This paper is dedicated to Professor David B. MacLean

HERBERT L. HOLLAND, ELAREF S. RATEMI, and (in part) LUIS CONTRERAS. Can. J. Chem. **72**, 1 (1994).

The 15-thia-15-deoxy analogue of prostaglandin E_1 methyl ester has been prepared by the zirconocene chloride mediated conjugate addition of an *n*-pentyl ethynyl sulfide derived anion to an appropriately substituted cyclopentenone. Similar methodology has also been used to prepare other 3-(3′-thia-1′-octenyl)-cyclopentanones.

HERBERT L. HOLLAND, ELAREF S. RATEMI et (in part) LUIS CONTRERAS. Can. J. Chem. **72**, 1 (1994).

On a préparé l'analogue 15-thia-15-désoxy de l'ester méthylique de la prostaglandine E_1 en procédant à une addition conjuguée, catalysée par le chlorure de zirconocène, d'un anion dérivé du sulfure d'éthynyle et de *n*-pentyle à une cyclopenténone substituée d'une façon appropriée. On a utilisé une méthodologie semblable pour préparer d'autres 3-(3′-thia-1′-octényl)cyclopentanones.

The synthesis of natural prostaglandins and structurally modified prostanoids has a long and extensive history (see, for example, refs. 1–3). One of the long-term goals in the production of modified prostaglandins has been the suppression or reduction of the normally rapid metabolic deactivation of these compounds (for an overview of PG activity and metabolism, see ref. 4); in this regard, the significance of C-15 in prostanoid metabolism is apparent from the rapid oxidation of the 15-hydroxyl group of natural PG's by the enzyme 15-hydroxyprostaglandin dehydrogenase, and modification of the molecule at or close to C-15 has indeed been productive in the development of longer term physiologically active prostanoids (5–7).

As a part of this endeavour, prostanoids modified by the presence of heteroatoms in place of ring or side-chain carbons have also been investigated, resulting in the synthesis of compounds incorporating, for example, sulfur atoms in both side chains (8, 9). However, there have been no reports to date of the preparation of prostanoids, such as **11**, containing sulfur at the metabolically important C-15 position. In view of this fact, we have undertaken the synthesis of a structurally modified prostanoid incorporating sulfur in place of C-15.

The 15-deoxy-15-thia analogue of PGE_1 methyl ester (**11**) was chosen as the synthetic target in view of the central position occupied by the PGE series in prostaglandin biochemistry (1), and also the comparative difficulty in simple construction of the PG_1 (as opposed to the PG_2) skeleton (10, 11). Thus, any synthetic method for **11** based on a conjugate addition approach should be in principle applicable to its PGE_2 analogue, via Noyori's "three-component coupling" method (11), whereas the reverse is not necessarily true. It is our intention in further studies to investigate both chemical and enzymatic methods for the oxidation of **11** at the 15 position, hence the choice of a 15-deoxy analogue as the initial synthetic target.

The essential feature of our synthetic approach is the conjugate addition of a 3-thia-alkenyl anion equivalent, corresponding to the lower side chain of the final product, to a suitably substituted cyclopentenone, such as **6** (Scheme 1). To establish the viability of this approach, it was necessary first to demonstrate that this addition would proceed with stereospecific formation of a product having *E* geometry about the double bond, and to this end the addition of a terminal anion equivalent of *E*-3-thia-1-octene (**14**) (12) to cyclopentenone (**1**), giving the 3-substituted cyclopentanone **7** (Scheme 2, line 1), was first investigated.

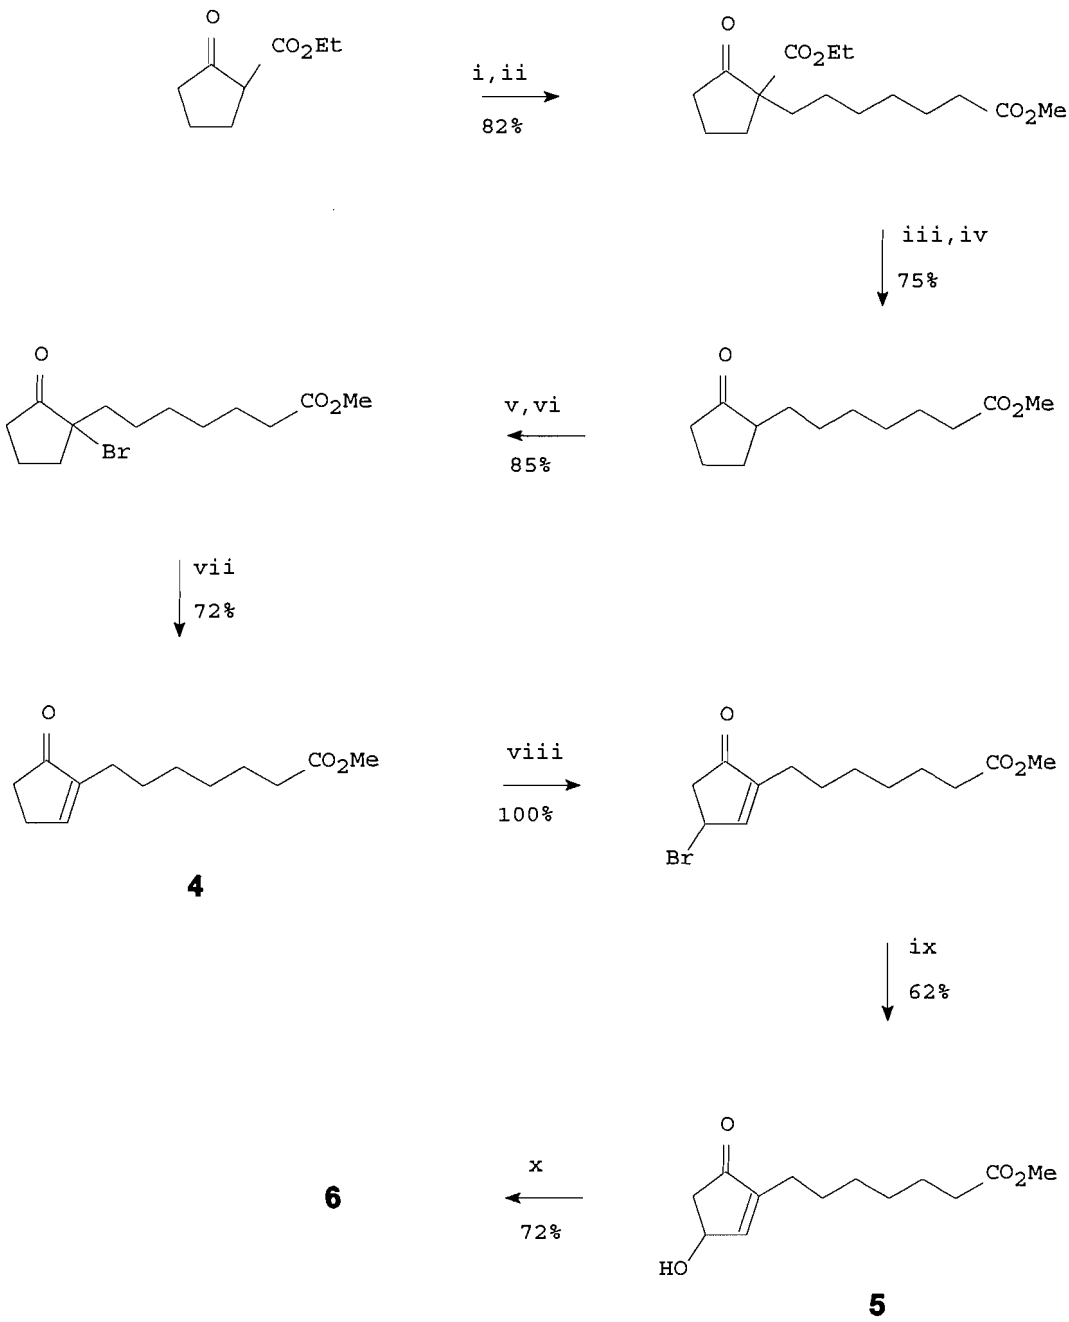
Of the methods available for the in situ generation of a terminal anion equivalent of *E*-3-thia-1-octene, the most successful was found to be that based on 3-thia-1-octyne (**13**), via generation of the higher order cuprate complex **14** (Scheme 3) using Schwartz's reagent (zirconocene hydride chloride) (12–14). Prepared using this methodology, the cyclopentanone **7**, obtained in 70% yield, clearly possessed *E* geometry about the olefinic bond based on an observed coupling constant of 16 Hz between the two olefinic hydrogens (12).

Addition of the complex **14** to a protected 4-hydroxycyclopentenone **3** (Scheme 2, line 3) proceeded in 55% yield to give product **9**. The 2-substituted cyclopentenones **4** and **6**, prepared as outlined in Scheme 1, were also used for the conjugate addition reaction of Scheme 2 (lines 4 and 6, respectively), and gave the corresponding *trans*-2,3-dialkyl cyclopentanones **10** and **12**. The synthesis of **4** by the route of Scheme 1 in an overall yield of 38% from 2-carboethoxycyclopentanone represents an improvement in both yield and utility on a similar route originally developed by Bagli et al. (10% overall yield) (15, 16). The preparation of the alcohol **5** in 62% yield from **4** by the allylic hydroxylation procedure of Baraldi et al. (17) is also superior to the previously reported method for this conversion stated to proceed in 40% yield (18).

When addition of **14** to the 2,4-disubstituted cyclopentenone **6** was carried out, giving the protected 15-thiaprostanoid **12** in 60% yield, careful control of the reaction conditions was found to be essential; when the reaction was carried out at –78°C, product formation was very slow (less than 10% conversion in 6 h, whereas stereoisomeric product mixtures were obtained at temperatures above –40°C. The all-*trans* relative stereochemistry of the ring substituents of the final product **11**, obtained following deprotection of **12**, was confirmed by analysis of both ^{1}HMR and ^{13}CMR spectra; a close correspondence of the resonance positions of the relevant carbons (C-8, -11, and -12; 54.6, 55.5, and 72.2 ppm) with the corresponding carbons of PGE_1

[1]This paper commemorates the professional career of our mentor, David B. MacLean, on the occasion of his retirement and elevation to the position of Professor Emeritus at McMaster University, Hamilton, Ontario.

[2]On leave from the Department of Chemistry, University of Venezuela, Caracas, Venezuela.



SCHEME 1: i, NaH/DME; ii, methyl 7-bromoheptanoate; iii, H^+; iv, *p*-toluenesulfonic acid/MeOH; v, Ac_2O/H^+; vi, Br_2; vii, $LiBr/Li_2CO_3$; viii, NBS; ix, H_2O/dioxane; x, DHP/H^+

(54.2, 54.6, and 71.6 ppm) and other closely related compounds of known *trans* stereochemistry was observed, together with a similar correspondence of the appropriate hydrogen resonance positions and coupling constants of **11** deduced from 2D ^{1}HMR analysis (19–21). This finding is consistent with the observation that the *trans* product is formed in similar conjugate additions of hydrocarbon-derived anion equivalents to substituted cyclopentenones (13, 14).

The production of **11** by the synthetic route outlined in the accompanying scheme provides an efficient method for the construction of 15-thiaprostanoids. The availability of intermediates, such as **5**, in chiral form (22) opens the possibility of synthesis of chiral 15-thia-PGE derivatives. Preliminary studies of the biological activity of **11** are currently being undertaken.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with an Analect 6260FX spectrometer. Proton NMR spectra were recorded at 200 MHz and carbon NMR spectra at 50.3 MHz (JMOD mode) with a Bruker AC200 spectrometer using deuteriochloroform as solvent and chloroform as internal standard. Mass spectra were obtained with a Kratos concept IS mass spectrometer in EI or CI mode (isobutane) as indicated. Thin-layer chromatography was performed on Merck silica gel 60F-254 and preparative column chromatography using 230–400 mesh silica gel (Merck 9385 or equivalent). HPLC analysis was carried out using a Perkin Elmer Series 3 chromatograph.

4-Hydroxycyclopent-2-enone (2)

This was prepared as described (23) by acid-catalyzed rearrangement of furfuryl alcohol to give, following chromatography (elution with hexane:ethyl acetate, 3:2), the title compound in 45% yield; R_f 0.34 (ethyl acetate); IR ν_{max}: 1720, 3425 cm^{-1}; ^{1}HMR δ: 2.21 (1H, dd, J = 2, 16 Hz, H-5), 2.72 (1H, dd, J = 6, 12 Hz, H-5), 5.02 (1H, m, H-4), 6.19 (1H, d, H-2), and 7.64 (1H, dd, H-3) ppm; ^{13}CMR δ: 43.4 (C-5), 69.2 (C-4), 133.7 (C-2), 164.2 (C-3), 207.2 (C-1) ppm; MS (EI) *m/z* (%): 98(88), 97(34), 80(3), 70(67), 55(77), 43(100).

4-Triethylsilyloxycyclopent-2-enone (3)

Triethylsilyl chloride (3 g) was added to a solution of the hydroxyketone **2** (1.47 g) in dry pyridine (20 mL). The mixture was stirred at ambient temperature for 30 min, then heated at 55°C for 45 min, cooled, diluted with water (40 mL), and extracted with dichloromethane. The extract was dried and evaporated to give an oil, which was chromatographed (ethyl acetate:hexane, 2:3) to give the title compound (2.92 g) as a pale yellow oil; R_f 0.66 (ethyl acetate: hexane 3:7); IR ν_{max}: 1590, 1720 cm^{-1}; ^{1}HMR δ: 0.65 (6H, q, CH_3CH_2-Si), 0.97 (9H, t, CH_3CH_2-Si), 2.22 (1H, m, H-5), 2.68 (1H, dd, J = 6, 16 Hz, H-5), 4.99 (1H, m, H-4), 6.15 (1H, dd, J = 1.1, 5.7 Hz, H-2), and 7.46 (dd, J = 2.2, 5.6 Hz, H-3) ppm; ^{13}CMR δ: 4.3 (3C), 6.2 (3C), 44.6 (C-5), 70.2 (C-4), 134.0 (C-2), 163.3 (C-3), and 205.6 (C-1) ppm; MS (EI) *m/z* (%): 212(3), 183(100), 155(35), 127(43), 125(73).

2-Carboethoxy-2-(6′-methoxycarbonylhexyl)-cyclopentanone

2-Carboethoxycyclopentanone (49.5 g) was added over 35 min to a stirred suspension of sodium hydride (8.1 g) in dry DME (320 mL), with the reaction temperature being maintained at 25°C. When gas evolution was complete, methyl 7-bromoheptanoate (70.7 g) was added, and the resulting mixture then refluxed under argon for 26 h. The mixture was cooled and filtered, the solids washed with ether, and the combined filtrate and washings evaporated. The resulting residue was added to water (200 mL) and the mixture acidified (10% HCl). Extraction with ether followed by drying and evaporation of the extract gave an orange oil (80 g) that, following chromatography (hexane:-ethyl acetate, 1:1), gave the title compound (75 g) as a colourless oil; R_f 0.45 (ethyl acetate:hexane 3:1); IR ν_{max}: 1730, 1748 cm^{-1}; ^{1}HMR included signals at δ: 1.24 (3H, t, OCH_2CH_3), 2.25 (2H, t, CH_2CO_2), 3.67 (3H, s, OCH_3), 4.17 (2h, q, OCH_2CH_3) ppm; ^{13}CMR δ: 13.9 (CH_3), 19.4, 24.4, 24.6, 28.6, 29.3, 32.6, 33.5, 33.8, 37.7, 51.2 (OCH_3), 61.1 (OCH_2), 64.0 (C-2), 170.9, 173.9, and 214.6 (C-1) ppm.

2-(6′-Methoxycarbonylhexyl)-cyclopentanone

A mixture of the above diester (65.5 g), acetic acid (195 mL), water (273 mL), and H_2SO_4 (77 mL) was heated under reflux for 20 h. The cooled mixture was then treated with 10% sodium bicarbonate (250 mL), and extracted with ether. The extract was washed (2 × 400 mL water followed by 400 mL 10% $NaHCO_3$), dried, and evaporated. Distillation of the residue (159–163°C, 0.09 Torr; 1 Torr = 133.3 Pa)

afforded a clear oil (R_f 0.3 (ethyl acetate:hexane 1:1); IR ν_{max}: 1710, 1748, 3102 cm^{-1}), which was esterified using dry methanol (250 mL), benzene (800 mL), and *p*-toluenesulfonic acid (1 g), refluxing in a Dean–Stark apparatus for 7 h. Conventional work-up gave the title ester (37 g), bp 120–125°C, 0.7 Torr (lit. (24) bp 135–140°C, 0.4 Torr); R_f 0.55 (ethyl acetate:hexane 4:1); IR ν_{max}: 1739, 1745 cm^{-1}; ^{1}HMR δ: 1.22–1.32 (8H, m), 1.55–1.98 (6H, m), 3.67 (3H, s, OCH_3); ^{13}CMR δ: 20.5, 24.7, 27.1, 28.7, 29.0, 29.4 (2C), 33.8, 37.9, 48.8 (C-2), 51.1 (OCH_3), 173.9, 221.0 ppm; MS (EI) *m/z* (%): 226(5), 195(9), 143(5), 97(9), 84(100).

1-Acetoxy-2-(6′-methoxycarbonylhexyl)-cyclopentene

A stirred solution of the above ester (28.2 g) and *p*-toluenesulfonic acid (270 mg) in acetic anhydride (57 mL) was heated while the acetic acid that formed was fractionally distilled. The original volume was maintained by periodic addition of acetic anhydride. When no more acetic acid distilled, the mixture was briefly heated to 140°C, then cooled and poured onto a stirred ice-cold mixture of saturated $NaHCO_3$ (400 mL) and hexane (300 mL). The organic phase was removed, dried, and evaporated, and the residue distilled to give a colourless oil (28.6 g, bp 81–85°C, 0.07 Torr); R_f 0.6 (ethyl acetate:hexane 4:1); IR ν_{max}: 1698, 1742 cm^{-1}; ^{1}HMR δ: 1.25–1.40 (6H, m), 1.61 (2H, m), 1.93 (4H, m), 2.14 (3H, s, $COCH_3$), 2.28 (4H, m), 2.45 (2H, m), 3.67 (3H, s, OCH_3) ppm; ^{13}CMR δ: 19.7, 20.6 (CH_3CO), 24.8, 26.2, 26.8, 28.8, 28.9, 30.9, 31.0, 33.9, 51.3 (OCH_3), 126.5 (C-2), 143.9 (C-1), 168.7, 174.1 ppm; MS (EI) *m/z* (%): 268(5), 194(100), 166(30), 123(33), 97(76), 84(37).

2-Bromo-2-(6′-methoxycarbonylhexyl)-cyclopentanone

A 500-mL 3-neck flask was fitted with a mechanical stirrer and two dropping funnels, cooled in ice, and charged with calcium carbonate (9 g) and chloroform (100 mL). To this cooled and stirred mixture were added simultaneously over 15 min a solution of the above enol acetate (22.5 g) in chloroform (10 mL) and a solution of bromine (13.4 g) in carbon tetrachloride (10 mL). The mixture was stirred at 5°C for a further 30 min, and the organic layer was then separated, washed (5% sodium thiosulphate, water, then saturated NaCl), dried, and evaporated at <40°C to yield the desired bromoketone, which was used directly in the next step without further manipulation.

*2-(6′-Methoxycarbonylhexyl)-cyclopent-2-enone (**4**)*

The crude bromoketone prepared as above (25.5 g) was added to an anhydrous, refluxing, and well-stirred mixture of LiBr (16.5 g) and Li_2CO_3 (16.5 g) in DMF (200 mL) under argon. The mixture was refluxed for a further 30 min, then cooled, poured into water (1 L), acidified (10% HCl), and extracted with ether. The ether extract was washed (water, saturated NaCl), dried, and concentrated to give an oil, which after distillation gave 13.5 g of the title compound, bp 95°C, 0.05 Torr (lit. (24) bp 145–150°C, 0.2 Torr); R_f 0.4 (ethyl acetate:hexane 1:1); IR ν_{max}: 1633, 1703, 1736 cm^{-1}; ^{1}HMR δ: 1.30–1.66 (8H, m), 2.16 (2H, m), 2.56 (2H, m), 3.66 (3H, s, OCH_3), 7.33 (1H, m, H-3) ppm; ^{13}CMR δ: 24.6, 24.8, 26.3, 27.5, 28.8, 28.9, 34.0, 34.5, 51.4 (OCH_3), 146.3 (C-2), 157.3 (C-3), 174.1, 209.9 ppm; MS (EI) *m/z* (%): 224(13), 193(43), 150(53), 123(42), 109(75), 96(100).

2-(6′-Methoxycarbonylhexyl)-4-bromocyclopent-2-enone

A stirred mixture of the above ketone (6 g), *N*-bromosuccinimide (freshly crystallized from water, 5.52 g), and 2,2-azadiisobutyronitrile (19 mg) in carbon tetrachloride (25 mL) was heated under reflux, and the reaction monitored by ^{1}HMR (appearance of peaks at δ 5.01, (H-4), 7.59 (H-3) ppm). After 5 h, the mixture was cooled to 5°C and filtered. The solids were washed with cold CCl_4 (3 × 20 mL), and the combined organic phase was washed (water, 5% sodium thiosulphate), dried, and evaporated to give 8.47 g of an orange oil, which was used directly in the next step.

*2-(6′-Methoxycarbonylhexyl)-4-hydroxycyclopent-2-enone (**5**)*

The crude bromoketone (above) was refluxed in aqueous dioxane (80 mL, 1:1) for 2.5 h. The reaction mixture was then cooled, the solvent evaporated, and the residue extracted with chloroform (4 × 40 mL). The extract was dried, evaporated, and purified by chromatography (10% stepwise elution from benzene to ethyl acetate) to give the title compound, 4.0 g, mp 46–48°C (lit. (25) mp 48–49°C); R_f 0.2 (ethyl acetate:hexane 3:7); IR ν_{max}: 1630, 1695, 1735 cm^{-1}; ^{1}HMR δ: 1.26–1.64 (8H, m), 2.13–2.36 (5H, m), 2.80 (1H, dd, J = 6, 14 Hz), 3.67 (3H, s, OCH_3), 3.45–3.95 (1H, br s, OH), 4.93 (1H, m, H-4) ppm; ^{13}CMR δ: 24.3, 24.7, 27.1, 28.7, 28.8, 34.0, 44.8, 51.4 (OCH_3), 68.4 (C-4), 147.0 (C-3), 155.9 (C-2), 174.0, 206.3 ppm; MS (EI) *m/z* (%): 240(2), 222(33), 190(89), 163(33), 111(48), 95(100).

*2-(6′-Methoxycarbonylhexyl)-4-(tetrahydropyranyloxy)cyclopent-2-enone (**6**)*

One drop of concentrated hydrochloric acid was added to a stirred mixture of the hydroxyester **5** (3.2 g) and dihydropyran (3.28 g), and the resulting mixture stirred at room temperature for 4 h. The solution was then diluted with ether, washed (saturated $NaHCO_3$ followed by saturated NaCl), dried, and evaporated to give an oil, 4.52 g, which was purified by chromatography (10% stepwise gradient elution from hexane to ethyl acetate) to give **6** (3.1 g), R_f 0.75 (ethyl acetate:hexane 3:1), IR ν_{max}: 1720, 1740 cm^{-1}; ^{1}HMR included signals at δ: 3.66 (3H, s, OCH_3), 3.85 (2H, m, $COCH_2$), 4.83–4.91 (2H, m, HC-O-CH), and 7.26 (1H, m, H-3) ppm; ^{13}CMR δ: 19.8, 24.4, 24.7, 25.3, 27.1, 28.7, 28.9, 30.8, 33.9, 42.2/43.2, 51.3, 62.7, 72.9/73.0, 98.4/98.6, 148.0/148.2, 153.5/155.3, 174.1, and 205.8/206.1 ppm; MS (EI) *m/z* (%): 324(0.2), 293(1), 223(12), 191(25), 163(22), 85(100).

*Preparation of the alkenyl cuprate complex **14***

All manipulations were performed in flame-dried apparatus under an argon atmosphere. A 50-mL 2-neck flask equipped with a low-temperature thermometer, magnetic stirrer bar, and a septum was charged with a solution of ethynyl *n*-pentyl sulfide (**13**, 61 mg) (12) in dry THF (3 mL). To this was added solid zirconocene hydride chloride (130 mg), and the mixture stirred until a yellow solution formed (ca. 30 min). This solution was cooled to –70°C, and then treated with methyllithium (0.75 mL, 1.4 M in ether). The resulting mixture was allowed to reach –50°C for 5 min, then recooled to –70°C.

Concurrently, copper(I) cyanide (43 mg) was placed in a 25-mL 2-neck flask fitted with a septum, low-temperature thermometer, and a magnetic stirrer bar. Tetrahydrofuran (2 mL) was added and the resulting slurry cooled to –70°C, then treated with methyllithium (0.38 mL, 1.4 M in ether). The mixture was allowed to reach –50°C, stirred until clear, recooled to –70°C, then cannulated into the alkenyl zirconocene solution, keeping both solutions at –70°C. The flask containing the cyanocuprate was washed with 1 mL of THF, and the washing cannulated as above. The resulting mixture was maintained at –50°C for 30 min, then cooled to –70°C in readiness for the conjugate addition reaction.

*3-(E-3′-Thia-1′-octenyl)cyclopentanone (**7**)*

A solution of cyclopent-2-enone (**1**) (0.25 mmol) in dry THF (2 mL) was added at –70°C to the reagent **14**, prepared as described above. The stirred mixture was allowed to reach –50°C and maintained at that temperature for 5 h. It was then cooled to –70°C and quenched with the addition of saturated ammonium chloride:ammonium hydroxide (9:1, 20 mL). Vigorous stirring of the mixture for 30 min produced a deep blue aqueous layer and a pale yellow organic layer, which was separated. The aqueous layer was extracted with ether (3 × 25 mL), and the combined organic extracts washed (saturated ammonium chloride:ammonium hydroxide, 9:1), dried, filtered through Celite, and evaporated. The residue was purified by chromatography (5% stepwise elution from hexane to ethyl acetate) to give the title compound in 70% yield; R_f 0.5 (ethyl acetate:hexane 1:4); IR ν_{max}: 1740 cm^{-1}; ^{1}HMR included signals at δ: 0.92 (3H, t, H-8′), 1.25–1.39 (8H, m, CH_2′s), 6.24 (1H, d, J = 16 Hz, H-2′), and 6.46 (dd, J = 6, 16 Hz, H-1′) ppm; ^{13}CMR δ: 13.8, 21.7, 22.3, 29.1, 30.9, 37.8, 39.2, 43.8, 54.0, 132.6, 141.0, and 216.4 ppm; MS (EI) *m/z* (%): 212(66), 141(64), 109(57), 91(32), 85(100); HRMS M^+: 212.1257; calcd. for $C_{12}H_{20}OS$: 212:1235.

trans-*2-(6′-Methoxycarbonylhexyl)-3-(*E*-3″-thia-1″-octenyl)-cyclopentanone (**10**)*

Conjugate addition of the complex **14** to 2-(6′-methoxycarbonylhexyl)-cyclopent-2-enone (**4**) as described above gave, following chromatography, the title compound in 62% isolated yield; R_f 0.55 (ethyl acetate:hexane 3:2); IR ν_{max}: 1740 cm^{-1}; ^{1}HMR included signals at δ: 0.90 (3H, t, H-8″), 1.1–1.8 (12H, m), 6.16 (1H, d, J = 16 Hz, H-2″) and 6.46 (dd, J = 6.5, 16 Hz, H-1″) ppm; ^{13}CMR δ: 13.8, 22.1, 24.7, 26.4, 27.7, 28.8, 29.0, 30.5, 30.6, 33.9, 35.7, 41.0, 43.6, 51.2, 54.0, 127.4, 131.9, 174.0, and 219.4 ppm; MS (EI) *m/z* (%): 354(0.4), 290(41), 259(28), 258(31), 230(17), 147(64), 92(100); HRMS M^+: 354.2245; calcd. for $C_{20}H_{34}O_3S$: 354:2228.

trans-*3-(*E*-3′-Thia-1′-octenyl)-4-triethylsilyloxycyclopentanone (**9**)*

Conjugate addition of the complex **14** to 4-triethylsilyloxycyclopent-2-enone (**3**), as described above gave, following chromatography (elution with hexane:ethyl acetate 7:3), the title compound in 55% isolated yield; R_f 0.54 (ethyl acetate:hexane 3:7); IR ν_{max}: 1742 cm^{-1}; ^{1}HMR included signals at δ: 0.56 (6H, q, CH_3CH_2Si), 0.92 (12H, t, CH_3CH_2Si and H-8′), 4.02 (1H, q, H-4), 5.51 (1H, dd, J = 7.5, 15 Hz, H-1′), and 6.11 (d, J = 15 Hz, H-2′) ppm; ^{13}CMR δ: 4.7(3C), 6.7(3C), 13.9, 22.6, 28.7, 28.9, 29.8, 41.7, 42.6, 53.5, 74.0, 127.3, 131.4, and 214.5 ppm; MS (EI) *m/z* (%): 342(8), 313(26), 271(14), 258(14), 249(24), relative to 183(100). HRMS M^+: 342.2035; calcd. for $C_{18}H_{34}O_2SSi$: 342.205.

trans-*2-(6′-Methoxycarbonylhexyl)-3-(*E*-3″-thia-1″-octenyl)-4-tetrahydropyranyloxycyclopentanone (**12**)*

Addition of the cuprate complex **14** to 2-(6′-methoxycarbonylhexyl)-4-(tetrahydropyranyloxy)-cyclopent-2-enone (**6**) (80 mg) as described above, followed by chromatography of the product (5% stepwise elution from hexane to ethyl acetate), gave **12** (80 mg, 60%) as a pale yellow oil, R_f 0.5 (ethyl acetate:hexane 1:4), which was used directly in the next step.

trans-*2-(6′-Methoxycarbonylhexyl)-3-(*E*-3″-thia-1″-octenyl)-4-hydroxycyclopentanone, (±)-15-thia-15-deoxy-PGE$_1$ methyl ester (**11**)*

A solution of the tetrahydropyranyl ether **12** (75 mg) in acetic acid:water:THF (4:2:1, 7 mL), was stirred at room temperature for 24 h. The yellow mixture was then neutralized by the addition of solid sodium bicarbonate and worked up with ether. The ethereal extract was washed with saturated $NaHCO_2$, dried, and evaporated to yield 39 mg of material, which after purification by chromatography (10% stepwise elution from benzene to ethyl acetate) gave (±)-15-thia-15-deoxy-PGE$_1$ methyl ester (**11**) (22 mg); R_f 0.3 (chloroform:methanol 97.3); IR ν_{max}: 1746, 3392 cm^{-1}; ^{1}HMR (PG numbering) δ: 0.92 (3H, t, H-20), 1.30–1.40 (8H, m, CH_2′s), 1.57–1.66 (7H, m, CH_2′s), 1.88 (1H, br s, OH), 2.0 (1H, m, H-8), 2.16–2.49 (2H, m, including H-12 as dd at 2.40), 2.30 (2H, t), 2.71 (2H, t), 2.78 (2H, dd), 3.67 (3H, s, OCH_3), 4.05 (1H, q, H-11), 5.45 (1H, dd, J = 8, 16 Hz, H-13), and 6.18 (1H, d, J = 14 Hz, H-14) ppm; ^{13}CMR (PG numbering) δ: 13.9 (C-20), 22.2 (C-19), 24.8 (C-3), 26.6 (C-7), 27.6 (C-6), 28.9, 29.0, 29.3 (C-4, -5, -17), 30.9 (C-18), 32.6 (C-16), 34.0 (C-2), 46.0 (C-10), 51.4 (OCH_3), 54.6 (C-8), 55.5 (C-12), 72.2 (C-11), 127.2 (C-13), 128.1 (C-14), 174.1 (C-1), and 214.3 (C-9) ppm; MS (CI) *m/z* (%): 371(1.5), 352(0.4), 306(1), 279(15), 241(11), 167(27), 149(85), 129(100); HPLC (15 × 0.46 cm ODS2-C_{18} column, chloroform eluent, 1.5 mL/min, UV_{254} detection): single peak at retention time 7.5 min.

This paper is dedicated to Professors Ian Spenser and David B. MacLean

STEVEN J. GOULD, JINCAN GUO, ANJA GEITMANN, and KARL DEJESUS. Can. J. Chem. **72**, 6 (1994).

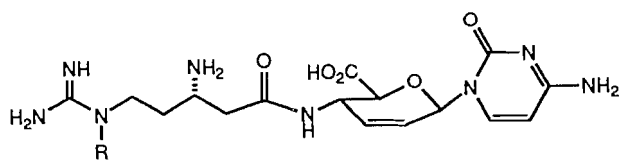
Intermediates in the biosynthesis of blasticidin S and its nucleoside co-metabolites were detected by altering fermentation conditions. Inhibitors of specific types of biochemical reactions that were expected to be involved in blasticidin biosynthesis were fed to *Streptomyces griseochromogenes*, in some cases with the inclusion of large quantities of the primary precursors of blasticidin S. The types of reactions and inhibitors used were (1) transaminase (aminooxyacetic acid and 2-methylglutamate), (2) amidotransferase (azaserine and 6-diazo-5-oxo-L-norleucine), (3) arginine biosynthesis (arginine hydroxamate), and (4) methyltransferase (ethionine). These manipulations apparently distorted the pools of precursors and (or) intermediates, and led to substantial accumulations of three known, previously minor, metabolites of *S. griseochromogenes*, cytosylglucuronic acid, pentopyranine C, and demethylblasticidin S, and of two new ones, pentopyranone and isoblasticidin S. New cytosyl metabolites were detected by HPLC with photodiode array detection. Fermentations to which arginine hydroxamate and cytosine had been added also produced three aberrant metabolites that were derived from pentopyranone and arginine hydroxamate.

STEVEN J. GOULD, JINCAN GUO, ANJA GEITMANN et KARL DEJESUS. Can. J. Chem. **72**, 6 (1994).

En modifiant les conditions de fermentation, on a pu détecter les intermédiaires dans la biosynthèse de la blasticidine S et de ses cométabolites nucléosidés. Des inhibiteurs de réactions biochimiques spécifiques attendues dans la biosynthèse de la blasticidine ont été données au *Streptomyces griseochromogenes*, dans certains cas avec inclusion de grandes quantités de précurseurs primaires de la blasticidine S. Les types de réactions et d'inhibiteurs utilisés sont : (1) la transaminase (acide aminooxyacétique et le 2-méthylglutamate); (2) amidotransférase (azasérine et 6-diazo-5-oxo-L-norleucine); (3) biosynthèse de l'arginine (hydroxamate d'arginine) et (4) méthyltransférase (éthionine). Ces manipulations ont apparemment modifié la répartition des précurseurs et (ou) des intermédiaires et ont conduit à des accumulations importantes de trois métabolites connus, mais antérieurement mineurs, du *S. griseochromogenes*, l'acide cytosylglucoronique, la pentopyranine C et la démethylblasticidine S, ainsi que deux nouveaux métabolites, la pentopyranone et l'isoblasticidine S. Grâce à la CLHP avec une photodiode comme détecteur, on a pu mettre en évidence la présence de nouveaux métabolites cytosylés. Les fermentations réalisées avec des substrats dans lesquels de l'hydroxamate d'arginine et de la cytosine avaient été ajoutés ont aussi conduit à la formation de trois métabolites aberrants dérivés de la pentopyranone et de l'hydroxamate d'arginine.

[Traduit par la rédaction]

Blasticidin S, an antifungal antibiotic produced by *Stretomyces griseochromogenes* first isolated by Takeuchi et al. in 1958, is used commercially for the control of *Piricularia oryzae* (rice blast) (1). Chemical degradation (2–5) and X-ray diffraction studies (6, 7) yielded the nucleoside structure **1**. Since then, a number of structurally related nucleoside antibiotics have been characterized, including gougerotin (8), mildiomycin (9), bagougeramines A and B (10), arginomycin (11), and antibiotic Sch 36605 (12).



1, R = CH_3
20, R = H

Blasticidin S is composed of *N*-methyl-L-β-arginine, **2** (blasticidic acid), and an unusual nucleoside (cytosinine), **3**. Seto et al. (13) had established that cytosine, **4**, D-glucose, **5**, L-α-arginine, **6**, and methionine, **7**, are the primary precursors (Scheme 1). We first became interested in the biosynthesis of **1** because of the potential relevance of our studies (14) on the L-β-lysine unit of another nucleoside antibiotic, streptothricin F, to the origin of the L-β-arginine moiety embedded in **1**. Indeed, both β-amino acids proved to be derived by 2,3-aminomutase reactions in which an intramolecular migration of nitrogen from C-2 to C-3 and a companion migration of the 3-pro*R* hydrogen to the 2-pro*R* position takes place (15, 16).

Feedings with [1-^{2}H]- and [2,3,4,6,6-$^2H_5$]-D-glucoses, used to probe the biosynthesis of the cytosinine moiety, revealed that the carbinol hydrogens H-1, -2, and -3 were retained in **1**, but that H-4 was lost. Retention of H-2 and H-3 indicated that the deoxygenations at these positions could not occur by simple dehydrations (17).

Efforts to incorporate more advanced putative intermediates proved inconclusive. We now report these results, as well as those of a subsequent program of feeding *inhibitors* of specific

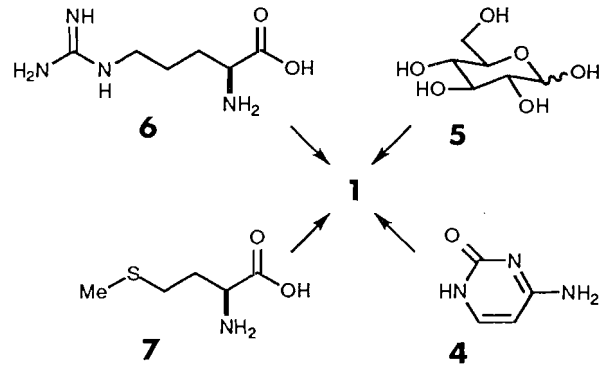


SCHEME 1

types of biochemical reactions that were expected to be involved in the biosynthesis of **1**. The latter approach successfully led to the identification of the roles of a number of intermediates in the metabolic matrix that includes the biosynthesis of **1**.

Experimental

General

[1-^{2}H]-D-Glucose was obtained from Cambridge Isotope Laboratories. Other organic chemicals were obtained from either Aldrich or Sigma Chemical Company.

*Preparation of [1-^{14}C]-blastidic acid, 2*a

A sample of [1″-^{14}C]-**1** hydrochloride (485 mg, 1.06 mmol, 5.97 × 10^6 dpm/mmol) was dissolved in 6 N HCl (10 mL), and stirred at room temperature for 6 h (these conditions caused significant decomposition of **3**). The mixture was neutralized to pH 4.0 and applied to an anion exchange column (Amberlite, IRA-410, 100 mesh, OH–, 2.5 cm × 30 cm), and the initial effluent immediately loaded onto a cation exchange column (Amberlite, IRC-50, 50 mesh, H^+, 2.5 cm × 20 cm). This was washed first with H_2O to neutrality and then with 0.5 N HCl until the eluates no longer contained **2***a*. The HCl eluate was concentrated by rotary evaporation at ambient temperature, and the remaining solution was lyophilized. Recrystallization of the lyophilized residue from EtOH gave pure **2***a* dihydrochloride (234 mg, 5.97 × 10^6 dpm/mmol, 85% yield).

*Preparation of [1′-^{14}C]-cytosinine, 3*a

A sample of [1′-^{14}C]-**1** hydrochloride (320 mg, 0.70 mmol, 3.85 × 10^6 dpm/mmol) was dissolved in 3 N H_2SO_4 (10 mL), and heated to 90°C for 40 h (18). The mixture was neutralized with $BaCO_3$ to pH 4.0, and the precipitate was removed by centrifugation at 3000 × *g* for 10 min. The supernatant was applied to an anion exchange column (Amberlite, IRA-410, 100 mesh, OH–, 2.5 cm × 30 cm), and the initial effluent discarded. The column was washed with H_2O (ca. 100 mL) to pH < 9 and then eluted with 0.5 N HCl. Fractions of ca. 20 mL were collected and monitored for **3** by HPLC (see conditions below; t_R = 3.4 min). Appropriate fractions were lyophilized and the crude product was recrystallized from H_2O–acetone to obtain pure **3***a* (69.4 mg, 3.54 × 10^6 dpm/mmol, 40% yield).

*Feeding [1′-^{14}C]-cytosinine, 3*a

A sample of **3***a* (9.3 × 10^5 dpm) was dissolved in deionized H_2O (10 mL) and fed sterilely by filtering through a Gelman membrane filter (Product No. 4192, pore size 0.2 μm) into a 200 mL production culture (synthetic medium) (18) 42 h after inoculation with a seed culture. After an additional 80 h, the fermentation was bioassayed (95 mg of **1** had been produced) and worked up as previously described (16) to yield 29.0 mg of pure **1**. Liquid scintillation counting revealed that this material was not radioactive.

*Feeding [1′-^{14}C]-blastidic acid, 2*a

A sample of **2***a* (1.1 × 10^6 dpm) was dissolved in deionized H_2O (10 mL) and fed sterilely in two equal portions to a 200 mL production culture (synthetic medium) 48 and 72 h after inoculation with a seed culture. After an additional 72 h, the fermentation was bioassayed (122 mg of **1** had been produced) and worked up as previously described to yield 29.4 mg of pure **1**. Liquid scintillation counting revealed that this material was not radioactive.

β-N-*Acetylcytosyl-2′,3′,4′,6′-tetrabenzoylglucose, 10*

N-Acetylcytosine (19) (215 mg, 1.40 mmol) and $Hg(CN)_2$ (783 mg, 3.10 mmol) were suspended in 6 mL of nitromethane in a dry 50-mL round-bottom flask. A distillation head was attached, the mixture heated, and ca. 1 mL of solvent was distilled. At this point, the heat was removed and α-1-bromotetrabenzylglucose (20) (923 mg, 1.40 mmol) in CH_2Cl_2 (1 mL) was added dropwise from the top of the distillation head. An additional aliquot of nitromethane (1 mL) was added, and the mixture once again heated at reflux. After 4.5 h, the yellow suspension was cooled to 0°C and filtered. The solid was washed with cold nitromethane, 30% aqueous KI, water, and EtOH. After standing overnight, a second crop could be recovered from the filtrate, and this was washed as described above. The combined solids were recrystallized from DMF–water to give 567 mg (77%): mp 250°C (dec.); IR: 1778, 1739, 1717 cm^{-1}; ^{1}H NMR (TFA-d_1) δ: 8.72 (d, 1H, *J* = 7.8 Hz), 8.02 (d, 2H, *J* = 7.6 Hz). 7.93 (d, 2H, *J* = 7.4 Hz), 7.85 (d, 2H, *J* = 7.6 Hz), 7.81 (d, 2H, *J* = 7.6 Hz), 7.69–7.61 (m, 3H), 7.55 (t, 1H, *J* = 7.6 Hz), 7.49–7.32 (m, 9H), 6.74 (bm, 1H), 5.56 (d, 1H, *J* = 9.0 Hz), 6.41 (t, 1H, *J* = 9.5 Hz), 6.15 (t, 1H, *J* = 9.6 Hz), 5.93 (t, 1H, *J* = 9.2 Hz), 4.87 (dd, 1H, *J* = 12.4, 1.9 Hz), 4.81–4.73 (m, 2H), 2.43 (s, 3H); ^{13}C NMR (TFA-d_1) δ: 178.54, 178.36, 172.63, 171.76, 171.59, 162.24, 161.54, 155.83, 154.05, 149,58, 148.34, 138.25, 138.03, 137.82, 137.61, 132.58, 132.45, 131.61, 131.53, 131.36, 130.39, 129.53, 129.01, 99.57, 85.96, 78.29, 76.60, 75.24, 71.96, 65.64, 25.93. Anal. calcd. for $C_{40}H_{13}N_3O_{11}$: C 67.52; H 1.84, N 5.91; found: C 67.60, H 1.70, N 5.84.

β-N-*Acetylcytosyl-2′,3′,4′,6′-tetrabenzoyl[1-^{2}H]glucose, 10*a

Using the same procedure, α-1-bromotetrabenzoyl[1-^{2}H]glucose (618 mg, 0.94 mmol), *N*-acetylcytosine (148 mg, 0.96 mmol), and $Hg(CN)_2$ (5.34 mg, 2.11 mmol) yielded 474 mg (66%) of **10***a*: ^{1}H NMR lacked the δ: 6.56 doublet, and the δ 5.93 triplet was a doublet (*J* = 9.5 Hz); ^{13}C NMR δ: 85.96 (bt).

β-*Cytosylglucose, 8*

Sodium (2 mg, 0.08 mmol) in a 25-mL round-bottom flask was washed with hexane, dried in a stream of N_2, and reacted with MeOH (2 mL) under a N_2 atmosphere. **10***a* (423 mg, 0.58 mmol) was added, followed by an additional 2 mL MeOH. The suspension was stirred at room temperature (RT) for 25 h, diluted with CH_2Cl_2 (10 mL), cooled to 0°C, and centrifuged. The resulting hygroscopic solid was dissolved in water and lyophilized to yield a fluffy white solid (113 mg, 71%) that had to be protected from moisture: ^{1}H NMR (D_2O) δ: 7.07 (d, 1H, *J* = 7.6 Hz), 6.06 (d, 1H, *J* = 7.7 Hz), 4.05 (d, 1H, *J* = 9.1 Hz), 3.90 (dd, 1H, *J* = 12.5, 2.0 Hz), 3.77 (dd, 1H, *J* = 12.5, 5.2 Hz), 3.72 (dd, 1H, *J* = 9.0, 9.1 Hz), 3.67 (t, 1H, *J* = 8.8 Hz), 3.65–3.61 (m, 1H), 3.53 (dd, 1H, *J* = 9.3, 9.2 Hz); ^{13}C NMR (D_2O) δ: 167.53, 159.45, 143.43, 98.51, 84.76, 80.20, 77.82, 72,75, 70.70, 62.09. Anal. calcd. for $C_{10}H_{15}N_3O_6$: C 43.96, H 5.53, N 15.39; found: C 43.90, H 5.62, N 15.11.

β-*Cytosyl[1-^{2}H]glucose, 8*a

Using the same quantities, **10***a* was deprotected to yield **8***a* (105 mg, 66%): ^{1}H NMR lacked the δ 4.05 doublet and the δ 3.72 triplet was now a doublet (*J* = 9.0 Hz); ^{13}C NMR δ: 85.76 (bt).

Culture maintenance, fermentation, and bioassay conditions

Standard culture maintenance, fermentation, and bioassay conditions have been described previously (16).

Inhibitor/precursor feedings

Inhibitors and precursors were added as sterile-filtered (pore size 0.2 μm) aqueous solutions at 50 h after inoculation of production

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

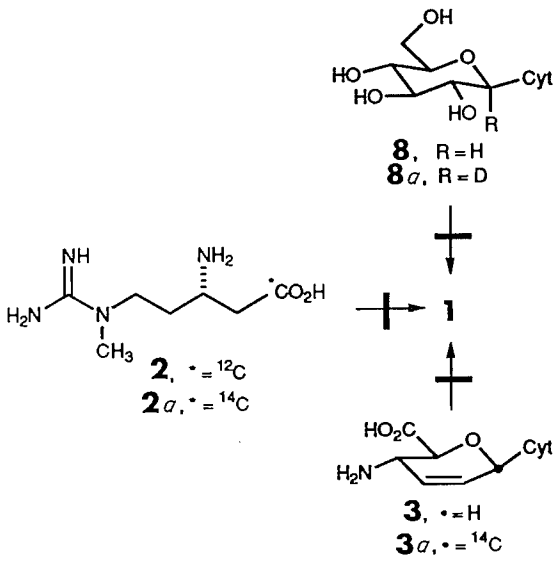
broths (100 mL in 500-mL Erlenmeyer flasks). The quantities of additives were cytosine 30 mg, arginine 200 mg, methionine 200 mg, aminooxyacetic acid 40 mg, 2-methylglutamate 50 mg, arginine hydroxamate 200 mg, 6-diazo-5-oxo-L-norleucine 30 mg, azaserine 31 mg, ethionine 50 mg.

HPLC analysis

For each experiment, 0.5 mL samples were taken at the times noted in the tables, centrifuged 10 min (Eppendorf microfuge), and either immediately analyzed or stored at –20°C. Twenty microlitre aliquots were injected for each analysis. The conditions for analytical HPLC (Waters Assoc. model 600E) were C_{18} RadialPak^R column, 0.8 cm × 10 cm (Waters Assoc. 4 μm packing), eluted with 95% H_2O, 5% CH_3CN, 0.15% TFA, 1.1 mL/min, with a Waters model 990+ photodiode array detector scanning the region 200–300nm. Chromatograms were printed out for absorption at 275 nm.

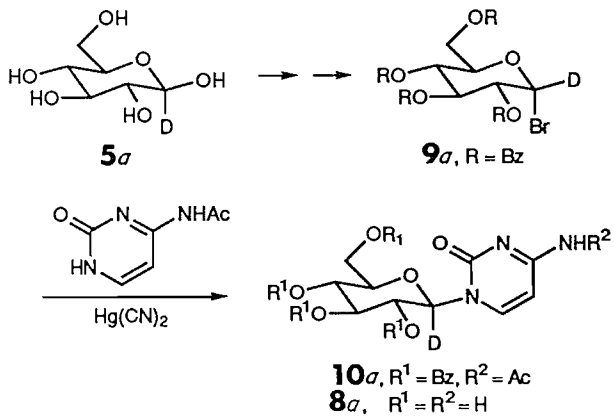
Results and discussion

A retrobiogenetic analysis fragmented **1** into **2** or β-arginine, itself, and **3**. The reconstruction of **1** from **2** and **3** by a mycelial suspension of *S. griseochromogenes* had been reported (18), but was not reproducible (private communication, H. Seto), and had been tested without the benefit of isotope labels. We, therefore, produced blasticidin S samples from biosynthetic incorporations of [1-^{14}C]arginine and [1-^{14}C]glucose, and hydrolyzed each to yield [1-^{14}C]-**2***a* and [1′-^{14}C]-**3***a*, respectively. Each was fed to cultures of *S. griseochromogenes*, and the blasticidin S produced by each was isolated and purified (16). However, neither sample was radioactive (Scheme 2) and, furthermore, much of the radioactivity had remained in the broth at the end of the fermentations.



SCHEME 2

We next tested cytosylglucose, **8**, as the first nucleoside intermediate. To test this, [1′-^{2}H]-**8***a* was synthesized as shown in Scheme 3. [1-^{2}H]-D-Glucose, **5***a*, was converted to the 1-bromotetrabenzoate (20) **9***a* and coupled with *N*-acetylcytosine (19) using standard Hg^{2+} catalysis (19). Methoxide then fully deprotected **10***a* to yield **8***a*. In the undeuterated series, a 9.1 Hz coupling between the H-1′ and H-2′ NMR resonances confirmed that the β anomer had been obtained. A sample of **8***a* (100 mg) was fed to a culture of *S. griseochromogenes*, but ^{2}H NMR analysis of the derived **1** failed to show any incorporation of deuterium (Scheme 2).



SCHEME 3

Numerous permutations on the same types of biochemical reactions could be proposed for the biosynthesis of **1** from the known precursors. Since each hypothetical sequence involved numerous intermediates, and in view of the negative results described above, it was clear that alternative approaches to conventional feeding experiments were needed to overcome potential permeability problems and to avoid the synthesis of a large number of putative, but incorrect, intermediates. A novel approach was adopted that altered fermentation conditions in order to block potential biosynthetic steps. This was done by feeding inhibitors of specific types of biochemical reactions, and in some cases large quantities of primary precursors were included. These manipulations were expected to distort the biosynthetic precursor pools and force the accumulation of biosynthetic intermediates or new metabolites in the fermentation broth.

Although this empirical approach lacks control over the effects an inhibitor may have at other points in the cellular metabolism, selective inhibition of secondary metabolism with little stress on primary metabolism seemed possible because in most cases the timings of bacterial growth and antibiotic production are well differentiated (21). In comparison with attempting to develop blocked mutants, this approach appeared to offer greater flexibility in selecting the inhibition points.

The selection of inhibitors for these studies was based on three assumptions: (*a*) the 4′-amino group is introduced after the formation of the cytosine glycosidic bond, (*b*) the nucleoside portion is coupled to the β-amino acid portion at a relatively late stage, and (*c*) δ-*N*-methylation occurs late in the overall pathway. Attention was therefore focused on blocking three potential biosynthetic points. These points, and the specific inhibitors tested, were (*a*) blocking transamination with transaminase inhibitors (aminooxyacetic acid (AOAA), **11** (22–24), and 2-methylglutamate (MeGlu), **12** (25)) or amidotransferase inhibitors (azaserine, **13** (26), and 6-diazo-5-oxo-L-norleucine (DON), **14** (27)); (*b*) blocking the availability of L-α-arginine with a L-α-arginine biosynthetic inhibitors (L-arginine hydroxamate (ArgH), **15** (28, 29), and **12**); and (*c*) blocking *N*-methylation with a methyltransferase inhibitor (L-ethionine (Eth), **16** (30, 31)).

To maximize both the effect and selectivity of the inhibitors, it was necessary to first determine the relative timing of bacterial growth and production of **1** (BS) so that inhibitors were fed at the onset of BS production. A synthetic medium (18) was chosen for production broths to simplify the interpretation of the inhibitor results. It was found that the bacteria entered log

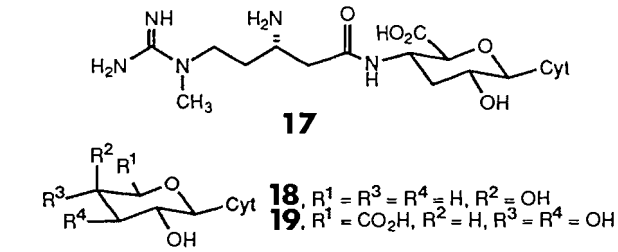
phase right after inoculation of production broths with the seed culture, and reached stationary phase within 84–96 h. **1** was first detected between 50 and 60 h after inoculation, and the accumulation typically lasted for 5 days. Therefore, inhibitors were fed at 50 h. Production of **1** and its related metabolities was initially assayed 168 h later. HPLC conditions were developed that separated authentic samples of **1**, blasticidin H, **17** (32), and pentopyranine C (PPNC), **18** (33, 34), and a photodiode array detector was used to easily identify new cytosine-containing metabolites.



The amounts of inhibitors initially used were comparable to those used in the literature, and some were subsequently adjusted according to the information obtained during the feeding experiments. In several preliminary feedings of either **11** or **15**, the production of two cytosyl metabolites was stimulated as much as 200–300% over a control broth, while the production of **1** was inhibited by 50–70%. One of these metabolites had an HPLC retention time identical to that of authentic **18**, while the other was considerably more polar. Further studies demonstrated that when cytosine was co-fed with either **11** or **15**, production of these two new metabolites was increased dramatically (Fig. 1). These were then purified and identified by NMR spectroscopy. The less polar compound was indeed **18**. The other, which was found to bind to both anion and cation exchange resins, indicating an acid, was identified as cytosylglucuronic acid (CGA), **19**. This compound had previously been isolated in milligram quantities from hundreds of litres of fermentation broth (35). In these latter inhibitor feedings, accumulation of a third new component was also slightly stimulated (ca. 2-fold). Purification by HPLC provided enough material for its identification by ^{1}H NMR spectroscopy as demethylblasticidin S (DeMeBS), **20** (36). Only a slight elevation for **20** was observed with ethionine when assayed at 168 h, although there was also a noticeable decrease in the amount of **1**.

With these initial successes, a more systematic study was developed to examine the effects of **11**, **15**, and **16**, as well as of

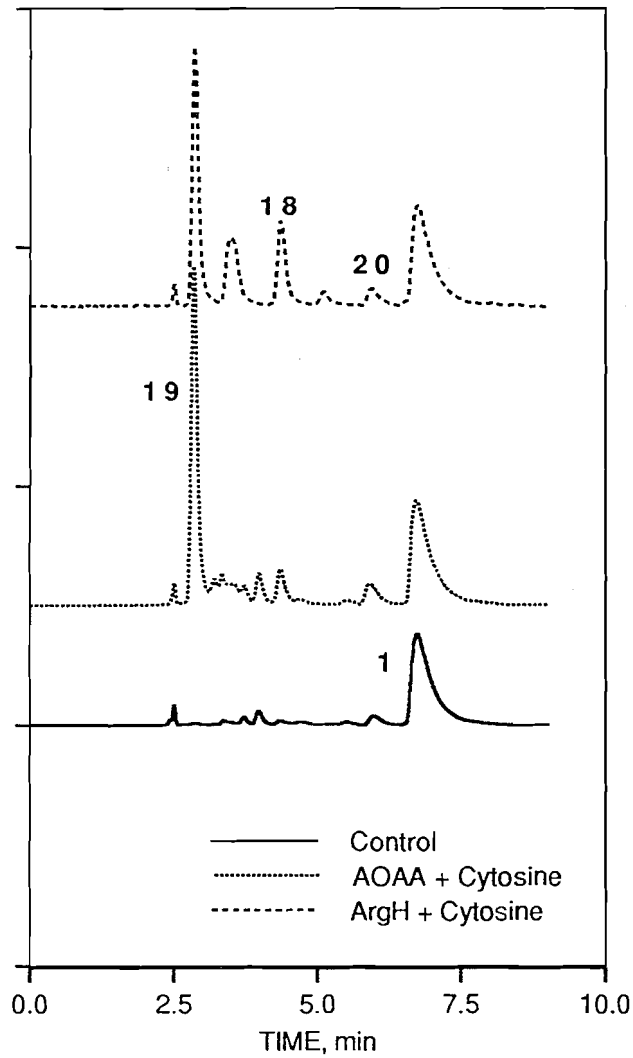


FIG. 1. HPLC of *Streptomyces griseochromogenes* fermentations with and without the addition of cytosine and the enzyme inhibitors aminooxyacetic acid (AOAA), **11**, or arginine hydroxamate (ArgH), **15**. See Experimental for conditions.

12, **13**, and **14**. Some of these inhibitors were also co-fed with the primary precursors cytosine, arginine, and methionine. Fermentations with each inhibitor were assayed at 12 h intervals for the first 4 days, and then daily for the next 3. A number of these were repeated on two or three occasions and, although the absolute amounts varied from one set of fermentations to another (each set was inoculated from the same seed culture for consistency), the relative levels of metabolites were similar. The more significant effects of the inhibitors on CGA (**19**), PPNC (**18**), DeMeBS (**20**), and BS (**1**) production are presented in Tables 1–3. Several trends were apparent, and are summarized as follows.

Feeding the primary precursors **4**, **6**, and **7** (data for the latter two not shown) had a stimulatory effect on the production of all four compounds assayed. Cytosine, which had been incorporated almost quantitatively into **1** as a radiolabeled tracer (13), had a much stronger effect than the other precursors. This was especially true for production of **19**, which was increased 30-fold at 96 h and 71-fold at 168 h. Co-feeding the precursors cytosine and arginine had an additive effect, and was the best

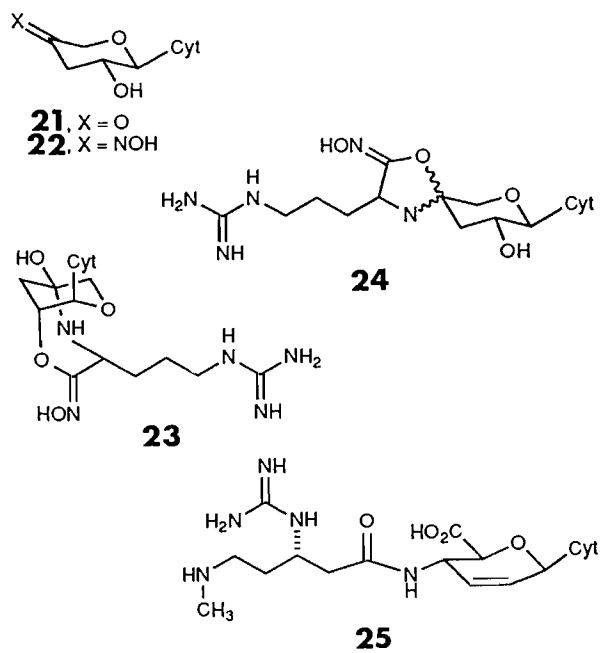
condition for accumulation of **20** (data not shown), presumably by overwhelming the pool of *S*-adenosyl-L-methionine.

Aminooxyacetic acid, **11**, substantially inhibited the production of **1** and **20** while moderately stimulating the production of **18** and **19**. In contrast, the glutamine-dependent amidotransferase inhibitors **13** and **14** showed much milder effects. The effect of **11** also appeared to be quite specific, since its inhibitory effect on the production of **1** could not be relieved by methionine, arginine, or β-arginine.

2-Methylglutamate had effects similar to those of **11**. At 96 h its effects on **18, 20**, and **1** were similar, although it enhanced **19** substantially more. At later time points, the inhibition of **20** was no longer noticeable, but the enhancement of **19** was even more pronounced. These effects were most likely due both to its action as a glutamate/PLP-dependent transaminase inhibitor and as an inhibitor of glutamate biosynthesis; the latter effect would indirectly inhibit arginine biosynthesis. While the effects of arginine hydroxamate, **15**, were very similar to those of **11**, it was particularly efficient, especially in the presence of added cytosine, in stimulating production of **18** (ca. 17-fold at 168 h).

Although in the initial study ethionine, **16**, showed hardly any effect on **20** after 168 h, assay at the earlier times now showed that **16** caused a transitory increase of **20** and decrease of **1**. The production of **20** was highest after 96 h, and decreased afterwards. Possibly **16** was degraded after longer periods of incubation. Nevertheless, the effect of **16** was consistent with our previous proposal that δ:-*N*-methylation occurs at a late stage in the pathway (16).

The effects of these metabolic inhibitors and primary precursors were next examined in fermentations in the standard complex medium (16), which normally produced much more of **1**. Although higher dosages of inhibitors were needed to bring about a comparable extent of inhibition, the same patterns of inhibition and stimulation were observed on the production of all four metabolites (data not shown). By using this system, substantial quantities of **19, 18**, and **20**, which were originally produced only in trace amounts, could now be easily purified (as much as 1.5 g/L of CGA) from a relatively small fermentation (typically 1 L). In addition to the four compounds already identified, HPLC analysis of the crude fermentation broth obtained from the complex medium supplemented by 1.0 g/L of **4** and 2.0 g/L of **15** revealed several new components. Photodiode array detection showed that at least five of those new components had UV spectra characteristic of the cylosine glycosides. Large-scale fermentations under these conditions allowed isolation of sufficient quantities of each to characterize them spectroscopically as **21–25** (37).



The in vivo use of specific enzyme inhibitors with *S. griseochromogenes* fermentations has led to the accumulation of four otherwise very minor metabolites, including one (**21**) that had

not been previously detected. This has led to an intimate view into the individual biochemical steps that lead to blasticidin S and the metabolic matrix that includes related cytosyl nucleosides. With these large accumulations now possible, **19** was confirmed as the first nucleoside intermediate (38) and CGA synthase, the first prokaryotic glucuronosyltransferase, was isolated and purified (39), demethylblasticidin S was shown to be the last intermediate in the overall pathway by its enzymatic conversion to **1** (40), and the mechanism and stereochemistry of C-3′ deoxygenation was established (41).

Nucleoside antibiotics comprise a large and structurally diverse group of microbial metabolites (42). Considering their numbers and significant biological activities, the sparsity of biosynthetic studies is at first surprising. However, real or anticipated permeability barriers have probably been significant impediments (42). Indeed, many of the most definitive studies have focused on the appendages to the nucleoside sugar (42–44). The in vivo use of specific enzyme inhibitors, which has proved so rewarding in the present study, is likely to be effective with other such "converging" pathways, where individual subpathways can be targeted. We are currently investigating the effects of additional inhibitors on blasticidin biosynthesis, as well as exploring the utility of this approach in probing further into the biosynthesis of streptothricin F.

This paper is dedicated to Professors Ian Spenser and David B. MacLean.

YOSHIO HANO, TARO NOMURA, and SHINICHI UEDA. Can. J. Chem. **72**, 12 (1994).

L-[3-^{13}C]Phenylalanine and L-[3-^{13}C]tyrosine were administered to *Morus alba* cell cultures, to produce intermolecular Diels–Alder type adducts of a prenylchalcone and a 2-arylbenzofuran such as chalcomoracin (**1**) as well as the adducts of two molecules of prenylchalcones such as kuwanon J (**2**) in high yields. The ^{13}C NMR spectra of **1** and **2** isolated from the cultures revealed that both amino acids were incorporated intact into chalcomoracin (**1**) and kuwanon J (**2**). This is the first example of direct NMR evidence for the almost equivalent incorporation of phenylalanine and tyrosine into the shikimate metabolites. This finding suggests the participation of a biosynthetic route from phenylalanine via *trans*-cinnamate to *p*-coumarate and from tyrosine to *p*-coumarate in this plant.

YOSHIO HANO, TARO NOMURA et SHINICHI UEDA. Can. J. Chem. **72**, 12 (1994).

On a introduit de la L-[3-^{13}C]phénylalanine et de la L-[3-^{13}C]tyrosine à des cultures de cellules *Morus alba* et il y a production, avec des rendements élevés, d'adduits de type Diels–Alder intermoléculaires d'une molécule de prénylchalcone avec un 2-arylbenzofurane, comme la chalcomoracine (**1**), et des adduits avec deux molécules de prénylchalcones, comme la kuwanone J (**2**). Les spectres RMN du ^{13}C des composés **1** et **2** révèlent que les deux acides aminés sont incorporés intacts dans ces composés. Ceci est le premier exemple de preuve RMN directe pour l'incorporation pratiquement équivalente de la phénylalanine et de la tyrosine dans des métabolites de l'acide shikimique. Ces résultats suggèrent que dans cette plante, il y a participation d'une voie biosynthétique permettant de transformer avec autant de facilité la phénylalanine et la tyrosine en *p*-coumarate alors que la transformation de la phénylalanine se fait par le biais d'un *trans*-cinnamate.

[Traduit par la rédaction]

Introduction

In previous papers (1–3), we reported the biosynthesis of optically active intermolecular Diels–Alder type adducts such as chalcomoracin (**1**) (4, 5) and kuwanon J (**2**) (6) with the aid of *Morus alba* cell cultures having a high pigment productivity (5). Many other possible biosynthetic Diels–Alder type constructions have also been reported (7–31). An experiment with administration of ^{13}C-labelled acetate to the cell cultures demonstrated that **1** and **2** are composed of two cinnamoylpolyketide-derived skeletons (1). Administration of the *O*-methylated precursory chalcones revealed that **1** and **2** are biosynthesized through an intermolecular Diels–Alder type cycloaddition reaction between a prenyl portion of the prenylchalcone as a diene and an α,β-unsaturated bond of the chalcone skeleton as a dienophile (2). Further administration experiments with [2-^{13}C]-labelled acetate demonstrated that the isoprenyl unit of **1** was labelled with ^{13}C in a different way from that of β-sitosterol co-occurring in the cell cultures (3). Although the ^{13}C-labelling pattern of β-sitosterol was consistent with that observed in the case of *Rabdosia japonica* tissue cultures (32), the prenyl unit of **1** was labelled with ^{13}C only at the two successive carbons corresponding to the starter acetate unit for the biosynthesis of mevalonate. This phenomenon implies that the ^{13}C-labelled acetate incorporated into the prenyl unit of **1** was not intact, but one reorganized through at least two passages of the tricarboxylic acid (TCA) cycle (1, 3).

Regarding the biosynthesis of **1** and **2**, recent findings obtained through the administration of ^{13}C-labelled glucose and glycerol revealed that the starter acetate unit is formed directly from the glycolysis, whereas the second and the third acetate units for mevalonate are formed by way of the pentosephosphate cycle (33).

This paper describes clear-cut NMR evidence for the equivalent participation of two aromatic amino acids, L-phenylalanine and L-tyrosine, in the biosynthesis of chalcomoracin (**1**) and kuwanon J (**2**).

Results and discussion

Both chalcomoracin (**1**) and kuwanon J (**2**) are composed of two molecules of cinnamoylpolyketide-derived skeletons (1). In the administration experiment with L-[3-^{13}C]phenylalanine to the *M. alba* cell cultures, a high ^{13}C-enrichment from the amino acid was observed at the C-3 and C-5″ positions of **1** (Fig. 1) as well as at the C-β and C-5″ positions of **2**. The ^{13}C-incorporation on the basis of enriched signal intensity was 33%. This finding indicates that the two cinnamoyl units in **1** and **2** originate from L-phenylalanine. An analogous experiment with L-[3-^{13}C]tyrosine also showed the same ^{13}C-labelling pattern as in the case of L-[3-^{13}C]phenylalanine. The ^{13}C-incorporation was 18%. Both L-tyrosine and L-phenylalanine are thus precursory to the prenylchalcones and prenylated arylbenzofurans in *M. alba* cell cultures.

Transformation of L-phenylalanine into L-tyrosine by direct

FIG. 1. ^{13}C labelling patterns of **1** and **2** in the administration experiments with L-[3-^{13}C]phenylalanine and L-[3-^{13}C]tyrosine. ●: ^{13}C-labelled positions.

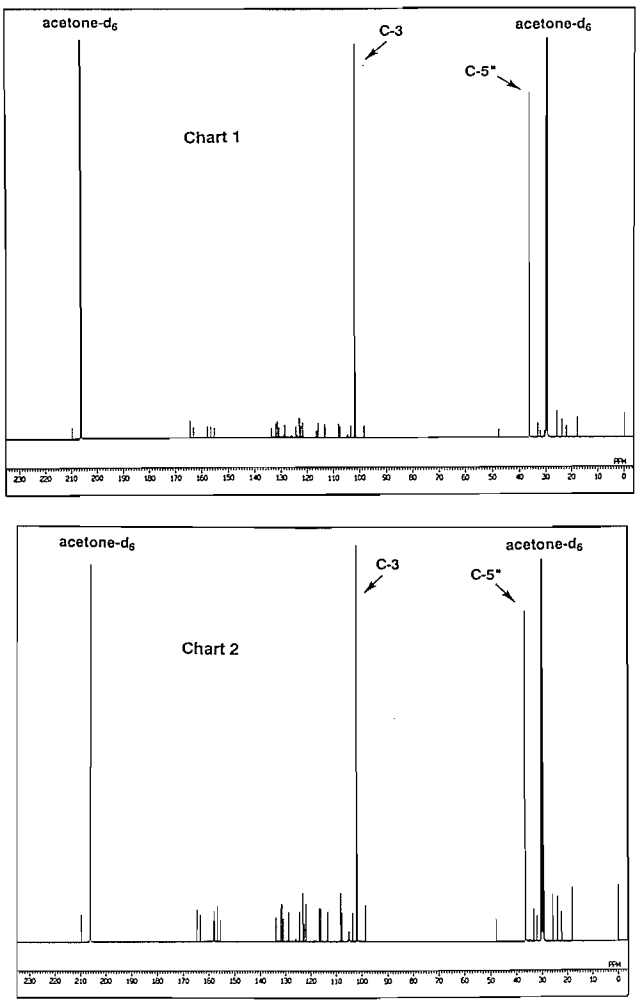

FIG. 2. Proton noise-decoupled ^{13}C NMR spectra. Chart 1: L-[3-^{13}C]phenylalanine-derived chalcomoracin (**1**); Chart 2: L-[3-^{13}C]tyrosine-derived chalcomoracin (**1**).

hydroxylation has been well established in mammal cells (34). An enzyme system isolated from spinach leaves also hydroxylated L-phenylalanine into L-tyrosine (35). In higher plants, however, direct conversion of L-phenylalanine into L-tyrosine has been rare (36).It has also been reported that the overlapping of the secondary metabolites from L-phenylalanine with those from L-tyrosine is restricted, because of the presence of two independent metabolic pathways for these aromatic amino acids in the biosynthesis of rosmarinic acid in *Mentha arvensis* and *Mentha piperita* (37). L-Phenylalanine has been known to be converted to *trans*-cinnamate, which, in turn, is subjected to 4-hydroxylation giving rise to *p*-coumarate through the action of cinnamate 4-hydroxylase in higher plants (38). The present study suggests that both L-phenylalanine and L-tyrosine are converted into *p*-coumarate, which is conclusively converted to chalcomoracin (**1**) and kuwanon J (**2**) in *M. alba* cell cultures.

Experimental

Materials and instruments

L-[3-^{13}C]Phenylalanine (99 at.% ^{13}C) and L-[3-^{13}C]tyrosine (99.8 at.% ^{13}C) were purchased from Isotec Inc., U.S.A. Wakogel C200 and B-5F (Wako Pure Chem. Osaka, Japan) were used for column chromatography and preparative thin-layer chromatography (TLC), respectively. The NMR data were recorded on a JEOL JNM EX-400 FTNMR spectrometer using $(CD_3)_2CO$ as a solvent and TMS as an internal standard. HPLC was carried out with an SSC (Senshu Scientific Co. Ltd., Tokyo) high-pressure liquid chromatograph with a UV detector using a Senshu Pak Silica-4251-N column (10 mm ϕ × 250 mm).

Administration experiment with L-[3-^{13}C]-phenylalanine

The induction of *M. alba* callus tissues from the seedlings or the leaves of a mulberry tree was described previously (5). The *M. alba* cells, placed in 10 300-mL flasks, were suspended each in 100 mL of sterilized water to which a 10% ethanol solution (10 mL) of L-[3-^{13}C]phenylalanine (137.9 mg) containing two drops of Tween 80 was added. After incubation of the cell suspension for 1 week in the dark at 25°C, the cells were harvested and lyophilized. The lyophilized cells (3.27 g) were extracted with methanol. Concentration of the methanol extract in vacuo gave a residue (0.39 g), which was extracted with acetone. The acetone extract was concentrated (0.23 g) and chromatographed on silica gel (70 g) using chloroform with increasing content of acetone as solvent. Combined fractions (0.02 g) eluted with chloroform–acetone (2:1) were subjected to preparative TLC (hexane–acetone 1:1), followed by HPLC (Senshu Pak Silica-4251-N, 10 mm ϕ × 250 mm) eluted with ether, to yield chalcomoracin (**1**, 11 mg) and kuwanon J (**2**, 2 mg), respectively.

Administration experiment with L-[3-^{13}C]tyrosine

L-[3-^{13}C]Tyrosine (116.0 mg) was administered to *M. alba* cell cultures and worked up in an analogous way to the experiment with L-[3-^{13}C]phenylalanine, giving rise to chalcomoracin (**1**, 11 mg) and kuwanon J (**2**, 2 mg), respectively.

Received January 18, 1993

This paper is dedicated to Professor David B. MacLean

YULIA ANTONIO, MA. ELIZABETH DE LA CRUZ, EDVIGE GALEAZZI, ANGEL GUZMAN, BRIAN L. BRAY, ROBERT GREENHOUSE, LILIA J. KURZ, DAVID A. LUSTIG, MICHAEL L. MADDOX, and JOSEPH M. MUCHOWSKI. Can. J. Chem. **72**, 15 (1994)

1-(2-Bromobenzyl)-2-alkanesulfonylpyrroles (**1***c*, **1***d*) and 1-(4-bromobutyl)-2-methylsulfonfylpyrrols (**8**) undergo oxidative radical cyclization with partial or complete reductive desulfonylation to the pyrrolizidine derivatives **5** and **9** by an AIBN initiated reaction with tri-*n*-butyltin hydride. These cyclizations are suggested to proceed via a pseudo $S_{RN}1$ process involving radical addition to the α position of the pyrrole nucleus not bearing the sulfonyl group. Reductive removal of the alkylsulfonyl moiety is proposed to occur in a second process after completion of the oxidative radical cyclization. The site of the radical addition is supported by deuterium labelling studies. Consistent with the timing of the loss of the sulonyl group is that 2-alkysulfonylpyrroles **11** are reductively desulfonylated under the same conditions that effect the oxidative radical cyclizations.

YULIA ANTONIO, MA. ELIZABETH DE LA CRUZ, EDVIGE GALEAZZI, ANGEL GUZMAN, BRIAN L. BRAY, ROBERT GREENHOUSE, LILIA J. KURZ, DAVID A. LUSTIG, MICHAEL L. MADDOX et JOSEPH M. MUCHOWSKI. Can. J. Chem. **72**, 15 (1994)

Lorsqu'ils sont soumis à une réaction initiée par l'AIBN et l'hydrure de tri-*n*-butylétain, les 1-(2-bromobenzyl)-2-alcanesulfonylpyrroles (**1***c*,**1***d*) et les 1-(4-bromobutyl)-2-méthylsulfonylpyrroles (**8**) subissent une cyclisation radicalaire oxydante accompagnée d'une désulfonylation réductrice partielle ou complète conduisant aux dérivés pyrrolizidine **5** et **9**. Il y a des indications à l'effet que ces cyclisations se produisent par le biais d'un processus pseudo $S_{RN}1$ impliquant une addition radicalaire sur la position α du noyau du pyrrole ne portant pas le groupe sulfonyle. Il est suggéré que l'élimination réductrice de la portion alkylsulfonyle se produit au cours d'un deuxième processus, après la cyclisation radicalaire oxydante. Le site de l'addition radicalaire est en accord avec les études de marquage au deutérium. En accord avec la séquence des réactions, il faut noter que les 2-alkylsulfonylpyrroles (**11**) sont désulfonylés d'une façon réductrice dans les conditions conduisant aux cyclisations radicalaires réductrices.

[Traduit par la rédaction]

Several years ago we embarked on a research program, the objective of which was to study the reactions of pyrroles with alkyl and aryl radicals. Although both radical addition and radical substitution reactions of pyrrole derivatives had been reported at that time (1, 2), only arylation had been systematically studied and was of preparative significance (see ref. 1 for a summary of these studies). Recently, Gravel et al. (3) and we (4–6) have reported synthetically useful examples of oxidative radical substitution of pyrrole derivatives in the intra- (3, 4, 6) and intermolecular (5) modes. This article describes our first studies on the intramolecular addition of radicals, generated with tri-*n*-butyltin hydride, to the pyrrole nucleus.

The radical species **2** (Scheme 1) were first selected for study based on the synthetic accessibility[6] of the precursor bromo compounds **1**. It was expected that the allylic radicals **3** generated by the cyclization of **2** would be converted into the dihydro compounds **4** by capture with tri-*n*-butyltin hydride. A closely related radical cyclization to C-2 of indoles has recently been reported by Ziegler and Jeroncic (7). When a solution of equimolar amounts of the bromo compound **1***a* and tri-*n*-butyltin hydride in benzene containing catalytic AIBN was heated at reflux temperature under flood lamp irradiation,[7] 1-benzylpyrrole (**6***a*) was the sole product formed (Table 1). In contrast, slow addition (syringe pump) of tri-*n*-butyltin hydride to the bromoaldehyde **1***b*, under conditions otherwise identical to those used for **1***a*, gave a mixture of two products. The minor material was the reductive debromination product **6***b*, while the major one (43%) was the pyrrole **5***b*, the product of oxidative radical cyclization. This compound was formed even though the reaction was conducted in degassed solution under an inert atmosphere!

The sulfone analog **1***c* of **1***a* was next examined, since such a strong electron-withdrawing substituent ($\sigma_m = 0.60$ for SO_2Me (8)) should decrease the SOMO–LUMO energy difference and accelerate the cyclization process (9) versus that of **1***a* and **1***b* ($\sigma_m = 0.35$ for CHO). Indeed, when **1***c* was subjected to the tri-*n*-butyltin hydride/AIBN reaction in boiling benzene, two new compounds were rapidly formed in 47 and 18% yields, respectively (35% recovered **1***c*, Table 1). The minor component of the

[1]This paper is dedicated to Professor David B. MacLean, an excellent chemist, a true Canadian, a gentleman of the first order, and a friend, in recognition of and admiration for his contributions to organic chemistry.

[2]Contribution no. 857 from the Syntex Institute of Organic Chemistry.

mixture was the reductively dehalogenated material **6***c*, but the major product was not the expected tricyclic sulfone **5***c*. The spectroscopic and microanalytical data were, however, fully consistent with structure **5***a*, the formal reductive desulfonylation product of **5***c*! When the reaction was effected with 2 equivalents of tri-*n*-butyltin hydride, **1***c* was consumed in <5h and **5***a* and **6***c* were isolated in 64 and 28% yields, respectively. Although the reactions were not studied in detail, compound **5***a* was also obtained from the *p*-tolylsulfone **1***d* but not from the 3-methylsulfonyl derivative **7***a*. Only the debrominated sulfone **7***b* was formed in the latter case.

The oxidative radical cyclization could also be effected with alkyl radical species. Thus, reaction of 1-(4-bromobutyl)-2-methylsulfonylpyrrole (**8***a*, Scheme 2) with 2 equivalents of tri-

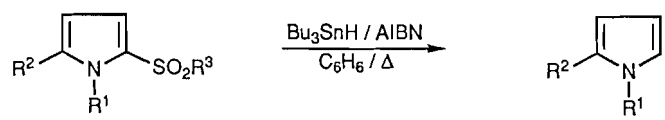
SCHEME 2

n-butyltin hydride, as for **1***c*, gave the known (10) pyrrolopyridine derivative **9***a* (60%), a small amount of the corresponding sulfone **9***b*, and the reductively debrominated compound **10***a* (Table 1). The 4-benzoyl congener **8***b* of **8***a* gave an analogous mixture of products except that now the major bicyclic product was the sulfone **9***b*.

The formation of compounds **9***b* and **9***d* suggested that the sulfones might be intermediates in the generation of the reductively desulfonylated products. Consistent with this supposition, 1-benzyl-2-methylsulfonylpyrrole (**11***a*, Scheme 3 and Table 2) was reduced to 1-benzylpyrrole (**12***a*) in over 70% yield by 1 equivalent of tri-*n*-butyltin hydride. In fact, this process has some degree of generality as shown by the data in Table 2. The reductive desulfonylation of arylsulfonyl compounds under such mild conditions is totally unprecedented; this type of reduction has only been reliably accomplished by various heterogeneous nickel based reagents (11). The process described herein seems, however, to be restricted to 2-sulfonylpyrroles, since both 1-benzyl-3-methylsulfonylpyrrole (**7***b*, Scheme 1) and diphenylsulfone were unaffected under the above conditions.[8,9]



11 **12**

SCHEME 3

The radical cyclizations in which compounds **5***a*, **5***b*, and **9***a*–**9***d* were formed are particularly intriguing since no apparent oxidant is present nor were products indicative of disproportionation processes observed. With regard to the sulfone-derived radicals, it was shown that an ipso addition process with subsequent loss of $RSO_2^{\cdot}$ was not a significant pathway for aromatization since compound **13** (Scheme 4) labelled with deuterium at C-5 (and partially deuterated at C-3,4)[10] gave a 5*H*-pyrrolo[2,1]isoindole **19** with at least 88%[11] loss of this deuterium atom by nmr, i.e., cyclization via **17** and not **15**.[12]

What then is the mechanism by which the radicals **3** (Scheme 1) and the related species from **8** (Scheme 2) are oxidized to the aromatic systems? We suggest, with the deuterium-labelled substrate **13** (Scheme 4) serving as an example, that tri-*n*-butyltin hydride functions as a base, removing the relatively acidic deuteron from the cyclic radical **16** to produce a radical anion **17**. **17** then undergoes single electron transfer with the starting material to give the radical **14** and the primary product **18**, which is subsequently reduced to **19**. Such a pseudo $S_{RN}1$ mechanism has recently been proposed by Bowman et al. (12) to rationalize various oxidative cyclizations in radical reactions, using tri-*n*-butyltin hydride, that they and others have observed.

Experimental

The melting points were determined in a Mel-Temp or a Buchi 510 melting point apparatus and are not corrected. The infrared spectra were measured with a Nicolet 5 PC FT, a Perkin–Elmer 1720, or a Perkin–Elmer 1420 infrared spectrophotometer. The ^1H nmr spectra were measured with a Varian EM-360, a Varian EM-390, a Varian Gemini-200, a Bruker WM 300, or a Bruker AM 500nmr spectrometer in deuteriochloroform and are expressed as parts per million from internal tetramethylsilane. When exchangeable protons were present, the data are given for deuterium oxide exchanged spectra. Those nmr spectra not found in the experimental section can be obtained from the Depository of Unpublished Data.[13] The high-resolution mass spectra were obtained with a Finnigan MAT 311A mass spectrometer on samples that were at least 95% pure as judged by nmr spectrometry.

The terms "worked up in the usual manner" or "the usual work-up" signify that the extract was dried over anhydrous magnesium or sodium sulfate and evaporated in vacuo.

1-(2-Bromobenzyl)pyrrole (1a)

Pyrrole (3.0 g, 44.8 mmol) was added portionwise to a stirred sus-

[8]Alkyl-2-pyrrolylsulfoxides undergo both desulfinylation and deoxygenation under these conditions, e.g., 1-benzyl-2-acetyl-5-methylsulfinylpyrrole was converted into 1-benzyl-2-acetylpyrrole (45%) and 1-benzyl-2-acetyl-5-methylthiopyrrole (14% (M. E. de la Cruz and Y. Antonio, unpublished data)).

[9]We have no data regarding the mechanism of this process.

[10]The method by which deuterium was introduced at C-5 of **13** (see experimental section) also resulted in partial deuteration (ca. 65% by nmr) at C-3,4.

[11]The nmr spectrum of **19** also showed that a small amount (10.5%) of the deuterium label was still present at C-3. This may imply a minor incursion of the ipso aromatization process or that partial scrambling of the label had occurred. Consistent with scrambling is that the nmr of **19** also showed ca. 25% loss of the label from C-1,2, although it is not obvious how such scrambling could occur. The mass spectrum shows that 0.90 ± 0.02 D was lost during the formation of **19** from **13** (note that 0.94 D was present originally at C-5 in **13** by nmr).

[12]**Note added in proof:** In contrast, Caddick et al. (26) have recently reported that the radicals derived from 1-halo-2-*p*-toluenesulfonylindoles (Bu_3SnH/AIBN) cyclize at C-2 to produce species that aromatize by loss of the *p*-toluenesulfonyl radical (i.e., by an addition–elimination process).

[13]These spectra can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

pension of sodium hydride (60% in mineral oil, 2.0 g, 50 mmol) in anhydrous dimethylformamide (100 mL) at 0°C (nitrogen atmosphere). Stirring was then continued at room temperature until hydrogen evolution had ceased (0.25 h). 2-Bromobenzyl bromide (10.0 g, 40 mmol) was added all at once and after 2 h the reaction mixture was poured into water and the product was extracted into ether. The extract was washed with water and after the usual work-up the crude product was purified by distillation to give an oil (8.7 g, 92%), bp 107–109°C/1 Torr (1 Torr = 133.3 Pa). Anal. calcd. for $C_{11}H_{10}BrN$: C 55.96, H 4.27, N 5.93; found: C 55.87, H 4.63, N 6.18.

*1-(2-Bromobenzyl)pyrrole-2-carboxaldehyde (**1**b)*

This compound was prepared from equimolar quantities of pyrrole-2-carboxaldehyde and 2-bromobenzyl bromide under conditions otherwise identical to those described for **1***a*. After crystallization from ethyl acetate, pure **1***b* (72% yield) had mp 90–92°C. Anal. calcd. for $C_{12}H_{10}BrNO$: C 54.56, H 3.81, N 5.30; found: C 54.34, H 3.79, N 5.04.

*1-(2-Bromobenzyl)-2-methylsulfonylpyrrole (**1**c)*

2-Methylthiopyrrole (13) was alkylated with 2-bromobenzyl bromide as described for **1***b*. The crude product (not characterized) from a 16 mmol reaction was dissolved in dichloromethane (400 mL) and the solution was cooled to 0°C. *m*-Chloroperbenzoic acid (80 wt.%, 7.1 g, 33 mmol) was added with stirring, and after 1 h the reaction mixture was washed with saturated sodium bicarbonate solution, dried over

anhydrous potassium carbonate, and the solvent was removed in vacuo. Crystallization of the crude product from hexane – ethyl acetate gave pure **1***c* (3.6 g, 71%), mp 102–103°C; nmr (300)δ: 2.90 (s, 3H, SO_2Me) 5.53 (s, 2H, CH_2), 6.30 (dd, 1H, $J_{3,4}$ = 4.0 Hz, $J_{4,5}$ = 2.7 Hz, H-4), 6.67 (, 1H, H-6′), 6.85 (t, 1H, H-5), 7.03 (dd, 1H, $J_{3,5}$ = 1.9 Hz, $J_{3,4}$ = 4.0 Hz, H-3), 7.18 (m, 1H, H-4′ or H-5′), 7.27 (m, 1H, H-5′ or H-4′), 7.61 (dd, 1H, J_o = 7.8 Hz, J_m = 1.4 Hz, H-3′). Anal. calcd. for $C_{12}H_{12}BrNO_2S$: C 45.87, H 3.85, N 4.45; found: C 45.82, H 3.90, N 4.38.

*1-(2-Bromobenzyl)-2-(4-methylphenylsulfonyl)pyrrole (**1**d)*

1-(2-Bromobenzyl)pyrrole (**1***a*) was reacted with an equilmolar amount of *p*-toluenesulfinylchloride (14) in the presence of triethylamine as described by Carmona et al. (15, Method C). The crude 1-(2-bromobenzyl)-2-(4-methylphenylsulfinyl)pyrrole from a 19.6 mmol reaction was then oxidized to the sulfone with *m*-chloroperbenzoic acid (37 mmol) as described for **1***c*. The crude product on crystallization from hexane – ethyl acetate gave pure **1***d* (5.0 g, 65%), mp 141–142°C. Anal. calcd. for $C_{18}H_{16}BrNSO_2$: C 55.40, H 4.13, N 3.59; found: C 55.58, H 4.21, N 3.52.

*1-(2-Bromobenzyl)-3-methylsulfonylpyrrole (**7**a)*

2-Methylthiopyrrole was alkylated with 2-bromobenzyl bromide as described for the synthesis of **1***c* and the crude 1-(2-bromobenzyl)-2-methylthiopyrrole (4.0 g, 14 mmol) was dissolved in dichloromethane (75 mL) and cooled to 0°C. *m*-Chloroperbenzoic acid (80%, 2.9 g, 14 mmol) was added to the stirred solution and after 1 h the reaction mixture was worked up as described for **1***c*. The crude 1-(2-bromobenzyl)-2-methylsulfinylpyrrole was dissolved in dichloromethane (50 mL), *p*-toluenesulfonic acid monohydrate (2.6 g) was added, and the solution was stirred at 25°C for 1.5 h. The solution was washed with saturated aqueous sodium bicarbonate solution and water, and then it was worked up in the usual manner. The product was purified by flash chromatography on silica gel using hexane – ethyl acetate – triethylamine (1:1:0.05) to elute pure 1-(2-bromobenzyl)-3-methylsulfinylpyrrole (2.1 g, 50%) as a solid that had mp 75–77°C after crystallization from hexane – ethyl acetate. Anal. calcd. for $C_{12}H_{12}BrNOS$: C 48.33, H 4.05, N 4.69; found: C 48.30, H 4.11, N 4.58.

m-Chloroperbenzoic acid (80 wt.%, 0.60 g, 2.8 mmol) was added to a stirred solution of the above sulfoxide (0.83 g, 2.8 mmol) in dichloromethane (20 mL) at 25°C. After stirring for 2 h at 25°C, the reaction mixture was worked up as for **1***c* to give material that was purified by flash chromatography on silica gel using hexane – ethyl acetate to elute pure **7***a* (0.70 g, 80%) as a solid that on crystallization from hexane – ethyl acetate had mp 122–124°C; nmr (300)δ: 2.81 (s, 3H, SO_2Me), 5.16 (s, 2H, CH_2), 6.54 (dd, 1H, $J_{2,5}$ = 1.8 Hz, $J_{4,5}$ = 2.6 Hz, H-5), 6.80 (t, 1H, H-4), 6.89 (dd, 1H, H-6′), 7.11 (t, 1H, H-2), 7.19 (td, 1H, H-5′), 7.27 (td, 1H, H-4′), 7.59 (dd, 1H, H-3′). Anal. calcd. for $C_{12}H_{12}BrNO_2S$: C 45.87, H 3.85, N 4.45; found: C 45.88, H 3.83, N 4.55.

*1-(4-Bromobutyl)-2-methanesulfonylpyrrole (**8**a)*

A solution of 2-methylthiopyrrole (1.5 g, 13 mmol) in anhydrous DMF (10 mL) was added to a stirred suspension of sodium hydride (60% in mineral oil, 0.58 g, 15 mmol) in dry DMF (100 mL) at 0°C. When hydrogen evolution had ceased (0.5 h), a solution of 1,4-dibromobutane (14.0 g, 66 mmol) in dry DMF (20 mL) was added and the reaction mixture was stirred for 3 h at room temperature. The reaction mixture was poured into water, and the product was extracted into ether. The ether extract was washed successively with water and saturated aqueous sodium chloride solution, and it was then worked up as usual. The crude 1-(4-bromobutyl)-2-methylthiopyrrole was then oxidized to the sulfone with *m*-chloroperbenzoic acid (29 mmol) as described for **1***c*. The crude product was purified by flash chromatography on silica gel using hexane – ethyl acetate (12:1 to 3:1) to elute **8***a* (2.3 g, 61%) as an oil; nmr (300)δ: 1.76–2.10 (m, 4H, CH_2CH_2), 3.11 (s, 3H, SO_2Me), 3.42 (t, 2H, *J* = 6.4 Hz, CH_2Br), 4.26 (t, 2H, *J* = 7.1 Hz, NH_2), 6.23 (dd, 1H, $J_{3,4}$ = 3.58 Hz, $J_{4,5}$ = 3.03 Hz, H-4), 6.89 (m, 2H, H-3, 5). Anal. calcd. for $C_9H_{14}BrNO_2S$: C 38.58, H 5.04, N 4.99; found: C 38.70, H 5.17, N 5.00.

*1-(4-Bromobutyl)-2-methanesulfonyl-4-benzoylpyrrole (**8**b)*

Bromine (5.6 g, 35 mmol) was added dropwise to methanol (25 mL) at –40°C, and this cold solution was added dropwise to a stirred slurry of potassium thiocyanate (7.1 g, 74 mmol) in methanol (25 mL) at –78°C. After 20 min at this temperature, this mixture was added to a stirred solution of 3-benzoylpyrrole (ref. 16, 6.0 g, 35 mmol) in methanol at –78°C. The reaction mixture was warmed to –40°C and after 0.5 h it was poured into water. The product was extracted into ethyl acetate, the extract was washed sucessively with saturated aqueous solutions of sodium bisulfite and sodium chloride, and then it was worked up as usual. Crystallization of the crude product from hexane – ethyl acetate gave pure 2-thiocyano-4-benzoylpyrrole (5.0 g, 63%) mp 180–181°C. Anal. calcd. for $C_{12}H_8N_2OS$: C 63.13, H 3.53, N 12.27; found: C 63.02, H 3.63, N 12.28.

A solution of sodium hydroxide (3.1 g, 78 mmol) in 50% aqueous methanol (30 mL) was added to a stirred solution of the above thiocyanate (7.4 g, 32 mmol) and methyl iodide (5.5 g, 39 mmol) in methanol (40 mL) at 0°C. The solution was then stirred at room temperature for 1.5 h and poured into water. Solid sodium bisulfite was added to bring the solution to pH 6, and the product was extracted into ether. The ether extract was washed with saturated sodium choloride solution and then worked up in the usual manner. The crude product was purified by flash chromatography on silica gel using hexane – ethyl acetate to elute pure 2-methylthio-4-benzoylpyrrole (5.4 g, 77%) as a solid that was used without further characterization in the next step.

A suspension of potassium carbonate (1.5 g, 11 mmol) in acetonitrile (25 mL) containing 2-methylthio-4-benzoylpyrrole (1.5 g, 6.9 mmol) and 1,4-dibromobutane (7.8 g, 36 mmol) was stirred at reflux temperature for 22 h. The cooled mixture was diluted with ethyl acetate (125 mL), then washed with water and saturated sodium chloride solution. After the usual work-up, the crude product was purified by flash chromatography on silica gel using hexane – ethyl acetate (4:1) to give pure 1-(4-bromobutyl)-2-methylthio-4-benzoylpyrrole (1.5 g, 60%), which was used directly in the next step.

A solution of Oxone (3.9 g, 6.3 mmol) in water (30 mL) was added all at once to a stirred solution of the above bromo compound (1.5 g, 4.2 mmol) in methanol (60 mL). The resulting slurry was stirred at room temperature for 3 h and then poured into water. The product was extracted into ethyl acetate; the extract was washed with saturated sodium chloride solution and then worked up as usual. The crude product was purified by flash chromatography on silica gel using hexane – ethyl acetate (3:1 to 1:1) to elute **8***b* as a solid (1.2 g, 73%), mp 99–100°C; nmr (300)δ: 1.90–2.16 (m, 4H, CH_2CH_2), 3.17 (s, 3H, SO_2Me), 3.45 (t, 2H, *J* = 6.34 Hz, CH_2Br), 4.33 (t, 2H, *J* = 7.33 Hz, CH_2N), 7.34 (d, 1H, *J* = 1.96 Hz, H-5), 7.47–7.62 (m, 4H, H-3, 3′, 4′, 5′), 7.83 (m, 2H, H-2′, 6′). Anal. calcd. for $C_{16}H_{18}BrNO_3S$: C 50.00, H 4.72, N 3.64; found: C 49.90, H 4.74, N 3.56.

*1-Benzyl-2-methylsulfonylpyrrole (**11**a)*

2-Methylthiopyrrole was alkylated with benzylchloride in the same manner as described for the synthesis of **1***b* to give 1-benzyl-2-methylthiopyrrole in 90% yield. This compound was converted into the sulfone **11***b* by oxidation with *m*-chloroperbenzoic acid (3.8 equiv., 2 h) as described for the synthesis of **1***c*. The crude product was purified by column chromatography on silica gel using hexane – ethyl acetate (4:1) to give pure **11***a* (67% yield), which had mp 62–63°C; nmr (200)δ: 2.56 (s, 3H, SO_2Me), 5.47 (s, 2H, CH_2), 6.28, (dd, 1H, $J_{3,4}$ = 3.63 Hz, $J_{4,5}$ = 2.95 Hz, H-4), 6.98 (m, 2H, H-3, 5), 7.12–7.17 (m, 2H, H-2′, 6′), 7.29–7.41 (m, 3H, H-3′, 4′, 5′). Anal. calcd. for $C_{12}H_{13}NO_2S$: C 61.25, H 5.57, N 5.95; found: C 61.46, H 5.54, N 5.97.

*1-Benzyl-2-phenylsulfonylpyrrole (**11**b)*

This compound was prepared from 2-phenylsulfonylpyrrole (17) and benzyl chloride in the manner described for the synthesis of **1***b*. Compound **11***b* was obtained as a solid (96% yield) that, after crystallization from dichloromethane–hexane, had mp 128–129°C. Anal.

calcd. for $C_{17}H_{15}NO_2S$: C 68.66, H 5.08, N 4.71; found: C 68.48, H 4.98, N 4.67.

*1-Benzyl-2-methylsulfonylpyrrole-5-carboxaldehyde (**11**c)*

A mixture of 2-methylthiopyrrole-5-carboxaldehyde (ref. 18, 2.30 g, 16.3 mmol), benzyl chloride (2.68 g, 21.2 mmol), and anhydrous potassium carbonate (11.2 g, 81.4 mmol) in dry DMF (23 mL) was stirred at room temperature for 16 h. The reaction mixture was poured into water, the product was extracted into ethyl acetate, and the extract was washed with water. After the usual work-up, 1-benzyl-2-methylthiopyrrole-5-carboxaldehyde was obtained as an oil (3.57 g, 95% yield); ir (film): 1657 cm^{-1}; nmr (200)δ: 2.35 (s, 3H, MeS), 5.71 (s, 2H, CH_2), 6.30 (d, 1H, J = 4.2 Hz, H-3), 7.00 (d, 1H, J = 4.2 Hz, H-4), 7.08–7.14 (m, 2H, H-2′, 6′), 7.22–7.34 (m, 3H, H-3′, 4′, 5′), 9.44 (s, 1H, CHO). Exact Mass calcd. for $C_{13}H_{13}NOS$: 231.0718; found: 231.0711.

The above sulfide was oxidized to the sulfone **11***c* with *m*-chloroperbenzoic acid (3 equiv., 4 h) as described for the synthesis of **1***c*. The crude product was purified by column chromatography on neutral alumina (Fluka, Act 11) using hexane – ethyl acetate (4:1) to elute **11***c* as a solid (46% yield) that had mp 60–62°C after crystallization from dichloromethane–methanol; ir ($CHCl_3$): 2824, 1682, 1327, 1217, cm^{-1}; nmr (200)δ: 2.58 (s, 3H, SO_2Me), 6.08 (s, 2H, CH_2), 6.95–7.19 (m, 4H, H-3, 4, 2′, 6′), 7.20–7.45 (m, 3H, H-3′, 4′, 5′), 9.85 (s, 1H, CHO). Anal. calcd. for $C_{13}H_{13}NO_3S$: C 59.30, H 4.98, N 5.32; found: C 59.40, H 4.99, N 5.33.

*2-Acetyl-5-methylsulfonylpyrrole (**11**d)*

Phosphorous oxychloride (12.7 g, 82.7 mmol) was added, with stirring under argon, to *N*-acetylmorpholine (10.9 g, 84.4 mmol) at –5°C. The reaction mixture was then stirred at 1 h at room temperature, cooled to 0°C, and a solution of 2-methylthiopyrrole (8.00 g, 70.7 mmol) in anhydrous 1,2-dichloroethane (25 mL) was added. The reaction mixture was stirred for 0.5 h at room temperature and then added cautiously to a solution of sodium carbonate (15 g) in water (160 mL). The two-phase mixture was stirred vigorously at reflux temperature for 2 h and, after cooling to room temperature, the organic phase was separated and combined with a dichloromethane extract of the aqueous phase. The organic phase was washed with saturated salt solution and after the usual work-up the crude product was purified by column chromatography on silica gel using hexane – ethyl acetate (9:1) to elute 2-acetyl-5-methylthiopyrrole as a solid (7.5 g, 68% yield). After crystallization from dichloromethane–hexane, this material had mp 79–81°C; ir ($CHCl_3$): 3437, 3263, 1641, cm^{-1}; nmr (200)δ: 2.41 (s, 3H, MeS or MeCO), 2.47 (s, 3H, MeCO or MeS), 6.24 (d, 1H, J = 3.93 Hz, H-4), 6.87 (d, 1H, J = 3.93 Hz, H-3). Anal. calcd. for C_7H_9NOS: C 54.16, H 5.84, N 9.02; found: C 54.20, H 5.85, N 8.99.

The above sulfide was oxidized to the sulfone **11***d* with *m*-chloroperbenzoic acid (3 equiv., 4 h) as described for **11***c* except that the solid product (90% yield) was eluted from the alumina column with dichloromethane. After crystallization from dichloromethane–hexane, compound **11***d* had mp 119–120°C; ir ($CHCl_3$): 3406, 3269, 1672, 1323, 1188 cm^{-1}; nmr (200)δ: 2.52 (s, 3H, MeCO), 3.18 (s, 3H, $MeSO_2$), 6.90 (q, 2H, J = 4.03, H-3, 4). Anal. calcd. for $C_7H_9NO_3S$: C 44.90, H 4.84, N 7.48; found: C 45.00, H 4.81,N 7.50.

*1-Methyl-2-acetyl-5-methylsulfonylpyrrole (**11**e)*

2-Acetyl-5-methylthiopyrrole was N-methylated using methyl iodide (5 equiv.) in the presence of potassium carbonate (10 mol equiv.) in DMF as described above (see synthesis of **11***c*). 1-Methyl-2-acetyl-5-methylthiopyrrole was obtained as an oil (96% yield); ir (film): 1651 cm^{-1}; nmr (200)δ: 2.39 (s, 3H, MeS or MeCO), 2.42 (s, 3H, MeCO or MeS), 3.96 (s, 3H, NMe), 6.20 (d, 1H, J = 4.23 Hz, H-4), 6.95 (s, 1H, J = 4.23 Hz, H-3). Exact Mass calcd. for $C_8H_{11}NOS$: 169.0561; found: 169.0559.

The above sulfide was oxidized to the sulfone **11***e* exactly as described for the synthesis of **11***d*. Chromatographically pure **11***e* was obtained as a solid (92% yield) that, after crystallization from dichloromethane–hexane, had mp 104–105°C; ir (KBr): 1681, 1307, 1147 cm^{-1}; nmr (200)δ: 2.54 (s, 3H, MeCO), 3.17 (s, 3H, $MeSO_2$), 4.23 (s, 3H, NMe), 6.94 (q, 2H, J = 4.34 Hz, H-3, 4). Anal. calcd. for $C_8H_{11}NO_3S$: C 47.74, H 5.50, N 6.96; found: C 47.83, H 5.51, N 6.90.

*1-Benzyl-2-acetyl-5-methylsulfonylpyrrole (**11**f)*

2-Acetyl-5-methylthiopyrrole was N-benzylated exactly as described above (see synthesis of **11***c*). 1-Benzyl-2-acetyl-5-methylthiopyrrole was obtained as an oil (91% yield). Exact Mass calcd. for $C_{14}H_{15}NOS$: 245.0874; found: 245.0878.

The above sulfide was oxidized to the sulfone **11***f* exactly as described for **11***c*, except that the product was eluted from the alumina column as a solid (83% yield) with hexane – ethyl acetate (85:15). After crystallization from dichloromethane–hexane **11***f* had mp 99–100°C. Anal. calcd. for $C_{14}H_{15}NO_3S$: C 60.62, H 5.45, N 5.05; found: C 60.59, H 5.38, N 5.03.

*1-Methyl-2-benzoyl-5-methylsulfonylpyrrole (**11**g)*

2-Benzoyl-5-methylsulfonylpyrrole (13) was N-methylated using methyl iodide (10 equiv.) in the presence of potassium carbonate (6 equiv.) in DMF as described for the synthesis of **11***c*. Crystallization of the crude product from dichloromethane–methanol gave a solid (64% yield), mp 89–90°C. Anal. calcd. for $C_{13}H_{13}NO_3S$: C 59.29, H 4.95, N 5.31; found: C 59.38, H 5.00, N 5.41.

*1-Benzyl-2-benzoyl-5-methylsulfonylpyrrole (**11**h)*

2-Benzoyl-5-methylsulfonylpyrrole (13) was N-benzylated as described above (see synthesis of **11***c*). Crystallization of the crude product from dichloromethane–methanol gave a solid (60% yield), mp 124–125°C. Anal. calcd. for $C_{19}H_{17}NO_3S$: C 67.23, H 5.05, N 4.12; found: C 67.42, H 4.98, N 4.00.

*Deuterated 1-(2-bromobenzyl)-2-methylsulfonylpyrrole (**13**)*

This compound was not prepared in the manner described above for the protio compound **1***c*. Instead, a synthesis of **13** was devised based on 1-phenylsulfonylpyrrole (19) as the starting material. The synthesis of **13** was carried out in parallel with that of the nondeuterated congener, for which the experimental details are given below.

1-Phenylsulfonylpyrrole (10.0 g) was added in one portion to deuteriotrifluoroacetic acid (prepared by addition of trifluoroacetic anhydride (52.2 mL) to deuterium oxide (20.0 mL, 99.9% D) at 0°C) with stirring (nitrogen atmosphere) at room temperature.[14] After 21 h, the solution was poured into a two-phase mixture of ether and excess saturated aqueous sodium bicarbonate solution. The organic phase was then worked up in the usual way to give deuterated 1-phenylsulfonylpyrrole (10.0 g), which showed 94.0% D (1.88 D) at C-2,5 and 67.6% D (1.32 D) at C-3,4 as determined from a comparison of the nmr signals (300) at δ 7.16 and 6.30 with the benzenoid multiplets at δ 7.48–7.62 and 7.84–7.87. Mass spectral analysis (molecular ions) showed an isotopic composition of 2.4% D_1, 19.5% D_2, 45.1% D_3, and 33.0% D_4 (3.09 D).

The thiocyanation of 1-phenylsulfonylpyrrole was carried out exactly as described by Kakushima and Frenette (20) for the thiocyanation of 1-(4-methylphenylsulfonyl)pyrrole. The crude product was subjected to purification by flash chromatography on silica gel using hexane – ethyl acetate (9:1) as the eluting solvent. A minor (9%) amount of a less polar material, which was 1-phenylsulfonyl-2-thiocyano-5-chloropyrrole, was obtained as an unstable oil. Exact Mass calcd. for $C_{11}H_7ClN_2O_2S_2$: 297.9637; found: 297.9637. The major (70%), more polar product was 1-phenylsulfonyl-2-thiocyanopyrrole, a solid with mp 74–76°C. Anal. calcd. for $C_{11}H_9N_2O_2S_2$: C 49.98, H 3.05, N 10.60; found: C 49.64, H 3.12, N 10.50.

Methyl iodide (1.6 g, 11.3 mmol) and 1 N sodium hydroxide solution (11.4 mL) was added to a stirred solution of 1-phenylsulfonyl-2-thiocyanopyrrole (1.0 g, 3.8 mmol) in methanol (40 mL) at room temperature. After 20 min, the reaction mixture was poured into dilute hydrochloric acid and the product was extracted into dichloromethane.

[14] We thank Dr. R. Frenette, Merck Frosst Canada Inc., Pointe Claire/Dorval, Quebec, for providing us with information regarding this deuteration reaction.

For personal use only.

After the usual work-up, 1-phenylsulfonyl-2-methylthiopyrrole was obtained as a solid (0.97 g, 100% yield) that, after crystallization from dichloromethane–methanol, had mp 91.5–92°C. Anal. calcd. for $C_{11}H_{11}NO_2S_2$: C 52.15, H 4.38, N 5.53; found: C 52.08, H 4.37, N 5.66.

1-Phenylsulfonyl-2-methylthiopyrrole was oxidized to the sulfone with *m*-chloroperbenzoic acid (2 equiv., 1 h) as described for the synthesis of **1***c*. The crude product was purified by column chromatography on Act II neutral alumina using dichloromethane to elute 1-phenylsulfonyl-2-methylsulfonylpyrrole as a solid (91% yield) that, after crystallization from ether – methylene chloride, had mp 133–134°C. Anal. calcd. for $C_{11}H_{11}NO_4S_2$: C 46.30, H 3.89, N 4.91; found: C 46.23, H 3.68, N 5.12.

Sodium hydroxide (1 mL, 1 N) was added to a solution of 1-phenylsulfonyl-2-methylsulfonylpyrrole (0.300 g, 1.05 mmol) in methanol (25 mL) and the mixture was warmed briefly to give a clear solution. The solution was left at room temperature for 0.5 h and then evaporated to dryness in vacuo. Water was added to the residue and the product was extracted into dichloromethane. After the usual work-up, 2-methylsulfonylpyrrole (0.153 g, 100% yeild) was obtained as a solid identical to an authentic specimen (13, 21).

Tetra-*n*-butylammonium bromide (0.30 g), 2-bromobenzylbromide (0.30 g), and 50% sodium hydroxide (1 mL) were added to a solution of 2-methylsulfonylpyrrole (0.153 g) in dichloromethane (25 mL) and the resulting mixture was vigorously stirred at room temperature for 2 h. Additional dichloromethane was added, and the organic phase was separated and worked up in the usual manner. The crude product was purified by column chromatography on silica gel using hexane – ethyl acetate to elute 1-(2-bromobenzyl)-2-methylsulfonylpyrrole (**1***c*) as a solid (0.224 g, 68% yeild) identical to a specimen prepared as described previously. The deuterated compound **13** prepared in the same way had 93.7 ± 3.2% D (0.94 D) at C-5 and 60.7 ± 0.3% D (1.21 D) at C-3,4 as determined by comparison of the integrals for the nmr multiplets of the pyrrole protons to those of the benzenoid multiplets centered at δ 6.67, 7.18, and 7.61. Mass spectral analysis (molecular ions) showed an isotopic composition of 3.5% D_0, 19.5% D_1, 43.5% D_2, and 31.9% D_3.

Oxidative radical cyclizations

*(a) Method A. 5H-Pyrrolo[2,1-a]isoindole-3-carboxaldehyde (**5**b)*

A solution of tri-*n*-butyltin hydride (0.529 g, 1.82 mmol) and azobisisobutyronitrile ((AIBN), 0.040 g) in dry, degassed benzene (10 mL) was added with a syringe pump to a solution of compound **1***b* (0.480 g, 1.82 mmol) in dry, degassed benzene (30 mL), which was irradiated with a 150-W flood lamp and heated at reflux (argon atmosphere) over a 24 h period. The reaction mixture was then heated at reflux while irradiating for an additional 33 h. The solvent was removed in vacuo, the residue was dissolved in ethyl acetate (20 mL), saturated aqueous potassium fluoride (10 mL) was added, and the mixture was agitated vigorously for 2 h. The mixture was filtered, poured into water, and extracted with ether. After the usual work-up, the crude product was purified by flash chromatography on silica gel using hexane – ethyl acetate (8:1) to elute the products. The major product (0.143 g, 43% yield) **5***b* was obtained as a solid together with a very minor amount (≤5%) of the known, oily 1-benzylpyrrole-2-carboxaldehyde (**6***b* (22)). Recrystallization of **5***b* from ethyl acetate gave a solid, mp 128–129°C; ir (KBr): 1653 cm^{-1}; nmr (300)δ: 5.23 (s, 2H, CH_2), 6.48 (d, 1H, J = 4.09 Hz, H-1), 7.10 (d, 1H, J = 4.09 Hz, H-2), 7.35 (td, 1H, J_o = 7.3 Hz, J_m = 1.2 Hz, H-7 or H-8), 7.42 (t, 1H J_o = 7.3 Hz, H-8 or H-7), 7.51 (d, 1H, J_o = 7.3 Hz, H-9), 7.66 (d, 1H, J_o = 7.3 Hz, H-6), 9.59 (s, 1H, CHO). Anal. calcd. for $C_{12}H_9NO$: C 78.67, H 4.95, N 7.64; found: C 78.49, H 5.06, N 7.32.

*(b) Method B. 5H-Pyrrolo[2,1-a]isoindole (**5**a)*

A solution of tri-*n*-butyltin hydride (1.0 g, 3.5 mmol) and AIBN (0.050 g) in dry, degassed benzene (20 mL) was added by syringe pump over a 4 h period to a solution of **1***c* (0.50 g, 1.6 mmol) in dry, degassed benzene (50 mL, argon atmosphere) at reflux temperature. The solution was heated at reflux for a further 1 h and then worked up as described above for the synthesis of **5***b*. The product mixture was separated by flash chromatography on silica gel using hexane–dichloromethane (6:1 to 3:1) to elute **5***a* (0.15 g, 64%) and 1-benzyl-2-methylsulfonylpyrrole (**6***c*, 0.10 g, 28%) as solids. Crystallization of **5***a* from hexane – ethyl acetate gave material with mp 86–88°C; nmr (300)δ: 4.89 (s, 2H, CH_2), 6.27 (m, 1H, $J_{1,2}$ = 3.54 Hz, $J_{1,3}$ = 1.08 Hz, $J_{1,5}$ = 0.5 Hz, H-1), 6.33 (q, 1H, $J_{1,2}$ = 3.54 Hz, $J_{2,3}$ = 2.59 Hz, H-2), 6.93 (m, 1H, $J_{1,3}$ = 1.08 Hz, $J_{2,3}$ = 2.59 Hz, $J_{3,5}$ = 0.6 Hz, H-3), 7.12 (td, 1H, $J_{7,8}$ = $J_{8,9}$ = 7.5 Hz, $J_{6,8}$ = 1.1 Hz, H-8), 7.26–7.73 m, 2H, H-7, 9), 7.46 (m, 1H, H-6). Anal. calcd. for $C_{11}H_9N$: C 85.13, H 5.84, N 9.02; found: C 84.95, H 5.89, N 9.00.

Crystallization of the sulfone **6***c* from hexane – ethyl acetate gave a solid, mp 68°C. Anal. calcd. for $C_{12}H_{13}NO_2S$: C 61.25, H 5.57, N 5.95; found: C 61.46, H 5.64, N 6.05.

*1-Benzyl-3-methylsulfonylpyrrole (7*b)

Obtained from **7***a* by method B except that additional portions of AIBN were added after 5 and 8 h of reflux. The product was purified by flash chromatography on silica gel (hexane – ethyl acetate (2:1 to 1:2)) to give a solid (59% yield) that had mp 94–95°C after crystallization from hexane – ethyl acetate; nmr (500)δ: 3.06 (s, 3H, SO_2Me), 5.07 (s, 2H, CH_2), 6.52 (m, 1H, H-4 or H-5), 6.71 (m, 1H, H-5 or H-4), 7.16 (m, 2H, H-2′, 6′), 7.26 (m, 1H, H-2), 7.35 (m, 3H, H-3′, 4′, 5′). Anal. calcd. for $C_{12}H_{13}NO_2S$: C 61.25, H 5.57, N 5.95; found: C 61.54, H 5.64, N 5.81.

*5,6,7,8-Tetrahydropyrrolo[1,2-a]pyridine (**9**a) and 3-methylsulfonyl-5,6,7,8-tetrahydropyrrolo[1,2-a]pyridine (**9**b)*

Reaction of **8***a* with tri-*n*-butyltin hydride as in method B (see also Table 1) gave a mixture that was separated by flash chromatography on silica gel (hexane–dichloromethane (8:1) to hexane–dichloromethane –ethyl acetate (1:1:1)).

The known (10) 5,6,7,8-tetrahydropyrrolo[1,2-*a*]pyridine (**9***a*) was obtained as an oil (60% yield); nmr (300)δ: 1.79–1.96 (m, 4H, C-6,7-CH_2CH_2), 2.77 (t, 2H, J = 6.2 Hz, C-8-CH_2), 3.93 (t, 2H, J = 6.1 Hz, C-5-CH_2), 5.82 (dd, 1H, $J_{1,2}$ = 3.39 Hz, $J_{1,3}$ = 1.76 Hz, H-1), 6.12 (t, 1H, H-2), 6.51 (dd after decoupling C-8-CH_2, 1H, $J_{1,3}$ = 1.76 Hz, $J_{2,3}$ = 2.65 Hz, H-3).

3-Methylsulfonyl-5,6,7,8-tetrahydropyrrolo[1,2-*a*]pyridine was obtained as an oil; nmr (300)δ: 1.79–2.05 (m, 4H, C-6,7-CH_2CH_2), 2.83 (t, 2H, J = 6.5 Hz, C-8-CH_2), 3.08 (s, 3H, SO_2Me), 4.22 (t, 2H, J = 6.1 Hz, C-5-CH_2), 5.93 (d, 1H, $J_{1,2}$ = 4.00 Hz, H-2), 6.88 (d, 1H, $J_{1,2}$ = 4.00 Hz, H-2). Exact Mass calcd. for $C_9H_{13}NO_2S$: 199.0667; found: 199.0670.

1-*n*-Butyl-2-methylsulfonylpyrrole (**10***a*) was obtained as an oil (17% yield). Anal. calcd. for $C_9H_{15}NO_2S$: C 53.70, H 7.51, N 6.96; found: C 53.78, H 7.91, N 7.10.

*1-Benzoyl-5,6,7,8-tetrahydropyrrolo[1,2-a]pyridine(**9**c) and 1-benzoyl-3-methylsulfonyl-5,6,7,8-tetrahydropyrrolo[1,2-a]pyridine (**9**d)*

Reaction of **8***b* with tri-*n*-butyltin hydride as in method B (see Table 1), except that an additional quantity of AIBN was added after 22 h total reflux, gave a mixture that was separated by flash chromatography on silica gel (hexane – ethyl acetate 4:1 to 1:1).

Compound **9***c* was obtained as a solid (24% yield) that, after crystallization from hexane–ether, had mp 75–76°C; ir (KBr): 1597 cm^{-1}; nmr (300)δ: 1.84–2.04 (m, 4H, C-6,7-CH_2CH_2), 3.17 (t, 2H, J = 6.40 Hz, C-8-CH_2), 3.98 (t, 2H, J = 5.96 Hz, C-5-CH_2), 6.41 (d, 1H, J = 3.05 Hz, H-2 or H-3), 6.47 (d, 1H, J = 3.05 Hz, H-3 or H-2), 7.40–7.51 (m, 3H, H-3′, 4′, 5′), 7.78 (dd, 2H, J_o = 8.0 Hz, J_m = 1.5 Hz, H-2′, 6′). Anal. calcd. for $C_{15}H_{15}NO$: C 79.97, H 6.71, N 6.22; found: C 79.90, H 6.79, N 6.16.

Compound **9***d* was obtained as a solid (40% yield) that, after crystallization from hexane–ether, had mp 164–166°C; ir (KBr): 1636, 1310, 1121 cm^{-1}; nmr (300)δ: 1.87–2.12 (m, 4H, C-6,7-CH_2CH_2), 3.12 (s, 3H, SO_2Me), 3.26 (t, 2H, J = 6.5 Hz, C-8-CH_2), 4.30 (t, 2H, J = 6.6 Hz, C-5-CH_2), 7.17 (s, 1H, H-2), 7.43–7.62 (m, 3H, H-3′, 4′, 5′), 7.74–7.77 (m, 2H, H-2′, 6′). Anal. calcd. for $C_{16}H_{17}NO_3S$: C 63.34, H 5.65, N 4.62; found: C 63.11, H 5.69, N 4.63.

Compound **10***b* was obtained as an oil (<5% yield). Anal. calcd. for $C_{16}H_{19}NO_3S$: C 62.92, H 6.27, N 4.59; found: C 63.06, H 6.46, N 4.35.

*Deuterated 5H-pyrrolo[2,1-a]isoindole (**19**)*

The oxidative radical cyclization of **13** was effected in the same manner as described for the conversion of **1***c* to **5***a*. Two reactions were run in duplicate (0.50 g scale) and gave deuterated **5***a* (i.e., **19**) in essentially the same yields as obtained for the undeuterated congener. Compound **19** had 10.5 ± 1.8% D at C-3 and 47.4 ± 5.2% D (0.95 D) at C-1 and C-2 as determined by comparison of the integrals (500 MHz) for the pyrrole protons to the total integral for the benzenoid protons. Mass spectral analysis showed an isotopic composition of 24.1 ± 0.6% D_0, 41.1 ± 0.5% D_1, and 34.8 ± 9.1% D_2. Thus the total loss of D by nmr was1.10 D (46.5%) vs. 0.90 D (44.5%) by mass spectrometry.

*Reduction of 2-sulfonylpyrroles (**11**) with tri-*n*-butyltin hydride*

A solution of the sulfone in anhydrous benzene (3–20 mL/mmol substrate) containing the appropriate amounts of tri-*n*-butyltin hydride and AIBN (see Table 2) was heated at reflux temperature in an argon atmosphere for the time specified in Table 2. The solvent was removed in vacuo and the residue was purified by preparative thin-layer chromatography on silica gel using the solvent system shown in Table 2. Known compounds were characterized by direct comparison with authentic specimens (see Table 2); new compounds are listed below.

*1-Benzyl-2-acetylpyrrole (**12**e)*

Oil; ir ($CHCl_3$): 1651 cm^{-1}; nmr (200)δ: 2.41 (s, 3H, Me), 5.58 (s, 2H, CH_2), 6.19 (dd, 1H, $J_{3,4}$ = 4.05 Hz, $J_{4,5}$ = 2.56 Hz, H-4), 6.90 (dd, 1H, $J_{3,5}$ = 1.75 Hz, $J_{4,5}$ = 2.56 Hz, H-5), 7.01 (dd, 1H, $J_{3,4}$ = 4.05 Hz, $J_{3,5}$ = 1.75 Hz, H-3), 7.09–7.13 (m, 2H, H-2′, 6′), 7.22–7.30 (m, 3H, H-3′, 4′, 5′). Anal. calcd. for $C_{13}H_{13}NO$: C 78.36, H 6.57, N 7.03; found: C 78.32, H 6.78, N 6.95.[15]

*1-Methyl-2-benzoylpyrrole (**12**f)*

Oil; ir ($CHCl_3$): 1615 cm^{-1}; nmr (200)δ: 4.03 (s, 3H, Me), 6.15 (m, 1H, H-4), 6.75 (m, 1H, H-3), 6.92 (m, 1H, H-5), 7.51 (m, 3H, H-3′, 4′, 5′), 7.83 (m, 2H, H-2′, 6′). Anal. calcd. for $C_{12}H_{11}NO$: C 77.81, H 5.99, N 7.56; found: C 77.85, H 6.11, N 7.23.[15]

*1-Benzyl-2-benzoylpyrrole (**12**g)*

Oil; ir ($CHCl_3$): 1625 cm^{-1}; nmr (200) δ: 5.71 (s, 2H, CH_2), 6.23 (m, 1H, H-4), 6.77 (m, 1H, H-3), 7.04 (m, 1H, H-5), 7.15–7.61 (m, 8H), 7.73 (m, 2H). Anal. calcd. for $C_{18}H_{15}NO$: C 82.73, H 5.78, N 5.36; found: C 82.71, H 6.04, N 5.38.[15]

Heteroatom-directed lateral lithiation: synthesis of isoquinoline derivatives from *N*-(*tert*-butoxycarbonyl)-2-methylbenzylamines[1,2]

ROBIN D. CLARK,[3] JAHANGIR,[3] AND JAMES A. LANGSTON
Institute of Organic Chemistry, Syntex Research, Palo Alto, CA 94304, U.S.A.

Received May 27, 1993

This paper is dedicated to Professor David B. MacLean

ROBIN D. CLARK, JAHANGIR, and JAMES A. LANGSTON. Can. J. Chem. **72**, 23 (1994).

Methodology for the preparation of isoquinoline derivatives from *N*-(*tert*-butoxycarbonyl)-2-methylbenzylamines (**1**) was developed. Conversion of **1** to the dilithio species followed by condensation with DMF afforded Boc-3-hydroxy-1,2,3,4-tetrahydroisoquinolines **3**, which could be dehydrated to 1,2-dihydroisoquinolines **4**. Hydrogenation of dihydro compounds **4** afforded the corresponding tetrahydroisoquinolines **5**. Treatment of the dilithio species from **1** with *N*-methoxy-*N*-methylamides afforded ketones **14**, which were converted to 3-substituted dihydro-isoquinoline **15**, tetrahydroisoquinolines (**16, 17**), or isoquinolines (**20**).

ROBIN D. CLARK, JAHANGIR et JAMES A. LANGSTON. Can. J. Chem. **72**, 23 (1994).

On a développé une méthodologie pour la préparation de dérivés isoquinoléines à partir de *N*-(*tert*-butoxycarbonyl)-2-méthylbenzylamines (**1**). La conversion des composés **1** en dérivés dilithiés suivie par une condensation avec le DMF conduit aux Boc-3-hydroxy-1,2,3,4-tétrahydroisoquinoléines (**3**) qui peuvent être soumises à une déshydratation conduisant aux 1,2-dihydroisoquinoléines (**4**). L'hydrogénation des composés dihydro **4** fournit les tétrahydroisoquinoléines correspondantes (**5**). Le traitement des espèces dilithiées des produits **1** avec des *N*-méthoxy-*N*-méthylamides conduit aux cétones **14** qui peuvent être transformées en dihydroisoquinoléines substituées (**15**), en tétrahydroisoquinoléines (**16** et **17**) et en isoquinoléines (**20**) en position 3.

[Traduit par la rédaction]

A number of heterocycle-forming annelations based on heteroatom-facilitated lateral lithiation reactions have recently been reported and these procedures offer useful alternatives to the more classical syntheses of important heterocycles, for example, indole (1) and isoquinoline (2) derivatives. We have described preliminary results on a synthesis of tetrahydroisoquinolines that was based on the lateral lithiation of *N*-(*tert*-butoxycarbonyl)-2-methylbenzylamine (**1***a*) (3). In this paper, we report details of that work and extensions that provide routes to a variety of substituted dihydroisoquinolines, tetrahydroisoquinolines, and isoquinolines.

Prior to our initial investigations, it had been demonstrated that *N*-benzylbenzamide underwent deprotonation at the α(benzylic) position (in addition to NH deprotonation) (4) and that *N*-pivaloylbenzylamine underwent both *ortho* and α-lithiation (5). It was subsequently reported that Boc-benzylamine was cleanly dilithiated to afford the *N*-α-dilithio species (6). However, based on the facility with which various toluenes undergo heteroatom-facilitated lateral lithiation (1, 7), we felt it likely that the methyl group of **1***a*, rather than the α position, would be the second site of deprotonation. In the event, treatment of **1***a* with two equivalents of *sec*-butyllithium at ca. –40°C gave the red-orange dilithio species **2***a* as evidenced by the formation of Boc-3-hydroxytetrahydroisoquinoline **3***a* as the sole product upon treatment with DMF (Scheme 1). We subsequently demonstrated that the Boc-phenylethylamine homolog of **1***a* also undergoes lateral lithiation under the same conditions and that only when the *N*-Boc group is extended by an additional methylene (phenylpropylamine derivative) does α-deprotonation become a competing, albeit minor, process (8).

Results of the application of this methodology to the synthesis of tetrahydroisoquinolines with substitutents at the 4-position or in the aromatic ring are presented in Scheme 2. The 3-hydroxy derivatives **3** obtained by DMF quench of the dilithio species **2** were isolable by crystallization and (or) silica gel chromatography and underwent rapid dehydration to the rather unstable 1,2-dihydroisoquinolines **4** upon brief treatment with HCl in THF. The dihydro compounds were hydrogenated to afford 1,2,3,4-tetrahydroisoquinolines **5**.

Several of the entries in Scheme 2 warrant further comment. Ring-halogenated tetrahydroisoquinolines, as exemplified by entries **5***b–d*, are not readily accessible by classical syntheses, for example, the Bischler–Napieralski (9) and Pictet–Spengler (10) procedures, which generally involve cyclizations onto electron-rich aromatic rings. Entry **1***f* demonstrated that lateral lithiation was the predominant pathway despite the presence of a 5-methoxy group that, in principle, could have induced competing ring (*ortho*) deprotonation at the 6-position. Entries **1***g–i* indicated a limitation of the methodology as 2-alkyl substituents other than methyl proved to be significantly more difficult to deprotonate, even when longer reactions times, higher temperatures, and the stronger base *tert*-BuLi were employed. This phenomenon was previously noted in the case of the related Boc-2-alkylanilines (1). An obvious exception is **1***j*, in which the additional phenyl group enhances the acidity of the methylene protons. With substrate **1***i*, the decreased rate of lateral lithiation allowed metalation *ortho* to the methoxy group in the appended aromatic ring to become a competing process.

The requisite benzylamines for the preparation of Boc derivatives **1***a–i* were either commercially available (**1***a*) or were, in general, prepared in straightforward fashion (Experimental). The preparation of the tetrasubstituted example **1***d*, which exemplifies several additional aspects of *ortho* and lateral lithiation methodology, is shown in Scheme 3. A previous report

[1]Dedicated to Professor D.B. MacLean in recognition of his outstanding contributions to natural product and alkaloid chemistry, which have encompassed isolation, structure determination, and synthesis. One of us (J) was fortunate enough to have obtained his doctoral training under D.B.M.'s mentorship. The work presented in this paper was inspired by the lateral metalation technology developed in Professor MacLean's laboratory for the synthesis of isoquinoline alkaloids.

[2]Contribution no. 880 from the Institute of Organic Chemistry.

from these laboratories introduced the 1-propenyl group for protection of benzamides in *ortho* lithiation reactions (11). One drawback of this methodology is that a mixture of *cis/trans* propenyl isomers is obtained, which complicates further synthetic steps. To obviate this inconvenience, in the present work we used the symmetric 2-methyl-1-propenyl group. Thus, benzamide **7** was obtained in quantitative yield by the lithium diisopropylamide (LDA)-induced isomerization (12) of the 2-methylallylbenzamide **6**. *ortho* Lithiation of **7** followed by treatment with iodoethane furnished the 2-ethyl derivative **8**. Attempts to effect lateral lithiation of **8** using organolithium bases were complicated by competing *ortho* lithiation as evidenced by formation of **9** and **10** upon treatment of the lithiated species with iodomethane (Scheme 3). However, it was found that lateral lithiation was the exclusive pathway when lithium 2,2,6,6-tetramethylpiperidide (LiTMP) was used as the base. LiTMP was superior to LDA, which gave only lateral metalation but with incomplete (ca. 70%) conversion. The superiority of LiTMP over LDA was also recently demonstrated in the lateral lithiation of *o*-tolualdehyde cyclohexylimine (13).

Compound **9**, with the 2-position effectively blocked to further metalation by the isopropyl group, was then subjected to the third consecutive lithiation reaction in the sequence to afford **11** after methylation. The 2-methyl-1-propenyl group was removed by acid hydrolysis to give the primary benzamide **12**, which was converted to **1***d*. We note in passing that **11** afforded the isoquinolone **13** upon lateral lithiation and treatment with DMF followed by dehydration with HCl (14). However, attempts to remove the *N*-protecting group from **13** with strong acid resulted in decomposition.

Acylation of dianion **2***a* was efficiently accomplished by treatment with *N*-methoxy-*N*-methylamides (15) to afford key intermediates **14***a–d* for the preparation of 3-substituted dihydro and tetrahydroisoquinolines (Scheme 4). Brief exposure of these ketones to a catalytic amount of trifluoroacetic acid in CH_2Cl_2 gave the Boc-1,2-dihydroisoquinolines **15**, which could be catalytically reduced to the corresponding Boc-protected tetrahydroisoquinolines **16**. Alternatively, the Boc group of **14** could be removed with trifluoroacetic acid, and reduction of the intermediate imine with sodium borohydride in ethanol afforded tetrahydroisoquinolines **17**. Several of the 3-substituted tetrahydroisoquinolines thus obtained were set up for additional ring closure reactions (Scheme 5). Deprotection of **16***b* with TFA followed by neutralization gave hexahydro-2*H*-benzo[*b*]quinolizine **18** and Pictet–Spengler reaction of **17***d* afforded the tetrahydro-5*H*-dibenzo[*b,g*]quinolizine **19**.

In addition to providing access to 3-substituted tetrahydroisoquinolines, the dihydroisoquinolines **15** can also serve as precursors to the corresponding isoquinolines. Thus, deprotection of **15***a* with TFA followed by treatment with iodine and KOAc in ethanol (16) afforded 3-butyl isoquinoline **20** (Scheme 6). Whereas the Reissert reaction (17) affords 1-substituted derivatives, 3-substituted isoquinolines are not readily accessible from classical isoquinoline syntheses, for example, the Pomeranz–Fritsch synthesis (18). Another versatile route for the preparation of 3-substituted isoquinolines based on the lateral lithiation of tolualdehyde imines has recently been reported (19).

A variant on the preparation of certain 3-substituted tetrahydroisoquinolines is shown in Scheme 7. Condensation of dianion **2***a* with veratraldehyde afforded adduct **21**, which cyclized to Boc-3(3,4-dimethoxyphenyl)tetrahydroisoquinoline **23** upon treatment with a catalytic amount of trifluoroacetic acid in CH_2Cl_2. This cyclization appears to require the presence of the 4-methoxy group, presumably through stabilization of the intermediate carbonium ion, as the corresponding unsubstituted phenyl congener **22** failed to cyclize under similar (or more strongly acid) conditions. In an attempt to prepare 3,3-disubstituted tetrahydroisoquinolines, the benzophenone and cyclohexanone adducts **24** and **26**, respectively, were similarly treated

with trifluoroacetic acid in CH_2Cl_2. However, **24** underwent almost immediate dehydration to stilbene **25** whereas **26** proved resistant to either cyclization or dehydration. Under strongly acidic conditions (neat trifluoroacetic acid or HCl in THF), the Boc group of **26** was removed while the tertiary alcohol remained intact.

In summary, the methodology reported herein can be used to prepare a variety of derivatives of the isoquinoline ring system. As has been amply demonstrated with heteroatom-directed *ortho* lithiation technology (7), Boc-directed *lateral* lithiations also can be used to synthesize compounds that might otherwise be difficult to prepare by classical means. Thus, lateral lithiation of **1** was used to prepare halogen-substituted tetrahydroisoquinolines and 3-substituted tetrahydroisoquinolines and isoquinolines. Applications to the preparation of more complex isoquinolines and isoquinoline-containing ring systems are underway and will be reported in due course.

Experimental

General information

Melting points were determined on a Thomas–Hoover capillary apparatus and are uncorrected. Thin-layer chromatography (tlc) was performed using Analtech silica gel GF glass plates. Medium-pressure chromatography (mpc) was performed with 230–400 mesh Merck Kieselgel. Microanalysis were carried out by the Syntex Analytical Department.

Proton (^1H) nmr spectra were recorded at 300 MHz on a Bruker WM 300 spectrometer in $CDCl_3$ or Me_2SO-d_6 solution referenced to internal tetramethylsilane (TMS). Chemical shifts, quoted as δ values, were measured in relation to TMS. Infrared (ir) spectra were run on a Nicolet 5 PC FT infrared spectrophotometer. Mass spectra were recorded with an Atlaswerke CH-7 spectrometer. High-resolution mass spectra (hrms) were obtained with a Finnigan MAT 311A mass spectrometer.

All lithiation reactions were carried out under an inert atmosphere (nitrogen or argon). THF was dried by distillation from Na–benzophenone under a nitrogen atmosphere immediately prior to use. "Usual work-up" refers to addition of aqueous NH_4Cl solution to the reaction mixture, extraction with EtOAc, washing the extract with water and brine, drying over Na_2SO_4, and evaporation on a rotary evaporator.

Typical procedure for the preparation of Boc-2-alkylanilines ***1****:* N-*(*tert*-butoxycarbonyl)-1-methylbenzylamine* **1a**

Di-*tert*-butyl dicarbonate (37 g, 170 mmol) was added to a cold (ice-bath) solution of 2-methylbenzylamine (Aldrich Chem. Co.) (20 g, 165

mmol) in THF (250 nmL). The resulting solution was stirred at room temperature for 4 h and was then concentrated in vacuo to a semi-solid. Crystallization from hexane (cooling in a Dry Ice – acetone bath) afforded **1***a* as a white solid (32 g, 88%); mp 50–51°C; ^{1}H nmr ($CDCl_3$) δ: 1.46 (s, 9H), 2.32 (s, 3H), 4.32 (d, 2H, J = 5.6 Hz), 4.70 (br m, 1H, NH), 7.18 (m, 4H); ms(EI), *m/z*(relative intensity): 221(5)M^+, 165(99), 164(79), 150(34), 120(16), 105(47), 104(100), 57(29). Anal. calcd. for $C_{13}H_{19}NO_2$: C 70.56, H 8.65, N 6.33; found: C 70.50, H 8.61, N 6.40.

The following compounds were similarly prepared.

N-*(*tert*-Butoxycarbonyl)-3-fluoro-2-methylbenzylamine* **1**b

This was prepared from 3-fluoro-2-methylbenzoic acid (Aldrich Chem. Co.) by conversion to the amide, LAH reduction, and reaction with di-*tert*-butyl dicarbonate; mp 69–70°C. Anal. calcd. for $C_{13}H_{18}FNO_2$: C 65.25, H 7.58, N 5.85; found: C 65.17, H 7.59, N 5.87.

N-*(*tert*-Butoxycarbonyl)-2-chloro-6-methylbenzylamine* **1**c

This was prepared from 2-chloro-6-methylbenzonitrile (Aldrich Chem. Co.) by reduction (borane–methylsulfide) and reaction with di-*tert*-butyl dicarbonate; mp 69–70°C. Anal. calcd. for $C_{13}H_{18}ClNO_2$: C 61.05, H 7.09, N 5.48; found: C 61.11, H 7.09, N 5.51.

N-*(*tert*-Butoxycarbonyl)-4-chloro-2-(2-propyl)-6-methylbenzylamine* **1**d

This was prepared from compound **12**, the preparation of which is described below; mp 69–70°C. Anal. calcd. for $C_{16}H_{24}ClNO_2$: C 64.52, H 8.13, N 4.70; found: C 64.79, H 8.23, N 4.82.

N-*(*tert*-Butoxycarbonyl)-4-methoxy-2-methylbenzylamine* **1**e

This was prepared from 4-methoxy-*o*-toluic acid by conversion to the amide, reduction with LAH, and reaction with di-*tert*-butyl dicarbonate; mp 79–80°C. Anal. calcd. for $C_{14}H_{21}NO_3$: C 66.90, H 8.42, N5.57; found: C 66.95, H 8.78, N 5.61.

N-*(*tert*-Butoxycarbonyl)-4,5-dimethoxy-2-methylbenzylamine* **1**f

This was prepared from 4,5-dimethoxy-*o*-toluic acid by conversion to the amide, reduction with LAH, and reaction with di-*tert*-butyl dicarbonate; mp 63–65°C. Anal. calcd. for $C_{15}H_{23}NO_4$: C 64.03, H 8.24, N 4.98; found: C 64.01, H 8.54, N 5.01.

N-*(*tert*-Butoxycarbonyl)-2-(1-*n*-butyl)benzylamine* **1**g

This was prepared by alkylation of the dilithio species **2***a* (see below) with 1-iodopropane; mp 46–48°C. Anal. calcd. for $C_{16}H_{25}NO_2$: C 71.45, H 9.00, H 5.95; found: C 71.64, H 9.17, N 5.54.

N-*(*tert*-Butoxycarbonyl)-2-(2-phenylethyl)benzylamine* **1**h

This was prepared from 2-bibenzylcarboxylic acid (Aldrich Chem. Co.) by conversion to the amide, reduction with LAH, and reaction with di-*tert*-butyl dicarbonate; mp 124–125°C. Anal. calcd. for $C_{20}H_{25}NO_2$: C 77.13, H 8.10, N 4.50; found: C 77.19, H 8.12, N 4.60.

N-*(*tert*-Butoxycarbonyl)2-((3-methoxyphenyl)ethyl)benzylamine* **1**i

This was prepared by alkylation of the dilithio species **2***a* with 3-methoxybenzyl chloride; mp 62–64°C. Anal. calcd. for $C_{21}H_{27}NO_3$: C 73.87, H 7.97, N 4.10; found: C 73.64, H 7.95, N 4.38.

N-*(*tert*-Butoxycarbonyl)-2-(phenylmethyl)benzylamine* **1**j

This was prepared from α-phenyl-*o*-toluic acid (Aldrich Chem. Co.) by conversion to the amide, reduction with LAH, and reaction with di-*tert*-butyl dicarbonate; mp 77–78°C. Anal. calcd. for $C_{19}H_{23}NO_2$: C 76.74, H 7.79, N 4.71; found: C 76.76, H 7.72, N 4.90.

General procedure for lithiation of **1** *followed by trapping with DMF*

A solution of the *N*-(*tert*-butoxycarbonyl)-2-methylbenzylamine **1***a* (5 mmol) in THF (10 mL) was cooled in an acetone–Dry Ice bath to ca. –60°C (internal temperature) and a solution of *sec*-BuLi (8.5 mL, 1.3 M in cyclohexane, 11 mmol) was added over a period of several minutes at such a rate as to maintain the internal temperature at ca. –30°C. The resulting bright orange solution was stirred for 5–10 min and DMF (0.58 mL, 7.5 mmol) was added. The now colorless reaction mixture was quenched with saturated aqueous NH_4Cl. The mixture was diluted with ether, washed with water and brine, and dried ($NaSO_4$). Removal of solvent in vacuo gave the crude product **3**, which was purified by crystallization (**3***a*, hexane) or mpc (**3***b*, **3***c*, **3***e*, **3***f*, EtOAc–hexane). Compounds **3***d* and **3***g–j* were used in the next step without purification.

The yields for the following compounds are given in Scheme 2.

*2-(*tert*-Butoxycarbonyl)-3-hydroxy-1,2,3,4-tetrahydroisoquinoline* **3**a: mp 97–98°C; ir (KBr): 3600–3200, 1682 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.52 (s, 9H), 2.98 (dd, 1H, J = 4.3, 15.4 Hz), 3.06 (dd, 1H, J = 4.3, 15.4 Hz), 3.65 (br s, 1H, OH), 4.46 (d, 1H, J = 15.7 Hz), 4.54 (d, 1H, J = 15.7 Hz), 5.80 (br m, 1H), 7.20 (m, 4H); ms (EI), *m/z* (% relative intensity)): 249 (3)M^+, 193 (38), 175 (44), 130 (32), 104 (100), 57 (96). Anal. calcd. for $C_{14}H_{19}NO_3$: C 67.45, H 7.68, N 5.62; found: C 67.57, H 7.82, N 5.79.

*2-(*tert*-Butoxycarbonyl)-5-fluoro-3-hydroxy-1,2,3,4-tetrahydroisoquinoline* **3**b: mp 137–138°C; ir (KBr): 3650–3200, 1668 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.51 (s, 9H), 2.97 (dd, 1H, J = 4.2, 16.4 Hz), 3.13 (dd, 1H, J = 4.2, 16.4 Hz), 3.45 (br s, 1H, OH), 4.35 (d, 1H, J = 16.2 Hz), 4.63 (d, 1H, J = 16.2 Hz), 5.92 (br m, 1H), 6.95 (m, 2H), 7.18 (m, 1H); ms (EI) *m/z* (% relative intensity): 267 (5)M^+, 211 (23), 193 (32), 167 (12), 148 (22), 122 (65), 57 (100). *2-(*tert*-Butoxycarbonyl)-8-chloro-3-hydroxy,1,2,3,4-tetrahydroisoquinoline* **3**c: mp 105–106°C; ir (KBr): 3660–3200, 1670 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.53 (s, 9H), 2.95 (dd, 1H, J = 3.7, 15.8 Hz), 3.10 (dd, 1H, J = 3.7, 15.8 Hz), 3.30 (br s, 1H, OH), 4.45 (d, 1H, J = 17.0 Hz), 4.70 (d, 1H, J = 17.0 Hz), 5.90 (m, 1HO, 7.14 (m, 2H), 7.27 (m, 1H); ms (EI), *m/z* (% relative intensity): 285 (7)M^+ + 2, 283 (18)M^+, 229 (6), 227 (18), 211 (12), 209 (32), 192 (12), 164 (16), 148 (22), 138 (44), 57 (100). Anal. calcd. for $C_{14}H_{18}ClNO_3$: C 59.26,H 6.40, N 4.94; found: C, 58.98, H 6.34, N 4.92.

*2-(*tert*-Butoxycarbonyl)-3-hydroxy-6-methoxy-1,2,3,4-tetrahydroisoquinoline* **3**e: Oil; ir (neat): 3650–3150, 1693 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.52 (s, 9H), 2.95 (dd, 1H, J = 4.3, 15.4 Hz), 3.05 (dd, 1H, J = 4.3, 15.4 Hz), 3.80 (s, 3H), 4.44 (2, 2H), 5.75 (br s, 1H), 6.87 (m, 2H), 7.08 (m, 1H); ms (EI), *m/z* (% relative intensity): 279 (5)M^+, 222 (50), 204 (15), 160 (100), 134 (32). Exact Mass (hrms) calcd. for $C_{15}H_{21}NO_4$: 279.147; found: 279.147.

*2-(*tert*-Butoxycarbonyl)-6,7-dimethoxy-3-hydroxy-1,2,3,4-tetrahydroisoquinoline* **3**f: mp 142–143°C; ir (KBr): 3640–3110, 1678 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.52 (s, 9H), 2.90 (dd, 1H, J = 3.9, 15.5 Hz), 3.02 (dd, 1H, J = 3.9, 15.5 Hz), 3.40 (br s, 1H, OH), 3.87 (s, 3H), 3.88 (s, 3H), 4.43 (m 2H), 5.80 (br m, 1H), 6.69 (s, 1H), 6.73 (s, 1H). Anal. calcd. for $C_{16}H_{23}NO_5(0.25\ H_2O)$: C 61.23, H 7.60, N 4.46; found: C 61.56, H 7.70, N 4.50; Exact Mass (hrms) calcd. for $C_{16}H_{23}NO_5$: 309.158; found: 309.158.

General procedure for dehydration of 3-hydroxy-1,2,3,4-tetrahydroisoquinolines **3**

To a solution of compound **3** (2 mmol) in THF (20 mL) was added 5 drops of concentrated HCl. The reaction mixture was stirred for 10 min at room temperature and then quenched with solid Na_2CO_3. The mixture was filtered and the filter cake was washed with EtOAc. The combined filtrate was evaporated in vacuo to afford the crude 1,2-dihydroisoquinoline **4**. Compounds **1***a* and **1***j* were isolated by mpc (EtOAc–hexane). Compounds **4***b,c,h* were used in the next step without purification. Yields for the following compounds are given in Scheme 2.

*2-(*tert*-Butoxycarbonyl)-1,2-dihydroisoquinoline* **4**a: Isolated as an unstable oil: ^{1}H nmr ($CDCl_3$) δ: 1.52 (s, 9H), 4.80 (br s, 2H), 5.66 (br d, 1H, J = 7.0 Hz), 6.80–7.19 (m, 5H).

*2-(*tert*-Butoxycarbonyl)-1,2-dihydro-4-phenylisoquinoline* **4**j: mp 96–98°C; ir (KBr): 1704 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.53 (s, 9H), 4.85 (s, 2H), 6.87–7.20 (m, 5H), 7.40 (m, 5H); ms (EI), *m/z* (% relative intensity): 307 (12)M^+, 251 (100), 206 (60). Anal. calcd. for $C_{20}H_{21}NO_2$: C 78.14, H 6.89, N 4.56; found: C 77.99, H 6.81, N 4.52.

General procedure for hydrogenation of 1,2-dihydroisoquinolines ***4*** *to 1,2,3,4-tetrahydroisoquinolines* ***5***

The 1,2-dihydroisoquinoline **4** (2 mmol) was dissolved in EtOAc (25 mL), 20% $Pd(OH)_2$ (100 mg) was added, and the mixture was hydrogenated in a Parr apparatus for ca. 12 h at 50 psi (1 psi = 6.9 kPa). The catalyst was removed by filtration through Celite and the filtrate was evaporated in vacuo to afford the crude tetrahydroisoquinoline **5**, which was purified by mpc (EtOAc–hexane). Yields for the following compounds are given in Scheme 2.

2-(tert-Butoxycarbonyl)-1,2,3,4-tetrahydroisoquinoline **5**a: mp 35–36°C; this material was identical to an authentic sample prepared from 1,2,3,4-tetrahydroisoquinoline.

2-(tert-Butoxycarbonyl)-5-fluoro-1,2,3,4-tetrahydroisoquinoline **5**b: mp 39–40°C; ir (KBr): 1698 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.48 (s, 9H), 2.81 (t, 2H, J = 5.9 Hz), 3.65 (t, 2H, J = 5.9 Hz), 4.58 (s, 2H), 6.88 (m, 2H), 7.14 (m, 1H); ms (EI), *m/z* (% relative intensity): 251 (5)M^+, 195 (50), 194 (100), 178 (23), 150 (43), 122 (17), 57 (79). Anal. calcd. for $C_{14}H_{18}FNO_2$: C, 66.91, H 7.61, N 5.28; found: C 66.86, H 7.61, N 5.28.

2-(tert-Butoxycarbonyl)-8-chloro-1,2,3,4-tetrahydroisoquinoline **5**c: mp 42–43°C; ir (KBr): 1692 cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.50 (s, 9H), 2.83 (t, 2H, J = 5.6 Hz), 3.64 (t, 2H, J = 5.6 Hz), 4.58 (s, 2H), 7.09 (m, 2H), 7.22 (m, 1H); ms (EI), *m/z* (% relative intensity): 210 (37)M^+, 194 (11), 168 (10), 168 (33), 138 (17), 103 (7), 57 (100). *3-*n*-Butyl-1,2,3,4-tetrahydroisoquinoline **17**a*

A solution of ketone **14***a* (1.07 g, 3.5 mmol) in CH_2Cl_2 (5 mL) was cooled in an ice-bath and trifluoroacetic acid (3 mL) was added. The mixture was stirred at room temperature for 1 h and was then concentrated in vacuo. The residue was dissolved in EtOH (10 mL) and the resulting solution was cooled in an ice-bath. $NaBH_4$ (0.5 g, 13 mmol) was slowly added in small portions and the mixture was stirred with warming to room temperature over 1 h. Aqueous 5% HCl (30 mL) was added and the mixture was basified with NH_4OH and extracted with CH_2Cl_2. The CH_2Cl_2 was dried (Na_2SO_4) and evaporated to give **17***a* as an oil that was homogeneous by tlc (5% MeOH–CH_2Cl_2); ^1H nmr ($CDCl_3$) δ: 0.93 (t, 3H, J = 6.9 Hz), 1.30–1.55 (m,6H), 1.86 (br s, 1H, NH), 2.50 (dd, 1H, J = 10.5, 16.2 Hz), 2.80 (dd, 1H, J = 3.9, 16.2 Hz), 2.85 (m, 1H), 4.06 (AB quartet, 2H, J_{AB} = 16.0 Hz), 6.96–7.12 (m, 4H); ms (EI), *m/z* (% relative intensity): 189 (4)M^+, 188 (3), 133 (16), 132 (100), 130 (21), 104 (18).

Hydrochloride salt: mp 149–151°C (EtOH–Et_2O). Anal. calcd. for $C_{13}H_{20}ClN$: C 69.16, H 8.93, N 6.20; found: C 68.93, H 8.87, N 6.32.

*3-(3,4-Dimethoxyphenyl)methyl-1,2,3,4-tetrahydroisoquinoline **17**d*

Crude **16***d* (0.80 g, 2.1 mmol), obtained as above, was dissolved in CH_2Cl_2 (10 mL) and trifluoroacetic acid (2 mL) was added. The resulting solution was allowed to stand at room temperature for 48 h. Additional CH_2Cl_2 (50 mL) was added and the mixture was washed (carefully) with aqueous $NaHCO_3$, dried (Na_2SO_4), and evaporated. Purification by mpc (3% MeOH–CH_2Cl_2, 0.5% NH_4OH) afforded **17***d* (0.48 g, 81%); mp 99–100°C; ir (KBr): 3650–3250 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.57–2.90 (m, 4H), 3.12 (m, 1H), 3.88 (s, 6H), 4.03 (s, 2H), 6.81 (m, 3H), 6.96–7.14 (m, 4H); ms (EI), *m/z* (% relative intensity): 152 (8) $M^+ - C_9H_{10}N$, 132 (100). Anal. calcd. for $C_{18}H_{21}NO_2$(0.2 H_2O): C 75.32, H 7.52, N 4.88; found: C 75.32, H 7.27, N 4.88.

*1,3,4,6,11,11a-Hexahydro-2*H*-benzo[*b*]quinolizine **18***

A solution of **16***b* (0.25 g, 0.77 mmol) in CH_2Cl_2 (10 mL) was treated with trifluoroacetic acid (1 mL) and the resulting mixture was stirred at room temperature for 2 h. The mixture was concentrated in vacuo, saturated $NaHCO_3$ solution was added, and the mixture was extracted three times with EtOAc. The EtOAc extract was washed with water and brine, dried (Na_2SO_4), and evaporated. Purification of the

residue by mpc (5% MeOH–CH_2Cl_2, 0.1% NH_4OH) afforded compound **18** (0.14 g, 94%); mp 42–43°C (lit. (20) mp 46–47°C); HCl salt, mp 252–254°C. Anal. calcd. for $C_{13}H_{18}ClN$: C 69.78, H 8.11, N, 6.26; found: C 69.37, H 8.00, N 6.23.

2,3-Dimethoxy-7,12,12a,13-tetrahydro-5H-dibenzo[b,g]quinolizine ***19***

A suspension of **17***d* (0.10 g, 0.35 mmol) in water (1 mL) was treated with concentrated HCl (3 drops) and 37% aqueous formaldehyde (0.6 mL) and the resulting solution was stirred at 95°C for 1 h. After dilution with water (10 mL), the mixture was basified with NH_4OH and extracted with EtOAc. The EtOAc extract was washed with water and brine, dried (Na_2SO_4), and evaporated. Purification by mpc (3% MeOH–CH_2Cl_2, 0.5% NH_4OH) gave **19** (0.09 g, 89%); mp 176–177°C; ^1H nmr ($CDCl_3$) δ: 2.72 (dd, 1H, J = 5.0, 16.8 Hz), 2.80 (dd, 1H, J = 5.0, 16.8 Hz), 2.92 (dd, 1H, J = 5.0, 16.8 Hz), 3.03 (dd, 1H, J = 5.0, 16.8 Hz), 3.23 (m, 1H), 3.78 (d, 1H, J = 15.5 Hz), 3.82 (d, 1H, J = 15.5 Hz), 3.84 (s, 3H), 3.85 (s, 3H), 3.97 (d, 1H, J = 15.5 Hz), 4.04 (d, 1H, J = 15.5 Hz), 6.55 (s, 1H), 6.58 (s, 1H), 7.10 (m, 4H); ms (EI), *m/z* (% relative intensity): 295 (42)M^+, 164 (100). Anal. calcd. for $C_{19}H_{21}NO_2$: C 77.26, H 7.17, N 4.74; found: C 77.15, H 7.20, N 4.85.

*3-*n*-Butylisoquinoline* ***20***

A solution of dihydroisoquinoline **15***a* (1.0 g, 3.5 mmol) in CH_2Cl_2 (2.5 mL) was treated with trifluoroacetic acid (2.5 mL) and the resulting mixture was stirred at room temperature for 15 min. The solution was concentrated in vacuo and the residue was dissolved in EtOH (20 mL). To this solution was added KOAc (0.98 g, 10 mmol) and I_2 (1.0 g, 4 mmol) and the mixture was heated under reflux for 2 h. The mixture was cooled to room temperature, diluted with aqueous NH_4OH, and extracted with EtOAc. The EtOAc was washed with aqueous $NaHSO_3$, water, and brine, dried (Na_2SO_4), and evaporated. Purification by mpc (2% MeOH–CH_2Cl_2) afforded **20** as a colorless oil. The ^1H nmr spectrum of this material was identical to that reported in ref. 19. The HCl salt had mp 202–203°C (EtOH–Et_2O).

*2-[2-((*tert*-Butoxycarbonyl)aminomethyl)phenyl]-1-(3,4-dimethoxyphenyl)ethanol* ***21***

A solution of anion **2***a*, prepared from **1***a* (0.50 g, 2.26 mmol) in THF (10 mL) as previously described, was treated with a solution of veratraldehyde (0.42 g, 2.49 mmol) in THF (2 mL) at –60°C. The reaction mixture was stirred at that temperature for 30 min and then worked up as usual to afford alcohol **21** (0.58 g, 66%) after mpc (40% EtOAc–hexane); mp 99–100°C; ir (KBr): 3600–3110, 1694 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.45 (s, 9H), 2.15 (br m, 1H, OH), 3.00 (dd, 1H, J = 8.5, 13.9 Hz), 3.10 (dd, 1H, J = 4.7, 13.9 Hz), 3.87 (s, 3H), 3.88 (s, 3H), 4.34 (d, 2H, J = 5.2 Hz), 4.87 (dd, 1H, J = 4.7, 8.4 Hz), 5.09 (br m, 1H,NH), 6.83 (d, 1H, J = 8.7), 6.92 (m, 2H), 7.17–7.32 (m, 4H); ms (EI), *m/z* (% relative intensity): 387 (6)M^+, 221 (9), 167 (100), 166 (73), 139 (24), 104 (50), 57 (34). Anal. calcd. for $C_{22}H_{29}NO_5$: C 68.19, H 7.54, N 3.62; found: C 68.17, H 7.44, N 3.55.

*2-(*tert*-Butoxycarbonyl)-(3-(3,4-dimethoxyphenyl))-1,2,3,4-tetrahydroisoquinoline* ***23***

A solution of **21** (0.25 g, 0.65 mmol) in CH_2Cl_2 (10 mL) was treated with trifluoroacetic acid (0.5 mL) and the resulting mixture was stirred at room temperature for 0.5 h. The usual work-up afforded **25** (0.21 g, 87%) after mpc (30% EtOAc–hexane); mp 58–60°C; ir (neat): 3570–3200, 1690 cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.43 (s, 9H), 3.06 (dd, 1H, J = 3.4, 15.7 Hz), 3.31 (dd, 1H, J = 6.1, 15.8 Hz), 3.68 (s, 3H), 3.78 (s, 3H), 4.23 (d, 1H, J = 16.4 Hz), 4.80 (d, 1H, J = 16.4 Hz), 5.44 (m, 1H), 6.67 (m, 3H), 7.13 (m, 4H); ms (EI), *m/z* (% relative intensity): 369 (21)M^+, 313 (33), 268 (40), 252 (24), 175 (40), 131 (19), 104 (29), 57 (36), 43 (100). Anal. calcd. for $C_{22}H_{27}NO_4$: C 71.52, H 7.37, N 3.79; found: C 71.51, H 7.51, N 3.63.

*2-[2-((*tert*-Butoxycarbonyl)aminomethyl)phenyl]-1,1-diphenylethanol* ***24***

A solution of dianion **2***a*, prepared from **1***a* (1.1 g, 5.0 mmol) in THF (10 mL) as described above, was treated with a solution of benzophenone (1.0 g, 5.5 mmol) in THF (5 mL) at –60°C. The reaction mixture was stirred at –60°C for 30 min and was then allowed to warm to 0°C. The usual work-up afforded alcohol **24** (1.2 g, 60%) after crystallization from hexane; mp 117–118°C; ir (KBr): 3600–3200, 1701 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.42 (s, 9H), 1.95 (br m, 1H, OH), 3.69 (s, 2H), 4.18 (br s, 2H), 4.80 (br m, 1H, NH), 6.63 (d, 1H, J = 7.5 Hz), 6.96 (t, 1H, J = 7.5 Hz), 7.14 (t, 1H, J = 7.5 Hz), 7.25 (m, 7H), 7.37 (m, 4H); ms (EI), *m/z* (% relative intensity): 403 (4)M^+, 347 (5), 312 (5), 269 (7), 221 (12), 183 (100), 165 (45), 105 (38), 104 (33). Anal. calcd. for $C_{26}H_{29}NO_3$: C 77.39, H 7.25, N 3.47; found: C 77.63, H 7.33, N 3.60.

*2-[2-((*tert*-Butoxycarbonyl)aminomethyl)phenyl]-1,1-diphenylethylene* ***25***

A solution of **24** (0.2 g, 0.5 mmol) in CH_2Cl_2 (5 mL) was treated with trifluoroacetic acid (0.75 mL) and the resulting mixture was stirred at room temperature for 15 min. Anhydrous K_2CO_3 (1.0 g), and CH_2Cl_2 (25 mL) were added and the mixture was filtered. Evaporation of the filtrate afforded compound **25** (0.16 g, 83%) after crystallization from hexane; mp 106–108°C; ir (KBr): 3620–3200, 1688 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.40 (s, 9H), 4.34 (d, 2H, J = 5.8 Hz), 4.63 (br m, 1H, NH), 6.88–7.40 (m, 15H); ms (EI), *m/z* (% relative intensity): 385 (26)M^+, 329 (36), 284 (70), 268 (100), 57 (68). Anal. calcd. for $C_{26}H_{27}NO_2$: C 81.00, H 7.06, N 3.63; found: C 81.25, H 7.06, N 3.81.

*1-[(2-((*tert*-Butoxycarbonyl)aminomethyl)phenyl)methyl]cyclohexan-1-ol* ***26***

Condensation of dianion **2***a* with cyclohexanone as described for the preparation of **25** afforded alcohol **26** in 50% yield after crystallization from hexane; mp 82–83°C; ir (KBr): 3600–3200, 1680 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.20 (m, 2H), 1.40–1.65 (m, 9H), 1.45 (s, 9H), 2.81 (s, 2H), 4.40 (br d, 2H, J = 5.0 Hz), 5.20 (br m, 1H, NH), 7.18 (m, 3H), 7.32 (m, 1H). Anal. calcd. for $C_{19}H_{29}NO_3$: C 71.44, H 9.15, N 4.38; found: C 71.47, H 9.21, H 4.52.

Mechanistic studies on diamine oxidase: oxidation of α,ω-diamines does not involve an enamine intermediate[1]

STEPHEN S. GAVIN, ANGELA M. EQUI, AND DAVID J. ROBINS[2]
Department of Chemistry, University of Glasgow, Glasgow G12 8QQ, U.K.

Received June 4, 1993

This paper is dedicated to Professor Ian Spenser

STEPHEN S. GAVIN, ANGELA M. EQUI, and DAVID J. ROBINS. Can. **72**, 31 (1994).

Three β,β,β′,β′-$^2H_4$-labelled α,ω-diamines were synthesized and incubated with pea seedling diamine oxidase. The aminoaldehydes formed by oxidative deamination cyclized to the corresponding imines, which were trapped with benzoylacetic acid. In all three cases the acetophenone derivatives produced were shown by NMR and mass spectrometry to contain four deuterium atoms. The retention of all four deuterium atoms demonstrates that oxidative deamination of α,ω-diamines catalyzed by pea seedling diamine oxidase does not involve an enamine intermediate as previously suggested.

STEPHEN S. GAVIN, ANGELA M. EQUI et DAVID J. ROBINS. Can. **72**, 31 (1994).

On a synthétisé trois β,β,β′,β′-$^2H_4$-α,ω-diamines et on les a incubées avec de la diamine oxydase de la semence de pois. Les trois aminoaldéhydes qui se forment par désamination oxydante se cyclisent en imines correspondantes que l'on peut piéger à l'aide d'acide benzoylacétique. Dans les trois cas, on a démontré, par RMN et par spectrométrie de masse, que les dérivés acétophénones qui se forment contiennent toutes quatre atomes de deutérium. La rétention des quatre atomes de deutérium démontre que, contrairement à ce qui avait été suggéré antérieurement, la désamination oxydante des α,ω-diamines catalysée par la diamine oxydase de la semence de pois n'implique pas d'intermédiaire énamine.

[Traduit par la rédaction]

Introduction

Decarboxylation of basic α-amino acids such as ornithine and lysine followed by the oxidative deamination of the resulting diamines, putrescine (**1**) and cadaverine (**2**), respectively, are key steps in amino acid metabolism and the biosynthesis of many alkaloids (1). Naturally occurring polyamines such as **1** also have an important function in the control of growth and proliferation processes (2). Putrescine is formed by decarboxylation of L-ornithine catalyzed by L-ornithine decarboxylase. The stereochemistry of this process was studied by several groups of workers (3–7). An analogous process operates on the homologue L-lysine, which leads to cadaverine on decarboxylation with L-lysine decarboxylase. Again this process was shown to proceed with retention of configuration (6–9). The next step in the metabolism of the diamines **1** and **2** is oxidative deamination to the corresponding aldehydes **5** and **6** catalyzed by diamine oxidase (DAO, EC 1.4.3.6) (Scheme 1). The stereochemistry of these processes was studied extensively by Spenser and co-workers (3, 10) and by other groups of workers (9, 11). DAO catalyses the removal of the 1-*pro-S* hydrogen from **1** and **2**.

A series of *N*-alkylputrescines was tested as substrates of DAO by Frydman et al. (12). With the surprising exception of *N*-methylputrescine, these diamines were shown to be oxidized to the corresponding aminoaldehydes. We repeated this work using an improved kinetic assay procedure, and demonstrated that *N*-methylputrescine was in fact a good substrate for pea seedling and pig kidney DAO (13). A range of derivatives of **1** and **2** was synthesized and assayed as substrates for these DAOs by several groups (14–16). Recently we obtained enzyme kinetic data for the DAO-catalyzed oxidation of α,ω-diamines with chain lengths ranging from 2 to 12. The highest V_{max} values were observed for chain lengths of 5 (**2**), 4 (**1**), and 6 (**3**), which together with the K_m data suggested that after initial attachment of one end of the substrate to the enzyme, the other end might also become attached to the enzyme thus creating a cyclic conformation (17). In their work on DAO, Frydman et al. (12) noted that 1,3-dimethylputrescine was a very poor substrate for the pea seedling and pig kidney DAO. They suggested that oxidation of putrescine (**1**) proceeds via an enamine intermediate (**4**) formed by abstraction of hydride from C-2 of putrescine (presumably tautomerism and hydrolysis of the resulting imine then produces the aldehyde). They postulated that 1,3-dimethylputrescine sterically hinders the formation of the enamine intermediate (**4**) thus accounting for its poorness as a substrate for DAO. We decided to test this hypothesis by preparing some α,ω-diamines containing deuterium labels at appropriate positions, so that the loss or retention of deuterium in the diamines during oxidative deamination catalyzed by DAO could be followed by NMR and mass spectrometry.

Results and discussion

DAO can be easily isolated and partially purified from pea seedlings (18). The cyclic imine **7** generated by the DAO-catalyzed oxidation of putrescine (**1**) can be trapped by reaction with benzoylacetic acid to form the substituted acetophenone **8**, which can be isolated and characterized (Scheme 1) (19). The corresponding derivatives (**9** and **10**) were also prepared for spectroscopic characterization (15, 20, 21). Three different ^2H-labelled α,ω-diamines were prepared for this study of the mechanism of DAO action. [2,2,3,3-$^2H_4$]Putrescine (**11**) dihydrochloride containing 98 ± 2% $^2H_4$ was made from succinonitrile by exchanging the protons for deuterium atoms followed by reduction and acidification in a modification of a published procedure (22). Samples of [2,2,4,4-$^2H_4$]cadaverine (**12**) dihydrochloride and [2,2,5,5-$^2H_4$]-1,6-diaminohexane (**13**) dihydro-

[1]This paper is dedicated to Professor Ian Spenser, an acknowledged expert in the determination of the stereochemistry of enzymic reactions and the elucidation of biosynthetic pathways to alkaloids. For several years our two groups published almost simultaneously but independently on the same aspects of the biosynthesis of pyrrolizidine and quinolizidine alkaloids and his thoroughness and attention to detail were always most impressive.

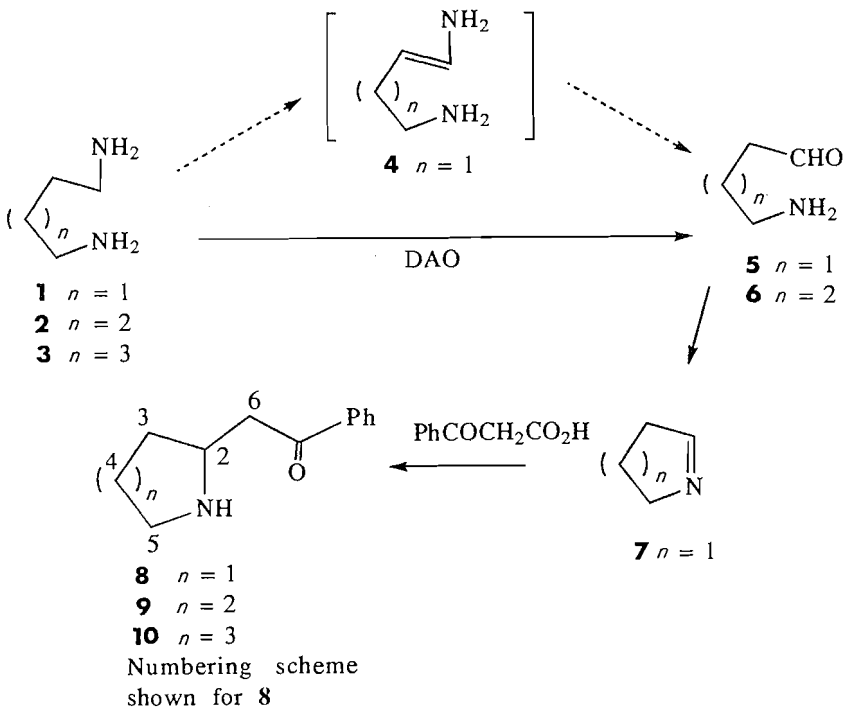

SCHEME 1

chloride were prepared in an analogous manner with $^2H_4$ contents of 96 ± 2% and 93 ± 2%, respectively.

Incubation of the tetradeuteriated putrescine (**11**) with DAO for one day at pH 7 in phosphate buffer in the presence of catalase and benzoylacetic acid gave 2-pyrrolidin-2-ylacetophenone in 76% yield. The product was purified by preparative TLC and the purity was checked by HPLC. The $^2H_4$ content of this product (**14**) was estimated to be 96 ± 2% by analysis of the integrals for the protons in the ^1H NMR spectrum of **14**. The signals observed for the protons at the 3- and 4-positions in **8** were barely visible in the ^1H NMR spectrum of **14** at δ1.3–1.9 and the protons at the 5-position of **14** were observed as an AB system. The signals for the 2-H and the 6-H protons were also greatly simplified to an ABX system. Furthermore, in the ^2H NMR spectrum of **14** four separate signals each with about the same intensity were observed. Finally, in unlabelled **8**, peaks were visible in the mass spectrum at *m/e* 190 and 189 (M^+), whereas in the labelled product (**14**) the major isotopic species were at *m/e* 194 and 193.

When the tetradeuteriated cadaverine (**12**) dihydrochloride was treated with DAO in a similar fashion, the corresponding piperidinylacetophenone (**15**) was obtained in 70% yield. Comparison of the ^1H NMR spectra of labelled and unlabelled material indicated that the $^2H_4$ content of **15** was 97 ± 2%. The protons at the 4-position in **15** were present as an AB system and signals for the 3-H and 5-H protons were absent. Signals for the remaining five protons overlapped each other. Four separate signals were observed with approximately the same intensity in the ^2H NMR spectrum of **15**. The mass spectrum of **15** in the molecular ion region contained peaks that were four mass units higher than those in the unlabelled material (**9**).

Finally incubation of [2,2,5,5-$^2H_4$]-1,6-diaminohexane (**13**) dihydrochloride with DAO as in the previous two cases afforded a sample of the seven-membered derivative (**16**) in 75% yield. The region δ 1.0–1.6 in the ^1H NMR spectrum of **16** integrated for four protons compared to eight in the corresponding spectrum for **10**. The ^2H NMR spectrum of **16** contained a broad unresolved band at δ 1.0–1.8. The $^2H_4$ content of **16** was estimated to be 94 ± 2% and comparison of the mass spectra of **10** and **16** in the molecular ion region confirmed the presence of the $^2H_4$-labelled species.

Thus enzyme-catalyzed oxidative deamination of specifically tetradeuteriated samples of **11**, **12**, and **13** by pea seedling DAO and trapping of the products using benzoylacetic acid produces acetophenone derivatives **14**, **15**, and **16**, which are almost entirely tetradeuteriated. Indeed no loss of deuterium was detected in any of these conversions within experimental error. From these results it is clear that oxidation of α,ω-diamines catalyzed by DAO cannot involve an enamine intermediate. (Observation of overall retention of deuterium by removal of deuteride from C-2 of the diamine and replacement of C-2 by the same deuterium in protonated form during tautomerism of the enamine (**4**) to the imine does not seem a likely process.)

Experimental

Melting points were measured with a Kofler hot-stage apparatus and are uncorrected. Organic solutions were dried with anhydrous Na_2SO_4, and solvents were removed under reduced pressure below 40°C. NMR spectra were obtained on a Bruker WP200-SY spectrometer operating at 200 MHz for ^1H, 50 MHz for ^{13}C, and 30.72 MHz for ^2H. EIMS were obtained on Kratos MS 12 or MS 902 instruments. Thin-layer chromatography was carried out on silica gel GF_{254} plates of 0.25 mm thickness developed with chloroform–methanol–concentrated ammonia (80:19:1), and the bases were located by the modified Dragendorff reagent (23). HPLC was performed on a Spectra-Physics SP8800 system with a reverse phase 5 μm ODS-Hypersil column (150 × 4.6 mm) using MeOH–H_2O (70:30) and a flow rate of 3.5 mL min^{-1}.

General procedure for the synthesis of [$^2H_4$]-labelled dinitriles

Deuterium oxide (35 mL, 99.3 at.% ^2H), 1,4-dioxane (10 mL), and diazabicyclo[5.4.0]undec-7-ene (364 mg, 4.56 mmol) were added to

the dinitrile (45.6 mmol). The mixture was stirred and heated at reflux for 24 h. The reaction mixture was cooled and the solvent was removed in vacuo to yield an amorphous solid. The solid was dissolved in 1 M HCl and the acidic solution was extracted with chloroform (5 × 25 mL). The organic extracts were dried (Na_2SO_4), filtered, and the solvent was removed in vacuo to yield an amorphous white solid, which was recrystallised from hot benzene. This process was repeated to obtain [$^2H_4$] incorporations of 93–98%.

[2,2,3,3-$^2H_4$]Succinonitrile: 2.87 g (75%); IR ($CHCl_3$) ν: 3010, 2250, 1460, 1070 cm^{-1}; ^{13}C NMR ($CDCl_3$) δ: 116.4 (2 × CN) ppm; MS *m/e(I)*: 84 (M^+) (6), 82 (15), 56 (100), 54 (68), 42 (66). HRMS, Exact Mass calcd. for $C_4D_4N_2$: 84.0625; found: 84.0617.

[2,2,4,4-$^2H_4$]Glutaronitrile: 3.22 g (72%); IR ($CHCl_3$) ν: 2990, 2880, 2250, 1450, 1050 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.15 (s, 2H) ppm; ^{13}C NMR ($CDCl_3$) δ: 33.1 (CH_2), 116.4 (2 × CN) ppm; MS *m/e(I)*: 98 (M^+) (6), 96 (8), 70 (100), 46 (65), 38 (75), 28 (64). HRMS, Exact Mass calcd. for $C_5H_2D_4N_2$: 98.0782; found: 98,0780.

[2,2,5,5-$^2H_4$]Adiponitrile: 3.57 g (70%); IR ($CHCl_3$) ν: 3005, 2990, 2250, 1450, 1070 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.80 (s, 4H) ppm; ^{13}C NMR ($CDCl_3$) δ: 27.7 (2 × CH_2), 116.4 (2 × CN) ppm; MS *m/e(I)*: 112 (M^+) (6), 110 (1), 86 (9), 61 (69), 55 (60), 44 (100), 28 (75). HRMS, Exact Mass calcd. for $C_6H_4D_4N_2$: 112.0939; found: 112.0940.

General procedure (24) for the synthesis of [$^2H_4$]-labelled diamine dihydrochloride salts

An oven-dried flask containing a septum-capped inlet and a magnetic stirring bar was equipped with a 12-in. Vigreux column. The flask was charged with the [$^2H_4$]-labelled dinitrile (15 mmol) and dry THF (1.5 mL) and brought to reflux under an atmosphere of nitrogen. Then borane – dimethyl sulphide complex in THF (16 mL, 32 mmol) was added dropwise over a period of 10 min. The dimethyl sulphide distilled off and was collected. This gave a clear residue, which was left for 15 min and then allowed to cool to room temperature. 6 M HCl (18 mL, 41 mmol) was added dropwise. The reaction mixture was then heated under reflux for 30 min. The resultant clear solution was cooled to 0°C giving a white precipitate (boric acid). The solution was filtered, and the filtrate was concentrated to approximately 5–10 mL giving a second precipitate of boric acid. The solution was again filtered, and the filtrate was evaporated to dryness giving a creamy white solid of diamine dihydrochloride. The solid was crystallized from 95% aqueous ethanol.

*[2,2,3,3-$^2H_4$]Putrescine (**11**) dihydrochloride:* 1.36 g (55%); IR (KBr disc) ν: 3075, 3025, 2010, 1605, 1473, 1395, 1335, 1170, 1145 cm^{-1}; ^1H NMR (D_2O) δ: 2.85 (br s 4H) ppm; ^{13}C NMR (D_2O, dioxane) δ: 23.9 (quintet, 2 × CD_2), 39.6 (2 × CH_2) ppm. Anal. calcd. for $C_4H_{10}D_4N_2Cl_2$: C 29.10, H 6.12, D 4.87, N 16.97%; found: C 29.08, H 6.20, D 4.90, N 16.98%.

*[2,2,4,4-$^2H_4$]Cadaverine (**12**) dihydrochloride*: 1.61 g (60%); IR (KBr disc) ν: 3080, 2000, 1600, 1475, 1160, 1145 cm^{-1}; ^1H NMR (D_2O) δ: 1.25 (br s 2H), 2.79 (br s, 4H) ppm; ^{13}C NMR (D_2O, dioxane) δ: 23.1 (C-3), 26.3 (quintet, C-2 and C-4), 39.8 (C-1 and C-5) ppm. Anal. calcd. for $C_5H_{12}D_4N_2Cl_2$: C 33.52, H 6.70, D 4.47, N 15.64%; found: C 33.61, H 6.73, D 4.48, N 15.72%.

*[2,2,5,5-$^2H_4$]-1,6-Diaminohexane (**13**) dihydrochloride:* 1.65 g (57%); IR (KBr disc) ν: 3080, 3020, 2000, 1600, 1475, 1175, 1145 cm^{-1}; ^1H NMR (D_2O) δ: 1.25 (s, 4H), 2.83 (s, 4H) ppm; ^{13}C NMR (D_2O, dioxane) δ: 25.7 (C-3 and C-4), 26.6 (quintet, C-2 and C-5), 40.1 (C-1 and C-6) ppm. Anal. calcd. for $C_6H_{14}D_4N_2Cl_2$: C 37.31, H 7.25, D 4.14, N 14.51%; found: C 37.30, H 7.26, D 4.02, N 14.54%.

Benzoylacetic acid

This was prepared as described (19) (75%) and used without purification; IR (Nujol) ν: 2500–3100 (acid OH), 1750 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.99 (s, 2H), 7.35–7.55 (m, 3H), 7.95 (dd, 2H) ppm.

General procedure for oxidative deamination of diamines using diamine oxidase and the subsequent coupling with benzoylacetic acid (19)

A solution of benzoylacetic acid (320 mg, 1.96 mmol), diamine dihydrochloride (0.1 M aqueous solution, 20 mL), and 0.02 M sodium phosphate buffer (pH 7, 7 mL) was prepared. The pH was adjusted to 7. Catalase (0.2 mg) and pea seedling DAO purified to step four (18) (300 μL, enzyme activity ca. 1200 units per mg) were added. The solution was incubated on a shaker at 25°C for 24 h. The pH of the reaction mixture was monitored and readjusted to neutrality as necessary. The solution was then acidified with dilute sulphuric acid and washed with diethyl ether (4 × 30 mL). The aqueous solution was basified with concentrated ammonia and extracted with chloroform (3 × 30 mL). The combined organic extracts were dried (Na_2SO_4), filtered, and evaporated to dryness under reduced pressure to yield an oily product. The products were purified by preparative TLC and the purity of each isolated product was checked by HPLC.

*2-Pyrrolidin-2-ylacetophenone (**8**) (19):* 229 mg (61%) (from putrescine dihydrochloride), R_f 0.40, R_t 2.85 min, IR (film) ν: 3680, 3020, 2400, 1680, 1635, 1600, 1525, 1215 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.30–1.90 (m, 4H), 2.35 (br s, NH), 3.0–3.7 (m, 5H), 7.35–7.60 (m, 3H), 7.93 (dd, 2H) ppm; ^{13}C NMR ($CDCl_3$) δ: 23.9 (C-4),30.7 (C-3), 41.9 and 45.1 (C-5 and C-6), 55.2 (C-2), 128.1 (2 × Ar-C), 128.6 (2 × Ar-C), 133.4 (Ar-C), 136.2 (Ar-C), 197.7 (C=O) ppm; MS *m/e(I)*: 190 ($M^+ + 1$) (4), 189 (M^+) (28), 188 ($M^+ - 1$) (9), 170 (19), 105 (45), 84 (21), 70 (100). HRMS, Exact Mass calcd. for $C_{12}H_{15}NO$: 189.1154; found: 189.1155.

*2-Piperidin-2-ylacetophenone (**9**) (15):* 350 mg (87%) (from cadaverine dihydrochloride), R_f 0.43, R_t 2.73 min, IR (film) ν: 3690, 3020, 2400, 1685, 1600, 1520, 1215, 1020, 930 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.3–1.75 (m, 6H), 2.68 (m, 1H), 3.03–3.14 (m, 4H), 3.43 (br s, NH), 7.35–7.51 (m, 3H), 7.92 (dd, 2H) ppm; ^{13}C NMR ($CDCl_3$) δ: 24.4 (C-4), 25.5 (C-5), 32.1 (C-3), 45.0 and 46.6 (C-6 and C-7), 52.8 (C-2), 128.0 (2 × Ar-C), 128.5 (2 × Ar-C), 133.2 (Ar-C), 136.8 (Ar-C), 199.1 (C=O) ppm; MS *m/e(I)*: 204 ($M^+ + 1$) (3), 203 (M^+) (18), 202 ($M^+ - 1$) (25), 186 (3), 105 (53), 98 (10), 84 (100), 77 (26), 43 (57). HRMS, Exact Mass calcd. for $C_{13}H_{17}NO$: 203.1310; found: 203.1289.

*2-Hexahydroazepin-2-ylacetophenone (**10**) (15):* 213 mg (50%) (from 1,6-diaminohexane dihydrochloride), R_f 0.40, R_t 2.70 min, IR (film) ν: 3670, 3010, 2395, 1680, 1600, 1515, 1215, 1015, 925 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.9–1.6 (m, 8H), 2.09 (br s, NH), 2.3–2.7 (m, 3H),

Photochemistry of a model lignin compound. Spin trapping of primary products and properties of an oligomer

L.R.C. BARCLAY,[1] G.R. CROMWELL, AND J.W. HILBORN

Department of Chemistry, Mount Allison University, Sackville, NB Canada E0A 3C0

Received April 21, 1993

This paper is dedicated to Professor David B. MacLean

L.R.C. BARCLAY, G.R. CROMWELL, and J.W. HILBORN. Can. J. Chem. **72**, 35 (1994).

α-Guaiacoxylacetoveratrone, 1, was selected as a model of a lignin structure component for photolysis and free radical spin trapping studies. The 3,4-dimethoxyphenacyl radical, Ar-COĊH$_2$, 2, thermally generated from α-bromoacetoveratrone with trimethyltin, was spin trapped by phenyl-*tert*-butylnitrone (PBN), and the spin-trapped radical identified by ESR and mass spectroscopy. Spin trapping by PBN of radical photoproducts from 1 gave a mixture of trapped radicals, according to ESR. These were separated as their hydroxylamines and identified by liquid chromatography/mass spectroscopy (LC/MS) under chemical ionization (CI) conditions. This LC/MS (CI) method identified the same phenacyl fragment, 2 (reduced), as well as a fragment tentatively attributed to a spin-trapped guaiacoxyl radical, chemically reduced to the hydroxylamine. Extended direct photolysis of 1 yields colored paramagnetic oligomers. The synthesis of 1-(3,4-dimethoxyphenyl)-2-(4-hydroxy-3-methoxyphenyl-ethanone(10), a rearranged, recombination photoproduct of 1, is described. A pathway for formation of oligomers as unstable dimers of 10 is presented.

L.R.C. BARCLAY, G.R. CROMWELL et J.W. HILBORN. Can. J. Chem. **72**, 35 (1994).

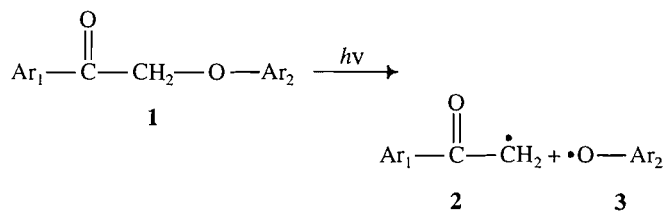
On a choisi l'α-guaïacoxylacétovératrone, **1**, comme modèle d'un composant de la structure de la lignine pour des études de photolyse et de piégeage de spin de radicaux libres. On a piégé le radical 3,4-diméthoxyphénacyle (Ar-COĊH$_2$, **2**), obtenu d'une façon thermique à partir de l'α-bromoacétovératrone et du triméthylétain, par la phényl-*tert*-butylnitrone (PBN) et on a identifié le radical piégé par RPE et par spectrométrie de masse. Selon la RPE, le piégeage de spin par le PBN des photoproduits radicalaires du composé **1** conduit à des mélanges de radicaux piégés. On les a séparé sous la forme d'hydroxylamines et on les a identifiés par chromatographie liquide/spectrométrie de masse (CL/SM) dans des conditions d'ionisation chimique (IC). Ce méthode de CL/SM (IC) a permis d'identifier le même fragment phénacyle, **2**, réduit, ainsi qu'un fragment attribué d'une façon préliminaire à un radical guaïacoxyle piégé, réduit chimiquement en hydroxylamine. Une photolyse directe plus longue du composé **1** fournit des oligomères paramagnétiques colorés. On décrit la synthèse de la 1-(3,4-diméthoxyphényl)-2-(4-hydroxy-3-méthoxyphényl)éthanone (**10**), un photoproduit de recombinaison réarrangé du produit **1**. On présente une voie possible pour la formation d'oligomères comme dimères instables du composé **10**.

[Traduit par la rédaction]

Introduction

Lignin is structurally a very complex polymer; however, known structural units are involved. Consequently, monomeric compounds, such as α-guaiacoxylacetoveratrone (**1**) and similar compounds, have been studied by different groups (1–6) as appropriate models for the photochemistry of lignin-type molecules, since they contain some structural features common in lignin. The chemistry of free radicals from photolysis of model lignin compounds like **1** is expected to provide important insights into the nature and inhibition of undesirable photoyellowing of papers from mechanical wood pulps containing lignin.

Considerable evidence on the photochemistry of lignin-type models like **1** supports a mechanism involving homolytic β-cleavage to give carbon and phenoxyl radicals (e.g., **2** and **3**; see Scheme 1). There is recent evidence to show that the photoyellowing process is linked to free radical autoxidation induced by initially formed carbon-centred and (or) phenoxyl radicals (7). The inhibition of photoyellowing has traditionally concentrated on the inhibition of processes subsequently initiated by radical reactions (8). On the other hand, it should be possible to *trap* the radicals initially formed *before* further reactions occur. This paper reports on our initial results using compound **1** as a model system chosen because information is available on its photochemistry.



Ar_1 = 3,4-dimethoxyphenyl; Ar_2 = 2-methoxyphenyl

SCHEME 1

The objectives of this study are (1) to determine if spin trapping by phenyl *tert*-butylnitrone (PBN) can be used to intercept radicals initially formed such as **2** and **3** before radical rearrangements and (or) recombinations occur; (2) to study the properties of colored oligomers, which also form on photolysis of **1** (1–3), and (3) to synthesize a phenolic rearranged-recombination isomer of **1** and study how its free radical chemistry is related to colored oligomers and presumably to the photoyellowing of lignin itself.

Results

1. Spin trapping the 3,4-dimethoxyphenacyl radical (**2**)

(a) Thermal generation of 2. Characterization of the spin adduct by LC/MS

We are unaware of any previous spin trapping studies of phenacyl-type radicals. Consequently, it was desirable to explore the spin trapping method using PBN on phenacyl and

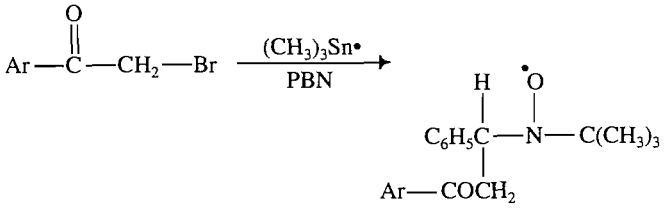
3,4-dimethoxyphenacyl (**2**) radicals that were generated thermally. For this independent characterization of the PBN-trapped **2** radical, we first generated type **2** radicals by bromine atom abstraction from α-bromoacetophenone and α-bromoacetoveratrone using photochemically generated trimethyltin radicals (9) in the presence of the spin trap, PBN. Photolyses of equimolar mixtures of hexamethylditin, α-bromoacetophenone (or α-bromoacetoveratrone), and PBN results in a typical 1:1:1 triplet of doublets identical for both systems with a_N = 14.8 G, a^{β}_H = 4.6 G, and g = 2.0059, and assigned to the phenacyl (or 3,4-dimethoxyphenacyl)-PBN radicals, **4**, **5**



4 Ar = C_6H_5-
5 Ar = 3,4-dimethoxyphenyl

The mixture from the spin trapping experiment was separated by PREP-TLC using 95:5 V/V methylene chloride – ethyl acetate and the paramagnetic component, located at R_f = 0.35, showed the typical ESR spectrum when subjected to LC/MS analysis. The major component at t_R = 1.57 min gave the MS shown in Fig. 1. This spectrum is consistent with the assigned structure for the 3,4-dimethoxyphenacyl-PBN radical (**5**). The highest mass ion observed, m/z = 357, isthe protonated molecular ion $[M + H]^+$. Such $[M + H]^+$ ions are common in LC/MS using protic solvents due to proton transfer from the solvent (10). Significant fragment ions and assignments are m/z = 269 (5.2%), $C_6H_5\overset{(+)}{C}HCH_2COC_6H_3(OCH_3)_2$; m/z = 180 (33%), $(CH_3O)_2C_6H_3\overset{(+)}{C}OCH_3$; m/z = 165 (100%), $(CH_3O)_2C_6H_3\overset{(+)}{C}O$; and m/z = 77 (36%), $C_6H_5^{(+)}$.

(b) Spin trapping during photolysis of α-guaiacoxylacetoveratrone (1)

Photolysis in benzene of a 4:1 molar ratio of **1** to PBN at 254 nm (where the respective molar absorptivities are 3800 and 2500) resulted in an intense ESR signal. The spectrum appears to contain a mixture of radicals, the major component having the same properties (measured a_N = 14.8 G, a^{β}_H = 4.6 G, g = 2.0059) as the 3,4-dimethyoxyphenacyl-PBN radical trapped above in (*a*). Attempts to separate the component radicals by TLC for LC/MS characterization were not successful.

The spin trapping experiment during photolysis of **1** was repeated and hydrazobenzene was added to the ESR sample. This immediately quenched the ESR signals. The products were separated by PREP-TLC as before in (*a*). Two new bands were separated, at R_f = 0.33 and 0.25. The former band (R_f = 0.33) was extracted into benzene and a portion of this extract treated with PbO_2. The resulting ESR spectrum was identical to that of the original 3,4-dimethoxyphenacyl-PBN (3,4-DMP-PBN) trapped radical. The remainder of this benzene extract was analyzed by LC/MS in the chemical ionization (CI) mode using methane as the ionization gas. This produced only two major peaks in the spectrum. A peak at m/z = 359 corresponds to the

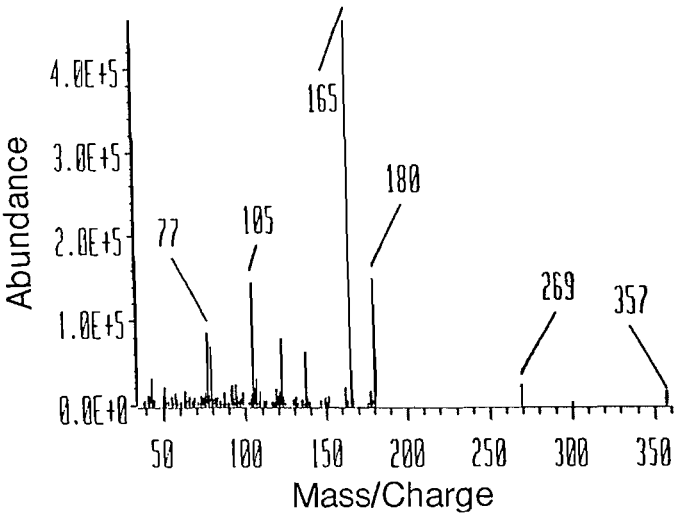


FIG. 1. Particle beam LC/MS spectrum of separated paramagnetic component from photolysis of α-bromoacetoveratrone with PBN and hexamethylditin in benzene.

$[M + 2H]^+$ ion, assigned to the parent [3,4-DMP-PBN-OH + $2H]^+$, and one at m/z = 181 assigned to the $[3,4\text{-DMP} + 2H]^+$ fragment ion. The LC/MS (CI) analysis of the second TLC band (R_f 0.25) also showed only two peaks, at m/z = 303 and 125. The peak at m/z = 303 corresponds to a trapped [quaiacoxyl-PBN-OH + $2H]^+$ species and the peak at m/z = 125 corresponds to a fragmentation forming an ionized guaiacoxyl fragment $[CH_3OC_6H_5OH + H]^+$ and a neutral PBN-OH fragment.

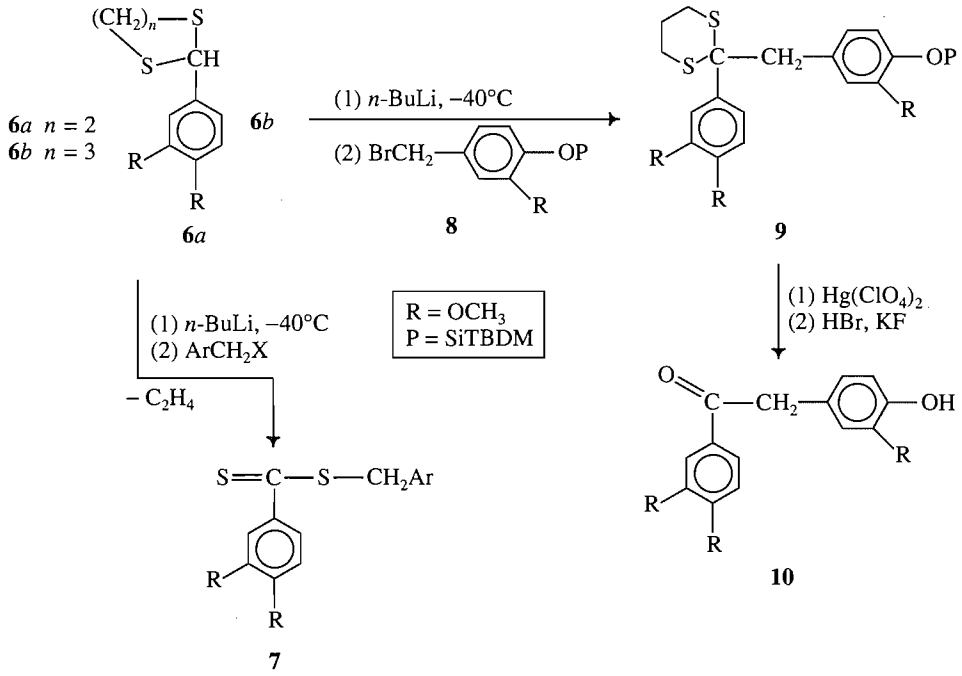
2. Oligomer formation from the photolysis of 1

Extended photolysis of **1** was carried out to obtain sufficient amounts of oligomeric material for analyses. For example, irradiation of a 7.45 × 10^{-3} M solution of **1** in benzene for 6 days gave a yellow-orange solution. Chromatography of the crude product on silica gel separated starting material **1** and other known compounds (6) in early fractions. Oligomeric material was isolated from a strongly adsorbed dark red band, which typically yielded 23 wt.% of a brown solid.

Oligomers have been reported before from the photolysis of **1** (1–3). It is not clear, however, if the same type of oligomer is formed from photolysis of **1** by different methods. The most prominent property of the oligomer formed in this photolysis of **1** is its strong and persistent paramagnetism, which has not been reported on previously. It exhibits a broad, single ESR signal in both the solid state and in solution. The signal intensity increases on ultraviolet irradiation but the signal does not decay entirely even on long standing. The g value (2.0036) is consistent with a radical on carbon adjacent to oxygen. Attempts to obtain resolved ^1H or ^{13}C NMR spectra were unsuccessful due to the strong paramagnetism. Other properties of this oligomer are outlined in Table 1.

3. Synthesis of a phenolic isomeric recombination compound of 1. Oligomer formation

The unusual paramagnetic properties of the oligomer can be accounted for by a structure formed from a weakly bonded dimer of a phenolic recombination product from **1** that readily dissociates into phenoxyl radicals. This postulate is consistent with the (GPC) molecular weight (a dimer requires 604), and



SCHEME 2

TABLE 1. Properties of oligomer from photolysis of α-guaiacoxylacetoveratrone (**1**)

Color:	Light-brown solid, red solution in benzene
Melting point:	196–200°C
Mol.Wt.:	622, number average from GPC[2]
Mass spectrum:	base peak at m/z = 165, under EI conditions, 3,4-$(CH_3O)_2C_6H_3{}^+CO$ fragment, the highest mass observed (using isobutaneCI) at m/z = 359 [fragment + H], peak at m/z = 303, assigned to "phenolic fragment" + H (see Part 3 below)
Infrared spectrum (KBr):	3423 cm^{-1} (broad) -OH (H-bonded), 1670 C=O (conjugated), 1595 and 1515 (aromatic), 1269 (strong) -O-CH_3

the spectroscopic properties (Table 1). The mass spectrum did not show a parent ion. However, the base peak under chemical ionization conditions (i-C_4H_9) at m/z = 303 is attributed to [fragment + H]$^+$ where the [fragment] is assigned to dissociation of the "dimer". We therefore undertook a complete synthesis of a phenolic isomeric recombination compound of **1**, 1-(3,4-dimethoxyphenyl)-2-(4-hydroxy-3-methoxyphenyl)ethanone (**10**), Scheme 2, to study its free radical chemistry, in particular its relationship to oligomer formation

Our initial attempts on the synthesis of **10** starting with the 3,4-dimethoxyphenyldithiolane **6***a*, resulted instead in formation of an interesting side product, the 3,4-dimethoxydithiobenzyl ester **7**, as the only new compound in 55% isolated yield. The reported Friedel-Crafts method for the synthesis of **10** (2) was not successful in our hands.

A successful synthesis of **10** was accomplished by starting with 2-(3,4-dimethoxyphenyl)-1,3-dithiane (**6***b*). The carbanion generated from **6***b* was reacted with 4-[(*tert*-butyldimethylsilyl)oxy]-3-methoxybenzyl bromide (**8**) to give the diprotected compound (**9**) in 70% yield. Removal of the protecting groups in two steps yielded the desired phenol, **10**, in 60% yield from **9**.

The synthetic phenol (**10**) gave the expected spectroscopic properties (Experimental, Preparation of **10**), and it appears to be the same as the compound reported by Castellan and coworkers (2). Solutions of this phenol rapidly became colored (orange-red) on exposure to air and light. Treatment of a benzene solution of **10** with the thermal azo initiator di-*tert*-butylhyponitrite (DBHN) at 37°C gave an orange solution that exhibited a broad persistent ESR signal similar to that observed for the oligomer, and TLC on the product mixture from **10** contained material with the same R_f as the oligomer formed on photolysis of **1**. Irradiation of a solution of **10** in benzene also gave the same persistent signal. ESR spectra of the oligomer and photolysis of **10** are given in Fig. 2.

Discussion

1. Spin trapping and mass spectroscopy analyses

The spin trapping of thermally generated 3,4-dimethoxyphenacyl radical, **2**, indicates that the PBN trapping competes against other known reactions such as rearrangement–decarbonylation, well known for phenacyl itself (11, 12), and recombination reactions (6). On the other hand, photolysis of **1** in the pressence of PBN gave a mixture of trapped radicals according to ESR studies. Evidence from the LC/MS(CI) of the reaction mixture separated after hydrazobenzene reduction together with regeneration of the same ESR spectrum on lead dioxide oxidation demonstrates that the substituted phenacylradical, **2**, is also spin trapped under photolysis conditions.

The LC/MS spectrum (Fig. 1) of the spin-trapped 3,4-DMP-PBN radical (**5**) provides a useful confirmation of its structure.

[2]The gel permeation chromatography was carried out at the PAPRICAN Laboratory, Pointe Claire, Quebec. The value of 622 is known to be high due to adsorption onto the gel.

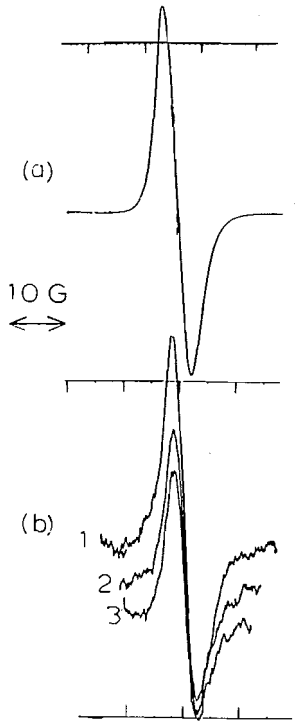

FIG. 2. ESR spectra: (*a*) oligomers separated from photolysis of **1**; (*b*) from irradiation of synthetic phenol, **10**, in ESR probe; 1, signal with light on; 2, light off; 3, light off 1.5 h; spectra recorded in benzene.

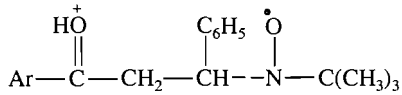
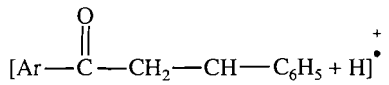
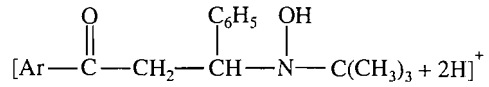
The parent ion was observed as $[M + H]^+$ at $m/z = 357$. We can assign this to the protonated parent molecule



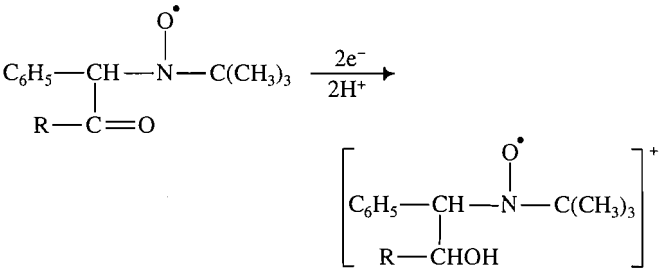
Then the peak at $m/z = 269$ is assigned to fragmentation giving



due to loss of $(CH_3)_3CNO$. The peak at $m/z = 180$ is attributed to fragmentation giving $[(CH_3O)_2\text{-}C_6H_3\text{-}COCH_2 + H]^+$ and that at $m/z = 165$ (the base peak) to $(CH_3O)_2\text{-}C_6H_3\text{-}CO^+$. The fragment at $m/z = 105$ could not be assigned with certainty but is probably due to fragmentation and rearrangement giving the $C_6H_5\text{-}\overset{H}{\overset{+}{C}}CH_3$ ion. Although we were unable to separate the *initial* mixture of trapped radicals from photolysis of **1** with PBN for mass spectroscopic analysis, the derived hydroxylamines were separated by preparative TLC. Their mass spectra obtained under "softer" CI conditions, using methane as the ionization gas, were remarkably simple. The component corresponding to spin trapping of the 3,4-dimethoxyphenacyl radical (established by PbO_2 oxidation back to the radical observed before) now gave only two major peaks in the higher mass range, at $m/z = 359$ and 181. The peak at $m/z = 359$ is assigned to the parent molecule

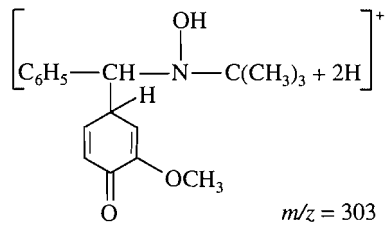


Ions corresponding to $[M + 2H]^+$ may appear unusual but they have been observed before in such LC/MS as those of nucleotide bases (13) and, more significantly to this study, in ion–molecule reactions of acyl spin adducts of PBN as proposed below (14):[3]



In our case, the fragment at $m/z = 181$ is assigned to $[(CH_3O)_2\text{-}C_6H_3\text{-}COCH_2 + 2H]^+$.

The LC/MS under CI conditions of the second component can be attributed to spin trapping and reduction of a PBN-trapped guaicoxyl radical, such as:

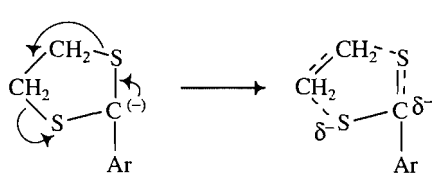


$m/z = 303$

In this event, the fragment at $m/z = 125$ corresponds to a fragment ion of the type $[CH_3OC_6H_4OH + H]^+$. There does not appear to be a precedent for spin trapping of phenoxyl radicals so these assignments are tenuous until independent evidence is obtained.

*2. The recombination phenolic compound (**10**) and colored oligomer formation*

Initial attempts to synthesize the phenolic compound, **10**, from the 1,3-dithiolane, ***6a***, resulted instead in an unexpected fragmentation reaction (Scheme 1). We suggest that the facile (–40°C) elimination of ethylene occurs via a stabilized cyclic six-electron transition state, for example:



followed by nucleophilic displacement of the resulting dithiobenzoate anion on added benzyl halide. We were unaware initially that a similar reaction had been reported for a synthesis

[3] This equation does not imply the mechanism for the ion–molecule reaction.

of aromatic dithioesters (15, 16). However, the procedure used before (15) involved elevated temperatures (150°C) over an extended time. Our results indicate that dithiobenzyl ester can be prepared under much milder conditions. It is expected that the dithiane protecting group in a six-membered ring (**6***b*, $n = 3$) would resist this elimination since a stable cyclic aromatic transition state is not available. So this reaction gives the required compound **9**, which is readily deprotected to give the desired phenol, **10**.

Treatment of the synthetic phenol under a variety of conditions (direct irradiation, heating with a thermal azo initiator, or oxidation with lead dioxide) all resulted in a broad persistent ESR signal comparable to that observed in the oligomer itself. These results can be explained by a dimeric structure of the oligomer that is in thermal equilibrium with a paramagnetic species as proposed in Scheme 3.

Experimental

General procedure

Melting points were measured on a Gallenkamp melting point apparatus and are uncorrected. Proton and carbon-13 nuclear magnetic resonance (^1H and ^{13}C NMR) spectra were obtained in $CDCl_3$ with TMS as an internal standard on either a Nicolet NB 360 or a Bruker AC 250 spectrometer and are recorded in ppm. Electron paramagnetic resonance (EPR) spectra were run on a Varian E3 EPR spectrometer to obtain hyperfine coupling constants and *g*-values. These measurements were typically run at a microwave frequency of 9.5 GHz, centre field 3400 gauss (G) with a 100 G sweepwidth. Mass spectra were obtained on a Hewlett Packard 5988A GC/LC/MS instrument using an HP 5890 Series II gas chromatograph and a Series 1050 HPLC both recorded using an ionization potential of 70 eV. The liquid chromatograph used an HP MOS Hypersil 5 μm 100 × 2.1 mm column with 80:20 Me-OH:H_2O as solvent for the analysis. An HP 59980A particle beam LC/MS interface was used for insertion into the ion source. Infrared spectra were obtained on a Perkin Elmer 1420 infrared spectrophotometer. Microanalysis were by Desert Analytics, Tuscon, Arizona.

Vanillin, acetophenone, 3,4-dimethoxyacetophenone, imidazole, *tert*-butyldimethlsilyl chloride, sodium borohydride, lithium bromide, trimethylsilyl chloride, ammonium chloride, sodium chloride, sodium bicarbonate, 3,4-dimethoxybenzaldehyde, benzyl chloride, 1,3-propanedithiol, 1,2-ethanedithiol, hexamethylditin, *p*-toluenesulfonic acid, phenyl-lithium, and *n*-butyllithium were obtained from Aldrich Chemical Co. and were used without purification. *N-tert-Butyl*-α-phenylnitrone (PBN) from Aldrich was sublimed before use. Potassium fluoride was obtained from B & A Specialty Chemicals Division. Hydrobromic acid (48%) was obtained from the Fisher Scientific Company. Mercuric perchlorate ($Hg(ClO_4)_2$) was prepared using the method described in the literature (17).

The preparative TLC was done using Kieselgel 60 $PF_{254+366}$ silica gel, and normal TLC for monitoring of reactions was done using Merck DC-Plastikfolien Kieselgel $60F_{254}$ silica gel sheets.

THF was distilled from CuCl and then from $LiAlH_4$ and kept over molecular sieves. Benzene was distilled and kept over molecular sieves prior to use. The other solvents for this study were obtained from either the Aldrich Chemical Co. or the BDH Chemical Co. and were distilled prior to use. Photolyses with PBN spin trap were carried out in a Rayonet Reactor using 350-nm lamps through Pyrex or at 254 nm in quartz tubes. Extended photolyses of **1** to form oligomers were done in a 400-mL immersion well using a 400-W Hanovia mercury medium-pressure lamp through Pyrex during a continual purge with argon.

Syntheses

Preparation of α-bromoacetoveratrone and α-bromoacetophenone

The α-bromoacetoveratrone and α-bromoacetophenone were prepared by the reported method (18). The ^{1}H NMR and GC/MS were consistent with their structures.

*Preparation of α-(2-methoxyphenoxy)acetoveratrone (**1**)*

Compound **1***a* was synthesized by the reported procedure (19) and the crude material was recrystallized four times from methanol; mp 92–93°C.

*Preparation of α-phenoxyacetophenone (**1**b)*

This compound was prepared by the reported procedure (19) and the crude material recrystallized from hexane; mp 70–71°C (lit. (5) mp 71–72°C). The product gave the expected mass spectrum.

*Preparation of 4-[(*tert*-butyldimethylsilyl)oxy]-3-methoxybenzaldehyde*

To a 50-mL round-bottom flask was added 2.0 g (0.013 mol) of vanillin, and it was dissolved in 10 mL of DMF under argon. To this solution was added 2.2 g (0.032 mol) of imidazole and, once it had dissolved, 2.4 g (0.016 mol) of *tert*-butyldimethylsilyl chloride was added. The reaction was stirred overnight after which water was added (20 mL) and it was extracted with ether (2 × 30 mL). The organic layer was washed with saturated $NaHCO_3$ solution, followed with a brine, and finally with water. The ether layer was dried ($MgSO_4$), filtered, and distilled under reduced pressure to give a colourless oil; 2.1 g, 61%; bp 136–138°C (1.5 Torr; 1 Torr = 133.3 Pa). IR and ^{1}H NMR were comparable to that given in the literature (20). ^{13}C NMR δ: 191.0, 127.6, 126.3, 120.7, 110.0, 108.7, 56.1, 55.5, 25.6, 18.5, –4.6; GC/MS, *m/z*: 251 (2, $M^+ - CH_3$), 210 (16), 209 (86), 194 (100), 193 (38), 165 (10), 163 (10), 73 (16).

*Preparation of 4-[(*tert*-butyldimethylsilyl)oxy]-3-methoxybenzyl alcohol*

The above aldehyde (1.20 g, 4.5×10^{-3} mol) was dissolved in 15 mL of absolute alcohol and sodium borohydride (0.25 g, 6.6×10^{-3} mol) was added. After stirring for 4 h water was added (40 mL), and the product was then extracted with ether (3 × 40 mL). The ether layer was washed with water (2 × 10 mL), then dried ($MgSO_4$), filtered, and rotoevaporated to yield a colourless oil; 1.04 g, 86%; bp 176–178°C (2.0 Torr). IR and ^{1}H NMR were comparable to those given in the literature (20). ^{13}C NMR δ: 151.0, 144.5, 134.5, 120.8, 119.5, 111.1, 63.5, 55.4, 25.7, 18.5, –4.7; GC/MS, *m/z*: 238 (15), 212 (9), 211 (60), 197 (15), 196 (100), 195 (10), 179 (16), 167 (28), 151 (8).

*Preparation of 4-[(*tert*-butyldimethylsilyl)oxy]-3-methoxybenzyl bromide (**8**)*

The procedure used was that outlined previously (20). The crude product was purified by column chromatography on silica gel by elution with hexane:ethyl acetate (5%). IR and ^{1}H NMR are in agreement with those given in the literature (20).

*Preparation of 2-(3,4-dimethoxyphenyl)-1,3-dithiolane (**6**a)*

The procedure used to prepare this compound is that outlined in ref. 15; mp 64–66°C (lit. (15) mp 62–65°C); IR (CCl_4): 2996, 2932, 2834, 1592, 1512, 1463, 1417, 1264, 1138, 1030 cm^{-1}; ^{1}H NMR δ: 7.11 (d, 1H, J = 1.8 Hz), 7.05 (dd, 1H, J_1 = 8.0 Hz, J_2 = 1.8 Hz), 6.78 (d, 1H, J = 8.1 Hz), 5.64 (s, 1H, CHSS), 3.90 (s, 3H, OCH_3), 3.87 (s, 3H, OCH_3), 3.52–3.49 (m, 2H), 3.37–3.32 (m, 2H); GC/MS *m/z*: 242 (82, M^+), 214 (32), 213 (21), 211 (17), 199 (15), 183 (100), 182 (36), 181 (55), 138 (15), 95 (14).

*Formation of 3,4-dimethoxybenzenecarbodithioic acid benzyl ester (**7**)*

To a 50-mL three-necked round-bottom flask equipped with a low-temperature thermometer, argon inlet, and a condenser was added 1.00 g (4.1×10^{-3} mol) of 2-(3,4-dimethoxyphenyl)-1,3-dithiolane (**6***a*). To this was added 15 mL of anhydrous THF and the dithiolane was completely dissolved. The solution was then cooled to –80°C. After 5 min 2.38 mL of a 1.8 M solution of phenyllithium was added and allowed to stir for 2 h. Then 0.54 mL (4.0×10^{-3} mol) of benzyl chloride was added and the temperature was allowed to warm to –40°C for 30 min after which it was allowed to warm to room temperature. After 6 h at room temperature, the solution was worked up as described previously (21). The crude compound was column chromatographed using 80:20 hexane:CH_2Cl_2 as eluent. Yield 0.70 g (2.3×10^{-4} mol, 55%) red solid, mp 62–63°C; IR (KBr): 2957, 1590, 1512, 1461, 1411, 1335, 1266, 1143, 1048, 1022, 760 cm^{-1}; ^{1}H NMR δ:7.75 (dd, 1H, J_1 = 8.5 Hz, J_2 = 2.1 Hz), 7.68 (d, 1H, J = 2.1 Hz), 7.39–7.29 (m, 5H), 6.79 (1H, J = 8.5 Hz), 4.58 (s, 2H), 3.91 (s, 3H, OCH_3), 3.90 (s, 3H, OCH_3); ^{13}C NMR[4] δ: 220.7 (q, CSS), 143.3 (q), 148.5 (q), 137.7 (q), 135.1 (q), 129.3, 128.7, 127.7, 120.2, 110.5, 109.9, 56.1 (OCH_3), 56.0 (OCH_3), 42.0 (CH_2-S); GC/MS, *m/z*: 304 (14, M^+), 182 (10), 181 (100), 137 (19), 91 (46). Anal. calcd. for $C_{16}H_{16}S_2O_2$: C 63.13, H 5.30; found: C 62.76, H 5.17.

*Preparation of 2-(3,4-dimethoxyphenyl) 1,3-dithiane (**6**b)*

To a 200-mL round-bottom flask was added 4.0 g (2.4×10^{-2} mol) of 3,4-dimethoxyphenylbenzaldehyde and 140 mL of dry benzene. To this was added 2.70 g (2.50 mL, 2.5×10^{-2} mol) of 1,3-propanedithiol and a catalytic amount of *p*-toluenesulfonic acid. The mixture was refluxed with a Dean–Stark trap for 4 h and then allowed to cool. The benzene layer was washed with 1 M sodium hydroxide solution, followed by a wash with water. The benzene was dried ($MgSO_4$), filtered, and rotoevaporated to yield an oil. The oil was recrystallized from diethyl ether to give white needles: yield 4.3 g, 70%, mp 94–96°C (lit. (22) mp 99–101°C). The ^{1}H NMR and MS were in agreement with the literature values (23). IR (KBr): 2965, 2945, 2896, 2840, 1603, 1588, 1513, 1465, 1261, 1138, 1020, 764 cm^{-1}; ^{13}C NMR δ:149.0, 131.7, 120.0, 111.0, 110.7, 55.9, 55.9, 51.2, 32.2, 25.1.

*2-(3,4-Dimethoxyphenyl)-2-{4-[(*tert*-butyldimethyldilyl)oxy]-3-methoxylbenzyl}-1,3-dithiane (**9**)*

Into an oven-dried 50-mL three-necked flask was added 0.53 g (2.07×10^{-3} mol) of the dithiane (**6***b*). Then 15 mL of anhydrous THF was added and the dithiane was stirred until it dissolved. The flask was next cooled to –40°C under an argon atmosphere when *n*-BuLi was added (2.5 M solution in hexanes) until complete conversion of the dithiane into the carbanion was accomplished (monitored by deuterium exchange using D_2O). The carbanion solution was then transferred quickly to a cold dropping funnel and the benzyl bromide, **8**, (0.70 g, 2.1×10^{-3} mol) in 5 mL of dry THF in a separate dropping funnel was added dropwise simultaneously into a magnetically stirred three-necked flask with 30 mL of THF at –40°C under an argon atmosphere. The solution was stirred and kept at –40°C for 5 h and then allowed to warm to room temperature overnight. The reaction mixture was rotoevaporated to remove the THF, and then treated with a saturated NH_4Cl solution and extracted with chloroform. The organic layer was dried over $MgSO_4$, filtered, and rotoevaporated to yield the crude oil, which was then column chromatographed (eluent: CH_2Cl_2) to give the pure silyl protected thioketal (**9**). Yield 0.75 g, 70%, mp 100–102°C; IR (KBr):2950, 2932, 2854, 1601, 1596, 1512, 1461, 1235, 1133, 1026, 908 cm^{-1}; ^{1}H NMR δ:7.28–7.24 (m, 2H), 6.77 (d, 1H, J = 9.0 Hz), 6.61 (d, 1H, J = 7.9 Hz), 6.28 (dd, 1H, J_1 = 8.0 Hz, J_2 = 1.6 Hz), 6.05 (bs, 1H), 3.90 (s, 3H), 3.75 (s, 3H), 3.51 (s, 3H), 3.16 (s, 2H), 2.77–2.58 (m, 4H), 1.98–1.95 (m, 2H), 0.96 (s, 9H), 0.10 (s, 6H); ^{13}C NMR δ:149.6, 148.4, 147.8, 143.8, 132.7, 127.7, 123.3, 122.2, 119.6, 114.8, 112.9, 110.4, 59.9, 55.9, 55.8, 55.1, 51.3, 27.6, 25.7, 25.2, 18.4, –4.7; GC/MS, *m/z*: 256 (13), 255 (100), 181 (15). Anal. calcd. for $C_{26}H_{38}S_2O_4Si$: C 61.62, H 7.56; found: C 61.42, H 7.70.

*Preparation of 1-(3,4-dimethoxyphenyl)-2-{4-[(*tert*-butyldimethylsilyl)oxy}-3-methoxylphenyl} ethanone*

The deprotection step is a modification of a literature procedure (24). The protected silyl thioketal, **9** (0.35 g, 6.9×10^{-4} mol), was dissolved in 3 mL of THF and 0.5 mL of water was added. To this solu-

[4] For ^{13}C NMR, q refers to quaternary carbons.

tion was added 0.14 g (1.4×10^{-2} mol) of $CaCO_3$ and this was allowed to stir at room temperature for 5 min, after which 0.5 mL of a 2.5 M aqueous solution of $Hg(ClO_4)_2$ was added slowly over 10 min. The solution was stirred for 1 h and then 30 mL of ether was added and the mixture filtered. The solvents were removed to leave the crude ketone, which was chromatographed (eluent: CH_2Cl_2) to obtain pure ketone, mp 129–130°C; IR (KBr):2935, 2860, 1675, 1587, 1517, 1462, 1290, 1153, 1024, 923, 787 cm^{-1}; ^1H NMR δ: 7.65 (dd, 1H, $J_1 = 8.4$ Hz, $J_2 = 2.0$ Hz), 7.56 (d, 1H, $J = 2.0$ Hz), 6.87 (d, 1H, $J = 8.4$ Hz), 6.80–6.69 (m, 3H), 4.16 (s, 2H, $COCH_2$), 3.94 (s, 3H, OCH_3), 3.91 (s, 3H, OCH_3), 3.77 (s, 3H, OCH_3), 0.98 (s, 9H, $C(CH_3)_3$), 0.13 (s, 6H, Si $(CH_3)_2$); ^{13}C NMR δ: 196.7(C=O), 153.2, 151.0, 149.0, 143.9, 129.8, 128.4, 123.5, 121.6, 120.9, 113.1, 110.7, 109.9, 56.0, 55.9, 55.5, 45.0, 25.7, 18.4, −4.6. GC/MS, *m/z*: 360 (12), 359 (47), 179 (21), 166 (10), 165 (100), 73 (18). Anal. calcd. for $C_{23}H_{32}O_5Si$: C 66.31, H 7.74; found: C 66.26, H 7.57.

*Preparation of 1-(3,4-dimethoxyphenyl)-2-(4-hydroxy-3-methoxyphenyl) ethanone (**10**)*

The desilylation procedure used was that given in ref. 25. The silyl protected ketone (0.050 g, 1.2×10^{-4} mol) was dissolved in 1 mL of anhydrous DMF and then 0.014 g (2.4×10^{-4} mol) of potassium fluoride was added followed by 1 drop of 48% hydrobromic acid. The solution was stirred for 24 h and the reaction was monitored by TLC (eluent: CH_2Cl_2). Work-up was as described in the reference and the crude material should not be column chromatographed but recrystallized from CH_2Cl_2:hexane. The pure material should be kept from light and heat sources due to the ease of colouration; mp 118–120°C (lit. (2) mp 119–119.5°C); IR (KBr): 3427 (O-H, 2935, 1667 (C=O), 1594, 1514, 1465, 1455, 1268, 1149, 1023, 880, 802, 771 cm^{-1}; ^1H NMR δ: 7.66 (dd, 1H, $J_1 = 8.4$ Hz, $J_2 = 2.1$ Hz), 7.55 (d, 1H, $J = 2.0$ Hz), 6.84–6.89 (m, 2H), 6.77 (s, 2H), 5.67 (bs, 1H, OH), 4.16 (s, 2H), 3.93 (s, 3H), 3.91 (s, 3H), 3.84 (s, 3H); ^{13}C NMR[4] δ: 196.7 (C=O), 153.3 (q), 149.1 (q), 146.6 (q), 144.6 (q), 129.7 (q), 126.8 (q), 123.5, 122.2, 114.5, 111.7, 110.7, 110.0, 56.0 (OCH_3), 55.9, 55.9 (2 × OCH_3), 44.8 (CH_2). GC/MS, *m/z*: 302 (6, M^+), 166 (10), 165 (100), 137 (14), 79 (10), 77 (10).

PATRICIA A. BURNS, NICHOLAS J. TAYLOR, and RUSSELL RODRIGO. Can. J. Chem. **72**, 42 (1994).

A synthesis of the tricycle **19** has been completed in 14% overall yield from guaiacol. Several chemical transformations of this compound including its reduction to an octahydro naphtho[1,8-*bc*]furan and conversion to the hitherto unknown azuleno-[8,1-*bc*]furan ring system are described.

PATRICIA A. BURNS, NICHOLAS J. TAYLOR et RUSSELL RODRIGO. Can. J. Chem. **72**, 42 (1994).

Utilisant le guaïacol comme produit de départ on a réalisé une synthèse du tricycle **19** avec un rendement global de 14%. On décrit plusieurs transformations chimiques de ces composés, y compris sa réduction en un octahydro naptho[1,8-*bc*]furane et sa conversion dans le système cyclique de l'azuléno[8,1-*bc*]furane inconnu jusqu'à maintenant.

The 2*H*-naphtho[1,8-*bc*]furan structural unit occurs at various oxidation levels in some terpenes and fungal metabolites. Its 5a-methyl (angular methyl) derivative **1** is a particularly important target for synthetic chemists because the development of an efficient general method for the preparation of **1** and closely related tricycles will be a significant step towards the synthesis of many natural products such as the pentacyclic marine quinones **2** and **3** (1), the fungal metabolites of *Gliocladium virens* **4** and **5** (2), and *Penicillium wortmanni* **6** (3). Some synthetic activity in this area has already been recorded by Kanematsu et al. (4) who applied their "furan transfer" protocol to prepare **7** in 6.3% yield from α-furyl methanol. In addition, both Xestoquinone **2** and Halenaquinone **3** have been synthesized in low yields (5) but in these instances the naphtho-[1,8-*bc*]furan unit was generated after the aromatic rings A and B had been attached. Very recently an oxidized variant, the furanocyclohexadienone lactone **8**, has been prepared (6) as part of a synthetic program directed at Wortmannin. We now report some of our synthetic work in this area.

The benzofuran ester **9** prepared from 2-methoxy-5-methylphenol as previously described (7) was saponified and the resulting acid **10** was converted to the diazoketone **11** through the acid chloride. All of several attempts to cyclize this material to the desired tricycle **12** via cationic intermediates with trifluoroacetic acid or boron trifluoride (8), or via carbenoids with rhodium(II) acetate (9) or silver oxide, failed to provide any isolable and identifiable product.[3] It was therefore apparent that the angular methyl group had to be introduced by different methods. The benzofuran **13**, prepared as described earlier (7) in 33% overall yield from 2-methoxyphenol, was subjected to one-carbon chain homologation in 63% yield by the Arndt–Eistert sequence to produce the acid **17** through the usual intermediates **14–16**. Intramolecular Friedel–Crafts cyclization to **18** was easily accomplished by either polyphosphoric acid (PPA) at 90°C (81%) or trifluoroacetic acid – trifluoroacetic anhydride (TFA–TFAA) in dry methylene chloride at 25°C (87%). Birch reduction[4] with potassium/liquid ammonia/*tert*-butanol followed by methylation (4.5 equiv. lithium bromide, followed by methyl iodide in THF–water) gave a 76% yield of the desired 5a-methylated-2*H*-naphthofuran **19**. The addition of the lithium bromide to exchange the potassium enolate for the lithium is necessary to preserve the selectivity of the methylation step. Without it, methylation on both sides of the C-5 carbonyl group was observed. The loss of the methoxyl group *para* to the C-5 carbonyl was not unexpected (10). The 200-MHz ^{1}H NMR spectrum of the product shows only one signal for the 5a methyl group at 1.36 ppm and no evidence could be found for the existence of more than one diastereomer in the product. The *cis* configuration at C-2a,5a was assigned to this product by the examination of models and was confirmed by an X-ray structure of a crystalline derivative (vide infra). This synthetic route provides the angularly methylated 2*H*-naphthofuran in 14% overall yield from 2-methoxyphenol. Although this was a reasonably efficient process there appeared to be room for improvement in the fact that the methoxyl group of the starting material was lost in the Birch reduction step and a great increase in efficiency would be possible if *o*-iodophenol, a commercial material, was used instead of guaiacol. The tedious *o*-iodination procedure necessary with the latter could then be avoided. Thus the benzofuran ester **20** was prepared from *o*-iodophenol as before (7) in two steps in 61% yield and homologated by the same Arndt–Eistert protocol to the ester **21** in 52% yield (32% overall from *o*-iodophenol). Unfortunately every attempt made, and a great many were tried, to cyclize the ester **21**, the acid **22**, or diazoketone **23** failed. All acidic reagents in Friedel–Crafts reactions, carbenoids, as well as the use of a Cu(I) triflate-promoted cyclization of a selenate ester **24** (11) failed. Mild conditions returned the starting material and forcing ones caused its destruction. The requirement for a *para*-methoxy group in a similar intramolecular Friedel–Crafts cyclization has been noted previously (12). In the hope that the benzofuran might cyclize better than the dihydrobenzofuran **22**, the methyl ester of the latter was dehydrogenated quantitatively with dichlorodicyanobenzoquinone (DDQ) in dioxan and saponified to provide the acid **25**. Friedel–Crafts cyclization with PPA or through the acid chloride with aluminum chloride was again not successful. The cyclopentanone **26** was the only isolable product (20% yield).

