficult and the best precursors still have only borderline suitability for an effective CVD process (4, 5). There are excellent precursors for CVD of copper having the formula [Cu(hfac)L] or $[Cu(hfac)L_2]$ (6), hfac = 1,1,1,5,5,5-hexafluoropentanedionato, but the corresponding silver complexes are considerably less volatile and many decompose before volatilization under vacuum. For example, $[Cu(hfac)(CH_2{=}CHSiMe_3)]$ is a liquid with high volatility but the corresponding silver complex is a solid which cannot be sublimed (4, 6). It has recently been shown that [Cu(hfac)(cod)], cod = 1,5-cyclooctadiene, is a monomer **A** but that the corresponding silver complex exists as a dimer $[Ag_2(\mu\text{-hfac})_2(cod)_2]$, with the unusual structure **B** (7). Of



A B C

course, the lower volatility of **B** can then be rationalized. One possible reason for the different structures is that silver(I) is larger than copper(I) and so can accommodate a higher coordination number (7). Of the known complexes of empirical formula [Ag(hfac)L], the best CVD precursors so far reported are $[Ag(hfac)(PR_3)]$, **C**, where R = Me or Et (4). They are monomeric and reliably volatile and they give silver films by CVD at temperatures of 250–350°C depending on the conditions used (4). However, they are still markedly less volatile than the copper analogues (6). Since both $[Cu(hfac)(PR_3)]$ and $[Cu(hfac)(PR_3)_2]$ are good precursors for CVD of Cu (6), it appeared useful to test the four-coordinate complexes $[Ag(hfac)(PR_3)_2]$ as CVD precursors. As part of this work, a new complex of empirical formula [Ag(hfac)(dmpm)], dmpm = $Me_2PCH_2PMe_2$, was prepared and characterized. It is not a useful precursor for CVD but its structure, which is reported below, provides another clue to explain the low volatility of β-diketonatosilver(I) complexes.

Experimental

All experiments were carried out under a nitrogen atmosphere by using standard Schlenk techniques. Infrared spectra were recorded by using a Perkin-Elmer System 2000 FT-IR spectrometer using KBr plates. A Perkin-Elmer DSC-7 Differential Scanning Calorimeter was used to obtain the decomposition temperature and melting point of the compound. The ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra were measured by using a Varian 300 Spectrometer. References used were internal TMS for ^1H and ^{13}C NMR spectra and 85% H_3PO_4 for ^{31}P NMR spectra.

Preparation of $[Ag_2(hfac)_2(\mu\text{-dmpm})_2]$

Silver(I) oxide (0.992 g, 4.28 mmol) was suspended in THF (30 mL). To this was added 1,1,1,5,5,5-hexafluoropentanedione (1.25 mL, 8.85 mmol). Most of the suspended material dissolved immediately. The reaction mixture was stirred for 30 min, then filtered through a pad of Celite. The volume of the clear yellow filtrate was reduced *in vacuo* to a yield 1,1,1,5,5,5-hexafluoropentanedionatosilver(I) (2.48 g) as a pale yellow solid. This solid decomposes slowly at room temperature was not fully characterized. To a solution of the above product (0.416 g) in CH_2Cl_2 (30 mL) was added slowly bis(dimethylphosphino)methane (1.32 g). The reaction mixture was stirred for 30 min at room temperature and the solvent was then evaporated under vacuum to yield a brownish solid. This was dissolved in acetone and decolorised with charcoal. The solution was centrifuged to yield a clear yellow solution from which the product was obtained in >90% yield. The single crystals for X-ray structural studies were grown from acetone/hexane solution by slow diffusion. Mp 189°C (by DSC). Anal. calcd. for $C_{10}H_{15}AgF_6O_2P_2$: C 26.63, H 3.35; found: C 26.61, H 3.19. NMR (CD_2Cl_2): $\delta(^1H) = 5.61$ (s, 1H, hfac), 1.98 (broad s, 2H, CH_2P_2), 1.42 (s, 18H, PMe_3); $\delta(^{13}C) = 175.7$ (q, $^2J(CF) = 30.6$ Hz, $C\text{-}CF_3$), 132.3 (q, $^1J(CF) = 291.4$ Hz, CF_3), 86.0 (s, CH), 31.4 (d, $^1J(PC) = 3.5$

Hz, CH_2P), 15.5 (d, ^1J(PC) = 4.5 Hz, PMe_3); $\delta(^{31}P) = -20.0$ (broad d, J(AgP) = ca. 500 Hz, dmpm). The coupling constants calculated from the low temperature ^{31}P NMR spectrum are $^1J(^{107}AgP)$ = 500 Hz, $^2J(PP)$ = 149 Hz, $^3J(^{107}AgP)$ = 1 Hz. Molar conductivity for a 10^{-3} M solution in CH_2Cl_2 at 25°C: $\Lambda_M = 2.0\ \Omega^{-1}\ cm^2\ mol^{-1}$.

X-ray structure determination of $[Ag_2(hfac)_2(\mu\text{-dmpm})_2]$, 2

A colourless crystal of dimensions 0.41 × 0.40 × 0.28 mm was wedged inside a Lindemann capillary tube, which was then flame sealed on both ends. The diffraction experiments were carried out by using an Enraf-Nonius CAD4F diffractometer at 295 K. Photo and automatic indexing routines, followed by least squares fits of 22 reflections ($23.9° \leq 2\theta \leq 29.7°$) gave cell constants (8) indicating an orthorhombic system. The Laue symmetry *mmm* was confirmed from an inspection of symmetry equivalent reflections. In total 4971 intensity data were collected in the 2θ range 0–55° ($-1 \leq h \leq 12$, $-1 \leq k \leq 19$, $-1 \leq l \leq 29$) in ω–2θ scan mode at variable scan speeds (1.18 to 4.12), so chosen as to optimize counting statistics within a maximum time per datum of 60 s. Background measurements were made by extending the scan by 25% on each side. Three standard reflections were monitored every 120 min of X-ray exposure time and crystal orientation checks were done for every 250 reflections measured. The data were processed using NRCVAX crystal structure programs (9) running on a SUN 3/80 workstation. An empirical absorption correction was applied to the data based upon the ψ scans of eleven reflections with θ ranging from 6.9 to 17.5 ($\mu = 13.36\ cm^{-1}$). The maximum and minimum correction factors were 0.999 and 0.911, respectively. The space group *Pbca* (No. 61) was uniquely determined from the systematic absences (10*a*). The equivalent reflections were averaged (R_{int} = 0.012) leaving 3769 ($I \geq 0\sigma(I)$) unique reflections. The structure was solved using the SHELXS-86 program (11) and subsequent difference Fourier techniques. The final full-matrix least-squares refinements on F were done using the SHELX-76 software (12). Scattering factors for neutral non-hydrogen atoms were taken from the International tables (10*b*). The hydrogen atoms were placed in the calculated positions (C—H = 0.95 Å) and they were included for the purpose of structure factor calculations only. A common thermal parameter was assigned and refined in the least-squares cycles. Anisotropic thermal parameters were assigned and refined for all the non-hydrogen atoms. In the final least-squares refinement cycles, the data converged at $R = 0.0495$ and $R_w = 0.0532$ for 2269 observations with $I \geq 2\sigma(I)$ and 192 variables using the weighting scheme $w = k/\sigma^2F + gF^2$, where $g = 0.000273$ and $w = 3.4623$. In the final difference Fourier synthesis the electron density fluctuated in the range from 0.84 to −1.13 e Å^{-3}; of these, the top five peaks were associated with F atoms. The maximum shift/esd in the final cycle was −0.0012. The secondary extinction coefficient was refined to $7.39(86) \times 10^{-4}$. The experimental details and crystal data are in Table 1, the positional and thermal parameters are in Table 2, anisotropic thermal parameters, calculated hydrogen atom coordinates, selected weighted least-squares planes and selected torsion angles have been included in the supplementary materials.

Results and discussion[2]

The compound $\{Ag(hfac)\}_n$, **1**, of unknown structure, was readily prepared by reaction of silver(I) oxide with 1,1,1,5,5,5-hexafluoropentanedione, hfacH, but, because it appears to have limited thermal stability, it was prepared and then used immediately. The complex $[Ag_2(hfac)_2(\mu\text{-dmpm})_2]$, **2**, which is an air-stable, colourless crystalline material, was synthesized by reaction of $\{Ag(hfac)\}_n$, **1**, with dmpm (reaction [1]). Compound **2** is soluble in chlorinated solvents and in acetone but is sparingly soluble in hexane. Unlike the complexes $[Ag(hfac)(PR_3)]$ (R = Me and Et) (4), compound **2** could not be sublimed under vacuum and so it is not useful as a precursor for CVD of silver. Complex **2** is decomposed thermally at 270°C, as measured by DSC.

The ^1H, ^{13}C, and ^{31}P NMR were used to characterize the solution properties of compound **2**. The ^1H NMR spectrum at room temperature contained a broad singlet resonance due to the CH_2P_2 protons for the dmpm ligands but at 0°C or below the resonance appeared as a quintet with J_{obs}(PH) = 5 Hz. This quintet appearance suggested the structure containing the $Ag_2(\mu\text{-dmpm})_2$ unit since the CH_2P_2 units should then give rise to an $[A_2X_2]_2$ spin system, for which a quintet appearance is possible and in which the observed coupling constant is $(1/2)\{^2J(PH) + {}^4J(PH)\}$. The room temperature ^{31}P NMR spectrum of **2** contained a broad doublet resonance but a much more complex spectrum was readily resolved at lower temperatures from +10°C to −90°C (Fig. 1). This indicates that compound **2** undergoes some form of exchange at room temperature, leading to partial loss of AgP coupling information. The complex ^{31}P NMR spectrum obtained at low temperature is due to overlapping spectra of isotopomers containing $^{107}Ag^{107}Ag$,

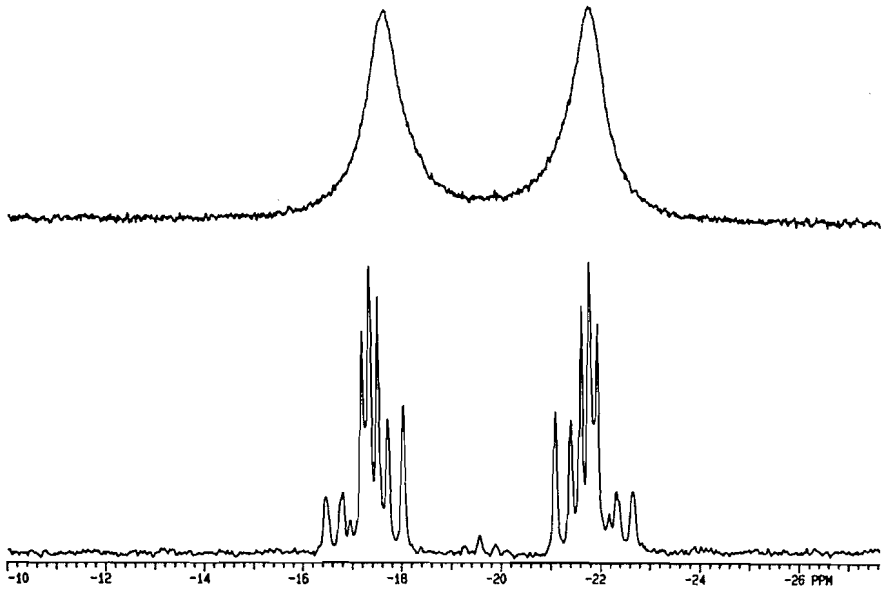

FIG. 1. The $^{31}P\{^1H\}$ NMR spectra of $[Ag_2(hfac)_2(\mu\text{-dmpm})_2]$, (*a*) at room temperature and (*b*) at −60°C.

[1] $\frac{2}{n}\{Ag(hfac)\}_n + 2dmpm \rightarrow$ 
$^{109}Ag^{109}Ag$, and $^{107}Ag^{109}Ag$ pairs in the binuclear $Ag_2(\mu\text{-dmpm})_2$ structure (13). Note that both ^{107}Ag (48%) and ^{109}Ag (52%) each have nuclear spin $I = 1/2$, and the spectral analysis of similar complexes has been reported earlier (13). The calculated coupling constants, $^1J(^{107}AgP)$ and $^1J(^{109}AgP)$ are 500 and 579 Hz, respectively. The ratio of $^1J(^{109}AgP)/^1J(^{107}AgP) = 1.158$, in agreement with the theoretical ratio of $\gamma(^{109}Ag)/\gamma(^{107}Ag) = 1.150$ (14). The $^1J(^{107}AgP)$ value of 500 Hz is only slightly lower than those of the ionic compounds, $[Ag_2\mu\text{-dmpm})_2](BF_4)_2$ (515 Hz, complex prepared by reaction of $AgBF_4$ with dmpm in the required ratio, spectrum recorded at −60°C) and $[Ag_2(\mu\text{-dppm})_2](BF_4)_2$ (505 Hz) (13). In complexes in which silver(I) is bound strongly to three ligands the magnitude of $^1J(^{107}AgP)$ is lower; for example, in $[Ag_2(\mu\text{-dmpm})_3]^{2+}$ it is 317 Hz (13).

The NMR data indicated a binuclear structure for **2** but it was not clear if the $hfac^-$ group was coordinated to silver or not. Hence an X-ray structure determination was carried out. The molecular structure of compound **2** is illustrated in Fig. 2 and selected bond distances are given in Table 3. The proposed binuclear structure is confirmed and each molecule has a crystallographically imposed centre of symmetry. The conformation is shown schematically as **I**. There is an $Ag_2(\mu\text{-dmpm})_2$ core with each silver(I) atom chelated by two oxygen atoms from hfac. The Ag—P bond distances of 2.408(2) and 2.411(2) Å are in the normal range for silver(I)–phosphorus bonds. However, the silver–oxygen bond distances (Ag(1)—O(1), 2.528(5) Å; Ag(1)—O(2), 2.632(5) Å) are significantly different, and both of them are longer than the normal covalent silver(I)–oxygen bond length of ca. 2.3 Å. This indicates that the $hfac^-$ ligand is only weakly bonded to silver and raises the question of whether the complex should be considered covalent or ionic $[Ag_2(\mu\text{-dmpm})_2]^{2+}(hfac^-)_2$. The ideal bond angles for 2- and 4-coordinate silver(I) are 180° (*sp* hybridization) and 109.5° (sp^3 hy-

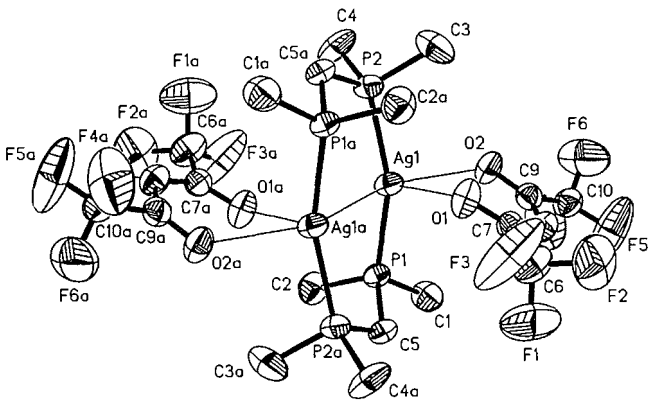

FIG. 2. The ORTEP representation of the molecular structure of $[Ag_2(hfac)_2(\mu\text{-dmpm})_2]$. 50% probability ellipsoids are shown and the hydrogen atoms are omitted for clarity.

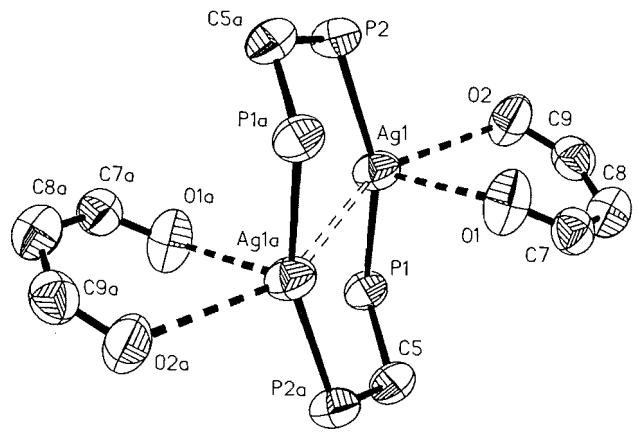

FIG. 3. The inner coordination sphere, emphasizing the distorted tetrahedral stereochemistry at silver(I) and the anti conformation.

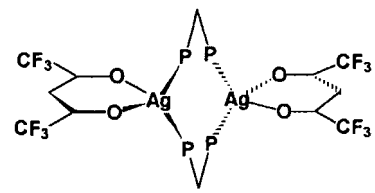
bridization), respectively, and the P(1)—Ag—P(2) angle of 160.02(7)° is best considered as distorted linear. The O(1)—Ag(1)—O(2) angle is only 69.5(2)° as a result of the long AgO distances. In [Ag(hfac)(PMe_3)], the angle O—Ag—O is 80.0–80.7(3)° (there are several independent molecules in the unit cell) due to the much shorter Ag—O distances of 2.268(8)–2.309(8) Å (4). Although structure determinations have been reported for many binuclear complexes containing $M_2(\mu\text{-}R_2PCH_2PR_2)_2$ units, only one has M = Ag. This is for the binuclear $[Ag_2(\mu\text{-}dppm)_2(NO_3)_2]$, **3**, which has the conformation **II** (15). The Ag—P distances of 2.436(2) and 2.417(2) Å are similar to those in **2** but the P—Ag—P angle in **3** is 138.3(1)° and the Ag—O bond distance is 2.416(5) (there is also a longer Ag...O contact at 2.689(6) Å). The smaller angle P—Ag—P and shorter Ag—O distance in **3** indicates that nitrate in **3** is coordinated more strongly than the $hfac^-$ ion in **2**. Since nitrate is usually considered a weakly coordinating anion to silver(I) (16), it seems clear that the $hfac^-$ ligand is very weakly coordinated in **2**. The complex $[Ag_2(cod)_2(\mu\text{-}hfac)_2]$, **4**, also has long Ag—O distances of 2.47(1)–2.56(1) Å, with two Ag...O distances of 2.72 Å assigned as non-bonding (7). The molar conductivity for a 10^{-3} M solution of **2** in CH_2Cl_2 at 25°C was Λ_M = 2.0 Ω^{-1} cm^2 mol^{-1}, under which conditions the 1:1 conductor $[Pr_4N]Cl$ and covalent *t*-Bu_3PAgCl have Λ_M = 19.0 and 0.75 Ω^{-1} cm^2 mol^{-1}, respectively (14). Hence, at least in dichloromethane, the equilibrium appears to favor the non-ionic structure for **2** but some ionization is indicated. The Ag...Ag distances in **2**, **3**, and **4** are similar at 3.153(1), 3.085(1), and 2.955(2) Å (7, 15); all are probably best considered as non-bonding distances, although very weak bonding of the kind very commonly observed in gold(I) complexes cannot be dismissed.

Interestingly, the complexes **2** and **3** adopt different conformations. Complex **2** adopts the anti (staggered) conformation, **I** (Fig. 3), while **3** adopts the *syn* (eclipsed) conformation, **II** (15). There is no obvious reason for the difference and both probably undergo easy, reversible anionic ligand dissociation in solution to give $[Ag_2(\mu\text{-}R_2PCH_2PR_2)_2]^{2+}$, with linear AgP_2 coordination (13). The solid state structure of **2** contains no plane of



I II

symmetry and therefore should give two MeP resonances in the ^1H or ^{13}C NMR spectra and two CF_3 resonances in the ^{13}C or ^{19}F NMR spectra, whereas only one resonance was observed in each case. The most probable mechanism for the apparent equivalence is reversible dissociation of $hfac^-$ in solution, even at low temperature. The loss of fine structure in the ^{31}P NMR spectrum at room temperature, with retention of a broad doublet splitting (Fig. 1), due to *J*(AgP) coupling indicates that the dmpm ligands undergo exchange within the $Ag_2(dmpm)_2$ unit perhaps by undergoing end-over-end exchange (13).

Conclusions

The complexes [Ag(hfac)(PMe_3)] and $[Ag_2(hfac)_2(\mu\text{-}dmpm)_2]$, **2**, have coordination numbers at silver(I) of 3 and 4, respectively. There is a major difference in the strength of binding of the $hfac^-$ ligand in the two cases, this being much weaker for complex **2**. As well as the structural evidence discussed above, the NMR evidence also supports the conclusion of weak $hfac^-$ binding in **2**. Thus, for complexes $[Ag(PR_3)_2X]$ the magnitude of the coupling constant $^1J(^{107}AgP)$ depends markedly on the strength of covalent bonding of the ligand X^- (14). This coupling constant for complex **2** falls in the range usually found for ionic ligands X^-. For example, the magnitude of $^1J(^{107}AgP)$ for **2** (500 Hz) is similar to those for the ionic compounds $[Ag_2(\mu\text{-dmpm}))]_2(BF_4)_2$ (515 Hz) and $[Ag_2(\mu\text{-dppm})]_2(BF_4)_2$ (505 Hz) (13, 14). Covalent bonding of X^- causes a marked decrease in ^1J(AgP) as the hybridization at silver(I) changes from *sp* towards sp^2.

The partial ionic nature of the $hfac^-$ ligands in **2** was unexpected since the effect is not observed in related copper complexes $[Cu(hfac)(PR_3)_2]$ (6). Of course, the apparent greater ionic character in the Ag(hfac) compared to the Cu(hfac) unit in related complexes may account in a simple way for the much lower volatility of silver(I) compared to copper(I) complexes with $hfac^-$ ligands, since the more polar nature will lead to stronger intermolecular forces. It has been noted earlier that [Cu(hfac)(cod)] is a monomer whereas the silver(I) analogue has the binuclear structure $[Ag_2(\mu\text{-hfac})_2(cod)_2]$, **4**, and that the different degrees of aggregation may account for the lower volatility of the silver(I) complex (7). Complex **4** also has long

Ag—O bonds and the binuclear structure may result not only from the larger size of Ag(I) compared to Cu(I) but also from the more ionic nature of the $hfac^-$ ligands in combination with Ag(I). If this interpretation is correct, it suggests that the search for more volatile silver(I) complexes for use as precursors for CVD of silver should focus on ligands which bind in a more covalent fashion to silver(I) than the $hfac^-$ ligand.

HSIEN-JU TIEN, SHAW-TAO LIN, and JINN-TSAIR SHEU. Can. J. Chem. **72**, 1610 (1994).

The 3-(3-nitroaryl)sydnones were prepared in good yields by the nitration of 3-aryl-4-acetylsydnones followed by deacetylation with aqueous barium hydroxide.

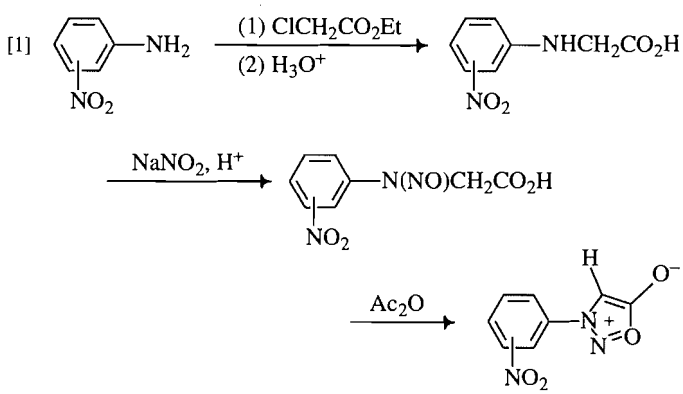
HSIEN-JU TIEN, SHAW-TAO LIN et JINN-TSAIR SHEU. Can. J. Chem. **72**, 1610 (1994).

On a préparé les 3-(3-nitroaryl)sydnones avec de bons rendements en effectuant la nitration des 3-aryl-4-acétylsydnones et en procédant ensuite à une désacétylation à l'aide d'hydroxyde de baryum aqueux.

[Traduit par la rédaction]

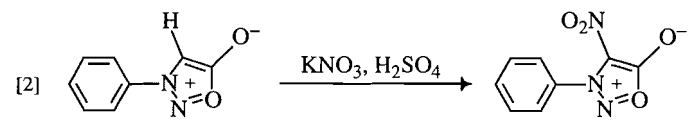
Introduction

Much attention has been given to the preparation of sydnones because of their mesoionic character and biological activities (1). Ordinarily, 3-(nitrophenyl)sydnones are prepared from corresponding anilines via a series of reactions as in eq. [1] (2).



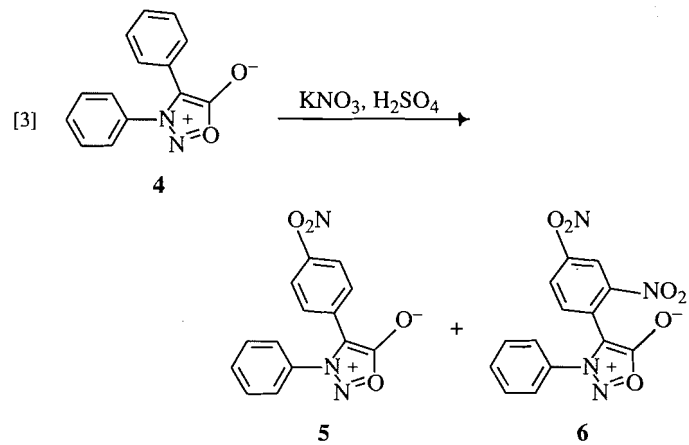
1

Some of the substituted anilines, unlike aniline, are not often commercially available. The mesoionic character exhibits an electron-withdrawing tendency at the N3 position and an electron-donating at the C4 position. These facts are reflected in the functionalization of sydnone derivatives, such as the nitration of 3-arylsydnones in eqs. [2] and [3]. With **2**, the nitronium



2 3

ion preferential reacts at C4 rather than at the phenyl ring (3). With **4**, electrophilic substitution occurs at position 4 of the C4-phenyl ring, followed by position 2 (4). Therefore, direct nitration of 3-arylsydnone is not a route to prepare 3-(nitroaryl)-



sydnones. Herein, we report a method to prepare 3-(nitroaryl)-sydnones by the nitration of 3-aryl-4-acetylsydnones, followed by the deacetylation using barium hydroxide as a catalyst (eq. [4]). Some of the PM3 calculation data will be used to explain the nitration results.

Results and discussion

The charge density distribution of the atoms of the sydnone ring has been discussed since this series of compounds has been known. However, the unequal distribution of electron density around the ring resulting in the mesoionic character is well accepted (5). The unequal electron densities of the atoms lead to the different nature between N3 and C4. We used a PM3 calculation package to obtain quantitative data for this feature of a series of compounds. The charge distributions at the carbons, nitrogens, and oxygens of compounds **2**, **4**, and **7–12** were calculated at the geometry with minimum potential energies and are listed in the Table 1. The charge at the atoms of sydnonyl rings reflect the nature of substituents of N3 and (or) C4. The electron-donating nature of methyl group decreases the positive charge of the N3 atom (**8**), while the phenyl ring decreases the negative charge of the C4 atom (**4**, **8**). The acetyl group

[h]Carbon atom of methyl of acetyl group.

decreases the charge densities of O6 and C5 and the increase in the charge density of C4 might result from its strong electron-withdrawing nature (**9–12**). The higher charge density at C4 atom is well corroborated with the orientation of nitration of **2** where the C4-NO_2 is the only product (3, 6). Also, the positive charge at N3 causes the sydnone ring to behave as an electron-withdrawing group and directs the nitration of phenyl group at C33. The nitration of **4** occurs at C44 and C42 rather than at the N3-phenyl ring, reflecting the higher negative charge density of C4 atom as calculated.

Neither direct nitration of 3-arylsydnones nor preparation from multiple substituted anilines is a useful procedure to pre-

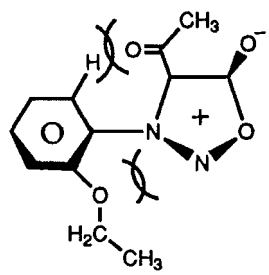
3-(4-Ethoxyphenyl)sydnone **7**
3-Methyl-4-phenylsydnone **8**

pare 3-(nitroaryl)sydnones. The title compounds are synthesized by nitrating 3-aryl-4-acetylsydnones, followed by removal of the blocking group. The methods of acetylation of sydnone at C4 are well established (7). The yields for nitration of C4-acetylsydnones to form 3-(3-nitroaryl)-4-acetylsydnones range from fair to good, depending upon the nature and position of the director group on the phenyl ring. Increasing the electron densities of the aryl ring by the C34-alkoxyl or -alkyl group enhances the yield of the nitration process and even produces the dinitro derivative **10***a*′ under a large excess of nitronium ion (Table 1). By contrast, under the same large excess of KNO_3, the nitration of methyl analogues yield only the mononitration product **12***a*. However, nitration of **13** is less facile than its methyl counterpart **14**. This result can be explained by



the steric hindrance of the *ortho* substituent causing more of an energy barrier for the coplanar between the phenyl and sydnone rings.

The sydnone ring is very labile in strong base. Therefore, the acetyl group cannot be removed while retaining the sydnone ring in the presence of either alkali hydroxide or alkoxide. Fortunately, the deacetylation can be carried out in a suspension of sydnone and barium hydroxide in water at room temperature. This involves the reaction of the hydroxyl ion with the carbon of the carbonyl group and transfer of a proton to C4, followed by the loss of an acetate ion (Scheme 1) (8). The carbonyl group of the sydnone ring must possess a normal carbonyl similar to that of β-di ketones or β-keto acids (8). However, the deacetylation reaction of **15***a* to yield 3-(2-nitro-6-methoxyl)sydnone (**15***b*) is mechanistically still unclear.

Experimental

All melting points were measured with a Yanaco MP-J3 apparatus and are uncorrected. ^1H NMR spectra were recorded on a Bruker AC-200 spectrometer, using tetramethylsilane as internal standard. Infrared spectra were recorded on a Hitachi 270-30 grating infrared spectrophotometer. Mass spectra were measured on a JMS-D100 spectrometer, using 70 eV ionization potential. Microanalysis were performed on a Heraeus CHN-O-Rapid analyzer. 3-Arylsydnones (2) and 3-aryl-4-acetylsydnones (7) were prepared according to the literature. The theoretical calculations were determined using a SGI workstation (model 4D20) and the PM3 software package from Biosym Technologies. The charge densities of atoms were recorded at their optimum geometry.

Nitration of 3-aryl-4-acetylsydnone: typical procedure

To an ice-cooled and stirred solution of 4-acetyl-3-phenylsydnone (1.50 g, 7.5 mmol) in H_2SO_4 (10 mL), KNO_3 (4.50 g, 30.0 mmol) was slowly added. After being stirred for 2 h at 5°C, the color of the solution changed from light brown to deep green. This solution was poured into ice water which yielded yellow precipitate. Following filtration, the crude product was recrystallized from 95% ethanol yielding **9***a* as white needles: 1.31 g (70% yield); mp 150–152°C; IR (KBr) $\nu_{C=O}$: 1776, 1656 cm^{-1}; IR (KBr) ν_{NO_2}: 1540, 1346 cm^{-1}; NMR (acetone-d_6) δ: 2.40 (s, 3H, Me), 8.02 (t, 1H, J = 8.0 Hz, aromatic), 8.21 (d, 1H, J = 8.0 Hz, aromatic), 8.68–8.59 (m, 2H, aromatic); MS *m/z* (relative intensity): 249 (M^+, 13), 149 (100). Anal. calcd. for $C_{10}H_7N_3O_5$: C 48.20, H 2.83, N 16.90; found: C48.10, H 2.83, N 16.90.

The following compounds were obtained according to this procedure.

3-(3-Nitro-4-methoxyphenyl)-4-acetylsydnone (***10***a)*:* mp 170–172°C; IR (KBr) $\nu_{C=O}$: 1798, 1668 cm^{-1}; IR (KBr) ν_{NO_2}: 1532, 1350 cm^{-1}; NMR (acetone-d_6) δ: 2.40 (s, 3H, C(O)Me), 4.15 (s, 3H, OMe), 7.64 (d, 1H, J = 9.1 Hz, aromatic), 8.04 (dd, 1H, J = 2.6, 9.1 Hz, aromatic), 8.33 (d, 1H, J = 2.6 Hz, aromatic); MS *m/z* (relative intensity): 279 (M^+, 1), 43(100). Anal. calcd. for $C_{11}H_9N_3O_6$: C 47.32, H 3.25, N 15.05; found: C 47.25, H 3.22, N 15.08.

3-(3,5-Dinitro-4-methoxyphenyl)-4-acetylsydnone (***10***a′) (same procedure, except 8 equiv. of KNO_3 was used): mp 161–162°C; IR (KBr) $\nu_{C=O}$: 1776, 1680 cm^{-1}; IR (KBr) ν_{NO_2}: 1548, 1348 cm^{-1}; NMR (acetone-d_6) δ: 2.42 (s, 3H, C(O)Me), 4.22 (s, 3H, OMe), 8.78 (s, 2H, aromatic); MS *m/z* (relative intensity): 324 (M^+, 5), 43(100). Anal. calcd. for $C_{11}H_8N_4O_8$: C 40.75, H 2.49, N 17.28; found: C 40.55, H 2.52, N 17.19.

3-(3-Nitro-4-ethoxyphenyl)-4-acetylsydnone (***11***a)*:* mp 150–152°C; IR (KBr) $\nu_{C=O}$: 1806, 1656 cm^{-1}; IR (KBr) ν_{NO_2}: 1538, 1286 cm^{-1}; NMR (acetone-d_6) δ: 1.48 (t, 3H, J = 6.9 Hz, CH_2CH_3), 2.40 (s, 3H, C(O)Me), 4.43 (q, 2H, J = 6.9 Hz, CH_2CH_3), 7.61 (d, 1H, J = 9.1 Hz, aromatic), 8.01 (dd, 1H, J = 2.6, 9.1 Hz, aromatic), 8.31 (d, 1H, J = 2.6 Hz, aromatic); MS *m/z* (relative intensity): 293 (M^+, 2), 43(100). Anal. calcd. for $C_{10}H_7N_3O_5$: C 48.20, H 2.83, N 16.86; found: C 48.10, H 2.83, N 16.90.

3-(3-Nitro-4-methyphenyl)-4-acetylsydnone (***12***a)*:* mp 126–128°C; IR (KBr) $\nu_{C=O}$: 1778, 1671 cm^{-1}; IR (KBr) ν_{NO_2}: 1532, 1357 cm^{-1}; NMR (acetone-d_6) δ: 2.41 (s, 3H, C(O)Me), 2.74 (s, 3H, Me), 7.82 (d, 1H, J = 8.3 Hz, aromatic), 8.00 (dd, 1H, J = 8.3, 2.1 Hz), 8.44 (d, 1H, J = 2.1 Hz, aromatic); MS *m/z* (relative intensity): 263 (M^+, 2), 43(100). Anal. calcd. for $C_{11}H_9N_3O_5$: C 50.20, H 3.45, N 15.96; found: C 50.17, H 3.41, N 15.97.

3-(5-Nitro-2-ethoxyphenyl)-4-acetylsydnone (***13***a)*:* mp 129–131°C; IR (KBr) $\nu_{C=O}$: 1806, 1793, 1758, 1665 cm^{-1}; IR (KBr) ν_{NO_2}: 1524, 1344 cm^{-1}; NMR (acetone-d_6) δ: 1.33 (t, 3H, J = 7.0 Hz, OCH_2CH_3), 2.40 (s, 3H, C(O)Me), 4.38 (m, 2H, OCH_2CH_3), 7.59 (d, 1H, J = 8.7

Hz, aromatic), 8.61 (dd, 1H, J = 8.7 Hz, aromatic), 8.63 (s, 1H, aromatic); MS *m/z* (relative intensity): 293 (M^+, 1), 43(100). Anal. calcd. for $C_{12}H_{11}N_3O_6$: C 49.15, H 3.78, N 14.33; found: C 49.04, H 3.73, N 14.34.

*3-(5-Nitro-2-tolyl)-4-acetylsydnone (**14**a):* mp 126–128°C; IR (KBr) $\nu_{C=O}$: 1776, 1666 cm^{-1}; IR (KBr) ν_{NO_2}: 1526, 1348 cm^{-1}; NMR (acetone-d_6) δ: 2.39 (s, 3H, Me), 2.41 (s, 3H, C(O)Me), 7.87 (d, 1H, J = 8.0 Hz, aromatic), 8.51 (dd, 1H, J = 8.0, 2.3 Hz, aromatic), 8.59 (d, 1H, J = 2.3 Hz, aromatic); MS *m/z* (relative intensity): 263 (M^+, 3), 43(100). Anal. calcd. for $C_{11}H_9N_3O_5$: C 50.20, H 3.45, N 15.96; found: C 50.10, H 3.43, N 15.94.

*3-(2-Nitro-5-methoxyphenyl)-4-acetylsydnone (**15**a):* mp 174–176°C; IR (KBr) $\nu_{C=O}$: 1792, 1658 cm^{-1}; IR (KBr) ν_{NO_2}: 1522, 1352 cm^{-1}; NMR (acetone-d_6) δ: 2.41 (s, 3H, C(O)Me), 4.04 (s, 3H, OMe), 7.52 (dd, 1H, J = 8.5, 2.0 Hz, aromatic), 7.81 (d, 1H, J = 2.0 Hz, aromatic), 8.13 (d, 1H, J = 8.5 Hz, aromatic); MS *m/z* (relative intensity): 279 (M^+, 3), 43(100). Anal. calcd. for $C_{11}H_9N_3O_6$: C 47.32, H 3.25, N 15.05; found: C47.07, H 3.27, N 14.98.

Deacetylation of 3-(Nitroaryl)-4-acetylsydnones: typical procedure

To a stirred solution of 3-(3-nitrophenyl)-4-acetylsydnone (**9***a*, 0.43 g, 1.7 mmol) in 95% EtOH, $Ba(OH)_2$ (0.49 g suspension in 15 mL of water) was added. After being stirred for 2 h at room temperature, the resultant solution was poured into ice water. Following filteration, the crude product was recrystallized from ethanol yielding **9**b as colorless crystals: 0.22 g (63% yield); mp 139–140°C. The IR spectrum was identical with the authentic sample (8). Compounds **10***b* (9), **12***b* (10), and **14***b* (9) were obtained from hydrolysis of the corresponding 4-acetylsydnones and identified by comparing the mp and IR spectra with authentic samples.

The following new compounds were obtained according to this hydrolysis procedure.

*3-(3-Nitro-4-ethoxyphenyl)sydnone (**11**d):* mp 126–128°C; IR (KBr) $\nu_{C=O}$: 1758 cm^{-1}; IR (KBr) ν_{NO_2}: 1532, 1362 cm^{-1}; NMR (acetone-d_6) δ: 1.46 (t, 3H, J = 6.8 Hz, OCH_2CH_3), 4.43 (q, 2H, J = 6.8 Hz, OCH_2CH_3), 7.42 (s, 1H, N—C4—H), 7.68 (d, 1H, J = 9.2 Hz, aromatic), 8.22 (dd, 1H, J = 9.2, 2.7 Hz, aromatic), 8.47 (d, 1H, J = 2.7 Hz, aromatic); MS *m/z* (relative intensity): 251 (M^+, trace), 193(100). Anal. calcd. for $C_{10}H_9N_3O_5$: C 47.82, H 3.61, N 16.73; found: C 47.77, H 3.57, N 16.73.

*3-(5-Nitro-2-ethoxyphenyl)sydnone (**13***b*): mp 144–146°C; IR (KBr) $\nu_{C=O}$: 1760 cm^{-1}; IR (KBr) ν_{NO_2}: 1528, 1346 cm^{-1}; NMR (acetone-d_6) δ: 1.46 (t, 3H, J = 7.1 Hz, OCH_2CH_3), 4.48 (q, 2H, J = 7.1 Hz, OCH_2CH_3), 7.22 (s, 1H, N—C4—H), 7.65 (d, 1H, J = 9.2 Hz, aromatic), 8.57 (dd, 1H, J = 9.2, 2.7 Hz, aromatic), 8.68 (d, 1H, J = 2.7 Hz, aromatic); MS *m/z* (relative intensity); 251 (M^+, 3), 165(100). Anal. calcd. for $C_{10}H_9N_3O_5$: C 47.82, H 3.61, N 16.73; found: C 47.74, H 3.53, N 16.78.

*3-(2-Methoxyl-6-nitrophenyl)sydnone (**15**b):* mp 156–158°C; IR (KBr) $\nu_{C=O}$: 1758 cm^{-1}; IR (KBr) ν_{NO_2}: 1532–1362 cm^{-1}; NMR (acetone-d_6) δ: 4.11 (s, 3H, OCH_3), 7.30 (s, 1H, aromatic), 7.64 (d, 1H, J = 8.0 Hz, aromatic), 7.79 (d, 1H, J = 8.0 Hz, aromatic), 7.95 (t, 1H, J = 8.0 Hz, aromatic); MS *m/z* (relative intensity): 237 (M^+, trace), 93(100%). Anal. calcd. for $C_9H_7N_3O_5$: C 45.37, H 3.00, N 17.61; found: C 45.58, H 2.97, N 17.72.

Preparation and application of 4′-carboxybenzo-15-crown-5, a drift-type crown ether phase transfer catalyst

MING-SENG CHOU AND JENG-SHONG SHIH[1]

Department of Chemistry, National Taiwan Normal University, Taipei, Taiwan 11718, Republic of China

Received September 15, 1993

MING-SENG CHOU and JENG-SHONG SHIH. Can. J. Chem. **72**, 1614 (1994).

A new "drift-type" crown ether phase transfer catalyst, 4′-carboxybenzo-15-crown-5 adsorbed on poly(styrene/divinylbenzene)-NR_2 resin, was synthesized and applied to catalyze the oxidation of benzhydrol with $NaMNO_4$ as an oxidant. Before the reaction, the drift-type crown ether catalyst was adsorbed on the resin with ion-pair (resin-NR_2H^+ ^-O_2C-monobenzo-15-crown-5) formation. During the reaction period the crown ether catalyst was released from the resin into the reaction solution as a homogeneous catalyst by adjusting the acidity of the solution to 10^{-1} M HCl to destroy the ion pair between the catalyst and the resin. After the reaction, the crown ether catalyst could be readsorbed on the resin by adjusting the concentration of HCl to 10^{-5} M and could be readily recovered by filtration. The catalyst, 4′-carboxybenzo-15-crown-5, was found to be a more effective catalyst than other crown ethers, such as 15-crown-5, 18-crown-6, monobenzo-15-crown-5, and dibenzo-18-crown-5.

MING-SENG CHOU et JENG-SHONG SHIH. Can. J. Chem. **72**, 1614 (1994).

On a effectué la synthèse d'un nouvel éther-couronne de type «à la dérive» pouvant agir comme catalyseur par transfert de phase, l'éther 4′-carboxybenzo-15-couronne-5 adsorbé sur de la résine poly(styrène/divinylbenzène)-NR_2, et on l'a utilisé pour catalyser l'oxydation du benzhydrol par le $NaMnO_4$. Avant la réaction, le catalyseur éther couronne est adsorbé sur la résine avec formation d'une paire d'ions (résine-NR_2H^+/éther ^-O_2C-monobenzo-15-couronne-5). En ajustant l'acidité de la solution à 10^{-1} M de HCl afin de détruire la paire d'ions formée par le catalyseur et la résine, on libère le catalyseur éther couronne de la résine au cours de la réaction et on l'introduit dans le milieu réactionnel sous la forme d'un catalyseur homogène. Après la réaction, on peut réadsorber le catalyseur éther couronne sur la résine en ajustant la concentration de HCl à 10^{-5} M et on peut alors le récupérer facilement par filtration. On a trouvé que le catalyseur 4′-carboxybenzo-15-couronne-5 est plus efficace que d'autres éthers couronnes comme les éthers 15-couronne-5, 18-couronne-6, monobenzo-15-couronne-5 et dibenzo-18-couronne-6.

[Traduit par la rédaction]

Introduction

Crown ethers have demonstrated a remarkable ability to complex alkali metal ions (1–5). Owing to this complexing ability, they can not only increase the solubility of the metal salts (MX) in organic solvents but also cause activation (6–10) of the anion (X^-) of salts, which results in the catalysis of anion-involved organic reactions, such as displacements, oxidations, and reductions in organic solvents. Crown ethers are used as homogeneous catalysts in most instances. For such homogeneous catalysts, difficulty in recovery and separation of the catalyst from reactants and products after reaction is often encountered. On the other hand, heterogeneous crown ether catalysts, for example, poly(crown ether), are easily recovered after the reaction (11–15). However, heterogeneous catalysts generally exhibit poorer catalytic ability than do the homogeneous catalysts. A new type of "drift-type" crown ether catalyst, 4′-carboxybenzo-15-crown-5, is designed and synthesized in this study. The drift-type catalyst can be drifted out and in reversibly between a solid phase and a solution by adjusting the experimental conditions. The drift-type catalyst is easily recovered, similar to a heterogeneous catalyst, yet has the high catalytic activity of a homogeneous catalyst. Before the reaction, the drift-type crown ether catalyst is adsorbed on a poly(styrene/divinylbenzene)-NR_2 resin by ion-pair formation (resin-NR_2H^+ $-O_2C$-benzo-15-crown-5). The catalyst is re-leased from the resin as a homogeneous catalyst during the reaction period by adjusting the pH of the reaction solution. It is readsorbed on the resin after the reaction by pH readjustment.

Experimental section

Apparatus

A Waters ALC 200 high-performance liquid chromatograph (HPLC) with a UV–visible detector was utilized to determine concentration of product (benzophenone) and reactant (benzhydrol) for the oxidation reaction as well as concentration of the crown ethers, 4′-carboxybenzo-15-crown-5 and mono-benzo-15-crown-5. FT-NMR (Jeol JNM-FX100), IR (Perkin–Elmer 735 B), and GC-MS (Jeol JMS-D300) spectrometers were employed for identification of the catalyst, products, reactants, crown ethers, and the chloromethylated as well as the alkylamine XAD, resins.

Chemicals

Dibenzo-18-crown-6, monobenzo-15-crown-5, and 15-crown-5 were synthesized as described by Gokel and Durst (16), Pedersen (1), and Cook (17) respectively. The 18-crown-6 was obtained from E. Merck. All other chemicals were of analytical reagent grade.

Preparation of the drift-type crown ether catalyst

The drift-type catalyst 4′-carboxybenzo-15-crown-5 was synthesized by oxidation of 4′-acetylbenzo-15-crown-5, which was prepared by acetylation of monobenzo-15-crown-5 (Fig. 1A).

4′-Acetylbenzo-15-crown-5 was prepared by stirring a mixture of 5.4 g (20 mmol) of benzo-15-crown-5 and 1.3 g (22 mmol) of acetic acid with 27 g of saturated diphosphorus pentoxide – methylsulfonic acid solution for 6 h (18), followed by extraction of the reaction mixture with chloroform (300 mL), evaporation of the chloroform, and recrystallization of the residue from hexane to give a 65% yield of 4′-cetylbenzo-15-crown-5 with mp 96–97°C; IR: 1680 (C=O) cm^{-1}; NMR ($CDCl_3$), δ: 2.55 (s), 4.0 (m), 6.6 (d), 7.0 (s), and 7.3 (d); MS: 310 (M^+).

4′-Carboxybenzo-15-crown-5 was obtained by dropwise addition of 150 mL of an aqueous solution of NaOH (22 g) to 7 mL of bromine water (138 mmol Br_2) at 0–10°C, mixing with 10.5 g (0.33 mmol) of 4′-acetylbenzo-15-crown-5 and stirring the solution at 20°C for 5 h. After extraction of the unreacted 4′-acetylbenzo-15-crown-5 with

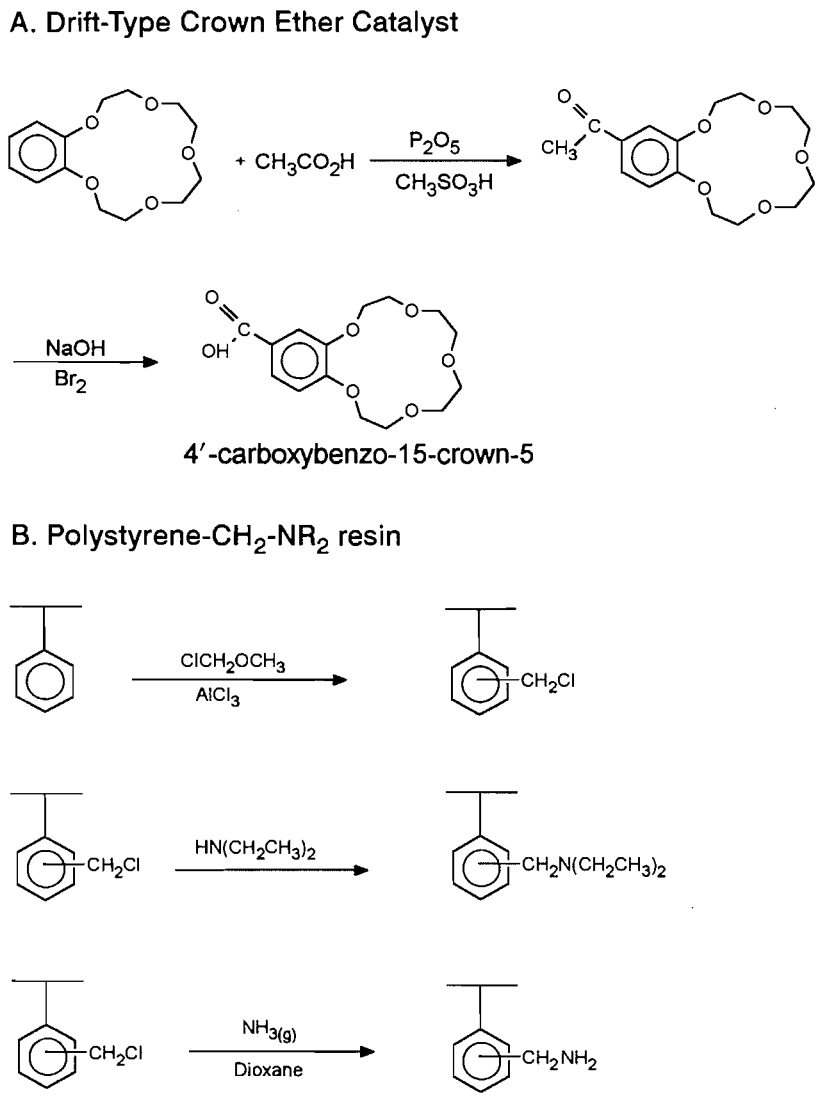

FIG. 1. Syntheses of drift-type crown ether catalyst and resin.

chloroform (300 mL), the aqueous solution was acidified with hydrochloric acid, which precipitated the product. Extraction with chloroform (300 mL), evaporation of the chloroform, and recrystallization of the residue from *n*-hexane gave an 83% yield of the desired product with mp 180°C; IR (KBr): 1720 (C=O) and 2800 (COOH) cm^{-1}; NMR ($CDCl_3$), δ: 3.6 (s), 4.0 (m), 7.0 (d), and 7.5 (m); MS: 312 (M^+).

Preparation of stationary resin

The scheme of synthesis of the alkylamine XAD resin is shown in Fig. 1B. A mixture of XAD-4 resin (poly(styrene/divinylbenzene), 200–400 mesh, 10 g), chloromethyl methyl ether (20 mL), dichloromethane (20 mL), and nitromethane (6 mL) was mixed well in an ice bath. Aluminum chloride ($AlCl_3$, 6 g) was slowly added as the catalyst for chloromethylation (19, 20) of XAD-4 resin. The chloromethylated resin (XAD-CH_2Cl) was mixed with diethylamine (20 mL) and refluxed for 72 h. After washing with methanol (300 mL), the XAD-$CH_2N(C_2H_5)_2$ resin was obtained and identified, with IR(KBr): 1390 (C—N) cm^{-1}. Similarly, other XAD-alkylamine resins, XAD-$CH_2N(CH_3)_3$ and XAD-CH_2NH_2, were prepared by the reactions of XAD-CH_2Cl with trimethylamine and NH_3, respectively. The ion exchange capacity of the alkylamine XAD resins was determined by titration of the -NH_2 or -NR_2 groups on the resins with HCl.

The adsorption capacity of a resin for 4′-carboxybenzo-B-15-crown-5 was determined by measuring the residual of crown ether in the aqueous solution after stirring an excess of crown ether and 1 g of the resin in water for 4 h and filtering. The concentration of crown ether was measured with a high-performance liquid chromatograph.

Catalysis and recovery of catalyst

A mixture of 120 mg of the drift-type catalyst 4′-carboxyl-B15C5 in 100 mL of dichloromethane or benzene and 5 g of XAD-$CH_2N(C_2H_5)_2$ resin was stirred for about 4 h for the adsorption of the catalyst on the resin (Fig. 2(1)). At the beginning of the reaction the crown ether catalyst was released into the dichloromethane or benzene solution by addition of 2 mL of 0.55 N HCl (Fig. 2(2)). The resin in the mixture was filtered and neutralized with 1 N NaOH, which resulted in the change of the resin from XAD-NR_2H^+ into XAD-NR_2. The acidified dichloromethane or benzene solution containing the crown ether catalyst was then mixed with 1 mmol (0.18 g) of benzhydrol (reactant) and 7 mmol (about 1 g) of $NaMnO_4$ as an oxidant (Fig. 2(3)). The mixture was stirred for 6 h for the oxidation of benzhydrol. The oxidation product, benzophenone, was determined with high-performance liquid chromatography. After the reaction, 2 mL of 1 N HCl was added to release the neutral form of the crown ether from the complex Na^+B15C5CO_2H. Sodium bisulfate was also added to decompose the unreacted $NaMnO_4$. The neutral XAD-NR_2 resin was then mixed with the acidified crown ether – dichloromethane or benzene solution to

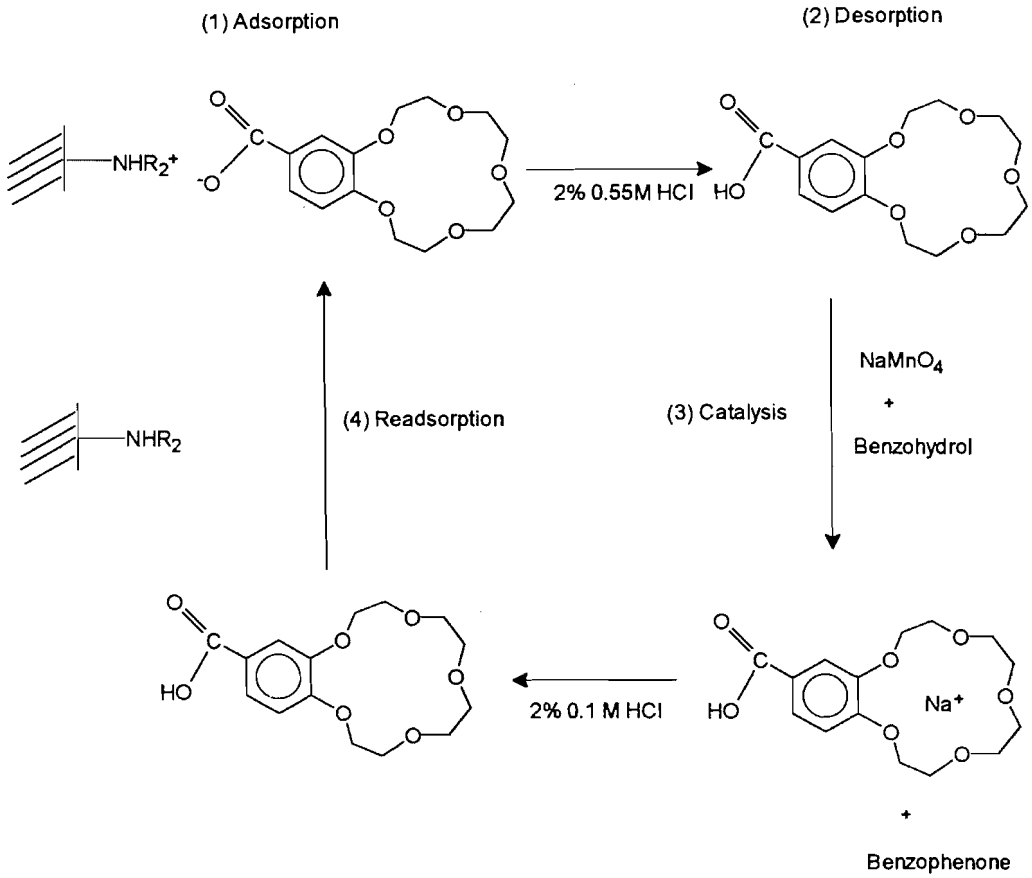

FIG. 2. Catalysis and recovery of 4′-carboxybenzo-15-crown-5 in organic solvents at 25°C.

readsorb the drift-type crown ether catalyst for recovery by filtration (Fig. 2(4)).

Results and discussion

The catalytic ability of the drift-type crown ether catalyst 4′-carboxy-B15C5 was first investigated.The crown ether compounds of 4′-carboxy-B15C5, benzo-15-crown-5(B15C5), 15-crown-5(15C5), dibenzo-18-crown-6(DB18C6), and 18-crown-6(18C6), were utilized as homogeneous catalysts for catalyzing the oxidation of benzhydrol with sodium permanganate ($NaMnO_4$) in benzene. Among the crown ethers, 4′-carboxy-B15C5 and B15C5 were found to exhibit better catalytic abilities than the other crown ether catalysts (Fig. 3). This finding indicates that the drift-type crown ether catalyst can perform very well as a homogeneous catalyst in relation to common crown ether catalysts. By use of the drift-type crown ether catalyst, the oxidation of benzhydrol in benzene can be dramatically catalyzed to give about a 95% yield of benzophenone in only 3 h at room temperature, as shown in Fig. 3. Crown ethers are well known to be sensitive to the size of the metal ions. Both 4′-carboxyl-B15C5 and B15C5 have cavity radii (ca. 1.1 Å) (21) that can fit the size (1.12 Å) (22) of the Na^+ ion of $NaMnO_4$ very well. This should lead to the formation of quite strong complexes between crown ethers and Na ions as well as an increase in the solubility of oxidant $NaMnO_4$ in benzene and activation of the MnO_4^-, which results in catalysis of the oxidation of benzhydrol.

The process of catalysis/recovery of the drift-type crown ether catalyst includes four steps (Fig. 2): (1) Adsorption of the catalyst on the resin; (2) releasing of the catalyst from the resin at the beginning of the reaction; (3) catalysis of the oxidation of benzhydrol; and (4) readsorption of the catalyst on the resin after the reaction. Each step of the process has been studied and is briefly discussed as follows:

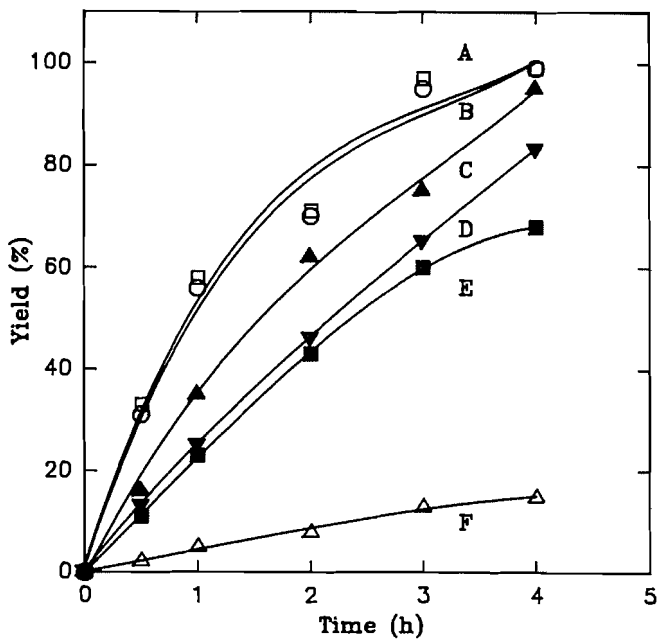

FIG. 3. Crown ether effect on oxidation of benzhydrol with $NaMnO_4$ in benzene at 25°C with (A) 4′-carboxybenzo-15-crown-5, (B) benzo-15-crown-5, (C) dibenzo-18-crown-6, (D) 18-crown-6, (E) 15-crown-5, and (F) without crown ether.

TABLE 1. Adsorption capacity of various XAD-amine resins for the crown ether 4′-carboxybenzo-15-crown-5 in dichloromethane

Resin	Ion exchange capacity (mequiv./g)	Adsorption of crown ether (mg/g)	Adsorption capacity of crown ether (mequiv./g)
XAD-NH_2	0.129	33.1	0.106
XAD-$N(C_2H_5)_2$	0.175	26.4	0.085
XAD-$N(CH_3)_3^+OH^-$	0.261	32.4	0.104

Step 1

The drift-type catalyst, 4′-carboxy-B15C5, is first adsorbed on a poly(styrene/divinylbenzene)-NR_2 (XAD-NR_2) resin prior to reaction. Various poly(styrene/divinylbenzene) resins, for example, XAD-$CH_2N(CH_3)_3^+{}^-OH$, XAD-$CH_2N(C_2H_5)_2$, XAD-CH_2NH_2, and XAD-CH_2Cl, are utilized for adsorbing the crown ethers, 4′-carboxy-B15C5, B15C5, and DB18C6, as well as benzoic acid. The study reveals that crown ethers B15C5 and DB18C6, which do not have the polar carboxylic acid group, are not adsorbed on these XAD resins. This indicates that the adsorption of crown ethers on these XAD resins cannot be attributed to nonpolar–nonpolar van der Waals forces. Resins such as XAD-CH_2Cl and XAD-4 that do not possess an ionized polar group cannot adsorb the crown ethers or benzoic acid. This also shows that the crown ethers, as well as benzoic acid, cannot be adsorbed on the resin by nonionic processes. Only 4′-carboxy-B15C5 and benzoic acid, which have carboxylic acid groups, can be adsorbed on the resins that have NR_2 groups. This suggests that adsorption of the drift-type crown ether catalyst 4′-carboxy-B15C5 on the XAD-NR_2 resins takes place by protonation of the amine group of the XAD-NR_2 resin and formation of ion pairs (resin-$NR_2H^+{}^-O_2C$-monobenzo-15C5).

The adsorption capacity of the resins for 4′-carboxy-B15C5 in dichloromethane was investigated. Results are listed in Table 1. Various XAD-NR_2 resins can absorb the drift-type catalyst with an adsorption capacity of about 0.1 mequiv./g (30 mg/g). About 0.4 mequiv. (120 mg) of the crown ether catalyst was used in most experiments of this study. This means that >4 g (actually, 5 g was used) of resin is necessary for complete adsorption of 120 mg (0.4 mequiv.) of the drift-type catalyst 4′-carboxy-B15C5. The adsorption of the crown ether by the XAD-$N(C_2H_5)_2$ resin (0.085 mequiv./g resin) is about half of the capacity of the resin (0.175 mequiv./g resin), which indicates that about 50% of amine sites on the resin can adsorb 4′-carboxy-B15C5 in dichloromethane.

Step 2

The catalyst 4′-carboxy-B15C5 is next released from the resin as a homogeneous catalyst at the beginning of the reaction by adding acid (HCl) to the dichloromethane solution. The pH (−log[acid added]) of aqueous dichloromethane solution was found to have a significant effect on the release of catalyst from the resin (Fig. 4). Thus an increase in concentration of H^+ (lower pH) in the solution results in enhanced release of the catalyst from the resin. This may be attributed to protonation of the carboxylate (COO^-) group of 4′-carboxy-B15C5 and decomposition of the ion-pair (resin-$NR_2H^+{}^-O_2C$-B15C5) between the catalyst and the resin, which results in the desorption and release of the catalyst from the resin. As indicated in Fig. 4, the crown ether catalyst is completely released from the resin at pH 2, which means that about 1 mmol of HCl must be added to the 100 mL dichloromethane solution. In the study of the oxidation reactions, 2 mL of 0.55 N HCl was added to the dichloromethane solution to release the catalyst.

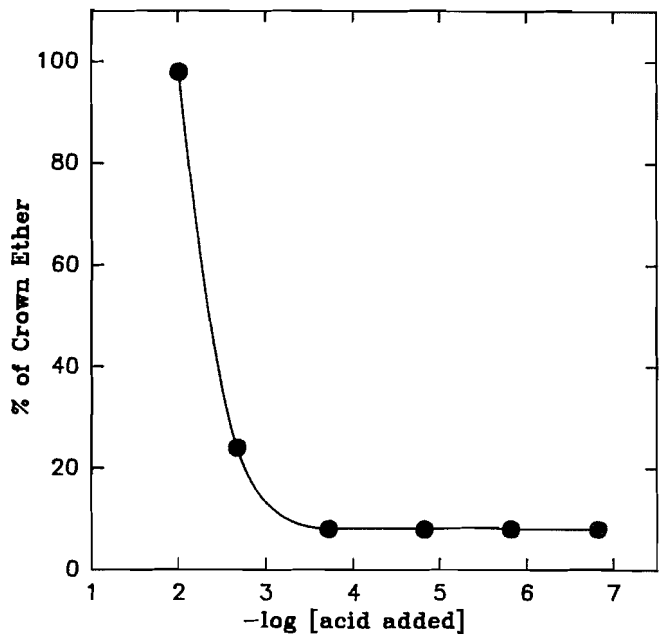

FIG. 4. Effect of the concentration of HCl acid added on desorption of the drift-type crown ether catalyst from the resin in 2% H_2O – CH_2Cl_2 solution.

Step 3

The drift-type catalyst 4′-carboxy-B15C5 is utilized as a homogeneous catalyst in the oxidation of benzhydrol. As mentioned above, 4′-carboxy-B15C5 has been shown to be as good a catalyst as B15C5 and better than any other crown ethers tested. Effects of crown ether concentration, cation of the oxidant, solvents, and temperature on the yield of the catalytic oxidation have been investigated in this study. The mechanism of the reaction can be expressed as follows.

(a) Anion activation

[1] $B15C5CO_2H + NaMnO_4 = Na^+B15C5CO_2H + MnO_4^-$

(b) Catalysis

[2] $2\,MnO_4^- + 5\,Bz_2CHOH = 2\,Mn^{2+} + 5\,Bz_2CO + 6\,OH^- + 2\,H_2O$

According to eqs. [1] and [2],

[3] $-d\,[B15C5CO_2H]/dt = d\,[MnO_4^-]/dt$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12

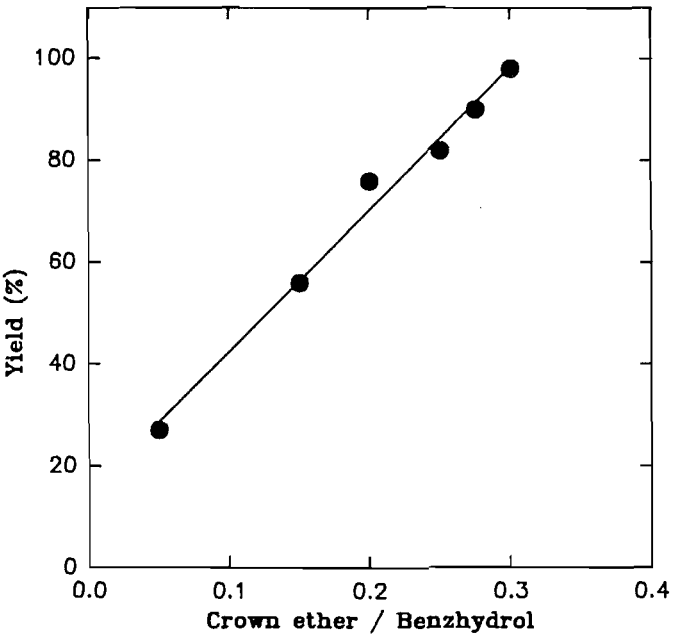

FIG. 5. Crown ether/benzhydrol mole ratio effect on oxidation of benzhydrol catalyzed by 4′-carboxybenzo-15-crown-5.

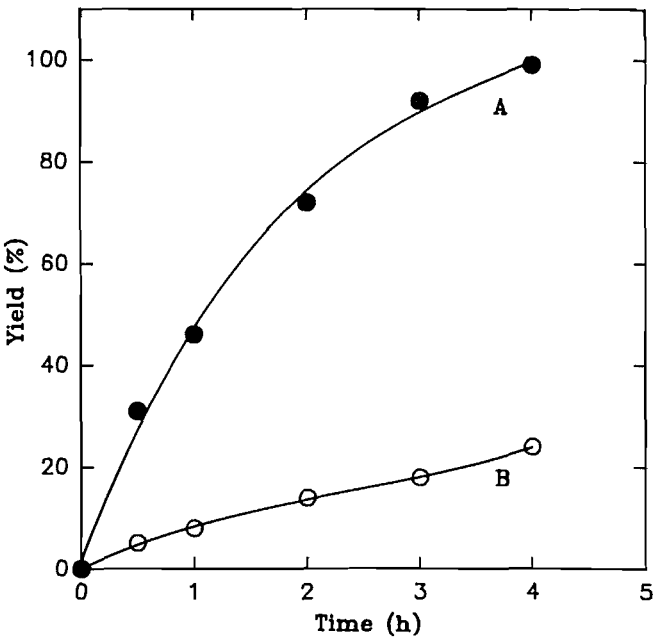

FIG. 6. Cation effect for oxidation of benzhydrol catalyzed by 4′-carboxybenzo-15-crown-5 with (A) $NaMnO_4$ and (B) $KMnO_4$.

and

[4] $-5\ d\ [MnO_4^-]/dt = 2\ d\ [Bz_2CO]/dt$

Therefore

[5] $d\ [Bz_2CO]/dt = 5/2\ d\ [B15C5CO_2H]/dt$

Division by $[Bz_2CHOH]$ gives

[6] $d\ ([Bz_2CO]/[Bz_2CHOH])/dt = 2.5\ d\ ([B15C5CO_2H]/[Bz_2CHOH])/dt$

Since $[Bz_2CO]/[Bz_2CHOH]$ = yield,

[7] $d\ (\text{yield})/dt = 2.5\ d\ ([B15C5CO_2H]/[Bz_2CHOH])/dt$

and

[8] $d\ (\text{Yield})/d([B15C5CO_2H]/[Bz_2CHOH]) = 2.5$

If this mechanism is correct, according to eq. [8] a plot of yield against ($[B15C5CO_2H]/[Bz2CHOH]$) should produce a straight line with a slope of 2.5. In agreement, a plot of yield against ($[B15C5CO_2H]/[Bz_2CHOH]$) gives a straight line with a slope of 2.54 (Fig. 5).

The cation effect of the oxidant on the reaction was also investigated. As shown in Fig. 6, $NaMnO_4$ is a superior oxidant to $KMnO_4$ in this reaction. The Na^+ ion (1.12 Å) can fit the cavity (ca. 1.1 Å) of the catalyst 4′-carboxy-B15C5 very well, which results in the formation of quite strong complexes between the Na^+ ion with the crown ether and dramatic catalysis of the reaction. In contrast, the K^+ ion with the size (radius) of 1.33 Å is too big for the cavity of the crown ether and leads toward a less activated MnO_4^- ion as well as a lower reactivity.

The solvent property is known to also be an important factor for the complexing ability of crown ethers with the metal ion. As shown in Fig. 7, benzene is a better solvent than dichloromethane or chloroform for the crown ether catalyzed oxidation of benzhydrol. Benzene with a dielectric constant (E) of 2.27 is less polar than chloroform (E = 4.80) or dichloromethane (E = 8.92) (23). This suggests that the catalytic ability of the crown ether is higher in less polar solvents. Since Na^+ ions are better solvated in more polar solvents such as chloroform, weaker crown ether – Na^+ complexes would be formed. In contrast, the solvation of Na^+ is weaker in a less polar solvent such as benzene, which results in the formation of strong complexes between the crown ether and the metal ion. This forma-

tion leads to more activated MnO_4^- anions and also more reactivity for the oxidation.

The temperature effect on the oxidation reaction was also investigated. Reaction at higher temperature (60°C) was found to be more rapid than at 25 and 40°C (Fig. 8).

Step 4

After the reaction, the drift-type crown ether is readsorbed on the XAD-N$(C_2H_5)_2$ resin. The crown ether is present in organic solvent as the complex Na^+B15C5CO_2H after the reaction. As was shown in Fig. 2, the crown ether can be produced in its neutral form B15C5CO_2H by the addition of 2% 0.1 M HCl. However, too large of an amount of HCl solution would drastically reduce the readsorption of the crown ether on the resin. The optimum acid concentration of the solution for readsorption of the crown ether was found to be 10^{-5} M HCl added (log[acid added] = 5) as shown in Fig. 9.

The identity of the organic solvent is also found to produce a significant effect on the readsorption of the crown ether (Table 2). Among the 10 solvents investigated, benzene, which has the lowest dielectric constant (2.27), appears to be the best solvent for the adsorption of the crown ether on the resin. As mentioned above, benzene is also the optimum solvent for the oxidation step. Therefore, benzene is identified as a good solvent for all of the drift-type catalytic processes, i.e., adsorption, release of the catalyst, catalysis of the oxidation, and readsorption of the catalyst.

The drift-type crown ether catalyst can theoretically be recycled forever. Some loss of the crown ether catalyst actually occurs after each cycle. The data in Table 3 show that the oxidation yield is 82.9% and 72.5% after the first and second cycles, respectively. The recovery of the crown ether is about 75% in each cycle.

Conclusion

The drift-type crown ether 4′-carboxy-B15C5 can be used as an efficient homogeneous phase transfer catalyst for catalyzing an organic reaction, such as the oxidation of benzydrol. This drift-type crown ether can also be easily recovered by readsorption on the XAD-NR_2 resin after the reaction. Thus, the drift-type crown ether catalyst was found to possess both the high catalytic capability of a homogeneous catalyst and the ease of use of a heterogeneous catalyst. In addition to the drift-type

crown ether catalyst, other kinds of drift-type catalysts, such as modified drift-type enzymes, can be envisaged.

Received October 4, 1993

R.A. BELL, J.F. BRITTEN, H.E. HOWARD-LOCK, C.J.L. LOCK, and M. SCHMIDT. Can. J. Chem. **72**, 1621 (1994).

The reaction of D-penicillamine and benzaldehyde yielded 2-phenyl-5,5-dimethylthiazolidine-4-carboxylic acid. The structure was determined by single crystal X-ray diffraction. Crystals were monoclinic, $P2_1$, $a = 9.785(2)$, $b = 6.941(1)$, $c = 10.399(2)$ Å, $\beta = 114.06(3)°$, $Z = 2$. Intensities were measured on a Rigaku AFC6R diffractometer with Cu Kα radiation and 1881 reflections were used to determine the structure. $R = 0.076$, $wR = 0.048$. The compound exists as an amino acid in the 2*S*,4*S* configuration. The conformation of the thiazolidine ring is determined by intermolecular hydrogen bonding. Bond lengths and angles are normal. ^{1}H and ^{13}C NMR spectra showed that epimerization takes place in d_4-CH_3OH solution, and the ratio of 2*S*,4*S* diastereomer to 2*R*,4*S* diastereomer at room temperature is 65:35.

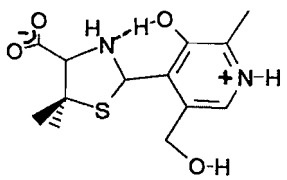
R.A. BELL, J.F. BRITTEN, H.E. HOWARD-LOCK, C.J.L. LOCK et M. SCHMIDT. Can. J. Chem. **72**, 1621 (1994).

La réaction de la D-pénicillamine et du benzaldéhyde conduit à l'acide 2-phényl-5,5-diméthylthiazolidine-4-carboxylique. On a déterminé sa structure par diffraction des rayons X par un cristal unique. Les cristaux sont monocliniques, $P2_1$, avec a = 9,785(2), b = 6,941(1) et c = 10,399(2) Å, $\beta = 114,06(3)°$ et $Z = 2$. On a mesuré les intensité à l'aide d'un diffractomètre Rigaku, modèle AFC6R, à l'aide du rayonnement Kα du Cu et on a utilisé 1881 réflexions indépendantes pour déterminer la structure. $R = 0,076$ et $R_w = 0,048$. Le composé existe sous la forme d'un acide aminé de configuration 2*S*,4*S*. La conformation du noyau thiazolidine est déterminée par une liaison hydrogène intramoléculaire. Les longueurs et les angles des liaisons sont normaux. Les spectres de RMN du ^{1}H et du ^{13}C démontrent que, en solution dans le d_4-CH_3OH, il se produit une épimérisation et que, à la température ambiante, le rapport des diastéréoisomères 2*S*,4*S* et 2*R*,4*S* est de 65 : 35.

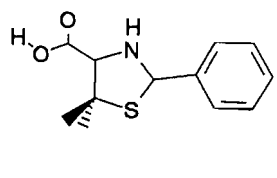
[Traduit par la rédaction]

Introduction

D-Penicillamine, when administered as a drug, interferes with a number of metabolic processes that involve vitamin B6. The fact that the interference is so general suggests that any interference occurs very early in any metabolic pathway or possibly even directly with the drug (1). Reaction of D-penicillamine with aldehydes and ketones is one of three types of biochemical reaction of the drug, and we have shown that D-penicillamine reacts directly with vitamin B6 forming a thiazolidine-4-carboxylic acid by condensation of the aldehyde group on vitamin B6 with the sulphydryl and amine groups on D-penicillamine, **1** (2).



1



2

D-Penicillamine is used in the treatment of rheumatoid arthritis (RA), but the time taken for any beneficial effect to be seen can be long (weeks), so that, generally, a nonsteroidal anti-inflammatory drug (NSAID) is given as well, to deal with short-term inflammation until the D-penicillamine takes effect. Many of these NSAIDs contain ketone groups and we were interested in seeing whether thiazolidine-containing condensation complexes could be formed with D-penicillamine. We have examined ketoprofen and tiaprofenic acid, but did not obtain products under physiological conditions. We speculate that this might be because of steric hindrance. We also attempted reactions with the related molecules benzophenone and benzaldehyde. No product was obtained with the sterically more demanding benzophenone, but a product, **2**, was obtained with benzaldehyde (3). We have examined the structure of the product and compared it to the results from the vitamin B6 experiments. There are significant differences in the two structures and we think these may be caused by intra- and intermolecular hydrogen bonding.

Experimental section

All chemicals and solvents were newly purchased as reagent grade and were generally used as received. Benzaldehyde was distilled before use. To avoid unwanted side reactions all operations were carried out under an atmosphere of dry nitrogen. Melting points (mp) were measured on a Gallenkamp melting point apparatus in open capillaries and are reported as measured.

Solutions for NMR studies were prepared in d_4-CH_3OH (99.8 at.% D; MSD Isotopes, Montreal) and concentrations were about 25 mg (solid)/mL. Proton NMR spectra and ^{13}C NMR spectra were recorded on a Bruker AC-200 spectrometer (at 200.13 MHz) with the deuterated solvent as internal reference. All spectra were obtained on natural-abundance compounds. Proton NMR spectra were obtained in 32–128 scans at a spectral width of 2404 Hz (16K, 0.29 Hz/data point, 3.408 s acquisition time). ^{13}C NMR spectra were obtained in 7000 scans at a spectral width at 12 195 Hz (16K, 1.49 Hz/data point, 0.672 s acquisition time). Line-broadening parameters used in processing the free induction decays were set slightly higher than their respective data point resolutions. Proton–proton NOE difference spectra were acquired by subtraction of a control FID from an on-resonance FID. The decoupler in the control FID irradiated a position in the spectrum where there were no proton signals. The on-resonance FID was obtained by selectively saturating the proton of interest. In both cases the same decoupler power and duration of saturation (5.0 s) were used. This saturation period also served as the relaxation delay for both the control and on-resonance FIDs. The decoupler was gated off during acquisition. Eight scans were acquired for both the control and on-resonance FIDs. This cycle of alternate acquisition of control and

on-resonance FIDs was repeated 12 times for a total of 96 scans for the final difference FID. A 90° ^{1}H pulse width of 9.4 μs was used. The difference FID was processed by use of exponential multiplication (line broadening: 4.0 Hz) and was zero-filled to 64K before Fourier transformation. The sample was not degassed.

5,5-Dimethyl-2-phenyl-thiazolidine-4-carboxylic acid, 2

D-(−)-Penicillamine (0.5 g) was added to a mixture of ethanol (6 mL) and benzaldehyde (0.5 mL, freshly distilled). The solution was stirred and heated for about 45 min. The almost clear mixture was filtered while hot and refrigerated for 4–5 h to yield colourless platelike crystals (0.64 g (83%), mp 145–146°C). NMR and vibrational spectra were similar to data in ref. 3. ^{1}H NMR (200 MHz, d_4-CH_3OH) 2*R*,4*S* diastereomer, δ: 7.57–7.51 (m, 5H, aromatic), 5.91 (s, 1H, C2-H), 3.97 (s, 1H, C4-H), 1.70 (s, 3H, C52-CH_3), 1.48 (s, 3H, C51-CH_3); *S*,*S* diastereomer, δ: 7.42–7.33 (m, 5H, aromatic), 5.67 (s, 1H, C2-H), 3.82 (s, 1H, C4-H), 1.73 (s, 3H, C52-CH_3), 1.44 (s, 3H, C51-CH_3). Ratio of diastereomers: 35% 2*R*,4*S* to 65% 2*S*,4*S*. ^{1}H NMR (200 MHz, d_6-DMSO) 2*R*,4*S* diastereomer, δ: 7.45 (m, 5H, aromatic), 5.83 (s, 1H, C2-H), 3.67 (s, 1H, C4-H), 1.32 (s, 3H, CH_3), 1.29 (s, 3H, CH_3); *S*,*S* diastereomer, δ: 7.45 (m, 5H, aromatic), 5.62 (s, 1H, C2-H), 3.56 (s, 1H, C4-H), 1.63 (s, 3H, CH_3), 1.51 (s, 3H, CH_3). Ratio of diastereomers: 70% 2*R*,4*S* to 30% 2*S*,4*S*. ^{13}C NMR (200 MHz, d_4-CH_3OH) 2*R*,4*S* diastereomer, δ: 170.97 (*C*OOH), 139.99 (C11), 74.57 (C2), 67.50 (C4), 58.41 (C5), 27.87 (C5-CH_3), 26.76 (C5-CH_3); *S*,*S* diastereomer, δ: 171.79 (*C*OOH), 139.08 (C11), 75.47 (C2), 69.50 (C4), 59.45 (C5), 29.98 (C5-CH_3), 28.71 (C5-CH_3). The remaining aromatic signals overlapped and could not be definitively assigned: they occurred at δ 129.88, 129.73, 128.86, 128.72.

Structure determination details for 2

For single crystal X-ray diffraction, crystals of 2-phenyl-5,5-dimethyl-thiazolidine-4-carboxylic acid were obtained by the slow evaporation (20°C) of an absolute ethanol solution. The unit cell was determined by least-squares refinement of 24 reflections between θ = 19.9° and θ = 55.7°. Hydrogen atoms were placed at calculated positions and constrained to ride on the atoms to which they were attached, except for atoms H(1) and H(3), which were placed at positions located in the electron density map and were not refined. The details of the structure determination follow, and positional parameters and isotropic temperature factors are given in Table 1.[2]

Crystal data

Empirical formula, $C_{12}H_{15}NO_2S$; colourless plate; crystal size, 0.30 × 0.30 × 0.03 mm^3; monoclinic, $P2_1$; a = 9.785 (2) Å, b = 6.941 (1) Å, c = 10.399 (2) Å, β = 114.06 (3)°; V = 644.9 (3) Å^3; Z = 2; formula weight, 237.3; density, calcd., 1.222 Mg m^{-3}; absorption coefficient, 2.121 mm^{-1}; F(000) = 252.

Data collection

Diffractomer used, Rigaku AFC6-R; CuKα (λ = 1.54178 Å); temperature 298 K; monochromator, highly oriented graphite crystal; 2θ range, 5.0–120.0°; scan type, ω–2θ; scan speed, 32° min^{-1} in ω, with up to 9 rescans; scan range (ω), 2° plus Kα separation; background measurement, stationary crystal and stationary counter at beginning and end of scan, each for 0.25 of total scan time; standard reflections, 3 measured every 100 reflections; index ranges, $0 \le h \le 11$, $0 \le k \le 8$, $-12 \le l \le 12$ and $-11 \le h \le 0$, $-8 \le k \le 0$, $-12 \le l \le 12$; reflections collected, 2232; independent reflections, 1881 (R_{int} = 3.93%); reflections used, 1881, absorption correction, by Ψ-scan, T_{min} = 0.7635, T_{max} = 1.000.

Solution and refinement

System used, Siemens SHELXTL PLUS (PC Version) (4); solution, direct methods; refinement method, full-matrix least squares; quantity minimized, $\Sigma w(|F_o| - |F_c|)^2$; absolute structure, from known configuration of D-penicillamine, and confirmed by the Rogers parameter of 0.94(7); extinction correction, not applied; hydrogen atoms, riding model, fixed isotropic U; weighting scheme, $w^{-1} = (\sigma(F))^2$ (2); number of parameters refined, 144; final R indices, R = 0.076, wR = 0.048; goodness-of-fit, S, 1.62; largest and mean Δ/σ, 0.000, 0.000; data-to-parameter ratio, 13.1:1; largest difference peak, 0.41 e Å^{-3}; largest difference hole, −0.41 e Å^{-3}. $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR = [\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2]^{1/2}$; $S = [\Sigma w(|F_o| - |F_c|)^2/(n - m)]^{1/2}$.

Discussion

Attempts to react D-penicillamine with ketoprofen and tiaprofenic acid under physiological conditions (water, pH 7.6, 37°C) were unsuccessful, probably because of the low solubility of the NSAIDs. Reaction under more drastic conditions (refluxing ethanol) was also unsuccessful. The solid recovered after reaction was D-penicillamine. Reaction of D-penicillamine with benzophenone under similar conditions also yielded no product. Benzaldehyde did react, however, and yielded **2**.

The structure of 2-phenyl-5,5-dimethylthiazolidine-4-carboxylic acid, **2**, is shown in Fig. 1 and bond lengths and angles are given in Table 2. The compound is an amino acid, which is not unusual for solid thiazolidine-4-carboxylic acids derived from D-penicillamine, and in agreement with the predictions based on the vibrational spectra (3). The configuration is 2*S*,4*S*, in contrast to the similar compound 2*R*,4*S*-2-(2′-methyl-3′-hydroxy-5′-hydroxymethylenepyridine-C4′)-5,5-dimethyl-thiazolidine-4-carboxylic acid, **1** (2). The energy required to change the torsional angles about bonds is small and thus variations in the conformation of thiazolidine rings can occur (6, 7). The conformations of the thiazolidine rings in compounds **1** and **2** differ from previous compounds (6, 7) and from each other, as is shown by the torsional angles within the thiazolidine rings

[2]Tables of anisotropic temperature factors, hydrogen atom parameters, best planes, and torsional angles can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada. Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

The hydrogen atom coordinates for **2** have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[a]Atom is related to that in Table 1 by $1 - x$, $-0.5 + y$, $1 - z$.

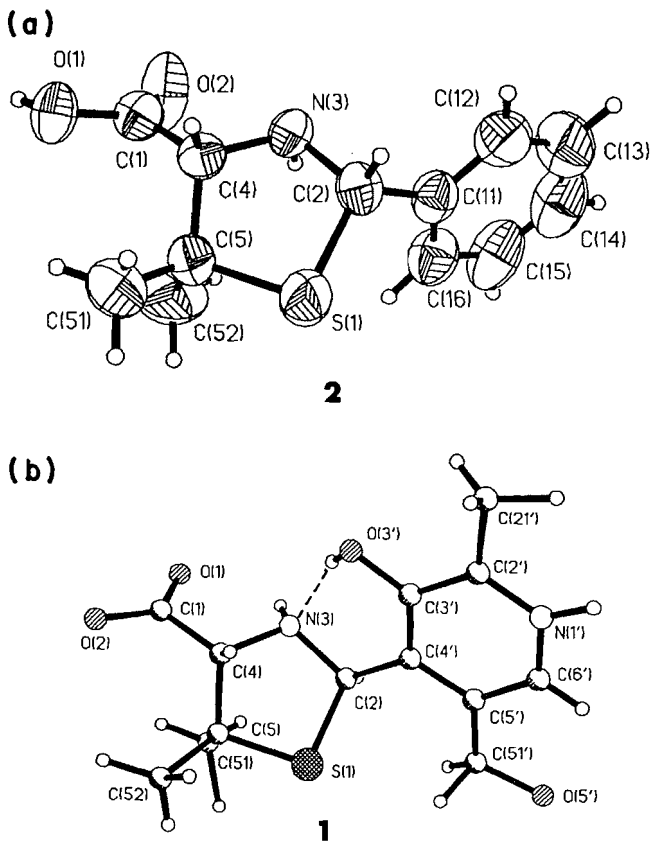

FIG. 1. (*a*) The structure of **2** showing the atom numbering. (*b*) The structure of **1**, oriented in roughly the same way, for comparison.

(Table 3). While both have the open-envelope conformation, for **1** S(1), C(2), N(3), C(4) are almost planar (max. dev. from plane 0.024 Å) and C(5) lies 0.689 Å below this plane, whereas for **2** the plane comprises C(5), S(1), C(2), N(3) (max. dev. from plane 0.046 Å) and C(4) lies 0.496 Å above this plane. The conformation in each case appears to be determined by hydrogen bonding. In the case of **1** there is a very strong intramolecular hydrogen bond between the 3′ hydroxy group on the vitamin B6 moiety and N(3) in the thiazolidine ring. This hydrogen bond determines the configuration at N(3). The alternative configuration at C(2), assuming the hydrogen bond was still present, would put all the bound hydrogen atoms at C(2), N(3), and C(4) on the same side of the thiazolidine ring and in essentially eclipsed conformations, giving rise to considerable steric hindrance. Even with the present conformation, the hydrogen atoms on C(2) and N(3) are eclipsed, but in this case the strength of the hydrogen bond must be sufficient to overcome the repulsion. No such hydrogen bonding is present in **2**, however, and steric hindrance is minimized by having the *S* configuration at C(2), such that the hydrogen atoms at C(2), N(3), and C(4) lie in a staggered *trans,trans* conformation. The configuration at N(3) is determined by the medium strong hydrogen bond between O(1) on one molecule and N(6) in a molecule related by the 2_1 axis at x, $z = 0.5$, as shown in Fig. 2. These hydrogen bonds connect molecules spiralling up the 2_1 axis in the *b* direction. Interactions between molecules in other directions are van der Waals.

TABLE 3. Torsional angles (deg) for **1** and **2**

Atoms	**1**	**2**
C(5)-S(1)-C(2)-N(3)	19.6	−6.4 (4)
S(1)-C(2)-N(3)-C(4)	4.0	27.6 (4)
C(2)-N(3)-C(4)-C(5)	−31.8	−41.5 (5)
N(3)-C(4)-C(5)-S(1)	43.1	34.0 (5)
C(4)-C(5)-S(1)-C(2)	−35.3	−14.8 (4)

Comparison of the corresponding bond lengths in the thiazolidine parts of **1** and **2** shows minimal differences (maximum deviation 1.53 σ, where $\sigma = (\sigma_1^2 + \sigma_2^2)^{1/2}$), except for C(4)—C(1), C(1)—O(1), and C(1)—O(2). For **1** the last two

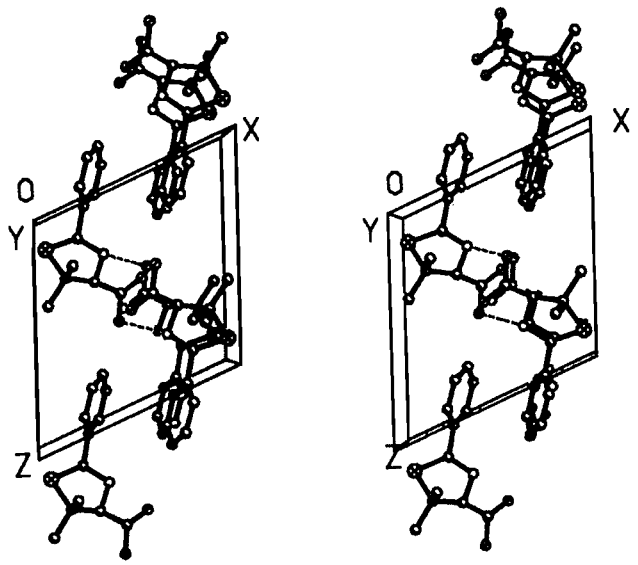

FIG. 2. The packing of **2** in the unit cell. The view is down *b*.

distances are nearly equal, (1.241(6), 1.260(6) Å), as expected for an ionized carboxylate group. For **2** there is a marked asymmetry (1.202(7), 1.306(6) Å), consistent with C=O and C—OH bonds. In addition, C(4)—C(1) in the latter compound is considerably shorter than in **1** (1.506(6) vs. 1.548(7) Å, 4.55σ).

There is considerably more variation in the corresponding angles between the two compounds. Differences of two or three degrees are common (2.00–9.72σ). There are significant differences in the C(4)—C(1)—O(1), C(4)—C(1)—O(1), and O(1)—C(1)—O(2) angles, as might be expected. The values for the angles observed for **2** are fairly close to those observed for the corresponding angles in the amino acid (*S*)-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid (differences: +3.9°, −2.9°, −1.0°) (6), whereas those for **1** agree better with the zwitterionic (*R*)-thiazolidine-4-carboxylic acid (7). We assume the variations in the other sets of corresponding angles are caused by the different conformations of the thiazolidine rings.

The proton NMR spectral parameters are given in the experimental section. All peaks are doubled because of epimerization of the thiazolidine compound in solution. The ^{1}H NMR spectrum alone is not sufficient to distinguish which set of peaks belongs to which diastereomer. An attempt was made, therefore, to assign the resonances in the *S,R* and *S,S* diastereomers based on the work of McMillan and Stoodley (8). Writing about the protons at C2 and C4 in similar compounds, they state: "In particular, if both stereoisomers at C2 are available, the isomer in which the C4 proton appears at lowest field possesses the *trans* configuration." Applying this rule to the above spectrum, the 2*R*,4*S* diastereomer produces the set of signals with lower intensity and the *S,S* diastereomer the set with higher intensity.

To prove this statement, an NOE experiment was performed on the same sample. With saturation of the more intense proton signal of C2 at δ = 5.67 ppm, a signal at δ = 3.82 ppm was observed that corresponds to the more intense proton signal of C4. From these results it can be deduced that these two protons are on the same side of the molecule, which assigns this set of peaks of the *S,S* diastereomer. Saturation of the C2 proton signal at δ = 5.910 ppm, which is the one with lower intensity, caused no signal. From this result it can be gathered that the distance between the saturated proton and other protons, especially the one on C4, is too long for any through-space interaction. This occurs for a saturated proton in an equatorial position. Therefore the set of peaks with lower intensity belongs to the 2*R*,4*S* diastereomer. Thus, the *S,S* and the 2*R*,4*S* diastereomers of 2-phenyl-5,5-dimethylthiazolidine-4-carboxylic acid are found in d_4-H_3OH solution with a ratio of approximately 65:35 at room temperature. This is in contrast to the results found previously for a d_6-DMSO solution of the same compound, where the corresponding ratio was 30:70. It seems probable that the different hydrogen-bonding properties of the solvents are the cause of the difference since the free energy difference between the *S,S* and 2*R*,4*S* diastereomers is −1.52 kJ mol^{-1} in d_4-CH_3OH solution and 3.10 kJ mol^{-1} in d_6-DMSO solution.

An additional NOE experiment was carried out on a d_4-CH_3OH solution of the diastereomers to assign the two diastereotopic methyl groups on C5. Irradiation of the more intense C4-H proton signal at δ 3.82 showed a distinct positive NOE for the CH_3 signal at δ 1.73. Thus C52 was assigned as *cis* to C4-H and C51 at δ 1.44 as *trans* to C4-H in the major (2*R*,4*S*) diastereomer in d_4-methanol.

Molecular shape effects on electron and ion behavior in dielectric liquids: *cis*- and *trans*-butene-2 between the freezing and critical points

SHINICHI SASAKAKI[1] AND GORDON R. FREEMAN
Department of Chemistry, University of Alberta, Edmonton, AB T6G 2G2, Canada
Received December 13, 1993

SHINICHI SASAKAKI and GORDON R. FREEMAN. Can. J. Chem. **72**, 1625 (1994).

Radiolysis free ion yields, electron mobilities, and ion mobilities were measured as functions of applied electric field strength in the liquids *cis*- and *trans*-butene-2 at temperatures from near their freezing points to near their critical points. The dielectric permittivities were also measured, to permit extraction of electron thermalization distances from free ion yield data. The thermalization distance distribution in each liquid was found to be the Gaussian YGP, rather than the exponential YE or YEP. This indicates that electrons are not captured before thermalization in either liquid. The density-normalized thermalization distances $b_{GP}d$ were ~40% larger in *cis*- than in *trans*-butene-2; this correlates with the more globular structure of the *cis*- molecules, which decreases the efficiency of electron energy loss collisions in the liquid phase. Electron mobilities were not appreciably different from those reported earlier. Cation mobilities in the liquids from the freezing points ($T/T_c \approx 0.35$, $d/d_c \approx 3.2$) up to ~400 K ($T/T_c \approx 0.92$, $d/d_c \approx 2.0$) are adequately described by the free-volume model. At densities $d/d_c < 2.0$ the mobilities are smaller than predicted by the free-volume model.

SHINICHI SASAKAKI et GORDON R. FREEMAN. Can. J. Chem. **72**, 1625 (1994).

Opérant à des températures allant de leurs point de congélation à leurs point critiques, on a mesuré les rendements en ions libres, les mobilités des électrons et les mobilités des ions produits, en fonction de la force du champ électrique appliqué, lors de la radiolyse des *cis*- et *trans*-but-2-ènes liquides. On a aussi mesuré les permittivités afin de pouvoir déterminer les distances de thermalisation des électrons à partir des données des rendements en ions libres. On a trouvé que la distribution des distances de thermalisation dans chaque liquide présente une forme gaussienne YGP plutôt qu'une exponentielle YE ou YEP. Ce résultat indique que, dans chacun des liquides, les électrons ne sont pas capturés avant la thermalisation. Les distances de thermalisation normalisées pour la densité, $b_{GP}d$, sont environ 40% plus grandes dans le *cis*- que dans le *trans*-but-2-ène; ce résultat est en bon accord avec la structure plus globulaire des molécules *cis* qui, en phase liquide, diminue l'efficacité des pertes d'énergie par collision. Les mobilités des électrons ne sont pas très différentes de celles rapportées antérieurement. Les mobilités des cations dans les liquides, des points de congélation ($T/T_c \approx 0{,}35$, $d/d_c \approx 3{,}2$) jusqu'à environ 400 K ($T/T_c \approx 0{,}92$, $d/d_c \approx 2{,}0$) sont décrites d'une façon adéquate par le modèle sans volume. À des densités d/d_c inférieures à 2,0, les mobilités sont plus faibles que celles prédites par le modèle de volume-libre.

[Traduit par la rédaction]

Introduction

The present work continues the study of distribution functions of secondary electron thermalization distances in X-irradiated liquids (1). The scattering of low energy electrons in a liquid is strongly dependent on the molecular structure (2). Comparison of electron behaviors in isomeric hydrocarbons is particularly useful, because physical properties such as molar volume and average polarizability are similar, so differences in electron scattering properties can be attributed to differences in molecular shape.

Isomers of special interest are *cis*- and *trans*-butene-2. Previous measurements showed remarkable differences in the radiolytic free ion yields (3, 4) and in the mobilities of thermal electrons (3, 5) in these liquids. It appears that electrons are captured to form transient anions in the *trans*- isomer. However, the free ion yields were measured over a smaller temperature range than more recent studies of other liquids, so it was desirable to extend the temperature range for these butenes.

In the present work, samples of *cis*- and *trans*-butene-2 were sufficiently purified that electrons generated in them had half lives up to 300 μs at low temperatures. Electron and ion mobilities were remeasured as functions of electric field strength at temperatures from the freezing point to near the critical region.

[1]Permanent address: Radiation Safety Control Center, National Laboratory for High Energy Physics (KEK), Oho 1-1, Tsukuba, Ibaraki, Japan 305.

Experimental

A. Sample preparation

cis-Butene-2 (Phillips Research Grade, 99.94%) or *trans*-butene-2 (Phillips Research Grade, 99.75%) was transferred from the cylinder into a grease-free vacuum line, and further purified. Air was removed and the liquid butene was stirred in a flask with lithium aluminum hydride powder for three or more days, then distilled under vacuum onto sodium hydroxide pellets and let stand for three days. Finally, the butene was transferred into a bulb containing sodium–potassium alloy, stirred gently for more than one week, then let sit on the alloy until transfer to the conductance cell. Between successive reagent treatments the butene was degassed by trap-to-trap distillation, with the receiver held at 77 K while pumping on the downstream side.

B. Apparatus and experimental method

Two types of conductance cell were used. The high-pressure conductance cell (HPC) was like that shown in ref. 6, and the low-pressure conductance cell (LPC) like that in ref. 7, except for the geometry of the metal pin lead-throughs. The separation between the electrode plates, 3.23 mm in HPC and 2.60 mm in LPC, were measured directly using precision calipers. The effective area of the collector plate, 2.62 cm^2 in HPC and 8.00 cm^2 in LPC, was determined from capacitance measurement (8) using liquid benzene and air as standards. The cell capacitances obtained using these two standards gave results that agreed within 0.2%.

Before filling with a liquid, the cell was heated to 600 K while evacuating to 10^{-5} Pa.

The temperature of the sample was controlled to within 0.2 K. Details of the cooling (9) and heating (10) systems, and of temperature control and measurement (11, 12) have been reported. The voltage sources and data collection system are described in ref. 12.

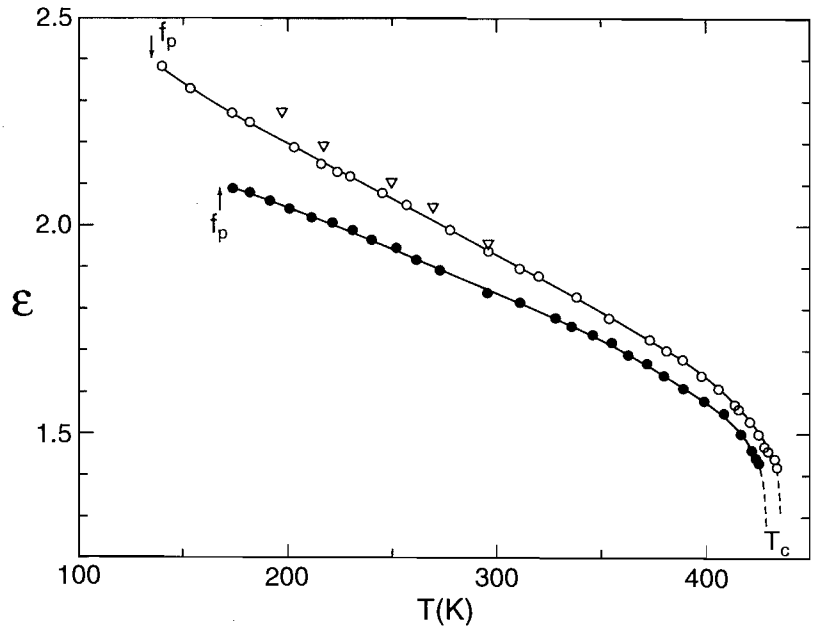

FIG. 1. Relative permittivities ϵ of *cis*- (○) and *trans*-butene-2 (●), measured as a function of temperature. ∇, Previous experimental values for *cis*-butene-2 (8).

To generate ion-electron pairs in the cell, a 0.10 or 1.0 μs pulse of 320 fJ (2 MeV) electrons from a van de Graaff accelerator was stopped in a 3 mm thick gold target to produce X rays. For each pulse a relative dose monitor measured the charge deposited on the gold target by the electron beam. The dose monitor was calibrated by LiF thermoluminescence (13) for each sample.

Ion mobilities were determined by time of flight (12). Electron mobilities were measured either by time of flight or by the electron conductance transient (ECT) method (14).

C. Physical properties

Static relative permittivities ϵ measured by the procedure of ref. 8 are plotted in Fig. 1 and listed in Table 1. The present values for *cis*-butene-2 are 1.0–2.7% lower than those at the same temperature reported in ref. 8.

Values of the liquid densities d of the 2-butenes reported in ref. 15*a* are only estimates; they do not vary sufficiently rapidly with T in the vicinity of the critical temperature T_c, and also the reported value of T_c for *cis*-butene-2 is 3 K lower than a more recent value (15*b*). Measured values of the density of liquid *n*-butane under its vapor pressure have recently been reported for the entire liquid range (15*c*). The liquids *cis*- and *trans*-butene-2 and *n*-butane have similar values of T_c (435.6, 428.6, 425.2 K) and d_c (240, 236, 228 kg/m^3) (15*b*), so densities of the two butenes were calculated from a plot of d/d_c against T/T_c made from the *n*-butane data (15*c*). Values of the densities are listed in Table 1. They are within 1% of those given in ref. 15*a* for *cis*-butene-2 at $226 < T/\mathrm{K} < 390$, and for *trans*- at $240 < T/\mathrm{K} < 400$.

Viscosities η were taken from ref. 15*a*, but they are unreliable near T_c.

Results and discussion

Free ion yields and electron thermalization distances

The electric field dependences of the free ion yields in *cis*- and *trans*-butene-2 at 296 K are shown in Fig. 2. Data obtained from the two cells HPC and LPC agree within 1%.

The lines in Fig. 2 were calculated from an extension (2) of the Onsager model (16). The model permits extrapolation of the yields to zero applied field strength and provides information about the distribution of thermalization distances of the secondary electrons. The free ion yield G_{fi}^E (ion pairs/16aJ) at applied field E(V/m) is given by

$$[1] \qquad G_{fi}^E = G_{tot} \int_{fi}^{\infty} \phi_{fi}^0(y)[1 + f(E, \epsilon, y, T)]F(y)dy$$

where G_{tot} is the total initial yield of ionizations, ϕ_{fi}^0 is fraction of the initial ion–electron pairs that escape geminate neutralization at $E = 0$, $f(E, \epsilon, y, T)$ is a function that describes the field dependence of escape, and $F(y)dy$ is the fraction of secondary electrons that have thermalization distances between y and $y + dy$. The model and eq. [1] are discussed in detail in ref. 2 and more briefly in ref. 17. The gas phase value of G_{tot} = 4.2 ionizations/16aJ was used (2, 18).

The electron thermalization distance distribution function that fits data from most liquids is a three-dimensional Gaussian with a power tail, and is denoted YGP (2):

$$[2] \qquad F(y) = \begin{cases} 0.96\ \mathrm{YG} & y < 2.4\ b_{GP} \\ 0.96[\mathrm{YG} + 0.5(b_{GP}^2/y^3)] & y > 2.4\ b_{GP} \end{cases}$$

where 0.96 is a normalization factor, $\mathrm{YG} = (4y^2/\pi^{1/2}b_{GP}^3)\exp(-y^2/b_{GP}^2)$, and b_{GP} is the most probable value of y.

The lines in Fig. 2 were calculated with eqs. [1] and [2], using b_{GP} = 6.46 nm in *cis*- and 4.72 nm in *trans*-butene-2. The fit is good for both compounds.

The measured yields at the lowest temperatures, near the freezing points, are shown in Fig. 3, and those at the highest temperatures, near the critical points, are shown in Fig. 4.

Several types of thermalization distance distribution function have been used from time to time (2, 19–24). The commonest alternatives to the three-dimensional Gaussian are one-dimensional exponentials. The simple exponential is designated YE:

$$[3] \qquad F(y) = \begin{cases} 0 & y < y_0 \\ b_E^{-1} \exp[(y_0 - y)/b_E] & y > y_0 \end{cases}$$

where y_0 is the reaction distance of the electron and ion and is

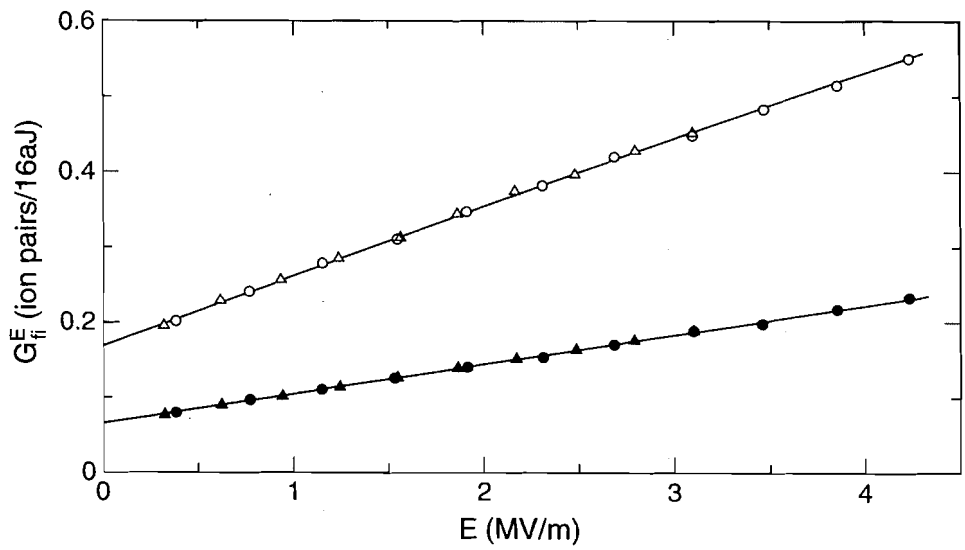

FIG. 2. Free ion yields in *cis*- (open symbols) and *trans*-butene-2 (solid symbols) at 296 K as a function of electric field strength. Results obtained in the LPC (○, ●) and HPC (△, ▲) are shown. The lines were calculated using distribution YGP and $G_{tot} = 4.2$, with $G^0_{fi} = 0.170$ and 0.068 ion pair/16aJ, and $b_{GP} = 6.46$ and 4.72 nm in *cis*- and *trans*-butene-2, respectively.

taken as 1 nm, and b_E is the attenuation coefficient. Another distribution, designated YEP, has a power tail added to YE for the outermost few percent of distances:

[4]
$$F(y) = \begin{cases} 0.97\ \mathrm{YE} & y - y_0 < 3.5\ b_{EP} \\ 0.97[\mathrm{YE} + 0.74\{b_{EP}^2/(y-y_0)^3\}] & y - y_0 > 3.5\ b_{EP} \end{cases}$$

where 0.97 is the normalization factor and b_{EP} replaces b_E in YE.

A Gaussian distribution of thermalization distances might arise from random scattering of electrons by the molecules to which they lose energy. An exponential distribution might arise from electron capture prior to thermalization (2, 21, 24).

Values of the yields calculated using these three distribution functions are shown in Figs. 3 and 4. Only YGP gave values

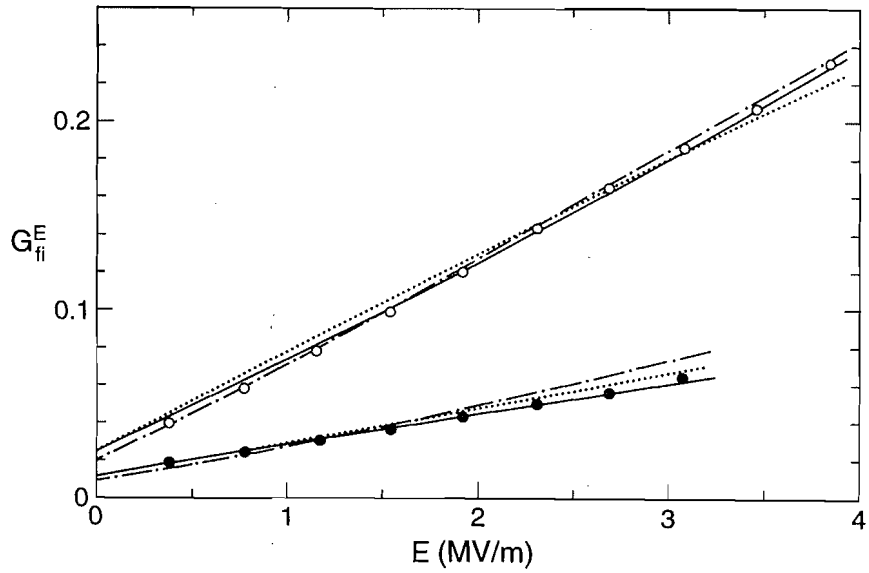

FIG. 3. Free ion yields in *cis*- (○, 140 K) and *trans*-butene-2 (●, 174 K) near the freezing points, as a function of electric field strength in the LPC. The lines were calculated using $G_{tot} = 4.2$ and: —, YGP, $b_{GP} = 5.26$ nm for *cis*-, 3.60 nm for *trans*-; ..., YEP, $y_0 = 1.0$ nm, $b_{EP} = 3.52$ nm for *cis*-, 2.26 nm for *trans*-: – · – ·, YE, $y_0 = 1.0$ nm, $b_E = 4.40$ nm for *cis*-, 3.14 nm for *trans*-.

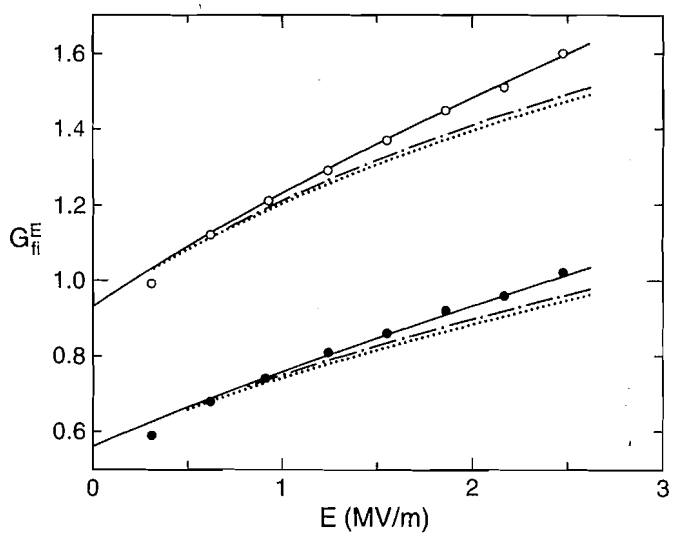

FIG. 4. Free ion yields in *cis*- (○, 434 K) and *trans*-butene-2 (●, 426 K) near the critical temperatures, as a function of electric field strength in the HPC. The lines were calculated using $G_{tot} = 4.2$ and: —, YGP, $b_{GP} = 15.5$ nm for *cis*- and 11.0 nm for *trans*-; ..., YEP, $y_0 = 1.0$ nm, $b_{EP} = 18.2$ nm for *cis*- and 11.2 nm for *trans*-: – · – ·, YE, $y_0 = 1.0$ nm, $b_E = 19.7$ nm for *cis*- and 12.4 nm for *trans*-.

that agreed with the experimental results over the entire temperature range. This indicates that the slowing-down electrons are not permanently captured before becoming thermalized in either *cis*- or *trans*-butene-2 (24).

The values of the most probable thermalization distances b_{GP} and the free ion yields extrapolated to zero applied electric field strength, G_{fi}^{0}, are listed in Table 2. Yields reported in 1973 (4) for these liquids at temperatures 183–293 K were about 25% higher than the present values, due to less accurate dosimetry.

If the efficiencies of the energy-loss collisions of the thermalizing electrons remained constant as the density of the liquid was changed, then the thermalization distance b_{GP} would be inversely proportional to the density; that is, the density-normalized thermalization distance $b_{GP}d$ would remain constant. The values of $b_{GP}d$ in *cis*-butene-2 are about 40% larger than those in the *trans*-isomer (Fig. 5), which means that electron energy-loss collisions are more effective in the latter. The lower efficiency in *cis*- correlates with the greater sphericity of the molecules (4, 25).

The efficiency of the energy-loss collisions increases ($b_{GP}d$ decreases) with increasing liquid density, except at the highest densities in *cis*-butene-2, near the freezing point, where the efficiency decreases ($b_{GP}d$ increases) again (Fig. 5). The behavior in *cis*-butene-2 is similar to that in propane, while that in *trans*-butene-2 is similar to that in ethene or cyclopropane (25). Transient anion formation has been suggested to occur in the latter three liquids (5, 25). Anion formation would be more favorable at the higher densities near the freezing points. The decrease of efficiency in *cis*-butene-2 or propane at the highest densities, as the crystalization temperature is approached, is attributed to a beginning of the ordering of the molecules in the liquid structure. The value of $b_{GP}d$ is larger in the ordered crystal than in the disordered liquid of the same compound (26).

The decrease of electron energy loss efficiency as the density decreases below 700 kg/m^3 is attributed to the looser packing of the liquid molecules, the resulting lower frequency of the intramolecular oscillations, and the reduced magnitude of the short-range electron–molecule interactions. The value of $b_{GP}d$ is determined mainly by inelastic collisions of the electrons at energies <0.1 aJ (2).

Electron mobilities

Electron mobilities in both liquids are independent of electric field strength up to the maximum used, 3.1 MV/m. The values obtained in the present work were virtually the same as those reported earlier (5), and nothing can yet be added to the discussion there.

Ion mobilities

Most of the samples contained a trace of impurity that scavenged some of the electrons. In those cases the ion conduc-

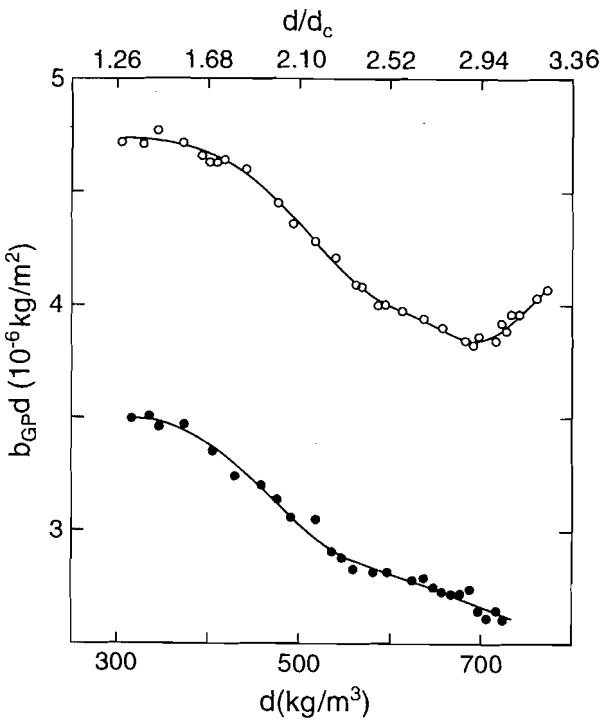

FIG. 5. Density-normalized thermalization distances $b_{GP}d$ plotted against density in *cis*- (○) and *trans*-butene-2 (●).

tance transient (ICT) consisted of a spike at the beginning due to electron conduction, followed by a "ramp" that corresponded to ion conduction, followed by a lower ramp that corresponded to slower ions. The ratio of the two ion mobilities obtained from the ratio of the ramp durations was 1.5 ± 0.1 at all temperatures in *cis*-, and for *trans*- it was 1.5 in the low temperature cell and 1.3 in the high temperature cell. Anion and cation mobilities in several alkanes and cycloalkanes under irradiation have been measured separately, and ratios $\mu_-/\mu_+ = 1.7$–2.2 were found (27, 28). The negative ions in these liquids resulted from electron capture by traces of impurities. We therefore assume that the slowest ions in the butenes were also cations; their mobilities are listed in Table 3.

The ion mobilities were independent of electric field strength up to the maximum used, 3.1 MV/m.

Arrhenius plots of μ_+ are slightly S-shaped (Fig. 6). The temperature coefficients E_μ between about 200 and 300 K are 4.9 kJ/mol in *cis*- and 4.6 kJ/mol in *trans*-; they increase at lower and higher temperatures. However, these temperature coefficients are relatively small, and densities of the liquids decrease greatly as the temperature is raised from near the freezing point to near the critical point. We therefore apply the free-volume model of ion transport (14):

$$[5] \qquad \mu_+ = \frac{A_+}{T^{1/2}} \left(\frac{V - V_0}{V_0} \right) \exp\left(-E_+/RT\right)$$

where A_+ is a constant, V is the molar volume, V_0 is the molar volume at which the liquid molecules are too crowded for diffusion to occur, E_+ is a residual exponential temperature coefficient (see below), and R is the gas constant. Equation [5] provided an adequate description of the ion mobilities in the liquids from their freezing points up to 400 K, above which the calculated mobilities were too high (Fig. 6). The parameter

T_m(K)[a]	287	270

[a] T_m is the temperature in the middle of the range used to estimate E_+.

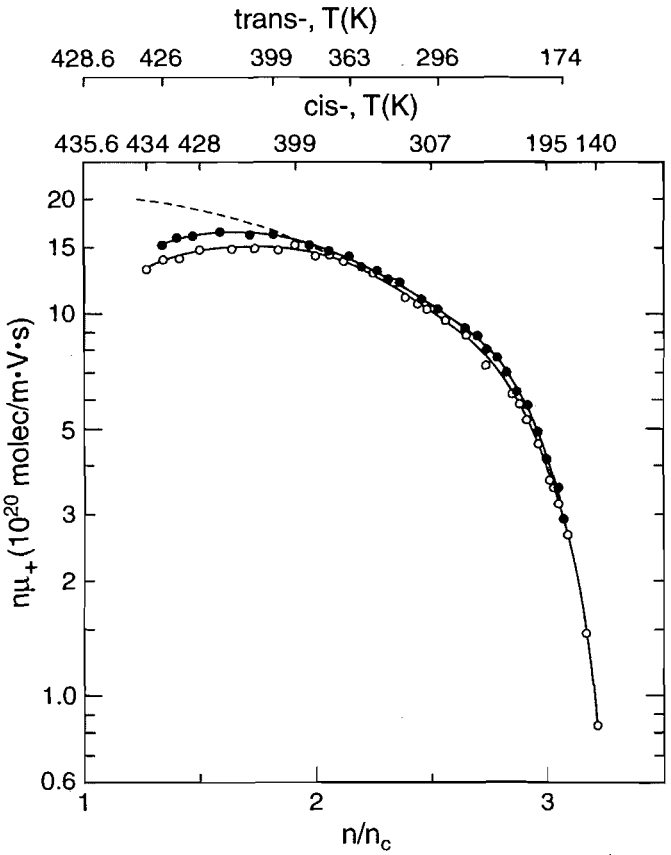

FIG. 7. Density-normalized mobilities as functions of relative number density (n_c is the number density in the critical fluid) in *cis*- (○) and *trans*-butene-2 (●). – – –, calculated from the free-volume model for both *cis*- and *trans*-.

values obtained by fitting eq. [5] to the experimental results up to 400 K are listed in Table 4.

The values $A_+ = 9.9$ and 7.4 (10^{-6} K$^{1/2}\cdot$ m^2/V·s) for radiolytic cations in *cis*- and *trans*-butene-2 are similar to those in the C_6 to C_{11} *n*-alkanes, which are 8–9 (10^{-6} K$^{1/2}\cdot$ m^2/V·s) (14). The value in a quite different liquid, CS_2, is also similar, 11×10^{-6} K$^{1/2}\cdot$ m^2/V·s (14). The similarity of A_+ values over such a wide range of nonpolar liquids (*cis*-butene-2 is slightly polar, with dipole moment 1.0×10^{-30} C·m (15*b*)) indicates that the cations are monomeric.

The values of V_0 correspond to 17.9 and 18.7 cm^3/mol per carbon atom in the molecules of *cis*- and *trans*-butene-2, respectively. They are similar to those for radiolytic cation mobilities in a series of *n*-alkanes, which range from 18.5 in C_6

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12

to 18.3 (cm^3/mol carbon) in C_{11} (14). If the sulfurs in CS_2 are taken as equivalent in volume to methyl groups, the value $V_0/3 = 17.1$ (cm^3/mol C or S) is obtained. This similarity of values again suggests that the cations are monomeric.

The values of E_+ are smaller than the thermal agitation energy RT (Table 4), so they are not typical "activation" energies. The value for *trans*-butene-2 is slightly negative (Table 4), which produces the curvature of the plot near 180 K in Fig. 6. The small exponential term can be thought of as a modifier of the V_0 term; it corresponds to a slight increase of V_0 with T in *cis*-, and to a slight decrease of V_0 with increasing T in *trans*-. This might be related to the stick-like structure of the *trans*- molecules and the more globular structure of the *cis*-. The flexible C_6 to C_{11} *n*-alkane molecules all give positive values of E_+, with $E_+/RT_m = 0.4$–0.6; the relatively globular CS_2 has $E_+/RT_m = 0.3$ (14). This commonality of values again indicates a simplicity in the diverse systems.

At $T \gtrsim 400$ K ($T/T_c \gtrsim 0.92$, in the liquids under their vapor pressure) the free volume model breaks down, which means that liquid viscosity ceases to be the controlling factor for ion mobility (14). In the low density gas phase, the controlling factor for ion mobility is the collision frequency with the gas molecules. Thus the product of ion mobility and number density n of the gas tends to be constant in gases (29). The density-normalized mobilities $n\mu_+$ in the present liquids are plotted against the relative densities n/n_c, where n_c is the number density of the particular critical fluid, in Fig. 7. The dashed line in Fig. 7 indicates values estimated from the free-volume model for both liquids. The model predicts mobilities that are too high at $n/n_c < 2.0$, which corresponds to $T > 400$ K in the liquids under their vapor pressure.

The values of $n\mu_+$ pass through a maximum in the low density liquids at $n/n_c \approx 1.7$ (Fig. 7). This is consistent with earlier reports that the transition from the mechanism of ion transport in normal liquids, which is governed by viscosity or free volume, to the transport mechanism in normal gases, which is governed by collision rate or number density, occurs in the relative density region $2.0 > n/n_c > 0.4 \pm 0.1$ (29–31).

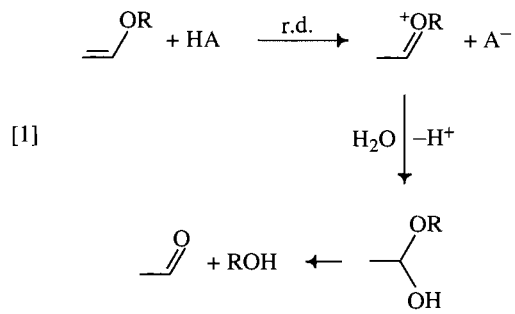
The hydrolysis of *cis*- and *trans*-1-methoxy-1,3-butadiene in aqueous solution occurs by hydron transfer to the δ-carbon atom with little or no β-hydronation to give crotonaldehyde as essentially the sole aldehyde product. The reaction gives appreciable hydronium-ion isotope effects in the normal direction (*cis*: $k_{H^+}/k_{D^+} = 2.60$, *trans*: $k_{H^+}/k_{D^+} = 3.52$) and shows general acid catalysis; five carboxylic acid catalytic coefficients for hydrolysis of the *trans* isomer give a good Brønsted relation with the exponent $\alpha = 0.59$. This is taken as evidence that these reactions occur by the conventional mechanism for vinyl ether hydrolysis involving rate-determining hydron transfer to substrate carbon followed by rapid formation and decomposition of a hemiacetal intermediate. Comparison of the reactivity of the present dienyl ethers with that of their monoenyl analog, methyl vinyl ether, shows that introduction of the second double bond decreases reactivity considerably: the hydronium-ion catalytic coefficient is reduced by a factor of 8.3 for the *trans* isomer and by a factor of 160 for the *cis* isomer. This reduction supports a hypothesis advanced to explain the occurrence of reaction by a different mechanism recently discovered in the hydrolysis of the strongly mutagenic polyenyl ether, fecapentaene-12.

YVONNE CHIANG, ROBERT ELIASON, GARY H.-X. GUO, et A. JERRY KRESGE. Can. J. Chem. **72**, 1632 (1994).

L'hydrolyse des *cis*- et *trans*-1-méthoxybuta-1,3-diènes en solution aqueuse se produit par un transfert d'hydron vers le carbone δ, avec peu ou pas de β-hydronation, et essentiellement il se forme uniquement du crotonaldéhyde comme produit aldéhydique. La réaction donne lieu à des effets isotopiques importants normaux de l'ion hydronium (k_{H^+}/k_{D^+} = *cis* 2,60 et *trans* = 3,52) et elle présente une catalyse acide généralisée; cinq coefficients catalytiques d'acide carboxylique pour l'hydrolyse de l'isomère *trans* donnent une bonne relation de Brønsted, avec un exposant $\alpha = 0,59$. On interprète ces données comme une preuve que ces réactions se produisent par le mécanisme conventionnel d'hydrolyse des éthers vinyliques impliquant, dans l'étape déterminante, un transfert d'hydron vers le carbone du substrat, puis la formation et la décomposition rapide d'un hémiacétal intermédiaire. Une comparaison de la réactivité des éthers diényles utilisés dans cette étude avec celle de leur analogue monoénylique, l'oxyde de méthyle et de vinyle, montre que l'introduction de la deuxième double liaison réduit considérablement la réactivité : le coefficient catalytique de l'ion hydronium est réduit par un facteur de 8,3 avec l'isomère *trans* et de 160 avec l'isomère *cis*. Cette réduction est en accord avec l'hypothèse préconisée pour expliquer l'existence d'une réaction impliquant un autre mecanisme qui a récemment été découverte lors de l'hydrolyse de l'éther polyénylique fortement mutagénique, le fécapentaène-12.

[Traduit par la rédaction]

The hydrolysis of simple vinyl ethers occurs through rate-determining hydron transfer from an acid catalyst to the β-carbon atom of the substrate, followed by rapid steps in which the alkoxycarbocation thus formed is hydrated and the ensuing hemiacetal is cleaved into aldehyde and alcohol products, eq. [1]. No exceptions to this reaction mechanism have so far been



[1]

found for vinyl ethers containing only one carbon–carbon double bond (1, for a brief review of the evidence and references to earlier literature). Recently, however, it was discovered that the acid-catalysed hydrolysis of the polyenyl ether of glycerol, fecapentaene-12, **1**, a strongly mutagenic substance found in human feces and believed to be responsible for colon cancer, gives the unexpected hydroxyaldehyde **2** and allyl alcohol as reaction products, and a mechanism for this reaction involving hydronation of a glycerol hydroxyl group followed by nucleophilic attack of water at the far end of the polyene system, eq. [2], was proposed (2). Further investigation revealed that analogs of **1** containing only one or two double bonds conjugated with the glycerol oxygen reacted normally by the mechanism of eq. [1] and that at least three conjugated double bonds were required for the unusual reactivity (3). Semiempirical calculations were then performed whose results suggested that increasing the number of double bonds in the polyene system raised the rate of reaction by the unusual mechanism, eq. [2], and lowered that by the conventional route, eq. [1], thus rationalizing the observed reaction differences (4).

We have provided experimental support for this hypothesis by studying the hydrolysis of 1-methoxy-1,3-butadiene, **3**: we found that this substance undergoes acid-catalyzed hydrolysis by the conventional mechanism of eq. [1], and that its rate of reaction is indeed slower than that of the monoenyl analog, methyl vinyl ether **4**. This result corroborates a previous, less detailed investigation of the hydrolysis of 1-ethoxy-1,3-butadiene, (5) **5**, whose results, when combined with the rate of hydrolysis of ethyl vinyl ether, (6) **6**, also shows that introduction of the second double bond produces a rate retardation.

Experimental section

Materials

A sample of *trans*-1-methoxy-1,3-butadiene (Aldrich Chemical Company, Inc.) used for kinetic measurements was purified by gas

[1]Part XXVIII: ref. 15.

[2] 
chromatography. The *cis* isomer was prepared by hydrogenation of *cis*-1-methoxybut-1-ene-3-yne (Aldrich Chemical Company, Inc.) using Lindlar catalyst (7), and a sample for kinetics was also purified by gas chromatography. The proton NMR spectra of both materials were consistent with their structures and with a previous report (8).

3-Butenal was prepared by controlled hydrolysis of its dimethyl acetal, itself obtained by reaction of allylmagnesium chloride with trimethylorthoformate (9). Two grams of the acetal (^{1}H NMR ($CDCl_3$), δ/ppm: 2.35–2.45 (2H, m), 3.31 (6H, s), 4.38–4.43 (1H, t), 5.08–5.19 (2H, m), 5.70–5.90 (1H, m)) was added to 10 mL H_2O containing a few drops of HCl (pH 5) and the mixture was shaken vigorously for 10 min. It was then immediately extracted with three 15 mL portions of diethyl ether, the ether extracts were dried with anhydrous $MgSO_4$, and the ether was removed by evaporation. The residue consisted of 60% 3-butenal plus 5% of the isomeric cronaldehyde (*trans*-2-butenal) and 35% of unreacted acetal. A pure sample of 3-butenal was obtained by distillation followed by preparative GC; ^{1}H NMR ($CDCl_3$), δ/ppm: 3.19–3.22 (2H, m), 5.17–5.34 (2H, m), 5.82–6.04 (1H, m), 9.63–9.73 (1H, t).

Cyanoacetic, chloroacetic, methoxyacetic, and acetic acids were purified by distillation; all other materials were best available commercial grades and were used as received.

Product analysis

The hydrolyses of *cis*- and *trans*-1-methoxy-1,3-butadiene were conducted separately by adding 4–6 drops of diene to 1 mL portions of 1.0 M aqueous $HClO_4$ and shaking the initially cloudy mixtures for several hours until they became clear. The mixtures were then extracted with 1 mL portions of $CDCl_3$ and the $CDCl_3$ extracts were dried with anhydrous Na_2CO_3 and their proton NMR spectra were taken.

Kinetics

Rates of hydrolysis of *cis*- and *trans*-1-methoxy-1,3-butadiene were measured spectroscopically by monitoring the decrease in absorbance of these dienyl ethers at λ = 245–250 nm. Measurements were made using a Cary model 2200 spectrometer whose cell compartment was thermostatted at 25.0 ± 0.1°C. Acid or buffer solutions were first allowed to reach temperature equilibrium with the spectrometer cell compartment, reactions were then initiated by injecting 2–5 μL portions of a methanol stock solution of dienyl ether substrate into the cuvette. Substrate concentrations in the reaction mixtures were ca. 10^{-4} M. Continuous recordings of absorbance, made over at least 4–5 half-lives, were fed into a computer and observed first-order rate constants were calculated by least-squares fitting of an exponential function. The data obeyed the first-order rate law well.

An initial-rate method was also used to determine rate constants for the slower reactions. Zero-order rates of change of absorbance, $\Delta A/\Delta t$, were measured for about 1% reaction, and these were then converted to first-order rate constants by dividing by the total absorbance change, $A_0 - A_\infty$, expected for 100% reaction: $k = (\Delta A/\Delta t)/(A_0 - A_\infty)$. Total absorbance changes were determined by first adding, to a cuvette containing only water, the same amount of substrate stock solution as used to determine $\Delta A/\Delta t$ and recording the absorbance of this solution; that gave a value of A_0. This solution was then acidified by adding a (known) small quantity of concentrated perchloric acid, waiting for a time corresponding to at least 10 hydrolysis half-lives, and then making another absorbance reading; this gave a value of A_∞. Substrate concentrations were chosen to make $A_0 - A_\infty$ equal to ca. one absorbance unit and an offset scale of the spectrometer was used to measure $\Delta A/\Delta t$. The method gave good results in agreement with rate determinations made by the conventional method (vide infra).

Results

Reaction products

Acid-catalyzed hydrolysis of 1-methoxy-1,3-butadiene by the route of eq. [1] can occur either by hydronation on the δ-carbon atom to give crotonaldehyde as the reaction product, eq. [3], or by hydronation on the β-carbon to give 3-butenal as the

[3] $CH_2{=}CHCH{=}CHOCH_3 \xrightarrow[H_2O]{H^+} CH_3CH{=}CHCHO + CH_3OH$

[4] $CH_2{=}CHCH{=}CHOCH_3 \xrightarrow[H_2O]{H^+} CH_2{=}CHCH_2CHO + CH_3OH$

reaction product, eq. [4]. We performed a product analysis for this reaction using a modification of a method employed before to determine the proportions of crotonaldehyde and 3-butenal formed in the ketonization of the corresponding enols (10). In that study, acid-catalyzed ketonization was followed by monitoring the absorbance increase at λ = 220 nm, where crotonaldehyde absorbs strongly but 3-butenal is transparent. Upon completion of the ketonization reaction, the final absorbance was recorded and the acidity was then changed to pH = 11, where 3-butenal is isomerized rapidly to crotonaldehyde. This produced an additional absorbance increase, from which, together with the final absorbance reading, the product composition could be calculated.

This method requires that no isomerization of 3-butenal to crotonaldehyde take place during the reaction being investigated. That condition was apparently satisfied in the ketonization study, but vinyl ether hydrolysis is a considerably slower process and we consequently could not assume that the requirement would be met in our case. We therefore determined the rate of acid-catalyzed isomerization of 3-butenal to crotonaldehyde[4] and found that, whereas only 1% isomerization occurred after 10

[4]Measurements at $[HClO_4]$ = 0.0095 and 0.095 M produced the rate law $k_{obs}/s^{-1} = (7.07 \pm 0.06) \times 10^{-6} + (1.11 \pm 0.01) \times 10^{-4}\ [HClO_4]$.

[a]Determined by the initial-rate method.

half-lives of the hydrolysis of *trans*-1-methoxy-1,3-butadiene, the extent of isomerization reached 20% after 10 hydrolysis half-lives of the more slowly reacting *cis*-1-methoxy-1,3-butadiene. Hydrolysis was therefore allowed to go to completion (10 half-lives) in the case of *trans*-1-methoxy-1,3-butadiene, but for *cis*-1-methoxy-1,3-butadiene it was stopped by pH adjustment to 11 after only 1 half-life (which corresponded to 1% isomerization). In the latter case, a minor correction for absorbance of the unreacted *cis*-1-methoxy-1,3-butadiene was included in calculating the product composition.

Determinations performed in 0.095 M $HClO_4$ solutions gave the following results: 99% crotonaldehyde and 1% 3-butenal for the hydrolysis of *trans*-1-methoxy-1,3-butadiene and 98% crotonaldehyde and 2% 3-butenal for the hydrolysis of *cis*-methoxy-1,3-butadiene. The uncertainties in these results are probably similar to the percentages of 3-butenal.

The essentially sole formation of crotonaldehyde as the initial product in these hydrolyses was confirmed by ^1H NMR examination of reactions performed in D_2O solution. Crotonaldehyde was the only aldehyde product detected, and the signal from its aldehydic proton was a clean doublet, produced by spin–spin coupling with a single adjacent vinyl proton, with no sign of the additional triplet structure expected from coupling with an adjacent vinyl deutron; deuterium would, of course, have entered and in part remained at this position if some of the crotonaldehyde observed had been formed by isomerization of initially produced 3-butenal.

This result is somewhat different from that obtained in a previous examination of the hydrolysis of *cis*- and *trans*-1-ethoxy-1,3-butadiene conducted in a 2/5 D_2O/diglyme solvent (5). NMR examination of deuterium incorporation into the crotonaldehyde produced there led to the conclusion that, whereas only crotonaldehyde was formed from the *trans* isomer, some 20% of 3-butenal was made initially from the *cis* isomer. The reason for this difference is not clear.

Kinetics

Rates of hydrolysis of *cis*- and *trans*-1-methoxy-1,3-butadiene were measured in dilute aqueous (H_2O and D_2O) solutions of perchloric and hydrochloric acids. Measurements were made over a range of acid concentrations and replicate determinations were made at each concentration. The data are summarized in supplementary table S1.[5]

[5]Tables S1 and S2 of rate data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A O52.

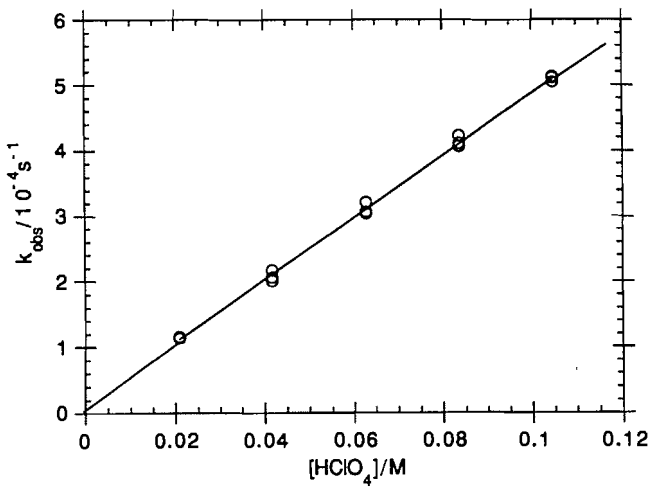

FIG. 1. Relationship between acid concentration and observed first-order rate constants for the hydrolysis of *cis*-1-methoxy-1,3-butadiene in perchloric acid solutions at 25°C.

As Fig. 1 illustrates, observed first-order rate constants proved to be accurately proportional to acid concentration, and second-order catalytic coefficients were therefore evaluated by linear least-square analysis. The results are summarized in Table 1. Combination of the catalytic coefficients for H_2O and D_2O solutions gives the isotope effects $k_{H^+}/k_{D^+} = 3.52 \pm 0.14$ for *trans*-1-methoxy-1,3 butadiene and $k_{H^+}/k_{D^+} = 2.60 \pm 0.09$ for *cis*-1-methoxy-1,3-butadiene.

Rate measurements were also made in carboxylic acid buffer solutions. Series of solutions of constant buffer ratio and constant ionic strength (0.10 M) but varying buffer concentration were used. The data are summarized in supplementary table S2.[5] With the weaker buffer acids this served to hold hydronium-ion concentrations constant, but with the stronger acids buffer failure occurred and hydronium-ion concentrations dropped regularly with decreasing buffer concentration (11). Observed rate constants were therefore adjusted to a common hydronium-ion concentrating using the known hydronium-ion catalytic coefficients determined in the perchloric acid solutions; hydronium-ion concentrations needed for this purpose were obtained by calculation using literature pK_a values for the carboyxlic acids and activity coefficients recommended by Bates (12).

Figure 2 shows that rate constants adjusted in this way are accurately proportional to buffer acid concentration, thus demonstrating the general acid catalysis expected for vinyl ether

For personal use only.

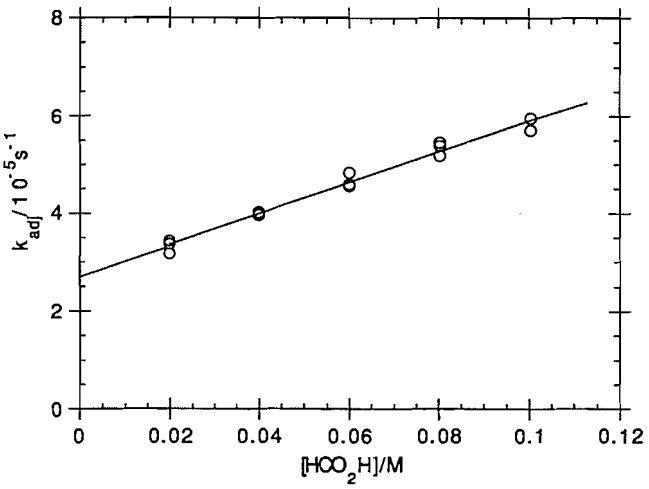

FIG. 2. Relationship between acid concentration and adjusted first-order rate constants for the hydrolysis of *trans*-1-methoxy-1,3-butadiene in formic acid buffer solutions at 25°C.

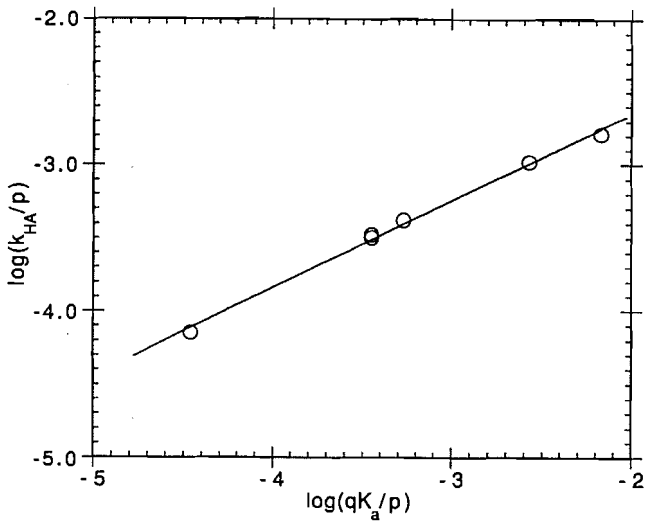

FIG. 3. Brønsted plot for the hydrolysis of *trans*-1-methoxy-1,3-butadiene in carboxylic acid buffer solutions at 25°C.

hydrolysis occurring by the conventional reaction mechanism of eq. [1]. The data were therefore analyzed by linear least-squares fitting of the rate law that applies in this situation, eq. [5]; the general acid catalytic coefficients obtained in this way

$$[5] \quad k_{adj}(\text{or } k_{obs}) = k_{H^+}[H^+] + k_{HA}[HA]$$

are listed in Table 1. They give a good Brønsted correlation, shown in Fig. 3, whose exponent is $\alpha = 0.59 \pm 0.02$.

Rates of hydrolysis of *trans*-1-methoxy-1,3-butadiene in formic acid solutions were determined by both the conventional technique, in which the reactions were allowed to run for several half-lives, and the initial-rate method. The results obtained by these two techniques are in excellent agreement: $k_{adj}/s^{-1} = (2.71 \pm 0.12) \times 10^{-5} + (3.28 \pm 0.17) \times 10^{-4}$ [HA] (conventional method) and $k_{adj}/s^{-1} = (2.72 \pm 0.08) \times 10^{-5} + (3.18 \pm 0.12) \times 10^{-4}$ [HA] (initial-rate method).

Hydronium-ion catalytic coefficients were also extracted from the buffer solution data by dividing the intercepts of eq. [5], $k_{H^+}[H^+]$, by the known hydronium-ion concentrations of these buffers. This produced six values for *trans*-1-methoxy-1,3-butadiene, whose average, $k_{H^+} = (9.50 \pm 0.40) \times 10^{-2}$ M^{-1} s^{-1}, agrees well with the result obtained in perchloric acid solutions, $k_{H^+} = (9.13 \pm 0.20) \times 10^{-2}$ M^{-1} s^{-1}. The single value obtained for *cis*-1-ethoxy-1,3-butadiene, $k_{H^+} = 5.21 \times 10^{-3}$ M^{-1} s^{-1}, is also consistent with the perchloric acid result for that substrate, $k_{H^+} = 4.75 \times 10^{-3}$ M^{-1} s^{-1}.

Discussion

Reaction mechanism

We have found that the hydrolysis of both *cis*- and *trans*-1-methoxy-1,3-butadiene gives strong hydronium-ion isotope effects in the normal direction ($k_H/k_D > 1$) and shows general acid catalysis. This is classic evidence for rate-determining hydron transfer to carbon (11), and it shows that these reactions occur by the conventional mechanism for vinyl ether hydrolysis shown in eq. [1]. This, of course, is the expected result, inasmuch as the newly discovered unusual mechanism of eq. [2] requires the presence of a hydroxyl group in the saturated alkyl portion of the vinyl ether, which is absent from the present substrates.

Reactivity

The hydronium-ion catalytic coefficients determined here show 1-methoxy-1,3-butadiene to be considerably less reactive than its monoenyl analog, methyl vinyl ether: comparison of $k_{H^+} = 0.76$ M^{-1} s^{-1} for the latter substance (13) with the present results gives a rate retardation of 1/8.3 for *trans*-1-methoxy-1,3-butadiene and 1/160 for *cis*-1-methoxy-1,3-butadiene. These rate ratios are similar to those that may be obtained from measurements of the rates of hydrolysis of *cis*- and *trans*-ethoxy-1,3-butadiene in 80% aqueous dioxane at single acid concentration (5) in combination with the rate constant reported for the hydrolysis of ethyl vinyl ether in the same medium (6); that comparison gives rate retardations of 1/7.2 and 1/103 for the *trans* and *cis* isomers, respectively, in the ethoxy series. These rate retardations provide good evidence for the hypothesis that the switch from the conventional mechanism for vinyl ether hydrolysis to the new mechanism shown in eq. [2] occurs in part because introduction of additional conjugated double bonds slows reaction by the conventional mechanism.

It is not clear, however, why hydrolysis of the present dienyl ethers should be slower than that of their monoenyl analog. Introduction of a second double bond in conjugation with the first will stabilize the vinyl ether, lowering the free energy of the initial state of the hydrolysis reaction. If this stabilization is lost in the transition state by hydron transfer to the α-carbon atom (eq. [4]), then the energy difference between initial state and transition state will increase and the reaction will be slowed. In the present case, however, hydronation takes place essentially exclusively on the δ-carbon atom, giving an allyl-type alkoxycarbocation, eq. [5]. The additional stabilization this will pro-

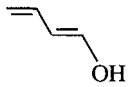
$$[5] \quad CH_2{=}CHCH{\equiv}CHOCH_3 \xrightarrow{H^+} CH_3\overset{+}{C}HCH{=}CHOCH_3 \leftrightarrow CH_3CH{=}\overset{+}{C}HCHOCH_3$$

duce should outweigh that conferred on the initial state, and that will lower the energy difference between initial state and transition state and raise the rate of reaction. We can offer no explanation for this apparent paradox.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

It is curious that in both the methoxy and the ethoxy series, the *trans* butadienyl ethers are considerably more reactive than their *cis* counterparts. This is opposite to the reactivity pattern shown by alkyl-substituted monoenyl ethers: in the latter case the *cis* isomers are more reactive than the *trans* (6), a difference that can be attributed to the greater thermodynamic stability of the *trans* isomer (14). The *trans* isomers are also more stable than the *cis* in the case of the butadienyl ethers (14), which makes the greater reactivity of the *trans* isomers all the more surprising.

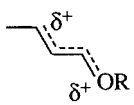
A similar difference in reactivity is shown by the butadienyl enols themselves: the *trans* isomer, **7**, has been found to



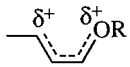
7

8

undergo acid-catalyzed ketonization by rate-determining hydron transfer from the hydronium ion 5.5 times more rapidly than the *cis* isomer, **8** (10). Hydronation here is also predominantly on the δ-carbon atom, and it has been suggested that the *trans* isomer is the more reactive because the incipient hydroxy-substituted allyl cation being formed in its transition state can more easily attain a planar configuration (10). It seems likely, however, that a Coulombic effect also operates, for the partial positive charges at oxygen and the γ-carbon atom of this cation will be farther apart in the ion formed from the *trans* isomer, **9**, than in that derived from the *cis*, **10**. This will make the *trans*



9



10

cation more stable than the *cis*, and a similar difference in the transition states leading to these cations will make the *trans* enol or enol ether more reactive than its *cis* counterpart.

The kinetics of formation of the thioester involved as an intermediate in the reaction between chromium(VI) and DL-penicillamine in aqueous media (pH = 1–8) containing different buffers (acetate, citrate, and phosphate) has been studied by monitoring the disappearance of chromium(VI) at 370 nm and application of the initial-rates method. The initial rate is directly proportional to the initial concentrations of both oxidant and reductant, and the rate vs. pH plots show bell-shaped profiles. The reaction is catalyzed by the buffer present in the medium, the catalytic power of each buffer increasing in the order acetate < citrate < phosphate. This is explained in terms of a mechanism involving the formation of a complex between the acidic form of the buffer and $HCrO_4^-$ previous to the formation of the thioester. Potassium chloride and sodium sulfate do not seem to have important specific effects on the reaction rate, their effect being that of an acceleration of the reaction as the ionic strength increases. On the contrary, the sulfates of magnesium, manganese(II), and zinc (the latter only in the presence of acetate buffer) have specific effects, indicating the probable formation of several complexes. The spectrophotometric detection of the thioester at 430 nm has allowed to confirm some of the conclusions extracted from the measurement of initial rates, and suggests that this intermediate might approach a steady-state behavior in the three buffers at pH > 6.25, and also that a bimolecular reaction with DL-penicillamine might be involved in its destruction.

JOAQUIN F. PEREZ-BENITO, DRISS LAMRHARI et CONCHITA ARIAS. Can. J. Chem. **72**, 1637 (1994).

En examinant la vitesse de disparition du chrome(VI) à 370 nm et en appliquant la méthode des vitesses initiales, on a étudié la cinétique de formation du thioester impliqué comme intermédiaire dans la réaction du chrome(VI) et la DL-pénicillamine, en milieu aqueux (pH = 1 à 8) contenant divers tampons (acétate, citrate et phosphate). La vitesse initiale est directement proportionnelle aux concentrations à la fois de l'oxydant et du réducteur et les courbes des vitesses en fonction du pH présentent des profils en forme de cloche. La réaction est catalysée par le tampon présent dans le milieu, le pouvoir catalytique de chacun des tampons augmentant dans l'ordre acétate < citrate < phosphate. On peut expliquer ces résultats en fonction d'un mécanisme impliquant la formation, avant la formation du thioester, d'un complexe entre la forme acide du tampon et le $HCrO_4^-$. Le chlorure de potassium et le sulfate de sodium ne semblent pas avoir d'effets spécifiques importants sur la vitesse de la réaction; leur effet se limite à une accélération de la réaction lorsque la force ionique augmente. Au contraire, les sulfates de magnésium, de manganèse(II) et de zinc (dans ce dernier cas, uniquement en présence du tampon acétate) possèdent des effets spécifiques, suggérant la formation probable de plusieurs complexes. La détection spectrophotométrique du thioester à 430 nm a permis de confirmer quelques-unes des conclusions tirées des mesures des vitesses initiales et elle suggère que cet intermédiaire peut approcher un comportement d'état stationnaire dans les trois tampons, à des pH > 6,25, et aussi qu'une réaction bimoléculaire avec la DL-pénicillamine peut être impliquée dans sa destruction.

[Traduit par la rédaction]

Introduction

The kinetics of reduction of chromium(VI) by the aminoacid DL-penicillamine (DL-2-amino-3-mercapto-3-methylbutanoic acid) and other thiols was studied in perchloric acid media by McAuley and Olatunji (1), reporting the spectrophotometric detection of an oxidant–reductant thioester involved as a relatively-stable intermediate. More recently, some interest has arisen on the kinetics and mechanism of this and similar reactions at physiological pH, since it seems probable that the mutagenic effects of the well-known carcinogen chromium(VI) require its previous reduction inside the cell, and glutathione and other biological thiols seem to be likely candidates as reductants (2, 3).

We have studied the reaction between chromium(VI) and DL-penicillamine in aqueous solutions under slightly acidic or neutral conditions. Our results indicate that the kinetics of formation of the corresponding thioester depends notably on the nature and concentration of the buffer present in the medium, and that some electrolytes have important specific effects on that formation.

Experimental section

Materials and methods

The solvent water was purified by deionization followed by double distillation (the first time from a potassium permanganate solution). The oxidant was potassium dichromate (although, under the conditions of this work, most of it was present in the solutions in the monomeric forms, $HCrO_4^-$ and CrO_4^{2-}). The reductant was DL-penicillamine (DL-PA). Three types of buffer were used: citric acid (H_3Cit) – sodium citrate (Na_3Cit), acetic acid (HAc) – sodium acetate (NaAc), and KH_2PO_4–K_2HPO_4 (in some experiments, the acid of each buffer mixture was replaced by HCl). The ionic strength was controlled when necessary with KCl. Besides this electrolyte, the effects of Na_2SO_4, $MgSO_4$, $MnSO_4$, and $ZnSO_4$ on the reaction rate were also studied.

The kinetics of the reaction was followed by monitoring the chromium(VI) decay at 370 nm with a Varian Cary 219 UV-VIS spectrophotometer. The formation and decay of the thioester intermediate were detected by following the reaction at 430 nm. The pH of the solutions was measured with a Metrohm 605 pH-meter provided with a combination electrode.

Determination of initial rates

In order to avoid that the reaction be too fast to be followed with a conventional spectrophotometer, in most of the experiments the concentration of DL-penicillamine was not large enough to assure a first-order decay of the reaction rate as the concentration of chromium(VI) decreased. Moreover, in some of the experiments designed to study the effect of the buffer, the concentration of the latter was so low that the pH of the solution increased appreciably as the reaction proceeded. A further deviation from the behavior expected for a first-

order kinetics was provoked by the relative stability of the thioester involved as intermediate.

Because of these reasons, the kinetic data for the reaction were obtained by application of the initial-rates method. The absorbances measured at 370 nm from the beginning of the reaction until around 25% of the initial chromium(VI) was destroyed were fitted against time by nonlinear least squares to the equation:

$$[1] \qquad \ln (A_t - A_\infty) = a + bt + ct^2$$

A_t and A_∞ being the absorbances at time t and at the end of the reaction, respectively, whereas a, b, and c are fitting parameters. The initial rate was then obtained as:

$$[2] \qquad r_0 = -b[\mathrm{Cr(VI)}]_0$$

The kinetic data given in this work are the averages of two independent determinations. Their reproducibility was assured in most cases within ± 1%.

Results

Stoichiometry

A spectrophotometric search for the stoichiometry was undertaken, mixing chromium(VI) and DL-penicillamine (RSH) in different proportions in citrate buffer (pH = 6.01) and allowing the solutions to react until completion. After one week, the absorbance at 370 nm was measured and, when represented against the reductant/oxidant ratio, it led to a curve instead of to a linear plot. The minimum ratio required for total consumption of chromium(VI) was $[\text{DL-PA}]_0/[\mathrm{Cr(VI)}]_0 = 2.3$. The results of this study (deposited as supplementary material[1]) are in agreement with those found by McAuley and Olatunji (1) in perchloric acid media, and suggest that at low values of that ratio there is a deviation from the main stoichiometry:

$$[3] \qquad 2HCrO_4^- + 6RSH + 8H^+ = 2Cr^{3+} + 3RSSR + 8H_2O$$

probably due to overoxidation of the main organic product (the disulfide, RSSR).

Kinetic data

The initial rate (r_0) was directly proportional to the initial concentrations of both oxidant and reductant (Table 1), thus allowing the determination of the second-order rate constants as $k_2 = r_0/[\mathrm{Cr(VI)}]_0[\text{DL-PA}]_0$. The initial rate vs. pH plots showed a certain dependence on the nature of the buffer (acetate, citrate, or phosphate), although in the three cases they had a bell-shaped profile with a maximum at pH = 5.5–6.0 (Fig. 1); similar bell-shaped rate vs. pH plots were also obtained by Connett and Wetterhahn (4) for the chromium(VI) oxidation of other thiols.

At constant pH, the second-order rate constants increased with the total concentration of buffer ($[B]_T$) according to the law (Fig. 2):

$$[4] \qquad k_2 = \frac{a' + b'[B]_T}{1 + c'[B]_T}$$

The dependences of the fitting parameters a', b', and c' on the pH have been studied; the data corresponding to both a' and b' are shown in Fig. 3, whereas those for c' have been deposited.[1] Parameter b' is a good measurement of the catalytic power of each buffer, which is in the sequence acetate < citrate < phosphate. Due to the fact that the reaction in the presence of phosphate buffer was very fast, accurate values of parameters a' and c' could be obtained only for the other two buffers. Parameter a' is an extrapolation of the second-order rate constant at zero concentration of buffer, and it should thus be independent of the buffer used; however, we can see that there is a slight deviation in the values corresponding to acetate and citrate buffers, indicating the existence of a small systematic error, although the two sets of values seem to be rather consistent. For the same buffers, parameter c' increased with increasing pH, being this effect much more pronounced for acetate than for citrate.

The influences of several electrolytes on the reaction rate have been investigated. Given that addition of those electrolytes resulted either in an increase or a decrease of the pH,

the effect of this change in pH was minimized by working near the maximum of the rate vs. pH plots (Fig. 1), where the rate is fairly independent of pH.

Potassium chloride accelerates the reaction both in acetate and citrate buffers, but much more in the latter case. The effect of sodium sulfate in acetate buffer is very similar to that of

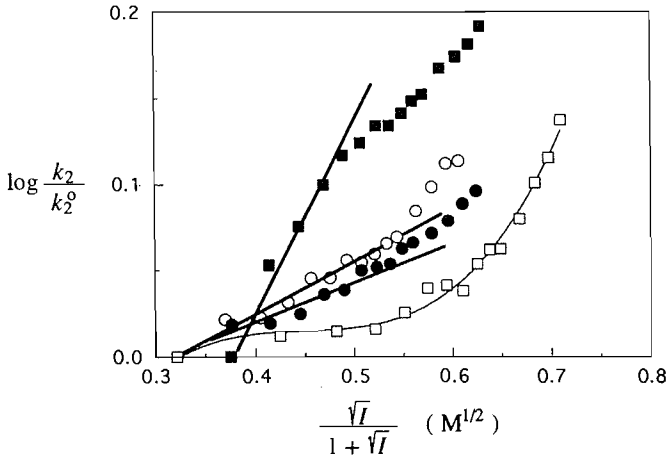

FIG. 4. Dependence of the second-order rate constant on the ionic strength for the reaction between chromium(VI) (5.15×10^{-4} M) and DL-penicillamine (4.80×10^{-3} M) at 25.0°C, k_2^0 being the value of the second-order rate constant corresponding to the ionic strength of the buffer, in the absence of any added electrolyte. Buffers: for the solid squares, Na_3Cit (5.58×10^{-2} M) – HCl (2.42×10^{-2} M); for the other three cases, NaAc (0.20 M) – HCl (2.42×10^{-2} M). Electrolytes: potassium chloride (solid squares, pH = 5.84–5.52, ionic strength 0.359 M + [KCl]; solid circles, pH = 5.53–5.62, ionic strength 0.224 M + [KCl]); sodium sulfate (open circles, pH = 5.53–5.48, ionic strength 0.224 M + 3 [Na_2SO_4]), and magnesium sulfate (open squares, pH = 5.53–5.07, ionic strength 0.224 M + 4 [$MgSO_4$]).

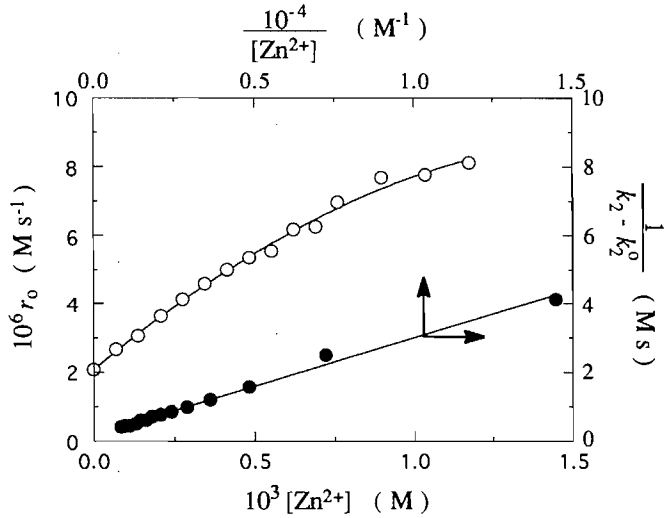

FIG. 5. Influence of the concentration of zinc sulfate on the kinetics of the reaction between chromium(VI) (5.15×10^{-4} M) and DL-penicillamine (4.80×10^{-3} M) in the presence of HAc (2.80×10^{-2} M) – NaAc (0.20 M) buffer at ionic strength 0.21 M, pH 5.50 ± 0.02 and 25.0°C. Open circles: r_0 vs. $[Zn^{2+}]$ plot. Solid circles: $1/(k_2 - k_2^0)$ vs. $1/[Zn^{2+}]$ plot, k_2^0 being the value of the second rate constant corresponding to the reaction in the absence of zinc ion. Except when indicated, the x and y axes are those situated below and on the left, respectively.

potassium chloride in the same buffer, but magnesium sulfate increases the reaction rate much less than expected from the ionic strength values (Fig. 4).

Zinc sulfate also accelerates the reaction in acetate buffer (Fig. 5), but this seems to be a catalytic effect, since it is much more pronounced than would be expected from the corresponding ionic strength values (this magnitude changed only a 2% between the extreme experiments). This effect seemed

to be specific of the acetate buffer, since it was not observed when the buffer was of the citrate type.

Manganese(II) ion is known to act either as a catalyst (5, 6) or (more frequently) as an inhibitor (7–9) of many chromium(VI) reactions. In the case of the Cr(VI)/DL-PA reaction, it seems to have both effects. At low reductant concentration an acceleratory effect of manganese(II) sulfate was observed, whereas at higher reductant concentrations the effect was clearly inhibitory (Table 2). In those experiments, both the total sulfate concentration and ionic strength were kept constant by adequate additions of zinc sulfate ($[ZnSO_4] + [MnSO_4] = 1.61 \times 10^{-2}$ M). To that end, it was first checked that zinc ion did not behave in the presence of citrate buffer as it did in that of acetate (see Fig. 5). Moreover, some of the series were repeated keeping the ionic strength constant with sodium sulfate instead of zinc sulfate, and the results obtained were notably similar, thus indicating that the kinetic effect shown in Table 2 was caused by manganese(II) ion.

The second-order rate constants fulfilled the Arrhenius law for the three buffers. The apparent activation parameters corresponding to the maximum in the rate vs. pH plot for each buffer (see Fig. 1) have been determined (deposited[1]).

Determination of the ionization constant of hydrogenchromate ion

The values of the initial absorbance at 370 nm, A^0_{370}, at different pHs (deposited[1]) allowed us to determine the value of the pK_a of hydrogenchromate ion at 2.1-M ionic strength (KCl). The buffer did not seem to affect significantly that equilibrium constant, since for the three buffers the value obtained was within the range $pK_a = 5.75 \pm 0.01$. This agrees well with the value reported by Connett and Wetterhahn at 0.5-M ionic strength (KCl), $pK_a = 5.98$ (4).

Detection of the thioester intermediate

As shown in Fig. 6, the oxidant–reductant thioester intermediate was stable enough for its accumulation and decay to be detected spectrophotometrically at 430 nm (1, 10). The influence of several experimental variables on the maximum absorbance observed at that wavelength was studied (deposited[1]). The maximum absorbance was directly proportional to the initial concentration of oxidant but was independent of that of reductant. In the presence of acetate buffer, it increased with additions of zinc sulfate to the solutions.

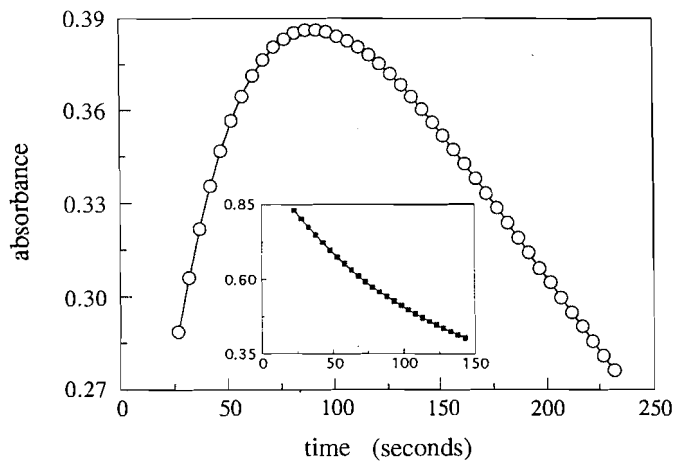

FIG. 6. Absorbance at 430 nm vs. time plot for the reaction between chromium(VI) (5.15×10^{-4} M) and DL-penicillamine (4.80×10^{-3} M) in the presence of HAc (2.80×10^{-2} M) – NaAc (0.20 M) buffer and zinc sulfate (2.77×10^{-4} M) at ionic strength 0.21 M, pH = 5.48 ± 0.01 and 25.0°C. Inset: absorbance at 370 nm vs. time plot for the same conditions.

At constant pH, the maximum absorbance increased with increasing concentration of buffer, the data being conveniently fitted to 2nd-degree polynomial:

[5] $$A^{max}_{430} = a'' + b''[B]_T + c''[B]_T^2$$

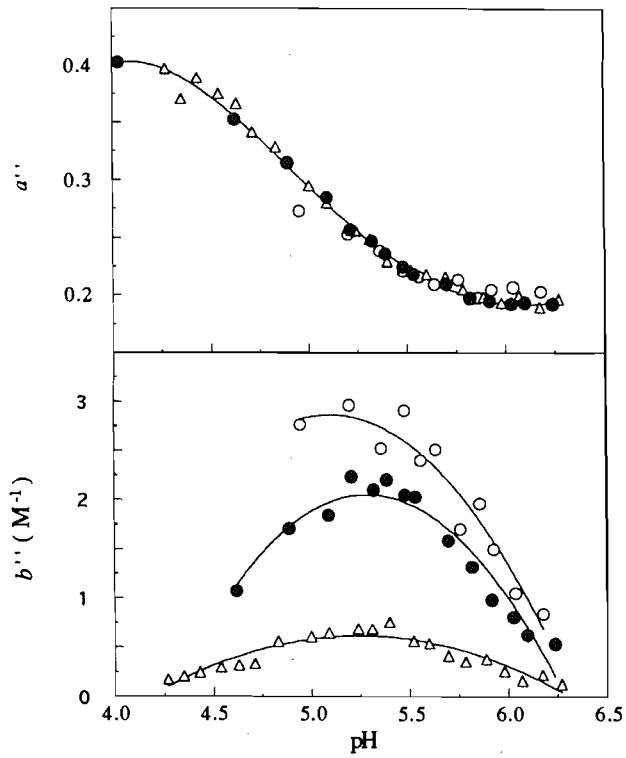

FIG. 7. Dependence of parameters a'' (above) and b'' (below) on the pH for the reaction between chromium(VI) (5.15×10^{-4} M) and DL-penicillamine (4.80×10^{-3} M) at ionic strength 2.1 M (KCl) and 25.0°C. Buffers: HAc–NaAc ([acid]/[base] = 0.01–2.44), triangles; H_3Cit–Na_3Cit ([acid]/[base] = 0.02–1.00), solid circles; and KH_2PO_4–K_2HPO_4 ([acid]/[base] = 1.25–25.00), open circles.

Parameter a'' is the value of the maximum absorbance that would be expected in the absence of any buffer, and the values extrapolated from the three buffers are quite consistent (Fig. 7, above). The stability of the intermediate decreased with increasing pH, and it could not be detected at pH > 6.25, suggesting that at neutral or basic pH the intermediate is in a steady state. On the other hand, it can also be seen in Fig. 7 (below) that the b'' vs. pH curves were very similar to the b' vs. pH plots (Fig. 3, below), since in both cases they showed bell-shaped profiles. Moreover, the sequence acetate < citrate < phosphate could be observed at any fixed pH for both parameters b' and b''.

Discussion

Mechanism in the absence of buffer

Given the pK_a values for hydrogenchromate ion (5.75, see above) and for the different ionizable groups of DL-penicillamine (1.8 for $-CO_2H$, 7.9 for $-NH_3^+$ and 10.5 for –SH) (11), within the pH range corresponding to the study of parameters a' and b' (pH = 4.3–6.5, see Fig. 3) there were two predominant forms of the oxidant (hydrogenchromate and chromate ions) and only one of the reductant (the zwitterionic form containing the groups $-CO_2^-$, $-NH_3^+$, and –SH). The mechanism that can be proposed for formation of the thioester intermediate in the absence of buffer is that corresponding to hydrogenchromate ion as the active form of the oxidant:

$$[6] \qquad CrO_4^{2-} + H^+ \overset{K_I}{\rightleftharpoons} HCrO_4^-$$

$$[7] \qquad HCrO_4^- + RSH \underset{\text{slow}}{\overset{k_{II}}{\longrightarrow}} RSCrO_3^- + H_2O$$

The rate law that can be deduced from this mechanism is:

$$[8] \qquad r = \frac{K_I k_{II}[Cr(VI)]_T[RSH][H^+]}{1 + K_I[H^+]}$$

where $[Cr(VI)]_T = [HCrO_4^-] + [CrO_4^{2-}]$. The expression corresponding to parameter a' (eq. [4]) is:

$$[9] \qquad a' = \frac{K_I k_{II}[H^+]}{1 + K_I[H^+]}$$

From eq. [9] it follows that parameter a' must increase with decreasing pH, reaching a plateau when $K_I[H^+] \gg 1$. Since the pK_a value for hydrogenchromate ion under the conditions of our work is 5.75, the plateau is expected to be found at pH < 4.75, in good agreement with Fig. 3 (above), leading to the value $k_{II} = 0.28 \pm 0.01$ M^{-1} s^{-1}. Moreover, the mechanism proposed also agrees well with the experimental data extrapolated for the maximum absorbance of the thioester intermediate in the absence of buffer, since a decrease in the pH is expected to result in an increase of the rate of formation of that intermediate (due to the protonation of CrO_4^{2-} to give the active form of the oxidant, $HCrO_4^-$), and the experimental data indicate that the intermediate accumulates much more at low values of the pH (Fig. 7, above).

Connett and Wetterhahn (2) have shown that there is a good correlation between the rate constant for formation of the thioester intermediate and the pK_a for ionization of the mercapto group of the thiol, so that the rate constant increases with increasing acidity of that group. The above mechanism can easily explain this finding if we take into consideration that in the transition state corresponding to the rate-determining step (eq. [7]) the hydrogen atom of the —SH group is already partially protonated to give (with an —OH group of the hydrogenchromate ion) a molecule of water.

Mechanism in the presence of buffer

We have seen in Fig. 1 that the pH dependence of the initial rate is rather complex, but the experimental data (Fig. 3) indicate that the complexity is not present if the reaction occurs in the absence of buffer, and can only be found when the reaction is performed in the presence of buffer. Therefore, the mechanism proposed for the reaction in the presence of buffer has to be more complex than that proposed above for the reaction in the absence of buffer. The catalytic effect that the different buffers can exert on the reaction (Fig. 2) can be explained in terms of the following mechanism:

$$[10] \qquad B + H^+ \overset{K_{III}}{\rightleftharpoons} A$$

$$[11] \qquad HCrO_4^- + A \overset{K_{IV}}{\rightleftharpoons} C + H_2O$$

$$[12] \qquad C + RSH \overset{K_V}{\rightleftharpoons} D$$

$$[13] \qquad D + OH^- \underset{\text{slow}}{\overset{k_{VI}}{\longrightarrow}} RSCrO_3^- + B + H_2O$$

where A and B stand, respectively, for the acidic and basic forms of the buffer, whereas C and D are two different complexes.

In the case of acetate buffer, A is a molecule of acetic acid and B an acetate ion. In the case of phosphate buffer, A = $H_2PO_4^-$ and B = HPO_4^{2-}. However, since the three pK_a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

of citric acid differ from each other much less than those of phosphoric acid (12), in the case of citrate buffer the roles of A and B may be played by several species with different degrees of protonation.

Chromium(VI) is known to form condensation complexes similar to C with a great variety of organic (13) and inorganic (14) substances. In particular, condensation of $HCrO_4^-$ and $H_2PO_4^-$ leads to $[HO_3P—O—CrO_3]^{2-}$ (15, 16).

The rate law deduced from the mechanism proposed is

$$[14] \qquad r = \frac{K_W K_I K_{III} K_{IV} K_V k_{VI} [Cr(VI)]_T [RSH][B]_T [H^+]}{(1 + K_I[H^+])(1 + K_{III}[H^+])}$$

where K_W is the water ionic product, $[Cr(VI)]_T = [HCrO_4^-] + [CrO_4^{2-}]$ and $[B]_T = [A] + [B]$. Thus, the expression corresponding to parameter b' (eq. [4]) is

$$[15] \qquad b' = \frac{K_W K_I K_{III} K_{IV} K_V k_{VI} [H^+]}{(1 + K_I[H^+])(1 + K_{III}[H^+])}$$

From eq. [15] it follows that parameter b' must take near-zero values in both very acidic and very alkaline solutions, and it must present a maximum at a certain pH which is a function of the pK_a of both hydrogenchromate ion and the acidic form of the buffer (A), which agrees well with the b' vs. pH plots found for the three buffers (Fig. 3, below). When the solution is acidified starting from pH = 6.5, parameter b' is found to increase first and then to decrease; according to the mechanism proposed, the initial increase is due to protonation of both the oxidant (eq. [6]) and buffer (eq. [10]), since complex C formed from the acidic forms of those two species (eq. [11]) presents a strong reactivity toward the reductant (eq. [12]); however, complex D formed in eq. [12] needs to react with a hydroxyl ion to yield the thioester intermediate $RSCrO_3^-$ (eq. [13]), what explains that, at low values of the pH, a further increase of the acidity of the medium results in a decrease of parameter b'. Moreover, Fig. 7 (below) confirms the existence of a certain pH at which the effect of the concentration of each buffer on the accumulation of the thioester intermediate is optimal.

In the case of acetate buffer, since A is a molecule of acetic acid, complex C must be an anion with electrostatic charge −1 (see eq. [11]), and so must be complex D (see eq. [12]), since RSH is a zwitterionic molecule containing the groups $—CO_2^-$ and $—NH_3^+$. Therefore, the rate-determining step (eq. [13]) is a reaction between two like-charged ionic species, which explains the increase of the second-order rate constant with increasing ionic strength (Fig. 4). Moreover, the effect of potassium chloride is more intense with citrate buffer than with acetate, what suggests that the role of the acidic form of citrate buffer (A) is played by a negatively charged species (H_2Cit^- or $HCit^{2-}$) rather than by a neutral molecule (H_3Cit). Hence, in the case of citrate buffer, complexes C and D have an electrostatic charge of −2 or −3.