The chemical properties of **19** were investigated next. Attempts were made to deoxygenate the carbonyl group at C-5. Initially the thioketal – Raney Ni desulfurization and the tosylhydrazone–hydride reduction (13) were contemplated. How-

ever, neither derivative could be obtained under the usual conditions but extensive decomposition of **19** took place instead. Reduction of the C-5 carbonyl group with sodium borohydride in ethanol could be accomplished in 93% yield to provide the alcohol **27** with the hydroxyl group in an apparently equatorial orientation ($J_{4,5}$ = 4.4 and 11.1 Hz). Attempts were now made to prepare the bromide or tosylate Treatment of the alcohol **27** with carbon tetrabromide and triphenylphosphine in methylene chloride or with 1,2-bis(triphenylphosphino) ethane tetrabromide (14) in the same solvent resulted in a complex mixture of products. Tosyl chloride in the presence of dimethylaminopyridine at 0°C also provoked decomposition. A recent report (15) suggests that even neopentyl alcohols can be deoxygenated efficiently by conversion to the 2,4,6-trichlorophenoxy thiocarbonyl ester followed by treatment with tributyl tin hydride. When this method was applied to **27**, extensive decomposition again resulted and the ^{1}H NMR spectrum of the product mixture showed aromatic absorption. An attempt was then made to prepare an imidazole thioester. Treatment of **19** with thiocarbonyldiimidazole in refluxing THF produced a 48% yield of a material identified as the azulenofuran **28**. The 250-MHz ^{1}H NMR spectrum showed the presence of three vinyl protons at 5.53 (1H) and 6.14 (2H) ppm. Irradiation of the former produced a clean AB pattern for H-6 and H-7 at 6.14 ppm. The proton at C-2a was found at 3.08 ppm as a multiplet that was coupled to a doublet at 2.91 ppm (H-8b) and to the protons at C-2 and C-3. The ^{13}C NMR spectrum was also in accord with this structure. No report could be found in the literature of the preparation or natural occurrence of this simple tricyclic system. It must arise in this instance by participation of the enol ether oxygen in displacing the imidazole ester at C-5 (Scheme 1). This proposal is supported by the fact that the 8a,8b-dihydro derivative of **27** (vide infra) when treated with thiocarbonyldiimidazole did provide the thioimidazole ester **29** in 65% yield.

In view of the presence of a carbonyl group in the natural products **2–6** at a position corresponding to C-8 of **19** it was decided to attempt oxidation at this allylic methylene group. Various chromium(VI) species (e.g., PDC, CrO_3 – dimethyl pyrazole (DMP)), DDQ, and allylic bromination with *N*-bromosuccinimide (NBS) caused decomposition, and the mixtures of products obtained showed aromatic signals in their ^{1}H NMR spectra. Thus in both the allylic bromination and DDQ oxidations the dihydrobenzofuran carboxylic acid **30** was obtained and characterized, in yields of 74 and 31%, respectively. Its formation is rationalized in Scheme 2 (X = Br or a positive charge). The first step (also the rate-determining step) in oxidations with quinones is generally believed to be hydride abstraction from the substrate; the cation (or ion pair) subsequently goes on to product(s). Since it appeared that the combination of positive centres at the C-5 and C-8 led to ring-opening

(X = Br or a positive charge)

SCHEME 2. The aromatization of **19**

and aromatization, the C-5 methyl ether **31** was prepared from the alcohol **27** in 82% yield by successive treatment with *n*-BuLi in THF–HMPA at −78°C and using excess methyl iodide. Every attempt at oxidation of this compound with various Cr(VI) and Ce(IV) reagents, DDQ, and NBS led to decomposition and the production of mixtures displaying aromatic signals in the ^{1}H NMR spectra.

Isobenzofurans are among the most reactive dienes known (16) and have been shown (17) to react even with cyclohexene to provide adducts in good yield. The isobenzofuran **33** (18), generated in situ with glacial acetic acid from the hydroxyphthalan **32**, was reacted with **19** in refluxing carbon tetrachloride for 2h. A crystalline product obtained in 50% yield displayed ^{1}H NMR signals consistent with the presence of both the methoxylated benzene ring and the tricyclic dienophile **19**. However, the vinyl protons of the 6,7 double bond were still present in the NMR spectrum of this compound at 5.19 (dd, H-7, $J_{6,7}$ = 10, $J_{7,8}$ = 3.65 Hz) and 5.98 ppm (dd, H-6, $J_{6,7}$ = 10 and $J_{6,8}$ = 1.7 Hz), suggesting that the reaction had taken place at C-8 and that the product **34** was not a Diels–Alder adduct. When dissolved in ethanol and stirred for 20 min with one drop of concentrated hydrochloric acid, a new crystalline material **35** was formed in 80% yield. An X-ray structure (Fig. 1) of this compound confirmed that it was derived from the expected product of reaction at C-8 of **19**, and established the relative stereochemistry of **19** to be *cis* at C-2a and C-5a as surmised previously. The formation of **34** and **35** is rationalized in Scheme 3 as an acid-catalysed aldol condensation between the oxonium ion **36** and enol ether **37** produced from **32** and **19**, respectively, in the acidic conditions employed, followed by rearrangement to the benzoxepin.

At this stage it appeared that any transformation of **19** into a synthon useful for the natural products would require the elimination of the C-5 oxygen and the C_{8a}—C_{8b} double bond. This objective was achieved as follows: the alcohol **27** was generated (but not isolated) as before and then reduced further with

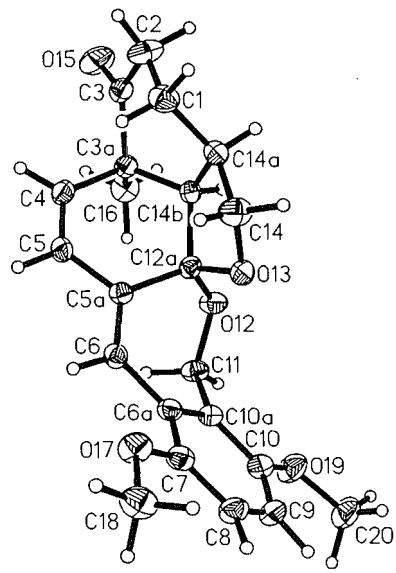

FIG. 1. Molecular plot of the X-ray crystallographic structure of **35**.

sodium cyanoborohydride in acidified solution to provide the alcohol **38** in 78% yield in a "one-pot" process. The relative stereochemistry of this alcohol is not evident from the ^{1}H NMR spectrum but it is assumed to be all *cis* at C-2a, 5a, 8a, and 8b from the X-ray structure of **35** and the well-known preference of 6/5 ring junctions for *cis* fusion. Deoxygenation of the alcohol could be achieved by radical procedures through several different intermediates. The imidazole thioester **29** could be obtained in 65% yield upon refluxing with thiocarbonyldiimidazole in benzene, the trichlorophenoxy thioester **39** in 23% yield by treatment with trichlorophenoxythiocarbonyl chloride in acetonitrile with a catalytic amount of dimethylaminopyridine, the xanthate **40** in 79% yield by reaction with *n*-butyl-

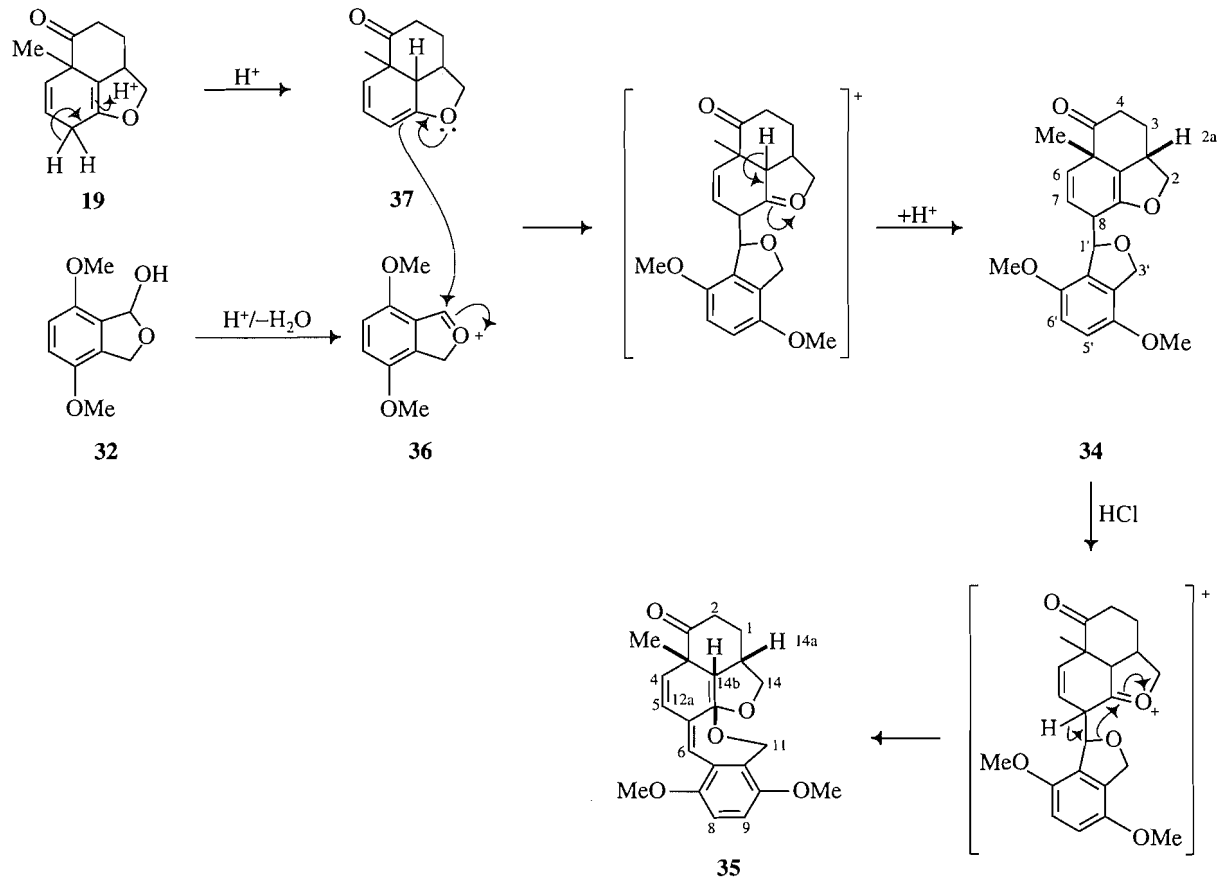

SCHEME 3. Aldol condensation of enol ether **37** with oxonium ion **36**

lithium at −78°C followed by carbon disulfide at 0°C and methyl iodide at 25°C. Preparation of the bromide, however, with CBr_4 and triphenylphosphine was unsuccessful. All three thio derivatives could be deoxygenated to **41** with tri-*n*-butyltin hydride and azobis isobutyro nitrile (AIBN) in refluxing toluene but the xanthate gave the best yield (69% in this step and 43% from **19**). Thus **41** is available from 2-methoxyphenol in 4.7% overall yield. No other diastereomer was detectable in the product but the *cis* stereochemistry at C-8a, 8b is to be expected for this 6/5 ring fusion. With the dihydro compound in hand, several attempts at allylic oxidation at C-8 were made. Various chromium(VI) reagents ($Cr(CO)_6$ and 90% *tert*-butyl hydroperoxide, dimethylpyrazole CrO_3, PCC), selenium dioxide with and without *tert*-butyl hydroperoxide, palladium(II) acetate and manganese dioxide, and DDQ all failed to oxidize the allylic methylene group. In many cases starting material was returned, but the PCC and DMP·CrO_3 oxidations of **41** gave 35% and 21% yields, respectively, of the γ-lactone **42**. Such oxidations of tetrahydrofurans to γ-lactones with Cr(VI) reagents are not unknown (19). Allylic bromination with NBS under various conditions was not successful and no method could be found to achieve allylic oxidation at C-8 of this tricyclic system. The final attempt to use **41** as a synthon depended on whether its unactivated double bond would undergo a Diels–Alder reaction with the reactive isobenzofuran **33**. This was tested by heating the precursor **32** in *p*-xylene with cyclohexene at 140°C with a catalytic amount of *p*-toluic acid for 36h. A 6:1 mixture of *endo*:*exo* adducts **43** was obtained in a total yield of 53%. The same conditions were then employed with **41** as the dienophile

but no cycloaddition products could be found even when heating was conducted in a sealed tube placed in refluxing xylene for 5 days. The starting material **41** was recovered from these reactions, indicating the lower reactivity of its cyclohexene double bond towards cycloaddition. The isobenzofuran was produced as before, but polymerized in the absence of a sufficiently reactive dienophile. High pressure is perhaps one way of forcing this reaction to occur but, even if it does, a satisfactory yield cannot realistically be expected and the requirement for several further transformations detracts from the value of this route to the marine quinones. Other approaches to the natural products **2–6** are being explored at present. They show some

promise of success and these results will be reported in due course.

Experimental

Melting points were determined on a Fischer Mel-Temp unit and are uncorrected. IR spectra were recorded on a Perkin Elmer 983 or a Bomem MB-100 Fourier Transform spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on Bruker AM-250, AC-200, or WP-80 spectrometers at the field strengths specified. Chemical shifts are reported in δ (ppm) and coupling constants (*J*) in hertz. Mass spectra were obtained on a Kratos MS 890 (at the Guelph MS Centre) or on a VG ZAB-E or VG 7070 spectrometer (at the S.W. Ontario Regional MS Centre at Hamilton). The EI and CI modes were used for ionization. Elemental analyses were performed by M-H-W Laboratories, Phoenix, Ariz.

*2-(2,3-Dihydro-7-methoxybenzo[*b*]furan-3-yl)acetic acid* ***14***

To a solution of ester **13** (5.50g, 23.3 mmol) in MeOH (100 mL) was added 50 mL of 10% NaOH and the resulting mixture was stirred for 5h at room temperature. The solution was cooled in ice and acidified with 2 N HCl. Extraction with EtOAc (3 × 50 mL) followed by washing the combined organic layers with water (2 × 50 mL) and drying (Na_2SO_4) provided 4.30g of crude product upon removal of the solvent under reduced pressure. The solid was recrystallized from Et_2O–hexane to give 4.00g (82%) of **14** as colourless plates; mp 99–100°C (lit. (20) mp 101–103°C); IR ($CHCl_3$): 3500–2500 (br), 3024, 1711, 1620, 1593, 1492, 1282, 723 cm^{-1}; ^1H NMR (250 MHz, $CDCl_3$) δ: 2.77 (AB of an ABX system, J_{AB} = 17.0, J_{AX} = 5.1, J_{BX} = 9.6, $\Delta\nu$ = 50.7, 2H, $CHCH_2CO_2H$), 3.88 (s, 3H, OMe), 3.87–3.94 (m, 1H, H-3), 4.35 (dd, $J_{2\alpha,2\beta}$ = 9.3, $J_{3,2\beta}$ = 6.4, 1H, H-2β), 4.83 (t, $J_{2\beta,2\alpha} = J_{3,2\alpha}$ = 9.3, 1H, H-2α), 6.76–6.88 (m, 3H, H-4, H-5, and H-6), 11.05 (br s, exchanged with D_2O, 1H, OH); LRMS (EI) *m/e*: 208 (87, M^+), 190 (11), 177 (20), 161 (13), 149 (100), 131 (13), 121 (55), 103 (12), 91 (36), 77 (19), 68 (16), 51 (14). Anal. calcd. for $C_{11}H_{12}O_4$: C 63.45, H 5.81; found C 63.37, H 5.83.

*1-Diazo-3-(2,3-dihydro-7-methoxybenzo[*b*]furan-3-yl)-2-propanone* ***15***

To a solution of oxalyl chloride (1.42 mL, 16.3 mmol) in benzene (50 mL) at room temperature was added a mixture of acid **14** (2.00g, 9.61 mmol) and pyridine (0.85 mL, 11 mmol) in benzene (40 mL) dropwise over 30 min. The resulting solution was stirred an additional 30 min, then filtered to remove pyridinium hydrochloride. The filtrate was concentrated in vacuo with the aid of a drying tube on the aspirator to prevent the ingress of moisture. Any remaining solvent was removed under high vacuum. The acid chloride thus obtained was not purified but taken up in benzene (20 mL) and added dropwise to an ice-cold solution of diazomethane. The solution was stirred at 0°C for 2h and slowly allowed to warm to room temperature. The mixture was stirred for 15h to allow excess diazomethane to evaporate. The Et_2O was removed in vacuo and the resulting yellow solid was recrystallized from Et_2O to provide 1.93g (87%) of **15** as yellow needles; mp 96.5–97.5°C; IR ($CHCl_3$): 3007, 2961, 2111, 1732, 1640, 1492, 1283, 1196, 951 cm^{-1}; ^1H NMR (250 MHz, $CDCl_3$) δ: 2.55–2.84 (m, 2H, $CHCH_2COCHN_2$), 3.86 (s, 3H, OMe), 3.90–4.00 (m, 1H, H-3), 4.28 (dd, $J_{2\alpha,2\beta}$ = 9.2, $J_{3,2\beta}$ = 6.1, 1H, H-2β), 4.80 (t, $J_{2\beta,2\alpha} = J_{3,2\alpha}$ = 9.2, 1H, H-2α), 5.26 (br s, 1H, $COCHN_2$), 6.73–6.85 (m, 3H, H-4, H-5, and H-6); LRMS (EI) *m/e*: 232 (19, M^+), 222 (13), 204 (15), 173 (12), 161 (34), 149 (55), 133 (9), 121 (100), 103 (10), 91 (56), 77 (32), 65 (16). Anal. calcd. for $C_{12}H_{12}N_2O_3$: C 62.06, H 5.21; found: C 62.28, H 5.34.

*Methyl 3-(2,3-dihydro-7-methoxybenzo[*b*]furan-3-yl)propionate* ***16***

Diazo ketone **15** (6.78 g, 29.6 mmol) was dissolved in MeOH (250 mL) and Ag_2O (7.54 g, 32.5 mmol) was added. The reaction mixture was stirred at room temperature for 2h, then filtered and concentrated. Flash chromatography of the crude oil on silica (40% EtOAc–hexanes eluent) afforded 6.49 g (93%) of **16** as a pale yellow oil. IR (neat): 2951, 1736, 1618, 1592, 1492, 1279, 1199, 773, 734 cm^{-1}, ^1H NMR (250 MHz, $CDCl_3$) δ: 1.88–2.15 (m, 2H, 2 × H-3′), 2.30–2.42 (m, 2H, 2 × H-2′), 3.44–3.56 (m, 1H, H-3), 3.67 (s, 3H, CO_2Me), 3.87 (s, 3H, ArOMe), 4.28 (dd, $J_{3,2\beta}$ = 5.8, $J_{2\alpha,2\beta}$ = 9.0, 1H, H-2β), 4.68 (t, $J_{3,2\alpha} = J_{2\beta,2\alpha}$ = 9.0, 1H, H-2α), 6.74–6.84 (m, 3H, H-4, H-5, H-6); LRMS (EI) *m/e*: 236 (78, M^+), 205 (18), 176 (15), 162 (100), 149 (97), 131 (13), 121 (59), 103 (11), 91 (77), 78 (20), 65 (17), 51 (16). Anal. calcd. for $C_{13}H_{16}O_4$: C 66.09, H 6.83; found: C 65.96, H 6.62.

*3-(2,3-Dihydro-7-methoxybenzo[*b*]furan-3-yl)propionic acid* ***17***

To ester **16** (3.03 g, 12.9 mmol) dissolved in THF (60 mL) was added 20 mL of 10% NaOH and the solution was stirred for 22h at room temperature. The solution was concentrated in vacuo and EtOAc (50 mL) was added. The solution was acidified with 2 N HCl and the layers separated. The aqueous layer was further extracted with EtOAc (2 × 50 mL). The organic extracts were combined, dried (Na_2SO_4), and the solvent removed under reduced pressure. Flash chromatography (silica, 50% Et_2O–hexanes eluent) followed by recrystallization from Et_2O – petroleum ether gave 2.5 g (87%) of **17** as colourless plates; mp 63–64°C; IR ($CHCl_3$): 3500–2500, 3023, 2942, 1708, 1618, 1491, 1278, 1197, 952 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.88–2.17 (m, 2H, 2 × H-3′), 2.38–2.48 (m, 2H, 2 × H-2′), 3.46–3.60 (m, 1H H-3), 3.87 (s, 3H, OMe), 4.30 (dd, $J_{3,2\beta}$ = 5.6, $J_{2\alpha,2\beta}$ = 9.1, 1H, H-2β), 4.69 (t, $J_{3,2\alpha} = J_{2\beta,2\alpha}$ = 9.1, 1H, H-2α), 6.74–6.88 (m, 3H, H-4, H-5, H-6), 10.75 (br s, exchanged with D_2O, 1H, OH); LRMS (EI) *m/e*: 222 (77, M^+), 208 (2), 189 (4), 176 (5), 162 (41), 149 (100), 131 (9), 121 (59), 103 (97), 91 (25), 77 (16), 65 (8). Anal. calcd. for $C_{12}H_{14}O_4$: C 64.85, H 6.35; found: C 65.00, H 6.37.

*8-Methoxy-2,2a,3,4,tetrahydronaphtho[1,8-*bc*]furan-5-one* ***18***

To acid **17** (4.00 g, 18.0 mmol) in CH_2Cl_2 (140 mL) was added trifluoroacetic acid (1.66 mL, 21.6 mmol) and trifluoracetic anhydride (3.05 mL, 21.6 mmol). The reaction mixture was stirred for 5 h. Water (75 mL) was added and the layers separated. The aqueous layer was extracted with CH_2Cl_2 (3 × 75 mL) and the organic layers combined, dried (Na_2SO_4), and concentrated in vacuo to provide a solid that was recrystallized from EtOAc–hexane to give 3.21 g (87%) of **18** as colourless plates. The same compound was prepared utilizing PPA as follows: phosphorus pentoxide (20.83 g, 0.147 mol) was combined with 85% orthophosphoric acid (16.67 mL, 0.145 mol) and heated at 160–165°C for 5h. Acid **17** (0.50 g, 2.2 mmol) was added to the PPA at 90°C and heated for 1 h, then cooled and poured into ice. The mixture was extracted with CH_2Cl_2 (3 × 50 mL) and the organic layer was washed with 10% K_2CO_3 (75 mL) and water (2 × 75 mL), then dried (Na_2SO_4) and concentrated; 0.37 g (81%) of **18** was obtained after recrystallization from EtOAc–hexanes; mp 114–115°C; IR (neat): 2999, 2941, 1670, 1616, 1600, 1274, 1099, 914, 803cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.93 (qd, $J_{4\alpha,3\beta} = J_{2a,3\beta} = J_{3\alpha,3\beta}$ = 12.7, $J_{4\beta,3\beta}$ = 4.6, 1H, H3β), 2.37 (dtd, $J_{3\beta,3\alpha}$ = 12.7, $J_{2a,3\alpha} = J_{4\alpha,3\alpha}$ = 4.6, $J_{4\beta,3\alpha}$ = 2.6, 1H, H-3α), 2.65 (AB of an ABMX system, J_{AB} = 17.6 J_{AX} = 2.6, J_{AM} = 4.6, J_{BM} = 12.7, J_{BX} = 4.6, $\Delta\nu$ = 29, 2H, 2 × H-4), 3.64–3.83 (m, 1H, H-2a), 3.96 (s, 3H, OMe), 4.17 (dd, $J_{2a,2\beta}$ = 11.9, $J_{2\alpha,2\beta}$ = 8.6, 1H, H-2β), 4.95 (t, $J_{2a,2\alpha} = J_{2\beta,2\alpha}$ = 8.6, 1H, H-2α), 6.83 (d, *J* = 8.5, 1H, H-7), 7.42 (d, *J* = 8.5, 1H, H-6); LRMS (EI) *m/e*: 204 (100, M^+), 190 (15), 176 (72), 162 (29), 148 (32), 134 (28), 119 (46), 105 (26), 91 (34), 77 (21), 51 (13). *3-(2,3-Dihydrobenzofuranyl) propionic acid **22***

This acid was prepared in 90% yield by the hydrolysis of ester **21** in THF–methanol (10:1) with 2 M sodium hydroxide for 3h at room temperature.[3]

*Methyl 3-(2,3-dihydrobeno[*b*]furan-3-yl)propioselenate **24***

In a dry box, $AlMe_3$ (12.5 mL of a 2 M solution in toluene, 25.0 mmol) was added to a flask containing selenium metal (2.05 g, 26.0 mmol). The mixture was refluxed for 2h, at which time it was cooled to room temperature and the unreacted Se was allowed to settle from the solution. A portion of this solution (1.34 mL, 2.67 mmol) was transferred to a solution of methyl ester **21** (0.500 g, 2.43 mmol) in 5 mL of argon-degassed CH_2Cl_2 at 0°C. The mixture was stirred at 0°C for 30 min, then allowed to warm to room temperature over 30 min. To the yellow solution was added sodium sulfate decahydrate (1 g) and the mixture was stirred for 20 min. The solution was extracted with Et_2O (3 × 20 mL) and the organic layer was dried (Na_2SO_4) and concentrated to provide 0.58 g (89%) of selenol ester **24** as a yellow oil. IR (neat): 3020, 2986, 1732, 1602, 1500, 1420, 1220, 1201, 1132, 1055, 906, 796 cm^{-1}; ^1H NMR (80 MHz, $CDCl_3$) δ: 1.85–2.40 (m, 2H, 2 × H-3′), 2.25 (s, 3H, Me), 2.53–2.82 (m, 2H, 2 × H-2′), 3.28–3.71 (m, 1H, H-3), 4.21 (dd, $J_{2\alpha,2\beta}$ = 8.9, $J_{3,2\beta}$ = 6.1, 1H, H-2β), 4.61 (t, $J_{2\beta,2\alpha}$ = $J_{3,2\alpha}$ = 8.9, 1H, H-2α), 6.68–6.95 (m, 2H, H-5, H-7), 7.05–7.28 (m, 2H, H-4, H-6); LRMS (EI) *m/e*: 269 (75, M^+), 254 (10), 175 (15), 163 (100), 119 (16), 103 (11), 91 (77), 78 (16), 65 (12), 51 (18). Anal. calcd. for $C_{12}H_{14}O_2Se$: C 53.54, H 5.24; found: C 53.62, H 5.16.

*Methyl 3-benzo[*b*]furan-3-yl)propionate*

To ester **21** (1.00 g, 4.85 mmol) in dry dioxane (25 mL) was added a solution of DDQ (1.32 g, 5.82 mmol) in dioxane (15 mL). The mixture was refluxed for 4h, then cooled. The solid was filtered off and washed with benzene (20 mL), then chloroform (20 mL). The filtrate and washings were combined and concentrated under reduced pressure. The benzofuran ester (0.999 g, 100%) was obtained as a colourless oil after flash chromatography (silica, 30%, EtOAc–hexanes eluent). IR (neat): 2951, 1738, 1452, 1167, 1094, 857, 747 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 2.67–2.75 (m, 2H, 2 × H-3′), 2.98–3.06 (m, 2H, 2 × H-2′), 3.68 (s, 3H, OMe), 7.19–7.33 (m, 2H, H-5, H-7), 7.43–7.57 (m, 3H, H-2, H-4, H-6); LRMS (EI) *m/e*: 204 (61, M^+), 173 (6), 145 (55), 131 (100), 115 (24), 103 (9), 91 (9), 77 (14), 63 (9), 51 (7), 45 (12). Anal. calcd. for $C_{12}H_{12}O_3$: C 70.58, H 5.92; found: C 70.49, H 5.78.

*3-(Benzofuran-3-yl)propionic acid **25***

To the foregoing ester (0.999 g, 4.89 mmol) dissolved in THF (30 mL) with a few drops of MeOH was added 10 mL of 10% NaOH. The solution was stirred at room temperature for 22h. The mixture was concentrated in vacuo and EtOAc (50 mL) added. This was acidified with 2 N HCl and the layers were separated. The aqueous layer was further extracted with EtOAc (2 × 50 mL) and the combined organics were washed with brine and dried (Na_2SO_4). Evaporation of the solvent followed by recrystallization from ether–hexanes gave 0.77 g (83%) of **25** as a colourless solid; mp 106–108°C; IR ($CHCl_3$): 3400–2500, 1710, 1451, 1284, 1118, 858 cm^{-1}; ^1H NMR (250 MHz, $CDCl_3$) δ: 2.75–2.81 (m, 2H, 2 × H-3′), 3.00–3.06 (m, 2H, 2 × H2′), 7.21–7.33 (m, 2H, H-5, H-7), 7.45 (s, 1H, H-2), 7.45–7.56 (m, 2H, H-4, H-6); LRMS (EI) *m/e*: 190 (58, M^+), 178 (7), 145 (29), 131 (100), 119 (15), 115 (14), 103 (9), 91 (14), 77 (14), 63 (6), 51 (5). Anal. calcd. for $C_{11}H_{10}O_3$: C 69.47, H 5.30; found: C 69.64, H 5.33.

2,3-Dihydro-1H-cyclopenta[b]benzofuran-3-one ***26***

Polyphosphoric acid was prepared by combining phosphorus pentoxide (0.85 g, 6.0 mmol) with 85% orthophosphoric acid (0.559 mL, 8.17 mmol) and heating at 85°C for 30 min. The acid **25** (0.100 g, 0.526 mmol) was added to the PPA and the mixture was heated at 90°C for 1h. The dark purple solution was cooled to 60°C and poured into ice water. Extraction with Et_2O (3 × 25 mL) was followed by washing the ether extracts with 20% NaOH (50 mL) and water (2 × 25 mL). The organic layer was dried (Na_2SO_4) and concentrated to give 13 mg (14%) of **26** after flash chromatography (silica, 10% EtOAc–hexanes eluent). The basic layer was acidified with 2 N HCl and extracted with EtOAc (2 × 25 mL). The organics were washed with brine (50 mL), dried (Na_2SO_4), and the solvent was removed to provide 76 mg of an orange polymeric material that was not characterized. **26** could be recrystallized from Et_2O–hexanes to afford colourless needles; mp 145–146°C; IR ($CHCl_3$): 3003, 2929, 1688, 1590, 1442, 1394, 1043, 820 cm^{-1}; ^1H NMR (250 MHz, $CDCl_3$) δ: 3.00–3.09 (m, 4H, 2 × H-2, 2 × H-1), 7.35 (td, J = 7.9, J = 1.1, 1H, H-7), 7.48–7.61 (m, 2H, H-5, H-6), 7.71 (d, J = 7.9, 1H, H-8); LRMS (EI) *m/e*: 172 (100, M^+), 144 (28), 115 (68), 89 (8), 63 (10); HRMS calcd. for $C_{11}H_8O_2$: 172.05242; found: 172.05240.

2,2a,3,4,5,5a-Hexahydro-5-hydroxy-5a-methyl-8H-naphtho[1,8-bc]furan ***27***

To **19** (450 mg, 2.37 mmol) in EtOH (20 mL) at 0°C was added $NaBH_4$ (24.2 mg, 0.639 mmol). After stirring for 1h at 0°C, water (10 mL) was added and the EtOH was removed under reduced pressure. The aqueous residue was extracted with EtOAc (3 × 20 mL) and the organic extracts were washed with water (50 mL), dried (Na_2SO_4), and concentrated in vacuo. The pale yellow oil was chromatographed (silica, 30% Et_2O–hexanes) to afford 424 mg (93%) of **27** as a colourless oil. IR (neat): 3439 (br), 2931, 1633, 1443, 1389, 1330, 1197, 1062, 1028, 1002, 948, 917, 729 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.11 (s, 3H, Me), 1.14–1.32 (m, 1H, H-3β), 1.47–1.79 (m, 2H, H-3α and H-4β), 1.83–1.95 (m, 1H, H-4α), 2.70–2.75 (m, 2H, 2 × H-8), 2.84–2.98 (m, 1H, H-2a), 3.46 (dd, $J_{4\alpha,5}$ = 4.4, $J_{4\beta,5}$ = 11.1, 1H, H-5), 3.96 (dd, $J_{2\alpha,2\beta}$ = 9.1, $J_{2a,2\beta}$ = 5.2, 1H, H-2β), 4.42 (t, $J_{2a,2\alpha} = J_{2\beta,2\alpha}$ = 9.1, 1H, H-2α), 5.75 (AB of ABXX′, J_{AB} = 9.9, J_{AX} = 2.1, J_{BX} = 3.3, Δν = 42, 2H, H-6, H-7); LRMS (EI) *m/e*: 192 (52, M^+), 177 (5), 159 (18), 148 (8), 133 (100), 119 (11), 105 (31), 91 (22), 77 (15), 65 (7). Anal. calcd. for $C_{12}H_{16}O_2$: C 74.96, H 8.39; found: C 74.88, H 8.41.

2a,3,4,8b-Tetrahydro-5-methyl-2H-azuleno[8,1-bc]furan ***28***

To a solution of **27** (70 mg, 0.36 mmol) in THF (2 mL) was added 1,1′-thiocarbonyldiimidazole (0.144 g of 90% technical grade, 0.728 mmol) and the mixture was stirred at 70°C for 3h. The solution was cooled to 25°C and water (10 mL) added. The mixture was extracted with CH_2Cl_2 (3 × 10 mL) and the organic extracts were combined and washed sequentially with 2 N HCl (10 mL), saturated $NaHCO_3$ (10 mL), and water (10 mL). The organic layer was dried (Na_2SO_4) and the solvent removed under reduced pressure to provide an oil, which was subjected to flash chromatography (silica, 20% Et_2O–hexanes eluent) to give 30 mg (48%) of **28** as a pale yellow oil. IR (neat): 2952, 2883, 1640, 1534, 1450, 1368, 1178, 777, 744 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.39–1.60 (m, 1H, H-3), 1.84 (s, 3H, Me), 2.11–2.24 (m, 1H, H-3), 2.39–2.53 (m, 1H, H-4), 2.61–2.70 (dd, $J_{3,4}$ = 7.4, $J_{4\alpha,4\beta}$ = 15.5, 1H, H-4), 2.91 (d, $J_{2a,8b}$ = 8.6, 1H, H-8b), 3.01–3.14 (m, 1H, H-2a), 4.08 (dd, $J2a,2\beta$ = 1.3, $J_{2\alpha,2\beta}$ = 8.8, 1H, H-2β), 4.36 (dd, $J_{2a,2\alpha}$ = 5.7, $J_{2\beta,2\alpha}$ = 8.8, 1H, H-2α), 5.53 (dd, $J_{8b,8}$ = 1.4, $J_{7,8}$ = 6.2, 1H, H-8), 6.14 (AB of an ABX system, J_{AB} = 11.3, J_{AX} = 6.1, Δν = 19.7, 2H, H-6, H-7); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 19.89, 31.99, 33.05, 43.96, 49.61, 76.42, 94.43, 125.67, 127.21, 128.25, 132.10, 155.28; LRMS (EI) *m/e*: 174 (91, M^+), 159 (7), 146 (85), 145 (100), 131 (23), 115 (16), 105 (16), 91 (22), 77 (17), 62 (18); HRMS calcd. for $C_{12}H_{14}O$: 174.1044; found 174.1041. Attempted dehydrogenation of ***19****, synthesis of 3-(2,3-dihydro-4-methylbenzol[b]furan-3-yl)propanoic acid* ***(30)***

To ketone **19** (118 mg, 0.621 mmol) in dry dioxane (3.5 mL) was added DDQ (0.141 g, 0.621 mmol) and the mixture refluxed for 7h. The solution was cooled and the solid was filtered off. The solid was washed with benzene and the filtrate was concentrated. Flash chromatography (silica, 40% Et_2O–hexanes eluent) afforded an orange oil that appeared as several spots on TLC. NMR analysis of this material revealed the absence of any vinylic protons and the presence of aromatic protons. This material was rechromatographed to furnish 40 mg (31%) of **30** as a colourless solid that could be recrystallized from Et_2O–hexanes.

Attempted bromination of ***19****, synthesis of* ***30***

To **19** (50 mg, 0.26 mmol) in CCl_4 (3 mL) was added freshly recrystallized NBS (50 mg, 0.27 mmol) and the mixture was heated at 60°C for 20 min. The succinimide was seen floating on top of the solution. The flask was cooled in ice and the solution was filtered. The filtrate was concentrated in vacuo. Flash chromatography (silica, 30% EtOAc–hexanes) provided 40 mg (74%) of **30**; mp 85.5–86°C; IR ($CHCl_3$): 3400–2500, 2931, 1709, 1596, 1453, 1244, 710, 649 cm^{-1}; ^1H NMR (250 MHz, $CDCl_3$) δ: 1.82–2.11 (m, 2H, 2 × H-3′), 2.31 (s, 3H, Me), 2.28–2.47 (m, 2H, 2 × H-2′), 3.47 (m, 1H, H-3), 4.33 (dd, $J_{2\alpha,2\beta}$ = 9.1, $J_{3,2\beta}$ = 3.1, 1H, H-2β), 4.49 (t, $J_{2\beta,2\alpha} = J_{3,2\alpha}$ = 9.1, 1H, H-2α), 6.63 (d, J = 7.8, 1H, H-5 or H-7), 6.67 (d, J = 7.8, 1H, H-5 or H-7), 7.04 (t, J = 7.8, 1H, H-6); LRMS (EI) *m/e*: 206 (36, M^+), 146 (15), 133 (100), 105 (46), 84 (25), 49 (38). Anal. calcd. for $C_{12}H_{14}O_3$: C 69.89, H 6.84; found: C 69.95, H 6.91.

2,2a,3,4,5,5a-Hexahydro-5-methoxy-5a-methyl-8H-naphtho[1,8-bc]furan ***(31)***

To a solution of **27** (172 mg, 0.895 mmol) and HMPA (171 μL, 0.980 mmol) in dry THF (4 mL) at −78°C was added *n*-BuLi (0.615 mL of a 1.6 M solution in hexanes, 0.98 mmol) dropwise. The solution was stirred at −78°C for 1h. MeI (0.111 mL, 1.77 mmol) was added and the solution allowed to warm to 25°C and stirred for 1h. Water (10 mL) was added and the organic solvents evaporated off under reduced pressure. The aqueous residue was extracted with EtOAc (3 × 10 mL). The organic extracts were combined, washed with brine (20 mL), dried (Na_2SO_4), and concentrated in vacuo. Flash chromatography (silica, 10% EtOAc–hexanes eluent) afforded 152 mg (82%) of methyl ether **31** as a colourless oil. IR (neat): 2933, 2885, 1668, 1582, 1202, 1098, 1000, 955, 932, 729 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.09 (s, 3H, Me), 1.15–1.50 (m, 2H, 2 × H-3), 1.84–1.97 (m, 2H, 2 × H-4), 2.70–2.74 (m, 2H, 2 × H-8), 2.84–3.01 (m, 1H, H-2a), 2.94 (dd, $J_{4\beta,5\beta}$ = 3.7, $J_{4\alpha,5\beta}$ = 7.4, 1H, H-5), 3.96 (dd, $J_{2\alpha,2\beta}$ = 9.1, $J_{2a,2\beta}$ = 5.4, 1H, H-2β), 4.42 (t, $J_{2a,2\alpha} = J_{2\beta,2\alpha}$ = 9.1, 1H, H-2α), 5.60 (dt, $J_{8,7}$ = 3.3, $J_{6,7}$ = 9.9, 1H, H-7), 5.88 (dt, $J_{7,6}$ = 9.9, $J_{8,6}$ = 2.1, 1H, H-6); LRMS (EI) *m/e*: 206 (45, M^+), 189 (16), 173 (19), 159 (23), 145 (36), 133 (100), 119 (12), 105 (34), 91 (22), 77 (14), 65 (7). HRMS calcd. for $C_{22}H_{24}O_5$: 368.1623; found: 368.1618.

*X-ray structure determination summary of **35***

Crystals of **35** ($C_{22}H_{24}O_5$) are triclinic, space-group $P\bar{1}$ with *a* = 9.411 (2), *b* = 9.694 (2), *c* = 11.478(3) Å, α = 99.92 (2)°, β = 113.50 (2)°, γ = 97.88 (2)° , *V* = 921.1 (4) $Å^3$; Mol. Wt. 368.4, *Z* = 2, D_c = 1.328 g/ cm^3, *F*(000) = 392, μ (MoKα) = 0.93 cm^{-1}.

Data were collected on a colourless prism of dimensions 0.42 × 0.40 × 0.32mm mounted on a Nicolet–Siemens P3m/V diffractometer at 295 K. Data were collected by the ω -scan method to a 2θ-maximum of 50° . From a total of 3265 absorption corrected (ψ-scan) independent reflections measured, 2439 with $F > 6\sigma(F)$ were considered observed and used in the structure solution and refinement. The structure was solved by direct methods (Siemens SHELXTL PLUS) and refined by full-matrix least-squares methods to *R* and *wR* values of 4.24 and 4.04%; the weighting scheme used was $w^{-1} = \sigma^2(F)$. Full details have been deposited as supplementary material.[5]

*5-Hydroxy-5a-methyl-2,2a,3,4,5,5a,8,8a-octahydro-2*H*-naphtho-[1,8-*bc*]furan **38***

To a solution of **27** (80 mg, 0.42 mmol) and $NaBH_3CN$ (27 mg of a 95.7% grade, 0.42 mmol) in EtOH (2 mL) was added one drop of bromocresol green – methyl red indicator. The solution was cooled to 0° C. One drop of concentrated HCl was added to maintain the yellow colour of the solution. The solution was warmed to 25°C and HCl was added a drop at a time as the solution turned blue. The mixture was stirred for 3.5h. Water (10 mL) was added and the EtOH was removed by evaporation under reduced pressure. The aqueous residue was extracted with EtOAc (3 × 10 mL). The organic extracts were combined, washed with water (25 mL), dried (Na_2SO_4), and concentrated in vacuo. Flash chromatography on silica (30% Et_2O–hexanes eluent) afforded 66 mg (82%) of **38** as a colourless oil.

*Direct reduction of **19** to **38***

Compound **19** (1.13 g, 5.94 mmol) and $NaBH_4$ (60.7 mg, 1.61 mmol) were allowed to react according to the procedure given above except that after 1h at 0°C the bromocresol green – methyl red indicator was added and the previous procedure was followed. After flash chromatography on silica (10% Et_2O–hexanes eluent), 0.886 g (78%) of **38** was obtained. IR (neat): 3415 (br), 2934, 2872, 1455, 1060, 1002, 941, 909, 732 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ : 1.13 (s, 3H, Me), 1.44–1.83 (m, 5H, 2 × H-3, 2 × H-4, H-8b), 1.95–2.09 (m, 1H, H-8α), 2.25–2.45 (m, 1H, H-2a), 2.51 (dtd, $J_{8\alpha,8\beta}$ = 15.7, $J_{8a,8\beta} = J_{7,8\beta}$ = 5.7, $J_{6,8\beta}$ = 0.9, 1H, H-8β), 3.61 (dd, $J_{2\alpha,2\beta}$ = 8.4, $J_{2a,2\beta}$ = 1.2, 1H, H-2β), 3.69–3.72 (q, 1H, $J_{4,5}$ = 11.1, 4.4, H-5), 3.89 (ddd, $J_{8b,8a}$ = 9.9, $J_{8\alpha,8a}$ = 11.4, $J_{8\beta,8a}$ = 5.6, 1H, H-8a), 4.03 (dd, $J_{2\beta,2\alpha}$ = 8.4, $J_{2a,2\alpha}$ = 6.1, 1H, H-2α), 5.70 (AB of an ABMX system, J_{AB} = 9.8, J_{BX} = 5.7, J_{BM} = 1.8, J_{AX} = 2.8, J_{AM} = 0.9, Δν = 39.6, 2H, H-6, H-7); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 19.65, 28.20, 30.11, 32.60, 34.63, 41.60, 53.28, 73.08, 73.81, 74.90, 123.12, 136.54; LRMS (EI) *m/e*: 194 (27, M^+), 176 (38), 161 (22), 145 (31), 135 (38), 119 (24), 108 (54), 93 (100), 79 (59), 69 (47). Anal. calcd. for $C_{12}H_{18}O_2$: C 74.19, H 9.34; found: C 74.39, H 9.08.

*5a-Methyl-2a,3,4,5,5a,8,8a,8b-octahydro-2*H*-naphtho[1,8-*bc*]-furanyloxythiocarbonyl-1-imidazole **29***

Alcohol **38** (200 mg, 1.03 mmol) and 1,1′-thiocarbonyldiimidazole (408 mg, 2.06 mmol) were refluxed in benzene (8 mL) for 5h. The solution was cooled to 25°C and the benzene removed under reduced pressure. Water (20 mL) was added to the residue and the mixture extracted with CH_2Cl_2 (3 × 20 mL). The organic layer was washed with 2 N HCl (25 mL), saturated aqueous $NaHCO_3$ (25 mL), and water (50 mL), then dried (Na_2SO_4) and concentrated in vacuo. Flash chromatography (silica, 50% Et_2O–hexanes eluent) provided a pale yellow solid, which was recrystallized from $CHCl_3$–hexanes to give 202 mg (65%) of **29** as colourless cubes; mp 152–154° C; IR (neat): 2934, 2879, 1458, 1380, 1330, 1319, 1277, 1233, 979, 738 cm^{-1}; ^1H NMR (250 MHz, $CDCl_3$) δ: 1.34 (s, 3H, Me), 1.60–1.81 (m, 3H, 2 × H-3, H-8b), 1.85–2.15 (m, 3H, 2 × H-4, H-8α), 2.39–2.51 (m, 1H, H-2a), 2.58 (dt, $J_{8\alpha,8\beta}$ = 16.2, $J_{7,8\beta} = J_{8a,8\beta}$ = 5.3, 1H, H-8β), 3.67 (dd, $J_{2a,2\beta}$ = 1.3, $J_{2\alpha,2\beta}$ = 8.6, 1H, H-2β), 3.98 (ddd, $J_{8\alpha,8a}$ = 11.5, $J_{8b,8a}$ = 10.0, $J_{8\beta,8a}$ = 5.3, 1H, H-8a), 4.08 (dd, $J_{2\beta,2\alpha}$ = 8.6, $J_{2a,2\alpha}$ = 6.1, 1H, H-2α), 5.53–5.64 (m, 3H, H-5, H-6, H-7), 7.05 (dd, *J* = 1.0, 1H, H-4′ or 5′), 7.63 (dd, *J* = 1.5, *J* = 1.0, 1H, H-4′ or 5′), 8.34 (t, *J* = 1.0, 1H, H-2′); LRMS (EI) *m/e*: 304 (32, M^+), 271 (7), 177 (100), 159 (8), 147 (10, 131 (9), 117 (11), 105 (20), 95 (21), 91 (24), 81 (34), 67 (35). HRMS calcd. for $C_{16}H_{20}N_2O_2S$: 304.1245; found: 304.1235.

*5a-Methyl-2a,3,4,5,5a,8,8a,8b-octahydro-2*H*-naphtho[1,8-*bc*]-furanyl-5-oxy-2,4,6-trichlorophenoxythiocarbonate **39***

To a solution of alcohol **38** (100 mg, 0.515 mmol) in benzene (2.5 mL) was added pyridine (42μ L, 0.52 mmol) and *N*-hydroxysuccinimide (12 mg, 0.10 mmol). Trichlorophenoxythiocarbonyl chloride (156 mg, 0.566 mmol) in benzene (2.5 mL) was added to the solution and the mixture was refluxed for 20h. The solution was filtered to remove any pyridine hydrochloride and the solvent was evaporated under reduced pressure. Water (10 mL) was added to the residue and this was extracted with EtOAc (3 × 10 mL). The organic layer was washed with water (25 mL), dried (Na_2SO_4), and concentrated in vacuo. Flash chromatography (silica, 20% EtOAc–hexane eluent) provided 48 mg (48%) of alcohol starting material and 49 mg (22%, 42% based on recovered starting material) of **39**. This was recrystallized from Et_2O–hexanes; mp 102–103° C; IR ($CHCl_3$): 2938, 2875, 1773, 1568, 1451, 1330, 1233, 1176, 1130, 1054, 1004, 820, 804, 756 cm^{-1}; ^1H NMR (250 MHz, $CDCl_3$) δ: 1.24 (s, 3H, Me), 1.53–2.16 (m, 6H, 2 × H-3, 2 × H-4, H-8b, H-8α), 2.32–2.50 (m, 1H, H-2a), 2.51–2.62 (m, 1H, H-8β), 3.65 (dd, $J_{2\alpha,2\beta}$ = 8.5, $J_{2a,2\beta}$ = 1.0, 1H, H-2β), 3.95 (ddd, $J_{8\alpha,8a}$ = 11.5, $J_{8b,8a}$ = 9.9, $J_{8\beta,8a}$ = 5.2, 1H, H-8a), 4.06 (dd, $J_{2\beta,2\alpha}$ = 8.5, $J_{2a,2\alpha}$ = 6.2, 1H, H-2α), 5.30 (dd, $J_{4,5}$ = 4.1, $J_{4,5}$ = 11.5, 1H, H-5), 5.60–5.70 (m, 2H, H-6, H-7), 7.39 (s, 2H, 2 × ArH); LRMS (EI) *m/e*: 434 (17, M^+), 194 (11), 178 (17), 177 (100), 147 (12), 105 (20), 81 (36), 67 (44), 45 (26). Anal. calcd. for $C_{19}H_{19}Cl_3O_3S$: C 52.61, H 4.41; found: C 52.88, H 4.78.

[5]Tables of crystal data, atomic coordinates, bond lengths and angles, anisotropic displacement factors, and observed and calculated structure factors can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

Tables of crystal data, atomic coordinates, and bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Methyl-5a-methyl-2a,3,4,5,5a,8,8a,8b-octahydro-2H-naphtho[1,8-bc]furanyl-5-xanthate ***40***

Compound **38** (564 mg, 2.90 mmol) was dissolved in dry THF (15 mL) and cooled to −78° C. *n*-BuLi (2.37 mL of a 1.6 M solution in hexanes, 3.80 mmol) was added dropwise to this solution and the mixture stirred at −78°C for 30 min, then at 0°C for 20 min. Dry carbon disulfide (0.263 mL, 4.37 mmol) was added dropwise and the reactin mixture was stirred at 0°C for 40 min. Iodomethane (0.727 mL, 11.6 mmol) was added and the solution stirred at 0°C for 20 min, then at 25°C for 30 min. The solution was poured into ice water (50 mL) and extracted with EtOAc (3 × 40 mL). The EtOAc layer was washed with saturated aqueous NH_4Cl (75 mL), and brine (75 mL), then dried (Na_2SO_4). Concentration in vacuo followed by flash chromatography (silica, 10% EtOAc–hexanes) afforded 0.652 g (79%) of **40** as a colourless oil. IR (neat): 2932, 2870, 1452, 1369, 1216, 1055, 1010, 968, 728 cm^{-1}; ^1H NMR (250 MHz, $CDCl_3$) δ: 1.29 (s, 3H, Me), 1.55–2.08 (m, 6H, 2 × H-3, 2 × H-4, H-8b, H-8α), 2.33–2.52 (m, 2H, H-2a, H-8β), 2.56 (s, 3H, SMe), 3.64 (dd, $J_{2\alpha,2\beta}$ = 8.6, $J_{2a,2\beta}$ = 1.4, 1H, H-2β), 3.96 (ddd, $J_{8\alpha,8a}$ = 11.5, $J_{8b,8a}$ = 9.9, $J_{8\beta,8a}$ = 5.3, 1H, H-8a), 4.06 (dd, $J_{2\beta,2\alpha}$ = 8.6, $J_{2a,2\alpha}$ = 6.1, 1H, H-2α), 5.58–5.68 (m, 3H, H-5, H-6, H-7); LRMS (EI) *m/e*: 284 (20, M^+), 251 (5), 237 (5), 177 (100), 159 (20), 133 (14), 117 (19), 105 (29), 91 (36), 81 (36), 79 (20), 67 (37), 55 (16), 41 (20). Anal. calcd. for $C_{14}H_{20}O_2S_2$: C 59.12, H 7.09; found: C 59.01, H 7.01.

5a-Methyl-2a,3,4,5,5a,8,8a,8b-octahydro-2H-naphtho[1,8-bc]furan ***41***

To a solution of xanthate **40** (620 mg, 2.18 mmol) in dry toluene (15 mL) at 90°C was added a solution of *n*-Bu_3SnH (1.99 mL, 7.19 mmol) and AIBN (221 mg) dropwise over 30 min. The solution was stirred an additional 30 min at 90° C, then cooled to 25° C. The solvent was removed by concentrating in vacuo and the residue chromatographed (silica, 100% hexane then 50% CH_2Cl_2–hexanes eluent) to provide 268 mg (69%) of **41**. IR (neat): 2927, 2868, 1459, 1365, 1060, 1006, 938, 724 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.11 (s, 3H, Me), 1.31–1.72 (m, 7H, 2 × H-3, 2 × H-4, 2 × H-5, H-8b), 2.00 (ddd, $J_{8\alpha,8\beta}$ = 15.3, $J_{8a,8\alpha}$ = 10.1, $J_{7,8\alpha}$ = 1.5, 1H, H-8α), 2.26–2.39 (m, 1H, H-2a), 2.42–2.55 (m, 1H, H-8β), 3.62 (dd, $J_{2\alpha,2\beta}$ = 8.3, $J_{2a,2\beta}$ = 1.3, 1H, H-2β), 3.89 (ddd, $J_{8\alpha,8a}$ = 11.1, $J_{8a,8b}$ = 10.1, $J_{8\beta,8a}$ = 5.2, 1H, H-8a), 4.04 (dd, $J_{2\beta,2\alpha}$ = 8.3, $J_{2a,2\alpha}$ = 6.1, 1H, H-2α), 5.45–5.46 (m, 2H, H-6, H-7); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 20.99, 26.82, 28.51, 32.64, 34.48, 35.12, 50.80, 65.92, 73.60, 74.41, 121.30, 139.54; LRMS (EI) *m/e*: 178 (68, M^+), 163 (20), 147 (34), 134 (36), 119 (27), 105 (43), 91 (66), 82 (100), 69 (65), 55 (32), 41 (72); HRMS calcd. for $C_{12}H_{18}O$: 178.1358; found: 178.1347.

5a-Methyl-2a,3,4,5,5a,8,8a,8b-octahydro-2H-naphtho[1,8-bc]furan-2-one ***42***

Chromium trioxide (438 mg, 4.38 mmol) was suspended in 5 mL of dry CH_2Cl_2 at −20°C and 3,5-dimethylpyrazole (421 mg 4.36 mmol) was added in one portion. After stirring at −20°C for 15 min, **41** (65 mg, 0.36 mmol) in CH_2Cl_2 (1 mL) was added and the mixture was stirred for 4h at −23°C. NaOH (3 mL of a 5 M solution) was added and the mixture was stirred at 0°C for 1 h. The layers were separated and the organic layer was washed with 0.5 N HCl (10 mL) to remove the DMP. The CH_2Cl_2 layer was subsequently washed with water (2 × 10 mL), and brine (10 mL). After drying (Na_2SO_4) and concentrating in vacuo, flash chromatography (silica, ether–hexane 1:1) provided 40 mg (62%) of starting material and 15 mg of **42** as a colourless oil. IR (neat): 2933, 2862, 1780, 1449, 1196, 1160, 1037, 1010, 967, 726 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.09 (s, 3H, Me), 1.39–1.71 (m, 6H, 2 × H-3, 2 × H-4, 2 × H-5), 1.88–2.04 (m, 2H, H-8, H-8b), 2.23 (ddd, $J_{8,8}$ = 14.9, $J_{8a,8}$ = 10.4, $J_{7,8}$ = 0.9, 1H, H-8), 2.71–2.52 (m, 2H, H-8, H-2a), 4.53 (td, $J_{8a,8\alpha} \approx J_{8a,8b} \approx$ 11.0, $J_{8a,8\beta}$ = 5.3, 1H, H-8a), 5.50–5.51 (m, 2H, H-6, H-7); LRMS (EI) *m/e*: 192 (42, M^+), 177 (5), 164 (12), 148 (33), 133 (100), 119 (31), 106 (68), 91 (96), 79 (63), 67 (34), 55 (29), 41 (58).

5,8-Dimethoxy-1,2,3,4,4a,9,9a,10-octahydro-9,10-epoxyanthracene ***43***

To a solution of **32** (150 mg, 0.765 mmol) in dry *p*-xylene (1.5 mL) was added dry cyclohexene (387μ L, 3.82 mmol) and toluic acid (11 mg, 0.076 mmol). The mixture was heated at 140°C for 36h. The solvent was removed under reduced pressure and the residue was subjected to flash chromatography (neutral alumina, 50% CH_2Cl_2–hexanes eluent) to provide 105 mg (53%) of a 6:1 mixture of *endo* and *exo* isomers of **43**. This mixture was recrystallized from Et_2O to provide colourless needles; mp 75–76° C; IR ($CHCl_3$): 3106, 2937, 2864, 1500, 1461, 1297, 1256, 1091, 985, 894, 846, 797 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ, *exo* isomer: 1.18–1.70 (m, 10H, 2 × H-1, 2 × H-2, 2 × H-3, 2 × H-4, H-4a, H-9a), 3.79 (s, 6H, 2 × OMe), 5.10 (s, 2H, H-9, H-10), 6.63 (s, 2H, 2 × ArH); *endo* isomer: 0.20–0.38 (m, 2H, H-4a, H-9a), 1.18–1.70 (m, 6H, 2 × H-2, 2 × H-3, H-4, H-1), 2.33–2.48 (m, 2H, H-1, H-4), 3.78 (s, 6H, 2 × OMe), 5.42 (d, *J* = 4.8, 2H, H-9, H-10), 6.65 (s, 2H, 2 × ArH); LRMS (EI) *m/e*: 260 (4, M^+), 242 (4) 227 (3), 201 (1), 178 (100), 163, (54), 135 (4), 115 (3), 92 (3), 77 (3), 67 (2), 41 (2). Anal. calcd. for $C_{16}H_{20}O_3$: C 73.82, H 7.74; found: C 73.61, H 7.73.

This paper is dedicated to Professor Ian Spenser

RALF LUTTERBACH, CARL MICHAEL RUYTER, and JOACHIM STÖCKIGT. Can. J. Chem. **72**, 51 (1994).

From cell suspension cultures of *Rauwolfia serpentina* Benth. a new enzyme activity was isolated and its properties determined. The enzyme is a soluble protein and catalyzes the transfer of a glucose moiety from UDPG to a wide variety of phenolic compounds with *p*-nitrophenol as one of the best substrates (K_m = 1.21 mM, UDPG = 0.54 mM). In contrast to the membrane-bound UDPG: vomilenine-21-OH-β-D-glucosyltransferase from *Rauwolfia serpentina* cells, this enzyme is not able to glucosylate indole alkaloids. The enzyme activity has been detected in 14 callus cultures belonging to 10 different plant families.

RALF LUTTERBACH, CARL MICHAEL RUYTER et JOACHIM STÖCKIGT. Can. J. Chem. **72**, 51 (1994).

On a isolé une nouvelle activité enzymatique à partir de cultures d'une suspension de cellules du *Rauwolfia serpentina* Benth. et on en a déterminé les propriétés. L'enzyme est une protéine soluble et elle catalyse le transfert d'une unité de glucose du UDPG à grande variété de composés phénoliques parmi lesquels le *p*-nitrophénol est l'un de ses meilleurs substrats (K_m = 1,21 mM, UDPG = 0,54 mM). Par opposition au UDPG lié à la membrane, la vomilénine-21-OH-β-D-glyucosyltransférase isolé de cellules de *Rauwolfia serpentina*, cet enzyme ne peut effectuer la glcosylation des alcaloïdes de l'indole. On a pu détecter l'activité enzymatique dans 14 cultures de callus appartenant à 10 familles différentes de plantes.

[Traduit par la rédaction]

Introduction

As reported previously, cell cultures of *Rauwolfia serpentina* (L.) Benth. ex Kurz contain a highly specific membrane-bound UDPG:[3] vomilenine glucosyltransferase (EC 2.4.1.-), which is responsible for the formation of the glucoalkaloid raucaffricine (1). In contrast to this we have found, in soluble protein extracts of *Rauwolfia* cells, high glucosyltransferase activities that catalyse preferentially the glucosylation of aromatic hydroxyl groups of a number of structurally diverse compounds. In this paper we describe the isolation and properties of this transferase activity.

Experimental

Materials and methods

Plant cell suspension cultures

Rauwolfia serpentina cells were cultivated under standard conditions in LS medium (2) as described recently (3). After a growth period of 7 days, cells were harvested, frozen with liquid nitrogen, stored at –25°C, and used as an enzyme source.

Enzyme isolation and enrichment

The cultured *Rauwolfia* cells (1 kg FW) to be used as the enzyme source were frozen with liquid nitrogen and homogenized for 2 min using a Braun-Starmix and 1.4 L Tris-HCl buffer (0.1 M, pH 8.5, 10 mM BME, 10 mM KCl, 1 mM EDTA). The mixture was stirred for 30 min at 4°C, filtered through cheesecloth, and centrifuged (20 min, 4500 × *g*). The supernatant (2.07 g protein) was subjected to ammonium sulphate precipitation (30–70% saturation) resulting in 1.58 g crude enzyme (27.7 nkat/g). The protein was dissolved in 230 mL of 0.2 M Tris-HCl buffer (pH 7.5, 10 mM BME) and dialyzed for 12 h against the same buffer at 0.02 M. The supernatant of centrifuged protein solution (11000 × *g*) was transferred to a DEAE DE 52 column. Fractionation of the protein (10 mL/fraction) was achieved with a linear gradient from 0 to 0.5 M KCl (20 mM Tris-HCl, pH 8.5, 10 mM BME) at a flow rate of 1 mL/min. Fractions 13–18 were combined and contained 174 mg protein (107 nkat/g) with a 7-fold enrichment. After concentration of the enzyme solution to 2.5 mL, the protein was subjected to gel chromatography (Fractogel 55 S, column 2.5 × 80 cm, and the above-mentioned buffer with a flow rate of 20 mL/h). Fractions (each 5 mL) 29, 30, and 31 were combined and contained 36 mg of the transferase (156 nkat/g) with a 10-fold enrichment. Proteinconcentrations were determined as previously reported (4).

Enzyme assays

For the determination of the enzyme activities dependent on culture conditions, temperature variation, kinetic data, and enzyme enrichment an HPLC assay with PNP as substrate was used. In a total volume of 0.25 mL (0.1 M Tris-HCl, pH 7.5) the enzyme solution was incubated for 30 min at 37°C in the presence of 1 mM PNP and excess of UDPG (2 mM). After addition of 0.75 mL MeOH containing 0.1 mg/mL dansyl-threonine as an internal standard, the precipitated protein was centrifuged off and the PNP-β-D-glucoside formed was quantitatively determined in the supernatant under the following conditions: HPLC column, LiChrocart^R supersphere 100 (RP-18), 4 × 125 mm; mobile phase, acetonitrile – KPi buffer (6.66 g KH_2PO_4, 2.8 mL 83% H_3PO_4 to 1 L, pH 2.3) = 38:62 under isocratic conditions; 1 mL/min flow; detection at 300 nm. Retention time of PNP-β-D-glucoside was 1.4 min. For the determination of the substrate specificity of the transferase an assay based on the TLC analysis of the appropriate radioactive glucosides from UDP-[^{14}C]-glucose (11.7 GBq/mmol) was employed.

A standard incubation mixture contained, in a volume of 0.15 mL (0.2 M Tris-HCl, pH 7.5), the appropriate substrate (2 mM), 0.5 mM UDP-[^{14}C]-G (4.625 KBq), and about 0.4 mg of a prepurified enzyme (1.8-fold). After incubation of the mixture for 2 h at 37°C, 0.3 mL MeOH was added, the mixture was centrifuged as above, and 10 µL of the mixture was chromatographed on TLC plates (Merck G/UV_{254}, 0.2 mm) in the solvent system EtOAc–MeOH–H_2O (7:2:1). The yield of ^{14}C-labelled glucosides formed was calculated after TLC scanning using a Rita 3200 instrument (Raytest).

Results

An enzyme with glucosylating activity could be isolated from *Rauwolfia* cell suspensions that were grown under stan-

dard conditions, transforming PNP into its ß-D-glucoside in the presence of UDPG. The transferase reaction was completely dependent on the presence of active protein. The reaction showed normal Michaelis–Menten kinetics for PNP (Fig. 1) and UDPG (Fig. 2). The double reciprocal plots of enzyme activity and substrate concentration gave linear relationships (Figs. 1 and 2). The apparent K_m values were found to be 1.21 mM for PNP (V_{max} = 40 pkat) and 0.54 mM for UDPG (V_{max} = 26.9 pkat). When the enzyme activity was measured at different pH, the optimum activity was found between pH 7.3 and 7.8. The enzyme tolerated a relatively broad pH range, with half-maximum activity at pH 6.5 and pH 8.3 (Fig. 3). The optimum temperature of the reaction was 37°C.

Dependency of the transferase activity on cell growth and nutrition medium

The enzyme activity in crude protein extracts of cells that were grown in 1 L LS medium increased with cell growth. After 4 days 18 nkat and 6.5 g DW were recorded, after 6 days 48 nkat and 10.6 g DW, and after 10 days 78 nkat and 18.3 g DW. During this growth period the total protein isolated from the cells by the standard procedure increased from 188 mg to 746 mg/L medium. The maximum value for the specific activity of the transferase (171 pkat/mg protein) could be measured on the fifth day of cell growth. When the protein and transferase content was determined after 7 days under constant conditions (inoculum per litre of medium corresponded to 2.2 g DW), the cultured cells in MS (5) and LS medium showed highest total and specific enzyme activities of 9 nkat/L (7.5 pkat/mg protein) and 7 nkat/L (5.5 pkat/mg protein), respectively. Significantly lower values were observed when cells were grown in APII or Ringe medium (6, 7).

Stability of the enzyme

When a crude soluble protein extract was stored at 4°C, the enzyme activity decreased after 2 days to 90% of the original activity and after 5 days 50% of the activity could still be measured, but after 2 weeks no transferase activity was detected. If the enzyme extract was frozen in the presence of 20% glycerol, 95% of the original enzyme activity was retained after 3 months of storage.

Transferase stability in the presence of organic solvents

To test the stability of the enzyme in relation to the organic solvent required to dissolve water-insoluble substrates, a range of solvents was tested.

The enzyme best tolerated DMSO and MeOH, 50% of the enzyme activity being retained at 22% and 14%, respectively. EtOH, DMF, and THF decreased the transferase activity to 50% at much lower concentrations, viz. 8%, 4%, and 3%, respectively.

Substrate and co-substrate specificity

The substrate specificity of the transferase activity was investigated using a broad variety of phenolic compounds (Table 1). Standard incubation conditions for substrates were used and results are summarized in Table 1. Three of the substrates, HQ (108%), ß-naphthol (120%), and thymol (140%), were more efficiently accepted as substrate when compared to PNP (100%) and MNP (101%). When PNP was used as substrate only TDPG showed a significant donor activity for glucose (18.5% relative activity), as compared with UDPG (100% relative activity). When different UDP-activated sugars were employed as substrate only UDP-glucuronic acid showed a very slight activity of 2.5% of UDPG.

Taxonomic distribution of the transferase activity in a variety of callus cultures

When the taxonomic occurrence of the enzyme was determined, we observed a very broad distribution. Using a selection of callus cultures as sources of the crude enzyme, we found the transferase in 14 different cultures belonging to 10 different plant families. For PNP as substrate only three cultures exceeded the enzyme activity of the *Rauwolfia* cells. For niclosamide as substrate, 10 cultures showed higher enzyme activities than the controls (*Rauwolfia* cells). Thymol was best glucosylated exclusively by a protein extract obtained from *R. serpentina* cells.

Discussion

We recently isolated and characterized a glucosyltransferase named UDPG: vomilenine-21-ß-D-glucosyltransferase (EC 2.4.1.-) from cell suspension cultures of *R. serpentina* Benth. (1). This enzyme catalyzes the formation of the glucoalkaloid raucaffricine, which is the major alkaloidal compound in these cells.

During these investigations we also detected other glucosylating enzyme activities, which did not transform the aglycone of raucaffricine but did glucosylate a range of phenolic compounds. To understand these transformations more precisely and to search our cell cultures for high glucosylating activities, we investigated this enzyme further. Two assays could be employed, one an HPLC-based method, and the other based on the radioactive ^{14}C-UDPG and TLC separations. Both methods allowed relatively fast and sensitive analyses for glucosylating enzymes. Having established these test systems, we searched and investigated our *Rauwolfia* cultures, which had been grown in a variety of different nutrition media, in order to find the conditions for optimum enzyme formation.

In fact, the transferase activity depends significantly on the nutrition medium used, ranging from 9 nkat/L in MS medium or 7 nkat/L in LS medium down to about 1.5 nkat/L in Ringe medium. Because we have continuously cultivated our *Rauwolfia* cells for many years in LS medium, we used the cell material grown under these conditions for enzyme isolation. In contrast to the membrane-bound UDPG-dependent vomilenine-glucosyltransferase, this transferase is a soluble protein that therefore can be simply enriched (10-fold) by ammonium sulphate precipitation and two-step column chromatography. When the enzyme was incubated with UDPG in the presence of PNP, the appropriate PNP-ß-D-glucoside was synthesized. This transferase reaction was absolutely dependent on the presence of active protein and proceeded best at a pH of 7.5, in contrast to the enzymatic vomilenine-glucoside biosynthesis showing an optimum at pH 6.3 (1).

The relatively high K_m value points to a rather low affinity of the enzyme towards the substrate PNP. This result is not surprising as PNP cannot be the natural substrate for this enzyme. At the present time the endogenous substrate of the transferase is not known. From broader substrate studies that included a number of phenolic compounds one can conclude that the enzyme has a relatively unspecific substrate acceptance because many of the phenolic compounds bearing hydroxy groups were glucosylated (Table 1). One must, however, keep in mind that the

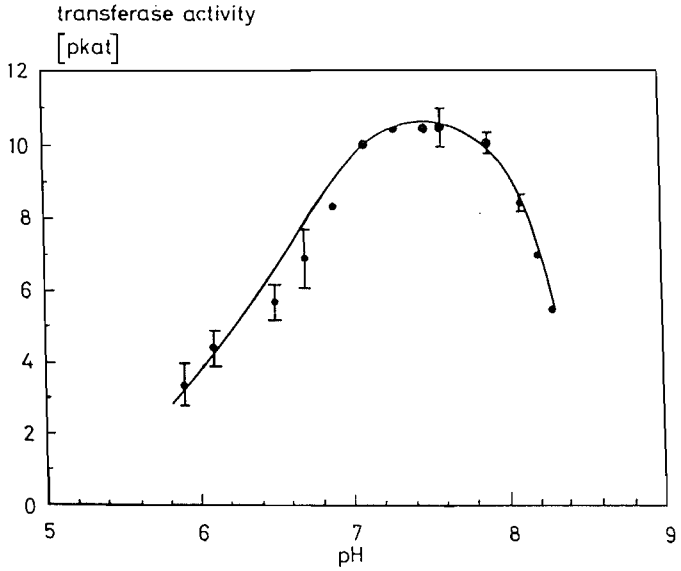

FIG. 3. The effect of pH on the PNP-glucosyltransferase activity. The assays were performed in presence of 0.49 mg enzyme and 0.2 mM KPi buffer.

studies on substrate specificity were carried out with a very crude enzyme preparation and, therefore, the possible occurrence of other glucosyltransferases in the extracts cannot be excluded. Clarification of this point must be deferred until the enzyme has been purified to homogeneity.

Like several glucosyltransferases already described, this enzyme has no great affinity for the nucleotide part of a number of nucleotide-activated glucoses. Based on the relative enzyme activity, UDP-glucose was the most efficient co-substrate but TDP-glucose was also accepted as co-substrate to an extent of 18.5%. All the other glucose nucleotides investigated exhibited nearly no effect (<1% relative activity), which is in agreement with, for example, the *p*-hydroxybenzoate glucosyltransferase or the flavonol glucosyltransferase described previously (8, 9). The sugar part of the co-substrate seems to be very important, because UDP-galactose, -mannose, or -xylose were not accepted by the enzyme. One of our future aims is to employ this enzyme on a preparative scale to glycosylate a variety of useful

compounds and thus to enhance their water solubility. A first attempt could be the taenicide niclosamide, which was efficiently transformed by the described enzyme here. To enhance the concentration of such substrates it was necessary to test the solvent tolerance of the enzyme. Of the several water-soluble solvents investigated, DMSO proved to be the solvent most tolerated by the enzyme, permitting about 10–22% DMSO with retained transferase activities of 50–80%. Obviously DMSO seems to be the solvent of choice to generate glucosides from water-insoluble substrates. All other solvents such as MeOH, EtOH, or THF were much more inhibiting to the enzyme.

We have also investigated the taxonomic distribution of this enzyme by testing a number of different callus cultures. In fact, the transferase activity was found in many cultures, indicating that it is a rather unspecific transferase. We detected it in 14 callus systems of 10 plant families (Table 2). Although this material will now be used to develop preparative scale glucosylation of different substrates, the current enzyme needs to be purified to confirm the broad substrate acceptance or to discover whether several transferases, each responsible for a glucosylation of small groups of phenols, are present in the tissue and cell cultures investigated.

Rearrangements of tricyclic ketones: [3.3.3]propellane formation via a γ-enolate revealed in an approach to the pentalenene skeleton through β-enolization[1]

HEMANT A. PATEL,[2] J.B. STOTHERS, AND S.E. THOMAS

Received May 31, 1993

This paper is dedicated to Professor David B. MacLean in recognition of his contributions to chemistry

HEMANT A. PATEL, J.B. STOTHERS, and S.E. THOMAS. Can. J. Chem. **72**, 56 (1994).

The known isomerization of the tricyclo[5.3.1.$0^{1,5}$]- to the [6.3.0.$0^{1,5}$]undecane skeleton by β-homoenolization led to examination of 2,9,9-trimethyl-6-methoxymethyltricyclo[5.3.1.$0^{1,5}$]undecanone (**6**) as a potential precursor for the synthesis of pentalenene, a naturally occurring sesquiterpenoid, utilizing a β-enolate rearrangement as a key step. While the anticipated rearrangement of **6** occurs, it is a minor process. The major rearrangement product arises by generation of a γ-enolate intermediate from a tricyclic enone formed by loss of methanol from **6**. This constitutes a new route to [3.3.3]propellanes and provides a third example of γ-enolate rearrangement. Structures of the products were established primarily from their ^{1}H and ^{13}Cmr spectra.

HEMANT A. PATEL, J.B. STOTHERS et S.E. THOMAS. Can. J. Chem. **72**, 56 (1994).

L'isomérisation connue du squelette tricyclo[5.3.1.$0^{1,5}$]undécane en tricyclo[6.3.0.$0^{1,5}$]undécane par β-homoénolisation a conduit à examiner l'utilité de la 2,9,9-triméthyl-6-méthoxytricyclo[5.3.1.$0^{1,5}$]undécanone (**6**) comme précurseur potentiel dans la synthèse du pentalènène, un sesquiterpénoïde naturel, en utilisant le réarrangement β-énolique comme étape clé. Même si le réarrangement désiré du produit **6** se produit, il s'agit d'un processus mineur. Le produit majeur de réarrangement provient d'un intermédiaire γ-énolique formé à partir de l'énone tricyclique **6**, par la perte de méthanol. Cette réaction constitue une nouvelle voie de préparation des [3.3.3]propellanes et fournit un troisième exemple d'un réarrangement γ-énolique. Les structures des produits ont été principalement déterminées à partir de leurs spectres rmn du ^{1}H et du ^{13}C.

Introduction

Over the past 15 years, several naturally occurring sesquiterpenoids with various angular triquinane carbon skeletons have been discovered (1). These compounds have attracted attention as targets for synthesis not only because of their inherently interesting structures but also since some possess biological activity. Two examples having the tricyclo[6.3.0.0]undecane ring system are pentalenene (**1**) (2) and isocomene (**2**) (3). Pentalenene is the biosynthetic precursor of the pentalenolactones (4), antibiotic metabolites produced by several *Streptomyces* species, and it has been synthesized by several groups through a variety of routes (1, 5). Isocomene cooccurs with the first carbocyclic propellane to be found in nature, modhephene (**3**) (6). Several syntheses of these fascinating structures have been described: isocomene (1, 7) and modhephene (8).

Our interest in the potential of β-enolate rearrangement as a preparative route to less accessible polycyclic carbon skeletons has led to a synthesis of the linear triquinane, hirsutene (9), and to the generation of the angular triquinane ring system through the rearrangement **4** → **5** (10). From this finding, we became interested in devising a sequence leading to **1** from an appropriate analog of **4**. To this end, ketone **6** was selected as a suitable compound for an initial investigation, with the interconversion **6** → **7** envisaged as the key step. We found that this reaction indeed occurs, but only as a minor process. The major rearrangement involves an unsaturated derivative of **6** and leads to the generation of a [3.3.3]propellane. We wish to describe here the results of our study of the behavior of **6** under typical homoenolization conditions (*t*-BuO^{-}/*t*-BuOH/185°C).

Results

Syntheses

The sequence employed for the preparation of ketone **6** is given in Scheme 1. The key step involves a well-known intramolecular Diels–Alder reaction (11) to furnish the [5.2.1.0] skeleton, which is then readily expanded to the required [5.3.1.0] system of **6**. The reaction of 2-methyloxetane (12) with methyl propargyl ether (13), as described by Yamaguchi et al. (14), gave 7-methoxyhept-5-yn-2-ol (**8**) in 88% yield. Hydrogenation of **8** over the Lindlar catalyst afforded 7-methoxy-*cis*-hept-5-en-2-ol (**9**) in 93% yield. Tosylation of **9** and condensation of this tosylate with sodium cyclopentadiene fur-

[1]Part 146 of the series ^{13}Cmr studies; for Part 145 see ref. 33.

nished a 5:3 mixture of two trienes in 84% yield.The ^{13}Cmr spectrum contained four methylene signals for each component, with only that at δ_C 68.0 (-CH_2O-) common to both, showing that **10** and its 3′-isomer were present. The cyclopentadienyl methylene proton bands, δ 2.925 (m, $\nu_{1/2}$ 4.5 Hz) and δ 2.845 (m, $\nu_{1/2}$ 4.1 Hz) with relative intensities of 5:3, respectively, indicated that **10** was the major component. In any event, the assignment was not critical since the intramolecular Diels–Alder cycloaddition proceeded in 82% yield to the desired [5.2.1.0] olefin **11** as a 2:1 mixture of the 2-epimers.

An excellent analogy for the transformation of **9** to **11** has been described by Breitholle and Fallis in the report of their synthesis of cedrol and cedrene (15). Their key step was the intramolecular Diels–Alder reaction of 1,5-dimethyl-4-hexenyl-2′-cyclopentadiene, prepared from sodium cyclopentadiene and 1,5-dimethyl-4-hexenyl tosylate. Although they obtained a single alkylcyclopentadiene isomer, in contrast to our results, they stressed that the Diels–Alder conditions may alter the equilibrium mixture of these isomers and, consequently, all

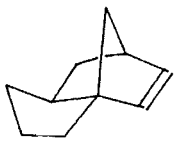
[b]Full data are given in Table 3; for the others, see Experimental.

possible intramolecular cycloaddition products should be considered. They concluded that the formation of the [5.2.1.0] skeleton would be expected to be strongly favored, as was observed in their case and in the present study. The isomeric internal Diels–Alder structures were excluded by the nmr spectra of the products in each of these studies. A second feature of this cycloaddition is the lack of a simple method to control the stereochemisty at C-2. In their synthesis of the cedrane skeleton, Breitholle and Fallis obtained a 1:1 mixture of the 2-epimers of the Diels–Alder cycloadduct but a 2:1 mixture of the 2-epimers of **11** was found in this work.

Hydroboration of **11** with $Siam_2BH$ in THF proceeded smoothly to give **12** in 74% yield; this was subsequently oxidized with pyridinium chlorochromate (16) to furnish **13** in 95% yield. Ring expansion to the desired [5.3.1.0] ring system was accomplished in a three-step sequence that had been demonstrated for several polycyclic ketones (17). Conversion of **13** to enol ether **14** (90%), cyclopropanation of **14** to **15** (81%), and ketonization in 88% yield gave **16** as a 2:1 epimeric mixture. Dimethylation of **16** with $MeI/NaNH_2/Et_2O$ proceeded in 80% yield to furnish **6**, as a 2:1 mixture of the 2-epimers, for our homoenolization experiments.

Consideration of the methylene shieldings in the ^{13}C spectra of these compounds led to a rational stereochemical assignment for the 2-methyl group in these epimeric pairs. Specific assignments for the individual carbons in **11–14** were made by comparing the shift data with the results for the compounds lacking the 2- and 6-substituents (10). The shifts for the 2-methyl and the skeletal methylene carbons in **11–14** are collected in Table 1.

In each of the sets of three methylene signals for **11** and **14**, those near 35 and 24 ppm could be readily assigned to C-3 and C-4, respectively, by comparison with the data for **17** and **18**. While the corresponding signals for the latter appear near 25 and 33 ppm, respectively, the 2-methyl group in **11** and **14** will deshield C-3 by ca. 9 ppm through its β-effect and the *exo*-6 methylene group will shield C-4 appreciably because these carbons are *syn*-periplanar. As a result, the C-3 and C-4 shieldings are reversed in **11** and **14**. The shifts for the third methylene signal, arising from C-10, differ by 6.5 ppm for each pair of epimers, which must reflect the orientation of the 2-methyl group. This group is either *syn* or *anti* to C-10 in the two epimers and, in the *syn* form, will exert a shielding effect thereon because of the relatively small dihedral angle relating the two centres. Analogous trends are also found for **12** and **13**



17

18

(see Table 1). A consistent difference of ca. 3 ppm is observed for the 2-methyl carbons in each epimeric mixture. In each pair, the minor form exhibits the more shielded 2-methyl and C-10 signals, and we can conclude, therefore, that the epimer having an *anti*-2-methyl group is predominant in each of these mixtures.

Assignments for these carbons in **6** and **16** are included in Table 1. These were also made by comparisons with the data for **4** and the parent ketone for which unequivocal assignments were available (10). For the two epimers of **6**, the C-11 shieldings differ by 7.5 ppm and, consequently, we can conclude that the desired *anti*-2-methyl epimer is the major form.

Homoenolization experiments

With the epimeric mixture of **6** in hand, we proceeded with our examination of its behavior under homoenolization conditions. After treatment of **6** with *t*-BuO^-/*t*-BuOH at 185°C for periods ranging from 24 to 240 h, we obtained neutral products in 53–80% yields by pentane extraction. Extraction of the aqueous phase after it was acidified furnished a single acidic product in 17–41% yields. The neutral fraction contained five major tlc spots; samples of each spot were examined by ^{13}Cmr to find that only partial separation had been achieved. Gas–liquid chromatographic (glc) analysis showed that the product contained two groups of components, a group of four having distinctly shorter retention times than a second group of three. The relative proportion of the first group slowly increased with reaction time, constituting ca. 75% of the neutral product after 240 h.

In the second group, two of the bands appeared to arise from two poorly resolved compounds and one, which slowly decreased with time, was easily shown to be the starting material. The first of the three bands was more symmetric and increased slowly to contain ~7% of the total neutral product after 240 h. ^{13}C spectra of samples collected by preparative glc indicated the presence of two closely related compounds in a 10:1 ratio. The major component, having a molecular formula

of $C_{16}H_{26}O_2$ by precise mass measurement, is an isomer of **6** with a cyclopentanone ring to judge from its carbonyl absorption (1730 cm^{-1}, δ_C 225.6); this is quite different from that for **6** (1700 cm^{-1}, δ_C 217.3, 217.5). From nmr spectra, the major compound was identified as **7**, accompanied by small amounts of its *syn*-2-methyl epimer. These were anticipated to form by β-enolate rearrangement of **6**. The results from $^{13}C\{^1H\}$ and $^1H\{^1H\}$ correlation spectra allowed complete assignments for the ^{13}C signals arising from **7**. Three ^{13}C methyl signals at δ_C 24.7, 26.4, and 59.0 correlated with ^1H singlets at δ 1.02, 1.06, and 3.28, respectively, while the highest field peak at δ_C 17.4 correlated with the proton doublet (δ 0.98, J = 7.0 Hz, 11-Me) coupled to H-11 (δ 1.98, m), which, in turn, is coupled to the 10-methylene protons near 1.4 and 1.6 ppm; these patterns correlate with the ^{13}C peaks, δ_C 44.1 (C-11) and 35.0 (C-10), respectively. An AX pattern, δ 2.17, δ 1.45, J_{AX} = 14.1 Hz, was readily assigned to the 2-methylene protons, which correlated with the methylene signal at δ_C 43.5 (C-2). The lowest field ^1H methine pattern at δ 2.28 (bd, J = 9.1 Hz), coupled to a methylene group near δ 1.4 and 2 .0, served to identify C-5 and -6, δ_C 58.2 and 31.8, respectively. The fourth methylene carbon signal, δ_C 22.8, arises from C-9. The ^{13}C data are collected in Table 2 with those for the minor component, *epi*-**7**, and **5**. From these data, it is clear that C-9 is strongly shielded by the methylene carbon on C-7, as expected since these are *syn*-periplanar. The shifts for C-2 in **7** and for C-5 in *epi*-**7** differ markedly from the corresponding shieldings in **5**. In **7**, C-2 is shielded by 7.4 ppm and C-5 by 5.1 ppm in *epi*-**7** relative to the values for **5**. This must reflect the orientation of the 11-methyl group and is only consistent with **7** bearing an *anti*-11-methyl group, i.e., *syn*-periplanar to C-2.

Preparative glc provided samples of the third band, which was found to contain a 2:1 mixture of alcohols. The ^{13}C spectrum showed these to be closely related to the starting material, LAH reduction of which gave an identical mixture. Therefore, these must be **19**; the ^{13}C data are listed in Table 3. Reduction of **6** was puzzling because the carbonyl group is unaffected under these conditions in the vast majority of ketones so far examined (18). To our knowledge, the only exceptions are 3-phenyl-6,6-dimethylcyclohexanone and its cycloheptanone analog from which small amounts of alcohols are formed under these conditions (19); but these are rather different systems.

For Bands 1–4 in order of increasing retention time in the first group, samples for characterization were obtained by preparative glc. Each was a mixture of epimers, but the relative proportions in two of these samples differed markedly from that of the initial ketone. All were found to have lost the methoxyl group and to contain one double bond. Band 3 constituted about 5% of the neutral product from short runs, while Band 2 was prominent in all samples, exhibiting a maximum of ~30% (72 h) and then decreasing to about 8%. Band 1 grew slowly to constitute about 45% of the total neutral product after 240 h, whereas Band 4 was a minor component in each of the product mixtures.

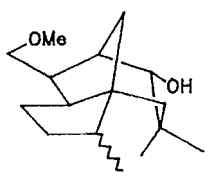
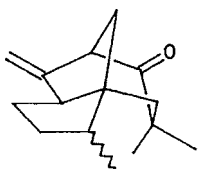
Band 3, which showed little change in relative intensity with time, consisted of a 2:1 epimeric mixture of ketones, each component of which gave rise to nmr signals for three methyl groups and those for an exocyclic methylene group. This showed that the methoxyl group had been lost, while the carbonyl absorption (δ_C 214.5) indicated that no major skeletal change had occurred. An identical mixture was prepared from the initial ketone by treatment with NaI/Me_3SiCl in MeCN (20), to replace the methoxyl group with iodide, followed by reaction with base to eliminate HI. Thus, this product was assigned structure **20** with which the ^{13}Cmr data are fully consistent; these may be compared with those for **6** (see Table 3). The replacement of C-6 with an sp^2 carbon produced marked shifts for C-5, C-6, C-7, and C-11, as expected, and the -3 ppm shift for the carbonyl signal is consistent with the formation of a β,γ-enone (21).

Band 2, a major product in the early neutral samples, was found to contain a 4:1 mixture of epimeric ketones from its ^{13}Cmr spectrum. It is isomeric with **20**, having a molecular formula of $C_{15}H_{22}O$ by precise mass measurement. The nmr spectrum of each epimer included signals for four C-methyl groups, one of which is olefinic (δ_H 1.57, δ_C 13.2, 13.5), together with those for two nonprotonated sp^2 carbons (δ_C 126.7, 154.1 and 127.3, 153.0). As in **20**, the carbonyl absorption at δ_C 215.0 and 215.2 indicated that no major skeletal change was involved. This product, therefore, was assigned structure **21** on the basis of the ^{13}C data (see Table 3).

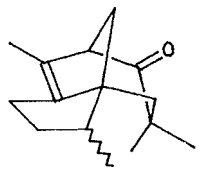
Since **20** and **21** must be related through a common allylic anion, additional evidence for these structures was sought by examination of the behavior of **20** in strong base. After treatment of **20** at 130°C with *t*-BuO–/*t*-BuOH for 24 h, the neutral fraction contained only **20** and **21** in a 4:1 ratio, and after 72 h this ratio was 1:1. This confirmed that **20** and **21** differ only in the position of the olefinic bond. For the neutral product, the



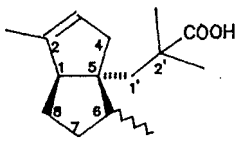
19



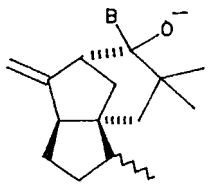
20



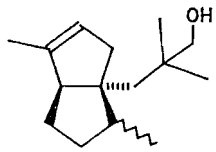
21



22



23



24

yields were 51 (24 h) and 43% (72 h) and, for the acid, 38 and 46%, respectively. The ^{13}C spectrum of the acidic product was virtually identical to that for the acidic fraction from the homoenolization experiments with **6**. Both contained two sets of 15 signals, ascribable to a pair of epimeric acids. The proportions of these acids differed slightly in the two cases, with a slight excess of one in the runs with **6**, but essentially equal proportions from **20** and **21**. From the ^{13}C spectra, each has a trisubstituted double bond, four methyl groups, of which one is olefinic, four methylene, two methine, and two quaternary carbons, as well as the carboxyl group. These data are consistent with structure **22**, which can arise from **20** and (or) **21** through Haller–Bauer cleavage after addition at the carbonyl carbon by the alkoxide base, collapse of which could generate an allylic anion (see **23**). Although this is one of a number of possible isomers, differing only in the position of the double bond, **22** must be the most stable. It may be noted that earlier studies had shown that *tert*-butyl esters do not survive under these reaction conditions and the corresponding acids are isolated. Assignment of the ^{13}C signals for the **22** epimers was made by comparison with the data for several model compounds (22) and by heteronuclear $^{13}C\{^1H\}$ correlation spectra. The ^{13}C data are collected in Table 4 and the ^{1}H data are in the experimental section.

The spectra of samples from Band 4 were strikingly similar to those exhibited by **22**, except that the carboxyl signals were replaced by those for hydroxymethyl carbons. Identical spectra were recorded for samples obtained by LAH reduction of **22**. Thus, this product is **24**; the ^{13}C data are collected in Table 4. The stereochemistry of the 6-methyl group in each epimeric pair **22** and **24** was revealed by the large difference found for the C-1′ shieldings. The upfield signal must arise from the *exo* epimer in which the 6-methyl is *syn*-periplanar to C-1′. Thus, these mixtures **22** and **24** contained a small excess of the *exo* epimer.

Band 1 increased slowly with reaction time to represent about 45% of the total neutral product after 240 h. Its ^{13}C spectrum revealed the presence of two epimers, in a 10:1 ratio, which gave rise to carbonyl absorption (1730 cm^{-1}, δ_C 224.0, 225.0) indicative of cyclopentanone rings. Exact mass measurement gave a molecular formula of $C_{15}H_{22}O$. For each of the two epimers, the ^{13}C spectrum included signals for two olefinic carbons of a trisubstituted double bond, and those for four methyl, of which one is olefinic, four methylene, one methine, and **three** quaternary carbons. With the ^{1}H, $^1H\{^1H\}$, and $^{13}C\{^1H\}$ COSY

[a]Shieldings in ppm from internal TMS; ^1H–^1H couplings in Hz listed within square brackets.

spectra, all protons of the major component were assigned and correlated with the carbon signals; from these data three structural subunits were identified.

The olefinic methyl protons (δ 1.67) exhibited allylic coupling to the olefinic proton (J = 1.5 Hz) and homoallylic coupling to a pair of methylene protons (J = 2.4 Hz) with which the olefinic proton is coupled (J = 2.2 Hz). These interactions, confirmed by decoupling, established the presence of a -CH_2-CH=C(CH_3)- unit. Methyl protons (δ 0.976, d, J = 6.4 Hz) coupled to a methine proton, which is also coupled to one of a pair of contiguous methylene groups, revealed a -$(CH_2)_2$-CH(CH_3)- unit. A $^{13}C\{^1H\}$ flock spectrum (23) showed that the methyl protons giving rise to singlets at δ 0.974 and 1.053 are both vicinally coupled to a methylene carbon whose protons appear as an AB pattern (δ 1.556, 1.650, J_{AB} = 13.5 Hz). Thus, a -$CH_2C(CH_3)_2$- unit was identified. The combination of these three units with the two quaternary centres and the carbonyl led to the propellene structures **25** and *epi*-**25** for these compounds. The ^1H and ^{13}C results for **25** are given in Table 5 with the ^{13}C results for *epi*-**25**. Within the strong proton spectrum of **25**, only the signals for H-7 (δ 5.24), the 3- and 11-methyl groups (δ 1.031, s; 1.073, s; 0.945, d, J = 6.4 Hz), and an AB system (1.71, 1.98, J = 13.7 Hz) for *epi*-**25** were easily discerned. Further, this AB system was correlated with the δ_C 49.7 signal in the $^{13}C\{^1H\}$ COSY spectrum, thereby identifying C-4 in *epi*-**25**. Since the C-4 shieldings will depend on the orientation of the 11-methyl group and C-4 absorbs at δ_C 42.8 in **25**, we conclude that the 11-methyl is *syn*-periplanar to C-4 in **25**, in which C-4 is shielded by –7 ppm. The C-6 shieldings also support this assignment, since these exhibit the opposite trend. The shift of +5.4 ppm for C-6 in **25** is consistent with an *anti*-periplanar relationship to the 11-methyl group.

[a]Given as the proportion, on a % molar basis, of isolated product.
[b]Estimated from a combination of glc and ^{13}Cmr data.
[c]Results from runs with the pure major epimer (see text).

The composition of the product mixtures from the experiments with **6** are listed in Table 6. These data include the results for a few runs with pure samples of the major epimer of **6**, small quantities of which were obtained by repeated chromatography over silica. The latter data confirmed that the major component in each epimeric mixture arose from the major epimer of **6**.

To shed more light on the sequence of formation of the neutral products, samples of **21** were treated with *t*-BuO$^-$/*t*-BuOH. The neutral fraction, isolated in 85% yield after 100 h at 150°C, was found to be virtually identical to the starting material, according to the ^{13}C spectra. At 185°C, glc analysis showed that **21** was transformed slowly to **25** and *epi*-**25** together with small amounts of unidentified neutral material. The mixture of propellenones constituted ca. 25 and 60% of the neutral fraction after 50 and 150 h, respectively. From the results of the experiments with **20** and **21**, it became clear that the sequence is **20** → **21** → **25** + *epi*-**25**. In principle, each of these is prone to Haller–Bauer cleavage leading to **22** since this process will generate an allylic carbanion, as noted above (see **23**). The results indicate, however, that **20** is the most susceptible to this cleavage, and the propellenones the least. It can be noted that **24** was not found in the products from the experiments with **20** or **21**.

Discussion

By analogy with our earlier findings for **4** (10, 24), we would anticipate β-proton abstraction from **6** at C-6 and -11 to generate the β-enolates **26** and **27**, or equivalent species, respectively. Cleavage of these β-enolates can proceed by either, or both, of two modes: *a* and *b* in Scheme 2. Path *a* regenerates starting material and *b* leads to rearranged product. For the corresponding β-enolates from **4**, the cleavage is unidirectional, since **5** is the only rearranged product (10) and H/D exchange was observed at C-6 but not at C-11 (24). The isolation of **7** and *epi*-**7** showed that proton abstraction proceeded at C-11 in **6** to form **27**, or its equivalent, with subsequent opening to the tricyclo[6.3.0.0]undecanone skeleton. In agreement with earlier results for **4**, there was no evidence of formation of the [4.3.2.0] system **28**, but, in sharp contrast, rearrangement to **7** is not a major mode of reaction for **6**.

Four neutral products from **6** lack the methoxyl group and contain an olefinic bond. This can be envisaged to involve an E1cB process through an "open" β-enolate, such as **29**, leading to **20**, as shown in Scheme 2. It should be noted that β-enolates are commonly depicted as cyclopropoxide ions as a convenient symbolism. Although results for many β-enolate rearrangements are readily accommodated by these species, the cyclopropoxide form may be a representation of the transition state between rapidly equilibrating "open" forms. Precise definition of β-enolates is difficult. In any event, isomerization **20** → **21** would involve abstraction of H-5, generating the allylic carbanion **30**, and protonation at the incipient methyl carbon to form **21**. Our data provide permissive evidence that **21** is the more stable. Introduction of the double bond through loss of the methoxyl renders both **20** and **21** susceptible to Haller–Bauer cleavage because collapse of the intermediates **31***a* and **31***b*, formed by addition of alkoxide ion at the carbonyl carbon, will give an allylic anion. The isolation of **22** indicates that the isomers differing only in the position of the double bond must be less stable.

Although the original objective of this study was doomed by the disappointingly low yields found for the interconversion **6** → **7**, the unexpected finding that **25** is the major rearrangement product was a welcome surprise for two reasons. The isolation of **25** not only illustrates a new route to the [3.3.3]propellane skeleton but it also provides an example of γ-enolate rearrangement, since its formation is readily rationalized in terms of **32**, or an equivalent species, formed from **20** and **21**, as outlined in Scheme 3. Cleavage of **32** by path *b* leads to **33**, which will equilibrate with **25** (*epi*-**25**) under the strongly basic conditions. Since **33** was not detected in the neutral product mixtures, this equilibrium clearly favors the skeleton having the endocyclic double bond.

Since the discovery that a ketonic carbonyl group can activate proton abstraction from carbons other than those to which it is directly bonded (25), the vast majority of the reported cases involve β-enolate formation (18). However, ^{1}H/^{2}H exchange studies have shown that γ-enolization occurs in a few systems (18), but rearrangement had been observed in only two cases (26, 27). Thus, the formation of **25** from **20** and **21** is a third example of γ-enolate rearrangement.

Although both **20** and **21** may undergo β-enolization to form tricyclo[6.3.0.0]undecenones **36***a–c*, it is conceivable that these were destroyed by Haller–Bauer cleavage to **22** (see Scheme 4).

The fate of **21** is distinctly different from that of its simpler analog **34**, which we had investigated earlier (28). The major neutral product from **34** was **35**, showing that the anticipated β-enolization at C-8 produced the [3.3.0] skeleton, but subsequent reduction of the olefinic bond had not been anticipated. Furthermore, the rest of the neutral product consisted of compounds having a *tert*-butoxyl group, showing that the addition of *t*-BuO– to the double bond in **34** is a competitive process. None of the products that would arise by the corresponding processes with **21** was detected.

An analogous competitive reduction process has been encountered in one other study in which it was found that **37** is reduced to **38** (27) under these conditions. We have ascribed the formation of both **35** and **38** to single electron transfer from *tert*-butoxide anion to the conjugated carbonyl group. A distinctly different reduction process was recently observed (19) in another homoenolization study in which it was found that **39** is reduced slowly to the corresponding alcohol. We suggested that this process may be initiated by formation of **40** through homolytic cleavage of the more substituted bond in the cyclic β-enolate formed from **39**, by analogy with the observation that **41** and **42** are in rapid equilibrium (29) and the fact that an oxy anion substituent has a significant weakening effect on the adjacent bonds (30). In any event, other reduction processes must be operative in the present system to produce **19** and **24**.

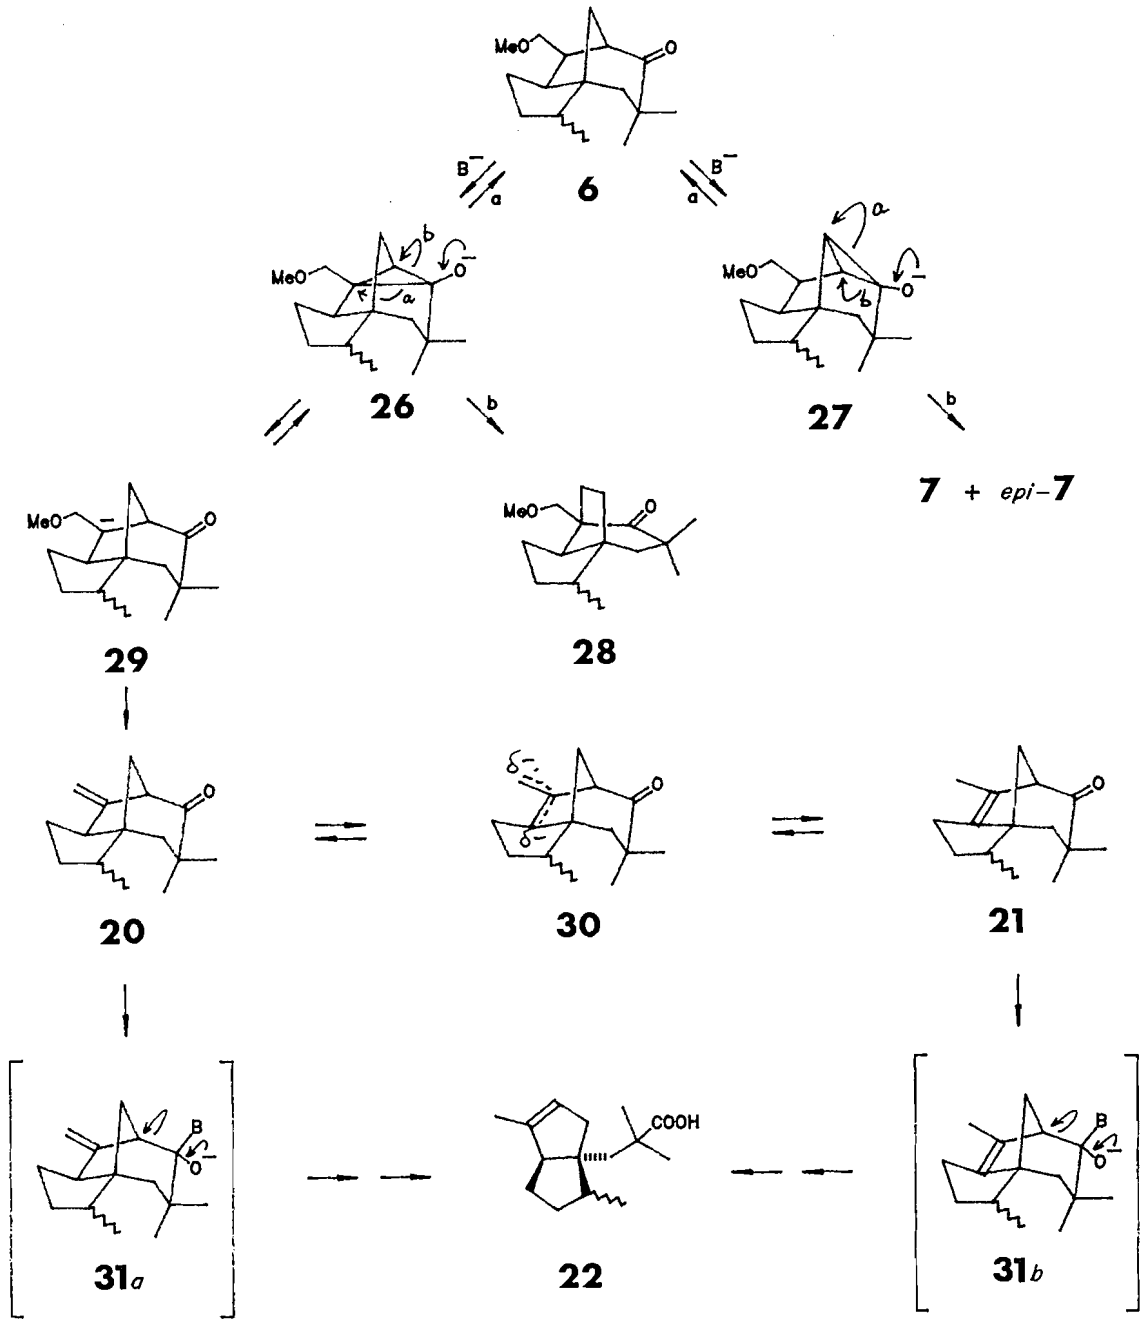

SCHEME 2

Alcohol **19** must arise simply from reduction of the carbonyl group in **6**. This process can be attributed to hydride transfer from the methoxide ion formed through the E1cB elimination in anion **29** (Scheme 2). The failure to detect formaldehyde is not surprising since it would have been easily lost during the work-up.

Alcohol **24** is a minor component in all of the neutral product mixtures from **6**, but was not found in the products obtained upon the same treatment of **20** or **21**. This observation leads us to suggest that its formation is triggered by hydride transfer from methoxide ion to the carbonyl group in **20** and (or) **21**. Subsequent cleavage of the resultant alkoxide through a retro-aldol reaction, as outlined in Scheme 5, would yield bicyclic aldehyde **43**, which could undergo a Cannizzaro reaction to give equimolar quantities of **22** and **24**. From the experiments with **20** and **21** as starting material, there is no doubt that **22** is primarily generated by their Haller–Bauer cleavage.

Experimental

Gas–liquid chromatography (glc) was carried out on a Varian 3300 instrument using a column of 5% SE-30 on Chromosorb W 80-100. Thin-layer chromatography (tlc) was done on Kiesel gel 60 F_{254} plates and flash chromatography (FC) columns were prepared as described in the literature (31). Tetrahydrofuran (THF) and ether were distilled from Na/benzophenone just before use. Pyridine, *tert*-butyl alcohol, diisopropylamine, and trimethylamine were distilled from CaH_2 and stored over 4A molecular sieves.

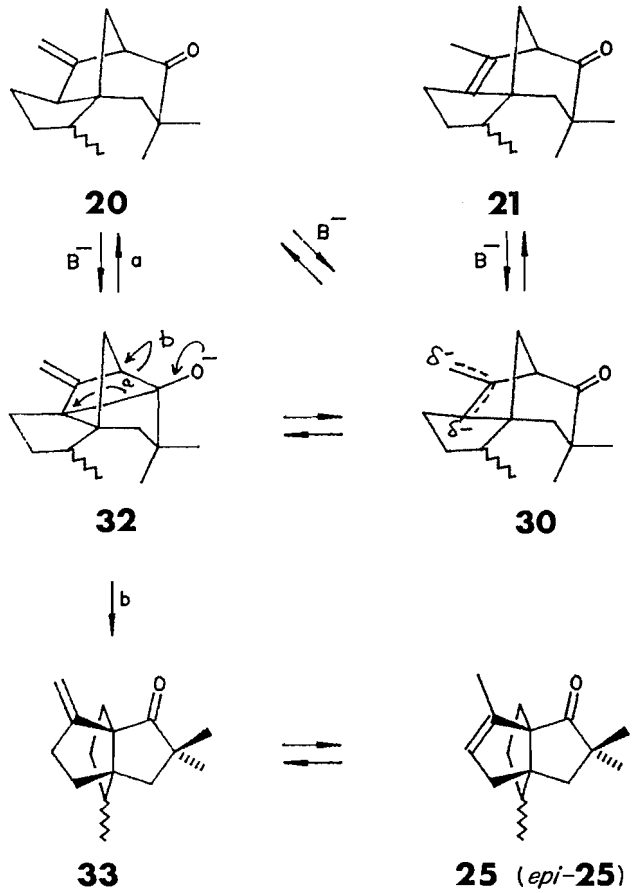

SCHEME 3

Infrared spectra were recorded with either a Beckman 4250 instrument or a Bruker/IBM FTIR 32 spectrophotometer. Mass spectra were obtained with either a Varian MAT-311A or a Finigan MAT 8230 instrument at 70 eV for routine spectra and at 20 eV for exact mass measurements.

Proton and carbon nmr spectra of each compound were obtained with Varian XL-200 (^{1}H) and XL-300 (^{13}C) spectrometers. The number of protons bonded to each carbon was found by recording either the APT or DEPT spectrum. Correlation spectra were obtained using the programs of the Varian software, $^1H\{^1H\}$ and $^{13}C\{^1H\}$ spectra with the HOMCOR and HETCOR sequences, while long-range $^{13}C\{^1H\}$ correlations were revealed with spectra recorded using the FLOCK sequence (23). While full assignments for the ^{13}Cmr spectra are presented, the fact that most of the compounds were obtained as C-2 epimeric mixtures precluded complete analysis of their ^{1}Hmr spectra, thereby limiting definitive assignments to those listed.

7-Methoxy-5-heptyn-2-ol (8)

To a stirred solution of methyl propargyl ether (13) (3.5 g, 0.05 mol) in THF (100 mL) under dry nitrogen was added *n*-BuLi (19.2 mL, 2.6 M in hexane) at –78°C. Stirring was continued for 20 min, before the sequential addition of 2-methyloxetane (12) (1.8 g, 0.025 mol) and $BF_3{\cdot}Et_2O$ (7.5 mL) at –78°C. This mixture was stirred at –78°C for 0.5 h before it was allowed to warm to room temperature and diluted with saturated NH_4Cl solution. After the product was extracted with ether (3 × 60 mL), the extracts were washed with brine, 10% $NaHCO_3$ solution, and brine again, before drying over anhydrous Mg_2SO_4. Removal of the solvent furnished a yellow oil. Distillation was attempted but led to decomposition; thus, the product was purified by FC (EtOAc – petroleum ether, 40:60) to furnish alcohol **8** (3.1 g, 88% yield); ir ($CDCl_3$): 3640, 3480 (OH), 2840 (OMe), 2240 (C≡C), 1090 (C—O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.10 (d, 3H, J = 6.1 Hz, H-1), 1.55 (dt, 2H, J = 6.1, 7.2 Hz, H-3), 2.25 (tt, 2H, J = 2.1, 7.2 Hz, H-4) 2.48 (s, OH), 3.26 (s, 3H, OMe), 3.81 (tq, 1H, J = 6.1, 6.1 Hz, H-2), 3.97 (t, 2H, J = 2.1 Hz, H-7); ^{13}Cmr ($CDCl_3$) δ: 23.2, 57.2 (2 × CH_3), 15.2, 37.5, 60.0 (3 ×

CH_2), 66.6 (CH), 75.9, 86.5 (C≡C). Exact Mass calcd. for $C_7H_{10}O$ (M – 32): 110.0732; found: 110.0736.

7-Methoxy-cis-*5-hepten-2-ol (9)*

A solution of alcohol **8** (0.67 g, 4.72 mmol) in THF – petroleum ether (20:80, 60 mL) containing 0.4 mL of pyridine and the Lindlar catalyst (135 mg) was hydrogenated at –15°C until one equivalent of H_2 was taken up. The progress of the reaction was also monitored by tlc. When the reaction was deemed complete, the catalyst was removed by filtration and the solvent evaporated. The residue was taken up in ether (100 mL) and the ethereal solution washed with 3% aqueous HCl and brine before drying over anhydrous $MgSO_4$. Evaporationof the solvent afforded **9** as a yellow oil (0.61 g, 93%): ir ($CHCl_3$): 3640, 3450 (OH), 3045 (=CH), 2840 (OMe), 1450 (C=C), 1100 (C—O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.08 (d, 3H, J = 6.3 Hz, H-1), 1.35–1.50 (m, 2H, H-3), 2.05–2.25 (m, 2H, H-4), 2.80 (bs, 1H, OH), 3.24 (s, 3H, OMe), 3.70 (tq, 1H, J = 6.3, 6.4 Hz, H-2), 3.8–4.0 (m, 2H, H-7), 5.4–5.6 (m, 2H, H-5,6); ^{13}Cmr ($CDCl_3$) δ: 23.3, 57.8 (2 × CH_3), 23.8, 28.4, 67.8 (3 × CH_2), 66.5 (CH), 125.8, 134.0 (2 × HC=). Exact Mass calcd. for $C_7H_{12}O$ (M – 32): 112.0888; found: 112.0892.

1-Methyl-6-methoxy-cis-*4-hexenyl-2′-cyclopentadiene (10)*

To a stirred solution of **9** (1.44 g, 10 mmol) in dry pyridine (12 mL), at ice-bath temperature, was added *p*-toluenesulfonyl chloride (2.87 g, 15 mmol) in small portions. The reaction mixture was then stirred at 0°C for 2 h and placed in a refrigerator for 12 h. The mixture was neutralized with ice-cold 30% aqueous HCl solution before extraction with ether (3 × 30 mL). The combined extracts were washed with water, 3% aqueous HCl, 5% aqueous $NaHCO_3$ solution, and brine before drying over anhydrous $MgSO_4$. Removal of the ether gave the desired tosylate of **9** (2.85 g, 96%) as a thick oil; ir ($CHCl_3$): 3040 (=CH), 2835 (OMe), 1580 (Ph), 1440 (C=C), 1180 (-SO_3R) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.20 (d, 3H, J = J.6 Hz, H-1), 1.45–1.7 (m, 2H, H-3), 1.8–2.1 (m, 2H, H-4), 2.39 (s, 3H, aryl-Me), 3.25 (s, 3H, OMe), 3.83 (d, 2H, H-7), 4.56 (tq, 2H, J = 6.5, 7.5 Hz, H-2), 5.3–5.5 (m, 2H, H-5,6), 7.3, 7.7 (AA′BB′ system of aryl CH's); ^{13}Cmr ($CDCl_3$) δ: 20.7, 21.5, 57.9 (3 × CH_3), 23.1, 36.3, 67.9 (3 × CH_2), 79.8 (CH), 127.0, 131.5 (2 × CH=), 127.6, 129.7 (2 × 2 aryl CH), 134.4, 144.5 (2 × aryl C).

Sodium sand was prepared by vigorously stirring sodium metal (0.345 g) in refluxing xylene (20 mL) under nitrogen. The xylene was decanted and the sodium sand washed with THF (2 × 20 mL). To a stirred suspension of the sand in 10 mL of THF was added freshly distilled cyclopentadiene in several portions until the sodium was consumed (ca. 3h). The resulting deep red-purple solution was then cooled in an ice-bath. A solution of the tosylate (2.98 g, 1 mmol) in THF (10 mL) was added slowly over 30 min and the reaction mixture was stirred overnight. The resulting light brown mixture was diluted with brine and then extracted with ether (3 × 50 mL). The combined extracts were washed with brine before drying over anyhdrous $MgSO_4$. Evaporation of the solvent left a dark brown oil, which was purified by FC (Et_2O – petroleum ether, 10:90) to give **10** as a light yellow oil (1.60 g, 84%); ir ($CHCl_3$): 3060, 3025 (=CH), 2840 (OMe), 1450 (C=C), 1105 (C—O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.06 (d, J = 6.8 Hz, 1-Me), 1.4–1.6 (m, H-2), 2.00 (m, H-3), 2.55 (m, H-1), 2.845 (m) and 2.925 (m) (int. ratio 3:5, =CCH_2C=′s), 3.28 (s, OMe), 5.4–5.6 (m, H-4, 5), 5.8–6.4 (m's, =CH's); ^{13}Cmr ($CDCl_3$) δ: (major component): 20.2, 57.7_6 (2 × CH_3), 25.4, 36.1, 40.9, 68.0 (4 × CH_2), 33.7 (CH), 124.8, 126.0, 133.0, 133.6, 133.7 (5 × =CH), 151.9 (sp^2-C); (minor component): 21.2, 57.8_1 (2 × CH_3), 25.4_6, 37.1, 40.6, 68.0 (4 × CH_2), 34.6 (CH), 125.6, 126.0, 130.4, 132.1, 133.4 (5 × =CH), 154.5 (sp^2-C). Exact Mass calcd. for $C_{13}H_{20}O$: 192.1514; found; 192.1514.

2-Methyl-exo-*6-methoxymethyltricyclo[5.2.1.0^{1,5}]dec-8-ene (**11**)*

Xylene (50 mL) was heated to reflux under nitrogen with stirring before the slow addition of triene **10** (1.92 g, 10 mmol) in xylene (50 mL) over the course of an hour. Heating under reflux was continued for 24 h before the xylene was removed under vacuum at 45–50°C (bath temperature) to furnish a dark oil. This Diels–Alder product was purified by FC (EtOAc – petroleum ether, 2.5:98.5) to give a 2:1 mixture of the 2-epimers of **11** (1.57 g, 82%) as a faintly yellow liquid, bp 90°C/0.2 Torr (Kugelrohr distillation; 1 Torr = 133.3 Pa); ir ($CHCl_3$): 3035 (=CH), 2820 (OMe), 1450 (C=C) cm^{-1}. ^{1}Hmr ($CDCl_3$) δ: (major epimer): 1.03 (d, 3H, J = 7.0 Hz, 2-Me), 2.70 (m, 1H, H-7), 3.31 (s, 3H, OMe), 3.2–3.35 (m, 2H, CH_2OMe), 6.03 ("t", 1 H, J ca. 6 Hz, H-8), 6.21 (d, 2H, J = 6.1 Hz, H-9); (minor epimer): 0.92 (d, 3H, J = 6.7 Hz, 2-Me), 2.70 (m, 1H, H-7), 3.27 (s, 3H, OMe), 6.08 (m, 2H, H-8,9); ^{13}Cmr ($CDCl_3$) δ: (major epimer): 20.0, 58.8, (2 × CH_3), 25.1, 37.2, 49.3, 75.6 (4 × CH_2), 32.5, 41.2, 46.1, 46.5 (4 × CH), 66.1 (quat C), 136.6, 138.1 (2 × CH=); (minor epimer): 17.2, 58.8 (2 × CH_3), 23.3, 34.8, 42.8, 75.6 (4 × CH_2), 33.3, 41.8, 46.3, 47.5 (4 × CH), 67.5, (quat C), 137.2, 140.3 (2 ×CH=). Exact Mass calcd. for $C_{13}H_{20}O$: 192.1514; found 192.1515.

2-Methyl-exo-*6-methoxymethyltricyclo[5.2.1.0^{1,5}]decan-8-one (**13**)*

To a stirred solution of BH_3·Me_2S (1.14 g, 15 mmol) in THF (30 mL) at 0°C under nitrogen was added 2-methyl-2-butene (2.1 g, 30 mmol) and stirring was continued at 0–10°C for 2 h. To this clear solution of $Siam_2BH$ was slowly added a solution of the tricyclic olefin **11** (0.96 g, 5 mmol) in THF (2 mL) over 20 min. Stirring was continued at 0° to –5°C for 4 h before the reaction mixture was left to stand with stirring overnight without cooling. The mixture was cooled as the excess $Siam_2BH$ was destroyed by the slow addition of cold water (0.4 mL) before the addition of 3 M aqueous NaOH (5 mL). Hydrogen peroxide (30%, 5.0 mL) was then added cautiously at room temperature and the mixture was allowed to stand for 24 h with stirring. After dilution with brine (20 mL), the reaction mixture was extracted with ether (3 × 45 mL). The combined extracts were washed with brine until neutral, 10% aqueous Na_2SO_3 solution (2 × 25 mL), and again with brine until the washings gave a negative peroxide test, before drying over anhydrous $MgSO_4$. Evaporation of the ether gave a viscous oil that was purified by FC (EtOAc – petroleum ether, 40:60) to yield alcohol **12** as a colorless, thick oil (0.81 g, 74%); ir ($CHCl_3$): 3630, 3470 (OH), 3020 (=CH), 2830 (OMe), 1465 (C=C), 1110 (C—O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (major epimer): 0.81 (d, 3H, J = 7.0 Hz, 2-Me), 3.1–3.24 (m, 2H, 6-CH_2O-), 3.25 (s, 3H, OMe), 3.85 (m, 1H, H-7); (minor epimer): 0.89 (d, 3H, J = 6.6 Hz, 2-Me); ^{13}Cmr ($CDCl_3$) δ (major epimer): 18.9, 58.6 (2 × CH_3), 23.8, 36.0, 36.4, 41.8, 73.8 (5 × CH_2), 33.6, 40.8, 47.9, 49.1, 75.2 (5 × CH), 58.9 (quat C); (minor epimer): 15.9, 58.6 (2 × CH_3), 22.6, 29.3, 34.4, 43.1, 73.8 (5 × CH_2), 34.3, 41.3, 49.1, 49.8, 75.3 (5 × CH), 60.3 (quat C). Exact Mass calcd. for $C_{13}H_{22}O_2$: 210.1619; found: 210.1623. A solution of **12** (0.21 g, 1 mmol) in CH_2Cl_2 (2 mL) was added to a stirred suspension of PCC (0.322 g, 1.5 mmol), NaOAc (0.028 g, 0.34 mmol), and Celite (300 mg) in CH_2Cl_2 (10 mL). This reaction mixture was stirred for 3.5 h at room temperature before the addition of ether and filtration through a short column of silica. The solvent was then evaporated and the residue purified by Kugelrohr distillation to yield **13** as a 2:1 mixture of 2-epimers (0.197 g, 95%), bp 110–115°C/0.2 Torr; ir ($CHCl_3$): 3040 (=CH), 2820 (OMe), 1740 (C=O), 1105 (C—O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (major epimer): 0.86 (d, 3H, J = 7.1 Hz, 2-Me), 3.24 (s, 3H, OMe), 3.2–3.3 (m, 2H, -CH_2O-); (minor epimer): 0.92 (d, 3H, J = 6.5 Hz, 2-Me), 3.24 (s, 3H, OMe); ^{13}Cmr ($CDCl_3$) δ (major epimer): 18.7, 58.5 (2 × CH_3), 24.2, 36.1, 39.1, 46.3, 72.6 (5 × CH_2), 34.5, 39.2, 47.8, 55.7 (4 × CH), 58.9 (quat C), 217.4 (C=O); (minor epimer): 15.6, 58.5, (2 × CH_3), 22.4, 32.8, 33.6, 46.9, 72.6 (5 × CH_2), 34.6, 40.0, 49.2, 55.3 (4 × CH), 60.0 (quat C), 217.5 (C=O). Exact Mass calcd. for $C_{13}H_{20}O_2$: 208.1463; found: 208.1463.

2-Methyl-exo-*6-methoxymethyltricyclo[5.3.1.0^{1,5}]undecan-8-one (**16**)*

A solution of **13** (208 mg, 1 mmol) in THF (1.0 mL) was added under N_2 at –70°C to a stirred solution of LDA (diisopropylamine (172 mg, 1.7 mmol), THF (2.5 mL), and *n*-BuLi (0.58 mL, 5.6 M in hexane) at –70°C, 20 min). Stirring at –70°C was continued for 1 h before the addition of quenching solution prepared by centrifugation of a mixture of TMSCl (333 mg, 3.1 mmol), Et_3N (42 mg, 0.42 mmol), and THF (1.0 mL) in a nitrogen-purged tube. After the reaction mixture was stirred at –70°C for another hour, it was allowed to warm to room temperature and, after 2 h, was diluted with saturated aqueous $NaHCO_3$ solution; the product was extracted with ether (3 × 25 mL). These extracts were washed with brine and then dried over $MgSO_4$. Removal of the solvent afforded a yellow oil that was purified by Kugelrohr distillation to yield colorless **14** as a mixture of 2-epimers (251 mg, 90%): bp 110°C/0.2 Torr; ir ($CHCl_3$): 3060 (=CH), 2820 (OMe), 1625 (C=C), 1105 (C—O), 860 ($SiCH_3$) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (major epimer): 0.15 (s, 9H, $SiMe_3$), 0.95 (d, 3H, J = 6.6 Hz, 2-Me), 3.30 (s, 3H, OMe), 3.25–3.40 (m, 2H, -CH_2O-), 4.87 (d, 1H, 0.6 Hz, H-9); (minor epimer): 0.15 (s, 9H, $SiMe_3$), 0.90 (d, 3H, J = 6.0 Hz, 2-Me), 3.30 (s, 3H, OMe), 4.68 (d, 1H, J = 0.6 Hz, H-9); ^{13}Cmr ($CDCl_3$) δ (major epimer): 0.0 (3), 19.9, 58.8 (5 × CH_3), 24.9, 36.3, 47.7, 75.4 (4 × CH_2), 33.2, 40.8, 48.9, 50.4, 107.6 (5 × CH), 65.1, 161.7 (2 × C); (minor epimer): 0.0 (3), 16.9, 58.8 (5 × CH_3), 23.1, 34.3, 41.2, 75.4 (4 × CH_2), 33.8, 41.4, 50.1, 50.6, 109.2 (5 × CH), 66.3, 161.9 (2 × C). Exact Mass calcd. for $C_{16}H_{28}O_2Si$: 280.1859; found: 280.1861.

Methylene iodide (456 mg, 1.7 mmol) was added to Zn/Ag couple (195 mg, 3.0 mmol) in ether (1.0 mL) and the mixture was warmed until refluxing occurred without external heating. When refluxing ceased, more ether (0.5 mL) was added and the mixture stirred for 1 h at room temperature. Trimethylsilyl enol ether **14** (280 mg, 1.0 mmol) in Et_2O (1.5 mL) was added and the mixture was heated under gentle reflux overnight. After cooling to 0°C, pyridine (320 mg, 4.05 mmol) and pentane (7.0 mL) were added with vigorous stirring. The precipitate that formed was removed by filtration and washed several times with pentane. The combined washings were concentrated at room temperature to furnish a light yellow oil which, upon FC (Et_2O – petroleum ether, 20:80), gave the cyclopropanated **15** as a colorless oil (237 mg, 81%); ir ($CHCl_3$): 3050 (cyclopropyl CH), 2820 (OMe), 1100 (C—O), 860, 840 (C—O—Si) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.11 (s, 9H, $SiMe_3$), 0.45–0.95 (m, 3H, cyclopropyl H's), 0.92 (d, 3H, J = 7.0 Hz, 2-Me), 3, .29 (s, 3H, OMe); ^{13}Cmr ($CDCl_3$) δ (major): 0.9 (3), 19.4, 58.5 (5 × CH_3), 10.5$_4$, 24.0, 32.5, 36.6, 74.2$_5$ (5 × CH_2), 22.3, 33.0, 40.2, 47.1, 49.3 (5 × CH), 60.2, 60.7 (2 quat C); (minor): 0.9 (3), 16.5, 58.5 (5 × CH_3), 10.5, 22.2, 25.6, 34.1, 74.3 (5 × CH_2), 24.4, 35.1, 40.3, 46.8, 50.5 (5 × CH), 60.2, 60.6 (2 quat C). Exact Mass calcd. for $C_{17}H_{30}O_2Si$: 294.2015; found: 294.2011.

To a solution of **15** (294 mg, 1.0 mmol) in MeOH (2.1 mL), stirring at 0°C, was added 0.42 mL of 3 M aqueous NaOH solution. Stirring was continued for 3 h before the mixture was allowed to stand in the refrigerator for 24 h. After removal of the methanol at 40°C under vacuum, the mixture was diluted with brine (5 mL) and extracted with ether (4 × 5 mL). The combined extracts were washed with brine before drying over anhydrous $MgSO_4$. Evaporation of the solvent gave a faintly yellow oil, which upon FC (Et_2O – petroleum ether, 40:60) furnished the desired tricyclic ketone **16** (194 mg, 88%) as a 2:1 mixture of the 2-epimers; ir ($CHCl_3$): 1700 (C=O), 1090 (C—O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.85 (d, 3H, J = 7.0 Hz, 2-Me), 2.55 (bd, 1H, J = 5 Hz, H-7), 3.22 (s, 3H, OMe), 3.15–3.35 (m, 2H, -CH_2O-); ^{13}Cmr ($CDCl_3$) δ (major epimer): 16.3, 58.5 (2 × CH_3), 25.2, 32.0, 35.4, 36.1, 41.7, 73.1 (6 × CH_2), 40.1, 43.2, 49.8, 57.1 (4 × CH) 53.9 (quat C), 213.2 (C=O); (minor epimer): 14.7, 58.5 (2 × CH_3), 23.3, 33.8, 33.9, 34.7, 36.0, 73.1 (6 × CH_2), 40.9, 44.5, 48.7, 55.6 (4 × CH), 56.1 (quat C), 213.4 (C=O). Exact Mass calcd. for $C_{14}H_{22}O_2$: 222.1620; found: 222.1617.

*2,9,9-Trimethyl-6-methoxymethyltricyclo[5.3.1.0^{1,5}]undecan-8-one (**6**)*

Ketone **16** (222 mg, 1.0 mmol) in Et_2O (1 mL) was added dropwise to a vigorously stirred suspension of $NaNH_2$ (211 mg, 5.4 mmol) in Et_2O (2.5 mL) at room temperature under nitrogen and the mixture was refluxed gently with stirring for 3.5 h before cooling to room temperature. Methyl iodide (0.4 mL, 6.5 mmol) was slowly added and the

For personal use only.

reaction mixture was refluxed overnight with vigorous stirring. After a second addition of methyl iodide (0.14 mL, 2.25 mmol), the mixture was refluxed for an additional 2.5 h before cooling to room temperature. Water (2 mL) was added and the product extracted with ether (3 × 15 mL). The combined extracts were washed with brine and then dried over anhydrous $MgSO_4$. After removal of the solvent, the product was purified by Kugelrohr distillation to yield **6** as a 2:1 mixture of epimers (201 mg, 80%): bp 120–125°C/0.1 Torr; ir ($CHCl_3$): 1700 (C=O), 1105 (C—O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ (major epimer): 0.85 (d, 3H, J = 7.2 Hz, 2-Me), 1.07 (s, 3H, 9-Me), 1.12 (s, 3H, 9-Me), 3.25 (s, 3H, OMe), 3.15–3.35 (m, 2H, -CH_2O-); (minor): 0.86 (d, 3H, J = 6.5 Hz, 2-Me), 1.07 (s, 3H, 9-Me), 1.12 (s, 3H, 9-Me), 3.24 (s, 3H, OMe); ^{13}Cmr: see Table 3. Exact Mass calcd. for $C_{16}H_{26}O_2$: 250.1933; found: 250.1926.

*Alcohol (**19**)*

A sample of the epimeric mixture **6** (20 mg, 0.08 mmol) in Et_2O (1 mL) was slowly added to a cooled suspension of LAH (10 mg, 0.25 mmol) in Et_2O (2 mL). After the addition, the mixture was stirred at room temperature for 1 h before the cautious addition of a few drops of water to destroy excess LAH. The mixture was acidified with 5% aqueous HCl (2 mL) and the product extracted with ether. The extracts were washed with saturated $NaHCO_3$ solution, brine, and water before drying over anhydrous $MgSO_4$. Evaporation of the ether afforded lightly colored **19** (18.5 mg, 91%); ir (film): 3550 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.82 (d, 6H, J = 6.8 Hz, 2-Me), 0.990 (s, 6H, 9-Me, major), 1.012 (s, 6H, 9-Me, minor), 3.1–3.3 (m, 4H, 2 × -CH_2O-), 3.28 (s, 6H, 2 ×MeO), 3.45 (m, 2H, 2 × -CH(OH)-); ^{13}Cmr: see Table 3. Exact Mass calcd. for $C_{16}H_{28}O_2$: 252.2089; found: 252.2094.

*2,9,9-Trimethyl-6-methylenetricyclo[5.3.1.0^{1,5}]undecan-8-one (**20**)*

Sodium iodide (270 mg, 1.8 mmol) was added to a solution of the epimeric mixture **6** (433 mg, 1.7 mmol) in dry acetonitrile (10 mL) under argon. A solution of trimethylsilyl chloride (0.7 mL, 600 mg, 5.4 mmol) in CH_3CN (0.7 mL) was very slowly added with stirring. As the reaction proceeded a yellow color developed and gradually intensified. The progress of the reaction was monitored at 0.5 h intervals by tlc and, after 3 h, the starting material had been consumed. The reaction mixture was diluted with water and extracted with ether. The combined extracts were washed with 10% aqueous $NaHCO_3$ solution, 10% sodium thiosulfate solution, water, and brine before drying over $MgSO_4$. Removal of the solvent gave a crude product that was purified by FC (Et_2O – hexane, 20:80) to give the expected 6-iodomethylene derivative (395 mg, 67%) and the analogous alcohol (80 mg. 20%), both as 2:1 epimeric mixtures. These were identified by ^{13}Cmr; the spectrum of the iodides had distinctive signals near δ_C 8 for the -CH_2I groups.

*2-Methyl-6-iodomethyl-**4***: ir (film): 1705 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.85 (d, 3H, J = 6.7 Hz, 2-Me minor), 0.88 (d, 3H, J = 7.0 Hz, 2-Me major), 1.121 (s, 6H, 9-Me), 1.165 (s, 6H, 9-Me), 3.0–3.3 (m, 6-CH_2I); ^{13}Cmr ($CDCl_3$) δ (major epimer): 16.4, 31.5$_1$, 31.5$_4$ (3 × CH_3), 8.2$_7$, 24.7, 35.8, 37.9, 46.5 (5 × CH_2), 41.4, 47.8, 50.0, 59.7 (4 × CH), 42.2, 55.5 (2 × C), 217.1 (C=O); (minor epimer): 14.6, 31.3, 31.4$_6$ (3 × CH_3), 8.2$_3$, 23.3, 30.3, 33.1, 42.2 (5 × CH_2), 41.3, 48.8, 49.9, 58.4 (4 × CH), 42.5, 57.1 (2 × C), 217.4 (C=O).

*2-Methyl-6-hydroxymethyl-**4***: ir (film): 1703, 3443 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.874 (d, 3H, J = 7.1 Hz, 2-Me major), 0.886 (d, 3H, J = 6.6 Hz, 2-Me minor) 1.107 (s, 6H, 9-Me), 1.155 (s, 6H, 9-Me), 3.4–3.7 (m, -CH_2O-); ^{13}Cmr ($CDCl_3$) δ (major epimer): 16.3, 31.4, 31.5 (3 × CH_3), 24.8, 35.9, 38.4, 46.8, 63.4 (5 × CH_2), 40.9, 46.6, 48.3, 55.8 (4 × CH), 42.2, 54.8 (2 × C), 218.7 (C=O); (minor epimer): 14.6, 31.2, 31.3 (3 × CH_3),23.3, 30.8, 33.2, 49.1, 63.1 (5 × CH_2), 40.9, 47.6, 48.2, 54.6 (4 × CH), 42.5, 56.6 (2 × C), 219.0 (C=O).

Under dry nitrogen, a 1 M solution of potassium *tert*-butoxide in anhydrous *tert*-butyl alcohol (2 mL) was added to the mixture of iodides (312 mg, 0.9 mmol) and the solution was stirred at 50°C for 2 h, after which time tlc indicated that the iodide had been consumed. The mixture was diluted with water and the product extracted with ether. The combined extracts were washed with cold water until neutral, then with brine before drying over $MgSO_4$. Evaporation of the solvent afforded a colorless oil (184 mg, 94%) that gave ^{13}Cmr spectra (Table 3) that were identical to those obtained for **20**, isolated from the neutral homoenolization product; ir (liquid film): 1700 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.849 (d, 3H, J = 7.0 Hz, 2-Me major), 0.857 (d, 3H, J = 6.7 Hz, 2-Me minor), 1.064 (s, 6H, 9-Me), 1.096 (s, 6H, 9-Me), 4.80 and 5.05 (multiplets, =CH_2). Exact Mass calcd. for $C_{15}H_{22}O$: 218.1671; found: 218.1674.

Homoenolization experiments

Our standard procedures for homoenolization experiments (32) were followed as outlined for **6**. To a solution of *t*-BuO–/*t*-BuOH (1.27 M, H_2O content <250 μg/mL) was added **6**, to obtain a solution that was 0.26 M in ketone. Aliquots (0.35 mL) were transferred to a series of 5-mL predried, thick-walled glass tubes; these tubes were then degassed and sealed before immersion in a Blue M constant high-temperature oil-bath at 185 ±1°C. These tubes were removed after intervals of several hours, cooled before opening, and the contents collected by washing with water and pentane. The neutral organic products were isolated by pentane extraction (3 × 15 mL) and the combined extracts dried over anhydrous magnesium sulfate. The aqueous layer was acidified with 10% aqueous HCl solution (10 mL) before ether extraction (3 × 15 mL) to recover any acidic organic products. The combined ether extracts were dried over magnesium sulfate.

To identify the acidic products, the oily residue obtained upon removal of the ether was examined by ^{13}Cmr. These data led to structure **22**, as described in the text; ^{1}Hmr ($CDCl_3$) δ (major epimer): 0.878 (d, 3H, J = 6.4 Hz, 6-Me), 1.148 (s, 3H, 2′-Me), 1.18 (s, 3H, 2′-Me), 1.56 (bs, 3H, 2-Me), δ1.47 (m, 1H, H-6), 1.417 (d, 1H, J = 14.6, Hz, H-1′), 1.887 (d, 1H, J = 14.6 Hz, H-1′), 2.01 (dm, 1H, J = 16.5 Hz, H-4), 2.199 (dm, 1H, J = 16.5 Hz, H-4), 2.56 (bd, 1H, J δ 9 Hz, H-1), 4.94 (m, 1H, H-3); (minor epimer): 0.837 (d, 3H, J = 6.6 Hz, 6-Me), 1.18 (s, 3H, 2′-Me), 1.206 (s, 3H, 2′-Me), 1.56 (bs, 3H, 2-Me), δ 1.67 (m, 1H, H-6), 1.711 (d, 1H, J = 14.7 Hz, H-1′), 1.968 (d, 1H, J = 14.7 Hz, H-1′), 1.819 (dm, 1H, J = 17 Hz, H-4), 2.219 (dm, 1H, J = 17 Hz, H-4), 2.61 (bd, 1H, J δ 9 Hz, H-1), 5.06 (m, 1H, H-3); ^{13}Cmr: see Table 4. Exact Mass calcd. for $C_{15}H_{24}O_2$: 236.1776; found: 236.1770.

*3,3,8,11-Tetramethyl[3.3.3]propell-8-en-2-one (**25**)*

The neutral product exhibiting the shortest retention time on glc analysis was assigned structure **25** as discussed in the text; ir (liquid film): 1730 cm^{-1}; ^{1}H and ^{13}Cmr data are listed in Table 5. Exact Mass calcd. for $C_{15}H_{22}O$: 218.1671; found: 218.1670.

*2,6,9,9-Tetramethyltricyclo[5.3.1.0^{1,5}]undec-5-en-8-one (**21**)*

The second band found by glc analysis was assigned structure **21** as discussed in the text; ir (liquid film): 1701 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.86 (d, 3H, J = 7.0 Hz, 2-Me minor), 0.88 (d, 3H, J = 6.5 Hz, 2-Me major), 1.12 (s, 6H, 9-Me), 1.13 (s, 6H, 9-Me), 1.56 (bs, 3H, 6-Me major), 1.57 (bs, 3H, 6-Me minor), 2.95 (bm, 1H, H-7); the ^{13}Cmr data are collected in Table 3. Exact Mass calcd. for $C_{15}H_{22}O$: 218.1671; found: 218.1674.

*2,6-Dimethyl-5-(3′-hydroxy-2′,2′-dimethylpropyl)bicyclo[3.3.0]oct-2-ene (**24**)*

The fourth glc band was found to contain a mixture of alcohols that was shown to be **24** as noted in the text; ir (liquid film): 3355 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.85 (d, 3H, J = 6.2 Hz, 6-Me minor), 0.87 (d, 3H, J = 6.6 Hz, 6-Me major), 0.927 (s, 12H, 2′-Me), 1.61 (bs, 6H, 2-Me), 5.03 (m, 1H, H-3 minor), 5.15 (m, 1H, H-3 major); ^{13}Cmr: see Table 4. Exact Mass calcd. for $C_{15}H_{26}O$: 222.1981; found: 222.1981.

*3,3,11-Trimethyl-7-methoxymethyltricyclo[6.3.0.0^{1,5}]undecan-4-one (**7**)*

The fifth glc band was assigned structure **7** on the basis of its physical data; ir (liquid film): 1730 cm^{-1}; ^{1}Hmr: see text; ^{13}Cmr: see Table 2. Exact Mass calcd. for $C_{16}H_{26}O_2$: 250.1933; found: 250.1935.

Some routes to C2-alkoxymethyl hex-2-enopyranosides[1]

GORDON WONG AND BERT FRASER-REID[2]

Paul M. Gross Chemical Laboratory, Duke University, Durham, NC 27708, U.S.A.

Received February 22, 1993

This paper is dedicated to Professors David B. MacLean and Ian Spenser

GORDON WONG and BERT FRASER-REID. Can. J. Chem. **72**, 69 (1994).

Several procedures for installing a C2 alkoxy group at C2 of a hex-2-enopyranoside have been investigated. The one that is most convenient for large-scale preparation begins with a 2-keto pyranoside, which is converted into the corresponding *exo* methylene derivative. An S_N2' rearrangement is effected with thionyl chloride, and the resulting primary allylic chloride is displaced with sodium benzylate.

GORDON WONG et BERT FRASER-REID. Can. J. Chem. **72**, 69 (1994).

On a examiné diverses méthodes d'introduire un groupe alcoxyle en position C2 d'un hex-2-énopyranoside. Celle qui semble la plus appropriée pour des préparations sur une haute échelle fait appel à un 2-cétopyranoside qui est transformé en dérivé exométhylène correspondant. On effectue ensuite un réarrangement S_N2' à l'aide du chlorure de thionyle avant de déplacer le chlorure allylique primaire qui en résulte avec du benzylate de sodium.

[Traduit par la rédaction]

A recent report from our laboratory described a route to the *trans*-decalin core, symbolized by **1***a*, via an intramolecular Diels–Alder (IMDA) reaction of a hex-2-enopyranoside of type **2** (1). This approach to **1** seemed attractive since all of the functional groups represented by labels **A** → **G** could be installed in, or derived from, precursor **2** (1). The success of the early venture, with preparation of a key intermediate for forskolin (1), prompted us to explore more expeditious methods for obtaining **2**. Use of a normal hexose precursor would require attaching carbon substituents at C1 and C2 of the pyranose precursor. In the reported synthesis (1), the latter had proved to be more problematic, and we therefore examined alternative methods. In doing so we have been mindful that in many naturally occurring terpenes the angular C19 methyl group, which corresponds to the C2 substituent of **2**, is functionalized (3) and hence provisions for this possibility ought to be made. The alkoxymethyl analog **2***b* was conceived as a valuable synthon. Its precursor would be alkene **3***b*. In this manuscript, we describe our efforts to prepare alkenes related to **3***b*.

In our recent work (1), the Corey–Winter reductive elimination strategy (3) had proven to be the method of choice for the preparation of C2-CH_3 alkenes of type **3***a*. Accordingly, our initial approaches to the alkoxymethyl analog **3***b* were undertaken with this reaction in mind. A particularly encouraging feature of the prototype study was the fact that the Corey–Winter reaction had succeeded with both diastereomeric *cis*- and *trans*-diol precursors of **3***a* (1). In the light of this precedent, the known uloside **4***a* (4), seemed a plausible starting material whose reaction with an alkoxymethyl anion would provide the required C2-functionalized carbon.

Benzyloxymethyl magnesium chloride (5) was tested first, but problems were encountered with its preparation from commercially available benzyloxymethyl chloride and also with its lack of stability. The lithio analog, obtained most conveniently by treating benzyloxymethyl tributylstannane with butyllithium as described by Still (6) was successful, giving the expected adduct **5***a* along with substantial amounts of the product from silyl migration, both of which underwent desilylation without event to give **5***b* in 74% overall yield. A more direct route to **5***b* arose from addition of an excess of the benzyloxymethyllithium to the known 3-*O*-acetyl uloside **4***b* (7).

In contrast to the previously described (2) results for the C2-CH_3 analog **3***a*, treatment of **5***b* with thiocarbonyl diimidazole gave nearly equal amounts of the corresponding thionocarbonate **8** and its uncyclized precursor, which could be partially pro-

[1]This paper is dedicated to Professors Dave MacLean and Ian Spenser with grateful thanks for their many kindnesses and help when one of us (B.F.R) was at the then fledgling University of Waterloo.

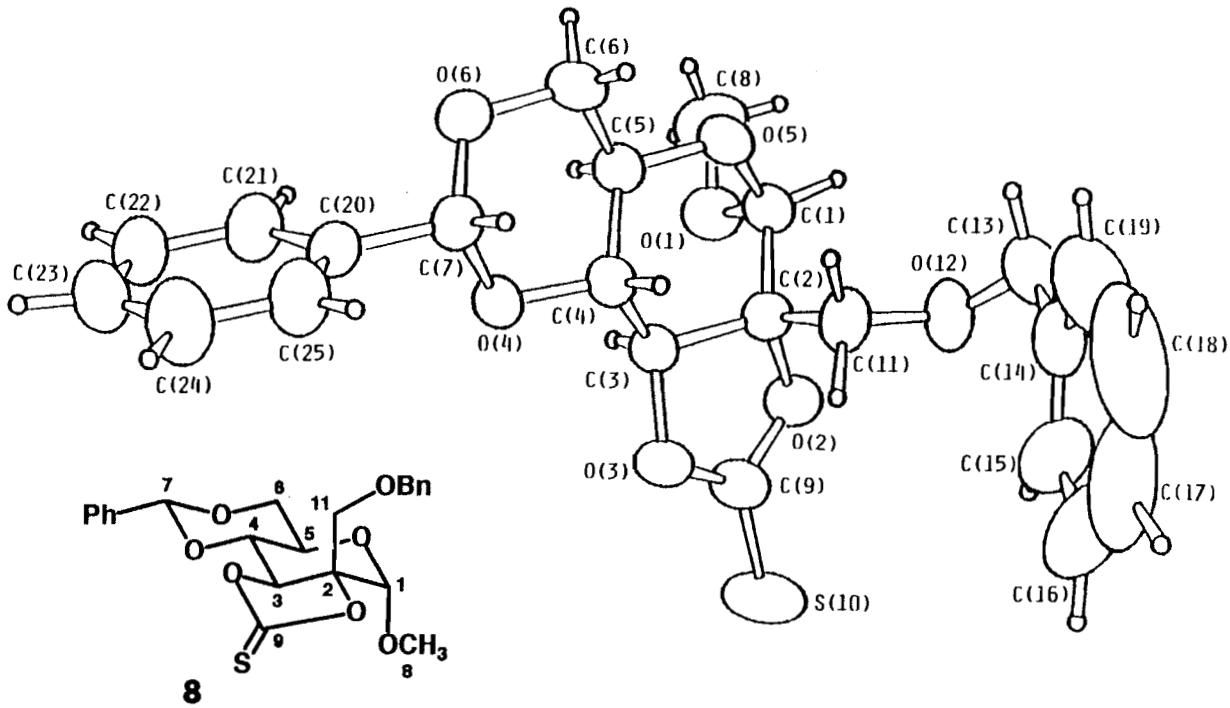

FIG. 1.ORTEP diagram (50% probability ellipsoids) showing the crystallographic atom numbering scheme and solid-state conformation of **8**. Small circles represent hydrogen atoms.

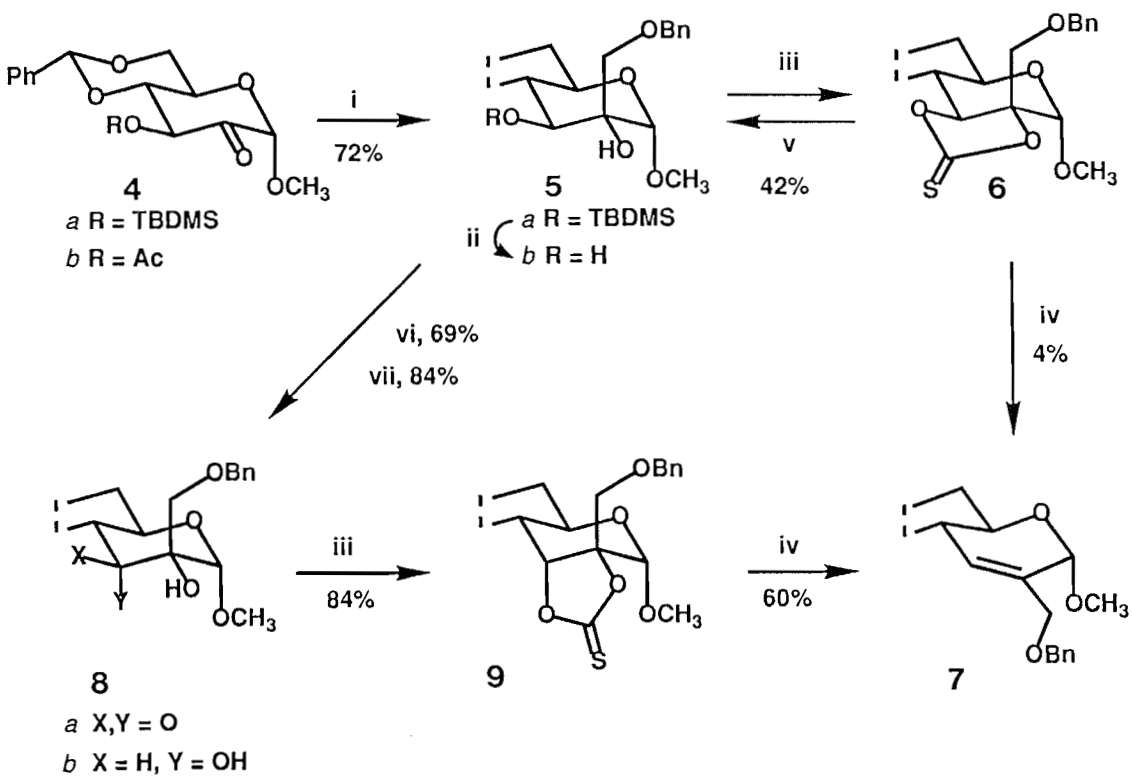
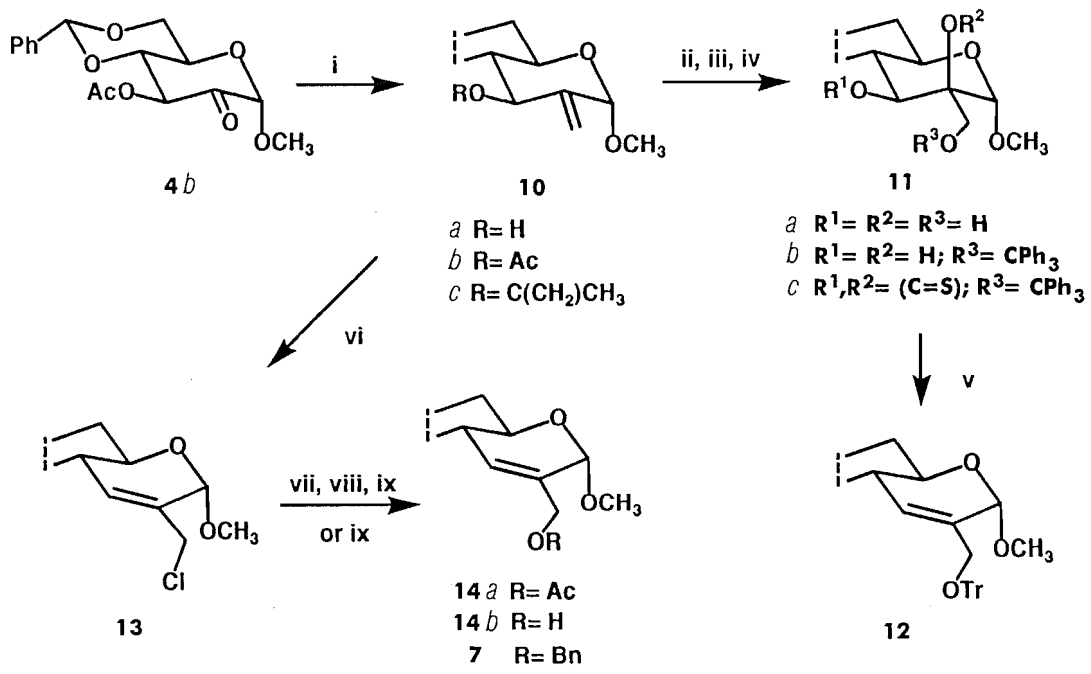


(i) Bu_3SnCH_2OBn, *n*BuLi, THF; (ii) TBAF,THF; (iii) $(im)_2C{=}S$, toluene; (iv) $P(OMe)_3$
(v) 1,3-dimethyl-2-phenyl-1,2-diazaphospholidene; (vi) Dess-Martin periodinane,CH_2Cl_2; (vii) $NaBH_4$, MeOH

SCHEME 1



(i) Cp_2TiCl_2 $AlMe_3$ gave **10***a* (75%), **10***b* (10%), **10***c* (5%); (ii) OsO_4, Et_4NOH, *t*-BuOOH, *t*-BuOH, THF, 30%; (iii) TrCl, DMAP, pyridine, 80%; (iv) NaH, CS_2, nBu_4NI CH_3I, 88%; (v) $P(OMe)_3$, 59%; (vi) $SOCl_2$, pyridine, THF; (vii) KOAc, HMPA, 51% from **10***b*; (viii) NaOMe, 64%; (ix) NaH, BnBr, THF, 81%; (x) NaOH, Bu_4NHSO_4, BnOH, CH_2Cl_2/water 19:1, ultrasound 4 days, 54% from **10***b*.

SCHEME 2

cessed to give **8** by prolonged treatment in toluene under reflux. The structure **8** was confirmed by the X-ray crystal structure shown in Fig. 1.[3]

By comparison with the corresponding C2-CH_3 analogue used earlier (2), the reaction of **8** was disappointing in that treatment with trimethylphosphite gave the desired alkene **10** in only 4% yield. Use of 1,3-dimethyl-2-phenyl-1,2-diazaphospholidene as recommended by Corey and Hopkins (8) was even more discouraging in that the only course of reaction with this reagent was regeneration of diol **5***b*.

There should be fewer problems with formation and reaction of this *cis*-fused thionocarbonate and hence the diol **5***b* was processed with this objective in mind. Oxidation to ketone **11***a* was best effected with the Dess–Martin reagent (9) and sodium borohydride reduction led to **11***b* without event. As expected, the thionocarbonate **12** was now obtained without complication, and reductive elimination to **10** proceeded in 60% yield. Thus although it involves one more step, the route via **12** was slightly higher yielding overall, and much easier operationally than that via **8**.

The results with **8** and **12** showed that the *cis*-fused thionocarbonate better underwent reductive elimination, in spite of the lack of preference that we had found in the earlier work (1). It was therefore of interest to see how the alternative *cis* analog (i.e., the *manno* counterpart) would fare. A C2-*exo* methylene derivative was seen as a plausible precursor since dihydroxylation should occur from the ß face.

Some deacetylation would be expected to accompany olefination of **4***b* with methylenetriphenylphosphorane, and hence an alternative route was examined. Tebbe's reagent (10) reacts with the carbonyl groups of ketones and esters, but the enol ether resulting from the latter would be readily hydrolysed. In the event, the best procedure turned out to be to treat **4***b* with 2.5 equivalents of Tebbe's reagent, which gave the allylic alcohol **10***a* as the major product and the corresponding acetate **10***b* as the minor. A third product, obtained in 4% yield, was assigned as the enol ether **10***c* since it decomposed to **10***a* on standing.

Dihydroxylation of **10***a* gave the triol **11***a*, which was processed to give the thionocarbonate **11***c*. Reductive elimination to **12** proceeded in virtually the same yield (59%) as had the diastereomer **9**.

The allylic alcohol **10***a* offered yet another alternative route to the desired alkene via S_N2' rearrangement. Indeed this was accomplished by treating **10***a* with thionyl chloride to give the 2-alkene **13**. Acetolysis then afforded **14***a* in 50% overall yield from **10***a*. Saponification to **14***b*, followed by benzylation, then gave the previously described alkene **7**. Alternatively, alkene **7** could be obtained directly from the chloride **13** in a yield of 54% by a process involving nucleophilic displacement with benzylate ion under phase transfer conditions (11).

In summary, four routes to the generalized hex-2-enopyranoside **3***b* have been examined: (*i*) **4***a* → **5** → **8** → **9** → **7**; (*ii*) **4***b* →

[3]Crystallographic data for **1** have been deposited and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

The ORTEP diagram, crystallographic data, tables of H-atom coordinates and of bond lengths and angles for **1** have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

(i) OsO_4, Et_4NOH, *t*-BuOOH, *t*-BuOH, THF, 30%; (ii) TrCl, DMAP, pyridine, 80%; (iii) NaH, CS_2, nBu_4NI CH_3I, 88%; (iv) $P(OMe)_3$, 59%; (v) $SOCl_2$, pyridine, THF; (vi) KOAc, HMPA, 51% from **13**; (vii) NaOMe, 64%; (viii) NaH, BnBr, THF, 81%; (ix) NaOH, Bu_4NHSO_4, BnOH, CH_2Cl_2/water 19:1, ultrasound 4 days, 54% from **13**.

SCHEME 3

10 → **11** → **12**; (*iii*) **4***b* → **13** → **14** → **7**; and (*iv*) **4***b* → **13** → **7**. The last is the most direct but, for large-scale preparations, the need for prolonged ultrasonication could present practical problems and, in such cases, route (*iii*) may be more attractive, particularly since the intermediates are crystalline. Routes (*i*) and (*ii*) are seen as second choices to (*iv*) and (*iii*), respectively.

Experimental

*Methyl 4,6-*O*-benzylidene-2-*C*-benzyloxymethyl-*α*,*D*-glucopyranoside* **5**b*, and its 3-*O*-tert-butyldimethysilymethyl derivative* **5**a

To (benzyloxymethyl)tributylstannane (7) (1.30 g, 3.16 mmol) and two crystals of 2,2-dipyridyl in dry THF (10 mL), cooled to –78°C under a stream of argon, was added *n*BuLi (1.35 mL, 2.06 M in hexane, 2.79 mmol) dropwise with stirring. The appearance of a red color indicated an excess of *n*BuLi; a few drops of the stannane were then added to dissipate the color. After stirring for 20 min, a cooled solution (–78°C) of ketone **4***a* (5) (714 mg, 1.81 mmol) in dry THF (10 mL) was added by cannula and stirring was continued for 1 h. The reaction was quenched by the addition of brine and diluted with ether, warmed to room temperature, and separated. The aqueous layer was extracted with ether (×2) and the combined extracts were washed with brine and dried over anhydrous Na_2SO_4. Flash chromatography (2–15% EtOAc –petroleum ether) gave **5***a* (674 mg, 72%) and the product of silyl migration (12%) as oils. For **5***a*: R_f 0.40 (20% EtOAc –petroleum ether); $[\alpha]_D^{20}$ +9.3 (*c* 1.00, $CHCl_3$); ^1H NMR (300 MHz, $CDCl_3$) δ: 0.03, 0.06 (s, 6H, $(CH_3)_2Si$), 0.82 (s, 9H, $(CH_3)_3CSi$), 2.69 (s, 1H, OH), 3.44 (s, 3H, OCH_3), 3.45 (d, 1H, *J* = 9.6 Hz, C*H*′HOBn), 3.65–3.85 (m, 4H, H4, H5, H6a, O*H*′HOBn), 4.01 (d, 1H, $J_{3,4}$ = 9.5 Hz, H3), 4.26 (dd, 1H, $J_{5,6e}$ = 4.2 Hz, $J_{6a,6e}$ = 9.5 Hz, H6e), 4.59, 4.63 (d, 2H, *J* = 12.4 Hz, PhCH_2O), 4.90 (s, 1H, H1), 5.46 (s, 1H, PhC*H*), 7.30–7.50 (m, 10 H, aromatic). ^{13}C NMR δ: 18.4, 25.9 (TBDMS), 55.6 (q, OCH_3), 62.5 (d, C5), 69.0 (t, Ph*C*H_2), 69.1 (t, C6), 73.8 (t, *C*H_2OCH_2Ph), 76.0 (s, C2), 80.7 (d, C4), 100.7 (d, C1), 101.7 (d, Ph*C*H), 126.1–137.9 (aromatic). MS *m/z*: 516 (M^+). Anal. calcd. for $C_{28}H_{40}O_7Si$: C 65.07, H 7.82; found: C 64.88, H 7.81.

*Methyl 4,6-*O*-benzylidene-2-*C*-benzyloxymethyl-*α*,*D*-glucopyranoside* **5**b

(*a*) Compound **5***a* (292 mg, 0.57 mmol) in dry THF (35 mL) was stirred with tetra-*n*-butylammonium fluoride (0.68 mL, 1.0 M in THF, 0.68 mmol) overnight. Evaporation of the solvent and flash chromatography (20–70% EtOAc –petroleum ether) gave **5***b* (200 mg, 88%) as an oil: R_f 0.48 (70% EtOAc – petroleum ether); $[\alpha]_D^{20}$ +27.3 (*c* 1.00, $CHCl_3$); ^1H NMR (300 MHz, $CDCl_3$) δ: 2.82, 2.97 (s, 2H, OH), 3.44 (s, 3H, OCH_3), 3.51 (t, $J_{3,4} = J_{4,5}$ = 9.9 Hz, H4), 3.71, 3.87 (d, 2H, *J* = 10.0 Hz, CH_2OBn), 3.71 (t, 1H, $J_{5,6a} = J_{6a,6e}$ = 9.9 Hz, H6a), 3.83 (td, 1H, $J_{5,6e}$ = 4.4 Hz, H5), 4.09 (d, 1H, H3), 4.25 (dd, 1H, H6e), 4.59, 4.62 (d, 2H, *J* = 12.0 Hz, PhCH_2), 4.80 (s, 1H, H1), 5.47 (s, 1H, Ph C*H*), 7.30–7.50 (m, 10H, aromatic). ^{13}C NMR δ: 55.8 (q, OCH_3), 62.8 (d, C5), 69.0 (t, C6), 69.4 (t, Ph*C*H_2), 72.9 (d, C3), 74.0 (t, *C*H_2OBn), 75.5 (s, C2), 79.7 (d, C4), 100.5 (d, C1), 102.1 (d, Ph*C*H), 126.4–137.5 (aromatic). MS *m/z*: 402 (M^+). Anal. calcd. for $C_{22}H_{26}O_7$: C 65.65, H 6.52; found: C 65.43, H 6.54.

(*b*) Compound **6** (13 mg, 0.03 mmol) in 1,3-dimethyl-2-phenyl-1,3-diazaphospholidine (18 mg, 0.09 mmol) was stirred under a stream of argon at 40°C for 12 h. Flash chromatography (30–50% EtOAc – petroleum ether) gave diol **5***b* (5 mg, 42%).

*Methyl 4,6-*O*-benzylidene-2-*C*-benzyloxymethyl-2,3-*O*-thionocarbonyl-*α*,*D*-glucopyranoside* **6**

Diol **5***b* (98 mg, 0.24 mmol) and 1,1′-thiocarbonyldiimidazole (90 mg, 0.51 mmol) in toluene (4 mL) were heated to reflux under a stream of argon for 12 h. Evaporation of the solvent and flash chromatography (10–70% EtOAc – petroleum ether) gave **6** (57 mg, 53%) as a white solid and the uncyclized, C-3 imidazoyl-*N*-thionocarbonyl derivative (44%) as an oil. For **6**: R_f 0.29 (30% EtOAc – petroleum ether); $[\alpha]_D^{20}$ –9.6 (*c* 1.00, $CHCl_3$); mp 158°C (recrystallized from methylene chloride – petroleum ether). ^1H NMR (300 MHz, $CDCl_3$)δ 3.51 (s, 3H, OCH_3), 3.68–3.72 (m, 4 H, H4, H6a, CH_2OBn), 4.02–4.10 (m, 1H, H5), 4.21–4.30 (m, 1H, H6e), 4.57, 4.64 (d, 2H, *J* = 12.2 Hz, PhCH_2O), 5.06 (d, 1H, $J_{3,4}$ = 11.0 Hz, H3), 5.07 (s, 1H, H1), 5.50 (s, 1H, PhC*H*), 7.30–7.50 (m, 10H, aromatic). ^{13}C NMR δ: 56.4 (q, OCH_3), 66.4 (d, C5), 68.3 (t, Ph*C*H_2), 69.0 (t, C6), 74.2 (t, *C*H_2OBn), 77.5 (d, C3), 79.8 (d, C4), 87.4 (s, C2), 98.5 (d, C1), 101.4 (d, Ph*C*H), 126.0–136.9 (aromatic), 190.2 (s, C=S). Structure confirmed by X-ray crystallography.

*Methyl 4,6-*O*-benzylidene-2-*C*-benzyloxymethyl-*α*,*D*-*erythro*-hex-2-enopyranoside* **7**

(*a*) Thionocarbonate **6** (32 mg, 0.07 mmol) was dissolved in trimeth-

ylphosphite (3 mL) and heated to reflux under a stream of argon for 12 h. Evaporation of the solvent and flash chromatography (0–20% EtOAc – petroleum ether) gave **7** (1 mg, 4%) as a white solid: R_f 0.56 (20% EtOAc – petroleum ether); $[\alpha]_D^{20}$ +84.7 (*c* 0.71, $CHCl_3$); mp 110°C. ^{1}H NMR (300 MHz, CDl_3) δ: 3.43 (s, 3H, OCH_3), 3.77–3.96 (m, 3H, H5, H6a, C*H*$_2$OBn), 4.10–4.22 (m, 2H, H4, CH_2OBn), 4.30 (dd, 1H, $J_{5,6e}$ = 3.0 Hz, $J_{6a,6e}$ = 8.9 Hz, H6e), 4.46, 4.55 (d, 2H, *J* = 12.0 Hz, PhC*H*$_2$O), 4.92 (s, 1H, H1), 5.57 (s, 1H, PhC*H*), 6.09 (br s, 1H, H3), 7.30–7.50 (m, 10H, aromatic). ^{13}C NMR δ: 56.3 (q, OCH_3), 64.3 (d, C5), 69.5 (t, C6), 70.0 (t, Ph*C*H$_2$), 72.5 (t, *C*H$_2$OBn), 75.5 (d, C4), 96.8 (d, C1), 102.3 (d, Ph*C*H), 129.2 (d, C3), 136.0 (s, C2), 126.3–137.4 (aromatic). Anal. calcd. for $C_{22}H_{24}O_5$: C 71.71, H 6.58; found: C 71.72, H 6.66.

(*b*) Compound **9** (20 mg, 0.05 mmol) was dissolved in trimethylphosphite (2 mL) and heated to reflux under a stream of argon for 18 h. The solvent was partially evaporated. Flash chromatography (5–15% EtOAc – petroleum ether) gave **7** (10 mg, 60%).

(*c*) Compound **14***b* (28 mg, 0.10 mmol) in dry THF (2 mL) was stirred with NaH (7 mg, 60% dispersion in oil, 0.17 mmol) under a stream of argon for 2 h. Tetra-*n*-butylammonium iodide (catalytic amount) and benzyl bromide (0.02 mL, 24 mg, 0.14 mmol) were added and the reaction stirred overnight. The mixture was diluted with brine, extracted with ether (×3), and the combined extracts washed with brine (×2) and dried over Na_2SO_4. Flash chromatography (5–15% EtOAc – petroleum ether) gave **7** (30 mg, 81%).

(*d*) To allylic chloride **13** (synthesized as below from allylic alcohol **10***b* (68 mg, 0.24 mmol)) in methylene chloride (3 mL) was added water (2 mL), benzyl alcohol (0.03 mL, 31 mg, 0.29 mmol), NaOH (60 mg, 1.5 mmol), and tetrabutylammonium hydrogen sulfate (98 mg, 0.29 mmol). The mixture was placed under a stream of argon and subjected to ultrasonication for 4 days. The mixture was diluted with CH_2Cl_2 and water then separated. The aqueous layer was extracted with CH_2Cl_2 (×2), and the combined extracts were washed with brine and dried over Na_2SO_4. Flash chromatography (5–15% EtOAc – petroleum ether) gave **7** (49 mg, 54% from **10***b*).

*Methyl 4,6-*O*-benzylidene-2-*C*-benzyloxymethyl-2,3-thionocarbonyl-*α*,*D*-allopyranoside* ***9***

To diol **5***b* (62 mg, 0.15 mmol) in dry methylene chloride (3 mL) was added Dess–Martin periodinane (9) (140 mg, 0.33 mmol) and the reaction mixture was stirred overnight at room temperature under a stream of argon. Methylene chloride, saturated $NaHCO_3$, and $Na_2S_2O_3$ solutions were added and stirring was continued for 30 min. The layers were separated and the organic layer dried over Na_2SO_4. Flash chromatography (10–50% EtOAc – petroleum ether) gave **8***a* (44 mg, 71%) as an oily solid: R_f 0.60 (70% EtOAc – petroleum ether); ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.39 (s, 3H, OCH_3), 3.74 (t, 1H, $J_{5,6a}$ = $J_{6a,6e}$ = H6a), 3.74 (br s, 1H, OH), 3.75, 3.99 (d, 2H, *J* = 10.6 Hz, C*H*$_2$OBn), 3.97 (td, 1H, $J_{4,5}$ = 10.0 Hz, $J_{5,6e}$ = 4.6 Hz, H5), 4.19 (d, 1H, H4), 4.32 (dd, 1H, $J_{6a,6e}$ = 10.0 Hz, H6e), 4.43, 4.70 (d, 2H, *J* = 12.2 Hz, PhC*H*$_2$O), 4.73 (s, 1H, H1), 5.38 (s, 1H, PhC*H*), 7.30–7.50 (m, 10H, aromatic). ^{13}C NMR δ: 55.9 (q, OCH_3), 66.0 (d, C5), 69.5 (t, C6), 72.8 (t, Ph*C*H$_2$), 73.7 (t, *C*H$_2$OCH$_2$Ph), 81.3 (d, C4), 82.6 (s, C2), 102.0 (d, Ph*C*H), 103.8 (d, C1), 126.4–137.2 (aromatic), 198.4 (s, C3). Ketone **8***a* (44 mg, 0.11 mmol) in methanol (2 mL) was stirred with sodium borohydride (2 mg, 0.05 mmol) under a stream of argon for 1 h. The reaction was quenched with a few drops of acetic acid and the solvent evaporated. The mixture was dissolved in ethyl acetate, washed with saturated $NaHCO_3$ solution (×2) and brine (×2), and dried over Na_2SO_4. Flash chromatography (30–70% EtOAc – petroleum ether) gave **8***b* (39 mg, 88%) as an oil: R_f 0.48 (70% EtOAc – petroleum ether); ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.44 (s, 3H, OCH_3), 3.57 (br s, 2H, C*H*$_2$OBn), 3.64 (t, 1H, $J_{5,6a}$ = $J_{6a,6e}$ = 10.0 Hz, H6a), 4.10 (td, 1H, $J_{4,5}$ = 10.0 Hz, $J_{5,6e}$ = 5.1 Hz, H5), 4.24 (br s, 1H, H3), 4.31 (dd, 1H, H6e), 4.45 (s, 1H, H1), 4.53, 4.71 (d, 2H, *J* = 12.2 Hz, PhC*H*$_2$O), 5.44 (s, 1H, PhC*H*), 7.30–7.50 (m, 10H, aromatic). ^{13}C NMR δ: 56.6 (q, OCH_3), 57.7 (d, C5), 69.3 (t, C6), 69.5 (d, C3), 71.6 (t, Ph*C*H$_2$), 73.2 (s, C2), 73.7 (t, *C*H$_2$OBn), 77.1 (d, C4), 101.6 (d, C1), 102.0 (d, Ph*C*H), 126.1–137.7 (aromatic). Compound **8***b* (39 mg, 0.10 mmol) and 1,1-thiocarbonyldiimidazole (36 mg, 0.20 mmol) in dry toluene (2 mL) was heated to reflux under a stream of argon overnight. Flash chromatography (10–50% EtOAc – petroleum ether) gave **9** (36 mg, 84%) as a white solid: R_f 0.47 (50%EtOAc – petroleum ether) $[\alpha]_D^{20}$ +131.3 (*c* 1.00, $CHCl_3$); mp 186°C. ^{1}H NMR (300 MHz, $CDCl_3$ δ: 3.42 (s, 3H, OCH_3), 3.63–3.75 (m, 3H, H4, H6a, C*H*$_2$OBn), 3.85 (d, 1H, *J* = 11.7 Hz, C*H*$_2$OBn), 4.21 (td, 1H, $J_{4,5}$ = $J_{5,6a}$ = 10.1 Hz, $J_{5,6e}$ = 5.2 Hz, H5), 4.34 (dd, 1H, $J_{6a,6e}$ = 10.1 Hz, H6e), 4.53 (s, 1H, H1), 4.58, 4.65 (d, 2H, *J* = 12.0 Hz, PhC*H*$_2$O), 5.15 (d, 1H, $J_{3,4}$ = 3.4 Hz, H3), 5.52 (s, 1H, PhC*H*), 7.30–7.50 (m, 10H, aromatic). ^{13}C NMR δ: 56.2 (q, OCH_3), 57.1 (d, C5), 67.5 (t, Ph*C*H$_2$), 68.8 (t, C6), 74.0 (t, *C*H$_2$OBn), 74.1 (d, C3), 78.7 (d, C4), 86.9 (s, C2), 98.2 (d, C1), 102.8 (d, Ph*C*H), 126.4–136.6 (aromatic), 191.4 (s, C=S). Anal. calcd. for $C_{23}H_{24}O_7S$: C 62.14, H 5.45, S 7.21; found: C 62.21, H 5.48, S, 7.12.

*Methyl 4,6-*O*-benzylidene-2-*C*-methylene-α,D-arabino-hexopyranoside,* ***10****a, and its 3-*O*-acetyl derivative* ***10****b*

The use of Tebbe's reagent was adapted from the published procedure 10*b*. In a dry box, titanocene dichloride (1.4, 5.62 mmol) was added to an oven-dried flask that was then closed with a septum. The flask was removed from the dry box and the septum wrapped with parafilm. Trimethyl aluminium (5.62 mL, 2 M in toluene, 11.24 mmol) was added and the methane gas generated was allowed to escape through the needle of a cannula that was then removed. The red solution was stirred for 4 days. Methane gas was vented once a day. Ketoacetate **4***b* (820 mg, 2.54 mmol) in THF (5 mL) was added by syringe and the solution stirred for 1 h. The septum was removed and anhydrous ether (5 mL) was added. Sixteen drops of 1 M $NaOH_{(aq)}$ was added over a period of 1 h and the stirring continued overnight. Ether and anhydrous Na_2SO_4 were added and stirring continued for 1 h. The mixture was filtered through Celite (eluted with a copious quantity of ether) and the solvent evaporated. Flash chromatography (0–40% EtOAc – petroleum ether) gave **10***b* (73 mg, 10%) and **10***a* (530 mg, 75%). A high R_f material was also obtained and was assigned as **10***c* since it rearranged on standing to give **10***a* (29 mg; 4%).

Site-directed mutation was introduced into the gene for the farnesyl diphosphate synthase of *Bacillus stearothermophilus*. To investigate the significance of the three C-terminal amino acids, where arginine is completely conserved throughout the farnesyl diphosphate synthases of prokaryotes and eukaryotes, three kinds of mutant enzymes, R295V, D296G, and H297L, which have replacements of arginine-295 with valine, aspartate-296 with glycine, and histidine-297 with leucine, respectively, were overproduced and purified to homogeneity. All of the three mutant enzymes showed similar catalytic activities to that of the wild-type enzyme, indicating that the basic amino acids including the conserved arginine in the C-terminal region are not essential for catalytic function. They were also similar to the wild-type enzyme with respect to pH optima, thermostability, reaction product, and kinetic parameters for allylic substrates. However, their K_m values for isopentenyl diphosphate are approximately twice that of the wild type.

TANETOSHI KOYAMA, KAZUHIRO SAITO, KYOZO OGURA, SHUSEI OBATA et AYUMI TAKESHITA. Can. J. Chem. **72**, 75 (1993).

On a introduit une mutation dirigée sur un site du gène de la synthase de la diphosphate de farnésyle du *Bacillus stearothermophilus*. Dans le but d'évaluer l'importance des trois acides aminés du terminal-C où l'arginine est complètement conservé au cours dans tous les synthases de la diphosphate de farnésyle des procaryotes et des eucaryotes, on a surproduit et purifié jusqu'à homogénéité trois types d'enzymes mutants, les R295V, D296G et H297L dans lesquels on a respectivement remplacé l'arginine-295 par la valine, l'aspartate-296 par de la glycine et l'histidine-297 par de la leucine. Les trois enzymes mutants présentent chacun des activités catalytiques similaires à celles de l'enzyme de type sauvage; ceci indique que les acides aminés basiques, y compris l'arginine conservé dans la région du terminal-C ne sont pas essentiels pour la fonction catalytique. Pour les substrats allyliques, elles sont aussi semblables à l'enzyme de type sauvage en ce qui a trait au pH optimal, à la thermostabilité, au produit réactionnel et aux paramètres cinétiques. Toutefois, leurs valeurs de K_m pour le diphosphate d'isopenténylé sont approximativement deux fois plus grandes que celle de l'enzyme de type sauvage.

Introduction

Prenyltransferases catalyze the condensation of isopentenyl diphosphate (IPP) with allylic diphosphates to synthesize prenyl diphosphates with various chain lengths and stereochemistries (1, 2). They are extremely interesting from the mechanistic viewpoint in that they catalyze the repetition of stereospecific condensation of IPP with allylic diphosphates to give products with chain lengths determined by the specificities of the individual enzymes (3, 4).

Farnesyl diphosphate (FPP) synthase (EC 2.5.1.10) is one of the prenyltransferases and it occupies a central point in isoprenoid chain elongation pathways. It catalyzes the condensations of IPP with dimethylallyl diphosphate (DMAPP) and with geranyl diphosphate (GPP) to produce FPP as the ultimate reaction product as shown in Scheme 1 (1). Comparison of the primary structures of prenyltransferases, including FPP synthase (5–9), geranylgeranyl diphosphate (GGPP) synthase (10), and hexaprenyl diphosphate (HPP) synthase (11), from a wide range

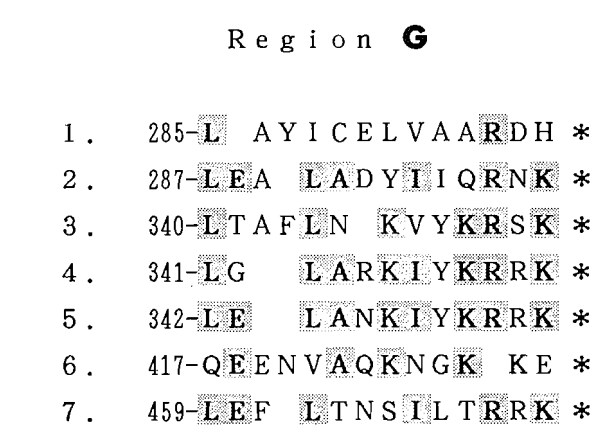

FIG. 1. Amino acid sequence alignment of Region **G** (C-terminal) within various prenyltransferases. Numbers attached to the left of the sequences indicate the position of the first amino acid displayed. Shaded areas indicate amino acids conserved in at least four out of the seven enzymes. 1, FPP synthase from *B. stearothermophilus* (9); 2, FPP synthase from *E. coli* (8); 3, FPP synthase from yeast (6); 4, FPP synthase from rat (5); 5, FPP synthase from human (7); 6, GGPP synthase from *N. crassa* (10); 7, HPP synthase from yeast (11).

of organisms has revealed the presence of seven conserved regions (9). These include regions characterized as rich in highly conserved aspartate and arginine residues. Site-directed mutagenesis studies carried out by Marrero et al. (12) using rat FPP synthase have recently shown that one of the highly conserved aspartate residues in Domain II (Region **F**) is essential for catalytic function while another one can be replaced with glutamate without significant change in catalytic properties. However, the significance of the highly conserved arginine residues remained unknown. Among the seven conserved regions in FPP synthases there are four highly conserved arginines in Regions **A**, **B** (two residues), and **G**. This paper describes the result of studies carried out, using the FPP synthase of *Bacillus stearothermophilus*, in an attempt to explore the role of the conserved arginine residue that occupies the third position from the carboxyl terminus. It also reports the effects of mutagenesis in the penultimate and the carboxyl terminus residues.

Experimental procedures

Materials

[1-^{14}C]IPP (1.95 TBq/mol) was purchased from Amersham Corp. Nonlabeled IPP, DMAPP, and GPP were the same preparations as used in the previous work (4). Restriction enzymes and other DNA-modifying enzymes were purchased from Takara Shuzo Co., Ltd. and Toyobo Co., Ltd. unless otherwise stated.

Site-directed mutagenesis

To introduce mutations in the structural gene for the FPP synthase of *B. stearothermophilus*, a *Bam*HI/*Hin*dIII DNA fragment from the clone pΔ1a (9) was subcloned into pTZ18R (Toyobo) yielding pEX47. Then single-stranded DNA templates were isolated with a helper phage, M13KO7 (13). Site-directed mutagenesis was conducted with uracil-enriched single-stranded DNA according to the procedure described by Kunkel et al. (14), and a series of mutated plasmids, pMu18, pMu88, and pMu84, were obtained. The nucleotide sequences of the mutagenic oligonucleotides are given in Fig. 2. The introduction of mutation was confirmed by sequencing the whole nucleotide sequence using the dideoxy chain-termination method (15) with a DNA sequencer (Applied Biosystems, model 373A).

Construction of expression vector systems for mutated FPP synthase

The *Nco*I/*Hin*dIII fragment of each of the three kinds of pMu plasmids into which a series of mutation had been introduced was ligated into the *Nco*I/*Hin*dIII site of pTrc99A (Pharmacia) to construct a series of recombinant plasmids, pEX121, pEX125, and pEX134 (Fig. 3).

Overproduction and purification of mutated FPP synthase

Each of the series of expression plasmids, pEX121, pEX125, and pEX134, was transformed into *E. coli* JM105, and the overnight culture of *E. coli* JM105 harboring the pEX plasmid in L-B medium (13) containing 50 μg/mL of ampicillin was inoculated into a 250-fold volume of M9YG medium (M9 salt (13) with 0.2% glycerol and 0.2% yeast extract) with 50 μg/mL of ampicillin. The *E. coli* cells were incubated at 30°C to an OD_{600} of 0.6–0.8, then isopropyl-ß-thiogalactopyranoside (IPTG) was added to a final concentration of 1 mM. The incubation was continued for additional 3 h at 30°C.

The mutated enzymes were purified essentially according to our previous paper, including heat treatment of the cell-free extracts followed by two chromatographic steps (9). The fractions of the mutated FPP synthases were analyzed for purity by sodium dodecyl sulfate – polyacrylamide gel electrophoresis (SDS–PAGE) (14%, ref. 16) with Coomassie Brilliant Blue staining, and fractions that proved to be homogeneous were used for further characterization. All of the mutated FPP synthases, R295V, D296G, and H297L, showed similar chromatographic properties to those of the wild-type enzyme during the purification procedure described above (data not shown).

FPP synthase assay

The enzyme activity was measured by determination of the amount of [1-^{14}C]IPP incorporated into butanol-extractable polyprenyl diphosphates (9). In a standard experiment, the incubation mixture contained, in a final volume of 1.0 mL, 50 mM Tris-HCl buffer of pH 8.5, 50 mM $MgCl_2$, 50 mM NH_4Cl, 5 mM KF, 50 mM 2-mercaptoethanol, 25 μM DMAPP or GPP, 25 μM [1-^{14}C]IPP (specific activity 37 GBq/mol), and a suitable amount of enzyme protein. After incubation at 55°C for 15 min, the reaction products were immediately extracted with 1-butanol. The butanol layer was washed with water and an aliquot of the extract was counted for radioactivity.

Product analysis

After enzymatic reaction at 55°C, the radioactive prenyl diphosphate in the reaction mixture was hydrolyzed to the corresponding alcohol with potato acid phosphatase according to the method of Fujii et al. (17).

The hydrolysate was extracted with pentane and analyzed by reversed phase thin-layer chromatography with LKC-18 (Whatman) in a solvent system of acetone–water (19:1). The positions of authentic standards were visualized with iodine vapor, and the distribution of radioactivity was detected.

Results

Effect of arginine specific reagents on FPP synthase activity

It has been shown that prenyltransferases such as the FPP synthases of pig liver (18) and human (19), undecaprenyl diphosphate synthase of *Lactobacillus plantarum* (20), and the HPP synthase of *Micrococcus luteus* B-P 26 (21) are sensitive to arginine-specific reagents.

To characterize the recombinant FPP synthase of *B. stearothermophilus*, we examined the effect of arginine-specific reagents, 2,3-butanedione and 1,2-cyclohexanedione, and found that both of these reagents strongly inhibited the enzyme with an I_{50} of approximately 5 mM.

Production of FPP synthase mutants

To examine the role of the conservative arginine residue in Region **G**, site-directed mutations were introduced in *B. stearothermophilus* FPP synthase. Figure 2 shows the C-terminal sequences of *B. stearothermophilus* FPP synthase and its mutated enzymes along with the sequences of mutagenic oligonucleotides.

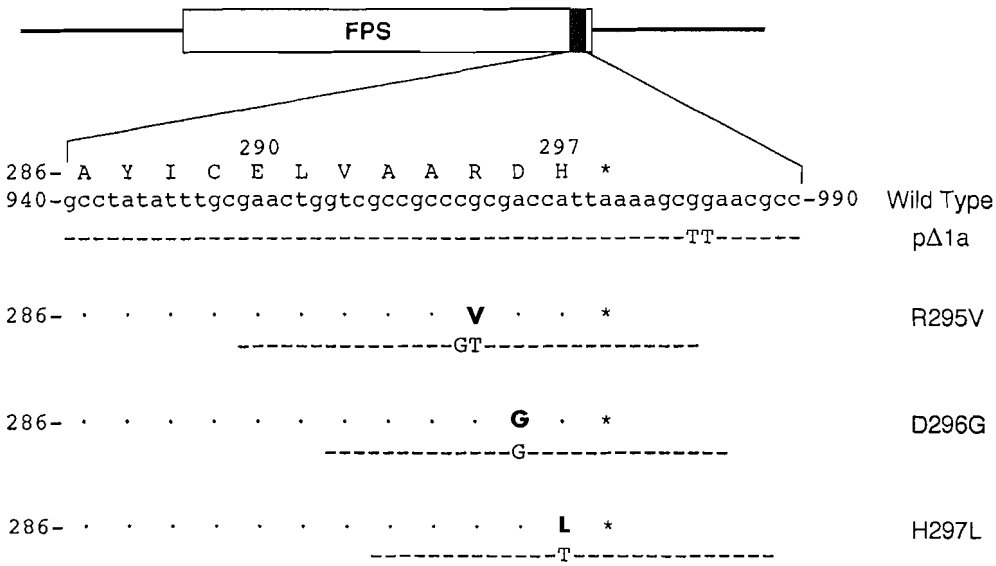

FIG. 2. Schematic presentation of wild-type and mutant FPP synthase gene sequences corresponding to the Region **G** (C-terminal). The nucleotide sequence of FPP synthase of *B. stearothermophilus* for residues 940–990 is shown. The sequences of mutagenic oligonucleotides are aligned underneath the wild-type sequence as well as that of pΔ1a corresponding to the FPP synthase gene (FPS). Nucleotides identical to those in the wild type are indicated by *dashes*, and altered nucleotides are indicated by *capital letters*. All mutant genes have been sequenced to verify point mutations. Amino acid sequences are also shown above the corresponding nucleotides. Dots indicate amino acids identical to those in the wild type.

The arginine residue at position 295, which is completely conservative in Region **G**, was changed to valine in order to produce a less basic mutant (R295V). The aspartic acid at 296 was replaced with glycine so that the C-terminal region was made less acidic (D296G). Substitution of leucine for the histidine at the C-terminus was made to prepare a mutant having a less basic C-terminal region (H297L).

To construct overexpression systems for these mutants, we employed plasmid pΔ1a, in which *Nco*I and *Hin*dIII sites were introduced immediately upstream and downstream, respectively, of the open reading frame of the *B. stearothermophilus* FPP synthase gene (9). The *Bam*HI/*Hin*dIII DNA fragment from pΔ1a was subcloned into pTZ18R and then oligonucleotide-mediated mutagenesis was conducted into the resulting plasmid, pEX47, to obtain a series of the mutated plasmids, pMu18, pMu88, and pMu84.

The *Nco*I/*Hin*dIII fragment of each of the pMu plasmids was ligated into the *Nco*I/*Hin*dIII site of pTrc99A, and expression plasmids pEX121, pEX125, and pEX134 were obtained. After transformation of *E. coli* JM105 with these plasmids, the FPP synthase mutants R295V, D296G, and H297L were overproduced and purified essentially according to the procedure for the production of wild-type recombinant FPP synthase (9). This procedure yielded proteins that gave a single band on SDS–PAGE, and the purities were judged, by staining with Coomassie Brilliant Blue, to be better than 95%.

Kinetic analysis of FPP synthase mutants

Kinetic parameters of the purified FPP synthase mutants are listed in Table 1. All the mutant enzymes showed catalytic activities comparable to that of the wild-type enzyme. H297L, especially was even better than the wild type in terms of specific activity and V_{max}. Even R295V, in which the highly conserved arginine had been replaced with valine, showed more than half the specific activity of the wild type. The K_m values of the mutant enzymes for IPP are approximately twice that of the wild type.

Effect of pH

The mutant enzymes showed similar pH–activity profiles to that of the wild-type enzyme, having pH optima around pH 8–8.5.

Thermostability

The mutant enzymes exhibited similar thermostabilities to that of the wild type, retaining enough activity even after heating at 60°C for at least 50 min.

Reaction product

Product analysis revealed that (all-*E*)-farnesyl diphosphate (FPP) was exclusively synthesized by all the mutant enzymes (data not shown).

Discussion

To study the significance of the conserved arginine residue in the C-terminal region, we carried out oligonucleotide-mediated mutagenesis and prepared three kinds of mutants of *B. stearothermophilus* FPP synthase, R295V, D296G, and H297L.

All these mutant enzymes showed FPP synthase activity, and their properties were similar to those of the wild-type enzyme. In other words, none of the three amino acid residues in the C-terminal region (Region **G**) is essential for enzyme activity. It is noteworthy, however, that the K_m values of the mutated enzymes for IPP are approximately twice as large as those of the wild-type enzyme, while those for the allylic substrates, DMAPP and GPP, are similar to those of the wild-type enzyme. These results suggest the possibility that the C-terminal region occupies a position that weakly affects the IPP binding site.

The specific activity of R295V is about half that of the wild type, while the other two mutants show values comparable to that of the wild type. Therefore, the arginine residue that is completely conserved at the third position from the C-terminus seems more important for enzymatic activity than the other two residues. Preference for the basic nature of the C-terminal region is also suggested by the observation that the replacement

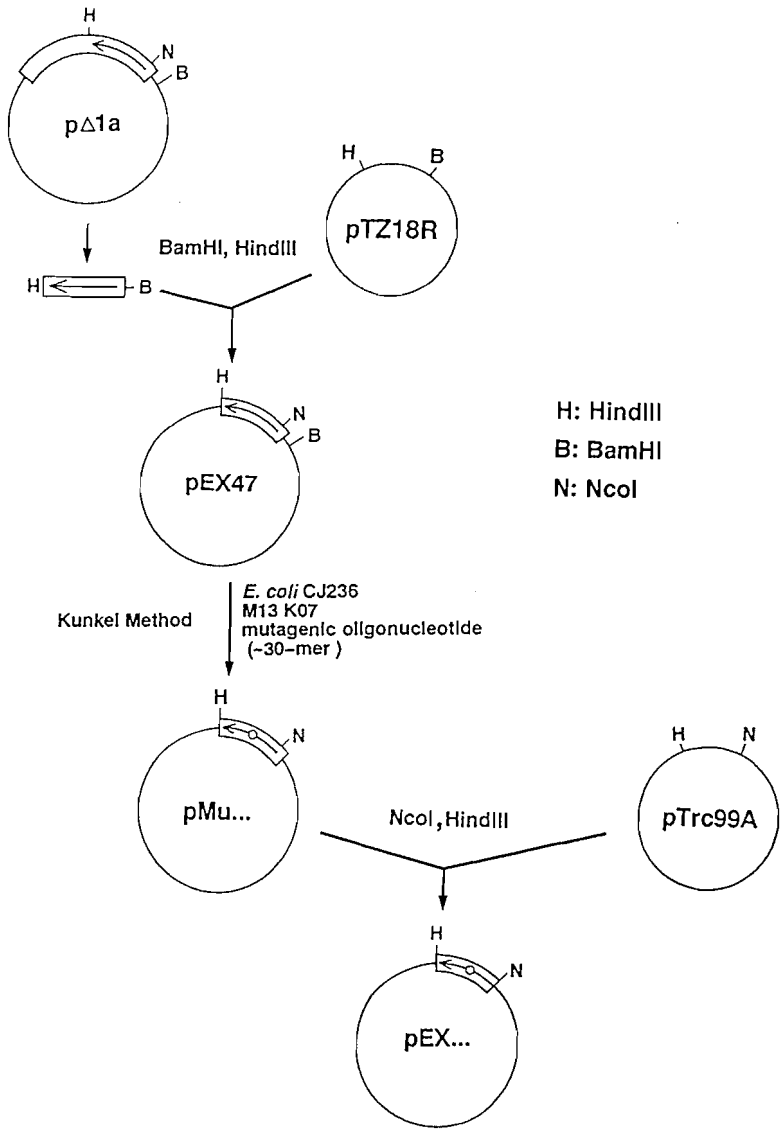

FIG. 3. Schematic diagram of construction of the plasmids. Restriction sites; H, *Hin*dIII; B, *Bam*HI; N, *Nco*I. The arrows indicate the coding region of the FPP synthase and open circles on the arrow indicate the point-mutated sites.

of the penultimate aspartate with glycine improved the V_m/K_m values for both DMAPP and GPP. However, it is surprising that the replacement of the C-terminal histidine with leucine is the most effective of the three in improving the enzymatic activity with respect to both specific activity and the V_m/K_m values for the allylic substrates.

It is interesting that the arginine residue conserved at the third position from the C-terminus is not essential for catalytic activity. However, this observation might not be surprising in view of the fact that the corresponding position is occupied by lysine and alanine in the GGPP synthases of *Nurospora crassa* (10) or *Erwinia herbicola* (22) and of *Erwinia uredovora* (23), respectively.

One or both of the arginine residues forming the RRG motif in Region **B** must be essential and responsible for the inhibition by arginine-specific reagents, because this motif is conserved not only in FPP synthases but also in GGPP synthases and HPP synthase.

According to the recent results of site-directed mutagenesis by Marrero et al. (12) in the aspartate-rich domain II, which is equivalent to Region **F** of *B. stearothermophilus* FPP synthase, the first aspartate is involved in the catalysis by the enzyme. These authors found that when the first aspartate in domain II was replaced with glutamate, the K_m value for IPP increased 23-fold but the K_m value for GPP did not change. This tendency is somewhat similar to our result in that the K_m values of the mutant enzymes for IPP increase while those for allylic substrates do not change significantly. Namely, the binding affinity for IPP is affected more easily by amino acid substitution than that of the allylic substrates. The C-terminal region might be located in a space in such a way that it affects the binding of IPP, though to a lesser extent than in the case of Region **F**.

To elucidate the reaction mechanism of prenyltransferase in more detail, it is indispensable to obtain information about its three-dimensional structure as well as data for the effect of site-directed mutagenesis on the catalytic function of the enzyme. Although crystallization of the FPP synthase of avian liver was reported by Reed and Rilling, no crystallographic information was available (24). As we recently succeeded in crystallization

Biosynthesis of pyrrolizidine alkaloids: putrescine and spermidine are essential substrates of enzymatic homospermidine formation

FRANK BÖTTCHER, DIETRICH OBER, AND THOMAS HARTMANN[1]

Institut für Pharmazeutische Biologie der Technischen Universität, D-38106 Braunschweig, Germany

Received June 8, 1993

This paper is dedicated to Professor Ian D. Spenser

sym-Homospermidine, the first pathway-specific intermediate of pyrrolizidine alkaloid (PA) biosynthesis, is formed from two moles of putrescine in an NAD^+-dependent reaction catalyzed by homospermidine synthase (HSS). In the overall process catalyzed by HSS, NAD^+ seems to function as hydride acceptor in the first part of the reaction and subsequently as hydride donor in the second part. This was proved with chirally C1-deuterated putrescines. Both a bacterial HSS (isolated from *Rhodopseudomonas viridis*) and the enzyme from PA-producing *Eupatorium cannabinum* transformed (*R*)-[1-^{2}H]putrescine and (*S*)-[1-^{2}H]-putrescine into homospermidine with a 100% retention of deuterium. Studies with deuterated and ^{14}C-labeled substrates revealed that in the presence of putrescine spermidine is a substrate of HSS. The putrescine semialdehyde moiety of spermidine is combined with putrescine and 1,3-diaminopropane is released. Kinetic studies with plant HSS documented that the putrescine semialdehyde moiety of spermidine is incorporated into homospermidine with the same affinity (K_m) and activity (V_{max}) as putrescine. Plant HSS is highly specific for putrescine and spermidine; spermidine is not a substrate in the absence of putrescine. It is suggested that in the biosynthesis of homospermidine and thus PAs, one of the two C4 units is derived from spermidine and the other one from putrescine. A scheme of the HSS-catalyzed reaction is proposed that fully accounts for the enzymatic data and the results of previous tracer studies. Bacterial HSS is less substrate specific and not as well adapted as plant HSS to accept spermidine as a substrate.

FRANK BÖTTCHER, DIETRICH OBER et THOMAS HARTMANN. Can. J. Chem. **72**, 80 (1994).

La *sym*-homospermidine, le premier intermédiaire spécifique à une voie de biosynthèse des alcaloïdes de la pyrrolizidine (AP), se forme à partir de deux molécules de putrescine dans une réaction qui dépend du NAD^+ et qui est catalysée par la synthase de l'homospermidine (SHS). Dans le processus global catalysé par la SHS, le NAD^+ semble agir comme un accepteur d'hydrure dans la première partie de la réaction et comme donneur d'hydrure dans la deuxième partie. Ceci a été prouvé à l'aide de putrescines chirales, deutérées en C1. La SHS bactérienne (isolée du *Rhodopseudomonas viridis*) et l'enzyme provenant du *Eupatorium cannabinum* produisant des AP transforment tous les deux la (*R*)-[1-^{2}H]putrescine et la (*S*)-[1-^{2}H]putrescine en homospermidine avec 100% de rétention du deutérium. Des études avec des substrats deutérés et marqués au ^{14}C ont révélé que, en présence de putrescine, la spermidine est un substrat de la SHS. La portion semialdéhyde de la putrescine présente dans la spermidine se combine avec la putrescine et du 1,3-diaminopropane est libéré. Des études cinétiques avec de la SHS de plante ont permis de confirmer que la portion semialdéhyde de la putrescine présente dans la spermidine s'incorpore dans l'homospermidine avec la même affinité (K_m) et la même activité (V_{max}) que la putrescine. La SHS de plante est très spécifique pour la putrescine et la spermidine; la spermidine n'est pas un substrat en l'absence de putrescine. On suggère que dans la biosynthèse de l'homospermidine, et donc dans celle des AP, l'une des deux unités en C4 provient de la spermidine alors que l'autre provient de la putrescine. On propose un schéma pour la réaction catalysée par la SHS qui explique complètement les données enzymatiques et les résultats d'études antérieures à l'aide de marqueurs. La SHS bactérienne est moins spécifique aux substrats et elle n'est pas aussi bien adaptée que la SHS de plante pour accepter la spermidine comme substrat.

[Traduit par la rédaction]

Introduction

Biosynthesis of retronecine, the basic moiety of many pyrrolizidine alkaloids (PAs), has independently been studied by I. D. Spenser using *Senecio vulgaris* and by D.J. Robins using *Senecio isatideus* (for review see refs. 1–3). Extensive tracer experiments carried out in the two laboratories confirmed that retronecine is derived from putrescine via a symmetrical intermediate such as *N*-(4-aminobutyl)-1,4-diaminobutane (*sym*-homospermidine) (4–7). Recently we found homospermidine synthase (HSS) to be the first enzyme of the alkaloid specific pathway (8). HSS catalyzes in an NAD^+-dependent reaction the formation of homospermidine from two moles of putrescine. Free Δ^1-pyrroline as an intermediate in homospermidine formation could be excluded. The enzyme that has previously been reported to occur in the bacterium *Rhodopseudomonas viridis* (9) and the legume *Lathyrus sativus* (10) was purified and characterized from root cultures of *Eupatorium cannabinum* and *Senecio* spec. (Asteraceae) (8).

Here we report that HSS from PA-producing plant sources uses spermidine with high efficiency instead of putrescine as donor of the 4-aminobutanyl moiety that is combined with the second mole of putrescine. The bacterial enzyme is also able to use spermidine, but less efficiently.

Results

Incorporation of chiral deuterated putrescines into homospermidine

In the overall reaction catalyzed by HSS, NAD^+ functions as electron acceptor in the first part of the reaction (oxidative deamination) and as electron donor in the second part (hydrogenation of the intermediate imine):

$$2 \times H_2N\text{-}(CH_2)_4\text{-}NH_2 + NAD^+ \rightarrow H_2N\text{-}(CH_2)_3\text{-}CH{=}N\text{-}(CH_2)_4\text{-}NH_2$$

$$+ NH_3 + NADH + H^+ \rightarrow H_2N(CH_2)_4\text{-}NH\text{-}(CH_2)_4\text{-}NH_2 + NAD^+$$

Kinetic studies suggest that the NAD^+-mediated hydride transfer may proceed enzyme-bound without external exchange (8). To prove this we incubated partially purified HSS of *Rhodopseudomonas viridis* (bacterial HSS) and *Eupatorium*

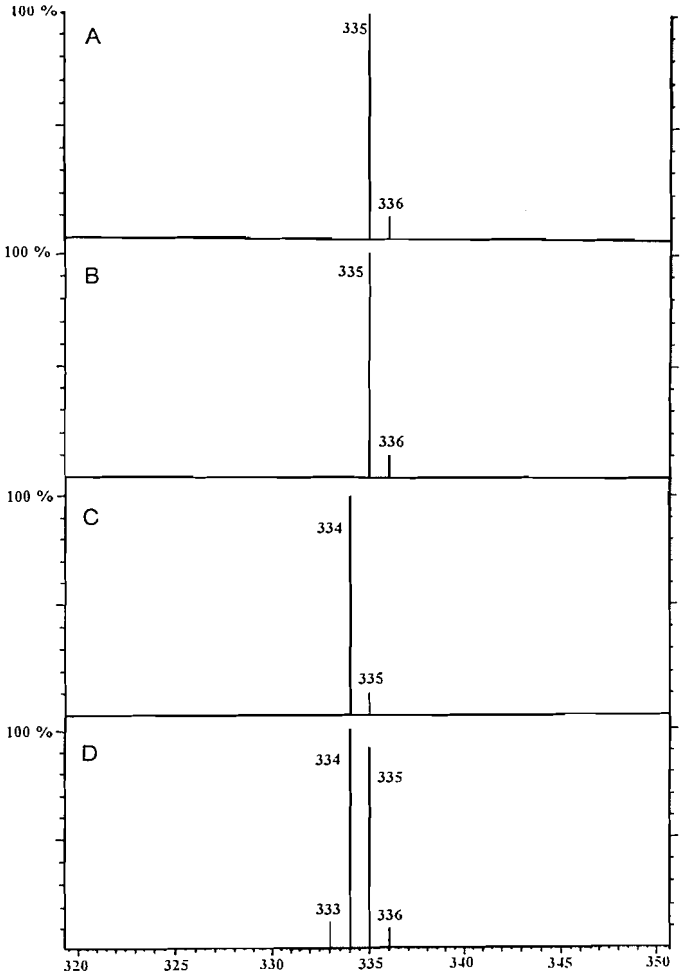

FIG 1. GC–MS analysis of *sym*-homospermidine (analyzed as the *N*-Carbomethoxy(NCM) derivative) synthesized by homospermidine synthase (HSS) incubated with chirally deuterated putrescines as substrates. M^+ (*m/z* 335) = incorporation of $2 \times {}^2H$; M^+ (*m/z* 334) = incorporation of $1 \times {}^2H$; M^+ (*m/z* 333) = undeuterated *sym*-homospermidine. *A*: Bacterial HSS incubated with (*R*)-[1-^{2}H]putrescine as substrate; *B*: bacterial HSS incubated with (*S*)-[1-^{2}H]putrescine as substrate; *C*: plant HSS incubated with (*S*)-[1-^{2}H]putrescine as substrate (in the presence of 0.5 mM spermidine added as stabilizing agent); *D*: bacterial HSS incubated with (*S*)-[1-^{2}H]putrescine in the presence of equimolar amounts of spermidine.

cannabinum (plant HSS), respectively, with (*R*)-[1-^{2}H]putrescine and (*S*)-[1-^{2}H]putrescine as substrates in the presence of NAD^+. GC–MS analysis of the *N*-carbomethoxy(NCM) derivatives of the homospermidine formed shows that with the bacterial enzyme the two deuterated substrates were incorporated into homospermidine without any loss of tracer (Fig. 1, *A* and *B*), i.e., occurrence of M^+ 335 (incorporation of $2 \times {}^2H$) and absence of M^+ 333 (undeuterated homospermidine) and M^+ 334 in the mass spectra.

Unexpectedly, under comparable experimental conditions the plant enzyme gave completely different results (Fig. 1*C*). M^+ 334 (incorporation of $1 \times {}^2H$) became the most dominant fragment. The result was essentially the same with either of the chirally deuterated putrescines. In comparison to bacterial HSS, the only difference was that the enzyme assay with plant HSS was achieved in the presence of 0.5 mM spermidine, which is needed to stabilize the enzyme (8). Addition of spermidine to the assay with bacterial HSS also leads to the appearance of the mass fragment M^+ 334 (Fig. 1*D*). This was the first indication that in the presence of putrescine spermidine is incorporated into homospermidine.

TABLE 1. Efficiency of bacterial and plant HSS to incorporate (*R*)-[1-^{2}H]putrescine into homospermidine in the presence of increasing proportions of spermidine

Substrates[a] [^{2}H]put:spd	% [1-^{2}H]putrescine incorporated (putrescine units)[b] *R. Viridis*	*E. cannabinum*
100: 0	100 (2.00)	
95: 5		97 (1.94)
83:17		63 (1.26)
75:25	88 (1.75)	58 (1.16)
60:40	81 (1.62)	57 (1.14)
48:52	74 (1.48)	
42:58		56 (1.12)

[a]Assay concentration of putrescine plus spermidine: 3.0 mM (bacterial enzyme); 0.25 mM (plant enzyme).

[b]100% = the two putrescine moieties of homospermidine are derived exclusively from putrescine; in parentheses are proportions of the two putrescine moieties in homospermidine derived from putrescine.

Incorporation of "spermidine-bound" putrescine into homospermidine

Incubation of bacterial HSS with a putrescine–spermidine mixture revealed that with increasing amounts of spermidine the incorporation of the "spermidine-bound" putrescine moiety into homospermidine increased. This was established by application of [1-^{2}H]putrescine (Table 1) as well as [^{14}C]putrescine and [^{14}C]spermidine, respectively. In the presence of equimolar concentrations of the two substrates, ca. 25% of the homospermidine formed was derived from spermidine (Table 1). The same results were obtained with plant HSS; the efficiency of spermidine incorporation, however, was considerably higher (Table 1).

Substrate specificity and proposed reaction mechanism of HSS

Bacterial and plant homospermidine synthases have been described as enzymes that catalyze reactions which are highly specific for putrescine as substrate (8–10). Reinvestigation of the substrate specificity revealed, indeed, that putrescine cannot be substituted by homologous diamines if offered as sole substrate (Table 2). If, however, homologous diamines such as 1,3-diaminopropane, cadaverine, or 1,6-diaminohexane are offered in the presence of putrescine, bacterial HSS produces, in addition to homospermidine, low but significant amounts of the respective homologous polyamines (Table 2). On the contrary, plant HSS was virtually unable to catalyze these side reactions. With the two enzymes, however, spermidine was found to be an efficient substrate in the presence of putrescine. The 160% turnover with plant HSS is due to the stabilizing effect of spermidine on the enzyme protein (8). If spermidine is offered as sole substrate or in the presence of diamines different from putrescine, no turnover was found with plant HSS, except the formation of trace amounts of 1,3-diaminopropane. On the other hand, the bacterial enzyme produces homospermidine, putrescine, and diaminopropane upon feeding of spermidine as sole substrate. In the presence of spermidine and various putrescine analogues, small amounts of the respective homologous polyamines are formed, as well as homospermidine.

The mechanism for the HSS-catalyzed reaction, illustrated in Scheme 1, accounts for the data given here and described pre-

TABLE 2. Substrate specificity of bacterial and plant homospermidine synthases

Substrate(s) (1 mM each)	Product(s) formed or expected to be formed	*R. viridis* (%)[a]	*E. cannabinum* (%)[a]

	1,3-Diaminopropane	+[c]	tr[c]

[a]Activities with putrescine as substrate were set 100% (i.e., bacterial HSS, 33 nmol/h and assay; plant enzyme, 1.8 nmol/12 h and assay). Quantification by radio HPLC; identity proved by GC–MS.

[b]Applied as ^{14}C-labeled substrates; in assays with two substrates (e.g., spermidine + putrescine where both substrates were available as labeled compounds, two assays were performed with, alternatively, one applied as tracer.

[c]Unequivocally identified by GC–MS; quantification not possible due to lack of radioactivity.

[d]— = not detectable, neither by radio HPLC nor GC–MS; tr = traces.

viously (8–10). We assume two binding sites, one for each of the two putrescine molecules. At site A (Scheme 1, I), which may bind either putrescine or spermidine, the NAD^+-dependent oxidativedeamination takes place. Ammonia is released if putrescine is the substrate and 1,3-diaminopropane if spermidine is the substrate. The semialdehyde formed is proposed to remain enzyme-bound, possibly linked as Schiff's base to a protein amino group (e.g., an ϵ-NH_2 group of a lysine residue) (Scheme 1, II/III). Site B specifically binds putrescine, which is suggested to react with the enzyme-bound semialdehyde by transaldimination (Scheme 1, III/IV) to yield an imine as enzyme-bound intermediate. Finally the imine is reduced at the expense of NADH and the homospermidine released (Scheme 1, IV/V). The two enzymes are assumed to bind either putrescine or spermidine to site A and putrescine to site B. In contrast to plant HSS, the bacterial enzyme also accepts some homologous diamines as substrates to some extent (Table 2), and may even bind spermidine in a manner such that putrescine is released as product in the course of the oxidative deamination, as indicated by the detection of both free putrescine and homospermidine (Table 2).

Substrate kinetics of HSS

The results documented in Tables 1 and 2 suggest that there are differences between the two enzymes in respect to their efficiency in using spermidine as substrate in addition to putrescine. Comparative kinetic studies were performed to manifest the role of the two substrates. In each case the incorporation of increasing concentrations of either putrescine or spermidine into homospermidine was measured in the presence of a constant level of the respective other substrate. To be well above the K_m values of putrescine, concentrations of 1 mM and 0.1 mM, respectively, were chosen for the bacterial and the plant enzymes. The Hanes plots show linear behaviour so that the K_m and V_{max} could be calculated for the two substrates (Fig. 2, Table 3). The kinetic data show that in the case of bacterial HSS putrescine is the better substrate for binding site A (Scheme 1, Fig. 2*A*, *C*). The K_m value for putrescine as sole substrate is six times lower than the K_m values for putrescine in the presence of spermidine and for spermidine in the presence of putrescine (Table 3). Furthermore V_{max} and V_{max}/K_m for spermidine are about 10 times lower than the comparable values for putrescine in the presence of spermidine. Although in the presence of the respective other substrate putrescine and spermidine bind to the enzyme with almost the same affinity, the turnover of the latter is much lower.

The situation is quite different with plant HSS. In comparison to bacterial HSS, its substrate affinity is much higher and the K_m and V_{max} values of the two substrates are almost identical (Fig. 2, Table 3). The latter indicates that spermidine not only binds to plant HSS with the same affinity as putrescine but shows also the same reactivity (Table 3).

Discussion

Homospermidine is the first intermediate of the alkaloid-specific pathway leading to PAs (8, 11). Tracer studies have shown

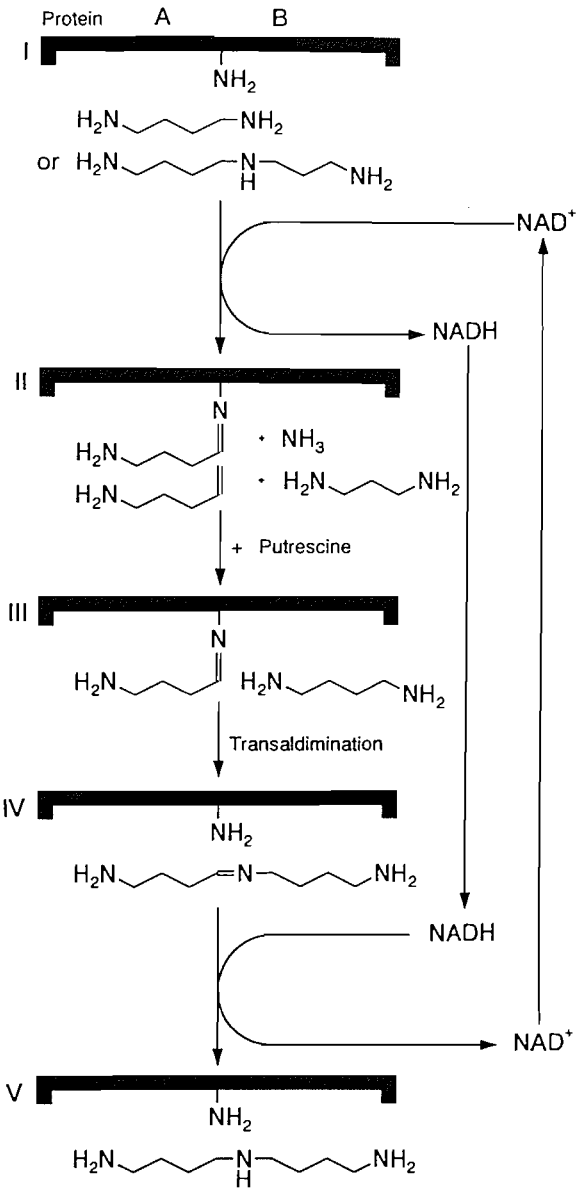

SCHEME 1. Proposed reaction mechanism for homospermidine synthase. A and B are two assumed binding sites.

that labeled free putrescine and the labeled diaminobutane moiety of spermidine are incorporated into PAs with equal efficiency (12–14). Because in PA-producing root cultures of *Senecio vulgaris* putrescine and spermidine exist in a highly dynamic state and are rapidly interconverted, it has been suggested that spermidine is incorporated into PAs via free putrescine (15). The enzymatic data presented here indicate that both free putrescine and "spermidine-bound" putrescine are directly incorporated into homospermidine and thus into the necine base of PAs. If we take into account the steady-state concentrations of putrescine and spermidine (i.e., 70–120 μM and 30–100 μM, respectively, on a fresh weight basis) in growing root cultures of *Senecio* and *Eupatorium* (8) we can assume that the incorporation of the two substrates is around 1:1, i.e., binding site A (Scheme 1) may be almost completely occupied by spermidine (see Table 1). The biosynthetic mechanism suggested here on the basis of enzymatic studies is, except for one deviation (see below), compatible with previous isotope tracer studies that established the symmetrical putrescine as an essential intermediate of necine biosynthesis (1–7). In fact, by tracer studies, even with sophisticated labeled precursors, it would not be possible to distinguish whether a putrescine moiety of homospermidine or a necine base is derived from free putrescine or is incorporated via spermidine.

The experiments with chirally ^{2}H-labeled putrescines proved that the ^{2}H is completely retained in the conversion of each of the (*R*)- and the (*S*)-[1-^{2}H]putrescine into homospermidine, as must be predicted from the mechanism of HSS. This is not fully in agreement with the plant tracer experiments carried out by Grue-Sorensen and Spenser (16) and Rana and Robins (17) who, in convincing experiments, followed the fate of chirally 1-^{2}H-labeled putrescines into the necine base (i.e., retronecine) formed, and analyzed the ^{2}H retention by means of ^{2}H NMR. These authors (Spenser, Robins and co-workers) found retention of 69% and 68%, respectively, of ^{2}H at the carbons that are affected in the formation of homospermidine (i.e., adjacent to the secondary amino group) if (*S*)-[1-^{2}H]putrescine was fed. When (*R*)-[1-^{2}H]putrescine was fed the retention was100%. Because the authors expected a diamine oxidase to be involved, which is known to remove stereospecifically the *pro-S* hydrogen from the methylene group of the primary amine, the predicted retention with (*S*)-[1-^{2}H]putrescine should be 50%. The authors explained the observed differences by the operation of an intramolecular deuterium isotope effect in the enzymatic oxidations involved. From our own results, one should expect a 100% retention. For the HSS reaction catalyzed with putrescine as sole substrate we were unable to detect any significant isotope effect. But it could be that this is associated with the incorporation of the 4-aminobutanyl moiety of spermidine into homospermidine or that it occurs at the stage of spermidine rather than homospermidine formation. Studies to resolve this are in progress in our laboratory.

Finally we have to put forward the question, why do plants substitute free putrescine at least partly by spermidine as biosynthetic precursor of PAs? Polyamines such as spermidine have been implicated in many plant growth and developmental processes (18). On the other hand, we know that in *Senecio* root cultures PA biosynthesis is functionally and spatially related to root growth; PAs do not show any significant degradation or turnover but their concentration in a growing root system is kept constant (15, 19). Thus, a direct metabolic linkage of PA biosynthesis to spermidine may offer a control mechanism to adjust the rate of PA biosynthesis to growth velocity.

Experimental

Preparation of bacterial homospermidine synthase (HSS)

Rhodopseudomonas viridis (DSM 134) was obtained from the German Collection of Microorganisms and Cell Cultures (DSM Braunschweig, Germany). The strain was cultured anaerobically in the medium given in ref. 20 in screw-capped 500-mL flasks in the light at 20–27°C. The cultures were harvested at the beginning of the stationary growth phase (ca. 7 days). The cells collected by centrifugation were treated twice with cold (–18°C) acetone in a Waring blender (30 s). Acetone-treated cells were collected by filtration under reduced pressure, air-dried, and ground in a mortar. The "acetone powder" (AP) retained HSS activity without loss for months if stored dry at –18°C.

For HSS preparation 1 g AP was suspended in 20 mL standard buffer (50 mM KH_2PO_4, 2 mM dithioerythritol (DTE), pH 8.5 adjusted with 5 M NaOH), stirred for 30 min at 4°C, and centrifuged, and the supernatant was desalted via a Sephadex G-50 column. The desalted extract was further purified by affinity chromatography via a spermidine-CH

At 1 mM putrescine:			
Spermidine	1.5	1.6	1.1
E. cannabinum HSS			
Putrescine[b]	0.013	14.5	1115
At 0.1 mM spermidine:			
Putrescine	0.015	11.0	733
At 0.1 mM putrescine:			
spermidine	0.012	8.8	733

[a]Bacterial HSS = nkat/mg protein; plant HSS = pkat/mg protein; K_m and V_{max} were calculated on the basis of the incorporation of the respective substrate into homospermidine.

[b]Residual spermidine concentration of the enzyme preparation <0.01 mM.

Sepharose 4B batch column (20 mL bed volume). The gel was equilibrated with 300 mL standard buffer, then 20 mL enzyme extract was mixed with the gel, and after 20 min elution was started. After washing, the column with standard buffer HSS activity was eluted with standard buffer supplemented with a mixture of spermidine plus putrescine (100 mM each). The active fractions were collected and desalted via Sephadex G 50 to remove the spermidine and putrescine. HSS activity remains stable for at least several weeks if kept cool at 4°C; the specific activity of HSS was about 10–20 nkat/mg protein.

Preparation of plant homospermidine synthase (HSS)

Enzyme preparations were obtained from root cultures of *Eupatorium cannabinum* following a four-step protocol: (1) preparation of a crude extract; (2) desalting via a Sephadex G 50 column; (3) ca. 10-fold concentration of the desalted crude extract by ultrafiltration; (4) protein separation by gel filtration via a Superdex TM 200 "high load" column. The whole procedure was the same as described previously (8). The preparation was immediately used for enzymatic studies due to the instability of plant HSS; the specific activity was about 10 pkat/mg protein. If spermidine-free enzyme preparations were required, extracts were desalted via PD-10 columns (Pharmacia) and the desalted eluate, which still contained residual spermidine up to 0.01 mM, was used immediately for enzyme assays.

Enzyme assays

(1) Bacterial HSS

The standard assay contained, in a total volume of 125 µl standard buffer, pH 8.5 1.0 mM [^{14}C]putrescine (0.05 µCi/assay), 0.2 mM NAD^+, and further additives as indicated. Assays were incubated for 10–60 min at 37°C. Formation of labeled homospermidine was followed quantitatively by radio TLC or radio HPLC as described previously (8).

(2) Plant HSS

Standard assays were performed and analyzed as described in ref. 8, except that the addition of 0.5 mM spermidine as protective agent was omitted.

Preparations of the two enzymes were essentially free of interfering enzyme activities such as diamine or polyamine oxidases or other enzymes that utilize either putrescine or spermidine.

HPLC analysis of polyamines

The various polyamines that were formed or were expected to be formed as reaction products of bacterial or plant HSS were separated by HPLC as benzoyl derivatives according to refs. 8 and 21. An RP-18 column (Nucleosil 25 cm, 4 mm i.d.; Macherey & Nagel) was applied. Elution: isocratically using the solvent system MeCN–H_3PO_4(1.5%) (40:60); parallel detection: (*a*) UV 230 nm, (*b*) radio monitoring. The retention times (R_t; min) for the polyamines in investigations were as follows: 1,3-diaminopropane, 5.2; putrescine, 5.5; cadaverine, 6.4; 1,6-diaminohexane, 8.7; spermidine, 8.4; *sym*-homospermidine, 9.5; *N*-[4-aminobutyl]-1,5-diaminopentane, 9.5; *N*-[4-aminobutyl]-1,6-diaminohexane, 16.3.

Identification of the reaction products of HSS

For unequivocal identification the reaction products were analyzed as *N*-carbomethoxy derivatives (NCM derivatives) by GC–MS (22). An aliquot (1.0 mL) of the aqueous enzymatic reaction was mixed with 20 µL of methyl chloroformate medium and left standing at room temperature for 15 min. The amine NCM derivatives were extracted into diethyl ether (3 × 1 mL each). The extracts were combined and the solvent evaporated. The residue was dissolved in 10–25 µL dichloromethane prior to GC–MS analysis. GC–MS: Carlo Erba 5160 gas chromatography equipped with 30 m × 0.32 mm fused-silica column (DB-1); conditions, injector 250°C, split-ratio 1:20, injection volume 1–2 µL, carrier gas He 0.75 bar (1 bar = 100 kPa), detector FID; the capillary column was directly coupled to a quadrupole mass spectrometer Finnigan MAT 4515. EI mass spectra were recorded at 40 eV. The NCM derivatives of the following diamines (applied as substrates) and polyamines (formed as products) were identified (see Table 2) by their Kovats indices (RI), and M_r (M^+): 1,3-diaminopropane, RI 1485, [M^+] *m/z* 190; putrescine, RI 1622, [M^+] *m/z*, 204; cadaverine, RI 1727, [M^+] *m/z* 218; 1,6-diaminohexane, RI 1838, [M^+] *m/z 232;* spermidine, RI 2365, [M^+] *m/z* 319; *sym*-homospermidine, RI 2467, [M^+] *m/z* 333; *N*-[4-aminobutyl]-1,5-diaminopentane, RI 2570, [M^+] *m/z* 347; *N*-[4-aminobutyl]-1,6-diaminohexane, RI 2678, [M^+] *m/z* 361.

The same GC–MS procedure was applied to analyse the deuterium incorporation.

Radiochemicals and deuterated putrescines

[1,4-^{14}C]Putrescine (108 mCi mmol^{-1}), [^{14}C]spermidine (*N*-(3-aminopropyl)-[1,4-^{14}C]tetramethylene-1,4-diamine) (109 mCi mmol^{-1}), and L-[U-^{14}C]lysine (312 mCi mmol^{-1}) were purchased from Amersham Braunschweig). [U-^{14}C]Cadaverine was prepared from labelled lysine by application of L-lysine decarboxylase (Sigma, Heidelberg).

(*S*)-[1-^{2}H]Putrescine (97% $^2H_1$ species) and (*R*)-[1-^{2}H]putrescine (99% $^2H_1$ species) were prepared according to the method described in ref. 23.

This paper is dedicated to Professors Ian Spenser and David B. MacLean

RONALD J. PARRY, SUNIL V. MHASKAR, MING-TEH LIN, ALAN E. WALKER, and ROBSON MAFOTI. Can. J. Chem. **72**, 86 (1994).

The biosynthesis of the phytotoxin coronatine has been investigated by administration of isotopically labeled precursors to *Pseudomonas syringae* pv. *glycinea*. The structure of coronatine contains two moieties of distinct biosynthetic origin, a bicyclic, hydrindanone carboxylic acid (coronafacic acid) and a cyclopropyl α-amino acid (coronamic acid). Investigations of coronafacic acid biosynthesis have shown that this compound is a polyketide derived from three acetate units, one butyrate unit, and one pyruvate unit. The two carbonyl oxygen atoms of coronafacic acid were found to be derived from the oxygen atoms of acetate. Additional experiments are described that rule out some possible modes for assembly of the polyketide chain. Coronamic acid is shown to be derived from L-isoleucine via the intermediacy of L-alloisoleucine. Examination of the mechanism of the cyclization of L-alloisoleucine to coronamic acid revealed that the formation of the cyclopropane ring takes place with the removal of only two hydrogen atoms from the amino acid, one at C-2 and the other at C-6. The nitrogen atom at C-2 of L-alloisoleucine is shown to be retained. On the basis of these observations, a mechanism is postulated for the cyclization reaction that involves the diversion of an enzymatic hydroxylation reaction into an oxidative cyclization. Finally, a precursor incorporation experiment with deuterium-labeled coronamic acid demonstrated that free coronamic acid can be efficiently incorporated into coronatine. This observation indicates that the cyclization of L-alloisoleucine to coronamic acid can occur before formation of the amide bond between coronafacic acid and coronamic acid.

RONALD J. PARRY, SUNIL V. MHASKAR, MING-TEH LIN, ALAN E. WALKER et ROBSON MAFOTI. Can. J. Chem. **72**, 86 (1994).

On a étudié la biosynthèse de la phytotoxine coronatine en administrant des précurseurs marqués au *Pseudomonas syringae* pv. *glycinea*. La structure de la coronatine contient deux portions d'origines biosynthétiques différentes : un acide hydrindanone carboxylique bicyclique (l'acide coronafacique) et un acide cyclopropylique α-aminé (l'acide coronamique). Des études sur la biosynthèse de l'acide coronafacique ont montré que ce composé est un polycétide dérivé de trois unités acétique, d'une unité butyrique et d'une unité pyruvique. On a trouvé que les deux atomes d'oxygène carbonyles de l'acide coronafacique sont dérivés des atomes d'oxygène de l'acide acétique. On décrit des expériences additionnelles qui permettent d'éliminer un certain nombre de modes d'assemblage de la chaîne polycétide. On démontre que l'acide coronamique est dérivé de la L-isoleucine par le biais de la L-alloisoleucine comme intermédiaire. L'examen du mécanisme de cyclisation de la L-alloisoleucine en acide coronamique a révélé que la formation du cyclopropane se produit avec l'enlèvement de seulement deux atomes d'hydrogène à partir de l'acide aminé, l'un en C-2 et l'autre en C-6. On a démontré que l'atome d'azote en C-2 de la L-alloisoleucine est conservé. Sur la base de ces observations, on propose un mécanisme pour la réaction de cyclisation qui implique la transformation d'une réaction enzymatique d'hydroxylation en une cyclisation oxydante. Finalement, une expérience d'incorporation d'un précurseur avec de l'acide coronamique marqué au deutérium a permis de démontrer que l'acide coronamique libre peut être incorporé efficacement dans la coronatine. Cette observation indique que la cyclisation de la L-alloisoleucine en acide coronamique peut se produire avant la formation de la liaison amide entre l'acide coronafacique et l'acide coronamique.

[Traduit par la rédaction]

Introduction

Coronatine (**1**) is a phytotoxin of novel structure that is produced by many pathovars of *Pseudomonas syringae*, including pv. *atropurpurea* (1,2), pv. *glycinea* (2,3), pv. *tomato* (4), and pv. *morsprunorum* (2). Infection of the host plants by these bacteria induces chlorosis on the leaves due to the production of coronatine(1,2). In addition, coronatine distorts leaf growth, inhibits root elongation, and causes hypertrophy when applied to the cut surface of potato tubers (5,6). Treatment of plant tissues with coronatine has been shown to stimulate the production of ethylene, and it has been hypothesized that the biological effects of coronatine on plant tissues are due to this stimulative effect (7).

Coronatine can be hydrolyzed to yield two components, the bicyclic acid (**2**), which is called (+)-coronafacic acid, and the cyclopropyl amino acid **3**, which has been dubbed (+)-coronamic acid (Fig. 1). The structure and absolute stereochemistry of coronafacic acid were elucidated by X-ray crystallographic analysis of its 7a epimer (1). The absolute stereochemistry of coronamic acid has been determined by X-ray analysis of its *N*-acetyl derivative (8). The structures of **2** and **3** suggest they should have distinct biosynthetic origins. The results of detailed

[a]Shifts were measured in deuterochloroform at 75.47 MHz.

investigations of the biosynthesis of coronafacic acid and coronamic acid will now be described.[3]

Results and discussion

Investigations of coronafacic acid (**2**) and coronamic acid (**3**) biosynthesis were carried out by administration of labeled precursors to liquid cultures of *Pseudomonas syringae* pv. *glycinea* strains PDDCC 4182 and 4180. These strains produce both coronafacic acid and coronatine when grown in Hoitink–Sinden medium (2). Compounds **1** and **2** were isolated from the culture broth as their methyl esters, after treatment with diazomethane.

Coronafacic acid

To elucidate the biosynthesis of coronafacic acid, it was necessary to assign the resonances present in its ^{13}C NMR spectrum. The complete assignment (Table 1) required the use of several techniques. Treatment of methyl coronafacate with D_2O/DCl led to the disappearance of the ^{13}C signal for C-2 from the noise-decoupled spectrum due to exchange of the hydrogens at C-2 for deuterium. Reduction of methyl coronafacate with lithium tri-*tert*-butoxyaluminum hydride yielded a single alcohol (**4**) (Fig. 1) in which the ^{13}C NMR signals for C-2 and C-7a were shifted upfield to 31.05 and 42.28 ppm, respectively. The hydroxyl group in **4** was assigned the α configuration on the basis of the assumption that the reagent will approach from the less-hindered face of the coronafacate skeleton.

Precursor incorporation experiments also provided a very powerful tool for assignment. The structure of coronafacic acid suggested that the compound was likely to be a polyketide. Therefore, sodium (1-^{13}C)-, (2-^{13}C)-, and (1,2-$^{13}C_2$)acetate were administered to *P. syringae* cultures. The results of these experiments (Table 2, expts. 1–3) clearly indicated that five molecules of acetate were incorporated into **2**. The positions of the labels and their connectivities were unequivocally established by a ^{13}C COSY analysis (10,11) of the methyl coronafacate derived from doubly ^{13}C-labeled acetate.

Since the incorporation experiments with ^{13}C-labeled sodium acetate indicated that C-1 and C-10 of the coronafacate moiety are derived from C-1 of an acetate unit, an experiment was carried out to determine whether or not the carbonyl oxygen atoms present at C-1 and C-10 are derived from the oxygen atoms of acetate. Administration of sodium (1-^{13}C, $^{18}O_2$)acetate yielded a sample of methyl coronatine in which the ^{13}C NMR signals for C-1 and C-10 exhibited upfield ^{18}O isotope-induced shifts of ca. 0.05 and 0.03 ppm, respectively (Table 2, expt. 4). One can therefore conclude that the carbonyl oxygens present at C-1 and C-10 of coronatine are derived from the oxygens atoms of an acetate unit (12).

The presence of an ethyl side chain in coronafacic acid suggested that butyrate might also serve as a specific precursor of this compound, since butyrate has been found to be the source of the ethyl side chains that are present in a number of polyketide antibiotics (13). This expectation was confirmed by administration of sodium (1-^{13}C)butyrate to *P. syringae* and isolation of a sample of methyl coronafacate that exhibited a 38% enrichment at C-5 (Table 2, expt. 5).[4]

The incorporation experiments with labeled acetate demonstrated that two carbon atoms of the coronafacate acid skeleton, C-3 and C-3a, are not derived from acetate. Glycine, glycerol, and pyruvate were therefore evaluated as sources of these carbon atoms. Of these compounds, only pyruvic acid appeared to be specifically incorporated. Administration of sodium (1-^{13}C)-, (2-^{13}C)-, and (3-^{13}C)pyruvate revealed the somewhat surprising fact that C-3 and C-3a of coronafacate are derived from C-2 and C-3 of pyruvate, respectively (Table 2, expts. 6–8). In these experiments, the remaining carbon atoms of coronafacate exhibited a labeling pattern consistent with the partial degradation of pyruvate to acetate. The intact incorporation of C-2 and C-3 of pyruvate into coronafacate was confirmed by administration of (2,3-$^{13}C_2$)pyruvate followed by analysis of the resulting labeled coronafacate by a ^{13}C COSY experiment (Table 2, expt. 9). The COSY experiment revealed the presence of ^{13}C–^{13}C connectivity between C-3 and C-3a, as well as the connectivities expected from degradation of the doubly labeled pyruvate to doubly labeled acetate.

Although the results of preceding experiments reveal the origin of all of the carbon atoms of the skeleton of coronafacic acid, they do not define the starting point for assembly of the polyketide chain, nor do they provide any insight into the mechanism for incorporation of pyruvate into the coronafacate skeleton. A potential solution to both these uncertainties is provided by the hypothesis shown in Scheme 1. This hypothesis postulates that pyruvate serves as the starter unit and that the first step in the assembly of the polyketide chain involves the condensation of acetyl or malonyl CoA with pyruvate to yield the mono CoA ester of citramalic acid (**5**). The plausibility of this hypothesis is enhanced by the fact that both (+)-(*S*) and (–)-(*R*) forms of citramalic acid have been reported to occur naturally (14,15), although the biosynthetic origins of citramalate have apparently never been examined. Initially, we decided to prepare the appropriate mono *N*-acetylcysteamine (NAC) ester of (^{13}C)-labeled (*S*)-citramalate for evaluation as a precursor. The NAC ester was utilized because the NAC esters of a number of polyketide intermediates have been successfully incorporated intact into polyketide natural products (16). The NAC ester of (5-^{13}C)-(*S*)-citramalate (**6**) was synthesized from l-malic acid as shown in Scheme 2*a*. The key steps in the synthesis make use of chemistry reported by Seebach et al. (17) and Schwab and Klassen (18). Unfortunately, administration of **6** to the coronatine fermentation yielded methyl coronafacate that exhibited no

[3]Portions of this work have been the subject of preliminary communications (9).

[4]In initial studies of coronafacate biosynthesis (ref. 9), an incorporation experiment with (1-^{13}C)butyrate failed to show enrichment. The reasons for this behavior are unclear.

TABLE 2. Incorporation of precursors into the coronafacic acid moiety (**2**) of coronatine

Expt.	Precursor	Labeling pattern
1	Sodium (1-^{13}C)acetate	C-1, C-5, C-7, C-8, C-10
2	Sodium (2-^{13}C)acetate	C-2, C-4, C-6, C-7a, C-9
3	Sodium (1,2-$^{13}C_2$)acetate	Connectivities between C-1, C2; C-4, C-10; C-5, C-6; C-7, C-7a; C-8, C-9
4	Sodium (1-^{13}C, $^{18}O_2$)acetate	Upfield isotope shifts of 0.05 ppm at C-1, 0.03 ppm at C-10
5	Sodium (1-^{13}C)butyrate	C-5
6	Sodium (1-^{13}C)pyruvate	No enrichment
7	Sodium (2-^{13}C)pyruvate	C-3; C-1, C-5, C-7, C-8, C-10
8	Sodium (3-^{13}C)pyruvate	C-3a; C-2, C-4, C-6, C-7a, C-9
9	Sodium (2,3-$^{13}C_2$)pyruvate	Connectivities between C-3, C-3a; C-1, C-2;C-4, C-10; C-5, C-6; C-7, C-7a; C-8, C-9
10	Ethyl (3-^{13}C)acetoacetate	C-8
11	Ethyl (2,3-$^{13}C_2$)acetoacetate	Connectivity between C-6, C-8 ($^1J_{CC}$ = 33.9 Hz)
12	Ethyl (2,3-$^{13}C_2$)-3-ketohexanoate	C-5
13	*N*-Acetylcysteamine ester of (2,3-$^{13}C_2$)-3-ketohexanoate	C-5

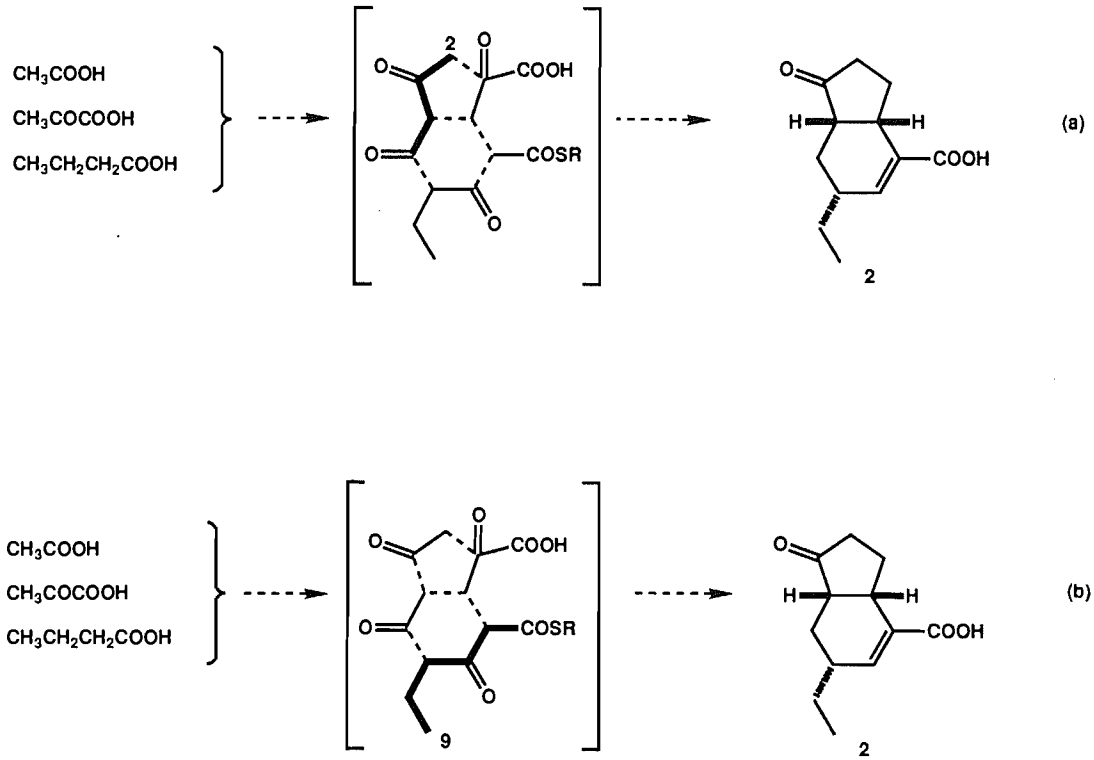
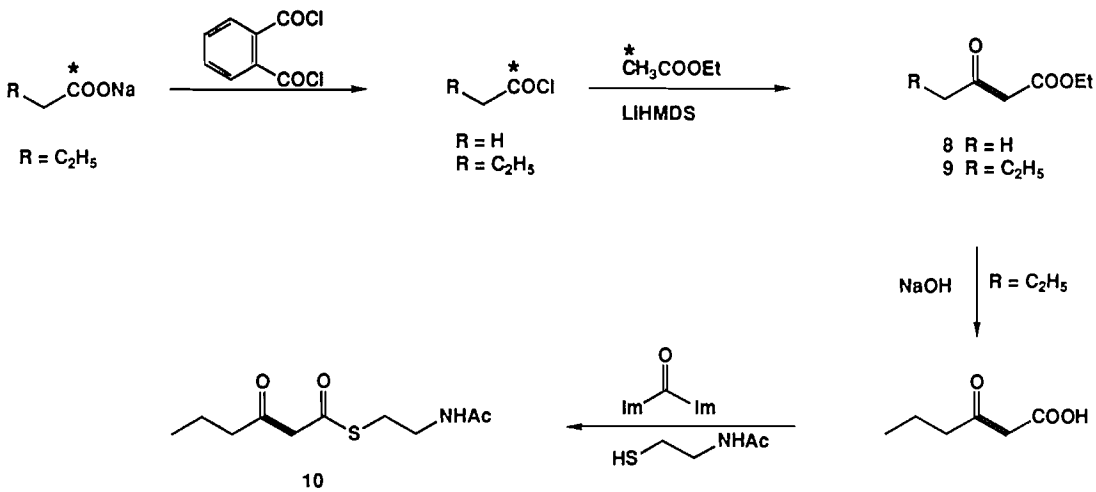


SCHEME 3



SCHEME 4

evidence of enrichment, not even that resulting from catabolism of the precursor to yield (2-^{13}C)acetate (data not shown). It therefore appeared necessary to examine the (*R*) form of citramalic acid as a precursor. For this purpose, the diethyl ester of (5-^{13}C)-(*R*)-citramalate (**7**) was synthesized (Scheme 2*b*) and evaluated. The diethyl ester was employed since no evidence of catabolism had been observed with the (*S*) precursor **6**. In the event, compound **7** also yielded methyl coronafacate that showed no signs of ^{13}C enrichment (data not shown). The results of these two experiments suggest that the hypothesis for polyketide assembly shown in Scheme 1 is incorrect. Although these observations indicate that pyruvate is not incorporated into coronafacate via the intermediacy of citramalate, they do not rule out the possibility that some metabolite of pyruvate serves as a starter unit. For example, pyruvate could be converted to phosphoenolpyruvate, which could then condense with malonyl CoA to yield a mono CoA ester of itaconic acid. The potential role of itaconic acid in coronafacate biosynthesis remains to be evaluated.

An alternative mode for assembly of the polyketide skeleton of coronafacic acid that can be envisioned proceeds from C-2 of the skeleton, with acetate serving as the starter unit and pyruvate serving as the terminating unit (Scheme 3*a*). If this hypothesis were correct, then a thiol ester of acetoacetic acid should be the intermediate resulting from the first polyketide condensation step. Investigations of this hypothesis were initiated by administering commercial ethyl (3-^{13}C)acetoacetate to *P. syringae*. The results of this experiment were quite unexpected: the isolated methyl coronafacate exhibited 27% enrichment at C-8, with no other detectable enrichments (Table 2, expt. 10)! This

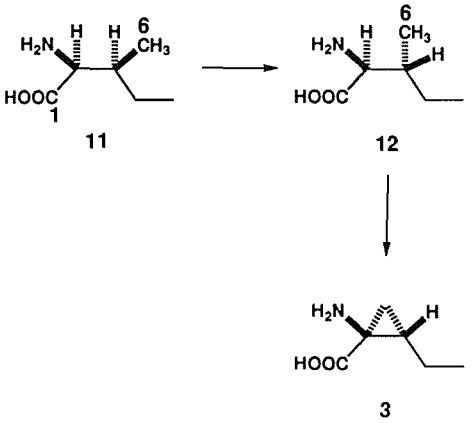
observation was confirmed by the synthesis (Scheme 4) and administration of ethyl (2,3-$^{13}C_2$)acetoacetate (**8**). In this instance, the resulting methyl coronafacate exhibited ^{13}C–^{13}C coupling between C-6 and C-8, but no trace of ^{13}C–^{13}C coupling was apparent between C-1 and C-7a (Table 2, expt. 11). Three conclusions can be drawn from these two precursor incorporation experiments. First, ethyl acetoacetate does not appear to be significantly catabolized to acetate by *P. syringae*. Second, ethyl acetoacetate is incorporated intact into the butyrate-derived portion of the coronafacate skeleton. Finally, since no coupling appears between C-1 and C-7a in the coronafacate derived from doubly labeled acetoacetate, the polyketide assembly process does not appear to begin at C-2 of the coronafacate skeleton. Consequently, the polyketide assembly mode hypothesized in Scheme 3*a* is probably not correct. The efficient and intact incorporation of ethyl acetoacetate observed in experiments 10 and 11 is quite remarkable since it is usually necessary to administer thiol esters of polyketide intermediates in order to observe intact incorporation (16). Furthermore, Vederas and co-workers (19) have reported that even the thiol esters of *acetate*-derived polyketide intermediates tend to be completely degraded unless special measures are taken.

A third mode of polyketide assembly that can be considered for coronafacate is one in which the assembly proceeds from C-9 of the coronafacate skeleton, with acetate serving as the starter unit (Scheme 3*b*). This hypothesis is consistent with the results obtained from the ethyl acetoacetate experiments, but it requires the rather unorthodox insertion of a pyruvate unit into the middle of the growing polyketide chain. If polyketide assembly indeed begins at C-9, then a thiol ester of 3-ketohexanoate should be an intermediate in the assembly process. Emboldened by the results with ethyl acetoacetate, we therefore synthesized ethyl (2,3-$^{13}C_2$)-3-ketohexanoate (**9**) (Scheme 4) and administered it to the coronatine fermentation. The results from this experiment provided a sharp contrast to those observed with ethyl acetoacetate, since the methyl coronafacate exhibited a 35% enrichment at C-5, but no ^{13}C coupling to C-4 was apparent (Table 2, expt. 12). Curiously, no significant enrichments were present at those carbons expected to be derived from C-2 of acetate. This may reflect the fact that the amount of acetate generated by catabolism of this precursor would be significantly less than the amount that was administered when acetate was used as a precursor. In any case, the labeling pattern indicates that the ethyl (2,3-$^{13}C_2$)-3-ketohexanoate had been catabolized to give (1-^{13}C)butyrate, which was then incorporated into coronafacate. Much the same result was observed when the NAC ester of (2,3-$^{13}C_2$)-3-ketohexanoate (**10**) was synthesized (Scheme 4) and evaluated as a precursor (Table 2, expt. 13). These observations can be interpreted in one of two ways: either 3-ketohexanoate is not an intermediate in coronafacate biosynthesis and the polyketide assembly does not proceed from C-9 (Scheme 3*b*) or 3-ketohexanoate is so readily catabolized by *P. syringae* that its intact incorporation into methyl coronafacate cannot be observed under the usual fermentation conditions.

Coronamic acid

The structure and absolute configuration of coronamic acid (**3**) suggest that the compound could be derived from L-isoleucine (**11**) via the intermediacy of L-alloisoleucine (**12**) (Scheme 5). This hypothesis was evaluated by administration of commercial (1-^{13}C)-L-isoleucine and (1-^{13}C)-L-alloisoleucine to *P. syringae*, followed by isolation of coronatine methyl ester. The results of these experiments (Table 3, expts. 1,2) demonstrated



SCHEME 5

that both of these amino acids are specific precursors, and, furthermore, they indicated that L-alloisoleucine is more efficiently incorporated than L-isoleucine. Since the formation of the cyclopropane ring of coronamic acid by cyclization of L-alloisoleucine would constitute a highly unusual process, it appeared important to verify that the methyl group of the amino acid (C-6) is indeed the source of the cyclopropane bridge. This was accomplished by administration of a mixture of (6-^{13}C)-DL-isoleucine and (6-^{13}C)-DL-alloisoleucine synthesized according to Scheme 6 to the coronatine fermentation. The ^{13}C NMR spectrum of the resulting coronatine methyl ester clearly showed that the cyclopropane bridge is derived from the methyl group of isoleucine (Table 3, expt. 3). These observations set the stage for more detailed investigations of the mechanism of the cyclization process.

The first mechanistic probe utilized a mixture of (6-^{13}C, 6-$^2H_3$)-DL-isoleucine and (6-^{13}C, 6-$^2H_3$)-DL-alloisoleucine prepared from (^{13}C, $^2H_3$)methyl iodide (Scheme 6) as a precursor. Examination of the ^{13}C NMR spectrum of the coronatine methyl ester obtained in this experiment while carrying out simultaneous ^1H and ^2H decoupling revealed the presence of a new ^{13}C resonance shifted upfield by 0.59 ppm relative to the signal for C-6′ of coronatine. The magnitude of the upfield isotopic shift indicates that two deuterium atoms are located at C-6′ (20). The conversion of L-alloisoleucine to coronamic acid therefore proceeds with the removal of one hydrogen atom from C-6 of the amino acid. It is also noteworthy that the level of ^{13}C incorporation observed in this experiment (Table 3, expt. 4) was dramatically lower than that observed when no deuterium was present at C-6 (Table 3, expt. 3). This difference in incorporation efficiency is presumably due to the operation of a substantial deuterium isotope effect.

The loss of only one hydrogen atom from C-6 of L-alloisoleucine during coronamic acid formation rules out the intermediacy of species with a C-6 oxidation level higher than that of an alcohol. Putative intermediates with the appropriate oxidation level would therefore include 3-methylene-L-norvaline and 6-hydroxy-L-alloisoleucine. The possible intermediacy of the former amino acid was evaluated by means of a precursor incorporation experiment with [L-^{14}C, 3-^3H]-L-alloisoleucine. The synthesis of L-alloisoleucine carrying the appropriate isotopic labels was accomplished using modifications of chemistry devised by Oppolzer et al. (21) (Scheme 7). Administration of a mixture of the labeled amino acids to *P. syringae* generated a sample of coronatine methyl ester that was purified chromato-

TABLE 3. Incorporation of precursors into the coronamic acid moiety (**3**) of coronatine

Expt.	Precursor ($^3H/^{14}C$)	Percent enrichment or incorporation	Labeling pattern
1	(1-^{13}C)-L-Isoleucine	9	C-1′
2	(1-^{13}C)-L-Alloisoleucine	60	C-1′
3	(6-^{13}C)-DL-Isoleucine + (6-^{13}C)-DL-alloisoleucine	31	C-6′
4	(6-^{13}C, 6-$^{2}H_3$)-DL-Isoleucine + (6-^{13}C, 6-$^{2}H_3$)-DL-alloisoleucine	0.5	^{13}C and 2 D at C-6′

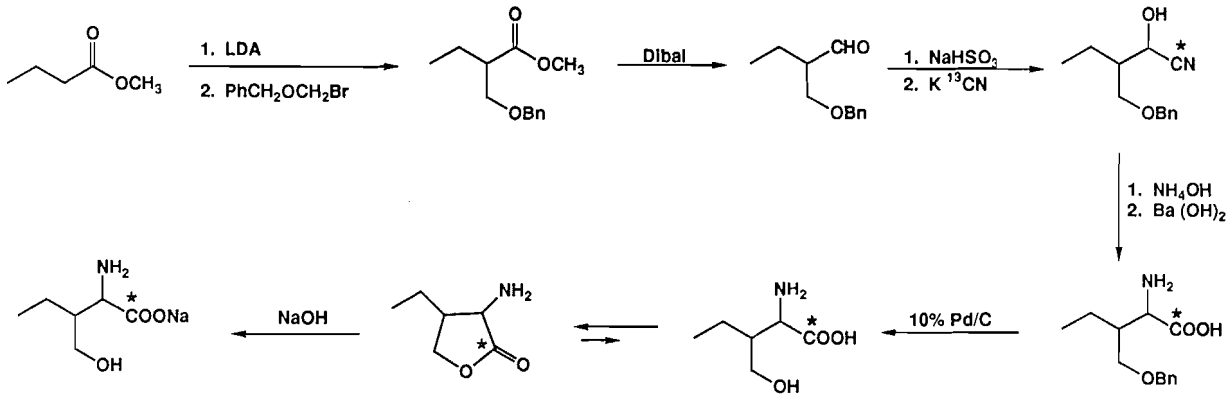
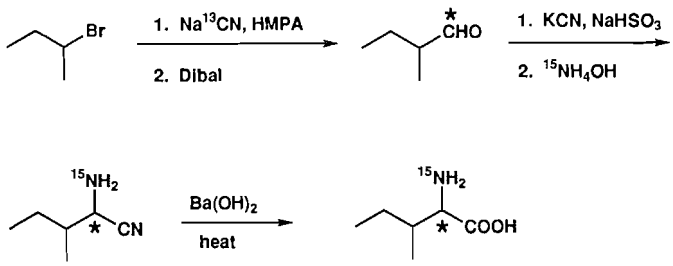


SCHEME 8

graphically and then reduced to the corresponding alcohol with lithium tri-*tert*-butoxyaluminum hydride. The radioactive alcohol was subjected to additional chromatography in order to remove any lingering radiochemical impurities. Comparison of the $^{3}H/^{14}C$ ratio in the doubly labeled alcohol with that in the doubly labeled alloisoleucine (Table 3, expt. 5) clearly shows that alloisoleucine is cyclized to coronamic acid without significant loss of the hydrogen atom present at C-3. The intermediacy of 3-methylene-L-norvaline in the cyclization process is thereby ruled out. To evaluate the potential intermediacy of 6-hydroxy-L-alloisoleucine in coronamate biosynthesis, a mixture of (1-^{13}C)-6-hydroxy-DL-isoleucine and (1-^{13}C)-6-hydroxy-DL-alloisoleucine was synthesized as shown in Scheme 8. Since the NMR spectrum of this mixture of amino acids indicated that they exist as the γ-lactones, the compounds were administered both in the lactone form and as the ring-opened sodium salts prepared by treatment of the lactones with one equivalent of sodium hydroxide. Both forms of the hydroxy amino acids failed to exhibit incorporation into coronatine (data not shown).

Another question to be addressed with respect to the mechanism of cyclization of L-alloisoleucine to coronamic acid concerns the fate of the nitrogen atom present at C-2 of the amino acid, i.e., one may inquire whether the cyclization process requires the loss of the α-amino group. This question was answered by means of an incorporation experiment with a mixture of (2-^{13}C, ^{15}N)-DL-isoleucine and (2-^{13}C, ^{15}N)-DL-alloisoleucine synthesized according to Scheme 9. When this mixture of amino acids was supplied to *P. syringae*, the resulting coronatine displayed a total ^{13}C enrichment at C-2′ of about 7.8%, of which 2.4% exhibited coupling to ^{15}N (Table 3, expt. 6). One can therefore conclude that the cyclization reaction proceeds without obligatory loss of the amino group of L-alloisoleucine.



SCHEME 9

The fact that the total ^{13}C enrichment exceeds the ^{15}N enrichment indicates that some loss of ^{15}N from the mixture of doubly labeled amino acids occurs in vivo. This loss might be associated with the conversion of L-isoleucine to L-alloisoleucine since one mechanism for this epimerization reaction could involve the intermediacy of an α-keto acid.

Coronatine is accompanied in the fermentation broth of *P. syringae* by a number of congeners, including *N*-coronafacoyl-L-valine (22), *N*-coronafacoyl-L-isoleucine (23), and *N*-coronafacoyl-L-alloisoleucine (23). The co-occurrence of these congeners has led to the suggestion that the formation of the cyclopropane ring of coronamic acid may take place after formation of the amide bond between L-isoleucine or L-alloisoleucine and coronafacic acid (22). If this hypothesis were correct, then *P. syringae* might not possess the capability of utilizing free coronamic acid for the biosynthesis of coronatine. Information bearing on this aspect of coronatine biosynthesis was obtained by carrying out an incorporation experiment with (4-$^{2}H_1$, 5-$^{2}H_1$)-DL-coronamic acid, which was synthesized as outlined in Scheme 10. The synthesis makes use of a coronamic acid synthesis reported by Baldwin et al. (24). Analysis of the resulting coronatine methyl ester by ^{13}C NMR revealed the presence of two triplets at 13.0 and 20.0 ppm, which could be assigned to C-5′ and C-4′ of coronatine methyl ester, respectively. The center of each triplet was shifted upfield by ca. 0.25 ppm relative to the resonance positions of C-4′ and C-5′ in unlabeled coronatine methyl ester, thereby indicating that one deuterium atom was present at C-4′ and at C-5′. Analysis of the same sample of coronatine methyl ester by ^{2}H NMR revealed the presence of deuterium resonances at 1.00 and 1.65 ppm. Integration of these two absorptions with respect to an internal benzene standard indicated a deuterium incorporation of ca. 32% at both C-4′ and C-5′ (Table 3, expt. 7). Consequently, it appears that coronamic acid is a highly efficient precursor of coronatine.

The results of the experiments summarized in Table 2 limit the number of mechanisms that can be envisioned for the oxidative cyclization of L-alloisoleucine to coronamic acid. The available evidence is consistent with the possibility that this cyclization is related to the oxidative cyclizations observed in the biosynthesis of isopenicillin N (25), deacetoxycephalosporin C (25), and clavaminic acid (26). Based upon the analogy provided by these processes, one could postulate that the formation of coronamic acid proceeds by the mechanism outlined in Scheme 11. The cyclization could be initiated by reac-

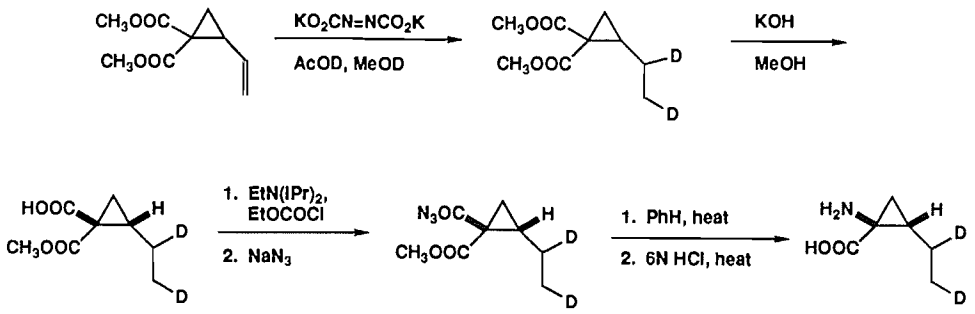
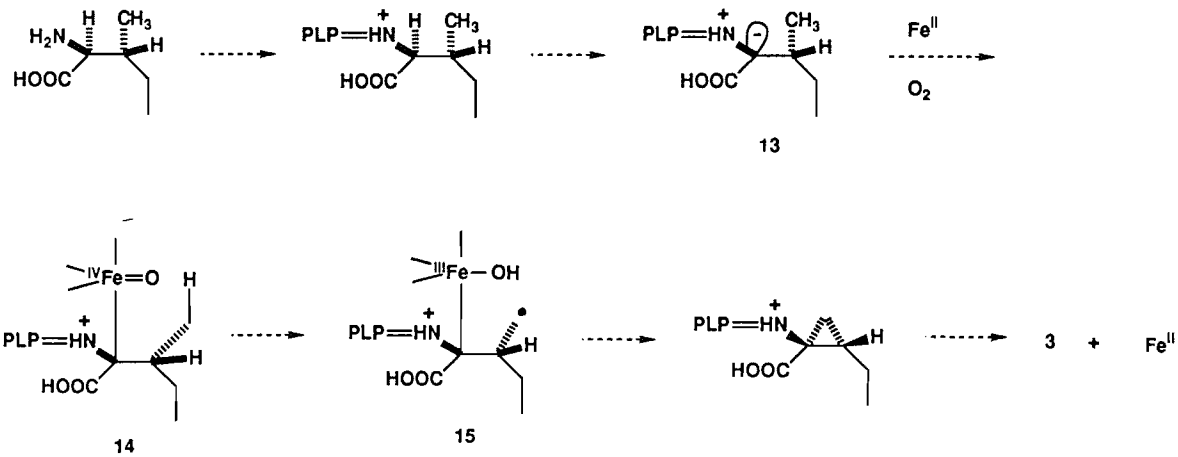


SCHEME 10



SCHEME 11

tion of L-alloisoleucine with pyridoxal phosphate (PLP) to yield a Schiff base, which could then be deprotonated to give the α-carbanion (**13**).[5] This carbanion could then react with a ferryl species formed from ferrous iron and molecular oxygen to yield the intermediate **14**. In this step, the carbanion would mimic the role of the thiol group or hydroxyl group in the isopenicillin N and clavaminate cyclizations, respectively. The next stage of the cyclization would involve abstraction of a hydrogen atom from the C-6 methyl group by the iron-oxo species to yield a carbon radical (**15**), which then collapses to give the PLP adduct of coronamic acid. Hydrolysis of the PLP adduct would finally yield free coronamic acid.

In conclusion, investigations of the biosynthesis of coronatine by means of precursor incorporation experiments have revealed that the biosynthesis of this phytotoxin possesses some novel features. The derivation of the coronafacic acid moiety of coronatine from C-2 and C-3 of pyruvate, as well as acetate and butyrate, appears to be unprecedented. Likewise, the formation of the coronamic acid moiety of coronatine by cyclization of L-alloisoleucine appears to involve a mechanism for cyclopropane ring formation that has not been previously encountered in Nature. A more detailed understanding of the biochemical processes underlying coronatine biosynthesis is likely to require the application of both chemistry and molecular biology to the solution of this problem.

[5]Since some amino acid epimerases do not require a cofactor to generate a carbanion at the α position of an amino acid, it is conceivable that the formation of a carbanion at the α position of L-alloisoleucine may be cofactor independent. See ref. 27.

Experimental

General procedures

Proton nuclear magnetic resonance spectra were taken on either a JEOL FX-90Q (90 MHz), an IBM AF300 (300 MHz), or a Bruker AC250 (250 MHz) spectrometer. Chemical shifts are given in parts per million downfield from tetramethylsilane (0.0 ppm) for spectra taken in $CDCl_3$. In other organic solvents, the solvent itself was used as the reference. In D_2O the water signal (4.80 ppm) was used as reference. Carbon-13 NMR spectra were taken on the same three instruments at 22.5, 75.45, and 62.89 MHz, respectively. Methanol (49.0 ppm) or *p*-dioxane (66.5 ppm) were used as an internal reference when D_2O was the solvent. Deuterium NMR spectra were obtained with the IBM AF300 instrument at 46.07 MHz. Deuterium-depleted water was used both as solvent and as reference. Benzene was added as a standard for the calculation of ^2H enrichment. Mass spectra were run on Finnigan 3300 and CEC 111021-110B mass spectrometers. Infrared spectra were recorded on a Nicolet 205 FT-IR spectrophotometer. All melting points were taken on a Fisher–Johns melting point apparatus and are uncorrected. Preparative thin-layer chromatography was accomplished using 0.75-mm layers of Merck silica gel, type PF-254. Analytical TLC was carried out using glass plates precoated with Cellulose F or Merck silica gel, type 60, F-254. Cellulose plates were visualized with short-wavelength ultraviolet light or by spraying with a 2% solution of ninhydrin in ethanol and heating. Silica gel plates were visualized with short-wavelength ultraviolet light, iodine vapor, or phosphomolybdic acid. Flash chromatography was carried out using silica gel, type 60A, 230–400 mesh as the stationary phase. Cellulose column chromatography utilized Merck microcrystalline cellulose. Coronatine and coronafacic acid production were monitored by high-pressure liquid chromatography (HPLC) on a Whatman octadecylsilane reversed-phase column (4.6 mm i.d. × 25 cm, 5 μm) using a Spectraphysics SP model 8700 solvent delivery system. Microbiological media for slants, agar plates, and fermentation broths were either pur-

For personal use only.

chased from Difco or prepared from the appropriate reagents. Fermentations were performed using a New Brunswick G-25R rotary shaker. The shaker was connected to a Forma Scientific CH/P 2067 circulating water bath in order to carry out fermentations of *P. syringae* at 18°C. Slants were either grown at room temperature or incubated at 30°C. Measurement of radioactivity was carried out with a Beckmann LS-3801 liquid scintillation counter.

Materials

Authentic samples of coronafacic acid and of coronatine were obtained as a gift from Dr. R.E. Mitchell. All reagents and compounds were purchased from Aldrich Chemical Co., Fluka, ICN, and sigma Chemical Co. and were purified, where necessary, by standard techniques. Radiolabeled compounds were purchased from Amersham Life Sciences. Stable isotopically labeled compounds were generally purchased from Cambridge Isotope Laboratories. (1-^{13}C)-l-Isoleucine and (1-^{13}C)-l-alloisoleucine were purchased from Tracer Technologies, Inc. (Somerville, Mass.). Unless otherwise stated, all reactions were performed under a dry nitrogen atmosphere.

Organism and fermentation

Pseudomonas syringae pv. *glycinae* (PDDCC no. 4182) was obtained from the Culture Collection of Plant Diseases Division of the New Zealand Department of Scientific and Industrial Research; *P. syringae* pv. *glycinae* (PDDCC no. 4180) was a gift from Professor Carol Bender of Oklahoma State University. The organism was maintained on mannitol–glutamate yeast agar slants which consisted of mannitol 1%, sodium L-glutamate 0.2%, KH_2PO_4 0.05%, NaCl 0.02%, $MgSO_4 \cdot 7H_2O$ 0.02%, yeast extract 0.025%, agar 1.5%, pH adjusted to 7.0 with dilute sodium hydroxide. For long-term storage, the organism was preserved by lyophilization in mist desiccans (28). For fermentation, *P. syringae* growing on one mannitol slant was suspended in 1.0 mL of sterile water and the suspension used to inoculate 100 mL of seed medium, which consisted of yeast extract (500 mg), glucose (500 mg), $MgSO_4 \cdot 7H_2O$ (20 mg), KH_2PO_4 (410 mg), K_2HPO_4 (360 mg), dissolved in 100 mL water with the pH adjusted to 6.8. The inoculated seed medium was incubated at 25°C, 250 rpm, for 24 h. After 24 h, the seed medium was used to inoculate 10 1-L flasks each containing 200 mL of production medium (10 mL of inoculum per flask). Production medium consisted of two solutions: (A) glucose (20.0 g), $MgSO_4 \cdot 7H_2O$ (0.4 g), KH_2PO_4 (8.2 g), K_2HPO_4 (7.2 g), dissolved in 2.0 L of water, and adjusted to pH 6.8 with 1 N NaOH. This solution was sterilized by autoclaving at 121°C for 20 min. After this solution had cooled to room temperature, 1 mL of solution (B) consisting of NH_4Cl (2.0 g) and biotin (2.0 mg) dissolved in 10 mL water was added to each production medium flask through a sterile filter. The inoculated fermentation flasks were incubated at 18°C, 200 rpm, and monitored for coronatine and coronafacic acid production by HPLC using 28% acetonitrile in H_2O containing 0.05% trifluoroacetic acid (flow rate = 1.5 mL/min, R_T = ca. 7 min for coronafacic acid, ca. 12 min for coronatine). The HPLC analysis indicated that coronatine production usually begins on day 1 and reaches a maximum after 5 days.

Isolation of methyl coronafacate and methyl coronatine

After 5 days the cells were removed by centrifugation at 8000 rpm for 40 min. The supernatant broth was filtered through glass wool, and stirred with a mixture of activated charcoal (20 g) and Celite (20 g) for 30 min before being loaded into a column and washed with 400 mL of distilled water. The column was then eluted with ca. 300 mL of acetone. The acetone elutant was concentrated fivefold, adjusted to pH 2.5 with 2.5 M H_2SO_4, and vigorously extracted three times with ethyl acetate. The combined ethyl acetate extracts were dried over anhydrous $MgSO_4$, filtered through Celite, and concentrated in vacuo. The acidic residue was dissolved in 2.0 mL methanol and treated with excess diazomethane. The excess diazomethane was blown off in the hood under a stream of nitrogen and the methanol removed in vacuo. The residue was further purified by preparative thin-layer chromatography (0.75 mm noncommercial silica gel plates, eluant 10% isopropanol in hexane). To obtain an adequate purification, it was necessary to develop the plate two or three times. This yielded, on average, 10 mg of coronatine as its methyl ester derivative and 4–6 mg of the methyl ester of coronafacic acid.

Administration of labeled precursors to P. syringae *pv.* glycinea

Precursors were pulse fed to the producing organism 24, 48, and 72 h after initiation of the fermentation. Both stable and radiolabeled precursors were dissolved in a suitable volume of Milli-Q water or ethanol and administrated to the fermentation flasks through a sterile Millipore filter (pore size 0.22 μm). In experiments employing precursors labeled with stable isotopes, about 100 mg were fed each day.

Synthesis of labeled precursors

*Synthesis of (5-^{13}C)-*N*-acetylcysteamine ester of* (S)*-citramalic acid (**6**)*

*A. Synthesis of (methyl-^{13}C)-(2S, 5S)-2-(*tert*-butyl)-5-(methoxycarbonyl)-5-(methyl)-1,3-dioxolan-4-one.* The ^{13}C-labeled dioxolane acid was prepared from L-malic acid and (^{13}C)methyl iodide using the procedure of Seebach et al. (17).

B. Synthesis of N*-acetylcysteamine ester of (methyl-^{13}C)-(2S, 5S)-2-(*tert*-butyl)-5-(methoxycarbonyl)-5-(methyl)-1,3-dioxolan-4-one.* The labeled dioxolane acid prepared in step A (375.0 mg, 1.74 mmol) was dissolved in 7.5 mL of dry CH_2Cl_2. *N*-Methylmorpholine (194.4 mg, 1.92 mmol) was then added at room temperature. The reaction mixture was cooled to –20°C for 15 min and diphenylphosphinic chloride (438 mg, 1.92 mmol) was then added. The reaction mixture was then stirred at room temperature for 20 min. Ether (10 mL) was added to the mixture and the precipitated *N*-methylmorpholine hydrochloride was removed by filtration. The salt was then washed with ether (3 × 30 mL) and the combined ether portions were washed with 15 mL of 10% $NaHCO_3$ and then with brine. After drying of the organic phase over anhydrous $MgSO_4$, the solvent was removed to furnish a thick oil, which was dissolved in dry THF (57 mL). The resulting solution was cooled in an ice bath to –3 to –4°C. A suspension of the thallium salt of *N*-acetylcysteamine in THF (19.8 mL, 1.92 mmol), prepared by the method of Schwab et al. (18), was added quickly, with vigorous stirring. The bright yellow reaction mixture was then stirred at –2 to –4°C for 18 h under an inert atmosphere. The solvent was removed from the reaction mixture and the residue redissolved in ether and filtered through Celite. The filtrate was taken to dryness in vacuo to give a thick, yellowish oil (835 mg). This oil was chromatographed on Florisil. Gradient elution with an ethyl acetate – hexane mixture furnished the product (401 mg) in 73% yield: ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.94 (s, 9H), 1.47 (d, $^1J_{CH}$ = 127.5 Hz, 3H), 1.97 (s, 3H), 2.9–3.5 (m, 6H), 5.17 (s, 1H), 5.8–6.0 (bs, 1H); ^{13}C NMR (62.89 MHz, $CDCl_3$) δ: 19.7 (enriched) ppm.

*C. (5-^{13}C)-*N*-acetylcysteamine ester of* (S)*-citramalic acid (**6**).* The 1,3 dioxolane NAC ester prepared in step B (254 mg, 0.8 mmol) was hydrolyzed with 2 N HCl (5.4 mL) at room temperature for 48 h under an argon atmosphere. The aqueous acid was then removed under reduced pressure, and remaining traces of HCl removed by twice adding water, which was then removed in vacuo. This procedure afforded the product as a colorless viscous oil (168 mg) in 84% yield: ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.45 (d, $^1J_{CH}$ = 125 Hz, 3H), 1.94 (s, 3H), 2.9–3.5 (m, 4H); ^{13}C NMR (62.89 MHz, $CDCl_3$) δ: 21.7 (enriched), 25.6, 28.1, 38.5, 52.3 ppm.

Synthesis of (5-^{13}C)-(R)*-citramalic acid diethyl ester (7)*

(*methyl*-^{13}C)-(2*R*, 5*R*)-2-(*tert*-Butyl)-5-(methoxycarbonyl)-5-(methyl)-1, 3-dioxolan-4-one (202 mg, 1 mmol), prepared (17) from D-malic acid using $^{13}CH_3I$, was dissolved in 30.0 mL of dry ethanol. Dry HCl gas was bubbled through the solution for 5 h. An exothermic reaction ensued. The reaction mixture was thenrefluxed for 18 h, after which time the ethanol was removed in vacuo. Column chromatography on silica gel furnished 161 mg of the diethyl ester of (*methyl*-^{13}C)citramalic acid in 79% yield: ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.24 (t, 3H), 1.29 (t, 3H), 1.42 (d, $^1J_{C-H}$ = 130 Hz, 3H), 2.67 (d, *J* = 15.6 Hz, 1H), 2.97 (d, *J* = 15.6 Hz, 1H), 4–4.35 (m, 4H); ^{13}C NMR (62.89 MHz, $CDCl_3$) δ: 14.09, 26.29 (enriched), 44.20, 60.83, 61.94, 103.5, 170.5, 175.5 ppm.

Synthesis of (2,3-$^{13}C_2$)ethyl acetoacetate (8)

A solution of LiHMDS in THF (10.5 mL, 10.5 mmol) was cooled to –78°C under dry nitrogen, and (2-^{13}C)ethyl acetate (440 mg, 5.0 mmol) was added to it. The solution was then stirred for 30 min to allow generation of the ester anion. To this mixture was then added (1-^{13}C)acetyl chloride (354 mg, 4.5 mmol) dissolved in dry THF (0.4 mL). The mixture was stirred at –78°C for 30 min. To this mixture 24 mL of 2 N HCl was added at the same temperature. The reaction was brought to room temperature over 2 h. It was then further acidified to pH 3 with 2 N HCl. The acidic solution was extracted with ether (3 × 4 mL). The combined ethereal extracts was dried over $MgSO_4$. Solvent removal and Kugelrohr distillation furnished 351 mg of (2,3-$^{13}C_2$)ethyl acetoacetate in 60% yield: ^{1}H NMR (250 MHz) δ: 1.28 (t, 3H), 2.27 (d, J_{CH} = 7.5 Hz, 3H), 3.45 (dd, J_{CH} = 130 Hz, $^2J_{CH}$ = 7.5 Hz, 2H), 4.19 (q, 2H); ^{13}C NMR (62.89 MHz, $CDCl_3$) δ: 14.01, 30.01, 50.14 (d, J = 38.4 Hz, enriched), 61.30, 167.5, 200.6 (d, J = 38.4 Hz, enriched) ppm.

Synthesis of (2,3-$^{13}C_2$)ethyl 3-ketohexanoate (9)

The compound was prepared from (2-^{13}C)ethyl acetate and (1-^{13}C)butyryl chloride following the procedure employed to synthesize doubly labeled ethyl acetoacetate. The yield was 69%: ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.92 (t, 3H), 1.28 (t, 3H), 1.5–1.75 (m, 2H), 2.45–2.6 (q, 2H), 3.63 (dd, $^1J_{CH}$ = 131.3 Hz, $^2J_{CH}$ = 6.3 Hz, 2H), 4.1–4.25 (q, 2H); ^{13}C NMR (75.45 MHz, $CDCl_3$) δ: 49.28 (d, J = 37.7 Hz, enriched), 202.83 (d, J = 37.7 Hz, enriched) ppm.

Synthesis of the N*-acetylcysteamine ester of (2,3-$^{13}C_2$)-3-ketohexanoate (10)*

A. Synthesis of (2-3-$^{13}C_2$)-3-ketohexanoic acid. Hydrolysis of ethyl (2,3-$^{13}C_2$)-3-ketohexanoate (**9**) was carried out at room temperature by stirring the ester (1.29 g, 8.2 mmol) with aqueous sodium hydroxide (0.82 g in 10 mL H_2O) for 20 h. The reaction mixture was doubly diluted with water and the pH adjusted to 12. The alkaline solution was then extracted with ether (3 × 30 mL) to remove neutral compounds. The aqueous phase was then acidified with 1 N HCl to pH 2. The free ß-keto acid was then extracted with $CHCl_3$ (3 × 80 mL) and the chloroform extracts dried over anhydrous Na_2SO_4. Removal of the $CHCl_3$ at room temperature furnished colorless crystals of the ß-keto acid (669 mg, 61% yield): ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.95 (t, 3H), 1.5–1.8 (m, 2H), 2.5–2.65 (q, 2H), 3.51 (dd, J = 13 Hz, J = 2.5 Hz, 2H).

B. Synthesis of the N*-acetylcysteamine ester of (2,3-$^{13}C_2$)-3-ketohexanoate (10).* 1,1′-Carbonyldiimidazole (488 mg, 3 mmol) was added to a solution of (2,3-$^{13}C_2$)-3-ketohexanoic acid (325 mg, 2.5 mmol) in dry acetonitrile (7.2 mL) at –5°C. The mixture was stirred for 1.5 h below 0°C, and a solution of freshly prepared *N*-acetylcysteamine (353 mg, 2.7 mmol) in dry acetonitrile (0.5 mL) was then added. The resulting mixture was stirred for another 1 h at the same temperature. The solvent was then removed in vacuo and residue dissolved in 15 mL water. This aqueous solution was extracted with ethyl acetate (3 × 50 mL), the combined extracts dried over anhydrous sodium sulfate, and the solvent was removed in vacuo to give 200 mg of residue. This residue was purified by flash chromatography on silica gel. Gradient elution with a mixture of ethyl acetate and hexane furnished nearly pure fractions of the ester. Traces of *N*-acetylcysteamine were removed from these fractions by preparative TLC to give 161 mg of the product in 28% yield: ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.93 (t, 3H), 1.5–1.75 (m, 2H), 1.98 (s, 3H), 2.4–2.6 (q, 2H), 2.9–3.15 (t, 2H), 3.35–3.55 (t, 2H), 3.71 (dd, $^1J_{CH}$ = 119.8 Hz, $^2J_{CH}$ = 5.2 Hz, 2H); ^{13}C NMR (62.89 MHz, $CDCl_3$) δ: 57.18 (d, J = 36.5 Hz, enriched), 202.15 (d, J = 36.5 Hz, enriched) ppm; HRMS, calcd. for $^{13}C_2C_8H_{17}NO_3S$: 233.0996; found (M^+): 233.0996; calcd. for $^{13}C_3C_7H_{17}NO_3S$: 234.1030; found (M + 1): 234.1028.

Synthesis of a mixture of (6-^{13}C)-DL-isoleucine and (6-^{13}C)-DL-alloisoleucine

The first synthesis developed for the preparation of these labeled amino acids involved the alkylation of the anion of *n*-butyl butyrate with (^{13}C)methyl iodide followed by diisobutyl aluminum hydride (DIBAL) reduction of the resulting ester to yield the corresponding aldehyde. Since difficulties were encountered with overreduction in the DIBAL step, an alternative synthetic route was devised. This is the one outlined below.

A. (5-^{13}C)-2-Methylbutyronitrile. *n*-Butyronitrile (2.0 g, 28.9 mmol) was added dropwise to a stirred solution of commercially available lithium diisopropylamide (3.71 g, 34.7 mmol) in 50 mL of dry THF at –78°C.The resulting yellow solution was stirred at –78°C for 30 min before (^{13}C)methyl iodide (4.13 g, 28.9 mmol) was added. The reaction mixture was stirred at –78°C for a further 1 h and then allowed to warm to 0°C over 3.5 h. The reaction mixture was quenched at 0°C by the addition of saturated aqueous NH_4Cl (30 mL). The THF was removed in vacuo and the residue extracted with CH_2Cl_2. The combined organic extracts were washed with water, saturated NaCl, dried over $MgSO_4$, filtered, and concentrated at atmospheric pressure. This gave 2.5 g of crude (5-^{13}C)-2-methylbutyronitrile as a pale yellow liquid, ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.0–1.1 (m, 3H), 1.35 (dd, $^1J_{CH}$ = 125 Hz, $^3J_{HH}$ = 7.9 Hz, 3H), 1.65–1.8 (m, 2H), 3.5–3.65 (m, 1H); ^{13}C NMR (62.89 MHz, $CDCl_3$) δ: 11.35, 17.58 (enriched), 26.58, 27.56, 77.0 ($CDCl_3$), 122.91.

B. (5-^{13}C)-2-Methylbutyraldehyde. Diisobutyl aluminum hydride (DIBAL) (37.2 mL, 37.2 mmol) was added dropwise to a stirred solution of (5-^{13}C)-2-methylbutyronitrile (2.5 g, 29.8 mmol) in dry CH_2Cl_2 (50 mL) at room temperature. The reaction mixture was stirred at room temperature for 1 h and quenched by cautiously adding 5% aqueous H_2SO_4. The aqueous and organic layers were separated and the aqueous layer extracted with CH_2Cl_2. The combined organic extracts were dried over $MgSO_4$, filtered through Celite, and concentrated at atmospheric pressure. This gave 2 g of crude (5-^{13}C)-2-methyl butyraldehyde.

C. (6-^{13}C)-2-Hydroxy-3-methylvaleronitrile. Ethanol (50 mL) was added to a solution of (5-^{13}C)-2-methylbutyraldehyde and sodium bisulfite (3.53 g, 34.6 mmol) in water (50 mL) until the solution became homogeneous and clear. The solution was stirred at room temperature for 1 h before potassium cyanide (1.99 g, 30.6 mmol) was added and the reaction mixture stirred at room temperature for 3 h. The ethanol was then removed in vacuo and the aqueous residue extracted with ether. The combined ether extracts were washed with water, saturated NaCl, dried over $MgSO_4$, filtered, and concentrated in vacuo. This gave 2.3 g of crude (6-^{13}C)-2-hydroxy-3-methylvaleronitrile.

D. (6-^{13}C)-2-Amino-3-methylvaleronitrile. The crude cyanohydrin from the previous step was dissolved in concentrated NH_4OH (34.6 mL) and ethanol (30 mL) was added until the solution became homogeneous and clear. The reaction mixture was then stirred at room temperature for 18 h. The ethanol was removed in vacuo and the aqueous residue extracted with ether. The combined ether extracts were washed with water, saturated NaCl, dried over $MgSO_4$, filtered, and concentrated in vacuo. This gave 1.7 g of the crude aminonitrile.

E. (6-^{13}C)-DL-Isoleucine/(6-^{13}C)-DL-alloisoleucine. The crude aminonitrile was dissolved in water (100 mL) and barium hydroxide (19.3 g, 61 mmol) added. The reaction mixture was then heated at reflux for 18 h. After cooling to room temperature, the solution was filtered and the filtrate taken to dryness. The solid white residue was redissolved in water (50 mL). This solution was treated twice with solid $(NH_4)_2CO_3$ to remove any remaining barium as insoluble barium carbonate. The filtrate was stirred in a water bath at 60–65°C for 1 h before being finally concentrated in vacuo. This gave 0.5 g of the crude amino acid mixture as a white solid. The remaining impurities were removed by repeated cellulose column chromatography (eluant: *n*-butanol:HOAc:H_2O (BAW), 4:1:2). This gave 169 mg (4.5% from *n*-butyronitrile) of the pure amino acid mixture as a flaky white solid: ^{1}H NMR (250 MHz, D_2O) (ca. 1:1 mixture of isoleucine and alloisoleucine) δ: 0.85 (dd, $^3J_{HH}$ = 6.9 Hz, $^1J_{CH}$ = 125.3 Hz, 3H, one diastereomer), 1.00 (t, $^3J_{HH}$ = 6.25 Hz, 3H), 1.25 (dd, $^3J_{HH}$ = 7.5 Hz, $^1J_{CH}$ = 125.9 Hz, 3H, other diastereomer), 1.36–1.50 (m, 2H), 2.04–2.12 (m, 1H), 3.69 (dd, $^3J_{HH}$ = 3.95 Hz, $^3J_{CH}$ = 3.92 Hz, 1H, one diastereomer), 3.76 (dd, $^3J_{HH}$ = 5.92 Hz, $^3J_{CH}$ = 5.90 Hz, 1H, other diastereomer); ^{13}C NMR (62.89 MHz, D_2O) δ: 11.14, 11.21, 13.42 (enriched), 14.79 (enriched), 24.56, 25.61, 35.70, 35.99, 58.58, 59.66, 174.3, 175.2 ppm.

Synthesis of a mixture of (6-^{13}C,$^{2}H_3$)-DL-isoleucine and 6-^{13}C,$^{2}H_3$)-DL-alloisoleucine

The synthesis of this mixture of labeled amino acids was carried out in the same manner as described for the preparation of the (6-^{13}C)-labeled compounds, except that (6-^{13}C, 6-$^{2}H_3$)methyl iodide was substituted for (6-^{13}C)methyl iodide. From 2.4 g of *n*-butyronitrile (34.3 mmol), 185 mg (4.1% yield) of a mixture of (6-^{13}C,$^{2}H_3$)-DL-isoleucine and (6-^{13}C,$^{2}H_3$)-DL-alloisoleucine was obtained as a flaky white solid: ^{1}H NMR (250 MHz, D_2O) (ca. 1:1 mixture of isoleucine and alloisoleucine) δ: 0.9–1.1 (m, 3H), 1.3–1.6 (m, 2H), 3.69 (dd, $^3J_{HH}$ = 3.95 Hz, $^3J_{CH}$ = 3.92 Hz, 1H), 3.76 (dd, $^3J_{HH}$ = 5.92 Hz, $^3J_{CH}$ = 5.90 Hz, 1H); ^{13}C NMR (62.89 MHz, D_2O) δ: 11.14, 11.21, 13.42 (enriched septet), 14.79 (enriched septet), 24.56, 25.61, 35.70, 35.99, 58.58, 59.66, 174.3, 175.2 ppm.

Synthesis of [3-^{3}H]-L-alloisoleucine

A. [3-^{3}H]-tert-Butyl 3-hydroxybutyrate. Unlabeled sodium borohydride (9 mg) was added to a stirred solution of *tert*-butyl acetoacetate (600 mg, 3.8 mmol) in dry ethanol (2.7 mL) at 0°C. The solution was stirredat 0°C for 15 m in and [^{3}H]sodium borohydride (100 mCi, specific activity 500 mCi/mmol) added. The reaction mixture was then stirred at 0°C for 30 min. The ice bath was removed and the mixture stirred at room temperature overnight. The reaction mixture was then cooled at 0°C, a further 65 mg of unlabeled sodium borohydride was added, and the reaction mixture was stirred at 0°C for 15 min and then at room temperature for 2 h. The ethanol was removed in vacuo, water was added, and the pH of the solution was adjusted to 5 with glacial acetic acid. The aqueous layer was extracted with ethyl acetate and the combined organic extracts were dried over anhydrous $MgSO_4$, filtered, and concentrated in vacuo. The clear residual oil was further purified by Kugelrohr distillation in vacuo (0.1 Torr). This gave 0.439 g (72%) of [3-^{3}H]-*tert*-butyl 3-hydroxybutyrate: bp 60–65°C at 0.1 Torr (1 Torr = 133.3 Pa); radiochemical yield, 11.1%; specific activity, 0.025 m Ci/mg: ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.2 (d, 3H), 1.4 (s, 9H), 2.4 (s, 3H), 3.1 (s, -OH), 3.9–4.2 (m, 2H); HRMS, calcd. for $C_8H_{16}O_3$: 160.1099; found (M^+): 160.1095; calcd. for $^{13}C_1C_7H_{16}O_3$: 161.1132; found (M + 1): 161.1129.

B. [3-^{3}H]-tert-Butyl 3-mesyloxybutyrate. Triethylamine (338 mg, 3.34 mmol) was added to a stirred solution of [3-^{3}H]-*tert*-butyl 3-hydroxybutyrate (0.435 g, 271 mmol) in 16 mL dry CH_2Cl_2 at room temperature. The solution was stirred at room temperature for 10 min, cooled in an ice bath to 0°C, and methanesulfonyl chloride (0.382 g, 3.34 mmol) added dropwise. After stirring at room temperature for a further 1 h, the reaction mixture was carefully poured into 1 M $NaHCO_3$ and the aqueous and organic layers separated. The aqueous layer was further extracted with CH_2Cl_2 and the combined organic extracts washed once with water, dried over anhydrous $MgSO_4$, filtered, and concentrated. The residual oil was further purified by Kugelrohr distillation. This gave [3-^{3}H]-*tert*-butyl 3-mesyloxybutyrate, 0.622 g (96%): ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.4 (s, 9H), 1.5 (s, 3H), 2.5–2.7 (m, 2H), 3.0 (s. 3H), 5.0–5.2 (m, 1H); HRMS, calcd. for $C_8H_{15}O_2$: 143.0690; found (M^+ – MsO): 143.0694; calcd. for $^{13}C_1C_7H_{15}O_2$: 144.0724; found (M + 1 – MsO): 144.0718.

C. [3-^{3}H]-trans-Crotonic acid. 1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU) (796 mg, 5.23 mmol) was added dropwise to a stirred solution of [3-^{3}H]-*tert*-butyl 3-mesyloxybutyrate (622 mg, 2.6 mmol) in 25 mL dry CH_2Cl_2. The reaction mixture was stirred at room temperature for 24 h before being quenched by the addition of 20 mL of 1 M acetic acid. The aqueous layer was extracted with CH_2Cl_2 and the combined organic extracts washed with water, dried over anhydrous $MgSO_4$, filtered, and concentrated in vacuo. The residual oil was purified by Kugelrohr distillation. This gave 0.37 g (2.6 mmol) of [3-^{3}H]-*tert*-butyl crotonate: ^{1}H NMR (90 MHz, $CDCl_3$) δ: 1.5 (s, 9H), 1.82 (dd, $^3J_{HH}$ = 7.7 Hz, $^4J_{HH}$ = 2.5 Hz, 3H), 5.74 (dd, $^3J_{HH}$ = 16.7, $^4J_{HH}$ = 2.5 Hz, 1H), 6.7–7.0 (m, 1H); HRMS, calcd. for $C_8H_{14}O_2$: 142.0993; found (M^+): 142.0994; calcd. for $^{13}C_1C_7H_{14}O_2$: 143.1027; found (M + 1): 143.1028.

The tritiated *tert*-butyl crotonate was dissolved in 25 mL of freshly distilled benzene and *p*-toluenesulfonic acid (84 mg, 0.44 mmol) added. The flask was fitted with a Dean–Stark trap and condenser and the whole heated at reflux for 1 h. The reaction mixture was cooled to room temperature and the benzene removed in vacuo. The white, crystalline solid was further purified by passage through a CC-4 silica gel column (15 g, eluant 5%–20% ethyl acetate – hexane). This gave 0.189 g (84%) of [3-^{3}H]-*trans*-crotonic acid as a white solid: ^{1}H NMR (90 MHz, $CDCl_3$) δ: 1.90 (dd, $^3J_{HH}$ = 7.7 Hz, $^4J_{HH}$ = 2.6 Hz, 3H), 5.82 (dd, $^3J_{HH}$ = 16.7 Hz, $^4J_{HH}$ = 2.6 Hz, 1H), 6.7–7.1 (m, 1H).

D. [3-^{3}H]-(+)-10′-Dicyclohexylsulfamoyl-L-isobornyl crotonate. Oxalyl chloride (290 mg, 2.29 mmol) was added dropwise to a stirred solution of [3-^{3}H]crotonic acid (190 mg, 2.20 mmol) in 10 mL dry benzene at room temperature. The solution was stirred at room temperature for 24 h and then at 40°C for 1 h. Silver cyanide (294 mg, 2.20 mmol) and (+)-10-dicyclohexylsulfamoyl-L-isoborneol (665 mg, 1.67 mmol) were added, the flask fitted with a reflux condenser, and the mixture heated at reflux for 72 h. After 72 h no chiral auxillary remained as shown by TLC analysis (SiO_2, 15% ethyl acetate – hexane). The reaction mixture was cooled to room temperature, filtered through Celite, and the benzene removed in vacuo. The residue was purified by flash chromatography (eluant 5%–20% ethyl acetate – hexane). This gave 232 mg (29.8%) of [3-^{3}H]-(+)-10-dicyclohexylsulfamoyl-L-isobornyl crotonate: ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.85 (s, 3H), 1.0 (s, 3H), 1.05–2.15 (m, 30H), 2.68 (d, *J* = 12.9 Hz, 1H), 3.1–3.35 (m, 3H), 5.05 (d, *J* = 8.6 Hz, 1H) 5.83 (d, *J* = 17.2 Hz, 1H), 6.8–7.03 (m, 1H); ^{13}C NMR (75.47, $CDCl_3$) δ: 17.86, 19.98, 20.39, 25.06, 26.34, 26.95, 29.77, 32.68, 39.33, 44.45, 49.03, 49.38, 53.56, 57.29, 77.87, 123.27, 143.69, 164.78, 205.5 ppm.

E. [3-^{3}H]-(3R)-(+)-10′-Dicyclohexylsulfamoyl-L-isobornyl-3-methylpentanoate. Ethyllithium (1.09 mmol) was added dropwise to a stirred solution of tetra-(tri-*n*-butylphosphine) copper(I) iodide (29) (424 mg, 0.27 mmol) in 7 mL dry ether at –78°C. The solution was stirred at –78°C for 30 min before boron trifluoride etherate (154 mg, 1.09 mmol) was added. After stirring at –78°C for a further 30 min, the tritiated isobornyl crotonate (225 mg, 0.49 mmol) was added as a solution in 2 mL ether/1 mL THF and the reaction mixture stirred for 2 h at –78°C. After 2 h the reaction mixture was quenched by the addition of 7 mL of saturated aqueous NH_4Cl and the aqueous layer extracted with ether. *m*-Chloroperoxybenzoic acid (245 mg, 1.42 mmol) was added to the combined ether extracts and the solution stirred for 10 min, filtered through Celite, and washed with 1 M NaOH until colorless. The ether extracts were further dried over anhydrous $MgSO_4$, filtered, and concentrated in vacuo. The residue was purified by flash chromatography (SiO_2, elutant 5%–20% ethyl acetate –hexane). This gave [3-^{3} H]-(+)-10-dicyclohexylsulfamoyl-L-isobornyl-3-methylpentanoate, 173 mg (71.5%) as a white solid: ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.85 (s, 6H), 0.93 (d, 3H), 1.00 (s, 3H), 1.05–2.4 (m, 32H), 2.55–2.7 (d, *J* = 14 Hz, 1H), 3.1–3.4 (m, 3H), 4.85–4.95 (dd, *J* = 5.1 Hz, *J* = 3.8 Hz, 1H); ^{13}C NMR (75.45 MHz, $CDCl_3$) δ: 11.25, 19.23, 19.93, 20.42, 25.13, 26.45, 26.97, 29.37, 30.09, 31.81, 32.71, 39.71, 41.85, 44.42, 49.06, 49.22, 53.63, 57.39, 78.34 ppm.

F. [3-^{3}H]-(2R, 3R)-2-Bromo-(+)-10′-dicyclohexylsulfamoyl-L-isobornyl-3-methylpentanoate. Butyllithium (0.595 mmol) was added dropwise to a stirred solution of diisopropylamine (60 mg, 0.595 mmol) in 6 mL dry THF between 0°C and –10°C. The solution was stirred for 30 min before being cooled to –78°C. A solution of the ester prepared under *E* was added in 4 mL of dry THF and the whole stirred at –78°C for 1 h. Trimethylsilyl chloride (105.8 mg, 0.974 mmol) was added and the reaction mixture stirred for 45 min before carefully recrystallized and dried *N*-bromosuccinimide (105.9 mg, 0.595 mmol) was added. The reaction mixture was stirred at –78°C for 5 h. After 5 h the reaction was quenched by the addition of aqueous NH_4Cl. The aqueous layer was extracted with ether; the combined extracts were washed with water and brine, dried over anhydrous $MgSO_4$, filtered, and concentrated in vacuo. The residue was purified by flash chromatography (SiO_2, eluant 4%–20% ethyl acetate – hexane). This gave 118 mg of the tritiated bromide as a white solid: ^{1}H NMR (90 MHz, $CDCl_3$) δ: 0.85 (s, 6H), 1.0 (s, 6H), 1.1–2.2 (m, 30H), 2.5–2.8 (d, *J* = 14 Hz, 1H), 3.0–3.6 (m, 3H), 4.0–4.22 (d, *J* = 7.6 Hz, 1H), 4.8–5.1 (m, 1H).

G. [3-^{3}H]-(2S, 3R)-2-Azido-(+)-10′-dicyclohexylsulfamoyl-L-isobornyl-3-methylpentanoate. DMF (3 mL) was added to a mixture of sodium azide (30.7 mg, 0.472 mmol) and the tritiated bromo ester (90.3 mg, 0.157 mmol) prepared under *F*, and the reaction was stirred at room temperature for 3 days with periodic monitoring by TLC (SiO_2, 10% ethyl acetate – hexane). After 3 days the reaction mixture was quenched with water and extracted with ether. The combined ether extracts were washed with water and saturated sodium chloride. They were then dried over anhydrous $MgSO_4$, filtered, and concentrated in vacuo. The residue was purified by flash chromatography (SiO_2, eluant 5%–15% ethyl acetate – hexane). This gave 72 mg (85%) of the tritiated azide: ^{1}H NMR (90 MHz, $CDCl_3$) δ: 0.75–1.00 (m, 12H), 0.95 (s, 3H), 1.0–2.2 (m, 31H), 2.4–2.7 (d, J = 14 Hz, 1H), 2.9–3.4 (m, 3H), 4.8–5.1 (m, 1H).

H. [3-^{3}H]-(2S, 3R)-2-Amino-(+)-10′-dicyclohexylsulfamoyl-L-isobornyl-3-methylpentanoate. A mixture of the tritiated azide from procedure *G* (72.1 mg, 0.133 mmol) and 5% palladium – barium sulfate catalyst (50.4 mg) in 5 mL absolute ethanol was stirred at room temperature for 24 h under hydrogen at atmospheric pressure. After 24 h the reaction mixture was filtered through Celite to remove the catalyst and the residue washed with $CHCl_3$. The filtrate was concentrated in vacuo and the residue purified by flash chromatography (SiO_2, 5%–50% ethyl acetate – hexane). This gave 53 mg (78%) of [3-^{3}H]-2-amino-(+)-dicyclohexylsulfamoyl-L-isobornyl-3-methylpentanoate: ^{1}H NMR (90 MHz, $CDCl_3$) δ: 0.75–1.2 (m, 12H), 1.2–2.2 (m, 30H), 2.5–2.9 (dd, J = 14 Hz, 1H), 2.95–3.5 (m, 3H), 3.8–4.1 (d, J = 3.8 Hz, 1H), 4.8–5.1 (m, 1H).

I. [3-^{3}H]-L-Alloisoleucine. A mixture of the tritiated amino ester prepared under *H* (53.3 mg, 0.103 mmol) and barium hydroxide (57.5 mg, 0.18 mmol) in 4 mL of water and 2 mL of ethanol was heated at reflux for 24 h. After 24 h the reaction mixture was cooled to room temperature, filtered through Celite, and concentrated in vacuo. The residue was redissolved in 10 mL water and treated with 8 mg $(NH_4)_2CO_3$. The milky white solution was filtered and concentrated before being redissolved in water and treated with a second batch of $(NH_4)_2CO_3$. The solution was filtered one more time to remove any remaining $BaCO_3$ and then stirred in a water bath at 60–65°C for 1 h. The water was then removed in vacuo and the white residue purified by flash chromatography (cellulose, eluant butanol:acetic acid:water (BAW) 12:3:5). This gave 13 mg (95%) of [3-^{3}H]-L-alloisoleucine whose specific activity was 11 μCi/mg: ^{1}H NMR (250 MHz, D_2O) δ: 1.0 (m, 6H), 1.3–1.5 (m, 2H), 1.9–2.1 (m, 1H), 3.6 (d, J = 0.36 Hz, 1H), 4.9 (s, D_2O); ^{13}C NMR (75.46 MHz, D_2O) δ: 11.17, 13.43, 25.65, 35.78, 58.58, 174.89 ppm.

Synthesis of [1-^{14}C]-L-alloisoleucine

A. [1-^{14}C]-(+)-10′-Dicyclohexylsulfamoyl-L-isobornyl butyrate. [1-^{14}C]Butyric acid (44 mg, 0.5 mmol) and oxalyl chloride (46 μL, 0.52 mmol) were allowed to react in 1 mL of dry benzene for 18 h at room temperature. The reaction mixture was then heated to 42°C for 30 min. After cooling to room temperature, (+)-10-dicyclohexylsulfamoyl-l-isoborneol (150 mg, 0.38 mmol) and AgCN (134 mg, 1.0 mmol) were added to the crude acid chloride along with 0.5 mL of dry benzene. The mixture was heated to gentle reflux for 48 h. The silver salts were removed by filtration through Celite and the filtrate evaporated in vacuo to give a residue that was chromatographed on silica gel to furnish the coupling product (131 mg) in 56% yield with a specific activity of 8.1 μCi/mg: ^{1}H NMR (90 MHz, $CDCl_3$) δ: 0.85 (s, 3H), 0.95 (t, 6H), 1.04–2.4 (m, 31H), 2.64 (d, J = 14 Hz, 1H), 2.95–3.4 (m, 3H), 4.8–5.04 (m, 1H). HRMS, calcd. for $C_{26}H_{45}NO_4S$: 467.3069; found (M^+): 467.3076; calcd. for $^{13}C_1C_{25}H_{45}NO_4S$: 468.3103; found (M + 1): 468.3110.

B. [1-^{14}C]-(+)-10′-Dicyclohexylsulfamoyl-L-isobornyl-2-bromobutyrate. Under a nitrogen atmosphere, diisopropylamine (290 mg, 2.9 mmol) in dry THF (45 mL) was cooled to 0°C and *n*-BuLi (1.1 mL, 2.6 M in hexane, 2.9 mmol) was added. After stirring at 0°C for 30 min, the reaction mixture was cooled to –78°C before a solution of the radioactive ester prepared in step *A* (808 mg, 1.7 mmol) in dry THF (15 mL) was added. The colorless reaction mixture was stirred at –78°C for 1 h before trimethylsilyl chloride (0.565 mL, 4.4 mmol) was added. After stirring for an additional 45 min at –78°C, recrystallized *N*-bromosuccinimide (518.7 mg, 2.82 mmol) in dry THF (22 mL) was added. The resulting cloudy yellowish reaction mixture was stirred at –78°C for 5 h and then quenched with water. After the usual aqueous work-up, the crude product was purified by flash chromatography on silica gel to furnish pure bromide (762 mg) in 81% yield: ^{1}H NMR (90 MHz, $CDCl_3$) δ: 0.85 (s, 3H), 1.0 (s, 3H), 1.04–2.4 (m, 32H), 2.8 (d, J = 14 Hz, 1H), 2.9–3.5 (m, 3H), 4.15 (dd, J = 5.8 Hz, 1H), 4.8–5.1 (m, 1H); ^{13}C NMR (75.47 Hz, $CDCl_3$) δ: 11.83, 19.80, 20.24, 24.91, 26.19, 26.76, 28.55, 30.20, 32.03, 33.03, 39.04, 44.06, 49.08, 49.27, 49.59, 53.36, 57.12, 79.91, 167.5 ppm; HRMS, calcd. for $C_{26}H_{44}NO_4BrS$: 545. 2174; found (M^+): 545.2171; calcd. for $^{13}C_1C_{25}H_{44}NO_4BrS$: 546.2208; found (M + 1): 546.2216.

C. [1-^{14}C]-(+)-10′-Dicyclohexylsulfamoyl-L-isobornyl crotonate. The radioactive bromide prepared in part *B* (762 mg, 1.37 mmol) was allowed to react with DBU (823 mg, 5.49 mmol) in 46 mL of dry benzene at reflux under nitrogen for 18 h. The resulting yellowish brown reaction mixture was worked up by addition of 1 M $NaHCO_3$ and water in succession. After drying the organic phase, the solvent was removed in vacuo and the residue purified by flash chromatography on silica gel to afford the pure crotonyl ester (468 mg) in 72% yield: ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.85 (s, 3H), 1.0 (s, 3H), 1.05–2.15 (m, 30H), 2.68 (d, J = 12.9 Hz, 1H), 3.1–3.35 (m, 3H), 5.05 (d, J = 8.6 Hz, 1H) 5.83 (d, J = 17.2 Hz, 1H), 6.8–7.03 (m, 1H); ^{13}C NMR (75.47 MHz, $CDCl_3$) δ: 17.86, 19.98, 20.39, 25.06, 26.34, 26.95, 29.77, 32.68, 39.33, 44.45, 49.03, 49.38, 53.56, 57.29, 77.87, 123.27, 143.69, 164.78, 205.5 ppm.

D. [1-^{14}C]-L-Alloisoleucine. The [^{14}C]-labeled crotonate ester prepared in part *C* was converted into [1-^{14}C]-L-alloisoleucine using the same sequence of reactions that was employed to convert [3-^{3}H]-(+)-10-dicyclohexylsulfamoyl-L-isobornyl crotonate into [3-^{3}H]-L-alloisoleucine. The specific activity of the resulting [1-^{14}C]-L-alloisoleucine was 7.5 μCi/mg.

Synthesis of a mixture of (2-^{13}C,^{15}N)-DL-isoleucine and (2-^{13}C,^{15}N)-DL-alloisoleucine

A. (1-^{13}C)-2-Methylbutyronitrile. (^{13}C)Sodium cyanide (2.0 g, 40.8 mmol) was added to a solution of 2-bromobutane (3.72 g, 27.2 mmol) in 50 mL HMPA at room temperature. The reaction mixture was stirred at room temperature for 48 h and then connected via a U-tube, cooled in liquid nitrogen, to a vacuum pump and distilled at room temperature. This gave 0.913 g (40%) of (1-^{13}C)-2-methylbutyronitrile as a colorless liquid: ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.05 (s, 3H), 1.3 (s, 3H), 1.55 (m, 2H), 2.5–2.65 (m, 1H); ^{13}C NMR (62.89 MHz, $CDCl_3$) δ: 11.347, 11.392, 26.585, 27.237, 26.266, 27.464, 122.914 (enriched) ppm.

B. (1-^{13}C)-2-Methylbutyraldehyde. DIBAL (13.4 mL, 13.4 mmol) was added dropwise to a stirred solution of (1-^{13}C)-2-methylbutyronitrile (0.913 g, 11 mmol) in dry CH_2Cl_2 (25 mL) at room temperature. After 1.5 h the reaction mixture was cautiously poured into 5% H_2SO_4 (50 mL) and the aqueous and organic layers separated. The aqueous layer was further extracted with dichloromethane and the combined organic extracts were dried over anhydrous $MgSO_4$, filtered, and concentrated by distillation at atmospheric pressure. The crude (1-^{13}C)-2-methylbutyraldehyde distilled at 90–92°C: ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.9–1.0 (t, 3H), 1.1–1.15 (t, 3H), 1.3–1.8 (m, 2H), 2.2–2.35 (m, 1H), 9.25–9.95 (d, $^1J_{CH}$, J = 40.9 Hz, 1H).

C. (2-^{13}C)-2-Hydroxy-3-methylvaleronitrile. Ethanol was added to a stirred solution of (1-^{13}C)-2-methylbutyraldehyde (0.95 g, 11 mmol) and sodium bisulfite (1.3 g, 12.5 mmol) in water (10 mL) until the solution became homogenous and clear. After stirring at room temperature for 1 h, potassium cyanide (0.73 g, 11.2 mmol) was added and the reaction mixture stirred at room temperature for 3 h. The ethanol was removed in vacuo and the aqueous layer extracted with ether. The combined ether extracts were washed with water, and with saturated NaCl. They were then dried over $MgSO_4$, filtered, and concentrated in vacuo. This gave 0.76 g (61%) of crude (2-^{13}C)-2-hydroxy-3-methyl valeronitrile.

For personal use only.

D. (2-^{13}C, ^{15}N)-2-Amino-3-methylvaleronitrile. Ethanol was added to a solution of (2-^{13}C)-2-hydroxy-3-methylvaleronitrile (0.76 g, 6.72 mmol) in (^{15}N)ammonium hydroxide (4.1 mL of a 3.3 N solution) until the solution became homogenous and clear. The reaction mixture was stirred at room temperature for 18 h, the ethanol removed in vacuo, and the aqueous layer extracted with ether. The combined ether extracts were washed with water, saturated NaCl, dried over $MgSO_4$, filtered, and concentrated. This gave 0.72 g of crude (2-^{13}C, ^{15}N)-2-amino-3-methylvaleronitrile.

E. Mixture of (2-^{13}C, ^{15}N)-DL-isoleucine and (2-^{13}C, ^{15}N)-DL-alloisoleucine. Barium hydroxide (8.2 g, 26 mmol) was added to a solution of (2-^{13}C, ^{15}N)-2-amino-3-methylvaleronitrile (0.721 g, 6.32 mmol) in water (50 mL). The flask was fitted with a reflux condenser and the mixture refluxed for 18 h. The reaction mixture was then cooled to room temperature, filtered through Celite, and the filtrate treated twice with $(NH_4)_2CO_3$ to remove barium as insoluble barium carbonate. The resulting clear filtrate was stirred at 60–65°C in a water bath for 1 h and finally concentrated in vacuo. Chromatography of the residue on a cellulose column (eluant BAW 12:3:5) gave 0.35 g (42%) of doubly labeled amino acid as a white solid: ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.6–0.75 (m, 6H), 1.0–1.25 (m, 2H), 1.65–1.85 (m, 1H), 3.4 (ddd, $^1J_{CH}$ = 162 Hz, $^3J_{HH}$ = 25 Hz, $^2J_{NH}$ = 6.4 Hz, 1H); ^{13}C NMR (62.89 MHz, $CDCl_3$) δ: 11.23, 11.29, 13.46, 14.82, 22.83, 24.61, 25.63, 35.99, 58.50, 58.59, 59.58, 59.67 (doublet, $^1J_{CN}$ = 68 Hz), 180.62 ppm.

Synthesis of (5-$^2H_1$, 6-$^2H_1$)-DL-coronamic acid

A. (6-$^2H_1$, 7-$^2H_1$)-1,1-Dicarbomethoxy-2-ethylcyclopropane. A flame-dried and cooled 1000-mL three-necked round-bottomed flask, fitted with a reflux condenser and dropping funnel, was charged with 1,1-dicarbomethoxy-2-vinylcyclopropane (1.0 g, 5.43 mmol) (30) and dipotassium azodicarboxylate (31) (68.9 g, 355 mmol) in 100 mL methanol-O-*d*. Acetic acid-O-*d* (30.1 mL) was added dropwise. The original deep yellow solution turned pale yellow and the methanol began to reflux. The acetic acid was added at such a rate as to maintain reflux. Once the addition was complete, the reaction mixture was stirred at room temperature. After 2.5 h the pale yellow solution had become white. After stirring for 5.5 h the reaction mixture was transferred to a 500-mL round-bottomed flask and the methanol removed in vacuo. The residue was dissolved in water (50 mL) and extracted with ether. The combined ether extracts were washed with 1 N $NaHCO_3$, water, and brine, dried over anhydrous $MgSO_4$, filtered, and concentrated in vacuo. The residue was purified by flash chromatography (SiO_2, elutant 5%–15% ethyl acetate – hexane). This gave 0.8 g (80%) of (6-$^2H_1$, 7-$^2H_1$)-1,1-dicarbomethyoxy-2-ethylcyclopropane as a clear liquid: ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.9 (m, 2H), 1.2–1.3 (m, 1H), 1.3–1.5 (m, 2H), 1.8–2.0 (m, 1H), 3.7 (s, 3H), 3.8 (s, 3H).

B. (6-$^2H_1$, 7-$^2H_1$)-1-Carboxy-1-carbomethoxy-2-ethylcyclopropane. Potassium hydroxide (0.25 g, 4.4 mmol) was added to a stirred solution of (6-$^2H_1$,7-$^2H_1$)-1,1-dicarbomethoxy-2-ethylcyclopropane in methanol (18 mL) at room temperature. The reaction mixture was stirred at room temperature for 4 days. The methanol was removed in vacuo and the residue dissolved in water (20 mL). The aqueous layer was extracted with ethyl acetate and the combined ethyl acetate extracts washed with brine, dried over $MgSO_4$, filtered, and concentrated in vacuo. This gave 0.41 g (85%) of (6-$^2H_1$, 7-$^2H_1$)-2-carboxy-1-carbomethoxy-2-ethylcyclopropane as a clear liquid, ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.95 (m, 2H), 1.4–1.7 (m, 1H), 1.7–1.8 (m, 1H), 1.9–2.15 (m, 2H), 3.7 (s, 3H).

C. (5-$^2H_1$, 6-$^2H_1$)-DL-Coronamic acid. Ethyl chloroformate (0.68 mL, 7.1 mmol) was added dropwise to a stirred solution of (6-$^2H_1$,7-$^2H_1$)-1-carboxy-1-carboxymethyl-2-ethylcyclopropane (0.41 g, 2.35 mmol) and *N*-ethyldiisopropylamine (0.82 mL, 4.72 mmol) in acetone (5 mL) at 0°C. The solution was stirred at 0°C for 30 min, a solution of sodium azide (0.76 g, 11.82 mmol) in water (5 mL) was added, and the reaction mixture was stirred at 0°C for 2 h. The acetone was removed in vacuo and the aqueous layer extracted with ethyl acetate. The combined ethyl acetate extracts were washed with water and saturated NaCl, dried over $MgSo_4$, filtered, and concentrated in vacuo. This gave 0.45 g of the crude acyl azide as a pale yellow oil. The crude acyl azide was dissolved in toluene (6 mL) and heated at reflux for 30 min. The reaction mixture was cooled to roomtemperature, and the toluene removed in vacuo. The brown residual oil was dissolved in 6 N HCl (6 mL) and the solution refluxed for 6 h. The solution was cooled to room temperature and the acid removed in vacuo. The residue was redissolved in water (7 mL) and loaded onto a strongly acidic ion-exchange resin (Dowex 50W-X8, H^+-form, 15 mL). After washing the column with water, the amino acid fraction was eluted with 2 N NH_4OH (60 mL) and concentrated in vacuo. This gave 0.250 g (40%) of (5-$^2H_1$, 6-$^2H_1$)-DL-coronamic acid as a pale yellow solid: TLC (cellulose, BAW, 4:1:2, R_f = 0.69); ^{1}H NMR (300 MHz, D_2O) δ: 0.75 (m, 2H), 1.15 (d, $^3J_{HH}$ = 1.2 Hz, 2H), 1.3–1.4 (m, 1H), 1.4–1.5 (m, 1H); ^{13}C NMR (62.89 MHz, D_2O) δ: 12.44 (t, $^1J_{CD}$ = 19 Hz), 17.05, 19.57 (t, $^1J_{CD}$ = 20 Hz), 27.61, 39.85, 174.11 ppm.

Synthesis of a mixture of (1-^{13}C)-6-hydroxy-DL-isoleucine and (1-^{13}C)-6-hydroxy-DL-alloisoleucine

A. Methyl 2-benzyloxymethylbutanoate. A solution of *n*-BuLi (2.04 M in hexane, 5.5 mL) was added with stirring to a solution of diisopropylamine (1.11 g, 11.0 mmol) in dry THF (20 mL) at 0°C. The resulting solution was stirred at 0°C for 30 min, then cooled to –78°C before adding methyl butanoate (1.05 g, 10.3 mmol). After the ester addition, the reaction mixture was stirred at –78°C for 1 h, and bromomethyl benzyl ether[6] (2.27 g, 11.3 mmol) was then added. Stirring at –78°C was continued for 30 min, after which time the reaction was allowed to warm to room temperature and then quenched with excess saturated aqueous NH_4Cl solution. The resulting mixture was concentrated in vacuo and ether (10 mL) was added. The organic phase was washed with 1 N HCl (3 × 20 mL), separated, and dried over $MgSO_4$. Removal of the ether in vacuo gave the crude product, which was purified by flash chromatography (SiO_2, 15% EtOAc in hexane) to yield 1.39 g (61%) of a yellowish oil: ^{1}H NMR (90 MHz, $CDCl_3$) δ: 0.90 (t, *J* = 7 Hz, 3H), 1.45–1.76 (m, 2H), 2.50–2.88 (m, 1H), 3.53–3.59 (m, 2H), 3.69 (s, 3H), 4.50 (s, 2H), 7.30 (s, 5H); ^{13}C NMR (22.5 MHz, $CDCl_3$) δ: 11.49, 21.96, 47.53, 51.43, 70.56, 73.03, 127.55, 128.27, 138.16, 174.85 ppm.

B. 2-Benzyloxymethylbutanal. A solution of DIBAL (5.3 mL, 1.0 M in CH_2Cl_2) was added with stirring to a solution of methyl 2-benzyloxymethylbutanoate (1.16 g, 5.22 mmol) in dry CH_2Cl_2 (20 mL) chilled to –78°C. The resulting solution was stirred at –78°C for 1 h and then quenched with excess saturated aqueous NH_4Cl. The reaction mixture was then warmed to room temperature and the aluminum salts solubilized by addition of 1 N HCl (30 mL). The organic layer was separated, washed with brine (10 mL), dried ($MgSO_4$), and concentrated in vacuo. The crude aldehyde was purified by flash chromatography (SiO_2, 15% EtOAc in hexane) to yield 845 mg (84%) of a colorless oil: ^{1}H NMR (90 MHz, $CDCl_3$) δ: 0.93 (t, *J* = 7 Hz, 3H), 1.45–1.90 (m, 2H), 2.32–2.65 (m, 1H), 3.64–3.71 (m, 2H), 4.50 (s, 2H), 7.31 (s, 5H), 9.69 (d, *J* = 2 Hz, 1H); ^{13}C NMR (22.5 MHz, $CDCl_3$) δ: 11.29, 18.97, 53.58, 68.22, 73.23, 127.55, 127.68, 128.40, 137.96, 203.93 ppm; MS [EI], *m/z*: 121, 116, 107 ($C_7H_7O^+$, base peak), 106, 105, 91.

C. Mixture of (1-^{13}C)-6-benzyloxy-L-isoleucine and (1-^{13}C)-6-benzyloxy-DL-alloisoleucine. 2-Benzyloxymethylbutanal (530 mg, 2.76 mmol) was added to a solution of sodium bisulfite (370 mg) in water (10 mL). Ethanol was then added with stirring until the mixture became homogeneous. The resulting solution was stirred at room temperature for 1 h, at which time (^{13}C)-KCN (184 mg, 2.83 mmol) was added. Stirring of the reaction mixture was then continued for 3 h. The solution was then concentrated in vacuo and the concentrated mixture extracted with ether. After removal of the ether, the residue was suspended in concentrated NH_4OH (10 mL) and ethanol added until the mixture was homogeneous. The resulting solution was stirred overnight at room temperature. The solution was again concentrated in vacuo and the concentrated mixture extracted with ether. Removal of the ether yielded a residue, which was added to a solution of $Ba(OH)_2 \cdot 8H_2O$ (2.25g, 7.14 mmol) in water (10 mL) and the mixture

[6]Prepared using gaseous HBr instead of gaseous HCl following the procedure of Conner et al. (32).

refluxed overnight. The white precipitate was filtered off and washed twice with hot water. The filtrate was concentrated in vacuo and then treated with solid ammonium carbonate (400 mg). The solution was boiled for 10 min and the precipitated $BaCO_3$ was removed by filtration. The filtrate was then treated again with solid ammonium carbonate. This process was repeated until no white precipitate formed. Finally, the clear solution was boiled to destroy excess ammonium carbonate and then taken to dryness in vacuo. The residue was purified by flash chromatography (SiO_2, 25% MeOH in $CHCl_3$) to afford 160 mg (25%) of a mixture of (1-^{13}C)-6-benzyloxy-DL-isoleucine and (1-^{13}C)-6-benzyloxy-DL-alloisoleucine as a yellowish oil: ^{1}H NMR (90 MHz, D_2O) δ: 0.64–0.94 (m, 3H), 1.16–1.56 (m, 2H), 2.04–2.40 (m, 1H), 3.42–3.56 (m, 2H), 4.09 (d, J = 3.6 Hz, 1H), 4.40 (s, 2H), 7.28 (s, 5H); ^{13}C NMR (22.5 MHz, D_2O, *p*-dioxane ref.) δ: 10.94, 19.66, 20.44, 40.87, 55.18, 69.49, 73.07, 128.44, 128.76, 175.1 (enriched) ppm.

D. Mixture of (1-^{13}C)-6-hydroxy-DL-isoleucine and (1-^{13}C)-6-hydroxy-DL-alloisoleucine. A mixture of (1-^{13}C)-6-benzyloxy-DL-isoleucine and (1-^{13}C)-6-benzyloxy-DL-alloisoleucine 332 mg, 1.40 mmol) was dissolved inmethanol (35 mL), 10% Pd/C (143 mg) and concentrated HCl (3 drops) were added, and the suspension was stirred under H_2 at atmospheric pressure for 24 h. The catalyst was then removed by filtration and the solution taken to dryness. The residue was purified by column chromatography (cellulose, BAW 6:1:1) to yield a mixture of the free amino acids weighing 70 mg (39%). On standing in aqueous solution at room temperature, this mixture was converted into a mixture of the corresponding γ-lactones: TLC (cellulose, BAW 6:1:1), R_f = 0.49 for free amino acids, R_f = 0.33 for lactonized amino acids; spectral data for the lactones: ^{1}H NMR (90 MHz, D_2O) δ: 0.96 (t, J = 7.5 Hz, 3H), 1.20–1.96 (m, 2H), 2.08–2.72 (m, 1H), 3.49 (d, J = 11 Hz, 1H), 3.89–4.10 (m, 1H), 4.33–4.65 (m, 1H); ^{13}C NMR (22.5 MHz, D_2O, *p*-dioxane ref.) δ: 11.13, 18.55, 42.17, 57.26, 61,95, 180.25 (enriched) ppm; HRMS, calcd. for $C_6H_{11}NO_2$: 129.07897; found (M^+): 129.07895; calcd. for $^{13}C_1C_5H_{11}NO_2$: 130.08232; found (M + 1): 130.08205.

Septatisine **3**, an atisane-type diterpenoid alkaloid, was isolated from the roots of *Aconitum septentrionale* Koelle. Its structure was established on the basis of homonuclear ^{1}H COSY, LRCOSY, NOESY, DNOE, fixed-evolution HETCOR, and selective INEPT techniques.

On a isolé la septatisine (**3**), un alcaloïde diterpénoïdique du type de l'atisane, à partir des racines de l'*Aconitum septentrionale* Koelle. On a déterminé sa structure à l'aide de techniques INEPT sélectives, HETCOR à évolution déterminée et de COSY, LRCOSY, NOESY et DNOE homonucléaires du ^{1}H.

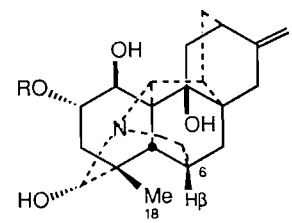
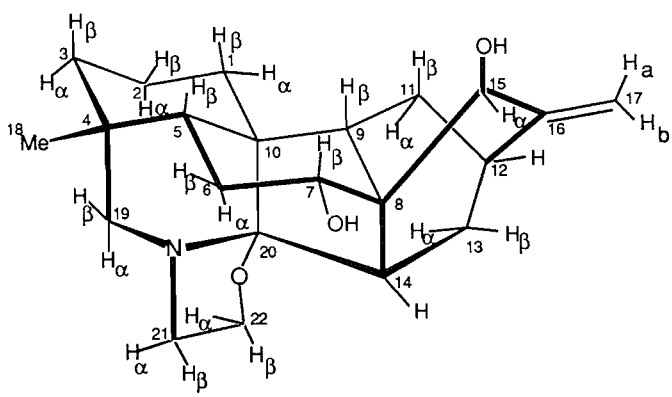
About a hundred years ago, the presence of alkaloids was noted in *Aconitum septentrionale* (1). Subsequently, more than 24 norditerpenoid alkaloids (C_{19}) have been isolated by Marion et al. (2), Yunusov and co-workers (3–5), and from our own laboratories (6–9). Only two diterpenoid alkaloids (C_{20}) of the hetisane type, septentriosine **1**, and 2-acetylseptentriosine **2**, were isolated from the roots (10, 11). We report herein the isolation and structure determination of a new atisane-type diterpenoid alkaloid (C_{20}) designated as septatisine **3**.

The molecular formula $C_{22}H_{31}NO_3$ of septatisine **3**, deduced from elemental analysis, was confirmed by hr-eims (70 eV, *m/z* 357.2287, M^+; calcd. for $C_{22}H_{31}NO_3$, 357.2304). This formula requires eight units of unsaturation, one of which was quite clearly accounted for by a terminal, and presumably exocyclic, methylene unit as indicated by the ^{1}H and ^{13}C nmr spectra: δ 4.94 (dd, J = 2.6, 1.2 Hz); 4.83 (dd, J = 2.1, 1.2 (Hz); δ 157.9 (s), 103.8 (t). This leads to the conclusion that septatisine is a diterpenoid (C_{20}) alkaloid with two additional carbons and the remaining seven units of unsaturation elaborated by a polycyclic system. The appearance of an isolated dimethylene proton coupled spin system in the homonuclear COSY (COSY) spectrum (δ 3.78 (ddd, J = 13.6, 12.1, 6.9 Hz), 3.56 (ddd, J = 13.6, 8.6, 2.2 Hz), 3.03 (ddd, J = 12.4, 12.1, 8.6 Hz), 2.81 (ddd, J = 12.4, 6.9, 2.2 Hz)) with the corresponding carbons located by a heteronuclear COSY (fixed evolution HETCOR) (12) spectrum (δ 61.7, 51.5), indicated that these two "additional" carbons were attached to the nitrogen[2] forming an ethanolamino grouping.



1 R = H
2 R = Ac

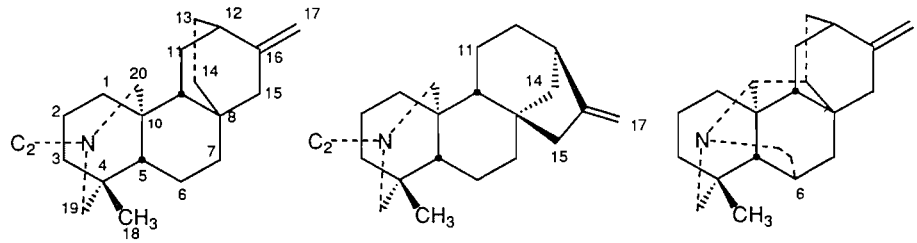


3 Septatisine

[1]Authors to whom correspondence may be addressed.

[2]Even with the fixed-evolution HETCOR, no correlations were observed between the H22 protons and C22, though this assignment was unambiguous as all other correlations were apparent.

Of the three most likely candidate diterpene alkaloidal skeleta, the atisane (**A**), veatchine (**B**), and hetisane (**C**) types, the hetisane skeleton was considered unlikely because the tertiary amino functionality allowed for no realistic option to attach the two "additional" carbons of the C_{22} formula. The veatchine skeleton was ruled out on the basis of the experiment to be described, and the atisane structure with one additional unit of unsaturation (C14/C20 bridge) was confirmed by spectroscopic methods.



A B C

Weak coupling between both vinylic methylene protons (H17a and H17b) with a carbinol proton (δ 4.49 br s) was observed in the COSY spectrum, as well as in the long-range COSY spectrum (LRCOSY, Δ = 0.25 s). Given the exocyclic nature of the double bond, this could only be allylic coupling, and therefore a secondary alcohol functionality was considered to be located at C15 (^{13}C: δ 68.7 from the fixed-evolution HETCOR spectrum). The methine nature of this carbinol carbon was confirmed by an APT experiment. That this oxygenated carbon was an alcohol and not part of an ether was shown by COSY and the LRCOSY spectra in which the doublet at δ 1.90 (J = 5.8 Hz, exchangeable with D_2O), indicated coupling with H15. In later spectra this resonance apparently broadened and moved downfield to the overlapped region at δ 2.0 with no coupling with H15 observed in the COSY spectra. Apparently the appearance of this OH resonance was very sensitive to the water concentration in the nmr sample.

No coupling was observed between either H17 and any other proton in either the COSY or LRCOSY spectra, but the second allylic position, H12, was located by a selective INEPT experiment. Saturation of the upfield H17 resonance, later shown to be H17a by nOe studies, resulted in an enhancement of a methine carbon (δ 34.5), which must therefore be C12. The fixed-evolution HETCOR spectrum enabled assignment of the proton attached to this methine carbon as a broad singlet (H12: δ 2.20). In the COSY spectrum, this broad singlet showed coupling with three other protons, which were three of the four members of two different methylene groups (H11α, H11ß, and H13α). Coupling with these methylene protons was partially obscured by overlap with other resonances, but the frequencies were sufficiently distinct that they could be resolved for identification. No coupling was observed between H12 and the fourth methylene proton of these two pairs in the COSY spectrum, but was readily apparent in the LRCOSY spectrum (Δ = 0.25 s, H13ß: δ 1.36 (dddd, J = 13.4, 12.2, 2.2, 2.0 Hz)). This latter resonance, which was cleanly resolved in the ^{1}H nmr spectrum, was most easily confirmed as one of the methylene pair adjacent to C12 from the HETCOR spectrum by its one-bond coupling with the same carbon as H13α (δ 27.4). The stereochemical assignments of all methylene pairs of protons were from nOe studies (vide infra).

These observations required that the exocyclic double bond be flanked by a secondary alcohol and a methine carbon, the latter of which was adjacent to two methylene carbons. This requirement can be met by both the atisane and veatchine skeleta with the secondary alcohol group at C15. Two APT experiments, one with a defocusing delay of 8 ms (optimal for $^1J_{1H,13C}$ = 125 Hz for detection of all carbons and the second with a defocusing delay of 4 ms for detection of quaternary carbons (13) (carbons with $^1J_{1H,13C}$ = 125 Hz are nulled) revealed that **3** contained one methyl carbon (δ 28.6), nine methylenes (δ 19.6, 27.4, 29.2, 30.2, 32.3, 41.3, 51.5, 57.3, and 61.7), six methines (δ 34.5, 44.0, 46.6, 49.6, 68.7, and 70.1), and four quaternary carbons (δ 34.4, 47.1, 50.0, and 104.6) in addition to the two sp^2 hybridized carbons (δ 103.8, t; 157.9, s). The downfield quaternary carbon at δ 104.6 indicated the presence of a carbinolamine.

These results account for 29 hydrogens, and the remaining two hydrogens required by the molecular formula must be present as two alcohol functionalities. The third oxygen must therefore be in a cyclic ether. (The sole methyl group can be assigned to C18, and since there is no way to terminate a chain with an oxygenated methine or quaternary carbon, a cyclic ether must be present.)

In both the atisane and hetisine structures, the basic skeleta, the exocyclic double bond, and the cyclic ether account for seven of the eight units of unsaturation. The remaining unit must therefore arise from an additional bridge in the basic alkaloidal skeleton. Location of this bridge in principle should have been possible from knowledge of the spin systems mapped by the COSY spectrum. This effort was stymied, unfortunately, by serious signal overlap in the ^{1}H nmr spectrum (and therefore also in the COSY) in all solvents examined. These solvents included $CDCl_3$, CH_2Cl_2, CD_3OD, Py-d_5, and C_6D_6, as well as titrations of **3** in $CDCl_3$ with Py-d_5, and C_6D_6.

The atisane skeleton with a C14/C20 bridge, as well as location of the carbinolamine-anchored cyclic ether, was established through selective INEPT studies. As mentioned above, one of the two "additional" carbons of the C_{22} formula was considered to be the nitrogenated terminus of an ethanolamine group. In addition, in the ^{1}H nmr spectrum an AB system typical for a C19 methylene group in C_{20} diterpene alkaloids appeared (δ 2.58, 2.35, J_{AB} = 11.4 Hz; ^{13}C: 57.3). This result indicated that nitrogen was bonded to two methylene groups and the quaternary carbinolamine carbon. Saturation of the downfield H19, later shown to be H19ß by nOe studies, resulted in the enhancement of the other nitrogenated methylene carbon of the "additional" C_2 unit, the methyl carbon assigned as C18, and two quaternary carbons: δ 34.4 and 104.6. The upfield quaternary carbon resonance could be assigned to C4 on the basis of its chemical shift, and downfield resonance to the carbinola-

mine carbon, which must be C20 since no other carbons can be attached to the nitrogen. If C20 is a carbinolamine carbon and is nonprotonated, then this must be the site of the additional bridge in the diterpene skeleton.[3]

In another selective INEPT experiment, saturation of the well-resolved methylene proton vicinal to H12 (δ 1.36, later assigned to H13ß) also resulted in an enhancement of the quaternary carbinolamine carbon C20, as well as an enhancement of the vinyl C16 carbon, confirming the location of this methylene group three bonds removed from the double bond. A polarization transfer from a methylene proton adjacent to the allylic C12 position is possible only in the atisane skeleton, and only with a C14/C20 bridge. (In principle, the veatchine skeleton with a C11/C20 bridge forming a cyclobutane ring would also account for this observation, with the H13 now as the allylic methine and H12 as the well-resolved methylene proton being saturated in the selective INEPT experiment. Such a structure, however, is quite incompatible with the carbon chemical shifts and is considered highly unlikely.)

With establishment of the basic carbon framework as the atisane skeleton with a C14/C20 bridge, all that remained was location of the fourth oxygenated carbon, location of the cyclic ether, determination of the stereochemistry of the alcohol functions, and then completion of the proton and carbon resonance assignments. The final oxygenated carbon was located at C7 by selective INEPT experiments as well. Saturation of H15, easily assigned by the allylic coupling with both H17a and H17b as discussed above, resulted in an enhancement of this oxygenated carbon. A reciprocal enhancement of C15 was observed upon saturation of the carbinol proton attached to this remaining oxygenated carbon (δ 4.21, dd, J = 8.7, 7.7 Hz).[4] The only possible site for a secondary carbinal carbon within three bonds of H15 in the atisane skeleton with a C14/C20 bridge is at C7. Location of the final oxygenated carbon at C7 requires that the H5 through H7 spin system be -CH-CH_2-CH-, and the H1 through H3 system be a trimethylene unit. The COSY spectrum clearly indicated that H7 was coupled to two other protons, one of which was a cleanly resolved multiplet (δ 2.28, ddd, J = 13.4, 13.3, 8.7 Hz, H6α) while the second proton, which also coupled with H6α, appeared in an overlapped portion of the spectrum (δ 2.10, overlapped with H11 and H1α). These two protons were the C6 methylene pair as shown by the fixed evolution HETCOR spectrum (δ 32.3). Both the C6 methylene protons in turn coupled to one other methine proton, also overlapped, but which could be resolved through extensive decoupling experiments (δ 1.25). The HETCOR spectrum located the carbon of this methine proton at δ 46.6, typical for C5 and completing the C5 through C7 ^{1}H and ^{13}C assignments.

The C1 through C3 system was considered to be an unsubstituted trimethylene sequence by appearance of a methylene carbon at δ 19.6, typical for C2 in structurally analogous terpenoid systems with nonoxygenated C1 and C3 methylene carbons as in spirasines (14), and in nominine and its derivatives (15). Since C12 was vicinal to two methylenes (C11 and C13), C6, C19, and the "additional" C2 unit were all methylenes, only three methylene carbons and no other substituents are to be accounted for in the formula, and these methylenes must be C1 through C3. In a selective INEPT experiment, saturation of a cleanly resolved multiplet (δ 0.90, ddd, J = 13.3, 13.3, 5.4 Hz) resulted in an enhancement of the carbinolamine carbon C20, as well as another quaternary carbon (δ 47.1, assigned as C10), and one of the three remaining methylene carbons (δ 41.3, C3). This proton was therefore assigned as H1ß (stereochemical assignment on the basis of coupling constants), with its methylene partner H1α located in the fixed evolution HETCOR spectrum (^{13}C: δ 30.2) in an overlapped region of the proton spectrum at δ 2.2 (overlapped with H6ß). In the COSY spectrum, H1ß showed coupling with H1α as well as with a second proton, also overlapped (δ 1.45). Coupling to a third proton (δ 1.55) was much weaker. In the same COSY spectrum H1α showed coupling with this third proton (δ 1.55, overlapped with one of the H11 protons), but not with the second proton as coupled with H1ß. The HETCOR spectrum nevertheless revealed that these two new protons were a methylene pair, and therefore these must be the C2 methylene protons (^{13}C: δ19.6). In the LRCOSY spectrum, mutual coupling between all protons of this vicinal pair of methylenes was observed. In a similar manner the C3 methylene protons and carbon were assigned. Thus, in the ^{1}H nmr spectrum a resolved multiplet (δ 1.11, ddd, J = 13.2, 13.2, 5.1 Hz and therefore assigned as H3ß) showed coupling with one of the C2 methylene protons (the same one that showed strong coupling with H1ß in the COSY spectrum) assigned to H2α on the basis of *trans*-diaxial coupling and nOe studies (vide infra). From the fixed evolution HETCOR experiment, H3α was located in an overlapped region of the spectrum at δ 1.25 (overlapped with H5). The C3 resonance was identical to the methylene carbon enhanced by saturation of H1ß in the earlier mentioned selective INEPT experiment. Thus, the C1 through C3 trimethylene subunit was confirmed.

The sole remaining question of the basic skeleton of **3** was the location of the cyclic ether. Of the three possibilities (C7/C20, C7/C22, and C20/C22), the first could be easily ruled out on the basis of strain. A C7/C20 ether linkage would have required that all four bonds to C20 be on the same face of a plane and this would be impossible for a tetrahedral carbon. A C7/C22 ether would also have involved considerable strain as well as severe steric interactions, most notably between the H21 protons and H6α and H22 and H14. Finally, several nOe spectra strongly favored the C20/C22 ether: a strong nOe observed in the 2D-nOe spectrum between H19α and H2α is incompatible with a C7/C22 ether linkage but is in excellent agreement with the C20/C22 linkage as these two protons only lie an estimated 1.45 Å apart. (Selective INEPT experiments to detect a polarization transfer from either one of the C22 methylene protons to C20 were unsuccessful. This was not surprising since the dihedral angle between C20 and either of the H22 protons is about 120° and therefore only small coupling between these nuclei would be expected.)

With the skeletal assignment **3** finished, all that remained to complete the structure assignment was determination of the stereochemistry of the C7 and C15 alcohol functions. The axial nature of the H7 proton was suggested by its coupling constants with the C6 methylene protons. This was confirmed by the observation of an nOe between H7 and H9 in both the 2D-nOe

[3]In this experiment an enhancement of C10 was also observed (δ 47.1). This enhancement may be the result of the reinforcement (additivity) of scalar coupling via two comparable four-bond pathways. Since we can not unambiguously state that this is the reason, this long-range heteronuclear coupling is not included in Table 3.

[4]The enhancement of C15 upon saturation of H7 was 180° out-of-phase with the enhancements of C8 and C14. Presumably this phase distortion (which is not uncommon) arises from significant differences in the heteronuclear coupling constants.

[a]Spectra were recorded in $CDCl_3$.
[b]Carbon multiplicities were determined by two APT experiments using defocusing delays of 8 and 4 ms (see text).
[c]"o" overlapped; chemical shifts from cross sections in HETCOR spectrum, coupling constants from extensive decoupling experiments.
[d]H11α and H11β were tentatively assigned on the basis of W-coupling between H13β and H11β as observed in the expended COSY spectrum.

and DnOe spectra, requiring that the C7 hydroxyl group be α-oriented. In addition, nOe's between H7 and H5 and H6ß were also observed in the DnOe spectrum, confirming the ß orientation of H7.

A DnOe experiment upon saturation of H15 revealed an nOe with H14 and a weaker nOe with H13ß. Though H14 and H13α were overlapped in the ^{1}H nmr spectrum, the assignment of the nOe to H14 was clear since an nOe was also observed with this same resonance upon saturation of H21ß. Furthermore, an nOe between H15 and H13α is highly unlikely given the extreme distance between these two protons (4.31 Å). Thus, H14, H15, and H21ß all lie on the same face of the molecule.

Other nOe's observed in the 2D-nOe or DnOe spectra enabled completion of the proton assignments. Thus, an nOe from the C18 methyl protons to H19ß, which in turn showed an nOe with H21α, distinguished the nitrogenated C19 and C21 methylene protons. The H21α proton showed an nOe with its *gem* partner, H21ß, which in turn had an nOe with H22ß as well as with H14; H22ß showed nOe's with its *gem* partner, H22α, as well as with H13α, thereby distinguishing the C13 and the C22 methylene protons. (The H14 and H13α resonances were overlapped and in principle the nOe's observed in the 2D-nOe between H21ß and H14, and those between H22ß and H13α, could have been H21ß with H13α and H22ß with H14. Molecular modelling clearly showed that this is unlikely since H14 is significantly closer to H21ß than H13α, 2.32 vs. 3.48 Å, while H22ß is closer to H13α than H14, 2.41 vs. 3.43 Å). In addition, an nOe between H12 and H17a distinguished the exocyclic methylene pair of protons.

The axial protons of the methylene pairs at C1, C3, and C6 (H1ß, H3ß, and H6α) were well resolved and could be assigned as axial on the basis of their coupling constants (Table 1). In addition, H19α showed nOe's with H2α and H3α in the 2D-nOe spectrum. (While the resonance of H2α was overlapped with one of the H11 protons, and H3α was partially overlapped with that of H5, the resolution was sufficient to assign H2α and H3α. Furthermore, an nOe between H19α and either H5 or any of the H11 protons is impossible). Thus, the methylene protons of C1, C2, C3, and C6 were distinguished, leaving only those of C11 unassigned. This last methylene pair was tentatively distinguished on the basis of W-coupling between H13ß with the higher field partner, assigned as H11ß, observed in the COSY spectrum. It must be stressed, however, that this assignment is tentative and made only on the basis that H11ß and H13ß have a near-perfect "W" relationship in molecular models.

Table 2 lists all observed nOe's with the estimated distances

between protons as predicted by MM2 calculations. Table 3 lists the long-range two- and three-bond heteronuclear $^1H/^{13}C$ couplings as observed from selective INEPT experiments.

It is noteworthy that septatisine **3** is the only example of an atisane-type diterpenoid alkaloid in which the C20 carbon of the oxazolidine ring is bridged with C14. In the case of atisine, the oxazolidine ring gives rise to a mixture of two inseparable epimers differing in configuration at C20 (16).

Experimental

General procedures

Melting points are corrected and were determined on a Thomas–Kofler hot stage equipped with a microscope and polarizer. The nmr spectra were recorded on a Varian XL-400 spectrometer (93.94 kG, 400 MHz for ^1H, 100 MHz for ^{13}C). The nmr sample of septatisine was 4 mg dissolved in 0.05 mL $CDCl_3$. Residual $CHCl_3$ and $^{13}CDCl_3$ were used as internal references (^1H: δ 7.24, ^{13}C: δ 77.0) for ^1H and ^{13}C nmr, respectively. The pulse sequences employed in the one- and two-dimensional nmr experiments were the standard Varian software, version 6.1c, except the fixed-evolution HETCOR pulse sequence, which was added to the Varian nmr pulse sequence library based on Reynold's program (17). An evolution time fixed at 0.020 s was employed for the-fixed evolution HETCOR, with a refocusing delay of 0.0019 s ($1/4J$, J = 130 Hz). The hrms spectrum was recorded on a Finnigan MAT 90 instrument (ei, 40 eV); eims was recorded on a Finnigan Quadrupole 4023 mass spectrometer.

Nuclear magnetic resonance multipulse sequences

One-dimensional ^1H nmr spectra were recorded with a spectral window of 4000 Hz and an acquisition time of 2.0 s, giving a digital resolution of 0.5 Hz per point. The spectral window and the acquisition time for one-dimensional ^{13}C nmr spectra were 20 000 Hz and 0.5 s, respectively, giving a digital resolution of 2.0 Hz per point. The ^{13}C multiplicities were assigned by APT experiment. The APT experiment was performed with a spectral window of 20 000 Hz, an acquisition time of 0.5 s, and a defocusing delay of 0.008 s, optimized for one-bond heteronuclear coupling of 125 Hz, in order to get better phased subspectra. A second APT experiment edited for detection of quaternary carbons only was performed with the same spectral window and acquisition time, but with a defocusing delay of 0.004 s (13). Long-range (two and three bond) heteronuclear ^1H, ^{13}C couplings were detected with one-dimensional selective INEPT experiments. The selective INEPT spectra were recorded with the excitation and refocusing delays optimized for different long-range heteronuclear coupling constants according to the formulae $\tau = 1/2J$ and $\delta = 1/3J$, respectively (18).

Isolation of septatisine 3

The basic fraction **C** (0.65 g) (9) was chromatographed on an Al_2O_3 rotor, and eluted with a gradient of hexane, Et_2O, and MeOH. Twelve fractions (50 mL each) were collected. Fractions 11 and 12 collected with 5% and 10% MeOH in Et_2O were combined and the residue (15.1 mg) was purified on a preparative tlc plate (Al_2O_3; 20 cm × 20 cm, 1 mm thick) to afford septatisine **3** (9.2 mg), mp 129–130°C; $[\alpha]^{19}_d$ +30.55 (*c* 0.37, $CHCl_3$); eims: *m/z* 357 (M^+, 33%), 340(70), 329(15), 314(20), 300(6), 286(13), 274(37), 55(50), 41(100). Anal. calcd. for $C_{22}H_{31}NO_3$: C 74.0, H 8.7, N 3.9%; found: C 74.4, H 9.2, N 3.9.

This paper is dedicated to Professors David B. MacLean and Ian Spenser

B. RENSON, P. MERLIN, D. DALOZE, J.C. BRAEKMAN, Y. ROISIN, and J.M. PASTEELS. Can. J. Chem. **72**, 105 (1994).

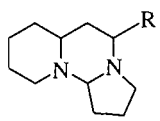
The administration of sodium [1-^{14}C] and [2-^{14}C] acetate, L-[U-^{14}C] glutamic acid, γ-amino [U-^{14}C] butyric acid, L-[U-^{14}C] ornithine hydrochloride, and [1,4-^{14}C] putrescine dihydrochloride to *Tetraponera* sp. ants resulted in the formation, for each feeding experiment, of labelled tetraponerine-8 (**2**). The distribution of radioactivity into **2** was established by chemical degradation. The results obtained favor the hypothesis that the pyrrolidine ring of tetraponerine-8 is derived from L-glutamic acid via L-ornithine and putrescine, while the 12-carbon chain is derived from the combination of six acetate units.

B. RENSON, P. MERLIN, D. DALOZE, J.C. BRAEKMAN, Y. ROISIN et J.M. PASTEELS. Can. J. Chem. **72**, 105 (1994).

L'administration de [1-^{14}C] et [2-^{14}C] acétate de sodium, d'acide L-[U-^{14}C] glutamique, d'acide γ-amino [U-^{14}C] butyrique, de L-[U-^{14}C] ornithine·HCl et de [1,4-^{14}C] putrescine·2HCl à des fourmis de l'espèce *Tetraponera* sp. conduit à l'isolement de tétraponérine-8 radioactive. La distribution de l'activité au sein de la molécule a été déterminée par dégradation chimique. Les résultats obtenus confortent l'hypothèse que le cycle pyrrolidine de la tétraponérine-8 se construit à partir de l'acide L-glutamique via la L-ornithine et la putrescine. La chaîne à 12 atomes de carbone se formerait quant à elle par condensation de six unités acétate.

Introduction

The tetraponerines are a group of tricyclic alkaloids isolated from the venom of the Neo Guinean ant *Tetraponera* sp. (1, 2). These insecticidal substances are 5-alkyldecahydro-pyrido-[1,2-*c*]pyrrolo[1′,2′-*a*] pyrimidines (**1**)[4] differing from each other by the length of the alkyl chain and (or) by the configuration of the cyclic junctions. Such a skeleton is new among natural products. The biosynthetic pathway to the tetraponerines is therefore a matter of particular interest.



1

The aim of the present paper is to shed light on the biosynthetic pathway of the tetraponerine ring system as represented by tetraponerine-8 (**2**), the major constituent of the ant's venom. To this end, we have developed a degradation procedure for **2**, which would allow us to locate radioactivity after administration of ^{14}C-labelled compounds to *Tetraponera* sp. workers to test the likelihood of hypothetical biosynthetic pathways.

Results and discussion

First of all, we needed adequate supplies of **2** to develop a degradation scheme of this alkaloid as well as to serve as carrier for labelled samples of **2** obtained from each feeding experiment. This was achieved by preparing (±)-tetraponerine-8, utilizing the stereoselective total synthesis we recently reported (3, 4).

To evaluate the distribution of label in **2**, the sequence of reactions shown in Fig. 1 was used. The N17—C5 bond[5] could be cleaved selectively by catalytic hydrogenation in the presence of hydrochloric acid. Treatment of the resulting diamine **3** with methanesulfonyl chloride furnished the sulfonamide **4**. Pyrolysis of the tetraalkylammonium hydroxide **5**, obtained by quaternization of **4** with methyl iodide followed by conversion into hydroxide using an anion exchange resin, led to a mixture from which olefin **6** (27–46%) and *N*-methylpyrrolidine (**7**; 25–47%) could be isolated. Interestingly, of the four possible isomeric olefins that might theoretically result from the elimination of *N*-methylpyrrolidine, only isomer **6** (E Δ^9) was obtained. This suggests that the elimination is stereoselective and proceeds preferentially through a E2 *syn* elimination taking place from a *syn*-periplanar conformation (5, 6). The elimination is also regioselective. The absence of a detectable amount of $\Delta^{9(12)}$ isomers can be explained by the influence of the sulfonamide group that renders the C-10 protons of **5** more acidic than the C-12 protons. The volatile *N*-methylpyrrolidine was trapped in liquid nitrogen and converted into its oxalate. The latter could be recrystallized repeatedly without difficulties whereas the corresponding hydrochloride was too hygroscopic to be purified to constant activity by recrystallization. Olefin **6** was further cleaved by oxidation with the mixture $NaIO_4$–$KMnO_4$ (7) into *N*-mesylpipecolic acid and caproic acid, which were purified by chromatography as their *p*-bromophenacyl esters **8** and **9**, respectively.

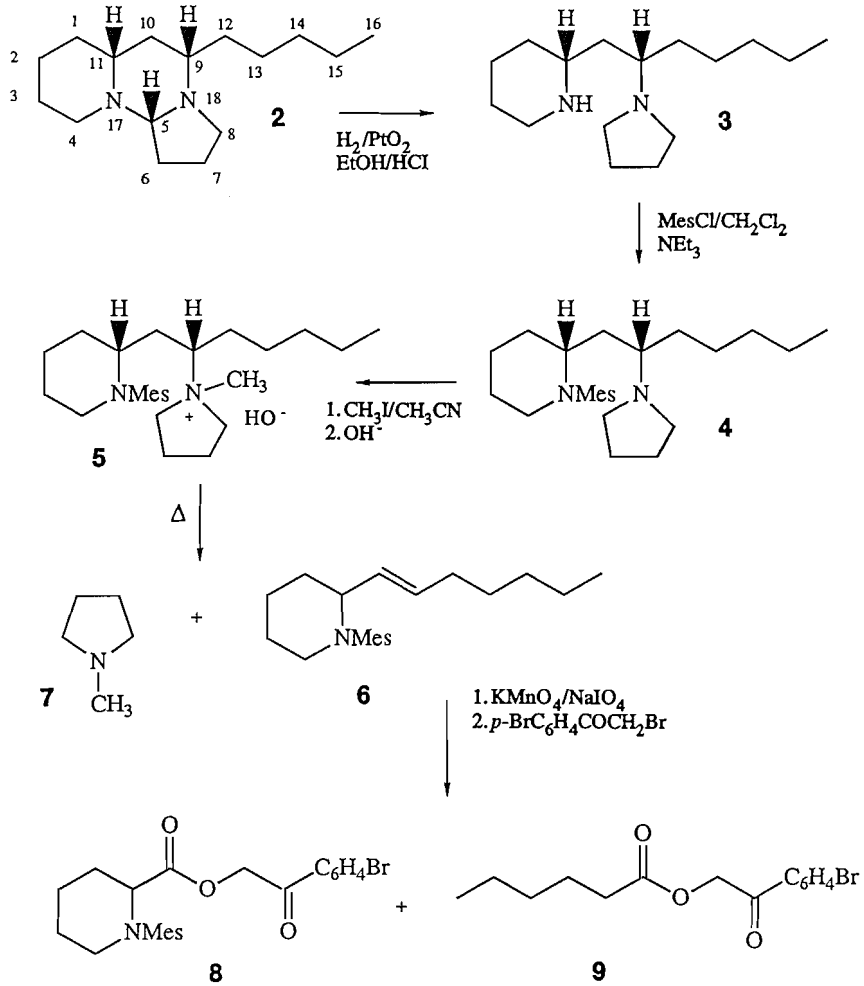

FIG. 1. Degradation of tetraponerine-8.

Insofar as structural relationships can be considered as a guide to biogenesis, the $C_{16}N_2$ skeleton of tetraponerine-8 might be thought to originate by condensation between either a suitably functionalized polyacetate chain such as **10** and putrescine (Fig. 2, pathway A), or a suitably functionalized 2-alkylpiperidine such as **11** and γ-aminobutyric acid (Fig. 2, pathway B). To test these alternative hypotheses, tracer experiments were performed by feeding *Tetraponera* sp. ants with aqueous solutions of sodium [1-^{14}C] and [2-^{14}C] acetate, L-[U-^{14}C] glutamic acid, γ-amino [U-^{14}C] butyric acid, L-[U-^{14}C] ornithine hydrochloride, and [1,4-^{14}C] putrescine dihydrochloride, respectively. A summary of the results of these experiments is presented in Table 1. Each experiment yielded radioactive tetraponerine-8, which was isolated as described in the experimental section. Before applying the degradation scheme of Fig. 1, inactive **2** was added as carrier to each isolated sample. These were then divided in two parts, each of which was separately degraded. After isolation of labelled sulfonamide **4**, inactive **4** was added as carrier and the resulting diluted sample was flash chromatographed repeatedly until constant activity was reached. The relative specific activities measured for the different degradation products are listed in Table 2 for the two replicates.

Sodium [2-^{14}C] acetate proved to be much more efficiently utilized than sodium [1-^{14}C] acetate for the formation of tetraponerine-8. This phenomenon is readily understood when one considers the fate of the carbon atoms of acetic acid when it enters the tricarboxylic acid cycle (8). The samples of tetraponerine-8 derived from the [1-^{14}C] and [2-^{14}C] acetate feeding experiments yielded olefin **6** (corresponding to carbon atoms C-1 to C-4 and C-9 to C-16) and *N*-methylpyrrolidine (**7**, corresponding to carbon atoms C-5 to C-8), which contained about 2/5 and 3/5 of the activity of intact tetraponerine-8, respectively. This suggests that acetate enters into both parts of the molecule by two independent pathways, its incorporation into **7** being more efficient than into olefin **6**. Moreover, within experimental error, the activity of olefin **6** is equally divided between the pipecolic acid moiety (corresponding to carbon atoms C-1 to C-4 and C-10 and C-11) and the caproic acid moiety (corresponding to carbon atoms C-12 to C-16 and C-9), suggesting that the 12-carbon linear chain of tetraponerine-8 might be formed by a linear combination of acetate units.

The results of feeding experiment 3 showed that the pattern of incorporation of activity from L-[U-^{14}C] glutamic acid into the tetraponerine skeleton was similar to that of acetate except that the incorporation into the pyrrolidine moiety was still more efficient than into olefin **6**. This could be explained by admitting that L-glutamic acid is an intermediate between acetate and the pyrrolidine ring moiety of tetraponerine-8 and that this precursor, after having been catabolized into acetate, is also incorporated into the 12-carbon linear chain of tetraponerine-8. It is well known that the two-carbon fragment at the oxidation level

[b]Relative specific activity (%; olefin **6** = 100).

of acetate is derivable from glutamic acid by degradation via α-ketoglutarate and the tricarboxylic acid cycle (9). Moreover, according to classical biogenetic concepts, the pyrrolidine ring of a variety of alkaloids is derived from L-ornithine, which is metabolically interconvertible with L-glutamic acid (10, 11).

Thus, the observed mode of incorporation of these three precursors into tetraponerine-8 is consistent with the hypotheses outlined in Fig. 2. At this stage of the work it was not yet possible to distinguish between the two alternative pathways of incorporation of L-glutamic acid into tetraponerine-8. This demanded additional feeding experiments with γ-amino [U-^{14}C] butyric acid, L-[U-^{14}C] ornithine hydrochloride, and [1,4-^{14}C] putrescine dihydrochloride.

The labelling pattern that was observed after incorporation of γ-aminobutyric acid (experiment 4) was almost identical to that obtained with acetate. This indicates that this acid does not serve as a true intermediate but suffers degradation to acetate. Indeed, γ-aminobutyric acid could enter the tricarboxylic acid ring via succinic semialdehyde and succinic acid (11). Conversely, the results of feeding experiments 5 and 6 were particularly informative. Indeed, L-ornithine and putrescine not only entered the tetraponerine skeleton with high incorporation, and putrescine better than L-ornithine, but the pyrrolidine moiety also contained most of the labelling of intact tetraponerine-8. Such a distribution of the activity led to the inference that these two metabolites serve as specific precursors for the pyrrolidine ring of tetraponerine-8.

It is well established that, in plants, L-ornithine and L-glutamic acid are readily interconverted reversibly while the formation of putrescine from L-ornithine by the action of the enzyme ornithine decarboxylase is an irreversible process (11).

Such pathways seem also to occur in the poison gland of *Tetraponera* sp. since, on incorporation of labelled L-ornithine or L-glutamic acid, some residual activity (15% and 25%, respectively) was recovered in the 12-carbon linear chain, indicating that a certain amount of these amino acids had been catabolized to acetate via the tricarboxylic acid cycle. On the other hand, no residual label could be detected in the carbon atoms of the 12-carbon linear chain after feeding labelled putrescine. All these results support pathway A of the biosynthetic scheme depicted in Fig. 2.

Nothing is known about the precise structure of the 12-carbon intermediate that combines with putrescine to furnish tetraponerine-8. It might be an acid (**10**, R = OH) or an aldehyde (**10**, R = H) similar to **10**. The latter can be regarded either as an oxidized derivative of lauric acid or as a degradation product resulting from the cleavage of, for example, an 18-carbon polyunsaturated fatty acid. Such processes of fracture are well documented and are known to proceed through cleavage of peroxidic fatty acids by a lyase to form aldehydes (11, 12).

In the plant kingdom, the couple ornithine/putrescine is the precursor of the atoms of the pyrrolidine ring of many alkaloids, e.g., the pyrrolizidine alkaloids, nicotine, hygrine, and some tropane alkaloids (10, 11, 13). The results we have presented here demonstrate that such a biogenetic pathway also takes place in the ant *Tetraponera* sp. It is the first time that this has been evidenced in the animal kingdom. Further feeding experiments are in progress to refine the biosynthetic scheme depicted in Fig. 2 (pathway A) and to investigate the biosynthesis of the other tetraponerines present in the defence secretion.

Experimental

General methods

The ^1H and ^{13}C nmr spectra were recorded in $CDCl_3$ at 250 and 62.8 MHz, respectively, using a Bruker WM 250 spectrometer. Chemical shifts are quoted in δ values downfield from internal TMS. Data are reported as follows: chemical shift (multiplicity (s = singlet, d = doublet, t = triplet, m = multiplet, br = broad), coupling constants in hertz, integration, assignment). The ir spectra were taken with a Bruker IFS 25 instrument. Electron impact mass spectra were recorded on a VG Micromass 7070 F spectrometer. Gas chromatographic (gc) analyses were carried out on a Varian 3700 apparatus using a PDMS capillary column (25 m) and tlc on neutral aluminium oxide $60F_{254}$ (type E; Merck) or silica gel Sil G/UV_{254} (0.25 mm; Macherey–Nagel) precoated plates. Silica gel column chromatographies were performed on silica gel 60 columns (0.04–0.063 mm; Macherey–Nagel) by the flash technique (14) or on Lobar pre-packed columns (size A (240-10); Lichroprep Si 60 (0.04–0.063 mm)). Alumina chromatographies were carried out on neutral aluminium oxide columns (Macherey–Nagel). Radioactive compounds were assayed in a Packard Tri-Carb 1600 TR liquid scintillation analyser using as solvent MeOH (100 μL) with Packard Insta-Gel liquid scintillation cocktail (10 mL). Triplicate samples of each compound were counted under comparable conditions of quenching.

Incorporation experiments

Tetraponera sp. ants (about 1000 per batch) were collected near Bogia along the North coast of Papua New Guinea. Hollow twigs housing ants were kept in 50 × 35 cm plastic trays. Water was provided ad libitum. After 3 days of starvation, the ants were fed with 1 mL of an aqueous solution of sucrose (1 M) containing the labelled precursor. They were killed 10 days later by dropping them into vials containing methanol. The extraction of the alkaloids and the purification of tetraponerine-8 (**2**) were performed as described in ref. 2. The results obtained from the different feeding experiments are reported in Table 1.

Degradation of tetraponerine-8

Each labelled sample of tetraponerine-8 was degraded in duplicate. Results of both replications are presented in Table 2.

Conversion of tetraponerine-8 (2) into sulfonamide 4

Typically, tetraponerine-8 (14.9 mg) was dissolved in ethanol (15 mL), HCl (12.5 N, 0.2 mL) and PtO_2 (7.5 mg) were added, and the mixture was stirred during 1 h under an atmosphere of hydrogen. The catalyst was filtered off and the solution evaporated to dryness in vacuo. The solid residue was dissolved in CH_2Cl_2 and the resulting organic phase was washed with an aqueous solution of NaOH (2 N) and evaporated to dryness. The resulting oil was dissolved in dry CH_2Cl_2 (7 mL), triethylamine (158 μL) and mesyl chloride (56 μL) were added at –78°C, and the solution was then allowed to warm up to room temperature. After evaporation of the solvent the residue was dissolved in CH_2Cl_2 (10 mL), and the organic phase was washed with an aqueous solution of ammonia (1.25%) and evaporated to dryness in vacuo. The resulting yellowish oil was then chromatographed over alumina (eluent: CH_2Cl_2–AcOEt 8:2). This yielded pure sulfonamide **4** (10.9 mg, yield: 55%). Spectral properties of **4**: ir (NaCl film): 2860 and 2796 (Bohlmann bands), 1326 and 1146 (SO_2 asymmetric and symmetric stretchings) cm^{-1}; ^1H nmr: 0.89 (t, 7, 3H, H_3C-16), 1.3–1.8 (m, 16H, CH_2), 1.95 (br s, 4H, H_2C-6 + H_2C-7), 2.05 (m, 1H, HC-9), 2.88 (s, 3H, SO_2CH_3), 2.41–2.77 (m, 4H, H_2C-5 + H_2C-8), 3.06 (ddd, 13/13/3, 1H, HaxC-4), 3.70 (brd, 1H, HeqC-4), 4.13 (m, 1H, HC-11); ^{13}C nmr: 14.0 (C-16), 18.6 (C-2), 22.6 (C-15), 23.7 (C-6, C-7), 25.2 and 25.7 (C-3, C-14), 28.4 (C-13), 30.2, 32.0 and 32.3 (C-1, C-10, C-12), 40.7 (C-4), 40.8 (-SO_2CH_3), 49.7 (C-11), 50.5 (C-5 + C-8), 60.9 (C-9); ms *m/z*: 330 ($M^{+\cdot}$, 1%), 259 ($M^{+\cdot} - C_5H_{11}\cdot$, 34), 162 ($M^{+\cdot} - C_{11}H_{22}N\cdot$, 100), 154 ($M^{+\cdot} - C_7H_{14}NO_2S\cdot$, 89), 98 ($C_6H_{12}N^+$, 5), 84 ($C_5H_{10}N^+$, 9), 70 ($C_4H_8N^+$, 5).

Hofmann degradation

Typically, freshly distilled methyl iodide (25 μL) was added to a solution of sulfonamide **4** (9.2 mg) in acetonitrile (0.5 mL) and the mixture stirred at room temperature for 3 h. After evaporation of the solvent, the solid residue was dissolved in MeOH (1 mL) and the solution eluted with water through a strongly basic anion exchanger column (Amberlite IRA-400, OH^-). The fractions containing the tetraalkylammonium hydroxyde **5** (positive Dragendorff and phenolphthalein tests) were combined and evaporated to dryness under vacuum. The residual yellowish oil was then pyrolyzed at 170°C for 3 h. The volatile components were caught in a liquid nitrogen trap, dissolved in acetone, and analyzed by capillary gc (CPWAX 52B, 120°C). The chromatogram showed a major peak whose retention time was identical (coinjection) to that of an authentic sample of *N*-methylpyrrolidine. Oxalic acid (2.5 mg) was then added to the acetone solution. After evaporation of the solvent, the resulting solid was recrystallized from acetone; this furnished *N*-methylpyrrolidine oxalate (2.3 mg, yield: 47%, mp 99–100°C). Flash chromatography of the solid residue of pyrolysis over silica gel (eluent: hexane–AcOEt 8:2) furnished olefin **6** (3 mg, yield: 41%). Spectral properties of **6**: ir (NaCl film): 1334 and 1146 (SO_2 asymmetric and symmetric stretchings) cm^{-1}; ^1H nmr (C_6D_6): 0.88 (t, 7, 3H, HC-16), 1.10–1.60 (m, 12H, CH_2), 1.87 (dt, 6/7, 2H, H_2C-12), 2.31 (s, 3H, SO_2CH_3), 2.56 (ddd, 13/13/2, 1H, HaxC-4), 3.50 (br d, 1H, HeqC-4), 4.52 (m, 1H, HC-11), 5.42 (ddt, 15.5/7/<1, 1H, HC-10), 5.55 (ddt, 15.5/0.5/6, 1H, HC-9); ^{13}C nmr (C_6D_6): 14.0 (C-16), 19.0 (C-2), 22.5 (C-15), 25.6 (C-3), 28.8 (C-13), 31.0, 31.4 and 32.4 (C-1, C-12, C-14), 38.7 (-SO_2CH_3), 41.4 (C-4), 55.0 (C-11), 125.6 (C-9), 134.9 (C-10); ms *m/z*: 259 ($M^{+\cdot}$, 8%), 188 ($M^{+\cdot} - C_5H_{11}\cdot$, 42), 180 ($M^{+\cdot} - CH_3SO_2\cdot$, 96), 162 ($M^{+\cdot} - C_7H_{13}\cdot$, 100), 84 ($C_5H_{10}N^+$, 36).

Lemieux – von Rudloff oxydation of 6

Typically, olefin **6** (2.9 mg) was dissolved in freshly distilled dioxane (3 mL); aqueous solutions of K_2CO_3 (3.8×10^{-2} M, 1 mL), $NaIO_4$ (0.1 M, 1 mL), and $KMnO_4$ (1.7×10^{-3} M, 1 mL) were added and the mixture was stirred at room temperature. The evolution of the reaction was monitored by tlc. After 24 h, 1 mL of each solution was added again. The reaction was complete after 80 h. The mixture was evaporated to dryness and the residue dissolved in CH_2Cl_2 (5 mL). The organic phase was washed with an aqueous solution of HCl (1 N) and evaporated to dryness. The residue was dissolved in MeOH (1 mL) and

the pH adjusted to 8.5 by adding dropwise a methanolic solution of KOH (0.01 N). The resulting solution was again evaporated to dryness and the residue dissolved into freshly distilled acetonitrile; *p*-bromophenacyl bromide (8 mg) and dicyclohexano-18-crown-6 ether (0.6 mg) were added and the mixture was refluxed for 1 h. The residue obtained after evaporation of the solvent was flash chromatographed on a silica gel column (eluent: toluene–AcOEt 99:1). This yielded *p*-bromophenacyl caproate (2.3 mg, yield: 65%) and *p*-bromophenacyl *N*-mesylpipecolate (2.7 mg, yield: 60%) successively. Spectral properties of **8**: ir (NaCl film): 1748 (ester C=O stretching), 1704 (arylketone C=O stretching), 1586 (phenyl C=C stretching), 1326 and 1148 (SO_2 asymmetric and symmetric stretchings) cm^{-1}; ^1H nmr: 1.20–2.00 (m, 5H, CH_2), 2.37 (br d, 1H, HeqC-1), 2.93 (s, 3H, SO_2CH_3), 3.28 (ddd, 12/12/3, 1H, HaxC-4), 3.73 (br d, 1H, HeqC-4), 4.92 (dd, 3.5/<1, 1H, HC-11), 5.29 (d, 16.5, 1H, OCH), 5.47 (d, 16.5, 1H, OCH'), 7.65 and 7.77 (aromatic protons); ms *m/z*: 406/404 ($[M + H]^+$), 326/324 ($M^{+\cdot} - CH_3SO_2\cdot$), 206 ($C_7H_{12}NO_4S^+$), 190 ($C_7H_{12}NO_3S^+$), 185/183 ($C_7H_4OBr^+$), 162 ($C_6H_{12}NO_2S^+$), 157/155 ($C_6H_4Br^+$), 84 ($C_5H_{10}N^+$). Spectral properties of **9**: ir (NaCl film): 1744 (ester C=O stretching), 1700 (arylketone C=O stretching), 1586 (phenyl C=C stretching) cm^{-1}; ^1H nmr: 0.91 (t, 7, 3H, H_3C-16), 1.26 –1.42 (m, 4H, H_2C-15 + H_2C-14), 1.70 (m, 2H, H_2C-13), 2.48 (t, 7.5, 2H, H_2C-12), 5.27 (s, 2H, OCH_2), 7.63 and 7.78 (aromatic protons); ms *m/z*: 314/312 ($M^{+\cdot}$), 216/214 ($M^{+\cdot} - C_6H_{10}O\cdot$), 200/198 ($M^{+\cdot} - C_6H_{10}O_2\cdot$), 185/183 ($C_7H_4OBr^+$), 157/155 ($C_6H_4Br^+$).

Synthesis of (2*S*,4*S*)- and (2*S*,4*R*)-[5,5,5-$^2H_3$] leucine from (*R*)-pulegone[1]

RICHARD K. HILL,[2] CLAUDIO ABÄCHERLI, AND SANJI HAGISHITA
Department of Chemistry, University of Georgia, Athens, GA 30602, U.S.A.

Received June 14, 1993

This paper is dedicated to Professors Ian Spenser and David B. MacLean

RICHARD K. HILL, CLAUDIO ABÄCHERLI, and SANJI HAGISHITA. Can. J. Chem. **72**, 110 (1994).

Beginning with (*R*)-pulegone, a CD_3 group attached to the stereogenic center containing CH_3 has been created by conversion to citronellal-1-*d*, exchange of the acidic hydrogens at C-2 by deuterium, and decarbonylation with Wilkinson's catalyst. Oxidation to isovaleric acid-d_3 and conversion to leucine by standard procedures gave the (2*S*,4*S*) and (2*R*,4*S*) diastereomers (**10** and **12**) of [5,5,5-$^2H_3$]leucine.

RICHARD K. HILL, CLAUDIO ABÄCHERLI et SANJI HAGISHITA. Can. J. Chem. **72**, 110 (1994).

Utilisant la (*R*)-pulégone comme produit de départ, on a créé un groupe CD_3 attaché au centre stéréogénique contenant le CH_3 par une transformation du produit de départ en citronellal-1-*d* suivie d'un échange des hydrogènes acides en C-2 par du deutérium et finalement d'une décarbonylation à l'aide du catalyseur de Wilkinson. Une oxydation en acide isovalérique-d_3 suivie de sa transformation en leucine par des techniques standard conduit aux diastéréoisomères (2*S*,4*S*) et (2*R*,4*S*) (**10** et **12**) de la [5,5,5-$^2H_3$]leucine.

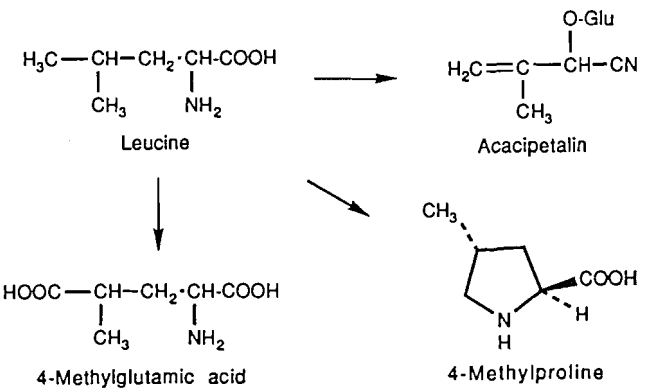
The amino acid leucine is a biosynthetic precursor of a number of varied natural products. The impetus of this paper is the existence and projected study of biosynthetic pathways in which one of the methyl groups of leucine is functionalized; examples (Scheme 1) include (*a*) dehydrogenation of one methyl to yield the isopropenyl moiety of acacipetalin and related cyanolipids (1); (*b*) oxidation of one methyl to afford *erythro* 4-methylglutamic acid in seedlings of *Gleditsia triacanthos* (2); and (*c*) bond formation between one methyl and nitrogen to provide the *trans*-4-methylproline unit of the monamycin antibiotics in *Streptomyces jamaicensis* (3).

These enzymatic oxidations of the leucine methyl group pose an interesting stereochemical question. The two methyl groups are diastereotopic, and consequently enzymatic attack is likely to be specific for just one methyl in each biosynthetic pathway. Experimental investigations to test such questions (4) require samples of leucine specifically labelled in either the *pro-R* or *pro-S* methyl. Indeed, an elegant study by Fuganti and coworkers (5) used a specifically ^{13}C-labelled leucine for incorporation into the C_5-isoprenoid units of echinuline and flavoglaucine.

Three synthetic routes to specific ^{13}C-methyl-labeled leucine samples have been published. In the first, Fuganti and co-workers (5) began with the enantiomers of [1-^{13}C]2-methyl-4-phenylbutanoic acid to incorporate ^{13}C stereospecifically into the *pro-R* and *pro-S* methyls of leucine. Later, Stevens and coworkers (6) prepared (2*S*,4*S*)-[5-^{13}C]leucine enzymatically from either ^{13}C-labeled acetolactate or (2*S*,3*S*)-[4-^{13}C]valine in cultures of an *Escherichia coli* strain. Finally, Aberhart and Weiller (7) also prepared a ^{13}C-labeled leucine from specifically labeled valine, by a chemical route.

Leucine "chirally" labelled with deuterium in one of the methyls has not been reported. While the methods used for $^{13}CH_3$-leucine would certainly be amenable to the preparation of CD_3-leucine, we considered that it would be advantageous in preparing this material to begin with a naturally occurring substance of high optical purity in which the "difficult" stereogenic center at C-4 is already present. One member of the "chiral pool" that appeared attractive is citronellal. Natural citronellal, however, has been shown to possess considerably less than 100% enantiomeric purity (8) and so, following the example of Overberger and Kaye (8*c*), (*R*)-(+)-pulegone was selected as an alternative source of the stereogenic center at C-5. The reaction scheme chosen to convert pulegone to optically pure leucine-5,5,5-d_3 is shown in Scheme 2.



SCHEME 1. Enzymatic transformations of a leucine methyl group.

(*R*)-Pulegone **1** was converted to (*R*)-citronellic acid **2** (R = H) by the published procedure (8*c*, 9). Reduction of the methyl ester **2** (R = CH_3) with lithium aluminum deuteride gave citronellol-1,1-d_2 **3**, which could be oxidized by pyridinium chlorochromate to citronellal-1-*d* **4**. The acidic hydrogens at C-2 were exchanged for deuterium by several exchanges with Na_2CO_3 in D_2O–CH_3OD, leading to citronellal-1,2,2-d_3 **5**.

In the key step, decarbonylation of the aldehyde was achieved with Wilkinson's catalyst, affording (6*S*)-[7,7,7-$^2H_3$]-2,6-dimethyl-2-heptene **6**, in which the pivotal asymmetric center containing methyl and trideuteriomethyl has been introduced with unambiguous configuration and conservation of the enantiomeric purity of pulegone. The double bond of **6** was oxidized by the Lemieux–Rudloff procedure (10) to (4*S*)-[5,5,5-$^2H_3$]-4-methylpentanoic acid **7**. The amino group was intro-

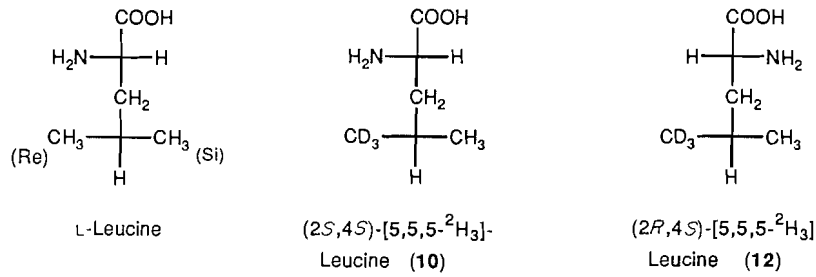

FIG. 1. Fischer projections of labeled leucines.

duced in the usual way by α-bromination followed by ammonolysis, and the amino acid was resolved by hog kidney acylase-catalyzed hydrolysis of the *N*-acetyl derivative **9**. This reaction yielded the (2*S*,4*S*) diastereomer **10** of leucine-5-d_3, and acid hydrolysis of the recovered amide **11** gave the (2*R*,4*S*) diastereomer **12**.

NMR spectra

Although the diastereomeric methyls of leucine cannot be differentiated in proton NMR spectra taken in D_2O or in acid solution, addition of base resolves the methyl signals into two distinct doublets, one centered at δ 0.701 and one at 0.718 ppm,[3] with a coupling constant of 6.1 Hz. This allows the diastereomeric purity of the synthetic samples to be analyzed.

The ^1H NMR spectrum of our synthetic (2*S*,4*S*)-[5,5,5-$^2H_3$]leucine **10** showed only the three-proton doublet at δ 0.718, while (2*R*,4*S*)-[5,5,5-$^2H_3$]leucine **12** showed only the doublet at δ 0.701 ppm, confir ming the stereochemical purity at C-4. Additional confirmation came from the ^2H NMR spectrum of **12**, which showed only a single CD_3 signal.[4] Finally, the ^{13}C NMR spectrum of **12** in alkaline solution showed only the upfield methyl signal at −45.17 ppm (relative to dioxan), while L-leucine displays two methyl signals at −45.05 and −43.89 ppm. The downfield methyl signal essentially disappears from the spectrum as a result of the broadening by three deuterium atoms (11).

These results demonstrate that in both the proton and carbon NMR spectra of leucine taken in alkaline solution, the upfield methyl signal is due to the *pro-S* methyl group (more appropriately, using the nomenclature of Prelog and Helmchen (12), the Re methyl group), while the downfield methyl signal is due to the *pro-R*, or Si, methyl. These methyls are identified in the Fischer projections shown in Fig. 1.

These conclusions seem to differ from those of Fuganti and co-workers (5), who assigned the upfield NMR signal to the *pro-R* methyl. The source of the difference lies in the stereochemical designators, not in actual configurations, since we come to the same conclusion in terms of structural formulae.

[3]The spectra were taken on samples dissolved in D_2O containing NaOH, using dioxan as an internal reference; the hydrogen δ values cited have been converted to the TMS scale by adding 3.57 (the chemical shift of dioxan relative to TMS) to the observed values.

[4]We thank Dr. Andrew Evans, JEOL, for his assistance in obtaining the deuterium NMR spectrum.

For personal use only.

The configuration at C-4 is erroneously assigned in ref. 5, where it appears that the Cahn–Ingold–Prelog rules were used incorrectly (13).[5]

This investigation has provided a source of two diastereomers of CD_3-leucine of fixed configuration at C-4, which should prove useful in biosynthetic studies of enzymatic reactions involving attack at a leucine methyl.

Experimental

NMR spectra were recorded on a JEOL PTF-100 spectrometer; samples were dissolved in $CDCl_3$, using TMS as an internal standard unless otherwise noted. Optical rotations were measured on a Perkin–Elmer 141 polarimeter in a 1-dm tube at the sodium D line. IR spectra were recorded on a Perkin–Elmer 257 spectrometer. Melting points are uncorrected.

(R)-(+)-Citronellic acid (**2**, R = H) was prepared from (+)-pulegone (Aldrich Chemical Co., $[\alpha]_D^{25}$ +21.5 (neat)) as described by Plesek (9) and Overberger and Kaye (8*c*). The twice-distilled acid had $[\alpha]_D^{25}$ +7.73 (neat). The infrared and NMR spectra were identical with those reported. The *methyl ester* (**2**, R = CH_3), bp 115°C (15 Torr; 1 Torr = 133.3 Pa) was prepared from diazomethane and had $[\alpha]_D^{25}$ +4.99 (neat) (lit. (9) $[\alpha]_D^{25}$ +5.45 (neat)).

(R)-[1,1-$^2H_2$]Citronellol (**3**) was prepared by reduction of methyl citronellate with lithium aluminum deuteride in THF, as described for the reduction of citronellic acid with lithium aluminum hydride (8, 9). The alcohol showed $[\alpha]_D^{25}$ +4.54 (neat) (lit. (9) $[\alpha]_D^{25}$ +5.37 (neat) for the unlabeled alcohol). IR (neat): 3330 (OH), 2910, 2200 and 2090 (C-D), 1450, 1375, 970, 825 cm^{-1}. NMR ($CDCl_3$) δ: 5.2 (1H, t, J = 6.0 Hz), 2.75 (1H, s), 1.73 (3H, s), 1.66 (3H, s), 0.93 (3H, d, J = 5.5 Hz), 2.5–1.0 (m). ^{13}C NMR δ: 131.13, 124.85, 60.17 (m, J = 22 Hz, CD_2OH), 39.75, 37.37, 29.32, 25.72, 25.60, 19.63, 17.68.

(R)-[1-$^2H_1$]Citronellal (**4**)

A solution of 9.75g of **3** in dry CH_2Cl_2 was added to a stirred suspension of 20.33g of pyridinium chlorochromate and 1.5g of sodium acetate in 75 mL of CH_2Cl_2. The mixture warmed slightly, turned black, and deposited a tarry material. After 2.5h at room temperature the solution was diluted with 200 mL ether, decanted from the gummy residue, and the residue was washed with several portions of warm ether until it became granular. The combined organic phases containing suspended fines were filtered through a 2 × 20 cm column of silica gel; the eluate was concentrated at reduced pressure and distilled at 105°C (1 Torr), giving 7.22g of the aldehyde. Redistillation gave 6.71g of citronellal, $[\alpha]_D^{25}$ +10.08 (neat); Pino and O'Donnell (8*a*, *b*) calculate rotations of +16.4 and +15.9 for the unlabeled aldehyde. IR (neat): 2910, 2070 (C-D), 1715, 1450, 1375, 1092, 825 cm^{-1}. NMR ($CDCl_3$)δ: 5.16 (1H, t, J = 7.0 Hz), 1.70 (3H, s), 1.62 (3H, s), 1.0 (3H, d, J = 6.0 Hz), 2.4–1.0 (m).

(R)-(+)-[1,2,2-$^2H_3$]Citronellal (5)

A solution containing 1.5g of **4**, 180 mg of anhydrous sodium carbonate, 8.0 mL of CH_3OD, and 2 mL of D_2O was refluxed for 15 min with exclusion of moisture, then distilled at atmospheric pressure to remove the solvents. Fresh CH_3OD (6.0 mL) was added and the mixture was again refluxed for 15 min and concentrated, then 5 mL CH_3OD and 1 mL D_2O were added and refluxed for 15 min. The mixture was concentrated, diluted with 4.0 mL of D_2O, and extracted with ether (3 × 50 mL). After drying and removal of the ether, the residue was distilled in a kugelrohr at 0.5 Torr and 105°C, giving 964 mg of **5**, $[\alpha]_D^{25}$ +12.67 (neat). IR (neat): 2915, 2090, 2040, 1710, 1450, 1375, 1085, 830 cm^{-1}. NMR (acetone-d_6) δ: 5.12 (1H, t, J = 6 Hz), 2.05 (3H, m), 1.66 (3H, s), 1.60 (3H, s), 1.4–1.1 (m), 0.95 (3H, d, J = 6.3 Hz). A barely discernible trace of the C-2 and C-1 protons was seen.

[5]The Standard Sub-rules for sequence ordering (p. 391) specify that higher atomic number precedes lower, and that this rule must be followed to exhaustion before considering atomic mass. Thus, $^{12}CH_2CH(NH_2)COOH$ must precede $^{13}CH_3$.

(S)-[5,5,5-$^2H_3$]-4-Methylpentanoic acid (7)

(a) Decarbonylation

A solution of 3.50g of **5** in 5.0 mL of freshly distilled benzonitrile was added to a suspension of 20g of tris(triphenylphosphine)rhodium chloride in 75 mL of benzonitrile, and the mixture was stirred and heated at 150–160°C under nitrogen for 1.5 h. The flask was then equipped for simple distillation and two fractions were collected, the first at bp 170–183°C, and a second of bp 190–200°C. Each was redistilled in a kugelrohr; the fraction of boiling range 145–160°C (1.79g) was mostly alkene **6**, contaminated with benzonitrile, but since further fractionation did not effect complete separation, this impure material was used in the next step. NMR ($CDCl_3$) δ: 5.2 (1H, poorly resolved triplet), 1.72 (3H, s), 1.63 (3H, s), 0.93 (3H, d, J = 5.0 Hz), 2.2–0.8 (m).

(b) Oxidation

A solution of 1.50g of impure **6** in 20 mL of acetone was added to a mixture of 10.8g of $NaIO_4$ and 3.4g of K_2CO_3 in 40 mL of water at 0°C. After 10 min, a solution of 375 mg of $KMnO_4$ in 12 mL of water was added dropwise, and the mixture was stirred overnight. The mixture was washed with ether (50 mL), acidified to Congo Red, shaken with sodium thiosulfate solution to remove the iodine, then extracted with ether (3 × 50 mL). The extracts were dried and concentrated, and the residue was distilled in a kugelrohr at 200°C, affording 351 mg of **7**. IR (neat): 2975, 2930, 2200 and 2055 (C-D), 1710, 1410, 1280, 1050, 930 cm^{-1}. NMR ($CDCl_3$) δ: 11.33 (1H, s), 2.38 (2H, t, J = 7.0 Hz), 1.57 (3H, m), 0.90 (3H, d, J = 5.5 Hz). The anilide, needles after recrystallization from hexane, had mp 108°C, (lit. (14) mp 109.5–110.5°C).

(2RS, 4S)-[5,5,5-$^2H_3$]-N-Acetylleucine (9)

(a) Bromination (cf. ref. 15)

To 500 mg of **7** and 900 mg of Br_2 was added a crystal of I_2 and 2 drops of PCl_3, and the mixture was stirred overnight at 60°C under a water-cooled condenser. Another drop of PCl_3 and 100 mg Br_2 were added and the mixture was heated 2 h at 100–110°C. The mixture was cooled, dissolved in 8 mL of saturated $NaHCO_3$ solution, washed with ether, acidified to Congo Red with 50% H_2SO_4, and extracted with ether (3 × 10 mL). After drying and concentration, distillation of the residue in a kugelrohr gave 525 mg of the bromoacid **8**, bp 135–140°C (15 Torr).

(b) Amination

A solution of the bromoacid (525 mg) in 12 mL of 27% NH_4OH was tightly stoppered and kept 9 days at room temperature. After concentration at reduced pressure to remove excess ammonia, the residue was acidified with 6 N HCl to Congo Red, washed with ether (2 × 30 mL), and concentrated to a small volume at reduced pressure. The residue was applied to a cation exchange resin column (1.5 × 15 cm, Bio-Rad AG 50W X4 200–400 mesh, H^+ form); the column was rinsed with 3 volumes of water and eluted with 1 N HCl. The fractions containing leucine hydrochloride were concentrated at reduced pressure, taken up in a small volume of water, and applied to a column of Dowex 1 X5, 20–50 mesh, anion exchange resin in the formate form. The column was eluted with water, eluting leucine (475 mg) immediately after the void volume.

(c) Acetylation

A solution of 193 mg of the crude leucine-d_3 in 2 mL of boiling glacial acetic acid was treated with 150 mg of acetic anhydride, refluxed for 5 min, and allowed to cool to room temperature over 2 h. Concentration left an oily residue, which partly crystallized on standing overnight in a desiccator. Warm acetone was added, the mixture was filtered, and the filtrate was concentrated to an oil that was taken up in 4 mL of boiling water. On cooling and seeding, a crop of 74 mg of crystals was collected, mp 156–160°C (lit. (16) mp 157–159°C for nondeuterated *N*-acetylleucine). A second crop of 32 mg was obtained by extraction of the filtrate with ethyl acetate, concentration, and crystallization from water.

Enzymatic resolution

A solution of 105 mg of **9** in 10 mL of water, adjusted to pH 7.4 with 0.5 N LiOH and 0.1 N acetic acid, was incubated with 2.3 mg of hog kidney Acylase I (Sigma, specific activity 1800 units/ mg) at 37°C for 140 min, at which time the pH was 7.0. Another 2.6 mg of the enzyme was added and incubation continued for 2 h. The mixture was heated to boiling for 30 s and quickly cooled in ice, filtered, and the pH was adjusted to 5.0 with dilute acetic acid. After concentrating to 2.5 mL, the solution was passed through a 1 × 12 cm column of BioRad AG 50W X4 (H^+) ion exchange resin and eluted with 5 volumes of water. The first two 10- mL fractions contained amide **11**, which was recrystallized from water to give 55 mg of (2*R*,4*S*)-[5,5,5-$^2H_3$]-*N*- acetylleucine, mp 179–181°C (lit. (17) mp 185°C for *N*-acetyl-D-leucine), $[\alpha]_D^{20}$ +21.9 (*c* 1 in 96% ethanol); *N*-acetyl-D-leucine is reported (17) to have $[\alpha]_D^{20}$ −21.3.

Elution of the ion-exchange column was continued with 1 N HCl; concentration of the first three acidic fractions gave the crystalline hydrochloride of **10**, which was taken up in 4 mL of water and applied to a column (1 × 10 cm) of Dowex 1 X8 resin (formate form). Slow elution with water, stopping when the eluate became acidic, and lyophilization of the eluate gave a solid residue, which was recrystallized from 80% ethanol to give 20 mg of (2*S*,4*S*)-[5,5,5-$^2H_3$]leucine (**10**), $[\alpha]_D^{20}$ +12.2 (*c* 0.45 in 6 N HCl); the rotation of L-leucine under these conditions was +14.4.

*(2R,4S)-5,5,5-$^2H_3$]Leucine **12***

Hydrolysis of **11** in refluxing 2 N HCl for 2h, followed by ion-exchange chromatography as described for **10**, gave **12**, $[\alpha]_D^{20}$ −12.8 (*c* 0.47 in 6 N HCl).

NMR spectra of labelled leucines

Proton NMR spectra were run on samples of 3.0 mg leucine and 12 mg NaOH in 0.60 mL of D_2O, using dioxane as an internal reference. Chemical shifts were converted to usual values, relative to TMS, by adding 3.57, the chemical shift of dioxane in D_2O.

Received July 26, 1993

This paper is dedicated to Professors Ian Spenser and David B. MacLean

RICHARD B. HERBERT, BARRIE WILKINSON, and GEORGE J. ELLAMES. Can. J. Chem. **72**, 114 (1994).

A unique aldolase, which was isolated from *Streptomyces amakusaensis*, is used to catalyse a reverse aldol reaction on representative racemic ß-hydroxy-α-amino acids (**3–6**) to give samples of the (2*R*,3*S*)-(D-*threo*)-enantiomers with excellent enantiomeric purity.

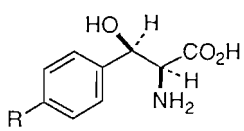
RICHARD B. HERBERT, BARRIE WILKINSON et GEORGE J. ELLAMES. Can. J. Chem. **72**, 114 (1994).

On a utilisé un enzyme unique, une aldolase isolée du *Streptomyces amakusaensis*, pour catalyser une réaction aldolique inverse sur des acides ß-hydroxy-a-aminés racémiques représentatifs (**3–6**); on obtient ainsi des énantiomères (2*R*,3*S*)-(D-*thréo*) avec une excellent pureté énantiomérique.

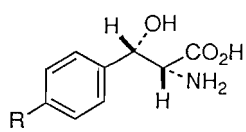
[Traduit par la rédaction]

β-Hydroxy-α-amino acids are important compounds. They are found both as naturally occurring compounds in their own right, for example, *threo*-β-hydroxyhistidine (1), and also as constituents of a range of antibiotics (refs. 2, 3, and refs. cited in ref. 4), for example, vancomycin (2). The synthesis of these amino acids is thus of importance, an importance which is increased by their use as intermediates in the synthesis of natural products, for example, β-lactams (5–7). It follows that the provision of these β-hydroxy-α-amino acids by synthesis has value and this is enhanced if they can be synthesized in homochiral form.

The synthesis of these amino acids has been achieved by a number of chemical methods (8). We have found one of these methods to have particular value (9) and have used it for the synthesis of (2*S*,3*R*)- and (2*R*,3*S*)-3-(4-hydroxyphenyl)serine, **1** and **3**, respectively, and (2*S*,3*R*)- and (2*R*,3*S*)-3-phenylserine, **2** and **4**, respectively (10); we have used these compounds here as reference materials.

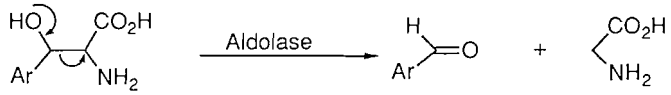


1 R = OH
2 R = H



3 R = OH
4 R = H
5 R = Br
6 R = NO_2

There has been very limited success in the use of enzymes for the chiral synthesis of β-hydroxy-α-amino acids (4, 11, 12). However, we have recently isolated (10) a novel aldolase from cultures of *Streptomyces amakusaensis* (ATCC 23876) that catalyses the conversion of β-hydroxy-α-amino acids (**7**) into the corresponding aldehyde (**8**) plus glycine (**9**) [Scheme 1]. The aldolase is easily isolated, is stable, shows broad substrate tolerance, is highly selective for *threo* stereochemistry and, where examined, is stereospecific for the (2*S*,3*R*) configuration (as **1**).



7 **8** **9**

SCHEME 1

Such a list of properties augers well for applications in synthesis and we report here on the use of the aldolase to prepare, very economically, four typical aromatic compounds of this type with (2*R*,3*S*) stereochemistry. This is an approach that we believe can find wide routine application.

Our current approach has been to synthesize, by straightforward chemical means, racemic *threo*-β-hydroxy-α-amino acids and this is then followed by enzyme-catalyzed resolution. The racemic *threo* isomer, which is thermodynamically favoured, is generally obtained as the major, if not exclusive, product of chemical synthesis. Incubation of this material with the aldolase results in lysis of the (2*S*,3*R*) isomer (as **1**) leaving the antipodal compound unchanged. The (2*R*,3*S*)-β-hydroxy-α-amino acid (as **3**) is then simply isolated by ion exchange chromatography.

The four compounds, (2*R*,3*S*)-3-(4-hydroxyphenyl)serine (**3**), (2*R*,3*S*)-3-phenylserine (**4**), (2*R*,3*S*)-3-(4-bromophenyl) serine (**5**), and (2*R*,3*S*)-3-(4-nitrophenyl)serine (**6**), were obtained in excellent isolated yield (74–82%). The enantiomeric purities of **4–6** were assayed through ^{1}H nmr examination of the corresponding *N*-camphanoyl derivatives. First, the *N*-camphanoyl derivatives of racemic material were examined in each case. Two sets of clearly separated signals were seen for the α and β protons of the amino acid moieties. Second, in the case of

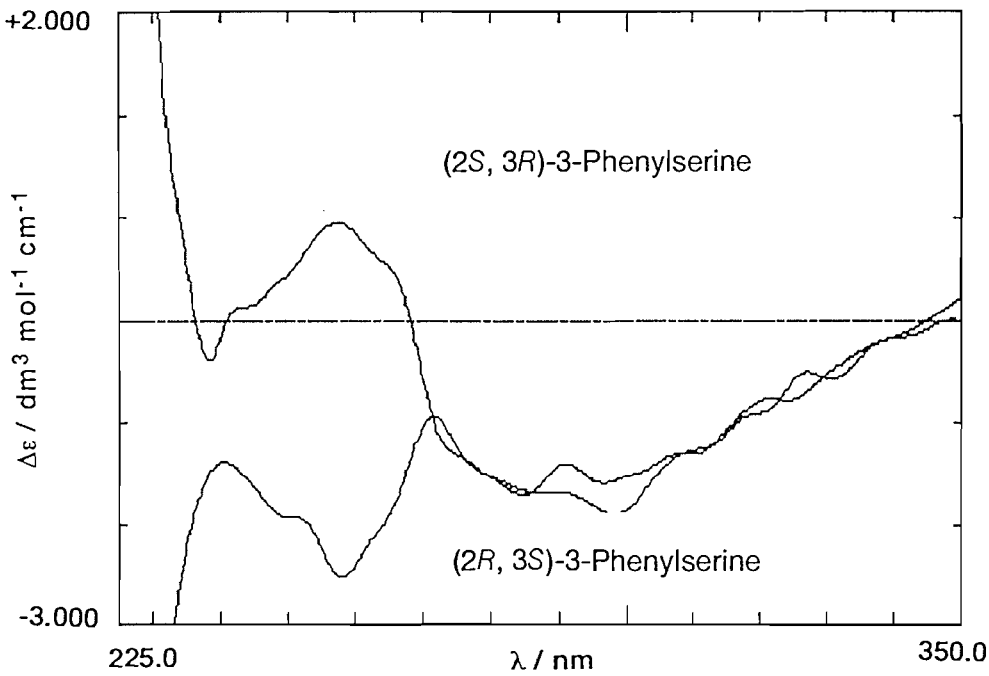

FIG. 1. CD spectra of (2*S*,3*R*)-3-phenylserine (**2**) synthesized according to ref. 9 and (2*R*,3*S*)-3-phenylserine (**4**) obtained by aldolase resolution, which was superimposable on synthetic **4**.

the aldolase-resolved compounds **4–6** only one set of signals could be discerned in each case, i.e., signals for a single stereoisomer. Within the limits of the nmr method we conclude, therefore, that the aldolase-resolved compounds are enantiomerically pure (>95%).

The chemically synthesized homochiral phenylserines **2** and **4** were converted into their *N*-camphanoyl derivatives, which were examined by ^{1}H nmr. They gave complementary signals for the α and β protons that corresponded to those of the racemate. Importantly, the data for the *N*-camphanoyl derivative of the (2*R*,3*S*) isomer (**4**) were identical to those of the aldolase-generated 3-phenylserine derivative. Further identity was seen in the CD spectra of the latter when compared to synthetic (2*R*,3*S*)-3-phenylserine (**4**) (Fig. 1); synthetic (2*S*,3*R*) material gave a spectrum of opposite sign. The foregoing results clearly show, in confirmation of earlier results (10), that the *S. amakusaensis* aldolase catalyses a stereospecific reverse aldol reaction on compounds of type **7** (Scheme 1) and that this reaction occurs exclusively with ß-hydroxy-α-amino acids having (2*S*,3*R*) stereochemistry.

We were unsuccessful in preparing the *N*-camphanoyl derivative of 3-(4-hydroxyphenyl)serine. Our estimation of the optical purity of the aldolase-generated (2*R*,3*S*) isomer is >92%, which is based on its optical rotation compared to those of chemically synthesized **1** and **3**.

The aldolase was simply obtained by sonication of *S. amakusaensis* cells and the protein was then partially purified; full details allowing the routine use of this enzyme are given in the Experimental. We have not yet defined the substrate limits of the aldolase but our results (10) indicate that they are wide. We have found aldolase activity to be present in cultures of two other *Streptomyces* species, which indicates that a family of enzymes exists.[2] This has ramifications for metabolism and also for applications in synthesis since individual family members may have different substrate preferences.

[2]D.R. Evans, R.B. Herbert, and B. Wilkinson. Unpublished results.

Experimental

Apparatus and general procedures were as published (13, 14) except as specified below. Optical rotations were measured on an Optical Activity AA-1000 automatic ranging polarimeter with a pathlength of 25 mm. Sonication of *Streptomyces amakusaensis* was performed using an Ultrasonics A180G apparatus. An MSE high-speed 18 centrifuge was used for centrifugation, which was carried out below 4°C. High-performance liquid chromatography was performed using a Varian 5000 LC pump, Hewlett Packard 1050 UV detector, Hewlett Packard HP 3396 integrator, Polymer Laboratories PLRP-S 8 μm, 100 Å, 250 × 4.6 mm reverse phase column eluting with H_2O:MeCN (1:1) at 1 mL min^{-1}. Reversed phase tlc was conducted using Whatman $LKC_{18}F$ reversed phase plates visualized by uv and (or) ninhydrin (0.2% in ethanol).

Preparation and purification of the Streptomyces amakusaensis *aldolase*

Streptomyces amakusaensis (ATCC 23876) was grown in ISP growth medium (1L) until tuberin production began (15). The cells were centrifuged at 10 000 *g* for 15 min, washed with 0.05 M sodium phosphate buffer (500 ml, pH 7.3) containing 0.1 mM dithiothreitol (DTT), 0.1 mM phenylmethylsulfonyl fluoride (PMSF), and 0.1 mM EDTA. The mixture was centrifuged at 10 000 *g* for 15 min. The cells were suspended in buffer (150 mL), sonicated below 10°C (40 microns, 2 × 30 s pulses) and centrifuged at 10 000 *g* for 15 min.

Ammonium sulfate (20 g) was added to the supernatant solution, the mixture was stirred at room temperature for 15 min and centrifuged at 10 000 *g* for 15 min. Ammonium sulfate (40 g) was added to the resulting supernatant solution and the procedure repeated. The resulting pellet was dissolved in the above buffer (20 mL) and the mixture dialysed twice against a 20-fold excess of the above buffer. DEAE–Sephadex-A50 ion exchange resin was prepared as described previously (4) and the dialysed enzyme solution was chromatographed using a 0.05–0.3 M sodium phosphate (pH 7.3) concentration gradient; the buffer contained 0.1 mM DTT, 0.1 mM PMSF, and 0.1 mM EDTA. The active

fractions were combined (70–100 mL) and precipitated by addition of ammonium sulfate (60 g/100 mL) and stirred at room temperature for 15 min. The mixture was centrifuged at 10 000 *g* for 15 min and the resulting pellet dissolved in 0.01 M sodium phosphate (20 mL, pH 7.3) containing 0.1 mM DTT and 0.1 mM EDTA and the solution was dialysed twice against a 20-fold excess of the same buffer. The resulting solution was diluted to 30 mL using the same buffer and was assayed as 1050 units of enzyme activity; 35 units mg^{-1} protein.

Enzyme assay

Streptomyces amakusaensis aldolase solution (0.5 mL) was added to a solution of composition 0.01 M sodium phosphate, 40 mM *threo*-3-(4-hydroxyphenyl)serine, and 0.1 mM pyridoxal 5-phosphate at pH 7.3 (4.5 mL). This solution was incubated at 25°C and assayed by hplc for production of 4-hydroxybenzaldehyde. One unit of enzyme activity is that amount of enzyme required to convert 1 μmol of *threo*-3-(4-hydroxyphenyl)serine into 1 μmol of 4-hydroxybenzaldehyde in 1 min at 25°C.

Synthesis of substrates

(a) Racemic-threo-*β-hydroxy-α-amino acids*

These were synthesized following literature methods, and were crystallized until no *erythro* isomer was detectable by proton nmr.

(threo)-*3-(4-Bromophenyl)serine (as* ***5****) (cf. ref. 16).* 4-Bromobenzaldehyde (3.49 g, 18.9 mmol), glycine (708 mg, 9.4 mmol), and KOH (1.06 g, 18.9 mmol) were dissolved in ethanol (70 mL) and the mixture was stirred at room temperature for 5 h. The Schiff's base product was hydrolysed using 2 M HCl (20 mL) with warming. The precipitate that formed on cooling was removed by filtration. The filtrate was washed with $CHCl_3$ (2 × 10 mL). The aqueous solution was neutralised with concentrated NH_3 and the resulting precipitate was collected and recrystallized from water–ethanol. Yield 67%; mp 184–186°C (dec.); ^{1}H nmr (300 MHz) δ(*d*-TFA): 7.57 (2H, d, 8.4 Hz, Ar), 7.30 (2H, d, 8.4 Hz, Ar), 5.63 (1H, d, 3.3 Hz, ß-H), 4.58 (1H, d, 3.3 Hz, α-H). (b) Optically active β-hydroxy-α-amino acids serving as reference compounds

The compounds (2*S*,3*R*)- and (2*R*,3*S*)-3-(4-hydroxyphenyl)serine, **1** and **3**, respectively, were synthesized by adaption of a published procedure (9). This involved condensing the (*R*) isomer of the glycine equivalent **10**, or its enantiomer, with 4-benzyloxybenzaldehyde. Hydrolysis of the product **11** obtained from **10** afforded the amino acid **3**; the isomer **1** was obtained similarly from the enantiomer of **10**. The corresponding 3-phenylserines **2** and **4** were obtained as previously reported (9). The imidazolidinone **10** and its enantiomer were obtained from Fluka Chemicals.

General procedure for the resolution of β-hydroxy-α-amino acids

The amino acid (2 mmol) was dissolved in 0.01 M sodium phosphate buffer (10 mL, pH 7.3) and methanol (5 mL). To this was added a mixed solution containing 0.2 mol pyridoxal 5-phosphate (2 mL) and *S. amakusaensis* enzyme solution (5 mL). The reaction mixture was incubated at 25°C for 8–10 h. The reaction was terminated by addition of 10% TFA (1 mL) and the mixture was centrifuged at 10 000 *g* for 15 min. The resulting supernatant was evaporated, dissolved in water (5 mL), and purified by ion exchange chromatography on Dowex 1-X8-400 resin eluting first with distilled water (50 mL) and then with a gradient of aqueous acetic acid (0.1–0.5 M). The product obtained after evaporation of the solvent was crystallized from water/ethanol.

(2R, 3S)-(D-threo)-3-(4-Hydroxyphenyl)serine (3). Yield 79%; mp 197–199°C (dec.); $[\alpha]_D^{25}$ +35.5 (*c* 0.5, H_2O); ^1H nmr (300 MHz) δ (*d*-TFA): 7.24 (2H, d, 8 Hz, Ar), 7.07 (2H, d, 8 Hz, Ar), 5.76 (1H, d, 3.3 Hz, ß-H), 4.53 (1H, d, 3.3 Hz, α-H); *m/z*, FAB: 198 $(m + 1)^+$.

(2R, 3S)-(D-threo)-3-Phenylserine (4). Yield 82%; mp 183–185°C (dec.); $[\alpha]_D^{25}$ +32.5 (*c* 0.5, H_2O); ^1H nmr (300 MHz) δ (*d*-TFA): 7.42 (5H, m, Ar), 5.76 (1H, d, 3.5 Hz, ß-H), 4.70 (1H, d, 3.5 Hz, α-H), *m/z*, FAB: 182 $(m + 1)^+$.

(2R, 3S)-(D-threo)-3-(4-Bromophenyl)serine (5). Yield 80%; mp 184–186°C (dec.); $[\alpha]_D^{25}$ +27 (*c* 0.3, H_2O); ^1H nmr (300 MHz) δ (*d*-TFA): 7.57 (2H, d, 8.4 Hz, Ar), 7.30 (2H, d, 8.4 Hz, Ar), 5.63 (1H, d, 3.3 Hz, β-H), 4.68 (1H, d, 3.3 Hz, α-H); *m/z*, FAB: 262 ($(m + 1)^+$, 100), 260 ($(m + 1)^+$, 84).

(2R, 3S)-(D-threo)-3-(4-Nitrophenyl)serine (6). Yield 74%; mp 174–176°C (dec.); $[\alpha]_D^{25}$ +27 (*c* 0.5, H_2O); ^1H nmr (300 MHz) δ (*d*-TFA): 8.33 (2H, d, 8.6 Hz, Ar), 7.72 (2H, d, 8.6 Hz, Ar), 5.76 (1H, d, 3.3 Hz, ß-H), 4.68 (1H, d, 3.3 Hz, α-H); *m/z*, FAB: 227 $(m + 1)^+$.

Measurement of Optical Purity

(a) The CD determinations were carried out using equimolar solutions in water of the chemically synthesized (2*S*,3*R*)-(L-*threo*)-3-phenylserine (**2**) and the (2*R*,3*S*)-(D-*threo*)-3-phenylserine (**4**) obtained by enzyme resolution and synthesis.

(b) General procedure for preparing N-camphanoyl derivatives of β-hydroxy-α-amino acids

A solution of β-hydroxy-α-amino acid (0.15 mmol) and sodium hydroxide (0.15 mmol) in water (0.5 mL) was added to (–)-camphanic acid chloride (0.15 mmol) in toluene (0.5 mL) and the mixture was shaken vigorously for 3 h at room temperature. The resulting mixture was washed with $CHCl_3$ (2 × 2 mL) and then acidified to pH 2. This was extracted with $CHCl_3$ (3 × 2 mL), dried over $MgSO_4$, and evaporated to dryness. The resulting white solid was assayed by proton nmr.

(c) The ^1H nmr analysis of resolved materials

The nmr spectra were obtained at 300 MHz in $CDCl_3$. Only a single set of lines was apparent for the material produced by enzymic resolution, i.e., the material appeared to be homochiral. Relevant data is given below.

N-(–)-Camphanoyl-(2R,3S)-(D-threo)-3-phenylserine. Resolved material: 4.94 (1H, dd, 1.8 and 9.0 Hz, α-H), 5.51 (1H, d, 1.8 Hz, ß-H); additional signals for racemate: 5.01 (0.5H, dd, 1.8 and 9.0 Hz, α-H), 5.59 (0.5H, d, 1.8 Hz, ß-H).

N-(–)-Camphanoyl-(2R,3S)-(D-threo)-3-(4-bromophenyl)serine. Resolved material: 4.95 (1H, dd, 1.8 and 8.2 Hz, α-H), 5.48 (1H, d, 1.8 Hz, ß-H); additional signals for racemate: 4.99 (0.5H, dd, 1.8 and 8.2 Hz, α-H), 5.47 (0.5H, d, 1.8 Hz, ß-H).

N-(–)-Camphanoyl-(2R,3S)-(D-threo)-3-(4-nitrophenyl)serine. Resolved material: 5.04 (1H, dd, 1.2 and 8.7 Hz, α-H), 5.64 (1H, d, 1.2 Hz, ß-H); additional signals for racemate: 5.10 (0.5H, dd, 1.2 and 8.7 Hz, α-H), 5.66 (0.5H, d, 1.2 Hz, ß-H).

The signals for the α-protons in the above showed coupling (8–9 Hz) to vicinal NH. These collapsed on standing in MeOD.

Acknowledgments

We are grateful for financial support of a CASE studentship (to B.W.) from the Science and Engineering Research Council (SERC) and Sterling Winthrop Pharmaceuticals Research Division. We thank Dr. Ian White, Department of Biochemistry and Molecular Biology, Leeds University, for assistance in enzyme purification and Miss Rebecca A. Robbins for CD spectra.

Cyclization of farnesyl diphosphate to pentalenene. Orthogonal stereochemistry in an enzyme-catalyzed $S_{E'}$ reaction[1]

DAVID E. CANE[2] AND STEVEN W. WEINER

Department of Chemistry, Box H, Brown University, Providence, RI 02912, U.S.A.

Received July 13, 1993

This paper is dedicated to Professor Ian D. Spenser

DAVID E. CANE and STEVEN W. WEINER. Can. J. Chem. **72**, 118 (1994).

Pentalenene synthase catalyzes the cyclization of farnesyl diphosphate (**1**) to the sesquiterpene hydrocarbon pentalenene (**4**). Separate incubations of (4*S*,8*S*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]farnesyl diphosphate (**1***a*) and (4*R*,8*R*)-[4,8-$^3H_2$, 4,8$^{14}C_2$]farnesyl diphosphate (**1***b*) with pentalenene synthase isolated from *Streptomyces* UC5319 and analysis of the derived labeled pentalenenes, **4***a* and **4***b*, respectively, by chemical degradation established that H-8*si* of FPP was lost upon cyclization to pentalenene. Consideration of the plausible conformations of the enzymatic cyclization intermediates indicates that the electrophilic allylic addition–elimination ($S_{E'}$) reaction in which the C-4,5 bond of pentalenene is formed involves an orthogonal relationship between the C—C bond being formed and the C—H bond that is ultimately broken.

DAVID E. CANE et STEVEN W. WEINER. Can. J. Chem. **72**, 118 (1994).

La pentalènène synthase catalyse la cyclisation du diphosphate de farnésyle (**1**) en hydrocarbure sesquiterpénique pentalènène (**4**). Des incubations séparées des diphosphates de (4*S*,8*S*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]farnésyle (**1***a*) et de (4*R*,8*R*)-[4,8$^3H_2$, 4,8-$^{14}C_2$]farnésyle (**1***b*) avec la pentalènène synthase isolée de *Streptomyces* UC5319 et une analyse des pentalènènes marqués, **4***a* et **4***b* respectivement, par une dégradation chimique a permis d'établir que le H-8*si* du diphosphate de farnésyle est perdu lors de la cyclisation en pentalènène. Une considération des conformations plausibles des intermédiaires enzymatiques de la cyclisation indique que la réaction électrophile d'addition–élimination allylique ($S_{E'}$), au cours de laquelle se forme la liaison C-4,5 du pentalènène, implique une relation orthogonale entre la liaison C—C qui se forme et la liaison C—H qui sera finalement brisée.

[Traduit par la rédaction]

The formation of carbon–carbon bonds by the electrophilic attack of carbenium ions on double bonds is one of the most important reactions in the biosynthesis of hundreds of isoprenoid metabolites, including linear polyprenols (dolichols, ubiquinones), cyclic terpenes (mono-, sesqui-, and diterpenes), and steroids and other triterpenes (cholesterol, α-amyrin) (1). Although this process has considerable precedent in solution phase chemistry and much is known about the physical organic chemistry of carbenium ions themselves, the enzymatic reactions remain poorly understood, both with respect to the means by which such reactive species are manipulated and stabilized by protein catalysts and the manner in which enzymes exercise regiochemical and stereochemical control over such reactions (2).

One particularly important subclass of these electrophilic reactions involves the quenching of positive charge resulting from the initial addition to the double bond by the removal of one of the original allylic protons. This allylic addition–elimination formally corresponds to an $S_{E'}$ process. Cornforth and Popjak have shown that the key chain elongation step of polyprenol biosynthesis, typified by the farnesyl diphosphate (FPP, 1) synthase reaction, involves a pair of net *syn* allylic addition–elimination reactions (3). (Scheme 1). By contrast, the closely analogous prototropic rearrangement of isopentenyl diphosphate (IPP, 2) to dimethylallyl diphosphate (DMAPP, 3) has been shown to occur with net *anti* stereochemistry (4). In more recent studies of the cyclization of farnesyl diphosphate (1) to the sesquiterpene hydrocarbon pentalenene (4), we have shown that the initial $S_{E'}$ reaction takes place with net *anti* stereochemistry (5) (Scheme 2). Overton has described model experiments in which an intramolecular $S_{E'}$ reaction was shown to proceed with clean *syn* stereochemistry (6), in contrast to arguments based on MO theory that had predicted a preferred *anti* pathway (7). On the other hand, the possibility could not be excluded that the observed stereochemistry might have resulted from a conformational bias in the substrate rather than from a stereoelectronic imperative. Since that time, there have been several documented examples of (predominant) *anti* stereochemistry in the mechanistically related alkylative or prototropic desilylation of allylsilanes (8). The divergent stereochemical course of various biological allylic addition–elimination reactions suggests that the precise position of substrates relative to enzymic bases may be more important to the outcome than an inherent physicochemical preference for one or the other stereochemistry. To explore this issue further, we have examined a second $S_{E'}$ reaction in the cyclization of FPP to pentalenene.

Pentalenene synthase is a soluble, monomeric enzyme of M_r 42.5 kDa obtained from *Streptomyces* UC5319 (9). A divalent metal cation, either Mg^{2+} or Mn^{2+}, is the only cofactor required. Extensive studies carried out in this laboratory support at mechanism in which FPP, folded as illustrated in Scheme 2, is initially cyclized to humulene (**5**), which undergoes further cyclization initiated by reprotonation at C-10 (5, 10). Consistent with this mechanistic and stereochemical model is the demonstration that cyclization of FPP takes place with net inversion of configuration at C-1 (5). Electrophilic attack on the *si* face of the C-10, 11 double bond is followed by removal the H-9*si* proton. The proton that is removed does not undergo exchange with the medium, but is redonated to the *re* face of the C-9,10 double bond of the intermediate humulene, leading to formation of the protoilludyl cation **6** (5, 10). Following a 1,2-hydride shift, the resultant cation **7** attacks the remaining double bond, leading, after loss of one of the original H-8 protons of FPP, to formation of pentalenene (**4**). We now report experiments which establish that this latter $S_{E'}$ reaction proceeds with neither *syn* nor *anti*

stereochemistry but involves a, presumably stepwise, orthogonal electrophilic addition – allylic proton elimination (11).

Results

The stereochemical course of the final deprotonation step was determined by incubation of samples of FPP, stereospecifically tritiated at C-8, with pentalenene synthase obtained from *Streptomyces* UC5319. The requisite labeled samples of FPP could be conveniently prepared by incubation of DMAPP and stereospecifically tritiated IPP with avian liver prenyl transferase (Scheme 3). Thus, condensation of DMAPP (**3**) and *E*-[4-^{3}H]IPP (**2***a*) was expected to afford (4*S*,8*S*)-[4,8-$^3H_2$]FPP

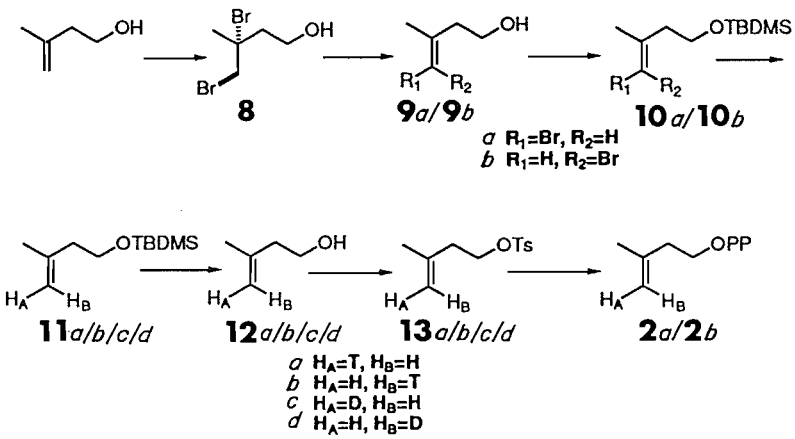
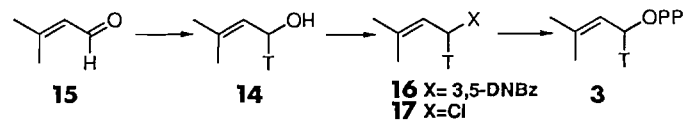


SCHEME 4

(**1***a*), whereas DMAPP (**3**) and *Z*-[4^{3}H]IPP (**2***b*) would yield (4*R*,8*R*)-[4,8-$^3H_2$]FPP (**1***b*) (3). The required samples of IPP labeled with tritium at either the 4*E* or 4*Z* positions were themselves prepared by a modification of the method of Ogura and coworkers (12), initially using deuterium in order to optimize both the incorporation of label and the degree of stereospecificity (Scheme 4).

Bromination (3, 12) of isopentenyl alcohol yielded the corresponding dibromide **8** in 92% yield. Dehydrobromination of **8** with 5 M methanolic KOH gave a 4:1 mixture of *E*- and Z-4-bromo-3-methyl-3-buten-1-ol, **9***a* and **9***a*, respectively, which were separated by flash chromatography on silica gel followed by medium pressure liquid chromatography (MPLC) on silica gel and converted into their respective *tert*-butyldimethylsilyl ethers **10***a* and **10***b* by treatment with *tert*-butyldimethylsilylchloride ((TBDMSCl) and imidazole in DMF. Metallation of **10***a* and **10***b* with 2.2 equivalents of *tert*-butyllithium at −78°C followed by quenching of the resulting bright yellow solution with trifluoroacetic acid 1-*d* (99.8 at.% *d*) at −78°C afforded stereospecifically deuterated isopentenyl *tert*-butyldimethylsilyl ethers **11***c* and **11***d*, respectively. Desilylation of **11***c* and **11***d* with tetra(*n*-butyl)ammonium fluoride (TBAF) in THF followed by treatment of the corresponding 4*E*- and 4*Z*-deuterated isopentenols, **12***c* and **12***d*, and *p*-toluenesulfonyl chloride in pyridine, yielded the tosylates **13***c* and **13***d* in 20% average overall yield from **10***a* and **10***b*. The individual steps of silylation and tosylation were achieved with yields of 80–93% and 80–100%, respectively. **13***c* was 96% deuterated, based on integration of the ^{1}H NMR signals for the *Z* and *E* olefinic protons at δ 4.67 and 4.78. Integration of the two olefinic signals in the ^{2}H NMR spectrum of **13***c* showed the *E*- to *Z*-deuterium ratio to be 92:8. By similar analysis, tosylate **13***d* was found to contain 85% deuterium, exclusively in the expected *Z* geometry.

Having worked out conditions for efficient and stereospecific labeling, both *E*- and *Z*-[4-^{3}H]-3methyl-3-buten-1-yl tosylates, **13***a* and **13***b*, were synthesized following the procedure outlined in Scheme 4, using tritiated trifluoroacetic acid (45 μCi/μmol).[3] Radiolabeled tosylates **13***a* (21.9 μCi/μmol) and **13***b* (41.2 μCi/μmol) were obtained in 34% and 23% overall yield, respectively, from the *tert*-butyldimethylsilyl ethers **11***a* and **11***b*. **13***a* and **13***b* were each converted to the corresponding samples of IPP, **2***a* and **2***b*, upon treatment with tris(tetra-(*n*-butyl)ammonium) hydrogen pyrophosphate in acetonitrile (13).



SCHEME 5

[1-^{3}H]DMAPP (**3**) was prepared from [1-^{3}H]dimethylallyl alcohol (**14**), readily obtained by reduction of 3-methyl-2-butenal (**15**) with sodium borotritide in methanol (Scheme 5). Unlabeled carrier dimethylallyl alcohol was added, and a portion of the isotopically diluted alcohol was derivatized as the 3,5-dinitrobenzoate **16**, which was recrystallized to constant specific activity (0.29 nCi/μmol). Treatment of **14** with triphenylphosphine in hexachloroacetone (HCA) (14) generated the allylic chloride **17**, which was converted to [1-^{3}H]-**3** with tris(tetra(*n*-butyl)ammonium)hydrogen pyrophosphate in acetonitrile (13).

For the prenyl transferase-catalyzed preparation of stereospecifically tritiated FPP, **2***a* and **2***b* were each mixed with commercially available [4-^{14}C]IPP. An equimolar mixture of *E*-[4-^{3}H, 4-^{14}C]IPP (**2***a*) (337 μM) and DMAPP (**3**) was incubated with avian liver prenyl transferase to give (4*S*,8*S*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP (**1***a*) (3, 12).[4] Under similar conditions an equimolar mixture of *Z*-[4-^{3}H, 4-^{14}C]IPP (**2***b*) (309 μM) and DMAPP (**3**) yielded (4*R*,8*R*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP (**1***b*). **1***a* and **1***b* were each purified by successive Sephadex G-25 gel filtration, C-18 reverse phase HPLC (16), and DEAE–Sephadex anion exchange chromatography. Since the ^{3}H specific activities of **2***a* and **2***b* were each greater than that of **3** by at least a factor of 10^6, the contribution of **3** to the measured ^{3}H/^{14}C ratio in **1***a* and **1***b* was negligible. The precise ^{3}H/^{14}C ratios for **1***a* and **1***b* were determined by hydrolysis of small samples of each

[3]Tritiated trifluoroacetic acid is conveniently prepared by reaction of trifluoroacetic anhydride with tritiated water.

[4]IPP can exhibit substrate inhibition by competing with DMAPP or geranyl diphosphate for binding to the allylic substrate region of the active site (cf. ref. 15). To minimize this problem, IPP and DMAPP are incubated at equimolar concentrations, rather than in the 2:1 ratio required by the stoichiometry of the FPP synthase reaction.

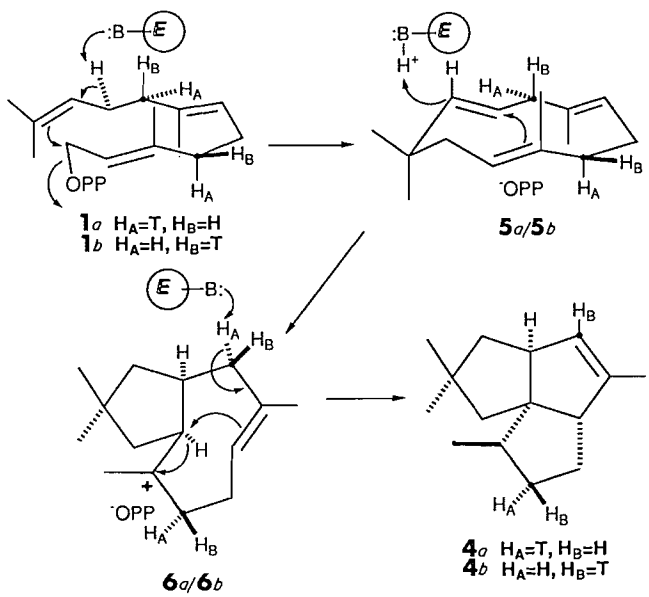
[b]Based on recrystallization of farnesyl diphenylurethane **18***b*.



SCHEME 6

labeled FPP with acid phosphatase, followed by the addition of unlabeled carrier *trans,trans*-farnesol and treatment with *N,N*-diphenyl carbamoyl chloride in pyridine (17) to give the diphenylurethanes **18***a* and **18***b*, respectively. **18***a* and **18***b* were each recrystallized to constant $^3H/^{14}C$ ratio, specific activity, and melting point (Scheme 3 and Table 1).

When (4*R*,8*R*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP, **1***b* ($^3H/^{14}C$ 6.95 ± 0.11), was incubated with crude pentalenene synthase obtained from cell-free extracts of *Streptomyces* UC5319, the resulting **4***b* retained 95% of the original tritium label, based on the $^3H/^{14}C$ ratio of the derived pair of diastereomeric *cis* 6,7-diols (10) **19***b* (β isomer) ($^3H/^{14}C$ 6.64 ± 0.04) and **20***b* (α isomer) ($^3H/^{14}C$ 6.58 ± 0.04), obtained after dilution of the enzymatically generated product with synthetic (±)-pentalenene (18) followed by treatment with osmium tetraoxide in pyridine (Scheme 7 and Table 1). The site of tritiation was established by hydroboration–oxidation followed by PCC oxidation (10) to give 7-keto pentalenane **21***b* ($^3H/^{14}C$ 3.46 ± 0.06). The isotope ratio found in the ketone was roughly half that of both **19***b* and **20***b* as well as 7-hydroxypentalenane (**22***b*), indicating that half the tritium label resided at C-7 of pentalenene (**4***b*) (Table 1).

In a complementary set of experiments, (4*S*,8*S*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP (**1***a*) ($^3H/^{14}C$ 6.02 ± 0.01) was cyclized to pentalenene (**4***a*) by incubation with crude pentalenene synthase (Scheme 6). After dilution with unlabeled (±)-pentalenene, the derived product was converted to the corresponding mixture of diastereomeric diols **19***a* and **20***a* (Scheme 7). The β isomer **19***a* was recrystallized to constant specific activity, $^3H/^{14}C$ ratio (3.17 ± 0.02), and melting point. These results indicated that 53% of the original tritium label had been retained in the enzymatically generated pentalenene. Hydroboration–oxidation followed by oxidation with PCC as before yielded 7-keto pentalenane (**21***a*) of essentially unchanged $^3H/^{14}C$ ratio (2.99 ± 0.05). These results established that H-8*si* of FPP was lost upon cyclization to pentalenene.

Discussion

Having identified which of the two diastereotopic H-8 protons of FPP is lost in the formation of pentalenene, it is possible to analyze the overall stereochemical course of the final electrophilic allylic addition–elimination reaction, which leads to formation of 4. From the absolute configuration of pentalenene (9, 10), it is evident that the cyclization of cation **7** involves attack on the *si* face of the *trans*-6,7 double bond (FPP numbering, Scheme 8). The *p* orbitals of **7** must be aligned in a parallel orientation for the electrophilic reaction to occur and allow formation of the carbon–carbon σ bond. In principle, formation of the new double bond in pentalenene could involve removal of either of the original allylic protons, H_A or H_B. If H_B (H*re*) were removed, the *p* orbital of the pentalenyl cation 23 would only have to rotate 30° in order to achieve the necessary parallel alignment with the C-H_B σ bond (Scheme 8). Since in fact H_A (H*si*) is removed, this *p* orbital must instead undergo a rotation of 90° prior to the final deprotonation. The final $S_{E'}$ reaction in the enzymic conversion of FPP to pentalenene cannot therefore be described as proceeding with either net *syn* or net *anti* stereochemistry. Intially, both H_A and H_B are *anti* to the newly formed carbon–carbon σ bond. When H_A (corresponding to H-8*si* of FPP) is eventually removed after internal bond rotations, it is actually *orthogonal* to the newly formed 5,6 σ bond of pentalenene.

Although a rotation of only 30° would have sufficed for proper overlap of the vacant *p*-orbital of **22** with the adjacent β proton, why then is a rotation of 90° required for deprotonation to occur? The most likely explanation is that the stereochemistry of deprotonation is determined by the relative positioning of the substrate and the relevant enzymic base. Intriguingly, this final deprotonation occurs immediately adjacent to the sites of deprotonation and reprotonation involved in the formation and further cyclization of the presumed humulene intermediate (5, 10). While the three C—H bonds in question, H-8*si* of FPP (H_A of **7**), H-9*si* of FPP, and H-1*re* of pentalenene are not parallel to each other, they do extend in the same general direction in the various intermediates (5, 10). It is tempting to speculate, therefore, that there is in fact a *single base* at the active site of pen-

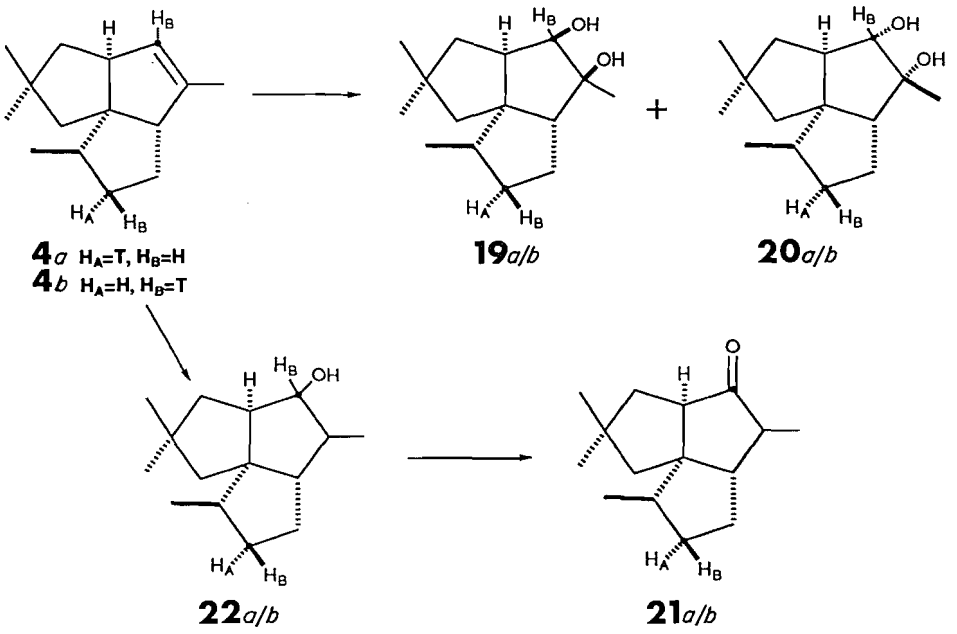
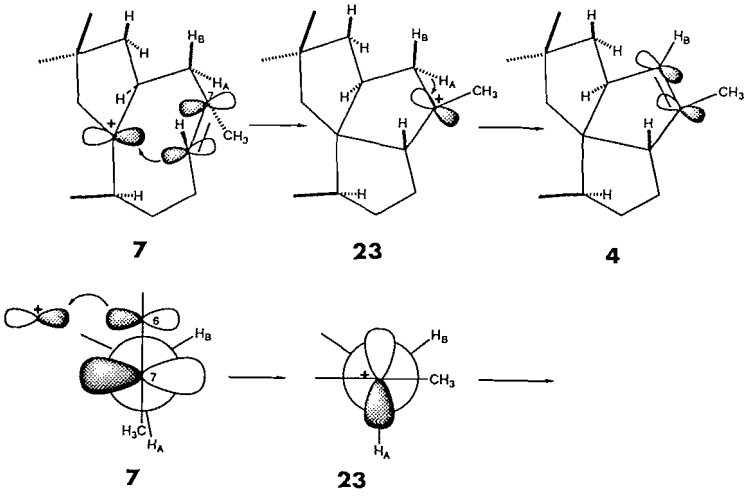


SCHEME 7



SCHEME 8

talenene synthase that is responsible for deprotonation, reprotonation, and deprotonation at C-9, C-10, and C-8 of the original farnesyl skeleton. We recently succeeded in cloning the relevant structural gene for pentalenene synthase and in obtaining high-level expression of recombinant cyclase in *Escherichia coli* (19). It should therefore be possible to test these predictions directly and to obtain additional insights into the mechanism and stereochemistry of the enzymatic conversion of farnesyl diphosphate to pentalenene.

Experimental

Materials and methods

Melting points were measured on a Thomas–Hoover capillary melting point apparatus and are uncorrected. Proton Fourier transform NMR spectra were routinely obtained at 250 MHz on a Bruker WM250 spectrometer, or at 400 MHz on a Bruker AM-400 spectrometer. Chemical shifts were referenced with respect to TMS at $\delta = 0$ or with respect to HOD at $\delta = 4.60$. ^{13}C NMR spectra were obtained at 100 MHz with broadband ^{1}H decoupling and chemical shifts were referenced with respect to the center of the triplet of $CDCl_3$ at $\delta = 77.0$. ^{2}H NMR spectra were obtained at 61 MHz, and chemical shifts were referenced with respect to $CDCl_3$ at $\delta = 7.24$. Infrared spectra were recorded on a Perkin–Elmer 1600 series FTIR spectrometer. Liquid films were scanned between sodium chloride plates. Radioactive samples were counted for both ^{3}H and ^{14}C activity by dissolving the sample in 5 mL Packard Opti-Fluor liquid scintillation fluid and measuring the activity on a Beckman LS 5801 liquid scintillation counter. For

determining specific activities and isotope ratios, the activity was measured to within a standard deviation of ±1%. Lyophilization of aqueous samples was achieved at (7–10) × 10^{-3} Torr (1 Torr = 133.3 Pa) on a Labconco lyophilizer. Centrifugation at 4°C was performed in a Sorvall RC-5 refrigerated centrifuge. Measurements of pH were obtained using a Corning pH/ion meter 150, which was calibrated with pH 4.01 and pH 7.41 buffers. Nanopure water was obtained from a Barnstead NANOpure II apparatus. Radiochemicals were purchased from ICN Radiochemical division (Costa Mesa, Calif.) and other chemicals were routinely purchased from Aldrich (Milwaukee, Wis.). Routine flash chromatography was performed on EM-Science Silica Gel 60 (particle size 40–63 μm, 200–400 mesh), and thin-layer chromatography (TLC) was routinely performed on Kieselgel-60 precoated silica gel plates. For reactions that required anhydrous conditions, glassware was routinely oven dried at 110°C, then cooled either under an atmosphere of dry nitrogen, or in a desiccator containing calcium sulfate (Drierite). Ether and THF were dried and distilled from sodium – benzophenone ketyl. Pentane, hexane, and methylene chloride were distilled from calcium hydride. Pyridine was distilled from calcium hydride and stored over KOH.

E- *and Z-4-Bromo-3-methyl-3-buten-1-ol (**9**a and **9**b) (3, 12)*

To 3,4-dibromo-3-methyl-buten-1-ol (**8**) (5.0 g, 19.4 mmol), prepared as previously described (3, 12), was added 5 M KOH in MeOH (25% excess) at 0°C under a slight positive pressure of nitrogen. The white milky reaction mixture was allowed to stir for 2 h at 25°C, then ether (5–10 mL) was added and the mixture was dried over anhydrous $MgSO_4$ and filtered. The filter cake was washed with several small portions of ether and the combined filtrates were neutralized with a few drops of glacial acetic acid. Solvent was removed via rotovap leaving 2.68 g of a yellow oil (83.9% crude yield). Partial separation of the *E* and *Z* isomers of **9** was achieved by flash chromatography on silica gel (2:1 v:v hexane:ethyl acetate). From the flash column, pure *E* isomer **9***a* could be separated from a mixture of *E* and *Z* isomers (1.51 g, 47.1% yield. A mixture of the *E* and *Z* isomers (223 mg, 1.35 mmol) was loaded onto a size B Lobar medium pressure column prepacked with Si 60 silica gel (particle size 40–63 μm) and eluted with 9:1 v:v hexane:ethyl acetate (5 mL/min, 20 psi (1 psi = 6.9 kPa)). The effluent was monitored by TLC (1:1 v:v hexane:ethyl acetate, visualized by *p*-anisaldehyde). The *Z* isomer **9***b*, R_f = 0.33, was obtained as a colorless oil (55 mg, 335 μmol) in 25% yield. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.85 (s, 3H, CH_3), 2.53 (t, *J* = 6.7 Hz, 2H, CH_2CH_2O), 3.78 (t, *J* = 6.7 Hz, 2H, CH_2O), 6.01 (s, 1H, C*H*=C). The *E* isomer **9***a*, R_f = 0.29, was obtained as a colorless oil (142 mg, 860 μmol) in 64% yield. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.83 (s, 3H, CH_3), 2.38 (t, *J* = 6.2 Hz, 2H, CH_2CH_2O), 3.72 (t, *J* = 6.3 Hz, 2H, CH_2O), 6.01 (s, 1H, C*H*=C).

E-*4-Bromo-3-methyl-3-buten-1-yl*-tert-*butyldimethylsilyl ether (**10**a)*

To a solution of *E*-4-bromo-3-methyl-3-buten-1-ol (**9***a*) (249 mg, 1.51 mmol) in 10 mL dry DMF were added imidazole (1.07 g, 15.3 mmol) and *tert*-butyldimethylsilyl chloride (Aldrich, 904 mg, 5.99 mmol). The reaction mixture was shaken vigorously for 5 min, effecting a complete consumption of starting material. To the reaction mixture was added 20 mL ether, followed by washing with 3 × 20 mL water. The aqueous layer was saturated with brine and back-extracted with ether. The ether layer was dried over anhydrous $MgSO_4$, and solvent was removed via rotovap. The colorless residue was purified by flash chromatography on silica gel (hexane, followed by 99:1 v:v hexane:ethyl acetate) to afford **10***a* as a colorless oil (391 mg,1.40 mmol) in 93% yield. IR (neat, cm^{-1}): 3074, 2954, 2929, 2896, 2857, 2738, 1632, 1472, 1431, 1408, 1381, 1361, 1288, 1256, 1213, 1161, 1105, 1006, 956, 939, 836, 775, 713, 662. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.02 (s, 6H, $(CH_3)_2Si$), 0.86 (s, 9H, $(CH_3)_3CSi$), 1.78 (s, 3H, CH_3), 2.29 (t, *J* = 6.6 Hz, 2H, CH_2CH_2OSi), 3.66 (t, *J* = 6.6 Hz, 2H, CH_2OSi), 5.92 (s, 1H, C*H*=C). ^{13}C NMR (100 MHz, $CDCl_3$) δ: −5.4, 18.2, 19.4, 25.9, 41.4, 61.2, 102.7, 138.9. MS (CI^+/CH_4) (M + 1) (^{79}Br): 279. HRMS, calcd. for $C_{11}H_{23}OSiBr$: 279.0773; found: 279.0791.

Z-*4-Bromo-3-methyl-3-buten-1-yl*-tert-*butyldimethylsilyl ether (**10**b)*

To a solution of *Z*-4-bromo-3-methyl-3-buten-1-ol (**9***b*) (61 mg, 372 μmol) in 1 mL dry DMF were added imidazole (122 mg, 1.74 mmol) and *tert*-butyldimethylsilyl chloride (222 mg, 1.48 mmol, Aldrich). The reaction was carried out as described for the *E* isomer **10***a*. **10***b* was obtained as a colorless oil (81 mg, 290 μmol) in 78% yield. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.04 (s, 6H, $(CH_3)_2Si$), 0.87 (s, 9H, $(CH_3)_3CSi$), 1.61 (s, 3H, CH_3), 2.42 (t, *J* = 6.9 Hz, 2H, CH_2CH_2OSi), 3.70 (t, *J* = 6.9 Hz, 2H, CH_2OSi), 5.90 (s, 1H, C*H*=C).

E-*[4-^{2}H]-3-Methyl-3-buten-1-yl*-tert-*butyldimethylsilyl ether (**11**c) (12)*

An oven-dried, nitrogen-cooled flask was charged with *E*-4-bromo-3-methyl-3-buten-1-yl-*tert*butyldimethylsilyl ether **10***a* (93 mg, 332 μmol), which had been dried at atmospheric pressure in a desiccator containing P_2O_5 for 12 h prior to use. Dry *N,N,N′,N′* tetramethylethylenediamine (TMEDA, 0.20 mL) and 1.5 mL dry ether were added via syringe. The reaction mixture was cooled to −78°C before the addition of *tert*-butyllithium (0.43 mL, 1.7 M in pentane, 731 μmol) via syringe. Upon addition of *tert*-butyllithium, the colorless solution turned bright yellow. After 5 min the reaction mixture was quenched with trifluoroacetic acid 1-*d* (Aldrich, 99.8 at.% *d*, 100 μL, 1.3 mmol). After an additional 5 min, the reaction mixture was warmed to 0°C, and 2 mL sodium phosphate buffer, pH 7.0, was added. The reaction mixture was warmed to room temperature and was extracted with 3 × 3 mL ether. The ether extract was washed with brine and solvent was removed via rotovap. The colorless oily residue was purified by flash chromatography on silica gel (5 g, hexane, then 99:1 v:v hexane:ethyl acetate), and solvent was removed in vacuo to afford 39 mg of a colorless oil (58% crude yield). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.03 (s, 6H, $(CH_3)_2Si$), 0.87 (s, 9H, $(CH_3)_3CSi$), 1.71 (s, 3H, CH_3), 2.21 (t, *J* = 7.0 Hz, 2H, CH_2CH_2OSi), 3.69 (t, *J* = 7.0 Hz, 2H, CH_2OSi), 4.66 (s, 1H, C*H*=C), 4.73 (s, 0.04 H, 4*Z*-C*H*=C). In addition, the following impurity peaks, each integrating to ca. 0.1 H, were present: 0.12 (s), 1.06 (s), 1.52 (s, H_2O), 1.65 (s), 1.69 (s), 2.10 (t), 2.45 (t), 3.61 (dt).

E-*[4-^{2}H]-3-Methyl-3-buten-1-yl-tosylate (**13**c)*

To the TBDMS ether **11***c* (39 mg, 0.19 mmol, assuming 100% purity) was added tetra(*n*-butyl)ammonium fluoride (TBAF, 1.0 M in THF, 400 μL, 0.40 mmol), and the reaction mixture was allowed to stir for 15 min. Then 1 mL water was added and the mixture was extracted with 5 × 2 mL CH_2Cl_2. The organic layer was washed with brine and dried over anhydrous Na_2SO_4. The organic layer was then concentrated to a volume of <1 mL by simple distillation of the solvent using a Vigreux column. Pyridine (1 mL) and *p*-toluenesulfonyl chloride (*p*-TsCl, recrystallized, 241 mg, 1.16 mmol) were added and the solution was stirred under nitrogen for 13 h. Solvent was partially removed via rotovap and the residual mixture was cooled to 0°C, mixed with 2 mL distilled water, and extracted with 2 × 3 mL ether. The organic layer was washed successively with 10% $NaHCO_3$ and saturated $CuSO_4$:$5H_2O$, and the aqueous washings were back- extracted with ether. The combined organic layers were washed successively with water and brine and then dried over anhydrous Na_2SO_4. Solvent was removed via rotovap and the residue was purified by flash chromatography on silica gel (5 g, 98:2 v:v hexane: ethyl acetate). **13***c* was obtained as a colorless oil (7 mg, 29 μmol) in 24% yield from **11***c*. (Unlabeled isopentenyl tosylate was obtained in 35% overall yield from pure, unlabeled isopentenyl-*tert*-butyldimethylsilyl ether, using the above procedure.) ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.54 (s, H_2O), 1.64 (s, 3H, CH_3), 2.33 (t, *J* = 6.8 Hz, 2H, CH_2CH_2OTs), 2.43 (s, 3H, ArCH_3), 4.10 (t, *J* = 6.9 Hz, 2H, CH_2OTs), 4.64 (s, 1H, C*H*=C), 4.75 (s, 0.04 H, 4*E*-C*H*=C), 7.30 (d, *J* = 8.0 Hz, 2H, Ar*H*), 7.76 (d, *J* = 8.3 Hz, 2H, Ar*H*). ^{2}H NMR (61 MHz, $CHCl_3$) δ: 4.71 (small br s), 4.83 (s). The ratio of areas of resonances at 4.83 and 4.71 in the ^{2}H NMR spectrum was 92:8.

Z-*[4-^{2}H]-3-Methyl-3-buten-1-yl*-tert-*butyldimethylsilyl ether (**11**d) (12)*

To an oven-dried, nitrogen-cooled flask charged with *Z*-4-bromo-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

3-methyl-3-buten-1-yl-*tert*-butyldimethylsilyl ether **10***b* (23 mg, 83 μmol), which had been dried at room temperature and at atmospheric pressure in a desiccator containing P_2O_5 for 12 h prior to use, was added dry TMEDA (80 μL) and 0.5 mL dry ether. The reaction mixture was cooled to −78°C before the addition of *tert*-butyllithium (0.11 mL, 1.7 M in pentane, 187 μmol) via dry syringe. Upon addition of *tert*-butyllithium, the reaction mixture became a bright yellow color. After 5 min, the reaction was quenched with trifluoroacetic acid 1-*d* (99.8 at.% *d*, Aldrich, 48 μL, 636 μmol). The product was isolated and purified in a manner completely analogous to that described for **11***c* to give a colorless oil (16 mg, 81 μmol if 100% pure) in 98% crude yield. The product was not analyzed by ^{1}H NMR at this point, but was used as is for making the tosylate **13***d*.

*Z-[4-^{2}H]-3-Methyl-3-buten-1-yl-tosylate (**13**d)*

To crude **11***d* (16 mg, 81 μmol) was added TBAF (1.0 M in THF, 160 μL, 160 μmol). The reaction was allowed to proceed for 10 min, after which 1 mL water was added. The aqueous solution was saturated with sodium chloride and extracted with 5 × 2 mL ether. Concentration of the ether extract and conversion to the tosylate **13***d* was carried out as described for the preparation of **13***c*. Purification by flash chromatography on silica gel (5 g, 98:2 v:v hexane:ethyl acetate) afforded **13***d* as a colorless oil (3 mg, 12 μmol) in 15% overall yield from **10***b*. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.54 (s, 2H, H_2O), 1.63 (s, 3H, CH_3), 2.33 (t, J = 6.9 Hz, 2H, CH_2CH_2OTs), 2.43 (s, 3H, ArCH_3), 4.11 (t, J = 6.9 Hz, 2H, CH_2OTs), 4.64 (s, 0.14 H, 4*Z*-C*H*=C), 4.75 (s, 1H, C*H*=C), 7.31 (d, J = 8.0 Hz, 2H, Ar*H*), 7.76 (d, J = 8.3 Hz, 2H, Ar*H*). ^{2}H NMR (61 MHz, $CHCl_3$) δ: 4.74 (s), 7.28 (s, $CDCl_3$).

*Z-[4-^{3}H]-3-Methyl-3-buten-1-yl tosylate (**13**b)*

To a solution of *Z*-4-bromo-3-methyl-3-buten-1-yl-*tert*-butyldimethylsilyl ether (**10***b*) (80 mg, 288 μmol, dried over P_2O_5) in 1.5 mL dry ether was added 0.20 mL dry TMEDA. The reaction mixture was cooled to −78°C under a slight positive pressure of nitrogen, and *tert*-butyllithium (0.38 mL, 1.7 M in pentane, 0.65 mmol) was added. A bright yellow color was immediately observed. Within 5 min, the reaction mixture was rapidly quenched with 60 μL (89 mg, 780 μmol) of tritiated trifluoroacetic acid (45 μCi/μmol) at −78°C. After an additional 5 min, the reaction mixture was warmed to 0°C and 2 mL of sodium phosphate buffer, pH 7.0, were added. The product, **11***b*, was isolated as described for **11***c*. The desilylation of **11***b* with TBAF (1.0 M in THF, 600 μL, 600 μmol) and the tosylation of crude alcohol **12***b* using 0.5 mL dry pyridine and *p*-TsCl (recrystallized, 297 mg, 1.56 mmol) were carried out as described for the preparation of **13***d*. Counting of an aliquot indicated a total activity for **13***b* of 6.01 × 10^9 dpm (2.73 mCi). The tosylate was recovered in 23% chemical yield (16 mg, 66 μmol, 41.2 μCi/μmol) from **10***b*. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.64 (s, 3H, CH_3), 2.33 (t, J = 6.8 Hz, 2H, CH_2CH_2OTs), 2.43 (s, 3H, ArCH_3), 4.10 (t, J = 6.9 Hz, 2H, CH_2OTs), 4.66 (s, 1H, *Z*-C*H*), 4.77 (s, 1H, *E*-C*H*), 7.31 (d, J = 8.0 Hz, 2H, Ar*H*), 7.77 (d, J = 8.5 Hz, 2H, Ar*H*).

E-*[4-^{3}H]-3-Methyl-3-buten-1-yl tosylate (**13**a)*

E-4-Bromo-3-methyl-3-buten-1-yl-*tert*-butyldimethylsilyl ether **10***a* (82 mg, 292 μmol, dried over P_2O_5) was metallated at −78°C with *tert*-butyllithium (0.42 mL, 1.7 M in pentane, 0.71 mmol) in TMEDA–ether and quenched with tritiated trifluoroacetic acid (45 mCi/mmol, 85 μL, 127 mg, 1.11 mmol) as described for the preparation of **11***c*. Desilylation of **11***c* with TBAF (1.0 M in THF, 600 μL, 600 μmol) gave the alcohol **12***a*, which was converted in the usual manner to the corresponding tosylate **13***a* (26 mg, 107 μmol, 21.9 μCi/μmol) in 34% chemical yield from **10***a*. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.64 (s, 3H, CH_3), 2.33 (t, J = 6.8 Hz, 2H, CH_2CH_2OTs), 2.43 (s, 3H, ArCH_3), 4.10 (t, J = 6.9 Hz, 2H, CH_2OTs), 4.66 (s, 1H, *Z*-C*H*), 4.77 (s, 1H, *E*-C*H*), 7.31 (d, J = 8.0 Hz, 2H, Ar*H*), 7.77 (d, J = 8.5 Hz, 2H, Ar*H*).

E-*[4-^{3}H]-3-Methyl-3-buten-1-yl diphosphate (**2**a) (**13**)*

To a solution of *E*-[4-^{3}H]-3-methyl-3-buten-1-yl tosylate **13***a* (2 mg, 8 μmol, 21.9 μCi/μmol) in 200 μL dry acetonitrile was added tris(tetra(*n*-butyl)ammonium) hydrogen pyrophosphate (101 mg, 112 μmol). The reaction was carried out for 2 h at room temperature under nitrogen, after which the reaction mixture was partitioned between 1 mL hexane and 1 mL water. The two layers were vortexed and a 10-μL aliquot of each layer was counted for ^{3}H activity. By comparison of the ^{3}H activity of the aqueous layer ((4.11 ± 0.04) × 10^4 dpm) with that of the hexane layer ((1.63 ± 0.07) × 10^3 dpm), it was determined that pyrophosphorylation had gone to 96% completion. Solvent was removed by passing a stream of nitrogen over the surface of the liquid, followed by drying at high vacuum, and the white solid residue was taken up to 1 mL 0.05 M triethylammonium bicarbonate, pH 8.0. This solution was applied to a DEAE–Sephadex anion exchange column previously equilibrated with 0.05 M triethylammonium bicarbonate at 4°C. The product was eluted using a linear gradient of 0.05–1.0 M triethylammonium bicarbonate. A total of 67 fractions (250 drops perfraction) was collected and a 10-μL aliquot of every other fraction was counted for radioactivity. Fractions 29–33 were combined and lyophilized at (5–10) × 10^{-3} Torr. Two 5-mL portions of 1.0 M ammonium hydroxide were added and the resulting solution was lyophilized each time to near dryness. The fluffy white solid was then taken up in 2 mL isopropanol:acetonitrile:0.1 M ammonium bicarbonate (4.5:2.5:3.0, v:v:v) and the solution was applied to a flash column of EM-Avicel Microcrystalline Cellulose (1.5 cm × 10 cm) previously equilibrated with 4 column volumes of the above elution buffer. The column was run at room temperature, a total of 60 fractions (3 mL each) was collected, and a 20-μL aliquot of every other fraction was counted for radioactivity. Fractions 5–19 were combined, a few drops of 1.0 M ammonium hydroxide were added, and the solution was concentrated to about half its original volume via rotovap over a period of 1 h. A few drops of 1.0 M ammonium hydroxide were added after approximately 30 min to keep the solution slightly basic. Acetonitrile and isopropanol were completely removed from the concentrated solution via SpeedVac over a period of 2 h, during which time a few drops of 1.0 M ammonium hydroxide was added intermittently. The resulting aqueous solution was lyophilized to dryness, then taken up in 5 mL 0.2 M ammonium hydroxide. **2***a*, total ^{3}H activity 3.51 × 10^8 dpm (160 μCi, 7.28 μmol), 92% yield from **13***a*. ^{1}H NMR (250 MHz, D_2O/NH_4OD) δ: 1.60 (s, 3H, CH_3), 2.22 (t, J = 6.6 Hz, 2H, CH_2CH_2OPP), 3.69 (dt, $J_1 = J_2$ = 6.5 Hz, 2H, CH_2OPP), 4.60 (H_2O very intense, obscuring the olefinic protons).

*Z-[4-^{3}H]-3-Methyl-3-buten-1-yl diphosphate (**2**b) (**13**)*

13*b* (6 mg, 25 μmol, 41.2 μCi/μmol) in 400 μL dry acetonitrile was reacted with tris(tetra(*n*-butyl)ammonium) hydrogen pyrophosphate (202 mg, 223 μmol) for 6 h at room temperature. The product was isolated and purified as described for **2***a* to give **2***b*, which was taken up in 10 mL 0.1 M ammonium hydroxide. Total ^{3}H activity 6.52 × 10^8 dpm (294 μCi, 7.13 μmol), 29% overall yield from **13***b*. ^{1}H NMR (250 MHz, D_2O/NH_4OD) δ: 1.60 (s, 3H, CH_3), 2.22 (t, J = 6.6 Hz, 2H, CH_2CH_2OPP), 3.69 (dt, $J_1 = J_2$ = 6.5 Hz, 2H, CH_2OPP), 4.60 (H_2O very intense, and obscuring the olefinic protons).

*[1-^{3}H]-3-Methyl-3-buten-1-ol (**14**)*

To a solution of 3-methyl-2-butenal (**15**) (15 mg, 180 μmol, Aldrich) in 250 μL methanol at 0°C, was added $NaBH_3T$ in methanol (316.7 μCi/μmol, 50 μCi/μL, 5 μL, 0.79 μmol), and the reaction was allowed to proceed at 0°C for 1 h. Unlabeled $NaBH_4$ was added (15 mg, 385 μmol), and the reaction was allowed to proceed for an additional 5–10 min, followed by the dropwise addition of 5% HCl (1 mL). The aqueous solution was extracted with 6 × 1 mL pentane. The combined pentane extracts were filtered through a Pasteur pipet containing anhydrous $MgSO_4$ into a flask charged with unlabeled carrier 3-methyl-2-buten-1-ol (516 mg, 5.99 mmol). Solvent was removed via rotovap for 5–10 min. The alcohol was stored at −10°C. ^{1}H NMR analysis of a sample of **14** prepared under the same conditions with unlabeled $NaBH_4$ indicated the absence of any 1,4 reduction.

The corresponding crystalline 3,5-dinitrobenzoate ester derivative **16**, which was obtained by reaction of a portion of the tritiated alcohol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

(152 mg, 1.76 mmol) and 3,5-dinitrobenzoyl chloride (423 mg, 1.97 mmol) in dry pyridine (1.5 mL) for 3.5 h, was recrystallized to constant specific activity (2.28×10^3 dpm ^{3}H/mg, 0.29 nCi/μmol) and mp (67.5–69.0°C) from benzene–hexane. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.55 (br, H_2O), 1.81 (s, with fine splitting, 6H, CH_3), 4.95 (d, J = 7.4 Hz, 2H, CH_2O), 5.49 (t with splitting, J = 7.4 Hz, 1H, C*H*=C), 9.17 (s with fine splitting, 2H, Ar*H*), 9.21 (s with fine splitting, 1H, Ar*H*).

*[1-^{3}H]-3-Methyl-2-buten-1-yl diphosphate (**3**) (13, 14)*

To a solution of [1-^{3}H]-3-methyl-2-buten-1-ol (**14**) (200 mg, 2.32 mmol, 0.29 nCi/μmol) in hexachloroacetone (1.7 mL, 975 mg, 3.68 mmol) at 0°C was added triphenylphosphine (645 mg, 2.46 mmol) in small portions over a period of 10 min. The reaction was allowed to proceed at room temperature for 20 min. Analysis of the reaction mixture by TLC (1:1 v:v hexane:ethyl acetate) showed that the alcohol had been completely consumed. The resulting thick dark brown slurry was cooled to −78°C, and the reaction flask was attached to a flash distillation apparatus. While the receiver flask was kept at room temperature, the distillation system was evacuated to 0.01–0.02 Torr for 1–2 min, then closed to the vacuum pump but kept under vacuum. The receiver flask was cooled to −78°C and the reaction flask was warmed to room temperature. The flash distillation proceeded for 1 h, at which time the system was bled to the atmosphere. When the reaction was carried out on unlabeled alcohol, the recovered 1-chloro-3-methyl-2-butene was analysed by ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.55 (br, <1H, H_2O), 1.73 (d, J = 11.2 Hz, 6H, $CH_3 \times 2$), 4.07 (d, J = 8.0 Hz, 2H, CH_2Cl), 5.44 (t, with fine splitting, J = 8.0 Hz, 1H, C*H*=C). Also present were two impurity peaks: 2.17 (s, 0.2 H), and 6.74 (s, 0.03 H). The labeled chloride **17**, without any further purification or analysis, was taken up in 1 mL dry acetonitrile and tris(tetra(*n*-butyl)ammonium) hydrogen pyrophosphate (1.60 g, 1.77 mmol) was added. The reaction proceeded at room temperature for 12 h. Analysis of an aliquot of the reaction mixture partitioned between 1 mL water and 1 mL hexane showed that the reaction had only gone to two-thirds completion. The volatile components of the reaction mixture were evaporated with a stream of nitrogen and the resulting thick brown oil was dissolved in 1 mL 0.05 M triethylammonium bicarbonate, pH 8.0, and then extracted with 3 × 1 mL hexane to remove any unreacted allylic chloride. A stream of nitrogen was passed over the aqueous layer to remove any traces of hexane. The aqueous solution was applied to a DEAE–Sephadex anion exchange column equilibrated with 0.05 M triethylammonium bicarbonate at 4°C. The product was eluted by a linear gradient of 0.05–1.0 M triethylammonium bicarbonate pH 8.0. A total of 52 fractions (250 drops each) was collected and a 100-μL aliquot of every other fraction was counted for radioactivity. Fractions 25–30 were combined and lyophilized to near dryness. Two portions of ammonium hydroxide (5 mL, 1.0 M) were added and each time the solution was lyophilized to near dryness. The white solid residue was taken up in 2 mL isopropanol:acetonitrile:0.1 M ammonium bicarbonate (4.5:2.5:3.0, v:v:v) and applied to a flash column of cellulose (1.5 cm × 8 cm) previously equilibrated with the same elution buffer. A total of 36 fractions (3 mL each) was collected and fractions 4–12 were combined. Solvent was removed successively by rotovap, SpeedVac, and lyophilization just to dryness. Intermittently, a few drops of 1 M ammonium hydroxide were added to keep the pH slightly basic. The recovered **3** was taken up in 2 mL 0.25 M ammonium hydroxide. Total ^{3}H activity 1.21×10^5 dpm (54.5 μCi, 190 μmol), 8% overall yield from the alcohol. ^{1}H NMR (250 MHz, D_2O/ND_4OD) δ: 1.37 (s, 3H, CH_3), 1.41 (s, 3H, CH_3), 4.09 (dd, $J_1 = J_2$ = 6.7 Hz, 2H, CH_2OPP), 5.09 (t with fine splitting J = 7.2 Hz, 1H, C*H*=C).

*(4R,8R)-[4,8-$^3H_2$,4,8-$^{14}C_2$]FPP (**1**b) (11)*

A mixture of *Z*-[4-^{3}H]-IPP (**2***b*, 41.2 μCi/μmol, 80.4 nCi/μL, 513 μL, 1.00 μmol), [4-^{14}C]IPP (47.9 μCi/μmol, 20 nCi/μL, 400 μL, 0.17 μmol), and [1-^{3}H]DMAPP (**3**, 0.29 nCi/μmol, 12.9 nmol/μL, 1.17 μmol) in 2.40 mL 20 mM Tris-HCl, pH 7.72, containing 10 mM $MgCl_2.6H_2O$ and 7 mM DTT, was incubated in a total volume of 3.8 mL with avian liver prenyl transferase (400 μL) that had been purified by literature methods (20) through the DE-52 step to a specific activity of 43.5 nmol min^{-1} (mg protein)$^{-1}$ (13.0 pmol min^{-1} μL^{-1}). The concentration of each substrate in the incubation mixture was 307 μM. A 20-μL aliquot of the mixture was counted for activity: ^{3}H 5.84×10^5 dpm, ^{14}C 9.55×10^4 dpm. After 2 h at 30°C, two separate 20-μL aliquots of the incubation mixture were withdrawn. One aliquot was mixed with 500 μL 1:1 v:v EtOH:6 N HCl and extracted with 1 mL hexane. The hexane layer was filtered through a Pasteur pipet column of silica gel, and the silica gel column was washed with 1 mL ether. The ether–hexane eluate (acid labile, hexane-extractable) was counted for radioactivity: ^{3}H 2.09×10^5 dpm, ^{14}C 2.97×10^4 dpm. The other aliquot was mixed with 500 μL 1:1 v:v EtOH:H_2O and extracted with 1 mL hexane. The hexane layer was filtered through a Pasteur pipet column of silica gel, and the column of silica gel was washed with 1 mL ether. The ether–hexane eluate (blank) was counted for radioactivity: ^{3}H 1.10×10^4 dpm, ^{14}C 1.63×10^3 dpm. Based on ^{14}C activity, 30% of the IPP has been turned over by the enzyme. After 2.5 h of incubation, the reaction mixture was applied to a column (20 cm × 2.5 cm) of Sephadex G-25 (100–300 μm bead size) swollen in Eluant One (see below). A total of 48 fractions (2–3 mL each) was collected, and a 10-μL aliquot of every other fraction was counted for activity. Fractions 14–36 were combined and stored at 4°C until further purification. The preparation of the various buffers for C-18 Reverse Phase HPLC (12) was as follows:

Solution A: $(n\text{-Bu})_4NHSO_4$ (6.8 g) and K_2HPO_4 (5.5 g) in nanopure water (100 mL) adjusted to pH 8.0. The solution was vacuum filtered through a Millipore HA filter.

Solution B: 10 mL solution A diluted with 490 mL nanopure water and vacuum filtered through a Millipore HA filter.

Solution C: 10 mL solution A diluted with 490 mL HPLC-grade methanol. The precipitated phosphate was removed by vacuum filtration through a Millipore FH filter. The filtrate was then diluted with 1470 mL Millipore FH-filtered methanol.

Eluant One: a mixture of solution C with solution B in a ratio of 15:85 v:v filtered by suction through a Millipore GV filter.

Eluant Two: a mixture of solution C with solution B in a ratio of 70:30 v:v filtered by suction through a Millipore FH filter.

Fractions 14–36 in Eluant One were loaded onto a Waters C-18 μ-Bondapak reverse phase HPLC column in a Z-module. The column was developed at 1.5 mL/min for 5 min using 100% Eluant One followedby a linear gradient up to 100% Eluant Two over a period of 15.4 min. The column was run with a flow rate of 1.5 mL/min using 100% Eluant Two for an additional 30 min. A total of 84 fractions of 50 drops each was collected. A 10-μL aliquot of every other fraction was counted for radioactivity. Fractions 37–43 were combined, mean retention time 28 min, corresponding to the retention time of [1-^{3}H]FPP used as a standard. Fractions 37–43 were loaded onto a column of DEAE–Sephadex previously swollen and equilibrated with 0.05 M triethylammonium bicarbonate pH 8.0 at 4°C. A linear gradient was established with 1.0 M triethylammonium bicarbonate pH 8.0. A total of 70 fractions of 250 drops each was collected. A 10-μL aliquot of every other fraction was counted for activity. Fractions 39–44 were combined, and the sample lyophilized almost to dryness at a pressure of $(7–10) \times 10^{-3}$ Torr. The residue was taken up in ca. 9 mL of 0.1 M ammonium hydroxide and lyophilized almost to dryness. Finally, the residue was taken up in ca. 5 mL 0.1 M ammonium hydroxide and lyophilized just to dryness. The sample was taken up in 1 mL 0.05 M ammonium hydroxide. **1***b*, total ^{3}H activity 9.60×10^6 dpm (9% radiochemical yield, based on [4-^{3}H]IPP (**2***b*)).