Although the mechanism proposed for the reaction in the presence of buffer is indeed in agreement with many experimental features of the reaction, the meaning of parameter c' (eq. [4]) is difficult to explain. At first view, one might think that this parameter is a consequence of the saturation that can be expected for the equilibrium depicted in eq. [11], since at high values of the buffer concentration the reaction must approach a situation where all the chromium(VI) has been complexed by the acidic form of the buffer and, so, a further increase in the total concentration of buffer does not result in an increase of the reaction rate. However, this interpretation does not agree well with the experimental behavior, since in that case a decrease of parameter c' with increasing pH would be expected (the complexation occurs between the acidic forms of the oxidant and buffer), and the situation observed was exactly the opposite.

An alternative explanation would be possible if we assume that there is a small reactivity between the basic form of the oxidant (CrO_4^{2-}) and the reductant (RSH), and that the contribution of this pathway to the total rate of formation of the thioester intermediate becomes important at pH > 6.5, where most of the chromium(VI) is present in the basic form. Furthermore, it has to be assumed also that CrO_4^{2-} can be complexed by the basic form of the buffer (B), and that the resulting complex is rather unreactive toward RSH, just the opposite of what occurs with complex C formed from the acidic forms of the oxidant ($HCrO_4^-$) and buffer (A) (see eqs. [11] and [12]). Although this explanation does not seem to us entirely satisfactory (the complexation cannot occur by condensation when B is an acetate ion), the A^0_{370} vs. pH plots indicated that the absorbance of the plateau corresponding to the basic form of the oxidant depends very definitely on the nature of the buffer present in the medium, what might indicate the existence of a complexation equilibrium between the basic forms of the oxidant and buffer. Moreover, the maximum absorbance was observed for acetate buffer, for which a rapid increase of parameter c' with increasing pH has been found.

Mechanism in the presence of zinc and acetate

We have seen in Fig. 5 that, when the reaction takes place in the presence of acetate buffer (but not in that of citrate), the initial rate increases very markedly with increasing concentration of zinc ion, and that this happens at concentrations of zinc sulfate too low to be explained by an effect of ionic strength. This catalytic effect can be explained by the following mechanism involving as intermediate a complex of zinc ion with both acetate and hydrogenchromate ions:

$$[16] \qquad Zn^{2+} + Ac^- + HCrO_4^- \overset{K_{VII}}{\rightleftharpoons} Ac^- - Zn^{2+} - HCrO_4^-$$

$$[17] \qquad Ac^- - Zn^{2+} - HCrO_4^- + RSH \underset{\text{slow}}{\overset{k_{VIII}}{\longrightarrow}} RSCrO_3^- + Zn^{2+} + Ac^- + H_2O$$

and leading to the following rate law:

$$[18] \qquad r = \frac{K_{VII} k_{VIII} [Cr(VI)]_T [RSH][Ac^-][Zn^{2+}]}{1 + K_{VII}[Ac^-][Zn^{2+}]}$$

where $[Cr(VI)]_T = [HCrO_4^-] + [Ac^-—Zn^{2+}—HCrO_4^-]$. Thus, the expression corresponding to the dependence of the second-order rate constant on the concentration of zinc ion is

$$[19] \qquad \frac{1}{k_2 - k_2^0} = \frac{1}{k_{VIII}} + \frac{1}{K_{VII} k_{VIII} [Ac^-]} \frac{1}{[Zn^{2+}]}$$

where k_2^0 is the value of the second-order rate constant in the absence of zinc ion. From the intercept and slope of the $1/(k_2 - k_2^0)$ vs. $1/[Zn^{2+}]$ linear plot (see Fig. 5), it can be deduced that $K_{VII} = (2.8 \pm 0.6) \times 10^3\ M^{-2}$ and $k_{VIII} = 5.6 \pm 1.0\ M^{-1}\ s^{-1}$. A comparison of the latter value to the above determined $k_{II} = 0.28 \pm 0.01\ M^{-1}\ s^{-1}$ indicates that the reaction between RSH and $Ac^-—Zn^{2+}—HCrO_4^-$ (eq. [17]) is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

twenty times faster than that between RSH and free $HCrO_4^-$ (eq. [7]). Moreover, the measurements of A_{430}^{max} confirmed that the accumulation of the thioester intermediate increases with increasing concentration of zinc ion in the presence of acetate buffer.

Mechanism in the presence of manganese(II) ion

It can be seen in Table 2 that when the ratio between the initial concentrations of reductant and oxidant is about 3 (corresponding to the stoichiometric ratio, according to eq. [3]) manganese(II) has a slight catalytic effect on the reaction, but when that ratio equals 7 the effect of that ion is inhibitory instead, and the inhibition observed is more intense as the reductant/oxidant ratio increases. Actually, manganese(II) ion is known to be an inhibitor for many chromium(VI) redox reactions, due to its ability to act as a trapping agent for the intermediate chromium(IV) (17); however, the maximum decrease in the reaction rate that can be expected from this effect is 50% (9), and for a reductant/oxidant ratio ≥ 34 we have observed that the inhibitory effect of manganese(II) ion on the chromium(VI)/DL-PA reaction exceeds that limit (and it would be probably larger at higher values of the reductant/oxidant ratio). Therefore, we must conclude that manganese(II) ion has other effects on the reaction aside from the trapping of chromium(IV).

The experimental findings can be explained if we assume that manganese(II) ion may form two different complexes, one with both the oxidant and the reductant and the other only with the reductant. Then, the mechanism of formation of the thioester intermediate catalyzed by manganese(II) ion at low values of the reductant/oxidant ratio would be:

$$[20] \qquad Mn^{2+} + HCrO_4^- + RSH \overset{K_{IX}}{\rightleftharpoons} [Mn(HCrO_4)(RSH)]^+$$

$$[21] \qquad [Mn(HCrO_4)(RSH)]^+ \xrightarrow[slow]{k_X} RSCrO_3^- + Mn^{2+} + H_2O$$

leading to the following rate law:

$$[22] \qquad r = K_{IX}k_X[HCrO_4^-][RSH][Mn^{2+}]$$

However, as the reductant/oxidant ratio increases, the complex formed in eq. [20] would be replaced by the one formed in this other equilibrium:

$$[23] \qquad Mn^{2+} + 2RSH \rightleftharpoons [Mn(RSH)_2]^{2+}$$

and, if we assume that this new complex is much less reactive toward the oxidant to form the thioester intermediate than the free RSH molecule, the inhibitory effect of manganese(II) ion at high values of the reductant/oxidant ratio would be easily explained.

Moreover, we have seen in Fig. 4 that the increase observed in the second-order rate constant when magnesium sulfate was added to the solution (especially at low concentrations of this electrolyte) was much lower than the increase expected from the ionic strength values (compare the data corresponding to $MgSO_4$ to those corresponding to Na_2SO_4 and KCl in the same buffer). This suggests that magnesium ion might form a complex with DL-penicillamine similar to that formed in eq. [23], so that the increase of the second-order rate constant with increasing ionic strength might be partially compensated by the inhibitory effect caused by Mg^{2+}. We can thus conclude that DL-penicillamine seems to have a notable capacity for the complexation of divalent cations, which is probably due to the zwitterionic character of the predominant form of the reductant for the pH range studied.

Destruction of the thioester intermediate

Although the kinetic data reported in this work are related only to the formation of the thioester intermediate and not to its destruction, the data corresponding to the measurement of the accumulation of $RSCrO_3^-$ can give us some evidences (albeit indirect) on the way of disappearance of this intermediate. Effectively, we have observed that, for the conditions of our experiments, the maximum absorbance measured at 430 nm (A_{430}^{max}) was directly proportional to the initial concentration of oxidant but was independent of that of the reductant. This suggests that, whereas hydrogenchromate ion is involved only in the formation of the thioester intermediate (see eq. [7]), the thiol is involved in both its formation and destruction, the latter according to the reaction:

$$[24] \qquad RSCrO_3^- + RSH \longrightarrow HCrO_3^- + RSSR$$

It should be noticed that, although we have written the intermediate chromium(IV) formed in eq. [24] as $HCrO_3^-$, there is no information in the literature on the predominant form of this species in slightly acidic or neutral aqueous solutions. In fact, $HCrO_3^-$ might react with the solvent to yield CrO^{2+}, which is known to be the predominant form of chromium(IV) in perchloric acid media (9, 18).

The thioester intermediate may also disappear by the reaction opposite to its formation (the reaction depicted in eq. [7] is reversible). Furthermore, although a bimolecular reaction of the thioester with a second RSH molecule to yield chromium(IV) and the disulfide RSSR (eq. [24]) is in agreement with most reports on the reactions between chromium(VI) and several thiols (1, 2, 4), O'Brien and Wang (19) have indicated that at low thiol concentrations the predominant pathway for the redox disappearance of the thioester is its unimolecular decomposition to yield chromium(V) (20–22) and the free radical RS· (22). Therefore, eq. [24] would be predominant only at high concentrations of RSH.

Received November 16, 1993

This paper is dedicated to Professors Ian Spenser and David B. MacLean

ROBERT L. WHITE, KEVIN C. SMITH, and ALPHONSE C. DEMARCO. Can. J. Chem. **72**, 1645 (1994).

The biosynthesis of 5-hydroxy-4-oxo-L-norvaline (HON) in *Streptomyces akiyoshiensis* has been investigated using ^{13}C-labelled substrates. Incorporations of ^{13}C label from sodium [1-^{13}C]-, [2-^{13}C]-, and [1,2-$^{13}C_2$]acetate indicated that HON was formed from a four-carbon compound derived from the citric acid cycle and the methyl carbon of acetate. Feeding experiments using DL-[4-^{13}C]- and DL-[2-^{13}C,^{15}N]aspartate demonstrated that aspartate served as the four-carbon precursor to HON. Both enantiomers of aspartate were metabolized by *S. akiyoshiensis*, but the D isomer was consumed at a slower rate. The distribution of ^{13}C label in the intracellular L-glutamic acid isolated in these feeding experiments is consistent with the operation of the citric acid cycle in *S. akiyoshiensis*. A biosynthetic hypothesis that involves a condensation reaction between acetyl or malonyl CoA and the β-carboxyl group of aspartate, and subsequent oxidative decarboxylation, is proposed to account for the incorporation results. An analogous condensation step has been proposed for the biosynthesis of other natural products, including the carbapenem antibiotics. DL-[2-^{13}C,^{15}N]Aspartate was synthesized from [2-^{13}C]diethylmalonate and potassium [^{15}N]phthalimide via diethyl [2-^{13}C,^{15}N]phthalimidomalonate.

ROBERT L. WHITE, KEVIN C. SMITH et ALPHONSE C. DEMARCO. Can. J. Chem. **72**, 1645 (1994).

Utilisant des substrats marqués au ^{13}C, on a étudié la biosynthèse de la 5-hydroxy-4-oxo-L-norvaline (HON) dans le *Streptomyces akiyoshiensis*. Les incorporations de marqueur ^{13}C des [1-^{13}C]-, [2-^{13}C]- et [1,2-$^{13}C_2$]-acétates de sodium indiquent que la HON se forme à partir d'un composé contenant quatre atomes de carbone qui serait dérivé du cycle de l'acide citrique et du carbone méthylique de l'acétate. Des expériences impliquant l'addition de DL-[4-^{13}C]- et DL-[2-^{13}C,^{15}N]aspartates ont permis de démontrer que l'aspartate sert de précurseur à quatre atomes de carbone pour la HON. Les deux énantiomères de l'aspartate sont métabolisés par le *S. akiyoshiensis*, toutefois l'isomère D est consommé plus lentement. La distribution du marqueur ^{13}C dans l'acide L-glutamique intracellulaire isolé de ces expériences est en accord avec l'opération du cycle de l'acide citrique dans le *S. akiyoshiensis*. Pour expliquer les résultats d'incorporation, on propose une hypothèse biosynthétique qui implique une réaction de condensation de l'acétyl ou du malonyl CoA avec le groupe β-carboxylique de l'aspartate, suivie d'une décarboxylation oxydante. Une étape de condensation analogue a été proposée pour la biosynthèse d'autres produits naturels, y compris des antibiotiques du carbapénème. On a synthétisé le DL-[2-^{13}C,^{15}N]aspartate à partir du [2-^{13}C]malonate de diéthyle et du [^{15}N]phtalimide de potassium, via le [2-^{13}C,^{15}N]phtalimidomalonate de diéthyle.

Introduction

The amino acid 2-amino-5-hydroxy-4-oxopentanoic acid, also known as 5-hydroxy-4-oxonorvaline or HON (**1**), was discovered during a search for the production of antitubercular antibiotics by strains of Streptomyces (1). Subsequently, it was isolated from the culture broth of *Streptomyces akiyoshiensis*, and its structure was assigned (1, 2) and confirmed by chemical synthesis (3). More recently, other synthetic routes have been explored in several laboratories (4), and HON has been reisolated from a *Streptomyces* sp. as the antifungal agent RI-331 (5).

The antifungal activity of HON has been attributed to the inhibition of protein biosynthesis caused by depletion of amino acids in the aspartate family (6). More specifically, HON has been shown to inhibit homoserine dehydrogenase (7), an enzyme needed for the conversion of aspartate to isoleucine, methionine, and threonine. An earlier report that HON had no effect on the biosynthesis of aspartic acid and asparagine in tumour cells (8) is consistent with the above observations. Although no mechanism for the inhibition of *Mycobacterium tuberculosis* and *M. bovis* by HON was suggested by the initial investigators (9), it may have been also due to enzyme inhibition, since HON was subsequently shown to be a competitive inhibitor of δ-aminolevulinic acid dehydratase isolated from *M. phlei* (10), an enzyme required for the biosynthesis of porphyrins.

HON is a member of a group of natural products known as nonprotein or unusual amino acids. These amino acids, as a group, possess a wide array of chemical structures, and often contain functional groups not commonly present in natural products (11). The structural diversity of the group means that many different and unrelated biosynthetic routes are needed for their formation. The biosynthetic precursor(s) of HON are not obvious, even though HON contains only five carbon atoms. If another amino acid serves as a precursor, then three general biosynthetic routes to HON are possible: degradation of a larger amino acid, functional group modification of another five-carbon amino acid, and chain extension of a smaller amino acid. Also, because HON contains a hydroxyketone functional group that is present in many carbohydrates, routes starting from carbohydrate or polyketide precursors, with addition of nitrogen at a later stage, can be envisioned. The aim of this investigation was to establish the biosynthetic origin of HON (12, for a preliminary communication of this work).

Results and discussion

As a prelude to biosynthetic experiments, the production of HON (**1**) by *S. akiyoshiensis* (ATCC 13480) was confirmed and its parameters established. Analysis by hplc (13), using pre-column derivatization with *o*-phthalaldehyde (OPA), demonstrated

[d]Two distinct peaks were obtained when this sample was co-chromatographed with the corresponding standard L isomer.

that one major metabolite containing a primary amino group accumulated between 48 and 120 h of incubation in cultures of *S. akiyoshiensis* growing on a medium containing starch and Pharmamedia as carbon and nitrogen sources, respectively. The metabolite was isolated from the culture broth (1, 2) by cation-exchange chromatography (Amberlite IR-120, H^+ form, NH_3 elution) and was separated from acidic amino acids (14) by anion-exchange chromatography (Dowex 1-X8, CH_3COO^- form). Treatment of the metabolite with periodate generated aspartate (**2**) and formaldehyde (Scheme 1): a characteristic reaction (2) of HON (**1**). The formaldehyde was trapped as its dimedone derivative (**3**), and aspartate was separated by anion-exchange chromatography (Dowex 1-X8, CH_3COO^- form, CH_3COOH elution) from neutral and basic amino acids and salts. Each compound isolated was characterized by spectroscopic methods.

The stereochemistry of the aspartic acid isolated was determined by an hplc method for the separation of diastereomeric OPA/*N*-acetylcysteine derivatives of amino acids (15) in which the mobile phase was adjusted to provide a baseline separation of D and L enantiomers. As shown in Table 1, aspartate (**2**) obtained by periodate cleavage of HON eluted as a single peak with a retention time (21.3 min) corresponding to that of L-aspartate (21.4 min), and separated from D-aspartate when a mixture of the sample and authentic D-aspartic acid was chromatographed. Analogous results were obtained when the anal-

[b]% HON formed in culture after the addition of labelled substrate. Calculated using chromatographic peak areas and based on the total amount of HON accumulated extracellularly during the experiment.
[c]Calculated from the amount of aspartic acid isolated.
[d]Calculated from the amount of 4,5-dihydroxynorvaline lactone HCl isolated.

ysis was repeated using the β-methyl ester of aspartate, but longer and more variable retention times were observed. These results confirmed the L configuration previously assigned (2) to HON (**1**) and, since the aspartate sample derived from HON contained less than 1% D-aspartic acid, established that *S. akiyoshiensis* produces only one enantiomer of the metabolite.

In subsequent experiments, HON (**1**) in culture supernatants was reduced with sodium borohydride (Scheme 1); the resulting mixture of 4,5-dihydroxynorvalines (**4***a* and **4***b*) was isolated by cation- and anion-exchange chromatography, and converted in concentrated HCl (2) to a mixture of diastereomeric γ-lactones (**5***a* and **5***b*). The presence of diastereomers was apparent in the ^{13}C nmr spectrum, which exhibited two peaks of similar chemical shift for each of the five γ-lactone carbons.

Glutamic acid was identified as the major intracellular amino acid of *S. akiyoshiensis* by hplc analysis of ethanolic mycelial extracts. The glutamic acid was isolated by anion-exchange chromatography (Dowex 1-X8, CH_3COO^- form, CH_3COOH elution), and its structure was confirmed by spectroscopic analysis. The L configuration was assigned to the intracellular glutamate after chiral hplc analysis as described for aspartate (Table 1). The sample isolated chromatographed as a single peak with a retention time (16.3 min) equivalent to that of authentic L-glutamic acid (15.5 min), and was separated from authentic D-glutamic acid. Moreover, more than 99% of the intracellular glutamic acid was present as the L enantiomer.

To distinguish among the speculative biosynthetic pathways to HON outlined above, aqueous solutions of ^{13}C-labelled substrates were administered to cultures of *S. akiyoshiensis*. As described in Table 2, the labelled substrates were added in two or more equal portions over a period of 24–30 h; the first addition was made after detection by hplc of a small amount of HON in the culture supernatant. Incubation was continued for an additional 24 h. HON was isolated from the resulting culture broth (Scheme 1) either as aspartic acid (C-1 to C-4 of HON) and formaldehyde (C-5 of HON) or as an intact five-carbon unit (i.e., 4,5-dihydroxynorvaline γ-lactone). Glutamate in mycelial extracts was separated from aspartate and recovered by chromatography on two successive anion-exchange columns. All ion-exchange separations were monitored by hplc. Isolated compounds were recrystallized prior to the determination of ^{13}C enrichments by nmr analysis, and sodium malonate was included in the amino acid samples as an internal standard because enrichment of all carbon atoms in these small molecules was possible.

As a general precursor of cellular metabolites, acetate provided an indication of the metabolic reactions involved in HON formation. As shown in Table 3, HON derived from [1-^{13}C]acetate (Expt. 1) was enriched in two carbons (C-1 and C-4), whereas in HON derived from [2-^{13}C]acetate all five carbons were enriched (Expt. 2). Equal enrichments (within the experimental error of nmr peak height comparisons) were evident for C-1 and C-4 in both experiments, and for C-2 and C-3 in the [2-^{13}C]acetate experiment. Also, the incorporation of label from [2-^{13}C]acetate into either C-2 or C-3 was larger than that into either C-1 or C-4. This enrichment pattern would be expected (16) if ^{13}C label from acetate were incorporated via the four-carbon intermediates of the citric acid cycle, and suggests that one of these (i.e., succinate, fumarate, malate, or oxaloacetate), or a substance derived from it (e.g., aspartate), is the precursor of C-1 to C-4 in HON. A more direct route from the methyl group of acetate to C-5 is suggested by the larger ^{13}C enrichment (2.8 versus ≤1.7%) observed at this position by both nmr and mass spectrometry (Expt. 2).

The C4 + C1 origin of HON indicated by the results of the initial experiments was tested by feeding [1,2-$^{13}C_2$]acetate (Expt. 3). Four-carbon intermediates generated by the first turn of the citric acid cycle would be expected to exhibit ^{13}C–^{13}C

[a]Enrichment (%) = 1.1(enrichment factor) − 1.1. The enrichment factor is the ratio of the normalized intensity of an individual peak in the spectrum of the enriched sample to the normalized intensity of the corresponding peak in the natural abundance ^{13}C nmr spectrum acquired using identical instrumental parameters. Peak normalization is described in the experimental section. The standard deviation of the peak heights for the natural abundance carbons in formaldehyde dimethone is given in parentheses.

[b]For Expts. 1, 2, and 4, C-1–C-4 correspond to C-1–C-4, respectively, of aspartate and C-5 corresponds to the central methylene of formaldehyde dimethone. For Expts. 3 and 5, the five carbons of HON correspond to those in 4,5-dihydroxynorvaline γ-lactones.

[c]Calculated from the relative intensities of the M^+ and the M + 1 ions in the mass spectrum of formaldehyde dimethone (**3**). The standard deviation calculated from the intensities measured in several scans is given in parentheses.

[d]Coupled signals in 4,5-dihydroxynorvaline γ-lactones: $^1J_{CC}$ = 53.1 and 54.0 Hz.

[e]Coupled signals in 4,5-dihydroxynorvaline γ-lactones: $^1J_{CC}$ = 32.0 and 33.0 Hz.

[f]Coupled signals: $^1J_{CC}$ = 52.8 Hz.

[g]Coupled signals: $^1J_{CC}$ = 51.0 Hz.

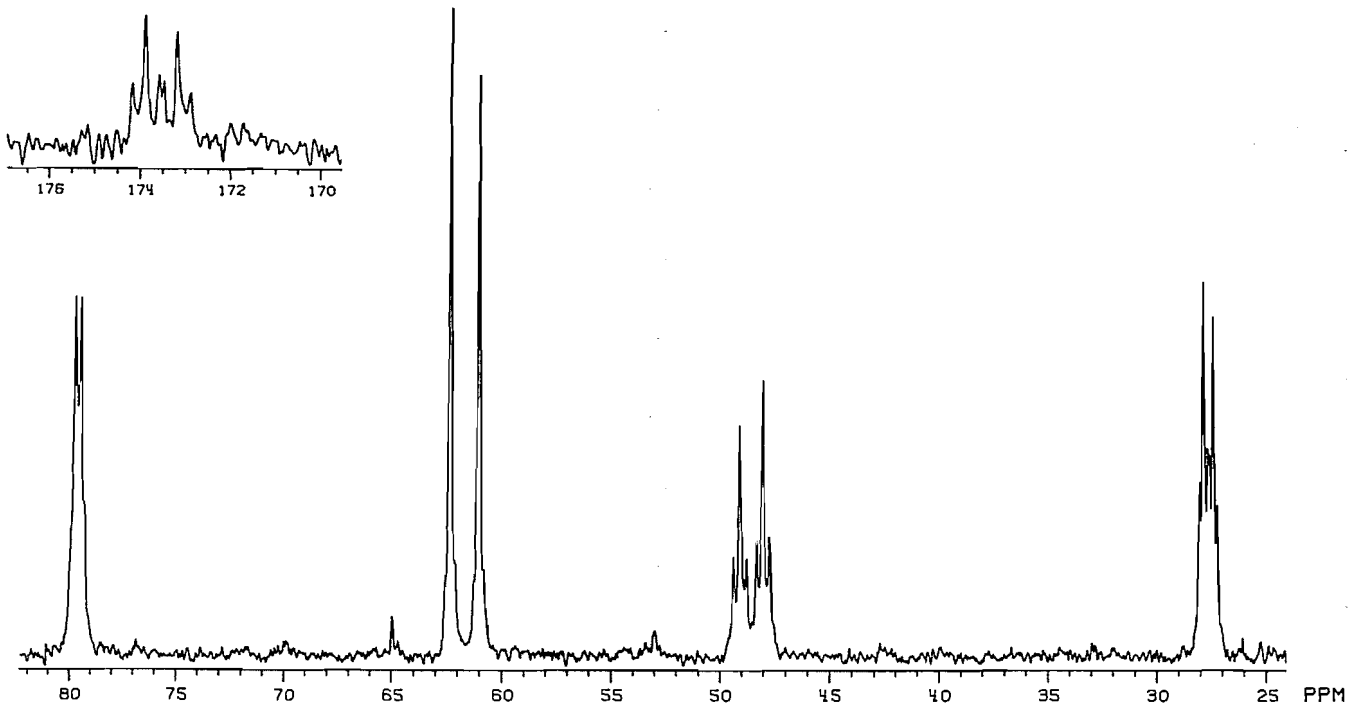

FIG. 1. The ^{13}C nmr spectrum of the mixture of diastereomeric 4,5-dihydroxynorvaline lactones showing coupled carbons derived from intact incorporation of [$^{13}C_2$]acetate into HON (Expt. 3).

coupling between C-1,C-2 and C-3,C-4 due to the symmetry of succinate and fumarate, and this pattern would be maintained on incorporation into HON. The fifth carbon in HON should not be coupled. The results of the feeding experiment (Table 3 and Fig. 1) support this interpretation. Coupling was observed between C-1,C-2 ($^1J_{CC}$ = 53.1 and 54.0 Hz) and C-3,C-4 ($^1J_{CC}$ = 32.0 and 33.0 Hz) in the 4,5-dihydroxynorvaline lactones (**5***a* and **5***b*) derived from HON, and C-5 was enriched (relative to the C-4 singlet), but not coupled.

Since *S. akiyoshiensis* accumulated relatively large amounts of L-glutamic acid, this provided an independent means of verifying that the labelled substrates were metabolized via the citric acid cycle. In each experiment, glutamate was isolated from 80% ethanol extracts of the mycelium and separated from aspartate by anion-exchange chromatography. The timing of the addition of labelled substrates was not optimized for incorporation into glutamate, and low or negligible incorporations of singly labelled acetates were observed (Expts. 1 and 2, Table 3). However, the ^{13}C nmr spectrum of glutamate isolated from *S. akiyoshiensis* fed [1,2-$^{13}C_2$]acetate (Expt. 3, Table 3) exhibited

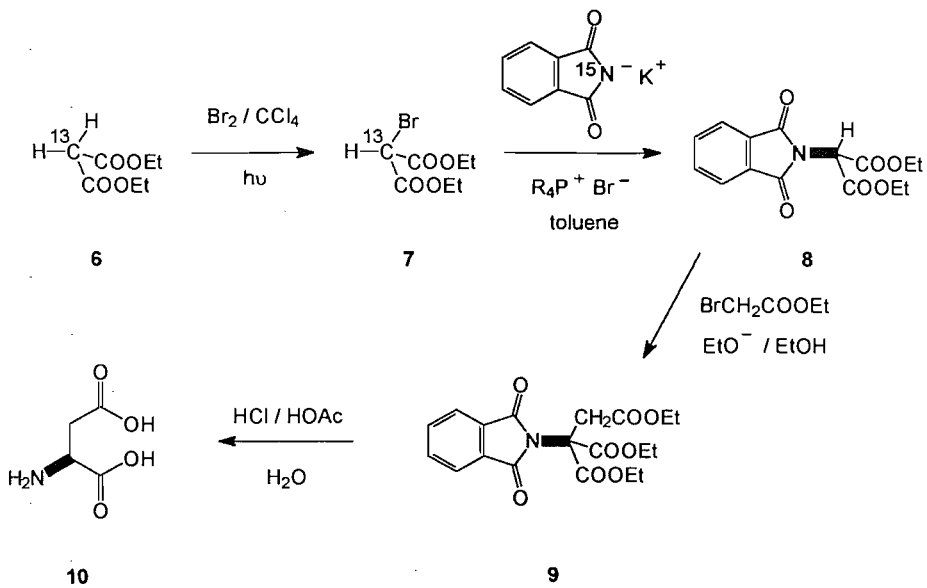

SCHEME 2. Synthesis of DL-[2-^{13}C,^{15}N]aspartic acid.

doublets superimposed on natural abundance singlets for C-1, C-2, C-4, and C-5, demonstrating the presence of ^{13}C–^{13}C coupling between C-1,C-2 (52.8 Hz) and C-4,C-5 (51.0 Hz)[2] and the intact incorporation of acetate units. Enrichment was observed for C-3, but no satellite signals were detected in the ^{13}C nmr spectrum. Incorporation of [1,2-$^{13}C_2$]acetate via the citric acid cycle (16) would provide α-ketoglutarate labelled at C-4,C-5 (coupled) on the first turn of the cycle, and at C-1,C-2 (coupled) and C-3 (not coupled) on the second turn. The coupled units would be broken up on subsequent turns of the cycle. Glutamate, formed from α-ketoglutarate by reductive amination or transamination, would maintain the pattern of coupling and enrichment in α-ketoglutarate. Therefore, the ^{13}C-incorporation patterns observed were consistent with the synthesis of glutamate from acetate via citrate, isocitrate, and α-ketoglutarate.

To distinguish among the possible four-carbon precursors of HON, label was introduced to this group using an asymmetric source, aspartic acid. Direct incorporation of aspartate (or another asymmetric precursor) labelled in one carbon should enrich a single carbon, whereas incorporation via a symmetrical molecule would place label equally in two positions. Of the four possible singly labelled aspartates, [4-^{13}C]aspartate was chosen (Expt. 4) because it was commercially available and no metabolic randomization of label was expected, since ^{13}C label in oxaloacetate derived from [4-^{13}C]aspartate would be lost as carbon dioxide after the first few steps of the citric acid cycle. As shown in Table 3, label from DL-[4-^{13}C]aspartate was incorporated mainly into C-4 of HON, but also to a smaller extent into C-1.[3] The incorporation of ^{13}C label mainly into C-4 of HON demonstrated that oxaloacetate, malate, or aspartate, and not a symmetrical four-carbon intermediate of the citric acid cycle, served as the C4 precursor of HON. The smaller ^{13}C enrichment at C-1 would be expected if a portion of the administered DL-[4-^{13}C]aspartate had been converted to a symmetrical citric acid cycle intermediate (e.g., fumarate) either via oxaloacetate and malate or directly by the action of carbon–nitrogen lyases such as aspartate ammonia lyase, EC 4.3.1.1 (18), argininosuccinate lyase, EC 4.3.2.1, and adenylosuccinate lyase, EC 4.3.2.2 (19). An equal distribution of ^{13}C at C-1 and C-4 would be obtained for the aspartate, malate, and oxaloacetate synthesized from carboxyl-labelled fumarate.

A distinction between aspartate and the citric acid cycle intermediates, oxaloacetate and malate, as HON precursors required a doubly labelled sample of aspartate to investigate the intact incorporation of the C—N bond in aspartate. The required DL-[2-^{13}C,^{15}N]aspartate (**10**) was synthesized (20–22) from diethyl [2-^{13}C]malonate (**6**) and potassium [^{15}N]phthalimide in a 65% overall yield (Scheme 2), and [2-^{13}C,^{15}N]glycine was recovered in a 19% overall yield. The $^1J_{CN}$ coupling of the synthesized aspartate was in agreement with that reported previously (23). The intact incorporation of this C—N unit, and thus the precursor role of aspartate, was demonstrated (Expt. 5) by the presence (Fig. 2) of two coupled ^{13}C nmr signals (centered at 49.1 and 48.1 ppm, $^1J_{CN}$ = ca 6 Hz for each), superimposed on the natural abundance signals in the mixture of diastereomeric γ-lactones of 4,5-dihydroxynorvaline. These signals are associated with C-2 in each of the diastereomeric γ-lactones, and consequently represent C-2 of HON. Similar spectra, in which only one of the coupled signals is separated from the uncoupled signals, have been used to support the incorporation of ^{13}C–^{15}N labelled precursors into naphthyridinomycin (24) and nocardicin A (25).

The samples of glutamate isolated from each of the aspartate feeding experiments were enriched with ^{13}C (Table 3). Enrichments at C-1 and C-3 from [4-^{13}C]- and [2-^{13}C,^{15}N]aspartate, respectively, and the absence of ^{13}C–^{15}N coupling are consistent with the synthesis of glutamate from aspartate via oxaloacetate, citrate, isocitrate, and α-ketoglutarate, and further

[2]Similar coupling constants for C-1,C-2 (52.7 Hz) and C-4,C-5 (54.9 Hz) have been reported for synthetically enriched glutamate samples (17).

[3]Note that the anion-exchange step in the purification sequence separated HON from acidic amino acids in the culture supernatant and that no aspartic acid was detected by hplc in the HON sample before it was cleaved by periodate. These steps were carried out carefully to ensure that the observed enrichment at C-4 of aspartate was not due to carry-over of the initial substrate.

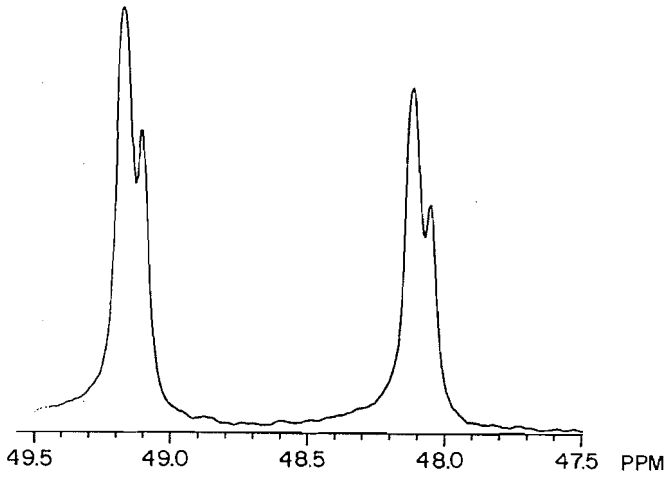

FIG. 2. The ^{13}C nmr spectrum of the mixture of diastereomeric 4,5-dihydroxynorvaline lactones derived from [2-^{13}C,^{15}N]aspartate showing ^{15}N coupling at carbon-2 (Expt. 5).

support the presence of the citric acid cycle in *S. akiyoshiensis*. The smaller ^{13}C enrichment observed at C-4 of glutamate derived from [2-^{13}C,^{15}N]aspartate can be explained by incorporation of label via the glyoxylate cycle (26).

In the aspartic acid feeding experiments (Expts. 4 and 5), significant amounts of the administered aspartic acid remained when the cultures were harvested; both the extra- and intracellular pools of this amino acid were isolated by ion-exchange chromatography and characterized. In each aspartic acid sample reisolated in Expt. 5, the nmr signal for C-2 appeared as a doublet ($^1J_{CN}$ = ca. 7 Hz) indicating that the coupling to ^{15}N had been maintained during transport through the cell membrane. Both the lack of an uncoupled signal for C-2 and the high enrichment of the doublet in the extracellular sample (96.5 times more intense than the corresponding signals for C-3) suggested that little or no dilution of the labelled aspartic acid had occurred. The enantiomeric compositions of the aspartic acids isolated in Expts. 4 and 5, determined by hplc separation of diastereomeric OPA derivatives (15), indicated that more than 96% of the extracellular and more than 98% of the intracellular aspartic acids were the D enantiomer in each experiment (Table 1). Thus L-aspartate was metabolized more quickly than D-aspartate; some metabolism of the D isomer was suggested by the partial recovery (approximately 50%) of the D-aspartate initially fed (Table 2).

The different rates of enantiomer metabolism were investigated in more detail by adding D- and L-aspartate to separate cultures of *S. akiyoshiensis*. Accumulation of HON and the levels of extra- and intracellular aspartate were monitored by hplc in duplicate cultures over 4 days. The extracellular concentration of HON increased over this period, but production of HON was not enhanced in any of the cultures supplemented with aspartic acid. The cultures supplemented with 3.8 and 7.5 mM L-aspartate were indistinguishable from unsupplemented control cultures after 17 and 41 h, respectively (Table 4). The failure to influence HON production was not due to rapid depletion of both aspartate enantiomers, since 89 h were needed for the initial 3.8 mM level of D-aspartate to fall to that of the control cultures, and about 15% of the D-aspartate added at 7.5 mM remained at 89 h after addition. Although intracellular accumulations of D- and L-aspartate were observed, they were not large enough to account for the extracellular decrease. Therefore,

TABLE 4. Extracellular concentrations of aspartate in cultures of *S. akiyoshiensis* supplemented with either D- or L-aspartate at 52 h after inoculation

Substrate added	[Aspartate] (mM)/time after addition				
	Initial	17 h	41 h	69 h	89 h
D-Aspartate	3.8	2.8	2.0	0.34	0.03
D-Aspartate	7.5	7.2	5.8	3.7	1.1
L-Aspartate	3.8	0.11	0.06	0.06	0.05
L-Aspartate	7.5	1.8	0.04	0.07	0.03
None	—	0.07	0.06	0.10	0.03

both enantiomers of aspartate were metabolized by *S. akiyoshiensis*, and the elevated intracellular levels in supplemented cultures vis-à-vis unsupplemented cultures indicated that transport across the cell membrane did not limit the rate of metabolism for either D- or L-aspartate. Thus the slower disappearance of D-aspartate must be due to a difference in metabolism.

Although D-aspartate is metabolized more slowly than L-aspartate, both are consumed by *S. akiyoshiensis* during the time that HON is formed in the culture. Thus the different rates of metabolism do not indicate which enantiomer is the more direct precursor of HON. Since L-aspartate and HON have identical configurations at C-2, direct incorporation of the L enantiomer (i.e., without bond cleavage at C-2) is the simplest explanation for intact incorporation of label from DL-[2-^{13}C,^{15}N]aspartate. On the other hand, a racemase-catalyzed inversion of stereochemistry without cleavage of the bond between C-2 and N could account for the incorporation of D-aspartate. This possibility was suggested to explain the incorporation of L-[^{14}C,^{15}N]aspartate into D-aspartate with maintenance of the $^{15}N/^{14}C$ ratio in *Streptococcus faecalis* (27); subsequently, an aspartate racemase (E.C. 5.1.1.13) was partially purified from this organism and characterized (28).

Of the three general routes referred to in the introduction for the biosynthesis of HON from another amino acid, only one is supported by the results of the isotopic feeding experiments. The incorporation of nitrogen and carbon atoms from aspartate and of one carbon atom from acetate are consistent with elongation of the carbon chain of aspartate via a Claisen or aldol condensation, followed by oxidation and decarboxylation (Scheme 3). Coupling of the condensation step to the hydrolysis of the thiolester group originally present in acetyl (**12***a*) or malonyl coenzyme A (**12***b*) to yield the β-ketoacid **13***b* would improve the energetics of this step. The product of the proposed aldol condensation, 2-amino-4-hydroxyadipic acid (**13***a*), has been isolated from *Vibrio cholera* (29), but its biosynthesis has not been investigated. The intermediacy of a β-ketoacid (**13***b*) is supported by the results of [$^2H_3$]acetate feeding experiments. Sodium [$^2H_3$]acetate was added to *S. akiyoshiensis* cultures and HON was isolated as either aspartic acid and formaldehyde (Expt. 6) or 4,5-dihydroxynorvaline (Expt. 7), which was subsequently cleaved to provide formaldehyde. Possible ^2H exchange of the hydrogens on C-5 of HON during isolation was minimized in Expt. 7 by reduction of HON directly in the culture supernatant to 4,5-dihydroxynorvaline. The formaldehyde derived from C-5 of HON was trapped as its dimedone derivative. Only 0.5 (±0.1)% and 0.7 (±0.2)% deuterium (Expts. 6 and 7, respectively) were found in these derivatives by mass spectrometry. The deuterium label was not exchanged during periodate cleavage and derivatization, as formaldehyde dime-

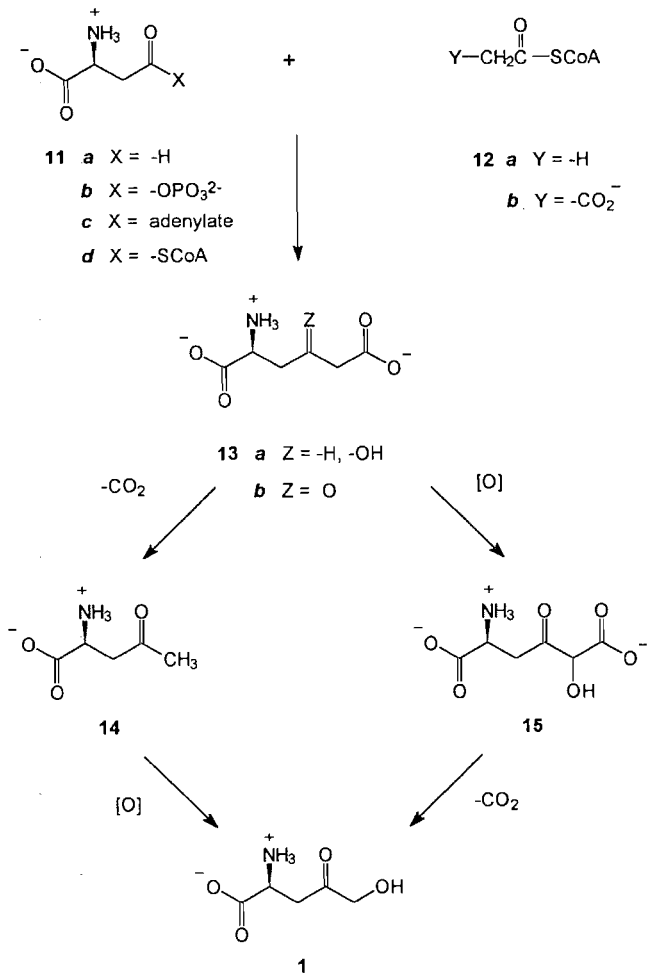

SCHEME 3. Hypothesis for the biosynthesis of HON (**1**) from aspartate and acetate derivatives.

thone isolated from the cleavage of 4,5-dihydroxynorvaline in D_2O (99.8% ^2H) contained only 1.3 (±0.5)% ^2H. In both experiments, the incorporation of deuterium was much lower than that of ^{13}C in Expt. 2 (Table 3). Since the methyl group of acetate is incorporated into C-5 of HON, deuterium should be located at C-5 in HON and in **13**. However, C-5 in **13***b* is located between two carbonyls, and the deuterium label would probably be lost rapidly by enolization.[4] Thus the lack of incorporation of the deuterium label is consistent with the intermediacy of a β-ketoacid such as **13***b*.

The presence of an oxidation step in the pathway is indicated by the observation that efficient aeration of *S. akiyoshiensis* cultures is required for HON production (31), but the oxidation and decarboxylation steps needed to convert the product of the condensation step (**13**) to HON (**1**) could occur simultaneously or in two alternative sequences (Scheme 3). There is some precedent for each of the latter. Decarboxylation of **13***b* yields 4-oxonorvaline (**14**),[5] an intermediate of ornithine degradation in *Clostridium sticklandii* (33), whereas an α-hydroxy-β-ketoacid (**15**) is formed if oxidation precedes decarboxylation. An analogous oxidation of a β-ketoacid to an α-chloro-β-ketoacid is catalyzed by a chloroperoxidase (34).

Several derivatives of aspartate (**11**) and acetate (**12**) are shown in Scheme 3 as possible substrates for the in vivo condensation reaction. Either a phospho anhydride, an adenylate derivative, a thiolester, or an aldehyde could serve as the activated aspartate derivative required for reaction with acetyl (**12***a*) or malonyl CoA (**12***b*). Both aspartyl phosphate (**11***b*) and aspartic semialdehyde (**11***a*) are well-known intermediates in the conversion of aspartate to homoserine in bacteria (35), and β-aspartyl adenylate (**11***c*) is known as an intermediate in the synthesis of asparagine from aspartate (36). Thiolesters are also well-known activated derivatives for carbon–carbon bond formation in fatty acid biosynthesis, and for the synthesis of peptide antibiotics (37). In the latter the thiolester is formed from the adenylate derivative of the amino acid, but formation of a thiolester from aspartyl phosphate is also possible.

A condensation between the carboxyl group of an amino acid (or the corresponding aldehyde) and a carbon derived from the methyl group of acetate has been proposed as a step in the biosynthesis of many natural products. Similar condensations extending the side chains of aspartate and glutamate have been proposed for fusaric acid (38) and thienamycin (39) biosynthesis, respectively, and condensations with the α-carboxyl of leucine, serine, lysine, phenylalanine, and picolinic acid have been suggested for the biosynthesis of pepstatin (40), elaiomycin (41), slaframine/swainsonine (42), tenellin (43), and caerulomycin (44), respectively. Also, on structural grounds, a Claisen condensation is a likely step in the biosynthesis of the modified amino acid residue in each of the peptides detoxin (45), galantin (46), and cyclotheonamide (47).

Other condensations that extend a carbon chain by one carbon are known. The formation of an α-aminoketone, δ-aminolevulinic acid, from glycine and succinyl CoA is catalyzed by δ-aminolevulinate synthase, EC 2.3.1.37 (48), and glyoxalate carboligase EC 4.1.1.47 (49) catalyzes the formation of an α-hydroxyaldehyde from two molecules of glyoxalate. Also, it has been suggested (26) that a thiamin-catalyzed condensation of glyoxalate with α-ketoglutarate to form 2-hydroxy-3-ketoadipate (a structure analogous to **15**) is the blocked step in type 1 hyperoxaluria (50), a disease in which large amounts of oxalate and L-glycerate are excreted in the urine. In each of these examples, C-2 of glycine or glyoxalate provides the one-carbon unit and, since C-2 of glyoxalate and glycine are labelled by [2-^{13}C]acetate, they are possible precursors of C-5 in HON. However, the highest ^{13}C enrichment was obtained at C-5, which suggests that acetate is incorporated via a more direct route.

Since the Claisen condensation in pepstatin biosynthesis occurs at the C-terminal leucine residue of a peptide (40) and *N*-acetylglutamate is an intermediate in the biosynthesis of ornithine from glutamate (51), it is conceivable that a derivative of aspartic acid or an aspartic acid residue in a peptide is involved in HON biosynthesis. Derivatization of the α-carboxyl group of aspartate would direct the Claisen condensation to the β position, and derivatization of nitrogen would serve as protection for the oxidation step. The modified amino acid, i.e., HON, could be liberated by hydrolysis in the final step of the pathway.

Experimental

Melting points were determined on a Mel Temp apparatus and are uncorrected. Nicolet 360 NB, Bruker AC250, and Varian EM-360L spectrometers were used to collect ^1H (361, 250, and 60 MHz) and ^{13}C

[4]The rate of enolization in another β-ketoacid, oxaloacetate, has been shown to be rapid (30).

[5]A peak that chromatographed with the same retention time as 4-oxonorvaline was discovered in *S. akiyoshiensis* cultures, but was subsequently shown to be due to another metabolite, as yet unidentified (32).

(90.8 and 62.9 MHz) nmr spectra. Chemical shifts are reported relative to either TMS in $CDCl_3$, HOD or external dioxane in D_2O. The ir spectra were obtained on a Perkin Elmer 683 infrared spectrometer and mass spectra were acquired by electron impact at 70 eV on a CEC 21-104 spectrometer. Labelled compounds were purchased from MSD Isotopes, Montreal, Que., and liquid cultures were incubated at 220 rpm in a Queue orbital shaker, model 4750.

Growth of Streptomyces akiyoshiensis

Streptomyces akiyoshiensis (ATCC 13480) was obtained from the American Type Culture Collection, Rockville, Md., U.S.A. It was maintained at −20°C in 20% glycerol as a spore suspension prepared from *S. akiyoshiensis* grown on semi-solid medium (malt extract 10 g/L, yeast extract 4 g/L, maltose 4 g/L, and agar 20 g/L) for 1 week at 27°C. Seed medium (malt extract 10 g/L, yeast extract 4 g/L, glucose 4 g/L, adjusted to pH 7.3 with aqueous NaOH prior to autoclaving) was inoculated with a loopful of spore suspension and incubated at 27°C with shaking for 48 to 72 h. Seed culture (1.0 mL) was added to starch–Pharmamedia medium (52) (100 mL, potato starch 50 g/L, Pharmamedia (Traders Protein, Fort Worth, Tex., U.S.A.) 30 g/L, $MgSO_4$ 10 g/L, KH_2PO_4 10.9 g/L, $Na_2HPO_4 \cdot 12\ H_2O$ 7.4 g/L) in a 2-L Erlenmeyer flask and incubated at 27°C with shaking for 96 h. The cultures were centrifuged (9600*g*, 30 min). The mycelial pellet was resuspended in a volume of water equal to the initial culture volume and centrifuged (9600*g*, 30 min). The water wash and the culture supernatant were combined.

HPLC analysis of amino acids

Portions (300 μL) of cultures were removed aseptically and centrifuged (15850*g*, 5 min). The supernatant was decanted and diluted with water (typically 50 μL was diluted to 500 μL). The pelleted mycelium was resuspended in ethanol (80% (v/v), 100 μL), allowed to stand at ambient temperature for 1 h, and centrifuged (15850*g*, 5 min). The ethanolic supernatant was decanted and diluted with water (typically 50 μL was diluted to 500 μL). Diluted culture broth or cell extract (20 μL) was mixed with an internal standard solution (20 μL, cysteic acid, 50 nmol/mL) and derivatized using a commercial *o*-phthalaldehyde reagent (Beckman Fluor-R, Beckman Instruments, Mississauga, Ont., or Sigma *o*-phthalaldehyde reagent, Sigma Chemical Company, St. Louis, Mo., U.S.A.) according to published conditions (13). The fluorescent OPA-derivatives were separated by gradient elution on a reversed-phase column as described previously (Figure 1b in ref. 13).

In addition to the analysis of extracellular and intracellular levels of amino acids, this hplc method was used to monitor all preparative separations of amino acids, as well as the periodate cleavage and borohydride reduction reactions described below. Aspartic acid, glutamic acid, and HON were identified by their retention times: 0.9, 1.5, and 1.2 min, respectively.

Feeding experiments

Labelled substrate was dissolved in sterile, deionized water (10 mL) and divided equally among production cultures of *S. akiyoshiensis* (100 mL/2-L Erlenmeyer flask, incubated with rotary shaking at 27°C) at 2 or 3 days after inoculation from the seed cultures (Table 2). At this point, the level of HON had reached ca. 40% of the maximum fermentation yield. In Expts. 1–6, an equal amount of labelled substrate was added in the same fashion 24 h later, and the incubation was continued for an additional 24 h. In Expt. 7, the sodium [$^2H_3$]acetate was added in four equal portions at the times given in Table 2.

*Isolation of extracellular HON (**1**) as aspartic acid (**2**) and formaldehyde*

The combined supernatants from a 500-mL culture (e.g., Expt. 2) were adjusted to pH 3.5 by the addition of oxalic acid, decolorized with charcoal, and filtered through Celite 545. The filtrate was applied to a column of Amberlite IR-120 (H^+ form, 2.5 × 45 cm). The column was washed with water (1 L) and eluted with ammonia (0.3 M). Fractions (200 mL) were collected and the amino acid-containing fractions were combined and concentrated in vacuo to ca. 150 mL to remove ammonia. The resulting solution was applied to a column of Dowex 1-X8 (acetate form, 2.5 × 45 cm) and the column was washed with water (500 mL). Aspartic acid and other acidic amino acids were retained on the column.

The sample effluent and the water wash, which contained HON and other neutral amino acids, were combined and concentrated in vacuo to ca. 100 mL. Solid $NaHCO_3$ was added to a final concentration of 0.5 M, and $NaIO_4$ (0.5 g) was added. The solution was swirled for 1 min and dimedone (5,5-dimethyl-1,3-cyclohexanedione, 0.85 g dissolved in 95% ethanol, 5 mL) was added. The reaction mixture was heated on a steam bath until a homogeneous solution was obtained. Upon storage of the solution at 4°C overnight, a white precipitate of formaldehyde dimethone (**3**) formed. It was collected by filtration and recrystallized twice from 70% aqueous ethanol to give 0.39 g. For unlabelled material isolated from cultures: mp 190–191°C (lit. (53) mp 189–190°C); ^1H nmr ($CDCl_3$, 60 MHz) δ: 3.10 (s, 2H), 2.26 (s, 8H), 1.08 (s, 12H); ^{13}C nmr ($CDCl_3$, 90.8 MHz) δ: 189.43 (s), 113.43 (s), 45.99 (t, $^1J_{CH}$ = 127 Hz), 31.77 (s), 29.48 (q, $^1J_{CH}$ = 123 Hz), 27.08 (q, $^1J_{CH}$ = 126 Hz), and 15.94 (t, $^1J_{CH}$ = 128 Hz); mass spectrum [*m/z* (relative intensity)] 292 (M^+, 100), 277 (10), 233 (6), 208 (10), 193 (6), 191 (8), 190 (6), 180 (12), 165 (47), 153 (6), 125 (10), 124 (14), 97 (10), 83 (16), 69 (13), 55 (16), 43 (13), 41 (12).

The filtrate from the formaldehyde derivatization reaction was applied to a column of Amberlite IR-120 (H^+ form, 2.5 × 45 cm) and the column was washed successively with water (500 mL) and ammonia (0.3 M). Fractions (200 mL) containing aspartic acid were combined, concentrated in vacuo, and applied to a column of Dowex 1-X8 (acetate form, 2.5 × 45 cm). The column was washed with water (500 mL) and eluted with acetic acid (0.5 M). Fractions (200 mL) containing aspartic acid (**2**) were combined and evaporated to dryness in vacuo. The resulting solid was recrystallized three times from aqueous ethanol to yield 235 mg. For unlabelled material isolated from cultures: ir: identical to authentic L-aspartic acid; ^1H nmr (D_2O, 250 MHz) δ: 4.07 (apparent t, 1H, splittings of 5.5 and 5.8 Hz), 3.1–2.9 (m, 2H); ^{13}C nmr (D_2O/NaOD, 90.8 MHz) δ: 182.36, 180.26, 53.99, 43.31.

*Isolation of extracellular HON (**1**) as 4,5-dihydroxynorvaline γ-lactone (**5**) and formaldehyde*

Sodium borohydride (150 mg) was added to the combined supernatants from a 300-mL culture (Expt. 3). The resulting solution, which contained 4,5-dihydroxynorvaline (**4**), was treated with oxalic acid and decolorizing charcoal, and chromatographed on Amberlite IR-120 and Dowex 1-X8 as described above. The sample effluent and water wash from the Dowex 1-X8 column were combined and evaporated in vacuo to dryness. The resulting oil was dissolved in concentrated HCl (50 mL) and heated on a steam bath for 30 min. The HCl was removed in vacuo, and the brown residue was dissolved in water (50 mL), treated with decolorizing charcoal, and filtered. The filtrate was evaporated to dryness in vacuo. The resulting hydrochloride salts of the diastereomeric γ-lactones of 4,5-dihydroxynorvaline (**5**) were stored in a desiccator over NaOH and washed with a mixture of isopropanol (25 mL) and methanol (4 mL) to yield 0.184 g. For unlabelled material isolated from culture: mp 206–210°C (lit. (2) mp 211–214°C); ir (Nujol): 3250 (N—H), 1770 (C═O) cm^{-1}; ^1H nmr (D_2O, 361 MHz) δ: 4.95–4.71 (m, 1H), 4.54 (dd, 1H, J = 10.9 and 9.7 Hz), 3.98–3.86 (m, 1H), 3.73–3.67 (m, 1H), 2.82–2.53 and 2.28–2.19 (m, 2H); ^{13}C nmr (D_2O, 90.8 MHz) δ: 173.83, 173.13, 79.72, 79.44, 62.32, 61.02, 49.04, 47.98, 27.83, 27.38.

In Expt. 7, a portion (20 mL) of the Dowex 1-X8 effluent, which contained 4,5-dihydroxynorvaline (**4**), was mixed with $NaHCO_3$ (0.84 g) and $NaIO_4$ (0.30 g). After 10 min, dimedone (5,5-dimethyl-1,3-cyclohexanedione, 0.50 g dissolved in 95% ethanol, 5 mL) was added, and the mixture was heated on a steam bath for 30 min. The solid product, which formed on cooling after the addition of 5 M acetic acid (1 mL), was collected by filtration and recrystallized from ethanol–water to provide formaldehyde dimethone (**3**, 142 mg) for mass spectrometric analysis: mp 188.5–189°C.

Reisolation of administered aspartic acid from extracellular fluids

In Expts. 4 and 5, in which labelled aspartic acids were administered

Can. J. Chem. Downloaded from www.nrcresearchpress.com by ESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

to *S. akiyoshiensis*, aspartic acid bound to the initial Dowex 1-X8 column (acetate form) was eluted with acetic acid (0.5 M). Aspartic acid-containing fractions were combined and evaporated to dryness in vacuo. The solid residue was dissolved in acetic acid (0.5 M, 5 mL), applied to a column of Dowex 1-X8 (acetate form, 2.5 × 48 cm) pre-equilibrated in acetic acid (0.5 M), and eluted with acetic acid (0.5 M). Fractions (25 mL) were collected. Fractions 30–56 were combined and evaporated to dryness in vacuo to give aspartic acid (58 mg). For aspartic acid isolated in Expt. 5: ^{13}C nmr (D_2O/DCl, 90.8 MHz) δ: 172.58, 170.20 (d, $^1J_{CC}$ = 61.5 Hz), 48.75 (d, $^1J_{CN}$ = 6.6 Hz), 33.25 (d, $^1J_{CC}$ = 37.9 Hz) (lit. (23) 49.2 (d, $^1J_{CN}$ = 7.0 Hz)).

Isolation of intracellular glutamic and aspartic acids

The mycelial pellet obtained by centrifugation of a 300-mL culture broth (e.g., Expt. 4) was suspended in 80% ethanol (300 mL) and allowed to stand at ambient temperature for 1 h. The mixture was centrifuged (9600*g*, 30 min) and the extraction was repeated on the pellet. The ethanol extracts were combined and concentrated in vacuo. The residue was dissolved in water (300 mL), and applied to a column of Dowex 1-X8 (acetate form, 2.5 × 45 cm). The column was washed with water (500 mL) and eluted with acetic acid (0.5 M). Amino acid-containing fractions were combined and evaporated to dryness in vacuo. The solid residue (114 mg) was dissolved in acetic acid (0.5 M, 5 mL), applied to a column of Dowex 1-X8 (acetate form, 2.5 × 48 cm) pre-equilibrated in acetic acid (0.5 M), and eluted with acetic acid (0.5 M). Fractions (25 mL) were collected. Glutamic acid-containing fractions (numbers 8–21) were combined and evaporated to dryness in vacuo. The residue (38 mg) was recrystallized from aqueous ethanol to give glutamic acid (25 mg). For unlabelled material isolated from cultures: mp 200–202°C (lit. (54) mp 211–213°C); ir: identical to authentic L-glutamic acid; ^{1}H nmr (D_2O, 250 MHz) δ: 3.81 (t, 1H, J = 6.3 Hz), 2.56 (apparent t, 2H, splittings of 7.5 and 7.8 Hz), 2.22–2.08 (m, 2H); ^{13}C nmr (D_2O/NaOD, 90.8 MHz) δ: 184.01, 183.82, 57.02, 35.26, 32.92.

In Expts. 4 and 5, aspartic acid-containing fractions (numbers 22–54) were combined and evaporated to dryness in vacuo. The residue (44 mg) was recrystallized from aqueous ethanol to give aspartic acid (34 mg). For aspartic acid isolated in Expt. 5: ^{13}C nmr (D_2O/DCl, 90.8 MHz) δ: 48.74 (d, $^1J_{CN}$ = 6.3 Hz) (lit. (23) 49.2 (d, $^1J_{CN}$ = 7.0 Hz)).

Determination of ^{13}C enrichments by nuclear magnetic resonance

Incorporation of isotopic label was determined from ^{13}C nmr spectra acquired at 90.8 MHz using 16k data points in a 10 kHz spectral window and processed using a line broadening of 2–5 Hz. Formaldehyde dimethone (**3**) samples were dissolved in $CDCl_3$ and the Lorentzian peak height of the signal (15.9 ppm) corresponding to the central methylene carbon was normalized to the average value of the Lorentzian peak heights of the carbons supplied by the dimedone reagent (55). Spectra of aspartate (**2**) and glutamate were obtained in D_2O–NaOH and sodium phosphate buffer (pH 11.5), respectively. Lorentzian peak heights in these samples were normalized to the Lorentzian peak height of the carboxyl signal of disodium malonate (177 ppm), which was added as an internal standard. Peak assignment of the carbons in the amino acids was based on the literature (56) and the assignment of C-4 (180 ppm) in aspartate was confirmed using the commercial, enriched sample. 4,5-Dihydroxynorvaline spectra were acquired in D_2O and peak heights were normalized relative to the average peak heights of the two uncoupled C-4 signals (79.4 and 79.7 ppm).

Determination of the enantiomeric composition of amino acids by high performance liquid chromatography

Synthesis of β-methyl aspartate standards (57, 58)

Aspartic acid (10.0 g, 0.075 mol) was added to a solution of concentrated sulfuric acid (4.2 mL) in methanol (110 mL, previously dried over 3Å molecular sieves), and the mixture was stirred and refluxed for 25 h. A solution of dimethylamine (18 mL) in methanol (62 mL) was added, and the reaction mixture was concentrated in vacuo. The resulting oil was dissolved in water (350 mL) and applied to a Dowex 1-X8 column (2.5 × 45 cm, CH_3COO^- form); the column was washed with water (750 mL). The sample effluent and the water wash were combined and evaporated to dryness in vacuo. The residue was dissolved in hot 95% ethanol; white crystals were obtained upon cooling.

β-Methyl D-aspartate (0.12 g, 11% from 1.0 g D-aspartic acid): mp 189–191°C (lit. (59) mp 188–190°C); ^{1}H nmr (D_2O, 250 MHz) δ: 4.05 (t, 1H, J = 5.5 Hz), 3.74 (s, 3H), 3.03 (d, 2H, J = 5.5 Hz); ^{13}C nmr (D_2O, 62.9 MHz) δ: 175.67, 175.32, 55.43, 53.48, 37.24.

β-Methyl DL-aspartate (3.80 g, 34%): mp 192–194°C (lit. (60) mp 201–202°C); ^{1}H nmr (D_2O, 250 MHz) δ: 4.04 (t, 1H, J = 5.5 Hz), 3.74 (s, 3H), 3.02 (d, 2H, J = 5.5 Hz); ^{13}C nmr (D_2O, 62.9 MHz) δ: 175.68, 175.31, 55.43, 53.48, 37.24.

β-Methyl L-aspartate (4.34 g, 39%): mp 187–189°C (lit. (61) mp 193–194°C, (62) mp 194–195°C); ^{1}H nmr (D_2O, 250 MHz) δ: 4.05 (t, 1H, J = 5.5 Hz), 3.74 (s, 3H), 3.03 (d, 2H, J = 5.5 Hz); ^{13}C nmr (D_2O, 62.9 MHz) δ: 175.66 (s), 175.31 (s), 55.43 (q), 53.47 (d), 37.23 (t).

Synthesis of β-methyl aspartate samples

Aspartic acid (1 mg) was heated at 65°C in a mixture of H_2SO_4 (8 μL) and methanol (200 μL) for 12 h. The solution was cooled to room temperature, diluted to 1.0 mL with water, and stored at 4°C until the hplc analysis was performed.

The hplc conditions (15)

Derivatization reagent (100 μL), prepared from incomplete *o*-phthalaldehyde reagent (1.0 mL, Sigma Chemical Co.) and *N*-acetylcysteine solution (0.20 mL, 5 mg/mL), were added to an amino acid solution and the reaction was allowed to proceed at ambient temperature for 15 min. The reaction was quenched by the addition of the mobile phase used for the separation (100 μL) and a portion of the resulting solution (20 μL) was chromatographed immediately on a Nucleosil 5 C18 column (4.6 × 250 mm, Phenomenex, Torrance, Calif., U.S.A.) using a mobile phase that contained acetonitrile, copper(II) acetate (2.5 mM), and L-proline (5 mM), adjusted to pH 6.0 with ammonium acetate. Enantiomers of aspartic acid and β-methyl aspartate were separated isocratically in mobile phases containing 1% and 5.8% acetonitrile, respectively, at a flow rate of 1.5 mL/min, whereas glutamic acid enantiomers separated in a mobile phase containing 2% acetronitrile at a flow rate of 2.5 mL/min.

*Synthesis of DL-[2-^{13}C,^{15}N]aspartic acid (**10**)*

*Diethyl [2-^{13}C]bromomalonate (**7**) (20, 21)*

A solution of bromine (1.01 g, 6.32 mmol) in CCl_4 (4 mL) was added dropwise to a stirred mixture of diethyl [2-^{13}C]malonate (**6**, 1.00 g, 6.24 mmol, 99.3 at.% ^{13}C) and CCl_4 (2.5 mL) in a two-necked flask equipped with a reflux condenser. After six drops of the bromine solution had been added, the reaction was initiated by irradiating the flask with a 100-W incandescent bulb. The remaining bromine solution was added over 15 min to maintain an orange-red color in the reaction mixture. The reaction mixture was refluxed for 1 h, diluted with an equal volume of CCl_4, washed with 5% $NaHCO_3$ (2 × 10 mL), dried over anhydrous $MgSO_4$, and evaporated in vacuo to yield diethyl [2-^{13}C]bromomalonate (**7**, 1.55 g). For unlabelled material: ^{1}H nmr (CCl_4, 60 MHz) δ: 4.6 (s, 1H), 4.2 (q, 4H, J = 7 Hz), 1.3 (t, 6H, J = 7 Hz).

*Diethyl [2-^{13}C,^{15}N]phthalimidomalonate (**8**) (21)*

Potassium [^{15}N]phthalimide (1.15 g, 6.21 mmol, 99.5 at.% ^{15}N) and hexadecyltri-*n*-butylphosphonium bromide (0.35 g, 0.69 mmol) were added to diethyl [2-^{13}C]bromomalonate (**7**, 1.55 g) in anhydrous toluene (20 mL), and the mixture was stirred for 20 h at 20°C. The mixture was filtered and the filtrate was concentrated in vacuo. The resulting yellow oil was dissolved in $CHCl_3$ (20 mL) and filtered through a column (0.7 × 10 cm) of silica gel (Aldrich grade 923, 100–200 mesh). The column was washed with $CHCl_3$ (125 mL). Column effluent was evaporated to dryness in vacuo to yield an oil (2.02 g) that crystallized immediately when seeded with a small crystal of diethyl phthalimidomalonate (**8**): ^{13}C nmr ($CDCl_3$, 90.8 MHz) δ: 54.42 (d, $^1J_{CN}$ = 13.1 Hz) (lit. (21) 54.5 (d, $^1J_{CN}$ 12.7 Hz)). For unlabelled material: mp 73.5–75°C (lit. (21) mp 75–76°C); ^{1}H nmr ($CDCl_3$, 361 MHz) δ: 7.91

Can. J. Chem. Downloaded from www.nrcresearchpress.com by ESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

(dd, 2H, J = 5.5 and 3.2 Hz), 7.81 (dd, 2H, J = 5.4 and 3.0 Hz), 5.49 (s, 1H), 4.37–4.27 (11 line m, 4 H), 1.32 (t, 6H, J = 7.2 Hz); ^{13}C nmr ($CDCl_3$, 90.8 MHz) δ: 166.47, 164.29, 134.39, 131.69, 123.81, 62.78, 54.42, 13.97.

*Triethyl [1-^{13}C,^{15}N]-1-phthalimido-1,1,2-ethanetricarboxylate (**9**) (22)*

Sodium ethoxide (190 mg of sodium in 4.3 mL absolute ethanol) was added to diethyl [2-^{13}C,^{15}N]phthalimidomalonate (**8**, 2.0 g) in absolute ethanol (20 mL). The mixture was stirred for 5 min at 20°C and the ethanol was removed in vacuo. Ethyl bromoacetate (8.00 g, 47.9 mmol) was added to the resulting orange oil and the mixture was heated for 2 h at 150°C. The excess ethyl bromoacetate was removed by vacuum distillation and the residue was extracted with ether (2 × 10 mL). The ether extracts were filtered and the collected solids were washed with ether (2 × 10 mL). The combined filtrates were evaporated to dryness in vacuo and placed under high vacuum to remove traces of ethyl bromoacetate. Triethyl [1-^{13}C,^{15}N]-1-phthalimido-1,1,2-ethanetricarboxylate (**9**) was obtained as an oil (3.17 g). For unlabelled material: ^1H nmr ($CDCl_3$, 361 MHz) δ: 7.85 (dd, 2H, J = 5.5 and 3.1 Hz), 7.74 (dd, 2H, J = 5.5 and 3.1 Hz), 4.36–4.28 (2 overlapped q, 4H, J = 7.1 Hz), 4.10 (q, 2H, J = 7.2 Hz), 3.46 (s, 2H), 1.29 (t, 6H, J = 7.1 Hz), 1.17 (t, 3H, J = 7.2 Hz); ^{13}C nmr ($CDCl_3$, 90.8 MHz) δ: 168.87, 167.09, 165.54, 134.19, 131.78, 123.52, 65.51, 63.02, 60.74, 36.39, 13.92, 13.79.

*DL-[2-^{13}C,^{15}N]Aspartic acid (**10**) (22)*

Water, concentrated HCl, and glacial acetic acid (7.0 mL of each) were added to the above oil. The mixture was refluxed for 43 h, concentrated in vacuo to two-thirds of its volume, diluted to 1 L with water, and applied to a column of Amberlite IR-120P (H^+ form, 2.5 × 46 cm). The column was washed with water (1.5 L) and eluted with ammonia (0.5 M). Fractions (200 mL) were collected and those containing aspartic acid (numbers 4–7) were combined, concentrated in vacuo to about 200 mL, and applied to a column of Dowex 1-X8 (acetate form, 1.5 × 25 cm). The column was washed with water (500 mL) and eluted with acetic acid (0.5 M). Fractions (75 mL) were collected and those containing aspartic acid (numbers 2–5) were combined and evaporated to dryness in vacuo. The white residue (577 mg) was recrystallized from aqueous ethanol to give DL-[2-^{13}C,^{15}N]aspartic acid (**10**, 543 mg, 65% yield from diethyl [2-^{13}C]malonate): ^{13}C nmr (D_2O/DCl, 90.8 MHz) δ: 49.06 (d, $^1J_{CN}$ = 7.1 Hz) (lit. (23) 49.2 (d, $^1J_{CN}$ = 7.0 Hz)).

The sample effluent and the water wash from the Dowex column were combined and evaporated to dryness in vacuo. The residue (165 mg) was recrystallized from aqueous ethanol to yield [2-^{13}C,^{15}N]glycine (89 mg, 19% yield from diethyl [2-^{13}C]malonate): ^1H nmr (D_2O, 250 MHz) δ: 3.54 (s and d, $^1J_{CH}$ = 143.4 Hz); ^{13}C nmr (D_2O, 62.9 MHz) δ: 175.15 (s and d, $^1J_{CC}$ = 53.4 Hz), 44.18 (d, $^1J_{CN}$ = 6.7 Hz).

Indenone synthesis. Improved synthetic protocol and effect of substitution on the intramolecular Friedel–Crafts acylation

PAUL GALATSIS,[1] JEFFREY J. MANWELL, AND JAMES M. BLACKWELL
Department of Chemistry and Biochemistry, University of Guelph, Guelph, ON N1G 2W1, Canada

Received October 15, 1993

PAUL GALATSIS, JEFFREY J. MANWELL, and JAMES M. BLACKWELL. Can. J. Chem. **72**, 1656 (1994).

An improved protocol for the construction of substituted indenones is presented. Also the effect of substitution on the intramolecular Friedel–Crafts acylation was noted. Specifically, if there is no substitution at the 2-position of the indenone poor yields of cyclized material were obtained, if at all, while the substitution of a methyl or ethyl group greatly improved the yield of cyclized material. Placement of a large group (e.g., benzyl) resulted in a diminuation of the improved yield. The new synthetic procedure could, in principle, allow for the construction of 2,3-disubstituted indenones. One example of this reaction mode was presented.

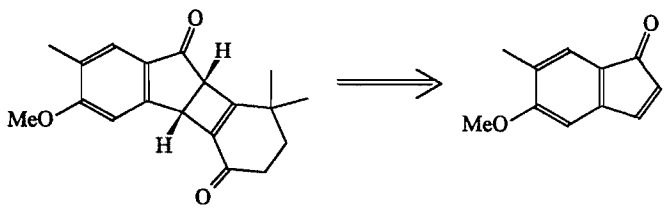
PAUL GALATSIS, JEFFREY J. MANWELL et JAMES M. BLACKWELL. Can. J. Chem. **72**, 1656 (1994).

On présente un protocole amélioré pour la synthèse d'indénones substituées. On note l'effet de substitution sur l'acylation intramoléculaire de Friedel–Crafts. D'une façon spécifique, s'il n'y a pas de substituant en position 2 de l'indénone, on obtient, au mieux, de faibles rendements de produits cyclisés; par ailleurs, si cette position est substituée par un méthyle ou un éthyle, on obtient de bien meilleurs rendements en produits cyclisés. Si le substituant est volumineux (comme un benzyle), il y a une diminution du rendement amélioré. La nouvelle méthode de synthèse pourrait, au moins en principe, permettre d'obtenir des indénones substituées en positions 2 et 3.

[Traduit par la rédaction]

Introduction

We recently reported a general method for the construction of substituted cyclobutenone derivatives (1). To apply this methodology towards the construction of the natural product neofavelanone **1** (2), we required ready access to disubstituted indenone **2** (see Scheme 1). For the synthesis to be viable, the



1 **2**

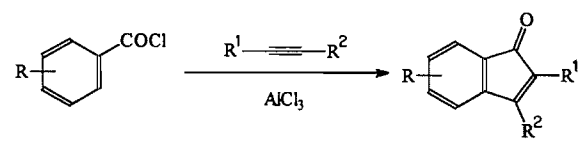
SCHEME 1

method for the synthesis would have to be rapid and proceed in good yield.

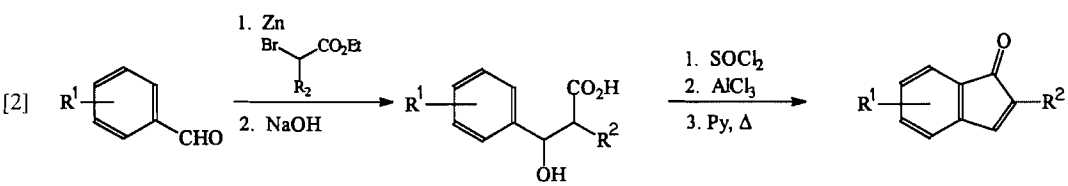
A great deal of work has been directed towards the synthesis of indanones (3). The methods include such procedures as intramolecular Friedel–Crafts acylation (3*a*, *c*) and a variation of the von Auwers reaction (3*d*). The interest in these compounds was twofold. Derivatives of indanone exhibited biological activity (e.g., antihypertensive or bronchodilatory activity) or they could serve as synthetic precursors to other natural products (e.g., steroids or gibberellic acid).

The synthesis of indenones is less well studied. A logical precursor to these compounds could be the corresponding indanone. However, poor yields, irreproducibility, or decomposition of the starting material were common outcomes. To our knowledge there exist only two general methods for the direct synthesis of indenone derivatives. The first one of these methods (4) is an aluminum chloride catalyzed addition of substituted benzoyl chlorides to acetylenic compounds (see reaction [1]). The second method (5) involves an intramolecular Friedel–Crafts acylation of β-chloro-β-arylpropionyl chlorides followed by a dehydrochlorination reaction (see reaction [2]).

[1]



[2]



We felt the second method to be more synthetically amenable to our desired system. Thus we began an investigation of this chemistry and now wish to report an improvement in the synthetic protocol and the effect of substitution at the 2-position of the indenone on the cyclization step.

Results and discussion

Application of the second method (5) towards the synthesis of **2** required access to aldehyde **3***d*. This compound could be prepared in good overall yield following the reported procedure (6). With aldehyde **3***d* in hand, we wished to simplify the Reformatsky reaction – saponification sequence of the reported procedure (5). We set out to see if direct treatment of aldehyde **3***d*

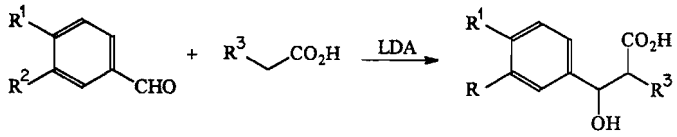
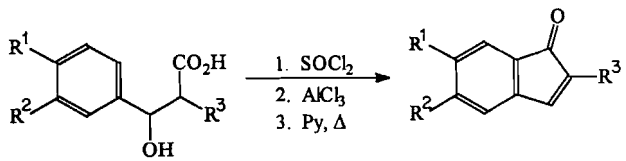
8	**5***h*	Me	MeO	Me	86
9	**5***i*	H	H	Et	93
10	**5***j*	H	H	Bn	81



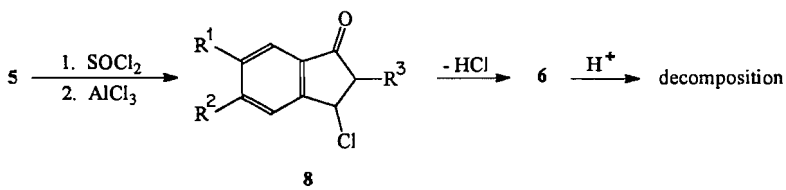
3 **4** **5**

with the dianion of acetic acid (**4**, R^3 = H) (7) would accomplish the equivalent transformation. This supposition was affirmed when we were able to isolate **5***d* in 93% yield (see Table 1). The generality of this approach to **5** was demonstrated by the fact that in addition to the dianion of acetic acid, we were able to carry out the aldol reaction with the dianions of propionic acid (**4**, R^3 = Me), butyric acid (**4**, R^3 = Et), and 3-phenylpropionic acid (**4**, R^3 = Bn). To obtain the yields presented in Table 1 for aldols **5**, one must allow the dianion to form at 0°C and then cool to −78°C before adding the desired aldehyde. With this protocol, one can routinely obtain these compounds. While compounds **5***e–j* were isolated as inseparable mixtures of diastereomers, this was not problematic, since both diastereomers gave rise to the same indenone derivative once the β-elimination step was completed.

With the formation of acid **5***d*, the Friedel–Crafts reaction – β-elimination sequence was attempted for the preparation of **2**. We were disappointed when only a 15% yield (see Table 2) was obtained for this transformation. However, when acid **5***h* was



5 **6**

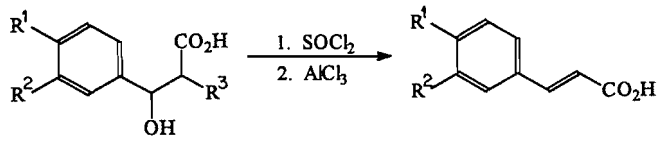


8

prior to treatment with pyridine. However, this mixture was routinely submitted to the elimination step in order to isolate the desired product under more favorable conditions. Furthermore, exposure of **6** to aluminum chloride under the standard reaction conditions resulted in a 20% decomposition of starting material after 30 min. While direct treatment of **5** with PPA or other Lewis acids resulted in no product formation, one could surmise that these acid conditions could also have resulted in destruction of any indenone that may have formed. This sensitivity of indenones has been previously described (3–5). In the case of **7***b*, *c*, subjected to these conditions, a 72% yield (see Table 2) of **6***h* was obtained. As one can see from Table 2, this trend was repeated for all the systems investigated. That is, only when a substituent was present at the 2-position of the indenone were synthetically acceptable levels of product formation witnessed. For compound **5***g*, treatment with thionyl chloride proceeded normally; however, upon treatment of this dichloro derivative with aluminum chloride only decomposition was observed. We are at a loss to provide an explanation for this result. For R^3 = H (Table 2, entries 1–4) one either isolates **6** in poor yield or a product of net dehydrochlorination from the dichloro derivative of **5**, in good yield, to afford the corresponding cinnamic acid derivative **7**.

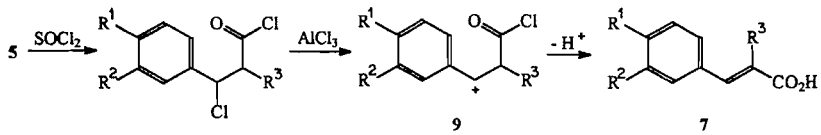
TABLE 2. Results of intramolecular Friedel–Crafts acylation from acid **5**

Entry	Compound	R^1	R^2	R^3	Yield (%)
1	**6***a*	H	H	H	5
2	**7***b*	Me	H	H	79
3	**7***c*	MeO	H	H	65
4	**2**	Me	MeO	H	15
5	**6***e*	H	H	Me	74
6	**6***f*	Me	H	Me	63
7	**6***h*	Me	MeO	Me	72
8	**6***i*	H	H	Et	79
9	**6***j*	H	H	Bn	40



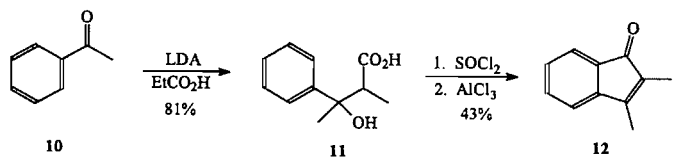
5 **7**

We feel these observations are consistent with the stability of the β-chloroindanone intermediate **8** in this two-step sequence. Exposure of **5** to thionyl chloride produces the corresponding β-chloro-acid chloride which under the influence of aluminum chloride gives rise to **8**. One could envisage that under the acidic conditions of this reaction an in situ β-elimination of chloride occurs to give **6**. These acidic conditions could then catalyze the decomposition of the indenone. With R^3 = H, this is a facile process; however, when R^3 = alkyl this process is stopped or at least slowed down enough to allow isolation of **8**. Treatment of **8** with pyridine then allows one to isolate **6** under basic conditions, which are more compatible with this functionality. Indeed, small amounts of **6** are found in the reaction mixture



complexation of the β-chlorine with the aluminum chloride would result in formation of benzylic cation **9**. Loss of a proton would then give rise to the observed cinnamic acid derivatives **7**.

In addition, this method could be used to generate alternate substitution patterns if, for example, a ketone were used in place of aldehyde **3**. One example of this was demonstrated with acetophenone (**10**). Aldol reaction of **10** with the dianion of propionic acid, as before, produced hydroxy-acid **11** in excellent yield. Intramolecular Friedel–Crafts acylation of **11** then afforded indenone **12**.



In summary, we have demonstrated that the aldol reaction of the dianion of carboxylic acids with aldehydes (and in principle ketones) provides direct access to acids **5** with improved yields. We have also shown that a substituent at the 2-position of the indenone appears to be necessary for optimal yields of indenones **6** by this method. Presently, an alternate method for the preparation of **2** is being pursued and this work will be reported when completed.

Experimental section

General procedures and materials

Melting points were taken on a Fischer–Johns melting point apparatus and are uncorrected. ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ at 400 and 100 MHz, respectively, unless specified otherwise.

All solvents used for chromatography were distilled prior to use. Reactions were monitored by TLC using E. Merck precoated silica gel 60 F-250 (0.25 mm thickness) aluminum backed plates. The plates were visualized by immersion in *p*-anisaldehyde solution and warming on a hotplate. E. Merck silica gel 60 (70–230 mesh) was used for column chromatography. All solvents were reagent grade and anhydrous solvents were dried prior to use as follows: diisopropylamine, pyridine, DMF, and CH_2Cl_2 were distilled from CaH_2; THF was distilled from benzophenone ketyl. Compounds obtained from commercial sources were used directly as received. Compounds **6***a*, **7***b*, and **7***c* are known compounds and commercially available. Also compounds **5***a*, **5***e*, **5***i*, **6***e*, **6***f*, **6***i*, and **12** have been reported in the literature (5, 8).

General procedure for the aldol reaction with dilithiocarboxylic acids

To a solution of diisopropyl amine (3.2 equiv.) in THF (20 mL) at −78°C was added *n*-BuLi (3.0 equiv., 2.5 M solution) and stirred for 30 min. Acid **4** (1.2 equiv.) in THF (2 mL) was added via cannula and the reaction was warmed to 0°C and stirred for 30 min. Cooling to −78°C preceded addition of the aldehyde **3** in THF (3 mL) via cannula. The reaction was allowed to slowly warm to room temperature and the stirring was maintained for 16–24 h. The reaction mixture was made basic with 15% NaOH solution and washed once with ether. The aqueous phase was acidified with 10% HCl solution and extracted five times with ether. The combined extracts were washed with brine solution, dried with anhydrous sodium sulfate, filtered, and the solvent removed in vacuo. The resulting product was recrystallized from ether–hexanes to afford a white solid.

3-Hydroxy-3-(4′-methylphenyl)propionic acid (5b)

Acetic acid (4.99 mmol, 0.287 mL) was deprotonated with LDA (diisopropylamine 13.31 mmol, 1.86 mL, and *n*-BuLi 12.48 mmol, 5.0 mL) and reacted with **3** (R^1 = Me, R^2 = H) (4.16 mmol, 0.50 g) according to the general procedure to afford after recrystallization 0.597 g (80%) of **5***b* (mp 93.5–95°C). IR ($CHCl_3$): 3550–2050, 1710, 1515, 1456, 1437, 1419, 1399, 1340, 1316, 1291, 1266, 1214, 1205, 1189, 1160, 1116, 1053, 1025, 1012, 953, 933, 895, 881, 852, 845, 819, 785, 727, 683, 628 cm^{-1}; ^1H NMR δ: 7.26 (d, 2H, J = 7.6 Hz), 7.17 (d, 2H, J = 8.0 Hz), 5.12 (dd, 1H, J = 9.6, 3.6 Hz), 2.78 (AB portion of ABX, 2H, J_{ab} = 16.4, J_{ax} = 9.2, J_{bx} = 3.6, Δνab = 31.72 Hz), 2.35 (s, 3H); ^{13}C NMR δ: 177.26, 139.08, 137.82, 129.32, 125.61, 70.07, 43.00, 21.12; HRMS calcd. for $C_{10}H_{12}O_3$: 180.0786; found: 180.0782.

3-Hydroxy-3-(4′-methoxyphenyl)propionic acid (5c)

Acetic acid (4.44 mmol, 0.254 mL) was deprotonated with LDA (diisopropylamine 11.80 mmol, 1.65 mL, and *n*-BuLi 11.10 mmol, 4.50 mL) and reacted with **3** (R^1 = MeO, R^2 = H) (3.70 mmol, 0.50 g) according to the general procedure to afford after recrystallization 0.667 g (93%) of **5***c* (mp 89–90°C). IR ($CHCl_3$): 3650–2350, 1710, 1612, 1514, 1404, 1303, 1251 cm^{-1}; ^1H NMR δ: 7.27 (d, 2H, J = 8.8 Hz), 6.87 (d, 2H, J = 8.0 Hz), 6.05 (br s, 1H), 5.08 (dd, 1H, J = 9.6, 3.6 Hz), 3.79 (s, 3H), 2.75 (AB portion of ABX, 2H, J_{ab} = 16.4, J_{ax} = 9.6, J_{bx} = 3.6, Δν_{ab} = 39.40 Hz); ^{13}C NMR δ: 176.87, 159.29, 134.24, 126.99, 114.00, 69.88, 55.27, 43.02; HRMS calcd. for $C_{10}H_{12}O_4$: 196.0735; found: 196.0727.

3-Hydroxy-3-(3′-methoxy-4′-methylphenyl)propionic acid (5d)

Acetic acid (1.60 mmol, 0.092 mL) was deprotonated with LDA (diisopropylamine 4.27 mmol, 0.60 mL, and *n*-BuLi 4.00 mmol, 1.60 mL) and reacted with **3** (R^1 = Me, R^2 = MeO) (1.33 mmol, 0.20 g) according to the general procedure to afford after recrystallization 0.261 g (93%) of **5***d* (mp 101.5–102.5°C). IR ($CHCl_3$): 3600–2440, 1710, 1614, 1588, 1506, 1462, 1418, 1315, 1260, 1180, 1134, 1066, 1038, 1004, 981, 901, 875, 818, 730, 668, 652 cm^{-1}; ^1H NMR δ: 7.11 (d, 1H, J = 7.6 Hz), 6.88 (s, 1H), 6.83 (d, 1H, J = 7.6 Hz), 5.13 (dd, 2H, J = 9.2, 3.2 Hz), 3.84 (s, 3H), 2.81 (AB portion of ABX, 2H, J_{ab} = 16.4, J_{ax} = 9.6, J_{bx} = 3.6, Δν_{ab} = 30.57 Hz), 2.20 (s, 3H); ^{13}C NMR δ: 177.19, 157.94, 140.99, 130.66, 126.52, 117.33, 107.21, 70.30, 55.30, 43.14, 15.98; HRMS calcd. for $C_{11}H_{14}O_4$: 210.0892; found: 210.0890.

2-Methyl-3-hydroxy-3-(4′-methylphenyl)propionic acid (5f)

Propionic acid (4.99 mmol, 0.372 mL) was deprotonated with LDA (diisopropylamine 13.31 mmol, 1.86 mL, and *n*-BuLi 12.48 mmol, 5.0 mL) and reacted with **3** (R^1 = Me, R^2 = H) (4.16 mmol, 0.50 g) according to the general procedure to afford a mixture of aldols 0.703 g (87%) of **5***f* (mp 71–73°C). IR ($CHCl_3$): 3650–2350, 1710, 1515, 1458, 1419, 1290, 1134, 1118, 1109, 1039, 1018, 986, 922 cm^{-1}; ^1H NMR δ: 7.26–7.12 (m, 10H), 5.12 (d, 1H, J = 3.6 Hz), 4.71 (d, 1H, J = 8.4 Hz), 2.88–2.76 (m, 2H), 2.35 (s, 3H), 2.34 (s, 3H), 1.14 (d, 3H, J = 7.2 Hz), 1.01 (d, 3H, J = 6.8 Hz); ^{13}C NMR δ: 181.14, 180.87, 138.05, 137.30, 129.27, 129.02, 126.66, 125.86, 76.17, 73.32, 47.05, 46.19, 21.14, 21.09, 14.33, 10.41; HRMS calcd. for $C_{11}H_{14}O_3$: 194.0943; found: 194.0947.

2-Methyl-3-hydroxy-3-(4′-methoxyphenyl)propionic acid (5g)

Propionic acid (4.44 mmol, 0.329 mL) was deprotonated with LDA (diisopropylamine 11.80 mmol, 1.65 mL, and *n*-BuLi 11.10 mmol, 4.5 mL) and reacted with **3** (R^1 = MeO, R^2 = H) (3.70 mmol, 0.50 g) according to the general procedure to afford a mixture of aldols 0.627 g (81%) of **5***g* (mp 50–52°C). IR ($CHCl_3$): 3650–2350, 1709, 1612, 1514, 1462, 1304, 1251, 1175, 1035, 1007, 919, 830 cm^{-1}; ^1H NMR δ:

7.27 (br d, 4H, J = 8.4 Hz), 6.89 (d, 2H, J = 8.4 Hz), 6.88 (d, 2H, J = 8.4 Hz), 5.09 (d, 1H, J = 4.0 Hz), 4.71 (d, 1H, J = 9.2 Hz), 3.81 (s, 3H), 3.80 (s, 3H), 2.88–2.75 (m, 2H), 1.16 (d, 3H, J = 7.2 Hz), 1.00 (d, 3H, J = 7.2 Hz); ^{13}C NMR δ: 180.65, 180.23, 159.39, 158.91, 133.25, 133.09, 127.96, 127.13, 113.84, 113.60, 75.88, 73.23, 55.15, 47.10, 46.28, 14.20, 10.51; HRMS calcd. for $C_{11}H_{14}O_4$: 210.0892; found: 210.0897.

*2-Methyl-3-hydroxy-3-(3′-methoxy-4′-methylphenyl)propionic acid (**5**h)*

Propionic acid (4.00 mmol, 0.298 mL) was deprotonated with LDA (diisopropylamine 10.67 mmol, 1.50 mL, and *n*-BuLi 10.00 mmol, 4.0 mL) and reacted with **3** (R^1 = Me, R^2 = MeO) (3.33 mmol, 0.50 g) according to the general procedure to afford a mixture of aldols 0.643 g (86%) of **5***h* (mp 96–98°C). IR ($CHCl_3$): 3650–2350, 1707, 1614, 1586, 1509, 1464, 1457, 1415, 1264, 1257, 1155, 1134, 1041, 1020, 993, 862, 819 cm^{-1}; ^{1}H NMR δ: 7.09 (br d, 2H, J = 8.0 Hz), 6.84 (br s, 2H), 6.80 (br, d, 2H, J = 7.2 Hz), 5.13 (d, 1H, J = 4.0 Hz), 4.71 (d, 1H, J = 9.2 Hz), 3.83 (s, 6H), 2.90–2.78 (m, 2H), 2.20 (br s, 6H), 1.16 (d, 3H, J = 7.2 Hz), 1.02 (d, 3H, J = 7.2 Hz); ^{13}C NMR δ: 181.11, 180.84, 157.98, 157.71, 139.96, 139.89, 130.50, 130.40, 126.85, 125.98, 118.78, 117.65, 107.92, 107.66, 76.48, 73.46, 55.31, 47.11, 46.28, 16.00, 15.94, 14.36, 10.50; HRMS calcd. for $C_{12}H_{16}O_4$: 224.1048; found: 224.1049.

*2-Benzyl-3-hydroxy-3-phenylpropionic acid (**5**j)*

Dihydrocinnamic acid (2.83 mmol, 0.425 g) was deprotonated with LDA (diisopropylamine 7.55 mmol, 1.06 mL, and *n*-BuLi 7.08 mmol, 2.8 mL) and reacted with **3** (R^1 = H, R^2 = H) (2.36 mmol, 0.250 g) according to the general procedure to afford a mixture of aldols 0.491 g (81%) of **5***i* (mp 151–153°C). IR ($CHCl_3$): 3650–2300, 1710, 1496, 1461, 1275, 1199, 1168, 1089, 1010, 979, 924, 896, 762, 704 cm^{-1}; ^{1}H NMR δ: 7.60–7.00 (m, 20H), 5.09 (d, 1H, J = 5.2 Hz), 4.82 (d, 1H, J = 7.2 Hz), 3.16–2.86 (m, 4H), 2.78–2.64 (m, 2H); ^{13}C NMR (CD_3COCD_3) δ: 175.27, 143.92, 140.15, 129.50, 129.03, 128.98, 128.37, 127.62, 126.89, 75.86, 56.40, 35.91; HRMS calcd. for $C_{16}H_{16}O_3$: 256.1099; found: 256.1085.

General procedure for the preparation of indenones

To a solution of acid **5** (1.0 equiv.) in CH_2Cl_2 (2 mL) was added a solution of $SOCl_2$ (2.4 equiv.) and DMF (0.03 equiv.) in CH_2Cl_2 (3 mL) via cannula over 30 min at room temperature. The reaction was stirred for 30 min and then heated at reflux for 15 min before removing the solvent in vacuo. This acid chloride in CH_2Cl_2 (2 mL) was added via cannula to a solution of $AlCl_3$ (1.1 equiv.) in CH_2Cl_2 (2 mL) at room temperature. After stirring for 30 min the reaction was poured into water, extracted four times with ether, and the combined extracts were washed successively with water, saturated $NaHCO_3$, and brine solution before drying with anhydrous Na_2SO_4. The solid was filtered, the solvent removed in vacuo. The crude **8** was dissolved in pyridine (1 mL) and heated at 70°C for 30 min to 2.5 h. After cooling to room temperature, the reaction was poured into water, extracted three times with ether, and the combined extracts were washed with 10% HCl solution, water, saturated $NaHCO_3$ solution, brine solution, and dried (Na_2SO_4). The solid was filtered, the solvent removed in vacuo, and the crude product purified by chromatography (20 g silica gel, EtOAc:hexanes = 1:9) to afford indenones **6**. Analytical samples were prepared by recrystallization from ether–hexanes.

*5-Methoxy-6-methyl-1-indenone (**2**)*

Treatment of **5***d* (0.51 mmol, 0.108 g) with $SOCl_2$ (1.23 mmol, 0.090 mL) and DMF (0.02 mmol, 0.002 mL) followed by $AlCl_3$ (0.56 mmol, 0.075 g) according to the general procedure afforded after chromatography 0.013 g (15%) of **2** as a yellow solid (mp 77–78°C). IR (CCl_4): 3001, 2957, 2927, 2856, 2836, 1710, 1610, 1587, 1506, 1488, 1464, 1456, 1296, 1281, 1270, 1244, 1168, 1160, 1151, 1131, 1115, 1095, 1067, 1043, 1001, 900, 856, 848 cm^{-1}; ^{1}H NMR δ: 7.40 (dd, 1H, J = 6.4, 0.4 Hz), 7.23 (s, 1H), 6.60 (s, 1H), 5.78 (d, 1H, J = 6.4 Hz), 3.89 (s, 3H), 2.16 (s, 3H); ^{13}C NMR δ: 197.95, 162.09, 147.87, 145.46, 127.30, 125.79, 122.30, 110.38, 105.63, 55.71, 16.27; HRMS calcd. for $C_{11}H_{10}O_2$: 174.06816; found: 174.0676.

*2,6-Dimethyl-5-methoxy-1-indenone (**6**h)*

Treatment of **5***h* (0.90 mmol, 0.200 g) with $SOCl_2$ (2.14 mmol, 0.156 mL) and DMF (0.03 mmol, 0.003 mL) followed by $AlCl_3$ (0.98 mmol, 0.131 g) according to the general procedure afforded after chromatography 0.122 g (72%) of **6***h* as an orange solid (mp 115–117°C). IR (CCl_4): 3055, 3003, 2957, 2938, 2919, 2855, 2839, 1717, 1608, 1478, 1466, 1344, 1269, 1243, 1078 cm^{-1}; ^{1}H NMR δ: 7.18 (s, 1H), 6.95 (s, 1H), 6.49 (s, 1H), 3.87 (s, 3H), 2.13 (s, 3H), 1.84 (d, 3H, J = 0.8 Hz); ^{13}C NMR δ: 198.12, 162.17, 145.81, 141.07, 136.24, 125.78, 124.13, 122.51, 104.79, 55.65, 16.11, 10.10; HRMS calcd. for $C_{12}H_{12}O_2$: 188.0837; found: 188.0849.

*2-Benzyl-1-indenone (**6**j)*

Treatment of **5***j* (0.39 mmol, 0.100 g) with $SOCl_2$ (0.94 mmol, 0.068 mL) and DMF (0.01 mmol, 0.001 mL) followed by $AlCl_3$ (0.43 mmol, 0.057 g) according to the general procedure afforded after chromatography 0.034 g (40%) of **6***j* as a solid (mp 98–99°C). IR (CCl_4): 3090, 3070, 3064, 3029, 2926, 2907, 2893, 1708, 1646, 1615, 1587, 1495, 1467, 1450, 1326, 1298, 1270, 1209, 1184, 1091, 959 cm^{-1}; ^{1}H NMR δ: 7.92 (d, 1H, J = 7.6 Hz), 7.68 (m, 2H), 7.62 (t, 1H, J = 7.6 Hz), 7.56 (d, 1H, J = 7.2 Hz), 7.51–7.37 (m, 5H), 4.06 (s, 2H); ^{13}C NMR δ: 194.32, 149.63, 138.02, 135.40, 134.72, 134.61, 133.92, 130.71, 129.65, 128.92, 127.67, 126.16, 124.45, 32.45; HRMS calcd. for $C_{10}H_{12}O_3$ (M − 1): 219.0810; found: 219.0806.

Enamines from formamides. Synthesis of 1,2,3,4-tetrahydro-1-substituted β-carbolines[1]

RAHUL VOHRA AND DAVID B. MACLEAN[2]
Department of Chemistry, McMaster University, Hamilton, ON L8S 4M1, Canada

Received December 20, 1993

RAHUL VOHRA and DAVID B. MACLEAN. Can. J. Chem. **72**, 1660 (1994).

Pyridines and benzopyridines substituted with trimethylsilylmethyl groups, α or γ to the nitrogen atom, have been found to react with formamides by way of a Peterson reaction to form enamines. Trimethylsilylmethylbenzene behaved similarly. The enamines prepared from N^b-formyl-N^a,N^b-dimethyltryptamine cyclized readily to β-carbolines. The reaction of formamides with lithiated 4-methylpyridines as a route to enamines was examined but proved to be less general and proceeded in lower yield than the route by way of the Peterson reaction. The nuclear magnetic resonance and mass spectra of the enamines and β-carbolines derived from **3** are discussed.

RAHUL VOHRA et DAVID B. MACLEAN. Can. J. Chem. **72**, 1660 (1994).

On a trouvé que les pyridines et benzopyridines substituées par des groupes triméthylsilylméthyles en α ou en γ de l'azote réagissent avec les formamides, par le biais d'une réaction de Peterson, pour conduire à la formation d'énamines. Le triméthylsilylméthylbenzène se comporte de la même manière. Les énamines préparées à partir de la N^b-formyl-N^a,N^b-diméthyltryptamine se cyclisent facilement en β-carbolines. On a examiné la réaction des formamides avec les 4-méthylpyridines lithiées, comme voie d'accès aux énamines, mais on a montré que la réaction est moins générale et qu'elle se produit avec un rendement plus faible que la voie impliquant la réaction de Peterson. On discute des spectres de résonance magnétique nucléaire et de masse des énamines et des β-carbolines dérivés du produit **3**.

[Traduit par la rédaction]

Introduction

It is known that acyclic enamines derived from tryptamine derivatives are effective precursors of β-carbolines (1–4). Cyclization of the enamines is brought about by treatment with acid and very likely proceeds, mechanistically, through an iminium ion intermediate in the same manner as the Pictet–Spengler reaction (5). We describe here an investigation of the preparation of enamines from formamides. We report that pyridines and benzopyridines, bearing a trimethylsilylmethyl group α or γ to the nitrogen atom, will react, by way of a Peterson reaction (6), with N^b-formyl-N^a,N^b-dimethyltryptamine to form enamines, suitable for elaboration to 1,2,3,4-tetrahydro-β-carbolines. Trimethylsilylmethylbenzene behaves similarly, and other formamides are shown to undergo the Peterson reaction to form enamines. We investigated also the reaction of lithio derivatives derived from 4-methylpyridines with several formamides as an alternative route to enamines. This approach proved to be less general and to proceed in lower yield than that proceeding through the trimethylsilylmethylpyridines.

Results and discussion

Synthesis of enamine precursors of β-carbolines from 3

The general approach to enamine precursors of β-carbolines by way of the Peterson reaction is outlined in Scheme 1. The pyridines and benzopyridines bearing trimethylsilylmethyl groups α or γ to the nitrogen atom, **1***a–g*, in the form of their lithio derivatives, **2***a–g*, reacted readily with **3**, in solution in tetrahydrofuran (THF). The enamines so formed, **4***a–g*, were converted into 1,2,3,4-tetrahydro-β-carbolines, **5***a–g*, by treatment with a saturated solution of hydrogen chloride in methanol. Trimethylsilylmethylbenzene undergoes a similar series of reactions, under different experimental conditions, to afford **4***h*, which cyclized under similar conditions to those used for **4***a–g*. There are only a few examples of the Peterson reaction applied to amides. Intermolecular reactions of this type have been reported by Woodbury and Rathke (7*a*) and by Agawa et al. (7*b*) and intramolecular reactions by Snieckus and co-workers (7*c–e*).

The pyridines and benzopyridines bearing a trimethylsilylmethyl group, compounds **1***a–g*, were prepared from the corresponding methylpyridines and methylbenzopyridines by treatment with lithium diisopropylamine (LDA) in tetrahydrofuran (THF) followed by treatment with trimethylsilyl chloride. The procedure used in the preparation of **1***a*, **1***b*, and **1***d–g* was patterned on that reported for the preparation of **1***b* (8) whereas the preparation of **1***c* was based on a published procedure (9). Compounds **1***a*, **1***b*, and **1***c* were isolated and purified by distillation in vacuo, whereas **1***d–g* were not isolated but were employed in situ in the preparation of enamines. Trimethylsilylmethylbenzene **1***h* was prepared from benzyl chloride (10).

Compound **3** was isolated in 1974 (11) as a by-product of a photochemical reaction and was synthesized by the same group by treatment of N^a,N^b-dimethyltryptamine with ethyl formate. We prepared **3** from N^b-formyltryptamine (12). A solution of the latter in dimethyl sulfoxide (DMSO) was treated with a solution of dimsyl sodium (2.25 equiv.) in DMSO and the red solution was stirred for 3 h before addition of iodomethane (3.0 equiv.); processing of the reaction mixture afforded **3** (92%). The ^{1}H and ^{13}C nmr spectra of **3** confirmed the earlier observation (11) that it is a mixture of rotamers.

Enamines **4***a–h* were prepared by way of the Peterson reaction between **3** and the lithio derivatives **2***a–h*. Lithio derivatives **2***a–c* were prepared by dropwise addition of a solution of the trimethylsilylmethyl compounds **1***a–c* in THF into a solution of LDA in THF. The solutions of **2***a–c*, so generated, were treated directly with a solution of **3** in THF to afford **4***a–c*, respectively. The enamines **4***d–g* were prepared from the methylbenzopyridines in a one-pot reaction without isolation of the trimethylsilylmethyl compounds. The conversion of **1***h* to **4***h* did not proceed under conditions that led to the formation of **4***a–c*. However, **4***h* was obtained when a solution of **1***h* in hexamethylphosphoric triamide (HMPTA) was treated first with *n*-BuLi in hexane and subsequently with a solution of **3** in THF.

The enamines were prone to decomposition on chromatography on silica gel. Purification of **4***a* and **4***b* was achieved by this

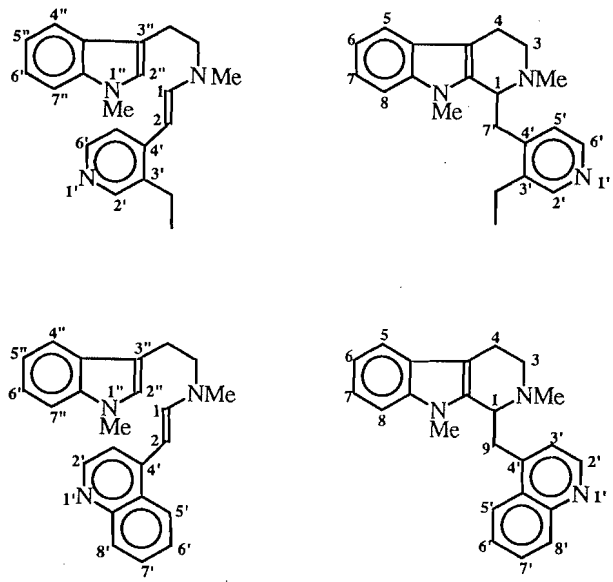
Ar = *a*, 3-ethylpyridin-4-yl; *b*, pyridin-4-yl; *c*, pyridin-2-yl; *d*, quinolin-4-yl; *e*, quinolin-2-yl; *f*, 3-methylquinolin-2-yl; *g*, 6,7-dimethoxyisoquinolin-1-yl; *h*, phenyl

SCHEME 1

method but with some loss of enamine. In other cases the crude enamines were used directly in the subsequent step. The 1,2,3,4-tetrahydro-β-carbolines, **5***a–h*, were prepared by treatment of the enamines with methanolic hydrogen chloride. The overall yields of the 1-substituted 1,2,3,4-tetrahydro-β-carbolines **5***a–c* and **5***h*, based on the trimethylsilyl derivatives **1***a–c* and **1***h*, were **5***a* (45%), **5***b* (44%), **5***c* (58%), and **5***h* (27%). The yields of **5***d–g* based on the methylated benzopyridines were **5***d* (34%), **5***e* (71%), **5***f* (63%), and **5***g* (61%). When **5***a* and **5***b* were prepared under the same conditions as **5***d–g*, namely, directly from 3-ethyl-4-methylpyridine and 4-methylpyridine, respectively, the yields of **5***a* and **5***b* were 58 and 56%, respectively. The preparation of **5***c* by this procedure was not attempted because of the tendency of 2-methylpyridine to form di-trimethylsilyl derivatives (8, 9). The preparation of **5***h* from toluene by this procedure was not considered feasible and was not attempted.

The structures assigned to all compounds are compatible with their ^{1}H nmr and mass spectra and their compositions. A characteristic feature of the ^{1}H nmr spectra of the enamines is the presence of an AB quartet ascribed to the vinylic protons of the enamine system, with coupling constants in the range 12.6–13.5 Hz, indicating that all compounds have the (*E*) configuration. The chemical shift of the higher field proton (H-2) in the spectra of **4***a–c* and **4***h* appeared in the range 4.90–5.17 and in the spectra of **4***d–g* in the range 5.28–5.77. The signals of the protons at H-1 appeared at lower field, lying in the range 6.88–7.92. In some cases the signals for this proton overlapped with those of aromatic protons in the same region and they could not be assigned definitively.

The ^{1}H nmr spectra of the 1,2,3,4-tetrahydro-β-carbolines, **5***a–h*, lack signals corresponding to H-1, H-2, and H-2″ present in the enamines. However, all exhibit a signal ascribed to H-1 of the 1,2,3,4-tetrahydro-β-carboline system and signals for the



two diastereotopic protons of the adjacent methylene group. These protons are designated H-7′a and H-7′b in **5***a–c* and **5***h*, the β-carbolines derived from the methyl pyridines and from toluene. The corresponding methylene protons in the benzopyridines are designated H-9′a and H-9′b.

The ^{13}C spectra of β-carbolines **5***a–h* are characterized by the presence of a signal in the range δ 57.2–59.8 assigned to C-1. The spectra show only small variations in chemical shift for the NMe carbons and for the methylene carbons at C-3 and C-4. There is, however, a broader range of chemical shift for C-7′ (in **5***a–c* and **5***h*) and for its counterpart C-9′ in **5***d–g*.

The mass spectra of the enamines **4***a–h* show two major pathways of fragmentation, illustrated in Scheme 2 (see Table 1 for ion abundances), which support their structures. Fission at "x"

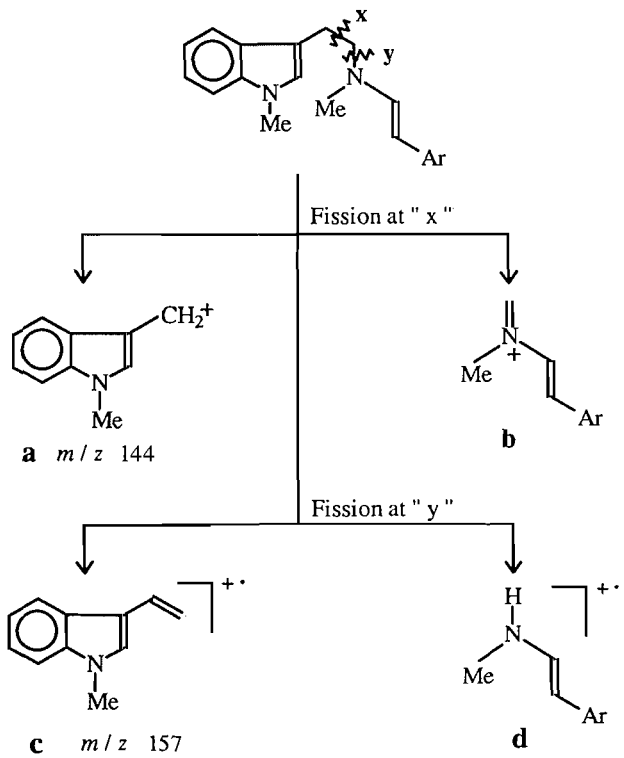

SCHEME 2

affords two even-electron ions **a** and **b**. Ion **a** at *m/z* 144, derived from the indole moiety, is the more abundant ion in the spectra of **4***a*, **4***b*, **4***d*, and **4***h*. Ion **b**, comprising the remainder of the molecule, is more abundant in the spectra of **4***c* and **4***e*–**4***g* and approximates the abundance of **a** in **4***h*. The greater abundance of **b** is observed in those compounds where the enamine function is situated α to the nitrogen atom of the pyridines, quinolines, and the isoquinoline (represented by Ar in the various formulas). It seems likely, therefore, that the aromatic nitrogen atom plays a part in charge stabilization as illustrated in the formula of **b** derived from **4***c*, Fig. 1. Analogous structures may be written for ion **b** derived from **4***e*–*g*. In the other compounds the enamine function is γ to the nitrogen atom and unable, sterically, to participate in charge stabilization. The relatively high abundance of **b** in **4***h* might result from charge stabilization through the structure illustrated in Fig. 1 for ion **b** derived from **4***h*.

Fission of the molecule at "y" affords two odd-electron ions, **c** and **d**. Ion **c** at *m/z* 157, derived from the indole moiety and the two-carbon side chain, has the same mass in **4***a*–*h*, and ion **d** comprises the remainder of the molecules plus a hydrogen atom, probably transferred from the indole moiety in the formation of ion **c**. In all but one instance, ion **c** is more abundant than **d**. Ion **d** is relatively more abundant in those compounds that have the enamine group situated α to the nitrogen atom than in those compounds where the enamine is γ to the nitrogen atom. Its stabilization in the α relative to their γ-substituted analogues may be a consequence of hydrogen bonding as illustrated for **d** derived from **4***c* in Fig. 1.

The molecular ion varies in intensity with the Ar group but never exceeds 40%. Previous reports (13–15) on the mass spectra of enamines have been concerned mainly with acyclic enamines derived from aliphatic aldehydes and ketones and secondary amines, e.g., morpholine, piperidine, pyrrolidine,

TABLE 1. Relative abundances of selected ions in the mass spectra of **4***a*–*h*

	Ion				
Enamine	M^+	**a**[a]	**b**	**c**[a]	**d**
4*a*	319(12)	100	175(46)	56	162(4)
4*b*	291(18)	100	147(45)	50	134(6)
4*c*	291(12)	45	147(100)	26	134(19)
4*d*	341(25)	100	197(68)	65	184(3)
4*e*	341(10)	31	197(100)	32	184(38)
4*f*	355(<1)	73	211(100)	65	198(31)
4*g*	401(38)	20	257(100)	42	244(32)

[a]In all compounds **a** appears at *m/z* 144 and **c** at *m/z* 157.

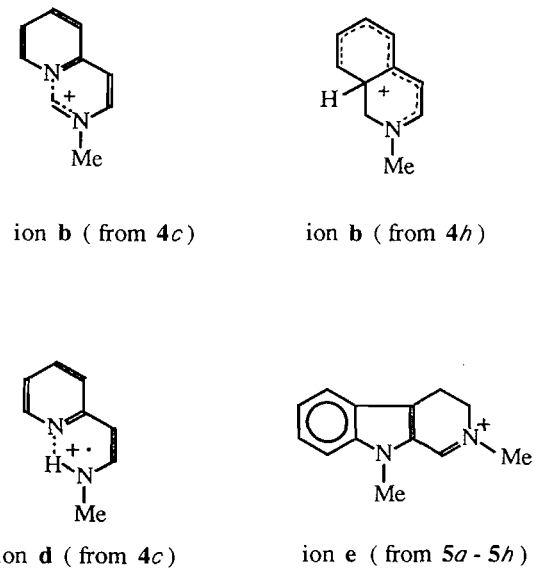

FIG. 1. Postulated structures of fragment ions in the EI spectra of enamines and β-carbolines.

and dialkyl amines. Formation of ions of type "**b**" was a dominant process in the spectra of those compounds as it is in the examples cited here. However, the presence of two aromatic systems in compounds **4***a*–*h* has a pronounced influence on their mode of fragmentation and leads to fragmentation pathways that were absent or not prominent in the compounds previously examined (13–15).

The mass spectra of the β-carbolines **5***a*–*h* are characterized by the presence of an abundant fragment ion at *m/z* 199 (ion **e**), the base peak in all spectra, derived from the 1,2,3,4-tetrahydro-β-carboline moiety. Fragment ions derived from the arylmethyl groups at C-1 of the β-carboline are uniformly of low abundance, as is the molecular ion. An ion at *m/z* 158 of low abundance is present in all spectra and, from its mass and composition, must be associated with the indole moiety.

Enamines from other formamides

We have found that dimethylformamide (DMF), *N*-formylmorpholine, and *N*-formyl-*N*-methyl-2-(3,4-dimethoxyphenyl)ethylamine undergo reactions under Peterson conditions to afford enamines in good yield. Like their counterparts derived from **3**, the enamines have the (*E*) configuration as evidenced by the coupling constants of the vinylic protons (J = 13.0–13.5 Hz). Compounds **6**, **7**, and **9** were derived from **1***a* as the tri-

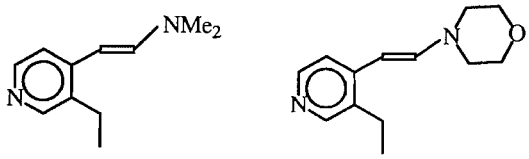
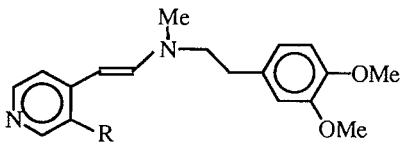
For personal use only.

methylsilylmethyl component and compound **10** from **1***b*. The facile formation of the enamines **4***a–h* and **6**, **7**, **9**, and **10** is very likely a consequence of the conjugation of the enamine function with the aromatic system. We have not applied the reaction to systems where conjugation of the putative enamine to an aromatic system would be precluded.



6 **7**



9 R = C_2H_5
10 R = H

N,N-Dimethylacetamide failed to yield an enamine under conditions that led to the formation of **6** from DMF. This result implies that amides, other than formamides, are unlikely to react under the conditions employed in this investigation. We found, also, that 3,4-dimethylquinoline failed to afford an enamine under conditions that were successful with 4-methylquinoline. Thus the reaction is sensitive to steric effects with respect to the amide employed and also to substitution on the aromatic ring, in the case of 4-methylquinolines.

Enamines by reaction of lithiated methyl pyridines with formamides

The reaction of organometallic reagents with formamides is a standard procedure for the introduction of an aldehyde function into an organic molecule. *N*-Formyl morpholine (16), *N*-formylpiperidine (17), and DMF (18) are often employed as the amide component. The reaction is considered to proceed through addition of the organometallic reagent to the amide carbonyl to afford a metalated hemiaminal. By quenching the reaction mixture with aqueous acid an aldehyde is liberated. This type of reaction has been applied also to enamine synthesis (19) using both Grignard and alkyl lithium reagents to add to dialkylformamides. It was reported that the adducts from Grignard addition afforded enamines spontaneously whereas those from alkyl lithium addition yielded enamines only after addition of a Lewis acid.

We considered that the hemiaminal intermediates that led to aldehydes upon quenching with aqueous acid might afford enamines upon quenching with aqueous alkali. In the event we found that enamines were formed from the reaction between lithiated 3-ethyl-4-methylpyridine with DMF, *N*-formylmorpholine, and **3**, when the reaction mixtures were processed under alkaline conditions. The yields of enamine were lower than those obtained by way of the Peterson reaction (for **6** (45% vs. 65%), for **7** (48% vs. 81%), and for **4***a* (33% vs. 60%)). However, we found that lithiated 4-methylpyridine failed to afford the desired enamine **4***b* under a variety of experimental conditions. Because of the lower yields of enamines and our failure to obtain **4***b*, this approach to enamine formation was not pursued further.

Conclusion

The preparation of enamines from formamides by way of the Peterson reaction has been investigated and shown to be applicable to formamides of different structural types. The main emphasis of this work has been directed to the preparation of enamines from **3** and their cyclization to 1,2,3,4-tetrahydro-β-carbolines bearing pyridylmethyl, benzopyridylmethyl, or benzyl groups at C-1. This method of preparation of β-carbolines complements the Pictet–Spengler reaction for 1,2,3,4-tetrahydro-β-carboline synthesis. It will find its main use in those cases where the aldehydes normally used in the Pictet–Spengler reaction are unstable or otherwise difficult to obtain.

Experimental

Apparatus, methods, and materials

The ^{1}H nmr spectra were recorded on Bruker AC 200, AC 300, and AM500 spectrometers at 200, 300, and 500 MHz, respectively, or on a Varian EM390 spectrometer at 90 MHz; $CDCl_3$ was the solvent and tetramethylsilane (TMS) was used as the internal standard, unless otherwise stated. Chemical shifts are reported in ppm (δ) downfield from the signal of TMS. The symbols, s (singlet), d (doublet), t (triplet), q (quartet), and m (multiplet), are used to report the multiplicity of signals. The ^{13}C nmr spectra were recorded at 125.76 MHz, at 75.46 MHz, and at 50.3 MHz on Bruker AM 500, AC 300, and AC 200 spectrometers, respectiveily, at ambient temperature. The carbon chemical shifts are quoted in ppm with reference to $CDCl_3$ (77.00 ppm). Spin decoupling and nuclear Overhauser experiments were employed to assign signals in the ^{1}H nmr spectra; selective proton decoupling, spin sort, and DEPT experiments were used to assign signals in the ^{13}C experiments.

EI (electron ionization) mass spectra were recorded at 70 eV on a VG Analytical ZAB-E mass spectrometer equipped with a VG 11-250 data system. Chemical ionization (CI) spectra were recorded on the same instrument using NH_3 at ~1 Torr (1 Torr = 133.3 Pa) as reagent gas. The peak intensities are given as a percent of the intensity of the base peak (100%). High-resolution mass spectra (hrms) measurements were performed on the above instrument under EI conditions.

All reactions involving lithiation were performed in apparatus dried in the oven at 120°C for at least 12 h and assembled hot under a stream of argon. Septa and syringes were used for transfer of reagents. Solvents and reagents were reagent grade and, when required, further purification was accomplished following published procedures. THF, used in lithiation reactions, was dried over sodium and distilled immediately before use. Trimethylsilylmethylbenzene (10), 6,7-dimethoxy-1-methylisoquinoline (20), and 2,3-dimethylquinoline (21) were prepared by methods described in the literature; 2- and 4-methylpyridine, 3-ethyl-4-methylpyridine, 2- and 4-methylquinoline, and *N*-formylmorpholine were obtained commercially.

Melting points were determined using a Fisher–Johns apparatus and are uncorrected. Thin-layer chromatography was performed using silica gel 60-F_{254} plates of 0.25 mm thickness. Samples were purified by preparative-layer, radial chromatography (2 or 4 mm layers) using silica gel PF_{254}. The plates were eluted sequentially with hexane, ethyl acetate, and methanol.

The homogeneity of the products was established on the basis of chromatographic and spectroscopic (^{1}H nmr and mass spectral) examination.

3-Ethyl-4-trimethylsilylmethylpyridine 1a

A solution of 3-ethyl-4-methylpyridine (500 mg, 4.13 mmol) in THF (5 mL) was added dropwise, under an argon atmosphere at −10°C, to a stirred solution of LDA (prepared from diisopropylamine

For personal use only.

(0.58 mL, 4.13 mmol) in THF (5 mL) and *n*-BuLi (1.65 mL, 2.5 M in hexane)). When addition was complete, the reaction mixture was stirred at 0°C for 30 min and for an additional 1 h at ambient temperature. Then the reaction mixture was cooled to 0°C, trimethylsilyl chloride (0.53 mL, 4.13 mmol) was added dropwise, and the mixture was stirred for 30 min. The solution was allowed to warm to room temperature and stirring was continued for 1 h. Water (5 mL) was added, the mixture was stirred for 5 min, and then extracted with CH_2Cl_2 (30 mL). The extract was washed first with water and then with brine and dried over anhydrous sodium sulfate. Evaporation of the solvent afforded an oil, which was purified by bulb-to-bulb distillation to afford **1***a* as a colorless oil (680 mg, 85%); bp 110°C, 5 Torr; ^{1}H nmr (90 MHz, $CDCl_3$) δ: 0.03 (9H, s, SiMe_3), 1.17 (3H, t, J = 7.0 Hz, CH_3), 2.10 (2H, s, CH_2 Si), 2.55 (2H, q, J = 7.0 Hz, CH_2CH$_3$), 6.85 (1H, d, J = 5.0 Hz, H-5), 8.26 (1H, d, J = 5.0 Hz, H-6), 8.33 (1H, s, H-2); ms *m/z* (EI): 193 (100), 192 (68), 178 (20), 165 (13), 150 (7). Exact Mass (hrms) calcd. for $C_{11}H_{19}NSi$: 193.1287; found: 193.1297.

4-Trimethylsilylmethylpyridine **1**b

This compound was prepared by the procedure described for the preparation of **1***a*. Yield, 85%; bp 105°C, 40 Torr; ^{1}H nmr (90 MHz, $CDCl_3$) δ: 0.03 (9H, s, SiMe_3), 2.05 (2H, s, CH_2SiMe$_3$), 6.90 (2H, d, $J \approx$ 5.0 Hz, H-3 and H-5), 8.40 (2H, d, J ≈ 5.0 Hz, H-2 and H-6); ms *m/z* (EI): 165 (62), 150 (14), 93 (26), 73 (100); ms *m/z* (CI–NH_3): 166 (100) [M + H]$^+$. Exact Mass (hrms) calcd. for $C_9H_{15}NSi$: 165.0974; found: 165.0987.

2-Trimethylsilylmethylpyridine **1**c

A solution of 2-methylpyridine (4.42 g, 47.5 mmol) in THF (5 mL) was added dropwise, under an argon atmosphere at −65°C, to a stirred solution of LDA (prepared from diisopropylamine (6.65 mL, 47.5 mmol) in THF (57 mL) and *n*-BuLi (19 mL, 1.6 M in hexane)). When addition was complete, the reaction mixture was stirred at −65°C for 1 h and then for an additional 0.5 h at −40°C. The reaction mixture was cooled to −65°C, trimethylsilyl chloride (3.0 mL, 23.7 mmol) was added dropwise, and the mixture was stirred for 1.5 h at −65°C. The solution was allowed to warm to room temperature and stirring was continued for 1 h. Water (10 mL) was added and the mixture was extracted with ether (3 × 15 mL). The combined extract was washed with water and then with brine and dried over anhydrous sodium sulfate. Evaporation of the solvent afforded an oil, which was purified by vacuum distillation to afford **1***c* as a colorless oil (3.0 g, 77%, based on Me_3SiCl); bp 98°C, 40 Torr; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.03 (9H, s, SiMe_3), 2.34 (2H, s, CH_2SiMe$_3$), 6.92–7.03 (2H, m, H-3, H-4), 7.44–7.56 (1H, m, H-5), 8.40–8.46 (1H, m, H-6); ms *m/z* (EI): 165 (18), 150 (100), 120 (9), 84 (18), 73 (63). ms *m/z* (CI–NH_3): 166 (M^+ + 1) (100), 150 (8). Exact Mass (hrms) calcd. for $C_9H_{15}NSi$: 165.0974; found: 165.0976.

N^b-*Formyl*-N^a,N^b-*dimethyltryptamine* **3**

Sodium hydride (2.32 g, 80% in mineral oil), suspended in dimethyl sulfoxide (38 mL), was heated at 80°C for 15 min to generate a 2 M solution of dimsylsodium. To a solution of *N*-formyltryptamine (6.1 g, 32.5 mmol) in dry DMSO (7 mL) was added dimsylsodium (37 mL, 73.4 mmol) at 20°C. The red solution was stirred for 3 h at 20°C, treated with MeI (4.7 mL, 75.8 mmol), and stirred an additional 30 min. Water (300 mL) was added to the reaction mixture and the resulting solution was extracted with CH_2Cl_2 (3 × 40 mL). The combined extract was washed with water and brine and dried over anhydrous Na_2SO_4. Evaporation of the dry extract afforded **3** (6.45 g, 92%) as an oil; ^{1}H nmr (500 Mz, $CDCl_3$) δ: 2.85 and 2.91 (3H, 2s, N^{b}Me), 2.96 and 2.99 (2H, 2 t, $J \approx$ 6.9 Hz and 7.6 Hz, CH_2CH$_2$N), 3.49 and 3.62 (2H, 2 t, $J \approx$ 6.9 and 7.6 Hz, CH$_2$CH_2N), 3.70 (3H, s, N^{a}Me), 6.80 and 6.89 (1H, 2 s, H-2), 7.10–7.13 (1H, t, H-5), 7.20–7.24 (1H, m, H-6), 7.26–7.29 (1H, overlapping d, H-7), 7.52 and 7.53 (1H, 2 d, $J \approx$ 7.5 Hz and 7.9 Hz, H-4), 7.78 and 8.03 (1H, 2 s, CH═O); ^{13}C nmr (125.8 MHz, $CDCl_3$) δ: 22.56 and 24.21 (CH_2CH$_2$N), 29.47 and 34.79 (N^{b}Me), 32.45 (N^{a}Me), 44.91 and 50.04 (CH$_2$CH$_2$N), 109.12 and 109.35 (C-7), 110.00 and 111.09 (C-3), 118.23, 118.60, 118.74, and 118.91 (C-4 and C-5), 121.49 and 121.68 (C-6), 126.59 and 126.96 (C-2), 127.30 and 127.71 (C-3a), 136.91 and 137.01 (C-7a), 162.29 and 162.53 (*C*H═O); ms *m/z* (EI): 216 (17), 157 (46), 144 (100), 115 (10), 44 (20); ms *m/z* (CI–NH_3): 234 [M + NH_4]$^+$ (100). Exact Mass (hrms) calcd. for $C_{13}H_{16}N_2O$: 216.1263; found: 216.1278.

(E)-*1-(*N^a,N^b-*Dimethyltryptaminyl)-2-(3-ethylpyridin-4-yl)ethene* **4**a

(a) From 3-ethyl-4-trimethylsilylmethylpyridine

A stirred solution of LDA, prepared from diisopropylamine (0.62 mmol) in THF (1 mL) and *n*-BuLi (0.4 mL, 1.6 M in hexane), was treated dropwise at −20°C under an argon atmosphere with a solution of **1***a* (100 mg, 0.52 mmol) in THF (1 mL). When the addition was complete, the temperature of the reaction mixture was raised to 25°C and the reddish-orange solution was stirred for 1 h before cooling to −60°C. The cooled solution was treated dropwise with a solution of **3** (118 mg, 0.54 mmol) in THF (1 mL) and stirred for 1 h. The temperature of the mixture was allowed to rise to 20°C and stirring was continued for 1 h more. The resulting mixture was processed in the usual manner to afford an oil, which was subjected to radial chromatography (silica gel, 60 PF_{254}, EtOAc). The major fraction **4***a* (100 mg, 60%) was obtained as a yellow oil; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 1.21 (3H, t, J = 7.5 Hz, CH$_2$CH_3), 2.58 (2H, q, J = 7.5 Hz, CH_2CH$_3$), 2.89 (3H, s, N^{b}Me), 3.00 (2H, apparent t, $J \approx$ 7.0 Hz, CH_2CH$_2$N), 3.49 (2H, apparent t, J = 7.0 Hz, CH$_2$CH_2N), 3.70 (3H, s, N^{a}Me), 5.05 (1H, d, J = 13.5 Hz, CH═CHN), 6.60–7.80 (6H, m, H-2″, H-5″, H-6″, H-7″, H-5′, CH═CHN), 7.60 (1H, d, J = 7.6 Hz, H-4″), 8.09 (1H, d, J = 5.4 Hz, H-6′), 8.15 (1H, s, H-2′); ms *m/z* (EI): 319 (12), 175 (46), 162 (4), 157 (56), 144 (100), 117 (14). Exact Mass (hrms) calcd. for $C_{21}H_{25}N_3$: 319.2048; found: 319.2034.

(b) From 3-ethyl-4-methylpyridine

The procedure was the same as that in part (*a*) except that 3-ethyl-4-methyl pyridine (69 mg, 0.57 mmol) was used instead of **1***a*, along with appropriate amounts of other reagents. Compound **4***a* was obtained as a yellow oil (60 mg, 33%).

(±)-*1,2,3,4-Tetrahydro-*N^a,N^b-*dimethyl-1-[(3-ethylpyridin-4-yl)methyl]-*β-*carboline* **5**a

Enamine **4***a* (200 mg, 0.63 mmol) was added at 0°C to a saturated solution of HCl in MeOH (1.5 mL) and the mixture was stirred for 10 min. The temperature was raised to 20°C and stirring was continued for 1 h. The reaction mixture was made basic with ammonia, and was taken to dryness under vacuum. The residue was treated with CH_2Cl_2 (10 mL) and water (5 mL), the organic layer was separated, and the CH_2Cl_2 extract was washed, in succession, with water and brine. The extract was dried over anhydrous sodium sulfate and the solvent removed to afford **5***a* as a light yellow solid (150 mg, 75%), mp 118–119°C; ^{1}H nmr (500 MHz, $CDCl_3$) δ: 1.19 (3H, t, $J \approx$ 7.6 Hz, CH$_2$CH_3), 2.44 (3H, s, N^{b}Me), 2.60–2.65, 2.93–3.02, 3.11–3.16, 3.31–3.39 (8H, 4 m, CH_2CH$_3$, 2 H-7′, 2 H-3, 2 H-4), 3.35 (3H, s, N^{a}Me), 3.92–3.96 (1H, dd, H-1), 7.10 (1H, t, J = 7.8 Hz, H-6), 7.16 (1H, d, J = 5.0 Hz, H-5′), 7.19 (1H, t, J = 7.8 Hz, H-7), 7.23 (1H, d, J = 8.1 Hz, H-8), 7.52 (1H, d, J = 7.8 Hz, H-5), 8.36 (1H, d, J = 5.0 Hz, H-6′), 8.40 (1H, s, H-2′). ^{13}C nmr (125.8 MHz, $CDCl_3$) δ: 15.09 (CH$_2$CH_3), 16.76 (C-4), 23.30 (CH_2CH$_3$), 29.59 (N^{a}Me), 36.25 (C-7′), 41.81 (N^{b}Me), 44.29 (C-3), 58.18 (C-1), 106.78 (C-4a), 108.86 (C-8), 118.24 (C-5), 119.10 (C-6), 121.42 (C-7), 124.21 (C-5′), 126.85 (C-4b), 135.23 (C-3′), 137.27 (C-9a), 137.98 (C-8a), 146.02 (C-4′), 147.34 (C-6′), 149.94 (C-2′); ms *m/z* (EI): 319 (1), 199 (100); ms *m/z* (CI–NH_3): 320 [M + H]$^+$ (20), 199 (100), 122 (20). The procedure described for the preparation of **4***d* was employed. From 6,7-dimethoxy-1-methylisoquinoline (100 mg, 0.49 mmol), and appropriate amounts of other reagents, compound **4***g* was obtained as a yellow oil that was used without purification in the next step; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 3.01 (3H, s, N^bMe), 3.08 (2H, apparent t, $J \approx 8.0$ Hz, CH_2CH_2N), 3.58 (2H, apparent t, $J \approx 8.0$ Hz, CH_2CH_2N), 3.69 (3H, s, N^aMe), 4.00, 4.01 (6H, 2 s, 2 OCH_3), 5.77 (1H, d, J = 12.6 Hz, C*H*=CHN) 6.88 (1H, s, H-2″), 6.96 (1H, s, H-5′), 7.04–7.34 (4H, m, H-4′, H-5″, H-6″, H-7″), 7.36 (1H, s, H-8′), 7.63 (1H, d, J = 7.0 Hz, H-4″), 7.92 (1H, d, J = 12.6 Hz, CH=C*H*N), 8.16 (1H, d, J = 5.6 Hz, H-3′); ms *m/z* (EI): 401 (38), 357 (3), 343 (17), 257 (100), 244 (32), 157 (42), 144 (20). Exact Mass (hrms) calcd. for $C_{25}H_{27}N_3O_2$; 401.2079; found: 401.2088.

*(±)-1,2,3,4-Tetrahydro-*N^a,N^b*-dimethyl-1-[(6,7-dimethoxyisoquinolin-1-yl)methyl]-β-carboline* **5**g

Enamine **4***g* (450 mg, 1.12 mmol) was subjected to the reaction conditions described for the preparation of **5***a*. Compound **5***g* was isolated as a yellow oil (275 mg, 61%), which was crystallized from EtOAc to afford yellow crystals, mp 101–102°C; ^{1}H nmr (300 MHz, $CDCl_3$) δ: 2.49 (3H, s, N^bMe), 2.66–2.75, 2.98–3.11, 3.41–3.52, 3.74–3.84 (6H, 2 H-3, 2 H-4, 2 H-9′), 3.20 (3H, s, N^aMe), 3.71, 3.98 (6H, 2 s, 2 OCH_3), 4.56–4.67 (1H, m, H-1), 7.02 (1H, s, H-5′), 7.20 (1H, s, H-8′), 7.05–7.53 (5H, m, H-5—H-8, H-4′), 8.40 (1H, d, J = 6.0 Hz, H-3′); ^{13}C nmr (75.5 MHz, $CDCl_3$) δ: 17.41 (C-4), 29.48 (N^aMe), 39.63 (C-9′), 41.70 (N^bMe), 45.00 (C-3), 55.70, 55.88 (2 OMe), 57.21 (C-1), 103.67, 104.96, 108.72, 117.87, 118.29, 118.67, 121.08 (aromatic *C*H), 105.95, 123.78, 132.98, 136.51, 137.13 (aromatic quaternary), 140.97 (C-3′), 149.74, 152.41 (C-6′ and C-7′), 156.79 (C-1′); ms *m/z* (EI): 401 (2), 343 (2), 199 (100), 183 (4), 158 (7); ms *m/z* (CI–NH_3): 402 $[M + H]^+$ (3), 204 (42), 199 (100). Exact Mass (hrms) calcd. for $C_{25}H_{27}N_3O_2$: 401.2103; found: 401.2084.

(E)-1-(N^a,N^b-Dimethyltryptaminyl)-2-phenylethene **4**h

To a stirred, ice-cooled solution of benzyltrimethylsilane (210 mg, 1.28 mmol) in HMPA (1.2 mL) was added *n*-BuLi (0.8 mL, 1.6 M in hexane). After the addition of *n*-BuLi was complete, the deep reddish solution was stirred for 1 h at 5–10°C before cooling to −10°C. The cooled solution was treated dropwise with a solution of **3** (290 mg, 1.34 mmol) in THF (1 mL) and then stirred for 30 min. The temperature of the reaction mixture was allowed to rise to 20°C and stirring was continued for 24 h. Water (50 mL) was added and the mixture was extracted with CH_2Cl_2 (3 × 5 mL). The extract was washed first with water, then with brine, and dried. Evaporation of the solvent afforded enamine **4***h* as an oil, which was used as such in the next step; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 2.71 (3H, s, N^bMe), 2.88 (2H, t, J = 7.0 Hz, CH_2CH_2N), 3.28 (2H, t, J = 7.0 Hz, CH_2CH_2N), 3.59 (3H, s, N^aMe), 5.03 (1H, d, J = 13.4 Hz, C*H*=CHN), 6.60–7.21 (9H, m, CH=C*H*N, H-2′–H-6′, H-2″, H-5″, H-6″, H-7″), 7.47 (1H, d, J = 7.6 Hz, H-4″); ms *m/z* (EI): 290 (18), 157 (50), 146 (98), 144 (100), 133(1), 77 (34); ms *m/z* (CI–NH_3): 291 $[M + H]^+$ (100). Exact Mass calcd. for $C_{20}H_{22}N_2$: 290.1782; found: 290.1780.

*(±)-1,2,3,4-Tetrahydro-*N^a,N^b*-dimethyl-1-phenylmethyl-β-carboline* **5**h

Enamine **4***h* from the previous reaction was subjected to the reaction conditions described for the preparation of **5***a*. Compound **5***h* was isolated as a colorless oil (100 mg, 27%, based on benzyltrimethylsilane); ^{1}H nmr (300 MHz, $CDCl_3$) δ: 2.44 (3H, s, N^bMe), 2.53–2.65, 2.90–3.03, 3.08–3.17, 3.31–3.41 (6H, 4 m, 2 H-3, 2 H-4, 2 H-7′), 3.28 (3H, s, N^aMe), 3.84–3.90 (1H, dd, H-1), 7.05–7.31 (8H, m, H-2′–H-6′, H-6–H-8), 7.52 (1H, d, J = 7.5 Hz, H-5); ^{13}C nmr (75.5 MHz, $CDCl_3$) δ: 16.97 (C-4), 29.40 (N^aMe), 40.87 (C-7′), 41.88 (N^bMe), 44.30 (C-3), 59.79 (C-1), 106.23 (C-4a), 108.75 (C-8), 118.10 (C-5), 118.62 (C-6), 121.01, 126.24, 128.35, 129.25 (C-7, C-2′–C-6′), 126.91 (C-4b), 135.98 (C-1′), 137.16 (C-9a), 139.67 (C-8a); ms *m/z* (EI): 199 (100), 183 (5), 158 (9), 91 (9); ms *m/z* (CI–NH_3): 291 $[M + H]^+$ (100), 199 (40). Exact Mass calcd. for $C_{20}H_{22}N_2$: 290.1783; found: 290.1793.

(E)-1-Dimethylamino-2-(3-ethylpyridin-4-yl)ethene **6**

(a) From 3-ethyl-4-trimethylsilylmethylpyridine

The procedure described for the preparation of **4***a* was employed, except that DMF was substituted for **3**. From **1***a* (100 mg, 0.52 mmol), and appropriate amounts of other reagents, compound **6** (60 mg, 65%) was obtained as a viscous oil that solidified in the freezer; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 1.21 (3H, t, J = 7.5 Hz, CH_2CH_3), 2.62 (2H, q, J = 7.5 Hz, CH_2CH_3), 2.89 (6H, s, NMe_2), 5.08 (1H, d, J = 13.5 Hz, C*H*=CHN), 6.98 (1H, d, J = 13.5 Hz, CH=C*H*N), 7.10 (1H, d, J = 5.4 Hz, H-5), 8.14 (1H, d, J = 5.4 Hz, H-6), 8.17 (1H, s, H-2); ^{13}C (50.3 MHz, $CDCl_3$) δ: 13.78 (CH_2CH_3), 23.40 (CH_2CH_3), 40.10 (NMe_2), 90.39 (*C*H=CHNMe$_2$), 114.9 (CH=*C*HNMe$_2$), 136.0 (C-3), 143.13, 145.89, 146.52 (C-2, C-5, and C-6), 145.29 (C-4); ms *m/z* (EI): 176 (100), 161 (17), 145 (22), 132 (45), 117 (20); ms *m/z* (CI–NH_3): 177 $[M + H]^+$ (100). Exact Mass (hrms) calcd. for $C_{11}H_{16}N_2$: 176.1313; found: 176.1317.

(b) From 3-ethyl-4-methylpyridine

3-Ethyl-4-methylpyridine (5.19 g, 42 mmol) was converted into its lithio derivative using the procedure described in the preparation of **1***a*. The reaction mixture was cooled to −60°C, treated with DMF (3.91 mL, 42 mmol), and stirred for 1 h at −60°C. The cooling bath was removed, the solution was brought to room temperature, and stirring was continued for 1 h more. Water (10 mL) and CH_2Cl_2 (100 mL) were added to the reaction mixture. The CH_2Cl_2 layer was separated and washed sequentially with water and brine. The extract was dried over anhydrous sodium sulfate. The drying agent was removed by filtration and the filtrate was evaporated to afford a brown oil; purification was effected by bulb-to-bulb distillation (bp 160°C, 0.1 Torr) to afford **6** (3.35 g, 45%).

(E)-1-Morpholinyl-2-(3-ethylpyridin-4-yl)ethene **7**

(a) From 3-ethyl-4-trimethylsilylmethylpyridine

The procedure was the same as that used for the preparation of **4***a* except that *N*-formylmorpholine was substituted for **3**. From **1***a* (100 mg, 0.52 mmol), and appropriate amounts of other reagents, compound **7** (90 mg, 81%) was obtained; mp 88–89°C; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 1.23 (3H, t, J = 7.6 Hz, CH_2CH_3), 2.64 (2H, q, J = 7.6 Hz,

CH_2CH_3), 3.15–3.28 (4H, m, CH_2-N-CH_2), 3.75–3.85 (4H, m, CH_2-O-CH_2), 5.38 (1H, d, J = 13.5 Hz, CH=CHN), 6.95 (1H, d, J = 13.5 Hz, CH=CHN), 7.21 (1H, d, J = 5.5 Hz, H-5), 8.19 (1H, d, J = 5.5 Hz, H-6), 8.21 (1H, s, H-2); ^{13}C (50.3 MHz, $CDCl_3$) δ: 14.37 (CH_2CH_3), 23.72 (CH_2CH_3), 48.52 (CH_2-N-CH_2), 66.11 (CH_2-O-CH_2), 93.90 (CH=CH-N), 116.19 (CH=CH-N), 133.53 (C-3), 144.50 (C-4), 142.79, 146.7, 149.38 (C-2, C-5, C-6); ms *m/z* (EI): 218 (100), 173 (7), 159 (22), 145 (40), 132 (45), 112 (32); ms *m/z* (CI–NH_3): 219 $(M + H)^+$ (100), 150 (12). Exact Mass (hrms) calcd. for $C_{13}H_{18}N_2O$: 218.1419; found: 218.1420.

(b) From 3-ethyl-4-methylpyridine

The procedure described for the preparation of **6** (method (*b*)) was employed, except that *N*-formylmorpholine was substituted for DMF. From 3-ethyl-4-methylpyridine (100 mg, 0.52 mmol), and appropriate amounts of other reagents, compound **7** (55 mg, 48%) was obtained.

N-*Formyl*-N-*methyl-2-(3,4-dimethoxyphenyl)ethylamine* ***8***

N-Formyl-2-(3,4-dimethoxyphenyl)ethylamine (22) (500 mg, 2.42 mmol) was treated with dimsyl sodium and CH_3I using the procedure described for the preparation of **3**. Compound **8** was obtained as an oil (430 mg, 80%); ^{1}H nmr (90 MHz, $CDCl_3$) δ: 2.73 (2H, apparent t, J = 6.0 Hz, CH_2CH_2N), 2.80 2.84 (3H, 2s, NMe), 3.40 (2H, apparent t, J = 6.0 Hz, CH_2CH_2N), 3.80 3.83 (6H, 2 s, 2 OMe), 6.56–6.90 (3H, m, H-2′, H-5′, and H-6′), 7.80–8.00 (1H, 2s, CH=O); ms *m/z* (EI): 223 (8), 164 (100), 151 (67), 107 (10). Exact Mass (hrms) calcd. for $C_{12}H_{17}NO_3$: 223.1208; found: 223.1211.

(E)-1-[N-Methyl-β-(3,4-dimethyoxyphenylethylamino)]-2-(3-ethylpyridin-4-yl)ethene ***9***

The procedure described for the preparation of **4***a* (method (*a*)) was employed, except that compound **8** was substituted for **3**. From **8** (100 mg, 0.52 mmol), and appropriate amounts of other reagents, compound **9** (95 mg, 56%) was obtained; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 1.21 (3H, t, J = 7.5 Hz, CH_3CH_2), 2.61 (2H, q, J = 7.5 Hz, CH_2CH_3), 2.79 (2H, apparent t, $J \approx$ 7.6 Hz CH_2CH_2N), 2.85 (3H, s, NMe), 3.40 (2H, t, J = 7.6 Hz, CH_2CH_2N), 3.86 (6H, s, 2 OCH_3), 5.06 (1H, d, J = 13.5 Hz, CH=CHN), 6.68–6.86 (3H, m, H-2′, H-5′, H-6′), 6.93 (1H, d, J = 13.5 Hz, CH=CHN), 7.01 (1H, d, J = 5.4 Hz, H-5″), 8.10 (1H, d, J = 5.6 Hz, H-6″), 8.15 (1H, s, H-2″); ms *m/z* (EI): 326 (22), 175 (100), 164 (42), 151 (20). Exact Mass (hrms) calcd. for $C_{20}H_{26}N_2O_2$: 326.1994; found: 326.2006.

(E)-1-N-Methyl-β-(3,4-dimethoxyphenyl)ethylamino-2-(pyridin-4-yl)ethene ***10***

The procedure was the same as that used for the preparation of **9**, except that **1***b* was substituted for **1***a*. From **1***b* (100 mg, 0.60 mmol), and appropriate amounts of other reagents, compound **10** (104 mg, 58%) was obtained; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 2.78 (2H, apparent, t, $J \approx$ 6.85 Hz, CH_2CH_2N), 2.81 (3H, s, *N*Me), 3.39 (2H, apparent, t, J = 6.85, CH_2CH_2N), 4.95 (1H, d, J = 13.5 Hz, CH=CHN), 6.68–7.02 (6H, m, H-2′, H-5′, H-6′, CH=CHN, H-3″, H-5″), 8.24 (2H, apparent d, $J \approx$ 5.6 Hz, H-2″, H-6″); ms *m/z* (EI): 298 (10), 164 (40), 151 (22), 147 (100). Exact Mass (hrms) calcd. for $C_{18}H_{22}N_2O_2$: 298.1681; found: 298.1694.

Electrochemical oxidation and kinetics of the decay of UV-absorbing intermediate of uric acid oxidation at pyrolytic graphite electrodes[1]

RAJENDRA N. GOYAL,[2] ALOK MITTAL,[3] AND DIVYA AGARWAL
Department of Chemistry, University of Roorkee, Roorkee, 247 667, India

Received May 14, 1993

RAJENDRA N. GOYAL, ALOK MITTAL, and DIVYA AGARWAL. Can. J. Chem. **72**, 1668 (1994).

The electrochemical oxidation of uric acid has been studied in 0.50 M NaCl and phosphate buffers of ionic strength 0.05 to 0.5 M. The kinetics of the decay of UV-absorbing intermediate generated during electrooxidation of uric acid (7,9-dihydro-1*H*-purine-2,6,8-(3*H*)-trione) has also been studied. On the basis of pseudo first order rate constants observed in different media, it has been concluded that the diimine species formed from the 2e, $2H^+$ oxidation of uric acid is attacked by water to give diol, which then decomposes in a series of reactions to give allantoin as the major product at pH 7.2. The possibility of attack by phosphate on diimine has been ruled out.

RAJENDRA N. GOYAL, ALOK MITTAL et DIVYA AGARWAL. Can. J. Chem. **72**, 1668 (1994).

On a étudié l'oxydation électrochimique de l'acide urique dans du NaCl 0,50 M et dans des tampons de phosphate, à des forces ioniques allant de 0,5 à 0,05 M. On a aussi étudié le cinétique de la décroissance de l'intermédiaire qui absorbe la lumière IV et qui est généré au cours de l'électrooxydation de l'acide urique (7,9-dihydro1*H*-purine-2,6,8-(3*H*)-trione). En se basant sur les constantes de vitesse de pseudo-premier order observé dans divers milieux, on en conclut que la diimine formée par une oxydation de l'acide urique par 2e– et $2H^+$ est attaquee par de l'eau pour donner un diol que se décompose alors par une série de réactons pour donner, à un pH de 7,2, l'allantoïne comme produit majeur. On a éliminé la possibilité d'une attaque de la diimine par le phosphate.

Introduction

The electrochemical oxidation of biologically important purines has attracted considerable attention in the last decade in the expectation that the mechanisms observed at the electrode–solution interface can provide a more detailed understanding of the enzymic redox reactions of these molecules, leading to insight about biological reaction pathways. The on-line combination of mass spectrometry with electrochemistry has also been claimed as a powerful tool to get chemical informations about electrochemically generated species with excellent time resolution (1, 2). The electrochemical oxidation of uric acid (I) has been studied in 1 M acetic acid by Dryhurst (3) and more recently by Volk et al. (4). It is now generally accepted that the oxidation of uric acid proceeds by 2e, $2H^+$ mechanism (Scheme 1) to give an unstable diimine species (II). Owens et al. (5) determined the half life of the diimine using chronopotentiometry and found it to be ≅20 ms. It has also been proposed (6) that in high phosphate medium (0.5 M) the diimine species is attacked by phosphate, whereas, in low phosphate medium (5 mM) attack by H_2O is preferred during electrolysis at reticulated viterous carbon electrode; however, no species with phosphate attached (III_b) was ever isolated.

The work reported in this paper was undertaken to investigate the effect of phosphate concentration on the electrochemical behaviour as well as kinetics of the decay of UV-absorbing intermediate generated during electrooxidation of uric acid at pyrolytic graphite electrode. It was believed that if phosphate competes with OH^- in attacking species (II), the kinetics of decay in absence of phosphate will be very different than in presence of phosphate (Scheme 1). In particular, we were interested in finding out whether the electrochemical behaviour of uric acid is dependent on the amount of phosphate present and also whether the kinetics of decay changes significantly from 0 to 500 mM phosphate media. The role of phosphate on the kinetics of decomposition of UV-absorbing intermediate has been explained on the basis of Brønsted equation modified on the basis of Debye Hückle theory (7). The products of electrooxidation of uric acid formed at physiological pH (pH 7.2) in low and high phosphate buffers have also been separated and analysed.

Experimental

Uric acid was obtained from Reanal, Hungary and used as received. Phosphate buffers (8) of different ionic strengths were prepared in the pH range 2.1 to 10.6. The stock solution of uric acid was prepared in doubly distilled water.

The equipments used for linear and cyclic sweep voltammetry and spectral studies were essentially same as has been described earlier (9, 10). The pyrolytic graphite electrode used in the studies was fabricated in the laboratory by the reported method (11). The kinetics studies were carried out using Beckman DU-6 spectrophotometer. All experiments were carried out at an ambient temperature of 22 ± 1°C.

Voltammetric studies were carried out by mixing 5.0 mL of the stock solution with 5.0 mL of buffer of different ionic strengths. The solution was bubbled with nitrogen for 8–10 min and the curves were recorded. For monitoring the kinetics of the decay of UV-absorbing intermediate, the solution of uric acid in buffers of different ionic strengths was electrolysed in a three compartment cell using PGE (6×1 cm^2) as working, platinum gauze as auxiliary and SCE as reference electrode, respectively, at a potential 50 mV more positive than peak I_a. When absorbance at λ_{max} reduced to about 50%, the potential was turned off and 2.0 mL solution was immediately transferred in a 1.0 cm^3 quartz cell and the change in absorbance with time at selected wavelengths were monitored.

For the identification of products of electrooxidation of uric acid in 0.5 M NaCl, 5 mM phosphate, and 0.50 M phosphate buffers (pH 7.2), the electrolysis was carried out in appropriate solution. The 1 mM solution of uric acid generally took about 3 to 4 h for complete oxidation. When peak I_a completely disappeared, electrolysis was stopped and the electrolysed solution was removed from the cell and lyopholised. The freeze-dried material was dissolved in 1 mL of H_2O and passed through sephadex G-10 (Sigma, bead size 40–80 μm) using water as an eluent.

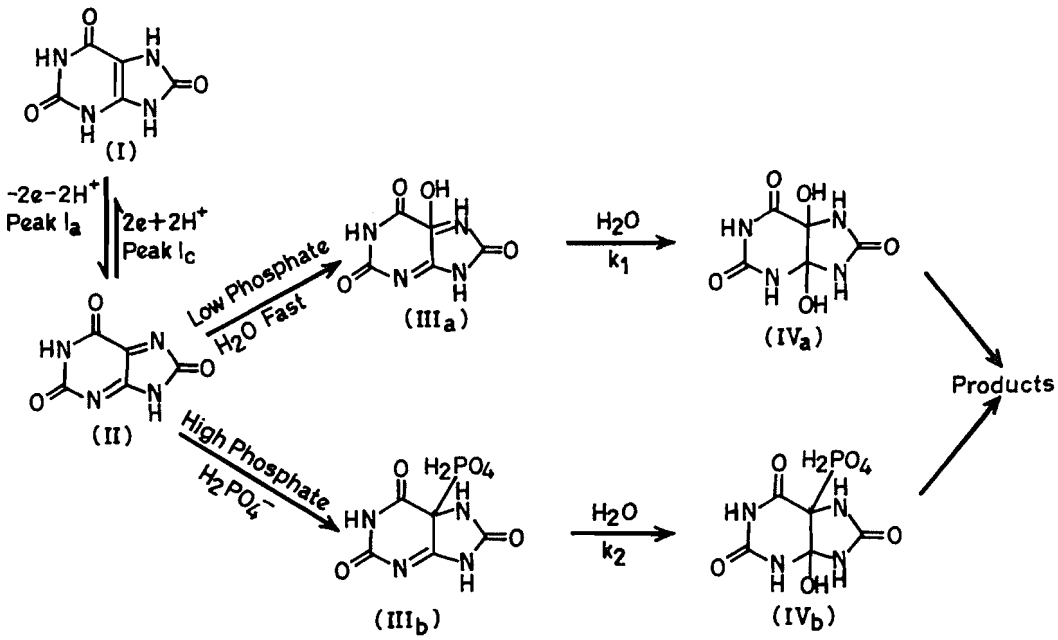

SCHEME 1. Oxidation of uric acid.

Fractions of 5 mL each were collected and their absorbance was monitored at 210 nm. The absorbance versus volume plot exhibited two peaks in gel permeation chromatography. The first peak between 110–190 mL was found to be due to phosphate and hence discarded. The second peak between 190–260 mL was collected, lyopholised, and analysed using mp, IR, mass and ^{1}H NMR spectra. Mass spectrum of the product was recorded on KRATOS model 50 mass spectrophotometer direct insertion probe at an electron beam voltage of 70 eV. NMR spectrum was obtained using Varian XL 300 spectrophotometer.

Results and discussion

Voltammetric studies

The linear sweep voltammograms of 1 mM uric acid (I) at a scan rate of 10 mV s^{-1} exhibited a single well-defined anodic peak (I_a) at pyrolytic graphite electrode in the entire pH range 2.1–10.6. The peak potential (E_p) was dependent on pH and shifted to less positive potential with increase in pH. A careful analysis of E_p vs. pH plot indicated two breaks at pHs 5.5 and 9.8 (Fig. 1) and dependence of E_p vs. pH can be represented by the following equations:

$$E_p = -0.1418\ \text{pH} + 1.6373\ (\text{pH } 2.14\text{–}5.75) \quad \text{V vs. SCE}$$

$$E_p = -0.0403\ \text{pH} + 0.6419\ (\text{pH } 5.75\text{–}9.80) \quad \text{V vs. SCE}$$

$$E_p = -0.0618\ \text{pH} + 0.7504\ (\text{pH } 9.80\text{–}10.63) \quad \text{V vs. SCE}$$

The earlier studies on electrooxidation of uric acid (3–5) indicated a linear E_p vs. pH graph without any break, whereas, in the present studies two clear breaks at pH 5.7 and 9.80 were noticed, which corresponds to the pK_a of uric acid. The dependence of E_p on pH clearly indicated that the species oxidized over the whole pH range is the conjugate base. This is the species predominating at pH > 9.80, and is rapidly formed from conjugate acid in the pH range 5.7–9.80 and from the species bearing two protons more than the conjugate base of pH < 5.7. As anodic mechanism involves oxidation of fully deprotonated species, the slop of E_p vs. pH plot becomes practically zero at pH > 9.80.

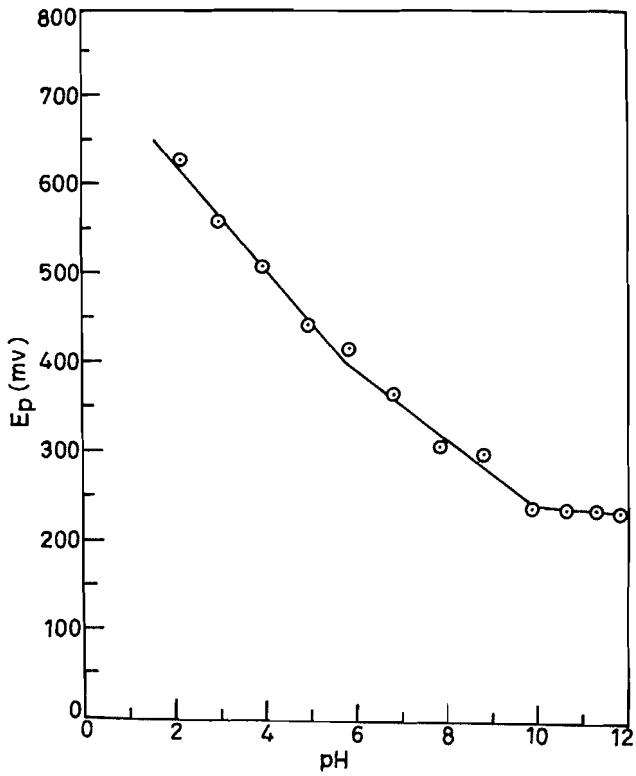

FIG. 1. Variation of the peak potential (E_p) with pH for the oxidation peak I_a of 1.0 mM uric acid, sweep rate 10 mV s^{-1}.

Cyclic voltammograms of (I) were recorded at a scan rate of 100 mV s^{-1} at different solid electrodes, viz., pyrolytic graphite, glassy carbon, and platinum electrodes. In phosphate buffer and at PGE, a well-defined pH dependent peak I_a was obtained during anodic sweep. Below pH 3.90, a bump close to background was also noticed. In the reverse sweep, two reduction peaks (I_c, II_c) were observed. Peak I_c formed a quasi reversible couple with peak I_a. Some typical cyclic voltammograms of uric acid are presented in Fig. 2. The cyclic voltammograms recorded in

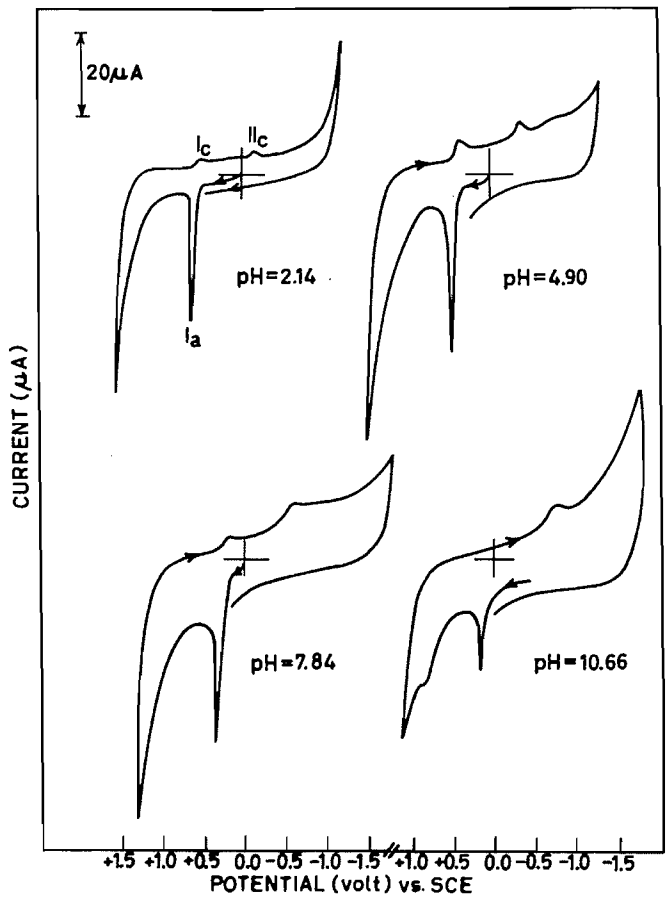

FIG. 2. Typical cyclic voltammograms of 1 mM uric acid in phosphate buffers (μ = 0.5 M) of different pH at pyrolytic graphite electrode (sweep rate 100 mV s^{-1}).

buffers of different ionic strength (5 mM – 0.5 M) were essentially similar with the only difference that at 5 mM ionic strength a post adsorption peak was noticed. The peak current of peak I_a was practically constant in the pH range 2.1–8.0, however, the peak current decreased at pH > 8.0 (Table 1). Peak current for peaks I_c and II_c were more or less constant in the entire pH range studied. The ratio of peak I_c/I_a was strongly dependent on pH and the ratio increased with increase in pH. The dependence of peak I_c on pH clearly suggested that the species involved in peak I_c reduction undergoes acid base catalyzed reaction. The ratio of peaks II_c/I_c was always close to 2.0 (Table 1). These peaks were also pH dependent and shifted to more negative potential with increase in pH. Their dependence on pH can be represented by the following equations:

$$E_p \text{ (pH 2.14–9.87)} = -0.051 \text{ pH} + 0.643 \quad \text{V vs. SCE (Peak } I_c\text{)}$$

$$E_p \text{ (pH 2.96–10.66)} = -0.061 \text{ pH} + 0.070 \quad \text{V vs. SCE (Peak } II_c\text{)}$$

At glassy carbon and platinum electrodes only peak I_a appeared during the anodic scan at a rate of 100 mV s^{-1}. However, no reduction peaks during cathodic scan were noticed. Hence, pyrolytic graphite was chosen for entire studies.

The effect of concentration on peak current of peak I_a was

TABLE 1. Effect of pH on the peak currents of 0.2 mM uric acid in 0.5 M phosphate solutions, sweep rate 100 mV s^{-1}

	Peak current (μA)			Peak ratio	
pH	I_a	I_c	II_c	I_c/I_a	II_c/I_c
2.14	60	5	11	0.08	2.2
2.96	50	6	13	0.12	2.1
3.90	45	5	10	0.11	2.0
4.90	45	6	11	0.13	1.8
5.86	45	5	12	0.11	2.4
6.80	45	5	12	0.11	2.4
7.84	45	6	12	0.13	2.0
8.79	35	5	12	0.14	2.4
9.87	25	5	11	0.20	2.2
10.66	20	6	12	0.30	2.0

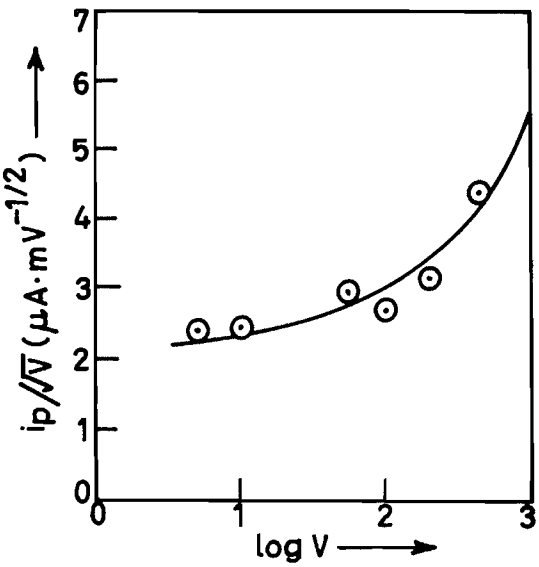

FIG. 3. Dependence of peak current function $i_p/\sqrt{v}$ with change in log (sweep rate).

studied in the concentration range 0.1 to 3 mM. The i_p vs. concentration plot was practically linear upto 2 mM but at higher concentration, the i_p values were more or less constant. The peak current for peaks I_c and II_c increased with increase in concentration of uric acid up to about 0.8 mM, however, at concentrations > 0.8 mM the peak currents became practically constant. The ratio of peaks II_c/I_c was always constant and equal to ~2.0 in the entire concentration range studied. This behavior indicated involvement of adsorption in the electrode reaction. Adsorption complications (12, 13) were further confirmed by the increase in peak current function ($i_p/v^{1/2}$) with increase in sweep rate as shown in Fig. 3.

It was interesting to observe that peak I_c increased with increase in sweep rate in the range 5–500 mV s^{-1}. The ratio of peak I_c/I_a increased from 0.17 at 5 mV s^{-1} to 0.45 at 500 mV s^{-1} (Table 2). The increase in peak I_c with increase in sweep rate suggested that the species responsible for peak I_c undergoes some type of follow up chemical reactions. The peak currents for peak II_c also increased with increase in sweep rate and the ratio of peaks II_c/I_c decreased from 0.24 to 0.20 with increase in sweep rate and at sweep rate >10 mV s^{-1} became almost constant.

TABLE 2. Effect of sweep rate on the peak currents of 0.5 mM uric acid in phosphate buffer (μ = 0.5 M) of pH 7.2

Sweep rate (mV s^{-1})	Peak current (μA)			Peak ratio	
	I_a	I_c	II_c	I_c/I_a	II_c/I_c
5	30	5	12	0.17	2.4

200	168	70	107	0.41	2.1
500	260	120	240	0.45	2.0

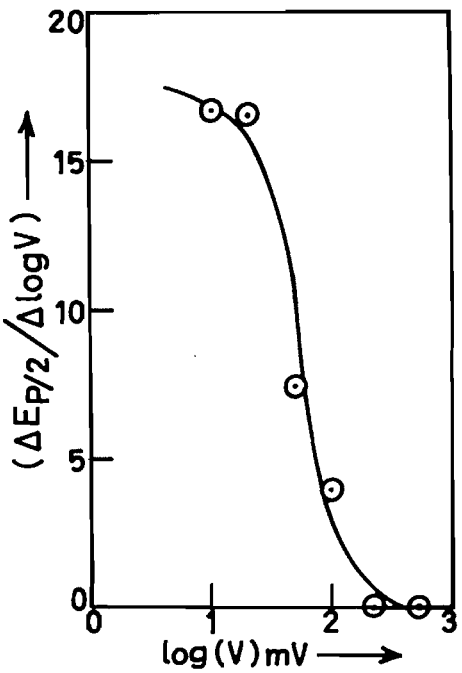

FIG. 4. Observed dependence of $\Delta E_{p/2}/\Delta$ log V on log V for the oxidation peak I_a of uric acid.

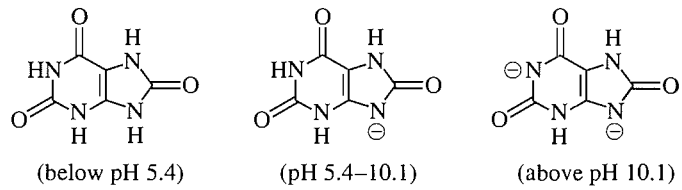
The peak potential of peak I_a also shifted to more positive potential with increase in sweep rate. The shift of E_p was 15 mV per ten fold increase in sweep rate in the range 5 to 100 mV s^{-1}, whereas the shift decreased to 8–10 mV at higher sweep rates. The plot of $\Delta E_{p/2}/\Delta$ log v vs. log v was S-shaped (Fig. 4) and clearly indicated that the nature of the electrode reaction is EC in which charge transfer is followed by an irreversible chemical reaction (14, 15). The EC nature of the reaction was further confirmed by the increase in I_c/I_a with sweep rate as expected for coupled chemical reactions (Fig. 5).

Spectral studies

Ultraviolet and visible spectra of compound (I) were monitored at different pH to determine the pK_a of the species. The absorbance at λ_{max} was plotted against pH and the resulting graph exhibited two breaks at around pH 5.5 and 10.1, indicating thereby the pK_{a1} and pK_{a2} of the compound (I). These values were essentially similar to the values obtained by E_p vs. pH relation (Fig. 1) and are similar to the pK_a values reported for uric acid in the literature (16, 17). Hence it is clear that below pK_{a1} uric acid exists mainly as a neutral species, whereas in the pH



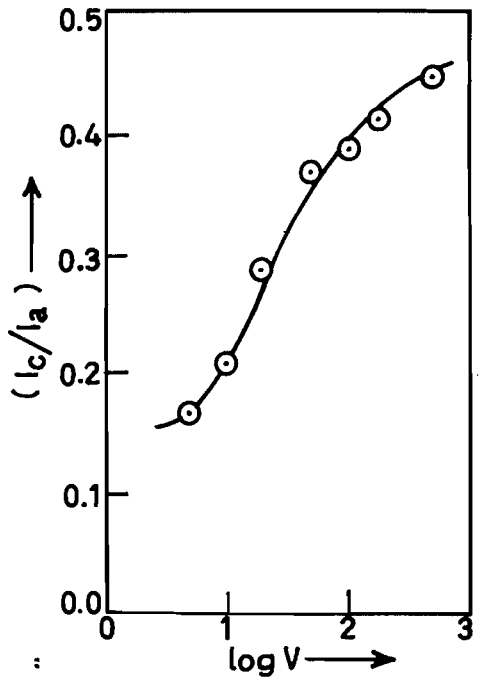


FIG. 5. Observed dependence of I_c/I_a on log V for 0.5 mM uric acid.

range 5.5–10.1, it exists as a mono anion. Out of the four hydrogen present in uric acid the hydrogen attached at position –9 has been found most acidic hence the anion has been suggested (16) to form at position –9.

UV/Visible spectra of 0.05 mM uric acid were also recorded during controlled potential electrolysis in acidic, neutral, and alkaline media to monitor the spectral changes during electrolysis. At pH 6.8, uric acid exhibited two well-defined λ_{max} at 240 nm and 292 nm. The peak at λ_{max} 240 nm was broad. With progress of electrolysis absorbance at these peaks decreased and almost vanished after an interval of 110 min (Fig. 6). The absorbance in the longer wavelength region (320–350 nm) also indicated some increase. Curve 10 in Fig. 6 represents the spectrum at the end of electrolysis with a broad shoulder at about 240 nm. This behavior indicated that π-chromophore system in the product has decreased. These spectral changes were practically similar to the ones observed in 0.5 M NaCl medium adjusted to desired pH with dilute HCl/NaOH.

Effect of ionic strength

The effect of ionic strength of the buffer constituents on the pseudo first order rate constant decay of the UV-absorbing intermediate was determined in the range 0.05–0.50 M at pHs 3.68, 6.75, and 10.0. The electrooxidation intermediate was generated by electrolysing the solution of uric acid in each ionic strength buffer (see Experimental) and then the decay of the intermediate was monitored by recording absorbance at selected wavelengths. These wavelengths were selected on the basis of UV/Vis spectral changes observed during electrolysis

as described earlier. In each case, time vs. absorbance profile showed an exponential decay in absorbance with increase in time, which then ultimately became constant and hence, the absorbance at this point was considered as A_∞. The values of rate constants were calculated by slope value of linear best fit equation of time vs. $\log_e (A-A_\infty)$ and are presented in Table 3.

At pH 3.68, the pseudo first order rate constant varied from 4.82×10^{-3} to 6.07×10^{-3} s^{-1} at 230 nm and 5.47×10^{-3} to 7.10×10^{-3} s^{-1} at 284 nm with change in the ionic strength of phosphate from 0.05 to 0.50 M. At pH 6.75, a significant increase in the rate constants were observed at both the wavelengths, whereas, at pH 10.0 the rate constants showed a large variation from 4.52×10^{-3} to 13.6×10^{-3} s^{-1} at λ = 240 nm and 1.96×10^{-3} to 8.65×10^{-3} s^{-1} at λ = 293 nm. The values of the rate constants observed are presented in the Table 1. To determine whether such a variation was due to attack of phosphate on diimine or simply due to ionic strength changes, Brønsted equation (7) was applied.

$$\log k = \log k_0 + 1.02\, Z_1 Z_2 \sqrt{\mu}$$

where k = rate coefficient at ionic strength μ, k_0 = rate coefficient at ionic strength zero, μ = ionic strength, and Z_1 and Z_2 = charges on ions.

In all the cases studied, it was found that the log k vs. $\sqrt{\mu}$ plot exhibited a straight line as shown in Fig. 7. This behavior indicated that the observed changes in the rate constants of the UV-absorbing intermediate are due to the changes in the ionic strength of phosphate and phosphate does not attack at the diimine intermediate as reported earlier. Figure 7 further indicated that at pH 3.68, the slope of plots of $\sqrt{\mu}$ and log k was zero, whereas at pH 6.7 and 10.0, the plots had positive slopes. The zero value of slope at pH 3.68 shows existence of one of the species in neutral form, however, a positive value of the slope indicates the presence of similar charges on both the species. As uric acid exists as a neutral species at pH 3.68 (below pK_{a1} 5.7) the values of Z_1Z_2 turns to zero and hence the slope of log k against $\sqrt{\mu}$ plot becomes zero as observed in Fig. 7. At pH 6.78, uric acid predominantly exists as a mono anion and a positive slope of (~1) in log k vs. $\sqrt{\mu}$ plot was observed. At pH 10.0, the slope of log k vs. $\sqrt{\mu}$ plot was found to increase significantly to ~2 (Fig. 7), due to the fact that at pH 10.0, which is higher than pK_{a2} of uric acid (9.80) the formation of dianion of uric acid increases the value of Z_1Z_2 to almost 2. Hence, the value of slope observed at this pH is double than at pH 6.78.

Thus, the observed changes in the rate constants were only due to changes in ionic strength was further confirmed by studying the oxidation of uric acid in 0.5 M NaCl solution adjusted to pH 3.68, 6.75, and 10.0 with dilute HCl/NaOH. The cyclic voltammetric behavior in 0.5 M NaCl was essentially similar to the corresponding buffer solution. Hence, the decay of UV-absorbing intermediate was monitored under conditions similar to the ones maintained for ionic strength studies. The rate constants were calculated at same wavelengths and are presented in Table 3. As the rate constants in 0.5 M NaCl did not show a significant variation from the solutions containing phosphate, it was concluded that the diimine species is attacked by water molecule to give diol and that the phosphate does not act as a nucleophile in this reaction. If phosphate competes with water in this reaction, it is expected that the rate constants will change significantly from 0.5 M NaCl to 0.5 M phosphate medium.

To further confirm that the phosphate moiety does not attack at diimine (II), the products of electrooxidation at pH 7.2 were characterized in 0.5 M NaCl adjusted to pH 7.2 with dilute NaOH; 0.05 M phosphate and 0.50 M phosphate buffers. In all

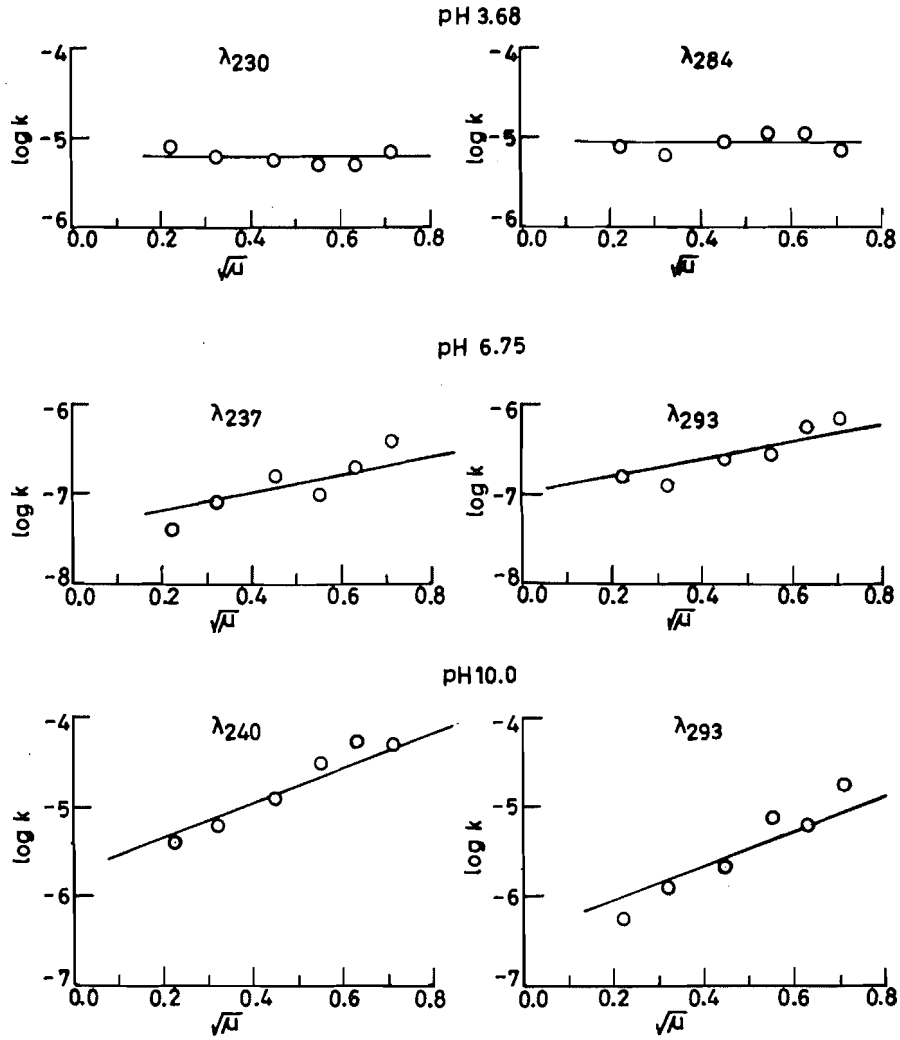

FIG. 7. Dependence of $\log_e k$ with increase in $\sqrt{\mu}$ for uric acid at different pHs.

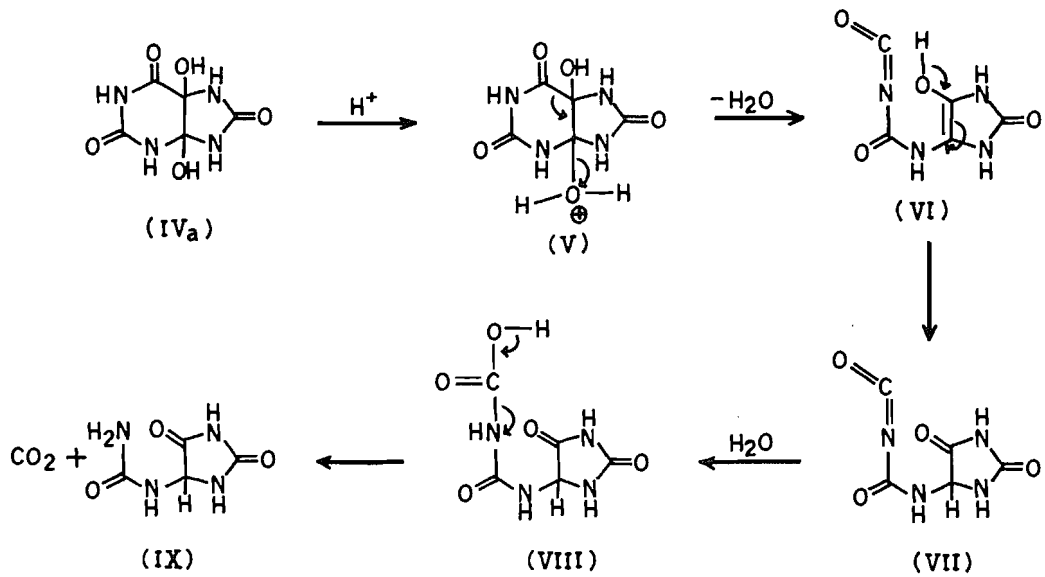

SCHEME 2. Tentative mechanism proposed for the formation of allantoin from uric acid at pH 7.2.

the cases only one chromatographic peak was observed in gel permeation chromatography. The colourless freeze dried material obtained had a mp 230°C. The mass spectra of the product exhibited a clear molecular ion peak at *m/e* 158 and indicated the product to be allantoin. The other high mass peaks observed in the fragmentation pattern were at 141 (8.6%); 140 (3.4%); 130 (32.3%); 129 (3.6%); 116 (4.8%); 115 (15.2%); 114 (10.8%); 113 (6.2%); 100 (4.0%); 99 (3.2%); 98 (14.3%). However, no attempt was made to explain the fragmentation pattern. The ^{1}H NMR spectrum indicated strong bands at δ = 5.28 (d, 1H); 5.8 (s, 3H); 8.04 (s, 1H) and 10.52 (s, 1H) and hence further supported the product as allantoin. Thus, the product of electrooxidation at pH 7.2 was found as allantoin in the presence or absenceof phosphate.

The observed results thus clearly indicate that the difference in rate constant values calculated for different phosphate concentrations is only due to change in ionic strength of the solutions and hence obeys Brønsted equations. Therefore, it is reasonable to conclude that phosphate moiety does not attack at diimine as suggested earlier (6) and only water attacks to give imine alcohol or diol, which in a series of reactions give allantoin as the product as shown in Scheme 2.

Reactions of 7-azaindole with niobium and tantalum pentachlorides and coupling to the azaindolyl-azaindolium cation

JACQUES POITRAS AND ANDRÉ L. BEAUCHAMP[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. centre-ville, Montréal, PQ H3C 3J7, Canada

Received January 10, 1994

JACQUES POITRAS and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **72**, 1675 (1994).

The reaction of $NbCl_5$ and $TaCl_5$ with 7-azaindole (Haza) at room temperature in benzene or dichloromethane yielded MCl_5(Haza) addition compounds. Under more severe conditions, the same compound was obtained with $TaCl_5$. For $NbCl_5$, some reduction to Nb(IV) was observed and $NbCl_5$(Haza), $NbCl_4$(Haza)$_2$, and the $(H_2aza)^+$ ion were identified in the reaction mixture by infrared spectroscopy. Oxidative coupling of two azaindole units via N7—C6 also took place during the reaction, since the 7-(azaindol-6-yl)azaindolium cation was found as counter-ion in the crystal structures of two complex salts. In the crystals of $(H_2aza\text{-}aza)[NbOCl_4(Haza)]\cdot 0.5CH_2Cl_2$ ($P\bar{1}$, $a = 7.255$ Å, $b = 12.412$ Å, $c = 14.277$ Å, $\alpha = 89.03°$, $\beta = 85.60°$, $\gamma = 76.66°$, $Z = 2$, $R = 0.062$), the anion is the roughly octahedral $[NbOCl_4(azaindole)]^-$ species containing a neutral N7-coordinated azaindole *trans* to the Nb═O bond. The $[NbOCl_5]^{2-}$ salt ($P\bar{1}$, $a = 7.527$ Å, $b = 10.168$ Å, $c = 10.467$ Å, $\alpha = 66.41°$, $\beta = 84.07°$, $\gamma = 85.51°$, $Z = 1$, $R = 0.037$) contains the distorted octahedral $[NbOCl_5]^{2-}$ ion disordered over two orientations. The infrared spectra suggest monomeric octahedral structures for the MCl_5(Haza) and $NbCl_4$(Haza)$_2$ complexes. ^1H NMR spectroscopy shows that $NbCl_5$(Haza) is not dissociated in CD_2Cl_2.

JACQUES POITRAS et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **72**, 1675 (1994).

La réaction de $NbCl_5$ et $TaCl_5$ avec le 7-azaindole (Haza) à température ambiante dans le benzène ou le dichlorométhane conduit au composé d'addition MCl_5(Haza). Dans des conditions plus vigoureuses, le même complexe est obtenu avec $TaCl_5$. Pour $NbCl_5$, il se produit une réduction en Nb(IV) et la spectroscopie infrarouge permet d'identifier $NbCl_5$(Haza), $NbCl_4$(Haza)$_2$ et l'ion $(H_2aza)^+$ dans le mélange réactionnel. Un couplage oxidant de deux motifs azaindole via N7—C6 se produit également durant la réaction, puisque le cation 7-(azaindol-6-yl)azaindolium est observé comme contre-ion dans les structures cristallines de deux sels complexes. Dans les cristaux de $(H_2aza\text{-}aza)[NbOCl_4(Haza)]\cdot 0.5CH_2Cl_2$ ($P\bar{1}$, $a = 7{,}255$ Å, $b = 12{,}412$ Å, $c = 14{,}277$ Å, $\alpha = 89{,}03°$, $\beta = 85{,}60°$, $\gamma = 76{,}66°$, $Z = 2$, $R = 0{,}062$), l'anion est l'espèce $[NbOCl_4(azaindole)]^-$ approximativement octaédrique, dans laquelle un azaindole neutre coordonné par N7 occupe un site *trans* à la liaison Nb═O. Le sel de $[NbOCl_5]^{2-}$ ($P\bar{1}$, $a = 7{,}527$ Å, $b = 10{,}168$ Å, $c = 10{,}467$ Å, $\alpha = 66{,}41°$, $\beta = 84{,}07°$, $\gamma = 85{,}51°$, $Z = 1$, $R = 0{,}037$) contient l'ion $[NbOCl_5]^{2-}$ de géométrie octaédrique déformée, désordonné selon deux orientations. La spectroscopie infrarouge indique une structure monomère octaédrique pour les composés MCl_5(Haza) et $NbCl_4$(Haza)$_2$. Le spectre RMN ^1H montre que $NbCl_5$(Haza) n'est pas dissocié dans CD_2Cl_2.

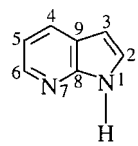
Introduction

Pyridine and related aromatic N-heterocyclic ligands are known to react with $NbCl_5$ and $TaCl_5$ (1). The simplest complexes expected to form with unidentate ligands are octahedral $MX_5\cdot L$ adducts, which have indeed been obtained with pyridines (2, 3) and, more recently, with imidazoles (4, 5). However, higher coordinations are possible with these metal centres (6–8) and other types of reactions often take place. The high affinity of Nb(V) and Ta(V) for oxygen donors makes the pentahalides extremely sensitive to moisture, leading to various oxo species and finally to the M_2O_5 oxides. Common oxygen-donor solvents tend to displace the nitrogen ligand from the coordination sphere. Oxygen abstraction from the solvent can also take place (9): for instance, MOX_3 adducts with bipyridine and phenanthroline were obtained when they were reacted with MX_5 in ether (10).

$NbCl_5$ can be reduced to the Nb(IV) state under relatively mild conditions by aromatic amines, but $TaCl_5$ is more resistant to reduction. McCarley et al. (2) have shown that the $NbCl_5$–pyridine system at room temperature yields 30% of $NbCl_5$(py) and 70% of the reduced $NbCl_4(py)_2$ complex. The oxidized species has been identified as the 4-pyridylpyridinium cation. When $NbBr_5$ was used as starting material, only 10% of $NbBr_5$(py) was obtained, whereas the redox pathway leading to $NbBr_4(py)_2$ represented 90% of the reaction. Metal reduction also took place with 4-picoline, bipyridine, and phenanthroline (6), but the oxidized species were not identified.

[1]Author to whom correspondence may be addressed.

7-Azaindole (Haza, **I**)[2] first attracted our attention because its N1-deprotonated anion is a potential binucleating agent, stabilizing pairs of nearby metal atoms (11–13). Monodentate coordination can also occur with both the anionic and the neutral forms (14–20). When protonated, the resulting H_2aza^+ cation simply acts as counter ion (20, 21). The present paper reports on the reactions of this ligand with $NbCl_5$ and $TaCl_5$, with special emphasis on the products generated by the redox pathway.



I

Experimental

Reactants and techniques

$NbCl_5$, $TaCl_5$, and $NbCl_4(THF)_2$ were stored in the glove box and used as received from Aldrich. 7-Azaindole (Aldrich) was used without further purification. The starting materials were transferred and weighed in Schlenk tubes under argon in the glove box. All reactions were carried out in a standard Schlenk system under dry argon. The solvents, dried over sodium (benzene, toluene, CH_2Cl_2) or $CaCl_2$ (acetonitrile) and distilled under argon, were vigorously outgassed im-

[2]1*H*-Pyrrolo[2,3-*b*]pyridine. Haza = neutral ligand, H_2aza^+ = N7-protonated cation, $(H_2aza\text{-}aza)^+$ = azaindolyl-azaindolium cation (IUPAC name: 7-(1*H*-Pyrrolo[2,3-*b*]pyridin-6-yl)-1*H*-pyrrolo[2,3-*b*]pyridin-7-ium).

mediately before use. Samples for analyses or physical measurements were prepared in the glove box.

For quantitative analysis, the samples were hydrolysed with 1 M NH_4OH and the mixture was acidified to pH 1 with 1.5 M HNO_3. Chlorine was then determined as AgCl by potentiometric titration with $AgNO_3$. For metal analysis, the hydrolysed mixture was heated to dryness on a hot plate, heated for 24 h in an oven at 1000°C (Nb) (22, 23) or 1100° (Ta) (22), and weighted as M_2O_5.

The IR spectra (4000–250 cm^{-1}) of Nujol mulls were recorded with a Perkin-Elmer 783 spectrophotometer by using KRS-5 windows. ^1H NMR spectra were taken in CD_2Cl_2 or $(CD_3)_2SO$ (Merck, Sharp & Dohme Canada) with Bruker WH-400 or Varian VXR-300 spectrometers. They were referenced to the residual solvent signal (δ = 5.30 ppm for CD_2Cl_2 and 2.50 ppm for $(CD_3)_2SO$) and converted to the usual TMS scale. Magnetic moments were determined at room temperature with an Evans magnetic susceptibility balance (Johnson-Matthey), calibrated with $HgCo(SCN)_4$ ($\chi = 16.44 \times 10^{-6}$ c.g.s.e.m.u.). The data were corrected for the diamagnetism of the ligands using Pascal's constants (24).

Preparative work

$TaCl_5$(Haza)

To azaindole (0.26 g, 2.2 mmol) were added $TaCl_5$ (0.72 g, 2.0 mmol) and dry benzene (15 mL). In the resulting orange solution, an orange precipitate appeared quickly. The mixture was stirred at room temperature for 12 h. The solid was filtered, washed with benzene, and dried in vacuo. Yield: 0.88 g, 92%. Anal. calcd. for $TaCl_5C_7H_6N_2$: Ta 38.0, Cl 37.2; found: Ta 38.6, Cl 36.9. The same compound was obtained with a similar yield (based on Ta) when a 1:2 $TaCl_5$:azaindole mixture was refluxed for 72 h.

$NbCl_5$(Haza)

Azaindole (0.54 g, 4.6 mmol) was added to the orange solution of $NbCl_5$ (1.22 g, 4.5 mmol) in benzene (25 mL). The solution turned brown quickly and a dark brown precipitate formed. The mixture was stirred at room temperature for 16 h. The product was filtered, washed twice with benzene, and dried in vacuo. Yield: 1.56 g, 89%. Anal. calcd. for $NbCl_5C_7H_6N_2$: Nb 23.9, Cl 45.7; found: Nb 23.8, Cl 44.4. The same product was obtained when dichloromethane was used as solvent. ^1H NMR (CD_2Cl_2): δ (ppm): 11.38 (s br, H1), 7.695 (d, H2), 6.878 (d, H3), 8.598 (dd, H4), 7.555 (dd, H5), 8.427 (dd, H6); coupling constants (Hz): ^3J(H2—H3) = 3.6, ^3J(H4—H5) = 7.9, ^4J(H4—H6) = 0.8, ^3J(H5—H6) = 6.0. The H2 and H3 signals sometimes appear as doublets of doublets, because of extra ^3J(H2—H1) and ^4J(H3—H1) couplings of 2.2 and 2.0 Hz, respectively.

$NbCl_4(Haza)_2$

The dark brown solution of $NbCl_4(THF)_2$ (1.32 g, 3.5 mmol) and azaindole (0.84 g, 7.1 mmol) in toluene (35 mL) was stirred for 24 h at room temperature. The orange precipitate was filtered, washed with toluene (15 mL), and dried in vacuo. Yield: 1.55 g, 94%. Anal. calcd. for $NbCl_4C_{14}H_{12}N_4$: Nb 19.7, Cl 30.1; found: Nb 19.5, Cl 29.9. Magnetic moment μ_{eff}: 1.36 B.M.

$(H_2aza)[NbCl_6]$

A mixture of $NbCl_5$ (1.35 g, 5.0 mmol) and azaindole (0.59 g, 5.0 mmol) in benzene (15 mL) was made as above for the preparation of $NbCl_5$(Haza). HCl gas was bubbled in the brown suspension, which turned orange. The orange precipitate was filtered, washed with benzene and dried in vacuo. Anal. calcd. for $NbCl_6C_7H_7N_2$: Nb 21.9, Cl 50.1; found: Nb 21.8, Cl 49.2.

$(H_2aza\text{-}aza)[NbOCl_4(Haza)]\cdot 0.5CH_2Cl_2$

A mixture of $NbCl_5$ (1.12 g, 4.2 mmol) and azaindole (1.00 g, 8.5 mmol) in dichloromethane (50 mL) was stirred for 4 days at room temperature. The brown precipitate was filtered and washed with dichloromethane. This light brown filtrate was left under argon and a few brown crystals appeared some weeks later. Their structure was determined by X-ray diffraction (see below).

$(H_2aza\text{-}aza)_2[NbOCl_5]$

To 60 mL of benzene was added 1.21 g (4.5 mmol) of $NbCl_5$ and 1.26 g (10.7 mmol) of azaindole, whereupon a brown precipitate of $NbCl_5$(Haza) formed. After refluxing for 72 h, a dark red suspension containing brown $NbCl_5$(Haza) and orange $NbCl_4(Haza)_2$ was obtained. The solid was then filtered and washed with 30 mL of dry acetonitrile. In the combined filtrate and washings kept under argon, a few air-stable colourless crystals appeared after a few days. The crystal structure was determined by X-ray diffraction (see below).

Crystallographic measurements and structure determination

The brown crystals of $(H_2aza\text{-}aza)[NbOCl_4(Haza)]\cdot 0.5CH_2Cl_2$ are very sensitive to moisture and the diffracted intensities were measured at low temperature, on a specimen transferred and sealed under dry argon in a Lindemann capillary. For the more stable colourless crystals of $(H_2aza\text{-}aza)_2[NbOCl_5]$, the data were collect at room temperature in open air. The crystallographic work was done with an Enraf-Nonius CAD-4 diffractometer, following similar procedures for the two compounds. The reduced triclinic cell was determined from 25 randomly distributed reflections, generated by the automatic search routine of the CAD-4 software and centred in the counter aperture. The cell was checked with axial photographs. The Niggli coefficients were not consistent with a symmetry higher than triclinic. Therefore, $P1$ and $P\bar{1}$ were the only possible space groups.

The crystal data and conditions for data collection are given in Table 1. Seven standard reflections were monitored every hour for crystal decay and every 200 reflections for misorientation. Half spheres of data were measured. For $(H_2aza\text{-}aza)[NbOCl_4(Haza)]\cdot 0.5CH_2Cl_2$, an absorption correction was not deemed necessary, considering the low absorption coefficient and small size of the crystal. In the case of $(H_2aza\text{-}aza)_2[NbOCl_5]$, the data were corrected for absorption (Gaussian integration, grid 10 × 10 × 10, transmission range = 0.38–0.63). Corrections for the effects of Lorentz and polarization were finally applied. The structures were solved by the direct methods of SHELX-76 (25). The nonhydrogen atoms were refined anisotropically by full-matrix least-squares procedures. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with individual weights w based on counting statistics. In both structures, problems were encountered with disorder.

For $(H_2aza\text{-}aza)[NbOCl_4(Haza)]\cdot 0.5CH_2Cl_2$, an E map revealed positions for Nb and the attached Cl atoms. Nonhydrogen atoms for a coordinated Haza unit and a $(H_2aza\text{-}aza)^+$ "dimer" were located from subsequent ΔF maps. After refinement of this model, the ΔF map showed six residuals of 1.2–2.3 e $Å^{-3}$, which were obviously due to Cl atoms of a disordered solvent molecule. Refinement of positions and occupancies (fixed U_{iso} = 0.09 $Å^2$) yielded relative values for the occupancy factors, which were normalized to make the sum equal to unity, assuming that each site was fully occupied by a CH_2Cl_2 molecule: Cl(11) = 0.25; Cl(12) = Cl(13) = 0.20; Cl(14) = 0.15; Cl(15) = Cl(16) = 0.10. Extra peaks could not be detected in the ΔF map for the solvent fractional carbon and hydrogen atoms. Although many peak pairs show the expected Cl···Cl separation of ~2.9 Å, no model corresponding to a small number of orientations of CH_2Cl_2 could be determined. In the final cycles, azaindole hydrogen atoms were introduced at idealized positions (C—H = 0.95 Å, N—H = 0.87 Å, U_{iso} = 0.076 $Å^2$). Their parameters were not refined, but their coordinates were recalculated after each cycle. The final residuals were R = 0.062 and R_w = 0.052. The general background in the final ΔF map was below ±0.8 e $Å^{-3}$. Attempts to refine this structure in the non-centric $P1$ space group failed.

For $(H_2aza\text{-}aza)_2[NbOCl_5]$, the E map in space group $P\bar{1}$ showed a Nb atom near the cell origin, together with three peaks suitably oriented to define, with their centrosymmetric counterparts, an approximately octahedral arrangement of what first appeared to be a $[NbCl_6]^-$ unit. However, one "Cl" peak was much weaker than the other two and Nb was actually displaced from the origin by 0.4 Å in the direction of the weak peak. This suggested a $[NbOCl_5]^{2-}$ unit disordered over two orientations with the Cl—Nb═O direction reversed (Fig. 1), where the low "Cl" peak would actually correspond to statistical occupancy by either O or Cl. A Nb site with half occupancy, two fully occupied Cl

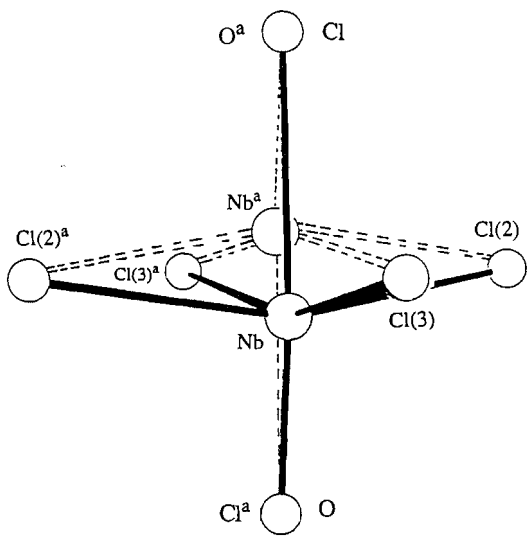

FIG. 1. $[NbOCl_5]^{2-}$ anion in the crystal of the $(H_2aza\text{-}aza)^+$ salt. Atoms are represented by spheres of arbitrary size. The central Nb atom is disordered over two symmetry-equivalent sites off the origin (occupancy 0.50) and the dashed bonds correspond to the alternate orientation of the anion. $a = -x, -y, -z$.

positions and a 12.5-electron "O/Cl atom" were introduced in the starting model. The $(H_2aza\text{-}aza)^+$ "dimer" clearly showed in the next ΔF map. Idealized hydrogen atoms were introduced and refinement was completed as described above. The final agreement factors were R = 0.037 and R_w = 0.043. The highest residual (0.38 e Å^{-3}) in the final ΔF map was near the disordered Nb atom.

Since an ordered $[NbOCl_5]^{2-}$ anion in a $P1$ unit cell could also have produced the features discussed above in an E map calculated in $P\bar{1}$ symmetry, structure determination and refinement were repeated in $P1$. However, the final results described the same structure as above with twice as many atomic positions and the anion remained disordered. Thus, the $P\bar{1}$ model was retained.

The scattering curves were taken from standard sources (26, 27). The anomalous dispersion coefficients of Nb and Cl were taken from Cromer (28). The refined coordinates for the two structures are listed in Tables 2 and 3, respectively.[3]

Results and discussion

When $TaCl_5$ is reacted with 7-azaindole in anhydrous ben-

[3]The supplementary material includes tables of refined temperature factors, hydrogen coordinates, geometry of hydrogen bonds, least-squares plane calculations, views of molecular packing and structure factor amplitudes for both structures, distances and angles for the $(H_2aza\text{-}aza)^+$ ion in the $[NbOCl_4(Haza)]^-$ salt, and infrared data for the Nb and Ta compounds (36 pages). Copies of material on deposit may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

Tables of hydrogen coordinates, and distances and angles for the $(H_2aza\text{-}aza)^+$ ion in the $[NbOCl_4(Haza)]^-$ compound have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

zene or dichloromethane, the orange $TaCl_5$(Haza) adduct is the only complex isolated, even when the mixture is refluxed for several days and excess ligand is used. Infrared data are consistent with the monomeric octahedral structure observed for the 2-methylimidazole adduct (5). With $NbCl_5$, a related dark brown $NbCl_5$(Haza) complex is obtained when a 1:1 mixture is stirred at room temperature for a short time. These Nb and Ta compounds should be isostructural, since their infrared spectra are virtually identical.

The orange Nb(IV) adduct $NbCl_4(Haza)_2$ can be prepared by substitution on $NbCl_4(THF)_2$. The magnetic moment (1.36 BM) corresponds to a monomeric octahedral species (1). From the available data on $NbCl_4L_2$ and $TaCl_4L_2$ compounds (7, 22, 29–33), there seems to be a preference for small monodentate ligands to give the *cis* isomer, although *trans* compounds are also known. In the present case, a single slightly split ν(Nb—Cl) band near 325 cm^{-1} is more consistent with the *trans* structure (see below), but the stereochemistry cannot be regarded as firmly established.

When $NbCl_5$–Haza mixtures are stirred for 4 days at room temperature or refluxed for a few hours, the suspension turns dark red. The very strong and broad ν(Nb—Cl) absorption of $NbCl_5$(Haza) at ~350 cm^{-1} is observed, but it includes a well-defined shoulder at ~320 cm^{-1} not found for pure $NbCl_5$(Haza). The solid does not contain *oxo* species, since the characteristic bands for ν(Nb═O) at 920 cm^{-1} or ν(Nb—O—Nb) at ~840 cm^{-1} are absent. These data, together with other diagnostic bands, suggest that $NbCl_4(Haza)_2$ is a major component of this mixture. The two complexes cannot be separated because they are insoluble or decompose in common solvents. The extra infrared bands of the solid mixture are assigned to the azaindolium cation by comparison with those of the $(H_2aza)^+$ salts of $[NbCl_6]^-$ (see below), Cl^- and ClO_4^- (21). However, the particular salt present in the mixture cannot be identified.

By analogy with the Nb–pyridine system (2), Nb(V)/Nb(IV) reduction can be assumed to be produced by azaindole, but no clues concerning oxidation products are provided by the infrared spectra. From the X-ray diffraction work done on two compounds obtained in small amounts from the reaction filtrates, an oxidized form of azaindole is found to be the azaindolyl-azaindolium cation shown in Fig. 2. Thus, azaindole undergoes N—C coupling to give a quaternary ammonium cation like pyridine, with the difference that coupling occurs at the γ carbon with pyridine, but at the α position here. In these crystals, the metal is present as the *oxo*-chloro anions $[NbOCl_4(Haza)]^-$ and $[NbOCl_5]^{2-}$, respectively. Since all reactants are devoid of oxygen, the fresh filtrates undoubtedly contain fully chlorinated species and the apparently less soluble oxo compounds are produced by serendipitous introduction of moisture into the Schlenk tube over several weeks.

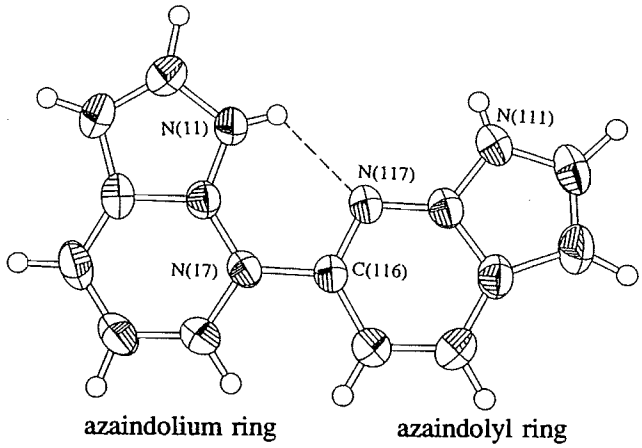

FIG. 2. ORTEP drawing of the $(H_2aza\text{-}aza)^+$ unit in $(H_2aza\text{-}aza)[NbOCl_4(Haza)]\cdot 0.5CH_2Cl_2$. Thermal ellipsoids correspond to 50% probability. Hydrogens are shown as spheres of arbitrary size. The dashed line represents a hydrogen bond.

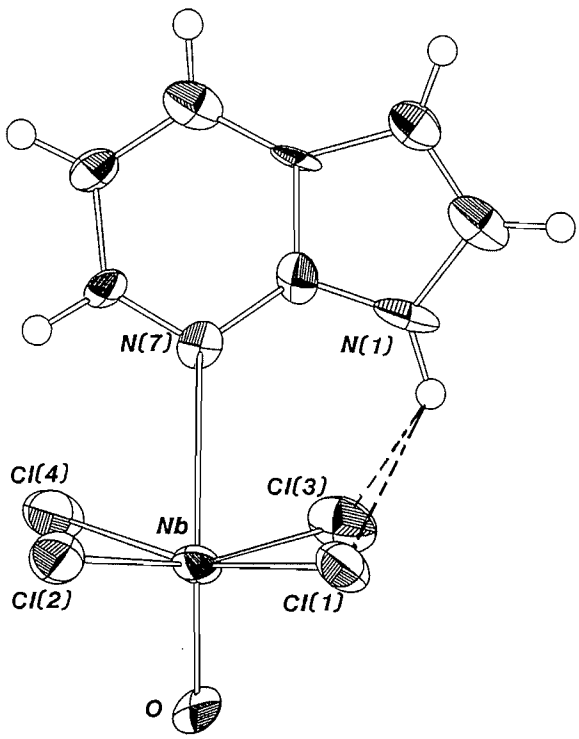

FIG. 3. ORTEP drawing of the $[NbOCl_4(Haza)]^-$ anion. Thermal ellipsoids correspond to 50% probability. Hydrogens are shown as spheres of arbitrary size. Dashed lines represent hydrogen bonds.

Crystal structures of $(H_2aza\text{-}aza)[NbOCl_4(Haza)]\cdot 0.5CH_2Cl_2$ and $(H_2aza\text{-}aza)_2[NbOCl_5]$

Both compounds contain the same $[H_2aza\text{-}aza]^+$ cation (Fig. 2) produced by N7—C6 coupling of two azaindole units. The metal is present as the six-coordinate *oxo*-chloro $[NbOCl_4(Haza)]^-$ (Fig. 3) and $[NbOCl_5]^{2-}$ anions (Fig. 1), respectively.

(a) $[H_2aza\text{-}aza]^+$ cation

The distance and angles observed for the $[NbOCl_5]^{2-}$ salt are compared with those of 7-azaindole in Table 4. The less accurate results from the $[NbOCl_4(Haza)]^-$ compound, provided as supplementary material (Table S-3)[3], are not significantly different. N7—C6 coupling does not appreciably affect bond lengths and angles in the azaindolyl unit, but greater differences are found in the azaindolium ring (14). The bond lengths are increased by ~0.02 Å in the C(16)—N(17)—C(18)—C(19) region, whereas N(11)—C(18) is shortened by the same amount. Also, the angle at N(17) in the six-membered ring increases by 3.0°, those at C(16) and C(18) decrease by 2.3 and 4.3°, respectively, whereas remote angles undergo smaller changes keeping the ring roughly planar: +1.5°, C(19); +2.1°, C(15). Similar changes are produced by protonation in $(H_2aza)_2[ZnCl_4]$ (25), the only structure containing a non-disordered 7-azaindolium ion, and an analogous pattern is observed in purines (34). The C(116)—N(17) distance of 1.456(5) Å is similar to those found in other N—C coupled systems (35, 36).

Each of the two units in $H_2aza\text{-}aza^+$ is approximately planar (Tables S-4 and S-9)[3]. In the $[NbOCl_5]^{2-}$ salt, no significant departure from planarity is noted for the azaindolium unit (mean atom-to-plane distance: 0.003 Å), but some distortion is detected in the azaindolyl ring (mean distance: 0.015 Å, maximum for C(115): 0.026 Å, σ = 0.004 Å). For the $[NbOCl_4(Haza)]^-$ salt, the mean distances calculated are ~0.016 Å for both units, but the standard deviations are greater (~0.015 Å) and the maximum deviation of 0.046 Å (for C(119)) is at the 3σ limit.

The dihedral angles between the two azaindole halves are 6.0(3) and 7(1)° for the $[NbOCl_5]^{2-}$ and $[NbOCl_4(Haza)]^-$ salts, respectively. A perfectly planar conformation would lead to severe steric hindrance, since the H(16)···H(115) separation of 1.95 Å, calculated from idealized hydrogen coordinates, is already below the normal van der Waals distance (2.1 Å). In principle, minimum non-bonded contact should rotate these two units as far apart as possible. The nearly coplanar structure, also approached in the 4-pyridylpyridinium cation (dihedral angle = 16.6°) (35), might be favored by the possibility for the π-electron system to encompass both rings if they are coplanar. More specific to the present case is the presence of a strong intramolecular N(11)—H(11)···N(117) hydrogen bond. This interaction is far from being linear (N—H—N ~115°, Tables S-5 and S-10)[3], but the short N···H distance (~2.07 Å) is highly favorable.

(b) $[NbOCl_4(Haza)]^-$

Crystal structures are known for $NbOCl_3L_2$ adducts with MeCN (37) and hexamethylphosphoramide (HMPA) (38), for $[NbOX_4L]^-$ compounds with L = MeCN (39), O_2PCl_2 (40), H_2O (40, 41), and THF (42), and for $[NbOCl_5]^{2-}$ salts (43–45). As observed in these systems, our equatorial Nb—Cl bonds are displaced away from Nb=O bond, despite the relatively large size of the azaindole ligand *trans* to the oxo group (Fig. 3): the O=Nb—Cl angles range from 94.1 to 99.3° (Table 5) and the Nb atom lies 0.261(2) Å above the plane through the four chlorines (Table S-4)[3]. The Nb=O distance of 1.691(9) Å is in the normal range (1.66–1.77 Å) (46) and consistent with a double bond. The Nb—Cl distances (2.375–2.395 Å, σ = 0.005 Å) compare well with those found for the above oxo compounds and for mutually *trans* Nb—Cl bonds in related species (47, 48). On the other hand, the Nb—N bond (2.534(11) Å) is much longer than those reported for $NbCl_5(NCH)$ (2.31 Å) (49) and $NbCl_5$(1-methylimidazole) (2.23 Å) (4), where the N-donor is *trans* to a chlorine. This is due to the high *trans* influence of the oxo group: in $NbOCl_3(MeCN)_2$ (37) and $NbOCl_3(HMPA)_2$ (38), for instance, the distances for the ligands *trans* to Nb=O

[a]Reference 14. Data for non-disordered tetrameric unit E—H.

are ~0.2 Å longer than for those *trans* to Nb—Cl. A similar effect of the imide group in $[NbCl_4(NBu^t)(py)]^-$ leads to a Nb—pyridine distance of 2.48 Å (50).

The formally neutral 7-azaindole ligands is bonded via N7. The distances and angles in coordinated azaindole (Table 5) show no significant differences with those found in free azaindole and other complexes containing monodentate N7-bonded azaindole (14, 16, 18–20). The ligand two-ring system is planar: the mean atom-to-plane distance (0.012 Å) corresponds to 1σ with the largest deviation (0.023(10) Å) found for N(7) (Table S-4)[3]. The azaindole ring making a ~45° angle with the Cl(2)—Nb(1)—Cl(3) and Cl(1)—Nb(1)—Cl(4) directions, the N(1)—H proton can form a bifurcated intramolecular hydrogen bond with equatorial chlorines, as observed for $ReOCl_3(Haza)_2$ and $ReOCl_3(Haza)(PPh_3)$ (19). The N(1)···Cl(1) and N(1)···Cl(3) separations of 3.19 and 3.32 Å, respectively (Table S-5)[3], are well within the range (2.91–3.52 Å) suggested by Stout and Jensen (51). The 6° difference between the Nb(1)—N(7)—C angles likely results from this interaction.

(c) $[NbOCl_5]^{2-}$

The $[NbOCl_5]^{2-}$ ion (Fig. 1) is disordered over two orientations in the crystal. The atoms in the equatorial plane, namely Cl(2), Cl(3), and their symmetry-equivalent counterparts, are common to both orientations. Of the two symmetry-equivalent axial "O/Cl" sites, one is occupied by chlorine and the other by oxygen in one individual, whereas the distribution is opposite in the other. The difference between the Nb=O and Nb—Cl distances is large enough to produce two resolved half-niobium atoms off the origin. This type of disorder is also present in alkali metal salts (44, 45), but the anion is reported to be ordered in the Ph_4As^+ salt (43).

The metal in $[NbOCl_5]^{2-}$ is considerably displaced (0.386(1) Å) from the plane of the four equatorial chlorines, in the direction of oxygen, leading to O=Nb—Cl angles between 95.0(1) and 103.2(1)°. One equatorial bond (2.501(1) Å) is longer than the other three (2.392–2.422 Å, σ = 0.001 Å) (Table 6), which are similar to those discussed above. The axial Nb—Cl distance is much greater (2.576(2) Å) because of the Nb=O *trans* influence. Our Nb=O distance (1.808(2) Å) seems to be appreciably above the normal 1.66–1.77 Å range (46) and longer than those observed for $[NbOCl_4(Haza)]^-$ (Table 5) and $[NbOF_5]^{2-}$ (1.68 Å) (52). However, this distance should not be regarded as very reliable, since the refined "O/Cl" coordinates probably represent two not exactly coincident positions for O and Cl, and refinement is largely controlled by the more electron-rich Cl atom. In this respect, the very large Nb=O distance of 1.967(6) Å reported for the Ph_4As^+ salt (43) is puzzling. Besides orientation disorder of the $[NbOCl_5]^{2-}$ ion, the possibility of partial substitution by $[NbCl_6]^{2-}$ in this crystal should be checked. Similar cases of abnormal bond lengths, first ascribed to "distortional" isomerism, have recently been shown to originate

from substitution of the M=O-containing molecule by an "isostructural" species of the reduced metal center, containing an M—Cl bond at the same place (53).

(d) Molecular packing

In both structures, the $(H_2aza\text{-}aza)^{2+}$ cations form hydrogen bonds with Cl atoms in the anions. Details on these and other intermolecular contacts are discussed in detail in the supplementary material, where stereoviews of the unit cells are provided.

NMR spectroscopy

$NbCl_5(Haza)$ and $TaCl_5(Haza)$ are insoluble or decompose in common solvents. In DMSO, the ligand is quantitatively displaced by solvent molecules, leading to ^1H NMR spectra identical to those of free 7-azaindole (15). Solubility for $NbCl_5(Haza)$ in CH_2Cl_2 is high enough to obtain an interpretable spectrum (experimental section). The signals are assigned as described earlier (15), using the coupling constants to identify H4 and H6. Coordination to N7 results in downfield shifts on most of the protons, as recently found for Re complexes (19). The largest displacements occur for H4 and H5 (+0.54 and +0.39 ppm, respectively), whereas the H_6 proton, close to the coordination site, is barely affected (–0.02 ppm). A broad signal at 11.4 ppm is observed for the N—H proton. These signals definitely originate from the $NbCl_5(Haza)$ species, because fast exchange does not take place between the complex and free azaindole: two sets of peaks are found when azaindole is added to the solution. This also shows that higher-coordinated complexes do not form to any detectable extent under these conditions.

Infrared spectroscopy

A list of frequencies for $(H_2aza)[NbCl_6]$, $NbCl_5(Haza)$, $TaCl_5(Haza)$ and $NbCl_4(Haza)_2$ is provided in Table S-12[3]. Most of the changes already identified for N7-coordination (12, 15, 18) are observed, thereby confirming this binding mode here. As a particularity of the present systems, two medium features of free azaindole at 428 and 419 cm^{-1} are now found at ~440 and 400 cm^{-1}, respectively. The γ(C—H) pattern at 700–800 cm^{-1} can be used to distinguish between the two types of compounds: the strong peaks of Haza at 789/762/715 cm^{-1} are found at ~792/780/720 cm^{-1} for (Nb,Ta)Cl_5(Haza) and 796/779/730 cm^{-1} for $NbCl_4(Haza)_2$. In the ν(N—H) region, the very broad band of free Haza is replaced by two sharp bands of medium intensity at ~3430 and ~3290 cm^{-1} for (Nb,Ta)Cl_5(Haza) and a single sharp band at 3400 cm^{-1} for $NbCl_4(Haza)_2$. The weak γ(N—H) absorption, observed near

850 cm^{-1} in the free ligand, shifts to ~530 cm^{-1} and becomes much stronger in the three complexes.

No ligand vibrations occur in the 250–390 cm^{-1} region, which includes only strong features for metal-centred modes. $NbCl_4(Haza)_2$ exhibits a slightly split band at ~320 cm^{-1} for ν(Nb—Cl). More complex patterns are usually observed for $NbCl_4L_2$ and $TaCl_4L_2$ compounds and since four infrared-active bands are expected for the *cis* isomer (C_{2v}) (54, 55), this geometry has been proposed (22, 30, 31). The presence of a single band here would be consistent with a *trans* structure (D_{4h}), in which case the slight splitting of the only infrared-active E_u mode would be due to solid-state effects. The *trans* structure has been proposed for $NbCl_4L_2$ complexes with various pyridines on the basis of EPR spectra in solution (56) and for crystals of $TaCl_4(py)_2$ (32).

$TaCl_5$(Haza) exhibits a very strong complex band centered at ~330 cm^{-1} and a weaker sharp peak at 372 cm^{-1}. Patterns similar, but displaced by approximately +20 cm^{-1} and –10 cm^{-1} are reported for the analogous systems with nitriles (57, 58) and PPh_3 (59), respectively. The main band of $NbCl_5$(Haza) at ~350 cm^{-1} is very broad and the high-frequency vibration is not resolved, although it is clearly present as a shoulder near 380 cm^{-1}. These results are consistent with a metal–chlorine vibration for a six-coordinate complex (60).

Azaindole protonation in the $[NbCl_6]^-$ salt can be detected from a number of characteristic spectral modification previously noted for the Cl^- and the ClO_4^- salts (21). In the fingerprint region, the azaindole doublet at 428/419 cm^{-1} has moved to 411/397 cm^{-1}. A single infrared-active Nb—Cl stretching mode of symmetry T_{1u} is expected for an octahedral $[NbCl_6]^-$ ion. The very strong band centred at 339 cm^{-1} occurs at the position observed for other salts (22, 57, 61). The presence of several shoulders is likely due to low site symmetry.

Conclusion

Both $TaCl_5$ and $NbCl_5$ form the octahedral MCl_5(Haza) adduct and there is no evidence for higher coordination in these systems. Under vigourous reaction conditions, Nb(V) is reduced, yielding the monomeric $NbCl_4(Haza)_2$ compound probably as the *trans* isomer. Azaindole oxidation leads to the azaindolyl-azaindolium ion, which is found as counter-ion in two complex salts. Efforts are being made to determine if this cation is the only oxidation product and C—N coupling takes place exclusively at the C6 site. The anionic form of this coupled species would be of interest as a binucleating agent providing three donor atoms.

Acknowledgments

We wish to thank M. Simard and F. Bélanger-Gariépy for their assistance in solving the X-ray structures. The financial support of the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged.

Acid-catalysed transformation of oleic acid, and 12-hydroxystearic acid, into γ-octadecanolactone. Evidence for the occurrence of a novel side reaction

ALESSANDRO GRANATA, FRANÇOISE SAURIOL, AND ARTHUR S. PERLIN[1]

γ-Octadecanolactone is produced in the reaction between oleic acid (*cis*-9-octadecenoic acid) and concentrated sulfuric acid at 80°C. To account for its formation, two types of mechanism have been considered. Both begin with protonation at C-9/C-10 to give a carbocation, following which the positive charge is transmitted to C-4, where nucleophilic attack by the carboxyl group is facilitated. One of them invokes a "zipperlike" succession of 1,2-shifts of intervening methylenic protons, whereas the other amounts to a stepwise migration of the alkene function along the carbon chain. Results obtained through the use of deuterated sulfuric acid to catalyse formation of the lactone allow for the existence of both types. However, each is characteristic of a different region of the C_{18} structure. Of the total isotope incorporated (individual molecules contained from zero to nine atoms of deuterium), >85% had been distributed relatively uniformly over the chain segment from C-7 to C-17, according to ^2H nuclear magnetic resonance spectra recorded in the presence of the shift reagent Yb(fod)$_3$, and ^{13}C nuclear magnetic resonance data. This evidence is consistent with the occurrence of a side reaction that creates many protonation sites over that specific region of the lactone's precursors. By contrast, as very little of the isotope had reached the proximity of the lactone ring, the latter is more likely to have been formed via the 1,2 shift type of mechanism. These events can also be initiated at other sites, as shown by the preparation of γ-octadecanolactone, and a comparably deuterated form of it, from 12-hydroxystearic acid. Reactions of these three stearic acid derivatives with HI, HBr, and HCl are described, by way of comparison.

ALESSANDRO GRANATA, FRANÇOISE SAURIOL et ARTHUR S. PERLIN. Can. J. Chem. **72**, 1684 (1994).

La γ-octadécanolacone se forme lors de la réaction de l'acide oléique (*cis*-octadéc-9-ènoïque) avec de l'acide sulfurique concentré, à 80°C. Pour expliquer cette formation, on a envisagé deux mécanismes. Les deux débutent par la protonation de la double liaison C-9/C-10 conduisant à un carbocation qui est suivie par une transmission de la charge positive vers le C-4 où une attaque nucléophile par le groupe carboxyle est facilitée. Un des mécanismes fait appel à une succession de déplacements-1,2 d'hydrure, à la manière d'une fermeture éclair, impliquant les protons des méthylènes alors que l'autre correspond à une migration par étape de la fonction alcène le long de la chaîne carbonée. Les résultats obtenus lorsqu'on a utilisé de l'acide sulfurique deutéré comme catalyseur peuvent être accommodés par les deux mécanismes. Toutefois, chacun est caractéristique d'une région différente de la structure en C_{18}. De la quantité totale d'isotope incorporé (les molecules individuelles contenaient de zéro à neuf atomes de deutérium), les spectres en résonance magnétique nucléaire du ^2H enregistrés en présence de réactif à déplacement Yb(fod)$_3$ et les données de la résonance magnétique nucléaire du ^{13}C indiquent que plus de 85% est distribué d'une façon uniforme sur le segment de chaîne allant de C-7 à C-17. Ces données sont en accord avec la présence d'une réaction secondaire qui crée plusieurs sites de protonation dans cette région spécifique des précurseurs de la lactone. Par ailleurs, comme très peu d'isotope arrive à proximité du cycle lactonique, ce dernier est probablement plus facilement formé par le biais d'un mécanisme impliquant des déplacements-1,2. Ces événements peuvent aussi être initiés à d'autres sites, comme on l'a démontré par la préparation de la γ-octadécanolactone ainsi qu'une de ses formes deutérée de la même maniére, à partir de l'acide 12-hydroxystéarique. Pour fins de comparaison, on décrit les réactions de ces trois dérivés de l'acide stéarique avec le HI, le HBr et le HCl.
[Traduit par la rédaction]

Introduction

In 1924, Clutterbuck (1) reported the isolation of γ-octadecanolactone (**1**) in 30% yield by heating oleic acid (*cis*-9-octadecenoic acid (**2**)) in concentrated sulfuric acid and water at 80°C for 6 h. We repeated that preparation, to use the lactone in studies to be mentioned presently, and verified its identity by contemporary methods. That compound **1** contains a five-membered ring was confirmed by the presence in its EI-mass spectrum of a base peak at *m/z* 85 ($C_4H_5O_2^+$), as well as by diagnostic evidence from a ^1H-COSY spectrum that the methine-proton signal located furthest downfield (δ 4.4) is that of H-4.

A distinctive chemical characteristic of lactone **1** in comparison with its shorter-chain γ-(or δ)-*n*-alkanolactone homologs, is its relative inertness in reactions with hydrogen halides (2, 3). For example, in 48% HBr under reflux, **1** undergoes ring opening to give a 30% yield of one product, the 4-bromoacid, whereas, by contrast, δ-dodecanolactone affords in 75% yield a mixture of 4-, 5-, 6-, 7-, 8-, 9-, 10-, and 11-bromododecanoic acids; and γ-octanolactone gives a mixture of 4-, 5-, 6-, and 7-bromooctanoic acids in 65% yield. Analogous results are found in reactions with 57% HI. Most striking is the fact (2) that the longest monohaloalkanoic acid (C_{18}) formed from among the series of lactones examined ($C_{18} \rightarrow C_6$) is the least susceptible to the migration of a halogen atom introduced initially by ring opening at C-4.

Carbocationic and olefinic intermediates likely (2, 3) play a key role in these isomerizations and rearrangements, whereby the formation of each mixture of haloacids involves a progression of the center of positive charge along the carbon chain, in the direction *away from* the carboxyl group. However, in the conversion of oleic acid into lactone **1**, the carbocation formed initially by protonation at either C-9 or C-10 must migrate in the opposite direction, i.e., *towards* the carboxyl group. These two types of substitution reactions, both of which are examined here, could have some common intermediates but, otherwise, are controlled by different circumstances: one, favoring ring opening of the lactone followed by the introduction of halogen substituents along the alkanoic acid chain, and the other, the

closure of a γ-lactone ring at the expense of the acid-labile alkene structure.

Results and discussion

The formation of γ-octadecanolactone from 12-hydroxystearic acid

Lactone **1** was also prepared by initiating its formation at a carbon atom beyond the C-9 or C-10 location on a C_{18} acid skeleton. Hence, the reaction of 12-hydroxystearic acid (**3**) with sulfuric acid under the same conditions as used with oleic acid gave **1** in 23% yield. This would be analogous to the use of a Δ^{11}- or a Δ^{12}-*n*-octadecenoic acid in place of oleic acid (although these variants were not tested). Therefore, it appears that a cationic charge generated in these reactions can be conducted with facility across sequences of at least eight methylene/methine groups (C-11 to C-4), until the interaction between a positive carbon atom and the carboxyl oxygen atom leads to closure of the lactone bridge. Although an earlier interaction at such centres as C-6 (ε-lactone) or C-5 (δ-lactone) also seems plausible, rearrangement to the more stable γ form should follow.

Reaction of oleic and 12-hydroxystearic acid with $^2H_2SO_4$

As already noted, the initial step in the formation of lactone **1** from oleic acid is assumed to be protonation of the Δ^9-alkene structure, with the formation of a carbocation intermediate. Subsequent steps, among possibilities to be discussed later, could include regeneration of the alkene repeatedly at new positions, Δ^8, Δ^7, etc., to allow for the eventual closure of the lactone bridge at C-4. Or, alternatively, the initial protonation could be simply followed by a succession of 1,2-hydride shifts, whereby the positive charge is transferred ultimately to the γ position. In the latter pathway, the proton is required only for initiation, whereas in the other type of sequence protons could be introduced anywhere between C-10 and C-4. Possibilities such as these were examined by the use of deuterosulfuric acid ($^2H_2SO_4$).

Isotopically labelled specimens of lactone **1** were prepared, and information about the level of incorporation of deuterium and its distribution within the molecule was obtained by mass spectrometry and nmr spectroscopy. A comparison of the chemical-ionization (CI) mass spectra of **1** and its deuterated analog showed that the latter consisted of a mixture of at least eight different compounds. As seen in the region of the molecular ion (Fig. 1A; NH_3 was the reagent gas), the peaks at *m/z* 283 and 300 correspond to MH^+ and MNH_4^+. The deuterated sample is represented in this region (Fig. 1B) by corresponding peaks that range from *m/z* 284 to 292 and from *m/z* 301 to 310. Most prominent among the latter group are the components that contain either two or three atoms of deuterium, i.e., of *m/z* 302 and 303, each representing about 20% of the total, whereas the 6% of unlabelled molecules of **1** represent a small content of hydrogen atoms in the medium (the incorporation of which should have been favored by the isotope effect).

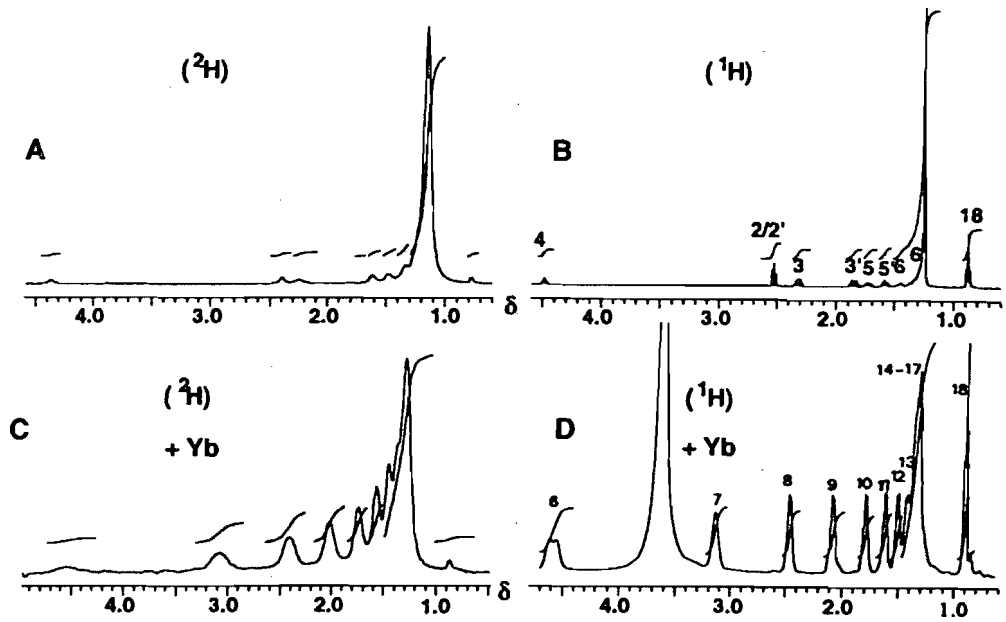

FIG. 2. The 76.7 MHz ^2H nmr spectra, and 500 MHz ^1H nmr spectra of deuterated γ-octadecanolactone: (A) the ^2H spectrum (solvent, $CHCl_3$); (B) the ^1H spectrum (solvent, C^2HCl_3); (C) and (D) the partial ^2H spectrum and the ^1H spectrum, respectively, following the introduction of $Yb(fod)_3$ (temp, 50°C). The ^1H assignments in (B) and (D) are based on COSY experiments.

The foregoing describes a reaction with $^2H_2SO_4$ for a 6 h period. However, samples of deuterated **1** recovered from reactions of 3 h and 20 h duration gave ms data differing by only a few percent from those in Fig. 1. Analogous experiments conducted with 12-hydroxystearic acid afforded lactone samples having similar isotopic compositions.

Patterns of ^2H-labelling within lactone 1-^2H

As to the location of the ^2H atoms within the lactone samples, it was readily apparent from EI mass spectra that little isotope had been introduced on the carbon atoms of the ring. That is, whereas both **1** and its deuterated analogs gave ion *m/z* 85 as the base peak (due to the ring moiety: $C_4H_5O_2^+$), the relative intensity of the *m/z* 86 peak, present as a minor component in all spectra, was only marginally higher in the spectra of the labelled species.

This was confirmed, and additional information obtained, from ^2H nmr spectra. Figure 2A represents the lactone recovered from a 20 h reaction with $^2H_2SO_4$. Using assignments based on the ^1H nmr spectrum (Fig. 2B), it is clear that a total of only ~10% of the isotope is accounted for by the minor signals associated with nuclei on the ring at C-2, -3, and -4, as well as at C-5, -6, and -18. The great majority of isotope is located in other methylene groups represented by the strong band at δ 1.2. Noteworthy is the evidence for stereoselective labelling, in that there is no ^2H resonance corresponding to signal ^1H-3 (δ 1.85 in Fig. 2B). It also appears likely, based on the relatively uniform intensities of the minor ^2H signals, that only one of the overlapping ^1H-2 signals in Fig. 2B has a ^2H-2 counterpart in Fig. 2A, and hence that a stereoselective replacement on C-2 had also occurred. Worth mentioning as well is the fact that a 3 h reaction with $^2H_2SO_4$ introduced less isotope into the minor sites represented in Fig. 2A, this being true especially of the methyl group, which produced only a barely detectable signal at δ 0.8. Hence, some isotope may be incorporated merely by prolonged treatment, and is unrelated to the formation of the lactone. As a "control," stearic acid was found to incorporate only a trace of ^2H, approximately one half of the isotope at C-2 according to ^2H nmr. (In striking contrast to this is the facile preparation of fully deuterated stearic acid (4) through isotopic exchange catalysed by Pt.)

The use of a shift reagent (5) was very helpful in the identification of the other sites of deuteration. Highly effective was Yb $(fod)_3$ (6) (the widely used Eu compound was far less so), which allowed for an extension of the range of individual ^1H and ^2H signals detectable, from those of the nuclei on C-6 (Figs. 2A and 2B) to those on C-13. The partial ^1H spectrum in Fig. 2D covers this region in which signal separation has become greatly enhanced; the methylene signal designations shown were obtained from a COSY experiment. Not included are the resonances for protons 2—5, already displayed in spectrum 2B, which were now shifted downfield over the region δ 22.0 (H-4) to δ 5.4 (H-5b). As a point of reference in the corresponding section of the ^2H spectrum (Fig. 2C), the ^2H-6 peak is observed at δ 4.6, in contrast to the value of δ 1.3 for the uncomplexed lactone (Fig. 2A), and it is far weaker than any of the peaks upfield of it (aside from that of the methyl group). From the appearance of the signals between δ 2.5 and 1.0, it is clear that the isotope had *not* been localized in a small number of sites, such as C-9/10, but was dispersed in a moderately uniform pattern over all carbon atoms from C-7 to, perhaps, C-17. This latter possibility seemed reasonable, because the integral for the major peak centered at δ 1.2 is sufficiently large to accommodate several ^2H signals comparable in size to those of the individual signals for the group ^2H-8 to ^2H-12. In fact, the inclusion of C-16 and C-17 was confirmed by ^{13}C data, presented below.

The ^1H nmr spectra of the deuterated lactone (Figs. 2B and 2D) differ in only minor respects from those of the unlabelled compound (not shown), because the ^2H atoms are so broadly distributed and are so greatly outnumbered by the protons remaining. More noticeable changes are observed in the ^{13}C nmr spectrum of the lactone (Fig. 3A) following the incorporation of the isotope (Fig. 3B). Most of the ^{13}C assignments are based on ^{13}C–^1H resonance correlations (HMQC) (7). Although

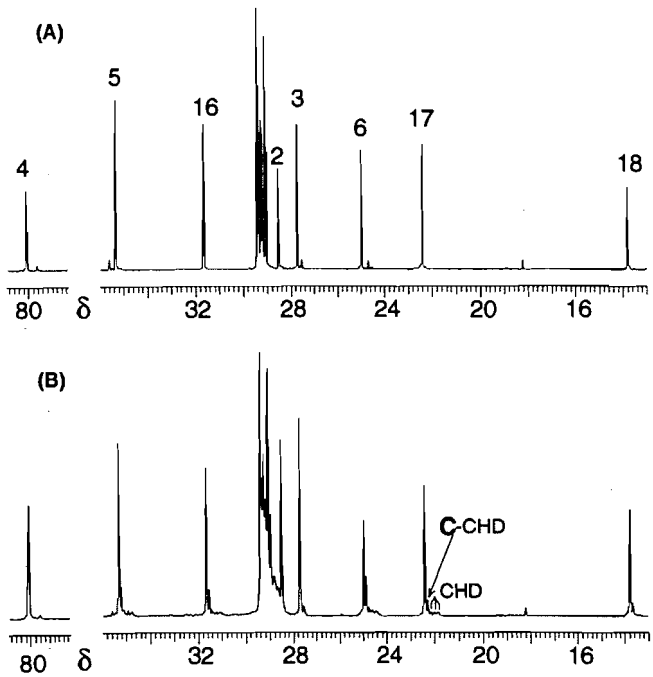

FIG. 3. The 125 MHz ^{13}C nmr spectra of (A) γ-octadecanolactone, and (B) deuterated γ-octadecanolactone. Representative of the signals in (B) is that of C-17, where *C*-CHD designates the portion of the signal affected by a β ^{2}H-isotope shift, and *C*HD the portion affected by an α ^{2}H-isotope shift (see text). The ^{13}CO signal appeared at δ 176.9. Based on HMBC experiments (see text), C-7 resonated at δ 29.1, and C-8 at δ 29.3.

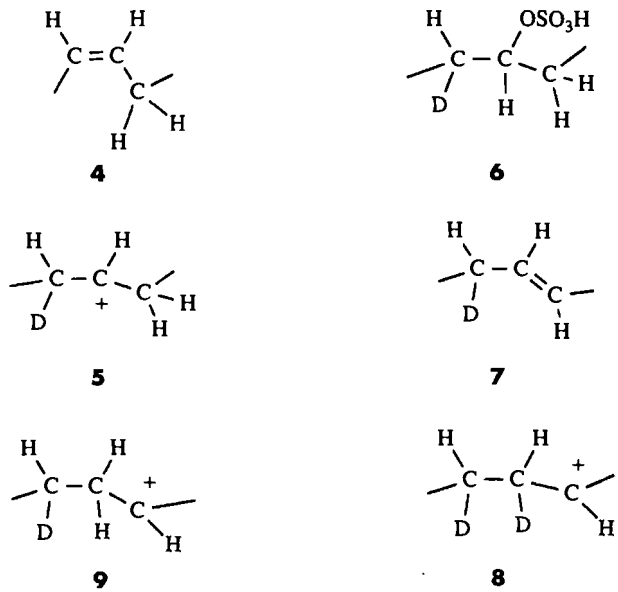
the chemical shifts of the 7- and 8-protons were not available directly (see Fig. 2B), identification of the ^{13}C-7 and -8 signals in Fig. 3A was feasible through application of the HMBC sequence (8), which correlated H-5 and H-6 with the more distant C-7 and C-8 nuclei through their small $^{2}J_{CH}$ and $^{3}J_{CH}$ couplings.

Many of the signals in Fig. 3A have more complex counterparts in Fig. 3B, which is attributable in the latter to upfield displacements caused by the presence of ^{2}H atoms that are attached directly (α) to some carbons, and (or) to adjacent (β) carbons. Several of the signals have three components, as illustrated for the C-17 resonance in the vicinity of δ 22: a singlet at its normal position (no isotope shift), a small, broad, peak (^{13}C-CHD, due to a β-isotope shift), and a small triplet (^{13}C HD, due to an α-isotope shift). Hence, the presence of the triplet at δ 31.1 confirms that C-16 was also deuterated, whereas the fact that the C-18 signal exhibits only a β-isotope shift (due to the ^{2}H atom on C-17) confirms that the methyl group was not labelled. Analogously, other nondeuterated carbons (no triplet signal component) are C-1 (δ 176.9; not shown), C-2 (δ 28.6), C-3 (δ 27.8), and C-4 (δ 80.7), in agreement with the ^{2}H nmr data (Fig. 2A, wherein the corresponding signals are weak, but detectable). The complex pattern of signals observed between δ 29.6 and 28.6 in Fig. 3B, which accounts for the resonances of carbons 7–15, reflects both α and β ^{2}H-isotope shifts as well as related ^{13}C–^{2}H coupling.

Possible reaction pathways

Overall, these spectra show that although the deuterium is surely introduced initially at C-9/10 of oleic acid, almost all of the isotope incorporated into lactone **1** becomes scrambled broadly along the carbon chain from positions 7 to 17. According to the ms data, individual molecules of the lactone preparations may have from one to nine or ten of these specific positions labelled, although most contain 2–3 atoms of deuterium.

Two types of reaction mechanism have already been mentioned. One offers a possible way of accounting for the very broad distribution of ^{2}H atoms. It is based on the assumption that the alkene group of oleic acid (or that of the product of dehydration of 12-hydroxystearic acid) undergoes a succession of rearrangements that are followed by deuteration at each new site. For example, the incorporation of a deuteron at C-9, followed by rearrangement of the π bond in the direction of the methyl terminus, allows for the entry of a second ^{2}H atom at C-10 (**4**→**5**→**7**→**8**). (Repeated formation and decomposition of alkyl hydrogen sulfate intermediates could also give rise to alkenes that are positional isomers (**4** → **5** → **6** → **7**)). Some molecules then acquire a third atom of the isotope (at C-11) following a second rearrangement and, ultimately, deuteration extending to C-16 and C-17 would be found.



Operation of an analogous sequence in the direction of the carboxyl terminus is assumed to account for the ample presence of ^{2}H on C-8 and C-7 (Fig. 2C). These contributions to the total number of doubly and triply labelled species would make them, as observed, the most populous overall. However, as suggested by the progressive decrease in the levels of deuteration observed for C-7, C-6, C-5, etc., the alkene rearrangement is a "side reaction," rather than a process engaged in the formation of the lactone ring.

For the latter purpose, a different mechanism is proposed, i.e., a succession of 1,2-hydride shifts (**5** → **9**) along the bridge of methylene groups between C-9 and C-4 (for oleic acid), or between C-12 and C-4 (for 12-hydroxystearic acid). The term "zipper mechanism" may be a useful description for such a pathway, by analogy with the term "acetylene zipper" (9, 10) that characterizes extensive multipositional rearrangements of alkynes.

We assume that the "zipper" functions independently of the side reaction, although both share intermediates of the same type (e.g., **5**), and also that the side reaction is dependent upon it for the dissipation of cationic charges that are created (as in **8**) in the protonation (deuteration) step. Accordingly, the progress of

[a]Data from ref 2.
[b]In a ratio (from left to right) of approx. 1:3:4:5:5.

the side reaction along the carbon chain is terminated at various sites en route by operation of the zipper to transfer the positive charge to C-4, where the overall transformation is completed. (If the side reaction itself, through reversal, were to serve this purpose, higher levels of deuteration should be found than are observed.) Ultimately, the longest segment of the alkyl chain over which the zipper mechanism is presumed to function is that linking C-4 with C-17.

It is worth noting that, without the isotopic evidence, there would have been no reason to anticipate that the transformation of oleic acid into γ-octadecanolactone is accompanied by a side reaction that penetrates so deeply into the sequence of (ostensibly inert) methylene groups between C-10 and C-18. Deuteration was used specifically to scan the chain segment between C-9 and C-4 but, in fact, it provided evidence that nearly every other carbon in the molecule is affected in some manner. Also, the evidence that the methyl group was not appreciably labelled is consistent, according to Markovnikov's rule, with the proposal that an ionic type of mechanism is involved. For the same reason, and the absence of appreciable deuteration at C-2 to C-4, free-radical pathways appear to be less likely.

Increasing the level of deuteration of lactone ***1***

The amount of isotope incorporated into the lactone may be raised by using a higher $^2H_2SO_4$/oleic acid ratio, although at the expense of the formation of lactone: its yield was reduced by two thirds when a 1.5-fold increase in $^2H_2SO_4$ was employed. In the CI mass spectrum of the product, the molecular-ion region contained bell-shaped clusters of peaks similar in appearance to those in Fig. 1B. However, the most prominent ions in this instance were *m/z* 290, 291 (MH^+) and *m/z* 307, 308 (MNH_4^+), respectively, corresponding to molecules containing 7 and 8 atoms of ^2H, and among the lesser species were molecules containing up to 13 atoms of ^2H.

Despite this substantial increase overall, the C-7 to C-17 portion of the alkyl chain again accounted for the great majority of the isotope. In the ^2H nmr spectrum, for example, about 80% of the isotope was represented by the major peak centered at δ 1.2, which, according to the corresponding spectrum in Fig. 2A, comprises the resonances of ^2H atoms on carbons 7–17. The ^{13}C spectrum of the product, when compared to that in Fig. 3B, showed clearly that the use of extra $^2H_2SO_4$ had enhanced the degree of ^1H–^2H exchange on some carbons that previously had been relatively lightly deuterated, i.e., carbons 5, 6, 17, and 17, whereas it had made far less of an impact on the others, i.e., carbons 2, 3, 4, and 18.

Consequently, these observations reinforce the evidence that the side reaction is promoted along the carbon chain primarily in the direction of the methyl terminus, and hence the suggestion that it is probably incidental to the formation of the lactone. Also, the fact that, even under forcing conditions, the methyl group itself (as well as C-2, etc.) undergoes little isotopic exchange supports the proposal that the latter process involves carbocationic, rather than radical, intermediates.

Reactions with hydrogen halides

In contrast to the foregoing examples, in which positive charge appears to be transferred across long sections of the C_{18} *n*-alkanoic acid chain, is the exceptional resistance of lactone **1** towards the formation of higher-numbered haloacids in reactions with hydrogen halides. As already noted (2), 48% HBr was found to produce only the 4-bromo isomer (also, see Table 1), and it appears that in 57% hydriodic acid, a second isomer (likely the 5-isomer, see Table 1) is formed in low yield, which is in marked contrast to the fact that shorter chain lactone analogs give an abundance of isomeric mixtures in the carbocation-mediated reactions. As one possibility, we have suggested (2) that isomerization occurs least readily with **1** because its alkyl chain is the least effectively solvated within the series in the aqueous hydrogen halide medium.

Although this may be a contributing factor, it has now been found that in the reaction generated by a hydrogen halide at positions more remote than C-4 or C-5 from the carboxyl end of the C_{18} chain there is little tendency again for isomeric halides

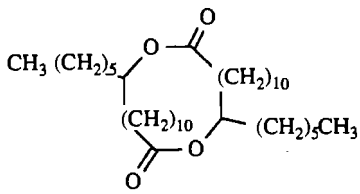
to be produced. Evidence of this was provided by the reactions of oleic and 12-hydroxystearic acids in 48% HBr under reflux, whereby the olefin gave a 1:1 mixture of two products (90% yield), and the latter acid only one product. Most probably, the products were a mixture of the 9- and 10-bromoacids, and the 12-bromoacid, respectively, on the basis of their ^{13}C nmr spectra. As shown by data (2) for the methine ^{13}C (Br) nuclei of an array of monobromo acids, represented in Table 1 by those for a mixture of bromododecanoic acids, there is a progressive increase (and eventually a discontinuity) in chemical shift as the number of the carbon atom increases. Accordingly, the value of δ 56.9 for the product that was obtained from lactone **1** indicates bromination at C-4, whereas downfield shifts of δ 58.8–58.7 are equally consistent with the likelihood that oleic acid simply gives a mixture of the 9- and 10-bromides, and (less definitive) that 12-hydroxystearic acid yields the 12-bromide.

Reactions of the three octadecanoic acid derivatives (**1**, **2**, and **5**) in 57% HI under reflux exhibited similar characteristics. In this instance, ^{13}C signals of the carboxyl groups of the products (Table 1) were more informative, because not only do they exhibit characteristic variations, but the alternative, methinyl $^{13}C(I)$, resonances generally overlap upfield those of some methylene ^{13}C signals. Lactone **1**, as already noted, afforded an 80% yield of two iodoacids, and 12-hydroxystearic acid a quantitative yield of only one. The relatively downfield location of the latter's carboxyl signal is consistent with substitution at a high carbon number, and hence with the likelihood that the product was simply 12-iodostearic acid (it was *not* stearic acid, the reduction product). By comparison, the smaller chemical shifts of the products from **1** show that the iodine atoms were much closer to the carboxyl group, i.e., likely at C-4 and C-5.

There was a total of five $^{13}COOH$ signals in spectra of the products obtained in close to quantitative yield from the reaction of oleic acid with HI. Of those, by comparison with data for iododododecanoic acids (Table 1), the two major signals had chemical shifts commensurate with iodination at the feasible positions furthest from the carboxyl group, i.e., at C-9 and C-10, whereas the progressive decrease in chemical shift for the other three isomers suggests that they are the 8-, 7-, and 6-iodoacids, respectively. This reaction is noteworthy in that it is the only one of the six reactions compared here in which appreciable isomerization occurs.

An additional comment about the reactions of 12-hydroxystearic acid is merited. Although only one bromo, and one iodo, acid was isolated, the transient occurrence of at least one other product was detected in short-term (1–6 h) reaction mixtures, and it was more prominent with HBr. As the possibility of self-association seemed likely, and with the knowledge (2) that HCl is far less reactive towards alkanolactones, 12-hydroxystearic acid was heated under reflux with 37% HCl for 18 h. As expected, the product proved not to be a chloroacid, but a neutral, higher molecular weight species. Its FAB mass spectrum contained a peak at *m/z* 565, which is consistent with a dimeric structure (M, 564), and the relative simplicity of its ^{13}C spectrum suggested that the material isolated consisted mainly of the symmetrical diolide (**10**) (for other preparations of diolides see, e.g., ref. 11).

One conclusion to be drawn from these observations is how markedly the reaction of oleic acid in HBr (or HI) differs from that in H_2SO_4. One would expect both reactions to have an initiation step in common, i.e., protonation at C-9/C-10 to generate a carbocation. Yet the formation of lactone **1** is the tangible outcome in H_2SO_4, whereas the same compound cannot occur even as an intermediate in HBr, because it should then give rise (2) to the 4-bromide, rather than to the mixture of 9- and 10-bromides found. Presumably there is a facile transfer of positive charges from C-9 to C-4 (as well as from C-9 to C-17) in one instance, but little or no migration of the charge in the other. That is, the reactions of oleic and 12-hydroxystearic acids with hydrogen halides are confined largely to the locus of the initial attack by the reagents. Such stability seems analogous to that of γ-octadecanolactone because, in marked contrast (2, 3) to short-chain lactones, it fails to yield a mixture of isomeric haloacids. Perhaps, as suggested previously (2), the longer chain alkane derivatives are less likely to be reactive in the *aqueous* hydrogen halide media because they are relatively poorly solvated.



10

Experimental

Nuclear magnetic resonance spectra were recorded with a Varian Unity 500 spectrometer operating at 500 MHz for ^1H, 76.7 MHz for ^2H, and at 125 MHz for ^{13}C. The probe temperature was 23 ± 1°C, the solvent was $CDCl_3$, sample concentrations were approximately 100 mg/mL, and chemical shifts are given with respect to TMS. In the ^{13}C experiments, the digital resolution was 1 Hz. Mass spectra were recorded with a double focusing Kratos MS25RFA mass spectrometer. Chemical ionization mass spectra were obtained with ammonia as the ionizing reagent. Hydriodic acid (57%, <0.01% stabilizer) was obtained from ACP chemicals. Deuterosulfuric acid (98%; 99% atoms ^2H) and hydrobromic acid (48%) were obtained from Aldrich Chemical Co., as were shift reagents $Yb(fod)_3$ and $Eu(fod)_3$. DL-12-Hydroxystearic acid was obtained from Eastman Chemicals.

γ-*Octadecanolactone* (*1*) (γ-*stearic lactone*)

(*a*) Following the procedure of Clutterbuck (1), concentrated H_2SO_4 (3.8 mL) was mixed, dropwise, with oleic acid (14.0 g), accompanied by vigorous stirring and external cooling at 0°C. The dark brown reaction mixture was then heated with stirring at 80–85°C for 6 h, water (22 mL) was introduced, and the bath temperature was raised to 115–120°C for 30 min. At room temperature, ether (250 mL) and water (200 mL) were added to the dark solid product; the ether layer was separated, washed successively with 1 M NaOH (2 × 50 mL) and saturated NaCl (2 × 50 mL), dried over anhydrous $MgSO_4$, and concentrated. A greyish solid was obtained; yield, (20%); mp 45–47°C (lit. (1) mp 52–53°C); ir (film, cm^{-1}); 1751 (C=O), 1195; ^1H nmr data are given in Fig. 2 and ^{13}C nmr data in Fig. 3. EI mass spectrum *m/z*: 282 [M], 85 (100%). CI mass spectrum (NH_3 induction) *m/z*: 300 [M + 18] (100%), 283 [M + 1], 272 [M + 18 – CO], 267, 255 [M + 1 – CO], 244, 239, 227.

(*b*) Under the same reaction conditions as in (*a*), (±)-12-hydroxystearic acid (1.5 g) was also converted into crystalline lactone **1**; yield 0.33 g (23%); identity confirmed by EI and CI mass spectroscopy and by ^1H and ^{13}C nmr spectroscopy.

Preparation of deuterated γ-*octadecanolactone*

Several preparations of deuterated lactone were obtained by the use of concentrated (98%) $^2H_2SO_4$ in place of concentrated H_2SO_4, under reaction conditions comparable to those described in (*a*). In addition to the reaction time noted there, periods of 3 h and 18 h were also selected, and, in the subsequent dilution of the reaction mixture, the introduction of ^2H_2O vs. H_2O was compared in separate runs. An

experiment was conducted as well with DL-12-hydroxystearic acid, using an initial reaction period of 6 h and ^2H_2O as the diluent. In each instance a crystalline specimen of deuterated lactone was isolated. When compared by EI and CI mass spectroscopy as well as by ^1H, ^2H, and ^{13}C nmr spectroscopy, the samples were found to differ little in their content and distribution of the isotope. Representative data are contained in Figs. 1–3.

Reactions of oleic and 12-hydroxystearic acid with hydrogen halides

Representative are the following (the reactions were not protected against light or oxygen):

Reaction of oleic acid with HI

A solution of oleic acid (0.60 g) in HI (57%, 5 mL) containing a suspension of red phosphorus (0.15 g) was heated under reflux for 18 h, and then cooled to room temperature. Saturated aqueous NaCl (5 mL) was added, followed by dichloromethane (50 mL), and the mixture was decolorized with concentrated sodium thiosulfate solution during the extraction. The organic layer was separated, washed with sodium chloride solution (2 × 5 mL), dried over anhydrous magnesium sulfate, and concentrated. A yellow oil was obtained, 0.85 g (97% yield), that according to ^1H and ^{13}C nmr spectra (see Table 1) consisted of a mixture of five monoiodooctadecanoic acids.

Reaction of 12-hydroxystearic acid with HBr

A solution of 12-hydroxystearic acid (0.63 g) in HBr (48%, 5 mL) was heated under reflux for 18 h. The reaction mixture was worked up as above, with omission of the washing with thiosulfate. A yellow oil was obtained, 0.67 g (90%), that according to ^1H and ^{13}C nmr spectra (see Table 1) consisted almost entirely of 12-bromostearic (12-bromooctodecanoic) acid.

Reaction of 12-hydroxystearic acid with HCl

A solution of 12-hydroxystearic acid (0.63 g) in HCl (ca. 37%, 5 mL) was heated under reflux for 18 h, followed by work-up as above. A brown oil was recovered, 0.50 g (83% yield), that according to its ^{13}C nmr spectrum consisted mainly of one component that, likely, was a macrocyclic dimer (diolide); ^1H nmr, δ: 5.0 (H-C_{12}-O); ^{13}C nmr, δ: 173.69 (C═O), 74.02 (C_{12}—O), 34.64, 34.09, 31.60, 29.63, 29.60, 29.13, 25.30, 25.20, 25.15, 22.50, 13.99; FAB mass spectrum *m/z*: 565 [M + 1] (structure **10** requires M 564), 547, 283, 265 (100%).

Kinetics of electroreduction of Zn^{2+} at mercury in nonaqueous solutions

MARILÉA MANZINI AND ANDRZEJ LASIA[1]

Département de chimie, Université de Sherbrooke, Sherbrooke, QC J1K 2R1, Canada

Received August 23, 1993

MARILÉA MANZINI and ANDRZEJ LASIA. Can. J. Chem. **72**, 1691 (1994).

The electroreduction of Zn^{2+} was studied in propylene carbonate (PC), acetonitrile (ACN), and hexamethylphosphoramide (HMPA) on mercury at various concentrations of tetraethylammonium perchlorate as a supporting electrolyte using dc polarography, cyclic voltammetry, chronoamperometry, and ac polarography. It was found that in PC and ACN the electroreduction process proceeds in one step. In HMPA, however, the electroreduction proceeds through a CEE mechanism in which a chemical reaction is followed by a charge transfer in two steps. The heterogeneous rate constants, corrected for the double layer effects, decrease with increase in the solvent donor number. The electroreduction process proceeds through the cation transfer mechanism.

MARILÉA MANZINI et ANDRZEJ LASIA. Can. J. Chem. **72**, 1691 (1994).

L'électroréduction du Zn^{2+} a été étudié dans le carbonate de propylene (PC), l'acétonitrile (ACN) et l'hexaméthylphosphoramide (HMPA) sur une électrode de mercure en présence de concentrations différentes de perchlorate de tétraethylammonium en utilisant la polarographie classique, la voltampérométrie cyclique, la chronoamperométrie et la polarographie ac. Notre étude a demontré que dans le PC et l'ACN l'électroréduction procède en une étape. Dans le HMPA la réduction procède par le mécanisme CEE dans lequel la réaction chimique est suivie par deux transferts de charge distincts. Les constantes de vitesse hétérogènes, corrigées pour les effets de la double couche électrique, diminuent avec le nombre donneur de solvant. L'électroréduction procède par le mécanisme de transfert de cation.

[Traduit par la rédaction]

Introduction

The electroreduction of Zn^{2+} at a mercury electrode has been studied in aqueous (1–13), nonaqueous (14–20), and mixed solutions (21–25). In non-complexing media this reaction can be described as:

[1] $$Zn^{2+} + 2e^- + Hg \leftrightarrow Zn(Hg)$$

Two different mechanisms have been suggested to explain Zn^{2+} electroreduction in aqueous solutions. Several authors (5, 6, 8, 9, 12, 13) proposed a simple two-electron transfer mechanism in one step. Others (1–4, 7) proposed two successive electron transfer reactions. In the latter mechanism Zn^+ has to appear as an intermediate. Until now, this intermediate species has never been observed in aqueous solutions.

The behaviour of the $Zn^{2+}/Zn(Hg)$ system in nonaqueous solvents (14–19) was also explained by the two abovementioned mechanisms (17, 19, 20, 22–25). Recently, it was proposed (14, 15) that zinc electroreduction in DMF and DMSO can be explained by assuming a successive charge transfer in two steps (15). This charge transfer mechanism can be represented not only as a subsequent electron transfer but as an ion transfer through the double layer.

[2] $$Zn^{2+}{}_{dl} + e^- \leftrightarrow Zn^{+}{}_{dl}$$

[3] $$Zn^{+}{}_{dl} + e^- \leftrightarrow Zn(Hg)$$

In this case, the transfer of the first electron should be slower than that of the "subsequent electron" because the reorganization energy around the intermediate ion of lower charge requires less electrostatic work (26). In this mechanism the species Zn^+ and Zn^{2+} must be present in the double layer and the position of the reaction site does not change with respect to the interface in the overall process.

In another mechanism (15, 27–30) the slow process is a cation transfer through the double layer in two steps:

[4] $$Zn^{2+}{}_c \leftrightarrow Zn^{2+}{}_b$$

[5] $$Zn^{2+}{}_b \leftrightarrow Zn^{2+}{}_a$$

[6] $$Zn^{2+}{}_a + 2e^- \leftrightarrow Zn(Hg)$$

where the site c is located in the diffuse layer, close to the outer Helmholtz plane (o.H.p.), site b in the inner layer, and site a is an adsorption site at the interface.

Reactions [4] and [5] involve an ion transfer from one site in the double layer to another, without an electron transfer. This case represents a cation transfer mechanism. The transfer coefficient, α, depends on the relative positions of sites a, b, and c in the double layer (15, 27, 31).

In the present paper Zn^{2+} electroreduction at a mercury electrode in propylene carbonate, PC, acetonitrile, ACN, and hexamethylphosphoramide, HMPA, was studied over a wide range of potentials. Double layer and solvent effects were studied in order to better understand the electroreduction process (27–31).

Experimental

$Zn(ClO_4)_2 \cdot 6H_2O$ (Alfa) was dried for 24 h at 140°C in vacuo over P_2O_5. $Zn(CF_3SO_3)_2$ was prepared from stoichiometric quantities of zinc oxide (BDH) and trifluoromethanesulfonic acid (Aldrich). It was dried in the same way as $Zn(ClO_4)_2 \cdot 6H_2O$. The former salt was used in propylene carbonate and HMPA and the latter in acetonitrile. Zn^{2+} concentration was 0.8 mM in propylene carbonate (PC) and acetonitrile (ACN) and 3.0 mM in hexamethylphosphoramide (HMPA).

Tetraethylammonium perchlorate (TEAP) was prepared using tetraethylammonium bromide (Aldrich) and perchloric acid (70% ACS). The salt obtained was recrystallized from deionized water and dried for 48 h at 70°C in vacuo over P_2O_5. Purification of PC (Anachemia), ACN (Anachemia), and HMPA (Aldrich) is described elsewhere (34). The solvents were stored in a dry box. Because of its instability HMPA was distilled just before the experiment. The water content, determined by the Karl–Fischer method, was 0.017% in PC, 0.013% in ACN, and 0.02% in HMPA. The results obtained in ACN were very sensitive to traces of water, and voltammetric and ac polarographic measurements in this solvent were carried out in a dry box.

A three-electrode cell was used during the experiments. The reference electrode was a silver wire in 0.05 M Ag^+ ($AgClO_4$ in PC and $AgNO_3$ in ACN and HMPA) + 0.1 M TEAP in the same solvent. A dropping mercury electrode was used as a working electrode in polarographic measurements. Chronoamperometric and voltammetric experiments were performed using a static mercury drop electrode, EG&G PAR model 303, radius 0.03 cm. All the potentials are given with respect to the reference redox system bis-biphenylchromium(I) tetraphenylborate/bis-biphenylchromium(0) ($BBCr^+/BBCr$) (32). The diffusion coefficient of zinc in mercury was taken as 1.4×10^{-5} cm^2 s^{-1} (33).

All the experiments were conducted at 25 ± 1°C. Dry ultrapure nitrogen presaturated with a solvent was bubbled through the solution to remove oxygen; during the measurements nitrogen flow was maintained over the solution surface.

The reversible half-wave, $E^r_{1/2}$, and the apparent standard, E^0, potentials were determined in PC and HMPA solutions from equilibrium potential, E_{eq}, measurements using the Nernst equation (35):

$$[7] \qquad E_{eq} = E^{0\prime} + \frac{RT}{2F} \ln \frac{[Zn^{2+}]}{[Zn(Hg)]}$$

and

$$[8] \qquad E^{0\prime} = E^r_{1/2} - \frac{RT}{nF} \ln \frac{D_r^{1/2}}{D_{ox}^{1/2}}$$

where R is the gas constant, T is the temperature, n is the number of electrons, F is the Faraday constant, $[Zn^{+2}]$ and [Zn(Hg)] are the concentrations of Zn^{2+} in the solution and Zn amalgam, and D_r and D_{ox} are the diffusion coefficients of the reduced and oxidized forms. Zinc amalgam was prepared by reducing Zn^{2+} on the static mercury drop electrode. The potentials were measured after stabilization.

Kinetic parameters were determined using dc polarography (in PC and HMPA), ac polarography (in ACN), cyclic voltammetry (all solvents), and chronoamperometry (in PC and ACN). The apparatus and data analysis used were described in previous papers (15, 36, 37).

Results and discussion

Polarography

PC and ACN

The electroreduction of Zn^{2+} at a mercury electrode in PC and ACN solutions with TEAP as a supporting electrolyte results in a single well-defined dc polarographic wave. The slopes of the logarithmic plots for Zn^{2+} electroreduction change from 52 to 73 mV in PC and from 34 to 67 mV in ACN as the TEAP concentration increases from 0.1 to 0.9 M. This behaviour suggests a quasi-reversible nature of the process in these solvents.

Figure 1 shows the dependence of the diffusion coefficients for Zn^{2+} on TEAP concentration in PC and ACN. The decrease in the diffusion coefficient, D_{ox}, with increasing ionic strength of the inert salt can be associated with the increase in the viscosity of the solutions (15, 34, 36). D_{ox} values for the pure solvents were determined from extrapolation to zero ionic strength. These values are 1.4×10^{-6} cm^2 s^{-1} and 1.14×10^{-5} cm^2 s^{-1} for PC and ACN, respectively.

HMPA

The electroreduction of Zn^{2+} at the mercury electrode in HMPA solutions results in a single ill-defined polarographic wave as shown in Fig. 2. The limiting current observed is much lower than that in other solvents. Subsequently, the Zn^{2+} concentration was increased to 3 mM because the polarographic waves were note well developed at lower concentrations.

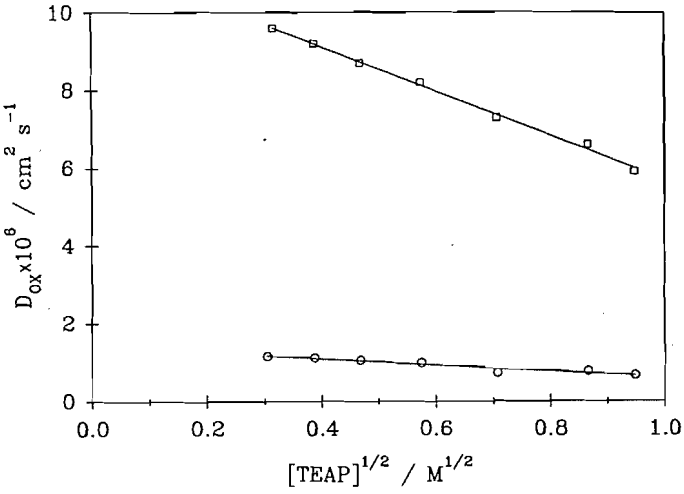

FIG. 1. Dependence of the Zn^{2+} diffusion coefficients on the TEAP concentration in (○) PC and (□) ACN solutions.

Another problem was the determination of the diffusion coefficient in this solvent. The value obtained from the polarographic measurements, Fig. 2, was 5.0×10^{-8} cm^2 s^{-1}. It is too low, compared with the one obtained by extrapolation of D_{ox} vs. inverse of the solvent viscosity, η^{-1} (9.0×10^{-7} cm^2 s^{-1}). When 10% of water was added to HMPA solutions, Fig. 3, the limiting current observed led to a diffusion coefficient of 5.6×10^{-7} cm^2 s^{-1}. Comparison of the diffusion coefficients of Cd(II) and Eu(III) (38, 39) determined in HMPA and HMPA + 10% H_2O solutions shows that addition of 10% of water does not affect their values. We concluded from this behaviour that the substantial decrease in the limiting current is caused by a chemical reaction preceding the electrochemical process. We therefore used the value determined in the presence of 10% of water in further analysis.

Kinetics of electroreduction

PC and ACN

The kinetic parameters, i.e., standard rate constants, k_s, and transfer coefficients, α, determined in PC and ACN solutions, are shown in Tables 1–3. They were obtained from voltammetric, chronoamperometric, and ac polarographic experiments. In ACN the voltammetric and ac polarographic experiments were obtained in a dry box because they were strongly affected by traces of humidity; however, the chronoamperometric measurements were carried out outside the dry box.

The rate constants determined decrease with increase in the supporting electrolyte concentration, and there is a small decrease in the value of the transfer coefficients. Results presented in Tables 2 and 3 confirm the influence of humidity on the kinetics in ACN; when the experiments were conducted in a dry box the rate constants measured were higher. In fact, studies performed in mixed solvents (40, 41) indicate that the rate constants decrease and pass through a minimum when water is added to the organic solvent.

The charge distribution in the double layer changes with change in the supporting electrolyte concentration. These changes affect the potential, ϕ_2, at the outer Helmholtz plane, o.H.p. The double layer effects can be taken into account using the Frumkin correction (42):

$$[9] \qquad \ln k_f = \ln k_{s,a} + (\alpha_a n - z) f \phi_2 - \alpha_a n f (E - E^{0\prime})$$

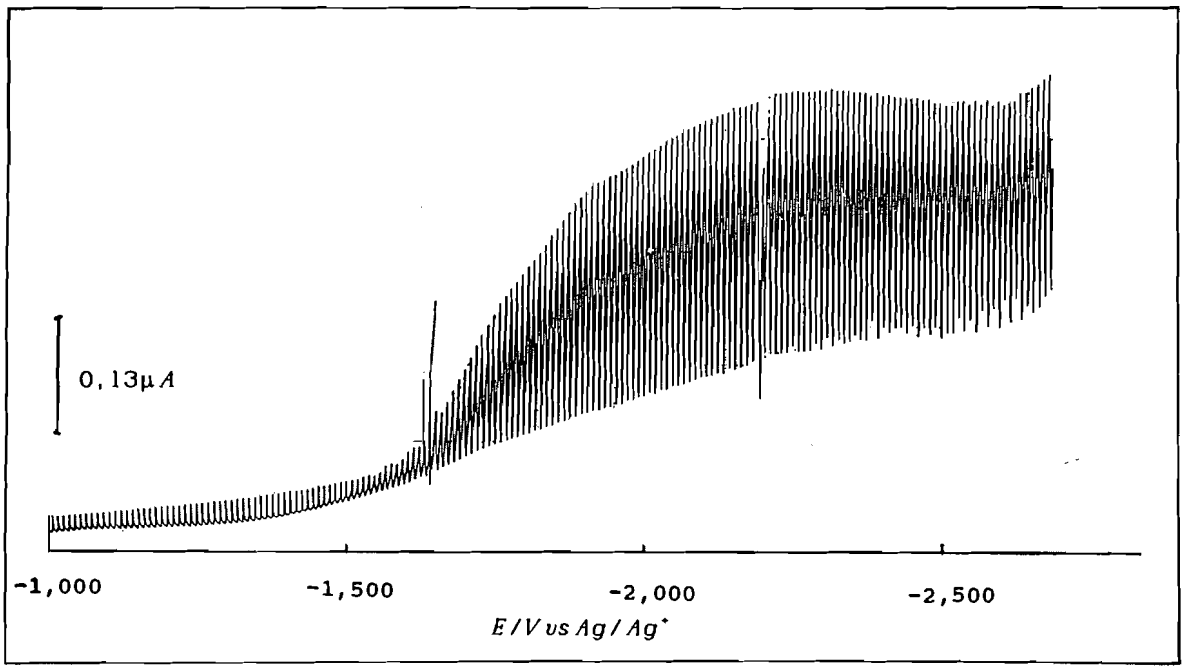

FIG. 2. Polarogram of Zn^{2+} electroreduction in pure HMPA solution; $[Zn^{2+}] = 3.0$ mM, [TEAP] = 0.1 M, $v = 5$ mV/s.

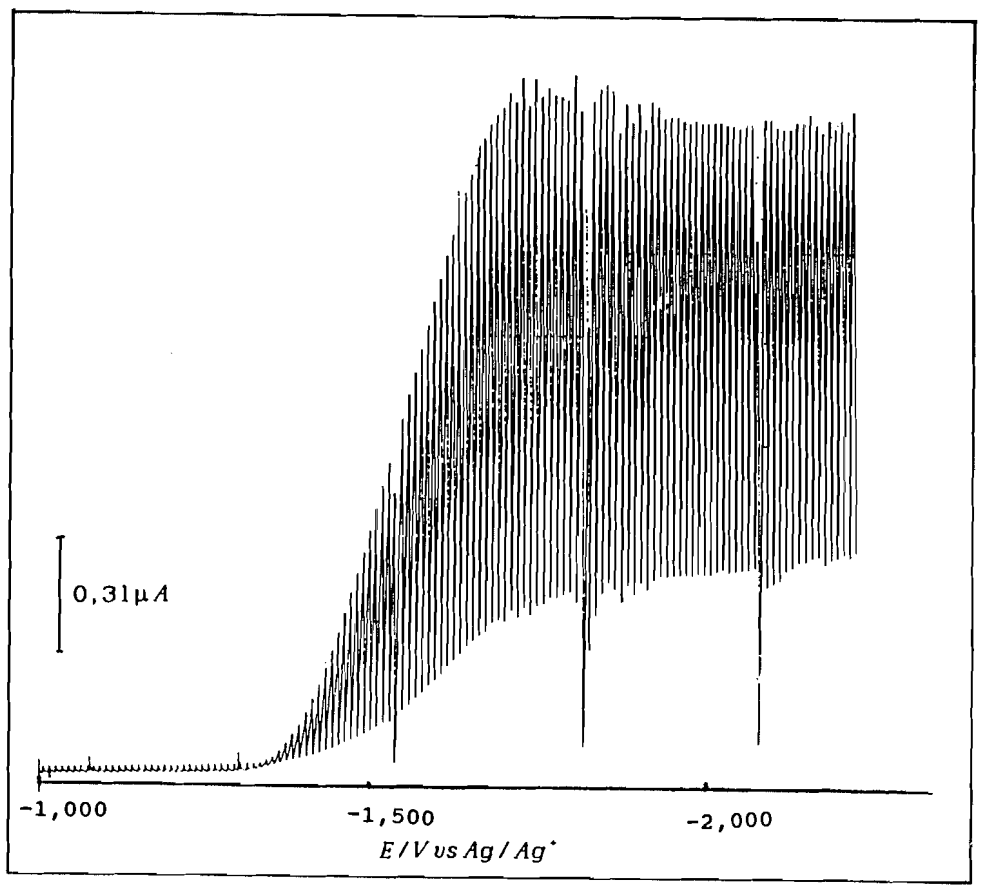

FIG. 3. Polarogram of Zn^{2+} electroreduction in HMPA + 10% H_2O; $[Zn^{2+}] = 3.0$ mM, [TEAP] = 0.1 M, $v = 5$ mV/s.

and

$$[10] \qquad \ln k_s = \ln k_{s,a} + (\alpha_a n - z) f \phi_2$$

where $k_{s,a}$ is the standard rate constant corrected for the double layer effects, α_a is the apparent transfer coefficient, z is the ion charge, and $f = F/RT$.

Figures 4 and 5 show examples of the corrected rate constants as functions of the potential in PC and ACN solutions. These curves were obtained from voltammetric data. The ϕ_2 values in PC solutions are very small and they are not significantly affected by the increase in the supporting electrolyte concentration; they change only between -11 and -3 mV. This behaviour is connected with the fact that the reduction potentials of Zn^{2+} in PC are close to the potential of zero charge. However, in ACN, where the reduction potential is much more negative than the potential of zero charge, ϕ_2 decreases from -70 to -32 mV as the supporting electrolyte concentration increases from 0.1 M to 0.9 M. The ϕ_2 values were obtained from double layer studies carried out earlier in this laboratory

(35). The corrected kinetic parameters are displayed in Tables 4 and 5. It is evident that the transfer coefficients measured in PC and corrected for double layer effects are independent of the supporting electrolyte concentration, although some dependence exists in ACN. Such a dependence was earlier found for Cd^{2+} electroreduction (36, 37). The corrected rate constants in PC, after elimination of the two smallest values from voltam-

metric or the two extreme values from the chronoamperometric measurements, do not show any dependence on concentration and their variation may come from experimental error. Besides, the Frumkin correction in this solvent is not very precise because the reduction potential is located very close to the potential of zero charge where ϕ_2 changes rapidly with the electrode potential (small errors in $E^{0'}$ cause large errors in ϕ_2). The slight nonlinearity of the corrected kinetic plots may be caused by that factor. However, in ACN the corrected rate constants obtained are independent of the supporting electrolyte concentration. Corrected plots shown in Figs. 4 and 5 are linear, which indicates that the electroreduction process is limited by one step as far as the kinetics of the overall process is concerned.

To confirm the above results the cyclic voltammograms were approximated using a nonlinear least-squares (NLS) technique. In this method the experimental cyclic voltammograms were approximated by the solution of the diffusion–kinetic problem using the Cranck–Nicolson method in each step (36, 43, 44). Tables 6 and 7 present kinetic parameters obtained by approximation assuming simple charge transfer in one step. For both solvents a good approximation was obtained. An example of the approximation of the cyclic voltammogram obtained in PC is shown in Fig. 6. An attempt to use a more complex sequential charge transfer mechanism (EE) produced meaningless results (negative transfer coefficients).

In conclusion, the kinetic measurements in PC and ACN indicate that Zn^{2+} electroreduction at mercury proceeds in a two-step mechanism. The slowest step is probably a cation transfer through the electrical double layer, from the position *c* located in the solution close to the o.H.p., to the position *a* located at or close to the electrode surface, reaction [11], followed by a

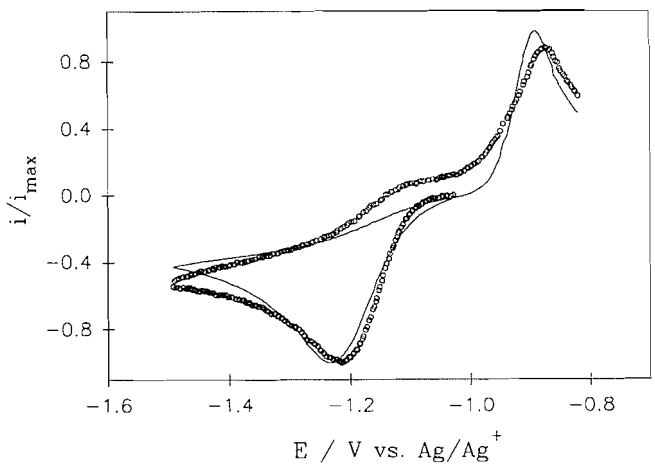

FIG. 6. Experimental (○) and approximated according to a simple charge transfer in one step (—) cyclic voltammogram of Zn^{2+} in PC; [TEAP] = 0.15 M, $[Zn^{2+}] = 0.8$ mM, $v = 2$ V s^{-1}, cathodic peak ~4 μA.

fast electroreduction with formation of the amalgam, reaction [12]:

[11] $Zn^{2+}{}_c \leftrightarrow Zn^{2+}{}_a$

[12] $Zn^{2+}{}_a + 2e^- \leftrightarrow Zn(Hg)$

The electron transfer mechanism, reactions [2] and [3], does not seem to be probable because it suggests formation of a neutral zinc atom in solution (close to the o.H.p.) that diffuses only towards the electrode surface. The latter fact is confirmed by coulometric experiments (15) in which 100% of zinc is found in mercury after electrolysis.

HMPA

The kinetic parameters obtained for the $Zn^{2+}/Zn(Hg)$ system in HMPA solutions were determined using the Koutecky analysis (45) and the approximation of cyclic voltammograms. Earlier studies of the electroreduction of alkali metal cations by Baranski and Fawcett (28, 29) indicated that the electrochemical behaviour in HMPA was different than that in other solvents. The authors attributed this differences to a slow partial cation desolvation reaction preceding the charge transfer process. This reaction was the rate-determining step in the electroreduction of Li^+. Because the desolvation step takes place in the double layer it can be considered as a heterogeneous process. The heterogeneous rate constant of the surface

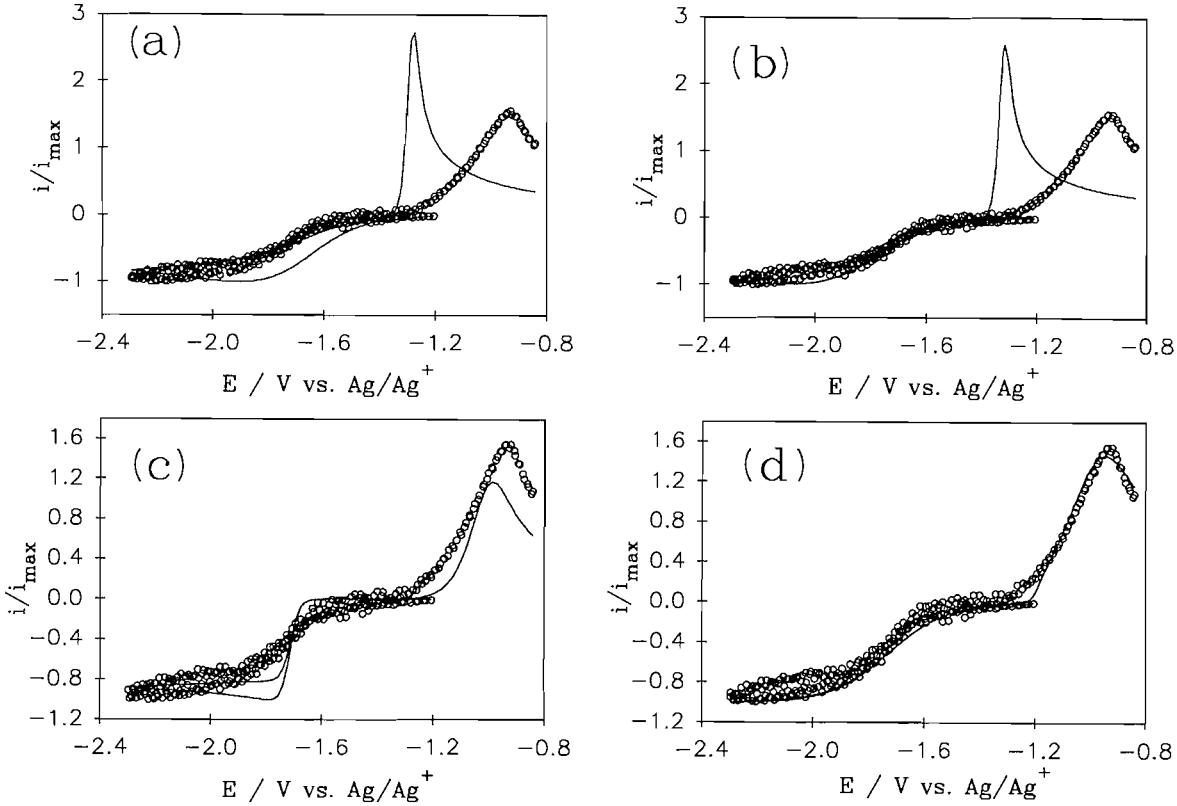

FIG. 7. Experimental (○) and (—) approximated cyclic voltammograms for the $Zn^{2+}/Zn(Hg)$ system in HMPA; $[Zn^{2+}] = 3.0$ mM, [TEAP] = 0.1 M, $v = 0.1$ V s^{-1}. (*a*) Simple charge transfer in one step (E); (*b*) mechanism EE; (*c*) mechanism CE; and (*d*) mechanism CEE, cathodic peak current ~1 μA.

chemical reaction, k_{1h}, may be obtained using the Koutecky method at the potentials of the polarographic plateau where the overall reaction kinetics is determined by the chemical reaction (rates of the heterogeneous charge transfer reactions are potential dependent and fast as negative potentials):

$$[13] \qquad F(\chi) = \frac{i_k}{i_g}$$

where $f(\chi)$ is a tabulated function (45), i_k is a kinetic current, i_g is a hypothetical limiting current in the absence of the preceding reaction limitations, and parameter χ is defined as:

$$[14] \qquad \chi = \left(\frac{12t}{7D_{ox}}\right)^{1/2} k_{1h}$$

For Zn^{2+} electroreduction the ratio of limiting currents in the absence and presence of 10% of water in HMPA was equal to ~0.3 and the value of the heterogeneous rate constant k_{1h} was determined as equal to 1.5×10^{-4} cm s^{-1}. The kinetic parameters were also determined by the NLS approximation of cyclic voltammograms assuming simple charge transfer in one step (E), subsequent charge transfer in two steps (EE), chemical reaction followed by a charge transfer (CE), and chemical reaction followed by two subsequent charge transfer processes (CEE). Figure 7 shows a few examples of these approximations. When the charge transfer in one or two steps was assumed, the NLS method approximated the anodic peak very poorly. In this case very low values of the transfer coefficient, which produced very asymmetrical peaks, were found, similar to those found earlier for Cd(II) in DMSO (36). In the case of mechanisms E, EE, and CE the parameters found did not have physical signficance because of the large errors of approximation. The best fit was obtained assuming the CEE mechanism (Fig. 7*d*) and the kinetic parameters obtained are shown in Table 8. The mechanism found is in agreement with the shape of the cathodic peak, which is characteristic for the chemically limited processes. The value of the first transfer coefficient, α_1, was assumed equal to 0.2 on the basis of polarographic measurements at the foot of the polarographic wave. The kinetic parameters obtained from approximation might be more reliable than those obtained from dc polarography because they were determined over a wider potential range. The large difference in values of the heterogeneous rate constant of the

TABLE 8. Kinetic parameters obtained by approximation of the cyclic voltammograms of Zn^{2+} in HMPA solutions, assuming a CEE mechanism; $[Zn^{2+}] = 3.0$ mM, $T = 25 \pm 1$°C; α_1 was supposed to be equal to 0.2

[a]From ref. 15.

preceding chemical reaction obtained from polarography and voltammetry may originate from the fact that the polarographic plateau in Fig. 2 is not well defined.

Therefore, the following mechanism of Zn^{2+} electroreduction in HMPA may be proposed:

$$[15] \quad [Zn(HMPA)_x]_c^{2+} \rightleftharpoons [Zn(HMPA)_y]_c^{2+} + (x-y)HMPA$$

$$[16] \quad [Zn(HMPA)_y]_c^{2+} \rightleftharpoons [Zn(HMPA)_y]_b^{2+}$$

$$[17] \quad [Zn(HMPA)_y]_b^{2+} \rightleftharpoons [Zn(HMPA)_y]_a^{2+}$$

$$[18] \quad [Zn(HMPA)_y]_a^{2+} + 2e \rightleftharpoons Zn(Hg) + yHMPA$$

where the heterogeneous desolvation reaction [15] is followed by a cation transfer through the double layer in two steps, reactions [16] and [17], and, at the electrode surface, the rate of amalgam formation, reaction [18], is fast. Therefore, the kinetic parameters k_{1h}, k_{s1}, and k_{s2} in Table 8 correspond to reactions [15]–[17], respectively. Similar mechanisms were observed for Zn^{2+} (EE) and Cd^{2+} (CE or CEE) electroreduction in DMSO (15, 37). The presence of a preceding chemical step in HMPA is connected with the strong solvating power of that solvent towards cations.

Solvent effects

Diffusion coefficients depend on the solvent viscosity according to the Stokes–Einstein equation (46):

$$[19] \quad D = \frac{k_B T}{6\pi r \eta}$$

where D is the diffusion coefficient, r is the particle radius, k_B the Boltzmann constant, and η the solvent viscosity. The dependence of D_{ox} on η^{-1} is shown in Fig. 8. Although the straight line is characterized by a high determination coefficient, $r^2 = 0.996$, there are no points in the middle region to better characterize that dependence.

The values of the half-wave potential depend on the solvent donor number, DN. The correlation between $E_{1/2}$ and DN has $r^2 = 0.947$; Gritzner (47) obtained $r^2 = 0.92$ for 13 solvents.

A comparison of the kinetic parameters of Zn^{2+} in different solvents is presented in Table 9. It is evident that solvent effects are very strong. The corrected rate constant changes 10^6 times as the solvent changes from ACN to HMPA. Figure 9 shows the dependence of ln $k_{s,a}$ on DN. Although there are only a few experimental points, a linear relation is fulfilled ($r^2 = 0.9$). Similar linear dependence was also observed for Cd^{2+} electroreduction in various solvents (34). However, no correlation was found between ln k_s (uncorrected) and DN ($r^2 = 0.56$).

Although the process was studied in four solvents only,

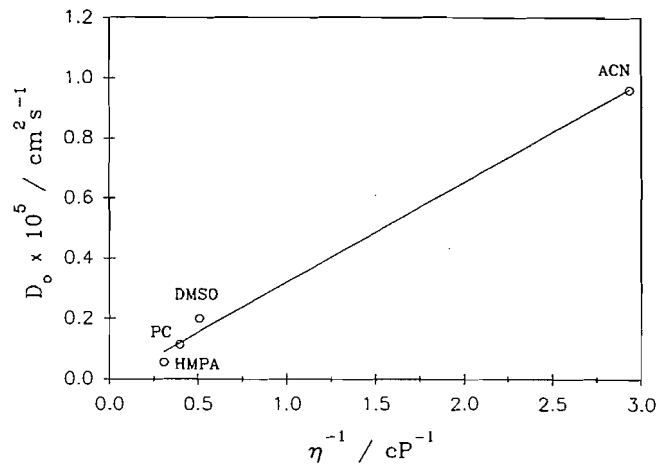

FIG. 8. Dependence of the Zn^{2+} diffusion coefficients on the inverse of the viscosity of the solvents.

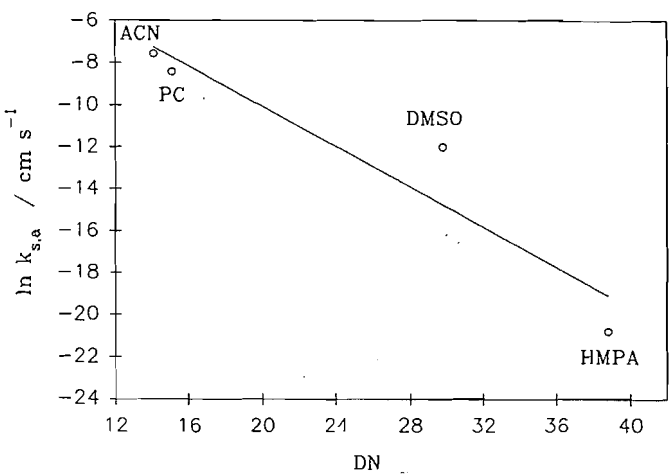

FIG. 9. Dependence of the corrected standard rate constant on the donor number solvents.

the results presented above indicate that the electroreduction mechanism and kinetics are strongly influenced by the nature of the solvent. In weakly solvating solvents (ACN, PC, small DN) Zn^{2+} is reduced in a mechanism containing one slow step. In more strongly solvating solvents (DMSO, HMPA) it is reduced in two (EE) or three (CEE) distinct steps. In HMPA there is a chemical reaction preceding the charge transfer reaction.

Conclusions

Electroreduction of Zn^{2+} was studied in PC, ACN, and HMPA using dc polarography, cyclic voltammetry, chronoam-

perometry, and ac polarography. It should be stressed that the measurements in these solvents were very difficult and much effort was required to obtain reproducible results. The measurements performed in ACN were very sensitive to the water content and different kinetic parameters outside and inside the dry box could be obtained. The reduction kinetics and mechanism are influenced by the solvent donor properties. In the solvents characterized by low values of donor number (ACN, PC) the charge transfer was controlled by the kinetics of one step. In DMSO (15), reaction proceeded through the EE mechanism and in HMPA the preceding heterogeneous chemical reaction was followed by the charge transfer in two steps (CEE mechanism). The preceding heterogeneous chemical reaction was earlier found for the electroreduction of alkali metal cations in HMPA (29) and Cd^{2+} in DMSO (37), and the EE mechanism was found for Zn^{2+} in DMSO (15).

The diffusion coefficients determined polarographically depend on the concentration of the supporting electrolyte; there is a linear relation between D_{ox} and the square root of the concentration of TEAP, Fig. 1, from which the diffusion coefficients in pure solvents were determined. In addition, the diffusion coefficients depend on the solvent viscosity, Fig. 8.

There is no dependence of the apparent rate constant, k_s, on the solvent donor number, $r^2 = 0.56$; however, the rate constants corrected for the double layer effects, $k_{s,a}$, correlate fairly well with DN ($r^2 = 0.9$). The results obtained may be explained by the cation transfer mechanism, in which the slow process is the cation transfer through the electrical double layer in one or two steps.

Enantioselective deprotonation of protected 4-hydroxycyclohexanones

MAREK MAJEWSKI[1] AND JOHN MACKINNON

Department of Chemistry, University of Saskatchewan, Saskatoon, SK S7N 0W0, Canada

Received January 10, 1994

MAREK MAJEWSKI and JOHN MACKINNON. Can. J. Chem. **72**, 1699 (1994).

A series of derivatives of 4-hydroxycyclohexanone (**1***a–g*) with the hydroxy group protected as a silyl ether (**1***a*, *b*), ether (**1***d*, *g*), an acetal (**1***c*), or an ester (**1***e*, *f*) were deprotonated with chiral, optically pure, lithium amides **3–9**. The resulting non-racemic enolates were trapped as enol acetates. The enantioselectivity of deprotonation was up to 74% ee.

MAREK MAJEWSKI et JOHN MACKINNON. Can. J. Chem. **72**, 1699 (1994).

On soumis une série de dérivés de la 4-hydroxycyclohexanone (**1***a–g*) dont l'hydroxyle était protégé par un ester silylique (**1***a* et **1***b*), un éther (**1***d* et **1***g*), un acétal (**1***c*) ou un ester (**1***e* et **1** *f*) à une déprotonation à l'aide d'amidures de sodium (**3–9**) chiraux, optiquement purs. On a piégé les énolates non racémiques obtenus sous la forme d'acétates énoliques. L'énantiosélectivité de la déprotonation s'élève jusqu'à 74% ee.

[Traduit par la rédaction]

Introduction

Deprotonation of cyclic ketones with chiral lithium amide bases is a topic of current interest (for a review see ref. 1). The reaction has been applied to enantioselective deprotonation of ketones having C_s symmetry (1), to kinetic resolution of racemic cyclic carbonyl compounds (2), and to regioselective deprotonation of cyclic, chiral ketones (3). In an imaginative recent paper Simpkins and co-workers brought together the two latter approaches to form a new concept, which was used to synthesize a chiral precursor to (+)-yohimbine (4).

Tactics based on deprotonation with chiral lithium amide bases were used in synthesis of several natural products and intermediates leading to natural products (5). To increase the usefulness of these tactics it is necessary that the scope and limitation of this deprotonation approach are more clearly defined, i.e., correlation between variables like structure of the base, structure of the ketone, reaction conditions (temperature, solvent, additives), and efficiency (enantiomeric excess) of enolization must be understood to the point that affords reasonable predictability. Alternatively, a large number of precedents might be substituted for understanding.

Cyclohexanone derivatives that were deprotonated enantioselectively in the past include several 4-alkylcyclohexanones (6*a–c*) as well as 2,6-dimethyl- and 3,5-dimethylcyclohexanone (6*d*, 7). All the above ketones are conformationally biased and it is reasonable to assume that "conformational anchoring" (1, 5*k*) would benefit enantioselective deprotonation by resulting in a system in which the base would have to differentiate between two enantiotopic axial hydrogens without interference from diastereotopic α-hydrogens (8). Experimental data, however, show that the extent of the conformational bias matters little, at least in some cases. Thus, 4-methyl-, 4-isopropyl-, and 4-*tert*-butylcyclohexanone when deprotonated with base **3**, in the presence of TMS-Cl, gave virtually identical optical purity (cf. Table 2) of the resulting TMS enol ethers (6*a*, 6*c*). Recently, 4-methyl-4-phenylcyclohexanone was deprotonated with base **3** and the TMS enol ether derived from this compound has shown 60% ee (5*j*). It should be noted that the degree of conformational bias for this compound is small; in 1-methyl-1-phenylcyclohexane the conformer with axial phenyl is more stable by only 0.32 kcal/mol (9).

Cyclohexanones substituted at the 4-position with alkyl groups have limited synthetic utility. Hoping to increase the synthetic appeal of enantioselective deprotonation of cyclic ketones, we decided to investigate enolization of cyclohexanone derivatives having a functional group containing oxygen at this position. We hoped that some derivatives of 4-hydroxycyclohexanone should be deprotonated with reasonable enantioselectivity despite the fact that, in general, alkoxy groups provide much less conformational bias than alkyl groups.

SCHEME 1

Results and discussion

First, we searched for a product, derived from an enolate, that will allow measurement of enantiomeric excess (ee) of deprotonation. Several derivatives of 4-hydroxycyclohexanone (compounds **1***a–g*) (Scheme 1) were deprotonated with LDA and the racemic enolates were quenched with electrophiles. The resulting compounds were analyzed using NMR with chiral additives and (or) chiral shift reagents, and by chromatography (HPLC and GC) on chiral columns. Enol acetates (**2**), formed in 65–75% yield, proved suitable for estimating the ee by NMR using chiral shift reagents.

Next, each of the ketones **1***a–g* was treated with a chiral, optically pure, lithium amide. Lithium dialkylamides used in this study are shown in Scheme 2. In selecting these reagents we were conscious of the fact that it is difficult to make a sweeping statement regarding the correlation between the structure of a lithium amide and its effectiveness as a reagent for enantioselective deprotonation. We tried to choose representative compounds of each of the three categories of lithium amides which were used successfully in the past (1), i.e.:

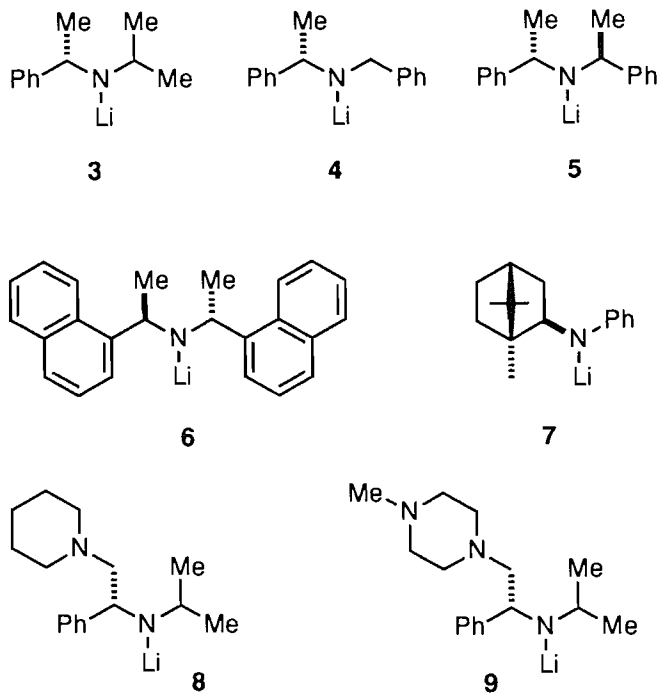
[a]Numbers represent enantiomeric excess (% ee) which was measured by NMR in the presence of a chiral shift reagent: $Eu(hfc)_3$ or $Pr(hfc)_3$. Yields of isolated products are given in parentheses.



SCHEME 2

(*i*) Derivatives of 1-phenylethylamine (both enantiomers of this amine are commercially available). These amides are exemplified by structures **3–5** in Scheme 2. In this group of compounds amides with two stereogenic centers having C_2 symmetry (e.g., **5**) often proved the best in past studies on different models (1, 5*h*). Taking this into account we have synthesized a new C_2-symmetrical amide **6** from (*R*)-1-(1-naphthyl)ethylamine.

(*ii*) Lithiated secondary amines derived from terpenes. Only a few of such compounds have been investigated to date (5*h*, 7) and camphor-derived amides were found by Simpkins to work especially well when 2,6-dimethylcyclohexanone was the substrate (1). In our study one of these compounds was tested (**7**).

(*iii*) Lithiated secondary amines derived from tertiary amides of amino acids. The application of these compounds to enantioselective deprotonation was pioneered by Koga's group and it was found that bi- and tridentate amines derived from phenylglycine (e.g., compounds **8** and **9** used in our study) worked well on several cyclic ketones (6*a*).

The selectivities of deprotonation of compounds **1***a–g* with lithium amides **3–9** are summarized in Table 1. The yields of the acetate products were, with a few exceptions, in the 60–90% range but the selectivities were modest. The most selective reactions involved the new C_2 symmetrical base **6**, which turned out to be a very promising reagent. The highest ee observed was 74% (base **6**, ketone **1***a*), which compares favorably with results of enantioselective deprotonation of 4-alkylcyclohexanones (ref. 6*a*, Table 2) and 4-methyl-4-phenylcyclohexanone (5*j*). In general, the bigger the protecting group the larger the ee, although this trend is not very precisely defined. Among the ethers, for example, benzyl ether (**1***g*) was consistently the best and gave higher ee values (with one exception) than the methyl and methoxymethyl ethers (**1***d* and **1***c*). Similarly ester **1***e* showed greater efficiency in enantioselective deprotonation reactions than ester **1***f*.

It should be noted that the ee of deprotonation of 4-methoxycyclohexanone **1***d* was much lower than that of 4-methylcyclohexanone. Clearly, a certain measure of steric bias is necessary.

The efficiency of enantioselective deprotonation can be greatly influenced by reaction conditions. Both our group (7) and others (10) observed that the presence of lithium salts in the reaction mixture can increase the ee, sometimes substantially. It was also reported that lowering the reaction temperature often resulted in measurable increase in enantioselectivity (1) and that HMPA, used as an additive, often had an interesting effect on selectivity (1): in cases where bases of structures **3–5** (or similar) were used, addition of HMPA usually resulted in the decrease in enantioselectivity. Some amides derived from bidentate or tridentate amines derived from phenylglycine (e.g., **8**, **9**) showed increased enantioselectivity when HMPA was added (1, 6*a*). This interesting difference in behavior could, perhaps, be a result of different species being responsible for deprotonation in both cases; that is, dimers originating from amides **3–6** could be the actual reactive species (7) whereas the amides **8** and **9** might react in their monomeric forms (11).

The results of our investigations of the effects of lowering the temperature and applying additives (LiCl, HMPA) on the system in question are shown in Table 3. A small temperature effect was observed in only one case: compound **1***f*, deprotonated with amide **8** at −100°C showed an increase in enantioselectivity from 48 to 58%. Addition of HMPA either had no effect or resulted in decreased ee values. And finally, addition of LiCl led to a measurable increase of reaction enantioselectivity when base **4** was used to deprotonate ketones **1***a* and **1***f*.

Conclusion

Our study shows that cyclohexanones having a protected hydroxy group at the 4-position can be enantioselectively

deprotonated with a number of chiral lithium amides. The selectivities were modest (highest ee was 74%) and it was concluded that, for best results, the protecting group ought to be bulky.

Experimental

General methods

All air-sensitive reactions were carried out under argon. THF was dried with sodium and distilled under nitrogen from sodium benzophenone ketyl. Diisopropylamine, triethylamine, pyridine, HMPA, and CH_2Cl_2 were distilled from CaH_2. Benzene was distilled from P_2O_5, and methanol from magnesium. All chiral amines were distilled under reduced pressure and stored under argon. Ac_2O was fractionally distilled from P_2O_5 and stored under argon. Lithium chloride was dried at 130°C and used directly. *n*-BuLi was periodically titrated using 2,5-dimethoxybenzyl alcohol as the indicator (12).

Flash chromatography was carried out using Merck Kieselgel 60 (230–400 mesh) with TLC being performed on precoated plates (Merck, silica gel 60, F254). Detection was by using UV light, iodine, or phosphomolybdic acid visualizing solution. Gas chromatography was done on a Hewlett Packard 5890A instrument using a methyl silicone gum column (HP-1, 5 m × 0.53 mm). Melting and boiling points are uncorrected. Optical rotations were measured using Perkin Elmer 241 polarimeter, concentrations are given in g/100 mL. ^1H NMR and ^{13}C NMR spectra were measured on a Bruker AM-300 spectrometer at 300 MHz and 75 MHz, respectively. $CDCl_3$ was used as solvent unless otherwise stated, with tetramethylsilane being used as the internal standard. Infrared spectra were recorded on a Biorad FTS-40 interferometer using a diffuse reflectance cell. Mass spectra were recorded on a VG analytical retrofit of a single-sectored, magnetic scanning MS-12, linked to a Zenith computer. Electron impact was accomplished at 70 eV and chemical ionization at 50 eV with ammonia as the carrier gas.

*1,4-Dioxaspiro[4.5]decan-8-ol (**10**) (ref. 13)*

A solution of 1,4-cyclohexanedione monoethyleneketal (10.00 g, 64 mmol) in THF (50 mL) was added dropwise to a slurry containing lithium aluminum hydride (2.92 g, 76.8 mmol) in THF (100 mL) at 0°C. Stirring was carried out overnight at room temperature. The mixture was cooled to 0°C, water (2.9 mL) was then added followed by 15% NaOH (2.9 mL) and a further 8.8 mL of water. The mixture was then extracted with AcOEt (3 × 75 mL). The organic extracts were combined, washed with $NaHCO_3$ solution (2 × 10 mL), and dried over $MgSO_4$. The solvent was removed in vacuo, which yielded the alcohol **10** as a colorless liquid (9.91 g, 98%); bp 252–254°C; IR (KBr): 3400 (OH), 2940 (CH), 921 (C-O) cm^{-1}; ^1H NMR δ: 3.89 (s, 4H), 3.73 (m, 1H), 2.27 (br s, 1H), 1.84–1.72 (m, 4H), 1.62–1.51 (m, 4H); ^{13}C NMR δ: 108.2, 67.9, 64.2, 64.1, 31.8, 31.5; MS (CI, NH_3), *m/e* (relative intensity): 176 ([M + 18], 7), 159 ([M + 1], 100), 99 (41).

*4-Hydroxycyclohexanone (**11**) (ref. 14)*

A solution of **10** (9.91 g, 62.7 mmol) in H_2O (100 mL) containing a catalytic amount of *p*-TsOH was refluxed for 2 h. The solution was cooled to room temperature, neutralized with solid $NaHCO_3$, and extracted with AcOEt (5 × 70 mL). The organic extracts were then combined and dried over $MgSO_4$. The solvent was then removed in vacuo to yield **11** (7.21 g, 99%); IR (KBr): 3340 (OH), 2941 (CH), 1709 (C=O), 950 (C-O) cm^{-1}; ^1H NMR δ: 4.22–4.16 (m, 1H), 3.34 (br s, 1H), 2.66–2.57 (m, 2H), 2.37–2.28 (m, 2H), 2.12–1.95 (m, 4H); ^{13}C NMR δ: 211.9, 65.7, 37.1, 33.5; MS (CI, NH_3), *m/e* (relative intensity): 132 ($[M + 18]^+$, 100), 131 (3), 114 (5), 99 (6).

*4-(tert-Butyldimethylsiloxy)cyclohexanone (**1**a)*

A solution of **11** (3.73 g, 32.7 mmol) in CH_2Cl_2 (25 mL) was added to imidazole (2.66 g, 39.3 mmol) in CH_2Cl_2 (100 mL) at 0°C. After 15 min, TBDMSCl (5.92 g, 39.3 mmol) in CH_2Cl_2 (30 mL) was added dropwise to the mixture. After stirring the solution overnight at room temperature, the reaction mixture was quenched by addition of water (25 mL) and was extracted with AcOEt (3 × 50 mL). The organic phase was washed with H_2O (2 × 25 mL), brine (2 × 15 mL), and dried over $MgSO_4$. The product was purified via flash column chromatography (hex:AcOEt 8:1, R_f 0.30) to yield **1***a* (6.96 g, 93%); bp 261–262°C; IR (KBr): 2954 (CH), 1726 (C=O) cm^{-1}; ^1H NMR δ: 4.14–4.10 (m, 1H), 2.70–2.59 (m, 2H), 2.25–2.17 (dt, 2H, J = 14.4, 4.4 Hz), 1.97–1.60 (m, 4H), 0.95 (s, 9H), 0.07 (s, 6H); ^{13}C NMR δ: 211.9, 65.7, 36.9, 34.1, 25.7, 25.6, 18.0, −4.9; MS (CI, NH_3), *m/e* (relative intensity): 246 ($[M + 18]^+$, 100), 229 ($[M + 1]^+$, 15), 188 (13), 172 (10), 171 (68), 97 (12), 92 (16), 91 (20). Anal. calcd. for $C_{12}H_{24}SiO_2$: C 63.10, H 10.59; found: C 63.31, H 10.44.

*4-(tert-Butyldiphenylsilyloxy)cyclohexanone (**1**b)*

TBDPSCl (4.1 mL, 15.8 mmol) in CH_2Cl_2 (50 mL) was added drop-

wise to a solution of **11** (1.50 g, 13.2 mmol) and imidazole (2.66 g, 39.3 mmol) in CH_2Cl_2 (100 mL) at 0°C. The resulting solution was stirred overnight at room temperature. The reaction mixture was then quenched with H_2O (5 mL) and washed with H_2O (2 × 10 mL), brine (2 × 10 mL), and the washings were extracted with AcOEt (2 × 40 mL). The organic extracts were combined and dried over $MgSO_4$. The solvent was then removed in vacuo and the residue was purified by flash column chromatography (hex:AcOEt 4:1, R_f 0.37) to yield **1***b* (3.76 g, 81%); mp 107–108°C; IR (KBr): 3067 (CH), 2957 (CH), 1706 (C═O) cm^{-1}; ^1H NMR δ: 7.68–7.66 (m, 4H), 7.44–7.38 (m, 6H), 4.14 (m, 1H), 2.73 (m, 2H), 2.22–2.17 (m, 2H), 1.97–1.92 (m, 2H), 1.80–1.77 (m, 2H), 1.09 (s, 9H); ^{13}C NMR δ: 211.7, 135.7, 133.9, 129.8, 127.7, 66.9, 37.0, 33.7, 27.0, 19.3; MS (CI, NH_3), m/e (relative intensity): 370 ([M + 18], 98), 295 (65), 275 (46), 274 (59), 217 (20), 216 (100), 196 (69), 78 (17). Anal. calcd. for $C_{22}H_{28}SiO_2$: C 74.95, H 8.00; found: C 74.7, H 8.19.

*4-Methoxymethoxycyclohexanone (**1**c)*

Ketone **11** (2.00 g, 17.6 mmol) and ethyldiisopropyl amine (4.52 g, 35.8 mmol) were added to a 100-mL round-bottom flask containing CH_2Cl_2 (50 mL) and the mixture was cooled to 0°C. MOMCl (4.0 mL, 52.7 mmol) was added dropwise and the reaction mixture was stirred for 1 h at 0°C, then for another 8 h at room temperature. The reaction mixture was quenched by addition of H_2O (10 mL), followed by extraction with AcOEt (2 × 25 mL). The organic phase was washed with $NaHCO_3$ (3 × 15 mL), brine (2 × 10 mL), and was then dried over $MgSO_4$. The solvent was then removed in vacuo and the residue was purified by flash column chromatography (hex:AcOEt 5:1, R_f 0.19) yielding **1***c* (1.61 g, 58%); bp 58–59°C at 0.6 Torr (1 Torr = 133.3 Pa); IR (KBr): 2928 (CH), 1719 (C═O), 1148 (C-O) cm^{-1}; ^1H NMR δ: 4.74 (s, 2H), 4.03–3.98 (m, 1H), 3.41 (s, 3H), 2.65–2.54 (m, 2H), 2.35–2.26 (m, 2H), 2.11–1.95 (m, 4H); ^{13}C NMR δ: 211.1, 94.7, 70.6, 55.3, 37.2, 31.2; MS (CI, NH3) *m/e* (relative intensity): 176 ([M + 18], 100), 159 ([M + 1], 29), 96 (17), 58 (29). Anal. calcd. for $C_8H_{14}O_3$: C 60.74, H 8.92; found: C 60.47, H 9.05.

*4-Methoxycyclohexanone (**1**d) (ref. 15)*

Compound **10** (2.01 g, 12.68 mmol) in THF (25 mL) was added to NaH (0.91 g, 38 mmol) in THF (50 mL) at 0°C and the mixture was stirred until evolution of hydrogen had ceased. MeI (8.99 g, 63.4 mmol) was then added slowly and the mixture was refluxed for 12 h. The solution was cooled to room temperature and Et_2O (50 mL) was added and the resulting mixture extracted with Et_2O (2 × 50 mL). The organic phase was then washed with $NaHCO_3$ (2 × 25 mL) and brine (2 × 10 mL). The organic extracts were then dried over $MgSO_4$ and the solvent was removed in vacuo to yield the 1,4-dioxaspiro[4,5]decan-8-ol methyl ether (2.00 g, 92%). The crude methyl ether was then added to a solution of H_2O (50 mL) containing a catalytic amount of *p*-TsOH and the mixture was refluxed for 1 h. The solution was then extracted with AcOEt (3 × 30 mL) and the organic phase was washed with $NaHCO_3$ (2 × 15 mL). The combined organic extracts were dried over $MgSO_4$, the solvent was removed in vacuo, and the residue was purified by flash column chromatography (hex:AcOEt 4:1, R_f 0.18) to yield **1***d* (2.01 g, 89%); IR (KBr): 2941 (CH), 2825 (CH), 1716 (C═O), 1079 (C-O) cm^{-1}; ^1H NMR δ: 3.60–3.56 (m, 1H), 3.37 (s, 3H), 2.57–2.47 (m, 2H), 2.26–2.17 (m, 2H), 2.10–2.00 (m, 2H), 1.95–1.87 (m, 2H); ^{13}C NMR δ: 211.2, 74.2, 56.0, 37.0, 30.0; MS (EI), *m/e* (relative intensity): 128 ($[M]^+$, 100), 114 (15), 113 (18), 99 (33), 97 (24), 96 (77), 74 (86), 71 (92).

*4-(Trimethylacetoxy)cyclohexanone (**1**e)*

Pivaloyl chloride (3.24 mL, 26.3 mmol) was added to a solution of **11** (1.50 g, 13.2 mmol) in pyridine (3 mL) and THF (75 mL) at 0°C and the reaction mixture was stirred for 10 h at room temperature. AcOEt (50 mL) was then added and the crude mixture was washed with $NaHCO_3$ (3 × 20 mL), brine (2 × 10 mL), the layers were separated, and the combined aqueous washings were extracted with AcOEt (2 × 25 mL). The combined organic extracts were dried over $MgSO_4$ and the solvent was removed in vacuo and purified by flash chromatography (hex:AcOEt 8:1, R_f 0.25) to yield the protected hydroxy ketone (**1***e*), (2.01 g, 77%); mp 50–52°C; IR (KBr): 2964 (CH), 1721 (C═O), 1281 (C-O), 1162 (C-O) cm^{-1}; ^1H NMR δ: 5.15–5.09 (m, 1H), 2.57–2.47 (m, 2H), 2.38–2.29 (m, 2H), 2.14–1.95 (m, 4H), 1.20 (s, 9H); ^{13}C NMR δ: 209.9, 177.7, 68.0, 37.2, 30.3, 27.2; MS (CI, NH_3), *m/e* (relative intensity): 216 ([M + 18], 100), 199 ([M + 1], 42.6), 96 (34). Anal. calcd. for $C_{11}H_{18}O_3$: C 66.60, H 9.15; found: C 66.40, H 9.34.

*4-(4′-Methoxybenzoyloxy)cyclohexanone (**1**f)*

Ketone **11** (1.71 g, 15.0 mmol) was added to Et_3N (50 mL) and the solution was cooled at 0°C. Anisoyl chloride (3.03 g, 18.0 mmol) was added to the cooled solution and the mixture was stirred at room temperature for 24 h. AcOEt (100 mL) was added and the organic phase was washed with $NaHCO_3$ (3 × 20 mL), brine (2 × 20 mL), and dried over $MgSO_4$. The organic portions were then combined and the solvent was removed in vacuo; the residue was purified by flash column chromatography (PhH:AcOEt 8:1, R_f 0.32) yielding **1***f* (3.35 g, 90%); mp 53–55°C; IR (KBr): 3001 (CH), 2957 (CH), 1705 (C═O), 1276 (C-O), 1256 (C-O) cm^{-1}; ^1H NMR δ: 8.03–8.00 (d, 2H, J = 8.7 Hz), 6.96–6.93 (d, 2H, J = 8.7 Hz), 5.41 (m, 1H), 3.88 (s, 3H), 2.69–2.60 (m, 2H), 2.47–2.40 (m, 2H), 2.28–2.10 (m, 4H); ^{13}C NMR δ: 209.9, 165.5, 163.5, 131.6, 122.6, 113.7, 68.6, 55.4, 37.3, 30.6; MS, *m/e* (relative intensity): 248 ($[M]^+$, 26), 152 (100), 136 (22), 135 (99), 96 (22), 92 (26), 77 (31). Anal. calcd. for $C_{14}H_{16}O_4$: C 67.70, H 6.50; found: C 67.65, H 6.50.

*4-Benzyloxycyclohexanone (**1**g) (ref. 16)*

Compound **10** (0.35 g, 2.22 mmol) in THF (25 mL) was added to NaH (0.117 g, 2.44 mmol) in THF (50 mL) at 0°C and the mixture was stirred until evolution of hydrogen had ceased. Benzyl bromide (0.455 g, 2.66 mmol) in THF (5 mL) was then added slowly and the mixture was refluxed for 12 h. The solution was cooled to room temperature, quenched with H_2O (10 mL), and extracted with Et_2O (2 × 50 mL). The organic phase was then washed with $NaHCO_3$ (2 × 25 mL), and brine (2 × 10 mL). The organic extracts were then finally dried over $MgSO_4$. The solvent was then removed in vacuo to yield the benzyl ether of **10**.

The crude benzyl ether was added to a solution of H_2O (50 mL) containing a catalytic amount of *p*-TsOH and refluxed for 1 h. The solutions was then extracted with AcOEt (3 × 30 mL) and the organic phase was washed with $NaHCO_3$ (2 × 15 mL). The combined organic extracts were dried over $MgSO_4$. The solvent was then removed in vacuo and the residue purified by flash column chromatography (hex:AcOEt 4:1, R_f 0.28) to yield **1***g* (0.290 g, 64%); bp 140–141°C at 1.5 Torr; IR (KBr): 3024 (C-H), 2944 (C-H), 1712 (C═O), 1101 (C-O) cm^{-1}; ^1H NMR δ: 7.38 (m, 5H), 4.61 (s, 2H), 3.83 (m, 1H), 2.68–2.58 (m, 2H), 2.32–2.23 (m, 2H), 2.21–2.12 (m, 2H), 2.02–1.94 (m, 2H); ^{13}C NMR δ: 211.0, 138.5, 128.4, 127.6, 127.4, 72.3, 70.3, 37.2, 30.5; MS (EI), *m/e* (relative intensity): 204 ($[M]^+$, 7), 104 (64), 98 (48), 91 (100), 65 (19).

Chiral amines

Chiral amines used to generate lithium amides **3**–**9**, respectively, are numbered below with numbers **3***a*–**9***a* to distinguish them from the amides shown in Scheme 2. Amines **3***a*–**5***a* and **7***a*–**9***a* were synthesized as described in the literature (6*d*, 2*c*, 17).

*(R,R)-Bis-(1-naphthylethyl)amine (**6**a)*

A solution of (*R*)-(−)-(1-naphthylethyl)amine (10 mmol, 1.62 mL), 1-acetonaphthone (10 mmol, 1.52 mL), and a catalytic amount of *p*-TsOH in benzene (50 mL) was purged under argon and the mixture was refluxed for 5 days in a Dean–Stark apparatus. The resulting solution was cooled to 0°C and was washed with a solution of $NaHCO_3$ (50 mL), with brine (50 mL), and dried over $MgSO_4$. The crude imine was then purified via flash column chromatography (2% MeOH in $CHCl_3$). The imine was dissolved in THF (100 mL) and then hydrogenated on a Parr apparatus for 6 h (40 psi (1 psi = 6.9 kPa), 10% Pd/C). The suspension was filtered and the solvent was removed in vacuo. The crude product contained two diastereoisomers of **6***a*: *meso* and *R,R*

For personal use only.

in a ratio of 7:93 (by GLC). Concentrated HCl was added carefully to convert the amine to its hydrochloride salt and the resulting salt was recrystallized from ethanol. The free amine was then regenerated by dissolving the salt in Et_2O (100 mL), followed by the slow addition of 2 M NaOH. The amine was then distilled under vacuum on a Kugelrohr apparatus (250°C at 0.1 Torr). Yield 1.52 g (47%); $[\alpha]_D^{22}$ −53.59 (*c* 3.9, MeOH); IR (KBr): 3294 (N-H), 3045 (C-H), 2956 (C-H), 776 (C=C) cm^{-1}; ^1H NMR δ: 7.84–7.72 (m, 8H), 7.54–7.49 (m, 2H), 7.40–7.35 (m, 2H), 7.25–7.18 (m, 2H), 4.54–4.47 (q, 2H, *J* = 6.6 Hz), 1.95–1.80 (br s, 1H), 1.46–1.44 (d, 6H, *J* = 6.6 Hz); ^{13}C NMR δ: 133.9, 131.5, 128.7, 127.1, 125.7, 125.4, 125.3, 125.2, 123.1, 122.8, 51.3, 24.4; MS (EI), *m/e* (relative intensity): 325 ($[M]^+$, 8), 170, (17), 156 (29), 155 (100), 148 (16), 113 (28). Anal. calcd. for $C_{24}H_{23}N$: C 88.57, H 7.12, N 4.30; found: C 88.29, H 7.02, N 4.11.

General procedure for synthesis of enol acetate derivatives

n-BuLi (0.39 mmol) was added dropwise to a solution of amine (0.39 mmol) in THF (25 mL) at 0°C and the resulting solution was stirred for 30 min. The solution was then cooled to −78°C, whereupon the ketone (0.45 mmol) in THF (2 mL) was added dropwise and stirred for 2 h. Ac_2O (0.76 mmol) was added and the reaction mixture was stirred for 30 min. NH_4Cl solution (2 mL) was added to quench the reaction and the mixture was then extracted with AcOEt (3 × 25 mL). The combined organic extracts were washed with NaCl solution (2 × 10 mL), $NaHCO_3$ solution (2 × 10 mL), and dried over $MgSO_4$. The solvent was removed in vacuo and the residue purified by column chromatography yielding a colorless oil (yields are shown in Table 1).

Modifications

(i) Lower temperature (−100°C): A solution of lithium amide (1.2 equiv.) was prepared in the usual manner and then cooled to −100°C. The ketone (1 equiv.) in THF was then added and the mixture was stirred at −100°C for 2 h. Ac_2O was then added at −78°C and the resulting solution was stirred for 30 min. The reaction was then quenched with saturated NH_4Cl solution.

(ii) Addition of HMPA: A solution of lithium amide (1.2 equiv.) was prepared as usual at 0°C. HMPA (1 equiv.) was added and the mixture was stirred at 0°C for 15 min. The solution was then cooled to −78°C and stirred for 2 h; Ac_2O was added and the mixture was stirred for 30 min before being quenched with NH_4Cl solution.

(iii) Addition of LiCl: A solution of lithium amide (1.2 equiv.) was generated at 0°C whereupon LiCl (0.4 equiv.) was added via a side arm and the cooled solution was stirred for 15 min. The temperature was lowered to −78°C, the ketone in THF was added, and the mixture was stirred for 2 h. Ac_2O was then added and, after stirring for a further 30 min the mixture was quenched with NH_4Cl solution.

Spectral data and analyses for enol acetates

DENISE O. SILVA and HENRIQUE E. TOMA. Can. J. Chem. **72**, 1705 (1994).

The reaction of *cis*-[$RuCl_2(dmso)_4$] (dmso = dimethylsulfoxide) with 4-*tert*-butylpyridine (tbpy) in chloroform leads to the all *cis* (*ccc*) and the *cis,cis,trans* (*cct*) geometrical isomers of [$RuCl_2(S\text{-}dmso)_2(tbpy)_2$]. The *cct* isomer exhibits a reversible cyclic voltammogram, ascribed to the $Ru^{II/II}$ redox couple with $E_{1/2}$ = 1.12 V versus SHE. The *ccc* isomer can be oxidized at $E_{1/2}$ = 1.27 V; however, the oxidized species undergoes a relaxation equilibrium, ($K_{s\rightarrow o}$ = 1.59), involving the S-to-O linkage isomerization of a coordinated dmso ligand ($k_{s\rightarrow o}$ 1.9 s^{-1} and $k_{O\rightarrow S}$ = 1.2 s^{-1}). The isomerization reaction in the Ru^{III} *ccc* isomer is discussed in terms of the competitive effects between the S-bound dmso and the tbpy ligands.

DENISE O. SILVA et HENRIQUE E. TOMA. Can. J. Chem. **72**, 1705 (1994).

La réaction du *cis*-[$RuCl_2(dmso)_4$] (dmso = diméthylsulfoxyde) avec la 4-*tert*-butylpyridine (tbpy) dans le chloroforme conduit à la formation des isomères géométriques complètement *cis* (*ccc*) et *cis,cis,trans* (*cct*) du [$RuCl_2(dmso)_4(tbpy)_2$]. L'isomère *cct* présente un voltampérogramme cyclique réversible, attribué au couple rédox $Ru^{II/III}$, avec $E_{1/2}$ = 1,12 V versus SHE. L'isomère *ccc* peut être oxydé à $E_{1/2}$ = 1,27 V; toutefois, les espèces oxydées subissent un équilibre de relaxation ($K_{s\rightarrow o}$ = 1,59) impliquant l'isomérisation d'un coordinat dmso de la liaison S vers O ($k_{s\rightarrow o}$ = 1,9 s^{-1} et $k_{O\rightarrow S}$ = 1,2 s^{-1}). On discute de la réaction d'isomérisation de l'isomère *ccc* du Ru^{III} en fonction des effets compétitifs entres les coordinats tbpy et dmso lié par le S.

[Traduit par la rédaction]

Introduction

Recent publications have focused on the chemistry of geometrical isomers of ruthenium(II) sulfoxide complexes of the type [$RuX_2(dmso)_4$], where X = Cl, Br; dmso = dimethylsulfoxide, with special emphasis on their pronounced antitumor activity (1, 2). These complexes can strongly bind to guanine bases, and by analogy to cisplatin they seem to inhibit the restriction enzymes that recognize DNA sequences containing two or more adjacent guanines (3). We started investigating the chemistry of mixed ruthenium(II) sulfoxide complexes because of the biological (4) and catalytical activity (5–9) of this type of complex, and of the recent progress in the design of new drugs, such as those containing nitroimidazole, employed in radiosensitizing measurements (10). In the course of our studies on the reaction of *cis*-[$RuCl_2(dmso)_4$] with L = N-heterocyclic ligands (11, 12) we have observed a general tendency of forming a mixture of two geometrical isomers of [$RuCl_2(S\text{-}dmso)_2L_2$]. Such isomers can be detected by HPLC and characterized based on their contrasting electronic spectra and cyclic voltammograms. However, the isolation of the pure species and the determination of their chemical properties have never been reported before. Recently, we succeeded in isolating the geometrical isomers of the [$RuCl_2(S\text{-}dmso)_2(tbpy)_2$] complex, where tbpy = 4-*tert*-butylpyridine, and here we report a comparative study on their properties, including the elucidation of the Ru–dmso linkage isomerization reactions in solution.

Experimental section

The starting complex, *cis*-[$RuCl_2(dmso)_4$] was prepared according to the method previously reported in the literature (13). The *cis,cis,cis*-[$RuCl_2(dmso)_2(tbpy)_2$] complex, (isomer B) was prepared by reacting 1.6 mL (10.8 mmol) of 4-*tert*- butylpyridine with 1.0 g (2.0 mmol) of *cis*-[$RuCl_2(dmso)_4$] dissolved in 125 mL of chloroform, and refluxing the mixture for 4 h under an argon atmosphere. The resulting orange solution was evaporated to 3 mL, at room temperature, and diethyl ether (20 mL) was added. After 4 days in the freezer (−15°C), a yellow solid precipitated. The solid was collected on a filter, washed with diethyl ether, and dried under vacuum. Anal. calcd. for $C_{22}H_{38}O_2N_2S_2Cl_2Ru$: C 44.14, H 6.34, N 4.68; found: C 44.4, H 6.4, N 4.5. Infrared spectrum: 3040 w, 3020 w, 2950 s, 2920 sh, 2900 sh, 2860 m (ν CH_3 tbpy, dmso); 1610 s, 1530 w, 1500 s, 1470 sh, 1455 w (ν ring tbpy), 1435 sh, 1420 s, 1400 sh (δ CH_3 dmso, tbpy); 1365 m (ν ring tbpy); 1310 m, 1300 w, 1285 sh, 1270 m (δ CH dmso, tbpy); 1230 m, 1195 w, 1125 w (β CH tbpy); 1095 s, 1075 s (ν SO dmso), 1065 m (β CH tbpy); 1010 vs (ring breath, tbpy); 960 m, 925 m, 910 m (ρ CH_3 dmso); 840 sh, 830 s (γ CH tbpy); 720 m, 670 s (ν CSC dmso); 570 m, 545 sh (β ring); 380 w (δ dmso); 440 m, 420 m (ν RuS); 375 m, 345 w (ν RuN); 295 w, 240 m (ν RuCl); w = weak, vw = very weak, m = medium, s = strong, sh = shoulder. The *cis,cis,trans*-[$RuCl_2(dmso)_2(tbpy)_2$] complex (isomer A) was isolated from the filtrate of the *cis,cis,cis* isomer, which was kept in the freezer (−15°C) for two months. The yellow–orange solid was collected on a filter, washed with diethyl ether, and dried under vacuum. Anal. found: C 44.1, H 6.2, N 4.5. Infrared spectrum: 3060 w, 3030 w, 2950 s, 2920 sh, 2860 m (ν CH_3 tbpy, dmso); 1610 s, 1535 w, 1495 s, 1475 sh, 1470 w (ν ring tbpy); 1435 sh, 1415 s, 1390 sh (δ CH_3); 1365 m (ν ring tbpy); 1310 m, 1295 w, 1275 sh, 1265 m (δ CH_3 dmso, tbpy); 1220 m, 1195 w (β CH tbpy); 1080 vs (ν SO dmso); 1010 vs, 1000 s (ring breath, tbpy); 958 m, 930 m, 910 m (ρ CH_3 dmso); 830 s, 825 sh (γ CH tbpy); 710 sh, 705 m (ν CSC dmso); 570 m, 540 vw (β ring); 385 w (δ dmso); 430 sh, 420 s (ν RuS); 345 m (ν RuN); 295 w, 230 m (ν RuCl); Unfortunately, up to the present time, we have not obtained suitable crystals for X-ray studies.

The electronic spectra were recorded on a Hewlett-Packard model 8452-A diode-array spectrophotometer. High-performance liquid chromatography, infrared spectra, and cyclic voltammetry measurements were carried out as previously reported (11). ^1H NMR spectra (in $CDCl_3$ versus TMS) were recorded on a Brucker AC 200 FT spectrometer.

Results and discussion

Spectroscopic and analytical characterization

The [$RuCl_2(dmso)_2(tbpy)_2$] isomers exhibit quite different retention times in HPLC, e.g. 1650 s (isomer A) and 1135 s (isomer B), for an isocratic elution with a 60:40 methanol–water mixture. Under the conditions of this work, the retention times for *cis*-[$RuCl_2(dmso)_4$], dmso, and tbpy, were 135, 146, and 753 s, respectively. Therefore, the purity of the samples can be readily confirmed by means of HPLC, from the observation of a single peak in the chromatograms.

For personal use only.

The isomers also exhibit contrasting ^1H NMR spectra. In the case of isomer A, a single resonance signal is observed for the $(CH_3)_2SO$ ligands at 3.257 ppm, and a single set of signals for the tbpy ligands at 8.970, 8.940 (*ortho*-H); 7.224, 7.190 (*meta*-H) and 1.264 ppm (CH_3). This result indicates that the two dmso and the two tbpy ligands occupy equivalent positions in the complex. In the case of isomer B, the resonance signals for the $(CH_3)_2SO$ ligands split into two doublets, at 3.695, 3.400 and 2.820, 2.694 ppm, indicating that the dmso ligands are non-equivalent, and exhibit little rotational freedom. For the coordinated tbpy ligands there are two peaks at 1.325 and 1.287 ppm (CH_3), a broad doublet at 8.763, 8.674 ppm (*ortho*-H) and two doublets at 7.335, 7.303, and 7.188, 7.156 ppm (*meta*-H), indicating two non-equivalent sites in the complex. In both cases, the relative intensities for the methyl protons of tbpy, dmso, and aromatic protons were consistent with the expected values, e.g. 4.5, 3.0, and 2.0, respectively.

Five geometrical isomers are theoretically possible for a pseudo-octahedral complex of the type $RuCl_2S_2N_2$. These isomers can be denoted, based on the corresponding sequence of ligands, as *cis,cis,cis* (*ccc*); *cis,cis,trans* (*cct*); *cis,trans,cis* (*ctc*); *trans,cis,cis* (*tcc*) and *trans,trans,trans* (*ttt*), respectively. The only species exhibiting two non-equivalent dmso and tbpy ligands in the coordination shell is the *ccc* isomer of C_1 symmetry, corresponding to the complex B. The results from the NMR spectra in this case are conclusive. The remaining isomers exhibit twofold rotational axis, and would lead to a single set of resonance signals for the dmso and tbpy ligands. The identification of isomer A, based exclusively on the NMR spectra, is not possible.

According to the literature (1), isomers containing *trans*-chloride ligands are less stable thermodynamically with respect to the *cis*-analogues, and their synthesis are usually carried out starting from the *trans*-$[RuCl_2(dmso)_4]$ complex, rather than from *cis*-$[RuCl_2(dmso)_4]$. Therefore, by ruling out the *tcc* and *ttt* configurations, one has to decide between *cct* and *ctc* configurations for isomer A. In this sense, it should be noted that a *trans*-cooperative interaction is favored when a π-donor ligand, such as Cl^-, is *trans* to a π-acceptor ligand, e.g. dmso, as in the case of the *cct* configuration. In the *ctc* case, the *trans*-dmso ligands would compete for the d_π electrons of ruthenium(II), leading to a less favorable configuration. According to the *trans*-competitive and *trans*-cooperative effects, the *cct* configuration for isomer A would be the most probable.

The infrared spectra for isomers A and B are complicated by the strong overlap of vibrational peaks of the dmso and tbpy ligands. A tentative assignment was carried out by comparison with the vibrational spectra of the free ligands, and of related complexes from the literature (10, 13–15). In general, the vibrational frequencies associated with the dmso and tbpy ligands are rather similar for both isomers; the main differences (Fig. 1) are in the ν-SO region (1100–1050 cm^{-1}) and in the region of the metal–ligand vibrations (430–350 cm^{-1}), which are more sensitive to the geometry of the complexes. Isomer B exhibits well resolved ν-SO peaks at 1095 and 1075 cm^{-1}, consistent with the presence of two non-equivalent dmso ligands, as expected for a *ccc* configuration. In contrast, isomer A exhibits a broad peak at 1080 cm^{-1}. Both isomers exhibit a composite peak in the region of 440–420 cm^{-1} ascribed to the ν-RuS vibrations. Isomer B exhibits two ν-RuN peaks at 375 and 345 cm^{-1}, in agreement with a *ccc* configuration, while isomer A exhibits only a single peak at 345 cm^{-1}, consistent with a *trans* configuration for the tbpy ligands. Therefore, according to the vibrational data, a *cct* configuration can be ascribed to isomer A.

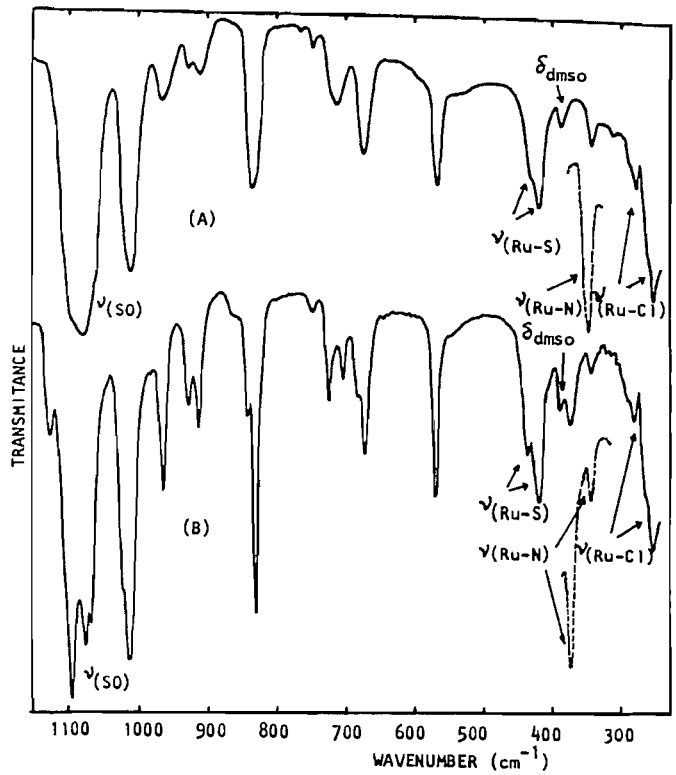

FIG. 1. Infrared spectra of (*A*) *cct*-$[RuCl_2(dmso)_2(tbpy)_2]$, and (*B*) of the *ccc* isomer, in KBr pellets (--- expanded scale).

The electronic spectra of the two isomers can be seen in Fig. 2. The absorption profiles for the two isomers are rather contrasting and can be deconvoluted into three Gaussian bands, located at 275, 315, and 366 nm for isomer B, and at 268, 316, and 430 nm for isomer A. Isomer B exhibits an additional shoulder at 240 nm, which is not resolved in the case of isomer A, ascribed to an internal π–π^* transition in the tbpy ligands. The visible–uv bands are relatively strong and consistent with ruthenium(II)-to-tbpy d_π–p_π^* charge transfer transitions, as in related systems reported in the literature (11, 16, 17). For isomer A, the occupied metal d_π orbitals transform according to the symmetry representations a_1, a_2, and b_1. The lowest unoccupied π^* orbitals of the tbpy ligands in *trans* configuration transform as a_1 and b_1. Based on symmetry and orbital overlap considerations (17), the strong bands at 268 and 316 nm can be ascribed to the $a_1(d_\pi) \rightarrow a_1$(tbpy) and $b_1(d_\pi) \rightarrow b_1$(tbpy) charge-transfer transitions. The third band at 430 nm is less intense and may be ascribed to a ligand field transition or to the $a_2(d_\pi) \rightarrow b_1$(tbpy) charge-transfer transition which is symmetry allowed, but involves weakly interacting orbitals. Isomer B has global C_1 symmetry; however, for comparison purposes, if one assumes a local C_{2v} symmetry for the two tbpy ligands in *cis* configuration, the lowest unoccupied π^* orbitals would transform according to a_2 and b_1. Analogously, the intense charge-transfer bands at 275 and 315 nm could be ascribed to the $a_2(d_\pi) \rightarrow a_2$(tbpy) and $b_1(d_\pi) \rightarrow b_1$(tbpy) transitions, while the weak band at 366 may be due to a ligand field transition

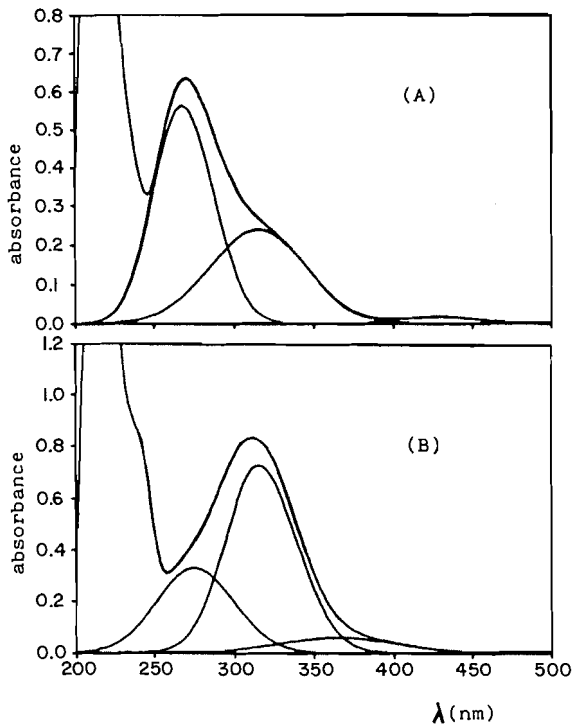

FIG. 2. Absorption spectra of (*A*) *cct*-$[RuCl_2(dmso)_2(tbpy)_2]$ (0.15 mmol dm^{-3}) and (*B*) of the *ccc* isomer (0.12 mmol dm^{-3}), in ethanol.

or to the $a_1(d_\pi) \rightarrow b_1(tbpy)$ transition, which is symmetry allowed, but involves weakly interacting orbitals.

Electrochemistry and linkage isomerization reactions

Typical cyclic voltammograms for isomers A and B can be seen in Fig. 3. Isomer A exhibits a normal voltammogram, consistent with a reversible monoelectronic process involving the $Ru^{III/II}$ redox couple, at $E_{1/2}$ = 1.12 V versus SHE. In contrast, the voltammograms of isomer B are much more interesting. By starting at 0.2 V, and scanning in the anodic direction, a single peak (ia_1) associated with the $Ru^{III/II}$ redox couple can be observed at $E_{1/2}$ = 1.27 V. In the reverse scan, the corresponding cathodic peak current (ic_1) becomes less intense, and a new peak (ic_2) grows up at $E_{1/2}$ = 0.55 V. This effect becomes very pronounced by starting at 1.8 V, as one can see in Fig. 3*C*. The ratios $[ic_1]/[ia_1]$ and $[ic_2]/[ia_2]$ are strongly dependent on the scan rates, and are consistent with the involvement of chemical reactions coupled to the electrochemical process.

The origin of ia_2 and ic_2 peaks might be due to a ligand dissociation or to an isomerization reaction. In the first case, the reaction would be repressed by an excess of the ligand, and the properties of the substituted product would depend on the nature of the solvent molecules. In the second case, the reaction would proceed independently of the presence of the ligands in solution, as in the case of a unimolecular process.

In order to test the hypothesis, the cyclic voltammograms were repeated in pure dmso solutions. The results were quite similar to those obtained in acetonitrile solutions, indicating the occurrence of a unimolecular reaction coupled to the electrochemical process.

The dramatic change of $E_{1/2}$ from 1.27 to 0.55 V associated with the chemical reaction is analogous to those previously reported (18) for the S- and O-bound linkage isomers of the $[Ru(NH_3)_5dmso]^{3/2+}$ complex. By analogy to the literature (18, 19), the pair of anodic and cathodic peaks at 0.55 V are ascribed to the O-bound isomer in the *ccc*-$[RuCl_2(dmso)_2(tpby)_2]$ complex, e.g.:

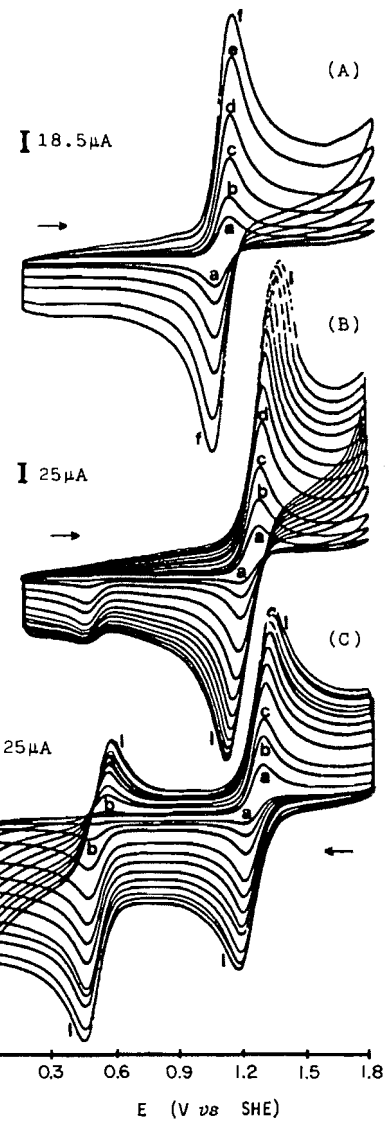

FIG. 3. Cyclic voltammograms of (*A*) *cct*-$[RuCl_2(dmso)_2(tbpy)_2]$ (1 mmol dm^{-3}) at (*a*) 10, (*b*) 20, (*c*) 50, (*d*) 100, (*e*) 200, (*f*) 300 mV s^{-1}, and of the *ccc* isomer, starting at (*B*) 0.2 V and (*C*) 1.8 V, at (*a*) 20, (*b*) 50, (*c*) 100, (*d*) 200, (*e*) 300, (*f*) 400, (*g*) 500, (*h*) 600, (*i*) 700, (*j*) 800, (*k*) 900, and (*l*) 1000 mV s^{-1} (acetonitrile, 25°C, [TEAP] = 0.10 mol dm^{-3}).

$$Ru^{III}—O \underset{k^{III}_{S\rightarrow O}}{\overset{k^{III}_{O\rightarrow S}}{\rightleftharpoons}} Ru^{III}—S$$

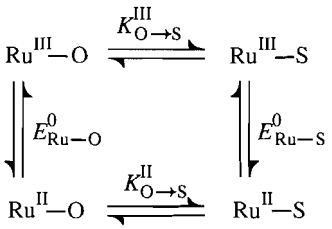
The equilibrium constant for the Ru^{III}—O/Ru^{III}—S reaction can be estimated from the cyclic voltammograms (Fig. 3*C*) starting at 1.8 V, after a few minutes, in order to ensure complete equilibration of the system. In the absence of kinetic effects, i.e. if the isomerization rates were much slower than the scan rates, the ratio $[ic_1]/[ic_2]$ would correspond to K^{III} = $[Ru^{III}—S]/[Ru^{III}—O]$, considering that the diffusion coefficients for the two isomers are practically the same. Unfortunately, because of the kinetic effects, this is only approximate, and K^{III} is better obtained from the plot of $[ic_1]/[ic_2]$ as a func-

tion of the inverse of the scan rates, v^{-1}, and extrapolating to $v \rightarrow \infty$. In this way, $K^{III}_{O\rightarrow S} = 0.63 \pm 0.04$.

The kinetic constants for the isomerization process were estimated from the working curves proposed by Shain and Nicholson (20), for a reversible chemical reaction preceding an electrochemical step (case III). The ratios i_k/i_d employed in this method, where i_k is the measured peak current and i_d is the corresponding diffusional current in the absence of chemical reactions, were obtained from $[ic_1] = i_k$, starting at 1.8 V, and from $[ia_1] = i_d$, starting at 0.2 V. The kinetic constants obtained in this way were:

$$k^{III}_{O\rightarrow S} = 1.2 \pm 0.3\ s^{-1} \text{ and } k^{III}_{S\rightarrow O} = 1.9 \pm 0.3\ s^{-1}$$

Based on the equilibrium constant $K^{III}_{O\rightarrow S}$ and on the electrochemical data, assuming $E^0 = E_{1/2}$, the following thermodynamic cycle can be solved in order to obtain $K^{II}_{O\rightarrow S}$,



In this way, $K^{II}_{O\rightarrow S} = 2.1 \times 10^{12}$, indicating that Ru^{II} has a very strong preference for the S donor atom in dmso.

The evaluation of the kinetic constants for the isomerization reaction in the Ru^{II} complex depends on the detection of the unstable Ru^{II}—O species before it converts to the Ru^{II}—S form. A simple way of generating the Ru^{II}—O isomer is to start from the Ru^{III}—O and Ru^{III}—S species, in equilibrium, e.g., at 1.8 V, and applying a fast potential scanning in the cathodic direction. The Ru^{II}—O species generated in this way can be detected in the reverse scan as a function of time, from ia_2 measured at the several scan rates, or indirectly, from the changes in the anodic peak currents, ia_1, corresponding to the Ru^{II}—S isomer. The dependence of ln $(ia_1/v^{1/2})$ or ln $(ia_2/v^{1/2})$ against time was linear, yielding a rate constant $k^{II}_{O\rightarrow S} = 1.0 \times 10^{-2}\ s^{-1}$. The reverse rate constant can be calculated as $k^{II}_{S\rightarrow O} = k^{II}_{O\rightarrow S}/K^{II}_{O\rightarrow S} = 5 \times 10^{-14}\ s^{-1}$.

According to these results, the *cct* isomer exhibiting two *trans*-Cl—Ru^{III}—SO bonds does not undergo linkage isomerization reactions, presumably because of the *trans*-cooperative interactions. In contrast, the *ccc* isomer isomerizes very rapidly to the O-bound form when it is oxidized to Ru^{III}. The main difference between these two isomers is the occurrence of a dmso ligand *trans* to a tbpy ligand. In the oxidized state, this combination seems to destabilize the complex, since the S-bound dmso is a strong π-acceptor ligand, in contrast to the O-bound species, and the tbpy ligand is not a strong enough π donor to interact in a cooperative way with the dmso ligand.

ERWIN BUNCEL, RICHARD M. TARKKA, and JULIAN M. DUST. Can. J. Chem. **72**, 1709 (1994).

Heats of formation (ΔH_f) for a series of aromatics that are progressively more electron deficient (benzene, **6**; nitrobenzene, **7**; 4-fluoronitrobenzene, **8**; 1,3-dinitrobenzene, **9**; 2,4,6-trinitroanisole, **2**; and 1,3,5-trinitrobenzene, **1**) were determined by semi-empirical AM1 calculations. As a probe of the factors that govern the regioselectivity exhibited in the formation of anionic σ-adducts (Meisenheimer complexes), experimental gas-phase ΔH_f values for the prototypical oxygen and carbon nucleophiles (hydroxide, methoxide, and methide anions) were used in a thermochemical calculation along with the calculated ΔH_f of the electrophiles and the adducts to determine the heats of complexation (ΔH_c). The present results show that for the series of nitroaryl electrophiles, **7**, **9**, and **1**, hydroxide and methide anions *exhibit the same regioselectivity based on thermodynamics of Meisenheimer complex formation.* Specifically, Meisenheimer complexes derived from attack at a position *para* to at least one nitro group (designated MC-4) are formed with the greatest exothermicity (ΔH_c). Exothermicity of complexation increases for both hydroxide and methide adduct formation as the number of nitro groups in the electrophile is increased, from **7** to **9** and to **1**, but formation of the methide adducts occurs uniformly with greater exothermicity than that of hydroxide adducts. These results are considered in light of solution calorimetric data that quantify adduct stability in condensed phases. Surprisingly, it is found that *regioselectivity inverts for CH_3^- as compared to OH^- and CH_3O^- in complexation with 2,4,6-trinitroanisole, 2.* Thus, while methoxide and hydroxide form adducts at C-1 of TNA with higher exothermicity than at C-3, methide preferentially forms an adduct at C-3 according to the same enthalpy criterion. These results arise from the degree of stereoelectronic stabilization that may be imparted to the respective Meisenheimer complexes formed from *ipso* attack, that is, the adducts (MC-1) that are geminally disubstituted with electronegative heteroatom groups. For the methoxide MC-1 of TNA, **2**, full stereoelectronic stabilization is provided by n–σ* donation from nonbonding electron pairs of the acetal-like methoxyl moieties to suitable C—O acceptor bonds. However, the methide moiety of the comparable MC-1 of TNA cannot partake in such an interaction and, so, with methide, MC-3 formation is preferred over MC-1. Further evidence is provided by consideration of the two energy minima obtained from optimization of the geometry of the oxygen-centred adducts formed by attack of methoxide at C-1 of TNA, **2**. In the presence of a point charge that simulates an ion-paired cation, an "M-shaped" conformer is favoured for MC-1, while in the absence of a counterion the "S-shaped" conformer is favoured. Without a complexing counterion M and S conformers are both local minima, while the "S" conformer constitutes the global minimum. The AM1 optimized structure for the "M" conformer compares favourably to published X-ray data. The greater exothermicity of formation of the "S" conformer in the absence of the counterion is indicative of stereoelectronic stabilization of the O-adduct. The geometry is rationalized as a result of minimizing steric repulsion and maximizing the n–σ* stabilization of the C-1 adduct.

ERWIN BUNCEL, RICHARD M. TARKKA et JULIAN M. DUST. Can. J. Chem. **72**, 1709 (1994).