*(4S,8S)-[4,8-$^3H_2$,4,8-$^{14}C_2$]FPP (**1**a)*

A mixture of *E*-[4-^{3}H]-IPP (**2***a*, 21.9 μCi/μmol, 39.9 nCi/μL, 548 μL, 1.0 μmol), [4-^{14}C]IPP (47.9 μCi/μmol, 20 nCi/μL, 218 μL, 0.09 μmol), and [1-^{3}H]DMAPP (**3**, 0.29 nCi/μmol, 12.9 nmol/μL, 1.08 μmol) in 1.95 mL 20 mM Tris-HCl, pH 7.72, containing 10 mM $MgCl_2.6H_2O$ and 7 mM DTT, was incubated with avian liver prenyl transferase (400 μL) in a total volume of 3.20 mL at 30°C for 2.5 h. The concentration of each substrate was 339 μM. The desired product, (4*S*,8*S*)-[4,8-$^3H_2$,4,8-$^{14}C_2$]FPP (**1***a*), was separated by successive

For personal use only.

Sephadex G-25, C-18 reverse phase HPLC, and DEAE–Sephadex anion exchange chromatography as described above for **1***b* (10% radiochemical yield, based on [4-^{3}H]IPP (**2***a*)).

*(4*R,*8*R*)-[4,8-$^3H_2$,4,8-$^{14}C_2$]Farnesyl diphenylurethane (**18**b) (17)*

An aliquot of a dilute solution of (4*R*,8*R*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP (**1***b*, 6.39×10^2 dpm ^{3}H/μL, 150 μL, total ^{3}H = 9.55×10^4 dpm) was taken up in NaOAc/HOAc buffer, pH 5.5, and incubated with acid phosphatase (Sigma, 8.5 mg) at 30°C for 3.5 h. Subsequently 1 mL EtOH was added, followed by unlabeled *trans,trans*-farnesol (Aldrich, 50 mg, 225 μmol) in 2 mL hexane. The mixture was extracted, and the hexane layer was filtered through a Pasteur pipet containing anhydrous $MgSO_4$. The mixture was further extracted with 5×2 mL hexane. Each hexane extract was filtered through anhydrous $MgSO_4$. Solvent was removed via rotovap. The residue was then taken up in 2 mL hexane and a 20-μL aliquot had ^{3}H 7.57×10^2 dpm, ^{14}C 1.11×10^2 dpm, corresponding to a total ^{3}H activity of 7.57×10^4 dpm (80% radiochemical yield from **1***b*). The radioactive farnesol was dissolved in 1 mL dry pyridine and reacted with *N,N*-diphenyl carbamoyl chloride (recrystallized from hexane, 205 mg, 882 μmol). The mixture was heated on an oil bath at 104°C for 11 h. The reaction mixture was cooled to room temperature and 1 mL water was added, followed by extraction with 5×2 mL ether. The ether extracts were washed with three portions of saturated $CuSO_4.5H_2O$ to remove the pyridine, and the $CuSO_4$ layer was back-extracted with ether. The combined ether extracts were washed with brine and dried over anhydrous $MgSO_4$. Solvent was removed via rotovap. The residue was purified by flash chromatography on silica gel (5 g, 98:2 v:v hexane:ethyl acetate) to give **18***b* as a white solid (74 mg, 178 μmol) in 80% yield. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.59 (s, 6H, $CH_3 \times 2$), 1.67 (s, 6H, $CH_3 \times 2$), 1.93–2.10 (m, 8H, CH_2, at C4, C5, C8, and C9), 4.69 (d, J = 6.8 Hz, 2H, CH_2O), 5.08 (bt, J = 6.7 Hz, 2H, C*H*=C, at C6 and C10), 5.33 (bt, J = 6.9 Hz, 1H, C*H*=C at C2), 7.15–7.35 (m, 10H, Ar*H*). **18***b* was recrystallized 4 times from methanol to constant specific activity, isotope ratio, and mp. ^{3}H/^{14}C 6.95 ± 0.10, mp 60.5–61.0°C (lit. (17) mp 61–62°C), 174 ± 0.4 pCi ^{3}H/μmol and 25.2 ± 0.5 pCi ^{14}C/μmol. From the isotope ratio and the specific activity of the diphenylurethane, the ^{3}H specific activity of *Z*-[4-^{3}H, 4-^{14}C]IPP (**2***b*) was calculated to be 36.7 μCi/μmol, and the ^{3}H specific activity of (4*R*,8*R*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP (**1***b*) was calculated to be 73.3 μCi/μmol.

*(4*S*,8*S*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]Farnesyl diphenylurethane (**18**a) (17)*

An aliquot of a solution of (4*S*,8*S*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP (**1***a*) was converted to the corresponding (4*S*,8*S*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]farnesyl diphenylurethane (**18***a*) as described above for **18***b*. The diphenylurethane was recrystallized 4 times from methanol to constant specific activity, isotope ratio, and mp. ^{3}H/^{14}C 6.02 ± 0.01, 104 ± 1 pCi ^{3}H/μmol, 17.6 ± 0.5 pCi ^{14}C/μmol, mp 60.5–61.5°C (lit. (17) mp 61–62°C). Based on the isotope ratio and the specific activity of the diphenylurethane, the ^{3}H specific activity of *E*-[4-^{3}H, 4-^{14}C]IPP (**2***a*) was calculated to be 20.4 μCi/μmol, and the ^{3}H specific activity of (4*S*,8*S*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP (**1***a*)was calculated to be 40.7 μCi/μmol.

Isolation of pentalenene synthase from Streptomyces *UC5319 (5, 9, 10)*

A vegetative medium consisting of Pharmamedia (2.5 g) and Bactodextrose (2.5 g) in 100 mL nanopure water, pH adjusted to 7.2, in a 500-mL flask was inoculated with spores of *Streptomyces* UC5319 and the culture incubated at 26°C at 300 rpm for 1 day and at 28°C at 300 rpm for an additional 1.5 days. A 40-mL portion of this 2.5-day-old vegetative culture was used to inoculate a production culture containing NaCl (8 g), $CaCO_3$ (5 g), Casein (acid type) (16.68 g), Bactodextrose (13.32 g), molasses (10 g), and Dextrin (corn type 3) (80 g) in 4 L nanopure water, pH adjusted to 7.2, in a 8-L cylindrical flask. The culture was shaken at 30 cycles/min at 32°C with continuous aeration (10 psi) for 2.5 days, then aeration was discontinued and the culture shaken at 30 cycles/min at 32°C for an additional 24 h. The contents of the flask were centrifuged (GS 3 rotor, 7500 rpm, 10 100 × *g*) at 4°C for 20 min and the mycelial pellet was suspended in 1.0 M KCl and recentrifuged at 10 100 × *g* at 4°C. The supernatant was decanted from the mycelial pellet. The above procedure was repeated successively with 0.8 M NaCl, nanopure water, and breaking buffer. The breaking buffer consisted of 50 mM K_2HPO_4, 10% glycerol (by volume), 1 mM EDTA – Na_2 in nanopure water. This solution was degassed in vacuo with vigorous stirring for 45 min, then chilled to 4°C, the pH adjusted to 7.2, and β-mercaptoethanol was added to a final concentration of 5 mM. The mycelial pellet was resuspended in 200 mL of breaking buffer, and phenylmethylsulfonyl fluoride (PMSF) (3.5 mg PMSF/1 mL acetone, 5 μL, final concentration 0.5 μM) was added. The resulting cell suspension was poured into a 350mL polycarbonate chamber containing a 100-ML volume of glass beads (0.5 mm diameter). Breaking buffer was added to barely cover the surface of the beads and air bubbles were removed with a glass stirring rod before the suspension was poured. The polycarbonate chamber was cooled with an ice-water jacket, and the cells were broken in a Biospec bead beater under a 15 s on/15 s off cycle for 6 min. The beads and the cellular debris were removed by centrifugation (GS 3 rotor, 7500 rpm, 10 100 × *g*) at 4°C for 20 min. The supernatant was decanted into a glass jar and stored at 4°C. Pentalenene synthase activity was assayed with [1-^{3}H]FPP (8.0 μM, 5.0×10^5 dpm/10 μL, 56.3 μCi/μmol, 10 μL, 4.0 nmol), in 480 μL 20 mM Tris buffer, pH 8.2, containing 10 μL of the cell-free extract. The mixture was incubated at 30°C for 10 min, then extracted with 1.5 mL hexane. The hexane extract was filtered through a Pasteur pipet of silica gel and the silica gel was washed with an additional 1.5 mL hexane. The hexane eluate was counted for radioactivity: ^{3}H 6.94×10^3 dpm corresponding to pentalenene synthase activity in crude cell-free extracts of 5.5 nmol/mL cell-free extract per 10 min.

*Preparative-scale cyclization of (4*R,*8*R*)-[4,8-$^3H_2$, 4,8$^{14}C_2$]FPP (**1**b) to pentalenene (**4**b)*

A mixture of (4*R*,8*R*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP (**1***b* 73.3 μCi ^{3}H/μmol, 9.59×10^4 dpm ^{3}H/10 μL, 700 μL, 41.2 nmol, final concentration 5.9 μM), Tris pH 8.2 (4.90 mL), and cell-free extract (1.40 mL), was incubated at 30°C for 2 h. The incubation was quenched after 2 h by addition of 3 mL ethanol along with 99 mg synthetic (±)-pentalenene in 10 mL of pentane. The mixture was extracted and the pentane layer was filtered through silica gel. The aqueous phase was further extracted with 2×10 mL pentane and each pentane extract was passed through the silica gel column. Counting of an aliquot indicated a total ^{3}H activity of 2.59×10^6 dpm and ^{14}C activity of 4.10×10^5 dpm (39% radiochemical yield). The solution was concentrated to ca. 2 mL by rotovap and stored at −10°C until further use.

*Enzymatic cyclization of (4*S,*8*S*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP (**1**a) to pentalenene (**4**a)*

A mixture of (4*S*,8*S*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP (**1***a*, 40.7 μCi ^{3}H/μmol, 3.29×10^4 dpm ^{3}H/10 μL, 1.20 mL, 43.7 nmol, final concentration 7.3 μM), Tris pH 8.2 (3.6 mL), and cell-free extract of *Streptomyces* UC5319 (1.20 mL) was incubated at 30°C for 2 h. After addition of carrier (±)-pentalenene (49 mg), the cyclization product was isolated as described above: total ^{14}C activity 2.49×10^5 dpm (39% radiochemical yield). The pentane extracts were concentrated to ca. 2 mL by rotovap and stored at −10°C until further use.

*6,7-Dihydroxypentalenane (**19**b) and (**20**b) (10)*

A 1.50-mL portion of a solution of pentalene (**4***b*) (74 mg, 363 μmol) derived from (4*R*,8*R*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP (**1***b*) was converted to the corresponding mixture of diastereomeric *cis*-6,7-diols **19***b* and **20***b* as previously described (10). The resulting diastereomers were separated by fractional recrystallization from CH_2Cl_2–hexane and each diastereomer was recrystallized to constant activity (**19***b*, ^{3}H $(3.85 \pm 0.02) \times 10^3$ pCi/μmol, ^{14}C $(5.80 \pm 0.06) \times 10^2$ pCi/μmol; **20***b*, ^{3}H $(3.74 \pm 0.18) \times 10^3$ pCi/μmol, ^{14}C $(5.69 \pm 0.25) \times 10^2$ pCi/μmol), and isotope ratio (Table 1) (**19***b* mp 147–148°C (lit. (9) mp 145–146°C); **20***b* mp 75–76.5°C (lit. (9, 10) mp 74.5–75°C)).

*Conversion of pentalenene derived from (4*R,8R*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]-FPP (**1**b) to 7-hydroxypentalenane (**22**b) (9, 10)*

A 500-μL aliquot of a pentane solution of pentalenene (25 mg, 120 μmol) derived from **1***b* was converted to 7-hydroxypentalenane (**22***b*) in 64.0% yield as previously described (9, 10).

*7-Ketopentalenane (**21**b) (9, 10)*

Oxidation of **22***b* with PCC as previously described (10) gave the corresponding ketone **21***b*. $^3H/^{14}C$ 3.46 ± 0.11, ^3H (1.92 ± 0.02) × 10^3 pCi/μmol, ^{14}C (5.55 ± 0.09) × 10^2 pCi/μmol (Table 1).

*6,7-Dihydroxypentalenanes (**19**a and **20**a)*

19*a* and **20***a* were prepared from pentalenene (**4***a*) derived from (4*S*,8*S*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]FPP (**1***a*) by procedures identical to those described above. The individual diastereomers were separated by fractional recrystallization and the β diastereomer (**19***a*) was recrystallized to constant activity (^3H (2.84 ± 0.09) × 10^3 pCi/μmol, ^{14}C (8.99 ± 0.34) × 10^2 pCi/μmol) and isotope ratio (Table 1); mp 147–148°C (9).

*Conversion of pentalenene derived from (4*S,8S*)-[4,8-$^3H_2$, 4,8-$^{14}C_2$]-FPP (**1**a) to 7-hydroxypentalenane (**22**a)*

The conversion of pentalenene (**4***a*) (10 mg, 49 μmol), derived from **1***a*, to **22***a* was carried out as described above.

*Preparation of 7-ketopentalenane (**21**a)*

21*a* was prepared from the corresponding alcohol **22***a* as described above. ^3H (2.49 ± 0.02) × 10^3 pCi/μmol, ^{14}C (8.31 ± 0.07) × 10^2 pCi/μmol (Table 1).

This paper is dedicated to Professor David B. MacLean

WILLIAM A. AYER, YU-TING MA, JIA-SEN LIU, MEI-FEN HUANG, L. WAYNE SCHULTZ, and JON CLARDY. Can. J. Chem. **72**, 128 (1994).

The structure of macleanine, a unique type of Lycopodium alkaloid, was deduced from its spectroscopic (especially ^1H and ^{13}C nuclear magnetic resonance) properties and from biogenetic considerations. The structure was verified by an X-ray crystallographic study of the hydroperchlorate.

WILLIAM A. AYER, YU-TING MA, JIA-SEN LIU, MEI-FEN HUANG, L. WAYNE SCHULTZ et JON CLARDY. Can. J. Chem. **72**, 128 (1994).

On a déduit la structrure de la macleanine, un type unique d'alcaloïde du *Lycopodium*, en se basant sur ses propriétés spectroscopiques (spécialement la résonance magnétique nucléaire du ^1H et du ^{13}C) et sur des considérations biogénétiques. On a vérifié la structure par une étude de diffraction des rayons X sur son perchlorate.

[Traduit par la rédaction]

Introduction

The discovery that the dinitrogenous Lycopodium alkaloid huperzine A (**1**) (1) is a potent acetylcholinesterase inhibitor (2) has stimulated renewed interest in this group of alkaloids (3). Huperzine A (**1**) is isolated from the Chinese folk medicinal plant *Huperzia serrata* (= *Lycopodium serrata*) (1) and has been shown to be identical with the alkaloid selagine, which had previously been isolated from *L. selago* and incorrectly assigned structure **2** (4, 5). Huperzine A is reported to increase efficiency for learning and memory in animals (1) and to show promise in the treatment of Alzheimer's disease and myasthenia gravis (6–8). Repeated chromatography of the mother liquors from a large-scale isolation of huperzine A (50 kg of *H. serrata*) (9) led to the isolation of a new alkaloid (17 mg) $C_{16}H_{26}N_2$ (**3**), which represents a unique structural type among the Lycopodium alkaloids.[3] We suggest the name macleanine for this alkaloid, in honor of D.B. MacLean, a pioneer in the field of Lycopodium alkaloids (10).

Results and discussion

The molecular formula $C_{16}H_{26}N_2$ for macleanine was established by high-resolution electron impact mass spectrometry (hreims) and confirmed by chemical ionization mass spectrometry (cims). The hreims shows the molecular ion as the base peak and, aside from the $M^+ - 15$ peak, the fragmentation pattern is quite different from that of previously reported Lycopodium alkaloids, many of which have very characteristic fragmentation patterns (11). Since the ^{13}C nmr spectrum and the ir spectrum of macleanine show no evidence for the presence of double bonds, the molecule must be pentacyclic. The ir spectrum does show NH absorption (3260 cm^{-1}), although the compound does not react with acetic anhydride–pyridine at room temperature. Since the ^{13}C nmr gives evidence for 25 carbon-bound hydrogens, and the ^1H nmr shows a single exchangeable hydrogen, one nitrogen is tertiary and the other is secondary. The lowest field signal in the ^{13}C nmr, a singlet at δ 84.9, suggests that one carbon in the molecule is attached to both nitrogens.

^1H–^1H COSY experiments indicate the presence of three isolated spin systems, one representing the hydrogens on carbons 14, 15, 16, 8, 7, and 6 and initiated at the easily recognizable signal for the C-16 methyl hydrogens, another representing the C-9, C-10, and C-11 methylenes originating at the C-9 H's at δ 3.40 and 2.95, and a third originating at the C-1 H's (δ 4.30 and 2.75) and extending along C-2, C-3, and C4. The signal for H-5 appears as a broad singlet at δ 3.20, which shows correlation with H-4 (δ 1.80) and H-6 (δ 1.20 and 1.85), and thus connects two of the spin systems. The dihedral angles between H-5 and the hydrogens on C-4 and C-6 in **3** are approximately 90°. An HMQC experiment established that the proton at δ 3.20 is located on a nitrogen-bearing carbon (δ 58.9). The ^1H and ^{13}C nmr spectra and relevant COSY, HMQC, and HMBC data are summarized in Table 1.

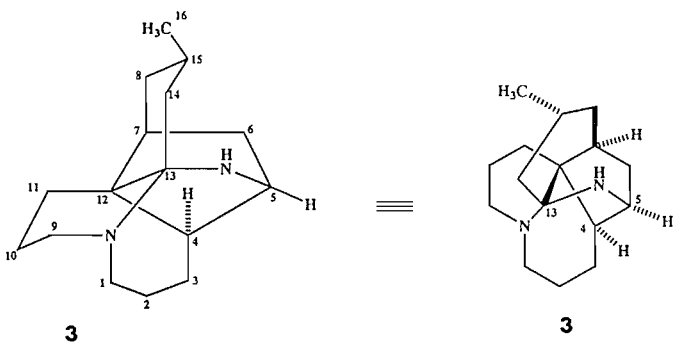
[a]An asterisk denotes overlapping signals.



At this stage, biogenetic reasoning suggested structure **3** as a possibility for macleanine. All Lycopodium alkaloids known to date possess functionality at C-5 (3, 10, 11). Fawcettimine (**4**) (Scheme 1) readily forms a transannular carbinolamine (**4***a*) (3, 12). We reasoned that if the C-5 carbonyl group of fawcettimine underwent reductive amination to **5**, and this formed the internal immonium ion **6** (the *trans* C—N double bond is in an eight-membered ring), transannular cyclization would lead to structure **3**. An HMBC experiment demonstrated that H-5 is three-bond coupled to the carbon (C-13) bearing the two nitrogens and another quaternary carbon (C-12) as well as to C-7 (see Table 1). It is not coupled to either C-1 or C-9, excluding C-3 as a possible location of the second nitrogen.

To unambiguously establish structure **3**, a crystalline perchlorate was prepared. Macleanine itself gives twinned crystals. A computer-generated perspective drawing of the final X-ray model of macleanine (**3**) is shown in Fig. 1. The absolute stere-

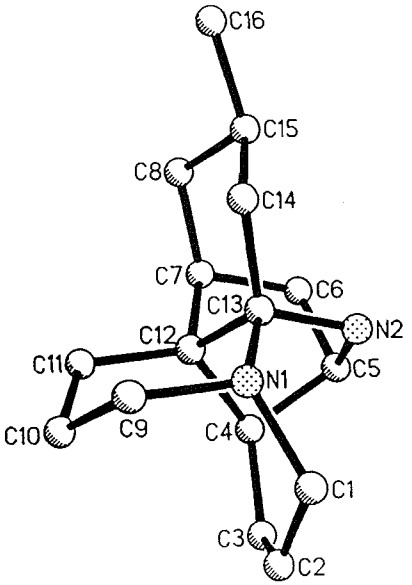

FIG. 1. A computer-generated perspective drawing of one of the independent molecules of macleanine (**3**) hydroperchlorate (anion omitted). The absolute configuration was determined from the anomalous scattering of the chlorine. Hydrogens are omitted for clarity.

ochemistry was determined by the absolute structure method (SHELXTL PLUS implementation) using the anomalous scattering from the chlorine atoms. The crystals contained two crystallographically independent molecules, but the polycyclic arrays of both had the same conformation. The six-membered carbocyclic ring and the piperidine ring containing N-1 have chair conformations, and the piperidine ring containing N-2 is in a boat conformation. The five-membered ring is in an envelope conformation with C-4 as the flap atom. The seven-membered ring is in an approximately pseudochair conformation. The X-ray structure unequivocally confirms structure **3** and shows that the absolute configuration fits the "normal" Lycopodium alkaloid pattern.

The possibility that macleanine (**3**) is an artefact of the isolation procedure seems remote since formation of intermediate **5** from a fawcettimine-type precursor would require a reductive process. Addition of ammonia to a C-13 carbonyl followed by displacement of a leaving group from C-5 (reduced), although not ruled out, seems unlikely.

The pentacyclic alkaloid **3** represents a new structural type among the Lycopodium alkaloids.

Experimental

Isolation of macleanine (3)

The total crude alkaloids from 50 kg of *Huperzia serrata* (= *Lycopodium serratum*) where isolated as previously described (9) and the pyridone alkaloid fraction was obtained by extraction with 0.5% aqueous NaOH. This fraction was chromatographed several times over silica gel (eluent 1–4% methanol in $CHCl_3$). The fractions that followed huperzine A (**1**) were further chromatographed over silica gel, eluting with acetone, then with acetone–methanol (40:1, 20:1, 10:1). The fraction eluted with acetone–methanol (10:1) provided macleanine (**3**, 17 mg), mp ~300°C (dec.), $[\alpha]_D$ + 12.5 (*c* 0.24, $CHCl_3$); ir ν_{max}: 3240 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr, see Table 1; hreims, *m/z* calcd. for $C_{16}H_{26}N_2$ (M^+): 246.2095; found; 246.2098 (100), 231 (7), 218 (37), 204 (24), 203 (17), 190 (10), 176 (26), 174 (23), 160 (14), 148 (14), 134 (17), 122 (16), 70 (42); cims (reagent gas ammonia): 247 ($M + H^+$, 100), 493 ($2M + H^+$).

Macleanine hydroperchlorate

Macleanine (**3**, 5 mg) in methanol was treated dropwise with methanolic perchloric acid (prepared by diluting 70% perchloric acid (1 mL) with methanol (9 mL)) to pH ~5.5. The crystalline perchlorate obtained (5 mg) was recrystallized from methanol–ether to give colorless crystals, mp 195–197°C. It crystallized as flat plates in the monoclinic space group $P2_1$ with $a = 8.244(1)$, $b = 15.226(2)$, $c = 3.853(2)$ Å and $\beta = 96.07(1)°$. The asymmetric unit contained two molecules of the perchlorate salt with empirical formula $C_{16}H_{27}ClN_2O_4$. A hemisphere of data — a Friedel redundant data set — for all reflections with $2\theta \leq 116°$ was collected using CuKα radiation (1.54178 Å). Of the 4706 independent reflections measured, 3630 (77%) were judged observed ($|F_o| \geq 4\sigma(F_o)$). The data set contains Friedel pairs. The data were corrected for absorption using a semi-empirical absorption correction. The structure was solved uneventfully using direct methods and refined using full-matrix least-squares techniques. The final model had anisotropic nonhydrogen atoms and isotropic riding hydrogens, and refinement converged to a standard crystallographic discrepancy index of 6.63% for the observed data. The absolute configuration was determined by an absolute structure refinement, and that refinement converged to an index of 1.03 ± 0.05 for the absolute stereochemistry shown. Refinement with η fixed at 1.0 of the structure and its enantiomer gave *R*-values of 0.085 and 0.095, respectively, a statistically significant difference (13). Archival X-ray data have been deposited with the Cambridge Crystallographic Data Centre.[4]

L'incorporation de $CH_3{}^{13}C^{18}O_2Na$ et de $CD_3CH_2{}^{13}CO_2Na$ dans l'alcaloïde de l'indolizidine, la cyclizidine **1**, produite par du *Streptomyces* de l'espèce NCIB 11649, comporte un oxygène attaché en position C-2 qui est dérivé d'une façon intacte de l'acétate alors que le noyau cyclopropyle est dérivé d'une unité intacte de propionate. Toutefois, le degré et la stéréochimie de l'incorporation du propionate de sodium deutéré indique qu'il subit une modification inattendue au cours de son incorporation dans le noyau cyclopropyle.

[Traduit par la rédaction]

Introduction

Cyclizidine **1** is an indolizidine alkaloid produced by *Streptomyces* species NCIB 11649. Its isolation and structure determination by NMR spectroscopy and X-ray crystallography were first reported in 1982 (1). Intriguingly, a very similar indolizidine alkaloid, indolizomycin **2**, was subsequently isolated from a strain created by protoplast fusion of two different *Streptomyces* species, neither of which produced any similar compounds (2). Cyclizidine is especially unusual because, to our knowledge, a monosubstituted cyclopropyl ring has only been reported in one other pair of natural products, the monoterpenes **3** and **4** (3). The biosynthetic pathway to cyclizidine is therefore of particular interest.

We previously established that cyclizidine **1** is derived from acetate and propionate units in a polyketide fashion as shown in Scheme 1 (4). Thus incorporation of $^{13}CH_3{}^{13}CO_2Na$ labelled four pairs of carbons (C-12/C-13, C-2/C-3, C-7/C-8, and C-5/C-6) and $CH_3CH_2{}^{13}CO_2Na$ labelled three carbons (C-14, C-10, and C-8a). As expected, $CD_3CH_2CO_2Na$ labelled the two methyl groups (C-9 and C-17) and two hydrogens on C-16 of the cyclopropyl ring.[3] We describe here further labelling studies that help to define possible mechanism(s) of formation of the five- and three-membered rings of cyclizidine.

Results and discussion

Incorporation of sodium [1-^{13}C,$^{18}O_2$]acetate

One possible mechanism for the formation of the five-membered ring is nucleophilic attack by the nitrogen atom on a 2,3-epoxide, as shown in Scheme 2(*a*). This mechanism would mean that the oxygen atom attached to C-2 in cyclizidine is derived from dioxygen. Alternative mechanisms could be proposed in which this oxygen atom is derived from the acetate precursor. To test this, $CH_3{}^{13}C^{18}O_2Na$ was synthesized starting with $K^{13}CN$ (5). Reaction with methyl iodide gave $CH_3{}^{13}CN$, which was hydrolysed in situ using ^{t}BuOK/$H_2{}^{18}O$. A portion of the labelled acetate was converted into its *p*-phenylphenacyl ester for analysis by NMR and MS, which showed ca. 90% ^{13}C and 75% ^{18}O per labelled site.

The ^{13}C NMR spectrum of cyclizidine derived from $CH_3{}^{13}C^{18}O_2Na$ showed a strong (ca. 6%) ^{13}C enrichment at the expected sites (C-12, C-2, C-7, and C-5). C-12 appeared in the spectrum as a singlet while the other three carbons gave multiplets (Fig. 1): C-7 showed a singlet flanked by a low intensity doublet (J 4 Hz) due to long-range coupling to C-5 in molecules in which both carbons are labelled (peak heights indicated that approximately one third of the molecules that had ^{13}C at C-7 also had ^{13}C at C-5); C-5 showed a singlet flanked by a low-intensity doublet and an even lower intensity triplet (each J ~4 Hz), the latter due to molecules in which C-2, C-5, and C-7 are all labelled; C-2 (δ 86.1) gave a pattern of peaks that could only be interpreted as two singlets (Δδ 0.02 ppm) each flanked by doublets (J ~4 Hz) due to coupling to C-5. The separation of the two singlets is in the range expected (6) for the isotopic shift due to ^{18}O singly bonded to ^{13}C and we can conclude that they represent ^{13}C–^{16}O and ^{13}C–^{18}O at C-2. The ratio of the peaks was ca. 40:60 (after allowing for the contribution of natural abundance to the ^{13}C–^{16}O peak). As the initial sodium acetate had 75% ^{18}O per site, it is evident that there has been some loss of ^{18}O but the majority has been retained intact at C-2.

The retention of ^{18}O from [^{18}O]acetate at C-2 of cyclizidine eliminates mechanisms involving a 2,3-epoxide such as shown in Scheme 2(a). Such an epoxide would be generated by epoxidation of a 2,3-double bond and the oxygen atom would thus derive from dioxygen and not be retained intact from the acetate precursor. Indeed the 7,8-epoxide seems to have been made in this way as the lack of any shifted peak for C-7 indicates that during the biosynthesis it has lost the ^{18}O that was originally attached at this position. While this experiment does not give any direct information about the origin of the oxygen atom attached to C-1, it is clear that the 1,2-diol is not derived by attack of water on a 1,2-epoxide. Hence it is likely that this oxygen atom is introduced either by hydroxylation at C-1 or by

[1] Dedicated to Prof Ian Spenser, who introduced one of us (F.J.L.) to biosynthesis, studying quinolizidine alkaloids, and was an excellent teacher of correct biosynthetic methods. The project described here arose from a desire to continue work on similar compounds, but in order to avoid competing on the quinolizidine (6,6) or pyrrolizidine (5,5) ring systems an indolizidine (6,5) alkaloid was chosen instead.

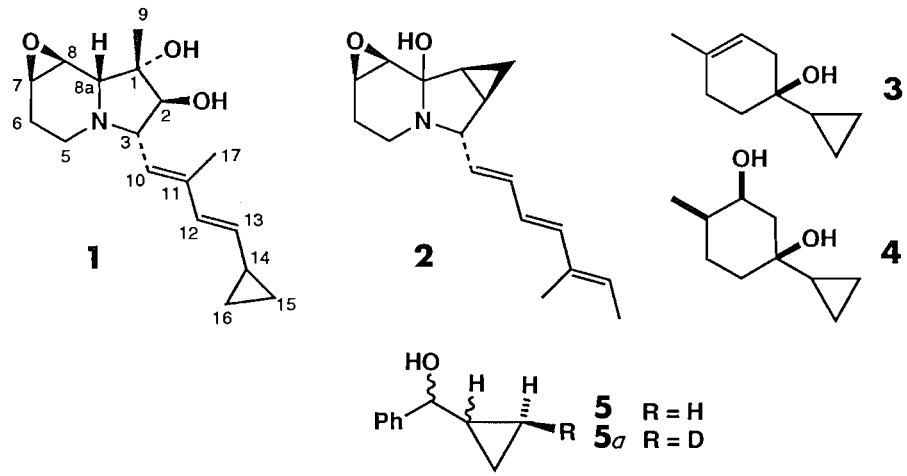

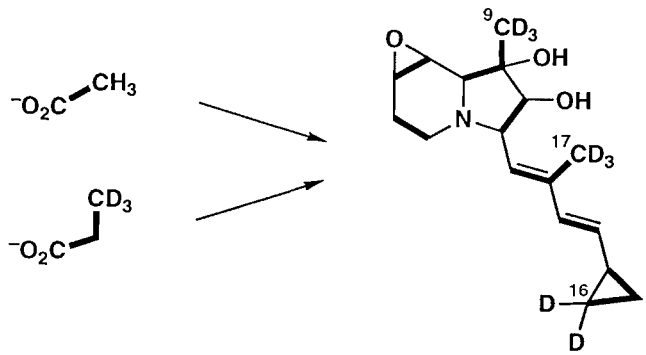

SCHEME 1. The incorporation of acetate and propionate units into cyclizidine.

epoxidation of a 1,8a double bound followed by nucleophilic attack by the nitrogen atom at C-8a, forming the six-membered ring as shown in Scheme 2(b).

Incorporation of sodium [1-^{13}C,3,3,3-$^{2}H_3$]propionate

In a previous communication (4), we reported that the ^{2}H NMR spectrum of cyclizidine derived from $CD_3CH_2CO_2Na$ shows incorporation into the two methyl groups, C-9 (δ 1.34) and C-17 (δ 1.76), and into two sites on C-16 of the cyclopropyl ring (δ 0.76 and 0.40), see Scheme 1. However, an unexpected feature of the spectrum (Fig. 2*a*) was that the deuterium incorporation per labelled site at C-16 was approximately half the level observed at each of the two methyl groups. To understand this phenomenon, it was necessary to determine whether this was due to exchange of these deuterium atoms for protium or due to a reduced level of incorporation of the whole C_3 unit. It was decided to test this by incorporation of $CD_3CH_2{}^{13}CO_2Na$; on formation of the cyclopropane ring, the deuteriated carbon should become attached to the ^{13}C atom and thus cause a detectable β-shift. The precursor was synthesized by treatment of $CH_3{}^{13}CO_2CH_2Ph$ with LDA followed by CD_3I and then hydrogenolysis of the resulting $CD_3CH_2{}^{13}CO_2CH_2Ph$.

In the ^{13}C NMR spectrum of the cyclizidine derived from this precursor three peaks were enhanced as expected. C-10 and C-8a appeared as singlets but C-14 showed a small natural abundance peak at δ 14.23 and shifted peaks 0.09 and 0.19 ppm upfield. These shifts are of the size expected (7) for isotopic shifts due to β-deuterium atoms and the peaks are therefore assigned to ^{13}C—CHD and ^{13}C—CD_2 respectively (Fig. 3). This observation of isotopic shifts proves that all three carbon atoms of the cyclopropane ring are indeed derived intact from a single propionate molecule, as had been previously assumed. The ratio of the intensities of the shifted peaks was ca. 1:6 (CHD:CD_2), indicating that little if any exchange had occurred at this site. As no significant exchange of deuterium has occurred, the low incorporation of deuterium in the cyclopropane ring must be due to low incorporation of the whole propionate unit. In confirmation of this, it was noticeable that the total area of the peaks corre-

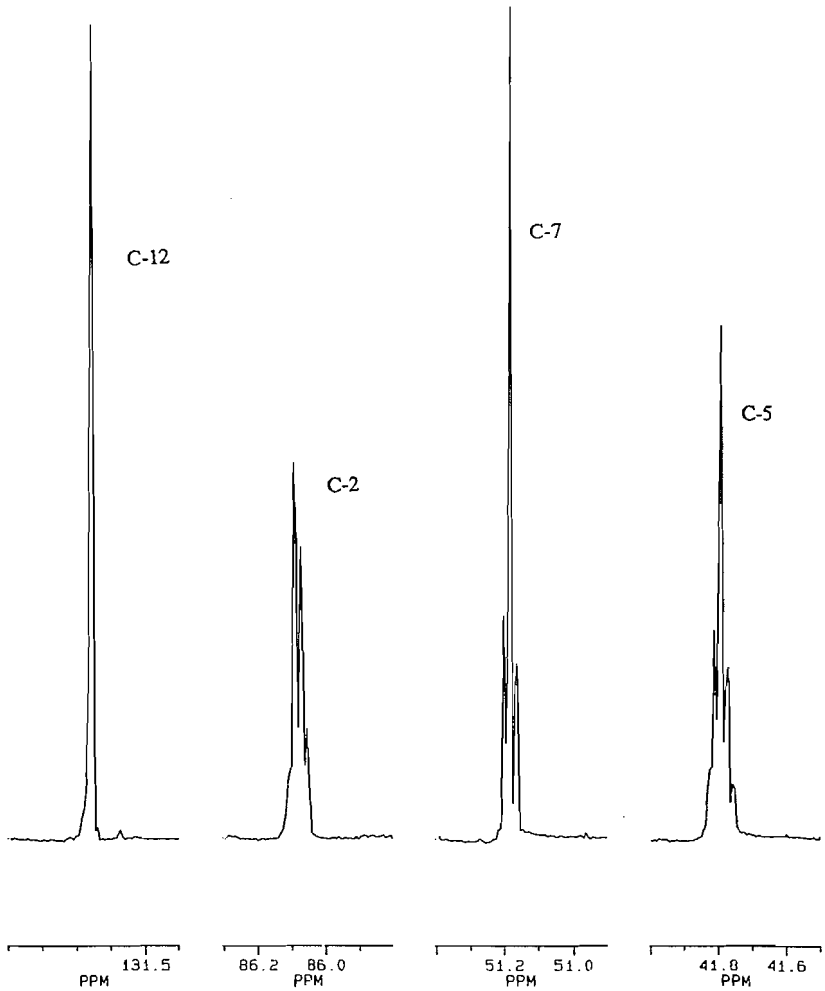

FIG. 1. Four regions, containing the enriched peaks, from the ^{13}C NMR spectrum of cyclizidine **1** derived from $CH_3{}^{13}C^{18}O_2Na$.

sponding to C-14 was about half the area of the other enriched peaks (C-10 and C-8a) whereas in the natural abundance ^{13}C spectrum all three peaks have comparable areas.

The lowered incorporation of propionate into the cyclopropyl ring appears to be due to the deuterium atoms, as undeuteriated $CH_3CH_2{}^{13}CO_2Na$ showed approximately equal incorporation into the three labelled sites of cyclizidine (4). The obvious conclusion is that there is an isotope effect for the reaction which removes the hydrogen atom from this methyl group. However, if the molecule at this stage is already committed to the biosynthesis of cyclizidine, it would be expected that the incorporation of the deuteriated precursor would only be delayed, not prevented. Therefore the final level of incorporation would not be significantly affected. If, on the other hand, the propionate unit is not already committed to the biosynthesis of cyclizidine, it would be expected that the incorporation of the deuteriated precursor into cyclizidine would be lowered as the deuteriated molecules could be diverted down a different pathway.

It was of importance to our experiments on the stereochemistry of propionate incorporation into the cyclopropyl ring that we determine whether C-3 of the propionate ends up as the pro*R* or pro*S* methylene group. In cyclizidine itself there is a very small difference in the ^{13}C chemical shifts of these two methylene groups but there is no way of telling which peak is which. In the proton NMR spectrum there is no discernible difference between the hydrogen atoms on the two adjacent carbon atoms. However, from our previous work (8) we knew that all four methylene protons are well separated in the proton NMR spectrum of phenyl cyclopropyl carbinol **5**. Furthermore these proton signals had been rigorously assigned (see Fig. 4*a*) on the basis of NOE and shift reagent results and by synthesis of a stereospecifically deuteriated form **5***a*.

Therefore a quantity of cyclizidine **1***a* derived by incorporation of $CD_3CH_2CO_2Na$ (synthesized in the same way as the corresponding ^{13}C-labelled material described above) was degraded by the sequence of reactions shown in Scheme 3 to give phenyl cyclopropyl carbinol **5***b*, initially as a racemate. This had to be resolved because if the deuterium atoms occupy the positions of H_A and H_B in one enantiomer then they will occupy the positions of H_C and H_D in the other (see structures in Fig. 4). Hence all four sites would show deuterium labelling.

The racemic alcohol was resolved by formation of the diastereoisomeric (1*S*)-camphanate esters **6**, which were separated by HPLC. Alkaline hydrolysis of the separate diastereoisomers gave back the enantiomeric alcohols (*S*)-**5***b* and (*R*)-**5***b*. The first eluted diastereoisomer had previously been assigned to the (*S*) alcohol and the second eluted one to the (*R*) alcohol on the basis of the chemical shifts of the Mosher's esters (8). This assignment has now been confirmed by an X-ray crystal structure of the latter diastereoisomer, which clearly shows its

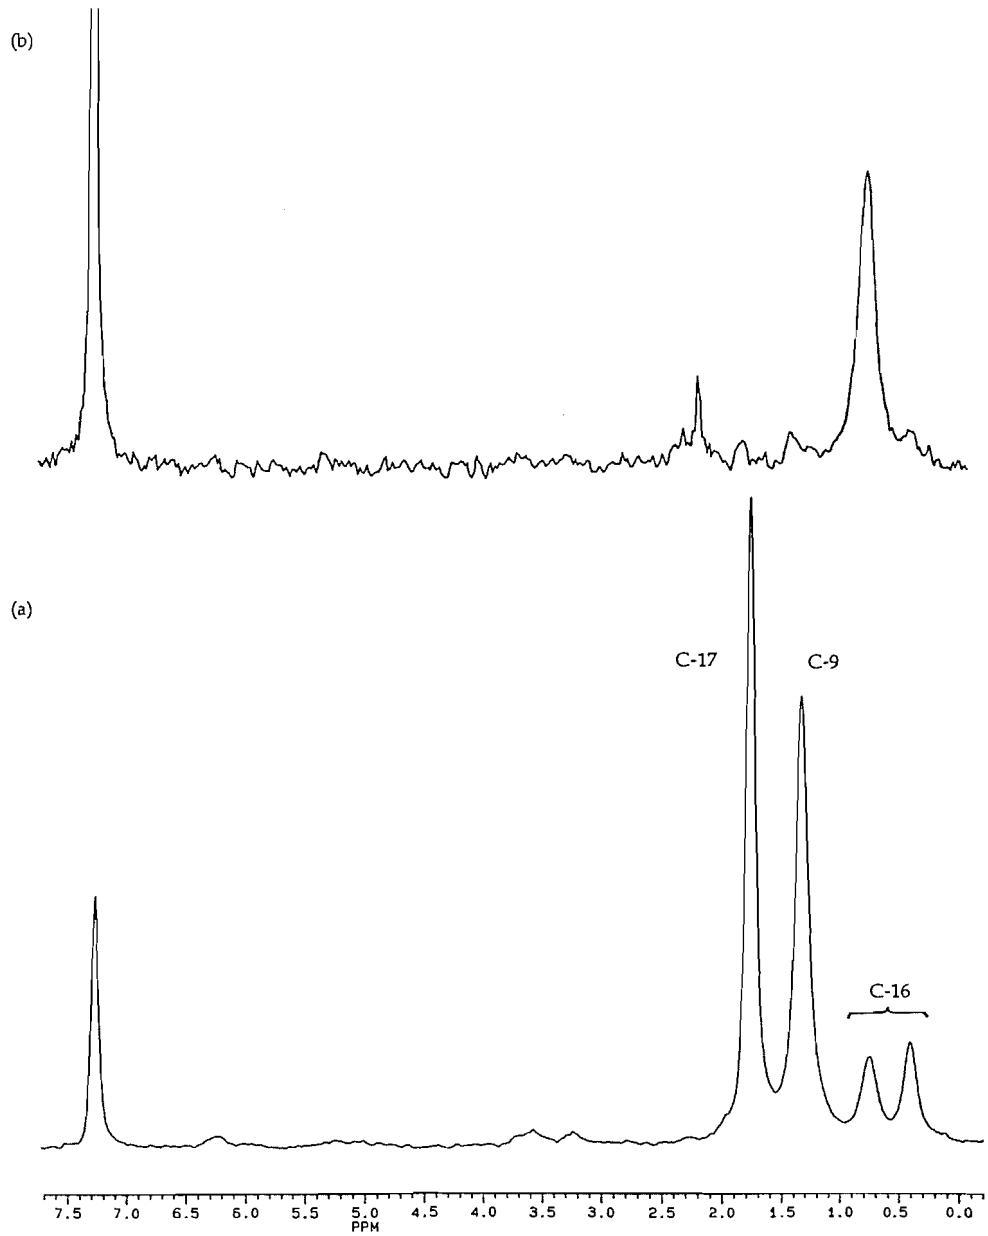

FIG. 2. ^2H NMR spectra of cyclizidine **1** derived from (*a*) $CD_3CH_2CO_2Na$ and (*b*) $CH_3CD_2CO_2Na$. The peaks at δ7.25 in both spectra are due to solvent ($CHCl_3$) and the small peak at δ 2.15 in (*b*) is due to some residual $CH_3CD_2CO_2Na$.

stereochemistry relative to that of the camphanate moiety (Fig. 5).

Partial deuterium NMR spectra of the separate enantiomers, (*S*)-**5***b* and (*R*)-**5***b*, derived from the deuteriated propionate are shown in Figs. 4*b* and 4*c*.[4] It can be seen that just two of the four methylene protons are deuteriated in each enantiomer, H_A and H_B in the (*R*) enantiomer and H_C and H_D in the (*S*) enantiomer. In each enantiomer this corresponds to the pro*S* methylene group. It is thus the pro*S* methylene on the cyclopropyl ring of cyclizidine that is C-16, i.e., derived from C-3 of propionate.

Incorporation of sodium [2-$^2H_2$]propionate

In accord with the established mechanisms of polyketide biosynthesis, it would be expected that the cyclopropyl ring of cyclizidine, being the chain-starter unit, would be derived direct from propionyl CoA, whereas the other propionate-derived units would be incorporated via methylmalonyl CoA. To test this, the incorporation of $CH_3CD_2CO_2Na$ was investigated. If the propionyl CoA is incorporated directly, one would expect retention of both deuterium atoms in the cyclopropane ring of cyclizidine. The deuteriated propionate precursor was made by exchange of the α protons of propionic acid in concentrated D_2SO_4.

Surprisingly, however, on incorporation of the $CH_3CD_2CO_2Na$ into cyclizidine, the ^2H NMR spectrum showed that deuterium was incorporated into only one of the positions on C-15 (δ 0.76) and not into the other position (δ 0.40), Fig. 2(*b*). This position was shown to be the one *cis* to the proton on C-14 by ^1H NOE experiments. As $CD_3CH_2CO_2Na$ has been shown to label the pro*S* methylene group in the cyclopropyl ring of

[4]In addition to the peaks shown in Fig. 4, a small peak was also observed at δ 1.2 for each enantiomer. This is due to deuterium in the cyclopropylmethine position, a result of biosynthetic scrambling of the label into position 14 of cyclizidine.

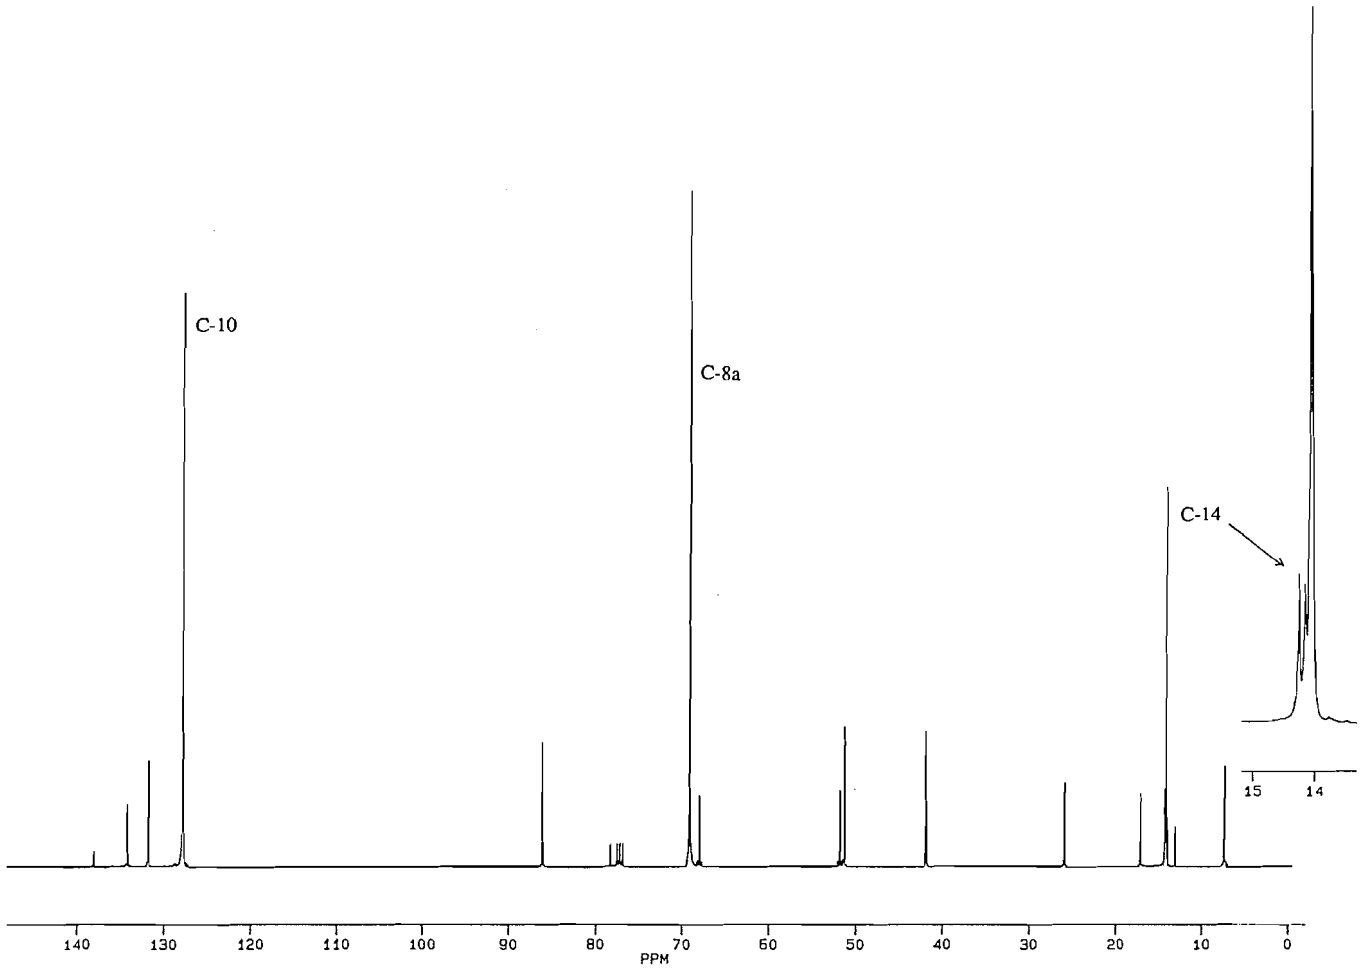

FIG. 3. ^{13}C NMR spectrum of cyclizidine **1** derived from $CD_3CH_2{}^{13}CO_2Na$.

cyclizidine, it can be assumed that $CH_3CD_2CO_2Na$ labels the pro*R* methylene, as shown in structure **1***b*, Scheme 4. Thus it can be seen that the retained deuterium atom is in the pro*R* position on this particular methylene group.

To determine which deuterium atom of the $CH_3CD_2CO_2Na$ is lost and which retained, (2*R*)- and (2*S*)-CH_3CHDCO_2Na were made by treatment of (2*S*)- and (2*R*)-2-bromopropionic acids with lithium triethylborodeuteride (9). The enantiomeric purities of the resulting monodeuteriated propionate salts were estimated at 96% *R* and 93% *S*, respectively, on the basis of the ^1H NMR spectra of their esters with methyl (*S*)-mandelate (10).

Each monodeuteriated propionate salt was mixed with sodium [1-^{14}C]propionate and fed to the organism. The samples of cyclizidine isolated from the two experiments showed comparable levels of ^{14}C (13 and 17% specific incorporation) but only (2*S*)-CH_3CHDCO_2Na showed any incorporation of deuterium by ^2H NMR spectroscopy. Again the only significant peak in the ^2H NMR spectrum was at δ 0.76. A rough estimate of the deuterium enrichment (obtained by comparing the peak areas for the enriched position and for the natural abundance ^2H signal from the solvent, $CHCl_3$) was 3%. When compared with the ^{14}C incorporation, this indicates that even the (2*S*)-[2-^2H]-propionate had exchanged ca. 80% of its deuterium during the biosynthetic process. The most unusual feature of this incorporation of deuterium, however, is that the deuterium atom in the pro*S* position of the propionate precursor ends up in the pro*R* position of its methylene group in cyclizidine, an overall inversion of configuration (see Scheme 4).

As explained above, the loss of any deuterium from C-2 of propionate was unexpected as propionyl CoA **7** was the assumed starter unit for the polyketide chain assembly. However, rapid and reversible carboxylation of the propionyl CoA **7** could occur to give (*S*)-methylmalonyl CoA **8** and this process is known (11) to result in loss of the pro*R* hydrogen atom (see Scheme 5). Reversible interconversion of (*S*)- and (*R*)-methylmalonyl CoA **9**, catalyzed by methylmalonyl CoA epimerase, results in the loss of the remaining hydrogen atom on C-2 (12) and this could then account for the observed partial loss of the pro*S* deuterium atom. These reversible enzymic reactions cannot, however, explain the observed inversion of configuration.

A biosynthetic pathway that could explain the inversion of configuration upon incorporation of (2*S*)-CH_3CHDCO_2Na into cyclizidine is outlined in Scheme 6. This scheme envisages that dehydrogenation of the propionate unit could occur at the stage of propionyl CoA (or later) with loss of the pro*R* hydrogen atom at C-2. Michael addition of HX (where X could be OH or some other leaving group) to the acrylyl unit could then occur with the hydrogen being added in the pro*S* position at C-2, thus achieving the inversion of configuration. The leaving group X could subsequently be involved in formation of the cyclopropane ring, possibly with simultaneous formation of the five-membered ring as shown in the step **10** → **11**.

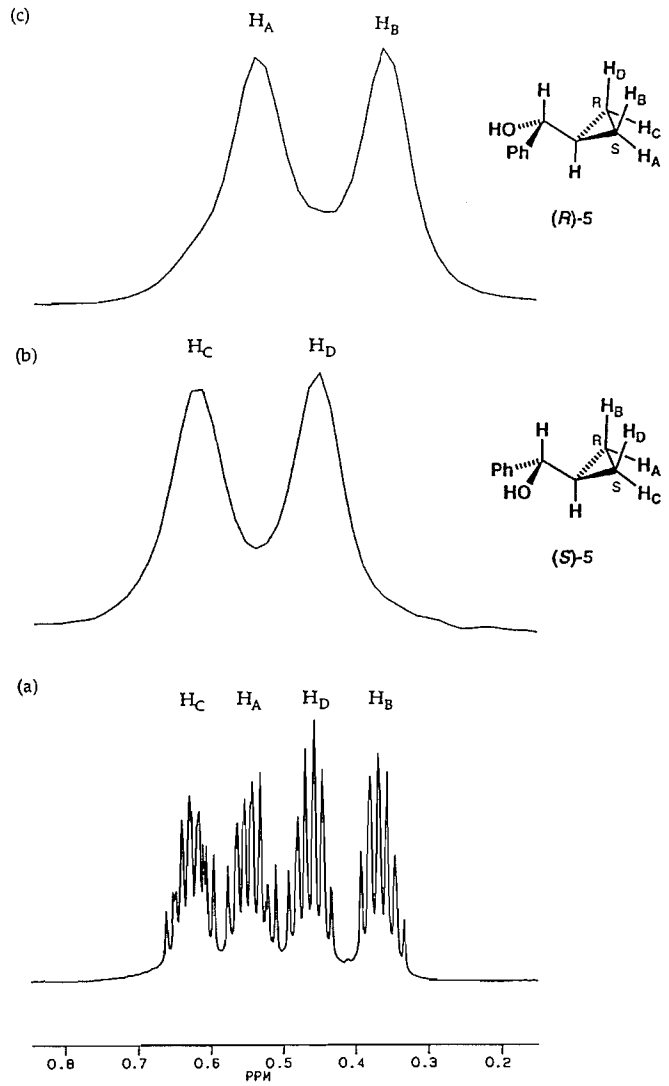

FIG. 4. (*a*) Part of the ^1H NMR spectrum of cyclopropyl phenyl carbinol **5**; assignments are as described in ref. 8. (*b*) and (*c*) Parts of the ^2H NMR spectra of (*S*)- and (*R*)-cyclopropyl phenyl carbinols **5***b* from degradation of cyclizidine **1***a* derived from $CD_3CH_2CO_2Na$.

The dehydrogenation of acyl CoA thioesters and then hydration of the resulting enoyl CoA thioesters to give β-hydroxyacyl CoA thioesters are well-known steps in the β-oxidation of fatty acids. An early study of short-chain acyl CoA dehydrogenase (13) reported that propionyl CoA is dehydrogenated at a reasonable rate but a later study (14) found only a very low rate. Other authors, however, have reported a propionyl CoA dehydrogenase that is involved in the interconversion of lactate and propionate (15). The acyl CoA dehydrogenases studied so far (16, 17) have catalyzed the antiperiplanar removal of the pro-2*R* and pro-3*R* hydrogen atoms, which is the stereochemistry required in our hypothesis. However, the stereochemistry of propionyl CoA dehydrogenase specifically has not been determined.

The enoyl CoA hydratase (crotonase) involved in fatty acid oxidation has been shown to hydrate acrylyl CoA (18) but it performs a *syn* addition of water to crotonyl CoA, giving (*S*)-3-hydroxybutyryl CoA with addition of the pro-*R* proton at C-2 (19, 20). Our hypothesis requires the opposite stereochemistry. However, in fatty acid biosynthesis the corresponding reaction does involve the pro-*S* proton of (*R*)-3-hydroxybutyryl ACP and in addition there are at least two reports of organisms that contain two different enoyl CoA hydratases for the conversion of crotonyl CoA into the (*R*) and (*S*) epimers of 3-hydroxybutyryl CoA (21, 22). It seems quite possible, therefore, that acrylyl CoA is hydrated in our cyclizidine-producing organism with addition of a proton in the pro-*S* position at C-2.

The pathway outlined in Scheme 6 is consistent with all the evidence currently available. It also provides an explanation of why the double bonds in the side chain of cyclizidine are within acetate- or propionate-derived units rather than between them as is more normal in polyketides. Furthermore, the isotope effect expected for the dehydrogenation of [3,3,3-$^2H_3$]propionyl CoA would explain why this precursor is incorporated better into the other two propionate-derived units than into the cyclopropyl ring of cyclizidine.

As yet the pathway shown in Scheme 6 is only one of several possibilities. Incorporation experiments with labelled acrylate and 3-hydroxypropionate are planned to test the proposal. However, the results presented in this paper do require that some unexpected reactions occur that cause the inversion of configuration at C-2 of the propionate unit destined to be the

cyclopropyl ring of cyclizidine. We feel that the pathway presented is the simplest explanation available.

Experimental methods

Melting points were determined on a Reichert Kofler hot-stage apparatus and are uncorrected. Ultraviolet spectra were recorded on a Uvikon 810 spectrophotometer. Infrared spectra were measured with a Perkin–Elmer 297 spectrometer using a polystyrene standard. Proton NMR spectra were recorded on Bruker WP-80 (80 MHz), WM-250 (250 MHz), and AM-400 (400 MHz) spectrometers, using the solvent signal as the standard. All spectra were recorded in deuteriochloroform unless otherwise stated. Deuterium NMR spectra were obtained on either the Bruker WM-250 (38 MHz) or the AM-400 spectrometer (61 MHz). Carbon NMR spectra were recorded on the Bruker WM-250 (62.5 MHz) or the AM-400 (100 MHz) spectrometer and the deuteriated solvent signal was again used as a standard; all spectra are proton noise decoupled unless otherwise stated. Mass spectra were recorded on AEI MS30 and MS50 spectrometers using electron impact ionization except where indicated. Optical rotations were measured for neat liquids on a Perkin–Elmer SP 241 polarimeter.

Flash column chromatography was carried out using Merck Kieselgel 60 (230–400 mesh). Analytical thin-layer chromatography (TLC) was carried out on commercially prepared plates, coated to a thickness of 0.25 mm with Merck Kieselgel GF_{254}. Preparative layer chromatography (PLC) was carried out on larger plates (20 ×20 cm) coated with the same silica gel (1 mm thick).

Radioactive counting was carried out with Packard Tri-Carb 2000CA scintillation analyser. Approximately, 1 mg of sample was weighed accurately and dissolved in an appropriate scintillant solution (either aqueous or toluene, 10 mL).

Organic solutions that had been in contact with water were dried with sodium sulphate unless otherwise stated. Removal of solvents in vacuo was carried out at water pump pressure on a Buchi rotary evaporator at 30°C, unless mentioned otherwise. All solvents were distilled before use. Standard procedures were used to purify all reagents and to dry solvents where indicated.

Production and isolation of cyclizidine 1

The *Streptomyces* strain NCIB 11649 was grown on Czapek dox agar slopes containing 2% yeast (at pH 7) and incubated at 27°C for 7 days. For cyclizidine production, 10 250-mL conical flasks each con-

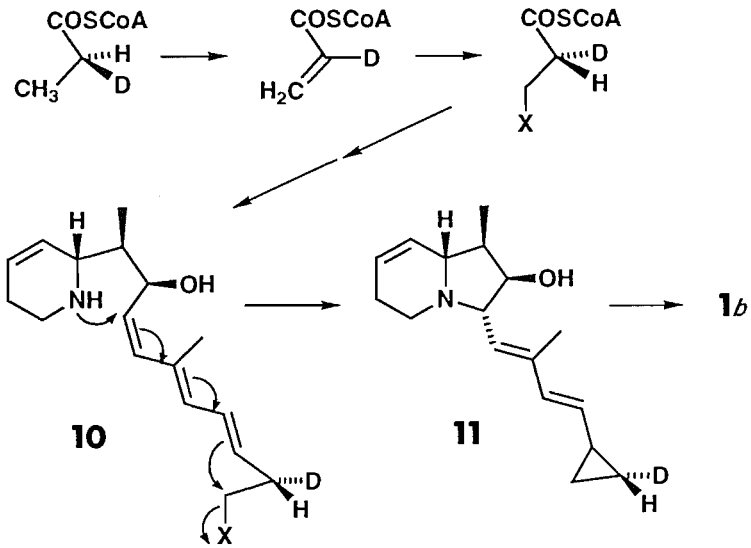
For personal use only.



SCHEME 6. A proposed mechanism for formation of the three- and five-membered rings of cyclizidine.

taining 100 mL of M15 medium were inoculated either from the slopes or from a previous liquid culture. The M15 medium was made up of the following: glucose (30 g), calcium carbonate (2.5 g), sodium chloride (5.0 g), bacteriological peptone (1.0 g), Lab LEMCO (5.0 g), and minor elements concentrate (1.0 mL), made up to 1 L with distilled water. The minor elements concentrate used was made up as follows: ferrous sulphate heptahydrate (1.0 g), copper sulphate pentahydrate (0.45 g), zinc sulphate heptahydrate (1.0 g), manganese sulphate tetrahydrate (0.1 g), and potassium molybdate (0.1 g), made up to 1 L with distilled water and clarified by the addition of a few drops of concentrated hydrochloric acid.

The inoculated flasks were incubated at 24°C in the dark, with shaking at 300 rpm. After 5 days of continuous shaking, the whole broth was adjusted to pH 7 and extracted with ethyl acetate (4 × 1000 mL). The combined organic layers were dried and evaporated in vacuo to give a crude yellow gummy solid with a strong mousy odour. PLC, eluting with ethyl acetate and then recrystallization from chloroform–hexane gave cyclizidine as a colourless odourless powder (up to 80–100 mg), mp 179–180°C (lit. (1) mp 176–178°C); R_f 0.41 (ethyl acetate); IR ($CHCl_3$):3450 (br, OH), 1640 (w, C=C), 950 (s, =C-H) cm^{-1}; UV (EtOH): 240, 260 nm (sh); MS: 291 (M^+), 217, 188, 161 (100%), 150, 98, 91, 56. ^1H and ^{13}C NMR were as reported previously (4). Anal. calcd. for $C_{17}H_{25}NO_3$: C 70.05, H 8.65, N 4.81%; M, 291.1834; found: C 70.06, H 8.81, N 4.76%; M^+, 291.1827.

For incorporation experiments, the precursor (250 mg) was dissolved in distilled water (10 mL) and 0.5 mL of this solution was injected into each of the 10 culture flasks twice, 24 and 36 h after inoculation.

Synthesis of sodium [1-^{13}C,$^{18}O_2$]acetate (5)

A mixture of methyl iodide (1.22 mL, 19.66 mmol), potassium [1-^{13}C]cyanide (1.3 g, 19.66 mmol), and [^{18}O]water (0.1 mL, 5 mmol) in dry methanol (6 mL) was heated at reflux under argon for 22 h and then distilled by vacuum transfer. [^{18}O]Water (0.9 mL, 40 mmol) and potassium *tert*-butoxide (2.2 g, 19.66 mmol) were added to the distillate and the mixture was heated at reflux under argon for 48 h. The solvents were removed in vacuo and the residue acidified with 30% aqueous phosphoric acid. The liquid was distilled into a second flask by vacuum transfer and made just alkaline with 10% aqueous sodium hydroxide. The solvents were removed in vacuo and the residue was dried in a vacuum oven for 2 h at 150°C to give the doubly labelled acetate salt as a white solid (0.668 g, 7.9 mmol, 40%); ^{13}C NMR (100 MHz, H_2O) δ: 25.63 (d, J_{CC} 52 Hz, CH_3), 164.09 (s, $^{13}C^{18}O_2$), 164.12 (s, $^{13}C^{18}O^{16}O$), and 164.15 (s, $^{13}C^{16}O_2$). Integration of these peaks gave ca. 58% $^{13}C^{18}O_2$, 34% $^{13}C^{18}O^{16}O$, and 7% $^{13}C^{16}O_2$.

4-Phenylphenacyl[1-^{13}C,$^{18}O_2$]acetate (5)

To a mixture of α-bromo-4-phenylacetophenone (47 mg, 0.173 mmol) and sodium [1-^{13}C,$^{18}O_2$]acetate (7 mg, 0.086 mmol) was added 18-crown-6 (2 mg), acetonitrile (1 mL), and benzene (1 mL). The solution was heated at reflux for 4 h, then evaporated in vacuo. PLC, eluting with ethyl acetate – hexane (2:8) gave the labelled phenylphenacyl acetate as a solid (14 mg, 0.054 mmol, 62%), mp 109–110°C (lit. (5) mp 110°C); R_f 0.67 (ethyl acetate – hexane, 2:3); ^1H NMR (400 MHz, $CDCl_3$) δ: 2.24 (3H, d, J_{CH} 7 Hz, $^{13}COCH_3$), 5.36 (2H, d, J_{CH} 4.4 Hz, $^{13}COOCH_2$), 7.41 (1H, m, *p*-Ar*H*ArCO), 7.48 (2H, m, *m*-Ar*H*ArCO), 7.51 (2H, d, *J* 8.5 Hz, *m*-Ar*H*CO), 7.63 (2H, m, *o*-Ar*H*ArCO), and 7.91 (2H, d, *J* 8.5 Hz, *o*-Ar*H*CO); HRMS: M^+ 259.1055. $C_{12}{}^{13}CH_{14}O^{18}O_2$ requires M, 259.1045. The spectrum also showed ca. 10% of the compound without the ^{13}C label; MS: 259 ($^{13}C^{18}O_2$, 98%), 258 ($^{12}C^{18}O_2$, 8), 257 ($^{13}C^{18}O^{16}O$, 60), and 255 ($^{13}C^{16}O_2$, 5).

Benzyl[1-^{13}C]acetate

To a stirred solution of [1-^{13}C]acetic acid (0.25 g, 4.1 mmol) in dry dichloromethane (5 mL) under argon, was added a solution of benzyl alcohol (0.47 mL, 4.5 mmol) in dry dichloromethane (5 mL) followed by a catalytic amount of 4-dimethylaminopyridine (3 mg). The mixture was cooled to 0°C and dicyclohexylcarbodiimide (0.95 g, 4.62 mmol) was added. The mixture was stirred at 0°C for 15 min and then at room temperature for 4 h, after which time TLC (10% methanol in dichloromethane) showed no acetic acid present. The precipitated urea was filtered off and washed with a small volume of dichloromethane (10 mL). The combined filtrate and washing were evaporated in vacuo. Flash column chromatography, eluting with ether–hexane (1:1), gave the labelled benzyl acetate as an oil (0.60 g, 4.0 mmol, 97%); R_f: 0.5 (ether–hexane, 1:1); IR (CH_2Cl_2): 1705 (s, C=O) and 1600 (s, Ar) cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ: 2.1 (3H, d, J_{CH} 7 Hz, ^{13}C-CH_3), 5.1 (2H, d, J_{CH} 3 Hz, Ar-CH_2), and 7.25 (5H, s, Ar-*H*); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 21.1 (d, J_{CC} 59 Hz, CH_3), 66.3 (s, Ar-CH_2), 128.24, 128.55 (s, *C*H aromatic), 135.92 (s, *C* aromatic), and 170.88 (s, ^{13}C=O, enriched signal); MS: 151 (M^+, 5%), 108 ($M^+ - CH_3CO$, 100), 91 (C_7H_{7+}, 55).

Benzyl[1-^{13}C,3,3,3-$^2H_3$]propionate

n-Butyllithium (1.6 M in hexane, 2.5 mL, 4.0 mmol) was added dropwise to a stirred solution of diisopropylamine (0.56 mL, 4.0 mmol) in dry tetrahydrofuran (8 mL) maintained at –78°C under an argon atmosphere. After 30 min the reaction mixture was warmed to 0°C for 15 min and then cooled to –78°C for 10 min. Benzyl[1-^{13}C]-acetate (0.6 g, 4.0 mmol) was then added dropwise and the solution was stirred for 30 min. Trideuteriomethyl iodide (1.0 g, 7.0 mmol) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

added to the solution at –78°C and it was then allowed to warm up gradually to room temperature. After 16 h the reaction was quenched with saturated aqueous ammonium chloride (20 mL) and extracted with dichloromethane (3 × 15 mL). The combined extracts were dried and evaporated in vacuo. Flash column chromatography, eluting with ether–hexane (1:9), followed by distillation gave the labelled benzyl propionate as an oil (0.38 g, 2.3 mmol, 58%); bp 125°C at 10 Torr (1 Torr = 133.3 Pa); R_f: 0.59 (ether–hexane, 1:1); IR ($CDCl_3$): 1680 (C═O) and 1450 (C═O) cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ: 2.29–2.41 (2H, m, ^{13}C-CH_2-CD_3), 5.11 (2H, d, J_{CH} 3.1 Hz, Ar-CH_2), and 7.34 (5H, s, Ar-*H*); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 27.3 (d, J_{CC} 57 Hz, CH_2CD_3), 66.0 (s, Ar-CH_2), 128.07, 128.16, 128.54 (phenyl *C*H), 136.11 (phenyl *C*), and 174.32 (^{13}C═O enriched); ^2H NMR (61 MHz, $CHCl_3$) δ: 1.13 (s, CD_3); MS: 168 (M^+, 24%), 108 (100), 91 (C_7H^{7+}, 99); HRMS: M^+, 168.1055; $C_9{}^{13}CH_9{}^2H_3O_2$ requires M, 168.1056.

Sodium[1-^{13}C,3,3,3-$^2H_3$]propionate

Benzyl [1-^{13}C,3,3,3-$^2H_3$]propionate (0.35 g, 2 mmol) was dissolved in methanol and hydrogenated over 10% palladium on charcoal (3 mg). The catalyst was filtered off and the acid was converted to the sodium salt by addition of 10% aqueous sodium hydroxide (0.8 mL, 2 mmol). The methanol was evaporated and the residue dissolved in water (15 mL) and extracted with ether (3 × 20 mL). The aqueous layer was evaporated in vacuo to give sodium [1-^{13}C,3,3,3-$^2H_3$]propionate as a solid (0.38 g, 3.8 mmol, 92%). IR (Nujol): 2220 (m, C—D), 1550 cm^{-1} (m, COO^-); ^1H NMR (400 MHz, CD_3OD) δ: 2.13 (2H, d, J_{CH} 5.8 Hz, CH_2) (the absence of any significant methyl proton signal at δ 1.1 ppm indicated >95% deuteration); ^{13}C NMR (100 MHz, CD_3OD) δ: 31.62 (d, J_{CC} 51 Hz, CH_2-CD_3) and 184.01 (s, ^{13}C═O enriched); ^2H NMR (61 MHz, H_2O) δ: 0.84 (s, CD_3).

Kuhn–Roth degradation of cyclizidine

Chromic acid solution was prepared by dissolving chromium trioxide (20.6 g) in water (60 mL) and concentrated sulphuric acid (17.6 mL). Cyclizidine **1** (41 mg, 0.14 mmol) was heated at reflux with chromic acid solution (10 mL) and steam distillation carried out. The distillate (80 mL) was made alkaline (pH 8–9) by the dropwise addition of aqueous sodium hydroxide using pH paper as an indicator. The aqueous phase was washed with ether (2 × 20 mL), evaporated in vacuo, and dried at 150°C for 2 h to give a mixture of sodium acetate and sodium cyclopropanecarboxylate (0.043 g) as a solid.

Conversion of sodium cyclopropanecarboxylate into phenyl cyclopropyl carbinol

Oxalyl chloride (0.25 mL, 2.77 mmol) was added to a stirred suspension of sodium cyclopropanecarboxylate (0.1 g, 0.9 mmol) in dry dichloromethane (0.5 mL) under argon at 0°C. After 30 min at 0°C and 30 min at room temperature, aluminium chloride (0.148 g, 1.1 mmol) and dry benzene (4 mL) were added. The mixture was heated at reflux for 30 min, then cooled, poured into ice-cold 3 M hydrochloric acid (10 mL), and extracted with dichloromethane (4 × 20 mL). The combined organic extracts were washed with water (2 × 20 mL) and then saturated brine (2 × 20 mL), dried, and evaporated in vacuo. Flash column chromatography, eluting with dichloromethane–hexane (6:4), gave a mixture of cyclopropyl phenyl ketone and benzophenone (0.367 g) as an oil. The two compounds could not be separated by column chromatography and so were taken on to the next reaction as a mixture.

The mixture of ketones (0.367 g) was dissolved in dry methanol (3 mL) and cooled to 0°C. Sodium borohydride (0.113 g, 2.99 mmol) was added and the solution was stirred at 0°C for 10 min and at room temperature for 30 min, then diluted with water (5 mL) and extracted with dichloromethane (4 × 20 mL). The combined extracts were dried and evaporated in vacuo. Flash column chromatography, eluting with ether–hexane (3:7), gave cyclopropyl(phenyl)methanol (97 mg, 0.655 mmol, 71% from the sodium salt) as an oil; R_f: 0.29 (dichloromethane); IR (CH_2Cl_2): 3550 (OH), 3040 (CH), 1603 (Ar) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.36, 0.45, 0.54, 0.62 (each 1H, m, cyclopropyl C-*H*), 1.16 (1H, m, COC*H*), 2.41 (1H, bs, O*H*), 3.97 (1H, d, *J* 8.3 Hz, C*H*OH), and 7.35 (5H, m, Ar*H*).

(R,S)-Cyclopropyl(phenyl)methyl (1S)-camphanate

To a stirred solution of the alcohol **5** (83 mg, 0.56 mmol) in dry dichloromethane under argon was added 4-dimethylaminopyridine (17 mg, 0.14 mmol), triethylamine (130 mg, 1.3 mmol), and (1*S*)-camphanyl chloride (158 mg, 0.73 mmol). The mixture was stirred at room temperature for 16 h, then poured into water (5 mL) and extracted with dichloromethane (3 × 15 mL). The combined organic extracts were dried and evaporated in vacuo. PLC, eluting continuously with ether–hexane (3:7), gave the diastereoisomeric camphanate esters (93 mg, 0.28 mmol, 50%); R_f: 0.18 (ether–hexane, 3:7); IR (CH_2Cl_2); 1800 and 1750 (C═O) cm^{-1}; UV (CH_2Cl_2): 256 nm; MS: 328 (M^+, 13%), 300 ($M^+ - C_2H_4$, 23), 131 (C_3H_5CHPh, 100); HRMS: M^+, 328.1701; $C_{20}H_{24}O_4$ requires M, 328.1674.

Separation of the two diastereoisomers was carried out on a Kontron semi-preparative column (50 cm ×8 mm) packed with 5 μm Spherisorb S5W silica, eluting with ethyl acetate – hexane (5:95) at 2.7 mL/min with detection by UV absorption at 264 nm.

(S)-Cyclopropyl(phenyl)methyl (1S)-camphanate was eluted first as an oil; ^1H NMR (400 MHz, CD_3COCD_3) δ: 0.36–0.70 (4H, m, cyclopropyl C-*H*), 0.89 and 1.05 (9H, 2 × s, camphanyl CH_3), 1.41 (1H, m, C*H*-C-O), 1,61, 1.93, 1.95, and 2.45 (each 1H, each m, camphanyl CH_2), 5.51 (1H, d, *J* 8.9 Hz, C*H*Ph), and 7.47 (5H, m, Ar*H*).

(R)-Cyclopropyl(phenyl)methyl (1S)-camphanate was eluted second and was recrystallized from ether–hexane; ^1H NMR (400 MHz, CD_3COCD_3) δ: 0.50–0.70 (4H, m, cyclopropyl C-*H*), 0.89, 1.06, and 1.14 (9H, 3 × s, camphanyl CH_3), 1.41 (1H, m, C*H*-C-O), 1.61, 1.93, 1.95, and 2.45 (each 1H, each m, camphanyl CH_2), 5.51 (1H, d, *J* 8.9 Hz, C*H*Ph), and 7.47 (5H, m, Ar-*H*). The other spectral data are the same as for the mixture of diastereoisomers.

Hydrolysis of the camphanates

The (*S*)-cyclopropyl(phenyl)methyl (1*S*)-camphanate (21 mg, 0.064 mmol) was heated at reflux with 10% methanolic potassium hydroxide (2 mL) for 1 h. The methanol was evaporated in vacuo, water (1 mL) was added, and the mixture was extracted with ether (3 × 10 mL). The combined organic layers were dried and evaporated in vacuo to yield the optically active alcohol (10 mg, 100%); spectroscopic data were as given above for the racemic alcohol.

The (*R*)-cyclopropyl(phenyl)methyl ester was hydrolysed similarly.

Preparation of the (R)-3,3,3-trifluoro-2-methoxy-2-phenylpropionate esters

A solution of the cyclopropyl phenyl carbinol (1.1 equiv.) in the minimum amount of dry dichloromethane was added to a solution of (*R*)-3,3,3-trifluoro-2-methoxy-2-phenylpropionic acid (1 equiv.) in the same solvent (2 mL) under argon. 4-Dimethylaminopyridine (2–4 mg) was then added. The mixture was cooled in ice, treated with dicyclohexylcarbodiimide (1.1 equiv.), and stirred at 0°C for 5–10 min and at room temperature for 4 h. The precipitated urea was filtered off and washed with a small volume of dichloromethane (1–2 mL) and the filtrate was evaporated. The residue was redissolved in dichloromethane, filtered again, evaporated, and purified by PLC to give the Mosher's ester (26%); IR ($CHCl_3$): 1730 (m, C═O), 1590 (w, Ar) cm^{-1}; MS: 364 (M^+), 224, 131; HRMS: M^+, 364.1281; $C_{20}H_{19}F_3O_3$ requires M, 364.1281.

The ester from the (*S*) alcohol gave ^1H NMR (250 MHz, $CDCl_3$) δ: 0.55–0.87 (4H, m, cyclopropyl CH_2-CH_2), 1.4 (1H, m, CH-C-O), 3.59 (3H, s, OCH_3), 5.36 (1H, d, *J* 9.2 Hz, CHOCO), 7.34 (10H, m, 2 × Ph).

The ester from the (*R*) alcohol gave ^1H NMR (400 MHz, $CDCl_3$) δ: 0.55–0.87 (4H, m, cyclopropyl CH_2-CH_2), 1.4 (1H, m, CH-C-O), 3.5 (3H, s, OCH_3), 5.5 (1H, d, *J* 9.2 Hz, CHOCO), 7.34 (10H, m, 2 × Ph).

Degradation of cyclizidine obtained after incorporation of sodium [3,3,3-$^2H_3$]propionate

Cyclizidine (228 mg, 0.78 mmol), obtained after incorporation of sodium [3-$^2H_3$]propionate, was subjected to Kuhn–Roth degradation as described above to give a mixture of sodium acetate and sodium cyclopropanecarboxylate (0.164 g) as a solid.

The salts (0.164 g) were converted as above into the cyclopropyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

phenyl ketone and then reduced to give the racemic cyclopropyl phenyl carbinol (46.4 mg, 0.31 mmol, 40% from cyclizidine).

The (1*S*)-camphanate esters (54 mg, 0.16 mmol, 53%) were prepared and separated by HPLC and each diastereoisomer was hydrolysed to give the optically active alcohol as described above. For the (*R*) alcohol, ^{2}H NMR (61 MHz, $CHCl_3$) δ: 0.36, 0.54, and 1.21. For the (*S*) alcohol, ^{2}H NMR (61 MHz, $CHCl_3$) δ: 0.46, 0.63, and 1.22.

Sodium [2-$^2H_2$]propionate

Deuteriated concentrated sulphuric acid (3 mL) was added dropwise to sodium propionate (0.5 g, 5 mmol) at 0°C under nitrogen. The mixture was then heated at 120°C for 20 min, then cooled in ice and deuterium oxide (3 mL) added. The solution was then poured into iced water (30 mL) and extracted thoroughly with ether (5 × 10 mL). The combined extracts were dried, concentrated in vacuo to a volume of 2 mL, redissolved in methanol (2 mL), and titrated with 10% aqueous sodium hydroxide until slightly alkaline, using phenolphthalein as indicator. The aqueous solution was evaporated to dryness and the residue dried in vacuo at 120°C to give the deuteriated sodium salt (0.2 g, 40%); IR (Nujol): 1550 (m, COO^-) cm^{-1}; ^{1}H NMR (80 MHz, NaOD/D_2O) δ: 1.6 (3H, br m, CH_3), 2.7 (ca. 0.3H, br m, residual CH_2); ^{2}H NMR (61 MHz, H_2O) δ: 2.3 (br s, CD_2).

(R)- and (S)-2-Bromopropionic acids

A solution of alanine (3.6 g, 0.04 mol) and potassium bromide (28.5 g, 0.24 mol) in cold 1.25 M aqueous sulphuric acid (288 mL, 0.36 mol) was treated with sodium nitrite (7.5 g, 0.11 mol) over 30 min at 0°C. After 1 h, ether (50 mL) was added and the mixture was warmed to room temperature and stirred for an additional hour. The two layers were separated, and the aqueous layer was thoroughly extracted with ether (4 × 50 mL). The combined organic extracts were dried over calcium chloride and evaporated in vacuo. The residue was distilled under vacuum to give the bromoacid.

(*S*)-2-Bromopropionic acid (3.0 g, 50%) was obtained from (*S*)-(+)-alanine; bp 66–68°C at 1 Torr (lit. (9) bp 70°C at 1 Torr); $[\alpha]_D$ –40.65 (neat) (lit. (9) $[\alpha]_D$ –45.2); IR (thin film): 3100 (br, COOH), 1710 (s, C=O) cm^{-1}; ^{1}H NMR (80 MHz, $CDCl_3$) δ: 1.8 (3H, d, *J* 7 Hz, CH_3), 4.4 (1H, q, *J* 7 Hz, CHBr), 9.5 (1H, br, COOH); MS: 154 and 152 (M^+), 110 and 108 ($M^+ - CO_2$), 109 and 107 (M^+ – COOH); HRMS: M^+, 151.9472; $C_3H_5{}^{79}BrO_2$ requires M, 151.9472.

(*R*)-2-Bromopropionic acid (2.5 g, 41%) was obtained from (*R*)-(–)-alanine; $[\alpha]_D$ +41.76 (neat) (lit. (9) $[\alpha]_D$ +44.2). Other data were the same as for the (*S*) isomer.

Sodium (R)-[2-^{2}H]propionate

A solution of 1 M lithium triethylborodeuteride in tetrahydrofuran (26 mL, 26 mmol, Aldrich Superdeuteride) was added to a solution of (*S*)-bromopropionic acid (1.25 g, 8 mmol) in dry tetrahydrofuran (2.5 mL), at 0°C. The stirred mixture was heated at reflux for 2 h and then stirred at room temperature for 18 h. The mixture was then cooled in ice, diluted with water (10 mL), and concentrated to 25 mL. A mixture of hydrogen peroxide (100 vol) and 2 M aqueous sodium hydroxide (1:1) was added until effervescence ceased. The resulting solution was washed with ether (3 × 15 mL), acidified to pH 3 with 1 M sulphuric acid, and steam distilled. The acidic distillate was made just alkaline with 1 M sodium hydroxide, using phenolphthalein as indicator, and evaporated to dryness in vacuo to yield sodium (*R*)-[2-^{2}H]propionate (0.38 g, 50%); IR (Nujol): 2180 (w, C-D), 1540 (COO^-) cm^{-1}; ^{1}H NMR (80 MHz, D_2O) δ: 1.15 (3H, dt, $J_{H\text{-}H}$ 7.6 Hz, $J_{H\text{-}D}$ 1.1 Hz, CH_3), 2.25 (1H, qt, $J_{H\text{-}H}$ 7.6 Hz, $J_{H\text{-}D}$ 2.2 Hz, CHD).

Sodium (S)-[2-^{2}H]propionate (0.43 g, 55%) was prepared in the same way from (*R*)-2-bromopropionic acid. All data were the same as for the (*R*) isomer.

(S)-Methoxycarbonyl(phenyl)methyl (R)-[2-^{2}H]propionate

A solution of sodium (*R*)-[2-^{2}H]propionate (90 mg, 0.9 mmol) in water (2 mL) was acidified to pH 6 with dilute hydrochloric acid and extracted thoroughly with ether (5 × 3 mL). The combined extracts were dried and the solvent was distilled off at atmospheric pressure to yield (*R*)-[2-^{2}H]propionic acid (50 mg, 74%).

The acid (30 mg, 0.4 mmol) was dissolved in dry dichloromethane (1 mL) and the mandelate ester (39 mg, 44%) was prepared as in ref. 10; IR (thin film): 2150 (w, C—D), 1740 (s, C=O), 1050 (m, C—O) cm^{-1}; ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.2 (3H, d, *J* 7.5 Hz, CH_3), 2.43 (1H, qt, $J_{H\text{-}H}$ 7.5 Hz, $J_{H\text{-}D}$ 2.3 Hz, CH_SD), 3.7 (3H, s, $COOCH_3$), 5.9 (1H, s, CH-O), 7.4 (5H, m, ArH); ^{2}H NMR (61 MHz, $CHCl_3$) δ: 2.53 (s, CHD); MS: 223 (M^+); HRMS: M^+, 223.0955; $C_{12}H_{13}{}^2HO_4$ requires M, 223.0951.

(S)-Methoxycarbonyl(phenyl)methyl (S)-[2-^{2}H]propionate

(*S*)-[2-^{2}H]propionic acid (30 mg, 0.4 mmol) obtained from sodium (*S*)-[2-^{2}H]propionate as above was converted to the corresponding mandelate ester (47 mg, 53%) as before; ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.2 (3H, d, *J* 7.5 Hz, CH_3), 2.53 (1H, qt, $J_{H\text{-}H}$ 7.5 Hz, $J_{H\text{-}D}$ 2.3 Hz, CDH_R), 3.7 (3H, s, $COOCH_3$), 5.9 (1H, s, CH-O), 7.4 (5H, m, ArH); ^{2}H NMR (61 MHz, $CHCl_3$) δ: 2.47 (s, CHD); MS: 223 (M^+); HRMS: M^+, 223.0955; $C_{12}H_{13}{}^2HO_4$ requires M, 223.0951.

Incorporation of sodium (S)-[1-^{14}C,2-^{2}H]propionate into cyclizidine

Sodium [1-^{14}C]propionate (5 μCi) and sodium (*S*)-[2-^{2}H]propionate (250 mg, 2.6 mmol, 4.22×10^6 dpm/mmol) were dissolved in distilled water (10 mL) and fed to the organism as described earlier. The cyclizidine obtained (40 mg, 0.14 mmol, 2.2×10^6 dpm/mmol, specific incorporation 51%, 17% per labelled site) was dissolved in chloroform (1.5 g, 14 mmol) and the ^{2}H NMR spectrum recorded. The peak areas of the signals due to deuterium at natural abundance (0.016%) in the chloroform and in cyclizidine (at δ 0.76 ppm) were in the ratio of 1:2. Thus the ^{2}H incorporation in cyclizidine is approximately $(0.016 \times 2 \times 14)/0.14 = 3.2\%$.

Incorporation of sodium (R)-[1-^{14}C,2-^{2}H]propionate

Sodium (*R*)-[1-^{14}C,2-^{2}H]propionate (5 μCi, 250 mg) was fed to the organism as for the (*S*)-isomer. The cyclizidine obtained (40 mg, 0.14 mmol, 1.7×10^6 dpm/mmol, specific incorporation 39%, 13% per labelled site) showed no significant incorporation of deuterium by ^{2}H NMR spectroscopy.

Acknowledgements

We would like to thank Dr. P. R. Raithby for determining the crystal structure, Dr. D.H. Williams for help with some of the ^{2}H NMR experiments, and the Cambridge Commonwealth Trust and the Science and Engineering Research Council (SERC) for studentships to P.S. and S.E.S. respectively.

Received May 21, 1993

This paper is dedicated to Professor David B. MacLean

LAWRENCE E. FISHER, JOAN M. CAROON, S. RUSSELL STABLER, SCOTT LUNDBERG, SHAHID ZAIDI, CAROLE M. SORENSEN, MARK L. SPARACINO, and JOSEPH M. MUCHOWSKI. Can. J. Chem. **72**, 142 (1994).

Reaction of primary amides (e.g., **1***a* or **6–13**) or *O*-methylhydroxamates (**1***b* and **1***c*) with a catalytic amount of $TiCl_4$ and one equivalent of aqueous HCl converts these compounds in good yields to carboxylic esters (when an alcohol is used as solvent) or to carboxylic acids (when 9 : 1 dioxane : H_2O is used as solvent). These conversions are chemoselective for primary amides: mono- and dialkyl amides are not affected by the reaction conditions. The hydrolysis conditions described do not compromise the stereochemical integrity of an adjacent chiral center. This is exemplified by the hydrolysis of naproxen amide (**34**) to naproxen (**33**) without detectable racemization as determined by chiral HPLC.

LAWRENCE E. FISHER, JOAN M. CAROON, S. RUSSELL STABLER, SCOTT LUNDBERG, SHAHID ZAIDI, CAROLE M. SORENSEN, MARK L. SPARACINO et JOSEPH M. MUCHOWSKI. Can. J. Chem. **72**, 142 (1994).

La réaction des amides primaires (par exemple **1***a* ou **6–13**) ou des *O*-méthylhydroxamates (**1***b* ou **1***c*) avec une quantité catalytique de $TiCl_4$ et un équivalent de HCl aqueux permet de transformer ces composés, avec d'excellents rendements, en esters carboxyliques (lorsqu'on utilise un alcool comme solvant) ou en acides carboxyliques (lorsqu'on utilise un mélange 9 : 1 dioxane : eau comme solvant). Ces transformations sont chémosélectives pour les amides primaires; les mono- et dialkyl amides ne sont pas affectés par les conditions des réactions. Les conditions d'hydrolyse décrites ne compromettent pas l'intégrité stéréochimique d'un centre chiral adjacent. Pour démontrer cette assertion, on présente comme exemple l'hydrolyse de la naproxenamide (**34**) en naproxen (**33**) qui, d'après une CLHP chirale, se fait sans racémisation détectable.

[Traduit par la rédaction]

We have shown that the *O*-methyl hydroxamic acid moiety is an efficient, easy to prepare *ortho*lithiation directing group for aryl and toluyl systems (1).[4] In addition, we demonstrated that reduction of the *O*-methyl hydroxamic acids to carboxamides could be efficiently accomplished with two equivalents of titanium(III) chloride in alcoholic solution (2). With aqueous (but not anhydrous) titanium(III) chloride it was noted that after prolonged reaction times some of the carboxamide was converted into the carboxylic ester corresponding to the alcohol used. Since Ti(III) chloride had no effect on the primary amide it was assumed that Ti(IV), formed as a consequence of the reduction of the hydroxamate, was the agent responsible for promoting the alcoholysis of the amide. Not only was this supposition found to be correct, it was also shown that the alcoholysis was catalytic in Ti(IV).[5] This paper describes optimized conditions for effecting the Ti(IV) catalyzed conversion of primary amides (**1***a*, **6–13**) to the corresponding carboxylic acids or esters. Also described herein are conditions for the Ti(IV) catalyzed alcoholysis and hydrolysis of *O*methylphenylacetohydroxamate (**1***b*) and *O*-methylbenzylhydroxamate (**1***c*).

Depending on whether an aqueous or alcoholic solvent is used, treatment of N-unsubstituted carboxamides with a catalytic amount of titanium(IV) chloride and one equivalent of aqueous hydrochloric acid converts this class of compounds into the corresponding carboxylic acids or esters. Thus, heating the carboxamide in a solution of the appropriate alcohol containing 10 mol% aqueous $TiCl_4$ and one molar equivalent of hydrochloric acid gave the corresponding esters in good yields (Table 1; refs. 2–15). The carboxylic acids were obtained when 10% aqueous dioxane was used as the solvent (Table 2; refs. 2–20). Not surprisingly, ester-amides **11** and **12** were both hydrolyzed completely to diacids when subjected to the aqueous hydrolysis conditions. Treatment of *O*-methylhydroxamates **1***b* and **1***c* with $TiCl_4$ also resulted in alcoholysis (in alcohol with one molar equivalent of hydrochloric acid, Table 1) or hydrolysis (in 10%aqueous dioxane, Table 2). Although these reactions did proceed in the absence of added aqueous hydrochloric acid, addition of one molar equivalent of aqueous HCl increased the rate considerably. Neither of these reactions proceeded appreciably, however, in the absence of Ti(IV).

Titanium(IV) alkoxides also catalyze the transformation of primary carboxamides to esters. For example, $Ti(OMe)_4$, $Ti(OEt)_4$, and $Ti(OiPr)_4$, in the appropriate alcohol as solvent, catalyze the conversion of **1***a* to the methyl, ethyl, and isopropyl esters **2**, **3**, and **4**, respectively. These results would suggest that the Ti(IV) species involved in the alcoholysis reaction probably is not $TiCl_4$, but rather some intermediate $Ti(Cl)_x(OR)_y$ complex. The Lewis acids boron trifluoride etherate, tin(IV) chloride, and silicon(IV) chloride (12) also catalyze these transformations, although with less efficiency than titanium(IV) chloride (Table 1).

N-Alkyl and *N,N*-dialkyl carboxamides are not affected under the conditions that transform unsubstituted carboxamides to esters or acids. For example, when monoethyl amide **35***a* or diethyl amide **35***b* are subjected to the reaction conditions that successfully converted **1** to **2** or **3**, they were recovered quanti-

tatively, even after prolonged (>48 h) reaction times (Scheme 1).[6]

Traditional methods to hydrolyze primary carboxamides usually require strongly basic or acidic conditions (21*b*, *c*). Under these conditions, a chiral center adjacent to the carbonyl group can be racemized. $TiCl_4$ catalyzed hydrolysis of naproxen amide (**34**) (synthesized from naproxen (**33**) via the acid chloride (22) to naproxen (**33**) (Scheme 2) occurred without detectable racemization, as determined by HPLC. This implies that the mechanism of hydrolysis does not involve enolization of the carbonyl group.

In conclusion, this study has shown that catalytic $TiCl_4$ and $Ti(OR)_4$ in the presence of aqueous HCl efficiently converts unsubstituted carboxamides to esters or acids. Two *O*-methyl hydroxamic acids are also shown to be converted to esters or acids by these conditions. Further, the hydrolysis reaction is

[6]A mild three-step method for tertiary amide hydrolysis has been reported (21*a*).

mild enough to leave adjacent chirality uncompromised, presenting an advantage over traditional, more vigorous, hydrolysis methods.

Experimental section

Melting points are uncorrected. All compounds reported are known and referenced where they appear in the tables. Determinations of enantiomeric purity were performed by analysis by direct HPLC using a Spectra-Physics 8800 ternary pump, Spectra-Physics SP8780 autosampler, and a Spectra Physics Spectra 100 variable wavelength detector connected to a Chiral-AGP column. The following conditions were used: column: Chiral AGP, 100 × 4.0 mm, 5 μm; mobile phase: 99.5% 4 mM NaH_2PO_4 + Na_2HPO_4 pH 7.0, 0.5% 2-PrOH;low rate: 0.8 mL/min; temperature: ambient; detection: 262 nm (22).

Optical rotations were measured on a JASCO DIP-360 instrument.

*General method for the syntheses of primary carboxamides or O-methylphenylacetohydroxamate (**1**b) or methylbenzylhydroxamate (**1**c)*

To a stirred solution of carboxylic acid in methylene chloride (CH_2Cl_2) at 0°C was added oxalyl chloride (2 molar equiv.) and *N,N*-dimethylformamide (DMF, 1 drop). The mixture was allowed to warm to room temperature and subsequently the CH_2Cl_2 was removed in vacuo. The residue was dissolved in CH_2Cl_2, cooled to 0°C, and treated with either NH_4OH (excess, to give the primary amide) or methoxylamine hydrochloride (1 equiv., and Et_3N, 2 equiv., to give the *O*-methyl hydroxamic acid). The reaction mixture was allowed to warm to room temperature and was shaken with 1 M HCl. The organic layer was separated and dried with Na_2SO_4, filtered, and the solvent was removed in vacuo to give the product.

*General method for the titanium(IV) chloride mediated alcoholysis of primary carboxamides or Omethylphenylacethydroxamate (**1**b) or methylbenzylhydroxamate (**1**c)*

To a solution of carboxamide or *O*-methyl hydroxamic acid (1 equiv.) in the appropriate alcohol (approximately 1 M in substrate) was added aqueous $TiCl_4$ (0.1 molar equiv.) and aqueous HCl (1 molar equiv.). The reaction mixture was then brought to reflux for the specified amount of time (Table 1). After being allowed to cool to room temperature, the reaction mixture was poured onto ice–H_2O and brought to neutrality with 1 M NaOH. Extraction with ethyl acetate (EtOAc), removal of water with Na_2SO_4, filtration again, and finally removal of solvent in vacuo gave the ester. If necessary, the product was recrystallized from the appropriate solvent.

*General method for the titanium(IV) chloride mediated conversion of primary carboxamides or Omethylphenylacethydroxamate (**1**b) or methylbenzylhydroxamate (**1**c) to carboxylic acids*

To a solution of carboxamide or *O*-methyl hydroxamic acid (1 equiv.) in 9:1 dioxane:H_2O(approximately 1 M in substrate) was added aqueous $TiCl_4$ (0.1 molar equiv.) and aqueous HCl (1 molar equiv.). The reaction mixture was then brought to reflux for the specified amount of time (Table 2). After being cooled to room temperature, the reaction mixture was poured onto ice–H_2O. Extraction with EtOAc, removal of water with Na_2SO_4, filtration again, and finally removal of solvent in vacuo gave the acid. If necessary, the product was recrystallized from the appropriate solvent.

General method for the Lewis acid mediated alcoholysis of primary carboxamides

To a solution of carboxamide (1 equiv.) in EtOH (approximately 1 M in amide) was added $SiCl_4$, $SnCl_4$, or BF_3_Et_2O (0.1 molar equiv.). To this mixture was added aqueous HCl (1 molar equiv.). The reaction mixture was then brought to reflux for the specified amount of time (Table 1). After being allowed to cool to room temperature, the reaction mixture was poured onto ice–H_2O and brought to neutrality with 1 M NaOH. Extraction with EtOAc, removal of water with Na_2SO_4, filtration again, and finally removal of solvent in vacuo gave the ester. If necessary, the product was recrystallized from the appropriate solvent.

General method for the $Ti(OR)_4$ mediated alcoholysis of primary carboxamides

To a solution of carboxamide (1 equiv.) in EtOH (approximately 1

M in amide) was added $Ti(OMe)_4$, $Ti(OEt)_4$, or $Ti(OiPr)_4$ (0.1 molar equiv.). To this mixture was added aqueous HCl (1 molar equiv.). The reaction mixture was then brought to the temperature specified for each entry in Table 1 for the specified amount of time. After being allowed to cool to room temperature, the reaction mixture was poured onto ice–H_2O and brought to neutrality with 1 M NaOH. Extraction with EtOAc, removal of water with Na_2SO_4, filtration, and finally removal of solvent in vacuo gave the ester. If necessary, the product was recrystallized from the appropriate solvent.

*6-Methoxy-α-methyl-2-naphthaleneacetamide (**34**)*

To a stirred solution of 6-methoxy-α-methyl-2-naphthaleneacetic acid (**33**) (27.4 g, 0.12 mol) in EtOAc (400 mL) and aqueous $NaHCO_3$ (400 mL of a 1 M solution) at 0°C was added oxalyl chloride (20.7 mL, 0.24 mol). The reaction mixture was allowed to warm to room temperature. The layers were allowed to separate and the organic layer was dried with Na_2SO_4, filtered, and evaporated in vacuo. The residue was redissolved in CH_2Cl_2 (450 mL), cooled to 0°C, and treated dropwise with NH_4OH (50 mL of a 37% aqueous solution). The reaction mixture was allowed to warm to room temperature and was carefully acidified with HCl (1 M) to pH 4. The organic layer was separated and dried with Na_2SO_4, filtered, and the solvent was removed in vacuo to give crude **34**. Recrystallization (acetone–hexane) gave crystalline **34** (26.1 g, 95%); mp 173–176°C (acetone–hexane) (lit. (22) mp 172–175°C); $[\alpha]^{25}_D$ + 20 (*c* 1, $CHCl_3$) (lit. (22) $[\alpha]^{25}_D$ + 20.2 (*c* 1, $CHCl_3$).

*6-Methoxy-α-methyl-2-naphthaleneacetic acid (naproxen) (**33**)*

To a solution of **34** (2.3 g, 0.01 mol) in 9:1 dioxane:H_2O (10 mL) was added aqueous $TiCl_4$ (1 mL, 1 M in $TiCl_4$, in CH_2Cl_2 or toluene) and aqueous HCl (1 mL of a 1 M solution). The reaction mixture was then brought to reflux for 15 h. After cooling to room temperature, the reaction mixture was poured onto ice–H_2O. Extraction with EtOAc, removal of water with Na_2SO_4, filtration again, and finally removal of solvent in vacuo gave the acid **33** as a solid that was crystallized from acetone–hexane (2.21 g, 96%; mp 153–155°C (acetone–hexane) (lit. (22) mp 154–155°C); $[\alpha]^{32}_D$ +66 (*c* 1, $CHCl_3$) (lit. (22) $[\alpha]^{25}_D$ + 66 (*c* 1, $CHCl_3$). Serially increasing injections of **33** (0.2–0.5 mg) dissolved in the mobile phase (1–5 μL) showed that **33** was 99.0% (*S*)-6-methoxy-α-methyl-2-naphthaleneacetic acid (22). This is compared to a USP batch that was shown to be 99.2% (*S*)-6-methoxy-α-methyl-2-naphthaleneacetic acid.

Stereoselective total synthesis of the marine sesterterpenoid (±)-palauolide

EDWARD PIERS[1] AND JOHN S.M. WAI

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, BC, V6T 1Z1, Canada

Received June 14, 1993

This paper is dedicated to Professors David B. MacLean and Ian D. Spenser

EDWARD PIERS and JOHN S.M. WAI. Can. J. Chem. **72**, 146 (1994).

A total synthesis of the antimicrobial, structurally unusual sesterterpenoid (±)-palauolide (**1**) is described. Methylenecyclohexane annulation of 3,6-dimethyl-2-cyclohexen-1-one (**4**) afforded a mixture of the bicyclic ketones **7** and **9** in a ratio of 94:6. Stereoselective conversion of this mixture into the phosphorodiamidate **46** was achieved via a five-step reaction sequence. Reduction of **46** with Li in $MeNH_2$ gave the bicyclic substance **47**, which was readily transformed in seven steps into the α,β-unsaturated aldehyde **54**. Subjection of **54** to a Julia olefin synthesis, employing reagent **56**, gave the furan **58**. Photooxygenation of **58** provided (±)-palauolide (**1**).

EDWARD PIERS et JOHN S.M. WAI. Can. J. Chem. **72**, 146 (1994).

On décrit une synthèse totale du (±)-palauolide (**1**), un sesquiterpénoïde antimicrobien de structure inhabituelle. L'annellation du méthylènecyclohexane avec la 3,6-diméthylcyclohex-2-én-1-one (**4**) fournit les cétones bicycliques **7** et **9** dans un rapport de 94 : 6. On a réalisé la transformation stéréosélective de ce mélange en phosphorodiamidate **46** par une séquence réactionnelle de cinq étapes. La réduction de **46** par du Li dans la $MeNH_2$ fournit le composé bicyclique **47** qui peut être facilement transformé, en sept étapes, en aldéhyde α,β-insaturé **54**. Lorsqu'on soumet le composé **54** à une synthèse d'oléfine de Julia, en utilisant le réactif **56**, on obtient le furane **58**. Une photooxygénation du composé **58** conduit au (±)-palauolide (**1**).

[Traduit par la rédaction]

Introduction

In 1982, Sullivan and Faulkner (1) isolated a new natural product from the methanolic extract of a mixture of sponges collected from Palau, Western Caroline Islands. This substance, which displays notable antimicrobial activity against *Bacillus subtilis* and *Staphylococcus aureus*, was named palauolide and was shown (1) to be a sesterterpenoid possessing the novel constitution and relative configuration depicted in structural formula **1**. Prior to the isolation of palauolide, the carbon skeleton present in this substance had not been encountered in natural product chemistry. However, it is appropriate to note that, structurally, palauolide (**1**) is closely related to the very large family of *trans*-clerodane diterpenoids, which share the basic carbon framework shown in **2** (2). The substituted γ-hydroxybutenolide moiety present in **1**, which is derived from an additional isoprene unit, is probably responsible for the observed biological activity of this natural product. We report in this paper a total synthesis of racemic palauolide (**1**).[2]

[2]For a preliminary account of this work, see ref. 3.

Results and discussion

(a) Conversion of 3,6-dimethyl-2-cyclohexen-1-one (4) into the bicyclic nitriles 11 and 12

At the outset of this synthetic endeavor, it was evident that the methylenecyclohexane annulation method developed previously in our laboratory (4) should serve as an effective vehicle for the preparation of the substituted bicyclo[4.4.0]decane portion of the palauolide structure. The necessary substrate for this process, 3,6-dimethyl-2-cyclohexen-1-one (**4**) was readily prepared by alkylation (lithium diisopropylamide (LDA), tetrahydrofuran (THF); MeI) of 3-methyl-2-cyclohexen-1-one (**3**) (see Scheme 1). Copper(I)-catalyzed conjugate addition of 2-(5-chloro-1-pentenyl)magnesium bromide (**5**)[3] to the enone **4** in the presence of $BF_3 \cdot Et_2O$ (4) provided the substituted cyclohexanone **6** (mixture of epimers, ratio ~2:1).

Exposure of **6** to *t*-BuOK in *t*-BuOH at 30°C for 12 h provided, in 89% yield, two bicyclic ketones in a ratio of approximately 94:6. A sample of each of these substances was obtained by subjecting the mixture to column chromatography on silica gel impregnated with 25% silver nitrate. In the ^1H nmr spectra of the two ketones, the angular methyl groups give rise to 3-proton singlets at δ 0.87 (major isomer) and 1.31 (minor isomer). On this basis, it is possible to conclude that the major and minor products are *trans*-fused and *cis*-fused, respectively (see ref. 6).

Since the intramolecular alkylation was carried out under conditions that would equilibrate the two stereogenic centers adjacent to the carbonyl function, four diastereomeric products **7–10** could have been produced. On the basis of conformational analyses, it is clear that, of the two possible *trans*-fused isomers, **7** is more stable than **8**, while in the case of the *cis*-fused substances, **9** is of lower energy than **10**. Therefore, it was concluded that the two products derived from methylenecyclo-

[3]This reagent was derived by sequential treatment of 5-chloro-2-trimethylstannyl-1-pentene (prepared via a procedure modified from that reported earlier (5), see Experimental) with MeLi and $MgBr_2$–etherate in THF at −78°C (4).

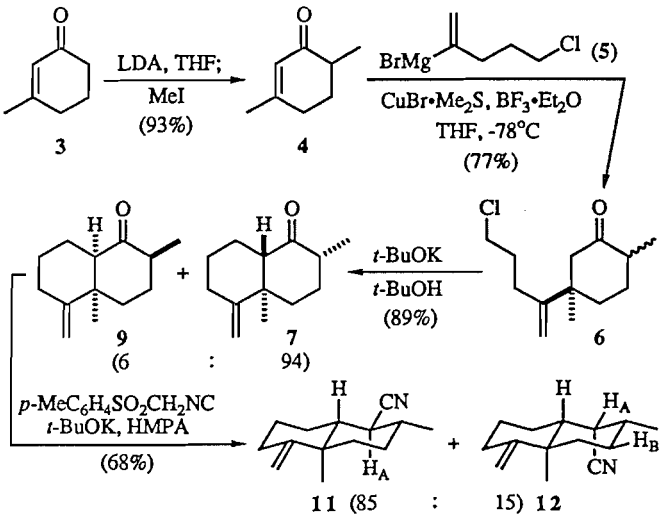
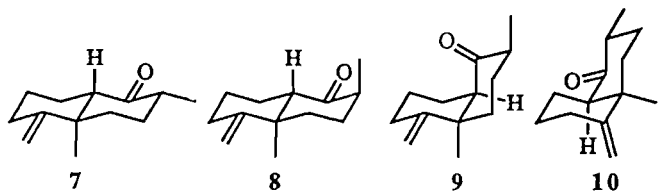


SCHEME 1

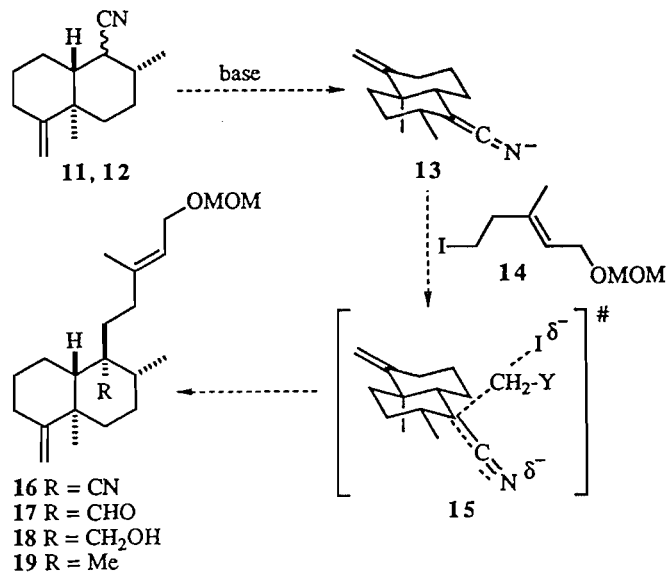


hexane annulation of **4** are the ketones **7** (major) and **9** (minor) (see Scheme 1).

Each of the three stereogenic centers of the ketone **7** possesses the correct relative configuration for an eventual synthesis of (±)-palauolide (**1**). At this stage of the synthesis, the carbonyl function of **7** was to be used as a handle for the introduction of the necessary appendages at this center. To this end, the 94:6 mixture of **7** and **9** was treated with (*p*-toluenesulfonyl)methyl isocyanide (TOSMIC) (**7**) and *t*-BuOK in dry *t*-BuOH–hexamethylphosphoramide (HMPA) (45°C, 88 h). This process produced a mixture of two epimeric nitriles in a ratio of about 85:15. Column chromatography of a portion of this mixture on 4:1 silica gel – silver nitrate allowed the isolation of a pure sample of each product. On the basis of ^{1}H nmr spectral data, these two substances were assigned structures **11** (major) and **12** (minor). In the spectra of **11** and **12**, the protons H_A give rise to a triplet (δ 2.08, J = 11.5 Hz) and a triplet of doublets (δ 2.60, J = 4.5, 1.3 Hz[4]). The coupling constants show clearly that H_A in **11** and **12** are axially and equatorially oriented, respectively. Furthermore, the angular methyl group of **12**, which bears a 1,3-diaxial relationship with the nitrile function, would be expected to resonate at lower field than the corresponding methyl in **11**. This was found to be the case. In the ^{1}H nmr spectra of **11** and **12**, the angular methyl functions produce singlets at δ 0.96 and 1.24, respectively.

It is interesting to note that the base-promoted reaction of the mixture of **7** and **9** with TOSMIC did not produce any nitrile products possessing *cis*-fused six-membered rings. This observation is in accord with reports (see, for example, ref. 8) that a *trans*-fused bicyclo[4.4.0]decan-2-one usually reacts faster with nucleophiles than the corresponding *cis*-fused isomer. Therefore, under conditions in which the two ketones are in equilibrium (as in the conversion of **7** and **9** into **11** and **12**), the

[4]It is likely that this small coupling constant arises from weak, long-range w-coupling between H_A and H_B in **12**.



SCHEME 2

products are often those derived mainly or even solely from the *trans*-fused substrate.

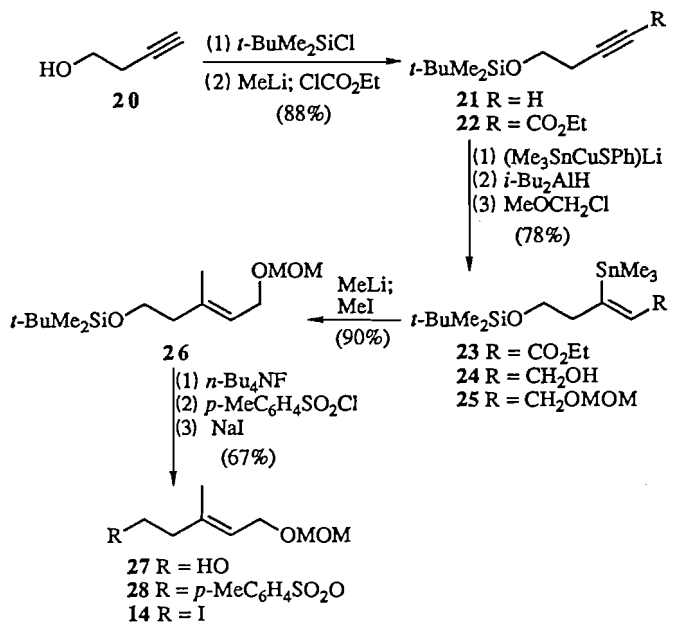
*(b) Attempted preparations of the substituted bicyclo[4.4.0]-decanes **19** and **34**. Unsuccessful approaches to the synthesis of (±)-palauolide (**1**)*

An initially investigated approach to the synthesis of (±)-palauolide (**1**) is outlined in general terms in Scheme 2. Treatment of the mixture of nitriles **11** and **12** with a suitable base would provide the anion **13**. Alkylation of the latter species with the electrophile **14** (MOM = CH_2OMe) would be expected to proceed preferentially via a transition state that can be (simplistically) represented by **15**. The alternative transition state, involving approach of **14** from the "bottom" face of **13**, would be notably destabilized by a steric interaction between the incoming electrophile and the angular methyl group present in **13**. Subjection of the expected alkylation product **16** to appropriate reduction procedures would provide the aldehyde **17** and (or) the alcohol **18**. Successful reductive deoxygenation of **17** or **18** would produce **19**, which possesses a functional group (allylic OMOM) suitable for use as a "handle" for the introduction of the functionalized butenolide unit present in the target compound **1**.

The required alkylating agent **14** was prepared from 3-butyn-1-ol (**20**) as summarized in Scheme 3. Reaction of **20** with *t*-BuMe_2SiCl–imidazole in *N,N*-dimethylformamide (DMF), followed by sequential treatment of the resultant ether **21** with MeLi and $ClCO_2Et$ in THF, gave the α,β-acetylenic ester **22**. Stereoselective conversion of **22** into the (*Z*)-β-trimethylstannyl α,β-unsaturated ester **23** was effected by reaction of the former substance with lithium (trimethylstannyl)(phenylthio)cuprate (9) in THF (−40°C, 9 h; NH_4Cl, H_2O) (10). Reduction of **23** and subsequent reaction of the resultant alcohol **24** with $MeOCH_2Cl$ in the presence of i-Pr_2NEt in CH_2Cl_2 produced the diether **25**. Transmetallation (MeLi, THF, −78°C) of the vinyltrimethylstannane function of **25** (11), followed by reaction of the resultant vinyllithium species with MeI, provided the (*E*) alkene **26**. Conversion of **26** into the required iodide **14**, via intermediates **27** and **28**, involved standard functional group interconversions.

Treatment of the 85:15 mixture of **11** and **12** (vide supra)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.



SCHEME 3

with LDA in THF–HMPA[5] at 0°C, followed by addition of the iodide **14**, produced a single alkylation product **16** (70%, 92% based on recovered starting materials), accompanied by the starting materials **11** and **12** (23%, ratio ~2:3, respectively) (eq. [1]). Also isolated was a small amount of the (volatile) diene **29**. Although this material was not fully characterized, its ^{1}H nmr spectrum showed the presence of the CH_2OMOM moiety, the vinyl methyl group, and four olefinic protons (δ 6.43 (dd, J = 11, 17 Hz, H_C), 5.63 (br t, J = 7 Hz, H_D), 5.23 (d, J = 17 Hz, H_B), 5.05 (d, J = 11 Hz, H_A). Thus, it is evident that, in the reaction of the iodide **14** with the nitrile anion derived from **11** + **12**, there is a competition between substitution and elimination. Nevertheless, the required product **16** could be isolated in good yield and, obviously, the recovered nitrile substrates could be recycled.

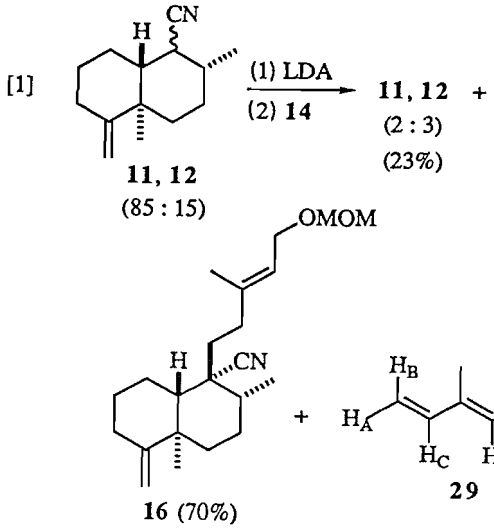
In the ^{1}H nmr spectrum of the alkylation product **16**, the angular methyl group gives rise to a singlet at δ 1.27, indicating that this moiety is in a 1,3-diaxial relationship with the CN function. Thus, strong evidence for the expectation (vide supra) that the alkylation reaction would proceed stereoselectively in the required sense was readily available.

When the nitrile **16** was treated with excess i-Bu_2AlH in PhH, Et_2O, THF, or 1,2-dimethoxyethane (DME) at room temperature, no reduction occurred and the substrate was recovered intact. On the other hand, reaction of **16** with i-Bu_2AlH in DME at 60°C for 6 h, followed by (sluggish) acid hydrolysis (HOAc, H_2O, THF, room temperature, 12 h) of the hindered imine function, provided the required aldehyde **17** in 87% yield (eq. [2]).

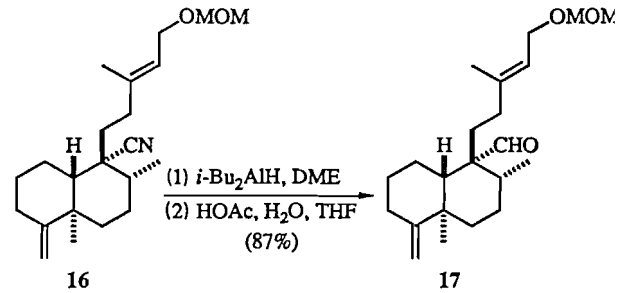
Treatment of **17** with hydrazine (10 equiv.) in MeOH (reflux, 24 h) provided the corresponding hydrazone **30** (ir 3250 cm^{-1}, broad) in good yield. However, although reductive conversion of the latter material into the required product **19** was attempted under a variety of conditions, these efforts did not produce synthetically useful results. For example, reaction of **30** with KOH

[5]Model studies, involving attempted alkylation of **11** + **12** with n-BuI, showed that treatment of the mixture of nitriles with LDA in THF, *in the absence of HMPA*, failed to deprotonate the equatorial nitrile **11** at an appreciable rate.

[1]



[2]



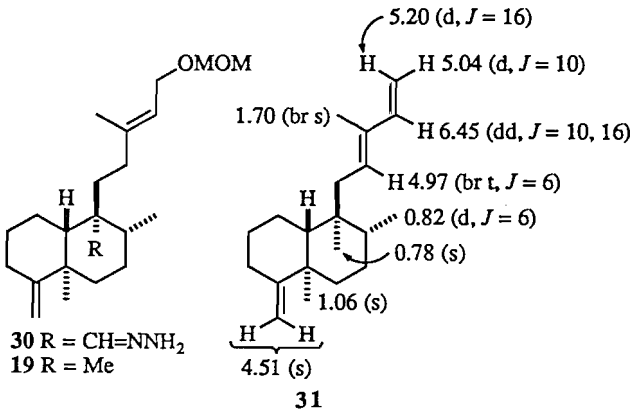
in diethylene glycol (DEG) at 210°C for 3 h produced two products, the chromatographically more polar, desired substance **19** (10% yield) and the less polar triene **31** (45% yield). The ^{1}H nmr spectrum of compound **19** exhibits the expected signals (δ 4.63, OCH_2O; 3.37, OCH_3; 1.66, vinyl Me) due to the OMOM- containing side chain. Resonances due to the exocyclic olefinic hydrogens and three methyl groups (δ 4.51, br s; 1.05 (s), 0.82 (d, J = 6 Hz), 0.74 (s)) are also present. These data, along with the fact that the latter set of signals have chemical shifts identical with those reported (1) for the corresponding functions of palauolide, provided strong evidence for the conclusion that the minor product derived from treatment of **30** with base possesses the constitution and relative configuration shown in **19**.

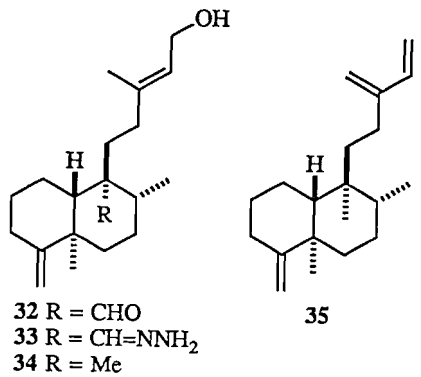
The ^{1}H nmr spectrum of the major product **31** is also in full accord with the structural assignment. The pertinent data are shown in conjunction with the structural formula (see **31**).

When a solution of the hydrazone **30** in DEG containing K_2CO_3 was heated slowly from 110 to 180°C, analyses (tlc) of aliquots of the reaction mixture indicated that substrate conversion began when the temperature reached ~160°C. Furthermore, both products **19** (minor) and **31** (major) appeared simultaneously. Application of an alternative method, involving reaction of the hydrazone **30** with t-BuOK in dimethyl sulfoxide (DMSO) (12) gave the triene **31** as the only isolated product, albeit in mediocre yield (36%).

Conversion of compound **17** into the hydrazone alcohol **33** was accomplished via a two-step reaction sequence involving Me_2BBr-mediated cleavage of the OMOM function (CH_2Cl_2, −78°C) (13), followed by reaction of the resultant alcohol aldehyde **32** with hydrazine in refluxing MeOH. Unfortunately, treatment of **33** with KOH or K_2CO_3 in DEG at 170°C for ~3 h again afforded, in each case, the triene **31** as the major product. Thus, all attempts to effect an efficient synthesis of the desired

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.





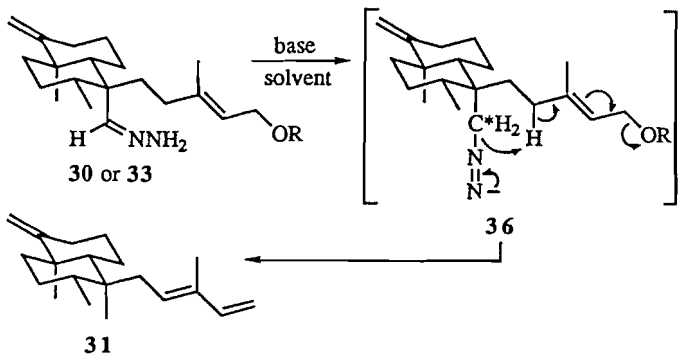
intermediates **19** or **34** by base-mediated reduction of the hydrazones **30** or **33** failed.

The results summarized above showed that the reduction–elimination reactions leading from the hydrazones **30** and **33** to the triene **31** are, with respect to the elimination processes, highly site-selective. In none of the reactions outlined above could the (possible) alternative triene **35** be detected in the reaction product. This selectivity can, perhaps, be best rationalized by postulating that the diene **31** is derived via an intramolecular elimination process involving the intermediacy of the anion **36** derived from the hydrazones **30** or **33** (see Scheme 4). Thus, although protonation of **36** on the H_2C^* group (see **36**) by the solvent would produce the desired products (**19** or **34**), a competitive, internal elimination process via a five-centered cyclic transition state would produce the diene **31**.

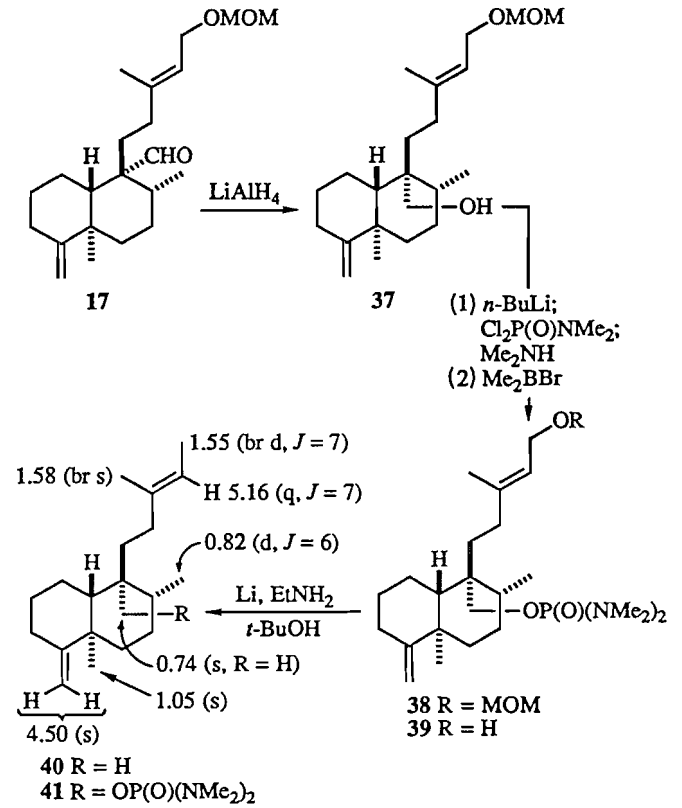
The synthetic difficulties associated with the endeavours outlined above led to attempts to prepare **19** or **34** by reduction of the phosphorodiamidate derivatives **38** or **39** (see Scheme 5). To that end, reduction of the aldehyde **17**, followed by sequential treatment of the derived alcohol **37** with *n*-BuLi (DME-*N,N,N′,N′*-tetramethylethylenediamine (TMEDA), room temperature), $Me_2NP(O)Cl_2$, and Me_2NH (0°C) (14) provided the required substrate **38**. Cleavage (Me_2BBr, CH_2Cl_2, −78°C, ref. 13) of the MOM ether function of **38** gave **39**.

Reduction (0°C, 30 min) of **38** with Li in $EtNH_2$ containing *t*-BuOH (15) gave, in 75% yield, the diene **40**. When the reductive process was carried out at −48°C for 15 min, the crude product consisted of a mixture of the starting material **38** and the phosphorodiamidate **41**. Thus, it appears that reductive cleavage of the allylic OMOM function is more facile than reduction of the CH_2-$OP(O)(NMe_2)_2$ moiety. Unfortunately, treatment of the substrate **39** under similar reductive conditions (Li, $EtNH_2$, *t*-BuOH, 0°C) also produced primarily the diene **40**.

The ^1H nmr spectrum derived from the diene **40** is in full



SCHEME 4



SCHEME 5

accord with the assigned structure. Some of the pertinent chemical shift data are portrayed in conjunction with the structural formula (see **40**).

(c) Completion of a total synthesis of (±)-palauolide (1)

In view of the fact that the work summarized above did not result in a successful approach to the synthesis of (±)-**1**, an alternative, less convergent route had to be developed. Explicitly, it appeared that alkylation of the nitriles **11** and **12** had to be performed with a reagent structurally more simple than the homoallylic iodide **14**. The electrophile that was selected was the iodide **42** (16), which was readily prepared from 3-chloro-1-propanol as shown in eq. [3].

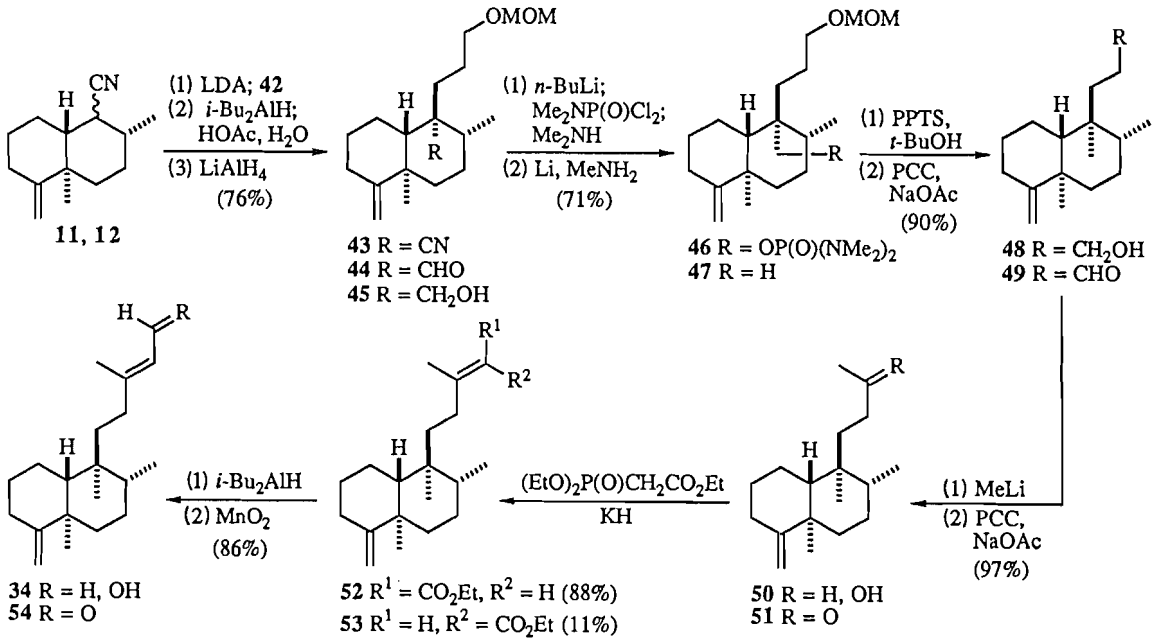


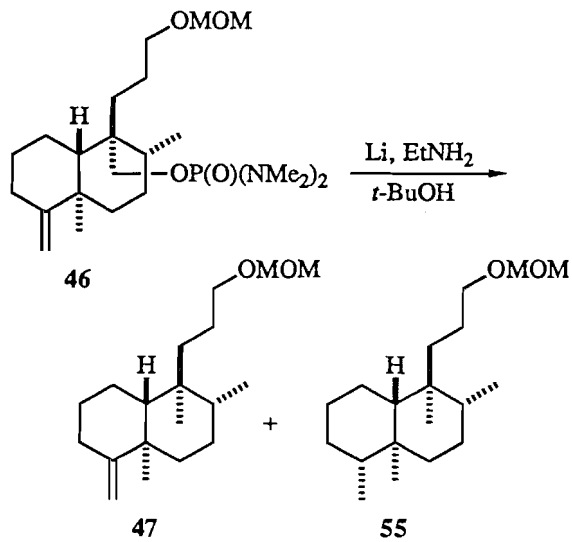
SCHEME 6

Conversion of the mixture of nitriles **11** and **12** into the bicyclic α,β-unsaturated aldehyde **54** is outlined in Scheme 6. Treatment of the anion derived from **11** and **12** with the iodide **42** provided, in nearly quantitative yield, the alkylation product **43**. As expected (vide supra), this reaction proceeded in a completely stereoselective manner. Conversion of **43**, via the intermediates **44** and **45**, into the phosphorodiamidate **46** was achieved efficiently by use of reagents and reaction conditions similar to those employed earlier for the preparation of **38** from **16**.

Subjection of substance **46** to conditions (Li, $EtNH_2$, *t*-BuOH, 0°C, 10 min) normally used (15) for reductive removal of the $OP(O)(NMe_2)_2$ moiety produced a 1:1 mixture of the desired product **47** and the bicyclic ether **55**[6] in which the carbon–carbon double bond on the bicyclic substructure had also been reduced (eq. [4]). When the reduction reaction was carried out at −10°C for 5 min, the ratio of products (**47**:**55**) improved to 2:1 and, when a more dilute solution of Li in $EtNH_2$ was employed, the product ratio was beneficially altered to ~25:1. However, reproduction of the latter result on a larger scale proved to be problematic. Fortunately, after additional experimentation, it was found that reduction (−20°C, 10 min) of **46** with Li in dry *methylamine* in the *absence* of *t*-BuOH provided, chemoselectively and reproducibly, the desired substance **47** in very good yield (Scheme 6). Thus, a suitably substituted bicyclo[4.4.0]decane, possessing the correct relative configuration at each of the four stereogenic centers, had been prepared stereoselectively and efficiently from the dimethylcyclohexenone **4**.

Treatment of the MOM ether **47** with pyridinium *p*-toluenesulfonate (PPTS) in *t*-BuOH (17) at 70°C for 12 h gave the alcohol **48** in 91% yield. A straightforward sequence of reactions, involving oxidation of **48** with pyridinium chloro-

[4]



chromate (PCC) in CH_2Cl_2 (18), addition of MeLi to the acquired aldehyde **49**, and oxidation (PCC) of the resultant mixture of epimeric alcohols **50**, produced, in excellent yield, the methyl ketone **51**. It should be noted that compound **51** has also been prepared by Sharma and Grayen (19) via a synthetic route very different from that described above. The ^1H nmr and ir spectral data reported (19) for this material agree very well with those derived from our intermediate.

Reaction of the ketone **51** with the potassium salt of triethyl phosphonoacetate in THF at room temperature produced, highly efficiently, a mixture of two geometrically isomeric α,β-unsaturated esters in a ratio of ~9:1. Fortunately, these substances were readily separated by column chromatography on silica gel. The expectation (20) that the major product, which was isolated in 88% yield, possesses the *E* configuration was confirmed by ^1H nmr spectroscopy. Thus, the vinyl methyl group of the *E* isomer **52**, being *cis* to the CO_2Et group, would be expected to give rise to a ^1H nmr signal at lower field than the resonance of the vinyl methyl function of the *Z* isomer **53**. In

[6]The configuration of the newly introduced secondary methyl group is assumed to be as shown in **55**. Presumably, dissolving metal reduction of the exocyclic double bond of **46** would lead to the more stable (equatorial Me group) of the two possible diastereomeric products. A pure sample of **55** could be obtained by reduction of **46** with Li–$EtNH_2$–*t*-BuOH at 0°C for 20 min (see Experimental).

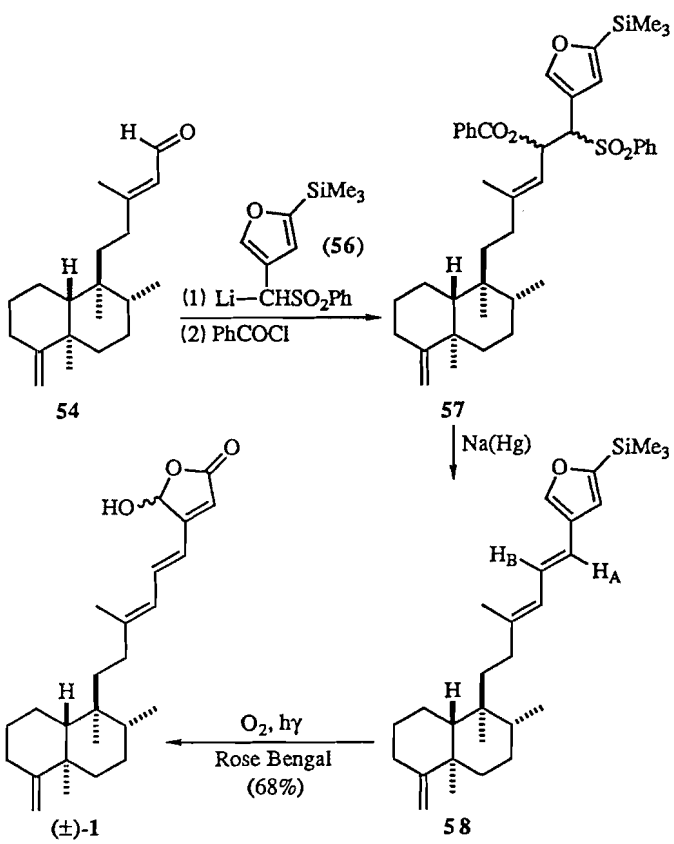

SCHEME 7

fact, the ^{1}H nmr spectra of the major and minor products exhibit vinyl methyl signals at δ 2.14 (d, J = 1.5 Hz) and 1.85 (d, J = 1.3 Hz), respectively.

Reduction (i-Bu_2AlH, THF) of the ester **52**, followed by oxidation (MnO_2, hexane) of the resultant allylic alcohol **34**, gave the α,β-unsaturated aldehyde **54**. In the ^{1}H nmr spectrum of **54**, the formyl proton and the adjacent olefinic hydrogen give rise to a doublet and a broad doublet (J = 8 Hz) at δ 9.97 and 5.86, respectively.

Completion of the total synthesis of racemic palauolide (**1**) was achieved as summarized in Scheme 7. Conversion of the α,β-unsaturated aldehyde **54** into the functionalized furan **58** was conveniently carried out by use of the Julia olefin synthesis (21). The reagent **56** required for this transformation was prepared as shown in eq. [5]. Thus, treatment of 4-chloromethyl-

[5] 
59 **60** R = H, **56** R = Li

2-trimethylsilylfuran (**59**) (22) with $PhSO_2Na$ in DMF at 80–90°C afforded the sulfone **60** in 72% yield. Reaction of the latter substance with n-BuLi in THF at −78°C provided a solution of reagent **56**.

Treatment (THF, −78°C) of the aldehyde **54** with reagent **56**, followed by reaction of the resultant alkoxide with benzoyl chloride (−78°C to room temperature) provided **57** as a mixture of diastereomers. Immediate reduction of this material with sodium amalgam in MeOH–THF at −20°C and subsequent chromatographic purification of the resultant crude product gave the furan **58** in 51% overall yield. The ^{1}H nmr spectrum of this intermediate shows that the coupling constant J_{AB} (see structural formula **58**) is 16 Hz, thus confirming that the newly introduced carbon–carbon bond possesses the expected (21) E configuration.

The final step for the synthesis of the target compound **1** was based on a method reported by Katsumura et al. (23). Thus, photosensitized oxygenation of **58**[7] in MeOH–CH_2Cl_2 at −78°C, followed by appropriate work-up and product purification, afforded (±)-palauolide (**1**), a pale yellow oil, in 68% yield. The spectral data derived from this material are in full accord with the structural assignment and the ^{1}H nmr spectrum was found to be in excellent agreement with that of natural palauolide.[8]

Conclusion

The work outlined above constitutes the first reported synthesis of the sesterterpenoid (±)-palauolide (**1**). Overall, the preparation of this biologically active, structurally unusual natural product was accomplished via a 17-step sequence of reactions, starting from 3,6-dimethyl-2-cyclohexen-1-one (**4**). Of particular note in this synthesis are (*a*) the efficient methylenecyclohexane annulation of **4** to produce the functionalized bicyclic ketone **7**; (*b*) the highly stereoselective alkylation of the mixture of nitriles **11** and **12** to afford **43**; (*c*) deoxygenation of the alcohol **45** via reduction of the phosphorodiamidate **46** with lithium in methylamine; (*d*) conversion of the α,β-unsaturated aldehyde **54** into the furan-triene **58** by use of a Julia olefin synthesis; and (*e*) oxidation of **58** with singlet oxygen to afford (±)-palauolide (1).

Experimental

General information

Distillation temperatures, which refer to short-path (Kugelrohr) distillations, and melting points are uncorrected. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded on $CDCl_3$ solutions. Signal positions (δ values) were measured relative to the Me_4Si resonance (internal standard) or the $CHCl_3$ signal (δ 7.25). Tin–proton coupling constants (J_{Sn-H}) are given as an average of the ^{117}Sn and ^{119}Sn values. For compounds containing the Me_3Sn function, high-resolution mass spectrometric measurements are based on ^{120}Sn and were measured on the (M^+ − Me) peak (25). Gas–liquid chromatography (glc) was performed on instruments equipped with flame ionization detectors and 25 m × 0.21 mm fused silica columns coated with cross-linked SE-54. Thin-layer chromatography (tlc) was carried out with commercial aluminum-backed silica gel plates (E. Merck, type 5554). Flash chromatography (26) and conventional column chromatography were accomplished with 230–400 and 70–230 mesh silica gel (E. Merck), respectively, unless otherwise indicated. Silica gel impregnated with $AgNO_3$ was prepared as follows. To a stirred solution of 12.5 g of

[7]After completion of our work (3), Kernan and Faulkner (24) reported that oxidation of 3-alkylfurans with singlet oxygen in the presence of a hindered amine base (e.g., i-Pr_2NEt) provides good yields of 3-alkyl-4-hydroxybutenolides. Therefore, it appears that the overall conversion of **54** into (±)-**1** could have been carried out successfully by initial use of a reagent similar in structure to **56**, but with the Me_3Si function replaced by a hydrogen. Obviously, such a reagent would be less expensive and more easily prepared than **56**.

[8]We are very grateful to Professor D.J. Faulkner for a copy of the ^{1}H nmr spectrum of natural palauolide.

$AgNO_3$ in 100 mL of distilled water was added 50 g of 70–230 mesh silica gel. Most of the water was removed under reduced pressure (20 Torr; 1 Torr = 133.3 Pa) and the residual material was dried over Drierite for ~16 h at room temperature under reduced pressure (0.02 Torr), with protection from light. Reagents and solvents were purified and dried using standard methods. Aqueous NH_4Cl–NH_4OH (pH 8) refers to a solution prepared by addition of aqueous NH_4OH (58%, ~50 mL) to saturated aqueous NH_4Cl (~950 mL).

Note: Unless otherwise stated, all reactions were carried out under an atmosphere of dry argon in flame-dried glassware.

Note: All compounds for which high-resolution mass measurements are given exhibited clean ^1H nmr spectra.

*3,6-Dimethyl-2-cyclohexen-1-one (**4**)*

To a cold (−78°C), stirred solution of LDA (42 mmol) in dry THF (50 mL) was added, dropwise, 3-methyl-2-cyclohexen-1-one (**3**) (4.5 mL, 40 mmol) and the mixture was stirred at −78°C for 30 min. Iodomethane (5 mL, 80 mmol) was added to the resultant white slurry and the mixture was allowed to warm gradually to room temperature and then was stirred overnight. The mixture was diluted with pentane and water. The phases were separated and the aqueous layer was extracted twice with pentane. The combined organic extracts were washed once with 2 N hydrochloric acid and three times with brine and then were dried ($MgSO_4$) and concentrated. Distillation (40–42°C/0.02 Torr; lit. (27) bp 95–100°C/22 Torr) of the remaining oil gave 4.6 g (93%) of the cyclohexenone **4**, a colorless oil that was homogeneous by glc analysis and exhibited ir (neat): 3031, 1672, 1635 cm^{-1}; ^1H nmr (80 MHz) δ: 5.83 (m, 1H), 3.72 (m, 1H), 2.50–1.40 (m, 4H), 1.96 (br s, 3H), 1.13 (d, 3H, J = 7 Hz).

5-Chloro-2-trimethylstannyl-1-pentene

To a cold (−78°C), stirred solution of $Me_3SnCu{\cdot}Me_2S$ (9) (80 mmol) in dry THF (500 mL) was added 5-chloro-1-pentyne (6.4 mL, 60 mmol) and the mixture was stirred at −78°C for 6 h. Acetic acid (3.4 mL, 60 mmol) was added and stirring was continued for 10 min. Aqueous NH_4Cl–NH_4OH (pH 8) and petroleum ether were added; the vigorously stirred mixture was opened to the atmosphere, and was allowed to warm to room temperature. The phases were separated and the blue aqueous layer was extracted twice with petroleum ether. The combined organic extracts were washed once with aqueous NH_4Cl–NH_4OH (pH 8) and twice with brine and then were dried ($MgSO_4$) and concentrated. Column chromatography (450 g silica gel, petroleum ether) of the residual liquid and distillation (80–85°C/25 Torr) of the acquired oil provided 9.6 g (62%) of the title compound, a colorless oil that displayed spectra identical with those recorded previously (5).

*5-(2-(5-Chloro-1-pentenyl))-2,5-dimethylcyclohexanone (**6**)*

To a cold (−78°C) solution of 5-chloro-2-trimethylstannyl-1-pentene (1.7 g, 6.4 mmol) in dry THF (50 mL) was added a solution of MeLi (6.6 mmol) in Et_2O. After the mixture had been stirred at −78°C for 20 min, solid $MgBr_2$–etherate (1.7 g, 6.6 mmol) was added in one portion and the milky solution was stirred for an additional 20 min. Solid $CuBr{\cdot}Me_2S$ (0.28 g, 1.4 mmol), $BF_3{\cdot}Et_2O$ (0.71 mL, 5.8 mmol), and 3,6-dimethyl-2-cyclohexen-1-one (0.75 mL, 5.3mmol) were added sequentially. After the bright yellow mixture had been stirred at −78°C for 3 h, aqueous NH_4Cl–NH_4OH (pH 8) was added. The vigorously stirred mixture was opened to the atmosphere and was allowed to warm to room temperature. The phases were separated and the blue aqueous layer was extracted twice with petroleum ether. The combined organic extracts were washed (once with pH 8 aqueous NH_4Cl–NH_4OH, twice with brine), dried ($MgSO_4$), and concentrated. Distillation (88–89°C/0.02 Torr) of the residual oil produced 0.93 g (77%) of **6** as a colorless oil that, on the basis of analyses by glc and ^1H nmr spectroscopy, consisted of a 2:1 mixture of epimers. This material exhibited ir (neat): 3098, 1705, 1640, 905 cm^{-1}; ^1H nmr (80 MHz) δ: 4.93 (br s, alkene protons of major isomer), 4.80 (m, alkene protons of minor isomer), 3.59 (br t, 2H), 2.90–1.20 (m, 11H), 1.15 (s, tertiary Me of minor isomer), 1.05 (d, J = 7 Hz, secondary Me of major isomer), 1.03 (s, tertiary Me of major isomer), 1.00 (d, J = 7 Hz, secondary Me of minor isomer). Exact Mass calcd. for $C_{13}H_{21}{}^{35}ClO$: 228.1281; found: 228.1276.

(1S,3R*,6R*)-3,6-Dimethyl-7-methylenebicyclo[4.4.0]decan-2-one (**7**) and (1R*,3S*,6R*)-3,6-dimethyl-7-methylenebicyclo-[4.4.0]decan-2-one (**9**)*

To a solution of *t*-BuOK (6.2 g, 55 mmol) in dry *t*-BuOH (40 mL) was added a solution of the chloro ketone **6** (6.3 g, 27 mmol) in *t*-BuOH (10 mL) and the solution was stirred at 30°C for 12 h. The solution was cooled and neutralized with 2 N hydrochloric acid. The mixture was extracted three times with petroleum ether. The combined organic extracts were washed three times with brine, dried ($MgSO_4$), and concentrated. Distillation (80–85°C/0.02 Torr) of the residual oil afforded 4.6 g (89%) of a colorless oil. Analysis of this material by glc showed that it consisted of a mixture of the two diastereomers **7** and **9** in a ratio of about 94:6, respectively. Column chromatography of 220 mg of this mixture on silica gel impregnated with 25% silver nitrate (25 g, 25:1 petroleum ether – Et_2O), followed by distillation of the acquired oils, gave 170 mg of the *trans* ketone **7** and ~4 mg of the less polar *cis* ketone **9**.

Compound **7** displayed ir (neat): 3086, 1713, 1638, 895, 876 cm^{-1}; ^1H nmr (400 MHz) δ: 4.70 (br s, 2H), 2.40–2.04 (m, 5H), 1.96 (dt, 1H, J = 4, 13 Hz), 1.90–1.78 (m, 2H), 1.69–1.50 (m, 3H), 1.32–1.15 (m, 1H), 0.99 (d, 3H, J = 6 Hz), 0.87 (s, 3H). Exact Mass calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1515.

Compound **9** showed ir (neat): 3084, 1708, 1639, 894, 874 cm^{-1}; ^1H nmr (400 MHz) δ: 4.74, 4.63 (br s, br s, 1H each), 2.39–2.25 (m, 4H), 2.17–2.08 (m, 2H), 1.92–1.55 (m, 6H), 1.31 (s, 3H), 0.98 (d, 3H, J = 6 Hz). Exact Mass calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1517.

(1R,2S*,3R*,6R*)-2-Cyano-3,6-dimethyl-7-methylenebicyclo[4.4.0]decane (**11**) and (1R*,2R*,3R*,6R*)-2-cyano-3,6-dimethyl-7-methylenebicyclo[4.4.0]decane (**12**)*

To a cold (0°C) solution of (*p*-toluenesulfonyl)methyl isocyanide (2.9 g, 15 mmol) in dry HMPA (17 mL) was added solid *t*-BuOK (4 g, 36 mmol) and the solution was stirred for 15 min. Dry *t*-BuOH (0.47 mL, 5 mmol) and a mixture of the ketones **7** and **9** (96:4, 960 mg, 5 mmol) were added and the mixture was stirred at room temperature for 1 h and at 45°C for 88 h. The mixture was cooled and poured into cold 1 N hydrochloric acid (40 mL). The mixture was extracted three times with petroleum ether and the combined organic extracts were washed once with water, twice with aqueous $CuSO_4$, and twice with brine and then were dried ($MgSO_4$) and concentrated. Flash chromatography (40 g silica gel, 19:1 petroleum ether – Et_2O) of the crude material and distillation (65–68°C/0.02 Torr) of the acquired liquid gave 690 mg (68%) of a colorless oil that consisted (glc analysis) of a mixture of the epimeric nitriles **11** and **12** (ratio ~85:15, respectively). Column chromatography of 100 mg of this material on silica gel impregnated with 25% silver nitrate (55 g, 25:1 petroleum ether – Et_2O) gave samples of each of the isomers.

The initially eluted, minor substance **12** exhibited ir (neat): 3070, 2225, 1638, 998, 895 cm^{-1}; ^1H nmr (400 MHz) δ: 4.61 (t, 1H, J = 1.5 Hz), 4.56 (br s, 1H), 2.60 (td, 1H, J = 4.5, 1.3 Hz), 2.41 (tdt, 1H, J = 1.5, 5, 14 Hz), 2.16 (br d, 1H, J = 14 Hz), 2.00–1.87 (m, 2H), 1.75–1.30 (diffuse m, 8H), 1.24 (s, 3H), 1.14 (d, 3H, J = 6.4 Hz). Exact Mass calcd. for $C_{14}H_{21}N$: 203.1674; found: 203.1676.

The more polar, major isomer **11** displayed ir (neat): 3070, 2225, 1638, 998, 895 cm^{-1}; ^1H nmr (400 MHz) δ: 4.68 (t, 1H, J = 1.7 Hz), 4.62 (br s, 1H), 2.36 (br t, 1H, J = 12 Hz), 2.17 (br d, 1H, J = 12 Hz), 2.08 (t, 1H, J = 11.5 Hz), 2.00–1.85 (m, 2H), 1.78–1.25 (diffuse m, 8H), 1.17 (d, 3H, J = 6.2 Hz), 0.96 (s, 3H). Exact Mass calcd. for $C_{14}H_{21}N$: 203.1674; found: 203.1676.

*Ethyl 5-tert-butyldimethylsiloxy-2-pentynoate (**22**)*

A solution of 3-butyn-1-ol (**20**) (3.8 mL, 50 mmol), *t*-$BuMe_2SiCl$ (9 g, 60 mmol), and imidazole (8.5 g, 125 mmol) in dry DMF (17 mL) was stirred at room temperature for 12 h. Aqueous $NaHCO_3$ was added and the mixture was extracted three times with petroleum ether. The

For personal use only.

combined extracts were washed twice with brine, dried ($MgSO_4$), and concentrated. Distillation (55–60°C/0.15 Torr) of the remaining oil gave 9 g (98%) of the silyl ether **21** (ir (neat): 3300, 2100, 1110, 632 cm^{-1}; ^1H nmr (80 MHz) δ: 3.72 (t, 2H, J = 7 Hz), 2.37 (dt, 2H, J = 2.5, 7 Hz), 1.92 (t, 1H, J = 2.5 Hz), 0.90 (s, 9H), 0.07 (s, 6H)), which was used directly for the next reaction.

To a cold (−78°C), stirred solution of **21** (9.2 g, 50 mmol) in dry THF (180 mL) was added a solution of MeLi (55 mmol) in Et_2O. After the solution had been stirred at −78°C for 10 min and at −20°C for 1 h, $ClCO_2Et$ (5.7 mL, 60 mmol) was added and the mixture was stirred at −20°C for 1 h and at room temperature for 1 h. The reaction mixture was diluted with Et_2O, was washed (twice with aqueous $NaHCO_3$, twice with brine), dried ($MgSO_4$), and concentrated. Distillation (75–78°C/0.02 Torr) of the residual oil yielded 11.5 g (90%) of the pentynoate **22**, a colorless oil that displayed ir (neat): 2230, 1705, 1250, 1110, 1080 cm^{-1}; ^1H nmr (80 MHz) δ: 4.20 (q, 2H, J = 7 Hz), 3.76 (t, 2H, J = 7 Hz), 2.52 (t, 2H, J = 7 Hz), 1.28 (t, 3H, J = 7 Hz), 0.90 (s, 9H), 0.07 (s, 6H). Exact Mass calcd. for $C_{12}H_{21}O_3Si$ (M^+ − Me): 241.1260; found: 241.1256.

*Ethyl (Z)-5-*tert*-butyldimethylsiloxy-3-trimethylstannyl-2-pentenoate (23)*

To a cold (−20°C), stirred solution of $Me_3SnSnMe_3$ (2.6 mL, 12 mmol) in dry THF (120 mL) was added a solution of MeLi (13 mmol) in Et_2O. The pale yellow solution was stirred at −20°C for 20 min and then solid PhSCu (28) (2.1 g, 12 mmol) was added. The red solution was stirred at −20°C for 15 min and then was cooled to −78°C. A solution of the pentynoate **22** (2.6 g, 10 mmol) in dry THF (5 mL) was added and the mixture was stirred at −78°C for 15 min and at −40°C for 9 h. Aqueous NH_4Cl–NH_4OH (pH 8) (~5 mL) and petroleum ether were added and the mixture was allowed to warm to room temperature. More petroleum ether was added to the slurry until the organic phase became nearly colorless. The mixture was filtered and the phases were separated. The organic phase was washed twice with brine, dried ($MgSO_4$), filtered through a short pad of Florisil, and concentrated. Distillation (91–95°C/0.02 Torr) of the residual oil gave 3.8 g (91%) of the *Z* ester **23**, a colorless liquid that displayed ir (neat): 1700, 1600, 1110, 1052 cm^{-1}; ^1H nmr (80 MHz) δ: 6.40 (t, 1H, J = 1 Hz, $^3J_{Sn-H}$ = 120 Hz), 4.18 (q, 2H, J = 7 Hz), 3.63 (t, 2H, J = 6.5 Hz), 2.63 (br t, 2H, J = 6.5 Hz), 1.28 (t, 3H, J = 7 Hz), 0.90 (s, 9H), 0.18 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.04 (s, 6H). Exact Mass calcd. for $C_{15}H_{31}O_3Si^{120}Sn$ (M^+ − Me): 407.1063; found: 407.1058.

*(Z)-5-*tert*-Butyldimethylsiloxy-3-trimethylstannyl-2-penten-1-ol (24)*

To stirred solution of the ester **23** (3.8 g, 9 mmol) in dry THF (90 mL) at −78°C was added a solution of *i*-Bu_2AlH (27 mmol) in hexanes. After the mixture had been stirred at −78°C for 1 h and at 0°C for 1 h, it was treated with saturated aqueous NH_4Cl (1.6 mL) and then was diluted with Et_2O. The mixture was stirred at room temperature for 5 min, was dried ($MgSO_4$), and then was filtered through a plug of Florisil and concentrated. Distillation (104–105°C/0.02 Torr) of the remaining liquid afforded 3.3 g (96%) of the alcohol **24**, a colorless oil that exhibited ir (neat): 3350, 1621, 1090, 1010 cm^{-1}; ^1H nmr (80 MHz) δ: 6.26 (br t, 1H, J = 6 Hz), 4.08 (t, 2H, J = 6 Hz, collapsed to a d on addition of D_2O), 3.57 (t, 2H, J = 7 Hz), 2.43 (t, 2H, J = 7 Hz), 1.18 (t, 1H, J = 6 Hz, exchanged with D_2O), 0.89 (s, 9H), 0.19 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.05 (s, 6H). Exact Mass calcd. for $C_{13}H_{29}O_2Si^{120}Sn$ (M^+ − Me): 365.0958; found: 365.0959.

*(Z)-5-*tert*-Butyldimethylsiloxy-1-methoxymethoxy-3-trimethylstannyl-2-pentene (25)*

To a cold (−20°C) solution of the alcohol **24** (3.3 g, 8.7 mmol) and i-Pr_2NEt (2.3 mL, 13 mmol) in dry CH_2Cl_2 (25 mL) was added $MeOCH_2Cl$ (1 mL, 13 mmol) and the mixture was stirred at room temperature for 12 h. The mixture was concentrated and the residual mixture was triturated four times with petroleum ether. The combined organic extracts were concentrated and the residue was filtered through a short column of silica gel (75 g, elution with 9:1 petroleum ether – Et_2O). Concentration of the combined eluate and distillation (90–93°C/0.02 Torr) of the remaining liquid provided 3.3 g (90%) of the diether **25**, a colorless oil that showed ir (neat): 1100, 1040 cm^{-1}; ^1H nmr (80 MHz) δ: 6.21 (t, 1H, J = 6 Hz), 4.63 (s, 2H), 4.01 (d, 2H, J = 6 Hz), 3.58 (t, 2H, J = 7 Hz), 3.38 (s, 3H), 2.45 (t, 2H, J = 7 Hz), 0.91 (s, 9H), 0.20 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.06 (s, 6H). Exact Mass calcd. for $C_{15}H_{33}O_3Si^{120}Sn$ (M^+ − Me): 409.1220; found: 409.1228.

*(E)-5-*tert*-Butyldimethylsiloxy-1-methoxymethoxy-3-methyl-2-pentene (26)*

To a cold (−78°C), stirred solution of the vinylstannane **25** (3.3 g, 7.8 mmol) in dry THF (65 mL) was added a solution of MeLi (8.5 mmol) in Et_2O and the solution was stirred at −78°C for 30 min. Iodomethane (1.2 mL, 20 mmol, freshly passed through a plug of basic alumina) was added and the mixture was stirred at −78°C for 90 min. The mixture was diluted with petroleum ether, was washed three times with brine, dried ($MgSO_4$), and concentrated. Distillation (81–83°C/0.02 Torr) of the residual oil gave 2 g (90%) of the alkene **26**, a colorless liquid that displayed ir (neat): 2725, 1100, 1050 cm^{-1}; ^1H nmr (80 MHz) δ: 5.36 (br t, 1H, J = 7 Hz), 4.61 (s, 2H), 4.04 (d, 2H, J = 7 Hz), 3.68 (t, 2H, J = 7 Hz), 3.35 (s, 3H), 2.23 (t, 2H, J = 7 Hz), 1.69 (br s, 3H), 0.88 (s, 9H), 0.03 (s, 6H). Exact Mass calcd. for $C_{12}H_{25}OSi$ (M^+ − OMOM): 213.1674; found: 213.1671.

(E)-5-Methoxymethoxy-3-methyl-3-penten-1-ol (27)

To a stirred solution of *n*-Bu_4NF (20 mmol) in dry THF (35 mL) at room temperature was added a solution of the diether **26** (2 g, 7.2 mmol) in dry THF (5 mL). After the solution had been stirred for 40 min, it was diluted with Et_2O, washed three times with brine, dried ($MgSO_4$), and concentrated. Distillation (81–83°C/0.02 Torr) of the remaining oil provided 1.1 g (98%) of the homoallylic alcohol **27**, a colorless oil that exhibited ir (neat): 3400, 1040, 922 cm^{-1}; ^1H nmr (80 MHz) δ: 5.48 (br t, 1H, J = 7 Hz), 4.65 (s, 2H), 4.11 (d, 2H, J = 7 Hz), 3.73 (t, 2H, J = 6.5 Hz), 3.40 (s, 3H), 2.30 (t, 2H, J = 6.5 Hz), 1.72 (br s, 4H, changes to a br s, 3H, upon addition of D_2O). Exact Mass calcd. for $C_6H_{11}O_2$ (M^+ − OMOM): 115.0759; found: 115.0762.

(E)-5-Iodo-1-methoxymethoxy-3-methyl-2-pentene (14)

A solution of the alcohol **27** (0.84 g, 5.3 mmol), *p*-$MeC_6H_4SO_2Cl$ (1.2 g, 6.3 mmol), and 4-*N*,*N*-dimethylaminopyridine (0.77 g, 6.3 mmol) in dry CH_2Cl_2 (15 mL) was stirred at room temperature for 12 h. The mixture was diluted with Et_2O, washed with saturated aqueous $NaHCO_3$ and brine, dried ($MgSO_4$), and concentrated. Flash chromatography (75 g silica gel, 1:1 petroleum ether – Et_2O) of the residual material yielded 1.2 g (75%) of the *p*-toluenesulfonate **28**, a rather unstable oil that was used directly for the next reaction.

To a solution of **28** (1.2 g, 3.8 mmol) in dry DMF (8 mL) was added solid NaI (1 g, 6.6 mmol) and the mixture was stirred at room temperature, with protection from light, for 4 days. Water was added and the mixture was extracted three times with pentane. The combined extracts were washed twice with brine, dried ($MgSO_4$), and concentrated. Distillation (48–51°C/0.02 Torr) of the remaining oil yielded 945 mg (91%) of the iodide **14**, a colorless oil that was stored over copper dust in a freezer. Compound **14** exhibited ir (neat): 1040 cm^{-1}; ^1H nmr (80 MHz) δ: 5.41 (br, t, 1H, J = 7 Hz), 4.63 (s, 2H), 4.07 (d, 2H, J = 7 Hz), 3.38 (s, 3H), 3.23 (t, 2H, J = 8 Hz), 2.58 (t, 2H, J = 8 Hz), 1.68 (br s, 3H). Exact Mass calcd. for $C_8H_{15}IO_2$: 270.0116; found: 270.0111.

(1S,2R*,3R*,6R*)-2-Cyano-2-((E)-5-methoxymethoxy-3-methyl-3-pentenyl)-3,6-dimethyl-7-methylenebicyclo[4.4.0]decane (16)*

To a stirred solution of LDA (1.2 mmol) in dry THF (10 mL) at 0°C was added sequentially dry HMPA (0.34 mL, 2 mmol) and a solution of a mixture of the nitriles **11** and **12** (200 mg, 0.98 mmol, 85:15, respectively) in 1 mL of dry THF and the mixture was stirred for 15 min. To the resultant yellow solution was added the iodide **14** (0.35 g, 1.3 mmol). The solution was allowed to warm to room temperature and was stirred overnight. The mixture was diluted with petroleum ether (50 mL), was washed sequentially with water, aqueous $CuSO_4$, and brine (× 2), and then was dried ($MgSO_4$) and concen-

For personal use only.

trated. Flash chromatography (35 g silica gel, 3:1 petroleum ether – Et_2O) of the residual oil gave 47 mg of a 2:3 mixture of the nitriles **11** and **12** and 250 mg (70%, 92% based on recovered starting materials) of the nitrile **16**, a colorless oil that displayed ir (neat): 2227, 1671, 1638, 1150, 1103, 1045, 895 cm^{-1}; ^1H nmr (400 MHz) δ: 5.35 (t, 1H, $J = 6.5$ Hz)), 4.62 (s, 2H), 4.60, 4.55 (s, s, 1H each), 4.05 (d, 2H, $J = 6.5$ Hz), 3.38 (s, 3H), 2.40 (br dt, 1H, $J = 5$, 13.5 Hz), 2.14 (br dd, 1H, $J = 4$, 13.5 Hz), 2.00–1.82 (m, 5H), 1.8–1.5 (m, 9H), 1.68 (s, 3H), 1.27 (s, 3H), 1.11 (d, 3H, $J = 6$ Hz). Exact Mass calcd. for $C_{22}H_{35}NO_2$: 345.2668; found: 345.2668.

(1S,2R*,3R*,6R*)-2-Formyl-2-((E)-5-methoxymethoxy-3-methyl-3-pentenyl)-3,6-dimethyl-7-methylenebicyclo[4.4.0]decane (**17**)*

To a stirred solution of the nitrile **16** (170 mg, 0.49 mmol) in dry DME (7 mL) at room temperature was added a solution of *i*-Bu_2AlH (2 mmol) in hexanes and the mixture was heated at 60°C for 6 h. The cooled mixture was poured cautiously into cold water and the resultant mixture was neutralized with 1 N hydrochloric acid. The mixture was extracted three times with Et_2O and the combined extracts were washed with brine, dried ($MgSO_4$), and concentrated. The residual oil was dissolved in a mixture of THF, HOAc, and water (4 mL, 3:1:0.15 by volume) and the solution was stirred at room temperature for 12 h. The mixture was concentrated under reduced pressure (0.02 Torr), the residual material was dissolved in Et_2O, and the solution was washed (aqueous $NaHCO_3$, brine), dried ($MgSO_4$), and concentrated to provide the aldehyde **17** (150 mg, 87%), a colorless oil that displayed one spot on tlc analyses and showed ir (neat): 1713, 1671, 1637, 1149, 893 cm^{-1}; ^1H nmr (400 MHz) δ: 9.98 (s, 1H), 5.36 (t, 1H, $J = 7$ Hz), 4.62 (s, 2H), 4.58 (br s, 2H), 4.06 (d, 2H, $J = 7$ Hz), 3.37 (s, 3H), 2.27 (br dt, 1H, $J = 5$, 13 Hz), 2.12 (br d, 1H, $J = 13$ Hz), 2.0–1.1 (diffuse m, 14H), 1.69 (s, 3H), 1.03 (d, 3H, $J = 7$ Hz), 0.96 (s, 3H). Exact Mass calcd. for $C_{22}H_{36}O_3$: 348.2664; found: 348.2658.

(1S,2R*,3R*,6R*)-2-(Hydroxymethyl)-2-((E)-5-methoxymethoxy-3-methyl-3-pentenyl)-3,6-dimethyl-7-methylenebicyclo[4.4.0]-decane (**37**)*

To a solution–suspension of $LiAlH_4$ (16 mg, 0.42 mmol) in dry Et_2O (3 mL) was added a solution of the aldehyde **17** (99 mg, 0.28 mmol) in dry Et_2O (1 mL) and the mixture was stirred at room temperature for 1 h. Solid $Na_2SO_4 \cdot 10H_2O$ was added in small portions until gas evolution ceased. The mixture was filtered and the collected material was washed three times with Et_2O. Concentration of the filtrate gave 92 mg (93%) of the alcohol **37**, a colorless oil that displayed ir (neat): 3469 (br), 1669, 1635, 1150, 1103, 1043, 892 cm^{-1}; ^1H nmr (400 MHz) δ: 5.47 (t, 1H, $J = 7$ Hz), 4.63 (s, 2H), 4.52 (br s, 2H), 4.06 (d, 2H, $J = 7$ Hz), 3.80, 3.70 (dd, dd, 1H each, $J = 6$, 12 Hz; each signal collapses to a d, $J = 12$ Hz, on D_2O addition), 3.38 (s, 3H), 2.27 (br dt, 1H, $J = 4$, 14 Hz), 2.11 (br d, 1H, $J = 14$ Hz), 1.93–1.40 (diffuse m, 12H), 1.71 (s, 3H), 1.27–1.11 (m, 2H), 1.06 (s, 3H), 1.02 (t, 1H, $J = 6$ Hz, exchanges with D_2O), 0.94 (d, 3H, $J = 6.5$ Hz). In a nOe difference experiment, irradiation at δ 1.06 (angular Me group) caused enhancement of the signals at 3.80 and 3.70. Exact Mass calcd. for $C_{21}H_{35}O_2$ ($M^+ - OMe$): 319.2637; found: 319.2636.

*Preparation of the phosphorodiamidate **38***

To a stirred solution of the alcohol **37** (23 mg, 66 μmol) in a mixture of DME (1 mL) and TMEDA (0.25 mL) at 0°C was added a solution of *n*-BuLi (73 μmol) in hexanes and the mixture was stirred at room temperature for 30 min. $Me_2NP(O)Cl_2$ (40 μL, 0.32 mmol) was added and the mixture was stirred at room temperature for 12 h. The mixture was cooled to 0°C and dry Me_2NH (1 mL) was added and stirring was continued for 2 h at 0°C. The mixture was diluted with Et_2O, washed twice with brine, and then was dried ($MgSO_4$) and concentrated. Column chromatography (2 g silica gel, 10:1 Et_2O–acetone) of the residual material gave 23 mg (71%) of the phosphorodiamidate **38**, a colorless liquid that exhibited ir (neat): 1667, 1634, 1224, 1041, 994, 891 cm^{-1}; ^1H nmr (270 MHz) δ: 5.34 (t, 1H, $J = 6.8$ Hz), 4.63 (s, 2H), 4.53 (s, 2H), 4.06 (d, 2H, $J = 6.8$ Hz), 4.00 (br m, 2H), 3.39 (s, 3H), 2.69, 2.66 (br s, br s, 6H each), 2.30–1.10 (diffuse m, 16H), 1.70 (s, 3H), 1.08 (s, 3H), 0.93 (d, 3H, $J = 6$ Hz).

*3-Iodo-1-methoxymethoxypropane (**42**)*

To a cold (−20°C), stirred solution of 3-chloro-1-propanol (8.4 mL, 0.1 mol) and i-Pr_2NEt (28 mL, 0.16 mol) in dry CH_2Cl_2 (200 mL) was added chloromethyl methyl ether (11.4 mL, 0.15 mol) and the mixture was stirred at room temperature for 12 h. The mixture was diluted with CH_2Cl_2, was washed three times with 1 N hydrochloric acid, once with saturated aqueous $NaHCO_3$, twice with brine, and then was dried ($MgSO_4$). The solution was concentrated by distillation of the solvent at atmospheric pressure through a 10 cm Vigreux column. Distillation (73–80°C/15 Torr) of the residual oil gave 11 g (80%) of 3-chloro-1-methoxymethoxypropane. A solution of the latter material in dry acetone (150 mL) containing sodium iodide (47 g, 0.32 mol) was stirred at 60°C for 30 h. The mixture was diluted with petroleum ether, filtered, and concentrated by distillation of the solvent through a Vigreux column (10 cm) at atmospheric pressure. Distillation (80–85°C/15 Torr) of the remaining oil yielded 13 g (70%) of the iodide **42** (16), a colorless oil that was stored over copper dust under an argon atmosphere in a freezer. This material displayed ^1H nmr (80 MHz) δ: 4.63 (s, 2H), 3.60 (t, 2H, $J = 6$ Hz), 3.40 (s, 3H), 3.30 (t, 2H, $J = 6$ Hz), 2.05 (quintet, 2H, $J = 6$ Hz).

(1S,2R*,3R*,6R*)-2-Cyano-2-(3-methoxymethoxypropyl)-3,6-dimethyl-7-methylenebicyclo[4.4.0]decane (**43**)*

To a cold (0°C), stirred solution of LDA (1.5 mmol) in a mixture of dry THF (11 mL) and dry HMPA (0.4 mL, 2.2 mmol) was added a solution of a mixture of the nitriles **11** and **12** (230 mg, 1.1 mmol, 85:15, respectively) in dry THF (~1 mL) and the solution was stirred at 0°C for 15 min. The iodide **42** (350 mg, 1.5 mmol) was added and the mixture was stirred at 0°C for 30 min and at room temperature for 1 h. The solution was diluted with petroleum ether, was washed once with 1 N hydrochloric acid, twice with aqueous $CuSO_4$, and twice with brine and then was dried ($MgSO_4$), filtered through a small pad of Florisil, and concentrated. Removal of traces of solvent (vacuum pump, 0.02 Torr) afforded 340 mg (99%) of the nitrile **43**, a colorless oil that was homogeneous by tlc and glc analyses and showed ir (neat): 2228, 1638, 1153, 1112, 1039, 921, 894 cm^{-1}; ^1H nmr (400 MHz) δ: 4.59 (br s, 3H, (1 alkene H and OCH_2O)), 4.55 (br s, 1H), 3.43 (t, 2H, $J = 6$ Hz), 3.35 (s, 3H), 2.34 (br dt, 1H, $J = 5$, 12 Hz), 2.14 (br d, 1H, $J = 12$ Hz), 2.00–1.20 (diffuse m, 14H), 1.27 (s, 3H), 1.11 (d, 3H, $J = 6$ Hz). Exact Mass calcd. for $C_{19}H_{31}NO_2$: 305.2355; found: 305.2356.

(1S,2R*,3R*,6R*)-2-Formyl-2-(3-methoxymethoxypropyl)-3,6-dimethyl-7-methylenebicyclo[4.4.0]decane (**44**)*

To a stirred solution of the nitrile **43** (340 mg, 1.1 mmol) in dry DME (11 mL) was added a solution of i-Bu_2AlH (4.4 mmol) in hexanes and the solution was warmed at 60°C for 6 h. The cooled mixture was poured cautiously into cold water and the resultant mixture was neutralized with 1 N hydrochloric acid and then was extracted three times with Et_2O. The combined extracts were washed (brine), dried (Na_2SO_4), and concentrated. The residual oil was dissolved in a mixture of THF, HOAc, and water (8 mL, 1:1:0.15 by volume) and the solution was stirred at room temperature for 12 h. The solvent was removed under reduced pressure (vacuum pump, 0.02 Torr), the residual material was dissolved in Et_2O, and the resultant solution was washed (aqueous $NaHCO_3$; brine), dried ($MgSO_4$), and concentrated to afford 290 mg (85%) of the aldehyde **44**, a colorless oil that displayed ir (neat): 1713, 1636, 1153, 1112, 1039, 921, 893 cm^{-1}; ^1H nmr (400 MHz) δ: 9.52 (s, 1H), 4.60 (s, 2H), 4.58 (br s, 2H), 3.50 (t, 2H, $J = 6$ Hz), 3.35 (s, 3H), 2.26 (br dt, 1H, $J = 5$, 12 Hz), 2.11 (br d, 1H, $J = 12$ Hz), 1.95–1.10 (diffuse m, 14H), 1.02 (d, 3H, $J = 6$ Hz), 0.98 (s, 3H). Exact Mass calcd. for $C_{19}H_{32}O_3$: 308.2351; found: 308.2359.

(1S,2R*,3R*,6R*)-2-(Hydroxymethyl)-2-(3-methoxymethoxypropyl)-3,6-dimethyl-7-methylenebicyclo[4.4.0]decane (**45**)*

To a solution–suspension of $LiAlH_4$ (70 mg, 1.8 mmol) in dry Et_2O (10 mL) was added an ethereal solution of the aldehyde **44** (280 mg,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

0.9 mmol) and the mixture was stirred at room temperature for 1 h. Solid $Na_2SO_4 \cdot 10H_2O$ was added in small portions to the stirred mixture until gas evolution ceased. The mixture was filtered and the collected material was washed three times with Et_2O. Concentration of the combined filtrate, followed by removal of last traces of solvent (vacuum pump, 0.02 Torr), afforded 250 mg (91%) of the alcohol **45**, a colorless oil that displayed ir (neat): 3462 (br), 1635, 1152, 1111, 1039, 921, 891 cm^{-1}; ^1H nmr (400 MHz) δ: 4.62 (s, 2H), 4.51 (br s, 2H), 3.78, 3.70 (d, d, 1H each, J = 12 Hz in each case), 3.51 (t, 2H, J = 6.5 Hz), 3.37 (s, 3H), 2.26 (br dt, 1H, J = 5, 12 Hz), 2.10 (br d, 1H, J = 12 Hz), 1.87 (br d, 1H, J = 12 Hz), 1.70–1.10 (diffuse m, 14H), 1.06 (s, 3H), 0.94 (d, 3H, J = 6 Hz). Exact Mass calcd. for $C_{19}H_{34}O_3$: 310.2508; found: 310.2509.

Preparation of the phosphorodiamidate ***46***

A solution of *n*-BuLi (0.77 mmol) in hexanes was added to a stirred solution of the alcohol **45** (220 mg, 0.7 mmol) in a mixture of dry DME (6 mL) and dry TMEDA (1.5 mL) at 0°C. After the mixture had been stirred for 15 min, $Me_2NP(O)Cl_2$ (0.45 mL, 3.6 mmol) was added and the solution was stirred at room temperature for 12 h. The mixture was cooled to 0°C, anhydrous Me_2NH (10 mL) was added, and stirring at 0°C was continued for 2 h. The solution was diluted with Et_2O, was washed twice with brine, dried ($MgSO_4$), and concentrated. Column chromatography (10 g silica gel, 10:1 Et_2O–acetone) of the residue, followed by removal of solvent from the acquired liquid (0.02 Torr), gave 270 mg (88%) of the phosphorodiamidate **46**, a colorless liquid that showed ir (neat): 1635, 1305, 1215, 1152, 1111, 1037, 920, 888 cm^{-1}; ^1H nmr (400 MHz) δ: 4.60 (s, 2H), 4.51 (s, 2H), 4.00, 3.95 (dd, dd, 1H each, J = 4, 12 Hz), 3.48 (t, 2H, J = 6 Hz), 3.35 (s, 3H), 2.66, 2.64 (d, d, 6H each, J = 4 Hz), 2.26 (br dt, 1H, J = 5, 12 Hz), 2.11 (br d, 1H, J = 12 Hz), 1.9–1.1 (diffuse m, 14H), 1.06 (s, 3H), 0.93 (d, 3H, J = 6 Hz). Exact Mass calcd. for $C_{23}H_{45}N_2O_4P$: 444.3117; found: 444.3119.

(1R,2R*,3R*,6R*)-2-(3-Methoxymethoxypropyl)-2,3,6-trimethyl-7-methylenebicyclo[4.4.0]decane (**47**)*

Dry liquid $MeNH_2$ (7 mL) was condensed into a cold (−78°C) flask containing Li metal (9 mg, 1.3 mmol) and the mixture was stirred at −30°C for 30 min. To the resultant dark blue solution was added a solution of the phosphorodiamidate **46** (99 mg, 0.2 mmol) in dry Et_2O (~0.5 mL) and the mixture was stirred at −20°C for 10 min. The mixture was treated cautiously with aqueous NH_4Cl (10 mL) and the resultant mixture was extracted three times with Et_2O. The combined extracts were washed (brine), dried ($MgSO_4$), and concentrated. Column chromatography (4 g silica gel, 20:1 petroleum ether – Et_2O) of the residual material gave 48 mg (81%) of the MOM ether **47**, a colorless oil that displayed ir (neat): 1636, 1147, 1112, 1078, 1039, 922, 891 cm^{-1}; ^1H nmr (400 MHz) δ: 4.60 (s, 2H), 4.49 (br s, 2H), 3.44 (t, 2H, J = 6 Hz), 3.36 (s, 3H), 2.28 (br dt, 1H, J = 5, 13.5 Hz), 2.09 (br d, 1H, J = 13.5 Hz), 1.87 (br d, 1H, J = 12 Hz), 1.63–1.00 (diffuse m, 13H), 1.04 (s, 3H), 0.80 (d, 3H, J = 6 Hz), 0.73 (s, 3H). Exact Mass calcd. for $C_{19}H_{34}O_2$: 294.2559; found: 294.2557.

(1S,2S*,3R*,6S*,7R*)-2-(3-Methoxymethoxypropyl)-2,3,6,7-tetramethylbicyclo[4.4.0]decane (**55**)*

Dry liquid $EtNH_2$ (1 mL) was condensed into a cold (−78°C) flask containing Li metal (11 mg, 0.29 mmol) and the mixture was stirred at 0°C for 20 min. A solution of the phosphorodiamidate **46** (13 mg, 29 μmol) and dry *t*-BuOH (0.11 mmol) in dry THF (0.5 mL) was added and the mixture was stirred at 0°C for 20 min. The mixture was treated with aqueous NH_4Cl (5 mL) and the resultant mixture was extracted three times with Et_2O. The combined extracts were washed (brine), dried ($MgSO_4$), and concentrated. Column chromatography of the residual material on silica gel (1 g, 15:1 petroleum ether – Et_2O) gave 7 mg (80%) of the ether **55**, a colorless oil that showed ir (neat): 1463, 1383, 1151, 1112, 1039 cm^{-1}; ^1H nmr (400 MHz) δ: 4.62 (s, 2H), 3.46 (t, 2H, J = 7 Hz), 3.37 (s, 3H), 1.8–0.8 (diffuse m, 17H), 0.78 (d, 3H, J = 7 Hz), 0.77 (s, 3H), 0.73 (d, 3H, J = 7 Hz), 0.70 (s, 3H). Exact Mass calcd. for $C_{19}H_{36}O_2$: 296.2715; found: 296.2707.

(1R,2S*,3R*,6R*)-2-(3-Hydroxypropyl)-2,3,6-trimethyl-7-methylenebicyclo[4.4.0]decane (**48**)*

A stirred mixture of the MOM ether **47** (65 mg, 0.22 mmol) and PPTS (0.55 g, 2.2 mmol) in *t*-BuOH (5 mL) was heated at 70°C for 12 h. The solvent was removed from the cooled mixture under reduced pressure (0.02 Torr) and the residual material was triturated three times with dry Et_2O. The combined organic solution was filtered and concentrated. Column chromatography (1 g silica gel, 7:3 petroleum ether – Et_2O) of the residue gave 50 mg (91%) of the alcohol **48**, a colorless oil that exhibited ir (neat): 3319 (br), 1635, 1055, 891 cm^{-1}; ^1H nmr (400 MHz) δ: 4.50 (br s, 2H), 3.57 (t, 2H, J = 6 Hz), 2.29 (br dt, 1H, J = 5, 12 Hz), 2.10 (br d, 1H, J = 12 Hz), 1.87 (br d, 1H, J = 12 Hz), 1.65–1.00 (diffuse, 14H), 1.05 (s, 3H), 0.80 (d, 3H, J = 6 Hz), 0.75 (s, 3H). Exact Mass calcd. for $C_{17}H_{30}O$: 250.2296; found: 250.2295.

(1R,2S*,3R*,6R*)-2-(2-Formylethyl)-2,3,6-trimethyl-7-methylenebicyclo[4.4.0]decane (**49**)*

To a stirred solution–suspension of PCC (70 mg, 0.32 mmol) and anhydrous NaOAc (5 mg, 61 μmol) in dry CH_2Cl_2 (5 mL) was added a solution of the alcohol **48** (60 mg, 0.24 mmol) in dry CH_2Cl_2 (0.5 mL). After the mixture had been stirred at room temperature for 1 h, it was diluted with dry Et_2O and then was filtered through a short pad of Florisil. Concentration of the filtrate gave 58 mg (99%) of the aldehyde **49**, a colorless oil that showed ir (neat): 1728, 1635, 892 cm^{-1}; ^1H nmr (400 MHz) δ: 9.74 (t, 1H, J = 2 Hz, 4.50 (br s, 2H), 2.30–2.16 (m, 3H), 2.10 (br d, 1H, J = 12 Hz), 1.88 (br d, 1H, J = 12 Hz), 1.70–1.15 (m, 11H), 1.05 (s, 3H), 0.81 (d, 3H, J = 6 Hz), 0.79 (s, 3H). Exact Mass calcd. for $C_{17}H_{28}O$: 248.2140; found: 248.2145.

(1R,2S*,3R*,6R*)-2-(3-Oxo-butyl)-2,3,6-trimethyl-7-methylene-bicyclo[4.4.0]decane (**51**)*

To a cold (0°C), stirred solution of the aldehyde **49** (22 mg, 88 μmol) in dry Et_2O (1 mL) was added a solution of MeLi (0.28 mmol) in Et_2O and the mixture was stirred at room temperature for 3 h. Solid $Na_2SO_4 \cdot 10H_2O$ was added in small portions until evolution of gas ceased. The mixture was diluted with Et_2O and filtered. Concentration of the filtrate gave a mixture of the epimeric alcohols **50** (ir (neat): 3349 (br); Exact Mass calcd. for $C_{18}H_{32}O$: 264.2453; found: 264.2455), which was used directly for the next reaction.

A solution of **50** in dry CH_2Cl_2 (~0.3 mL) was added to a solution–suspension of PCC (31 mg, 0.14 mmol) and anhydrous NaOAc (3 mg, 36 μmol) in dry CH_2Cl_2 (1 mL) and the mixture was stirred at room temperature for 1 h. The mixture was diluted with Et_2O and then was filtered through a short pad of Florisil. Concentration of the filtrate gave 22 mg (97%) of the ketone **51**, a colorless oil that displayed ir (neat): 1718, 1635, 891 cm^{-1}; ^1H nmr (400 MHz) δ: 4.51 (br s, 2H), 2.28 (br dt, 1H, J = 5, 12 Hz), 2.13 (s, 3H), 2.21–2.05 (m, 1H), 1.88 (br d, 1H, J = 12 Hz), 1.65–1.10 (diffuse m, 13H), 1.05 (s, 3H), 0.80 (d, 3H, J = 7 Hz), 0.78 (s, 3H). Exact Mass calcd. for $C_{18}H_{30}O$: 262.2297; found: 262.2298.

(1R,2S*,3R*,6R*)-2-((E)-4-Ethoxycarbonyl-3-methyl-3-butenyl)-2,3,6-trimethyl-7-methylenebicyclo[4.4.0]decane (**52**) and the corresponding Z isomer **53***

To a stirred suspension of KH (~30 mg, ~0.75 mmol) in dry THF (3 mL) at room temperature was added $EtO_2CCH_2P(O)(OEt)_2$ (140 μL, 0.7 mmol) and the mixture was stirred for 30 min. A solution of the ketone **51** (17 mg, 65 μmol) in dry THF (0.5 mL) was added and the mixture was stirred at room temperature for 15 h. Solid $Na_2SO_4 \cdot 10H_2O$ was added; the mixture was diluted with Et_2O, and then was filtered through a pad of Celite. Concentration of the filtrate provided an oil that, on the basis of analysis by tlc and glc, consisted of a mixture of two compounds in a ratio of about 9:1. Column chromatography of this material on silica gel (2 g, 50:1 petroleum ether – Et_2O) gave 2 mg (10%) of the first-eluted *Z* ester **53** and 19 mg (88%) of the chromatographically more polar *E* ester **52**.

Compound **53** showed ir (neat): 1718, 1648, 1151, 890 cm^{-1}; ^1H nmr (400 MHz) δ: 5.60 (br s, 1H), 4.50 (br s, 2H), 4.12 (q, 2H, J = 7.5 Hz), 2.55 (br dt, 1H, J = 4,12 Hz), 2.32, 2.24 (br ddd, br ddd, 1H each,

J = 5, 12, 12 Hz in each case), 2.11 (br d, 1H, J = 12 Hz), 1.90 (m, 1H), 1.85 (d, 3H, J = 1.5 Hz), 1.74–1.22 (diffuse m, 11H), 1.25 (t, 3H, J = 7.5 Hz), 1.05 (s, 3H), 0.85 (d, 3H, J = 6 Hz), 0.73 (s, 3H). Exact Mass calcd. for $C_{22}H_{36}O_2$: 332.2715; found: 332.2721.

The *E* ester **52** displayed ir (neat): 1718, 1646, 1148, 892 cm^{-1}; ^1H nmr (400 MHz) δ: 5.63 (br s, 1H), 4.51 (br s, 2H), 4.14 (q, 2H, J = 7.5 Hz), 2.29 (br dt, 1H, J = 5, 13.5 Hz), 2.14 (d, 3H, J = 1.5 Hz), 2.15–2.07 (m, 1H), 2.02–1.78 (m, 3H), 1.66–1.22 (m, 11H), 1.28 (t, 3H, J = 7.5 Hz), 1.05 (s, 3H), 0.81 (d, 3H, J = 6 Hz), 0.74 (s, 3H). Exact Mass calcd. for $C_{22}H_{36}O_2$: 332.2715; found: 332.2715.

(1R,2S*,3R*,6R*)-2-((E)-5-Hydroxy-3-methyl-3-pentenyl)-2,3,6-trimethyl-7-methylenebicyclo[4.4.0]decane (**34**)*

To a cold (−78°C), stirred solution of the ester **52** (19 mg, 57 μmol) in dry Et_2O (1 mL) was added a solution of i-Bu_2AlH (0.25 mmol) in hexanes. After the solution had been stirred at −78°C for 1 h and at 0°C for 2 h, it was treated with saturated aqueous NH_4Cl (0.1 mL) and then was diluted with Et_2O. The mixture was stirred at room temperature for 5 min and then was dried ($MgSO_4$) and filtered through a pad of Florisil. Concentration of the filtrate gave 16 mg (98%) of the allylic alcohol **34**, a colorless oil that displayed ir (neat): 3327 (br), 1636, 1000, 891 cm^{-1}; ^1H nmr (400 MHz) δ: 5.37 (t, 1H, J = 8 Hz), 4.50 (br s, 2H), 4.12 (d, 2H, J = 8 Hz), 2.29 (br dt, 1H, J = 5, 13.5 Hz), 2.10 (br d, 1H, J = 13.5 Hz), 1.93–1.18 (diffuse m, 15H), 1.65 (br s, 3H), 1.03 (s, 3H), 0.81 (d, 3H, J = 6 Hz), 0.72 (s, 3H). Exact Mass calcd. for $C_{20}H_{34}O$: 290.2610; found: 290.2614.

(1R,2S*,3R*,6R*)-2-((E)-4-Formyl-3-methyl-3-butenyl)-2,3,6-trimethyl-7-methylenebicyclo[4.4.0]decane (**54**)*

A solution of the allylic alcohol **34** (15.8 mg, 55 μmol) in hexane was added to MnO_2 (70 mg) and the suspension was stirred at room temperature for 3 h. The mixture was filtered through a pad of Celite and the collected material was washed four times with dry Et_2O. Concentration of the combined filtrate afforded 14 mg (88%) of the aldehyde **54**, a colorless oil that showed ir (neat): 1676, 1633, 1611, 1195, 891 cm^{-1}; ^1H nmr (270 MHz) δ: 9.97 (d, 1H, J = 8 Hz), 5.86 (br d, 1H, J = 8 Hz), 4.51 (br s, 2H), 2.16 (d, 3H, J = 0.8 Hz), 2.4–1.1 (diffuse m, 16H), 1.06 (s, 3H), 0.81 (d, 3H, J = 6 Hz), 0.77 (s, 3H). Exact Mass calcd. for $C_{20}H_{32}O$: 288.2453; found: 288.2446.

*4-(Phenylsulfonylmethyl)-2-trimethylsilylfuran (**60**)*

A stirred mixture of 4-(chloromethyl)-2-trimethylsilylfuran (**59**) (22) (0.56 g, 2.95 mmol), $PhSO_2Na$ (0.58 g, 3.5 mmol), and dry DMF (2.5 mL) was heated at 80–90°C for 2.5 h. The cooled solution was diluted with Et_2O, was washed twice with brine, and then was dried ($MgSO_4$), filtered, and concentrated. Column chromatography of the residual material on neutral alumina (activity III, 20 g, 1:4 petroleum ether – Et_2O) gave 0.62 g of the sulfone **60**, an oil that displayed ir (neat): 1681, 1587, 1479, 1448, 1310, 1251, 1152 cm^{-1}; ^1H nmr (80 MHz) δ: 7.8–7.3 (m, 6H), 6.45 (s, 1H), 4.15 (s, 2H), 0.25 (s, 9H). Exact Mass calcd. for $C_{14}H_{18}O_3SiS$: 294.0746; found: 294.0744.

(1R,2S*,3R*,6R*)-2-((E,E)-6-(2-Trimethylsilyl-4-furyl)-3-methyl-3,5-hexadienyl)-2,3,6-trimethyl-7-methylenebicyclo[4.4.0]-decane (**58**)*

To a cold (−78°C), stirred solution of the sulfone **60** (25.5 mg, 87 μmol) in dry THF (0.9 mL) was added a solution of *n*-BuLi (~80 μmol) in hexanes and the solution was stirred for 20 min. A solution of the aldehyde **54** (10 mg, 35 μmol) in ~0.3 mL of dry THF was added and the solution was stirred at −78°C for 3 h. Freshly distilled PhCOCl (10 μL, 87 μmol) was added and the reaction mixture was allowed to warm to room temperature over a period of 1.5 h. The solution was diluted with Et_2O, was washed once with saturated aqueous $NaHCO_3$, twice with brine, and then was dried ($MgSO_4$) and concentrated. The remaining oil was dissolved in a 3:1 mixture of dry THF and dry MeOH (1 mL) and the solution was cooled to −20°C. Sodium amalgam (4%, 23 mg) was added and the mixture was stirred at −20°C for 2 h. Additional amalgam (13 mg) was added and stirring was continued for 1 h. The mixture was diluted with pentane, was washed twice with brine, and then was dried ($MgSO_4$) and concentrated. Column chromatography of the residue on neutral alumina (activity III, 2 g, 50:1 pentane – Et_2O) gave 7.5 mg (51%) of compound **58**, a clear liquid that showed ir (neat): 1635, 1250, 891, 844 cm^{-1}; ^1H nmr (400 MHz) δ: 7.58 (s, 1H), 6.76 (s, 1H), 6.56 (dd, 1H, J = 10, 16 Hz), 6.30 (d, 1H, J = 16 Hz), 5.89 (d, 1H, J = 10 Hz), 4.50 (br s, 2H), 2.30 (br dt, 1H, J = 5, 13.5 Hz), 2.12 (br d, 1H, J = 13.5 Hz), 1.97–1.20 (diffuse m, 14H), 1.80 (s, 3H), 1.05 (s, 3H), 0.82 (d, 3H, J = 6 Hz), 0.74 (s, 3H), 0.27 (s, 9H). Exact Mass calcd. for $C_{28}H_{44}OSi$: 424.3161; found: 424.3161.

*(±)-Palauolide (**1**)*

A solution of the furan **58** (7.5 mg, 17 μmol) and a catalytic amount of Rose Bengal (~1.7 μmol) in a 10:3 mixture of MeOH and CH_2Cl_2 was cooled to −78°C. While a stream of oxygen was bubbled through the solution, the latter was irradiated for 8 min with a halogen–tungsten lamp (650 W, 110 V, operated at 50 V) through an aqueous sodium nitrite filter (74 g per L of H_2O). The solution was purged with argon and then was allowed to stand at room temperature in the dark for 3 h. Removal of the solvent and column chromatography (1.5 g silica gel, 7:3 hexane–EtOAc) of the residual material gave 4.5 mg (68%) of (±)-palauolide (**1**), which exhibited ir (neat): 3340 (br), 1757, 1634, 1614, 890 cm^{-1}; ^1H nmr (400 MHz) δ: 7.14 (dd, 1H, J = 11, 15.5 Hz), 6.29 (d, 1H, J = 15.5 Hz), 6.23 (d, 1H, J = 8.5 Hz, collapses to a singlet on addition of D_2O), 5.97 (d, 1H, J = 11 Hz), 5.87 (s, 1H), 4.51 (br s, 2H), 2.30 (br dt, 1H, J = 5, 13.5 Hz), 2.12 (br d, 1H, J = 13.5 Hz), 2.07–1.10 (diffuse m, 15H), 1.88 (s, 3H), 1.06 (s, 3H), 0.82 (d, 3H, J = 6 Hz), 0.75 (s, 3H). Exact Mass calcd. for $C_{25}H_{36}O_3$: 384.2664; found: 384.2660.

The winged bean acidic lectin (WBA II) binds the H-type 2 human blood group related trisaccharide (α-L-Fuc-(1c → 2b)-β-D-Gal-(1b → 4a)-β-D-GlcNAc-OMe, **1**). Interactions that importantly contribute to the specificity of the complex formation are provided by CH_2-6b, OH-4b, OH-3b, and OH-2c of **1**. On the basis of the relative activities of the monodeoxy and mono-*O*-methyl derivatives of **1**, the hydroxyl groups at the 3a, 6a, and 4c positions become located at the periphery of the combining site, whereas the CH_3O-1a, NHAc-2a, and CH_3-5c groups are more remote from the protein surface and fully exposed to bulk water. Whereas the WBA II lectin marginally recognizes the H-type 1 related trisaccharide (α-L-Fuc-(1c → 2b)-β-D-Gal-(1b → 3a)-β-D-GlcNAc-OMe, **23**), the de-*N*-acetyl derivative (**24**) is bound 3.4 times more strongly than **1**. This and other results, which are related to changes in interaction between the ligand and the apron of the combining site, are attributed to changes in hydration that lead to enthalpy–entropy compensation. In certain cases, the interactions are found to stabilize the complex.

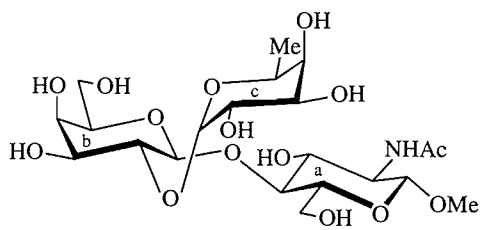
RAYMOND U. LEMIEUX, MING-HUI DU, ULRIKE SPOHR, SHREETA ACHARYA et AVADHESHA SUROLIA. Can. J. Chem. **72,** 158 (1994).

La lectine acide de la fève ailée (WBA II) se lie au trisaccharide (α-L-Fuc-(1c → 2b)-β-D-Gal-(1b → 4a)-β-D-GlcNAc-OMe, **1**, relié au groupe sanguin humain H-type 2. Les interactions qui contribuent d'une façon importante à la spécificité de la formation du complexe sont fournies par le CH_2-6b, le OH-4b, le OH-3b et le OH-2c du composé **1**. En se basant sur les activités relatives des dérivés monodésoxy et mono-*O*-méthyl du composé **1**, les groupes hydroxyles aux positions 3a, 6a et 4c se trouvent localisés à la périphérie du site de combinaison alors que les groupes CH_3O-la, NHAc-2a et CH_3-5c se trouvent à des positions plus éloignées de la surface de la protéine et pleinement exposées à l'eau de la solution. Alors que la lectine de la fève ailée ne reconnaît que marginalement le trisaccharide α-L-Fuc-(1c → 2b)-β-D-Gal-(1b → 3a)-β-D-GlcNAc-OMe, **23**, relié au groupe H-type 1, le dérivé dés-*N*-acétylé **24** se lie 3,4 fois plus fortement que le composé **1**. Ce résultat et d'autres qui sont reliés aux changements dans l'interaction entre le coordinat et le tablier du site qui se combine sont attribués aux changements dans l'hydratation qui conduit à une compensation enthalpie–entropie. Dans certains cas, on a trouvé que les interactions stabilisent le complexe.

[Traduit par la rédaction]

Introduction

In 1985, Kortt (1) reported the isolation of three acidic lectins (I, II, III) (p*I* ≃ 5.5) from the seeds of winged bean (*Psophocarpus tetragonolobus*). These proved to be dimeric glycoproteins of molecular weight approximately 54000. Although the agglutinations of trypsinized human type A, B, or O (H) erythrocytes by these lectins were inhibited by D-galactose derivatives and D-galactose-containing di- and trisaccharides, the inhibitions were very weak. Accordingly, it was concluded that the lectins may recognize a complex carbohydrate determinant not represented by the sugar structures that were examined (1). More recently (2), affinity chromatography provided an electrophoretically homogeneous preparation, termed WBA II, which was found to possess an affinity for a dog-intestine H-fucolipid. Indeed, it was subsequently shown (3) that the affinity for 2′-fucosyllactose (α-L-Fuc-(1 → 2)-β-D-Gal-(1 → 4)-α,β-D-Glc) is 13 times greater than that for the H-disaccharide (α-L-Fuc-(1 → 2)-α,β-D-Gal). Since the 2′-fucosyllactose is bound 14 times more strongly than an H (type 1)-related pentasaccharide (α-L-Fuc(1 → 2)-β-D-Gal-(1 → 3)-β-D-GlcNAc-(1 → 3)-β-D-Gal-(1 → 4)-α,β-D-Glc), it was anticipated that WBA II would have a strong affinity for the H-type 2 blood group-determinant, namely, α-L-Fuc-(1 → 2)-β-D-Gal-(1 → 4)-β-D-GlcNAc (**1**).



H-type 2-OMe (**1**)

A purpose of this communication is to confirm the affinity of the WBA II lectin for the type 2 trisaccharide (**1**). Mainly, however, we wish to report the delineation of the surface of **1** that is recognized by WBA II using our recently published method, which is based on the determination of the effects on binding of both deoxygenation and *O*-methylation at each of the various

hydroxyl positions (4). On the basis of this information the changes in the thermodynamic parameters caused by various structural modifications are examined in terms of the observed enthalpy–entropy compensations. As was found in several other cases (5–7), the surface of **1** that is recognized by WBA II is relatively small and polyamphiphilic.

Discussion

The thermodynamic parameters for the binding of **1** and its various congeners by the WBA II lectin (reported in Table 1) were calculated from the association constants at various temperatures in the range 15–30°C. These were determined by measuring the changes in the intensity of fluorescence on competing the binding of the oligosaccharide with *N*-dansyl-D-galactosamine as previously described (3). These data are presented in Table 2 and Fig. 1 and are considered to be sufficiently significant for the purposes of this communication, especially in view of the quality of Fig. 2. To present differential changes in free energy for inhibitions that were too weak to measure using the immunofluorescence assay, values are reported in Table 1 that were obtained using a radioimmunoassay.

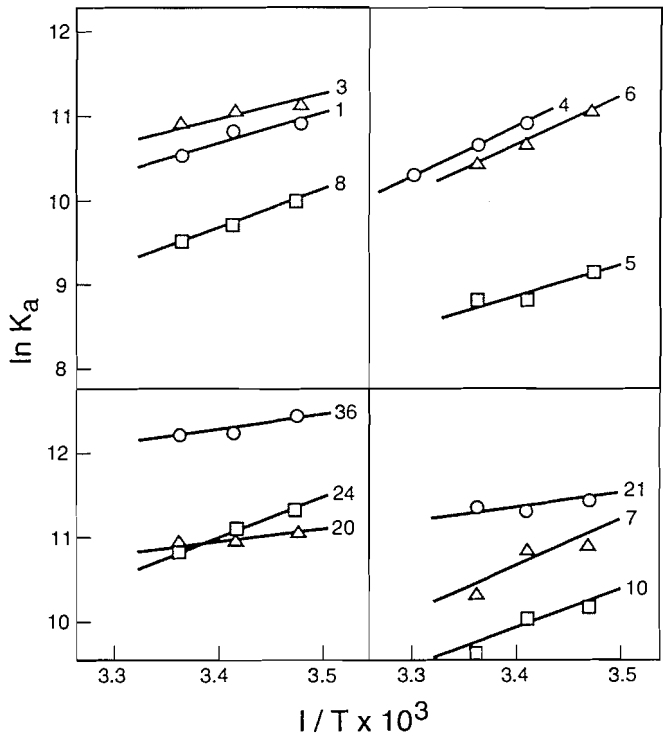

FIG. 1. van't Hoff plots of the data presented in Table 2.

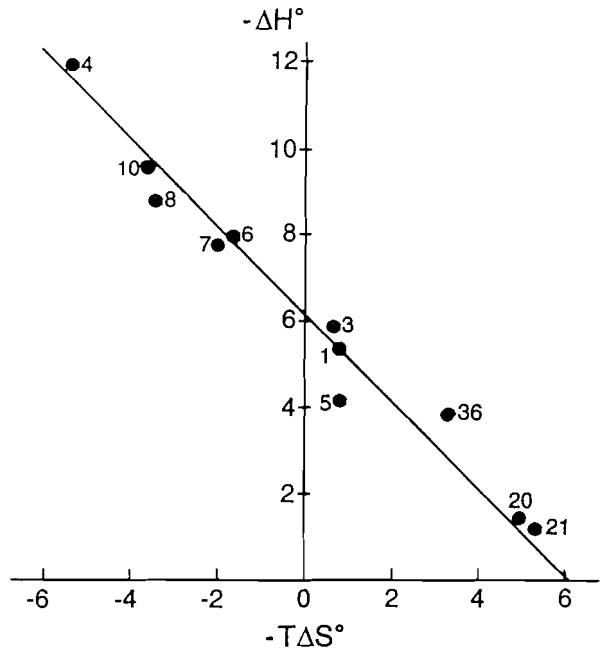

FIG. 2. Plots of the thermodynamic parameters for the binding of the WBA II lectin with **1** and the various congeners of **1** listed in Table 1. The line through the plots was arbitrarily drawn with a slope of one to illustrate the enthalpy–entropy compensation.

The projection formula for **1** provides an indication of its conformational preference (8, 9) that is adequate for an appreciation of the inhibition data presented in Table 1. That is, an examination of the inhibition data at once indicates that the recognition of **1** by the lectin is largely restricted to a series of contiguous groups (indicated by asterisks in Table 1) that extend from the 6b substituent of the β-D-Gal unit to the 2c substituent of the α-L-Fuc unit. It is seen that although changes in structure about the β-D-GlcNAc residue produced relatively minor effects on the extent of the binding reaction, a variety of changes in the other two sugar units strongly decreased the activities, in several cases to such low levels that these are declared as inactive. The plots in Fig. 2 of the thermodynamic parameters, reported in Table 1, show that the expected enthalpy–entropy compensation phenomenon (10) was observed with an overall precision within ±0.5 kcal/mol. As previously discussed (6, 10) these compensating changes are expected to arise mainly from structural changes in the hydration shells about the position of the change in the structure of the congener both in solution and in the complex with the lectin. A discussion of these data best begins by examining the relative effects of monodeoxygenation and of mono-*O*-methylation at each of the eight hydroxyl groups of **1**.

Although deoxygenation at the 3a position to produce compound **4** strongly affected the thermodynamic parameters, the change caused only a negligible differential change in free energy. Since the 3a-*O*-methyl derivative (**5**) showed appreciable activity ($\Delta\Delta G^0$ = 1.0 kcal/mol), it is concluded that, in the complex, the 3a hydroxyl of **1** remains in contact with the aqueous phase. The major compensating changes (−6.5 and −6.2 kcal/mol) in the thermodynamic parameters that were observed for the 3a-deoxy derivative (**4**) are expected to arise from the changes in the hydration shells about the 3a position, both as the reagent and in the complex, as the result of the change from the hydrophilic 3a-OH group of **1** to the hydrophobic 3a-H group of **4**. The less hydrophilic and larger 3a-OMe group of **5** causes smaller incremental changes in the thermodynamic parameters than for **4**. Similarly, both deoxygenation and *O*-methylation at the 6a position to yield **6** and **7** resulted in little change in potency of binding. Since these changes in structure caused relatively small changes in the thermodynamic parameters, the 6a-OH group likely resides in the complex at an appreciable distance from the periphery of the combining site. The effects of other changes at the 6a position will be discussed in connection with Table 3. It is particularly noteworthy that the substitution of the 5a-methyl group of **6** by hydrogen to form **8** caused only a 0.6 kcal/mol change in ΔG^0. The substantial decrease in enthalpy ($\Delta\Delta H^0$ = −3.5 kcal/mol) was compensated by a corresponding strong decrease in entropy. Therefore, it is apparent that the 5a-methylene group of the GlcNAc unit does not come into direct contact with the combining site.

The hydroxyl group at the 6b position of the Gal unit appears to remain in contact with the aqueous phase in view of the low but readily discernible potencies of both the 6b-deoxy and 6b-*O*-methyl derivatives (**9** and **10**, respectively). However, the 6b-methylene group participates in the complementarity required for effective recognition since the 6b-*nor* derivative (**11**) of **9** is highly inactive.

The axial 4b-hydroxyl group is surely involved in a strong polar interaction deep in the combining site since both deoxygenation and *O*-methylation at this position led to the inactive congeners, **12** and **13**. On the other hand, deoxygenations at both the 3b and 2c positions provided weakly active compounds (**14** and **16**, respectively). It is expected, therefore, that these hydroxyl groups are near the periphery of the combining site and in contact with water once the complex is formed. However, since both their *O*-methyl derivatives, **15** and **17**, are essentially inactive, it is concluded for reasons previously presented (4) that, in the complex, the 3b- and 2c-hydroxyl groups

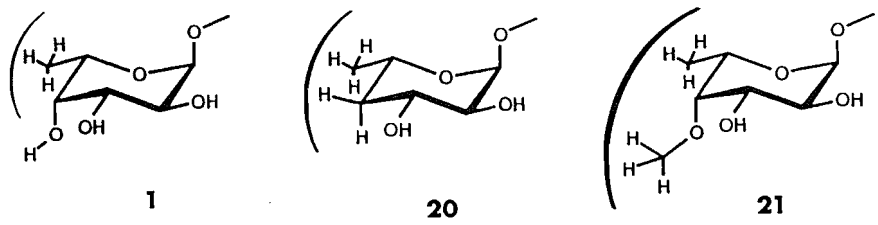

FIG. 3. The changes in hydrophobicity of the group about the 4c position of the fucosyl residue of the H-type 2-OMe trisaccharide (**1**) on preparing the congeners **20** and **21** (Table 1). It is seen that there exists a relationship between the sizes of the hydrophobic groups and the increases in entropy ($T\Delta S$ = 0.8 (**1**), 5.0 (**20**), 5.3 (**21**)) as is to be expected on the basis of hydrophobic effects (11). It is to be noted that, in the trisaccharide, these regions are surrounded by polar groups and, therefore, are amphiphilic in character.

[b]Y human blood group determinant.

are hydrogen bonded to amino acid residues at the periphery of the combining site. In contrast, the 3c-hydroxyl group must come to reside near the periphery of the combining site but to remain bonded to water since both the 3c-deoxy (**18**) and 3c-*O*-methyl (**19**) derivatives provide readily discernible inhibition.

The high potencies of both the 4c-deoxy and 4-*O*-methyl derivatives of **1** (**20** and **21**, respectively) indicate that the 4c-hydroxyl group remains in the aqueous phase. The near 4 kcal/mol decreases in enthalpy for both these congeners is noteworthy. In both cases, the change was from a hydrophilic hydroxyl to a hydrophobic methoxy group, one smaller and the other much larger. It is likely coincidental that these changes should cause very similar changes in the thermodynamic parameters. In contrast to all the other reactions presented in Table 1, which are all enthalpy driven, both these complexations are entropy driven. Clearly, therefore, the binding of the 4c-hydroxyl group to water molecules importantly stabilizes the complex and it is apparent that the stability of the hydration shell over the oligosaccharide part that remains exposed to water also contributes to the stability of the complex. Evidently, the region about the 4c position of **1** in the complex is not as favorable for the organization of water molecules to provide so-called "flickering clusters" (11) as for **20** and **21**. The large increases in entropy that accompany the formation of the latter complexes must largely arise from the release of water molecules from over the larger hydrophobic features of the α side of the c-fucosyl unit as is displayed in Fig. 3. These data, therefore, leave no doubt that hydrophobic effects play roles in these associations. It is to be noted, however, that these effects may be associated with the release of water from polyamphiphilic surfaces, as was postulated by Beierbeck and Lemieux (12).

Although the data presented in Table 1 indicate little direct involvement of the β-D-GlcNAc unit in the binding of **1**, as seen in Table 4, both the H-type 1-β-OMe (**23**) and H-disaccharide-β-OMe (**25**) are very weak inhibitors as compared to **1**. Since *N*-deacetylation of **23** to produce the amine **24** caused a 150-fold increase in potency (a decrease of 2.9 kcal/mol in differential change in free energy), it is apparent that the combining site cannot readily accommodate the acetyl group of **23**. As was seen above when discussing the relative potencies of **6** and **8**, the 5a-Me group of **6** does not importantly come into contact with the protein. Likely, therefore, the amino group of **25** encounters a hydrophilic environment with which it is much more compatible for hydration of the complex than is the hydrophobic 5a-methyl group of **6**. It may have been expected that the so-called H-disaccharide (**25**) would be bound more strongly than the H-type 1 trisaccharide **24**. That this proved to not be the case may well be importantly related to changes in

26	β-D-Gal-(1b → 4a)-β-D-GlcNAc-OMe	0.5	3.1

[a]Radioimmunoassay (13).

the stabilities of the various hydration shells. The very low activity of **26** may be in large part due to the lack of a substituent at the 2b position of the β-D-Gal unit. For example, *N*-acetyl-D-galactosamine is 5.2 times more potent than D-galactose (3).

The relative potencies of **1** and a number of congeners (**27** to **36**) involving changes in the β-DGlcNAc unit are reported in Table 3. On the basis of the foregoing discussion, all the structural changes were made at positions that remain in the aqueous phase once the complex has formed. Therefore, it is expected that all the effects noted on binding arise at least in part from changes in hydration both of the congener prior to complexation and of the complex itself.

It is seen (Table 3) that all the deoxygenated products are well entertained in terms of complex formation. Indeed, as seen for compound **31**, the replacement in **1** of the ring oxygen by methylene and the hydroxyl groups at positions 2a, 3a, and 6a by hydrogen led to only a 0.42 kcal/mol differential change in free energy. Evidently, therefore, the binding of **31** caused little change in the strength of the hydration of binding since the organization of water molecules over its large hydrophobic surface was not affected. However, as seen from the potencies of compounds **32–36**, changes in the substituent at the 6a position can have an effect. This is not surprising since the 6a-methylene group is surely not far from the periphery of the combining site and there exists freedom of rotation about the 5a-carbon to 6a-carbon bond. Therefore, at least two energetically favorable orientations of the 6a substituent can be offered by hydration, namely, the two with *syn*-clinal relationships to the ring oxygen. It is apparent that one of these orientations can provide favorable noncovalent interactions with the apron of the combing site since some of the structural changes substantially improve the strength of binding. This is especially so for the substitution of the acetyl group of **35** by a pivaloyl group to form **36**. Evidently the more hydrophobic and larger *tert*-butyl group of **36** encounters a complementary hydrophobic region on the apron of the combining site. In our experience to date, all structural changes in an epitope that involved groups that become bound by the receptor below the periphery of its combining site have resulted in inactive compounds. It is apparent, therefore, that efforts to improve the binding of an epitope should concentrate on causing stronger interaction with the apron of the combining site. That this is not always the case is illustrated by the relative potencies of compounds **5** and **27**. It is apparent that any substituent at position 3a that is larger than a hydroxyl group causes an adverse nonbonded interaction with the protein. It is to be noted in this regard that the methylation of the OH-3a to form **5** caused a 1 kcal change in free energy that was not well compensated by a change in entropy. This result is likely related, at least in part, to a loss of complementarity and not only to a change in hydration. Similar considerations apply to the binding of **36**, except that in this instance the substituent brought on a much greater increase in complementarity which stabilizes the complex by 0.88 kcal/mol.

Experimental

The isolation of the winged bean acidic lectin was carried out as described recently (2). The thermodynamic parameters were determined by fluorescence substitution titration at three different temperatures, as described previously (3). The radioimmunoassays were performed according to a published procedure (13). The plastic tubes were coated using a solution of WBA-II (100 μg/mL) in 0.1 N phosphate. The artificial antigen ([α-L-Fuc-(1 → 2)-β-D-Gal-(1 → 4)-β-D-GlcNAc-O$(CH_2)_8$CONH]$_{16}$-BSA-^{125}I) provided about 200000 cpm/100 μL. In the absence of inhibitor the lectin-coated tubes acquired about 35–45% of these counts.

Except for the mono-*O*-methyl derivatives of **1** that are presented in Table 1, the syntheses of the various other congeners used in this study have already been reported (6, 7, 14). The mono-*O*-methyl derivatives were prepared following procedures similar to those used for the synthesis of *O*-methyl derivatives of the Lewis b tetrasaccharide (4). These syntheses will be reported in connection with a study of the binding of **1** by the lectin I of *Ulex europaeus*.[5]

We describe the synthesis of three novel analogues of propionyl-coenzyme A, in which the sulfur atom has been replaced by methylene, ethylene, and thiomethylene, respectively. All three analogues, propionyl-dethia(carba)-CoA (**1**), propionyl-dethia-(dicarba)-CoA (**2**), and *S*-(2-oxobutanyl)-CoA (**3**) were characterized by ^1H and ^{31}P NMR spectroscopy and FAB mass spectrometry. Propionyl-CoA–oxaloacetate transcarboxylase from *Propionibacterium shermanii* accepted the novel analogues as substrates and carboxylated them to the corresponding methylmalonyl-CoA analogues (**4–6**). The latter were further converted into the succinyl-CoA analogues by the coenzyme-B_{12}-dependent methylmalonyl-CoA mutase from the same organism. The succinyl-CoA analogues, succinyl-dethia(carba)-CoA (**7**), succinyl-dethia(dicarba)-CoA (**8**), and 4-carboxy(2-oxobutanyl)-CoA (**9**) were obtained on a preparative scale and their Michaelis constants (K_m) with methylmalonyl-CoA mutase were determined to be 0.136, 2.20, and 0.132 mM, respectively (K_m for succinyl-CoA is 0.025 mM). The V_{max} values for **7**, **8**, and **9** are 1.1, 0.013, and 0.0047 μmol min^{-1} U^{-1}, respectively (V_{max} for succinyl CoA is 1.0). The utility of the novel coenzyme A analogues in enzyme mechanistic studies is discussed.

YIMIN ZHAO, MARTINA MICHENFELDER, et JÁNOS RÉTEY. Can. J. Chem. **72**, 164 (1994).

On décrit la synthèse de trois nouveaux analogues du propionyl-coenzyme- A dans lesquels l'atome de soufre a été remplacé respectivement par un méthylène, un éthylène et un thiométhylène. On a caractérisé les trois analogues, le propionyl-déthia(carba)-CoA (**1**), le propionyl-déthia(dicarba)-CoA (**2**) et le *S*-(2-oxo-butanyl)-CoA (**3**) par spectroscopie RMN du ^1H et du ^{31}P et par spectrométrie de masse FAB. La propionyl-CoA–oxaloacétate transcarboxylase du *Propionibacterium shermanii* accepte les nouveaux analogues comme substrats et par carboxylation les transforme en analogues méthylmalonyl- CoA correspondants (**4–6**). Par la suite, on a transformé ces derniers en analogues succinyl-CoA en les soumettant à la méthylmalonyl-CoA mutase dépendante du coenzyme-B_{12} provenant du même organisme. On a obtenu les analogues succinyl-CoA, succinyl-déthia(carba)-CoA (**7**), succinyl-déthia(dicarba)-CoA (**8**) et 4-carboxy(2-oxobutanyl)-CoA (**9**) à une échelle préparative et on a déterminé que leurs constantes de Michaelis (K_m) avec la méthylmalonyl-CoA mutase sont respectivement 0,136, 2,20 et 0,132 mM (K_m de la succinyl-CoA est égale à 0,025 mM). Les valeurs de V_{max} pour les composés **7**, **8** et **9** sont respectivement 1,1, 0,013 et 0,0047 μmol min^{-1} U^{-1} (V_{max} pour le succinyl-CoA est égal à 1,0). On discute de l'utilité des nouveaux analogues du coenzyme A dans des études mécanistiques d'enzymes.

[Traduit par la rédaction]

Introduction

Coenzyme A esters play important roles as substrates or regulators of a great number of enzymic reactions including carboxylation–decarboxylations, Claisen-type or aldol-type condensations, thioclastic cleavage, reductions, dehydrogenations, hydration–dehydrations, acylations, isomerizations, and epimerizations. While in some of these reactions the thiolester bond is cleaved, in others it is retained in the product(s). Under neutral and alkaline conditions thiolesters can spontaneously hydrolyse, which may complicate mechanistic studies. In 1978 Stewart and Wieland (1) synthesized a nonhydrolysable analogue of acetyl-CoA, acetonyldethia-CoA (acetyl-CH_2CoA), in which the sulfur had been replaced by methylene. This analogue turned out to be a powerful inhibitor of some enzymic reactions (1, 2), and an allosteric effector of others (2). It was a good substrate for the biotin-enzyme acetyl-CoA carboxylase (3).

Following our interest in the mechanism of propionic acid metabolism, we prepared three different analogues of propionyl-CoA, namely propionyl-dethia(carba)-CoA **1**, propionyl-dethia(dicarba)-CoA **2**, and 2oxobutanyl-CoA **3**. We describe here the syntheses and spectroscopic characterization of these three analogues, as well as their behaviour in some enzymic reactions. A short communication on compound **1** appeared earlier (4).

Results

*Synthesis of propionyl-dethia(carba)-coenzyme A(**1**)*

Following the strategy applied for the total synthesis of coenzyme A (5) and of acetyldethia(carba)CoA (1), the preparation of two key intermediates, propionyl-dethia(carba)pantetheine-4-phosphate (**10**) and adenosine-2′,3′ cyclophosphate 5′ phosphomorpholidate (**11**), was envisaged (Scheme 1). Michael addition of nitromethane to ethylvinylketone gave 1-nitro-4-oxo-hexane (**12**) in 50% yield. After protection of the keto function as the 1,3-dioxolane (**13**, 80%), the nitro group was reduced with Raney nickel to furnish 2-(3-aminopropyl)-2-ethyl-1,3-dioxolane (**14**) in 82% yield. Condensation of the latter with 4-nitrophenyl benzyloxycarbonyl-β-alanine (**15**) (6, 7) resulted in 2-[3-(*N*-benzyloxycarbonyl-β-alanyl)-aminopropyl]-2-ethyl-1,3-dioxolane (**16**, 64.5%). Removal of the *N*-benzyloxycarbonyl protecting group by catalytic hydrogenation was followed, without isolating the intermediate **17**, by condensation in the melt with (−)(*R*)-pantolactone. Two subsequent filtrations, first through a Dowex 50 W × 4 (H^+), then through a Dowex 2 × 8 (^-OH) column, removed the protecting ketal group and afforded propionyl-dethia(carba)pantetheine **18** in 50% yield (based on **16**). Phosphorylation of **19** was carried out with cyanoethylphosphate in analogy to the procedure of Stewart and Wieland (1) and yielded propionyl-dethia(carba)pantetheine-

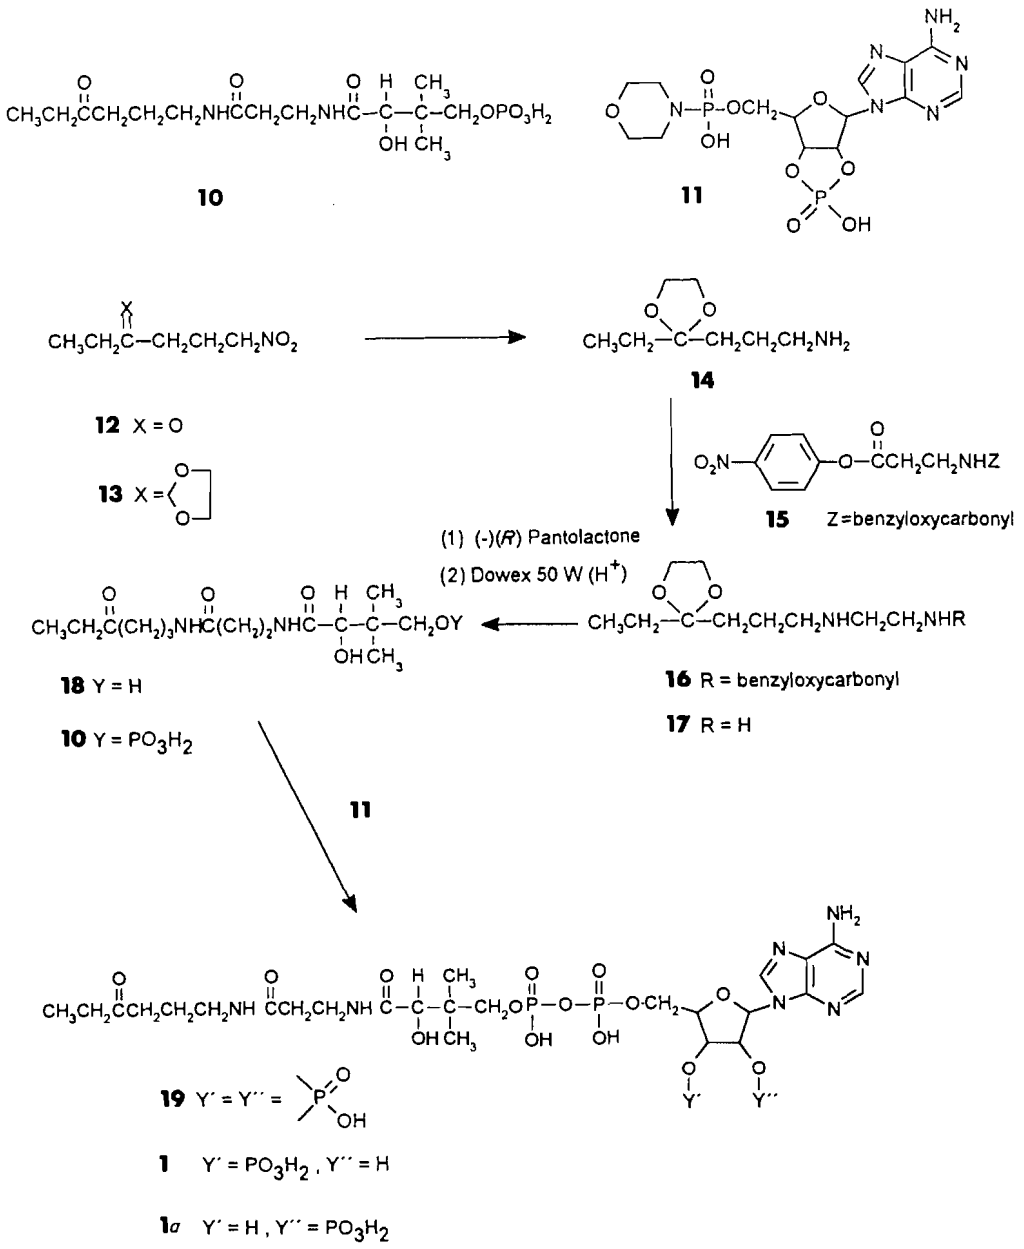

SCHEME 1

4-phosphate (**10**, 42%). Adenosine-2′,3′-cyclophosphate-5′-phosphomorpholi- date (**11**) was prepared according to one of the methods described by M. Yoshikawa et al. (8), Nikawa et al. (3), or A. Simoncsits and J. Tomasz (9). Compound **11** was first described by Moffat and Khorana (5).

Having the two key intermediates **10** and **11** in hand, their condensation to the coenzyme-A analogue could be realized. Acid hydrolysis of the product (**19**) led to a mixture (41%), which was partially separated to propionyl-CH_2CoA (**1**) and propionyl-CH_2-isoCoA (**1***a*) by DEAE cellulose chromatography using a linear LiCl gradient. The final preparation of **1** still contained ~9% **1***a* and was charaterized by ^{1}H and ^{31}P NMR spectroscopy.

Synthesis of propionyl-dethia(dicarba)-coenzyme A **2**

Except for the initial steps, the same method was used as described for analogue **1** (Scheme 2). In the first step the anion of cyanoacetic acid ethylester was added to ethylvinylketone to yield 2-cyano-5-oxoheptanoic acid ethylester (35%). Protection of the keto group afforded 2-(3-cyano-3-carbethoxyethyl)-2-ethyldioxolane (**21**) (83%). The carbethoxy group was removed by heating **21** in a solution of sodium chloride in dimethyl sulfoxide and water to furnish 2-(3-cyanopropyl)-2-ethyldioxolane (**22**) in 69% yield. Reduction of **22** with $LiAlH_4$ gave 2-(4-aminobutyl)-2-ethyldioxolane (**23**) (76%), which was treated further as described for its lower homologue (**14**). This analogous synthesis yielded, after chromatographic separation, propionyl-CH_2CH_2-CoA (**2**) and propionyl-CH_2CH_2-isoCoA (**2***a*) in similar quantities. Both were characterized by ^{1}H and ^{31}P NMR spectroscopy and **2** also by FAB mass spectrometry.

Synthesis of S*-(2-oxobutyl)-coenzyme A (3)*

Compound **3** was synthesized by reaction of coenzyme A

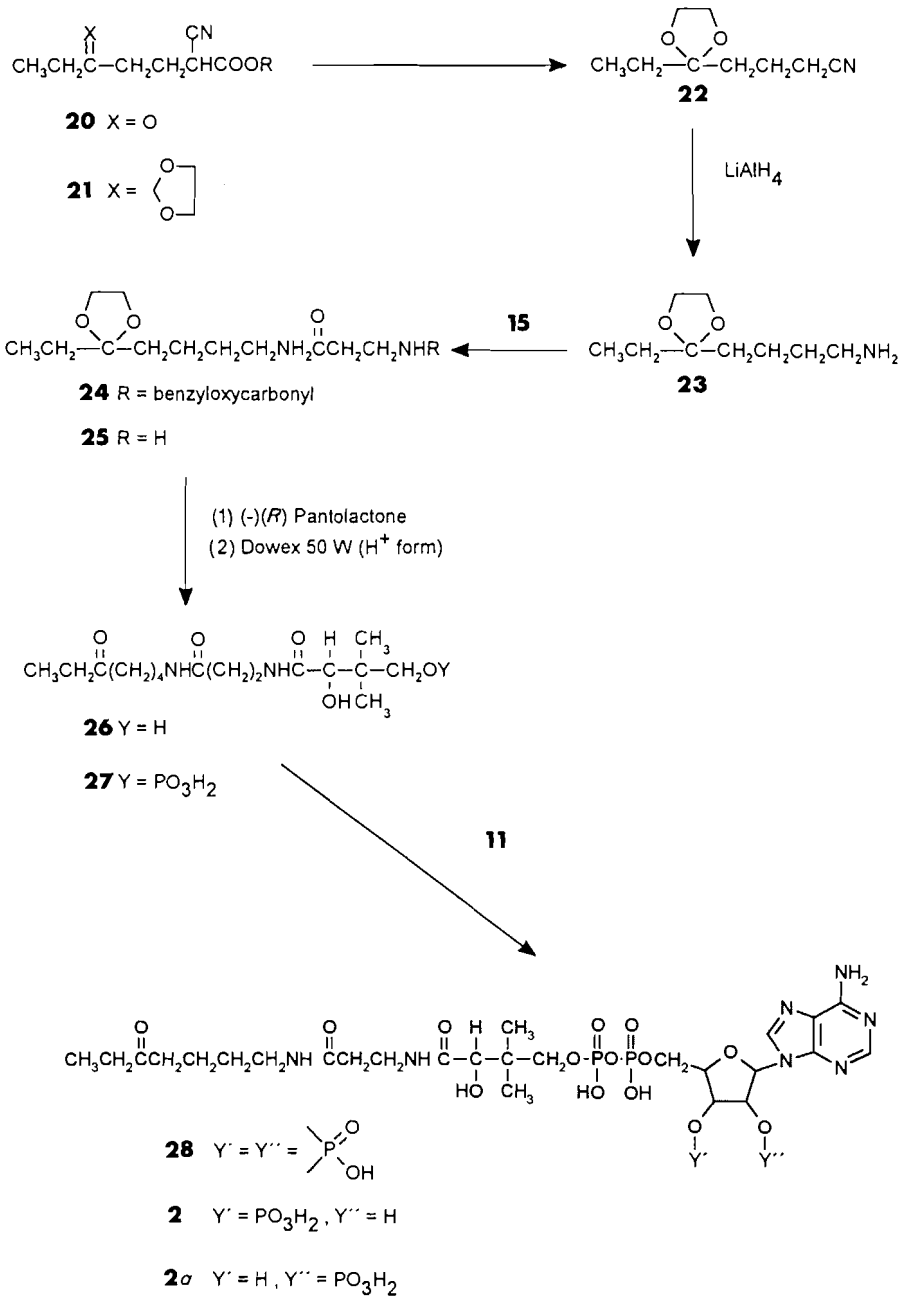

SCHEME 2

with an excess of 1-bromo-2-butanone. After work-up and chromatography as described for analogues **1** and **2** the product was characterized by FAB mass spectrometry and ^{1}H and ^{31}P NMR spectroscopy. Both measurements were consistent with the anticipated structure **3** (see Experimental).