Utilisant des calculs semi-empiriques AM1, on a déterminé les chaleurs de formation (ΔH_f) d'une série de composés aromatiques de plus en plus électrodéficients (benzène, **6**; nitrobenzène, **7**; 4-fluoronitrobenzène, **8**; 1,3-dinitrobenzène, **9**; 2,4,6-trinitroanisole, **2**; et 1,3,5-trinitrobenzène, **1**). Comme sonde des facteurs qui gouvernent la régiosélectivité exhibée lors de la formation d'adduits-σ anioniques (complexes de Meisenheimer), on a utilisé les valeurs de ΔH_f expérimentales de la phase gazeuse de nucléophiles oxygénés et carbonés typiques (anions hydroxyde, méthylate et méthylure) de concert avec les valeurs calculées des ΔH_f électrophiles et des adduits dans un calcul thermochimique effectué en vue de déterminer les chaleurs de complexation (ΔH_c). Les résultats obtenus démontrent que pour la série des nucléophiles nitroaryles **7**, **9** et **11**, les anions hydroxyde et méthylure *présentent la même régiosélectivité, si on se base sur la thermodynamique de la formation des complexes de Meisenheimer.* D'une façon spécifique, les complexes de Meisenheimer obtenus par une attaque en position *para* par rapport à au moins un groupe nitro (appelé MC-4) se forment avec la plus grande exothermicité (ΔH_c). Avec l'augmentation du nombre de groupes nitro, en passant du composé **7** à **9** et à **1**, l'exothermicité de la complexation augmente pour la formation de l'adduit hydroxyde ainsi que méthylure; toutefois, la formation des adduits méthylures se fait toujours avec une plus grande exothermicité que pour les adduits hydroxyde. On considère ces résultats à la lumière de données calorimétriques qui quantifient la stabilité des adduits en phase condensée. D'une façon surprenante, on a trouvé que *pour la complexation avec le 2,4,6-trinitroanisole, 2, la régiosélectivité s'inverse pour le CH_3^- par rapport avec le OH^- et le CH_3O^-.* Alors que les anions méthylate et hydroxyde forment des adduits en C-1 du TNA avec une plus grande exothermicité qu'en C-3, le méthylure formerait donc, suivant les mêmes critères, préférentiellement un adduit en C-3. Ces résultats découlent du degré de stabilisation stéréoélectronique qui peut être transmis aux complexes de Meisenheimer respectifs par une attaque *ipso*, c'est-à-dire aux adduits (MC-1) qui sont disubstitués d'une façon géminée avec des groupes hétéroatomiques négatifs. Pour le MC-1 du méthanolate du TNA, **2**, toute la stabilisation stéréoélectronique est fournie par un don n–σ* des paires d'électrons non liés d'un méthoxyle ressemblant à un acétal à des liai-

sons C—O appropriées agissant comme accepteur. Toutefois, la portion méthylure du MC-1 comparable du TNA ne peut pas prendre part à une telle interaction et avec le méthylure la formation d'un MC-3 est préférée à celle d'un MC-1. D'autres données sont obtenues par la considération des deux minima d'énergie obtenues par optimisation de la géométrie des adduits centrés sur l'oxygène et formées par l'attaque du méthylate en C-1 du TNA, **2**. En présence d'une charge ponctuelle qui simule un cation apparié, un conformère en «forme de M» est favorisé pour le MC-1 alors que, en l'absence d'un contre-ion, le conformère «en forme de S» est favorisé. En l'absence d'un contre-ion agissant comme complexant, les conformères M et S sont tous les deux des minima locaux alors que le conformère S est le minimum global. La structure optimisée par AM1 du conformère M se compare favorablement avec les données de diffraction des rayons x qui ont été publiées. L'exothermicité plus élevée observé pour la formation du conformère S en l'absence de contre-ion indique la présence d'une stabilisation stéréoélectronique de l'adduit-O. On rationalise la géométrie sur la base d'une minimisation de la répulsion stérique et une maximisation de la stabilisation n–σ^* avec l'adduit C-1.

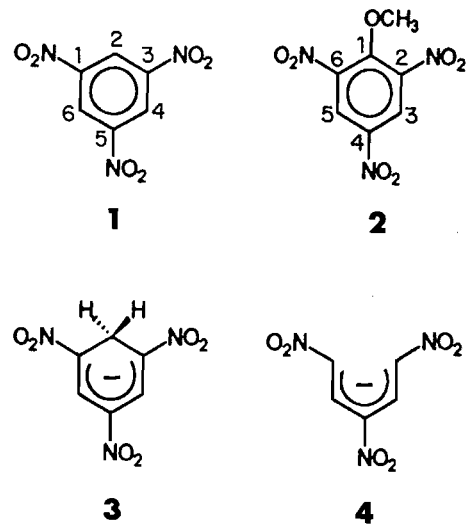
[Traduit par la rédaction]

Introduction

Anionic σ-adducts, also termed Meisenheimer (1) or Jackson–Meisenheimer complexes (2), arise from σ-bond formation between nucleophiles ($Nu:^-$) and electron-deficient aromatic or heteroaromatic substrates, typified by 1-X-2,4,6-trinitrobenzene electrophiles (3). The interaction may be represented generally by Scheme 1. When X is a ring proton, the electrophile E is TNB (**1**) and a single adduct is formed by reaction at an unsubstituted site (solid boxed portion of Scheme 1); when X represents a substituent other than H, isomeric Meisenheimer complexes (i.e., MC-1 and MC-3) result from nucleophilic attack at C-1 and C-3 sites, respectively. Attack at C-1 of a substrate that bears a good leaving group leads to formation of a metastable MC-1 that decomposes to give a new 1-Nu-2,4,6-trinitrobenzene derivative. Thus, the pathway defined by attack at C-1 and expulsion of X^- represents the S_NAr mechanism of nucleophilic aromatic substitution (4) (dashed portion of Scheme 1), where k_1 (the rate coefficient for C-1 attack) is usually rate determining. However, if X is a relatively poor nucleofuge such as methoxy (E = 2,4,6-trinitroanisole, TNA, **2**), then both MC-1 and MC-3 may be observable, depending upon solvent and temperature (5, 6).

The kinetic preference (k_1 vs. k_3) shown by nucleophiles in such reactions with **2**, as well as the thermodynamic stability of the adducts ($K_1 = k_1/k_{-1}$ vs. $K_3 = k_3/k_{-3}$), yield patterns of regioselectivity that have constituted an important area of recent inquiry (7, 8). In the course of these investigations we have classified the various types of potential regioselectivity[3] in MC formation for 1-X-2,4,6-trinitrobenzenes (7), ranging from thermodynamic and kinetic preference for formation of MC-1 (termed K1T1, and exemplified by the reaction of TNA with phenoxide as an O-nucleophile) (*7a*), among other systems (9, 10), to the more commonly reported kinetic preference for MC-3 formation, coupled with formation of MC-1 as the product of thermodynamic control, i.e., K3T1 as illustrated by the TNA-alkoxide systems (5, 11). Most recently we have detailed K1T3 regioselectivity in the TNA – mesitoxide system (*7b*), the exact inverse of K3T1 behaviour (7). These patterns of reactivity are shown in Fig. 1 as qualitative energy profiles.

We have been especially interested in the formation of Meisenheimer complexes by electron-deficient substrates, such as **1** and **2**, with ambident nucleophiles, including phenoxide ion as a carbon- and oxygen-nucleophile (7, 11), aniline as a carbon- and nitrogen-nucleophile (12), and dopamine (3,4-dihydroxyphenylethylamine) as a carbon-, nitrogen-, and oxygen-nucleophile (13). Our recent finding that phenoxide, as an O-nucleophile, displays the K1T1 pattern of behaviour in its reaction with **2**, in contrast to the K3T1 behaviour exhibited by methoxide, has led us to scrutinize the connection between the type of nucleophile and the type of behaviour displayed. The present theoretical study thus probes the intrinsic reactivity of carbon- vs. oxygen-centred nucleophiles in Meisenheimer complex formation, as well as those features of the substrates and nucleophiles that govern the regioselectivity found in condensed phase studies of these systems.



1 **2** **3** **4**

The historical development of theoretical calculations on Meisenheimer complexes (MCs), and their generally nitro-substituted parent compounds, parallels the development of computational chemistry. Early calculations were of the Hückel molecular orbital (HMO) type (14–16) or used the Pariser–Parr–Pople (PPP) self-consistent field (SCF) method to obtain information such as π-electron distribution in the MC, substituent effects, and electronic transition energies. Generally, these studies were limited to the anionic adduct that would arise from addition of hydride ion to TNB (**3**) or to model compounds such as the pentadienyl system, substituted with one or more electron-withdrawing groups (e.g., **4**).

More recently, theoretical studies have fallen into two broad categories: (*a*) ab initio calculations on MC models and (*b*) semi-empirical calculations on the Meisenheimer complexes themselves. For example, ab initio calculations at the STO-3G level have been run to delve into the question of structure of cyclohexadienate anions: planar or fully delocalized in a homocyclopentadienyl structure (17, 18). The semi-empirical stream has concentrated on the determination of fully optimized structures and physical properties (e.g., charge distribution) for

[3]Our previous terminology for K1T1 (Kinetic preference for C-1 attack, coupled with Thermodynamic preference for C-1 attack) was KC-1,1, indicating Kinetic Control favouring MC-1 formation (7). K1T1 now replaces KC-1,1 and similarly KC-1,3 is now designated as K3T3, TC-1,1 as K3T1, and TC-1,3 as K1T3. We thank Prof. J.F. Bunnett for suggesting this alternative classification.

X = H, E = **1** = TNB; MC-1 = MC-3
X = OCH_3, E = **2** = TNA

SCHEME 1

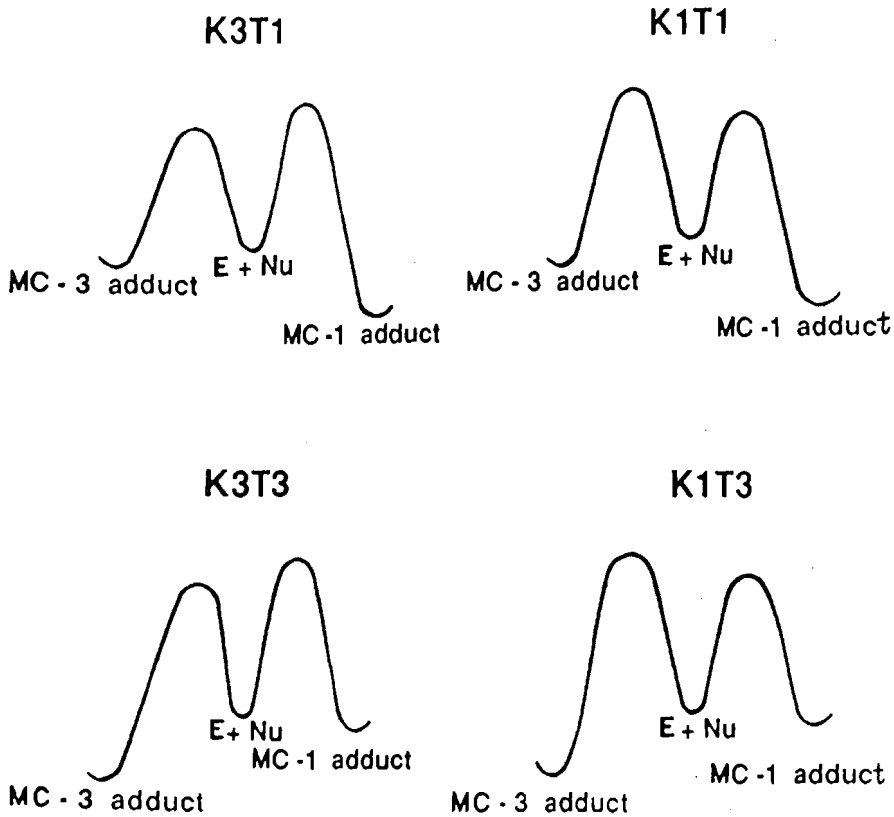

FIG. 1. Qualitative free energy profiles detailing the different patterns of regioselectivity: K3T1 represents the case where the MC-3 adduct is favoured kinetically, but the MC-1 adduct is the product of thermodynamic control; K1T1 describes kinetic and thermodynamic preference for the MC-1 adduct; K3T3 describes kinetic and thermodynamic preference for the MC-3 adduct; and K1T3 represents the case where the MC-1 adduct is favoured kinetically, but the MC-3 adduct is the product of thermodynamic control. The different classes of regioselectivity (K3T1, etc.) are discussed in the text. Energetics are exaggerated for clarity.

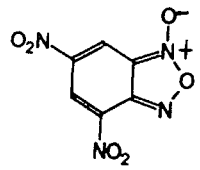
actual MCs. Our MNDO exploration of the structures, charge densities, and heats of formation of the hydroxide MCs formed from **1** and from the super-electrophile, 4,6-dinitrobenzofuroxan, **5**, is an example of this type of theoretical study (19).



5

In comparing the two categories of calculations, it is generally found that ab initio calculations, performed with relatively sophisticated basis sets, yield better estimates of the values for physical properties than do semi-empirical methods. However, the requirement of relatively large basis sets (e.g., 6-31+G*) limits the systems suitable for study by high-level ab initio methods to relatively small molecules. As a result, semi-empirical methods are the methods of choice for investigating large MCs (20).

At the same time as the advent of high-speed computers has made larger molecules amenable to ab initio calculations, semi-empirical calculations have also improved. These SCF calculations, most commonly Dewar's MINDO/3 (21), MNDO (22), and AM1 (23) methods, are parameterized to experimental data and empirically adjusted for average correlation and thermal energies. AM1 represents an advance over the MNDO method in that the tendency of MNDO to overestimate core–core repulsions has been corrected by adjustment of the core repulsion function. This correction alleviates the MNDO weaknesses: failure to reproduce hydrogen bonds, overestimation of activation enthalpies, and incorrect formation enthalpies for crowded and strained molecules (23). As such, the calculations presented here represent a refinement over earlier calculation results performed at the MNDO and MINDO/3 levels.

To assess trends in MC stability as a function of both nucleophile and electrophile type, and of the site of addition to the electrophile, we have calculated the heats of formation of a variety of OH^-, CH_3O^-, and CH_3^- adducts formed with a wide range of nitroaromatics. The results, including fully optimized structures and comparative heats of formation, will be discussed in light of known X-ray structures of MCs and the condensed phase reactions of **1** and **2** with nucleophiles. The importance of stereoelectronic effects on the stability of MCs will emerge from the discussion.

Experimental

Method

All calculations were carried out using an IBM 3081 computer. The AMPAC version 2.10 of AM1 (23) was the program used for all calculations reported herein. All structures were fully optimized using a Fletcher–Powell minimization (24) to a self-consistent field (SCF) that satisfied Herbert's test and were characterized as local minima; no negative force constants were obtained after running the "FORCE" option. The restricted Hartree–Fock (RHF, closed shell) scheme was used throughout. All optimizations were carried out using the "PRECISE" option.

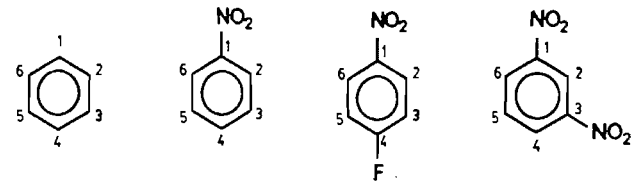
Input geometries

The input geometry for a given neutral nitroaromatic was constructed from the AM1 optimized geometry of a less highly substituted aromatic. For example, the AM1 optimized geometry for nitrobenzene (NB, **7**), which has been reported (20*a*), was used as the template for construction of the input geometry of 4-fluoronitrobenzene (4-FNB, **8**). Slightly perturbed geometries, obtained from initial optimization, were generally used as input for a second run to ensure convergence.

The input geometries of the MCs assumed standard sp^3 hybridization of the carbon at the site of addition, while the other ring carbons and nitro groups were entered as being perfectly coplanar. The O—CH_3 bonds were placed antiperiplanar to the sp^3 C—H (or C—OCH_3) bond, as suggested by X-ray data (25).

Systems studied

Full optimizations and calculations of the energetics were done for all possible regioisomers of the following systems (substrate:nucleophile): TNB:OH^-, TNB:OCH_3^-, TNB:CH_3^-, TNA:OH^-, TNA:OCH_3^-, TNA:CH_3^-, B:OH^-, B:CH_3^-, NB:OH^-, NB:CH_3^-, 4-FNB:OH^-, 4-FNB:CH_3^-, 1,3-DNB:OH^-, and 1,3-DNB:CH_3^-, where TNB, TNA, B,



6 **7** **8** **9**

NB, 4-FNB, and 1,3-DNB refer to 1,3,5-trinitrobenzene, 2,4,6-trinitroanisole, benzene, nitrobenzene, 4-fluoronitrobenzene, and 1,3-dinitrobenzene, respectively. Summaries of the calculations, including fully optimized geometries, are available as Supplementary Material (Supplementary Figs. 1–37 and Supplementary Tables 1–37).[4] Supplementary Figs. 1–37 show the optimized structures and numbering schemes used in the AM1 calculations and correspond to the relevant Supplementary Table. For example, Fig. 4 illustrates the electrophile, nitrobenzene, while Table 4 contains the calculation results, including ΔH_f, dipole moment, ionization potential, bond lengths, and atomic charges.

Results

The enthalpies of formation of the series of fully optimized neutral nitroaromatics and fully optimized MCs are presented in Tables 1 and 2. Reaction enthalpies (heats of complexation, ΔH_c) were calculated for the following reaction:

[1] $Nu^-: + E \rightarrow MC$

where E represents the aromatic substrate, $Nu^-:$ is OH^-, CH_3^-, or CH_3O^-, and MC identifies the resultant Meisenheimer complex. The standard thermochemical eq. [2] follows from eq. [1]:

[2] $\Delta H_c = \Delta H_f(MC) - [\Delta H_f(E) + \Delta H_f(Nu^-:)]$

where the reaction enthalpy, ΔH_c, refers to eq. [1]. The reaction enthalpies for formation of the various adducts are listed in Table 2.

In determining the reaction enthalpies, experimental values for the gas-phase heats of formation of the nucleophiles were used rather than the values calculated by AM1. It is recognized that the heats of formation of small anions that bear a highly localized charge are not reproduced well by AM1 (20, 23*a*, *b*). Although the AM1 ΔH_f of CH_3O^- agrees well with the experi-

mental value (20), we have chosen to use the experimental gas-phase ΔH_f of the nucleophiles as compiled in a recent critical review (−32.7 kcal/mol for OH^-, +33.2 kcal/mol for CH_3^-, and −33.2 kcal/mol for CH_3O^-) (23*c*) for calculating reaction enthalpies, for the sake of self-consistency.

The MCs are designated according to the site of addition, numbering from the nitro substituent, if present, according to the structures, **1**, **2** and **6**–**9**. Thus, attack of a nucleophile at C-2 would lead to the Meisenheimer complex, MC-2, attack at C-4 would lead to MC-4, and so on. For 2,4,6-trinitroanisole, **2**, MC-1 refers to the product of addition at C-1 while MC-3 represents the product of nucleophilic addition to the C-3 site, as per the numbering of structure **2**.

Hydroxide and methide Meisenheimer complexes (MCs) of benzene, nitrobenzene, 4-fluoronitrobenzene, and 1,3-dinitrobenzene

The heats of formation (ΔH_f) of a series of aromatic compounds, ranging from relatively electron-rich (B, **6**) to successively electron-poor (NB, **7**; 4-FNB, **8**; and 1,3-DNB, **9**) were calculated. These enthalpies of formation are tabulated, along with ΔH_f values for the corresponding regioisomeric OH^- and CH_3^- MCs, in Table 1. All optimized geometries, both for the neutral aromatics and the anionic σ-adducts, were deemed satisfactory; no bond lengths or angles were found to be unusually large or small and these were found to agree reasonably well with published AM1 results in the case of some of the neutrals (20*a*, 23*a*) and with X-ray data in the case of the MCs (16, 25), as discussed below. Importantly, the energetics for the few systems shared with previous AM1 studies were replicated satisfactorily. Thus, the calculated heats of formation for B, **6**; NB, **7**; and 1,3-DNB, **9**, are in accord with those reported by Dewar et al. (23*a*) and Bunton and co-workers (20*a*).

It is noteworthy that although attempts were made to calculate the structures of the hydroxide adducts that would arise from nucleophilic attack of hydroxide on the *ipso* carbon bearing a nitro group for substrates **8** and **9**, no local minima representing these putative adducts could be located on the potential energy surface. Instead, the inputs optimized to the phenols produced by nucleophilic displacement of nitrite from the ring.

Hydroxide, methoxide, and methide adducts of TNB and TNA

Fully optimized AM1 structures for the hydroxide, methoxide, and methide MCs of TNB, **1**, and TNA, **2**, were calculated (cf. Supplementary Figs. and Tables 26–28 for **1** and Supplementary Figs. and Tables 29–37 for **2**). The optimized structures derived from CH_3O^- attack on **1** and for the MC-1 derived from CH_3O^- attack on **2** are in good agreement with published X-ray structures (16, 25) (vide supra).

For the methoxide adduct MC-1 of TNA the calculation provided two local minima, corresponding to the "M-shaped" and "S-shaped" conformations (Supplementary Tables 34 and 35, respectively) shown in Fig. 2. The S conformer is the global minimum.

Discussion

Insightful information can be obtained from semi-empirical calculations for the minimum energy reaction pathways (MERPs) for formation of anionic σ-adducts (25), from the charge densities of the neutral substrates, and the resultant MCs (26), as well as intermediate species that potentially exist on the MERP to MC formation (20). Previous calculations of the

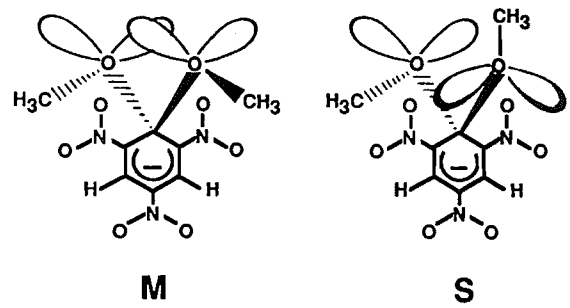

FIG. 2. The conformational minima for the CH_3O^- MC-1 of TNA, **2**. The "S-shaped" conformer, in which one methyl of the CH_3O-C(1)-OCH_3 moiety is pointed "down" and the other "up" and in which the lone pairs of the oxygens are staggered, is favoured by 4.4 kcal/mol over the "M-shaped" conformer, according to the AM1 calculations. In the M conformer both methyl groups point "down". The lone pairs of the oxygen of the "up" methoxyl in the S form can each participate partly in n–σ* stabilization, whereas the lone pairs of the oxygen of the "down" methoxyl cannot. Consequently, stereoelectronic stabilization in the M form is not possible. In this figure, the C(1)—O bond lengths are exaggerated for clarity. Note that in both the M and S forms the CH_3O-C(1)-OCH_3 moiety places the methyls in the same plane.

MERP at the MNDO (27) and AM1 (20) levels have located minima, of varying degrees of shallowness, for charge-transfer complexes and for complexes resulting from single electron transfer (i.e., radical–radical anion pairs). On the other hand, the factors governing the propensity of a given nucleophile and substrate to form one regioisomer over another, as a function of the nature of the substrate and nucleophile, have not hitherto been probed by AM1 on the basis of the energetics of formation of the regioisomeric MCs. The present study concentrates on these energetics; the heats of complexation, ΔH_c (eq. [1]), for various regioisomers were therefore calculated for the reaction of a series of nitroaromatic substrates with OH^-, CH_3O^-, and CH_3^- as nucleophiles.

1. Comparative trends in the reaction enthalpies for formation of Meisenheimer complexes

*(a) Effect of increasing NO_2 substitution (E = **6**, **7**, **9**, **1**)*

For comparable sets of both OH^- and CH_3^- MCs there is a definite increase in the exothermicity of adduct formation as a function of increasing nitro group substitution of the ring (Table 2). The overall order of decreasing exothermicity for formation of OH^- adducts (ΔH_c) when comparing the most stable regioisomer for each substrate–nucleophile pair, is MC-2 of **1** > MC-4 of **9** > MC-4 of **7** > MC-1 of **6**, with numerical differences in ΔH_c of 19.2, 23.2, and 37.3 kcal, respectively. A similar trend was found for the corresponding CH_3^- MCs.

Comparison of solution (CH_3O^-/CH_3OH) calorimetric data (28, 29) with our present calculations reveals a remarkable agreement between the experimental and the calculated energetics. In this regard, Strauss and co-workers (28) found nitro substitution of a cyclohexadienate ring in a position *ortho* to the site of nucleophilic attachment to be worth 9 kcal of stabilization, whereas *para* NO_2 substitution stabilized the Meisenheimer complex by 30 kcal/mol. Fendler et al. (29) later obtained values of 10.3 kcal/mol for *ortho* and 21.0 kcal/mol for *para* substitution, i.e., a ratio of 1:2 for *ortho* as compared to *para* substitution. On this basis one would expect MC-4 of **9** to be formed with an exothermicity of between 12 and 19 kcal/mol relative to MC-4 of **7** (33–50% of 37.3 kcal/mol, the difference

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

in ΔH_c between MC-1 of **6** and MC-4 of **7**). The $\delta\Delta H_c$ value, according to AM1, is 23.2 kcal/mol. Similarly, the second *ortho* NO_2 substitution that occurs on going from MC-4 of **9** to MC-2 of **1** should be worth 12–19 kcal/mol; the calculated difference is 19.2 kcal/mol. Therefore, the *proportionality* of the energetics is maintained in the calculations as in the solution calorimetric work.

Clearly, the trend to more exothermic ΔH_c values with increasing nitro group substitution arises from both the relative destabilization of the parent nitroaromatic and the relative stabilization of the resultant MC (ΔH_f) as seen from Table 1.

*(b) Effect of nucleophile (CH_3^- vs. OH^-) with **1**, **9**, **7**, and **6***

For a given aromatic substrate and a given site of attack the reaction enthalpy favours formation of the MC with CH_3^- compared with OH^-. Benzene, for example, forms MC-1 with CH_3^- with a ΔH_c of −43.0 kcal/mol, while formation of the corresponding OH^- MC has an associated reaction enthalpy of −24.5 kcal/mol. Besides the energetic preference for C-adduct formation over O-adduct formation, there is also a trend to greater MC stability with increased nitro substitution of the ring. It is interesting, then, that the "gap" in exothermicity between CH_3^- and OH^- adducts also increases with monotonic increase in the number of ring NO_2 groups. The differences in heats of complexation between the CH_3^- MC-2 of **1** and the OH^- MC-2 of **1** is 24.9 kcal in favour of the methide adduct. The ΔH_c gap between the OH^- and CH_3^- MC-4 of **9** narrows to 23.5 kcal, and further to 21.4 kcal favouring the C-adduct (MC-4) of **7** over the corresponding O-centred MC.

Significantly, Crampton and co-workers have reported kinetic and thermodynamic parameters for a series of nitro- and cyano-substituted carbanions with TNB, **1**, as well as 2,4,6-trinitrotoluene (30). The experiments clearly show the thermodynamic preference for C-adduct formation over O-adduct formation with TNB, when formation of the methoxide MC-2 of **1** was used as the reference. For example, the ratio of the equilibrium constants ($K(CH(CN)_2^-/K(MeO^-)$) for formation of MC-2 of **1** with malononitrile anion as compared to methoxide is approximately 2; adjustment for differences in Brønsted basicity increases the value of the ratio of the constants to ca. 10^3 (30*a*). Interestingly, when Marcus (31) intrinsic rate constants, k_0 (measured by extrapolation of log k vs. log K plots to $K = 1$) were compared for the nitroalkane anions, cyanoalkyl anions, and methoxide ion, the nitrocarbanions were found to be inherently less reactive in MC formation than the cyanoanions by a factor of 10^5 and less reactive than methoxide by a factor of 10^4 (30*b*). This was attributed to the greater requirement for electronic, structural, and solvent reorganization concomitant with MC formation by the nitroalkyl anions as compared to the cyanocarbanions and methoxide ion. The cyanocarbanions were considered more localized than the nitrocarbanions. Thus, our present AM1 results, which circumvent the need to consider solvent reorganization, are in accord with the observed greater exothermicity of complexation with carbanions as compared to oxyanions.

It is tempting, in light of the clear-cut thermodynamic preference for CH_3^- over OH^- adduct formation, to conclude that in the case of an ambident (C- and O-)nucleophile, C-attack at a given site should be more exothermic than O-attack. However, the differences in ground-state enthalpies between OH^- (ΔH_f = −32.7 kcal/mol) and CH_3^- (ΔH_f = +33.2 kcal/mol) (23*c*) that contribute to the relative exothermicities of adduct formation when these two nucleophiles are compared, are absent when an ambident nucleophile (e.g., phenoxide) is used. Therefore, if ground-state enthalpy differences ($\delta\Delta H_f$) of the nucleophiles are important in determining the thermodynamic stability of the Meisenheimer complexes, conclusions drawn from comparing individual O-nucleophiles and C-nucleophiles may not be valid for ambident O- and C-nucleophiles in Meisenheimer complexation. The relevance of the present findings to such ambident nucleophiles will emerge from the discussion of MC formation that results in geminal disubstitution with electronegative heteroatoms (below). Further, it is important to note that *there is no difference in regioselectivity shown by OH^- as compared to CH_3^- in formation of adducts with **7** and **9** as measured by ΔH_c for the various regioisomeric adducts.* In this regard, the most favoured regioisomeric adducts formed by reaction of OH^- or CH_3^- with either **7** or **9** are the MC-4 adducts that arise from attack at the site *para* to at least one nitro group. The MC-2 complexes of **7** and **9** are formed with the next greatest exothermicity; in these, CH_3^- and OH^- are attached to a site *ortho* to one, or both, NO_2 groups. The least thermodynamically favoured regioisomers are MC-3 of **7** and MC-5 of **9**, both of which are formed by attack of the nucleophiles at a site *meta* to all NO_2 functions.

In summary, in comparing **6**, **7**, **9**, and **1**, a series of progressively more electron-deficient substrates, it is apparent that complexes formed from either OH^- or CH_3^- at the same site of attack are increasingly stabilized by increasing NO_2 group substitution of the electrophile. For this same series of electrophiles, complexes formed by CH_3^- are favoured thermodynamically over those formed by OH^-, although both nucleophiles show the same regioselectivity.

2. Regioselectivity in Meisenheimer complex formation. The role of geminal disubstitution with electronegative heteroatoms

Further understanding accrues from examination of selected pairs of structurally related adducts involving electronegative atoms and hydrogen as substituents (Table 2). The OH^- MC-4 of 4-fluoronitrobenzene, **8**, is formed with an exothermicity of 7 kcal relative to the OH^- MC-4 of nitrobenzene, **7** (i.e., $\delta\Delta H_c$ = −7.0 kcal/mol). Replacement of H by F in the respective MC is thus worth 7 kcal of exothermicity. In fact, comparison of the OH^- MC-1 of **2** with OH^- MC-2 of **1** (Table 2) yields virtually the same enthalpy difference: 6.9 kcal favouring MC-1 of TNA, **2**, over MC-2 of **1**. Therefore, replacement of H by OCH_3 in the comparable MC is also worth 7 kcal. Further, with **8**, OH^- and CH_3O^- both form the most stable adduct at the position bearing F (i.e., *para* to the NO_2 group), whereas CH_3^- forms the most stable adduct *ortho* to the nitro group. These observations emphasize the stabilization that accompanies geminal disubstitution with electronegative heteroatoms.

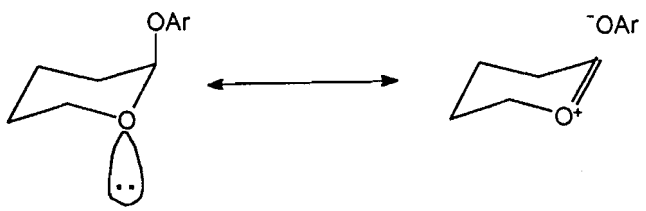
Relief of internal strain has been suggested by us (7, 32) and others (33, 34; see also ref. 10) as a possible origin of the thermodynamic preference of the C-1 site of attack on TNA by nucleophiles. Thus, formation of an adduct by attack at a position substituted by an electronegative group, as in formation of the OH^- and CH_3O^- MC-1 of TNA, **2**, would be thermodynamically favoured since the process would convert a strained sp^2-hybridized carbon center (one bearing a substituent) to a less strained sp^3-hybridized center in the MC. Such strain is suggested, for example, by the X-ray structure of the ethyl ether, 2,4,6-trinitrophenetole, in which the *ortho* nitro groups flanking the ethoxy group are twisted from the plane of the ring by 33° and 62°, respectively, presumably as a result of accommo-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

dating spatially the ethoxy group at C-1 (16). Since TNB, **1**, is not similarly substituted, formation of MC-2 of **1** would not involve such a release of strain and the difference in ΔH_c between MC-1 of **2**, which is substituted at C-1, and MC-2 of **1** could then reflect this stabilization due to relief of strain. On the other hand, the same enthalpy difference ($\delta\Delta H_c$) is exhibited by the CH_3O^- MC-4 pair formed from 4-fluoronitrobenzene (**8**), and nitrobenzene (**7**), even though **8** lacks any buttressing *ortho* nitro groups. It is difficult to see how **8** would be strained relative to **7** and, therefore, the observed $\delta\Delta H_c$ cannot be attributed to relief of strain in this case.

It is interesting that the present study indicates that the CH_3^- MC-1 of TNA (**2**) is slightly less stable than the C-3 adduct, although the OH^- MC-1 of TNA is 4.0 kcal more stable than the comparable C-3 adduct. Again, if relief of internal strain were the source of the regioselectivity shown by CH_3O^- (and OH^-), then the C-1 site should also be the preferred site of attack for CH_3^-. Therefore, even though the argument based on relief of internal strain may indeed be applicable in the comparison of **1** and **2** (and their adducts) it lacks generality as an explanation.

An alternative view to the internal-strain model holds that geminal substitution with two electronegative heteroatom groups is, in itself, stabilizing (35–37). The mechanism of this stabilization may be anionic hyperconjugation (38). However, qualitative molecular orbital theory would impute the stabilization to favourable n–σ^* interaction(s) between the lone pair electrons of one substituent and the antiperiplanar bond of the other substituent. The latter approach treats 1,1-dialkoxy MCs (such as the CH_3O^- MC-1 of **2**) as acetals (39); n–σ^* stabilization in acetals has been invoked to account for the anomeric effect on the preferred conformation of 2-alkoxytetrahydropyrans and related systems (40). In valence bond terms this constitutes a contribution to the resonance hybrid from a no-bond canonical form, as illustrated below for a 2-aryloxytetrahydropyran. The stabilization imparted by this no-bond form accounts for the preference of the aryloxy group for an axial position, as well as for the observed bond lengths, i.e., relatively short cyclic C—O bond. C—CH_3 bonds are relatively poor acceptors due to the high energy level of the fragment σ^* orbital (39); the lack of lone pairs clearly prohibits methide from acting as an "n" donor. Thus, stereoelectronic effects are not expected to stabilize the CH_3^- MC.[5]



Examination of the adduct formation enthalpies for the TNA system, using the same approach, provides even more convincing evidence for the importance of stereoelectronic stabilization. Comparison of the CH_3^- MC-2 of **1** with the analogous MC-1 of **2** shows that formation of the C-1 methide adduct of TNA is actually 1.3 kcal less exothermic relative to MC-2 of TNB. As a result, in these cases, other regioisomeric Meisenheimer complexes become thermodynamically preferred. Consequently, the CH_3^- MC-2 of **8** is formed with an exothermicity of 2.8 kcal over the CH_3^- MC-4 of **8**. Similarly, the CH_3^- MC-3 of **2** has an associated reaction enthalpy that is slightly (0.1 kcal) more exothermic than that for MC-1 formation. *These results contradict the trend outlined above in which the regioselectivity exhibited by electrophiles **7** and **9** is invariant with the identity of the nucleophile.* Clearly, a significant change has followed from introduction of a substituent bound to the aromatic ring through a heteroatom, which leads to a difference in regioselectivity exhibited by the nucleophiles that is not found for substrates of the general formula $C_6H_n(NO_2)_{6-n}$ that do not contain other heteroatom substituents.

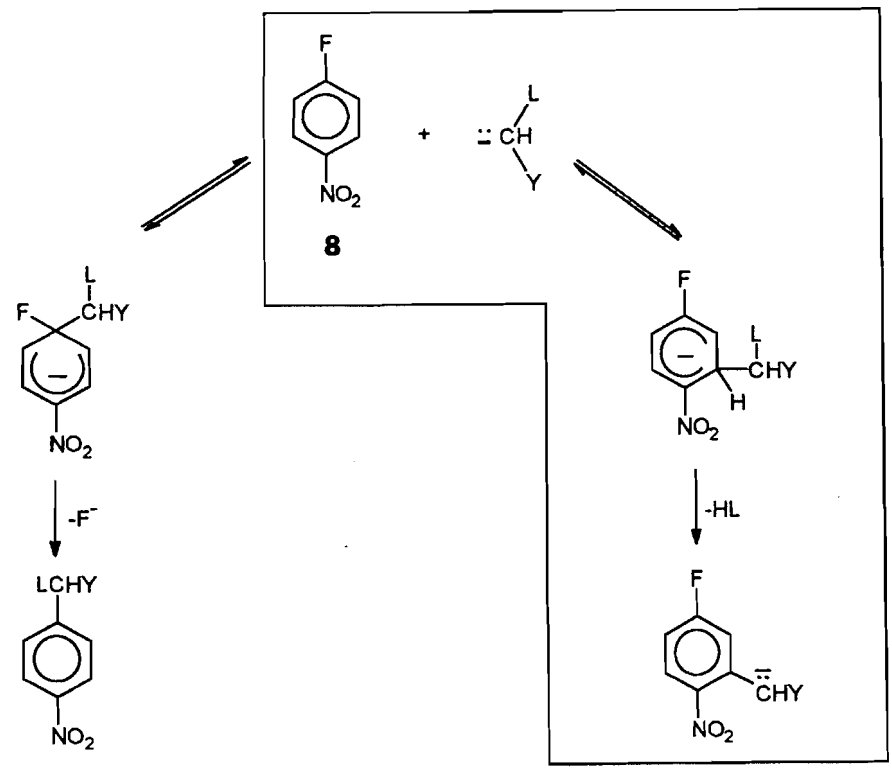
It is pertinent to note that in solution the CH_3O^- MC-3 of TNA is kinetically preferred, while the corresponding MC-1 of **2** is the product of thermodynamic control in a pattern of regioselectivity we have termed K3T1 (Fig. 1) (5, 7). It is equally important to note that with a carbon nucleophile, CH_3^-, the C-3 position is thermodynamically preferred over the C-1 site according to the present AM1 calculations. Further, we have found that TNA reacts with PhO^- as a C-nucleophile, to form the C-3 TNA phenoxide adduct (MC-3 of **2**) as the kinetic product of C-attack (7). Similar behaviour has been found with other ambident C-nucleophiles, such as acetonate anion in reaction with related picryl ethers where the only C-adduct observed in alkaline media by ^1H NMR is the acetonate MC-3 (42). However, in basic media, C-adducts are typically formed irreversibly and hence the relative thermodynamics associated with formation of these regioisomers is obscured. The present AM1 study suggests that these adducts are the products of *both kinetic and thermodynamic preference* and thus these cases can be designated as the first reported examples of K3T3 behaviour (cf. Fig. 1 and Introduction).

The extensive work of Makosza and co-workers (8) in elaborating the vicarious nucleophilic substitution (VNS) of hydrogen is also germane to the present discussion. In essence, a carbanion may attack an activated aromatic ring (typified by 4-fluoronitrobenzene, **8**, in Scheme 2) either at a site occupied by the substituent (e.g., fluorine) or occupied by hydrogen. In the former case the attack usually leads to formation of metastable MC and then to displacement of the ring substituent. In the latter case the addition is effectively reversible due to the poor nucleofugality of hydride ion. However, if the carbanion is itself substituted with a suitable leaving group, L, then attack at the position bearing the hydrogen can lead to a base-promoted β-elimination of HL after initial MC formation. (The immediate product is a nitrobenzylic carbanion that is usually protonated in work-up.) This second overall irreversible pathway constitutes the VNS mechanism (8) (solid boxed portion of Scheme 2).

For VNS to occur competitively with (or faster than) S_NAr displacement of a ring substituent, HL elimination, as the rate-determining step in the VNS process, must be faster than addition to a substituted ring position, the analogous usual S_NAr rate-determining step (4). By implication, the rate constant for attack at an unsubstituted position must be faster than the rate coefficient associated with HL elimination or with attack at a substituted position.

It is therefore important to note that in a recent review of the

[5]It is believed that n–σ^* donation into the C—CNO_2 system should be less favourable energetically due to the relatively high energy level of the C—Cσ^* orbitals (cf. ref. 41). Note also that stabilization due to such donation into antibonding orbitals of fragments of the trinitrocyclohexadienate ring would necessarily be constant and would apply equally to adducts like MC-3 of **2**; this factor would be the same in comparing regioisomers and cannot account for the observed regioselectivity in Meisenheimer complex formation.



SCHEME 2

VNS reaction Maskosza generalized the regioselectivity of this reaction: "In 4-Z-nitrobenzenes, the reaction can only proceed *ortho* to the nitro group" (*8a*). Thus, for **8** (Scheme 2) VNS should yield a product in which the erstwhile carbanion is attached to C-2 (*ortho* to the nitro group and *meta* to the fluoro group). The present AM1 calculations predict an order of preference for addition of C-2 > C-4 > C-3, based on the exothermicity of MC formation for CH_3^- with **8**. Note, again, that OH^- and CH_3O^- prefer attack at C-4 over attack at any other position. As required by the VNS mechanism, the thermodynamics of regioselectivity for carbanions favours attack at the position *ortho* to the nitro group.

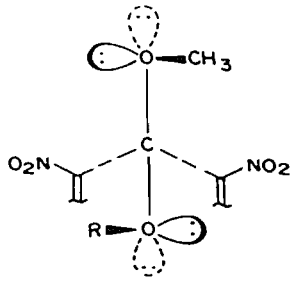
For more highly substituted aromatics the comparison becomes more difficult since substituents perforce affect both the competitive addition steps of VNS and S_NAr mechanisms, respectively, but also the rate-determining elimination step of the VNS route. Further, with more highly substituted electrophiles steric factors come into play to a greater extent.

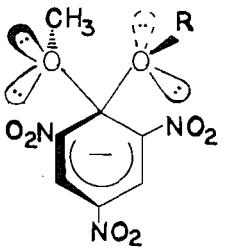
Further evidence in support of stereoelectronic stabilization is found in comparison of the two minimum energy conformations of the CH_3O^- MC-1 of TNA, **2**, the "M-shaped" and "S-shaped" conformers. The "M-shaped" conformation that places both methyl groups over the trinitrocyclohexadienate ring is slightly less stable than the CH_3O^- MC-3 of TNA, **2**. On the other hand, rotation of one of the CH_3O groups by 180° to the "S-shaped" conformation stabilizes the C-1 adduct by 4.4 kcal, and makes the C-1 adduct the product of thermodynamic control. Because n–σ^* interactions are not possible in the M conformer, yet exist for the S conformer, stereoelectronic stabilization of the MC due to n–σ^* interaction(s) is the most likely source of the enhanced stability of CH_3O^- C-1 adduct of **2**. This result is discussed further with respect to the corresponding X-ray structures (vide infra).

What appears to distinguish the thermodynamics of K3T1 behaviour is stereoelectronic stabilization afforded by geminal diheterosubstitution. We have previously recognized the importance of such disubstitution as one factor in determining the regioselectivity of attack by phenoxide vs. methoxide in picryl derivatives (32). In a study of the reaction of CN^- with TNA, **2**, MC-1 was found to be thermodynamically less stable than the corresponding MC-3; overall K1T3 regioselectivity was observed in this system (*6a*). It could be argued, therefore, that whenever the two electronegative groups in a geminal disubstituted adduct are different (e.g., CN and OCH_3 in the CN^- MC-1 of TNA) the degree of stabilization may be diminished (*6a*). However, this view is challenged by the efficacy of stabilization found for the "unsymmetrical" OH^- MC-4 of **8** and by the fact that the symmetrical CH_3O^- MC-1 of **2** is only favoured by 2.6 kcal over the CH_3O^- MC-2 of **1** (as compared to the unsymmetrical OH^- of MC-1 of **2**, which is formed with an exothermicity of 6.9 kcal relative to the OH^- MC-2 of **1**).

Three factors are significant in assessing the degree of stereoelectronic stabilization that may be attained by a geminal disubstituted adduct. First, energy levels for lone pair and relevant acceptor bond should be similar for maximum interaction (refs. 7, 40, 41, and footnote 5). Secondly, though perhaps obviously, the optimum interaction can only be achieved if both substituents can act as donor and acceptor towards one another; both substituents require lone pairs to act as donors. Finally, steric hindrance may prevent the donor and acceptor groups from achieving optimal conformations. In this regard, we have previously noted (7) that a conformation that would maximize the n–σ^* stabilization for a complex such as the CH_3O^- MC-1 of TNA should orient donor lone pairs and acceptor C—O bonds antiperiplanar to each other, as in the structure OS (where OS indicates that the groups R and CH_3 are arranged on opposite

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.





OS

sides of the O-(C-1)-O axis). OS is also drawn according to the "rabbit-ear" convention. The most suitable conformer of the CH_3O^- MC-1 of **2**, according to the present AM1 calculations, is the "S-shaped" conformer (Fig. 2), *which places neither lone pair of either acetal-like oxygen in the antiperiplanar position, but which permits partial interaction of* both *lone pairs with the relevant acceptor C—O bond.* In the S-shaped conformation a trade is made: n–σ^* stabilization for minimization of steric hindrance between the groups at C-1 and between these groups and the nitro groups of the trinitrocyclohexadienate ring (see discussion of X-ray structures below).

While the OH^- MC-1 of TNA has *not* been observed in solution by high-field ^1H NMR, the OH^- MC-3 of TNA, **2**, is readily observed (7, 43). How can this be reconciled with the present AM1 calculation results, which show that the OH^- MC-1 of **2** is formed with a 7.5 kcal/mol greater exothermicity than is the OH^- MC-3 of TNA? The key is that a favourable kinetic pathway exists for decomposition of the OH^- MC-1 of **2** in solution, namely, expulsion of methanol and formation of the delocalized picrate anion. No such facile route would be open to the OH^- MC-2 of **1**, given the poor leaving group ability of hydride anion, any more than this route is open to the OH^- MC-3 of TNA (refs. 11*a*, 44, and footnote 6). Hence, assuming that OH^- attack at C-3 is kinetically controlled leads to K3T1 behaviour for the TNA-OH^- system: initial formation of the OH^- MC-3 of **2** followed by conversion to picrate anion, *presumably via the OH^- MC-1* (7).

It should also be reiterated that the difference in enthalpy of adduct formation ($\delta\Delta H_c$) compares well with the solution calorimetric free energy differences ($\delta\Delta G$) reported previously (28, 29). Thus, based on the AM1 data, the difference in reaction enthalpy between the CH_3O^- MC-2 of **1** and the CH_3O^- MC-1 of **2** is 2.6 kcal in favour of the 1,1 TNA•OCH_3^- adduct (i.e., ΔH_c MC-1 of **2** − ΔH_c MC-2 of **1** for CH_3O^- as nucleophile = −2.6 kcal). Fendler et al. (29) assigned 4.2 kcal stabilization to geminal disubstitution with CH_3O^-, based on this and similar comparisons of free energy differences.

3. Structures of the Meisenheimer complexes

(a) Comparison of the X-ray and AM1 optimized structures of the CH_3O^- MC-2 of TNB (1)

Further evidence supporting the importance of stereoelectronic effects as factors affecting the relative adduct formation enthalpies derives from comparison of the calculated structures to available X-ray data, specifically the CH_3O^- MC-2 of TNB, **1**, and the MC-1 of TNA, **2**. The data given in the Supplementary Tables 28, 34, and 36 show that all AM1 bond lengths correspond well to those found by X-ray by Destro et al. (45); while C—C bond lengths were systematically overestimated in the theoretical study, the average error was only 0.014 Å or ca. 1%. Similarly, the C—N bond lengths were generally overestimated and the N—O bond lengths, by comparison to the X-ray structures, routinely underestimated, though again, the average error was small: only 0.03 Å (<3%).

The X-ray crystal structure of the CH_3O^- MC-2 of **1** contains an interesting structural feature: the adduct is boat-like, with C-1 and C-4 distorted from the plane defined by C-2:C-3:C-5:C-6. The "top" face of the molecule, (i.e., the side of substitution) is also the direction of pucker of the molecule (16). AM1 correctly predicts C-1 to be bent slightly out of this plane on the side of substitution, though the effect is small (Supplementary Table 28). The puckering of C-4 is not, on the other hand, reproduced by AM1. Given that Destro et al. (16) suggested that the C-4 puckering was an artifact induced by crystal packing forces, the absence of puckering about C-4 in the AM1 gas-phase calculations is not unexpected and, in fact, supports the previous interpretation of the role of packing forces on the structure (45).

Finally, the slight asymmetry found in the X-ray structure of the CH_3O^- MC-2 of **1** is not observed in the calculated AM1 structure. For example, in the X-ray structure the C—C bond between C-5 and C-6 is somewhat longer than the comparable bond between C-2 and C-3, while in the AM1 optimized structure these bonds are identical in length. These differences between X-ray and calculated structures have been noted previously (27) and also attributed to packing forces present in the crystal, but absent in the gas-phase structures predicted by AM1.

(b) Comparison of the X-ray and AM1 optimized structures of the CH_3O^- MC-1 of TNA (2)

The X-ray structure of the CH_3O^- MC-1 of TNA, **2**, was found to lack the puckering found for the CH_3O^- MC-2 of TNB (25). Both O—CH_3 bonds in the X-ray structure were found to be oriented antiperiplanar to the opposite C—O bonds. The plane defined by the bonding axis through CH_3-O-(C-1)-O-CH_3 is perpendicular to the trinitrocyclohexadienate ring (Supplementary Tables 34 and 36).

Contrary to the X-ray results, AM1 predicts the M conformation of C_{2v} symmetry about C-1, which places both methyl groups over the aryl ring to be 4.4 kcal less stable ($\delta\Delta H_{AF}$) than the S conformer, which places only one methyl group over the ring. Our above comparisons of heats of complexation, are therefore based on the more stable S conformation (Fig. 2). However, when a simulated counterion was added to the input geometry (SPARKLE option of AM1) only the M conformation was found to exist as a local minimum (Fig. 3). This result suggests that the positive counterion induces the M conformation in the solid phase, by coordination to the oxygen atoms not only of the acetal-like CH_3O^- groups at C-1, but also of the flanking *ortho* nitro groups. The attached methoxyl groups would thus be inhibited from rotating and prevented from taking up a conformation that permits n–σ^* interaction.

Complexation of the positive counterion has been proposed as a rationale for the high *ortho*:*para* ratio for the products that arise from displacement of a fluorine *ortho* to a nitro group in 2-fluoronitrobenzene by *tert*-butoxide (in *t*-BuOH) as compared to displacement of a *para* fluorine (46). Stabilization imparted to the incoming *tert*-butoxide anion by the bridging of the K^+

[6]E. Buncel and R.A. Manderville, unpublished work.

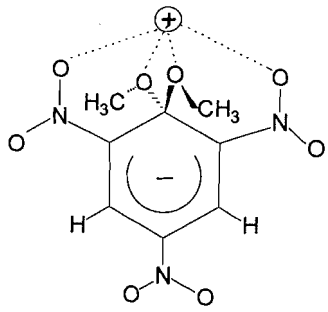

FIG. 3. The CH_3O^- MC-1 of TNA, **2**, ion paired to a hypothetical counterion simulated by a point charge (AM1 calculation using the SPARKLE option). Compare the structure to that of the "M-shaped" conformer (Fig. 2).

counterion to the *ortho* nitro group was suggested as providing a lower energy pathway for *ortho* displacement by *tert*-butoxide in *tert*-butyl alcohol solvent (46).

A more rigorous model for the cation association that apparently promotes the M conformation for the CH_3O^- MC-1 of **2** comes from the work of Crampton and co-workers who have studied the kinetics and thermodynamics of MC formation with a variety of O-nucleophiles and counterions (10, 47). While these studies show that the counterion is indeed complexed to the geminal diether oxygens and to the oxygens of the *ortho* nitro groups ("pseudo-crown-ether arrangement") in the CH_3O^- MC-1 of **2**, the CH_3O^- MC-2 of **1** does not show this type of association of the cation with the adduct, indicating that this ion pairing requires both O-CH_3 groups to be present (47, see also ref. 8*h*). More pertinent is the finding that the C-1 adduct is the product of thermodynamic control even when crown ethers are used to eliminate counterion complexation with the CH_3O^- MC-1 of TNA. No shift in the pattern of regioselectivity from K3T1 (see Fig. 1) to any other type of behaviour occurs. Consequently, while the M conformer is preferred in the solid state and possibly in some condensed media, the present results indicate that the S conformer is the more stable of the two structures. Again, this is consistent with the view that stereoelectronic stabilization via n–σ^* donation is important in assigning intrinsic thermodynamic stabilities of Meisenheimer complexes.

In solution it is reasonable to expect that the degree of complexation of cation to MC-1 of **2** will depend on the medium. Hydroxylic media along with a counterion that is relatively small, e.g., Na^+, would favour the M conformer (47), while the intrinsically more stable S conformer would be expected to predominate in a good cation-solvating solvent such as DMSO (48). Thus, in hydroxylic media, it is expected that with moderately small cations the CH_3O^- of **2** will be stabilized by ion pairing; MC-1 is then the thermodynamically preferred regioisomer.[7] The corresponding CH_3O^- MC-3, although formed first, would rearrange to the MC-1 regioisomer as is observed in solution (5, 7). When ion pairing is disrupted through the use of crown ethers, MC-1 is still preferred because this adduct can take up the inherently more stable S conformation. Recall that in the S-shaped conformation partial n–σ^* stabilization is possible for both O – lone pair orbitals interacting with the geminal C—O acceptor bonds. Therefore, there is no change in regioselectivity when crown ethers are present in these and related systems.

Clearly, a MC formed from CH_3^- attack must involve an insignificant degree of stereoelectronic stabilization compared to the MC formed from CH_3O^- attack since no lone pairs are present on the bonded CH_3 fragment; n–σ^* donation from CH_3 to the C-O-CH_3 antibonding orbital is energetically costly, regardless of the preferred conformation of the adduct (M or S). As well, the C—CH_3 bond would be less efficient as an acceptor than the O—CH_3 bond because of the comparatively high n–σ^* energy gap (40, 41). Neither conformation would confer any extraordinary stability on the CH_3^- MC-1; hence MC-3 becomes the preferred regioisomer (albeit only favoured by an exothermicity of 0.1 kcal in the present AM1 calculations).

Conclusions

Several important conclusions may be drawn from the present AM1 theoretical study. These are summarized as follows:

1. For a series of electrophiles that are progressively substituted with more electron-withdrawing nitro groups, that is, nitrobenzene, **7**, 1,3-dinitrobenzene, **9**, and 1,3,5-trinitrobenzene, **1**, hydroxide and methide anions, as model oxygen and carbon nucleophiles, *exhibit the same regioselectivity based on thermodynamics of Meisenheimer complex formation.* Thus, Meisenheimer complexes derived from attack at a position *para* to at least one nitro group (designated MC-4) are formed with the greatest exothermicity (ΔH_c).

2. Exothermicity of complexation increases for both OH^- and CH_3^- adduct formation as the number of nitro groups in the electrophiles is increased (**7** to **9** to **1**), but formation of the CH_3^- adducts occurs uniformly with greater exothermicity than that of OH^- adducts. The proportionality of stabilization, as a function of nitro group substitution, was shown to correspond well with that found by solution calorimetric methods (28, 29).

3. Unexpectedly, it is found that *regioselectivity inverts for CH_3^- as compared to OH^- and CH_3O^- in complexation with 2,4,6-trinitroanisole, 2.* Thus, while CH_3O^- and OH^- form MC-1 with TNA with higher exothermicity than MC-3, CH_3^- preferentially forms MC-3 on the basis of the same enthalpy criterion. Therefore, in adduct formation with **2**, CH_3O^- displays the thermodynamics associated with K3T1 regioselectivity, in accord with the known solution behaviour (5, 7), while CH_3^- exhibits the thermodynamics linked to K3T3 behaviour.

4. It is shown that stereoelectronic stabilization of geminally disubstituted Meisenheimer complexes, arising from significant overlap of donor substituent lone pairs with the acceptor σ-bond of the other substituent, accounts for the greater exothermicity of complexation of OH^- and CH_3O^- at C-1 as compared to C-3 of TNA. However, the methide moiety of the comparable MC-1 of TNA cannot partake in such an n–σ^* interaction and, consequently, with CH_3^-, MC-3 formation is preferred over MC-1.

5. Confirmation of this stereoelectronic stabilization for the oxygen geminal disubstituted adducts of TNA derives from examination of the optimized CH_3O^- MC-1 structures of TNA, which show that the preferred conformation, in a medium in which the counterion would be well separated from the adduct, has an "S-shape" rather than an "M-shape" (Fig. 2). In the S

[7]Bernasconi and Howard (39*a*) arrived at a complementary conclusion from the analysis of the kinetics of spiro Meisenheimer complex formation and ring-opening decomposition. In methanol solvent they argued in favour of the "M-shaped" conformer as the preferred geometry for the CH_3O^- MC-1 of TNA, although they recognized the S-shaped conformer as the more stable one in the absence of cation complexation and solvation effects.

For personal use only.

conformation n–σ^* interaction is possible, whereas in the M conformation it is not.

The present study emphasizes the utility of the AM1 method to assess the thermodynamic stability of Meisenheimer complexes and thus to predict patterns of regioselectivity. Also revealed is the modulation of regioselectivity as a function of the nature of the nucleophile, specifically oxygen versus carbon nucleophiles. Stereoelectronic stabilization is recognized as a major factor in influencing regioselectivity in Meisenheimer complex formation.

TED SCHAEFER, JEREMY P. KUNKEL, ROBERT W.J SCHURKO, and GUY M. BERNARD. Can. J. Chem. **72**, 1722 (1994).

The ^{1}H nuclear magnetic resonance spectrum of 2-phenyl-1,3-dithiane, as a dilute solution in a CS_2–C_6D_{12}–TMS solvent mixture at 300 K, is analyzed to yield 8 chemical shifts and 22 distinct coupling constants, ^nJ(H,H), n = 2–6. The coupling constant between H-2 and the *para* proton indicates, first, that the bisected conformer (phenyl plane perpendicular to the pseudo plane of the dithiane ring) is most stable and, second, that the apparent twofold barrier to rotation about the Csp^2—Csp^3 bond is 9.6 kJ/mol. The AM1, STO-3G, and STO-3G* computations confirm the twofoldedness of the barrier; the AM1 barrier is 9.4 kJ/mol. The empirical equation, ^3J(H,H) = 13.36 cos^2 ϕ + 9.59 cos ϕ − 0.43, reproduces the vicinal coupling constants of the $CH_2CH_2CH_2$ fragments and implies puckering angles ϕ_{ee}, ϕ_{ea}, and ϕ_{ae} of 54°, 61°, and 64°, respectively. It is implied that ^3J at ϕ = 0° is larger than at ϕ = 180°. This results is discussed in terms of the latest theoretical approach to ^3J in the HCCH fragment. The ^4J(H,H) signs and magnitudes for the $CH_2CH_2CH_2$ fragment agree reasonably well with theory. For the CH_2SCH fragment, ^4J(H,H) values are positive, in contrast to corresponding numbers in the propanic fragment, perhaps the first experimental values for certain rigid orientations about a heteroatom. INDO MO FPT computations on propane, dimethyl ether, and dimethyl sulfide confirm the experimental trend in ^4J(H,H). ^2J(H,H) and ^5J(H,H) values are compared to those in related molecules. The striking differential shifts of the axial and equatorial protons are attributed to differential van der Waals interactions with the 3p lone-pair orbital on sulfur. A comparison of the ring proton chemical shifts with those in phenylcyclohexane and isopropylbenzene implies that C—S bonds are weaker net electron donors by hyperconjugation than are C—C bonds. It is also proposed that the *ortho* protons are deshielded by intramolecular van der Waals interactions with the 3p orbitals on the sulfur atoms.

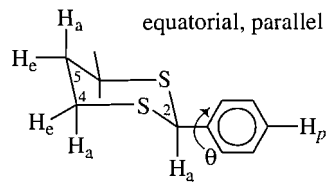
TED SCHAEFER, JEREMY P. KUNKEL, ROBERT W.J SCHURKO et GUY M. BERNARD Can. J. Chem. **72**, 1722 (1994).

Le spectre résonance magnétique nucléaire du ^{1}H du 2-phényl-1,3-dithiane, déterminé à 300 K, en solution diluée dans un mélange de solvants formé de CS_2, de C_6D_{12} et de TMS, a été analysé et on en a déduit 8 déplacements chimiques et 22 constantes de couplage distinctes, ^nJ(H,H), n = 2 – 6. La constante de couplage entre le proton H-2 et le proton en *para* indique, en premier lieu, que le conformère avec bissection (dans lequel le plan du phényle est perpendiculaire au pseudo plan du noyau dithiane) est le plus stable et, deuxièmement, que la barrière binaire apparente à la rotation autour de la liaison Csp^2—Csp^3 est de 9,6 kJ/mol. Des calculs AM1, STO-3G et STO-3G* confirment que la barrière est binaire; les calculs AM1 indiquent que la barrière est de 9,4 kJ/mol. L'équation empirique, ^3J(H,H) = 13,36 cos^2 ϕ + 0,59 cos ϕ − 0,43, permet de reproduire les constantes de couplage vicinales du fragment $CH_2CH_2CH_2$ et ceci implique que les angles de plissement ϕ_{ee}, ϕ_{ea} et ϕ_{ae} sont respectivement de 54°, 61° et 64°. On discute de ce résultat en fonction de l'approache théorique la plus récente concernant ^3J dans le fragment HCCH. Les signes et les amplitudes des ^4J(H,H) du fragment $CH_2CH_2CH_2$ sont en bon accord avec la théorie. Pour le fragment CH_2SCH, les valeurs de ^4J(H,H) sont positives et ce résultat est en opposition avec les valeurs correspondantes dans le fragment propanique et cette disparité est peut être due au fait qu'il s'agit des premières valeurs expérimentales pour certaines orientations rigides autour d'un hétéroatome. Des calculs d'OM FPT effectués sur le propane, l'éther méthylique et le disulfure de méthyle confirment la tendance expérimentale observée dans les ^4J(H,H). Les differences importantes observées pour les déplacements chimiques des protons axiaux et équatoriaux sont attribuées aux interactions de van der Waals différentes de ces atomes avec la paire d'électrons 3p libre du soufre. Une comparaison des déplacements chimiques des protons du noyau avec ceux observés dans le phénylcyclohexane et l'isopropylbenzène implique que, comparées aux liaisons C—C, les liaisons C—S sont d'une façon globale des donneurs d'électrons par hyperconjugaison qui sont plus faibles. On propose aussi que les protons en *ortho* sont plus déblindés par des interactions intramoléculaires de van der Waals avec les orbitales 3p des atomes de soufre.

[Traduit par la rédaction]

Introduction

A precise analysis of the ^{1}H nmr spectrum of 2-phenyl-1,3-dithiane, **1**, yields, not only the chemical shifts of the eight distinct types of protons and the larger coupling constants such as the vicinal coupling constants between the alkyl protons, but also a variety of long-range coupling constants. Thus, the proton in the methine bond can couple with all 11 other protons in the molecule in a stereospecific manner. For example, $^6J(H,H_p)$, the coupling constant over six formal bonds to the *para* proton of the phenyl group, depends on the angle of twist, θ, about the Csp^2—Csp^3 bond and can be related to the conformational minimum energy about that bond; an assessment of the barrier to rotation about the bond also follows from $^6J(H,H_p)$. Again, the



^3J(H,H) values for the alkyl protons provide measures of the flattening or pucker of the dithiane ring; in **1**, they suggest that ^3J is larger at a dihedral angle of 0° than at 180°. Because sulfur is considered to have an electronegativity equal to that of carbon in formulations of the substituent dependence of ^3J, this result is intriguing. The signs and magnitudes of ^4J(H,H) are also of interest, in that some involve a CCC, others a CSC fragment. An additional point of discussion is the striking variation in the chemical shifts of the axial and equatorial protons in **1**.

TABLE 1. ^{1}H nmr spectral parameters for 2-phenyl-1,3-dithiane[a] at 300 K

Parameter	Value	Parameter	Value
ν_o	220.104[b,c]	$^3J_{4a,5a} = {}^3J_{5a,6a}$	12.423
ν_m	2159.372	$^3J_{4a,5e} = {}^3J_{5e,6a}$	2.423
ν_p	2147.603	$^3J_{4e,5a} = {}^3J_{5a,6e}$	2.945
ν_2	1507.1[d]	$^3J_{4e,5e} = {}^3J_{5e,6e}$	4.560
$\nu_{4a} = \nu_{6a}$	874.494	$^4J_{4a,6a}$	−0.248
$\nu_{4e} = \nu_{6e}$	826.411	$^4J_{4a,6e} = {}^4J_{4e,6a}$	−0.379
ν_{5a}	557.165	$^4J_{4e,6e}$	1.427
ν_{5e}	606.775	$^4J_{2a,4a} = {}^4J_{2a,6a}$	0.186
$^3J_{om}$	7.764	$^4J_{2a,4e} = {}^4J_{2a,6e}$	0.480
$^3J_{mp}$	7.458	$^5J_{2a,5a}$	±0.043[e]
$^4J_{oo}$	1.997	$^5J_{2a,5e}$	±0.078[e]
$^4J_{op}$	1.252	$^2J_{4a,4e} = {}^2J_{6a,6e}$	−13.990
$^4J_{mm}$	1.426	$^2J_{5a,5e}$	−13.858
$^5J_{om}$	0.582	No. of assigned transitions	16.375
$^4J_{20}$	−0.467	No. of peaks	337[f]
$^5J_{2m}$	0.271	Largest deviation	0.017
$^6J_{2p}$	−0.181	Root-mean-square deviation	0.007

[a]4.8 mol% in CS_2 containing also 10.0 mol% of C_6D_{12} and 0.5 mol% of TMS.
[b]In Hz at 300.135_2 MHz to high frequency of internal TMS.
[c]The standard deviations in the parameters were all ≤0.0003 Hz, but the latter are given here only to a precision of 0.001 Hz.
[d]Transitions in this spectral region could not be assigned reliably; see Experimental.
[e]Because of footnote *d* these signs are not certain, although the least-squares fitting procedure yielded positive signs.
[f]Not counting degeneracies of the many peaks in the band due to H-2.

Accordingly, we report precise ^{1}H nmr spectral parameters for **1** as a dilute solution in a CS_2–C_6D_{12}–TMS solvent mixture. A Karplus equation is deduced for ^3J(H,H). Its parameters are discussed in terms of the pucker of the dithiane moiety and in terms of the theory of vicinal coupling constants. The proton–proton coupling constants over four bonds within this moiety are compared with the ones available for a *tert*-butylcyclohexane derivative, and from theory. The apparent twofold barrier to rotation about the Csp^2—Csp^3 bond is reduced and compared with that for phenylcyclohexane. Semiempirical, AM1, as well as STO-3G and STO-3G* molecular orbital computations of this barrier are given. The chemical shifts of the alkyl protons are discussed in terms of the perturbations caused by the mainly 3*p* lone pair on sulfur and the ring proton shieldings in terms of van der Waals interactions. ^2J(H,H) and ^5J(H,H) for the dithiane ring are noted.

Experimental

A 4.8 mol% solution of **1** (Aldrich) in a CS^2–C_6D_{12}–TMS solvent mixture (see Table 1 for details) was filtered into a 5 mm o.d. nmr sample tube. The tube was degassed by five cycles of the freeze–pump–thaw procedure and was then flame-sealed under vacuum to produce a reasonably symmetrical top. The ^{1}H nmr spectra were acquired with an AM 300 nmr spectrometer at a probe temperature of 300 K, in the manner previously described in detail (1). The peak widths at half height in the aromatic region were less than 0.1 Hz, many being about 0.05 Hz. Similar remarks apply to the alkyl proton spectrum, but H-2, being coupled to 11 other protons with couplings constants of less than 0.5 Hz in magnitude, gave an unassignable band of peaks.

The AM1 (2), STO-3G(3), and STO-3G*(4) computations used the program GAUSSIAN 92 (5) and were done for various angles of twist about the Csp^2—Csp^3 bond in **1**. At each angle the geometry was optimized with the proviso that the phenyl group remain a planar entity.

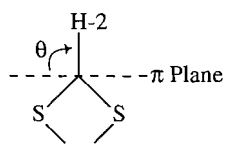
Results and discussion

Spectral analysis

The ^{1}H nmr spectrum was analyzed with the computer program NUMARIT (6), greatly modified and arranged to be partially self-assigning by R. Sebastian. In all, 16 375 transitions were assigned to some 337 peaks for the 12-spin system. However, transitions could not be assigned in the H-2 region, that of the methine proton. This means that the signs of ^5J(H-2, H-5) in the dithiane ring are uncertain; those to the aromatic protons are, however, known, as are the signs of ^4J(H,H). The H-2 peaks coalesce to a broad band because H-2 couples to at least 10 protons with coupling constant magnitudes of less than 0.5 Hz. The final spectral parameters had standard deviations of 0.0003 Hz or less and are given in Table 1.

*The internal rotation barrier in **1***

The coupling constant over six formal bonds, ^6J(H-2, H_p) ≡ ^6J, is proportional to $\sin^2\theta$, as in **2** (7), and $^6J(\theta = 90°)$ is somewhat dependent on the electronegativity of the substituents at the sp^3 carbon atom (8). For isopropylbenzene, $^6J(\theta = 90°)$ is −1.12 Hz (9). The electronegativities of carbon and sulfur are



2

identical, to a first approximation, so that the same value of $^6J_{90}$ will here be taken for the dithiane. The expectation value of $\sin^2\theta$ follows at −0.181/−1.12 or 0.169 at 300 K. A hindered rotor model (7) then yields the apparent twofold barrier to rotation about the Csp^2—Csp^3 bond as 9.6 kJ/mol, as does a classical averaging procedure. This value for **1** is somewhat higher than that of 7.1 kJ/mol deduced for phenylcyclohexane (10). Both molecules clearly adopt the parallel or bisected conformation in the conformation of lowest energy, that in which the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

C(2)—H bond lies in the phenyl plane. Certainly, this is true for **1** in the crystal (11).

The foldedness of the barrier to internal rotation was probed with the three basis sets above, with the results that

$$V_2/\text{kJ/mol} = 9.44 \sin^2\theta - 0.12 \sin^2 2\theta, \quad \text{AM1}$$

$$V_2/\text{kJ/mol} = 12.38 \sin^2\theta - 0.21 \sin^2 2\theta, \quad \text{STO-3G}$$

$$V_2/\text{kJ/mol} = 13.31 \sin^2\theta - 0.16 \sin^2 2\theta + 0.26 \sin^2 3\theta, \quad \text{STO-3G*}$$

The angle θ is zero for the bisected conformation. The assumption of a predominantly twofold barrier, in $\sin^2\theta$, is a good one apparently because any fourfold, in $\sin^2 2\theta$, and sixfold, in $\sin^2 3\theta$, terms are rather small. The AM1 results agrees closely with the twofold barrier deduced fro the solution of **1** in CS_2–C_6D_{12}. The solvent effect on the barrier is not known, of course. Calculations with much larger basis sets are not feasible at present for a molecule of this size.

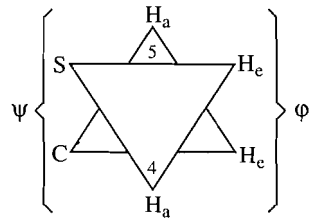
The energy difference between the equatorial and axial conformers of **1** was also calculated. As expected (10), the axial conformer has the perpendicular orientation of the phenyl group instead of the bisected or parallel orientation in the equatorial conformer, as in **1**. As in phenylcyclohexane (10), repulsive interactions with the axial C(4)—H and C(6)—H bonds destabilize the bisected orientation of the phenyl group in the axial conformer. The axial is computed as 8.96, 13.21, and 13.47 kJ/mol less stable than the equatorial conformer by the AM1, STO-3G, and STO-3G* procedures, respectively. The most recent measurement of the free energy difference yields 9.8 kJ/mol (12). The inversion barrier for 1,3-dithiane in CS_2 solution is 39.3 ± 1.3 kJ/mol (13). The assumption in this paper of a negligible amount of the axial conformer of 2-phenyl-1,3-dithiane in solution at 300 K appears reasonable.

The pucker of the dithiane moiety

The vicinal coupling constant, ^3J(H,H), is sensitive to the dihedral angle, ϕ, between the protons (14, 15), but also depends on the CCH angles, the *s* character of the hybrid orbitals at the two carbon atoms in the HCCH fragment, on various overlap integrals, themselves dependent on the C—C distance, and on the effective nuclear charges at the carbon atoms (16, 17). It follows that substituents, X, at carbon will also perturb ^3J(H,H), a perturbation whose magnitude may well depend on the dihedral angle between the C—X and the vicinal C—H bonds. It is therefore not surprising that, while the Karplus equation relating ^3J(H,H) to ϕ is of great stereochemical significance, its quantitative application requires circumspection. The following discussion of the four ^3J(H,H) values in **1** illustrates this point (see **3**).

The ^3J values in Table 1 are ^3J(4a,5a) = 12.423, ^3J(4a,5e) = 2.422, ^3J(4e,5a) = 2.946, and ^3J(4e, 5e) = 4.560 Hz, differing by up to 0.3 Hz from earlier (18, 19) values. In cyclohexane, ^3J(a,a) is 12.85, ^3J(e,e) is 2.92, while ^3J(a,e) are 3.61 Hz in CS_2 solution (20, 21). These numbers were analyzed to yield a dihedral angle of 57°, the HCH angle being somewhat less than a tetrahedral value (22). The data for **1** therefore suggest that the dithiane ring is puckered, that is, that ψ is larger than the 56° commonly accepted for cyclohexane (22). In the crystal of **1** the value of ψ is 62.5 ± 2.5° (11).

Lambert defines the quantity, *R*, as $\{^3J(a, a) + {}^3J(e, e)\}/\{^3J(a, e) + {}^3J(e, a)\}$, a measure of the degree of pucker (23). The perturbation of ^3J caused by an electronegative substituent, if independent of the relative orientation of the C—H and C—X bonds, is removed by this division. For **1**, *R* is 3.16, compared to 2.16 for cyclohexane (23). Furthermore, if the S-CH_2CH_2-C fragment possesses pseudotrigonal projection symmetry, as in **3**, and if ^3J is given by the simplified expression, $A \cos^2\phi$, then ψ follows as 63° (23). It must also follow that ϕ_{aa} is 183°, ϕ_{ee} is 57°, and that ϕ_{ae} and $\phi_{e,a}$ are 63°.



3

Note, however, that the values of ^3J(4a,5e) and ^3J(4e,5a), at 2.422 and 2.946 Hz, respectively, are not the same. The equal angles, ϕ_{ea} and ϕ_{ae}, underlying the derivation of *R*, imply the equality of the two coupling constants *unless* the electronegativity of sulfur differs from that of carbon. The generalized Karplus equation (24) would assume the equality of the two (Huggins) electronegativities.

In an attempt at a better assessment of the endocyclic torsion angles in **1**, the following approach is taken, somewhat similar to the discussion of Slessor and Tracey (25). The original formulation (14) writes $^2J = J_0 \cos^2\phi - 0.28$ for $0° \leq \phi \leq 90°$ and $^3J = {}^3J_{180} \cos^2\phi - 0.28$ for $90° \leq \phi \leq 180°$. This formulation will be used here because there is good reason (16, 17) to believe that ^3J is more sensitive to changes in CCH angles and C—C distances at torsion angles greater than 90° than it is for torsion angles less than 90°. Accordingly, the smaller ^3J values for **1**, corresponding to $\phi < 90°$, may well be the more reliable sources of ϕ_{ee}, ϕ_{ea}, and ϕ_{ae}. Furthermore, in cyclohexane the HCH angle is smaller than its tetrahedral value. In consequence, the pseudo-trigonal symmetry is lost. The projection angles, as in **3**, for example, are no longer 120° but may be as small as 115°. In **1**, these projection angles, ω, can be different at C-4 and C-5. We shall adjust their values so as to obtain a single J_0 and consistent values of the three ϕ values above. The adjustment proceeded with the result that ω at C-5 was 115° and was 118° at C-4, taking $\omega < 120°$. The former value is that found by Slessor and Tracy (25) for cyclohexane. In gaseous 1,3-dithiane (26) the HCH angles are somewhat smaller than in cyclohexane (22). An example of the calculations goes as follows. One has

$$^3J(4e,5e)/{}^3J(4e,5a) = (J_0 \cos^2 \phi_{ee} - 0.28)/[J_0 \cos^2 (115 - \phi_{ee}) - 0.28]$$

where $115 - \phi_{ee} = \phi_{ea}$ and the first subscript of ϕ refers to H-4, the second to H-5. Again,

$$^3J(4e,5e)/{}^3J(4a,5e) = (J_0 \cos^2 \phi_{ee} - 0.28)/[J_0 \cos^2 (118 - \phi_{ee}) - 0.28]$$

where $118 - \phi_{ee} = \phi_{ae}$, and 118° is the value for the CH_2 group at C-4. The upshot is that ϕ_{ee}, ϕ_{ea}, and ϕ_{ae} are 53.9 ± 0.1°, 61.1 ±

[i]From Table 1, ^4J(4e, 6e).

0.1°, and 64.1 ± 0.1°, respectively, corresponding to a J_0 of 13.97 ± 0.10 Hz; the significant figures indicate the error of fit only, of course. The average of ϕ_{ea} and ϕ_{ae} is 62.6°, very close to the ψ value give by the *R* value of Lambert. For 1,3-dithiane in the gas phase ψ is 64.1° (26).

With the values of ω as given above, two equations in J_{180} follow. They are

$$^3J(4a,5e)/^3J(4a,5a) = (J_0/J_{180}) \cos^2 \phi_{ae}/\cos^2 (115 + \phi_{ae})$$

and

$$^3J(4e,5a)/^3J(4a,5a) = (J_0/J_{180}) \cos^2 \phi_{ae}/\cos^2 (118 + \phi_{ea})$$

Use of $^3J_0$, ϕ_{ea} and ϕ_{ae} yields $^3J_{180}$ as 12.69 ± 0.16 Hz. The equation,

$$^3J(H,H) = 13.36 \cos^2\phi + 0.59 \cos \phi - 0.43$$

reproduces the four coupling constants with an average deviation of 0.04 Hz if the angles above are used; ϕ_{aa} is 179.1°. The striking conclusion is that the coefficient of cos ϕ is positive, that is, $^3J_{180} < {}^3J_0$. The following points are relevant to this conclusion.

First, even if ω is taken at 120° and (or) the term *C* in $A \cos^2\theta - C$ is omitted, the conclusion holds. The condition $\omega > 120°$ was not tested because $\omega < 120°$ for cyclohexane and because in 1,3-dithiane the HCH angle is quoted (26) as being even smaller than in cyclohexane. In cyclohexane, J_{180} is 12.94 Hz and J_0 = 12.50 Hz (20, 21) for an ω of 118°. Second, the coefficient of cos ϕ is not required to be negative by theory because it is the difference between large terms of opposite signs (16). In fact, for the latest formulating of ^3J(H,H), which takes CCH angles into consideration (16, 17), the *B* term is 0.3 Hz for tetrahedral angles and hence $J_{180} < J_0$ in the ideal case. Third, the exact values of ϕ for **1** above are not to be taken too literally; it does appear, however, that $\phi_{ae} > \phi_{ea} > \phi_{ee}$. Fourth, the formulations under consideration here apply to molecules without highly electronegative atoms; in their presence negative *B* terms may well occur.

^{4}J(*H,H*) *in the dithiane moiety*

Long-range coupling constants over four bonds are a result of competition among several coupling mechanisms and can be positive or negative (27). Table 2 presents some particular theoretical (27) and experimental values for ^4J(H,H) in the propanic fragment, those for axial and equatorial protons in the ideal chair form of a six-membered alicyclic ring. The theoretical values are for propane itself and of course, substituent effects can alter these numbers (27). However, neither carbon nor sulfur are strongly electronegative and hence the comparisons in Table 2 may be of some value even though, furthermore, the angles involved experimentally are clearly not exactly 60° or 180°. The early data for 1-*tert*-butylcyclohexane (28) are averages over a range of values. Those for **1** are single values of relatively high precision. Qualitatively, theory and experiment are in reasonable agreement.

Of greater interest here are the ^4J(H,H) values for **1** that involve the C—S—C fragment. ^4J(2,4a) = ^4J(2,6a) = 0.19 Hz and ^4J(2a,4e) = ^4J(2a,6e) = 0.48 Hz. Both are now positive, unlike such couplings in the propanic fragments in Table 2 (the second-order spectra **1** could not be reproduced with different signs of these coupling constants). These couplings constants are perhaps the first examples whose signs are know for definite orientations of the C—H bonds relative to the C—X—C plane (there are some examples for five-membered rings in which a dual pathway (29) is important for ^4J(H,H)).

The positive shift in $^4J_{aa}$ and $^4J_{ae}$ in fragment C—S—C is reproducible by INDO MO FPT (30) computations, as follows. The geometries of propane, dimethyl ether, and dimethyl sulfide were optimized using the STO-3G* basis and the ^4J values were computed with these geometries. The $^4J_{ae}$ values changed from −0.54 to −0.28 to −0.03 Hz in going from CH_2 to O to S, respectively, in the C—X—C fragment; for $^4J_{aa}$ the values are −0.79, −0.45, and 0.93 Hz. Thus, the qualitative theoretical trend bears out the experimental algebraic increase in the ^4J(H,H) values measured for the dithiane. It would be useful to measure signs of ^4J(H,H) for the C—O—C fragment in 1,3-dioxane derivatives. The INDO MO FPT computations also suggest positive shifts in $^4J_{ee}$; measurements would require axial substituents at position 2 in these six-membered rings or equatorial substituents at C-5.

The coupling constants, ^{2}J*(H,H) and* ^{5}*(H,H) in the dithiane ring*

^2J(H,H) in cyclohexane is −12.88(5) to −13.05(5) Hz (20, 21), not far from the −13.42 ± 0.26 Hz (31) in propane. In **1**, ^2J(H,H) at C-4 is −13.99 Hz and is −13.86 Hz at C-5. In the molecular orbital model (32) of substituent perturbations of ^2J(H,H), inductive electron withdrawal (donation) from the CH_2 fragment leads to an increase (decrease) in ^2J(H,H), whereas hyperconjugative electron shifts cause the opposite corresponding signs in the changes induced in ^2J(H,H). The lat-

TABLE 3. Proton chemical shift data in ppm for the alkyl protons of 2-phenyl-1,3 dithiane, **1**

	1		
Proton	δ^a	Δ^b	$\Delta\chi^c$
2a	5.021	3.885	0.52_3
2e	—	—	—
4a = 6a	2.914	1.778	0.00_2
4e = 6e	2.753	1.146	0.00_1
5a	1.856	0.720	0.12_6
5e	2.002	0.415	0.06_2

[a]From Table 1, 4.8 mol% in CS_2–C_6D_{12}–TMS.

[b]$\Delta = \delta - \delta_a$ or $\Delta = \delta - \delta_e$, where $\delta_a = 1.136$ and $\delta_e = 1.607$ for a 5% solution in CS_2 of 1,1,2,2,3,3,4,4-octadeuterocyclohexane at −103°C (20, 21).

[c]The deshielding due to the phenyl ring.

est computations on methane (33) imply that a decrease of one degree in the HCH angle entails a change of –0.72 Hz in ^2J(H,H). Because the electronegativities of carbon and sulfur are so similar, the small decrease of ^2J(H,H) in **1** relative to cyclohexane could be a result of hyperconjugative withdrawal of electron density by sulfur from both CH_2 moieties (the 3*p* orbital approaches the axial C(5)—H bond reasonably closely) and (or) of small decreases in the HCH angles in **1** relative to cyclohexane. The comparison in a previous section of HCH angles in 1,3-dithiane and cyclohexane suggests that changes in HCH angles are a distinct possibility as a cause of the smaller ^2J(H,H)values in **1**. More cannot be established at present.

Turning to ^5J(H,H), the magnitude of ^5J(2a,5e), at about 0.08 Hz, is nearly twice as large as that of ^5J(2a,5a), at about 0.04 Hz. These numbers can be compared to the magnitude of 0.9 Hz, for ^5J(2e,5e) in some 1,3-dioxane derivatives (34, 35); here larger rear-lobe interactions of C—H bonds are likely. Unfortunately, the signs of these couplings constants are not known.

The chemical shifts of the alkyl protons

In Table 3 the chemical shifts of the alkyl protons of **1** are compared with the chemical shifts of the axial and equatorial protons in cyclohexane. Because the electronegativities of sulfur and of the replaced methylene group are essentially equal, the relatively large deshieldings of H-4 and H-5 are remarkable., as is the fact that an axial proton is more deshielded than its equatorial partner. To isolate these differential shifts from those caused by the diamagnetic anisotropy, $\Delta\chi$, of the phenyl group in **1**, the model in ref. 36 was applied. This model relates the shift cause by $\Delta\chi$ to $\langle\sin^2\theta\rangle$, the expectation value of $\sin^2\theta$, where θ is the torsion angle about the Csp^3—Csp^2 bond in **1**. The value of $\langle\sin^2\theta\rangle$, deduced in a previous section, is required because it determines whether or not, on average, the alkyl proton lies in the shielding or deshielding region of the magnetic field from the induced dipole in the phenyl group. For example, if $<\sin^2\theta>$ is zero, then H-5a and H-5e lie in the phenyl plane and experience their maximum deshielding. These anisotropy shifts are given in Table 3. They are negligible for H-4 protons because of the average geometry of **1**.

The remaining differential shifts are here attributed to intramolecular van der Waals interactions (37) originating from the mainly 3*p* lone-pair orbital on sulfur, for the following reasons. In previous work (38–40) we have shown that a close approach of a C—H bond to a 3*p* orbital of sulfur leads to a marked deshielding of its proton. For example, in 2-methylthiobenzaldehyde, δ(CHO) is 10.27, the molecule existing as a mixture of planar O-*syn* and O-*anti* conformers in solution (39); the 3*p* orbital lies essentially perpendicular to the molecular plane. For 2-*tert*-butylbenzaldehyde, only the O-*anti* conformer exists and, furthermore, the bulky alkyl group is twisted nearly 90° out of the benzene plane. In consequence, the 3*p* orbital is now oriented in the benzene plane and δ(CHO) becomes 10.70, its larger value being attributed to the proximity of this lone pair and the C—H bond of the formyl group. In an independent and earlier discussion (41) it was noted that, in an axial orientation of the phenyl group in 2-methyl-2-phenyl-1,3-dithiane, the *ortho* protons were deshielded by about 0.6 ppm relative to the *meta* and *para* protons. An axial phenyl group was assumed to be predominantly oriented to bring the *ortho* C—H bonds close to the 3*p* lone pairs on the sulfur atoms (see the conformation deduced for a mimic of axial phenylcyclohexane (10)) and the deshielding of the *ortho* protons was attributed to interactions with the proximate 3*p* orbitals.

Of course, a quantitative treatment of intramolecular van der Waals shifts is difficult (42). They must depend on some power of the distance (45, 46) between the C—H bond and the 3*p* orbital on sulfur as well as on their relative orientation. It is possible to parameterize the proton shifts, in an additive fashion, in terms depending on the dihedral angles between the C—H bonds and the 3*p* orbitals on sulfur. Such a parameterization can also reproduce the proton shift differences observed (41) for the inverting molecule, 1,3-dithiane. However, it is possible that modern molecular orbital calculations (45, 46) will soon be able to reproduce such differential shifts. Therefore, it is simply noted here that the axial C—H bond of a given methylene group has a significantly greater proximity to the 3*p* lone pair than does the equatorial C—H bond (they point away from the 3*p* orbitals and (or) are oriented roughly in the nodal plane of these orbitals). The values of Δ–$\Delta\chi$ in Table 3 are then a measure of the differential van der Waals shifts at a given methylene moiety. As expected, the differential shift at C-5 is smaller than that, for example, at C-4.

The aromatic chemical shifts

For dilute solutions of benzene, phenylcyclohexane (10), and isopropylbenzene (9) in CS_2 solutions at 300 K, the δ values of the *para* protons are 7.218, 7.004, and 7.017, respectively; for **1**, it is 7.155. Accordingly, the C—S bond in **1** can be considered as a electron donor by a σ–π mechanism; the barriers to rotation about the Csp^2—Csp^3 bonds in these three molecules are similar, so that the α C—H bonds have very similar hyperconjugative interactions in these molecules. In these terms, the C—S bonds is only 30% as effective as a C—C bond in redistribution of electron density in the phenyl group. Again, relative to benzene, the *ortho* protons in phenylcyclohexane and isopropylbenzene are shielded by 0.172 and 0.144 ppm, respectively, as expected from the discussion of the *para* proton shifts. The *ortho* protons of **1**, however, are deshielded by 0.112 ppm. On the basis of the *para* proton shift in **1**, a shielding of about 0.05 ppm would have been expected. The net deshielding of about 0.16 ppm is attributed to van der Waals interactions with the 3*p* lone pair on sulfur, four formal bonds distant. In the bisected, most stable, conformation of **1**, one of the *ortho* protons and H-5a, three bonds distant from sulfur are essentially equidistant from sulfur; the other *ortho* proton is too far removed from the 3*p* orbital to undergo deshielding. Further averaging of shifts comes from oscillation about the Csp^2—Csp^3 bond. It is therefore plausible that the *ortho* protons undergo deshielding by intramolecular van der Waals interactions.

Ditopic thiacyclophanes containing the $S(CH_2)_2X(CH_2)_2S$ (X = O, S) linkage. Synthesis and structures of 2,5,8,17,20,23-hexathia[9](1,2)[9](4,5)cyclophane and 5,20-dioxa-2,8,17,23-tetrathia[9](1,3)[9](4,6)-2,5-bis(ethoxy)cyclophane

STEPHEN J. LOEB[1] AND GEORGE K.H. SHIMIZU

Department of Chemistry and Biochemistry, University of Windsor, Windsor, ON N9B 3P4, Canada

Received January 28, 1994

STEPHEN J. LOEB and GEORGE K.H. SHIMIZU. Can. J. Chem. **72**, 1728 (1994).

The Cs^+/DMF mediated reactions of 1,2,4,5-tetra(bromomethyl)benzene and 1,2,4,5-tetra(bromomethyl)3,6-bis(ethoxy)benzene with dithiols $HSCH_2CH_2XCH_2CH_2SH$ (X = S,O) were explored in order in order to ascertain the effect of structural variations on the regioselectivity of double ring-closure. Although a structure with bis(*ortho*) geometry was the target molecule, the major products are those with a bis(*meta*) structure. Two crystal structures, one with a bis(*ortho*) structure, 2,5,8,17,20,23-hexathia[9](1,2)[9](4,5)cyclophane, **1**, and one with a bis(*meta*) structure, 5,20-dioxa-2,8,17,23-tetrathia[9](1,3)[9](4,6)-2,5-bis(ethoxy)cyclophane, **7**, are reported. **1** crystallized in the triclinic space group $P\bar{1}$ with a = 8.583(3), b = 11.806(3), c = 5.448(2) Å, α = 97.18(2), β = 107.18(2), γ = 99.40(2)°, V = 511.6(6) Å^3, and Z = 1. The structure refined to R = 6.48% and R_w = 7.13% for 1020 reflections with $F_o^2 > 3\sigma(F_o^2)$. **7** crystallized in the triclinic space group $P\bar{1}$ with a = 9.568(2), b = 9.577(2), c = 8.312(2) Å, α = 113.53(2), β = 94.58(2), γ = 114.94(2)°, V = 604.3(7) Å^3, and Z = 1. The structure refined to R = 3.86% and R_w = 4.20% for 1129 reflections with $F_o^2 > 3\sigma(F_o^2)$. Both compounds sit on a crystallographic centre of symmetry and have the thioether linkages oriented on opposite sides of the central aromatic ring.

STEPHEN J. LOEB et GEORGE K.H. SHIMIZU. Can. J. Chem. **72**, 1728 (1994).

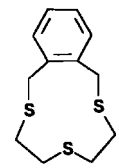
Afin de déterminer l'effet des variations de structure sur la régiosélectivité de double cyclisation, on a étudié les réactions, catalysées par le Cs^+/DMF, du 1,2,4,5-tétra(bromométhyl)benzène et du 1,2,4,5-tétra(bromométhyl)-3,6-bis(éthoxy)benzène avec les dithiols $HSCH_2CH_2XCH_2CH_2SH$ (X = S ou O). Même si la molécule cible possédait une géométrie bis(*ortho*), les produits principaux sont ceux d'une structure bis(*méta*). On a déterminé les deux structures cristallines, soit celle de la structure bis(*ortho*), 2,5,8,17,20,23-hexathia[9](1,2)[9](4,5)cyclophane (**1**) et celle de la structure bis(*méta*), 5,20-dioxa-2,8,17,23-tétrathia[9](1,3)[9](4,6)-2,5-bis(éthoxy)cyclophane (**7**). Le composé **1** cristallise dans le groupe d'espace triclinique $P\bar{1}$, avec a = 8,586(3), b = 11,806(3) et c = 5,448(2)Å, α = 97,18(2), β = 107,18(2) et γ = 99,40(2)°, V = 511,6(6) Å^3 et Z = 1. On a affiné la structure jusqu'à des valeurs de R et R_w de 6,48% et 7,13% respectivement pour 1020 réflexions avec $F_o^2 > 3\sigma F_o^2$. Le composé **7** cristallise dans le groupe d'espace triclinique $P\bar{1}$, avec a = 9,568(2), b = 9,577(2) et c = 8,312(2)Å, α = 113,53(2), β = 94,58(2) et γ = 114,94(2)°, V = 604,3(7) Å^3 et Z = 1. On a affiné la structure jusqu'à des valeurs de R et R_w de 3,86% et 4,20% respectivement pour 1129 réflexions avec $F_o^2 > 3\sigma F_o^2$. Les deux composés se retrouvent sur un centre de symétrie crystallographique et ils possèdent tous les deux des liaisons thioéthers orientées dans des directions opposés du cycle aromatique central.

[Traduit par la rédaction]

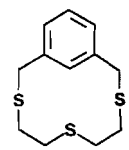
Introduction

The synthesis of ditopic thioether macrocycles is currently an active area of research (1–9). One of the most successful approaches towards this goal has been the incorporation of a rigid durene fragment into the macrocyclic framework (5, 6). The durene fragment functions as a central spacing unit and serves to compartmentalize the two metal binding sites.[2] An appealing aspect of this design strategy is that, with the appropriate choice of starting materials, the resultant ligands would be ditopic analogs of the thiacyclophanes, TT[9]OC (11–15) and TT[9]MC (16).

The known coordination chemistry of these thiacyclophanes provides a good model for predicting the bonding preferences of the ditopic versions. Although both molecules have exodentate conformations, the *ortho* and *meta* substitution patterns have dramatically different effects on the coordinating ability of the ligand. The *o*-xylyl fragment introduces strain into the free ligand conformation, which favours an *exo*-to-*endo* conformational change and facial S_3-coordination to a single metal centre. In contrast, the *m*-xylyl group prevents this type of S_3-coordination by reinforcing a rigid exodentate conformation. Thus, TT[9]OC coordinates facially to transition metals with tetrahedral, trigonal bipyramidal, and octahedral geometry. Some structurally characterized examples include $[Ag(TT[9]OC)(PPh_3)]^+$ (12), $[Mo(CO)_3(TT[9]OC)]$ (11), $[Ir(COD)(TT[9]OC)]^+$ (17), and $[PdCl_2(TT[9]OC)]$ (16). The macrocycle, TT[9]MC is a much poorer ligand and the only structurally characterized complex of this thiacyclophane bound to a transition metal is $[PdCl_2(TT[9]MC)]$ (16) in which TT[9]MC acts as a bidentate chelate coordinating through one benzylic S-atom and the central aliphatic S-atom with the third sulphur exodentate. It would, therefore, be anticipated that the *ortho* isomer of the durene-based macrocycles, **1**, would exhibit a significantly richer coordination chemistry than the *meta* isomer, **4**.



TT[9]OC



TT[9]MC

The difficulty lies with the synthesis of **1**. The preparation of thiacyclophanes **1** and **4**, employ a common starting material, 1,2,4,5-tetra(bromomethyl)benzene, and a bis-cyclization reac-

[2]This design strategy has been employed by others towards the goal of ditopic macrocycle synthesis. Lee et al. reported the synthesis of a very similar group of oxo crown ethers. These authors incorporated an aromatic fragment between two polyether chains containing four, five and six oxygen donors and controlled the regioselectivity of the cyclization via the choice of alkaline base (10).

7 (X = OEt, E = O)

tion has the potential to produce any combination of *ortho*, *meta*, or *para* substituted cyclization products. Herein, we describe (*i*) our initial attempts to effect control over the cyclization reaction in order to exclusively produce **1** and (*ii*) the synthesis and single crystal X-ray structures of **1** and **7**.

Experimental section

General

Compound **1** was prepared as described previously (5). 1,2,4,5-Tetra(bromomethyl)benzene, 3-thiapentane-1,5-dithiol, 3-oxapentane-1,5-dithiol, cesium carbonate, duroquinone, $NaBH_4$, bromoethane, *N*-bromosuccinamide, benzoyl peroxide, and all deuterated solvents were purchased from Aldrich and used as received. All reactions were conducted under an atmosphere of N_2(g) using standard Schlenk techniques and all solvents were degassed prior to use. ^1H and $^{13}C\{^1H\}$ were recorded at 300.1 and 75.4 MHz, respectively, on a Brüker AC300 spectrometer locked to the deuterated solvent. Elemental analyses were performed by Canadian Microanalytical Services, Delta, British Columbia.

Preparation of 3,6-bis(ethoxy)-1,2,4,5-tetramethylbenzene, 2

$NaBH_4$ (5.980 g, 158 mmol) was suspended in anhydrous ethanol (120 mL). To this suspension was added dropwise, a solution of duroquinone (5.910 g, 36.0 mmol) in anhydrous ethanol (75 mL). This mixture allowed to stir for 12 h. Deionized water (150 mL) and two drops of concentrated HCl(aq) were then added and the solution stored for 12 h at −5°C resulting in the precipitation of durohydroquinone as a white fluffy solid. Yield: 5.42 g (94%). ^1H NMR ($CDCl_3$): δ (ppm) 4.20 (s, 2H, OH), 2.15 (s, 12H, CH_3). Na metal (1.58 g, 68.7 mmol) was dissolved in anhydrous ethanol (300 mL). The durohydroquinone, as prepared above (5.192 g, 31.2 mmol), was then added to this solution and the purple mixture warmed to 50°C for 2 h. Bromoethane (6.808 g, 62.5 mmol) was then slowly syringed into this reaction mixture and the ethanolic solution brought to reflux for 4 h. The ethanol was removed in vacuo and the residue treated with 0.1 M NaOH(aq) (100 mL). The NaOH solution was decanted and the residue dissolved in diethyl ether (100 mL) and extracted with deionized water (100 mL). The diethyl ether layer was then separated, dried over anhydrous $MgSO_4$ and the solvent removed in vacuo. The resulting yellow residue was then dissolved in a minimum volume of anhydrous ethanol and stored at −5°C for 24 h. The product precipitated as a white solid which was filtered and collected. The ethanol solution was then concentrated and again stored at −5°C resulting in the further precipitation of white solid which was filtered, dried, and combined with the first precipitate. Yield: 5.13 g (74%). ^1H NMR ($CDCl_3$): δ (ppm) 3.70 (q, 4H, OCH_2), 2.14 (s, 12H, $ArCH_3$), 1.38 (t, 6H, CH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ (ppm) 151.76 (ArO), 127.62 (ArMe), 68.30 (CH_2), 15.60 ($ArCH_3$), 12.88 (CH_3). Anal. calcd. for $C_{14}H_{22}O_2$: C 75.62, H 9.99; found: C 75.55, H 9.92.

Preparation of 1,2,4,5-tetra(bromomethyl)-3,6-bis(ethoxy)benzene, 3

2 (1.450 g, 6.52 mmol), *N*-bromosuccinamide (5.108 g, 28.7 mmol), and a catalytic amount of benzoyl peroxide were combined in CCl_4 (40 mL). This mixture was brought to reflux while irradiating with a UV lamp. After 2 h, the white solid which had originally been suspended in the solution was dissolved and a precipitate was observed floating on the surface of the CCl_4 solution, indicating conversion of NBS to succinamide. The mixture was filtered and the CCl_4 removed in vacuo. The residue was recrystallized from ethanol giving **3** as a white microcrystalline solid. Yield: 2.98 g (85%). ^1H NMR ($CDCl_3$): δ (ppm) 4.74 (s, 8H, CH_2Br), 4.20 (q, 4H, OCH_2), 1.52 (t, 6H, CH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ (ppm) 153.70 (C(Ar)—O), 133.15 (C(Ar)—Me), 70.89 (OCH_2), 23.27 (CH_2Br), 15.67 (CH_3). Anal. calcd. for $C_{14}H_{18}Br_4O_2$: C 31.26, H 3.38; found: C 31.19, H 3.33.

Preparation of 2,5,8,17,20,23-hexathia[9](1,3)[9](4,6)cyclophane, 4

A solution of 1,2,4,5-tetra(bromomethyl)benzene (7.558 g, 16.8 mmol) and 3-thiapentane-1,5-dithiol (7.55 g, 33.6 mmol) in DMF (400 mL) was added using a constant addition funnel to a stirred suspension of Cs_2CO_3 (12.01 g, 36.9 mmol) in DMF (900 mL) at 55°C over a period of 2 days. The DMF was removed in vacuo after completion of addition and the resulting orange residue extracted with CH_2Cl_2 (150 mL). The organic extract was filtered, washed with 0.1 M NaOH(aq) (2 × 100 mL), and dried over anhydrous $MgSO_4$. This fraction was concentrated to 50 mL and added dropwise to boiling absolute ethanol (300 mL) which was filtered while hot. The ethanol was then removed in vacuo and the resulting yellow residue dissolved in $CHCl_3$ (30 mL). Diffusion of *n*-hexane into this solution gave **4** as a microcrystalline white solid. Yield: 6.57 g (90%). mp 203–205°C. ^1H NMR ($CDCl_3$): δ (ppm) 7.03 (s, 2H, aromatic), 4.07 (s, 8H, benzylic), 2.20–2.50 (m, 16H, SCH_2CH_2S). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ (ppm) 135.33, 134.94 (aromatic), 32.67 (benzylic), 32.08, 30.84 (SCH_2CH_2S). Anal. calcd. for $C_{18}H_{26}S_6$: C49.71, H 6.04; found: C 49.80, H 5.99.

Preparation of 5,20-dioxa-2,8,17,23-tetrathia[9](1,3)[9](4,6)cyclophane, 5

1,2,4,5-Tetra(bromomethyl)benzene (2.164 g, 4.81 mmol) and 3-oxapentane-1,5-dithiol (1.370 g, 9.62 mmol) were dissolved in DMF (150 mL) and added, over 3 days, to a suspension of Cs_2CO_3 (6.89 g, 21.1 mmol) in DMF (800 mL) stirring at 55°C. Upon completion of addition, the DMF was removed in vacuo and the resulting yellowish residue dissolved in CH_2Cl_2 (100 mL) and filtered. The CH_2Cl_2 solution was washed with 0.1 M NaOH(aq) (2 × 100 mL) and deionized water (100 mL) then dried over anhydrous $MgSO_4$. The solvent was removed in vacuo and the ^1H NMR spectrum of this crude product mixture revealed the presence of three isomers in a 16:3:1 ratio. Recrystallization of the crude product from anhydrous ethanol yielded the major isomer, **5**, as a white microcrystalline solid. Yield 1.55 g (80%). ^1H NMR ($CDCl_3$): δ 7.44 (s, 2H, aromatic), 3.94 (s, 8H, benzylic), 3.05 (t, 8H, OCH_2), 2.47 (t, 8H, SCH_2). $^{13}C\{1H\}$ NMR ($CDCl_3$): δ 135.10, 133.68 (aromatic), 68.78 (OCH_2), 33.59 (benzylic), 29.19 (SCH_2). Anal. calcd. for $C_{18}H_{26}O_2S_4$: C 53.68, H 6.52; found: C 53.58, H 6.49. The minor products were assigned the structures of the *ortho* and *para* cyclization products based on the position of the aromatic singlet in the ^1H NMR ($CDCl_3$); *ortho* isomer δ 7.12 (s, 2H, aromatic) and *para* isomer δ 7.00 (s, 2H, aromatic).

Preparation of 2,5,8,17,20,23-hexathia[9](1,3)[9](4,6)-2,5-bis(ethoxy)cyclophane, 6

3-Thiapentane-1,5-dithiol (1.275 g, 8.26 mmol) and **3** (2.222 g, 4.13 mmol) were combined in DMF (150 mL) and added over 3 days, via constant addition funnel, to a suspension of Cs_2CO_3 (5.922 g, 18.1 mmol) in DMF (600 mL). Upon completion of addition, the DMF was removed in vacuo and the residue dissolved in CH_2Cl_2 (300 mL). The CH_2Cl_2 solution was washed with aqueous 0.1 M NaOH (2 × 100 mL) and deionized water (1 × 100 mL) then dried over anhydrous $MgSO_4$. The suspension was filtered and the CH_2Cl_2 solution evaporated slowly resulting in precipitation of the *meta* cyclization product, **6**, as a microcrystalline white solid. Yield: 1.94 g (90%); mp (dec) 245°C. ^1H NMR ($CDCl_3$): δ (ppm) 4.32 (d, 4H, benzylic), 4.09 (d, 4H, benzylic), 3.75 (q, 4H, OCH2), 2.71 (d of t, 4H, SCH_2), 2.56 (d of t, 4H, SCH_2), 2.24 (d of t, 4H, SCH_2), 1.99 (t, 6H, CH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ (ppm) 154.58 (C(Ar)—O), 130.48 (C(Ar)), 72.58 (OCH_2), 31.88, 30.74, 25.50 ($CH_2SCH_2CH_2S$), 15.47 (CH_3). Anal. calcd. for $C_{22}H_{34}O_2S_6$: C 50.52, H 6.57; found: C 50.48, H 6.52.

Preparation of 5,20-dioxa-2,8,17,23-tetrathia[9](1,3)[9](4,6)-2,5-bis(ethoxy)cyclophane, 7

3-Oxapentane-1,5-dithiol (0.250 g, 1.81 mmol) and **3** (0.487 g, 1.81 mmol) were dissolved in DMF (125 mL) and added over 2 days via slow addition funnel to a suspension of Cs_2CO_3 (1.297 g,

3.70 mmol) in DMF (500 mL). Upon completion of addition, the DMF was removed in vacuo and the residue dissolved in CH_2Cl_2 (200 mL). This solution was washed with aqueous 0.1 M NaOH (2 × 100 mL) and deionized water (1 × 100 mL) then dried over $MgSO_4$. The $MgSO_4$ was filtered off and the CH_2Cl_2 removed on the rotary evaporator. The yellowish residue was recrystallized from ethanol giving the *meta* cyclization product, 5,20-dioxa-2,8,17,23-tetrathia[9](1,3)[9](4,6)-2,5-bis(ethoxy)cyclophane, **7**, as a crystalline white solid. Yield: 0.378 g (85%); mp dec. 235°C. ^{1}H NMR ($CDCl_3$): δ (ppm) 4.32 (d, 4H, benzylic), 3.95 (d, 4H, benzylic), 3.77 (q, 4H, $PhOCH_2$), 3.37 (d of t, 4H, SCH_2CH_2O), 2.60 (m, 8H, SCH_2CH_2O), 2.24 (d of t, 4H, SCH_2CH_2O), 1.47 (t, 6H, CH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ (ppm) 154.45 (C(Ar)—O), 131.09 (C(Ar)), 72.54 ($PhOCH_2$), 67.91 (CH_2OCH_2), 27.37, 26.06 (CH_2SCH_2), 15.50 (CH_3). Anal. calcd. for $C_{22}H_{34}O_4S_4$: C 53.83, H 7.00; found: C 53.78, H 7.00.

General X-ray crystallography

Diffraction experiments were performed on a four-circle Rigaku AFC6S diffractometer with graphite monochromatized Mo Kα radiation. The unit cell constants and orientation matrices for data collection were obtained from 20 centred reflections ($15° < 2\theta < 35°$). Instrument parameters, crystal data, and data collection parameters are summarized in Table 1. The intensities of three standard reflections were recorded every 150 reflections and showed no statistically significant changes over the duration of the data collections. The intensity data were collected using the ω–2θ scan technique, in four shells ($2\theta < 30$, 40, 45, and 50°). Empirical absorption coefficients were small and thus, no absorption corrections were applied to the data. The data were processed using the TEXSAN software package running on a VAX 3520 computer (18). Refinements were carried out by using full-matrix least-squares techniques on *F* by minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = 1/\sigma^2(F_o)$ and F_o and F_c are the observed and calculated structure factors. Atomic scattering factors (19) and anomalous dispersion terms (20, 21) were taken from the usual sources. Fixed H-atom contributions were included with C—H distances of 0.95 Å and thermal parameters 1.2 times the isotropic thermal parameter of the bonded C atoms. No H atoms were refined, but all values were updated as refinement continued.

X-ray structure determination of ***1***

Colourless crystals of **1** were grown by diffusion of *n*-hexane into a chloroform solution of the compound. Initial cell symmetries indicated a primitive triclinic cell which was checked by a cell reduction routine (18). A statistical analysis of intensity distributions was consistent with the centrosymmetric space group $P\bar{1}$ and this was confirmed by a successful solution refinement. A total of 1809 reflections were collected and 1020 unique reflections with $F_o^2 > 3\sigma(F_o^2)$ were used in the refinement. The positions of the sulphur atoms were determined by direct methods (SHELX86) (18) from the *E*-map with highest figure of merit. The remaining carbon atoms were located from a single difference Fourier map calculation. In the final cycles of refinement all non-hydrogen atoms were assigned anisotropic thermal parameters. This resulted in $R = 0.0648$ and $R_w = 0.0713$ at final convergence. A goodness-of-fit calculation resulted in a value of 2.095. The Δ/σ value for any parameter in the final cycle was less than 0.01. A final difference Fourier map calculation showed no peaks of chemical significance; the largest being 0.666 electrons/Å^3, which was associated with C(6). Atomic positional parameters and selected bonding parameters are summarized in Tables 2 and 3. Thermal parameters, hydrogen atom parameters and a listing of $10|F_o|$ vs. $10|F_c|$ are deposited as supplementary material in Tables S-1, S-2, and S-5.[3]

[3]Supplementary Tables S-1 through S-4 may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Tables of hydrogen atom parameters for 1 and 7 have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge, Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K. 778.

X-ray structure determination of **7**

Colourless crystals of **7** were grown by slow evaporation of a chloroform solution of the compound. Initial cell symmetries indicated a primitive triclinic cell which was checked by a cell reduction routine (18). A statistical analysis of intensity distribution was consistent with the centrosymmetric space group $P\bar{1}$ and this was confirmed by a successful solution refinement. A total of 2267 reflections were collected and 1129 unique reflections with $F_o^2 > 3\sigma(F_o^2)$ were used in the refinement. The positions of the sulphur atoms were determined by direct methods (MITHRIL) (18) from the E-map with highest figure of merit. The remaining oxygen and carbon atoms were located from a series of difference Fourier map calculations. In the final cycles of refinement, all non-hydrogen atoms were assigned anisotropic thermal parameters. This resulted in $R = 0.0386$ and $R_w = 0.0420$ at final convergence. A goodness-of-fit calculation resulted in a value of 1.652. The Δ/σ value for any parameter in the final cycle was less than 0.01. A final difference Fourier map calculation showed no peaks of chemical significance; the largest being 0.291 electrons/Å^3, which was associated with the methyl carbon, C(5). Atomic positional parameters and selected bonding parameters are summarized in Tables 4 and 5. Thermal parameters, hydrogen atom parameters, and a listing of $10|F_o|$ vs. $10|F_c|$ are deposited as supplementary material in Tables S-3, S-4, and S-6.[3]

Results and discussion

The reaction of two equivalents of 3-thiapentane-1,5-dithiol with one equivalent of 1,2,4,5-tetra(bromomethyl)benzene, employing Kellogg's Cs^+-mediated cyclization method for the synthesis of macrocyclic thioethers (22), yields the bis-*meta* cyclization product, **4**, in a yield of 90%. No other cyclization products were isolated from this reaction nor observed in the ^{1}H NMR spectrum of the reaction mixture. Compound **1** could only be prepared employing a metal template method devised by Sellmann and Zapf (23) for the synthesis of 1,4,7-trithiacyclononane (9S3). This synthetic route relies on coordination of the $[SCH_2CH_2SCH_2CH_2S]^{2-}$ thiolate to Mo(0) to obtain the desired regioselectivity for bis(*ortho*) cyclization. Thus, the "$Mo(CO)_3$" templated cyclization of two equivalents of 3-thiapentane-1,5-dithiol with one equivalent of 1,2,4,5-tetra(bromomethyl)benzene proceeds in a bis-*ortho* fashion to give **1** in 20% isolated yield (5). We have previously reported this synthesis of **1** and the X-ray structures of complexes *anti*-$[Cu_2(PPh_2Me)_2(\mathbf{1})]$ $[ClO_4]_2$, *anti*-$[Ag_2(PPh_3)_2(\mathbf{1})][BF_4]_2$ and *syn*-$[Cu_2(\mu\text{-}Ph_2PCH_2CH_2PPh_2)(\mathbf{1})][PF_6]_2$ (5). For binuclear coordination and eventual activation of a single substrate, the *syn*-conformation of **1** is required so that both metal ions are bonded on the same side of the aromatic ring. Complexes of compound **1**, however, showed a tendency to adopt an *anti* conformation in the absence of a bridging ligand.

This work describes our initial investigation into the regioselectivity of this particular cyclization reaction with focus on finding a way to: (*i*) circumvent the template route for the preparation of bis(*ortho*) products and (*ii*) favour a *syn* conformation for these compounds. The first approach taken was to change the nature of the central donor atom of the tridentate chain from sulphur to oxygen. The rationale for this strategy was that since the donor atoms in oxa crown ethers preferentially adopt endodentate orientations (24, 25) this would decrease the strain associated with the $SCH_2CH_2XCH_2CH_2S$ bracket in an *ortho*-xylyl product. The resulting macrocycle, which would contain two S_2O donor sets, would still possess sufficient soft-acid character for coordination to transition metals (8, 9, 17).

The results of the cyclization of two equivalents of 3-oxapentane-1,5-dithiol and one equivalent of 1,2,4,5-tetra(bromomethyl)benzene revealed that the regioselectivity of the bis-cyclizations was altered slightly. A comparison of the aromatic resonances in the ^{1}H NMR spectrum of the crude product mixture to that of the respective monomeric analogs and integration of the aromatic region showed the yields of the three possible isomers to be 80, 15, and 5% for the *meta*, *ortho*, and *para* cyclization products, respectively. The *meta*-isomer, **5**, could be isolated in pure form by repeated, fractional crystallization, but

only small, contaminated samples of the *ortho* and *para* compounds have been obtained to date.

The second approach taken to alter the regioselectivity of the bis-cyclization reaction was to functionalize the vacant sites of the central durene fragment with an ethoxy group. It was hoped that since the substitution site would be "inside the ring" of a *meta*-isomer that these derivatives would offer some steric hindrance to the cyclization proceeding in a *meta* fashion. Thus, compound **2** was prepared from durohydroquinone by a Williamson ether synthesis with bromoethane and then brominated using NBS to yield **3**. The bis-cyclization reactions then proceeded, employing Kellogg's method, between two equivalents of either 3-thiapentane-1,5-dithiol or 3-oxapentane-1,5-dithiol and one equivalent of **3**. The ^{1}H NMR spectra of the product mixtures revealed that the ethoxy group has almost no effect on the regioselectivity of the cyclization. In the case of the all sulphur compound, only the *meta*-isomer **6** was produced and for the oxygen-containing products the product distribution was essentially identical to that observed in the absence of the ethoxy group. The *meta*-isomer, **7**, was isolated and the regiochemistry of this product confirmed by single crystal X-ray structure determination.

Compound **1** was crystallized by diffusion of *n*-hexane into a $CHCl_3$ solution of the compound. A perspective ORTEP drawing of **1** with the atom numbering scheme is shown in Fig. 1. The ditopic macrocycle, **1**, crystallizes with one molecule per unit cell such that the molecule resides on a crystallographic centre of symmetry. Figure 1 illustrates the compartmentalization of the S_6 donor set into two distinct S_3 sets while Fig. 2 shows the orientation of the two chelating rings with respect to one another and the aromatic ring. Clearly, the ligand adopts an *anti* conformation that places the aliphatic chains on opposite sides of the aromatic ring. The conformation of the $SCH_2CH_2SCH_2CH_2S$ linkages is very similar to that found for this same feature in the X-ray structure of TT[9]OC (11). The S—C—C—S torsional angles are 155.3(5) and 173.0(3)° and the C—C—S—C torsional angles are 80.5(7), 85.8(7), 77.9(7), and 71.9(7)°. The dihedral angle between the aromatic ring and

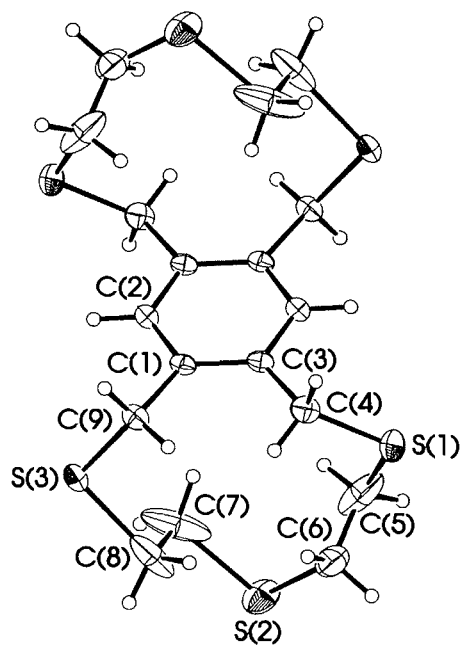

FIG. 1. Perspective ORTEP drawing of **1** showing the atom-numbering scheme. Thermal ellipsoids of 30% are shown.

the plane defined by the three sulphur atoms on one side of the ligand is 96.2°.

Crystals of **7** were grown by slow evaporation of a chloroform solution of the compound. Perspective ORTEP drawings of **7** are shown in Figs. 3 and 4. The macrocycle **7** crystallizes with one molecule per unit cell. The view of the structure shown in Fig. 3 confirms that the cyclization of the bis(ethoxy) substituted durene derivative does indeed proceed in a *meta* fashion and that the ethoxy group does not provide sufficient steric bulk to direct the cyclization otherwise. The ethoxy group simply folds out of the way of the tridentate donor chain enabling the cyclization to proceed relatively unimpeded. This molecule sits on a crystallographically imposed centre of sym-

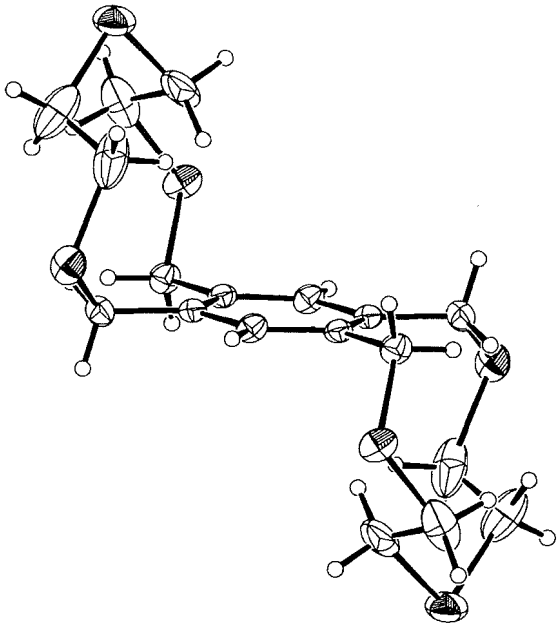

FIG. 2. Perspective ORTEP drawing of **1** showing an alternate view emphasizing the relative orientation of the aliphatic thioether chains.

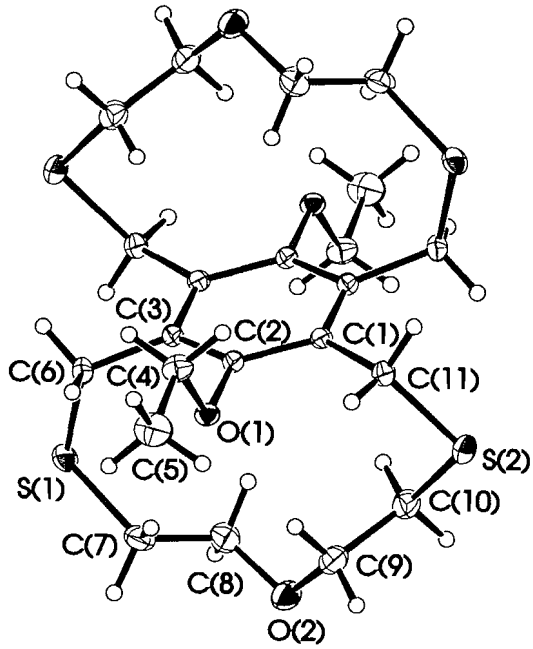

FIG. 3. Perspective ORTEP drawing of **7** showing the atom-numbering scheme. Thermal ellipsoids of 30% are shown.

metry. This molecule also adopts an *anti* conformation that places, not only the aliphatic chains, but also the ethoxy groups on opposite sides of the aromatic ring as shown in Fig. 4. The S—C—C—O torsional angles are 175.4(3) and 174.1(3)°, the C—C—O—C torsional angles are 81.0(6) and 83.6(6)° and the C—S—C—C torsion angles are 66.9(4) and 96.7(4)°. The dihedral angle defined by the aromatic ring and the three donor atoms on one side of the macrocycle is 76.1°.

It was noted during the isolation of macrocycles **6** and **7** that they possessed substantially lower solubility in solvents ($CHCl_3$, CH_2Cl_2, benzene) in which their non-functionalized analogs, **4** and **5** displayed very good solubility. Intuitively, this

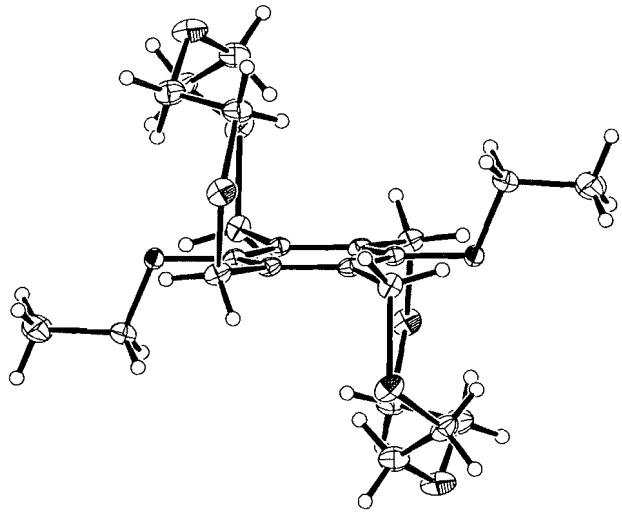

FIG. 4. Perspective ORTEP drawing of **7** showing an alternate view emphasizing the relative orientation of the aliphatic oxythioether chains and the ethoxy groups.

difference in solubility seemed too great to be accounted for strictly on the basis of the addition of two ethoxy groups. The principal cause of the reduced solubility was the greatly increased rigidity of the macrocycles as the effect of the ethoxy substitution was to confine the nine-membered, aliphatic chain to one side of the molecule. For compounds **4** and **5**, the ^1H NMR spectra show an AA′BB′ pattern with second order effects for the ethylene region and a single resonance for the benzylic protons due to rapid inversion at the sulphur atoms. For compounds **5** and **6**, the second order effects are removed for the AA′BB′ pattern and the benzylic protons are a pair of doublets consistent with a lack of inversion at sulphur and the chelate chain being restricted to one side of the molecule (26). Although both *syn* and *anti* isomers are possible, it is very likely that the *anti* isomer observed in the solid state is the "locked conformation" in solution.

The results of this study indicate the overwhelming preference of the $SCH_2CH_2XCH_2CH_2S$ (X = S, O) chelate chain to cyclize in a *meta* fashion for xylyl-based thioethers. From molecular modeling studies it was determined that an even bulkier alkoxy group would likely not provide a sufficient barrier to *meta* cyclization. In order for the functionality to serve as a more considerable barrier more bulk at the α-position to the central aromatic ring would be required. Interestingly, a similar reaction between two equivalents of the propylene-linked dithiol, 4-thiaheptane-1,7-dithiol, and one equivalent of 1,2,4,5-tetra(bromomethyl)benzene proceeds to give exclusively the bis-*ortho* cyclization product in ca. 60% yield. A study of the regioselectivities of these bis-cyclizations base on the length of the thioether chain was the subject of a previous publication (6). These investigations add to the body of information that will hopefully lead to control of the regioselectivity of thiacyclophane formation and produce desired ditopic ligands, such as **1**, for application in transition metal coordination chemistry.

Received February 7, 1994

WOLFGANG KLIEGEL, DIERK NANNINGA, ULF RIEBE, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **72**, 1735 (1994).

Oxime diarylborinates, **4**, were obtained from several aliphatic and aromatic aldoximes as well as from cyclic ketoximes by acylation with a diarylborinic acid or anhydride (R_2B-X, R = aryl, X = OH or OBR_2). Compounds **4** could also be synthesized by condensation of an (aminoxy)-diarylborane, which supposedly has a cyclodimeric BONBON structure, with an aldehyde or with a ketone. Crystals of 3,3,6,6-tetrakis(4-methoxyphenyl)-2,5-diethylidene-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, **4***b*, are monoclinic, a = 7.9182(9), b = 19.7582(9), c = 9.6779(8) Å, β = 91.598(8)°, Z = 2, space group $P2_1/n$. The structure was solved by direct methods and refined by full-matrix least-squares procedures to R = 0.033 and R_w = 0.034 for 2344 reflections with $I \geq 3\sigma(F^2)$. A dimeric structure featuring a central six-membered BONBON ring has been established for the oxime diarylborinate **4***b*. This represents the first structurally characterized example of a monocyclic BONBON ring.

WOLFGANG KLIEGEL, DIERK NANNINGA, ULF RIEBE, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **72**, 1735 (1994).

On a préparé les diarylborinates d'oximes, **4**, en procédant à l'acylation de plusieurs aldoximes aliphatiques et aromatiques ainsi que diverses cétoximes cycliques à l'aide d'un acide ou d'un anhydride diarylborinique (R_2B-X, R = aryle, X = OH ou OBR_2). On peut aussi synthétiser les composés **4** par condensation d'un (aminoxy)-diarylborane, qui possèderait une structure cyclodimère BONBON, avec un aldéhyde ou une cétone. Les cristaux du 3,3,6,6-tétrakis(4-méthoxyphényl)-2,5-diéthyléne-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, **4***b*, sont monocliniques, groupe d'espace $P2_1/n$, avec a = 7,9182(9), b = 19,7582(9) et c = 9,6779(8) Å, β = 91,598(8)° et Z = 2. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de R = 0,033 et R_w = 0,034 pour 2344 réflexions avec $I \geq 3\sigma(F^2)$. On a déterminé que, pour le composé **4***b*, il s'agit d'une structure dimère comportant un cycle central BONBON à six chaînons. Ceci correspond au premier exemple caractérisé d'un cycle BONBON monocyclique.

[Traduit par la rédaction]

Introduction

Over 100 years ago Beckmann (1) proposed the formation of oxime dimers in inert solvents. The dimerization of **1** was later recognized as a consequence of cyclic stabilization by O—H···N hydrogen bonding in associates like **2** (2). Six-membered dimers of the general formula **2** were also found in the solid state by X-ray crystallographic analyses of various oximes (3) and were further characterized (4) by ab initio calculations of the most simple example, formaldoxime (**2**, $R^1 = R^2$ = H), along with a neutron diffraction study of glyoxime at 9 K. It is known that iminoxyboranes **3**, which can be envisaged as borinic acid esters of oximes, are able to dimerize in an equilibrium reaction to the six-membered BONBON ring compounds **4** if steric and electronic conditions allow the formation of a twofold Lewis acid–base adduct (5–9).[2] Formally, in the cyclic dimer **4** both of the "chelated" protons in **2** are replaced by borenium ions (R_2B^+), in accordance with the concept of the chelation of "pseudometal" cations (10). In the solid state, the complete association of **3** should allow a structural characterization of the dimeric form **4** by X-ray crystallographic analysis. To the best of our knowledge, no structure analysis of a type **4** compound has been published to date with the exception of a preliminary report of some crystallographic data (without any details on the molecular structure) for the acetonoxime derivative **4** ($R = R^1 = R^2$ = Me) (5). In the course of our structural investigations of the BONBON ring systems only *B*-monoaryl derivatives (boronates) have been characterized thus far, the BONBON ring being part of a polycyclic skeleton in all reported cases (11).

To provide an example of a type **4** compound suitable for X-ray analysis we synthesized a series of oxime diarylborinates **3**/**4** (R = aryl). The reaction product from (dimethylamino)-diphenylborane and acetone oxime has been described in the literature (8) as the dimeric diphenylborinate **4** (R = Ph, $R^1 = R^2$ = Me). Using diarylborinic acid or the respective anhydride we did not succeed in preparing the acetone oxime derivative (12). We did, however, obtain the desired diarylborinates from several aliphatic and aromatic aldoximes (**4***a–j*) as well as from cyclic ketoximes (**4***k* and **4***l*) by acylation with a diarylborinic acid or anhydride (R_2B-X, R = aryl, X = OH or OBR_2). Compounds **4** could also be synthesized by condensation of an (aminoxy)-diarylborane, which supposedly has a cyclodimeric BONBON structure **5** (13), with an aldehyde leading to **4***b* or with a ketone leading to **4***k* and **4***l*, for example. Evidence for the cyclodimeric structure **4** comes from the ^{11}B nmr spectra, which show signals between $\delta(Et_2OBF_3)$ = 6.5 and 8.0 ppm, indicative

[1]Previous paper in this series: ref. 24.

[2](Ethylideniminoxy)-diethylborane, mp 79–81°C, was originally reported as a monomer (**3**, R = Et, R^1 = Me, R^2 = H) (6). The ^{11}B nmr signal at δ = 7.34 ppm, however, as already mentioned in the literature (7), contradicts a monomeric structure and supports that of a dimer of the type **4**.

of the presence of tetracoordinate boron even in solution (14), and also from the solid state infrared spectra of the diphenylborinate derivatives, which display substantially weakened ν_{16} phenyl ring stretching vibrations at 1600 cm^{-1}, also consistent with tetracoordination at the phenylboron centres (11, 15). The C=N absorption bands between 1635 and 1662 cm^{-1} are not distinctly different from those of free oximes and thus give no hints about cycloadduct formation. The ^1H nmr spectra, as well, provide no evidence supporting the structure **4**. In both the EI and CI mass spectra of several examples, the highest mass feature with prominent abundance is the molecular ion of the monomer **3**, reminiscent of similar dissociations of BONBON dimers in the gas phase reported for oxime borinates (5, 7, 8, 11). The highest quality crystals were obtained by recrystallization of the dianisylborinate of acetaldoxime, **4***b*, which was characterized by an X-ray analysis to provide unambiguous proof of the cyclodimeric BONBON structure **4**.

Experimental

General procedures for the synthesis of dimeric (alkylideniminoxy)-diarylboranes, 4

Method A

Diarylborinic acid (R_2BX, R = aryl, X = OH, 2 mmol) or oxybis(diarylborane) (R_2BX, R = aryl, X = OBR_2, 1 mmol) and an oxime (2 mmol) are dissolved in 10 mL of ethanol and heated rapidly to a boil. Crystallization occurs spontaneously or upon cooling and (or) partial evaporation. Recrystallization is carried out from the solvent specified in each case.

Method B

2-(Diarylboryloxy)ethylamine (R_2BX, R = aryl, X = $OCH_2CH_2NH_2$, 5 mmol) is dissolved in 20 mL of aqueous sulfuric acid (25%) under stirring until complete dissolution, and then extracted with 4 × 50 mL of ether. The collected ether extracts are washed out with 3 × 10 mL of water, dried with Na_2SO_4, and the solvent is distilled off in vacuo. The residue (oily or solid) is dissolved in 20 mL of ethanol and mixed with a solution of an oxime (5 mmol) in 20 mL of ethanol. After rapid heating to boiling temperature the solution is cooled down, and if necessary partially evaporated, to induce crystallization.

Method C

3,3,6,6-Tetraaryl-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane (**5**, R = aryl, 1 mmol) and an aldehyde or ketone (1 mmol) are heated in 30 mL of benzene under reflux for 30 min with continuous removal of water using a Dean–Stark trap. Partial evaporation and cooling of the solution yields crystals, which are washed, if necessary, with cold ethanol.

Method D

3,3,6,6-Tetraaryl-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane (**5**, R = aryl, 1 mmol) is dissolved in 10 mL of absolute ethanol with slight heating and mixed with an aldehyde or ketone (2 mmol). After 15 min of refluxing the solution is partially evaporated and, if necessary, cooled down to induce crystallization.

All compounds of type **4** give a deep blue color reaction with diphenylcarbazone in methanolic solution, indicating the presence of diarylboron moieties (16).

*3,3,6,6-Tetraphenyl-2,5-diethylidene-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, 4*a

From oxybis(diphenylborane) and acetaldoxime (method A). Yield: 95%, colorless crystals, mp (dec.) 239–241°C (from benzene/diethyl ether). Infrared (KBr): 1665 cm^{-1} (C=N). EI mass spectrum (70 eV, 200°C), *m/z*: 223 (42%, 1/2 M^+), 222 (22%), 208 (48%), 181 (28%, Ph_2BO), 165 (34%, Ph_2B), 164 (12%), 163 (12%), 154 (6%), 153 (10%), 146 (4%, 1/2 $M^+ - C_6H_5$), 119 (14%), 105 (38%, PhBOH), 104 (24%, PhBO), 89 (8%), 77 (100%, C_6H_5). Anal. calcd. for $C_{28}H_{28}B_2N_2O_2$: C 75.38, H 6.33, B 4.85, N 6.28; found: C 75.37, H 6.38, B 4.88, N 6.27.

*3,3,6,6-Tetrakis(4-methoxyphenyl)-2,5-diethylidene-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, 4*b

From 2-[bis(4-methoxyphenyl)boryloxy]ethylamine (17) and acetaldehyde oxime (method B). Yield: 73%. From 3,3,6,6-tetrakis(4-methoxyphenyl)-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane (**5**, R = $4\text{-}CH_3OC_6H_4$) (see below for preparation) and freshly distilled acetaldehyde (method C). Yield: 36%. Colorless crystals, mp (dec.) 195°C (from ethanol), 201–202°C (from CH_2Cl_2 – petroleum ether). Infrared (KBr): 1662 cm^{-1} (C=N); ^1H nmr (400 MHz, $CDCl_3$/TMS), δ (ppm): 2.10 (d, J = 6 Hz, 2 =C-CH_3), 3.79 (s, 4 OCH_3), 6.82 and 7.21 (d and d, AA′BB′, 16 aromatic H), 7.00 (q, J = 6 Hz, 2 N=CH); ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$), δ (ppm): 7.8 ($w_{1/2}$ = 385 Hz). EI mass spectrum (70 eV, 120°C), *m/z*: 283 (100%, 1/2 M^+), 241 (64%, $OB(C_6H_4OCH_3)_2$), 225 (48%, $B(C_6H_4OCH_3)_2$), 183 (6%), 160 (10%), 149 (26%), 135 (14%), 119 (10%), 107 (18%, $C_6H_4OCH_3$), 92 (24%, C_6H_4O), 77 (30%, $C_6H_4OCH_3 - CH_2O$). Anal. calcd. for $C_{32}H_{36}B_2N_2O_6$: C 67.87, H 6.41, B 3.82, N 4.95; found: C 67.86, H 6.42, B 3.83, N 4.75.

Crystals suitable for X-ray crystallography were obtained by slow evaporation of a solution of **4***b* in CH_2Cl_2 – petroleum ether at room temperature.

3,3,6,6-Tetrakis(4-fluorophenyl)-2,5-diethylidene-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, ***4****c*

From 2-[bis(4-fluorophenyl)boryloxy]ethylamine (18) and acetaldehyde oxime (method B). Yield: 68%, colorless crystals, mp (dec.) 216–217°C (from ethanol). Infrared (KBr): 1663 cm^{-1} (C=N); ^1H nmr (400 MHz, $CDCl_3$/TMS), δ (ppm): 2.14 (d, J = 6 Hz, 2 CH_3), 6.93–7.02 (m, 8 aromatic H + 2 N=CH), 7.18–7.26 (m, 8 aromatic H). EI mass spectrum (70 eV, 90°C), *m/z*: 259 (100%, 1/2 M^+), 244 (96%, $(OBC_6H_4F)_2$), 217 (62%, $OB(C_6H_4F)_2$), 201 (76%, $B(C_6H_4F)_2$), 170 (10%), 151 (10%), 148 (18%), 137 (15%), 123 (66%, $HOBC_6H_4F$), 107 (14%), 95 (95%, C_6H_4F), 75 (38%). Anal. calcd. for $C_{28}H_{24}B_2F_4N_2O_2$: C 64.91, H 4.67, B 4.17, N 5.41; found: C 64.90, H 4.64, B 3.95, N 5.28.

3,3,6,6-Tetrakis(4-chlorophenyl)-2,5-diethylidene-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, ***4****d*

From 2-[bis(4-chlorophenyl)boryloxy]ethylamine (17) and acetaldehyde oxime (method B). Yield: 55%, colorless crystals, mp (dec.) 209–211°C (from ethanol). Infrared (KBr): 1660 cm^{-1} (C=N); ^1H nmr (400 MHz, $CDCl_3$/TMS), δ (ppm): 2.14 (d, J = 6 Hz, 2 CH_3), 7.00 (q, J = 6 Hz, 2 N=CH), 7.16 and 7.24 (d and d, AA′BB′, 16 aromatic H). EI mass spectrum (70 eV, 130°C), *m/z*: 414/416 (16/14%, $(OBC_6H_4Cl)_3$), 291/293 (92/60%, 1/2 M^+), 276/278 (94/64%, $(OBC_6H_4Cl)_2$), 249/251 (54/36%, $OB(C_6H_4Cl)_2$), 233/235 (47/30%, $B(C_6H_4Cl)_2$), 164 (24%), 153 (36%), 139 (76%, $HOBC_6H_4Cl$), 111 (100%, C_6H_4Cl), 75/77 (60/35%). Anal. calcd. for $C_{28}H_{24}B_2Cl_4N_2O_2$: C 57.59, H 4.14, B 3.70, Cl 24.29, N 4.80; found: C 57.33, H 4.14, B 3.62, Cl 24.92, N 4.61.

3,3,6,6-Tetraphenyl-2,5-dipropylidene-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, ***4****e*

From oxybis(diphenylborane) and propionaldehyde oxime (method A). Yield: 90%, colorless crystals, mp (dec.) 215–216°C (from ethanol). Infrared (KBr): 1660 cm^{-1} (C=N); ^1H nmr (90 MHz, $CDCl_3$/TMS), δ (ppm): 0.97 (t, J = 6 Hz, 2 CH_3), 2.66 (m, 2 $-CH_2-$), 6.87 (t, J = 6 Hz, N=CH), 7.24–7.28 (m, 20 aromatic H); ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$), δ (ppm): 7.8 ($w_{1/2}$ = 425 Hz). Anal. calcd. for $C_{30}H_{32}B_2N_2O_2$: C 75.98, H 6.80, N 5.91; found: C 76.15, H 6.79, N 5.87.

3,3,6,6-Tetraphenyl-2,5-dibutylidene-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, ***4****f*

From oxybis(diphenylborane) and butyraldehyde oxime (method A). Yield: 92%, colorless crystals, mp (dec.) 199–200°C (from ethanol). Infrared (KBr): 1660 cm^{-1} (C=N); ^1H nmr (90 MHz, $CDCl_3$/TMS), δ (ppm): 0.84 (t, J = 7 Hz, 2 CH_3), 1.36 (m, 2 CH_2CH_3), 2.61 (m, 2 N=CH-CH_2), 6.88 (t, J = 6 Hz, N=CH), 7.21–7.36 (m, 20 aromatic H); ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$), δ (ppm): 7.6 ($w_{1/2}$ = 385 Hz). Anal. calcd. for $C_{32}H_{36}B_2N_2O_2$: C 76.52, H 7.22, B 4.30, N 5.58; found: C 76.43, H 7.14, B 4.08, N 5.53.

3,3,6,6-Tetraphenyl-2,5-diisobutylidene-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, ***4****g*

From oxybis(diphenylborane) and isobutyraldehyde oxime (method A). Yield: 98%, colorless crystals, mp (dec.) 206-208°C (from ethanol). Infrared (KBr): 1655 cm^{-1} (C=N); ^1H nmr (90 MHz, $CDCl_3$/TMS), δ (ppm): 0.92 (d, J = 7 Hz, 4 CH_3), 3.54 (m, 2 N=CH-CH_2), 6.65 (d, J = 9 Hz, 2 N=CH), 7.22–7.36 (m, 20 aromatic H); ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$), δ (ppm): 6.94 ($w_{1/2}$ = 340 Hz). EI mass spectrum (70 eV, 120°C), *m/z*: 251 (65%, 1/2 M^+), 208 (100%, 1/2 $M^+ - C_3H_7$), 181 (72%, Ph_2BO), 165 (26%, Ph_2B), 105 (38%, PhBOH), 77 (66%, C_6H_5). Anal. calcd. for $C_{32}H_{36}B_2N_2O_2$: C 76.52, H 7.22, N 5.58; found: C 75.99, H 7.20, N 5.30.

3,3,6,6-Tetraphenyl-2,5-bis(2-ethylbutylidene)-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, ***4****h*

From oxybis(diphenylborane) and 2-ethylbutyraldehyde oxime (method A). Yield: 68%, colorless crystals, mp (dec.) 188–189°C (from ethanol – diethyl ether). Infrared (KBr): 1657 cm^{-1} (C=N); ^1H nmr (400 MHz, $CDCl_3$/TMS), δ (ppm): 0.69 (t, J = 7 Hz, 4 CH_3), 1.13 (sept, J = 7 Hz, 2 CH_2CH_3), 1.33 (sept, J = 7 Hz, 2 CH_2CH_3), 3.11 (sext, J = 9 Hz, 2 N=CH-C*H*) , 6.65 (d, J = 9 Hz, 2 N=CH), 7.21–7.58 (m, 20 aromatic H); ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$), δ (ppm): 8.0 ($w_{1/2}$ = 430 Hz). EI mass spectrum (70 eV, 110°C), *m/z*: 481 (3%, $M^+ - C_6H_5$), 447 (4%), 410 (24%), 312 (16%, $(PhBO)_3$), 306 (68%), 279 (100%, 1/2 M^+), 208 (54%, $(PhBO)_2$), 181 (53%, Ph_2BO), 165 (23%, Ph_2B), 146 (10%), 119 (16%), 105 (37%, PhBOH), 104 (22%, PhBO), 77 (36%, C_6H_5). Anal. calcd. for $C_{36}H_{44}B_2N_2O_2$: C 77.44, H 7.94, B 3.87, N 5.02; found: C 77.45, H 7.85, B 3.86, N 4.85.

3,3,6,6-Tetraphenyl-2,5-dibenzylidene-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, ***4****i*

From oxybis(diphenylborane) and benzaldehyde oxime (method A). Yield: 63%, colorless crystals, mp (dec.) 237–238°C (from tetrahydrofuran). Infrared (KBr): 1635 cm^{-1} (C=N). Poor solubility of the compound in appropriate solvents precluded nmr spectra. EI mass spectrum (70 eV, 190°C), *m/z*: 312 (9%, $(OBPh)_3$), 285 (38%, 1/2 M^+), 208 (80%, $(OBPh)_2$), 181 (40%, $OBPh_2$), 180 (46%), 165 (34%, BPh_2), 105 (26%, PhBOH), 104 (40%, PhBO), 97 (22%), 83 (20%), 77 (100%, C_6H_5). Anal. calcd. for $C_{38}H_{32}B_2N_2O_2$: C 80.03, H 5.66, B 3.79, N 4.91; found: C 79.79, H 5.79, B 3.69, N 4.46.

3,3,6,6-Tetrakis(4-methoxyphenyl)-2,5-dibenzylidene-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, ***4****j*

From bis(4-methoxyphenyl)borinic acid (17, 19) and (*Z*)-benzaldoxime (method A). Yield: 44%, colorless crystals, mp (dec.) 212–215°C (from ethanol). Infrared (KBr): 1635 cm^{-1} (C=N); ^1H nmr (400 MHz, d_6-DMSO/TMS), δ (ppm): 3.80 (s, 4 CH_3), 6.97 and 7.67 (d and d, AA′BB′, 16 aromatic H), 7.40–7.46 (m, 6 aromatic H + 2 N=CH), 7.94–7.99 (m, 4 aromatic H). CI mass spectrum (iso-butane, pos. mode, 120°C), *m/z*: 345 (18%, 1/2 M^+), 331 (60%, $M^+ - CH_2$), 303 (16%), 271 (22%), 242 (50%), 183 (27%), 169 (39%), 141 (21%), 122 (100%), 104 (40%), 78 (22%), 77 (20%). Anal. calcd. for $C_{42}H_{40}B_2N_2O_6$: C 73.07, H 5.84, B 3.13, N 4.06; found: C 72.57, H 5.84, B 3.16, N 4.08.

3,3,6,6-Tetraphenyl-2,5-dicyclopentylidene-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, ***4****k*

From oxybis(diphenylborane) and cyclopentanone oxime (method A). Yield: 89%. From 3,3,6,6-tetraphenyl-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane (13) and cyclopentanone (method D). Yield: 63%. Colorless crystals, mp (dec.) 199–200°C (from ethanol). Infrared (KBr): 1661 cm^{-1} (C=N); ^1H nmr (400 MHz, $CDCl_3$/TMS), δ (ppm): 1.47 and 1.58 (quint and quint, J = 7 Hz, 2 C-CH_2-CH_2-C), 1.65 and 2.85 (t and t, J = 7 Hz, 2 N=C(CH_2)$_2$), 7.14–7.22 (m, 20 aromatic H); ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$), δ (ppm): 6.5 ($w_{1/2}$ = 470 Hz). EI mass spectrum (70 eV, 70°C), *m/z*: 263 (66%, 1/2 M^+), 234 (48%), 221 (16%), 181 (70%, $OBPh_2$), 159 (43%), 130 (26%), 105 (60%, PhBOH), 77 (100%, C_6H_5). Anal. calcd. for $C_{34}H_{36}B_2N_2O_2$: C 77.59, H 6.89, B 4.11, N 5.32; found: C 77.72, H 6.90, B 4.16, N 5.24.

3,3,6,6-Tetraphenyl-2,5-dicyclohexylidene-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, ***4****l*

From oxybis(diphenylborane) and cyclohexanone oxime (method A). Yield: 68%. From 3,3,6,6-tetraphenyl-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane (13) and cyclohexanone (method D). Yield: 40%. Colorless crystals, mp (dec.) 178–179°C (from ethanol). Infrared (KBr): 1641 cm^{-1} (C=N). ^1H nmr (90 MHz, $CDCl_3$/TMS), δ (ppm): 0.70–1.12 (m, 4 C-C-CH_2-C-C), 1.15-1.70 (m, 2 N=C(CH_2CH_2)$_2$), 1.93 and 2.75 (t and t, J = 6 Hz, 2 N=C(CH_2CH_2)$_2$), 7.1 (m_c, 20 aromatic H); ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$), δ (ppm): 7.3 ($w_{1/2}$ = 430 Hz). EI mass spectrum (70 eV, 120°C), *m/z*: 277 (83%, 1/2 M^+), 234 (64%), 200 (25%), 181 (52%, $OBPh_2$), 173 (48%), 158 (17%), 130 (20%), 105 (35%, PhBOH), 96 (82%), 77 (100%, C_6H_5). CI mass spectrum (NH_3, pos. mode, 100°C), *m/z*: 278 (50%, 1/2 M^+ + H), 182 (45%, $OBPh_2$ + H), 114 (100%). Anal. calcd. for $C_{36}H_{40}B_2N_2O_2$: C 78.00, H 7.27, B 3.90, N 5.05; found: C 77.74, H 7.28, B 3.93, N 4.90.

[a]Temperature 294 K, Rigaku AFC6S diffractometer, Cu-K_α (λ = 1.54178 Å) radiation, graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, stationary background counts at each end of the scan (scan/background time ratio 2:1, up to 8 rescans), $\sigma^2(F^2) = [S^2(C + 4B)]/Lp^2$ (S = scan rate, C = scan count, B = normalized background count), function minimized $\Sigma w(|F_o|-|F_c|)^2$ where $w = 4F_o^2/\sigma^2(F_o^2)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2}$. Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(F^2)$.

3,3,6,6-Tetrakis(4-methoxyphenyl)-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, 5 (R = 4-$CH_3OC_6H_4$)

Bis(4-methoxyphenyl)borinic acid (19) (1.21 g, 5 mmol) is dissolved in 5 mL of ethanol (with slight warming). After the addition of a solution of hydroxylamine (base, 0.17 g, 5 mmol) in 5 mL of ethanol the mixture is refluxed for 5 min. From the cooled solution colorless crystals are obtained. Yield: 0.87 g (68%), mp (dec.) 200–201°C. Infrared (KBr): 3250, 3200 cm^{-1} (N-H); ^{1}H nmr (90 MHz, d_6-DMSO/TMS), δ (ppm): 3.63 (s, 4 CH_3), 6.70 and 7.19 (d and d, 16 aromatic H), 7.66 (s, br, exchangeable, 2 NH_2). Anal. calcd. for $C_{28}H_{32}B_2N_2O_6$: C 65.41, H 6.27, B 4.21, N 5.45; found: C 65.29, H 6.43, B 4.26, N 5.10.

X-ray crystallographic analysis of **4***b*

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 85.9–102.3°. The intensities of three standard reflections, measured every 200 reflections throughout the data collection, showed only small random fluctuations. The data were processed,[3] corrected for Lorentz and polarization effects, and absorption (empirical, based on azimuthal scans for three reflections).

[3]TEXSAN/TEXRAY structure analysis package (Version 5.1), Molecular Structure Corp. 1985.

*Here and elsewhere refers to symmetry operation: $-x$, $-y$, $1 - z$.

The structure was solved by direct methods, the coordinates of the non-hydrogen atoms being determined from an *E*-map. The molecule has crystallographic inversion symmetry. Non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms of the C(2) methyl group were found to be (6:4) disordered over two sites. These hydrogen atoms were fixed in calculated positions (C—H = 0.98 Å, $B_H = 1.2\ B_{bonded\ atom}$, methyl group orientations based on difference map positions) and the remaining hydrogen atoms were refined with isotropic thermal parameters. A correction for secondary extinction was applied (Zachariasen type), the final value of the extinction coefficient being $8.97(6) \times 10^{-4}$. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* (20). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, and bond angles appear in Tables 2–4, respectively. A stereoview of the molecule is shown in Fig. 1. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least-squares planes are included as sup-

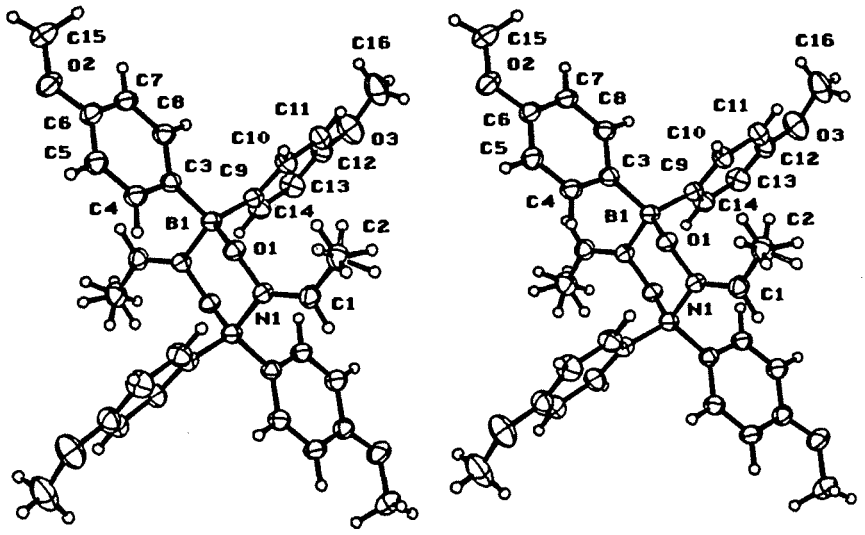

FIG. 1. Stereoview of **4***b*; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

plementary material.[4] Measured and calculated structure factor amplitudes are available from the authors on request.

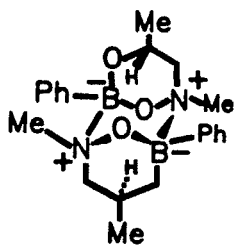
Results and discussion

The X-ray analysis of **4***b* establishes the postulated cyclic dimer form of the oxime diarylborinate. The centrosymmetric dimer manifests itself as a six-membered BONBON ring having a slightly flattened chair conformation. To the best of our knowledge, this structure represents the first example of a monocyclic BONBON ring structure established by an X-ray structure analysis. A similar BONBON ring system, also having a chair conformation, has recently been characterized as part of the tricyclic skeleton of compound **6** (11).

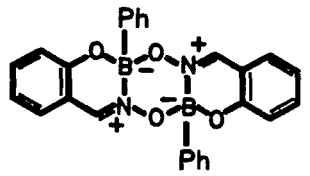
[4]Supplementary material mentioned in the text may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen atom coordinates and bond lengths and angles involving hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

The N→B coordinative bonds in **4***b* (1.616(2) Å) are 0.079(3) Å shorter than the corresponding bonds in the BONBON ring incorporated into the polycyclic ring system of compound **6** (1.695(2) Å) (11). The sum of the N—O and O—B bond distances in **4***b* (2.901(3) Å) is very similar to the corresponding sum for **6** (2.918(3) Å), but in **4***b* the N—O bonds are significantly shorter, and the O—B bonds significantly longer, than those in **6**. The relatively short N—O (1.389(1) Å) and long O—B (1.512(2) Å) bonds in **4***b* may be compared with those reported for another oxime derivative having a BONBON ring structure: the polycyclic phenylboronate of salicylaldoxime, **7** (N—O = 1.3865(14) and 1.3903(14) Å, O—B = 1.479(2) and 1.472(2) Å) (21). It should be noted, however, that the conformations of the BONBON rings in **4***b* and **7** are quite



6



7

different. In compound **6** the N—O and O—B distances are 1.453(1) and 1.465(1) Å, respectively. The oxime C=N bonds in **4***b* (1.278(2) Å) are not significantly different from those in **7** (1.275(2) and 1.277(2) Å) (21) and in a number of dimeric hydrogen-bonded oximes of the type **2**: phenylpropane dioxime (1.278 Å) (3*b*), acetophenone oxime (1.278 Å) (3*d*), phenylpyridylketone oxime (1.276(2) Å) (3*e*), and methoxyindanone oxime (1.277(2) Å) (3*g*).

The substitution about the oxime function in **4***b* adopts the (*Z*) configuration, allowing more space for the bulky diarylboron group. The O(1)N(1)C(1)C(2)B(1)* oxime group is planar to within 0.032(1) Å, although this represents a statistically significant deviation from planarity. The torsion angles O(1)-N(1)-C(1)-C(2) = −4.2(2)° and C(2)-C(1)-N(1)-B(1)* = −177.2(1)° are also consistent with approximate planarity of the oxime group. The steric requirements of the planar oxime moieties

may be responsible for the widening of the O—N—B angles within the six-membered BONBON ring of **4***b* (115.4(1)°) relative to the corresponding angles in **6** (106.80(7)°) (11), in spite of the overall structural similarity of the six-membered heterocycles in these two molecules. The intracyclic N—O—B angles in **4***b* are also widened (113.6(1)°) relative to those in **6** (111.75(7)°), whereas the N—B—O angles in the two compounds are virtually identical (104.9(1)° in **4***b*, 104.98(8)° in **6**).

The slight flattening of the BONBON chair in the oxime derivative **4***b* resembles that reported for 1,4-bisacyl piperazines (22), which is thought to be controlled by the planarity about the partial C=N double bonds of the amide groups at the 1- and 4-positions of the six-membered ring. The oxime C=N bonds in **4***b* act in a similar way to produce the flattened chair conformation.

The B—C(aryl) bond lengths of **4***b* (1.597(2) and 1.604(2) Å) are within the range normally observed for tetracoordinated arylboron compounds (23). The geminal *B*-aryl rings are oriented roughly perpendicular to one another (the dihedral angle between normals to the mean planes is 71.3°), an arrangement normal for geminal substituents at small atoms. All intermolecular distances correspond to normal van der Waals interactions, the shortest nonbonded contact between non-hydrogen atoms being O(3)···C(2) = 3.475(2) Å.

From the X-ray crystallographic analysis of **4***b* and the chemical shifts from the ^{11}B nmr spectra of **4***b*,*e*,*f*,*g*,*h*,*k*, and *l* in deuterochloroform solution, it can be concluded that the (alkylideniminoxy)diarylboranes **3** exist predominantly in the cyclodimeric form **4** having a six-membered BONBON ring system that adopts a chair conformation. This conclusion is indirectly corroborated by the synthesis of the same materials from compounds **5**, bearing in mind that the BONBON ring structure for **5** is only assumed, although very probable. Under the conditions of EI and CI mass spectrometry experiments, these rings dissociate into monomers that represent the "molecular ions" ($1/2M^+$).[5]

Systematic sequences of well-balanced Gaussian basis sets

MARIUSZ KLOBUKOWSKI
Department of Chemistry, University of Alberta, Edmonton, AB T6G 2G2, Canada

Received July 26, 1993[1]

MARIUSZ KLOBUKOWSKI. Can. J. Chem. **72**, 1741 (1994).

Systematic sequences of Gaussian basis sets with controlled energy errors for the studies of convergence of the basis set effects on the computed results of molecular calculations are presented. The basis sets were prepared for atoms H–Ne and Al–Ar and may be used in systematic *ab initio ad limitem* studies of molecular structure and properties.

MARIUSZ KLOBUKOWSKI. Can. J. Chem. **72**, 1741 (1994).

On présente des séquences systématiques d'ensembles de bases gaussiennes avec des erreurs d'énergie contrôlées qui peuvent être utilisées pour des études de convergence des effets d'ensembles de base sur les résultats de calculs moléculaires. On a préparé les ensembles de base des atomes H–Ne et Al–Ar et on peut les utiliser dans des études *ab initio ad limitem* de structures et de propriétés moléculaires.

Introduction

Almost a decade ago, we have published the first compilation of the well-tempered basis sets (1) and used them in calculations of molecular structure and properties (2–5). The main stimulus for the development of these new basis sets was the perceived need to provide a collection of basis sets for use in molecular calculations devoid of basis set errors. This objective was achieved by using very large expansions in terms of primitive Gaussian functions. The realization of this goal leads thus to two problems, both connected with computational efficiency: The first one is the evaluation of the molecular integrals, and the second is the optimization of the exponential parameters of the basis sets (usually done in atomic calculations). Many of the frequently-used computer codes achieve savings in the integral and gradient evaluation times via utilizing the sharing of exponents within the shells of the atomic functions (6–8). We have therefore designed the well-tempered basis sets in which all exponents are *shared* between the *s*, *p*, *d*, and *f* spaces in atomic calculations. To address the second problem, we expanded the even-tempered formula, originally suggested by Reeves (9) and then extensively studied by Ruedenberg and co-workers (10–16):

$$[1] \quad \zeta_{k,l} = \alpha_l \beta_l^k \qquad k = 1, ..., N_l$$

where N_l is the number of primitive functions in symmetry l, and the parameters α_l and β_l are different for different l's. We modified this formula in order to improve the distribution of both the small and large exponential parameters, and called the resulting basis sets *well-tempered:*

$$[2] \quad \zeta_k = \alpha\beta^{N-k+1}\left[1 + \gamma\left(\frac{N-k+1}{N}\right)^{\delta}\right] \qquad k = 1, ..., N$$

In recent work, Huzinaga et al. (17, 18) used a modified version of eq. [2],

$$[3a] \quad \zeta_N = \alpha$$

$$[3b] \quad \zeta_{N-k+1} = \zeta_{N-k+2}\,\beta\left[1 + \gamma\left(\frac{k}{N}\right)^{\delta}\right] \qquad k = 2, ..., N$$

The idea that it may be advantageous to modify the even-tempered formula was independently proposed by Wilson who, discussing the even-tempered sequences of Gaussian functions in a review of the many-body perturbation theory of molecules (19), suggested the generalized recursion $\zeta_{k+1} = \zeta_k\,(\beta + \gamma k)$, which rewritten as $\zeta_{k+1} = \zeta_k\beta(1 + \gamma' k)$ has the form resembling eq. [3].

These basis sets, together with the ones developed by Schmidt and Ruedenberg (16), Partridge (20, 21), and Clementi et al. (22, 23), aimed at providing very large expansions which are essentially free of BSSE. However, these basis sets are almost intractable in the studies on larger molecular systems for which the smaller basis sets are still being used (24–29), the developments in computer hardware notwithstanding. These smaller basis sets are usually of a fixed size for the atoms in each row of the periodic table; this size was predetermined mainly on the basis of computational efficiency in the molecular calculations. However, these basis sets exhibit very nonuniform error with respect to the atomic number: the larger the value of Z for a basis set of fixed size the larger the error. Such basis sets are then not balanced, and when used in molecular calculations, may lead to differential basis set errors between the constituent atoms of a molecule. Furthermore, within each basis set for a given atom, it often happens that the *s*, *p*, etc. spaces are not represented with equal accuracy, thus potentially leading to differential basis set effects within each atomic basis set.

The present work constitutes an extension of the previous work on the Gaussian basis sets done in this laboratory and was undertaken in order to build a family of Gaussian expansions which would exhibit controlled basis set errors. These basis sets would be *well balanced* (30), and, in the words of Clementi, would provide "poor atomic sets for all atoms, medium sets for all atoms, good atomic set for all the atoms in the molecule" (31). Furthermore, their availability would establish the basis for systematic studies of convergence patterns in molecular energy and properties. Need for such basis has been stressed for the first time by Schwarz (32) and reiterated by Schmidt and Ruedenberg (16) (who developed the concept of *energy-balanced* even-tempered basis sets) and by Wilson (33) (who followed the convergence within the universal basis sets (34)). In addition, the systematic build-up of the basis sets was designed so as to assist in the understanding of the relationship and the role of the *s* and *p* spaces in approaching the Hartree–Fock limit of the total energy.

In our previous work we demonstrated that while for very

[1]Revision received March 14, 1994.

large basis sets, as the basis set approaches completeness, the quality of results does not depend on the formula used to generate the exponential parameters ζ of the basis set (35). However, as the size of basis is reduced, a device is needed to increase the large values of ζ, which are too small compared with the ones obtained in the full optimization. Furthermore, we also determined (35) that the errors in exponents generated with the original well-tempered formulas, eqs. [2] and [3], could be reduced by a factor of two if the exponents are not shared between the atomic symmetries. The best formula used int he present work is obtained when the fourth degree polynomial expansion of log ζ is used:

$$[4] \quad \log \zeta_{k,l} = \sum_{i=1}^{5} P_{i,l} k^{i-1}$$

This formula has the added advantage that the initial values of parameters, P_i required in the optimization process are readily obtained via the least-squares fitting to a set of exponents from a known basis set. (In this work, the procedure SVDFIT (36) was used for fitting.) Furthermore, as pointed out by Mezey and Hass, the use of ln ζ in the optimization instead of ζ is advantageous (37). From the comparison of eqs. [1] and [4] we see that $\alpha_l \approx 10^{P_{1,l}}$ and $\beta_l \approx 10^{P_{2,l}}$.

With only ten parameters per atom to be optimized, a large number of basis sets could be generated to provide a uniform description at each atomic site in molecular calculations. All calculations were performed on IBM RS/6000 workstations.

II. Calculations and results

The optimization of parameters in the generator formula was done using the Powell's method of conjugate directions as modified by Brent (38). As shown previously (35), the method is very efficient (despite the lack of derivatives) and sufficiently accurate: the errors in the atomic total energy were found to be only 1–2 μhartree.

The reference Hartree-Fock energies, computed with the Froese–Fischer code (39), are collected in Table 1. The errors ΔE, δs, and δp for the generated basis sets are shown in Tables 2–8 for the atoms hydrogen through neon and in Tables 12–16 for aluminum through argon. The error ΔE is defined as the difference between the total energy computed with a given basis set and the Hartree-Fock energy $\Delta E = E_{\text{basis}} - E_{\text{Hartree-Fock}}$. In order to measure whether each symmetry is represented equally well, we defined two parameters, δ_s and δ_p. The errors δ_s and δ_p indicate whether the basis set is internally balanced; they were evaluated by calculating how much the total energy is lowered upon addition of another s and p function, respectively. Specifically,

$$\delta_s = E(N_s.N_p) - E(N_s + 1.N_p)$$

$$\delta_p = E(N_s.N_p) - E(N_s.N_p + 1)$$

The notation $(N_s.N_p)$ is used to represent a basis set with N_s s-type and N_p p-type uncontracted functions. The values in italics were estimated using the observed regular behaviour of δs and δp. To save space, the tables are somewhat distorted from the optimum format of the quasi-diagonal matrix in which the columns are labeled by N_s and the rows by N_p. The results are arranged so that moving down a column results in simultaneous increase in the number of s and p functions; moving right along a row increases the number of s functions only; and moving along the lines parallel to the counter-diagonal increases the number of p functions.

TABLE 1. Hatree–Fock total energies[a] for atoms hydrogen through argon

total energies converge to the limiting Hartree–Fock value: It requires only 10*s*, 13*s*, 17*s*, and 18*s* functions for H, He, Li, and Be, respectively, to reach the Hartree–Fock energy with sub-μhartree error. The comparison of the exponents generated with eq. [4] for hydrogen and those which were optimized using the gradient methods by Matsuoka and co-workers (40) shows that the formula gives very accurate rendering of the individually optimized exponents. These values are also rather close to the set generated by Huzinaga (41).

B. Boron – Neon

The collection of results for the atoms boron through neon is shown in Tables 3–8. For an increasing atomic number *Z*, the errors in the total energy, ΔE, also increase. As the number of Gaussian functions increases, the errors become smaller, and eventually reach sub-μhartree values, which are reached with larger basis sets for heavier atoms. The errors δ_s and δ_p of course are equal and very small for the largest basis sets; for the remaining ones it seems that the internal balance of the *s* and *p* spaces is observed for $N_s = N_p + 5$ for the smallest sets, and $N_s = N_p + 6$ or 7 for the medium-size basis sets.

The decoupling of the *s* and *p* exponents results in the variational freedom which is demonstrated in the constant errors δ_s and δ_p: The total energy is lowered by the same amount when one *p* functions is added to a basis set with any value of N_s. Taking as an example the series of basis sets (12.8), (13.8), (14.8), ..., for neon (Table 8), we observe $\delta_p = 176$ μhartree. The constancy still approximately holds even for the smallest basis with $N_p = 4$. Similarly, the addition of one s function to a basis set with any N_p results in identical lowering of the total energy (although the structure in the tables makes this effect a little more difficult to observe).

Inspection of the optimized values of the parameters in the generator formula of eq. [4] shows that the role of the cubic and quartic terms for the s space decreases with the increasing basis set size, while the values of the quadratic term remain almost constant. For the *p* space the changes are similar, although the values of the higher-order terms are larger. In other words, while it may be sufficient to truncate the series (4) at the cubic term for the *s* space, such truncation may lead to larger errors for the smaller basis sets due to inadequate flexibility in the *p* symmetry.

It is interesting to observe that, unlike in the case of the even-tempered basis sets studied by Schmidt and Rudenberg (16), the present basis sets of structure analogous to their (2*N*.*N*), or ($2N_p$.N_p) in our notation, are not necessarily energy balanced, as may be seen in the unequal values of δs and δp. The relationship $\delta s \approx \delta p$ seen for the basis sets ($2N_p$.N_p) of lighter atoms, deteriorates as the atomic number *Z* increases.

Finally, it may be interesting to compare the errors of some of the smaller basis sets with the ones determined using unconstrained optimization of exponents: Table 9 shows the results for the (9.5) and (10.6) basis sets in relation to basis sets of the same size optimized by Huzinaga (41). It is quite clear from Table 9 that the generator formula of eq. [4] is very effective in approximating the fully optimized basis set exponents. Furthermore, the difference between the total energies of the fully optimized Huzinaga's functions and the present ones is much smaller than the error with respect to the Hartree–Fock limit.

C. Aluminum – argon

The errors for the basis sets for atoms aluminum through argon are presented in Tables 10–15. It appears that in order to achieve similar errors as for the analogous atoms from the previous row of the periodic table, five additional functions are needed for the lighter atoms while only three suffice for the heavier ones. While for the larger basis sets the internal balance is observed for $N_s = N_p + 5$ or 6, in parallel with the behaviour seen for the second row atoms, the constraints on the p space in the smallest basis sets result in large δ_p errors and, in consequence, make them internally unbalanced. For the two sets of basis sets with $N_s = 2N_p$, namely those with $N_p = 7$ and 8, the errors in the p space are much larger than those in s space, making these basis sets internally unbalanced.

TABLE 9. Comparison of total energies (in hartree) and total energy errors (in mhartree) for B–Ne[a]

Atom	E_T (this work)	ΔE_1[a]	E_T (Huzinaga)	ΔE_2[b]
		Basis (9.5)

F (^2P)	−99.395406	−0.520	−99.395586	−13.423
Ne (^1S)	−128.527176	−0.49	−128.52674	−19.43
		Basis (10.6)		
B (^2P)	−24.528235	−0.051	−24.528282	−0.775
C (^3P)	−37.687298	−0.037	−37.687324	−1.284
N (^4P)	−54.398912	−0.013	−54.398909	−2.009
O (^3P)	−74.806337	0.015	−74.806295	−3.076
F (^2P)	−99.404916	−0.030	−99.404870	−4.403
Ne (^1S)	−128.540923	−0.05	−128.54094	−6.13

[a] $\Delta E_1 = E_T$(Huzinaga) − E_T (this work).
[b] $\Delta E_2 = E_T$(Hartree–Fock) − E_T (Huzinaga).

The values of the optimized parameters, compared with analogous values for the first-row atoms, reveal diminished role of the cubic and quartic terms in the expansion of log ζ, especially for the *s* space. However, these terms appear to be required for the expansion in *p* space.

The results for two smaller basis sets, (11.7) and (12.8), are compared in Table 16 with the fully optimized basis sets of Huzinaga (42). As seen in the case of analogous atoms from the preceding row, the errors between the fully optimized and formula-based basis sets are much smaller that the energy differences between the fully optimized energies and the Hartree–Fock limit.

III. Conclusions

The perfect internal balance may be somewhat elusive goal: as the number of the primitive functions may increase only by an integer value, it is impossible to find the basis sets for which $\delta_s = \delta_p$. However, for practical purposes, the approximate relationship $\delta_s \approx \delta_p$ should be sufficient. The recommended basis sets which exhibit the approximate internal balance are the ones for which $N_s = N_p + 5$ or 6, provided that, for the atoms of the third row, $N_p > 9$.

With the help of the data presented in the Tables 2–8 and 10–15 it is now possible to choose, for each atomic site in molecular calculations, the basis sets with similar values of ΔE, and thus ensure external balance of the basis sets (31). For example, in the calculation of boron fluoride, the (9.5) basis for boron should be used with (10.6) or (11.6) basis for fluorine; all these basis sets have approximately the same value of ΔE (and approximate internal balance). The error for the (9.5) basis for fluorine is more than ten times larger than that for boron,

TABLE 16. Comparison of total energies (in hartree) and total energy errors (in mhartree) for Al–Ar[a]

Atom	E_T (this work)	ΔE_1[a]	E_T (Huzinaga)	ΔE_2[b]
		Basis (11.7)		
Al (^2P)	−241.850796	−4.75	−241.85555	−21.16
Si (^3P)	−288.821509	−8.53	−288.83004	−24.32
P (^4P)	−340.679568	−9.91	−340.68948	−29.30
S (^3P)	−397.458150	−10.45	−397.46860	−36.30
Cl (^2P)	−459.427648	−10.74	−459.43839	−43.68
Ar (^1S)	−526.754941	−10.00	−526.76494	−52.57
		Basis (12.8)		
Al (^2P)	−241.865993	−2.38	−241.86837	−8.34
Si (^3P)	−288.842000	−3.02	−288.84502	−9.34
P (^4P)	−340.704751	−3.15	−340.70790	−10.88
S (^3P)	−397.488491	−2.52	−397.49101	−13.89
Cl (^2P)	−459.463144	−1.48	−459.46462	−17.45
Ar (^1S)	−526.795884	−0.56	−526.79644	−21.07

[a]$\Delta E_1 = E_T$ (Huzinaga) − E_T (this work).
[b]$\Delta E_2 = E_T$ (Hartree–Fock) − E_T (Huzinaga).

TABLE 17. Recommended combinations of compatible basis sets[a]

	Error in total energy (in μhartree)

[a]The subscript in the basis set label multiplied by the first entry in the column gives the actual total energy error.

mainly due to the inadequate expansion of the p space. Similarly, for the calculations on boron chloride, the (9.5) basis set of boron should be matched with chlorine's (14.10) basis set. The sets of matching basis sets with similar total energy errors (external balance) are suggested in Table 17 (the basis sets selected show approximate internal balance). For the selected basis sets, the parameters in the generator formula of eq. [4] are collected in Tables 18–22. The detailed tables containing the results of atomic calculations for these basis sets are available as supplementary material.[2]

For each atom, there is a number of basis sets exhibiting sub-μhartree accuracy in the total energy; choosing any of them for molecular calculations should give identical answers. However, for reasons of computational economy (if that notion may be brought up when discussing basis sets of the very large size required to reach sub-μhartree accuracy), one may select, for e.g. fluorine, the (22.14) basis set rather than (21.17). The matching basis sets may be useful in the studies of convergence of results of molecular computations, thus enabling conducting the first-principles, *ab initio*, calculations to their basis-set limit, *ad limitem*.

The performance of the internally balanced basis sets which also provide external energy balance can be ultimately evaluated only in molecular calculations. For the calculations on molecules, however, we need to study the contraction schemes for the primitive basis sets (the most efficient being the general contraction scheme (11)) and to investigate the polarization functions. Such work is now in progress.

[2]This supplementary material can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

Acknowledgments

Grant of computer time on the workstation IBM RS/6000 model 580, hosted by the Computing and Network Services of the University of Alberta, is gratefully acknowledged. This work was partly supported by a grant from Natural Sciences and Engineering Research Council of Canada. The comments of Professor Huzinaga during a discussion of the present results are much appreciated.

The interactions of the La(III) cation with D-ribose and with D-arabinose in aqueous solution were investigated by ^{139}La NMR spectroscopy. In the case of D-ribose, the formation of a La(III)–sugar complex was indicated by variations of the ^{139}La chemical shift and linewidth with an increase of the sugar concentration in solution. In contrast, the complexation of La(III) by arabinose is very weak and almost undetectable by ^{139}La NMR. On the basis of a 1:1 stoichiometry, the stability constant for the complex of La(III) with D-ribose was calculated from the observed ^{139}La chemical shift values. A similar treatment was done for the viscosity corrected ^{139}La linewidths using arabinose as an uninteractive reference. The stability constants, K, obtained independently from ^{139}La chemical shifts and linewidths are in good agreement, 2.8 ± 0.5 and 2.2 ± 0.6 M^{-1} respectively at 299.0 ± 0.5 K. The thermodynamic parameters for the complexation of La(III) by D-ribose could also be obtained: $\Delta H^0 = -12 \pm 2$ kJ mol^{-1}, and $\Delta S^0 = -31 \pm 5$ J K^{-1} mol^{-1}. These values are in very good agreement with those obtained by calorimetric measurements.

ZHIGANG CHEN, NICOLE MOREL-DESROSIERS, JEAN-PIERRE MOREL et CHRISTIAN DETELLIER. Can. J. Chem. **72**, 1753 (1994).

On a étudié par résonance magnétique nucléaire du ^{139}La les interactions du cation La(III) avec le D-ribose et avec le D-arabinose en solution aqueuse. Dans le cas du D-ribose, la formation d'un complexe La(III)-sucre fut mise en évidence par les variations des déplacements chimiques et largeurs de raie du ^{139}La lors d'un accroissement de la concentration du sucre dans la solution. Au contraire, la complexation du La(III) par l'arabinose est très faible et presque indétectable par RMN du ^{139}La. Sur la base d'une stoechiométrie 1:1, à partir des valeurs des déplacements chimiques du ^{139}La, on a calculé la constante de stabilité du complexe de La(III) avec le D-ribose. Une approche similaire a été utilisée dans le cas des largeurs de raie corrigées pour la viscosité, en se servant de l'arabinose comme d'une référence non interagissante. Les constantes de stabilité obtenues indépendamment à partir des deux séries de mesure sont en bon accord: 2,8 ± 0,5 et 2,2 ± 0,6 M^{-1} à 299,0 ± 0,5 K. Les paramètres thermodynamiques caractérisant la complexation du La(III) par le D-ribose ont pu aussi être obtenus: $\Delta H^0 = -12 \pm 2$ kJ mol^{-1}, et $\Delta S^0 = -31 \pm 5$ J K^{-1} mol^{-1}. Ces valeurs sont en bon accord avec celles obtenues par mesures calorimétriques.

Introduction

The formation of complexes between carbohydrates and metal cations in solution, topic reviewed by Angyal (1), has been of interest for a long time. The interaction between sugars and metal cations is weak: only those sugars (or isomers) with hydroxyl groups in a specific arrangement can compete with water molecules to form stable complexes with metal cations in aqueous solution. For example, the most favorable sites for the coordination are *axial-equatorial-axial* hydroxyl groups in a six-membered ring or vicinal *cis-cis*-triol groupings in a five-membered ring. The higher equilibrium constants of complexation are observed in the case of trivalent lanthanide cations (1).

Several techniques, such as paper electrophoresis (2), thin-layer ligand-exchange chromatography (3), and NMR of the ligands (4–6), have been used to characterize the interaction between sugars and metal cations in solution. However, the stability constants for the complex formation have still to be determined in a fully satisfactory manner. Some results obtained from different experimental methods differ significantly. For example, by using a calorimetric method, Morel and co-workers have determined the stability constants for the case of D-ribose (7–9). The value they find for Ca^{2+}-ribose in water is in excellent agreement with that determined electrochemically by using a liquid-membrane electrode selective to Ca^{2+} ions (10) but much smaller than other reported values (6, 11–13). This discrepancy is presumably due to the fact that the stability constants are comparatively small (<5 M^{-1} in most cases) and that, accordingly, their accurate determination is difficult. It probably also reflects the fact that the various determinations have been made under quite different concentration conditions. Whereas Morel and co-workers could keep the electrolyte at almost infinite dilution, the other experimental approaches, in particular the older NMR determinations, required high concentrations to observe complex formation. Under the latter conditions the activity coefficient effects can not be neglected: the stability constants calculated from the concentrations may indeed differ significantly from the actual ones. Moreover, the equilibrium between the sugar isomers present in solution may be shifted by the presence of a large quantity of salt; this, of course, makes the various results hardly comparable. It should be possible to avoid these problems by working with modern NMR instruments and hence to get spectroscopic results that can be compared with the calorimetric ones.

The metal cation NMR spectroscopy of quadrupolar nuclei has proved to be a powerful technique to characterize the com-

plexation between metal cations and macrocyclic ligands in solution (14). More particularly, the stoichiometry of such complexes present in small amounts in solution could be determined (15, 16). However, a similar approach has been used very rarely for the study of metal cation – sugar interactions: for example, the binding of Na^+ to D-ribose and to *cis*-inositol in water was observed through the variation of the ^{23}Na spin–lattice relaxation rates in the presence of sugar (17). In pyridine, the large dissymmetry of the electronic distribution around the sugar-complexed sodium cation permitted to define precisely the complexation parameters (18, 19).

In the present work, ^{139}La NMR was used to investigate the interaction of La(III) with D-ribose and with arabinose in aqueous solution. These two sugars have been chosen because some of the ribose isomers present in aqueous solution readily bind La(III) whereas arabinose, following Morel et al. (7–10), can be considered as a noninteractive reference. The analysis of the ^{139}La chemical shifts and linewidths allowed the calculation of the thermodynamic parameters for the La(III)–D-ribose complex. The NMR values are in good agreement with the calorimetric determinations.

Experimental

D-Ribose (Aldrich), $LaCl_3.7H_2O$ (Aldrich, 99.999%), and D-arabinose (Pfanstiehl Labs.) were dried 24 h under vacuum over P_2O_5 prior to use. The lanthanum content of $LaCl_3.7H_2O$ was determined by titration with EDTA. The solutions for the NMR measurements were prepared by dissolving an appropriately weighted quantity of the lanthanum salt or of the sugar in triply distilled water. All spectra were recorded within 24 h of the preparation of the samples. The pH values (5.0 ± 0.1) for the stock solutions was adjusted by very small amounts of HCl or NaOH solutions.

The NMR samples were made by transferring the stock solutions into 10 mm NMR tubes which were then sealed under argon with Parafilm. ^{139}La NMR spectra were recorded at 42.37 MHz on a Varian XL-300 spectrometer. The ^{139}La chemical shifts were referenced to a 0.100 M $La(NO_3)_3$ aqueous solution containing 20% D_2O. The 90° pulse width was 16 μs. The temperature was measured with a thermocouple submerged in water in a non-spinning NMR tube. The temperature of the samples was estimated to be reliable to ±0.5 K.

Results and discussion

Figure 1 shows a series of ^{139}La NMR spectra for a 0.040 M $LaCl_3$ aqueous solution in the presence of various amounts of D-ribose. In the absence of sugar ($R = [\text{sugar}]_0 / [\text{La(III)}]_0 = 0$), the ^{139}La NMR spectrum is characterized by a chemical shift of 1.34 ppm and a linewidth of 110 Hz. The signal results from the population average of aquated La(III) and ion pair species (20). The percentage of ion pairing was previously calculated to be 3.8% for this concentration of lanthanum chloride (20). In the rest of this study, on the basis of this small percentage, the competitive effect of the ion pair formation on the sugar complexation was assumed to be negligible. The same assumption was previously made by Lenkinski and Reuben (6) since they observed that the complexation results did not depend upon the anion nature (chloride or perchlorate). In the presence of sugar ($R > 0$), the ^{139}La chemical shifts and linewidths increased with an increase of R, indicating theLa(III)–sugar complex formation. The chemical exchange was fast on the ^{139}La chemical shift time scale since only one Lorentzian signal was observed for all the values of R.

Similar experiments were done with arabinose, and the ^{139}La NMR spectra are shown on Fig. 2. In contrast with the case of D-ribose, the ^{139}La NMR chemical shifts were almost constant.

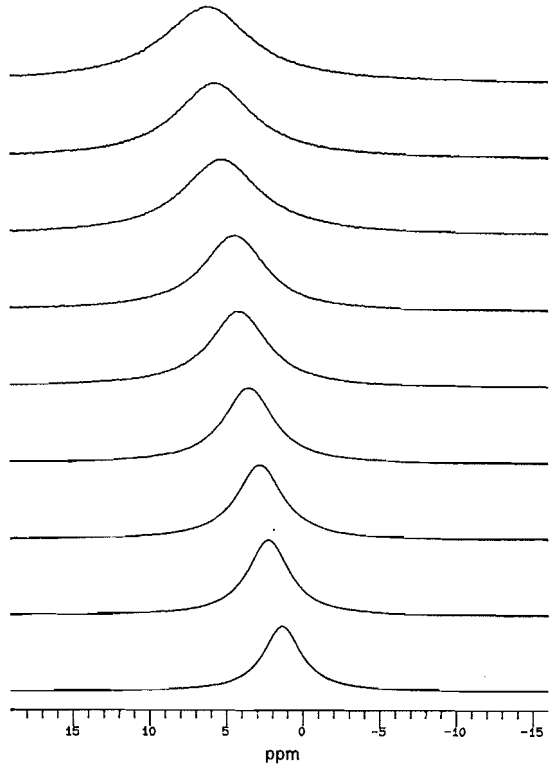

FIG. 1. ^{139}La NMR spectra of a 0.040 M $LaCl_3$ aqueous solution in the presence of D-ribose. From top to bottom: $R = ([\text{D-ribose}]_0 / [\text{La(III)}]_0) = 7.99, 7.10, 6.08, 5.07, 4.06, 3.04, 2.03, 1.01, 0$. $T = 299$ K.

This is in agreement with a very weak, almost undetectable by ^{139}La NMR, complexation of La(III) by arabinose. The linewidths, on the other hand, increase with an increase of R, due to an increase of the viscosity of the solution. These observations confirm (7–10) that arabinose can reasonably be used as an inactive reference and that the complexation between La(III) and D-ribose readily occurs. To calculate the stability constant for the complex of La(III) with D-ribose, the following equations were derived, on the basis of a 1:1 stoichiometry.

[1] $\underset{(A)}{\text{La(III)}} + \underset{(S)}{\text{ribose}} \rightleftharpoons \underset{(B)}{\text{(La(III) ribose)}}$

[2] $K = [B] / ([A] \times [S])$

where A ≡ La(III), B ≡ (La(III)ribose), and S ≡ ribose.

Since $[A] = [La]_0 - [B]$ and $[S] = R\,[La]_0 - [B]$, eq. [3] can be derived from eqs. [1] and [2].

[3] $[B] = 0.5\,C - (0.25\,C^2 - D)^{1/2}$

Here $C \equiv [La]_0 + R[La]_0 + K^{-1}$ and $D \equiv [La]_0^2$.

The observed ^{139}La chemical shifts, δ_{obs}, are the population-averaged values of δ_A and δ_B, the chemical shifts characterizing, respectively, the solvated and the 1:1 complexed La(III) cation

Therefore,

[4] $\delta_{obs} = ([B]/[La]_0) \times \delta_B + (([La]_0 - [B]) / [La]_0) \times \delta_A$

On the basis of eqs. [3] and [4], δ_A, δ_B, and K were determined from a non-linear regression on the observed ^{139}La

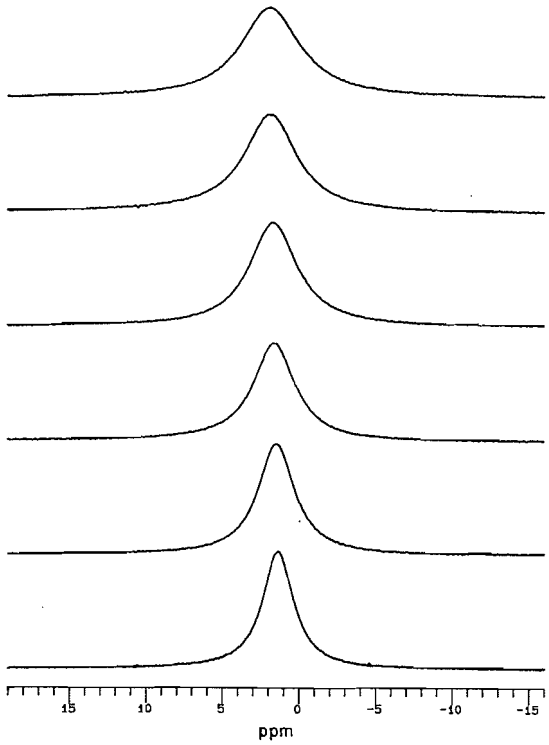

FIG. 2. ^{139}La NMR spectra of a 0.040 M $LaCl_3$ aqueous solution in the presence of D-arabinose. From top to bottom: R = ([arabinose]$_0$/[La(III)]$_0$ = 9.71, 7.77, 5.82, 3.88, 1.94, 0. T = 299 K.

chemical shifts values. Table 1 reports K values and the corresponding ^{139}La chemical shifts for the solvated and complexed La(III) cations at different temperatures. Figure 3 shows the ^{139}La chemical shifts as a function of R for both sugars at 300 K. The solid line in Fig. 3 is calculated from the parameters reported in Table 1 and the data points are experimental. Figure 4 gives the ^{139}La chemical shifts as a function of R in the case of D-ribose for various temperatures. In Fig. 4, the solid lines are calculated and the points reported are experimental .data.

As mentioned previously, the ^{139}La NMR linewidths increase with an increase of R for both sugars. The variations of the linewidthsis much larger in the case of ribose than in the case of arabinose. Since the chemical shift variation with R is very small in the case of arabinose, the increase of the linewidths might be considered as resulting from a viscosity increase. Assuming that the viscosity variations caused by the presence of different quantity of sugar in the solutions are the same in the cases of D-ribose and of arabinose, the ^{139}La NMR linewidths observed in the case of D-ribose were corrected by subtracting the viscosity effects. The viscosity reduced linewidths were analyzed by a procedure similar to the one used for the chemical shifts analysis, on the basis of eq. [5].

$$[5]\quad (\nu_{1/2})_{obs} = ([B] / [La]_0) \times (\nu_{1/2})_B + (([La]_0 - [B]) / [La]_0) \times (\nu_{1/2})_A$$

where $(\nu_{1/2})_B$ and $(\nu_{1/2})_A$ are the viscosity-corrected ^{139}La NMR linewidths for the La(III) cations, respectively, in the solvated site and in the site complexed by D-ribose.

The K value obtained for the temperature of 299 K is 2.2 ± 0.6 M^{-1}, which is compatible with the value obtained through the chemical shift analysis (see Table 1). Figure 5 shows the viscosity reduced linewidths as a function of R for the ribose. As above, the solid line is calculated and the data points are experimental.

TABLE 1. ^{139}La chemical shifts characterizing La(III) in the solvated and in the ribose-complexed sites and the stability constants, K, reported at different temperatures[a]

T(K)[b]	δ_A(ppm)[c]	δ_B(ppm)[d]	K[e]
299	1.19	11.4 ± 0.8	2.8 ± 0.5
303	1.14	10.8 ± 0.7	2.7 ± 0.5
312	0.61	10.2 ± 0.5	2.6 ± 0.3

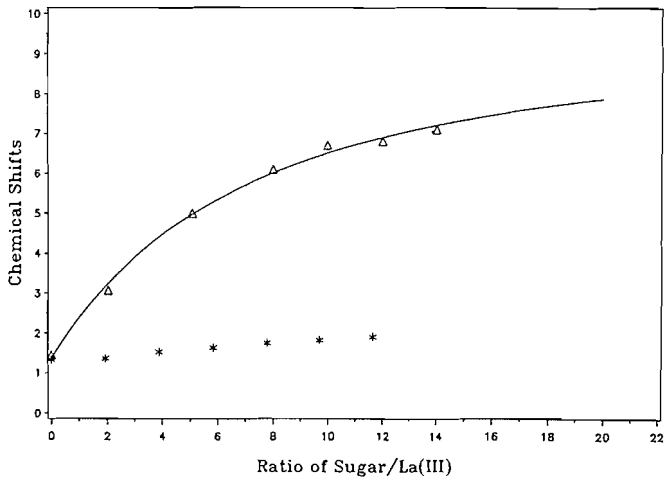

FIG. 3. ^{139}La chemical shifts as a function of R. (△): D-Ribose; (★): D-Arabinose. T = 299 K. The solid line is calculated, and the data points are experimental.

D-Ribose exists in solution as an equilibrium mixture of mainly six isomers: 21% of α-pyranose ($^1C_4$ and $^4C_1$ conformers), 59% of β-pyranose ($^1C_4$ and $^4C_1$ conformers), 6% of α-furanose and 14% of β-furanose (1). Among the ribopyranose forms, only the $^1C_4$ and $^4C_1$ conformers of the α-anomer and the $^1C_4$ conformer of the β-anomer bear a complexing site, while among the ribofuranose forms only the α-anomer does (8). However, in the present study, the metal cation NMR parameters (chemical shift and transverse relaxation) do not discriminate amongst the various complexes formed with the different isomers. In the treatment above, it was implicitely assumed that all complexes had the same chemical shift (δ_B) and the same characteristic linewidth ($(\nu_{1/2})_B$). Since, in all the complexes, the local geometries around the metal cation are expected to be very similar, the assumption seems reasonable. However, the treatment of the NMR data must be limited to a "global" phenomenon, considering only one type, averaged, of complexed site.Therefore, the stability constants given in Table 1 are overall values for the whole of ribose isomers present in solution.

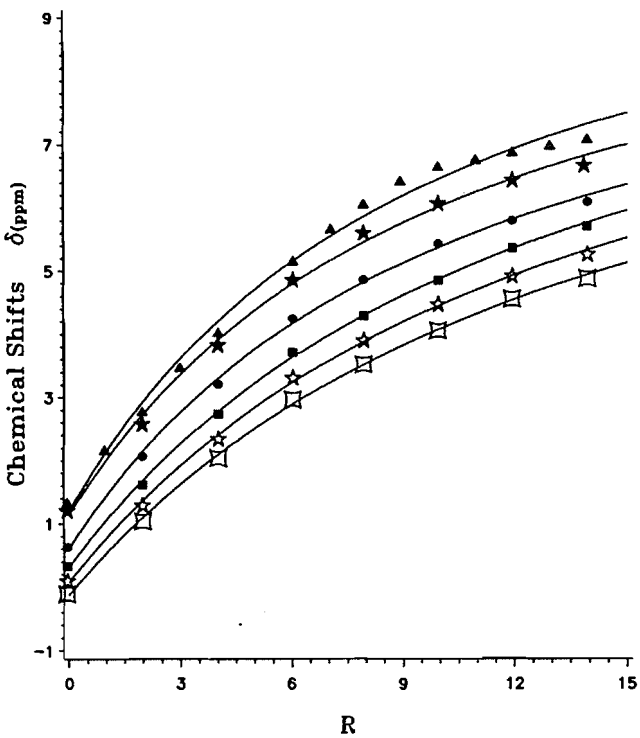

FIG. 4. ^{139}La chemical shifts as a function of R. From top to bottom: T = 336 K, 328 K, 320 K, 312 K, 303 K, and 299 K. The solid lines are calculated and the data points are experimental.

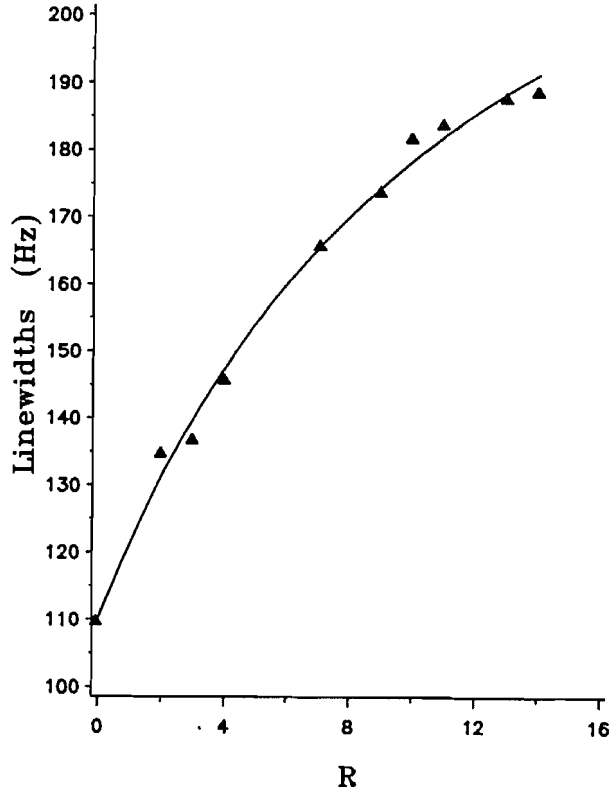

FIG. 5. Viscosity corrected ^{139}La linewidths as a function of R for the case of D-ribose. T = 299 K. The solid line is calculated and the data points are experimental.

Recently, Morel-Desrosiers et al. (21) have determined by calorimetry the thermodynamic properties of association of the trivalent lanthanide cations (La(III) → Tb(III)) with ribose in water. Through an approach based on the comparison of the behaviour of the complexing sugar with that of non-complexing epimer, they have isolated the properties characterizing solely the specific interactions between the cation and the complexing sequence of hydroxyl groups. Once converted to an overall value, their stability constant for La(III) is equal to 1.3 ± 0.2 M^{-1} at 298.15 K. This is relatively small compared to the value of 2.8 ± 0.5 M^{-1} given in Table 1. However, the agreement is better with the value of 2.2 ± 0.6 M^{-1} deduced from the analysis of the viscosity reduced linewidths. Values of 3.6 and 0.9 were reported by Lenkinski and Reuben (6) for La(III)–α-D-furanose and La(III)–β-D-pyranose, respectively, at 52°C: these values, once converted to the overall stability constant, appear, considering the temperature, to be compatible with the value given in the present work.

The enthalpy and entropy of complex formation were calculated from the temperature dependence of the equilibrium constants, given in Table 1: $\Delta H^0 = -12 \pm$ kJ mol^{-1} and $\Delta S^0 = -31 \pm 5$ J K^{-1} mol^{-1}. These values are in very good agreement with those directly obtained by calorimetric measurements (17) and converted here, for comparison, to overall values (that is, given with respect to the whole of ribose isomers): ΔH^0 = –9.6 kJ mol^{-1} and ΔS^0 = –30 J K^{-1} mol^{-1}.

Conclusions

Both chemical shifts and linewidths of the ^{139}La NMR spectra are very sensitive to complex formation, and can be used to characterize the complexation process. One of the most important advantages of this method is that the experiments can be done at a constant, low, salt concentration.The lanthanum chloride concentration used throughout the present work was 0.040 M; if necessary, given the high receptivity of ^{139}La, one could work at the subcentimolar level. Because, in water, the ^{139}La NMR signals are not too broad (100–500 Hz), the NMR observations can be performed in a reasonable amount of time. At such a low concentration, the activity coefficient effects are negligible. Moreover, the potential formation of complexes of higher stoechiometries, such as 2:1 or 1.2, is not favoured. Compared to other techniques, the metal cation NMR provides the information directly related to the cation coordination shell and thus allows to study the inner-sphere complexes. It was shown here that the effect of the other interactions on the chemical shifts is weak and that the viscosity correction of the linewidths leads to results in agreement with the chemical shifts ones. Obviously, ^{139}La NMR spectroscopy is particularly appropriate for the study of the interactions of La(III) with polyols in solution.

Cyclization of $Ph_2Si(NHNHMe)_2$. II. Reactions with methyl iodide, HCl, and Ph_2SiCl_2, and thermolysis

JILIANG HE AND JOHN F. HARROD[1]

Chemistry Department, McGill University, Montreal, QC H3A 2K6, Canada

Received January 10, 1994

JILIANG HE and JOHN F. HARROD. Can. J. Chem. **72**, 1759 (1994).

The reaction of $Ph_2Si(NHNHMe)_2$ (**1**) with MeI results in a mixture of two six-membered ring isomers, 1,2,4,5-tetraaza-1,4-dimethyl-3,3,6,6-tetraphenyl-3,6-disilacyclohexane (**2**), 45%, and 1,2,4,5-tetraaza-1,5-dimethyl-3,3,6,6-tetraphenyl-3,6-disilacyclohexane (**3**), 40%. The reaction of **1** with HCl or Ph_2SiCl_2 proceeds in a similar fashion. The thermolysis of **1** is studied from 25–600°C. In the range of 250–300°C, about 50% of **1** is converted into **2**, **3**, and 1,2,4-triaza-1-methyl-4-methylamino-3,3,5,5-tetraphenyl-3,5-disilacyclopentane, **8**. Possible pathways for the formation of **2**, **3**, and **8** in these cyclization reactions are discussed.

JILIANG HE et JOHN F. HARROD. Can. J. Chem. **72**, 1759 (1994).

La réaction du $Ph_2Si(NHNHMe)_2$ (**1**) avec le MeI conduit à la formation de deux cycles à six chaînons isomères, le 1,2,4,5-tétraaza-1,4-diméthyl-3,3,6,6-tétraphényl-3,6-disilacyclohexane (**2**), 45%, et le 1,2,4,5-tétraaza-1,5-diméthyl-3,3,6,6-tétraphényl-3,6-disilacyclohexane (**3**), 40%. La réaction du composé **1** avec le HCl ou le Ph_2SiCl_2 se produit d'une façon semblable. On a étudié la thermolyse du composé **1** entre 25 et 600°C. Entre 250 et 300°C, environ 50% du composé **1** se transforme en produis **2** et **3** et en 1,2,4-triaza-1-méthyl-4-méthylamino-3,3,5,5-tétraphényl-3,5-disilacyclopentane, **8**. On discute des diverses voies de formation des composés **2**, **3** et **8** dans ces réactions de cyclisation.

[Traduit par la rédaction]

Introduction

Silylhydrazine ring compounds, containing the Si—N—N unit, constitute an important family of cyclic silicon–nitrogen compounds (1). The most widely exploited synthetic method for the preparation of these compounds is the intermolecular reaction of a hydrazine with a dihalosilane with the elimination of hydrogen halide (2–5). They are also obtainable by a number of other synthetic routes (6–10). We recently reported the synthesis of bis(2-methylhydrazino)diphenylsilane, **1**, by a catalytic dehydrocoupling method (9). This novel silylhydrazine compound possesses several different functionalities, including two N—H groups of different acidities (11), labile Si—N bonds (12), and two different basic nitrogen atoms which can serve as nucleophiles.

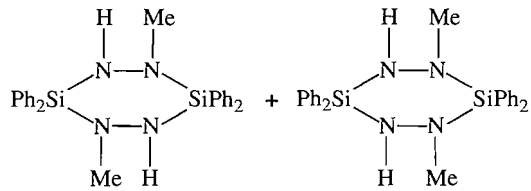
In the present paper we report two modes of cyclization of **1**, brought about either by the reaction with reagents MeI, HCl, and Ph_2SiCl_2 or by thermolysis.

Results and discussion

Reactions of $PH_2Si(NHNHMe)_2$ with MeI, HCl, and Ph_2SiCl_2

The reaction of **1** with an equimolar amount of iodomethane in toluene unexpectedly yielded a mixture of two tetraazadisilacyclohexane isomers, 1,2,4,5-tetraaza-1,4-dimethyl-3,3,6,6-tetraphenyl-3,6-disilacyclohexane, **2**, and 1,2,4,5-tetraaza-1,5-dimethyl-3,3,6,6-tetraphenyl-3,6-disilacyclohexane, **3**, with no other detectable silylhydrazine formation. In a typical experiment, compounds **2** and **3** accounted for 56% and 44% in the product, respectively, measured by ^{1}H-NMR spectra. The separation of **2** from the mixture was accomplished by recrystallization from a hot hexane solution, cooled to ambient temperature. The isolated yield of **2** was 45%. Further recovery of **2** was effected by partial evaporation of the hexane and cooling the solution of 4°C. After this procedure, **3** was isolated in 40% yield by removing hexane under reduced pressure. This product was contaminated with about 15% of **2**. **3** was obtained in higher purity by recrystallization from pentane solution. ^{1}H and

[1] $Ph_2Si(NHNHMe)_2 + MeI \longrightarrow$



2 **3**

^{29}Si-NMR and EI-MS spectra were consistent with the assigned structures for the both compounds, as reported elsewhere (11). Both **2** and **3** were colorless crystalline solids. They are mildly moisture-sensitive but can be handled in air for a short period of time without significant decomposition.

In order to better understand the origin of the product distribution, the reaction was followed by ^{1}H-NMR spectroscopy. In the early stages of the reaction, **2** was the dominant product. The proportion of **3** in the product increased gradually as the reaction proceeded and finally accounted for 46% of the product. With an 0.6 to 1.0 mole equivalent of MeI to **1**, approximately same product distribution was obtained. The results are summarized in Table 1.

These experiments indicate that HI produced in the reaction can play the same role as MeI before the hydrazonium iodide salt precipitates completely. This was confirmed by the reaction of **1** with anhydrous HCl (in diethyl ether). A similar result to that with MeI was obtained, except for a small amount of a new unidentified compound (18%) in the product. For most silylhydrazines, the Si—N bond is readily cleaved solvolytically by acids, or by anhydrous hydrogen halides in solution, as shown in reaction [2] (13):

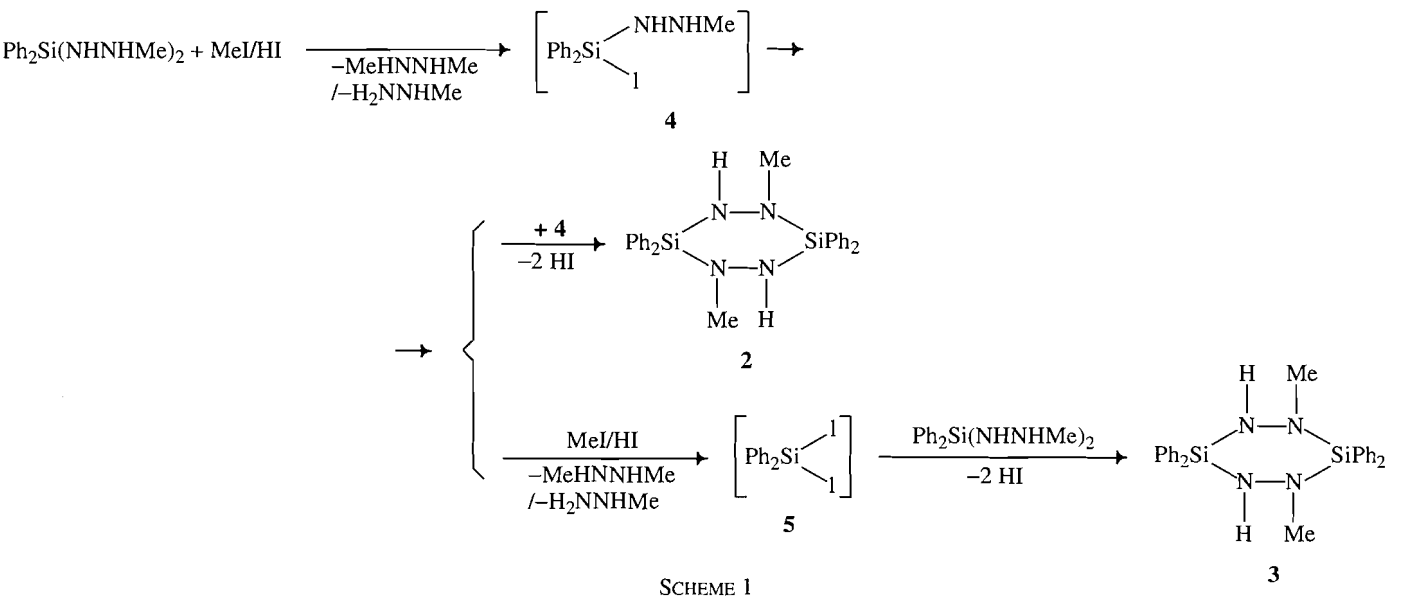
TABLE 1. Reactions of $Ph_2Si(NHNHMe)_2$ with MeI, HCl, and Ph_2SiCl_2, and the product distribution

Reaction	Molar ratio	Time (h)	Product distribution (%)[a] 2	3
$Ph_2Si(NHNHMe)_2$ + MeI	1:1	3	47	10
		10	56	44
	1:0.8	12	55	45
	1:0.6	12	58	42
$Ph_2Si(NHNHMe)_2$ + HCl[b]	1:1	24	58	24
$Ph_2Si(NHNHMe)_2$ + Ph_2SiCl_2[c]	1:1	16	45	29

[a]Based on ^1H NMR measurement.
[b]The product also consists of 18% of unidentified compound(s).
[c]The product also consists of 26% of **6**.



SCHEME 1

A possible pathway which accounts for the formation of **2** and **3** is shown in Scheme 1. The first step is the formation of an iodosilyl-substituted methylhydrazine, **4**, through the attack of MeI on **1**, with the elimination of MeHNNHMe. **4** is apparently a reactive intermediate since it is not observed and such a compound has not been synthesized, although fluorosilyl-substituted hydrazines have recently been prepared and isolated by Klingebiel (*7e*). **4** can either undergo autocondensation with another molecule of the same identity to yield **2** by the elimination of two molecules of HI, or it can be further attacked by MeI to form diiododiphenylsilane, **5**, which can react with **1**, with ring closure, to give **3** by HI elimination. In addition to precipitation as methylhydrazonium iodides, the HI formed in the reaction can also form **4**, or **5** by displacement of one, or two, moles of H_2NNHMe.

2 and **3** are also the products of the reaction of Ph_2SiCl_2 with **1**. In addition to **2** (45%) and **3** (29%), a third product, **6**, is also produced. In the early stages of reaction, compounds **3** and **6** predominate, but the amount of **2** increases gradually with the passage of time. Compound **6** was not isolated in a pure state, but it was tentatively assigned as $Ph_2Si(NHNMeSiPh_2Cl)_2$ based on its ^1H and ^{29}Si-NMR spectra. This compound is one of the expected products of reaction of Ph_2SiCl_2 with **1**. As the reaction proceeds, Ph_2SiCl_2 is depleted and the formation of **3** and **6** slows down. The reaction of **1** with HCl begins to compete and the relative rate of formation of **2** increases.

Thermolysis of $Ph_2Si(NHNHMe)_2$

A thermogravimetric analysis of **1** was performed from 25 to 600°C. Figure 1 shows the total weight loss which starts at ~200°C and ends at ~450°C. Within this temperature range, the weight loss at 265 and 332°C, respectively, occurs dramatically (as indicated by the DTG curve), while the DTA curve shows a slight exotherm at ~300°C. This fact suggests that a major decomposition (or structural change) occurs around 300°C.

In order to understand the thermal behavior, an NMR study of the thermal decomposition product at 250, 300, and 350°C was carried out. Figure 2 shows the ^1H-NMR spectra of the products at these temperatures. The results indicate that 52% of **1** is converted into **8** (31%), **2** (14%), and **3** (7%) at 250°C under the same heating conditions as that in Fig. 1. The remainder of the product was a mixture of unreacted **1** and an unidentified compound. **8** was assigned the structure 1,2,4-triaza-1-methyl-4-methylamino-3,3,5,5-tetraphenyl-3,5-disilacyclopentane, based on ^1H and ^{29}Si-NMR data, as reported elsewhere (11). The unknown compound is probably $Ph_2(MeHNHN)SiNHNMeSi(NHNHMe)Ph_2$, **7**. However, its structure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

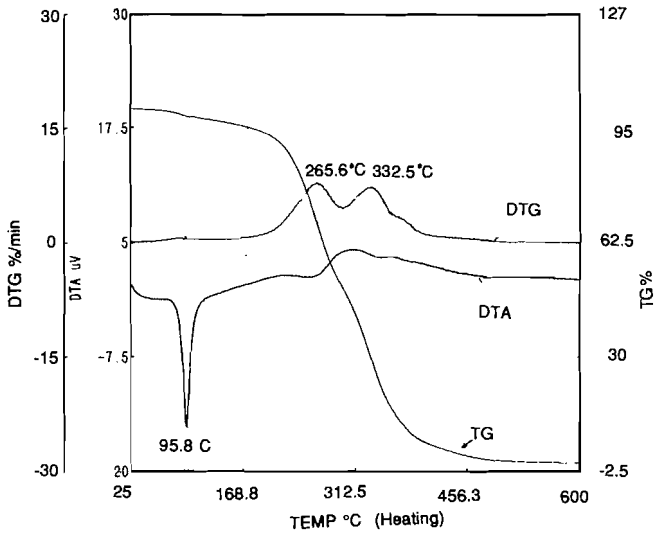


FIG. 1. Thermogravimetric analysis of $Ph_2Si(NHNHMe)_2$ at a heating rate of 10°C/min under a flow of N_2 (120 mL/min).

could not be assigned unequivocally on the basis of NMR data. At 300°C, **1** was completely converted to a mixture of **8** (16%), **2** (21%), and **3** (17%), and about 46% of uncharacterised oligomers.

$Si(NHR)_4$ has been previously reported to undergo polycondensation on heating, with the loss of amine to form complex polymers containing six- and /or four-membered $(SiN)_n$ rings (14). A similar condensation could occur with **1**. A proposal for the mechanism of formation of **8**, **2**, and **3** is shown in Scheme 2. In this scheme two molecules of **1** undergo self-condensation to form intermediate **7**. Under the same conditions, intramolecular condensation of **7** takes place to yield compounds **8**, **2**, and **3** by pathways, *1*, *2*, and *3*, in which three different nitrogen atoms serve as the species which can attack the two silicon atoms.

By comparison of the products of 250 and 300°C, it is evident that the formation of **8** (5-membered ring) is more favorable at 250°C. Because the 5-membered ring is kinetically favored at lower temperature and thermodynamically unstable at higher temperature. Indeed, when pure compound **8** was heated to 300°C under the same conditions, **2** and **3** were obtained.[2] In accordance with the mechanism in Scheme 2, the formation of **2** is favored over that of **3** (in which two NMe groups are on the same Si atom) due to the unfavorable steric effect. The weight loss (ca. 50%) at 300°C in the TGA does not correlate with that (17%) depicted in Scheme 2. This difference is probably due to the loss of **1**, or small ring compounds by sublimation or evaporation at high temperature under the flow of N_2.

The product at 350°C is more complicated. The ^{1}H-NMR spectrum shows that the composition of the residue is dominated by phenyl groups. Decomposition could be the main thermal behavior at this temperature, as a gaseous product was observed to evolve from the residue during heating. In a study of the gaseous pyrolysis products of silylhydrazines (from $MeRSiCl_2 + H_2NNH_2$), Colombier reported that the major species were CH_3SiH_3 (300°C), NH_3 (250–500°C), CH_4 (400–1000°C), and H_2 (maximum at 800°C), in addition to hydrazine (15). Similar products could result from our system at 350°C or higher temperature.

[2]When compound **8** was heated at 300°C under the same conditions as that of **1**, the pyrolysis residue consisted of **2** (27%), **3** (23%), oligomeric product (33%) and 17% of **8** remained, as measured by ^{1}H-NMR.

Experimental

Reagents and analytical methods

All reactions were carried out under an atmosphere of dry argon. The solvents used were dried over Na/benzophenone and distilled prior to use. Bis(2-methylhydrazino)diphenylsilane (**1**) was prepared by the catalytic dehydrocoupling reaction of diphenylsilane with methylhydrazine as described elsewhere (9). Other chemicals were used as received from Aldrich Chemical Co. All glassware was heated to at least 120°C and evacuated and purged several times with dry argon. ^{1}H (^{29}Si, ^{15}N)-NMR spectra were recorded on a Varian XL-200 (300, 500) FT-NMR at 20°C with internal TMS (^{1}H, ^{29}Si) and external CH_3NO_2 (^{15}N) as standards. Benzene-d_6 was used as solvent. Low resolution mass spectra were obtained on a Du Pont 21-492b spectrometer with an ionizing energy of 70 eV. IR spectra were recorded on a Bruker IFS-88 spectrometer with a resolution of 4 cm^{-1} under dry N_2 purge, using a mercury cadmium telluride detector.

Reactions of $Ph_2Si(NHNHMe)_2$ with MeI, HCl, and Ph_2SiCl_2

Reaction of $Ph_2Si(NHNHMe)_2$ with MeI

The reaction was carried out in a 50 mL Schlenk flask at ambient temperature under dry argon. **1** (1.28 g, 4.72 mmol) was dissolved in 20.0 mL of toluene–hexane (10:1), into which MeI (0.29 mL, 4.72 mmol) was added dropwise with stirring by a long needle syringe. Precipitation took place immediately in the solution upon the addition of MeI. Stirring was periodically stopped so that the clear layer of solution could be sampled for ^{1}H-NMR measurements. Compound **2** was the major product (ca. 80% in selectivity) in the first 3 h. After 10 h, the reaction was complete, and the salt was filtered under an argon atmosphere. The toluene–hexane was removed under reduced pressure. The final yields were 56% for **2** and 44% for **3**, as measured by ^{1}H-NMR. Various stoichiometric ratios of MeI with **1** were tried and the results were listed in Table 1.

The residue was redissolved in hot *n*-hexane (20 mL), and the solution was cooled to ambient temperature to give pure **2** in an isolated yield of 0.48 g (45%). After isolation of **2**, the solvent was stripped, the residue was redissolved in 10 mL of hexane, and the solution was cooled to 4°C to remove residual **2**. The mother liquor was then evaporated to yield **3** in 85% isomeric purity (0.43 g, 40%). **3** was further purified by recrystallization from concentrated pentane solution at 4°C.

Analytical data for **2**: ^{1}H-NMR (200 MHz): δ 2.89 (s, 6H, NCH), 3.44 (s, 2H, NH), 7.20 (m, 12H, Ph), 7.70 (m, 8H, Ph). ^{29}Si-NMR (56.9 MHz): −19.92. ^{15}N{^{1}H}-NMR (HMQC, 499.84 MHz): δ −311.82 (N{H}). EI-MS (*m/e*, abundance, fragmentation): 452(100) [M$^{\cdot+}$ − HNNHMe], 378(19) [M$^{\cdot+}$ − HNNHMe − NMe], 331(26) [M$^{\cdot+}$ − SiPh − MeH], 302(22) [M$^{\cdot+}$ − HNNHMe − SiPh], 226(12) [M$^{\cdot+}$ − HNNMe − $SiPh_2$]. IR (neat, ν cm^{-1}): 3331s, 3302s (N—H); 1018vs, 994s (Si—N). mp: 149–150°C.

Analytical data for **3**: ^{1}H-NMR (200 MHz): δ 2.83 (s, 6H, NCH), 3.39 (s, 2H, NH), 7.20 (m, 12H, Ph), 7.82 (m, 8H, Ph). ^{29}Si-NMR (56.9 MHz): δ − 18.52 (SiNH), −18.73 ($SiNCH_3$). IR (neat, ν cm^{-1}): 3373s, 3321s (N—H); 1022s, 998s (Si—N). mp: 102–104°C.

Reaction of $Ph_2Si(NHNHMe)_2$ with HCl

The general procedure was the same as in the previous experiment. **1** (1.36 g, 5.00 mmol) was dissolved in 20.0 mL of toluene–hexane (10:1), into which 5.0 mL of anhydrous HCl (5.00 mmol, 1.0 M in diethylether) was added dropwise with stirring by a long needle syringe. Fuming and precipitation took place immediately as HCl contacted the solution. The mixture was periodically sampled for ^{1}H-NMR measurement. The reaction was complete in 24 h. After work-up, the final product was **2** (58%), **3** (24%), and 18% of an unidentified product, by ^{1}H-NMR.

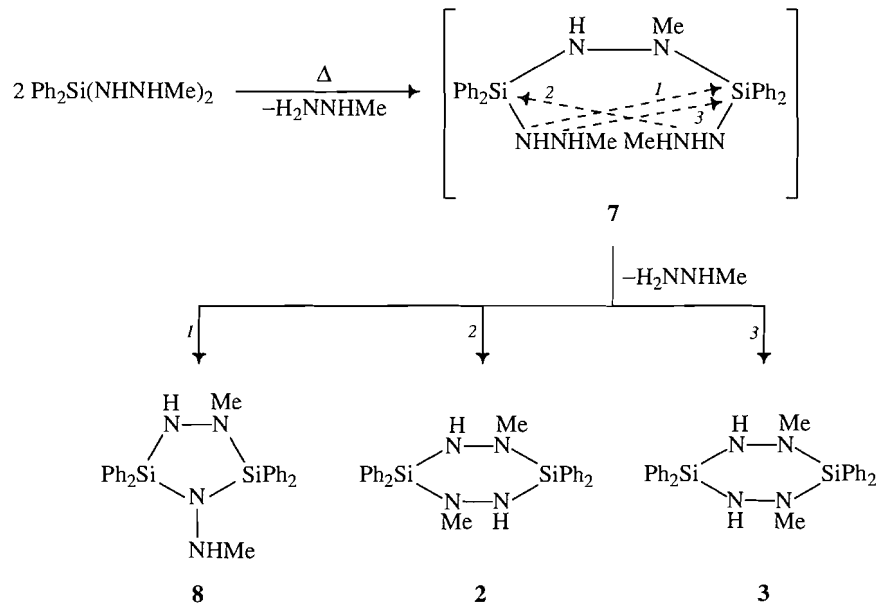

SCHEME 2

Reaction of $Ph_2Si(NHNHMe)_2$ with Ph_2SiCl_2

The procedure described above was followed. **1** (1.42 g, 5.20 mmol) was dissolved in 15.0 mL of toluene–hexane (10:1), into which 0.55 mL of Ph_2SiCl_2 (2.60 mmol) was added dropwise with stirring by a long needle syringe. Precipitation took place immediately in the solution upon the addition of Ph_2SiCl_2. The mixture was periodically sampled for ^{1}H-NMR measurement. Compound **3** was formed mainly in the early stages of the reaction, and the proportion of compound **2** increased gradually through the reaction. The formation of compound **6** occurred continuously throughout the reaction. The reaction was complete in 16 h. After work-up, the final product gave **2** (45%), **3** (29%), and **6** (26%), as measured by ^{1}H-NMR.

Analytical data for **6**: ^{1}H-NMR (200 MHz): δ 2.79 (s, 6H), 3.21 (s, 2H), 7.15 (m, 18H, Ph), 7.50 (m, 12H, Ph). ^{29}Si-NMR (56.9 MHz): −4.56 (SiCl), −8.75 (SiN_2).

Thermolysis of $Ph_2Si(NHNHMe)_2$

Thermogravimetric analysis (TGA) was performed on a Seiko 220 TG/DTA instrument. A flow of N_2 (~120 mL/min) was maintained during the TGA runs. The sample (8.80 mg) was heated in an alumi-

num pan at a rate of 10°C/min from 25 to 600°C. The result is shown in Fig. 1. The weight loss (5%) at 90–170°C was attributed to the presence of solvent (toluene) in the sample.

General procedure for preparing NMR samples

About 80 mg of $Ph_2Si(NHNHMe)_2$ was placed in an NMR tube, which was heated in a furnace at ca. 10°C/min up to a given temperature (250, 300, and 350°C, respectively) under argon atmosphere, and held at the desired temperature for 5 min. The furnace was then removed to let the tube cool to ambient temperature. The liquid formed during heating was removed under reduced pressure. C_6D_6 (0.5 mL) was then added into the tube to dissolve the residue and the sample was analysed by NMR spectroscopy.

In order to trap and identify the liquid formed on heating, a larger amount of **1** (ca. 1.00 g) was placed in a 10 mL Schlenk tube (1.5 cm in diameter) which was connected to a trap immersed in liquid nitrogen. The sample was heated to 300°C and the volatile product was collected under vacuum in the trap. This product was found to be H_2NNHMe. ^{1}H-NMR: d 2.32 (s, 3H, NCH), 3.05 (br, 3H, NH).

At 250°C, the residue was composed of **8** (31%), **2** (14%), **3** (7%), **1**, and some unidentified compound(s) (total 48%). Analytical data for **8**: ^{1}H-NMR (200 MHz): δ 2.41 (d, $^3J_{HNCH}$ = 4.2 Hz, 3H, N^4CH_3), 2.79 (s, 3H, N^1CH_3), 2.89 (q, $^3J_{HNCH}$ = 4.2 Hz, 1H, N^4H), 3.23 (s, 1H, N^2H), 7.20 (m, 12H, Ph_2Si), 7.86 (m, 8H, Ph_2Si). ^{29}Si-NMR (59.6 MHz): δ −16.38 (SiNH), −17.55 ($SiNCH_3$). $^{15}N\{^1H\}$-NMR (HMQC, 499.84 MHz, $^1J_{N—H}$ = 90 Hz): δ −307.02 ($N^2\{H\}$), −326.68 ($N^4\{H\}$). IR (neat, ν cm^{-1}): 3433–3315 br, (N—H); 994s, 934s (Si—N).

At 300°C, $Ph_2Si(NHNHMe)_2$ was completely converted to **8** (16%), **2** (21%), **3** (17%), and oligomeric product (46%).

At 350°C, a gaseous product was observed to evolve from the residue during heating. The pyrolysis residue consisted of **2** and **3** (total, 10%) and an uncharacterised oligomeric product.

Electronic effects on crown ether conformation. X-ray crystal structure and ^{13}C NMR study in solution and the solid phase of 4-nitrobenzo-9-crown-3 ether[1]

G.W. Buchanan, A.B. Driega, A. Moghimi, and C. Bensimon

Ottawa–Carleton Chemistry Institute, Department of Chemistry, Carleton University, 1125 Colonel By Drive, Ottawa, ON K1S 5B6, Canada

Received November 10, 1993[2]

G.W. Buchanan, A.B. Driega, A. Moghimi, and C. Bensimon. Can. J. Chem. **72**, 1764 (1994).

The X-ray crystal structure of the title material has been determined and the results are compared to previous findings for benzo-9-crown-3 itself. The ^{13}C NMR spectrum in solution has been unambiguously assigned using COSY and HETCOR methods. The solid phase ^{13}C spectrum has been obtained and the 7,10-d_4 derivative has been examined to aid in spectral assignments.

G.W. Buchanan, A.B. Driega, A. Moghimi et C. Bensimon. Can. J. Chem. **72**, 1764 (1994).

On a déterminé la structure cristalline du composé mentionné dans le titre par diffraction des rayons x et on a comparé les résultats avec ceux obtenus au cours d'une étude antérieure sur l'éther benzo-9-couronne fondamental. Faisant appel aux méthodes COSY et HETCOR, on a pu attribuer sans ambiguïté le spectre rmn du ^{13}C. On a déterminé le spectre du ^{13}C en phase solide et, dans le but d'aider à faire des attributions spectrales spéciales, on a étudié le dérivé 7,10-d_4.

[Traduit par la rédaction]

Introduction

Despite the substantial number of studies of benz-annelated crown ether stereochemistry using X-ray crystallographic methods, little attention has been paid to the possible electronic effects of aromatic substituents on crown ether conformation. Such effects might be expected to be substantial due to the possibility of varying degrees of conjugative electron release by the oxygen atoms bonded directly to the aromatic moiety as a result of the influence of substituents with a variety of electronic demand. The influence of a 4-nitro group on the ^{13}C NMR chemical shifts of dibenzo-18-crown-6 has been explored (1) and the results have been discussed in terms of transmission of the electronic effects throughout the molecule, however no X-ray data are reported. Presently we report the X-ray crystal structure of 4-nitrobenzo-9-crown-3 ether and compare the findings to our earlier results (2) for benzo-9-crown-3 itself. The introduction of the 4-nitro group permits an unambiguous assignment of the solution phase ^{13}C NMR spectrum and subsequently aids in the assignment of the solid phase ^{13}C spectrum. Finally the geometrical dependence of the aryl—O—*CH_2—^{13}C chemical shift on the C—C—O—*C torsion angle in benz-annelated crown ethers is clarified.

Results and discussion

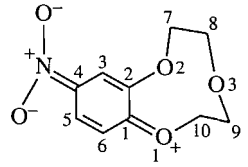
The structure and numbering scheme for 4-nitrobenzo-9-crown-3 (**1**) are shown in Fig. 1. The ORTEP diagram is illustrated in Fig. 2 and the ^{13}C NMR spectra are in Fig. 3. Table 1 contains bond lengths and bond angles while torsion angles are collected in Table 2. Crystallographic data are listed in Table 3 and atomic parameters in Table 4. In Table 5 are presented the ^{13}C NMR data.

(i) X-ray crystal structure

It is of interest to compare the torsion angle data for the C and O framework of **1** with those for benzo-9-crown-3, **2**, (2). Such a comparison shows that the overall geometries have many similarities, since only eight torsional networks change their geometries by more than 1° and the largest change is 9.6°. Details of the changes in excess of 1° are shown below.

	Torsion angle (deg)		
Network	**1**	**2**	Difference
C10—O1—C1—C2	−0.9	−10.5	9.6
C10—O1—C1—C6	179.0	170.3	8.7
C7—O2—C2—C3	73.9	79.9	6.0
C7—O2—C2—C1	−108.5	−105.0	3.5
O3—C9—C10—O1	−66.2	−63.3	2.9
O2—C7—C8—O3	−63.3	−66.7	3.4
C1—O1—C10—C9	91.4	98.4	7.0
C9—O3—C8—C7	111.7	108.7	3.0

The most pronounced effect of the introduction of the 4-nitro group is to induce a flattening effect in the C10—O—Cl—C2 and C10—O1—C1—C6 units so that there is essentially a planar conformation induced in the C10—O—aryl geometry. Such an effect is intuitively reasonable based on the known electron-withdrawing character of the nitro moiety. Thus the resonance structure **1***b* depicted below for **1** most accurately describes the electronic distribution in the molecule, with the C1—O1—C10 bond angle of 123.3° indicating sp^2 hybridized O1. The C2—O2—C7 angle of 115.4° is almost identical to the C8—O3—C9 angle of 114.4°. Thus the hybridization at O2 can be regarded as essentially sp^3.



1*b*

As expected, less pronounced nitration induced changes occur in the geometry in the vicinity of O2 and C7, due to the *meta* disposition of O2. The nitro group is twisted by only about 3° out of the plane of the aromatic ring. The increase in sp^2 character at O1 upon nitration induces a slight expansion of the O3—C9—C10—O1 angle to 66.2° in **1** from 63.9° in **2**. The

FIG. 1. Structure and numbering scheme for **1**.

normal *gauche* geometry (3, 4) for O—C—C—O torsional units in crown ethers is clearly retained in both compounds when sp^3 hybridized carbons are the central atoms of such units.

With respect to the bond angles of **1**, there is a large observed difference between the O1—C1—C2 angle of 128.1° and the O1—C1—C6 angle of 112.5°. Such a difference also occurs in the corresponding carbons of benzo-9-crown-3 itself and hence cannot be due to the introduction of the nitro group. From the ORTEP diagram and inspection of molecular models, it appears that the expansion of the O1—C1—C2 angle results from a molecular structural adjustment to minimize a potentially repulsive transannular interaction involving the equatorial H on C10 and O2.

(ii) Solution ^{13}C NMR spectrum

The ^{13}C NMR spectrum of **1** at 100.6 MHz shows 10 lines as expected, with resonances for C3 and C5 being nearly identical in chemical shift. Assignments of all resonances can be done unambiguously using a combination of 1D and 2D NMR techniques. Initially, C1, being *para* to the nitro group, will be the most deshielded quaternary carbon (5). Using this as a starting

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid, esd's refer to the last digit in the table.

point, the C2 and C4 assignments follow directly. The aromatic proton on C6 is the most shielded due to its disposition *ortho* to oxygen and *meta* to the NO_2 function. Also its multiplicity in the ^1H spectrum is consistent with this assignment. The aromatic proton on C3 shows only long range (^4J) coupling to H5. With the aromatic proton assignments in hand, the protonated aromatic C's were assigned via ^1J HETCOR. The solution ^1H and ^{13}C NMR spectra of the C7,10-d_4 version of **1** permitted elucidation of the resonance positions of C7,10 protons and carbons. Distinction between C7 and C10 protons was made on the basis of long range ^{13}C—^1H HETCOR (J = 5.0 Hz) since the assignments for their respective vicinal carbons C2 and C1 are clear. Subsequently the C8 and C9 protons were assigned via $^1H^1H$ COSY and the C7, C8, C9, and C10 carbons via ^1J HETCOR. Data are collected in Table 5.

(iii) Solid phase ^{13}C NMR spectrum

This spectrum is shown in Fig. 3. The most deshielded aromatic carbons are attributed to C1 and C2, respectively, with chemical shifts within 1–2 ppm of those found in solution. The C4 resonance is an asymmetric doublet, characteristic of a carbon bonded to the quadrupolar N atom. Resonances for C3, C5, and C6 are overlapping. With respect to the aliphatic resonances, the range of chemical shifts observed is 7.5 ppm, which is within 1 ppm of that found previously for benzo-9-crown-3 (2). The dipolar dephased spectrum of **1**-C7,10-d_4, clearly indicated that resonances at 69.9 and 77.4 ppm arise from C7 and C10. In solution, C7 resonates at 75.7 and C10 at 71.7 ppm, respectively. Although clearly some conformational averaging will occur in solution, we feel confident that the solid phase shift for C7 of **1** is 77.4 ppm and that of C10 is at 69.9 ppm.

TABLE 5. Solution and solid phase ^{13}C NMR chemical shifts for **1** (∂_c from TMS)

	^{13}C NMR shift	
Position	Solution (0.2 M in $CDCl_3$)	Solid
C1	157.3	157.7
C2	150.6	148.0
C3	120.1	121.2
C4	142.6	140.0
C5	120.3	121.2
C6	122.1	121.2
C7	75.4	77.4
C8	72.8	73.5
C9	72.0	70.7
C10	71.7	69.9

It remains to examine the origin of the 7.5 ppm shift difference between C7 and C10, with C10 being the more shielded site. Recently (2), we have calculated the dependence of CH_3 shielding of anisole on the CH_3—O—C—C dihedral angle. The results are depicted in Fig. 4.

Clearly, the aryl—O—*C resonance is most shielded for the *cis*-coplanar ($\theta = 0°$) and *trans*-coplanar ($\theta = 180°$) situations, with maximum deshielding occuring in the perpendicular conformation. Examination of the two aryl—O—*C angles involving each of C7 and C10 reveals substantial differences. For C7, the C7—O2—C2—C3 angle is 73.9° while the C7—O2—C2—C1 angle is −108.5°. In contrast, the C10 site appears to be nearly coplanar with the aromatic ring, with the C10—O1—C1—C2 angle being −0.9° and the C10—O1—C1—C6 angle 179.0°. These solid state geometries, coupled with the results of the anisole calculations, would lead one to expect that C10 should be shielded relative to C7 by ca. 10 ppm. The experimental NMR difference is 7.5 ppm. We regard this as satisfactory agreement, given that the calculations are for a model compound rather than for **1**, and are for the gas phase situation, rather than the solid.

The fundamental origin of the angular dependence of the OCH_3 shielding in methoxybenzenes has been discussed by Grant and co-workers (6). For non-planar OCH_3, the C—O bond is destabilized by the absence of conjugation between the O lone pairs and the aromatic π system. Thus the antibonding C—O orbital has a lower energy in non-planar than planar conformers. This reduces the ΔE (average electronic excitation energy) term in the denominator of the paramagnetic shielding term. Since this is a negative shielding term, a deshielding results.

Experimental

(i) Materials

The synthesis of benzo-9-crown-3-d_4 has been reported previously (7). Nitration of this material to give **1** was carried out using the following procedure which is similar to that reported for the synthesis of dinitrodibenzo-18-crown-6 ether (8). Benzo-9-crown-3-d_4 (3.3 g, 0.018 mol) was dissolved in a mixture of CH_2Cl_2 (70 mL) and glacial acetic acid (50 mL) and 1 drop of 96% H_2SO_4 was added with stirring. To this solution was added 8.0 mL of 70% HNO_3 and the mixture was stirred at ambient temperature for 15 min before refluxing for 3 h. After cooling, the acidic reaction mixture was neutralized by the addition of aqueous Na_2CO_3 while keeping the mixture cool in an ice bath. Following extraction with CH_2Cl_2, the organic extracts were backwashed with saturated $NaHCO_3$ and H_2O and dried over $MgSO_4$. Solvent removal gave a crude yellow solid which was recrystallized from

absolute ethanol to yield 2.4 g (59%) of **1**, mp. 93.5–95.0°C. High resolution MS: *m/z* for $C_{10}H_7O_5N_1D_4(M^+)$, calcd 229.0888, found 229.0926.

(ii) Spectra

Solution NMR spectra were recorded using a Bruker AMX-400 spectrometer equipped with a 5 mm inverse probe and an Aspect X32 computer. An Aspect 3000 processing controller was employed and all standard microprograms used are in the Bruker Software Library.

$^1H^1H$ COSY experiments were run using N-type phase cycling with a 45° mixing pulse. Free induction decays were acquired over 1024 data points for each of the 256 values of the evolution time, with a digital resolution of 5 Hz/point. The raw data were zero filled in F1 prior to transformation using the qsine window function for both F1 and F2. The matrix was symmetrized about the diagonal.

For the $^1H^{13}C$ HETCOR experiments, the free induction decays were typically acquired over 1024 data points for each of the 512 values of the evolution time, with a digital resolution of ca. 8 Hz/point in F2 and 4 Hz/point in F1. The raw data were zero filled in F1 prior to transformation using the qsine window function for both F1 and F2. The proton relaxation delays were set to 1 s. For 1-bond couplings, delays were set to emphasize couplings of 104 Hz, while for the long range HETCOR experiment, delays were set to correspond to couplings of 5 Hz.

Solid phase ^{13}C NMR spectra were recorded at 45.3 MHz using a Bruker CXP-180 spectrometer using cross polarization magic angle spinning (CPMAS) conditions described previously (9). For the dipolar dephased spectra, the ^1H decoupler was gated off for a period of 40 μs during the delay before the ^{13}C acquisition.

(iii) X-ray crystallographic measurements and structure solution

A summary of the crystallographic data is given in Table 3. Diffraction intensities were collected on a Rigaku diffractometer using MoKα radiation at −90°C. The θ/2θ scan technique with profile analysis (10) was employed. The space group was determined by systematic absences. Unit cell parameters were obtained by refinement of the setting angles of 25 reflections with 2θ values in the range of 40–46.9°. Lorentz and polarization factors were applied but no correction for absorption was made. The structure was solved by direct methods plus Fourier maps and was refined by full-matrix least-squares analysis with weights based on counting statistics. Non-H atoms were refined anisotropically and H atoms were refined isotropically. All calculations were performed using the NRC VAX crystal structure programs (11). Anisotropic thermal parameters and structure factor tables are available as supplementary data.[3]

PIERFRANCESCO BRAVO, MASSIMO FRIGERIO, GIOVANNI FRONZA, VADIM SOLOSHONOK, FIORENZA VIANI, GIANCARLO CAVICCHIO, GIANCARLO FABRIZI, and DORIANO LAMBA. Can. J. Chem. **72**, 1769 (1994).

(2*S*,2′*R*,R_S)-2-(Fluoromethyl)-2-{[(4-methylphenyl)sulfinyl][phenyl]methyl}oxirane (**4**) was obtained in high chemical yield and with high diastereoselectivity by reacting diazomethane with pure (3*R*,R_S)-1-fluoro-3-[(4-methylphenyl)sulfinyl]-3-phenylpropan-2-one (**3**), but also with its (3*S*,R_S)-**3**-diastereoisomer, in the latter case through inversion of the configuration at carbon 3. The corresponding methyl enol ethers **6** were isolated as by-products. NMR experiments and molecular modelling calculations were performed in order to clarify the equilibria in solution and the preferred conformations of both ketones **3**. Several variously substituted, sulfur-free tertiary α-(fluoromethyl)carbinols were obtained from the main reaction product (2*S*,2′*R*,R_S)-**4** through appropriate elaborations of the sulfinyl group and of the oxirane ring. The structure of (2*S*,2′*R*,R_S)-**4** was established by X-ray analysis of the open-chain derivative (2*S*,2′*R*,R_S)-1-bromo-3-fluoro-2′-{[(4-methylphenyl)sulfinyl][phenyl]methyl}propan-2-ol (**7**).

PIERFRANCESCO BRAVO, MASSIMO FRIGERIO, GIOVANNI FRONZA, VADIM SOLOSHONOK, FIORENZA VIANI, GIANCARLO CAVICCHIO, GIANCARLO FABRIZI et DORIANO LAMBA. Can. J. Chem. **72**, 1769 (1994).

Le (2*S*,2′*R*,R_S)-2-(fluorométhyl)-2-{[(4-méthylphényl)sulfinyl][phényl]méthyl}oxirane (**4**) fut obtenu avec d'excellents rendements chimiques et avec une diastéréosélectivité élevée en faisant réagir du diazométhane avec de la (3*R*,R_S)-1-fluoro-3-[(4-méthylphényl)sulfinyl]-3-phénylpropan-2-one (**3**) pure ou sous la forme de mélange avec le diastéréoisomère (3*S*,R_S)-(**3**); dans ce dernier cas, la réaction se fait par le biais d'une inversion de configuration au niveau du carbone 3. Les éthers énoliques méthyles correspondants (**6**) sont isolés comme sous-produits. Des expériences de RMN et des calculs de modelage moléculaire ont été exécutés pour clarifier les équilibres en solution et les conformations privilégiées des deux cétones **3**. On a préparé de nombreux α-(fluorométhyl)carbinols tertiaires sans soufre et portant divers groupes fonctionnels par élaborations appropriées du groupe fonctionnel sulfinyle et de l'anneau oxirane à partir du produit principal de la réaction le (2*S*,2′*R*,R_S)-**4**. La structure du (2*S*,2′*R*,R_S)-**4** a été déterminée par diffraction des rayons X du dérivé aliphatique (2*S*,2′*R*,R_S)-1-bromo-3-fluoro-2′-{[(4-méthylphényl)sulfinyl][phényl]méthyl)propan-2-ol (**7**).

[Traduit par la rédaction]

Introduction

The current surge of activity in the synthesis of fluoro analogs of organic natural substances and of biologically active molecules (1) has prompted searches for improved, easily accessible, fluorinated chiral building blocks (2). Our efforts in this area have centered on the preparation and use of sulfoxide-based fluorinated reagents. The 1-fluoro substituted-3-arylsulfinylpropan-2-ones **3** (R = H, alkyl, aryl; $R_F = CH_2F, CF_3$), easily accessible from fluorinated acetic acid esters **1** and chiral aryl alkyl sulfoxides **2** (Scheme 1), have been the chirons of choice for the construction of a number of target molecules of biological interest (3–5). In all cases the key step of the synthetic routes has been the transfer of chirality from sulfur to carbon, obtained by stereoselective hydride-promoted reduction of the carbonyl (6). Elimination of the chiral auxiliary sulfinyl group and carbon chain elaboration to the final target molecules followed. Some deoxyfluoro-pentoses and -hexoses, some fluoro-substituted acyclic nucleoside analogs, and the four diastereoisomers of 4-deoxy-4-fluoromuscarine (for biological testing) were obtained by that route (3–5).

While searching for an alternative route to achieve the chirality transfer from sulfur to the carbon chain, we found that, under appropriate reaction conditions, the transfer of the methylene group from diazomethane to the carbonyl can occur with excellent diastereofacial selectivity (7). This route yields some new highly versatile chirons (**4**, see Scheme 1) that may undergo a large number of transformations with high regio- and stereocontrol.

Expanding on this methodology, we will be reporting (P. Bravo et al., results to be published) on the high-yield preparation of a broad spectrum of chiral and enantiomerically pure 2,2-disubstituted oxiranes obtained by the action of diazomethane on a series of β-ketosulfoxides, some of them γ-polyhalogenated, as well as on a number of α-substituted and γ-mono- or polysubstituted β-ketosulfoxides.

In the present paper we wish to report (8) on the most remark-

able case of diastereoselection found while studying these methylene transfer reactions, i.e., the synthesis of (2*S*,2′*R*,R_S)-2-fluoromethyl-2-{[(4-methylphenyl)sulfinyl]methyl}oxirane **4** from the corresponding ketones (2*S*,R_S)- and (2*R*,R_S)-**3** (Scheme 1, R = Ph, $R_F = CH_2F$) and on some synthetically useful transformations performed on **4**.

Results and discussion

As already described (9), 1-fluoro-3-[(4-methylphenyl)sulfinyl]-3-phenylpropan-2-one (**3**) is obtained by acylating the lithium salt of benzyl 4-methylphenyl sulfoxide (**2**) with ethyl fluoroacetate (**1**) in tetrahydrofuran (THF).

A mixture of the two diastereoisomers (3*R*,R_S)- and (3*S*,R_S)-**3** is obtained in a 1.0:1.8 ratio and both compounds can be obtained in optically pure form by fractional crystallization (see Experimental).

The reactivity towards diazomethane and the diastereoselectivity of the process were tested both on diastereoisomerically pure ketones and on mixtures, in three different solvents: methanol, THF, and ethyl ether. In all cases examined, a mixture of oxiranes **4** and of (*E*) and (*Z*) methyl enol ethers **6** was observed, in different relative ratio depending on the stereochemistry of the starting ketones and the reaction medium.

When an approximately 0.5 M ethereal solution of diazomethane (10) was added at 0°C to a methanolic solution of optically pure (3*R*,R_S)-1-fluoro-3-[(4-methylphenyl)sulfinyl]-

3-phenylpropan-2-one **3**, a fast reaction occurred (in less than 5 min) and the product mixture was isolated in about 96% overall yield. The ^1H and ^{19}F NMR analysis of the crude showed the presence of two oxiranes (^{19}F NMR δ: −228.5 and −227.4 ppm) and of two enol ethers (^{19}F NMR δ: −212.0 for (*E*)-**6** and δ: −217.3 ppm for (*Z*)-**6**). The main oxirane (δ: −228.5 ppm) was isolated in optically pure form in 83.8% yield and the (2*S*,2′*R*,R_S) absolute stereochemistry was determined as reported (vide infra). The other compounds mentioned were detected in amounts of less than 6% (see Experimental). When the ethereal solution of diazomethane was added to a 2:1 mixture of 3*R*/3*S* ketones **3** in three different solvents (methanol, THF, and ethyl ether) the resulting mixtures showed the following: (*a*) (2*S*,2′*R*,R_S)-**4** (^{19}F NMR δ: −228.5 ppm) was always the main product, being isolated in, respectively, 76, 70, and 65% yield; (b) another oxirane (^{19}F NMR δ: −229.2 ppm) was detectable in reaction mixtures in, respectively, 5, 8, and 4% yield; (*c*) the other two oxiranes (^{19}F NMR δ: −227.4 and −226.8 ppm) were only detectable in the third case by NMR analyses on the crude; (*d*) *E*/*Z*-**6** methyl enol ether mixtures were present in, respectively, 15, 16, and 13% yield. Comparable results were obtained starting from a ca. 1:1 mixture of diastereoisomeric ketones **3** (see Experimental). Moreover, when optically pure (3*S*,R_S)-**3** ketone was reacted with diazomethane in the same three solvents, (2*S*,2′*R*,R_S)-**4** was still the main reaction product although the stereochemistry at C-2′ was opposite to the corresponding stereochemistry of the starting ketone. The oxirane could be isolated in optically pure form in, respectively, 45, 60, and 62% yields whilst the remaining three oxiranes were present in slightly different relative ratios (27, 14, and 13% respectively, see Experimental). As the global yield was always nearly quantitative, the *E*/*Z*-**6** methyl enol ether mixtures accounted for the remaining reaction products.

In conclusion, the same (2*S*,2′*R*,R_S)-**4** oxirane was surprisingly obtained in all cases, both starting from an optically pure ketone or from different mixtures of the two diastereoisomers, in a largely prevailing amount. This implies that in the reaction medium an equilibrium between the two ketones may occur, that the reaction rate of diazomethane may be higher for one diastereoisomer than for the other, and that the approach to the carbonyl group may be preferred from one side rather than from the other.

Therefore, the final products ratio may be influenced by different factors: epimerization rates of the ketones, equilibrium composition, presence of enolic forms, preferred conformations of the diastereoisomeric ketones, and catalytic effect of methanol on the reaction of diazomethane on carbonyls (11).

The supposed species present in solution at equilibrium and the products isolated from the reaction are reported in Scheme 2.

To obtain further information on the nature of the reported equilibria, the reaction progress was monitored by ^{19}F NMR, through progressive spectral recordings of solutions of both diastereoisomeric ketones **3** in perdeuterated methanol. Moreover, to obtain some information about the different reactivity of diazomethane on both ketones **3**, their respective preferred conformations were investigated by molecular modelling calculations based on minimum energy convergence.

Equilibration experiments

The ^{19}F NMR spectrum of (3*S*)-**3**, just after dissolution in perdeuterated methanol, shows a triplet of doublets at −227.02 ppm (J(F, CH_2) = 16.6 Hz, J(F, H-3) = 2.4 Hz) (Fig. 1 (*a*′)) consistent with the presence of a single diastereoisomer. During this time two new triplets appear at −227.06 and −226.56 ppm (J(F, CH_2) = 46.6 Hz) lacking the long-range coupling ^4J(F, H-3) (Fig. 1 (b′), (c′)). The signal at −227.06 ppm can be assigned to the C-3 deuterated form of (3*S*)-**3**, the fluorine chemical shift being shifted to high field by 0.04 ppm with respect to (3*S*)-**3** because of the isotopic effect of the deuterium atom four bonds away. The second signal at −226.56 ppm can be attributed to the deuterated species of (3*R*)-**3** formed in solution by epimerization at position 3. The thermodynamic equilibrium is reached in about 30 h showing a ca. 4:6 ratio of the two epimeric forms (3*S*)- and (3*R*)-**3**, respectively (Fig. 1(*c*)).

The (3*R*)-**3** fluoroketone behaves similarly. Just after dissolution in methanol the ^{19}F NMR spectrum displays a triplet of doublets at −226.52 ppm (J(F, CH_2) = 46 Hz, J(F, H-3) = 2.1 Hz) (Fig. 1(*a*)). After some time two new signals appear at −226.56 and −227.06 ppm (Fig. 1(*b*)) that can be assigned to the C-3 deuterated species (3*R*)- and (3*S*)-**3**, respectively. In this case the equilibration rate is slower than that observed for (3*S*)-**3** and the thermodynamic equilibrium is reached after ca. 3 days (Fig. 1(*c*)). The enolic forms (*E*)- or (*Z*)-**5** were undetectable by ^1H and ^{19}F NMR measurements. These experiments show that the epimerization process at C-3 for (3*S*)- and (3*R*)-**3** is rather slow in solution.

On the contrary their reaction with diazomethane is very fast, leading in a few minutes to the formation of (2*S*,2′*R*,R_S)-**4** as main product. This was true both for the reactions reported in the Experimental and for test reactions run in an NMR tube. These findings suggest that in the presence of diazomethane the epimerization rate of ketones is much faster than that observed in methanol only. Incorporation of deuterium can be taken as positive evidence for the transient formation of enolic forms **5**.

Molecular modelling calculations

As outlined above, the fluoroketones (3*S*)-**3** and (3*R*)-**3** show a peculiar behaviour, which can be summarized as follows: (*i*) they epimerize slowly in solution to form a mixture of ca. 60% of (3*R*)-**3** and 40% of (3*S*)-**3** (methanolic solution); (*ii*) they react immediately with diazomethane, leading to the formation of the (2*S*,2′*R*)-**4** oxirane as main product. These observations suggest that diazomethane would react preferentially with the (3*R*)-**3** isomer, which is generated in a fast-catalysed reaction. Possibly a rationale of this behaviour may be found in the conformational properties of the two molecules, since a particular conformation may explain, in principle, the marked preference of the reactivity towards diazomethane.

To this end we performed some molecular mechanics calculations[4] on the two fluoroketones. The conformational space was explored starting from a minimized random structure and varying the two most significant torsional angles, OSC_3C_2 (ϕ_1) and SC_3C_2O (ϕ_2), over 360° in steps of 30°. Every conformation obtained in this way was minimized and the values of the strain energy have been reported as a function of ϕ_1 and ϕ_2 in a bidimensional plot. As a result of this searching procedure, the (3*R*)-**3** epimer shows two isoenergetic minima having ϕ_1,ϕ_2, defined according to Kline and Prelog, of ca. −45°,−90° and 60°,90°, respectively. The epimer (3*S*)-**3**

[4]The calculations were performed with the MMX Version 89.000 program (Serena Software, Box 3076, Bloomington, IN 47402-3076, U.S.A.).

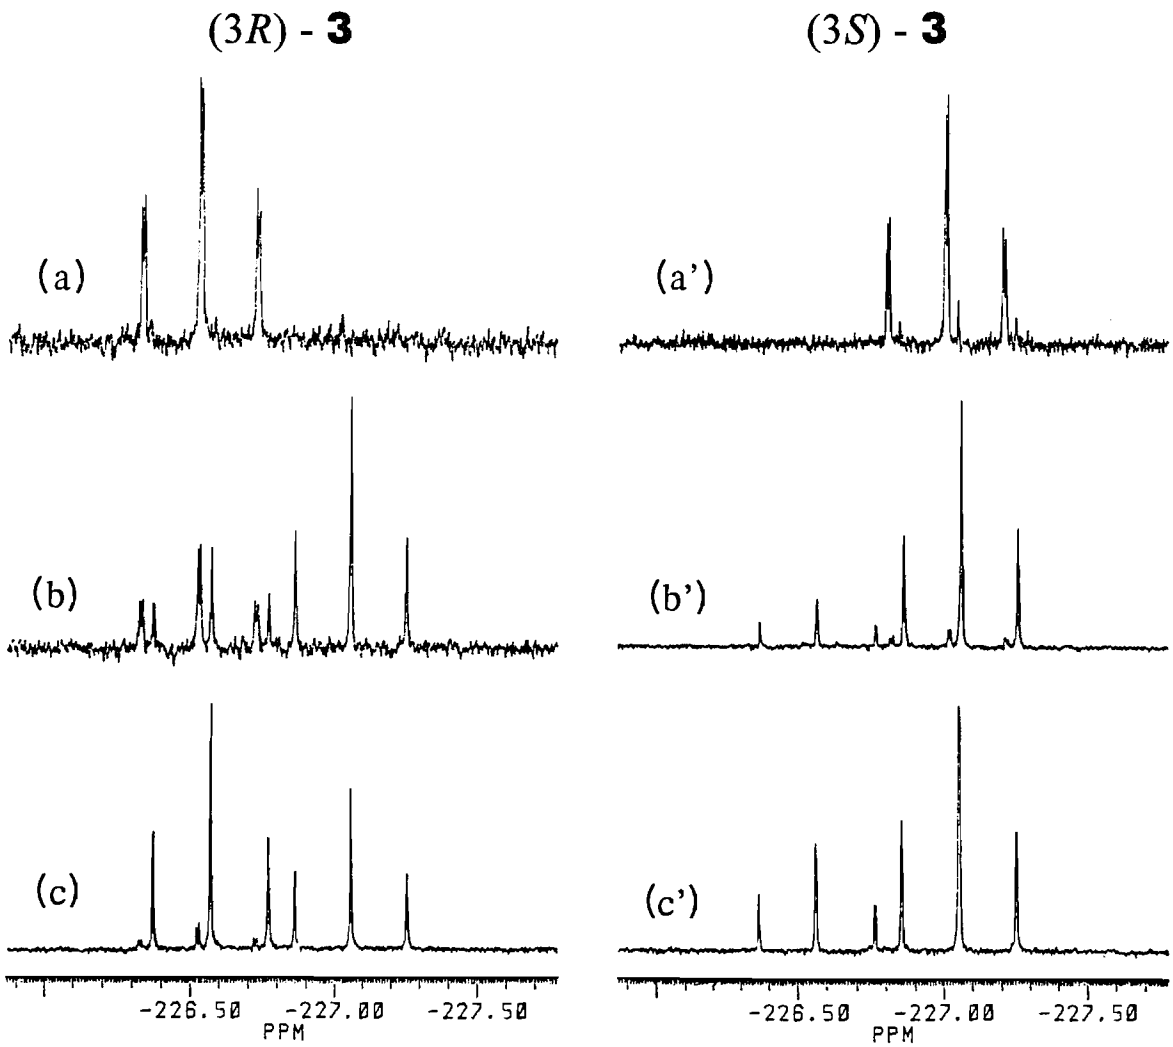

FIG. 1. ^{19}F NMR spectra of (3*R*,R_S)- and (3*S*,R_S)-**3** in CD_3OD. (3*R*,R_S)-**3**: (*a*) just after dissolution; (*b*) after 4 h; (*c*) after ca. 3 days (thermodynamic equilibrium). (3*S*,R_S)-**3**: (*a'*) just after dissolution; (*b'*) after 2 h; (*c'*) after 12 h; (*c*) after ca. 30 h.

shows only one minimum, having the same strain energy of the minima found for (3*R*)-**3**, with ϕ_1,ϕ_2 of ca. 180°,0°, respectively.

These results can help to tentatively explain the observed behaviour of the two ketones. Although the calculated energy minima are practically the same, the (3*R*)-**3** isomer shows two minimum energy conformations, while the (3*S*)-**3** shows only one, and this fact may account for the observation that in solution the equilibrium is shifted in favour of (3*R*)-**3**. Moreover, from the molecular mechanics calculations the conformation of (3*R*)-**3** (ϕ_1,ϕ_2 of ca. −45°, −90°) shows a side of the carbonyl group well exposed, while the other side is hindered by the presence of the *p*-tolyl group (Fig. 2). Thus, reasonably, for this molecular conformation, diazomethane has no difficulty to approach the carbonyl group, leading to the (2*S*,2'*R*)-**4** epoxide, the main reaction product.

The second conformation of (3*R*)-**3** (ϕ_1,ϕ_2 of ca. 60°,90°) may be considered less favoured to the attack of diazomethane, at least from the point of view of steric hindrance, since the carbonyl group has the sulfoxide group on one side and the phenyl residue on the other side (Fig. 3).

Finally, the conformational analysis of (3*S*)-**3** shows one minimum only, where the carbonyl is hindered on both sides by the presence of the two aromatic rings (Fig. 4). Furthermore, an inspection of Fig. 4 shows that the H—C(3) bond is nearly perpendicular to the carbonyl plane, and therefore enolization of (3*S*)-**3** should be a favored process.

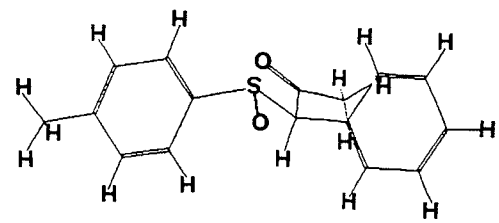

FIG. 4. Calculated minimum-energy conformation of (3*S*)-**3**.

Elaboration of the synthon

Some synthetically useful elaborations have been performed starting from the main reaction product (2*S*,2′*R*,R_S)-**4** in order to obtain differently substituted tertiary α-(fluoromethyl)carbinols, useful chiral building blocks for new fluorinated materials (12) (Scheme 3). Among the various reagents available to open the highly reactive oxirane ring (13) were chosen: bromide ion to introduce a halogen atom (14), water and benzylamine to introduce oxygen and nitrogen functions, and the cyanide ion to introduce to nitrile group (15). In all cases mentioned, the chiral auxiliary sulfinyl group was reductively removed.

Specifically, treatment of (2*S*,2′*R*,R_S)-**4** with cupric bromide and lithium bromide (1:2 molar ratio) in anhydrous THF afforded the (2*S*,2′*R*,R_S)-fluoromethyl bromohydrine **7** in 96% yield. X-ray analysis on a crystal sample of **7** gave stereochemical informations on the C-2 and C-2′ chiral centres (see below). Reaction of (2*S*,2′*R*,R_S)-**4** with water in THF and catalytic amounts of perchloric acid aqueous solution gave (2*S*,2′*R*,R_S)-fluoromethyl diol **8** in 90% yield, and treatment of the same starting oxirane **4** with benzylamine in THF gave (2*S*,2′*R*,R_S)-fluoromethyl aminoalcohol **11** in 95% yield.

Removal of the sulfur atom was carried out in two steps: first, reduction of the sulfinyl group to the thio group following the Oae procedure (16) (NaI, trifluoroacetic anhydride in acetone at −20°C) and, second, reductive desulfenylation promoted by Raney nickel in ethanol at reflux under a hydrogen atmosphere. Accordingly, fluorodiol **8** gave the thio derivative **9** in 90% yield, and (*S*)-2-benzyl-3-fluoropropan-1,2-diol (**10**) was obtained from the second step in 76.4% yield.

On the other hand, the fluoromethyl amino alcohol **11**, upon treatment with sodium iodide and trifluoroacetic anhydride, gave the corresponding trifluoroacetyl derivative **12**, which after reaction with Raney nickel afforded a nearly 1:1 mixture of *N*-trifluoroacetyl *N*-benzyl amino alcohol **13** and trifluoromethyl amino alcohol **14** in 62% global yield.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

Finally, alkaline treatment of **13** and **14** gave, respectively, optically pure (*S*)-2-benzyl-1-benzylamino-3-fluoropropan-2-ol (**15**) and (*S*)-1-amino-2-benzyl-3-fluoropropan-2-ol (**16**).

A different strategy had to be employed for the synthesis of hydroxy fluoronitrile **19** because, due to the basic medium, the deprotonation at C-2′ became absolutely competitive with the opening of the oxirane ring by cyanide ion. To prepare **19**, the sulfoxide group was deoxygenated to (2*S*,2′*R*)-**17** and the oxirane ring was opened by potassium cyanide in the presence of lithium perchlorate to give (3*S*,3′*R*)-hydroxy nitrile **18** in 50% isolated yield. After removal of the *p*-tolylthio group with Raney nickel under a hydrogen atmosphere, (*S*)-3-benzyl-4-fluoro-3-hydroxybutanenitrile (**19**) was isolated in optically pure form in 65% yield.

Structural assignments

The reaction of (3*S*)-**3** and (3*R*)-**3** with diazomethane can give rise to the formation of four diastereoisomeric oxiranes, which have been recognized by NMR spectroscopy.

The oxiranes (2*S*,2′*R*)-**4**, the main reaction product, and (2*S*,2′*S*)-**4** were isolated and analysed separately, while (2*R*,2′*R*)-**4** and (2*R*,2′*S*)-**4**, the minor products of the reaction, were analysed as a mixture with the main isomers.

The presence of the oxirane ring in compounds **4** was recognized from the value of the geminal coupling constant $J(H_3, H'_3)$ of ca. 4 Hz (see Experimental), which is characteristic of the oxirane ring. Attempts to determine the relative stereochemistry of the epoxides **4** from long-range couplings or intramolecular NOE enhancements were unsuccessful. Only (2*R*,2′*S*)-**4** shows a long-range coupling $^4J(H_2, H_3)$ of 1.3 Hz, suggesting a rather rigid conformation around the C2—C2′ bond, but this coupling is not diagnostic for the configuration assignment. Thus the configuration of the main product (2*S*,2′*R*)-**4** was established by X-ray analysis after conversion to the bromo derivative **7** and that of (2*S*,2′*S*)-**4** by CD analysis of the corresponding sulfide (see below), while the configuration of the minor products (2*R*,2′*S*)-**4** and (2*R*,2′*R*)-**4** was not assigned. The reduction of the sulfoxides (2*S*,2′*R*)-**4** and (2*S*,2′*S*)-**4** led to the obtainment of the two diastereoisomeric sulfides (2*S*,2′*R*)- and (2*S*,2′*S*)-**17**, respectively, without the opening of the oxirane ring, as shown by the value of $J(H_3, H'_3)$ of ca. 4.6 Hz.

The reaction on the oxirane ring of many nucleophile reagents, performed on both sulfoxide- and sulfide-bearing moieties, led to the formation of the derivatives **7**–**19**. In all cases the oxirane ring is opened leaving a tertiary OH group linked to the carbon C-2, while the entering group (OH, $NHCH_2Ph$, CN, Br) is linked to the methylene carbon C-3. The opening of the oxirane ring was evidenced by the change in the $^2J(H_3, H'_3)$, which varies from ca. 4 Hz to 11–17 Hz, depending on the nature of the C-3 substituent.

X-ray crystallographic analysis of the bromohydrin 7

Colourless polyhedron-shaped crystals were grown by slow concentration of a isopropyl ether solution at 25°C. A crystal with approximate dimensions 0.35 × 0.30 × 0.25 mm was used for data collection and set on a Siemens R3m/V diffractometer. Accurate unit cell dimensions were determined by least-squares fit of the setting angles of 25 selected reflections (2θ = 60°–84°). Crystal data are as follows: $C_{17}H_{18}BrFO_2S$, FW = 385.3, orthorhombic, a = 8.637(2), b = 9.983(2), c = 19.798(2) Å, V = 1707.1(2) Å^3, Z = 4, ρ_c = 1.499 Mg m^{-3}, $F(000)$ = 784, μ(Cu-Kα) = 45.50 cm^{-1} (25°C, Cu-Kα radiation λ = 1.54178 Å), space group $P2_12_12_1$. Intensities were measured using graphite-monochromated Cu-Kα radiation with θ–2θ scans to 2θ = 136° (h −10/1, k −12/1, l −23/1). The intensities of three check reflections (0 0−2, −1−1−3, 0−4 0) measured every 100 reflections throughout the data collection showed only small random fluctuations. The data were corrected for Lorentz, polarization, and absorption effects (ψ scan, minimum and maximum transmission factors 0.658 and 0.936), no extinction correction.

Of the 2513 reflections measured, 2227 were unique (R_{int} = 0.0065) and 2049 had $F_o \geq 4\sigma(F_o)$. The structure was solved[5] by the use of the automatic Patterson solution method to locate the heavy atom. A Fourier phased on the bromine atom revealed all the remaining non-H atoms. The structure as then refined isotropically and anisotropically by full-matrix least-squares procedure. Difference Fourier maps, computed at the end of the anisotropic least-squares refinement, showed all H atoms in configurationally feasible positions; these were refined with isotropic displacement coefficients. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with $w = [\sigma^2(F_o) + 0.0010F_o^2]^{-1}$. In the final cycles of refinement the maximum parameter shift corresponded to 0.366σ. A final difference Fourier map showed no features ≥0.50 e Å^{-3}. Refinement converged[6] with R = 0.0303, wR = 0.0439, and S = 1.14 for the 2049 $F_o \geq 4\sigma(F_o)$. The final positional and equivalent isotropic displacement parameters for the non-H atoms are given in Table 1. Bond lengths and valence angles are listed in Table 2. Anisotropic displacement parameters and tables of observed and calculated structure factors have been deposited.[7]

A perspective view of **7** is shown in Fig. 5. On the basis of the known absolute configuration at sulfur (*R*), the relative configurations at the new chiral centre C(2) and at C(3) are *S* and *R*, respectively. The Hamilton *R* test confirmed the absolute configuration assignment at higher than 99.5% confidence. The conformation around the central S(1)—C(3) bond is *transoid*, the torsional angle C(2)—C(3)—S(1)—C(30), defining the orientation of the phenyl ring and the fluoromethyl moiety, being 164.5(2)°. The molecular geometry at S(1) conforms to that found for related *p*-tolylsulfinyl derivatives (17–21).

Circular dichroism experiments

To establish the absolute stereochemistry at C-2 and C-2′ of the less abundant isolated oxirane **4** obtained from (3*R*,R_S)-**3**, circular dichroism measurements were made. For this purpose, both isolated epoxides **4** were reduced at the sulfur atom to give thio derivatives **17**.

By X-ray analyses on (2*S*,2′*R*,R_S)-**7**, information on the absolute stereochemistry at C-2 and C-2′ of the most abundant epoxide (2*S*,2′*R*,R_S)-**4** and, consequently, of its thio derivative (2*S*,2′*R*)-**17**, was obtained.

(2*S*,2′*R*)-**17** showed a negative maximum at 199 nm and a

[5]All calculations, including the drawing of Fig. 5, were performed with SHELXTL-Plus, Version 4.23 (1991), by G.M. Sheldrick and available from Siemens Analytical Instruments Inc. The scattering factors used were those employed by SHELXTL-Plus.

[6]$R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$; $wR = \{\Sigma w(|F_o| - |F_c|)^2/\Sigma w(|F_o|^2\}^{1/2}$; $S = \{\Sigma w(|F_o| - |F_c|)^2/(n - m)\}^{1/2}$.

second negative absorption at 230 nm. On the contrary, the investigated thio oxirane **17** showed a positive maximum at 199 nm and a second positive absorption at 231 nm.

Assuming that the absorption was mainly due to the electronic transitions of benzylic and sulfide chromophores (22) and that the opposite CD behaviour was the consequence of chromophores situated in an enantiomeric environment (23), an opposite stereochemistry at C-2′ was assigned.

By $[\alpha]_D^{20}$ measurements and NMR spectral analyses (see Experimental), a diastereoisomeric relationship was established: as a consequence, the absolute stereochemistry of the less abundant oxirane was assigned as (2*S*,2′*S*)-**17**.

Experimental

Apparatus, materials, and methods

^1H, ^{13}C, and ^{19}F NMR spectra were recorded with a Bruker AC 250L spectrometer in $CDCl_3$. C_6F_6 was used as internal standard (δ_F = −162.90) for ^{19}F. The $[\alpha]_D^{20}$ values were determined on a Jasco DIP-181 polarimeter. Melting points are uncorrected and were obtained on a capillary apparatus. Thin-layer chromatography (TLC) was run on silica gel $60F_{254}$ Merck; flash column chromatography was performed with silica gel 60 (60–200 μm, Merck). THF was freshly distilled from lithium aluminium hydride, diisopropylamine was freshly distilled from calcium hydride, and a 2.6 M solution of *n*-butyllithium in hexanes (Aldrich) was employed. Diazomethane was distilled from an ethanol–water (3:1, 100 mL) solution of potassium hydroxide (15 g) to which an ethereal solution (400 mL) of Diazald (64.2 g) was added dropwise. Ethyl ether was previously washed with an acidic (H_2SO_4) aqueous solution of ferrous sulfate. In other cases, commercially available reagent grade solvents were employed without further purification.

Synthesis of 1-fluoro-3-[(4-methylphenyl)sulfinyl]-3-phenylpropan-2-one (3)

A solution of (+)-(*R*) benzyl 4-methylphenyl sulfoxide (**2**, 5.0 g, 21.7 mmol) was added to a solution of LDA (28.2 mmol, 4.0 mL) in THF (50 mL) at −78°C under argon. Into the resulting yellow solution at −60°C was dropped ethyl fluoroacetate (**1**, 6.3 mL, 65.1 mmol) in THF (5 mL); the reaction was quenched with a saturated aqueous solution of ammonium chloride, extracted with ethyl acetate (3 × 100 mL), dried over anhydrous sodium sulfate, and the solvent was evaporated. Flash chromatography of the residue (4:1 toluene:ethyl acetate as eluent) gave a 1.0:1.8 (^{19}F NMR ratio) mixture of (3*S*,R_S)- and (3*R*,R_S)-**3**. Crystallization of the crude mixture from ethyl acetate afforded (3*S*,R_S)-**3** in pure form. The mother liquors were treated with hexane, and the solid obtained was filtered, analysed by ^{19}F NMR, and identified as a ca. 1:1 mixture of the two diastereoisomers. The mother liquors thus enriched were treated with another portion of hexane to give pure (3*R*,R_S)-**3** as white crystals.

(3*S*,R_S)-**3**: mp 117–119°C (ethyl acetate); $[\alpha]_D^{20}$ +341.3 (*c* 0.1, $CHCl_3$); R_F (4:1 toluene:ethyl acetate) 0.35; ^1H NMR ($CDCl_3$) δ: 2.42 (s, 3H, CH_3), 4.58 (d, 2H, CH_2, $J(CH_2, F)$ 48.0 Hz), 4.96 (d, 1H, CH, J(CH, F) 2.0 Hz), 7.22–7.45 (m, 9H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −226.8 (td, $J(CH_2, F)$ 48.0, J(CH, F) 2.2 Hz); ^{19}F NMR (CH_3OH) δ: −227.0 (td, $J(CH_2, F)$ 46.5, J(CH, F) 2.1 Hz). Anal. calcd. for $C_{16}H_{15}FO_2S$: C 66.19, H 5,21; found: C 66.12, H 5.20%.

(3*R*,R_S)-**3**: mp 111–113°C (hexane); $[\alpha]_D^{20}$ −83.3 (*c* 0.5, $CHCl_3$); R_F (4:1 toluene:ethyl acetate) 0.35; ^1H NMR ($CDCl_3$) δ: 2.27 (s, 3H, CH_3), 4.92 (d, 2H, CH_2, $J(CH_2, F)$ 48.0 Hz), 4.96 (d, 1H, CH, J(CH, F) 2.0 Hz), 7.0–7.4 (m, 9H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −227.3 (td, $J(CH_2, F)$ 48.0, J(CH, F) 2.2 Hz; ^{19}F NMR (CH_3OH) δ: −226.5 (td, $J(CH_2, F)$ 46.5, J(CH, F) 2.1 Hz). Anal. calcd. for $C_{16}H_{15}FO_2S$: C 66.19, H 5.21; found: C 65.98, H, 5.19%.

Reaction of the ketones 3 with diazomethane

The reaction was run by dissolving ketones in three different solvents: methanol (method A), THF (method B), and ethyl ether (method C).

General procedure

A solution of the starting compound **3** (1 g, 3.3 mmol) dissolved in a solvent (100 mL) at 0°C was treated portionwise with an ethereal solution of diazomethane (ca. 0.5 M) and kept at the same temperature until the yellow colour of the diazomethane solution persisted (ca. 50 mL was needed). The reaction progress was monitored by TLC (3:2 chloroform:ethyl acetate as eluent), and after ca. 10 min all starting compound **3** disappeared. A few drops of acetic acid were added to destroy the diazomethane excess, the solvent was evaporated under reduced pressure (benzene (3 × 2 mL) was added to remove the acetic acid), and the residue was purified by flash chromatography (4:1 chloroform:ethyl acetate).

Method A

Starting from (3*R*,R_S)-**3**, a 1.0:1.8 mixture (the ratio was measured from the ^{19}F NMR spectrum) of (*E*)-(R_S)-3-fluoro-2-methoxy-1-phenyl-1-[(4-methylphenyl)sulfinyl]propene (*E*)-**6** (^{19}F NMR ($CDCl_3$) δ: −212.0 ppm) and (*Z*)-**6** (^{19}F NMR ($CDCl_3$) δ: −217.3 ppm) in 6.7% global yield was isolated along with a mixture of oxiranes **4** (89.3% global yield) whose ^{19}F NMR signals resonated at δ −228.5 and −227.4 ppm, respectively. After crystallization of the latter mixture (1:1 hexane:ethyl acetate) the major oxirane was obtained in pure form.

(2*S*,2′*R*,R_S)-**4**: mp (isopropyl ether) 89–91°C; $[\alpha]_D^{20}$ −197.4 (*c* 1.1, $CHCl_3$); R_F (4:1 chloroform:ethyl acetate) 0.35; ^1H NMR ($CDCl_3$) δ: 2.31 (s, 3H, CH_3), 3.08 (d, 1H, H-3, $J(H_3, H'_3)$ 4.0 Hz), 3.88 (td, 1H, H′-3, $J(H'_3, F)$ 4.0, $J(H'_3, CHF)$ 1.0 Hz), 4.18 (d, 1H, H-2′, $J(H_{2'}, F)$ 1.0 Hz), 4.31 (dd, 1H, CH*H*′F, J(H′, F) 47.1, J(H′, H) 10.1 Hz), 4.42 (ddd, 1H, C*H*H′F, J(H, F) 47.0 Hz), 6.95–7.30 (m, 9H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −228.5 (tdd, $J(F, H)_{gem}$ 47.0, $J(F, H'_3)$ 4.0, $J(F, H_{2'})$ 1.0 Hz). Anal. calcd. for $C_{17}H_{17}FO_2S$: C 67.08, H 5.63; found: C 67.27, H 5.61%.

Similar results were observed starting from mixtures in different ratios (1.0:1.3 or 1.0:2.0) of (3*S*,R_S)- and (3*R*,R_S)-**3**, respectively. From a 1.0:2.0 (3*S*)-/(3*R*)-**3** mixture, ^{19}F NMR analysis of the crude gave a 1.0:1.4 ratio of, respectively, (*E*) and (*Z*) enol ethers **6** in 15% global yield and 76.3% (isolated yield) of (2*S*,2′*R*,R_S)-**4** along with traces (<5%) of two different oxiranes whose ^{19}F NMR signals resonated at −227.4 and −229.2 ppm.

From a 1.0:1.3 (3*S*)/(3*R*)-**3** mixture, the same analysis on the crude gave a 1.0:1.5 ratio of (*E*)- and (*Z*)-**6** in 24.0% global yield, (2*S*,2′*R*,R_S)-**4** in 55.0% isolated yield, 9% of the oxirane **4** resonating at −229.2 ppm (^{19}F NMR), and 7.6% of a mixture of epoxides showing ^{19}F NMR signals at −226.8 and −227.4 ppm.

Starting from a solution of (3*S*,R_S)-**3**, a 1.0:1.1 mixture of (*E*)- and (*Z*)-**6** (21.9% yield) and a 1.7:1.0:10.0:3.3 ratio of all four possible oxiranes (^{19}F NMR ($CDCl_3$) signals being at δ −226.8, −227.4, −228.5 and −229.2 ppm, respectively) in 72.5% global yield were obtained.

Method B

When a solution of (3*S*,R_S)-**3** in THF was treated with diazomethane, a 1.0:1.5 mixture of (*E*)- and (*Z*)-**6** (16.3% global yield) and a 1.0:3.6:25.4:1.5 mixture of oxiranes **4** (^{19}F NMR ($CDCl_3$) signals being at δ −226.8, −227.4, −228.5, and −229.2 ppm, respectively) (73.6% global yield) were obtained. Similarly, from a 1.0:2.0 (3*S*)/(3*R*)-**3** mixture, a 1.0:1.4 (*E*)/(*Z*)-**6** mixture (16.3% global yield) and a 8.6:1.0 mixture of (2*S*,2′*R*,R_S)-**4** and oxirane resonating at −229.2 ppm in 77.7% global yield were obtained. Flash chromatography on the crude (7:3 toluene:ethyl acetate) afforded (2*S*,2′*S*,R_S)-**4**.

(2*S*,2′*S*)-**4**: $[\alpha]_D^{20}$ +311.9 (*c* 0.7, $CHCl_3$); ^1H NMR ($CDCl_3$) δ: 2.34 (s, 3H, CH_3), 2.95 (dt, 1H, H-3, $J(H_3, H'_3)$ 4.0, $J(H'_2, H_3)$ 1.3, $J(H_3, F)$ 1.3 Hz), 3.92 (dd, 1H, H′-3, $J(H'_3, F)$ 5.6 Hz), 4.00 (d, 1H, H-2′), 4.12 (dd, 1H, C*H*H′F, J(H, H′) 10.6, J(H, F) 47.5 Hz), 4.45 (dd, 1H, CH*H*′F, J(H′, F) 47.2 Hz), 6.75–7.30 (m, 9H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −229.15 (tdd, $J(F, H)_{gem}$ 47.3 Hz, $J(F, H'_3)$ 5.6, $J(F, H_3)$ 1.3 Hz).

Method C

Starting from a solution of (3*S*,R_S)-**3** in ethyl ether, a 1.0:2.3 mixture of (*E*)- and (*Z*)-**6** (15.1% global yield) and a 1.0:3.2:25.2:1.0 mixture of oxiranes **4** (^{19}F NMR ($CDCl_3$) signals being at δ −226.8, −227.4, −228.5, and −229.2 ppm, respectively) (75.6% global yield) were obtained. From the 1.0:2.0 (3*S*)/(3*R*)-**3** mixture, a 1.0:3.0 (*E*)- and (*Z*)-**6** mixture (12.9% yield) and a 1.0:2.1:15.5:1.0 mixture of the same oxiranes **4** in 81.3% global yield were obtained.

(2*R*,2′*S*)- or (2*R*,2′*R*)-**4**: ^1H NMR ($CDCl_3$) δ (mixture with other epoxides): 2.35 (s, 3H, CH_3), 2.82 (dd, 1H, H-3, $J(H_3, H'_3)$ 4.5, $J(H_3, F)$ 3.5 Hz), 2.97 (d, 1H, H′-3), 4.00 (d, 1H, H-2′, $J(H_{2'}, F)$ 1.0 Hz), 4.55 (dd, 1H, H-1, $J(H_1, H'_1)$ 10.2, $J(H_1, F)$ 47.3 Hz), 5.18 (dd, 1H, H′-1, $J(H'_1, F)$ 47.3 Hz), 6.3–7.2 (m, 9H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −227.43 (td, CH_2F, $J(CH_2, F)$ 47.3, $J(F, H_3)$ 3.5 Hz).

For personal use only.

(2*R*,2′*R*)- or (2*R*,2′*S*)-**4**: ^{1}H NMR ($CDCl_3$) δ (analysed in mixture with other epoxides): 2.34 (s, 3H, CH_3), 2.97 (d, 1H, H-3, $J(H_3, H'_3)$ 4.0 Hz), 3.36 (dd, 1H, H-3′, $J(H'_3, F)$ 4.0 Hz), 3.81 (d, 1H, H-2′, $J(H_{2'}, F)$ 1.0 Hz), 4.68 (dd, 1H, H-1, $J(H_1, H'_1)$ 10.2 Hz, $J(H_1, F)$ 47.2 Hz), 4.48 (dd, 1H, H′-1, $J(H'_1, F)$ 47.0 Hz), 6.3–7.2 (m, 9H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −226.77 (td, CH_2F, $J(CH_2, F)$ 47.2 Hz, $J(H'_3, F)$ 4.0 Hz).

Synthesis of (2S,2′R,R$_S$)-1-bromo-3-fluoro-2′-{[(4-methylphenyl)-sulfinyl][phenyl]methyl]propan-2-ol (7)

Cupric bromide (2.3 g, 10.5 mmol) and lithium bromide (1.8 g, 21.0 mmol) were suspended in anhydrous THF (20 mL; distilled from $LiAlH_4$) cooled at 0°C under argon. A solution of (2*S*,2′*R*,*R*$_S$)-**4** (2.0 g, 6.6 mmol) in THF (10 mL) was added dropwise. Stirring was continued for up to 1 h, until disappearance of the starting oxirane, then 10 mL of a phosphate buffer solution (pH 10) was added, and the resulting mixture was diluted with water and extracted with ethyl acetate (3 × 20 mL). After drying over anhydrous sodium sulfate and solvent evaporation, the residue was purified by flash chromatography (3:2 hexane:ethyl acetate), and pure (2*S*,2′*R*,*R*$_S$)-**7** (1.7 g, 96% yield) was isolated; mp 119–120°C (isopropyl ether); $[\alpha]_D^{20}$ −76.2 (*c* 1.2, $CHCl_3$); R_F (3:2 hexane:ethyl acetate) 0.35; ^{1}H NMR ($CDCl_3$), δ: 2.31 (s, 3H, CH_3), 3.73 (dd, 1H, H-3, $J(H_3, F)$ 1.2, $J(H_3, H'_3)$ 10.8 Hz), 3.76 (dd, 1H, H′-3, $J(H'_3, F)$ 1.5 Hz), 4.17 (s, 1H, H-2′), 4.53 (dd, 1H, H-1, J(H-1, $J(H_1, F)$ 46.8, $J(H_1, H'_1)$ 10.2 Hz), 4.60 (dd, 1H, H′-1, $J(H'_1, F)$ 46.8 Hz), 5.38 (s, 1H, OH), 7.0–7.4 (m, 9H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −227.6 (t, CH_2F, $J(CH_2, F)$ 46.8 Hz). Anal. calcd. for $C_{17}H_{18}BrFO_2S$: C 53.00, H 4.71; found: C 52.87, H 4.69%.

Synthesis of (2S,2′R,R$_S$)-3-fluoro-2-{[(4-methylphenyl)sulfinyl]-[phenyl]methyl]propan-1,2-diol (8)

To a stirred solution of (2*S*,2′*R*,*S*$_S$)-**4** (2.0 g, 6.6 mmol) in THF (20 mL) and water (1 mL) at room temperature was added dropwise perchloric acid (0.5 mL of a 70% aqueous solution). The solution was stirred for 10 h at the same temperature, the solvent was removed under reduced pressure, water (10 mL) was added, and extraction was made with chloroform (3 × 20 mL). The organic layers were dried over anhydrous sodium sulfate, the solvent was removed, and the residue was purified by flash chromatography (1:1 hexane:ethyl acetate as eluent).

Pure (2*S*,2′*R*,*R*$_S$)-**8** was obtained as a solid: mp 130–132°C (isopropyl ether); $[\alpha]_D^{20}$ −174.4 (*c* 1.2, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ: 2.30 (s, 3H, CH_3), 3.61 (dd, 1H, H-3, $J(H_3, H'_3)$ 11.5, $J(H_3$, OH-3) 7.0 Hz), 3.78 (dd, 1H, H′-3, $J(H'_3$, OH-3) 7.0 Hz), 3.98 (t, 1H, OH-3), 4.07 (s, 1H, H-2′), 4.33 (dd, 1H, H-1, $J(H_1, F)$ 46.7, $J(H_1, H'_1)$ 9.5 Hz), 4.41 (dd, 1H, H′-1, $J(H'_1, F)$ 46.7 Hz), 7.0–7.3 (m, 9H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −231.4 (t, CH_2F, $J(CH_2, F)$ 46.7 Hz). Anal. calcd. for $C_{17}H_{19}FO_3S$: C 63.33, H 5.94; found: C 63.12, H 5.92%.

Synthesis of (S)-2-benzyl-3-fluoropropan-1,2-diol (10)

To a stirred solution of (2*S*,2′*R*,*R*$_S$)-**8** (1.0 g, 3.1 mmol) and sodium iodide (1.4 g, 9.3 mmol) in acetone at −40°C, under an argon atmosphere, a solution of trifluoroacetic anhydride (2.2 mL, 15.5 mmol) in the same solvent was added dropwise. When the starting compound **8** was no longer present, saturated aqueous solutions of sodium sulfite and sodium hydrogen carbonate were added, along with ethyl acetate. The organic phase was dried over anhydrous sodium sulfate and the solvent was evaporated under reduced pressure. The residue was purified by flash chromatography (4:1 hexane:ethyl ether) to give (2*S*,2′*R*)-**9** in 90% yield as a yellowish oil: $[\alpha]_D^{20}$ −307.2 (*c* 1.0, $CHCl_3$); R_F (4:1 hexane:ethyl ether) 0.35; ^{1}H NMR ($CDCl_3$) δ: 2.25 (s, 3H, CH_3), 2.90 (br s, 1H, OH-3), 3.28 (s, 1H, OH-2), 3.75 (d, 1H, H-3, $J(H_3, H'_3)$ 11.0 Hz), 2.84 (dd, 1H, H′$_3$, $J(H'_3, F)$ 2.0 Hz), 4.16 (dd, 1H, H-1, $J(H_1, H'_1)$ 9.5, $J(H_1, F)$ 47.0 Hz), 4.33 (s, 1H, H-2′), 4.50 (dd, 1H, H′-1, $J(H'_1, F)$ 47.0 Hz), 6.95–7.45 (m, 9H, aromatic hydrogens). Anal. calcd. for $C_{17}H_{19}FO_2S$: C 66.64, H 6.25; found: C 66.58, H 6.26%.

To the thio derivative (2S,2′R)-**9** (800 mg, 2.8 mmol) dissolved in absolute ethanol (10 mL) dry Raney nickel (2.4 g) was added and air was removed by vacuum pump. Ethanol was refluxed under a hydrogen atmosphere for 3 h and, after complete disappearance of the substrate, the Raney nickel was filtered off, the solvent was evaporated, and the residue was flash chromatographed (7:3 hexane:ethyl acetate as eluent) to give (S)-**10** (390 mg, 76.4% yield) as a yellow oil: $[\alpha]_D^{20}$ −2.65 (c 1.2, $CHCl_3$); R_F (7:3 hexane:ethyl acetate) 0.35; ^{1}H NMR ($CDCl_3$) δ: 2.65 (br s, 2H, OH-2 and OH-3), 2.82 (dd, 1H, H-2′, $J(H_{2'}, H'_{2'})$ 14.0, $J(H_{2'}, H_3)$ 2.0 Hz), 2.88 (dd, 1H, H′-2′, $J(H'_{2'}, F)$ 2.0 Hz), 3.51 (dd, 1H, H-3, $J(H_3, H'_3)$ 11.5 Hz), 3.59 (dd, 1H, H′-3, $J(H'_3, F)$ 1.5 Hz), 4.19 (dd, 1H, H-1, $J(H_1, F)$ 47.0, $J(H_1, H'_1)$ 9.5 Hz), 4.29 (dd, 1H, H′$_1$, $J(H'_1, F)$ 47.0 Hz), 7.2–7.4 (m, 1H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −231.3 (t, CH_2F, $J(CH_2, F)$ 47.0 Hz). Anal. calcd. for $C_{10}H_{13}FO_2$: C 65.20, H 7.11%; found: C 65.13, H 7.09%.

Synthesis of (S)-1-amino-2-benzyl-3-fluoropropan-2-ol (16)

To a stirred solution of sulfinyl oxirane (2*S*,2′*R*,*R*$_S$)-**4** (1.5 g, 4.93 mmol) in THF (20 mL) was added benzylamine (20 mL, 189.4 mmol) at room temperature. After 2 days, THF was evaporated off and the residue was purified by flash chromatography (3:2 hexane:ethyl acetate) to give the corresponding amino alcohol (2*S*,2′*R*,*R*$_S$)-**11** as a yellowish oil (95% yield): $[\alpha]_D^{20}$ −69.4 (*c* 1.1, $CHCl_3$); R_F (3:2 hexane:ethyl acetate) 0.30; ^{1}H NMR ($CDCl_3$) δ: 2.04 (s, 1H, OH-2), 2.30 (s, 3H, CH_3), 2.67 (d, 1H, H-3, $J(H_3, H'_3)$ 12.0 Hz), 2.85 (d, 1H, H′-3), 3.72 (d, 1H, NC*H*H′Ph, J(H, H′) 13.5 Hz), 3.79 (d, 1H, NCH*H*′Ph), 4.19 (s, 1H, H-2′), 4.39 (dd, 1H, H-1, $J(H_1, H'_1)$ 9.5, $J(H_1, F)$ 47.0 Hz), 4.44 (dd, 1H, H′-1, $J(H'_1, F)$ 47.0 Hz), 7.0–7.4 (m, 14H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −229.4 (t, CH_2F, $J(CH_2, F)$ 47.0 Hz). Anal. calcd. for $C_{24}H_{26}FNO_2S$: C 70.05, H 6.37, N 3.40; found: C 70.15, H 6.35; N 3.42%.

The derivative **11** (1.15 g, 2.7 mmol) was dissolved in acetone (25 mL), sodium iodide (1.25 g, 8.1 mmol) was added, and the mixture was cooled at −40°C under a nitrogen atmosphere. A solution of trifluoroacetic anhydride (1.87 mL, 13.5 mmol) in acetone (25 mL) was added dropwise. To the resulting reaction mixture a saturated aqueous solution of sodium sulfite and sodium hydrogen carbonate was added, acetone was evaporated off, and extraction was made with ethyl ether (3 × 20 mL). The collected organic layers were dried over anhydrous sodium sulfate and the solvent was evaporated to give a residue that by flash chromatographic purification (9:1 hexane:ethyl ether) afforded (2*S*,2′*R*)-1-(*N*-trifluoroacetyl)benzylamino-3-fluoro-2-{[(4- methylphenyl)thio][phenyl]methyl}propan-2-ol (**12**) (98% yield) as a yellowish oil: $[\alpha]_D^{20}$ −135.94 (*c* 1.2, $CHCl_3$); R_F (9:1 hexane:ethyl ether) 0.40; ^{1}H NMR ($CDCl_3$) δ: 2.22 (s, 3H, CH_3), 3.48 (d, 1H, H-3, $J(H_3, H'_3)$ 14.5 Hz), 3.97 (dd, 1H, H-1, $J(H_1, H'_1)$ 9.5, $J(H_1, F)$ 46.5 Hz), 4.04 (d, 1H, H-2′, $J(H_{2'}, H'_3)$ 2.0 Hz), 4.22 (s, 1H, OH), 4.27 (dd, 1H, H′-3), 4.28 (dd, 1H, H′-1, $J(H'_1, F)$ 46.5 Hz), 4.62 (d, 1H, NC*H*H′Ph, J(H, H′) 16.5 Hz), 5.02 (d, 1H, NCH*H*′Ph), 6.90–7.45 (m, 14H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −226.0 (t, 1F, CH_2F, $J(CH_2, F)$ 46.5 Hz), −68.9 (s, 3F, $COCF_3$). Anal. calcd. for $C_{26}H_{25}F_4NO_2S$: C 63.53, H 5.13, N 2.85; found: C 63.35, H 5.12, N 2.86.

The thio derivative **12** (1.0 g, 2.5 mmol) was dissolved in absolute ethanol (30 mL), Raney nickel (2.7 g) was added, and the mixture was heated at reflux under hydrogen atmosphere for 1 h and 40 min. Raney nickel was filtered off, the ethanol was evaporated, and flash chromatographic purification (65:35 hexane:ethyl ether as eluent) gave a mixture (1.7:1.0) of, respectively, the following products: (S)-2-benzyl-3-fluoro-1-[(N-trifluoroacetyl)benzylamino]propan-2-ol (**13**, 39% yield); $[\alpha]_{365}^{20}$ −7.42 (c 1.0, $CHCl_3$); R_F (65:35 hexane:ethyl ether) 0.45; ^{1}H NMR ($CDCl_3$) δ: 2.77 (dd, 1H, H-2′, $J(H_{2'}, H'_{2'})$ 13.8, $J(H_{2'}$, H′$_3$) 2.4 Hz), 2.86 (dd, 1H, H′-2′, $J(H'_{2'}, F)$ 2.0 Hz), 3.27 (s, 1H, H-2′), 3.46 (d, 1H, H-3, $J(H_3, H'_3)$ 14.7 Hz), 3.59 (dd, 1H, H′-3), 4.12 (dd, 1H, H-1, $J(H_1, H'_1)$ 9.6, $J(H_1, F)$ 46.8 Hz), 4.18 (dd, 1H, H′-1, $J(H'_1, F)$ 46.8 Hz), 4.74 (d, 1H, NC*H*H′Ph, J(H, H′) 16.2 Hz), 4.93 (d, 1H, NCH*H*′Ph), 7.12–7.45 (m, 10H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −225.4 (t, 1F, CH_2F, $J(CH_2, F)$ 46.8 Hz), −69.0 (s, 3F, $COCF_3$). Anal. calcd. for $C_{19}H_{19}F_4NO_2$: C 61.79, H 5.18, N 3.79; found: C 61.86, H 5.20, N 3.80%; and (S)-2-benzyl-3-fluoro-1-[(trifluoroacetyl)amino]propan-2-ol (**14**, 23% yield): $[\alpha]_D^{20}$ −13.91, $[\alpha]_{365}^{20}$ −53.60 (c 0.8, $CHCl_3$); R_F (same solvent) 0.35; ^{1}H NMR ($CDCl_3$) δ: 2.38 (s, 1H, OH-2), 2.85 (dd, 1H, H-2′, $J(H_{2'}, H'_{2'})$ 14.0, $J(H_{2'}, H_3)$ 2.0

For personal use only.

Hz), 2.94 (dd, 1H, H′-2′, J(H′$_{2'}$, F) 1.8 Hz), 3.48 (ddd, 1H, H-3, J(H$_3$, H′$_3$) 14.0, J(H$_3$, NH) 5.5 Hz), 3.58 (dd, 1H, H′-3, J(H′$_3$, NH) 6.3 Hz), 4.17 (dd, 1H, H-1, J(H$_1$, H′$_1$) 9.5, J(H$_1$, F) 47.0 Hz), 4.30 (dd, 1H, H′-1, J(H′$_1$, F) 47.0 Hz), 6.70 (br, 1H, NH), 7.27–7.45 (m, 5H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −230.1 (t, 1F, CH_2F, J(CH_2, F) 47.0 Hz), −77.0 (s, 3F, $COCF_3$). Anal. calcd. for $C_{12}H_{13}F_4NO_2$: C 51.62, H 4.69, N 5.02; found: C 51.65, H 4.68, N 5.04%.

The trifluoroacetyl derivatives **13** (100 mg, 0.27 mmol) and **14** (100 mg, 0.36 mmol) were separately dissolved in THF (2 mL) and treated with a 2.5% aqueous solution of potassium hydroxide (1 mL). Stirring was continued for 5 h, the THF was evaporated, and the following compounds were obtained in pure form by flash chromatographic purification: (*S*)-2-benzyl-1-benzylamino-3-fluoropropan-2-ol (**15**) (95% yield): $[\alpha]^{20}_{365}$ −9.33 (*c* 0.5, $CHCl_3$); R_F (3:2 cyclohexane:ethyl acetate) 0.35; ^{1}H NMR ($CDCl_3$) δ: 1.70 (br, 2H, OH and NH), 2.58 (dd, 1H, H-3, *J*(H$_3$, H′$_3$) 12.5, *J*(H$_3$, H′$_{2'}$) 1.7 Hz), 2.78 (dd, 1H, H-2′, *J*(H$_2$, H′$_{2'}$) 13.5, *J*(H$_{2'}$, F) 2.0 Hz), 2.82 (dd, 1H, H′-3, *J*(H′$_3$, F) 1.1 Hz), 2.86 (dd, 1H, H′-2′), 3.75 (d, 1H, NC*H*H′Ph, *J*(H, H′) 13.5 Hz), 3.80 (d, 1H, NCH*H*′Ph), 4.18 (d, 2H, CH_2F, *J*(CH_2, F) 47.0 Hz), 7.20–7.40 (m, 5H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −228.5 (t, CH_2F, *J*(CH_2, F) 47.0 Hz). Anal. calcd. for $C_{17}H_{20}FNO$: C 74.70, H 7.37, N 5.12; found: C 74.64, H 7.39, N 5.10%; and (*S*)-1-amino-2-benzyl-3-fluoropropan-2-ol (**16**, 90% yield): $[\alpha]^{20}_D$ −9.33 (*c* 0.3, $CHCl_3$); R_F (1:1 ethyl acetate: methanol) 0.35; ^{1}H NMR ($CDCl_3$) δ: 2.80–2.90 (m, 3H, H-3, H′-3, and H-2′), 2.95 (d, 1H, H′-2′, *J*(H$_{2'}$, H′$_{2'}$) 13.5 Hz), 4.24 (d, 2H, CH_2F, *J*(CH_2, F) 47.0 Hz), 7.20–7.40 (m, 5H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$ + CD_3OD) δ: −230.2 (t, CH_2F, *J*(CH_2, F) 47.0 Hz). Anal. calcd. for $C_{10}H_{14}FNO$: C 65.55, H 7.70, N 7.64; found: C 65.28, H 7.67, N 7.61%.

Synthesis of (2S,2′R)- and (2S,2′S)-2-fluoromethyl-2-{[(4-methylphenyl)thio][phenyl]methyl}oxirane (17)

(2*S*,2′*R*,*R*$_S$)-**4** (1.0 g, 3.3 mmol) was treated with sodium iodide and trifluoroacetic anhydride following the procedure already described. The thio oxirane (2*S*,2′*R*)-**17** was obtained in 98% yield; $[\alpha]^{20}_D$ −249.24 (*c* 1.0, $CHCl_3$); R_F (9:1 hexane:ethyl ether) 0.40; ^{1}H NMR ($CDCl_3$) δ: 2.29 (s, 3H, CH_3), 2.84 (d, 1H, H-3, *J*(H$_3$, H′$_3$) 4.5 Hz), 3.06 (t, 1H, H′-3, *J*(H′$_3$, F) 4.5 Hz), 4.49 (dd, 1H, H-1, *J*(H$_1$, F) 47.0, *J*(H$_1$, H′$_1$) 10.2 Hz), 4.54 (s, 1H, H-2′), 4.58 (dd, 1H, H′-1, *J*(H′$_1$, F) 47.0 Hz), 6.95–7.45 (m, 9H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −228.8 (td, CH_2F, *J*(CH_2, F) 47.0, *J*(F, H′$_3$) 4.5 Hz). Anal. calcd. for $C_{17}H_{17}FOS$: C 70.80, H 5.94; found: C 70.68, H 5.96%.

In the same way, (2*S*,2′*S*,*R*$_S$)-**4** was reduced to the corresponding thio derivative (2*S*,2′*S*)-**17** in 76% yield: $[\alpha]^{20}_D$ +268.6 (*c* 0.3, $CHCl_3$); R_F (9:1 hexane:ethyl ether) 0.35; ^{1}H NMR ($CDCl_3$) δ: 1.82 (s, 3H, CH_3), 2.32 (d, 1H, H-3, *J*(H$_3$, H′$_3$) 4.8 Hz), 2.54 (dd, 1H, H′-3, *J*(H′$_3$, F) 4.5 Hz), 4.12 (dd, 1H, H-1, *J*(H$_1$, H′$_1$) 10.2, *J*(H$_1$, F) 47.5 Hz), 4.48 (dd, 1H, H′-1, *J*(H′$_1$, F) 47.3 Hz), 4.54 (d, 1H, H-2′, *J*(H$_{2'}$, F) 1.1 Hz), 6.70–7.35 (m, 9H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −230.5 (t, CH_2F, *J*(CH_2, F) 46.8 Hz).

(2*S*,2′*R*)-3-fluoro-1-iodo-2-{[(4-methylphenyl)thio][phenyl]methyl}propan-2-ol (**20**) (19% yield) was also obtained: $[\alpha]^{20}_D$ +179.0 (*c* 0.2, $CHCl_3$); R_F (9:1 hexane:ethyl ether) 0.25; ^{1}H NMR ($CDCl_3$) δ: 2.29 (s, 3H, CH_3), 2.55 (s, 1H, OH), 3.23 (dd, 1H, H-3, *J*(H$_3$, H′$_3$) 10.5, *J*(H$_3$, F) 2.0 Hz), 3.35 (dd, 1H, H′$_3$, *J*(H′$_3$, F) 2.5 Hz), 4.42 (d, 1H, H-2′, *J*(H$_{2'}$, F) 1.2 Hz), 4.59 (dd, 1H, H-1, *J*(H$_1$, F) 47.0, *J*(H$_1$, H′$_1$) 9.5 Hz), 4.66 (dd, 1H, H′-1, *J*(H′$_1$, F) 47.0 Hz), 7.0–7.45 (m, 9H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −228.2 (t, *J*(CH_2, F) 47.0 Hz). Anal. calcd. for $C_{17}H_{18}FIOS$: C 49.05, H 4.36; found: C 48.92, H 4.35%.

Synthesis of (S)-3-benzyl-4-fluoro-3-hydroxybutanenitrile (19)

To a solution of sodium cyanide (96.7 mg, 1.97 mmol) in acetonitrile (10 mL) heated at 60°C under an Ar atmosphere for 15 min, lithium perchlorate (209 mg, 1.97 mmol) was added, followed in 10 min by dropwise addition of a solution of (2*S*,2′*R*)-**17** (380 mg, 1.32 mmol) in acetonitrile (1 mL). The mixture was stirred at 60°C for 1.5 h, then 10 mL of water was added, the solvent was removed under reduced pressure, and the organic layers were extracted with ethyl acetate (3 × 15 mL), washed with water (5 mL), and dried over anhydrous sodium sulfate. The crude was purified by flash chromatography (3:2 cyclohexane:ethyl acetate) to give (3*S*,3′*R*)-4-fluoro-3-hydroxy-3-{[(4-methylphenyl)thio][phenyl]methyl}butanenitrile (**18**, 187 mg, 45% yield): $[\alpha]^{20}_D$ −223.9 (*c* 0.8, $CHCl_3$): mp 80–82°C (ethyl acetate:hexane); ^{1}H NMR ($CDCl_3$) δ: 2.29 (s, 3H, CH_3), 2.90 (dd, 1H, H-3, *J*(H$_3$, H′$_3$) 16.5, *J*(H$_3$, F) 1.5 Hz), 2.99 (dd, 1H, H′-3, *J*(H′$_3$, F) 1.5 Hz), 2.99 (s, 1H, OH), 4.24 (dd, 1H, H-1, *J*(H$_1$, H′$_1$) 9.5, *J*(H$_1$, F) 46.5 Hz), 4.32 (d, 1H, H-2′, *J*(H$_{2'}$, F) 1.5 Hz), 4.30 (dd, 1H, H′-1, *J*(H′$_1$, F) 46.5 Hz), 7.0–7.45 (m, 9H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −229.6 (t, CH_2F, *J*(CH_2, F) 46.5 Hz). Anal. calcd. for $C_{18}H_{18}FNOS$: C 68.55, H 5.75, N 4.44; found: C 68.51, H 5.73, N 4.46%.

Into a mixture of Raney nickel (560 mg) and (3*S*,3′*R*)-**18** (187 mg, 0.59 mmol) in absolute ethanol (18 mL) was bubbled Ar for 10 min at room temperature. Then the mixture was heated at 75°C for 4 h. Raney nickel was filtered off, and ethanol was evaporated under reduced pressure. The residue was chromatographed on silica gel (4:1 hexane:ethyl acetate) to give (*S*)-**19** in 65% yield: $[\alpha]^{20}_D$ −15.8 (*c* 0.5, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ: 2.25 (br s, 1H, OH), 2.59 (m, 2H, H-3 and H′-3), 3.00 (m, 1H, H-2′ and H′-2′), 4.31 (dd, 1H, H-1, *J*(H$_1$, H′$_1$) 10.2, *J*(H$_1$, F) 47.1 Hz), 4.36 (dd, 1H, H′-1, *J*(H′$_1$, F) 47.1 Hz), 7.25–7.45 (m, 5H, aromatic hydrogens); ^{19}F NMR ($CDCl_3$) δ: −228.7 (t, CH_2F, *J*(CH_2, F) 47.1 Hz). Anal. calcd. for $C_{11}H_{12}FNO$: C 68.38, H 6.26, N 7.25; found: C 68.11, H 6.24, N 7.23%.

Does the Csp^2—Csp^3 barrier in ethylbenzene have a hyperconjugative component? An indirect experimental and theoretical approach

TED SCHAEFER,[1] ROBERT W. SCHURKO, AND GUY M. BERNARD
Department of Chemistry, University of Manitoba, Winnipeg, MB R3T 2N2, Canada

Received February 21, 1994

TED SCHAEFER, ROBERT W. SCHURKO, and GUY M. BERNARD. Can. J. Chem. **72**, 1780 (1994).

The proton chemical shifts and the proton spin–spin coupling constants are reported for 1-phenyl-1-butyne and 1-phenyl-1-pentyne dissolved in CS_2/C_6D_{12} and acetone-d_6. The long-range coupling constants between the methylene and ring protons are used to derive the twofold barriers to internal rotation in these molecules. They are 0.5 ± 0.1 kJ/mol; the perpendicular conformer is the most stable, the one in which the C(3)—C(4) bond of the side chain lies in a plane perpendicular to the phenyl group. This energetic preference is assigned to the difference between C—C and C—H hyperconjugative interactions with the aromatic π electron system, the C—C interaction being larger. Comparison of the twofold components of the internal rotational barriers in biphenyl and diphenylacetylene, that in the latter amounting to 40% of that in the former, implies that the hyperconjugative component of the internal barrier in ethylbenzene is 1.2 ± 0.3 kJ/mol, a minor component of the total magnitude. Molecular orbital computations of the conformational energies of 1-phenyl-1-butyne all agree that the perpendicular conformer has the lowest energy but only to the extent of 0.1 kJ/mol at most.

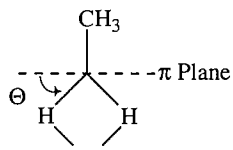
TED SCHAEFER, ROBERT W. SCHURKO et GUY M. BERNARD. Can. J. Chem. **72**, 1780 (1994).

On rapporte les déplacements chimiques et les constantes de couplage du proton des composés 1-phényl-1-butyne et 1-phényl-1-pentyne dissous dans du CS_2/C_6D_{12} et dans l'acétone-d_6. On a utilisé les constantes de couplage à longue distance entre les protons du méthylène et ceux du cycle pour déduire les barrières doubles à la rotation interne dans ces molécules. Elles sont de 0,5 ± 0,1 kJ/mol; le conformère perpendiculaire est le plus stable, celui dans lequel la liaison C(3)—C(4) de la chaîne latérale est dans un plan perpendiculaire au groupe phényle. On attribue cette préférence énergétique à la différence entre les interactions hyperconjuguées des liaisons C—C et C—H et le système d'électrons π, les interactions C—C étant plus grandes. La comparaison des composantes doubles des barrières de rotation internes dans le biphényle et le diphénylacétylène, cette interaction étant de 40% plus élevée dans le biphénylacétylène, implique que le constituant d'hyperconjugaison de la barrière interne de l'éthylbenzène, un constituant minoritaire, est de 1,2 ± 0,3 kJ/mol. Les calculs d'orbitales moléculaires des énergies conformationelles du 1-phényl-1-butyne confirment que le conformère perpendiculaire a la plus basse énergie mais la différence est tout au plus de 0,1 kJ/mol.

[Traduit par la rédaction]

Introduction

In a discussion of the first ab initio molecular orbital calculations of the barrier to rotation about the Csp^2—Csp^3 bond in ethylbenzene (1), it is suggested that a hyperconjugative component may be present in addition to a larger steric component. The stable perpendicular conformer of ethylbenzene, **1**, is analogous to the computed stable conformer of the propyl cation. Such stabilization will naturally be smaller in the neutral than in the charged molecule. Because the hyperconjugative, σ–π electron, interaction is proportional to $\sin^2\theta$, where θ is the angle by which a bond in the side chain twists out of the benzene plane (2), **1** represents the conformation in which the C—C bond interacts most strongly with the π electron system. The C—H bonds are situated such that their hyperconjugative interactions are rather small, $\sin^2\theta$ being 0.25. There is no agreement in the literature concerning the relative hyperconjugative abilities of C—H and C—C bonds (3–14). These have been variously assessed as C—C > C—H, C—C ~ C—H, or C—H > C—C.



1

One comparison (10) of the conformational behaviour of alkylbenzene cations and anions suggests that C—H is greater than C—C hyperconjugation in the former but that the opposite is true for the anions. How much these conclusions would be altered by steric considerations is problematical. Another comparison, based on neutral 4-alkylbenzyl radicals, does not suffer from this uncertainty; it is concluded (14) that the C—C bond is 40–60% as effective as C—H hyperconjugation for delocalizing spin density and, furthermore, that it is 75–90% as effective in delocalizing charge density in 4-alkylcumyl cations. As another example of the many investigations of this topic, a simple molecular orbital analysis of magnetic circular dichroism data (4) for neutral alkylbenzenes concludes that there exists little, if any, difference between the hyperconjugative ability of C—H and C—C bonds.

An alternative approach to the matter would involve the measurement of the relative energetic contribution, $E_{C-C} - E_{C-H}$, to the hyperconjugative stabilization of a given conformation of a neutral alkylbenzene. Such a measurement is unknown to us and is difficult, simply because a separation of hyperconjugative (probably small) from other components, such as steric, is not straightforward.

Returning to ethylbenzene, the barrier is very likely dominated by steric repulsion between the methyl group and the *ortho* C—H bonds of the phenyl group. However, insertion of a C≡C bond between the ethyl and phenyl groups removes the steric repulsions during rotation about the Csp—Csp^2 and Csp—Csp^3 bonds. Hyperconjugation between the C—C and C—H bonds of the ethyl group and the π electrons of the phenyl group can still occur via the triple bond although, of course, it will be

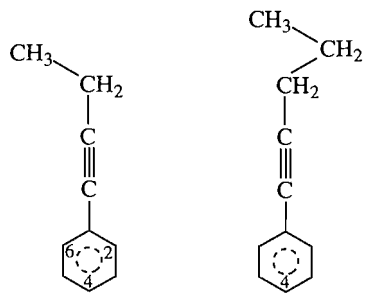
reduced in magnitude compared to ethylbenzene. Thus, the conjugational barrier to rotation in diphenylacetylene, at 2.4 kJ/mol (15, 16), is rather smaller than in biphenyl if the twofold component of the barrier in the latter is taken as a measure of the conjugational barrier in the absence of the triple bond. The twofold component of the internal barrier in biphenyl is about 6.1 kJ/mol (17). Again, in phenylpropynal, $C_6H_5{\equiv}CC\text{-}CHO$, the planar conformer is more stable than the perpendicular conformer by 6 ± 2 kJ/mol, attributable to conjugation between the formyl and phenyl π electron systems (18). The internal rotational barrier in benzaldehyde, also twofold, is >19 kJ/mol (19).

In 1-phenyl-1-butyne, **2**, the ethyl group can hyperconjugate with the aromatic π electron system via the triple bond. Any conformational preferences with respect to the aromatic plane will be reflected in the σ–π electron-mediated coupling constant between the methylene protons and the ring protons, $^8J(H, CH_2)$, as discussed previously (18, 20). This coupling constant varies as $^8J_{90}\sin^2\theta$ and an estimation of $^8J_{90}$ can be had (19). The measured ^8J then yields $\langle\sin^2\theta\rangle$, that is, the value of $\sin^2\theta$ averaged over the internal motion, which, in turn, is governed by the internal rotational potential. As an example, if in **2** a



2 **3**

hyperconjugative interaction stabilizes a conformation analogous to **1** sufficiently strongly, then $\langle\sin^2\theta\rangle$ approaches 0.25; if, however, the internal motion about the C*sp*—C*sp*^{3} bond is unhindered, the associated value of $\langle\sin^2\theta\rangle$ is 0.5. It also turns out that $^6J(H, CH_2)$ in **2** and **3** can be used in this fashion.

Accordingly, the precise analyses of the ^{1}H nmr spectra of 1-phenyl-1-butyne, dissolved in a nonpolar and a polar solvent, are reported here. The ensuing ^6J and ^8J values are used to deduce the ease of internal motion of the ethyl group relative to the plane of the phenyl group. In addition, ^{1}H nmr spectral data are obtained for 1-phenyl-1-pentyne, **3**, affirming that the coupling constant data are not peculiar to the butyne derivative. Confirmation of the experimental results is also sought via molecular orbital computations of the relative energies of the planar and perpendicular conformers of the phenylbutyne.

Experimental

Dilute solutions (see Table 1 for details) of 1-phenyl-1-butyne and 1-phenyl-1-pentyne (Aldrich) in CS_2/C_6D_{12}/TMS and acetone-d_6/TMS solvent mixtures were transferred to 5 mm o.d. nmr sample tubes. These were degassed by five cycles of the freeze–pump–thaw procedure and were then flame-sealed to provide reasonably symmetric tops. The ^{1}H nmr spectra were acquired on an AM 300 nmr spectrometer using documented techniques (19, 21). Acquisition times of 50 s and some resolution enhancement (LB of −0.11 and a GB of 0.6) produced linewidths at half height of about 0.03 Hz in the aromatic region, so that splittings of 0.04 Hz were cleanly resolved.

Molecular orbital computations used the computer program GAUSSIAN 86 (22) and employed the AM1 parameterization (23) as well as the STO-3G (24), 6-31G (25), and 6-31G* (26) basis sets. The carbon and hydrogen atoms of the phenyl group in 1-phenyl-1-butyne were constrained to lie in a plane during the geometry optimization procedures, all other bond angles and lengths being allowed to vary. INDO MO FPT (27) computations of spin–spin coupling constants were done for STO-3G MO geometries of the butyne derivative.

Results and discussion

Spectral analyses

The ^{1}H nmr spectra were analyzed with a greatly modified version (R. Sebastian) of the computer program NUMARIT (28). The spectral parameters appear in Table 1. Signs of the long-range coupling constants between the ring protons and those in the side chain are known from previous work on 1-phenyl-1-propyne (18). The sign of $^4J(CH_2, CH_3)$ in 1-phenyl-1-pentyne follows from a comparison of simulated with experimental spectra, some of which are displayed in Fig. 1. Although the linewidths are considerably larger for the methyl protons than for the aromatic protons, these spectra illustrate how the sign of a very small coupling constant follows from a complete analysis.

*$^{6,8}J(H, CH_2)$ and the relative orientation of the alkyl and phenyl groups in **2** and **3***

The derivation of the internal barriers in **2** and **3** goes as follows. As discussed previously (18, 20), $^8J(H, CH_2)$ is a σ–π electron coupling constant and, as such, varies as $\sin^2\theta$ where θ is the angle by which the C—H bond of the methylene group twists out of the aromatic plane. This functional dependence is confirmed by our INDO MO FPT computations on 1-phenyl-1-propyne (18) and on **2**. Hence $^8J(H, CH_2) = {}^8J_{90}\langle\sin^2\theta\rangle$. Furthermore, the INDO MO FPT computations on **2**, using the optimized STO-3G MO geometries, yield the angle dependence of $^6J(H, CH_2)$ as dominated by a term, 0.270 $\sin^2\theta$, and containing a small term, 0.028 $\sin^2(\theta/2)$. For a twofold barrier, $\langle\sin^2(\theta/2)\rangle$ is 0.5. The magnitudes of the coefficients in these terms depend on the parameterization of the semiempirical algorithm. We shall assume that $^6J(H, CH_2)$ is also a pure σ–π coupling constant.[2]

For the propyne, the expectation value of $\sin^2\theta$ is 0.5 because the internal barrier is effectively zero (29). Because $^{6,8}J$ in 1-phenyl-propyne are known, the extremes in $^{6,8}J$, their values at θ = 90°, follow. However, the magnitudes of $^{6,8}J_{90}$ for the methylene group depend somewhat on the substituent, R, in CH_2R; in **2** and **3**, R is CH_3 and CH_2CH_3, respectively. If the electronegativity of R, E_R, is greater than that of hydrogen, the C—H bonds of the methylene group are polarized so as to reduce the σ–π (hyperconjugative) overlap with π electrons. Hence nuclear spin state information is not as effectively transmitted and $^{6,8}J_{90}$ decrease in magnitude, a calibration[3] yielding its value as $^8J(H, CH_2)/{}^8J(H, CH_3) = (1.15 \pm 0.01)/1.20$.

The experimental values of $\langle\sin^2\theta\rangle$ are then matched to values obtained from a hindered rotor model (34), which computes $\langle\sin^2\theta\rangle$ as a function of the internal barrier, the reduced moment of inertia of the molecule, and the temperature. At ambient tem-

[2]If a constant amounting to 10% of the ^6J values in Tables 1 and 2 is subtracted from their magnitudes, to account for a term in $\sin^2(\theta/2)$, the $\langle\sin^2\theta\rangle_{300}$ values are not significantly altered in Table 2.

[3]Thus, for the most electronegative R, fluorine, it has been shown experimentally (30) that $^6J_{90}(H, CH_2)$ is −0.94 Hz, as compared to a $^6J_{90}(H, CH_3)$ of −1.20 Hz in toluene (31). Again, for an oxygen substituent, $^6J_{90}(H, CH_2)$ is −1.02 Hz (32, 33). The assumption of a linear dependence of $^6J_{90}$ on E_R, and values of 4.0, 3.5, 2.5, and 2.1 for F, O, C, and H, respectively, yields a $^6J_{60}$ of −1.15 ± 0.01 Hz for R = CH_3 or CH_2CH_3.

[a]5.0 mol% in CS_2, containing also 10.0 mol% C_6D_{12} and 0.5 mol% of TMS.
[b]5.0 mol% in acetone-d_6, containing also 0.5 mol% of TMS.
[c]In Hz at 300.135$_2$ MHz to high frequency of internal TMS; the standard deviations of the spectral parameters are all less than 0.001 Hz.
[d]This is the mean of ^3J and $^3J'$ in an AA'BB' analysis. ^3J and $^3J'$ do not differ by as much as 0.4 Hz while the ^2J values are strongly correlated. Hence only the sum of ^3J and $^3J'$ is very reliable. The *gauche* conformer is somewhat less stable than the *trans* by about 0.3 kJ/mol.

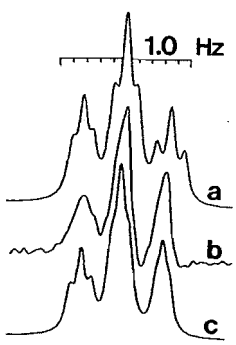

FIG. 1. Part of the ^{1}H nmr spectrum at 300 MHz and 300 K of the methyl protons in 1-phenyl-1-pentyne, as a 5.0 mol% solution in a CS_2/C_6D_{12}/TMS solvent mixture, is displayed in (*b*). In (*a*) the computed spectrum has $^4J(CH_2, CH_3)$ as +0.08 Hz and as −0.08 Hz in (*c*).

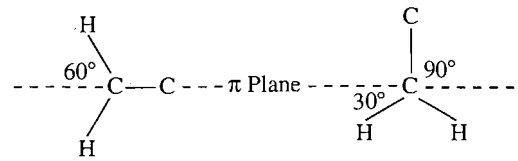
peratures, barriers of less than about 12 kJ/mol, and reduced moments of inertia of about 10^{-38} gm cm^2, the values of $\langle\sin^2\theta\rangle$ are insensitive to the precise value of the inertial properties. The barriers in **2** and **3** are assumed to be twofold, as expected intuitively (hyperconjugation), and confirmed by at least some of the molecular orbital computations described below.

Table 2 presents the internal barriers and experimental values of $\langle\sin^2\theta\rangle$. For **2** and **3**, $\langle\sin^2\theta\rangle$ is always less than 0.5, implying that the conformation analogous to **1** is most stable. In other words, if the internal barriers in **2** and **3** are hyperconjugative in origin, then C—C is larger than C—H hyperconjugation. More precisely, if the hyperconjugative stabilization, E(h.c.), is proportional to $\sin^2\theta$, where θ is the angle by which the C—H or C—C bonds twist out of the phenyl plane, and if the barrier is twofold, then **4** and **5** entail the relationship, $E_{C—C} > E_{C—H}$; the barriers in Table 2 are the measures of $E_{C—C} - E_{C—H}$.



$E(h\cdot c) = 1.5E_{C—H}$ **4**

$E(h\cdot c) = E_{C—C} + 0.5E_{C—H}$ **5**

The errors quoted for the twofold barriers in Table 2 are based on an uncertainty of 0.01 Hz in the calibration of the correction factor for electronegativity and an error[4] of 0.001 Hz in the measured values of $^{6,8}J$; the standard form of error propagation was used.[5] On the assumption that the barrier values are the

[4]The standard deviations of $^{6,8}J$ ranged from 0.0002 to 0.0007 Hz, as obtained from the least-squares fit of many transitions (Table 1).

[5]The values of $\langle\sin^2\theta\rangle$, proportional to the measured values of $^{6,8}J(H, CH_2)$, are very sensitive to V_2 for small values of the latter. Thus, for an increase of V_2 from zero to 4.2 kJ/mol, $\langle\sin^2\theta\rangle$ changes from 0.500 to 0.405, whereas a further increase of V_2 from 4.2 to 13.4 kJ/mol is needed to cause a further decrease of 0.100 in $\langle\sin^2\theta\rangle$ at 300 K.

TABLE 2. The twofold internal rotational barriers in phenyl-C≡C-CH_2R (R = CH_3, CH_2CH_3) derived from $^{6,8}J$(H, CH_2)

R	$-^6J$/Hz	$\langle\sin^2\theta\rangle_{300}$	V_2^c (kJ/mol)	$-^8J$/Hz	$\langle\sin^2\theta\rangle_{300}$	V_2^c (kJ/mol)

CH_2CH_3	0.278(1)	0.492(b)	0.3(2)	0.225(1)	0.468(6)	1.3(2)
			Acetone-d_6			
H	0.298(1)	0.500	0	0.254(1)	0.500	0
CH_3	0.280(1)	0.490(6)	0.4(2)	0.240(1)	0.493(6)	0.3(2)
CH_2CH_3	0.281(1)	0.492(6)	0.3(2)	0.238(1)	0.489(6)	0.4(2)

[a]It is assumed that the barrier in 1-phenyl-1-propyne, very likely sixfold if it were present, effectively vanishes (29).

[b]For R = CH_3 and R = CH_2CH_3, the expectation values of $\sin^2\theta$ come from $\langle\sin^2\theta\rangle = {}^{6,8}J(H, CH_2)/\{2 \times {}^{6,8}J(H, CH_3)\}$ (1.15 ± 0.01)/1.20}; see text. A value of $\langle\sin^2\theta\rangle$ <0.5 means that the perpendicular conformer is most stable.

[c]V_2 comes from tables giving $\langle\sin^2\theta\rangle_{300}$ as a function of V_2, derived from a hindered rotor model as referenced in the text; the temperature is 300 K.

same for **2** and **3** and that they do not depend on the solvent, the hyperconjugative barrier is then 0.5(1) kJ/mol (if the apparent outlier, 1.3 kJ/mol, is excluded, one has 0.4(1) kJ/mol, but there is no solid evidence for its exclusion). Clearly, the barrier is very small; nevertheless, all eight values of $\langle\sin^2\theta\rangle$ in Table 2 agree that the perpendicular, **4**, is more stable than **5**.

The estimated hyperconjugative barrier in ethylbenzene

The conjugational barrier favouring planarity in tolane (diphenylacetylene) is 2.4 kJ/mol, amounting to 40% of the twofold component of the barrier in biphenyl, presumably also arising from conjugation of the π electrons of the two phenyl groups.[6] The σ–π or hyperconjugative component of the barrier in ethylbenzene is then (0.5 ± 0.1) 2.5 or 1.2 ± 0.3 kJ/mol. The barrier height in ethylbenzene has been variously deduced (35, 36) and ranges from 4.8 to 9.2 kJ/mol, so that the hyperconjugative contribution amounts to a minor component of the barrier.

Molecular orbital computations on 1-phenyl-1-butyne, 2

The AM1 computations on **2**, done at intervals of 15° in the torsion angle, predict a twofold barrier with the perpendicular conformer, **4**, being most stable by 0.1 kJ/mol. The STO-3G MO optimizations agree formally with this conclusion, having **4** most stable by 0.02 kJ/mol. Again, the 6-31G and 6-31G* computations find **4** of lower energy than **5** by 0.07 and 0.06 kJ/mol, respectively. These last numbers are perhaps just within the level of significance of such computations. In this sense the computations are in qualitative agreement with the experimental deductions for the molecules in solution. Whether the inclusion of electron correlation would alter the theoretical prediction is unknown. It is true that C—H and C—C hyperconjugation in neutral molecules has been a subject of controversy, no doubt because it is small energetically, as also indicated by the present results. The most recent discussions concentrate on structural changes induced by this phenomenon. One (37), based on $^1J(^{13}C, ^{13}C)$ variations, concludes that C—C hyperconjugation is negligible; the other (8), based on a comparison of experimental bond lengths with their theoretical analysis, concludes that C—C and C—H bonds can hyperconjugate in neutral, ground-state molecules.

Further considerations

(a) Isopropylphenylacetylene

According to the present experimental measurements, for isopropylphenylacetylene the most stable conformer would be that in which the methine C—H bond lay in the aromatic plane. If the presence of a second methyl group does not alter $E_{C-C} - E_{C-H}$ (there are now two C—C bonds and only one C—H bond for hyperconjugative interactions), then the magnitude of the twofold internal barrier will equal that in **2**. The barrier should be accessible to the techniques described here as soon as the compound itself becomes available.

(b) $^3J(CH_2, CH_2)$ in 3

The apparently large value, 1.3(2) kJ/mol, for V_2 in 1-phenyl-1-pentyne dissolved in CS_2/C_6D_{12} arouses the suspicion that a steric component might be present. Models imply that, in a *gauche* arrangement of the CH_3 and $C_6H_5C{\equiv}C$ groups about the C—C bond of the CH_2-CH_2 fragment, the distance of closest approach of a methyl proton and a proton in an *ortho* C—H bond could be somewhat less than 3 Å, consistent with such a suspicion. In a *trans* arrangement of the two groups the closest distance would be 4 Å, that between the ring proton and the 4-methylene protons (just as in the butyne derivative). However, a larger population of the *gauche* conformer in the nonpolar solvent should be reflected in a change of $^3J(CH_2, CH_2)$ between the two solvents (38, 39). This change is not significant (Table 1). Furthermore, $^6J(H, CH_2)$ for **3** in the two solvents also indicates no change in barrier between the solutions. A longer alkyl chain could conceivably give rise to steric components of the barrier.

If the substituent dependence of the vicinal coupling constants in 1,2-disubstituted ethanes, as given by Phillips and Wray (39), is used with eq. 5c of Abraham and Gatti (38), then

[6]It is interesting that the σ–π transmitted coupling constant in 1-phenyl-1-propyne (18), a $^8J(H, CH_3)$ of −0.251(1) Hz in CS_2/C_6D_{12} (18), is 42% of the −0.602(2) Hz for $^6J(H, CH_3)$ in toluene dissolved (31) in the same solvent mixture. Exactly the same proportion holds for $^6J(H, CH_3)$ and $^4J(H, CH_3)$ in these molecules. Of course, while the transmission of the spin polarization giving rise to these coupling constants and the hyperconjugative energetics both arise from σ–π electron interactions, it does not follow that their magnitudes are directly proportional to one another.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

the *gauche* conformer of **3** has a population of 0.64. This conformer is twofold degenerate, so that the *trans* conformer is favoured by an enthalpy of 0.3 kJ/mol. From a number of theoretical computations of ^4J(H, H) in propane (40), it is clear that the *gauche* conformer has a positive $^4J(CH_2, CH_3)$, the *trans* a negative. In **3**, ^4J is about -0.09 Hz, so that the presence of a significant population of the *trans* conformer seems assured.

(c) Solvent dependence of ^nJ(H, H) for the aromatic protons

The pattern of the solvent dependence of the aromatic proton coupling constants in Table 1 follows precisely that observed for a variety of monosubstituted benzenes in this laboratory. ^3J increases by about 0.02 Hz in passing from $CS_2/C_6/D_{12}$ to acetone-d_6 solutions; $^4J_{26}$ and $^5J_{25}$ increase as well, but $^4J_{24}$ decreases while $^4J_{35}$ is insensitive to solvent. These changes are not artifacts of the spectral analytical procedures; they are apparently not a function of the polarity or of other obvious properties of the substituents. The cause of these changes is not known and remains under investigation.

Nickel(II) and palladium(II) chelates of dehydroacetic acid Schiff bases derived from thiosemicarbazide and hydrazinecarbodithioate

ABDULLA AL KUBAISI[1] AND KAMAL Z. ISMAIL

Department of Chemistry, Faculty of Science, University of Qatar, Box 2713, Doha-Qatar

Received July 16, 1993[2]

ABDULLA AL KUBAISI and KAMAL Z. ISMAIL. Can. J. Chem. **72**, 1785 (1994).

Dehydroacetic acid Schiff bases DAE (**1**) and DATS (**2**) were isolated from the reaction of dehydroacetic acid (2-acetyl-5-hydroxy-3-oxo-4-hexenoic acid-δ-lactone) with hydrazine-*S*-methylcarbodithioate and the corresponding acid amide, thiosemicarbazide, respectively. Reaction of such Schiff bases with nickel(II) and palladium(II) ions afforded the dimeric monoligand chelates $[M(DAE\text{-}2H)]_2$ and $[M(DATS\text{-}2H)]_2$; M = Ni(II) or Pd(II). In the presence of monodentate Lewis bases, B, square-planar chelates [M(DAE-2H)B] and [M(DATS-2H)B], in which B = pyridine or triphenylphosphine, were isolated. The stoichiometry and structure of the isolated organic ligands and their chelates were confirmed through elemental analyses, molecular weight determination, and infrared, ultraviolet–visible, and ^1H and ^{13}C nuclear magnetic resonance spectroscopy.

ABDULLA AL KUBAISI et KAMAL Z. ISMAIL. Can. J. Chem. **72**, 1785 (1994).

On a isolé les bases de Schiff DAE (**1**) et DATS (**2**) de l'acide déhydroacétique en faisant réagir l'acide déhydroacétique (δ-lactone de l'acide 2-acétyl-5-hydroxy-3-oxo-hex-4-ènoïque) avec l'hydrazine du carbodithioate de *S*-méthyle et l'amide correspondant, la thiosemicarbazide, respectivement. Les réactions de telles bases de Schiff avec des ions nickel(II) et palladium(II) fournissent les chélates dimères monocoordinés $[M(DAE)\text{-}2H)]_2$ et $[M(DATS)\text{-}2H)]_2$ dans lesquels M = Ni(II) ou Pd(II). En présence des bases de Lewis monocoordinées, B, on isole des chélates plans carrés $[M(DAE)\text{-}2H)B]_2$ et $[M(DATS)\text{-}2H)B]_2$ dans lesquels B = pyridine ou triphénylphosphine. On a déterminé la stoechiométrie et la structure des coordinats organiques isolés en faisant appel à des analyses élémentaires, des déterminations de masses moléculaires et à des spectres infrarouges, ultraviolet–visible et résonance magnétique nucléaire du ^1H et du ^{13}C.

[Traduit par la rédaction]

Introduction

Dehydroacetic acid, DA, is an important and biologically active compound. Studies have shown that the compound has both antibiotic and fungicidal effects (1). In aqueous solutions, even at very low concentrations (0.02–0.2%), DA shows a strong antiseptic effect (2). The compound is widely used in food technology. It is used to enhance vitamin C stability and protect vegetables during food processing (3) and as a preservative in such products as fish sausages (4). Above all, the structure of DA appeals to inorganic chemists working in the field of coordination chemistry.

On the other hand, hydrazinecarbodithioates and the corresponding acid amide, thiosemicarbazide, and their corresponding Schiff bases show very interesting biological properties, such as antitumour (5, 6), antibacteria (7), and antiviral activities, in addition to a wide range of chemotherapeutic activities. Coordination of such compounds with metal ions such as nickel, iron, and copper often enhances their activity (7, 8), as reported for pathogenic fungi (9).

The antifungal activity of thiosemicarbazones and their corresponding metal chelates is substitution dependent, mainly upon the chemical nature of the segment attached to the C=S carbon atom (10–13). Similarly, substitution in the ring system of Schiff bases derived from compounds containing carbonyl groups attached to N-heterocyclic ring systems, thiosemicarbazides, and their corresponding metal chelates highly affects the biological activity of these compounds (13, 14). So, there is an important structure–activity relationship in these systems. In this manuscript, we use the carbonyl compound, DA, which is reported to have some biological activity, to form Schiff bases with both hydrazinecarbodithioate and thiosemicarbazide. The prepared Schiff bases may show enhanced biological activity. The corresponding nickel(II) and palladium(II) chelates were also prepared. We used elemental analyses and different spectroscopic techniques to elucidate both stoichiometry and structure for all isolated compounds. In future work we aim, with the assistance of our Zoology Department, to test our compound for biological activity.

Results and discussion

The reaction, in boiling ethanol, of hyrazine-*S*-methylcarbodithioate and its corresponding acid amide, thiosemicarbazide, with dehydroacetic acid, 2-acetyl-5-hydroxy-3-oxo-4-hexenoic acid-δ-lactone, afforded the corresponding Schiff bases DAE (**1**) and DATS (**2**), respectively (Scheme 1). Mass spectrometry fragmentation patterns as well as the infrared spectroscopic data revealed that condensation took place with the branched carbonyl group of the heterocyclic ring system of dehydroacetic acid. When mixed with metal acetates, compounds **1** and **2** reacted as dibasic tridentate anionic ligands. The coordination centres are the oxygen atom of the ring carbonyl, the sulphur atom, and the imine nitrogen $[ONS]^{2-}$.

Reaction of nickel(II) acetate with DAE and DATS in the molar ratio 1:1 gave brown crystalline chelates of stoichiometry $[Ni(DAE\text{-}2H)]_2$ and $[Ni(DATS\text{-}2H)]_2$, respectively, where (DAE-2H), and (DATS-2H) are the dinegative anion forms of the ligands DAE and DATS, respectively. The corresponding palladium chelates $[Pd(DAE\text{-}2H)]_2$ and $[Pd(DATS\text{-}2H)]_2$ were similarly isolated as orange solids. Elemental analyses of these chelates (Table 1) showed monoligand metal chelate stoichiometry, i.e., one ligand per metal center. Since our ligands **1** and **2** are only tridentate, one should expect dimerization to complete the coordination. The solution electronic spectra in $CHCl_3$ (Table 2) show several absorption bands. The uv absorption bands between ca. 270 and 320 nm are assigned to localized L–L* transitions of the dianion form of the ligands (in alkaline solution, the unchelated ligand absorbs at ca. 280 and 320 nm).

2	DATS	44.81 (45.19)	4.56 (4.27)	17.42 (17.01)	13.27 (12.91)	— —
2*a*	[Ni(DATS-2H)]$_2$	36.24 (36.14)	3.02 (2.80)	14.07 (13.27)	10.73 (10.21)	17.71 (17.46)
2*b*	[Ni(DATS-2H)Py]	44.56 (44.41)	3.71 (3.71)	14.85 (14.13)	8.48 (8.05)	15.59 (15.61)
2*c*	[Ni(DATS-2H)Tpp]	57.85 (56.90)	4.28 (4.11)	7.5 (7.00)	5.71 (5.70)	10.53 (11.20)

The absorption around 370 nm is due to a charge transfer transition, whereas the *d–d* transition absorption manifold appears at ca. 460–510 nm. No absorption bands appeared beyond 550 nm, which is consistent with square-planar arrangements around the metal ion (15). Such arrangements can only be achieved through dimerization of the monoligand metal chelates (16), which was confirmed by determination of the molecular weights of the isolated chelates using freezing point depression. The reaction of these dimeric chelates with monodentate Lewis bases such as pyridine (Py) and triphenylphosphine (Tpp) in ethanol gave adducts of the general formula [M(DAE-2H)B] and [M(DATS-2H)B], where B is the monodentate Lewis base. The elemental analyses of the isolated compounds and their electronic spectra in $CHCl_3$, which are consistent with the square-planar structure, as well as their infrared spectra confirm the proposed structure for these chelates.

The infrared spectra of both ligands and selected metal chelates are listed in Table 2. The spectra of the chelates show no absorption bands corresponding to νN—H and νC=S (the two absorption bands appear at ca. 3100 cm^{-1} and 1530 cm^{-1}, respectively, in the free ligand), implying tautomerization followed by deprotonation of the thiol tautomer form of the ligand during complex formation. The spectra of the ligands, however, display a sharp νC=O absorption band at ca. 1700 cm^{-1} confirming that the condensation takes place on the side-chain carbonyl group of the acid; otherwise, two distinct bands would have been observed due to nonequivalent ring and side-chain carbonyl groups. The palladium center in **1***a*, **1***b*, and **1***f* exhibits a stronger tendency to shift the aromatic νC=C towards νC=O than does nickel in the analogous chelates. Because of nearby conjugation created by complex formation, the νC=N at ca. 1540 cm^{-1} is shifted about 100 cm^{-1} towards lower frequencies.

The isolated ligands and their corresponding chelates were studied by both ^{1}H and ^{13}C nmr spectroscopy. In their ^{1}H nmr spectra, both ligands **1** and **2** showed two signals in the methyl region. The first, at δ 2.25 ppm, is due to -N=C-CH_3 methyl and the second, at δ 2.6 ppm, is due to $OCCH_3$ protons. A third signal in **1** at δ 2.5 ppm is attributed to the methyl ester, SCH_3. While no significant shifts were observed with the first and sec-

ond signals as a result of metal chelation or adduct formation, the third signal suffered downfield shifts upon chelation and was more sensitive to the nature of the base in the isolated adducts. The disappearance of the proton signal of both the C-H (the parafinic ring CH) and the N-H (they appear at δ 7.2 and δ 9.82 ppm in the free ligands) on chelation, along with the stoichiometry, confirms the dibasic tridentate nature of both ligands in their chelation. The olefinic proton shift was incoming base-dependent, with triphenylphosphine causing a larger upfield shift than pyridine. The notable shielding with triphenylphosphine may be attributed to a virtual effect, from the three sterically hindered phenyl groups. The pyridine base exhibited three symmetrical proton environments showing a doublet at ca. δ 8.7 ppm of the α-CH proton, a triplet centered at ca. δ 7.9 ppm of the γ-CH, and a triplet at ca. δ 7.4 ppm of the β-CH. The α-CH proton appeared downfield shifted with respect to the other protons and further splittings were observed upon resolution-enhanced measurements, uncovering a long-range coupling between the remote protons. The nature of the metal ion did not significantly affect the pyridine proton chemical shifts. However, slight downfield shifts were observed upon replacing the $-SCH_3$ with $-NH_2$. The dispersion of proton chemical shifts of the pyridine hydrogens was not observed for the phenyl protons of triphenylphosphine base in the isolated adducts. Only two wide unresolved bands centered at ca. δ 7.4 ppm and δ 7.75 ppm were detected, due to phenyl protons for both Ni(II) and Pd(II) chelates. The ^1H nmr data are listed in Table 3.

The ^{13}C nmr spectra of some selected chelates were recorded for comparison. The discussion is confined to carbon nuclei whose chemical shift is affected by complex formation. Upon complexation and regardless of the nature of base, both SCH_3 and $NC\text{-}CH_3$ signals were deshielded by ca. 2.5 ppm due to donation of electron density from S and N atoms as a result of coordination to the central metal ion. The ^{13}C nmr chemical shifts of compounds **1** and **2** are almost identical. Replacement of the $-SCH_3$ by $-NH_2$ in **2** caused an upfield shift for the *C*=S carbon by ca. 4.5 ppm due to shielding effects by back-donation from the N atom. Deprotonation of the OC-*C*H-CO carbon is unmistakably deduced by ^{13}C nmr; the OC-*C*H-CO carbon signal observed at ca. 97 ppm in the free ligands is severely shifted upon complexation. The conjugation in the ring system, resulting from complexation, severely deshielded the OC-*C*H-CO carbon. In general, coordinated triphenylphosphine exhibits a deshielding effect on the *C*-S and *C*-O-M carbons, due to its higher electron-withdrawing ability than is the case with pyridine.

Experimental

Preparation of organic ligands and their chelates

Preparation of ammonium hydrazinecarbodithioate (17)

The ammonium hydrazinecarbodithioate was prepared by treating

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

hydrazine hydrate (100%, 1.0 mol), in absolute ethanol (300 mL), with concentrated ammonium hydroxide (50 mL) in a 1-L beaker. The reaction mixture was cooled to 5°C in an ice bath and stirred for 15 min using a mechanical stirrer. The equivalent molar ratio of carbon disulphide (1.0 mol) was added dropwise. The reaction mixture was constantly stirred after each addition and the temperature was kept at or below 5°C. The white product was filtered off, washed with ethanol and ether, and dried.

Preparation of S*-methylhydrazinecarbodithioate (18)*

An aqueous solution of ammonium hydrazinecarbodithioate (12.5 g, 0.1 mol, in 100 mL water) was strongly shaken with methyl iodide (14.5 g, 0.1 mol). The latter was added in small portions and the mixture was shaken after each addition. The product was filtered off, washed with water, dried, and recrystallized from benzene – petroleum ether (mp = 82°CC).

Preparation of Schiff bases

A mixture of 0.1 mol of dehydroacetic acid and 0.1 mol of *S*-methylhydrazinecarbodithioate or thiosemicarbazide in ethanol was refluxed for 1 h. On evaporation and cooling, the corresponding Schiff bases **1** and **2** were isolated as yellowish solids.

Preparation of metal chelates

A clear hot solution of metal acetate (0.01 mol) in ethanol was mixed with a boiling solution of the Schiff base (0.01 mol) and the mixture was refluxed for ca. 2 h. The reaction mixture was then evaporated and cooled to yield the corresponding dimeric chelates, $[M(DAE\text{-}2H)]_2$ and $[M(DATS\text{-}2H)]_2$. The corresponding adducts were prepared by treating the resulting adducts [M(DAE-2H)B] and [M(DATS-2H)B] where B = Py or Tpp.

Measurements

The electronic spectra were recorded in chloroform on a Perkin–Elmer S22 spectrophotometer. Infrared spectra were measured in the solid state using the KBr disk technique and a Nicolet FT-IR 5IOP spectrometer. The ^1H and ^{13}C nmr spectra were measured on a 100 MHz Bruker nuclear magnetic resonance spectrometer. Finally, the formation of dimeric chelates was confirmed by determining the molecular weights cryoscopically by measuring the freezing point depression of nitrobenzene solution containing a known amount of the solute. The molal freezing point depression constant (K_f = 7.00°C/molal) for nitrobenzene was determined using benzil as a standard.

β-Deuterium kinetic isotope effects for identity processes: bromide ion substitution at 1-bromo-1-arylethanes and 2-bromooctane

ALLAN R. STEIN

Department of Chemistry, Memorial University of Newfoundland, St. John's, NF A1B 3X7, Canada

Received October 12, 1993

ALLAN R. STEIN. Can. J. Chem. **72**, 1789 (1994).

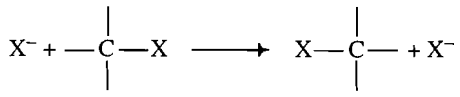
While deuterium kinetic isotope effects for solvolyses have been extensively studied, other nucleophilic substitutions have received less attention, and identity processes, that is, substitutions where the nucleophile and leaving group are the same, have rarely been examined. Identity reactions must pass through a truly symmetrical stage, a transition state or an intermediate, so that data will be of interest to both theoretical and experimental chemists. Values of k_H/k_D have been determined by polarimetry for bromide exchange– racemization at $ArCHBrCH_3/CD_3$ (Ar = C_6H_5, 4-Br- and 4-Me-C_6H_4, and 3,4,-dimethyl-C_6H_3) in acetone, acetonitrile, and nitromethane. Observed values are analogous to values seen in solvolyses. They range from 1.01 to 1.35 and, in some cases, increase markedly as the concentration of Bu_4NBr decreases. Solvolyses are either first order or pseudo first order whereas plotting observed racemization rate versus [Bu_4NBr] allows separation of first- and second-order components; those species giving more stable carbocations in the more dipolar solvents, the systems showing k_H/k_D variation with Br^- concentration, alone show an appreciable first-order component. The second-order k_H/k_D ratio averages 1.062 ±–0.018 at temperatures ranging from 25 to 50°C for all substrates in the three solvents, very analogous to the values seen for racemization of 1,1,1-d_3-2-bromooctane or solvolysis of ethyl substrates but considerably lower than the typical solvolysis values of 1.15–1.25 for *secondary*, and 1.35–1.5 for *tertiary* substrates. The first-order k_H/k_D values obtained are higher, 1.1–1.5. These and other results are discussed.

ALLAN R. STEIN. Can. J. Chem. **72**, 1789 (1994).

Les effets isotopiques cinétiques du deutérium sur les solvolyses ont fait l'objet de nombreuses études; toutefois, d'autres substitutions nucléophiles ont reçu beaucoup moins d'attention et les processus d'identité, les réactions de substitutions dans lesquelles le nucléophile et le nucléofuge sont les mêmes, ont rarement été examinés. Les réactions d'identité doivent nécessairement passer par une étape, un état de transition ou un intermédiaire, vraiment symétrique; ces données devraient donc présenter de l'intérêt pour les chimistes tant expérimentaux que théoriques. Faisant appel à la polarimétrie, on a déterminé les valeurs des k_H/k_D pour la réaction d'echange – racémisation des $ArCHBrCH_3/CD_3$ (Ar = C_6H_5, 4-Br-, 4-Me-C_6H_4 et 3,4-diméthyl-C_6H_3) dans l'acétone, l'acétonitrile et le nitrométhane. Les valeurs observées sont semblables à celles obtenues lors des solvolyses. Elles varient de 1,01 à 1,35 et, dans quelques cas, elles augmentent beaucoup avec une diminution de la concentration de Bu_4NBr. Les solvolyses sont soit du premier ordre ou du pseudo premier ordre alors que, dans notre cas, la courbe de la racémisation en fonction de la concentration de Bu_4NBr permet de séparer les composantes du premier et du deuxième ordre; seules les espèces conduisant à carbocations les plus stables dans les solvants les plus dipolaires, les systèmes présentant une variation du k_H/k_D en fonction de la concentration du Br^-, présentent une portion importante des réaction du premier ordre. Pour tous les substrats, dans les trois solvants, à des températures allant de 25 à 50°C, le valeur du rapport k_H/k_D des réactions du deuxième ordre rend une moyenne de 1,062 ± 0,018 et elles sont très semblables à celles observées lors de la racémisation du 1,1,1-d_3-2-bromoéthane ou de la solvolyse des substrats avec des groupes éthyles; elles sont toutefois beaucoup plus basses que les valeurs typiques de 1,15 à 1,25 ou 1,35 à 1,5 observées lors de solvolyses de substrats *secondaires* ou *tertiaires*. Les valeurs des k_H/k_D du premier ordre sont plus élevées (1,1–1,5). On discute de ces valeurs et d'autres résultats.

[Traduit par la rédaction]

A continuing research interest of ours has been the ion-pair mechanism for nucleophilic substitutions, especially bimolecular substitutions at saturated carbon (1,2). As part of the mechanistic evidence, β-deuterium kinetic isotope effects were desired. The empirical β-deuterium isotope effects reported here are apparently the first measured for an "identity process," which, in the case of a nucleophilic substitution, Scheme 1,



SCHEME 1. An identity process.

requires that the nucleophile and the leaving group are identical species. Such processes can, in principle, be followed by either of two methods: by isotopic exchange using *radio* or stable isotopes of the nucleophile/leaving group if they are available, or by optical activity changes, racemization, if the substrate has a chiral centre at the site of substitution. Both approaches have been used.

Radio-tracer studies were an essential part of the early evidence for the S_N2 reaction mechanism first proposed by Hughes and Ingold. Hughes et al. (3) followed *radio*-iodide exchange with 2-iodooctane, and *radio*-bromide exchanges with 1-bromo-1-phenylethane and 2-bromopropanoic acid in the mid-1930s. Others have also used *radio* tracers to follow exchanges (4–9). We employed the electrodeposition of silver halide at a silver anode, a method developed and extensively used by Beronius (5), to follow *radio*-halide exchanges (6, 7).

Racemization kinetics of chiral alkyl halides, together with halide exchanges, were used by Hughes to show that bimolecular nucleophilic substitutions are accompanied by inversion of stereochemistry (3). These studies were a major, if not *the* major, bulwark of the S_N2 mechanistic proposal. While isotopic exchange methods can, in principal, be used for any substrate, racemizations are limited to species that can show chirality, substrates such as those used in this study.

For the studies reported here, racemizations of chiral *protio* and *deutero* substrates were used. The principal system studied is indicated in Scheme 2. β-Deuterium kinetic isotope effects were determined in acetone, acetonitrile, and nitromethane over

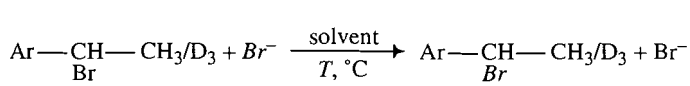

SCHEME 2. The identity process studied.

a range of temperatures and as a function of bromide ion concentration (as the tetrabutylammonium salt).

Results

The β-D_3-labelled 1-phenylethanols were made with *deutero*-methyl magnesium iodide and the corresponding benzaldehyde, where that was commercially available, or by metal hydride reduction of the β-*deutero*-acetophenone, which was either commercially available (acetophenone itself) or prepared by exchange using basic D_2O and a phase transfer agent (PTA). For such exchanges, the procedures of Starkes (11), modified as indicated, was used. Racemic alcohols with isotopic purities of 99.7–99.9% (by nmr) were obtained. These alcohols were converted to the corresponding $ArCHBrCH_3/D_3$ substrates used in these studies by procedures analogous to those already described (10, 12).

Racemizations with *protio* and *deutero* substrates, using the same batch of electrolyte solution, were alternated to minimize any effects due to variation in experimental conditions upon the measured isotope effects. Similarly, if one of the pair of unlabelled and labelled bromides had significantly greater optical activity than the other, it was diluted with racemic material to keep substrate concentrations approximately equal while using near full-scale deflections of the recorder at the same recorder and instrument settings. Two to seven runs were done at each temperature and ionic bromide concentration reported. Standard deviations within a run, from the weighted least-squares analysis of rotation versus time, were always considerably smaller than the differences between duplicate runs.

Second-order rate constants reported in this paper are for inversion (or substitution), that is, they are one half the observed racemization rate constants because substitution with inversion in an identity process results in the loss of two units of enantiomeric excess. First-order rate constants are those for racemization; there is no analogous factor of two here (16).

Actual, directly measured, rate constants and the calculated kinetic isotope effects are reported in Table 1 for 0.0200 M Bu_4NBr in acetone at 25°C and 0.00500 M Bu_4NBr in acetonitrile and nitromethane at 40°C.

Previous studies established that, in acetone, racemizations of all substrates examined are cleanly second order; a plot of observed racemization rate versus the concentration of added halide salt has a zero, or very near zero, intercept (7). The plot, however, is nonlinear because ion pairing of the bromide ion with its cation reduces the activity coefficient of the nucleophile as its concentration, a salt, is increased. The plot of rate versus the activity of the bromide ion was, thus, linear with a zero or very nearly zero intercept for all substrates. Consequently, deuterium kinetic isotope effect determinations were done at only a single concentration of tetrabutylammonium bromide in acetone.

In acetonitrile and nitromethane, in contrast to acetone, there is no evidence of ion pairing of the Bu_4NBr over the concentration ranges employed yet, especially those substrates giving more stable carbocations (i.e., 4′-methyl- and 3′,4′-dimethylphenyl-1-bromoethanes) show a marked dependence of the measured k_H/k_D upon the concentration of Bu_4NBr. Typical values for the methyl-substituted substrates in nitromethane are shown as a footnote to Table 1. A change in Bu_4NBr concentration from 0.02 to 0.001 M increases the observed isotope effect from 1.08 to 1.27! Even larger variations are seen for the 3′4′-dimethyl substrate in nitromethane, lower ones for these two substrates in acetonitrile.