*Conversion and kinetic behaviour of the propionyl-coenzyme A analogues **1**, **2**, and **3** with transcarboxylase*

Propionyl-CH_2-CoA **1**, propionyl-CH_2CH_2 CoA **2**, and *S*-(2-oxobutyl)-CoA **3** were carboxylated to the corresponding methylmalonyl derivatives **4**, **5**, and **6** by incubation with propionyl-CoA–oxaloacetate transcarboxylase from *Propionibacterium shermanii* in the presence of oxaloacetate, lactate dehydrogenase, and NADH. The reaction is summarized in eq. [1]

[1] propionyl-X-CoA + oxaloacetate + NADH + H^+ $\xrightarrow[\text{lactate dehydrogenase}]{\text{transcarboxylase}}$ methylmalonyl-X-CoA + lactate + NAD^+

Additions of lactate dehydrogenase and NADH were necessary to push the equilibrium to the right. After precipitation of the products with acetone, the centrifuged pellets were dried, dissolved in deuterium oxide, and their ^{1}H NMR spectra recorded. All signals could be assigned to the expected structures (see Experimental). Upon prolonged incubation in deuterated phosphate buffer ($p^2H = 7.1$) the methyl doublet at 1.20 ppm slowly changed and was eventually converted into a singlet. This was a measure for the $H/^2H$ exchange rate of the α proton of the methylmalonyl moiety.

TABLE 1. Comparison of the K_m and V_{max} values of propionyl-S-CoA and its analogues **1**, **2**, and **3** and in the transcarboxylase reaction

Substrate	K_m (mM)	V_{max} (μmol min^{-1} U^{-1})
$CH_3CH_2\overset{O}{\overset{\|}{C}}S\text{-CoA}$	0.047	1
$CH_3CH_2\overset{O}{\overset{\|}{C}}CH_2\text{-CoA}$	0.15	0.5
$CH_3CH_2\overset{O}{\overset{\|}{C}}CH_2CH_2\text{-CoA}$	0.14	0.025
$CH_3CH_2\overset{O}{\overset{\|}{C}}CH_2S\text{-CoA}$	0.44	0.020

TABLE 2. Comparison of the K_m and V_{max} values of succinyl-S-CoA and its analogues **7**, **8**, and **9** in the methylmalonyl-CoA mutase reaction and the length of X in succinyl-X-CoA (*d*)

Substrate	*d* (Å)	K_m (mM)	V_{max} (μmol min^{-1} U^{-1})
$HOOCCH_2CH_2\overset{O}{\overset{\|}{C}}S\text{-CoA}$	2.75	0.025	1.0
$HOOCCH_2CH_2\overset{O}{\overset{\|}{C}}CH_2\text{-CoA}$	2.48	0.136	1.1
$HOOCCH_2CH_2\overset{O}{\overset{\|}{C}}CH_2CH_2\text{-CoA}$	3.83	2.20	0.013
$HOOCCH_2CH_2\overset{O}{\overset{\|}{C}}CH_2S\text{-CoA}$	4.16	0.132	0.0047

The kinetic measurements with **1**, **2**, and **3** were carried out according to the published assay method (11). The K_m and V_{max} values were determined by the method of Lineweaver–Burk (11) and are listed in Table 1.

*Conversion of the propionyl-coenzyme A analogues **1**, **2**, and **3** into the corresponding succinyl derivatives **7**, **8**, and **9** with an enzyme cocktail*

On an analytical scale, the reaction sequence was monitored directly in the NMR tube. In separate experiments each of the analogues, i.e., propionyl-CH_2-CoA **1**, propionyl-CH_2CH_2-CoA **2**, or *S*-(2-oxobutanyl)-CoA **3**, was dissolved in deuterated phosphate buffer. The reaction was initiated by addition of a lyophilized enzyme mixture consisting of methylmalonyl-CoA mutase, epimerase, and transcarboxylase (12) (eq. [2]).

[2] propionyl-X-CoA + oxaloacetate $\xrightarrow[\text{epimerase, mutase}]{\text{transcarboxylase}}$ succinyl-X-CoA + pyruvate

Conversions of the analogues to their succinyl derivatives could be followed by ^1H NMR spectroscopy. On a preparative scale, the same reactions were carried out in aqueous (nondeuterated) phosphate buffer. After chromatography of the products on a DE-32 column, essentially pure succinyl-CoA analogues, i.e., succinyl-CH_2-CoA (**7**), succinyl-CH_2CH_2-CoA (**8**), and *S*-(2-oxo-4-carboxybutyl)-CoA (**9**), were obtained and characterized by ^1H and ^{31}P NMR spectroscopy.

The K_m and V_{max} values of **7**, **8**, and **9**, as substrates of methylmalonyl-CoA mutase, were determined by the usual spectrophotometrical assay (10, 12) and by using the method of Lineweaver–Burk (11). The results are summarized in Table 2.

Discussion

The synthesis of the novel propionyl-CoA analogues **1**, **2**, and **3** was carried out by conventional methods. While in the case of **1** and **2** a strategy similar to that used for the total synthesis of coenzyme A (5) was applied (Schemes 1, 2), **3** was available by a much simpler procedure involving the reaction of 1-brom-2-butanone with commercial coenzyme A.

Comparison of the geometry of the new analogues with that of natural propionyl-S-CoA is of interest (Table 2). Whereas the C—C bond is shorter than the C—S bond, in propionyl-CH_2CH_2-CoA **2** we have a slightly longer and in propionyl-CH_2-S-CoA **3** a substantially longer CoA chain, respectively.

It is noteworthy that all three propionyl-CoA analogues are substrates of the propionyl-CoA–oxaloacetate transcarboxylase (Table 1). Since acetyl-CH_2CoA was carboxylated by acetyl-CoA carboxylase (3) it was not surprising that its propionyl homologue **1** was also a transcarboxylase substrate. The longer CoA chain has a relatively small effect on K_m but a larger one on V_{max}. In all cases it is possible to carry out the enzymic carboxylation on a preparative scale and to spectroscopically characterize the products.

Prolonged observation of the ^1H NMR spectrum of **1** permitted determination of the spontaneous $^1H/^2H$ exchange rate of the α proton in the methylmalonyl moiety. With a half lifetime of 140 min at p^2H^2 7.1, it was somewhat faster than the value of $t/2 = 480$ min at p^2H^2 7.1 reported for methylmalonyl-thiolester (13).

The enzymically produced methylmalonyl-CoA analogues **4**, **5**, and **6** were also accepted as substrates by the coenzyme B_{12}-dependent methylmalonyl-CoA mutase. In the presence of the transcarboxylase, the epimerase, and the mutase, the propionyl-CoA analogues **1**, **2**, and **3** were converted in one pot into the corresponding succinyl-CoA analogues **7**, **8**, and **9** on a preparative scale. These nonhydrolysable succinyl derivatives were used as substrates to determine the kinetic constants of the mutase reaction (Table 2).

A comparison of the K_m values reveals that both the length of the CoA chain and the presence of sulfur is important. Succinyl-CH_2CH_2-CoA (**8**) has the lowest affinity for the mutase, while succinyl-CH_2S-CoA has only a slightly higher K_m than succinyl-S-CoA. Interestingly, the shorter the CoA chain, the higher the V_{max} value.

The novel, nonhydrolysable, propionyl, methylmalonyl, and succinyl-CoA analogues may be useful in mechanistic and structural studies of the corresponding enzymes by ESR, NMR, and CD spectroscopy as well as by X-ray crystallography.

Experimental

Equipment

^1H NMR, ^{31}P NMR, mass and IR spectra were recorded with the following instruments: Bruker WH 250 or AM 400, Bruker WH 300,

[2]The p^2H was determined in deuterium oxide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

Varian MAT CH-5 or Finnigan MAT 90, and Beckman IR-8, respectively.

For enzyme assays a Perkin Elmer 550A (UV–vis) spectrometer was used. Melting points were determined in a Büchi apparatus according to Dr. Tottoli.

For HPLC separations a Merck–Hitachi instrument was used.

Materials

Ethylvinylketone, cyanoethylphosphate, β-alanine, (−)-(*R*)-pantolactone, phosphorus oxychloride, and coenzyme B_{12} were products of Fluka (Buchs, Switzerland). Trimetaphosphate, 5′-AMP, and 2′(3′)-AMP were from Sigma (St. Louis, U.S.A.), and DE-32 cellulose from Whatman (Maidstone, England). Coenzyme A, lactate dehydrogenase, NAD^+, and NADH were from Boehringer (Mannheim, Germany). Methylmalonyl-CoA mutase, propionyl-CoA–oxaloacetate transcarboxylase and methylmalonyl-CoA epimerase were isolated from *Propionibacterium shermanii* (10, 12).

Syntheses

1-Nitro-4-oxo-hexane (12) was synthesized as described for the 5-methyl derivative (14): 1 g (11.9 mmol) ethyl vinyl ketone yielded 0.87 g (5.95 mmol) **12** (50%). ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 1.06 (t, J = 8.3 Hz, 3H), 2.26 (quint, J = 7.8 Hz, 2H), (quart, J = 8.3 Hz, 2H), 2.58 (t, J = 7.8 Hz, 2H), 4.43 (t, J = 7.8 Hz, 2H).

*2-(3-Nitropropyl-)2-ethyl-1,3-dioxolane (**13**)* was obtained in analogy to the 2-isopropyl derivative (14); 0.66 g (4.5 mmol) **12** yielded 0.8 g (3.57 mmol) **13** (80%). ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 0.91 (t, J = 8.3 Hz, 3H), 1.65 (quart, J = 8.3 Hz, 2H), 1.73 (m, 2H), 2.11 (quint, J = 7.5 Hz, 2H), 3.95 (s, 4H), 4.41 (t, J = 7.5 Hz, 2H).

*2-(3-Aminopropyl-2-ethyl-1,3-dioxolane (**14**)* was synthesized as described for the 2-isopropyl derivative (14). Starting from 5.75 g (30.5 mmol) **13** we obtained 4.0 g (25 mmol) **14** (82%). ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 0.93 (t, J = 8.3 Hz, 3H), 1.35 (s, 2H), 1.55 and 1.68 (m, 6H), 2.70 (t, J = 7.8 Hz, 2H), 3.98 (s, 4H).

*2-(3-[(N-Benzyloxycarbonyl-β-alanine)-aminopropyl)-2-ethyl-1,3-dioxolane (**16**)* was obtained in analogy to the 2-isopropyl derivative (14). Reaction of 1 g (6.28 mmol) **14** with 2.18 g (6.3 mmol) 4-nitrophenyl benzyloxycarbonyl-β-alanine (**15**) afforded 1.47 g (4.06 mmol) **16** (64.5%); mp 56–57°C; IR (KBr): 3320 (s), 3080 (w), 2980 (s), 2960 (s), 2880 (m), 1685 (s), 1635 (s), 1545 (s), 1460 (w), 1430 (w), 1370 (w), 1335 (m), 1265 (m), 1240 (m), 1190 (w), 1160 (w), 1135 (w), 1070 (m), 910 (w), 750 (w), 690 (m) cm^{-1}. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 0.91 (t, J = 8.3 Hz, 3H), 1.65 (m, 6H), 2.41 (t, J = 5.85 Hz, 2H), 3.26 (quart, J = 6.4 Hz, 2H), 3.5 (quart, J = 5.85 Hz, 2H), 3.95 (s, 4H), 5.08 (s, 2H), 5.46 (s, 1H), 5.78 (s, 1H), 7.33 (s, 5H), MS (T_d 130°C, 70 eV, *m/e*): 56 (14%), 57 (62), 65 (10), 69 (17), 70 (10), 73 (23), 77 (22), 79 (43), 86 (42), 91 (85), 96 (10), 97 (13), 98 (19), 99 (23), 101 (100), 102 (15), 107 (29), 108 (37), 113 (18), 130 (49), 139 (10), 142 (23), 227 (31), 335 (11), M^+ = 364 (6). Anal. calcd.: C 62.6, H 7.74, N 7.68; found: C 62.2, H 7.96, N 7.74%.

*Propionyl-dethia(carba)pantetheine (**18**)* was synthesized as described for the isobutanoyl derivative (14): 0.854 g (2.34 mmol) **16** yielded 370 mg (1.16 mmol) **18** (50%). IR (film): 3320 (s), 3100 (w), 2990 (s), 2970 (s), 1710 (s), 1650 (s), 1640 (s), 1570 (s), 1550 (s), 1530 (s), 1470 (m), 1440 (m), 1380 (m), 1360 (m), 1300 (m), 1250 (w), 1080 (m), 1050 (m), 880 (w) cm^{-1}. ^{1}H NMR (D_2O, 250 MHz) δ: 0.78 (s, 3H), 0.81 (s, 3H), 0.90 (t, J = 7.9 Hz, 3H), 1.63 (quint, J = 7.7 Hz, 2H), 2.4 (m, 6H), 3.05 (t, J = 7.7 Hz, 2H), 3.36 (AB system, J = 12 Hz, 2H), 3.41 (m, 2H), 3.86 (s, 1H). MS (T_d 160°C, 70 eV, *m/e*): 57 (43%), 58 (13), 71 (100), 72 (24), 86 (24), 98 (22), 99 (30), 100 (13), 115 (26), 116 (26), 157 (13), M^+ 1 = 317 (<1%).

*Propionyl-dethia(carba)pantetheine-4′-phosphate (**10**)* was obtained as described for the isobutanyl derivative (14). Reacting 637 mg (1.98 mmol) **18** with 1 g (2.63 mmol) cyanoethylphosphate (6) we obtained 470 mg (0.83 mmol) **10** (42%). IR (KBr): 3360, (s), 2940 (m), 1710 (m), 1655 (s), 1545 (m), 1450 (w), 1380 (w) 1245 (w), 1080 (s), 990 (s) cm^{-1}. ^{1}H NMR (D_2O, 250 MHz) δ: 0.83 (s, 3H), 0.98 (s, 3H), 1.0 (t, J = 9 Hz, 3H), 1.73 (quint, J = 6.5 Hz, 2H), 2.5 (m, 6H), 3.16 (t, J = 6.5 Hz, 2H), 3.52 (t, J = 5.5 Hz, 2H), 3.74 (m, 2H), 4.10 (s, 1H). ^{31}P NMR (D_2O, H_3PO_4 ext.) δ: 6.2 (s).

*Propionyl-dethia(carba) coenzyme A (**1**)* was prepared as described for its isobutanoyl analogue (14). Starting from 141.5 mg (0.25 mmol) **10** and 298.4 mg (0.62 mmol) adenosine-2′,3′ cyclophosphate-5′-phosphomorpholidate (**11**) we obtained a 48 mg (0.05 mmol) mixture of **1** and propionyl-dethia(carba) isocoenzyme A (**1***a*); 23 mg of this mixture was rechromatographed on a DE 32 cellulose column (2.2 ×30 cm) with an LiCl gradient (14). The first eluted peak contained **1***a* (8.0 mg, 8.3 μmol) while **1** appeared in the second peak (8.3 mg, 8.6 μmol). ^{1}H NMR of **1** (D_2O, pD = 3, 250 MHz) δ: 0.60 (s, 3H), 0.70 (s, 3H), 0.83 (t, J = 6.8 Hz, 3H), 1.51 (quint, J = 6.6 Hz, 2H), 2.32 (m, 6H), 2.91 (t, J = 6.6 Hz, 2H), 3.30 (t, J = 7.0 Hz, 2H), 3.60 (ABX system, J = 12 Hz, J = 5 Hz, 2H), 3.90 (s, 1H), 4.1 (m, 2H), 6.09 (d, J = 8.3 Hz, 1H), 8.18 (s, 1H), 8.43 (s, 1H). ^{31}P NMR (D_2O, 121.48 MHz, H_3PO_4 ext.) δ: = −7.89 (m), 2.7 (s).

*2-(3-Cyano-3-carbethoxyethyl)-2-ethyldioxolane (**21**)*

2-Cyano-5-oxoheptanoic acid ethylester (15) (9.4 g, 48 mmol) in benzene (25 mL) in the presence of 4.2 mL (75 mmol) ethyleneglycol and 0.2 g toluene sulfonic acid was refluxed for 6 h. The reaction water was removed continuously by a separatory funnel. After neutralization with 2% NaOH (15 mL), the resulting solution was washed with water, then dried with anhydrous K_2CO_3. Distillation of the product yielded 9.6 g (40 mmol) **21** (83%); bp 135°C/1.0 Torr (1 Torr = 133.3 Pa). ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 0.92 (t, J = 7.5 Hz, 3H), 1.34 (t, J = 7.1 Hz, 3H), 1.65 (quart, J = 7.5 Hz, 2H), 1.84 (t, J = 6.7 Hz, 2H), 2.06 (m, 2H), 3.66 (t, J = 6.7 Hz, 1H), 3.97 (s, 4H), 4.30 (quart, J = 7.1 Hz, 2H). MS (T_d 130°C, 70 eV, *m/e*): 87 (15%), 101 (100), 124 (7), 154 (3), 198 (12), 212 (32), M^+ + 1 = 241 (21). Anal. calcd.: C 59.73, H. 7.94, N 5.80; found: C 59.87, H 8.07, N 5.68%.

*2-(3-Cyanopropyl)-2-ethyl-1,3-dioxolane (**22**)*

To 7.8 g (32 mmol) **21** dissolved in dimethyl sulfoxide (2.5 mL) were added 1.89 g NaCl and water (1.18 mL). The stirred mixture was heated to 180°C for 7 h. After cooling, water (80 mL) was added and the resulting solution was extracted 5 times with 40-mL portions of ether. The combined extracts were dried with anhydrous $MgSO_4$. Distillation of the product yielded 3.7 g (22 mmol, 69%) **22**; bp 95°C/0.85 Torr. ^{1}H NMR (CD_3Cl, 250 MHz) δ: 0.92 (t, J = 7.5 Hz, 3H), 1.64 (quart, J = 7.5 Hz, 2H), 1.78 (m, 4H), 2.42 (m, 2H), 3.97 (s, 4H). MS (T_d 100°C, 70 eV, *m/e*): 57 (55%), 68 (32), 96 (50), 101 (100), 110 (10), 140 (96), 154 (14), M^+ = 169 (6). Anal. calcd.: C 63.88, H 8.93, N 8.27; found: C 63.95, H 8.97, N 8.14%.

*2-(4-Aminobutyl)-2-ethyl-1,3-dioxolane (**23**)*

To a suspension of 1 g $LiAlH_4$ in 20 mL dry ether a solution of 3.12 g (18 mmol) **22** in 25 mL dry ether was introduced under stirring (1 h). After 4 h reflux ice was added. Work-up afforded 2.4 g (13.8 mmol) **23** (76%); bp 110°C/0.75 Torr. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 0.90 (t, J = 7.5 Hz, 3H), 1.52 (m, 4H), 1.66 (m, 4H), 2.72 (t, J = 6.8 Hz, 2H), 3.97 (s, 4H). MS (T_d 100°C, 70 eV, *m/e*): 56 (23%), 57 (26), 73 (5), 82 (10), 84 (5), 101 (100), 102 (5), 128 (12), 144 (18), M^+ = 173 (<1). Anal. calcd.: C 62.39, H 11.05, N 8.08; found: C 62.33, H 11.15, N 7.97%. The following compounds (**24**, **25**, **26**, **27**, and **2**) were prepared as described for the lower homologues **16**, **18**, **10**, and **1**.

*2-(4-[(N-Benzyloxycarbonyl-β-alanine)-aminobutyl]-2-ethyl-1,3-dioxolane **24***

Educts: 11.5 g (66 mmol) **23**, 22.7 g (66 mmol) **15**. Yield: 21 g (55 mmol) **24** (83%); mp 48–50°C. ^{1}H NMR ($CDCl_3$, 250 MHz) δ: 0.90 (t, J = 7.5 Hz, 3H), 1.43 (m, 4H), 1.63 (m, 4H), 2.41 (t, J = 5.6 Hz, 2H), 3.27 (quart, J = 5.6 Hz, 2H), 3.52 (quart, J = 5.6 Hz, 2H), 3.93 (s, 4H), 5.12 (s, 2H), 5.54 (s, 1H), 5.62 (s, 1H), 7.38 (s, 5H). MS (T_d 130°C, 70 eV *m/e*: 57 (9%), 91 (56), 101 (100), 144 (12), 227 (4), 333 (5), 349 (15), M^+ = 378 (4). Anal. calcd.: C 63.4, H 7.99, N 7.40; found: C 63.86, H 8.41, N 7.37%.

*Propionyl-dethia(dicarba)-pantetheine **26***

Educts: 5.7 g (15 mmol) **24**, 2.2 g (17 mmol) (−)-(*R*)-pantolactone.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

Yield: 2.5 g (7.5 mmol) **26** (50%); mp 57–59°C. ^{1}H NMR (D_2O, 250 MHz) δ: 0.90 (s, 3H), 0.95 (s, 3H), 1.03 (t, J = 7.5 Hz, 3H), 1.56 (m, 4H), 2.57 (t, J = 6.4 Hz, 2H), 2.66 (m, 4H), 3.27 (t, J = 6.4 Hz, 2H), 3.56 (AB, J = 12 Hz, 2H), 3.63 (m, 2H), 4.10 (s, 1H). MS (T_d 130°C, 70 eV, *m/e*: 57 (41%), 71 (100), 100 (26), 113 (26), 130 (37), 171 (16), 200 (25), 227 (12), 258 (7), 282 (3), M^+ = 330 (0.2). Anal. calcd.: C 58.16, H 9.15, N 8.48; found: C 57.66, H 9.32, N 8.51%.

Propionyl-dethia(dicarba)-pantetheine-4′-phosphate (27)

Educts: 0.9 g (2.7 mmol) **26**, 2.2 g (6.6 mmol) cyanoethylphosphate (6). Yield: 0.59 g (1.1 mmol) **27** (41%). ^{1}H NMR (D_2O, 250 MHz) δ: 0.90 (s, 3H), 0.95 (s, 3H), 1.03 (t J = 7.5 Hz, 3H), 1.56 (m, 4H), 2.57 (t, J = 7.1 Hz, 2H), 2.66 (m, 4H), 3.27 (t, J = 7.1 Hz, 2H), 3.56 (AB, J = 12 Hz, 2H), 3.63 (t, J = 7.1 Hz, 2H). ^{31}P NMR (D_2O, 121.49 MHz, H_3PO_4 ext.) δ: 5.0 (s). FAB-MS: 55 (81%), 70 (29), 113 (52), 154 (42), 229(100), 294 (56), 319 (26), 370 (39), 451 (15), 529 (10), $M^+ + 2$ = 547 (18). Anal. calcd.: C 45.51, H 6.92, N 6.63; found: C 45.24, H 7.18, N 6.54%.

Propionyl-dethia(dicarba)-coenzyme A (2)

Educts: 0.52 g (0.95 mmol) **27**, 1.194 g (2.48 mmol) **11**. Yield: 0.102 g (0.12 mmol) mixture of **2** and **2***a*. After separation on DE-32 cellulose (see **1** and ref. 14): 38 mg (0.045 mmol) **2***a* and 40 mg (0.048 mmol) **2**. ^{1}H NMR (D_2O, 400 MHz) δ: 0.74 (s, 3H), 0.86 (s, 3H), 0.97 (t, J = 7.5 Hz, 3H), 1.45 (m, 4H), 2.43 (t, J = 6.2 Hz, 2H), 2.51 (m, 4H), 3.10 (t, J = 6.0 Hz, 2H), 3.46 (t, J = 6.0 Hz, 2H), 3.66 (ABX, J_1 = 11.2 Hz, J_2 = 5.4 Hz, 2H), 4.00 (s, 1H), 4.22 (s, 2H), 4.40 (m, 1H), 4.64 (m, 1H), 6.18 (d, 1H), 8.26 (s, 1H), 8.56 (s, 1H). ^{31}P NMR (D_2O, 121.49 MHz, H_3PO_4 ext.) δ: −0.3 (s), −15.1 (d, J = 21.9 Hz), −15.6 (d, J = 21.9 Hz). FAB-MS of **2**, *m/e*: 832 (M^+ + 1) (calcd. 831.458).

S-*2-Oxobutyl-coenzyme A* ***3*** was synthesized by reacting, under argon, 25 mg (32 μmol) coenzyme A (Li_3-salt) in 2.5 mL 0.04 M Li_2CO_3 solution with 25 mg (166 μmol) 1-bromo-2-butanone dissolved in 5 mL ethanol. After 12 h the solution was added dropwise to 150 mL acetone and the precipitate collected by centrifugation. The product was purified by chromatography on DE-32 cellulose (see **1** and ref. 14). Yield: 13 mg (15 μmol, 47%). ^{1}H NMR (D_2O, 400 MHz) δ: 0.72 (s, 3H), 0.86 (s, 3H), 0.98 (t, J = 7.5 Hz, 3H), 2.42 (t, J = 6.2 Hz, 2H), 2.57 (t, J = 6.4 Hz, 2H), 2.63 (quart, J = 7.5 Hz, 2H), 3.28 (t, J = 6.2 Hz, 2H), 3.44 (t, J = 6.4 Hz, 2H), 3.65 (ABX, 2H), 3.97 (s, 1H), 4.20 (m, 2H), 4.54 (m, 2H), 6.13 (d, J = 6.2 Hz, 1H), 8.24 (s, 1H), 8.54 (s, 1H). FAB-MS *m/e*: 862 (M^+ + 1) (calcd. 861.363).

*Ezymatic carboxylation of the propionyl-coenzyme A analogues **1**, **2**, and **3** to the methylmalonyl-coenzyme A analogues **4**, **5**, and **6***

In a typical experiment 10 μmol propionyl-CoA analogue was incubated with 30 μmol oxaloacetate, 12 μmol NADH, 6 U propionyl-CoA–oxaloacetate transcarboxylase, and 5 U lactate dehydrogenase in 5 mL potassium phosphate buffer (0.05 M, pH 7.2) for 3 h at room temperature. For chromatographic purification see propionyl-CoA analogues. Yield: ca. 5 μmol (50%). ^{1}H NMR of **4** (D_2O, 250 MHz) δ: 0.73 (s, 3H), 0.88 (s, 3H), 1.21 (d, J = 7.5 Hz, 3H), 1.71 (quint, J = 6.6 Hz, 2H), 2.45 (t, J = 7.4 Hz, 2H), 2.65 (m, 2H), 3.13 (t, J = 6.6 Hz, 2H), 3.45 (t, J = 7.4 Hz, 2H), 3.55 (m, 1H), 3.66 (unresolved ABX, 2H), 4.00 (s, 1H), 4.25 (m, 2H), 6.20 (d, J = 6.2 Hz, 1H), 8.28 (s, 1H), 8.58 (s, 1H). ^{1}H NMR of **5** (D_2O, 250 MHz) δ: 0.74 (s, 3H), 0.86 (s, 3H), 1.24 (d, J = 7.6 Hz, 3H), 1.50 (m, 4H), 2.45 (t, 2H), 2.63 (m, 2H), 3.15 (t, 2H), 3.48 (t, 2H), 3.57 (m, 1H), 3.70 (ABX, unresolved, 2H), 4.02 (s, 1H), 4.25 (s, 2H), 4.58 (m, 1H), 6.20 (d, J = 6.2 Hz, 1H), 8.29 (s, 1H), 8.59 (s, 1H). ^{1}H NMR of **6** (D_2O, 250 MHz) δ: 0.74 (s, 3H), 0.87 (s, 3H), 1.28 (d, J = 7.5 Hz, 3H), 2.49 (t, J = 6.2 Hz, 2H), 2.64 (t, J = 6.4 Hz, 2H), 3.34 (t, J = 6.2 Hz, 2H), 3.48 (t, J = 6.4 Hz, 2H), 3.67 (unresolved ABX, 2H), 3.78 (quart, 1H), 4.01 (s, 1H), 4.25 (m, 2H), 4.60 (m, 1H), 6.22 (d, J = 6.2 Hz, 1H), 8.33 (s, 1H), 8.58 (s, 1H).

*Enzymatic carboxylation and isomerization of the propionyl-coenzyme A analogues **1**, **2**, and **3** to the succinyl-coenzyme A analogues **7**, **8**, and **9***

In a typical experiment 4 μmol propionyl-CoA analogue was incubated with 16 μmol oxaloacetate, 20 μg coenzyme B_{12}, and a mixture of propionyl-CoA–oxaloacetate transcarboxylase, methylmalonyl-CoA epimerase, and methylmalonyl-CoA mutase, 1 U of each, in 2 mL of potassium phosphate buffer (0.2 M, pH 6.8) for 12 h at room temperature. The reaction was terminated at 0°C with 0.1 M perchloric acid (→ pH 3). After removal of the precipitated proteins by centrifugation the pH of the solution was adjusted to 6 with 2 M K_2CO_3. Removal of the crystalline potassium perchlorate was followed by lyophilization. Yield: ca. 40%. ^{1}H NMR of **7** (D_2O, 250 MHz) δ: 0.55 (s, 3H), 0.72 (s, 3H), 1.50 (quint, J = 5.8 Hz, 2H), 2.25 (m, 3H), 2.40 (t, J = 5.8 Hz, 2H), 2.53 (d, J = 6.2 Hz, 2H), 2.95 (t, J = 5.8 Hz, 2H), 3.30 (t, J = 6.8 Hz, 2H), 3.53 (ABX, J = 12 Hz, J_{HP} = 6 Hz, 2H), 3.86 (s, 1H), 4.10 (m, 2H), 6.06 (d, J = 7.5 Hz, 1H), 8.15 (s, 1H), 8.43 (s, 1H). ^{1}H NMR of **8** (D_2O, 400 MHz) δ: 0.75 (s, 3H), 0.86 (s, 3H), 1.48 (m, 4H), 2.46 (m, 4H), 2.75 (t, 2H), 3.08 (t, 2H), 3.44 (t, 2H), 3.65 (unresolved ABX, 2H), 3.97 (s, 1H), 4.20 (m, 2H), 4.54 (m, 1H), 6.15 (d, J = 6.2 Hz, 1H), 8.24 (s, 1H), 8.54 (s, 1H). ^{1}H NMR of **9** (D_2O, 400 MHz) δ: 0.72 (s, 3H), 0.86 (s, 3H), 2.46 (m, 4H), 2.58 (t, J = 6.4 Hz, 2H), 2.84 (t, J = 7.2 Hz, 2H), 3.30 (t, J = 6.2 Hz, 2H), 3.46 (t, J = 6.4 Hz, 2H), 3.65 (unresolved ABX, 2H), 3.97 (s, 1H), 4.20 (m, 1H), 6.13 (d, J = 6.2 Hz, 1H), 8.24 (s, 1H), 8.54 (s, 1H).

The formation of corydaline and related alkaloids in *Corydalis cava* in vivo and in vitro

MARTINA RUEFFER, WOLFGANG BAUER, AND MEINHART H. ZENK

Lehrstuhl für Pharmazeutische Biologie der Universität, Karlstrasse 29, 80333 Munich, Germany

Received June 28, 1993

This paper is dedicated to Professors David B. MacLean and Ian D. Spenser

MARTINA RUEFFER, WOLFGANG BAUER, and MEINHART H. ZENK. Can. J. Chem. **72,** 170 (1994).

The biosynthesis of corydaline and thalictricavine has been investigated by application of [8-^{3}H]-labelled palmatine and berberine to *Corydalis cava* bulb tissue. In both cases, high incorporation into the respective (14*R*,13*S*)corydaline and -thalictricavine was observed. (*S*)-[14-^{3}H, 8-^{14}C]Scoulerine was also transferred into corydaline with all of the tritium being lost, indicating that a redox reaction had taken place in the transition of the (14*S*) to the (14*R*) product. A partly enriched protein fraction catalyzed the reduction of both protoberberine precursors to the 7,8-dihydro intermediate, which was subsequently methylated at C-13 at the expense of *S*-adenosylmethionine (SAM) and reduced at C-14 by a B-type reaction with NADPH as reductant. The identity of the product was unequivocally established by NMR, MS, and CD measurements. This biosynthetic route is in full agreement with previously published predictions based on in vivo experiments.

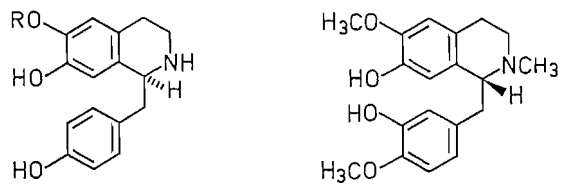
MARTINA RUEFFER, WOLFGANG BAUER et MEINHART H. ZENK. Can. J. Chem. **72,** 170 (1994).

On a étudié la biosynthèse de la corydaline et de la thalictricavine en appliquant de la palmatine et de la berbérine marquées au [8-^{3}H] à des tissus bulbaires de *Corydalis cava*. Dans les deux cas, on a observé une incorporation élevée dans les (14*R*,13*S*)-corydaline et -thalictricavine respectives. La (*S*)-[14-^{3}H, 8-^{14}C]scoulérine se transforme aussi en corydaline avec une perte des trois atomes de tritium; ceci indique qu'il se produit une réaction rédox lors de la transformation du produit (14*S*) en produit (14*R*). Une fraction partiellement enrichie en protéines catalyse la réduction des deux précurseurs protoberbérines en un intermédiaire 7,8-dihydrogéné qui est ultérieurement méthylé en C-13 aux dépens de la *S*-adénosylméthionine (SAM) et réduit en C-14 par une réaction de type B à l'aide NADPH qui agit comme réducteur. On a déterminé sans ambiguïté l'identité du produit en faisant appel à des mesures de RMN, de SM et de DC. Cette voie de biosynthèse est en parfait accord avec les prédictions publiées antérieurement et qui étaient basées sur des expériences in vivo.

[Traduit par la rédaction]

The biosynthesis of select alkaloids of the protoberberine type has been clarified at the enzyme level using plant cell cultures both from the *Berberidaceae* and the *Ranunculaceae* (1–3). These alkaloids, formed from two molecules of tyrosine, posed an interesting biosynthetic problem, in that tyrosine labelled both the isoquinoline "upper" and the benzyl "lower" portion of the benzylisoquinolines, while the more immediate, dihydroxylated precursors DOPA or dopamine unpredictably labelled only the "upper" half of these molecules (4). This question was elegantly and expertly posed again more recently (5). This intriguing problem was solved when it could be demonstrated that the trihydroxylated (*S*)-norcoclaurine but not the tetrahydroxylated (*S*)-norlaudanosoline is the precursor of the benzylisoquinoline alkaloids (6). (*S*)-Norcoclaurine is derived from the enzyme-catalyzed stereoselective condensation of dopamine with *p*-hydroxyphenylacetaldehyde (1). The biosynthetic pathway to berberine is now completely known also at the enzyme level (1–3). One of the remaining questions was, however, by which mechanism the (*R*)-configurated tetrahydroprotoberberine molecules are formed. It was found that a highly stereoselective and reversible enzyme system using NADPH and protoberberine alkaloids as substrates reduced the C ring of protoberberines to yield the (*R*)-configurated tetrahydroprotoberberines (7). The hitherto claimed precursor role of (*R*)-reticuline (8) in the biosynthesis of these alkaloids is incorrect.

Corydalis cava is a rich source of benzylisoquinoline alkaloids and variously modified molecules (9), among them (+)-corydaline (10, 11). The structure of this compound had been elucidated (12, 13) and the stereochemistry of both asymmetric centers was solved (14). This alkaloid is of biosynthetic interest because it belongs to the (14*R*) series of the tetrahydroprotoberberines and, in addition, contains a rare one-carbon unit as methyl group at C-13.



(*S*)-Norcoclaurine: R = H
(*S*)-Coclaurine: R = CH_3

(*R*)-Reticuline

In an admirable set of experiments, MacLean, Spenser, and co-workers (5, 15) first found that corydaline was synthesized along the protoberberine route with its C-methyl group being supplied by methionine (15). Later, the important observation was made that palmatine and not (*R,S*)-tetrahydropalmatine was the immediate precursor of corydaline (15). Some uncertainty, however, remained as to the true intermediates and precursors of this alkaloid. We now set out to clarify at the enzyme level the route by which this (*R*)-configurated, C-methylated alkaloid is formed in the genus *Corydalis*. First, the incorporation experiments reported by Holland et al. (5) were repeated but, instead of *C. solida*, differentiated plants of *C. cava*, which contain (14*R*,13*S*)-thalictricavine (16) and (14*R*,13*S*)-tetrahydrocorysamine (17), in addition to (14*R*,13*S*)-corydaline (11), were used. Coptisine, palmatine, and berberine, all tritium-labelled in the 8-position, were separately supplied to bulbs of *C. cava* and, after being metabolized, the corresponding C-methylated end products were isolated. High relative incorporation rates of 24–38% were observed (Table 1). These data confirm and extend the previous results obtained with a different plant species by Holland et al. (5). The above incorporation experiment was

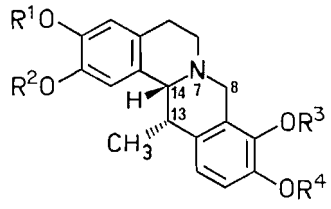
Palmatine : $R^1 = R^2 = R^3 = R^4 = CH_3$

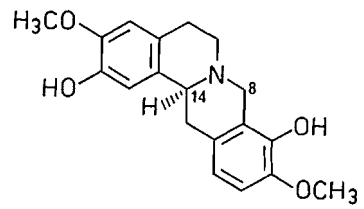


Corydaline : $R^1 = R^2 = R^3 = R^4 = CH_3$
Tetrahydrocorysamine : $R^1 + R^2 = -CH_2-$; $R^3 + R^4 = -CH_2-$
Thalictricavine : $R^1 + R^2 = -CH_2-$; $R^3 = CH_3$; $R^4 = CH_3$

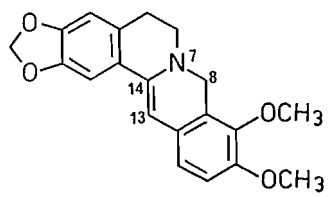
TABLE 1. Feeding of [8-^{3}H]protoberberines to *Corydalis cava* bulb tissue

Substrate	Product isolated	Total activity (dpm)	Product specific activity (dpm/μmol)	Relative incorporation (%)
Coptisine[a]	Tetrahydrocorysamine	9.60×10^5	3.07×10^6	32
Palmatine[a]	Corydaline	5.47×10^5	5.0×10^5	24
Berberine[a]	Thalictricavine	9.65×10^5	1.1×10^5	38

[a]Specific activity: 3.33×10^4 Bq/μmol; a total of 1.85×10^5 Bq was fed.



(*S*)-Scoulerine



7,8-Dihydroberberine

repeated using a mixture of (*S*)-[14-^{3}H]scoulerine and (*S*)-[8^{14}C]scoulerine, the $^3H/^{14}C$ ratio being 9.8:1. (+)-Corydaline was isolated from the tissue, diluted with unlabelled carrier corydaline, and recrystallized 6 times. Constant specific activity was attained already after the fourth recrystallization. A 2.6% relative incorporation of (*S*)-scoulerine into corydaline was found and the initial $^3H/^{14}C$ ratio of 9.8:1 was lowered to 0.01:1. This indicated clearly that the tritium label was almost completely removed from position 14 of the (*S*)-scoulerine molecule and substantiated the previously found reversal of configuration from (*S*) to (*R*) by an oxido-reduction process as established for the formation of (*R*)-tetrahydroprotoberberines from protoberberines (7).

Since the *C. cava* tissue obviously has a high metabolic potential to convert protoberberines into the corydaline-type compounds, a cell-free system was tested to produce corydaline in vitro. A crude homogenate was prepared from *C. cava* bulbs, and was freed of contaminating low molecular weight compounds by treatment with Sephadex G 25. Unlabelled palmatine was incubated with NADPH and [C^{3}H$_3$]SAM in the presence of *C. cava* crude protein extract at pH 7.5. As shown in Fig. 1*A*, under these conditions a product was formed that had the same R_f value as authentic corydaline. Almost all radioactive SAM had been converted to this product. In control experiments either using heat-denatured enzyme (Fig. 1*B*) or omitting NADPH (Fig. 1*C*), no reaction occurred. In addition, the newly formed product had the same R_f value as corydaline in several other TLC solvent systems. To ascertain the identity of this product, the compound was diluted with unlabelled corydaline (calculated specific activity 1.5×10^4 dpm/μmol), and recrystallized 6 times to yield a specific activity of 1.06×10^4 dpm/μmol. This experiment proved that corydaline was indeed formed under the conditions given in Fig. 1. Extension of this type of experiment showed that neither (*R*)- nor (*S*)-tetrahydropalmatine could serve as acceptor for the activated methyl group of SAM, and verified the in vivo experiments of Holland et al. (5) with regard to the precursorship of palmatine at the in vitro level.

To obtain more insight into this rather complex reaction of reduction and C-methylation, we attempted to partially purify the corresponding enzyme. Since in preliminary experiments it was found that berberine was the best substrate, this substance was used for further experiments, (+)-thalictricavine being the end product of the reaction. The purification of the catalytic activity was carried out using 40 g of deep-frozen cells. Alkaloids and other low molecular weight material were removed from the protein solution by passage through an XAD column. The eluate was loaded directly onto a DEAE-Sephacel column and the enzyme eluted with KCl. The pooled fractions were chromatographed on a hydroxyapatite column at pH 6.5. The enzyme did not bind to this column but was eluted with the washthrough. This protein solution was subjected to affinity

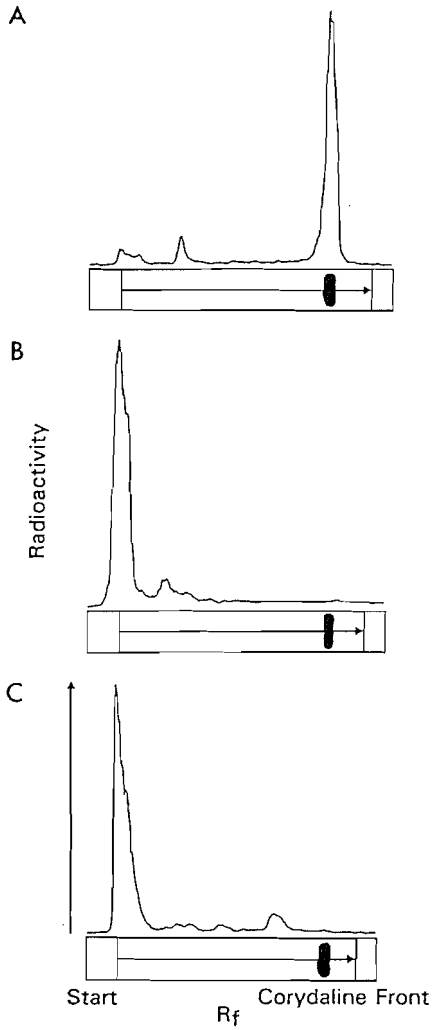

FIG. 1. Radioscan of an incubation mixture after TLC separation consisting of *A*: 25 nmol palmatine, 1 μmol NADPH, 27 pmol [C^3H_3]SAM (5×10^6 dpm), 860 μg *Corydalis cava* protein, in a total volume of 460 μL 50 mM KPO_4^{2-} buffer, pH 7.5; *B*: as in *A*, but with heat-denatured protein; *C*: as in A but without NADPH.

chromatography employing an SAH-AH Sepharose 4B matrix. Elution of the enzyme was achieved with KCl. This procedure yielded a 54-fold purified enzyme with 32% yield based on the crude homogenate. The purification procedure is summarized in Table 2. The enzyme is a cytosolic protein; no evidence for its occurrence in an organelle could be found. The enriched enzyme showed a pH optimum at 8.0 and a temperature optimum at 37°C (Figs. 2*A* and *B*). The M_r of the enzyme was determined by gel permeation HPLC (using appropriate marker proteins) and showed a distribution coefficient that corresponds to a M_r of 56 000, assuming a globular shape of the protein. Lineweaver–Burk plots showed apparent K_M values of 5 μM for berberine, 16 μM for NADPH, and 2.7 μM for SAM as substrates. Using the same three substrates, a K_i value of 2.6 μM was determined for SAH, which demonstrates that this homocysteine derivative, a reaction product, is a potent inhibitor of the methyltransferase reaction.

The product of the reaction was rigorously identified by physical methods. Large-scale standard incubations (total of 300 mL) were performed with [$^{13}CH_3$]SAM and a DEAE prepurified enzyme fraction. After 5 h of incubation at 37°C the mixture was passed through an XAD column that adsorbed the alkaloids. The column was washed thoroughly with distilled water and subsequently eluted with methanol. The eluate was evaporated and subjected to NMR analysis. Figure 3 shows a section of the NMR spectrum depicting clearly the ^{13}C-enriched carbon atom, which is attached to C-13 of thalictricavine (Fig. 3*B*). An aliquot of the enzymic reaction product was subjected to mass spectrometry (EI-mode) and yielded a mass peak at 354 *m/z* (Fig. 4*B*), one mass unit more than the unlabelled reference (Fig. 4*A*), as expected. Furthermore, a prominent benzylic fragment of *m/z* 179 was observed, which represents the D ring of corydaline with the $^{13}CH_3$ group originating from SAM attached to it (Fig. 4*B*). No doubt, the reaction product is thalictricavine. To ascertain the correct stereochemistry of the thalictricavine formed, a CD spectrum of the enzyme-synthesized product was recorded. The CD spectrum of this compound shown in Fig. 5 is identical with that one published previously (14). The enzyme-synthesized product is therefore (+)-thalictricavine, identical with that compound previously isolated from various *Corydalis* species (5, 10–13, 15, 16).

Finally, the substrate specificity of this enzyme was of considerable interest. Employing the reductive enzyme assay in the presence of [C^3H_3]SAM, NADPH, and various alkaloidal substrates using a 50-fold purified enzyme, the results shown in Table 3 were obtained. All protoberberines tested so far, except dehydroscoulerine, served as methyl group acceptor to varying degrees. Fully substituted protoberberines possessing no free OH group (berberine, palmatine) were the best substrates, followed by alkaloids having one unsubstituted OH group (columbamine, jatrorrhizine). The tetrahydroprotoberberines were completely inactive. Dehydroscoulerine was absolutely inactive in this system. This is in accord with the previously found reductase (7), which also is almost inactive with this substrate. It is most likely that this reductase, which operates in two steps (7), first reducing the 7,8 double bond and subsequently the 13,14 double bond, to yield the (*R*)-tetrahydroprotoberberines, is identical with that needed for (+)-thalictricavine biosynthesis. The assumption that this very enzyme is involved in thalictricavine biosynthesis is supported by the fact that 7,8-dihydroberberine serves indeed as an excellent substrate for the methyltransferase with concomitant reduction to the (*R*)-configurated (+)-thalictricavine (Table 3). Presuming that the previously found reductase (7) is involved in (+)-thalictricavine formation, the hydrogen transfer from NADP^{3}H should also follow a B-type reaction. Incubation of berberine in the presence of SAM and either 4A-^{3}H-NADPH or 4B-^{3}H-NADPH (18) under optimal conditions, and isolation of the (+)- thalictricavine formed, clearly showed that absolutely no tritium was transferred from 4A-^{3}H-NADPH, while 48.8% of the radioactivity of the 4B-^{3}H-NADPH was found in thalictricavine. This clearly demonstrated that the reductase involved is a B-type enzyme and most likely identical with the (*R*)-specific reductase found previously in *C. cava* (7). The (*R*)- or (*S*)-tetrahydroprotoberberines do not serve as acceptors for the methyl group of SAM.

The biosynthesis of (+)-corydaline and congeners has now been worked out at the enzyme level. The protoberberine molecule is enzymically reduced by a specific dehydrogenase (7) to a 7,8-dihydro derivative. This intermediate (which can also be supplied in a synthetic form) acts at C-13 as an acceptor for the

SAH-AH Sepharose 4B	84	2.6	32.3	32	53.8

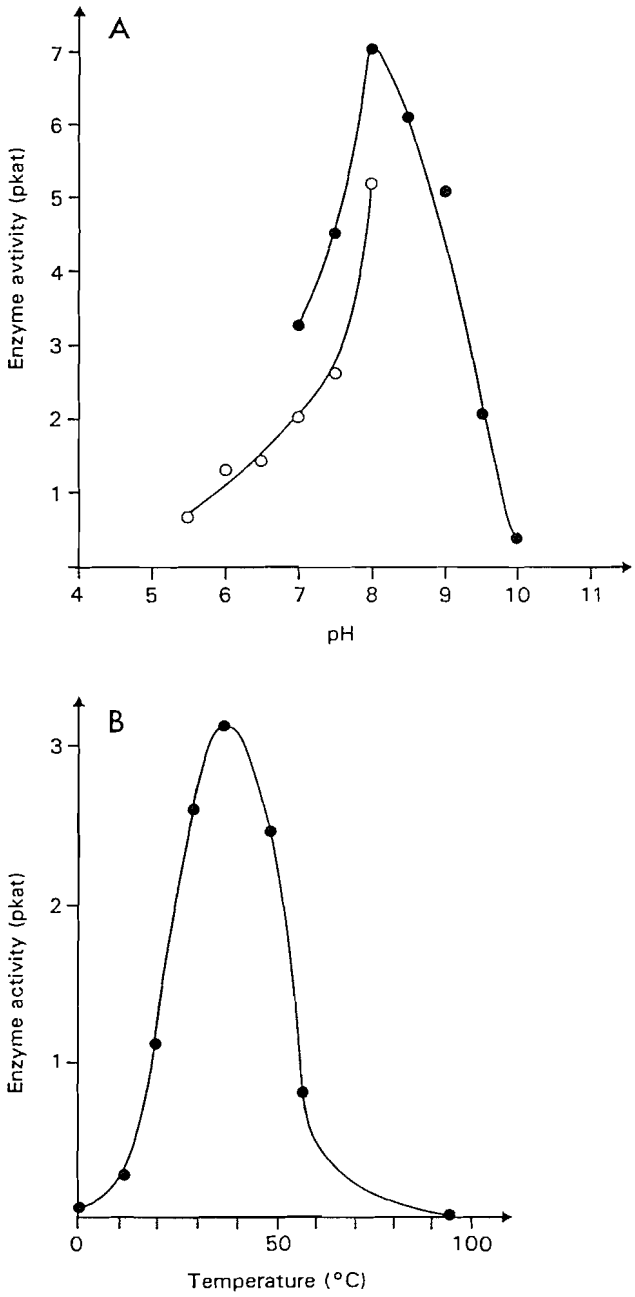

FIG. 2. *A*: pH profile of the catalytic activity of the 50-fold enriched enzyme system yielding thalictricavine using standard incubation mixtures with 100 μM each of (●—●) Tris-HCl buffer; (○—○) KPO_4^{2-} buffer, at 37°C. *B*: Temperature profile using the standard incubation assay at pH 8.0.

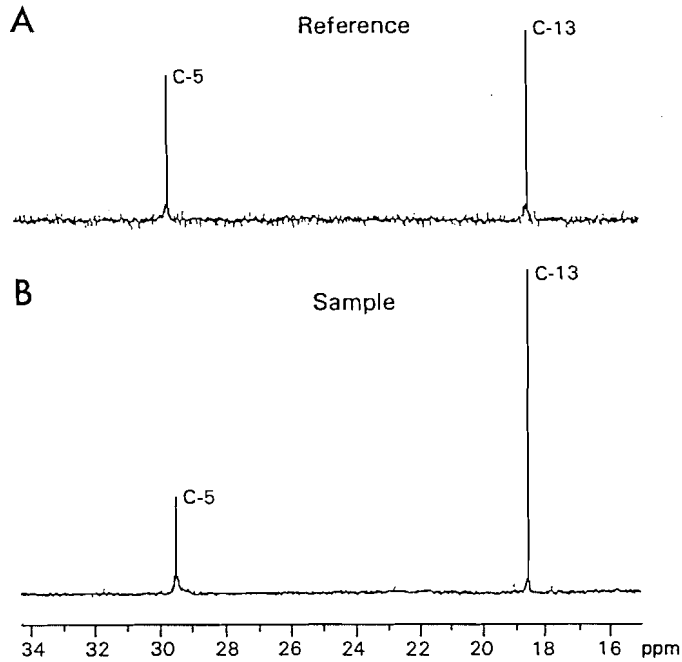

FIG. 3. Partial proton-decoupled ^{13}C NMR spectra of thalictricavine. *A*: unlabelled reference compound; *B*: enzyme product formed by transfer of the methyl group from [$^{13}CH_3$]SAM.

SAM-derived methyl group, and is subsequently reduced in a B-type reaction at the expense of NADPH to yield the (14*R*,13*S*)-(+)-corydaline-type molecule. The course of reaction is depicted in Scheme 1. It is most rewarding to see that the prediction of MacLean and Spenser and co-workers (5, 15) based entirely on in vivo feeding experiments and theoretical considerations could be verified by the results given here, which were obtained in vitro.

Experimental

Plant material

Plants of *Corydalis cava* were grown in pots in the greenhouse of this institute. Plant cell cultures of *Corydalis cava* were cultivated in 1-L Erlenmeyer flasks containing 250 mL Linsmaier and Skoog medium (19) over a period of 7 days at 23°C on a gyratory shaker (100 rpm) at 750 lux. The cells were then harvested by suction filtration, frozen in liquid nitrogen, and stored at −20°C.

Reference alkaloids

Thalictricavine, corydaline, and tetrahydrocorysamine were a kind gift of Prof. Slavik (Brno). Berberine and scoulerine were purchased from Roth (Karlsruhe). Coptisine and palmatine were donated by Dr. T. Tanahashi (Kobe). 7,8-Dihydroberberine was synthesized according to ref. 20.

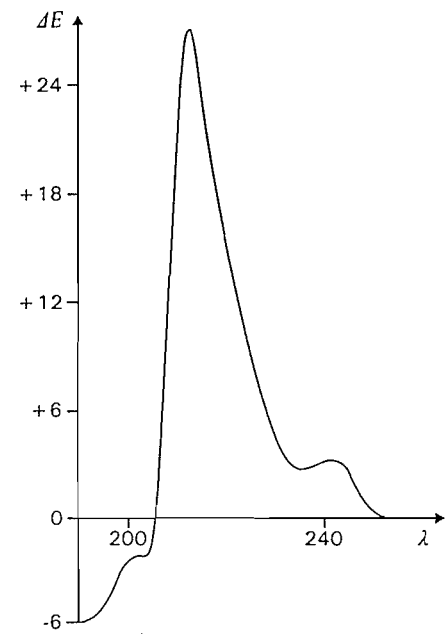

FIG. 5. CD spectrum of enzymically formed thalictricavine (concentration: 0.92 mg/2 mL methanol). Note positive value at 236 nm and 206 nm, negative at 192 nm analogous to (+)-corydaline (14).

TABLE 3. Substrate specificity of *S*-adenosylmethionine: protoberberine-13C-methyltransferase

Substrate[a]	Product formed (pmol)	Relative activity (%)
Berberine	900	100
Dihydroberberine	837	93
(*R,S*)-Canadine	0	0
Columbamine	243	27
Coptisine	189	21
Dehydroscoulerine	0	0
Jatrorrhizine	603	67
Palmatine	837	93

[a]The respective substrate (10 nmol) and 1 pkat of the enzyme were added to the standard assay and incubated for 15 min at 30°C.

Labelled chemicals

[C^3H_3]Methionine (3.15×10^9 Bq/μmol) was purchased from Amersham (U.K.) and transformed to *S*-adenosyl-(L)-methionine (SAM) by SAM-synthetase, isolated from *Escherichia coli* EWH 47 according to ref. 21. [$^{13}CH_3$]SAM was synthesized by the same procedure using [$^{13}CH_3$]methionine. Stereospecifically labelled 4A- and 4B-^{3}NADPH were synthesized according to the method of Moran et al. (18). [8-^{3}H]-Labelled coptisine, palmatine, and berberine were synthesized by simultaneous reduction of all three protoberberines with NaB^3H_4 and reoxidation of the corresponding (*S*)-tetrahydroprotoberberines was performed with (*S*)-tetrahydroprotoberberine oxidase (22). (*S*)-[8-^{14}C]Scoulerine was synthesized enzymatically in a two-step reaction by incubating (*S*)-norreticuline and [$^{14}CH_3$]SAM, first with *S*-adenosylmethionine:coclaurine-*N*-methyltransferase (23) and then with the berberine bridge enzyme (24). (*S*)-[14-^{3}H]Scoulerine was produced by incubation of (*R,S*)-[1-^{3}H]reticuline with the berberine bridge enzyme (24).

Application experiments

Young bulbs of *Corydalis cava* were cut into small pieces of 0.5 g fresh weight and incubated in 1 mL Knop's nutrient solution with berberine, coptisine, or palmatine (each 7.83×10^4 Bq/μmol). After extraction with methanol the labelled alkaloids were purified on TLC plates in three solvent systems: (1) ethyl acetate:2-butanone:formic acid:H_2O (50:30:10:10), R_f thalictricavine = 0.89, R_f corydaline = 0.86, R_f tetrahydrocorysamine = 0.94; (2) cyclohexane:diethylamine (9:1), R_f thalictricavine = 0.63, R_f corydaline = 0.55, R_f tetrahydrocorysamine = 0.71; (3) dioxane:cyclohexane:diethylamine (10:20:0.5), R_f thalictricavine 0.84, R_f corydaline = 0.75, R_f tetrahydrocorysamine = 0.77.

Enzyme assay

Berberine (10 nmol), 1 nmol [C^3H_3]SAM (20 000 cpm), and 100 nmol NADPH were incubated with 20 μmol KPO_4^{2-} buffer (pH 8.0) and 0.1–1 mg protein in a total volume of 250 μL for 30 min at 37°C (standard incubation mixture). The reaction was stopped by the addition of 200 μL sodium carbonate buffer (pH 9.5) and the reaction product extracted with 400 μL isoamyl alcohol for 10 min in a rotary shaker. After centrifugation (3 min in an Eppendorf centrifuge) the radioactivity of a 200-μL aliquot was determined in a scintillation counter.

Enzyme purification

Corydalis cava deep-frozen cultivated cells (40 g) were ground with a chilled mortar and pestle in 80 mL 10 mM KPO_4^{2-} buffer (pH 6.5, 10 mM β-mercaptoethanol) for 15 min, filtered through four layers of cheesecloth, and centrifuged for 10 min at 20 000 × *g*. The supernatant was passed through an XAD-2 column (Serva, Heidelberg, 2.5 cm × 20 cm) to remove the alkaloids and pumped onto a DEAE column (DEAE-Sephacel, Pharmacia, 2.5 cm × 25 cm, equilibrated with the extraction buffer) at a flow rate of 1 mL/min. Elution was per-

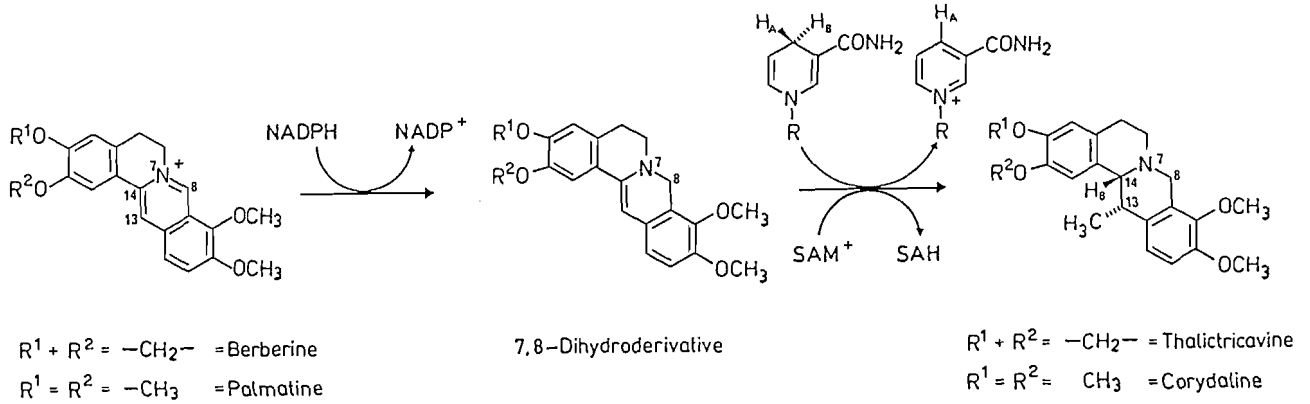

SCHEME 1

formed with a gradient from 0–1 M KCl over 8 h in fractions of 2.5 mL. The active fractions (98–115) were combined (57 mL) and pumped onto a hydroxyapatite column (Biorad, 1 cm × 15 cm, equilibrated with 10 mM KPO_4^{2-} buffer, pH 6.5, 10 mM β-mercaptoethanol) at a flow rate of 0.3 mL/min. The enzyme did not bind to the column but was eluted with the washthrough in 55 mL. This solution was slowly (0.2 mL/min) loaded onto an SAH-AH-Sepharose column (Pharmacia 1 cm × 5 cm, equilibrated with 10 mM KPO_4^{2-} buffer, pH 7.5, 10 mM β-mercaptoethanol) and eluted with a linear gradient up to 1 M KCl in 4 h. Fractions of 1.5 mL were collected. Enzyme activity was eluted with 1 M KCl in 7.5 mL.

Product identification

For identification of the product, four of the following large-scale assays were prepared: 10 mmol KPO_4^{2-} buffer, pH 8.5, 1 μmol [$^{13}CH_3$]SAM, 10 μmol berberine, 50 μmol NADPH, 50 μmol NADP, 50 μmol glucose-6-phosphate, 5 units glucose-6-phosphate-dehydrogenase (Serva, Heidelberg), and 75 mL enzyme solution (DEAE- eluate, 100 mg protein) in a total volume of 250 mL. After incubation (5 h at 37°C) the mixtures were passed through an XAD-2 column (2 cm × 10 cm) and the alkaloids eluted with methanol. After concentration under a stream of nitrogen, the product was purified by TLC (Macherey & Nagel, Polygram SIL G/UV 254, solvent system cyclohexane:diethylamine (9:1), R_f thalictricavine = 0.6, R_f SAM = 0.0), eluted with methanol, and subjected to mass spectrometry (MS 80 RFA, Kratos, EI, 70 eV) and ^{13}C NMR (in deuterated methanol–DMSO, AM, 360, Bruker). The CD spectrum was measured in ethanol with a CD-6 (Jobin-Yvon) instrument.

Stereospecificity of H-transfer from 4A- and 4B-^{3}H-NADPH

To test the stereospecificity of the reduction reaction 100 000 cpm 4A- or 4B-^{3}H-NADPH (18) (1.63×10^8 Bq/μmol), 10 nmol berberine, and 1 nmol SAM were incubated with 0.2 pkat of the enzyme in 50 μmol KPO_4^{2-} buffer, pH 8.0, at 30°C for 1 h. The reaction product was purified by TLC (cyclohexane:diethylamine (9:1), R_f thalictricavine = 0.6) and eluted with methanol. Scintillation counting of the methanol eluate showed no incorporation with 4A-^{3}H-NADPH, but with 4B-^{3}H-NADPH 48775 cpm (48.8%) could be detected in thalictricavine.

Use of aromatic thia fatty acids as active site mapping agents for a yeast Δ^9 desaturase[1]

PETER H. BUIST[2] AND DALE M. MARECAK

Ottawa–Carleton Chemistry Institute, Department of Chemistry, Carleton University, 1125 Colonel By Drive, Ottawa, ON K1S 5B6, Canada

Received June 23, 1993

This paper is dedicated to Professors David B. MacLean and Ian D. Spenser

PETER H. BUIST and DALE M. MARECAK. Can. J. Chem. **72**, 176 (1994).

The Δ^9 desaturating system of *Saccharomyces cerevisiae* can sulfoxidize methyl *S*-benzyl-8-mercaptooctanoate as well as its naphthyl analogue but the corresponding isomers where sulfur is bonded to the aromatic ring do not function as substrates. We have accounted for these results in terms of a conformational model. We have also accumulated some evidence that suggests that dealkylation of these thia analogues does not compete with sulfoxidation. Our recently discovered chiral shift reagent (*S*)-(+)-α-methoxyphenylacetic acid (MPAA) can be used to determine the optical purity and absolute configuration of all sulfoxides prepared in this work.

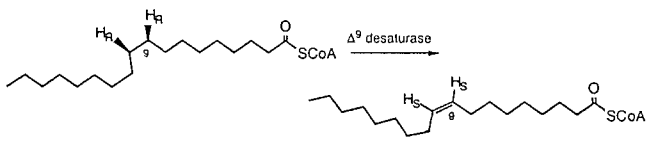
PETER H. BUIST et DALE M. MARECAK. Can. J. Chem. **72**, 176 (1994).

Le système de la *S. cerevisiae* qui provoque une désaturation en Δ^9 peut provoquer une sulfoxydation du *S*-benzyl-8-mercaptooctanoate de méthyle et de son analogue naphtylé; toutefois, les isomères correspondants dans lesquels le soufre est lié au noyau aromatique ne peuvent pas agir comme substrats. On explique ces résultats en fonction d'un modèle conformationnel. On a aussi accumulé des données qui suggèrent que la désalkylation des ces thia analogues n'est pas en compétition avec leur sulfoxydation. On peut utiliser le réactif chiral que nous avons récemment découvert, l'acide (*S*)-(+)-α-méthoxyphénylacétique (MPAA) pour déterminer la pureté optique et la configuration absolue des tous les sulfoxydes préparés au cours de ce travail.

[Traduit par la rédaction]

Introduction

As a class of reactions, irreversible biooxidations involving oxygen – transition metal complexes are poorly understood from a mechanistic point of view. A particularly mysterious biological reaction is the dehydrogenation (desaturation) of stearoyl CoA to give oleyl CoA. The enzyme responsible for



catalyzing this process is typically an iron-containing protein, which binds molecular oxygen and receives the necessary reducing equivalents from NADH via an intermediary electron transfer protein (1). A fresh perspective on the mechanism of desaturation has recently surfaced following the observation that a well-known hydroxylating enzyme system, rat liver cytochrome P_{450}, is also capable of acting as a dehydrogenase with certain substrates (2). Thus dehydrogenation and hydroxylation appear to be part of a single reaction manifold in which the ionization potential (I.P.) of the putative radical intermediate controls the choice of oxidative pathway (3) (see Scheme 1).We have proposed[3] that desaturases lower the I.P. of the carbon radical through the use of a neighbouring negatively charged protein residue such as a carboxylate to stabilize the incipient carbocation.

A logical consequence of this mechanistic scheme is that the Δ^9 desaturase of *Saccharomyces cerevisiae* should be able to oxygenate the appropriate sulfide analogues, presumably via a mechanism involving a radical cation intermediate (*4a,b*) (see Scheme 2). We have shown recently that thia fatty acid analogues (**1–4**) are indeed converted to chiral sulfoxides with high enantioselectivity (5). During the course of this investigation, we were somewhat puzzled by the fact that the apparent ratio of 9-sulfoxidation:10-sulfoxidation varied from ca. 2:1 in favour of the 9-thia compound for the dialkyl series (compounds **1**, **2**) to ca. 10:1 in the benzyl series (compounds **3**, **4**). Since **3** and **4**

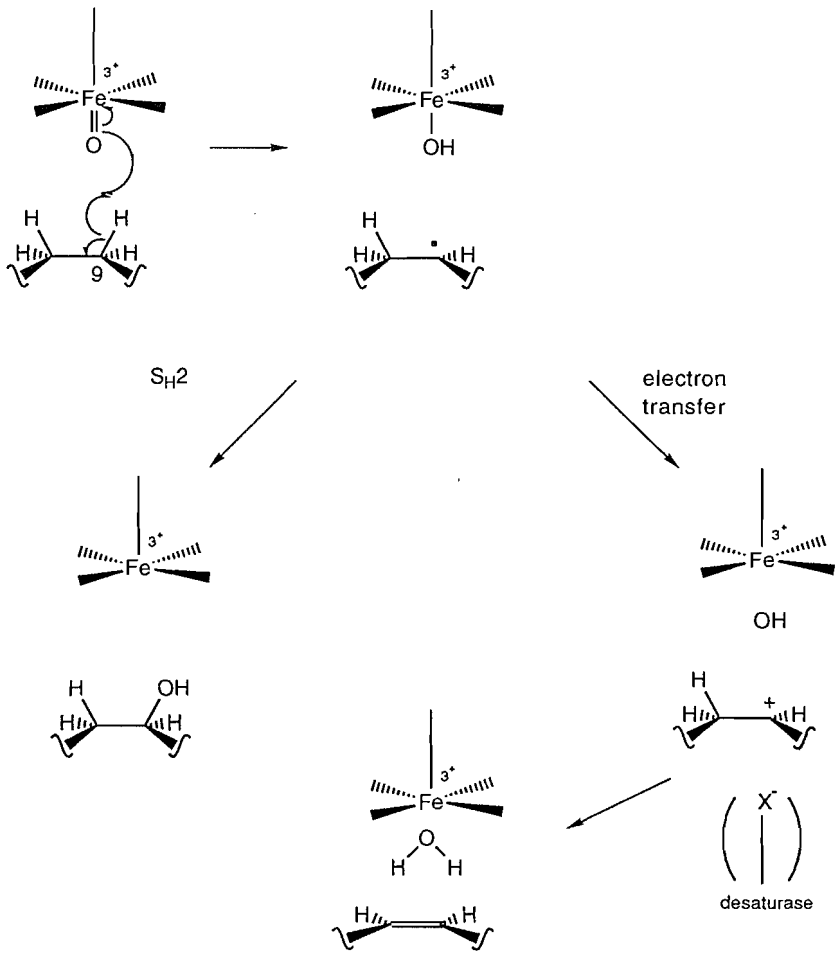

SCHEME 1

have different overall chain lengths, we decided to examine pairs of aromatic thia substrates of equivalent chain length. In this paper, we present the somewhat surprising results of this investigation.

Results and discussion

Aromatic sulfides (**5–8**) were synthesized and administered to *S. cerevisiae* using standard methodology (5). The culture medium was extracted and analyzed for the presence of the corresponding sulfoxide. Racemic sulfoxide reference standards were prepared by oxidation of the corresponding sulfide using one equivalent of MCPBA.

We fully expected **5** to be a better substrate for sulfoxidation than **4**, not only because it has the same overall chain length as our best substrate (**3**) but also because its ionization potential is lower than that of **4**. (The I.P. of ethyl phenyl sulfide is 7.88 eV while that of benzyl methyl sulfide is 8.42 eV (6)). It was therefore most surprising to find that this compound yielded the corresponding sulfoxide in very low yield (3%) and in racemic form. The stereochemical analysis of the sulfoxide product was carried out in a straightforward manner by examining the effect of (*S*)-(+)-α-methoxyphenylacetic acid (MPAA) on the ^{1}H NMR resonances of the C-9 hydrogens using methodology we developed recently (5).

Since desaturase-mediated sulfoxidation normally occurs with high enantioselectivity, we conclude that sulfoxidation of **5** was due entirely to an autoxidative process. This was confirmed by the feeding of a chain-shortened analogue (**6**), which cannot be a substrate of desaturase due to severe steric problems in an active site that force stearoyl CoA into a *cisoid* conformation at C-9,10 (vide infra). Once again, a small amount of racemic sulfoxide (3% yield) was isolated. It is interesting to note that prior to our studies, the only report (7) of a baker's yeast-mediated sulfoxidation was that of an aryl sulfide (**9**), which yielded a 5% yield of racemic sulfoxide! The unsaturated fatty acids present in yeast cells as well as the lower I.P. of the conjugated sulfide would be expected to enhance this autooxidation process.[4]

The apparent unsuitability of **5** as a substrate for our desaturase stimulated a further study in which we examined the desaturase-mediated oxidation of a pair of naphthyl analogues of equivalent chain length (**7**, **8**). As anticipated, the naphthyl compound (**7**) gave rise to optically active sulfoxide, albeit in reduced yield (10%, 13%; 2 separate incubations) and with lower e.e. (75 ± 3%). The stereochemical analysis of this sulfoxide was carried out in two ways — using (*R*)-(−)-*N*-3,5-dinitrobenzoyl-α-methylbenzylamine (8) and MPAA (5) as chiral shift reagents. As shown in Fig. 1, addition of the former reagent to a racemic sample of sulfoxide resulted in the production of a singlet for the ^{1}H NMR resonances, due to the C-10

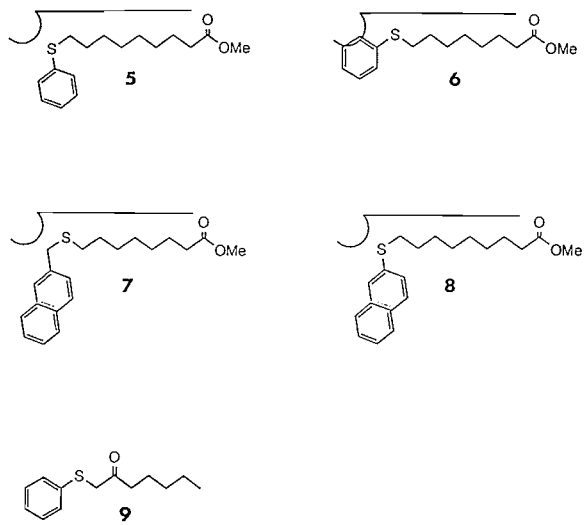

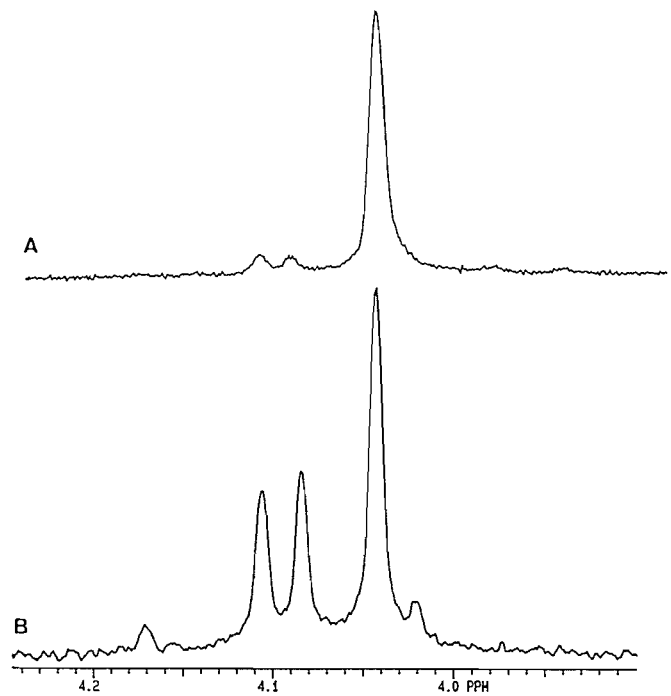

FIG. 1. Effect of addition of 3 equiv. of (*R*)-(−)-*N*-3,5-dinitrobenzoyl-α-methylbenzylamine on ^{1}H NMR (200 MHz) resonances due to the C-10 methylene protons of (*A*) sulfoxide produced from **7** by diverted desaturation and (*B* racemic sulfoxide produced from **7** by treatment with MCPBA.

methylene protons of one enantiomer, and an AB quartet for the corresponding ^{1}H NMR resonances of the other enantiomer. Also, signals due to the methylene protons as far away as C-2 were split by the shift reagent. This behaviour is in marked contrast to that of the benzyl analogue (**3**), which we reported on earlier (5). We assign the "*S*" absolute configuration to the major enantiomer in our biological sample assuming our MPAA-binding model, which we recently developed, is correct (5). According to this model, the resonances due to the C-10 methylene protons of the minor enantiomer are shifted upfield relative to the corresponding signals of the major enantiomer (see Figs. 2 and 3). We do not have a good explanation for the fact that the % e.e. of the biological sulfoxide derived from **7** is reduced relative to that observed for biological sulfoxides derived from **1–4**. It should be mentioned at this point that the amount of sulfoxide derived from autoxidation is usually very small (<1%) for dialkyl sulfides.

In marked contrast to the behaviour of **7**, which is obviously a reasonable substrate for the yeast desaturase, the *S*-napthyl isomer (**8**) yielded only traces of sulfoxide product as determined by TLC comparison with an authentic standard. In this case, insufficient material was isolated to allow stereochemical analysis.

Clearly both **5** and **8** are not being oxidized to sulfoxide by the yeast desaturase, even though the sulfur atom should be accessible to the enzymatic oxidant. It occurred to us that our sulfides may be undergoing chain cleavage as well as or, indeed, instead of, oxygenation (see Scheme 3). It is known (4*a*) that cytochrome P_{450} can dealkylate certain benzylic sulfides; since desaturases normally carry out an elimination reaction, one might expect deprotonation of the radical cation intermediate derived from sulfides to be a viable alternative to oxygenation. Thus, for example, cleavage of **7** would release 2-naphthaldehyde, which would be reduced by the yeast cells to the corresponding alcohol. Indeed, addition of 2-naphthaldehyde to a growing yeast culture at a level corresponding to 0.2% cleavage of substrate followed by extraction in the normal way gave rise to 2-naphthalenemethanol, which was easily detectable by TLC (R_f 0.22, silica gel, 25% EtoAc–hexane, UV detection). Similarly, a limit of detection for 2-naphthalenethiol corresponding to 1% cleavage of **8** was established. However, examination of extracts from all incubations carried out to date involving aromatic thia analogues failed to turn up any evidence that these sulfides are undergoing a cleavage process.

The failure of **5** and **8** to act as substrates of the Δ^9 desaturase of *S. cerevisiae* is striking. The most likely explanation for this phenomenon is as follows: We assume that the desaturase active site is constructed in such a way that C-8, C-9, C-10, and C-11 of stearoyl CoA are forced to adopt a *cisoid* coplanar conformation corresponding to that of the product olefin. This assumption is strengthened by the fact that oleyl CoA but not its

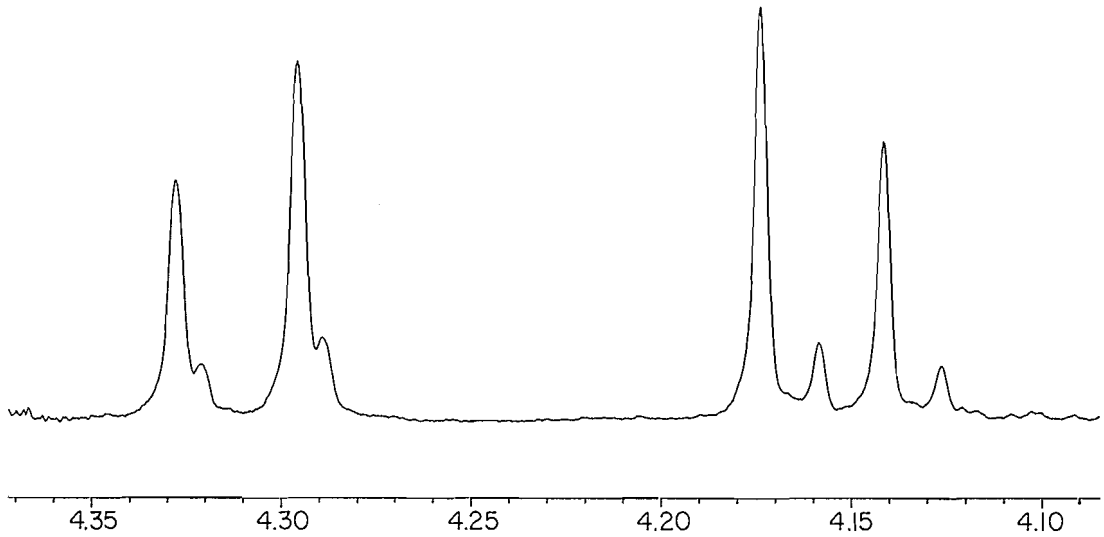

FIG. 2. Effect of addition of 3 equiv. of (*S*)-(+)-α-methoxyphenyl acetic acid on ^{1}H NMR (400 MHz) resonances due to the C-10 methylene protons of sulfoxide produced from **7** by diverted desaturation.

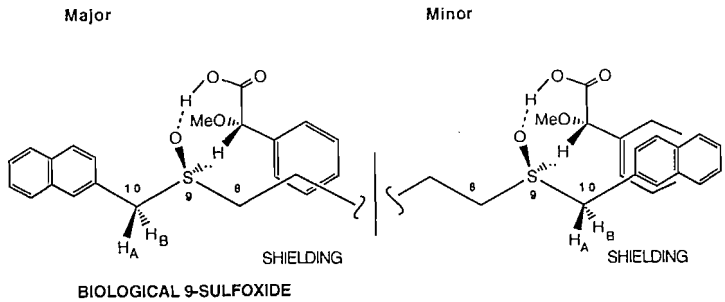

FIG. 3. Binding model for the interaction of (*S*)-(+)-α-methoxyphenyl acetic acid with the two enantiomers of the sulfoxide derived from **7**.

trans isomer shows strong product inhibition in a closely related purified in vitro system(9). To fit into the active site pocket, the 9-benzyl compound (**3**) must tilt its aromatic ring nearly 90°, as shown in Fig. 4, to avoid repulsive interactions between the *ortho* aromatic hydrogen and the hydrogens of the C-8 methylene. Oxidation at sulfur can now proceed. However, for the 10-S-phenyl substrate (**5**), this conformational requirement would be a significant stumbling block during formation of the resonance-stabilized sulfur radical cation. Such resonance stabilization requires a coplanar aromatic ring, which is clearly not achievable in a *cisoid* conformation (see Fig. 4).

Alternatively, **5** may not be able to adopt proper conformation for binding to the enzyme. An abundance of physical and chemical evidence (10) (UV spectra, C—S bond shortening, and C—S—C bond angle widening, decreased nucleophilicity of sulfur atom) suggests that the $3sp^3$–$2p\pi$ interaction between the sulfur atom and the phenyl ring is significant, although the extent to which this effect blocks rotation around the S—C (phenyl) bond is not known. There may in fact be a distinct preference for the π system of the aromatic ring to align with one of the lone pairs of the sulfur atom.

Similar argumentation can be advanced for the two naphthyl systems.

Conclusion

The results presented above point to the strict geometric requirements of the Δ^9 desaturase active site and are helping us to design future mechanistic probes and alternate substrates. In addition, further studies are indicated to determine more accurately the dynamics of a sterically congested aryl sulfide system.

Materials and methods

General methods

All NMR spectra were obtained using dilute $CDCl_3$ solutions at the frequency indicated. All chiral shift experiments involving sulfoxides were carried out using $CDCl_3$ that had been treated with $MgSO_4$ and Woelm basic alumina. Chemical shifts are expressed in ppm and are referenced to tetramethylsilane.

Mass spectra were obtained by direct probe using a VG 7070 E mass spectrometer operating in the Cl (isobutane) mode. Flash chromatography using silica gel (230–400) mesh was used to purify substrates and sulfoxide products isolated from the feeding experiments. Analytical TLC was performed using Merck glass plates precoated with silica G/UV 254. Visualization of UV-inactive materials was accomplished by using a combination of I_2 vapour followed by a water spray.

Unless otherwise stated, all reagents and starting materials were purchased from Aldrich Chemical Company and used without purification. Chiral materials were used without improving their optical purity. All air- and moisture-sensitive reactions were performed under N_2. Unless otherwise noted, organic extracts were shaken with saturated NaCl, dried over Na_2SO_4, and evaporated on a rotary evaporator.

Synthesis of substrates

Aryl thia fatty acids were synthesized by adding the thiophenol to

an alcoholic solution of the appropriate ω-bromo fatty acid in the presence of two equivalents of sodium hydroxide (11). **7** was prepared by alkylating the dilithio salt of 8-mercaptooctanoic acid with 2-(bromoethyl)naphthalene (12). The crude carboxylic acid products were methylated with BF_3–MeOH (13) and purified by flash chromatography (4% EtOAc–hexane) to give colourless low-melting solids or liquids.

A. Methyl S-Phenyl-9-mercaptononanoate (5)

Thiophenol (0.54 g, 4.9 mmol) and 8-bromooctanoic acid (1.1 g, 5.0 mmol) was added to a solution of KOH (0.87 g, 16 mmol) in ethanol (50 mL) and the resultant solution was gently refluxed for 15 h. The solution was concentrated to 10 mL in vacuo, acidified, and extracted with CH_2Cl_2 to yield a crude solid product (1.25 g) which was methylated using 10% BF_3–MeOH (13) to give a pale brown oil (1.30 g). This material was purified by flash chromatography (4% EtOAc–hexane) to give a colourless solid (1.17 g, 89% isolated yield): mp 29–30°C; ^{1}H NMR (200 MHz) δ: 7.1–7.35 (5H, m, phenyl), 3.66 (3H, s, C(O)OC*H*$_3$), 2.91 (2H, t, SC*H*$_2$CH$_2$), 2.3 (2*H*, t, CH$_2$C(O)OCH$_3$), 1.57–1.68 (4H, m, SC*H*$_2$CH$_2$CH$_2$, C*H*$_2$CH$_2$C(O)OCH$_3$), 1.29–1.5 (8H, br s, (C*H*$_2$)$_3$); MS *m/e*: 281 ((M + 1)$^+$), 249 ((M − OCH$_3$)$^+$). Synthesis of sulfoxide products

Racemic sulfoxides were prepared by treating sulfides with one equiv. of MCPBA (Lancaster) at 0°C in CH_2Cl_2 for 1 h. Contaminating sulfone and sulfide were removed by flash chromatography (60% EtOAc–hexane) to give colorless oils or low-melting solids. The analytical data obtained for these compounds are as follows.

A. (±)-Methyl S-*Phenyl-9-mercaptononanoate* S-*oxide:* oil, ^{1}H NMR (200 MHz) δ: 7.5–7.65 (5H, m, phenyl), 3.66 (3H, s, C(O)OC*H*$_3$), 2.78 (2H, t, S(O)C*H*$_2$CH$_2$), 2.29 (2*H*, t, CH$_2$C(O)OCH$_3$), 1.57–1.68 (4H, m, SC*H*$_2$CH$_2$CH$_2$, C*H*$_2$CH$_2$C(O)OCH$_3$), 1.5–1.8 (8H, br s, (C*H*$_2$)$_3$); MS *m/e*: 297 ((M + 1)$^+$), 265 ((M − OCH$_3$)$^+$). Anal. calcd. for $C_{16}H_{24}O_3S$: C 64.83, H 7.82; found: C 64.59, H 8.16.

B. (±)-Methyl S-*Phenyl-8-mercaptooctanoate* S-*oxide:* oil, ^{1}H NMR (200 MHz) δ: 7.47–7.35 (5H, m, phenyl), 3.65 (3H, s, C(O)OC*H*$_3$), 2.76 (2H, t, S(O)C*H*$_2$CH$_2$), 2.27 (2*H*, t, C*H*$_2$C(O)OCH$_3$), 1.50–1.75 (4H, m, SC*H*$_2$CH$_2$CH$_2$, C*H*$_2$CH$_2$C(O)OCH$_3$), 1.2–1.5 (6H, br s, (C*H*$_2$)$_3$); MS *m/e*: 283 ((M + 1)$^+$), 251 ((M − OCH$_3$)$^+$). Biological synthesis of sulfoxides using S. cerevisae

A typical incubation was carried out as follows: The strain of baker's yeast used in this experiment was wild-type *Saccharomyces cerevisae*, no. ATTC 12341. Cultures were grown in YPD medium (1.0% yeast extract, 2.0% bactopeptone, 2.0% D-glucose), at 30°C in a rotary incubator shaker set at 150 rpm. Starter culture (4 mL) containing 5×10^8 cells was used to inoculate 300 mL of sterile medium in a 1-L Erlenmeyer flask.

A 50-mg portion of thia fatty acid methyl ester was added as a solution (5% w/v) in absolute ethanol to each culture flask, and the inoculated cultures were then incubated for 24 h to give a final cell density of 3×10^{10} cells/flask. The addition of exogenous fatty acid did not affect the growth of the organism with respect to control cultures.

Culture media was collected by centrifugation (6000 × *g*, 10 min); the supernatant was brought to 1.5 M in NaCl, acidified to pH 1.5 with 3 M HCl, and then extracted with CH_2Cl_2 (2 × 30 mL), $CHCl_3$ (2 × 30 mL), CCl_4 (1 × 30 mL). The combined organic extracts were dried over anhydrous Na_2SO_4 (8 g, 4 h). The decanted solution was evaporated in vacuo to give a crude residue, which was methylated using an ethereal diazomethane solution. (The sulfoxide product is excreted from the cells as the free acid.) TLC analysis of the extract was carried out on silica gel plates (80% EtOAc–hexane) Purification of the sulfoxide product was performed by flash chromatography (silica gel, 65% EtOAc–hexane).

Biologically produced sulfoxides were compared with the authentic synthetic standards on the basis of ^{1}H NMR, R_f, and MS data.

This paper is dedicated to Professor Ian D. Spencer

JONATHAN P. LEE, SHENG-WAN TSAO, CHING-JER CHANG, XIAN-GUO HE, and HEINZ G. FLOSS. Can. J. Chem. **72**, 182 (1994).

The biosynthesis of naphthomycin A (**1**) in *Streptomyces collinus* was studied in feeding experiments with single and multiple ^{13}C-labeled precursors followed by ^{13}C NMR analysis of the labeling and ^{13}C–^{13}C coupling patterns in the product. The results indicate that **1** is assembled via the polyketide pathway from 3-amino-5-hydroxybenzoic acid (**2**) as the starter unit (mC_7N unit) plus seven propionate and six acetate chain extension units. **2** is synthesized via the shikimate pathway by a process that attaches the nitrogen to the carbon derived from C1 of erythrose 4-phosphate, consistent with a new branch of the shikimate pathway recently discovered to operate in the biosynthesis of the mC_7N unit of rifamycin B.

JONATHAN P. LEE, SHENG-WAN TSAO, CHING-JER CHANG, XIAN-GUO HE et HEINZ G. FLOSS. Can. J. Chem. **72**, 182 (1994).

On a étudié la biosynthèse de la naphtomycine A (**1**) dans le *Streptomyces collinus* en procédant à des expériences au cours desquelles on a fourni des précurseurs comportant des marqueurs au ^{13}C simples ou multiples alors que l'on a suivi le marquage par une analyse RMN du ^{13}C et par les patrons de couplage ^{13}C–^{13}C dans le produit. Les résultats indiquent que le produit **1** s'assemble par le biais d'une voie impliquant la formation d'un polycétide à partir de l'acide 3-amino-5-hydroxybenzoïque (**2**) (unité mC_7N) et des sept unités propioniques et six chaînes acétiques agissant comme extensions. Le composé **2** est synthétisé par une voie impliquant l'acide shikimique, par un processus que attache un azote au carbone dérivé du C1 4-phosphate d'érythrose; ceci est en accord avec une nouvelle branche de la voie shikimique découverte récemment et qui est impliquée dans la biosynthèse de l'unité mC_7N de la rifamycine B.

[Traduit par la rédaction]

Naphthomycin A (**1**), first isolated from *Streptomyces collinus* Tü 105 by Balerna et al. (1), is a naphthalenic ansamycin (2, 3) antibiotic that contains an unusually large number of carbon atoms, 23, in its ansa chain. Its constitutional formula was first proposed by Williams (4) and later revised by Rinehart and coworkers (5). The structure was subsequently confirmed by X-ray crystallography, which, together with chemical degradations, also established the absolute configuration (6). Naphthomycin A co-occurs with a number of congeners (1, 7, 8) and is structurally related to actamycin (8, 9) and the naphthoquinomycins (10). Unlike other ansamycins, **1** is active against Gram-positive bacteria and its mode of action is different from that of other naphthalenic ansamycins, which generally inhibit bacterial RNA polymerase. Its action is antagonized by vitamin K and by sulfhydryl compounds like cysteine (1).

In this paper we report the results of studies on the biosynthesis of naphthomycin A that show that its formation probably follows a pathway similar to that previously demonstrated for rifamycin S (11–13), geldanamycin (14, 15), actamycin (9, 16), and ansatrienin (13, 17, 18).

Results and discussion

The origin of the carbon framework of both the naphthoquinoid nucleus and the macrocyclic ansa bridge of naphthomycin A was studied in shake cultures of *S. collinus* Tü 105 by feeding ^{13}C-labeled precursors followed by ^{13}C NMR analysis of the product. These experiments were preceded by preliminary studies in which the same compound labeled with ^{14}C was fed to evaluate its general level of incorporation (data not shown). On the basis of time course studies of naphthomycin A formation, the labeled precursors were added to production cultures at 24 h after inoculation, and incubation was continued for an additional 40–55 h. Naphthomycin A could be isolated from the culture broth in yields of about 70 mg/L by extraction of the acidified broth with ethyl acetate and purification by column chromatography on Sephadex LH-20, followed by preparative thin-layer chromatography on silica gel.

The analysis of the products from these experiments for their ^{13}C distribution is reliant upon assignment of the signals in the ^{13}C NMR spectrum of **1**. Naphthomycin A gives a ^{13}C NMR spectrum with 40 well-resolved signals (Table 1). Based upon chemical shift theory the spectrum was divided into four regions: 202–165 ppm, with five carbonyl atoms; 165–120 ppm, 20 aromatic-olefinic methine or quaternary carbon atoms; 80–30 ppm, eight methylene, methine, or alkoxy carbon atoms; and 25–10 ppm, seven methyl carbon atoms. The proton-coupled spectrum distinguished C31 with no observable proton coupling and C28 with a single coupling ($J_{C28-H27}$ =

4.6 Hz) from C1, C11, and C23, which all demonstrated multiple and complex proton couplings. The remaining signals in the spectrum demonstrated mixtures of complex first- and second-order coupling patterns and could not be further assigned by this method. DEPT (19) experiments were conducted, resulting in the further assignment of 10 signals in the congested aromatic-olefinic region as methine and the remaining 10 as quaternary carbon atoms. In addition, two signals were assigned to the methylene carbon atoms C10 and C14. The further analysis of the spectrum relied on 2D NMR spectroscopy, particularly a 2D-INADEQUATE (20) experiment on a sample of **1** obtained by feeding [U-$^{13}C_3$]glycerol. This analysis identified coupled, and hence connected, sets of two and three carbon atoms. Combining these data with connectivities obtained from 2D ^{13}C–proton heteronuclear correlation experiments (normal and long-range, HETCOR (21) and COLOC (22)) and 2D proton–proton homonuclear correlation experiments (normal and long-range COSY (23, 24)), we were able to observe connectivities from individual biosynthetically intact units of two or three ^{13}C atoms to their attached protons, and then to either ^{13}C atoms of adjacent intact units or their attached protons. This allowed the complete assignment of both the carbon (Table 1) and proton (Table 2) NMR spectra of naphthomycin A; these assignments are consistent with literature data on closely related compounds (7*b*, 10).

With these assignments at hand we proceeded to probe the biosynthetic origin of **1**. Based on analogy to other ansamycins (9, 11, 14) it was assumed that carbon atoms 1 through 26 and their attached methyl groups are of polyketide origin, whereas the quinoid ring and the attached nitrogen atom and C27 repre-

sent a mC_7N unit of non-polyketide origin. The branching methyl groups in other ansamycins, as in the majority of bacterial polyketides, arise from the incorporation of propionate instead of acetate units; their formation by methylation of a polyacetate chain, as in boromycin (25) and aplasmomycin (26), seems to be the exception. Hence we decided to feed [1-^{13}C]propionate and [1-^{13}C] and [2-^{13}C]acetate.

In the feeding experiment with propionate, 770 mg of sodium [1-^{13}C]propionate and 25 μCi of sodium [1-^{14}C]propionate (specific radioactivity ~2.7 μCi/μmol) were combined in an aqueous solution and pulse fed to seven 100-mL shake cultures starting 24 h after inoculation at 12 h intervals. Fifteen milligrams of **1** was isolated after 72 h and the specific incorporation of ^{14}C was 213%. The ^{13}C NMR spectrum of this sample (Table 1) showed many slightly enriched signals, but seven signals were rather highly enriched. These were carbon atoms 1, 7, 11, 17, 19, 21, and 25, i.e., all the carbon atoms expected to arise from C1 of propionate if proprionate units are incorporated into the polyketide chain to give rise to the branching methyl groups.

The feeding of sodium [1-^{13}C]acetate (600 mg) with 25 μCi of sodium[1-^{14}C]acetate (specific radioactivity ~5 μCi/μmol) was carried out analogously, and 19.3 mg of **1** was isolated with a specific incorporation of ^{14}C of 50%. The ^{13}C NMR spectrum of this sample (Table 1) contained 11 significantly enriched signals (1.9–4.5 times natural abundance). Five of these signals were identical to those enriched by [1-^{13}C]proprionate and six (carbon atoms 3, 5, 9, 13, 15, and 23) were uniquely labeled. Similarly, 840 mg of sodium [2-^{13}C]acetate and 25 μCi of sodium[2-^{14}C]acetate (specific radioactivity ~3.7 μCi/μmol) was fed, resulting in 12 mg of **1** being isolated with a 40% specific incorporation of ^{14}C. The ^{13}C NMR spectrum of this sample (Table 1) contained 21 signals that were significantly enhanced (1.9–6.8 times natural abundance). None of these carbon atoms, except C19, were significantly labeled in the two previous feeding experiments. The enhanced signals included those for C4, C6, C10, C14, C16, and C24, the carbon atoms expected to arise from C2 of acetate if acetate units were incorporated directly into the polyketide chain. In addition, in every propionate-derived unit the carbon atoms expected to arise from C3 and C2 of propionate were labeled; small enrichments were sometimes also seen in the carbon atoms corresponding to C1 of proprionate. The appearance of ^{13}C from acetate in moieties derived from propionate is easily rationalized by acetate metabolism through the citric acid cycle to succinate and ultimately to methylmalonyl-CoA. In both acetate feedings six enriched signals were detected that did not appear in propionate-derived moieties. It was therefore concluded that, as expected, six acetate and seven proprionate units, in the form of malonyl-CoA and methylmalonyl-CoA, respectively, are condensed to form the major portion of the skeleton of **1**, i.e., the entire framework except the mC_7N unit (Fig. 1).

The origin of the mC_7N unit of ansamycin antibiotics, e.g., rifamycin (11, 27, 28), geldanamycin (14,15), or ansatrienin (13, 17) is related to the shikimate pathway, whereas the mC_7N units found in acarbose and validamycin (29) or manumycin-type (30) antibiotics have different origins unrelated to the shikimate pathway. To shed light on the origin of the mC_7N unit in **1** we employed multiple ^{13}C labeling ("bond labeling") using [U-$^{13}C_3$]glycerol, a highly diagnostic general precursor of actinomycete secondary metabolites.

[U-$^{13}C_3$]Glycerol (432 mg, 99% ^{13}C) and unlabeled glycerol (837 mg) were mixed and fed to 10 100mL cultures of *S. collinus* to give 51 mg of **1**. In the ^{13}C NMR spectrum of this material all signals except for that of C29 were enriched and coupled either to one or two additional ^{13}C nuclei. C29 was possibly enriched, but definitely showed no coupling to any other carbon atom. Using a 2D-INADEQUATE experiment we were able to detect nine intact assemblies of three ^{13}C atoms and six intact units of two ^{13}C atoms, which were all mutually discrete (Table 3). In addition, several of the coupling patterns for intact units of three ^{13}C atoms were found to be superimposed upon overlapping patterns for two intact units of two ^{13}C atoms, e.g., signals for C38–C26–C25 were superimposed on signals for C38–C26 and C26–C25 (also overlapping).

The appearance of coupling between each pair of carbon atoms in the acetate-derived units of the polyketide moiety is expected, based on the well-known metabolic sequence glycerol → dihydroxyacetone phosphate → phosphoenolpyruvate (PEP) → pyruvate → acetyl-coenzyme A. The appearance of intact assemblies of three coupled ^{13}C atoms in the propionate-derived units, in addition to overlapping pairs of coupled carbon atoms, implies that in *S. collinus* PEP or pyruvate must be carboxylated to oxalacetate which, by action of malate dehydrogenase, fumarase, and succinate dehydrogenase, give rise to succinate labeled contiguously in C1, C2, and C3. Activation to the CoA ester and rearrangement by methylmalonyl-CoA mutase will then produce two species of methylmalonyl-CoA, one labeled contiguously in C1, C2, and C3 and the other in C2 and C3. However, the appearance of two coupled carbon atoms in C1 and C2 of the propionate units without coupling to C3 is not as easily rationalized.

In the mC_7N unit, two intact assemblies of three coupled ^{13}C atoms were detected, C27–C27a–C28 and C31a–C31–C30, while C29 was not observed to be coupled to any other ^{13}C. This pattern is typical of shikimate pathway metabolites and results from conversion of glycerol via dihydroxyacetone phosphate and phosphoglyceraldehyde into hexose phosphates containing two coupled three-carbon units ((C1–C2–C3 and C4–C5–C6). Transketolase then generates erythrose 4-phosphate still containing one intact three-carbon unit in C2–C3–C4 but with no coupling to C1, which condenses with another intact three-carbon unit in the form of PEP. Thus, the shikimate pathway origin of the mC_7N unit in **1** is clearly established.

The groups of Rickards (16, 31), Ghisalba and Nüesch (28, 32), and Rinehart (33) have established 3-amino-5-hydroxy-

C4 and C3	55

[a]Additional pairs of coupled carbons were detected which coincided with intact three-carbon assemblies.

benzoic acid (**2**) as the proximate precursor of the shikimate pathway-derived mC_7N units of rifamycin, actamycin, ansamitocin, mitomycin, geldamycin, and streptovaricin, and we have shown that **2** is also a specific precursor of the mC_7N unit of ansatrienin A (17). In contrast, the mC_7N unit of pactamycin is derived from 3-aminobenzoic acid rather than **2** (34). To probe whether **2** is the precursor of the mC_7N unit of **1** we synthesized both [7-^{13}C]- and [7-^{14}C]-**2** by the procedure of Rickards and co-workers (35). A mixture of 362 mg [7-^{13}C]-**2** (99 atom% ^{13}C) and 5 μCi [7-^{14}C]-**2** (specific radioactivity 0.35 μCi/μmol) was fed to 12 100mL cultures of *S. collinus* to give 7.2 mg of labeled **1**. The specific incorporation of ^{14}C was 64%. The NMR spectrum of this sample showed only one highly enriched signal at 131.5 ppm corresponding to C27. From these data it was concluded that **2** is a specific and highly efficient precursor of the mC_7N unit of **1**.

The identification of **2** as a specific precursor of the mC_7N unit of ansamycins and mitomycins does not answer the question of how this molecule is generated through the shikimate pathway. This question is particularly intriguing since neither shikimic acid itself (14, 18, 27, 36) nor an earlier pathway intermediate, dehydroquinic acid (37), is incorporated into the mC_7N unit. At least in one case, ansatrienin A, it was shown that this is not due to lack of cell permeability to the precursor, because ^{13}C-shikimic acid labeled another part of the molecule, but not the mC_7N unit (18). Thus the formation of **2** must branch off from the main pathway at an earlier stage. Another intriguing feature is the finding, in the cases of the mitomycins (37) geldanamycin (15) and ansatrienin A (38), that the nitrogen atom of the mC_7N unit is attached to the carbon atom corresponding to C5, not C3, of a shikimate-equivalent moiety. The same conclusion is reached about the mC_7N unit of **1** from the results of the [U-$^{13}C_3$]glycerol experiment presented above. Since C29 shows no coupling whereas C31 is the center of a coupled three-carbon assembly, C29 corresponds to C5 and C31 to C3 of shikimate or dehydroshikimate, i.e., the nitrogen in this case is similarly attached to the C5-equivalent carbon atom.

Recent work from this laboratory (13) has shed some light on the mode of formation of **2** by demonstrating that cell-free extracts of the rifamycin producer, *Nocardia mediterranei*, efficiently convert 3,4-dideoxy-4-amino-D-*arabino*-heptulosonic acid 7-phosphate (aminoDAHP, **3**), but not DAHP, and 5-deoxy-5-amino-3-dehydroshikimic acid (aminoDHS, **4**) into **2**. The enzyme catalyzing the aromatization of **4** into **2** has recently been purified to homogeneity and the gene encoding it has been cloned.[3] These findings lend considerable support to the pathway shown in Fig. 2 for the formation of **2**. All the results of the present study are consistent with and support such a pathway also for the formation of the mC_7N unit of **1**.

In summary, the results of this study indicate that the carbon framework of **1** is assembled by the polyketide pathway from a shikimate pathway-derived starter unit, **2**, presumably as its coenzyme A thioester, and chain extension by seven propionate

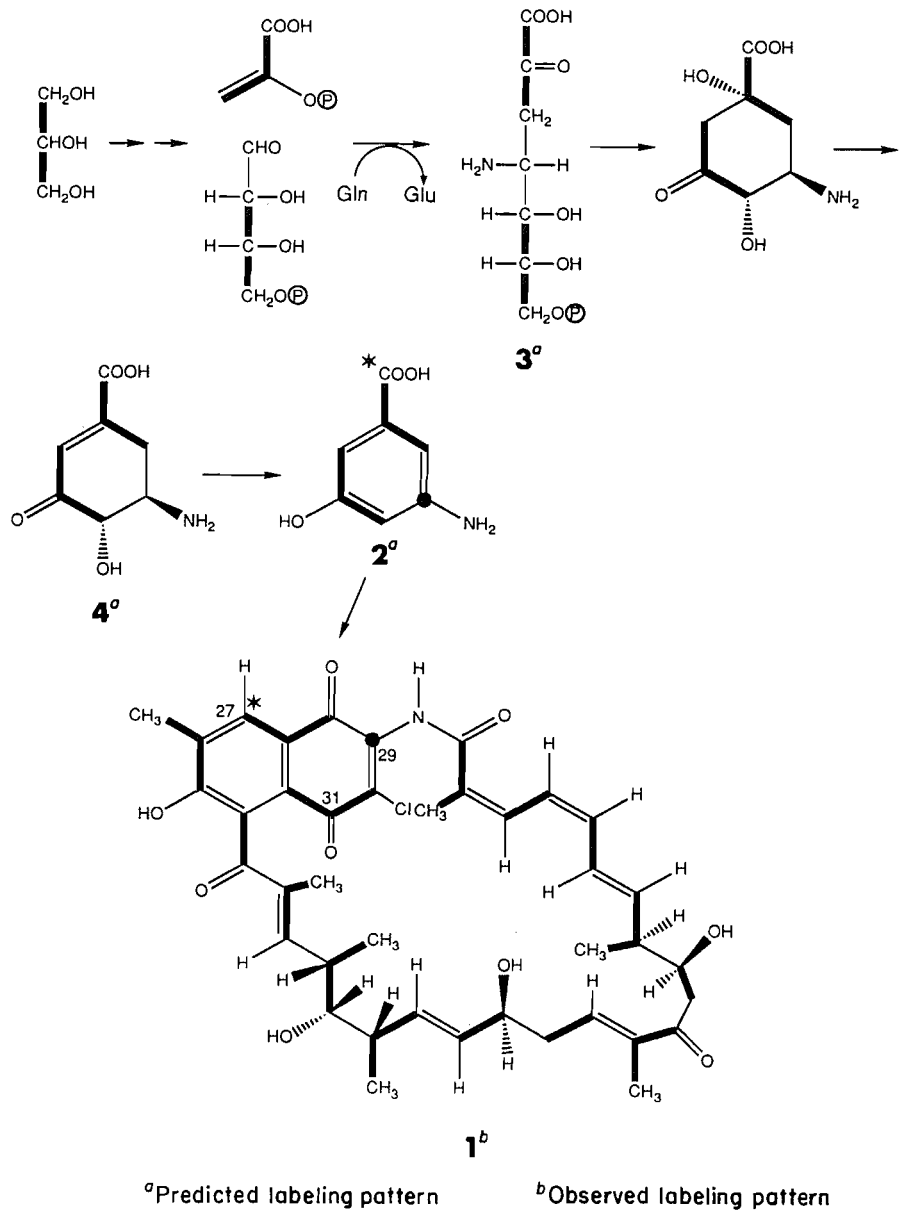

FIG. 2. ^{13}C–^{13}C coupling pattern observed in **1** after feeding [U$^{13}C_3$]glycerol, and proposed mode of formation of the mC_7N unit.

(methylmalonyl-CoA) and six acetate (malonyl-CoA) units. The terminal unit of the polyketide chain that in **1**, uniquely among the naphthomycins, is distinguished by a methyl group at C2, is also derived from propionate rather than by methylation of an acetate-derived moiety. All the labeling patterns in the mC_7N unit are consistent with its formation by a new branch of the shikimate pathway recently demonstrated in rifamycin biosynthesis, which involves amino analogs of the normal pathway intermediates.

Experimental section

Materials

Chemicals were obtained from Aldrich Chemical Co., Alfa Products, or Eastman Organic Chemicals and were of reagent grade or of the highest grade commercially available. Radiolabeled compounds were purchased from NEN or Amersham. Sodium [1-^{13}C] and [2-^{13}C]acetate and sodium [1-^{13}C]propionate were obtained from MSD Isotopes. [U-$^{13}C_3$]Glycerol was synthesized from K^{13}CN (99 at.% ^{13}C) and [1,2-$^{13}C_2$]acetic acid (99 at.% ^{13}C), both provided by the Los Alamos Stable Isotope Resource, via diethyl malonate and diethyl 2-acetoxymalonate as previously described (39). [7-^{14}C] and [7-^{13}C]-**2** were synthesized from 3-bromo-5-nitroanisole and Cu^{14}CN, respectively, by the procedure of Herlt et al. (35). The culture of *S. collinus* Tü 105 as well as full-fat soybean meal (Schoenenberger, Magstadt, Germany) were a gift of Prof. H. Zähner, Tübingen. Reference samples of naphthomycins were provided by Prof. A. Zeeck, Göttingen.

General methods

^{13}C NMR spectra were recorded on Varian XL200, Bruker WM-300, and Bruker AM 500 nuclear magnetic resonance spectrometers operating at 50.1, 75.5, and 125.1 MHz, respectively. High-field ^1H NMR spectra and H:C heteronuclear correlation spectra were recorded at 500.12 MHz (proton frequency) on a Bruker AM 500 instrument. Chemical shifts are given relative to Me_4Si as an internal standard or were adjusted to the Me_4Si scale by reference to the solvent, CHD_2COCD_3, resonance at δ_H 2.04 ppm or the $(CD_3)_2CO$ resonance at δ_C 29.5 ppm.

Preparative thin-layer chromatography was performed on 1.0 mm 20 × 20 cm silica gel 60F-254 plates supplied by Brinkmann. Column chromatography was performed on a 3.2 × 50 cm column of Sephadex

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

LH-20 supplied by Sigma. Radioactivity determinations were carried out by liquid scintillation counting on a Beckman LS-7500 spectrometer using AQUASOL® Universal LSC Cocktail (NEN). Counting efficiencies were determined with [^{14}C]toluene as an internal standard.

Fermentation

Streptomyces collinus Tü 105 was maintained as a frozen spore suspension in 20% glycerol. The spores were prepared from agar slants (0.4% yeast extract, 1% malt extract, 0.4% glucose, 2% agar in distilled water, pH adjusted to 7.4) grown at 30°C for 7–10 days. The spore suspensions were used to inoculate production cultures of 100 mL sterile medium (1 g full-fat soy bean meal, 2 g glucose, 100 mL tap water) in 500 mL baffled Erlenmeyer flasks, which were inoculated at 27–28°C on a New Brunswick G-25 orbital shaker at 300 rpm for 64–79 h. Labeled precursors were added as Millipore filter-sterilized solutions 24 h after inoculation either in one portion or several portions in 12 h intervals.

Isolation of ***1***

At the end of the fermentation 2% Hyflo Super Cel® was added to the culture broth followed by filtration through filter paper on a Buchner funnel. The filtrate was brought to pH 4 with 1.0 N HCl and extracted with 3 × 50 mL of ethyl acetate per production flask. The solids on the filter were washed extensively with 500 mL of methanol and the methanol was evaporated under reduced pressure. Water (10 mL) was added to the residue and the suspension was extracted with 3 × 75 mL of ethyl acetate. The two ethyl acetate extracts were combined and evaporated under reduced pressure. The crude extract was chromatographed on a Sephadex LH-20 column with methanol as solvent. The **1**-containing fractions were combined and evaporated to dryness under reduced pressure. The residue was triturated with ethyl acetate and the solution applied to a preparative silica gel plate, which was developed with ethyl acetate:benzene, 4:1. The **1**-containing band was scraped from the plate and the product eluted from the silica gel with ethyl acetate. The ethyl acetate solution was evaporated to a dark oil under reduced pressure. The oil was held under vacuum for 46 h and solidified when the pressure was below 0.1 Torr (1 Torr = 133.3 Pa). Yields ranged from 50 to 220 mg/L.

Acknowledgements

We are indebted to Prof. H. Zähner, Tübingen, for providing the culture of *S. collinus* as well as valuable advice, to Prof. A. Zeeck, Göttingen, for reference compounds, and to the Los Alamos Stable Isotope Resource, supported by NIH (grant RR02231) and USDOE/OHER, for the supply of ^{13}C-labeled synthetic starting materials. Financial support of this work by the NIH through research grant Al 20264 is also gratefully acknowledged.

Cysteine synthase (EC 4.2.99.8) in higher plants is responsible for biosynthesis of not only cysteine but also some nonprotein amino acids such as β-(pyrazol-1-yl)-L-alanine. The cDNA of a cysteine synthase from spinach (*Spinacia oleracea*) was inserted into pET8c (=pET3d) under the transcriptional control of strong T7 promoter to yield an overexpression vector pCEK1. The amount of the exogenous cysteine synthase was increased up to 40% of the total soluble protein of *Escherichia coli* transformed with pCEK1. β-(Pyrazol-1-yl)-L-alanine, a specific metabolite in plants of the Cucurbitaceae, was biosynthesized by overexpressed cysteine synthase from pyrazole in the presence of *O*-acetyl-L-serine and serine, in vitro and in vivo, respectively. The present study provides the system for mechanistic investigation of biosynthesis of cysteine and biogenetically related β-substituted alanines at molecular genetic level.

KAZUKI SAITO, REIKO KANDA, MAKOTO KUROSAWA et ISAMU MURAKOSHI. Can. J. Chem. **72**, 188 (1994).

La cystéine synthase (EC 4.2.99.8) des plantes supérieures n'est pas uniquement responsable de la biosynthèse de la cystéine, mais aussi de quelques acides aminés non protéiniques comme la β-(pyrzol-1-yl)-L-alanine. On a inséré la cADN d'une cystéine synthase provenant d'épinards (*Spinacia oleracea*) dans le pET8c (=pET3d) sous le contrôle transcriptionnel du puissant promoteur T7 pour obtenir un vecteur de sur expression pCEK1. On a augmenté la quantité de cystéine synthase exogène jusqu'à 40% de la protéine soluble totale d'*Escherichia coli* transformé par du pCEK1. Utilisant une cystéine synthase surexprimée, on a biosynthétisé la β-(pyrzol-1-yl)-L-alanine, un métabolite spécifique dans les cucurbitacées, à partir de pyrazole en présence de *O*-acétyl-L-sérine et de sérine respectivement in vitro et in vivo. L'étude actuelle fournit le système qui permet de faire l'étude du mécanisme de biosynthèse de la cystéine et des alanines β-substituées biogénétiquement apparentées au niveau génétique moléculaire.

[Traduit par la rédaction]

Introduction

Nonprotein amino acids form a large group of plant secondary products (1). Some nonprotein β-substituted alanines show interesting biological activities, such as neuroactive and antimycotic activities, which are potentially useful for pharmaceutical research and development (Table 1) (2). These β-substituted alanines are formed from *O*-acetyl-L-serine (OAS) as a common precursor (Fig. 1). These reactions are catalyzed by cysteine synthase (CSase) (*O*-acetyl-L-serine (thiol)-lyase, EC 4.2.99.8) or by specific enzymes distinct from CSase, depending on the products formed: β-(pyrazol-1-yl)-L-alanine (β-PA) (3) and mimosine (4) are biosynthesized by CSases; willardiine is produced by the enzyme(s) different from CSase (5).

Little is known about the precise reaction mechanism of these pyridoxal phosphate-dependent enzymes and the molecular mechanism determining the substrate specificity governing formation of these structurally diverse compounds, since the enzymatic activity is usually very low in plant cells and only a limited amount of purified enzyme preparation is available for mechanistic study. Therefore, it is a prerequisite for further study to establish an overexpression system of genes for plant biosynthetic enzymes in heterologous cells such as *Escherichia coli*.

Recently, we isolated cDNA clones encoding CSases in spinach (*Spinacia oleracea*) (6, 7), which can utilize pyrazole as a substrate to form β-PA as well as H_2S to form cysteine. In the present study, we established an overexpression system of a cDNA of spinach CSase in *E. coli* by using a pET vector based on a T7 polymerase expression system. β-PA, a plant-specific secondary product, was biosynthesized by the action of exogenous CSase in vitro and in vivo.

Results and discussion

The *Nco*I fragment containing a full-length cDNA encoding a spinach CSase was obtained from an expression plasmid pKM1 (6). This 1.2-kb fragment was ligated into the *Nco*I site of pET8c (=pET3d) just under the ϕ10 promoter sequence of T7 DNA to yield overexpressing plasmids pCEK1 and pCEK2, with sense and antisense orientation, respectively, with respect to the promoter (Fig. 2). The expression system, pET system, employed in this study is based on the strong ϕ10 promoter in the pET plasmid by combination with lysogenic T7 RNA polymerase gene and suitable for overexpression of a heterologus gene in *E. coli* (8). The expression of T7 RNA polymerase gene is controlled by the *lacUV5* promoter, which is inducible by isopropyl β-D-thiogalactoside (IPTG). The plasmids, pCEK1 and pCEK2, were transferred into *E. coli* BL21 (DE3, pLysE) or overexpression.

The total soluble proteins of *E. coli* transformed with the expression plasmids were analyzed by SDS–polyacrylamide gel electrophoresis (PAGE) and subsequent dye staining (Fig. 3A). The protein bands corresponding to the spinach CSase A of 35 kDa were evident in the extract of transformant with the overexpressing vector, pCEK1, but not in that of the antisense pCEK2. The amount of CSase A was increased maximally up to 40% of the total soluble protein of *E. coli* (pCEK1). The corresponding band in *E. coli* NK3, a cysteine auxotrophic mutant, transformed with pKM1, a vector with transcriptional control of *lacZ* promoter for an exogenous gene, is evidently not accumulated in the crude protein extract by this dye staining. This is

TABLE 1. Naturally occurring nonprotein β-substituted alanines formed from OAS in plants

Name	Structure	Source genus	Biological activity
β-(Pyrazol-1-yl)-L-alanine		*Citrullus*	
β-(Isoxazolin-5-on-2-yl)-L-alanine		*Pisum, Lathyrus, Lens*	Antimycotic
L-Quisqualic acid		*Quisqualis*	Neuroexcitatory (Glu receptor agonist), vermicide
L-Mimosine		*Mimosa, Leucaena*	Depilatory, thyrotoxic
L-Willardiine		*Pisum, Acacia, Fagus*	Neuroactive

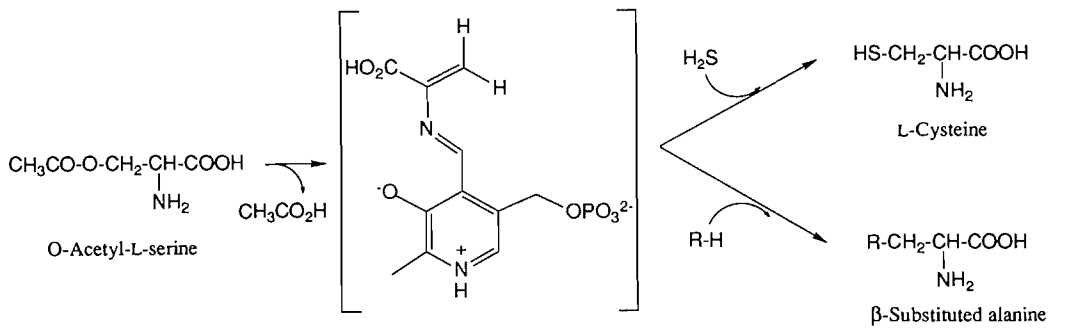

FIG. 1. Biosynthetic pathway of cysteine and nonprotein β-substituted alanines from OAS as a precursor. These amino acids are biosynthesized from OAS via an aminoacryl adduct of amino acid and pyridoxal phosphate as a common intermediate. The reactions are catalyzed by either isoenzyme of CSase or specific synthase distinct from CSase.

certainly due to the low expression level of exogenous cDNA by pKM1 compared with that by pCEK1.

The accumulation of immunoreactive and functionally active translation product of the cDNA was demonstrated by Western blot analysis and CSase enzymatic assay of the extracts of *E. coli* (Fig. 3B). The immunoreactive polypeptide of 35 kDa was detected in the protein extract of *E. coli* transformed with pCEK1 and pKM1 using antibody against CSase A. The concentration of CSase protein was higher in the pCEK1 transformant than in the pKM1 cell. The high enzymatic activity of CSase was also detected in the extracts of these *E. coli* transformants.

The purified CSase from spinach has been reported to have the ability to catalyze the formation of β-PA from pyrazole and OAS (9). However, that enzyme preparation was still a mixture of CSase A and CSase B. The cloned and overexpressed CSase A in *E. coli* was examined to determine whether this isoform could catalyze the formation of β-PA (Table 2). The overexpression plasmid, pCEK1, was able to synthesize β-PA from pyrazole and OAS. Low but substantial activities were also detected in the cell extracts transformed with pCEK2 and pKM1. These activities were presumably due to the bacterial endogenous CSases of *E. coli* BL21 and to the *lacZ*-driven expression of cDNA in pKM1.

The overexpression system in *E. coli* was applied to biosynthesis of β-PA in vivo (Fig. 4). The production of β-PA in vivo by *E. coli* culture was achieved only when both serine and pyrazole were fed to the culture medium, whereas feeding only

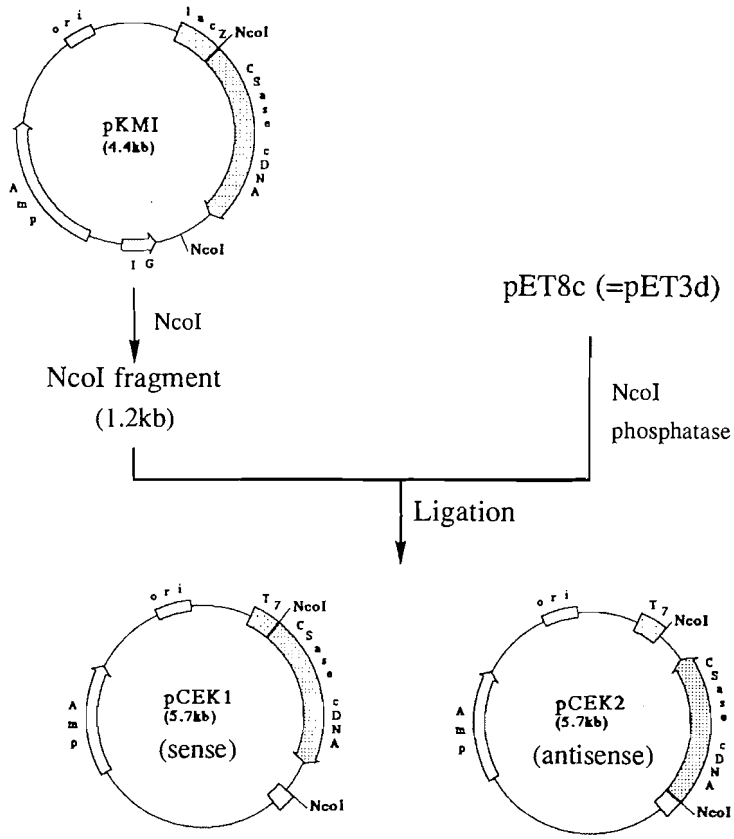

FIG. 2. Construction of a pET-derived vector for overexpression of CSase cDNA. The 1.2-kb *Nco*I fragment of pKM1 containing a full-length cDNA of spinach CSase A was ligated into phosphatase-treated *Nco*I site of pET8c (=pET3d) to afford overexpression vectors, pCEK1 and pCEK2, with sense and antisense orientations, respectively. In the 1.2-kb *Nco*I fragment, the first ATG codon was placed inside of 5′-*Nco*I restriction site. The *Nco*I fragment contained the 3′-untranslated region of 277 bp length including 22-bp poly(A) tail.

pyrazole did not result in the production of β-PA. These results suggested that the supply of OAS was strictly controlled in the *E. coli* cells; the metabolic flow from serine to OAS, however, could be enhanced to some extent by feeding of high concentration of serine. Any other transformants with pCEK2, pKM1, and a control plasmid, pTV118N, failed to produce a detectable amount of β-PA in vivo. This study is one of the first successful examples to show that a plant-specific product was biosynthesized in vivo by expression of cDNA for biosynthetic enzyme in heterologous cells.

Recently, we identified the functional Lys residue, responsible for the binding of pyridoxal phosphate cofactor, in deduced amino acid sequence of CSase A by site-directed mutagenesis experiments (10). By employing directed mutagenesis, it would be interesting to clarify the region determining substrate specificity, the tertiary enzyme structure responsible for the stereochemical course of the reaction, and the essential amino acid sites for protein–protein interaction of the complex of CSase and serine acetyltransferase for supply of OAS (11). The present investigation provides the experimental system for such further research into the biosynthetic enzymes of β-substituted alanines at the molecular genetic level and also represents the first example of production of a plant-specific metabolite by DNA strategy in *E. coli* cells.

Experimental section

Plasmid construction

General method of DNA engineering followed was that of Sambrook et al. (12). The expression plasmid, pKM1, was a derivative of pTV118N (Takara, Kyoto) and contained a full-length cDNA encoding CSase A isolated from *S. oleracea* (6) under the transcriptional control of *lacZ* promoter. The initial ATG codon was engineered to be placed inside of *Nco*I restriction site by oligonucleotide-directed mutagenesis. The *Nco*I fragment (1.2 kb) harboring the full-length cDNA was ligated by using a ligation kit (Takara, Kyoto) into the phosphatase-treated *Nco*I site of an expression vector pET8c (=pET3d) (8) to yield the overexpression vectors, pCEK1 and pCEK2, with sense and antisense orientations, respectively.

Culture of E. coli *transformants and expression of the cDNA*

A cysteine auxotrophic *E. coli* NK3 (Δ*trpE5 leu-6 thi hsdR hsdM*$^+$ *cysK cysM*) lacking endogenous CSase loci was transformed with pKM1. The overexpression vectors, pCEK1 and pCEK2, were transferred into *E. coli* BL21 (DE3, pLysE) in which lysogenic T7 RNA polymerase gene was placed under the *lacUV5* promoter for induction by IPTG. Transformed *E. coli* was precultured in LB medium (12) supplemented with carbenicillin (Cb) (100 mg/L) with continuous rotary shaking at 37°C for 3 h; IPTG (1 mM) was added to induce the expression and incubation was continued for 3 h.

Protein extraction and analysis by SDS–PAGE and Western blotting

Escherichia coli cells cultured in 10 mL LB-Cb medium were harvested by centrifugation at 1000 × *g* (3000 rpm, Hitachi RPR 20-2 rotor) for 15 min at 4°C. The pellet was suspended in 1 mL of homogenizing buffer (200 mM potassium phosphate (pH 8.0), 0.5 mM EDTA, 10 mM 2-mercaptoethanol, and 250 mM sucrose) and sonicated for 15 s, four times, at 100 W in an ice-water bath. The resulting solution was centrifuged at 15 000 g (11 000 rpm, RPR 20-2 rotor) for 15 min at 4°C. The supernatant was used as a soluble protein extract

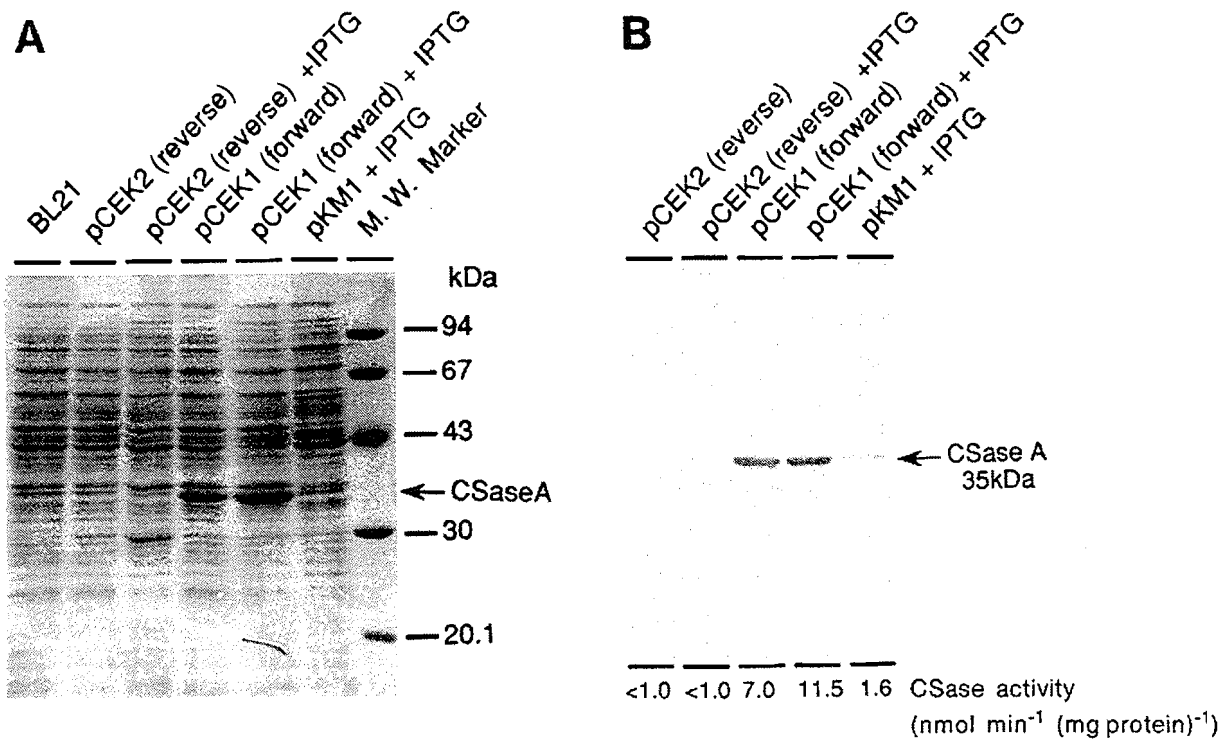

FIG. 3. (*A*) SDS–PAGE and Coomassie brilliant blue staining of the soluble protein in *E. coli* transformants. Twenty micrograms of total soluble proteins of (left to right) *E. coli* BL21 (DE3, pLysE), transformed BL21 (pCEK2), IPTG-induced BL21 (pCEK2), transformed BL21 (pCEK1), IPTG-induced BL21 (pCEK1), IPTG-induced *E. coli* NK3 transformed with pKM1, and the molecular weight marker (Pharmacia) were separated in 12% acrylamide gel (14). Proteins were stained with the blue dye. (*B*) Wester blot analysis and assay of CSase activity in *E. coli* transformants. The total soluble proteins (2.5 μg) of (left to right) *E. coli* BL21 (pCEK2), IPTG-induced BL21 (pCEK2), BL21 (pCEK1), IPTG-induced BL21 (pCEK1), and IPTG-induced *E. coli* NK3 (pKM1) were separated in 12% SDS–PAGE and transblotted onto a Nylon filter (Immobilon P, Millipore). Immunoreactive proteins against rabbit anti-CSase A were visualized by peroxidase staining using 3,3′-dimethylaminobenzidine as a developer. Enzymatic activity of CSase in the soluble protein extracts was determined as described in the experimental section.

TABLE 2. Formation of β-PA in vitro by the protein extracts of *E. coli* transformants from OAS and pyrazole

Plasmid/host *E. coli*	β-PA formation (nmol min^{-1} (mg $protein^{-1}$))
pCEK1/BL21 (DE3, pLysE)	89.0±12
pCEK2/BL21 (DE3, pLysE)	2.9±0.5
pKM1/NK3	8.6±1.5
pTV118N/NK3	Not detectable

for SDS–PAGE, Western blotting, and enzymatic assay. Protein was determined by the method of Bradford (13).

SDS–PAGE was carried out in 12% acrylamide gel by the standard method of Laemmli (14). The molecular weight marker kit (Pharmacia) was used for calibration. Protein was stained with Coomassie brilliant blue dye using a "Quick CBB" kit supplied by Wako (Kyoto).

For Western blot analysis, proteins separated by SDS–PAGE were electrochemically transferred onto Immobilon P membrane (Millipore) with a semidry transblot apparatus (Atto, Tokyo). Proteins blotted onto the membrane were reacted with rabbit antiserum raised against purified CSase A from spinach with 1:1000 dilution. The immunoreactive proteins were visualized by peroxidase staining using 3,3′-diaminobenzidine as a developer as reported previously (15).

In vitro assay for the formation of cysteine and β-PA

The reaction mixture contained 50 mM potassium phosphate (pH 8.0), 6.25 mM OAS, 5 mM H_2S or 50 mM pyrazole, and enzyme preparation corresponding to 2–50 μg of protein in a final volume 0.5 mL. Incubation was carried out at 30°C for 10–30 min.

For the assay of cysteine formation, reaction was terminated with the addition of 0.1 mL of 7.5% trichloroacetic acid and treated with acid ninhydrin reagent at 100°C for 10 min. The absorption was measured at 560 nm in the resulting solution due to cysteine–ninhydrin adduct.

For the assay of β-PA formation, the reaction mixture was acidified with 1 N HCl and filtered through a 0.45-μm membrane filter. The concentration of β-PA was determined with an automatic amino acid analyzer (Hitachi 835-10) using standard operating conditions as described (3).

Biosynthesis of β-PA in vivo of E. coli *culture*

After *E. coli* was precultured in 10 mL LB-Cb medium for 1.5 h at 37°C, IPTG (1 mM), serine (50 mM), and pyrazole (50 mM) were added in the culture medium and incubation was continued. An aliquot of 1 mL was taken every hour from the mixture and was centrifuged at 1000 × *g* for 15 min to separate cells and medium. The cells were broken by sonication, and the resulting solution was acidified by HCl and filtered. The concentration of β-PA in the cells was determined by an automatic amino acid analyzer as reported (3).

Lupin alkaloids 6. Stereochemistry of bis-quinolizidine alkaloids with γ-oxo-α,β-enamine system

TADEUSZ BRUKWICKI, WALERIA WYSOCKA,[1] AND BARBARA NOWAK-WYDRA
Faculty of Chemistry, A.Mickiewicz University, Grunwaldzka 6, PL 60-780 Poznań, Poland

Received May 26, 1993

This paper is dedicated to Professor Ian D. Spenser

TADEUSZ BRUKWICKI, WALERIA WYSOCKA, and BARBARA NOWAK-WYDRA. Can. J. Chem. **72**, 193 (1994).

^{1}H NMR, ^{1}H,^{1}H and ^{1}H,^{13}C COSY, and 2D *J*-resolved spectra of multiflorine (**1**) and 13α-hydroxymultiflorine (**2**) in $CDCl_3$ were taken. Some erroneously determined chemical shifts in **1** were corrected and for the first time signals in **2** were assigned. Most of the coupling constants in **1** and **2** were established. A coupling constant of H7–H17β and chemical shifts for H17β, C14, and C8 were used to define the conformational equilibrium of boat or chair forms in the C rings, in **1** and **2** in solution. The results obtained confirm the previous findings based on chemical shifts of C12: ca. 75 and 70% of the "boat" conformer in **1** and **2**, respectively, at room temperature. Of all the criteria used, the H7–H17β coupling constant seems to be least sensitive to the influence of substituents at rings A and D. From the Haasnoot equation, torsion angles of HCCH in regions of molecular geometry featuring low sensitivity to conformational changes were calculated. The hydroxyl group at position 13α has a slight influence on the geometry of ring D.

TADEUSZ BRUKWICKI, WALERIA WYSOCKA et BARBARA NOWAK-WYDRA. Can. J. Chem. **72**, 193 (1994).

On a enregistré les spectres de RMN du ^{1}H, les spectres COSY du ^{1}H,^{1}H et ^{1}H,^{13}C et les spectres résolus de *J* en 2-D de la multiflorine (**1**) et de la 13α-hydroxymultiflorine (**2**) dans le $CDCl_3$. On a corrigé quelques déplacements chimiques du composé **1** qui comportaient des erreurs et on a, pour la première fois identifié les signaux du composé **2**. On a établi la plupart des constantes de couplage des composés **1** et **2**. On a utilisé une constante de couplage de H7–H17β, des déplacements chimiques de H17β et de C14 et de C8 pour définir l'équilibre conformationnelle des formes bateau ou chaise des cycles C dans les composés **1** et **2** en solution. Les résultats obtenus confirment les premières observations basées sur les déplacements chimiques du C12 : environ 75 et 70% de conformère «bateau» dans les composés **1** et **2** respectivement, à la température de la pièce. De tous les critères utilisés, la constante de couplage H7–H17β semble être la moins sensible à l'influence des substituants sur les cycles A et D. On a calculé, à partir de l'équation de Haasnoot, les angles de torsion HCCH dans les régions de géométrie moléculaire caractérisant la faible sensibilité aux changements conformationnels. Le groupe hydroxy en position 13α a une légère influence sur la géométrie du cycle D.

[Traduit par la rédaction]

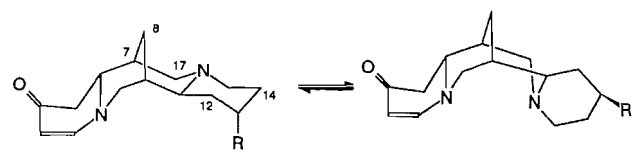
Introduction

We recently published the ^{13}C NMR spectra of multiflorine (**1**) and 13α-hydroxymultiflorine (**2**), alkaloids of *Lupinus albus* that have a labile *trans-cis* bis-quinolizidine skeleton and contain a γ-oxo-α,β-enamine system in ring A (1). According to these spectra, compounds **1** and **2** proved to exist in a conformational equilibrium of forms differing in the conformation of ring C (Fig. 1). This was the first attempt at quantitative analysis of a conformational equilibrium in bis-quinolizidine alkaloids.

In this paper, we have extended our studies on the equilibrium by applying ^{1}H NMR spectroscopy. We have assumed that in the bis-quinolizidine systems conformational changes affect primarily the coupling constants H7–H17β and chemical shifts of H17β, which directly reflect changes in the conformation of ring C. Thus their application would allow us not only to verify the data obtained by ^{13}C NMR, but also to facilitate (or even in some cases make possible) the calculation of contributions of particular conformers in compounds whose substituents at ring D or in its vicinity induce changes in the chemical shifts of C12 and C14, or in some three-ring compounds.

Determination of coupling constants would enable us also to examine the effect of the 13α-hydroxyl group on the ^{1}H NMR spectrum, as well as to determine the geometry of those fragments of the molecules which do not differ significantly in their structure in the two basic conformers of **1** and **2**. To this end, a modified version of the Karplus equation can be used (3).

^{1}H NMR chemical shifts of **1** have been recently published by Takamatsu et al. (4). However, we found some of their assignments to be erroneous, and thus decided to carry out our own investigation.



1, R = H; **2**, R = OH

FIG. 1. Conformational equilibrium in multiflorine (**1**) and 13α-hydroxymultiflorine (**2**).

Results

Complete assignment of the ^{1}H NMR signals of multiflorine (**1**) and 13α-hydroxymultiflorine (**2**) has been achieved (Table 1) by the analysis of HOMO or HETERO COSY (^{1}H,^{1}H and ^{13}C,^{1}H respectively) and 2D *J*-resolved spectra as well as by a thorough analysis of the integration of the 1.2–1.9 ppm fragment.

Inaccuracies in Takamatsu's results (4) derive partly from inappropriate differentiation between some α and β protons. It is obvious that the pseudotriplets at 2.68 ppm clearly observed in the spectrum may come only from an axial H5α, which has two large coupling constants of a similar value (geminal and axial–axial), and not from H5β, as was given in ref. 4.[2] A more

FIG. 2. High-field fragment of ^{1}H, ^{13}C heteronuclear shift correlation (HETCOR) spectrum of multiflorine (**1**).

complex issue is the assignment of signals of protons at C12 and C14. We have taken more precise spectra only for the controversial range concerned. As follows from the ^{1}H,^{13}C COSY spectrum of fragments 22–40 ppm / 1.2–3.5 ppm (Fig. 2), signals of all protons at C12 and C14 are localized close to each other, with those at C12 slightly upfield. A similar conclusion can be drawn from analysis of the ^{1}H,^{1}H COSY spectrum (Fig. 3): the group of cross-peaks attributed to both H12 coupled with H11 is localized slightly upfield of the groups of cross-peaks attributed to both H14 coupled with H15eq and H15ax. More information is provided by an appropriate fragment of the 2D *J*-resolved spectrum (Fig. 4). It clearly exhibits two axial signals of three large coupling constants: at 1.58 ppm and at 1.51 ppm. A sum of the coupling constants for the signals at 1.58 ppm is 46 Hz, which is in agreement with that expected for H14ax, while that for the signal at 1.51 ppm is only 39.6 Hz, which agrees with the fact that H12ax has one less vicinal coupling. The sum of the coupling constants for the signal at 1.49 ppm is 30 Hz, which is rather large for an equatorial proton yet acceptable for H14eq, which has one geminal, two equatorial–equatorial, two

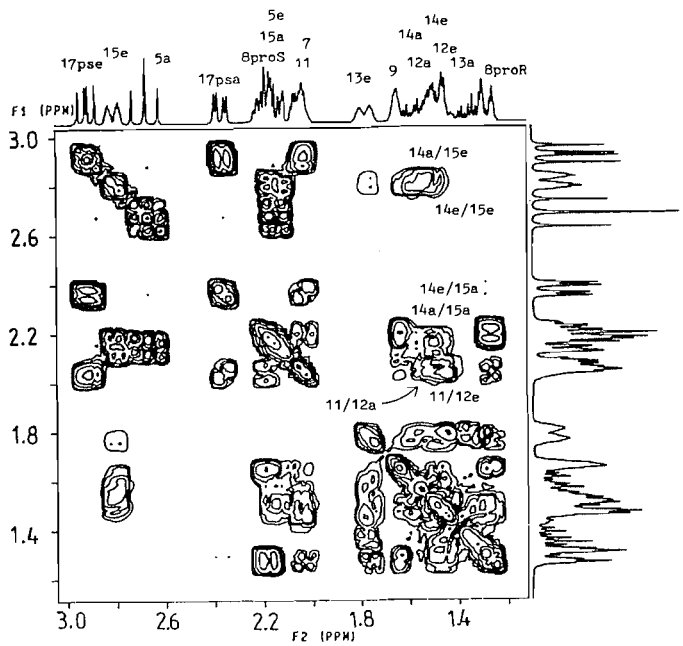

FIG. 3. The 1.2–3.0 ppm fragment of the COSY-45 spectrum of multiflorine (**1**).

equatorial–axial, and one long-range coupling of the W type. The signal of H12eq has one less equatorial–equatorial coupling. Scrutiny of the integration in the 1D NMR spectrum within the 1.2–1.85 ppm fragment allows us to assign the low-intensive and less well-developed signal at 1.46 ppm in the 2D *J*-resolved spectrum to H12eq. Unfortunately, we cannot determine the values of the coupling constants for this proton, probably because its signal is not first order.

In conclusion, contrary to Takamatsu's findings (4), we do not see the second signal in the 1.58–1.60 ppm region, yet we can see two signals within the range 1.50–1.45 ppm; as well, we arrange the axial and equatorial signals differently, as presented in Table 2.

Analogously, on the basis of the results of HOMO and HETERO COSY ($^1H,^1H$ and $^{13}C,^1H$, respectively) and 2D *J*-resolved spectra, we have assigned the ^1H NMR spectrum of 13α-hydroxymultiflorine (**2**). Values of the chemical shifts are given in Table 1.

In both compounds considered, the $^1H,^1H$ coupling constants were in part determined directly from 1D ^1H NMR or from 2D *J*-resolved spectra. In some cases we relied on the spectrum of multiflorine in another solvent (benzene[3]). Some of the *J*-constants are not, however, first order. Although they are mostly geminal, they can also affect the vicinal ones. The coupling constants determined for multiflorine are given in Table 3 (with the appropriate notes), and those for 13α-hydroxymultiflorine in Table 4.

Discussion

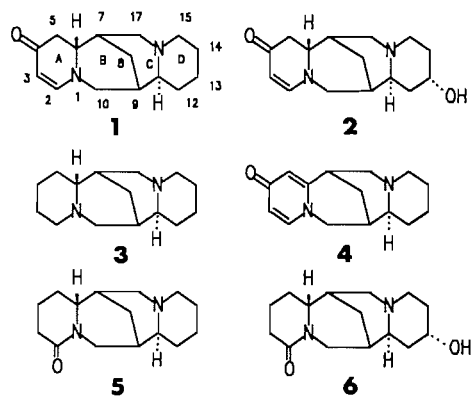
Conformational equilibrium

Bis-quinolizidine alkaloids with a sparteine skeleton (**3**) may assume one of two conformations, which differ in the form of ring C: in the boat **b** and the chair **c**. Usually, compounds exist as mixtures of both conformers. Compounds whose structure resembles the structure of those studied and in which the equilibrium is clearly shifted towards one of the forms may serve as models of the pure conformers (2). In sparteine, almost 100% of the molecules adopt the **3b** conformation, whereas 5,6-didehydromultiflorine (**4**) was used as a model compound for a chair conformer. In our previous paper, a comparison of the chemical shifts of C12 indicated that **1** and **2** assume 74 and 67% of a boat conformer, respectively. We also discussed the reasons for such a proportion in the conformational equilibrium (1).

Now, ^1H NMR spectra supply us with new criteria for establishing conformational equilibrium: a coupling constant H7–H17β and a chemical shift of H17β. In sparteine, the coupling constant H7–H17β is 10.8 Hz (both in benzene solution (5) and in $CDCl_3$[4]), while in 5,6-didehydromultiflorine it is 2.7 Hz.[4] As follows from appropriate values found for **1** and **2** (Tables 3 and 4), the contribution of the boat conformer in mixtures of the two conformers both in **1** and **2** is equal to 75 and 70%, respectively.

In chloroform solution, the chemical shifts of sparteine and 5,6-didehydromultiflorine were found to be 2.70 and 3.36 ppm, respectively. Following Eliel's method (2*b*) and applying appropriate values for **1** and **2** (Table 1), we determined the contribution of the boat form in multiflorine and 13α-hydroxymultiflorine to be 67 and 61%, respectively. The reason why these values differ slightly from the others in Table 5 seems to be the shielding effect of ring A, in particular, in the model compound **4**. For the same reason, chemical shifts of C17, C11, and H11 cannot be of use in the determination of the conformational equilibrium in **1** and **2**.

The presently available $^1H,^{13}C$ COSY spectra enabled us to realize that previously we had erroneously assigned signals of C13 and C14 in multiflorine (1). (Correct data were recently published also by Mohamed et al. (6)). Thus, by applying a procedure identical to that in ref. 1, from the chemical shifts of C14 in **1** and **2** we calculated the contribution of the boat conformer: 70 and 68%, respectively. For C8, we obtained similar results: 70 and 69%, yet they may be affected by ring A. The percent contribution of the boat conformer in multiflorine (**1**) and in 13α-hydroxymultiflorine (2), determined via different methods, is shown in Table 5.



The similarity of values established by using different criteria (Table 5) testifies to the correctness of the applied method of determining the conformational equilibrium. The most reliable are the data obtained in cases where the chemical shift or cou-

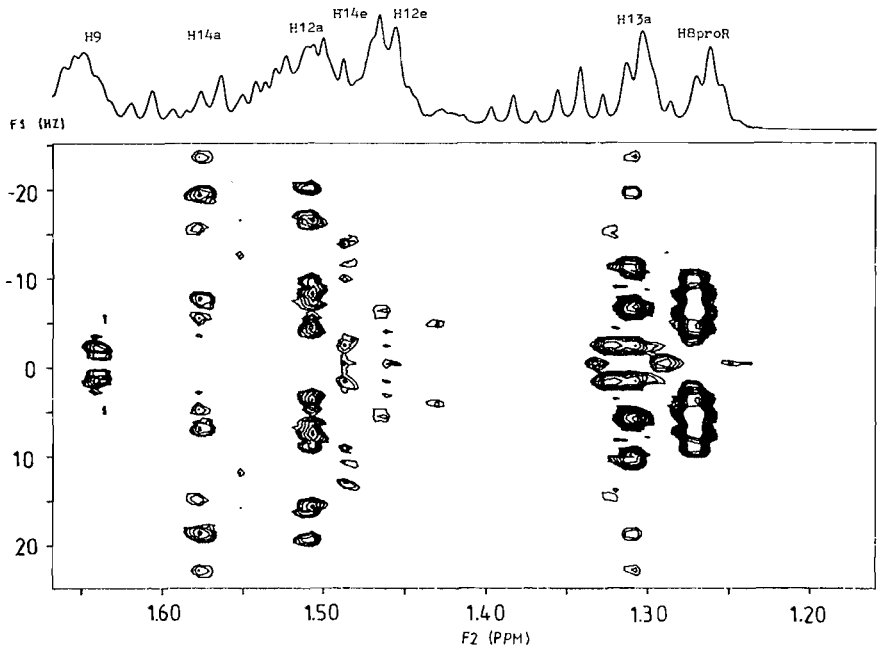

FIG. 4. High-field fragment of 2D *J*-resolved spectrum of multiflorine (**1**).

TABLE 2. Signals of the ^{1}H NMR spectra of multiflorine (**1**) whose assignment in the present paper differs from that in the paper by Takamatsu et al. (4)

Proton no.	Chemical shifts, ppm from TMS	
	According to Takamatsu	This paper
5α (ax)	2.16	2.68
5β (eq)	2.68	2.16
12α (eq)	1.58	1.46
12β (ax)	1.47	1.51
14α (eq)	1.60	1.49
14β (ax)	1.51	1.58

pling constant involved in a given criterion are not affected by any other factors except for the conformational change (or their influence is negligible), while the difference in the corresponding values in model compounds is rather significant. For both of the alkaloids studied, such a criterion is $J_{7-17\beta'}$ and for multiflorine also $\delta_{C(12)}$.

It should be noticed that in all the cases considered the population of the boat conformer in 13α-hydroxymultiflorine is slightly lower than in multiflorine, thus this result is by no means accidental. This can be accounted for by the contribution of a hydroxyl group in an intermolecular hydrogen bond, as we postulated earlier (1).

It is also worth mentioning that in the ^{1}H,^{1}H COSY spectrum of **1** and **2** a weak coupling of H8pro*R* with H17α occurs. Besides, the signal of H17α in the spectrum of **2** is coupled with one of the signals within the range in which the signals originating from protons 5α, 11, 15α, and 15β are observed. This coupling must be the one between H17α and H11. In the COSY spectrum of multiflorine such a coupling might be masked by the cross-peak H7/H17α, as in the 1D ^{1}H NMR spectrum the H11 signal overlaps the signal of H7. Such couplings can be explained best by the significant contribution of a "chair" conformer in which the H8pro*R* and H17α, as well as H11 and H17α, are coplanar.

Geometry of molecules

Table 6 lists torsion angles HCCH calculated for multiflorine (**1**) and 13α-hydroxymultiflorine (**2**) from the Haasnoot equation (3) and X-ray diffraction data for **1** (7), lupanine (**5**) (8), and 13α-hydroxylupanine (**6**) (10) with the typical geometry of methylene groups taken into account (11). In the case of some angles, in particular those that belong to rings B and D in **1** and **2**, agreement between results obtained via the two methods is satisfactory. Some of the observed discrepancies may be due to difficulty in determination of the coupling constant.

The reason why the value of the H5βC5C6H6 angle is smaller than expected is that in the Haasnoot equation for three substituents the effect of the neighboring carbonyl oxygen has not been taken into account. The other discrepancies may be explained by the presence of the conformational equilibrium. Especially large is the difference in the value of the H7C7C17H17β angle calculated by either NMR or X-ray methods and it made us apply $J_{7-17\beta}$ to determine the conformational equilibrium. Conformational changes also exert a slight influence on coupling constants involving the two H8 (more on those from flagpole H8pro*S*) and H11.

Unfortunately, we do not have a good set of model compounds, whose structures would be resolved by X-ray studies, to be applied in examining the influence of the axial hydroxyl group on the geometry of ring D. Rings B, C, and D in compounds **1** and **2** have structures quite similar to those in lupanine (**5**) and 13α-hydroxylupanine (**6**). Lupanine has a boat conformation of ring C both in the solid (8) and in solution (9) (more precisely, the conformational equilibrium in solution is heavily shifted towards conformer **5b**; cf. ref. 1, footnote b), whereas 13α-hydroxylupanine (as well as **2** (1)) as a solid has a chair conformation of ring C (11), and in solution the conformational equilibrium in **6** is clearly shifted towards the dominance of a boat conformation (9). However, in both conformers of **6** the

value of the HCCH torsion angles in the C12C13C14 region should not be much different, as suggested by a similarity of values for the corresponding torsion angles determined from X-ray diffraction for **5** and **6** (8, 10) for a geometry typical of the methylene group (11) (Table 6). Not all HCCH torsion angles in **1** and **2** were satisfactorily determined from NMR spectra, yet the data compiled in Table 6 indicate a surprising agreement between the torsion angles involving protons at C12, C13, and C14 determined via NMR for **2** and those established from X-ray diffraction for **1**. It can be observed therefore that in **2** the axial hydroxyl group only slightly affects the geometry of the nearest surroundings.

In contrast, an α-hydroxyl group exerts a significant effect on the chemical shift of protons in ring D (Table 1). This effect is similar to that resulting from a comparison of 5α,17α-pregnan-2-one with its 3α,6α-dihydroxy derivative (12): α, 2.48 ppm; β-ax, 0.27 ppm; β-eq, 0.09 ppm; γ-ax, 0.47 ppm; and γ-eq, −0.28 ppm. This effect in **1** and **2** testifies to a similar conformation of both these compounds. It is worth stressing that chemical shifts of protons H12 and H14 proposed by Takamatsu et al. (4) show a worse agreement between the effect of the hydroxyl group in **2** and that observed in the above mentioned steroid compounds.

Conclusions

1. All ^{1}H chemical shifts and most coupling constants in multiflorine and 13α-hydroxymultiflorine were determined.

2. Precise analysis of ^{1}H NMR (coupling constants and inte-

TABLE 5. Percent of the "boat" conformer in multiflorine (**1**) and 13α-hydroxymultiflorine (**2**) in ca. 5% solution in $CDCl_3$ at room temperature

Method	Criterion	Multiflorine (**1**)	13α-Hydroxymultiflorine (**2**)
^{1}H NMR	$J_{7-17\beta}$	75	70
	$\delta_{H(17\beta)}$	67	61
^{13}C NMR	$\delta_{C(12)}$(1)	74	67
	$\delta_{C(14)}$	70	68
	$\delta_{C(8)}$	70	69

gration), ^{1}H,^{1}H and ^{1}H,^{13}C COSY, 2D *J*-resolved spectra, and the effect of the axial hydroxyl group enabled us to correct the assignment of signals of the 5α, 5β, 12α, 12β, 14α, and 14β protons proposed by Takamatsu et al. (4).

3. The method of studying the conformational equilibrium was extended to include the coupling constant H7–H17β and chemical shift of H17β in the ^{1}H NMR spectrum. In the case of **2**, these new criteria allow us to avoid the application of a correction for the effect of hydroxyl group necessary in the previously published method (1). Likewise, the method of quantitative determination of the equilibrium was extended by some new criteria using the ^{13}C NMR spectra.

4. All the applied criteria give comparable results. Slightly lower values for the population of the boat conformer when a chemical shift of H17β is the considered criterion are caused by the effect of ring A.

5. Torsion angles in **1** calculated from the Haasnoot equation (3) for molecules in solution in the region with geometry slightly sensitive to conformational changes are close to the corresponding angles in the solid determined by X-ray studies.

6. HCCH torsion angles calculated from the Haasnoot equation for 13α-hydroxymultiflorine in solution are in agreement with those in multiflorine. The axial hydroxyl group does not significantly affect the geometry of ring D.

Experimental

Multiflorine (**1**) and 13α-hydroxymultiflorine (**2**) were isolated from *Lupinus albus* seeds (cv. BAC) (13, 14).

[d]Angles involving the OH group.

All NMR spectra were recorded at ambient temperature on a Varian Gemini 300 spectrometer operating at 300.075 and 75.462 MHz for ^1H and ^{13}C, respectively. The spectra were obtained in $CDCl_3$ and chemical shifts were referenced to internal TMS for ^1H data and $CDCl_3$ for ^{13}C data ($\delta_C(^{13}CDCl_3) = 77.0$).

The 2D $^1H,^1H$ COSY, the $^1H,^{13}C$ COSY (HETCOR), and 2D homonuclear ^1H *J*-resolved NMR spectra were obtained using standard Varian programs.

The accuracy of coupling constant measurements from 2D *J*-resolved spectra is estimated as ±0.6 Hz.

Earlier work in this laboratory has shown the intact incorporation of [1-^{13}C]hexanoate into averufin (**1**), a key intermediate in aflatoxin B_1 biosynthesis. Parallel experiments with equimolar amounts of [1-^{13}C]butyrate, [1-^{13}C]-3-oxo-octanoate, and [1-^{13}C]-5-oxo-hexanoate gave no detectable specific incorporation of heavy isotope but low and equivalent background incorporation comparable to [1-^{13}C]acetate. Three of these potential intermediates in polyketide formation were reexamined as their corresponding *N*-acetylcysteamine (NAC) thioesters. The NAC thioester of [1-^{13}C]hexanoic acid gave a remarkably high 22% intact incorporation while the NAC thioester of [1-^{13}C]-3-oxo-octanoic acid afforded nearly 5% when an equimolar amount was administered to the producing organism *Aspergillus parasiticus* (ATCC 24551). In contrast, the NAC thioester of [1-^{13}C]butyric acid showed no selective enrichment of averufin. This negative result was tested further in a more sensitive experiment with the NAC thioester of [2,3-$^{13}C_2$]butyric acid. No $^1J_{CC}$ coupling was detectable, indicating an incorporation efficiency of <0.1%. [1-^{13}C,$^{18}O_2$]Hexanoate was prepared and gave a 53% retention of ^{18}O relative to the ^{13}C internal standard in keeping with previous experiments with [1-^{13}C,$^{18}O_2$]acetate. It is concluded from these data that the initial C_6 segment of polyketide biosynthesis is unlikely to arise by β-oxidation of a higher fatty acid but more probably is generated by a specialized fatty acid synthase (FAS) that provides this unit either separately to the polyketide synthase (PKS) or as part of a larger FAS/PKS fusion. While these two physical arrangements cannot be distinguished by these experiments, both must accommodate comparatively efficient exchange of the NAC thioesters of both hexanoic and 3-oxo-octanoic acid, but not the NAC thioester of butyric acid.

SUSAN W. BROBST et CRAIG A. TOWNSEND. Can. J. Chem. **72**, 200 (1994).

Des travaux antérieurs effectués dans notre laboratoire ont démontré que le [1-^{13}C]hexanoate s'incorpore d'une façon intacte dans l'avérufine (**1**), un intermédiaire clé dans la biosynthèse de l'aflatoxine B_1. Des expériences parallèles avec des quantités équimoléculaires de [1-^{13}C]butyrate, de [1-^{13}C]-oxo-octanoate et de [1-^{13}C]-5-oxo-hexanoate n'ont pas permis de détecter d'incorporation spécifique de l'isotope lourd; seulement des incorporations faibles, équivalentes au bruit de fond, comparables à celle du [1-^{13}C]acétate. On a réexaminé trois de ces intermédiaires potentiels dans la formation du polycétides sous la forme de thioesters de la *N*-acétylcystéamine (NAC). Lorsqu'on administre des quantités équimoléculaires à l'organisme *Aspergillus parasiticus* (ATCC 24551) qui les produit, le thioester de la NAC de l'acide [1-^{13}C]hexanoïque conduit à une incorporation intacte étonnante de 22% alors que le thioester de la NAC de l'acide [1-^{13}C]-3-oxo-octanoïque en fournit environ 5%. Par opposition, le thioester de la NAC de l'acide [1-^{13}C]butyrique ne présente pas d'enrichissement sélectif de l'avérufine. On a évalué ce résultat négatif plus à fond à l'aide d'une expérience sensible impliquant le thioester de la NAC de l'acide [2,3-$^{13}C_2$]butyrique. On n'a pas observé de couplage $^1J_{CC}$; ce résultat indique que l'efficacité de l'incorporation est inférieure à 0,1%. On a préparé du [1-^{13}C,$^{18}O_2$]hexanoate et il conduit à une rétention de 53% du ^{18}O par rapport au ^{13}C agissant comme référence interne; ce résultat est en accord avec les expériences antérieures avec du [1-^{13}C,$^{18}O_2$]acétate. Sur la base de ces données on conclut que le segment initial en C_6 de la synthèse du polycétide ne provient probablement pas d'une oxydation β d'un acide gras de poids moléculaire plus élevé, mais qu'il est vraisemblablement généré par une synthase d'acide gras spécialisée (FAS) qui fournit cette unité soit d'une façon séparée par rapport à la synthase de polycétide (PKS) ou dans le cadre d'une fusion plus large FAS/PKS. Alors que l'on ne peut pas distinguer entre ces deux arrangements physiques sur la base des expériences réalisées, les deux doivent toutefois accommoder un échange efficace des thioesters de la NAC des acides tant hexanoïque que 3-oxo-octanoïque, mais pas de l'acide butyrique.

[Traduit par la rédaction]

In 1982 we made the unexpected and intriguing observation that [1-^{13}C]hexanoate incorporated label intact into averufin (**1**), a central intermediate in the biosynthesis of the potent mycotoxin aflatoxin B_1 (**2**). The efficiency of linear fatty acid utilization in these whole-cell experiments was 3–4% at C-1′. The specific incorporation was seen in a background of ca. 0.5% at all carboxyl-derived carbons throughout the molecule. This nonspecific labeling is due to β-oxidation of the hexanoate to [1-^{13}C]acetyl CoA and secondary incorporation of the latter in accord with the conventional view of polyketide biosynthesis (1). This experiment was followed by a series under the same experimental conditions in which *equimolar* amounts of [1-^{13}C]butyrate, [1-^{13}C]-5-oxo-hexanoate, and [1-^{13}C]-3-oxo-octanoate were tested. In each instance no intact incorporation of these potential substrates could be detected by ^{13}C{^{1}H}NMR spectroscopy. Only degradation to [1-^{13}C]acetyl CoA was seen and secondary incorporation of heavy isotope as above, comparable to that observed from [1-^{13}C]acetate itself (2).

While in bacteria and plants polyketide starter units have been demonstrated from low molecular weight branched acids (derived from transamination and oxidative decarboxylation of the homologous amino acids (see for example ref. 3)) and propionate (4), exceptions are few to the general observation that "extra" carbon atoms in fungal polyketides are derived from methionine (5). The classic exception to this general rule is the perturbation of orsellinic acid biosynthesis in *Penicillin baarnense* reported by Mosbach in which added propionate gave rise to the appearance of homoorsellinate (6). Similarly, Steyn's group determined that the C_3 primer of aurovertin B (7) and

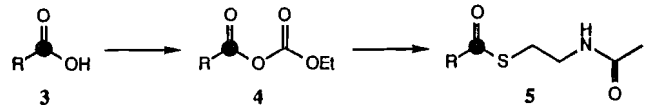
SCHEME 1

asteltoxin (8) can arise either by direct incorporation of propionate or by the net utilization of acetate and a C_1 unit from methionine.

The suggestion that fatty acids could initiate polyketide biosynthesis was made by Birch more than 30 years ago (9). Yet, apart from two examples that can be recalled from plants (butyrate into margaspidin (10) and octanoate into coniine (11)), failed incorporations of fatty acids, when reported, have been the general rule (see for example ref. 12). The utilization of hexanoate in the biosynthesis of the fungal metabolite averufin, therefore, was an important experimental step forward in the understanding of polyketide biosynthesis. Report of these results (1, 2) was soon followed by the incorporation of acetoacetate into nonactin (13) and octanoate into the chain-terminating unit of fungichromin (14). Successes, however, were limited. Attempts to demonstrate the intact incorporation of free acids derived from linking together of two or three ketide units into macrolides, polyethers, and other secondary metabolites were completely unsuccessful (15, 16). The earlier, crucial finding of Lynen (17) that *N*-acetylcysteamine (NAC) thioesters could substitute for the corresponding CoA thioesters to load biosynthetic intermediates onto fatty acid synthase (FAS) was recalled at this time by the NMR studies of Schwab et al. (18) examining the inhibition of β-hydroxydecanoylthioester dehydrase by the NAC thioester of 3-decynoic acid (19). Testing of potential polyketide intermediates as their NAC thioesters (15, 16) came as a methodological breakthrough that has since been successfully applied in a number of systems and has experimentally secured the central idea of processivity in polyketide chain elongation (see for example ref. 20).

Questions remained, however, from our first experiments. Why was butyrate not detectably incorporated if hexanoate gave a readily observable enrichment? Should one expect that 3-oxo-octanoate, derived by the addition of the first clearly polyketide C_2 unit to a saturated primer, might be successfully incorporated? It could be the case that both of these putative intermediates were utilized but at such low levels that they could not be experimentally detected above natural abundance by single-site ^{13}C-labeling methods. In the hope of achieving greater sensitivity in these experiments, a series of NAC thioesters were prepared and examined for their incorporation into averufin.

The mixed anhydride method of Kass and Brock (21) using freshly prepared *N*-acetylcysteamine (22) gave the NAC thioesters of [1-^{13}]butyric acid and [1-^{13}C]hexanoic acid in 70–80% yields. This approach is summarized in Scheme 2. [2,3-$^{13}C_2$]Butyric acid was prepared by reaction of the dianion of [2-^{13}C]acetic acid and [1-^{13}C]iodoethane in the presence of added HMPA (23). [1-^{13}C]Hexanoic acid was synthesized according to the protocol of Cane et al. from 1-iodopentane and K^{13}CN (24). The yields of the latter two acids were greater than 80%.



3 4 5

SCHEME 2

Benzyl [1-^{13}C]acetate (25) was treated with lithium hexamethyldisilazide followed by hexanoyl chloride to give the β-ketoester **7** (R = CH_2Ph) in 77% yield. Hydrogenolysis proceeded smoothly to afford the known acid **7** (R = H) (26). Not unexpectedly, thioesterification using the method of Kass and Brock (21) did not take place owing presumably to the self-condensation of the mixed anhydride **4** under the reaction conditions. Literature precedent (27) notwithstanding, attention was turned toward DCC-activated coupling in the presence of 4-dimethylaminopyridine (28). The NAC thioester **8** of 3-oxo-octanoic acid was obtained in about 70% yield as a crystalline solid.

The NAC thioesters of [1-^{13}C]acetic acid, [1-^{13}C]butyric acid, [1-^{13}C]hexanoic acid, and [1-^{13}C]-3-oxo-octanoic acid were administered in equimolar amounts to cell suspensions of *Aspergillus parasiticus* under carefully controlled conditions as was done earlier with the carboxylic acids (1, 2). Freshly prepared mycelial pellets were weighed into 12 250-mL Erlenmeyer flasks (10 g per flask) containing 100 mL of a replacement medium (29). The ^{13}C-labeled thioesters were

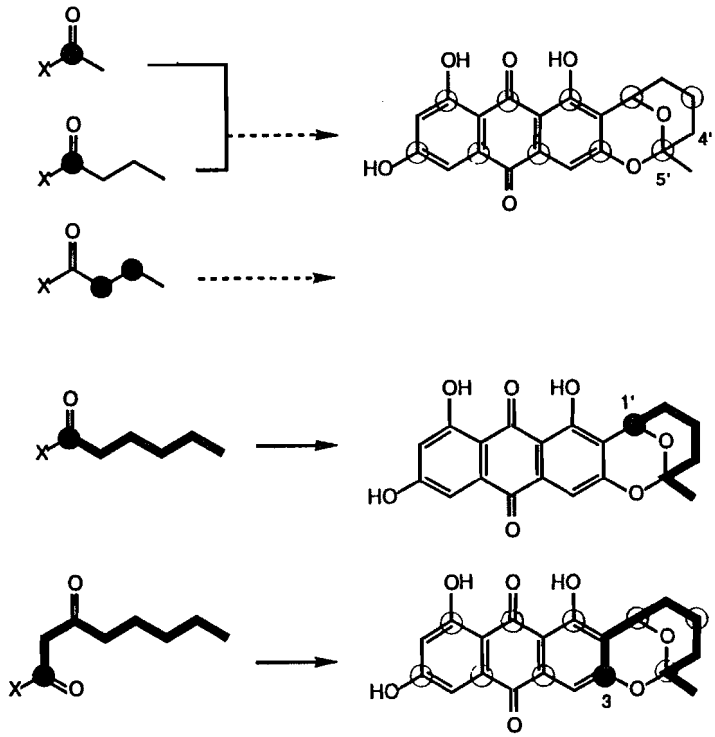
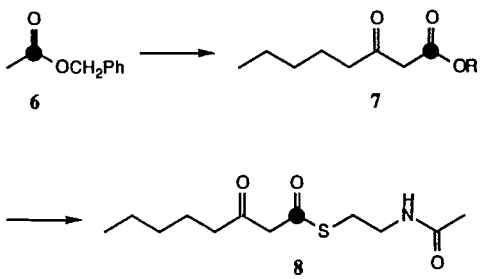
TABLE 1. Incorporation of ^{13}C-labeled carboxylic acids (X = OH) and their corresponding *N*-acetylcysteamine thioesters (X = NAC) into averufin by mycelial suspensions of *A. parasiticus* (ATCC 24551)





SCHEME 3

apportioned equally among the shaken cultures in acetone solution and, after 48 h, the averufin produced was isolated and purified for $^{13}C\{^1H\}$NMR analysis. The results from the free acids and corresponding NAC thioesters are shown in Table 1.

The sites and levels of isotopic enrichment were determined by comparison to averaged signal intensities at natural abundance. The results were striking in their clarity. [1-^{13}C]-Hexanoate, which as its free acid had given a 3–4% incorporation, as its NAC thioester gave a remarkably high 22% specific incorporation superimposed once again on a ca. 0.5% secondary incorporation from [1-^{13}C]acetyl CoA. [1-^{13}C]-3-Oxo-octanoate, which previously had given no detectable incorporation as its free acid, now showed a 4.7 ± 0.7% enhancement of the resonance for C-3 (30) within the anthraquinone nucleus of averufin when incorporated as its NAC thioester. While substantially lower in efficiency than the NAC thioester of [1-^{13}C]hexanoic acid, this result suggested successful linking of the apparent aliphatic starter with the first C_2 unit at the keto oxidation state. In contrast, the NAC thioester of [1-^{13}C]butyric acid showed no convincing enrichment of the averufin side chain. More sensitive analysis using the NAC thioester of [2,3-$^{13}C_2$]butyric acid revealed no intact incorporation of a C_4 unit measurable as $^1J_{CC}$ coupling between C-4′ and C-5′. The detection limit of this analysis correlated to an incorporation rate of <0.1% given the high signal/noise ratio of the NMR spectrum obtained. Therefore, apart from the intact incorporations shown by the labeled NAC thioesters of hexanoic acid and 3-oxo-octanoic acid, *all* of the tested substrates gave low extents of enrichment comparable to those from [1-^{13}C]acetate or its NAC thioester at carboxyl-derived centers throughout averufin.

Based on these observations, several conclusions can be drawn about the first steps of aflatoxin biosynthesis. First, it could be supposed that a 1,3,6,8-tetrahydroxyanthraquinone **9**, a known natural product from a related *Aspergillus* (31), and a C_6 fatty acid/CoA ester **10** are separately generated and joined to form norsolorinic acid (**11**, Scheme 4), the first anthraquinone intermediate of aflatoxin biosynthesis (32). This possibility can be eliminated on symmetry grounds. Thus, while **9** is symmetrical, its labeling pattern from [1,2-$^{13}C_2$]acetate in **11** is not (30, 33). A Friedel–Crafts-like reaction of this sort is unprecedented in natural product biosynthesis and, if it were to occur, it would require condensation in a non-random manner on the synthase-bound anthraquinone prior to its release from the protein. Owing as well to the inherently poor reactivity of anthraquinones to electrophilic addition, this possibility seems highly unlikely. Moreover, it would not accommodate the specific incorporation of the NAC thioester of [1-^{13}C]-3-oxo-octanoic acid.

Second, it could be visualized that a polyketide synthase (PKS) responsible for assembling norsolorinic acid (**11**) may selectively and with high affinity bind hexanoyl CoA arising

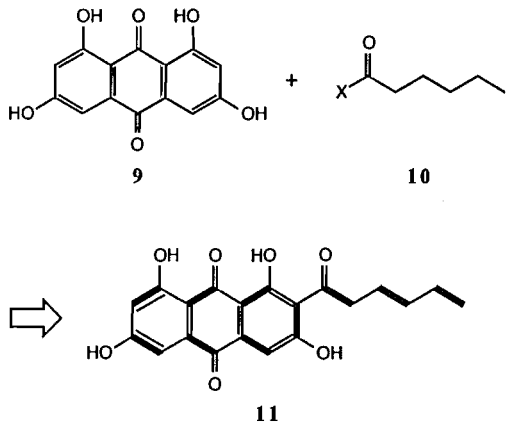
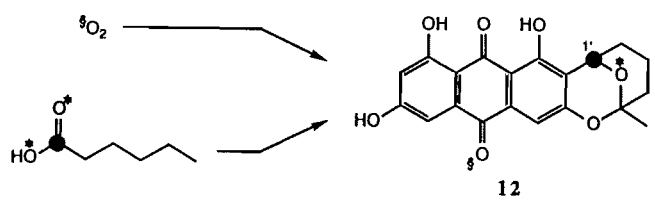


SCHEME 4

from normal fatty acid degradation (2). This possibility is probably not likely. [1-^{13}C,$^{18}O_2$]Acetate was incorporated into averufin and shown to label every oxygen except that at C-10, which was derived from molecular oxygen ($O^{\S}$, Scheme 5) (34). Some exchange of acetate-bound oxygen isotope was observed, as is commonly the case in experiments of this sort, to give an incorporation of 40% at C-1′, that carbon corresponding to C-1 of a potential hexanoyl starter. While 60% of the oxygen at this ^{13}C-labeled site was not accounted for in this experiment, the comparable levels of heavy isotope uptake at this and other sites in averufin suggest that β-oxidation cannot be the source of the first six carbons. Oxygen incorporation through this latter mechanism would be from the aqueous medium, not from acetate. Moreover, given the efficiency with which the NAC thioester of hexanoic acid is incorporated when supplied exogenously, it seems unlikely that hexanoyl CoA ester produced intracellularly could not compete with the already poor incorporation of administered labeled acetate (0.5–1% per site) and, thus, reduce the observed labeling of both isotopes at C-1′. Such a reduction is not evident.

To examine this implication more closely, a sample of [1^{13}C,$^{18}O_2$]hexanoate was prepared by extension of Cane's method (24) and administered to mycelial suspensions of *A. parasiticus*. ^{13}C{^{1}H}NMR analysis of the isolated averufin (**12**, Scheme 5) showed a 53% incorporation of ^{18}O relative to the ^{13}C internal standard at C-1′, as evidenced by the relative proportion of a 0.027 ppm upfield-shifted resonance (for an overview of this method see ref. 35). Therefore, both [1-^{13}C,$^{18}O_2$]-acetate and [1-^{13}C, $^{18}O_2$]hexanoate label C-1′ and its attached oxygen with high and comparable efficiencies.



SCHEME 5

In view of these arguments we are led to the following interpretation of the data. The hexanoyl unit is likely prepared by a specialized FAS that releases, for example, hexanoyl CoA, hexanoyl ACP, or channels this unit in an enzyme complex with the PKS to lead on to norsolorinic acid. Alternatively, but indistinguishable by the information presently available, the FAS and PKS are part of one large polyprotein such that the saturated C_6 unit is never released, for example, as a CoA ester, yet can fairly readily exchange with exogenously supplied thioester to load the C_6 site for further PKS elaboration with malonyl CoA. Recent disclosures of the organization and proposed function of the erythronolide genes (36) could be cited to favor this latter view. Nonetheless, the role of a specialized FAS, whether a separately expressed enzyme or part of a larger fusion to give a multifunctional protein, accommodates the "starter effect" noted by Chandler and Simpson on incorporation of diethyl [2-^{13}C]malonate into averufin (37), and, indeed, the slightly increased levels of secondary acetate incorporation detected at C-5′ in the present experiments (ca. 0.7%). Moreover, stereochemical experiments of the enoyl thioester reductase steps resulting in formation of both the averufin side chain and the fatty acids of *A. parasiticus* show a common configurational outcome (38) in contrast to polyketide natural products from other fungi (39). Purification of the protein or proteins responsible for norsolorinic acid synthesis and determination of the genetic organization and expression of the gene or genes that encode them are of considerable interest. As experiments advance to this stage, it may be possible to answer why the NAC thioesters of hexanoic acid and 3-oxo-octanoic acid can be utilized so efficiently in the biosynthesis while the corresponding thioester of butyric acid cannot.

Experimental

General synthetic methods

Melting points were determined in open capillaries using a Thomas–Hoover apparatus and are uncorrected. IR spectra were recorded on a Perkin–Elmer model 599B or a Series 1600 FTIR spectrometer. Proton NMR spectra were obtained using a Varian CFT-20 spectrometer fitted with a probe to operate at 80 MHz or, as indicated, a Varian XL-400 spectrometer operating at 400 MHz. Unless otherwise noted, chemical shifts (δ) are reported downfield of tetramethylsilane as an internal standard. ^{13}C NMR spectra were recorded using a Varian XL-400 spectrometer operating at 100 MHz with the chemical shifts given from deuteriochloroform (δ_C 76.89) or d_6-DMSO (δ_C 39.69) as internal reference. Mass spectra were obtained through the services of mass spectrometry facilities in the Department of Chemistry at Johns Hopkins University (VG Micromass 70-S). Elemental combustion analyses were carried out by Galbraith Laboratories, Inc. (Knoxville, Tenn.).

Analytical thin-layer chromatography was performed on Analtech GHLF Uniplate glass plates coated with silica gel (0.25 mm) containing a fluorescent indicator, and using the mobile phase noted. Column chromatography was conducted on Merck Silica Gel 60 (230–400 mesh), using the column size and mobile phase indicated. Flash column chromatography was conducted under 60 Torr (1 Torr = 133.3 Pa) pressure with silica gel 60, size finer than 0.063 mm (E. Merck).

Dry tetrahydrofuran (THF) and dry ether were distilled from sodium benzophenone ketyl prior to use. Hexamethylphosphoric triamide (HMPA) was distilled under reduced pressure from calcium hydride and stored over molecular sieves (4 Å) under nitrogen. All other reagents were of reagent grade or purified further as indicated.

Biological procedures: strains and culture conditions

The averufin-accumulating mutant *Aspergillus parasiticus* ATCC 24551 was maintained on slants of potato dextrose agar (Difco) plus 0.5% yeast extract. Plates subcultured from these slants were grown for 7 days in the dark before use.

The growth medium used for cultivation of the organisms in submerged culture in shaken flasks was the minimum mineral medium (A&M) of Adye and Mateles (40). The replacement medium (RM) was the nitrogen-free resting cell medium of Hsieh and Mateles (29) containing various amounts of glucose.

Shaken cultures were incubated in cotton-stoppered Erlenmeyer flasks in the dark at 28°C and the indicated revolutions/min in a New Brunswick Scientific model G-25-K gyrotary incubator shaker; static cultures were grown in cotton-stoppered Erlenmeyer flasks or Fernbach flasks at 28°C in the dark. For inoculation of liquid cultures, a 7-day-old plate culture was flooded with a 0.85% saline solution (9 mL) containing 0.5% Tween (1 mL) and a 5-mm inoculating loop was used to generate a suspension of spores; the suspension was transferred to a tube containing the saline solution (9 mL) and mixed well to produce a suspension of ca. 10^6 conidiospores per 1 mL.

All broths, slants, and equipment were sterilized at 125°C/20 psi (1 psi = 6.9 kPa) for 20 min prior to inoculation.

N-(2-Mercaptoethyl)acetamide (N-acetylcysteamine)

The procedure of Kass and Brock was used (21). A three-necked 250-mL round-bottomed flask equipped with a pH electrode and argon inlet was charged with *N,S*-diacetylcysteamine (2.09 g, 13.0 mmol; prepared by the method of Schwab and Klassen (22)) and 70 mL of water. The solution was cooled to 0°C and solid potassium hydroxide (2.43 g, 43.3 mmol) was added. The reaction mixture was stirred 1 h at room temperature, and the solution was adjusted to pH 7, saturated with NaCl, and extracted three times with dichloromethane. The combined organic extracts were dried over anhydrous sodium sulfate and concentrated in vacuo to give *N*-acetylcysteamine (1.42 g, 91% yield) as a clear, colorless oil that was prepared just prior to use. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 6.2–5.8 (m, 1H, NH), 3.43 (dt, J = 6, 6 Hz, 2H, -CH_2NH-), 2.71 (dt, J = 8, 6 Hz, 2H, -CH_2SH), 2.00 (s, 3H, CH_3CO), 1.34 (t, J = 8 Hz, SH).

General procedure for preparing NAC thioesters (21)

To a flame-dried three-necked round-bottomed 250-mL flask equipped with magnetic stirring bar and argon inlet was added 50 mL of dry THF and the carboxylic acid **3** (2.5 mmol). The solution was cooled to 0°C and triethylamine (0.35 mmol, 0.25 g, 2.5 mmol) followed by ethyl chloroformate (0.24 mL, 0.27 g, 2.5 mmol) was added and stirred 1 h at 0°C under argon. To a second three-necked 100-mL round-bottomed flask equipped with magnetic stirring bar, potassium hydroxide (1.4 g, 25 mmol) and 40 mL of water were added and stirred until the KOH had dissolved. Diacetylcysteamine (1.2 g, 7.5 mmol) was dissolved in the alkaline solution and allowed to stir at room temperature for 1 h. The pH was then adjusted to 7.8 with 6 N HCl and the solution was added via syringe to the mixed anhydride **4** at 0°C. If the mixture was cloudy, sufficient water was added to maintain a homogeneous solution. The pH was adjusted to 8.0 with 1 N NaOH and maintained at that pH throughout the reaction. The solution was allowed to stir for 1 h at room temperature, was acidified to pH 3.0 with 6 N HCl, and then was saturated with NaCl. The mixture was extracted three times with ether. The combined organic extracts were washed with 5% $NaHCO_3$ and brine and were dried over magnesium sulfate. Filtration and concentration in vacuo gave a clear colorless semisolid. TLC visualization under shortwave UV showed one spot (6:1 dichloromethane:acetone). Spray I followed by Spray II showed magenta spots indicating thioesters and (or) disulfides.

Spray I (sodium nitroprusside (41): 1.5 g of sodium nitroferricyanide, 5 mL of 2 N HCl, 95 mL of absolute methanol, and 10 mL of concentrated ammonium hydroxide (28%). Filter after mixing the above reagents together.

Spray II (methanolic sodium hydroxide): 2 g of NaOH, 5 mL of distilled water, and 95 mL of absolute methanol.

Dipping (spraying) a TLC plate with Spray I showed free thiols (here any residual *N*-acetylcysteamine). Taking the same TLC plate and dipping it in Spray II showed thioesters and disulfides as magenta spots on a yellow background. Dipping in ether intensifies the spots if weak (41). Purification by flash chromatography (20 g, 230–400 mesh, 6:1 dichloromethane:acetone) afforded the *N*-acetyl-*S*-acylcysteamines **5** as white solids. Other data are listed separately for each compound below.

[1-^{13}C]Butanethioic acid S-*[2-(acetylamino)ethyl]ester*

The compound was prepared from [1-^{13}C]butyric acid by acidification of the sodium salt (0.29 g, 2.6 mmol. 90 at% ^{13}C). The NAC thioester was obtained in 73% yield as a white solid, mp 21–23°C (lit. (42) mp 21–23°C). R_f = 0.25 (6:1 dichloromethane:acetone, visualized with Sprays I and II). IR($CHCl_3$): 3448, 3330, 3008, 2969, 2936, 2875, 1673, 1521, 1463, 1440, 1408, 1373, 1360, 1266, 1236, 1221, 1174, 1150, 1114, 1040 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ: 5.9–5.8 (m, 1H, NH), 3.44 (dt, J = 6, 6 Hz, 2H, -CH_2NH-), 3.03 (t, J = 6.6 Hz, 2H, -CH_2S-), 2.55 (dt, J = 7.5, 5.8 Hz, 2H, -C$H_2{}^{13}$CO-), 1.96 (s, 3H, CH_3CO-), 1.73–1.6 (m, 2H, -CH_2CH_3), 0.96 (t, J = 7.3 Hz, 3H, -CH_3); EIMS, *m/z* (relative intensity) (unlabeled material): 189 (M^+, 2), 161 (4), 130 (18), 119 (75), 118 (30), 102 (14), 86 (27), 71 (70), 60 (98), 43 (100). Exact Mass (unlabeled material): 189.0825; calcd. for $C_8H_{15}NO_2S$: 189.0824.

[1-^{13}C]Hexanethioic acid S-*[2-(acetylamino)ethyl]ester*

[1-^{13}C]Hexanoic acid (0.29 g, 2.5 mmol) gave the corresponding NAC thioester in 79% yield as a white solid, mp 43–45°C. R_f = 0.56 (6:1 dichloromethane:acetone, visualized by Sprays I and II). IR ($CHCl_3$): 3450, 3330, 3007, 2959, 2930, 2870, 1672, 1520, 1463, 1440, 1407, 1373, 1360, 1266, 1234, 1221, 1210, 1174, 1147, 1120, 1040 cm–^{1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ: 6.0–5.9 (m, 1H, NH), 3.43 (dt, J = 6, 6 Hz, 2H, -CH_2NH-), 3.02 (t, J = 6.6 Hz, 2H, -CH_2S-), 2.57 (dt, J = 7.3, 5.8 Hz, 2H, -$CH_2{}^{13}$CO-), 1.97 (s, 3H, CH_3CO-), 1.71–1.63 (m, 2H, -CH_2CH_2CO-), 1.33–1.28 (m, 4H, -$CH_2CH_2CH_3$), 0.90 (t, J = 7 Hz, 3H, -CH_3); EIMS, *m/z* (relative intensity) (unlabeled material): 217 (M^+, 1), 161 (1), 158 (8), 132 (7), 119 (78), 118 (23), 102 (11), 99 (40), 86 (17), 76 (15), 72 (26), 71 (39), 60 (85), 55 (12), 43 (100). Exact Mass (unlabeled material): 217.1139; calcd. for $C_{12}H_{21}NO_2S$: 217.1137.

Dicyclohexylcarbodiimide-activated esterification of carboxylic acids (28)

To a flame-dried 10-mL three-necked round-bottomed flask equipped with magnetic stirring bar and argon inlet was added the carboxylic acid (2.5 mmol), 3 mL dichloromethane, 10 mol% dimethylaminopyridine, and *N*-acetylcysteamine (8.5 mmol) in 2 mL of dichloromethane. The mixture was cooled to 0°C and DCC (2.5 mmol) was added. The reaction mixture was stirred at 0°C for 5 min and then warmed to room temperature, at which time dicyclohexylurea (DCU) precipitated. After stirring for 3.5 h at room temperature, the reaction mixture was filtered through Celite to remove DCU and was concentrated in vacuo, providing a yellow semisolid. Purification by flash chromatography (19 g silica, 230–400 mesh, 6:1 dichloromethane: acetone) gave the *N*-acetyl-*S*-cysteamine thioesters as white solids. Other data are listed below for each compound.

[1-^{13}C]Ethanethioic acid S-*[2-(acetylamino)ethyl]ester*

[1-^{13}C]Acetic acid (0.25 g, 4.09 mmol, 99 at% ^{13}C) and one equivalent of *N*-acetylcysteamine were combined to give the NAC thioester (0.56 g, 85% yield) as a clear colorless oil. R_f = 0.36 (6:1 dichloromethane:acetone, visualized by Spray I followed by Spray II). ^{1}H NMR (80 MHz, $CDCl_3$) δ: 6.5–6.25 (m, 1H, NH), 3.40 (dt, J = 6, 6 Hz, -CH_2NH-), 3.06 (t, J = 6.7 Hz, 2H, -CH_2S-), 2.35 (d, J = 6.2 Hz, 3H, $CH_3{}^{13}$CO-), 1.96 (s, 3H, CH_3CONH).

[2,3-$^{13}C_2$]Butanethioic acid S-*[2-(acetylamino)ethyl]ester*

[2,3-$^{13}C_2$]Butyric acid (2.66 mmol) yielded the NAC thioester (250 mg, 50% yield) as a white solid, mp 21–23°C (lit. (42) mp 21–23°C). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 6.5–6.27 (m, 1H, NH), 3.42 (dt, J = 6, 6 Hz, 2H, -CH_2NH-), 3.03 (t, J = 6.5 Hz, 2H, -CH_2S-), 2.56 ($^1J_{CH}$ = 124 Hz, $^2J_{CH}$ = 4.7 Hz, $^3J_{HH}$ = 7.4 Hz, 2H, -$^{13}CH_2$CO-), 1.98 (s, 3H, CH_3CO-), 1.68 ($^1J_{CH}$ = 123 Hz, $^2J_{CH}$ = 4.2 Hz, $^3J_{HH}$ = 7.4 Hz, 2H, -$^{13}CH_2CH_3$), 0.95 ($^2J_{CH}$ = 4.7 Hz, $^3J_{CH}$ = 4.4 Hz, $^3J_{HH}$ = 7.4 Hz, 3H, -CH_3).

[1-^{13}C]-3-Oxo-octanoic acid S-*[2-(acetylamino)ethyl]ester*

[1-^{13}C]-3-Oxo-octanoic acid (0.398 g, 2.5 mmol) afforded the NAC thioester in 69% yield as a white solid, mp 86–89°C. IR ($CHCl_3$): 3450, 3330, 3004, 2960, 2933, 2870, 1721, 1672, 1613, 1524, 1464,

For personal use only.

1440, 1407, 1365, 1266, 1233, 1217, 1177, 1101, 1087, 1040 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ: 6.75–6.25 (m, 1H, NH), 3.70 (d, J = 6.2 Hz, -^{13}CH_2CO-), 3.42 (dt, J = 6, 6 Hz, 2H, -CH_2NH-), 3.13 (t, J = 6.4 Hz, -CH_2S-), 2.53 (t, J = 7.3 Hz, 2H, -CH_2CO-), 1.99 (s, 3H, CH_3CO-), 1.75–1.25 (m, 6H, -$CH_2CH_2CH_2$-), 0.90 (t, J = 6.8 Hz, CH_3CH$_2$-); EIMS *m/z* (relative intensity) (unlabeled material): 259 (1), 200 (1), 141 (25), 119 (80), 118 (19), 102 (2), 99 (32), 86 (12), 84 (50), 76 (10), 72 (23), 71 (19), 69 (31), 60 (94), 56 (15), 44 (20), 43 (64), 41 (24), 30 (100). Exact Mass (unlabeled material): 259.1248; calcd. for $C_{12}H_{21}NO_3S$: 259.1242.

[1-^{13}C]Hexanoic acid (24)

To a 25-mL three-necked round-bottomed flask equipped with nitrogen inlet, magnetic stirring bar, and reflux condenser were added MeOH (6.3 mL), H_2O (0.24 mL), 1-iodopentane (3.27 mL, 4.97 g, 25.1 mmol), and potassium [^{13}C]cyanide (1.63 g, 24.6 mmol, 99% ^{13}C). The mixture was allowed to heat to reflux for 48 h. The hexanenitrile (assume 24.6 mmol) was distilled directly into a 50-mL round-bottomed flask at 55°C (15 Torr) as a clear colorless liquid. Water (0.95 mL, 53 mmol) and 29.5 mL of 0.85 M potassium *tert*-butoxide (25 mmol) in *tert*-butanol were added; the solution was heated to reflux for 48 h under nitrogen and was then cooled to room temperature, affording a white precipate. The residue obtained upon evaporation of the solvent was redissolved in water and acidified with 10% aqueous HCl to pH 2. The aqueous solution was extracted with ether three times. The organic layers were combined and washed with water, brine, and were dried over anhydrous magnesium sulfate. Filtration and concentration in vacuo gave a clear yellow liquid. The liquid was purified by Kugelrohr distillation at 85°C to give [1^{13}C]hexanoic acid as a clear colorless liquid (2.35 g, 80% yield). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.33 (dt, J = 7.3, 5.8 Hz, 2H, CH_2^{13}CO-), 1.80–1.50 (m, 2H, -CH_2CH$_2$^{13}CO-), 1.50–1.25 (m, 4H, CH_2CH_2CH$_3$), 0.90 (t, J = 7 Hz, 3H, -CH_3).

[1-^{13}C,$^{18}O_2$]Hexanoic acid, sodium salt

The method used was similar to that for preparing analogously labeled sodium propionate by Cane et al. (24). To a flame-dried 25-mL round-bottomed flask equipped with nitrogen inlet, magnetic stirring bar, and reflux condenser were added methanol (3.8 mL), H_2^{18}O (98% ^{18}O, 0.15 mL), 1-iodopentane (1.98 mL, 15.19 mmol), and potassium [^{13}C]cyanide (99% ^{13}C, 0.99 g, 15.03 mmol). The mixture was heated to reflux for 48 h. After cooling, the mixture was distilled into a 50-mL round-bottomed flask for direct hydrolysis of the nitrile. To the latter flask, equipped with magnetic stirring bar, reflux condenser, and nitrogen inlet, were added 0.85 M potassium *tert*-butoxide in *tert*-butanol (17.8 mL, 15.13 mmol) and H_2^{18}O (98% ^{18}O, 0.64 mL, 32 mmol). The product was obtained as described above to give [1-^{13}C,$^{18}O_2$]hexanoic acid as a colorless liquid (0.78 g, 45% yield). Water (10 mL) and 1 N NaOH (6.7 mL) were added to the carboxylic acid. The mixture was stirred for 30 min at room temperature and then concentrated in vacuo to give a white solid, mp 260°C (dec.). ^{1}H NMR (400 MHz, D_2O) δ: 2.19 (dt, J = 7.3, 5.9 Hz, 2H, -CH_2 ^{13}C$^{18}O_2$), 1.61–1.54 (m, 2H, -CH_2CH$_2$^{13}C$^{18}O_2$), 1.37–1.26 (m, 4H, -CH_2CH_2CH$_3$), 0.89 (t, J = 7.1 Hz, 3H, -CH_3); ^{13}C NMR (100 MHz, D_2O, partial) δ: 183.07 (^{13}C$^{16}O_2$), 183.04 (^{13}C^{16}O^{18}O), 183.01 (^{13}C$^{18}O_2$). Estimation of isotope content of the acid by ^{13}C NMR was 17.9% (^{13}C,$^{16}O_2$), 45.6 (^{13}C,^{16}O,^{18}O), and 36.5 (^{13}C,$^{18}O_2$). The mass spectrum gave the isotopic cluster (M + Na^+) as follows: EIMS *m/z* (unlabeled): 161 (100), 162 (7.03), 163 (1.03), 164 (0.02), 165 (0.32) and 166 (0.03); (labeled): 161 (6.96), 162 (39.99), 163 (8.3), 164 (100), 165 (10.73), 166 (81.4), and 167 (4.54). From these data it can be shown that the contributions of labeled materials are as follows: 18.1% (^{13}C$^{16}O_2$), 45.4% (^{13}C^{16}O^{18}O), and 36.5% (^{13}C$^{18}O_2$).

*Benzyl [1-^{13}C]acetate (**6**) (25)*

To a flame-dried 10-mL round-bottomed flask equipped with reflux condenser, argon inlet, and magnetic stirring bar were added sodium [1-^{13}C]acetate (99% ^{13}C, 0.80 g, 9.64 mmol), methyl ethyl ketone (3 mL), benzylchloride (1.02 mL, 1.12 g, 8.87 mmol), and triethylamine (0.04 mL, catalytic). The heterogeneous mixture was heated to a vigorous reflux for 8.5 h. At this time water was added to dissolve the salt and the aqueous and organic layers were separated. The aqueous phase was extracted with dichloromethane and the organic layers were combined, washed with brine, and dried over anhydrous magnesium sulfate. Filtration and concentration in vacuo provided 1.32 g of **6** as a clear colorless liquid (98% yield). ^{1}H NMR (80 MHz, $CDCl_3$) δ: 7.35 (s, 5H, phenyl), 5.11 (d, J = 3.2 Hz, 2H, C_6H_5CH_2-), 2.10 (d, J = 6.9 Hz, 3H, CH_3^{13}CO-).

Benzyl [1-^{13}C]-3-oxo-octanoate (7, R = CH_2Ph)

To a 50-mL flame-dried three-necked round-bottomed flask containing a nitrogen inlet and magnetic stirring bar were added 13 mL of dry THF and 18.3 mL (18.3 mmol) of lithium hexamethyldisilazide (1.0 M in THF). The stirred solution was cooled to −78°C and benzyl [1-^{13}C]acetate **6** (1.26 mL, 8.7 mmol) was added, followed in 30 min by hexanoyl chloride (1.2 mL, 8 mmol). After 35 min, 2 N hydrochloric acid (13 mL) was added at −78°C and the reaction was allowed to warm to room temperature and stir 35 min more. The mixture was poured into water and extracted with ethyl acetate three times. Concentration of the dried organic extract in vacuo afforded a yellow oil. Purification by flash chromatography (80 g silica, 230–400 mesh, 10:1 hexane:ethyl acetate) provided 1.54 g of product **7** (R = CH_2Ph) as a clear colorless oil (77% yield). R_f = 0.55 (10:1 hexane:ethyl acetate). ^{1}H NMR (80 MHz, $CDCl_3$) δ: 7.35 (s, 5H, phenyl), 5.17 (d, J = 3.3 Hz, 2H, $C_6H_5CH_2$-), 3.47 (d, J = 7.4 Hz, 2H, -^{13}COCH_2CO-), 2.49 (t, J = 7.2 Hz, 2H, -CH_2CO-), 1.75–1.25 (m, 6H, -$CH_2CH_2CH_2$-), 0.87 (virtually coupled triplet, 3H, -CH_3).

[1-^{13}C]-3-Oxo-octanoic acid (7, R = H)

To a 250-mL Parr bottle were added benzyl [1-^{13}C]-3-oxo-octanoate (1.54 g, 9.67 mmol), ethyl acetate (10 mL), and 10% palladium on carbon (100 mg). Debenzylation was carried out under hydrogen at 40 psi for 12 h. The catalyst was removed by filtration through Celite and washed with 1:1 ethyl acetate: ethanol. Concentration in vacuo provided [1-^{13}C]-3-oxooctanoic acid as a while solid (0.89 g, 90% yield), mp 73–74°C (lit. (26) mp 73–74°C). R_f = 0.07 (10:1 hexane: ethyl acetate, visualized with bromocresol green.). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.47 (d, J = 7.4 Hz, 2H, -^{13}COCH_2CO-), 2.49 (t, J = 7.2 Hz, 2H, CH_2CO-), 1.75–1.25 (m, 6H, -$CH_2CH_2CH_2$-), 0.87 (t, J = 7 Hz, 3H, CH_3).

[2,3-$^{13}C_2$]Butanoic acid (23)

To a flame-dried 50-mL round-bottomed flask equipped with reflux condenser, magnetic stirring bar, and argon inlet were added THF (9.5 mL) and diisopropylamine (1.99 mL, 1.44 g, 14.2 mmol). After cooling to 0°C, [2-^{13}C]acetic acid (99% ^{13}C, 0.37 mL, 6.37 mmol) was added dropwise giving a milky white suspension, which became homogeneous after the addition of three equivalents of HMPA (3.3 mL, 19.11 mmol). The resulting solution was heated for 2 h at 50°C to facilitate dianion formation. After cooling to room temperature, [1-^{13}C]-1-iodoethane (99% ^{13}C, 500 mg, 3.18 mmol) was added slowly via syringe and the alkylation was allowed to proceed for 12 h. The product was isolated by acidification with ice-cold 10% HCl and extraction with ether. The combined organic layers were washed three times with 10% HCl, water, and brine. The organic extract was dried over anhydrous sodium sulfate, filtered, and concentrated to obtain the crude product as an orange liquid. Any ethyl esters formed in the reaction were saponified with 1 N NaOH and extracted with ether. The aqueous layer was acidified to pH 2 with 2 N HCl and was extracted back into ether. The ether extract was washed with water, brine, and was dried over anhydrous sodium sulfate. Filtration and concentration in vacuo gave a pale yellow liquid, which was Kugelrohr distilled (50°C, 15 Torr) to give a colorless liquid (0.24 g, 85% yield based on 1-iodoethane). ^{1}HNMR (400 MHz, $CDCl_3$) δ: 2.32 ($^1J_{CH}$ = 124 Hz, $^2J_{CH}$ = 4.7 Hz, $^3J_{HH}$ = 7.4 Hz, 2H, -^{13}CH_2CO-), 1.65 ($^1J_{CH}$ = 123 Hz, $^2J_{CH}$ = 4.2 Hz, $^3J_{HH}$ = 7.4 Hz, 2H, -^{13}CH_2CH$_3$), 0.95 ($^2J_{CH}$ = 4.7 Hz, $^3J_{CH}$ = 4.4 Hz, $^3J_{HH}$ = 7.4 Hz, 3H, -CH_3).

Incorporation of sodium [1-^{13}C,$^{18}O_2$]hexanoate into averufin

Four 500-mL portions of A&M medium (40) contained in 2-L Erlenmeyer flasks were inoculated and allowed to shake at 175 rpm at 28°C in the dark for 48 h. The mycelial pellets were filtered on cheesecloth and rinsed with RM (1.62 g glucose/L) (29). Ten grams each (wet weight) was resuspended in 100 mL of RM contained in each of 12 250-mL Erlenmeyer flasks. Sodium [1^{13}C,$^{18}O_2$]hexanoate (178 mg, 1.25 mmol, 14.9 mg per flask) was dissolved in 24 mL of H_2O and filtered through a sterile 0.2-μm membrane and 2 mL of the filtrate was pipetted into each flask. The flasks were allowed to shake 48 h at 28°C in the dark. The mycelial pellets were filtered on cheesecloth and rinsed with water. The collected mycelial pellets were steeped in acetone and filtered. The acetone extract was concentrated to ca. 300 mL and was extracted four times with ether until the ether layer was nearly colorless. The combined organic extracts were washed with water and brine, and were dried over anhydrous sodium sulfate. Filtration and concentration in vacuo gave an orange solid. Purification by flash chromatography (18 g silica, 230–400 mesh, 97:3 $CHCl_3$:MeOH) gave 59 mg of averufin as an orange solid. ^{13}C NMR (100 MHz, $CDCl_3$ with five drops d_6-DMSO) δ: 188.81 (C-9), 180.99 (C-10), 164.67 (C-6), 164.30 (C-8), 159.71 (C-3), 158.34 (C-1), 134.53 (C-11), 132.86 (C-14), 115.63 (C-2), 109.06 (C-5), 108.57 (C-12), 108.15 (C-13), 107.99 (C-7), 107.5 (C-4), 100.53 (C-5′), 66.32 (C-1′), 35.33 (C-4′), 27.33 (C-6′), 26.9 (C-2′), 15.43 (C-3′); δ: 66.324 (C-1′–^{16}O), 66.297 (C-1′–^{18}O).

Enrichment of averufin labeled with both ^{13}C and ^{18}O was determined to be 31.5% based on peak areas in the NMR spectrum. EIMS gave *m/z* (unlabeled) 368 (100), 369 (22.4), 370 (5.1), 371 (1.2), and 372 (0.02); and for the labeled compound 369 (100), 369 (25.2), 370 (5.8), 371 (2.7), and 372 (1.3). From these data it can be shown that the contributions of labeled species are as follows: 67.7% (^{13}C,^{16}O) and 32.3% (^{13}C,^{18}O). To determine the incorporation of doubly labeled hexanoate into averufin, an assumption was made about the utilization of the hexanoate fed. Of the three peaks integrated in the ^{13}C NMR spectrum of [1-^{13}C,$^{18}O_2$]hexanoate, half of the area of the peak corresponding to ^{13}C,^{16}O,^{18}O-labeled material was used since statistically only half of the oxygens could be retained in the conversion to averufin. With this in mind a corrected figure of 59.3% was obtained for the maximum ^{13}C,^{18}O-enrichment that could be observed in averufin. Dividing the 31.5% enrichment actually obtained for the [^{13}C,^{18}O]-averufin by 59.3% gave 53% retention of ^{18}O in averufin relative to the ^{13}C internal standard.

Administration of NAC thioesters to ATCC 24551

A common procedure was used to test the incorporation of all the NAC thioesters. Mycelial pellets were prepared as above and resuspended in 12 250-mL Erlenmeyer flasks containing 100 mL each of RM. The ^{13}C-labeled NAC thioester was dissolved in 24 mL of acetone and 2 mL was pipetted into each flask. The flasks were allowed to shake 48 h at 28°C in the dark at 175 rpm. The mycelial pellets were then filtered on cheesecloth and rinsed with distilled water. The averufin produced was isolated as above.

Administration of [1-^{13}C]ethanethioic acid S-*[2(acetylamino)-ethyl]ester*

The yield of averufin was 8 mg. The estimation of incorporation by ^{13}C NMR was 0.3% at C-5′. EIMS *m/z* (unlabeled): 368 (100), 369 (22.4), 370 (5.1), and 371 (1.2); (labeled): 368 (100), 369 (26.6), 370 (7.9), and 371 (3.5). The mass spectrum (EI) indicated that the overall level (for 10 sites) of carbon-13 in the molecule was 3.8% above natural abundance.

Administration of [1-^{13}C]butanethioic acid S-*[2(acetylamino)-ethyl]ester*

The yield of averufin was 11.6 mg. Estimation of incorporation by ^{13}C NMR was 0.36% at C-3′ (however, see below). EIMS *m/z* (unlabeled): 368 (100), 369 (22.4), and 370 (5.1); and for the labeled compound: 368 (100), 369 (27.0), and 370 (6.8). The mass spectrum indicated that the level of carbon-13 was 4.4% above natural abundance (for 10 sites).

Administration of [2,3-$^{13}C_2$]butanethioic acid S-*[2(acetylamino)-ethyl]ester*

The yield of averufin was 25 mg. A ^{13}C NMR spectrum showed no intact incorporation of the thioester, as evidenced by the lack of coupling at a detection limit of <0.1% between C-4′ (δ 35.78) and C-5′ (δ 100.9).

Administration of [1-^{13}C]hexanethioic acid S-*[2(acetylamino)-ethyl]ester*

The yield of averufin was 18 mg. Estimation of incorporation by ^{13}C NMR spectroscopy was 22% at C-1′ by peak height analysis compared to natural abundance. EIMS *m/z* (unlabeled): 368 (100), 369 (22.4), 370 (5.1), and 371 (1.2); and for the labeled compound: 368 (100), 369 (62.8), 370 (25.7), and 371 (7.5). From these data it can be shown that the level of enrichment (M + 1) by mass spectrometry was 26%.

Administration of [1-^{13}C]-3-oxo-octanoic acid S-*[2(acetylamino)-ethyl]ester*

Estimation of incorporation by ^{13}C NMR spectroscopy gave 4.7 ± 0.7% at C-3 compared to natural abundance. Incorporation was ca 0.7% per site at alternating carbons, giving a total of 7% secondary incorporation due to acetate. EIMS gave *m/z* (unlabeled): 368 (100), 369 (22.4), 370 (5.1), and 371 (1.2); (labeled): 368 (100), 369 (35.1), 370 (10.5), and 371 (2.8). The level of enrichment (M + 1) estimated by mass spectrometry was 10.9% in the entire molecule.

Acknowledgments

Professor J.W. Bennett is thanked for kindly providing the averufin-accumulating mutant used in this work. We are grateful to the National Institutes of Health (ES01670) for their support of this work, and to the National Science Foundation for grant awards that enabled purchase of the major analytical instrumentation used (NMR: RR01934 and PCM 83-03176; MS: RR02318).

Received May 11, 1993

This paper is dedicated to Professor David B. MacLean

PHILIP G. HULTIN and WALTER A. SZAREK. Can. J. Chem. **72**, 208 (1994).

The 1-(3-thianyl)uracil (**9**) and 9-(3-thianyl)adenine (**14**) nucleoside analogs have been prepared from the key intermediate, (±)-(3β,5β)-3-amino-5-(hydroxymethyl)thiane (**6**). Analog **9** was converted into a mixture of diastereomeric sulfoxides (**10**) that afforded, by a Pummerer reaction, a mixture of (±)-1-{(2′β,3′β,5′β)-2′-acetoxy-5′-(acetoxymethyl)thian-3′-yl}-2,4(1*H*,3*H*)-pyrimidinedione (**11***a*) and its 6′-β isomer (**11***b*). The EI mass spectra of the nucleoside analogs are discussed. The uracil nucleoside analogs have been evaluated also for their anti-HIV and antitumor activities.

PHILIP G. HULTIN et WALTER A. SZAREK. Can. J. Chem. **72**, 208 (1994).

On a préparé le 1-(3-thianyl)uracile (**9**) et la 9-(3-thianyl)adénine (**14**), des analogues de nucléosides, à partir de l'intermédiaire clé, (±)-(3β,5β)-3-amino-5-(hydroxyméthyl)thiane (**6**). On a transformé l'analogue **9** en un mélange de sulfoxydes diastéréoisomères (**10**) qui, par réaction de Pummerer, conduit à un mélange de la (±)-1-{(2′β,3′β,5′β)-2′-acétoxy-5′-(acétoxyméthyl)thian-3′-yl}-2,4(1*H*,3*H*)-pyrimidinedione (**11***a*) et son isomère 6′-β (**11***b*). On discute des spectres de masse en IE des analogues de nucléoside. On a aussi évalué les analogues nucléoside de l'uracile pour leurs activités anti-HIV et antitumorale.

[Traduit par la rédaction]

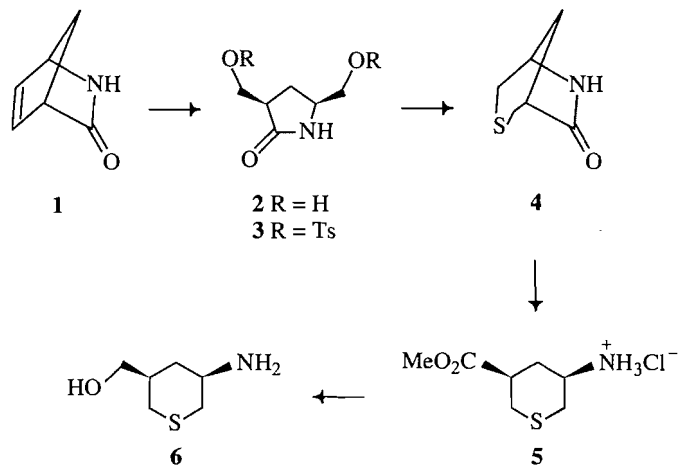
Introduction

Nucleoside analogs have received much attention as a result of their antiviral (1) and antitumor (2) activities. Interest in replacement of the carbohydrate moiety by other heterocycles was recently stimulated by the announcement of the potent anti-HIV activity of the 1,3-oxathiolanyl nucleoside BCH-189 by Belleau and co-workers (3). The chemistry and biological activity of 1,3-oxathiolanyl (4), 1,3-dioxolanyl (5), oxolanyl (6), thiolanyl (7), and pyrrolidinyl (8) nucleosides have been reported by several groups. Nucleosides derived from 1,4- dioxane, 1,4-oxathiane, and 1,4-oxazine have also been prepared and their antiviral activities determined (9).

We have published the results of studies of the synthesis, structure, and antitumor activities of nucleoside analogs having 1,4-oxathianyl, 1,4-dithianyl, 1,4-dioxanyl, 1,4-oxazinyl, 1,4-thiazinyl, and 1,3-thiazolidinyl groups replacing the sugar ring (10). As part of this ongoing project, we wished to prepare the 3-thianyl nucleosides **9**, **10**, and **14**, and to determine their activities against HIV and a variety of human cancers. It was anticipated that **9**, **10**, and **14** would have antitumor properties similar to those of our earlier six-membered heterocyclic analogs, but that they should prove to be more stable *in vivo* since the base ring is not attached by a glycosidic linkage.

Results and discussion

Since our analogs do not involve a glycosidic linkage, the pyrimidine- or purine-ring system had to be constructed on an aminothiane already possessing the desired *cis* stereochemistry. *cis*-3-Amino-5-(hydroxymethyl)thiane (**6**) was prepared as shown in Scheme 1 from the known bicyclic lactam **1** (11). This lactam was prepared as a racemate, and, consequently, our analogs were also racemic; however, **1** can be obtained in optically pure form from a microbiological resolution (12), and is available commercially now in both enantiomeric forms.[3]



SCHEME 1

Ozonolysis of **1** followed by reduction with sodium borohydride afforded the diol **2**, which was converted directly into ditosylate **3** (57.5% overall). Double displacement with sodium sulfide in hot *N*,*N*-dimethylformamide gave the bicyclic thianelactam **4**, in 68% yield after recrystallization, with the required *cis*-3,5 stereochemistry in place. The lactam was esterified using methanol containing concentrated aqueous hydrochloric acid. It is noteworthy that initial attempts to perform this reaction under anhydrous conditions were unsuccessful, but that addition of even a small amount of water promoted a facile, complete conversion of **4** into **5**. The crystalline amino alcohol **6** then could be obtained in 93% yield by reduction with lithium borohydride.

Synthesis of uracil derivatives

Preparation of the uridine analogs **9** and **10** is shown in Scheme 2. The required acylisocyanate **7** was made by a literature method (13), and condensed with **6** in *N*,*N*-dimethylformamide–benzene in the cold, to afford the acylurea derivative **8** in 78% yield. Cyclization was effected by brief boiling in 2 N

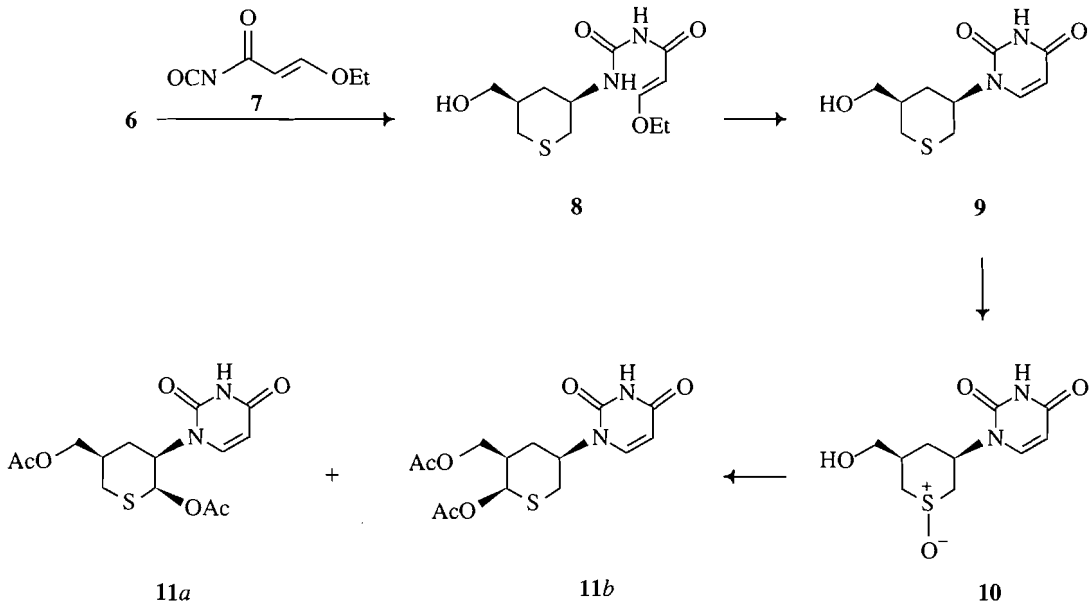


SCHEME 2

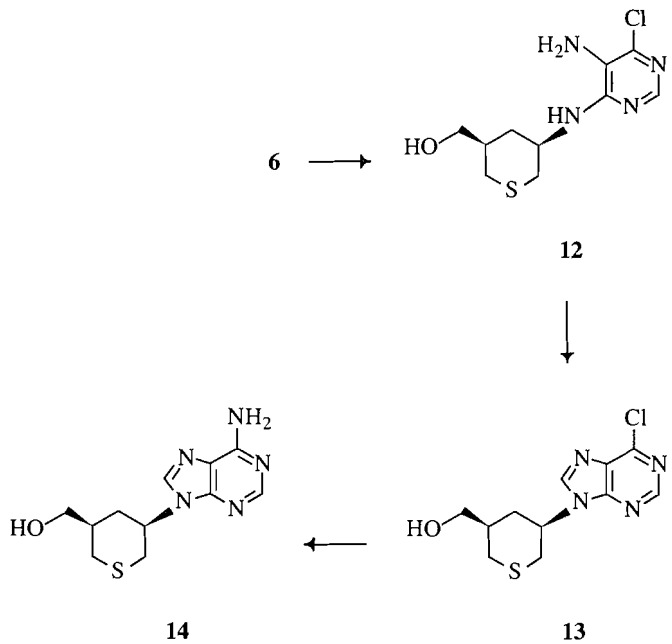
sulfuric acid, to give the nucleoside analog **9** as a crystalline solid.

We also wished to prepare the sulfoxide **10**. Treatment of **9** with sodium metaperiodate in ice-cold water gave **10** as an unresolvable mixture of diastereomers. Although the ^{1}H nmr spectrum of **10** was complicated by overlap of all the signals, even at 400 MHz, assignment of the signals attributable to the major and minor products was possible using a COSY experiment. The major product was identified as the axial sulfoxide by the downfield shift of the ^{1}H NMR signals of the axial protons, H-3′ and H-5′, relative to those of the minor product, as well as by the smaller chemical-shift differences between the signals of the geminal-proton pairs, H-2′$_{ax}$/H-2′$_{eq}$ and H-6′$_{ax}$/H-6′$_{eq}$ (see ref. 14). Because of signal overlap, nmr integration could not be used to estimate the axial:equatorial ratio of **10**. Treatment of **10** with *tert*-butyldimethylsilyl chloride provided the corresponding primary silyl ether derivative, in whose nmr spectrum the signals of the vinylic H-5 protons of the major and minor components were well separated. Integration of these signals allowed the axial:equatorial ratio of **10** to be estimated as 12:5.

We explored the use of the Pummerer reaction to install oxygen functionality at C-6′ of our analog. Treatment of **10** with hot acetic anhydride in the presence of *p*-toluenesulfonic acid afforded a 1:1 mixture of regioisomeric products **11***a*,*b* in 65% yield, which co-eluted on silica gel chromatography. The products were identified as 2′- and 6′-axial acetoxy derivatives by ^{1}H nmr spectroscopy in deuterated pyridine solution, which showed no axial–axial couplings for the thioketal-type protons. Partial purification of the 2′-acetoxy isomer **11***a* was achieved by recrystallization from *N*,*N*-dimethylformamide–isobutanol; this sample was useful for achieving a complete assignment of the ^{1}H nmr spectrum. Because of the difficulty in effecting separation of **11***a* and **11***b*, and the low solubility of these compounds, further elaboration of them was not pursued.

Synthesis of adenine derivatives

As shown in Scheme 3, **6** was condensed with 5-amino-4,6-dichloropyrimidine in 1-butanol at reflux temperature (11), to give **12** (88%). The purinyl ring was completed by treatment



SCHEME 3

with triethyl orthoformate under acid catalysis, followed by brief exposure to 0.5 N hydrochloric acid (15); chloropurine derivative **13** precipitated from solution in 64% yield. Subsequent displacement of chloride by methanolic ammonia in a glass bomb at 75°C gave the desired analog (**14**) of adenosine in 41% yield after recrystallization from 2-propanol.

Anti-HIV and antitumor assays

Nucleoside analogs **9** and **10** were submitted to the U.S. National Cancer Institute (N.C.I.) for anti-HIV screening by the soluble-formazan assay in human T4 lymphocytes (16). The IC_{50} value for each compound was found to be $>10^{-3}$ M in this system. These compounds were screened also by N.C.I. against a panel of human leukemia, lung cancer, colon cancer, CNS

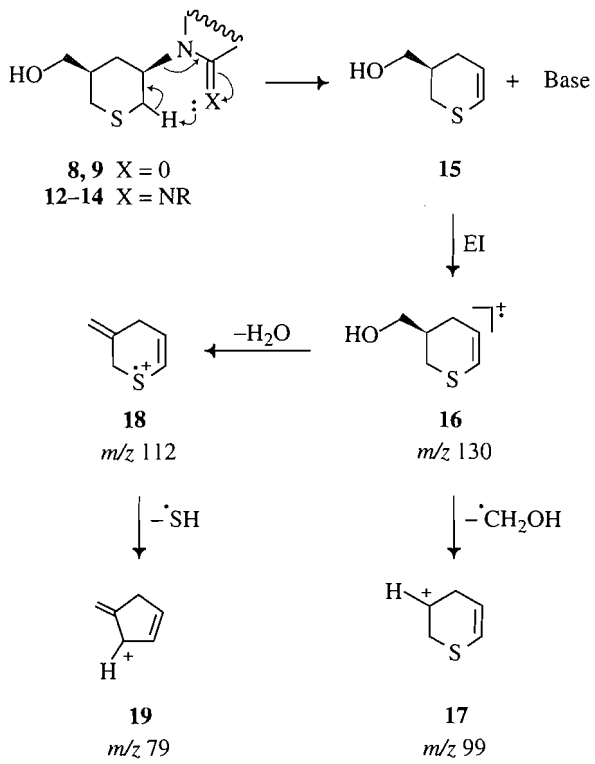

SCHEME 4

cancer, melanoma, ovarian cancer, and renal cancer cell cultures; analog **9** displayed weak activity (GI_{50} 5.6×10^{-5} M) against CNS cancer SNB-75 cells, but **9** and **10** were inactive otherwise ($GI_{50} > 10^{-4}$ M) in this assay. In none of these tests was any significant toxicity observed.

Compounds **9**, **10**, and **11***a* were screened also against HIV in MT-4 T-cells, by both reverse transcriptase assay and indirect immunofluorescence detection of viral p24 antigen.[4] No significant anti-HIV activity was found in these tests.

Mass-spectral observations

Routine EI mass spectra revealed an interesting common fragmentation for the thiane derivatives **8**, **9**, and **12–14**. These molecules afforded weak or no molecular ions, and their spectra displayed a sequence of major fragments at *m/z* 130, 112, 99, and 79. This pattern can be explained by a facile *thermal* elimination promoted by Lewis-basic atoms in the substituent side chain, as shown in Scheme 4. A mechanism of this type has recently been proposed by Lafortune et al. (17) to explain the fragmentation of thymidine in SIMS-TOF mass spectrometry. Subsequent electron-impact ionization of the neutral unsaturated product **15** then affords the observed fragments. The molecular formulas of all the proposed fragments have been determined by high-resolution measurements. A transformation of the type **18** → **19** was observed previously in the spectrum of methyl vinyl sulfide (18), which ejects sulfhydryl radical to give allyl cation by alkyl migration.

The thermal character of the initial elimination is suggested by the absence of any fragment ions characteristic of McLafferty or similar reactions of $M^{+\cdot}$. It is also supported by the behavior of the urea **8** under hot- and cold-injection conditions. This compound may produce fragments at *m/z* 99 by two pathways. High-resolution measurements showed the presence of a 1:1 mixture of ion **17** and acylium ion $[C_5H_7O_2]^+$ when the injection probe was heated, while only the product $[C_5H_7O_2]^+$, arising from direct electron-impact ionization of intact **8**, was observed on cold injection.

The Pummerer product **11** appears to fragment by a similar pathway, but competing loss of HOAc complicates analysis of the spectrum. Interestingly, the sulfoxide **10** gives a strong molecular ion and no fragments related to the sequence of Scheme 4, despite the enhanced acidity of its C-2′ protons.

Experimental

The ^{1}H nmr spectra were recorded on a Bruker AM-400 or AC-F 200 spectrometer at 400.136 or 200.132 MHz. The signals due to residual protons in the deuterated solvents indicated were used as internal standards. Chemical shifts are reported in ppm (δ) downfield from the position of tetramethylsilane (TMS). The symbols s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), and br (broadened) are used to describe the multiplicity and shape of the signals. The ^{13}C nmr spectra were obtained at 100.6 MHz on the AM-400 spectrometer or at 50.323 MHz on the AC-F 200 spectrometer. The JMOD spin-echo sequence (19) was used to aid in peak identification. Chemical shifts in ppm (δ) downfield from the position of TMS were measured using the solvent signals as internal standards, except for spectra measured in D_2O, where 1,4-dioxane-H_8 (δ 66.5) (20) was added as a standard.

EI mass spectra were recorded on a VG Micromass 7070F mass spectrometer at an ionizing voltage of 70 eV, or on a VG Analytical ZAB-E mass spectrometer, and CI spectra were recorded using NH_3 at ~1 Torr (133.3 Pa) as reagent gas; data are given as *m/z* (% relative intensity). The exact masses were determined under EI conditions. Except where noted, the high-resolution measurements were performed by peak matching using perfluorokerosene as a reference standard, at a resolution of ~4000.

Melting points were determined using a Fisher–Johns apparatus, and are uncorrected. Flash chromatography was performed on Kieselgel 60 (230–400 mesh), and thin-layer chromatography (TLC) was performed on glass plates coated with Kieselgel 60.

The homogeneity of the products was established on the basis of chromatographic, spectroscopic (^{1}H and ^{13}C nmr), and melting-point determinations.

(±)-(3β,5β)-3,5-Bis(p-toluenesulfonyloxymethyl)-1-aza-2-oxocyclopentane (3)

A solution of freshly recrystallized lactam **1** (see ref. 11) (8.2 g, 75 mmol) in dry methanol (300 mL) was purged with oxygen, while being cooled to −60°C in a Dry Ice – acetone bath. Ozone was passed through the solution at −60°C, until TLC analysis (0.5% methanol in ethyl acetate as eluant) and the presence of the blue color of an excess of ozone indicated completion. The temperature of the solution was allowed to rise to −30°C over 20 min, while the excess of ozone was purged with a stream of oxygen. Sodium borohydride (2.84 g, 75 mmol) was added slowly, while the temperature rose to −5°C. Stirring was continued for 1 h, and then Dowex-50 (H^+) ion-exchange resin was added to bring the apparent pH to 5. The mixture was filtered and the filtrate was concentrated. The residual oil was evaporated several times from methanol, and then left overnight on a vacuum pump, to provide diol **2** as a solid (10.01 g, 92%). A sample recrystallized from methanol–ether had mp 91–92°C; ^{1}H nmr (D_2O, 400 MHz) δ: 1.67 (1H, ddd, $J_{4\alpha,4\beta}$ = 13 Hz, J_{vic} = 9 Hz, $J_{vic'}$ = 7 Hz, H-4α), 2.31 (1H, ddd, $J_{4\beta,4\alpha}$ = 13 Hz, J_{vic} = 10 Hz, $J_{vic'}$ = 8 Hz, H-4β), 2.74 (1H, m, H-3), 3.46 (1H, dd, J_{gem} = 12 Hz, $J_{to\,5}$ = 6 Hz, 5-CH_2OH), 3.63 (1H, dd, J_{gem} = 12 Hz, $J_{to\,5}$ = 4 Hz, 5-CH_2OH), 3.68 (1H, dd, J_{gem} = 11 Hz, $J_{to\,3}$ = 5 Hz, 3-CH_2OH), 3.76 (1H, dd, J_{gem} = 11 Hz, $J_{to\,3}$ = 6 Hz, 3-CH_2OH), 3.70–3.80 (1H, m, H-5); ms (EI): 114 (M − CH_2OH)$^+$

[4]We thank Dr. Mark A. Wainberg of the Lady Davis Institute for Medical Research at The Sir Mortimer B. Davis-Jewish General Hospital, Montreal, for conducting these assays.

(100%), 96 (M − CH_2OH − H_2O)$^+$ (80.4%), 84 (M − CH_2O − CH_2OH)$^+$ (36.2%); ms (CI): 146 (M + H)$^+$ (100%), 163 (M + NH_4)$^+$ (6.4%), 291 (2M + H)$^+$ (2%). Exact Mass calcd. for $C_5H_8NO_2$ (M − CH_2OH)$^+$: 114.0555; found (hrms): 114.0551.

Without further purification, **2** (9.929 g, 68.4 mmol) was dissolved in freshly distilled, dry pyridine (200 mL) under an argon atmosphere. 4-Dimethylaminopyridine (0.852 g, 6.97 mmol) was added, and the mixture was cooled in an ice–water bath. *p*-Toluenesulfonyl chloride (28.7 g, 150.5 mmol) was added in several portions, and the mixture was stirred for 1 h. The pyridine was then evaporated under vacuum at 35°C. The residue was dissolved in ethyl acetate (200 mL), and the solution was washed successively with water (50 mL), a saturated aqueous solution of copper sulfate (50 mL), and water (50 mL). The combined aqueous layers were extracted with dichloromethane (50 mL), and the combined organic layers were dried ($MgSO_4$) and concentrated. Flash chromatography (ethyl acetate as eluant) of the residue afforded a sample of **3** (19.4 g, 57.5% overall), which was recrystallized from ethyl acetate; mp 131–132°C; ^{1}H nmr ($CDCl_3$, 200 MHz) δ: 1.62 (1H, ddd, $J_{4\alpha,4\beta}$ = 13.3 Hz, J_{vic} = 9 Hz, J_{vic} = 7 Hz, H-4α), 2.38 (1H, ddd, $J_{4\beta,4\alpha}$ = 13.3 Hz, J_{vic} = 9.6 Hz, J_{vic} = 7.3 Hz, H-4β), 2.43 (3H, s, ArCH_3), 2.45 (3H, s, ArCH_3), 2.61–2.81 (1H, m, H-3), 3.78–3.96 (2H, m, H-5 and 5-C*H*OTs), 4.06 (1H, m, 5-C*H*OTs), 4.08 (1H, dd, J_{gem} = 9.9 Hz, $J_{to\ 3}$ = 6 Hz, 3-C*H*OTs), 4.20 (1H, dd, J_{gem} = 9.9 Hz, $J_{to\ 3}$ = 3.7 Hz, 3-C*H*OTs), 6.21 (1H, br s, NH), 7.33 (2H, d, *J* = 8.4 Hz, aromatic), 7.36 (2H, d, *J* = 8.4 Hz, aromatic), 7.73 (2H, d, *J* = 8.4 Hz, aromatic), 7.78 (2H, d, *J* = 8.4 Hz, aromatic); ^{13}C nmr ($CDCl_3$, 50 MHz) δ: 21.72 (2 × Ar*C*H$_3$), 26.04 (C-4), 40.81 (C-3), 50.91 (C-5), 69.06 (*C*H_2OTs), 72.21 (*C*H_2OTs), 128.00 (4 × *meta*-aromatic C's), 130.02 (2 × *ortho*-aromatic C's), 130.19 (2 × *ortho*-aromatic C's), 132.23 (2 × *para*-aromatic C's), 132.26 (2 × *para*-aromatic C's), 145.23 (aromatic *C*-S), 145.51 (aromatic *C*-S), 174.26 (C-2). Anal. calcd. for $C_{20}H_{23}NO_7S_2$: C 52.97, H 5.11, N 3.09, S 14.14; found: C 52.81, H 5.13, N 3.13, S 13.88.

(±)-3-Thia-6-aza-7-oxobicyclo[3.2.1]octane (4)

To a solution of ditosylate **3** (17.0 g, 37.5 mmol) in *N*,*N*-dimethylformamide (300 mL) was added sodium sulfide nonahydrate (10.8 g, 45 mmol), and the mixture was stirred at 90°C for 45 min. Heating was stopped, and the solvent was evaporated in vacuo. The residue was taken up in acetone (100 mL), and the resulting suspension was filtered. The filtrate was concentrated to produce an oil that deposited a solid on standing under vacuum. The solid product was collected by filtration and washed with a small amount of ethyl acetate. The filtrate was concentrated and the residue was chromatographed (gradient elution using 0% → 4% methanol in ethyl acetate) to afford further product. The combined solids were recrystallized from ethyl acetate – hexanes to give **4** (3.67 g, 68%); mp 198–200°C (sealed capillary); ^{1}H nmr ($CDCl_3$, 400 MHz) δ: 1.73 (1H, dd, $J_{8ax,8eq}$ = 11.6 Hz, $J_{8ax,5}$ = 1.5 Hz, H-8_{ax}), 2.37 (1H, m, H-8_{eq}), 2.52 (1H, br dd, $J_{2eq,2ax}$ = 12.8 Hz, $J_{2eq,1}$ = 4.5 Hz, H-2_{eq}), 2.59–2.69 (2H, m, H-4_{eq} and H-5), 2.96 (1H, dd, $J_{4ax,4eq}$ = 12 Hz, $J_{4ax,5}$ = 1.5 Hz, H-4_{ax}), 3.03 (1H, d, $J_{2ax,2eq}$ = 12.8 Hz, H-2_{ax}), 3.98 (1H, br dd, $J_{1,8eq}$ = 5.8 Hz, $J_{1,2eq}$ = 4.5 Hz, H-1), 6.31 (1H, br s, NH); ^{13}C nmr (D_2O, 100 MHz) δ: 25.69 (C-4), 30.04 (C-2), 35.76 (C-8), 39.87 (C-5), 50.83 (C-1), 181.51 (C-6). An analytical sample was obtained by sublimation at 0.2 Torr and 110°C. Anal. calcd. for C_6H_9NOS: C 50.32, H 6.34, N 9.78, S 22.39; found: C 50.36, H 6.29, N 9.78, S 22.79.

(±)-(3β,5β)-3-Amino-5-(methoxycarbonyl)thiane hydrochloride (5)

A solution of lactam **4** (3.00 g, 20.95 mmol) in methanol (50 mL) was treated with concentrated hydrochloric acid (0.25 mL), and the mixture was heated at reflux temperature for 12 h. Heating was stopped, and the solvent was evaporated. The residual solid was recrystallized from isoamyl alcohol. The product crystals were washed with ether and dried in vacuo at 110°C to give **5** (4.05 g, 91%); mp 167–168°C; ^{1}H nmr (DMSO-d_6, 400 MHz) δ: 1.49 (1H, apparent q, J_{app} = 12 Hz, H-4_{ax}), 2.30 (1H, br d, $J_{4eq,4ax}$ = 12 Hz, H-4_{eq}), 2.51 (1H, dd, $J_{2ax,2eq}$ = 13.5 Hz, $J_{2ax,3}$ = 12 Hz, H-2_{ax}), 2.61 (1H, dd, $J_{6ax,6eq}$ = 13 Hz, $J_{6ax,5}$ = 12 Hz, H-6_{ax}), 2.70–2.83 (3H, m, H-2_{eq}, H-5 and H-6_{eq}), 3.26 (1H, m, H-3), 3.64 (3H, s, OCH_3), 8.50 (3H, br s, NH_3^+); ^{13}C nmr (DMSO-d_6, 100 MHz) δ: 28.17 (C-6), 29.34 (C-4), 32.11 (C-2), 43.18 (C-5), 49.12 (C-3), 51.98 (OCH_3), 172.50 (C=O). Anal. calcd. for $C_7H_{13}NO_2S$·HCl: C 39.71, H 6.67, N 6.62, S 15.14; found: C 39.78, H 6.65, N 6.59, S 15.87.

(±)-(3β,5β)-3-Amino-5-(hydroxymethyl)thiane (6)

A stirred suspension of **5** (3.5 g, 16.5 mmol) in dry oxolane (40 mL) was treated with a 2 M solution of lithium borohydride in oxolane (15 mL, 30 mmol). The resulting clear solution was heated at reflux temperature for 2 h. The reaction mixture was cooled, methanol (25 mL) was added slowly, and then concentrated hydrochloric acid was added dropwise until the solution was acidic to pH paper; the solvents were evaporated. The residue was dissolved in methanol (50 mL) and the solution was evaporated; the residue was then dissolved in concentrated aqueous ammonia (70 mL). The solution was continuously extracted with chloroform overnight. The dried ($MgSO_4$) extracts were concentrated to yield **6** as a solid (2.27 g, 93%). An analytical sample was obtained by recrystallization from dichloromethane–hexanes; mp 124–125°C; ^{1}H nmr ($CDCl_3$, 400 MHz) δ: 0.85 (1H, apparent q, J_{app} = 12 Hz, H-4_{ax}), 1.55 (3H, br s, OH and NH_2), 1.93–2.04 (2H, m, H-4_{eq} and H-5), 2.23 (1H, dd, $J_{2ax,2eq}$ = 13 Hz, $J_{2ax,3}$ = 12 Hz, H-2_{ax}), 2.33 (1H, dd, $J_{6ax,6eq}$ = 13 Hz, $J_{6ax,5}$ = 10 Hz, H-6_{ax}), 2.56–2.65 (2H, m, H-2_{eq} and H-6_{eq}), 2.98 (1H, dddd, $J_{3,2ax}$ = 12 Hz, $J_{3,4ax}$ = 12 Hz, $J_{3,4eq}$ = 3.5 Hz, $J_{3,2eq}$ = 3 Hz, H-3), 3.45 (1H, dd, J_{gem} = 11 Hz, $J_{to\ 5}$ = 7 Hz, CH_2OH), 3.53 (1H, dd, J_{gem} = 11 Hz, $J_{to\ 5}$ = 6 Hz, CH_2OH); ^{13}C nmr ($CDCl_3$, 50 MHz) δ: 30.16 (C-4), 36.75 (C-6), 38.80 (C-2), 42.32 (C-5), 50.73 (C-3), 67.06 (CH_2OH); ms (EI): 147 (M$^+$) (24.4%), 116 (M − CH_2OH)$^+$ (7.3%), 104 (M − C_2H_5N)$^+$ (12.8%), 86 (M − CH_2SCH_3)$^+$ (100%). Exact Mass calcd. for $C_6H_{13}NOS$: 147.0719; found (hrms): 147.0707. Anal. calcd. for $C_6H_{13}NOS$: C 48.95, H 8.90, N 9.51, S 21.77; found: C 48.80, H 8.91, N 9.31, S 23.12.

(±)-trans-*3-Ethoxy*-N-*[N'-[(3'β,5'β)-5'-(hydroxymethyl)thian-3'-yl]-carbamoyl]propenamide (8)*

Following the procedure of Shealy and O'Dell (13*a*), silver cyanate was dried at 100°C and <1 Torr in the dark for 2 h. A solution of amine **6** (1.47 g, 10 mmol) in dry, distilled *N*,*N*-dimethylformamide (50 mL) was dried over 3 Å molecular sieves under an argon atmosphere until needed. All glassware was dried overnight at 140°C, and assembled while hot, under an argon atmosphere.

A suspension of silver cyanate (4.5 g, 30 mmol) in dry benzene (20 mL) was heated at reflux temperature for 30 min, under an argon atmosphere. A solution of *trans*-3-ethoxypropenoyl chloride (13*b*) (2.00 g, 15 mmol) in dry benzene (10 mL) was added using a syringe, and the mixture was boiled for 45 min. Heating and stirring were stopped, and the suspended solids were allowed to settle for 2 h.

The solution of amine **6** was transferred to a dry flask by cannula, under argon pressure, and cooled to −60°C. A 20-mL portion (~10 mmol) of the acyl isocyanate solution was removed with a syringe, and was added dropwise to the amine over 15 min. The temperature was raised quickly to −30°C. Stirring was continued as the mixture warmed gradually to 23°C overnight. The solvent was then evaporated under high vacuum, and the residue was re-evaporated from ethanol (50 mL). Traces of solvent were removed on the vacuum pump, and the solid product was recrystallized from 95% ethanol to afford **8** (2.26 g, 78%); mp 171–172°C; IR ν_{max} (KBr): 3510 (sh, OH), 3310, 3230 (sh, NH), 2980 (vinyl CH), 1700, 1670, 1605 (s, C=O), 1530, 1510 (C=C) cm^{-1}; ^{1}H nmr ($CDCl_3$, 400 MHz) δ: 1.11 (1H, apparent q, J_{app} = 12 Hz, H-4_{ax}), 1.37 (3H, t, *J* = 7 Hz, CH_3), 1.56 (1H, br s, OH), 2.00–2.13 (2H, m, H-4_{eq} and H-5), 2.29 (1H, dd, $J_{2ax,2eq}$ = 13 Hz, $J_{2ax,3}$ = 11 Hz, H-2_{ax}), 2.43 (1H, dd, $J_{6ax,6eq}$ = 12.5 Hz, $J_{6ax,5}$ = 11 Hz, H-6_{ax}), 2.64 (1H, br d, $J_{2eq,2ax}$ = 13.5 Hz, H-2_{eq}), 2.87 (1H, ddd, $J_{6eq,6ax}$ = 13 Hz, $J_{6eq,5}$ = 2 Hz, $J_{6eq,2eq}$ ~1.5 Hz, H-6_{eq}), 3.48 (1H, dd,

[5]For the Exact Mass determinations of peaks at *m/z* 99 and 79 in compounds **8** and **9**, peak matching to $C_2H_6O_2$ = 74.03678 and CH_2Cl_2 = 83.9536 was used for calibration.

*(±)-1-{(3′β,5′β)-5′-(Hydroxymethyl)thian-3′-yl}-2,4(1H,3H)-pyrimidinedione S-oxide (**10**)*

To a solution of sulfide **9** (1.00 g, 4.13 mmol) in water (30 mL) at 0°C was added sodium periodate (0.929 g, 4.34 mmol) in a minimum amount of water, and the reaction mixture was stirred for 1 h. An excess of solid sodium bisulfite was added with cooling, and the solution was evaporated. The solid residue was dried in vacuo, and extracted with methanol (3 × 30 mL). The extracts were filtered, the filtrate was evaporated, and the residue was chromatographed by gravity on flash-grade silica, using a chloroform–methanol gradient (10% → 20%) as eluant. No separation of sulfoxide diastereomers was observed. Evaporation of the combined product fractions afforded a glassy oil, which was dissolved in water. The solution was freeze-dried, to afford **10** as an amorphous powder (0.732 g, 69%); mp > 155°C; IR ν_{max} (KBr): 3404 (br, OH), 1685 (C=O), 1101 (S=O) cm^{-1}; ^{1}H nmr (D_2O, 400 MHz) major (axial S=O) diastereomer δ: 1.72 (1H, apparent q, J_{app} = 12 Hz, H-4′$_{ax}$), 1.93 (1H, br d, $J_{4'eq,4'ax}$ = 12 Hz, H-4′$_{eq}$), 2.38 (1H, dd, $J_{6'ax,6'eq}$ = 13.5 Hz, $J_{6'ax,5'}$ = 13 Hz, H-6′$_{ax}$), 2.50 (1H, m, H-5′), 2.92 (1H, dd, $J_{2'ax,2'eq}$ = 14 Hz, $J_{2'ax,3'}$ = 14 Hz, H-2′$_{ax}$), 3.04 (br d, $J_{6'eq,6'ax}$ = 13.5 Hz, H-6′$_{eq}$), 3.18 (1H, m, H-2′$_{eq}$), 3.45–3.56 (2H, m, CH_2OH), 4.96 (1H, m, H-3′), 5.71 (1H, d, $J_{5,6}$ = 8 Hz, H-5), 7.52 (1H, d, $J_{6,5}$ = 8 Hz, H-6); minor (equatorial S=O) diastereomer δ: 1.60 (1H, apparent q, J_{app} = 12 Hz, H-4′$_{ax}$), 1.84 (1H, br d, $J_{4'eq,4'ax}$ = 12 Hz, H-4′$_{eq}$), 1.88–1.98 (1H, m, H-5′), 2.44 (1H, dd, $J_{6'ax,6'eq}$ = 12 Hz, $J_{6'ax,5'}$ = 12 Hz, H-6′$_{ax}$), 2.96 (1H, dd, $J_{2'ax,2'eq}$ = 12 Hz, $J_{2'ax,3'}$ = 12 Hz, H-2′$_{ax}$), 3.45–3.56 (3H, m, CH_2OH and H-6′$_{eq}$), 3.63 (1H, br d, $J_{2'eq,2'ax}$ = 12 Hz, H-2′$_{eq}$), 4.53 (1H, m, H-3′), 5.72 (1H, d, $J_{5,6}$ = 8 Hz, H-5), 7.55 (1H, d, $J_{6,5}$ = 8 Hz, H-6); ^{13}C nmr (D_2O, 100 MHz) major (axial S=O) diastereomer δ: 31.34 (C-5′), 31.87 (C-4′), 45.98 (C-6′), 48.05 (C-3′), 52.31 (C-2′), 64.80 (CH_2OH), 102.20 (C-5), 143.71 (C-6), 151.71 (C-2), 166.12 (C-4); minor (equatorial S=O) diastereomer δ: 31.34 (C-4′), 33.30 (C-5′), 45.41 (C-6′), 50.01 (C-3′), 51.35 (C-2′), 64.39 (CH_2OH), 102.29 (C-5), 143.10 (C-6), 151.55 (C-2), 166.05 (C-4). Treatment of **10** with *tert*-butyldimethylsilyl chloride afforded the corresponding silyl ether derivative (TLC: **10**, R_f = 0.26; silyl ether, R_f = 0.76; using 8:2 (v/v) chloroform–methanol as eluant). The ^{1}H nmr signals attributable to H-5 in the two diastereomers of this derivative were separated sufficiently at 400 MHz (Δδ = 0.098 ppm) to show the diastereomer ratio to be 12:5.

*(±)-1-{(2′β,3′β,5′β)-2′-Acetoxy-5′-(acetoxymethyl)thian-3′-yl}-2,4(1H,3H)-pyrimidinedione (**11**a)*

A mixture of sulfoxide **10** (200 mg, 0.77 mmol), acetic anhydride (15 mL), and *p*-toluenesulfonic acid (cat.) was heated in an oil bath at 100°C under a nitrogen atmosphere for 2.5 h. The excess of acetic anhydride was evaporated under vacuum. The dried residue was adsorbed on a small amount of silica gel, applied to a silica gel column, and chromatographed using a gradient of chloroform–methanol (0% → 2%) as eluant. All of the product fractions could be seen on TLC analysis, using 2% (v/v) methanol in chloroform as eluant, to contain two components (R_f = 0.17 and 0.23) in approximately equal proportions. Evaporation of these fractions afforded a mixture of **11***a* (2′-β) and its 6′-β isomer **11***b* (171 mg, 65%). Recrystallization of this material from isobutanol–*N*,*N*-dimethylformamide effected a partial resolution, affording 22 mg (8.3%) of an 8:1 mixture of **11***a*:**11***b*; ^{1}H nmr (pyridine-d_5, 400 MHz) δ: 1.83 (1H, br d, $J_{4'eq,4'ax}$ = 12.3 Hz, H-4′$_{eq}$), 2.01 (3H, s, CH_3-11′), 2.04 (3H, s, CH_3-9′), 2.16 (1H, apparent q, J_{app} = 12.4 Hz, H-4′$_{ax}$), 2.45 (1H, m, H-5′), 2.53 (1H, br d, $J_{6'eq,6'ax}$ = 13.4 Hz, H-6′$_{eq}$), 2.76 (1H, dd, $J_{6'ax,6'eq}$ = 13.2 Hz, $J_{6'ax,5'}$ = 11.9 Hz, H-6′$_{ax}$), 4.07 (1H, dd, J_{gem} = 11.0 Hz, $J_{to\ 5'}$ = 6.8 Hz, CH_2OAc), 4.12 (1H, dd, J_{gem} = 11.0 Hz, $J_{to\ 5'}$ = 5.9 Hz, CH_2OAc), 5.32 (1H, ddd, $J_{3',4'ax}$ = 13.2 Hz, $J_{3',2'}$ = 2.4 Hz, $J_{3',4'eq}$ = 3.5 Hz, H-3′), 5.89 (1H, d, $J_{5,6}$ = 8.1 Hz, H-5), 6.44 (1H, d, $J_{2',3'}$ = 2.4 Hz, H-2′), 7.66 (1H, d, $J_{6,5}$ = 8.1 Hz, H-6); ^{13}C nmr (pyridine-d_5, 50 MHz) δ: 20.65 (C-9′ and C-11′), 26.17 (C-4′), 27.94 (C-6′), 40.15 (C-5′), 56.76 (C-3′), 67.66 (C-7′), 71.34 (C-2′), 102.14 (C-5), 141.18 (C-6), 152.26 (C-2), 164.09 (C-4), 169.38 (C-10′), 170.67 (C-8′); ms (EI): 342 (M^+) (3.8%), 282 (M − HOAc)$^+$ (20.1%), 230 (M − pyrimidinedione)$^+$ (13.2%), 222 (M − 2HOAc)$^+$ (28.5%), 113 (pyrimidinedione + H)$^+$ (100%): Exact Mass calcd. for $C_{14}H_{18}N_2O_6S$: 342.0886; found (hrms): 342.0887.

*(±)-5-Amino-6-chloro-4-{[(3′β,5′β)-5′-(hydroxymethyl)thian-3′-yl]-amino}pyrimidine (**12**)*

According to the method of Daluge and Vince (11), a solution of amino alcohol **6** (250 mg, 1.7 mmol), 5-amino-4,6-dichloropyrimidine (563 mg, 3.44 mmol), and triethylamine (1.2 mL, 8.5 mmol) in *n*-butanol (10 mL, dried over 3 Å molecular sieves) was heated at reflux temperature in a nitrogen atmosphere for 24 h. The mixture was cooled, and the solvent was evaporated. The residue was adsorbed on a small amount of silica gel, and applied to a silica gel column. Elution with ethyl acetate afforded **12** as a yellowish solid (412 mg, 88%); mp 177–178°C; ^{1}H nmr (DMSO-d_6, 400 MHz) δ: 1.10 (1H, apparent q,

[6]The overlapping signals at δ 151.20 ppm could be separated by addition of ~20% (v/v) of benzene-d_6 to the sample.

This paper is dedicated to Professor Ian D. Spenser

HAJIME KUBO, SHIGERU OHMIYA, and ISAMU MURAKOSHI. Can. J. Chem. **72**, 214 (1994).

It was demonstrated that the attack of Grignard reagents such as methyl-, allyl-, and 3,3-dimethoxypropyl magnesium bromides on 11,12-dehydrocytisine occurs on the α-face, to give the corresponding 11α-alkylcytisine. (−)-Camoensine and (−)-camoensidine were synthesized from (−)-cytisine via the Grignard reaction. The absolute stereochemistry of the above alkaloids was confirmed to be 7*R*, 9*R*, 11*R* and 6*S*, 7*R*, 9*R*, 11*R*, respectively.

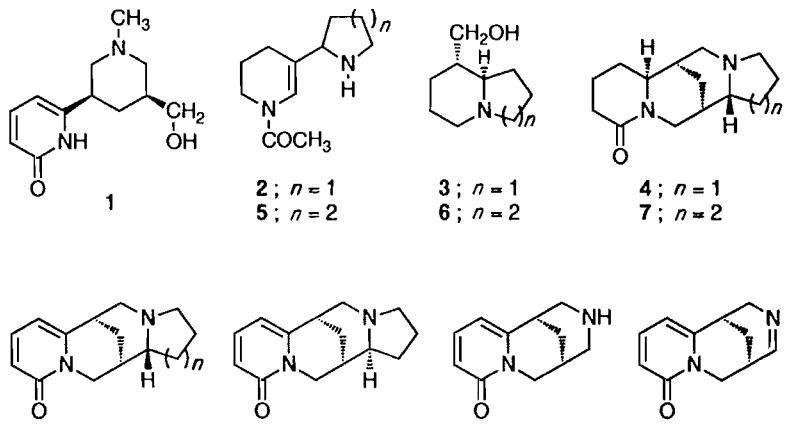
HAJIME KUBO, SHIGERU OHMIYA et ISAMU MURAKOSHI. Can. J. Chem. **72**, 214 (1994).

On a démontré que l'addition de réactifs de Grignard, comme les bromures de méthyl-, allyl- et 3,3-diméthoxypropylmagnésium, sur la 11,12-déhydrocytisine se produit par la face α et qu'elle conduit aux 11α-alkylcytisines. Faisant appel à une addition de Grignard, on a synthétisé la (−)-camoensine et la (−)-camoensidine à partir de la cytisine. On a confirmé que les configurations absolues des alcaloïdes mentionnés plus haut sont respectivement 7*R*, 9*R*, 11*R* et 6*S*, 7*R*, 9*R*, 11*R*.

[Traduit par la rédaction]

Lupin alkaloids occur mainly in the Papilionoideae of the family Leguminosae, such as the genera *Sophora* (1), *Euchresta* (2), and *Thermopsis* (3). Most lupin alkaloids contain a quinolizidine ring system, while a few, such as kuraramine (**1**) and ammodendrine (**5**) (4) contain piperidine ring(s) as structural units.

We have found that *Maackia* species (Leguminosae) accumulate atypical alkaloids such as maackiamine (**2**) (5), tashiromine (**3**) (6), and (−)-camoensidine (**4**) (7). These compounds are structurally related to typical lupin alkaloids but they differ in that they contain a pyrrolidine ring in place of a piperidine ring or an indolizidine ring system instead of a quinolizidine ring system. For example, **2**, **3**, and **4**, respectively, correspond to the typical lupin alkaloids, ammodendrine (**5**), epilupinine (**6**), and (−)-lupanine (**7**) (Scheme 1). *Camoensia* species (Leguminosae) accumulate indolizidine-type alkaloids such as (−)-leontidine (**10**), (−)-camoensine (**8**), (−)-camoensidine (**4**), etc. but do not contain quinolizidine-type alkaloids (8, 9), while in *Maackia* species the two types of alkaloids occur together (5–7). Comparison of the absolute stereochemistry of the two types of alkaloids is of interest in connection with their biosynthesis.



SCHEME 1

Santamaria and Khuong-Huu (8) reported the absolute stereochemistry of the tetracyclic indolizidine-type of alkaloids (−)-camoensine (**8**) and (−)-camoensidine (**4**), which were isolated from *Camoensia maxima*. Their assignments were based on that of (−)-leontidine (**10**), which had been isolated from *Leontice* species (Berberidacea) by Iskandarov et al. (11). The stereochemistry of (−)-leontidine (**10**) had, in turn, been assigned to be 7*R*, 9*R*, 11*R* by reference to (−)-cytisine (**11**), the absolute configuration of which is known (10). (−)-Leontidine

[a]Spectra were run in $CDCl_3$.

was synthesized (11) from (−)-cytisine, via a Grignard reaction of 11,12-dehydrocytisine (**12**) with allyl magnesium bromide giving 11-allylcytisine (11), which was then cyclized to (−)-leontidine (**10**). However, questions of the absolute configuration of (−)-leontidine (**10**) and (−)-camoensidine (**4**) remain, especially that of the stereochemistry at C-11: (1) the synthesis of **10** via the Grignard reaction demands an attack by the Grignard reagent from the more hindered side; (2) the ^{13}C NMR spectrum reported (9) for (−)-camoensidine (**4**) is not in agreement with that of **4** isolated from *Maackia* species, the relative stereochemistry of which was nevertheless established as **4** (7). We therefore reinvestigated the Grignard reaction of 11,12-dehydrocytisine (**12**) with some alkyl magnesium halides, from a stereochemical standpoint. One of the Grignard adducts obtained, 11α-(3,3-dimethoxypropyl)cytisine (**15**), was transformed to (−)- camoensidine (**4**) via (−)-camoensine (**8**) and hence the absolute stereochemistry of **4** and **8** was determined. The results obtained are reported here.

11,12-Dehydrocytisine (**12**) was obtained in 40% yield by treatment of 12-chlorocytisine, derived from (−)-cytisine, with KOH–MeOH. The position of the imine group was assigned as the $C_{(11)}$-$N_{(12)}$ by ^{1}H NMR decoupling experiments: The signal due to the C-9 proton (δ 2.90) was simplified by selective irradiation of the C-10β proton (δ 4.33) and of the C-11 imine proton (δ 7.86).

Dehydrocytisine **12** was reacted with the Grignard reagents, methyl magnesium bromide, allyl magnesium bromide, and 3,3-dimethoxypropyl magnesium bromide, in THF to give the corresponding 11-alkylcytisines (**13–15**) in 60, 23, and 24% yields, respectively.

The products were shown to be 11α-alkylcytisines by nuclear Overhauser effect (NOE) experiments and analysis of the ^{1}H NMR and ^{13}C NMR spectra. Assignments were based on decoupling experiments and ^{1}H–^{1}H and ^{1}H–^{13}C correlation spectroscopy (COSY), taking into account the assignments for (−)-cytisine and its derivatives (Tables 1 and 2). The signals of the H-13α (δ 2.74) and the H-8_{exo} (δ 2.23) protons of 11-methylcytisine (**13**) were enhanced by irradiation at the CH_3-11 signal (δ 1.31). This indicates that the C-ring of **13** possesses a chair conformation and that the CH_3-11 group is oriented axially (Scheme 2). Hence, the absolute configuration of the C-11 of **13** must be *R*. This result is supported by observa-

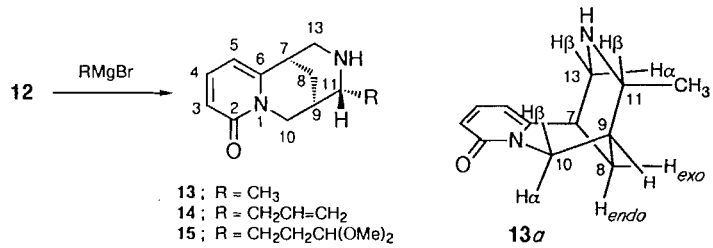

SCHEME 2

tion of an NOE between the C-10β and C-11 protons and of higher field chemical shifts of the C-8 and C-13 carbons in the ^{13}C NMR spectrum of **13** in comparison with those of cytisine (**11**) (Table 2).

The ^1H NMR and ^{13}C NMR spectra of 11-allylcytisine (**14**) and 11α-(3,3-dimethoxypropyl)cytisine (**15**) showed very similar patterns to that of 11-methylcytisine (**13**) (Tables 1 and 2), indicating that they have the same absolute stereochemistry. This was confirmed by an enhancement of the signal due to the C-11 proton (δ 3.03 for **14**, δ 2.91 for **15**) in NOE experiments, on irradiation of the signal of the C-10β proton (δ 4.13 for **14**, δ 4.13 for **15**). The above results demonstrate that the attack of the Grignard reagents on 11,12-dehydrocytisine (**12**) takes place from the α-face.

Treatment of 11-(3,3-dimethoxypropyl)cytisine (**15**) with 10% – HCl-Zn gave a tetracyclic α-pyridone-type alkaloid in 85% yield. This compound was identical with (−)-camoensine (**8**) isolated from *Camoensia maxima* and *C. brevicalyx* (^{13}C NMR and $[\alpha]_D$) (9). The absolute stereochemistry of (−)-camoensine (**8**) is therefore 7*R*, 9*R*, 11*R*, which was the same as that of the typical lupin alkaloid, (−)-anagyrine (**9**).

Catalytic hydrogenation of (−)-camoensine (**8**) with PtO_2 in AcOH yielded a tetracyclic piperidone-type alkaloid in 95% yield. This compound was identical with an authentic sample of (−)-camoensidine (**4**) isolated from *Maackia* species.[3] Thus, the absolute configuration of (−)-camoensidine (**4**) is 6*S*, 7*R*, 9*R*, 11*R*, which is the same as that of (−)-lupanine (**7**).

The above assignments are in agreement with the results obtained by Santamaria and Khuong-Huu (8) but different from those of Iskandarov et al. (11). It would appear that epimerization at C-11 occurs in the course of the cyclization of 11-allylcytisine (**14**) to (−)-leontidine (**10**) in the Iskandarov synthesis.

It is of interest from a biosynthetic and chemotaxonomic point of view that the structurally related alkaloids, (−)-lupanine (**7**) and (−)-camoensidine (**4**), coexist in the same plant and have the same absolute stereochemistry. Further investigation of the absolute configuration of tashiromine and maackiamine is being undertaken in our laboratories.

Experimental

The following equipment was used to obtain physical data: infrared spectra, Hitachi 215 grating infrared spectrometer; ^1H and ^{13}C NMR spectra, JEOL JNM-GSX 270 spectrometer with tetramethylsilane (TMS) as an internal standard; optical rotations, Jasco DIP-181 polarimeter; EIMS, JEOL D-300 spectrometer. Column chromatography was carried out with Kiesel gel 60 (230–400 mesh, Merck). Thin-layer chromatography (TLC) was performed on 0.25 mm precoated silica gel (60 F_{254}, Merck), and spots were detected by exposure to I_2 vapor or spraying with Dragendorff's reagent.

11,12-Dehydrocytisine ***12***

Dehydrocytisine **12** was prepared from (−)-cytisine (**11**) by the procedure reported by Bohlmann et al. (12). **12**, δ_H ($CDCl_3$): 7.86 (1H, m, 11-H), 7.25 (1H, dd, J = 9.2, 6.7 Hz, 4-H), 6.39 (1H, dd, J = 9.2 and 1.8 Hz, 3-H), 6.01 (1H, dd, J = 6.7, 1.8 Hz, 5-H), 4.33 (1H, ddd, J = 15.3, 1.2, 1.2 Hz, 10β-H), 3.93 (1H, dddm, J = 18.3, 3.7, 3.7 Hz, 13-H), 3.76 (1H, ddm, J = 18.3, 1.8 Hz, 13-H), 3.56 (1H, dd, J = 15.3, 5.5 Hz, 10α-H), 3.12 (1H, m, 7-H), 2.90 (1H, m, 9-H), 2.12 (1H, dm, J = 13.5 Hz, 8-H), 1.90 (1H, dm, J = 13.5 Hz, 8-H).

11α-Methylcytisine ***13***

A solution of methyl magnesium bromide (1 mmol) in THF (2 mL) was added at room temperature with stirring under argon to a solution of **12** (5.2 mg, 0.028 mmol) in dry THF (3 mL). After stirring for 8 h, the reaction mixture was quenched by addition of H_2O, made basic with concentrated NH_4OH and extracted three times with CH_2Cl_2. The combined CH_2Cl_2 extracts were dried and evaporated to dryness in vacuo. The residue was purified by silica gel column chromatography using CH_2Cl_2–MeOH (20:1) to yield 11α-methylcytisine **13** (3.3 mg, 60%) as a colourless oil. **13**, $[\alpha]_D^{20}$ −108.7 (*c* 1.0, EtOH); *m/z*(%): 204 (M^+, 100), 160 (34), 148 (55), 147 (78), 146 (80), 134 (22), 96 (60), 58 (93).

11α-Allylcytisine ***14***

A solution of allyl magnesium bromide (10 mmol) in THF was added at room temperature with stirring under argon to a suspension of the hydrochloride of **12** (203 mg, 0.90 mmol) in dry THF (10 mL). After stirring for 8 h, the reaction mixture was treated with H_2O (3 mL), made alkaline with concentrated NH_4OH and then extracted three times with CH_2Cl_2. The combined extracts were dried and concentrated in vacuo. The residue was separated by silica gel column chromatography with CH_2Cl_2–MeOH (20:1) to give 11α-allylcytisine **14** (48 mg, 23%) as a colourless oil. **14**, $[\alpha]_D^{20}$ −94.7 (*c* 1.0, EtOH); *m/z*(%): 230 (M^+, 64), 189 (9), 169 (23), 148 (38), 147 (63), 146 (41), 134 (21), 84 (100).

11α-(3,3-Dimethoxypropyl)cytisine ***15***

A solution of 3,3-dimethoxypropyl magnesium bromide (2 mmol) in dry THF was added at room temperature with stirring under argon to a solution of **12** (88.4 mg, 0.47 mmol) in dry THF (5 mL). The reaction mixture was stirred for 60 h, treated with H_2O (5 mL), made alkaline with concentrated NH_4OH, and then extracted three times with CH_2Cl_2. The combined extracts were dried and evaporated to dryness

[3]The question of the ^{13}C NMR spectrum of (−)-camoensidine isolated from Camoensia brevicalyx (9) remains.

This paper is dedicated to Professors David B. McLean and Ian D. Spenser

JULIAN M. DUST and ERWIN BUNCEL. Can. J. Chem. **72**, 218 (1994).

To elucidate the reactivity of super-electrophiles such as 4,6-dinitrobenzofuroxan as compared to normal electrophiles such as 1,3,5-trinitrobenzene, reaction of isopropoxide ion ($iPrO^-$) with a series of ambident super-electrophiles was studied by 400 MHz ^1H nuclear magnetic resonance spectroscopy. The 2-(nitroaryl)-4,6-dinitrobenzotriazole 1-oxides, **1–3**, possess both a super-electrophilic (C-7) site and a normal electrophilic (C-1′) site. Nucleophiles can demonstrate selectivity for attack at C-7, which leads to formation of persistent anionic σ-adducts (Meisenheimer complexes), as compared to C-1′, which leads to N-2:C-1′ bond scission. The most reactive substrate, 2-(2′,4′,6′-trinitrophenyl)-4,6-dinitrobenzotriazole 1-oxide (Pi-DNBT, **1**) was found to be the least selective substrate in C-7 adduct formation, while 2-(2′,4′-dinitrophenyl)- and 2-(4′-nitrophenyl)-4,6-dinitrobenzotriazole 1-oxides (DNP-DNBT, **2**, and NP-DNBT, **3**, respectively) showed increasing selectivity towards $iPrO^-$, in turn. These results are discussed on the basis of overall selectivity for C-7 adduct formation and the relative selectivity of $iPrO^-$ as compared to methoxide and *tert*-butoxide ions. The conclusions are illustrated using comparative energy profiles. In terms of pathways for decomposition of the adducts, the C-7 adducts decompose via dissociation back to substrate and nucleophile and, thence, through C-1′ adduct formation to the scission products. However, for **1**, the C-7 adduct **1***a* has now been found to decompose to 7-isopropyl-2-picryldinitrobenzotriazole, **1***c*. The possible mechanism of this formal internal redox will be discussed.

JULIAN M. DUST et ERWIN BUNCEL. Can. J. Chem. **72**, 218 (1994).

Afin d'évaluer la réactivité des super-électrophiles, comme le 4,6-dinitrobenzofuroxane, par rapport à celle d'électrophiles normaux, comme le 1,3,5-trinitrobenzène, on a utiliser la résonance magnétique nucléaire du ^1H à 400 MHz pour étudier la réaction de l'ion isopropylate ($iPrO^-$) avec une série de superélectrophiles ambidents. Les 2-(nitroaryl)-4,6-dinitrobenzotriazole 1-oxydes, **1–3**, possèdent un site superélectrophile (C-7) ainsi qu'un site électrophile normal (C-1′).Les nucléophiles permettent de démontrer une sélectivité pour l'attaque en C-7 qui conduit à la formation d'adduits σ anioniques persistants (complexes de Meisenheimer) alors que l'attaque en C-1′ conduit à une scission de la liaison N-2:C-1′. On a trouvé que le substrat le plus réactif, la 2-(2′,4′,6′-trinitrophényl)-4,6-dinitrobenzotriazole 1-oxyde (Pi-DNBT, **1**), est le substrat le moins sélectif pour la formation d'un adduit en C-7 alors que les 2-(2′,4′-dinitrophényl)- et 2-(4′-nitrophényl)-4,6-dinitrobenzotriazole 1-oxydes (respectivement la DNP-DNBT, **2**, et NP-DNBT, **3**) présentent chacune une sélectivité de plus en plus grande vis-à-vis du $iPrO^-$. On discute de ces résultats en fonction de la sélectivité globale de la formation d'adduits en C-7 et la sélectivité relative du $iPrO^-$ comparée à celles des ions méthylate et *tert*-butylate. On illustre les conclusions en utilisant des profils d'énergie. En termes de chemins réactionnels conduisant à la décomposition des adduits, les adduits en C-7 se décomposent par le biais d'une dissociation redonnant le substrat et le nucléophile et, en conséquence, aux produits de scission par la formation d'un adduit en C-1′. Toutefois, pour le composé **1**, on a maintenant trouvé que l'adduit en C-7, **1***a*, se décompose en 7-isopropyl-2-picryldinitrobenzotriazole, **1***c*. On discute du mécanisme possible de cette réaction rédox interne formelle.

[Traduit par la rédaction]

We have been concerned with studies of super-electrophiles, a class of heteroaromatic compounds that show exalted reactivity with nucleophiles in formation of σ-bonded anionic (Meisenheimer) complexes (1). These are typified by 4,6-dinitrobenzofuroxan (DNBF), much as conventional electron-deficient aromatics are well represented by 1,3,5-trinitrobenzene (TNB) (1–6). A straightforward comparison suffices to demonstrate the enhanced reactivity of these compounds as compared to normal electrophiles. Thus, the forward rate constant for formation of the methoxide adduct of DNBF, DNBF·OMe^-, is 265-fold larger than the corresponding rate constant for formation of the methoxide adduct of TNB, TNB·OMe^-, while the equilibrium constant for formation of the DNBF·OMe^- adduct is 9.1×10^8 times larger than the constant for TNB·OMe^- formation (2, 7). Moreover, DNBF reacts quantitatively at room temperature with such weak carbon nucleophiles as aniline (8) or 1,3,5-trimethoxybenzene (9) to give Meisenheimer C-adducts that are formally products of electrophilic aromatic substitution of the respective benzene rings. In fact, we have used the reaction of DNBF with indole, 2-methylindole, and 1,2,5-trimethylpyrrole to quantify the electrophilicity of DNBF and have shown that *DNBF is more electrophilic than such strong electrophiles as the 4-nitrobenzenediazonium cation and the proton* (10). On these grounds, DNBF and related compounds may be justifiably termed super-electrophiles.

One of our approaches to understanding the exalted reactivity of super-electrophiles has been to design novel ambident substrates, comprising the 2-(nitroaryl)-4,6-dinitrobenzotriazole 1-oxide family, **1–3** (*8b*, 11–14), that contain both types of electrophilic sites. In common with DNBF, the series possesses a

super-electrophilic centre at C-7, but also a second electrophilic centre, C-1′, analogous to that in picryl derivatives. The initial result of C-7 attack for the 2-(nitroaryl)-4,6-dinitrobenzotriazole 1-oxide series, as outlined in Scheme 1 (Path a), is formation of a relatively persistent C-7 σ-bonded anionic adduct, **1***a*–**3***a*. The ultimate products of nucleophilic reaction with **1–3** are the substituted nitroaromatics **5–7**, and the 4,6-dinitrobenzotriazole 1-oxyanion, $DNBT^-$, **4**, which arise from attack on the conventional electrophilic C-1′ site (Path b) with formation of the metastable Meisenheimer adducts **1***b*–**3***b*, followed by their ready decomposition in an overall S_NAr displacement (15). Hence for the series **1–3**, reaction at C-7 as compared to C-1′ provides a direct measure of selectivity (k_1 vs. k_2) for complex formation at the C-7 vs. the C-1′ site, as well as insight into the factors affecting the super-electrophilicity of the C-7 position, while avoiding the difficulties inherent in comparing the electrophilicity of two different molecules.

In fact, a broad range of selectivities has been demonstrated for various members of the 2-(nitroaryl)-4,6-dinitrobenzotriazole 1-oxide family. The initial determination of the super-electrophilicity of the C-7 site was based, for example, on the comparatively high electrophilicity shown by the C-7 site of **1** (2-(picryl)-4,6-dinitrobenzotriazole 1-oxide, Pi-DNBT) towards ethanethiol (8*b*); the reactivity of TNB (1–7) and that of DNBF (10, 15*a*, 16, 17) provided benchmarks for comparison. This conclusion has been extended to the other members of the series, **2** and **3**, on the basis of reactivity with phenoxide ion. With this ambident (C- and O-) nucleophile, **1** yields only the products of N-2:C-1′ bond cleavage (**4** and picryl phenyl ether) (8*b*, 11), although formation of a transient C-7 O-adduct could be postulated as arising from an initial rapid equilibrium. However, the observation of C-7 phenoxide C-adducts of **2** and **3** (in a statistical *ortho*:*para* ratio of 2:1) demonstrates the super-electrophilicity of this site, as well as the decreased tendency for N-2:C-1′ bond rupture that follows from the progressive

decrease in the number of NO_2 groups attached to the 2-nitroaryl moiety (13).

Most recently, our comparative study of the selectivity shown by methoxide and *tert*-butoxide towards the C-7 and C-1′ sites indicated the importance of steric factors in determining the degree of regioselectivity in adduct formation with these substrates (14). A greater percentage of C-7 adduct was found to form with MeO^- than with $tBuO^-$ under equimolar conditions, while with an excess of alkoxide MeO^- also was more reactive towards the C-1′ site than was $tBuO^-$. Taken together, $tBuO^-$ was found to be the more selective nucleophile in attack at C-7, in accord with the lesser reactivity of the nucleophile. Reaction at both sites was shown to be governed primarily by steric hindrance, as measured by E_s (Taft's steric substituent constant (18)), rather than by basicity as a measure of the nucleophilicity of the attacking nucleophile (19).

In the present paper we report the results of our 400 MHz ^{1}H nmr study of the reaction of the full series of 2-(nitroaryl)-4,6-dinitrobenzotriazole 1-oxides with iso-propoxide ($iPrO^-$). The behaviour of $iPrO^-$ in reaction with **1–3** would be expected to be intermediate between that found for MeO^- and $tBuO^-$ since its basicity and steric bulk both lie in between these two alkoxides. As such, the present study completes a consistent series of alkoxides. However, some of the behaviour found prompted a reinvestigation of the reaction of methoxide ion with **1**. This distinctive behaviour will be highlighted, while other features of the reactivity of $iPrO^-$ will be discussed in relation to the other alkoxides and the regioselectivity considerations that have already proven useful in examination of these systems (8, 12–15).

Results

The reactions of substrates **1–3** with iso-propoxide (iPrOK) were studied by 400 MHz ^{1}H nmr spectrometry. Chemical shifts (ppm relative to TMS or CD_2HSOCD_3 present in the $(CD_3)_2SO$ solvent) and coupling constants (Hz) for all observed complexes, **1***a*, **2***a*, and **3***a*, are listed in Table 1; integrals support the assignments made. An internal integration standard (1,4-dibromobenzene, DBB) permitted calculation of the concentrations of all observable species at any given time (13) and forms the basis of the extent of formation data tabulated (Table 2). Experiments were carried out under a variety of concentration regimes: equimolar and two to five equivalents of iPrOK.

Reaction of Pi-DNBT (1) with iPrOK

(a) Equimolar $iPrO^-$ conditions

Injection of 1 equivalent of iPrOK in 2-propanol (3.00 M) into a solution of Pi-DNBT in $(CD_3)_2SO$ (final concentration 2.58×10^{-2} M) led to initial broadening and a decrease in intensity of the signals due to **1**, concomitant with appearance of small signals ascribable to the C-7 adduct, **1***a*. These peaks appear at 9.294 (s, $H_{3',5'}^C$) and 6.047 (s, H_7^C). The H_5^C peak is obscured by resonances of **4** that are present even in the initial spectrum (acquired within 4 min). Comparison with the H_5^C signals of related adducts (8, 11–14) shows that these peaks are typically found between 8.6 and 8.8 ppm; the protons (H_5 and H_7) of the leaving group, **4**, are found in the same region, depending upon the degree of protonation. In this case, the signals that represent **4** are centred at 8.719 and 8.697. Picrate anion, $PicO^-$, is also found in the initial spectrum (8*b*, 11–14).

In some repetitions of this experiment peaks were also noted at 9.286 (s), 8.652 (s), 6.210 (ill-resolved d, J ca. 7), and 5.989 (d, J ca. 7), ascribed to $H^c_{3',5'}$, H^c_5, O*H*, and H^c_7, respectively, of the C-7 Pi-DNBT adduct (**1***a*, Nu = OH). This assignment rests on separate experiments with **1** and OH^-.[3]

The presence of both $DNBT^-$ and $PicO^-$ signifies that displacement, presumably via the C-1′ adduct, **1***b*, has occurred along with formation of the C-7 adduct, **1***a*. However, isopropyl picrate, **5**, was not detected in this system as the result of overlap of the peaks of **5** with signals of other species present. (Separately prepared **5** has peaks at 9.103 (s, $H_{3,5}$), 4.496 (septet, J = 6.11, C*H* methine), and 1.253 (d, J = 6.11, CH_3).) Reaction of **5** with OH^- or $iPrO^-$, via S_N2 or S_NAr pathways for OH^- or via S_N2 displacement for $iPrO^-$, could generate $PicO^-$ and account for the lack of observation of **5** in the system.

A control experiment shows that the C-7 Pi-DNBT·OP*ri*$^-$ complex, **1***a*, is acid labile; peaks due to **1***a* disappear from the spectrum upon introduction of trifluoroacetic acid (TFA). This behaviour was found previously for alkoxide O-adducts but not phenoxide C-adducts of **1–3** (8, 11–14) and constitutes further support for the assignment of these resonances to the O-centred C-7 adduct, **1***a*.

Interestingly, from the first spectrum onwards the system includes an unknown singlet at 9.240. This peak increases in intensity as the reaction is monitored. Its assignment will be discussed below.

Thus, the sequence of changes observed in the reaction was as follows: initial formation of the C-7 adduct, **1***a* (Nu = OP*ri*), accompanied by evidence of N-2:C-1′ bond rupture via **1***b* and the appearance of the species responsible for the 9.240 singlet. The C-7 adduct rapidly declines in concentration (Table 2) and its signals cannot be detected after 1 h of observation. At that point the system contains $PicO^-$, **4**, and the unknown species.

(b) Excess $iPrO^-$ conditions (3 equivalents)

The initial spectrum from the reaction of **1** with an excess of iPrOK contains no signals for **1** or **5**, but prominent signals for **4** and $PicO^-$ are present. Moreover, a singlet at 8.715 can be assigned to $H_{3,5}$ of the 1,1 $iPrO^-$ adduct of isopropyl picrate, **5**, on the basis of a control experiment in which **5** was treated with an excess of $iPrO^-$ (3 equiv.) in $(CD_3)_2SO$. In the initial spectrum peaks were observed for the 1,1 adduct, as well as for its 1,3 regioisomer at 8.400 (br s, H_5) and 6.272 (br s, H_3) (22). The 1,3 $iPrO^-$ adduct of **5** rapidly gives way to the 1,1 adduct.

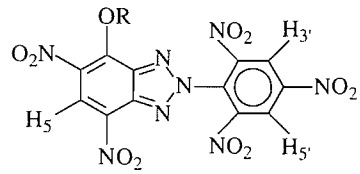
In summary, reaction of an excess of iPrOK with **1** results in relatively clean displacement to give **5**, which reacts further with $iPrO^-$ to yield the observed 1,1 adduct of isopropyl picrate. Significantly, the unknown peak at 9.240, observed under equimolar reaction conditions, is not present in this concentration regime.

*(c) Reinvestigation of the reaction of **1** with MeOK*

As previously reported (11, 12), reaction of **1** with MeO^- follows Scheme 1. However, in the present study peaks are also noted at 9.237 and 8.310 (both singlets, 2H:1H) that increase in intensity in tandem with the decline in the intensity of the peaks due to **1***a* (Nu = OMe) and along with growth in the signals of **4** and $PicO^-$.

Comparison of the Pi-DNBT,$iPrO^-$ and MeO^- reaction systems suggests that these peaks (i.e., 9.240 in the former and the 9.237, 8.310 set in the latter system) represent similar species, products that arise from a pathway not described by Scheme 1.

Observation of the signals of the C-7 Pi-DNBT·OH^- adduct in some experiments rules out this species as a candidate for the unknown resonances (20*b*). However, an overall process of deoxygenation has been observed in the reaction of MeO^- with the related 4-nitrobenzofuroxan (21), yielding a 7-alkoxy derivative and (or) a 7-oxyanion of 4-nitrobenzofurazan. Partly on the basis of this comparison, the signals of the unknown species are tentatively assigned to the respective 7-alkoxy-2-(picryl)-4,6-dinitrobenzotriazole, **1***c*. Accordingly, the signal found at 9.240 in the Pi-DNBT,$iPrO^-$ system and at 9.237 in the Pi-DNBT,MeO^- system could belong to the ring protons ($H_{3',5'}$) of **1***c* (where OR = OP*ri* or OMe, as required). It should be noted that these signals would not be expected to differ significantly as a function of the attached alkoxyl group of **1***c*.



1*c*

Conversely, the slight difference suggests that two separate but similar species are present in the two reaction systems, rather than the 7-oxyanion of 2-(picryl)-4,6-dinitrobenzotriazole alone. In the Pi-DNBT,MeO^- system another singlet was observed at 8.310 and may reasonably be ascribed to H_5 of **1***c*.

Deoxygenation of related benzotriazole 1-oxides has been reported in a number of systems, even under very mild conditions (23). For example, 2-(4′-fluorophenyl)-4,6-dinitrobenzotriazole 1-oxide was noted to undergo deoxygenation to the corresponding benzotriazole simply by heating the material to reflux in ethanol (24). Consequently, it is important to note that the signals found in the Pi-DNBT reaction systems do not correspond to the anticipated resonances of 2-(picryl)-4,6-dinitrobenzotriazole, the product of direct deoxygenation of **1**, i.e., it would exhibit a pair of doublets for H_5 and H_7 of the dinitrobenzotriazole moiety.

*Reaction of DNP-DNBT (**2**) with iPrOK*

(a) Equimolar $iPrO^-$ conditions

The broadened and diminished resonances of DNP-DNBT, **2**, are joined by new signals 5 min after the reagents are mixed and the first spectrum recorded. These signals can be assigned to the C-7 DNP-DNBT·OP*ri*$^-$ complex, **2***a*: 8.892 (d, J = 2.50, $H^c_{3'}$) 8.767 and 8.745 (d,d, J = 8.81, 2.50, $H^c_{5'}$), 8.725 (s, H^c_5), 8.171 (d, J = 8.81, $H^c_{6'}$), and 5.992 (s, H^c_7). These peaks are not quantifiable until later when partly overlapping signals become resolved (Table 2). A partly resolved multiplet can be seen at 4.078 (J ca. 7) and can be attributed to the methine proton of the attached iPrO group of **2***a*, but the methyl signals are not detected and are likely obscured by the large 1.260 doublet due to the methyls of iPrOK and iPrOH. The C-7 DNP-DNBT·OH^- complex (**2***a*, Nu = OH) is identified by the observation of a series of peaks including doublets at 6.071 and 5.964 (J ca. 6 for both) due to O*H* and H^c_7, as well as a singlet at 8.674 that corresponds to H^c_5.[3] Note that the adduct **2***a* (Nu = OH) was observed previously in the DNP-DNBT,OR^- reaction system (13, 14, 20). In accord with these assignments the signals are found to

[3]E. Buncel and R.A. Manderville, unpublished data. See ref. 20*b*.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

disappear upon acidification with TFA. Simultaneously, the resonances assigned to **2** increase in intensity (12–14).

No significant N-2:C-1′ bond cleavage had occurred in this system even after monitoring the reaction for 4 h.

(b) Excess iPrO⁻ conditions (2 equivalents)

Five minutes after mixing, the ^{1}H nmr spectrum of the reaction mixture of 3 equivalents iPrOK with **2** consists of broad, unresolved humps. With time these resolve to reveal signals ascribable to **4** and peaks due to the other scission product: 2,4-dinitrophenyl isopropyl ether, **6**.

Therefore, the reaction system using 2 equivalents of iPrOK was examined. In this case, the initial spectrum obtained shortly after mixing contains resonances assigned to the C-7 adduct, **2***a* (Nu = iPrO). Peaks are also noted that are attributed to the DNP-DNBT·OH⁻ adduct, **2***a* (Nu = OH).

Under these conditions the signals due to the C-7 DNP-DNBT·OPr*i*⁻ adduct, **2***a*, were still dominant in the spectrum even after 3 days had elapsed. Smaller resonances ascribed to **4** and to the ether, **6**, could be noted. The signals of **6** were in fair agreement with those of separately prepared **6**, i.e., 8.696 (d, J = 2.68, H_3), 8.436 and 8.415 (d,d, J = 9.31, 2.68, H_5), 7.604 (d, J = 9.31, H_6), 5.022 (septet, J = 6.00, C*H* methine), and 1.345 (d, J = 6.00, CH_3's).

There was no evidence for formation of adducts derived from **6**. Nor was 2,4-dinitrophenoxide ion (or the phenol) observed in the system over the 3 day period of examination.

Reaction of NP-DNBT (5) with iPrOK

(a) Equimolar iPrO⁻ conditions

Signals, albeit small ones, are observed upon mixing equimolar iPrOK in 2-propanol with NP-DNBT, **3**, in $(CD_3)_2SO$. These weak signals, acquired within 5 min, contrast with the intense resonances due to free **3**. No peaks due to the isopropyl ether, **7**, that would result from N-2:C-1′ bond scission, could be seen in the initial spectrum or in subsequent spectra obtained at intervals over the next 5 h.

The signals due to the C-7 adduct, **3***a*, are located at 8.696 (s, H^c_5), 8.343 and 8.446 (d,d, J = 9.04, $H^c_{2',6'}$ and $H^c_{3',5'}$), and 6.039 (s, H^c_7) (Table 1). Upon acidification with TFA the signals listed above disappear, as expected for acid-labile O-centred Meisenheimer adducts (12–14).

(b) Excess iPrO⁻ conditions (3 and 5 equivalents)

The spectrum recorded after injection of 3 equivalents of iPrOK contains small broad resonances due to **3**, along with more prominent peaks attributable to the C-7 NP-DNBT·OPr*i*⁻ adduct, **3***a*.

At longer times (ca. 2 h) small peaks appear that are ascribed to the isopropyl ether, **7**. The full assignment is only possible at longer times when the spectrum becomes completely resolved. The signals of **7** are found at 8.175 and 7.113 (A_2X_2 d,d, J = 9.01, $H_{3,5}$ and $H_{2,6}$), 4.802 (septet, J = 6.01, C*H* methine), and 1.306 (d, J = 6.01, CH_3's). Simultaneous with the appearance of the peaks due to **7**, resonances that correspond to **4** are also noted. However, even after 2 days had elapsed **3***a* was the dominant species; **3***a* and **7** were found in a ratio of 2:1 at this point.

Addition of 5 equivalents of iPrO⁻ to the solution of **3** leads to a very rapid cleavage reaction. The only peaks visible in the first spectrum are those ascribable to the ether, **7**, and to **4**.

Discussion

1. Reaction pathways

Scheme 1 describes the main reactions of nucleophiles with the members of this family of ambident electrophiles: 2-(2′,4′,6′-trinitrophenyl)-, 2-(2′,4′-dinitrophenyl)-, and 2-(4′-nitrophenyl)-4,6-dinitrobenzotriazole 1-oxides, i.e., Pi-DNBT, **1**, DNP-DNBT, **2**, and NP-DNBT, **3**, respectively. Generally, then, attack of a nucleophile (Nu) including iPrO⁻ at C-7 of **1–3** generates a C-7 anionic σ-complex, **1***a*–**3***a*, respectively, whereas attack at C-1′ leads to irreversible formation of the anionic nucleofuge, DNBT⁻, **4**, and a 1-Nu-$(NO_2)_n$-benzene derivative, **5–7**, presumably via the corresponding C-1′ adduct, **1***b*–**3***b*. The spectroscopic parameters for the C-7 adducts are summarized in Table 1. The pathway whereby these persistent C-7 adducts arise is designated Path a in Scheme 1, while the latter route is designated Path b. Comparison of the selectivity for a given path supplies important information on the nature of these super-electrophiles, and these selectivity considerations for the series, **1–3**, will be dealt with below (Sect. 3).

From another perspective Path b constitutes a route for the decomposition of the C-1′ adduct. The inability to observe the C-1′ adducts in this or related systems (11–15, 20) is consistent with rapid and effectively irreversible decomposition of these adducts to **4** and the ethers, **5–7**, and is the only pathway available for decomposition of the C-1′ adduct, if the reversion to substrate (rate constant, k_{-2}) can be ignored. Note that DNBT⁻, **4**, is a resonance-stabilized anion and would be expected to be a good leaving group and that decomposition of the C-1′ adduct by N-2:C-1′ bond scission releases the steric congestion about this bond. The removal of substrate and nucleophile from the system via Path b drives the breakdown of the C-7 adduct (k_{-1}). We previously derived kinetic equations for the disappearance of the C-7 adduct predicated upon the assumption that the rate coefficient for formation of the C-1′ adduct, k_2, is rate determining (13, 14). Observation of the C-7 adduct would require a relatively high stability for the C-7 adduct as compared to the C-1′ adduct (larger K_1 than K_2) as well as a slower formation of the C-1′ adduct (lower k_2 than k_1) relative to formation of the C-7 adduct.

Spectroscopic evidence suggests that another pathway exists for decomposition of the C-7 adduct of Pi-DNBT, **1***a*. Thus, **1** reacts with iPrO⁻ not only via Paths a and b but also to give the 7-isopropyl ether of picryl 4,6-dinitrobenzotriazole, **1***c*, a product of formal internal redox. Similar evidence is found in the reaction of **1** with MeO⁻ where the corresponding ether can be tentatively identified. This suggests the generality of this competitive sequence for **1**. However, neither DNP-DNBT, **2**, nor NP-DNBT, **3**, shows this behaviour.

Moreover, the cleavage product in the reaction of Pi-DNBT, **1**, with iPrO⁻, i.e., isopropyl picrate, **5**, is arguably almost as electrophilic as the picryl moiety of **1** and, so, reacts with iPrO⁻ under the excess concentration regime. Picryl ethers such as **5** generally react with alkoxides to give a kinetically preferred 1,3 adduct that gives way with time to the thermodynamically more stable 1,1 adduct (25). When an excess of iPrO⁻ was used in the reaction with **1** the only Meisenheimer adduct detected was the 1,1 adduct of **5**. Cleavage of **1** was complete and the only other product detected was **4**, the DNBT⁻ leaving group. A separate control experiment confirmed the regioselectivity in this system (i.e., 1,3 → 1,1 isomerization), a pattern of behaviour that we recently defined as K3T1 (25*a*, 26). In the reaction of **1** with an excess of iPrO⁻, therefore, rearrangement of the kinetically favoured 1,3 adduct to the 1,1 adduct was complete at the time of first observation.

In contrast to the behaviour of **1**, no Meisenheimer complexes were formed from the isopropyl ethers, **6** and **7**. Instead,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

under excess $iPrO^-$ conditions relatively clean cleavage of the N-2:C-1′ bond of **2** and **3** occurs as the dominant process yielding the ethers, **6** and **7**, which are unreactive, notably even when 5 equivalents of $iPrO^-$ are allowed to react with **3**.

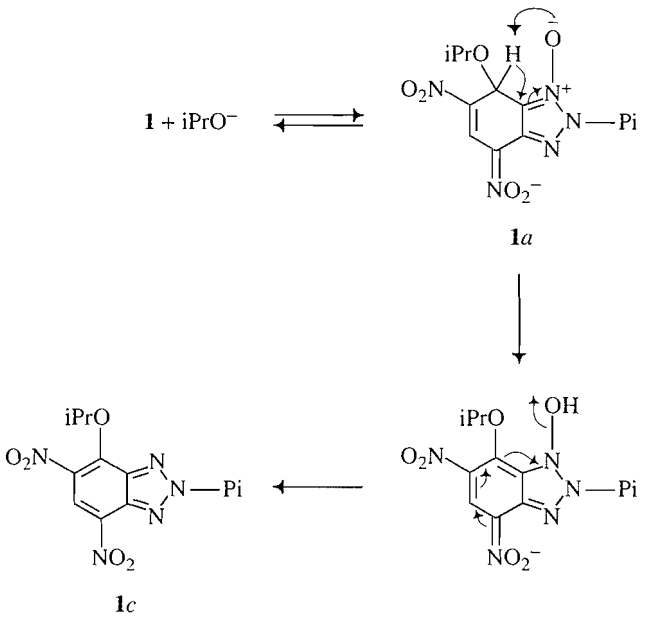
2. Mechanism of formation of the 7-alkoxy-2-picryl-4,6-dinitrobenzotriazole

In the reaction of **1** with either equimolar MeO^- or $iPrO^-$ the spectroscopic data are consistent with formation of a 7-alkoxy-2-picryl-4,6-dinitrobenzotriazole, **1***c* (OR = OMe or OiPr). These ethers apparently form along with C-7 adduct formation in the respective systems and constitute an alternate decomposition pathway for **1***a*. Formally, **1***c* (OR = OPr*i*) can be viewed as the result of nucleophilic attack at C-7 of **1** followed by an internal redox of the C-7 adduct, **1***a*, involving deoxygenation of the *N*-oxide. Interestingly, when the reactions are performed with an excess of alkoxide, **1***c* does not form. Also pertinent is the observation that over time the signals assignable to **1***c* increase in intensity as those of the corresponding C-7 complex, **1***a*, decline. Note that the scission products, **4** and the ether **5**, also increase in concentration at the expense of the C-7 adduct but, even after all **1***a* has disappeared from the system, unmodified substrate remains.

It appears that the 7-alkoxy-2-picryl-4,6-dinitrobenzotriazoles do not arise from starting substrate alone, but from the C-7 adducts. (Pi-DNBT left in $(CD_3)_2SO$ alone slowly reacts to yield picrate ion and **4**; no products of deoxygenation are detected.) In the Pi-DNBT,RO^- systems formation of **1***c* is competitive with N-2:C-1′ bond scission under the equimolar regime, but scission alone is detected with excess nucleophile, suggesting that while the rate of the scission process is dependent on the concentration of available nucleophile (cf. k_2 in Scheme 1), the deoxygenation process is not.

The mechanism previously advanced to account for the formation of the related 7-methoxy-4-nitrobenzofurazan from the C-7 methoxide adduct of 4-nitrobenzofuroxan is consistent with the observations in the present system (21). As applied to the reaction of **1** with $iPrO^-$, formation of the C-7 adduct, **1***a* (Nu = iPrO), is followed by internal transfer of the sp^3-bound proton to the *N*-oxide oxygen. Deoxygenation was demonstrated recently in the reaction of aryloxides with 4-nitrobenzofuroxan (27), where it was pointed out that the internal proton transfer step is analogous to the Cope reaction (28). In a subsequent step, hydroxide is ejected to yield the ether, **1***c* (Scheme 2). Note that after C-7 adduct formation, which may be regarded as a pre-equilibrium step, the internal proton transfer step and the expulsion of hydroxide from the nitronate anion are both visualized as unimolecular steps. Therefore, whether the proton transfer or the expulsion of OH^- is taken to be rate determining, use of an excess of nucleophile would not affect the overall rate.

Alternatively, an intermolecular process may operate.[4] In this case **1***a* is first protonated at the *N*-oxide oxygen. The C-7 site is then deprotonated, followed by expulsion of the OH^- from N-1. The lack of formation of **1***c* under excess $iPrO^-$ conditions could, then, result from difficulty in protonation of the *N*-oxide under these alkaline conditions. Although also consistent with the data in the present study, we favour the intramolecular mechanism (Scheme 2) previously found in related systems (21, 27).



SCHEME 2

3. Selectivity considerations

We previously analysed the reactions of 2-nitroaryl-4,6-dinitrobenzotriazole 1-oxides, **1–3**, on the basis of qualitative selectivity arguments (8, 13, 14) where selectivity (*S*) was defined as the ratio of the forward rate constants for formation of the C-7 as compared to C-1′ adduct. Since the constant for C-7 adduct formation is designated k_1 for **1–3** and k_2 represents the forward rate constant for formation of the C-1′ adducts (Scheme 1), hence $S = k_1/k_2$.

In comparing the series of electrophiles, the percentage of adducts formed (% C-7, % C-1′, Table 2) under selective equimolar conditions serves as a guide to the selectivity for the C-7 position since the ratio of the products must partly reflect the magnitudes of the rate-determining coefficients (k_1, k_2) involved. Clearly, the product ratios must also reflect the relative stabilities of the respective complexes. Two other factors also hinder a more quantitative analysis. First, the data were obtained at somewhat different times due to the initial broadness found in the reaction of **2** with $iPrO^-$.[5] Secondly, the intervention of OH^- in the reaction of **2** and the competitive deoxygenation of the C-7 adduct in the reaction of **1** preclude a more exact determination of the selectivity. However, because the origin of **1***c* requires formation of the C-7 adduct (vide supra), the percentage of **1***a* formed in the Pi-DNBT,$iPrO^-$ reaction system may be taken as the sum of **1***a* and **1***c* (Table 2).

With these limitations it is nonetheless apparent that **2** and **3** are more selective C-7 electrophiles than is **1**. Thus, reaction of **1** with $iPrO^-$ leads to formation of the products of both Paths a and b, visible in the first spectrum, and the C-7 adduct is *not* the dominant species. The selectivity indicated by the ratio of percentages of adducts (% C-7/% C-1′ = 10.3/31.0 = 0.33) is low. Under similar conditions **2** reacts to give a long-lived C-7

[4]We thank a referee for this suggestion.

[5]We previously attributed the broadness found in the spectra of **2** reacting with nucleophiles to the intervention of minor competitive free radical pathways. It should be noted that the substrates are structurally similar to the well-known nitrone spin traps (29). Even low concentrations of radicals could be trapped and persist, giving rise to paramagnetic broadening (30, 31).

adduct, **2***a*, and a C-7 adduct due to OH^- attack; no products attributable to N-2:C-1′ bond scission are present. The contrast between these two systems is even more striking when the spectra obtained for both at ca. 1 h are compared (Table 2). At this time no C-7 adduct remains in the system involving **1**, while the reaction of **3** with $iPrO^-$ is similar to that of **2**. After 7 min 18.2% of **3** has been converted into the C-7 adduct, **3***a*, while only 6.6% of **1***a* is found in the Pi-DNBT system at 4 min, a ratio of 2.75 in favour of the C-7 NP-DNBT·OPr*i*$^-$ adduct, **3***a*.

The comparison between **2** and **3** is more problematic. Using the % C-7/% C-1′ guide to selectivity, it could be concluded that both substrates are equally selective since no products derived from C-1′ attack are observed in either reaction system. It is also clear that a higher percentage of C-7 adduct is formed in the reaction of $iPrO^-$ with **2** than with **3** (41.2% **2***a* vs. 18.2% **3***a*), suggesting that **3** is less selective in C-7 adduct formation than **2**. However, the overall reactivity (as measured by the total percentage conversion, Table 2) also declines in going from **1** to **3**; at 35 min only 18% of **3** has reacted (**3***a* alone), while at 30 min 48% of **1** has reacted. This general decline in reactivity for **3** as compared to **1** or **2** may mask the selectivity of **3**.

In the reaction of phenoxide as an oxygen-centred nucleophile with **2** and **3** the latter was found to be more selective (13) and it seems reasonable on this basis to assign greater selectivity to **3** than to **2**. It is significant that when **2** was treated with a 3-fold excess of $iPrO^-$ scission was complete within the time required for the spectrum to resolve, while similar treatment of **3** yields only **3***a* and *unreacted* **3**, and even after 2 days **3***a* is the major species present. In fact, 5 equivalents of nucleophile are needed to cause clean cleavage of the N-2:C-1′ bond.

It could be argued that the relatively low percentage of C-7 adduct formed from **1** initially (6.6% **1***a* within 4 min of mixing) as compared to the higher amounts of **2***a* and **3***a* formed, indicates that C-7 of **1** is much less electrophilic than C-7 of **2** or **3** and that increasing C-7 electrophilicity accounts for increasing selectivity in going from **1** to **3**. Such a proposition is, however, untenable. Although the C-7 site of **1–3** is remote from the 2-nitroaryl substituent, the electrophilicity of the C-7 site will be modified as successive electron-withdrawing NO_2 groups are removed from the nitroaryl moiety, but this should result in *declining electrophilicity at C-7*. However, as NO_2 groups are removed from the nitroaryl ring the C-1′ site should become even less reactive. It is moot as to whether a decrease in inductive electron withdrawal from C-1′ (reduced positive charge density in the starting state) or reduced stability of the C-1′ adduct (reduced ability to delocalize negative charge in the final state) accounts for the expected decline in reactivity; which effect applies depends upon the position of the transition state (32). Therefore, progressive removal of NO_2 groups from the 2-nitroaryl moiety will have a larger effect on reactivity at the proximate C-1′ site than at the distant C-7 site. The trend in selectivity is primarily due to the decline in reactivity at C-1′ that is only slightly mitigated by the decline in electrophilicity of the C-7 position in proceeding from **1** to **3**.

The percent conversion (Table 2) is a measure of the overall reactivity of the substrates. Thus, at 1 h 59% of **1** has been converted to products, while the total conversion for **2** at ca. 1 h is 53%. The corresponding conversion of **3** would be expected to be around 18% at 1 h, unchanged from the degree of conversion found at 7 min and at 35 min. Therefore, while selectivity for C-7 attack by $iPrO^-$ increases from **1** to **2** and to **3**, in turn, the overall reactivity of the substrates is decreasing in the same order. The most selective substrate is the least reactive one (33).

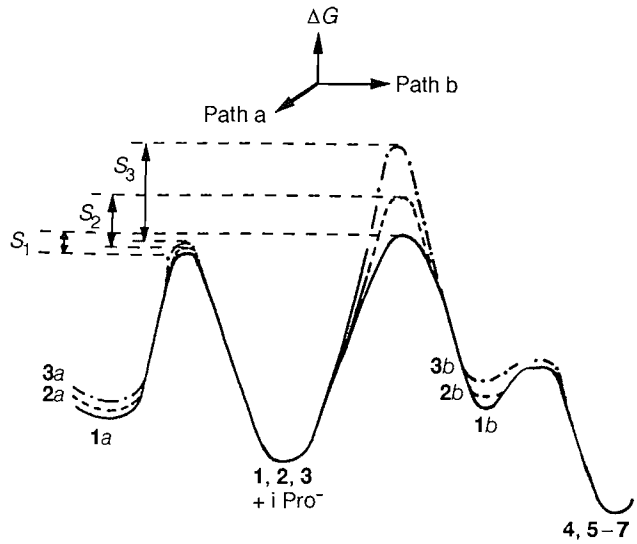


FIG. 1. Attack by $iPrO^-$ at C-7 of the substrate, **1–3**, gives rise to the adducts, **1***a* (solid line), **2***a* (broken line), and **3***a* (dot and dash line) and is shown as the left-hand branch of the energy profile (Path a, Scheme 1). The right-hand branch (Path b) indicates the energetics involved in attack at C-1′ of the substrates, which yields the metastable C-1′ adducts, **1***b*–**3***b*. These C-1′ adducts decompose by N-2:C-1′ bond rupture to yield $DNBT^-$, **4**, and the respective isopropyl nitroaryl ethers, **5–7**. The selectivity, *S*, for a given substrate is shown as the energy gap between the respective activation barrier heights for attack at C-7 (k_1) and C-1′ (k_2).

In our recent study of the reaction of MeO^- and $tBuO^-$ with **2**, it was found that the reactivity and selectivity of the alkoxides was governed primarily by steric hindrance. *tert*-Butoxide proved to be more selective than methoxide (14) even though attack at C-7 was less favourable for $tBuO^-$ than for MeO^-. It is notable, then, that with **2** MeO^- forms 83.5% C-7 adduct (62 min), $tBuO^-$ forms 27.6% C-7 adduct (67 min), and $iPrO^-$, which is intermediate in steric bulk, falls nicely in between by forming 41.2% of **2***a* (61 min).

4. Comparative energy profiles

It has proven useful in previous studies to combine selectivity and other information gleaned from the reactions of **1–3** to construct comparative energy – reaction coordinate diagrams to describe the overall behaviour of the electrophiles in these systems (13, 14).

In constructing such profiles it is expedient to assume that the inherent stability of each member of the series is equal. Given the structural similarities of **1–3** this seems to be an acceptable first approximation. Therefore, Fig. 1 describes attack at the C-7 site (left-hand branch; Path a, Scheme 1) as compared to C-1′ attack (right-hand branch; Path b). Since the deoxygenation reaction (Scheme 2) is restricted to **1** and since competitive OH^- attack at C-7 is only significant with **2**, these processes have been omitted from the profiles.

In the Path a portion of the composite profile, the activation barrier for C-7 attack has been shown to increase slightly for **2** (broken line) as compared to **1** (solid line) and for **3** (dot and dash line) as compared to **2**, in accord with the influence of stepwise removal of NO_2 groups from the 2-nitroaryl ring. This

same inductive effect would be expected to impact on the stability of the resultant C-7 adducts; **3***a* would be expected to be slightly less stable than **2***a* and so on for **1***a*.

In assessing selectivity on the comparative energy profile, Path b is of greater importance since the major effects on selectivity involve the activation barrier for attack at C-1′. Here the kinetic barrier rises more abruptly as each NO_2 group is removed from the 2-nitroaryl ring.

Although isopropyl picrate, **5**, can react further in the presence of excess $iPrO^-$, unlike the isopropyl ethers **6** and **7**, all the ethers that arise from N-2:C-1′ scission are shown as having equal stability.

Examination of both branches of the energy profile clearly shows that the activation barriers for Path a attack at C-7 are lower than those for C-1′ attack, in agreement with the known super-electrophilicity of the C-7 site (8–14). Selectivity can be seen to arise mostly from the variation in the C-1′ kinetic barrier; the selectivity of **1**, for example (S_1), is shown as the difference in barrier heights for C-7 versus C-1′ reaction. Concordant with the discussion of selectivity (vide supra) the energy gap represented by S_3 is larger than that for S_2, which is larger than that for selectivity, S_1.

Conclusions

In the first comparison of reaction of a single alkoxide, $iPrO^-$, with the full series of 2-(nitroaryl)-4,6-dinitrobenzotriazole 1-oxides, **1–3**, we have shown that selectivity for C-7 complex formation increases in going from **1** to **3**. Such selectivity is largely the result of the increasing energetic cost of attack at C-1′ that follows from the stepwise removal of stabilizing nitro groups from the 2-nitroaryl moiety. This selectivity and other aspects of the relative energetics of the C-7 and C-1′ adducts are summarized using a composite energy profile (Fig. 1).

While confirming Paths a and b (Scheme 1) as the general routes for reaction of nucleophiles with the ambident electrophiles, **1–3**, we have also presented evidence for formation of 7-isopropyl-2-(2′,4′,6′-trinitrophenyl)-4,6-dinitrobenzotriazole, **1***c*, the product of formal internal redox involving the $iPrO^-$ C-7 adduct of Pi-DNBT, i.e., **1***a* (Scheme 2). Thus, the C-1′ adducts can all decompose to $DNBT^-$, **4**, and the isopropyl ethers, **5–7**, via Path b. The C-7 adducts decompose back to substrate and nucleophiles (and, hence, to the C-1′ adducts and on). However, for **1***a* an additional pathway for decomposition exists: formation of a 7-alkoxy-2-picryl-4,6-dinitrobenzotriazole, **1***c*.

Experimental

2-Propanol (HPLC grade, Caledon) was dried by reflux with and distillation from CaH_2 (34). $(CD_3)_2SO$ (Merck) was dried with 4A molecular sieves as recommended by Burfield and Smithers (35). All other solvents were obtained from commercial sources and purified as described previously (14). The alkoxide solution (iPrOK ca. 3 M) was prepared by dissolution of freshly cut potassium metal in the purified 2-propanol, under N_2, in a nitrogen-filled drybox; the solution was standardized against standard HCl (14). Isopropyl picrate, **5**, was prepared by the method of Farmer (36), yield: 3.7%, mp 92–94°C (lit. (37) mp 95°C). The isopropyl ether of 2,4-dinitrobenzene, **6**, was made by the procedure of Whalley (38) by reaction of 2,4-dinitrofluorobenzene (Aldrich) with 2-propanol in the presence of triethylamine, yield (after recrystallization from aqueous 2-propanol): 37%, mp 55–56°C (lit. (38) mp 56°C). Melting points were determined with a Thomas–Hoover melting point apparatus and are uncorrected.

The Bruker AM-400 MHz nmr spectrometer was adjusted as previously reported (13, 14). Samples of the substrates, **1–3** (final concentration: ca. 0.02 M), were prepared from stock solutions in dry $(CD_3)_2SO$ by injection into Wilmad PP-507 nmr tubes, which contained dry $(CD_3)_2SO$ and 1,4-dibromobenzene as an internal integration standard. Reaction was initiated by injection of a calculated amount of the isopropoxide solution and spectra were recorded at various intervals as described previously (12–14).

ortho and remote metalation – cross coupling strategies. Total synthesis of the naturally occurring fluorenone dengibsinin and the azafluoranthene alkaloid imeluteine[1]

J.-M. Fu, B.-P. Zhao, M.J. Sharp, and V. Snieckus[2]

Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Waterloo, Waterloo, ON N2L 3G1, Canada

Received October 26, 1993

This paper is dedicated to Professors David B. MacLean and Ian D. Spenser

J.-M. Fu, B.-P. Zhao, M.J. Sharp, and V. Snieckus. Can. J. Chem. **72**, 227 (1994).

The total synthesis of the naturally occurring fluorenone, dengibsinin (**7***a*), and the azafluoranthene alkaloid, imeluteine (**30***e*), is described. Using combined *ortho* metalation – cross coupling sequences that terminate in Friedel–Crafts (**18***b* → **6***d*) and remote metalation (**21***a,b* → **6***c,d*) reactions, the synthesis of fluorenone dimethyl ethers **6***c* and **6***d* is reported. **6***c* and **6***d* were shown not to be identical to dengibsinin dimethyl ether and dengibsin dimethyl ether, respectively, derived from the natural products. This work, together with synthetic and structural evidence from Sargent and Talapatra, led to the reassignment of structures for dengibsinin (**7***a*) and dengibsin (**7***b*). Using the metalation – cross coupling approach, the synthesis of the reassigned dengibsinin (**7***a*) is presented. Two alternate unsuccessful approaches to imeluteine are briefly described (**31** + **32** and **33** + **34**). The successful approach incorporates the remote metalation – double cyclization, **43** → **44**, as the key step.

J.-M. Fu, B.-P. Zhao, M.J. Sharp et V. Snieckus. Can. J. Chem. **72**, 227 (1994).

On décrit la synthèse totale de la fluorénone d'origine naturelle, dengibsinine (**7***a*), et de l'alcaloïde azafluoranthène, imélutéine (**30***e*). Faisant appel à des séquences de métallation *ortho* et de couplage croisé qui se terminent par des réactions de Friedel–Crafts (**18***b* → **6***d*) et des réactions de métallation à des sites éloignés (**21***a,b* → **6***c,d*) on a réalisé la synthèse des éthers diméthyliques (**6***c* et **6***d*) de la fluorénone. On a démontré que ces deux éthers ne sont pas identiques aux éthers diméthyliques de la dengibsinine et de la dengibsine obtenues respectivement à partir de produits naturels. Ces résultats ainsi que les données de structure obtenues par Sargent et Talapatra conduisent à une réattribution des structures de la dengibisinine (**7***a*) et de la dengibsinine (**7***b*). Utilisant l'approche de métallation – couplage croisé, on a réalisé la synthèse de la molécule réassignée comme structure de la dengibisinine (**7***a*). On décrit brièvement deux essais infructueux (**31** + **32** et **33** + **34**) de synthèse de l'imélutéine. L'approche qui a réussi comporte, comme étape clé, une métallation avec double cyclisation.

[Traduit par la rédaction]

During the course of work aimed to establish synthetic links between the Directed *ortho* Metalation (DoM) strategy (1) and transition metal catalyzed cross-coupling reactions (2), the concept of the complex induced proximity effect (CIPE) was unified and brought into prominence by Beak and Meyers (3) and by Klumpp (4). This concept defines pathways in which functional group – reagent preequilibrium complexation is a significant event prior to subsequent irreversible, and necessarily intramolecular, reaction at a proximate site. While CIPE is undoubtedly of broader mechanistic value (3), it has been most notably invoked in organolithium transformations to rationalize formation of (*a*) surprising kinetic in lieu of expected thermodynamic products and (*b*) substantial accelerations of normally unfavorable reactions. As a consequence, it has created new opportunities in the design of regio- and stereo-specific reactions. In contemplating the X-ray structure of a 2,6-diphenyl benzamide,[3] we reasoned that such complexation and entropic factors may induce remote metalation in **1** (Scheme 1) as a function of H_1/H_2 hydrogen relative acidities to give species **2**, which could cyclize to fluorenone **3** in an intramolecular version of the classical amide–RLi condensation reaction. Such a reaction would constitute an anionic Friedel–Crafts equivalent with the following advantages over the latter process: (*a*) mild conditions, which would tolerate greater functional group diversity; (*b*) regioselectivity dictated by the availability of directed metalation groups (DMGs) in the aromatic ring in which the incipient carbanion is generated, i.e., **2**, X = OMe; (*c*) complementarity, i.e., **2** → **3** vs. **1** → **4**, X = OMe; and (*d*) chemoselectivity, i.e., avoidance of dibenzopyranone product **5** in acid-sensitive oxygenated systems **1**, Y = OPG (see below). Herein we report[4] the application of this remote aromatic metalation concept for the construction of the naturally occurring fluorenone dengibsinin (**7***a*) and the azafluoranthene alkaloid, imeluteine (**30***e*). In a sequel,[3] we shall present general methodological results on the Suzuki cross-coupling reaction for precursor teraryls **1** and the corresponding biaryls (6) and their remote metalation-induced cyclization to substituted fluorenones, condensed fluorenones, and azafluorenones (5*a*).

Synthesis of dengibsinin (7*a*)

In 1985, Talapatra et al. (7) reported on the structural elucidation of two fluorenones isolated from *Dendrobium gibsonni* Lindl, an Indian Orchidaceae endemic to the Sikkim Himalayas, Khasia mountains, and Burma, which is used as an epiphytic herb. These natural products, named dengibsinin and dengibsin, were assigned structures **6***a* and **6***b*, respectively, on the basis of ^{1}H NMR spectra of the parent compounds, their dimethyl ether, and their diacetate derivatives. These, at that time,[5] unique structures stimulated retrosynthetic analysis according to the remote aromatic metalation strategy (Scheme 1). During the course of our efforts, the structures of dengibsinin and dengibsin were revised by Sargent (9) to **7***a* and **7***b*, respectively, on the basis of reinterpretation of the spectral data and synthesis of the misassigned **6***a* and **6***b*, their respective

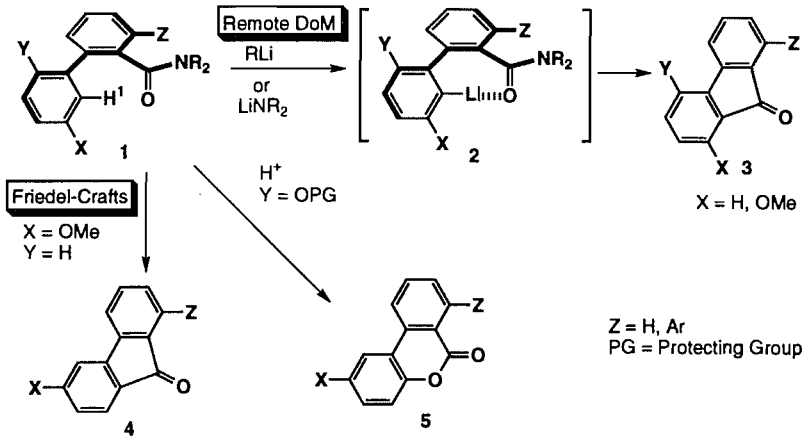
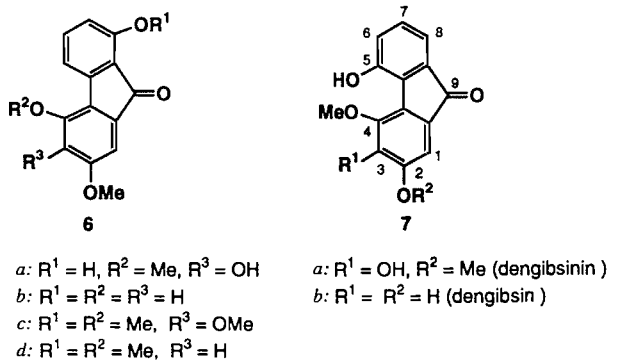
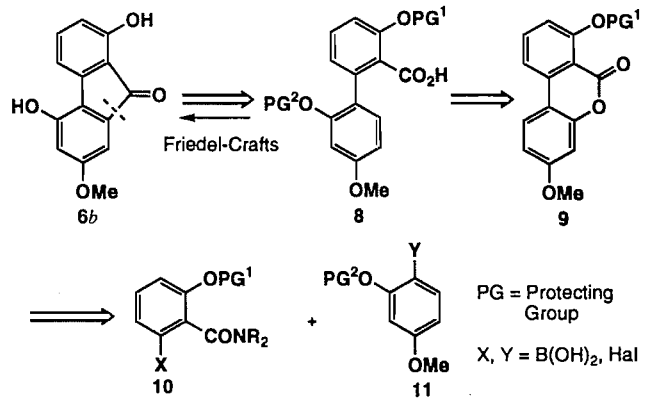


SCHEME 1



dimethyl ethers, **6***c* and **6***d*, and the natural products themselves. On the basis of additional IR data and reinterpretation of ^{1}H NMR spectra, Talapatra et al. (10) also reassigned the structures of dengibsinin (**7***a*) and dengibsin (**7***b*).

In efforts undertaken prior to knowledge of structural revision, "dengibsin" (**6***b*) was targeted by retrosynthetic analysis (Scheme 2) aimed to take advantage of the developed cross-coupling methodology of benzamide boronic acids with aryl halides (**10** + **11**) (6), the associated general synthesis of dibenzopyranones (→ **9**) (11), and, ultimately, a Friedel–Crafts cyclization to form dengibsin (**8** → **6***b*). The synthesis was initiated by metalation–boronation of the readily available *ortho*-anisamide **12** (Scheme 3) to give the corresponding boronic acid **13**, which, without purification, was subjected to cross coupling with **14**, prepared from the known 2-bromo-4-methoxyphenol, to afford the biaryl **15** in good yield. Quantitative conversion of **15** into the dibenzopyranone **16** was achieved under refluxing acetic acid conditions. Ring opening – phenol protection was effected by dissolution of **16** in 50% NaOH solution followed by slow addition of benzyl bromide and dimethyl sulfate to yield biaryls **17***a* and **17***b*, respectively. Adaptation of the Gassman "anhydrous hydroxide" procedure (12) led smoothly to the carboxylic acids **18***a* and **18***b*. Although treatment of **18***a* with TFAA "returned" the dibenzopyranone **16** in high yield, the use of these conditions on **18***b* provided **6***d* in 16% yield, the major product again being the pyranone **16**. The physical and spectral properties of compound **6***d* did not correspond to dengibsin dimethyl ether but agreed closely with **6***d*, which was unambiguously synthesized (see below). Facile dealkylative cyclizations of biaryls to dibenzopyranones analogous to the conversion **18** → **16** were noted previously (13) and attributed to the proximity of the 2,2′-reacting groups. Sargent



SCHEME 2

encountered similar by-products in his syntheses of dengibsinin (**7***a*) and dengibsin (**7***b*) (9). These and other discouraging results in our Friedel–Crafts cyclization attempts were superseded by the discovery of the remote metalation route to fluorenones.[3]

Towards this end, the requisite biary amides **21***a* and **21***b* (Scheme 4) were rapidly prepared by Suzuki cross coupling of *o*-anisamide boronic acid **13** with aryl bromides **20***a* and commercial **20***b*, respectively, both of which are also easily accessible from commercial products. Concurrent optimization of remote metalation conditions[3] led to the choice of LDA and allowed conversion of **21***a* and **21***b* into the fluorenones **6***c* and **6***d*, respectively, in good yields. Physical and spectral data of these materials were in agreement with those reported for the **6***c* and **6***d* synthesized by Sargent (9) and, in the case of **6***d*, with the compound obtained by TFAA cyclization (Scheme 3) but not with those of dengibsinin dimethyl ether and dengibsin dimethyl ether. With these results in hand, we turned to retrosynthetic analysis of the revised structures **7***a* and **7***b* for the naturally occurring fluorenones.

Of the two strategic bonds in **7** (Scheme 5) for anionic cyclization, dissection leading to most profitable convergence dictates consideration of the key amide **22**, which, upon scission of the biaryl bond, retrogrades in a cross-coupling mode to the aryl boron **23** and aryl halide **24** derivatives. Previous experience (5*a* and footnote 3) suggested the use of boronate ester (**23**, R = alkyl), aryl iodide (**24**, X = I), and anhydrous conditions for circumventing problems of competitive protodeboronation in the sterically hindered cross coupling to the tri-*ortho*-substituted biaryl **22**. Towards this end, the boronate ester **26** (Scheme

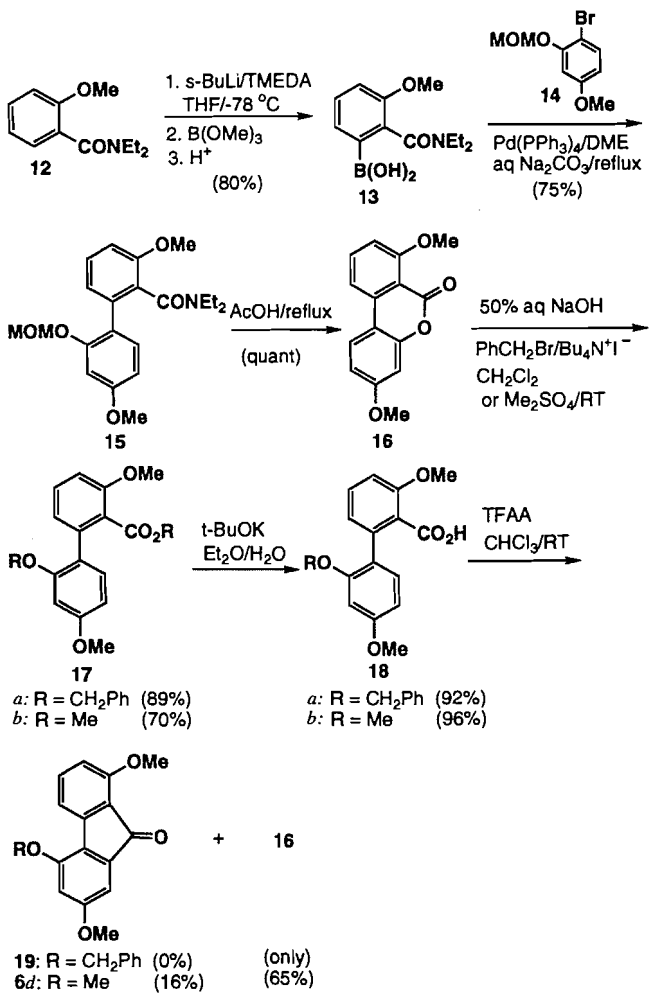
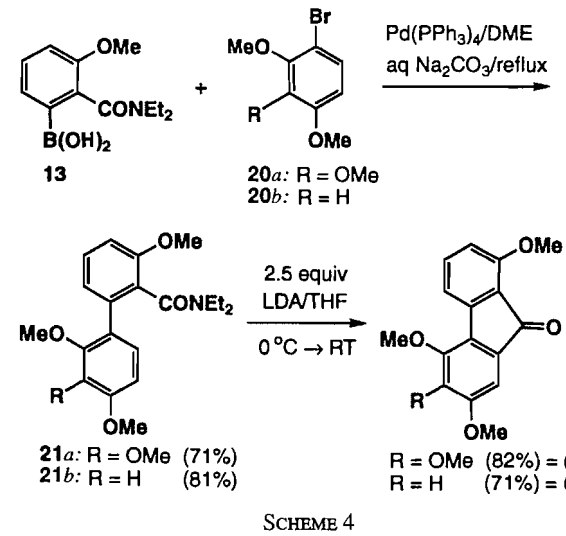
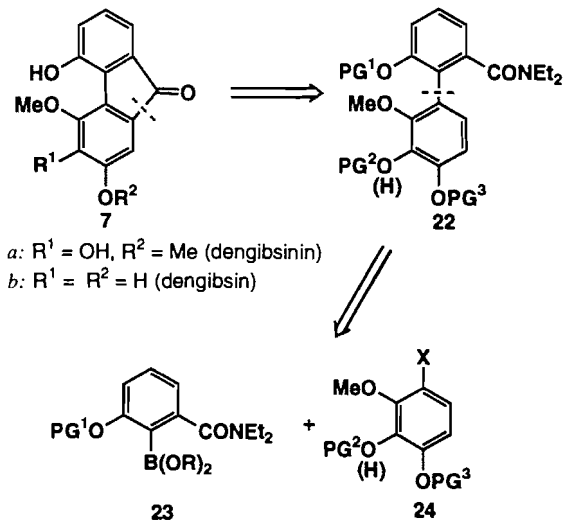


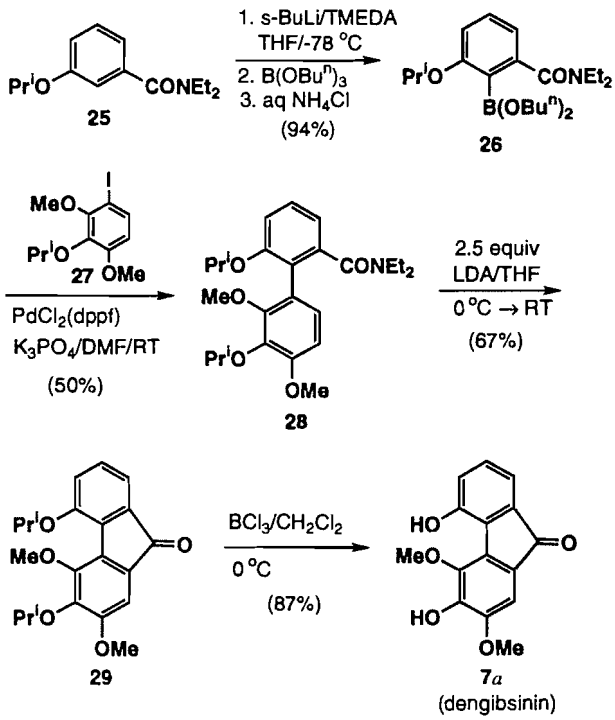
SCHEME 3



SCHEME 4



SCHEME 5



SCHEME 6

6) was prepared in high yield from *m*-isopropoxybenzamide **25** and the aryl iodide **27** partner was obtained in two steps from 2,6-dimethoxyphenol by sequential isopropylation and electrophilic iodination. A thorough investigation of anhydrous conditions was undertaken (Table 1) which indicated that (*a*) the toxic thallium carbonate (14) was an inefficient base compared to potassium phosphate (entry 1), (*b*) DMF is a superior solvent compared to THF (entries 2, 7 vs. 4, 5), and (*c*) $PdCl_2$(dppf) is the catalyst of choice (entries 6, 7). The optimum mildest conditions (entry 7) were based on those reported by Suzuki and co-workers (15) during the course of our studies on highly hindered aryl–aryl coupling reactions.

The key biphenylamide **28** thus obtained in modest yield was subjected to the LDA-induced cyclization conditions and led smoothly to the fluorenone **29**, which, upon treatment with boron trichloride following the excellent procedure of Sala and Sargent (16), afforded dengibsinin (**7***a*) whose physical and spectroscopic properties were shown to be identical to those reported for the natural product (7, 9). The total synthesis of dengibsinin was thus achieved in about eight steps and 27% overall yield based on **25**, which may be compared to the ten-step 1.3% overall yield based on 2-hydroxy-3,4-dimethoxylbenzoic acid reported by Sargent (9) and our earlier

TABLE 1. Conditions for the cross coupling reaction of aryl boronate **26** with aryl halide **27**

Entry	Catalyst	Solvent	Temperature, °C	Base	Yield, %
1	$Pd(PPh_3)_4$	DMF	130–140	Tl_2CO_3	11
2	$Pd(PPh_3)_4$	DMF	110–110	K_3PO_4	50
3	$Pd(PPh_3)_4$	DME	Reflux	K_3PO_4	30
4	$Pd(PPh_3)_4$	THF	Reflux	K_3PO_4	13
5	$PdCl_2$(dppf)	THF	Reflux	K_3PO_4	35
6	$PdCl_2$(dppf)	DMF	60–70	K_3PO_4	48
7	$PdCl_2$(dppf)	DMF	RT	K_3PO_4	50

approach (Scheme 3), both of which suffer from deficiencies in regiochemistry.

Numerous attempts to apply this strategy to the total synthesis of dengibsin (**7***b*) failed (17) for a variety of reasons before an alternate remote metalation route was successfully executed (18).

Synthesis of imeluteine (30*e*)

The biosynthetically intriguing azafluoranthenes (**30**, Scheme 7) make up a small group of alkaloids (19), the earliest members of which, rufescine (**30***d*) and imeluteine (**30***e*) were isolated by Cava et al. (20) 20 years ago from *Abuta rufescens*

	R^1	R^2	R^3	Name
a:	H	H	H	Triclisine
b:	H	H	OH	Telitoxine
c:	OMe	H	OH	Norrufescine

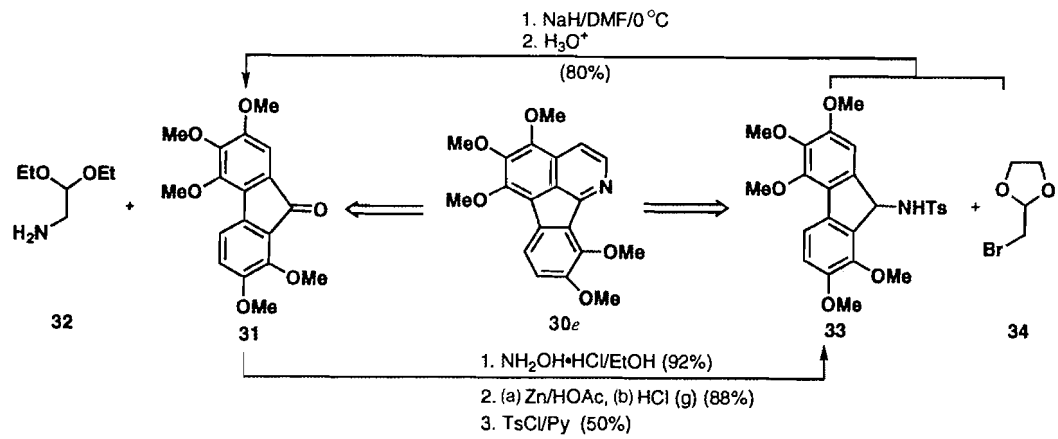
e:	OMe	OMe	OMe	Imeluteine

SCHEME 7

and *A. imene* (Menispermaceae). Subsequently, two biogenetically related tropoloisoquinoline alkaloids were also isolated from the same family by Menachery and Cava (21*a*; see also 21*b*). A decade ago, Patel and MacLean (22) reported, as an initial foray towards the synthesis of the azafluoranthene alkaloids, the preparation of a tetrahydro-tetramethoxy analogue in 17% overall yield using both DoM and an interesting lactam Bischler–Napieralski cyclization. Synthetic efforts to date on the azafluoranthene alkaloids have resulted in routes based on Pschorr cyclization and inverse electron demand Diels–Alder strategies to telitoxine (**30***b*), rufescine (**30***d*), and imeluteine (**30***e*) (19). The parent ring system, 3,4-dihydro-2-azafluoranthene, was first prepared by Campbell and Reid (23) proceeding from oxidative cleavage of fluoranthene. Subsequently, this compound has been found as a significant pollutant in coal tar (24), city air (25), and cigarette smoke (26). A successful route to the tropoloisoquinoline alkaloids has defied efforts to date.[6]

In view of the readily discernable fluorenone substructure, the azafluoranthene alkaloids appeared opportune targets for application of the combined metalation (*ortho* and remote) – cross-coupling strategy. The initial efforts were focussed on a



SCHEME 8

retrosynthetic analysis (Scheme 8) based on imeluteine (**30***e*) as the target and ultimate heteroanellation via a Bobbitt modification of the Pomeranz–Fritsch reaction (27), using the pentamethoxyfluoreonone **31** and aminoacetaldehyde diethyl acetal **32** as precursors. The fluoreone **31** was rapidly and efficiently procured (Scheme 9) by cross coupling of the DoM-derived benzamide boronic acid **35** with the methoxylated bromobenzene **20***a* to give the biaryl amide **36** followed by LDA-mediated remote metalation–cyclization. Despite a previous ominous report by Buck[7] concerning the failure to obtain a Schiff base from the reaction of a substituted fluorenone with **32**, we undertook a series of studies to effect the condensation of **31** with **32**. Under a variety of acid-catalyzed conditions, either starting fluorenone (TsOH (28), BF_3·Et_2O (29)) was recovered or decomposition ($TiCl_4$ (30)) occurred. An alternate heteroannelation

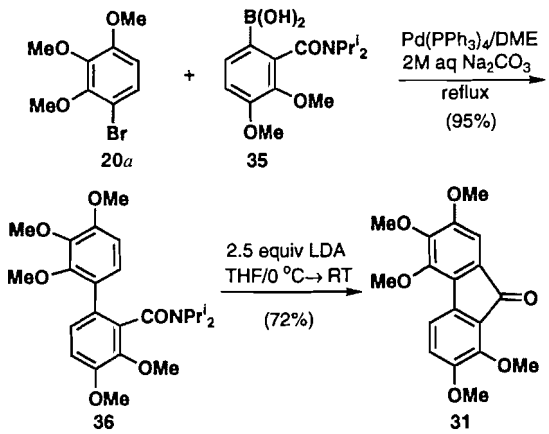
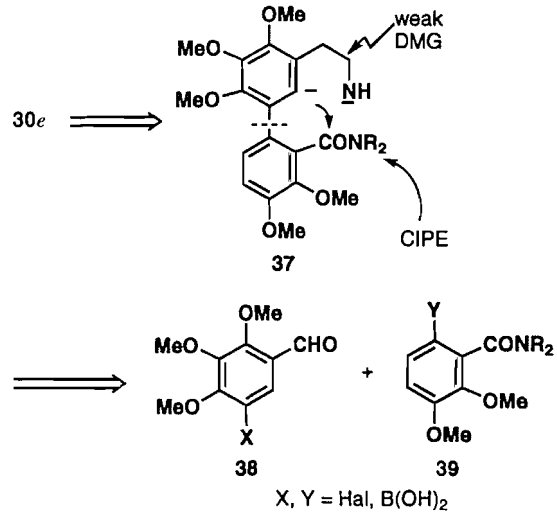


SCHEME 9

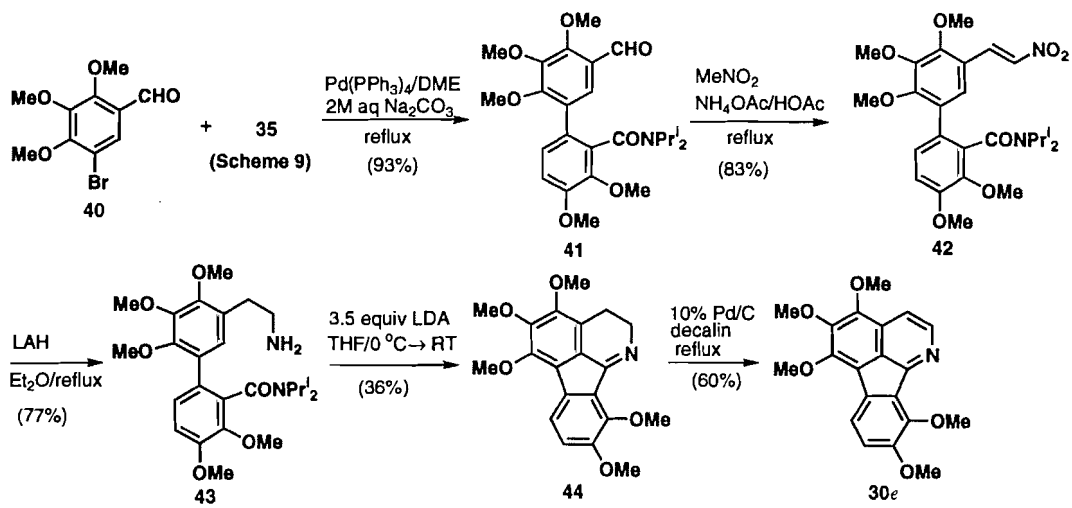


SCHEME 10

approach was based on a recent isoquinoline synthesis starting with benzyl bromide and *N*-tosyl aminoacetaldehyde dimethyl acetal (31). Inverting the condensation partners of this model led to the retrosynthetic consideration of 9-*N*-tosylaminofluorene **33** and the bromoacetal **34** as the precursors. While **33** was conveniently prepared in three steps from fluorenone **31** (Scheme 8), its condensation with **34** under NaH/DMF conditions (32) led to toluenesulfinate elimination and hydrolysis to return **31** in high yield, a result which has precedent (33).

These discouraging results prompted a completely different retrosynthetic analysis of imeluteine (Scheme 10) based on the key intermediate biaryl **37** in which the ethylamino tether is poised for an intramolecular heteroannelation subsequent to the remote metalation–cyclization step. In this analysis, the known weak-DMG effect of the ethylamino group (34) could be envisaged to further facilitate the CIPE-mediated remote metalation process. The biaryl **37** was envisaged to arise from the benzaldehyde **38** and benzamide **39** partners in which the former is ready for classical chain extension methodology.

To initiate this attack on imeluteine, the bromobenzaldehyde **40** (Scheme 11), available by two direct routes in 68% overall yield (see experimental section), was cross coupled with the previously prepared (Scheme 8) benzamide boronic acid **35** to furnish the biaryl aldehyde **41** in high yield. Chain extension by condensation with nitromethane (35) afforded the nitrostyrene **42**, which, upon reduction with LAH (35), smoothly led to the phenethylamine **43** without complications of amide reduction due to its sterically hindered nature (36). Exposure of **43** to excess LDA was rewarded by the formation of dihydroimeluteine **44**, albeit in low yield. To conclude the synthesis, **44** was subjected to dehydrogenation conditions (35) to furnish imeluteine (**30***e*) whose identity with the natural product was established following the usual criteria. The synthesis, effected in five steps and 13% overall yield, compares favorably with that reported (15 steps, 4.9% overall yield (37), five steps, 14.3% overall yield (20*a*)).



SCHEME 11

Conclusions

Using the concept of CIPE-induced (3, 4) remote metalation in combination with directed *ortho* metalation and cross coupling strategies (Scheme 1), a general approach to substituted and condensed fluorenones has been developed.[3] As reported herein, this integrated approach leads to relatively fast and effi-

cient assemblies of two diverse natural products, dengibsinin (Scheme 6) and imeluteine (Scheme 11). In the former, a problematical classical Friedel–Crafts approach (Scheme 3) has been overcome by the use of the remote metalation–cyclization step (Scheme 5), which occurs under mild LDA conditions. In the latter, the DoM – cross coupling tactics allow the rapid construction of an appropriate biaryl intermediate in which the amide serves as a linchpin in the subsequent one-pot formation of two rings that is initiated by the remote metalation process (Scheme 10). Both syntheses illustrate a new methodology for fluorenone ring formation, which constitutes an anionic equivalent of the Friedel–Crafts process and which, by virtue of its mild conditions and regioselectivity, may complement and (or) supersede that classical method for the synthesis of condensed fluorenones.

Experimental section

General procedures

Melting points were determined on a Buchi SMP-20 apparatus and are uncorrected. IR spectra were recorded on a Perkin–Elmer 983 or on a BOMEM MB-100 infrared spectrophotometer in neat, $CHCl_3$, or KBr pellet form. ^1H NMR and ^{13}C NMR spectra were recorded on a Bruker AM-250 or on an AC-200 instrument with tetramethylsilane as internal standard unless otherwise stated. Mass spectra (MS) were determined on a high-resolution Varian MAT-CH7 instrument at 70 eV. Microanalyses were performed by M-H-W Laboratories, Phoenix, Ariz. All compounds were purified by column chromatography and crystallization or distillation.

Tetrahydrofuran and diethyl ether were freshly distilled from sodium benzophenone ketyl under nitrogen prior to use. DME was used directly without purification. *n*-BuLi, *s*-BuLi, and *t*-BuLi were purchased from Aldrich Chemical Co., as solution in hexane, cyclohexane, and pentane, respectively. They were stored in resealable containers and titrated periodically against 2,5-dimethoxybenzyl alcohol (38). Diisopropylamine (DIA) and *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) were dried over and distilled from CaH_2 and stored under argon. LDA was always freshly prepared by stirring a 1:1 mixture of DIA and *n*-BuLi at 0°C for 10 min. All commercial materials were purchased from Aldrich Chemical Co. or Lancaster Synthesis Ltd. Palladium catalyst was prepared according to literature procedures (39) and stored in sealed containers in a refrigerator.

All the reactions were performed in oven-dried glassware under argon, using syringe – septum cap techniques. The "−78°C" temperature designated is approximate as achieved by a Dry Ice – acetone bath. The phrase "standard work-up" refers to addition of water, extraction with CH_2Cl_2, washing the organic extract with brine solution, drying (Na_2SO_4), filtration, and evaporation to dryness in vacuo. Flash chromatography was carried out using Merck silica gel 60 (0.04–0.06 mm) purchased from BDH Chem. Co. Canada with EtOAc–hexane as eluent unless otherwise specified.

Synthesis of tertiary benzamides

The following benzamides were prepared by the standard thionyl chloride – dialkylamine reaction.

N,N-*Diethyl 2-methoxybenzamide* (***12***): bp 90–95°C/0.1 Torr (lit. (11) bp 105–106°C/0.25 Torr; 1 Torr = 133.3 Pa).

N,N-*Diisopropyl 2,3-dimethoxybenzamide*: mp 107–108°C (hexane–EtOAc) (lit. (11) mp 107–108°C).

N,N-*Diethyl 3-isopropoxybenzamide* (***25***)

A mixture of *N,N*-diethyl 3-hydroxybenzamide (17.1 g, 88.4 mmol), K_2CO_3 (18.8 g, 136 mmol), KI (22.6 g, 136 mmol), and 2-bromopropane (12.8 mL, 136 mmol) in acetonitrile (300 mL) was heated at 80°C for 48 h. After cooling, the mixture was subjected to filtration and the filtrate was evaporated to dryness in vacuo. Standard work-up followed by flash chromatography (1:1) afforded 16.18 g (78%) of **25**, bp 160–163°C/4 Torr; IR (neat) ν (max): 1636 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.22–7.32 (m, 1H), 6.87–6.94 (m, 3H), 4.55 (sept, J = 6.1 Hz, 1H), 3.15–3.70 (br, 4H), 1.34 (d, J = 6.1 Hz, 6H), 1.00–1.30 (br, 6H); MS *m/z* (rel. intensity): 235 (M^+, 42), 192 (77), 164 (23), 163 (44) 121 (100); HRMS calcd. for $C_{14}H_{21}NO_2$: 235.1573; found: 235.1568.

Preparation of boronic acids

A solution of the benzamide (1 mmol), dissolved in anhydrous THF (2 mL) was added dropwise to a solution of a 1:1 *s*-BuLi (1.1 mmol) – TMEDA (1.1 mmol) complex in anhydrous THF (3 mL) at −78°C. The resulting mixture was stirred at −78° for 1 h and treated with $B(OMe)_3$ (2–3 mmol) followed by warming to ambient temperature over 4 h. Saturated aqueous NH_4Cl solution (2 mL) was added and THF was removed in vacuo. The residue was subjected to standard work-up to afford the crude product, which was used in cross coupling reactions without further purification.

2-N,N-*Diethylcarboxamido-3-methoxyphenyl boronic acid* (***13***): see ref. 11.

2-N,N-*Diisopropylcarboxamido-3,4-dimethoxyphenyl boronic acid* (***35***): see ref. 11.

Di-n-*butyl B-[2-isopropoxy-6-(*N,N-*diethylcarboxamido)phenyl] boronate* (***26***)

A solution of **25** (4.707 g, 20.0 mmol) in THF (20 mL) was added dropwise to a stirred solution of *s*-BuLi (16.92 mL of 1.30 M solution, 22.0 mmol) and TMEDA (3.32 mL, 2.557 g, 22.0 mmol) in THF (80 mL) at −78°C. The resulting solution was stirred at −78°C for 2 h and treated with tributyl borate (18.4 g, 80.0 mmol), followed by stirring below −40°C for an additional 4 h. The reaction was quenched with NH_4Cl solution at −40°C. Standard work-up followed by short-path distillation afforded 7.324 g (94%) of **26**, bp 150–155°C/0.01 Torr; IR (neat) ν (max): 1628 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.25 (dd, J = 7.8, 1.1 Hz, 1H), 6.90–6.81 (m, 2H), 4.55 (sept, J = 6.1 Hz, 1H), 3.84 (t, J = 6.6 Hz, 4H), 3.68–3.13 (m, 4H), 1.53 (m, 4H), 1.33–1.31 (d, J = 6.1 Hz, 6H), 1.47–1.10 (m, 10H), 0.89 (t, J = 7.2 Hz, 6H); MS *m/z* (rel. intensity): 390 (M^+, 6), 348 (52), 322 (22), 318 (33), 280 (100), 265 (26), 262 (21), 192 (20), 163 (41), 121 (60); HRMS calcd. for $C_{22}H_{38}BNO_4$: 390.2896; found: 390.2828.

Preparation of aryl halides

4-Bromo-3-(methoxymethoxy)anisole (***14***)

2-Bromo-5-methoxyphenol was prepared using a literature procedure (40), bp 102–104°C/30 Torr (lit. (41) bp 150°C/25 Torr); ^1H NMR ($CDCl_3$) δ: 7.30 (d, J = 8.0 Hz, 1H), 6.63 (d, J = 2.5 Hz, 1H), 6.39 (dd, J = 8.0, 2.5 Hz, 1H), 3.73 (s, 3H), 3.54 (s, 1H). A solution of 2-bromo-5-methoxyphenol (4.8 g, 24 mmol) in DMF (50 mL) was added dropwise to a suspension of NaH (1.2 g, 50% in oil, 25 mmol) in DMF (100 mL) at 0°C and the light gray mixture was stirred at 0°C for 1 h. To the mixture was added dropwise chloromethyl methyl ether (3.8 mL, 50 mmol) and the whole was allowed to warm to room temperature and poured into a 5% NaOH solution (100 mL). Extraction with Et_2O followed by standard work-up and distillation afforded 5.35 g (90%) of **14**, bp 83–85°C/0.1 Torr; IR ($CHCl_3$) ν (max): 1590, 1483 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.40 (d, J = 8.8 Hz, C5-H), 6.75 (d, J = 2.6 Hz, 1H, C2-H), 6.39 (dd, J = 8.8, 2.6 Hz, 1H, C6-H), 5.22 (s, 2H), 3.77 (s, 3H), 3.51 (s, 3H); MS *m/z* (rel. intensity): 248 (M^+, 95), 246 (M^+, 100), 218 (60), 216 (59). Anal. calcd. for $C_9H_{11}O_3Br$: C 43.75, H 4.49; found: C 43.92, H 4.61.

1-Bromo-2,3,4-trimethoxybenzene (***20***a)

A mixture of 1,2,3-trimethoxybenzene (24.0 g, 142 mmol) and *N*-bromosuccinimide (25.4 g, 142 mmol) in CCl_4 (350 mL) was stirred at room temperature for 12 h and concentrated in vacuo. Standard work-up followed by distillation afforded 31.9 g (91%) of **20***a*, bp 117–120°C/3.5 Torr (lit. (42) bp 97°C/0.5 Torr); ^1H NMR ($CDCl_3$) δ:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

7.20 (d, J = 9.0 Hz, 1H), 6.59 (d, J = 9.0 Hz, 1H), 3.90 (s, 3H), 3.88 (s, 3H), 3.85 (s, 3H).

1-Iodo-3-isopropoxy-2,4-dimethoxybenzene (27)

To a suspension of 2-isopropoxy-1,3-dimethoxybenzene (9) (4.691 g, 23.9 mmol) and silver trifluoroacetate (5.279 g, 23.9 mmol) in $CHCl_3$ (20 mL) was added a solution of iodine (6.067 g, 23.9 mmol) in $CHCl_3$ (180 mL) dropwise. The resulting mixture was stirred at room temperature for 3 h and subjected to filtration. The filtrate was washed with dilute Na_2SO_3 solution. Standard work-up followed by flash chromatography (1:5) afforded 7.37 g (96%) of **27**, bp 100–102°C/0.02 Torr; ^{1}H NMR ($CDCl_3$) δ: 7.40 (d, J = 8.8 Hz, 1H), 6.49 (d, J = 8.8 Hz, 1H), 4.42 (sept, J = 6.2 Hz, 1H), 3.87 (s, 3H), 3.82 (s, 3H), 1.29 (d, J = 6.2 Hz, 6H); MS *m/z* (rel. intensity): 322 (M^+, 22), 280 (100), 265 (25); HRMS calcd. for $C_{11}H_{15}IO_3$: 322.0067; found: 322.0063.

5-Bromo-2,3,4-trimethoxybenzaldehyde (40)

Following a literature procedure (43), **40** was prepared in two steps in 68% overall yield. In an alternative procedure, a mixture of 2,3,4-trimethoxybenzaldehyde (0.216 g, 1.1 mmol) and Br_2 (0.194 g, 1.21 mmol) in acetic acid (2 mL) was stirred at room temperature for 12 h. Standard work-up followed by flash chromatography (1:5) afforded 0.200 g (67%) of **40**, oil (lit. (43) bp 172–178°C/10 Torr); ^{1}H NMR ($CDCl_3$) δ: 10.23 (s, 1H), 7.78 (s, 1H), 4.04 (s, 3H), 4.01 (s, 3H), 3.93 (s, 3H); MS *m/z* (rel. intensity): 376 (M^+, 98), 274 (100).

Cross coupling reaction to biaryls

A mixture of $Pd(PPh_3)_4$ (0.05 mmol) and aryl halide or aryl triflate (1 mmol) in DME (5 mL) was stirred at room temperature for 5 min. To this mixture was added dropwise in sequence a solution of arylboronic acid (1.5 mmol) dissolved in the minimum amount of EtOH (1 mL) and an aqueous solution of 2 M Na_2CO_3 (2 mL). The resulting mixture was heated under reflux for 12 h, cooled, and the solid was removed by filtration. The filtrate was evaporated to dryness and the residue was washed with Et_2O. Standard work-up followed by flash chromatography afforded the biaryl product.

N,N-*Diethyl 3,4′-dimethoxy-2′-(methoxymethoxy)-2-biphenylcarboxamide (15)*

4-Bromo-3-methoxymethoxyanisole **14** (2.90 g, 12.0 mmol) was coupled with **13** (4.00 g, 16.0 mmol) in the presence of $Pd(PPh_3)_4$ (0.48 g, 0.48 mmol) to afford, after standard work-up followed by flash chromatography (1:1), 3.80 g (75%) of **15**, bp 170–175°C/0.05 Torr; IR ($CHCl_3$) ν (max): 1614 cm–^{1}; ^{1}H NMR ($CDCl_3$) δ: 7.30–7.20 (m, 2H), 6.90 (m, 2H), 6.75 (d, J = 2.4 Hz, 1H), 6.53 (dd, J = 8.5, 2.3 Hz, 1H), 5.09 (s, 2H), 3.85 (s, 3H), 3.79 (s, 3H), 3.39 (s, 3H), 3.16 (m, 2H), 2.88 (m, 2H), 0.89 (t, J = 7.1 Hz, 3H), 0.74 (t, J = 7.1 Hz, 3H); MS (CI) *m/z* (rel. intensity): 373 (M^+, 24), 358 (29), 301 (58), 271 (100). Anal. calcd. for $C_{21}H_{27}NO_5$: C 67.54, H 7.29, N 3.75; found: C 67.47, H 7.29, N 4.09.

N,N-*Diethyl 3,2′,3′,4′-tetramethoxybiphenyl-2-carboxamide (21*a)

2,3,4-Trimethoxybromobenzene **20***a* (5.68 g, 23.0 mmol) was coupled with **13** (7.53 g, 30.0 mmol) in the presence of $Pd(PPh_3)_4$ (1.06 g, 0.92 mmol) to afford, after standard work-up followed by flash chromatography (1:4), 6.11 g (71%) of **21***a*, mp 93–95°C (cyclohexane); IR (KBr) ν (max): 1623 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.32 (dd, J = 8.1, 7.9 Hz, 1H, C5-H), 7.04 (d, J = 8.6 Hz, 1H, C6′-H),6.88–6.94 (m, 2H), 6.64 (d, J = 8.6 Hz, 1H, C5′-H), 3.86 (s, 3H), 3.85 (s, 3H), 3.84 (s, 3H), 3.72 (s, 3H), 2.79–3.31 (m, 4H), 0.97 (t, J = 7.1 Hz, 3H), 0.77 (t, J = 7.1 Hz, 3H); MS *m/z* (rel. intensity): 373 (M^+, 62), 342 (67), 302 (34), 301 (100), 300 (24), 283 (35), 271 (40), 255 (22). Anal. calcd. for $C_{21}H_{27}NO_5$: C 67.54, H 7.29, N 3.75; found: C 67.91, H 7.42, N 3.77.

N,N-*Diethyl 3,2′,4′-trimethoxybiphenyl-2-carboxamide (21*b)

2,4-Dimethoxybromobenzene **20***b* (1.023 g, 4.71 mmol) was coupled with **13** (1.558 g, 6.20 mmol) in the presence of $Pd(PPh_3)_4$ (0.268 g, 0.23 mmol) to afford, after standard work-up followed by flash chromatography (1:4), 1.306 g (81%) of **21***b*, mp 104–106°C (hexane–CH_2Cl_2); IR (KBr) ν (max): 1623 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.33–7.26 (m, 2H), 6.93 (d, J = 8.7 Hz, 1H, C6-H), 6.88 (d, J = 8.3 Hz, 1H, C4-H), 6.50–6.45 (m, 2H), 3.84 (s, 3H), 3.80 (s, 3H), 3.72 (s, 3H), 3.22–3.11 (m, 1H), 2.96–2.70 (m, 3H), 0.89 (t, J = 7.1 Hz, 3H), 0.74 (t, J = 7.1 Hz, 3H); MS *m/z* (rel. intensity): 343 (M^+, 56), 271 (100), 243 (23). Anal. calcd. for $C_{20}H_{25}NO_4$: C 69.95, H 7.34, N 4.08; found: C 70.68, H 7.11, N 3.74.

N,N-*Diethyl 2′,4′-dimethoxy-6,3′-diisopropoxybiphenyl-2-carboxamide (28)*

A mixture of $PdCl_2$(dppf) (0.073 g, 0.10 mmol), 2,4-dimethoxy-3-isopropoxy-iodobenzene **27** (0.328 g, 1.02 mmol), **26** (0.474 g, 1.21 mmol), and anhydrous K_3PO_4 (0.509 g, 2.40 mmol) in anhydrous DMF (10 mL) was stirred at room temperature for 30 h and poured onto crushed ice. Extraction with EtOAc, drying (Na_2SO_4), and evaporation to dryness in vacuo followed by flash chromatography (1:4) afforded 0.220 g (50%) of **28**, bp 170–175°C/0.01 Torr; IR (neat) ν (max): 1636 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.28 (dd, J = 8.0, 8.0 Hz, 1H, C4-H), 7.03–6.85 (m, 3H), 6.62 (d, J = 8.6 Hz, 1H, C5′-H), 4.39–4.29 (m, 2H), 3.89 (s, 3H), 3.83 (s, 3H), 3.34–3.23 (m, 2H), 2.81–2.60 (m, 2H), 1.30 (d, J = 6.1 Hz, 6H), 1.22 (d, J = 6.1 Hz, 3H), 1.16–0.80 (m, 6H), 0.69 (t, J = 7.0 Hz, 3H); MS *m/z* (rel. intensity): 429 (M^+, 59), 387 (20), 356 (53), 344 (20), 315 (24), 314 (22), 273 (55), 249 (20), 248 (100), 241 (51), 213 (26); HRMS calcd. for $C_{25}H_{35}NO_5$: 429.2517; found: 429.2504.

N,N-*Diisopropyl-2′,3,3′,4,4′-pentamethoxybiphenyl-2-carboxamide (36)*

2,3,4-Trimethoxybromobenzene (1.73 g, 7.0 mmol) was coupled with **35** (2.98 g, 10.0 mmol) in the presence of $Pd(PPh_3)_4$ (0.410 g, 0.35 mmol) to afford 2.88 g (95%) of **32**, mp 170–171°C (hexane–EtOAc); IR ($CHCl_3$) ν (max): 1615 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.26 (d, J = 8.7 Hz, 1H, C6′-H), 7.09 (d, J = 8.5 Hz, 1H, C6-H), 6.92 (d, J = 8.5 Hz, 1H, C5-H), 6.62 (d, J = 8.7 Hz, 1H, C5′-H), 3.92 (s, 3H), 3.89 (s, 3H), 3.86 (s, 3H), 3.84 (s, 3H), 3.83 (s, 3H), 3.59 (sept, J = 6.6 Hz, 1H), 3.24 (sept, J = 6.8 Hz, 1H), 1.51 (d, J = 6.8 Hz, 3H), 1.19 (d, J = 6.8 Hz, 3H), 1.02 (d, J = 6.6 Hz, 3H), 0.63 (d, J = 6.6 Hz, 3H); ^{13}C NMR ($CHCl_3$) δ: 166.6, 153.1, 151.6, 151.4, 145.0, 141.9, 135.6, 134.2, 126.7, 126.5,125.4, 110.9, 106.4, 61.5, 60.9, 60.5, 56.0, 55.6, 50.6, 45.3, 23.0, 20.7, 20.4, 20.2, 19.7; MS *m/z* (rel. intensity): 431 (M^+, 40), 400 (77), 331 (100); HRMS calcd. for $C_{24}H_{33}NO_6$: 431.2335; found: 431.2305.

2′-N,N-*Diisopropylcarboxamido-3′,4′,2,3,4-pentamethoxybiphenyl-5-formaldehyde (41)*

5-Bromo-2,3,4-trimethoxybenzaldehyde (**40**) (2.20 g, 8.00 mmol) was coupled with 2-*N,N*-diisopropylcarboxamido-3,4-dimethoxyphenylboronic acid (**35**) (3.22 g, 10.4 mmol) in the presence of $Pd(PPh_3)_4$ (0.44 g, 0.40 mmol) to afford 3.41 g (93%) of **41**, mp 110–112°C (EtOAc); IR ($CHCl_3$) ν (max): 1681, 1622 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 10.23 (s, 1H, CHO), 7.57 (s, 1H, C6′-H), 7.02 (d, J = 8.5 Hz, 1H, C6-H), 6.92 (d, J = 8.5 Hz, 1H, C5-H), 4.03 (s, 3H), 3.93 (s, 3H), 3.90 (s, 3H), 3.87 (s, 3H), 3.86 (s, 3H), 3.67 (sept, J = 6.6 Hz, 1H), 3.27 (sept, J = 6.8 Hz, 1H), 1.49 (d, J = 6.8 Hz, 3H), 1.11 (d, J = 6.8 Hz, 3H), 1.06 (d, J = 6.6 Hz, 3H), 0.87 (d, J = 6.6 Hz, 3H); ^{13}C NMR ($CHCl_3$) δ: 188.6, 166.2, 157.7, 152.1, 145.6, 145.0, 134.9, 133.9, 129.9, 128.7, 127.9, 126.4, 124.1, 111.2, 62.3, 61.5, 60.9, 55.7, 50.8, 45.4, 21.0, 20.5, 20.1, 19.6; MS *m/z* (rel. intensity): 459 (M^+, 33), 428 (50), 359 (100); HRMS calcd. for $C_{25}H_{33}NO_7$: 459.2248; found: 459.2249.

*Friedel–Crafts approach to the putative dengibsin dimethyl ether (6*d)

*3,7-Dimethoxy-6*H*-dibenzo[*b,d*]pyran-6-one (16)*

Amide **15** (4.00 g, 10.7 mmol) was dissolved in glacial acetic acid (20 mL) and the solution was heated under reflux for 4 h, cooled, and poured onto ice water. Standard work-up followed by flash chromatography (1:2) afforded 1.98 g (97%) of **16**, mp 159–160°C (hexane–

CH_2Cl_2); IR ($CHCl_3$) ν (max): 1726 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.89 (d, J = 8.8 Hz, 1H), 7.69 (t, J = 8.1 Hz, 1H), 7.57 (d, J = 8.0, 1H), 6.98 (d, J = 8.2 Hz, 1H), 6.80–6.70 (m, 2H), 4.03 (s, 3H), 3.86 (s, 3H); MS *m/z* (rel. intensity): 256 (M^+, 100), 227 (73). Anal. calcd. for $C_{15}H_{12}O_2$: C 70.31, H 4.72; found: C 70.09, H 4.56.

*Benzyl-2′-benzyloxy-3,4′-dimethoxy-2-biphenylcarboxylate (**17**a)*

According to a modification of a literature procedure (44), a 50% NaOH aqueous solution (25 mL) was added (0.5 mL/min) to a solution of **16** (1.00 g, 3.9 mmol), benzyl bromide (3.34 g, 19.5 mmol), and tetra-*n*-butylammonium iodide (7.20 g, 19.5 mmol) in CH_2Cl_2 (25 mL). The resulting mixture was stirred at room temperature until no **16** could be detected by TLC. The organic layer was separated. Standard work-up followed by flash chromatography (1:1) afforded 1.58 g (89%) of **17***a*, bp 220–225°C/0.05 Torr; IR ($CHCl_3$) ν (max): 1724 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.25–7.18 (m, 10H), 7.08 (d, J = 8.0 Hz, 1H), 7.05–6.95 (m, 2H), 6.88 (d, J = 8.4 Hz, 1H), 6.40 (m, 2H), 5.05 (s, 2H), 4.85(s, 2H), 3.84 (s, 3H), 3.73 (s, 3H); MS *m/z* (rel. intensity): 454 (M^+, 13), 346 (12), 241 (10), 91 (100). Anal. calcd. for $C_{29}H_{26}O_5$: C 76.63, H 5.77; found: C 76.59, H 5.85.

*Methyl 3,2′,4′-trimethoxy-2-biphenylcarboxylate (**17**b)*

According to a modification of a literature procedure (44), compound **16** (0.200 g, 0.78 mmol) was dissolved in a minimum amount of dimethyl sulfate (2 mL) and 50% NaOH solution was added dropwise until the starting material was no longer observable by TLC. 50% NaOH solution (5 mL) was then added, and the mixture stirred for 6 h to hydrolyze the excess dimethyl sulfate. Standard work-up followed by flash chromatography (1:1) afforded 0.170 g (70%) of **17***b*, mp 113.5–114°C (hexane–CH_2Cl_2); IR ($CHCl_3$) ν (max): 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.36 (t, J = 7.9, 1H), 7.11 (d, J = 8.9 Hz, 1H), 6.95–6.85 (m, 2H), 6.49 (m, 2H), 3.85 (s, 3H), 3.82 (s, 3H), 3.71 (s, 3H), 3.60 (s, 3H); MS *m/z* (rel. intensity): 302 (M^+, 100), 271 (92), 179 (45). Anal. calcd. for $C_{17}H_{18}NO_5$: C 67.54, H, 6.00; found: C 67.35, H 5.94.

*2′-Benzyloxy-3,4′-dimethoxy-2-biphenyl carboxylic acid (**18**a)*

Following the Gassman method (12), to a stirred suspension of potassium *tert*-butoxide (1.06 g, 9.45 mmol) in dry diethyl ether (5 mL) at 0°C was added water (0.048 mL) via syringe and the slurry was stirred for 5 min. Compound **17***a* (0.540 g, 1.19 mmol) was added, the ice bath was removed, and the reaction mixture was stirred at room temperature until **17***a* could not be observed by TLC. The reaction was quenched by adding ice-water until two clear layers formed. The aqueous layer was separated and acidified with concentrated HCl. The acidified solution was extracted with Et_2O to afford 0.390 g (92%) of **18***a*, mp 149–150°C (hexane–CH_2Cl_2); IR ($CHCl_3$) ν (max): 1723 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.30–7.05 (m, 7H), 6.87 (d, J = 7.8 Hz, 1H), 6.85 (d, J = 8.1 Hz, 1H), 6.45–6.35 (m, 2H), 4.94 (s, 2H), 3.79 (s, 3H), 3.68 (s, 3H); MS *m/z* (rel. intensity): 364 (M^+, 15), 256 (42), 227 (21), 91 (100). Anal. calcd. for $C_{22}H_{20}O_5$: C 72.52, H 5.53; found: C 72.29, H 5.43.

*3,2′,4′-Trimethoxy-biphenyl-2-carboxylic acid (**18**b)*

Following the above procedure, compound **17***b* (0.087 g, 0.29 mmol) was converted into **18***b* (0.080 g, 96%) as a clear colourless oil, IR ($CHCl_3$) ν (max): 1740, 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.39 (t, J = 8.0, 1H), 7.15 (d, J = 8.2 Hz, 1H), 6.92–6.90 (m, 2H), 6.53 (dd, J = 8.3, 2.3 Hz, 1H, C5′-H), 6.46 (d, J = 2.3 Hz, 1H, C2′-H), 3.90 (s, 3H), 3.83 (s, 3H), 3.65 (s, 3H), CO_2H undetected; MS *m/z* (rel. intensity): 288 (M^+, 100), 257 (91), 242 (26); HRMS calcd. for $C_{16}H_{16}O_5$: 288.0998; found: 288.0995.

*2,4,8-Trimethoxyfluoren-9-one (**6**d)*

TFAA (0.5 mL) was added dropwise to a solution of **18***b* (0.080 g, 0.28 mmol) in $CHCl_3$ (5 mL) at room temperature. After stirring for 4 h, the solution was poured into ice water. Standard work-up followed by flash chromatography (1:1) afforded, besides **16** (0.047 g, 65%), product **6***d* (0.012 g, 16%), mp 141–143°C (hexane–CH_2Cl_2) (lit. (9) mp 137–139°C); IR (KBr) ν: 1697 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.36 (dd, J = 7.7, 7.4 Hz, 1H, C6-H), 7.33 (d, J = 7.4 Hz, 1H, C5-H), 6.85 (d, J = 2.0 Hz, 1H, C1-H), 6.69 (dd, J = 7.7 Hz, 1H, C7-H), 6.54 (d, J = 2.0 Hz, 1H, C3-H), 3.96 (s, 3H), 3.92 (s, 3H), 3.85 (s, 3H). These spectral data were in accord with those reported (9) for synthetic **6***d* prepared as described below.

Remote metalation reactions to fluorenones

*2,3,4,8-Tetramethoxyfluoren-9-one (**6**c)*

To a solution of LDA (1.25 mmol) in THF (2 mL) was added a solution of **21***a* (0.188 g, 0.50 mmol) in THF (1 mL) at 0°C. The resulting mixture was stirred at room temperature for 10 h. Standard work-up followed by flash chromatography (1:6) afforded 0.124 g (82%) of **6***c*, mp 151–153°C (hexane–CH_2Cl_2) (lit. (9) mp 154–155°C); IR (KBr) ν (max): 1689 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.40 (dd, J = 7.8, 7.3 Hz, 1H, C6-H), 7.34 (dd, J = 7.3, 1.4 Hz, 1H, C5-H), 7.06 (s, 1H, C1-H), 6.76 (dd, J = 7.8, 1.4 Hz, 1H, C7-H), 4.00 (s, 3H), 3.97 (s, 3H), 3.94 (s, 3H), 3.92 (s, 3H). These spectral data were in accord with those reported (9) for synthetic **6***c* prepared by a different method.

*2,4,8-Trimethoxyfluoren-9-one (**6**d)*

To a solution of LDA (1.25 mmol) in THF (2 mL) was added the solution of **21***b* (0.172 g, 0.50 mmol) in THF (1 mL) at 0°C. The mixture was stirred at room temperature overnight. Standard work-up followed by flash chromatography (1:6) afforded 0.096 g (71%) of **6***d*, mp 141–143°C (hexane–CH_2Cl_2) (lit. (9) mp 137–139°C); IR (KBr) ν: 1697 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.36 (dd, J = 7.7, 7.4 Hz, 1H, C6-H), 7.33 (d, J = 7.4 Hz, 1H, C5-H), 6.85 (d, J = 2.0 Hz, 1H, C1-H), 6.70 (dd, J = 7.7, 1.3 Hz, 1H, C7-H), 6.54 (d, J = 2.0 Hz, 1H, C3-H), 3.96 (s, 3H), 3.92 (s, 3H), 3.85 (s, 3H). These spectral data were in accord with those reported (9) for synthetic **6***d* prepared by a different method.

*1,2,5,6,7-Pentamethoxyfluoren-9-one (**31**)*

To a solution of LDA (2.5 mmol) was added a solution of **36** (0.431 g, 1 mmol) in THF (2 mL) at 0°C and the mixture was allowed to warm to room temperature over 10 h. Standard work-up followed by flash chromatography (1:2) afforded 0.236 g (72%) of **31**, mp 128–130°C (MeOH); IR ($CHCl_3$) ν (max): 1706 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.35 (d, J = 8.0 Hz, 1H, C4-H), 7.02 (s, 1H, C8-H); 6.86 (d, J = 8.0 Hz, 1H, C3-H), 4.07 (s, 3H), 3.98 (s, 3H), 3.95 (s, 3H), 3.90 (s, 3H), 3.87 (s, 3H); ^{13}C NMR ($CDCl_3$) δ: 190.4, 153.7, 153.0, 149.0, 148.6, 147.8, 135.7, 130.2, 129.5, 125.0, 117.9, 116.8, 103.9, 61.9, 60.9, 60.4, 56.3; MS *m/z* (rel. intensity): 330 (M^+, 100), 315 (20); HRMS calcd. for $C_{18}H_{18}O_6$: 330.1098; found: 330.1097.

*Synthesis of Dengibsinin (7*a*)*

*2,4-Dimethoxy-3,5-diisopropoxyfluoren-9-one (**29**)*

To a solution of LDA (5.98 mmol) in THF (8 mL) was added a solution of **28** (1.028 g, 2.39 mmol) in THF (4 mL) at 0°C and the mixture was stirred at room temperature for 8–10 h. Standard work-up followed by flash chromatography (1:4) afforded 0.569 g (67%) of **29**, mp 132–134°C (hexane); IR (KBr) ν (max): 1703 cm^{-1}; ^1H NMR δ: 7.26 (dd, J = 6.9, 1.4 Hz, 1H, C8-H), 7.16 (dd, J = 8.2, 6.9 Hz, 1H, C7-H), 7.10 (s, 1H, C1-H), 7.05 (dd, J = 8.2, 1.4 Hz, 1H, C6-H), 4.50–4.74 (m, 2H), 3.88 (s, 3H), 3.86 (s, 3H), 1.42 (d, J = 6.1 Hz, 6H), 1.35 (d, J = 6.1 Hz, 6H); MS *m/z* (rel. intensity): 356 (M^+, 25), 272 (100), 257 (32). Anal. calcd. for $C_{21}H_{24}O_5$: C 70.77, H 6.79; found: C 71.03, H 6.94.

*2,4-Dimethoxy-3,5-dihydroxyfluoren-9-one (**7**a, dengibsinin)*

To a solution of **29** (0.035 g, 0.10 mmol) in CH_2Cl_2 (3.4 mL) at 0°C was added boron trichloride (2 mL of 1.0 M solution in CH_2Cl_2, 2.00 mmol). The resulting mixture was stirred for 1.5 h at 0°C and quenched with saturated NH_4Cl solution at 0°C. Standard work-up followed by flash chromatography (1:4) afforded 0.023 g (87%) of **7***a*, mp 218–220°C (hexane–CH_2Cl_2) (lit. (9) mp 225–227°C); IR (KBr) ν (max): 3259, 1688 cm^{-1}; ^1H NMR δ: 9.14 (s, 1H, C5-OH), 7.19 (dd,

J = 7.0, 1.9 Hz, 1H, C8-H), 7.17 (dd, J = 7.4, 7.0 Hz, 1H, C7-H), 7.10 (s, 1H, C1-H), 6.99 (dd, J = 7.4, 1.9 Hz, 1H, C6-H), 6.15 (br, 1H, C3-OH), 4.14 (s, 3H), 3.96 (s, 3H); MS *m/z* (rel. intensity): 272 (M^+, 100), 257 (35). These data were in good agreement with those reported for synthetic (9) and natural (7, 10) dengibsinin.

*Synthesis of imeluteine (**30**e)*

N-*Tosyl-9-amino-1,2,5,6,7-pentamethoxyfluorene (**33**)*

A mixture of **31** (0.28 g, 0.845 mmol) and $NH_2OH{\cdot}HCl$ (0.118 g, 1.7 mmol) in 70% aqueous EtOH (10 mL) was refluxed for 5 h. After cooling, the mixture was diluted with water (10 mL) and subjected to filtration. Recrystallization of the crude product from EtOH yielded 0.270 g (92%) of 1,2,5,6,7-pentamethoxyfluoren-9-one oxime, mp 214–216°C (EtOH); IR ($CHCl_3$) ν (max): 3400–2700 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 10.92 (s, 1H, OH, exchangeable with D_2O), 7.99 (s, 1H, C8-H), 7.56 (d, J = 8.2 Hz, 1H, C4-H), 6.90 (d, J = 8.2 Hz, 1H, C3-H), 4.01 (s, 3H), 4.00 (s, 3H), 3.96 (s, 3H), 3.95 (s, 3H), 3.93 (s, 3H); ^{13}C NMR ($CDCl_3$) δ: 153.0, 152.0, 151.7, 148.4, 145.7, 144.8, 133.1, 126.9, 126.7, 126.5, 118.3, 113.7, 109.9, 61.0, 60.5, 60.4, 56.4, 56.2; MS *m/z* (rel. intensity): 345 (M^+, 100), 329 (51); HRMS calcd. for $C_{18}H_{19}NO_6$: 345.1212; found: 345.1221.

Zinc dust (1.16 g, 17.8 mmol) was added in small portions to a stirred solution of 1,2,5,6,7-pentamethoxyfluoren-9-one oxime (1.226 g, 3.55 mmol) in a mixture of glacial HOAc (5 mL) and water (0.25 mL). The mixture was refluxed for 2 h and allowed to cool to room temperature. Water (5 mL) was added, the mixture was filtered, and the residue was washed with 5% HOAc (2 mL). The combined filtrate was mixed with an equal amount of concentrated HCl, and the mixture was kept at 0°C for 12 h. The solid was collected by filtration, washed with cold concentrated HCl, and dried to yield 1.15 g (88%) of 9-amino-1,2,5,6,7-pentamethoxyfluorene hydrochloride, which was converted into its tosylate. A mixture of 9-amino-1,2,5,6,7-pentamethoxyfluorene hydrochloride (0.200 g, 0.55 mmol) and tosyl chloride (0.114 g, 0.6 mmol) in pyridine (3 mL) was stirred at room temperature for 12 h. Et_2O (20 mL) was added, and the resulting mixture was washed in sequence with water, 0.5 N aqueous HCl, and water. Concentration to dryness afforded **33** (0.130 g, 50%), mp 103–105°C (hexane–Et_2O); IR ($CHCl_3$) ν: 3383, 1582 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.91 (d, J = 8.2 Hz, 2H, C3′5′-H), 7.50 (d, J = 8.3 Hz, 1H, C4-H), 7.35 (d, J = 8.2 Hz, 2H, C2′,6′-H), 6.99 (s, 1H, C8-H), 6.88 (d, J = 8.3 Hz, 1H, C3-H), 5.44 (d, J = 7.5 Hz, 1H, C9-H), 4.84 (d, J = 7.5 Hz, 1H, NH, exchangeable with D_2O), 3.97 (s, 3H), 3.89 (s, 3H), 3.84 (s, 3H), 3.79 (s, 3H), 3.45 (s, 3H), 2.45 (s, 3H); ^{13}C NMR ($CDCl_3$) δ: 153.3, 151.5, 146.4, 143.3, 142.7, 139.5, 138.6, 133.8, 133.4, 129.6, 128.6, 127.6, 127.1, 117.6, 113.8, 105.7, 77.2, 61.0, 60.5, 60.2, 57.3, 56.1, 21.5; MS *m/z* (rel. intensity): 485 (M^+, 100), 330 (50); HRMS calcd. for $C_{25}H_{27}NO_7S$: 485.1501; found: 485.1500.

N,N-*Diisopropyl 5′-(E-2-nitroethyl)-2′,3,3′,4,4′-pentamethoxybiphenyl-2-carboxamide (**42**)*

A mixture of **41** (4.62 g, 10.6 mmol), nitromethane (1.45 mL, 25.1 mmol), glacial HOAc (5 mL), and NH_4OAc (0.775 g, 10.06 mmol) was refluxed for 2 h. After cooling, the mixture was poured onto crushed ice and the whole was extracted with ether. The extract was dried (Na_2SO_4), filtered, and evaporated to dryness in vacuo. Flash chromatography (1:1) afforded 4.2 g (83%) of **42**, mp 174–176°C (EtOAc); IR ($CHCl_3$) ν (max): 1716, 1616 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 8.14 (d, J = 13.7 Hz, 1H, CH=*CH*NO_2), 7.71 (d, J = 13.7 Hz, 1H, *CH*=CHNO_2), 7.51 (s, 1H, C6′-H), 7.05 (d, J = 8.4 Hz, 1H, C6-H), 6.93 (d, J = 8.4 Hz, 1H, C5-H), 3.99 (s, 3H), 3.93 (s, 3H), 3.91 (s, 3H), 3.90 (s, 3H), 3.86 (s, 3H), 3.57 (sept, J = 6.6 Hz, 1H), 3.22 (sept, J = 6.8 Hz, 1H), 1.50 (d, J = 6.8 Hz, 3H), 1.09 (d, J = 6.8 Hz, 3H), 1.04 (d, J = 6.6 Hz, 3H), 0.65 (d, J = 6.6 Hz, 3H); ^{13}C NMR ($CDCl_3$) δ: 175.1, 166.8, 155.2, 154.0, 152.3, 146.1, 145.2, 137.5, 133.9, 128.7, 127.6, 125.3, 118.4, 111.3, 61.6, 61.2, 60.7, 55.8, 50.9, 45.6, 20.7, 20.5, 20.1, 20.0; MS *m/z* (rel. intensity): 502 (M^+, 25), 471 (100), 402 (52); HRMS calcd. for $C_{26}H_{34}N_2O_8$: 502.2306; found: 502.2300.

N,N-*Diisopropyl 5′-(2-aminoethyl)-2′,3,3′,4,4′-pentamethoxybiphenyl-2-carboxamide (**43**)*

To a well-stirred suspension of $LiAlH_4$ (1.5 g, 41 mmol) in ether (20 mL) was added dropwise a solution of **42** (4.12 g, 8.24 mmol) in THF (10 mL) and the mixture was refluxed for 6 h. Excess of $LiAlH_4$ was decomposed by dropwise addition of ice-cold 6 N HCl with cooling. The aqueous layer was separated, basified with 28% NH_4OH solution, and the whole was extracted with Et_2O (30 mL). The organic phase was dried (Na_2SO_4), and purged with HCl gas to afford 3.41 g (77%) of **43** hydrochloride, mp 160–163°C; IR ($CHCl_3$) ν (max): 3308, 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.09 (s, 1H, C6′-H), 7.06 (d, J = 8.6 Hz, 1H, C6-H), 6.92 (d, J = 8.6 Hz, 1H, C5-H) 3.92 (s, 3H), 3.88 (s, 3H), 3.87 (s, 3H), 3.86 (s, 3H), 3.83 (s, 3H), 3.58 (sept, J = 6.6 Hz, 1H), 3.23 (sept, J = 6.8 Hz, 1H), 2.88 (t, J = 6.3 Hz, 2H), 2.70 (m, 2H), 1.50 (d, J = 6.8 Hz, 3H), 1.43 (br s, 2H, exchangeable with D_2O), 1.15 (d, J = 6.8 Hz, 3H), 1.02 (d, J = 6.6 Hz, 3H), 0.65 (d, J = 6.6 Hz, 3H); MS (CI) *m/z* (rel. intensity): 474 (M^+ + 1, 100); HRMS calcd. for $C_{26}H_{38}N_2O_6$ + H: 475.2808; found: 475.2787.

*3,4-Dihydroimeluteine (**44**)*

To a solution of LDA (2.2 mmol) in THF (5 mL) was added a solution of **43** (0.285 g, 0.605 mmol) in THF (1 mL) at 0°C. The mixture was stirred for 10 h. Standard work-up followed by flash chromatography (2:1) afforded 0.076 g (36%) of **44**, mp 105–106°C (MeOH) (lit. (20*a*) mp 105–106°C); IR ($CHCl_3$) ν (max): 1644 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.44 (d, J = 8.1 Hz, 1H, C7-H), 6.89 (d, J = 8.1 Hz, 1H, C8-H), 4.03 (s, 3H), 3.96 (s, 3H), 3.95 (s, 3H), 3.90 (s, 3H), 3.87 (s, 3H), 4.24 (t, J = 8.0 Hz, 2H), 2.75 (t, J = 8.0 Hz, 2H); MS *m/z* (rel. intensity): 355 (M^+, 69), 326 (44).

*Imeluteine (**30**e)*

A solution of **44** (0.040 g, 0.113 mmol) in freshly distilled decalin (4 mL) was refluxed at 200–220°C for 3 h under argon in the presence of 10% Pd/C (20 mg). After cooling, Et_2O was added and the catalyst was collected by filtration. Evaporation of the filtrate to dryness followed by flash chromatography (1:2) afforded 0.024 g (60%) of imeluteine (**30***e*), mp 145–146°C (MeOH) (lit. (20*a*) mp 146–147°C); IR ($CHCl_3$) ν (max): 1581 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 8.68 (d, J = 6.0 Hz, 1H, C2-H), 7.63 (d, J = 8.0 Hz, 1H, C7-H), 7.60 (d, J = 6.0 Hz, 1H, C3-H), 6.94 (d, J = 8.0 Hz, 1H, C8-H), 4.18 (s, 3H), 4.11 (s, 3H), 4.10 (s, 3H), 4.04 (s, 3H), 3.95 (s, 3H); ^{13}C NMR ($CDCl_3$) δ: 158.0, 153.1, 150.6, 149.9, 148.4, 147.1, 144.5, 131.9, 126.2, 124.1, 122.1, 119.6, 113.6, 113.1, 62.1, 61.4, 61.3, 56.5; MS *m/z* (rel. intensity): 353 (M^+, 100), 324 (77). These data are in full accord with those reported for synthetic (20*a*, 37) and natural product (20*b*) samples of imeluteine.

Diastereoselectivity in the synthesis of D-glycero-D-aldoheptoses by 2-trimethylsilylthiazole homologation from hexodialdo-1,5-pyranose derivatives

NAVEEN K. KHARE,[1] RAMESH K. SOOD,[2] AND GERALD O. ASPINALL[3]

Department of Chemistry, York University, North York, Toronto, ON M3J 1P3, Canada

Received May 20, 1993

This paper is dedicated to Professors David B. MacLean and Ian D. Spenser

NAVEEN K. KHARE, RAMESH K. SOOD, and GERALD O. ASPINALL. Can. J. Chem. **72**, 237 (1994).

An exploration of the synthesis of D-*glycero*-D-*altro*-heptose, a constitutent of O antigen chains in lipopolysaccharides from *Campylobacter jejuni* serotypes O:23 and O:36 led to a study of the 2-trimethylsilylthiazole homologation procedure for heptose synthesis. In contrast to the diastereoselective formation of a 1,2:3,4-di-*O*-isopropylidene-D-*glycero*-α-D-*galacto*-heptopyranose derivative from 1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-hexodialdo-1,5-pyranose, methyl 2,3,4-tri-*O*-benzyl-D-hexodialdo-1,5-pyranosides with the *gluco* and *manno* configurations showed no preference for the formation of compounds with the D-*glycero* configuration. Attempts to achieve high diastereoselectivity in the conversion of L-*glycero* into the D-*glycero* isomers by oxidation at C-6 followed by reduction with L-selectride were unsuccessful with the thiazole adducts, but the desired products were formed in similar reactions of methyl 2,3,4-tri-*O*-benzyl-7-*O*-*tert*-butyldimethylsilyl-D-heptopyranosides. The approach to homologation in the *altro* series was thwarted by epimerization at C-5 in the attempted formation of methyl 2,3,4-tri-*O*-benzyl-α-D-*altro*-hexodialdo-1,5-pyranoside. The successful synthesis of methyl D-*glycero*-α-D-*altro*-heptopyranoside from methyl α-D-glucopyranoside was achieved by homologation followed by configurational alteration from the D-*gluco* to the D-*altro* series.

NAVEEN K. KHARE, RAMESH K. SOOD et GERALD O. ASPINALL. Can. J. Chem. **72**, 237 (1994).

Une exploration de la synthèse du D-*glycéro*-D-*altro*-heptose, un constituant des chaînes O antigéniques des lipopolysaccharides des sérotypes O:23 et O:36 du *Campylobacter jejuni* a conduit à étudier la possibilité d'utiliser la procédure d'homologation du 2-triméthylsilylthiazole pour réaliser la synthèse d'heptoses. Par opposition à la formation diastéréosélective d'un dérivé 1,2:3,4-di-*O*-isopropylidène-D-*glycéro*-α-D-*galacto*-heptopyranose à partir 1,2:3,4-di-*O*-isopropylidène-α-D-*galacto*-hexodialdo-1,5-pyranose, les 2,3,4-tri-*O*-benzyl-D-hexodialdo-1,5-pyranosides de méthyles avec des configurations *gluco* et *manno* ne présentent aucune préférence pour la formation de composés avec la configuration D-*glycéro*. Les essais effectués sur des adduits thiazoles dans le but d'obtenir une grande diastéréosélectivité lors de la conversion des isomères L-*glycéro* en D-*glycéro* par le biais d'une oxydation en C-6 suivie par une réduction à l'aide de L-sélectride se sont avérés vains; toutefois, les produits désirés se forment lors de réactions semblables avec des 2,3,4-tri-*O*-benzyl-7-*O*-*tert*-butyldiméthylsilyl-D-heptopyranosides de méthyle. L'approche à l'homologation dans la série *altro* ne peut être réalisée à cause d'une épimérisation en C-5 lorsqu'on essaie de former le 2,3,4-tri-*O*-benzyl-α-D-*altro*-hexodialdo-1,5-pyranoside de méthyle. On a réalisé la synthèse du D-*glycéro*-α-D-*altro*-heptopyranoside de méthyle à partir de l'α-D-glucopyranoside de méthyle en procédant à une homologation suivie d'une modification de configuration de la série D-*gluco* à D-*altro*.

[Traduit par la rédaction]

Introduction

L-*glycero*-D-*manno*-Heptose is a commonly encountered component of the core region of lipopolysaccharides (LPS) on Gram-negative bacteria (1). In view of the immunological importance of this region of LPS structure considerable attention has been directed to efficient methods for the preparation of derivatives of the sugar for incorporation into synthetic oligosaccharides (2–6). Methods of choice have been those involving a one-carbon extension from benzyl (**1**) or methyl (**2**) 2,3,4-tri-*O*-benzyl-α-D-*manno*-hexodialdo-1,5-pyranoside of which that involving reaction with (phenyldimethylsilyl)magnesium chloride (**4**) proceeds with high diastereoselectivity to give derivatives of L-*glycero*-D-*manno*-heptose from which glycosides of the parent sugar may be readily obtained. In a recent study of the O antigen chains of LPSs of *Campylobacter jejuni* serotypes O:23 and O:36 unusual heptose sugars were found as four variants with the same configurationally unusual *altro* ring configuration (7). LPS preparations all contained trisaccharide, -3-β-D-GlcNAc-(1→3)-α-D-Gal-(1→2)-α-Hep 1-, repeating units with the same linkages and anomeric configurations, but with the heptose residue present in varying proportions as 6-deoxy-D-*altro*-heptose (8) and 6-deoxy-3-*O*-methyl-D-*altro*-heptose (unpublished synthesis with G.V. Reddy), for which enantiomeric configurations have been confirmed, and D-*glycero*-D-*altro*-heptose and 3-*O*-methyl-D-*glycero*-D-*altro*-heptose or their respective enantiomers. In view of the close structural, and presumably also biosynthetic, relationship between the four variants it was highly probable that all had the α-D-*altro* ring configuration. It was still necessary to confirm the absolute configurations of the two latter sugars through the synthesis of defined reference compounds before making preparative quantities for oligosaccharide assembly. The only reported C-6 homologation of a D-hexodialdo-1,5-pyranose derivative proceeding with high diastereoselectivity for the formation of the D-*glycero* product is that reported by Dondoni et al. (5, 6) using 2-(trimethylsilyl)thiazole (TMSthiazole) as a one-carbon synthon in reaction with 1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-hexodialdo-1,5-pyranose (**3**). This procedure therefore seemed worthy of exploration for the synthesis of D-*glycero*-D-*altro*-heptose derivatives. Two alternative overall strategies seemed possible starting from D-glucopyranose derivatives: (A) 2,3-inversion to gain entry into the D-altropyranose series, followed by C-6 homologation; and (B)

C-6 homologation in the D-glucopyranose series, followed by 2,3-inversion of the D-*glycero*-D-*gluco*-heptopyranose product. In the event unexpected problems were encountered in both proposed routes. Route A was rejected at an early stage when it was observed that oxidation of methyl 2,3,4-tri-*O*-benzyl-α-D-altropyranoside to give the dialdohexo-1,5-pyranoside was accompanied by substantial epimerization at C-5 with formation of the corresponding β-L-*galacto* derivative. Route B ultimately proved successful for the preparation of the desired heptoses but no diastereoselectivity was observed in the C-6 homologation reaction. We report herein syntheses of these heptoses in confirmation of their absolute configurations, but discuss first diastereoselectivity in the TMSthiazole homologation together with experiments related to the C-5 epimerization accompanying oxidation at C-6 of both altrose and galactose derivatives.

Results and discussion

Configurational assignments for heptose derivatives epimeric at C-6

All homologations were performed and the thiazole adducts were converted into heptose derivatives as described by Dondoni et al. (5, 6) and *O*-debenzylated. Since all 10 diastereomeric heptitol heptaacetates are separable by gas–liquid chromatography (glc) (9) (see Table 1 for examples now reported), formation of these derivatives by hydrolysis of glycosides, reduction, and acetylation was the simplest method for distinguishing the pairs of D-*glycero*/L-*glycero* epimers that may result from C-6 homologations. Other, sometimes quantitatively dominant, compounds are produced in varying amounts due to accompanying 1,6- and (or) 1,7-anhydroheptose formation under hydrolysis conditions, as in the case of D-*glycero*-D-*altro*-heptose (7). In the example reported by Dondoni et al. (5, 6), the absolute configuration at C-6 of the thiazole adduct, (6*S*)-1,2:3,4-di-*O*-isopropylidene-6-(2-thiazolyl)-α-D-*galacto*-hexo-1,5-pyranose (**4**), formed as the sole product from 1,2:3,4-di-*O*-isopropylidene-D-*galacto*-hexodialdo-1,5-pyranose (**3**), was established by conversion into a previously characterized D-*glycero*-α-D-*galacto*-heptose derivative (10). However, derivatives of defined configuration from rarely encountered heptoses are unlikely to be available for comparison. Furthermore for the compounds of present interest, we have found that the differences in nmr parameters for C-6 and H-6 in epimeric heptose derivatives are insufficiently consistent to provide a basis for configurational assignments.

Diastereoselectivity in C-6 homologation of mannose and glucose derivatives

With access to heptitol heptaacetates derived from L-*glycero*- and D-*glycero*-D-*manno*-heptoses for comparison, the TMSthiazole homologation reaction was examined as an alternative to the above-mentioned homologation of **1** with (phenyldimethyl)silylmethylmagnesium chloride, which had been used in the preparation of derivatives of L-*glycero*-D-*manno*-heptose with high diastereoselectivity (3, 4). Diastereoselectivity in homologation was first examined for methyl 2,3,4-tri-*O*-benzyl-α-D-*manno*-hexodialdo-1,5-pyranoside (**2**), prepared as required on Swern oxidation (11) of methyl 2,3,4-tri-*O*-benzyl-α-D-mannopyranoside with oxalyl chloride and methyl sulfoxide. Reaction of **2** with TMSthiazole gave the chromatographically separable 6-(2-thiazolyl)-derivatives (**5** and **6**) in respective yields of 55 and 37%. Conversion of **5** and **6** into the respective methyl 2,3,4-tri-*O*-benzylheptopyranosides (**7** and **8**), in four steps with overall yields of 60–70%, by successive *N*-methylation, reduction with $NaBH_4$, hydrolysis in the presence of $HgCl_2$, and reduction again with $NaBH_4$. Since this research was completed Dondoni et al. (12) have reported an improved procedure for the thiazole to formyl deblocking protocol. Configurational assignments for **7** and **8** were made by conversion into L-*glycero*- and D-*glycero*-D-*manno*-heptitol heptaacetates.

TMSthiazole homologation of the hexodialdo-1,5-pyranoside (**9**) formed on oxidation of methyl 2,3,4-tri-*O*-benzyl-α-D-glucopyranoside was next explored with very similar results to those in the mannose series. Reaction of **9** with TMSthiazole furnished a mixture of 6-(2-thiazolyl) derivatives from which **10** and **11** were obtained in chromatographically pure form in yields of 54 and 18%. These compounds were converted into the corresponding methyl 2,3,4-tri-*O*-benzylheptopyranosides **12** and **13**, as described above, and thence after *O*-debenzylations into the respective methyl glycosides **14** and **15**. Compounds **14** and **15** (and similarly others elsewhere) were converted into their acetylated derivatives **16** and **17** to provide satisfactory elemental analyses and to give well-dispersed one-dimensional ^1H nmr spectra for structural assignments. Relative configurations were assigned after conversion of **14** and **15** into heptitol heptaacetates that were indistinguishable on glc from those derived respectively from L-*glycero*- and D-*glycero*-D-*gluco*-heptitols.

Configurational inversions at C-6 of heptose derivatives

In the light of the preceding results attention was turned to the

possibility of achieving a high-yield conversion of L-*glycero* into the epimeric D-*glycero* compounds. Dondoni et al. (13) have described inversion of configuration at C-6 of the (2-thiazolyl) derivative **4** by oxidation to the 6-ulose followed by stereoselective reduction with L- or K-selectride to give the (6*R*) epimer (**18**).

With formation of the L-*glycero* compound **7** as the major product of TMSthiazole homologation in the *gluco series* the possibility of achieving improved overall yields of D-*glycero*-D-*gluco*-heptose derivatives by configurational inversions at C-6 was examined for three derivatives. The 6-(2-thiazolyl) derivative **10** was oxidized with periodinane (14) and the resulting 6-ulose, without purification, was treated with L-selectride to regenerate a mixture of thiazolyl derivatives **10** and **11**, now in the proportions of 2:3. Alternative methods for the configurational inversion were explored for 7-*tert*-butyldiphenylsilyl (TBDPS) and 7-*tert*-butyldimethylsilyl (TBDMS) derivatives of **12** and **13**. In the case of a preliminary experiment performed on TBDPS derivatives from an unresolved mixture of **12** and **13**, Swern oxidation (11) to give the 6-ulose followed by reduction with L-selectride gave back derivatives of **12** and **13** in the same proportions. Samples of the respective TBDMS derivatives (**19** and **20**) of **12** and **13** were prepared so that the reduction of the 6-ulose could be monitored, and complete conversion of **19** to **20** was achieved when **19** was submitted to the oxidation–reduction sequence. A single product was detected by tlc as reduction of the 6-ulose with L-selectride proceeded, but when the reaction mixture was quenched with alkaline hydrogen peroxide, a mixture of products was formed. The chromatographic mobilities of these substances indicated retention of a silyl substituent. Since treatment of these substances with tetrabutylammonium fluoride gave **13** as the sole product, it is probable that intramolecular silyl migration, from O-7 to O-6, had taken place.

In the *manno* series, preparation of the TBDMS derivative **21** from **7** was followed by Swern oxidation (11) to the 6-ulose, reduction with L-selectride, and *O*-desilylation to give the D-*glycero* epimer **8** as the only detectable product and in 80% isolated yield.

Diastereoselectivity in C-6 homologation of altrose and galactose derivatives

Treatment of methyl 2,3,4-tri-*O*-benzyl-α-D-altropyranoside with oxalyl chloride and methyl sulfoxide gave a mixture of hexodialdo-1,5-pyranosides, as judged by the appearance of two aldehydic protons in the ^1H nmr spectrum and, most prominently in the ^{13}C nmr spectrum, of two sets of resonances assignable to ring carbons of the expected methyl 2,3,4-tri-*O*-benzyl-α-D-*altro*-hexodialdo-1,5-pyranoside (**22**) and the C-5 epimer, methyl 2,3,4-tri-*O*-benzyl-β-L-*galacto*-hexodialdo-1,5-pyranoside (**23**) in the approximate ratio of 1:4. The correctness of this conclusion was confirmed by reduction of the mixture of hexodialdo-1,5-pyranosides with $NaBH_4$ followed by acetylation to give a mixture of methyl 6-*O*-acetyl-2,3,4-tri-*O*-benzyl-hexopyranosides in the somewhat altered ratio of 2:3 with glc retention times coincident with those of standard α-D-altrose and β-D-galactose derivatives. Confirmation of the L-*galacto* configuration for the main component was obtained by *O*-debenzylation of the mixture of tri-*O*-benzyl glycosides followed by hydrolysis and conversion of the resulting reducing sugars into acetates of chiral 2-butyl glycosides (15). These results confirmed that epimerization at C-5 had occurred, leading to the formation of the β-L-*galacto* isomer as the major component of the mixture of hexodialdo-1,5-pyranosides. Mixtures of **22** and **23** in the same proportions were obtained on oxidation of methyl 2,3,4-tri-*O*-benzyl-α-D-altropyranoside with periodinane (14), indicating that the epimerization was not just a base-catalyzed reaction promoted by the use of triethylamine in the Swern oxidation.

A rapid interconversion of **22** and **23**, with the composition of isomers on further reaction dependent on the relative rates of formation of different products, was indicated in the above-mentioned reduction to give stereoisomeric products in changed proportions. In an exploration of the stereochemical consequences of the C-6 homologation with TMSthiazole, reaction of the mixture of **22** and **23** gave only one detectable product, which was assigned the structure methyl (6*R*)-2,3,4-tri-*O*- benzyl-6-(2-thiazolyl)-β-L-galactopyranoside (**24**) on the basis of the following evidence. The ^{13}C nmr spectra of **24** and the derived methyl 2,3,4-tri-*O*-benzyl-L-*glycero*-

β-L-*galacto*-heptopyranoside (**25**) showed resonances for carbon atoms of the β-*galacto* ring configuration and none for those of the α-*altro* configuration. *O*-Debenzylation of **25** followed by hydrolysis, reduction, and acetylation gave a single heptitol heptaacetate coincident on glc with that formed from the enantiomeric L-*glycero*-D-*manno*-heptose (= D-*glycero*-D-*galacto*-heptose) and therefore confirmed the relative configuration of the chiral centres.

The reversibility of the *altro–galacto* interconversion was also examined in the formation of hexodialdo-1,5-pyranose derivatives in the more accessible D-galactose series. In a reexamination of the oxidation of 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose as reported by Dondoni et al. (5, 6), the ^1H and ^{13}C nmr spectra of the corresponding hexodialdo-1,5-pyranose (**3**) showed only the *galacto* isomer with no trace of the *altro* derivative. TMSthiazole homologation likewise gave only the reported (6*S*)-1,2:3,4-di-*O*-isopropylidene-6-(2-thiazolyl)-α-D-galactopyranose (**4**). In confirmation of this observation, independent evidence for the configurational assignments at C-6 in **4** and in its C-6 epimer (**18**) was obtained by their conversions into 1,2:3,4-di-*O*-isopropylidene-D-*glycero*-D- *galacto*-heptopyranose (**26**) and the corresponding L-*glycero*-D- *galacto* compound (**27**), and thence into heptitol heptaacetates that were identical (gc) to samples prepared from the corresponding D-*glycero*-D-*galacto*-heptose and L-*glycero*-D-*gluco*- heptose (= L-*glycero*-D-*galacto*-heptose).

As expected, a parallel series of oxidation and TMSthiazole homologation reactions starting from methyl 2,3,4-tri-*O*-benzyl-β-D-galactopyranoside afforded compounds enantiomeric with those described above that were derived from methyl 2,3,4-tri-*O*-benzyl-α-D-altropyranoside. Comment here is restricted to a few salient points and details are given later. Oxidation of the D-galactopyranoside gave the corresponding mixture of *galacto* and *altro* dialdohexopyranosides in the ratio of 3:1 and, as expected, only a single product (**28**) with the D-*glycero*-α-D-*galacto* configuration was isolated from the ensuing TMSthiazole homologation. Although there were small differences in the magnitudes of the optical rotations of **28** and the corresponding methyl 2,3,4-tri-*O*-benzylheptopyranoside **29**, compared with those of the L-*galacto* compounds **24** and **25**, the enantiomeric pairs were chromatographically indistinguishable and ^1H and ^{13}C nmr spectra showed no significant differences.

The stereoselectivity of configurational inversion at C-6 of **28** by oxidation and subsequent reduction with L-selectride was also examined. Two fractions were separated by preparative tlc and the structures of the products, which were obtained in insufficient quantity and purity for elemental analysis, were established from nmr spectra data and conversions to the corresponding heptitol heptaacetates. The nmr spectra of the derivative from the first fraction showed the presence of a single component with the *galacto* configuration, and further processing furnished L-*glycero*-D-*galacto*-heptitol heptaacetate derived from the product of C-6 inversion. The ^{13}C nmr spectrum of the second fraction showed the presence of compounds with α-*altro* and β-*galacto* configurations, and further processing of the fraction afforded a mixture of two heptitol heptaacetates. Comparison of their glc retention times with those of reference compounds with the D-*glycero*-D-*galacto* and the D-*glycero*-D-*altro* configurations showed that the second fraction of the oxidation–reduction sequence consisted of the product from unchanged starting compound **28** and only one of two possible products arising from epimerization at C-5 of the 6-ulose, that with the L-*glycero*-L-*altro* configuration.

Synthesis of derivatives of D-glycero-D-altro-*heptose*

The preceding studies of C-6 homologations of D-hexodialdo-1,5-pyranose derivatives provided abundant evidence that route B is the only practical strategy for the synthesis of D-*glycero*-D-*altro*-heptose derivatives and ruled out any reac-

tions involving carbonyl groups at C-6 of compounds having the *altro* ring configuration. Methyl 7-*tert*-butyldiphenylsilyl-D-*glycero*-α-D-*gluco*-heptopyranoside (**31**) was best prepared by *O*-silylation of methyl glycoside **15**, since silylation of **13** to give the TBDPS derivative (**30**) followed by hydrogenolysis was accompanied by ~25% *O*-desilylation. Reaction of **31** with benzaldehyde dimethylacetal in the presence of catalytic amounts of *p*-toluenesulfonic acid gave the 4,6-*O*-benzylidene derivative **32**. Several methods for the preparation of methyl 2,3-anhydro-4,6-*O*-benzylidene-D-*glycero*-α-D-*manno*-heptopyranoside (**35**) were explored. In the course of these experiments samples of the 2-tolylsulfonyl ester **33** and the *O*-silyl epoxide **36** were obtained in adequate purity for structural characterization by nmr but not for elemental analysis. These samples were of value in monitoring the procedure of Hicks and Fraser-Reid (16) in which treatment of **32** with sodium hydride and tosyl imidazole led to the formation in a single operation of a derivative with the desired 2,3-anhydro-*manno* configuration but this reaction was accompanied by *O*-desilylation to give the epoxide **35**. The initially formed tosyl ester **33** was rapidly converted into the silylated epoxide **34**, but by the time all starting material (**32**) had reacted, much **34** had undergone *O*-desilylation. Prolongation of the reaction led to complete conversion into the epoxide **35**. This further reaction turned out to be advantageous since the 7-*O*-silyl expoxide (**34**) proved to be quite unreactive under normal conditions of epoxide opening. The *O*-desilylated epoxide **35** underwent normal diaxial opening on reaction with aqueous sodium hydroxide to yield methyl 4,6-*O*-benzylidene-D-*glycero*-α-D-*altro*-heptopyranoside (**36**), and *O*-debenzylidenation gave methyl D-*glycero*-α-D-*altro*-heptopyranoside (**38**). The nmr data for the respective acetylated derivatives (**37** and **39**) of these two compounds supported the *gluco* to *altro* configurational change. Confirmation of the relative configuration was obtained by hydrolysis of the glycoside **38**, followed by reduction to give the heptitol and a mixture of 1,6- and 1,7-anhydroheptoses, whose acetylated derivatives were coincident on glc with those derived from the *C. jejuni* O:36 LPS (7). A sample of the heptose was converted into the (*R*)- and (*S*)-2-butyl glycosides whose acetylated derivatives were identical (glc) with those similarly derived from the polysaccharide, thus confirming the absolute configuration of the naturally occurring sugar as D-*glycero*-D-*altro*-heptose. In like manner, methoxide opening of epoxide **35** afforded methyl 4,6-*O*-benzylidene-3-*O*-methyl-D-*glycero*-D-*altro*-heptopyranoside (**40**) and the derived compounds **41–43** were characterized in the same way as for compounds **36–38**. Conversion of a sample of methyl glycoside **41** into (*R*)- and (*S*)-2-butyl glycosides followed by acetylation for glc comparison with those derived from the *C. jejuni* O:23 LPS (7) confirmed that the naturally occurring heptose was 3-*O*-methyl-D-*glycero*-D-*altro*-heptose.

In summary, these studies have shown that the high diastereoselectivity observed by Dondoni et al. (5, 6) in the C-6 homologation of a hexodialdo-1,5-pyranose derivative using 2-trimethylsilylthiazole as a one-carbon synthon is restricted to the galactose series. The unidirectional attack at the *si* face of the 6-aldehyde in this series is presumably governed by the steric effect of the axial oxygen substituent at C-4. No such stereoselectivity was found with glucose and mannose derivatives. In the galactose series a further observation was made that might have escaped attention if experiments had not also been performed in the altrose series. Oxidation of methyl 2,3,4-tri-*O*-benzyl-α-D-altropyranoside was accompanied by epimerization at C-5 with the formation of an equilibrium mixture of 5-epimeric hexodialdo-1,5-pyranosides favouring the β-L-*galacto* isomer **23** over the α-D-*altro* isomer **22** in the ratio of 3:1. In the opposite direction, oxidation of the enantiomeric β-D-galactoside gave the corresponding mixture of products with the α-L-altropyranoside as the minor component. For the monocyclic methyl 2,3,4-tri-*O*-benzyl hexopyranosides, rapid equilibration may be presumed with product composition on further reaction being kinetically determined. Thus rapid and irreversible reduction with sodium borohydride gave back a mixture of hexopyranosides in approximately the same proportions from glc analysis as indicated by nmr for the hexodialdo-1,5-pyranosides. In contrast the TMSthiazole addition, of presumably reversible character, gave a single detectable product with the β-*galacto* ring configuration. In the D-series high diastereoselectivity, as reported by Dondoni et al. (5, 6), led to the formation of the 6-(*S*) thiazolyl derivative **28** and thence of the D-*glycero*-D-*galacto*-heptopyranoside **29**. In reexamining the preparation of 1,2;3,4-di-*O*-isopropylidene-α-D-*galacto*-hexodialdo-1,5-pyranose (**3**), nmr showed no evi-

dence for epimerization at C-5 in this conformationally more rigid fused ring derivative. The enolization mechanism for epimerization would require the adoption of a trigonal carbon at C-5 with energetically unfavourable conformational changes in the fused ring system. It is noteworthy that no evidence was obtained for C-5 epimerization in the preparation of hexodialdo-1,5-pyranosides in the mannose and glucose series.

The conversion of (6*S*)- (**4**) into the epimeric (6*R*)-1,2;3,4-di-*O*-isopropylidene-6-(2-thiazolyl)-α-D-galactopyranose (**18**) by oxidation to the thiazolyl heptose-6-ulose followed by stereoselective reduction with L-selectride (5, 6) appeared to establish in principle a route for conversion of D-*glycero*- to the 6-epimeric L-*glycero*-D-heptopyranose derivatives. In our hands this stereoselectivity is not general and seems to be restricted to the conformationally rigid fused ring system in **18** where reduction of the thiazolyl heptose-6-ulose would require unidirectional attack on the *re* face at C-6 analogous to that on the *si* face of the hexodialdo-1,5-pyranose **3** in the formation of thiazolyl derivative **4**. Reaction starting from the (6*S*)-(2-thiazolyl)-β-D-galactopyranoside **28** gave a mixture of products that could be converted into derivatives of D-*glycero*- and L-*glycero*-β-D-galactopyranosides, and L-*glycero*-α-L-altropyranosides. The analogous reaction sequence with the corresponding thiazolyl derivatives in the glucose and mannose series showed no stereoselectivity. Stereoselective reductions were achieved here, but in the *opposite direction* when the heptoside-6-uloses from the severely hindered 7-TBDMS L-*glycero*-α-D-*manno*- (**19**) and α-D-*gluco*- (**20**) heptopyranosides were treated with L-selectride.

In reaching our initial objective, that of developing a synthesis of D-*glycero*-D-*altro*-heptose to confirm the absolute configuration of the O antigen constituent in the LPS of *C. jejuni* serotype O:36, the C-6 homologation was achieved first with the formation of derivatives of D-*glycero*-D-*gluco*-heptose. The well-known series of transformations from D-glucopyranosides to D-altropyranosides with inversions at C-2 and C-3 presented unexpected difficulties in the formation, and subsequent ring opening, of the intermediate 2,3-anhydro-*manno*-heptose derivative bearing a 7-*O*-TBDMS substituent until that protecting group could be removed after its purpose had been served.

Experimental

General methods

The following solvents were dried and purified by distillation over the reagents specified in parentheses: dichloromethane (phosphorus pentoxide), oxolane (lithium aluminum hydride), methanol (magnesium–iodine), toluene (sodium). Light petroleum (bp 30–60°C) and ethyl acetate used as chromatographic solvents were freshly distilled immediately before use. Acetonitrile, *N,N*-dimethylformamide, and methyl sulfoxide were purchased already dried and glass-distilled. Evaporations were conducted under diminished pressure at <40°C. Thin-layer chromatography (tlc) was conducted on plates coated with Silica Gel $60F_{254}$ (Merck). Optical rotations were measured with a Perkin–Elmer 141 polarimeter, for solutions in $CHCl_3$ at ~20°C unless otherwise stated.

^1H, ^{13}C (often in the JMODXH mode), and 2D ^1H nmr spectra were recorded with a Bruker AM 300 spectrometer. Solutions in chloroform-*d* were referenced to internal tetramethylsilane as internal reference. Solutions in D_2O were referenced to internal acetone (δ_H 2.17 ppm and δ_C 30.5 ppm). Chemical shifts and coupling constants are first-order values and assignments in ^1H nmr spectra on the basis of double resonance or COSY experiments are specified in parentheses. Spectra are reported only in sufficient detail to substantiate chemical changes effected and for configurational assignments. The following characteristic resonances were observed consistently and are not cited individually other than when the groups were first incorporated: for thiazolyl derivatives at δ_H ~ 7.7 (H-4′) and 7.3 (H-5′), and δ_C ~171 (C-2′), 142 (C-4′) and 119 (C-5′), for benzyl ethers at δ_H ~ 7.4–7.2 (Ph-H) and 5.0–4.8 (CH_2Ph), and δ_C ~137 and 127 (aromatic C) and 75–72 (Ph-CH_2); and for *O*-isopropylidene derivatives at δ_H 1.5–1.3 ($(CH_3)_2C$), and δ_C ~108 ($(CH_3)_2C$) and 26–24 ($(CH_3)_2C$). The glc analyses were carried out on a Hewlett–Packard model 5890 A chromatograph. Separations were performed using a DB-23 (30 m × 0.25 mm) column with the following programs: (A) for alditol acetates, isothermally at 220°C unless specified at 200°C; (B) for 2-butyl glycoside acetates, 200°C (10 min), 200° → 240°C at 2°/min. Microanalyses were by Canadian Microanalytical Service, Ltd., Delta, B.C.

Preparations of hexodialdo-1,5-pyranose derivatives

Typical oxidations were performed by the addition of freshly distilled methyl sulfoxide (0.23 mL, 3 mmol) in dichloromethane (4 mL) to oxalyl chloride (1.2 mL, 2.4 mmol) in dichloromethane (10 mL) at −60°C. After 5 min substrate (~0.5 g, 1 mmol) in dichloromethane was added dropwise. After 30 min the reaction was quenched by the addition of triethylamine (2 mL) in dichloromethane (5 mL), and the solution was allowed to rise to room temperature, washed twice with water, dried, and concentrated. Completeness of reaction was checked by tlc for disappearance of initial substrate and, if necessary, by nmr (appearance of an aldehydic proton singlet at δ ~9.7 in the ^1H spectrum, appearance of aldehydic carbonyl resonance at δ ~198, and disappearance of C-6 resonance of substrate at δ ~62 in the ^{13}C spectrum). The hexodialdo-1,5-pyranose derivative was used directly without further purification in the TMSthiazole homologation reaction.

*Addition of 2-(trimethylsilyl)thiazole to methyl 2,3,4-tri-*O*-benzyl-α-D-manno-hexodialdo-1,5-pyranoside 2*

2-(Trimethylsilyl)thiazole (0.4 mL) was added to **2** (from methyl 2,3,4-tri-*O*-benzyl-α-D-mannopyranoside (17) (0.5 g)) in dichloromethane (10 mL) at 0°C under nitrogen. The mixture was kept at 0°C overnight and then at room temperature for 3 h. Solvents were evaporated, and the residue in oxolane (10 mL) was treated with 1 M tetrabutylammonium fluoride (2.8 mL) for 30 min. Solvent was partly evaporated and the residue was treated with aqueous sodium hydrogen carbonate and extracted with ethyl acetate. The extract was dried, concentrated, and chromatographed on silica gel (dichloromethane containing 3% of acetone) to give, in order of elution, **5** (320 mg, 55%) and **6** (216 mg, 37%). Methyl (6*R*)-2,3,4-tri-*O*-benzyl-6-(2-thiazolyl)-α-D-mannopyranoside (**5**) had $[\alpha]_D$ +29 (*c* 1.0); ^1H nmr, δ: 5.33 (s, 1H, H-6), 4.64 (s, 1H, H-1), 3.04 (s, 3H, OCH_3); ^{13}C nmr, δ_C: 99.3 (C-1), 80.1, 74.7, 74.2, 73.6, 70.3 (C-2 to C-6), 54.7 (OCH_3). Anal. calcd. for $C_{31}H_{33}NO_6S$: C 67.98, H 6.07, N 2.55, S 5.85; found: C 67.96, H 5.98, N 2.55, S 5.85. Methyl (6*S*)-2,3,4-tri-*O*-benzyl-6-(2-thiazolyl)-α-D-mannopyranoside (**6**) had $[\alpha]_D$ +31 (*c* 1.0); ^1H nmr, δ: 5.39 (d, 1H, $J_{5,6}$ 3.4 Hz, H-6), 4.75 (d, 1H, $J_{1,2}$ 1.7 Hz, H-1), 3.28 (s, 3H, OCH_3); ^{13}C nmr, δ_C: 98.9 (C-1), 80.1, 75.1, 74.6, 73.8, 72.3 (C-2 to C-6), 54.9 (OCH_3). Anal. calcd. for $C_{13}H_{33}NO_6S$: C 67.98, H 6.07, N 2.55, S 5.85; found: C 67.75, H 6.00, N 2.55, S 5.85.

*Methyl 2,3,4-tri-*O*-benzyl-L-glycero- (7) and methyl 2,3,4-tri-*O*-benzyl-D-glycero- (8) α-D-manno-heptopyranoside*

Formyl deblocking from the thiazole ring and subsequent reduction were carried in four successive steps. (1) Compounds **5** and **6** (150 mg, 0.27 mmol each) were separately treated with methyl iodide (0.17 mL, 2.7 mmol) in boiling acetonitrile (7 mL) for 24 h. (2) After removal of solvent, the residues in methanol (5 mL) were each treated with $NaBH_4$ (21 mg, 2 equiv.) at −10°C for 30 min, after which acetone (2 mL) was added to destroy excess of hydride. Solvent was evaporated, the residue were treated with saturated aqueous NaCl and extracted into ethyl acetate, and the extracts were concentrated. (3) The separate residues in acetonitrile (0.4 mL) were added to solutions of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

$HgCl_2$ (90 mg, 1.2 equiv.) in acetonitrile–water (4:1, 5 mL), and the solutions were stirred at room temperature for 15 min. Reaction mixtures were filtered, and the filtrates were concentrated. The residues were treated with saturated aqueous NaCl, extracted with chloroform, and the extracts were concentrated. (4) $NaBH_4$ (21 mg each, 2 equiv.) was added portionwise during 30 min to the crude aldehydic products in methanol (10 mL) at room temperature. Acetic acid – water (1:1) was added dropwise to each solution to destroy excess of hydride and bring the solutions to pH 7, the respective solutions were concentrated, and the residues were chromatographed on silica gel.

Methyl 2,3,4-tri-*O*-benzyl-L-*glycero*-α-D-*manno*-heptopyranoside (**7**) (82 mg, 61%), formed from **5**, was eluted with dichloromethane containing 6% of acetone and had $[\alpha]_D$ +25 (*c* 1.0) (lit. $[\alpha]_D$ +30 (18), $[\alpha]_D$ +23 (19)); ^{1}H nmr, δ: 4.65 (s, 1H, H-1), 4.11 (t, 1H, $J_{3,4} \sim J_{4,5} \sim$ 9.5 Hz, H-4), 3.94 (m, 1H, H-6), 3.84 (dd, 1H, $J_{2,3}$ 3.0 Hz, $J_{3,4}$ 9.4 Hz, H-3), 3.80–3.60 (m, 3H, H-2, H-7), 3.55 (dd, 1H, $J_{5,6}$ 1.4 Hz, $J_{4,5}$ 9.7 Hz, H-5); ^{13}C nmr, δ_C: 99.5 (C-1), 80.0, 74.5, 74.3, 72.5, 69.4 (C-2 to C-6), 65.0 (C-7) (lit. (17, 18) for similar nmr data).

Methyl 2,3,4-tri-*O*-benzyl-D-*glycero*-α-D-*manno*-heptopyranoside (**8**) (76 mg, 57%), formed from **6**, was eluted with dichloromethane containing 4% of acetone and had $[\alpha]_D$ +35 (*c* 1.0); ^{1}H nmr, δ: 4.68 (d, 1H, $J_{1,2}$ 2.1 Hz, H-1), 4.02 (t, 1H, $J_{3,4} \sim J_{4,5} \sim$ 9.3 Hz, H-4), 3.93 (m, 2H, H-3, H-6), 3.80–3.63 (m, 4H, H-2, H-5, H-7); ^{13}C nmr, δ_C: 99.0 (C-1), 80.5, 76.9, 74.4, 72.5, 71.1 (C-2 to C-6), 62.9 (C-7) (lit. (20) for similar data).

Samples of **7** and **8** were each hydrogenolyzed in ethanol over palladium 5% on charcoal, the resulting methyl glycosides were hydrolyzed, and the heptoses were reduced and acetylated. The glc analysis showed the formation, respectively, of heptaacetates of L-*glycero*-D-*manno*-heptitol and D-*glycero*-D-*manno*-heptitol.

*Addition of 2-(trimethylsilyl)thiazole to methyl 2,3,4-tri-*O*-benzyl-α-D-gluco-hexodialdo-1,5-pyranoside* **9**

Treatment of **9** (from methyl 2,3,4-tri-*O*-benzyl-α-D-glucopyranoside (21) (18 g, 38.8 mmol)) in dichloromethane (125 mL) with TMSthiazole (6.5 mL, 39.2 mmol) with subsequent processing, as described for **2**, afforded a mixture of **10** and **11** that was chromatographed on silica gel (light petroleum – ethyl acetate, 2:1). Methyl (6*R*)-2,3,4-tri-*O*-benzyl-6-(2-thiazolyl)-α-D-glucopyranoside (**10**) (11.57 g, 54.3%) had mp 110–112°C, and $[\alpha]_D$ +35 (*c* 1.0); ^{1}H nmr, δ: 5.24 (bs, 1H, H-6), 4.48 (d, 1H, $J_{1,2}$ 3.4 Hz, H-1), 4.16 (m, 1H, H-5), 4.06 (t, 1H, *J* 9.3 Hz, H-3 or H-4), 3.77 (t, 1H, *J* 9.6 Hz, H-4 or H-3), 3.51 (dd, 1H, $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 9.5 Hz, H-2); ^{13}C nmr, δ_C: 98.1 (C-1), 81.9, 79.6, 76.9, 72.4, 69.8 (C-2 to C-6). Anal. calcd. for $C_{31}H_{33}NO_6S$: C 67.98, H 6.07, N 2.55, S 5.85; found: C 67.77, H 5.89, N 2.53, S 6.05.

Methyl (6*S*)-2,3,4-tri-*O*-benzyl-6-(2-thiazolyl)-α-D-glucopyranoside (**11**) (3.84 g, 18%) had $[\alpha]_D$ +33 (*c* 1.0); ^{1}H nmr, δ: 5.30 (d, 1H, $J_{5,6}$ 3.5 Hz, H-6), 4.60 (d, 1H, $J_{1,2}$ 3.8 Hz, H-1), 4.11 (dd, 1H, $J_{5,6}$ 3.5 Hz, $J_{4,5}$ 10 Hz, H-5), 4.04 (t, 1H, *J* 9.2 Hz, H-3 or H-4), 3.67 (t, 1H, *J* 9.4 Hz, H-4 or H-3), 3.43 (dd, 1H, $J_{1,2}$ 3.4 Hz, $J_{2,3}$ 9.5 Hz, H-2); ^{13}C nmr, δ_C: 97.8 (C-1), 82.0, 79.9, 78.6, 72.4, 71.9 (C-2 to C-6). Anal. calcd. for $C_{31}H_{33}NO_6S$: C 67.98, H 6.07, N 2.55, S 5.85; found: C 67.89, H 5.93, N 2.50; S 6.20.

Methyl 2,3,4-tri-*O*-benzyl-L-*glycero*-α-D-*gluco*-heptopyranoside (**12**) (4.5 g, 71%), formed from **10** (7 g), as described for **7** and **8**, was eluted with dichloromethane containing 8% of acetone and had $[\alpha]_D$ +53 (*c* 1.0); ^{1}H nmr, δ: 4.54 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 3.97–3.50 (m, 7H, H-2 to H-7′); ^{13}C nmr, δ_C: 97.4 (C-1), 81.1, 79.0, 76.5, 69.9, 68.3 (C-2 to C-6), 64.0 (C-7). Anal. calcd. for $C_{29}H_{34}O_7$: C 70.42, H 6.92; found: C 70.49, H 7.06.

Methyl 2,3,4-tri-*O*-benzyl-D-*glycero*-α-D-*gluco*-heptopyranoside (**13**) (1.1 g, 71%), formed from **11** (2 g), as described for **7** and **8**, was eluted with dichloromethane containing 8% of acetone and had $[\alpha]_D$ +55 (*c* 1.0); ^{1}H nmr, δ: 4.53 (d, 1H, $J_{1,2}$ 3.4 Hz, H-1), 4.05–3.50 (m, 7H, H-2 to H-7′); ^{13}C nmr, δ_C: 97.7 (C-1), 82.1, 80.2, 79.7, 72.6, 69.8 (C-2 to C-6), 62.8 (C-7). Anal. calcd. for $C_{29}H_{34}O_7$: C 70.42, H 6.92; found: C 70.41, H 6.82.

Methyl L-*glycero*-α-D-*gluco*-heptopyranoside (**14**) (40 mg), from hydrogenolysis of **12** (100 mg) in ethanol (50 mL) over palladium 5% on charcoal, had mp 153–155°C, $[\alpha]_D$ +157 (*c* 1.0 MeOH); ^{1}H nmr (D_2O), δ: 4.73 (d, 1H, $J_{1,2}$ 3.66 Hz), 3.32 (s, 3H, OCH_3). The derived pentaacetate (**16**) had $[\alpha]_D$ +86 (*c* 1.0); ^{1}H nmr, δ: 5.46 (t, 1H, $J_{2,3} \sim J_{3,4} \sim$ 9.8 Hz, H-3 or H-4), 5.27 (m, 1H, H-6), 5.04 (t, 1H, $J_{3,4} \sim J_{4,5} \sim$ 9.8 Hz, H-4 or H-3), 4.99 (d, 1H, $J_{1,2}$ 3.7 Hz, H-1), 4.90 (dd, 1H, $J_{1,2}$ 3.7 Hz, $J_{2,3}$ 10 Hz, H-2), 4.29 (dd, 1H, $J_{6,7}$ 5.7 Hz, $J_{7,7'}$ 11.2 Hz, H-7), 4.21 (dd, 1H, $J_{6,7'}$ 7.5 Hz, $J_{7,7'}$ 11.2 Hz, H-7′), 4.08 (dd, 1H, $J_{5,6}$ 2.0 Hz, $J_{4,5}$ 10.2 Hz, H-5), 3.40 (s, 3H, OCH_3), 2.12, 2.08, 2.05, 2.01, 2.00 (5 s, 15H, $OCOCH_3$). Anal. calcd. for $C_{18}H_{26}O_{12}$: C 49.76, H 6.03; found: C 49.56, H 5.86.

Methyl D-*glycero*-α-D-*gluco*-heptopyranoside (**15**) (20 mg), from hydrogenolysis of **13** (60 mg) in ethanol (25 mL) over palladium 5% on charcoal, had $[\alpha]_D$ +107 (*c* 1.0, MeOH); ^{1}H nmr (D_2O), δ: 4.72 (d, 1H, $J_{1,2}$ 3.4 Hz), 3.35 (s, 3H, OCH_3). The derived pentaacetate (**17**) had $[\alpha]_D$ +127 (*c* 1.0); ^{1}H nmr, δ: 5.44 (t, 1H, *J* 10.1 Hz, H-3 or H-4), 5.22–5.17 (overlapping ddd, 1H, $J_{5,6}$ 2.8 Hz, $J_{6,7}$ 4.1 Hz, $J_{6,7'}$ 7.2 Hz, H-6), 5.08 (dd, 1H, *J* 9.2 and 10.2 Hz, H-4 or H-3), 4.94 (d, 1H, $J_{1,2}$ 3.6 Hz, H-1), 4.84 (dd, 1H, $J_{1,2}$ 3.7 Hz, $J_{2,3}$ 10.3 Hz, H-2), 4.36 (dd, 1H, $J_{7,7'}$ 11.8 Hz and $J_{6,7}$ 4.0 Hz, H-7a), 4.19 (dd, 1H, $J_{7,7'}$ 11.8 and $J_{6,7'}$ 7.23 Hz, H-7′), 4.01 (dd, 1H, $J_{5,6}$ 2.8 Hz, $J_{4,5}$ 10.1 Hz, H-5), 3.40 (s, 3H, OCH_3), 2.12, 2.08, 2.05, 2.01, 2.00 (5 s, 15H, $OCOCH_3$). Anal. calcd. for $C_{18}H_{26}O_{12}$: C 49.76, H 6.03; found: C 49.57, H 5.92.

Methyl glycosides **14** and **15** were hydrolyzed, and the heptoses were reduced and acetylated. The glc analysis showed the formation, respectively, of heptaacetates of L-*glycero*-D-*gluco*-heptitol and D-*glycero*-D-*gluco*-heptitol.

*Configurational inversions at C-6 of derivatives of methyl 2,3,4-tri-*O*-benzyl-L-*glycero*-α-D-*gluco*-heptopyranoside by an oxidation–reduction sequence*

(A) Thiazolyl derivative **10** (3.7 g, 6 mmol) in dichloromethane (10 mL) was added to periodinane (3.4 g, 8 mmol) at 0°C and the solution was kept for 30 min at 0°C and then at room temperature for 3.5 h. The solution was diluted with ether (100 mL) and poured with stirring into saturated aqueous $NaHCO_3$ (75 mL) containing $Na_2S_2O_3 \cdot 5H_2O$, and shaken for 5 min. The organic layer was separated, washed successively with saturated aqueous $NaHCO_3$, water, and aqueous sodium chloride, dried, and concentrated. L-Selectride (1 M in oxolane, 14 mL) was added to the resulting syrup (3.7 g) in oxolane at −78°C and stirred for 1 h. The reaction was quenched with a solution of aqueous 10% NaOH (20 mL) and 30% hydrogen peroxide (10 mL), and the mixture was stirred at room temperature for 2 h. Solvents were evaporated, the mixture was extracted with ethyl acetate, and the extract was washed with saturated aqueous NaCl, dried, and concentrated. Column chromatography, as above, furnished **10** (1.6 g) and **11** (1.4 g), characterized by tlc and their ^{1}H and ^{13}C nmr spectra, and incompletely separated mixture (0.5 g).

(B) Methyl glycoside (**12**) (4 g, 8 mmol) in *N,N*-dimethylformamide (30 mL) containing imidazole (1.2 g, 17.8 mmol) was treated with *tert*-butyldimethylsilyl chloride (1.34 g, 8.8 mmol) for 1 h at room temperature. The solution was diluted with ether, washed with water, dried, and concentrated. The product was chromatographed on silica gel (light petroleum – ethyl acetate, 2:1) to yield methyl 2,3,4-tri-*O*-benzyl-7-*O*-*tert*-butyldimethylsilyl-L-*glycero*-α-D-*gluco*-heptopyranoside (**19**) (4.9 g, 99%), $[\alpha]_D$ +7.4; ^{1}H nmr, δ: 4.52 (d, 1H, $J_{1,2}$ 3.47 Hz, H-1), 3.26 (s, 3H, OCH_3), 0.82 (s, 9H, $(CH_3)_3Si$), −0.012, −0.014 (2 s, 6H, CH_3Si). Anal. calcd. for $C_{35}H_{48}O_7Si$: C 69.04, H 7.94; found: C 69.00, H 7.85.

Methyl 2,3,4-tri-*O*-benzyl-7-*O*-*tert*-butyldimethylsilyl-D-*glycero*-α-D-*gluco*-heptopyranoside (**20**), similarly prepared as a reference sample, had $[\alpha]_D$ +11 (*c* 1.0); ^{1}H nmr, δ: 4.56 (d, 1H, $J_{1,2}$ 3.4 Hz, H-1), 3.37 (s, 3H, OCH_3), 0.85 (s, 9H, $(CH_3)_3Si$), 0.00 (2 s, 6H, CH_3Si). Anal. calcd. for $C_{35}H_{48}O_7Si$: C 69.04, H 7.94; found: C 68.94, H 7.74.

Oxidation of **19** (4.9 g, 7.9 mmol) with oxalyl chloride (9 mL, 18 mmol) and methyl sulfoxide (1.63 mL, 24.5 mmol) as described above and monitored by tlc afforded the 6-ulose, which was treated directly in oxolane (30 mL) with L-selectride (1 M in oxolane, 16 mL). After 30 min tlc showed the formation of an altered product with the mobility of **20** and only trace amounts of **19**. When the reaction was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

quenched with alkaline hydrogen peroxide, tlc showed the formation of modified products without loss of silyl substituent. *O*-Desilylation (22) on treatment of the mixture in oxolane (30 mL) with tetrabutylammonium fluoride (1 M in oxolane, 15 mL) gave **13** (3.6 g, 90%), $[\alpha]_D$ +55 (*c* 1.0), identical (tlc, ^1H and ^{13}C nmr, and diastereomeric purity by conversion to the heptitol heptaacetate for glc analysis) to the previously prepared sample.

Configurational inversion at C-6 of methyl 2,3,4-tri-O-benzyl-L-glycero-α-D-manno-heptopyranoside by oxidation–reduction

Methyl heptoside **7** (47 mg, 0.09 mmol) in *N,N*-dimethylformamide (3 mL) containing imidazole (14 mg, 0.2 mmol) was treated with *tert*-butyldimethylsilyl chloride (16 mg, 0.1 mmol) for 4 h at room temperature. Thin-layer chromatography showed that reaction was incomplete, and further TBDMS (16 mg) and imidazole (14 mg) were added and reaction was continued for another 2 h. The solution was diluted with ether, washed with water, dried, concentrated, and chromatographed on silica gel (light petroleum – ethyl acetate, 3:1) to give methyl 2,3,4-tri-*O*-benzyl-7-*O*-*tert*-butyldimethylsilyl-L-*glycero*-α-D-*manno*-heptopyranoside (**21**) (53 mg, 90%), $[\alpha]_D$ +24 (*c* 1.0); ^1H nmr, δ: 4.56 (d, 1H, $J_{1,2}$ 2.78 Hz, H-1), 3.22 (s, 3H, OMe), 0.83 (s, 9H, $(CH_3)_3Si$), 0.00, −0.01 (2 s, 6H, CH_3Si). Anal. calcd. for $C_{35}H_{48}O_7Si$: C 69.04, H 7.94; found: C 68.92, H 7.97.

Oxidation of **21** (40 mg, 0.06 mmol) with oxalyl chloride (184 μL) and methyl sulfoxide (33 μL) in dichloromethane at −78°C, as described above and monitored by tlc, afforded the 6-ulose, which was treated directly in oxolane (5 mL) with L-selectride (1 M in oxolane, 136 μL) for 1 h. The reaction was quenched by the addition of alkaline hydrogen peroxide (10% aqueous NaOH and 30% H_2O_2, 2:1) to give a mixture of compounds that was treated with tetrabutylammonium fluoride (1 M in oxolane, 133 μL). The residue was chromatographed on silica gel to give **8** (26 mg, 80%), $[\alpha]_D$ +33 (*c* 1.0), as the sole detectable product, which was indistinguishable (tlc, ^1H and ^{13}C nmr) from the previous sample, and was further characterized by conversion into D-*glycero*-D-*manno*-heptitol heptaacetate (glc analysis). Treatment of the above-mentioned 6-ulose with sodium borohydride in methanol gave configurationally altered silyl ether (DDManHep) and **21** (LDManHep) in the approximate ratio of 9:1.

Oxidation of methyl 2,3,4-tri-O-benzyl-α-D-altropyranoside and addition of 2-(trimethylsilyl)thiazole to the resulting hexodialdo-1,5-pyranoside mixture

Methyl 2,3,4-tri-*O*-benzyl-α-D-altropyranoside (23) (250 mg, 0.53 mmol) was oxidized with oxalyl chloride (0.6 mL, 1.2 mmol) and methyl sulfoxide (0.11 mL, 1.43 mmol), as described previously, and gave a mixture of products (**22** and **23**) as indicated by the appearance of two aldehydic protons in the ^1H nmr spectrum at δ 9.76 and 9.59 in the approximate ratio of 1:4. The ^{13}C nmr spectrum showed inter alia two sets of resonances in the same relative proportions corresponding to those of ring carbon atoms of methyl glycosides having the β-galactopyranose (δ_C 104.6 (C-1), 80.8, 78.8, 78.5, and 74.7 (C-2 to C-5)) and α-altropyranose (δ_C 101.1 (C-1), 75.8, 74.6, 74.0, and 71.5 (C-2 to C-5)) configurations. Part of the mixture was reduced with $NaBH_4$ in methanol. One portion of the reduction product was acetylated and gc analysis on column B showed the presence of two components with the retention times of 6-*O*-acetyl-2,3,4-tri-*O*-benzyl derivatives of methyl β-D-galactopyranoside and methyl α-D-altropyranoside in the approximate ratio of 3:2. Another portion of the reduction product was *O*-debenzylated for hydrolysis, followed by (*a*) reduction and acetylation to give the corresponding mixtures of galactitol and altritol hexaacetates, and (*b*) glycosidation with (*R*)- and (*S*)-2-butanol and acetylation to give products with the retention times (glc on a DB-5 (15 m × 0.25 mm) column, 230°C (5 min), 230° → 260°C, 2°/min, 260°C) of derivatives of L-galactose and D-altrose.

2-TMSthiazole (0.12 mL was added to the remaining mixture of hexodialdo-1,5-pyranosides **22** and **23** (150 mg) as described previously, and chromatography on silica gel (light petroleum – ethyl acetate, 2:1) gave methyl (6*R*)-2,3,4-tri-*O*-benzyl-6-(2-thiazolyl)-β-L-galactopyranoside (**24**) (103 mg, 59%), $[\alpha]_D$ −4 (*c* 1.0); ^1H nmr, δ: 4.26 (d, 1H, $J_{1,2}$ 7.7 Hz, H-1), 3.87 (dd, 1H, $J_{1,2}$ 7.7 Hz, $J_{2,3}$ 9.7 Hz, H-2), 3.53 (s, 3H, OCH_3); ^{13}C nmr, δ_C: 105.2 (C-1), 81.8, 79.3, 75.9, 73.8, 70.1 (C-2 to C-6), 57.4 (OCH_3). Anal. calcd. for $C_{31}H_{33}NO_6S$: C 67.98, H 6.07, N 2.55; found: C 67.82, H 6.15, N 2.55.

Methyl 2,3,4-tri-*O*-benzyl-L-*glycero*-α-L-*galacto*-heptopyranoside (**25**) (50 mg, 74%), formed from **24** (75 mg), as described for **7** and **8**, was chromatographed on silica gel with dichloromethane containing 8% of acetone and had $[\alpha]_D$ +13 (*c* 1.0); ^1H nmr, δ: 4.24 (d, 1H, $J_{1,2}$ 7.6 Hz, H-1), 3.51 (s, 3H, OCH_3); ^{13}C nmr, δ_C: 105.0 (C-1), 82.1, 79.5, 74.0, 71.9, 69.1 (C-2 to C-6), 63.8 (C-7). Anal. calcd. for $C_{29}H_{34}O_7$: C 70.42, H 6.92; found: C 70.28, H 6.94.

A sample of **25** was hydrogenolyzed in ethanol over palladium 5% on charcoal, the resulting methyl glycoside was hydrolyzed, and the heptose was reduced and acetylated. The glc analysis showed the formation, respectively, of a heptitol heptaacetate with the retention time of the corresponding derivative of L-*glycero*-D-*manno*-heptitol (= enantiomer of L-*glycero*-L-*galacto*-heptitol).

*2-(Trimethylsilyl)thiazole homologation of 1,2:3,4-di-O-isopropylidene-α-D-galacto-hexadialdo-1,5-pyranose **3** and configurational inversion of product **4** at C-6*

A solution in dichloromethane (10 mL) of compound **3** (1 g, 3.84 mmol), from oxidation of 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose with oxalyl chloride and methyl sulfoxide showed ^{13}C nmr, δ_C: 199.0 (CHO), 108.3 (C-1), 95.5, 72.5, 70.9, 69.7 (C-2 to C-5), and was reacted with TMS thiazole (0.72 mL, 4.37 mmol), as described previously, and silica gel chromatography (light petroleum – ethyl acetate, 2:1) furnished (6*S*)-1,2:3,4-di-*O*-isopropylidene-6-(2-thiazolyl)-α-D-galactopyranose (**4**) (780 mg, 60%), mp 178–180°C (lit. (6) mp 170–172°C), $[\alpha]_D$ −67 (*c* 1.0); ^1H nmr, δ: 5.57 (d, 1H, $J_{1,2}$ 4.9 Hz, H-1), 5.14 (d, 1H, $J_{5,6}$ 7.9 Hz, H-6), 4.65 (dd, 1H, $J_{2,3}$ 2.3 Hz, H-2), 4.54 (dd, 1H, $J_{4,5}$ 1.3 Hz, H-4), 4.33 (dd, 1H, H-2), 4.10 (dd, 1H, H-5); ^{13}C nmr, δ_C: 96.2 (C-1), 70.7, 70.4, 70.3, 69.4, 68.0 (C-2 to C-6).

1,2:3,4-Di-*O*-isopropylidene-D-*glycero*-α-D-*galacto*-heptopyranose (**26**) (182 mg, 72%), formed from **4** (300 mg), as described for **7** and **8**, was chromatographed on silica gel (dichloromethane containing 10% of acetone) and had $[\alpha]_D$ −57 (*c* 1.0); ^1H nmr: δ: 5.50 (d, 1H, $J_{1,2}$ 4.9 Hz, H-1), 4.63 (dd, 1H, $J_{2,3}$ 2.3 Hz, $J_{3,4}$ 7.9 Hz, H-3), 4.46 (dd, 1H, $J_{4,5}$ 1.6 Hz, H-4), 4.30 (dd, 1H, H-2), 3.88–3.68 (m, 4H, H-5, 6, 7, 7′); ^{13}C nmr, δ_C: 96.2 (C-1), 70.7, 70.6, 70.5, 69.9, 67.3 (C-2 to C-6), 63.8 (C-7). Anal. calcd. for $C_{13}H_{22}O_7$: C 53.78, H 7.64; found: C 53.46, H 7.74. Compound **26** was hydrolyzed, and the resulting heptose was reduced and acetylated. The glc analysis showed the formation, respectively, of the heptaacetate of D-*glycero*-D-*galacto*-heptitol (= L-*glycero*-D-*manno*-heptitol).

Thiazole adduct **4** (49 mg) was oxidized with oxalyl chloride and methyl sulfoxide and the product, without further purification, was reduced with L-selectride, as reported by Dondoni et al. (13), and the isolated (6*R*)-1,2:3,4-di-*O*-isopropylidene-6-(2-thiazolyl)-α-D-galactopyranose (**18**) (30 mg, 60%) had mp 102–104°C (lit. (13) mp 98–100°C); ^1H nmr, δ: 5.57 (d, 1H, $J_{1,2}$ 4.8 Hz, H-1), 5.34 (d, 1H, $J_{5,6}$ 4.8 Hz, H-6), 4.63 (dd, 1H, $J_{2,3}$ 2.4 Hz, $J_{3,4}$ 8.0 Hz, H-3), 4.46 (dd, 1H, $J_{4,5}$ 1.6 Hz, H-4), 4.32 (dd, 1H, H-2), 4.15 (dd, 1H, H-5); ^{13}C nmr, δ_C: 96.4 (C-1), 72.4, 71.9, 70.9, 70.8, 69.8 (C-2 to C-6).

1,2:3,4-Di-*O*-isopropylidene-L-*glycero*-α-D-*galacto*-heptopyranose (**27**) (13 mg, 63%), formed from **18** (25 mg), as described for **7** and **8**, was chromatographed on silica gel (dichloromethane containing 10% of acetone) and had mp 98–100°C, $[\alpha]_D$ −41 (*c* 1.0); ^1H nmr, δ: 5.59 (d, 1H, $J_{1,2}$ 5.0 Hz, H-1), 4.62 (dd, 1H, $J_{2,3}$ 2.3 Hz, $J_{3,4}$ 7.9 Hz, H-3), 4.36–4.33 (m, 2H), 3.79–3.77 (m, 4H); ^{13}C nmr, δ_C: 96.4 (C-1), 71.6, 71.3, 70.8, 70.5, 67.5 (C-2 to C-6), 62.4 (C-7). Anal. calcd. for $C_{13}H_{22}O_7$: C 53.78, H 7.64; found: C 53.93, H 7.63. Compound **27** was hydrolyzed, and the resulting heptose was reduced and acetylated. The glc analysis showed the formation of the heptaacetate of L-*glycero*-D-*galacto*-heptitol (= L-*glycero*-D-*gluco*-heptitol).

Oxidation of methyl 2,3,4-tri-O-benzyl-β-D-galactopyranoside and addition of 2-(trimethylsilyl)thiazole to the resulting hexodialdo-1,5-pyranoside mixture

Methyl 2,3,4-tri-*O*-benzyl-β-D-galactopyranoside (24) (1.09 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

2.3 mmol) was oxidized with oxalyl chloride (2.4 mL, 4.8 mmol) and methyl sulfoxide (0.47 mL, 6.1 mmol), as described previously, and gave a mixture of products corresponding to enantiomers **22** and **23**, as indicated by the appearance of two aldehydic protons in the ^{1}H nmr spectrum at δ 9.68 and 9.53 in the approximate ratio of 1:6. The ^{13}C nmr spectrum showed inter alia two sets of resonances in the same relative proportions corresponding to those of ring carbon atoms of methyl glycosides having the β-galactopyranose (δ_C 104.6 (C-1), 80.8, 78.8, 78.5, and 74.7 (C-2 to C-5)) and α-altropyranose (δ_C 101.1 (C-1), 75.8, 74.6, 74.0, and 71.5 (C-2 to C-5)) configurations. A portion of the mixture was reduced with $NaBH_4$ in methanol, the reduction product was acetylated, and glc analysis on column B showed the presence of components with the retention times of 6-*O*-acetyl-2,3,4-tri-*O*-benzyl derivatives of methyl β-D-galactopyranoside and methyl α-D-altropyranoside in the approximate ratio of 3:1. 2-TMSthiazole (0.45 mL) was added to the remaining mixture of hexodialdo-1,5-pyranosides (950 mg) was described previously, and chromatography on silica gel (light petroleum – ethyl acetate, 2:1) gave methyl (6*S*)-2,3,4-tri-*O*-benzyl-6-(2-thiazolyl)-β-D-galactopyranoside (**28**) (853 mg, 76%), $[\alpha]_D$ +2.5 (*c* 1.0); ^{1}H nmr, δ: 4.20 (d, 1H, $J_{1,2}$ 7.6 Hz, H-1), 3.46 (s, 3H, OCH_3); ^{13}C nmr, δ_C: 104.7 (C-1), 81.4, 78.9, 75.8, 73.5, 69.3 (C-2 to C-6), 56.9 (OCH_3). Within experimental limits these spectra were identical to those of the enantiomer **24**. Anal. calcd. for $C_{31}H_{33}NO_6S$: C 67.98, H 6.07, N 2.55; found: C 67.92, H 6.14, N 2.53.

Methyl 2,3,4-tri-*O*-benzyl-D-*glycero*-α-D-*galacto*-heptopyranoside (**29**) (220 mg, 60%), formed from **28** (407 mg), as described for **7** and **8**, was eluted from silica gel with dichloromethane containing 5% of acetone and had mp 101–103°C and $[\alpha]_D$ −18 (*c* 1.0); ^{1}H nmr, δ: 4.21 (d, 1H, $J_{1,2}$ 7.6 Hz, H-1), 3.47 (s, 3H, OCH_3); ^{13}C nmr, δ_C: 104.8 (C-1), 81.9, 79.3, 73.8, 72.4, 69.0 (C-2 to C-6), 63.6 (C-7). Anal. calcd. for $C_{29}H_{34}O_7$: C 70.42, H 6.92; found: C 70.41, H 6.88. A sample of **29** was hydrogenolyzed in ethanol over palladium 5% on charcoal, the resulting methyl glycoside was hydrolyzed, and the heptose was reduced and acetylated. The glc analysis showed the formation of a heptitol heptaacetate with the retention time of the corresponding derivative of L-*glycero*-D-*manno*-heptitol (= enantiomer of L-*glycero*-L-*galacto*-heptitol).

Configurational inversions at C-6 and C-5 of methyl (6S)-2,3,4-tri-O-benzyl-6-(2-thiazolyl)-β-D-galactopyranoside (28)

Thiazolyl derivative **28** (85 mg, 0.15 mmol) was oxidized as described previously with oxalyl chloride (0.175 mL, 0.35 mmol) and methyl sulfoxide (0.03 mL, 0.45 mmol). The product (84 mg), without purification, was reduced with L-selectride (0.3 mL, 0.33 mmol) in oxolane. The resulting syrup was separated by preparative layer chromatography (multiple development in light petroleum – ether–methanol, 14:6:1) to give two main fractions.

Fraction 1 (15 mg) had $[\alpha]_D$ +5 (*c* 1.0); ^{1}H nmr, δ: 5.25 (d, 1H, $J_{5,6}$ 3.58 Hz, H-6), 4.22 (d, 1H, $J_{1,2}$ 7.7 Hz, H-1), 3.84 (d, 1H, $J_{2,3}$ 9.7 Hz and $J_{1,2}$ 7.7 Hz, H-2), 3.52 (dd, 1H, $J_{2,3}$ 9.7 Hz and $J_{3,4}$ 2.8 Hz, H-3), 3.41 (s, 3H, OCH_3); ^{13}C nmr, δ_C: 105.1 (C-1), 81.9, 79.1, 75.9, 75.6, 72.4 (C-2 to C-5), 57.0 (OCH_3). The sequence of operations, formyl deblocking, *O*-debenzylation, hydrolysis, reduction, and acetylation, gave a single heptitol heptaacetate coincident on glc analysis (column A) with the corresponding derivative from L-*glycero*-D-*galacto*-heptose. The ^{13}C nmr spectrum of fraction 2 (39 mg) showed the presence of signals assignable to anomeric C-1 resonances of compounds with β-galacto (δ_C 104.3) and α-altro (δ_C 99.6) ring configurations and, without individual specifications, to two sets of carbon atoms 2 to 6. Formyl deblocking furnished a mixture of methyl tri-*O*-benzyl heptopyranosides whose ^{13}C nmr spectrum likewise showed anomeric carbon resonances at δ_C 105.1 and 100.5 consistent with the presence of β-*galacto* and α-*altro* configurational isomers together with two sets of other carbon resonances. This mixture of compounds was *O*-debenzylated by formic acid with 5% palladium on charcoal as catalyst, hydrolyzed, reduced, and acetylated. The glc analysis (column A) showed the presence of two heptitol heptaacetates coincident with those from D-*glycero*-D-*galacto*-heptose and D-*glycero*-D-*altro*-heptose.

Conversion of methyl D-glycero-D-gluco-heptopyranoside into methyl D-glycero-D-altro-heptopyranoside derivatives

Methyl 2,3,4-tri-*O*-benzyl-7-*O*-*tert*-butyldiphenylsilyl-D-*glycero*-α-D-*gluco*-heptopyranoside (**30**) was prepared as described for **19** and had $[\alpha]_D$ +9 (*c* 1.0); ^{1}H nmr, δ: 7.63–7.10 (m, 25H, Ph-H), 4.61 (d, 1H, $J_{1,2}$ 3.60 Hz, H-1), 3.24 (s, 3H, OCH_3), 1.05 (s, 9H, $(CH_3)_3Si$) Anal. calcd. for $C_{45}H_{52}O_7Si$: 73.73, H 7.15; found: C 73.45, H 7.04.

Similarly, silylation of methyl D-*glycero*-α-D-*gluco*-heptopyranoside (**15**) (2 g, 8.9 mmol) followed by chromatography on silica gel (dichloromethane–methanol, 9:1) afforded methyl 7-*O*-*tert*-butyldiphenylsilyl-D-*glycero*-α-D-*gluco*-heptopyranoside (**31**) (2.9 g, 71%), $[\alpha]_D$ +59 (*c* 1.0, methanol); ^{1}H nmr, δ: 7.68–7.32 (m, 10H, Ph-H), 4.61 (d, 1H, $J_{1,2}$ 3.6 Hz, H-1), 3.24 (s, 3H, OCH_3). Exact Mass calcd. for $C_{24}H_{34}O_7Si$ + H: 463.2135; found: 463.2152; calcd. for $C_{24}H_{34}O_7Si$ + Na: 485.1941; found: 485.1971.

A solution of **31** (1 g, 2.16 mmol), benzaldehyde dimethyl acetal (0.67 mL, 2 equiv., 3.9 mmol), and *p*-toluenesulfonic acid (50 mg) in toluene (50 mL) was kept at 30°C for 1 h under reduced pressure (aspirator), to ensure removal of methanol. Solid $NaHCO_3$ was added, the solution was concentrated, the residue was partitioned between dichloromethane and water, and the organic layer was dried and concentrated. The residue was chromatographed on silica gel (dichloromethane containing 1% of methanol) to give methyl 4,6-*O*-benzylidene-7-*O*-*tert*-butyldiphenylsilyl-D-*glycero*-α-D-*gluco*-heptopyranoside (**32**) (913 mg, 76%), $[\alpha]_D$ +94 (*c* 1.0); ^{1}H nmr, δ: 7.60–7.22 (m, 15H, Ph-H), 5.57 (s, 1H, C*H*Ph), 4.69 (d, 1H, $J_{1,2}$ 3.10 Hz, H-1), 3.34 (s, 3H, OCH_3), 1.03 (s, 9H, $(CH_3)_3Si$). Exact Mass calcd. for $C_{31}H_{38}O_7Si$ + H: 551.2465; found: 551.2465.

Compound **32** (630 mg, 1.14 mmol) was added to sodium hydride (55 mg, 2 equiv.) in *N*,*N*-dimethylformamide (10 mL) and the mixture was stirred for 30 min. *N*-Tosylimidazole (280 mg, 1.1 equiv.) was added and the mixture was stirred at room temperature for 4 days. Thin-layer chromatography showed the successive formation after 1 h of 2-*O*-tosyl derivative (**33**) and *O*-silyl epoxide (**34**), and, after 24 h, complete reaction of **32** and conversion of **33** into **34**, but now the appearance of *O*-desilylated epoxide (**35**). After 84 h conversion of **34** into **35** was complete. The reaction mixture was poured into ice-water, the product was extracted with dichloromethane, and the organic layer was washed with water, concentrated, and chromatographed on silica gel (light petroleum – ethyl acetate, 9:1) to give methyl 2,3-anhydro-4,6-*O*-benzylidene-D-*glycero*-α-D-*manno*-heptopyranoside (**35**) (236 mg, 70%), $[\alpha]_D$ +20 (*c* 1.0); ^{1}H nmr (including ^{1}H–^{1}H COSY), δ: 7.52–7.25 (m, 5H, Ph-H), 5.69 (s, 1H, C*H*Ph), 4.92 (d, 1H, H-1), 3.49 (d, 1H, $J_{2,3}$ 3.7 Hz, H-3), 3.34 (s, 3H, OCH_3), 3.18 (d, 1H, $J_{2,3}$ 3.7 Hz, H-2), 1.03 (s, 9H, $(CH_3)_3Si$). Anal. calcd. for $C_{15}H_{18}O_6$: C 61.21, H 6.16; found: C 61.16, H 6.18.

The ^{1}H nmr spectrum of **33** showed inter alia resonances at δ 7.8–7.2 (m, 14H, Ph-H), 5.57 (s, 1H, acetal C*H*Ph), 4.83 (d, 1H, $J_{1,2}$ 3.7 Hz, H-1), 4.39 (dd, 1H, $J_{1,2}$ 3.8 Hz, $J_{2,3}$ 9.4 Hz, H-2), 4.16 (t, 1H, $J_{2,3} \sim J_{3,4}$ = 9.3 Hz, H-3), 3.31 (s, 3H, OCH_3), 2.43 (s, 3H, CH_3-$C_6H_4SO_2$), 1.03 (s, 9H, $(CH_3)_3C$). On acetylation the resonance of H-3 is shifted to δ 5.60. The ^{1}H nmr spectrum of **34** showed inter alia resonances at δ 7.7–7.2 (m, 10H, Ph-H), 5.66 (s, 1H, acetal C*H*Ph), 4.89 (s, 1H, H-1), 3.51 (d, 1H, $J_{2,3}$ 3.7 Hz, H-3), 3.40 (s, 3H, OCH_3), 3.17 (d, 1H, $J_{2,3}$ 3.7 Hz, H-2), 1.06 (s, 9H, $(CH_3)_3C$).

Compound **35** (151 mg) was heated at 100°C in 1 M aqueous sodium hydroxide for 12 h. Liquid–liquid extraction of the solution with chloroform afforded methyl 4,6-*O*-benzylidene-D-*glycero*-α-D-*altro*-heptopyranoside (**36**) (140 mg, 87%), which crystallized from ether–methanol and had mp 209–211°C, $[\alpha]_D$ +92 (*c* 1.0, methanol); ^{1}H nmr (D_2O), δ: 7.55–7.42 (m, 5H, Ph-H), 5.85 (s, 1H, Ph-C*H*), 4.67 (s, 1H, H-1), 3.35 (s, 3H, OMe); ^{13}C nmr, δ: 129.4, 128.2, 126.0 (aromatic C), 101.4 (Ph-*C*H), 101.0 (C-1), 79.0, 74.3, 69.5, 67.5, 58.3 (C-2 to C-6), 60.1 (C-7), 54.7 (OCH_3). Anal. calcd. for $C_{15}H_{22}O_7$: C 57.68, H 6.45; found: C 57.34, H, 6.33. Acetylation of **36** under standard conditions afforded the tri-*O*-acetyl derivative **37**, which had $[\alpha]_D$ +92 (*c* 1.0); $[\alpha]_D$ +55 (*c* 1.0); ^{1}H nmr (1 D with decoupling and ^{1}H–^{1}H COSY), δ: 7.47–7.26 (m, 5H, Ph-H), 5.23 (1H, br s, H-3), 5.00 (d, 1H, $J_{2,3}$ 2 Hz, H-2), 4.60 (s, 1H, H-1), 4.49 (d, 1H, $J_{7,7'}$ 12 Hz, H-7), 4.27

(dd, 1H, $J_{7,7'}$ 12 Hz, $J_{6,7'}$ 5 Hz, H-7'), 4.06 (m, 3H, H-4, H-5, H-6), 3.36 (s, 3H, OMe), 2.14, 2.12, 2.10 (3 s, 9H, OAc).

O-Benzylidene compound **36** (110 mg) was heated in acetic acid – water (4:1) for 2 h at 80°C and concentration of the solution gave methyl D-*glycero*-α-D-*altro*-heptopyranoside (**38**) (70 mg, 86%), $[\alpha]_D$ +68 (*c* 1.0, methanol); ^{1}H nmr (D_2O), δ: 4.61 (s, 1H, H-1), 3.24 (s, 3H, OMe); ^{13}C nmr, δ_C: 100.4 (C-1), 70.8, 70.0, 69.4, 69.1, 65.0 (C-2 to C-6), 61.3 (C-7), 55.0 (OCH_3). The penta-*O*-acetyl derivative **39** had $[\alpha]_D$ +50 (*c* 1.0); ^{1}H nmr (1 D with decoupling and ^{1}H–^{1}H COSY), δ: 4.94 (dd, 1H, $J_{1,2}$ 1.7 Hz, $J_{2,3}$ 4.1 Hz, H-2), 4.62 (d, 1H, $J_{1,2}$ 1.3 Hz, H-1), 4.43 (dd, 1H, $J_{7,7'}$ 12 Hz, $J_{6,7}$ 3.8 Hz, H-7), 4.18 (dd, 1H, $J_{7,7'}$ 12 Hz, $J_{6,7'}$ 7.2 Hz, H-7'), 3.40 (s, 3H, OMe), 2.13, 2.12, 2.10, 2.07, 2.05 (5 s, 15H, OAc); ^{13}C nmr, δ_C: 99.2 (C-2), 69.8, 69.4, 67.3, 66.6, 65.8 (C-2 to C-6), 61.9 (C-7), 55.6 (OCH_3). Anal. calcd. for $C_{18}H_{26}O_{12}$: C 49.76, H 6.03; found: C 49.83, H 5.95.

Hydrolysis of methyl heptoside (**38**), followed by treatment of the product with $NaBH_4$ and acetylation, gave products that were coincident on gc with the heptitol heptaacetate formed from the O:36 glycan with accompanying 1,6- and 1,7-anhydroheptose tetraacetates. Further samples of the hydrolyzate were converted into glycoside acetates on reaction with (*R*)- and (*S*)-2-butanol followed by acetylation. Comparison (gc on column A) of these glycoside acetates with those similarly derived from the hydrolysate of the O:36 glycan showed that the natural heptose was D-*glycero*-D-*altro*-heptose.

Anhydro glycoside **35** (34 mg) was boiled with methanolic 2 M sodium methoxide (10 mL) for 16 h. Solvent was evaporated and the residue in dichloromethane was washed successively with water, saturated NaCl, and again water, dried, concentrated, and chromatographed on silica gel (light petroleum – ethyl acetate, 4:1, later 2:1) to give methyl 4,6-*O*-benzylidene-3-*O*-methyl-D-*glycero*-α-D-*altro*-heptopyranoside (**40**) (28 mg, 74%), $[\alpha]_D$ +81 (*c* 1.0); ^{1}H nmr, δ: 7.52–7.26 (m, 5H, Ph-H), 5.67 (s, 1H, Ph-C*H*), 4.60 (s, 1H, H-1), 3.58, 3.41 (2 s, 6H, OMe). Acetylation of **40** gave the di-*O*-acetyl derivative **41**, $[\alpha]_D$ +45 (*c* 0.5); ^{1}H nmr (1 D with decoupling and ^{1}H–^{1}H COSY), δ: 7.52–7.26 (m, 5H, Ph-H), 5.67 (s, 1H, Ph-C-*H*), 5.09 (d, 1H, $J_{2,3}$ 2.5 Hz, H-2), 4.58 (s, 1H, H-1), 4.47 (dd, 1H, $J_{7,7'}$ 12 Hz, $J_{6,7}$ 1.7 Hz, H-7), 4.26 (dd, 1H, $J_{7,7'}$ 12 Hz, $J_{6,7}$ 5.9 Hz, H-7'), 4.15 (t, 1H, $J_{4,5} \sim J_{5,6} \sim$ 9.6 Hz, H-5), 4.05–3.99 (m, 1H, H-6), 3.95 (dd, 1H, $J_{4,5}$ 9.5 Hz, $J_{3,4}$ 2.9 Hz, H-4), 3.71 (t, 1H, *J* 2.4 Hz, H-3), 3.58, 3.39 (2 s, 6H, OMe), 2.14, 2.09 (2 s, 6H, OAc); ^{13}C nmr, δ_C: 137.2 (quat. aromatic C), 129.2, 128.3, 126.4 (aromatic C), 101.9 (Ph-*C*-H), 99.4 (C-1), 77.5, 76.3, 75.6, 70.0, 60.1 (C-2 to C-6), 63.2 (C-7), 59.2, 55.8 (2 OCH_3). Anal. calcd. for $C_{20}H_{26}O_9$: C 58.51, H 6.38; found: C 58.24, H 6.35.

Hydrolysis of **40** (27 mg) in acetic acid – water (4:1) for 1 h at 80°C gave methyl heptoside (**42**) (18 mg), $[\alpha]_D$ +92 (*c* 1.0, methanol), which was converted into the acetylated derivative (**43**), $[\alpha]_D$ +86 (*c* 1.0); ^{1}H nmr (1 D with decoupling and ^{1}H–^{1}H COSY), δ: 5.33 (ddd (apparent quintet), 1H, $J_{5,6} = J_{6,7'} \sim$ 3.8 Hz, H-6), 5.11 (dd, 1H, $J_{3,4}$ 3.5 Hz, $J_{4,5}$ 9.1 Hz, H-4), 5.04 (dd, 1H, $J_{1,2}$ 1.7 Hz, $J_{2,3}$ 4.5 Hz, H-2), 4.60 (s, 1H, H-1), 4.43 (dd, 1H, $J_{6,7}$ 3.6 Hz, $J_{7,7'}$ 12.0 Hz, H-7), 4.28 (dd, 1H, $J_{4,5}$ 9.1 Hz, $J_{5,6}$ 4.0 Hz, H-5), 4.18 (dd, 1H, $J_{6,7'}$ 7.4 Hz, $J_{7,7'}$ 12.0 Hz, H-7'), 3.66 (t, 1H, $J_{2,3} = J_{3,4} \sim$ 3.9 Hz, H-3), 3.45, 3.40 (2 s, 6H, OCH_3), 2.14, 2.13, 2.10, 2.05 (4 s, 12H, OAc). Anal. calcd. for $C_{17}H_{26}O_{11}$: C 50.24, H 6.45; found: C 50.44, C 6.47.

Hydrolysis of methyl heptoside (**42**), followed by treatment of the product with $NaBH_4$ and acetylation, gave products that were coincident on gc with the *O*-methylheptitol hexaacetate formed from the O:23 glycan with accompanying 1,6- and 1,7-anhydro-3-*O*-methylheptose triacetates. Further samples of the hydrolyzate were converted into glycoside acetates on reaction with (*R*)- and (*S*)-2-butanol followed by acetylation. Comparison (gc on column A) of these glycoside acetates with those similarly derived from the hydrolysate of the O:23 glycan showed that the natural heptose was 3-*O*-methyl-D-*glycero*-D-*altro*-heptose.

Syntheses of methyl glycosides of 6-deoxyheptoses

GERALD O. ASPINALL,[1] ARMANDO G. MCDONALD,[2] AND RAMESH K. SOOD[3]

Department of Chemistry, York University, North York, Toronto, ON M3J 1P3, Canada

Received May 20, 1993

This paper is dedicated to Professors David B. MacLean and Ian D. Spenser

GERALD O. ASPINALL, ARMANDO G. MCDONALD, and RAMESH K. SOOD. Can. J. Chem. **72**, 247 (1994).