As Fig. 1 clearly indicates, this apparent concentration dependence arises from mixed kinetics (1, 6). For such cases first- and second-order components of the reaction can be separated by plotting the observed rate versus the concentration of the nucleophile, or its salt. First- and second-order components were obtained by linear regression analysis of all data, Table 3 the activation parameters determined, Table 2, and used to recalculate the rate constants and kinetic isotope effects at 30.00°C included in Table 3. A comparison of the kinetic isotope effects in Tables 1 and 3 confirms the necessity of such a separation of the rate components. Note that, except for 4′-methyl and 3′,4′-dimethyl substrates in acetonitrile and nitromethane, the first-order component is very small, Table 3

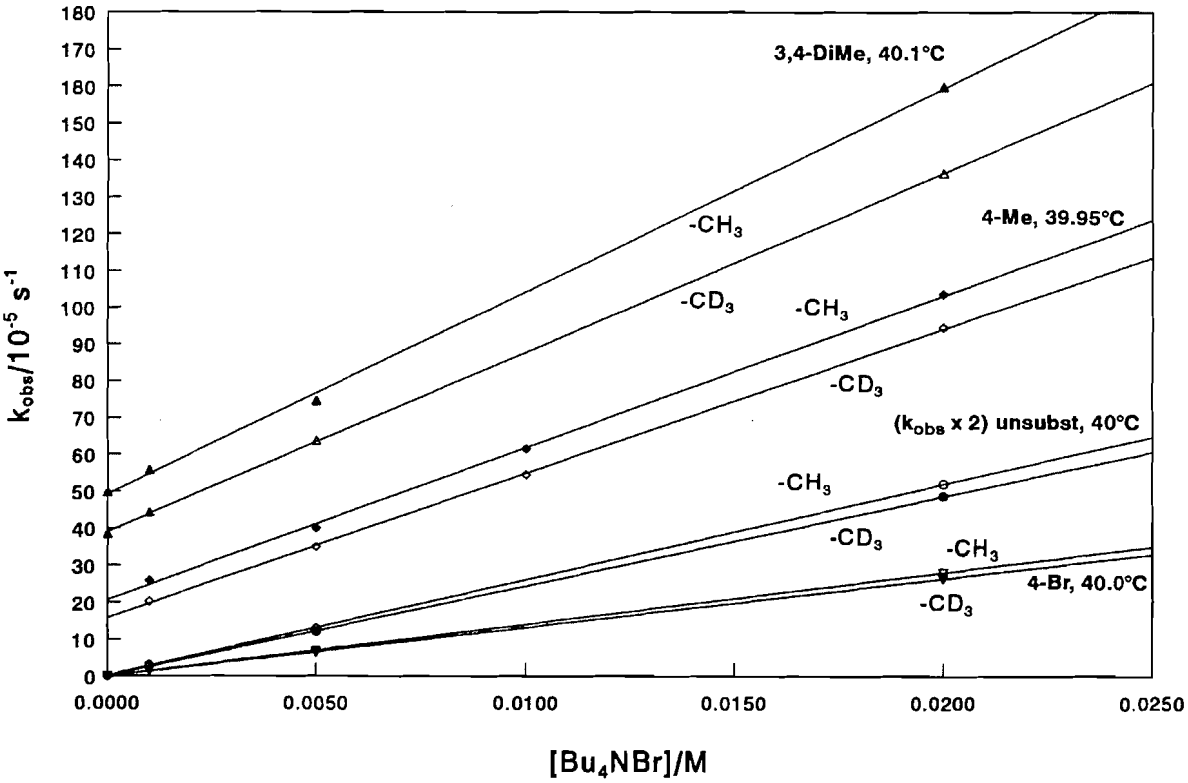

FIG. 1. Observed rate of racemization versus [Bu_4NBr]; separation of unimolecular (intercept) and bimolecular (slope) contributions in CH_3NO_2 at 40°C.

Uncertainties in these small rate constants are relatively large and the corresponding k_H/k_D is even more uncertain. Obviously, care must be exercised in attaching significance to such results.

For comparison, β-deuterium kinetic isotope effects for an identity process at a non-benzylic secondary carbon were desired. Chiral 1,1,1-d_3-2-bromooctane, and its *protio* analog, were prepared. In acetonitrile, a linear plot, with a zero intercept, for observed rate of racemization versus concentration of bromide ion was obtained so that a single Bu_4NBr concentration, 0.02500 M, was used for isotope effect measurements. Racemizations have, to date, only been done in acetonitrile at 60°C, giving $k_H = (5.923 \pm 0.040) \times 10^{-4}$ L mol^{-1} s^{-1} and $k_H/k_D = 1.084 \pm 0.006$.

Discussion

Deuterium kinetic isotope effects have commonly been determined and were the basis for much mechanistic discussion over the years. β-Deuterium effects are generally rather small secondary effects because the isotopically substituted atom is not directly involved in reaction progress. For the hydrolysis of *tert*-butyl chloride, presumedly a reaction through a carbocation, Robertson and co-workers (13) obtained an isotope effect of 2.387, or 1.101 per D. In our case, with three deuteriums, values of $(1.10)^3$ or 1.34 might be expected if the reactions were unimolecular. Such normal effects are usually attributed to hyperconjugative overlap of the C—H (or C—D) bond orbital with the empty, or electron deficient, developing *p*-orbital on the carbon undergoing the substitution. As such, the amount of overlap should reflect the degree of charge on the central carbon at the transition state. Isotope effects for reactions through a carbocation thus are larger than those following a concerted substitution, that is, the bimolecular mechanism. Consequently, the value of 1.34 per CD_3 group would represent a near-maximum value for substitution.

Shiner and Humphrey have confirmed that there is also an inductive effect, by using bridgehead deuteration where hyperconjugation is prohibited by stereochemistry. Inductive effects lead to smaller, inverse, effects, in Shiner's case about 0.986 per D (14). Of course, for a methyl group adjacent to the carbon undergoing substitution, only one of the C—D bonds can be appropriately orientated for hyperconjugation; the other two deuteriums on the methyl carbon exert inductive effects. Thus the measured k_H/k_D is the product of the normal hyperconjugative and inverse inductive contributions.

Almost all, or at the very least the vast majority, of k_H/k_D measurements for nucleophilic substitutions have been for solvolysis reactions. In fact, we have been unsuccessful in finding any reports of β-deuterium kinetic isotope effect measurements for identity processes. Unfortunately, in solvolysis, all reactions are kinetically first order, whether they are in fact first or actually pseudo first order. If first- and second-order processes are in competition and there is no way to determine the individual contributions, interpretation of the results is bound to be fraught with difficulty! Conversely, the lack of deuterium isotope effect data for identity processes, and the individual first- and second-order components for systems other than those reported here for the 1-phenylethyl system, makes interpretation of our results more difficult.

In fact the only published β-deuterium effects for identity processes have been obtained through force field calculations by McKenna et al. (15). Some of his results, those for the reaction RBr + Br^-, are presented in Table 4 along with the hydrolysis data of Robertson quoted in the paper. To facilitate comparison, both the calculated and measured effects are con-

	deutero	65.09 ± 0.76	−68.2 ± 2.5	75.4 ± 2.9	−69.8 ± 9.4

verted to the contribution for d_3 that is for one CD_3 group. McKenna's and Robertson's data (15) are somewhat more consistent with the values reported in Table 1 than with those in Table 3. Thus, in the more dipolar acetonitrile and nitromethane solutions, 4′-methyl- and 3′4′-dimethylphenyl-1-bromoethanes follow mixed kinetics with observed net isotope effects similar to an "ordinary" secondary substrate, isopropyl bromide, in the even more ionizing media, water. Does that imply that the latter reaction also has mixed kinetics?

Solvolyses data abound in the literature. A cross section of typical results is tabulated in Table 5 for comparison with the results reported in this paper. These studies are grouped according to the type of system studied. On a per CD_3 basis, for aqueous and mixed aqueous solvents, primary substrates show k_H/k_D values similar to those for the second-order component of the identity reaction reported here, that is about 1.03–1.04. Secondary substrates, that is isopropyl, 1-arylethyl, and other substrates, give hydrolysis isotope effects of about 1.15–1.26, more in line with those substrates showing mixed kinetics prior to separation of first- and second-order components as reported in Table 1. The effects reported for hydrolysis of *tert*-butylsubstrates, about 1.35 per CD_3, are more comparable to the unimolecular components of this study.

For racemizations of 2-bromooctane and 1,1,1-d_3-2-bromooctane in acetonitrile, a plot of observed rate versus nucleophile concentration is linear with a zero intercept. This identity process is cleanly second order. At 60°C, $k_H = (5.923 \pm 0.040) \times 10^{-4}$ L mol^{-1} s^{-1} and $k_H/k_D = 1.084 \pm 0.006$, which is not far from the average second-order component value for all the 1-phenyl-1-bromoethanes in acetonitrile as reported in Table 3, 1.065 ± 0.031 for the recalculated values at 30°C or 1.062 ± 0.012 for the actual values at various temperatures (25–50°C).

If the current results for identity processes give representatives values for "pure bimolecular" and "pure unimolecular" nucleophilic displacements at secondary carbon, then it appears that ethyl substrates alone hydrolyse by bimolecular substitution, *tertiary* substrates by unimolecular, and *secondary* substrates such as isopropyl and phenylethyl follow mixed kinetics apparently with a large first-order component. A number of the authors whose data are presented in Table 5 have reached conclusions that are not at variance with these observations.

For the phenylethyl substrates in the presence of the base lutidine, we have shown that the loss of optical activity could contain nucleophilic substitution and elimination components (6). Elimination, even in the presence of added base, was a relatively small component of the process except for 4-methyl and 3,4-dimethyl substrates at the lower Bu_4NBr concentrations especially in nitromethane. Except for an apparent solvent effect, the elimination rate was independent of lutidine concentration. Without added base, no elimination, as seen by increase in bromide concentration, was observed for any of the substrates in any of the solvents examined. Nor was the elimination rate with added lutidine affected by the initial bromide ion concentration. Thus, no second-order elimination component was detected. However, a first-order elimination–readdition process could contribute to the first-order isotope effect component reported in this paper. While deprotonation of the carbocation intermediate would, presumedly, show a primary kinetic isotope effect, that deprotonation is occurring *after* the transition state for the overall process and should contribute comparatively little to the observed isotope effects.

As is possible for our first-order component, part of the solvolytic isotope effect reported for some of the compounds in Table 5 is likely due to the much larger primary isotope effect associated with elimination rather than with substitution processes. The Sridharan and Vitullo (20) and the Humski, Sendi

[a]The unimolecular component for these reactions was very small; uncertainties in the rate constants and the isotope effects are thus comparatively large.
[b]Recalculated values were obtained using the thermodynamic activation parameters reported in Table 2.

jarevevic, and Shiner (21) results make that most obvious. Unfortunately, the current study is the only one that allowed separation of uni- and bimolecular components — solvolyses and, under solvolysis conditions, also competing eliminations are first or pseudo first order.

Unfortunately, substituent, solvent, and temperature effects on the isotope effects are largely masked because the imperfect reproducibility of the kinetic data and the manipulation required to separate the first- and second-order components result in quite large standard deviations. Other approaches such as the differential methods (31), while they might improve the precision in measuring the observed k_H/k_D, would not allow separation of the first- and second-order components of the racemization. Consequently, any detailed discussion of identity kinetic isotope effects should await completion of the much more extensive study currently in progress.

However, it is apparent that the contribution of a β-CH_3/CD_3 in a bimolecular nucleophilic substitution is very nearly the same whether the reaction is hydrolysis of a primary substrate or bromide exchange at an aryl-substituted, or other secondary,

centre. Solvolyses at secondary (and tertiary) centres give larger β-D_3 k_H/k_D effects, likely because the reactions are mixtures of substitution and elimination processes, either or both of which can have uni- and (or) bimolecular components.

Experimental

All solvents used for kinetics were HPLC or reagent grade, dried by final distillation from calcium hydride under nitrogen, which was dried with a train of concentrated H_2SO_4 and molecular sieves. Commercial anhydrous ether was used for Grignard reactions. Tetrahydrofuran (THF) was dried by shaking and storing over KOH, followed by refluxing over, then distillation from, $LiAlH_4$, again under dried nitrogen. The polarimeter cell was oven dried at about 60°C, other glassware used for the kinetics, at 125°C. Kinetics solutions were prepared, and all transfers made, in a nitrogen-flushed glove box.

Kinetics of racemization were followed with a Perkin Elmer model 141MC polarimeter fitted with a retransmitting potentiometer and a recorder. Actual rotations due to the solutions were not recorded; the rate of change alone was required. Temperature control was better than ±0.05° with a thermostated circulating constant temperature bath and a jacketed 10-cm quartz polarimeter cell. Times and rotations, as voltages, were read from the recorder trace and processed using standard weighted linear regression analysis. Generally 3–5 half-lives were used except for those cases with a significant first-order component, where the reaction accelerated with time due to increasing bromide ion concentration as competing elimination occurred (1, 6). Initial slopes from, generally, about a single half-life were used for such runs. Error limits, where reported, are one standard deviation. Standard deviations of one part in 5 000–40 000 were normal for individual kinetic runs and agreement between duplicate runs was generally better than one percent. For each solvent, at each temperature and nucleophile concentration, two to seven runs were averaged.

Preparation of substrates

Achiral alcohols and esters

Protio. Except for 1-phenylethanol, which was commercially avail-

[a]Measured rotation for 1.00 cm of neat liquid at 25°C at the wavelength indicated for the material from the (+)-1-amino-1-phenylethane salt of the corresponding biphthalate.
[b]Boiling points for the *protio* material; those for the *deutero* materials were almost identical.

able (Aldrich), these were made, under dry nitrogen, from the corresponding ketone (Aldrich) by reduction, at reflux for several hours in THF, with 1.05 equivalents of $LiAlH_4$. The alcohol was not isolated. Phthalic anhydride (Fisher), which had been recrystallized from chloroform, 1.02 equivalents, was added to the cooled solution and reflux, with magnetic stirring, was continued overnight. The solution was concentrated and taken up in ether and ice-cold, approximately 2 M, HCl. The ethereal layer was washed 2–4 times with cold aqueous acid, water, and saturated brine. The ethereal solution was concentrated on a rotovac and the biphthalate allowed to crystallize. If desired, the half-ester was recrystallized from heptane but, generally, it was resolved directly.

1-Phenylethanol was converted to the lithium salt by refluxing with 1.1 equivalents of LiH in THF, phthalic anhydride was added, and the solution subsequently treated analogously.

Deutero. D_3-Acetophenone, which is commercially available (Aldrich), was treated analogously to the *protio* ketones.

To 4-bromobenzaldehyde (Aldrich), *p*-tolualdehyde (Anachemia), or heptanal (Aldrich) in anhydrous ether, 1.01 equivalents of CD_3MgI in ether (Aldrich) was added over 30 min at ice temperatures. The solution was refluxed for several hours and the acidified, washed several times with cold dilute acid, water, dilute Na_2CO_3 solution, and saturated brine. After drying over K_2CO_3, the ether was removed and the alcohol vacuum distilled: β-D_3-4′-bromophenylethanol, bp 100–102°C/2.0 Torr (1 Torr = 133.3 Pa); 4′-methylphenylethanol, bp 93–93.5°C/5.4 Torr; 2-octanol, bp 84–86°C/14.5 Torr. No, or at most a minute amount of, CD_2H group was detectable in the nmr. Yields were greater than 90%, and isotopic purities, as measured by nmr, were 99.7% or greater.

The β-D_3-alcohols were converted to their lithium salts by refluxing with 1.1 equivalents of LiH in THF and the biphthalate ester was prepared as for the *protio* equivalent above.

β-D_3-3′,4′-Dimethylacetophenone was made from the corresponding *protio* material by exchange (11). Under dry nitrogen, 25.0 g of 3′,4′-dimethylacetophenone and 1.95 g of tricaprylmethylammonium chloride was stirred at 30°C for about 30 min with four 15-mL batches of D_2O (99.95%) approximately 1.5 M in NaOD (Aldrich). After standing briefly to permit phase separation, each of the aqueous phases was removed from the pear-shaped flask by pipet. After exchange, three washes of the organic phase with 5-mL portions of D_2O saturated in KCl for anion exchange,[1] were followed by vacuum distillation of the product, bp 79–81.5°/1.6 Torr, 91.5%, greater than 99.7% CD_3 by nmr. The biphthalate ester was prepared, using LiH, as described above.

Optical resolutions

Using (+)- and (−)-1-amino-1-phenylethanes (Eastman), procedures analogous to those already described were used for both *protio* and *deutero* substrates (10). Ether was used as solvent for all but the 4′-bromo material, where acetone was used. With the *deutero* material, when difficulty was experienced in obtaining diastereomeric salt crystals in the resolutions, a small-scale sample was seeded with *protio* salt crystals and the resulting crystals used as seeds to initiate crystallization for the full-scale resolution. Combined yields of the two diastereomeric salts were greater than 80%, generally over 90%, based upon starting alcohol or ketone. The resolved materials were stored as the salts until required for kinetics.

Preparation of chiral bromides

Chiral alcohols were recovered from their diastereomeric salts by partition between ice-cold aqueous hydrochloric acid and ether, followed by base-catalyzed hydrolysis of the biphthalate esters as previously described (10).

Except for 3′,4′-dimethylphenyl-1-bromoethane, which was prepared using gaseous HBr in benzene as previously described (10), all of the chiral alcohols were converted to the bromides with diphos and bromine (12). (The dimethyl alcohol gave almost totally racemic product with the diphos procedure.) The clear, colourless bromides very slowly racemize and discolour even in the freezer, where they were stored between kinetic runs at −12°C. The 4′-methyl- and 3′,4′-dimethylphenyl-1-bromoethanes were prepared freshly every 7–10 days; the others, while much more stable, were prepared every 3 or 4 weeks.

Measured optical rotations for neat alcohol, and the resulting bromide, from the (+)-1-amino-1-phenylethane salt of the corresponding biphthalate, are reported in Table 6 together with the appropriate boiling points. All nmr and ir spectra were as expected. No OH was present in the ir of the bromides and the CD_2H signal in the nmr was, at most, barely detectable by nmr, generally representing >99.7% isotopic purity.

Kinetics of racemization

Bu_4NBr (Eastman) was dried at ~1 Torr and 50–60°C for 5–6 h and

[1]In initial runs, 3,4-dimethylacetophenone, about 87.5% CD_3-, 12.5% CD_2H-, as determined by nmr, was obtained whereas, based upon the amount of deuterium to hydrogen in the exchange cycles, the product should have been about 99.8% isotopically pure. The composition was essentially unchanged by recycling the substrate with fresh batches of D_2O and PTA. The counterion was no longer chloride, but rather deuteroxide, and heating for vacuum distillation caused Hoffman elimination of HOD from the tricaprylmethylammonium deuteroxide. Under the basic conditions, the HOD back-exchanges with the acetophenone to equilibrium. The ratio of D_2- to D_3-acetophenone was, in fact, almost exactly that expected after such equilibrium back-exchange. Anion exchange by washing the product several times with D_2O saturated in KCl before vacuum distillation solved the problem.

weighed and transferred in the glove box. Stock solutions, usually 0.0200 or 0.0500 M in electrolyte, were made, sealed in hypo vials with Teflon-lined caps, and diluted as required. Such stock solutions gave reproducible results for several months but were generally prepared freshly every few weeks. Diluted solutions were stored in volumetrics with glass stoppers and freshly prepared daily or, when the reactions were especially slow, after each pair of *protio* and *deutero* runs.

In the glove box, 25 mL of the diluted Bu_4NBr solution was prepared, 5.0 mL was pipetted into the polarimeter cell, and a weighted amount of chiral substrate added by syringe. The amount of substrate used was determined by the rotation of the resultant solution. A rotation of 0.4° gives near full-scale deflection on the recorder at moderate amplification. When rotations of a pair of substrates differed markedly, racemic material was added to the more active substrate so that similar total concentrations for the *protio* and *deutero* materials were used. The Teflon stoppers were inserted, the cell transferred to the circulating, constant temperature bath, and the contents of the cell thoroughly mixed while equilibrating to the pre-set temperature before the cell was inserted into the Perkin Elmer model 141MC polarimeter. Time was measured from the recorder trace, zero being when the pen crossed a dark time line. Runs with *protio* and *deutero* substrates, using the same solutions, were alternated.

About 60 data pairs of rotations, as recorder pen displacements or voltages, and times were read from the recorder chart and treated with standard weighted linear regression analysis routines. Half-lives ranged from about 12 min to several days. A linear regression of observed rate of racemization versus concentration of Bu_4NBr gave the first-order rate constant as the intercept, the second-order constant as the slope.

A ^{139}La and ^{17}O nuclear magnetic resonance study of the nature of La(III) first coordination sphere in acetonitrile solutions of hydrated lanthanum nitrate

ZHIGANG CHEN AND CHRISTIAN DETELLIER[1]

Ottawa–Carleton Chemistry Institute, University of Ottawa Campus, Ottawa, ON K1N 6N5, Canada

Received December 1, 1993[2]

ZHIGANG CHEN and CHRISTIAN DETELLIER. Can. J. Chem. **72**, 1797 (1994).

The nature of the first coordination sphere of the La(III) cation in acetonitrile solutions of $La(NO_3)_3.6H_2O$ was investigated by ^{139}La and ^{17}O NMR. All three nitrate anions are coordinated to La(III). There is a competition between water and acetonitrile molecules for the occupancy of the La(III) first coordination sphere. The ^{139}La and ^{17}O NMR results, obtained for various concentrations of $La(NO_3)_3.6H_2O$, were quantitatively interpreted through a chemical equilibrium model. It was shown that the presence of only two La(III) species, $\{La(III)\ (NO_3^-)_3\}$ and $\{La(III)\ (NO_3^-)_3.H_2O\}$, in rapid exchange in solution could account for all the NMR results. The variation of the ^{139}La and ^{17}O NMR parameters (chemical shifts and relaxation rates) with the concentration of $La(NO_3)_3.6H_2O$ results from the population increase of the species $\{La(III)\ (NO_3^-)_3.H_2O\}$. The chemical exchange between free and coordinated water molecules is also fast on the ^{17}O NMR time scale. The ^{17}O NMR signal of water is considerably broadened when it coordinates to the La(III) cation. This broadening was attributed to both direct and indirect interactions between the two quadrupolar nuclei ^{17}O and ^{139}La. The direct interaction comes from an increase of the electric field gradient at the ^{17}O nucleus when a water molecule coordinates to the La(III) cation. The indirect interaction results from an ^{17}O–^{139}La scalar coupling. The detailed analysis of the ^{17}O NMR spectra also allowed the determination of the indirect coupling constant between coordinated $^{17}OH_2$ and $^{139}La(III)$, $|^1J(^{17}O—^{139}La)|$: 88 ± 13 Hz.

ZHIGANG CHEN et CHRISTIAN DETELLIER. Can. J. Chem. **72**, 1797 (1994).

On a étudié par RMN du ^{139}La et de l'^{17}O la nature de la première couche de coordination de La(III) dans des solutions de $La(NO_3)_3.6H_2O$ dans l'acétonitrile. Les trois anions nitrate sont coordinés au La(III), alors que molécules d'eau et d'acétonitrile sont en compétition pour l'occupation de la première couche de coordination du La(III). On a proposé une interprétation quantitative des résultats de la RMN du ^{139}La et de l'^{17}O obtenus en variant la concentration de $La(NO_3)_3.6H_2O$. La présence de deux espèces chimiques, $\{La(III)\ (NO_3^-)_3\}$ et $\{La(III)\ (NO_3^-)_3.H_2O\}$, en échange rapide, rend compte des résultats de RMN. La variation des paramètres de RMN du ^{139}La et de l'^{17}O (déplacements chimiques et vitesses de relaxation) avec la concentration de $La(NO_3)_3.6H_2O$ résulte d'un accroissement de la population de l'espèce $\{La(III)\ (NO_3^-)_3.H_2O\}$. A l'échelle de temps de la RMN de l'^{17}O, l'échange chimique entre molécules d'eau "libres" et coordinées est, lui aussi, rapide. Le signal de RMN de l'^{17}O de l'eau est fortement élargi lorsque l'eau se coordine au cation La(III). Cet élargissement a été attribué à des interactions directes et indirectes entre les deux noyaux quadripolaires, ^{139}La et ^{17}O. L'interaction directe provient d'un accroissement du gradient de champs électrique au site du noyau d'^{17}O lors de la coordination d'une molécule d'eau sur le cation La(III). L'interaction indirecte résulte d'un couplage scalaire ^{17}O–^{139}La. L'analyse détaillée des spectres de la RMN de l'^{17}O a aussi permis la détermination de la constante de couplage indirecte entre $^{17}OH_2$ coordiné et $^{139}La(III)$, $|^1J(^{17}O—^{139}La)|$: 88 ± 13 Hz.

Lanthanide ions are increasingly used as spectroscopic probes in biochemical and biological systems (1, 2), and a more detailed knowledge of their coordination behavior in the presence of specific ligands in solutions is needed. However, many aspects of their coordination chemistry remain unclear. For example, the nature and the structure of the chemical species present in aqueous solutions of their salts are not yet fully understood (3–5).

It is likely that ion pairs be formed in the solutions of the tripositive lanthanoid ions ("Ln^{3+}": Y^{3+}, La^{3+}–Lu^{3+}), particularly in poorly coordinating solvents. Bunzli and co-workers (6, 7) have investigated the interactions between lanthanoid cations and the perchlorate anion in anhydrous acetonitrile solutions by FTIR spectroscopy. They found that inner sphere complexes of Ln^{3+} with ClO_4^- were formed in these systems (6, 7). The nature of the solutions of lanthanide chloride in methanol and methanol–water mixtures has been studied by several techniques, including X-ray diffraction (8, 9), NMR spectroscopy (8–11), ultrasonic absorption measurements (12), and UV-Visible spectroscopy (13). On the basis of these studies, evidences were found that contact ion pairs are formed between Ln^{3+} and Cl^- in water–methanol solutions. As the methanol molar fraction is larger, the degree of Ln–Cl inner sphere coordination increases. Inner sphere complexes of Ln^{3+} with nitrate and perchlorate anions were also found to be formed in methanol–water solutions (13).

Metal cation NMR in solution is a powerful and sensitive probe of the nature of the immediate electronic environment of the metal cation (5, 14). Among the lanthanide series, the quadrupolar ^{139}La nucleus ($I = 7/2$; $Q = 0.21 \times 10^{-28}$ m^2) is the best candidate for such studies (15) since its receptivity compared to ^{13}C is 342. In the present work, we investigate, by means of ^{139}La and ^{17}O NMR spectroscopies, the nature of the La^{3+} coordination sphere when the salt $La(NO_3)_3.6H_2O$ is dissolved in anhydrous acetonitrile. These NMR techniques permit one to characterize the competition between small amounts of water and bulk solvent molecules for the occupation of the La(III) first coordination shell. A model is proposed, and a quantitative interpretation of the results is given, allowing the calculation of the equilibrium constant of formation of the monohydrated species, $La(NO_3)_3.H_2O$. The coupling constant, $^1J_{^{139}La—^{17}O}$, between the La^{3+} cation and the water molecule in its first coordination sphere could be estimated.

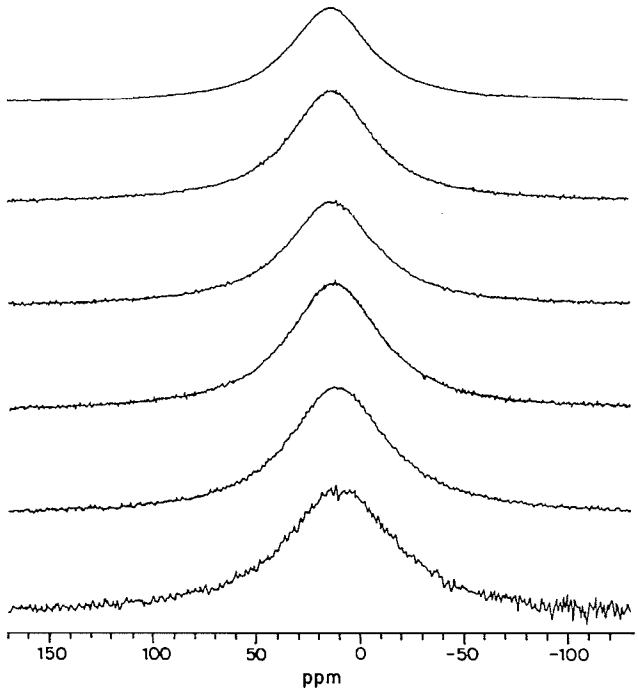

FIG. 1. A series of ^{139}La NMR spectra for various concentrations of $La(NO_3)_3.6H_2O$ in acetonitrile. Top to bottom [La(III)] = 0.100, 0.050, 0.040, 0.030, 0.020, and 0.010 M, T = 300 K.

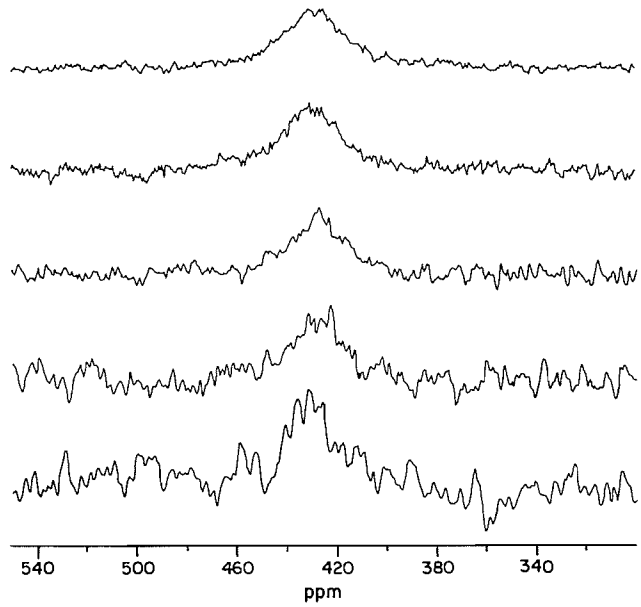

FIG. 2. A series of ^{17}O NMR spectra of the nitrate region for $La(NO_3)_3.6H_2O$ solutions in acetonitrile. Top to bottom [La(III)] = 0.090, 0.070, 0.050, 0.025, and 0.015 M, T = 300 K.

Experimental

$La(NO_3)_3.6H_2O$ (Aldrich 99.999%) was used without further purification. Acetonitrile (BDH Assured) was dried as previously reported (16).

The stock solutions for NMR investigations were prepared by dissolving an appropriately weighted quantity of hydrated lanthanum nitrate in dried acetonitrile. The lanthanum content of lanthanum nitrate was determined by titration with EDTA using xylenol orange as indicator. Results confirmed the hexahydrated lanthanum nitrate formula. The solutions thus made were transferred into 10 mm NMR tubes sealed under argon with Parafilm. ^{139}La NMR spectra were obtained at 42.37 MHz on a Varian XL-300 NMR spectrometer. A 0.10 M solution of $La(NO_3)_3$ in D_2O:H_2O 20:80 (v/v) was used as an external reference for the chemical shift measurements. The instrumental conditions were chosen as described previously (17). The linewidths at half-height and the chemical shifts were obtained from a complete lineshape analysis of the experimental Lorentzian lines. The errors on their determination was evaluated to be 40 Hz and 0.5 ppm, respectively.

The natural abundance ^{17}O NMR spectra were measured at 40.66 and at 67.77 MHz, respectively, on a Varian XL-300 and on a Bruker AMX-500 NMR spectrometers. The chemical shifts were referenced to external 100% D_2O. The error on their determination was evaluated to be 0.2 ppm.

The temperature in the probe was controlled, and all the experiments were performed at 300.0 ± 0.5 K.

Results

The chemical shifts and linewidths of the ^{139}La NMR spectra have been measured as a function of $La(NO_3)_3.6H_2O$ concentration in acetonitrile. In the range of concentrations studied, the ^{139}La NMR spectra consist of a single Lorentzian line. Figure 1 shows a series of ^{139}La NMR spectra for various concentrations, from 0.010 to 0.100 M. The ^{139}La NMR signals shift downfield, from 7.9 to 12.0 ppm, and the linewidths values decrease from 2750 to 1930 Hz, as the concentration of La(III) increases from 0.0050 to 0.10 M.

These results indicate that at least two different La(III) species, with different chemical environments, coexist and exchange rapidly in the solution. The formation of these different La(III) solution sites can result from the interactions of La(III) with the nitrate anion, water, and/or solvent molecules.

Figures 2 and 3 show series of ^{17}O NMR spectra for various concentrations of $La(NO_3)_3.6H_2O$ in acetonitrile. Two ^{17}O NMR signals were observed: one at 430 ppm, attributed to the nitrate anion (18, 20) (Fig. 2), and one at higher fields, in the range −3 to 11 ppm, attributed to water (19–21) (Fig. 3*a*). The ^{17}O NMR chemical shifts and linewidths of the nitrate anion are independent of the $La(NO_3)_3.6H_2O$ concentrations, in the limits of the experimental errors. The ^{17}O NMR chemical shifts of water, on the other hand, vary with the concentrations of hydrated lanthanum nitrate, from −2.26 to 10.6 ppm in the La(III) concentration range of 0.0050 to 0.100 M. These characteristics indicate the presence of one type of NO_3^- and of at least two types of water molecules. As it has been shown by several studies (12, 18, 19), all three nitrate anions are expected to be coordinated to the La(III) cation, while it is a variable number of water molecules which is expected to be in the first coordination sphere of the La(III). The different La(III) sites, which are observed on the ^{139}La NMR spectra (Fig. 1), are thus attributed to chemical species characterized by a different number of water molecules coordinated to La(III). The following model is proposed (eq. [1]–[7]). For more clarity, the number (unknown) of acetonitrile molecules directly coordinated to La(III) is not indicated.

$$[1] \qquad \{La(NO_3)_3.xH_2O\} + \{H_2O\} \rightleftharpoons \{La(NO_3)_3.(x+1)H_2O\}$$

Let us define [A] and [B] as [A] = $[La(NO_3)_3.xH_2O]$ and [B] = $[La(NO_3)_3.(x+1)H_2O]$, then

$$[2] \qquad K = \frac{[B]}{[A] \times [H_2O]}$$

[a]Number of water molecules in the first coordination shell of La(III); see eq. [1].
[b]^{17}O NMR chemical shift of the water molecule coordinated to La(III).
[c]Equilibrium constant (see eq. [2]).
[d]All errors are given as one standard deviation, σ, from the non-linear regression.

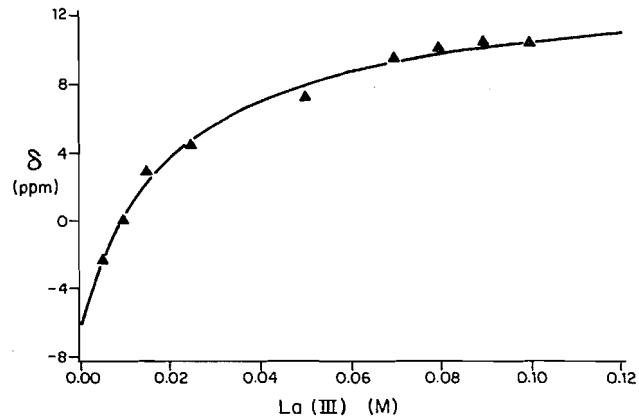

FIG. 4. ^{17}O chemical shifts as a function of [$La(NO_3)_3.6H_2O$] in acetonitrile. The data points are experimental and the curve is calculated from the values of the parameters reported in Table 1.

Since

$$[5] \qquad [A] = [La]_0 - [B]$$

$$[6] \qquad [H_2O] = (6 - x) \times [La]_0 - [B]$$

and

$$[7] \qquad [H_2O]_c = x\,[La]_0 + [B]$$

the observed ^{17}O NMR chemical shifts of water for $La(NO_3).6H_2O$ acetonitrile solutions can be fitted by a non-linear regression procedure through eqs. [2] and [4] to [7] using δ_c, K, and x as the adjustable parameters. In order to limit the number of adjustable parameters, the ^{17}O NMR chemical shift of free water, δ_f, was taken as an experimental value. Only a very slight dependence of δ_f upon the water concentration could be observed when given amounts of water were added to anhydrous acetonitrile. For water concentrations of 0.62 and 0.31 M, chemical shifts of −5.92 and −6.10 ppm were respectively observed: −6.00 ppm was choosen as the value of δ_f for the non-linear regression analysis. The results of this regression are reported in Table 1. In Fig. 4, the points are the experimental values of the ^{17}O NMR chemical shifts of water and the curve is calculated from the parameters reported in Table 1. The non-linear regression gave a value for x (see eq. 1) of zero.

Similarly, δ_A, δ_B, and K can be used as adjustable parameters in the series of eqs. [2], [3], [5], and [6]. Again, in order

[g]Equilibrium constant (eq. [2]) determined from linewidth variation.
[h]All errors are given as one standard deviation, σ, from the nonlinear regression.

to limit the number of adjustable parameters, x is taken equal to zero, as found from the ^{17}O NMR data. The results are reported in Table 2. Figure 5 shows the observed ^{139}La NMR chemical shifts as a function of $La(NO_3)_3.6H_2O$ concentrations in acetonitrile solutions, in which the points are experimental and the line is calculated from the values of the adjustable parameters reported in Table 2, with $x = 0$.

A similar treatment was made for the ^{139}La NMR linewidths ($\nu_{1/2}$).

$$[8] \qquad (\nu_{1/2})_{obs} = (\nu_{1/2})_A \left(1 - \frac{[B]}{[La]_0}\right) + (\nu_{1/2})_B \frac{[B]}{[La]_0}$$

$(\nu_{1/2})_A$, $(\nu_{1/2})_B$, the linewidths respectively for site A and site B, and K are used as adjustable parameters. The results are also given in Table 2. It is worth stressing that the K values obtained independently from the ^{17}O NMR chemical shift data and from both ^{139}La NMR chemical shift and linewidth data are in good agreement (log K = 0.9 ± 0.3; 1.1 ± 0.4; 0.8 ± 0.2). Figure 6 gives the variations of $(\nu_{1/2})_{obs}$ with the concentration of hydrated lanthanum nitrate. The points are experimental and the curve is calculated on the basis of the values of the parameters of Table 2 with $x = 0$.

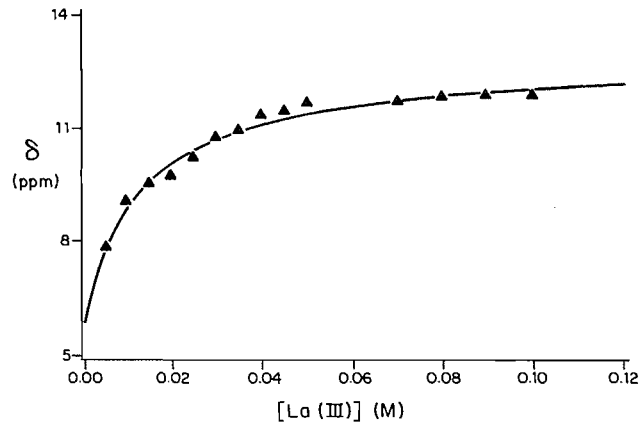

FIG. 5. ^{139}La chemical shifts as a function of $[La(NO_3)_3.6H_2O]$ in acetonitrile. The data points are experimental and the curve is calculated from the values of the parameters reported in Table 2.

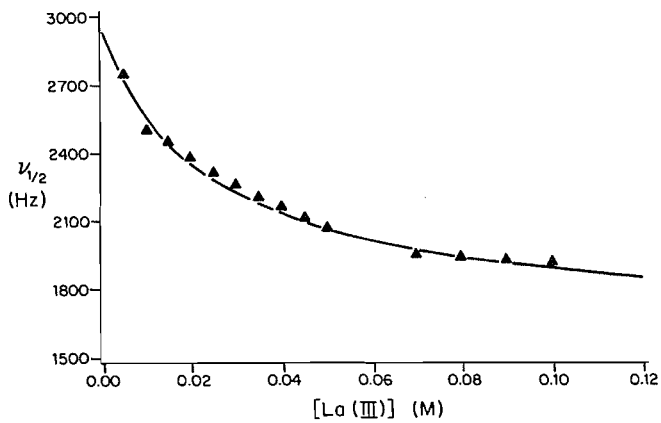

FIG. 6. ^{139}La transverse relaxation rates as a function of $[La(NO_3)_3.6H_2O]$ in acetonitrile. The data points are experimental and the curve is calculated from the values of the parameters reported in Table 2.

Discussion

The ^{139}La NMR chemical shift of $La(NO_3)_3$ in acetonitrile is 5.8 ± 0.6 ppm (Table 2). Evans and Missen (19) have investigated the interactions between NO_3^- and La(III) by progressively adding $(NBu_4)(NO_3)$ to anhydrous acetonitrile solutions of lanthanum perchlorate. They found that both ^{139}La NMR chemical shift and linewidth first increased then decreased as the ratio of NO_3^-/La(III) increased. For a ratio of 3:1 (NO_3^-/La(III)), the observed ^{139}La NMR chemical shift was 10 ± 2 ppm (see ref. 19, Fig. 3). This value is comparable with our result although the systems involved are not identical.

The ^{139}La NMR chemical shift of $La(NO_3)_3.H_2O$, 12.9 ± 0.2 ppm, is at higher frequency than the one of $La(NO_3)_3$. The shift is caused by the probable replacement of acetonitrile molecules in the first coordination shell of La(III) by water. A similar result was reported by Evans and Missen (19). They showed that the progressive addition of water to an anhydrous $La(ClO_4)_3$ solution in acetonitrile caused the ^{139}La NMR signals to shift downfield.

The value of the equilibrium constant of eq. [1] (with $x = 0$) ($K \approx 10$) is also in good agreement with the concept that less donating solvent molecule (acetonitrile) is replaced by a more donating one (water) in the first coordination sphere of La(III).

The calculated ^{139}La NMR linewidths for $La(NO_3)_3$ and $La(NO_3)_3.H_2O$ are 2.9 and 1.6 kHz, respectively. Again, the calculated linewidth value of $La(NO_3)_3$ is in the same order of magnitude than that reported by Evans and Missen (19) ($\nu_{1/2} \approx 3.8 \pm 0.2$ kHz for a ratio NO_3^-/La(III) of 3:1, estimated from Fig. 3 of ref. 19). The ^{139}La linewidth value for $La(NO_3)_3.H_2O$ is smaller than that for $La(NO_3)_3$. This indicates a higher symmetry of the electronic charge distribution around the ^{139}La nucleus in $La(NO_3)_3.H_2O$ than in $La(NO_3)_3$,

when an oxygenated ligand (water) replaces one or several acetonitrile molecules in the first coordination sphere of La(III) also coordinated by three nitrate groups.

The ^{17}O NMR chemical shift of free water in acetonitrile is about −6 ppm. This shift is understood on the basis of hydrogen bond breaking, resulting in an increased shielding of the ^{17}O nucleus (20). Values of -11.3 ± 0.6 and −6.8 ppm have been reported in the literature (18, 21) for the ^{17}O chemical shift of water in acetonitrile.

The ^{17}O NMR chemical shift of a water molecule coordinated to the lanthanum cation is 120 ± 4 ppm. Paramagnetic lanthanide cations have been used as "shift reagents" in ^{17}O NMR measurements (20), but, unfortunately, there is not any ^{17}O NMR data on water coordinated to diamagnetic lanthanide cation available in the literature, and a direct comparison of the δ_c (^{17}O) obtained in this work is not possible. However, ^{17}O NMR chemical shifts of coordinated water of +6 ppm in $Al(H_2O)_6^{3+}$ (22), −131.8 ppm in $Pd(H_2O)_4^{2+}$ (23), and 126 ppm in *cis*-$Co(en)_2(H_2O)_2^{2+}$ (24) have been reported. Even in diamagnetic systems, the ^{17}O NMR chemical shift of water varies widely upon complexation, and is very dependent upon the nature of the metal cation. From Fig. 3 it is also apparent that the ^{17}O signal of coordinated water is considerably broadened, compared to the signal of non-coordinated water (characterized by a linewidth of 25 Hz and a coupling constant $^1J_{^1H—^{17}O}$ of 80 Hz). From the data of Table 1, and on the basis of eq. [1], a simulation of the various ^{17}O NMR spectra as a function of the total water concentration was performed. Examples of this simulation are given on Fig. 3*b*, for the cases of Fig. 3*a*. The success of the simulation is consistent with the proposed model, a system of two species in very fast chemical exchange. The characteristic $^{17}OH_2$ NMR linewidth of the species $La(NO_3)_3.H_2O$ could be determined as an average value from the simulations: it is equal to (400 ± 50) Hz. Thus the coordination of a water molecule to the La(III) cation results in an increase of the $^{17}OH_2$ linewidth from 25 to 400 Hz. This broadening can result from three possible contributions which will be considered: chemical exchange, quadrupolar relaxation and scalar relaxation of the second kind. A moderately fast exchange between free and coordinated water molecules would result in a broadening of the ^{17}O NMR signal depending upon the square of the observation frequency (25). In order to test for this contribution, the ^{17}O NMR spectra of two samples, ($[La(NO_3)_3.6H_2O] = 0.050$ and 0.090 M), were recorded at 40.66 MHz and at 67.77 MHz (respectively 7.05 T and 11.75 T NMR spectrometers) (26). In the error limits of the experiments, the linewidths were identical and a chemical exchange contribution to the broadening could be ruled out.

An increase in the electric field gradient at the ^{17}O nucleus is expected when a water molecule coordinates to the La(III) cation. Since ^{17}O is a quadrupolar nucleus ($I = 5/2$, $|Q| = 0.026\ 10^{-28}\ m^2$), the interaction of this increased electric field gradient with the ^{17}O quadrupole moment will increase the quadrupolar relaxation and consequently the ^{17}O linewidth. This contribution to the ^{17}O linewidth is defined as $(\pi T_{2Q})^{-1}$ in the following discussion.

Since ^{139}La has a natural abundance of 99.91%, the line broadening of the coordinated water ^{17}O NMR signal could also result from the indirect quadrupolar interaction between the ^{17}O and ^{139}La nuclei (^{17}O–^{139}La coupling). The transverse relaxation rate of ^{139}La(III) in the species $La(NO_3)_3.H_2O$ is about 5 000 Hz (Table 2). Since the system is under extreme narrowing conditions, T_1 and T_2 are equal. From the known values of the coupling constants involving the ^{17}O nucleus (27), it is expected that $T_1^{-1}(^{139}La) \gg |^1J(^{139}La—^{17}O)|$. Under these conditions, an indirect coupling between ^{17}O and ^{139}La cannot be directly observed since the multiplet caused by the coupling would be collapsed (28). However, this coupling can provide a relaxation mechanism to the ^{17}O nucleus (scalar relaxation of the second kind), and its contribution to the ^{17}O linewidth, $(\nu_{1/2})_J$, is given by eq. [13] (29)

$$[13] \qquad (\nu_{1/2})_J = \tfrac{4}{3}\pi J^2 T_1(^{139}La) I(I+1)$$

where $T_1(^{139}La)$ is the ^{139}La longitudinal relaxation time, I is the ^{139}La nuclear spin number, and J is $|^1J(^{139}La—^{17}O)|$.

Combining the contributions from the direct quadrupolar interaction and the scalar relaxation, the ^{17}O linewidth for the coordinated H_2O molecule can be expressed as:

$$[14] \qquad (\nu_{1/2})_c = (\pi(T_{2Q})_c)^{-1} + 21\pi J^2 T_1(^{139}La)$$

where the subscript "c" refers to coordinated water. Under extreme narrowing conditions, $T_{1Q} = T_{2Q}$ for ^{17}O and $T_1 = T_2$ for ^{139}La, so that:

$$[15] \qquad (T_2^{-1})_c = (T_{1Q}^{-1})_c + 21\pi^2 J^2 T_2(^{139}La)$$

If $(T_{1Q}^{-1})_c$ was known, eq. [15] would allow the determination of the value of J, since $(T_2^{-1})_c$ and $T_2(^{139}La)$ are known ($\pi \times 400$ Hz and 5 000 Hz, respectively). Contrary to T_2, T_1 is generally not affected by the scalar relaxation of the second kind (except in the very rare cases where the frequencies of observation of the two nuclei are very close, which is not the case here) (29), so that a measurement of the ^{17}O longitudinal relaxation rate, $(T_1^{-1})_{obs}$, could provide $(T_{1Q}^{-1})_c$. The measurement gave 5.18×10^{-3} s for a $La(NO_3)_3.6H_2O$ concentration of 0.090 M. This value is an average of the characteristic relaxation rates of water in its two chemical sites, "free", $(T_1^{-1})_f$, and coordinated, $(T_1^{-1})_c$. This is expressed in eq. [16]:

$$[16] \qquad (T_1^{-1})_{obs} = P_f(T_1^{-1})_f + P_c(T_1^{-1})_c$$

where P_f and P_c are respectively the population of free and coordinated water molecules. $(T_1^{-1})_f$ was measured as 78.5 s^{-1}, and the populations are known from the data reported in Tables 1 and 2: in the conditions of the experiment, $P_f = 0.867$ and $P_c = 0.133$. It can be calculated that $(T_1^{-1})_c \doteq (T_{1Q}^{-1})_c = 938\ s^{-1}$. With this value, $|^1J(^{139}La—^{17}O)|$ can be calculated from eq. [15]: 88 ± 13 Hz. This is, to the best of our knowledge, the first reported value of a coupling $^{139}La—^{17}O$. It corresponds to a reduced coupling constant value of $K_{^{139}La—^{17}O} = 38\ N\ A^{-2}\ m^{-3}$, which is in the order of magnitude of other reduced coupling constants of transition metal nuclei with ^{17}O (for example, ^{95}Mo ($K = 38$), ^{99}Te ($K = 36$), or ^{99}Ru ($K = 31$)) (30).

In conclusion, the ^{139}La and ^{17}O NMR chemical shifts and linewidths have been measured as a function of the concentration of $La(NO_3)_3.6H_2O$ in acetonitrile. The results have been quantitatively interpreted through a chemical equilibrium model, in which two La(III) species, $La(NO_3)_3$ and $(La(NO_3)_3.H_2O)$ (with an unknown number of acetonitrile molecules coordinated to La(III), in both cases), coexist and exchange rapidly in solution. The detailed analysis of the ^{17}O NMR relaxation data allowed the evaluation of the indirect

coupling constant $|^1J(^{139}La—^{17}O)|$ for the coordinated water molecule.

The possibility of complexation between an acidic promoter like BF_3 and the alcoholic aglycone has been studied as a key mechanistic intermediate in glycosylation reactions operating via an electron-deficient anomeric carbon. The BF_3 complexes at O3′, O4′, O5′, and N3 of the model compound of 3′-,4-*N*-diacetyl-2′-deoxyribocytosine (**1**) have been studied. The last regioisomer of the four BF_3 complexes was found to have the weakest hydrogen bond and yet was the most stable isomer energetically. Furthermore, the O5′ nucleophilicity of this isomer was the most pronounced, as evaluated by Bader-type charge density topological analysis at the HF/6-31G**//HF/3-21G level of theory. This indicates that such a complex will make glycosylation at the O5′ oxygen possible.

TING-HUA TANG, DENNIS M. WHITFIELD, STEPHEN P. DOUGLAS, JIRI J. KREPINSKY et IMRE G. CSIZMADIA. Can. J. Chem. **72**, 1803 (1994).

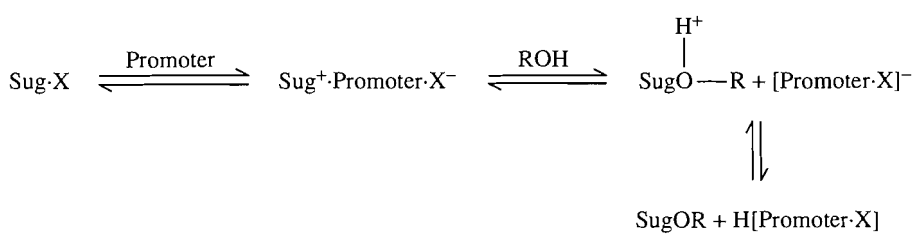
On a étudié la possibilité de complexation entre un promoteur acide comme le BF_3 et une aglycone alcoolique comme modèle de l'intermédiaire mécanistique des réactions de glycosylation se produisant par le biais d'un atome de carbone anomère déficient en électron. On a étudié les complexes du BF_3 avec les positions O3′, O4′, O5′, et N3 du composé modèle, la 3′-,4-*N*-diacétyl-2′-déoxyribocytosine (**1**). On a trouvé que le dernier des quatre complexes du BF_3 possède la liaison hydrogène la plus faible, mais que d'un point de vue énergétique il s'agit de l'isomère le plus stable. De plus, suivant une évaluation par une analyse topologique de la densité de charge du type Bader faite au niveau HF/6-31G**//HF/3-21G de la théorie, le caractère nucléophile du O5′ de cet isomère est le plus prononcé. Ces résultats indiquent qu'un tel complexe rend la glycosylation de l'oxygène O5′ possible.

[Traduit par la rédaction]

1. Introduction

Certain hydroxyl groups of carbohydrates do not undergo glycosylation (1,2) using Koenigs–Knorr conditions or its variants for the formation of glycosidic bonds. In some cases the secondary hydroxyl is far more reactive than the primary one. Such anomalous reactivity makes difficult the planning and execution of multistep oligosaccharides syntheses. Furthermore, the application of biologically active oligosaccharides, glycopeptides, and glycolipids in biomedical sciences, biotechnology industries, and new generation of therapeutic agents is becoming very important and therefore a deeper understanding of this unusual reactivity is essential for the rational development of oligosaccharide syntheses.

The reaction mechanism for Koenigs–Knorr type of glycosylation reactions (2) (see Scheme 1*a*) involves the activation of the glycosyl donor by the promoter to generate a reactive electron-deficient species which is approached by a nucleophilic alcohol acceptor, and after proton transfer the glycoside is formed.



SCHEME 1*a*

Signs +, − do not necessarily describe separate charges. They just refer to electron deficiency (+) or surplus (−). Nowhere in this mechanism is an interaction of the promoter with the acceptor considered. Our recent observations (2, 3), however, suggest that complexation of the promoter by the acceptor can alter dramatically the glycosylation. This conclusion is further supported by our recent theoretical consideration (1). Somewhat similar observations were made a long time ago when certain deriva-

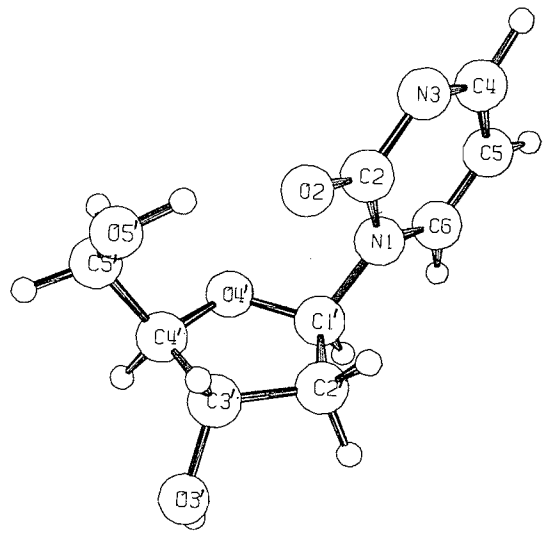

FIG. 2. Model compound (**3**) mimicing 2-deoxycytidine derivative (**1**) and the atomic labels of interest.

tives of the primary carbohydrate hydroxyl were found to enhance reactivity of the otherwise unreactive primary hydroxyls (4, 5). In the case of the galactosylation of the 5′-hydroxyl of nucleosides complexation of the nucleosides by the promoter has been suggested to favourably improve reactivity. In the present work we did a theoretical study on a prototypic Lewis acid promoter BF_3 and its complexes with the nucleoside (Scheme 1*b*).

2. Computational methods

The Gassian 92 program (6) has been used and the computations were carried out on an Apollo DN 10000 and an HP-750 minicomputer at the Department of Chemistry, University of Toronto. The starting or input geometries for the *ab initio* computation were constructed on the basis of model compound reported in our previous publication (1). *Ab initio* energies, reported in this paper, are for the fully optimized geometries, obtained by energy gradient optimization at the HF/3-21G level of theory (7). Single point calculations were performed at the HF/6-31G**//HF/3-21G level of theory (8).

The Bader-type topological analysis of charge density (9, 10) was performed at the HF/6-31G** polarized basis set on the HF/3-21G optimized geometries. The topological properties of the electronic density were determined by the atoms in molecules theory (9, 10) using the AIMPAC program.[2]

3. Results and discussion

I. Molecular Structure of Model Compounds

In our previous study (1) model compound **2** has been used to mimic 3′-*O*-,4-*N*-diacetyl-2′-deoxyribocytosine (**1**) (c.f. Figs. 1 and 2). Compound **1** has been shown to have a *syn* conformation in dichloromethane (DCM) that is stabilized by O5′—H···O2 hydrogen bonding. Our previous study (1) confirmed that model compound **2** (c.f. Fig. 3(*a*)) also has the same type of hydrogen bonding as compound **1** and that the hydrogen bonded structure is the global minimum energy conformation in the gas phase. However, model compound **2** has the shortcoming of not possessing a secondary OH at its 3′ position of the furanose ring.

We now wish to report the results of the computations on model compound **3**, which has an OH at C3′, thus the primary and secondary OH group may be compared (c.f. Fig. 2). Model compound **3** still lacks the 4-acetamido group from the heteroaromatic ring of the parent compound **1**. Presumably, this group does not significantly affect the molecular structure, complex stability and the hydroxyl reactivity studied here. Figure 3 and Table 1 clearly illustrate that the structures of the two model compounds (**2** and **3**) are very similar, both having the C5′—OH···O2 hydrogen bond.

II. Structure and stability of Lewis acid (BF_3) complexes with the model compounds

Lewis acids, such as BF_3 usually used as an ether complex, are frequently used as promoters in glycosylation reactions. In fact, such promoters have been shown to overcome the unreactivity of compound **1** in glycosylation reaction. It is postulated that this effect is caused by complexation with aglycone. There are a number of electronegative sites (lone pairs) in model compound **3** that may complex with the electropositive BF_3. Complexation of BF_3 by alcohols and amines is well known, for example see ref. 11. In the present study the following sites (labelled A, B, C, and D) were investigated.

3

In the case of nitrogen there is only one lone pair; therefore only one BF_3 complex may be formed. However, in the case of oxygen there are two lone pairs and therefore two BF_3 complexes may be formed. These two complexes may be related to one another as enantiomeric pairs.[3] In the present study, arbitrarily, only one of these two structures was studied. When O3′ and O4′ were complexed the *S* configuration and when O5′ was complexed the *R* configuration were studied (details to be discussed

[3]Numbers 1, 2, and 3 represent the order of piorities the ligands are attached to the oxygen in assigning the *R* and *S* absolute configurations.

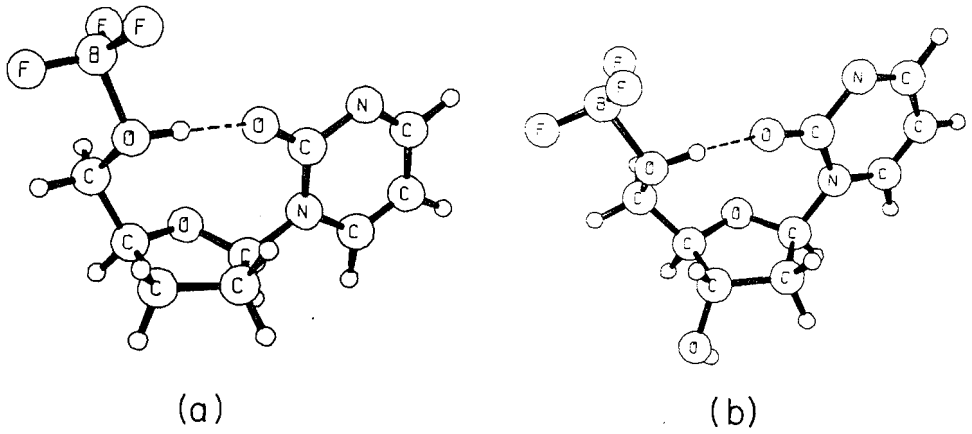

FIG. 4. 3-21G optimized geometries of BF_3 complexes with the model compounds **2** (**2***A*) and **3** (**3***A*).

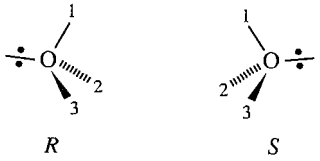

later). Figure 4 shows the BF_3 complexes of model compounds **2** and **3** with the BF_3 attached to O5′. These complexes are labelled as **2***A* and **3***A*. These two structures seem to be remarkably similar as can be judged graphically (Fig. 4) or numerically (Table 2). All four BF_3 complexes of model compound **3**, three of which (**3***A*, **3***B*, and **3***C*) involve complexation with the oxygen atoms (O5′, O3′, and O4′) of the furanose ring as well as the fourth complex, with complexation at nitrogen atom N3 (**3***D*) of the heteroaromatic ring, are shown in Fig. 5. All geometrical parameters are summarized in Table 2. The energetics associated with the complexation is given in Table 3. The stabilization energies associated with the Lewis complex formation are given in parenthesis in Table 3. It is noticeable that there is a marked change in these ΔE values on going from 3-21G//3-21G to the 6-31G**//3-21G level of theory. It is not clear at this stage which one of the two sets of numbers is more reliable. The values obtained at 6-31G**//3-21G level of theory could be more reliable because of the larger 6-31G** basis set but it was computed at a fixed geometry optimized at the 3-21G level of theory. For this reason a systematic basis set study has been carried out on a model complexation reaction:

$$C_2H_5OH + BF_3 \rightarrow C_2H_5O(H)\cdot BF_3$$

Geometry optimizations were carried out with three different basis sets (STO-3G, 3-21G, and 6-31G**) and the complexation energies were evaluated at these levels of theory. In addition, single point calculations were performed for the STO-3G and 3-21G geometry optimizations at several basis set levels up to 6-31G**. The results of a total of eight such computations are given in Table 4. Clearly, the single point calculations at the 6-31G** level of theory, irrespective of whether the STO-3G or 3-21G basis sets were used for the geometry optimization, are quite close to each other and they are also very close to the best results obtained by geometry optimization at the HF/6-31G**// HF/6-31G** level of theory. Thus we may regard the BF_3 complex formation energies for **3***A*, **3***B*, **3***C*, and **3***D* of −13.88, −8.57, −10.49, and −14.58 kcal/mol, respectively as the best estimates of the true values. Such semiquantitative results are expected to show the correct relative abundance of these BF_3 complexes (in percentage):

3*D*	>	**3***A*	>	**3***C*	>	**3***B*
88.3		11.6		0.1		0.0

with a very high population (p_i = 88.3%) calculated for **3***D* from the Boltzmann distribution at 25°C:

$$[1] \quad p_i = \frac{e^{-\Delta E_i/RT}}{\sum_{i=1}^{\text{all isomers}} e^{-\Delta E_i/RT}}$$

Transition metals like Ag(I) and Cu(II) are known experimentally to preferentially coordinate to the N3 of cytosine, suggesting a similarity with BF_3 complexes (12). On the basis of Boltzmann population (p_i) we can eliminate isomers **3***B* and **3***C* as likely candidates for glycosylation since they are present in minute proportions only. However, isomers **3***D* and **3***A* could, at least in principle, compete as nucleophiles in the glycosylation reaction. Whether they do or not depends on the relative nucleophilicities of the oxygen attached to C5′. It follows that the nucleophilicity of the O5′ lone pairs must be evaluated for the isomers of BF_3 complexes and that of the parent compound (II). Such an analysis can be performed using the Bader-type charge density analysis (6).

III. Charge density distribution analysis of Lewis acid (BF_3) complexes of model compounds

In addition to the energetic considerations mentioned above, there is an alternative way to analyse hydrogen bonding as has been discussed in the literature (1). This involves the topological analysis of the charge density distribution, which can be used to analyse intramolecular hydrogen bonding. Some insight should be gained concerning the reactivity of the furanose OH groups in particular.

Recently, inter- and intramolecular hydrogen bondings have been analysed by using Bader-type topological analysis of charge density distribution (9, 10, 13). The topological properties of the electronic density distribution is based on the gradient vector field of the electronic density $\nabla\rho(\boldsymbol{r})$, and on the Laplacian of the electronic density $\nabla^2\rho(\boldsymbol{r})$. Several excellent reviews have been published (9, 10) on this subject, therefore

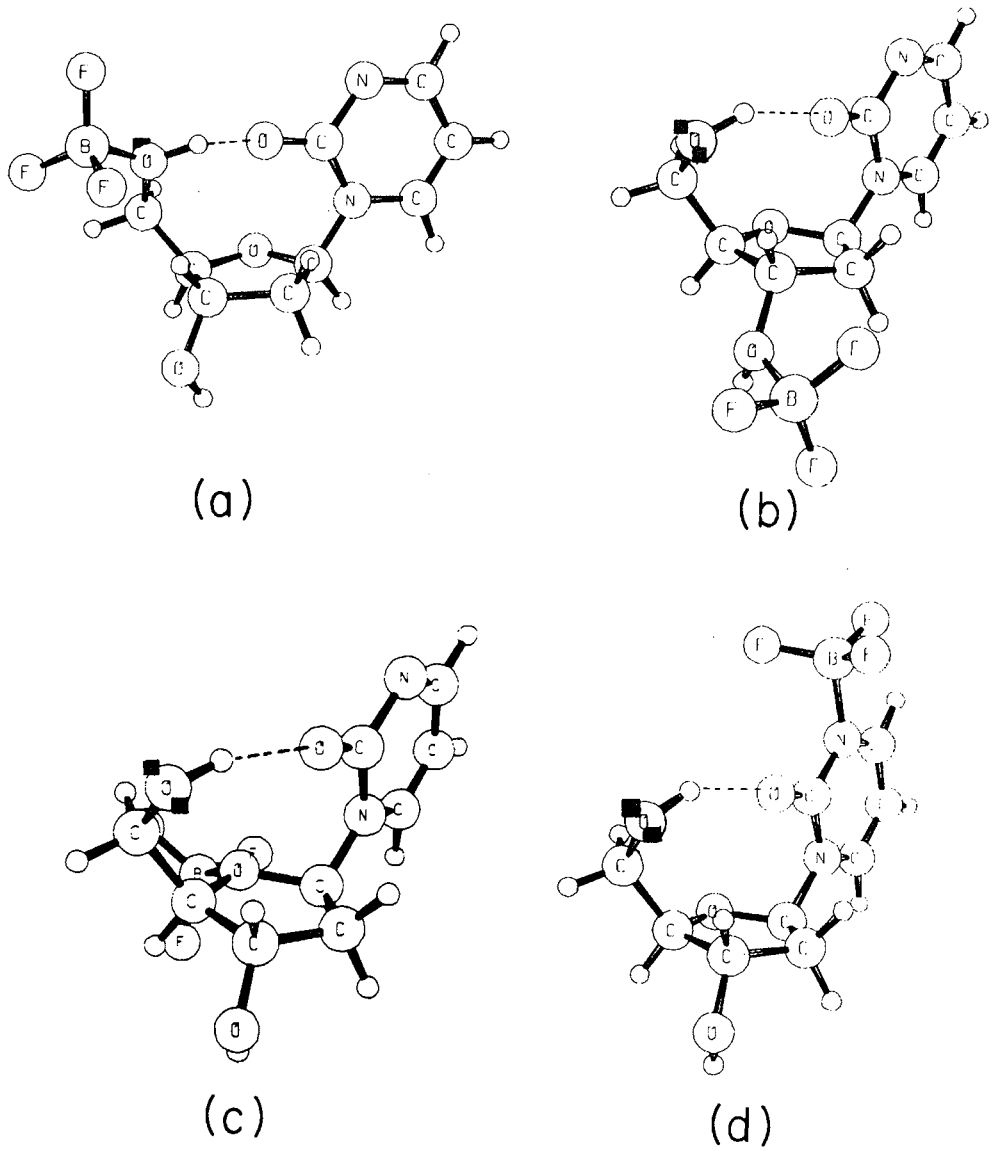

FIG. 5. 3-21G optimized geometries of BF_3 complexes with the model compound **3**: **3***A* (*a*), **3***B* (*b*), **3***C* (*c*), and **3***D* (*d*). The nonbonded Laplacian concentrations of O5′ are indicated by solid squares.

only a brief description of selected topological parameters, pertinent to the present work, is discussed here. The electronic charge distribution of a molecule is described by $\rho(\boldsymbol{r}, \boldsymbol{X})$ where **r** is a variable position vector in ordinary three-dimensional space with components r_1, r_2 and r_3 and $\boldsymbol{X}$ represents a particular set of nuclear coordinates in the space corresponding to the nuclear configurations of the molecule in question. An atom in a molecule is defined (9, 10) as a region of real three-dimensional space bounded by a zero-flux surface of the gradient vector field of $\rho(\boldsymbol{r})$; that is, a surface for which all points on this surface satisfy the equation

$$[2] \quad \nabla\rho(\boldsymbol{r})\cdot n(\boldsymbol{r}) = 0$$

where $n(\boldsymbol{r})$ is the unit vector normal to the surface at $\boldsymbol{r}$. Two interacting atoms in a molecule form a critical point in the electronic density, where

$$[3] \quad \nabla\rho(\boldsymbol{r}) = 0$$

called a bond critical point (BCP). The pairs of gradient paths, which originate at a BCP and terminate at the neighbouring nuclei ("attractor" in the gradient field of $\rho(\boldsymbol{r})$) define a line, through which electronic charge distribution, $\rho(\boldsymbol{r})$, is a maximum with respect to any lateral displacement, called an atomic interaction line. The presence of such a line, linking two nuclei in a molecule, which exists in a minimum energy geometry, implies that the two atoms are bounded to one another and in this instance this line is called a bond path. The necessary condition for two atoms to be bonded to one another is therefore that their nuclei be linked by a bond path. The network of bond paths for a molecule in a given nuclear configuration $\boldsymbol{X}$ defines the molecular graph which essentially is the union of the closures of the bond paths. Such a topological graph usually corresponds to the commonly drawn chemical bond network. The charge density, $\rho(r)$, at the bond critical point is related to the bond order and therefore the bond strength (14). The eigenvalues associated with the second derivatives of ρ, at the bond critical point (λ_1, λ_2, and λ_3) indicate how rapidly the density

[a]Total SCF energies are given in au (Lewis complex formation energies in parentheses are given in kcal/mol).

changes, away from the bond critical point (BCP), r_b. These three eigenvalues (λ_1, λ_2, and λ_3) represent the curvatures of charge density along the three different directions. For a normal single bond, such as C—C bond in ethane, the two negative curvatures (λ_1 and λ_2), perpendicular to the bond line, are equal. However, in the case of a double bond, one curvature (in the direction of the π bond) will be much smaller than the other. This difference may be described by the ellipticity of the bond, which is defined as

$$[4] \quad \epsilon = \lambda_1/\lambda_2 - 1$$

For a single bond $\lambda_1 \approx \lambda_2$, therefore $\epsilon \approx 0$. For a double bond $\lambda_1 > \lambda_2$, therefore $\epsilon > 0$. For an aromatic system, in general, ϵ is

the between a typical single and a typical double bond. Furthermore, for triple bonds, since $\lambda_1 \approx \lambda_2$, again ϵ is equal or close to zero. In practice, the trace or the sum of the second partial derivative values

$$[5] \quad \nabla^2\rho(\boldsymbol{r}_b) = \Sigma_{j=1,3}\partial^2\rho(\boldsymbol{r}_b)/\partial x_j^2$$

at the bond critical point (BCP), denoted by $\boldsymbol{r}_b$, is negative for a covalent interaction. The trace of $\nabla^2\rho(\boldsymbol{r}_b)$ is positive for an interaction between closed-shell system (including ionic interactions). For a very polar covalent bond the trace could be close to zero: either a small positive or a small negative value.

A critical point, at which $\rho(\boldsymbol{r})$ has one negative curvature and two positive curvatures, can be defined as a ring critical point. The existence of a ring critical point in a molecule indicates that the molecule contains a ring structure.

Of particular interest to this study is the Laplacian of the electronic charge density, the quantity at any point,

$$[6] \quad \nabla^2\rho(\boldsymbol{r}) = \Sigma_{j=1,3}\partial^2\rho(\boldsymbol{r})/\partial x_j^2$$

determines the regions of space wherein electronic charge is locally concentrated or depleted. From the definition of a second derivative, one finds that $\rho(\boldsymbol{r})$ is greater than the average of its values over an infinitesimal sphere centered on $\boldsymbol{r}$, when $\nabla^2\rho(\boldsymbol{r}) < 0$, and $\rho(\boldsymbol{r})$ is less than this average when $\nabla^2\rho(\boldsymbol{r}) > 0$. Thus a local maximum (or minimum) in $-\nabla^2\rho(\boldsymbol{r})$ signifies a local concentration (or depletion) of electronic charge. It has been reported (15) that these magnitudes of $-\nabla^2\rho(\boldsymbol{r})$ can be used to study the preferred orientation of electrophilic and nucleophilic attack. The site of Laplacian depletion favours nucleophilic and the site of Laplacian concentration favours electrophilic attack. Moreover, in some series of closely related molecules the Laplacian can give quantitative formation concerning relative protonation energies (16). The numbers, locations, and relative sizes of the bonded and nonbonded concentration of charge in the valence shell of a bonded atom as determined by the Laplacian of $\rho(\boldsymbol{r})$ are found to be in generally good agreement with corresponding properties that are ascribed to bonded and nonbonded pairs in Gillespie's VSEPR model of molecular geometry (17).

The theory of atoms in molecules has been widely applied to many chemical problems including the description of hydrogen-bonded systems (see for example refs. 6(*a*), 8, 9, and 10).

Table 5 shows the computed topological properties of electronic density for compounds **2**, **2***A*, **3**, **3***A*, **3***B*, **3***C*, and **3***D*. Comparing all the data in Table 5 (i.e. the ellipticity, ϵ; the density at the bond critical points (BCP), ρ_b; the Laplacian of the density at the BCP, $\nabla^2\rho(\boldsymbol{r}_b)$; and the two distances X—BCP and BCP—Y along the bond paths), it is clear that model compounds **2** and **3** as well as their BF_3 complexes at O5′ (**2***A* and **3***A*) are very similar in terms of the topological properties of the electronic density at the BCP. Furthermore, the ρ_b values associated with the O5′H···O2 hydrogen bond of **3***B*, **3***C*, and **3***D*, which are 0.0327, 0.0322, and 0.0268, respectively, are considerably smaller (about 50%) than that of the **3***A* complex (0.0604). Last, but not least, the magnitudes of the ρ_b values at the BCP of O5′H···O2 hydrogen bond have the following order:

$$3B \sim 3C > 3D$$

indicating that the above hydrogen bond is the weakest in the **3***D* isomer.

The outcome of any glycosylation reaction is critically dependent on the nucleophilicity of the electron pairs of the oxygen O5′. There is one lone pair in **3***A* since the other lone pair is tied up with the BF_3 complexation; however, all other isomers of the complex (**3***B*, **3***C*, and **3***D*) have two lone pairs. These two lone pairs are classified according to the location of these concentrations as *endo* and *exo* (cf. Fig. 6(*a*)). As a comparison, Fig. 6(*b*) shows the contour line diagram of calculated Laplacian concentrations of model compound **3** in a plane containing O5′— and the positions of concentrations associated with the two lone pairs. Also, Fig. 7(*a*) shows the projections of the two nonbonded Laplacian concentrations of O5′ are coincident on the C5′—O5′—H plane and Fig. 7(*b*) is the relief map of calculated Laplacian concentration of model compound **3** at the same C5′—O5′—H plane. Figure 5 shows the molecular structures and the locations of these concentrations that are associated with the *endo* and *exo* lone pairs. The magnitude of the concentrations, that can be used as a measure of O5′ nucleophilicity (15), are summarized in Table 6.

As may be judged from the values of these concentrations the "*exo* lone pair" (i.e. the *exo* sites) are more nucleophilic than the *endo* sites. Furthermore, **3***A* (in which O5′ is complexed) is not very nucleophilic. However, O5′ is more nucleophilic (larger magnitude of Laplacian concentration) in complex **3***D* than in any of the other isomers. The *exo* concentrations, measuring the nucleophilicities of O5′ at its *exo* site are plotted in Fig. 8. Clearly **3***A* is out of line since the nucleophilicity of O5′ cannot be compared to that of the other isomers simply because O5′ is the site of complexation. However, the other sites isomers (**3***B*, **3***C*, and **3***D*) show a reasonable trend.

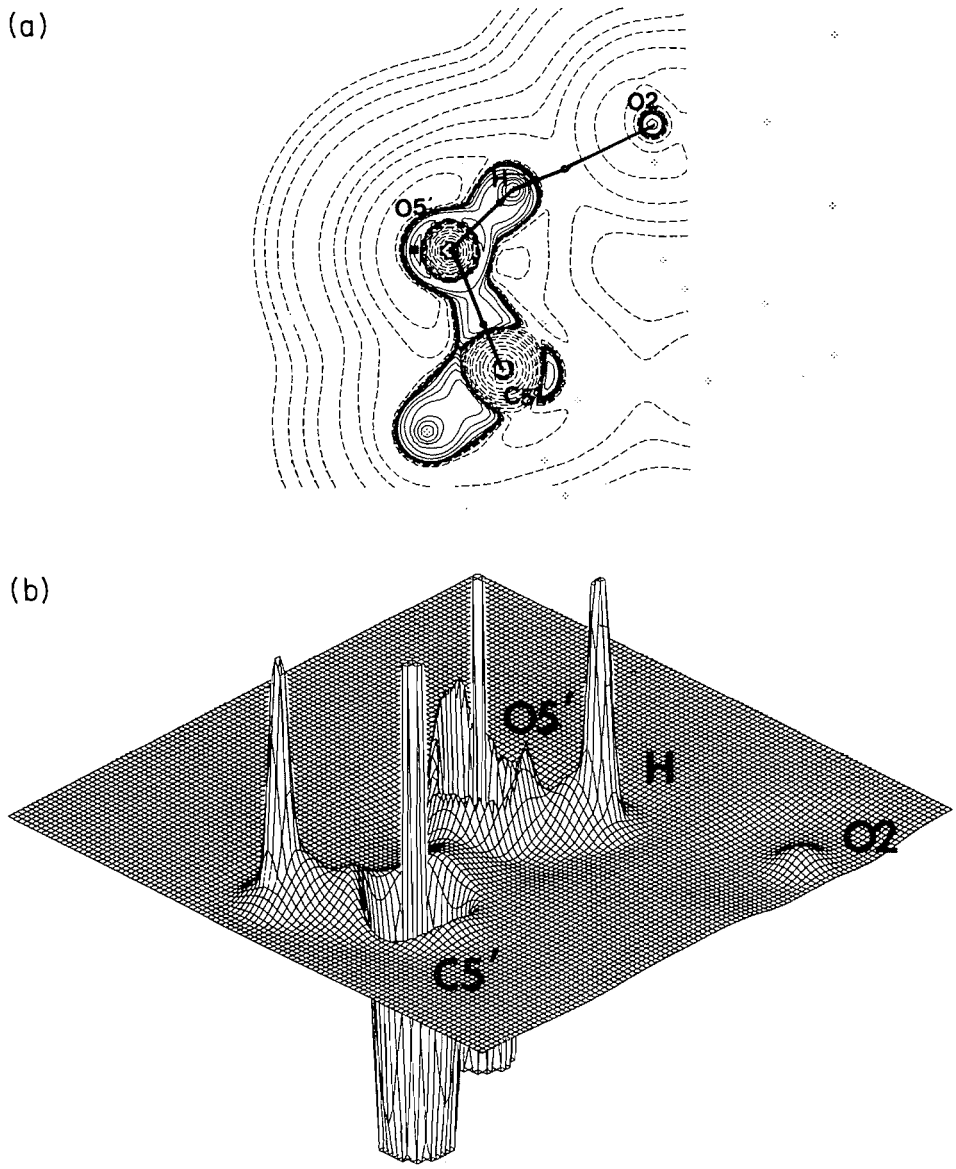

FIG. 7. (*a*) Contour line diagram of calculated (6-31G**//3-21G) Laplacian concentration ($-\nabla^2\rho(\boldsymbol{r})$) of model compound **3** in the plane of C5′—O5′—H. Bond paths (heavy solid lines) and BCPs (solid circles) are shown for $\rho(\boldsymbol{r})$. Regions of Laplacian concentration (depletion) as determined by $\nabla^2\rho < 0$ ($\nabla^2\rho > 0$) are denoted by solid (dashed) contours. The projections of the two nonbonded Laplacian concentrations of O5′ are coincident on the C5′—O5′—H plane (indicated by the solid square). (*b*) Relief map of $-\nabla^2\rho(\boldsymbol{r})$ representing the same information as (*a*).

TABLE 6. Nonbonded Laplacian concentrations at O5′ of model compounds **2**, **3** and their BF_3 complexes (**2***A*, **3***A*, **3***B*, **3***C*, and **3***D*)[a]

Molecule	*endo* concentration[b]	dl	*exo* concentration[b]	d2
2	−6.475684	0.6340	−6.512562	0.6337
2*A*	—	—	−6.570339	0.6320
3	−6.480095	0.6339	−6.527476	0.6335
3*A*	—	—	−6.361397	0.6336
3*B*	−6.441080	0.6342	−6.550981	0.6332
3*C*	−6.470822	0.6339	−6.547680	0.6333
3*D*	−6.503868	0.6336	−6.596710	0.6329

[a]Laplacian concentrations and their distances from nuclei O5′ (dl and d2) are given in Bohr atomic unit (au).

[b]The *exo* lone pair of O5′ points away from the furanose ring and the *endo* lone pair of O5′ points towards the furanose ring.

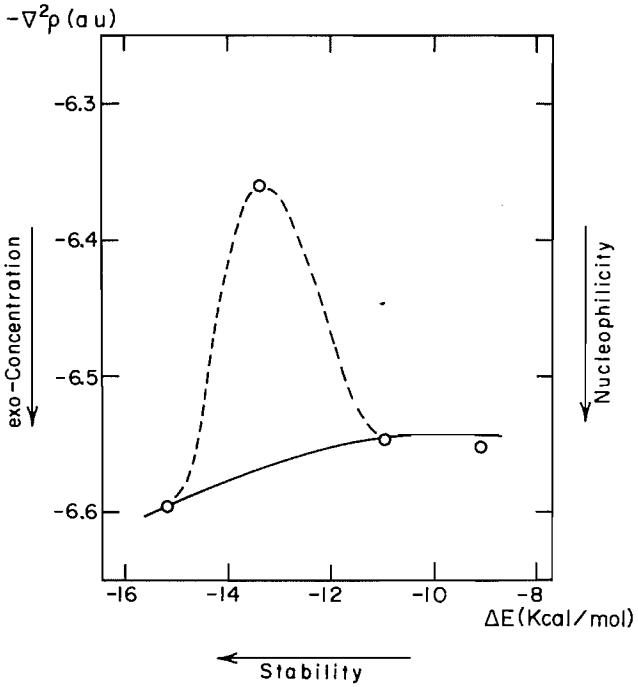

FIG. 8. The variation of *exo* concentration (i.e. $-\nabla^2\rho$) as a measure of nucleophilicity at the *exo* site of O5′ with the exothermic complexation energy of the BF_3 Lewis complexes of **3** (i.e. **3***A*, **3***B*, **3***C*, and **3***D*).

4. Conclusion

Model compound **3** used in the present study compared well with the model compound **2** used in the previous study (1) in terms of molecular geometry and their BF_3 complexes. These results suggests that both model compounds mimic well compound **1** studied experimentally.

The BF_3 complexes of **3** were studied at three oxygen sites (O5′, O3′, and O4′ denoted as **3***A*, **3***B*, and **3***C*) and one nitrogen site (N3) of the heteroaromatic aglycone denoted as **3***D*. The relative stability, as measured by the energy of complex formation, was found to be as

3*D*	>	**3***A*	>	**3***C*	>	**3***B*
88.3		11.6		0.1		0.0

with the percentage abundance shown above numerically.

The relative nucleophilicities of the *exo* lone pairs of O5′, as measured by the Laplacian concentration of the charge density ($-\nabla^2\rho$), was found in the following order:

← nucleophilicity			
3*D*	**3***B*	**3***C*	**3***A*
−6.597	−6.551	−6.548	−6.361

The combination of the above two qualities suggests that isomer **3***D* is the most likely species to be involved in the glycosylation reaction.

A convenient procedure for the efficient preparation of alkyl (*Z*)-3-iodo-2-alkenoates

EDWARD PIERS,[1] TIMOTHY WONG, PHILIP D. COISH, AND CHRISTINE ROGERS
Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, BC V6T 1Z1, Canada

Received February 1, 1994

EDWARD PIERS, TIMOTHY WONG, PHILIP D. COISH, and CHRISTINE ROGERS. Can. J. Chem. **72**, 1816 (1994).

Reaction of alkyl 2-alkynoates with sodium iodide (1.6–5.5 equiv.) in acetic acid (6.2–13 equiv.) at 115°C provides good to excellent yields of the corresponding alkyl (*Z*)-3-iodo-2-alkenoates.

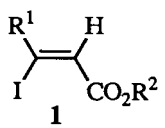
EDWARD PIERS, TIMOTHY WONG, PHILIP D. COISH et CHRISTINE ROGERS. Can. J. Chem. **72**, 1816 (1994).

La réaction des 2-alkynoates d'alkyles avec l'iodure de sodium (1,6–5,5 équiv.) dans l'acide acétique (6,2–13 équiv.) à 115°C conduit aux (*Z*)-3-iodo-2-alkénoates d'alkyles correspondants avec des rendements allant de bon à excellent.

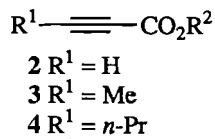
[Traduit par la rédaction]

Introduction

Alkyl (*Z*)-3-iodo-2-alkenoates (general structure **1**), along with substances that have been or could readily be derived therefrom, are useful intermediates for organic synthesis (1–20). Recently, it has been reported (17–20) that **1** (R^1 = H) can be produced by reaction of alkyl propynoates **2** with lithium or sodium iodide in acetic acid at 70°C. However, this protocol requires reaction times that are quite lengthy (12–24 h) and has been applied to only two higher homologs of **2**, namely **3** (R^2 = Me) (19) and **4** (R^2 = Et) (17). In the latter case, the yield of **1**



1



2 R^1 = H
3 R^1 = Me
4 R^1 = *n*-Pr
5 R^1 = alkyl or functionalized alkyl

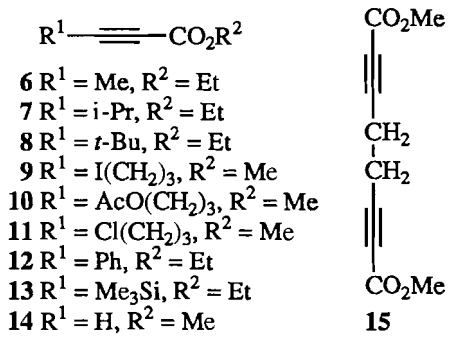
(R^1 = *n*-Pr, R^2 = Et) was very low (22%) (17). Indeed, we have found that this procedure (17–20) generally works poorly or not at all for substrates of general structure **5** in which R^1 is larger than methyl.

In connection with current research projects in our laboratory, we required a number of substances of general structure **1** in which the R^1 group is more bulky than methyl and, in some instances, is functionalized. We report herein a procedure, significantly modified from those reported earlier (17–20), that effects the efficient conversion of α,β-acetylenic esters **5** into the alkyl (*Z*)-3-iodo-2-alkenoates **1**. Essentially, the procedure that we have developed employs sodium iodide, a limited amount of acetic acid, and a reaction temperature (115°C) considerably higher than that employed previously (17–20). Under these conditions, substrates **5**, including those with functionalized or bulky (e.g., *tert*-butyl) R^1 groups, are transformed smoothly and efficiently into iodo esters of general structure **1**.

Results and discussion

(a) The α,β-unsaturated acetylenic substrates

The acetylenic ester starting materials **6**–**15** employed in this study are listed in Chart 1. Of these materials, a number (**6**, **12**–**14**) are commercially available, while others have been reported previously: **7** (21), **8** (22), **9** (22), **11** (23), **15** (24). Compound **10** was prepared by treatment of methyl 6-(tetrahydropyranyloxy)-2-hexynoate (22) with ethanoyl chloride (25) (see Experimental). Collectively, these ester substrates contain a variety of functional groups and have alkyl groups attached to C-3 of the alkyl propynoate unit that are sterically small, medium, and large (see compounds **6**–**8**).



6 R^1 = Me, R^2 = Et
7 R^1 = i-Pr, R^2 = Et
8 R^1 = *t*-Bu, R^2 = Et
9 R^1 = $I(CH_2)_3$, R^2 = Me
10 R^1 = $AcO(CH_2)_3$, R^2 = Me
11 R^1 = $Cl(CH_2)_3$, R^2 = Me
12 R^1 = Ph, R^2 = Et
13 R^1 = Me_3Si, R^2 = Et
14 R^1 = H, R^2 = Me

CHART 1

(b) Preparation of alkyl (Z)-3-iodo-2-alkenoates and related substances

Initially, we carried out a series of experiments that involved treatment of ethyl 2-butynoate (**6**) with varying amounts of sodium iodide and acetic acid at a variety of temperatures. These studies quickly revealed that the rate of conversion of the substrate into ethyl (*Z*)-3-iodo-2-butenoate (**16**) (see Chart 2) increased significantly at temperatures above 100°C. Furthermore, it was found that the reaction product **16** was produced cleanly and efficiently (> 95% yield) when a stirred solution–suspension of **6** and sodium iodide (~1.6 equiv.) in a small amount of acetic acid (~6.7 equiv.) was heated at ~115°C for 90 min. Under these conditions, there was no indication of the formation of ethyl (*E*)-3-iodo-2-butenoate.

Subjection of the substrates **7**–**15** (Chart 1) to reaction conditions identical with or similar to those outlined above provided the results summarized in Table 1 (see Chart 2 for the structural formulas of the reaction products).

As shown by the data given in Table 1, the conversions investigated were generally efficient and complete in convenient reaction times. Of the reactions involving structurally "simple" substrates (Table 1, entries 1–3, 7, 9), the transformations of ethyl 4,4-dimethyl-2-pentynoate (**8**) and ethyl 3-phenylpropy-

[d]Also isolated, in 3% yield, was compound **20**.
[e]Also obtained were 19% of the starting material **13** and 28% of ethyl (*Z*)-3-iodopropenoate (**23**).

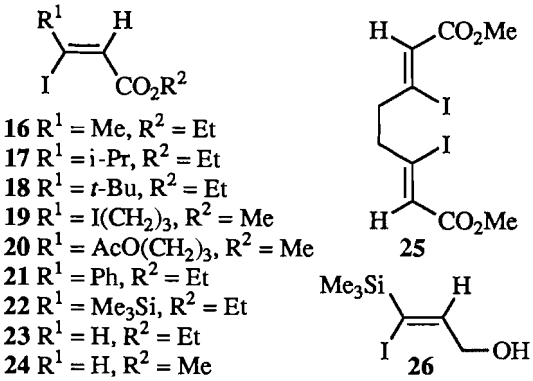

CHART 2

noate (**12**) into the corresponding (*Z*)-3-iodoalkenoates **18** and **21** (entries 3, 7) are particularly noteworthy. Because of the presence of the sterically bulky *tert*-butyl and phenyl groups in **8** and **12**, respectively, the reactions were, relatively speaking, quite slow and, in each case, the use of larger quantities of sodium iodide and acetic acid was found to be beneficial. Under these circumstances, the products **18** and **21** were produced cleanly and efficiently.

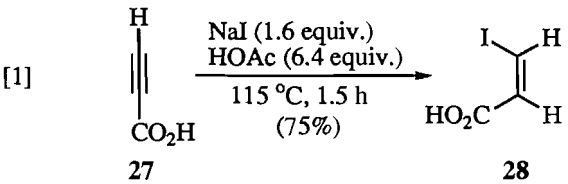
Functionalized substrates were also employed successfully (entries 4–6). Methyl (*Z*)-3,6-diiodo-2-hexenoate (**19**) could be derived from either the iodo ester **9** (entry 4) or the chloro ester **11** (entry 6). In each of these reactions, there was also produced a small amount of the acetoxy iodide **20**. The latter substance was also derived in very good yield from the α,β-acetylenic ester **10** (entry 5), thus showing that an acetoxy function is stable under the reaction conditions.

The use of this method for the conversion of ethyl 3-(trimethylsilyl)propynoate (**13**) into the structurally novel substance ethyl (*Z*)-3-iodo-3-(trimethylsilyl)propenoate (**22**) turned out to be quite inefficient (entry 8). A significant side reaction in this (sluggish) process involved protonative loss of the Me_3Si function to produce the iodo ester **23**.

More successful was the application of the developed procedure to a substrate possessing two α,β-acetylenic ester functions (entry 10). In this case, dimethyl 2,6-octadiyndioate (**15**) was converted in good yield into the structurally interesting diiodo ester **25**, a crystalline solid with melting point 73–74°C.

In each of a number of representative cases (substances **16**–**18**, **25**), the expected (17–20) configuration of the product was confirmed by use of nuclear Overhauser enhancement (nOe) difference experiments (see Experimental). To confirm the structure of product **22**, this material was reduced with diisobutylaluminum hydride to afford the known (26) alcohol **26** (Chart 2).

Finally, our procedure was employed to effect the conversion of propynoic acid (**27**) into (*Z*)-3-iodopropenoic acid (**28**)



(eq.[1]). The required reaction time was quite short (1.5 h) and, following a simple workup procedure, crystalline **28** (2, 20, 27) was obtained in 75% yield.

Conclusion

This brief study resulted in the development of an effective general protocol for the conversion of alkyl 2-alkynoates into synthetically useful alkyl (*Z*)-3-iodo-2-alkenoates. The procedure is straightforward, the reaction times are conveniently short, and, importantly, the process works well for a structurally diverse set of substrates.

Experimental

General information

Distillation temperatures, which refer to short path (Kugelrohr) distillations, and melting points are uncorrected. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded using $CDCl_3$ as the solvent. Signal positions (δ values) were measured relative to those of Me_4Si (δ = 0) or $CHCl_3$ (δ = 7.25). Carbon nuclear magnetic resonance (^{13}C nmr) spectra were recorded using $CDCl_3$ as the solvent and the signal positions are given relative to that of $CDCl_3$ (δ = 77.0). Infrared (ir) spectra were obtained on liquid films (NaCl plates), unless otherwise noted. Flash chromatography (28) was carried out with 230–400 mesh silica gel (E. Merck), while radial chromatography was performed with a Chromatotron model 7924, using plates coated with silica gel 60, PF_{254}, with $CaSO_4$ (E. Merck no. 7749).

Note: All reactions were carried out under an atmosphere of argon in flame- or oven-dried glassware.

*Methyl 6-acetoxy-2-hexynoate (**10**)*

Ethanoyl chloride (4.2 mL, 59 mmol) was added to a solution of methyl 6-(tetrahydropyranyloxy)-2-hexynoate (22) (2.68 g, 11.8 mmol) in dry THF (25 mL) and the resultant mixture was stirred at room temperature for 23 h. Saturated aqueous $NaHCO_3$ (50 mL) and diethyl ether (100 mL) were added and the phases were separated. The organic phase was washed with brine, dried ($MgSO_4$), and concentrated. Flash chromatography (150 g silica gel, 3:1 petroleum ether – Et_2O) of the crude product and distillation (90–110°C/0.3 Torr (1 Torr = 133.3 Pa)) of the acquired liquid afforded 1.51 g (70%) of the acetylenic ester **10**, a colorless oil that displayed ir (neat): 2239, 1737, 1719, 1255, 1046 cm^{-1}; ^1H nmr (400 MHz) δ: 1.88 (quintet, 2H, J = 7 Hz), 2.04 (s, 3H), 2.42 (t, 2H, J = 7 Hz), 3.73 (s, 3H), 4.13 (t, 2H, J = 7 Hz). Anal. calcd. for $C_9H_{12}O_4$: C 58.69, H 6.57; found: C 58.62, H 6.73. Exact Mass calcd. for $C_8H_9O_4(M^+ - Me)$: 169.0501; found: 169.0492.

*General procedure for the conversion of α,β-acetylenic esters **6–15** into alkyl (Z)-3-iodo-2-alkenoates*

An oil bath was preheated at 115°C for 15 min. A flask (argon atmosphere) containing a mixture (suspension) of the α,β-acetylenic ester, sodium iodide, and glacial acetic acid was placed in the oil bath and the mixture was stirred at 115°C for the specified time. The bath was removed and the brown mixture was transferred while hot to a separatory funnel containing water (~8–10 mL per mmol of ester substrate). The reaction flask was washed with a mixture of water (~2–5 mL) and diethyl ether (~25–30 mL per mmol of ester substrate). The washings were added to the separatory funnel. The phases were separated and the aqueous phase was washed with diethyl ether. The combined organic phases were washed sequentially with saturated aqueous sodium bicarbonate, 1 M aqueous sodium thiosulfate, and brine (~8–10 mL of each solution per mmol of ester substrate), and then were dried ($MgSO_4$ or Na_2SO_4) and concentrated. Distillation of the remaining material from basic alumina (~30–50 mg per mmol of ester substrate) provided the alkyl (Z)-3-iodo-2-alkenoate. Details regarding quantities of reactants, reaction times, distillation temperatures, and yields are given in Table 1.

The following substances were prepared via the general procedure. Any deviations from this protocol are noted in each case.

*Ethyl (Z)-3-iodo-2-butenoate (**16**) (16) (Table 1, Entry 1)*

Colorless oil, ir (neat): 1728, 1629, 1309, 1180 cm^{-1}; ^1H nmr (400 MHz) δ: 1.28 (t, 3H, J = 7 Hz), 2.71 (d, 3H, J = 1.5 Hz), 4.20 (q, 2H, J = 7 Hz), 6.27 (q, 1H, J = 1.5 Hz). In nOe difference experiments, irradiation at each of δ 2.71 and 6.27 caused enhancement of the signals at 6.27 and 2.71, respectively; ^{13}C nmr (50.3 MHz) δ: 14.2, 36.5, 60.5, 113.1, 125.6, 164.2. Anal. calcd. for $C_6H_9IO_2$: C 30.02, H 3.78, I 52.87; found: C 29.84, H 3.71, I 52.60. Exact Mass calcd.: 239.9648; found: 239.9646.

*Ethyl (Z)-3-iodo-4-methyl-2-pentenoate (**17**) (Table 1, Entry 2)*

Colorless oil, ir (neat): 1730, 1619, 1192, 1033 cm^{-1}; ^1H nmr (400 MHz) δ: 1.11 (d, 6H, J = 7 Hz), 1.29 (t, 3H, J = 7 Hz), 2.46 (septet, 1H, J = 7 Hz), 4.20 (q, 2H, J = 7 Hz), 6.39 (s, 1H). In nOe difference experiments, irradiation at each of δ 2.46 and 6.39 resulted in enhancement of the signals of 6.39 and 2.46, respectively; ^{13}C nmr (50.3 MHz) δ: 14.2, 23.0, 43.8, 60.5, 122.8, 131.8, 164.9. Anal. calcd. for $C_8H_{13}IO_2$: C 35.84, H 4.89; found: C 35.69, H 4.93. Exact Mass calcd.: 267.9961; found: 267.9955.

*Ethyl (Z)-3-iodo-4,4-dimethyl-2-pentenoate (**18**) (Table 1, Entry 3)*

Colorless oil, ir (neat): 1733, 1611, 1301, 1179, 1040 cm^{-1}; ^1H nmr (400 MHz) δ: 1.22 (s, 9H), 1.29 (t, 3H, J = 7 Hz), 4.21 (q, 2H, J = 7 Hz), 6.38 (s, 1H). In nOe difference experiments, irradiation at each of δ 1.22 and 6.38 caused enhancement of the resonances at 6.38 and 1.22, respectively; ^{13}C nmr (50.3 MHz) δ: 14.2, 30.3, 42.1, 60.7, 123.0, 136.0, 165.5. Anal. calcd. for $C_9H_{15}IO_2$: C 38.32, H 5.36, I 44.98; found: C 38.44, H 5.36, I 44.71. Exact Mass calcd.: 282.0118; found: 282.0111.

*Methyl (Z)-3,6-diiodo-2-hexenoate (**19**)*

*(a) From methyl 6-iodo-2-hexynoate (**9**) (Table 1, Entry 4)*

Radial chromatography (4 mm plate, 5:1 petroleum ether – diethyl ether) of the crude product, followed by distillation of the acquired oils, gave the diiodide **19** (77%) and the iodo acetate **20** (9%) (vide infra). Compound **19**, a colorless oil, displayed ir (neat): 1730, 1624, 1219, 1175 cm^{-1}; ^1H nmr (400 MHz) δ: 2.09 (quintet, 2H, J = 7 Hz), 2.80 (td, 2H, J = 7, 1 Hz), 3.13 (t, 3H, J = 7 Hz), 3.73 (s, 3H), 6.44 (t, 1H, J = 1 Hz); ^{13}C nmr (50.3 MHz) δ: 4.2, 32.0, 47.7, 51.7, 118.8, 126.0, 164.7. Anal. calcd. for $C_7H_{10}I_2O_2$: C 22.13, H 2.65, I 66.80; found: C 22.35, H 2.69, I 66.60. Exact Mass calcd. for $C_7H_{10}IO_2$ (M^+ – I): 252.9726; found: 252.9729.

*(b) From methyl 6-chloro-2-hexynoate (**11**) (Table 1, Entry 6)*

Radial chromatography (2 mm plate, 130 mL of 85:15 petroleum ether – diethyl ether and then 75:25 petroleum ether – diethyl ether) of the crude product gave compound **19** (80%) and the iodo acetate **20** (3%) (vide infra). The spectral data of **19** were found to be identical with those recorded above.

*Methyl (Z)-6-acetoxy-3-iodo-2-hexenoate (**20**) (Table 1, Entry 5)*

Colorless oil, ir (neat): 1734, 1624, 1243, 1174 cm^{-1}; ^1H nmr (400 MHz) δ: 1.92 (quintet, 2H, J = 7 Hz), 2.02 (s, 3H), 2.74 (t, 2H, J = 7 Hz), 3.70 (s, 3H), 4.03 (t, 2H, J = 7 Hz), 6.34 (s, 1H); ^{13}C nmr (50.3 MHz) δ: 20.9, 28.2, 44.4, 51.6, 62.5, 119.9, 125.3, 164.7, 170.9. Anal. calcd. for $C_9H_{13}IO_4$: C 34.64, H 4.20, I 40.66; found: C 35.00, H 4.22, I 40.37. Exact Mass calcd.: 311.9859; found: 311.9864.

*Ethyl (Z)-3-iodo-3-phenylpropenoate (**21**) (Table 1, Entry 7)*

Radial chromatography (4 mm plate, 9:1 petroleum ether – ethyl acetate) of the crude product, followed by distillation of the acquired liquid, produced the iodo ester **21**, a yellow oil that displayed ir (neat): 1724 cm^{-1}; ^1H nmr (400 MHz) δ: 1.31 (t, 3H, J = 7 Hz), 4.26 (q, 2H, J = 7 Hz), 6.61 (s, 1H), 7.32–7.33 (m, 3H), 7.49–7.52 (m, 2H); ^{13}C nmr (50.3 MHz) δ: 14.3, 60.8, 116.1, 126.9, 128.4, 128.8, 130.0, 143.3, 164.6. Anal. calcd. for $C_{11}H_{11}IO_2$: C 43.73, H 3.67, I 42.00; found: C 43.76, H 3.76, I 41.80. Exact Mass calcd.: 301.9804; found: 301.9803.

*Ethyl (Z)-3-iodo-3-(trimethylsilyl)propenoate (**22**) (Table 1, Entry 8)*

Radial chromatography (4 mm plate, 4:1 petroleum ether – dichloromethane) of the crude product, followed by distillation of the acquired liquids, gave 34 mg (19%) of the starting material **13**, along with the iodo silane **22** (35%) and ethyl (Z)-3-iodopropenoate (**23**) (20, 29) (65 mg, 28%). Compound **22**, a colorless oil, exhibited ir (neat): 1731, 1290, 1251, 1176, 844 cm^{-1}; ^1H nmr (400 MHz) δ: 0.23 (s, 9H), 1.31 (t, 3H, J = 7 Hz), 4.23 (q, 2H, J = 7 Hz), 6.89 (s, 1H); ^{13}C nmr (100.6 MHz) δ: –1.7, 14.2, 60.8, 125.6, 134.6, 164.1. Anal. calcd. for $C_8H_{15}IO_2Si$: C 32.22, H 5.07; found: C 32.27, H 5.00. Exact Mass calcd.: 297.9886; found 297.9890.

Ethyl (Z)-3-iodopropenoate (**23**) (20, 29), a colorless oil, displayed ir (neat): 1728, 1600, 1324, 1198, 1166, 1028, 807 cm^{-1}; ^1H nmr (400 MHz) δ: 1.30 (t, 3H, J = 7 Hz), 4.23 (q, 2H, J = 7.0 Hz), 6.86 (d, 1H, J = 9 Hz), 7.42 (d, 1H, J = 9 Hz); ^{13}C nmr (50.3 MHz) δ: 14.2, 60.8, 94.6, 129.9, 164.6.

*Methyl (Z)-3-iodopropenoate (**24**) (19, 20) (Table 1, Entry 9)*

The hot reaction mixture was poured into 200 mL of water (separatory funnel). The reaction flask was washed with a mixture of water (10 mL) and diethyl ether (60 mL) and the washings were added to the separatory funnel. The phases were separated and the aqueous phase was extracted with diethyl ether. The combined organic phases were washed (saturated aqueous sodium bicarbonate (20 mL), saturated aqueous sodium thiosulfate (20 mL), brine (20 mL)), dried ($MgSO_4$), and concentrated. Distillation of the derived oil gave methyl (Z)-3-iodopropenoate (**24**) (19, 20), a colorless oil that showed ^1H nmr (400

MHz) δ: 3.77 (s, 3H), 6.89 (d, 1H, J = 9 Hz), 7.45 (d, 1H, J = 9 Hz); ^{13}C nmr (50.3 MHz) δ: 51.6, 95.1, 129.4, 164.8.

Dimethyl (Z,Z)-3,6-diiodo-2,6-octadiendioate (25) (Table 1, Entry 10)

The crude product was passed through a short column of basic alumina (1 g, activity 1, elution with dichloromethane). Concentration (water aspirator, then vacuum pump) of the eluate afforded the diiodo diester **25**, a crystalline solid. This material exhibited mp 73–74°C (from petroleum ether – diethyl ether); ir (KBr): 1722, 1614, 1427, 1326, 1161, 1053, 875 cm^{-1}; ^{1}H nmr (400 MHz) δ: 2.95 (s, 4H), 3.71 (s, 6H), 6.38 (s, 2H). In nOe difference experiments, irradiation at each of δ 2.95 and 6.38 caused enhancement of the resonances at 6.38 and 2.95, respectively; ^{13}C nmr (50.3 MHz) δ: 46.5, 51.7, 117.2, 126.4, 164.5. Anal. calcd. for $C_{10}H_{12}I_2O_4$: C 26.69, H 2.69, I 56.40; found: C 26.87, H 2.75, I 56.46. Exact Mass calcd.: 449.8823; found: 449.8826.

(Z)-3-Iodo-3-trimethylsilyl-2-propen-1-ol (26)

To a cold (–78°C), stirred solution of ethyl (Z)-3-iodo-3-(trimethylsilyl)propenoate (**22**) (21 mg, 0.07 mmol) in 1.8 mL of dry diethyl ether was added a 1 M solution of diisobutylaluminum hydride in hexanes (0.21 mL, 0.21 mmol, 3 equiv.). The mixture was stirred at –78°C for 75 min and at 0°C for 95 min. Saturated aqueous ammonium chloride (1.5 mL) was added and the mixture was allowed to warm to room temperature. Water (15 mL) and diethyl ether (20 mL) were added and the phases were separated. The aqueous phase was extracted with diethyl ether (2 × 20 mL) and the combined organic phases were washed (brine), dried (Na_2SO_4), and concentrated. Radial chromatography (1 mm plate, 85:15 petroleum ether – diethyl ether) of the remaining liquid and subjection of the acquired oil to reduced pressure (0.3 Torr) afforded 13.5 mg (75%) of the alcohol **26** (26), a colorless oil that displayed ir (neat): 3331, 1250, 1031, 881, 842 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.18 (s, 3H), 1.6–1.7 (br s), 4.26 (d, 2H, J = 5 Hz), 6.49 (t, 1H, J = 5 Hz). In nOe difference experiments, irradiation at δ 6.49 caused enhancement of the signals at 0.18 and 4.26, while irradiation at δ 0.18 increased the intensity of the signal at 6.49; ^{13}C nmr (50.3 MHz) δ: –1.7, 69.5, 112.6, 146.4. Exact Mass calcd. for $C_6H_{13}IOSi$: 255.9780; found: 255.9787.

(Z)-3-iodopropenoic acid (28)

An oil bath was preheated to 115°C for 15 min. A flask (argon atmosphere) containing a solution–suspension of propynoic acid (**27**) (514 mg, 7.34 mmol), sodium iodide (1.76 g, 11.7 mmol), and glacial acetic acid (2.69 mL, 47.0 mmol) was placed in the oil bath and the mixture was stirred at 115°C for 90 min. The mixture was cooled to room temperature and the acetic acid was removed under reduced pressure (0.3 Torr, –78°C trap, ~10 min). The remaining dark oil was treated with dry diethyl ether (40 mL) and the resultant mixture was filtered. The collected material was washed with dry diethyl ether (~70 mL). The combined filtrate was washed with saturated aqueous sodium thiosulfate (20 mL) and the aqueous phase was extracted with diethyl ether (4 × 10 mL). The combined organic extracts were dried (Na_2SO_4) and concentrated (water aspirator pressure, followed by vacuum pump, 0.3 Torr). Crystallization of the remaining viscous oil from hot diethyl ether – petroleum ether (cooled to 0°C) gave 1.09 g (75%) of the iodo acid **28**, which exhibited mp 62–64°C (lit. (27) mp 63–65°C); ^{1}H nmr (400 MHz) δ: 6.96 (d, 1H, J = 9.5 Hz), 7.67 (d, 1H, J = 9.5 Hz), 11.95 (br s, 1H); ^{13}C nmr (100.6 MHz) δ: 98.0, 129.4, 169.7. Exact Mass calcd. for $C_3H_3IO_2$: 197.9177; found: 197.9181.

JACQUES Y. ROBERGE, PIERRE GIGUERE, PIERRE SOUCY, YVES L. DORY, and PIERRE DESLONGCHAMPS. Can. J. Chem. **72**, 1820 (1994).

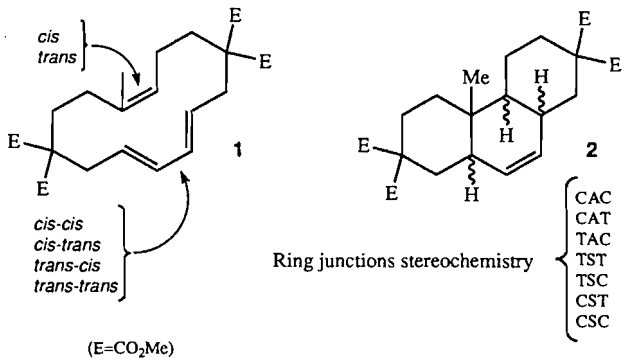
Transannular Diels–Alder reactions of four 14-membered macrocyclic trienes (**27**, **28**, **43**, and **44**) possessing a dimethyl tetrasubstituted dienophile have been investigated. Macrocycles having a *cis-trans-cis* (CTC) (**27**), a CTT (**43**), and a TTT (**44**) geometry produced the predicted *trans-syn-cis* (TSC) (**45**), *cis-anti-cis* (CAC) (**48**), and TAC (**49**) tricycles, respectively. The TTC macrocycle (**28**) gave exclusively the TST tricycle (**46**), no CSC tricycle (**47**) being observed. TTT macrocycle (**44**) underwent macrocyclization at a lower temperature than the TTC isomer (**28**).

JACQUES Y. ROBERGE, PIERRE GIGUERE, PIERRE SOUCY, YVES L. DORY et PIERRE DESLONGCHAMPS. Can. J. Chem. **72**, 1820 (1994).

La réaction de Diels–Alder transannulaire de quatre triènes macrocycliques à 14 chaînons (**27**, **28**, **43** et **44**) possédant un diénophile tétrasubstitué contenant deux groupes méthyles est décrite. Les macrocycles ayant une géométrie *cis-trans-cis* (CTC) (**27**), CTT (**43**) et TTT (**44**) conduisent respectivement aux tricycles *trans-syn-cis* (TSC) (**45**), *cis-anti-cis* (CAC) (**48**) et TAC (**49**). Le macrocycle TTC conduit exclusivement au tricycle TST (**46**), l'autre produit possible, le tricycle CSC n'ayant pas été observé. Le macrocycle TTT donne le produit de cycloaddition au cours de la réaction de macrocyclisation; par contre, le macrocycle TTC requière une température beaucoup plus élevée pour la réaction.

Introduction

When looking at the strategy based on the transannular Diels–Alder reaction (Scheme 1) on macrocyclic trienes, one



SCHEME 1

might wonder what the limitations of such an approach are. We have already shown (1) that transannular Diels–Alder reactions involving trisubstituted dienophiles (*cis* or *trans*) are limited only by the geometry of their diene counterparts: not surprisingly *cis-cis* dienes cannot lead neatly to their expected adducts because the required *cisoid* geometry of a *cis-cis* diene is extremely disfavored. On the other hand, *cis-trans* dienes give good yields of Diels–Alder adducts when the transannular Diels–Alder strategy is used. Very few intramolecular Diels–Alder examples involving this kind of *cis-trans* dienes have been reported in the literature (2), where the dienophile moiety was, moreover, activated. The transannular Diels–Alder reaction using *trans-trans* dienes is a very facile process indeed, since the corresponding macrocycles are not easily isolated due to their high reactivity.

The model study involving trisubstituted dienophiles was undertaken because the corresponding transannular Diels–Alder adducts are the cores of steroid or terpene natural or unnatural compounds. Triterpenes (Scheme 2) could similarly derive from transannular Diels–Alder reaction products from macrocyclic trienes featuring tetrasubstituted dienophiles.

We wish to report a study of such systems with *cis* and *trans* tetrasubstituted non-activated dienophiles and *cis-trans* and *trans-trans* dienes, the *cis-cis* diene being omitted for the reasons discussed above.

Results and discussion

The four required macrocycles (Scheme 3), whose general formula is summarized by the structure **8**, lead retrosynthetically to the two dienophile synthons **9** (*E* and *Z*) and the two diene synthons **10** (*EZ* and *EE*) where X, X′, Y, and Y′ are suitably protected alcohols or activated leaving groups. Such an approach is very convenient for the proposed study because of its high convergence. It is obvious that natural product syntheses based on the results of this model study could follow very different paths where the synthons would be chosen according to the desired targets.

Synthesis of the macrocyclic trienes 27 and 28 possessing a cis *dienophile (Schemes 4 and 6)*

The *Z* diol **11** (3) was monoprotected by means of *tert*-butyldiphenylsilyl chloride and imidazole (4) to yield the silyl ether **12** in 50% yield. The alcohol **12** was transformed into the mesylate **13**, which was subsequently treated with sodium dimethyl malonate to afford the substituted malonate **14** in 89% yield. The malonate anion of **14** generated by using sodium hydride was then left to react either with the requisite *EZ* allylic chloride (5) (chlorine on *E* side) or with its *EE* isomer (5) to afford the *ZEZ* and *EEZ* trienes **15** and **16**, respectively, in 76% and 70% yield. The silyl ether **15** was deprotected by means of tetrabutylammonium floride to give the alcohol **17** in 95% yield. The monosubstituted malonate **21** was synthesized from the alcohol **17** by the same two-step procedure used to prepare the malonate **14** from the alcohol **12**; subsequent cleavage of the tetrahydropyranyl ether with pyridinium *p*-toluenesulfonate (6) afforded

7 **8** **9** **10**

SCHEME 3

the allylic alcohol **23** (73% overall yield), which was transformed into the allylic chloride **25** using Meyers' conditions (7) in 71% yield.

Slow injection of the allylic chloride **25** into a suspension of cesium carbonate in a 1:1 mixture of *N,N*-dimethylformamide and tetrahydrofuran (high dilution conditions) to generate the malonate anion led to the CTC (or TCC) macrocyclic triene **27** in 83% yield.

The *EEZ* allylic chloride **26** was prepared from the silyl ether **16** by the same five-step sequence used to synthesize the isomeric allylic chloride **25** from **15**, and with similar yields. The crude allylic chloride **26** was slowly added to a suspension of cesium carbonate as in the case of the isomeric *ZEZ* allylic chloride **25**. However, the macrocyclization proved to be a difficult process; three macrocycles were observed. The desired TTC macrocycle **28** was obtained in 50% yield; the dimeric macrocycle **29** was also formed in 5% yield as well as the 12-membered ring macrocycle **30** (5% yield), generated through an S_N2 displacement of the allylic chlorine atom in **26**.

*Synthesis of the macrocyclic trienes **43** and **44** possessing a* trans *dienophile (Schemes 5 and 6)*

The *E* diol **31** (3) was transformed into the dimesylate **32**, which was then treated without purification with sodium dimethyl malonate and potassium iodide to give the dimalonate **33** in 76% overall yield. The *ZEE*, *EZE*, and *EEE* trienic alcohols **37**, **38**, and **39** were prepared from **33**, in the same way that **17** and **18** had been made from the malonate **14**, in 55, 52, and 64% yield from the corresponding allylic chlorides. The allylic alcohols **37** and **38** were transformed into the allylic chlorides **40** and **41**, which underwent internal SN_2 displacement of their allylic chlorine atoms when treated with cesium carbonate under high dilution conditions. Thus, the resulting CTT (or TCT) macrocyclic triene **43** was obtained in 54% yield from **37** and 76% yield from **38**. Similar treatment of the crude allylic chloride **42**, obtained from **39**, did not lead to the expected TTT macrocyclic triene **44** but rather, as already observed for other TTT systems (1, 8), directly to the corresponding TAC (or CAT) Diels–Alder adduct **49** in 28% yield from the allylic alcohol **39**.

For comparison, it has to be noted that *trans-trans* dienes usually undergo easy intramolecular Diels–Alder cyclization, as already observed for other TTT and TTC trienic systems possessing trisubstituted dienophiles (8). In these two cases, the TTC macrocycle could only be isolated when the macrocyclization was performed at 60°C. Such a temperature was found to be too low for the TTT macrocycle to be formed from its *EEE* allylic chloride precursor. Macrocyclization of the *EEE* system at 80°C led directly to the corresponding TAC and CAT tricycles; the TTC macrocycle also experienced Diels–Alder reaction at that temperature, thus showing how favored these Diels–Alder reaction processes are. In the present case, differing only by the heavier substitution of the dienophile moiety, the TTC macrocycle was isolated whereas the TTT isomer was not. Moreover, the TTC system required a temperature of 160°C for the cycloaddition reaction to take place, which is at least 80°C higher than that needed for the TTT isomeric system. Thus,

TTT macrocyclic trienes are shown to be more prone to Diels–Alder cyclization than their TTC isomers.

The Diels–Alder reaction (Schemes 6 and 7)

The CTC macrocycle **27** underwent the Diels–Alder reaction (yield 88%) when heated at 350°C for 3.5 h in toluene and in a sealed tube. The *trans-syn-cis* (TSC being identical to CST) structure of the only observed adduct **45** was determined by NMR analysis and comparison with other TSC and CST adducts (9) related to **45**; it corresponds to the expected Diels–Alder adduct obtained via the steric interaction free transition state **A** in a chair-boat-chair conformation (Scheme 7).

The macrocycle TTC **28** is the only one that can theoretically give rise to two adducts: namely, the TST tricycle **46** issued from the transition state **B** and the CSC tricycle **47** from the transition state **C**. Experimentally, the TTC macrocycle **28** was heated at 160°C for 90 min in toluene, the TST tricycle **46** only was formed in 100% yield; its geometry was determined by NMR analysis: the NMR spectrum shows that the molecule is symmetrical and that the protons at positions 7 and 10 (Scheme 3) are axial ($J_{H7,H6} = J_{H10,H11} = 3.5$ and 13.5 Hz). The TST tricycle **46**, having its B ring in a boat conformation, as in the transition-state-like structure **B**, is the only compound that can match these spectroscopic data. Thus, the highly favored chair-boat-chair transition state **B** alone is observed. The alternative transition state **C**, having two 1,3-diaxial steric interactions between the ester groups and the diene, is much too disfavored to compete with **B**. As a result no CSC tricycle **47** is obtained in the transannular Diels–Alder reaction of **28**.

The CTT macrocycle **43** was treated in the same way as the isomeric TTC macrocycle **28**; the CAC tricycle **48**, whose structure was confirmed by X-ray analysis (10) (Fig. 1), was obtained in 65% yield via the transition state **D**, which displays one 1,3-diaxial steric interaction between one ester and the E side of the diene. As discussed before, the TTT macrocycle [**44**] was not isolated, but rather the corresponding TAC (TAC = CAT) macrocycle **49**, whose structure was established by X-ray analysis[2] (Fig. 1), resulted from the cyclization of the chloride **42** (28% from the allylic alcohol **39**, Scheme 5). The transition

SCHEME 5

state **E** that must arise to generate the tricycle **49** displays the same 1,3-diaxial steric interaction as already observed in the other *E* dienophile containing transition-state **D**. **E** is, however, much preferred to **D** because it involves an *EE* diene, whose *cisoid* conformation is sterically favored.

Conclusion

Transannular Diels–Alder reactions involving tetrasubstituted non-activated dienophiles are easy processes that lead neatly to the expected adducts. Of particular importance are the TTT trienic systems, which still undergo electrocyclization at low temperature, and which can then be handled on a large scale. Moreover, the TAC (or CAT) TTT adducts characterized by the basic skeleton **6** (Scheme 2) can be utilized in triterpene syntheses where the B, C, and D rings would be obtained in a stereospecific manner. Work in that direction is currently being carried out in our laboratories. The lower temperature necessary for TTT trienes to undergo Diels–Alder cyclization with regards to their TTC equivalents seems to be a general trend, since this intriguing phenomenon has once again been observed (9, 11). The reason remains unfortunately unclear: simple Dreiding model manipulation suggests that, in both the *transoid* and the *cisoid* diene ground state conformations, the dienophile is held close and parallel to the diene in TTT systems; such is not the case for TTC macrocycles, where both reacting centres are kept far apart and perpendicular to each other for minimum interactions to be reached. Molecular modelling calculations are currently underway to quantify these crude observations.

Experimental part

Melting points were recorded on a Rinco M-50 apparatus and are uncorrected. MS data were determined at 70 eV on a VG Micromass ZAB-1F spectrometer. The ir absorption spectra were measured on a Perkin Elmer 681 from neat compounds or chloroform solutions. Proton (^1H) and carbon (^{13}C) nmr spectra were recorded on a Bruker WM-250. Chemical shifts are reported relative to TMS (δ 0.00) with residual $CHCl_3$ (δ 7.26) or residual C_6D_6 (δ 7.21) as internal standard.

All reactions were conducted in oven-dried (120°C) or flame-dried glassware under an atmosphere of dry argon, unless otherwise stated. All reported compounds were homogeneous by thin-layer chromatography with at least two different solvent systems.

Silyl ether ***12***

To a solution of the diol **11** (100 mg, 0.69 mmol) in tetrahydrofuran (2.3 mL) was added imidazole (47 mg, 0.69 mmol) and *tert*-butylchlorodiphenylsilane (135 μL, 0.52 mmol) at room temperature. The resulting solution was stirred for 2 h, then more *tert*-butylchlorodiphenylsilane (45 μL, 0.17 mmol) was added and the mixture was stirred for a further 1 h. Solvent was removed and the product was purified by flash column chromatography using hexane and ethyl acetate (7:3) as eluent to give the title compound (132 mg, 50%); ir ($CHCl_3$) ν: 3620, 3450, 3060, 2950, 2850, 1110, 1080 cm^{-1}; ^1H nmr (80 MHz) δ (ppm): 1.05 (9H, s, Me_3CSi), 1.60 (3H, m, *Me*C=CMe), 1.64 (3H, m, MeC=C*Me*), 2.23 (2H, t, J = 6.5 Hz, CH_2CH_2OH), 2.37 (2H, t, J = 7 Hz, CH_2CH_2OSi), 3.57 (2H, t, J = 6.5 Hz, CH_2OH), 3.67 (2H, t, J = 7 Hz, CH_2OSi), 7.3–7.5 (6H, m, *Ph*), 7.6–7.8 (4H, m, *Ph*); ms *m/e*: 325 ($M^+ - CMe_3$).

Malonate ***14***

To a solution of the alcohol **12** (1.64 g, 4.28 mmol) and triethylamine (0.87 mL, 6.27 mmol) in dichloromethane (150 mL) was added methanesulfonyl chloride (0.39 mL, 5.04 mmol) at 0°C. The solution was stirred for 2.5 h at 0°C; water was added and the organic layer was washed with brine and dried ($MgSO_4$), solvent was removed, and the crude mesylate **13** (1.97 g) was used directly in the next step without further purification.

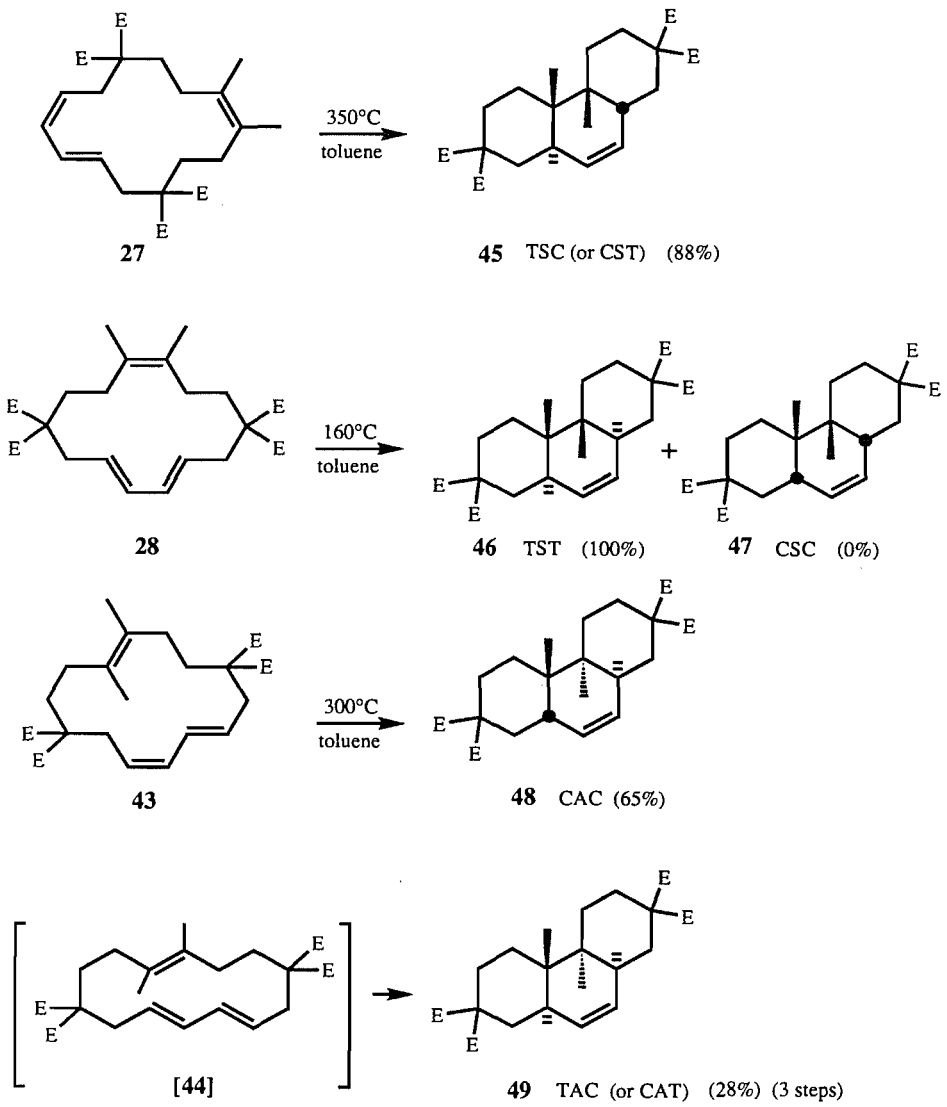

SCHEME 6

To a suspension of sodium hydride (60% in oil, 730 mg, 18.26 mmol) in tetrahydrofuran (30 mL) and *N,N*-dimethylformamide (30 mL) at 0°C was added dimethyl malonate (2.3 mL, 20.25 mmol). The mixture was stirred at 0°C for 15 min. Potassium iodide (0.31 g, 1.90 mmol) was first added, followed by a solution of the mesylate **13** (1.97 g) in tetrahydrofuran (30 mL). The resulting mixture was heated at 95°C for 6 h. The reaction was quenched with saturated aqueous ammonium chloride and the mixture was extracted several times with ether. The combined ether extract was washed with brine. Drying ($MgSO_4$) and removal of solvent under reduced pressure gave an oil, which was purified by chromatography on silica gel (hexane:ethyl acetate, 4:1) to yield the title compound as an oil (1.80 g, 89%); ir (neat) ν: 3050, 2950, 2860, 1735, 1110 cm^{-1}; ^1H nmr (250 MHz) δ (ppm): 1.03 (9H, s, Me_3CSi), 1.52 (3H, s, $MeC{=}CMe$), 1.59 (3H, s, $MeC{=}CMe$), 1.85–2.0 (4H, m, $(CH_2)_2C(CO_2Me)_2$), 2.27 (2H, t, J = 7 Hz, CH_2CH_2OSi), 3.28 (1H, t, J = 7.5 Hz, $CH(CO_2Me)_2$), 3.62 (2H, t, J = 7 Hz, CH_2OSi), 3.72 (6H, s, CO_2Me), 7.3–7.45 (6H, m, *Ph*), 7.6–7.7 (4H, m, *Ph*); ms *m/e*: 439 ($M^+ - CMe_3$).

Procedure for the preparation of trienic diethers

Triene ***15***

A solution of the malonate **14** (452 mg, 0.96 mmol) in tetrahydrofuran (4 mL) was slowly added to a suspension of sodium hydride (60% in oil, 47 mg, 1.16 mmol) in *N,N*-dimethylformamide (6 mL) and tetrahydrofuran (14 mL) at 0°C. The mixture was stirred for 20 min at 0°C and 10 min at room temperature. A solution of the required allylic chloride (5) (200 mg, 0.92 mmol) in tetrahydrofuran (4 mL) was added at 0°C and the resulting mixture was stirred for 23 h at room temperature. Saturated aqueous ammonium chloride was poured into the mixture and the aqueous phase was extracted several times with a mixture of ether and hexane (2:1). The combined organic extract was dried ($MgSO_4$) and solvent was removed. The residue was purified by flash column chromatography (hexane:ethyl acetate, 9:1) to give the title compound (496 mg, 76%); ir ($CHCl_3$) ν: 3010, 2945, 2855, 1735, 1197, 1110 cm^{-1}; ^1H nmr (80 MHz) δ (ppm): 1.03 (9H, s, Me_3CSi), 1.45–1.7 (12 H, m, $MeC{=}CMe$ and $(CH_2)_3$ THP), 1.85–2.0 (4H, m, $(CH_2)_2C(CO_2Me)_2$), 2.27 (2H, t, J = 7 Hz, CH_2CH_2OSi), 2.71 (2H, d, J = 7 Hz, $CH{=}CHCH_2C(CO_2Me)_2$), 3.60 (4H, m, OCH_2 THP and CH_2OSi), 3.70 (6H, s, CO_2Me), 4.24 (2H, m, $THPOCH_2$), 4.62 (1H, m, $OCHO$ THP), 5.4–5.7 (2H, m, $CH{=}CHCH{=}CH$), 6.0–6.3 (2H, m, $CH{=}CHCH{=}CH$), 7.35–7.5 (6H, m, *Ph*), 7.6–7.75 (4H, m, *Ph*); ms *m/e*: 619 ($M^+ - CMe_3$).

was cooled to 0°C and methanesulfonyl chloride (2.16 mL, 28 mmol) was added dropwise. The solution was stirred for 2 h at 0°C. Then, water was added and the combined organic extract was washed with brine and dried ($MgSO_4$), the solvent was removed, and the crude dimesylate **32** (3.59 g) was used right away in the next step.

Dimethyl malonate (6.68 mL, 58.5 mmol) was slowly added to a suspension of sodium hydride (53 mmol) in a mixture of tetrahydrofuran and *N,N*-dimethylformamide (180 mL, 1:1) at 0°C. The resulting mixture was stirred for 20 min at room temperature. A solution of the dimesylate **32** (3.59 g) in dry tetrahydrofuran (70 mL) was added, followed by potassium iodide (1.94 g, 11.7 mmol). The resulting mixture was heated with an oil bath at 95°C for 12 h. The reaction vessel was cooled to room temperature and its content was poured into a separatory funnel containing saturated aqueous ammonium chloride and water (1:1). The solution was extracted with hexane and ether (1:1). The organic layers were combined, washed with water and brine, dried ($MgSO_4$), and concentrated under reduced pressure. The product was purified by flash column chromatography using hexane and ether (11:9) as eluent. The solid obtained was crystallized in hexane and ether to afford the title compound (3.31 g, 76%); mp 54–55°C; ir ($CHCl_3$) ν: 3030, 2960, 2870, 1740, 1440 cm^{-1}; ^1H nmr (80 MHz) δ (ppm): 1.58 (6H, s, *Me*C=C*Me*), 1.85–2.1 (8H, m, $(CH_2)_2$-(Me)C=CMe$(CH_2)_2$), 3.30 (2H, m, $CH(CO_2Me)_2$), 3.74 (12H, s, CO_2Me); ms *m/e*: 372 (M^+).

Procedure for the preparation of trienic alcohols

ZEE Trienol 37

A solution of the dimalonate **33** (1.56 g, 4.19 mmol) in tetrahydrofuran (20 mL) was slowly added to a suspension of sodium hydride (3.0 mmol) in tetrahydrofuran and *N,N*-dimethylformamide (60 mL, 2:1) at 0°C. The resulting mixture was stirred for 30 min at room temperature, then cooled to 0°C. A solution of the *EZ* chlorodiene (5) (567 mg, 2.62 mmol) in tetrahydrofuran (20 mL) was added and the reaction mixture was stirred for 20 h at room temperature. It was cooled to 0°C and quenched by adding saturated aqueous ammonium chloride and water. The mixture was extracted with hexane and ether (1:1). The organic layers were combined, washed with water and brine, dried ($MgSO_4$), and filtered on silica gel using hexane and ether (1:1) as eluent. The filtrate was concentrated under reduced pressure and the crude product was dissolved in dry methanol (100 mL). A catalytic amount of pyridinium paratoluenesulfonate was added and the solution was heated at 55°C for 3 h. Methanol was evaporated under reduced pressure. Flash column chromatography using dichloromethane and ethyl acetate (4:1) as eluent afforded the title compound (670 mg, 55% from the chlorodiene) and unreacted dimalonate **33** (738 mg); ir ($CHCl_3$) ν: 3610, 3015, 2950, 1757, 1435 cm^{-1}; ^1H nmr (250 MHz) δ (ppm): 1.58 (6H, s, *Me*C=C*Me*), 1.85 (4H, s, $(CH_2)_2C(CO_2Me)_2$), 1.9–2.1 (5H, m, $(CH_2)_2CH(CO_2Me)_2$ and O*H*), 2.73 (2H, d, J = 7.5 Hz, CH=CHC*H*$_2$C$(CO_2Me)_2$), 3.30 (1H, t, J = 7 Hz, C*H*$(CO_2Me)_2$), 3.72 (6H, s, CO_2Me), 3.73 (6H, s, CO_2Me), 4.28 (2H, t, J = 5.5 Hz, C*H*$_2$OH), 5.4–5.7 (2H, m, C*H*=CHCH=C*H*), 6.04 (1H, t, J = 11 Hz, OCH_2-CH=C*H*), 6.39 (1H, dd, J = 11, 15 Hz, OCH_2CH=CHC*H*=CH); ms *m/e*: 468 (M^+), 450 ($M^+ - H_2O$).

Procedure for the macrocyclizations

Macrocycle 27

Methanesulfonyl chloride (50 μL, 0.64 mmol) was slowly added at 0°C to a solution of the trienol **23** (100 mg, 0.21 mmol), collidine (85 μL, 0.64 mmol), and lithium chloride (54 mg, 1.28 mmol) in *N,N*-dimethylformamide (4 mL). The mixture was stirred at 0°C for 5 h, then water (4 mL) was added, and the resulting mixture was extracted several times with ether and hexane (1:1). The organic extract was washed with saturated aqueous cupric nitrate. Drying ($MgSO_4$) and removal of solvent afforded an oil that was purified by flash chromatography (hexane:ethyl acetate, 4:1) to give the allylic chloride **25** (41 mg, 40%) and unreacted allylic alcohol **23** (44 mg); ir (CH_2Cl_2) ν: 3000, 2955, 2860, 1730, 1435, 1204 cm^{-1}; ^1H nmr (80 MHz) δ (ppm): 1.58 (6H, s, *Me*C=C*Me*), 1.84 (4H, s, CH_2(*Me*)C=CMeCH_2), 1.9–2.0 (4H, m, CH_2CH_2(*Me*)C=CMeCH_2CH_2), 2.73 (2H, d, J = 7.5 Hz, CH=CHCH_2C$(CO_2Me)_2$), 3.27 (1H, m, C*H*$(CO_2Me)_2$), 3.72 (12H, s, CO_2Me), 4.17 (2H, d, J = 8 Hz, ClCH_2), 5.45–5.75 (2H, m, C*H*=CHCH=C*H*), 6.05–6.3 (2H, m, CH=C*HCH*=CH).

The allylic chloride **25** (41 mg, 0.08 mmol) dissolved in tetrahydrofuran (5 mL) and *N,N*-dimethylformamide (5 mL) was slowly added, by means of a syringe pump, over a period of 5 h to a suspension of cesium carbonate in tetrahydrofuran (8 mL) and *N,N*-dimethylformamide (8 mL) at 70°C. The reaction mixture was stirred for a further 3 h at 70°C. The cold mixture was filtered and the solvent was removed under reduced pressure. Flash chromatography (dichloromethane:hexane:ethyl acetate, 30:19:1) of the residue afforded the title compound, which was crystallized from dichloromethane and hexane (32 mg, 83%); mp 246–247°C; ir (CH_2Cl_2) ν: 2950, 1730, 1435, 1205 cm^{-1}; ^1H nmr (250 MHz) δ (ppm): 1.56 (3H, s, *Me*C=CMe), 1.57 (3H, s, MeC=C*Me*), 1.7–1.95 (8H, m, $(CH_2)_2$(Me)C=CMe$(CH_2)_2$), 2.75 (4H, d, J = 9 Hz, CH_2CH=CHCH=CHCH_2), 3.73 (12H, s, CO_2Me), 5.01 (1H, dt, J = 11, 7.5 Hz, C*H*=CHCH=CH), 5.43 (1H, dt, J = 15, 7.5 Hz, CH=CHCH=C*H*), 6.16 (1H, t, J = 11 Hz, CH=C*H*-CH=CH), 6.53 (1H, dd, J = 15, 11 Hz, CH=CHC*H*=CH); ^{13}C nmr (62 MHz) δ (ppm): 171.44 (*C*O_2Me), 132.54 (CH=*C*HCH=CH), 129.55 (CH=CH*C*H=CH), 128.89 (*C*H=CHCH=CH), 128.00 (MeC=CMe), 127.26 (MeC=*C*Me), 124.36 (CH=CHCH=*C*H), 58.09 ($C(CO_2Me)_2$), 57.20 ($C(CO_2Me)_2$), 52.51 (CO_2Me), 52.40 (CO_2Me), 35.31 (CH_2CH=CHCH=CHCH_2), 30.50 (CH_2-CH=CHCH=CH*C*H_2), 29.35 (CH_2(Me)C=CMe*C*H_2), 28.76 (CH_2CH_2(Me)C=C), 28.56 (C=CMeCH_2*C*H_2), 18.49 (*Me*C=CMe), 18.11 (MeC=C*Me*). Exact Mass (M^+) calcd.: 450.2253; found: 450.2253.

Macrocycle 28

The allylic chloride **26** was used without purification. Injection time: 10 h, additional stirring: 9 h; solvent: acetonitrile; temperature: reflux. The crude product was purified by flash chromatography (ethyl acetate:hexane, 1:4) to yield the title compound **28** (50% yield from **24**) together with the macrocycles **29** (5%) and **30** (5%).

Macrocycle 28. Synthesis and characterization of *O,O*-alkylene dithiophosphate derivatives of dimethyl- and trimethylgermane. Crystal structure of $Me_2Ge[S_2POCMe_2CMe_2O]_2$

JOHN E. DRAKE,[1] ANIL G. MISLANKAR, AND RAJU RATNANI[2]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, ON N9B 3P4, Canada

Received February 14, 1994

JOHN E. DRAKE, ANIL G. MISLANKAR, and RAJU RATNANI. Can. J. Chem. **72**, 1830 (1994).

The *O,O*-alkylene dithiophosphate derivatives of dimethyl- and trimethylgermane $Me_2Ge[S_2POCMe_2CMe_2O]_2$, $Me_2Ge[S_2POCH_2CMe_2CH_2O]_2$, $Me_2Ge[S_2POCH_2CEt_2CH_2O]_2$, $Me_3Ge[S_2POCMe_2CMe_2O]$, $Me_3Ge[S_2POCH_2CMe_2CH_2O]$, and $Me_3Ge[S_2POCH_2CEt_2CH_2O]$ have been prepared in 70–85% yields by reaction of the salts of the appropriate *O,O*-alkylene dithiophosphoric acid with dichlorodimethyl- and chlorotrimethylgermane. The compounds were characterized by infrared, Raman, and ^1H, ^{13}C, and ^{31}P NMR spectroscopy. The crystal structure of $Me_2Ge[S_2POCMe_2CMe_2O]_2$ was determined and it crystallizes as monoclinic in the space group $P2_1/a$ (No. 14) with the cell parameters a = 12.368(6) Å, b = 6.897(2) Å, c = 17.923(3) Å, β = 99.00(3)°, V = 2450(2) Å^3, Z = 4, R = 0.0455, and R_w = 0.0394. The environment about germanium is essentially that of a distorted tetrahedron resulting in a S—Ge—S angle of 89.9(1)° and a C—Ge—C angle of 121.6(5)°. In contrast with analogous non-cyclic diorganodithiophosphatogermanes, the terminal sulfur atoms are oriented towards germanium rather than away from it to give an average Ge---S intramolecular distance of 3.49(3) Å. The spectra are interpreted as indicating that the dithiophosphate groups are linked in identical fashion in all compounds **1–6**. The ^1H and ^{13}C NMR spectra are of particular interest in that, unlike the spectra reported previously for related species, the substituents on the atoms in both the five- and six-membered rings maintain their non-equivalence in solution.

JOHN E. DRAKE, ANIL G. MISLANKAR et RAJU RATNANI. Can. J. Chem. **72**, 1830 (1994).

On a préparé les dérivés dithiophosphates des diméthyl et triméthylgermanes : $Me_2Ge[S_2POCMe_2CMe_2O]_2$, $Me_2Ge[S_2POCH_2CMe_2CH_2O]_2$, $Me_2Ge[S_2POCH_2CEt_2CH_2O]_2$, $Me_3Ge[S_2POCMe_2CMe_2O]_2$, $Me_3Ge[S_2POCH_2CMe_2CH_2O]_2$ et $Me_3Ge[S_2POCH_2CEt_2CH_2O]_2$, avec des rendements allant de 70 à 85% en faisant réagir les sels appropriés de l'acide *O,O*-alkylène dithiophosphorique avec les dichlorodimèthyl et chlorotriméthylgermanes. On a caractérisé les composés par spectroscopie infrarouge, Raman et par la RMN du ^1H, du ^{13}C et du ^{31}P. On a déterminé la structure cristalline du composé $Me_2Ge[S_2POCMe_2CMe_2O]_2$, il cristallise dans le groupe d'espace monoclinique $P2_1/a$ (No 14) avec a = 12,368(6) Å, b = 6,897(2) Å, c = 17,923(3) Å, β = 99,00(3)°, V = 2450(2) Å^3, Z = 4, R = 0,0455 et R_w = 0,0394. L'environnement autour de l'atome de germanium est essentiellement celui d'un tétraèdre déformé résultant d'un angle S—Ge—S de 89,9(1)° et d'un angle C—Ge—C de 121,6(5)°. Contrairement aux analogues diorganodithiophosphatogermanes non cycliques, les atomes de soufre terminaux sont plutôt orientés vers le germanium, au lieu de s'en éloigner, pour donner une distance intramoléculaire moyenne Ge---S de 3,49(3) Å. Les spectres révèlent que les groupes dithiophosphates sont liés de la même façon dans tous les composés **1–6**. Les spectres de RMN du ^1H et du ^{13}C sont d'un intérêt particulier en ce sens que contrairement aux autres spectres répertoriés pour les espèces apparentées, les substituants sur les atomes dans les cycles à cinq et à six chainons maintiennent leur non-équivalence en solution.

[Traduit par la rédaction]

Introduction

Earlier reports on a variety of sulfur-containing groups attached to germanium have included studies on dithiocarbamate, dithiophosphate, and dithiocarbonate (xanthate) derivatives (1–3). In general, a variety of modes of bonding through sulfur have been established for a wide range of both transition and main group elements (4–7). In germanium dithiocarbamates, although there is only one distinct Ge—S bond, the second sulfur atom is oriented towards germanium at distances that indicate anisobidentate and in some cases close to bidentate character (1, 8–10). By contrast, there are no secondary interactions between germanium and the terminal sulfur atom in germanium dithiocarbonates and *O,O*-dialkyldithiophosphates because the orientation of the groups result in an oxygen atom being closer to germanium rather than the second sulfur atom (2, 11–14). However, in related tin compounds such as $Ph_2Sn[S_2P(O\textit{i}\text{-}Pr)_2]_2$, the dithiophosphate groups are bidentate (15) and in $Sn(S_2COEt)_4$, two dithiocarbonates are bidentate and two are monodentate (16). There have been extensive reports of the use of cyclic dithiophosphates as ligands with transition metals (17–23) as well as a few with main group elements (24–27) but none with germanium.

We report on the synthesis and characterization of dimethyl- and trimethylgermanium dithiophosphates of the type $Me_2Ge[S_2POGO]_2$ and $Me_3Ge[S_2POGO]$, where G = —CMe_2CMe_2—, —$CH_2CMe_2CH_2$—, and —$CH_2CEt_2CH_2$—. The X-ray crystal structure of $Me_2Ge[S_2POCMe_2CMe_2O]_2$, **1**, shows the second sulfur atom of the dithiophosphate groups oriented toward germanium, in contrast to that found for the non-cyclic dithiophosphate analogues. The NMR spectra of all of these compounds show features that have not been reported previously for derivatives of these cyclic dithiophosphates and suggest that the solid state structure is maintained in solution.

Experimental

Materials

Dichlorodimethyl- and trichloromethylgermane were obtained from Alfa and were used as supplied. Sodium and ammonium salts of *O,O*-alkylene dithiophosphates were prepared in the manner described in the literature and their purity was checked by ^1H, ^{13}C, and ^{31}P NMR

spectroscopy (28). Benzene, toluene, carbon disulfide, and *n*-hexane were dried and distilled prior to use. All the reactions were carried out under vacuum in air and moisture-free conditions to prevent the formation of germanium oxides.

Synthesis of dimethyl- and trimethylgermane derivatives of alkylene dithiophosphates

$Me_2Ge[S_2POCMe_2CMe_2O]_2$, 1

Typically, the sodium salt of *O,O*-2,3-dimethylbutylene dithiophosphate, $Na[S_2\overline{POCMe_2CMe_2O}]$ (0.476 g, 2.03 mmol) and benzene (10 mL) were placed in a reaction vessel and degassed at −196°C. Me_2GeCl_2 (0.1 mL, 0.87 mmol) was then distilled into the vessel and the contents were allowed to gradually warm up to ambient temperature and then stirred for 8 h. The reaction mixture was filtered to separate NaCl and any unreacted salt after which the solvent was evaporated off *in vacuo* to yield a white solid of the desired product. This was dissolved in toluene which was then layered with *n*-hexane. Crystals appeared after 3–5 days as the *n*-hexane diffused into the toluene solution at 0°C. Thus was formed $Me_2Ge[S_2\overline{POCMe_2CMe_2O}]_2$ (**1**): colorless crystals; mp 144–145°C; yield 82%; IR 1138 s, 953 s and 918 vs (compared with 1138 s, 955 s, and 902 vs in the corresponding starting salt). Unfortunately, the crystals grown in the toluene/*n*-hexane mixture were not suitable for X-ray diffraction studies. A few of these crystals were dissolved in CS_2 and slow evaporation of the CS_2 at 4°C produced colorless needle-like crystals which were of X-ray quality and were used for crystal structure determination.

$Me_2Ge[S_2\overline{POCH_2CMe_2CH_2O}]_2$, 2, $Me_2Ge[S_2\overline{POCH_2CEt_2CH_2O}]_2$, 3, $Me_3Ge[S_2\overline{POCMe_2CMe_2O}]$, 4, $Me_3Ge[S_2\overline{POCH_2CMe_2CH_2O}]$, 5, $Me_3Ge[S_2\overline{POCH_2CEt_2CH_2O}]$, 6

These compounds were prepared by essentially the same method as just described using Me_2GeCl_2 or Me_3GeCl and the sodium or ammonium salt of the appropriate dithiophosphoric acid in slight excess to ensure complete substitution of chlorine. Thus were formed the following compounds. $Me_2Ge[S_2\overline{POCH_2CMe_2CH_2O}]_2$, **2**, white solid; mp 155–157°C; yield 76%; IR 1048 vs and 990 vs (compared with 1051 s and 1001 s in the corresponding starting salt). Anal. calcd. for $C_{12}H_{26}O_4P_2S_4Ge$: C 29.33, H 5.51; found: C 30.08, H 5.79. $Me_2Ge[S_2\overline{POCH_2CEt_2CH_2O}]_2$, **3**; white solid; mp 94–95°C; yield 78%; IR 1070 s, 1019 vs, 991 s, and 934 s (compared with 1071 s, 1021 vs, 1000 vs, and 937 s in the corresponding starting salt). $Me_3Ge[S_2\overline{POCMe_2CMe_2O}]$, **4**; white solid; mp 70–72°C; yield 80%; IR 1140 s, 956 s, and 919 vs (compared with 1138 s, 955 vs, and 902 vs in the corresponding starting salt). $Me_3Ge[S_2\overline{POCH_2CMe_2CH_2O}]$, **5**; white solid; mp 93–95°C; yield 74%; IR 1048 s and 993 s (compared with 1051 s and 1001 s in the corresponding starting salt). $Me_3Ge[S_2\overline{POCH_2CEt_2CH_2O}]$, **6**; white solid; mp 56–57°C; yield 71%; IR 1070 s, 1019 s, 993 vs, and 933 s (compared with 1071 s, 1021 vs, 1000 vs, and 937 s in the corresponding starting salt). Anal. calcd. for $C_{10}H_{23}O_2PS_2Ge$: C 35.02, H 6.73; found: C 35.07, H 6.67. Unfortunately, despite extensive efforts to grow X-ray quality crystals, none were obtained for compounds **2**–**6**.

Physical measurements

All solvents were distilled prior to use. The elemental analyses were performed at Guelph Chemical Laboratories, Guelph, Ontario, Canada. The infrared spectra were recorded on a Nicolet 5DX FT spectrometer as KBr pellets and far infrared spectra on a Bomem IR Spectrometer between polyethylene films as Nujol mulls. The Raman spectra were recorded on a Spectra-Physics 164 spectrometer using the 5145-Å exciting line of an argon ion laser with samples sealed in capillary tubes. The ^1H and ^{13}C NMR spectra were recorded on a Bruker 300 FT NMR spectrometer in $CDCl_3$ solutions using Me_4Si as internal standard. The ^{31}P NMR spectra were recorded on a Bruker 200 FT NMR spectrometer in $CDCl_3$ using H_3PO_4 as external standard. The melting points were determined on a Fisher–Johns apparatus.

X-ray crystallographic analysis

A needle-like crystal of $Me_2Ge[S_2\overline{POCMe_2CMe_2O}]_2$, **1**, was sealed in a thin-walled glass capillary and mounted on a Rigaku AFC6S diffractometer, with graphite-monochromated MoKα radiation.

Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 25 carefully centered reflections in the range $20° < 2\theta < 27°$ corresponded to a monoclinic cell whose dimensions are given in Table 1. The systematic absences ($h0l$, $h = 2n + 1$; $0k0$, $k = 2n + 1$) are observed. Based on packing considerations, statistical analyses of intensity distributions and the successful solution and refinement of the structure, the space group was determined to be $P2_1/a$ (No. 14).

The data were collected at a temperature of 23 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 50.0°. The ω scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.34° with a takeoff angle of 6.0°. Scans of $(0.84 + 0.30 \tan\theta)°$ were made at a speed of 8.0°/min (in ω). The weak reflections ($I < 10.0\sigma(I)$) were rescanned (maximum of 2 rescans) and the counts were accumulated to assure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. The diameter of the incident beam collimator was 0.5 mm, and the crystal-to-detector distance was 285.0 mm.

Of the 3197 reflections which were collected, 3015 were unique ($R_{int} = 0.084$). The intensities of three representative reflections that were measured after every 150 reflections remained constant throughout data collection indicating crystal and electronic stability (no decay correction was applied).

The linear absorption coefficient for MoKα is 17.0 cm^{-1}. An empirical absorption correction, based on azimuthal scans of several reflections, was applied which resulted in transmission factors ranging from 0.84 to 1.00. The data were corrected for Lorentz and polarization effects.

The structure was solved by direct methods (for structure solution methods, see ref. 29). The non-hydrogen atoms other than oxygen and carbon atoms were refined anisotropically and the hydrogen atoms were included in their idealized positions with C—H set at 0.95 Å and with isotropic thermal parameters set at 1.2 times that of the carbon atom to which they were attached. The final cycle of full-matrix least-squares refinement[3] was based on 1178 observed reflections ($I > 3.00\sigma(I)$) (and 136 variable parameters and converged (largest parameter shift was 0.001 times its esd) with unweighted and weighted agreement factors of $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.0455$ and $R_w = [(\Sigma w(|F_o| - |F_c|)^2/\Sigma w f_o^2)]^{1/2} = 0.0394$.

The standard deviations of an observation of unit weight[4] was 1.39. The weighting scheme was based on counting statistics and included a factor ($p = 0.01$) to downweight the intense reflections. Plots of $\Sigma w(|F_o| - |F_c|)^2$ versus $|F_o|$, reflection order in data collection, $\sin\theta/\lambda$, and various classes of indices showed no unusual trends. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.35 and −0.33 e/Å^3, respectively.

Neutral-atom scattering factors were taken from Cromer and Waber (30). Anomalous dispersion effects were included in F_c (31); the values for $\Delta f'$ and $\Delta f''$ were those of Cromer (32). All calculations were performed using the TEXSAN (33) crystallographic software package of Molecular Structure Corp.

The final atomic coordinates and equivalent isotropic thermal

[3]Least-squares: function minimized: $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2(F_o^2)$, $\sigma^2(F_o^2) = [S^2(C + R^2B) + (pF_o^2)^2]/(Lp)^2$, S = scan rate, C = total integrated peak count, R = ratio of scan time to background counting time, Lp = Lorentz-polarization factor, and $p = p$ factor.

[4]Standard deviation of an observation of unit weight: $[\Sigma w(|F_o| - |F_c|)^2/N_o - N_v)^{1/2}$, where N_o = number of observations and N_v = number of variables.

parameters for the non-hydrogen atoms are given in Table 2, important distances and bond angles in Tables 3 and 4, and an ORTEP diagram in Fig. 1. Tables of final thermal parameters of non-hydrogen atoms, final fractional coordinates, and thermal parameters of hydrogen atoms, and observed and calculated structure factors have been deposited.[5]

Results and discussion

Several cyclic dithiophosphate compounds of germanium were prepared in 70–85% yields by the action of a slight excess of the appropriate sodium or ammonium salt of *O,O*-alkylene dithiophosphoric acid with dichlorodimethyl- or chlorotrimethylgermane in benzene in accordance with the equations

$$Me_2GeCl_2 + 2MS_2\overline{POGO} \rightarrow Me_2Ge[S_2\overline{POGO}]_2 + 2MCl$$

$$Me_3GeCl + MS_2\overline{POGO} \rightarrow Me_3Ge[S_2\overline{POGO}] + MCl$$

where M = Na, NH_4; G = —CMe_2CMe_2—, —$CH_2CMe_2CH_2$—, and —$CH_2CEt_2CH_2$—. The reaction mixtures were stirred for approximately 8 h at room temperature followed by filtration to separate solid NaCl, NH_4Cl, or unreacted dithiophosphate salt. The solvent was pumped off to obtain a white solid which was recrystallized from fresh toluene at 4°C.

All of the compounds **1–6** are stable on exposure to atmospheric oxygen and moisture and in common organic solvents such as benzene, *n*-hexane, toluene, carbon disulfide, and chloroform; the latter being used as the preferred solvent for NMR spectroscopic studies. Solid samples of **1–6** are stable over a long period, particularly when kept refrigerated, as can be confirmed by the fact that NMR spectra recorded after several months show no changes from the spectra recorded initially. All of the compounds have sharp melting points and their ^{1}H NMR spectra confirm that they are 99% pure relative to any hydrogen-containing impurities.

Extensive attempts were made to grow X-ray quality crystals using a variety of solvents or solvent mixtures for **1–6**,

but unfortunately it was only possible to do so for $Me_2Ge[S_2POCMe_2CMe_2O]_2$, **1**.

*The crystal structure of $Me_2Ge[S_2\overline{POCMe_2CMe_2O}]_2$, **1***

Dimethylbis(*O,O*-2,3-dimethylbutylene dithiophosphato)germane, **1**, crystallizes in the space group $P2_1/a$ and its ORTEP diagram (Fig. 1) illustrates that the immediate environment about germanium is that of a distorted tetrahedron. The C—Ge—C angle of 121.6(5)° is considerably larger than the all-tetrahedral angle but is essentially identical to that found in $Ph_2Ge[S_2CNEt_2]_2$ and in the starting material Me_2GeCl_2 (34). Naturally, the S—Ge—S angle is much smaller than the all tetrahedral angle but at 89.9(1)° it is wider than those in $Ph_2Ge[S_2CNEt_2]_2$ or $Me_2Ge[S_2CNMe_2]_2$ (35), which are 84.4(1) and 87.0(1)°, respectively. The distortions are considerably larger than that found in the related non-cyclic dithiophosphate, $Ph_2Ge[S_2P(OMe)_2]_2$, where the C—Ge—C and S—Ge—S angles are 115.8(3) and 103.5(1)°, respectively (2). The Ge—C bond distances in **1** are comparable to those in $Me_2Ge[S_2CNMe_2]_2$, 1.921(7) and 1.910(6) Å, $Ph_2Ge[S_2CNEt_2]_2$, 1.928(3) Å, and $Ph_2Ge[S_2P(OMe)_2]_2$, 1.931(7) Å. The Ge—S bond lengths of 2.268(4) and 2.275(4) Å in **1** are similar to those in $Ph_2Ge[S_2CNEt_2]_2$ and $Me_2Ge[S_2CNMe_2]_2$, but longer than those in $Ph_2Ge[S_2P(OMe)_2]_2$, 2.255(4), and $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$, 2.252(3) Å. The xanthate and dithiophosphate ligands are undoubtedly monodentate, with Ge---S distances to the terminal sulfur atom averaging 4.754(1) Å in $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$ and 5.38(2) Å in $Ph_2Ge[S_2P(OMe)_2]_2$. The longer Ge—S bonds in **1** and $Ph_2Ge[S_2CNEt_2]_2$ could arise because the ligands are mono- or anisobidentate, with the closing down of the S—Ge—S angle allowing room for the non-bonding, or anisobonding, sulfur atom to be oriented toward germanium. No such closing down of the angle is required or observed for the monodentate ligands in $Ph_2Ge[S_2P(OMe)_2]_2$ or $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$, where the second sulfur atom is oriented away from germanium, and the S—Ge—S angles are similar to the X—Ge—X angles reported in the gas phase for Me_2GeCl_2 and Me_2GeBr_2 where no secondary intramolecular interactions can be involved. In $Me_2Ge[S_2CNMe_2]_2$ and $Ph_2Ge[S_2CNEt_2]_2$ (1, 9), the anisobonding sulfur atoms give Ge---S distances of 3.16(1) and 3.183(1) Å, respectively, which are well within the sum of the van der Waals radii of germanium and sulfur of 3.75 Å (36), whereas those in $Me_2Ge[S_2\overline{POCMe_2CMe_2O}]_2$, **1**, of 3.471(4) and 3.517(4) Å, are relatively long. In the related tin compounds, $Me_2Sn[S_2\overline{POCMe_2CMe_2O}]_2$ (25) and $Ph_3Sn[S_2\overline{POCMe_2CMe_2O}]$ (26), the aniso Sn---S distances are shorter, ranging from 3.130(1) to 3.411(3) Å, whereas in non-cyclic dithiophosphate tin derivatives, the dithiophosphate groups are fully bidentate as is illustrated by the structure of $Ph_2Sn[S_2P(Oi\text{-}Pr)_2]_2$, in which all four Sn—S bonds cover the range 2.678(1) to 2.689(1) Å (15). Thus, although non-cyclic dithiophosphate derivatives of tin are generally bidentate and those of germanium are monodentate, the cyclic dithiophosphates of tin appear to be anisobidentate and those of germanium, if not also anisobidentate, are at least oriented in a similar fashion.

The P—S(Ge) bonds in $Me_2Ge[S_2POCMe_2CMe_2O]_2$, **1**, are only slightly longer, 2.064(5) Å, than the P=S bonds, 1.908(5) Å. These relatively small differences are typical of all metal dithiophosphates, irrespective of their mode of bonding, and are similar to those reported for the diligands, $[OCMe_2CMe_2OP(S)S]_2$ (37) and $[(i\text{-}PrO)_2P(S)(S)]_2$ (38). In view of this insensitivity to changes in environment, it is not surprising that the distortion around phosphorus from all tetrahedral angles is similar to that found in $Ph_2Ge[S_2P(OMe)_2]_2$ (2). The orientation in the five-membered ring system is such that two of the carbon methyl atoms are at an average distance of 3.24(5) Å from the phosphorus atom and the other two are at 3.80(2) Å. A view down the C—C bond of the ring shows that the four methyl groups attached to them are in the staggered configuration expected for the more stable arrangement with the pair at 3.24(5) Å pointing above and below the approximate plane of the distorted ring in an arrangement essentially identical to that observed in $Me_2Te[S_2\overline{POCMe_2CMe_2O}]_2$ (27).

Infrared and Raman spectra

The infrared spectra of **1–6**, particularly in the region around 1000 cm^{-1}, contain distinctive strong bands which are similar, but not identical, to those of the starting salts. These are summarized in the Experimental section. The similarity of these characteristic features suggests either that the bonding within the dithiophosphate groups is essentially unchanged or that, in any case, the vibrational spectra are unlikely to provide definitive evidence as to the mode of attachment of the dithiophosphate.

Features in the infrared and Raman spectra involving bonding to germanium are summarized in Table 5. The Ge—C stretching vibrations in **1–3** are assignable to peaks at essentially the same positions and relative intensities in both effects as reported for Me_2GeCl_2, 638 and 579 cm^{-1} respectively, for the asymmetric and symmetric stretches (39). This is to be expected because the Ge—C bond lengths and C—Ge—C bond angles are similar in **1** and Me_2GeCl_2, as discussed above, and the similarity in structure presumably extends to **2** and **3**. The same comparison holds true when the assignments of the Ge—C stretching vibrations in compounds **4–6** are compared with those of Me_3GeCl (40). The assignments of the Ge—S stretching vibrations in **1–6** are made readily by comparisons with those reported for the analogous *O,O*-

dialkyldithiophosphates (41). The vibrational spectra are consistent with the dithiophosphate groups being bonded in similar fashion in all six derivatives.

Nuclear magnetic resonance spectra

The ^1H NMR spectra data for compounds **1–6** are presented in Table 6. The splitting patterns and relative intensities of peaks are consistent with the proposed structures. All of the derivatives show a sharp singlet assignable to the CH_3 groups attached to germanium. The chemical shifts in the $Me_2Ge[S_2\overline{POGO}]_2$ derivatives, **1–3**, are similar to that in Me_2GeBr_2, 1.47 ppm, whereas the values in the $Me_3Ge[S_2\overline{POGO}]$ species, **4–6**, are close to that of Me_3GeCl, 0.78 ppm. Changes in these chemical shifts have been related to changes in the electronegativity of the groups attached to germanium so the effective electronegativity of these cyclic dithiophosphate groups is presumably of a similar order of

$Me_3Ge[S_2\overline{POCH_2CMe_2CH_2O}]$, **5**	3.58	76.84	32.52 [6.8]	22.32 21.03	
$Me_3Ge[S_2\overline{POCH_2CEt_2CH_2O}]$, **6**	3.58	74.28 [9.1]	37.31 [4.3]	23.36 22.38	7.18 6.85

[a]The spectra were recorded in $CDCl_3$ and reported in ppm from Me_4Si.
[b]Values of the coupling constants for the doublets arising from P-C coupling, J(P-C), are given in square brackets [ ].
[c]Peaks attributable to the corresponding salts are seen in $Na[S_2\overline{POCMe_2CMe_2O}]$ at 90.69 and 24.63 ppm, in $Na[S_2\overline{POCH_2CMe_2CH_2O}]$ at 77.92 [7.3], 34.55, and 23.20 ppm; and in $NH_4[S_2\overline{POCH_2CEt_2CH_2O}]$ at 75.29 [7.4], 39.58, 24.91, 8.79 ppm.

magnitude (9, 41). The shift of approximately 0.7 ppm per dithiophosphate group replacing a methyl group is close to that observed for related germanium derivatives with sulfur donating ligands (1) and the consistency of the chemical shifts reflects the fact that all of the compounds probably have identical linkages.

The observation of two peaks in the ^1H NMR spectrum of **1**, at 1.42 and 1.46 ppm, indicates that the eight methyl groups in the two dithiophosphates are in two different environments. This is in agreement with the structure of **1**, in which the carbon atoms in one set of four methyl groups are at an average distance of 3.24(5) Å from phosphorus and in the other set of four the average distance is 3.80(2) Å. However, the maintenance of the non-equivalence in solution is surprising because there have been no reports of such splitting in the NMR spectra of other derivatives containing similar cyclic dithiophosphates (17–24, 27) including those of $Me_2Sn[S_2\overline{POCMe_2CMe_2O}]_2$ and $Ph_2Sn[S_2\overline{POCMe_2CMe_2O}]_2$ where only single peaks were reported at 1.4 and 1.0 ppm, respectively (24).

The splitting patterns seen in the ^1H NMR spectra of all of these germanium derivatives are thus apparently unique for these cyclic dithiophosphates. Compounds **2**, **3**, **5**, and **6** all display the same complex pattern arising from the non-equivalence of the hydrogen atoms of the CH_2 groups in the six-membered ring. The feature is displayed in Fig. 2 for compound **2** where the eight CH_2 protons give two sets of multiplets that approximate to 1:1:1:1 quartets, one centered at 4.24 and the other at 3.89 ppm. The multiplet at 4.24 ppm is a doublet, which is the result of geminal spin–spin coupling with a value for $J(H_aH_b)$ of 10.5 Hz, and which is further split into a doublet by coupling with phosphorus to give a value for $J(PH_a)$ of 5.7 Hz. The second multiplet at 3.89 ppm is more

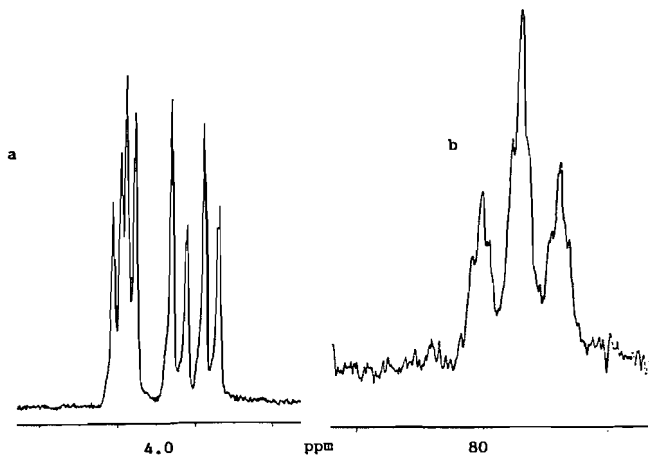

FIG. 2. Pertinent sections of the (*a*) ^1H and (*b*) ^{31}P NMR spectra of $Me_2Ge[S_2\overline{POCH_2CMe_2CH_2O}]_2$, **2**. The ^{31}P NMR spectrum illustrated is run without hydrogen decoupling.

clearly split into two doublets because the coupling to phosphorus is much larger with the value of the $J(PH_b)$ coupling constant being 25.5 Hz. The appearance of these two multiplets in the spectra of **3**, **5**, and **6** is essentially the same because the values of the chemical shifts and coupling constants are virtually identical in all four compounds. Thus the two protons on carbon are non-equivalent, as was observed for the two methyl groups substituted in the corresponding positions in the five-membered rings in **1** and **4**, and the values of the spin–spin coupling constants with phosphorus are different. It is reasonable to assume, by analogy with cyclohexane, that protons H_a and H_b occupy axial and equatorial positions respectively in a boat configuration and thus have different values for $J(PH)$. The ^{31}P NMR spectrum was recorded without

For personal use only.

hydrogen decoupling and the resulting spectrum for **2**, which is a triplet of triplets, is also displayed in Fig. 2 to provide a representative sample. The larger triplet has a coupling constant of 25.5 Hz, as expected for coupling of phosphorus with the two equatorial protons, and the triplet is further split into a triplet from coupling of the phosphorus with the two axial protons with a value of 5.7 Hz for this coupling constant. It is worth noting that a typical value for J(PH) in the starting salts and related cyclic dithiophosphate derivatives that do not show the two separate couplings fall between those of these $J(PH_a)$ and $J(PH_b)$ values (18, 19, 22–24).

The $^{13}C\{H\}$ NMR spectra data for compounds **1–6** are presented in Table 7. The peaks attributable to CH_3—Ge are close to the value of 10.72 ppm found for Me_2GeCl_2 and for related dithio derivatives such as $Me_2Ge[S_2P(OEt)_2]_2$, 9.3 ppm (43), and $Me_2Ge[S_2CNMe_2]_2$, 13.7 ppm (1). Similarly, in compounds **4–6**, the CH_3—Ge peaks are comparable to 4.8 ppm in Me_3GeCl and to 3.6 and 3.2 ppm respectively in $Me_2Ge[S_2P(OEt)_2]$ and $Me_3Ge[S_2CNMe_2]$ (45, 1). All of the other peaks can be readily assigned to the various carbon atoms of the cyclic dithiophosphate groups at positions close to, but not identical to, those of the corresponding salts and acids. However, again in contrast to the features in the salts, acids, or metal derivatives where only single peaks are observed indicating identical or averaged positions, duplication of peaks is observed for compounds **1–6** for all of the atoms attached to the rings. In general, the values of the coupling constants, $J(P^2C)$ and $J(P^3C)$, which are included in Table 7, are typical of such groups in a variety of environments, as is the fact that these couplings are not observed in a consistent manner (18, 19, 22, 24, 27).

The $^{31}P\{H\}$ NMR spectra, which are presented in Table 6 along with the ^1H NMR data, show a single peak in all compounds **1–6**, consistent with both dithiophosphate groups being in identical environments. It has been proposed that the difference in the phosphorus chemical shift between a derivative and that of the free acid is an accurate indicator of the mode of binding, so that downfield shifts in the range 8–15 ppm are associated with bidentate ligands, and negligible shifts or even upfield shifts with monodentate linkages (42). In compounds **1–6** the downfield shifts range from 2.8 ppm in **2** to 9.2 ppm in **6**, and therefore are consistent with the ligands remaining aniso- or monodentate rather than becoming bidentate. In **1**, where the solid state structure suggests the presence of a monodentate ligand but with the second sulfur atom oriented toward rather than away from germanium, the shift is 6.2 ppm. This shift is considerably smaller than those observed for analogous dimethyltellurium derivatives, 11 to 16 ppm (27), which had similar solid state structures but were assumed to become bidentate in solution.

The similarities in the ^1H, ^{13}C, and ^{31}P NMR spectra of **1–6**, suggest that the weak anisobidenticity found in the solid state structure of **1**, is maintained in solution for all six compounds, in contrast to its tin and tellurium analogues where exchange of bonded and aniso-bonded sulfur apparently occurs (24, 27).

The structure of the O-chain portion of the lipopolysaccharide isolated from three different strains of *Pseudomonas syringae* ssp. *savastanoi* has been determined by chemical and NMR spectral analysis. For all of the strains the O-chain consists of a tetrasaccharide repeating unit of three α-L-Rha*p* and one terminal nonreducing α-D-Fuc*p*3NAc. Two rhamnosyl residues are 3-linked and the third one is 2,3-linked. LPS from an olive strain, avirulent on oleander, was shown to attenuate the response of oleander plants inoculated with a homologous strain.

MATTEO ADINOLFI, MARIA MICHELA CORSARO, ROSA LANZETTA, CARMELA ELSA MARCIANO, MICHELANGELO PARRILLI, ANTONIO EVIDENTE et GIUSEPPE SURICO. Can. J. Chem. **72**, 1839 (1994).

Faisant appel à des analyses chimiques et de RMN, on a déterminé la structure de la partie de la chaîne oxygénée du lipopolysaccharide isolé des trois souches différentes de *Pseudomonas syringae* ssp. *savastanoi*. Pour chacune des souches, cette chaîne est formée d'un motif constitutif tétrasaccharidique formé de trois α-L-Rha*p* et d'une unité terminale non-réductrice α-D-Fuc*p*3NAc. Deux des résidus rhamnosyles sont liés par la position 3 alors que le troisième est lié par les positions 2,3. On a démontré que le lipopolysaccharide provenant d'une souche d'olive, avirulent sur l'oléandre, atténue la réponse des plants d'oléandre inoculés avec une souche homologue.

Introduction

Pseudomonas syringae ssp. *savastanoi* (= *P. savastanoi*) is a bacterium that incites tissue overgrowth on an Apocynacea plant (oleander), olive, and some other Oleaceae plants (jasminum, ash, privet, phylirrea). Strains isolated from oleander also induce knots on Oleaceae but strains from Oleaceae are avirulent on oleander (1). The molecular basis of this host–pathogen specificity is poorly understood. Exopolysaccharides and the cell wall lipopolysaccharides (LPS) of phytopathogenic bacteria have been correlated with pathogenesis; the chemical structure and physical conformation of these complex molecules may play a role in the early infection process and in the determination of specificity of plant–bacterial interactions (2). For example, in the case of *Agrobacterium tumefaciens*, a bacterium that shares several features with *P. savastanoi* (3), LPS isolated from non-oncogenic strains inhibit tumor formation by virulent strains (4).

This report deals with the isolation and characterization of the O-chain of LPS from olive and oleander strains of *P. savastanoi*.

The role of LPS on the infectivity and virulence of the olive and oleander pathogen was also considered.

Results and discussion

Lipopolysaccharides were isolated from three strains (ITM519, ITM317, and PVF5) of *P. savastanoi* by extraction with phenol–water followed by gel-filtration chromatography, and the O-chain polysaccharide was obtained from LPS by hydrolysis with dilute acetic acid and purified by gel filtration. For the ITM519 and ITM317 O-chains an apparent molecular weight of 53 000 Da was estimated (see Experimental).

The ^{1}H NMR (Table 1) of the O-chain polysaccharide, obtained from all of the LPS, displayed in the anomeric zone, in addition to very minor signals (see Fig. 1*a*), four signals of similar intensities in the range 5.04–4.85 ppm, of which only one appeared as a doublet (3.9 Hz), while the others were broad singlets. Furthermore the presence of four methyl doublets in the range 1.00–1.18 ppm suggested the 6-deoxy nature of the monosaccharide residues. A fifth methyl signal at δ 1.87 indicated the presence of an acetyl group.

In agreement with the ^{1}H NMR data, the ^{13}C NMR spectrum (Table 1) showed four anomeric signals in the range 102.7–96.3 ppm, four methyl signals (C-6 of 6-deoxyhexoses) at δ 17.1–17.3 (three) and at δ 15.7 (one), and the signals of an *N*-acetyl group (Me at δ 22.5, CO at δ 174.9), in addition to one signal at δ 51.6, indicating a carbon bearing nitrogen (5).

The $^1J_{C,H}$ values (Table 1) of the anomeric signals, determined by a coupled DEPT experiment, indicated an α anomeric configuration for all of residues (6).

2D NMR H,H COSY and one-bond H,C COSY spectra allowed us to identify the chemical shifts of all protons and carbons of each residue (Table 1). In addition it was possible, starting from the anomeric proton doublet at δ 4.88, to identify the

[d]Overlapped signals.

patterns of the spin system for all of the connected protons, except for H-4, and the $^3J_{H,H}$ values. Therefore, the *galacto* configuration for the residue was recognized (7).

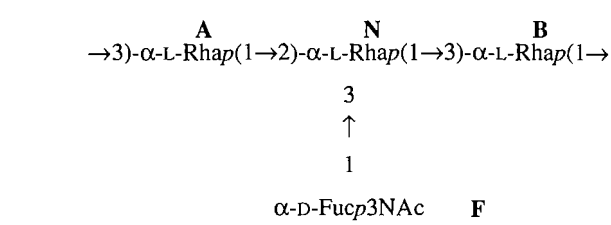
The above data suggested a polysaccharide built up of α-rhamnopyranosyl and 3-acetamido-3,6-dideoxy-α-galactopyranosyl (Fuc*p*3NAc) units in the 3:1 ratio. Furthermore, it was possible to identify the carbons of each residue involved in the interglycosidic linkage on the basis of the ^{13}C glycosylation shifts (Table 1) (8). In particular, two rhamnosyl residues are 3-linked and the other one is 2,3-linked, while the Fuc*p*3NAc is a nonreducing terminal unit.

Chemical analysis confirmed the above suggestion. Actually, the acid hydrolysis of the O-chain polysaccharide yielded rhamnose and Fuc*p*3NAc in a ca. 3.5:1 ratio (Fuc*p*3NAc standard was not available to establish the corrected response factor). The configuration for all of the rhamnose units was safely established to be L on the basis of the good agreement between the $[\alpha]_D$ value (+9) measured for the obtained rhamnose sample and the literature value (+8.7) (9). The configuration D for the Fuc*p*3NAc was suggested by the positive value (+6.5) of $[\alpha]_D$ of the O-chain polysaccharide, taking the strong positive $[\alpha]_D$ value (+238) (10) of methyl 3-acetamido-3,6-dideoxy-α-D-galactopyranoside into consideration.

The methylation analysis also gave the expected sugars, namely, 2,4-di-*O*-methyl-L-rhamnose, 4-*O*-methyl-L-rhamnose, and 3,6-dideoxy-2,4-di-*O*-methyl-3-*N*-methylacetamido-D-galactose, although the stoichiometry of the analysis was not very good.

To define the sequence of monosaccharides, a ROESY (11) experiment was performed. The projections of the ROESY experiment for each anomeric signal are given in Fig. 1, which shows the proton systems with which the anomeric protons establish NOE contacts. In addition to some internal NOEs, each anomeric proton displayed, almost exclusively, NOEs with the protons of only one unit, indicating its spatial proximity to this unit. Actually, the anomeric protons of the **N** units showed NOEs with the **B** protons (Fig. 1b), while both the **A** and **F** anomeric protons exhibited NOEs with those of nodal **N** units (Figs. 1*c* and 1*d*). In particular, the anomeric **A** proton displayed a very strong effect on H-2, suggesting that **A** was linked at C-2 and, consequently, **F** at C-3 of the **N** unit. Finally, the **B** anomeric proton showed NOEs with those of the **A** unit (Fig. 1*e*).

From these results, the structure **1** of the complete tetrasaccharide repeating unit can be defined.



1

The configuration D for the Fuc*p*3NAc unit was substantiated

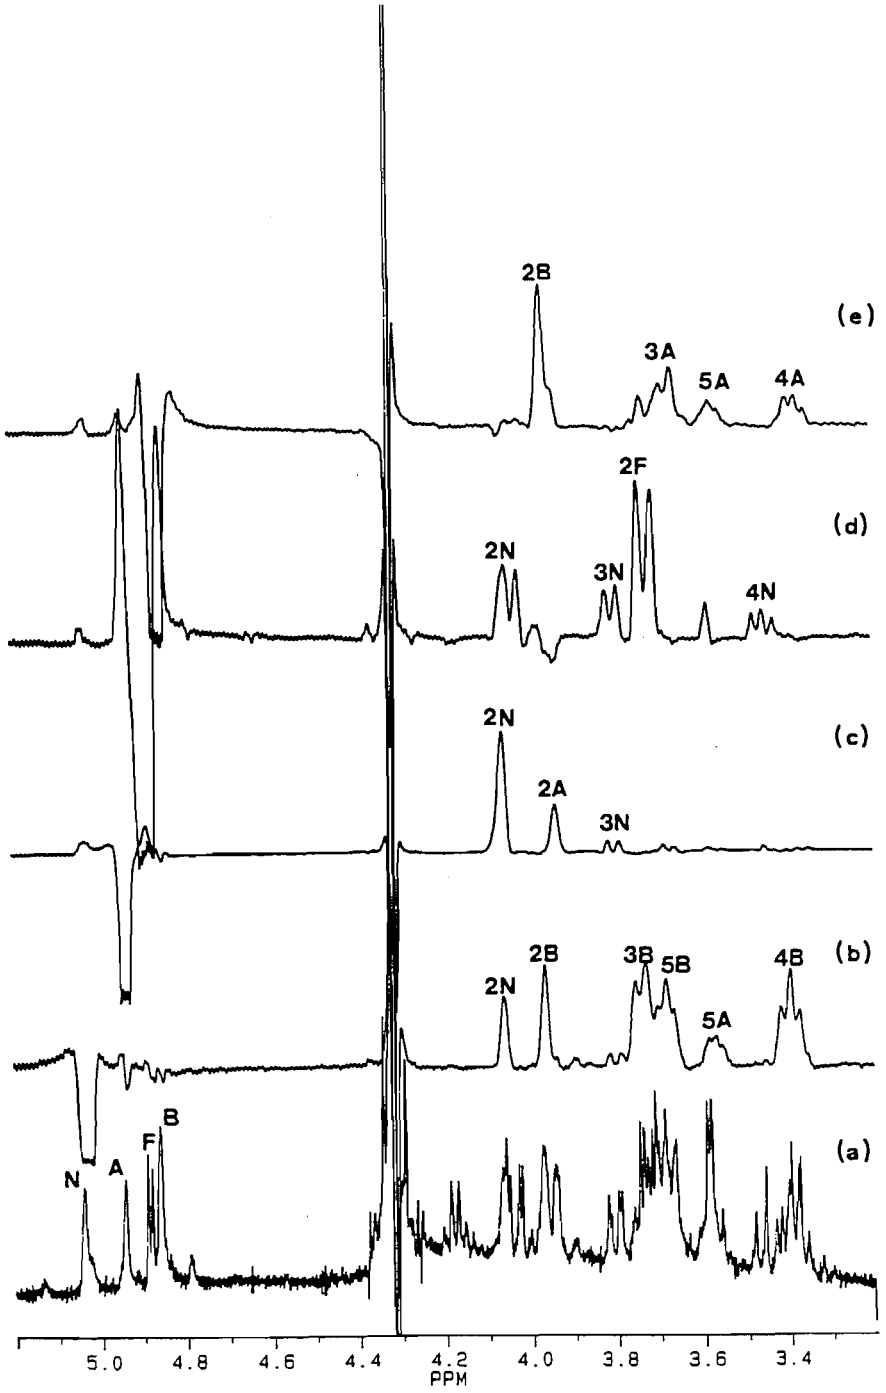

FIG. 1. ^{1}H NMR spectra (*a*) and ROESY projections (*b*)–(*e*) of O-chain polysaccharide between 3.2 and 5.2 ppm measured in D_2O at 50°C.

by analysis of the effects exerted (9) by the configuration of Fuc*p*3NAc on the ^{13}C NMR chemical shifts of the repeating unit (12, 13). The observed (corrected by +0.4 ppm in order to refer to internal standard methanol, δ 50.15) and calculated (12, 13) ^{13}C chemical shifts for structure **1** are given in Table 2. The normalized deviation ($S = \Sigma\Delta^2/n$) for structure **1** is 1.2, a lower value than the limit (≤ 1.5) taken as a measure of the good correspondence between observed and calculated ^{13}C NMR spectra (13). The alternative structure with L-Fuc*p*3NAc was safely ruled out, since the *S* value is 12.2.

When this work was completed, a paper describing the isolation of the same O-chain from *Pseudomonas syringae* pv. *tomato* was published (14). This latter result is not surprising because there is no direct correlation between O-chain structures and host–plant differentiation. Actually, strains of the same pv. of *P. syringae* show different O-chains, while different pv. of *P. syringae* show same O-chain (15). In accordance with this observation, our O-chain results are very different from that of LPS found in a strain of *P. s.* pv. *savastanoi* isolated from knots of diseased Spanish olive trees. Actually, this latter appeared to mainly contain rhamnose (38%) and glucose (33%) (16).

As far as the chemotaxonomic point of view is concerned, our strains may be classified in the I chemotype, as well as *P. s.* pv. *tabaci* (15).

TABLE 2. ^{13}C chemical shift data calculated (observed) for O-chain polysaccharide **1**

Constituents	Chemical shifts (ppm)

F α-D-Fuc*p*3NAc-(1→	97.0 (96.7)	66.7 (66.5)	52.2 (52.0)	71.65 (71.2)	68.0 (67.7)	16.9 (16.1)

Pure LPS isolated from olive strain ITM317 was used in a series of experiments to test the inhibition of tumor formation by virulent oleander strains.

The results of the inoculation experiments showed that *P. savastanoi* knot formation in oleander leaves is insensitive to exogeneously supplied LPS isolated from heterologous strains of the bacterium. Only when LPS was supplied in great weight excess relative to the amount of LPS on the surfaces of the bacterium in the inoculum was a somewhat inhibitory effect observed. Therefore, particles of bacterial cell envelopes other than purified LPS should be investigated in order to elucidate the failure of olive strains to infect oleander plants.

Experimental

General

The ^1H and ^{13}C NMR spectra were obtained at 400 and 100 MHz, respectively, with a spectrometer equipped with a dual probe, in the Fourier transform mode at 50°C. ^{13}C and ^1H chemical shifts were measured in D_2O solutions using 1,4-dioxane (67.4 ppm) and TSP, respectively, as internal standards. The DEPT experiment was performed using a polarization transfer pulse of 135° and a delay adjusted to an average C,H coupling of 160 Hz. The standard Bruker software (XHCORR) was used to perform the heteronuclear H,C COSY experiment under the following conditions: the time domain in f_2 was 1K, 128 spectra were collected with 1600 scans, the spectral width was 10 000 Hz in f_2 and 2000 Hz in the f_1 domain, delays were optimized for $^1J_{C,H}$ = 160 Hz. Fourier transformation was performed with a shifted sine-bell function in both dimensions. H,H COSY and ROESY experiments were performed with standard COSY, with a second pulse of 45°, and ROESYPH pulse sequences under the following conditions: the time domain in f_1 was 1K and in f_2 1K, SW = 2000 Hz. For the ROESY experiment the best results were obtained with a mixing time of 200 ms; the FID matrix was processed with a trapezoidal shifted function.

Total carbohydrates were determined by the phenol–H_2SO_4 test (17). UV absorbance was determined in H_2O solutions. Alditol acetates were separated on an SP-2330 capillary column (Supelco, 30 m × 0.25 mm i.d., flow rate 1 mL/min) at 240°C using N_2 as carrier gas, in a gas chromatograph equipped with a flame-ionization detector. Partially methylated alditol acetates were analysed by GLC–MS, using an SP-2330 capillary column (Supelco, 30 m × 0.25 mm i.d., flow rate 0.8 mL/min, He as carrier gas) with the temperature programme: 170°C for 3 min, 170 → 240°C at 4°/min, 240°C for 30 min (18). Methylation was performed according to Hakomori (19) with KCH_2SOCH_3, MeI in DMSO. Methylated product was recovered through adsorption on a C_{18} Sep-Pak. GLC of the partially methylated alditol acetates was carried out on a column identical with that used for GLC–MS. Paper chromatography was carried out on Whatman 3MM paper with 4:1:5 BuOH–AcOH–H_2O (upper phase) as the developer, and indication with aniline – diphenylamine phosphate. Optical rotations were determined in H_2O solutions.

Bacterial strains

Three strains of *P. savastanoi* were used in this study: strain ITM519 (collection of Istituto Tossine e Micotossine da Parassiti Vegetali del CNR, Bari, Italy) was isolated from infected oleander plants from South Italy; strains ITM317 and PVF5 (collection of Istituto di Patologia e Zoologia Forestale ed Agraria, Università di Firenze, Firenze, Italy) were isolated from infected olive plants from South and Central Italy, respectively. Colonies of strains ITM519 and ITM317 are typical of *P. savastanoi* while strain PVF5 is a naturally occurring, levan-positive nonfluorescent variant of the bacterium (20). Bacteria were stored on nutrient glycerol agar slants at 4°C and new stock cultures were established at monthly intervals.

Media and growth conditions

For solid cultures, bacteria were grown on plates (18 cm) containing nutrient glycerol agar medium (nutrient broth, 0.8%; glycerol, 1.5%; agar, 1.5%); distilled water, 1 L) laid on the top of the agar with a circular piece of dialysis tubing (cutoff of 3000). Following incubation at 26°C for 5–7 days, depending on the strain, bacteria were scraped off the upper side of the tubing, dispersed by shaking in 0.85% (w/v) NaCl, and centrifuged at 10 000 *g* for 30 min. Washing and centrifugation were repeated twice. Alternatively, bacteria were grown in shake culture (100 rpm) in nutrient glycerol broth or in King's medium B (21) to late log phase (after ca. 72 h at 26°C). The cells were harvested by centrifugation and washed three times with 0.85% (w/v) NaCl. Harvested cells from both solid and liquid cultures were frozen at –40°C and lyophilized.

Preparation of cellular lipopolysaccharides

Dry cells of *P. savastanoi* ITM 317 (1.83 g), obtained from colonies grown on nutrient glycerol agar solid culture, were suspended in 27 mL of distilled H_2O and extracted with phenol according to the conventional procedure (22). The resulting aqueous phase was dialyzed (cutoff 12 000 – 14 000) for 2 days. Contents of the tube were lyophilized; the residue was dissolved in distilled H_2O (40 mL) and brought to 1.5% (w/v) NaCl and 1.5% (w/v) Cetavlon (hexadecyltrimethylammonium bromide) while stirring at room temperature for 10 min. This mixture was then centrifuged and the supernatant was mixed with 10 volumes of 95% EtOH and left overnight at –20°C. The resulting precipitate was collected by centrifugation, dissolved in distilled H_2O, and dialyzed as described above. The contents were lyophilized to yield "crude" LPS (140 mg).

When the same procedure was used to extract the LPS from *P. savastanoi* strain ITM 519 (2.16 g, dry weight) and strain PVF5 (1.54 g), grown on King's medium B and on solid culture, respectively, 96 and 29 mg of "crude" LPS were obtained.

Purification of LPS (23)

Crude LPS samples (134 mg of ITM317, 80 mg of ITM519, and 20 mg of PVF5) were purified by chromatography on Bio-Gel A15m (Bio-Rad). The column (2.5 × 50 cm) was equilibrated and eluted with 300 mM triethylamine (TEA) neutralized to pH 7 with HCl. The samples were dissolved in a solution of 300 mM TEA and 10 mM EDTA,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

adjusted to pH 7 with HCl prior to application to the column. Two-millilitre fractions were collected and monitored for hexose, KDO (24), and UV absorbance at 260 and 280 nm. Fractions containing both hexose and KDO were combined, dialyzed against distilled water for 1 week, and lyophilized to yield purified LPS (95 mg from ITM317, 58 mg from ITM519, and 16 mg from PVF5).

Isolation of the O-chain

The polysaccharide O-chain was obtained by hydrolysis of the purified ITM317 LPS (95 mg) in 23 mL of 1 N AcOH in a sealed tube for 3 h at 110°C. After cooling, the sample was centrifuged at 4000 *g* for 25 min. The supernatant liquid was adjusted to pH 5 with pyridine, evaporated to 6.5 mL in vacuo, and applied to a 2.5 × 50 cm Sephadex G-50 column. The sample was eluted with pyridine acetate buffer at pH 4.26, at a flow rate of 20 mL/h. The fractions (2 mL/tube) were analysed for hexose and KDO. The high molecular weight carbohydrate fractions (O-chain) were combined, lyophilized, and then applied to a Sephadex G-100 column (2.5 × 100 cm), eluting with pyridine acetate buffer at pH 4.26. The LPS of ITM519 (58 mg) and of PVF5 (10 mg) were hydrolysed with 16 mL and 3 mL of 1 N AcOH, respectively, and chromatographed as above. The carbohydrate-containing fractions in the included volume were combined, dialyzed, and lyophilized, yielding 26 mg ($[\alpha]_D$ +6.5 (*c* 0.4, H_2O, r.t.)) for ITM317, 28 mg for ITM519, and 6 mg for PVF5.

The molecular weight for the ITM519 and ITM317 O-chains was estimated to be 53 000 Da by gel filtration on a Bio-Gel P-100 column (50 mM NaOAc, pH 5.2), calibrated with dextran standards.

Hydrolysis of native and methylated materials (25)

A sample (1 mg) of the ITM317 native O-chain was suspended in 200 μL of 2 M H_2SO_4. Glacial AcOH (1.8 mL) was added and the solution was heated at 100°C for 9 h (sealed tube). After removal of AcOH by repeated codistillations with water in vacuo, H_2SO_4 was neutralized by the addition of water (1 mL) and $BaCO_3$ (120 mg). The slurry was centrifuged and the supernatant solution was filtered through at C_{18} Sep-Pak. $NaBD_4$ (5 mg) was added to the filtrate and the mixture was left for 1 h at room temperature. After evaporation of H_2O, the sample was acetylated with pyridine/Ac_2O (1:2 v/v, 20 min at 120°C). Methanol and then toluene were added. After evaporation in vacuo, alditol acetates were extracted with CH_2Cl_2 from the residue.

GLC–MS and GLC analysis of the sample revealed the presence of Fuc3NAc (26) and rhamnose in the ratio of ca. 1:3.5.

A sample of the ITM317 native O-chain (1 mg) was methylated (see General) and then treated as above. GLC–MS and GLC analysis gave 2,4-di-*O*-methylrhamnose, 4-*O*-methylrhamnose, and 3,6-dideoxy-2,4-di-*O*-methyl-3-*N*-methylacetamidogalactose.

The same procedures were used for the ITM519 and PVF5 samples and gave results identical with those from ITM317.

A sample of the ITM317 native O-chain (6 mg) was hydrolysed with 2 M H_2SO_4 as above. Paper chromatography (see General) of the crude yielded L-rhamnose (3.5 mg), $[\alpha]_D$ +9 (*c* 0.3, H_2O, r.t) (lit. $[\alpha]_D$ (9): +8.9).

Inoculation of plants

LPS from strain ITM317 was dissolved in distilled water at 50°C and the solution was mixed with viable cells of strain ITM519 (2×10^7 cells/mL) to obtain final concentrations of 40 μg/mL (an amount obtained from about 8.9×10^8 whole bacteria) and 80 μg/mL bacterial suspension. The purified LPS bacterial cells were injected into oleander leaves separately: first LPS and 15 min later ITM519. Control leaves were inoculated with LPS, ITM519, ITM317, and distilled water.

Received January 7, 1994

BOZENA BORECKA, T. STANLEY CAMERON, M. AZAD MALIK, and BARRY C. SMITH. Can. J. Chem. **72**, 1844 (1994).

Aryltellurium(IV) trichlorides react with 3-methyl-1-cyclohexene to give aryl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichlorides. The X-ray crystal structure of *p*-anisyl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichloride is reported. Single crystals of *p*-$MeOC_6H_4$(*trans*-2-Cl-*trans*-3-MeC_6H_9)$TeCl_2$ are triclinic, space group $P\bar{1}$ (No. 2) with a = 10.419(2) Å, b = 10.906(3) Å, c = 8.285(3) Å, α = 92.40(3)°, β = 95.85(2)°, γ = 61.71(3)°, V = 824.6 Å^3, D(calcd) = 1.761 g cm^{-1} for Z = 2. The structure was refined to R = 0.0444 (R_w = 0.0458).

BOZENA BORECKA, T. STANLEY CAMERON, M. AZAD MALIK et BARRY C. SMITH. Can. J. Chem. **72**, 1844 (1994).

Les trichlorures d'aryltellure(IV) réagissent avec le 3-méthylcyclohex-1-ène pour donner des dichlorures d'aryl(*trans*-2-chloro-*trans*-3-méthylcyclohexan-1-yl)tellure(IV). Faisant appel à la diffraction des rayons X, on a déterminé la structure cristalline du dichlorure de *p*-anisyl((*trans*-2-chloro-*trans*-3-méthylcyclohexan-1-yl)tellure(IV). Les cristaux uniques du *p*-$MeOC_6H_4$(*trans*-2-Cl-*trans*-3-MeC_6H_9)$TeCl_2$ sont tricliniques, groupe d'espace $P\bar{1}$ (No. 2) avec a = 10,419(2), b = 10,906(3) et c = 8,285(3) Å, α = 92,40(3), β = 95,85(2) et γ = 61,71(3)°, V = 824,6 Å^3, D(calcd) = 1,761 g cm^{-1} pour Z = 2. On a affiné la structure jusqu'à des valeurs de R = 0,0444 et R_w = 0,0458.

[Traduit par la rédaction]

Introduction

Aryltellurium(IV) trichlorides behave as polar aryldichlorotellurium(IV) chlorides in addition reactions with cycloalkenes (1, 2). The X-ray crystal structures of *p*-tolyl(*trans*-2-chloro-1-cyclohexyl)tellurium(IV) dichloride (3) and *p*-anisyl(*trans*-2-chloro-1-cyclohexyl)tellurium(IV) dichloride (unpublished results) establish that tellurium has a pseudo trigonal bipyramidal configuration with chlorines occupying axial positions and aryl and cyclohexyl carbons occupying equatorial positions. The cyclohexyl groups have chair conformations with tellurium and chlorine in adjacent equatorial positions.

It is shown here that aryltellurium(IV) trichlorides undergo addition reactions with 3-methyl-1-cyclohexene to give aryl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichlorides. A reaction mechanism is proposed. The structure of *p*-anisyl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichloride has been determined by X-ray crystallography.

Experimental

A mixture of *p*-anisyltellurium(IV) trichloride (4) (2.00 g, 5.9 mmol) and 3-methyl-1-cyclohexene (0.58 g, 6.0 mmol) in chloroform (40 cm^3) was boiled under reflux (2 h). Some dark green decomposition products were removed by filtration. The yellow filtrate was shaken with charcoal and refiltered. The colourless filtrate was evaporated gently under reduced pressure. The transparent viscous residue crystallised from light petroleum (bp 40–60°C) to give colourless *p*-anisyl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichloride (1.30 g, 3.0 mmol, 51%), mp 105–106°C. Other aryl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichlorides were prepared similarly in chloroform or carbon tetrachloride although reactions of 3,5-dimethoxylphenyltellurium(IV) trichloride gave better yields in diethyl ether. Yields, mps, and analytical data are summarised in Table 1. NMR spectra were recorded on a Varian VXR 400 spectrometer.

Data collection

A suitable crystal of *p*-anisyl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichloride was mounted on a glass fibre. An Enraf-Nonius CAD4 was used to measure the unit cell dimensions and collect data. The crystal and data collection parameters are listed in Table 2. The unit cell constants were obtained by least squares analysis of the diffractometer setting angles of 25 well centered reflections in the range 2θ = 30–36°. The intensities were reduced to a standard scale using routine procedures (5). Lorentz and polarisation corrections were applied and absorption corrections (6) were performed. Scattering factors for neutral atoms (7, 8) were corrected for the real part of anomalous dispersion. All calculations and refinements were performed with TEXSAN (5).

Lattice parameters	a = 10.419(2) Å b = 10.906(3) Å c = 8.285(3) Å α = 92.40(3)° β = 95.85(2)° γ = 61.71(2)° V = 824.6(9) Å^3
Space group	$P\bar{1}$ (#2)
Z value	2
D_{calcd}	1.761 g/cm^3
F_{000}	428
$\mu_{(MoK\alpha)}$	22.88 cm^{-1}

(*B*) Intensity measurements

Diffractometer	Enraf-Nonius CAD-4
Radiation	MoKα (λ = 0.70926 Å)
Temperature	18°C
Attenuator	Zr foil, (factor = 19.0)
Take-off angle	2.8°
Detector aperture	2.0–2.5 mm horizontal 2.0 mm vertical
Crystal to detector distance	21 cm
Scan type	w–2θ
Scan rate	1.6–3.3°/min (in ω)
Scan width	(1.00 + 0.35 tan θ)°
$2\theta_{max}$	49.8°
No. of reflections measured	Total: 3102 Unique: 2885 (R_{int} = 0.031)
Corrections	Lorentz-polarization Absorption (trans. factors: 0.645–1.0) Decay (–21.00% decline)

Structural analysis and refinement

The cell dimensions and lack of systematically absent reflections confirmed the space group as $P\bar{1}$. The position of tellurium was determined from a Patterson map and the remaining non-hydrogen atoms were located in subsequent difference-Fourier syntheses. The structure was refined initially by a full-matrix least-squares procedure with independent isotropic temperature factors on the atoms. Absorption corrections were then applied (6). Hydrogen atoms were placed in their geometrically calculated positions, d(C—H) 0.95 Å and were not refined. The final refinements with anisotropic temperature factors on the non-hydrogen atoms and individual isotropic temperature factors on the hydrogen atoms gave R = 0.0455 and R_w = 0.0458 (on full data R = 0.0556). A full-matrix least-squares method was employed. The function minimised was $\Sigma w(|F_o| - |F_c|)^2$ where w is the weight. The details are given in Table 3. No correction for extinction was applied. The final difference map had no recognisable residual features other than several peaks of approximately 1 e Å^{-3} near tellurium. Figure 4 was produced with ORTEP (9).

Results and discussion

Aryltellurium(IV) trichlorides, $ArTeCl_3$(Ar = p-$MeOC_6H_4$, p-$EtOC_6H_4$, 2,4-$(MeO)_2C_6H_3$, 3,4-$(MeO)_2C_6H_3$, and 3,5-Me_2-4-HOC_6H_2), undergo addition reactions with a slight excess of 3-methyl-1-cyclohexene in boiling organic solvents. The products are identified as aryl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichlorides.

TABLE 3. Experimental details of structure solution and refinement

Structure solution	Patterson
Refinement	Full-matrix least-squares
Function minimized	$\Sigma w (\|F_o\| - \|F_c\|)^2$
Least-squares weights	$4F_o^2/\sigma^2(F_o^2)$
p-factor	0.03
Anomalous dispersion	All non-hydrogen atoms
No. observations ($I > 3.00\sigma(I)$)	2000
No. variables	172
Reflection/parameter ratio	11.63
Residuals: R; R_w	0.0455; 0.0458
Goodness-of-fit indicator	2.708
Maximum shift/error in final cycle	0.00
Maximum peak in final diffraction map	1.164 e$^-$/Å^3
Minimum peak in final diffraction map	–1.390 e$^-$/Å^3

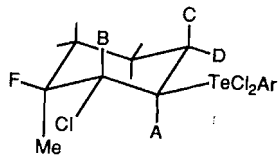

FIG. 1. Diagramatic representation of aryl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichlorides with letters A to D and F assigned to five hydrogen atoms.

NMR spectra

Letters are assigned to five cyclohexyl hydrogens in Fig. 1 in order to assist discussion of the proton spectra of aryl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichlorides.

The hydrogens that were alkenic originally appear as well-resolved multiplets. The cyclohexyl H-CTe protons (A) appear as a triplet through coupling with two adjacent *trans*-axial protons B and C, ^3J ca. 12 Hz, that is split further into doublets by the *cis*-equatorial proton D, ^3J ca. 5 Hz. The chemical shifts of H—CTe (A) protons show a greater dependence on aryl group and their signals are at higher field than those of cyclohexyl H—CCl (B) protons which appear as doublets of doublets through coupling with only one *trans*-axial proton A and one *cis*-equatorial proton F, ^3J(B—F) ca. 5 Hz. Coupling is not observed with protons from the C-methyl group (that replaces axial hydrogen E) which appear as a doublet near δ 1.2 ppm, ^3J ca. 7 Hz, through coupling with geminal proton F. The cyclohexyl A and B signals from *p*-anisyl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichloride are reproduced in Fig. 2. Chemical shifts and coupling constants for cyclohexyl A and B protons in five aryl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichlorides are summarised in Table 4. Coupling constants are at the high end of the expected range (2, 10). These patterns establish that tellurium and chlorine occupy adjacent *trans*-equatorial positions in solution whereas methyl has an axial position that is *cis* to chlorine.

The proton signals of cyclohexyl methylene groups, aryl groups, and alkyl, alkoxy, and hydroxy substituents resemble those of corresponding aryl(*trans* 2-chloro-1-cyclohexyl)tellurium(IV) dichlorides (2).

Aryl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium-

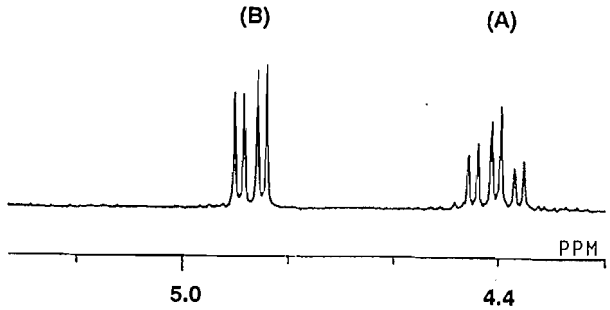

FIG. 2. Proton NMR spectrum at 400 MHz of axial H—CTe (A) and H—CCl (B) protons of *p*-anisyl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichloride in C_6D_6.

(IV) dichlorides show carbon-13 NMR carbon-tellurium signals near δ 70 ppm relative to TMS and carbon—chlorine signals near δ 65 ppm. Methyl, methoxy, and six cyclohexyl carbons appear upfield and aryl carbons appear downfield with identical carbons showing signals of higher intensity.

Mechanism

The proposed mechanism is illustrated in Fig. 3. 3-Methylcyclohexene has a semi-chair conformation with methyl occupying an equatorial position in solution. Cationic aryldichlorotellurium(IV) reacts to form a bicyclo[4.1.0]heptane intermediate with cyclic telluronium and methyl on opposite sides of the cyclohexyl ring. Ring opening through bimolecular nucleophilic attack by chloride occurs at carbon with an axial hydrogen as predicted by the Furst–Plattner rule (see, for example, ref. 11). The conformationally unstable intermediate shown in square brackets is formed by Walden inversion of an approximately linear chloride—carbon—tellurium transition state. Ring-inversion leads to the favoured chair form of aryl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium-(IV) dichloride having chlorine and bulky $TeCl_2Ar$ groups in equatorial positions and methyl in an axial position. Complete selectivity is achieved. No other cyclohexyltellurium derivatives were observed despite a thorough search of all the samples.

Crystal structure

The structure of *p*-anisyl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichloride is shown in Fig. 4. Positional parameters and isotropic temperature factors are given in Table 5. Interatomic distances and angles are listed in Tables 6 and 7. Anisotropic temperature factors for non-hydrogen atoms are given in Table 8 (deposited).[1]

[1]Copies of material on deposit can be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, ON K1A 0S2, Canada.

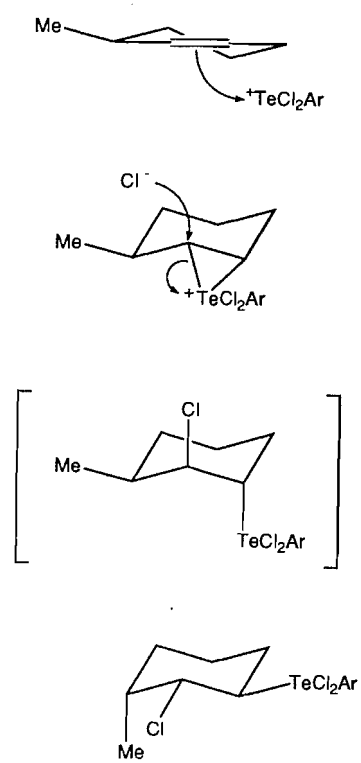

FIG. 3. Proposed scheme for reactions of aryltellurium(IV) trichlorides with 3-methylcyclohexene.

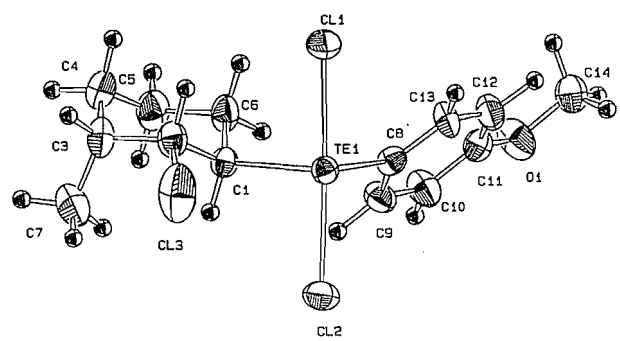

FIG. 4. X-ray crystal structure of *p*-anisyl(*trans*-2-chloro-*trans*-3-methyl-1-cyclohexyl)tellurium(IV) dichloride.

Tellurium has the expected pseudo trigonal bipyramidal configuration with two chlorines in axial positions, two carbon rings in equatorial positions, and the lone pair of electrons of tellurium in the third equatorial position. Internuclear distances within the co-ordination sphere are as follows: Te(1)—Cl(1)

C2	C3	C7	114.7(9)				

2.485(2), Te(1)—Cl(2) 2.503(2), Te(1)—C(1) 2.194(7), Te(1)—C(8) 2.101(7) Å. The bond lengths agree well with values reported earlier (3, 12) with Te—C(alkyl) longer than Te—C(aryl). The Cl(1)—Te(1)—Cl(2) bond angle of 176.39(7) is smaller than 180°, and the C(1)—Te(1)—C(8) bond angle of 100.7(3) is smaller than 120°, presumably because of the presence of nonbonding electrons on tellurium. The cyclohexyl ring adopts the usual chair conformation with tellurium and chlorine in adjacent equatorial positions but with methyl in an axial position.

Two series of 2,4,6-triphenylverdazyls substituted at the C(3) position of the heterocyclic ring are obtained using new convenient synthetic methodology. Thus, crown ether assisted solid–liquid phase-transfer catalysis promotes the formation of 3-*n*-alkyl-substituted 2,4,6-triphenylverdazyls in the reactions of 1,3,5-triphenylformazan with *n*-alkyl bromides. Under PTC conditions, methylation of 3-(4-nitrophenyl)-1,5-diphenylformazan with methyl iodide exclusively gives the corresponding verdazyl radical. 3-Substituted 2,4,6-triphenylverdazyls containing various di(cyclo)alkylamino moieties at the C(3) position of the verdazyl ring are prepared by the reaction of 1,3,5-triphenylformazan with the corresponding 1-[*N*,*N*-di(cyclo)alkylaminomethyl]benzotriazoles under the efficient catalysis of barium hydroxide monohydrate. Sonication of this reaction allows the yields of the verdazyls to be substantially increased. A bis-verdazyl *N*,*N*-bonded in the C(3) positions was synthesized. All the radicals obtained were characterized by microanalysis, and by UV–visible and ESR spectroscopy.

ALAN R. KATRITZKY, SERGEI A. BELYAKOV, H. DUPONT DURST, RUIXIN XU et NARESH S. DALAL. Can. J. Chem. **72**, 1849 (1994).

Faisant appel à une nouvelle méthodologie de synthèse, on a obtenu deux séries de 2,4,6-triphénylverdazyles substitués en position C(3) de l'hétérocycle. La catalyse par transfert de phase solide–liquide assistée par un éther-couronne favorise la formation des 3-*n*-alkyl-2,4,6-triphénylverdazyles lors des réactions des 1,3,5-triphénylformazane avec des bromures de *n*-alkyles. Dans des conditions de transfert de phase, la méthylation du 3-(4-nitrophényl)-1,5-diphénylformazane par l'iodure de méthyle conduit uniquement au radical verdazyle correspondant. On a préparé des 2,4,6-triphénylverdazyles substitués par des portions di(cyclo)alkylamino en position (C)3 du cycle verdazyle en faisant réagir du 1,3,5-triphénylformazane avec les 1-[*N*,*N*-di(cyclo)alkylaminométhyl]benzotriazoles correspondants en présence de monohydrate d'hydroxyde de baryum comme catalyseur efficace. La sonication de cette réaction permet d'obtenir des rendements beaucoup plus élevés de verdazyles. On a synthétisé un bis-verdazyle lié aux positions C(3) par deux N. On a caractérisé tous les radicaux obtenus par des microanalyses, des spectres UV–visible et par spectroscopie RPE.

[Traduir par la rédaction]

Introduction

Verdazyls (1,2,3,4-tetrahydro-*s*-tetrazin-1-(2*H*)-yls), discovered by Kuhn and Trischmann (1, 2) represent a class of extraordinarily stable free radicals, in which the stability is enhanced by an extensive symmetrical delocalization of the unpaired electron. Only five atoms of the *s*-tetrazine ring participate in the delocalization of spin density, while the C(3) atom is generally believed to be excluded from the conjugated system (3). Based on this principle, one could expect that substituents at the C(3) atom of the heterocycle would not affect the properties of verdazyls. However, the properties of radicals in this series, especially their spectral characteristics, vary widely depending on the number (none, one, or two) and type (alkyl, alkenyl, alkynyl, aryl, oxo, amino, etc.) of the C(3) substituents (3).

Efficient methods for the preparation of the C(3)-substituted verdazyls include: (*i*) reaction of formazans with aliphatic aldehydes in acidic media followed by reduction of the intermediate verdazylium cations, and (*ii*) alkylation of formazans by primary alkyl halides in DMF in the presence of base. The latter is followed by two consecutive reactions: cyclization of the *N*-alkylformazan intermediates, and dehydrogenation of the cyclized leuco-verdazyls, frequently by atmospheric oxidation (2). Method (*i*) is more useful for the preparation of formazans with strongly electron-withdrawing substituents (O.M. Polumbrik, personal communication), but its applicability is limited to aliphatic aldehydes unbranched at the α-carbon atom (e.g., formaldehyde, acetaldehyde, and propionaldehyde), and it fails for aromatic aldehydes (3). Method (*ii*) is more general but has the significant disadvantage that a large excess of alkylating agent is required, which leads to alkylation of the intermediate tetrahydro-*s*-tetrazine (leuco-verdazyl) as a side reaction (2). For triarylformazans containing strongly electron-withdrawing substituents such as nitro groups in the phenyl rings, this side reaction predominates, and verdazyls of this type cannot be obtained by this method (4).

The alkylation of formazans is also limited to reactive electrophiles as reaction partners. Primary alkyl iodides have been used in most cases, although activated bromides such as propargyl (5) or benzyl bromide (1, 2) have also been utilized. These reactions generally require 6–12 h to reach completion (2). The successful use of *n*-alkyl bromides has not been described previously.

3-[*N*,*N*-Di(cyclo)alkylamino]-substituted verdazyls differ from the other verdazyls due to their unique chemical and physico-chemical properties, which include anomalous reaction with acids, enhanced solubility, and unusual spectral characteristics (5, 6). The reaction of formazans with formaldehyde and secondary alkyl or cycloalkyl amines has remained the primary

method employed for their preparation (5) and can be classified as a variation of method (*ii*), i.e., Mannich-type alkylation of the formazan N—H group in the presence of base (barium oxide/barium hydroxide mixture). Unfortunately, this reaction requires a large excess of both formaldehyde (in the form of paraformaldehyde) and of the secondary amine. Moreover, the reaction is slow (in most cases 12–24 h) and, despite this, still gives poor yields (<16%). Only a few cyclic *sec*-amines were employed to obtain the 3-*N*-cycloalkylaminoverdazyls, and no 3-*N,N*-dialkylaminoverdazyls were isolated; it was mentioned, however, that open-chain *sec*-amines can react in a similar way (5).

The only other reported route to 3-*N,N*-dialkylaminoverdazyls involves the reaction of 1,3,5-triphenylformazan, *N,N,N′,N′*-tetramethyldiaminomethane, and paraformaldehyde in DMF (6). The latter two reagents apparently react with traces of water to give, initially, dimethylaminomethanol. Subsequent aminoalkylation leads to the 3-(*N,N*-dimethylamino)-2,4,6-triphenylverdazyl in 32% yield. However, the starting bis-(dialkylamino)methanes required for this method are not always easy to prepare, and the yield of radicals is only moderate.

One important general feature of the previous studies dealing with method (*ii*) is that a mixture of BaO and $Ba(OH)_2 \cdot 8H_2O$ is usually employed as the base, typically with a large excess of BaO (2, 4), while $Ba(OH)_2 \cdot 8H_2O$ is used in only catalytic amounts. Presumably, during the reaction, dehydration of the $Ba(OH)_2 \cdot 8H_2O$ by BaO occurs due to the latter's strong hydrophilic nature, but this is uncertain since both bases are insoluble in DMF. As shown by Sinisterra and co-workers, a modified barium hydroxide catalyst, C-200, which contains 80% $Ba(OH)_2 \cdot H_2O$ and 20% anhydrous BaO, is a versatile reagent for various organic reactions, and has found application in Michael additions (7), Claisen–Schmidt condensations (8), and the Wittig–Horner reaction (9). The superior catalytic activity of C-200 in comparison with $Ba(OH)_2 \cdot 8H_2O$ was indicated by the improved yields noted in the Michael addition of diethyl malonate to chalcone (7), the Horner reaction of furfural with triethyl phosphonoacetate (9), and also by the decrease in yield observed when the C-200 active sites were selectively poisoned (7). The two-step mechanism postulated for reactions of C-H active compounds in the presence of barium hydroxide (7) involves the adsorption of the substrate and formation of the corresponding carbanion at the active site of the catalyst. This is followed by the surface reaction of the adsorbed carbanion, i.e., reaction occurs at the solid–liquid interface.

It is also well known that reactions at solid–liquid interfaces are promoted by crown ethers (10) (solid–liquid phase-transfer catalysis, PTC). As established earlier (11), crown ethers are the preferred catalysts for solid–liquid PTC. Dicyclohexano-18-crown-6 (DC18C6) is one of the most widely used crown ethers for this purpose (10).

We have now found that the preparation of two series of 3-substituted verdazyls, 3-(*n*-alkyl)- and 3-[*N,N*-di(cyclo)alkylamino]-2,4,6-triphenylverdazyls, is significantly improved by the use of barium hydroxide monohydrate as an active catalyst. 3-(*n*-Alkyl)-2,4,6-triphenylverdazyls were prepared employing the $Ba(OH)_2 \cdot H_2O$/DC18C6 system in place of the earlier used combination of $BaO/Ba(OH)_2 \cdot 8H_2O$ in the alkylation of formazans by alkyl halides. This now permits the use of the *n*-alkyl bromides as alkylation substrates in the preparation of the 3-(*n*-alkyl)-2,4,6-triphenylverdazyls, thus circumventing the shortcomings of the previous procedures. Moreover, we found that the reaction of 1,3,5-triphenylformazan with 1-[*N,N*-di(cyclo)-alkylaminomethyl]benzotriazoles in DMF in the presence of $Ba(OH)_2 \cdot H_2O$ at ambient temperatures leads smoothly to 3-[*N,N*-di(cyclo)alkylamino]-2,4,6-triphenylverdazyls in yields of 37–69%. The limitations of the earlier routes are now effectively overcome by the use of Mannich reactants with preformed stoichiometry. In comparison with previous methods, our approach provides improved yields of verdazyls, and shortens reaction times.

Results and discussion

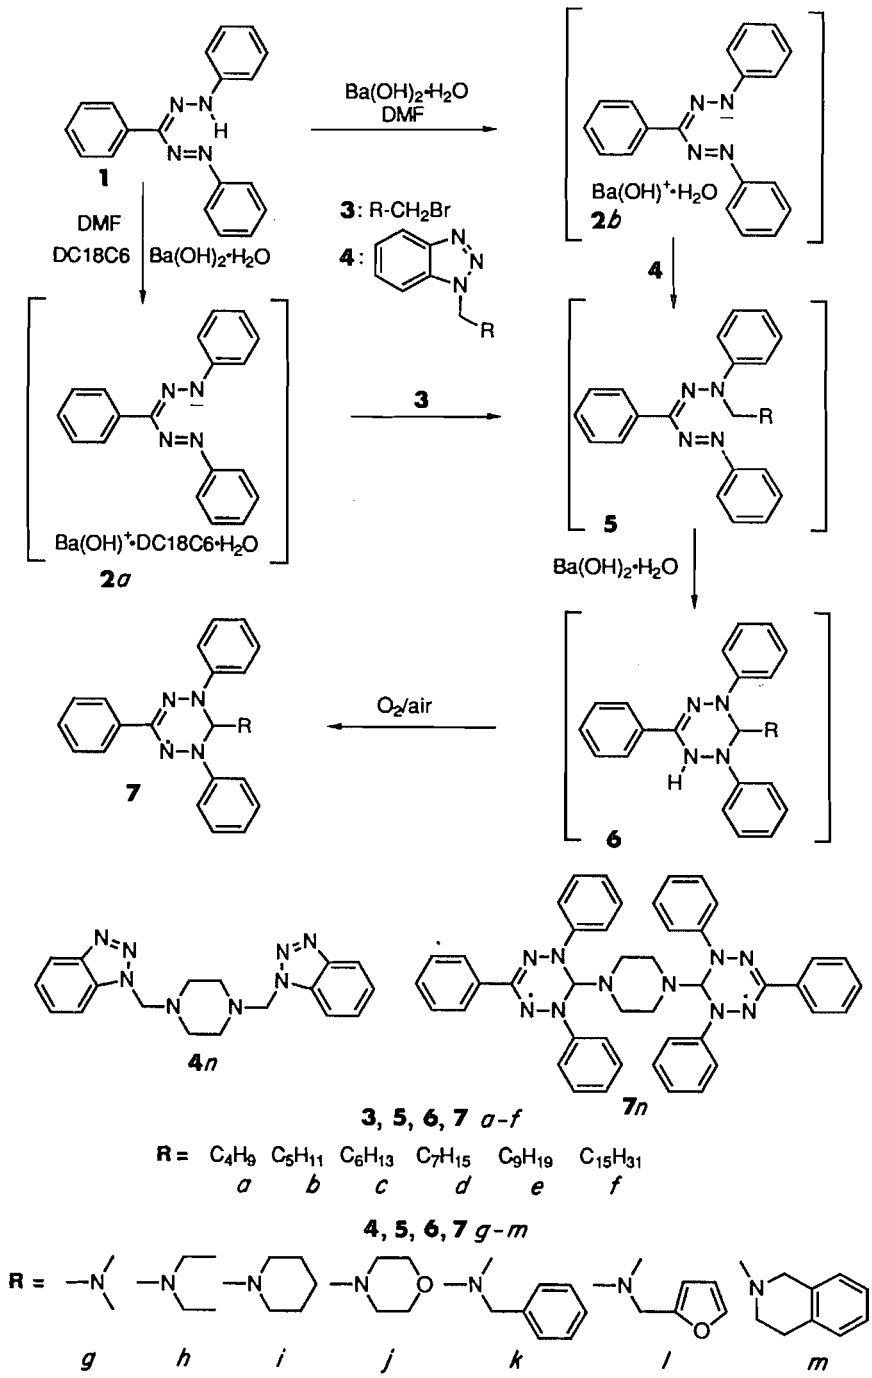
A possible general reaction sequence for these transformations is shown in Scheme 1. It includes the formation of formazan anions **2***a*, *b*, but by two different ways: in the case of our preparation of 3-*n*-alkylverdazyls the reaction occurs in the solution by crown-assisted transfer of anion **2***a* into the organic phase (solid–liquid PTC), while anion **2***b* is formed directly on the surface of the barium catalyst. After alkylation of the anions **2***a*, *b* by alkyl bromides **3**, or by Mannich bases **4**, respectively, the *N*-alkylformazans **5** are spontaneously cyclized into leucoverdazyls **6**. In situ oxidation of the latter finally gives the 3-substituted verdazyls **7**.

1. Syntheses of 3-(n-alkyl)-2,4,6-triphenylverdazyls 7a–f

Formazans, by virtue of their ability to react with both strong acids and bases, can be considered as amphoteric. In strongly acidic conditions they form formazanium cations (12), whereas in basic media they apparently give rise to the anionic species by loss of the acidic NH proton. This anion formation takes place at the surface of barium hydroxide, as does the subsequent alkylation. The catalyst's effectiveness decreases with time as the result of the elimination of hydrogen halide, which poisons the catalyst. Due to the heterogeneous character of the interaction, the reaction rate is low, and requires a large excess of $BaO/Ba(OH)_2 \cdot 8H_2O$ (10–15 mol/mol of formazan) and alkyl halide (ca. 30–40 mol/mol of formazan) (2).

It was anticipated that the transfer of the reaction into the liquid phase would accelerate the reaction. Crown ethers and solid bases (carbonates or hydroxides of alkaline or alkaline earth metals) in solid–liquid PTC form cation-complexed ion pairs (11), which are soluble in the organic phase in which the reaction occurs (10). No precise data for the solid–liquid phase transfer of barium hydroxides by DC18C6 are yet available. However, the ionic radius of Ba^{2+} fits the DC18C6 cavity very well (13), and the stability of the complex DC18C6:Ba^{2+} is quite high ($\log K > 5$; enthalpy of complex formation in acetonitrile, $\Delta H = -48.1$ kJ mol^{-1} (14)). At the same time, DC18C6 shows little or no interaction with the solvent molecules, which assists successful phase transfer (14). Indeed, DC18C6 was found to be an effective ligand for selective transport of Ba^{2+} in a competitive system (Mg^{2+}, Ba^{2+}, Ca^{2+}) from a chloroform liquid membrane system when crown ether cooperatively acts with *n*-alkanoic acids (15). DC18C6 also efficiently extracts barium nitrate (16) and barium picrate (17) from neutral solutions into chloroform. Recently the transfer process of KOH into a toluene phase through solid phase KOH in the presence of DC18C6 was described (18). Considering the similar ionic radii of K^+ and Ba^{2+} cations (13), it might be possible to use DC18C6 for the interfacial transfer of barium hydroxide.

In our case (Scheme 1), when a mixture of formazan **1**, $Ba(OH)_2 \cdot H_2O$, and DC18C6 in DMF was stirred for several



SCHEME 1

minutes, the color changed from red to crimson. This apparently indicates the formation of a soluble complex **2***a* that owes its deep color to its ionic character. Addition of an *n*-alkyl bromide leads to the *N*-alkylformazan **5**, and to the liberation of the DC18C6·Ba(OH)Br complex. Since the cyclization of **5** to leuco-verdazyl **6** occurs rapidly in the presence of strong bases, thermally, or in the presence of acids (4), we found that heating the mixture smoothly led to the leuco compound **6**, which, in turn, was oxidized to verdazyl **7** by passing a stream of air through the reaction medium. The consecutive nature of the reaction leads to various concentrations of *N*-alkylformazan **5**, leucoverdazyl **6**, and radical **7**. The presence of oxygen, however, prevents the undesirable formation of *s*-tetrazine anion from **6** by means of its reaction with the catalytic complex. This anion could otherwise be easily alkylated to give the side product, *N*-alkyl-*s*-tetrazine.

As was noted earlier (10), the presence of a small amount of water is very important in solid–liquid PTC; moreover, in some reactions involving the participation of C-200 barium hydroxide catalyst, a small amount of water must be added to the reaction mixture to increase the reaction rate to an acceptable level (9). Although the role of water in both cases is not clear, its presence is probably also important in the alkylation of formazans, and as such the addition of BaO (a strong dehydrating agent) is not necessary.

The reversibility of DC18C6 in the present procedure is illus-

trated in Scheme 2. The ion pair formed on the surface of $Ba(OH)_2 \cdot H_2O$ from the latter and formazan (For-H) is transferred into the liquid phase by DC18C6. The reaction proceeds in the solution. After alkylation, a complex of barium hydroxybromide with DC18C6 can either free the crown ether (thus involving it again in the catalytic cycle) or react to include another molecule of formazan in the catalytic alkylation process.

We have used this modified method to obtain in good yields a series of new 3-(*n*-alkyl)-2,4,6-triphenylverdazyls. All the verdazyls obtained (Table 1) form deeply colored (dark-green) crystals. Their melting points steadily decrease as the number of CH_2 units in the alkyl substituent increases. The spectral properties of the radicals are collected in Table 2.

The UV–VIS spectra of verdazyls **7***a–f* exhibit absorption bands typical for this class of compounds: (*i*) two intense bands with maxima at 285 and 320 nm in the UV region, (*ii*) two almost equal in intensity and wavelength (near 405 and

For personal use only.

425 nm), and (*iii*) one long-wave band responsible for the deep green color of such radicals (near 720 nm). This set of bands is characteristic for π–π^* transitions of a highly conjugated chromophoric chain. As expected, the length of the substituent at the C(3) atom of the heterocycle, which is not involved in the conjugation, exerts only minor influence on the position of the long-wave maximum.

Crystalline samples of the radicals **7***a–f* exhibited intense, single-peak, ESR spectra centered at the *g*-value of 2.0032 ± 0.0002 with a signal bandshape of Lorentzian form, as expected for concentrated free radical samples. The linewidth between points of maximum slope, ΔH_s, is quite narrow, varying from 1.41 to 2.03 G depending on the length of alkyl chain in radicals **7***a–f*. This indicates a strong exchange interaction between the unpaired electrons. ESR spectra of **7***a–f* obtained in well-degassed (10^{-4} Torr; 1 Torr = 133.3 Pa) benzene or hexane showed the nine-peak hyperfine patterns usual for verdazyls in the intensity ratio of 1:4:10:16:19:16:10:4:1, with an average spacing of approximately 5.75 G, in agreement with earlier studies (3).

Our modified method was also successfully used to obtain 6-(4-nitrophenyl)-2,4-diphenylverdazyl (**8**). As previously shown (4), alkylation of 3-(4-nitrophenyl)-1,5-diphenylformazan by methyl iodide in the presence of $BaO/Ba(OH)_2 \cdot 8H_2O$ in DMF led exclusively to 1-methyl-6-(4-nitrophenyl-1,2,3,4-tetrahydro-*s*-tetrazine. Radical **8** was obtained in 70% yield after a short reaction time with a small excess of the alkylating agent.

2. *Syntheses of 3-[N,N-di(cyclo)alkylamino]-2,4,6-triphenylverdazyls 7g–n*

Initial attempts to synthesize 3-(benzotriazol-1-yl)-2,4,6-triphenylverdazyl by the reaction of 1,3,5-triphenylformazan with 1-hydroxymethylbenzotriazole in both acidic and neutral media gave only 2,4,6-triphenylverdazyl. The well-known lability of the N—CH_2 bond in 1-hydroxymethylbenzotriazole and the leaving-group character of benzotriazole suggested the possible aminoalkylation of formazans (i.e., **1**) with benzotriazolyl derivatives **4**.

When amine **4**, formazan **1**, and $Ba(OH)_2 \cdot H_2O$ are stirred in DMF (Scheme 1), the *N'*-[*N,N*-di(cyclo)alkylaminomethyl]formazan, formed via aminoalkylation, immediately cyclizes into leuco-verdazyl **6** by the action of base (barium hydroxide) if heated to 60°C. Atmospheric oxygen was used to oxidize leuco compound **6** into radical **7**.

The optimum molar ratio of reagents depends on the reactivity of the amines **4** (Table 3). Dialkylamines (**7***g, h*) react more slowly than cycloalkylamines (**7***i, j*) and a larger excess of the former is required. Those dialkylamines in which the aromatic or heteroaromatic systems are connected with the carbon atom at the β position to the active methylene group show an intermediate reactivity (**7***k–m*). The same regularity is observed regarding the optimum preparative conditions. When di(cyclo)alkylamines **7***g, i, j* (**7***h* being the only exception) were employed, heating the reaction mixture for 0.5–3 h gave the corresponding leuco compounds **6** and then the radicals **7**, while in the case of **7***k–m* acceptable yields of verdazyls **7** were obtained only by extended stirring at room temperature.

1-[*N,N*-Di(cyclo)alkylaminomethyl]benzotriazoles **4** are solid compounds that can be easily prepared by a one-pot procedure from benzotriazole, formaldehyde, and the corresponding *sec*-amines in high yield (19, 20). Their use as aminoalkylation agents in Mannich-type reactions is of considerable interest because of the preformed stoichiometry between the reagents commonly used in Mannich reactions (i.e., formaldehyde and amine). Compounds **4** reversibly dissociate into iminium salts in polar solvents (21, 22), and these are the reactive entities in Mannich reactions. As shown for the case of radical **7***n*, we employed this strategy to obtain the first representative of a bis-verdazyl *N,N*-bonded in the C(3) position.

A possible mechanism of the reaction is given in Scheme 3. In the dipolar aprotic solvent (DMF) **4** exists partly in the form of the iminium salt (eq. [1]). Formazan **1** reacts with the active sites of $Ba(OH)_2{\cdot}H_2O$ to give the corresponding salt, which remains bound to the insoluble catalyst surface (eq. [2]). Subsequently, 5-(*N,N*-dialkylaminomethyl)-1,3,5-triphenylformazan **5** (formed as the result of fast ion exchange) is transferred from the interfacial reaction site into the DMF solution (eq. [3]). A further transformation of **5** into radical **7** via leuco-verdazyl intermediate **6** occurs according to the established mechanism (1). Indeed, the formation of ion–molecule pairs from **4***g–n* and the distribution of the positive charge in their structure appear to play a key role in this reaction. Attempts to use benzotriazolyl derivatives **4** in which one of the hydrogens of the active methylene group is replaced by an alkyl or aryl substituent, or in which a nitrogen atom is bound to an aromatic system (aniline, carbazole, phenoxazine, etc.), failed.

Interestingly, radicals **7***g*, *m* were also obtained in yields higher than 60% after ultrasonic treatment of the reaction mixture containing formazan **1**, the corresponding benzotriazole derivative **4**, $Ba(OH)_2{\cdot}H_2O$, and DMF. As shown by Fuentes and Sinisterra, ultrasound positively affects the Canizzaro reaction carried out in heterogeneous (solid–liquid) phase in the presence of active barium hydroxide catalyst, which contains 80% of $Ba(OH)_2{\cdot}H_2O$ (23). It was suggested that the reaction takes place by single electron transfer by means of reducing sites of the solid catalyst; in our case, however, the process is apparently accelerated by the efficient degassing of the porous cavities of the catalyst. Since the reaction occurs on the catalyst surface, the role of surface accessibility is extremely important. Ultrasound increases it by (*i*) development of the surface of catalyst by cavitation; (*ii*) cleaning the surface of the catalyst by removal of gas bubbles trapped in the pores. Thus, while the detailed mechanism and nature of this ultrasonic process remain

to be investigated, its usefulness in our procedure is quite evident.

Spectral properties of the radicals **7***g–n* are collected in Table 4. The UV–VIS absorption spectra of the radicals **7***g–n* consist of three intense bands in the UV region and three bands of lower intensity in the visible region. The presence of the highly conjugated heterocyclic system containing an odd number of π-electrons dictates the position of the first electronic transition at about 680–685 nm. The hypsochromic shift of the long-wave absorption maxima of **7***g–m* (35–40 nm) from the position of the analogous maximum in the spectrum of unsubstituted 2,4,6-triphenylverdazyl (720 nm (3)) is explained by the steric interaction of the bulky di(cyclo)alkylamino substituent at the C(3) atom with the conjugated heterocyclic ring. However, the C(3) atom only fixes the cyanine-like system (four nitrogens and one C(6) carbon) in a *cis–cis* arrangement and does not take part in the unpaired electron density transfer (3). Therefore, the change of the substituent in the structure of **7***g–m* does not strongly affect the position of their long-wave maxima. The UV–VIS spectrum of bis-radical **7***n* differs slightly from the spectra of mono-radicals **7***g–m* in the visible region (bathochromic shift of all the three maxima is about 13–15 nm).

The ESR spectra of the radicals **7***g–n* (1 mM solutions of radicals in well-degassed toluene) exhibit well-resolved nine-line patterns in the intensity ratio 1:4:10:16:19:16:10:4:1, which is typical for verdazyl radicals. The *g*-values of **7***g–n* are (2.0032–2.0033) ± 0.0002, and the hyperfine coupling constants, a_N, of the four equivalent nitrogen atoms of the verdazyl ring are between 5.46 and 5.61 G (Table 4), which is also in good agreement with the data for other verdazyls (3). It should be mentioned that a good resolution in the ESR spectra of **7***g–n* can be achieved only when their solutions are well degassed; apparently the complexation of verdazyls with the oxygen of the air is an important factor. However, the ESR spectra of the solid verdazyls were single peaks. The ΔH_s, linewidth between points of maximum slope, values of the crystalline samples of **7***g–n* vary in the range from 1.30 G (**7***g*) to 2.92 G (**7***m*) (Table 4), due to rapid electron exchange among neighboring free radical molecules.

Conclusion

The enhanced catalytic activity demonstrated by the combination of $Ba(OH)_2 \cdot H_2O$ and DC18C6 under solid–liquid phase transfer catalysis results in improved preparation of 3-(*n*-alkyl)-2,4,6-triphenylverdazyls. In addition, this reagent combination substantially decreases the quantities of base and alkylating agent required and allows the use of the more available and more stable *n*-alkyl bromides in place of the iodides. *p*-Nitrophenyl-substituted triarylverdazyls can be easily obtained by alkylation of the corresponding formazans under the conditions of solid–liquid PTC with the use of the DC18C6/$Ba(OH)_2 \cdot H_2O$ system, whereas the previous method failed due to dominating side reactions (4). On the other hand, the Mannich-type reaction of 1,3,5-triphenylformazan with 1-[*N*,*N*-di(cyclo)alkylaminomethyl]benzotriazoles in the presence of the active catalyst, $Ba(OH)_2 \cdot H_2O$, carried out in a dipolar aprotic solvent (DMF), leads to the aminoalkylation of the formazan N—H bond followed by stepwise cyclization–oxidation reactions to yield 3-[*N*,*N*-di(cyclo)alkylamino]-2,4,6-triphenylverdazyls. The aminoalkylation reaction apparently takes place on the catalyst surface, whereas cyclization and oxidation occur in the solution. Reaction is promoted by the use of ultrasound, which positively affects the catalyst surface activity and results in higher yields of radicals. By comparison with previous procedures, the present method has the advantages of rapidity, versatility, ease of scale-up, and improved yields.

Experimental

The UV–visible spectra were obtained using a Perkin–Elmer 330 spectrophotometer. Melting points were determined on a Bristoline hot-stage microscope and are uncorrected. The ESR spectra were recorded on a Bruker ER 300 spectrometer (frequency 9.5 GHz). *g*-Values were determined by utilizing a digital frequency counter, Hewlett–Packard 5420, and DPPH as a standard. Nitrogen hyperfine coupling, a_N, were measured from 1 mM solutions in benzene (**7***a–f*) or toluene (**7***g–n*), and their comparison with computer simulations. Ultrasonic treatments (methods D, E) were performed by use of the compact high-performance ultrasonic system FS3 (Fisher Scientific Co., peak output 70 W, frequency 55 kHz). Methyl iodide, *n*-alkyl bromides, and DC18C6 (mixture of *cis-syn-cis* and *cis-anti-cis* isomers) were purchased from Aldrich, $Ba(OH)_2 \cdot H_2O$ from the J.T. Baker Chemical Co., and DMF from the Fischer Scientific Co. All reagents were used as received. 1,3,5-Triphenyl- and 3-(4-nitrophenyl)-1,5-diphenylformazans were synthesized following literature procedures (24). 1-[*N*,*N*-Di(cyclo)alkylaminomethyl]benzotriazoles **4***g–m* and the corresponding bis-derivative **4***n* were prepared by known methods (19, 20). Compounds **4***g–n* were recrystallized from ethanol and gave satisfactory microanalysis data, and ^1H and ^{13}C NMR spectra.

General procedure for the preparation of verdazyls 7a–f

A mixture of triphenylformazan (1.65 mmol), DC18C6 (0.067 mmol), and $Ba(OH)_2 \cdot H_2O$ (3.30 mmol) in DMF (25 mL) was stirred vigorously for 5 min. The appropriate *n*-alkyl bromide (3.30 mmol) was added in one portion, and the mixture was heated to 60°C under stirring. After 10 min, a fast stream of air was passed through the reaction mixture with stirring and heating. Completion of the reaction was monitored by TLC (phase: silica gel; eluent: chloroform). The reaction was stopped when the TLC no longer indicated the initial red formazan (this takes usually about 1.0–1.2 h). The reaction mixture was cooled, diluted with diethyl ether (75 mL), and the solid filtered. The filtrate was washed with water (3 × 50 mL), the organic layer was separated, dried over anhydrous sodium sulphate, removed under vacuum, and the residue triturated with a mixture of petroleum ether and methanol. The solid product obtained was filtered off and washed with a mixture of petroleum ether and methanol. Analytical samples of radicals **7***a–f* were obtained after column chromatography (phase: aluminum oxide basic, Brockmann activity I; solvent/eluent:hexane).

The general procedure for the synthesis of verdazyls **7***g–n* is illustrated with reference to compound **7***g*.

3-Dimethylamino-2,4,6-triphenyl-3,4-dihydro-2H-1,2,4,5-tetrazin-1-yl (3-N,N-dimethylamino-2,4,6-triphenylverdazyl) 7g

Method A

The solid **4***g* (0.59 g, 3.32 mmol) was added to a mixture of 1,3,5-triphenylformazan **1** (0.50 g, 1.66 mmol), $Ba(OH)_2 \cdot H_2O$ (0.63 g, 3.32 mmol), and DMF (25 mL), which was initially stirred at room temperature for 5 min. The mixture was heated to 60°C under stirring, while a stream of air was passed through it. After 0.5 h the mixture was cooled, ether (30 mL) was added, and organic phase was collected by filtration. Water (50 mL) was added, and the mixture was extracted with additional ether. The organic layer was dried over anhydrous sodium sulfate, concentrated under vacuum, and the oily crude product quickly triturated with methanol (10 mL). The resulting solid was collected by filtration and recrystallized from methanol–DMF to give black-green crystals of **7***g* (0.22 g, 37%).

Method D

A mixture of **1** (0.25 g, 0.83 mmol), **4***g* (0.29 g, 1.66 mmol), $Ba(OH)_2 \cdot H_2O$ (0.31 g, 1.66 mmol), and DMF (20 mL) was placed in a

round-bottom flask and sonicated at room temperature for 2 h while immersed in a water bath. After a standard work-up procedure (see above), radical **7***g* was isolated in 63% yield.

*6-(4-Nitrophenyl)-2,4-diphenyl-3,4-dihydro-2H-1,2,4,5-tetrazin-1-yl (6-(4-nitrophenyl)-2,4-diphenylverdazyl) **8***

A mixture of 3-(4-nitrophenyl)-1,5-diphenylformazan (0.150 g, 0.43 mmol), DC18C6 (0.005 g, 0.013 mmol), and $Ba(OH)_2 \cdot H_2O$ (0.164 g, 0.86 mmol) in DMF (10 mL) was stirred for 5 min followed by addition of methyl iodide (0.054 mL, 0.86 mmol) in one portion. After 2–3 min of stirring, the mixture became brown. Stirring was continued for 15 min at room temperature (TLC no longer indicated the presence of formazan) and then for 5–7 min at 40–50°C while an air stream was passed through the mixture. After cooling, benzene (30 mL) was added, the solid was filtered off, and the filtrate was washed with water (2 × 50 mL). The organic layer was evaporated under vacuum, and the crude product was triturated with methanol, yielding 0.108 g (70%) of **8**, mp 205–206°C (lit. (25) mp 206–207°C).

A highly stereoselective preparation of *syn*-1,2-diols from secondary α-allenic alcohols via iodocyclization. Synthesis of (±)-*threo*-L-factor and (±)-disparlure

RICHARD W. FRIESEN[1] AND ANDRÉ GIROUX

Department of Medicinal Chemistry, Merck Frosst Centre for Therapeutic Research, P.O. Box 1005, Pointe Claire-Dorval, QC H9R 4P8, Canada

Received March 25, 1994

RICHARD W. FRIESEN and ANDRÉ GIROUX. Can. J. Chem. **72**, 1857 (1994).

The iodocyclization of the *N*-tosyl carbamates **5** of secondary α-allenic alcohols **4** is described. The reaction sequence involves the addition of iodine to the terminal olefin of the allene moiety of **5** resulting in the formation of an isomeric mixture of *Z* and *E* diiodides **6** and **7**. This initial process is followed, in the same pot, by reaction of the diiodides with silver carbonate. Hydrolysis of the resulting *trans* imino carbonates **8** provides *syn*-1,2-diols **10** in a highly diastereoselective (>50:1) and regioselective (>20:1) fashion. Oxazolidinones **9** are minor products that arise from the participation of the carbamate nitrogen atom in the cyclization reaction. The regioselectivity of the cyclization reaction from **6/7** to **8** is highly dependent upon the reaction solvent with the optimum results being obtained in ether/MeCN mixtures (10:1 to 50:1) or CH_2Cl_2. The synthetic utility of the vinyl iodo diols **10** is demonstrated by the synthesis of (±)-*threo*-5-hydroxy-4-decanolide (**17**) ((±)-*threo*-L-factor) and (±)-*cis*-7,8-epoxy-2-methyloctadecane (**24**) ((±)-disparlure). The key step in each synthesis involves the conversion of the vinyl iodide moiety of **10** into the alkynes **15** or **18** (from **10***j* and **10***k*, respectively) via a high-yielding dehydrohalogenation reaction.

RICHARD W. FRIESEN et ANDRÉ GIROUX. Can. J. Chem. **72**, 1857 (1994).

L'iodocyclisation des *N*-tosylcarbamates **5** des alcools α-alléniques secondaires **4** est décrite. La séquence des réactions implique l'addition de l'iode sur l'oléfine terminale de la portion allène du composé **5**, conduisant à la formation d'un mélange *Z* et *E* des diiodures isomères **6** et **7**. Cette première réaction est suivie d'une réaction unipot des diiodures avec du carbonate d'argent. L'hydrolyse des imino carbonates *trans* **8** qui en résultent, conduit aux *syn*-1,2-diols **10** de manières hautement diastéréosélective (>50 : 1) et régiosélective (>20 : 1). Les oxazalidinones **9** sont des produits secondaires provenant de la participation de l'atome d'azote du carbamate dans la réaction de cyclisation. La régiosélectivité de la réaction de cyclisation des composés **6/7** en composés **8** dépend fortement du solvant de la réaction, les meilleurs résultats étant obtenus avec des mélanges d'éther/MeCN (10:1 à 50:1) ou du CH_2Cl_2. L'utilité des iododiols vinyliques **10** est démontrée en synthétisant les composés suivants : le (±)-*thréo*-5-hydroxy-4-décanolide (**17**) (le (±)-*thréo*-L-facteur) et le (±)-*cis*-7,8-époxy-2-méthyloctadécane (**24**) ((±)-disparlure). L'étape fondamentale de chaque synthèse implique la transformation de la portion iodure vinylique du composé **10** en alcynes **15** ou **18** (respectivement à partir des composés **10***j* et **10***k*) par l'intermédiaire d'une réaction de déshydrohalogénation ayant un rendement élevé.

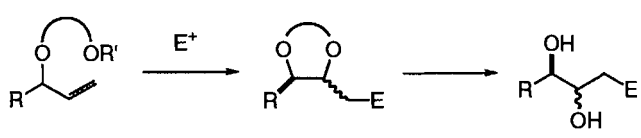
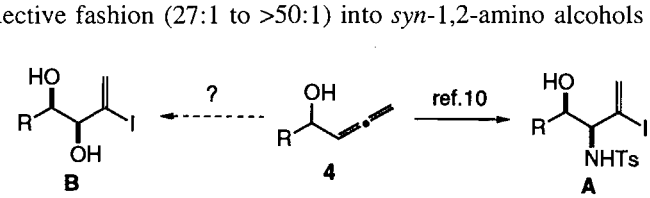
Introduction

There has been a great deal of effort directed toward the stereocontrolled preparation of vicinal diols in the context of the total synthesis of polyoxygenated natural products. As a result of these studies, several useful and stereoselective methods have emerged for the synthesis of *anti*- and *syn*-1,2-diols including (*a*) the reduction (1) or alkylation (2) of α-hydroxy (or alkoxy) carbonyl compounds, (*b*) the reaction of a carbonyl group with α-hydroxy carbanions (3) or γ-alkoxyallyl organometallics (4),[2] (*c*) the dihydroxylation of *trans* disubstituted olefins (5),[3] and (*d*) the electrophile (E) induced cyclofunctionalization reactions of allylic alcohol derivatives (for two excellent reviews, see ref. 6). These latter reactions, illustrated by the conversion of **1** to **2**, have been performed on a variety of allylic alcohol derivatives **1** including trichloroacetaldehyde-derived hemiacetals (7), esters (7), carbamates (8), and carbonates (9). For those systems in which the internal asymmetric induction of the reaction has been addressed, the *trans*-substituted heterocycle **2** that leads to the *syn*-1,2-diol **3** usually predominates over the *cis* derivative of **2**. Typical cyclization diastereoselectivities for this process range from 4:1 to 13:1.



1 **2** **3**

In previous papers we (10, 11) and others (12) have demonstrated that α-allenic alcohols **4** are useful substrates with respect to cyclofunctionalization reactions. Carbamate derivatives of these alcohols can be converted in a highly diastereoselective fashion (27:1 to >50:1) into *syn*-1,2-amino alcohols **A**



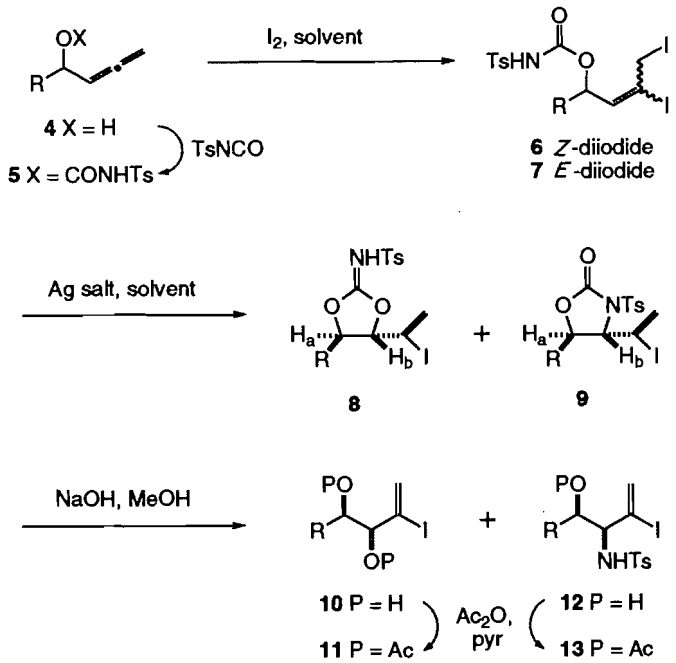
B **4** **A**

via an iodocyclization process (10*a*, *b*). Due to our general interest in the cyclofunctionalization reactions of α-allenic alcohol derivatives in the context of acyclic stereocontrol, we wished to determine whether α-allenic alcohol derivatives could also be used to prepare vicinal diols **B** via a similar strategy. If successful, the vicinal diol/vinyl iodide products would be potentially useful and versatile synthetic intermediates. Herein, we describe the details of the highly diastereoselective synthesis of *syn*-1,2-diols **10** from secondary α-allenic alcohols according to a cyclofunctionalization strategy employing car-

[1]Author to whom correspondence may be addressed. Phone: (514) 428-3164. Fax: (514) 695-0693.

[2]References 3 and 4 list examples of these types of reactions that provide *syn* diols as the major diastereomer.

[3]The reference most pertinent to this discussion is that of the dihydroxylation of 1,3-dienes (5) leading to 3,4-dihydroxy-1-alkenes.



SCHEME 1

bamate derivatives of **4**.[4] The potential synthetic utility of the *syn*-1,2-diols **10** is demonstrated by short syntheses of (±)-*threo*-5-hydroxy-4-decanolide (**17**) (*threo*-(±)-L-factor) and (±)-*cis*-7,8-epoxy-2-methyloctadecane (**24**) ((±)-disparlure).

Results and discussion

The method whereby α-allenic alcohols **4** are converted into the *syn*-1,2-amino alcohols **12** (Scheme 1) involves the initial formation of *N*-toluenesulfonyl carbamates **5**, followed by a cyclofunctionalization reaction in the presence of iodine and base to form *trans* oxazolidinones **9** (10). This iodocyclization process involves the intermediacy of an isomeric mixture of diiodides **6/7** wherein iodine has added to the terminal double bond of the allene system. Under basic reaction conditions (K_2CO_3), intramolecular S_N2' displacement of the allylic iodide in each isomer by the carbamate nitrogen atom generates the *trans* oxazolidinone.

It is known (14) that carbamates can act as ambident nucleophiles in intramolecular displacement reactions, the regioselectivity that is observed (nitrogen vs. oxygen participation) being highly dependent on the nature of the reaction conditions. For example, the intramolecular opening of epoxides by carbamate nucleophiles under basic reaction conditions favours nitrogen participation (S_N2 like). However, under Lewis acidic conditions (S_N1 like) the regioselectivity is altered and the carbonyl oxygen becomes the participating nucleophile.[5] According to the latter mode of reactivity, we reasoned that treatment of the diiodide intermediates **6/7** with a silver salt might result in the generation and nucleophilic trapping of a cationic species by the carbamate carbonyl oxygen to form **8**.

(a) Iodocyclization regioselectivity and diastereoselectivity

Our initial efforts in this area were directed toward finding the optimal conditions for achieving regioselective participation of the carbamate carbonyl oxygen atom in the cyclization/displacement reaction of **6/7** as illustrated in Scheme 1. The *N*-tosyl carbamate **5***a* (R = *n*-heptyl) derived from α-allenic alcohol **4***a*[6] (TsNCO, ether) was treated with iodine as described previously (10) to afford a 1:1 *Z*/*E* mixture of diiodides **6***a* and **7***a* (Scheme 1). Using this diiodide mixture, a variety of cyclization reaction conditions were surveyed. The solvent (MeCN, Et_2O, CH_2Cl_2) and silver salt ($AgBF_4$, AgOTf, Ag_2CO_3, $AgNO_3$) were systematically varied and the resulting crude mixtures were inspected by ^1H NMR spectroscopy to determine the reaction regioselectivity. Although cyclized products **8***a* and **9***a* were observed in the majority of cases, it quickly became evident that Ag_2CO_3 was the salt of choice. In contrast to the other silver salts, many of the reactions using Ag_2CO_3 were extremely clean and gave excellent mass recovery. The solvent effect on the cyclization of **6***a*/**7***a* using this salt was then studied in detail and some of the results are summarized in Table 1, entries 1–7.

While no reaction was observed in ether (entry 1), presumably due to the insolubility of Ag_2CO_3 in this solvent, the cyclization that was carried out in MeCN (entry 2) did provide cyclized products **8***a* and **9***a* in a ratio of 1.4:1. Only a *single* stereoisomer of each cyclization product was observed in the spectrum of this reaction mixture. The ratio of **8***a* to **9***a* was easily established by integration of the vinyl proton resonances (δ 6.58 and 6.05 for **8***a*; δ 6.55 and 6.01 for **9***a*) and the methine proton resonances H_b (see table) in the ^1H NMR spectrum of the crude material. To facilitate isolation and purification, the crude mixture was hydrolyzed (aqueous NaOH, MeOH) and acetylated (Ac_2O, pyridine, DMAP) to provide **11***a* and **13***a* in yields of 55 and 34%, respectively, after chromatography. The isolated yield ratio correlated well with the integrated ratio observed in the ^1H NMR spectrum. None of the stereoisomeric products related to **11***a* and **13***a* could be found or isolated (diastereoselectivity >50:1).[7]

The relative stereochemistry in the cyclized products **8***a* and **9***a* was assigned as follows. While the *syn* amino acetate **13***a* was identical with material prepared previously (10), difference NOE experiments were performed on **8***a* in order to assess the stereochemistry of the oxygen cyclized product. Irradiation of the methylene proton resonance RCH_2CH_aO (δ 1.80, $CDCl_3$) resulted in the enhancement of the resonances of both protons H_a and H_b (δ 4.58 and 4.74, J_{ab} = 6.8 Hz), confirming the relative *trans* stereochemistry in **8***a*.

High degrees of regioselectivity favouring the production of **8***a* over **9***a* were observed in ether/MeCN solutions containing small amounts of MeCN (entries 3–5) as well as in CH_2Cl_2 solution (entry 7). In all cases, only a single stereoisomer **8***a* was observed in the crude mixture (by ^1H NMR) and only a single diacetate **11***a* was isolated. It should be noted that all of these reactions were repeated several times and the range of regioselectivities that were observed in each solvent are reported in the table. As can be seen in entry 6, there is a limit to the dilution of MeCN with ether that is successful; a 100:1 ratio of ether to MeCN does not provide cyclized products. In addition, there is some variability from one experiment to the next in the ratio of **8***a*:**9***a* that is observed in each of the 10:1 and 50:1

[4]For a preliminary account of this work, see ref. 13.

[5]For a more detailed discussion on the factors affecting regioselectivity in the reactions of ambident nucleophiles, see ref. 15.

[6]The α-allenic alcohols **4** were prepared according to the procedure described in ref. 16.

[7]We have been unable to isolate the *anti* diol. Thus, without an authentic standard and with the apparent lack of other resonances in the ^1H NMR spectra, we estimate the diastereoselectivity as >50:1.

[a]Cyclization reactions carried out according to the general procedure (see experimental section) in the solvents indicated. E = ether, A = acetonitrile.
[b]Crude reaction mixture in $CDCl_3$.
[c]Overall, isolated yields of analytically pure products **10** or **11** from allenic alcohols **4**. Value in parentheses refers to the isolated yield of the corresponding amine **13**, which was described previously (10*a*, *b*).
[d]No reaction.
[e]Unable to determine.

mixtures of ether:MeCN. The reason for this observation is unclear (other than experimental variability), but what is obvious from these data is that the cyclization regioselectivity is highly dependent upon the reaction solvent. The subtle differences in solvent polarity and the solubility of Ag_2CO_3 in the particular medium are presumably the key factors that affect the S_N2'/S_N1 nature of the cyclization reaction, and as a result the reaction regioselectivity.[5]

With these results in hand, the procedure was applied to a variety of α-allenic alcohols **4***b*–**4***n* (Scheme 1; Table 1, entries 8–26) wherein the steric size and makeup of the R group was varied (R = 1°, 2°, 3° alkyl, CH=CHR, and aryl) and in two cases included common alcohol protecting groups (entries 8–11). The conversion of the alcohols **4** to the imino carbonates **8** was carried out in one pot (see experimental section) with each of the cyclization reactions being performed in the standard solvent systems of 10:1 ether/MeCN or CH_2Cl_2. In some cases (entries 8–19) cyclization was followed by hydrolysis and acetylation to provide the *syn* diacetates **11** while in several other cases, the sequence was terminated prior to acetylation (entries 20–25) to afford the *syn*-1,2-diols **10**. The yields of **10** or **11** are good to excellent in the majority of cases (vide infra) and the reaction mixtures are extremely clean. In each case, a single imino carbonate **8** and a single *syn*-1,2-diol **10** or diacetate **11** was observed. The relative stereochemistry was assigned in the case of **8***f* by difference NOE experiments similar to those described previously for **8***a*. Irradiation at the frequency of the $(CH_3)_3C$ resonance (δ 0.86, $CDCl_3$) resulted in enhancement of the resonances of both of the protons H_a and H_b (δ 4.19 and 4.78, J_{ab} = 4.5 Hz), confirming the *trans* stereochemistry. Therefore, by analogy, the cyclization of **6**/**7** with Ag_2CO_2 produces solely (diastereoselectivity >50:1[7]) the *trans* diastereomers **8** (J_{ab} = 4.5–6.8 Hz) regardless of the steric size of the R group in the α-allenic alcohol **4**.

The reaction regioselectivity was consistently high, favouring the imino carbonates **8** over the oxazolidinones **9**. In certain cases (**4***b*, **4***d*, and **4***e*), alternative cyclization reaction solvent systems were tested and these conditions exhibited regioselectivity ratios in line with those observed for the cyclization of **6***a*/**7***a*. Again, the regioselectivity was established by integration of the vinyl proton resonances and (or) the resonances of H_b for each of **8** and **9** in the ^1H NMR spectra of the crude reaction mixtures. The chemical shift of H_b in **8** was typically 0.3–0.4 ppm downfield of the corresponding H_b resonance in **9** (see table). The vinyl proton resonances were less well separated but often proved to be useful for comparison purposes. Typically, the vinyl proton resonances of **8** were 0.03–0.04 ppm downfield of the corresponding resonances in **9**. In several cases, the amino acetates **13** had been previously prepared (10) and identified (entries 12–17). For

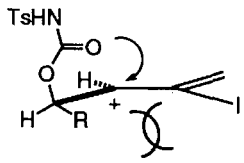
these examples, the isolated yield ratio of **11**:**13** corresponds well with the integrated ratios.

There are limitations to this methodology since certain highly unsaturated systems (allylic or benzylic alcohols) are not good substrates. As can be seen from entries 19 and 26, α-allenic alcohols **4***h* and **4***n* either produced the cyclized product **8***h* in low yield (entry 19) or did not provide any recognizable product (entry 26). However, a closely related analogue of each underwent iodocyclization successfully to provide the intermediate **8** (compare entries 18/19 and entries 25/26). Apparently, for each of **4***h* and **4***n*, the initial reaction to form the *N*-tosyl carbamate **5** is the problematic step. Decomposition upon treatment of the alcohol **4** with TsNCO is relatively rapid. Attempts at stabilizing the carbamate intermediate **5** in each case (treating with triethylamine for example (12*c*)) were not successful. The reason for the difference in stability between two closely related compounds is not known but it does put a small limitation on the generality of the reaction.

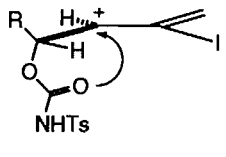
(b) Cyclization mechanism – rationale for stereoselectivity

Two related mechanisms merit consideration when attempting to rationalize the stereochemical outcome of the reaction from **6**/**7** to **8**. In this cyclization, iodide should be effectively removed from the reaction mixture by the precipitation of AgI. This precludes the involvement of iodide in a reversible process and suggests that the cyclization is under kinetic control.

In the first pathway, cyclization of **6**/**7** proceeds via attack of the carbamate carbonyl oxygen atom on the developing allylic cationic intermediate **14** that is formed by the reaction of **6**/**7** with Ag^+. Intermediate **14**, generated from either of the isomeric diiodides **6** or **7**, can cyclize out one of two rotomeric forms, **14A** or **14B**. Due to the large steric interactions between



14A



14B

the R group and the vinyl iodide moiety in the cyclization transition state arising out of conformer **14A**, the energetically more favourable pathway would derive from the alternative conformer, **14B**. The product of cyclization from **14B** is the *trans* imino carbonate **8**. Thus, regardless of the geometry of the starting diiodide **6** or **7**, cyclization via an S_N1-like mechanism occurs in a highly diastereoselective manner.

An alternative and closely related mechanism involves a process in which iodide departure and oxygen attack are more synchronous (S_N2' like). However, a S_N2' mechanism would appear to be less likely since **8** is formed regioselectively over **9**, a result that implies an S_N1-like pathway (14, 15). Nevertheless, this mechanistic possibility also predicts that the *trans* diastereomer **8** should be formed preferentially.[8] Thus, both the S_N2' mechanism and the S_N1 mechanism described above rationalize the observed *trans* diastereoselectivity in the formation of **8**.

In general, and irrespective of the actual mechanism of the iodocyclization, the transformation of the α-allenic alcohols **4** into either the *syn*-1,2-diols **10** or *syn*-1,2-diacetates **11** is a highly regio- (>20:1) and diastereoselective (>50:1) process and proceeds in synthetically useful yields. Furthermore, the presence of the vinyl iodide moiety enables one to consider a variety of synthetic operations. One possibility that exists is the conversion of this functionality into an alkyne via dehydrohalogenation (17). Using such a reaction, short and high-yielding syntheses of (±)-*threo*-L-factor (**17**) (Scheme 2) and (±)-disparlure (**24**) (Scheme 3) have been developed, illustrating the potential of the functionalized *syn*-1,2-diols **10** for the stereocontrolled synthesis of acyclic compounds.

*(c) Synthesis of (±)-*threo*-5-hydroxy-4-decanolide (**17**) ((±)-*threo*-L-factor)*

The isolation of two diastereomeric 5-hydroxy-4-decanolides (**17** and its diastereomer) from *Streptomyces griseus* was reported in 1982 (18*a*). These compounds were originally proposed to be autoregulators of the biosynthesis of the anthracycline antibiotic leukaeomomycin (hence the name L-factors). Although both the *erythro* and *threo* L-factors were subsequently shown to be biologically inactive (18*b*),[9] a variety of efficient synthetic approaches to these natural products have been described (20). The majority of these syntheses derive from carbohydrates in which the stereoselective formation of the preexisting diol moiety is not a key issue.

syn Diol **10***j* was converted to the corresponding acetonide (2-methoxypropene, CSA, DMF) and in the same pot was dehydrohalogenated by treatment with $NaN(TMS)_2$ to afford the alkyne **15** in 91% yield over two steps (Scheme 2). Deprotonation of **15** (MeLi, THF) followed by trapping of the resulting lithium acetylide with ethyl chloroformate provided the α,β-acetylenic ester **16** in 95% yield. Hydrogenation of **16** (H_2, Pd–C, EtOH) followed by acid-catalyzed lactonization (6 N HCl, MeOH) yielded (±)-*threo*-5-hydroxy-4-decanolide (**17**) in 93% yield.[10] The overall yield of **17** for the nine-step, six-pot sequence from **4***j* is 60%.

*(d) Synthesis of (±)-*cis*-7,8-epoxy-2-methyloctadecane (**24**) ((±)-disparlure)*

The sex attractant of the female gypsy moth *Porthetria dispar* (L.) was isolated in 1974 (21*a*) and the structure and absolute configuration were established as (+)-(7*R*,8*S*)-*cis*-7,8-epoxy-2-methyl-octadecane (**24**) ((+)-disparlure) (21). Many groups have reported the synthesis of **24** both in racemic and enantiomerically pure form (21, 22). In the majority of cases, these syntheses employ natural products as starting materials wherein the relative stereochemistry of the asymmetric centers is already established. Notable exceptions include syntheses that utilize the Sharpless asymmetric epoxidation (22*b*, *c*) or dihydroxylation (22*d*) as key reactions or employ chiral sulfoxides (22*e*, *f*) to introduce asymmetry. We have prepared (±)-disparlure **24** via a short, high-yielding sequence (Scheme 3) from diol **10***k*, further illustrating the synthetic utility of the vinyl iodo diols **10**.

syn Diol **10***k* was converted in 93% yield to the acetylenic

[8]Such an S_N2' mechanism has been described in detail for the *base-induced* cyclization of **6**/**7** to form **9** (10*b*). In this S_N2' pathway, the geometry of the starting diiodides is irrelevant to the stereochemical outcome of the reaction and the *trans* diastereomer **9** is the major product from each diiodide isomer. Thus, by analogy, the stereochemical outcome of an S_N2' mechanism in the present study is predicted to be *trans* as well.

[9]It is noteworthy that a related 5-hydroxy-γ-lactone named muricatacin has been isolated from the tropical fruit *Annona muricata L.* and exhibits cytotoxic activity (19).

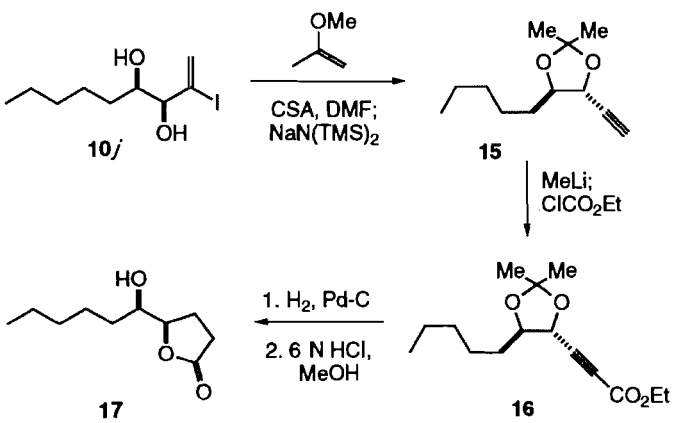
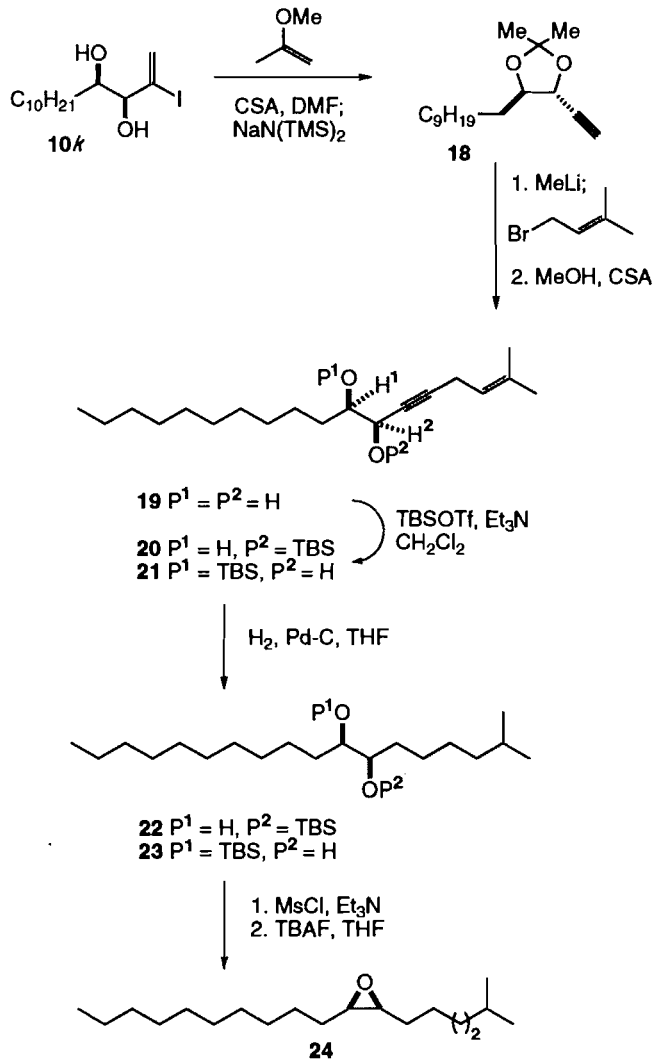


SCHEME 2



SCHEME 3

acetonide **18** as described above for the preparation of **15**. Deprotonation of **18** (MeLi, THF) was followed by trapping of the resulting lithium acetylide with 4-bromo-2-methyl-2-butene in the presence of HMPA. In the absence of HMPA, no alkylation occurred. The crude enyne acetonide was deprotected (MeOH, CSA) to yield diol **19** in 75% over two steps. The synthetic plan called for the monosilylation of diol **19** and the eventual formation of the *cis* epoxide of (±)-disparlure by an intramolecular displacement reaction of a suitably activated alcohol (22*g*). Treatment of **19** with TBSOTf (CH_2Cl_2, Et_3N) at −78°C provided **20** and **21** in 90% combined yield and in a ratio of 1.3:1, while at 0°C a 1:1.3 ratio of the same compounds was obtained in 87%. The regioselectivity of this reaction was not an issue since we were operating in the racemic mode. However, for the sake of simplicity these isomers were conveniently separated by column chromatography and used separately in the subsequent reactions.[11] The position of the silyl moiety in each isomer was readily established by decoupling experiments. The H^2 resonance (δ 4.16) in **21** was simplified upon irradiation at the resonance frequency of the both the O*H* proton (δ 2.44) and the allylic methylene protons (δ 2.87). Conversely, irradiation at the resonance frequency of the O*H* proton (δ 2.47) in **20** simplified the H^1 resonance (δ 3.48) while irradiation at the resonance frequency of the allylic methylene protons (δ 2.86) simplified the H^2 resonance (δ 4.06). Enynes **20** and **21** were hydrogenated (10% Pd–C, THF) individually to afford the corresponding alcohols **22** and **23** in yields of 96 and 97%, respectively. Epoxidation of each was accomplished by mesylation (MsCl, Et_3N, 0°C) of the free hydroxyl followed by treatment of the crude mixture with TBAF in THF at room temperature overnight (22*g*). (±)-Disparlure **24** was obtained in 83% yield from **22** and 78% yield from **23**.[12]

Experimental

General information

^1H NMR spectra were recorded in $CDCl_3$, unless stated otherwise, and are reported using TMS or $CHCl_3$ as internal standard. Broad band proton-decoupled ^{13}C NMR spectra were recorded in $CDCl_3$ using $CDCl_3$ as the internal standard. IR spectra were recorded on neat samples unless stated otherwise. Solvents were anhydrous and transferred via syringes under an argon atmosphere. Workup procedures involving the drying of organics was done with $MgSO_4$. Column chromatography was carried out on 230–400 mesh silica gel, eluting with the solvents indicated. Elemental analyses were performed by Oneida Research Services, Inc., Whitesboro, N.Y. The secondary α-allenic alcohols **4**, prepared by the two-step procedure of Landor and coworkers from the corresponding aldehydes and THP-protected propargyl alcohol in yields of 80–90% (16), were not characterized by combustion analysis but were homogeneous by TLC analysis and gave satisfactory spectroscopic data indicative of their purity. The alcohols **4** exhibited excellent stability when stored at −5°C (freezer temperature). Alcohols **4***a*, **4***d*, **4***e*, and **4***f* have been reported previously (10*b*).

8-Triisopropylsiloxy-1,2-octadien-4-ol (4b)

Colorless liquid; IR: 3600–3100, 1955, 835 cm^{-1}; ^1H NMR (400 MHz) δ: 1.00–1.10 (m, 21H), 1.40–1.65 (m, 6H), 1.78 (br s, 1H), 3.66 (t, 2H, J = 6.4 Hz), 4.15 (m, 1H), 4.80 (m, 2H), 5.20 (q, 1H, J = 6.5 Hz); ^{13}C NMR (100 MHz) δ: 12.0, 18.0, 21.7, 32.8, 37.2, 63.3, 69.7, 77.3, 94.8, 207.0. Pale yellow liquid; IR: 3600–3100, 1955, 1660, 1615 cm^{-1}; ^{1}H NMR (300 MHz) δ: 0.87 (t, 3H, J = 7.1 Hz), 1.25–1.40 (m, 4H), 1.77 (br s, 1H), 2.02 (q, 2H, J = 6.6 Hz), 4.60 1M, 1H), 4.85 (dd, 2H, J = 2.5, 6.6 Hz), 5.25 (q, 1H, J = 6.5 Hz), 5.50 (dd, 1H, J = 6.6, 15.4 Hz), 5.69 (td, 1H, J = 6.6, 15.4 Hz); ^{13}C NMR (100 MHz) δ: 13.8, 22.1, 31.1, 31.7, 70.4, 77.6, 94.2, 130.9, 132.6, 207.1. Exact Mass calcd. for $C_{10}H_{16}O$ (M^+): 152.1201; found: 152.1206.

*1,2,5-Heptatrien-4-ol (**4**n)*

Colorless liquid; IR: 3650–3100, 1954, 1655, 1615 cm^{-1}; ^{1}H NMR (300 MHz) δ: 1.68 (ddd, 1H, J = 0.8, 1.5, 6.3 Hz), 1.91 (br s, 1H), 4.58 (m, 1H), 4.84 (m, 2H), 5.24 (q, 1H, J = 6.5 Hz), 5.53 (qdd, 1H, J = 1.5, 6.5, 15.3 Hz), 5.71 (dqd, 1H, J = 1.0, 6.5, 15.3 Hz); ^{13}C NMR (100 MHz) δ: 17.5, 70.4, 77.7, 94.1, 127.4, 132.3, 207.1. Exact Mass calcd. for $C_7H_{10}O$ (M^+): 110.0732; found: 110.0734.

General procedure A: preparation of syn *diacetates **11***

The procedures described below for the preparation of **11***a* are general. To a solution of 1,2-undecadien-3-ol (**4***a*) (210 mg, 1.25 mmol) in ether (5 mL; note that some of the reactions were carried out in alternative solutions, Table 1) at room temperature was added *p*-TsNCO (0.2 mL, 1.1 equiv.). After stirring for 30 min at room temperature, solid I_2 (350 mg, 1.1 equiv.) was added periodically until the solution stayed colored (~1 h). Ag_2CO_3 (344 mg, 1.1 equiv.) and MeCN (0.1 mL) were added sequentially and the resulting mixture was stirred for 15 h (3–15 h depending upon substrate) at room temperature. The reaction mixture was filtered through Celite, washing with ethyl acetate, and the filtrate was concentrated. The crude mixture was analyzed by ^{1}H NMR spectroscopy (Table 1, entry 5) and then was dissolved in methanol (10 mL) and 1 N NaOH (10 mL). After stirring at room temperature overnight, the methanol was removed and the solution was neutralized (to ~pH 7) by the addition of 1 N HCl. The mixture was extracted with CH_2Cl_2 (3 × 20 mL) and the combined organics were dried and concentrated to provide the crude diol **10***a*. The residual material containing the diol **10***a* was dissolved in pyridine (5 mL) and Ac_2O (0.6 mL, 5 equiv.) and DMAP (10 mg) were added. The mixture was stirred at room temperature for 15 h and then water (20 mL) was added. The aqueous layer was extracted with ethyl acetate (3 × 20 mL) and the combined organics were washed with 1 N HCl (2×), saturated $NaHCO_3$, and water, dried, and concentrated. The residual material was subjected to flash chromatography (hexane/ethyl acetate, 5:1, v/v) to provide **11***a* (377 mg, 76%), which was eluted first, followed by **13***a* (20 mg, 3%).

The diacetates **11**, prepared according to the above procedures, exhibited the following physical properties. The solvent used for the cyclization reaction is given below.

syn-*3,4-Diacetoxy-2-iodo-1-undecene (**11**a)*

Colorless oil; IR: 1742, 1615, 1245–1210 cm^{-1}; ^{1}H NMR (300 MHz) δ: 0.87 (t, 3H, J = 7.0 Hz), 1.25–1.35 (m, 10H), 1.40–1.60 (m, 2H), 2.05 (s, 3H), 2.10 (s, 3H), 4.99 (br d, 1H, J = 6.2 Hz), 5.26 (ddd, 1H, J = 5.3, 6.2, 7.5 Hz), 6.02 (d, 1H, J = 1.8 Hz), 6.47 (dd, 1H, J = 1.0, 1.8 Hz); ^{13}C NMR (100 MHz) δ: 13.8, 20.6, 22.4, 24.6, 28.8, 29.0, 30.2, 31.5, 72.5, 78.6, 104.4, 129.6, 169.3, 169.9. Anal. calcd. for $C_{15}H_{25}O_4I$: C 45.47, H 6.36; found: C 45.58, H 6.38.

syn-*3,4-Diacetoxy-2-iodo-8-triisopropylsilyloxy-1-octene (**11**b)*

Following general procedure A (ether:MeCN 10:1), alcohol **4***b* (264 mg, 0.86 mmol) was converted to **11***b* (365 mg, 78%). Colorless oil; IR: 1750, 1615, 1240–1210 cm^{-1}; ^{1}H NMR (300 MHz) δ: 0.99–1.23 (23H) 1.35–1.62 (m, 4H), 2.05 (s, 3H), 2.10 (s, 3H), 3.67 (m, 2H), 4.99 (dd, 1H, J = 0.7, 6.2 Hz), 5.27 (ddd, 1H, J = 5.0, 6.2, 7.5 Hz), 6.02 (d, 1H, J = 1.5 Hz), 6.48 (dd, 1H, J = 0.7, 1.5 Hz); ^{13}C NMR (100 MHz) δ: 12.0, 18.0, 20.7, 20.8, 21.3, 30.3, 32.5, 62.9, 72.6, 78.9, 104.6, 129.9, 169.4, 170.0. Anal. calcd. for $C_{21}H_{39}O_5SiI$: C 47.91, H 7.47; found: C 48.24, H 7.69.

syn-*3,4-Diacetoxy-8-benzyloxymethoxy-2-iodo-1-octene (**11**c)*

Following general procedure A (ether:MeCN 10:1), alcohol **4***c* (224 mg, 0.86 mmol) was converted to **11***c* (313 mg, 75%). Colorless oil; IR: 1745, 1615, 1240–1212 cm^{-1}; ^{1}H NMR (300 MHz) δ: 1.38–1.46 (m, 2H), 1.52–1.67 (m, 4H), 2.05 (s, 3H), 2.11 (s, 3H), 3.57 (t, 1H, J = 6.4 Hz), 4.60 (s, 2H), 4.74 (s, 2H), 5.00 (d, 1H, J = 6.1 Hz), 5.27 (m, 1H), 6.03 (d, 1H, J = 1.7 Hz), 6.48 (dd, 1H, J = 0.9, 2.5 Hz), 7.29 (m, 5H); ^{13}C NMR (100 MHz) δ: 20.8, 21.7, 29.3, 30.2, 67.5, 69.3, 72.5, 78.8, 94.6, 104.5, 127.6, 127.8, 128.4, 130.0, 137.9, 169.4, 170.1. Anal. calcd. for $C_{20}H_{27}O_6I$: C 48.99, H 5.55; found: C 49.21, H 5.52.

syn-*3,4-Diacetoxy-2-iodo-6-methyl-1-heptene (**11**d)*

Following general procedure A (ether:MeCN 3:1), alcohol **4***d* (189 mg, 1.49 mmol) was converted to **11***d* (393 mg, 74%). White solid; mp 72–73°C; IR (KBr): 1735, 1618, 1250–1218 cm^{-}; ^{1}H NMR (300 MHz) δ: 0.93 (d, 3H, J = 6.6 Hz), 0.94 (d, 3H, J = 6.5 Hz), 1.22–1.35 (m, 1H), 1.42–1.55 (m, 2H), 2.05 (s, 3H), 2.10 (s, 3H), 4.96 (dd, 1H, J = 0.8, 6.2 Hz), 5.37 (m, 1H), 6.02 (d, 1H, J = 1.7 Hz), 6.47 (dd, 1H, J = 1.0, 1.7 Hz); ^{13}C NMR (100 MHz) δ: 20.8, 21.7, 23.3, 24.3, 39.5, 71.2, 79.3, 104.7, 129.9, 169.5, 170.1. Anal. calcd. for $C_{12}H_{19}O_4I$: C 40.70, H 5.41; found: C 40.99, H 5.31.

syn-*1,2-Diacetoxy-3-iodo-1-cyclohexyl-3-butene (**11**e)*

Following general procedure A (ether:MeCN 5:1), alcohol **4***e* (254 mg, 1.66 mmol) was converted to **11***e* (435 mg, 70%). White solid; mp 37–38°C; IR (KBr): 1738, 1615, 1238–1210 cm^{-1}; ^1H NMR (300 MHz) δ: 1.00–1.30 (m, 6H), 1.55–1.80 (m, 5H), 2.06 (s, 3H), 2.11 (s, 3H), 5.16 (t, 1H, J = 5.4 Hz), 5.19 (d, 1H, J = 5.6 Hz), 6.00 (d, 1H, J = 1.8 Hz), 6.44 (dd, 1H, J = 0.9, 1.7 Hz); ^{13}C NMR (100 MHz) δ: 20.4, 20.5, 25.5, 25.6, 25.8, 27.0, 29.2, 37.6, 75.3, 77.4, 104.7, 128.8, 169.0, 169.7. Anal. calcd. for $C_{14}H_{21}O_4I$: C 44.23, H 5.57; found: C 44.51, H 5.68.

syn-*1,2-Diacetoxy-3-iodo-1-tert-butyl-3-butene (**11**f)*

Following general procedure A (ether:MeCN 10:1), alcohol **4***b* (225 mg, 1.78 mmol) was converted to **11***f* (476 mg, 75%). White solid; mp 74–75°C; IR (KBr): 1760, 1620, 1220; ^1H NMR (300 MHz) δ: 0.97 (s, 9H), 2.13 (s, 3H), 2.15 (s, 3H), 5.15 (d, 1H, J = 2.4 Hz), 5.43 (m, 1H), 5.89 (dd, 1H, J = 0.7, 1.9 Hz), 6.32 (dd, 1H, J = 1.3, 1.9 Hz); ^{13}C NMR (100 MHz) δ: 20.5, 20.8, 26.5, 34.5, 76.1, 76.7, 106.1, 126.7, 168.9, 169.9. Anal. calcd. for $C_{12}H_{19}O_4I$: C 40.69, H 5.41; found: C 41.11, H 5.30.

syn-*1,2-Diacetoxy-3-iodo-1-(3,4-methylenedioxyphenyl)-3-butene (**11**g)*

Following general procedure A (ether:MeCN 10:1), alcohol **4***g* (135 mg, 0.71 mmol) was converted to **11***g* (221 mg, 75%). White solid; mp 110–111°C; IR (KBr): 1735, 1615, 1248–1218 cm^{-1}; ^1H NMR (300 MHz) δ: 2.03 (s, 3H), 2.09 (s, 3H), 5.14 (dd, 1H, J = 0.7, 7.9 Hz), 5.84 (d, 1H, J = 1.8 Hz), 5.92 (d, 1H, J = 7.9 Hz), 5.93 (s, 2H), 6.23 (dd, 1H, J = 0.9, 1.8 Hz), 6.73 (dd, 1H, J = 0.5, 7.8 Hz), 6.87 (s, 1H), 6.91 (dd, 1H, J = 1.0, 7.8 Hz); ^{13}C NMR (100 MHz) δ: 20.8, 75.2, 79.2, 101.1, 104.1, 107.8, 108.1, 121.6, 129.4, 131.1, 147.6, 147.9, 169.2, 169.4. Anal. calcd. for $C_{15}H_{15}O_6I$: C 43.08, H 3.62; found: C 43.29, H 3.56.

syn-*1,2-Diacetoxy-3-iodo-1-(4-methoxyphenyl)-3-butene (**11**h)*

Following general procedure A (ether:MeCN 10:1), alcohol **4***h* (102 mg, 0.58 mmol) was converted to **11***h* (68 mg, 29%). Colorless oil; IR: 1740, 1615, 1240–1218 cm^{-1}; ^1H NMR (300 MHz) δ: 2.05 (s, 3H), 2.11 (s, 3H), 3.79 (s, 3H), 5.20 (d, 1H, J = 7.9 Hz), 5.84 (d, 1H, J = 1.8 Hz), 6.00 (d, 1H, J = 8.0 Hz), 6.21 (dd, 1H, J = 0.7, 1.6 Hz), 6.86 (d, 2H, J = 8.7 Hz), 7.34 (d, 2H, J = 8.7 Hz); ^{13}C NMR (100 MHz) δ: 21.0, 55.2, 76.2, 79.4, 104.3, 113.9, 127.8, 129.1, 131.2, 159.9, 169.4, 169.6. Anal. calcd. for $C_{15}H_{17}O_5I$: C 44.58, H 4.24; found: C 45.85, H 4.45.

General procedure B: preparation of syn-*diols **10***

Following general procedure A described above, 1,2-octadien-3-ol (**4***i*) (5.00 g, 39.6 mmol) was converted into the crude diol **10***i* using 10:1 ether:MeCN (60 mL:6 mL). The residual material was subjected to flash chromatography (toluene/acetone, 6:1, v/v) to provide the diol **10***i* (8.54 g, 80%) as a white solid.

The diols **10**, prepared according to the above procedures, exhibited the following physical properties.

syn-*3,4-Dihydroxy-2-iodo-1-octene (**10**i)*

White solid; mp 48–48°C; IR (KBr): 3600–3100, 1625, 1050; ^1H NMR (300 MHz) δ: 0.92 (t, 3H, J = 7.1 Hz), 1.30–1.55 (m, 6H), 2.37 (br s, 1H), 2.96 (br s, 1H), 3.58 (br m, 1H), 3.77 (br m, 1H), 6.00 (d, 1H, J = 1.7 Hz), 6.49 (dd, 1H, J = 1.1, 1.7 Hz); ^{13}C NMR (100 MHz) δ: 20.0, 22.5, 27.6, 32.5, 73.0, 80.2, 113.0, 127.6. Anal. Calcd. for $C_8H_{15}O_2I$: C, 35.57; H, 5.60. Found: C, 35.87; H, 5.46.

syn-*3,4-Dihydroxy-2-iodo-1-nonene (**10**j)*

Following general procedure B (ether:MeCN 10:1), alcohol **4***j* (953 mg, 6.80 mmol) was converted to **10***j* (1.45 g, 75%). White solid; mp 61–62°C; IR (KBr): 3500–3050, 1625, 1050; ^1H NMR (300 MHz) δ: 0.85 (t, 3H, J = 6.9 Hz), 1.20–1.50 (m, 8H), 3.17 (br s, 2H), 3.51 (dd, 1H, J = 0.7, 5.7 Hz), 3.70 (m, 1H), 5.94 (d, 1H, J = 1.6 Hz), 6.44 (dd, 1H, J = 1.1, 1.6 Hz); ^{13}C NMR (100 MHz) δ: 14.0, 22.5, 25.1, 31.6, 32.6, 73.0, 80.2, 113.1, 127.6. Anal. calcd. for $C_9H_{17}O_2I$: C 38.04, H 6.03; found: C 38.31, H 5.87.

syn-*3,4-Dihydroxy-2-iodo-1-tetradecene (**10**k)*

Following general procedure B (ether:MeCN 10:1), alcohol **4***k* (2.57 g, 12.22 mmol) was converted to **10***k* (3.68 g, 85%). White solid; mp 49–50°C; IR (KBr): 3600–3050, 1625, 1050; ^1H NMR (300 MHz) δ: 0.85 (t, 3H, J = 6.7 Hz), 1.20–1.50 (m, 18H), 2.26 (br s, 1H), 2.86 (br s, 1H), 3.55 (br d, 1H, J = 5.0 Hz), 3.75 (m, 1H), 5.97 (dd, 1H, J = 0.4, 1.7 Hz), 6.44 (dd, 1H, J = 1.1, 1.7 Hz); ^{13}C NMR (100 MHz) δ: 14.1, 22.7, 25.5, 29.3, 29.47, 29.52, 29.58, 31.9, 32.7, 73.0, 80.2, 112.9, 127.7. Anal. calcd. for $C_{14}H_{27}O_2I$: C 47.46, H 7.68; found: C 47.40, H 7.72.

syn-*3,4-Dihydroxy-5-iodo-1-phenyl-5-hexene (**10**l)*

Following general procedure B (ether:MeCN 10:1), alcohol **4***l* (280 mg, 1.61 mmol) was converted to **10***l* (424 mg, 83%). White solid; mp 77–77.5°C; IR (KBr): 3600–3050, 1720, 1610, 1050 cm^{-1}; ^1H NMR (300 MHz) δ: 1.70–1.85 (m, 2H), 2.56 (br s, 1H), 2.70 (ddd, 1H, J = 7.1, 9.3, 13.8 Hz), 2.86 (ddd, 1H, J = 5.6, 8.9, 13.8 Hz), 3.01 (br d, 1H, J = 5.6 Hz), 3.58 (br t, 1H, J = 5.2 Hz), 3.77 (m, 1H), 5.97 (d, 1H, J = 1.7 Hz), 6.45 (dd, 1H, J = 1.1, 1.7 Hz), 7.15–7.30 (m, 5H); ^{13}C NMR (100 MHz) δ: 31.8, 34.4, 72.6, 80.3, 112.6, 126.0, 127.9, 128.4, 141.5. Anal. calcd. for $C_{12}H_{15}O_2I$: C 45.30, H 4.75; found: C 45.13, H 4.79.

(E)-syn-*3,4-Dihydroxy-2-iodo-1,5-decadiene (**10**m)*

Following general procedure B (ether:MeCN 10:1), alcohol **4***m* (302 mg, 1.98 mmol) was converted to **10***m* (478 mg, 81%). Colorless oil; IR: 3600–3050, 1665, 1610, 1050; ^1H NMR (300 MHz) δ: 0.85 (t, 3H, J = 7.1 Hz), 1.20–1.40 (m, 4H), 2.01 (q, 2H, J = 6.7 Hz), 2.77 (br s, 1H), 3.28 (br s, 1H), 3.51 (d, 1H, J = 5.7 Hz), 4.15 (t, 1H, J = 6.7 Hz), 5.37 (m, 1H), 5.79 (m, 1H), 5.92 (d, 1H, J = 1.6 Hz), 6.41 (dd, 1H, J = 1.0, 1.6 Hz); ^{13}C NMR (100 MHz) δ: 13.8, 22.0, 30.9, 31.8, 74.7, 80.2, 112.4, 127.2, 127.9, 135.0. Anal. calcd. for $C_{10}H_{17}O_2I$: C 40.56, H 5.79; found: C 40.35, H 5.77.

*Acetylenic acetonide **15***

To a solution of the diol **10***j* (800 mg, 2.82 mmol) in DMF (7 mL) at room temperature was added 2-methoxypropene (0.4 mL, 1.5 equiv.) and CSA (5 mg). The mixture was stirred at room temperature overnight and then $NaN(TMS)_2$ (3.1 mL of a 1 M solution in THF) was added dropwise. The resulting mixture was stirred for 10 min at room temperature and then water (40 mL) was added. The mixture was extracted with ethyl acetate (3 × 50 mL) and the combined organics were washed twice with water, dried, and concentrated. The residual oil was subjected to flash chromatography (hexane/ethyl acetate, 15:1, v/v) to provide the alkyne **15** (502 mg, 91%) as a colorless liquid; IR: 3280, 2120 cm^{-1}; ^1H NMR (400 MHz) δ: 0.87 (t, 3H, J = 7.1 Hz), 1.25–1.55 (m, 6H), 1.38 (s, 3H), 1.44 (s, 3H), 1.60 (m, 2H), 2.49 (d, 1H, J = 2.1 Hz), 4.01 (td, 1H, J = 6.1, 7.8 Hz), 4.17 (dd, 1H, J = 2.1, 7.8 Hz); ^{13}C NMR (100 MHz) δ: 14.0, 22.5, 25.3, 26.1, 27.1, 31.7, 32.3, 70.3, 74.5, 80.9, 81.5, 109.8. Anal. calcd. for $C_{12}H_{20}O_2$: C 73.43, H 10.27; found: C 73.44, H 10.23.

α,β-*Acetylenic ester **16***

To a solution of alkyne **15** (209 mg, 1.07 mmol) in THF (4 mL) at −78°C was added MeLi (1.14 mL of a 1.4 M solution in ether, 1.5 equiv.) dropwise. The resulting solution was stirred for 10 min at −78°C followed by 30 min at 0°C, and then ethyl chloroformate (0.15 mL, 1.5 equiv.) was added. The cold bath was removed and the solution was stirred for 30 min. Water (25 mL) was added and the mixture was extracted with ethyl acetate (3 × 2 mL). The combined extracts were dried and concentrated. The residual material was subjected to flash chromatography (hexane/ethyl acetate, 11:1, v/v) and provided the ester **16** (271 mg, 95%) as a colorless oil; IR: 2218, 1715 cm^{-1}; ^1H NMR (400 MHz) δ: 0.87 (t, 3H, J = 7.1 Hz), 1.28 (t, 3H, J = 7.1 Hz), 1.25–1.50 (m, 6H), 1.39 (s, 3H), 1.43 (s, 3H), 1.61 (m, 2H), 4.09 (m, 1H), 4.21 (q, 2H, J = 7.1 Hz), 4.27 (d, 1H, J = 7.5 Hz);

For personal use only.

^{13}C NMR (100 MHz) δ: 13.9, 22.5, 25.3, 25.8, 27.0, 31.7, 35.5, 62.2, 69.9, 77.7, 81.2, 83.7, 110.6, 153.1. Anal. calcd. for $C_{15}H_{24}O_4$: C 67.14, H 9.01; found: C 67.08, H 8.90.

*(±)-threo-5-Hydroxy-4-decanolide ((±)-threo-L-factor) (**17**)*

A mixture of the ester **16** (211 mg, 0.79 mmol) and 10% Pd–C (200 mg) in ethanol (5 mL) was stirred under H_2 (1 atm; 101.3 kPa) for 2 h at room temperature. The resulting mixture was filtered through Celite, washing with ethyl acetate, and then the filtrate was concentrated. The residual material was dissolved in methanol (5 mL) and 6 N HCl (1 mL) was added. The resulting mixture was heated gently (~50°C) for 2 h and then the methanol was removed on the rotary evaporator. Brine (20 mL) was added and the mixture was extracted with ethyl acetate (3 × 50 mL). The combined organics were dried and concentrated. The residual material was subjected to flash chromatography (hexane/ethyl acetate, 1:1 v/v) to provide the lactone **17** as a colorless oil (136 mg, 93%) that solidified in the freezer. This material, a white solid, exhibited mp 32–33°C; IR: 3700–3100, 2980–2850, 1760, 1455, 1180, 1030, 920 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.85 (t, 3H, J = 6.7 Hz), 1.21–1.40 (m, 5H), 1.40–1.54 (m, 3H), 2.10 (m, 1H), 2.20 (m, 1H), 2.30 (br d, 1H, J = 5.4 Hz), 2.45 (ddd, 1H, J = 8.7, 9.9, 17.9 Hz), 2.57 (ddd, 1H, J = 5.2, 9.9, 17.9 Hz), 3.53 (m, 1H), 4.38 (dt, 1H, J = 4.4, 7.4 Hz); ^{13}C NMR (100 MHz) δ: 13.9, 22.4, 24.0, 25.1, 28.6, 31.6, 32.8, 73.5, 82.9, 177.4. Anal. calcd. for $C_{10}H_{18}O_3$: C 64.49, H 9.74; found: C 64.48, H 9.63.

*Acetylenic acetonide **18***

Following the procedure described for the preparation of **15**, diol **10***k* (3.63 g, 10.2 mmol) was converted into alkyne **18** (2.55 g, 93%). This material, a colorless liquid, exhibited IR: 3300, 2115 cm^{-1}; ^{1}H NMR (300 MHz) δ: 0.86 (t, 3H, J = 6.6 Hz), 1.20–1.50 (m, 16H), 1.38 (s, 3H), 1.44 (s, 3H), 1.62 (m, 2H), 2.48 (d, 1H, J = 2.1 Hz), 4.01 (dt, 1H, J = 7.8, 6.0 Hz), 4.16 (dd, 1H, J = 2.1, 7.8 Hz); ^{13}C NMR (125 MHz) δ: 14.1, 22.7, 25.7, 26.1, 27.1, 29.3, 29.4, 29.5, 29.6, 31.9, 32.4, 70.3, 74.5, 80.9, 81.5, 109.8. Anal. calcd. for $C_{17}H_{30}O_2$: C 76.64, H 11.35; found: C 76.56, H 11.51.

syn-*7,8-Dihydroxy-2-methyl-2-octadecen-5-yne (**19**)*

To a solution of alkyne **18** (1.02 g, 3.83 mmol) in THF (20 mL) at −78°C was added MeLi (6.9 mL of a 1.4 M solution in ether, 2.5 equiv.) dropwise. The resulting solution was stirred for 10 min at −78°C followed by 30 min at 0°C, and then 4-bromo-2-methyl-2-butene (1.33 mL, 3 equiv.) and HMPA (2 mL) were added successively. The cold bath was removed and the solution was stirred for 90 min at room temperature. Water (50 mL) was added and the mixture was extracted with ethyl acetate (3 × 50 mL). The combined extracts were washed successively with 1 N HCl, water, brine, dried, and concentrated. The residual material and CSA (50 mg) were dissolved in MeOH (20 mL) and refluxed for 10 h. After cooling to room temperature, the solution was concentrated and the residue subjected to flash chromatography (hexane/ethyl acetate, 5:2, v/v). The diol **19** (847 mg, 75%) was obtained as a colorless solid; mp 42–43°C; IR ($CHCl_3$): 3580, 2920, 2845 cm^{-1}; ^{1}H NMR (300 MHz) δ: 0.84 (t, 3H, J = 6.7 Hz), 1.20–1.70 (m, 18H), 1.59 (br s, 3H), 1.67 (d, 3H, J = 1.1 Hz), 2.73 (br s, 1H), 2.83 (br s, 1H), 2.88 (d, 2H, J = 6.9 Hz), 3.53 (br m, 1H), 4.08 (br m, 1H), 5.12 (m, 1H); ^{13}C NMR (100 MHz) δ: 14.1, 17.7, 17.8, 22.7, 25.5, 25.6, 29.3, 29.53, 29.58, 29.60, 31.9, 32.4, 66.4, 75.1, 78.0, 85.9, 118.4, 134.1. Anal. calcd. for $C_{19}H_{34}O_2$: C 77.50, H 11.64; found: C 77.71, H 11.51.

syn-*7-tert-Butyldimethylsiloxy-2-methyl-2-octadecen-5-yn-8-ol (**20**) and* syn-*8-tert-butyldimethylsiloxy-2-methyl-2-octadecen-5-yn-7-ol (**21**)*

To a solution of diol **19** (700 mg, 2.38 mmol) and Et_3N (0.7 mL, 2.1 equiv.) in CH_2Cl_2 (20 mL) at 0°C was added TBSOTf (0.57 mL, 1.05 equiv.) dropwise over 5 min. The resulting mixture was stirred for 15 min and then the cooling bath was removed. After 15 min, water (50 mL) was added and the mixture was extracted with CH_2Cl_2 (3 × 50 mL). The combined organics were dried and concentrated and the residual material was subjected to column chromatography (hexane/ether, 15:1, v/v). Alcohol **20** (368 mg, 38%) eluted first and was obtained as a colorless oil; IR: 3575, 3600–3300, 830 cm^{-1}; ^{1}H NMR (300 MHz) δ: 0.11 (s, 3H), 0.13 (s, 3H), 0.85 (t, 3H, J = 6.8 Hz), 0.88 (s, 9H), 1.20–1.70 (m, 18H), 1.60 (br s, 3H), 1.68 (d, 3H, J = 0.9 Hz), 2.47 (d, 1H, J = 3.3 Hz), 2.86 (br d, 2H, J = 6.9 Hz), 3.48 (m, 1H), 4.06 (dt, 1H, J = 7.1, 2.0 Hz), 5.13 (m, 1H); ^{13}C NMR (100 MHz) δ: 14.1, 17.7, 17.8, 18.2, 22.7, 25.4, 25.7, 25.8, 29.3, 29.56, 29.63, 31.9, 32.2, 67.5, 75.1, 78.5, 85.5, 118.6, 133.9. Anal. calcd. for $C_{25}H_{48}O_2Si$: C 73.46, H 11.84; found: C 73.64, H 12.26.

The more polar alcohol **21** (478 mg, 49%) was obtained as a colorless oil; IR: 3650–3300, 830 cm^{-1}; ^{1}H NMR (300 MHz) δ: 0.07 (s, 3H), 0.10 (s, 3H), 0.85 (t, 3H, J = 6.9 Hz), 0.89 (s, 9H), 1.20–1.70 (m, 18H), 1.59 (s, 3H), 1.67 (d, 3H, J = 1.1 Hz), 2.44 (d, 1H, J = 7.1 Hz), 2.87 (br d, 2H, J = 6.9 Hz), 3.66 (br q, 1H, J = 6.0 Hz), 4.16 (m, 1H), 5.14 (m, 1H); ^{13}C NMR (100 MHz) δ: 14.1, 17.6, 17.9, 18.1, 22.6, 25.0, 25.4, 25.9, 29.3, 29.49, 29.53, 29.56, 29.7, 31.9, 33.8, 65.0, 75.8, 79.3, 84.3, 118.8, 133.5. Anal. calcd. for $C_{25}H_{48}O_2Si$: C 73.46, H 11.84; found: C 73.42, H 11.93.

syn-*7-tert-Butyldimethylsiloxy-2-methyl-8-octadecanol (**22**)*

A mixture of enyne **20** (340 mg, 0.83 mmol) and Pd–C (10%, 200 mg) in THF (15 mL) was stirred under a H_2 atmosphere (1 atm) for 24 h. The mixture was filtered through Celite, washing well with ethyl acetate, and concentrated. The residue was filtered through a short plug of silica eluting with hexane/ether (15:1, v/v) to provide alcohol **22** (332 mg, 96%) as a colorless oil; IR: 3560, 3650–3300, 830 cm^{-1}; ^{1}H NMR (300 MHz) δ: 0.04 (s, 3H), 0.05 (s, 3H), 0.83 (d, 6H, J = 6.6 Hz), 0.86 (t, 3H, J = 6.8 Hz), 0.87 (s, 9H), 1.10–1.70 (m, 27H), 2.10 (br s, 1H), 3.39 (br m, 1H), 3.47 (dt, 1H, J = 6.1, 4.2 Hz); ^{13}C NMR (100 MHz) δ: −4.1, 14.1, 18.1, 22.59, 22.60, 22.68, 25.3, 25.89, 25.95, 27.7, 27.9, 29.3, 29.6, 29.7, 31.9, 33.9, 34.1, 38.9, 72.7, 75.2. Anal. calcd. for $C_{25}H_{54}O_2Si$: C 72.39, H 13.12; found: C 72.23, H 12.84.

syn-*8-tert-Butyldimethylsiloxy-2-methyl-7-octadecanol (**23**)*

A mixture of enyne **21** (450 mg, 1.1 mmol) and Pd–C (10%, 300 mg) in THF (20 mL) was stirred under a H_2 atmosphere (1 atm) for 24 h. The mixture was filtered through Celite, washing well with ethyl acetate, and concentrated. The residue was filtered through a short plug of silica eluting with hexane/ether (15:1, v/v) to provide alcohol **23** (434 mg, 95%) as a colorless oil; IR: 3560, 3650–3250, 830 cm^{-1}; ^{1}H NMR (300 MHz) δ: 0.05 (s, 3H), 0.06 (s, 3H), 0.84 (d, 6H, J = 6.6 Hz), 0.87 (t, 3H, J = 6.8 Hz), 0.88 (s, 9H), 1.10–1.70 (m, 27H), 2.10 (d, 1H, J = 6.9 Hz), 3.39 (m, 1H), 3.47 (dt, 1H, J = 6.2, 4.1 Hz); ^{13}C NMR (100 MHz) δ: −4.1, 14.1, 18.1, 22.60, 22.65, 22.67, 25.0, 25.9, 26.2, 27.4, 27.9, 29.3, 29.6, 29.9, 31.9, 33.7, 34.1, 39.0, 72.6, 75.1. Anal. calcd. for $C_{25}H_{54}O_2Si$: C 72.39, H 13.12; found: C 72.53, H 13.55.

*(±)-cis-7,8-Epoxy-2-methyloctadecane ((±)-disparlure) (**24**)*

To a solution of alcohol **22** (233 mg, 0.56 mmol) and Et_3N (0.17 mL, 2.2 equiv.) in CH_2Cl_2 (10 mL) at 0°C was added MsCl (0.052 mL, 1.2 equiv.) and the mixture was stirred for 30 min. Water (20 mL) was added and the aqueous was extracted with CH_2Cl_2 (3 × 20 mL). The combined organics were dried and concentrated. The residue was dissolved in THF (10 mL) and TBAF (1.7 mL, 3 equiv.) was added. After stirring at room temperature for 15 h, water was added and the mixture extracted with ethyl acetate (3 × 50 mL). The combined organics were dried, concentrated, and subjected to flash chromatography (hexane/ether, 20:1, v/v) to provide (±)-disparlure (**24**) (132 mg, 83%) as a colorless oil; IR: 2920, 2850, 1460, 1360, 1320, 1260, 725 cm^{-1}; ^{1}H NMR (300 MHz) δ: 0.84 (d, 6H, J = 6.6 Hz), 0.85 (t, 3H, J = 6.4 Hz), 1.10–1.60 (m, 27H), 2.86 (app quintet, 2H, J = 4.2 Hz); ^{13}C NMR (100 MHz) δ: 14.0, 22.56, 22.64, 26.6, 26.8, 27.3, 27.81, 27.85, 27.86, 29.3, 29.5, 29.6, 31.9, 38.9, 57.2. Anal. calcd. for $C_{19}H_{38}O$: C 80.78, H 13.56; found: C 80.94, H 13.10.

In a similar manner, alcohol **23** (450 mg, 1.1 mmol) was converted into (±)-**24** (269 mg, 88%).

One-pot synthesis of precocene I and II and a formal synthesis of robustadial A and B via 2-phenyl-4*H*-1,3,2-benzodioxaborin

SUZANNE BISSADA, CHEUK K. LAU, MICHAEL A. BERNSTEIN, AND CLAUDE DUFRESNE[1]

Medicinal Chemistry Department, Merck Frosst Centre for Therapeutic Research, P.O. Box 1005, Pointe Claire-Dorval, QC H9R 4P8, Canada

Received March 16, 1994

SUZANNE BISSADA, CHEUK K. LAU, MICHAEL A. BERNSTEIN, and CLAUDE DUFRESNE. Can. J. Chem. **72**, 1866 (1994).

The reaction of a phenol, an α,β-unsaturated aldehyde, and phenylboronic acid yields a 2-phenyl-4*H*-1,3,2-benzodioxaborin. Upon heating, this compound decomposes to an orthoquinone-methide intermediate, which undergoes an electrocyclization reaction to a chromene ring system. This method has been applied to the synthesis of precocenes **I** and **II** and the robustadial A and B.

SUZANNE BISSADA, CHEUK K. LAU, MICHAEL A. BERNSTEIN et CLAUDE DUFRESNE. Can. J. Chem. **72**, 1866 (1994).

La réaction d'un phénol avec un aldéhyde α,β-insaturé et de l'acide phénylboronique fournit une 2-phényl-4*H*-1,3,2-benzodioxaborine. Par chauffage, ce composé se décompose en un intermédiaire orthoquinone-méthane qui subit une réaction d'électrocyclisation conduisant à un système cyclique du chromène. On a appliqué cette méthode à la synthèse des précocènes **I** et **II** et des robustadials A et B.

[Traduit par la rédaction]

Introduction

The benzopyran family, of which the title compounds are part, is widely distributed in nature and plays an important role in a number of biological processes (1). Precocene I and II, isolated from *Ageratum houstonianum*, exert strong antihormonal activity in sensitive insects (2, 3) whereas robustadial A and B (5), isolated as a Chinese herbal medicinal extract of *Eucalyptus robusta* leaves, are useful in the treatment of malaria (4).

The most challenging task in synthesizing robustadials is the stereoselective construction of the spiro ring junction at the 2-position of a benzopyran ring, while preserving the integrity of the 6,6-dimethylbicyclo[3.1.1]heptane ring systems known to be sensitive to rearrangement under the acid conditions of the classical method for chromene ring system synthesis. This method requires three steps: (*a*) an acid-catalyzed cyclization to chromanone from a phenol and an α,β-unsaturated acid, (*b*) a reduction, and (*c*) a dehydration (6).

We have shown (7) that the reaction of α,β-unsaturated aldehydes, phenols, and phenylboronic acid results in the formation of the chromene ring system. 2-Phenyl-4*H*-1,3,2-benzodioxaborins are produced in situ, and they decompose to orthoquinone-methide intermediates. The latter undergo an electrocyclization reaction resulting in the formation of a chromene ring. We now report on the successful use of this methodology in the preparation of precocene I and II, and in a formal synthesis (8) of robustadial A and B.

Results and discussion

Precocene I was prepared by heating 3-methoxyphenol (**1**), 3-methyl-2-butenal (**2**), phenylboronic acid and propanoic acid in benzene with azeotropic removal of water. The desired product **3** was isolated in 95% yield. Precocene II was prepared similarly using 3,4-dimethoxyphenol (**4**) as starting material, affording **5** in 97% yield (Scheme 1). It is interesting to note that a single regioisomer was formed in each case. The boronic acid catalyzed condensation therefore exhibits a strong regioselectivity, probably for steric reasons. The reaction is believed to proceed via the intermediates **6** and **7**.

This process may now be applied to the synthesis of the robustadial skeleton. In this case, the α,β-unsaturated aldehyde **11** was required in order to form the desired 2-spiropinene-2*H*-1-benzopyran ring system. The aldehyde **11** was prepared from (1*R*)-(+)-nopinone (**8**) (Scheme 2). Homologation by a Wadsworth–Emmons reaction with triethyl phosphonoacetate and sodium hydride afforded **9**,[2] which in turn was reduced with DIBAL-H at –78°C to give **10**.[2] The alcohol **10** was oxidized with tetra-*n*-propylammonium perruthenate and *N*-methyl morpholine *N*-oxide (9), giving the desired **11**.[2] Using the reaction conditions described above, with 3,5-dimethoxyphenol (**12**) and **11**, we obtained a 3:2 diastereoisomer ratio of **13***a* and **13***b* in 66% combined yield.[3] With the spiropinene 2*H*-1-benzopyran ring system in hand, the next transformation towards robustadials was the replacement of the chromene C=C bond with a carbonyl at C4. To explore the desired transformation, the model compound **14** (Scheme 3) was subjected to oxymercuration (10) and bromohydrin formation reactions without success. On the other hand, hydrogenation to the 2,3-dihydro-4*H*-1-benzopyran ring system **15** and oxidation with ceric ammonium nitrate (CAN) (11) gave the desired chromanone **16** (6*a*, 6*b*). Applying this method to the spiro chromene system of robustadial precursors, the mixture of **13***a* and **13***b* was hydrogenated with 10% Pd on charcoal to give **17***a* and **17***b*[3] and this mixture was oxidized with CAN in a biphasic system to yield 52% of **18***a* and **18***b*. The two diastereoisomers were separated by hplc (Scheme 4) and correlated with the literature ^{1}H nmr, nOe and 2D-nmr spectral data for these precursors of robustadial A and B (8).

In summary, we have disclosed a novel and efficient route to precocene I and II via a 2-phenyl-4*H*-1,3,2-benzodioxaborin intermediate. This method was also applied to the synthesis of the robustadial skeleton, which was elaborated into a key chromanone intermediate, therefore constituting a formal synthesis of robustadial A and B.

Experimental

General information

Proton and carbon nuclear magnetic resonance spectra were obtained on a Bruker AM250 spectrometer or AM300 spectrometer. Elemental analyses were performed by Guelph Chemical Laboratories Ltd, Guelph, Ontario. Flash chromatography was performed using Merck silica gel 60, 230–400 mesh.

7-Methoxy-2,2-dimethyl-2H-1-benzopyran — precocene I, 3

A mixture of 3-methoxyphenol (0.565 g, 4.56 mmol), phenylboronic acid (0.889 g, 7.30 mmol), 3-methyl-2-butenal (0.766 g, 9.12 mmol), and propanoic acid (0.1 g, 1.36 mmol) in benzene was heated under reflux for 20 h, with azeotropic removal of water using a Dean–Stark trap. The reaction mixture was quenched with cold ammonium acetate (20%) and extracted with ethyl acetate. The extract was dried over Na_2SO_4 and evaporated to dryness. The residue was chromatographed, using 10% ethyl acetate in hexane as the eluent. The title compound was obtained in 95% yield (0.82 g) as an oil; ir (neat): 3050, 1630, 1600, 1450 cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$), δ: 1.40 (s, 6H), 3.77 (s, 3H), 5.49 (d, 1H, J = 10 Hz), 6.19 (d, 1H, J = 10 Hz), 6.60–6.80 (m,

3H). Anal. calcd. for $C_{12}H_{14}O_2$: C 75.76, H 7.42; found: C 75.54, H 7.26. Exact Mass calcd. for $C_{12}H_{14}O_2$ (M + 1): 191.10720; found: 191.10710.

6,7-Dimethoxy-2,2-dimethyl-2H-1-benzopyran — precocene II, 5

According to the previous procedure, using 3,4-dimethoxyphenol, the title compound was obtained in 97% yield after chromatography; ^{1}H nmr (300 MHz, $CDCl_3$), δ: 1.42 (s, 6H), 3.75 (s, 3H), 3.80 (s, 3H), 5.45 (d, 1H, J = 10 Hz), 6.02 (m, 2H), 6.57 (d, 1H, J = 10 Hz). Anal. calcd. for $C_{13}H_{16}O_3$: C 70.89, H 7.32; found: C 71.24, H 7.44. Exact Mass calcd. for $C_{13}H_{16}O_3$ (M + 1): 221.11776; found: 221.11775.

E/Z Ethyl 6,6-dimethylbicyclo[3.1.1]-2-heptylidene acetate, 9

Triethyl phosphonoacetate (34.5 g, 154 mmol) was added dropwise to a suspension of NaH (3.71 g, 154 mmol) in THF (225 mL) at 0°C, followed by a rapid addition of (1*R*)-(+)-nopinone (12.54 g, 90.8 mmol). The solution was heated at 50°C for 20 h. The reaction mixture was quenched with cold ammonium acetate (20%) and extracted with ethyl acetate. The extract was dried over Na_2SO_4 and evaporated to dryness. The residue was chomatographed with 5% ethyl acetate in hexane. The title compound was obtained in 87% yield (16.44 g) as an oil; ir (neat): 3090, 2980, 1725, 1680 cm^{-1}; ^{1}H nmr (300 MHz, $CDCl_3$), *E/Z* isomers, δ: 0.74 (s, 3H), 1.20–1.34 (m, 6H), 1.39 (d, 1H, J = 10 Hz), 1.80–2.72 (m, 4H), 3.14–3.21 (m, 1H), 3.99 (m, 1H), 4.1 (m, 3H), 5.47 (s, 1H); resolved signals of the minor isomer: 1.45 (d, 1H, J = 10 Hz), 5.6 (s, 1H); ^{13}C nmr ($CDCl_3$), major isomer, δ: 168.88, 166.62, 113.00, 112.57, 59.24, 53.73, 40.40, 27.21, 26.02, 23.62, 22.40, 22.06, 14.36. Anal. calcd. for $C_{13}H_{20}O_2$: C 74.96, H 9.68; found: C 75.24, H 9.77. Exact Mass calcd. for $C_{13}H_{20}O_2$ (M + 1): 209.15410; found: 209.15410.

E/Z-2-(6,6-Dimethylbicyclo[3.1.1]-2-heptylidene)ethanol, 10

To a solution of **9** (8.6 g, 41.3 mmol) in toluene (40 mL) at –78°C was added dropwise DIBAL-H 1.5 M in toluene (66 mL, 99.12 mmol). The reaction mixture was stirred for 15 min, then quenched with 0.5 M HCl (150 mL), and extracted with ethyl acetate. The organic phase was dried over Na_2SO_4, filtered, and evaporated. The residue was chromatographed using 30% ethyl acetate in hexane. The title compound was obtained as an oil in 95% yield (0.63 g) as a mixture of isomeric olefins; ir (neat); 3600, 3010, 1514, 1430 cm^{-1}; ^{1}H nmr (300 MHz, $CDCl_3$,), *E/Z* isomers, δ, isomer 1: 0.70 (s, 3H), 1.2 (s, 3H), 1.36 (s, 1H, J = 10 Hz), 1.84 (m, 3H), 2.1–2.2 (dd, 1H, J = 8 Hz, J = 12 Hz), 2.3–2.5 (m, 2H), 2.52–2.65 (m, 1H), 2.8 (t, 1H, J = 5 Hz), 3.95–4.20 (m, 2H), 5.2 (m, 1H); resolved signals of the minor isomer: 0.72 (s, 3H), 1.25 (s, 3H), 1.46 (d, 1H, J = 10 Hz), 2.00 (m, 2H), 5.40 (t, 1H, J = 5 Hz); ^{13}C nmr ($CDCl_3$), major isomer, δ: 146.86, 120.50, 58.79, 52.30, 45.17, 40.72, 40.66, 24.47, 26.00, 21.89, 19.43. Anal. calcd. for $C_{11}H_{18}O$: C 79.46, H 10.91; found: C 79.36, H 10.80. Exact Mass calcd. for $C_{11}H_{18}O+H^+$; 167.14359; found: 167.14355.

E/Z-2-(6,6-Dimethylbicyclo[3.1.1]-2-heptylidene)ethanal, 11

To **10** (0.50 g, 3.0 mmol), *N*-methyl morpholine *N*-oxide (0.52 g, 4.5 mmol), and 4Å molecular sieve (1.50 g) in dichloromethane (6 mL) was added tetra-*N*-propylammonium perruthenate (0.053 g, 0.15 mmol). The reaction was stirred for 5 min at room temperature. The reaction mixture was then filtered through a pad of Celite and concentrated. The residue was chromatographed using 20% ethyl acetate in hexane. The title compound was isolated as an oil in 95% yield (0.46 g); ir (neat): 2970, 1710, 1600, 1390; ^{1}H nmr (300 MHz, $CDCl_3$), *E/Z* isomers, δ, isomer 1: 0.77 (s, 3H), 1.31 (s, 3H), 1.49 (d, 1H, J = 10 Hz), 1.90–2.13 (m, 3H), 2.2–2.65 (m, 1H), 2.74–2.83 (m, 1H), 3.16 (d, 1H, J = 8 Hz), 3.55 (t, 1H, J = 5 Hz), 5.7 (d, 1H, J = 8 Hz), 9.98 (d, 1H, J = 8 Hz); resolved signals of the minor isomer: 0.78 (s, 3H), 1.55 (d, 1H, J = 10 Hz), 5.9 (d, 1H, J = 8 Hz), 9.85 (d, 1H, J = 8 Hz); ^{13}C nmr ($CDCl_3$), major isomer, δ: 190.35, 124.48, 57.95, 53.71, 40.37, 32.76, 26.55, 25.54, 25.87, 23.45, 22.10. Thermally unstable for MS or combustion analysis.

5,7-Dimethoxy-2-(6,6-dimethylbicyclo[3.1.1]-2-heptylidene)-2H-1-benzopyran, 13a, 13b

A mixture of **11** (0.555 g, 3.3 mmol), 3,5-dimethoxyphenol (0.521 g, 3.3 mmol), phenylboronic acid (0.825 g, 6.7 mmol), and propanoic acid (0.68 mL, 0.66 mmol) in benzene (7 mL) was heated under reflux for 3 h with azeotropic removal of water using a Dean–Stark trap. The reaction mixture was quenched with cold ammonium acetate (20%) and extracted with ethyl acetate. The extract was dried over Na_2SO_4 and evaporated to dryness. The residue was chromatographed eluting with 5% ethyl acetate in hexane. The title compound was obtained as a 3:2 mixture of **13***a* and **13***b* as oil in 66% yield (0.65 g). Major isomer, ^{1}H nmr (300 MHz, $CDCl_3$), δ: 0.98 (s, 3H), 1.19 (s, 3H), 1.68 (d, 1H, J = 10 Hz), 1.84–2.2 (m, 6H), 2.36 (t, 1H, J = 5 Hz), 3.76–3.78 (m, 6H), 5.59–5.05 (m, 1H), 5.99–6.03 (m, 2H), 6.51–6.56 (m, 1H). Anal. calcd. for $C_{19}H_{24}O_3$: C 75.97, H 8.05; found: C 75.79, H 8.17. Exact Mass calcd. for $C_{19}H_{24}O_3$ (M + 1): 301.18036; found: 301.18038.

2,3-Dihydro-5,7-dimethoxy-2,2-dimethoxy-4H-1-benzopyran, 15

5,7-Dimethoxy-2,2-dimethyl-2*H*-1-benzopyran (**14**) (*6a*) (0.6 g, 2.72 mmol) was dissolved in ethanol (6 mL), and 10% palladium on charcoal (60 mg) was added. The reaction mixture was hydrogenated using a Parr apparatus at 40 psi (1 psi = 6.9 kPa) for 40 min. The mix-

ture was filtered on a pad of Celite, and then was evaporated to dryness. The title compound was obtained in 100% yield (0.6 g) as an oil; ^{1}H nmr (300 MHz, $CDCl_3$), δ: 1.35 (s, 6H), 1.75 (t, 2H, J = 7.5 Hz), 2.58 (t, 2H, J = 7.5 Hz), 3.78 (s, 3H), 3.82 (s, 3H), 6.05 (s, 2H). Anal. calcd. for $C_{13}H_{18}O_3$: C 70.24, H 8.16; found: C 69.98, H 8.25. Exact Mass calcd. for $C_{13}H_{18}O_3$ (M + 1): 223.13341; found: 223.13361.

2,3-Dihydro-5,7-dimethoxy-2,2-dimethyl-4H-1-benzopyran-4-one, ***16***

To 2,3-dihydro-5,7-dimethoxy-2,2-dimethyl-4*H*-1-benzopyran (**15**) (0.300 g, 1.35 mmol) in acetic acid (14 mL) and water (14 mL) was added, in small portions, ceric ammonium nitrate (4.5 g, 8.20 mmol). The resulting mixture was heated in bath oil at 100°C for 20 min. The reaction mixture was quenched with ammonium acetate (20%) and extracted with ethyl acetate. The organic phase was dried over sodium sulfate and filtered, then chromatographed using 19:1 hexane in ethyl acetate to yield 60% (0.19 g) of an oil, which has a ^{1}H nmr spectrum corresponding to that previously described in ref. 6*a*.

2,3-Dihydro-5,7-dimethoxy-2-(6,6-dimethylbicyclo[3.1.1]-2-heptylidene)-4H-1-benzopyran, ***17a 17b***

To **13**a, **13**b (0.30 g, 1.09 mmol) in ethanol was added 0.3 g of palladium on charcoal 10%. The mixture was hydrogenated using a Parr apparatus at 40 psi for 40 min. The reaction mixture was filtered through a pad of Celite to yield 0.30 g or 100% of the title compounds. Major isomer, ^{1}H nmr, δ: 1.00 (s, 3H), 1.26 (s, 3H), 1.73–2.3 (m, 10H), 2.50–2.56 (m, 2H), 3.74 (s, 3H), 3.77 (s, 3H), 6.0 (m, 2H); resolved signals of the minor isomer: 1.17 (s, 3H), 1.21 (s, 3H); ^{13}C nmr ($CDCl_3$), major isomer, δ: 159.29, 158.25, 155.28, 103.19, 93.99, 90.67, 81.15, 55.30, 49.36, 41.25, 40.77, 38.51, 32.52, 31.87, 28.31, 27.70, 26.48, 24.94, 16.42. Anal. calcd. for $C_{19}H_{26}O_3$; C 75.46, H 8.66; found: C 75.26, H 8.74. Exact Mass calcd. for $C_{19}H_{26}O_3$ (M + 1); 303.19601; found: 303.19603.

2,3-Dihydro-5,7-dimethoxy-2-(6,6-dimethylbicyclo[3.1.1]-2-heptylidene)-4H-1-benzopyran-4-one, ***18a, 18b***

Using the procedure described for compound **16**, the title compound was obtained, in 52% yield, as an oil, which was purified by a hplc reverse-phase C_{18}, 8 × 10 Waters RCM column, solvent: 10% H_2O, 90% MeOH; λ = 280 nm sens 1; RT: **18***a*, 4.68 min; **18***b*, 7.35 min. "The isomers **18***a* and **18***b* were identified by correlation with reported spectra data (8):" minor isomer, precursor of the unnatural isomer of robustadial **18***b*: ir (neat): 3060, 1684, 1595, 1460 cm^{-1}; ^{1}H nmr (500 MHz, $CDCl_3$), δ: 6.06 (d, 1H, J = 2.2 Hz), 5.95 (d, 1H, J = 2.2 Hz), 3.85 (s, 3H), 3.79 (s, 3H), 2.62 (m, 2H), 1.75–2.34 (m, 7H), 1.17 (s, 3H), 1.11 (s, 3H), 1.02–1.04 (m, 1H); ^{13}C nmr (500 MHz, $CDCl_3$), δ: 190.54 (s), 166.01 (s), 163.35 (s), 161.85 (s), 105.84 (s), 93.99 (d), 92.17 (d), 86.24 (s), 56.07 (q), 55.25 (q), 50.00 (t), 48.17 (d), 40.63 (d), 38.38 (s), 28.36 (t), 27.29 (q), 26.73 (t), 23.85 (t), 23.18 (q). Crystal chemistry of tetraradial species. Part 5. Interaction between cation lone pairs and phenyl groups in tetraphenylborates: crystal structures of Me_3S^+, Et_3S^+, Me_3SO^+, Ph_2I^+, and 1-azoniapropellane tetraphenylborates[1,2]

OSVALD KNOP,[3] T. STANLEY CAMERON, PRADIP K. BAKSHI,[4] ANTONY LINDEN,[5] AND STEPHEN P. ROE

Received March 18, 1994

OSVALD KNOP, T. STANLEY CAMERON, PRADIP K. BAKSHI, ANTONY LINDEN, and STEPHEN P. ROE. Can. J. Chem. **72**, 1870 (1994).

Determination of the crystal structures of the tetraphenylborates of the trimethylsulfonium (Me_3S^+, $P2_1/n$), triethylsulfonium (Et_3S^+, *Cmcm*), trimethylsulfoxonium (Me_3SO^+, $P2_1/m$), diphenyliodonium (Ph_2I^+, *Pnma*), and 1-azoniapropellane ($C_{10}H_{18}N^+$, $P2_1/n$) cations has shown that when regions of high local electron density (lone electron pairs) are present in the cation, the cation orients itself so as to minimize the repulsion between the lone pair(s) and the nearest anion phenyl groups, i.e. the cation orientation responds to the lone pair – aromatic π system interaction. This behaviour contrasts with the formation of H...π hydrogen bonds in tetraphenylborates of organic ammonium cations containing *N*-hydrogens and provides corroborative evidence for our previous finding: (*1*) given the opportunity, a cation *N*-hydrogen will form a hydrogen bond to a phenyl group(s) of the anion; (2) the orientation of the cation to form the N—H(N)...π bond is thus a manifestation of a *positive* hydrogen-bonding tendency rather than a passive response to overall packing requirements in the crystal. The geometries of the above cations are compared to those reported in the literature and those of Me_3S^+ and Me_3SO^+ have also been optimized by *ab initio* (RHF/6-31G*) methods.

OSVALD KNOP, T. STANLEY CAMERON, PRADIP K. BAKSHI, ANTONY LINDEN et STEPHEN P. ROE. Can. J. Chem. **72**, 1870 (1994).

La détermination de la structure cristalline des tetraphénylborates des cations suivants: triméthylsulfonium (Me_3S^+, $P2_1/n$), triéthylsulfonium (Et_3S^+, *Cmcm*), triméthylsulfoxonium ($Me_3\ SO^+$, $P2_1/m$), diphényliodonium (Ph_2I^+, *Pnma*) et 1-azoniapropellane ($C_{10}H_{18}N^+$, $P2_1/n$), montre qu'en présence de régions à forte densité électronique locale (doublet électronique libre) dans le cation, ce dernier s'oriente de façon à minimiser la répulsion entre le doublet libre et les groupes phényles de l'anion les plus rapprochés, i.e. l'orientation du cation répond à l'interaction doublet libre avec le système π aromatique. Ce comportement contraste avec la formation des liaisons hydrogène H...π dans les tétraphénylborates des cations ammonium organiques contenant des liaisons N—H et fournit des preuves qui confirment nos résultats antérieurs à savoir: (*1*) si l'opportunité se présente, un cation ayant une liaison N—H formera des liaisons hydrogène avec le ou les groupes phényles de l'anion; (2) l'orientation du cation en vue de former la liaison N—H(N)...π est alors une manifestation d'une tendance positive à former une liaison hydrogène plutôt qu'une réponse passive à l'entassement global inévitable dans le cristal. On compare les géométries de ces cations avec celles répertoriées dans la littérature et on a optimisé les géométries des cations Me_3S^+ et Me_3SO^+ par les méthodes *ab initio* (RHF/6-31G*).

Previously (1, 3) we have shown that, given the opportunity, a cation *N*-hydrogen, H(N), will form a hydrogen bond to a phenyl group(s) of the tetraphenylborate (TB) counter anion, and that the orientation of the cation to form the H-bond is a manifestation of a *positive* H-bonding tendency (reinforced by ion charge interaction) rather than a passive response to overall packing requirements in the crystal. We now offer evidence that when regions of high local electron density (lone electron pairs, LP or L for short) are present in the cation in place of an H(N) atom, the orientation which the cation assumes with respect to the nearest phenyl ring(s) is significantly different from (sometimes the opposite of) that which would be expected if an H(N) atom were present.

The compositions and geometries of the five title cations were chosen to illustrate to maximum effect how the cation orientation depends on the nature of the interactive end of the cation. The cations discussed in the following (Table 1) and intended to provide contrast to the H-bonding cations (1, 3) are either of the quaternary ammonium variety, in which the N atom is sterically shielded from the anion by CH_3 or CH_2 groups (4MTB, ImB, AzPpTB), or they contain one or more oriented LPs on the terminal (central) atom (3MSTB, 3ESTB, 3MTeTB, 3MSOTB, 2PhITB). The sources of the structural information are listed in Table 1.

To provide comparison with the results of the previously (4) so treated Me_3S^+ cation, we have also optimized (RHF/6-31G*) the equilibrium molecular geometry of the Me_3SO^+ ion in C_3 and C_{3v} symmetries. The optimized geometries are compared in some detail with those from experiment, both in the title compound and in crystal structures reported in the literature.

The crystal data of the five title compounds are assembled in Table 2. Details of the crystal structure and other determinations (Tables A–F) have been deposited[6] (see also Experimental). The following tables and figure are available: Table A. Posi-

Hydrogen-bonded vs. nonbonded cations

The crystal structures of TBs of small cations are dominated by the packing of the anions. In the case of small *organic* cations this packing, which tends to be quite symmetric, is often based on the space group *Cmcm* or subgroup (1, 3). The freedom the cation has in these structures is restricted essentially to its orientability inside the wedge-shaped spaced formed by the phenyl rings.[7] These anion systems are therefore well suited for testing the propensity of the cation to interact with the phenyl groups and the nature of the cation–anion pair interaction. When a cation tends to form a H bond(s) to a phenyl group(s), this tendency is reinforced by the ionic charge. However, because of the large size of the anion the single charge is spatially greatly diluted, and while the net charge on the interacting cation hydrogen is larger than that on a CH_3 or CH_2 hydrogen in the cation, it is not dramatically so (cf. ref. 3). A cation orientation suggestive of H-bonding can therefore be legitimately interpreted as arising from a H-bonding interaction and not from Coulombic interaction as such. This is demonstrated by the following examples, in which geometries of the situations involving H bonding are compared side by side with the corresponding situations involving only ionic charge interaction.

In Figs. 1 and 2 the orientations of the H-bonding cations in 2MTB, 3MTB, and ImA are contrasted with the orientations of the cations in 4MTB, AzPpTB, and ImB, which do not contain *N*-hydrogens and thus are incapable of forming N—H...π bonds. A dramatic display of the effect of the presence of H(N) on cation orientation results when $Me_2NH_2^+$ is compared with Me_4N^+, and $Me_2C{=}NHMe^+$ with $Me_2C{=}NMe_2^+$. In the first pair the cations are rotated about their respective N...B axes so as to achieve bonding in $Me_2NH_2^+$ but "antibonding" of the corresponding two Me groups in Me_4N^+. In the iminium pair, the planar cation in ImA orients itself, in the plane bisecting the angle between the two phenyl rings, in such a way that the solitary H(N) forms a symmetrically bifurcated N—H...2π bond. In ImB the Me groups facing the rings are more or less equidistant, with the *N*-Me groups (one of which would correspond to H(N) in ImA) directed away from the rings. Since all the drawings in Fig. 1 are on the same scale (and similarly in Fig. 2), it is

[7] Thus the crystal structure of the TB is not determined (or even significantly influenced) by the presence of (oriented) LPs on the cation, the latter affecting only the cation orientation but not the packing as a whole (cf. ref. 4).

immediately evident that the H-bonded cations are closer to the phenyl rings than the nonbonded ones. The difference in the cation–ring distances is reflected in the comparison of the N...π_c (π_c, ring centre) and N...B separations for the H-bonded and nonbonded cations (Table 3).

The N...π_c vs. N...B points in Fig. 3 correspond to situations (1, 3) in which the cation is contained in the wedge-shaped space between two phenyl rings of an anion that are related by a pseudo-S_4 axis passing through the B atom. The points for the cations containing two H(N) atoms, both engaged in N—H...π bonds, fall in a relatively small area with N...B separations below ~4.8 Å. This region is well separated from that for the cations which contain no H(N) and thus no N—H...π bonds, and in which the N atom is isolated from the associated phenyl rings by CH_3 or CH_2 groups. For cations containing a *single* H(N) atom one ring is engaged in a N—H...π bond while the other is nonbonded. For each such cation there are thus two points in the plot. The points corresponding to bonding interaction fall in the general 2H(N)—cation region, albeit at somewhat longer N...B distances, while the others have d(N...π_c) > 4

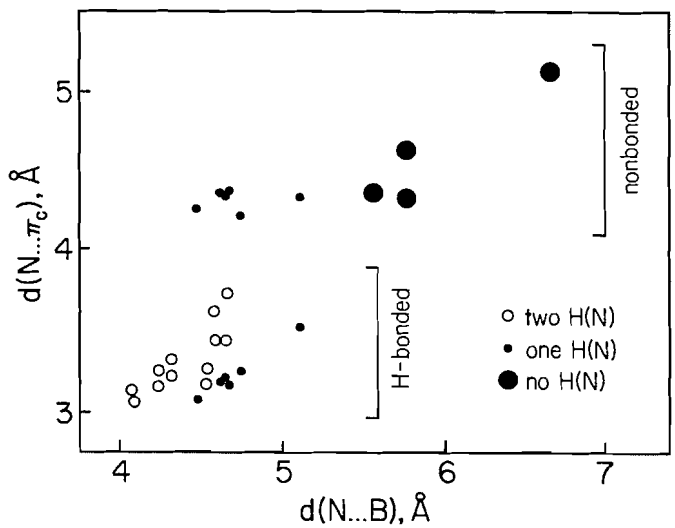

FIG. 3. Correlation of the shortest N...π_c and N...B distances in the tetraphenylborates of Table 3 and of refs. 1 and 3.

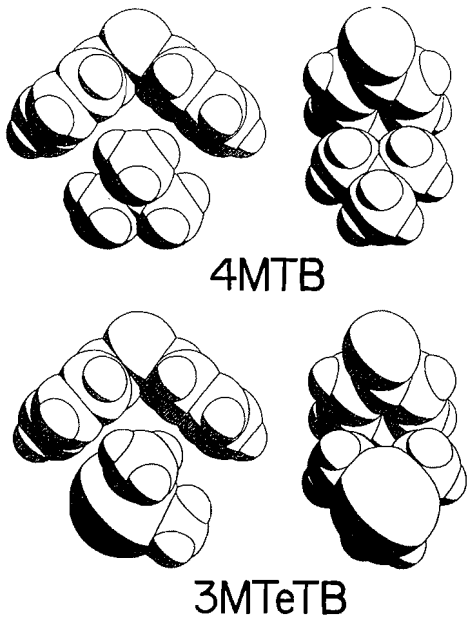

FIG. 4. Cation orientation in the isostructural pair 4MTB/3MTeTB. (Left) The proximal Me pair is oriented sideways in the wedge-shaped space formed by the nearest phenyl rings. Only one of the two cation orientations in 3MTeTB is shown; the other is obtained by reflection in the mirror plane through the B atom and perpendicular to the page. (Right) Side view with the front phenyl ring omitted for clarity. The four figures are to scale.

Å, consistent with the absence of H bonding. These $d(N...\pi_c)$ separations are greater than or equal to the sums of the van der Waals radii of the atoms in the CH_3 or CH_2 groups interposed between the N atom and the associated phenyl ring. There is no overlap between the H-bonded and the nonbonded region of the $N...\pi_c$ vs. N...B plot. The difference between the situations for which N—H...π bonding is claimed and those in which such bonding is absent is therefore clear-cut and significant, leaving no doubt that a difference in kind indeed exists between the two.

Effect of oriented lone electron pairs

In 4MTB the proximal pair of Me groups is oriented sideways in the wedge-shaped space formed by the two nearest phenyl groups (Figs. 1 and 2). In this cation orientation the Me hydrogens avoid the rings and the distance of the cation centroid from the anion is minimized. We now ask, how does this situation change when a Me group is replaced by an oriented lone pair?

The answer is provided by comparing 4MTB with Me_3TeL^+ in 3MTeTB. These two TBs are closely isostructural (*Cmcm*, $(a_N/a_{Te}):(b_N/b_{Te}):(c_N/c_{Te}) = 1.010:1.006:0.993$) and their structures are spatially completely determined by the anion packing. The cations are fully ordered in 4MTB but in 3MTeTB they are in a twofold orientational disorder across a mirror plane. Juxtaposition of $Me_2NMe_2^+$ and Me_2TeMeL^+ (Fig. 4) shows that the LP is oriented away from the phenyl rings, in preference to an orientation in which it would replace one of the (presumably bulkier) proximal Me groups in 4MTB. The reason for the orientational disorder and for 4MTB and 3MTeTB being isostructural is thus apparent.[8]

The reluctance of the LP to face a phenyl ring is demonstrated in a somewhat different way by the cation orientations in 3MSTB and 2PhITB (Figs. 5 and 6). In 3MSTB the unique LP on the S atom points *between* phenyl rings from three anions, one from each. The two LPs on the iodine atom in Ph_2I^+ are expected to be oriented tetrahedrally relative to the two I—C(α) bonds, i.e. with their axes in Figs. 5 and 6 in the page. Indeed, these directions are seen to skirt the nearest rings, in the plane bisecting the ring pair 1,1′ and clear of rings 2 and 3.

A similar avoidance of the phenyl rings by the oriented LP is displayed by Et_3S^+ in 3ESTB (Figs. 7 and 8). The shortest $S...\pi_c$ distances in 3MSTB and 3ESTB, 3.89 and 3.94 Å, are greater than the estimated van der Waals contact of 3.7 Å. In 3MSOTB the ring-avoiding tendency of the LPs on the O atom is more difficult to visualize, but it is undoubtedly present. The shortest $O...\pi_c$ distance, $O...\pi_c(2) = 3.68$ Å (Table 3, Figs. 5 and 6), is well above the value estimated for a van der Waals contact, 3.3 Å.

To facilitate recognition of the spatial relationships involving the LPs in the structures under discussion, Fig. 9 shows projections of the immediate cation environments that are designed to emphasize the orientation(s) of the pertinent LPs. The gap between the O atom and ring 2 (perpendicular to the S—O bond) in 3MSOTB is particularly noticeable: the $O...\pi_c(2) = 3.68$ Å separation is only ~0.2 Å smaller than the shortest $S...\pi_c$ distance in 3MSTB, 3.89 Å, a fact to consider in conjunction with the equality of the volumes V_1 per formula unit of 3MSOTB and 3MSTB (see under 3MSOTB below).

Individual crystal structures

None of the five title structures appears to have been reported previously.

3MSTB

Unlike in the corresponding Te compound 3MTeTB (6), the cations in 3MSTB are fully ordered. The two compounds are not isostructural: the 3MTeTB (*Cmcm*) structure is of a distorted NaCl type, while 3MSTB may be regarded as a highly distorted zincblende arrangement.

The anisotropic thermal parameters of the cation atoms are all reasonable and can be accounted for moderately well on the rigid-body-motion (RBM) model: $R(U_{ij}) = 13.2\%$, $R_w(U_{ij}) = 13.0\%$, $\text{rms}(U_{ij}) = 0.0060$, $\text{rms}[\text{esd}(U_{ij})] = 0.0047$ Å^2. The principal axis L_1 of libration coincides approximately with the quasi-C_3 axis of the cation, with L_2 and L_3 perpendicular to it. The mean librational amplitudes about these axes are 3.4°, 6.5°, and 7.5°, respectively. The bond lengths corrected on this model are S—C(1), 1.776(9) → 1.791 Å; S—C(2), 1.772(8) → 1.795 Å; S—C(3), 1.776(8) → 1.795 Å.

3ESTB

The cation in this structure is positionally disordered. The disorder was treated as a twofold orientational disorder across a mirror plane ||(001). Attempts to refine the structure as fully ordered in $Cmc2_1$ were not successful.

[8]It would be of interest to investigate why 3PhTeTB is not isostructural with 4PhAsTB and 4PhSbTB (Table 1). 3PhTeTB is triclinic, with a large unit cell ($V = 6483$ Å^3, $Z = 8$), while the other two are tetragonal ($V = 3600$ and 3628 Å^3, respectively, $Z = 4$). The structure of 3PhTeTB has not been determined; attempts to determine the structures of 4PhAsTB and 4PhSbTB have so far been unsuccessful (ref. 7; Knop et al., unpublished results). It appears likely that all three structures derive from a primitive CsCl-type tetragonal cell with $a \sim 11$, $c \sim 7$ Å, $Z = 1$ 4PhAsTB and 4PhSbTB, $a\sqrt{2} \times a\sqrt{2} \times 2c$; 3PhTeTB, $a\sqrt{2} \times a\sqrt{2} \times$ 4c.

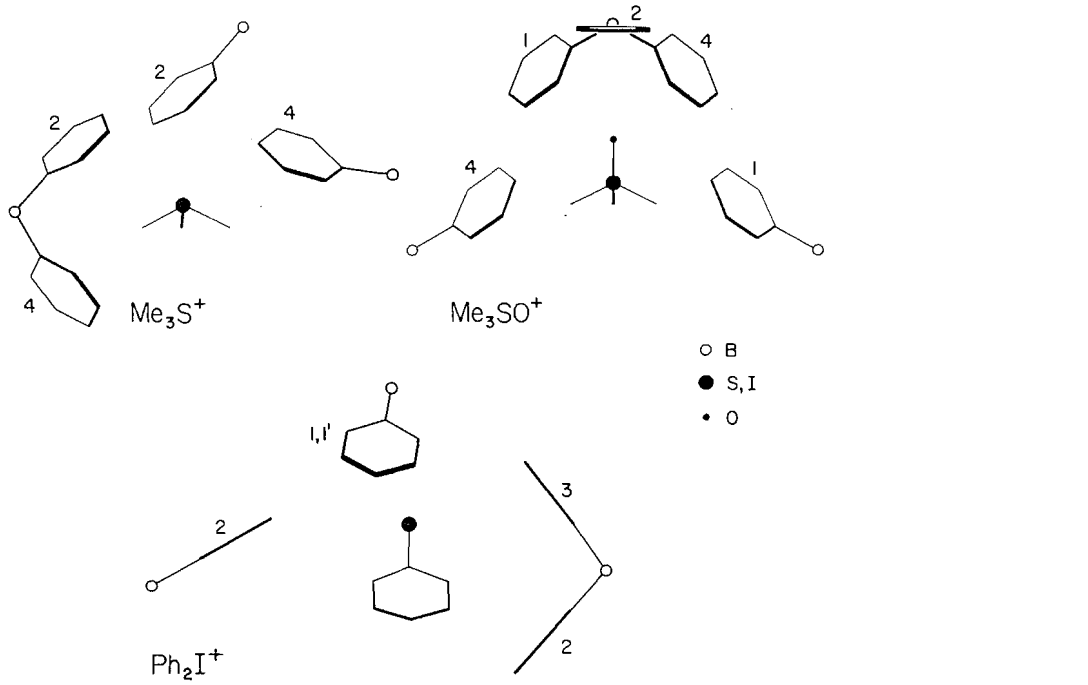

FIG. 5. Orientation of the presumed lone electron pair(s) on the S, O, and I atoms relative to the phenyl rings of the nearest anion(s) in 3MSTB, 3MSOTB, and 2PhITB, respectively. The crystallographic mirror plane passing through the I atom of 2PhITB and through the B atoms of the anions is in the page.

The anion packing is of the same type as in 4MTB and 3MTeTB (both *Cmcm*, cf. Fig. 3 of ref. 3), and in 3MSOTB ($P2_1/m \subset Cmcm$) if the unit cell is properly transformed (see under 3MSOTB). The ion packing in these structures is of a distorted NaCl type. The difference in the volumes per formula unit, V_1(3ESTB) − V_1(3MSTB), is 58.3 Å^3, i.e. 19.4 Å^3/CH_2, an unexceptionable value.

3MSOTB

When the $P2_1/m$ unit cell of Table 2 (a, b, c, β) is doubled to a B-centred cell (a', b', c', β') by the transformation $\boldsymbol{a'} = \boldsymbol{a} + \boldsymbol{c}$, $\boldsymbol{b'} = \boldsymbol{b}$, $\boldsymbol{c'} = -\boldsymbol{a} + \boldsymbol{c}$, a nearly orthogonal cell results, β' = 91.4°. On change of setting ($\boldsymbol{a''} = \boldsymbol{a'}$, $\boldsymbol{b''} = \boldsymbol{c'}$, $\boldsymbol{c''} = \boldsymbol{b}$) this cell can be directly related to an orthorhombic cell that is obtained from *Cmcm* by a dichromatic subgroup descent in symmetry (9, 10): $Cmcm \rightarrow Cm'c'm$ (no. 63/462), $P2_1/m \subset Cmcm$. The dimensions of the transformed cell are similar to those of other *Cmcm* TB structures:

Compound	a, Å	b, Å	c, Å	β, deg	V, Å^3
3MSOTB	11.489	15.379	12.790	91.4	2260
4MTB	11.565	15.635	12.868	90	2327
3MTeTB	11.445	15.539	12.955	90	2304
3ESTB	10.939	16.173	14.097	90	2494

i.e. these structures differ only in the way the cations are accommodated in the fixed anion arrangement.

The anion in 3MSOTB is of symmetry C_s, but geometrically it is close to a C_{2v} or even D_{2d} conformation (Table D). The geometry of the cation is discussed in some detail below.

Remarkably, the volume per formula unit V_1(3MSOTB) is the same as V_1(3MSTB), 565 Å^3. This would seem to indicate that in both 3MSTB and 3MSOTB it is the bulk of the methyl groups rather than the effective size of the S or O atom as such

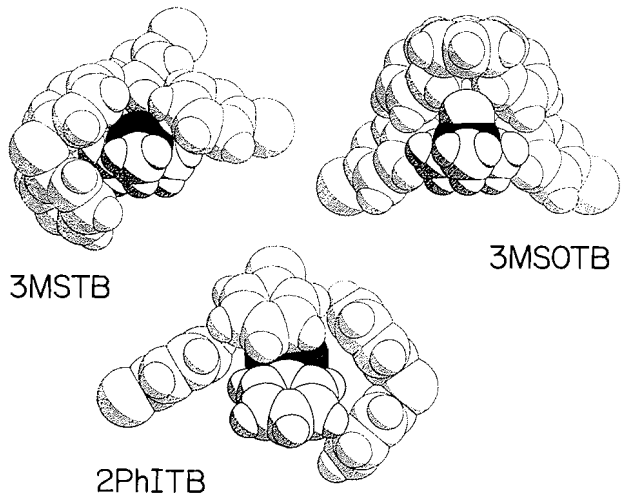

FIG. 6. Space-filling representation of the cation–anion pairs of Fig. 5. The S and I atoms are shown in black.

that governs the closeness of approach of the oriented cation to its associated phenyl rings. In other words, the observed S...π and O...π distances do not represent the "true" such distances but are controlled by external factors that make them too long, in such a way that both the S atom and the S—O group can be accommodated in the structure without the difference between the two manifesting itself in the unit volume. This would also apply to 3ESTB.

The thermal motion of the cation is consistent with RBM: $R(U_{ij}) = 5.9\%$, $R_w(U_{ij}) = 6.6\%$, rms(U_{ij}) = 0.0032, rms[esd(U_{ij})] = 0.0029. The largest-amplitude (mean, ~9°) libration is about an axis perpendicular to the S—O bond, i.e. to (010). The bond lengths corrected on the RBM model are S—O, 1.422(6) → 1.445 Å; S—C(1), 1.737(7) → 1.757 Å; S—C(2), 1.730(10) → 1.760 Å. The corrections to the bond angles are within 0.3°.

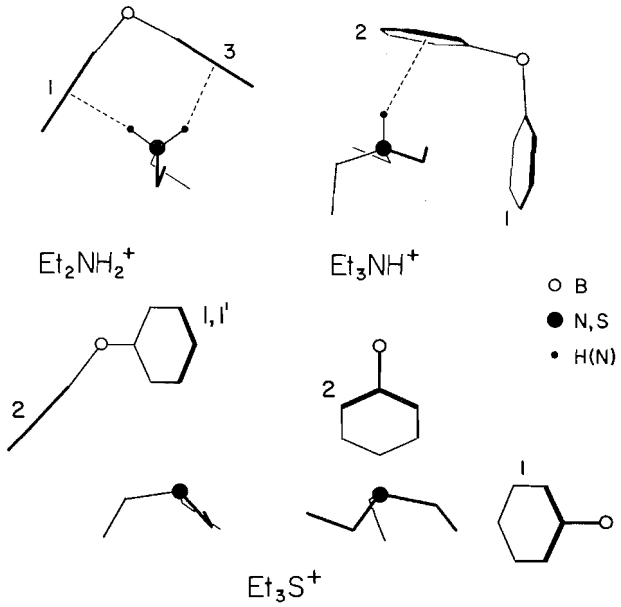

FIG. 7. Comparison of the hydrogen-bonding orientations in 2ETB and 3ETB with the "antibonding" orientation in 3ESTB. The N and S atoms are shown in black. The side view of the cation–anion pair in 3ESTB (left) shows the avoidance of the nearest phenyl rings by the lone pair on the S atom.

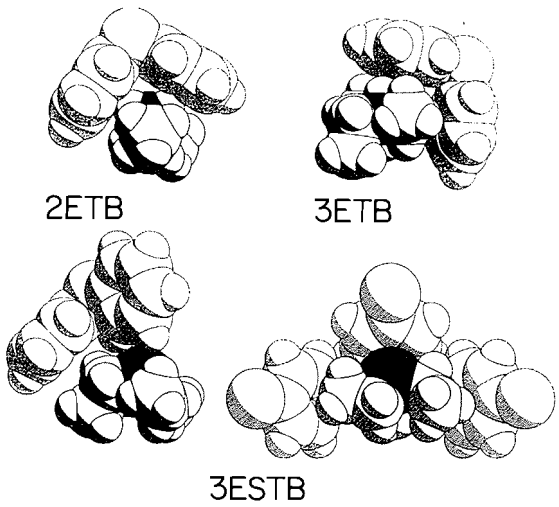

FIG. 8. Space-filling representation of the cation–anion pairs of Fig. 7. The N and S atoms are shown in black.

2PhITB

The free refinement of 2PhITB was characterized by large temperature factors, not only on the cation atoms, but also on some of the anion carbons (Table C; U_{33} of C(32) and C(33), ~0.26 Å^2). This is quite exceptional for a TB ion. The crystal did undergo slow deterioration during the data acquisition and an analytic decay correction had to be applied, but it is difficult to see how the gradual loss of crystal integrity would have affected the outcome of the structure determination *selectively*, by singling out a ring-carbon U_{ii} here and there in the structure. A more plausible explanation is to be sought in the particulars of the local structural arrangement.