Methyl α-D-glycopyranosides of 6-deoxy-D-*altro*-heptose, 6-deoxy-D-*manno*-heptose, and 6-deoxy-D-*talo*-heptose have been prepared. Displacements of methyl 2,3,4-tri-*O*-benzylhexopyranoside 6-trifluoromethanesulfonates with potassium cyanide, followed by reduction of the resulting heptopyranosidurononitriles with diisobutylaluminum hydride, hydrolysis of the imine, further reduction with sodium borohydride, and catalytic *O*-debenzylation, give the corresponding methyl 6-deoxyheptopyranosides. Configurational change at C-4 of methyl 6-deoxy-7-*O*-*tert*-butyldiphenylsilyl-α-D-*manno*-heptopyranoside to give the *talo* isomer was effected by oxidation followed by stereoselective reduction. ^{1}H nuclear magnetic resonance data of the glycosides, and gas chromatography of acetylated glycosides of (*R*)- and (*S*)-2-butanol serve to establish ring and enantiomeric configurations of the parent sugars when these are encountered as constituents of lipopolysaccharides or extracellular carbohydrate polymers, as in *Campylobacter* species.

GERALD O. ASPINALL, ARMANDO G. MCDONALD et RAMESH K. SOOD. Can. J. Chem. **72**, 247 (1994).

On a préparé les α-D-glycopyranosides de méthyle des 6-désoxy-α-D-*altro*-heptose, 6-désoxy-D-*manno*-heptose et 6-désoxy-D-*talo*-heptose. Les déplacements des 6-trifluorométhanesulfonates des 2,3,4-tri-*O*-benzylhexopyranosides de méthyle par le cyanure de potassium, suivis par la réduction des heptopyranosidurononitriles par l'hydrure de diisobutylaluminium, une hydrolyse de l'imine, une nouvelle réduction par le borohydrure de sodium et finalement une *O*-débenzylation catalytique conduit aux 6-désoxyheptopyranosides de méthyles correspondants. Pour effectuer un changement de configuration en C-4 du 6-désoxy-7-*O*-*tert*-butyldiphénylsilyl-α-D-*manno*-heptopyranoside de méthyle dans le but d'obtenir l'isomère *talo*, on a procédé à une oxydation suivie par une réduction sélective. On a fait appel aux données de la résonance magnétique nucléaire du ^{1}H des glycosides et à la chromatographie gazeuse des glycosides acétylés par les (*R*)- et (*S*)-2-butanol pour établir la grandeur des cycles et les configurations énantiomères des sucres parents rencontrés comme constituants des lipopolysaccharides ou comme hydrates de carbones polymériques extracellulaires, comme dans les espèces *Campylobacter*.

[Traduit par la rédaction]

Introduction

6-Deoxyheptoses are rare constituents of bacterial polysaccharides, and until very recently only two examples had been reported, 6-deoxy-D-*galacto*-heptose as a component sugar of the *Yersinia (Pasteurella) pseudotuberculosis* type II A lipopolysaccharide (LPS) (1), and 6-deoxy-D-*altro*-heptose as a constituent of the polysaccharide antigen from the Gram-positive *Eubacterium saburreum*, strain L 49 (2). In a series of investigations on the lipopolysaccharides from *Campylobacter* species further examples have been found. The O antigen chains in LPS from *C. jejuni* serotypes O:23 and O:36 have been shown to contain units of four closely related types, →3)-β-D-Glc*p*NAc-(1 → 3)-α-D-Gal*p*-(1 → 2)-α-*altro*-Hep*p*-(1-, in which the variable heptose residues differed in the presence or absence of deoxygenation at C-6 and methylation at O-3 (3), but were of unspecified enantiomeric configurations. One of the variants was 6-deoxy-α-*altro*-heptose, but of different ring size from that from the *E. saburreum* polysaccharide. From another *Campylobacter* strain, *C. coli* serotype O:30, a water-soluble extracellular antigenic polymer has been characterized as a teichoic acid-like structure with a poly(ribitol phosphate) backbone with pendant glycobiosyl units, 6-d-Hep*p*-(1 → 3)-β-D-Glc*p*NAc-(1-. As with the 6-deoxy-α-*altro*-heptose, the relative configuration of this deoxyheptose constituent was established by nmr correlation spectroscopy and shown to be β-*talo* (4), but without designation of absolute configuration. In both instances it was necessary to synthesize reference compounds of defined enantiomeric configuration from which to provide, separately, diastereomeric mixtures of (*R*)- and (*S*)-2-butyl glycoside acetates (5) for comparison with the corresponding derivatives from the polysaccharide constituents.

Garegg, Lindberg, and co-workers (6, 7) have reported syntheses of 6-deoxyheptoses with the D-*manno* and D-*galacto* configurations by homologations at C-6 of the corresponding methyl 2,3,4-tri-*O*-benzyl-hexodialdo-1,5-pyranosides by reaction with methoxymethylenetriphenylphosphorane, but with rather unsatisfactory yields. We describe here an alternative approach with the cyanide displacement of 2,3,4-tri-*O*-benzyl-α-D-glycopyranoside 6-sulfonate esters used by Baer et al. (8) in the preparation of 6-deoxy-D-*gluco*-heptopyranosidurononitriles, followed by a two-step reduction involving treatment with diisobutylaluminum hydride (DIBAH), hydrolysis of the resulting imine, and further reduction with sodium borohydride. In the event this proved to be a fortunate choice for the synthesis of the *altro* derivative since, as reported in the accompanying paper (9), the attempted formation of the α-D-*altro*-hexodialdo-1,5-pyranoside by oxidation of methyl 2,3,4-tri-*O*-benzyl-α-D-altropyranoside (**1**) (10) was accompanied by configurational inversion at C-5 with the formation of the corresponding β-L-*galacto* derivative as the major product.

Results and discussion

Altrose derivative **1** was converted into the trifluoromethanesulfonate for immediate displacement by cyanide to give the 6-deoxyheptosidurononitrile **2**. Two-step reduction of **2** with DIBAH, with hydrolysis of the imine and further treatment with sodium borohydride, afforded methyl 2,3,4-tri-*O*-benzyl-6-deoxy-α-D-*altro*-heptopyranoside (**3**) in adequate yield, and

thence, by catalytic hydrogenolysis over palladium on carbon, methyl 6-deoxy-α-D-*altro*-heptopyranoside (**4**). For further analytical and spectroscopic characterization a portion of **4** was converted into the tetra-*O*-acetyl derivative (**5**). Hydrolysis of a sample of methyl glycoside **4** followed by reduction and acetylation furnished the 6-deoxyheptitol hexaacetate, which was indistinguishable by gas–liqud chromatography (glc) from the component in the *C. jejuni* serotypes O:23 and O:36 polysaccharide hydrolyzates (3).

In identical manner methyl 2,3,4-tri-*O*-benzyl-α-D-mannopyranoside (**6**) (6) was converted successively into the 6-deoxyheptosidurononitrile (**7**), methyl 2,3,4-tri-*O*-benzyl-6-deoxy-α-D-*manno*-heptopyranoside (**8**), the parent methyl glycoside (**9**), and for further characterization the tetra-*O*-acetyl derivative (**10**) of **9**. The previously prepared (6) methyl 6-deoxy-α-D-*manno*-heptopyranoside (**8**) served as a convenient starting material for the synthesis of the C-4 epimer with the *talo* configuration. Protection of O-7 in **8** as the *tert*-butyldiphenylsilyl derivative **11** was followed by isopropylidenation with 2,2-dimethoxypropane in acetone to give methyl 6-deoxy-2,3-di-*O*-isopropylidene-7-*O*-*tert*-butyldiphenylsilyl-α-D-*manno*-heptopyranoside (**12**). The key step in the overall transformation was the Swern oxidation (dimethyl sulfoxide – oxalyl chloride) (11) from which reaction the intermediate deoxyheptosid-4-ulose was immediately treated with sodium borohydride. The reduction proceeded with high diastereoselectivity, only traces of the *manno* starting material (**12**) being detected in the reaction product, and the desired *talo* isomer (**13**) was isolated in chromatographically and spectroscopically homogeneous form in 85% yield. The configurational change at C-4 was confirmed by changes in the ^1H nmr spectrum, notably at H-4, which showed coupling constants $J_{3,4}$ = 9.2 Hz and $J_{4,5}$ = 9.4 Hz. Deprotection of **13** afforded methyl 6-deoxy-α-D-*talo*-heptopyranoside (**14**), which was further characterized as the tetra-*O*-acetate (**15**).

Hydrolysis of **14** and conversion of the reducing sugar into the 6-deoxyheptitol hexaacetate gave a derivative that was indistinguishable by glc from that formed from the 6-deoxyheptose constituent of the *C. coli* O:30 carbohydrate polymer. It was then observed that the three diastereomeric 6-deoxyheptitol hexaacetates could not be differentiated on glc columns. However, hydrolysis of the methyl glycosides **4**, **9**, and **14**, followed by glycosidation with (*R*)- and (*S*)-2-butanol and acetylation, gave in each case equilibrium mixtures of 2-butyl glycoside tetraacetates whose identities were established by chemical ionization (ci) glc-ms. These sets of derivatives served two purposes. The primary purpose was to distinguish the mixtures formed *either* from each of the enantiomeric alcohols and a given sugar anantiomer *or* from an enantiomerically pure alcohol and each sugar enantiomer (Table 1). Thus the reactions of sugars in polysaccharide hydrolyzates with a chiral 2-butanol gave the corresponding mixtures of chiral glycosides whose retention times defined the enantiomeric sugars of immediate interest as 6-deoxy-D-*altro*-heptose from *Campylobacter jejuni* serotype O:23 (3) and 6-deoxy-D-*talo*-heptose from the teichoic acid-like polymer from *C. coli* serotype O:30 (4). In addition the retention times of at least some of the components from each set of 2-butyl glycoside tetraacetates from diastereomeric sugars were sufficiently different to distinguish the parent 6-deoxyheptoses.

The ^1H nmr data were obtained from 1D spectra and, with the aid of ^1H COSY correlations, resonances were assigned for individual carbon-bound protons for the methyl glycosides **4**, **9**, and **14** (Table 2), and the corresponding tetraacetates **5**, **10**, and **15** (Table 2). The vicinal coupling constants $J_{n,n+1}$ were in accord with all glycoside derivatives in the $^4C_1$ conformation. A long-range W coupling between H-2 and H-4 was detected in the COSY spectra of **15**. The observation of such a coupling had been a key factor in the assignment of the *talo* configuration for the 6-deoxyheptose constituent of *C. coli* polymer (4).

Experimental

General procedures

Unless otherwise stated, experimental methods and spectroscopic analyses were performed as described in the previous paper (9).

Derivatives of 6-deoxyheptoses for glc and glc–ms analysis

trated and converted into 6-deoxyheptitol hexaacetates for glc analysis (12).

(*b*) Hydrolyzates were converted in chiral 2-butyl glycoside tetraacetates as described by Gerwig et al. (5) for glc analysis. The identities of the desired chiral glycosides were confirmed by ci glc–ms.

*Methyl 2,3,4-tri-*O*-benzyl-6-deoxy-*α*-D-*altro*-heptopyranosyluronononitrile 2*

Triflic anhydride (0.79 mL, 4.68 mmol) was added to a solution of 2,6-di-*tert*-butylpyridine (1.16 mL, 5.1 mmol) in dry dichloromethane at −15°C and, after stirring for 10 min, a solution of **1** (1.08 g) in dry dichloromethane was added dropwise and the mixture was stirred at −15°C for 1 h. The solution was poured into aqueous 5% sodium hydrogen carbonate, the organic layer was separated, dried, and concentrated. The residual syrup in acetonitrile:water (9:1, 30 mL) was treated with potassium cyanide (0.24 g, 3.68 mmol) for 2.5 h at room temperature, the solution was concentrated, and the residue was dissolved in ethyl acetate, washed successively with 1 M HCl, aqueous saturated $NaHCO_3$, and water, dried, and concentrated. The residual syrup was chromatographed on silica gel (light petroleum – ethyl acetate, 3.5:1) to give compound **2** (0.9 g, 82%), $[\alpha]_D$ +85 (*c* 1.35); ir ν_{max}: 2250 (C≡N) cm^{-1}; ^{1}H nmr δ: 4.68–4.26 (m, 8H, H-1, H-5, 3 × CH_2Ph), 3.81 (t, 1H, H-2), 3.71 (d, 1H, H-3), 3.61 (3.61 (dd, 1H, $J_{3,4}$ 3.0 Hz, $J_{4,5}$ 9.66 Hz), 3.42 (s, 3H, OMe), 2.80 (dd, 1H, $J_{5,6}$ 3.08 Hz, $J_{6,6'}$ 16.7 Hz, H-6), and 2.5 (dd, 1H, $J_{5,6'}$ 8.3 Hz, H-6′). Anal. calcd. for $C_{29}H_{31}NO_5$: C 73.55, H 6.59, N 2.95; found: C 73.83, H 6.45, N 2.93.

*Methyl 2,3,4-tri-*O*-benzyl-6-deoxy-*α*-D-*altro*-heptopyranoside 3*

DIBAH (1 M in hexane, 0.73 mL) was added to a solution of **2** (0.314 g, 0.66 mmol) in dry toluene (5 mL) at 0°C; after 30 min a further quantity of DIBAH solution (0.2 mL) was added and reaction was terminated after 10 min by the addition of methanol (0.5 mL) followed by aqueous 2 M HCl (0.5 mL). The mixture was stirred for 45 min and filtered, the aqueous layer in the filtrate was extracted with ether, and the combined organic layers were washed with 2 M HCl, aqueous saturated $NaHCO_3$, and water, dried, and concentrated. Sodium borohydride (10 mg) was added to the residual syrup in methanol (5 mL); the solution was stirred at room temperature for 30 min before excess of hydride was destroyed by the addition of acetone, evaporated to dryness, and then evaporated again (×3) with methanol. The residue in ethyl acetate was washed successively with aqueous 2 M HCl, saturated $NaHCO_3$, and water, dried, and concentrated to a syrup that was chromatographed on silica gel (light petroleum – ethyl acetate, 2:1) to give **3** (0.168 g, 53%), $[\alpha]_D$ +87 (*c* 0.8); ^{1}H nmr δ: 4.67–4.26 (m, 8H, H-1, H-5, and 3 × CH_2Ph), 3.83–3.69 (m, 4H, H-2,3,7,7′), 3.56 (dd, 1H, $J_{3,4}$ 3.1 Hz, $J_{4,5}$ 9.2 Hz, H-4), 3.39 (s, 3H, OMe), 3.17 (t, 1H, exchanged with D_2O, OH), 2.13–2.05 (m, 1H, H-6), and 1.79 (m, 1H, H-6′). Anal. calcd. for $C_{29}H_{34}O_6$: C 72.78, H 7.16; found: C 72.68, H 7.21.

Methyl 6-deoxy-α-D-altro-heptopyranoside 4 and the tetra-O-acetyl derivative 5

Compound **3** (75 mg, 0.15 mmol) in ethanol (5 mL) was hydrogenolyzed over palladium 5% on carbon for 72 h. Filtration of the mixture and concentration of the filtrate afforded **4** (30 mg), $[\alpha]_D$ +100 (*c* 1.98, water); ^{13}C nmr (D_2O) δ_C: 100.6 ($^1J_{C,H}$ 166.9 Hz, C-1), 58.3 (C-7), 55.7 (OMe), 32.7 (C-6). Acetylation of a sample of **4** followed by chromatography on silica gel (light petroleum – ethyl acetate, 2.5:1) furnished tetraacetate **5**, which gave a single peak on glc (program A, isothermal at 200°C), $R_{[Me\ Ac_4\ \alpha\text{-D-}Manp]}$ 1.33, $[\alpha]_D$ +77 (*c* 1.01); ^{13}C nmr δ_C: 170.8, 169.9, 169.6, 169.2 (4 × CH_3CO), 98.5 ($^1J_{C,H}$ 167.3 Hz, C-1), 60.3 (C-7), 55.4 (OMe), 30.2 (C-6), 20.8, 20.75, 20.7, 20.6 (4 ×

CH_3CO). Anal. calcd. for $C_{16}H_{24}O_{10}$: C 51.05, H 6.42; found: C 51.13, H 6.41.

Methyl 2,3,4-tri-O-benzyl-6-deoxy-α-D-manno-heptopyranosyluruononitrile 7

Conversion of compound **6** (4.03 g, 8.68 mmol) into the triflate ester, and thence by reaction with potassium cyanide, as described for **2**, yielded **7** (2.43 g, 59%), $[\alpha]_D$ +44 (*c* 1.35); ir ν_{max}: 2240 (C≡N) cm^{-1}; ^1H nmr δ: 4.70 (s, 1H, H-1), 3.87 (dd, 1H, $J_{3,4}$ 8.9 Hz, H-3), 3.79 (dd, 1H, $J_{2,3}$ 2.8 Hz, H-2), 3.76 (dd, 1H, $J_{4,5}$ 9.1 Hz, H-4), 3.74 (dd, 1H, $J_{5,6}$ 5.5 Hz, $J_{5,6'}$ 2.9 Hz, H-5), 3.34 (s, 3H, OMe), 2.74 (dd, 1H, $J_{6,6'}$ 16.4 Hz, H-6), and 2.5 (m, 1H, H-6′). Anal. calcd. for $C_{29}H_{31}NO_5$: C 73.55, H 2.95, N 2.95; found: C 73.21, H 6.53, N 2.81.

Methyl 2,3,4-tri-O-benzyl-6-deoxy-α-D-manno-heptopyranoside 8

Reduction of **7** (1.8 g, 3.8 mmol) with DIBAH, as described for the preparation of **3**, yielded **8** (0.91 g, 50%), $[\alpha]_D$ +31 (*c* 1.8) (lit. (6) $[\alpha]_D$ +39); ^1H nmr δ: 4.66 (d, $J_{1,2}$ 1.8 Hz, H-1), 3.86 (dd, 1H, $J_{3,4}$ 9.0 Hz, H-3), 3.79 (dd, 1H, $J_{2,3}$ 2.8 Hz, H-2), 3.76 (m, 2H, H-5, H-7), 3.75 (dd, 1H, $J_{4,5}$ 8.8 Hz, H-4), 3.30 (s, 3H, OMe), 2.10 (m, 1H, H-6), and 1.84 (m, 1H, H-6′). Anal. calcd. for $C_{29}H_{34}O_6$: C 72.78, H 7.16; found: C 72.42, H 7.13.

Methyl 6-deoxy-α-D-manno-heptopyranoside 9 and the tetra-O-acetyl derivative 10

Hydrogenolysis of **8** (0.91 g, 1.90 mmol), as described for the conversion of **3** into **4**, afforded **9** (0.33 g, 84%); ^{13}C nmr (D_2O) δ_C: 100.9 ($^1J_{C,H}$ 170.2 Hz, C-1), 58.4 (C-7), 54.8 (OMe), 33.4 (C-6). Acetylation of a sample of **9** followed by chromatography on silica gel (light petroleum – ethyl acetate, 2.5:1) furnished tetraacetate **10**, which gave a single peak on glc (program A, isothermal at 200°C), $R_{[Me\ Ac_4\ \alpha\text{-D-Man}p]}$ 1.29, $[\alpha]_D$ +59 (*c* 1.65) (lit. (6) $[\alpha]_D$ +62); ^{13}C nmr δ_C: 170.8, 169.9, 169.85, 169.8 (4 × CH_3CO), 98.4 ($^1J_{C,H}$ 172.4 Hz, C-1), 60.2 (C-7), 55.0 (OMe), 30.4 (C-6), 20.8 (2C), 20.7, 20.6 (4 × CH_3CO). Anal. calcd. for $C_{16}H_{24}O_{10}$: C 51.05, H 6.42; found: C 51.30, H 6.33.

Methyl 6-deoxy-7-O-tert-butyldiphenylsilyl-α-D-manno-heptopyranoside 11

Imidazole (0.26 g, 2.4 equiv.) and *tert*-butyldiphenylsilyl chloride (0.523 g, 1.2 equiv.) were added successively to compound **10** (0.33 g, 1.59 mmol) in *N,N*-dimethylformamide (5 mL) and the mixture was stirred at 25°C for 16 h. Dichloromethane was added to the mixture, and the solution was washed with water, dried, concentrated, and chromatographed on silica gel (light petroleum – ethyl acetate, 1:4) to give **11** (0.446 g, 63%), $[\alpha]_D$ +43 (*c* 1.5); ^1H nmr δ: 7.66, 7.44–7.25 (m, 10H, aromatic), 4.64 (d, 1H, $J_{1,2}$ 0.9 Hz, H-1), 3.92 (dd, 1H, $J_{2,3}$ 3.3 Hz, H-2), 3.84 (m, 2H, H-7), 3.80 (dd, 1H, $J_{3,4}$ 8.8 Hz, H-3), 3.70 (dd, 1H, $J_{5,6}$ 4.2 Hz, H-5), 3.60 (dd, 1H, $J_{4,5}$ 9.4 Hz, H-4), 3.27 (s, 3H, OMe), 2.11 (m, 1H, H-6), 1.75 (m, 1H, H-6′), and 1.04 (s, 9H, *tert*-butyl). Exact Mass calcd. for $C_{24}H_{34}O_6Si$ + H: 447.2203; found: 447.2182.

Methyl 6-deoxy-2,3-O-isopropylidene-7-O-tert-butyldiphenylsilyl-α-D-manno-heptopyranoside 12

A solution of compound **11** (0.411 g, 9.21 mmol) in acetone (5 mL) containing 2,3-dimethoxypropane (0.4 mL) and *p*-toluenesulfonic acid (5 mg) was stirred at 25°C for 1 h. The reaction was quenched by the addition of $NaHCO_3$ (20 mg), the mixture was concentrated, and the residue in dichloromethane was washed successively with aqueous $NaHCO_3$ and water, dried, and concentrated. The residue was chromatographed on silica gel (light petroleum – ethyl acetate, 4:1) to give **12** (0.391 g, 87%), $[\alpha]_D$ +22 (*c* 1.05); ^1H nmr δ: 7.66, 7.45–7.26 (m, 10H, aromatic), 4.85 (s, 1H, H-1), 4.13 (dd, 1H, $J_{3,4}$ 9.2 Hz, H-3), 4.12 (dd, 1H, $J_{2,3}$ ~3 Hz, H-2), 3.85 (m, 2H, H-7), 3.73 (m, 1H, H-5), 3.60 (t, 1H, $J_{4,5}$ 9.4 Hz, H-4), 3.33 (s, 3H, OMe), 2.03 (m, 1H, H-6), 1.83 (m, 1H, H-6′), 1.53, 1.36 (2s, each 3H, $C(CH_3)_2$), 1.06 (s, 9H, *tert*-butyl). Exact Mass calcd. for $C_{27}H_{38}O_6Si$ + H: 487.2516; found: 487.2490. Anal. calcd. for $C_{27}H_{38}O_6Si$: C, 66.69, H 7.88; found: C 66.86, H 7.86.

Methyl 6-deoxy-2,3-O-isopropylidene-7-O-tert-butyldiphenylsilyl-α-D-talo-heptopyranoside 13

A solution of **12** (0.361 g, 0.74 mmol) in dichloromethane (5 mL) was added dropwise to a stirred mixture of Me_2SO (0.23 mL, 3.24 mmol) in dichloromethane (4 mL) and oxalyl chloride (1.2 mL, 0.24 mmol) in dichloromethane (10 mL) at −78°C, at which temperature the mixture was kept for 45 min. The reaction was quenched by the addition of triethylamine (2 mL) in dichloromethane (5 mL); it was stirred for 30 min at −78°C and then brought slowly to 20°C. The solution was diluted with dichloromethane (20 mL) and washed three times with water, dried, and concentrated. The residual 4-ulose was reduced by stirring with sodium borohydride (56 mg, 2 equiv.) in methanol (10 mL) at 25°C for 90 min. Excess of hydride was destroyed by the addition of acetone, the mixture was concentrated, evaporated with methanol (×3), and the residue was chromatographed on silica gel (light petroleum – ethyl acetate, 4:1) to give **13** (0.306 g, 85%), $[\alpha]_D$ +27 (*c* 0.82); ^1H nmr δ: 7.68–7.62, 7.46–7.26 (m, 10H, aromatic), 4.94 (s, 1H, H-1), 4.22 (dd, 1H, $J_{3,4}$ 5.1 Hz, H-3), 4.05 (dd, 1H, $J_{2,3}$ 6.7 Hz, H-2), 4.01 (t, 1H, $J_{4,5}$ 4.9 Hz, H-4), 3.88 (m, H, H-7), 3.79 (m, 1H, H-7′), 3.57 (d, 1H, $J_{5,6}$ <2 Hz, H-5), 3.38 (s, 3H, OMe), 2.04 (m, 1H, H-6), 1.81 (m, 1H, H-6′), 1.58, 1.38 (2s, each 3H, $C(CH_3)_2$), and 1.05 (s, 9H, *tert*-butyl). Exact Mass calcd. for $C_{27}H_{38}O_6Si$ + H: 487.2516; found: 487.2534. Anal. calcd. for $C_{27}H_{38}O_6Si$: C, 66.69, H 7.88; found: C 66.46, H 7.74.

Methyl 6-deoxy-α-D-talo-heptopyranoside 14

A solution of **13** (0.246 g, 5.06 mmol) in oxolane (5 mL) was treated with 1 M tetrabutylammonium fluoride in oxolane (1.4 mL) at 25°C for 30 min and concentrated. The residue was treated with aqueous saturated $NaHCO_3$ (20 mL), the mixture was extracted with ethyl acetate, and the extract was dried and concentrated. The residual product was heated in aqueous 2 M acetic acid (5 mL) at 80°C for 2 h, and the solution was concentrated. A solution of the residue in water was extracted with dichloromethane, and the aqueous layer was concentrated to a syrup that was chromatographed on silica gel (methanol–dichloromethane, 1:9) to give **14** (90 mg, 86%), $[\alpha]_D$ +84 (*c* 3.0, water); ^{13}C nmr (D_2O) δ_C: 101.6 ($^1J_{C,H}$ 171.3 Hz, C-1), 58.3 (C-7), 55.0 (OMe), 33.0 (C-6). Acetylation of a sample of **9** followed by chromatography on silica gel (light petroleum – ethyl acetate, 2.5:1) furnished tetraacetate **15**, which gave a single peak on glc (program A, isothermal at 200°C); $R_{[Me\ Ac_4\ \alpha\text{-D-Man}p]}$ 2.25, $[\alpha]_D$ +81 (*c* 1.02); ^{13}C nmr δ_C: 170.7, 170.3, 169.9, 169.5 (4 × CH_3CO), 99.4 ($^1J_{C,H}$ 172.2 Hz, C-1), 60.4 (C-7), 55.1 (OMe), 29.9 (C-6), 20.8, 20.7, 20.6, 20.5 (4 × CH_3CO). Anal. calcd. for $C_{16}H_{24}O_{10}$: C 51.05, H 6.42; found: C 50.87, H 6.28.

The conformations of the biologically active taxol analogs Taxotere®, **3R**, **4R**, and **4S**, and the biologically inactive analog **3S** were evaluated in $CDCl_3$ and DMSO–water solution using ^1H NMR coupling constant and NOESY data and molecular modeling. The solution structures of Taxotere® were very similar to those detected previously for taxol. The A-ring side chain conformations of analogs **3** and **4** could not be defined with the same precision as had been possible for taxol, but the conformational possibilities could be significantly limited by the data. Analogs **3R**, **4R**, and **4S** (but not **3S**) can mimic the dominant conformation of taxol in chloroform, but no logical relationship between biological activity and aqueous solution conformation could be detected.

HOWARD J. WILLIAMS, A. IAN SCOTT, REINER A. DIEDEN, CHARLES S. SWINDELL, LISA E. CHIRLIAN, MICHELLE M. FRANCL, JULIA M. HEERDING et NANCY E. KRAUSS. Can. J. Chem. **72**, 252 (1994).

Faisant appel aux constantes de couplage en RMN du ^1H obtenues pour des solutions de $CDCl_3$ ou aqueuses de DMSO, à des données NEOSY et à de la modélisation moléculaire, on a évalué les conformations des analogues biologiquement actifs du taxol, les Taxotere® **3R**, **4R** et **4S**, et de l'analogue biologiquement inactif **3S**. Les structures du Taxotere® en solution sont très semblables à celles détectées antérieurement pour le taxol. Les conformations de la chaîne latérale du cycle A des analogues **3** et **4** n'a pas été déterminée avec la précision qui avait été possible pour le taxol; toutefois, les possibilités conformationnelles ont pu être sérieusement limitées par les données. Les analogues **3R**, **4R** et **4S** (mais pas le **3S**) peuvent reproduire la conformation dominante du taxol dans le chloroforme; toutefois, on ne peut détecter aucune relation logique entre l'activité biologique et la conformation en solution aqueuse.

[Traduit par la rédaction]

Introduction

The diterpenoid antineoplastic drug taxol (1, 2) is distinct from other anti-mitotic agents, such as the vinca alkaloids, in that it promotes the assembly and inhibits the disassembly of microtubules, both in vitro and in vivo (3). Whereas the structure–activity profile that is emerging[3] hints at an intriguing interaction between taxol and its microtubular binding site(s), there is currently available no molecular-level structural information on the taxol–microtubule complex.[4]

Recent spectroscopic and molecular modeling studies (6) have been effective in determining the conformations of the flexible taxol A-ring side chain in hydrophobic and hydrophilic media as a preliminary step toward filling this gap. In hydrophobic media, taxol was found to adopt mainly the A-ring side chain H-C2′-C3′-H *gauche* conformation observed in the solid state structure of Taxotere®, with the alternative H-C2′-C3′-H *gauche* conformation (having the 2′-OH hydrogen bonded to the 4-OAc group) being a minor but detectable species by vibrational circular dichroism spectroscopy. NOESY data indicated little interaction between the A-ring side chain and the diterpenoid portion of the structure in hydrophobic media and suggested the side chain to be rather extended (6*e*). In hydrophilic media, however, the A-ring side chain H-C2′-C3′-H *anti* conformation was found by ^1H NMR spectroscopy to be dominant and the side chain was shown through NOESY experiments to interact more strongly with the diterpenoid substructure in a more compact, somewhat globular conformation (6*e*).

Therefore, the question arose as to whether these conformational features could be related to the biological activities of the taxol analogs Taxotere® (7), the baccatin III *R*- and *S*-*N*-benzoylisoserine esters **3R** and **3S**, and the baccatin III *R*- and *S*-phenyllactate esters **4R** and **4S**, respectively (8). Previously, **3R** and **3S** were shown to possess divergent microtubule assembly activities, **3R** being "active" and **3S** inactive, whereas **4R** and **4S** were essentially equally active. Herein, we provide NMR and molecular modeling data on the solution conformations of these compounds in both hydrophobic and hydrophilic media.

Results

Although in Taxotere® (**2**) the acetoxy group at C-10 is replaced by a hydroxyl group, a structural alteration known to have little effect on biological activity, the main difference between taxol (**1**) and the five analogs studied consists of changes in the C-13 side chain substitution pattern and in the configuration at C2′. In Taxotere® (**2**) the side chain benzamide is replaced by an *O*-*tert*-butylcarbamate group, whereas analogs **4** are lacking it altogether; in analogs **3**, the 3′-Ph is absent. Taxotere®, **3R**, and **4R** have the natural *R* configuration at C2′,

while **3S** and **4S** have the *S* configuration. Configurational variation at C2′ is of interest because the 2′-OH plays an essential role in the structure–activity profile of taxol.

Our earlier (6*e*) experiments with taxol indicated that its conformation, as judged by the side chain coupling constants and nOe's observed, was quite invariant for solutions in DMSO-d_6 or D_2O:DMSO, 3:7 (v/v), as hydrophilic solvent systems. Obtaining high-quality spectra in pure water solution is difficult due to solubility problems, making extensive 2-D studies impractical, so DMSO–H_2O solvent mixtures were used for these experiments.

The NMR spectral properties for compounds **2–4** in the above media are assembled in Tables 1–4. Corresponding molecular modeling studies are summarized in Tables 5–14.[5] Due to the close resemblance of the different spectra to each other and to that of taxol **1**, in most cases the signals were readily assigned and COSY spectra were essentially used for confirmation. However, the NOESY data were essential for the confirmation of the assignments of the different methyl groups and especially for the determination of spatial relationships between different protons.

Taxotere® (2)

In $CDCl_3$, the characteristic triplet of H13 at 6.19δ shows COSY cross-peaks with the $H14_{\alpha,\beta}$ doublet at 2.25δ as well as the singlet of Me18 at 1.89δ. Correlations with $H20_\alpha$ (4.30δ and H2 (5.66δ) identify the signal at 3.89δ as H3. $H20_\alpha$ is coupled to $H20_\beta$ (4.16δ), which is overlapping with H7. The latter shows couplings to $H6_\alpha$ (2.57δ) and $H6_\beta$ (1.85δ, under Me18) and H5 (4.92δ), the latter correlated to $H6_\alpha$ and $H6_\beta$. Finally, the NH signal (5.41δ) is coupled to H3′ (5.24δ), which shows a cross-peak to H2′ at 4.60δ. A correlation between this signal and the broad peak at 3.35δ identifies the latter as OH2′.

The NOESY spectrum shows nOe's equivalent to those observed earlier for taxol (6*e*) and permits the assignment of the remaining methyl groups: Me16 (1.11δ) and Me17 (1.21δ) are differentiated through their dipolar couplings to H2 and H13, respectively. H2 exhibits an nOe cross-peak to Me19 (1.73δ) while H10 is correlated to Me18. However, with the exception of an nOe between *o*-OBz and $H20_\alpha$, no dipolar couplings between side chain protons and the large ring system are observed.

By analogy with the major chloroform solution conformer observed for taxol (6) and in agreement with the results of Dubois et al. (6*f*), we propose that Taxotere® adopts to a large degree low-energy conformer **6** (Table 5; Fig. 2). Conformer **6** is very similar to the conformer exhibited by Taxotere® in the solid state (9). It is consistent with hydrogen bonding between the 2′-OH and the side chain ester carbonyl oxygen detected for taxol by vibrational circular dichroism (VCD), a technique sensitive to chiral environments near hydrogen bonds (10), and for analogs **3** and **4** in chloroform solution[6] (see below) and which seems very likely to obtain for Taxotere® in the same solvent. The low value for $J_{H2'-H3'}$ calculated for **6** must be increased by a degree of rotational averaging to that observed experimentally for Taxotere® in chloroform (4.5 Hz).

In DMSO–D_2O solution, NMR assignments are also straightforward, and the Ph-group protons are also well resolved. The two protons $H14_\alpha$ and $H14_\beta$ (1.86 and 1.70δ) show COSY cross-peaks to H13 (5.83δ). H2 (5.39δ) and H3 (5.64δ) are correlated as well. $H6_\alpha$ (2.24δ) and $H6_\beta$ (1.60δ) show cross-peaks to each other as well as to the broad multiplet at 4.0δ, resulting from the overlapping signals of H7, $H20_\alpha$, and

[a]In 100% DMSO-d_6.

$H20_\beta$. H7 is further coupled to a broad signal at 5.02δ, which is therefore attributed to OH7. For the side chain, the doublet at 7.45δ is correlated to H3′ (4.78δ), which in turn is correlated to H2′ (4.31δ), which itself is correlated to OH2′ (5.9δ).

These assignments are confirmed and completed by the NOESY data. H13 exhibits nOe's to Me18 (1.72δ) and Me17 (0.98δ). H2 is dipolarly coupled to H10 (4.51δ), H20 (4.0δ), H3, H19 (1.50δ), and Me16 (0.96δ). H5 shows cross-peaks with H7, H3, and Me18. H7 is dipolarly coupled to OH7, Me19, and H3, which in turn shows cross-peaks to OAc4, $H14_\alpha$, Me18, and Me19. Finally, H10 exhibits nOe correlations to Me17 and Me18.

Most interesting are nOe's observed between the side chain and the ring system protons. H3′ shows cross-peaks to $H6_\alpha$, OAc4, and $H6_\beta$, while H2′ exhibits dipolar couplings to OAc4 and Me18. Combined with the increase in $J_{H2'-H3'}$, these data indicate that Taxotere® undergoes a striking conformational change in hydrophilic solvent. With the exception of the OAc4 interaction, this favors low-energy conformer **12** and the nOe involving H3′ and 4-OAc must arise from contributions made by alternative conformers. However, as observed previously for taxol (6*e*), Taxotere® shows a pronounced preference in this solvent for *anti* H-C2′-C3′-H conformer **12** that is distinctly different from that observed in the solid state and in chloroform solution.

*Baccatin III 13-(*R*-N-Benzoylisoserinate) (**3R**)*

In $CDCl_3$, assignments are straightforward. The two diastereotopic hydrogens $H3'_a$ and $H3'_b$ overlap near 3.84δ while H3 is nearby at 3.75δ. The NOESY spectrum confirms the methyl group assignments through the cross-peaks observed between H13–Me17, H13–Me18, and H2–Me16, H2–Me19. The most interesting nOe observed is a weak correlation between H2′ and OAc4.

The two $J_{H2'-H3'}$ values for **3R** in $CDCl_3$, both 4.5 Hz, are significantly higher than that observed for taxol (2.7 Hz). These values could reflect a single predominant conformation for **3R** having appropriate side chain C2′H—C3′H_2 dihedral angles, or, more likely, increased side chain bond rotational mobility in **3R**, which would equalize and raise the two diastereotopic $J_{H2'-H3'}$ values from that observed for taxol in the same solvent. Indeed, modeling fails to identify a conformation consistent with the former scenario, whereas the observation for **3R** in $CDCl_3$ solution of a side chain – diterpenoid skeleton nOe interaction involving the H2′ and 4-OAc (not observed for taxol or Taxotere® in $CDCl_3$) is consistent with the latter. A study of **3R** in chloroform employing VCD indicates a hydrogen bond between the 2′-OH and the side chain ester carbonyl oxygen (9), thus placing the focus on conformers **18**, **19**, and **22** (Table 7). Therefore, it seems likely that **3R** in $CDCl_3$ is conformationally heterogeneous, but that low-energy conformer **19**, analogous in its side chain torsion angles to the major taxol conformer in $CDCl_3$ and possessing low $J_{H2'-H3'}$ values, is a significant contributor.

In DMSO–H_2O solution, the different signals are again easily attributed to the corresponding hydrogen atoms. Interest-

[a]Abbreviations are s: small (≤1.5 Hz); n: not determined.

ingly, inspection of the NOESY spectrum reveals dipolar interactions between H2′ and OAc4, H2′, and Me18, as well as between $H3'_\beta$ and OAc4. The magnitudes of the two $J_{H2'-H3'}$ values detected for **3R** in this medium are closely similar and consistent with rotational averaging about C2′—C3′. Molecular modeling implicates as major contributors low-energy conformers **23–25** (Table 8). These conformers place those protons that are dipolar coupled (H2′ and 4OAc, H2′ and Me18, and H3′ and 4-OAc) in reasonable proximity (within 2.8–4.2 Å). Conformer **27**, which is very similar in its A-ring side chain torsional characteristics to the major aqueous taxol conformer (6*e*), is not inconsistent with the nOe data. However, its high relative energy makes it unlikely to be a significant contributor to the mix of conformers exhibited by **3R** in this solvent.

*Baccatin III 13-(*S*-N-benzoylisoserinate) (**3S**)*

In $CDCl_3$, except for a few chemical shift changes (see, for example H2–H2′, H3–$H3'_a$–$H3'_b$, Me18–Me19), the spectrum resembles very closely that of **3R** and the assignments are therefore straightforward. The NOESY spectrum gives the usual correlations between H10 and Me18, H13 and Me17, H2 and Me19 as well as H2 and Me16, permitting the assignment of the methyl groups, but does not indicate any proximity between the side chain and the baccatin-III ring system.

The somewhat divergent $J_{H2'-H3'}$ values observed for **3S** in chloroform suggest a less conformationally mobile side chain. Again, VCD measurements point to the importance of hydrogen bonding between the 2′-OH and the side chain ester carbonyl oxygen, as in conformers **29**, **31**, and **34** (Table 9). Of these three, a mixture of low-energy conformers **29** and **31** is most consistent with the $J_{H2'-H3'}$ values detected for **3S** since the pro-*R* and pro-*S* H3′ are calculated to exhibit large and small $J_{H2'-H3'}$ values, respectively, in **29**, and vice versa in **31**. Conformational averaging of $J_{H2'-H3'}$ in this way is consistent with the experimental data.

In DMSO–H_2O, the spectra resemble those of **3R** quite closely, and the assignments are straightforward. The most interesting nOe observed is the one between H2′ and OAc4, indicating some proximity between the side chain and the ring system as was observed for **3R**. As in the case of **3R** in this solvent mixture, the two $J_{H2'-H3'}$ values of **3S** are essentially identical in magnitude and consistent with rotational averaging about C2′—C3′. Three of the conformers in Table 10, **36**, **38**, and **39**, show close contacts (2.8–3.2 Å) between the dipolar coupled H2′ and 4-OAc protons. Of those, **39** is somewhat reminiscent of the major aqueous taxol conformer in its disposition of the benzamide group, but its high relative energy would appear to reduce its contribution to the conformer equilibrium of **3S** in aqueous DMSO.

*Baccatin III 13-(*R*-3-phenyllactate) (**4R**)*

In $CDCl_3$, peaks are again readily assigned. It is striking that the two acetate groups, OAc4 and OAc10, generally separated by about 0.2 ppm in **1**, **2**, **3R**, and **3S**, fall almost into a single line for this compound (2.16 and 2.18δ). The most remarkable feature of the spectrum, however, is the NOESY cross-peak between *m*-Ph and Me17 protons, suggesting some over-the-top interaction between the side chain and the ring system.

As in the case of **3R** in $CDCl_3$, **4R** exhibits $J_{H2'-H3'}$ values

For personal use only.

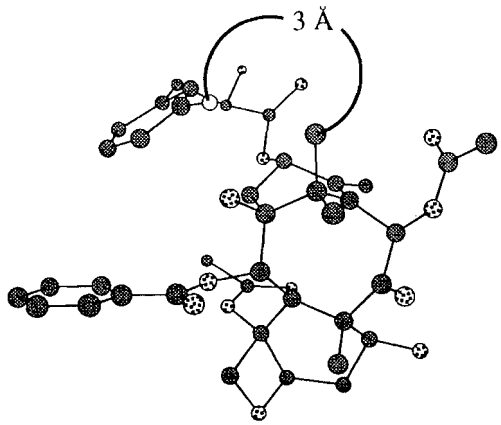

FIG. 3. Possible structure, which brings 3′ Ph into close proximity with Me17.

that are essentially equivalent in magnitude and indicative of rotational averaging. VCD measurements detect hydrogen bonding between the 2′-OH and the side chain ester carbonyl oxygen (11).Thus, **4R** in chloroform probably is a conformational mixture of **42**, **43**, and **45** (Table 11). Consistent with this degree of side chain mobility is the observation of an nOe interaction between the *meta* 3′-Ph protons and those on the 17-Me. Modeling failed to identify stable conformations with appropriately small distances between these protons, but it seems likely that **4R** can reside briefly in conformations related to **42** and **43** that bring these protons into close contact (see Fig. 3).

In DMSO–H_2O, assignments are again straightforward but the NOESY spectrum exhibits *no* dipolar correlations between the side chain and the ring system. The only evidence for some conformational changes occurring, besides the absence of the *m*-Ph and Me17 crosspeak observed in $CDCl_3$, is that the two acetate groups are again moved apart by 0.15 ppm (2.07 and 1.92δ, respectively). This hydrophilic medium appears to impart a degree of rotational restriction about C2′—C3′, as evidenced by more divergent $J_{H2'-H3'}$ values. The failure to detect nOe interactions between the *meta* 3′-Ph protons and those of Me17 in this medium suggests a generally globular conformation with the A-ring side chain wrapped within the concave region of the diterpenoid skeleton. These considerations together with the analogy of the major aqueous conformer observed for taxol point to conformer **47** as an important contributor to the description of **4R** in polar medium.

Baccatin III 13-(S-3-phenyllactate) (4S)

General aspects of the spectra of **4S** in $CDCl_3$ are similar to those of **4R**, and signals for the two OAc groups again occur at almost the same chemical shift (2.21 and 2.19δ). The major difference between the two spectra is that the H3′ protons are well separated ($\delta(H3'_a) = 3.22$, $\delta(H3'_b) = 2.96$) for the *S* epimer, while in the *R* epimer they form a tight AB system at 3.08 and 3.04δ as was observed earlier for **3R** and **3S**. In the NOESY spectrum the usual cross-peaks are observed, as well as couplings between the *m*-Ph and Me17 protons.

The $J_{H2'-H3'}$ values for **4S** in $CDCl_3$ are the most divergent among analogs **3** and **4**, and suggest the greatest degree of side chain C2′—C3′ rotational immobilization. Molecular modeling and the usual observation by VCD of hydrogen bonding between the 2′-OH and the side chain ester carbonyl oxygen (11) for **4S** in chloroform solution point to conformers **53**, **54**, and **55**. Of these three, conformers **53** and **55** possess the appropriate small–large combination of $J_{H2'-H3'}$ values that arise from the diastereotopic H3′ and, on that basis, must predominate. In principle, stereospecific isotopic replacement of the diastereotopic H3′'s would allow a choice to be made between dominant contributions by **53** or **55** since in **53** it is the pro-*R* H3′ that is expected to exhibit the larger $J_{H2'-H3'}$ whereas in **55** the pro-*S* H3′ is expected to do likewise. In the absence of this information, one can only say that it is *either* conformer **53** *or* conformer **55** which contributes most importantly to the description of **4S** in chloroform, but not both. Analog **4S** in chloroform resides at least briefly (as does **4R**) in conformations that bring the *meta* 3′-Ph and the 17-Me into close contact notwithstanding the loss of side chain rotational freedom evidenced by $J_{H2'-H3'}$, as indicated by the observation of appropriate NOESY signals.

In DMSO–H_2O three striking changes are noted in the spectra: the signals corresponding to the two acetate groups separate to 2.18 and 2.07δ, the triplet of H13 is shielded by 0.25 ppm, and the NOESY crosspeak between *m*-Ph and Me17 disappears, as observed before for **4R**. Among analogs **3** and **4** in this medium, it is again **4S** which exhibits the most divergent $J_{H2'-H3'}$ values, suggestive of the greatest degree of C2′—C3′ rotational preference. Like **4R**, **4S** fails to exhibit the nOe interaction between the *meta* 3′-Ph protons and those on the 17-Me that it did in chloroform solution. This suggests a globular conformation like the one detected for taxol in aqueous solution and suggested for **4R** in this solvent. However, without additional experimental data — especially data in which diastereotopic H3′ is involved in the larger $J_{H2'-H3'}$ — it is impossible to decide which is dominant among conformers **60–62**, and **64** (Table 14; those that have appropriately divergent $J_{H2'-H3'}$ values). It is tempting to dismiss **64** based on its high relative energy.

Discussion

We (8) and the French team (11) have speculated about the bound ligand conformation recognized by the microtubular taxol binding site that might be implicated by the taxol (**1**) and Taxotere® (**2**) solution conformations. Such speculation can form the basis of preliminary taxol analog design efforts. Previously, the focus was on the Taxotere® solid state structure (12) that is comparable to the major chloroform solution structures of both Taxotere® and taxol. The taxol aqueous dimethyl sulfoxide structure is an alternative candidate (6*e*). However, until better structural information on the microtubular taxol binding site and the taxol–microtubule complex is available, the question of whether it is the taxol conformation in hydrophobic (i.e., chloroform solution) or hydrophilic (i.e., aqueous dimethyl sulfoxide solution) media, *or neither*, that is recognized by microtubules will remain debatable. This caveat notwithstanding, it is a useful exercise, at this time, to compare the solution conformations accessible to taxol analogs **3** and **4** to those accessible to taxol, with a view toward suggesting an explanation for the spectrum of biological activity exhibited by **3** and **4**.

One of the most important solution conformational differences between taxol and Taxotere®, and analogs **3** and **4**, is that **3** and **4** clearly have more mobile A-ring side chains. This is manifested by **3S**, **4R**, and **4S** in chloroform solution in A-ring side chain – diterpenoid skeleton nOe interactions not observed for **1** and **2**, and, to varying degrees, by **3R** and **4R** in chloro-

form solution and by **3R** and **3S** in aqueous dimethyl sulfoxide solution in rotationally averaged $J_{H2'-H3'}$ values. For this reason and, in some cases, because the available experimental data are insufficient to choose among conformers suggested by molecular modeling, more equivocation is necessary in specifying solution structures for **3** and **4** than for **1** and **2**. Of analogs **3** and **4**, **4S** appears to possess the most rotationally restricted A-ring side chain in both chloroform and aqueous dimethyl sulfoxide solution. Perhaps not coincidentally, **4S** is also the most biologically active among taxol analogs **3** and **4**.

Figure 4 indicates how conformer **19**, accessible to **3R**, mimics the relevant substructure of the major chloroform solution conformer for taxol, whereas none of the candidate conformers for biologically inactive **3S** in chloroform project the benzamide similarly. Likewise, Fig. 5 shows how the accessible phenyllactate side chain of conformer **45** of **4R** in chloroform overlays onto the corresponding part of the taxol chloroform conformer. As noted above, it is impossible, based on the available data, to choose between conformers **53** and **55** for **4S** in chloroform solution. However, the similar projection of the 3′-Ph in **55** and in the major taxol chloroform conformer and the dissimilar projection of the same group in **53** are striking.

FIG. 5. Conformations for **4R** and **4S** in chloroform for comparison with the corresponding taxol structure.

In contrast, there is no consistently logical comparison between the major taxol aqueous solution conformer and the dominant aqueous conformers of analogs **3** and **4**. For example, Fig. 6 demonstrates that the A-ring side chain of high-energy conformer **27** for **3R** best mimics the respective taxol substructure in this medium. Likewise, high-energy conformer **39** of **3S** projects its A-ring side chain in the same manner as taxol. Thus, as one might expect, biologically inactive **3S** does not compare well conformationally to taxol in aqueous media, but neither does biologically active **3R**. The A-ring side chain of aqueous conformer **47** for biologically active taxol analog **4R** (Fig. 7), which appears to be an important contributor to its conformational equilibrium, compares very well to the appropriate part of the taxol aqueous conformer. Again, however, it is difficult to detect conformational similarities between taxol and **4S**, the most active of analogs **3** and **4**. The best candidate is low-energy conformer **61**, which orients its 3′-Ph group appropriately, but at the expense of misdirecting its 2-OH group.

The correspondence of the chloroform conformers with biological activity and the failure to detect a similar relationship between the aqueous conformers of taxol, Taxotere®, and analogs **3** and **4** suggest that the conformation of taxol in hydrophobic media (i.e., in chloroform in the present study) is related to the conformation of taxol at its microtubular binding site. This notion is not unreasonable given the hydrophobicity of taxol itself, and a similar effect seen in peptides during binding in which the hydrophilic conformation only slightly influences binding conformation at a hydrophobic active site has been referred to as "hydrophobic collapse" (13). However, the evaluation of this hypothesis awaits data on the features of tubulin and microtubules responsible for recognition of taxol, and on the ligand–protein complex. These studies are now in progress.

Experimental

Source of the chemicals studied

Taxotere® **2** was a gift from Rhone-Poulenc Rorer, Centre de Recherche de Vitry Alfortville, Quai Jules Guesde 13, BP 14, f94404 Vitry-sur-Seine, France. Taxol analogs **3R**, **3S**, **4R**, and **4S** were prepared as previously described.

NMR studies

^{1}H NMR spectroscopy was performed either at 500 MHz on a Varian Unity 500 equipped with a Sun data system or a Bruker AM-500 with an ASPECT 3000 data system, or at 300 MHz on a Bruker WM-300 spectrometer with an ASPECT 2000 data system. Spectra were taken at room temperature except as noted, and NOESY spectra were acquired in DMSO–water solution at 30°C. ^{1}H chemical shifts are referenced to tetramethylsilane for the $CDCl_3$ samples (δ(TMS) =

0.00) and to dimethyl sulfoxide for the DMSO-containing samples (δ(DMSO-d_5 = 2.49)).

1D-Spectra were taken with 16k data points (0.4 Hz/point), while the 2D experiments were performed with matrix sizes of 1k × 0.256k for COSY spectra and 2k × 0.512k for NOESY spectra. NOESY experiments were performed using mixing times of 0.6 s. Off-line spectral work-up and some NOESY-conformational studies were performed on a Silicon Graphics Iris Indigo workstation using SYBYL-TRIAD software from Tripos Associates.

Molecular modeling

Internal coordinate Monte Carlo conformational searching (13) was carried out on a Silicon Graphics 4D/35 workstation using MacroModel (14) (version 3.1) with the included version of the MM2 force field (15) and the Still chloroform and water continuum solvation models (16). The inspection and analysis of the conformational data were facilitated by the use of SYBYL (version 5.5, Tripos Associates). All taxane starting structures were generated from the Taxotere® crystal structure coordinates (9). Tables 5–15 listing conformational types determined with dihedral angles and calculated coupling constants have been deposited and are available from the National Research Council of Canada (see footnote 5). Additional details of our modeling and conformer analysis protocol that led to the characteristic taxol analog conformers in Tables 5–14 are described in ref. 6*e*. Coordinates for given structures may be obtained by e-mail from cswindel@cc.brynmawr.edu.

A protocol to separate the intermediates on the biosynthetic pathway to pantothenate on HPLC is described. Feeding experiments with L-[U-^{14}C]valine to pea leaf disks result in incorporation of radioactivity into 2-ketoisovalerate, ketopantoyl lactone, and pantoyl lactone, providing the first experimental evidence that the biosynthetic pathway to pantothenate is the same in plants and bacteria.

CAROL E. JONES, JANE E. DANCER, ALISON G. SMITH et CHRIS ABELL. Can. J. Chem **72**, 261 (1994).

On décrit un protocole pour séparer, par CLHP, les intermédiaires dans la biosynthèse du pantothénate. Des expériences impliquant l'addition de L-[U-^{14}C]valine à des disques de feuilles de pois provoquent l'incorporation de la radioactivité dans le 2-cétoisovalérate, dans la cétopantanoyl lactone et dans la pantanoyl lactone; ces résultats procurent la première preuve expérimentale que la voie de la biosynthèse du pantothénate est la même avec les plantes et avec les bactéries.

[Traduit par la rédaction]

Pantothenate **4** (vitamin B_3) is the precursor of coenzyme A. Studies to establish the biosynthetic pathway have been carried out in microorganisms, but pantothenate must also be produced in plants. In this paper we describe the first experimental evidence that the same pathway to pantothenate is used in plants and bacteria.

The biosynthesis of pantothenate in microorganisms has been shown to involve three steps (Scheme 1) (1, 2). The first committed step is the formation of ketopantoate **2** from α-ketoisovalerate (**1**, α-KIVA) catalysed by the enzyme ketopantoate hydroxymethyltransferase (KPHMT). This enzyme has been purified to homogeneity from *Escherichia coli* (3), and recently the *E. coli panB* gene, which codes for KPHMT, has been cloned, sequenced, and overexpressed (4).

Ketopantoate **2** is reduced to pantoate **3** by ketopantoate reductase. Low levels of enzyme activity have been detected in *E. coli*, *Saccharomyces cerevisiae* (5), *Salmonella typhimurium* (6), and *Pseudomonas maltophilia* 845 (7). Ketopantoyl lactone reductase, which reduces the corresponding lactone **5** of pantoate, has been found in *S. cerevisiae* (8) and bacteria (5). The conversion of pantoate **3** to pantothenate **4** involves the condensation of pantoate with ß-alanine and is catalysed by pantothenate synthetase. The *E. coli* enzyme has been purified (9).

The only evidence for the operation of the pathway to pantothenate in plants has been the isolation of a ketopantoate auxotroph of *Datura innoxia* P. Mill, thought to be unable to convert α-KIVA **1** to ketopantoate **2** (10). We set out to establish the biosynthetic pathway to pantothenate in plants. Our initial approach was to assay for KPHMT (3, 11) and ketopantoate reductase activity (7, 12) in crude homogenates of plant sources believed to be rich in coenzyme A, including broad beans and cauliflower florets, as well as in pea leaves. However, none of the assays with plant preparations reproducibly showed enzyme activity, suggesting that the levels of activity were below the sensitivity threshold of the assays being used. These results were not surprising as previous attempts to detect enzyme activity in plants had been unsuccessful (10).

This failure prompted us to use an alternative approach of feeding pea seedlings a radioactive precursor and looking for conversion into pathway intermediates. L-[U-^{14}C]Valine **8** was used as it is readily deaminated *in vivo* to give α-KIVA **1**, the first putative intermediate on the pantothenic acid pathway. Complications were anticipated as valine will be readily incorporated into protein, and α-KIVA will also be incorporated into leucine **12** (Scheme 1).

It was necessary to find an analytical system to resolve the potential intermediates on the pantothenate pathway from one another, and from related compounds that could be derived from α-KIVA on the pathway to leucine. A series of standards consisting of compounds derived from α-KIVA on the pantothenate and leucine pathways were therefore assembled. DL-2,3-Dihydroxyisovalerate **7**, the precursor of 2-ketoisovaleric acid, was prepared by the bis-hydroxylation of 3,3-dimethylacrylic acid (13). Ketopantoyl lactone **5** was synthesized by the bro-

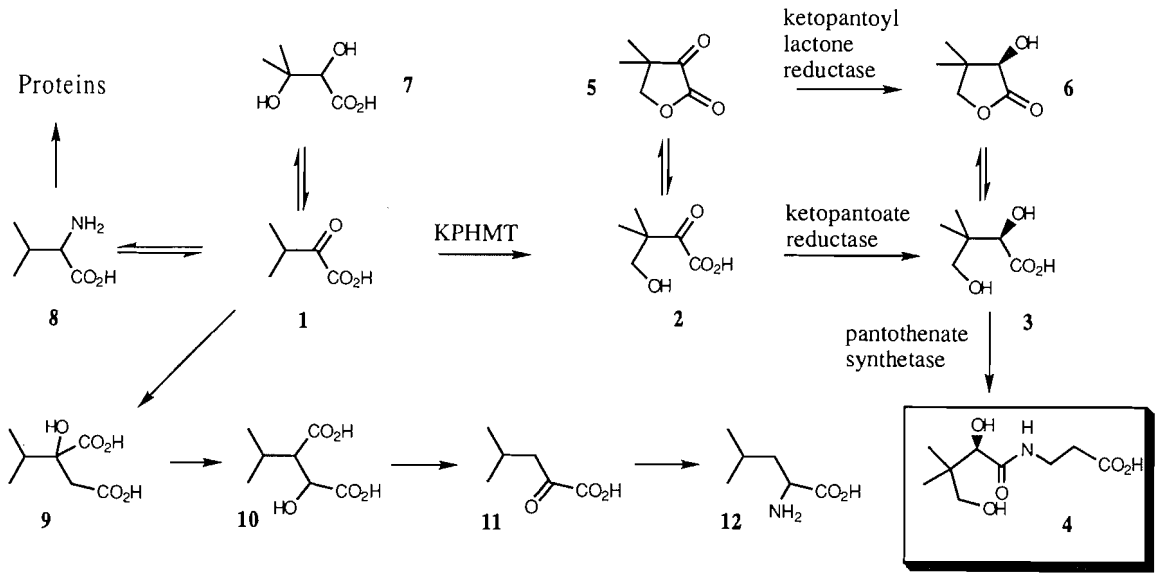

SCHEME 1. The biosynthetic pathway from α-KIVA to pantothenate as established for microorganisms. The scheme also shows the alternative fates of L-[U-^{14}C]valine in an in vivo feeding experiment.

mine oxidation of pantoyl lactone **6** (14). Pantoyl lactone **6**, α-KIVA **1**, 2-isopropylmalate **9**, and 2-ketoisocaproate **11** were all purchased commercially.

It was found that the pantothenate intermediates were well resolved by HPLC on a Bio Rad Organic Acids containing a strong cation-exchange resin. The lactone forms of ketopantoate and pantoate were analysed since these are formed under the acidic conditions used (8). Pantothenate is degraded to pantoyl lactone in acid and so cannot be detected intact under these conditions. The pantothenate pathway standards were also well resolved from the leucine pathway standards 2-isopropylmalate **9** and 2-ketoisocaproate **11**, as well as DL-2,3-dihydroxyisovalerate **7**. An HPLC trace of a mixture of these compounds is shown in Fig. 1*A*.

Having found a method to resolve the potential intermediates on the pantothenate pathway, attention was turned towards finding feeding conditions. L-[U-^{14}C]Valine was first fed to 14-day-old pea seedlings to establish the level of uptake through the exposed xylem. After 4 h, 15% of the valine was taken up and 45% of this was incorporated into protein. Less than 0.01% of the radioactivity was found in the fractions expected to contain intermediates on the pantothenate pathway. This prompted us to attempt an alternative feeding regimen.

To increase the incorporation of valine, the radiolabel was fed in a vacuum infiltration experiment to pea leaf disks. The first differentiated leaves from 2-week-old peas were cut with a cork borer to give disks (15), and floated on a solution containing L-[U-^{14}C]valine (16). The leaf disks were initially placed under vacuum to remove air bubbles that might interfere with the uptake of label. The vacuum was then released and the disks illuminated for several hours to enhance transpiration. In these experiments approximately 50% of the L-[U-^{14}C]valine was taken up, with 0.3% of the radioactivity ending up in the organic acids fraction.

The organic acids fraction was analysed by HPLC, monitoring the elution of compounds from the column using a radioactivity detector. The radioactivity trace for peas fed for 4 h is shown in Fig. 1*B*. Based on the retention times found for authentic standards, the peak at 10–11 min corresponds to α-KIVA **1** and the peak between 15 and 16 min to ketopantoyl lactone **5**. This peak increased in relative intensity from 3 to 4 h and then decreased so that it was barely visible after 24 h. The small peak at 23 min corresponds to pantoyl lactone **6**. There are several small peaks between 12 and 14 min in all traces that have the same retention time as some of the leucine pathway standards. A large unidentified peak at 8–9 min was seen in all traces. The same pattern of peaks was observed in HPLC traces from feedings after 3, 4, 5, and 24 h, although the relative intensity of the peaks varied, depending on the feeding time. The exact correspondence of the retention times of the peaks due to radioactivity and those for the authentic standards suggests that radioactivity from L-[U-^{14}C]valine is being incorporated into these compounds.

The incorporation of radioactivity from L-[U-^{14}C]valine into α-KIVA **1**, ketopantoyl lactone **5**, and pantoyl lactone **6** (which could derive from pantoate **3** or pantothenate **4**) demonstrates that these compounds are formed in plants and provides compelling evidence that the pathway to pantothenate in plants is similar to that in microorganisms. The fractionation protocol described in this paper should provide a handle, which has until now been elusive, to study the pathway to pantothenate in plants and to approach the isolation of the individual plant enzymes. This result complements the recent report of the purification of pantothenate kinase from spinach, where an HPLC protocol to look at phosphorylated intermediates on the common pathway between pantothenate and coenzyme A was described (17).

Experimental

HPLC elution conditions

DL-2,3-Dihydroxyisovaleric acid was prepared by the bis-hydroxylation of 3,3-dimethylacrylic acid (13). Ketopantoyl lactone was synthesized by the bromine oxidation of pantoyl lactone (14). Pantoyl lactone, α-KIVA (as the sodium salt), and 2-isopropylmalate were all purchased from Aldrich Chemical Co., Dorset, U.K. 2-Ketoisocaproate (as the sodium salt) was purchased from the Sigma Chemical Co., Dorset, U.K.

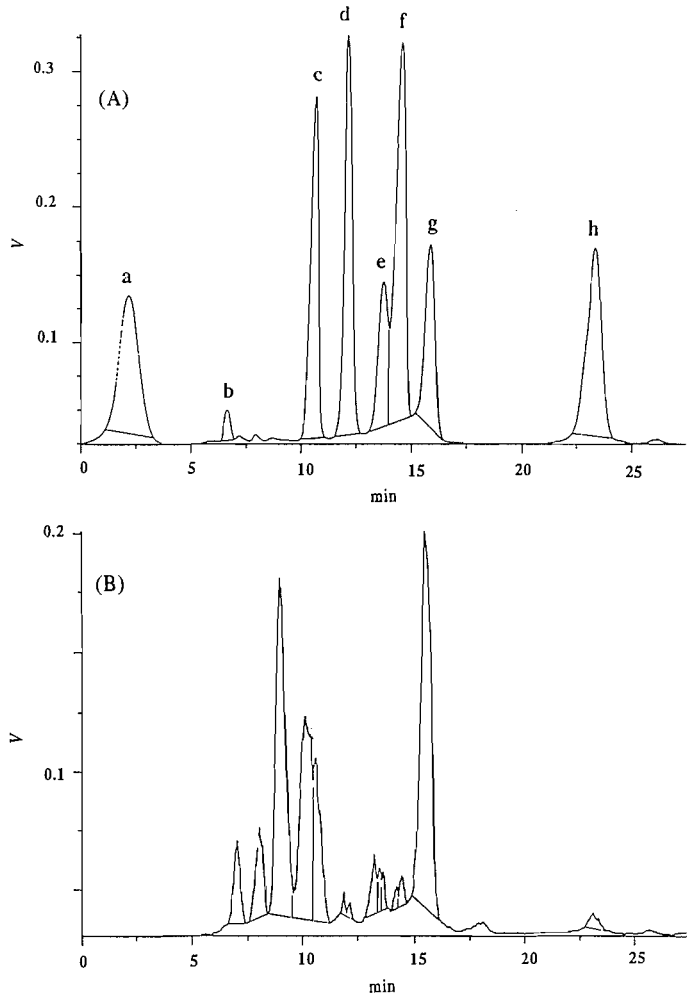

FIG. 1. (*A*) HPLC trace of a mixture of standards. Detection is by UV absorbance at 225 nm. Peaks a and b are due to unidentified impurities, peak c: α-KIVA **1**; d: dihydroxyisovalerate **7**; e: 2-isopropylmalate **9**; f: α-ketoisocaproate **11**; g: ketopantoyl lactone **5**; h: pantoyl lactone **6**. (*B*) HPLC trace of the organic acids fraction from the 4 h feeding experiment with L-[U-^{14}C]valine to pea leaf disks (four experiments combined). The ordinate measures radioactivity detected by a Reeve model 970 radioactivity detector fitted with a heterogeneous flow cell. All HPLC were run on a Bio-Rad Organic Acids column (300 × 7.8 mm) eluting with 4 mM sulphuric acid at a flow rate of 0.6 mL/min.

Standards (10–50 μg) or the fraction from the Sephadex SP-C-25-H^+ column from feeding experiments (10–150 μl) were analysed by HPLC on an organic acids column (Bio-Rad Laboratories Ltd., Hertfordshire, U.K.) (300 × 7.8 mm) containing Aminex HPX-87H resin. Samples were eluted with 4 mM sulphuric acid at a flow rate of 0.6 mL/min. Elution of samples from the column was monitored by UV absorbance at 225 nm and by radioactivity detection using a Reeve model 970 radioactivity detector (Reeve Analytical, Glasgow, U.K.), fitted with a heterogeneous flow cell. Retention times were found to vary by up to ±1 min over a period of months, so the column was calibrated with standards each time samples from feeding experiments were analysed.

Valine uptake by pea shoots

Pea seedlings (14 days old) were harvested and placed in a solution of 10 μL L-[U-^{14}C]valine (474 MBq/mmol, 85 kBq/mL) made up to 1 mL with distilled water. The stems were immediately recut under the surface. After 2 h the shoot was cut above the liquid surface and ground in a mortar with 1 mL distilled water. The sample was centrifuged for 5 min in a microfuge and the supernatant counted.

Valine feeding of pea leaf disks

Leaf disks (6 mm) were prepared from 14-day-old peas (*Pisum sativum* var Onward) using a cork borer, and were floated on distilled water before use. Leaf disks (seven per sample) were put in a small vial containing 100 μL L-[U-^{14}C]valine (10.4 GBq/mmol, 1.85 MBq/mL) and 400 μL distilled water. The vial was placed under vacuum for 15 min and illuminated by a bright light. The vacuum was slowly released and the samples left for 3–24 h. The supernatant was then carefully removed and the leaf disks washed three times with 5 mL distilled water. The disks were transferred to a mortar containing liquid nitrogen and 300 μL of an aqueous solution of authentic pathway standards (sodium 2-ketoisovalerate (60 μg), ketopantoyl lactone (120 μg), and pantoyl lactone (240 μg)) and ground to a fine powder. A solution of 0.4 M perchloric acid (1.5 mL) was added and the sample allowed to thaw before centrifuging in a microfuge for 5 min. The supernatant was applied to an Accubond SPE column® (Fisons Scientific Equipment, Loughborough, U.K.) to remove phenolic compounds. The column had been previously washed with 2 mL methanol and 2 mL 0.4 M perchloric acid. The sample was eluted in 4 mL 0.4 M perchloric acid, and the pH adjusted to 8–9 with 1 M KOH before evaporating to dryness. The resulting residue was resuspended in 300 μL distilled water and the pH adjusted to 7 with 0.1 M HCl.

Amino acids were removed by applying a 250 μL aliquot of the sample to a column of Sephadex SP-C-25-H^+ (18) (Sigma Chemical Co., Dorset, U.K.) prepared in a disposable Pasteur pipette to a bed height of 4 cm. The column had been previously equilibrated with 1.5 mL 7% formic acid, then rinsed with distilled water to neutral pH. The organic acids fraction was eluted with 1.5 mL distilled water, adjusted to pH 8 with 1 M KOH, and evaporated to dryness. It was resuspended in 250 μL 4 mM sulphuric acid and an aliquot (150 μL) analysed by HPLC. The amino acid fraction was eluted from the SP Sephadex column with 3 mL distilled water followed by 4.5 mL 0.3 M ammonium hydroxide.

MICHAEL A. BROOK, GRANT D. CROWE, and HENK HIEMSTRA. Can. J. Chem. **72**, 264 (1994).

Allyldimethylsilyl triflate **2** may be prepared by a protiodesilylation reaction between diallyldimethylsilane and triflic acid. This compound possesses both a silyl-substituted carbon nucleophile and the Lewis acid necessary for activation of an electrophile. Upon exposure to an aromatic aldehyde (e.g., *p*-$MeOC_6H_4CHO$), the homoallylic alcohol **4** is formed in good yield. The synthetic advantages of the intramolecular Cope-type cyclization reaction are discussed.

MICHAEL A. BROOK, GRANT D. CROWE et HENK HIEMSTRA. Can. J. Chem. **72**, 264 (1994).

On a préparé le triflate d'allyldiméthylsilyle (**2**) par une réaction de protiodésilylation entre le diallyldiméthylsilane et l'acide triflique. Ce composé possède à la fois un carbone substitué par un silyle qui peut agir comme nucléophile et l'acide de Lewis nécessaire à l'activation d'un électrophile. Mis en présence d'un aldéhyde aromatique (par exemple *p*-$MeOC_6H_5CHO$), l'alcool homoallylique **4** se forme avec un bon rendement. On discute des avantages en synthèse de la réaction de cyclisation intramoléculaire de type Cope.

[Traduit par la rédaction]

Introduction

The combination of silicon-based nucleophiles (enol silyl ethers, allylsilanes, vinylsilanes, etc.) and Lewis acid activated electrophiles is a powerful synthetic method for the construction of carbon–carbon bonds (1). Silyl nucleophiles react with a variety of electrophiles including carbonyl compounds, and, additionally, with those such as acetals and tertiary alkyl halides (2), "S_N1 electrophiles," which won't react with the usual organometallic reagents. For most of these reactions, stoichiometric or excess quantities of the Lewis acid "catalyst" are required.

Trimethylsilyl trifluoromethanesulfonate ($Me_3SiOSO_2CF_3$, TMSOTf)(3) is a very strong, monodentate Lewis acid (4) "catalyst" that will activate a variety of heteroatom-bearing electrophiles stoichiometrically, including carbonyl compounds (1) and imines (5). However, a more appealing combination is that of silyl enol ethers, carbonyl compounds, and TMSOTf, in which case the Lewis acid is truly catalytic (6). The carbon analogue of a silyl enol ether, an allylsilane, reacts much less efficiently with carbonyl compounds (acetals generally yield better results) and only in unusual cases may TMSOTf be successfully used catalytically (7).

We were interested in developing an allylsilane reagent which, by virtue of an intra- rather than an intermolecular coupling reaction with an electrophile, would be more efficient and which would ultimately require only catalytic amounts of a Lewis acid. It seemed possible that an allylsilyl triflate might possess these properties, particularly as the reaction with an aldehyde, for example, should be an intramolecular Cope-type cyclization (Scheme 1). If so, the potential exists for enhanced control of relative stereochemistry (bold bond, if R″ ≠ H). We report herein the feasibility of preparing allylsilyl triflates by the addition of triflic acid to diallylsilanes **1** and, subsequently, the reactivity of these species **2** towards carbonyl compounds.

Results and discussion

Preparation of the allylsilyl triflate

Allylsilanes readily react with electrophiles to give, usually (addition reactions have in some cases been observed: ref. 8), an S_E2' reaction involving loss of the silicon. With diallyldimethylsilane **1** as starting material, it was possible with triflic acid to cleave only one of the two allyl groups leading to **2** (Scheme 2). Depending on the conditions used, other products were also ob-tained. There was always a small amount of $Me_2Si(OTf)_2$ **5** formed. Changes in the reaction procedure (particularly solvent and temperature changes) could minimize but not completely suppress this. Any traces of water were manifested by the formation of isopropoxysilanes **6**, which, after subsequent complete hydrolysis of the reaction mixture, gave 2-propanol and **7**.[3]

In the hope of preparing completely pure **2**, a ligand redistribution reaction was attempted. In the silicone industry, the met-

[1]It is a great pleasure to dedicate this communication to Dave MacLean and to thank him for his support, friendship, and our scientific collaboration.

[3] ^1H NMR ($CDCl_3$, 200 MHz) **2**, δ: 0.49 (s, 6H), 1.92 (d, 2H, J = 8.2 Hz), 5.05 (m, 2H), 5.76 (apparent sextet, 1H, J = 8.2 Hz); **5**, δ: 0.87 (s, 6H); **6**, δ: 0.56 (s, 6H), 1.53 (d, 6H, J = 5.5 Hz), 1.73 (d, 2H, J = 6.8 Hz), 4.99 (m, 2H), 5.22 (sept, 1H, J = 5.5 Hz), 5.60 (m, 1H); $TfOMe_2SiOiPr$, δ: 0.56 (s, 6H), 1.53 (d, 6H, J = 6.2 Hz), 5.23 (sept, 1H, J = 6.2 Hz). Hydrolysis of the reaction mixture containing **2** led to the same product that results from the hydrolysis of $Me_2(H_2C{=}CH\text{-}CH_2)SiCl$, the known (9) disiloxane **7** $(H_2C{=}CH\text{-}CH_2SiMe_2)_2O$.

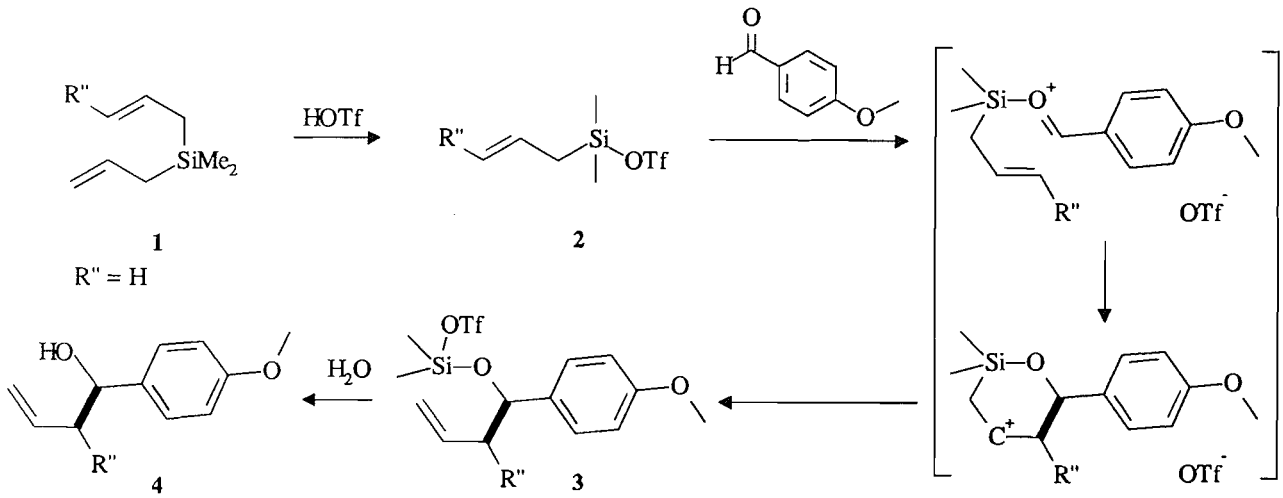
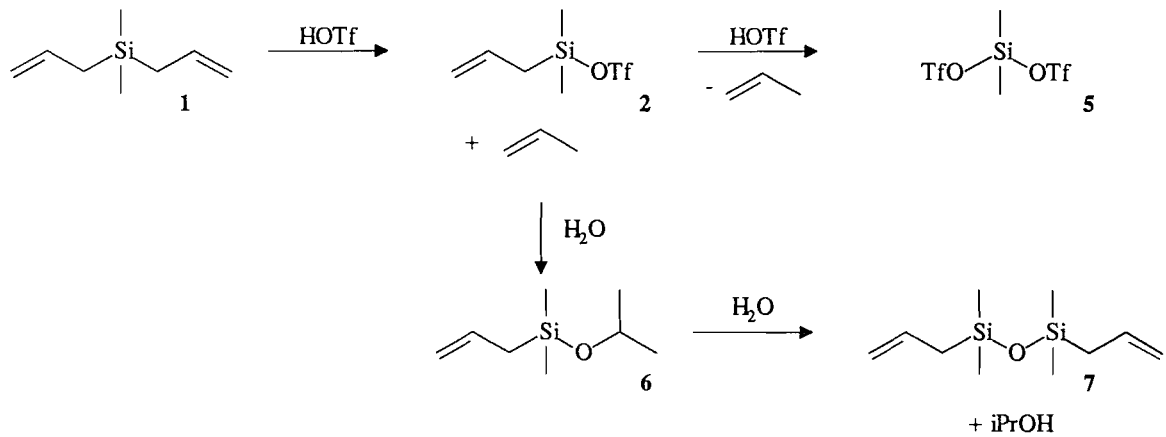


SCHEME 1



SCHEME 2

athesis of groups on silicon is an important preparative method, the efficiency of which depends upon the relative lability of the groups to be exchanged. For example, while halogens and alkoxy groups will redistribute without catalysts, less labile groups such as H and SiR_3 require weak catalysts such as $R_4N^+X^-$ salts, and unactivated alkyl groups require strong Lewis acids such as $AlCl_3$ (10). Although we expected that the silyl triflate would act as its own Lewis acid catalyst, a reaction between the ditriflate **5** and starting material **1** after refluxing at 61°C for 2 h led to a mixture of **1**, **5**, and **2**[4] (1:1:2, Scheme 3). We have yet to determine whether this represents the equilibrium mixture or whether longer reaction times, higher temperatures, or stronger catalysts[4] are required to force the equilibrium completely to the right.

Reaction of 2 with electrophiles

The normal mechanism for electrophilic attack at allylsilanes[5] is *anti*-S_E2' (7) in which case the silyl group does not directly interact with the electrophile·Lewis acid complex **8** (Fig. 1). To determine if the proposed cyclic transition state (Scheme 1) was reasonable, we examined three conformers as the carbenium ion goes from an "open" structure **9**, via a proposed structure on the reaction path in which the allyl terminus and carbonyl carbon distance is constrained **10** (α = 2.5 Å), to a fully cyclized, β-silyl stabilized cation **11**. Molecular models[6] indicate that a relatively small energy cost is associated with constraining the system in a ring (steric energy **10** = 16.6 kcal/mol, arising primarily from van der Waals terms) when compared to the acyclic minimum (steric energy **9** = 9.3 kcal/mol). More interestingly, the calculated torsional angles between the C—Si bond and the developing *p* orbital of ϕ = 12° and 38°, for **10** and **11**, respectively, are nearly optimal (0°) for the β-effect (12), a factor that will serve to stabilize the (developing) cyclic β-silyl carbocation and compensate for any increased van der Waals interactions. From these results, and in analogy with related radical six-ring cyclizations (13), the proposal of a cationic Cope-type cyclization seems reasonable.

With the allylsilyl triflate in hand, we examined its reactivity towards carbonyl electrophiles. Upon exposure of the solution

[4]If stronger catalysts are required, the redistribution technique would not be appropriate for our purposes. We want to have only one, **intramolecular** Lewis acid catalyst present and, furthermore, wish to avoid separating the hydrolytically unstable triflates from other Lewis acidic materials.

[5]In certain circumstances, when steric bulk interferes with *anti* attack (11*a*) or with electronwithdrawing groups such as fluorine on silicon (11*b*), *syn* attack of the electrophile may be observed.

[6]The structure was modeled using PCMODEL (Serena software, Bloomington, Indiana) with the parameters provided for C^+ "transition state" atoms.

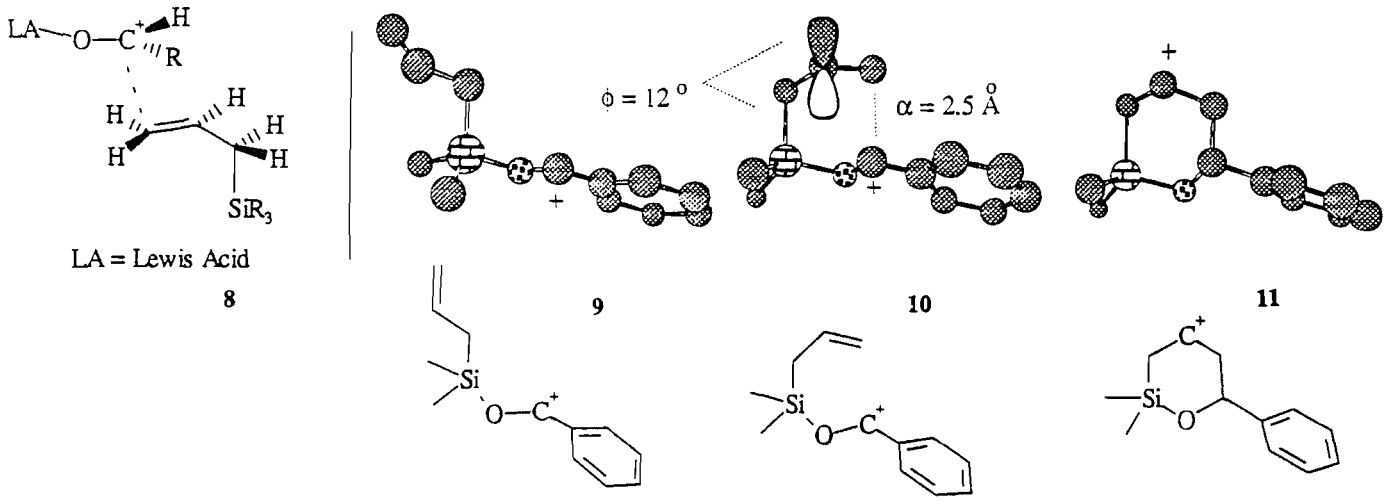

FIG. 1. **8**: Normal open *anti* approach of a Lewis acid activated aldehyde to an allylsilane. **9**: Minimized acyclic intermediate. **10**: Intramolecular *syn* approach, minimized with constraint α = 2.5 Å (resultant ϕ Si—C—C—p orbital = 12°). **11**: Fully cyclized structure (resultant ϕ Si—C—C—p orbital = 38°).

of **2** in $CHCl_3$ to *p*-$MeOC_6H_4CHO$, subsequent work-up,[7] and chromatography, the desired product **4** (14) was isolated in 78% yield (Scheme 1). While other aromatic aldehydes react similarly (PhCHO, 68% (15)), no reaction was observed with ketones such as cyclohexanone as the electrophile source.[8]

We performed a kinetic study to differentiate between an intermolecular, second-order reaction between the allylsilane component and a Lewis acid activated ketone and the proposed first-order, intramolecular cyclization reaction. The reaction between benzaldehyde and the allylsilyl triflate at −62°C in $CDCl_3$ was shown to be first order, consistent with the hypothesis of a cyclic transition state.[9]

Conclusion

Using diallylsilyl compound **1**, it is possible to perform sequential electrophilic addition, desilylation, substitution reactions. The first, with triflic acid, leads to the formation of a silyl nucleophile **2**, which, since it bears a triflate group, is also Lewis acidic. Thus, the addition of a second electrophile, an aldehyde, results in a Cope-type, self-catalyzed condensation giving **4**. In addition to the potential diastereoselective benefits that should arise from a cyclic transition state in the second reaction (Scheme 1, R″ ≠ H), it may be possible to develop related systems in which the active Lewis acidic silyl triflate is present in true catalytic rather than in stoichiometric quantities. Our examination of these questions and the reactivity of other carbon electrophiles will be reported in due course.

Acknowledgment

We gratefully acknowledge the financial support of this research by the Natural Sciences and Engineering Research Council of Canada, and thank the Netherlands' Organisation for the Advancement of Pure Research (NWO) for providing a Visiting Scientist Fellowship to M.A.B.

[7]Typical experimental procedure: To **1** (0.2 mL, 1.0 mmol) in $CHCl_3$ (4 mL) under N_2 at −78°C was added TfOH (0.08 mL, 0.95 mmol). After 45 min, *p*-$MeOC_6H_4CHO$ (0.11 mL, 0.9 mmol) was added. After 2 h, the solution was allowed to warm to 0°C, during which time the solution colour changed from yellow to blue-purple. Following quenching with $NaHCO_3$ solution and extraction with ether, **4** was isolated following flash chromatography (Et_2O: petroleum ether 2:5).

[8]We have not determined whether the reaction does not occur or whether silylation of the enol takes place (3). In the latter case, after hydrolysis, the cyclohexanone would be recovered.

[9]This interpretation is predicated on the interaction between the Lewis acidic silyl triflate and the aldehyde being rapid compared to the rate-determining cyclization.

Separation of metal-cyanide complexes by reversed-phase ion-interaction high-performance liquid chromatography

LOUIS GIROUX[1] AND DWIGHT J. BARKLEY[2]

Core Technologies and Services Laboratory, Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology, Energy, Mines and Resources Canada, 555 Booth Street, Ottawa, ON K1A 0G1, Canada

Received January 5, 1993[3]

LOUIS GIROUX and DWIGHT J. BARKLEY. Can. J. Chem. **72,** 269 (1994).

Reversed-phase ion-interaction chromatography has been used to study the separation of Cu(I), Ag(I), Ni(II), Au(I), Co(III), Fe(III), and Fe(II) cyano complexes on silica and carbon-based reversed-phases with UV detection at 215 nm. Separation of the metal-cyanide complexes was affected by a number of experimental factors including the nature and concentration of the organic modifier, nature and concentration of the ion-pairing reagent, pH, and ionic strength of the mobile phase. Differences between the elution order of metallo-cyanides observed in the present work and in other investigations under similar experimental conditions are explained by a difference in the ionic strength of the mobile phase. Finally, this technique is used to analyze metal-cyanide complexes in a gold mill solution.

LOUIS GIROUX et DWIGHT J. BARKLEY. Can. J. Chem. **72,** 269 (1994).

La chromatographie d'appariement d'ions a été utilisée afin d'étudier la séparation de métallo-cyanures de Cu(I), Ag(I), Ni(II), Au(I), Co(III), Fe(III) et Fe(II) sur des colonnes à polarité de phases inversées de silice et de carbone avec détection UV à 215 nm. La séparation de ces complexes est influencée par de nombreux paramètres tels le type et la concentration du solvant organique, le type et la concentration de l'ion compensateur ainsi que par le pH et la force ionique de la phase mobile. Les différences entre l'ordre d'élution des métallo-cyanures observés dans la présente étude et au cours de travaux antérieurs sous des conditions expérimentales semblables sont expliquées en fonction de la variation de la force ionique de la phase mobile. Finalement, la technique est utilisée afin d'analyser la teneur en complexes métallo-cyanures d'une solution provenant d'un réservoir situé à proximité d'une mine d'or.

Introduction

In aqueous solution, cyanide can exist in different distinguishable forms. "Free cyanide" represents both CN^- ion and molecular HCN in a solution. They may come from alkali metal-cyanides or metallocyanide complexes that dissociate or decompose to varying extents. This kind of cyanide is the most toxic. On the other hand, "complexed cyanide" is coordinated to an element and is therefore bonded inside a complex. The most important cyano complexes involved in environmental issues are those of iron, copper, zinc, nickel, cobalt, and cadmium. Formation constants for these complexes are well established ranging from a low for $Cd(CN)_4^{2-}$ ($\log \beta = 18.9$) to a high for $Co(CN)_6^{3-}$ ($\log \beta = 64.0$) (1). The toxicity of this kind of cyanide is controlled by the acidity of the medium (toxicity increases as pH decreases) and to the amount of exposure to sunlight.

There are four ways to express cyanide levels in environmental samples: total cyanide, weak acid dissociable cyanide, cyanide amenable to chlorination, and free cyanide. Total cyanide is the amount determined by the acid reflux/distillation method; it includes weak acid dissociable cyanide and cyanides contained in all metallo-cyanide complexes except those of gold, cobalt, and platinum which do not release cyanide under any usual analytical conditions. Weak acid dissociable cyanide includes the cyanide ion, hydrogen cyanide, and cyano complexes of cadmium, copper, nickel, silver, and zinc but not those of iron (ferro and ferricyanides). Cyanide amenable to chlorination is the difference between the total amount of cyanide before and after chlorination; it is a measure of the ionisable cyanide species present in a sample (non-ionisable cyanide species are not oxidized by chlorine). In the gold processing industry, cyano complexes of cadmium, zinc, etc. (i.e. complexes with formation constants of $\log \beta < 20$) are also considered free cyanides.

The above procedures only lead to a partial differentiation of the various categories of cyanides in a solution. These methods can be subject to interference from components that are usually present along with the cyanide in samples from gold mill operations: sulphides, reduced sulphur compounds, and thiocyanates produced in the ore treatment process or with oxidizing agents such as chlorine (2). Furthermore, it is documented that different metallo-cyanides can exhibit varying degrees of environmental persistence and toxicology. For example, labile complexes such as $Cd(CN)_4^{2-}$ and $Zn(CN)_4^{2-}$ are less persistent and more toxic to fish than the more stable $Cu(CN)_3^{2-}$ and $Ni(CN)_4^{2-}$. On the other hand, strong metallo-cyanides, $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$, by virtue of their high formation constants, could tentatively be expected to show limited toxicity. However, they are also known to photodecompose into free cyanides upon exposure to light (3). All these factors clearly indicate the need for more complete speciation studies, particularly in view of the widespread use of cyanide in gold extraction.

In reversed-phase ion-interaction chromatography, both stationary and mobile phases are the same as in regular reversed-phase techniques. A pairing-ion, usually hydrophobic, is also added to the mobile phase. Samples from this mode of separation are ionisable and can form an ion-pair with the pairing-ion. In the case of separation of metal-cyanide anions ($M(CN)_n^{z-ny}$, where $ny > z$), the pairing-ion present in the mobile phase is a cation, and is typically a quaternary ammonium ion.

Back in 1985, Pohlandt (4) was the first to use ion-interaction

chromatography to separate and quantify metal-cyanide complexes in gold processing solutions. Since then, several groups from Australia (5, 8) and South Africa (6, 7) have used the same method to separate metallo-cyanides. They have successfully applied the principle of ion-interaction chromatography to analyze precious metals in gold processing solutions and metallurgical and plant samples.

The main objective of this paper is to comment on the significant differences in the elution order of cyanometallate complexes of Cu(I), Ag(I), Ni(II), Au(I), Co(III), Fe(III), and Fe(II) on C_{18} and on the carbon-based reversed phases observed in our study and those of other scientists (5, 6, 8). This paper also discusses the effect of changing variables as (*i*) the nature and concentration of the organic modifier, (*ii*) the nature and concentration of the ion-pairing reagent, (*iii*) pH, and (*iv*) ionic strength of the mobile phase on the chromatographic separation of anionic cyano complexes at 215 nm. Finally, we have applied the reversed-phase ion-interaction chromatographic technique to determine the amount of metallo-cyanide in a leach liquor originating from a reservoir located near a Canadian gold mine.

Experimental

HPLC system

The HPLC system consisted of a Spectra Physics precision isocratic pump (Model 8810, Spectra Physics, San Jose, CA), a Spectra Physics SP 8810 autosampler with a Valco sample valve and a 50 μL sample loop, and a variable wavelength detector (Linear UVIS-200, Reno, NV) operating at 215 nm. The signal from the detector was monitored with a Spectra Physics SP-4270 computing integrator.

Three silica-based C_{18} reversed-phase columns (150 × 4.6 mm) were used in this study: (*i*) Supelcosil LC-18-DB (5 μm particle size), (ii) Millipore-Waters Nova-Pak C_{18} (4 μm particle size), and (*iii*) Du Pont – Zorbax R_x-C_{18} (5 μm particle size). These columns are restricted to mobile phases in the pH range 2–8. A crosslinked organic polymer (styrene–divinylbenzene) column, Interaction/ACT-1 (150 × 4.6 mm, 10 μm particle size), and a porous graphite column, Shandon-Hypercarb (100 × 4.6 mm, 7 μm particle size), were also used in this study. The last two columns are reported to be stable from pH 0–14.

Atomic absorption instrument

Atomic absorption spectroscopic analysis of the metals in a gold mill solution was performed with a GBC Model 908 AAS instrument (Dandenong, Australia).

Reagents and procedures

Mobile phases

Mobile phases were prepared using water purified with a Millipore (Bedford, MA) Milli-Q water treatment system, Burdick and Jackson of Canada LC-grade organic solvents (acetonitrile, methanol, ethanol, acetone, or tetrahydrofuran forming binary mixtures with water), an appropriate ion-interaction reagent and an inorganic modifier, NaH_2PO_4 (J.T. Baker Inc., Canada).

The ion-interaction reagents used were the tetraalkylammonium hydroxide series, $R_4N^+OH^-$ where R = C_1–C_4 (Sigma Chemical Co., St. Louis, MO) and the alkyltriethylammonium phosphate series, $R(C_2H_5)_3N^+H_2PO_4^-$ where R = C_5–C_8 and C_{12} (Regis Chemicals, Morton Grove, IL).

The mobile phases were filtered immediately prior to use through 0.45 μm Millipore-type membrane filters and degassed before use. An adjustment to the ionic strength of the mobile phases was made by adding NaH_2PO_4. The ionic strength values quoted in this paper are calculated using *solely* the concentration of the phosphate salt, taking into account the pH dependency of phosphate species ($H_2PO_4^-$ and HPO_4^{2-}), and do *not* include the concentrations of the pairing-ion reagent salts. The pH of the mobile phases were measured with a Corning Model 250 pH meter equipped with a glass–calomel electrode.

Metal-cyanide complexes

Standard solutions of the cyanide complexes of Zn(II), Au(I), Co(III), Fe(II) (Aldrich Chemical Co., Milwaukee, WI), Cd(II), Ni(II) (Alpha Inorganics, Beverly, MA), and Fe(III) (Allied Chemicals, New York, NY) were prepared by dissolving weighed amounts of the respective potassium salts in 0.1 M NaOH (BDH Inc., Canada). Solutions containing Cu(I) and Ag(I) complexes were prepared by the dissolution of CuCN (BDH Inc., USA) and AgCN (Fisher Scientific Ltd., Canada) with stoichiometric amounts of KCN (J.T. Baker Inc., Canada) in 0.1 M NaOH. Standard solutions containing mixtures of the metal-cyanide complexes were prepared from the individual standard solutions. Standard solutions were kept at an alkaline pH and stored in darkness to minimize degradation (3).

Most of the results reported in this investigation were obtained at a mobile phase pH of approximately 8. At this pH, individual complexes and mixtures of the various complexes are found to be appreciably more stable than at pH less than 8. When the pH of the eluent is lowered from 8 to 6, we observe (*i*) an increase in retention times for the cyanometallates and (*ii*) increasingly broader and unsymmetrical peaks caused by a greater dissociation of the complexes.

Gold mill sample

The metal-cyanide complexes were from a leach liquor sample from a Canadian gold mine.

Chromatographic separations

All separations were carried out at room temperature using a mobile-phase flow-rate of 1.0 mL min^{-1}. Each time we used a new column, or each time we studied the characteristics of a new mobile phase mixture, we allowed the analytical column to equilibrate with eluent for 1 h. Metallo-cyanides were identified by retention times. Under our chromatographic conditions, we were able to get absorption peaks for all complexes except Cd(II) and Zn(II) cyanides. These complexes were very weakly absorbing at 215 nm and at the same time decompose in the mobile phase, hence they were not studied further. Our method yielded reasonable results only when special care was taken to prepare the eluent because small variations in the concentrations of the mobile phase components had a marked effect on the retention times of the complexes.

Results and discussion

As mentioned in the Introduction, the focus of this paper is to explain the significant differences between our elution sequence of metal-cyanide complexes and those from other studies under apparently similar experimental conditions. Let us first make a few general comments on the effect of certain experimental parameters on the separation of anionic cyano complexes using reversed-phase ion-interaction chromatography.

Nature and concentration of the organic modifier

When using ion-interaction techniques to separate solutes, retention times and selectivities are markedly dependant on the mobile-phase composition and, in particular, on its organic solvent (9–11). By increasing the concentration of the organic modifier, acetonitrile or methanol, in the mobile phase, there is a decrease in retention times of the complexes on C_{18} columns, as has been observed (5, 6). We picked acetonitrile over methanol as the organic modifier since it provided a better resolution of the eluted complexes. When the concentration of the organic modifier in the mobile phase remains constant (32–40% v/v of acetonitrile), the complex retention times are longer on the carbon-based column because of its hydrophobic character (12).

Nature and concentration of the ion-interaction reagent

In reversed-phase ion-interaction systems, the anionic reten-

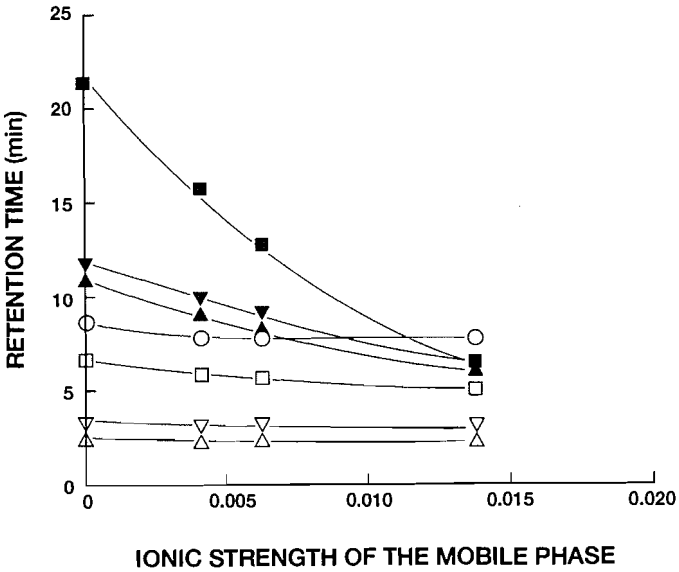

FIG. 1. Effect of ionic strength of the mobile phase on retention times of metal-cyanide complexes. As described in the text, the ionic strength values given in this figure are based exclusively on the concentrations of the phosphate species (Na_2HPO_4 and NaH_2PO_4) and *not* on the concentrations of the tetrabutylammonium ion; e.g. an ionic strength of zero, $I = 0$, refers to eluents prepared *without* the presence of phosphate ions. Experimental conditions: *column*, Waters Nova-Pak C_{18}; *mobile phase*, 4 mM tetrabutylammonium ion $(C_4H_9)_4N^+$, 32% v/v of acetonitrile, NaH_2PO_4 for ionic strength adjustment and pH = 8; *flow rate*, 1 mL min^{-1}; *detector*, UV at 215 nm; *sample volume*, 50 μL. Symbols for the cyanide complexes are as follows: △: Cu(I), ▽: Ag(I), □: Ni(II), ○: Au(I), ▲: Co(III), ▼: Fe(III), ■: Fe(II).

tion times increase with increasing pairing-ion (cation) concentration (9). Furthermore, increased pairing-ion concentration (e.g. tetrabutylammonium) leads to an increased retention of the metallo-cyanide complexes on the C_{18} columns. This observation, as reported by other workers (4, 6, 8), is attributed to an increase in the effective ion exchange capacity of the column.

The retention times of solutes also change with the type of pairing-ion. We have used the tetraalkylammonium series, where alkyl = C_1–C_4, and the alkyltriethylammonium series, where alkyl = C_5–C_8 and C_{12} straight chain groups in our studies while maintaining a constant pairing-ion concentration of 5 mM. Our results show that the tetrabutylammonium pairing-ion is more effective in separating the various metallo-cyanate complexes (4).

pH of the mobile phase

The mobile phase pH can be a useful parameter for achieving and optimising selectivity in reversed-phase liquid chromatography (13). When the pH of the mobile phase was lowered from 8 to 6, retention times increased for most complexes. A change in pH, however, had no effect on the retention time of the silver complex and led to a decrease in retention time for the copper complex. A possible explanation for an increased retention time of the five complexes at pH = 6 is that there is a greater ratio of di-to-monohydrogen phosphate ions $[H_2PO_4^-] = 14.3[HPO_4^{2-}]$, as calculated from the ionisation constant $K_2 = 7 \times 10^{-8}$.

Ionic strength

When the ionic strength of the mobile phase increases, the formation of ion-pairs generally decreases since the secondary ions compete to form ion-pairs with the pairing-ions (14). A plot of the ionic strength of the mobile phase on the retention time of the metal-cyanide complexes is shown in Fig. 1. Most complexes show shorter retention times. The greatest change is found in Fe(II) cyanide. At zero-ionic strength (based *exclusively* on the concentration of the phosphate species in the eluent, see Experimental), Fe(II) and Fe(III) cyanides are well separated; however, they were coeluted at an ionic strength of about 14×10^{-3}. At pH 8, adding phosphate ions (HPO_4^{2-} and $H_2PO_4^-$) to the mobile phase seems to reduce the electrostatic interaction between the most negatively charged Fe(II) complex (−4) and the pairing-ion more so than other complexes. Low negatively charged complexes such as Cu(I) (−2), Ag(I) (−1), and Au(I) (−1) show no change in their retention times.

By varying the ionic strength in the mobile phase there are changes in retention times and the elution order of metal-cyanide complexes. We shall elaborate on the second point in the following paragraph.

Elution order of metal-cyanide complexes

In this study, the cyano complexes elution order is identical to that reported by one group (7) but quite different from that reported by other groups (5, 6, 8).

In our study, when the mobile phase (i.e. organic solvent (acetonitrile), ion-interaction reagent (tetrabutylammonium hydroxide), and inorganic modifier (NaH_2PO_4)) were identical, all three silica-based C_{18} columns (Supelcosil, Waters, and Du Pont) gave essentially the same elution order for the complexes. The only difference between the Supelcosil column and the Waters and Du Pont columns was for Co(III) and Au(I) complexes; Co(III) is eluted earlier on the Supelcosil column and retained longer on both the Waters and Du Pont columns at relatively low ionic strengths ($<7 \times 10^{-3}$, again based *only* on the concentration of the phosphate species, see Experimental section) in the mobile phase. Pohlandt-Watson and Hemmings (7) used a similar Supelcosil column under similar mobile phase conditions and obtained essentially the same results (Cu(I), Ag(I), Ni(II), Co(III), Au(I), Fe(III), and Fe(II)). Our elution order was Cu(I), Ag(I), Ni(II), Au(I), Co(III), Fe(III), and Fe(II). Grigorova et al. (6) and Haddad and co-workers (5, 8), using a Waters Nova-Pak C_{18} column, observed the order Cu(I), Ag(I), Fe(II), Co(III), Ni(II), Fe(III), and Au(I). Here Grigorova et al. used a mobile phase of 2.5 mM tetrabutylammonium hydrogen sulphate – methanol (70:30 v/v), and Haddad and co-workers used a mobile phase of 5 mM tetrabutylammonium hydroxide – acetonitrile (77:23 v/v) (5) or 5 mM tetrabutylammonium chloride and/or bromide–acetonitrile (76:24 v/v) (8). In our work, while we have used a number of mobile phases consisting of various concentrations of ion-interaction reagents (e.g. tetraalkylammonium hydroxide or alkyltriethylammonium phosphate series), inorganic modifier (NaH_2PO_4), and organic solvents (acetonitrile, methanol, ethanol, acetone, or tetrahydrofuran), our best separation was achieved by using 4 mM tetrabutylammonium hydroxide – acetonitrile (68:32 v/v) for the mobile phase adjusted to a pH of about 8 with NaH_2PO_4.

The following are the major differences in mobile phases used in our work and those of Grigorova (6) and Haddad (5, 8): (*i*) counter-anion: HPO_4^{2-} and $H_2PO_4^-$ (major) and OH^- (minor) in our work HSO_4^-, Cl^-, Br^-, and OH^- in references 5, 6, and 8 bound to the cationic ion-pairing reagents containing a

complex	mg L^{-1}
$Cu(CN)_3^{2-}$	0.7
$Ag(CN)_2^-$	7.3
$Ni(CN)_4^{2-}$	4.0
$Au(CN)_2^-$	5.1
$Co(CN)_6^{3-}$	4.5
$Fe(CN)_6^{3-}$	3.7
$Fe(CN)_6^{4-}$	3.0

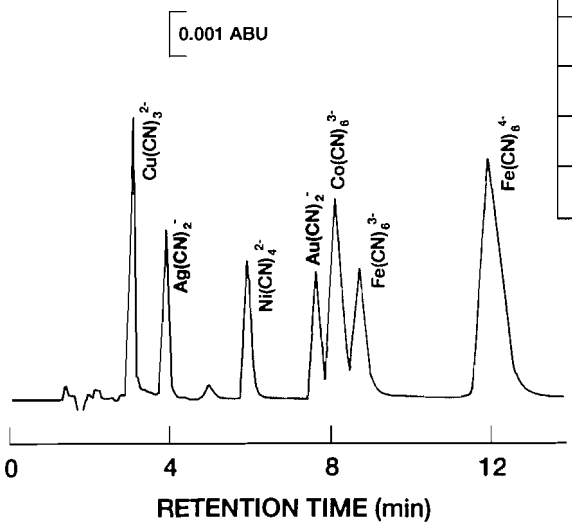

FIG. 2. Chromatogram of a synthetic mixture. Experimental conditions: *column*, Du Pont-Zorbax R_x-C_{18}; *mobile phase*, 4 mM tetrabutylammonium ion $(C_4H_9)_4N^+$, 35% v/v of acetonitrile, 1.25 mM NaH_2PO_4 and pH = 8; *flow rate*, 1 mL min^{-1}; *detector*, UV at 215 nm; *sample volume*, 50 μL.

quaternary nitrogen atom (R_4N^+, where R = C_4H_9 for most separations) and (*ii*) the presence of an inorganic modifier (NaH_2PO_4) in our work and none in references 5, 6, and 8. Haddad and Kalambaheti (8) and this group agreed that counter-anions only change the retention times of complexes (longer retention times for HPO_4^{2-}, $H_2PO_4^-$, and OH^- ions than Cl^- and Br^- ions) and *not* on their elution order. However, Pohlandt has shown that by adding inorganic modifiers (borates, carbonates, hydroxide, and phosphates) to the mobile phase the relative positions of the iron cyanide complexes, Fe(II) and Fe(III), in the chromatograms are affected (4). Furthermore, depending on the nature and concentration of the salt, the elution order for iron and gold complexes may be changed while the order of the other metallo-cyanides remains unchanged. For example, when the concentration of carbonate – hydrogen carbonate mixture added is less than 0.5 mM, the iron cyanide complexes were eluted after the gold complex but when the concentration is greater than 1.02 mM, iron cyanide complexes were eluted before the gold complex. Figure 1 illustrates the change in elution order of the complexes upon increasing the ionic strength of the mobile phase. At ionic strengths less than 6.5×10^{-3} (based exclusively on the concentration of phosphate species), an elution order of Cu(I), Ag(I), Ni(II), Au(I), Co(III), Fe(III), and Fe(II) is obtained on the Waters column, an order identical to that observed by Pohlandt-Watson and Hemmings (7) on a Supelcosil column. At ionic strengths between 7 and 9×10^{-3}, the elution orders for the Au(I) and Co(III) complexes are reversed. Furthermore, Au(I) complex is eluted before Fe(III) and Fe(II) complexes at ionic strengths of 9 and 11.5×10^{-3}, respectively. At an ionic strength of about 14×10^{-3}, the elution order takes the form Cu(I), Ag(I), Ni(II), Co(III), Fe(II) and Fe(III) co-eluted, and Au(I). A simple extrapolation of the ionic strength from 14×10^{-3} to approximately 20×10^{-3} (based on the concentration of phosphate ions only, as before) tentatively yields an identical elution order (Cu(I), Ag(I), Fe(II), Ni(II), Co(III), Fe(III), and Au(I)), as that found by Grigorova et al. (6) and Haddad and co-workers (5, 8), both of whose studies must have been carried out at ionic strengths somewhat higher than ours. To conclude, the ionic strength of the mobile phase is important to the elution order of metallo-cyanide complexes on silica-based columns. Different elution orders were observed depending on the ionic strength of the mobile phase and the presence of inorganic modifiers such as NaH_2PO_4. This work uses a Waters Nova-Pak C_{18} column and moderately low ionic strengths ($< 6 \times 10^{-3}$) whereas other workers used somewhat higher ($> 15 \times 10^{-3}$) ionic strengths (5, 6, 8).

Analysis of metal-cyanide complexes in a gold mill solution

Before analyzing a gold mill sample, we first analyzed complexes mixtures. Their calibration curves were linear over the concentration range 0.2 to 10 mg L^{-1}. A typical chromatogram is shown in Fig. 2. Figure 3 shows the gold mill complexes and their concentrations. The amount of metal deduced from concentrations of cyano complexes from liquid chromatographic (LC) method and atomic absorption spectrometry (AAS) showed good agreement except for copper, which was approximately 2.5 times higher by the LC determination (Table 1).

The higher Cu concentration might be attributed to a positive interference by UV-absorbing anions present in the sample and appear as interfering peaks in the final chromatogram (8) (such as Br^-, NO_2^-, NO_3^-, and SCN^-; SCN^- being the most likely present in gold mill effluents (2)). Although the gold mill sample was not analyzed for thiocyanate (SCN^-) in aqueous solution (16), this ion has a strong absorption band maximum in the far ultraviolet spectrum ($\epsilon \sim 3 \times 10^3$ M^{-1} cm^{-1}) at approximately 46 000 cm^{-1} (217 nm) which is near our detection wavelength (215 nm). Fagan and Haddad, using similar condi-

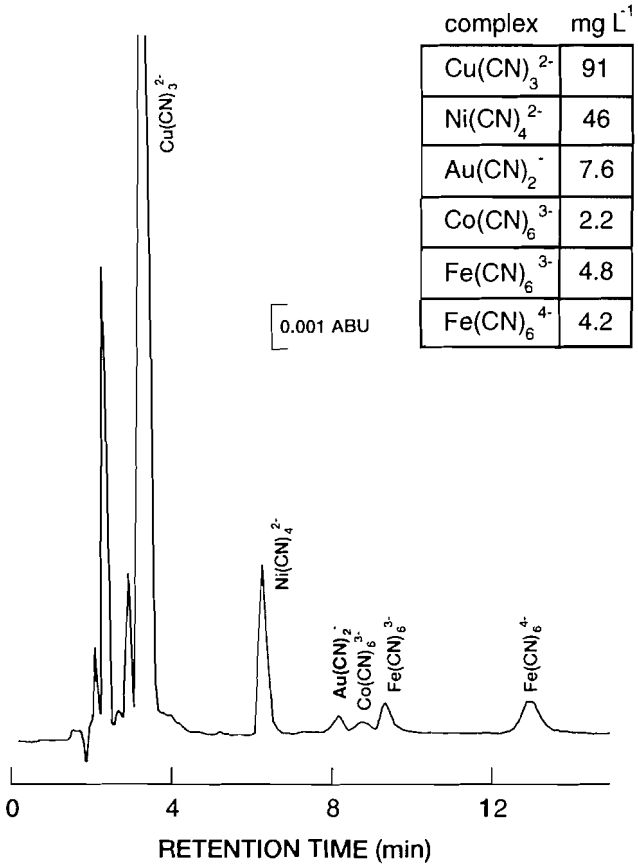

FIG. 3. Chromatogram of a gold mill solution from a Canadian mine. Experimental conditions: same as in Fig. 2.

tions, showed the thiocyanate ion to elute immediately before the copper(I) cyanide complex (17).

Conclusions

Reversed-phase ion-interaction chromatography can separate Cu(I), Ag(I), Ni(II), Au(I), Co(III), Fe(III), and Fe(II) cyanide complexes on silica-based C_{18} reversed-phase columns. These columns exhibited greater efficiency, selectivity, and stability than organic polymer and porous graphite columns which were used in the preliminary stages of our study. The difference between the elution orders of metallo-cyanides we observed and those in other studies was due to the difference in ionic strength of the mobile phase. Our procedure was simple and fast and usually took less than 15 min. The lower detection limit for cyanometallate complexes was about 0.1 mg L^{-1}. Our method can also be used to analyze gold mill samples, thus enabling the Canadian gold mining industry to better monitor metal-cyanide levels.

Acknowledgments

Financial support for this project and the permission to publish this paper was granted by the Department of Energy, Mines and Resources Canada. The authors wish to extend sincere thanks to L. McCullogh for his assistance in the AAS measurements, to S. Duguay, C. Glasgow, and E. Hinchberger for their help in the preparation of figures, and to P. Carrière, G. Laflamme, V. McNamara, Dr. G. Deschênes, and Dr. P. Riveros for useful discussions.

Analysis of alkyl ketene dimer (AKD) by potentiometric titration

S. NYARKU[1] AND B. BRUCE SITHOLÉ[2]

Process Chemistry Division, Pulp and Paper Research Institute of Canada, 570 St. John's Boulevard, Point Claire, QC H9R 3J9, Canada

Received August 13, 1993

S. NYARKU and B. BRUCE SITHOLÉ. Can. J. Chem. **72,** 274 (1994).

A simple and precise potentiometric titration method has been developed for the determination of milligram quantities of alkyl ketene dimer (AKD) in non-aqueous solvents. It involves the addition of chloroform solutions of AKD to an excess of an organic base followed by the titration of excess base with perchloric acid in glacial acetic acid. The method was used to determine non-reacted AKD extracted from hand-sheets: our results agreed with those obtained by capillary gas chromatography. The method was also used to monitor the stability of AKD formulations. Wood resin components and stearone, a hydrolysis product of AKD, do not interfere.

S. NYARKU et B. BRUCE SITHOLÉ. Can. J. Chem. **72,** 274 (1994).

Un titrage potentiométrique simple et précis nous permet de déterminer la concentration de dimère d'alcanes cétèniques (AKD), de l'ordre du milligramme, dans des solvants non-aqueux. Une solution d'AKD dans du chloroforme est ajoutée à une base organique de concentration excessive et la base résiduelle est par la suite titrée avec de l'acide perchlorique préparée dans de l'acide acétique glaciale. Cette méthode a été utilisée pour la détermination de la quantité d'AKD non-réagi, extraite de formettes, et les résultats correspondent à ceux obtenus par chromatographie capillaire en phase vapeur. La méthode a également servi à vérifier la stabilité des formulations d'AKD. Les composés de la résine du bois ainsi que la stéarone, un produit de l'hydrolyse de l'AKD, n'interfèrent pas.

Introduction

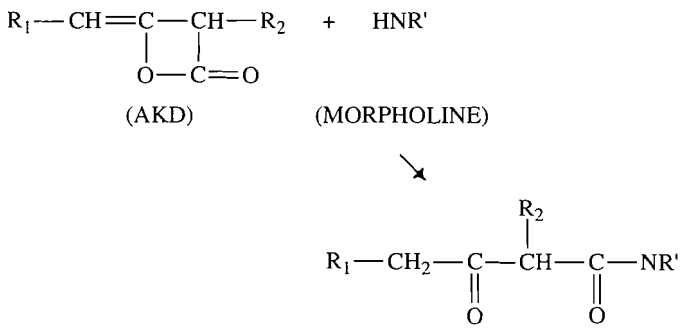
Alkyl ketene dimer (AKD) is a sizing agent commonly used in neutral and alkaline papermaking. It belongs to a class of reactive sizes which react with cellulosic fibres to render the surface hydrophobic (1, 2). Sizing efficiency depends on several factors including retention, particle distribution on the fibre surfaces, spreading, and the extent of chemical reaction of the size. Several forms of AKD exist in alkaline papermaking systems. First, there is some evidence (3, 4) that it can bond chemically to hydroxyl groups of cellulosic fibres to form β-keto esters producing the required sizing effects and properties. This form is commonly called reacted or bound AKD. At best, only about 50% of the AKD reacts to affect the sizing of the paper (5, 6). It is therefore important to know the fate of the non-reacting AKD. Second, AKD can be physically adsorbed on the surface of paper fibres without chemical bonding; this form is called non-reacted or unbound AKD. Non-reacted AKD also contributes to sizing. However, reacted AKD is about three times more efficient (4). Third, AKD may be hydrolyzed to form keto-acids and ketones. Finally, when AKD does not interact with paper fibres and is not retained in the paper, it can be found in process waters in both unchanged and hydrolyzed forms. Therefore, in alkaline papermaking it is important to determine the proportion of the AKD added that is retained in the paper and the proportion of AKD added that exists in other forms, in order to properly understand the sizing process.

A number of methods have been used to analyze AKD. The more widely used methods involve the hydrolysis of AKD to yield a ketone (stearone), or the methylation of AKD to form keto-esters, followed by the analysis of stearone or keto-esters using chromatographic techniques, notably HPLC and GC (1, 6–8). GC mass spectrometry and pyrolysis GC have been used recently (9, 10). Radioactive tracer studies with ^{14}C have also been used to determine the proportion of reacted and unreacted AKD on paper fibres (5) while solid state NMR studies have been conducted with ^{13}C-labelled AKD (11). Ultrasonic attenuation of paper in water has been correlated with the amount of AKD in paper (12). The unique absorption band of AKD by its four-membered lactone ring at 1860 cm^{-1} in the infrared spectrum has been used both to identify and to quantify the dimer (13). Spectrophotometric techniques have been investigated, and used to investigate the effect of ageing on sizing (14).

This paper reports a new titration procedure developed to analyze AKD. The procedure, based on titrimetry, offers some advantages over chromatographic techniques.

Theory

Ketones and diketenes are known to react with organic bases (15). This reaction can be used to measure concentrations of AKD by first reacting AKD with an excess base, and then measuring the excess base by titrimetry. In this report morpholine was selected as the base mainly because, as a secondary amine, it is less susceptible to interferences than other bases bearing primary amino groups. The reaction of AKD with morpholine may be represented by



The developed procedure involves the addition of excess morpholine to AKD, followed by potentiometric back-titration of the excess morpholine with perchloric acid in acetic acid.

Experimental

1. Materials

An AKD sample and an AKD emulsion (as used in alkaline papermaking mills) were obtained from a supplier in the paper industry. ACS reagent quality morpholine and perchloric acid were used as purchased without further purification. HPLC grade solvents were used in all investigations. A Metrohm 655 Dosimat automatic titrator connected to a Corning pH meter (Model 130) with a combination electrode was used for potentiometric titrations. Measurements were taken on the relative potential scale. The system was interfaced to a simple Apple computer system with a software program which gave a screen display of the progress of the titration and also allowed for determination of the titration end-point. As the titrations were done under non-aqueous conditions, all glassware and apparatus were dried carefully in an oven to ensure that the titrations would work properly.

2. Preparation of perchloric acid solution in acetic acid

An approximately 0.10 M perchloric acid solution was prepared by adding 4.3 mL 69–72% perchloric acid in 100 mL glacial acetic acid, followed by 15 mL acetic anhydride. The resulting mixture was allowed to cool for about 30 min before diluting to 500 mL with glacial acetic acid. This solution was then standardized with potassium hydrogen phthalate (KHP).

3. Standardization of perchloric acid solution with KHP

The perchloric acid solution was standardized by potentiometric titration with KHP. KHP (0.1064 g) was added to 25 mL glacial acetic acid and the mixture was heated gently to assist the dissolution of the solid. After cooling, the resulting solution was potentiometrically titrated with the perchloric acid, using the system described above. Three drops of a visual indicator, crystal violet, were added to display a purple-to-green colour change at the end-point. This change was sharp enough to be used as a visual indicator. However, in this work all end-point volumes were determined by a second derivative titration plot.

4. Preparation of morpholine solution in chloroform

Morpholine has a molar mass of 87.12 g/mol and a density of 0.996 g/mL. The approximately 0.10 M stock solution used in the experiments was prepared by diluting 0.90 mL morpholine with chloroform to 100.0 mL in a volumetric flask.

5. Standardization of morpholine solution with perchloric acid

Morpholine solution (5.00 mL) was transferred to a 100 mL titration beaker, followed by 20 mL chloroform. The mixture was titrated potentiometrically with standardized perchloric acid.

6. Titration of morpholine after the addition of AKD

Morpholine solution (5.00 mL) was added to 10.00 mL of 10 000 ppm AKD solution, followed by 10 mL chloroform. The mixture was allowed to stand for 15 min before potentiometric titration with the perchloric acid solution. The titration was repeated with larger volumes of the AKD solution and a calibration curve prepared from the results.

7. Precision

Precision of the titration procedure was determined by titration of 5 replicate samples of the same AKD solutions.

8. Interferences

The interferences of wood resin and stearone on the titration procedure was investigated by titration in the presence of 5.00 mL of 1000 ppm solutions of resin acids, fatty acids, tall oil, or stearone. The results were compared to the values obtained in the absence of the compounds.

9. Reaction kinetics

These were determined by titration of replicate samples which had been allowed to equilibrate for 15, 30, 60, 130, 250, 360, 400, and 500 min. The data points were analyzed to determine the reaction rate.

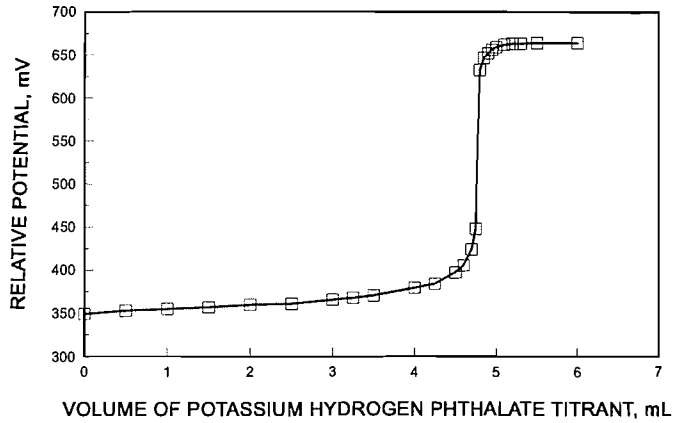

FIG. 1. Standardization of perchloric acid by potentiometric titration with potassium hydrogen phthalate.

10. Effect of the addition of various solvents

Due to the formation of a precipitate during the titration process, various solvents were used to determine their effect on the titration curves and the formation of the precipitate. The solvents investigated were acetone, acetonitrile, and toluene; these were chosen because of their polarity indices and their ability to dissolve AKD.

11. Stability of AKD mill emulsions

AKD emulsions can hydrolyze to yield stearone which is not effective in sizing and causes sticky deposition problems in pulp and papermaking (5). Conditions which induce hydrolysis include high temperature and change in pH of the AKD formulation (5). For example, recommended shelf lives of commercial emulsions are 2 weeks, 4 weeks, and 1 year at storage temperatures of 32°C, 24°C, and 4°C, respectively. It would be useful to have an easy method that could be used to monitor the stability of emulsions. A sample of an AKD emulsion was made to hydrolyze rapidly by adjusting its pH from 2.5 to 6 and equilibrating overnight. The original and hydrolyzed samples were then analyzed by the titrimetric procedure on 1 mL portions of the emulsions.

12. Unreacted AKD in paper

Handsheets sized with AKD were prepared in the laboratory using a Mark V Dynamic Handsheet Mold.[3] The handsheets were pressed at 420 kPa, dried on a cylinder speed dryer at 105°C, and cured for 10 min in an oven at 110°C. The unreacted AKD in the paper was extracted with chloroform (10) and the chloroform extracts were evaporated to known small volumes before analysis for AKD content by the potentiometric titration procedure. The results were confirmed by analysis of the same extracts by capillary gas chromatography (4).

Results and discussion

Figure 1 shows a typical titration curve for the standardizations of perchloric acid where the endpoint is clearly defined. Figure 2 shows a typical titration curve for the standardization of morpholine. During titration a precipitate was observed at a titre reading of about 2.00 mL, accompanied by a drop in the relative potential reading, as indicated by a bend in the initial rise of the titration curve. Second derivatives of titration plots were used to determine the end-points in all titration experiments. Titrations of the morpholine solution in the presence of

[3]B.B. Sitholé et al. In preparation.

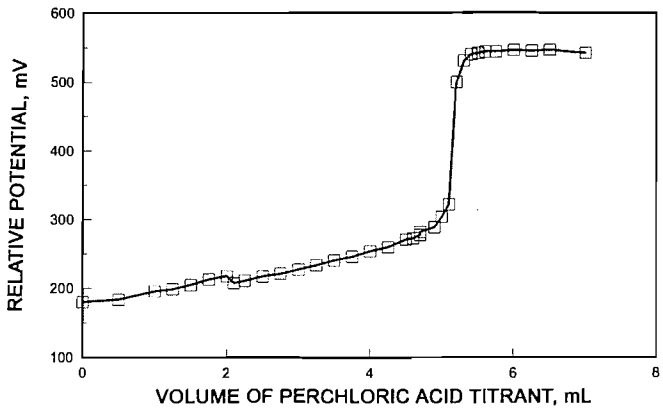

FIG. 2. Potentiometric titration of morpholine with perchloric acid.

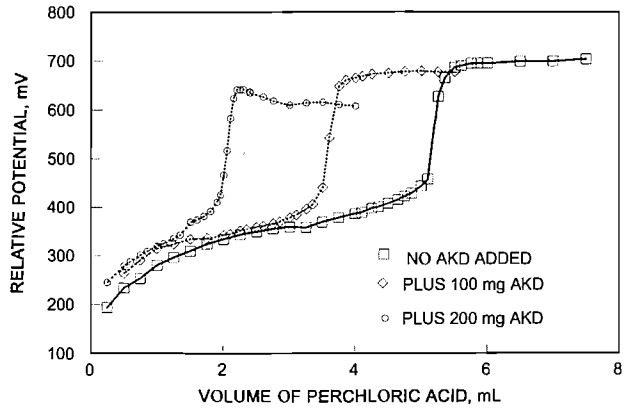

FIG. 3. Potentiometric titration of morpholine with and without AKD present.

AKD are shown in Fig. 3. From these titrations a linear calibration curve was prepared (Fig. 4) which was used to determine concentrations of unknown AKD solutions in the 1% range such as AKD formulations used in alkaline paper mills.

For lower concentrations of AKD more dilute solutions are required to prepare a calibration curve. Such a calibration curve, prepared by titrations with 0.0010 M stock solutions (100-fold dilutions of the solutions used in Fig. 4), could easily be described by the equation:

$$Y = -1.00 \times 10^{-3}X + V$$

where Y is the concentration of added AKD in ppm; X is the volume, in mL, of perchloric acid used to titrate the excess morpholine; V is the volume, in mL, of perchloric acid used to titrate the blank; and 0.001 is the slope of the straight line. This calibration curve was suitable for determining small amounts of AKD retained in paper.

The results of the precision studies, shown in Table 1, indicate good reproducibility of the technique, and the relative standard deviation was 1%. Although the formation of precipitates did not affect the titration end-points it was decided to investigate solvents which did not produce precipitates. No precipitates formed in the presence of polar solvents like acetone and acetonitrile; toluene, a non-polar solvent, caused the precipitate to occur earlier than in the case of chloroform alone. From these results it was decided to add acetone to the samples prior to titration to eliminate the formation of precipitate. Thus, subsequent experiments were performed in the presence of 5.0 mL of acetone.

Wood resin components and stearone did not interfere with the titration procedure, indicating that the procedure can be used to evaluate the stability of AKD emulsions and to determine the concentration of AKD in chloroform extracts of paper.

Kinetic studies

The reaction of AKD and morpholine may be represented by

	AKD + morpholine	⟶	AKD – morpholine
at time zero	a		
at time t	$a-x$		

a is the initial concentration of AKD, $a - x$ is the concentration of AKD remaining at time t, and x is the concentration of AKD – morphine generated, then for a first order reaction, the reaction rate is

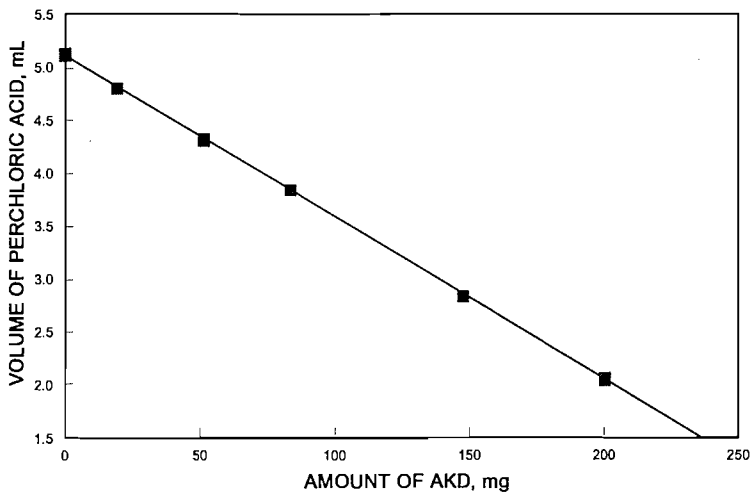

FIG. 4. Calibration curve for potentiometric titration of AKD with morpholine after equilibration for 15 min (200 mg AKD is equivalent to 20 mL of 10 000 ppm AKD solution).

TABLE 1. Reproducibility of the titration procedure – titration of 1.00 mL 5000 ppm AKD solution in 10 mL of 0.001 M morpholine

Sample	End-point, mL
1	5.480
2	5.393
3	5.416
4	5.348
5	5.320
Average	5.391±0.062

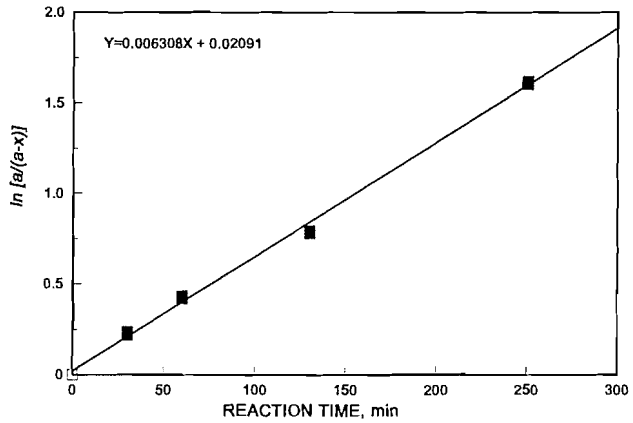

FIG. 5. Kinetics of the reaction between AKD and morpholine — a first order reaction.

$$\frac{dx}{dt} = k(a - x)$$

and the integrated equation is

$$\ln \frac{a}{a - x} = kt$$

When $\ln a(a - x)$ is plotted against time t, a straight line passing through the origin is obtained. The kinetic data indicate a first order reaction of AKD with morpholine (Table 2 and Fig. 5). It takes 6 h to complete a reaction between AKD and morpholine. However, it is not necessary to wait for all the AKD to be consumed before analysis; reproducible results were obtained if the samples were equilibrated for equal times, e.g., 15 min when about a fifth of the AKD will have been consumed. The kinetics are such that the concentration of AKD does not change much during the titration period.

Using the titration method to determine the amount of AKD extracted from paper

Titration was used to determine the amount of non-reacted AKD in laboratory-made papers sized with 2000 and 5000 ppm AKD. The amount of unreacted AKD in the chloroform extracts of the papers was determined first by titration and then by capillary GC. Table 3 (triplicate determinations) shows the good agreement between the two methods. Hence titration can be used in studies pertaining to AKD retention in alkaline papermaking.

Using titration to monitor the stability of AKD emulsions

Analysis of AKD emulsions showed there was 93.06 and 81.06% AKD in the original and hydrolyzed samples, respectively; thus hydrolysis caused a 13% loss of AKD in the hydrolyzed sample. Studies have shown that about 15% of the reactive diketene groups in commercial formulations are lost after 5 weeks storage at room temperature (16). The potentiometric titration result indicates the potentiometric procedure can be used to monitor the stability of AKD emulsions at mills as the equipment used is easily available. The method is much less cumbersome than analysis by gas chromatography which would entail drying aliquots of the emulsions, dissolution in chloroform, filtration, and derivatization of the AKD in the extracts before analysis.

TABLE 2. Kinetic data for the reaction of AKD with morpholine at room temperature

Reaction time t, min	Concentration of AKD found, ppm	$\ln a/(a - x)$
0	0	0
30	1222	0.239
60	1992	0.4269
130	3123	0.7869
250	4594	1.616
360	5733	—
400	5733	—
500	5733	—

TABLE 3. Comparison of the amounts of AKD in chloroform extracts by titration and GC analysis

	Concentration of unreacted AKD, ppm	
	Titration method	GC method
Sample 1: 2000 ppm AKD added	250, 247, 252	249, 248, 250
Sample 2: 5000 ppm AKD added	750, 753, 748	766, 768, 779

Conclusions

A new potentiometric method for the analysis of AKD has been developed and used to determine AKD amounts in sized paper samples and to monitor stability of AKD emulsions. Wood resin components and AKD hydrolysis products do not interfere in the analysis. Linear calibration curves were obtained for ppm samples and for samples in the percent range. This method is much faster and less cumbersome than chromatographic techniques.

G.V. SHUSTOV, A.V. KACHANOV, I.I. CHERVIN, R.G. KOSTYANOVSKY, and A. RAUK. Can. J. Chem. **72,** 279 (1994).

Structural features, configurational stability, and chiroptical properties of the nonplanar amide group in α-lactams were investigated by means of ab initio (6-31+G*) molecular orbital calculations on (1*R*)-aziridinone **1**, (1*R*)-1-methylaziridinone **2**, (1*R*,3*R*)-3-methylaziridinone **3**, (1*R*,3*R*)-1,3-dimethylaziridinone **4***a*, its *cis* diastereomer (1*S*,3*R*)-1,3-dimethylaziridinone **4***b*, and (1*R*,3*R*)-3-*tert*-butyl-1-methylaziridinone **5**, and by experimental CD spectra of 1-*tert*-butyl- and 1-(1′-adamantyl)-substituted 3(*R*)-3-*tert*-butylaziridinones **6** and **7**. The nitrogen inversion barriers of **4***a* and **4***b* are 2.8 and 1.6 kcal mol^{-1}, respectively. The lowest excited singlet state of all of the aziridinones is a valence state (the n_O–π_{CO}* transition); the second is a Rydberg state (the n_N–3*s* transition). The signs of the first and second Cotton effects in the CD spectra of the compounds **6** and **7** coincide with the calculated ones for **1** and **2** and the *trans* isomers **3**, **4***a*, and **5**. According to the calculated and experimental data for aziridinones **1–7** as well as to the well-known data for other nonplanar amides, the sign of the first Cotton effects is determined by the intrinsic chirality of the nonplanar amide chromophore and obeys a spiral rule. For cases where the chromophore has the conformation around the N—C(O) bond, which is close to the antiperiplanar, a reverse octant rule is proposed.

G.V. SHUSTOV, A.V. KACHANOV, I.I. CHERVIN, R.G. KOSTYANOVSKY et A. RAUK. Can. J. Chem. **72,** 279 (1994).

On a étudié les caractéristiques structurales, la stabilité configurationelle et les propriétés chiroptiques du groupe amide non planaire des α-lactames en faisant appel à des calculs d'orbitales moléculaires ab initio au niveau (6-31+G*) sur la (1*R*)-aziridinone **1**, la (1*R*)-1-méthylaziridinone **2**, la (1*R*,3*R*)-3-méthylaziridinone **3**, la (1*R*,3*R*)-1,3-diméthylaziridinone **4***a* ainsi que son diastéréoisomère *cis*, la (1*S*,3*R*)-1,3-diméthylaziridinone **4***b* et la (1*R*,3*R*)-3-*tert*-butylazirinidone **5** et à des expériences de dichroïsme circulaire (DC) sur 1-*tert*-butyl- et 1-(1′-adamantyl)-(3*R*)-3-*tert*butylaziridinones **6** et **7**. Les barrières à l'inversion de l'azote pour les composés **4***a* et **4***b* sont respectivement de 2,8 et 1,6 kcal mol^{-1}. L'état singulet excité le plus bas pour toutes les aziridinones est un état de valence (la transition n_O–π_{CO}*) et le deuxième est un état de Rydberg (la transition n_N–3*s*). Les signes des premier et deuxième effets Cotton (EC) observés dans les spectres de DC des composés **6** et **7** coïncident avec ceux calculés pour **1** et **2** et les isomères *trans* **3**, **4***a* et **5**. Sur la base des données expérimentales et calculées pour les aziridinones **1–7** ainsi que les données bien connues pour d'autres amides non planaires, le signe du premier EC est déterminé par la chiralité intrinsèque du chromophore de l'amide non planaire et il obéit à la règle de la spirale. Dans les cas où la conformation autour de la liaison N—C(O) du chromophore est pratiquement anti-périplanaire, on propose une inversion de la règle de l'octant.

[Traduit par la rédaction]

Introduction

A nonplanar amide group is contained in β-lactam antibiotics (1) and found in peptides (2). Unusual chemical and spectroscopic properties associated with the group, as well as the potential pharmacological activity of nonplanar amides, have attracted a great deal of attention (3). Most recently, these compounds were used for modelling the action of proteolitic fermenting reagents (4*a*), with respect to the problem of the origin of rotation barriers (4*b*), and as effective chiral reagents (4*c*). Hence there is great importance to recognition of the presence of the nonplanar amide group and to the determination of the absolute stereochemistry of compounds containing it. Both problems can be solved simultaneously by means of CD spectroscopy on the basis of the wavelength of the first (long wavelength) Cotton effect (CE) (3*a*) and using chiral rules connecting the sign of the CE with the stereochemistry of a molecule (3*a*, 5). It goes without saying that for the confident application of these rules and for the establishment of their limits, it is necessary to study the chiroptical properties of as a wide a range of nonplanar amides as possible. From this standpoint, 1,3-dialkylaziridinones (α-lactams), obtained earlier (6) in optical active form, are of special interest. The pyramidal configuration of the nitrogen atom and, therefore, the nonplanarity of the amide group in the ground state of α-lactams are established by X-ray diffraction (7) and confirmed by quantum chemical calculations (3*c*, 8). Weakening of the amide conjugation follows from the data of IR (3*a*, 3*c*, 9*a*), UV (9*b*), and PE spectra (9*a*, 9*c*).

A peculiarity of α-lactams, in comparison with other nonplanar amides, is incorporation of the N—C(O) amide bond into the strained three-membered ring. In the present work, an attempt to elucidate an influence of this peculiarity on the stereochemistry and the chiroptical properties of the amide chromophore was undertaken. For this purpose, ab initio quantum chemical calculations have been carried out on a series of aziridinones, including the parent molecule **1**, *N*-methylaziridinone **2**, (3*R*)-3-methylaziridinone **3**, the *cis* and *trans* isomers of (3*R*)-1,3-dimethylaziridinone **4***a* and **4***b*, and (3*R*)-1-methyl-3-*tert*-butylaziridinone **5**. The structure of the transition state to nitrogen inversion in **4**, **4-TS**, was also determined. For all compounds, the theoretical chiroptical properties were calculated. Experimentally, the CD spectra of two (3*R*)-1,3-dialkylaziridinones, **6**, and **7**, have been studied. The compounds **6** and **7**

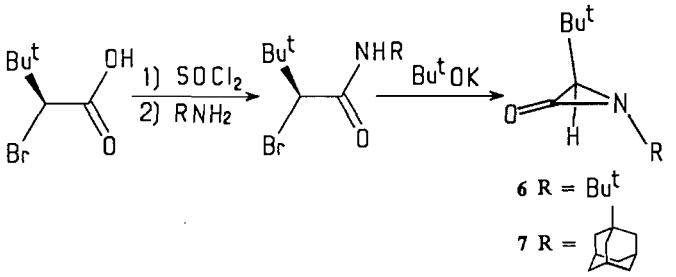
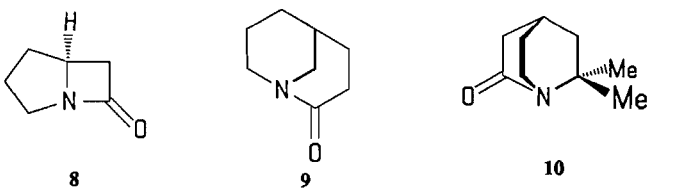
were obtained by cyclization of the corresponding amides of (*S*)-α- bromo-3,3-dimethylbutyric acid (Scheme 1). The (*R*)-absolute configuration at the C3 atom of aziridinones **6** and **7** follows from the stereochemistry of the cyclization.



SCHEME 1

The possibilityof the application of a spiral rule (3*a*, 5) and a reverse octant rule (5*b*) to different instances of the nonplanar amide chromophore have been analyzed on the basis of the present aziridinone study, as well as by existing data on the chiroptical properties of other relatively rigid nonplanar amides, i.e., (1*S*,4*R*)-1-azabicyclo[3.2.0]heptan-7-one **8** (10*a*) (1*R*,5*R*)-1-azabicyclo[3.3.1]nonan-2-one **9** (10*b*), and (1*R*,4*S*)-6,6-dimethyl-1-azabicyclo[2.2.2]octan-2-one **10** (footnote 2).



Results and discussion

Ab initio calculations were carried out earlier (3*c*, 8*b*) only for the parent aziridinone **1**, and only for its stationary states. We have carried out calculations on the parent, as well as on a number of alkylsubstituted aziridinones (Fig. 1). In particular, (3*R*)-1,3-dimethylaziridinone **4** and (3*R*)-1-methyl-3-*tert*-butylaziridinone **5** are more realistic models of the obtained α-lactams, which are stable only with N and C3 substituents (6, 11). Owing to constraints imposed by the small ring, the nitrogen atom has a pyramidal configuration in the ground state of aziridinones and, together with the carbonyl, forms the intrinsically chiral nonplanar amide group (Fig. 1). The out-of-plane angle (β, Fig. 1) is 51° for the two N—H aziridinones **1** and **3**, and 43°, 43°, and 44° for the *N*-methyl and *trans*-dialkylaziridinones **2**, **4***a*, and **5**, respectively. The nitrogen pyramid in the *cis*-dimethylaziridinone **4***b* is more flattened (β = 39°) owing to steric repulsion of the methyl groups. Even the modest flattening of the nitrogen pyramid in the *cis* isomer **4***b* leads to strengthening of the n_N–π_{CO}^* amide conjugation that is expressed in some shortening of the N—C(O) bond (−0.008 Å). Only a slight lengthening of the C=O bond (+0.002 Å) is calculated. The largest change of the bond lengths along this line is observed at reaching the nitrogen inversion transition state **4-TS**, which has the maximum amide conjugation. Nevertheless, even in the transition state **4-TS**, the nitrogen arrangement is not exactly planar (β = 2°), a consequence of the nonsymmetrical substitution at the C3 atom. The methyl group at the nitrogen atom has the *cis* orientation with respect to the methyl group at C3. Thus, the transition state **4-TS** is closer to the *cis* isomer **4***b* than to *trans*-**4***a* on the inversion coordinate.

It is of interest to note the nonplanarity of the carbonyl C2 atom in all of the computed structures, the distortion from planarity being always to the same side of the ring as the

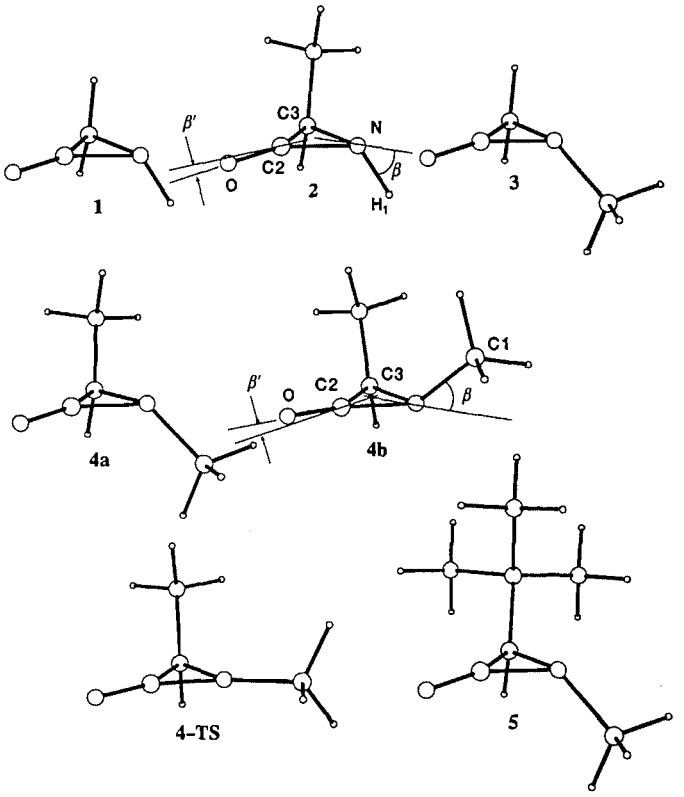


FIG. 1. Structures optimized at the 6-31 + G* level. FIG. 2. The two upper occupied MOs involved in the electronic transitions of aziridinone **4***a*. Contour values, 0.075.

N-substituent or *anti* to the orientation of the N lone pair. It can be supposed that the nonplanarity of the C2 atom is connected with the asymmetrical environment on the side of the nitrogen atom or rather with the sp^n hybridization of the nitrogen lone electron pair, but not with the effect of the C2 atom insertion into the three-membered ring, because the transition to **4-TS** with almost planar nitrogen arrangement and with almost pure *p*-character of the nitrogen lone pair leads to the virtually complete flattening of C2 atom ($\beta' = 0.7°$ in **4-TS**). It is well known that in three-membered rings an overlapping of *cis*-oriented vicinal sp^n orbitals (the dihedral angle between the orbital axes is 0°) is more than the overlap of *trans*-oriented orbitals (12) (the dihedral angle is about 110°). Therefore, the *cis* orientation of the carbonyl with respect to the *N*-methyl group in compounds **1–5** is as expected for maximum n_N–π_{CO}* overlap.

The inequality of the outer valence angles at the carbonyl C2 atom, which is more pronounced than observed for other lactams (13), is a general structural feature of aziridinones. Evidently, as also observed elsewhere (13), the positive difference $\angle$C3C2O − $\angle$NC2O = 7.8 ± 0.9° in the valence angles (Fig. 1) is caused by the interaction of the nonbonding n_O orbital of the carbonyl oxygen with the Walsh orbitals of the aziridinone ring: a destabilizing interaction with the occupied orbital of the C2—C3 bond and a stabilizinginteraction with the antibonding orbital of the C2—N bond. An admixture of the Walsh orbitals with the n_O orbital in MO 23 (HOMO) and MO 22 (HOMO-1) may be seen on Fig. 2.

The nitrogen inversion barriers were determined for the *trans* and *cis* isomers of 1,3-dimethylaziridinone (**4***a* and **4***b*). The barriers, 2.8 kcal mol^{-1} and 1.6 kcal mol^{-1}, which should be typical for 1,3-dialkylaziridinones, in general, are less than that calculated for *N*-formylaziridine (≈6 kcal mol^{-1}) (5*a*). Undoubtedly in both the cases (aziridinone **4** and *N*-formylaziridine), the stabilization of the inversion transition state by the n_N–π_{CO}* amide conjugation is the main reason of the low pyramidal stability of the nitrogen atom, as is the case with unstrained amides. A characteristic feature of the electronic structure of the *N*-acylaziridine moiety, namely a stabilizing interaction between the π_{CO}* orbital and an occupied Walsh orbital of the ring, may be responsible for the higher barrier to inversion in *N*-acylaziridines. This interaction is not available in any conformation of aziridinones or in the (nearly) planar transition state to inversion in the *N*-acyl compounds.

Thus, the nonplanar amide group in α-lactams is more configurationally labile than in *N*-acylaziridines. However, unlike the latter, the inversion of the intrinsic chirality of this group is carried out only by the nitrogen inversion path and can be effectively controlled by the steric interaction of substituents at the N and C3 atoms. Indeed, assuming $\Delta S^0 = 0$, the calculated difference in energies of the *trans* and *cis* isomers **4***a* and **4***b* (Fig. 1) gives their ratio 88.7:11.3. Although we did not pursue the point with **5** because of its size, it is reasonable to expect that in the case of more bulky *tert*-alkyl N and C substituents in aziridinones **6** and **7**, the equilibrium is shifted completely towards the *trans* isomer.

An intense negative band of the dichroic absorption is observed in the 250-nm region of the CD spectra of (3*R*)-aziridinones **6** and **7** (Table 1, Figs. 3 and 4). The band sign coincides with the calculated sign for the CE of the first (lowest energy) electronic transition of each of the aziridinones investigated theoretically, with the exception of the *cis* diastereomer **4b** (Table 2). Aziridinones **1** and **2** do not possess an asymmetric carbon atom, but the sense of twist of the α-lactam chromophore is the same as in **3**, **4***a*, and **5**, and opposite to that found in **4***b*. The (3*R*)-*cis* isomer **4***b* has the rotational strength of the first transition with opposite sign. Therefore, the first CE sign in the CD spectra of aziridinones is determined only by the nitrogen configuration. The latter determines the chirality of the whole amide group. Right-spiral chirality (positive torsion O=C—N—C1 angle) corresponds to the (*S*)-absolute configuration of the nitrogen atom in aziridinones **1–3**, **4***a*, and **5**, and vice versa (**4***b*).

At first glance, there appears to be a discrepancy between the calculation and experiment in respect of the second CE of (3*R*)-*trans*-aziridinones. Thus, according to the calculation, the second CE of **4***a* and **5** has the same sign (negative) as the first CE (Table 2), while the short-wavelength part (at 200 nm) of the experimental CD spectra of aziridinones **6**, and **7** is characterized by a positive dichroic absorption (Table 1, Fig. 3). However, the moderate asymmetry of the 250-nm CD absorption band of both **6** (Fig. 3) and **7** (Fig. 4) suggests the possibility of a second negative component to the short-wavelength side of the first. Decomposition of the observed band at 250 nm in the CD and UV spectra of aziridinones **6** and **7** into their Gaussian components permits an additional CE near 230 nm, coinciding in sign with the first CE (Table 1, Fig. 4). Nevertheless, the experimental ratio of both the rotational and oscillator strengths of the first and second Gaussian components (Table 1) is significantly different from the ratio that is predicted theoretically (Table 2) for both **4***a* and **5**. It is of interest to note that the coincidence in sign between the first and second transitions is pre-

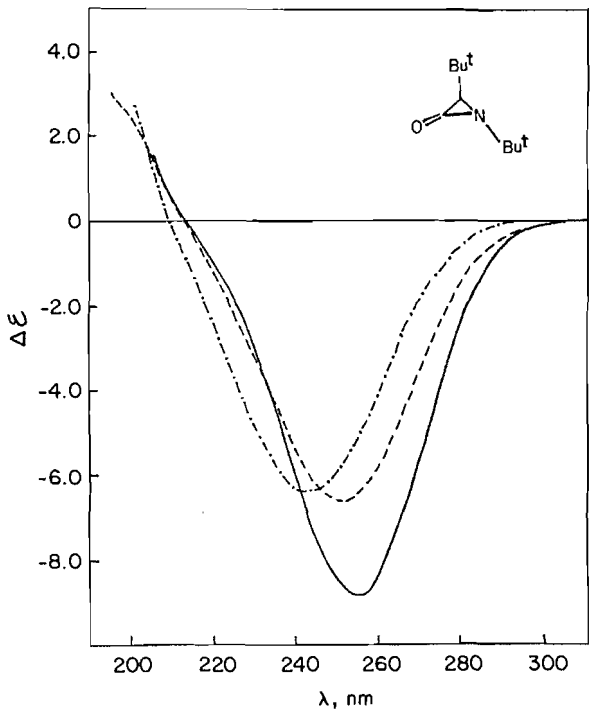

FIG. 3. The CD spectra of aziridinone **6** in heptane (—), gaseous phase (---) (see footnote *d* in Table 1), and MeOH (-·-).

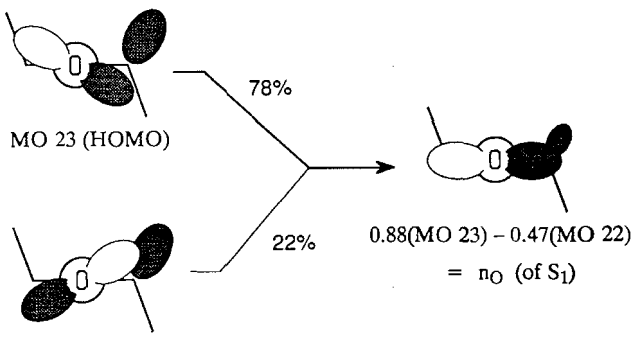
dicted for the three *N*-alkylated aziridinones **2**, **4***a*, and **5**. In the case of the N—H aziridinones **1** and **3**, a strong CE of opposite sign is predicted for the second transition.

According to the calculations, only the first excited singlet state of aziridinones is a valence state. The next higher excited states have been determined as Rydberg states (Table 2). The first electronic transition is to the antibonding π_{CO}^* orbital and the second one is to a diffuse orbital which may be loosely described as a molecular 3*s* orbital (Fig. 5).Unlike the Rydberg transition, the first transition is not pure in the sense that it originates from a single canonical MO. One may deduce the initial orbital of the first electronic transition (i.e., the lower singly occupied MO), by examining the configurational mixing (5*b*) which comprises the lowest excited singlet state. The state description is dominated by two sets of configurations, one with MO 23 as the initial orbital and the other with MO 22 (Fig. 2). Both sets terminate in the same MO, the π_{CO}^* orbital (Fig. 5). As a result of such treatment, for example for *trans*-aziridinone **4***a* (Scheme 2), the initial orbital of the first transition is found



SCHEME 2

as almost pure 2*p* orbital of the carbonyl oxygen, lying in the ring plane and containing a minimum contribution of the nitrogen orbitals. Therefore, the first electronic transition of aziridinones can be described as the $n_O \rightarrow \pi_{CO}^*$ transition. The low values for the computed and experimental oscillator strengths (Tables 1 and 2) are consistent with such an assignment. Thus

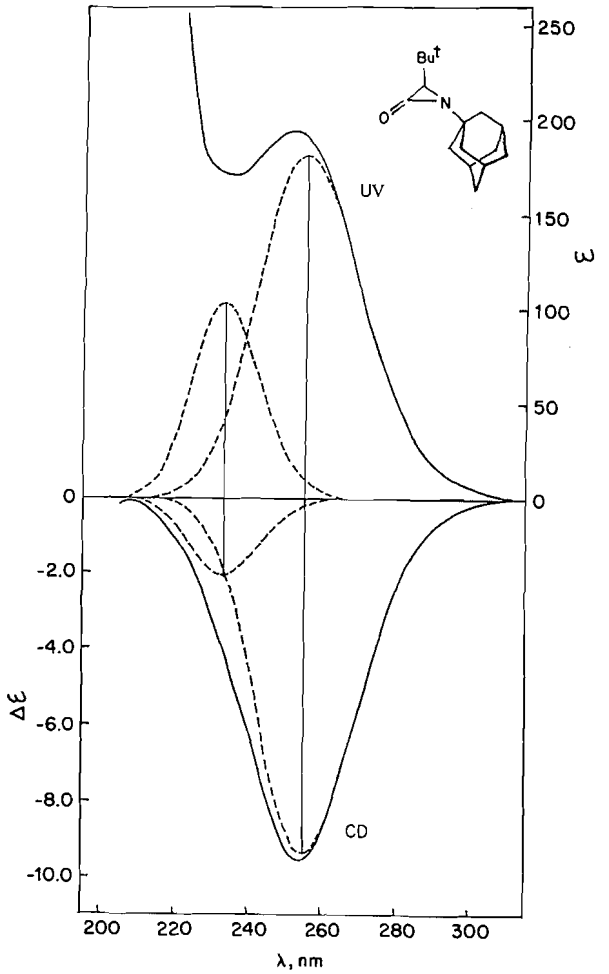

FIG. 4. The CD and UV spectra of aziridinone **7** in heptane and their Gaussian components (---).

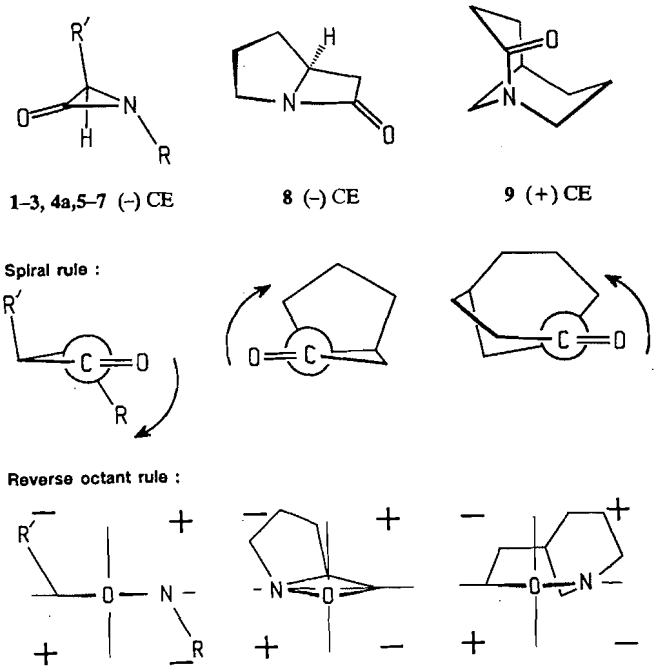
the evident bathochromic shift (20–30 nm) of the first CE of aziridinones in comparison with usual planar amides as in the case of *N*-acylaziridines (5*a*) is caused mainly by lowering of the π_{CO}^* orbital energy, owing to a weakening of the amide conjugation.

Unlike the first excited state, the second one is formed almost exclusively by electron transition from MO 23 (HOMO) which has a considerable contribution of the nitrogen lone electron pair (Fig. 2). As a whole, this orbital is similar to the n_N orbital of *N*-formylaziridine (5*a*), from which the second electronic transition is to the 3*s* orbital in this compound. The evident hypsochromic shift of the observed dichroic absorption band in the CD spectra of aziridinones **6** and **7** in MeOH in comparison with the spectra in *n*-heptane and gaseous phase (Table 1, Fig. 3) is consistent both with the participation of the heteroatom lone electron pairs in the first and second electronic transition, and with the Rydberg nature of the second. Thus, a complete analogy in the orbital origin of the lower electronic transitions is observed between 1,3-*trans*-aziridinones and *N*-acylaziridines. The same conclusion is obtained for *cis*-aziridinones **4***b*.

The quasi-symmetry of aziridinones, i.e., quasi-C_s of the *cis* isomer **4***b* and quasi-C_2 of *trans*-aziridinones **1–3**, **4***a*, and **5–7**, makes them suitable models for testing the chiral rules. It is the spiral rule (3*a*, 5) and reverse octant rule (ROR) (5*b*), which connect the first CE sign with the stereochemistry of a molecule containing the nonplanar amide chromophore. According to the first rule, the positive CE corresponds to the negative torsion O=C—N—C angle and vice versa; on the second rule, the CE sign can be predicted as in the case of the usual carbonyl chromophore (14), but with the reverse octant signs (5*b*). It is necessary to note the same $n_O \rightarrow \pi_{CO}^*$ orbital origin of the nonplanar amide and carbonyl chromophores. The interchangeability of the rules follows from the examination of the stereochemistry and chiroptical properties of *N*-acyl- and *N*-nitrosoaziridines, and cyclopropylketones (5*b*).

At first glance one can come to the same conclusion in the cases of (3*R*)-*trans*-aziridinones **3**, **4***a*, and **5–7**, azetidinone **8**, and azabicylooctanone **9** (in the boat–chair conformation) as shown in Scheme 3. However, an attempt to apply the ROR to



SCHEME 3

(3*R*)-*cis*-aziridinone **4***b* evidently indicates a limitation of the rule, because the methyl groups at the N and C3 atoms are found in oppositely signed octants and perturbations of the groups should compensate each other, resulting in a reduced rotational strength. Nevertheless according to the calculation, the value of the rotational strength of the $n_O \rightarrow \pi_{CO}^*$ transition of (3*R*)-*cis*-aziridinone **4***b* is even larger in absolute magnitude than that calculated for the (3*R*)-*trans*-isomer **4***a* (Table 2). In contrast to the ROR, the spiral rule correctly connects the first CE sign with the intrinsic chirality of the chromophore in (3*R*)-*cis*-aziridinone **4***b* (Scheme 4). On the other hand, the ROR well works in the cases of azabicyclooctanone **9** (in the chair–chair conformation) and quinuclidone **10** (Scheme 5).

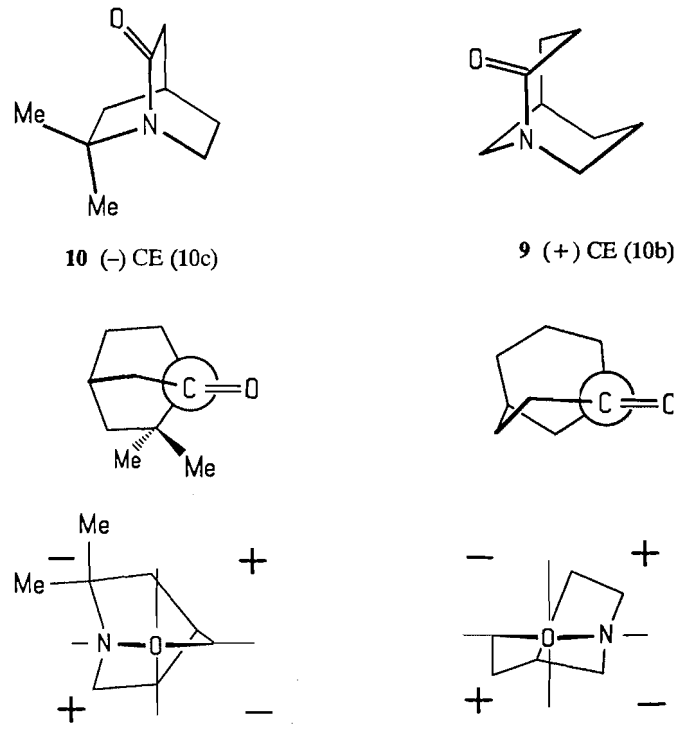


SCHEME 5

These compounds have a conformation around the N—C(O) bond, which is close to symmetrical antiperiplanar, and it is difficult to determine the sign of the torsion O=C—N—C angle for them.

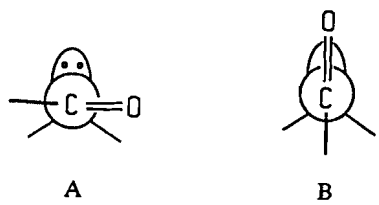
Conclusions

1,3-Dialkylaziridinones (α-lactams), as do earlier investigated *N*-acylaziridines (5*a*), possess the stereochemically labile intrinsically chiral amide group. Inversion of the configuration of this group is carried out by pyramidal inversion of the nitrogen under the control of a carbon chiral centre. The chiroptical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

properties of the nonplanar amide chromophore connected with the first electronic transition are independent from whatever influence causes the chromophore to become nonplanar. 1,3-Dialkylaziridinones and *N*-acylaziridines, for which nonplanarity of the amide chromophore is caused by insertion of the nitrogen atom into a strained three-membered ring, have the same features of the CD spectra as bicyclic amides (3*a*). All the compounds are different from virtually planar amides by the position of the long-wavelength absorption and high intensity of the first CE, the sign of which is determined only by the intrinsic chirality of the chromophore. In fact, the chromophore chirality is determined by the carbon chiral centres (thermodynamic control of the isomers populations) or by the chirality of a bicyclic molecule. Thus, there is the possibility of determination of the absolute stereochemistry of nonplanar amides on the basis of the first CE sign.

Both the chiral rules discussed above, which aim to connect the first CE sign with the absolute stereochemistry of the nonplanar amide, are empirical in character. Nevertheless, the spiral rule more correctly reflects the spiral nature of the nonplanar amide chromophore and may be used for all occurrences. In practice, this rule is preferred for compounds with a pronounced helicity of the chromophore, i.e., with the *syn*-clinal conformation (A, Scheme 6) around the N—C(O) bond. On the other hand, the ROR rule is more reliable for amides with a configuration that is close to antiperiplanar (B, Scheme 6):



A B

SCHEME 6

Methods

Experimental

The CD spectra were measured on a JASCO J-500A spectropolarimeter with DP-500N dataprocessor, the UV spectra were measured on a Specord UV VIS spectrophotometer, the NMR spectra were measured on a Bruker WM-400 spectrometer (^{1}H, 400.13 MHz; ^{13}C, 100.62 MHz, in $CDCl_3$ from TMS), and optical rotation angles were determined on Autopol III and Polamat A polarimeters.

Amides of (S)-2-bromo-3,3-dimethylbutyric acid

A solution of (*S*)-2-bromo-3,3-dimethylbutyric acid (3.12 g, 16 mmol) (was prepared from L-*tert*-leucine according to ref. 15) and $SOCl_2$ (3.81 g, 32 mmol) in CH_2Cl_2 (15 mL) was refluxed for 7 h. After removal of the solvent in vacuo, the residual clear liquid (3.1 g) was dissolved in CH_2Cl_2 (20 mL) and added to a solution of *tert*-alkylamine (32 mmol) in CH_2Cl_2 (50 mL) with cooling (0°C) and stirring. After 2 h at 20°C, the reaction mixture was washed with 10% aqueous HCl (2 × 30 mL), water, and saturated aqueous $NaHCO_3$ (2 × 30 mL), and then dried ($CaCl_2$). After removal of the solvent, the residue was recrystallized from *n*-hexane–CH_2Cl_2.

(S)-N-tert-Butyl-2-bromo-3,3-dimethylbutyramide: yield 82%; mp 164–165°C (lit. (11*a*) mp 156–157°C racemate); $[\alpha]_D^{20}$ −36.6° (*c* 2.5, $CHCl_3$). ^{1}H NMR δ: 1.14 (9H, Bu^{t}C), 1.37 (9H, Bu^{t}N), 4.00 (1H, CH), 5.86 (1H, br s, NH).

(S)-N-(1′-Adamantyl)-2-bromo-3,3-dimethylbutyramide: yield 86%; mp 196–197°C (lit. (11*b*) mp 173–174°C racemate); $[\alpha]_D^{20}$ −32.1° (*c* 3.2, $CHCl_3$). ^{1}H NMR δ (*J*, Hz): 1.14 (9H, Bu^{t}C), 1.68 (6H, t, Ad, δ-CH_2, ^3J = 3.0), 2.01 (6H, d, Ad, β-CH_2, ^3J = 2.9), 2.06 (3H, br m, Ad, γ-CH), 3.97 (1H, CH), 6.22 (1H, br s, NH).

Aziridinones 6 and 7

Potassium *tert*-butoxide (0.74 g, 6.6 mmol) was added to a solution of (*S*)-amide (6 mmol) in absolute ether (100 mL) with cooling (−20°C) and stirring. After 15 min at 20°C, the precipitate was filtered off and the filtrate was evaporated in vacuo. The product was extracted from the residue with pentane. After removal of pentane, the residue was twice distilled in vacuo (aziridinone **6**) or twice recrystallized from *n*-hexane at −3°C (aziridinone **7**). Optical purities of the aziridinones, ≈86% for **6** and ≈88% for **7**, were determined according to Ref. 6*d* from the ^{1}H NMR spectra in $CDCl_3$–CCl_4 (1:4) in the presence of two equivalents of (*R*)-1-(9-anthryl)-2,2,2-trifluoroethanol by integration of the methine proton signals.

(3R)-1,3-Di-tert-butylaziridinone **6**: yield 43%; bp 29–32°C (0.2 Torr; 1 Torr = 133.3 Pa); $[\alpha]_D^{20}$ −253.8° (*c* 0.9, heptane) (lit. (6*c*)) bp 60°C (0.5 Torr), $[\alpha]_D^{20}$ −267.3° (*c* 1.25, hexane)). ^{1}H NMR δ: 0.99 (9H, Bu^{t}C), 1.29 (9H, Bu^{t}N), 2.74 (1H, CH). ^{13}C NMR δ (*J*, Hz): 26.95 (qm, $(CH_3)_3CC$, ^1J = 125.5, ^3J = 4.9, 2.8), 27.58 (qm, $(CH_3)_3CN$, ^1J = 126.2, ^3J = 4.2), 31.14 (m, Me_3CC, ^2J = 4.2), 54.09 (dm, CH, ^1J = 195.5, ^3J = 5.6), 55.98 (m, Me_3CN, ^2J = 4.2), 160.99 (d, CO, ^2J = 3.2).

(3R)-1-(1′-Adamantyl)-3-tert-butylaziridinone **7**: yield 58%; mp 75–76°C (lit. (11*b*) mp 79°C racemate); $[\alpha]_D^{20}$ −206.9 (*c* 1.0, heptane). ^{1}H NMR δ: 0.99 (9H, Bu^{t}C), 1.68 (6H, br t, Ad, δ-CH_2), 1.85 (6H, br q, Ad, β-CH_2), 2.14 (3H, br m, Ad, γ-CH), 2.83 (CH). ^{13}C NMR δ (*J*, Hz): 27.05 (q, $(CH_3)_3C$, ^1J = 126.2), 29.16 (d, Ad, γ-CH, ^1J = 133.2), 31.15 (Me_3C), 35.81 (t, Ad, δ-CH_2, ^1J = 127.6), 40.91 (t, Ad, β-CH_2, ^1J = 127.6), 53.30 (dm, CH, ^1J = 160.9, ^3J = 5.6), 56.29 (Ad, α-C), 160.88 (d, CO, ^2J = 3.1).

Theoretical

The geometries of (1*S*)-aziridinone **1**, (1*S*)-1-methylaziridinone **2**, (1*S*,3*R*)-3-methylaziridinone **3**, (1*S*,3*R*)-1,3-dimethylaziridinone **4***a*, its *cis*-diastereomer (1*R*,3*R*)-1,3-dimethylaziridinone **4***b*, and (1*S*,3*R*)-3-*tert*-butyl-1-methylaziridinone **5** were fully optimized by Hartree–Fock SCF calculations at the 6-31+G* level (16) by using the GAUSSIAN 90 (17) or 92 (18) system of programs. In the case of the (3*R*)-1,3-dimethylaziridinones **4***a* and **4***b*, the transition structure for pyramidal inversion at N, **4-TS**, was also located. The transition properties were determined with the same basis set. The diffuse *s* and *p* functions in this basis set permit a better description of the lowest few valence states and the identification of Rydberg states. Ionization potentials are calculated using a many body perturbation theory correction to Koopmans' theorem based on the work of Pickup and Goscinski (19). The frontier orbitals are displayed as modified Jorgensen–Salem plots (20).

The method used to calculate oscillator and optical rotatory strengths is the same as was used previously (5, 21, 22) and has been described in detail elsewhere (23). Partially correlated wave functions for the ground and excited states are determined to first order in Rayleigh–Schrödinger perturbation theory,

$$[1] \quad \Psi_n = \Psi_n^0 - \Sigma_j a_{nj} \Phi_j^0$$

where

$$[2] \quad a_{nj} = \langle \Psi_n^0 | H | \Phi_j^0 \rangle / (\langle \Phi_j^0 | H | \Phi_j^0 \rangle - \langle \Psi_n^0 | H | \Psi_n^0 \rangle)$$

H is the exact Hamiltonian, Φ_j^0 is a singlet singly or more highly excited configuration derived from the Hartree–Fock determinant, Φ_{HF}, and Ψ_n^0 is a linear combination of strongly interacting Φ_l^0 ($l \neq j$) selected from at most singly excited configurations. Thus, for the ground state, $\Psi_0^0 = \Phi_{HF}$. All configurations for which the interaction coefficient a_{nj} (eq. [2]) was greater than 0.05 were included in the zero-order part of the CI wave function. For reasons of expediency, the CI calculation was restricted to a window of 14 occupied orbitals and 48 unoccupied orbitals for each system.

Electric dipole transition moments in the length $\langle r \rangle_{0n}$ and velocity $\langle v \rangle_{0n}$ formalism and magnetic dipole transition moments $\langle m \rangle_{0n}$ are explicitly evaluated from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

[3] $\langle r\rangle_{0n} = \Psi_0|\mu|\Psi_n\rangle$

[4] $\langle v\rangle_{0n} = \langle\Psi_0|\nabla|\Psi_n\rangle/(E_n - E_0)$

[5] $\langle m\rangle_{n0} = -i\langle\Psi_n|m|\Psi_0\rangle$

where the dipole, gradient, and magnetic moment operators, μ, ∇, and m, have their usual definitions and

[6] $E_n = \langle\Psi_n|H|\Psi_n\rangle$

Oscillator strengths f_{0n} are calculated by the mixed formalism

[7] $f_{0n} = \frac{2}{3}\langle\Psi_0|v|\Psi_n\rangle \cdot \langle r\rangle_{n0}$

Optical rotatory strengths are evaluated as

[8] $[R_{0n}]^r = \langle r\rangle_{0n} \cdot \langle m\rangle_{n0}$

and in the origin independent form

[9] $[R_{0n}]^v = \langle v\rangle_{0n} \cdot \langle m\rangle_{n0}$

The extent of agreement between eqs. [8] and [9] serves as a measure of the quality of the wave function and the reliability of the calculated rotational strengths for the particular states.

Using lethality to brine shrimp, activity-directed fractionation of extracts of *Asimina parviflora* (Michx.) Dunal. (Annonaceae) has led to the isolation of two new and four known acetogenins (**1–6**). Compound **1**, parvifloracin, is the first nonadjacent bistetrahydrofuran acetogenin with 35 carbons. Compound **2**, parviflorin, is an unusual adjacent bistetrahydrofuran acetogenin with 35 carbons. Bullatacin (**3**), molvizarin (**4**), annonacin (**5**), and goniothalamicin (**6**) are also reported for the first time from this plant. Brine shrimp lethality test data and comparative cytotoxicities of **1–6** against three human solid tumor cell lines are presented.

SUNIL RATNAYAKE, ZHE-MING GU, LAURA R. MIESBAUER, DAVID L. SMITH, KARL V. WOOD, DEAN R. EVERT et JERRY L. MCLAUGHLIN. Can. J. Chem. **72**, 287 (1994).

Utilisant la létalité pour la crevette d'eau salée comme activité permettant l'orientation du fractionnement des extraits du *Asimina parviflora* (Michx.) Dunal (Annonaceae), on a isolé deux nouvelles acétogénines et quatre autres qui étaient déjà connues (**1–6**). Le composé **1**, la parvifloracine, est la première acétogénine à 35 carbones à contenir deux tétrahydrofuranes non adjacents. Le composé **2**, la parviflorine, est une acétogénine inhabituelle à 35 carbones avec deux tétrahydrofuranes adjacents. C'est aussi la première fois que l'on rapporte l'extraction de la bullatacine (**3**), de la molvizarine (**4**), de l'annonacine (**5**) et de la goniothalamicine (**6**) de cette plante. On présente les données du test de létalité pour la crevette d'eau salée ainsi que les cytotoxicités comparatives des composés **1–6** contre trois lignes de cellules tumorales solides des humains.

[Traduit par la rédaction]

Introduction

Asimina parviflora (Michx.) Dunal., dwarf paw paw, is a small shrub native to the southeastern United States (1). In our search for new potential anticancer and pesticidal constituents from the Annonaceae, we investigated the twigs for bioactive compounds. The brine shrimp lethality test (2, 3) (BST) detected bioactivity and was used to direct the fractionation. In a previous paper (4), we reported the isolation, identification, and cytotoxic activities of two new (asimicilone and 6-*cis*-decosenamide) and three known (asimicin, (+)-syringaresinol, and β-sitosterol β-D-glucopyranoside) natural compounds from the twigs. Further fractionation of the aqueous methanol soluble residue of the 95% ethanol extract has now led to the isolation of two new (**1**, **2**) and four known (**3–6**) annonaceous acetogenins. Parvifloracin (**1**) is the first nonadjacent bis-THF (tetrahydrofuran) ring acetogenin having 35 carbons and is the first nonadjacent bis-THF ring acetogenin reported in the genus *Asimina*. Parviflorin (**2**) is an adjacent bis-THF ring acetogenin with 35 carbons. Only three acetogenins with 35 carbons have been reported previously in the adjacent bis-THF ring class (neoannonin (5), molvizarin (6), and itrabin (7)). Bullatacin (**3**), molvizarin (**4**), annonacin (**5**), and goniothalamicin (**6**) are previously known acetogenins and are reported for the first time from this plant. These compounds were identified by using chemical and spectroscopic analyses. In this paper we discuss their isolation, identification, and cytotoxic activities.

Results and discussion

Parvifloracin (**1**) was obtained as a whitish wax with $[\alpha]_D^{22}$ +18.75 (*c* 0.08, EtOH). ^{1}H NMR, ^{13}C NMR, and mass spectral data of **1** and its acetate, trimethylsilyl (TMS), and perdeuterotrimethylsilyl (d-TMS) derivatives suggested that **1** belongs to the relatively rare class of bioactive nonadjacent bis-THF acetogenins (8–11). The high resolution FAB mass spectrum of **1** showed *m/z* at 611.4512 for MH^+ (calculated 611.4523) corresponding to the molecular formula $C_{35}H_{62}O_8$. The prominent absorption peak at 3466 cm^{-1} in the IR spectrum and the four successive losses of H_2O (*m/z* 18) from the molecular ion in the CIMS (*m/z* values at 592, 574, 556, 538) indicated the presence of four hydroxyl groups. These were further confirmed by preparation of a tetraacetyl derivative (**1***a*). The ^{1}H NMR spectrum of **1***a* showed four, three-proton singlets at δ 2.03, 2.07, 2.08, and 2.09 and two multiple proton resonances at δ 4.83 (3H) and

n	9	9	9	9	11
m	5	5	7	7	5

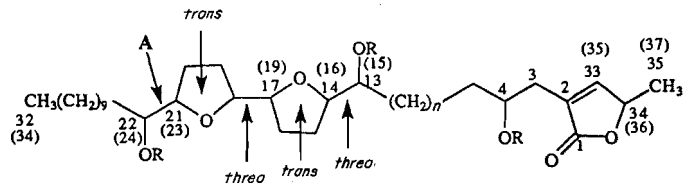
5.10 (1H) corresponding to downfield shifts on secondary hydroxyl-bearing carbons as compared with **1**. The CIMS of **1*a*** also showed successive losses of four AcOH units (*m/z* 60) from the MH^+ of the tetraacetate (*m/z* 719, 659, 599, 539). The tetra-TMS derivative (**1*b***) of **1** confirmed the presence of four hydroxyl groups by successive losses of TMSOH (*m/z* 90) from the derivatized molecule (*m/z* 808, 718, 628, 538).

The presence of an α,β-unsaturated γ-lactone subunit with an hydroxyl group at position 4 was suggested by the following characteristic features (8–11): a strong IR absorption peak (carbonyl) at 1745 cm^{-1} and a UV maximum at 223 nm; six proton resonances at δ 7.19 (1H, q, H-33), 5.06 (1H, qq, H-34), 3.87 (H, m, H-4), 2.53 (1H, dddd, H-3a), 2.40 (1H, dddd, H-3b), and 1.43 (3H, d, H-35); and six carbon resonances at δ 174.63 (C-1), 151.86 (C-33), 130.09 (C-2), 77.97 (C-34), 69.87 (C-4), and 19.06 (C-35).

The existence of two, nonadjacent tetrahydrofuran rings was suggested by proton resonances at δ 3.80 (H-13, -18, -21) and 3.87 (H-10) in **1** and 3.85 (H-10) and 3.96 (H-13, -18, -21) in **1*a*** and carbon resonances at δ 79.24 (C-10) and δ 81.96, 82.66, 82.68, (C-13, -18, -21) (8–11). The protons (δ 3.41, H-14, 17, and -22) attached to secondary hydroxylated carbons (δ 74.07, 74.25, 74.37 for C-12, -17, and -22) could be easily distinguished from those of the THF-flanking protons and carbons, as they resonated upfield compared with the latter. Two of these hydroxyl groups were assigned as adjacent to one THF ring, and one was assigned as adjacent to the other ring. The upfield shift of C-10 to δ 79.24 indicated that there was no hydroxyl group adjacent to one side of one of the THF rings. These conclusions were further supported by proton resonances of **1*a*** at δ 3.85 (H-10), 3.97 (H-13, -18, -21) and 4.83 (H-14, -17, -22). These NMR data are very similar to those of bullatanocin (**7**) and gigantecin (**8**), which are presented in Tables 1 and 2 for comparative purposes, as well as other nonadjacent bis-THF ring acetogenins (8–10).

The EIMS data of **1**, together with its tetraacetate (**1*a***), tetra-TMS (**1*b***), and d-TMS (**1*c***) derivatives, clearly resolved the carbon skeleton and the placement of the THF rings (Table 3). EIMS fragmentation patterns indicated that the two THF rings were located at C-10 and C-18 along the hydrocarbon chain and also supported the placement of the four hydroxyl groups at C-4, C-14, C-17, and C-22, as originally indicated by the NMR data.

The relative stereochemistries within the carbon centers C-13/C-14, C-17/C-18, and C-21/C-22 were determined by comparing the ^{13}C NMR signals of **1** for the hydroxylated carbons C-14, C-17, and C-22 at δ 74.07, 74.25, and 74.37 respec-



Compound	2	2*a*	3	4	9	9*a*

tively, as well as the ^1H NMR signals of **1** at δ 3.41 (H-13, -17, -22) and 3.80 (H-13/15, -17/19, -21/23/14), with those of model compounds of known relative stereochemistry (12–15). The comparison clearly indicated that the relative configurations between the above couples of adjacent chiral carbons were *threo*. Comparing with a group of diacetyl dibutylated bis-THF rings of known relative stereochemistry (13–15), the ^1H NMR signals of **1*a*** at δ 3.97 (H-13, -18, -21) and 4.83 (H-14, -17, -22) further supported these *threo* assignments, and the ^1H NMR signals of **1*a*** at δ 3.97 for H-18 and H-21 indicated the *trans* configuration of the substitution pattern of the C-18 to C-21 THF ring. Thus, the structure of compound **1** was determined as illustrated and named parvifloracin. Parvifloracin is the first nonadjacent bis-THF ring acetogenin with only 35 carbons, and this is the first report of the presence of a nonadjacent bis-THF ring acetogenin in the genus *Asimina*.

The second compound, parviflorin (**2**), was also isolated as a whitish wax with $[\alpha]_D^{22}$ +18.33 (*c* 0.06, EtOH). The high resolution CI mass spectrum of **2** showed *m/z* at 595.4573 for MH^+ (calculated 595.4574), corresponding to the molecular formula $C_{35}H_{62}O_7$. The prominent absorption peak at 3452 cm^{-1} in the IR spectrum and three successive losses of H_2O (*m/z* 18) from the molecular ion in the CIMS (*m/z* 577, 559, 541) indicated the presence of three hydroxyl groups. These were further confirmed by preparation of an acetyl derivative (**2*a***). The ^1H NMR spectrum of **2a** showed two singlets at δ 2.03 and 2.08 (three and six protons, respectively) and two multiple proton resonances at δ 4.83 (2H) and 5.01 (1H) corresponding to the downfield shifts on secondary hydroxyl-bearing carbons as compared with **2**. The CIMS of **2*a*** and EIMS of **2*b*** also showed successive losses of three AcOH units (*m/z* 60) from the triace-

tate **2***a* (*m/z* 661, 601, 541) as well as three TMSOH units (*m/z* 90) from the tri-TMS derivative **2***b* (*m/z* 721, 631, 541), respectively.

The presence of an α,β-unsaturated γ-lactone subunit with an hydroxyl group at the C-4 position (8–11) was suggested by a strong IR absorption peak (carbonyl) at 1753 cm^{-1} and UV maximum at 221 nm; six proton resonances at δ 7.17 (1H, q, H-33), 5.04 (1H, qq, H-34), 3.87 (1H, m, H-4), 2.53 (1H, dddd, H3a), 2.40 (1H, dddd, H-3b), and 1.43 (3H, d, H-35); and six carbon resonances at δ 174.52 (C-1), 151.71 (C33), 131.13 (C-2), 77.97 (C-34), 69.98 (C-4), and 19.16 (C-35).

The existence of two adjacent THF rings was demonstrated by proton resonances at δ 3.84 (H-14, 17, -18, -21) in **2** and 3.96 (H-14, -17, -18, -21) in **2***a*, and carbon resonances at δ 81.77, 81.79, 83.12, 83.15 (C-14, -17, -18, -21) (4, 8, 11, 16). The protons (δ 3.39, H-13 and -22) attached to secondary hydroxylated carbons (δ 74.05 and 74.07 for C-13 and -22) could be easily distinguished from those of the THF-flanking protons and carbons, as they resonated upfield compared with the latter. These assignments were further supported by proton resonances of **2***a* at δ 3.96 (H-14, -17, -18, -21) and δ 4.86 (H-13 and -22). These data are very similar to those of asimicin, which are presented in Tables 4 and 5 for comparative purposes, as well as other adjacent bis-THF ring acetogenins (4, 8, 11, 16, 17).

The EIMS and CIMS data of **2**, together with those of its triacetate (**2***a*), tri-TMS (**2***b*), and tri-dTMS (**2***c*) derivatives, resolved the carbon skeleton and placement of the THF rings (Table 6). Though the NMR data are very similar to those of asimicin (4, 8, 16, 17), the mass spectral data indicated that this

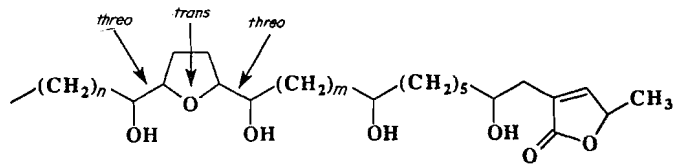
34/(36)	77.97	77.92
35/(37)	19.17	19.05

NOTE: *a–f* indicate that the assignments may be interchangeable within each group.

compound is lacking two carbons in the hydrocarbon chain bearing the lactone ring. This conclusion was suggested by the *m/z* 283 (base peak) in the EIMS of **2**, together with *m/z* 427 (EIMS, 100%) in **2***b* and *m/z* 445 (EIMS, 100%) in **2***c*. These data confirmed that the positions of the THF rings are from C-14 to C-21. Other major mass fragments of **2**, e.g., at *m/z* 353/241 and 171/423, demonstrated that the second THF ring is attached to C-18, and this conclusion was supported by the mass spectral data of **2***b* and **2***c*. As usual, flanking OH groups are on each side of the adjacent bis-THF rings; this is true with all adjacent bis-THF ring acetogenins isolated so far, and both the NMR and mass spectral data substantiate this observation (8, 11).

The relative stereochemistries within the carbon centers C-13/C-14, C-17/C-18, and C-21/C-22 were determined by comparing the ^{13}C NMR signals of **2** for the hydroxylated carbons C-13 and C-22 at δ 74.05 and 74.07, as well as the ^{1}H NMR signals of **2** at δ 3.39 (H-13 and -22) and 3.84 (H-14, -17, -18 and -21), with those of model compounds of known relative stereochemistry (12–15). The comparison clearly showed that the relative configuration between the above pairs of adjacent chiral carbons were all of the *threo* type. By comparing with those of a group of diacetyl dibutylated bis-THF rings of known relative stereochemistry (13–15), the ^{1}H NMR signals of **2***a* at δ 3.85 (H-14, -17, -18, -21) and 4.83 (H-13, -22) further supported these *threo* assignments, and the ^{1}H NMR signals of **2***a* at δ 3.96 for H-14 and -17, and H-18 and -21, indicated the *trans* configuration of the substitution pattern of the C-14 to C-17 and C-18 to C-21 THF rings. The configuration of the chiral centers at C-4 and C-34 may be suggested to be 4*R*, 34*S*, since, as previously discussed, so far with the C-37 compounds, all are 4*R*, 36*S*. Thus, the structure of compound **2** was determined as illustrated and named parviflorin. This C-35 skeleton is relatively rare, since only three similar compounds (neoannonin (5), molvizarin (6) and itrabin (7)) have been reported to date.



Annonacin (**5**) $n = 11$ $m = 4$

Goniothalamicin (**6**) $n = 13$ $m = 2$

Compounds **3** and **4** were also isolated as whitish waxes. ^{1}H NMR data were very similar in both cases, but mass spectral data showed different fragmentation patterns. The EIMS and CIMS of **3** and the EIMS of the TMS derivative of **3** showed identical fragments with bullatacin, an adjacent bis-THF ring acetogenin, previously isolated from *Annona bullata* (18), *Annona squamosa* (11), *Annona reticulata* (11), and *Asimina triloba* (17). TLC of **3** and bullatacin together gave the same R_f values. The EIMS and CIMS of **4** and the EIMS of the TMS derivative of **4** gave identical data with those of molvizarin, recently reported from *Annona cherimolia* (6). Therefore, **3** and **4** were identified as bullatacin and molvizarin, respectively.

Compounds **5** and **6** were also isolated as whitish waxes. ^{1}H NMR, EIMS, and CIMS of **5** and **6** and EIMS of their TMS derivatives clearly showed that these compounds were annonacin (previously isolated from several *Annona* species (11)) and goniothalamicin (previously isolated from *Goniothalamus giganteus* (19) and *Annona muricata* (20)), respectively; both are mono-THF ring acetogenins which are relatively rare in the *Asimina* genus. TLC with standard compounds available in our laboratory also confirmed the identity of these compounds.

Table 7 shows certain biological activities of all these compounds. As expected, both parvifloracin (**1**) and parviflorin (**2**) showed significant cytotoxicity to the three human solid tumor cell lines. Compound **1** showed very high toxicity against both lung and breast carcinoma cell lines. Compound **2** showed high toxicity against lung carcinoma with moderate toxicity against the colon cancer cell line. Both bullatacin (**3**) and molvizarin (**4**) showed high toxicity against all tumor cell lines; and bullatacin, thus far, is the most bioactive compound isolated from this plant. The mono-THF ring acetogenins, **5** and **6**, showed lesser activities than the bis-THF compounds, but they were still comparably as active as adriamycin. The mechanism of action of several acetogenins has been recently established; they are powerful inhibitors of NADH:ubiquinone oxidoreductase (complex I) in mitochondrial electron transport systems (25–27).

Experimental

Instrumentation

Optical rotations were measured on a Perkin Elmer 241 polarimeter. IR spectra were obtained on a Perkin Elmer 1420 IR spectrometer. UV spectra were obtained on a Beckman DU-7 UV spectrometer. ^{1}H and ^{13}C NMR spectra were obtained on a Varian VXR-500S spectrometer. Low resolutions EIMS and CIMS data were collected on a Finnigan 4000 spectrometer. Low resolution EIMS data of TMS derivatives were taken on a Kratos MS50. Exact masses for MS measurements were obtained on a Kratos MS50 spectrometer through peak matching. HPLC was performed with a Rainin HPLC using a Dynamax software system and a silica gel column (250 × 21 mm) equipped with a Rainin UV-1 detector set at 220 nm. Analytical TLC was made on silica gel

plates (0.25 mm) developed with $CHCl_3$–MeOH (9:1 and 9.5:0.5) and hexane–acetone (3:2) and visualized using 5% phosphomolybdic acid in EtOH (8).

Plant material

Twigs of *A. parviflora* were collected and identified by one of us (D.R.E.) near Tifton, Ga., during August 1990. A voucher specimen is preserved in the herbarium of the Department of Medicinal Chemistry and Pharmacognosy, Purdue University.

Bioassays

The extracts, fractions, and pure compounds were routinely tested for lethality to brine shrimp larvae. In vitro cytotoxicity tests (7 days) to determine ED_{50} values against human tumor cell lines, were carried out at the Purdue Cancer Center, Cell Culture Laboratory, using standard protocols for A-549 (human lung carcinoma (24)), MCF-7 (human breast carcinoma (25)), and HT-29 (human colon adenocarcinoma (26)) with adriamycin as a positive control; ED_{50} values <4 μg/mL for pure compounds are considered significant.

Extraction and isolation

The twigs (<1 cm diameter, 3.5 kg) were extracted and partitioned, and the bioactive fraction (F005) was subjected to vacuum liquid column chromatography as described in a previous paper (4). Fraction 4 from the above column was further chromatographed using a gravity column and chromatotron plates to give three active fractions (fractions 4-5-2-2 (BST LC_{50} 5.56), 4-5-3-2 (BST LC_{50} 0.198), and 4-5-3-3 (BST LC_{50} 0.498)). A portion of fraction 4-5-3-2 (50 mg) was chromatographed on HPLC using hexane–THF–MeOH (90:1:9) to yield 31 mg asimicin, 12 mg parviflorin (**2**), 18 mg bullatacin (**3**), and 8 mg molvizarin (**4**). A portion of fraction 4-5-3-3 (43 mg) was chromatographed on HPLC in similar manner to yield 22 mg parvifloracin (**1**). Similarly, fraction 4-5-2-2 (34 mg) gave 15 mg annonacin (**5**) and 8 mg goniothalamicin (**6**) on HPLC separation.

m/z (%): $[MH]^+$ 611 (100), $[MH - H_2O]^+$ 593 (12), $[MH - 2H_2O]^+$ 575 (42), $[MH - 3H_2O]^+$ 557 (11), $[MH - 4H_2O]^+$ 539 (2), 351 (22), 333 (3), 281 (9). EIMS data are given in Fig. 1. ^1H and ^{13}C NMR spectral data are given in Tables 1 and 2, respectively.

Acetylation of ***1***

Four milligrams of **1** was mixed with anhydrous pyridine – acetic anhydride (1:1) at room temperature overnight to give 3 mg of tetraacetate (**1***a*). CIMS (isobutane) *m/z* (%): 779 (5), 719 (100), 669 (29), 599 (6), 539 (20); EIMS *m/z* (%): 625 (2), 565 (20), 505 (2), 323 (100), 283 (36), 263 (30), 223 (10), 183 (4), 123 (16).

TMS and d-TMS derivatization of ***1***

A small quantity of **1** (<1 mg) was treated with 20 μL of *N,O*-bis(trimethylsilyl)acetamide (BSA) or d_{18}-bis(trimethylsilyl)trifloroacetamide (BSTFA) and 2 μL of pyridine (10:1) and heated at 70°C for 30 min to yield tetra-TMS derivative (**1***b*) or tetra-d-TMS derivative (**1***c*). EIMS data of both **1***b* and **1c** are given in Fig. 1.

*Parviflorin (****2****)*

Whitish wax (12 mg); R_f value on silica gel TLC in $CHCl_3$–MeOH (9.5:0.5), 0.37; $[\alpha]D^{22}$ +18.33° (*c* 0.06, EtOH); UV (EtOH) λ_{max} 223 nm (ϵ = 8405); IR (film) cm^{-1}: 3452, 1753, 1648. CIMS (isobutane) *m/z* (%): $[MH]^+$ 595 (72, $[MH - H_2O]^+$ 577 (100), $[MH - 2H_2O]^+$ 559 (17), $[MH - 3H_2O]^+$ 541 (1), 283 (46). EIMS data are given in Fig. 2; ^1H and ^{13}C NMR spectral data are given in Tables 3 and 4, respectively.

Acetylation of ***2***

Four milligrams of **2** was mixed with anhydrous pyridine – acetic anhydride (1:1) at room temperature overnight to give 3 mg of triacetate (**2***a*). CIMS (isobutane) *m/z* (%): 721 (8), 661 (100), 601 (95), 541 (16); EIMS *m/z* (%): 609 (1), 507 (9), 489 (10), 447 (11), 437 (51), 387 (7), 377 (27), 353 (9), 293 (26), 265 (11), 183 (3), 153 (5), 123 (26), 95 (100).

TMS and d-TMS derivatization of ***2***

A small quantity of **2** (<1 mg) was treated with 20 μL or BSA of BSTFA and 2 μL of pyridine (10:1) and heated at 70°C for 30 min to yield tetra-TMS derivative (**2***b*) or tetra-d-TMS derivative (**2***c*). EIMS data of both **2***b* and **2***c* are given in Fig. 2.

Rotamers of dimethyl(acetyl)(η^5-cyclopentadienyl)platinum(IV) in the gas phase

M.C. JENNINGS AND R.J. PUDDEPHATT

Department of Chemistry, University of Western Ontario, London, ON N6A 5B7, Canada

Received August 6, 1993

M.C. JENNINGS and R.J. PUDDEPHATT. Can. J. Chem. **72**, 294 (1994).

The platinum(IV) complex, $[CpPt(CH_3)_2(COCH_3)]$, was examimed by IR spectroscopy in the gas phase and found to exist as an equilibrium mixture of two rotational conformers. The equilibrium was examined as a function of temperature by using gas phase IR and the energy difference between the rotamers was determined. Molecular modelling studies were also carried out and are consistent with a model in which the conformers correspond to different rotational positions of the acetyl group.

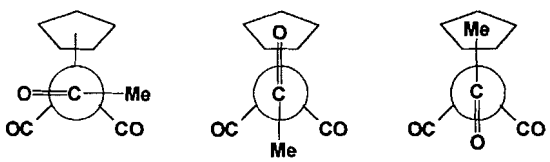
M.C. JENNINGS et R.J. PUDDEPHATT. Can. J. Chem. **72**, 294 (1994).

On a examiné le spectre infrarouge du complexe de platine(IV), $[CpPt(CH_3)_2(COCH_3)]$ en phase gazeuse et on a trouvé qu'il existe sous la forme d'un équilibre entre deux conformères rotationnels. On a déterminé la position de l'équilibre en fonction de la température à l'aide de l'ir en phase gazeuse et on a déterminé la différence d'énergie entre les rotamères. On a aussi réalisé des études des modèles moléculaires et elles sont en accord avec un modèle dans lequel les conformères correspondent à des positions rotationnelles différentes du groupe acétyle.

[Traduit par la rédaction]

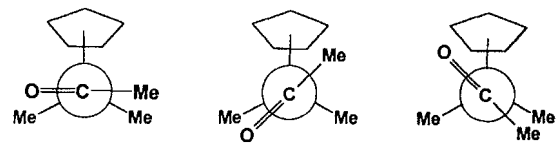
Introduction

Infrared spectroscopy is well known as a useful tool for the study of isomerization reactions. For example, solution IR has been used to monitor both *cis*-to-*trans* and *fac*-to-*mer* isomerizations for organometallic complexes of the group 6 metals (1). Recently, the technique has been used for monitoring the equilibria between rotamers of organometallic complexes of the group 7 and 8 metals in solution (2–5). In particular, the η-cyclopentadienyl (Cp) derivatives $[CpFeL_2R]$ (L = CO, PR_3, R = alkyl, acyl, silyls) have been examined in great detail. Infrared spectroscopy provided evidence for the rotamers and allowed the thermodynamic properties to be determined experimentally (3*c*, 3*e*, 4), with the interpretations aided by theoretical studies using Extended Hückel, *ab initio*, and molecular modelling calculations (4–6). There has been some controversy about the precise interpretation (4, 5), but it is currently thought that the more stable rotamers are **A** and **B**, with **C** at higher energy.



The complexes $[CpPtMe_3]$ and $[(\eta\text{-}C_5H_4Me)PtMe_3]$ are known to be excellent precursors for the chemical vapor deposition of platinum films (7). While extending this work to include platinum(IV) complexes of the general type [CpPtRR′R″] (R,R′,R″ = alkyl, acyl) as CVD precursors, it was noted that the IR spectrum of the known complex $[CpPtMe_2(COCH_3)]$, **1** (8), in the gas phase contained two bands due to ν(C═O), suggesting, by analogy to the case of $[CpFe(CO)_2(COMe)]$, the presence of two rotamers. Before the recent burst of interest in iron complexes, Shaver had already reported that **1** gave two carbonyl bands in the IR spectrum in both the solid state and in solution in hexane or carbon tetrachloride and had correctly interpreted this in terms of conformational isomers (8). At least two out of the three rotamers **D–F** were hypothesized to be present (8).

Since no study of this type of rotamers in the gas phase has been made (3–5, 8), a more detailed investigation of the gas phase equilibrium was carried out and is reported below. It should also be noted that, since the time of Shaver's study (8), molecular mechanics calculations have become routine and have led to conformational analysis of these molecules in terms of pseudooctahedral rather than pseudotetrahedral stereochemistry at the central metal (4, 5) and this naturally modifies the interpretation.



Results and discussion

The infrared spectrum of **1** in the gas phase at 70°C contained bands due to the cyclopentadienyl and methyl groups (9) and two extra, overlapping bands due to ν(C═O) at 1693 and 1667 cm^{-1} (Fig. 1*a*). Curvefitting allowed the ratio of absorbances $A(1667)/A(1693) = 0.92$ to be determined. Subsequent study showed that the IR spectrum of **1** in CH_2Cl_2 at 20°C also contained two bands due to ν(CO) at 1692 and 1668 cm^{-1} with $A(1668)/A(1692) = 0.99$ (Fig. 1*b*). The IR spectrum of a microcrystalline, sublimed sample of **1** as a Nujol mull was less well resolved but two ν(C═O) bands were observed at 1657 and 1694 cm^{-1} with $A(1657)/A(1694) = 3.2$ (Fig. 1*c*). Shaver reported ν(C═O) for **1** = 1693 (s) and 1663 (m) cm^{-1} in CCl_4 solution (8). If the two bands are assigned to two rotamers, then clearly both rotamers are present in both solution and gas phases; even in the solid state there is evidence for two rotamers (8). It should be noted that the ^1H NMR spectrum of **1** contained single resonances due to the C_5H_5, MePt, and MeCO protons even at low temperature (−80°C) and in agreement with the literature (8) and so, if rotamers are present, they must interconvert rapidly in solution to give a time-averaged NMR spectrum.

The relative absorbances of the two peaks due to ν(C═O) of **1** in the gas phase changed as a function of temperature, indicating a temperature dependence of the relative populations of the rotamers. By making the assumptions that there are only two rotamers and that the extinction coefficients for ν(C═O) are the

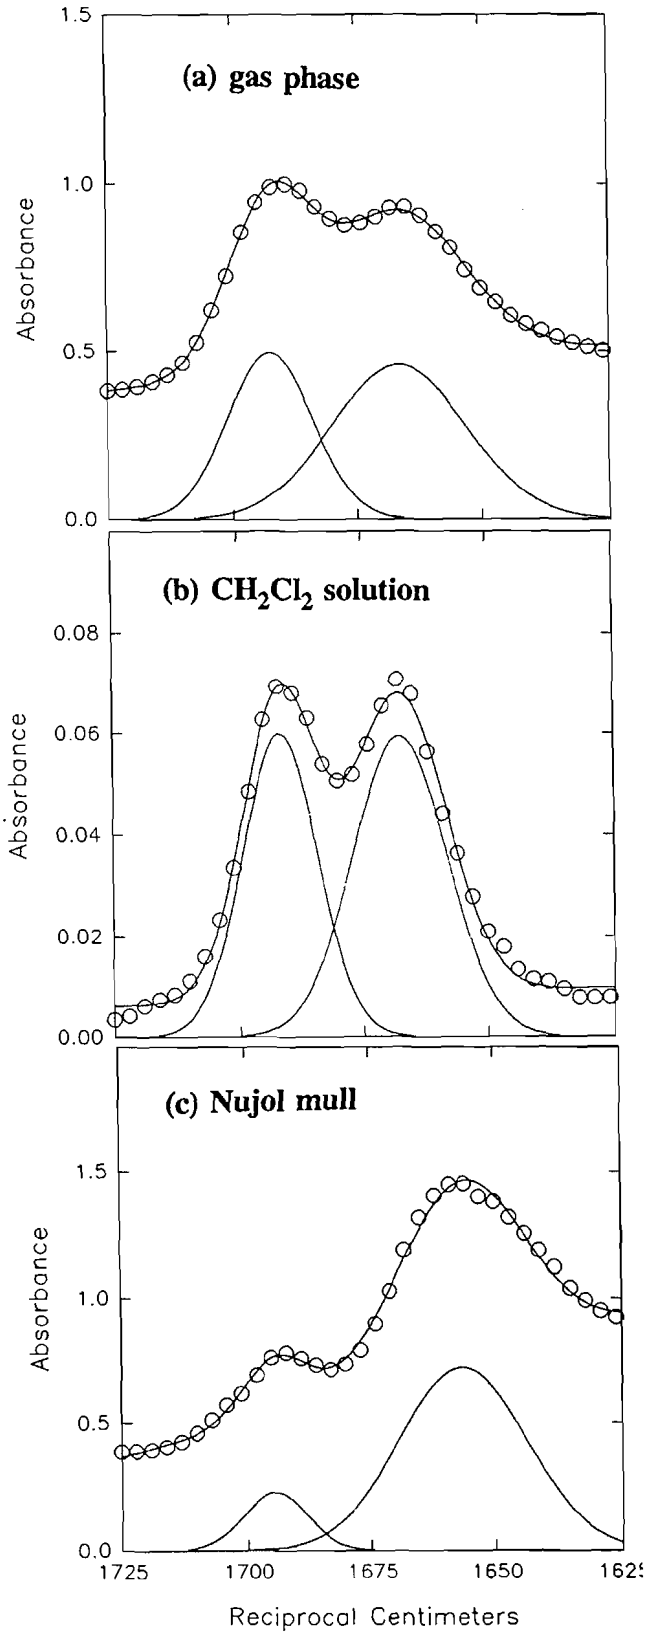

FIG. 1. Expanded IR spectrum with the fitted curve and the two individual curves of [$CpPtMe_2(COMe)$]: (*a*) in the gas phase at 70°C; (*b*) in CH_2Cl_2 solution at 20°C; (*c*) as a Nujol mull.

TABLE 1. Equilibrium constants, K, for rotameters as a function of temperature

Temperature (°C)	K
70	0.92
100	0.83
130	0.81
200	0.69

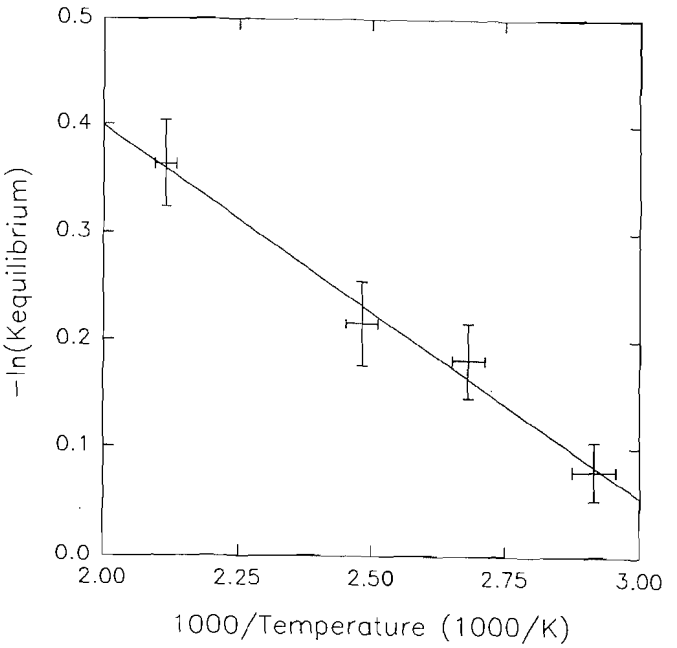

FIG. 2. Plot of ln K vs. $1/T$ (K) for [$CpPtMe_2(COMe)$] in the gas phase. The correlation coefficient for the graph, $R = 0.993$.

same for each rotamer, the equilibrium constant at each temperature can be estimated. In particular, the ratio of the absorbances due to ν(C═O) (Table 1) can be equated to the equilibrium constant, K, at each temperature. Similar assumptions have been made for the iron complexes discussed earlier (*3f*, 4). A plot of ln K vs. $1/T$ was linear (Fig. 2). From this plot, the enthalpy and entropy for the equilibrium were determined as $\Delta H_0 = -0.69 \pm 0.06$ kcal mol^{-1} and $\Delta S_0 = -2.17 \pm 0.04$ cal K^{-1} mol^{-1}. It should be noted that the enthalpy effect favours the rotamer with ν(C═O) = 1667 cm^{-1} and the entropy effect favours that with ν(C═O) = 1693 cm^{-1}. The enthalpy difference between rotamers for **1** is similar to those for similar complexes such as [$CpFe(CO)_2(SiCl_2Me)$] ($\Delta H_0 = 0.8$ kcal mol^{-1}) and [$CpFe(CO)_2(CH_2Ph)$] ($\Delta H_0 = 1.1 \pm 0.3$ kcal mol^{-1}) (*3e*, 4).

While the IR spectra of **1** indicate the presence of two rotamers, the precise structures cannot be determined by this method. Hence molecular modelling studies were carried out on **1** using an MMX package (10). The global minima are shown schematically as **1***a* and **1***b* in Fig. 3, with the minimum energy conformations viewed approximately down the acylplatinum bond shown below. The enthalpy difference between the most stable conformation **1***a* and conformation **1***b* is calculated to be 0.8 kcal mol^{-1}, in good agreement with the observed value of 0.69 ± 0.06 kcal mol^{-1}. No global minimum was identified for

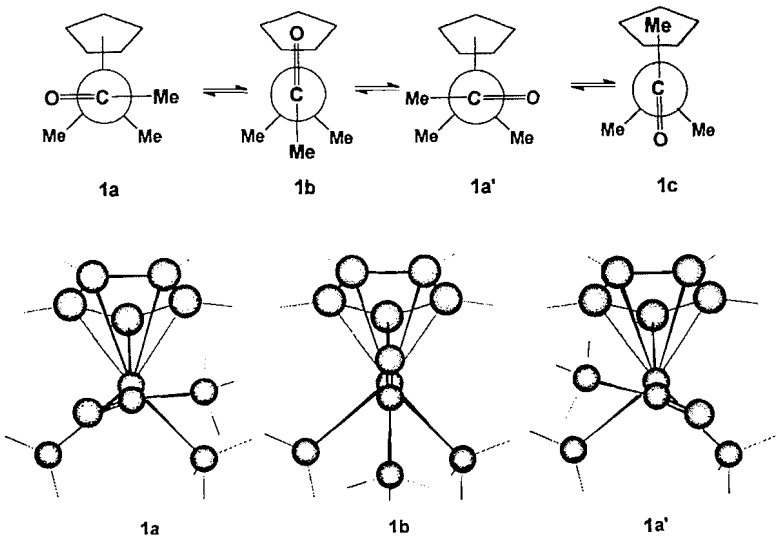

FIG. 3. The probable rotamers of $[CpPtMe_2(COMe)]$ and, below, the minimized structures for **1***a* and **1***b*.

the third possible rotamer **1***c*. The enthalpy of activation to rotation between the equivalent conformations **1***a* and **1***a'* via **1***b* was calculated to be 1.1 kcal mol^{-1} and via **1***c* it was 1.6 kcal mol^{-1}. Of course these barriers are much too low to allow observation of different rotamers by NMR spectroscopy. Mechanical spectroscopic studies have been carried out for **1** in a polymer matrix and indicated a barrier to rotation of the cyclopentadienyl ligand of 5.5 ± 0.6 kcal mol^{-1}, but this barrier is thought to arise from interactions between the Cp ligand and the matrix (11). The MMX calculations suggest a very low barrier to Cp ligand rotation in **1**. The optimized bond angles between the η^1 ligands (Me and MeCO) were in the range 90 ± 10° for all conformers, indicating that the complexes should be considered pseudooctahedral with the Cp ligand occupying three coordination sites, rather than pseudotetrahedral.

It should be noted that the calculated energy differences between rotamers and the activation energies to rotation are small and should therefore be treated with caution. If the calculated relative energies are correct, then the gas phase IR bands at 1667 and 1693 cm^{-1} can be assigned to rotamers **1***a* and **1***b*, respectively. There are two reasons to doubt this assignment. Firstly, in $[CpFe(CO)_2R]$, π-backbonding to R is thought to be stronger in the upright rotamer corresponding to **1***b*, although this is partly due to the presence of the π-acceptor carbonyl ligands and might be different in **1** in which the methyl ligands are σ-bonding only (6). The MMX-based assignment indicates that **1***b* has a *higher* ν(C═O) stretching frequency than **1***a*, indicating weaker backbonding to the acetyl group in **1***b*. Secondly, there are two equivalent rotamers of **1***a* but only one of **1***b*, and so the entropy effects might be expected to favour **1***a*. The MMX-based assignment indicates that the entropy effect favours **1***b*.

In conclusion, it has been shown that the equilibrium between rotamers in organotransition metal complexes can be studied by FTIR in the gas phase as well as in solution, provided the complexes have sufficient volatility. Molecular mechanics calculations can aid the assignment of structure to the rotamers (4, 5) but, since the calculated energy differences are small and since, as explained above, there are other reasons to doubt the assignments in the present case (6), our conclusions should be considered tentative until more sophisticated models than the MMX package used in this work are developed.

Experimental

Complex **1** was prepared according to the literature procedure (8) and was purified by sublimation under vacuum. ^{1}H-NMR($CDCl_3$): 1.14 (s, 6H, CH_3, ^2J(PtH) = 84.8 Hz), 2.46 (s, 3H, $C(O)CH_3$, ^3J(PtH) = 7.1Hz), 5.82 ppm (s, 5H, C_5H_5, ^2J(PtH) = 5.7 Hz). MS: found: *m/z* = 333; calcd. for $[CpPtMe_2(COMe)]^+$: *m/z* = 333. MP = 65°C.

Infrared spectroscopy

Gas phase IR spectra were recorded by using a Perkin-Elmer system 2000 FT-IR supported by the Infra Red Data Manager. The gas phase IR cell used was a glass cell (pathlength 10 cm, volume 78.2 mL) with two Teflon stopcocks and a cold finger attachment. The cell was equipped with NaCl windows and the entire cell was wrapped with heating tape and thermally controlled using a Eurotherm 808 controller coupled to a J-type thermocouple. In a typical experiment, the IR cell was charged with 25 mg of **1**, then evacuated at room temperature and then heated to the desired temperature before recording the IR spectrum. Spectra were recorded over the temperature range 70–200°C, limited at the low end by the volatility of **1** and at the high end by its stability limit.

The absorbance data from 1725–1625 cm^{-1} was loaded into a curve-fitting program and the spectrum was fitted with two Gaussian curves. Figure 1*a* shows the raw data points, the fitted curve and the two individual curves that sum to give the fitted curve. Excellent fits were obtained, from which the absorbance of the individual peaks as a function of temperature were determined.

The atoms of **1** were entered into the program PCMODEL-386, with the cyclopentadienyl ring as an aromatic substructure. The hydrogen atoms were placed in idealized positions. The Pt—C distances of the two methyl groups were initially fixed at 2.1 Å and the Pt—C distances of the Cp ring were all fixed at 2.3 Å, based on X-ray data on related complexes (7, 12). The initial structure also had the acetyl group staggered with respect to the Cp ring. From this starting point, the structure was allowed to minimize, giving one of the global minimum configurations. Barriers to rotation were then estimated by varying a dihedral angle defined as $\mathbf{CH_3C(O)PtCH_3}$ over the range 0–360° in 5° increments, with full minimization at each angle (4). The lowest energies occurred at torsion angles of 148 and 303°, corresponding to structures **1***a* and **1***a'*, while a much shallower minimum occurred at a dihedral angle of 50° corresponding to structure **1***b* (Fig. 3).

On the structure of S_4^{2+} and its formation from $2S_2^+$. *Ab initio* SCF and CASSCF studies

MOUSUMI SANNIGRAHI AND FRIEDRICH GREIN

Department of Chemistry, University of New Brunswick, Fredericton, NB E3B 6E2, Canada

Received June 22, 1993

MOUSUMI SANNIGRAHI and FRIEDRICH GREIN. Can. J. Chem. **72,** 298 (1994).

Ab initio studies up to the MP2/6-31G* level were performed on the geometry and energy of S_4^{2+}. Eleven different structures were considered. In the RHF/6-31G* method, the square structure is the most stable, followed by the *trans*-planar C_{2h} structure. S_4^{2+} (square) is 105.9 kcal/mol less stable than $2S_2^{2+}$. Minimum energy paths were calculated for the reaction $2S_2^+ \rightarrow S_4^{2+}$, both in C_{2v} and D_{2h} symmetry. Using RHF/6-31G*, the transition state lies about 50 kcal/mol above the energy of square planar S_4^{2+}. Using CASSCF or MP2 methods this energy can be significantly lowered (to about 33 kcal/mol in MP2/6-31G*). Calculated vibrational frequencies for the square structure are also given and compared with experimental values.

MOUSUMI SANNIGRAHI et FRIEDRICH GREIN. Can. J. Chem. **72,** 298 (1994).

On a effectué des études *ab initio* jusqu'au niveau MP2/6-31G* sur la géométrie et l'énergie de l'ion S_4^{2+}. On a considéré onze structures différentes. Dans la méthode RHF/6-31G*, la structure carrée est la plus stable, suivie par la structure *trans*-planaire, C_{2h}. L'ion S_4^{2+} (carré) est 105,9 kcal/mol moins stable que $2S_2^{2+}$. On a calculé les voies d'énergie minimale pour la réaction $2S_2^{2+} \rightarrow S_4^{2+}$ alors que les deux sont dans la symétrie C_{2v} et D_{2h}. Lorsqu'on utilise la méthode RHF/6-31G*, l'état de transition se trouve à environ 50 kcal/mol au-dessus de l'énergie du S_4^{2+} plan carré. En utilisant les méthodes CASSCF ou MP2, on peut diminuer considérablement cette énergie (jusqu'à environ 33 kcal/mol avec la méthode RHF/6-31G*). On rapporte aussi les fréquences vibrationnelles calculées pour la structure carrée et on les compare avec les valeurs expérimentales.

[Traduit par la rédaction]

Introduction

The first experimental identification that S_4^{2+} was square planar was made by Stevens (1) using magnetic circular dichroism. Gillespie et al. (2, 3), Clark et al. (4), and Minkwitz et al. (5) have carried out vibrational studies. Based on Gillespie's work (2), the bond distance of square planar S_4^{2+} was evaluated to be 2.00 Å (6). Passmore and co-workers (7–9) determined the structure of S_4^{2+} by X-ray crystallography. The most recent crystal structure determination of $S_4(AsF_6)_2 \cdot AsF_3$ leads to an average S—S bond distance of 1.999(6) Å for square planar S_4^{2+}. In addition to the dication, S_4^+ and S_4 have also been subjected to experimental investigation. The first evidence for the existence of S_4 and S_4^+ came from mass spectrometry experiments conducted on sulfur vapors by Berkowitz and co-workers (10, 11).

In most previous theoretical studies on S_4^{2+} (12–16), the cation has been assumed to possess a square (D_{4h}) structure based on the experimental results for S_4^{2+} and for the analogous cations Se_4^{2+} and Te_4^{2+} (17–20). While the planar D_{4h} structure is expected to have 6π-electron stabilization (21), the open chain form has the advantage of being less strained than the cyclic form. Theoretical studies on the D_{4h} isomer of S_4^{2+} were performed by Kao (14) who also included the rectangle (D_{2h}), the *cis*-planar (C_{2v}), *trans*-planar (C_{2h}), and the *gauche* (C_2) structure, using RHF methods with an STO-3G and a 44-31G basis set. It should be noted that none of the basis sets included polarization functions which are considered to be essential for calculations on sulfur compounds. The *trans*-planar form with a S—S short bond of 2.055 Å and a long bond of 2.383 Å at an angle of 104.9° was found to be the most stable, contrary to experimental results. The possibility of the existence of other isomers like the puckered ring (D_{2d}), tetrahedron (T_d), trigonal pyramid (C_{3v}), and trigonal planar structure (D_{3h}) was not explored. The structure and bonding of square planar S_4^{2+} have also been studied by Saethre and Gropen (12) using an ECP model and a Huzinaga basis set appended with *d*-functions. The S—S bond distance was found to be 1.999 Å.

In this paper we have undertaken an extensive *ab initio* study on the geometry of S_4^{2+}, taking eleven different structures into consideration and using a high level of basis set. In addition, we have also traced the reaction path for the dissociation of S_4^{2+} into two units of S_2^+.

Computational methods

Ab initio calculations were performed at various levels of theory using the GAUSSIAN suite of programs (22, 23). The geometries of eleven isomers, square planar (D_{4h}), rectangular (D_{2h}), rhombus (D_{2h}), *cis*-planar (C_{2v}), *cis*-nonplanar (C_2), *trans*-planar (C_{2h}), *trans*-nonplanar (C_2), trigonal planar (D_{3h}), trigonal pyramidal (C_{3v}), puckered ring (D_{2d}), and tetrahedral (T_d), were completely optimized, the overall symmetry being the only constraint, at the closed-shell restricted Hartree–Fock (RHF) level of theory with 3-21G* and 6-31G* basis sets. These basis sets include polarization functions which are known to be a requisite for studies on sulfur compounds if accurate results are desired (24, 25). Electron correlation has been taken into account by performing MP2/6-31G* geometry optimizations on the four most stable isomers. The potential energy curve for the dissociation of S_4^{2+} to two units of S_2^+ was traced in D_{2h} and C_{2v} symmetry, taking the distance between the mid-points of the S—S bonds as the reaction co-ordinate. To calculate the energy of the open-shell system S_2^+ the ROHF option of HONDO (26) was employed.

Results

Optimized geometries

The optimized equilibrium geometries for the different isomers of S_4^{2+} are given in Table 1.

At the 3-21G* level, the *cis*-planar isomer was found to be the most stable, followed closely by the rectangular and the *trans*- and *square*-planar forms. The rhombic isomer optimized to a square and the *cis*- and *trans*-nonplanar isomers became planar *cis* and *trans*, respectively. The *cis*-planar isomer was more stable than the rectangular form by 0.44 kcal/mol and dif-

TABLE 1. Optimized geometries and relative energies of various structures of S_4^{2+} (distances in Å, energies in kcal/mol)

Structure of S_4^{2+}	3-21G*			6-31G*		
	R	r	ΔE	R	r	ΔE
Square planar D_{4h}	1.985	1.985	1.36	1.990	1.990	0.00
Rectangular D_{2h}	2.962	1.779	0.44	2.963	1.778	10.00
cis-Planar C_{2v}	2.620	1.793	0.0[a]	2.404	1.840	7.04[e]
trans-Planar C_{2h}	2.375	1.821	0.59[b]	2.274	1.840	5.59[f]
Trigonal planar D_{3h}	—	1.840	108.22	—	1.855	110.00
Trigonal pyramidal C_{3v}	—	2.069	110.40[c]	—	2.082	113.80[g]
Puckered ring D_{2d}	—	2.118	95.11[d]	—	2.105	92.59[h]
Tetrahedral T_d	—	2.242	148.77	—	2.213	145.51

[a] $\theta = 102.3°$. [e] $\theta = 109.1°$.
[b] $\theta = 107.3°$. [f] $\theta = 107.1°$.
[c] $\theta = 135.9°$. [g] $\theta = 137.0°$.
[d] $\theta = 49.7°$. [h] $\theta = 49.6°$.

fered from the *trans* and square forms by 0.59 and 1.36 kcal/mol, respectively.

At the 6-31G* level the square planar isomer was found to be the most stable, 5.59 kcal/mol more stable than the *trans*-planar, 7.04 kcal/mol more than the *cis*-planar and 10.00 kcal/mol more than the rectangular isomer.

At the MP2/6-31G* level only the D_{4h}, D_{2h}, C_{2v}, and C_{2h} structures were studied. Here, the rectangular D_{2h} isomer was found to be the most stable, with $R = 3.063$ and $r = 1.889$ Å, followed by the square isomer at $\Delta E = 11.4$ kcal/mol and $R = 2.057$ Å. The *trans*-planar structure dissociated, whereas the *cis*-planar optimized to the rectangle.

According to Table 1 the optimized structures can be divided into two categories: regular-bonded and long-bonded. Among the regular-bonded ones are the square (1.98–2.06 Å), the tetrahedron (2.21–2.24 Å), the trigonal planar structure (1.84–1.85 Å), the puckered ring (2.10–2.12 Å), and the trigonal pyramidal structure (2.07–2.08 Å) (with optimized S—S distances given in parentheses). In all cases, the geometries were severely restricted, and all bond distances were forced to be the same. The most important long-bonded structure is the rectangle, with R = 2.96–3.06 Å, consisting of two S_2^+ units (r = 1.78–1.89 Å) loosely bound together. The *cis*-planar (R = 2.40–2.62 Å) and *trans*-planar (R = 2.27–2.37 Å) forms may also be included in this category, since in each case the two S_2^+ units (1.79–1.84 Å for *cis*-planar, and 1.82–1.84 Å for *trans*-planar) are weakly coupled. The ranges given for the bond distances arise from the differences in basis set and are seen to be quite small. Obviously, the deviations for long bonds are larger than for regular bonds.

Ignoring the structures which have (predictably) high energies, namely the tetrahedron, trigonal planar, puckered ring, and trigonal pyramidal, the structures competing for the lowest energy are the square structure with regular bonds, and the rectangular structure and the *trans*-planar and *cis*-planar structures with long bonds. Unfortunately, the methods and basis sets used do not allow for a clear decision on the most stable structure (in gas phase). It so happens that the square structure has an energy very similar to those of the long-bonded structures. The 6-31G* basis set predicts the square structure to be the most stable, in agreement with the measured crystal structure. The optimized R of 1.990 Å is very close to the experimental value of 2.0 Å. As will be discussed later, the square isomer represents a 6π electron system, whereas the rectangle corresponds to a π^*–π^* complex.

The optimized bond distances of S_2^+ are 1.781 Å in ROHF/3-21G* and 1.787 Å in ROHF/6-31G*. In 3-21G*, two S_2^+ units are more stable than the *cis*-planar structure of S_4^{2+} (the most stable one in this basis set) by 124.0 kcal/mol (and 125.4 kcal/mol relative to the square structure). In the 6-31G* basis set, two S_2^+ units are more stable than the square structure by 105.9 kcal/mol. The bond distance in an isolated S_2^+, 1.78–1.79 Å, is very similar to the (short) S—S distance in the long-bonded structures (1.78 Å).

Reaction paths for $2S_2^+ \rightarrow S_4^{2+}$

According to the optimized geometries given above, the reaction path $2S_2^+ \rightarrow S_4^{2+}$ will have two minima, one at a large distance (R = 2.3–3.0 Å) corresponding to the π^*–π^* complex, and the other at $R \cong 1.9$ Å, corresponding to a π-stabilized square. Therefore, two transition structures are expected, TS1 between the product and the π^* complex, and TS2 between the π^* complex and the reactants. The approach of the two S_2^+ radicals can be carried out in C_{2v} symmetry, which will go via the *cis*-planar complex and lead to a square-planar product, or in D_{2h} symmetry, in which case one gets the rectangle as an intermediate and again the square as a product. D_{2h} is a more restricted version of C_{2v}.

At large distances, one may also consider a nonplanar D_{2d} approach where the two S_2^+ units are perpendicular to each other. Enforcing D_{2d} symmetry would, however, lead to a tetrahedral product, which is shown to be highly unstable with respect to the square structure. A C_{2h} approach might also be considered, since it would allow in the 6-31G* basis set a *trans*-planar structure (lower in energy than *cis*-planar) as intermediate. However, a rotation about the central S—S bond would have to be performed in order to arrive at a square-planar product.

Overall, it was found best to study the C_{2v} pathway as well as the more restricted D_{2h} pathway. The reaction intermediates will be a *cis*-planar structure in C_{2v} and a rectangular structure in D_{2h}.

Woodward–Hoffmann analysis shows that the ground-state reaction leading from a square-planar structure to the reactants is symmetry forbidden, and requires a change in electron configuration. Figure 1 presents the Woodward–Hoffmann diagrams. The orbital labels S (symmetric) and A (antisymmetric) follow the general convention. Two planes of symmetry are preserved, indicated by I and II. For the reactants, the AS MO

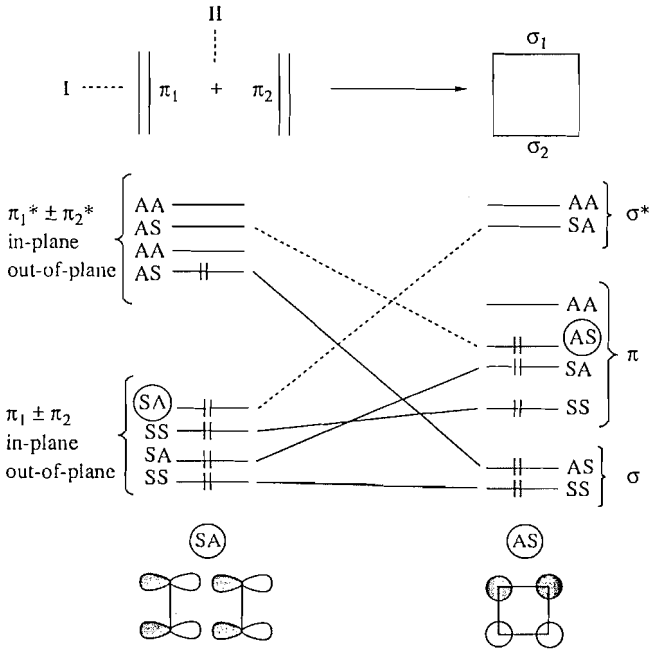

FIG. 1. Woodward-Hoffmann diagram for reaction $2S_2^+ \rightarrow S_4^{2+}$ (square).

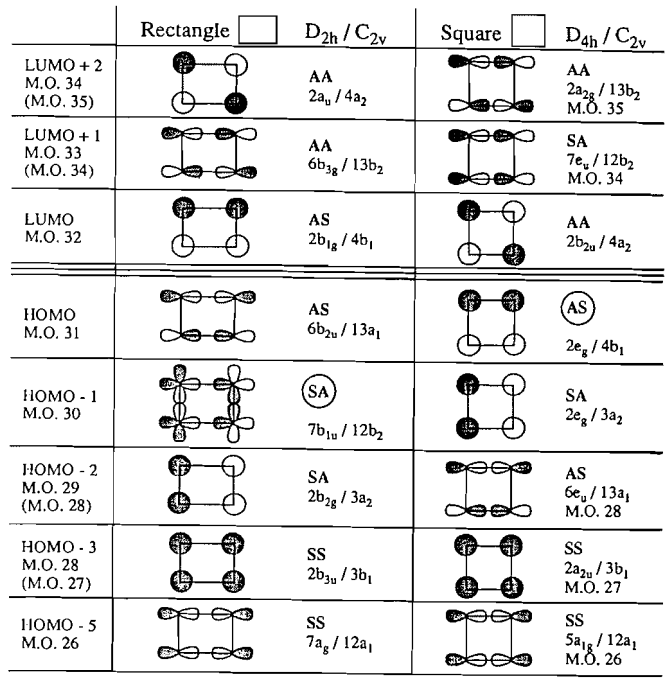

FIG. 2. MO diagrams for rectangular and square-planar S_4^{2+}, corresponding to MO's used in Fig. 1.

AS MO arising from in-plane and in-phase π_1^* and π_2^* interactions has been doubly occupied,since on approach this MO is more stable than the corresponding out-of-phase combination AA. Since the reaction intermediate is a π^*–π^* complex (with π_1^* and π_2^* in phase), the intermediate then has the same orbital occupation as the reactants.

It is seen that the occupied second SA orbital of the reactants (circled) crosses into an unoccupied SA MO of the product, and that in turn the occupied AS orbital of the product (circled) crosses into an unoccupied AS orbital of the reactants. The form of the occupied SA and AS orbitals involved in the crossing is shown at the bottom of Fig. 1. In C_{2v} (D_{2h}) symmetry, the crossing SA orbital of the reactants is a b_2 (b_{1u}) species, and the AS counterpart of the product is b_1 (b_{1g}). In D_{4h} symmetry, this last orbital is e_g.

In Fig. 2, the MO's of the rectangular complex and the square-planar product corresponding to those of the WH analysis are shown schematically together with the calculated ordering. It is seen that $7b_{1u}$ ($12b_2$ in C_{2v}) is occupied in the rectangle, and $2e_g$ ($4b_1$ in C_{2v}, $2b_{1g}$ in D_{2h}) in the product. Therefore, the SCF configuration of the rectangle (in D_{2h}/C_{2v} notation) is $...7b_{1u}^2 2b_{1g}^0/...12b_2^2 4b_1^0$, whereas of the product it is $...7b_{1u}^0 2b_{1g}^2/...12b_2^0 4b_1^2$. The reaction of $2S_2^+$ to the S_4^{2+} intermediate complex is symmetry allowed, since S_4^{2+} consists of two S_2^+ units loosely bound via favorable π^* interactions.