Ring 3 of the anion is perpendicular to m||(010) and almost parallel to (001) (fig. 10). The largest U_{ii} are associated with atoms C(32) and C(33) and correspond to translations ||c, i.e. perpendicular to the ring. The nearest cation phenyl rings are 1′

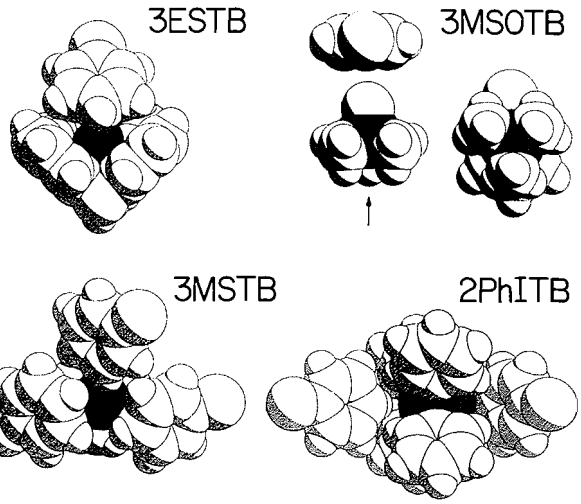

FIG. 9. Avoidance of the phenyl rings by the lone pairs on the S and I atoms. 3MSTB and 3ESTB: projection down the threefold cation axis, LP on the S atom pointing upward from the page. 3MSOTB: (left) the S—O bond is vertical in the page; (right) projection down the S—O bond (arrow), the O atom eclipsed by the S atom and points downward from the page. 2PhITB: projection down the bisector of the cation; the two LPs on the iodine point downward and sideways from the page. The S and I atoms are in black, the cations are in heavier line.

and 1″, and from Fig. 10 it is immediately evident that the C and H atoms closest to ring 3 are C(4)′ and H(4)′ of ring 1′. In fact, H(32)...H(4)′ ~ 1.76 Å is the shortest (static) H(anion)...H(cation) distance in the structure, well below the van der Waals contact of ~2.4 Å; all the other distances between the placed phenyl hydrogens are longer than 2.3 Å. The unusually short distance of 1.76 Å appears to be the direct cause of the large U_{33} values on C(32) and C(33). Seeking to minimize the repulsion between H(32) and H(4)′ (and between the symmetry counterparts of these hydrogens, Fig. 10), ring 3 undergoes a librational motion about its C(31)—C(34) axis, which is approximately parallel to a. Support for this assumed shutter mechanism (not necessarily cooperative though possibly correlated by a lattice mode) comes from TLS analysis of the thermal parameters of ring 3. While the motion of the ring is not too well accounted for on an RBM model (carbons only, $R(U_{ij})$ = 11.9%, $R_w(U_{ij})$ = 8.7%, rms(U_{ij}) = 0.0085 Å^2; carbons plus boron, $R(U_{ij})$ = 13.4%, $R_w(U_{ij})$ = 9.5%, rms(U_{ij}) = 0.0087, rms[esd(U_{ij})] = 0.0036 Å^2),[9] the directions of the principal libration axes $\boldsymbol{L}$ and the relative magnitudes of the mean librational amplitudes about these axes leave little doubt that the above explanation of the large U_{33} values is better than qualitatively valid: L_1||c, ~1°; L_2||b, ~3°; L_3||a, ~22° (cf. inset of Fig. 10). Since the proposed repulsion-minimizing mechanism involves the cation rings, the large U_{ii} values on the cation come as no surprise.

Several attempts to model the separate pivoting motions of the rings in terms of twofold positional disorder were only partially successful, indicating that the complexity of the dynamic disorder in this crystal resists a simple treatment. The best attempt to resolve the disorder, by splitting the C(32) and C(33) positions and those of all six cation carbons (Tables A–C) produced an overall improvement (Table 2) and significantly lowered the largest U_{ii} in both the anion and the cation.

The cation is of C_s symmetry, with an angle of 100.4°

[9]When U_{ij} = 0 for atoms in special positions are included, rms[esd(U_{ij})] = 0.0030 Å^2.

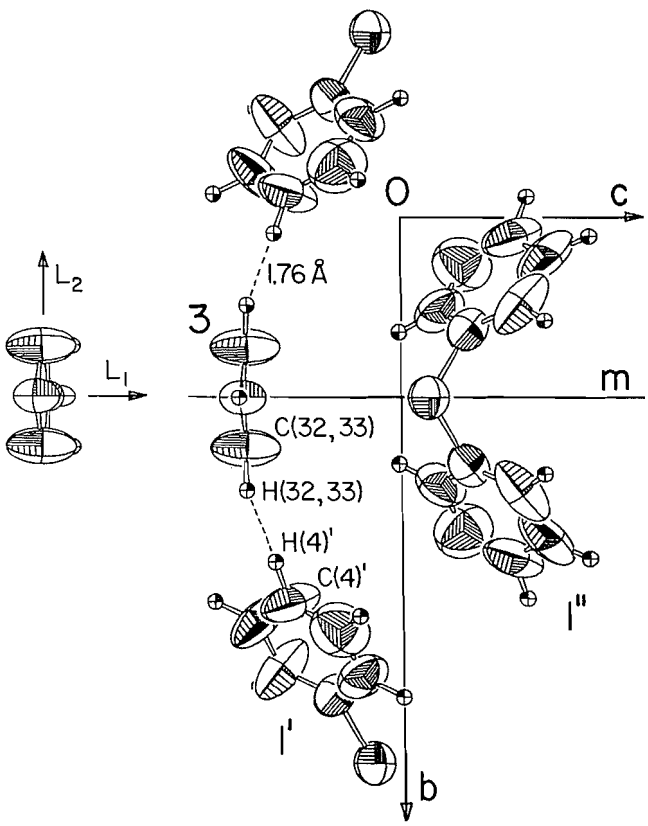

FIG. 10. Thermal motion in 2PhITB (projection on (100); 50% probability ellipsoids). Atoms C(32) and H(32) in ring 3 of the anion are eclipsed by atoms C(33) and H(33), respectively. The H(cation...H(anion) distance of 1.76 Å is between H(32) and H(4)′ (see text). Inset (left): projection of ring 3 down its principal libration axis L_3, as obtained from a TLS analysis.

between the best planes through the ring skeletons (mean deviation $\bar{\delta}$(C) from planarity, 0.023 Å). The iodine atom is 0.113 Å out of the ring planes. The cation geometry is compared with that of the handful of reported Ph_2I^+ cations below.

AzPpTB

The anions in this structure are arranged in an approximate fc packing, but the positions of the cation centroids cannot be described as corresponding to the NaCl or the zincblende arrangements without invoking severe, unnatural distortions.

The cation symmetry is very close to C_{3v} with the unique N—C axis ⊥(100) (Fig. A).[6] The mean deviations of the C and N atoms from the best planes corresponding to m_v of C_{3v} are 0.149, 0.150, and 0.142 Å for rings 1 (N — C(1, *n*) — C), 2 (N — C(2, *n*) — C), and 3 (N — C(3, *n*) — C), respectively (cf. Table A); the respective inter-ring angles 2/1, 3/1, and 3/2 are 120.0°, 120.3°, and 119.7°. The means of the endocyclic angles in rings 1–3 are 104.7(5)°, 104.7(5)°, and 104.8(10)°, respectively, with the corresponding sums of 523.5°, 523.5°, and 524.0° (ideal sum for a planar pentagon, 540°).

The thermal motion of the cation approximates only moderately well to the RBM model: $R(U_{ij}) = 12.5\%$, $R_w(U_{ij}) = 11.7\%$, $\text{rms}(U_{ij}) = 0.0059$, $\text{rms}[\text{esd}(U_{ij})] = 0.0028$ Å^2. Corrections to the bond lengths calculated on this model amount to ~0.02 Å; those to the bond angles are within 0.15°. The mean librational amplitudes about the principal axes of libration are 4.6°, 5.7°, and 6.6°.

Ion geometry

Title cations

The bond lengths and angles in the cations are listed in Table D. In Tables 4–7 the geometries of these less common cations

are also compared with the available literature reports[10] as well as (for Me_3S^+ and Me_3SO^+) with the RHF/6-31G* optimized geometries of the free cations (Table F).

The experimental means for Me_3S^+ (Table 4) are d(S—C) = 1.782(12) Å, C—S—C = 101.8(7)° (n = 33; uncorrected for thermal motion). Both values are within 2σ of the *ab initio* values. The geometry of the free Me_3S^+ configuration converged in the optimization from an initial C_3 to C_{3v} symmetry, with the six H atoms directed toward and the three H′ atoms away from the LP on the S atom.

The geometry of the Me_3SO^+ ion is like that of Me_3S^+ with the oxygen atom symmetrically added. The three H′ atoms are below the plane of the C atoms, away from the S atom (Figs. 6 and 9). The means for the uncorrected experimental data sets of

[10]The accuracy of some of the older structure determinations involving Me_3S^+ (24), Et_3S^+ (25), Me_3SO^+ (26, 27), and Ph_2I^+ (28) is limited and those determinations have not been considered here.

[b]Angle between best planes through the carbon skeletons of the phenyl rings.
[c]R2/R1 angle calculated from the published atom coordinates.
[d]Centrosymmetric $Ph_2I—(X)_2—IPh_2$ μ_2-dimers. Phenyl rings constrained to regular hexagons.

Table 5 are d(S—O) = 1.435(6) Å (n = 12), d(S—C) = 1.745(6) Å, O—S—C = 112.6(4)°, C—S—C = 106.2(6)° (n = 36). These means compare well with the calculated values. The optimization process for Me_3SO^+ likewise proceeded from an initial C_3 symmetry to C_{3v}

The mean S—C bond length in Me_3SO^+, 1.745(6) Å, is shorter than in Me_3S^+, 1.782(12) Å. Statistical tests (t test and analysis of variance) show that this difference is significant at the 99.5% level: t = 15.7, $t_{0.005,60}$ = 2.92; F = 245, $F_{0.005,1,60}$ = 8.49). Similarly, the mean C—S—C angle in Me_3S^+, 101.8(7)°, is smaller than that in Me_3SO^+, 106.2(6)°, a highly significant difference (t = −29.2, $t_{0.005,60}$ = 2.92; F = 854, $F_{0.005,1,60}$ = 8.49). These differences are also present in the 6-31G* values of d(S—C) and C—S—C as well as in the electron densities at the critical points in the S—C bonds, 1.296 e/Å^3 for Me_3S^+ and 1.441 e/Å^3 for Me_3SO^+, the lower electron density corresponding to the longer bond. The reduction of the C—S—C angle in Me_3S^+ relative to Me_3SO^+ can be regarded as reflecting a greater lateral repulsion exerted by the LP on the S atom compared to that of the S—O bond, in accordance with the tenets of the VSEPR model.

The geometry of the Et_3S^+ ion in 3ESTB is not as well defined as that of Me_3S^+ because of the orientational disorder. However, the mean S—C bond length for the cations in Table 6, 1.789(35) Å, is indistinguishable from the corresponding mean for Me_3S, 1.782(12) Å; with 3ESTB excluded, the mean bond length is 1.803(10) Å, i.e. still well within the 2σ statistics.

Structural information on the diphenyliodonium ion, Ph_2I^+, is far from abundant (Table 7). The means for the available values are $\bar{d}$(I—C) = 2.093(16) Å, ⟨C—S—C⟩ = 93.0(12)°, and the mean angle ⟨C(2)—C(1)—C(6)⟩ at the α carbon is 121.8(10)°, i.e. essentially undistorted (cf. refs. 29–32). The dihedral angles R2/R1 between the ring planes range from ~85° to ~100°; they undoubtedly are sensitive to packing and secondary binding forces. The geometry of the I atom is thus tetrahedral.[11]

Our search of the Cambridge Crystallographic Data file failed to uncover a previous structure determination involving the 1-azoniapropellane cation, hence no comparison can be made.

traphenylborate anion

The geometry of the anion in the five title compounds is not exceptional. These structures contain five distinct TB ions, corresponding to 16 distinct phenyl groups. Although one of the anions is of symmetry C_{2v}, two of symmetry C_s and two of symmetry C_1, the actual anion geometry is always recognizably close to D_{2d}. The overall means of the B—C bond lengths, the C—B—C valence angles α and α′, and the endocyclic C(2)—C(1)—C(6) angles at the α carbon are indistinguishable from the corresponding means reported for 20 TB anions in ref. 1, and statistically more homogeneous:[12]

Parameter	Value	
	This work	Ref. 1
$\bar{d}$(B—C), Å	1.644(2)	1.646(10)
α	104.2(2)°	104.4(17)°
α′	112.2(2)°	112.1(17)°
⟨C(2)—C(1)—C(6)⟩	114.8(2)°	115.0(9)°

The planarity of the 16 phenyl rings is satisfactory (Table E). The overall mean deviation of the C atoms from the best planes through the ring skeleton is 0.006(3) Å (0.007(4) Å in ref. 1). The corresponding deviations of the B atom from the ring plane are listed in Table E, which also contains the interplane angles.

Conclusions

The organization of the crystal structures of the tetraphenylborates of small organic ammonium cations is dominated by the anion packing. The cations are accommodated in the wedge-shaped spaces formed by the phenyl rings of the nearest anion neighbour or sometimes by rings from two or more anion neighbours. The orientation of the cation in this space depends on whether or not the cation contains one or more *N*-hydrogen atoms. When an H(N) atom is present, it will engage in a H-bond to the nearest phenyl group. The resulting N—H(N)...π bond(s) can be of a variety of types (cf. ref. 1). When other contenders for H-bonds are simultaneously present in the structure (e.g. a solvent molecule, Cl^-), the cation may engage in H-bonds to these as well as to phenyl groups.

When the H(N) atom(s) is replaced by an alkyl or an alkyl-like group, the cation will orient itself in such a way that the repulsion between the alkyl and the phenyl groups as well as the

n $(C_5H_5N)_2I^+$ (33) donation of the LP on the N atom to the iodine
this ion to be centrosymmetric.

[12]The number in parentheses is the standard deviation for the sample population; it does not include the esd's from the individual structure determinations.

cation–anion distance are minimized. When the cation nitrogen is replaced by an atom X containing an oriented LP (e.g. S, Te, I) but with no H(X) atom attached to it, the LP will tend to avoid the phenyl groups. The strength of the ring-avoiding tendency decreases in the order LP > [CH_3, CH_2] > H(N), i.e. from a positive ring-avoiding tendency to a positive H-bonding tendency.

As a result of this and the preceeding investigations in this series (1, 3) the case for the existence of N—H(N)...π bonding as a positive H-bonding tendency to the delocalized π systems of the phenyl groups can be regarded as established.

Experimental

Preparation

The desired TB was precipitated from an aqueous or aqueous-alcoholic solution of the requisite cation halide by adding aqueous solution on $NaBPh_4$ at room temperature. The precipitate was washed with water and redissolved in acetone. Water was then added dropwise until reprecipitation occurred. The solution was restored by adding a minimum amount of acetone and set aside for recrystallization by slow evaporation at room temperature.

Structure determination

An Enraf-Nonius CAD-4 four-circle diffractometer and a Rigaku AFC5R diffractometer were used in the data acquisition (cf. Table 2). The intensities ($\omega/2\theta$) were reduced and corrected for Lorentz and polarization effects by routine procedures (34, 35). Low-angle reflections were examined for possible second-order intensity leakage from their respective strong $2h2k2l$ homologues. Empirical absorption corrections (8) were applied; extinction corrections were obtained where they seemed indicated. Scattering factors for neutral atoms and anomalous dispersion corrections were taken from ref. 36.

The structures were solved by the direct method. The function minimized in the refinement was $\Sigma w(|F_o| - |F_c|)^2$. Unit weights were used throughout. The temperature factor is defined as $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$. The hydrogen atoms were placed geometrically (C—H, 1.08 Å) and not refined ($U_{iso}(H) = 1.2B_{eq}(C)$ of the attached C atom). The computer programs of refs. 8, 35, and 37–39 were used in the structure solving, refinement, and presentation.

It must again be emphasized that in general organic cation TB crystals are weak and fickle scatterers (3). Significant reflections were seldom observed above a $(\sin\theta)/\lambda$ limit of 0.48 $Å^{-1}$ ($\theta \simeq 20°$ for Mo radiation). Since in this laboratory X-ray data collection routinely extends to a limit of 0.55 $Å^{-1}$ ($\theta = 23°$), the ratio of observed reflections to total measured unique reflections never exceeded 50%. When attempts were made to collect the data at lower temperatures they produced little if any improvement in these ratios.

Tables of structure factors are available from the Senior Editor (Tables G–L).

Systematic absences. *Cmcm* (3ESTB): hkl, $h + k$ odd; $0kl$, k odd; $h0l$, h, l odd; $hk0$, $h + k$ odd; $h00$, h odd; $0k0$, k odd; $00l$, l odd. *Pnma* (2PhITB): $0kl$, $k + l$ odd; $hk0$, h odd; $h00$, h odd; $0k0$, k odd; $00l$, l odd. $P2_1/n$ (3MSTB, AzPpTB): $h0l$, $h + l$ odd; $0k0$, k odd; $h00$, h odd; $0k0$, k odd; $00l$, l odd. $P2_1/m$ (3MSOTB): $0k0$, k odd.

Other comments. The 2PhITB crystal showed signs of progressive deterioration during the intensity collection. An analytic decay correction was therefore applied.

Ab initio *calculations*

The equilibrium molecular geometries of the Me_3S^+ and Me_3SO^+ cations were optimized, at the RHF/6-31G* level, using GAUSSIAN 86 (40) supplemented by AIMPAC (41). The optimizations were started in configurations of C_3 symmetry but in both cases converged to C_{3v} conformations. As a check, the two geometries were also optimized, independently, with C_{3v} as the imposed symmetry, but the differences between the C_3 and the $C_3 \rightarrow C_{3v}$ calculations were very minor.[13] The results of the C_{3v} optimizations are listed in Table F and partially also in Tables 4 and 5.

The present result for Me_3S^+ supersedes that of the earlier (Table 7 of ref. 4) calculation. The small discrepancies between the latter and Table F are attributable to the use of an earlier version of GAUSSIAN implemented on a different computer.

[13] Me_3S^+: $E(C_{3v}) = -516.11091$ au $\sim E(C_3 \rightarrow C_{3v})$. Me_3SO^+: $E(C_{3v}) = -590.90229$ au $\sim E(C_3 \rightarrow C_{3v})$.

Face-selective Diels–Alder reactions of (1*R*,5*R*)-3-formyl-6,6-dimethylbicyclo[3.1.1]hept-3-en-2-one

HSING-JANG LIU, YANHONG LI,[1] AND ERIC N.C. BROWNE[2]

Department of Chemistry, The University of Alberta, Edmonton, AB T6G 2G2, Canada

Received March 15, 1994

HSING-JANG LIU, YANHONG LI, and ERIC N.C. BROWNE. Can. J. Chem. **72**, 1883 (1994).

The stereofacially differentiated enone aldehyde **11** was chosen to study the effects of steric and electronic influence on the Diels–Alder reaction. Under Lewis acid catalysis, **11** adds to dienes at low temperatures at a reasonable rate. Yields of desired chiral adducts are good to high with zinc chloride and boron trifluoride etherate catalysis. In all cases only products of addition to the *Re* face of general type **27** were observed. The regiochemistry of the adducts is exclusively that predicted by the *ortho* and *para* rules. The stereochemistry shows a very high selectivity in favour of aldehyde-*endo* transition state products. Unusual by-products were also obtained in some examples and mechanisms of these unexpected reactions are discussed.

HSING-JANG LIU, YANHONG LI et ERIC N.C. BROWNE. Can. J. Chem. **72**, 1883 (1994).

On a choisi le cétoaldéhyde insaturé **11**, différencié stéréofacialement, pour étudier les effets stériques de l'influence électronique sur la réaction de Diels–Alder. En présence d'un catalyseur de Lewis et à basse température, le composé **11** s'additionne sur les dièenes avec un rendement raisonnable. Les rendements en adduits chiraux désirés varient de bon à élevé avec le chlorure de zinc et l'éthérate trifluorure de bore comme catalyseurs. Dans tous les cas, on n'observe que les produits d'addition sur la face *Re* du type général **27**. La régiochimie des adduits est exclusivement celle prédite par les règles *ortho* et *para*. La stéréochimie montre une très grande sélectivité en faveur d'un aldéhyde-*endo* dans l'état de transition. On a également obtenu des produits secondaires inhabituels dans certains cas et on discute des mécanismes de ces réactions inattendues.

[Traduit par la rédaction]

Introduction

In recent years we have reported on a series of Diels–Alder reactions of 4,4-dimethyl-2-cyclohexenones **1** (1), **2** (1, 2), **3** (1, 3, 4), **4** (5) and several closely related cross-conjugated cyclic unsaturated carbonyl compounds **5** (6), **6** (7), **7** (8, 9), **8** (10, 11), **9** (12), and **10** (12). These studies showed that structural features in the dienophile and the nature of the Lewis acid strongly influence the regio- and stereoselectivity of the reaction. The use of various directing components such as cross-conjugated carbalkoxy groups or additional double bonds has provided a probe into the effect of structural, steric, and electronic features on the course of Diels–Alder additions by the study of their influence on the relative stabilities of the various possible orientational transition states. We also explored diastereofacial selectivity of some of these dienophiles (**8–10**). Additions to **8** and **9** ($n = 1, 2$) take place preferentially from the less hindered face while additions to **9** ($n = 0$) and **10** are from the more hindered face.

One of the most interesting features apparent in comparing this assemblage of dienophiles is the effect of the carbonyl directing substituents on the *exo* or *endo* orientation of addition. Dienophiles **4–8** exhibit preferential additions with diene orientation *endo* to the exocyclic ester directing substituent. Compounds **3** and **10** are preferentially keto-*endo* directed while the few examples we have reported to date for **9** ($n = 0$) exhibit reversal of selectivity depending on the diene used. Although the unusual behavior of **9** ($n = 0$) remains to be thoroughly explored and reported, the contrasting *exo–endo* orientation differences between the other groups of dienophiles raise important questions. What is the relative directing influence of the possible exocyclic substituents (alkyl, ketone, ester, aldehyde, halogen, nitrile, heteroatom, etc.)? Is the contribution of additional conjugation to the endocyclic carbonyl (such as the second cyclic double bond of **3** and **10**) the principal directing influence, overriding any contribution from the exocyclic directing substituent (in the same qualitative way that *ortho*-rule addition tyically supersedes *para*-rule addition of appropriately substituted dienes)? From a theoretical perspective, could secondary orbital effects really be the sole mechanism through which these orientational effects are manifested? From a practical viewpoint, can semi-empirical or theoretically based rules be identified to predict products in various novel systems in such a way as to allow strategic placement of directing influences into synthetic plans?

As a lead-in to the wider examination of Diels–Alder reactivity that these questions demand, and to improve on the stereoselectivity and yields of additions to **8**, we have turned our attention to enone aldehyde **11**. The formyl group is more strongly electron withdrawing and sterically smaller than the corresponding ester group in **8**. On these accounts alone the aldehyde-*endo* transition state **11***a* should be more strongly favoured over the keto-*endo* transition state **11***b* than the preference (11) for the corresponding ester-*endo* transition state of **8***a* over its keto-*endo* transition state **8***b*. The study also offers an interesting opportunity for comparison of the secondary oribital effect between the ester and aldehyde substituents. The elaboration[3] or removal[4] of the formyl group from the adducts can be addressed with a wider variety of methods than the carbalkoxy group so that **11** might prove to be even more synthetically useful than **8**.[5] The results of our investigations of Diels–Alder reactions of **11** are presented.

Results and discussion

*1. Preparation of enone aldehyde **11***

Enone aldehyde **11** was synthesized in high yield from (−)-

β-pinene **12**[6] in three steps (Scheme 1). We have already described the ozonolysis of β-pinene and its hazards[7] in reporting on the preparation of enone ester **8**. In the present study a modified procedure for ozonolysis of (−)-β-pinene in dichloromethane–methanol at higher concentration followed by reductive work-up with dimethyl sulfide gave (+)-nopinone (**13**) in an improved yield of 93%. Its spectral data were identical to those previously reported (11). We repeated the preparation several times and once, instead of chromatography, carried out purification by vacuum distillation without incident. The problems reported by others (22, 23) might be due to incomplete reduction of the ozonolysis products or improper handling of the work-up procedure. The following are some important precautions to consider in conducting this reaction: (*i*) A persistent blue or purple colour of the reaction solution can not serve as an indication of completion of the ozonolysis. We found that even when the purple colour remained, there was still considerable starting material remaining in the reaction mixture. Typically, only about 78% yield of product was formed (11). On the other hand, when tlc analysis showed the complete consumption of starting material, ketone **13** was obtained in 93% isolated yield. (*ii*) After the ozonolysis is complete, oxygen gas must be blown through the reaction mixture (5–10 min) to remove the excess of ozone. (*iii*) The reducing agent (dimethyl sulfide) must be added at low temperature (−78°C) and then the reaction mixture should be allowed to warm slowly over 2–4 h to room temperature. (*iv*) The amount of the reducing agent should be in excess and the reduction time should be suficiently long (overnight) to ensure the completion of the reaction.

The formyl group was introduced by the method of Watt and co-workers (24), treating **13** with sodium hydride and ethyl formate. The reaction was catalyzed by a few drops of ethanol and proceeded smoothly to give keto aldehyde **14** in 93% yield. Spectral data indicated that compound **14** was a mixture (7:2.5:1) of its tautomer and epimers. The ratio of the three components varied with the purity of the compound or with different solvents or temperatures. Dehydrogenation of **14** was carried out in two steps using the approach of Liotta et al. (25): phenylselenenylation followed by oxidative elimination of the resulting selenide to give enone aldehyde **11** in about 70% yield.

The desired product was always accompanied by epoxide **15**, presumably as a result of overoxidation. The epoxidation was very sensitive to the pH of the reaction media. When the oxidation was carried out under neutral conditions, the amount of epoxide increased rapidly and even became the major product (**11**:**15** = 1:1.2). When the selenide solution was oxidized immediately after washing with 1 N hydrochloric acid, only a small amount of epoxide was formed (**11**:**15** = 8:1). Compounds **11** and **15** were not separable by either column chromatography or bulb-to-bulb distillation. Pure epoxide **15** was recovered after the subsequent Diels–Alder reaction in which enone aldehyde **11** was totally consumed.

The mechanism for the generation of epoxide **15** remains unclear. The accepted mechanism for epoxidation of an α,β-unsaturated ketone or aldehyde by hydrogen peroxide, by 1,4-addition of hydroperoxide followed by ring closure with elimination of hydroxide (26–28), does not fit very well in this case. An alkaline medium would be required to deprotonate hydrogen peroxide and generate the hydroperoxide. In this case, there was no base present. If any hydroperoxide was present, it must have come from equilibrium dissociation of hydrogen peroxide (29). Such a process would not be sufficient to induce epoxidation of a normal α,β-unsaturated ketone or aldehyde. But in compound **11** the double bond is doubly activated and thus more highly reactive to Michael addition. Under neutral conditions, once the epoxidation is initiated by a trace of hydroperoxide, the epoxidation could be catalyzed by the hydroxide generated in the ring closure reaction. This process could lead to epoxide **15** as the major product. When the reaction is carried out under acidic conditions the hydroxide would be neutralized, the epoxidation process inhibited, and epoxide **15** would be obtained as only a minor by-product.

Recently, Reich suggested an alternative mechanism for the oxidation step.[8] In his opinion the rate of oxidation of the selenide to selenoxide is relatively slow. The observed rapid oxidation rate usually observed is attributed to perseleninic acid ($RSeO_3H$), which is generated during the reaction (30). It is perseleninic acid that acts as the true oxidant which enables the reaction to proceed at the fast rate observed. This is reasonable since perseleninic acid is a very strong oxidant. It should be possible to accelerate the oxidation by adding seleninic acid to the reaction mixture as a catalyst, thus reducing the amount of epoxidation so that a higher yield of the desired product may be achieved. To confirm this proposal several reactions were carried out using benzeneseleninic acid as a reagent. The results

[6]Commercial (−)-β-pinene was obtained from Aldrich Chemical Co. and had an optical purity of 92%.

[7]See footnote 11 in ref. 11.

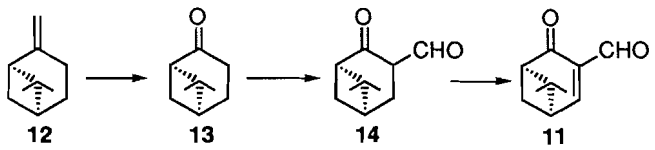

SCHEME 1

are listed in Table 1. We did observe a significant increase in the reaction rate but no obvious improvement in yield or product ratio. It is conceivable that the seleninic acid catalyzed both oxidation and epoxidation and thus the rates of both reactions increased to about the same extent. In fact, when 0.5 equivalents of seleninic acid was used, the ratio of the two products dropped to 5:1. Of many runs using this preparation, the best **11**:**15** ratio obtained was 12:1 after purification by bulb-to-bulb distillation.

Another side reaction also occurred during the oxidation. A small amount (3–8%) of **14** was always recovered. The intermediate selenide and selenoxide are both sterically congested at the C-3 position and may be relatively labile. Attack by a nucleophile such as hydrogen peroxide at the selenium atom could result in displacement of the selenium center, leaving a carbanion **16** and leading to formation of **14** after protonation. Several other methods were examined to improve on the production of enone aldehyde **11**, including 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) (31), sodium periodate (30), magnesium mono-perphthalate (MMPP),[9] hydrogen peroxide (30), and ozone (30) oxidation of **14** as well as non-oxidative elimination of the selenide (32). These alternative procedures gave no useful yield of product.

*2. Diels–Alder reactions of enone aldehyde **11***

A variety of Lewis acids and conditions were explored for the Diels–Alder reaction of enone aldehyde **11** with isoprene. The results of these investigations are summarized in Table 2. The particular Lewis acids chosen were previously noted as particularly suitable catalysts for related cross-conjugated enone dienophiles (6, 33). The Diels–Alder reaction of **11** was very sensitive to the choice of Lewis acid catalyst. The milder Lewis acid catalysts gave better yields. Good yields of product **17** were obtained with zinc chloride and boron trifluoride etherate. When ferric chloride and stannic chloride were used, the yields dropped drastically. This result may be due to greater stability of the strained ring system of the reactant and the product under the relatively mild acidic conditions of boron trifluoride etherate and zinc chloride catalysis and degradation by the stronger Lewis acids. In further investigations of the scope of the Diels–Alder reaction of **11**, only boron trifluoride etherate and zinc chloride were used as catalysts. Adducts were obtained in good to high yields and the results are summarized in Table 3.

[9]The experiment was made using MMPP in the manner used in ref. 30 for *m*-chloroperbenzoic acid.

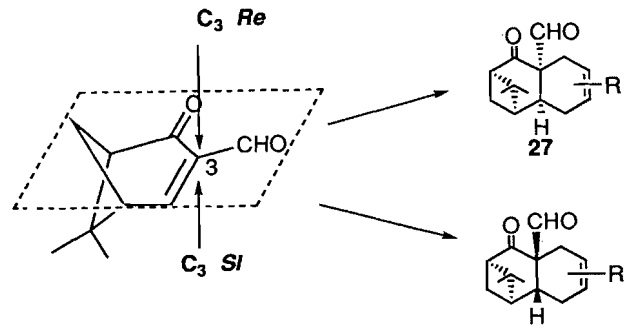

TABLE 2. Lewis acid catalyzed Diels–Alder addition of isoprene to enone aldehyde **11**

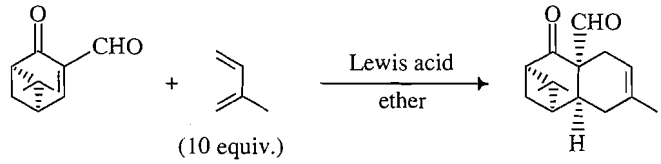

11 **17**

Lewis acid (equiv.)	Temp. (°C)	Time (h)	Yield (%)

In principle, Diels–Alder addition to enone aldehyde **11** could occur from either the sterically more hindered *Si* face or the less hindered *Re* face to give stereochemically distinct products (Scheme 2). In all cases, only the products of the addition to the *Re* face (general structure **27**) were obtained. The *gem*-dimethyl group in **11** presumably served to direct the Diels–Alder addition to the less hindered *Re* face, as indicated by the stereochemistry of the ring junction of the adducts. The structures of the adducts were established using spectroscopic methods including ^1H nmr, ^1H decoupling, and nOe experiments. The results of the nOe experiments are summarized in Table 4.

A. Addition to isoprene

The reaction of enone aldehyde **11** with isoprene under zinc chloride catalysis in ether at –20°C gave the adduct in 74% yield after 18 h. When boron trifluoride etherate was used as a

catalyst the reaction was finished in 2 h to give 84% yield of the adduct. Structure **17** could be assigned to the adduct if the Diels–Alder addition followed the normal *para* rule. However, orientational reversal, in violation of the *para* rule, in the Diels–Alder reaction of a 2-substituted diene has been observed (1, 2, 4). To rule out the possibility that the addition of isoprene to **11** could produce the regioisomer **28**, extensive ^1H decoupling experiments were carried out and all the protons of the adduct were assigned. A doublet of doublets assigned to H4e was observed to couple to H5 with a coupling constant of 7.0 Hz, as expected for the $CH_3C{=}CH_xCH_yH$ system (J_{xy} = 4–10 Hz). The regioisomeric adduct **28** would be expected to show a smaller coupling constant for the $CH_x{=}C(CH_3)CH_yH$ system (J_{xy} = 0–3 Hz) (34). On the basis of this ^1H nmr spectral data, structure **17** rather than **28** was assigned to the Diels–Alder adduct.

The stereochemistry of the ring junction was determined by nOe experiments. Irradiation of the ring junction proton (H8) signal at δ 2.94 resulted in enhancements of the formyl proton and the *endo*-methyl protons at δ 0.73. This implied that the formyl group and the *gem* dimethyl were on the same face as the ring junction proton. Thus the addition of isoprene obeyed the *cis* principle and occurred on the less hindered *Re* face of **11** to give adduct **17**. When the methyl at δ 1.32 was irradiated, nOe enhancements of H1, H11*exo*, H9 and the *endo*-methyl at δ 0.73 were observed. From this experiment, the *gem*-dimethyl and the *exo* and *endo* protons of the methylene bridge were assigned. The appearance of the *exo* methyl signal further down field than the *endo* methyl signal is probably due to shielding of the *endo* methyl by the ketone carbonyl. The signal at δ 2.52 (H11*exo*, dddd) was coupled to H1 (J = 5.5 Hz), H9 (J = 8.5 Hz), H11*endo* (J = 11.0 Hz) and H8 (W-coupling, J = 2.0 Hz). On the other hand the signal at δ 1.89 (H11*endo*), which was strongly shielded relative to H11*exo*, appeared as a readily recognizable doublet (J = 11.0 Hz) as the dihedral angles of H11*endo* to H1 and H9 were each about 90°.

B. Addition to trans*-piperylene*

When enone aldehyde **11** was reacted with *trans*-piperylene at −20°C under zinc chloride catalysis two adducts in a ratio of 170:1 were obtained in 60% yield. With boron trifluoride etherate catalysis two adducts in a ratio of 64:1 were formed in 71% yield. The adducts showed only one spot on the tlc plate and could not be separated by flash chromatography. The adducts displayed two sets of signals in the ^{13}C nmr APT spectrum and in the ^1H nmr spectrum. Since the product obtained was a mixture of two inseparable diastereomers the specific rotation was not measured. If the Diels–Alder reaction followed the normal *ortho* rule, then the structures of the adducts could tentatively be assigned as **18** and **19**. To conclusively determine the regiochemistry of the adducts, extensive ^1H decoupling experiments were carried out on the major isomer and a complete spectral assignment was made. The ring junction proton (H8), which appeared as a dddd at δ 2.80, was coupled to H7ax (J =

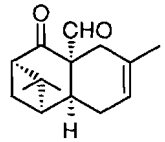
 **25**	*endo* CH_3	0.82	2.3 (CHO), 8.2 (*exo* CH_3), 6.8 (H8)

10.5 Hz), H7e (J = 7.5 Hz), H9 (J = 2.0 Hz), and H11*exo* (W-coupling, J = 2.0 Hz). This coupling pattern indicated that two hydrogen atoms were attached to C7. Thus the methyl substituent could only be located at C4 and the major isomer was assigned the regiochemistry of structure **18**.

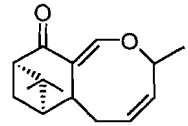
The stereochemistry of **18** was determined by nOe experiments. Irradiation of the *endo* methyl (δ 0.71) resulted in nOe enhancement of H8. According to the *cis* principle the formyl group should be on the same face as H8. This indicated that the addition of *trans* piperylene occurred from the *Re* face. Saturation of the methyl doublet (δ 1.40) produced enhancement of the formyl proton, indicating that the C4 methyl is on the same face as the aldehyde group. These experiments conclusively established the stereochemistry of the major adduct as that shown by **18**.

The presence of a trace amount of a minor isomer could only be detected by high-resolution nmr. Some ^{1}H nmr signals of the minor isomer were separated from those of the major isomer. The rest were buried under the signals of the major isomer. Therefore nOe and decoupling experiments were not performed on the minor adduct since it was impossible to complete all the spectral assignments. Compared to previous results obtained from our group (11), the two adducts should be epimers, so the minor isomer was tentatively assigned structure **19**.

In addition to adducts **18** and **19**, an unexpected product was formed during the Diels–Alder reaction between enone aldehyde **11** and *trans*-piperylene, with either boron trifluoride etherate or zinc chloride catalysis, in 14 and 15% isolated yield, respectively. This compound showed an intense spot under the uv lamp (short wavelength) on a tlc plate and greater polarity than the Diels–Alder adducts. It was isolated as a white crystalline compound by column chromatography. Based on the spectral data, structure **29** was assigned to the by-product, which



28



29

might have formed by a stepwise 1,4-cyclization process (see Scheme 3) instead of a Diels–Alder reaction. The reason for generation of this unexpected type of by-product in this partic-

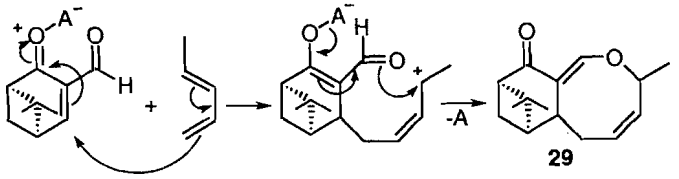

SCHEME 3

ular case and not in any other example described here is not clear to us at this time.

C. Addition to trans-*2-methyl-1,3-pentadiene*

At –40°C the boron trifluoride etherate catalyzed Diels–Alder reaction of enone aldehyde **11** with *trans*-2-methyl-1,3-pentadiene proceeded smoothly to give a colourless liquid in 82% yield. Although the products showed only one spot on tlc and could not be separated by flash chromatography, the ^{1}H nmr spectrum indicated the presence of two compounds in a ratio of 133:1. Assuming that the reaction followed the normal *ortho* and *para* rules, the structures of the two adducts could be tentatively assigned as keto aldehydes **20** and **21**. Previous observations indicated that the coupling pattern of the ring junction proton (H8) could be used to determine the regiochemistry of the Diels–Alder adducts of 1-substituted dienes. Detailed ^{1}H decoupling experiments of the major isomer showed that irradiation of the signal at δ 2.82 (H8, dddd) led to a change in multiplicity of the signals at δ 2.47 (H11*exo*), 2.10–2.30 (two protons, H7ax and H9), and 1.98 (H7e). As for the previous cases, this coupling pattern indicated that two hydrogen atoms were attached to C7 and consequently the methyl substituent must be at C4, confirming the regiochemistry of the major isomer as shown by structure **20**.

To determine the stereochemistry of the ring junction and the C4 methyl, nOe experiments were carried out on the major isomer. When proton H8 (δ 2.82) was irradiated, enhancement on the *endo* methyl (δ 0.66) was observed. This indicated that the H8 proton was on the same face as the *gem*-dimethyl group and therefore the addition of the diene occurred from the *Re* face of **11**. The stereochemistry of the formyl group was then assigned in accordance with the *cis* principle. When the signal at δ 1.40 (C4 methyl) was irradiated nOe enhancements of H5, H4 and the formyl proton signals were observed. This confirmed the position and the stereochemistry of the methyl substituent of the major isomer as that specified by structure **20**.

The ^{1}H nmr spectral data of the minor isomer were incomplete. Therefore we could not unambiguously assign the structure of the minor isomer. The tentative assignment as structure **21** was based on the previous findings on a similar system (11).

D. Addition to 2,3-dimethylbutadiene

Enone aldehyde **11** reacted with 2,3-dimethylbutadiene using boron trifluoride etherate as a catalyst to give a colourless liquid in 92% yield. The spectral data were consistent with the proposed structure **22**. Again the stereochemistry was determined by nOe experiments. Irradiation of the *endo* methyl at δ 0.71 resulted in enhancement of H8 (δ 2.88), the formyl proton (δ 9.71), and the *exo* methyl (δ 1.70). These findings supported the assigned stereochemistry of **22** resulting from the addition of the diene exclusively from the *Re* face of enone aldehyde **11**.

E. Addition to 2-tert-*butyldimethylsiloxy-3-methyl-1,3-butadiene*

To examine the addition of more highly functionalized dienes we considered silyloxydiene **23**. We previously observed (6) that silyloxy dienes such as **23** and **30** are extremely sensitive to the acidity of some Lewis acids and only zinc chloride produces useful yields. The reaction of **23** (10 equiv.) with **11** catalyzed by zinc chloride was much faster than other additions to **11** reported here. The product was obtained in 70% yield after purification by column chromatography. The spectral data supported the general structural features of the expected Diels–Alder adduct except that the formyl group was absent. Evidently the formyl group was eliminated during the reaction or work-up and so the *cis* principle could not be applied directly to the structure assignment. In addition, several signals were at unexpected downfield shifts in the ^{1}H nmr spectrum.

To determine the regio- and stereochemistry of this adduct, nmr decoupling studies were carried out. Irradiation of the protons at δ 4.00 (H4e and H7e) led to a change in multiplicity of the signals at δ 3.38 (H4ax), 2.34 (H7ax) and 1.43 (C5-CH_3). When the signal at δ 3.31 (H8) was irradiated, the signal at δ 3.38 (H4ax) was also irradiated, due to their close proximity. Changes in multiplicity of the signals at δ 4.00 (H4e), 3.71 (H3), 1.94 (H9), and 1.43 (C5-CH_3) were observed. Irradiation of the proton at δ 2.29 (H1) led to a change in multiplicity of the signals at δ 1.94 (H9) and 1.73 (H11*exo*). These results confirmed that structure **24** expressed the correct regiochemistry of the adduct.

To determine the stereochemistry of the ring junction, nOe experiments were carried out. From the spectral data of other compounds in this series the methyl singlet at higher field (δ 0.89 for this compound) usually represented the *endo* methyl group. When the singlet at δ 0.89 was irradiated, nOe enhancements of the signals at δ 2.29 (H1), δ 1.94 (H9), and δ 1.73 (H11*exo*) were observed. These results indicated that the methyl singlet at δ 0.89 was due to the *exo* methyl. The absence of the formyl group could cause the exchange of the chemical shifts between the two geminal methyl groups. We tried to irradiate proton H8 at δ 3.31; however, proton H4ax at δ 3.38 was so close to H8 that it was also irradiated and the results of this experiment were inconclusive. Therefore the stereochemistry of the ring junction could not be determined by nOe experiments. The large coupling constant (11 Hz) observed for H3 suggested a *trans* ring junction as depicted by structure **24**; however, we do not consider this assignment to be conclusive since this coupling could be to the adjacent H4ax.

Since the diene **23** was used in large excess (10 equiv.), 19.4% of the diene was recovered intact after column chromatography. Diels–Alder dimerization of diene **23** also occurred during the reaction and 12% yield of the dimeric adduct **31** was obtained. We wanted to determine if the formyl group was lost from an initial adduct such as **32** to give **24**. It could have been eliminated during the reaction or during the work-up. Also, since this addition was faster than other zinc chloride catalyzed additions of **11**, there was a possibility that the excess of the relatively costly diene **23** could be reduced without lowering the yield. We ran the reaction again with 5 equivalents of diene **23**. The reaction was monitored carefully to observe when the formyl group was removed. After complete conversion a sample of the reaction mixture was concentrated and the ^{1}H nmr spectrum of the residue was recorded before addition of saturated sodium bicarbonate solution. The spectrum showed the absence of a formyl group in the crude mixture, indicating its loss during the cycloaddition reaction. The yield of product **24** was not affected by the reduction in the amount of the diene used.

F. Addition to 1,3-cyclopentadiene

Attempts to induce addition of 1,3-cyclopentadiene to **11** with boron trifluoride etherate as catalyst were unsuccessful due to rapid polymerization of the diene. When zinc chloride was used, the Diels–Alder reaction produced a mixture of two inseparable adducts (20:1 by ^{1}H nmr) in 52% yield. Preliminary analysis of the spectral data indicated that the structures of the adducts could be assigned as **25** and **26**. Extensive ^{1}H decoupling experiments on the major isomer led to the assignment of all its protons. The ring junction proton (H8) appeared at δ 3.17 as a multiplet. Irradiation of the signals at δ 3.01 (H7) and 2.30 (H9) led to a small change in multiplicity of the signal at δ 3.17. In an nOe experiment, when the *endo* methyl at δ 0.82 of the major isomer was irradiated, enhancement of the signals at δ 3.17, δ 9.81 and δ 1.32 were observed. Therefore the major product was assigned with both H8 and the formyl group in the α-orientation. Previous observations indicated that the addition of dienes to enone aldehyde occurred exclusively from the *Re* face of **11**. It was therefore expected that exclusive addition of cyclopentadiene to the *Re* face of **11** would also occur, so the minor isomer would most likely contain an α-H8 and an α-formyl group as well.

The stereochemistry of the methylene bridge of the bicyclo[2.2.1]heptene ring system was determined by comparing the difference in chemical shifts between the two vinylic protons with the known compounds **33** and **34** (11). Since the major isomer exhibited a larger difference in chemical shift between the two vinylic protons (Δδ 0.30) than the minor isomer (Δδ 0.11), it was assigned structure **25** while the minor isomer was assigned structure **26**.

G. endo*-Selectivity of the addition*

All dienes in this study added to enone aldehyde **11** with very high diastereomeric excess and mention of this *endo*-selectivity is appropriate. As we have described for related dienophiles (1, 7, 8, 11), there are two dienophilic components in **11**: the α,β-unsaturated ketone (**11***c*) and the α,β-unsaturated aldehyde (**11***d*). It would be unnecessary to distinguish between these two moieties except in certain cases for 1- and 4-substituted dienes. *endo*-Addition to either the enone or the α,β-unsaturated aldehyde moiety would give stereochemically distinguishable products. Determining which dienophilic moiety would control the reaction pathway should be a function of the secondary orbital overlap with the diene. The addition of 1-substituted dienes (Table 3, Entries 1–3 and 9) to **11** occurred predominantly with secondary orbital overlap with the aldehyde (as in aldehyde-*endo* transition state **11***a*) rather than with the ketone carbonyl (as in keto-*endo* transition state **11***b*). Comparison of the two transition states indicates that the addition by **11***b* would encounter some steric interaction between the C2–C3 zone of the diene and the methylene bridge of the dienophile. We believe that the enhanced aldehyde-*endo* selectivity exhibited by **11** over the moderate ester-*endo* selectivity of keto-ester **8** is a reflection of improved secondary orbital effect participation by the aldehyde carbonyl. The dramatic increase in reaction rate for additions to **11** over additions to **8** reflects the greater electron-withdrawing character of the aldehyde group of **11** over the ester group of **8** which we had predicted.

H. Optical purity

The (−)-β-pinene used to prepare enone aldehyde **11** had an optical purity of 92%. Optically active nmr shift reagents such as Eu(hfc)$_3$ have been used to evaluate the optical yield of reactions (35, 36). Direct application of Eu(hfc)$_3$ to adduct **17** showed separation of the signals for the *gem*-dimethyl groups. The chemical shift difference (Δδ) increased with an increase in the amount of Eu(hfc)$_3$ added. In all experiments the integrals of the split signals were consistently in the ratio of 96:4. Thus the optical purity of the starting material (92%) was retained in the Diels–Alder adducts. The enantiomeric set of adducts that would be obtained from the relatively unavailable enantiomeric (+)-β-pinene could nevertheless be prepared easily using the conversion of (+)-α-pinene to (−)-nopinone reported by Lavallee and Bouthillier (37). The (−)-nopinone so obtained would provide the enantiomer of **11** by the method we have described.

3. Removal of the formyl group

Having successfully generated various Diels–Alder adducts of enone aldehyde **11**, we wished to demonstrate that the formyl group, as an effective tool for controlling stereoselectivity, is not only easily introduced but also easily removed. Treatment of **17** with saturated aqueous potassium carbonate in a methanol mixture at room temperature for 18 h gave a single product in quantitative yield. The spectral data for this product were comparable with those previously reported for ketone **35** (11).

Treatment of the mixture of adducts **18** and **19** (64:1) under the same conditions for 18 h did not give any detectable amount of product. The starting material was recovered intact. However, after refluxing for 15 h a colourless liquid was isolated in 92% yield. After chromatographic separation, two products were obtained in a ratio of 1:6. Based on the spectral data and the ratio of the two products, structures **36** and **37** were assigned to the two compounds. Starting with a 64:1 mixture of **18** and **19**, it is impossible that the minor product in the 6:1 mixture originated from the minor component of the starting material. The two deformylation products must both be derived from the major starting material and must be epimeric at C3. The stereochemistry of C3 remained to be determined. Extensive ^{1}H COSY experiments of the major isomer resulted in the assignment of all the protons. The ring junction proton (H8) appeared at δ 2.71 as a multiplet. Its multiplicity changed when the H3 (δ 2.55) and H11*exo* (δ 2.40) protons and the multiplet at δ 1.98–2.20 (H9, H7, and other) were irradiated individually. Attempted nOe irradiation of proton H8 at δ 2.71 did not provide useful information since H3 was simultaneously irradiated. However, the ^{1}H nmr spectrum showed proton H3 as a doublet of doublets with coupling constants of 12.0 and 5.5 Hz. This large coupling constant (12 Hz) indicated that the major isomer had a *trans* ring junction (**36**) while the minor isomer could be assigned with a *cis* ring junction (**37**).

Conclusion

The Diels–Alder reaction of enone aldehyde **11** with various dienes provided good to high yields of chiral adducts in very high diastereomeric excess with complete diastereofacial selectivity. The observed regiochemistry was as predicted by the *ortho* and *para* rules. The formyl substituent of the adducts can be removed or elaborated to achieve synthetic goals. Enone aldehyde **11** is a potentially versatile intermediate for chiral synthesis by asymmetric Diels–Alder reactions.

alytical laboratory of this department. Fourier transform infrared spectra (ir) were recorded on a Nicolet 7199 or Nicolet MX-1 FT-IR spectrophotometer, and unless otherwise stated, were obtained in chloroform cast. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded on a Bruker WH-80, Bruker WH-200, Bruker WH-300, Bruker WH-400, or Bruker AM-400 spectrometer using deuteriochloroform ($CDCl_3$) as solvent unless otherwise stated. Tetramethylsilane (TMS) was used as an internal reference. Coupling constants are reported to ±0.5 Hz. Chemical shift measurements are reported in ppm downfield from TMS in delta (δ) units. The following abbreviations are used: s = singlet, δ = doublet, t = triplet, q = quartet, m = multiplet, and br = broad. Carbon-13 nuclear magnetic resonance (^{13}C nmr) spectra were recorded on a Bruker WH-300 (75 MHz) or Bruker WH-400 (125 MHz) spectrometer, and were obtained on solutions in deuteriochloroform as the internal reference, setting the central peak at 77.00 ppm. The ^{13}C nmr multiplicities were derived from APT (Attached Proton Test) experiments (38, 39). Methyl and methine groups are shown as signals possessing an antiphase (a) with respect to the deuteriochloroform signal, whereas methylene groups, quaternary carbons, and carbonyl groups appear in phase (p) with it. Nuclear Overhauser enhancement (nOe) experiments were determined in the difference mode in which a control (undecoupled) spectrum was computer subtracted from the irradiated spectrum after Fourier transformation. Positive enhancements are defined as signals possessing antiphase with respect to the irradiated signal. Samples for nOe measurements were deoxygenated with argon gas for 10 min. High resolution electron impact mass spectra (ms) were recorded using an A.E.I. model MS-50 mass spectrometer. Optical rotations were determined on a Perkin–Elmer 241 polarimeter. Specific rotations ($[\alpha]_D$) are reported in degrees at the specified temperature and concentration (*c*) is given in grams per 100 millilitre in the specified solvent.

All reactions were carried out under slight positive pressure of argon. Bulb-to-bulb distillation was performed using a Kugelrohr distillation apparatus. Flash chromatography (40) was used routinely for purification and separation of product mixtures using silica gel (Merck, 230–400 mesh). All solvents for chromatography were distilled prior to use. Concentrations of solvent systems used in column chromatography are given by volume. Analytical thin layer chromatography (tlc) was carried out on aluminum sheets precoated (0.2 mm layer thickness) with Merck silica gel 60 F_{254}. Ultraviolet-active materials were detected by visualization under a uv lamp (254 or 350 nm). Visualization of tlc chromatograms was completed by dipping in an ethanol solution of vanillin (5% w/v) and sulfuric acid (5% v/v), followed by charring on a hot plate. Alternatively, an aqueous solution of phosphomolybdic acid (3% w/v) containing ceric sulfate (0.5% w/v) and sulfuric acid (3% v/v) was used as the dipping solution, followed by charring on a hot plate.

Materials

Anhydrous reaction solvents were distilled under argon from the appropriate drying agents before use. Tetrahydrofuran (THF) was freshly distilled from a solution of sodium and benzophenone. Pyridine and dichloromethane were distilled from calcium hydride. Ether was distilled from lithium aluminum hydride. Reactions requiring anhydrous conditions were performed in oven- or flame-dried glassware that was assembled and allowed to cool while being purged with argon. Argon was passed through a column of 4 Å molecular sieves and self-indicating silica gel. Unless otherwise stated, anhydrous magnesium sulfate was used for drying organic solutions.

*(1R,5S)-(+)-6,6-Dimethylbicyclo[3.1.1]heptan-2-one (**13**)*

WARNING: See footnote 11 in ref. 11. Ozone was passed through a −78°C solution of (1*S*,5*S*)-(−)-β-pinene[6] (10.0 g, 73.5 mmol) in dichloromethane–methanol (1:1, 30 mL). After 3.5 h a persistent blue

For personal use only.

colour appeared. The reaction was stopped after a further 40 min when tlc showed no starting material remaining. Excess ozone was purged with oxygen for 10 min and the reaction mixture turned colourless. Dimethyl sulfide (27.5 mL, 0.37 mol) was added to the reaction mixture at –78°C, then the mixture was allowed to gradually warm to room temperature while stirring overnight. The solvent was removed under reduced pressure on a rotary evaporator. Flash chromatography of the residue, eluting with 2–10% ether in petroleum ether, gave pure **13** (7.2 g) as a colourless oil. A second chromatography of impure fractions gave additional **13** (2.2 g, total yield 9.4 g, 93%): $[\alpha]_D^{23}$ +15.0 (neat), +29.6 (*c* 1.32, $CHCl_3$);[10] ir: 1708 (C=O) cm^{-1}; ^1H nmr (300 MHz) δ: 2.47–2.64 (complex, 3H), 2.34 (ddd, 1H, *J* = 19.0, 9.0, 2.5 Hz, C-3 H_α), 2.21 (m, 1H), 1.87–2.10 (complex, 2H), 1.55 (d, 1H, *J* = 10.0 Hz), 1.40 (s, 3H, *exo* CH_3), 0.82 (s, 3H, *endo* CH_3); ^{13}C nmr (75 MHz) δ: 215.0 (C=O), 58.0 (*C*HC=O), 41.2 (CMe_2), 40.5 (*C*HCMe_2), 32.8 (*C*H_2C=O), 25.9 (*exo* CH_3), 25.3 (CH_2), 22.2 (*endo* CH_3), 21.5 (CH_2); ms M^+ calcd. for $C_9H_{14}O$: 138.1045; found: 138.1046. Anal. calcd. for $C_9H_{14}O$: C 78.21, H 10.21; found: C 78.06, H 10.21.

*(1R,5R)-3-Formyl-6,6-dimethylbicyclo[3.1.1]heptan-2-one (**14**)*

Sodium hydride (60% oil dispersion, 800 mg, 20.0 mmol) was suspended in tetrahydrofuran (30 mL) under argon. Ethyl formate (25 mL, 0.31 mol) was added at 0°C and stirred for 10 min. A solution of nopinone (**13**) (1.38 g, 10.0 mmol) in tetrahydrofuran (25 mL) containing 98% ethanol (7 drops) was added dropwise at 0°C over 30 min. The reaction mixture was allowed to gradually warm to room temperature. After 3 h at room temperature a saturated aqueous solution of ammonium chloride (25 mL) was added. The mixture was separated and the aqueous phase was extracted with ether – petroleum ether (1:1, 3 × 20 mL). The combined organic phases were washed with water and saturated aqueous sodium chloride, dried, filtered, and concentrated. Flash chromatography of the residue, eluting with 5–10% ether in petroleum ether, gave keto aldehyde **14** (1.55 g, 9.34 mmol, 93% yield) as a colourless oil that solidified on standing. This compound was a 7:2.5:1 mixture of isomers. The major isomer gave the following signals: ^1H nmr (300 MHz) δ: 13.35 (br s, 1H, enol *OH*), 7.18 (br s, 1H, enol =*CH*), 2.41–2.58 (complex, 6H), 1.41 (s, 3H, *exo* CH_3), 0.90 (s, 3H, *endo* CH_3). The two minor isomers also showed distinguishable signals in the nmr spectrum: δ 9.65, 9.40 (s, 1H each, C*H*O), 1.44, 1.40 (s, 3H each, *exo* CH_3), 0.93, 0.82 (s, 3H each, *endo* CH_3). The mixture also gave the following analytical data: ir: 3310 (enol OH), 1725 (CHO), 1713 (C=O), 1653 (chelated β-hydroxy-α,β-unsaturated ketone carbonyl), 1598 (C=C) cm^{-1}; ^{13}C nmr (75 MHz) δ: 209.4 (C=O), 163.9 (=CHOH), 107.2 (=*C*C=O), 54.1 (*C*HC=O), 39.6 (*C*Me_2), 39.4 (*C*HCMe_2), 27.5 (CH_2), 26.0 (CH_3), 25.3 (CH_2), 21.5 (CH_3); ms M^+ calcd. for $C_{10}H_{14}O_2$: 166.1004; found: 166.1009. Anal. calcd. for $C_{10}H_{14}O_2$: C 72.25, H 8.49; found: C 72.43, H 8.73.

*(1R,5R)-3-Formyl-6,6-dimethylbicyclo[3.1.1]hept-3-en-2-one (**11**) and (1R,3R,5S,6R)-3-formyl-7,7-dimethyl-4-oxatricyclo-[4.1.1.0^{3,4}]heptan-2-one (**15**)*

Pyridine (0.53 mL, 6.5 mmol) was added to a solution of phenylselenenyl chloride (1.37 g, 7.15 mmol) in dichloromethane (30 mL) at 0°C under argon. The colour of the solution changed from dark red to yellow-brown and white fumes were generated. After stirring for 10 min a solution of keto aldehyde **14** (1.08 g, 6.5 mmol) in dichloromethane (10 mL) was added. At the end of the addition, which took about 3 min, an instantaneous colour change from yellow-brown to bright yellow occurred, indicating completion of the selenenylation reaction; tlc analysis confirmed that no starting material remained. After 5 min the reaction mixture was washed with aqueous 1 N hydrochloric acid (2 × 30 mL). The organic layer was cooled to 0°C and aqueous 30% hydrogen peroxide solution (0.5 mL) was added dropwise. After stirring for 5 min aqueous 30% hydrogen peroxide (0.5 mL) was added. Another portion of aqueous hydrogen peroxide solution (15%, 1.0 mL) was added dropwise 7 min later. The resulting mixture was stirred for 1.5 h, then water (5 mL) was added and the phases were separated. The organic phase was washed with saturated aqueous sodium bicarbonate and brine, dried, filtered, and concentrated. Flash chromatography of the residue, eluting with 2–30% ether in petroleum ether, gave a light yellow oil (746 mg) as a mixture of enone aldehyde **11** and epoxide **15** (7:1, ca. 70% yield). The following nmr data were attributed to the enone aldehyde **11**: ^1H nmr (300 MHz) δ: 10.00 (s, 1H, C*H*O), 8.31 (dd, 2H, *J* = 6.5, 1.5 Hz, =C*H*), 2.75–2.95 (complex, 3H, C*H*C*H*$_{exo}$C*H*), 2.12 (d, 1H, *J* = 9.0 Hz, CH*H*$_{endo}$), 1.57 (s, 3H, *exo* CH_3), 1.02 (s, 3H, *endo* CH_3); ^{13}C nmr (75 MHz) δ: 200.7 (C=O), 168.6 (CHO), 165.4 (CH=), 132.2 (C=), 58.3 (*C*HC=O), 54.8 (C), 44.7 (*C*HCMe_2), 40.4 (CH_2), 26.6 (CH_3), 21.5 (CH_3). The mixture showed the following spectral data: ir: 2830, 2710 (CHO, weak), 1724, 1691, 1657 (saturated and conjugated C=O), 1593 (C=C) cm^{-1}; ms M^+ calcd. for $C_{10}H_{12}O_2$: 164.0833; found: 164.0837; calcd. for $C_{10}H_{12}O_3$: 180.0786; found: 180.0781. Epoxide **15** was recovered in pure form from a typical Diels-Alder reaction mixture after dienophile **11** was totally consumed. It showed the following spectral data: ir: 1741 (CHO), 1710 (C=O), 1100 (C-O) cm^{-1}; ^1H nmr (300 MHz) δ: 9.65 (s, 1H, C*H*O), 3.89 (d, 1H, *J* = 4.5 Hz, CHC*H*O), 2.71 (dd, 1H, *J* = 11.0, 6.0 Hz, CH*H*$_{exo}$), 2.58 (dd, 1H, *J* = 6.0, 6.0 Hz, C*H*C=O), 2.38 (ddd, 1H, *J* = 11.0, 6.0, 4.5 Hz, C*H*CMe_2), 2.09 (dd, 1H, *J* = 11.0, 11.0 Hz, CHC*H*$_{endo}$), 1.49 (s, 3H, *exo* CH_3), 1.09 (s, 3H, *endo* CH_3); ^{13}C nmr (75 MHz) δ: 201.8 (C=O), 194.7 (CHO), 58.9 (CH), 56.7 (*C*HC=O), 50.0 (C), 40.7 (*C*HCMe_2), 26.5 (CH_3), 21.1 (CH_3), 20.7 (CMe_2), 20.4 (CH_2); ms M^+ + 1 calcd. for $C_{10}H_{13}O_3$: 181.0865; found: 181.0863.

General procedure for boron trifluoride etherate catalyzed reactions

The Diels–Alder reactions of enone aldehyde **11** with boron trifluoride etherate as catalyst were carried out in a manner similar to the following example.

*(1R,3R,8S,9R)-(−)-3-Formyl-6,10,10-trimethyltricyclo-[7.1.1.0^{3,8}]-undec-5-en-2-one (**17**)*

Isoprene (0.54 mL, 5.4 mmol, 10 equiv.) in ether (7 mL) was added to a solution of a mixture of **11** and **15** (9:1, 100 mg) at –20°C under argon, followed by addition of boron trifluoride etherate (0.07 mL, 0.54 mmol). After stirring for 2 h a saturated aqueous sodium bicarbonate solution (7 mL) was added. The mixture was separated and the aqueous layer was extracted with ether (3 × 7 mL). The combined organic layers were washed with water and brine, dried, filtered, and concentrated. Flash chromatography of the residue, eluting with 2–30% ether in petroleum ether, gave **17** as a colourless oil (105.2 mg, 84% yield): $[\alpha]_D^{23}$ –115.87 (*c* 0.75, $CHCl_3$); ir: 1730 (CHO), 1698 (C=O), 1600 (C=C) cm^{-1}; ^1H nmr (300 MHz) δ: 9.70 (s, 1H, C*H*O), 5.33 (m, 1H, C*H*=), 2.94 (dddd, 1H, *J* = 10.0, 7.5, 2.0, 2.0 Hz, CHC*H*CH$_2$), 2.83 (dd, 1H, *J* = 16.0, 7.0 Hz, CH*H*$_{ax}$CH=), 2.61 (dd, 1H, *J* = 5.5, 5.5 Hz, C*H*C=O), 2.52 (dddd, 1H, *J* = 11.0, 8.5, 5.5, 2.0 Hz, CH*H*$_{exo}$), 2.22 (dddd, 1H, *J* = 16.0, 8.0, 2.5, 2.5 Hz, CH*H*$_e$CH=), 2.15 (complex, 2H, C*H*CMe_2, CH*H*$_{ax}$C=), 1.91 (m, 1H, CH*H*$_e$C=), 1.89 (d, 1H, *J* = 11.0 Hz, CH*Hendo*), 1.74 (br s, 3H, CH_3C=), 1.32 (s, 3H, *exo* CH_3), 0.73 (s, 3H, *endo* CH_3); ^{13}C nmr (75 MHz) δ: 212.9 (C=O), 200.9 (CHO), 139.8 (CH_3C=), 116.4 (CH=), 68.2 (C), 61.9 (C), 57.5 (*C*H), 47.8 (CH), 33.4 (CH_2), 33.0 (CH_2), 30.4 (CH), 26.5 (=C*C*H$_3$), 25.3 (CH_2), 23.1 (CH_3), 21.7 (CH_3); ms M^+ calcd. for $C_{15}H_{20}O_2$: 232.1464; found: 232.1462. Anal. calcd. for $C_{15}H_{20}O_2$: C 77.55, H 8.68; found: C 77.43, H 8.94.

General procedures for zinc chloride, ferric chloride, and stannic chloride catalyzed reactions

The Diels–Alder reactions of enone aldehyde **11** with isoprene using ferric chloride and stannic chloride as catalysts were carried out by the method of the example procedure described above. Specific temperatures and times are reported in Table 4. The general procedure for zinc chloride catalyzed reactions was slightly different from the boron trifluoride catalyzed reactions. Zinc chloride (91.4 mg, 0.67 mmol, 1 equiv.) was flame-dried under vacuum and dissolved in ether (5 mL) at room temperature under argon to give a clear solution. A solution of a

[10]See analytical data and footnote 15 in ref. 11.

For personal use only.

mixture of **11** and **15** (10:1, 110 mg, 0.60 mmol of **11**) in ether (2 mL) was added dropwise and a thick pale yellow precipitate formed. After a few minutes, the precipitate stuck onto the wall of the round-bottomed flask and the solution became clear again. After stirring for 10 min, the reaction mixture was cooled to –20°C and then isoprene (0.7 mL, 6.7 mmol, 10 equiv.) was added. The work-up procedure and purification were the same as those described above. Specific times and temperatures are reported in Tables 2 and 3.

*(1R,3R,4R,8S,9R)-3-Formyl-4,10,0-trimethyltricyclo[7.1.1.0^{3,8}]-undec-5-en-2-one (**18**) and (1R,3R,4S,8S,9R)-3-formyl-4,10,10-trimethyltricyclo[7.1.1.0^{3,8}]undec-5-en-2-one (**19**)*

After purification, the reaction with *trans*-piperylene gave a mixture of isomers **18** and **19** (64:1 ratio). The nmr spectra showed two sets of signals; the major set for isomer **18**: ^{1}H nmr (300 MHz) δ: 10.04 (s, 1H, C*H*O), 6.00 (m, 1H, C*H*═), 5.42 (ddd, 1H, *J* = 9.5, 3.0, 3.0 Hz, ═C*H*), 2.80 (dddd, 1H, *J* = 10.5, 7.5, 2.0, 2.0 Hz, CHC*H*CH$_2$), 2.62 (dd, 1H, *J* = 5.5, 5.5 Hz, C*H*C═O), 2.58 (m, 1H, CH$_3$C*H*CH═), 2.48 (dddd, 1H, *J* = 11.0, 5.5, 5.5, 2.0 Hz, CHH_{exo}), 2.34 (ddd, 1H, *J* = 15.0, 7.5, 7.5 Hz, CHH_eCH═), 2.10 (ddd, 1H, *J* = 5.5, 5.5, 2.0 Hz, C*H*CMe$_2$), 1.89 (d, 1H, *J* = 11.0 Hz, CHH_{endo}), 1.85 (m, 1H, CHH_{ax}CH═), 1.40 (d, 3H, *J* = 7.5 Hz, CH_3CH), 1.31 (s, 3H, *exo* CH_3), 0.71 (s, 3H, *endo* CH_3); ^{13}C nmr (75 MHz) δ: 211.0 (C═O), 204.3 (CHO), 130.9 (═CH), 127.9 (CH═), 68.3 (CH), 57.6 (CH), 56.2 (CH), 50.3 (C), 41.9 (CMe$_2$), 39.7 (CH), 32.4 (CH$_3$), 28.1 (CH$_2$), 26.3 (CH$_3$), 24.2 (CH$_2$), 21.4 (CH$_3$); the minor set for isomer **19**: ^{1}H nmr (300 MHz) δ: 9.63 (s, 1H, C*H*O), 6.00 (m, 1H, C*H*═), 5.75 (dddd, 1H, *J* = 9.5, 6.0, 1.5, 1.5 Hz, ═C*H*), 3.0 (m, 1H, CHC*H*CH$_2$), 2.88 (ddd, 1H, *J* = 14.0, 7.0, 7.0 Hz, CH$_3$C*H*CH═), 2.20 (ddd, 1H, *J* = 15.5, 7.0, 7.0 Hz, C*H*HCH═), 2.03 (ddd, 1H, *J* = 6.0, 6.0, 2.5 Hz, C*H*CMe$_2$), 1.32 (s, 3H, *exo* CH_3), 1.05 (d, 3H, *J* = 7.0 Hz, CH_3CH), 0.66 (s, 3H, *endo* CH_3); ^{13}C nmr (75 MHz) δ: 131.1, 128.3 (CH═CH), 71.5 (CH), 57.2 (CH), 48.1 (CH$_3$), 40.7 (CH), 26.7 (CH$_3$), 26.5 (CH$_2$), 20.8 (CH$_2$), 19.1 (CH$_3$). The following data are reported for the mixture of **18** and **19**: ir: 1723 (CHO), 1693 (C═O) cm^{-1}; ms M$^+$ calcd. for $C_{15}H_{20}O_2$: 232.1463; found: 232.1461. Received March 31, 1994

GUANGZHEN G. MENG, BRIAN R. JAMES, and KIRSTEN A. SKOV. Can. J. Chem. **72**, 1894 (1994).

Condensation of pyrrole with a benzaldehyde and 4-pyridinecarboxaldehyde mixture yields the six possible *meso*-substituted phenyl or pyridyl porphyrins. Nitration of four of these has yielded 13 other porphyrins containing one to four 4-nitrophenyl moieties, and $SnCl_2$ reduction of eight of these nitrophenylporphyrins gives the corresponding 4-aminophenyl(phenyl)- or 4-aminophenyl(phenyl)(4-pyridyl)-porphyrins. Twelve of the porphyrins are new, but all 27 are fully characterized by ^1H NMR; resonances for every proton within each of the phenyl, pyridyl, and pyrrole rings are assigned. Trends in UV–VIS data are discussed, while IR and mass spectral data are noted for selected porphyrins.

GUANGZHEN G. MENG, BRIAN R. JAMES et KIRSTEN A. SKOV. Can. J. Chem. **72**, 1894 (1994).

La condensation du pyrrole avec un mélange de benzaldéhyde et de 4-pyridinecarboxyaldéhyde conduit à un mélange des six porphyrines possibles substituées en *méso* par des groupes phényle ou pyridyle. La nitration de quatre de ces isomères a fourni 13 autres porphyrines comportant de une à quatre portions 4-nitrophényles et la réduction de huit de ces dérivés nitrés par du $SnCl_2$ a fourni les porphyrines correspondantes portant des substituants 4-aminophényl(phényle) ou 4-aminophényl(phényl)(4-pyridyle). Douze de ces porphyrines sont des produits nouveaux, mais on a complètement caractérisé les 27 par RMN du ^1H; on a attribué chacun des protons de chaque noyau phényle, pyridyle ou pyrrole. On discute des tendances dans les spectres UV alors que l'on a déterminé les spectres IR et de masse de certaines porphyrines.

Introduction

A limitation of radiotherapy is the lack of selectivity toward tumor cells, especially toward the hypoxic tumor cells (1). Porphyrin drugs used in photodynamic therapy (PDT) have good selectivity toward tumors because of accumulation in cancer cells, but the therapy has a limitation governed by tissue penetration of the light (2). The rationale for the work described here was that the radiosensitization abilities of porphyrins (3–5) might be improved by introduction of certain groups (including nitro groups and metal ions, which have been shown in non-porphyrin systems to act as radiosensitizers (6)), with the tumor accumulation abilities being retained or improved, possibly by balancing lipophilicity and hydrophilicity of the porphyrin or by introducing nitro group(s) (6). Use of such a drug, which first accumulates in tumors, then kill cells via sensitization of the cells to ionizing radiation, may overcome the noted limitations of both radiotherapy and PDT because hypoxic cells might be selectively sensitized and X-rays are known to penetrate tissues well. If appropriate porphyrin compounds can be synthesized, they may also have potential for use in other aspects of cancer treatments and diagnosis, including PDT (7), chemotherapy (8), boron neutron capture therapy (9), and magnetic resonance imaging diagnosis (10). This paper reports the synthesis and characterization of porphyrins containing within *meso* substituents some functional groups that might possibly be beneficial for DNA binding ($-NH_2$, pyridine), and for radiosensitization ($-NO_2$ (6)). The *meso* substituents, phenyl and pyridine, can also be further functionalized to give water solubility by sulfonation of the phenyl (11*a*) or methylation of the pyridine (11*a*).

Early studies on natural porphyrin free-bases suggested that their use as radiosensitizers was not promising (3, 4). Some encouraging results for use of synthetic porphyrins and metalloporphyrins as radiosensitizers were published recently by O'Hara et al. (5); the highest radiosensitization efficiencies were found for cobalt(III) complexes of Tet(MPy)P (5,10,15,20-tetrakis(4-methylpyridinium)porphyrin) and Tet(SPh)P (5,10,-15,20-tetrakis(4-sulfonatophenyl)porphyrin), although no details were given on the synthesis or characterization of the porphyrin species. Figure 1 shows the porphyrin structures and abbreviations use in the present work.

Based on the findings in various laboratories on the importance of the presence of a nitro aromatic group in an electron affinic radiosensitizer (6), the work reported here evolved from an initial study focused on synthesis of nitrophenyl-containing porphyrins. The porphyrins were synthesized via a method combining monopyrrole/aromatic aldehyde condensation with subsequent modifications of the *meso* phenyls. Thus, condensation of pyrrole, benzaldehyde, and 4-pyridinecarboxaldehyde gives a mixture of six porphyrins (**1**–**6**, Fig. 1), which is separated by column chromatography. The subsequent modifications, determined by structure design of the required porphyrins, are nitration of phenyls (giving compounds **7**–**19**, Fig. 1), and reduction of the nitro groups to form amines (giving compounds **19**–**27**, Fig. 1). Sulfonation of the phenyl groups, methylation of the pyridyls, metallation of the porphyrins, and biological testing of selected porphyrin bases and metalloporphyrins are reported elsewhere (11).

Experimental section

Pyrrole, benzaldehyde, and 4-pyridinecarboxaldehyde were purchased from Aldrich Chemical Company. Other chemicals (including nitric acid, sulfuric acid, etc.) were analytical grade, and were used

FIG. 1. Porphyrin structures and abbreviations; B = bis, D = di, T = tri(s), Tet = tetra(kis), P = porphyrin.

TABLE 1. ^{1}H NMR data for **1–6**[a]

Porphyrin	Pyrrole	3,4,5-Ph	2,6-Ph	3,5-Py	2,6-Py	*N*-Pyrrole
1, TetPhP	8.85 s (8)	7.78 m (12)	8.23 m (8)	—	—	−2.78 s (2)
2, TPhPyP	8.90 d, 8.87 s, 8.81 d (2, 4, 2)	7.78 m (9)	8.23 m (6)	9.04 q (2)	8.18 q (2)	−2.80 s (2)
3, *cis*-DPhBPyP	8.92 d, 8.88 s, 8.85 s, 8.81 d, (2, 2, 2, 2)	7.80 m (6)	8.22 m (4)	9.05 q (4)	8.18 q (4)	−2.84 s (2)
4, *trans*-DPhBPyP	8.91 d, 8.81 d, (4, 4)	7.80 m (6)	8.22 m (4)	9.05 q (4)	8.18 q (4)	−2.84 s (2)
5, PhTPhP	8.94 d, 8.86 s, 8.83 d (2, 4, 2)	7.81 m (3)	8.22 m (2)	9.06 m (6)	8.18 m (6)	−2.88 s (2)
6, TetPyP	8.88 s (8)	—	—	9.08 q (8)	8.19 q (8)	−2.92 s (2)

[a]In $CDCl_3$ at ~20°C; δ signal pattern (number of protons).

without further purification. TLC plates (0.2 cm) of alumina (neutral, activity I) and of silica gel, and silica gel were BDH products. The alumina activity I (neutral, Fisher Chemicals) was converted to activity III and IV types by mixing with 10 and 15% water, respectively, 24 h before using.

NMR spectra were recorded on a Varian XL-300 or a Bruker WH-400 instrument operating in the Fourier transform mode, using TMS as reference (s = singlet, d = doublet, q = quartet, m = multiplet). UV–VIS spectra were recorded on a Perkin Elmer 552A spectrometer, with quartz cells (0.100 or 1.00 cm). Mass spectroscopy (NH_3 chemical ionization) was performed by the mass spectroscopy laboratory, Department of Chemistry, U.B.C. Infrared spectra (Nujol mulls) were recorded on a Nicolet 5DX FTIR spectrometer. Microanalyses were performed by Mr. P. Borda of the Department of Chemistry, U.B.C.

Porphyrins 1–6

These porphyrins, comprising TetPhP (**1**), TPhPyP (**2**), *cis*-DPhBPyP (**3**), *trans*-DPhBPyP (**4**), PhTPyP (**5**), and TetPyP (**6**), with phenyl and (or) pyridyl *meso* substituents, were synthesized from condensation of pyrrole, benzaldehyde, and 4-pyridinecarboxaldehyde (2:1:1) as described generally by Little et al. (12). Benzaldehyde (3.0 mL), 4-pyridinecarboxaldehyde (4.0 mL), and pyrrole (4.4 mL) were added to hot propionic acid (250 mL) in a 500 mL round-bottom flask, and the mixture was refluxed for 1 h. A precipitate (0.55 g) was filtered off from the cooled reaction mixture. The filtrate was concentrated to about 50 mL and then acetone (500 mL) was added with stirring; the mixture was filtered to yield another 1.78 g of precipitate, which was combined with the precipitate collected earlier. A portion of this crude product (0.5 g), a mixture of the six porphyrins, was dissolved in $CHCl_3$ (180 mL) and loaded on a column of silica gel (5 × 30 cm); **1** and **2** were eluted off successively with $CHCl_3$ (~1.5 L), while the mixture of **3–6** was eluted off using a mixed solvent (9:1 $CHCl_3$/MeOH). The solution of **3–6** was evaporated to dryness, and then the residue was dissolved in minimum $CHCl_3$ (~150 mL), loaded on a column of alumina activity III (3 × 70 cm), and eluted with $CHCl_3$ (~2 L). Four purple bands appeared on the column. *trans*-DPhBPyP (**4**) was first eluted and then the solvent in the column was forced out under N_2 pressure. The bands were removed using a spatula ("digging out" the bands saved time and eluant), and the alumina portions containing porphyrin were washed on fret filters using a mixed solvent to dissolve the porphyrins (9:1 $CHCl_3$/MeOH, ca. 0.2 L for each portion). The bands in order from top to bottom on the column contained TetPyP (**6**), PhTPyP (**5**), and *cis*-DPhBPyP (**3**). All the porphyrin solutions were washed with 5% Na_2CO_3 solution and then water; the organic phases containing the porphyrins were evaporated to dryness. Acetone (~10 mL) was added to the residues, and these were filtered off and air-dried. The yields (%) for the porphyrins were 7.5 (**1**), 9.0 (**2**), 4.5 (**3**), 1.5 (**4**), 2.0 (**5**), and 1.0 (**6**).

TetPyP (**6**) was also synthesized by the condensation of pyrrole and 4-pyridinecarboxaldehyde (1:1) in propionic acid as described above. The main portion of the propionic acid was evaporated off first, and then the porphyrin product was precipitated by addition of acetone; this precipitate was filtered, washed with acetone, and air-dried (25% yield).

^{1}H NMR data for **1–6** are shown in Table 1. UV–VIS data for these and other porphyrins are shown in Table 2. Samples of **3** and **5** obtained from the alumina column were contaminated by alumina, and gave low C and N values by elemental analysis. Alumina was found to be slightly soluble in $CHCl_3$, and in 9:1 $CHCl_3$/MeOH, probably to ~20 mg L^{-1} at ambient conditions. Further purification of **3** and **5** was not attempted. Elemental analyses for **1–6** are given in Table 3, together with data for other porphyrins. Mass spectral data for **3** and **5** are given in the footnote *c* of Table 3.

Nitrations

The nitration reactions were performed with concentrated HNO_3. Generally, a porphyrin (0.2–0.5 g) was dissolved in, or mixed with, acetic acid (30–50 mL) in a Schlenk tube, which was placed in an ice-bath. Concentrated H_2SO_4 (10 mL), which was used as dehydration reagent in some cases, was added dropwise with stirring, and then concentrated HNO_3 (10–20 mL) was added similarly before the ice-bath was removed. A stopcock on the side arm of the Schlenk tube was left open to avoid buildup of pressure. The reaction mixture changed from purple to green when either H_2SO_4 or HNO_3 was added. The ratio of the reactants and the reaction time used depend on the porphyrin and the intended degree of nitration, which was monitored by TLC (silica gel or alumina). Samples for TLC were first neutralized with Na_2CO_3 solution and extracted with $CHCl_3$; then the $CHCl_3$ solutions were introduced onto the TLC plates, which were developed using $CHCl_3$. The retention time of a porphyrin increased with the number of nitro groups.

When the intended nitration was complete, cold water (about the same volume as the reaction mixture) was added slowly to quench the reaction with liberation of heat. The hot mixture was cool by an ice-bath and neutralized first with concentrated NaOH, then with dilute Na_2CO_3 to pH ~8 (the color of the reaction mixtures changed from green to purple or brown at pH ≥4). The product was extracted with $CHCl_3$ (100–200 mL), the $CHCl_3$ portion was washed with water (3 × 100 mL), and the $CHCl_3$ layer was evaporated to dryness. The residue was washed with acetone (~50 mL), filtered off, and dried.

Nitration usually gave a mixture of products, and column chromatography was used to separate them. The compositions of the reaction mixtures, reaction times, details about column chromatography, and other experimental conditions for each porphyrin are described below.

7, (NPh)TPhP

TetPhP (0.5 g) was dissolved in acetic acid (50 mL), and concentrated HNO_3 (20 mL) was added with stirring. Reaction was monitored using TLC (silica gel, 0.2 cm) and, when no TetPhP could be detected

(~1 h), the reaction was stopped and the crude product was collected as described above. This was passed through alumina (activity III, 3 × 10 cm) with $CHCl_3$ as eluant to separate out some non-porphyrin materials, which remained on the top of the column. The eluted solution was evaporated to dryness, and 0.51 g crude product was collected; this was loaded onto alumina (activity I, 3 × 30 cm), and eluted with $CHCl_3$, when three brown bands were observed. After a trace of TetPhP was eluted, solutions of **7** and *cis*- and *trans*-B(NPh)DPhP (**8** and **9**) were collected successively. The solutions were evaporated to dryness and the residues were washed with acetone and air-dried; **7** (0.40 g, 74% yield), and **8** and **9** (~0.03 g as a by-product) were isolated.

8 and 9, cis- *and* trans-*B(NPh)DPhP*

All conditions were as described above for the synthesis of **7**, except that the reaction time was ~5 h, when no **7** could be detected by TLC (silica gel). After a trace of **7** was eluted, **8** and **9** were eluted together from alumina (activity I, 3 × 30 cm); 0.40 g, 70% yield. Attempts to separate **8** and **9** on an alumina column failed.

10, T(NPh)PhP

Conditions were as described above for the synthesis of **7**, but the reaction mixture was stirred for ~2 d, when no **8** and **9** were present according to TLC (silica gel); **10** was collected in ~30% yield via the major eluted band from alumina (activity I, 3 × 30 cm). Traces of **8** and **9**, and the tetra-nitro product **11**, were also separated and isolated in small quantities (~2% yield each).

An attempt to prepare Tet(NPh)P (**11**) failed because the required, lengthy reaction time (≥ 7 d) damaged the porphyrin structure. Purification of **11**, isolated as by-product from the synthesis of **10**, failed because of its low solubility in common solvents; **11** was identified only by ^1H NMR of a dilute solution in $CDCl_3$ (see Table 4 below).

12, cis-*(NPh)DPhPyP*

Conditions and procedures were as used for the synthesis of **7**, except that TPhPyP (**2**) (0.50 g) was used as precursor; the reaction was stopped after 5 h when no **2** could be detected by TLC (alumina, activity I, 0.2 cm). After a trace of **2**, **12** was eluted by $CHCl_3$ from alumina (activity III, 3 × 30 cm); the solution of **12** was collected, washed with water, and the $CHCl_3$ layer was separated and evaporated to dryness. The residue was then washed with acetone and air-dried (60% yield).

13 and 14, cis- *and* trans-*B(NPh)PhPyP*

Conditions and precursor were as described above for the synthesis of **12**, but the reaction was stopped after 20 h when no **12** could be detected by alumina TLC. After a trace of **12** eluted, **13** and **14**, and a small amount of T(NPh)PyP (**15**), were eluted from alumina (activity III, 3 × 30 cm). The *cis* and *trans* isomers were observed as the two major bands on the column, but were collected together because of poor separation (~60% yield). A smaller amount (20 mg) of this mixture was separated using a longer column (2 × 40 cm), the *trans* isomer being eluted first; about equal amounts of the two isomers were obtained.

15, T(NPh)PyP

Conditions were again the same as described for the synthesis of **12**, but the reaction was stopped after 40 h when a significant amount of **15** could be detected by alumina TLC. After **13** and **14** were eluted by $CHCl_3$, **15** was eluted out with 9:1 $CHCl_3$/MeOH from alumina (activity III, 3 × 30 cm) (~30% yield).

16, cis-*(NPh)PhBPyP*

cis-DPhBPyP (**3**) (0.20 g) was mixed with acetic acid (30 mL) and concentrated H_2SO_4 (10 mL), and then concentrated HNO_3 (10 mL) was added dropwise, and the mixture was stirred. The reaction was stopped after 20 h when no **3** could be detected by alumina TLC. The isolated crude product was separated using alumina (activity IV, 2 × 60 cm). After a trace of **3** was eluted, **16** and a trace of *cis*-B(NPh)BPyP (**17**) were collected; the yield of **16** was 55%.

17, cis-*B(NPh)BPyP*

The conditions were the same as those given for the synthesis of **16**. The reaction was stopped after 24 h when no **3** or **16** could be detected by alumina TLC. The crude product was separated on alumina (activity IV, 2 × 40 cm). After a trace of **16** was eluted, **17** was collected (~70% yield).

18, trans-*B(NPh)BPyP*

Conditions were again the same as described for the synthesis of **16**, but *trans*-DPhBPyP (**4**) (0.20 g) was used as precursor and the reaction was stopped after 24 h when no **4** and no mono-nitration product could be detected by alumina TLC. The solubilities of the crude product (70% yield) in $CHCl_3$ or CH_2Cl_2 were low. The crude product looked ~90% pure by TLC and ^1H NMR data; a portion (20 mg) was purified on alumina activity IV (2 × 40 cm) using $CHCl_3$ as eluent (~200 mL).

19, (NPh)TPyP

Conditions were the same as for the synthesis of **16**, but PhTPyP (**5**) was used as precursor. The reaction was stopped after 2 d when no **5** could be detected by alumina TLC. The pure product (~60% yield) was separated from a green impurity using alumina (activity IV, 2 × 40 cm) with $CHCl_3$ as eluent (~200 mL).

Elemental analyses of the nitrated porphyrins (for samples stored and weighed in air) are shown in Table 3; footnote *c* contains some mass spectral data for **16** and **18**. The ^1H NMR and UV–VIS data are given in Tables 4 and 2, respectively.

Reductions of the nitroporphyrins

Reductions were performed according to a literature method (13). Generally, the nitroporphyrin (0.1 g) was dissolved in $CHCl_3$ (20 mL) in a 250 mL round-bottom flask with magnetic stirring; acetic acid (30 mL) and then a solution of $SnCl_2$ (0.3 g in 30 mL concentrated HCl) were added. The mixture was stirred and refluxed overnight, and then was neutralized with concentrated NaOH and dilute Na_2CO_3 solutions to pH 8–9, an ice-bath being used for cooling; H_2O (100 mL) and $CHCl_3$ (100 mL) were then added. The organic layer was separated, filtered, washed with water (3 × 100 mL), and then evaporated to dryness. The crude product was purified on alumina (activity IV, 2 × 30 cm), using ~250 mL $CHCl_3$ or a 9:1 mixture of $CHCl_3$/MeOH as eluent. The yield was ≥ 90% for all the porphyrins.

To synthesize *cis*- and *trans*-B(APh)DPhP (**21** and **22**), a mixture of *cis*- and *trans*-B(NPh)DPhP (**8** and **9**) was used as the precursor, but a separation of the aminophenyl isomers was achieved on alumina ($CHCl_3$ as eluent). The *trans* isomer was eluted first from the column.

The (APh)TPyP (**27**) compound was synthesized from (NPh)TPyP (**19**), but only the ^1H NMR spectrum was recorded. A pure sample of **27** was not obtained because its low solubilities in common solvents made column chromatography impractical.

The more polar *cis*-(APh)PhBPyP (**26**) prepared from **16** was purified on an alumina column using $CHCl_3$/MeOH as eluent. The other aminophenylporphyrins, (APh)TPhP (**20**), T(APh)PhP (**23**), *cis*-(APh)DPhPyP (**24**), and *trans*-B(APh)PhPyP (**25**), prepared from **7**, **10**, **12**, and **14**, respectively, were purified using $CHCl_3$ as eluent.

The UV–VIS and ^1H NMR data and elemental analyses (for samples stored and weighed in air) for these aminophenylporphyrins are shown in Tables 2, 5, and 3, respectively; some mass spectral data for **26** are given in footnote *c* of Table 3.

Table 6 lists the ^1H NMR assignments for each pyrrole proton of all 27 porphyrins, while some infrared data for selected porphyrins are summarized in Table 7 (deposited).[2]

Results and discussion

Hydration of porphyrins

Associated water molecules of hydration are commonly

[c]**11** was isolated in trace amounts, and was not pure (see experimental section, under **10**).
[d]Low concentration of the compound in the NMR sample.

found in samples of porphyrin free-bases (14, 15). Our samples were only dried under vacuum at room temperature, and elemental analyses were carried out on samples stored in air; hydration is evident, as judged by elemental analyses, by the intensity of the water signals in the ^{1}H NMR spectra, and by IR spectra in the 3200 cm^{-1} region. The hydration is probably related to the possibility of H-bonding between associated water molecule(s) and the pyrrole -N or -NH, the phenyl $-NH_2$ or $-NO_2$, or the pyridyl moieties. The elemental analyses for (NPh)TPhP (**7**), B(NPh)DPhP (**8** and **9**), and (APh)TPhP (**20**) were reported previously and are consistent with no hydration (13*a*) as found in the present work. The porphyrins TPhPyP (**2**) (14) and (NPh)TPyP (**19**) (15) have been reported as hydrated, with one-half and one water molecule, respectively, while the present data support zero and one-half water molecule, respectively. Comparison of the elemental analysis data with those of identical porphyrins (**1**, **3–6**, **10**, and **23**) reported in the literature cannot be made because such data were not reported (13*a*, 14, 16).

*Synthesis of the porphyrins **1–6***

The syntheses of these porphyrins were reported recently (16), following the earlier procedure described by Little et al. (12). The present work differs from that recent report (16), in that a significant amount of porphyrin product, besides that precipitated directly from the reaction mixture, was collected by precipitation from the concentrated condensation-reaction mixture using acetone, and therefore the yield was higher. Further, for the separation of the six porphyrins, alumina (activity III) and silica gel chromatographies with $CHCl_3$ as eluent were used instead of those reported using silica gel with a mixed solvent, $CHCl_3$–acetone–MeOH (16). All six porphyrins could be separated on a single alumina column, although use of silica gel to first separate TetPhP (**1**) and TPhPyP (**2**), followed by use of the alumina to separate the other four porphyrins, was more efficient. There is an advantage in using a single solvent because it can be readily recovered.

Mass, ^{1}H NMR (in $CDCl_3$), and UV–VIS (in CH_2Cl_2) spectroscopy data for **1–6** have been reported recently (16). The present ^{1}H NMR data (Table 1) are in good agreement with the reported data, but there are some differences in the UV–VIS data: e.g., the ε values for **3–6** are 10–20% lower in the present work, while for **2** the values were ~8% higher than the reported values (16). The alumina impurity in samples of **3** and **5** would

[a]Chemical shift in ppm, peak pattern; in $CDCl_3$ unless stated otherwise.

account for our low ε values, although minor differences may also result from the difference in solvent used ($CHCl_3$ vs. CH_2Cl_2). Our UV–VIS and ^{1}H NMR data for **2** agree with those reported by another group (14), although there is some disagreement about the assignments of the NMR signals for **2** (see below).

Synthesis of nitroporphyrins 7–19

The reagents used for nitrations of the porphyrins varied according to the structures of the porphyrins. Generally, the more pyridyl and nitrophenyl groups present, the stronger the reagent needed. For example, the nitration of TPhPyP (**2**) is more difficult than that of TetPhP (**1**), the protonated pyridyl in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 85.192.166.187 on 09/08/12
For personal use only.

the reaction medium presumably reducing activity for electrophilic substitution. The first nitration of **2** gives almost solely the *cis* isomer **12** (as judged by ^{1}H NMR), which means that the phenyl *trans* to the pyridyl is more inert. However, the nitration of **12** results a mixture of the *cis*- and *trans*-B(NPh)PhPyP, **13** and **14**, in approximately equal amounts; this simply means that a phenyl group that is *trans* to the pyridyl or *trans* to the nitrophenyl has similar reactivity for a nitration under these experimental conditions. The reaction times for nitration were significantly dependent on temperature, and were even subject to variation within room temperature. Thus, it was more reliable to monitor the reaction by TLC than to control the reaction time at room temperature.

Strong nitration reagents such as NO_2 in acetone, and nitronium tetrafluoroborate, have been used for the nitration of 2,3,7,8,12,13,17,18-octaethylporphyrin (OEP) (17, 18) and fuming nitric acid has been used for the nitration of TetPhP (13*a*). These reagents are strong oxidants and the low nitration yields probably result from destruction of the porphyrin ring structure. Under reaction conditions used in present work, NO_2 was produced gradually by using nitric acid mixed with a dehydration reagent such as acetic acid or a mixture of acetic acid and sulfuric acid; the relatively mild reaction conditions generally gave 55–75% yields from the porphyrin precursors, but **10** and **15** were obtained in only 30% yield because of prolonged reaction times.

The (NPh)TPhP (**7**) and Tet(NPh)P (**11**) porphyrins were synthesized previously by direct condensation of the appropriate aldehyde(s) and pyrrole, but the yields were very low (<3%) (13*b*, 19), while (NPh)TPyP (**19**) was synthesized by direct condensation with 7% yield (15); the low yields probably result from the high activity of 4-nitrobenzaldehyde (19). Porphyrin **7** (55% yield), a mixture of *cis*- and *trans*-B(NPh)DPhP (**8** and **9**) (28% yield), and T(NP)PhP (**10**) (no yield reported), were synthesized previously by nitration of TetPhP (**1**) using fuming nitric acid (13*a*).

The ^{1}H and ^{13}C NMR, UV–VIS, IR, and mass spectra of **7** and the **8/9** mixture have been reported before (no physical data were reported for **10**) (13*a*, 13*b*). The more limited spectral data obtained in the present work agree with those reported except that the ϵ value for the Soret band of **7** obtained here (in $CHCl_3$) was about 25% lower than the reported value (in CH_2Cl_2) (13*a*). The synthesis and ^{1}H NMR and UV–visible spectra of (NPh)TPyP (**19**) were reported (15) during the course of the present work; our ϵ values were all about 100% higher than those reported (in the same solvent) and there are some disagreements about the assignments of the ^{1}H NMR signals (see below).

The methods used in the present work gave higher overall yields of porphyrins **7–10** and **19** and seven other new nitrophenylporphyrins (**12–18**).

*Synthesis of aminophenylporphyrins **20–27***

The (APh)TPhP (**20**), T(APh)PhP (**23**), and (APh)TPyP (**27**) porphyrins were synthesized and characterized previously by elemental analysis, ^{1}H NMR, and mass spectroscopy (13*a*, 13*b*, 15); the data obtained here for these porphyrins agree with those in the literature. The other five aminophenylporphyrins (**21**, **22**, **24–26**) are new compounds.

^{1}H NMR spectra

The chemical shifts, patterns, and relative intensities of the ^{1}H NMR signals, plus the information from the syntheses, were used to assign a structure to a synthesized porphyrin. In the following discussion, a pyrrole proton refers to a proton bonded to a pyrrole carbon atom, while the proton associated with the pyrrole nitrogen is referred to as an *N*-pyrrole proton.

A nitration always occurs at the *para* position of a *meso* phenyl. This was evident by the characteristic two doublets of the ^{1}H NMR spectrum corresponding to the *meta* and *ortho* protons of a 4-nitrophenyl group. The formation of a 4-aminophenyl derivative was confirmed by the two doublets for the *meta* and *ortho* protons of the aminophenyl, and the appearance of a singlet for the amine protons at δ 4.00–4.05 in $CDCl_3$, the singlet disappearing when D_2O was added to the NMR samples.

All substituents at the *meso* positions have characteristic chemical shifts: NPh gives two doublets or multiplets at about 8.4 and 8.6 ppm (J_{HH} = 8.6 Hz); APh gives two doublets at about 8.0 and 7.1 ppm (J_{HH} = 8.1 Hz) and one singlet at about 4.0 ppm (-NH_2 protons); Py gives two doublets or quartets at about 9.1 and 8.2 ppm; and Ph usually gives two multiplets at about 8.2 and 7.8 ppm. The ^{1}H NMR spectrum within a 4-substituted phenyl ring (APh, NPh) or a 4-pyridyl ring is strictly an AA′BB′ type, which is usually too complex to be analyzed for *J* values (20). However, the spectra of APh and NPh appear as AB quartets with significant coupling between only the 2 and 3 and the 5 and 6 protons, other couplings being negligible. The coupling constants noted above were obtained in this manner, and do not vary with porphyrin type. The same approximation cannot be applied to the 4-Py and Ph systems because more complex spectra are obtained.

The assignments of the coupled signals for a *meso* substituent are achieved simply by comparisons with related spectra. For instance, a comparison of the spectrum of TetPhP (**1**) to that of TPhPyP (**2**) (Table 1) shows that **2** has a new set of signals (8.18 and 9.04) for the pyridyl group, while the phenyl signals at 7.78 and 8.23 ppm reduce in intensity from 12 and 8H to 9 and 6H, respectively, and the pyrrole signal of **1** at 8.85 ppm splits into two doublets and one singlet; the *N*-pyrrole signal at –2.8 ppm scarcely changes. The signals of the nitro- and aminophenyl protons are assigned similarly.

Assignments of ^{1}H NMR signals to specific protons of the meso *substituent*

The signals for the phenyl protons (2,6 or 3,4,5) in the spectrum of TetPhP (**1**) (Table 1) are easily assigned by consideration of their intensities and the distances from the protons to the porphyrin ring, which provides deshielding effects (21). When the 4-phenyl proton is replaced by a nitro or an amino group, the chemical shifts for the 2,6 or 3,5 set can be calculated according to the shielding parameters of the group within aromatic compounds (Fig. 2) (22). Thus, for example, the calculated value for the 2,6-NPh protons is 8.41, i.e., 0.17 + 8.23 (the value for the 2,6-protons of the unsubstituted phenyl, Table 1), while the average observed value is 8.38 (Table 4). Similarly, the other calculated (observed) values from Tables 1, 4, and 5 are: 3,5-NPh 8.73 (8.63), 2,6-APh 7.99 (7.98), and 3,5-APh 7.03 (7.05). The parameters have been used similarly by Sun et al. (23) to calculate the shifts for the protons of the 3-nitrophenyl group of 5-(3-nitrophenyl)-10,15,20-triphenylporphyrin. Thus, a doublet is readily assigned to each kind of proton type (2,6- or 3,5-) for either the nitrophenyl or aminophenyl group; the "least satisfactory" agreement (within 0.1 ppm) is seen for 3,5-NPh protons. Figure 3 exemplifies a spectrum (for (NPh)TPhP, **7**) in the δ 7.6–9.0 region, and the assignments of the signals (see Table 4).

The shielding parameters for the N atom within a pyridine are

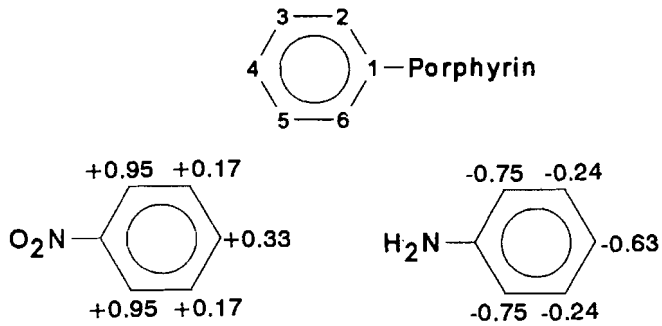

FIG. 2. Diagram illustrating shielding parameters for the $-NO_2$ and $-NH_2$ groups.

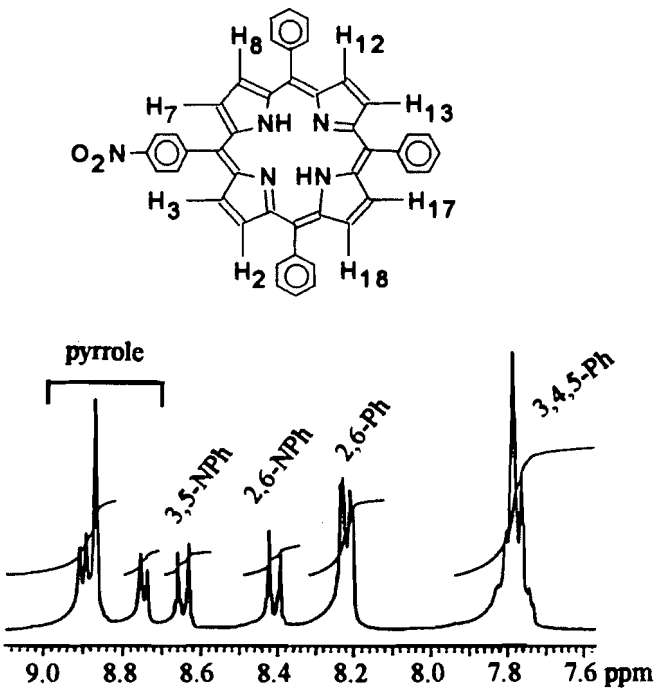

FIG. 3. ^1H NMR spectrum (δ 7.6–9.0) of (NPh)TPhP (**7**) in $CDCl_3$ at ~20°C; the pyrrole protons show the expected pattern (see Fig. 7).

not listed in the literature (22). The spectrum of pyridine in $CDCl_3$ was thus recorded, and the shielding parameters were calculated using δ 7.27 as the chemical shift for benzene (22); the chemical shifts of the 4-pyridyl in a porphyrin were calculated (see Fig. 4) using the chemical shifts for the phenyl groups of TetPhP as described above for the NPh and APh groups. These calculated data agree very well with the observed data, which show average values of 9.04 and 8.15 ppm for the 3,5 and 2,6-pyridyl protons, respectively (see Tables 1, 4, and 5).

The signals of the pyridyl protons within pyridylporphyrins have been assigned (without reasoning) in a few literature reports. In contrast to our assignments, Williams et al. (14) assigned signals at δ 9.01 and 8.22 to the 2,6- and 3,5-Py protons of TPhPyP (**2**), respectively, and Ding et al. (15) similarly assigned signals at δ 9.06 and 8.15 to the 2,6- and 3,5-Py protons of (NPh)TPyP (**19**), respectively. Consistent with our work, Sari et al. (16) have assigned signals at δ 9.1–9.4 and 8.2 to the 3,5 and 2,6-Py protons, respectively, for porphyrins **1–6**. Ding et al. (15) assigned the signals of the nitrophenyl protons within (NPh)TPyP (**19**) as δ 8.66 and 8.38 for the 2,6-NPh and

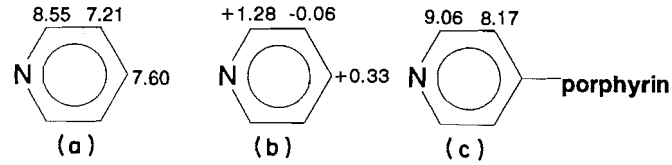

FIG. 4.Diagram illustrating chemical shifts (*a*) and shielding parameters (*b*) for pyridine, and calculated chemical shifts (*c*) for a 4-pyridyl substituent in a porphyrin.

3,5-NPh protons, respectively, the reverse of those assignments given by us which are also consistent with the assignments for the 3-nitrophenyl porphyrin given by Sun et al. (23). The signals of the aminophenyl protons within (APh)TPyP (**27**) were also assigned by Ding et al. (15) and are consistent with those given here.

Identification of isomers using ^1H NMR

The ^1H NMR spectral patterns of the pyrrole protons readily distinguish between *cis* and *trans* isomers. Figure 5 shows the C_2 symmetry elements of the two isomers of the A_2B_2P type; the treatment ignores the *N*-pyrrole protons because there is fast tautomer interconversion at room temperature in organic solvents (24). For the *cis* isomer, the four types of pyrrole protons give rise to two singlets (for $H_{7(8)}$, $H_{17(18)}$) and two coupled doublets (for $H_{3(12)}$, $H_{2(13)}$), while the two types of pyrrole protons of the *trans* isomer give two doublets for any pair of adjacent protons, e.g., H_2, H_3. Figure 6 shows the spectra of *cis*- and *trans*-DPhBPyP (**3** and **4**) for the pyrrole protons.

It is straightforward to predict the expected patterns for the pyrrole protons for the various combinations of *meso* substituents, and the patterns shown in Fig. 7 are those found experimentally. For example, the pyrrole protons for (NPh)TPhP (**7**) (Fig. 3) correspond to pattern **II**. In some cases, the signals overlap; for example, T(APh)PhP (**23**) of pattern **II** shows only one of the doublets, the second one overlapping with the singlet to give a broad "singlet" corresponding to six protons (Table 5). Figure 8 shows the spectra for *cis*- and *trans*-B(APh)DPhP (**21** and **22**); the *cis* spectrum (type **III**) is readily distinguished from the *trans* (type **IV**) even though the two singlets overlap the two doublets. Figure 9 shows a more complex example for *cis*- and *trans*-B(NPh)PhPyP (**13** and **14**) of types **V** and **VI** respectively; the four doublets of type **VI** are easily seen, but more imagination is needed to recognize the six doublets and a singlet of type **V** for the *cis* isomer!

Assignments of the signals for the pyrrole protons

For this discussion the numbering scheme of Fig. 7 is used; also, as shown by the full names of the porphyrins in Fig. 1, the 5,10,15,20-*meso* positions are assigned in alphabetical order to the *meso* substituents, if possible (thus, an aminophenyl substituent is always in the 5-*meso* position). The *J* value for two coupled protons on the same pyrrole ring is 4.7 Hz, and is independent of porphyrin type.

The singlet for pyrrole protons in the spectrum of (NPh)TPhP (**7**) (Fig. 3, Table 4) is assigned to H_{12}, H_{13}, H_{17}, and H_{18} because of their equivalence. The two doublets have been assigned using NOE experiments. When the 2,6-NPh protons (doublet at δ 8.41) are irradiated, positive enhancements are observed for the δ 8.74 pyrrole doublet and for the δ 8.64 doublet of the 3,5-NPh protons, while no enhancement is observed for the other pyrrole doublet at δ 8.90; when irradiation is on the

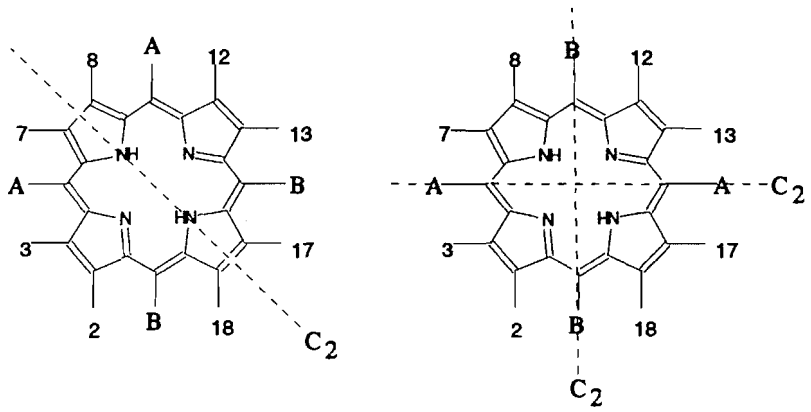

FIG. 5. The C_2 symmetry elements of *cis*- and *trans*-A_2B_2P type porphyrins.

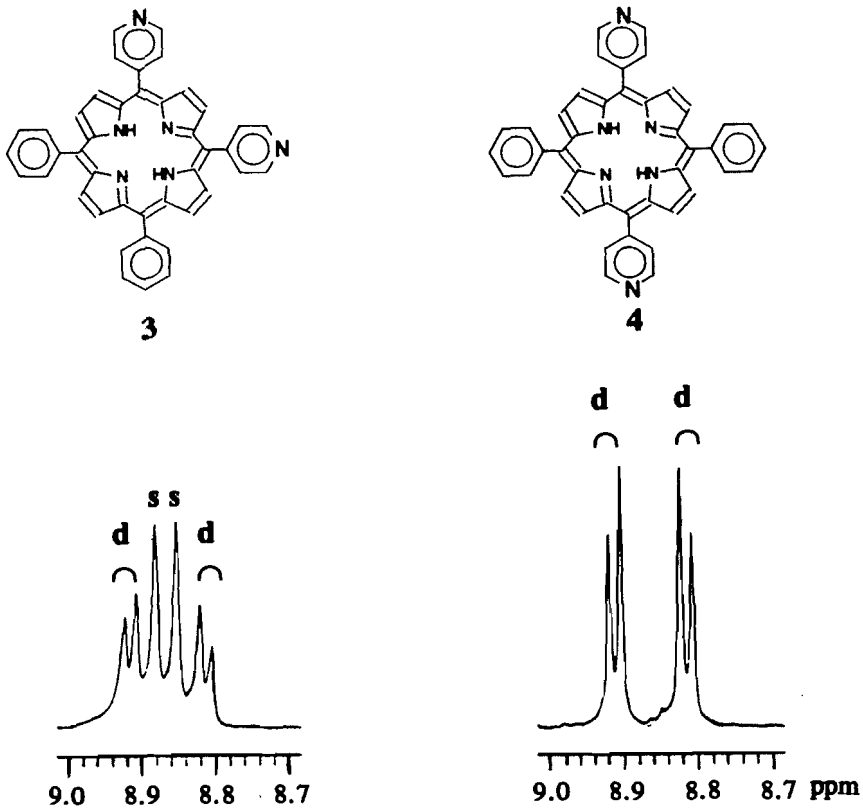

FIG. 6. H NMR spectrum (δ 8.7–9.0) of *cis*- and *trans*-DPhBPyP (**3** and **4**) in $CDCl_3$ at ~20°C.

pyrrole signal at δ 8.74, an enhancement results in the δ 8.41 signal of the 2,6-NPh protons, but not in the other phenyl or nitrophenyl signals. These data show clearly that the doublet at δ 8.74 corresponds to the pyrrole protons H_3 and H_7, because they are closer to the 2,6-NPh protons than H_2 and H_8, to which the other pyrrole doublet at δ 8.90 is thus assigned. Of several resonance structures that can be drawn, those shown in Fig. 10 predict lower electron density at C_2 and C_8 than at C_3 and C_7, and correlate with the NMR assignments. The same predictions pertain for any electron-withdrawing *meso* substituent, including 4-Py: the pyrrole proton adjacent to such a substituent resonates at a higher field than the other, same-ring pyrrole proton (and vice versa). For the electron-donating 4-APh group, resonance structures akin to those in Fig. 10 now reveal increased electron density at C_2 and C_8, and thus for (APh)TPhP (**20**) the H_2 and H_8 resonances are assigned within the δ 8.82 m, and the H_3, H_7 resonances to the δ 8.93 d (the integrations are also consistent with these assignments, the two "more unique" H_3 and H_7 protons giving the 8.93 doublet of relative intensity 2 (Table 5)).

Use of the rationalizations given above allows for assignment of the signals in patterns **II** and **IV**, and the doublets of pattern **III**. For the assignments of the singlets of pattern **III**, some observations summarized in Fig. 11 were used. In the spectrum of TPhPyP (**2**), the δ 8.87 singlet for the pyrrole protons "between" two phenyls is closer to the δ 8.90 doublet at lower field, while in the spectrum of PhTPyP (**5**), the δ 8.86 singlet for the pyrrole protons "between" two pyridyls is closer to the δ 8.83 doublet at higher field. A conclusion drawn is that in the spectrum of *cis*-DPhBPyP (**3**), the δ 8.88 singlet at lower field corresponds to the pyrrole protons "between" the two phenyls, while the δ 8.85 singlet at higher field relates to the

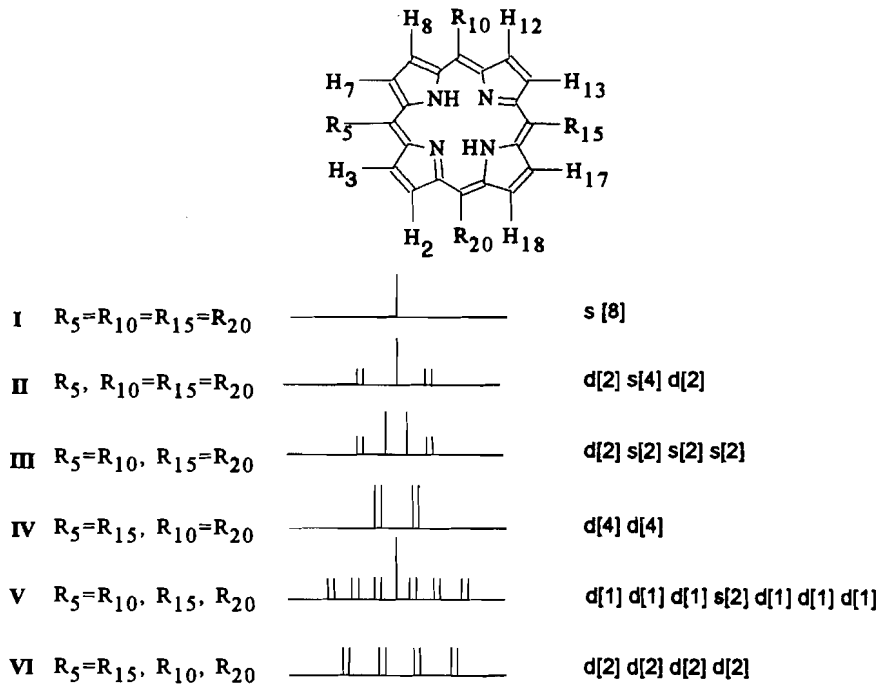

FIG. 7. The basic patterns for the ^{1}H NMR spectra of the pyrrole protons; the relative position of the singlet may vary.

protons "between" the two pyridyls. This is confirmed by an NOE experiment. When the 2,6-Py protons (the quartet at δ 8.18) are irradiated, positive enhancements are observed for the δ 8.85 (s) and δ 8.81 (d) pyrrole signals, and for the signal of 3,5-Py protons (quartet at δ 9.05), while no enhancements are observed for the pyrrole signals at δ 8.92 (d) and δ 8.88 (s). This experiment simply means that the pyrrole protons corresponding to the signal at δ 8.85 (s) and δ 8.81 (d) are closer to the 2,6-Py protons than the protons corresponding to the signals at δ 8.92 (d) and δ 8.88 (s). Thus, noting that the singlet for the pyrrole protons "between" two phenyls within TPhPyP (**2**), (NPh)TPhP (**7**), and *cis*-(NPh)DPhPyP (**12**) is at δ 8.86–8.88, while the singlet for the pyrrole protons "between" two nitrophenyls within T(NPh)PhP (**10**) and *cis*-B(NPh)PhPyP (**13**) is at δ 8.78–8.79, it is reasonable to assign the δ 8.77 s and 8.86 s resonances of the spectrum of a mixture of *cis*- and *trans*-B(NPh)DPhP (**8** and **9**), respectively, to the pyrrole protons (H_7 and H_8) "between" the two nitrophenyls and those (H_{17} and H_{18}) "between" the two phenyls of **8**. Thus, even from the spectrum of a mixture of **8** and **9** (Table 4), complete assignment of the pyrrole protons of each isomer can be made: Fig. 12 summarizes the data for **8**, while **9** just gives the two doublets at δ 8.90 (adjacent to the Ph) and δ 8.73 (adjacent to the NPh).

The resonances for the pyrrole protons of the porphyrins containing two different *meso* substituents, **2–5**, **7–10**, **15**, **17–23**, and **27** (patterns **II–IV**), are thus readily assigned, and these are summarized in Table 6.

For the porphyrins having three different *meso* substituents, **12–14**, **16**, and **24–26** (patterns **V** and **VI**), the problem of the assignment was more challenging. However, it is noted that the difference in chemical shifts (Δ) between the coupled doublets of the two protons on the same pyrrole ring was characteristic of the two adjacent *meso* substituents; the actual shifts differ somewhat within similar type porphyrins but Δ is essentially constant. For phenyl/pyridyl substituents Δ = 0.10 ppm (e.g., for **2–5**, **12–14**, **16**, **24–26**, Δ = 0.10 ± 0.01, see Tables 1, 4, and 5); similarly for nitrophenyl/phenyl (**7–10**, **12–14**, **16**), Δ = 0.165 ± 0.005; for aminophenyl/phenyl (**20–26**), Δ = 0.11 ± 0.01; for nitrophenyl/pyridyl (**12–19**), Δ = 0.055 ± 0.005; and for aminophenyl/pyridyl (**24–27**), Δ = 0.215 ± 0.005. Further, the coupled doublets have more intense peaks for the "inside" signals, because of second-order coupling. Using this information and the Δ correlation, the coupled doublets can be selected and assigned to specific protons within a particular pyrrole ring. For example, the assignments of the pyrrole protons of *cis*-(NPh)DPhPyP (**12**) and *cis*-(APh)PhBPyP (**26**) are shown in Figs. 13 and 14, respectively. In Fig. 13, the 2H doublet at δ 8.89 is composed of two 1H doublets that are part of couplings with the doublets at δ 8.79 (Δ = 0.10) and at δ 8.73 (Δ = 0.16); similarly, in Fig. 14 the broad 2H doublet pattern centred at δ 8.77 is seen to be composed of two overlapping 1H doublets. Standard 2D-NMR experiments have been carried out to confirm the coupling of the doublets. Table 6 lists also the pyrrole resonances for the pattern **V** and **VI** porphyrins.

Split signals for pyrrole protons have been recorded by many authors (12*b*, 13*a*, 14–16), but only the pyrrole signals for 5-(2-nitro-5-hydroxy-phenyl)-10,15,20-tris(4-tolyl)porphyrin have been assigned; Little (12*b*) suggested that the H_3 and H_7 resonate at higher fields than H_2 and H_8, which agrees with the assignments of the nitroporphyrins presented here.

UV–VIS, infrared, and mass spectra

The synthesized porphyrin free-bases show typical optical spectra, consisting of a dominant Soret band around 400 nm and four visible bands (from 500 to 650 nm) labeled as I, II, III, and IV on going from longer to shorter wavelengths (24, 25). Of the types of spectra classified as etio, rhodo, oxorhodo, and phyllo, according to the relative intensities of the four visible bands (24), the porphyrins synthesized in this work generally

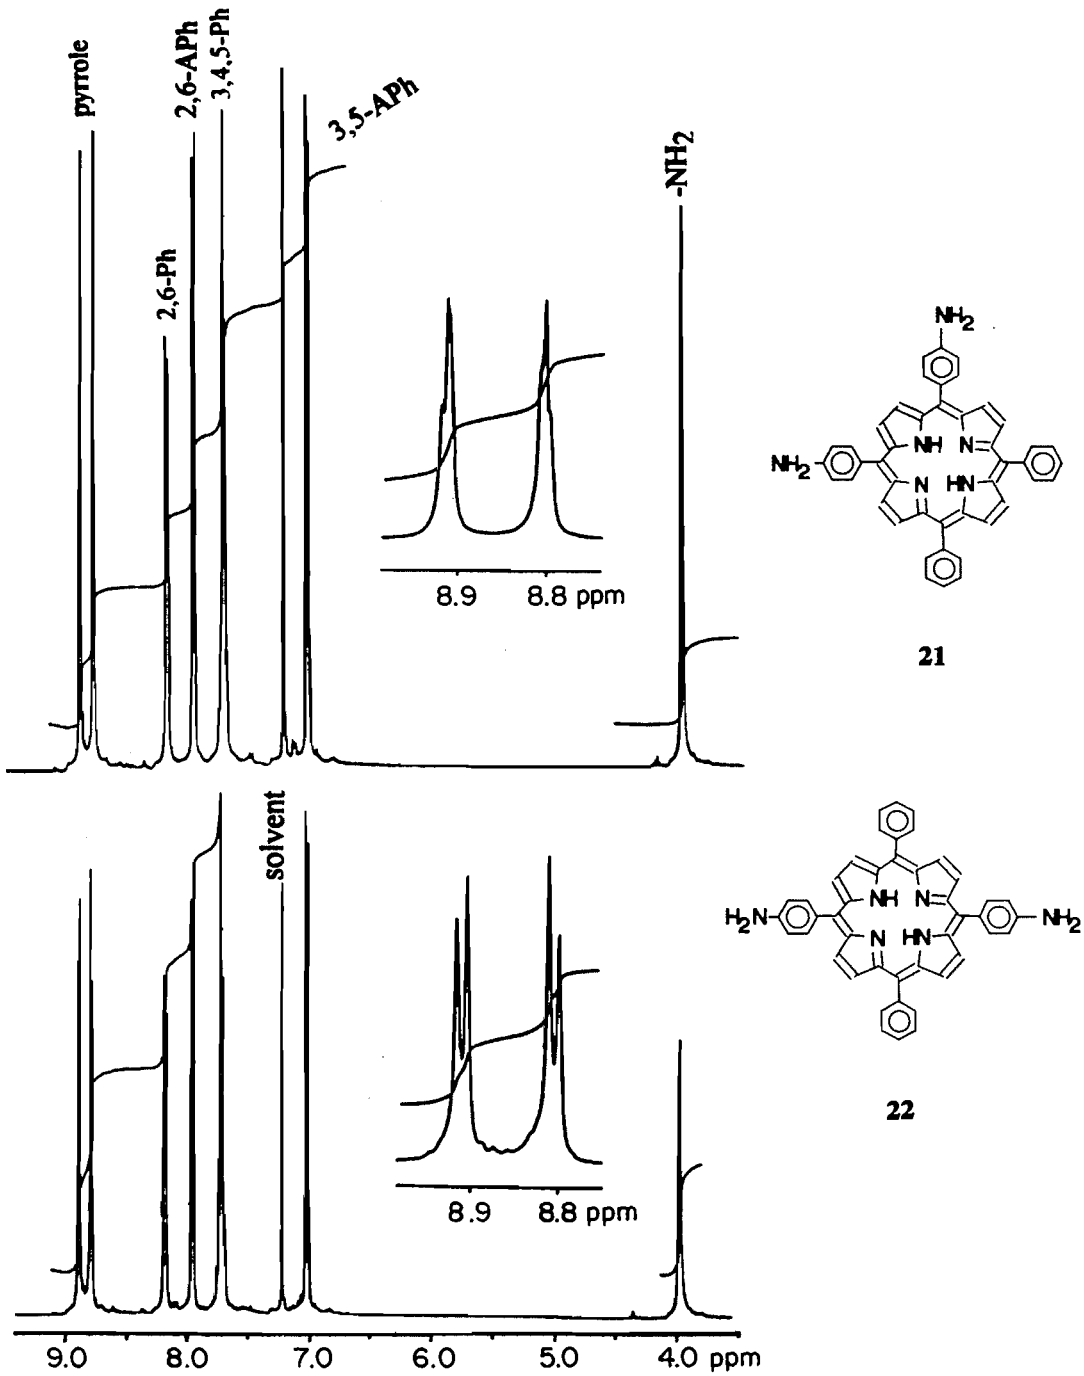

FIG. 8. ^{1}H NMR spectra (δ 4.0–9.0) of *cis*- and *trans*-B(APh)DPhP (**21** and **22**) in $CDCl_3$ at ~20°C.

give etio spectra (with intensities: IV > III > II > I, Table 2), but there are a few exceptions, porphyrins **5** (PhTPyP), **6** (TetPyP), and **19** (NPh)TPyP) having phyllo-type spectra (IV > II > III > I). Phyllo-type spectra are believed to result from the presence of asymmetry in the π-electron cloud (24); however, the fact that **2** (TPhPyP) has an etio-type and **6** (PhTPyP) a phyllo-type spectrum suggests that other factors are involved, because these porphyrins have the same symmetry. Porphyrins **24** (*cis*-(APh)DPhPyP) and **25** (*trans*-B(APh)PhPyP) are exceptional in that band I is more intense than band II, a trend that does not fit any of the four standard types.

The data of Table 2 show that the Soret band shifts to longer wavelength with nitration of a phenyl substituent, the shift increasing with the number of NPh groups (compare data for **1**, **7–10**, and **2**, **12–15**). The same trends are seen on reduction of the NPh groups to the aminophenyls (cf. data for **7–10** vs. **20–23**, **12** vs. **24**, and **14** vs. **25**). Such red shifts observed on alkylation of pyrrole hydrogen have been attributed to the electron-donor properties of the substituents (25), but, as we observe such a shift for the electron-withdrawing $-NO_2$ and for the electron-donating $-NH_2$ group, increasing conjugation on going from Ph→NPh→APh offers a more general rationalization (19). The resonance forms (Fig. 15) cannot come fully into play because the phenyl moieties are sterically prevented from

becoming coplanar with the porphyrin ring (19, 26), but more effective conjugation (and therefore a lower excitation energy) is apparent through the resonance forms shown for the NPh and APh groups. The only trends noticed in the visible bands are generally small red shifts on going from Ph to NPh to APh substituents for all four bands.

Little can be said about the differences noted between the extinction coefficients recorded in the present work for the isolated pure porphyrins and those reported in the literature (13*a*, 13*b*, 14–16). Our ϵ values were measured at 1×10^{-5} M concentration, and Beer's law studies (the classic method for investigating possible aggregation (27)) were not performed for these particular porphyrins, while the literature data in most cases did not give the concentration used. Beer's law and ^{1}H NMR studies on the water-soluble, sulfonated, and methylpyridinium porphyrin derivatives reveal "significant deviations" because of aggregation phenomena (11, 28).

Table 7 (deposited)[2] lists IR data for porphyrins **1–6**, **16**, **17**, **26**, **27**; the assignments of the common peaks for the porphyrin ring structure can be found in the literature (19, 29). The spectrum of TetPhP agrees with that given in the literature (19). Peaks at about 1517 and 1348 cm^{-1}, attributed to ν_{NO_2} (13*b*), are found for *cis*-(NPh)PhBPyP (**16**) (medium intensity) and *cis*-B(NPh)BPyP (**17**) (very strong) within the nitro porphyrins, and peaks at around 1618 cm^{-1} (δ_{NH} (13*b*)) are seen for aminoporphyrins. The intensity of the ν_{CN} band found for the pyrrole and pyridyl rings at ~1595 cm^{-1} (29, 30) naturally increases with increasing pyridyl content.

CI (NH_3) mass spectra were recorded for a few representative porphyrins, **3**, **5**, **16**, **18**, and **26**; the data listed (footnote *c*, Table 3) give peaks with relative intensity >20%. The major peaks seen are $[M]^+$, $[M + 1]^+$, and $[M + 2]^+$, which are common in porphyrin mass spectra (31); the $[M + NH]^+$ and $[M + NH_2]^+$ peaks, observed also for the aminoporphyrins, presumably arise from the ionizing chemical (NH_3) fragments, possibly associating with the aminophenyl groups.

Received February 15, 1994

ROBIN A. COX, DAVID B. MOORE, and ROBERT S. MCDONALD. Can. J. Chem. **72**, 1910 (1994).

A study of the rates of the cyclizations **1** → **3** and **2** → **4** as a function of medium acidity and temperature in aqueous sulfuric acid has been performed. The latter reaction is five times faster at all acidities. An excess acidity kinetic analysis reveals the probable involvement of a water molecule in the reaction in both cases. Mechanistic possibilities suggested by the observations are discussed; it is proposed that the water molecule acts as a base catalyst during the rate-determining ring closure.

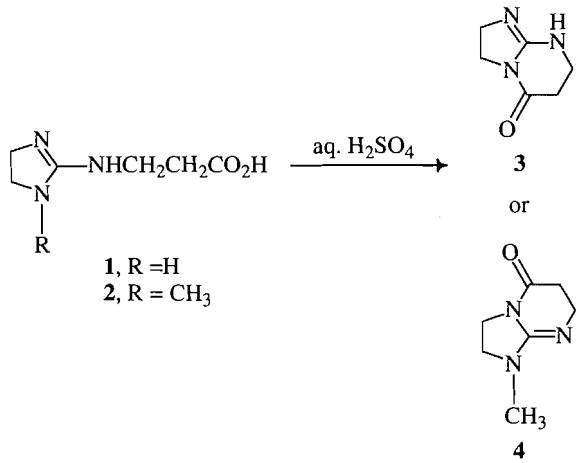
ROBIN A. COX, DAVID B. MOORE et ROBERT S. MCDONALD. Can. J. Chem. **72**, 1910 (1994).

On a effectué une étude des vitesses des cyclisations **1** → **3** et **2** → **4** en fonction de l'acidité du milieu et de la température, dans de l'acide sulfurique aqueux. À tous les niveaux d'acidité, la deuxième réaction est cinq fois plus rapide. Une analyse de l'acidité cinétique en excès révèle qu'une molécule d'eau est probablement impliquée dans la réaction, dans chacun des cas. On discute des diverses possibilités de mécanismes suggérées par ces observations; on suggère que la molécule d'eau agit comme catalyseur basique au cours de l'étape déterminant la vitesse de la fermeture du cycle.

[Traduit par la rédaction]

Introduction

Many important drugs are guanidine derivatives, for example: cimetidine, a histamine H_2-receptor antagonist (1), clonidine, an antihypertensive (2), and amiloride, a diuretic (3). Cyclic compounds containing the guanidine unit result when suitably substituted imidazolines are treated with acids (4). This paper concerns the mechanisms of the ring closures of the 2-substituted imidazolines **1** and **2**, giving **3** and **4**, respectively (4), as shown below, which take place in aqueous sulfuric acid solution. Few studies of ring-closure reactions in this medium exist; two exceptions are the hydantoic acid to hydantoin ring closure studied by Güler and Moodie (5), and the reversible cyclization of 3-ureidopropanoic acid derivatives studied by Pojarlieff and co-workers (6).



The rate data obtained are analyzed using the excess acidity method (7, 8), which has been successfully applied to many reactions in aqueous sulfuric acid, for instance, ester (9), thioester (10), amide (11), and acylhydrazine (12) hydrolyses, enolizations (13, 14), aldol condensations (14), hydrations of alkenes and alkynes (15, 16), and most recently aromatic hydrogen exchange (17) and phenylazo ether cleavage (18).

Experimental

Materials

Samples of *N*-(2-imidazolin-2-yl)-β-alanine **1** and *N*-(1-methyl-2-imidazolin-2-yl)-β-alanine **2** (4) were kindly supplied by Dr. John V. Greenhill of the University of Bradford, and were used without further purification. Aqueous sulfuric acid solutions were prepared by dilution of reagent grade acid (Fisher) with glass-distilled water and were left to mix and cool overnight. The solutions were then thoroughly mixed and the concentrations determined by titration of accurately weighed portions with aqueous sodium hydroxide that had been standardized against primary standard potassium acid phthalate.

Spectra

Ultraviolet spectra were recorded on either a Beckman model 24 or a Gilford Response spectrophotometer. The imidazolines **1** and **2** showed only end absorption in the UV region in water and aqueous sulfuric acid, no λ_{max} above 200 nm being observed. The final UV spectra after the reaction was complete were essentially identical to those quoted by Greenhill et al. (4) for the reaction products 2,3,7,8-tetrahydroimidazo[1,2-*a*]pyrimidin-5(6*H*)-one **3** or 1-methyl-1,2,3,7-tetrahydroimidazo[1,2-*a*]pyrimidin-5(6*H*)-one **4**. The UV spectral data were as follows (λ_{max} (log ε)): **3**, 221 (4.37); **4**, 217 (4.23). No systematic changes in the UV spectrum were observed for either **1** or **2** over the range of sulfuric acid concentrations used in the kinetic study.

Kinetics

Kinetic runs were initiated by injecting 2.5–10 μL of a stock solution of the substrate in water (9.4 mg/mL) into 3 mL of an acid solution in a cuvette that had been temperature pre-equilibrated for 20–30 min in the cell compartment of the Gilford spectrophotometer. Circulating constant temperature water was supplied by a Haake bath. Successive scans revealed the appearance of the product absorption maximum as given above. For both compounds the analytical wavelength chosen was 218 nm; both reactions exhibited low-wavelength isosbestic points, at 201 nm for **1** and 206 nm for **2**.

Kinetic runs were monitored over at least three half-lives, and a final absorbance reading (A_∞) was taken after at least 10 half-lives. Rate

constants k_ψ were obtained from the slopes of semilogarithmic plots of $(A_\infty - A_t)$ vs. time in the usual way. Any runs that did not give linear plots over at least 80% of the reaction, or that gave correlation coefficients of less than 0.999, were discarded. Normally at least four replicate runs were obtained at each acidity, generally giving rate constants agreeing within 6–7%. The k_ψ values were found to be independent of the initial substrate concentration over the range 1.9×10^{-4} to 4.5×10^{-5} M.

Results

The observed pseudo-first-order rate constants k_ψ for **1** → **3** are given in Table 1, and those for **2** → **4** in Table 2. These are averages of three to seven replicate runs, in most cases at 40°C. Product formation was quantitative. Results were also obtained at four other temperatures in 69.26% H_2SO_4, enabling calculation of activation parameters as before (9, 11, 17), see Table 3.

The rate data were analyzed using the excess acidity method (8), and to this end plots of log k_ψ − log C_{H^+} against X are given for **1** and **2** in Fig. 1. As before, X was corrected to the measurement temperature (9), 40°C for the Fig. 1 results; values of X and log C_{H^+} were taken from Cox and Yates (19). If linear, these plots would indicate an A-1 or an A-S_E2 mechanism for these reactions, but they curve downwards, which means an A-2 mechanism is operative. The species reacting with the substrate can be identified by subtracting, for example, the log water activity from the Fig. 1 y-axis, and this is done in Fig. 2, using temperature-correct literature water activities calculated from the thermodynamic data in ref 20. The observed linearity means that the transition state contains one water molecule as well as the substrate and a proton (8). The statistical information regarding these lines is given in Table 3 with the activation parameters. Points at one X-value were rejected as being off the line for each compound (17), probably due to an acid concentration error.

TABLE 3. Activation parameters, slopes, and intercept log k_2 values for the cyclizations **1** → **3** and **2** → **4**

Quantity	Compound **1**	Compound **2**

[a]Correlation coefficient. One point was not included in the fit for both compounds (17), see Fig. 2.
[b]Root-mean-square error of the fit.

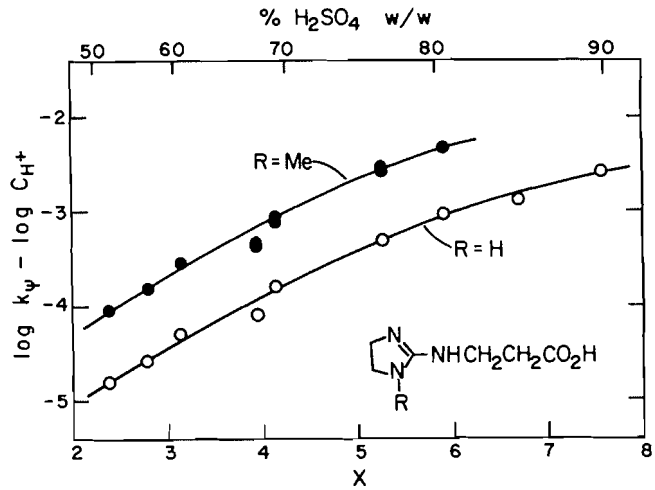

FIG. 1. Excess acidity plots of log k_ψ − log C_{H^+} against X for the cyclizations of **1** and **2** in aqueous sulfuric acid at 40°C, assuming an A-1 or A-S_E2 reaction; for convenience a % H_2SO_4 w/w scale is given at the top of the figure.

Discussion

The curves in Fig. 1 clearly show an upward trend, due to the acid catalysis. This means that a second proton must be involved in the reaction, since molecules like **1**–**4** all protonate on the imino nitrogen in the pH range. For instance the pK_{BH^+} values of the acylguanidines **3** and **4** are 8.36 and 8.56 (4), and the values for **1** and **2** would most likely be nearer the 14 or so of ordinary guanidines (21). The most logical place to expect the second protonation is on the side-chain CO_2H group, as shown in eq. [1], rather than in the guanidine system, in which further protonation would be very difficult; for instance the pK_a of $RC(=NH_2^+)—NH_3^+$ has been estimated to be about −19 (22), and that of diprotonated tetramethylguanidine to be about −11 (23).

The curvature in Fig. 1 could be caused by the variation of the extent of protonation with acidity, if the $pK_{SH_2{}^{2+}}$ values of the substrates are within the range of acidity covered by the rate

[1] 

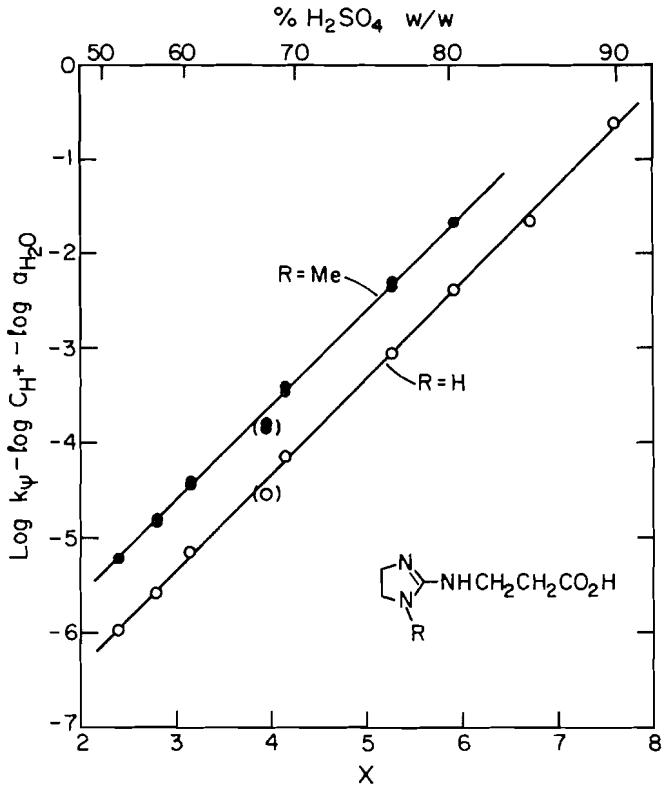

FIG. 2. Excess acidity plots for the cyclizations of **1** and **2** in aqueous sulfuric acid at 40°C, assuming an A-2 reaction with one water molecule; see Fig. 1.

measurements. Uncharged carboxylic acids are half-protonated at an acidity corresponding to about 80% H_2SO_4 (9, 24), already in the upper range of our measurements, and for a charged acid still stronger acid would be expected to be necessary. Also, no changes in the initial spectra of **1** and **2** were observed over the entire acidity range studied. Thus this possibility did not seem likely; however, it is not difficult to analyze the rate data on this basis by curve-fitting eq. [2] (8) using standard techniques (25), and this was done.

$$[2]\quad \log k_\psi - \log(C_{SH^+}/(C_{SH^+} + C_{SH_2^{2+}})) - \log C_{H^+} = \log (k_1/K_{SH_2^{2+}}) + m^\ddagger m^* X$$

$$[3]\quad \log(C_{SH_2^{2+}}/C_{SH^+}) - \log C_{H^+} = m^* X + pK_{SH_2^{2+}}$$

In this procedure the curvature in the Fig. 1 plots is ascribed to the protonation correction term in eq. [2], $\log(C_{SH^+}/(C_{SH^+} + C_{SH_2^{2+}}))$, and this is then used in the curve-fit to give values of m^* as slopes and $pK_{SH_2^{2+}}$ as intercepts according to the excess acidity equation for basicities, eq. [3] (19). When this is done the following values are obtained: for **1**, $pK_{SH_2^{2+}} = -3.84 \pm 0.15$, $m^* = 0.510 \pm 0.015$; and for **2**, $pK_{SH_2^{2+}} = -2.61 \pm 0.08$, $m^* = 0.495 \pm 0.046$. These are reasonable values for the protonation of *uncharged* carboxylic acids (26), but the basicities seem insufficiently negative for the second protonation of one that is already positively charged. However, the 1.23 pK units difference between the two basicities seems quite unreasonable, considering that the only difference between **1** and **2** is the presence of an *N*-methyl group in **2** a *long* way away from the protonation site. Thus we attribute all of the curvature in Fig. 1 to an A-2 reaction involving water, as stated above, and not to the onset of the second protonation within the acidity range of the measurements.

[4] 
Having established the involvement of water, the mechanism given in eq. [4] is proposed. The diprotonated substrate **5** ring-closes, assisted by a water molecule acting as a base, in the rate-determining step. Base assistance is necessary to provide a pair of electrons for the ring closure, because the nitrogen lone pairs in **5** are involved in guanidinium resonance. (Consequently, base attack on the exocyclic N-H in **5**, rather than on the one shown, is less likely, because in this case guanidinium resonance would be lost in the ring-closed product.) The proton loss from nitrogen shown is concerted with ring closure because the pK_a changes from about +13 to about −11 as the C—N bond forms, so the energy of the transition state is considerably reduced by transferring it (27).[3] Protonation on the *gem*-diol then leads to essentially irreversible water loss, giving the sta-

ble species **6**, which undergoes no further reaction in the acidic reaction medium.

[5] $k_\psi C_{SH^+} = k_2 a_{SH_2^{2+}} a_{H_2O}/f_\ddagger$

[6] $K_{SH_2^{2+}} = a_{SH^+} a_{H^+}/a_{SH_2^{2+}}$

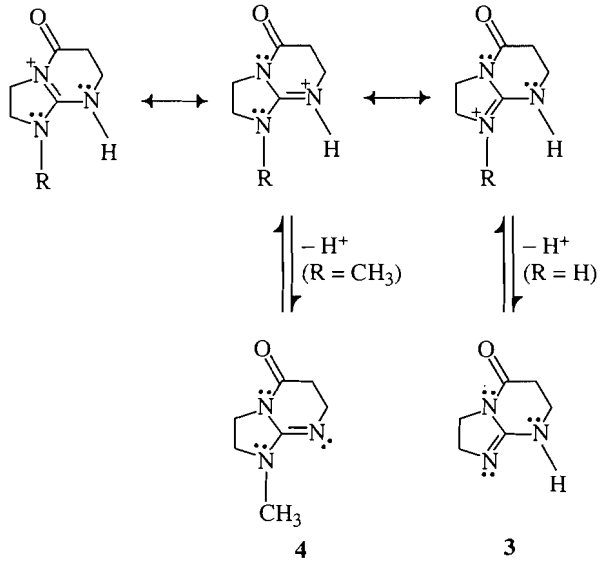
[7] $k_\psi C_{SH^+} = (k_2/K_{SH_2^{2+}}) C_{SH^+} C_{H^+} a_{H_2O} (f_{SH^+} f_{H^+}/f_\ddagger)$

[8] $\log k_\psi - \log C_{H^+} - \log a_{H_2O} = \log(k_2/K_{SH_2^{2+}}) + m^\ddagger m^* X$

The excess acidity rate equations that apply are readily derived as follows (8). Absolute rate theory requires the equality of eq. [5], essentially all of S being in the monoprotonated form SH^+ as discussed above. The definition of $K_{SH_2^{2+}}$ given in eq. [6] enables substitution for $a_{SH_2^{2+}}$, and separation of activities a into molar concentrations C and molar activity coefficients f results in eq. [7]. Taking logarithms and rearranging, and making the usual excess acidity assumption about the log activity coefficient ratio being linear in X (8), leads to the rate equation for the reaction, eq. [8]; this is accurately obeyed, see Fig. 2 and the information in Table 3.

Differentiation to **3** and **4** evidently takes place during work-up, as shown in eq. [9]; the C=N arrangement in **3** must be the more stable of the two possibilities, since it is the only product observed from the reaction of **1** (4). (We do not mean to imply that the resonance structures in eq. [9] are different species; this is simply a convenient illustration of product formation.) The reaction of **2**, with an *N*-methyl, is faster than that of **1** (R = H) by a factor of 5–6, and has an enthalpy of activation about 4 kcal mol^{-1} lower (see Table 3). This seems reasonable; the electron-releasing methyl group in **2** will stabilize the ring-closed product, and should therefore also stabilize the transition state leading to it, increasing the reaction rate. The activation entropies are large and negative, consistent with a bimolecular reaction that is also a cyclization. The $m^\ddagger m^*$ slopes are around one, quite typical for A-2 reactions like this (7).

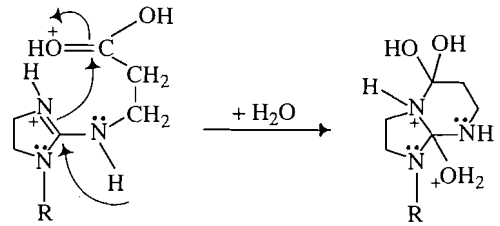
[9]



4 **3**

To find water acting in the role of base is actually not very common in reactions in sulfuric acid. In fact it had recently become doubtful as to whether water acting as a base would show up at all in the kinetics when using the excess acidity method. It had been reported that the curvature found in excess acidity plots for some acid-catalyzed enolization processes, as followed by enol bromination, was due to two water molecules acting as a base (13). However, this has subsequently been shown to be wrong, the curvature being an artifact caused by insufficiently effective bromine scavenging by the enol; once this was taken into account, plots of $\log k_\psi - \log C_{H^+}$ against X for this reaction were in fact linear, not curved (28). The only other reported case of water acting as a base in the excess acidity treatment occurs in the acid-catalyzed aldol condensation of acetaldehyde (14), and this is a bit shaky due to the second-order nature of the reaction causing an extra f_S term to appear in the activity coefficient ratio, which causes an unknown amount of curvature. Thus the precedents for this role for water in reactions in strong acids are not good, despite the often-quoted early work of Bunnett (29), before the present study.

[10]



Another role is possible for the water molecule, and that is to have it act as a nucleophile, as shown in eq. [10]. This also supplies a pair of electrons for the ring closure, but it is regarded as a less likely mechanism for a number of reasons. (*a*) The amidinium ion resonance is lost during the eq. [10] process, and the product has two localized positive charges in close proximity. This seems improbable. (*b*) Comparing **1** with **2**, the electron-donating methyl group in **2** would make **5** *less* susceptible to nucleophilic attack, resulting in slower reaction rather than the faster one observed. (*c*) Nucleophilic additions by water in sulfuric acid usually involve more than one water molecule; for instance, ester hydrolysis needs two (9) and amide hydrolysis three, at least in less concentrated acid (11). Only one is needed here.

In summary, it is seen that ring-closure reactions are possible, albeit slow, in the sulfuric acid medium, and that a water molecule is necessary as a base catalyst. This reaction should prove to be a useful synthesis for cyclic guanidine derivatives and related compounds.

Received February 4, 1994

LAURIER L. SCHRAMM and LOREN G. HEPLER. Can. J. Chem. **72**, 1915 (1994).

We have measured (du Nouy ring and maximum bubble pressure methods) suspension–air surface tensions of aqueous suspensions of montmorillonite and have observed that these surface tensions are larger than those of pure water at the same temperatures. Further measurements have shown that dispersed montmorillonite also increases the suspension–toluene interfacial tension compared with that of pure water–toluene. Similar measurements on aqueous suspensions of kaolinite have yielded suspension–air interfacial tensions with uncertainties as large as the observed (small) effect, and also shown that the suspension–toluene interfacial tension is decreased (opposite to the effect of montmorillonite) by amounts larger than the experimental uncertainties. Measurements of maximum bubble pressures at different flow rates have provided information about the effect of surface age on observed surface tensions.

LAURIER L. SCHRAMM et LOREN G. HEPLER. Can. J. Chem. **72**, 1915 (1994).

On a mesuré (par les méthodes du cercle de Nouy et de la pression maximale de la bulle) les tensions de surface suspension/air de suspensions aqueuses de montmorillonite et on a observé que, aux mèmes températures, ces tensions de surface sont plus importantes que celle de l'eau pure. Des mesures additionnelles ont permis de montrer que la montmorillonite dispersée augmente aussi la tension interfaciale de la suspension/toluène par rapport à celle de l'eau pure/toluène. Des mesures semblables sur des suspensions aqueuses de kaolinite ont fourni des tensions interfaciales suspension/air pour lesquelles les incertitudes sont aussi importantes que le (faible) observé et on aussi permis de démontrer que la tension interfaciale suspension/toluène diminue (effet opposé à celui de la montmorillonite) par des quantités plus importantes que les incertitudes expérimentales. Des mesures par la méthode des pressions maximales de la bullel à diverses vitesses d'écoulement ont fourni de l'information concernant l'effet de l'age de la surface sur les tensions de surface observées.

[Traduit par la rédaction]

Introduction

Many aqueous systems found in industry and in nature contain dispersed clays or other finely divided solids. Examples include heat and mass transfer operations, the casting of ceramics, mineral flotation, and solids-stabilized emulsions. Several properties (such as viscosities, light scattering, and electrophoretic mobilities) of such systems have been investigated many times. On the other hand, the surface tensions (suspension–air) and interfacial tensions (suspension–liquid) of systems containing finely dispersed solids (such as clays) have not received much attention. In fact it is quite common, when dealing with such systems, to remove the solids and measure and report surface and interfacial tensions on a solids-free basis. This is in spite of evidence that such properties for the *suspensions* can be important in various fields.

Our specific interest in this problem arose in two connections: (*i*) the effects of clays on recovery of bitumen from oil (tar) sands by the hot water flotation process used commercially in Canada by Syncrude and Suncor, and (*ii*) the properties and possible treatment of the tailings "sludge" that is a troublesome by-product of the hot water flotation process.

In addition to the above specific interests there is a general interest in measuring and understanding surface and interfacial tensions of systems that consist of dispersions of finely divided particles. Some reasons for such interests are as follows.

Surface tensions of aqueous solutions of inorganic electrolytes are well-known to be larger than the surface tension of pure water at the same temperature. For example, the surface tension of 2M (10.5 mass%) sodium chloride solution is about 3.3 mN/m larger than the surface tension of water at the same (room) temperature. Such elevated surface tensions are not limited to solutions of inorganic electrolytes; aqueous solutions of sucrose and some other organic non-electrolyte solutes have larger surface tensions than does water at the same temperature. It is commonly believed that these increased surface tensions are due to strong interactions (hydration) of water with many ionic solutes and also with many non-ionic solutes. Chaudhury and Good (1) have reported their theory of negative adsorption and increased surface tension due to solutes such as sucrose.

Many other solutes (both electrolytes and non-electrolytes) cause the surface tensions of their solutions to be smaller than the surface tension of water at the same temperature. Among these solutes are substances that are called surfactants because of their dramatic effects on surface tension and some other properties (2).

In contrast to these well-known effects of solutes (*dissolved* substances) on the surface tension of water, consider the non-effect of a rock sitting on the bottom of a beaker of water. Consideration of the differences between solutes (NaCl, sucrose, etc.) and the rock leads to interesting questions about aqueous polymers ("small" polymers are similar to conventional solutes, but sufficiently large polymers may be regarded as small suspended particles) and about aqueous suspensions of finely divided solids. It is easy to observe that some such finely divided solids reside on or near the surface of water, and it is also easy to observe that solids in some dispersions settle (rapidly or slowly) away from the surface to become systems that

are similar in some ways to the beaker of water with a rock at the bottom. These considerations made us suspect that some systems containing finely divided solids dispersed in water would exhibit surface and/or interfacial tensions different from those of pure water.

The exploratory measurements described in this paper were undertaken to answer some of the general questions mentioned above, and also to lead in the direction of data that would be relevant to specific problems with oil sand flotation and processing.

It is appropriate to mention several other investigations that are directly or indirectly related to the surface and interfacial tensions that are the subject of this investigation.

Salmang et al. (3) and Taylor and Howlett (4) have investigated physical properties of ceramic casting slips, which typically consist of suspensions of kaolinite in water in the presence of deflocculating agents. They found that the commonly used casting slip suspensions can have surface tensions that are several mN/m greater than that of pure water. Surface tensions slightly smaller than that of pure water were observed after wetting agents were added to the casting slip suspensions, whereas much larger surface tensions were observed when "skins" of particles formed at the suspension-air interface. In the oil sands industry, Gewers (5) has reported on the effects of clay "skins" at the oil–water interface.

Brian and Chen (6) have measured the surface tensions of suspensions of iron oxide and silicon dioxide particles in two liquids (water and isoparaffin). Their surface tensions for suspensions of these solids in water were larger than for pure water, while suspensions in isoparaffin had surface tensions that were smaller than for the pure liquid. These authors wrote "In conclusion, while some statistically significant effects were observed, for practical purposes the surface tension of the liquid was unaffected by the addition of solid particles." We do not disagree with their experimental results, but we do suggest that results of several other investigations and our own results reported here show that their conclusion is too restrictive; some finely divided solids do have a "practical" effect on surface tensions.

Adam (7) has written "Powdered solids are very useful emulsifiers, and are frequently used, and it is found that emulsions of either the oil-in-water or water-in-oil type can be stabilized by them." Adam has gone on to discuss stabilization in terms of contact angles and points out the systematic investigation by Pickering, published in 1907, that has led to the use of the term "Pickering emulsions" to denote emulsions stabilized by fine particles (see also refs. 2 and 8). Levine et al. (9–11) have provided a theoretical analysis of the stabilization of emulsions by fine particles at the interface, including some specific consideration of the bitumen–water interface. Menon et al. (12–17) have published several accounts of their investigations of emulsions stabilized by finely divided solids; these papers provide convincing evidence that such solids can have important effects on interfacial tensions. Finally, we note that Goldenberg et al. (18) have reported on the effects of suspended clays on transport in porous media containing gas bubbles.

Experimental

Wyoming montmorillonite ("Upton Wyoming montmorillonite", A.P.I. 25, Wards Natural Science Est., Rochester, N.Y.) and Georgia kaolinite ("Georgia kaolin", well crystallized, KGa-1, Clay Minerals Soc., Source Clay Repository) were used. The <2 μm equivalent spherical diameter fraction was isolated and prepared in the sodium form by treatments described previously by Ewin et al. (19) and Schramm and Kwak (20). Typical samples of the montmorillonite have cation exchange capacities of about 97 meq/100g and specific surface areas in the range 40–45 m^2/g (21–23), while the kaolinite has a CEC of about 2 mequiv./100 g and a specific surface area of about 10 m^2/g (24). Extensive characterizations have been given elsewhere for the Upton Wyoming montmorillonite (21) for the Georgia kaolinite (24). The suspensions were adjusted to pH 9.4 ± 0.2 with NaOH.

TABLE 1. Suspension–air and suspension–toluene interfacial tensions of systems containing Na-montmorillonite suspended in water at 24.5°C[a]

Mass% clay in water	Suspension–air surface tension (mN/m)	Suspension–toluene interfacial tension (mN/m)
0	72.1	36.0
0.15	73.5	37.3
0.30	73.8	39.5
0.98	73.7	39.0
1.49	73.9	38.8
2.14	74.1	39.1
3.00	74.1	39.5

[a]Measurements were made with the du Nouy ring method. Uncertainties are estimated to be about ±0.6 mN/m.

Some surface (liquid–air) and some interfacial (liquid–liquid) tensions were measured with the classical du Nouy ring method (Fisher Scientific, Surface Tensiometer Model 20) as described by Adamson (25), Harkins and Alexander (26), and Padday (27). Pure liquid standards used were methanol, ethylene glycol, toluene, and distilled-deionized water. Some surface tensions were measured with a modified differential maximum bubble pressure method that uses carefully displaced capillaries so that the measurements are independent of density, the importance of which has been discussed by Schramm (28). The flow arrangement allowed for continuously variable, stable gas flow rates capable of producing bubble periods ranging from 0.1 s to longer than 90 s. The waveforms characterizing the gas-pressure changes during bubble growth and breakaway cycles were recorded and used in the evaluation of effective surface ages (29). Each capillary was stainless-steel, with a carefully machined round orifice and a smooth 45° knife edge tip. For both measurement techniques uncertainties are estimated to be about ±0.6 mN/m for the Na-montmorillonite suspensions and about ±0.9 mN/m for the Na-kaolinite suspensions.

Densities of the suspensions were measured using a vibrating reed densitometer (Anton Paar, Graz, Austria, Model DMA 46) and also with 25 mL pychnometers.

Results

Measurements (by the du Nouy ring technique) on suspensions of Na-montmorillonite in water showed that the surface tension is increased compared with that of pure water. Similar measurements showed that the suspension–toluene interfacial tension is also increased by Na-montmorillonite, compared with that of pure water. These results are shown in Table 1 and illustrated in Fig. 1.

The qualitative reliability of the surface tensions cited above was confirmed by the application of the maximum bubble pressure method. The results, shown in Fig. 2 for a surface age of 50 s, again show that the surface tension of water is increased by Na-montmorillonite, with the amount of increase being nearly independent of temperature. The surface age of 50 s was long enough that there was minimal dependence of measured surface tension on bubble flow rate (age). Other illustrations of the increase in surface tension over that of pure water caused by the Na-montmorillonite are shown in Fig. 3, while Fig. 4 shows

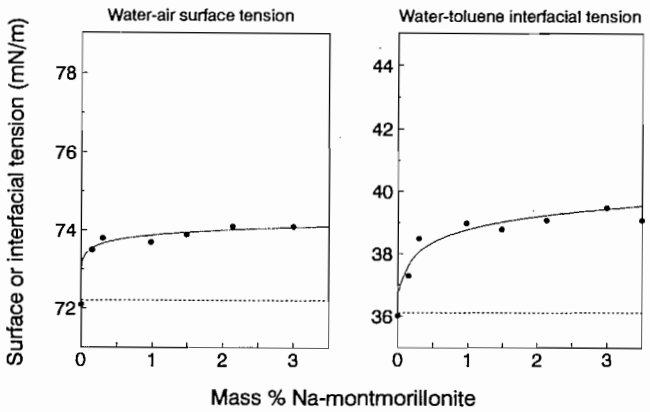

FIG. 1. Suspension–air and suspension–toluene surface and interfacial tensions for aqueous suspensions of Na-montmorillonite, as measured with the du Nouy ring technique at 24.5°C. The broken lines show the values measured for pure water.

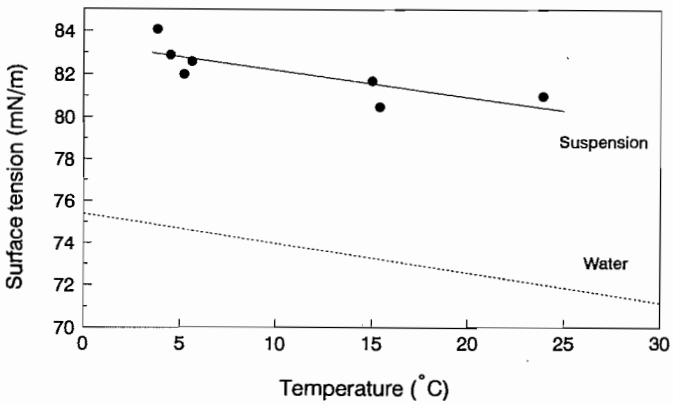

FIG. 2. Suspension–air surface tensions for aqueous suspensions of Na-montmorillonite (5 mass%), as measured with the maximum bubble pressure technique at different temperatures. The broken line shows the values measured for pure water.

a comparison of results obtained with the two independent methods (du Nouy ring and maximum bubble pressure).

We next consider the effect of Na-kaolinite on surface and interfacial tensions. The suspension–toluene interfacial tensions for Na-kaolinite are clearly lower than for pure water (Table 2 and Fig. 5), which is opposite to the effect of the Na-montmorillonite. On the other hand, the suspension–air surface tensions measured by du Nouy ring (Table 2 and Fig. 6) are not changed significantly (considering experimental uncertainties) from those for pure water.

The results of measurements by the maximum bubble pressure method show that surface tensions of Na-kaolinite suspensions are dynamic; they depend on the gas flow rate (surface age) as shown in Figs. 7 and 8. The Na-kaolinite suspensions showed decreased surface tension at fast flow rates (short surface ages) and larger surface tensions at slower flow rates (older surfaces).

Uncertainties in our results for suspensions of kaolinite are larger than for similar experiments with montmorillonite, presumably because the suspensions of kaolinite settle more rapidly than do the suspensions of montmorillonite.

Discussion

It was stated in the Introduction that surface tensions of aqueous solutions of inorganic electrolytes are larger than the surface tension of pure water at the same temperature. Therefore suspending sodium-form clays in water should have a positive effect on surface tension due to the counterions. For 5 mass% suspensions, the highest clay concentration used in this work, Na-montmorillonite contributes a sodium ion concentration of 5.1×10^{-2} M while Na-kaolinite contributes a sodium ion concentration of 1.05×10^{-3} M. But the anion must be considered as well. As an illustration we consider the addition to water

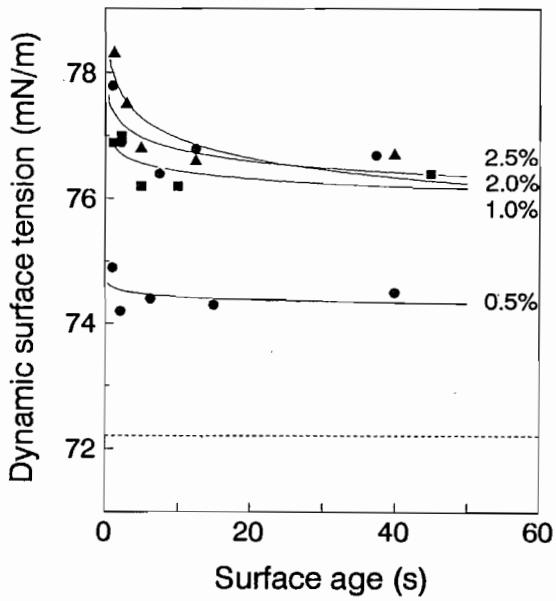

FIG. 3. Suspension–air surface tensions for aqueous suspensions of Na-montmorillonite, as measured with the maximum bubble pressure technique at 23.0°C for different surface ages. The solid curves indicate results for different concentrations (expressed as mass%) of clay. The broken line shows the value measured for pure water (it is independent of surface age).

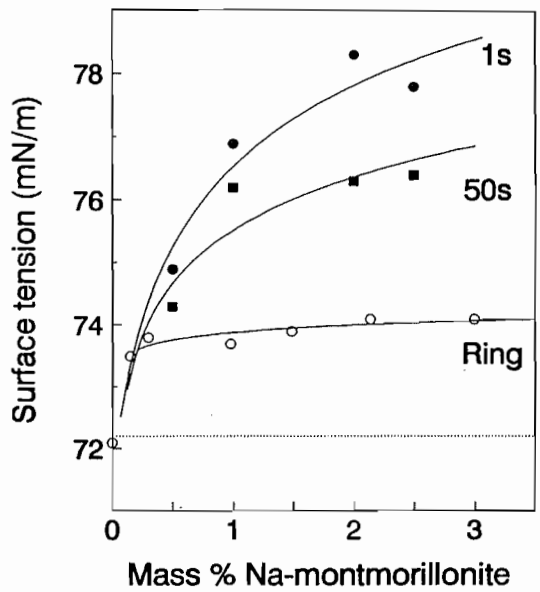

FIG. 4. Comparison of suspension–air surface tensions for aqueous suspensions of Na-montmorillonite, as measured with the du Nouy ring and maximum bubble pressure techniques. The curves with solid symbols represent bubble pressure results for two different surface ages. The broken line shows the value measured for pure water.

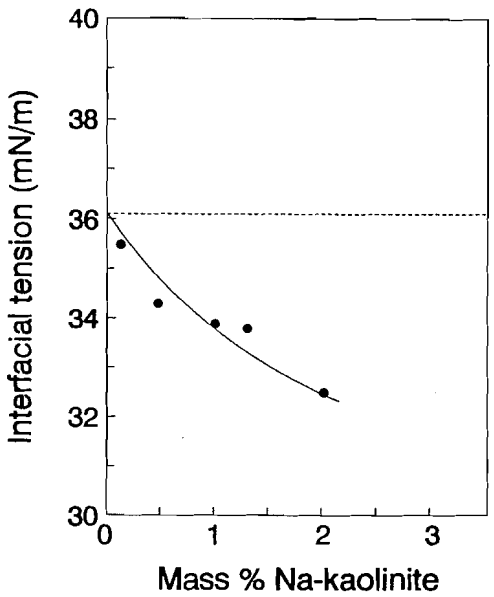

FIG. 5. Suspension–toluene interfacial tensions for aqueous suspensions of Na-kaolinite, as measured with the du Nouy ring technique at 24.5°C. The broken line shows the value measured for pure water.

of these concentrations of sodium in the form of NaCl. A 5.1×10^{-2} M NaCl solution (representing the ionic concentration of a 5% suspension of Na-montmorillonite) has a surface tension of 72.84 mN/m at 20°C which is only 0.09 mN/m larger than the surface tension of pure water at the same temperature. Similarly, the surface tension of 1.05×10^{-3} M NaCl solution at 20°C (representing the ionic concentration of a 5% suspension of Na-kaolinite) is only 0.002 mN/m larger than that of pure water at the same temperature. All of the changes in surface tension due to the presence of clay particles and their counterions determined in this work are of much greater magnitude than would be expected based on the addition of the same number of equivalents of the clay-counterions with simple anions.

There are at least two ways to interpret the observation that colloidal clays dispersed in water can raise or lower surface and interfacial tensions. The first can be expressed in terms of the Gibbs adsorption equation

$$d\gamma^\circ = -RT\Gamma \, d \ln a$$

where Γ is the surface excess adsorption per area and a is the activity of adsorbing species. From this point of view one might

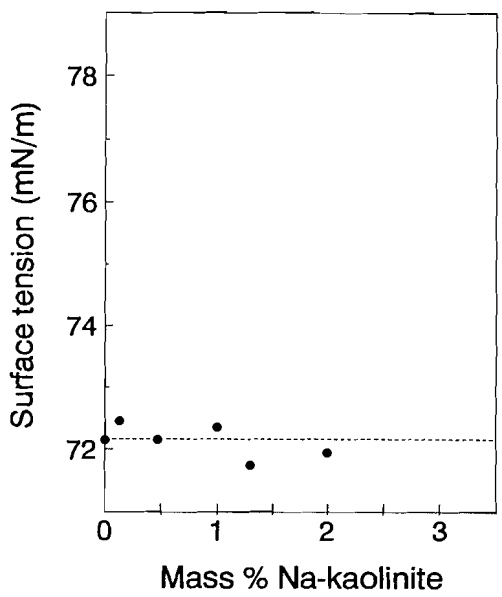

FIG. 6. Suspension–air surface tensions for aqueous suspensions of Na-kaolinite, as measured with the du Nouy ring technique at 24.5°C. All surface tensions are within experimental uncertainty equal to the value measured for pure water (broken line).

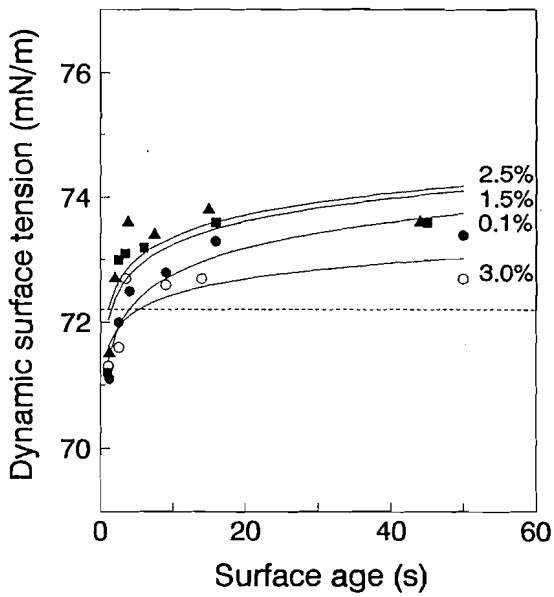

FIG. 7. Suspension-air surface tensions for aqueous suspensions of Na-kaolinite, as measured with the maximum bubble pressure technique at 23.0°C for different surface ages. The broken line shows the value measured for pure water.

conclude that the montmorillonite particles tend to be negatively adsorbed while the kaolinite particles tend to positively adsorb. This is consistent with a study of adhesion of small particles to large air bubbles in suspensions by Goldenberg et al. (18). They found that in dilute electrolyte solutions clays of low cation exchange capacity (kaolinite) adhered to bubble surfaces and formed surface structures. In contrast, clays of high cation exchange capacity (smectite) tended not to adhere to the bubble surfaces.

An alternative point of view can be drawn from the work of Menon et al. (12–14) who found that when fine solids were

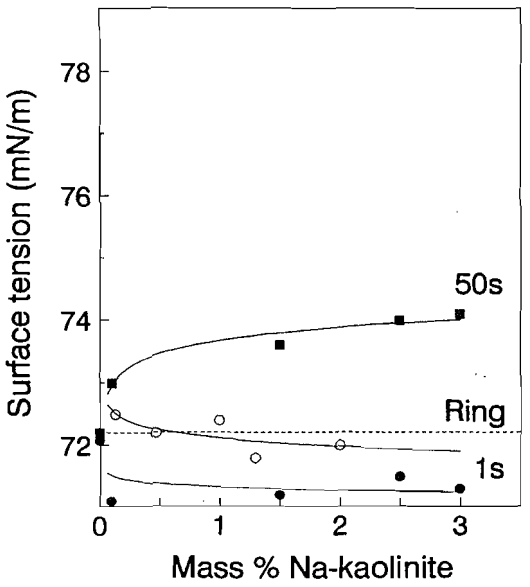

FIG. 8. Comparison of suspension–air surface tensions for aqueous suspensions of Na-kaolinite, as measured with the du Nouy ring and maximum bubble pressure techniques. The curves with solid symbols represent bubble pressure results for two different surface ages. The broken line shows the value measured for pure water.

forced to accumulate at the oil–water interface the presence of the solids at the interface could either raise or lower interfacial tension. Menon et al. associate changes in interfacial tension with degrees of repulsive interaction among particles present at the interface. High interfacial coverages with shale dust particles (clays coated with asphaltic material) were found to raise or lower interfacial tension depending on the extent of surface coverage and particle orientations. At high particle coverages the interfacial tensions were raised, presumably due to net electrostatic repulsions. When the negative charge of the clay was almost completely countered by the adsorption of asphaltenes, interfacial tension lowering was observed.

Another feature of the particle interaction model is that dynamic effects (dynamic surface or interfacial tensions) might be expected, due to the formation of a monolayer followed by particle rearrangements. Support for this can be found in a recent paper by Williams and Berg (30) that describes the phenomenon of adsorption and aggregation of colloidal particles at air–liquid interfaces.

Results of our measurements by the du Nouy ring method and the maximum bubble pressure method are in good qualitative agreement. Each method leads to measured surface tensions for aqueous suspensions of Na-montmorillonite that are larger than the surface tension of water without suspended clay at the same temperature. There are, however, quantitative disagreements. For example, extrapolation of the surface tensions shown in the left hand diagram of Fig. 1 leads to a predicted surface tension amounting to a little less than 75 mN/m for a 5 mass% suspension of Na-montmorillonite, whereas the value from the maximum bubble pressure method (Fig. 2) is a little more than 80 mN/m at the same temperature. For du Nouy ring measurements the effective surface ages are not well known. The ring was initially equilibrated with the solution (or suspension) but some changes still can take place at the meniscus surface where new surface is created as the ring is raised, even when the ring is raised as slowly as possible. By assuming that the surface age was older for the ring method than for the bubble pressure method, we can account for part (only part) of the discrepancy noted above.

In the present systems the extent to which the particles may have been present at the interfaces is not known for certain. Our results are, however, consistent with the available literature in that it seems that where the interfacial properties of suspensions are concerned – significant interparticle repulsive forces (high charge density particles such as montmorillonite) can cause surface or interfacial tension elevation while near-zero or attractive forces (low or zero charge density particles such as kaolinite) can cause surface or interfacial tension lowering. A related aspect is the effect of particle size on the results. The particle sizes were not measured in this work. However, it is known from the results of other investigations that the Na-kaolinite particles were larger than the Na-montmorillonite particles. The latter would be expected from other work to have a major dimension of about 300 nm and a minor dimension of about 2.4 nm (31). The possible effect of particle size on the surface or interfacial tensions of suspensions should be investigated in future work. This is an important aspect because different exchange cations will influence the particle sizes in suspension. In montmorillonite suspensions particularly, tactoid formation is very much dependent on the counterion (31).

For the present we conclude only that colloidal clays dispersed in water can raise or lower surface and interfacial tensions by amounts significantly larger than experimental uncertainties, and that the time-dependence of suspension surface tensions can be appreciable. These effects of suspended clay particles (and possibly other colloidal solids) on surface and interfacial tensions are surely important in connection with stabilities of certain emulsions and may be important in other systems.

Acknowledgements

We are grateful to Brian Turnbull and Z.M. Ding for assistance with the measurements, and to Visiting Professor Shmuel Yariv and the journal's manuscript reviewers for helpful advice. We thank Syncrude Canada Ltd. and the Alberta Oil Sands Technology and Research Authority (Strategic Program) for their support of this research and for their permission to publish this report. L.L.S. also thanks the Petroleum Recovery Institute for providing the facilities and time needed to do some of the bubble pressure measurements and to prepare part of this report.

Excess volumes V^E, excess viscosities η^E, and excess free energies of activation of flow G^{*E} of binary mixtures of 2-chloro-2-methylpropane with isomeric butanols have been calculated from experimental measurements of density and viscosity at 298.15 K. The results are correlated by means of a Redlich–Kister type equation and explained in terms of molecular interactions.

PILAR CEA, CARLOS LAFUENTE, HECTOR ARTIGAS, FELIX M. ROYO et JOSE S. URIETA. Can. J. Chem. **72**, 1921 (1994).

Utilisant des mesures expérimentales de densité et de viscosités obtenues à 298,15 K, on a calculé les volumes en excès, V^E, les viscosités en excès, η^E, et les énergies libres d'activation d'écoulement en excès, G^{*E}, de mélanges binaires du 2-chloro-2-méthylpropane avec les butanols isomères. On a établi une corrélation entre les résultats et une équation du type de Redlich–Kister et on les a expliqués en fonction d'interactions moléculaires.

Introduction

The study of the thermodynamics and transport properties of liquid mixtures provides information about intermolecular forces and the microscopic structure of liquids. As a continuation of previous work in our laboratory (1–5), we here report excess volumes V^E, excess viscosities η^E, and excess free energies of activation of flow G^{*E}, at 298.15 K for binary mixtures of 2-chloro-2-methylpropane with isomeric butanols. These compounds have several uses in the chemical industry (e.g., 2-chloro-2-methylpropane is used in Friedel–Crafts reactions).