Single configuration methods like SCF do not allow for a smooth transition between two different configurations. The best one can do with SCF methods is to follow the individual configuration, and note their crossing point. In multireference methods an avoided crossing is encountered, at an energy somewhat lower than the energy of the configuration crossing point. The configurations now change smoothly into each other, resulting in a rounded-off potential maximum at the transition state.

For this purpose, the CASSCF option (27, 28) contained in GAUSSIAN90 was employed. Only two electrons, and two configurations ($..7b_{1u}^2 2b_{1g}^0 + ...7b_{1u}^0 2b_{1g}^2$ in D_{2h} symmetry) were correlated. For the lack of sufficient computer time, only the region around the transition state TS1 was investigated and the basis was restricted to 3-21G*.

In Figs. 3 and 4, minimum energy paths are given for the C_{2v} reaction in the 3-21G* and 6-31G* basis sets, respectively. Figures 5 and 6 show the corresponding minimum energy paths for D_{2h} symmetry. Figure 7 gives the D_{2h} path in the MP2/6-31G* optimization. In D_{2h} symmetry, the reaction coordinate is R, the same as that used before. However, in C_{2v} symmetry, R_{MM}, the distance between the midpoints of two S_2^+ units is chosen; it is defined in Fig. 3. In D_{2h} symmetry, R is of course identical to R_{MM}. In these figures, energy differences are given relative to the lowest-energy structure, which is the square structure in most but not all cases.

In both C_{2v} and D_{2h} pathways, TS1 is much higher in energy than TS2, as is expected from the Woodward–Hoffmann arguments given earlier. On the other hand, the TS2 energy is still quite high, about 25 kcal/mol above the π^* complex. Whereas TS1 is represented by a sharp peak, TS2 is very shallow, and occurs at high R values (about 5–6 Å).

The optimized values of R, R_{MM}, r, θ, and ΔE are summarized in Table 2. TS1, obtained from the crossing of the two SCF configurations, occurs at an energy (3-21G*/6-31G*) of 43.4/48.0 kcal/mol for the C_{2v} path, and 46.6/51.3 kcal/mol for the D_{2h} path (all relative to the square structure). CASSCF calculations performed in 3-21G* reduce the C_{2v} value from 43.4 to 36.0 kcal/mol, and the D_{2h} value from 46.6 to 39.0 kcal/mol. Only partial mixing of the two configurations could be accomplished. The transition state moved from R = 2.33 Å to R = 2.37–2.38 Å.

The second transition state TS2 has R_{MM} = 6.1 Å in C_{2v} with an energy 27.6/26.4 kcal/mol higher than the π^* complex, and R = 5.25 Å in D_{2h}, lying 28.2/25.4 kcal/mol above the π^* complex.

In the D_{2h} pathway calculated by MP2/6-31G*, TS1 has R =

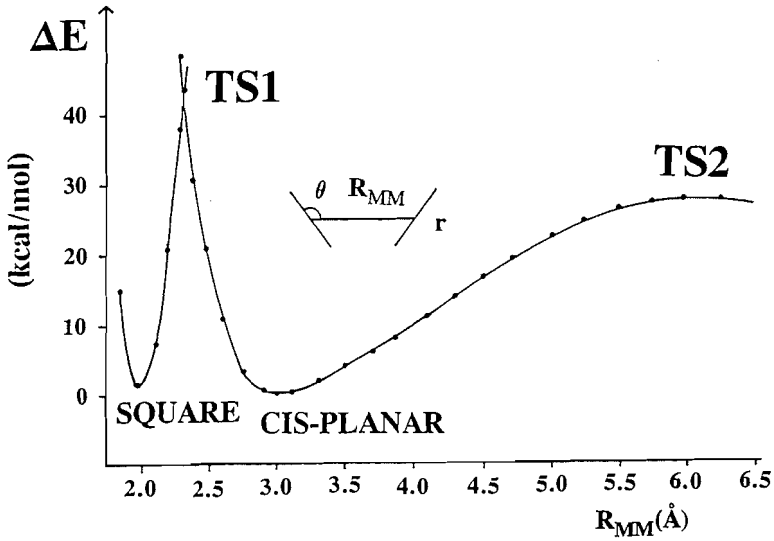

FIG. 3. Minimum energy path (RHF/3-21G*) for reaction $2S_2^+ \rightarrow S_4^{2+}$ in C_{2v} symmetry. Due to a change in electron configuration, TS1 is not well described in this method.

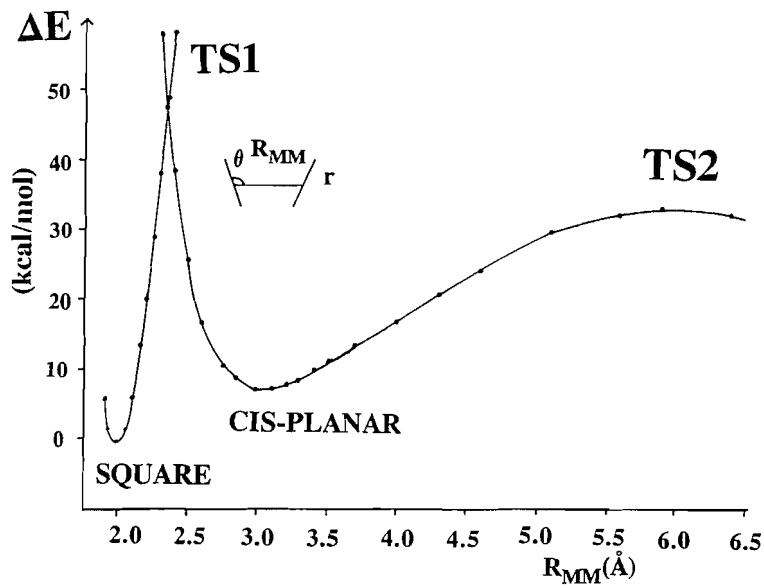

FIG. 4. Minimum energy path (RHF/6-31G*) for reaction $2S_2^+ \rightarrow S_4^{2+}$ in C_{2v} symmetry.

2.42 Å, and lies 21.7 kcal/mol above the square-planar form, whereas TS2 has a much shorter R (3.78 Å), lying only 3.2 kcal/mol above the rectangular structure (here it is the most stable). In this method, the energies of both transition states are significantly lower and the separation of the two S_2^+ units in TS2 has also decreased.

Vibrational frequencies

The vibrational frequencies of S_4^{2+} in its square form have been determined experimentally (2–5). The results considered to be the best (3) are shown in Table 3. Theoretical results, obtained with 3-21G* and 6-31G* basis sets, at the respective optimized square geometries, are also given in Table 3. Since the calculated frequencies are usually too large, it is customary to multiply them by a factor of 0.9. Such has been done here.

In the 6-31G* basis set, the largest disagreement between (scaled) theoretical and observed frequencies is 38 cm^{-1} for the B_{2g} vibration. The lowest energy vibration, B_{2u}, is both infrared- and Raman-forbidden, and has not been observed. B_{2u} is an out-of-plane vibration.

Conclusion

In crystal form, the structure of S_4^{2+} has been clearly established to be D_{4h}. *Ab initio* calculations show that because of a strong repulsion between two positive charges, the π-bonded D_{4h} structure competes with a loosely bonded S_2^+ dimer (C_{2v} or C_{2h}) in stability. The dimer results from π*–π* interaction. The Woodward–Hoffmann forbidden formation of S_4^{2+} (square) from $2S_2^+$ has an activation barrier of about 50 kcal/mol relative to the square structure (in RHF/6-31G*), the energy of

which can be lowered by configuration mixing (CASSCF) or by Möller–Plesset methods. Calculated vibrational frequencies compare well with experimental values.

Much higher levels of correlation methods (e.g. extensive MCSCF, or multireference CI) appear to be necessary to firmly establish the most stable structure of the intermediate, and thereby its energetic relation to the square structure. The same comment applies to a reliable estimate of the activation barrier. Nonconcerted mechanisms for the formation of S_4^{2+} are of interest and will be studied in future work.

CONSOLACIÓN P. MENAUT, JOSÉ M. PICO, JOSEFA FERNÁNDEZ, JOSÉ L. LEGIDO, and M. INMACULADA PAZ ANDRADE. Can. J. Chem. **72,** 304 (1994).

Experimental excess molar enthalpies h^E at 298.15 K and normal atmospheric pressure were obtained for the binary mixtures 1,2-dichloropropane + (2-propanone, 2-butanone, or 2-pentanone), 1,3-dichloropropane + (2-butanone or 2-pentanone), 1,4-dichlorobutane + (2-butanone or 2-pentanone) using a Calvet microcalorimeter. The h^E values for all the mixtures were negative. The experimental results used to test the capability of the interaction parameters of two versions of the UNIFAC group-contribution model to predict the proximity effect in these kind of mixtures.

CONSOLACIÓN P. MENAUT, JOSÉ M. PICO, JOSEFA FERNÁNDEZ, JOSÉ L. LEGIDO et M. INMACULADA PAZ ANDRADE. Can. J. Chem. **72,** 304 (1994).

Utilisant un microcalorimètre Calvet, on a mesuré les enthalpies molaires mieux expérimentales, h^E, à 298,15 K et à la pression normale des mélanges binaires 1,2-dichloropropane + (2-propanone, 2-butanone ou 2-pentanone), 1,3-dichloropropane + (2-butanone ou 2-pentanone) et 1,4-dichlorobutane + (2-butanone ou 2-pentanone). Les valeurs de h^E sont négatives pour tous les mélanges. On a utilisé les données expérimentales pour vérifier l'utilité des paramètres d'interaction de deux versions du modèle de contribution de groupe UNIFAC pour prédire l'effet de proximité dans ce type de mélange.

[Traduit par la rédaction]

Introduction

Group-contribution methods are powerful tools for estimating the thermophysical and thermodynamic properties of pure compounds and mixtures from experimental data on related substances. One of the problems with the current group-contribution models is the difficulty in predicting the thermodynamic properties of mixtures using a fixed set of parameters for the two main groups in the same molecule because the behaviour of the mixture varies with the proximity of the main groups.

The Cl—Cl proximity effect for dichloroalkane + alkane and dichloroalkane + polychloroalkane was analyzed by Kehiaian *et al.* (1–3) using the DISQUAC model. We have yet to find studies of this effect for dichloroalkane + 2-ketone binary mixtures.

Experimental excess enthalpies h^E of dichloroalkane + 2-ketone are very scarce in the literature. Heats of mixing of 2-propanone + dichloromethane have been measured at various temperatures (4–6), h^E of 1,2-dichloropropane + 2-propanone have been measured by Bougard and Jadot (7) and recently Kechavarz *et al.* (8) presented h^E data of 1,2-dichloroethane with several ketones. This lack of information and our interest in the proximity effect prompted us to investigate on thermodynamic properties of dichloroalkane + 2-ketone mixtures.

The present paper reports excess molar enthalpies at 298.15 K of the binary mixtures of 1,2-dichloropropane + (2-propanone, 2-butanone, or 2-pentanone), 1,3-dichloropropane + (2-butanone or 2-pentanone), 1,4-dichlorobutane + (2-butanone or 2-pentanone).

Experimental

2-Propanone (Aldrich >0.999), 1,3-dichloropropane and 1,4-dichlorobutane (Aldrich >0.99), 1,2-dichloropropane and 2-pentanone (Fluka >0.99), and 2-butanone (Fluka >0.995) were subjected to no further purification other than drying with Union Carbide 0.4 nm molecular sieves. Their densities measured with an Anton Paar 60/602 densimeter agree well with the literature values (9–11).

Binary mixtures were prepared by using a Mettler H51 balance (precision of 10^{-5} g) and air-tight stoppered bottles. Possible error in the mole fractions is estimated to be less 10^{-4}. All molar quantities are based on the IUPAC (12) relative atomic mass table.

Excess molar enthalpies, h^E, were measured with a standard Calvet microcalorimeter linked to a microcomputer through an analog digital card. The microcalorimeter was calibrated electrically using a stabilized current source (E.J.P. 30, Setaram). The performance of the apparatus was checked by determining excess enthalpies of *n*-hexane + cyclohexane at 298.15 K; our results differ by less than 1% from those of McGlashan and Stoeckli (13).

Results

Experimental results for the excess molar enthalpies at 298.15 K are listed in Table 1. To each set of h^E values a Redlich-Kister function

$$[1] \quad h^E/(\mathrm{J}\cdot\mathrm{mol}^{-1}) = x(1-x)\cdot\sum_{p=0}^{q} A_p\cdot(2x-1)^p$$

was fitted, where x is the molar fraction of dichloroalkane. The coefficients A_p and the standard deviation s given in Table 2 were calculated by unweighted least-squares method. The number of coefficients was determined using an F-test (14). Figure 1 shows the measured values of h^E plotted against x together with the curve fitted. The excess molar enthalpies for the system 1,2-dichloropropane + 2-propanone have been previously measured by Bougard and Jadot (7) at 302.92 K. Their equimolar excess enthalpies are 1% lower than our values at 298.15 K, both $h^E(x)$ curves have the same shape.

Discussion

In all mixtures studied the molar excess enthalpies are negative over the whole range of composition. In Fig. 2 the equimolar excess molar enthalpies $h^E(0.5)$ are plotted together with

those of López *et al.* (15) for the binary mixtures containing the same dichloroalkanes and certain ketones. With the ketones the excess molar enthalpies are more negative for 1,2-dichloropropane (α,β positions of the chloro atoms) than for the α,ω-dichloroalkanes, being $h^E(0.5)$ slightly greater for the systems containing 1,4-dichlorobutane. The variation of h^E with ketone length is very similar for the three dichloroalkanes: first $h^E(0.5)$ diminishes rapidly from 2-propanone to 2-butanone, varying slowly from 2-butanone to 2-heptanone. It is interesting to note that the general behaviour of these mixtures is very similar to that observed in ester + dichloroalkane (16) but is completely different to that of 1-chloroalkane + 2-ketone, which presents positive excess enthalpies and a linear variation of h^E with the 1-chloroalkane length (17, 18).

Among the group-contribution models able to predict excess

enthalpies only the Larsen *et al.* (19, 20) and Dang and Tassios (21–23) versions of the UNIFAC model provide interaction parameters corresponding to the alkanone + chloroalkane systems. The predictions of the two versions are listed in Table 3 and plotted in Fig. 2 together with the experimental values for h^E(0.5). The mean deviation for the system containing 1,2-dichloropropane is about 9% for the Dang and Tassios version and 10% for the Larsen *et al.* version. For other mixtures the mean deviation is higher and in some cases its magnitude is of the same order as the experimental values. This is because the interaction parameters for both versions are calculated using the experimental values of 1,2-dichloroalkane + 2-propanone at 302.92 K as h^E database (19, 22).

Our analysis again shows that group-contribution models have great difficulties in predicting the variation of h^E with the distance between the two main groups (proximity effect). Two solutions have been proposed to solve this problem: (*a*) Define new functional groups whose atoms have the same electrical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

charge in all molecules containing that functional group. The group should be approximately electroneutral (see Wu and Sandler, refs. 24, 25). However, the dichloroalkanes considered here have not yet been studied, (*b*) Keep the group definition the same and as simple as possible for any given class of compounds, but allow the interaction parameters to vary with the structure as in the DISQUAC model (1–3).

More experimental g^E and v^E data are needed to determine the parameters of DISQUAC and Nitta-Chao Models (26). Measurements of these quantities would be of interest to complete the theoretical studies of these mixtures.

On the role of hexafluoroisopropanol in Diels–Alder reactions of acid-sensitive reagents

CARLOS CATIVIELA, JOSÉ I. GARCÍA, JOSÉ A. MAYORAL,[1] AND LUIS SALVATELLA

Departamento de Química Orgánica y Química Física, Instituto de Ciencia de Materiales de Aragón, Universidad de Zaragoza-Consejo Superior de Investigaciones Científicas, 50009 Zaragoza, Spain

Received July 16, 1993

CARLOS CATIVIELA, JOSÉ I. GARCÍA, JOSÉ A. MAYORAL,[1] and LUIS SALVATELLA. Can. J. Chem. **72**, 308 (1994).

1,1,1,3,3,3-Hexafluoro-2-propanol (HFIP) is described as an excellent solvent for those Diels–Alder reactions in which Lewis-acid-sensitive reagents are used, leading to high yields with good regio- and *endo/exo* selectivities under very mild conditions.

CARLOS CATIVIELA, JOSÉ I. GARCÍA, JOSÉ A. MAYORAL[1] et LUIS SALVATELLA. Can. J. Chem. **72,** 308 (1994).

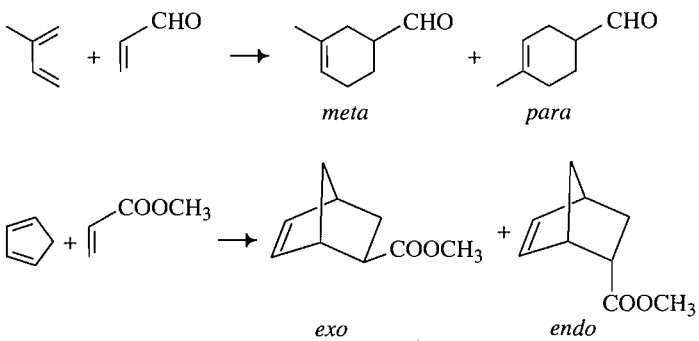
On met en évidence que le 1,1,1,3,3,3-hexafluoropropan-2-ol (HFIP) est un excellent solvant pour les réactions de Diels–Alder dans lesquelles on utilise des réactifs sensibles aux acides de Lewis; il en résulte d'excellents rendements avec de bonnes régio- et *exo/endo*-sélectivités, dans des conditions très douces.

[Traduit par la rédaction]

Introduction

In the last few years several works dealing with the effect of solvent on intermolecular Diels–Alder reactions have been published (1). Recently, we studied (2) how the solvent modifies the rate, *endo/exo*, and diastereofacial selectivities of the Diels–Alder reaction between (−)-menthyl acrylate and cyclopentadiene. In particular, solvents with a high hydrogen-bond-donating (HBD) ability, namely fluorinated alcohols, lead to selectivities that are comparable to those obtained when Lewis acids are used as catalysts. Therefore they behave as mild Lewis acids. These results prompted us to study the effect of this kind of solvents on the rate and *endo/exo* selectivity of the reaction between methyl acrylate and cyclopentadiene (Scheme 1).

To the best of our knowledge, there is no systematic work on the effect of the solvent on the regioselectivity of these reactions, so we have also studied the effect of fluorinated alcohols on the rate and regioselectivity of the reaction between isoprene and acrolein (Scheme 1).



SCHEME 1

Results and discussion

Table 1 gathers the rate constants of the previously mentioned reactions carried out in several reaction media. The variation of the measured kinetic constants of the reaction between methyl acrylate and cyclopentadiene is plotted against the concentration of 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP) in Fig. 1. As can be seen, the rate constant increases until 30% HFIP is present in the reaction medium, and then it remains constant.

To explain this behaviour, a specific interaction between the HBD solvent and the dienophile can be proposed. In fact, the dienophile IR carbonyl band moves from 1731 to 1709 cm^{-1} when passing from toluene to toluene/HFIP 70:30, spectra at intermediate HFIP concentrations showing the simultaneous presence of both carbonyl bands. It can thus be concluded that HFIP behaves as a mild Lewis acid.

However, when pure HFIP is used as a solvent, a further increase in the rate constant is experimentally observed. Two possible explanations could account for this abnormal behaviour. On the one hand, the change of the bulk properties of the reaction medium may modify the value of the rate constant through a nonspecific solvation mechanism. Alternatively, it is well known that HFIP is a relatively strong Brønsted acid ($pK_a = 9.3$), so that very reactive protonated dienophile species can be envisaged.

In the case of the acrolein IR carbonyl band, the simultaneous presence of both free (1699 cm^{-1}) and solvent-associated (1687 cm^{-1}) bands is observed until toluene/HFIP 90:10, which agrees with the noticeable increase in the rate constant observed when passing from 0% to 10% HFIP (Table 1 and Fig. 1). From this proportion of HFIP a further increase in the rate constant was not to be expected on the basis of a specifically solvated dienophile as reactive intermediate. However, a steady increase in the rate constant with the concentration of HFIP is observed. This increase is more marked when passing from 70 to 100% HFIP. The above mentioned hypotheses may again account for this behaviour. To choose between the hypotheses, the reaction was carried out in the presence of a small amount of a stronger Brønsted acid, namely trifluoroacetic acid (TFA, $pK_a = 0.52$), whose Lewis acidity (as defined by the Kamlet–Taft empirical solvent parameter α) was not expected to be very different from that of HFIP. The results obtained show that this reaction medium gives rise to a further acceleration of the reaction rate (Table 1). The noticeable increase in reaction rate is in agreement with a catalysis through proton transfer.

It might be thought that the behaviour of the HFIP is due to the presence of traces of hydrogen fluoride. To rule out this possibility, the reaction in pure HFIP was repeated in the presence of triethylamine. The reactions with and without NEt_3 led to almost identical results. A slight difference in rate was observed, which can be attributed to a base-catalyzed addition of HFIP to the dienophile, detected by GC–MS. However, the regioselectivity remained unchanged, which enables us to rule out the existence of a hydrogen fluoride-catalyzed reaction.

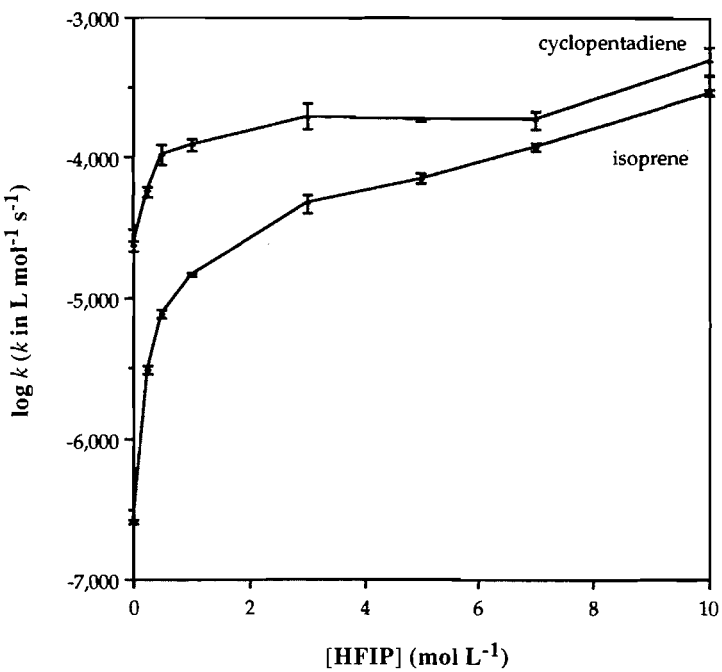

FIG. 1. The effect of concentration of HFIP on rates of the reactions of methyl acrylate with cyclopentadiene, and of isoprene with acrolein

The differences between both dienophiles deserve separate comment. The results obtained suggest that the ability of HFIP to transfer a proton to the dienophile increases with the possibility of solvation of the protonated intermediate by other molecules of HFIP, and with the basicity of the dienophile. Therefore, in pure HFIP, both dienophiles can be protonated, given the efficient solvation of the protonated species, but in reaction media with low proportions of HFIP, only the most basic dienophiles can lead to stable protonated intermediates.

Table 2 gathers the *para/meta* and *endo/exo* selectivities obtained in the reactions of isoprene with acrolein, and of cyclopentadiene with methyl acrylate, respectively (Scheme 1).

With regard to *para/meta* selectivities, the behaviour observed is parallel to that of the rate constants, the greatest increase being observed when passing from 0 to 5% HFIP. The influence of the abovementioned protonated intermediate on regioselectivity is corroborated by the reaction carried out in the presence of a small amount of TFA (Table 2).

endo/exo Selectivity also increases noticeably with the first addition of HFIP, and then remains almost constant. Unlike the rate constant, *endo/exo* selectivity does not significantly increase when the reaction is carried out in pure HFIP. To clarify this point, it would be useful to carry out some experiments in the presence of TFA. Unfortunately, in these conditions, a fast and

[d]Trifluoroacetic acid.

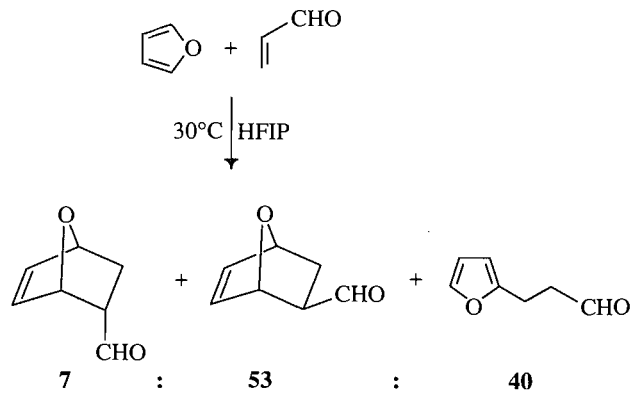
extensive oligomerization was experimentally observed. The diene oligomerization was also observed in reaction media with high concentrations of HFIP. The existence of this lateral reaction is in agreement with the role of the HFIP as a Brønsted acid.

It is well known that Diels–Alder reactions using acrolein as the dienophile often give undesirable results due to the fact that acrolein easily polymerizes. To overcome this problem, a variety of homogeneous (5) and heterogeneous (6) Lewis acids, high pressures (7), and acetals of acrolein (8) have been employed. Even under these conditions yields obtained with open-chain dienes are often less than 65%. Recently higher conversions (95%) were obtained by using uncommon organometallic compounds as catalysts (9). On the other hand, high percentages of conversion with high regioselectivities can be obtained in the reaction of acrolein and isoprene in solvent mixtures containing HFIP. When the reaction is carried out in a different fluorinated alcohol, namely, 2,2,2-trifluoroethanol (TFE, $pK_a = 12.9$), the conjugate addition of the solvent to the acrolein is observed, but this reaction does not take place with the more acidic and less nucleophilic HFIP.

It is noteworthy that the use of aqueous media in this reaction improves the results when compared with an "inert" solvent such as toluene. However, better results are obtained with HFIP, even in small proportions, which suggests that this solvent plays a catalytic role.

Recently, lithium perchlorate – diethyl ether was reported to be an excellent reaction medium for Diels–Alder reactions. Nevertheless, HFIP allows us to obtain a noticeably higher regioselectivity. Furthermore, HFIP has two additional advantages, namely, the higher solubility of reagents, and the easy recovery of most of the HFIP with a high degree of purity.

The reaction between methyl acrylate and cyclopentadiene in pure HFIP is fast and a high *endo/exo* value, slightly greater than that obtained with $LiClO_4$– ether, is observed. However, the best selectivity is achieved in methanol/water 70:30, with a reaction rate similar to that obtained in HFIP, and without extensive diene oligomerization. These results suggest that aqueous mixtures are more suitable for cyclopentadiene reactions.



SCHEME 2

While HFIP is a suitable solvent for reactions of Lewis-acid-sensitive reagents, such as acrolein, it is not so good when they are sensitive to Brønsted acids, such as cyclopentadiene and 2,3-dimethylbutadiene. Thus, in the reaction between the latter and acrolein, cycloadducts are obtained in only 44% yield, and diene oligomerization is experimentally observed. Finally, we considered it was worth testing a cycloaddition where both diene and dienophile are acid-sensitive, namely the reaction between furan and acrolein (Scheme 2). In 48 h acrolein completely disappears, giving the corresponding oxanorbornene derivatives (*exo/endo* = 7.6) as major products. This is a very good result for a Diels–Alder reaction of furan (10). Together with the two Diels–Alder cycloadducts, 3-(2-furyl)-propanal is obtained. It has been reported (10) that oxanorbornene derivatives can lead thermally to this kind of product. However, all our treatments were carried out at room temperature, and the formation of the 3-(2-furyl)propanal was observed over short reaction times. Thus we propose that the use of a nucleophilic diene such as furan leads to a concurrence between the Diels–Alder and the conjugate addition, the former being the favoured reaction.

To sum up, HFIP is a suitable and recoverable solvent for Diels–Alder reactions, above all when the reagents are Lewis-acid-sensitive. The Friedel–Crafts addition observed when furan is used as diene indicates the possibility of using HFIP in a variety of acid-catalyzed organic reactions.

Experimental

HFIP, TFE, and TFA were purchased from Aldrich and used without further purification. Toluene, ether, and methanol were dried and purified according to standard procedures. ^1H NMR spectra were recorded in a Varian Unity 300 MHz apparatus. GC–MS experiments were performed using a VG Autospec trisector EBE spectrometer.

Reaction procedures

Isoprene + acrolein

A solution of isoprene (408 mg, 6 mmol) in the corresponding reaction medium (2 mL) was added to a thermostated (30 ± 0.1°C) solution of acrolein (112 mg, 2 mmol) in the same solvent or solvent mixture (2 mL). The solution was magnetically stirred and the reaction monitored by gas chromatography (FID from Hewlett–Packard 5890 II; cross-linked methyl silicone column, 23 mm × 0.2 mm × 0.33 μm; helium as carrier gas, 17 psi (1 psi = 6.9 kPa); injector temperature 230°C, detector temperature 250°C, oven temperature program: 50°C (3 min) – 25°C/min – 75°C (12 min); retention times: acrolein 1.9 min, toluene 4.8 min, *meta* cycloadduct 14.4 min, *para* cycloadduct 14.7 min).

In the reaction carried out in pure HFIP the stirring was maintained for 3 h, the solvent recovered by distillation under reduced pressure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

(3.4 mL, 85% with a purity ≥ 98% determined by GC), and the mixture obtained dissolved in methylene chloride (5 mL) and treated with $Na_2CO_3 \cdot 10H_2O$. The solution was separated by filtration and the solvent eliminated under reduced pressure to afford 196 mg (79%) of a 11:1 mixture of *para* and *meta* cycloadducts. The ^1H NMR of the mixture did not indicate great differences between both adducts. The structural assignment of the cycloadducts was made on the basis of the experimental results previously described (5*a*, 9*a*, 11). Recently, a new method based on mass spectrometry coupled with theoretical calculations was reported for the structural assignment of Diels–Alder regioisomers (12). The results obtained through this methodology are in complete agreement with those previously described. ^1H NMR ($CDCl_3$), δ ppm: 9.674 (CHO *meta*), 9.665 (CHO *para*, d, J = 0.978 Hz), 5.37–5.38 (bs, 1H), 2.41–2.43 (m, 1H), 1.92–1.97 (m, 2H), 1.65–1.70 (m, 1H), 1.624 (d, J = 0.486 Hz). MS spectra: *para* cycloadduct, m/z = 124 ($M^{\cdot+}$, 70%), 67(100%); *meta* cycloadduct, m/z = 124 ($M^{\cdot+}$, 44%), 95(100%).

Cyclopentadiene + methyl acrylate

A solution of freshly distilled cyclopentadiene (396 mg, 6 mmol) in the corresponding reaction medium (2 mL) was added to a thermostated (30 ± 0.1°C) solution of methyl acrylate (172 mg, 2 mmol) in the same solvent or solvent mixture (2 mL). The solution was magnetically stirred and the reaction monitored by gas chromatography (FID from Hewlett-Packard 5890 II; cross-linked methyl silicone column, 23 mm × 0.2 mm × 0.33 μm; helium as carrier gas, 17 psi; injector temperature 230°C, detector temperature 250°C. oven temperature program: 50°C (3 min) – 25°C/min – 100°C (9 min); retention times: methyl acrylate 2.7 min, *exo* cycloadduct 12.7 min, *endo* cycloadduct 12.9 min). The structural assignment of the cycloadducts was made on the basis of their ^1H NMR spectra (13).

Furan + acrolein

A solution of furan (408 mg, 6 mmol) in HFIP (2 mL) was added to a thermostated (30 ± 0.1°C) solution of acrolein (112 mg, 2 mmol) in HFIP (2 mL). The solution was magnetically stirred for 48 h and the reaction monitored by TLC. The HFIP and the excess of furan were eliminated under reduced pressure and the mixture obtained was dissolved in methylene chloride (5 mL) and treated with $Na_2CO_3 \cdot 10H_2O$. The solution was separated by filtration and the solvent eliminated under reduced pressure. The resulting mixture was analysed by ^1H NMR in $CDCl_3$, its composition being determined by integration of the CHO signals: 9.790 ppm (t, J = 1.5 Hz, Friedel–Crafts adduct), 9.608 (d, J = 3.9 Hz, *exo* cycloadduct), 9.376 (d, J = 3.0 Hz, *endo* cycloadduct). The structural assignment of the cycloadducts was made taking into account the differences in the respective ^1H NMR spectra. Thus, the chemical shift of the formyl proton should be greater in the *exo* adduct because of the anisotropic effect of the double bond. This behaviour was previously described for other 2-substituted-7-oxabicyclo[2.2.1]hept-5-enes, carrying a carboxylic acid or ester substituent (14).

ADRIAN L. SCHWAN, MICHAEL R. ROCHE, JOHN F. GALLAGHER, and GEORGE FERGUSON. Can. J. Chem. **72**, 312 (1994).

Several acyclic α-chlorosulfoxides have been shown to undergo a γ-dehydrochlorination upon treatment with LDA. The proposed immediate products of γ-dehydrochlorination, thiirane-*S*-oxides, are unstable under the basic conditions and react further with the LDA; the isolated products are usually *E*-alkenes and (or) *E*-vinyl sulfoxides. Some of the proposed intermediate thiirane-*S*-oxides, compounds **6**, **7**, **8**, and **18**, were synthesized independently and treated with one equivalent of LDA in order to mimic the second step of the overall dehydrochlorination/ring opening sequence. The products obtained from the reactions of compounds **6** and **18** compared favourably with those products which were believed to arise from certain conformations of α-chlorosulfoxides **1kB** and **1e**, respectively. The addition of one equivalent of LDA to **1kA** afforded a mixture containing thiirane-*S*-oxide **8**, which is proposed as the immediate product of γ-dehydrochlorination of **1kA**. The configurations of **1kB** and **1hA** were both shown to be *threo* by X-ray crystallographic studies. Those conformations which are preferred for the dehydrochlorination possess a geometry where the sulfinyl oxygen is *anti* to any of the substituents of the ring carbons.

ADRIAN L. SCHWAN, MICHAEL R. ROCHE, JOHN F. GALLAGHER et GEORGE FERGUSON. Can. J. Chem. **72**, 312 (1994).

On démontre que, par traitement avec du LDA, plusieurs α-chlorosulfoxydes subissent une γ-déshydrochloration. Les produits immédiats proposés pour cette réaction, les *S*-oxydes de thiirane, sont instables dans les conditions basiques de la réaction et réagissent à nouveau avec le LDA; les produits isolés sont habituellement des (*E*)-alcènes et (ou) des (*E*)-vinylsulfoxydes. On a synthétisé par des voies indépendantes quelques-uns des intermédiaires *S*-oxydes de thiirane proposés, les composés **6**, **7**, **8** et **18**, et, dans le but d'évaluer leur comportement dans la deuxième étape de la séquence globale de déshydrochloration/ouverture de cycle, on les a soumis à l'action d'un équivalent de LDA. Les produits obtenus lors des réactions des composés **6** et **18** se comparent favorablement avec les produits qui devraient être obtenus respectivement à partir de certaines conformations des α-chlorosulfoxydes **1kB** et **1e**. L'addition d'un équivalent de LDA sur le composé **1kA** conduit à un mélange contenant l'oxyde de thiirane **8** que l'on propose comme intermédiaire lors de la γ-déshydrochloration du produit **1kA**. Faisant appel à des études cristallographiques par diffraction des rayons X, on a déterminé que les configurations **1kB** et **1hA** sont *thréo*. Les conformations privilégiées pour la déshydrochloration possèdent une géométrie dans la quelle l'oxygène du sulfinyle est *anti* par rapport à tous les substituants carbonés du cycle.

Introduction

The Ramberg–Bäcklund (α-halosulfone) rearrangement has been a popular synthetic tool for the synthesis of alkenes for several decades (1, 2). While related reactions have not met with the consistent acceptance of the α-halosulfone approach (3, 4), some variations have nevertheless been shown to be efficient routes to alkenes (4). Vogel, Weinges et al. (4) have shown that certain cyclic α-chloro*sulfoxides* undergo γ-dehydrochlorination to furnish the corresponding cycloalkene in high yield. Since the sulfoxide group possesses a chiral sulfur, it occured to us that the deprotonation/dehydrochlorination step in the γ-dehydrochlorination of α-chlorosulfoxides may proceed with some selectivity for either of the diastereotopic hydrogens that are the target of the base. Unfortunately, the obtention of alkene products in the previous work (4) affords no such stereochemical information.

The expected immediate products of γ-dehydrohalogenation of α-chlorosulfoxides are thiirane-*S*-oxides. Bonini et al. (5) have shown that some thiirane-*S*-oxides are attacked at sulfur by lithium amides and lithium alkyls to create alkene and at hydrogen (deprotonation) to induce ring opening and formation of lithium ethenesulfenate ions. The sulfenates could be captured at sulfur with methyl iodide to afford vinyl sulfoxides. The different ratio of alkene to vinyl sulfoxide was found to be dependent on the stereochemistry of the starting thiirane-*S*-oxides. Moreover, the *E*:*Z* ratio of the alkenes and of the vinyl sulfoxides was also found to be dependent on the stereochemistry of the starting thiirane-*S*-oxides (5). In a preliminary communication (6), we reported the γ-dehydrohalogenation of a series of acyclic α- chlorosulfoxides and one example that indicated the existence of stereochemical forces governing the course of the reaction.

It seemed to us that the stereochemical dependence on the mode of the deprotonation/ring opening of the thiirane-*S*-oxides and its efficiency could provide a handle for the evaluation of the γ-dehydrohalogenation of α-halosulfoxides. In this paper we demonstrate that the stereochemcial attributes of the reaction seem to be general and we report on chemistry aimed at determining the origin of the stereochemical constraints.

Results and discussion

Several α-chlorosulfoxides were prepared, including some diastereomeric mixtures and some separable pairs of diastereomers that were initially identified as the more polar and less polar isomers.[3] Each diastereomer was exposed to two equivalents of LDA at −78°C or 0°C and the mixtures were quenched with MeI or $PhCH_2Br$. Under these conditions, vinyl sulfoxides and alkenes were obtained in variable yields. In general those chlorosulfoxides with a phenyl attached to the α-carbon (to the sulfinyl) were consumed at −78°C; most of the other systems

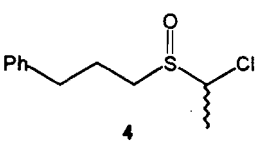
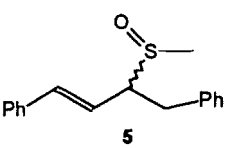
SCHEME 1





were warmed to 0°C to complete the reaction. The yields of vinyl sulfoxide and of alkene are listed in Table 1 (Scheme 1). Many systems failed to yield any alkene, while chlorosulfoxide **1g** afforded only tetramethyl ethylene. Vinyl sulfoxide geometry was established using the H-C=C-H ^{1}H NMR coupling constants where possible. Three particularly important cases (vide infra) could not be assigned on this basis, so the usefulness of lanthanide shift reagents was explored. It is known that the

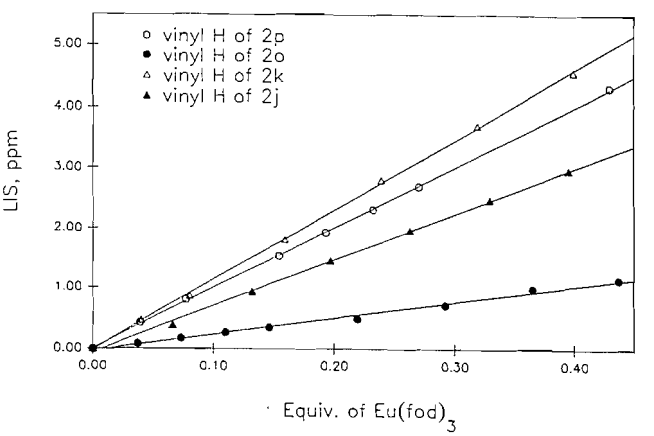


FIG. 1. Dependence of vinyl hydrogen ^{1}H NMR chemical shift on Eu(fod)$_3$ concentration.

sulfinyl functionality binds such reagents strongly (5, 7), and that vinyl hydrogens *cis* to the sulfinyl moiety in a vinyl sulfoxide are shifted noticeably downfield (5). Hence, isomers **2k**, **2o**, and **2p** as well as **2h** were mixed with increasing amounts of Eu(fod)$_3$ (see Experimental) in an NMR tube. The change in chemical shift of the vinyl hydrogen of each of the substrates was compared to the relative amount of shift reagent present and the data are presented in Fig. 1. It is clear that the vinyl hydrogens *cis* to a methylsulfinyl group (as in **2h**, **2k**, and **2p**) are most affected by the presence of the shift reagent; this is manifested by a conspicuous downfield movement. On the other hand, with **2o** the change in chemical shift of the vinyl hydrogen is much less significant, as expected for a hydrogen *trans* to the sulfoxide.

We suggest that the chemistry taking place is consistent with previous work (4, 5) and that our obtaining of vinyl sulfoxides

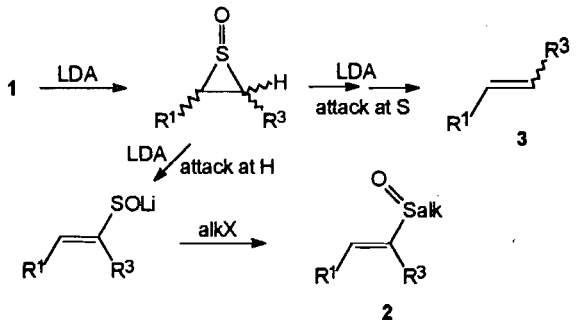

SCHEME 2

and alkenes is best explained by the following mechanism. The LDA induces a γ-dehydrochlorination reaction to form a short-lived thiirane-*S*-oxide, which is then attacked by a second equivalent of LDA at either sulfur or hydrogen (Scheme 2). Ring closure of **1g** yields tetramethyl ethylenesulfide-*S*-oxide, a compound that bears no ring hydrogens; further attack is only at sulfur in this instance. Each pair of diastereomers affords somewhat similar products although the less polar diastereomers among the sets tended to undergo the γ-dehydrochlorination less efficiently. The reactions of compounds **1h** and **1k** are shown in Schemes 3 and 5. In those reactions, the yields or identity of the products were notably different. Chlorosulfoxide **1hA** provided **2e** and **2h** in a ratio 1.66:1, whereas with **1hB** the ratio reverses to 1:15. The different reactivities of **1kA** and **1kB** are also striking. The γ-dehydrochlorination and subsequent reactions of **1kA** yielded alkene **3k** and vinyl sulfoxides **2k** and **2o**, but its corresponding diastereomer **1kB** afforded **2k** and, as a major product, **2p**, the vinyl sulfoxide possessing *cis-trans* geometry opposite to **2o**.

Due to the measurable differences in their chemistry, compounds **1hA/B** and **1kA/B** were viewed as suitable examples for a more detailed analysis of the conformations required for γ-dehydrochlorination and perhaps the origin of the stereochemical requirements of the ring closure. To begin, the relative stereochemistry of the chlorine and the sulfinyl oxygen in one of the starting isomers had to be determined. This was accomplished by single crystal X-ray analysis for two compounds, chlorosulfoxides **1kB** and **1hA**. Suitable crystals of **1kB** and **1hA** were obtained by recrystallization from 60–80 petroleum ether. The crystal structure analyses proceeded smoothly; the molecular dimensions are entirely in accord with accepted values and serve to establish the structures and relative stereochemistry unequivocally. Views of **1kB** and **1hA** showing the configuration and the conformation adopted in the solid state are in Fig. 2; from these diagrams it is clear that both **1kB** and **1hA** have the *threo* configuration. In both **1kB** and **1hA** in the solid state, the conformation adopted has the side chain maximally extended with the O—S—C—Cl torsion angle −57.9(3)° in **1kB** and 47.9(5)° in **1hA**.

The approach described herein entails the independent synthesis of transient thiirane-*S*-oxides of known stereochemistry and their treatment with *one* equivalent of LDA. Analysis of the products may allow some conclusions about the mode of ring closure to the thiirane-*S*-oxides. The mechanistic dissection requires two assumptions. The first is that the γ-dehydrochlorination proceeds via a double inversion mechanism from a conformation where the H—C, C—S, S—C, and C—Cl bonds form a "W" as in Fig. 3. Such a conformation seems to be the

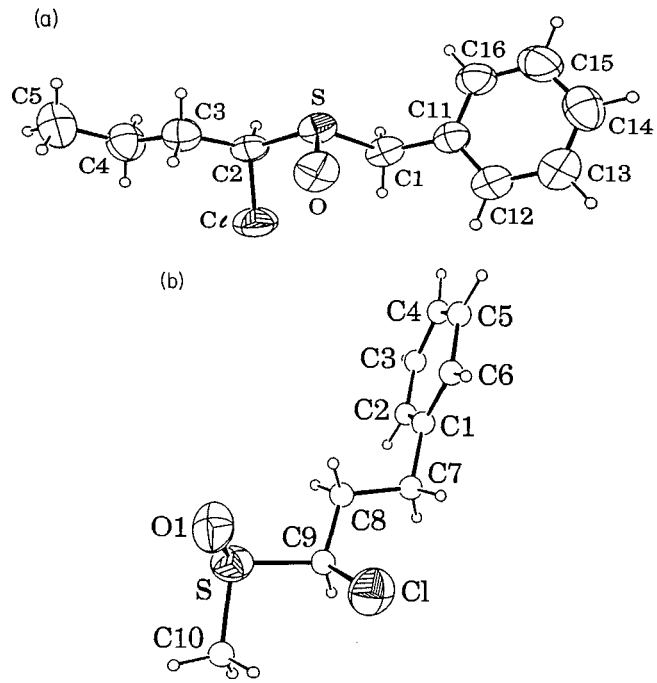

FIG. 2. AN ORTEP view of (*a*) molecule **1kB** and (*b*) **1hA** showing the *threo* configuration and the crystallographic numbering schemes. Thermal ellipsoids are drawn at the 50% level for non-H atoms; H atoms are shown as spheres of a small size.

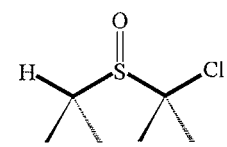

FIG. 3. Assumed "W" conformation for the γ-dehydrochlorination of α-chlorosulfoxides.

preferred geometry of dehydrohalogenation of α-halosulfones (1) and it is the only geometry available for the cyclic compounds of Vogel and Weinges (4). Those compounds undergo the γ-dehydrochlorination very efficiently (85–90%). Furthermore, the anion stabilizing effects of n–σ^* hyperconjugation (9) with the S—CClR′R″ bond are maximized when deprotonation occurs when the H—C, C—S, and S—C bonds are aligned as in the W conformation. The second assumption requires that the ring closure step is totally independent of the ensuing deprotonation step. This second assumption may not be valid due to the Lewis basic properties of the sulfinyl oxygen and the Lewis acidic nature of the lithium cations present. Some sort of coordination of the oxygen to a lithium cation may be present in the dehydrochlorination/ring opening mixture that cannot be matched by the use of thiirane-*S*-oxides alone.

Based on the first assumption, the possible conformations for ring closure of **1kA** and of **1kB** (two each) are shown in Scheme 3. From these drawings it can be seen that the conformation of **1kB** bearing *syn* phenyl and propyl groups (**C1**) should close to thiirane-*S*-oxide **6**. If the phenyl and propyl groups are *anti* (**C2**) during the dehydrochlorination, the product should be **7**. Similarly, for the *erythro* isomer **1kA**, closure of one conformation (**C3**) leads to **8** while reaction of the other (**C4**) affords **9**.

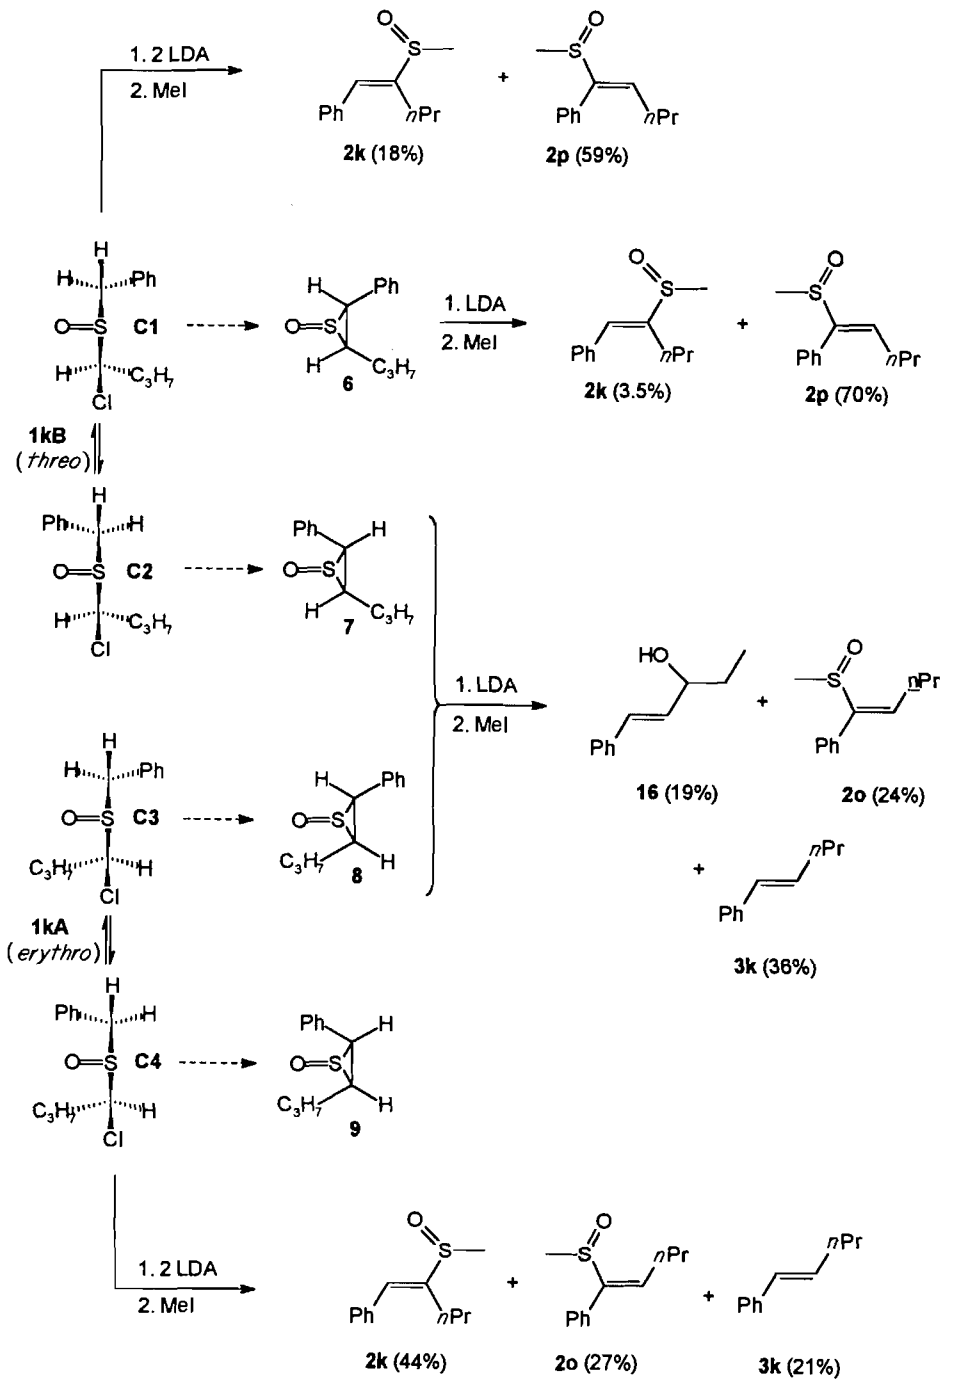
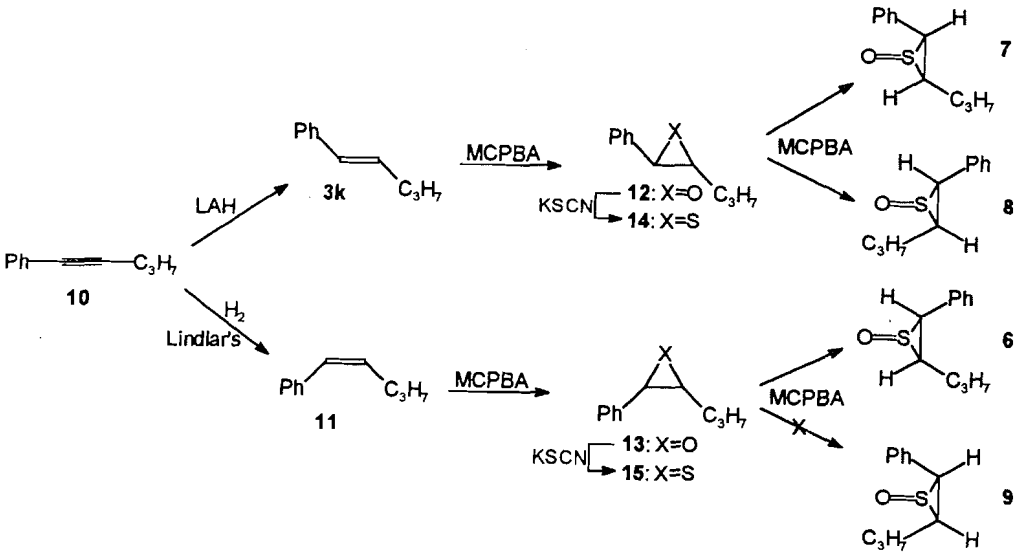


SCHEME 3

Using an oxidation step it was believed that **7** and (or) **8** would be accessible from thiirane **14**. Thiirane-*S*-oxide **6** should be readily available from thiirane **15** by oxidation. Thiirane-*S*-oxide **9** would probably be inaccessible via oxidation of **15** since oxidation of *cis*-stilbenesulfide affords only the isomer where the sulfinyl oxygen is *anti* to the phenyl groups (10). The requisite thiiranes were prepared from 1-phenylpentyne (**10**) as indicated in Scheme 4. Not surprisingly, oxidation of **15** afforded only one product; it was assigned the structure of thiirane-*S*-oxide **6** (10). Compound **6** is a thermally sensitive species and all handling of it was done at temperatures lower than 0°C. The reaction of **6** with LDA afforded predominantly vinyl sulfoxide **2p** (70%, 98% geometrically pure) and **2k** (3.5%) (Scheme 3). This result is in keeping with ring closure via conformation **C1**, since the products from γ-dehydrochlorination of **1kB** were **2p** (59%) and **2k** (18%) (Scheme 3). The yields are not exact matches with one another. The difference may be due to partial breakdown of our second assumption regarding the dependence of the two steps of the α-chlorosulfoxide to sulfenate reaction. It is also possible that the γ-dehydrochlorination does not proceed exclusively via **C1**, but that conformation **C2** is also important. Hence closure of **1kB** via **C2** to **7** may be responsible for the eventual formation of **2k**. Also worth noting at this stage is that the substituent



SCHEME 4

geometry of **6** is maintained during the conversion of **6** to **2p**. Bonini et al. observed similar retention of stereochemistry during the reaction of LDA with *cis*-stilbenesulfide-*S*-oxide (5).

The oxidation of thiirane **14** afforded a thermally sensitive mixture of thiirane-*S*-oxides **7** and **8**. The major isomer was judged to be compound **8** based on the relative ^{1}H NMR chemical shifts of the ring hydrogens of **7** and **8** (10). Separation of these isomers was impossible owing to their instability. Even removal of the chlorobenzoic acid oxidation by-product and dichloromethane solvent led to some decomposition of the components of the mixture. Therefore the mixture was treated as soon as possible with one equivalent of LDA. The products obtained were **2o** (24%, 95% geometric purity), *E*-1-phenylpentene (**3k**, 36%), and *E*-1-phenyl-1-penten-3-ol (**16**, 19%) (Scheme 3). Vinyl sulfoxide **2k** was not among the products of the reaction. The isolation of **16** is quite unexpected. The possibility existed that **16** originated from the decomposition products of either **7** or **8** and was not a product from the direct reaction of **7** or **8** with LDA.[4] To test this theory, a mixture of **7** and **8** was allowed to thermally decompose and alcohol **16** was indeed a significant component of the resulting mixture. Moreover, **16** was shown to survive the LDA treatment, as it was isolated (21%) from the LDA mediated reaction of the decomposed **7/8** mixture. It follows then that **16** is not a product of the reaction of **7** or **8** with LDA, but arises from partial decomposition of the substrates *before* the base reaction.

The other two products are compatible with the proposed ring closure mechanism. Conformation **C3** probably closes to **8**, which in turn affords **2o** since **2o** was obtained from both **1kA** (Scheme 3) and **8** directly. Similarly, alkene **3k** is a product common to both reactions. Therefore it can be concluded with some confidence that a significant share of **1kA** reacts by way of conformation **C3**.

The most telling evidence in support of the intermediacy of **8** in the ring closure of **1kA** is the observation of **8** in the reaction mixture. Thus the addition of *one* equivalent to LDA to a cold solution of **1kA** afforded a mixture that after work-up was

[1] 
1kA (*erythro*) **8** (10-20%)

shown by ^{1}H NMR to contain **8** (eq. [1]). The mixture also included starting material and unidentified alkenes. The substituents on each face of **8** probably provide a steric barrier that retards the deprotonation, a reaction that was observed to be rapid for other substrates. The relatively slow reactivity of **8** allowed for its observation, and its detection provides clear evidence that **C3** is at least one of the conformations involved in the γ-dehydrochlorination of **1kA**.

The absence of **2k** is inexplicable. It is tempting to parallel the inability to analyze **9** with the absence of significant amounts of **2k** in the reaction mixtures of **6**, **7**, and **8** and state that **9** must be the main source of **2k**. However, it seems unlikely that γ-dehydrochlorination via **C4** would be very competitive. The alignment of all three substituents on one face of thiirane-*S*-oxide **9** during its formation would certainly lead to large nonbonded interactions. The possibility also exists that the preliminary assumptions surrounding this study have imperfections. At this time we cannot offer a sound explanation for the lack of **2k** in the reactions of the thiirane-*S*-oxides with LDA.

The second set of compounds that we scrutinized were the family of α-chlorosulfoxides containing **1e**, **1hA**, and **1hB**. Using the same assumptions as earlier, Scheme 5 depicts the only conformation available for the γ-dehydrochlorination of each of **1hA** and **1hB**. Due to a rapid sigmatropic rearrangement, thiirane-*S*-oxide **17** is unattainable (10). However, *anti*-4-phenyl-1,2-epithiobutane-*S*-oxide (**18**) could be synthesized by a pathway similar to that portrayed in Scheme 4. Its reaction with one equivalent of LDA at −78°C afforded **2e** (58%) and **2h** (12%) (Scheme 5). The reaction of **1hB** with two equivalents of LDA at −78°C provided a radically different result (Scheme 5) and the first conclusion to be made is that **1hB** does not close to **18**. Since **18** and **17** are the only two possible ring closure products, it follows then that **1hB** must close to **17** as Scheme 5 suggests. More importantly, although **17** cannot be

[4]Reasonable mechanisms can be proposed for the formation of **16** by way of LDA reacting with **7** or **8** and subsequent rearrangements or by a thermal reaction of **8** using LDA at a later stage.

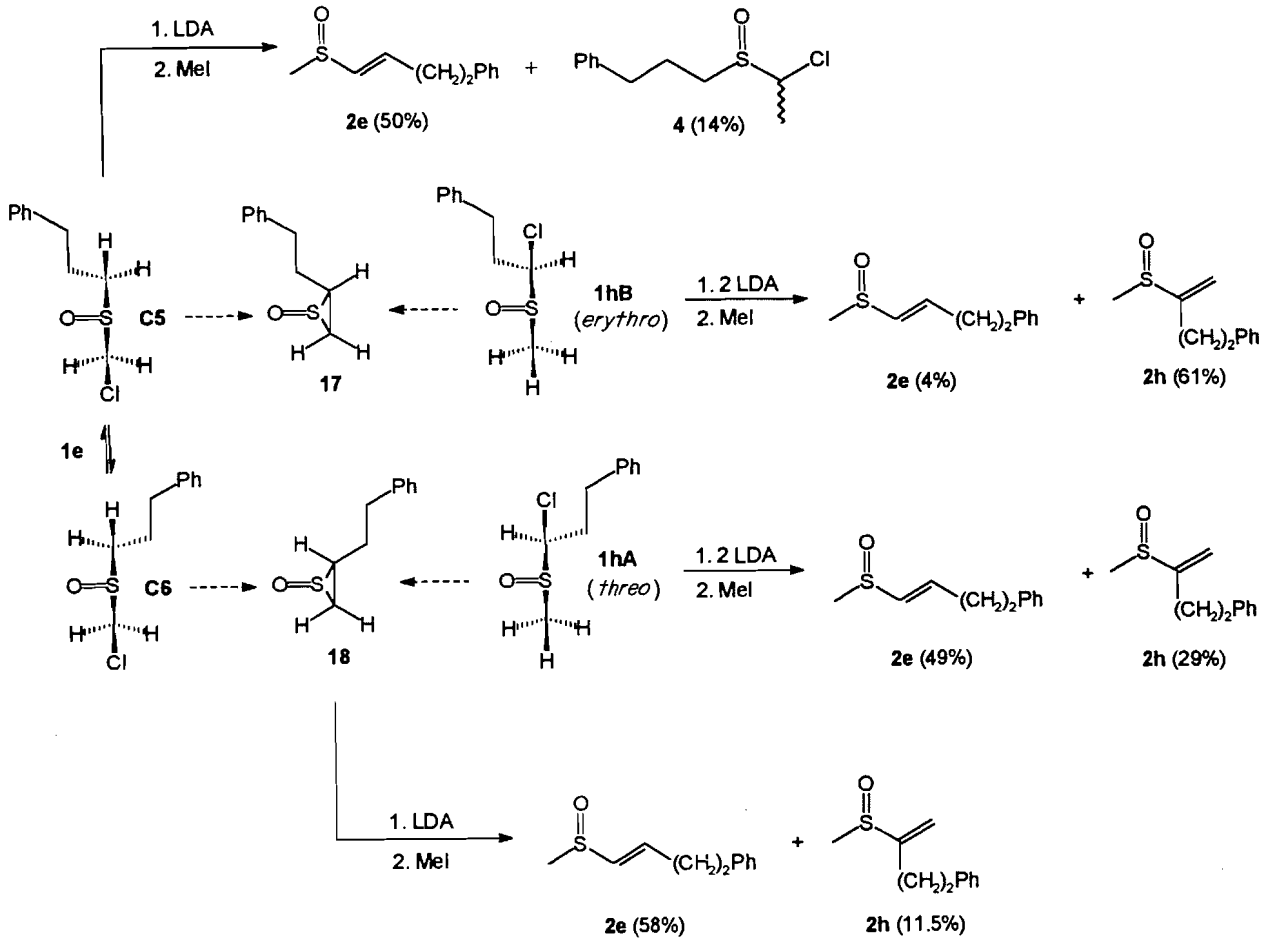

SCHEME 5

directly synthesized, *the 2-step reaction of 1kB serves as a reliable assessment of the deprotonation/ring opening behaviour of 17*. Consequently, we have essentially determined the ring opening products of **17** and **18**. The reaction of **1hA** with two equivalents of LDA and the reaction of **18** gave a parallel set of products (Scheme 5). The product ratio is not exact, but there remains enough evidence to suggest that **18** is a important intermediate on the pathway from **1kA** to **2e** and **2h**.

The γ-dehydrochlorination of **1e** may proceed through **C5** and (or) **C6** to afford transient thiirane-*S*-oxides **17** and (or) **18**, respectively, as shown in Scheme 5. Since the LDA chemistry of **17** and **18** is now established, determination of the preferred conformation of γ-dehydrochlorination of **1e** is relatively effortless. The only dehydrochlorination product arising from **1e** is vinyl sulfoxide **2e** (Table 1, entry no. 5; Scheme 5). Therefore **C6** is the preferred conformation for ring closure to thiirane-*S*-oxide **18**, since **18** and LDA yield predominately **2e**. The recovery of some **2h** from the reaction of **18**, but not from the **1e** mixture, is the lone inconsistency here.

Since the product manifold from the reaction of **18** does not exactly match that from **1e**, additional experiments were performed on **18** in order to better mimic the reaction conditions of **1e**. One experiment involved the addition of **18** to a cold equilibrated THF solution of LDA, LiCl, and di(isopropyl)amine. In a second experiment, LDA was added to a cold equilibrated THF solution of **18**, LiCl, and di(isopropyl)amine. However, in both cases, **2h** was a component of the reaction mixture and the **2h**:**2e** ratio was equal to that indicated in Scheme 5. The presence of **1h** in the reaction mixture of **18** is probably due to partial collapse of the initial assumptions made for this analysis.

The chemistry presented herein is evidence that acyclic, rotationally unconstrained α-chlorosulfoxides can undergo the γ-dehydrochlorination reaction with variable efficiency. The use of LDA, however, does not allow for the routine isolation of the proposed thiirane-*S*-oxide intermediates. Rather, the thiirane-*S*-oxides are attacked at sulfur or at hydrogen to afford ring-opened products. The LDA reaction of certain thiirane-*S*-oxides has provided a chemical means to obtain the geometrical requirements for the γ-dehydrochlorination of α-chlorosulfoxides such as **1kB**, **1e**, **1hB**, and **1hA**. The technique allows one to conclude that, upon ring closure, compounds represented by **1kB** and **1e** prefer the conformation where the sulfinyl oxygen is *anti* to the substituents of the ring carbons. We have also learned that the ring deprotonation step is apparently not completely independent on the preceding γ-dehydrochlorination reaction. Finally, the foregoing analysis offers strong evidence supporting the proposed mechanism presented in Scheme 2.

Experimental

General

Melting points were obtained on a Gallencamp capillary melting point apparatus and are uncorrected. All ^{1}H NMR spectra were run in $CDCl_3$ solution on a Varian Gemini 200 MHz NMR instrument or a Varian Unity 400 MHz NMR spectrometer using TMS or residual pro-

tium in $CDCl_3$ as internal standard. ^{13}C NMR spectra were obtained on the same instruments and were calibrated to the 77.0 ppm peak of $CDCl_3$. Infrared spectra were recorded as neat samples on a Bomem MB 100 IR spectrometer. Mass spectra were obtained using a Kratos MS890 double focusing mass spectrometer. Unless otherwise indicated, chromatographic separations were done either by flash chromatography on Merck silica gel or by centrifugal chromatography on a Chromatotron T instrument equipped with a 4 mm Merck Kieselgel 60 P_{254} silica gel plate. Solvents were distilled prior to use on the Chromatotron. THF was freshly distilled from benzophenone ketyl before use. Elemental analyses were performed by Guelph Chemical Laboratories.

Preparation of α-chlorosulfoxides **1**

α-Chlorosulfoxides **1a**, **1b**, **1c**, and **1d** have been synthesized previously (11). The other chlorosulfoxides were prepared by one of the following four methods.

Method A

The corresponding sulfide was stirred in dry CCl_4 at ice-water temperature. Solid, finely divided NCS (1.2 equiv.) was added in small portions. The mixture was allowed to stir for 4 h while the temperature warmed. The solution was filtered to remove the succinimide and was diluted with two volumes of CH_2Cl_2. This solution was cooled to −78°C (Dry Ice – acetone) and stirred with an efficient magnetic stirrer. A dry solution of MCPBA (0.90 equiv.) in CH_2Cl_2 was added dropwise over 15 min. The mixture was allowed to stir and warm over 6 h. It was recooled in ice water and filtered with suction through Celite. The filtrate was washed with 10% Na_2CO_3 solution (2 × 40 mL), with brine (30 mL), dried over $MgSO_4$, filtered, and concentrated.

Method B

A three-neck flask was equipped with a stir bar, a gas inlet, a low-temperature thermometer, and a gas outlet connected to a KOH/H_2O trap. The flask was charged with thiol, aldehyde, and CH_2Cl_2 (ca. 35 mL) and was cooled to −35°C (Dry Ice/ethanol–water). HCl was bubbled through the solution at a rate so that the temperature of the solution did not rise above −15°C. Reactions usually were 1.5 h in duration and were teminated when ^1H NMR or GC indicated a complete reaction. At this time solid $CaCl_2$ (3.5 equiv.) was added in small portions (**CAUTION**! vigorous effervescence). After all the $CaCl_2$ was added, the flask was attached to a rotary evaporatory with a water aspirator running at intermediate strength. The cold bath was maintained as the remaining HCl was removed. After about 45 min the solution was diluted with dry CH_2Cl_2 and was oxidized as in Method A above.

Method C

A flask charged with CH_2Cl_2, sulfoxide, and dry CaO was cooled to −78°C (Dry Ice – acetone). SO_2Cl_2 (1.2 equiv.) was added dropwise via syringe. The reaction stirred for 30 min and was quenched with an equal volume of water. The layers were separated and the aqueous layer was extracted with CH_2Cl_2 (1 × 40 mL). The combined organic layers were washed with brine, dried over $MgSO_4$, filtered, and concentrated.

Method D

The corresponding sulfoxide was stirred in dry CCl_4 at ice-water temperature. Solid, finely divided NCS (1.2 equiv.) was added in small portions. The mixture was allowed to stir for 4 h while the temperature warmed. An equal volume of ether was added to the mixture and it was filtered and concentrated.

*3-(Chloromethylsulfinyl)propyl benzene (**1e**)*

(Method B) From 7.07 g (47.0 mmol) of 3-phenylpropanethiol and 1.76 g (58.8 mmol) of paraformaldehyde was obtained 4.76 g (47%) of **1e** via recrystallization of the concentrated oxidation mixture; mp 58.5–60°C (60–80 petroleum). Spectral data for **1e**: IR (neat), cm^{-1}: 3005, 2935, 2866, 1603, 1498, 1457, 1398, 1145, 1076, 1045(s), 1007, 915, 862, 747; ^1H NMR (200 MHz), δ: 7.35–7.16 (m, 5H), 4.35 (abq centered at 4.35, J = 11.0 Hz, 2H), 2.82 (m, 4H), 2.15 (pentet, 7.7 Hz, 2H); ^{13}C NMR (50.3 MHz), δ: 139.93, 128.48, 128.30, 126.28, 55.90, 49.00, 34.43, 23.50; MS (ei), *m/z*(%): 218(0.4), 216(0.9), 119(28), 118(100), 115(24), 105(20), 103(12), 92(22), 91(99), 89(10), 78(10), 77(18), 63(25), 62(10); MS (ei, high resolution), *m/z*, calcd. for $C_{10}H_{13}{}^{35}ClOS$: 216.0373; found: 216.0369. Anal. calcd. for $C_{10}H_{13}ClOS$: C 55.42, H 6.05. found: C 55.36, H 5.93.

*1-Chloro-1-(methylsulfinyl)dodecane (**1f**)*

(Method C) From 3.20 g of dodecyl methyl sulfoxide was obtained 1.43 g (39%) of **1f** after chromatography. A recrystallized sample gave a 5.5:1 mixture of diastereomers; mp 64–65°C (30–60 petroleum). Spectral data for **1f**: IR (neat), cm^{-1}: 2947, 2908, 2849, 1464, 1291, 1043(s), 948, 727; ^1H NMR (200 MHz) (major isomer), δ: 4.48 (dd, J = 4.4 and 9.7 Hz, 1H), 2.62 (s, 3H), 2.30 (m, 1H), 1.96 (m, 1H), 1.72–1.48 (m, 2H), 1.28 (s (br), 16H), 0.90 (t, 3H); ^{13}C NMR (50.3 MHz) (major isomer), δ: 73.46, 34.05, 31.74, 30.80, 29.41 (2 C's), 29.30, 29.16, 29.12, 28.69, 26.14, 22.50, 13.91; MS (ei), *m/z*(%): 269(0.2), 267(0.9), 251(8), 249(20), 97(23), 85(31), 83(30), 71(47), 69(54), 64(100), 57(85), 55(53); MS (ei, high resolution), *m/z*, calcd. for $C_{13}H_{26}{}^{35}ClS$ ($[M - OH]^+$) 249.1464; found; 249.1448; calcd. for $C_{13}H_{26}{}^{37}ClS$ ($[M - OH]^+$): 251.1434; found: 251.1416; MS (ci, (methane)), *m/z*(%): 269(2.9), 267(8.1), 215(13), 87(7.5), 43(100). Anal. calcd. for $C_{13}H_{27}ClOS$: C 58.51, H 10.20; found: C 58.16, H 10.56.

*2-(1-Chloro-1-methylethylsulfinyl)propane (**1g**)*

(Method A) From 4.30 g (28.8 mmol) of isopropyl sulfide was obtained 1.07 g (22%) of **1g** after chromatography. Spectral data for **1g**: IR (neat), cm^{-1}: 2974, 2931, 1456, 1374, 1158, 1113, 1052(s); ^1H NMR (200 MHz), δ: 3.24 (septet, J = 7.0 Hz, 1H), 1.85 (s, 3H), 1.80 (s, 3H), 1.42 (d, J = 7.0 Hz, 3H), 1.28 (d, J = 7.0 Hz, 3H); ^{13}C NMR (50.3 MHz), δ: 79.40, 46.59, 28.47, 24.12, 20.13, 14.66; MS (ei), *m/z*(%): 170(0.5), 168(1.5), 126(8), 124(15), 93(5), 92(100), 91(36), 90(17), 88(6), 86(37), 84(57), 79(22), 77(73), 76(7), 75(11), 74(6), 59(15); MS (ei, high resolution), *m/z*, calcd. for $C_6H_{13}{}^{35}ClOS$: 168.0373; found: 168.0361;

*3-Chloro-3-(methylsulfinyl)propyl benzene (**1hA**)*

(Method D) From 1.16 g of 3-phenylpropyl methyl sulfoxide was obtained, after chromatography and recrystallization, 604 mg (44%) of **1hA**; mp 58–58.5°C (60–80 petroleum). Spectral data for **1hA**: IR (neat), cm^{-1}: 3059, 3031, 2941, 1602, 1497, 1453, 1425, 1404, 1052(s), 1028, 986, 945, 746; ^1H NMR (200 MHz), δ: 7.35–7.20 (m, 5H), 4.39 (dd, J = 4.0 and 10.2 Hz, 1H), 3.03 (m, 1H), 2.86 (m, 1H), 2.68–2.50 (m, 1H), 2.56 (s, 3H), 2.32 (m, 1H); ^{13}C NMR (50.3 MHz), δ: 139.08, 128.59, 128.40, 126.47, 72.44, 34.33, 32.71, 31.83; MS (ei), *m/z*(%): 218(1.2), 216(3.0), 155(9), 154(12), 153(29), 152(23), 118(11), 117(82), 116(10), 115(34), 92(24), 91(100), 89(10), 77(9), 65(34), 64(18), 63(18); MS (ei, high resolution), *m/z*, calcd. for $C_{10}H_{13}{}^{35}ClOS$: 216.0373; found: 216.0364; calcd. for $C_{10}H_{13}{}^{13}ClOS$: 218.0343; found: 218.0335. Anal. calcd. for $C_{10}H_{13}ClOS$: C 55.42, H, 6.05; found: C 55.59, H 6.05.

*3-Chloro-3-(methylsulfinyl)propyl benzene (**1hB**)*

(Method A) From 2.10 g (13.8 mmol) of sulfide was obtained a mixture of **1hB** and **1e**. Flash chromatography achieved partial separation. The impure **1hB** was dissolved in hot 60–80 petroleum and was allowed to cool on the bench. The remainder of the impurity (**1e**) crystallized out. The mother liquor was placed in the freezer (−22°C) to afford 583 mg of **1hB** (19%); mp 118.5–119°C. Spectral data for **1hB**: IR (neat), cm^{-1}: 3062, 3027, 2932, 2859, 1603, 1497, 1453, 1419, 1057(s), 946, 751; ^1H NMR (200 MHz), δ: 7.37–7.20 (m, 5H), 4.38 (dd, J = 2.9 and 10.2 Hz, 1H), 3.06 (ddd, J = 13.8, 9.0, and 4.7 Hz, 1H), 2.85 (dt, J = 13.8 and 8.0 Hz, 1H) 2.71 (s, 3H), 2.63 (m, 1H), 2.21 (m, 1H); ^{13}C NMR (50.3 MHz), δ: 139.17, 128.67, 128.56, 126.55, 74.19, 36.57, 33.38, 31.40; MS (ei), *m/z*(%): 218(2.7), 216(6.8), 155(16),

*2-Chloro-2-(2-phenylethylsulfinyl)ethyl benzene (**1jA**)*

(Method A) From 2.48 g (10.2 mmol) of 2-phenylethyl sulfide was obtained a crude mixture containing **1jA**. The mixture was chromatographed once and recrystallized three times from 60–80 petroleum to afford 597 mg (20%) of **1jA**; mp 82.5–84°C. Spectral data for **1jA**: IR (neat), cm^{-1}: 3062, 3029, 2933, 1603, 1496, 1454, 1263, 1047(vs), 934, 747; ^1H NMR (200 MHz), δ: 7.38–7.17 (m, 10H), 4.60 (dd, J = 3.0 and 9.0 Hz, 1H), 3.69 (dd, J = 3.0 and 14.5 Hz, 1H), 3.33 (m, 1H), 3.19–3.01 (m, 4H); ^{13}C NMR (50.3 MHz), δ:138.40, 134.63, 129.76, 128.78, 128.54 (2 C's), 127.43, 126.82, 73.13, 51.21, 38.78, 28.16; MS (ei), *m/z*(%): 292(1.8). 154(32), 141(37), 140(13), 139(88), 138(11), 105(100), 104(50), 103(86), 92(23), 91(47), 79(18), 78(14), 77(44); MS (ei, high resolution), *m/z*, calcd. for $C_{16}H_{17}{}^{35}ClOS$: 292.0685; found: 292.0664; calcd. for $C_{10}H_{17}{}^{37}ClOS$: 294.0655; found: 294.0645. Anal. calcd. for $C_{16}H_{17}ClOS$: C 65.63, H 5.85; found: C 65.68, H 5.83.

*2-Chloro-2-(2-phenylethylsulfinyl)ethyl benzene (**1jB**)*

(Method D) From 5.65 g (21.9 mmol) of 2-phenylethyl sulfoxide was obtained, after chromatography and recrystallization, 4.21 g (65%) of **1jB**; mp 70–71°C (60–80 petroleum ether/EtOAc). Spectral data for **1jB**: IR (neat), cm^{-1}: 3062, 3029, 2934, 1602, 1495, 1454, 1267, 1051(s), 943, 743; ^1H NMR (400 MHz), δ: 7.38–7.22 (m, 10H), 4.59 (dd, J = 5.7 and 9.0 Hz, 1H), 3.62 (dd, J = 5.7 and 14.2 Hz, 1H), 3.25–3.10 (m, 3H), 3.01 (m, 2H); ^{13}C NMR (125 MHz), δ: 138.31, 135.18, 129.52, 128.85 (2 C's), 128.52, 127.59, 126.97, 73.84, 50.68, 38.42, 29.13; MS (ei), *m/z*(%): 292(1.9), 240(8), 154(28), 141(27), 140(12), 139(84), 138(18), 105(100), 104(34), 103(56), 91(36); MS (ei, high resolution), *m/z*, calcd. for $C_{16}H_{17}{}^{35}ClOS$: 292.0685; found: 292.0680; calcd. for $C_{10}H_{17}{}^{37}ClOS$: 294.0655; found: 294.0662. *(1-Chlorobutylsulfinyl)methyl benzenes (**1kA** and **1kB**)*

(Method B) The compounds were prepared from 4.84 g (39.0 mmol) of α-toluenethiol and 2.75 g (39.3 mmol) of butyraldehyde. Chromatography yielded two fractions. The less polar fraction was composed of 1.94 g (22%) of **1kA**; mp 29.5–31°C (30–60 petroleum). Spectral data for **1kA**: IR (neat), cm^{-1}: 3062, 3032, 2949, 2874, 1496, 1458, 1057, 760, 699; ^1H NMR (200 MHz), δ: 7.34 (s, 5H), 4.25–4.19 (m, 2H), 3.98 (d, J = 13.5 Hz, 1H), 2.15 (m, 1H), 1.87 (m, 1H), 1.68 (m, 1H), 1.42 (m, 1H), 0.90 (t, J = 7.3 Hz, 3H); ^{13}C NMR (50.3 MHz), δ: 130.22, 128.42, 128.21, (4th aryl C not evident), 69.92, 53.85, 32.47, 18.06, 12.68; MS (ei), *m/z*(%): 232(0.7), 230(1.8), 92(62), 91(100), 90(8), 89(14), 65(54), 63(10), 55(28), 53(5), 51(6), 45(6); MS (ei, high resolution), *m/z*, calcd. for $C_{11}H_{15}{}^{35}ClOS$: 230.0529; found: 230.0512. Further elution afforded 2.43 g (27%) of **1kB**; mp: 58–59°C (60–80 petroleum). Spectral data for **1kB**: IR (neat), cm^{-1}: 2950, 1494, 1454, 1041 (vs), 760, 697; ^1H NMR (200 MHz), δ: 7.37 (s, 5H), 4.34 (dd, J = 5.8 and 8.8 Hz, 1H), 4.18 (abq centered at 4.18, J = 12.5 Hz, 2H), 2.09 (m, 2H), 1.55 (m, 2H), 0.91 (t, J = 7.1 Hz, 3H); ^{13}C NMR (50.3 MHz), δ: 129.95, 129.34, 129.14, 128.74, 71.47, 55.56, 34.72, 19.51, 12.93; MS (ei), *m/z*(%): 232(1.0), 230(2.3), 121(6), 93(6), 92(71), 91(100), 90(15), 89(27), 77(8), 66(6), 65(65), 64(6), 63(19), 55(42), 53(7), 51(9), 45(6); MS (ei, high resolution), *m/z*, calcd. for $C_{11}H_{15}{}^{35}ClOS$: 230.0529; found: 230.0532. Anal. calcd. for $C_{11}H_{15}ClOS$: C 57.33, H 6.55; found: C 57.26, H 6.55.

*1-Chloro-1-(ethylsulfinyl)ethanes (**1lA** and **1lB**)*

(Method C) The compounds were prepared from 1.80 g (17.0 mmol) of ethyl sulfoxide. Chromatography yielded two fractions. The less polar fraction was distilled to afford 740 mg (31%) of **1lA**; bp 41°C/0.3 Torr (1 Torr = 133.3 Pa). Spectral data for **1lA**: IR (neat), cm^{-1}: 2962, 2879, 1451, 1377, 1058, 1022, 973, 778; ^1H NMR (200 MHz), δ: 4.53 (q, J = 6.7 Hz, 1H), 3.07 (dq, J = 6.5 and 13.4 Hz, 1H), 2.80 (dq, J = 6.7 and 13.4 Hz, 1H), 1.70 (d, J = 6.7 Hz, 3H), 1.41 (t, J = 6.5 Hz, 3H); ^{13}C NMR (50.3 MHz), δ: 66.54, 43.07, 19.21, 6.11; MS (ei), *m/z*(%): 142(2.8), 140(8.7), 78(100), 77(15), 65(16), 63(82), 61(18); MS (ei, high resolution), *m/z*, calcd. for $C_4H_9{}^{37}ClOS$: 142.0031; found: 142.0031; calcd. for $C_4H_9{}^{35}ClOS$: 140.0061; found: 140.0062. The more polar fraction was distilled to afford 651 mg (27%) of **1lB**; bp 40–41°C/0.1 Torr. Spectral data for **1lB**: IR (neat), cm^{-1}: 2974, 2938, 2878, 1451, 1377, 1067, 1050, 1022, 973, 780; ^1H NMR (200 MHz), δ: 4.68 (q, J = 6.9 Hz, 1H), 2.84 (m, 2H), 1.87 (d, J = 6.9 Hz, 3H), 1.35 (t, J = 6.5 Hz, 3H); ^{13}C NMR (50.3 MHz), δ: 67.37, 42.45, 18.46, 7.21; MS (ei), *m/z*(%): 142(2.3), 140(6.6), 78(100), 77(17), 65(18), 63(92), 61(19), 59(12); MS (ei, high resolution), *m/z*, calcd. for $C_4H_9{}^{37}ClOS$: 142.0031; found: 142.0030; calcd. for $C_4H_9{}^{35}ClOS$: 140.0061; found: 140.0062.

*Reactions of chlorosulfoxides **1** with LDA*

General procedure

To a three-neck round-bottom flask containing a stir bar was attached a serum cap, a three-way stopcock, and a stopper. The flask was flame-dried under vacuum and allowed to cool under dry N_2. It was charged with THF (10–20 mL), diisopropyl amine (2.3 equiv.), and cooled to −78°C. *n*-BuLi (2.15 equiv.) was added dropwise. The mixture was allowed to stir at 0°C for 30 min and was cooled to −78°C. The substrate (ca. 0.7–3.7 mmol) in THF (8–20 mL) was added dropwise and the mixture was stirred as indicated below. The mixtures were then quenched at −78°C with excess MeI in THF (4 mL). In some instances $PhCH_2Br$ (1 equiv. in THF (8 mL)) was employed as the electrophile; those are noted below. The mixture was then stirred for 12 h at which time saturated aqueous NH_4Cl (20 mL) was added. The layers were separated and the aqueous layer was extracted with EtOAc (2 × 10 mL). The combined organics were washed with brine and dried over $MgSO_4$. After filtration and concentration, the mixtures were subjected to centrifugal chromatography using EtOAc–hexanes mixtures as the mobile phase.

The different experimental conditions come about from the duration of chlorosulfoxide exposure to the base. Conditions A: chlorosulfoxide is stirred at −78°C for 1 h; Conditions B: chlorosulfoxide is stirred at −78°C for 20 min; Conditions C: chlorosulfoxide is stirred at 0°C for 1 h. The base treatment of chlorosulfoxide **1g** is an exception to this general procedure. That treatment is referred to as Conditions D in Table 1 and was as follows: An LDA in THF solution (3.15 equiv., prepared as above) was added to chlorosulfoxide **1g** in THF at −78°C. The cold bath was removed and the mixture was allowed to warm to room temperature. Tetramethylethene was identified as a component of the mixture by co-injection with an authentic sample on different

For personal use only.

capillary GC columns. It was quantitated against an added internal standard of toluene. The yield of tetramethylethene was found to be ca. 90%.

*Reaction of **1a***

(Cond. A) From 247 mg (2.20 mmol) of **1a** was obtained 139 mg (38%) of **2a** using $PhCH_2Br$ as the electrophile; mp 48–49.5°C (60–80 petroleum) (lit. (12) mp 34–35°C).[5] Spectral data for **2a**: IR (neat), cm^{-1}: 3064, 3031, 1601, 1495, 1454, 1371, 1042, 986; ^1H NMR (200 MHz), δ: 7.36–7.23 (m, 5H), 6.58 (dd, J = 16.6 and 9.8 Hz, 1H), 5.96 (d, J = 16.6 Hz, 1H), 5.88 (d, J = 9.8 Hz, 1H), 3.98 (s, 2H); ^{13}C NMR (50.3 MHz), δ: 139.85, 130.04, 129.20, 128.51, 128.11, 122.09, 59.74; MS (ci, methane), *m/z*(%): 167(11), 149(6), 117(11), 115(8), 92(40), 91(100), 89(8), 65(33). Anal. calcd. for $C_9H_{10}OS$: C 65.03, H 6.06; found: C 65.03, H 5.89.

*Reaction of **1b***

(Cond. B) From 371 mg (1.97 mmol) of **1b** was obtained styrene (**3b**) (8%) and 196 mg (60%) of **2b**; mp: 60–61°C; (lit. (13) mp 61–62°C). The styrene was quantitated by determining the relative amounts of the two products in the crude mixture by ^1H NMR and extrapolating back once **2b** was isolated and quantitated.

*Reaction of **1c***

(Cond. B) From 244 mg (0.92 mmol) of a 3:2 mixture of diastereomers of **1c** and 2.4 equivalents of LDA was obtained by chromatography 40.5 mg (24%) of *trans*-stilbene (**3c**) and 112 mg (50%) of **2c** (5).

*Reaction of **1d***

(Cond. C) From 988 mg (3.71 mmol) of **1d** was obtained 286 mg (32%) of **2d**; mp 45–46°C (30–60 petroleum). Spectral data for **2d**: IR (neat), cm^{-1}: 3029, 2999, 2951, 2919(s), 2849(s), 1471, 1462, 1045(s), 974; ^1H NMR (200 MHz), δ: 6.54 (dt, J = 6.7 and 15.3 Hz, 1H), 6.32 (d, J = 15.3 Hz, 1H), 2.66 (s, 3H), 2.27 (m, 2H), 1.49 (m, 2H), 1.30 (s (br) 16H), 0.91 (t, J = 6.5 Hz); ^{13}C NMR (50.3 MHz), δ: 141.45, 133.71, 40.36, 31.75, 31.66, 29.36 (2 C's), 29.29, 29.09 (2 C's), 28.80, 27.83, 22.41, 13.83; MS (ei), *m/z*(%): 244(6), 229(210, 228(26), 227(100), 213(11), 123(7), 111(12), 110(21), 109(17), 97(27), 96(14), 95(34), 87(88), 83(34), 82(16), 81(36), 69(40), 68(16), 67(32), 61(18), 57(32), 55(55); MS (ei, high resolution), *m/z*, calcd. for $C_{14}H_{28}OS$: 244.1854; found: 244.1846. Anal. calcd. for $C_{14}H_{28}OS$: C 68.79, H 11.55; found: C 68.64, H 11.80.

*Reaction of **1e***

(Cond. A) From 397 mg (1.84 mmol) of **1e** was obtained 52 mg (14%) of **4**, 14 mg of **1e**, and 170 mg (50%) of **2e**. (Yields based on consumed **1e**.) Spectral data for **2e**: IR (neat), cm^{-1}: 3026, 3023, 2956, 1632(w), 1602, 1496, 1453, 1419, 1044(vs), 959, 748; ^1H NMR (200 MHz), δ: 7.33–7.15 (m, 5H), 6.50 (dt, J = 6.6 and 15.5 Hz, 1H), 6.24 (d, J = 15.5 Hz, 1H), 2.79 (t, J = 7.5, 2H), 2.55 (q, J = ca. 7 Hz, 2H), 2.53 (s, 3H); ^{13}C NMR (50.3 MHz), δ: 140.32, 138.91, 134.64, 128.33, 128.27, 126.09, 40.55, 34.28, 33.42; MS (ei), *m/z*(%): 195(M + 1, 13), 194(14), 177(10), 131(42), 130(22), 129(25), 128(13), 115(11), 103(19), 92(67), 91(100), 89(12), 88(19), 87(63), 86(75), 84(88), 77(12), 65(31), 63(14); MS (ei, high resolution), *m/z*, calcd. for $C_{11}H_{14}OS$: 194.0762; found: 194.0762. Spectral data for **4**: IR (neat), cm^{-1}: 3027, 2936, 2862, 1603, 1496, 1450, 1373, 1051(vs), 747; ^1H NMR (200 MHz), δ: 7.33–7.17 (m, 5H), 4.48 (q, J = 6.7 Hz, 1H), 2.99 (m, 1H), 2.84–2.65 (m, 3H), 2.17 (m, 2H), 1.83, (d, J = 6.7 Hz, 3H); ^{13}C NMR (50.3 MHz), δ: 140.18, 128.50, 128.39, 126.28, 67.60, 49.06, 34.53, 23.76, 19.14; MS (ei), *m/z*(%): 231(M + 1, 19), 230(7), 168(10), 119(19), 118(100), 117(49), 115(11), 105(13), 92(11), 91(86), 77(11), 65(13), 63(12); MS (ei, high resolution), *m/z*, calcd. for $C_{11}H_{15}{}^{35}ClOS$: 230.0532; found: 230.0515.

[5]The melting point discrepancy cannot be accounted for.

*Reaction of **1f***

(Cond. C) From 193 mg (0.724 mmol) of **1f** was obtained 56 mg (31%) of **2f** and 87 mg (49%) of **2d**. Spectral data for **2f**: IR (neat), cm^{-1}: 2924, 2854, 1629(w), 1461, 1061(s), 920; ^1H NMR (200 MHz), δ: 5.87 (s, 1H), 5.58 (s, 1H), 2.58 (s, 3H), 2.44–2.10 (m, 2H), 1.59 (m, 2H), 1.27 (s (br), 16H), 0.88 (t, J = 7.4 Hz, 3H); ^{13}C NMR (50.3 MHz), δ: 154.83, 114.98, 39.16, 31.69, 29.38 (2 C's), 29.29, 29.10 (2 C's), 28.91, 27.83, 27.72, 22.44, 13.85; MS (ei), *m/z*(%): 245(1.5), 244(0.1), 229(13), 228(17), 227(100), 97(17), 95(15), 83(28), 81(16), 69(38), 67(16), 64(18), 57(21), 55(55); MS (ci(methane)), *m/z*(%): 245 ([M + 1]$^+$, 54), 230 (16), 229(100), 227(16), 213(15), 88(42); MS (ei, high resolution), *m/z*, calcd. for $C_{14}H_{27}S$ ([M − OH]$^+$) 227.1827; found: 227.1839.

*Reaction of **1hA***

(Cond. B) From 216 mg (0.998 mmol) of **1hA** was obtained 56 mg (29%) of **2h** and 94 mg (48%) of **2e**. Spectral data for **2h**: IR (neat), cm^{-1}: 3061, 3027, 2924, 2858, 1630(w), 1603, 1496, 1454, 1419, 1051(vs), 934, 749; ^1H NMR (200 MHz), δ: 7.34–7.19 (m, 5H), 5.91 (s, 1H), 5.62 (s, 1H), 2.92 (t, J = 7.7 Hz, 2H), 2.62–2.45 (m, 2H), 2.54 (s, 3H); ^{13}C NMR (50.3 MHz), δ: 153.64, 140.17, 128.51, 128.31, 126.39, 115.83, 39.17, 34.15, 29.68; MS (ei), *m/z*(%): 194(40), 177(19), 131(37), 130(41), 116(18), 115(28), 92(61), 91(100), 89(10), 77(16), 73(20), 65(47), 64(14), 63(21). MS (ei, high resolution), *m/z*, calcd. for $C_{11}H_{14}OS$: 194.0762; found: 194.0751.

*Reaction of **1hB***

(Cond. B) From 160 mg (0.739 mmol) of **1hB** was obtained 87 mg (61%) of **2h** and 6 mg (4%) of **2e**.

*Reaction of **1iA***

(Cond. C) From 329 mg (1.62 mmol) of **1iA** was obtained α-methylstyrene (**3i**) (6%), 64 mg (22%) of **2i** (14), and 20 mg (7%) of **2m** (14). The α-methylstyrene was quantitated by determining the relative amounts of it and **2i** in the crude mixture by ^1H NMR and extrapolating back once **2i** was isolated and quantitated.

*Reaction of **1iB***

(Cond. C) From 329 mg (1.62 mmol) of **1iB** was obtained 137 mg (54%) of **2i** and 44 mg (17%) of **2m**.

*Reaction of **1jA***

(Cond. C) From 425 mg (1.45 mmol) of **1jA** was obtained an inseparable mixture of **2j** (40 mg, 10%) and **2n** (35 mg, 9%). Partial spectral data for **2n**: ^1H NMR (200 MHz), δ: 7.35–7.06 (m, 10H), 5.82 (qt, J = 1.5 and ca. 7.5 Hz, 1H), 2.50 (s, 3H). The remainder of the peaks were obscured by those for **2j**. ^{13}C NMR (50.3 MHz), δ: 145.00, 138.45, 137.94, 134.88, 129.47, 128.73, 128.67, 128.18, 126.67, 126.57, 38.46, 33.89, 31.42; IR (neat) (mixture of **2j** and **2n**), cm^{-1}: 3060, 3028, 2918, 1601, 1494, 1453, 1045(s), 948, 741; MS (ei), (mixture of **2j** and **2n**) *m/z*(%): 270(3), 253(23), 206(33), 205(31), 129(25), 128(21), 115(29), 103(13), 91(100), 77(16), 65(18).

*Reaction of **1jB***

(Cond. C) From 575 mg (1.97 mmol) of **1jB** was obtained 296 mg (56%) of **2j** and 57 mg (11%) of **5** as a 3:2 mixture of diastereomers. Spectral data for **2j**: mp 52–54°C (60–80 petroleum); IR (neat), cm^{-1}: 3060, 3026, 2913, 1601, 1495, 1453, 1045(s), 950, 744; ^1H NMR (200 MHz), δ: 7.37–7.21 (m, 8H), 7.10 (m, 2H), 6.62 (t, J = 7.4 Hz, 1H), 3.81 (abq, J = 16.4 Hz, 2H), 3.57 (d, J = 7.4 Hz, 2H), 2.41 (s, 3H); ^{13}C NMR (50.3 MHz), δ: 143.12, 138.19, 137.13, 133.57, 128.79, 128.65, 128.35, 128.27, 126.82, 126.54, 39.71, 34.38, 30.27; MS (ei), *m/z*(%): 270(4.6), 207(13), 206(56), 205(14), 129(31), 128(16), 115(19), 103(10), 91(100). Anal. calcd. for $C_{17}H_{18}OS$: C 75.52, H 6.71; found: C 75.45, H, 6.85. Spectral data for **5**: ^1H NMR (400 MHz) (diastereomer 1), δ: 7.41–7.23 (m, 10H), 6.50 (d, J = 15.8 Hz, 1H), 6.25 (dd, J = 9.3 and 15.8 Hz, 1H), 3.42 (m, 2H), 3.12 (dd, J = 13.3 and 8.3 Hz, 1H), 2.48 (s, 3H); ^1H NMR (400 MHz) (diastereomer 2), δ: 7.33 (m, 10H), 6.51 (d, J = 15.8 Hz, 1H), 5.99 (dd, J = 15.8 and

9.7 Hz, 1H), 3.63 (dt, J = 3.6 and ca. 9.9 Hz, 1H), 4.36 (dd, J = 3.6 and 13.6 Hz), 3.07 (dd, J = 10.1 and 13.6 Hz, 1H), 2.61 (s, 3H); ^{13}C NMR (100.6 MHz) (diastereomer 1), δ: 137.41, 135.69, 129.28, 128.61, 128.58, 128.49, 128.29, 126.77, 126.58, 120.52, 65.85, 35.04, 34.54; ^{13}C NMR (100.6 MHz) (diastereomer 2), δ: 137.16, 135.73, 129.48, 128.68 (2 C's), 128.53, 128.44, 126.73, 126,53, 121.44, 69.88, 35.85, 35.22; IR (neat) (mixture of isomers), cm^{-1}: 3059, 3027, 2921, 2854, 1601, 1495, 1452, 1413, 1260, 1039(s), 971, 748; MS (ei), (mixture of isomers) *m/z*(%): 270(0.3), 207(28), 206(54), 205(22), 191(13), 129(31), 128(25), 117(27), 115(24), 105(23), 103(10), 91(100), 77(14); MS (ci, methane) *m/z*(%): 271(0.5), 269(4.5), 207(32), 206(96), 205(23), 191(12), 133(20), 131(17), 129(21), 128(24), 127(13), 117(19), 115(17), 105(23), 103(15), 100(25), 92(18), 91(100), 89(17), 83(20), 81(14), 79(13), 78(13), 77(21), 75(17), 73(33).

Reaction of ***1kA***

(Cond. A) From 260 mg (1.13 mmol) of **1kA** was obtained *E*-1-phenyl-1-pentene (**3k**) (21%), 64 mg (27%, 96% pure, inseparable from 4% of **2p**) of **2o**, and 104 mg (44%) of **2k**. Alkene **3k** was quantitated by determining the relative amounts of it and **2k** in the crude mixture by ^{1}H NMR and extrapolating back once **2k** was isolated and quantitated. Spectral data for **2k**: IR (neat), cm^{-1}: 2961, 2930, 2872, 1492, 1454, 1416, 1057(s), 755, 697; ^{1}H NMR (200 MHz), δ: 7.41–7.28 (m, 5H), 7.16 (s, 1H), 2.75 (m, 1H), 2.65 (s, 3H), 2.25 (m, 1H), 1.63 (sextet, J = 7.0 Hz, 2H), 0.98 (t, J = 7.0 Hz, 3H); ^{13}C NMR (50.3 MHz), δ: 146.33, 134.91, 129.27, 128.97, 128.74, 128.27, 39.75, 28.31, 21.64, 13.86; MS (ei), *m/z*(%): 208(11), 192(13), 191(56), 145(63), 144(31), 143(22), 137(19), 130(27), 129(60), 128(31), 117(48), 116(26), 115(81), 105(19), 103(14), 92(29), 91(100), 89(11), 77(13), 67(10), 65(12), 63(10); MS (ei, high resolution), *m/z*, calcd. for $C_{12}H_{16}OS$: 208.0918; found: 208.0924. Spectral data for **2o**: IR (neat), cm^{-1}: 3056, 2959, 2931, 2870, 1645(w), 1492, 1460, 1443, 1414, 1063(vs), 762, 703; ^{1}H NMR (200 MHz), δ: 7.44–7.21 (m, 5H), 6.44 (t, J = 7.6 Hz, 1H), 2.36, (s, 3H), 2.20 (q, J = 7.6 Hz, 2H), 1.50 (sextet, J = 7.4 Hz, 2H), 0.90 (t, J = 7.3 Hz, 3H); ^{13}C NMR (50.3 MHz), δ: 144.81, 133.84, 132.05, 129.19, 128.96, 128.75, 36.85, 30.27, 22.10, 13.47; MS (ei), *m/z*(%): 208(1.6), 146(12), 145(100), 130(20), 129(15), 128(17), 117(42), 116(13), 115(42), 105(17), 103(17), 102(11), 91(87), 77(13), 67(13); MS (ei, high resolution), *m/z*, calcd. for $C_{12}H_{16}OS$: 208.0918; found: 208.0928.

Reaction of ***1kB***

(Cond. A) From 219 mg (0.95 mmol) of **1kB** was obtained 116 mg (59%, 96% pure, inseparable from 4% of **2o**) of **2p** and 36 mg (18%) of **2k**. Spectral data for **2p**: IR (neat), cm^{-1}: 2959, 2929, 2869, 1491, 1450, 1049(s), 761, 700; ^{1}H NMR (200 MHz), δ: 7.40 (m, 5H), 6.18 (t, J = 7.8 Hz, 1H), 2.54 (m, 2H), 2.14 (s, 3H), 1.54 (m, 2H), 1.00 (t, J = 7.1 Hz); ^{13}C NMR (50.3 MHz), δ: 143.90, 141.47, 134.40, 129.20, 128.58, 128.34, 37.43, 29.93, 22.42, 13.44; MS (ei), *m/z*(%): 208(8), 191(42), 145(77), 143(16), 130(20), 129(19), 128(25), 117(44), 116(14), 115(50), 105(19), 103(14), 102(10), 92(26), 91(100), 77(13), 67(9); MS (ei, high resolution), *m/z*, calcd. for $C_{12}H_{16}OS$: 208.0918; found: 208.0933. Anal. calcd. for $C_{12}H_{16}OS$: C 69.19, H 7.74; found: C 68.88, H 8.00.

Reaction of ***11A***

(Cond. C) From 255 mg (1.81 mmol) of **11A** was obtained 120 mg (34%) of an inseparable mixture of **2l** and **2q** (**2l**:**2q** = 2.4:1) using $PhCH_2Br$ as the electrophile. Spectral data for **2l** and **2q**: IR (neat) (mixture of isomers), cm^{-1}: 3062, 3030, 2921, 2857, 1644, 1602, 1495, 1450, 1035(vs) 769; ^{1}H NMR (400 MHz) (major isomer), δ: 7.33–7.17 (m, 5H), 5.89 (m, 1H), 3.89 (s, 2H), 1.87 (s, 3H), 1.67 (d, J = 6.9 Hz, 3H); ^{1}H NMR (200 MHz) (minor isomer), δ: 7.33–7.17 (m, 5H), 5.89 (m, 1H), 4.10 (d, J = 12.3 Hz, 1H), 3.89 (d, J = 12.3 Hz, 1H), 1.97 (s, 3H), 1.32 (d, J = 7.1 Hz, 3H); ^{13}C NMR (50.3 MHz) (mixture of isomers), δ: 137.55, 137.39, 132.90, 130.60, 130.14, 129.91, 129.83, 129.67, 128.48, 128.36, 127.96, 127.89, 57.86, 57.04, 13.60, 13.45, 12.46, 8.43; MS (ei), (mixture of isomers) *m/z*(%): 194(1.1), 145(6), 92(24), 91(100), 65(20). MS (ci, methane (mixture of isomers)), *m/z*(%): 195(7.4), 145(7.6), 92(14), 91(100), 65(11).

Reaction of ***11B***

(Cond. C) From 127 mg (0.90 mmol) of **11A** was obtained 93 mg (53%) of an inseparable mixture of **2l** and **2q** (**2l**:**2q** = 3.5:1) using $PhCH_2Br$ as the electrophile.

Synthesis of E-*2-phenyl-3-propyloxirane (**12**)*

To an ice-cooled mixture of 1-phenyl-1-pentyne (**10**) (Aldrich) (13.1 g, 90.8 mmol) in THF (200 mL) was added solid $LiAlH_4$ (8.62 g, 227 mmol) in small portions. The ice bath was removed and the mixture was refluxed for 20 h after which time the flask was cooled in ice and the mixture was quenched by the dropwise addition of water (10 mL). The mixture was filtered with suction through Celite. More water (200 mL) was added and the solution was extracted into pentane (3 × 50 mL). After drying ($MgSO_4$), filtration, and concentration (aspirator), GC indicated that product **3k** was 94% pure. To the crude **3k** was added CH_2Cl_2 (150 mL). The mixture was stirred while MCPBA (21.5 g (73% active), 90.8 mmol) in CH_2Cl_2 (250 mL) was added dropwise from an addition funnel. Stirring continued at room temperature for 14 h. The mixture was then filtered with suction through Celite, washed with saturated aqueous Na_2CO_3 (2 × 40 mL) and with brine, and dried over $MgSO_4$. After filtration and concentration (aspirator), the oxide was distilled to afford 10.1 g (68%, 94% pure by GC) of **12** (15); bp 62–63°C/0.4 Torr.

Synthesis of E-*1-phenyl-1,2-epithiopentane (**14**)*

A mixture containing **12** (2.83 g, 17.5 mmol), KSCN (2.54 g, 26.2 mmol), MeOH (20 mL), and H_2O (10 mL) was refluxed for 50 h. After cooling, H_2O (25 mL) was added to the mixture and it was extracted with 30–60 petroleum ether (3 × 20 mL). The organic extracts were combined, washed with H_2O (2 × 10 mL) and brine, and were dried over $MgSO_4$. After filtration and concentration (aspirator), the crude **14** was subjected to column chromatography on Al_2O_3(I) with hexanes as eluent. The elution afforded **3k**, **12**, and then **14** (739 mg, 24%). Spectral data for **14**: IR (neat), cm^{-1}: 3059, 3026, 2959, 2929, 2870, 1600, 1492, 1452, 1378, 1074, 1031, 759, 741; ^{1}H NMR (200 MHz), δ: 7.28 (s, 5H), 3.61 (d, J = 5.4 Hz, 1H), 3.04 (dt, J = 5.4 and 6.8 Hz, 1H), 1.91 (m, 1H), 1.69–1.51 (m, 3H), 0.99 (t, J = 6.9 Hz, 3H); ^{13}C NMR (50.3 MHz), δ: 139.35, 128.45, 127.42, 126.83, 44.78, 44.04, 38.51, 22.26, 13.71; MS (ei), *m/z*(%): 178(52), 149(16), 146(30), 136(27), 135(55), 122(15), 121(18), 118(28), 117(100), 116(21), 115(52), 104(27), 92(18), 91(75), 87(16), 77(13), 65(12); MS (ei, high resolution), *m/z*, calcd. for $C_{11}H_{14}S$: 178.0813; found: 178.0820.

Synthesis of E-*1-phenyl-1,2-epithiopentane-1-oxides (**7** and **8**)*

To a mixture of thiirane **14** (384 mg, 2.16 mmol) in dry CH_2Cl_2 (20 mL) cooled to −78°C was added dropwise a dry solution of MCPBA (511 mg (73% active), 2.16 mmol) in CH_2Cl_2 (20 mL). After 25 min the mixture was filtered with suction. The MCBA was precipitated from the cold solution as described by Kondo and Negishi (10). Usually four filtrations were required. The solvent was removed under reduced pressure while maintaining a cold bath and the result was a crude mixture of **7** and **8** (348 mg, 3.5:1 ratio, 83%). Partial spectral data for **7** and **8**: ^{1}H NMR (200 MHz), δ (major isomer): 3.52 (d, J = 10.5 Hz, 1H), 2.78 (dt, J = 10.5 and ca. 6.8 Hz, 1H); δ (minor isomer): 3.28 (d, J = 10.1 Hz, 1H), 3.20 (dt, 1H): ^{13}C NMR (50.3 MHz), δ (probable peaks for major isomer): 133.59, 128.89, 128.51, 126.63, 59.27, 51.51, 25.95, 21.78, 13.37.

Reaction of ***7*** *and* ***8*** *with LDA*

To a mixture of LDA (1.26 mmol) and THF (10 mL) stirred at −78°C was added thiirane-*S*-oxides **7** and **8** (228 mg, 1.17 mmol) in THF (10 mL). After stirring for 20 min at −78°C, excess MeI in LDA was added. The mixture was stirred for 12 h as the temperature warmed and work-up was as described for the α-chlorosulfoxides. The reaction afforded **3k** (36%), 36 mg (19%) of alcohol **16**, and 59 mg

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

(24%, contaminated with 5% of **2p**) of **2o**. The latter two products were obtained by chromatography. Alkene **3k** was quantitated by determining the relative amounts of it and **16** in the crude mixture by ^{1}H NMR and extrapolating back once **16** was isolated and quantitated.

Synthesis of Z-*2-phenyl-3-propyloxirane (**13**)*

A mixture of 1-phenyl-1-pentyne (4.71 g, 32.7 mmol), Lindlar's catalyst (Aldrich) (0.88 g), and quinoline (120 mg) were stirred in 60–80 petroleum ether (75 mL). A hydrogen containing balloon was attached to the apparatus and the H_2 was exposed to the mixture. The balloon was refilled 5 times over the course of 4 days at which time the mixture was filtered. The mixture was shown by GC to be 89% alkene **11**. The solution of **11** was stirred while MCPBA (7.74 g (73% active), 32.8 mmol) in CH_2Cl_2 (120 mL) was added dropwise from an addition funnel. Stirred continued at room temperature for 14 h. The mixture was then handled as for **12** above to afford 3.06 g (57%, 96% pure by GC) of **13** (15); bp 47–48°C/0.05 Torr.

Synthesis of Z-*1-phenyl-1,2-epithiopentane (**15**)*

A mixture containing **13** (1.77 g, 1.0 mmol), KSCN (1.47 g, 15.1 mmol), MeOH (20 mL), and H_2O (7 mL) was refluxed for 38 h. More KSCN (0.91 g) was added to the solution and it was refluxed for 4 h longer. Work-up as above for **14** afforded crude **15**, which was subjected to column chromatography on Al_2O_3(I) with hexanes as eluent. The elution afforded **11**, **13**, and then **15** (735 mg, 38%). Spectral data for **15**: IR (neat), cm^{-1}: 3059, 3026, 2959, 2929, 2870, 1600, 1492, 1452, 1378, 1074, 1031, 759, 741; ^{1}H NMR (400 MHz), δ: 7.42–7.25 (m, 5H), 4.15 (d, J = 6.9 Hz, 1H), 3.18 (m, 1H), 1.55–1.38 (m, 3H), 1.16 (m, 1H), 0.85 (t, J = 7.2 Hz, 3H); ^{13}C NMR (100.6 MHz), δ: 135.82, 129.16, 127.90, 127.24, 42.91, 42.54, 32.87, 22.56, 13.69; MS (ei), *m/z*(%): 178(80), 177(12) 149(31), 146(25), 136(35), 135(89), 122(27), 121(35), 118(28), 117(82), 116(26), 115(61), 104(25), 92(26), 91(100), 87(25), 78(12), 77(19), 65(15); MS (ei, high resolution), *m/z*, calcd. for $C_{11}H_{14}S$: 178.0813; found: 178.0808.

Synthesis of Z-*1-phenyl-1,2-epithiopentane-1-oxide (**6**)*

To a mixture of thiirane **15** (354 mg, 1.99 mmol) in dry CH_2Cl_2 (20 mL) cooled to −50°C was added dropwise a dry solution of MCPBA (464 mg (73% active), 1.96 mmol) in CH_2Cl_2 (15 mL). After 15 min the mixture was filtered with suction. The remaining MCBA was precipitated from the cold solution as described by Kondo and Nagishi (10). Usually three filtrations were required. The solvent was removed under reduced pressure while maintaining a cold bath and the result was fairly pure **6** (334 mg, 87%). Spectral data for **6**: IR (neat), cm^{-1}: 3059, 3029, 2960, 2931, 2871, 1601, 1495, 1454, 1381, 1062(vs), 978, 758; ^{1}H NMR (200 MHz), δ: 7.30 (m, 3H), 7.15 (m, 2H), 4.16 (d, J = 11.1 Hz, 1H), 3.37 (ddd, J = 5.7, 11.1, and 16.8 Hz, 1H), 1.58 (m, 2H), 1.41 (m, 1H), 1.17 (m, 1H), 0.95 (t, J = 7.2 Hz, 3H): ^{13}C NMR (50.3 MHz), δ: 131.41, 128.61, 128.41, 127.95, 58.95, 58.75, 26.96, 21.78, 13.57.

*Reaction of **6** with LDA*

To a mixture of LDA (0.96 mmol) and THF (10 mL) stirred at −78°C was added thiirane-*S*-oxide **6** (162.5 mg, 0.84 mmol) in THF (5 mL). After stirring for 15 min at −78°C, excess MeI in LDA was added. The mixture was stirred for 5 h as the temperature warmed and work-up was as described for the α-chlorosulfoxides. Chromatography afforded 204 mg (70%) of **2p** and 6 mg (3.5%) of **2k**.

*Search for **8** from **1kA***

A solution of **1kA** (161 mg, 0.70 mmol) in THF (10 mL) was stirred at −78°C. LDA (1.0 molar equiv., 1.4 M in cyclohexane, Aldrich) was added all at once. After 10 min, aqueous NH_4Cl (10 mL) was added and the cold solution was filtered with suction. The filtrate was concentrated while the temperature was kept below 0°C. Analysis of the mixture by ^{1}H NMR indicated the ring hydrogen peaks for **8** as well as peaks corresponding to **1kA** and several alkene containing species. The chemical yield of **8** was judged to be 10–20% from this NMR.

Synthesis of anti-*4-phenyl-1,2-epithiobutane*-S-*oxide (**18**)*

4-Phenylbutene (10.96 g, 83.0 mmol) was oxidized using MCPBA as described for **2k** and **11** above. The crude 2-(phenylethyl)oxirane (16) was stirred with KSCN (13.0 g, 134 mmol), MeOH (150 mL), and H_2O (50 mL) for 20 h. Work-up as above for **14** and **15** gave crude 4-phenyl-1,2-epithiobutane. Distillation of the mixture afforded 6.51 g (48% from alkene) of 4-phenyl-1,2-epithiobutane, 99.3% pure by GC; bp 79–81°C/0.45 Torr. Spectral data for 4-phenyl-1,2-epithiobutane: IR (neat), cm^{-1}: 3061, 3025, 2987, 2529, 2856, 1603, 1495, 1450, 1070, 747; ^{1}H NMR (400 MHz), δ: 7.28 (m, 2H), 7.21 (m, 3H), 2.91–2.76 (m, 3H), 2.49 (dd, J = 1.0 and 6.3 Hz, 1H), 2.22–2.12 (m, 1H), 2.15 (dd, J = 1.0 and 5.6 Hz, 1H), 1.73 (m, 1H); ^{13}C NMR (100.6 MHz), δ: 141.17, 128.47, 128.42, 126.04, 38.33, 35.64, 35.38, 25.95; MS (ei), *m/z*(%): 164(20), 131(20), 123(67), 117(37), 115(11), 104(10), 91(100), 65(21); MS (ei, high resolution), *m/z*, calcd. for $C_{10}H_{12}S$: 164.0657; found: 164.0674. To a stirred solution of 4-phenyl-1,2-epithiobutane (1.03 g, 6.28 mmol) in dry CH_2Cl_2 (20 mL) cooled to −78°C was added dropwise a dry solution of MCPBA (1.48 g (73%), 6.26 mmol) in CH_2Cl_2 (15 mL). The cold mixture was stirred for 45 min and was filtered with suction. The remainder of the work-up was as described for **6** above. Flash chromatography on silica gel in a jacketed, water-cooled column using ether as the eluent provided fractions of pure **18**. Low-temperature concentration of the combined fractions afforded 594 mg (53%) of **18**. Spectral data for **18**: IR (neat), cm^{-1}: 3066, 3025, 2923, 2855, 1603, 1496, 1454, 1065(vs), 748; ^{1}H NMR (200 MHz), δ: 7.37–7.18 (m, 5H), 3.02–2.82 (m, 1H), 2.86 (t, J = 7.4, 2H), 2.67 (dd, J = 6.7 and 10.3 Hz, 1H), 1.98 (dd, 6.7 and 9.6 Hz), 1.80–1.52 (m, 2H); ^{13}C NMR (50.3 MHz), δ: 139.86, 128.59, 128.47, 126.42, 49.53, 41.48, 33.87, 31.23.

*Reaction of **18** with LDA*

To a mixture of LDA (0.91 mmol) and THF (10 mL) stirred at −78°C was added thiirane-*S*-oxide **18** (153 mg, 0.85 mmol) in THF (5 mL). After stirring for 20 min at −78°C, excess MeI in LDA was added. The mixture was stirred overnight as the temperature warmed and work-up was as described for the α-chlorosulfoxides. Chromatography afforded 19 mg (11.5%) of **2h** and 96.5 mg (58%) of **2e**.

Lanthanide shift reagent experiments

The substrate (11–17 mg of compounds **2h**, **2k**, **2o**, **2p**) was placed in a 5-mm NMR tube along with 0.4 mL of $CDCl_3$. The ^{1}H NMR spectrum was recorded on the 400 MHz instrument. Small increments (2.94 mg or factors thereof) of Eu(fod)$_3$ (Resolve-Al EuFOD (Aldrich)) in $CDCl_3$ were added and the ^{1}H NMR was recorded after each addition. Specific attention was given to the downfield movement of the vinyl hydrogen of each substrate. The change in vinyl hydrogen chemical shift was compared to the amount of shift reagent added and the data are presented in Fig. 1.

*Crystal structure analyses of **1kB** and of **1hA***

Details of crystal data, data acquisition, structure solution, and refinement for both **1kB** and **1hA** are concisely summarized in Table 2. In each case the data crystal decayed somewhat over the course of the data collection; this was allowed for by appropriate scaling. The full crystallographic data (fractional coordinates, thermal parameters, molecular dimensions and structure factor listing) have been deposited.[6]

Synthesis, reactions, and interconversions of some 2-(trimethylsilyl)ethyl substituted sulfur compounds

ADRIAN L. SCHWAN,[1] DENIS BRILLON,[2] AND ROBERT DUFAULT

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry and Biochemistry, University of Guelph, Guelph, ON N1G 2W1, Canada

Received July 19, 1993

ADRIAN L. SCHWAN, DENIS BRILLON, and ROBERT DUFAULT. Can. J. Chem. **72**, 325 (1994).

In an effort to probe the compatibility of the 2-(trimethylsilyl)ethyl sulfur moiety with standard organosulfur transformations, several 2-(trimethylsilyl)ethanethiol derivatives have been prepared in excellent yield. Thus 2-(trimethylsilyl)ethanethiol (**1**) and 2-(trimethylsilyl)ethyl disulfide (**4**) and its corresponding thiosulfinate **9** and thiosulfonate **10** have been synthesized. One method of formation of **4** involves the breakdown of a 1-(trimethylsilyl)ethyl unit while the 2-(trimethylsilyl)ethyl fragment survives. Oxidation of **4** or **9** to **10** did not proceed efficiently with common reagents, but proceeded well with an iodine/water system. 2-(Trimethylsilyl)ethyl sulfide (**11***a*) and its oxides (**13**, **14**) were also prepared in good yield. Sulfoxide **13** and 2-(trimethylsilyl)ethyl *tert*-butyl sulfoxide **15** were shown to be good precursors to 2-(trimethylsilyl)ethanesulfinyl chloride (**16**). (Trimethylsilyl)methyl sulfine reacted with **16** in an inefficient manner to give thiosulfonates **10**, **19**, and **20**. 2-(Trimethylsilyl)ethanesulfenyl chloride could be generated and captured by addition across cyclohexene. The reaction of thiosulfinate **9** with several thiosilanes is an excellent method for the synthesis of 2-(trimethylsilyl)ethyl containing mixed disulfides.

ADRIAN L. SCHWAN, DENIS BRILLON et ROBERT DUFAULT. Can. J. Chem. **72**, 325 (1994).

Afin de pouvoir étudier la compatibilité de la portion 2-(triméthylsilyl)éthyle sulfurée avec les transformations standard des composés organosulfurés, on a préparé plusieurs dérivés du 2-(triméthylsilyl)éthanethiol avec d'excellents rendements. On a ainsi synthétisé le 2-(triméthylsilyl)éthanethiol (**1**), le disulfure de 2-(triméthylsilyl)éthyle (**4**) ainsi que les thiosulfinate (**9**) et thiosulfonate (**10**) correspondants. Une méthode de préparation du composé **4** implique la désintégration d'une unité 1-(triméthylsilyl)éthyle alors que le fragment 2-(triméthylsilyl)éthyle survit. Sous l'influence des réactifs ordinaires, l'oxydation des composés **4** ou **9** en **10** ne se produit pas d'une façon efficace; toutefois, elle se produit bien dans un système iode/eau. On a aussi préparé le sulfure de 2-(triméthylsilyl)éthyle (**11***a*) et ses oxydes (**13** et **14**) avec de bons rendements. On a montré que le sulfoxyde **13** et 2-(triméthylsilyl)éthyl *tert*-butyl sulfoxyde sont de bons précurseurs du chlorure de 2-(triméthylsilyl)éthanesulfinyle (**16**). La (triméthylsilyl)méthyl sulfine réagit inefficacement avec le composé **16** pour conduire aux thiosulfonates **10**, **19** et **20**. Le chlorure de 2-(triméthylsilyl)éthanesulfényle peut être généré et capturé par addition sur du cyclohexène. La réaction du thiosulfinate **9** avec plusieurs thiosilanes est une excellent méthode de synthèse des disulfures mixtes contenant des unités 2-(triméthylsilyl)éthyles.

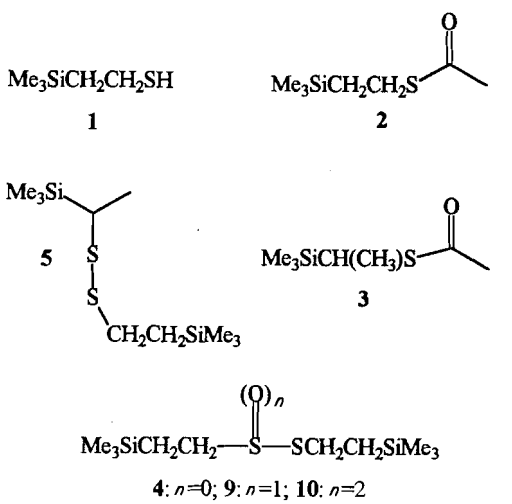
[Traduit par la rédaction]

Introduction

Combining organosulfur and organosilicon chemistry into one molecule offers a new array of synthetic methods (1). A subclass of this field is the chemistry of 2-(trimethylsilyl)ethyl sulfur compounds. Fuchs and co-workers (2) have shown that sulfur atoms can be introduced as a 2-(trimethylsilyl)ethyl unit using either nucleophilic or electrophilic chemistry, with subsequent removal of the 2-(trimethylsilyl)ethyl moiety. Schwan and Dufault have shown that the 2-(trimethylsilyl)ethyl group can be removed from alkyl and aryl 2-(trimethylsilyl)ethyl sulfoxides under Pummerer-like conditions (3). This fragmentation reaction serves as a useful preparation of sulfinyl chlorides. 2-(Trimethylsilyl)ethanesulfonyl chloride has been shown to be an excellent reagent for the functionalization and hence protection of amines (4). Deprotection with fluoride supplies the free amine as well as trimethylsilyl fluoride, sulfur dioxide, and ethylene. Similarly a 2-(trimethylsilyl)ethanesulfonyl-protected carbamate is a suitable reagent for Mitsunobu reactions (5).

The presence of a trimethylsilyl group β to a sulfoxide can also enhance the reactivity of the hydrogens α to the silicon during thermal sulfenic acid formation via [2,3] elimination reactions (6, 7). Furthermore, in some instances the silicon group itself is eliminated (6).

This field has tremendous potential for the generation of several types of sulfur-containing species via fragmentation chemistry and for strategic placement of sulfur atoms in organic molecules, as the Fuchs work indicates. Hence it is important to: (*i*) establish reliable routes to several 2-(trimethylsilyl)-ethanethiol and 2-(trimethylsilyl)ethane sulfur acid derivatives and (*ii*) determine the sorts of organosulfur transformations for which the 2-(trimethylsilyl)ethyl group is tolerant.



Results and discussion

The logical starting point in this exercise is the thiol. 2-(Trimethylsilyl)ethanethiol or β-ethyl silyl thiol (BEST, **1**) has been prepared previously. The synthesis is achieved by

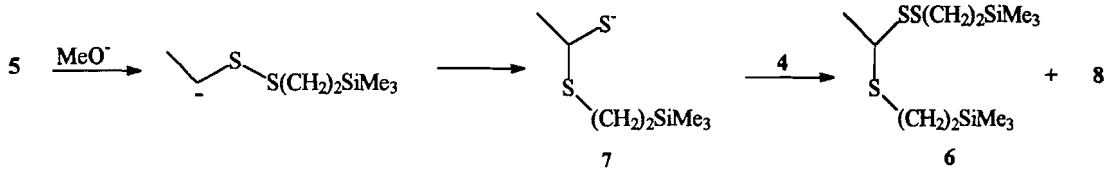

SCHEME 1

reduction (2) or hydrolysis (8) of 2-(trimethylsilyl)ethyl thiolacetate (**2**). Thiolester **2** is prepared by radical addition of thiolacetic acid to vinyltrimethylsilane (8). This yields two regioisomers (**2** and **3**) in a 90:10 ratio and distillation on a spinning band column is an excellent method for the removal of **3**. Pure **2** is then converted to thiol **1** by hydrolysis with potassium carbonate in a methanol–water solution. Under these hydrolysis conditions the thiol is obtained essentially quantitatively, with 98.5% purity (GC analysis). Distillation affords **1** in 95% yield, which represents an improvement over other methods (2, 8).

[1] $$2 \xrightarrow[N_2]{K_2CO_3} \underset{\mathbf{8}}{Me_3SiCH_2CH_2S^-} \xrightarrow{I_2} 4$$

Disulfide **4** can be obtained if the thiolacetate hydrolysis mixture is treated with I_2 (reaction [1], 99.7%). An interesting reaction was observed when we attempted to convert the contaminated **2** to **4** all in one pot. This was accomplished by treating the crude **2/3** mixture with methanolic KOH and allowing the mixture to stir for several days in a vessel open to air. Under the KOH/MeOH/air conditions, a sample of 90% pure **2** gave pure disulfide **4** in 57% yield. This corresponds to an 64% yield based on the amount of **2** actually present. The hydrolysis–oxidation sequence is a particularly robust approach that allows one to start with **2** that may be contaminated by α-silylthiolacetate **3**. A compound giving a retention time expected for isomeric disulfide **5** was observed by GC in the early stages of the reaction,[3] but decomposed under extended exposure to the methanolic KOH mixture. The disappearance of the unwanted isomer means one can prepare disulfide **4** without distilling the original thiolacetate mixture.

The loss of **5** could be followed by GC and was accompanied by an increase in intensity of a newer peak that had significantly longer retention time; when the reaction was stopped, only the new compound and **4** were evident. During the isolation of **4**, the new compound was also recovered and was assigned the structure **6**. This assignment was based primarily on NMR and MS data. In the ^{1}H NMR, there are two different sets of multiplets for the two $-CH_2CH_2-$ groups as well as the doublet and quartet expected for a 1,1-disubstituted ethyl unit. The MS provided major peaks corresponding to $[TMSCH_2CH_2S]^+$ (m/z = 133) and $[TMSCH_2CH_2SCHCH_3]^+$ (m/z = 161) fragments. The reaction conditions likely cause desilylation of the α-silyl species **5**. The short-lived anion probably rearranges via a precedented mechanism (9) to thiolate **7** (Scheme 1). Since this occurs after the formation of **4** is mostly complete, **7** probably then attacks a molecule of **4** to afford **6**. If the hydrolysis of **2** is complete, but the air oxidation of **8** to **4** is sluggish, then **7** can simply combine with **8** to yield **6**. Although this method of formation of **4** sacrifices two 2-(trimethylsilyl)ethyl units for every one unwanted 1-(trimethylsilyl)ethyl isomer, it is a simple synthetic alternative.

The oxidation of disulfide **4** to *S*-2-(trimethylsilyl)ethyl 2-(trimethylsilyl)ethanesulfinothioates[4] (**9**) with MCPBA is a facile operation with **9** being obtained in 95% yield. Thiosulfinate **9** was also obtained by reacting **1** with 2-(trimethylsilyl)-ethanesulfinyl chloride (vide infra). Some chemistry of **9** is demonstrated in a later section of this paper. The conversion of **9** to thiosulfonate **10** and the direct oxidation of **4** to **10** were not trivial tasks. Common oxidizing agents such as MCPBA, MMPP, and peracetic acid solution were not very successful (Table 1). The best yield for the conversion from **9** to **10** was 43% using MMPP while the transformation of **4** to **10** could only be achieved in 32% yield using MCPBA. The general belief is that thiosulfinates are oxidized by electrophilic reagents such as MCPBA and peracetic acid to afford a transient *vic*-disulfoxide (10). That *vic*-disulfoxide then fragments or rearranges to eventually yield the final product, a thiosulfonate. This pathway is not particularly effective for the oxidation of **9**, perhaps because the 2-(trimethylsilyl)ethyl groups are not compatible with the intermediates involved in the rearrangement to thiosulfonate. On the assumption that I_2 in an aqueous medium (11) may circumvent the *vic*-disulfoxide route by direct interaction with the sulfinyl group of **9**, we attempted oxidations with that reagent system. The I_2/H_2O combination proved satisfactory for the oxidation of **4** to **10** and was excellent for the conversion of **9** to **10** (Table 1). Although we found good success with the I_2/H_2O system, we are not in a position at this stage to confirm our initial assumptions regarding its mode of action.[5]

An uncommon, low yielding, but more direct approach to the thiosulfonate **10** was performed by oxidizing **2** with MCPBA. One equivalent of MCPBA yielded a mixture of **2** and **9**. Optimization of the oxidation conditions to 1.5 to 2 equivalents of MCPBA effected complete consumption of thiolacetate **2** and recovery of **10** in up to 28% yield. It is known that the oxidation of alkyl thiolesters with electrophilic agents first creates α-ketosulfoxides, which may break down under the reaction conditions to afford dialkyl disulfides (12). Under our conditions, it is probably disulfide **4** that is formed first and then is oxidized to **10**.

The symmetrically substituted 2-(trimethylsilyl)ethyl sulfide (**11***a*) was prepared by radical addition of **1** to vinyltrimethylsilane. Radical addition to the terminal carbon occurred 92% of the time; the desired isomer (**11***a*) was obtained pure by chromatography. The sulfide is readily oxidized to the sulfoxide (**13**) with $NaIO_4$ (3) (Scheme 2). The sulfoxide was also ob-

[3]Thiolacetates **2** and **3** are consumed in ca. 3 h under these conditions.

[4]The proper nomenclature is as listed for **9** and is *S*-2-(trimethylsilyl)ethyl 2-(trimethylsilyl)ethanesulfonothioates for **10**. We will use the trivial names of thiosulfinate for **9** and thiosulfonate for **10**.

[5]As part of a separate investigation, we are studying the scope and mechanism of the oxidation of other disulfides and thiosulfinates with the I_2/H_2O system.

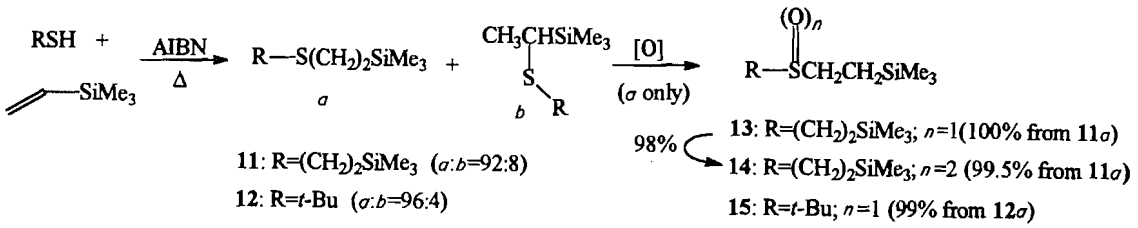
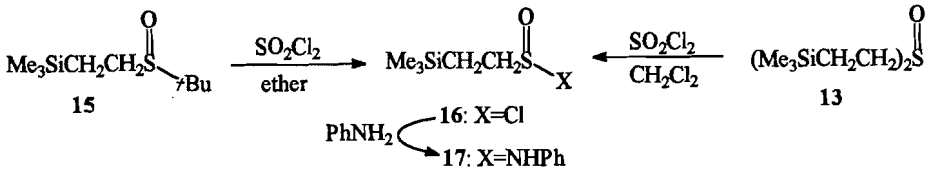
TABLE 1. Syntheses of thiosulfonate **10**[a]

Starting material	Reagent	Temperature (°C)	Yield of **10** (%)
4	CH_3CO_3H (3.2 equiv., CH_2Cl_2)	−78 to +20	13
4	MCPBA (3.2 equiv., THF)	−78 to +20	32
4	MMPP (2.25 equiv., THF)	0	28[b]
4	I_2, $NaHCO_3$, H_2O; then $AgNO_3$	10 to 20	67
4	I_2, Ag_2CO_3, $NaHCO_3$, H_2O/dioxane	20[c]	72[d]
9	CH_3CO_3H (1.15 equiv., CH_2Cl_2)	−30 to +20	38
9	MCPBA (0.8 equiv., CH_2Cl_2)	−40 to +20	23
9	MMPP (1.75 equiv., THF)	17	43
9	I_2, H_2O/dioxane	0	90–95
2	MCPBA (1.5–2 equiv., CH_2Cl_2)	−78 to +20	<28[e]

[a]See experimental section for details.
[b]This mixture also contained **9** (18%).
[c]This mixture was stirred for 120 h.
[d]8% of **4** was also recovered.
[e]Yields were variable.



SCHEME 2

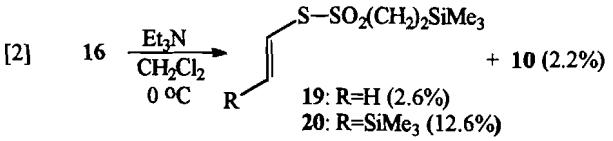


SCHEME 3

tained from the reaction of $LiCH_2S(O)CH_2Li$ and $TMSCH_2Cl$. This approach is not recommended: the yield was low and proper purification was extremely difficult. Sulfone (**14**) was obtained by oxidation of both sulfide **11***a* and sulfoxide **13** using peracetic acid solution. Our syntheses of **11***a* and **14** represent improvements over previously reported procedures (13).

As previously reported, the reaction of **13** with sulfuryl chloride affords 2-(trimethylsilyl)ethanesulfinyl chloride (**16**) in 67% isolated yield (Scheme 3) (3). 2-(Trimethylsilyl)ethyl chloride was a coproduct in this reaction (ca. 20%). Sulfinyl chloride **16** is also accessible via a shorter overall pathway, as shown in Scheme 3. The reaction of *tert*-butyl 2-(trimethylsilyl)ethyl sulfoxide (**15**) with sulfuryl chloride in ether[6] cleanly afforded **16**, probably via a fragmentation pathway. The structure of sulfinyl chloride **16** was confirmed by spectroscopic means while mass spectrometry was obtained on its *N*-phenyl sulfinamide derivative (**17**). The reaction of **16** with thiol **1** in the presence of base provides an alternative route to thiosulfinate **9** (57%).

Attempts were made to generate and capture trimethylsilylmethyl sulfine (**18**). Reaction of sulfinyl chloride (**16**) with of 0.65 equivalent of Et_3N usually affords sulfine, which can then be captured by the remaining sulfinyl chloride (14). The products isolated were vinyl 2-trimethylsilylethanethiosulfonate (**19**) and 2-(trimethylsilyl)ethenyl 2-trimethylsilylethanethiosulfonate (**20**) along with some thiosulfonate **10** (reaction [2]). We believe the oxygens on thiosulfonates **19** and **20** are on the sulfur opposite the vinyl group. The ^{13}C NMR chemical shift of the CH_2 group adjacent to the SO_2 in **10** is at 59.45 ppm while the CH_2 group next to the divalent sulfur resonates at 32.79 ppm. The ^{13}C NMR spectra of **19** and **20** show peaks at 58.58 and 58.22 ppm, respectively, with no peaks in the 15–50 ppm range. The absence of any peaks around 32 ppm for **19**



[6]In methylene chloride, the reaction mixture has many contaminants including 2-(trimethylsilyl)ethyl chloride and *tert*-butanesulfinyl chloride.

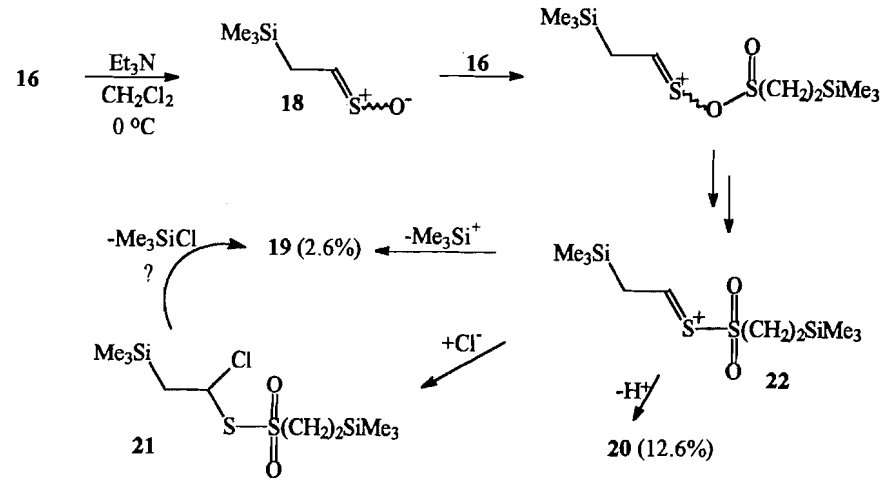
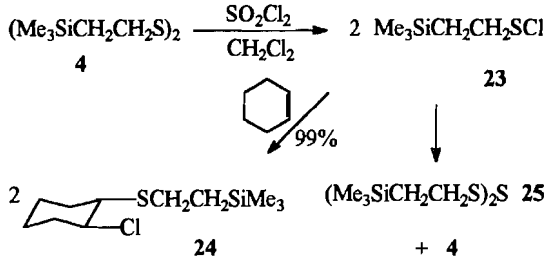


SCHEME 4



SCHEME 5

and **20** and the appearance of resonances close to 59 ppm provide evidence that the sulfonyl portion of **19** and **20** bears the 2-(trimethylsilyl)ethyl unit

Thiosulfonates **19** and **20** can be accounted for by branching off of the normal scheme leading to chlorinated thiosulfonate **21** (14) (Scheme 4). Rather than chloride capture of ion **22** at carbon, chloride attacks **22** at silicon to form the vinyl group. Chloride or amine base may also remove a hydrogen to yield **20**. The silicon atom has been shown to activate protons α to it (6). It is also possible that chloride does add to **22** to give **21**, which then loses TMSCl. The total yield of **19** and **20** could only be idealized to 15%. Obviously silylated sulfine **19** does not behave well under this treatment. Unchlorinated thiosulfonate (**10** in this case) is a recognized by-product and its formation has been accounted for previously (9*a*, 14*c*). Thiosulfonate **10** is the lone reaction product when ether or hexanes are employed as the reaction solvent.

The reaction of disulfide **4** with sulfuryl chloride was viewed as a method for the generation of 2-trimethylsilylethanesulfenyl chloride (**23**). The reaction was carried out at −78°C in CH_2Cl_2. Five minutes after the addition of sulfuryl chloride, cyclohexene was added to capture any sulfenyl chloride that had formed. β-Chlorosulfide **24** was formed in 99% yield (Scheme 5). The clean cleavage of the sulfur-sulfur bond without interference of the silicon group is quite different behaviour from 2-(trimethylsilyl)ethyl sulfoxides. In those instances, the 2-(trimethylsilyl)ethyl moiety is smoothly removed when the sulfoxides are treated with sulfuryl chloride (3). If nothing is added to capture **23**, two products result; one is disulfide **4**, which can simply arise from the reaction of two of **23** coming together (15). The second product that is formed is symmetric trisulfide **25**; Scheme 6 depicts one possible mechanism for its formation.[7] The total yield of the two products was variable (ca. 30–60%). In the mixtures containing **25**, GC chromatograms also showed the presence of 2-(trimethylsilyl)ethyl chloride, the expected by-product (Scheme 6). Under the sulfuryl chloride conditions, the yield of **25** can be optimized to 50%. The structure of **25** was confirmed by independent synthesis using the chemistry introduced by Capozzi et al. (16) for the preparation of symmetric trisulfides. Thus **25** was synthesized from bis(trimethylsilyl) sulfide and thiosulfinate **9** in 63% yield (reaction [3]).

[3] **9** + $Me_3Si—S—SiMe_3$ ⟶ **25** (63%) + **4** (16%)

The work of Capozzi et al. (16) also provided us with a method to generate mixed disulfides containing the 2-(trimethylsilyl)ethyl unit. The reaction involves the treatment of thiosulfinates with alkyl trimethylsilyl thioethers (reaction [4]).

[4] **9** + $RSSiMe_3$ (**27**) ⟶ $Me_3Si(CH_2)_2S—SR$ (**26**)

Several of the required trimethylsilyl thioethers are known compounds and were prepared according to established procedures (17). New silylated thioethers were prepared using the same methods. One unique starting material, trimethylsilyl thioacetate (**27***f*) was prepared as in reaction [5]. Due to the

[5] 
nearby carbonyl oxygen we were concerned that the silicon group may actually prefer an attachment to the oxygen. A previous reaction of thiolacetic acid and hexamethyldisilazane afforded the silylated product (**27***f*) with the silicon attached to the oxygen (18). An infrared spectrum of our material as a neat

[7]Other mechanistic possibilities exist and may be concurrent, since the union of two of **23** is actually a redox process that affords Cl_2 as a co-product. The low yield of **25** and low variable yields of (**4** + **25**) suggest that Cl_2 may be breaking down the molecules to small, unisolable fragments.

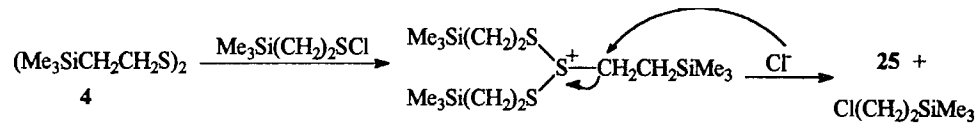

SCHEME 6

TABLE 2. Syntheses of mixed disulfides $RSSCH_2CH_2TMS$ (**26**) from trimethylsilyl thioethers **27** and thiosulfinate **9** (reaction [4])

Disulfide	R	Temperature (°C)	Yield (%)[a]
26*a*	CH_3	20–45	24
26*b*	$c\text{-}C_6H_{11}$	20–45	99
26*c*	$PhCH_2$	20–45	94
26*d*	$p\text{-}ClC_6H_4$	0–20	92
26*e*	$EtOC(O)CH_2$	0–45	88
26*f*	$CH_3C(O)$	0–20	87

[a]Isolated yields after chromatography.

liquid confirmed this structural assignment, since the spectrum contained a very weak carbonyl stretch (1715 cm^{-1}).[8] Even though the silylated thiolacetic acid was primarily a thiocarbonyl compound, the species performed as desired under the usual conditions. All of the mixed disulfides were synthesized in good yield with the exception of **26***a*. (Table 2) The trimethylsilyl thioether (**27***a*) required for the synthesis of **26***a* was a commercial product of unknown purity[9] and is also a volatile compound. Either of these reasons may be responsible for the low yield of **26***a*. *p*-Chlorophenylthiosilane was the most reactive thiosilane in our collection. The increased reactivity of arylthiosilanes over alkylthiosilanes has been recently noted (19). The 2-(trimethylsilyl)ethyl sulfur unit survives very well under the Capozzi reaction conditions. With the isolation of disulfide **26***f* in high yield we provide evidence that the Capozzi method is also satisfactory for the preparation of alkyl acyl disulfides, regardless of the atom attachment of the trimethylsilyl group in the starting silylated ester/thioester.

Experimental

General

Melting points were obtained on a Gallencamp capillary melting point apparatus and are uncorrected. All ^1H NMR spectra were obtained in $CDCl_3$ on a Varian Gemini 200 MHz instrument or a Varian Unity 400 MHz NMR spectrometer. Peaks were calibrated to the residual protium in $CDCl_3$ (7.26 ppm) or to internal tetramethylsilane. ^{13}C NMR spectra were obtained on the same instruments and were calibrated to the $CDCl_3$ (77.00 ppm). Infrared spectra were recorded as neat samples on a Bomem MB 100 IR spectrometer. Mass spectra were obtained using a Kratos MS890 double focussing mass spectrometer. Elemental analyses were performed by Guelph Chemical Laboratories. Gas chromatography was performed on a Varian 3400 capillary gas chromatograph equipped with a low-temperature SPI injection port. The chromatograph was equipped with a 15 m J&W DB-5 capillary GC column. Carrier gas (helium) flow was set to provide a constant column head pressure of 8 psi (1 psi = 6.9 kPa). Analytical TLC was performed using 0.25 mm Merck Kieselgel 60 F_{254} precoated silica gel plates. Visualization was accomplished with UV light, iodine and (or) anisaldehyde – sulfuric acid solution. Unless otherwise indicated, preparative chromatographic separations were done by flash chromatography on Merck silica gel (230–400 mesh). Dry ether was distilled from benzophenone ketyl directly prior to use. Dry CH_2Cl_2 was distilled from CaH_2 directly before use. Vinyltrimethylsilane was obtained from Hüls America (formerly Petrarch) and was used directly.

*Preparation of 2-(trimethylsilyl)ethanethiol (**1**)*

A 250-mL one-necked round-bottom flask, equipped with a reflux condenser and septum/balloon, was charged with vinyltrimethylsilane (63 g, 0.63 mol), thiolacetic acid (42.6 g, 0.561 mol), and AIBN (1.2 g). The mixture was brought to gentle reflux (oil bath 60–63°C) for 3.5 h. The mixture was then distilled on a spinning band distillation set-up using a water vacuum-line. The compound **3** (mixed with **2**) was collected at 82–84°C (14–18 Torr; 1 Torr = 133.3 Pa) (lit. (8) bp of pure **3** 81–82°C (22 Torr)) until GC analysis indicated a purity of >98% for distilled compound **2**; a total of 16.4 g of **2** and **3** were distilled from the mixture. The remaining distillate was cooled to 20°C and then distilled (83°C, 15 Torr) through a short-path distillation apparatus to give **2** (79.4 g, 80%; 99.7% pure by GC). In the following procedure all solvents were deoxygenated at 14 Torr for 0.5 h prior to use; except for diethyl ether. Potassium carbonate (4.42 g, 32 mmol) was added in one portion to a stirred solution of pure thiolacetate **2** (5.0 g, 28.4 mmol) in methanol (30 mL), water (15 mL), and ether (15 mL) under nitrogen at 20°C. The flask was equipped with a rubber septum and an N_2 balloon. The solution was stirred for 3.5 h at 20°C, and citric acid nonahydrate (6.7 g, 32 mmol) was added without a stopper on the flask. Diethyl ether was added (150 mL) and the organic layer was washed with a 1% aqueous citric acid solution (5 × 15 mL). The organic layer was dried on Na_2SO_4 and the solvent was removed in vacuo while maintaining a water bath temperature of 20°C to afford crude thiol **1** (3.79 g, 99.7%, 98.5% purity by GC). The compound was distilled under vacuum (56–57°C (26 Torr) (lit. (20) bp 52–54°C (25 Torr)) to afford pure **1** (3.63 g, 95%; 100% GC purity).

*Synthesis of disulfide **4***

To a mixture of **2** (62.1 g, 0.353 mmol), MeOH (900 mL), and H_2O (500 mL) was added solid K_2CO_3 (56 g). This mixture was stirred at room temperature for 4 h and solid I_2 (44.8 g, 0.176 mmol) was added in small portions. Then saturated aqueous $Na_2S_2O_3$ solution (100 mL) was added and the mixture was extracted with 30–60 petroleum ether (3 × 150 mL). The combined organic extracts were dried over Na_2SO_4 and concentrated (aspirator) to afford pure **4** (46.8 g, 99.7%; 100% pure by GC). Spectral data for **4**: IR (cm^{-1}): 2953, 1417, 1251, 1157, 1013; ^1H NMR (400 MHz) δ: 0.03 (s, 9H), 0.94 (m, 2H), 2.74 (m, 2H); ^{13}C NMR (100.6 MHz) δ: −1.77, 17.17, 34.80; MS (EI), *m/z*(%): 266(1), 238(16), 210(40), 195(17), 101(23), 74(26), 73(100). Anal. calcd. for $C_{10}H_{26}S_2Si_2$: C 45.05, H 9.83; found: C 45.19, H 9.64.

*One-pot synthesis of disulfide **4***

Crude thiolacetate **2** was prepared as above from vinyl trimethylsilane (14.2 g, 0.142 mol), thiolacetic acid (9.58 g, 0.126 mol), and AIBN (280 mg). To the crude mixture was added MeOH (200 mL) and KOH (13.2 g (85%), 0.200 mol). The mixture was stirred for 5 days without a stopper. Water (400 mL) was added and the mixture was extracted with pentane (3 × 60 mL). The combined organic extracts were dried over Na_2SO_4 and were filtered and concentrated (aspirator). Fractional distillation afforded **4** (9.64 g, 57%, bp 84–85°C (0.35 Torr)) followed by **6** (1.07 g) bp 123–124°C (0.4 Torr). Chromatogra-

[8]Our IR spectrum and our ^1H NMR data compared favourably to the data in the literature (18) for the *O*-silylated isomer.

[9]Methyl trimethylsilyl thioether (**23***a*) was purchased from Aldrich and was used without purification.

phy of the fraction containing **6** using 30–60 petroleum ether afforded pure **6**. Spectral data for trisulfide **6**: IR (cm^{-1}): 2954, 1442, 1416, 1251, 1158, 958, 939; ^1H NMR (400 MHz) δ: 0.02 (s, 9H), 0.03 (s, 9H), 0.78–1.00 (m, 4H), 1.63 (d, J = 6.8 Hz, 3H), 2.66–2.83 (m, 4H), 3.94 (q, J = 6.8 Hz, 1H); ^{13}C NMR (100.6 MHz) δ: −1.75 (2 C's), 17.07, 17.31, 22.29, 27.59, 35.79, 51.45; MS (EI), *m/z*(%): 165(22), 161(70), 133(75), 101(71), 74(32), 73(100); MS (CI, methane), *m/z*(%): 399($(M + TMS)^+$, 8), 327($(M + H)^+$, 5), 193(36), 165(72), 163(44), 162(58), 161(100), 135(16), 134(21), 133(86), 101(74), 91(22), 75(15), 74(23), 73(95). Anal. calcd. for $C_{12}H_{30}S_3Si_2$: C 44.16, H 9.68; found: C 44.57, H 9.27.

*Synthesis of 2-(trimethylsilyl)ethyl 2-(trimethylsilyl)ethanethiosulfinate (**9**)*

A solution of MCPBA (283 mg (73%), 1.2 mmol) in CH_2Cl_2 (10 mL) was added slowly to a solution of disulfide **4** (320 mg, 1.20 mmol) in CH_2Cl_2 (25 mL) at −40°C (Dry Ice – MeCN). The solution was stirred for 1 h and dry NH_3 was impinged on the surface of the solution to precipitate ammonium chlorobenzoate. The mixture was filtered with suction through Celite and was concentrated (aspirator). The crude material was purified by chromatography (EtOAc:30–60 petroleum ether; 1:19) to give thiosulfinate **9** (325 mg, 96%). Recrystallization from 30–60 petroleum ether gave mp 36–38°C and the following spectral data for **9**: IR (cm^{-1}): 2953, 2900, 1415, 1255(s), 1161, 1082(s), 1014; ^1H NMR (400 MHz) δ: 0.03 (s, 9H), 0.05 (s, 9H), 1.06 (m, 4H), 3.04 (m, 2H), 3.17 (m, 2H); ^{13}C NMR (100.6 MHz) δ: −1.87, −1.80, 10.40, 19.02, 28.99, 52.24; MS (EI), *m/z*(%): 256(10), 91(14), 73(100), 64(62); MS (CI, methane), *m/z*(%): 283($(M + H)^+$, 2.6), 205(26), 149(20), 148(23), 147(61), 134(22), 133(26), 132(32), 117(49), 106(24), 101(63), 91(35), 90(15), 85(36), 75(75), 74(59), 73(100), 59(38). Anal. calcd. for $C_{10}H_{26}OS_2Si_2$: C 42.50, H 9.27; found: C 42.61, H 9.65.

*Formation of thiosulfonate **10** by oxidation of **4***

Using MCPBA

A solution of MCPBA (276 mg (73%), 1.20 mmol) was added to a solution of disulfide **4** (100 mg, 0.376 mmol) in THF (8 mL) at −78°C. The solution was stirred while it warmed to 20°C over 6.5 h. Aqueous $NaHCO_3$ (10 mL) and 30–60 petroleum ether (10 mL) were added to the mixture; the layers were separated and the organic layer was dried over Na_2SO_4 and concentrated (aspirator). Chromatography (EtOAc:30–60 pet. ether 1:11) gave thiosulfonate **10** (36 mg, 32%). Spectral data for **10**: mp 29–30°C (30–60 petroleum ether); IR (neat) cm^{-1}: 2951, 1416, 1319, 1249, 1162, 1123; ^1H NMR (400 MHz) δ: 0.06 (s, 9H), 0.08 (s, 9H), 0.97 (m, 2H), 1.13 (m, 2H), 3.19 (m, 4H); ^{13}C NMR (100.6 MHz) δ: −1.96, −1.90, 10.61, 17.57, 32.79, 59.45; MS (EI), *m/z*(%): 178(14), 163(43), 147(46), 101(57), 90(24), 75(29), 74(20), 73(100), 59(21), 58(24); MS (CI, methane), *m/z*(%): 371($(M + TMS)^+$, 3), 343($(M + 45)^+$, 11), 315($(M + OH)^+$, 36), 299($(M + H)^+$, 0.3), 163(30), 153(15), 147(32), 101(58), 75(15), 74(28), 73(100). Anal. calcd. for $C_{10}H_{26}O_2Si_2S_2$: C 40.22, H 8.78; found: C 39.85, H 8.86.

Using MMPP

MMPP (720 mg, 80% pure) was added to a solution of disulfide **4** (100 mg, 0.376 mmol) and sodium bicarbonate (200 mg) in THF (7.5 mL) at 0°C. The solution was stirred for 8.5 h at 0°C. Water (10 mL) and 30–60 petroleum ether (20 mL) were added. The organic layer was dried over Na_2SO_4, filtered, and concentrated (aspirator). Chromatography gave the thiosulfonate **10** (31 mg, 28%) and the thiosulfinate **4** (19 mg, 18%).

Using peracetic acid

Peracetic acid solution (530 mg (35% active), 2.01 mmol) was added to a solution of **4** (100 mg, 0.376 mmol) in CH_2Cl_2 (10 mL) stirred at −78°C. The cold bath was removed and the mixture was stirred at 20°C for 6.5 h. Aqueous $NaHCO_3$ (10 mL) and 30–60 petroleum ether (10 mL) were added to the mixture; the layers were separated and the organic layer was dried over Na_2SO_4 and concentrated (aspirator). Chromatography gave thiosulfonate **10** (14 mg, 13%).

Using I_2 and Ag_2CO_3

Silver carbonate (170 mg, 0.616 mmol) was added to a mixture of disulfide **4** (101 mg, 0.376 mmol), sodium bicarbonate (250 mg, 0.298 mmol), and iodine (500 mg, 1.97 mmol) in dioxane (3 mL) and water (1 mL) at 20°C. The mixture was stirred with a gas outlet for 5 days at 20°C and was filtered and rinsed with water (5 mL) and 30–60 petroleum ether:ether (1:1) (20 mL). The aqueous layer was washed once with 30–60 petroleum ether (10 mL) and the combined organic layers were washed with a 5% aqueous sodium dithionite solution until the iodine coloration disappeared. The organic layer was dried over Na_2SO_4, filtered, and concentrated (aspirator). The crude material was purified by chromatography to give thiosulfonate **10** (82 mg, 72%) and some recovered disulfide **4** (8 mg, 8%). The yield of **10** based on consumed **4** was 79%.

Using I_2 and $AgNO_3$

A solution of silver nitrate (54 mg, 0.320 mmol) in water (2 mL) was added slowly (5 min) at 10°C to a solution of disulfide **4** (80 mg, 0.301 mmol), sodium bicarbonate (170 mg, 2.0 mmol), and iodine (170 mg, 0.66 mmol) in dioxane (3 mL). Some more iodine (220 mg) and $NaHCO_3$ (150 mg) were added after 4 h at 20°C. The mixture was stirred for a total of 50 h at 20°C. Work-up and chromatography as for **10** above afforded only thiosulfonate **10** (60 mg, 67%).

*Formation of thiosulfonate **10** by oxidation of **9***

Using MCPBA

A solution of MCPBA (34 mg (73%), 0.20 mmol) was added to a solution of **9** (50 mg, 0.177 mmol) in THF (8 mL) at −40°C. The solution was stirred for 40 min at −40°C and then at 20°C for 4 h. Chromatography (EtOAc:30–60 petroleum ether 1:11) of the mixture gave thiosulfonate **10** (12 mg, 23%).

Using MMPP

MMPP (210 mg, (80% pure), 0.341 mmol) was added to a solution of **9** (54 mg, 0.195 mmol) and sodium bicarbonate (200 mg) in THF (7.5 mL) at 17°C. The solution was stirred for 25 min at 17°C. Water (10 mL) and 30–60 petroleum ether (10 mL) were added. The organic layer was dried over Na_2SO_4, filtered, and concentrated (aspirator). Chromatography gave thiosulfonate **10** (23 mg, 43%).

Using peracetic acid

Peracetic acid solution (152 mg (35% active), 0.578 mmol) was added to a solution of **9** (50 mg, 0.177 mmol) and CH_2Cl_2 (2 mL) stirred at −30°C. The cold bath was removed and the mixture was stirred at 20°C for 3 h. Aqueous $NaHCO_3$ (10 mL) and 30–60 petroleum ether (10 mL) were added to the mixture; the layers were separated and the organic layer was dried over Na_2SO_4 was concentrated (aspirator). Chromatography gave thiosulfonate **10** (20 mg, 38%).

Using I_2

Thiosulfinate **9** (60 mg, 0.213 mmol) was added to a solution of iodine (60 mg, 0.236 mmol) in dioxane (2 mL) and water (1 mL) under nitrogen at 0°C. The solution was stirred for 1.5 h at 0°C, 30–60 petroleum ether:ether (1:1) (30 mL) was added. Work-up and chromatography as above afforded pure thiosulfonate **10** (60.5 mg, 95%) as a solid.

Formation of thiosulfonate **10** by oxidation of thiolacetate **2**

A solution of MCPBA (390 mg, 2.27 mmol) in CH_2Cl_2 (10 mL) was added over 10 min to a solution of the thiolacetate **2** (200 mg, 1.14 mmol) in CH_2Cl_2 (25 mL) at −78°C. The solution was stirred and warmed to room temperature over 14 h. The solvent was removed (aspirator) and the crude mixture was chromatographed to give thiosulfonate **10** (48 mg, 28%) as an oil.

*Synthesis of 2-(trimethylsilyl)ethyl sulfide (**11**a)*

A 25-mL flask was charged with thiol **1** (1.64 g, 12.2 mmol), vinyltrimethylsilane (1.90 g, 19.0 mmol), and AIBN (34 mg). The flask was heated under nitrogen at 50°C, then was sealed with a rubber septum.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

The mixture was stirred at 73°C for 4 h. The crude mixture was concentrated and chromatographed twice using 30–60 petroleum ether as the eluting solvent to afford pure sulfide **11***a* (2.52 g, 88%) as an oil (GC purity: >99%). Spectral data for **11***a*: IR (neat) cm^{-1}: 2934, 1419, 1253, 1162, 1098, 1008; ^1H NMR (400 MHz) δ: 0.02 (s, 9H), 0.85 (m, 2H), 2.55 (m, 2H); ^{13}C NMR (100.6 MHz) δ: −1.77, 17.21, 27.26; MS (EI), *m/z*(%): 234(11), 163(55), 73(100). Anal. calcd. for $C_{10}H_{26}SSi_2$: C 51.21, H 11.17; found: C 51.43, H 11.43.

*Synthesis of 2-(trimethylsilyl)ethyl sulfoxide (**13**)*

To a stirred flask cooled to 0°C containing sulfide **11***a* (2.70 g, 11.5 mmol), MeOH (90 mL), and water (40 mL) was added solid $NaIO_4$ (2.47 g, 11.5 mmol). After 20 min of stirring, the ice bath was removed and the contents were stirred for 3.5 h longer. At that time, the solid was removed by suction filtration and the solid was washed with small portions of CH_2Cl_2. The liquid residue was diluted with an equal volume of water and was extracted with CH_2Cl_2 (3 × 30 mL). The combined organic layers were washed with brine, dried over $MgSO_4$, filtered, and concentrated (aspirator) to afford **13** (2.82 g, 98%) as a white crystalline solid; mp 51–52°C (30–60 petroleum ether). Spectral data for **13**: IR (neat) cm^{-1}: 2952, 1414, 1248, 1166, 1038; ^1H NMR (400 MHz) δ: 0.06 (s, 18H), 0.79 (dt, J = 4.7 and 13.7 Hz, 2H), 0.98 (dt, J = 4.7 and 13.7 Hz, 2H), 2.61 (m, 4H); ^{13}C NMR (100.6 MHz) δ: −1.89, 8.69, 46.47; MS (EI), *m/z*(%): 251($(M + H)^+$, 0.5), 222(19), 194(26), 163(16), 147(26), 133(20), 101(27), 75(29), 74(31), 73(100), 59(16); MS (CI, methane), *m/z*(%): 251($(M + H)^+$, 14), 235(38), 180(18), 179(18), 91(16), 90(51), 74(19), 73(44). Anal. calcd. for $C_{10}H_{26}OSSi_2$: C 47.98, H 10.48; found: C 48.02, H 10.86.

*Synthesis of **14** by oxidation of **13***

Peracetic acid solution (854 mg, (35%) 3.2 mmol) was added all at once to a solution of the sulfoxide **13** (500 mg, 2.0 mmol) in dichloromethane (10 mL) at 0°C. The solution was stirred for 1.5 h at 0°C, and K_2CO_3 (100 mg) and $MgSO_4$ (500 mg) were added. The mixture was diluted with petroleum ether (10 mL), decanted, concentrated, and purified by chromatography (EtOAc:hexanes 1:5) to give sulfone **14** (519 mg, 98%); mp 120.5–121.5°C (30–60 petroleum ether) (lit. (13) mp 122–123°C). Spectral data for **14**: IR (neat) cm^{-1}: 2955, 1417, 1313, 1255, 1172, 1130, 1105; ^1H NMR (400 MHz) δ: 0.06 (s, 9H), 1.01 (m, 2H), 2.87 (m, 2H); ^{13}C NMR (100.6 MHz) δ: −2.03, 8.28, 47.79; MS (EI), *m/z*(%): 223(30), 210(44), 147(59), 101(38), 75(16), 74(31), 73(100), 58(17); MS (CI, methane), *m/z*(%): 339($(M + TMS)^+$, 3.5), 311($(M + 45)^+$, 12), 267($M + H)^+$, 0.3), 223(57), 210(31), 147(49), 101(51), 75(19), 74(33), 73(100). Anal. calcd. for $C_{10}H_{26}O_2SSi_2$: C 45.09, H 9.85; found: C 45.00, H 10.22.

*Synthesis of **14** by oxidation of **11**a*

An aqueous solution of peracetic acid (35%) (800 mg, 3.82 mmol) was added all at once to a solution of sulfide **11***a* (251 mg, 1.07 mmol) in dichloromethane (8 mL) at 0°C. Treatment as indicated above gave sulfone **14** (284 mg, 99.5%).

Synthesis of tert*-butyl 2-(trimethylsilyl)ethyl sulfide (**12**a)*

Sulfide **12***a* was prepared in a manner similar to the synthesis of **11***a* using *tert*-butanethiol (5.28 g, 58.7 mmol), vinyltrimethylsilane (6.22 g, 62.2 mmol), and AIBN (137 mg). GC of the crude material showed the **12***a*:**12***b* ratio to be 96:4. Distillation of the reaction mixture afforded sulfide **12***a* (10.2 g, 86%) as a liquid (GC purity: 97.3%); bp 39–40°C (1.1 Torr). Spectral data for **12***a*: IR (neat) cm^{-1}: 2921, 1459, 1363, 1255, 1163, 855; ^1H NMR (400 MHz) δ: 0.01 (s, 9H), 0.79 (m, 2H). 1.30 (s, 9H), 2.53 (m, 2H); ^{13}C NMR (50.3 MHz) δ: −1.73, 16.81, 23.38, 30.87, 41.84; MS (EI), *m/z*(%): 190(5.6), 107(14), 91(54), 75(19), 73(100), 59(16), 57(79); MS (EI, high resolution), *m/z*(%) calcd. for $C_9H_{22}SSi$: 190.1212; found: 190.1218.

Synthesis of tert*-butyl 2-(trimethylsilyl)ethyl sulfoxide (**15**)*

Sulfide **12***a* was oxidized in a manner similar to **11***a* using sulfide **12***a* (6.31 g, 33.1 mmol), MeOH (55 mL), water (25 mL), and $NaIO_4$ (7.89 g, 33.1 mmol). Treatment and work-up as described above for **13** afforded quite pure **15** (6.56 g, 96%). A recrystallized sample gave mp 28–30°C and the following spectral data: IR (neat) cm^{-1}: 2933, 1467, 1363, 1252, 1159, 1034, 859; ^1H NMR (400 MHz) δ: 0.04 (s, 9H), 0.77 (dt, J = 4.7 and 13.7 Hz, 1H), 1.19 (dt, J = 4.6 and 13.7 Hz, 1H), 1.20 (s, 9H), 2.40 (m, 2H); ^{13}C NMR (100.6 MHz) δ: −1.83, 10.38, 22.98, 40.84, 52.81; MS (CI, methane), *m/z*(%): 207($(M + H)^+$, 95), 91(28), 90(100), 89(36), 74(370, 73(88), 57(22). Anal. calcd. for $C_9H_{22}OSSi$: C 52.37, H 10.74; found: C 52.36, H 10.70.

*Synthesis of sulfinyl chloride **16** by fragmentation of sulfoxide **13***

To a dry solution of CH_2Cl_2 (35 mL) and sulfoxide **13** (4.01 g, 16.0 mmol) stirred at −78°C was added SO_2Cl_2 (2.66 g, 19.7 mmol). The mixture was stirred for 20 min at −78°C and was allowed to warm to room temperature over 2 h. The volatile components were removed under vacuum. ^1H NMR of the mixture showed **16** to be the major product, with 2-(trimethylsilyl)ethyl chloride as a minor product (ca. 20%). The crude mixture was distilled under vacuum to afford 1.99 g (67%, some decomposition occurred) of pure **16**, bp 59–60°C (0.25 Torr). **CAUTION:** Although we have not encountered any problems, there is always a danger of explosion when distilling sulfinyl chlorides (21). Spectral data for **16**: IR (neat) cm^{-1}: 2942, 1412, 1370, 1252, 1153, 846; ^1H NMR (400 MHz) δ: 0.08 (s, 9H), 1.07 (m, 2H), 3.31 (m, 2H); ^{13}C NMR (100.6 MHz) δ: −1.96, 8.73, 60.85.

*Synthesis of sulfinyl chloride **16** by fragmentation of sulfoxide **15***

The synthesis of **16** above was repeated using **15** (6.16 g, 29.9 mmol) and SO_2Cl_2 (2.69 mL, 32.9 mmol) in ether at −78°C for 2 h before slowly warming to room temperature. The volatile components were removed under vacuum to afford **16** (5.58 g (>95% pure), >96% yield).

*Derivatization of **16***

Aniline (1.04 mL, 11.38 mmol) was added over 2 min to a solution of **16** (1.03 g, 5.55 mmol) in ether (25 mL) at 0°C. The solution was stirred 30 min at 20°C followed by filtration with suction through a frit. Removal of the solvents in vacuo afforded the crude sulfinanilide **17**. The mixture was dissolved in warm 30–60 petroleum ether (8 mL) and a minimum of CH_2Cl_2 and was stored −20°C overnight. The crystals were collected by filtration and the mother liquor was concentrated to yield a second batch of crystals. The recovered solid was washed quickly with cold petroleum ether and dried under vacuum to afford a total of 1.34 g (94%) of **17**. A second recrystallization gave crystals with mp 81–83°C (30–60 petroleum ether/CH_2Cl_2). Spectral data for **17**: IR (neat) cm^{-1}: 3157, 2955, 1601, 1496, 1245, 1052, 857; ^1H NMR (400 MHz) δ: 0.08 (s, 9H), 0.99 (m, 2H), 3.05 (m, 2H), 7.02–7.32 (m, 5H); ^{13}C NMR (100.6 MHz) δ: −1.96, 9.59, 51.55, 118.22, 122.90, 129.39, 141.49; MS (CI, methane), *m/z*(%): 314($(M + TMS)^+$, 12), 242($(M + H)^+$, 4), 213(44), 165(43), 150(19), 124(36), 123(16), 101(28), 93(50), 75(28), 74(23), 73(100).

*Reaction of sulfinyl chloride **16** with thiol **1** to form thiosulfinate **9***

A solution of thiol **1** (220 mg, 2.18 mmol) in CH_2Cl_2 (5 mL) was added slowly to a solution of sulfinyl chloride **16** (400 mg, 2.16 mmol) and K_2CO_3 (1 g) in CH_2Cl_2 (10 mL) at 0°C. The solution was stirred for 1 h and ether (10 mL) was added. The mixture was filtered and concentrated (aspirator). Purification as above gave thiosulfinate **9** (345 mg, 57%).

*Generation and capture of trimethylsilylmethyl sulfine (**18**)*

Triethyl amine (700 μL, 5.03 mmol) was added over a period of 5 min to a solution of sulfinyl chloride **16** (1.42 g, 7.70 mmol) in CH_2Cl_2 (40 mL) at 0°C. The solution was allowed to warm to room temperature and was stirred for 8 h. After concentration (aspirator), the mixture was chromatographed (EtOAc:petroleum ether 1:14 to 1:10 to 1:8) to afford 2-(trimethylsilyl)ethenyl 2-(trimethylsilyl)ethanethiosulfonate **20** (288 mg, 12.6%) followed by **10** (58 mg, 2.2%) and then ethenyl 2-(trimethylsilyl)ethanethiosulfonate **19** (46 mg, 2.6%). Spectral data for **20**: IR (neat) cm^{-1}: 2956, 2900, 1549, 1372, 1331, 1254,

For personal use only.

1168, 1131, 849; ^{1}H NMR (400 MHz) δ: 0.06 (s, 9H), 0.13 (s, 9H), 1.13 (m, 2H), 3.22 (m, 2H), 6.38 (d, J = 17.9 Hz, 1H), 6.72 (d, J = 17.9 Hz, 1H); ^{13}C NMR (100.6 MHz) δ: −2.02, −1.65, 10.80, 58.58, 130.71, 142.15; MS (CI, methane), *m/z*(%): 369((M + TMS)$^+$, 9), 345((M + 45)$^+$, 22), 297((M + H)$^+$, 0.7), 210(23), 204(23), 189(32), 163(52), 147(46), 137(16), 101(70), 93(34), 92(63), 91(92), 75(40), 74(53), 73(100), 59(19), 58(16). Spectral data for **19**: IR (neat) cm^{-1}: 2942, 1413, 1318, 1252, 1173, 1129, 844; ^{1}H NMR (400 MHz) δ: 0.06 (s, 9H), 1.15 (m, 2H), 3.24 (m, 2H), 5.75 (s, J = 16.6 Hz, 1H), 5.80 (d, J = 9.1 Hz, 1H), 6.56 (dd, J = 9.1 and 16.6 Hz, 1H); ^{13}C NMR (100.6 MHz) δ: −2.00, 10.67, 58.21, 125.95, 126.12; MS (EI), *m/z*(%): 297((M + TMS)$^+$, 3), 269((M + 45)$^+$, 14), 225((M + H)$^+$, 1), 210(18), 149(19), 147(27), 137(59), 117(42), 101(82), 75(46), 74(50), 73(100), 59(35), 58(24).

*Capture of 2-(trimethylsilyl)ethanesulfenyl chloride (**23**) with cyclohexene*

Neat SO_2Cl_2 (223 mg, 1.65 mmol) was added to a solution of disulfide **4** (400 mg, 1.50 mmol) in dry CH_2Cl_2 (18 mL) at −78°C. After 5 min cyclohexene (1 mL) was quickly added. The mixture was allowed to stir for 30 min at −78°C and then for 1 h at room temperature. Concentration of the mixture (aspirator) afforded rather pure β-chlorosulfide **24** (744 mg, 99%). Spectral data for **24**: IR (neat) cm^{-1}: 2940, 2859, 1443, 1251, 848; ^{1}H NMR (400 MHz) δ: −0.03 (s, 9H), 0.82 (m, 2H), 1.35–1.71 (m, 6H), 2.14–2.25 (m, 2H), 2.61 (t, J = 8.6 Hz, 2H), 2.83 (m, 1H), 4.03 (m, 1H); ^{13}C NMR (50.3 MHz) δ: −1.85, 17.28, 22.80, 23.41, 27.85, 30.32, 33.48, 49.90, 63.76; MS (EI), *m/z*(%): 252(7.1), 250(17), 209(9), 207(23), 114(29), 101(27), 93(31), 91(19), 81(83), 80(42), 75(29), 74(26), 73(100). Anal. calcd. for $C_{11}H_{23}ClSS$: C 52.87, H 8.87; found: C 52.61, H 8.84.

*Synthesis of trisulfide **25** from disulfide **4***

A solution of SO_2Cl_2 (1.0 M in CH_2Cl_2, 0.94 mL, 0.94 mmol) was added to a solution of disulfide **4** (250 mg, 0.94 mmol) in dry CH_2Cl_2 (12 mL) at −78°C. The solution was then stirred for 7 h at 20°C. Concentration (aspirator) and chromatography (30–60 petroleum ether) afforded trisulfide **25** (93 mg, 50%) as an oil. Spectral data for **25**: IR (neat) cm^{-1}: 2953, 1416, 1252, 1158, 1013, 849; ^{1}H NMR (400 MHz) δ: 0.04 (s, 9H), 0.05 (s, 9H), 1.01 (m, 4H), 2.93 (m, 2H), 3.02 (m, 2H); ^{13}C NMR (100.6 MHz(δ: −1.74, 16.86, 17.13, 34.88, 35.37; MS (CI, methane), *m/z*(%): 371((M + TMS)$^+$, 15), 343((M + 45)$^+$, 14), 315((M + CH_4 + H)$^+$, 56), 299((M + H)$^+$, 1), 298(M, 2), 255(46), 242(61), 163(27), 101(69), 74(29), 73(100). Anal. calcd. for $C_{10}H_{26}S_3Si_2$: C 40.21, H 8.77; found: C 40.05, H 8.69.

*Synthesis of trisulfide **25** from bis(trimethylsilyl) sulfide and thiosulfinate **9***

Bis(trimethylsilyl) sulfide (22) (480 mg, 2.75 mmol) was added to a solution of thiosulfinate **9** (727 mg, 2.58 mmol) in distilled anhydrous $CHCl_3$ (4 mL) at 20°C. The solution was stirred for 24 h at 45°C and then was concentrated (aspirator). Chromatography (30–60 petroleum ether) afforded trisulfide **25** (481 mg, 63%) and disulfide **4** (108 mg, 16%).

*Preparation of trimethylsilyl thioethers **27***

Thiosilane **27***a* was purchased from Aldrich. Thiosilanes **27***b*, **27***c*, and **27***d* were prepared according to established procedures (17).

*Carboethoxyethyl trimethylsilyl sulfide **27**e*

Following the method of Glass (17*b*), a mixture of ethyl 2-mercaptoacetate (7.00 g, 58.2 mmol), hexamethyldisilazane (16.8 g, 104 mmol), and imidazole (129 mg, 1.93 mmol) was heated at 130°C 18 h under nitrogen. After cooling, thiosilane **27***e* (10.43 g, 93%) was collected by distillation (bp 97–98°C (14 Torr)) of the crude mixture. Spectral data for **27***e*: IR (neat) cm^{-1}: 2967, 2352, 1737, 1416, 1367, 1273, 1147, 1035; ^{1}H NMR (400 MHz) δ: 0.29 (s, 9H), 1.23 (t, J = 7.2 Hz, 3H), 3.14 (s, 2H), 4.13 (q, J = 7.2 Hz, 2H); ^{13}C NMR (100.6 MHz) δ: 0.50, 13.95, 27.87, 61.21, 170.98.

*Trimethylsilyl thioacetate **27**f*

Note: this flask must be equipped with a gas outlet, and the reaction must be performed under the fumehood. Lithium hydride (555 mg, 6.98 mmol) was added under nitrogen in portions of 50 mg to a solution of thiolacetic acid (4.83 g, 63.4 mmol) in dry dichloromethane (30 mL) at 0°C. The mixture was stirred for 10 min at 0°C. Neat trimethylchlorosilane (10 mL, 79.3 mmol) was then rapidly added. The reaction mixture was stirred for 20 min at 0°C, then for 2 h at 20°C. The mixture was filtered under nitrogen through a frit (dried and purged with nitrogen). The filtrate was distilled at 760 Torr, then under reduced pressure (14 Torr) using the water line equipped with a calcium chloride trap. A first fraction of yellow liquid was collected at 80–84°C (1.5 g), and a second fraction of an orange liquid identified as **27***f* (6.5 g, 66%) was collected at 82–84°C (18 Torr) (lit. (18) bp 84–85°C (18 Torr). Spectral data for **27***f*: IR (neat) cm^{-1}: 2960, 1715 (weak), 1285 (s), 1253, 1217, 1016, 851 (s); ^{1}H NMR (400 MHz) δ: 0.38 (s, 9H), 2.53 (s, 3H); ^{13}C NMR (100.6 MHz) δ: −0.01, 37.20, 161.13.

*General synthesis of 2-(trimethylsilyl)ethyl containing disulfides **26***

Thiosilane **27** was added under nitrogen to a solution of thiosulfinate **9** (0.5 equiv.; ca. 0.5 M in solvent) in dried and distilled chloroform at 0 or 20°C (Table 2). The temperature was raised and the mixture was stirred until reaction was complete (GC). The solvent was removed in vacuo (aspirator), and the crude product was purified by chromatography to afford disulfide **26**.

*2-(Trimethylsilyl)ethyl methyl disulfide (**26**a)*

A mixture of **9** (300 mg, 1.06 mmol) and **27***a* (300 μL) in chloroform (2 mL), heated at 45°C for 36 h, afforded after chromatography (petroleum ether 30–60) disulfide **26***a* (94 mg, 24%) as an oil. GC analysis: 99+% pure. Spectral data for **26***a*: IR (neat) cm^{-1}: 2953, 2916, 1420, 1252, 1157, 1095, 1014, 952; ^{1}H NMR (400 MHz) δ: 0.04 (s, 9H), 0.94 (m, 2H), 2.41 (s, 3H), 2.75 (m, 2H); ^{13}C NMR (100.6 MHz) δ: −1.75, 17.01, 23.24, 33.96; MS (EI), *m/z*(%): 152(39), 137(32), 101(22), 74(16), 73(100); MS (CI, methane), *m/z*(%): 253((M + TMS)$^+$, 19), 225((M + 45)$^+$, 70), 181((M + H)$^+$, 12), 165(26), 153(22), 149(36), 148(53), 147(100), 75(47), 73(66).

*2-(Trimethylsilyl)ethyl cyclohexyl disulfide (**26**b)*

A mixture of **9** (300 mg, 1.06 mmol) and **27***b* (550 μL) in chloroform (3 mL) heated at 45°C for 8 h, afforded after chromatography (30–60 petroleum ether – 2% EtOAc) disulfide **26***b* (520 mg, 99%). GC analysis: 100% pure. Spectral data for **26***b*: IR (neat) cm^{-1}: 2932, 2853, 1447, 1338, 1252, 1199, 1156, 1095, 1006; ^{1}H NMR (400 MHz) δ: 0.02 (s, 9H), 0.90 (m, 2H), 1.32 (m, 5H), 1.61 (m, 1H), 1.80 (m, 2H), 2.01 (m, 2H), 2.73 (m, 3H); ^{13}C NMR (100.6 MHz) δ: −1.74, 17.08, 25.65, 26.11, 32.96, 36.05, 49.54; MS (EI), *m/z*(%): 248(6.3), 222(15), 221(21), 220(85), 138(77), 123(31), 101(18), 83(28), 74(22), 73(100), 55(20). Anal. calcd. for $C_{11}H_{24}S_2Si$: C 53.20, H 9.75; found: C 53.11, H 10.05.

*2-(Trimethylsilyl)ethyl benzyl disulfide (**26**c)*

A mixture of **9** (500 mg, 1.77 mmol) and **27***c* (963 mg, 4.91 mmol) in chloroform (3 mL) heated at 45°C for 16 h afforded after chromatography (petroleum ether – 5% EtOAc) disulfide **26***c* (853 mg, 94%). GC analysis: 100% pure. Spectral data for **26***c*: IR (neat) cm^{-1}: 3062, 3029, 2952, 1601, 1494, 1454, 1415, 1252, 1199, 1157, 1096, 1070, 1016; ^{1}H NMR (400 MHz) δ: −0.05 (s, 9H), 0.77 (m, 2H), 2.35 (m, 2H), 3.90 (s, 2H), 7.34 (m, 5H); ^{13}C NMR (100.6 MHz) δ: −1.83, 16.94, 34.52, 43.67, 127.35, 128.45, 129.27, 137.90; MS (EI), *m/z*(%): 256(1.4), 229(16), 228(73), 101(27), 92(39), 91(100), 74(28), 73(98), 65(21). Anal. calcd. for $C_{12}H_{20}S_2Si$: C 56.23, H 7.87; found: C 56.02, H 7.89.

*2-(Trimethylsilyl)ethyl p-chlorophenyl disulfide (**26**d)*

Thioether **27***d* (190 μL, 0.798 mmol) was added at 0°C to a solution of **9** (90 mg, 0.319 mmol) in chloroform (1 mL). After 15 h at 20°C, chromatography (30–60 petroleum ether) afforded **26***d* (162 mg,

92%). GC analysis: 98% pure. Spectral data for **26***d*: IR (neat) cm^{-1}: 2953, 1571, 1473, 1415, 1388, 1252, 1158, 1091, 1011; ^1H NMR (400 MHz) δ: 0.01 (s, 9H), 0.93 (m, 2H), 2.77 (m, 2H), 7.30 (d, J = 8.7 Hz, 2H), 7.45 (d, J = 8.7 Hz, 2H); ^{13}C NMR (100.6 MHz) δ: −1.91, 16.79, 34.80, 128.67, 129.03, 132.54, 136.30; MS (EI), *m/z*(%): 278(0.8), 276(1.9), 250(14), 248(31), 145(10), 143(27), 108(22), 101(30), 92(85), 91(89), 90(17), 75(18), 74(30), 73(100), 65(22), 63(18). Anal. calcd. for $C_{11}H_{17}ClS_2Si$: C 47.82, H 6.21; found: C 47.61, H 5.88.

*2-(Trimethylsilyl)ethyl ethoxycarbonylmethyl disulfide (**26**e)*

Thioether **27***e* (643 mg, 3.35 mmol) was added at 0°C to a solution of **9** (450 mg, 1.54 mmol) in chloroform (3 mL). After 9 h at 45°C, chromatography (30–60 petroleum ether – EtOAc 20:1 to 10:1) afforded **26***e* (705 mg, 88%). GC analysis: 100% pure. Spectral data for **26***e*: IR (neat) cm^{-1}: 2957, 1736, 1407, 1265, 1138, 1029; ^1H NMR (400 MHz) δ: 0.03 (s, 9H), 0.92 (m, 2H), 1.30 (t, J = 7.2 Hz, 3H), 2.80 (m, 2H), 3.45 (s, 2H), 4.21 (q, J = 7.2 Hz, 2H); ^{13}C NMR (100.6 MHz) δ: −1.80, 14.14, 16.90, 34.67, 41.62, 61.64, 169.73; MS (EI), *m/z*(%): 224(36), 160(16), 117(26), 101(15), 91(15), 75(21), 74(15), 73(100); MS (CI, methane), *m/z*(%): 325($(M + TMS)^+$, 17), 297($(M + 45)^+$, 9), 253($(M + H)^+$, 1), 225(38), 224(54), 160(44), 119(34), 117(48), 92(25), 91(41), 75(39), 74(29), 73(100). Anal. calcd. for $C_9H_{20}O_2S_2Si$: C 42.82, H 7.98; found: C 42.96, H 8.11.

*2-(Trimethylsilyl)ethyl acetyl disulfide (**26**f)*

Thioester **27***f* (163 mg, 1.10 mmol) was added at 0°C to a solution of **9** (137 mg, 0.486 mmol) in chloroform (2 mL). After 15 h at 20°C, chromatography (30–60 petroleum ether – EtOAc 8:1) afforded **26***f* (176 mg, 87%). Spectral data for **26***f*: IR (neat) cm^{-1}: 2954, 1722, 1418, 1351, 1252, 1159, 1112, 1013; ^1H NMR (400 MHz) δ: 0.01 (s, 9H), 0.91 (m, 2H), 2.45 (s, 3H), 2.76 (m, 2H); ^{13}C NMR (100.6 MHz) δ: −1.87, 16.93, 28.86, 34.98, 195.12; MS (EI), *m/z*(%): 180(5.1), 133(18), 101(17), 91(15), 74(15), 73(100); MS (CI, methane), *m/z*(%): 281($(M + TMS)^+$, 15), 253($(M + 45)^+$, 43), 209($(M + H)^+$, 4), 181(51), 180(42), 151(30), 138(48), 123(24), 101(63), 91(21), 75(21), 74(44), 73(100), 59(17). Anal. calcd. for $C_7H_{16}OS_2Si$: C 39.62, H 7.60; found: C 39.71, H 7.84.

Received June 30, 1993

J. IRURRE, F. MARQUILLAS, A. ALVAREZ-LARENA, and J.F. PINIELLA. Can. J. Chem. **72**, 334 (1994).

5-Ethyl-5,6-dihydro-11*H*-dibenzo[*b,e*]azepine-6-thione has been synthesized and studied in the solid state and in solution by X-ray diffraction and ^{1}H DNMR, respectively. The crystals are monoclinic, $P2_1/n$, $a = 9.642(1)$, $b = 13.757(2)$, $c = 9.889((2)$ Å, $\beta = 98.57(1)°$, $Z = 4$. The structure has been solved by direct methods and refined to an R value of 0.040 for 1771 reflections with $I > 2.5\sigma(I)$. The seven-membered ring has a slightly deformed boat conformation. The activation barrier associated with the inversion ring has been determined, being $\Delta G^{\ddagger} = 21.6$ kcal/mol.

J. IRURRE, F. MARQUILLAS, A. ALVAREZ-LARENA et J.F. PINIELLA. Can. J. Chem. **72,** 334 (1994).

On a préparé et étudié la 5-éthyl-5,6-dihydro-11*H*-dibenzo[*b,e*]azépine-6-thione, dans son état solide par diffraction des rayons-X, et en dissolution par la ^{1}H RMND. Les cristaux sont monocliniques, $P2_1/n$, $a = 9{,}642(1)$, $b = 13{,}757(2)$, $c = 9{,}889(2)$ Å, $\beta = 98{,}57(1)°$, $Z = 4$. La structure a été résolue au moyen de méthodes directes et raffinée à une valeur de $R = 0{,}040$ par 1771 réflexions avec $I > 2{,}5\sigma(I)$. Le cycle heptagonal a une conformation bateau légèrement déformée. La barrière d'activation associée avec l'inversion du cycle a été determinée, étant $\Delta G^{\ddagger} = 21{,}6$ kcal/mol.

Introduction

11*H*-Dibenzo[*b,e*]azepine derivatives are a class of interesting compounds in consequence of their pharmacological properties, among them antidepressant and neuroleptic effects (1, 2). In these compounds the seven-membered ring usually assumes a boat conformation and an interconversion of one boat (I) to another (II) is observed (Fig. 1).

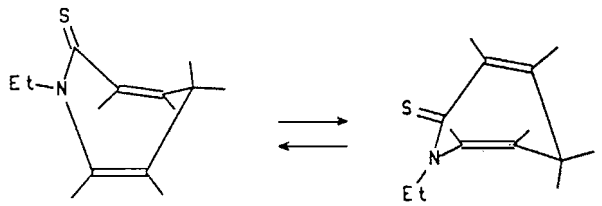

FIG. 1.

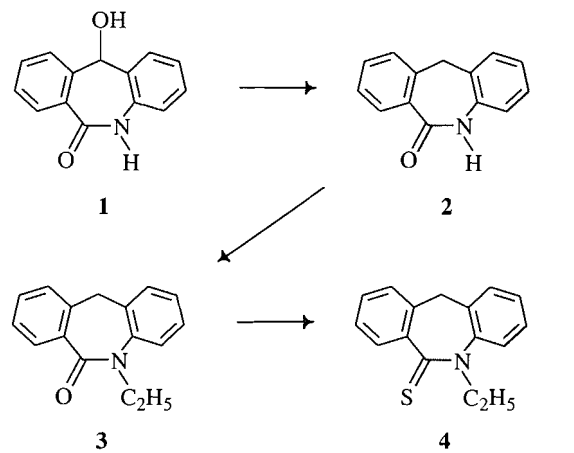
Some of us have synthesized and studied 11*H*-dibenzo[*b,e*]-azepines having an interconversion energy high enough to allow the separation of atropisomers (3). The atropisomers obtained are nonsuperimposable mirror images and therefore they are enantiomers. Their energy barriers were measured by racemization kinetics.

Now, we present the synthesis and conformational study of 11*H*-dibenzo[*b,e*]azepines **3** and **4** having a lower interconversion energy barrier than the above cited compounds. In this work the study has been carried out by dynamic nuclear magnetic resonance. We have also determined the conformation of **4** in the solid state by X-ray diffraction. The compounds **3** and **4** have been obtained according to Scheme 1. The lactam **2**, previously described (4), has been synthesized in the present work by a new method (reducing **1** with HI/AcOH). The alkylation of lactam **2** with iodoethane affords the *N*-ethyl derivative **3**. The thiolactam **4** is obtained from **3** by treatment with phosphorus pentasulphide in boiling pyridine.



SCHEME 1

Experimental

General

The melting points were measured but not corrected. The IR spectra were taken on a Bomen–Michelson 100 apparatus. ^{1}H NMR spectra were recorded with TMS as internal standard on a Bruker AC80 (80 MHz) at 308 K; for the ^{1}H DNMR measurements this instrument is provided with a variable temperature unit calibrated with an ethylene glycol standard. The mass spectra were obtained using a Hewlett–Packard 5995 AGC/MS system at 70 eV. The UV spectra were recorded in a Hewlett–Packard 8450A instrument. CHN microanalyses were carried out on a Carlo–Erba EA1108 instrument.

Synthesis of 6-dihydro-11H-dibenzo[b,e]azepine-6-one (2)

A mixture of 5.0 g (22 mmol) of the alcohol **1**, 100 mL of acetic acid, and 30 mL of hydroiodic acid 57% was heated to reflux for 5 h. The reaction mixture was poured on water, decolourized with a $NaHSO_3$ solution, and the solid **2** that separated was filtered and dried. Yield 3.9 g (85%), mp 200°C (lit. (4) mp 202–204°C); IR (KBr) ν/cm^{-1}; 3180, 3100 (NH), 3040, 2970, 2920, 1655 (C=O), 1590, 1580,

Synthesis of 5-ethyl-5,6-dihydro-11H-dibenzo[b,e]azepine-6-one (3)

A 60% dispersion of 0.6 g NaH in mineral oil (15 mmol) was washed with petroleum ether. The resulting NaH was added to a solution of 3.0 g (14 mmol) of the lactam **2** in 20 mL of dioxane. The mixture was stirred for 15 min and 2.3 g (15 mmol) of iodoethane were added. The solution was heated to reflux for 2 h. After evaporation of the solvent, the residue was distributed between a water–chloroform system. The organic layer was dried ($MgSO_4$). After evaporation of the solvent the residue was chromatographed through silica gel using chloroform as eluent. The compound **3** obtained was crystallized from ethanol. Yield 2.8 g (81%), mp 90°C; IR (film) ν/cm^{-1}: 3075, 3040, 2980, 2940, 1640 (C=O), 1600, 1580, 1495, 1460, 1380; UV (CH_3CN) λ/nm (log ε): 221 (4.28), 237 (3.99), 277 (3.52); ^{1}H NMR ($CDCl_3$) δ: 7.90–7.00 (m, 8H, ArH), 4.61 and 3.83 (2m, 2H, NCH_2), 4.25, 4.09, 3.59, 3.42 (q, J = 13.1, 2H, $ArCH_2Ar$), 1.31 (t, 3H, CH_3); MS *m/e*: 237 (98%), 222 (20), 209 (100), 208 (27), 180 (22), 165 (27), 152 (15). Anal. calcd. for $C_{16}H_{15}NO$: C 80.98, H 6.37, N 5.90; found: C 81.05, H 6.47, N 5.73.

Synthesis of 5-ethyl-5,6-dihydro-11H-dibenzo[b,e]azepine-6-thione (4)

A mixture of 1.6 g (6.7 mmol) of the lactam **3**, 50 mL of pyridine, and 4.5 g (20 mmol) of phosphorus pentasulphide was heated to reflux for 20 h. After evaporation of the solvent, the residue was distributed between a water–chloroform system. The organic layer was dried ($MgSO_4$). After evaporation of the solvent the residue was chromatographed through silica gel using chloroform as eluent. The compound **4** obtained was crystallized from ethanol. Yield 1.1 g (63%), mp 103°C; IR(film) ν/cm^{-1}: 3070, 2980, 2940, 1600, 1570, 1490, 1470, 1395, 1350, 1120 (C=S); UV (CH_3CN) λ/nm (log ε): 219 (4.31), 313 (4.16), 404 (2.73); ^{1}H NMR (DMSO-d_6) δ: 8.00–7.00 (m, 8H, ArH), 5.40 and 4.30 (2m, 2H, NCH_2), 3.97, 3.81, 3.74, 3.58 (q, J = 12.9, 2H, $ArCH_2Ar$), 1.26 (t, 3H, CH_3); MS *m/e*: 253 (100%), 252 (33), 225 (61), 224 (8), 193 (21), 192 (46), 178 (20), 165 (19). Anal. calcd. for $C_{16}H_{15}NS$: C 75.85, H 5.97, N 5.53, S 12.65; found: C 75.48, H 6.20, N 5.52, S 12.54.

X-ray structure determination and refinement

A suitable monocrystal (0.58 × 0.47 × 0.25 mm) was mounted on an Enraf–Nonius CAD4 automatic diffractometer using graphite-monochromated Mo Kα radiation. The cell parameters were obtained by a least-squares fit of 25 well-centred reflections in the range of 20° < 2θ < 28°. Intensity data were collected using the ω/2θ scan mode in the range 2° < 2θ < 50°. Crystal data and measurement conditions are given in Table 1. One intense reflection monitored every hour did not show any significant change in intensity during data collection. Intensities were corrected for Lorentz and polarization effects but not for absorption. The structure was solved by direct methods using the SHELXS program (5). All non-H atoms were found in this step. The refinement was performed by full-matrix least-squares methods (6). The positions of H-atoms were calculated and an overall isotropic thermal parameter was refined. The last anisotropic refinement cycle converged to R = 0.040, Rw = 0.051 with $Rw = \Sigma\Delta F w^{1/2}/\Sigma F_o w^{1/2}$ where $w = 1/(\sigma^2(F_o) + 0.00235F_o^2)$

Maximum and minimum heights in the final difference Fourier were 0.19 and −0.21 e Å^{-3}. The final atomic coordinates and equivalent isotropic temperature factors are given in Table 2. The scattering factors were taken from the International Tables for X-ray Crystallography (1974).

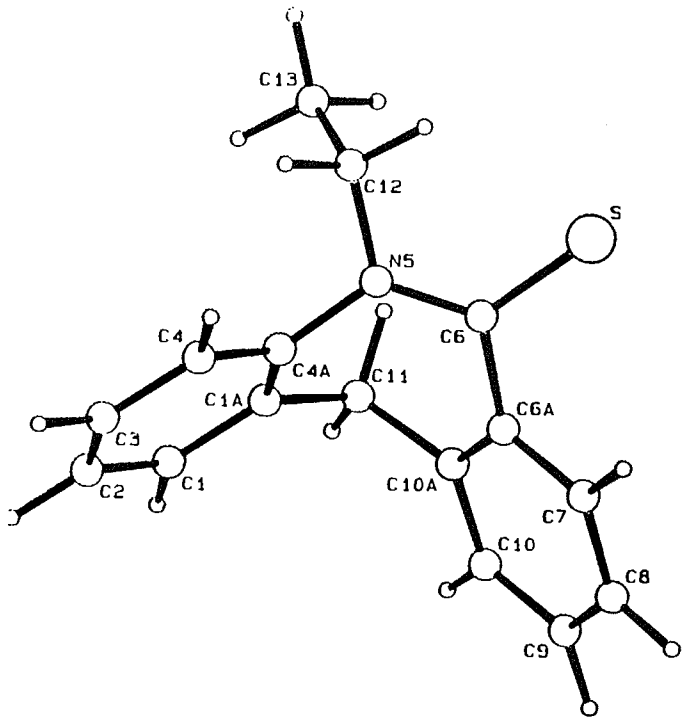

FIG. 2. Perspective view of the molecule.

Results and discussion

A view of the molecule is presented in Fig. 2. Bond distances, bond angles, and torsion angles are given in Tables 3, 4, and 5.[2]

The bond lengths and angles conform to standard values. The nitrogen is trigonal planar: the summation of the three bond angles around the nitrogen is 360.0°, and the C4A, N5, C12, and C6 deviations from their mean plane are small: 0.006(2), −0.014(2), 0.008(3), and 0.006(2) Å, respectively. Table 6 contains relevant conformational information about the title compound and all the 11*H*-dibenzo[*b,e*]azepines whose structures have been reported in the Cambridge Structure Database (7).In compound **4**, the seven-membered ring exhibits a boat conformation. The deviation from a pure boat is small, as pointed out by the asymmetry index ΔC_s[11]. This conformation is usual in this kind of compounds, although there are structures closer to a

[2]A full set of atomic coordinates, bond lengths and angles, and structure factor tables can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

Tables of atomic coordinates and bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

sofa conformation: BUCVAW (ΔC_s^{6a} = 13.1°), DENYUQ (ΔC_s^{4a} = 18.7°), and MIANSB (ΔC_s^{6a} = 17.5°). In these three molecules the bow, stern, and Ar–Ar′ interplanar angles are greater than in the case of 11*H*-dibenzo[*b*,*e*]azepines with a small ΔC_s[11]. The title compound, **4**, shows high values for these angles, in spite of its small asymmetry index ΔC_s[11]. In compound **4**, both aromatic rings form similar angles (38.8(1)° and 37.0(1)°) with the seven-membered ring mean plane. Both atropisomers are present in the unit cell (the space group does not below to an enantiomorph crystal class).

In solution, the ring inversion has been studied using ^{1}H DNMR for compound **4** and its antecedent **3**. The free energy for the conformational interconversion has been evaluated according to the coalescence temperature "lineshape" method (8).

The kinetic constant $K_c = \pi/\sqrt{2}\sqrt{\Delta\nu^2 + 6J^2}$ (9, 10). The analyzed signals belong to the two diastereotopic protons of the C11 methylene group. Table 7 shows the results obtained in the present work and those previously reported for compound **2** (11). From these results one remarks the increase of conformational rigidity when the hydrogen atom on N5 is substituted by an ethyl group (6.5 kcal/mol) as well as when the oxygen atom on the lactam is replaced by sulphur in the thiolactam function-

ality (4.2 kcal/mol). Both are steric effects that increase the instability of the intermediate conformations between the two boats. These steric effects are independent but additive to the strong angular strain from the C=N double bond character of the lactam or the thiolactam. This strain increases the population of the unstable planar intermediate conformation at the expense of the more flexible conformations of the seven-membered ring, where the C—N bond has a bond order near one, and thus the interconversion barrier is increased.

FULVIO CORRADINI, ANDREA MARCHETTI, MARA TAGLIAZUCCHI, LORENZO TASSI, and GIUSEPPE TOSI. Can. J. Chem. **72,** 339 (1994).

Thermodynamic properties from conductance data are reported for the $NaBPh_4$ electrolytic solutions in 2-methoxyethanol (component 1)/water (component 2) binary solvent mixtures, working at 19 temperatures ranging from −10 to +80°C and for 6 mixtures covering the $0.1865 \leq x_1 \leq 1$ composition range. Experimental conductivity data were analysed using the Fuoss–Hsia equation, and the chosen salt was found to associate to a certain extent in these solvent mixtures. The resulting dissociation constants (K) of the ion-pair have been used to test some empirical equations $K = K(T)$, $K = K(x_1)$, and $K = K(T, x_1)$. Furthermore, the present findings have been compared with our previously reported results from working with picric acid in the same mixtures and experimental conditions.

FULVIO CORRADINI, ANDREA MARCHETTI, MARA TAGLIAZUCCHI, LORENZO TASSI et GIUSEPPE TOSI. Can. J. Chem. **72,** 339 (1994).

On a déterminé les propriétés thermodynamiques de solutions électrolytiques de $NaBPh_4$ dans des mélanges binaires de solvants formés 2-méthoxyéthanol (composé 1)/eau (composé 2) à partir de données de conductance obtenues à 19 températures allant de −10 à +80°C et pour 6 mélanges de solvant couvrant les compositions $0{,}1865 \leq x_1 \leq 1$. On a analysé les données expérimentales de conductivité à l'aide de l'équation de Fuoss-Hsia et on a trouvé que le sel choisi est toujours partiellement associé dans ces mélanges de solvant. On a utilisé les constantes de dissociation (K) obtenues pour la paire d'ions de cet électrolyte pour évaluer quelques équations empiriques représentant les fonctions $K = K(T)$, $K = K(x_1)$ et $K = K(T, x_1)$. De plus, on a comparé les données obtenues avec les résultats que nous avons rapportés antérieurement en travaillant avec de l'acide picrique dans les mêmes mélanges et dans les mêmes conditions expérimentales.

[Traduit par la rédaction]

Introduction

In some recent investigations (1–4), we have studied the solvent effects on ionization and dissociation reactions that take place in binary nonaqueous and water (W) mixed media.

Initially, we chose picric acid (HPi) as the weak electrolyte and 1,2-ethanediol (ED) and 2-methoxyethanol (ME) as the nonaqueous solvents. Furthermore, we applied the conductometric method at 19 temperatures between $-10 \leq t/°C \leq +80$ and we worked with binaries covering the whole miscibility field expressed by the mole fraction of one component ($0 \leq x_i \leq 1$) in the mixed solvent systems. However, we encountered a number of difficulties in the computer analysis of experimental conductivity data in pure water and in the water-rich regions (1, 3), hence we have limited our investigations only to the region that is rich in organic solvent. Similar studies might have become more common in recent years, but a careful examination of the literature shows that very few papers report on the thermodynamic behavior and dissociation of reference electrolytes (5, 6).

Electrolytes in pure and mixed organic solvents are used in theoretical chemistry and chemical technology; it is therefore desirable to know their thermodynamic and transport properties in these media. Since these chemicals are important, it would be useful to generalize their electrolytic behavior in pure organic solvents and in water-mixed media either empirically or theoretically.

A wide variety of thermodynamic assumptions have been proposed in the literature, usually followed by interpretations of the values obtained. To expand on our knowledge, we have planned a series of studies on $NaBPh_4$ in ME/W mixtures, with an eye to learn the thermodynamic and thermomechanical behavior of the species in the mixed solvents. To investigate the physico-chemical aspects of solvent–cosolvent interactions, we have compared our findings with those previously obtained (7, 8).

Experimental

Materials

2-Methoxyethanol (containing <0.05% of water by mass according to Karl-Fischer titrations) was Carlo Erba (Milan) high purity grade. It was stored over 3 Å molecular sieves for many days before use, and the final purity was checked by gas chromatography (99.7% by mass), which confirmed the absence of other significant organic components. Water for making up the binaries was twice distilled over $KMnO_4$ in a quartz apparatus, and had specific conductance $< 7 \times 10^{-7}$ S cm^{-1} at 25°C. Sodium tetraphenylborate (STB), supplied by Fluka, was purified by recrystallization from hot acetone (spectrograde quality) and desiccated at 80°C.

Apparatus

The apparatus and procedures for measuring density (7), viscosity (8), and dielectric constant (ϵ) (3) have been described. Experimental ϵ values are summarized in Table I and is available as supplementary material.[2] Conductances of the solutions were measured with a Wayne Kerr 6425 Precision Component Analyzer, operating in the 2.5×10^{-9} to 10 S scale-end range, with a sensitivity of $\pm 0.01 \times 10^{-9}$ S and a field frequency of 1 kHz. This instrument is equipped with platinum electrodes (cell constants 10.538 cm and 1.040 cm) for measurements in the lower and upper specific conductivity (χ) limit, respectively. The thermostated measuring cell was embedded in a polyurethane protective jacket, and the temperature was controlled by a Lauda K2R thermostatic bath maintained to ±0.02°C over the entire temperature range. The thermal control was checked by a thermoresistance Pt 100 (Tersid, Milan) inserted into the measuring cell, collecting the resistance values by using the above mentioned WK 6425 PCA. Karl Fischer titrations were performed with an automatic titration system

(Crison model KF431) equipped with a digital burette (Crison model KF738).

Procedure

The mixtures were prepared by weight just before use, by means of a Mettler PM 4800 Δ-range balance. The estimated error in the 2-methoxyethanol mole fraction, x_1, is $\leq 1.5 \times 10^{-4}$.

Different concentrations of $NaBPh_4$ solutions were obtained by successive dilution of the stock solution which was freshly prepared by weight. Concentrations in volume were then calculated from weight concentrations and densities.

Conductance readings were recorded when they become invariant with time and at regular interval of 15 min for each measurement. Solvent conductance corrections were applied to all data at different temperatures.

Results and discussion

The composition of the six solvent mixtures are denoted by the letters A to F, and the mole fraction and molarity of ME and W are shown in Table 1.

To determine the dissociation constants K ($K = K_A^{-1}$) for $NaBPh_4$ (STB) in the selected binary solvent system, conductance measurements were performed at 19 temperatures in the −10 to +80°C range, at 5°C intervals, for at least six different electrolytic concentrations and for each solvent mixture. The experimental data, reporting the equivalent conductances of STB in pure ME and in five binary ME/W mixtures, are tabulated in Tables II–VII.[2] The conductance data have been analysed with a more general conductivity equation proposed by Fuoss–Hsia (9), using a computer program that we modified to take into account the variation of the solution concentration with density. The following equation (10)

Equation 1

was used where the symbols have their usual meaning (3) and an iterative calculation procedure gives the association constant K_A, the limiting ionic conductivity Λ_0, and the interionic distance parameter $\mathring{a}$. To start the procedure an initial Λ_0 is necessary, and this quantity is estimated from an Onsager Λ vs. $C^{1/2}$ plot. In general, only a few iterations are necessary to provide convergence on K_A, Λ_0, and $\mathring{a}$.

The dissociation constant

Table 2 summarizes the dissociation constants of STB in ME/W mixtures obtained using eq. [1]. Unfortunately, there is poor agreement between our K value in the pure solvent ME and those reported in the literature at 25°C ($K = 4.14 \times 10^{-2}$) obtained by other authors (11). Figure 1 shows the plots K vs. t/°C for each binary mixture. These curves are obtained by fitting each set of experimental data using an equation of the type

$$[2] \quad \ln K = a_0 + a_1 T + a_2/T + a_3 \ln T$$

which represents the most commonly used integrated Van't Hoff equation for the dependence $K = K(T)$. The a_i coefficients in eq. [2], obtained by a multilinear regression program TSP (12), are listed in Table VIII (supplementary material), along with the standard deviation $\sigma(\ln K)$ for each binary mixture.

A brief examination of Fig. 1 shows the following features. (*i*) The curves change progressively in shape from convex with a temperature coefficient $d \ln K/dT < 0$ (A, B) up to mixture C, then turn into concave with a temperature coefficient $d \ln K/dT > 0$ (mixtures D, E, F). In particular, starting from pure ME (mixture A) the dissociation constant increases as the mole fraction of water in the mixture increases until curve C ($V_1/V_2 = 80/20$), and then decreases (inverting slope with respect to mixtures A and B) for mixtures D and E. It should be noted that in mixture E we get the lowest K for this electrolyte in the solvent system at the low temperatures. From this composition ratio, the K values further increase rapidly. (*ii*) Curve C shows a maximum around the middle temperature in the range investigated. (*iii*) Taking into account the progressive and regular variation of the $K = K(T)$ curves on passing from mixtures A to F and that the composition of binary solvent varies continuously in the range $0.1865 \leq x_1 \leq 1$, we can assume the K value also varies continuously between that in ME (solvent A) and that for mixture F at each temperature investigated.

Now, starting from the best-fitting equation [2], it is possible to evaluate the thermodynamic parameters for the ion-pair dissociation reaction in ME/W binaries by applying the standard thermodynamic relations of the form:

$$[3] \quad \Delta H^0 = R(a_1 T^2 - a_2 + a_3 T)$$

$$[4] \quad \Delta S^0 = R[a_0 + 2a_1 T + a_3(1 + \ln T)]$$

which provide the values for ΔH^0 and ΔS^0, respectively. Associated with these calculations are uncertainties originating from experimental errors in K and the choice of the function to represent the integrated Van't Hoff equation $K = K(T)$.

Figure 2 shows the variation of ΔH^0 and ΔS^0 with temperature. Useful information that can be derived from these curves include information on solute species, solute–solvent and solvent–cosolvent interactions.

It should first be noted that the signs and trends of ΔH^0 and ΔS^0 are different for different electrolytes. In particular, when considering the dissociation enthalpy, we are concerned with enthalpy changes due to differences between solvated ion pairs in solution and solvated free ions, and with changes in enthalpy due to differences in solute–solvent–cosolvent interactions.

We therefore divide the solvent systems into two distinct regions (13), M_I and M_{II}. Obviously, the thermodynamic properties to be described are sensitive to solute–solvents and solvent–cosolvent interactions.

(*i*) Region M_I, of composition $1 \geq x_1 \simeq 0.4792$

In this composition range, the thermodynamic properties of the solute exhibit a sharp solvent–cosolvent concentration dependence, reflecting an evident disruption of the heterocooperative fluctuations in the solvating sphere. Furthermore, except for pure ME (system A) for which the temperature coef-

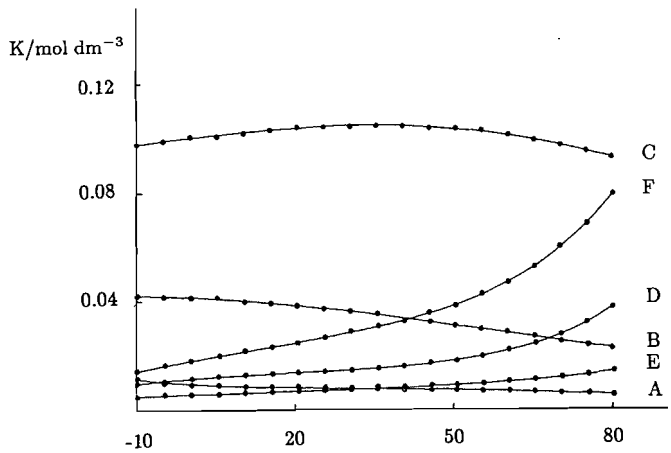

FIG. 1. Experimental dissociation constants of $NaBPh_4$ in 2-methoxyethanol/water at different temperatures and best fitting curves calculated by eq. [2].

ficient $d\Delta Y/dT < 0$ (with $Y = H^0, S^0$), the trend of the curves B, C in Fig. 2 seems to be strongly influenced by the hydrophobic character of ME and tetraphenylborate ion. In fact, the counterion Na^+ could probably be solvated through dipole- and dipole-induced interactions either by ME or W. On the other hand, BPh_4^- ion could be solvated only by ME via weaker interactions provided by short-contact distances between the phenyl groups and the alkyl chains —CH_2—CH_2— in the solvent molecules. A further description in terms of structural models could be made, taking into account that the lower boundary of M_I would correspond to a cosolvent concentration beyond which mixed solvated ions exist, since $d\Delta Y/dT < 0$ in this region, the slope decreases with increasing temperature, and is different for different composition. Thus we assume that the binary mixture having zero temperature coefficient ($d\Delta Y/dT = 0$) is a limiting composition. Within this region mixed solvated solute species can exist, at least to the first solvation sphere.

(*ii*) Region M_{II}, of composition $0.4792 \simeq x_1 > 0.1865$

In this region, dissociation is always endothermic. The variation in thermodynamic properties could reflect a situation in which mixed hydrogen bonding in the solvation sphere is replaced by coordination of the major component in the mixed solvent. In other words, in this region ME molecules should play a co-solute role towards the water molecules rather than a cosolvent role towards STB.

As for entropy, curves B, C and in part curve A, suggest that at a certain temperature an ordered structure is achieved around the solute and it may appear in the form of an ion pair or a free ion, even though this observation is not in agreement with thermokinetic effects. A more reliable explanation takes into account that an increase in temperature brings a decrease in the dielectric constant. Consequently, the charged species could act as structure maker in solution, their electrical field being strong enough to correctly orient the surrounding solvent molecules that form the solvation shell even as the temperature increases. Furthermore, this assumption agrees with the observation that electrostriction between adjacent species is reduced at higher temperatures, when the solvent dielectric constant is reduced compared with that at lower temperature.

In general, positive ΔS^0 values (or very small negative values in restricted temperature range) are obtained in the M_{II} region, confirming that solute dissociation acts as structure-breaker in these mixtures. This observation is in perfect agreement with thermokinetic effects.

We now perform an empirical study of the trend of K vs. binary composition to identify the dissociation behavior of STB in these mixed solvents. We have therefore plotted K vs. x_2 at certain temperatures as shown in Fig. 3.

At any temperature, the curve K vs. x_2 reaches a relative

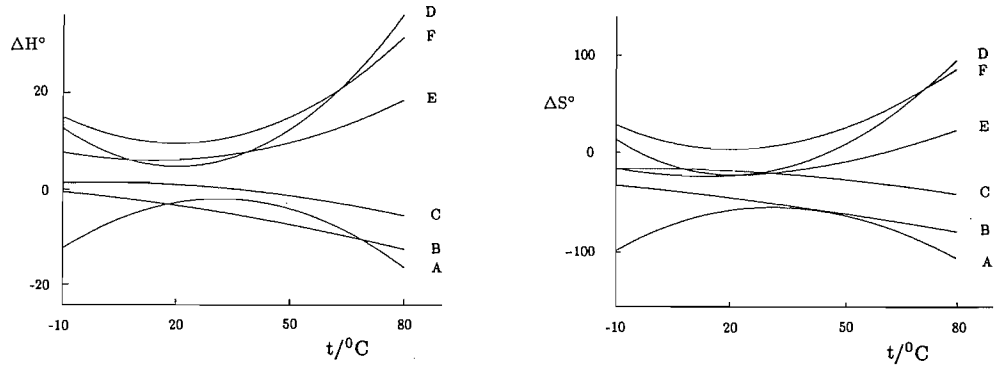

FIG. 2. Dependence on the temperature of ΔH^0 (kJ mol^{-1}), left, and ΔS^0 (J mol^{-1} K^{-1}), right, for the dissociation of $NaBPh_4$ in 2-methoxyethanol/water solvent system.

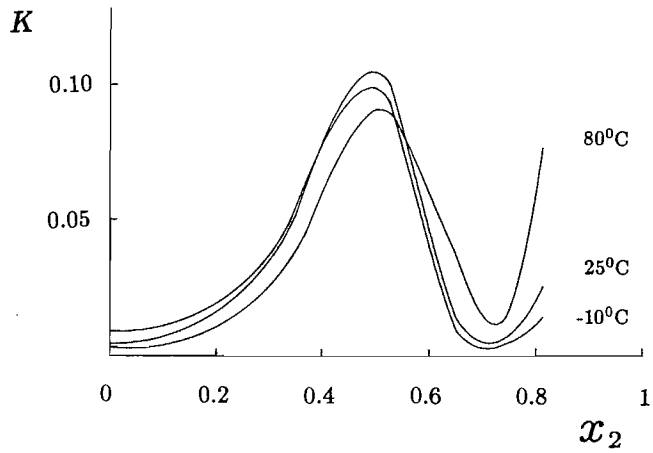

FIG. 3. Dissociation constants (K/mol dm^{-3}) of $NaBPh_4$ in 2-methoxyethanol/water solvent system as a function of binary composition at some selected temperatures.

maximum at $x_2 = 0.5$ (ME:W = 1:1) and then a relative minimum at $x_2 \simeq 0.65$ (ME:W = 1:2). A stable solvent–cosolvent complex ME·2W has been suggested in a previous work (7). According to our observation, this adduct shows the smallest interactions and solvabilities towards the constituting ions of the chosen solute. Consequently the ion-pair in this structure is stabilized and this is manifested as a minimum in the dissociation constant.

Nonlinear relationships like those shown in Fig. 3 suggest that correlation functions could be used to establish the dependence of K on binary composition. Because no model equation $K = K(x_1)$ is available in the literature, and our investigation is restricted to the $100/0 \geq V_1/V_2\% \geq 50/50$ composition range, the simplest attempt of correlation is represented by a polynominal expansion of the general form

$$[5] \quad \ln K = \sum_{j=0}^{n} b_j x_1^j$$

in which coefficients b_j for $n = 4$ are given in Table IX[2] along with the corresponding standard deviation $\sigma(\ln K)$ at each temperature studied.

Now, two empirical relationships are available: $K = K(T)$ and $K = K(x_1)$. To shorten the interpolation procedure, we have derived a single function $K = K(T, x_1)$ combining eqs. [2] and [5]

TABLE 3. c_i coefficients of eq. [6] for $NaBPh_4$ in the 2-methoxyethanol/water solvent system

Variable quantity	Coefficient	Value
	c_0	232.94
x_1	c_1	16851

tainty $\overline{\Delta K}$, evaluated by

$$[7] \quad \overline{\Delta K} = \frac{1}{N} \sum_{N} \frac{|K_{\text{exptl}} - K_{\text{calcd}}|}{K_{\text{exptl}}}$$

equals ±0.04 over all the 114 experimental K values in Table 2.

The interionic distance parameter

Table 4 summarizes the ion size-fitting parameter, *å*, obtained for $NaBPh_4$ in ME/W mixtures. Literature (14, 15) states that this fitting parameter is dependent on the conductivity equation [1] chosen and it appears to be related strictly to the association constant. This point introduces uncertainties in the determination of *å* and K_a, and the interpretation of the data obtained is ambiguous because of their mutual adjustment.

Nevertheless, being keeping the suggestions in literature in mind (14, 15), we can still get some information on the fitting parameter *å*. Even though we are not sure how *å* varies with temperature, as shown in Table 4, we can suggest trend. We can classify the mixtures into two groups, A, B, C and D, E, F (Table 4).

The first group is characterized by a very large *å* value, ranging from 7.43 to 14.4 Å, which is an indication of the presence of solvent-separated ion-pairs. It should be noted that the bulk solution in this composition range is probably formed by clusterized ME·2W units immersed in a matrix of additional ME molecules (7). Therefore, any solvation process should be performed first by free ME molecules and, eventually, by the voluminous ME·2W clusters. Consequently solvated ions could only interact at very long distances as shown in Table 4.

The second group of curves (D, E, F) seems to show a very different behavior. In fact, the value of *å* ranges from 1.06 to 4.11 Å, and only at temperatures higher than 70°C does the fitting parameter become significantly greater than 3 Å. Therefore in this composition range one suggests that the ion pairs are slightly separated by solvent molecules, the bulk of the solution comprises ME·2W complex adduct and water molecules.

A significant feature in the electrolytic behaviour of STB in ME/W mixture is that the bolaform tetraphenyl ion remains unsolvated in mixtures with $x_1 \leq 0.3494$ (mixture D), although the cut-off concentration might change.

Conclusions

Certain conclusions may be drawn from our results, when our previous work on the same mixtures are taken into consideration. Changes in the thermodynamic properties of a dissociating electrolyte, induced by changing solvent composition, often provide useful insights into the structural character of the binary systems. In fact, from the thermodynamic behaviour of the reference electrolyte we have witnessed the formation of a termolecular stable solvent–cosolvent aggregate ME·2W. The intrinsic characteristics and low dipole moments of ME·2W indicate poor solvability towards free ions since the solutes have low K values.

The present findings reinforce our previous observations and confirm the existence of a "limiting mixture" in the ME/W solvent system. In an earlier paper (3), a determination of the experimental dissociation constant of HPi in the same solvent system at various temperatures has been reported, and a sharp change in the trend in $K = K(T)$ curves allowed us to propose the existence of a singular binary composition that was called "limiting mixture". This particular solvent mixture was identified by an unambiguous inversion of the trend from concave to convex and its composition corresponded to two well-defined regions, separated by $x_1 \simeq 0.65$ (ME:W = 2:1).

Now, a comparison between our results and those in ref. 7 shows that the "limiting mixture" for the binary solvent system is not that detected using HPi, but the ME·2W termolecular adduct that was also observed by studying volumic properties of the mixed solvents (7). However, it should be noted that the behaviour of the electrolytes (HPi and STB) in ME/W mixtures should probably be attributed to the very different molecular structures of the selected species, in particular those of anions.

The apparent disagreement in these findings is an incentive to study other solutes in the same binary systems and to study other solvents so that we might understand the specific interactions between the different molecules.

R.J. HELLEUR and PIERRE THIBAULT. Can. J. Chem. **72**, 345 (1994).

The operating conditions for pyrolysis–desorption ammonia chemical ionization mass spectrometry and tandem mass spectrometry have been optimized and the technique evaluated for the production and analysis of structurally-informative pyrolytic fragmentation ions corresponding to intact anhydrohexose oligosaccharides, using amylose as the model polysaccharide. Among the various parameters examined it was found that the nature of the solvent used to adhere the sample to the emitter coil and the configuration of the emitter and the rate at which it is heated all play important roles in determining the efficiency of the pyrolytic process and the production of high mass fragment ions. Adjustment of reagent gas pressure together with source temperature also influence the chemical integrity of high mass oligomeric pyrolysis products. Under optimal operating conditions using ammonia reagent gas, the analyses of cellulose, laminarin, agars, and chitin gave relatively abundant ions corresponding to ammonium (or protonated) adducts of up to anhydrohexose tetrasaccharide. More importantly, the generation of such higher mass fragment ions provided a sustained ionic current of sufficient duration to perform tandem mass spectrometric analyses.

R.J. HELLEUR et PIERRE THIBAULT. Can. J. Chem. **72**, 345 (1994).

On a optimisé le mode opératoire de la pyrolyse/spectrométrie de masse par ionisation chimique par désorption d'ammoniac et de la spectrométrie de masse en tandem et on a évalué la technique pour le production et l'analyse d'ions de fragmentation pyrolytique pouvant fournir de l'information sur la structure d'oligosaccharides d'anhydrohexoses intacts, en utilisant l'amylose comme polysaccaride modèle. Parmi les divers paramètres examinés, on a trouvé que la nature du solvant utilisé pour faire adhérer l'échantillon sur la bobine émettrice et la configuration de l'émetteur ainsi que la vitesse à laquelle il est chauffé jouent tous des rôles importants dans la détermination de l'efficacité du processus pyrolytique et dans la productions des ions fragmentés de masse élevée. Un ajustement de la pression gazeuse du réactif avec la température de la source influence aussi l'intégrité chimique des produits de pyrolyse oligomérique de masse élevée. Dans des conditions d'opération optimales utilisant de l'ammoniac comme gaz réactif, les analyses de cellulose, de laminarine, d'agars et de chitine donnent toutes des ions relativement abondants correspondant aux adduits ammonium (ou protonés) de composés allant jusqu'au tétrasaccharide d'anhydrohexose. Ce qui est encore plus important est que la génération d'ions fragments d'une masse aussi élevée fournit un courant ionique pendant une période telle qu'elle permet de réaliser des analyses par spectrométrie de masse en tandem.

[Traduit par la rédaction]

Introduction

Pyrolysis – mass spectrometry (Py–MS) has a great potential for the rapid investigation of complex biopolymers such as polysaccharides, where structural information can be obtained from the fragment ions produced directly from solid samples. Several types of Py–MS techniques have been employed on carbohydrates including laser Py–MS (1, 2), Curie-point Py–MS (3, 4), and in-source, or, pyrolysis–desorption chemical ionization mass spectrometry (Py–DCI-MS) (5–8). Laser pyrolysis, often loosely referred to as laser desorption, is very well suited for the structural analysis of polysaccharides where intact "parent-molecular ions" and thermal fragmentation ions are generated following sample desorption using intense laser radiation. However, practical problems such as controlling the amount of energy deposited per unit sample volume and the technically complex instrumentation required still prevent laser Py–MS from becoming a routine analytical technique. Curie-point pyrolysis involves sample pyrolysis by inductive heating of a ferromagnetic filament using a high frequency coil. Although this method allows for very rapid heating rates and reproducible discrete pyrolysis temperatures, Curie-point Py–MS investigations are normally limited to the analysis of low mass pyrolysis products. Mass fragments higher than 250 dalton are usually not detected due to low transmission of these fragments to the ion source.

The in-source pyrolysis/ionization technique, Py–DCI–MS, where the sample is deposited on a platinum coil and then inserted inside a chemical ionization source by means of an extended probe, is a very simple procedure readily compatible with commercial MS instruments. A number of Py–DCI–MS investigations have been carried out to rapidly characterize polysaccharides using both positive-ion (5–8) and negative-ion (7, 8) chemical ionization. The most useful conditions for the analysis of carbohydrates involve ammonia positive-ion chemical ionization. Under in-source pyrolysis, polysaccharides fragment into a series of ions corresponding to intact, desorbed oligosaccharides with a terminal anhydro-sugar unit or with attached sugar ring-cleavage fragments (9). The ions generated are dependent on the position of the polymeric linkage and monomeric structure, and the resulting mass spectra of a range of polysaccharides thus reveal significant information on the structure of the original polymer. Further information on both carbohydrate linkage and sequencing may be obtained from tandem mass spectrometry (MS/MS) of the intact oligosaccharide fragments (5, 8, 10), although these experiments are difficult to reproduce for high mass fragment ions due to their short signal duration.

Recently, Py–DCI–MS was applied to the characterization of a native polysaccharide isolated from *Yersinia ruckeri* (10). Under appropriate pyrolysis and ionization conditions this polysaccharide yielded anhydrohexosamine fragments which facilitated identification of the trimeric repeating unit of the polymer. MS/MS analyses of the trimeric fragments provided additional evidence of the proposed structure. Subsequently, off-line pyrolytic experiments of the bacterial polysaccharide revealed similar fragmentation characteristics, confirming that anhydro-oligosaccharides are the primary products of Py–DCI–MS.

Many of the previous Py–DCI–MS studies have not involved optimization of pyrolytic and ionization steps. In this paper we report optimization of the operating conditions of Py–DCI–MS in order to raise its analytical potential in characterizing a wider range of polysaccharide structures. As might be expected, various parameters such as heating rate and chamber temperature and pressure have important implications concerning the observation of "intact fragments" and useful mass spectral characteristics. The results of a systematic study of these and other parameters for Py–DCI–MS (and Py–DCI–MS/MS) analysis, such as proper sample adhesion and shape of the emitter coil are presented. The objectives of this study were to achieve (*i*) maximum generation and duration of medium-sized oligosaccharide fragments, and (*ii*) reproducible and structurally-informative mass spectra from a range of structurally different polysaccharides.

Experimental

Materials

Cellulose, amylose, chitin, laminarin, methanol, heptanol, ethane diol, glycerol, and tetraethylene glycol dimethyl ether (TGDE) were purchased from Sigma Chemicals. DCI platinum filaments were either purchased from VG Analytical, Manchester, UK, or fabricated. Agar samples, **V** and **VI**, were obtained from Dr. J.S. Craigie, NRC, Halifax.

Sample application

If necessary, polysaccharides were ground down to fine particles (100–250 μm). The samples (approximately 50 μg) were applied to the platinum filament as shown in Fig. 1. This technique allows for reasonably accurate sample weight measurements and reproducible sample size. The suspension on the filament was allowed to evaporate down in the vacuum lock before the DCI probe was inserted into the ion source. This pre-evaporation resulted in a satisfactory removal of much of the solvent, and was noted to distribute the sample evenly around on the filament surface.

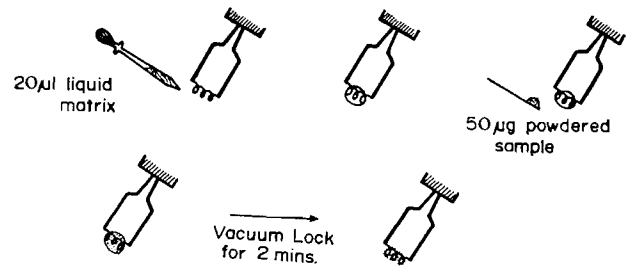

FIG. 1. Method of sample application onto the DCI filament.

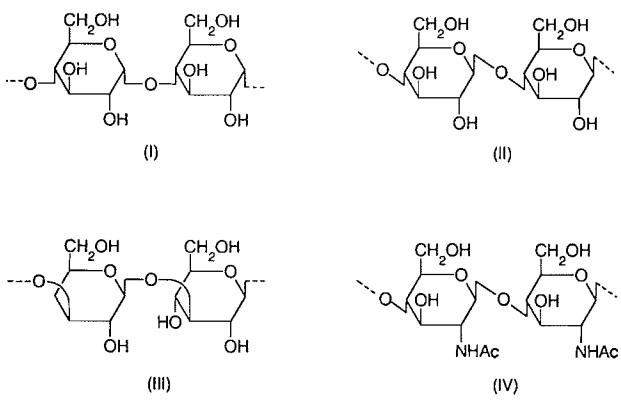
Py–DCI–MS (MS/MS) analysis

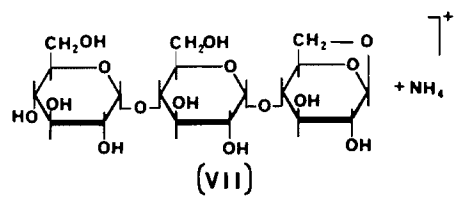
Py–DCI mass spectra were obtained using a VG Analytical ZAB-EQ hybrid tandem mass spectrometer (VG Analytical, Manchester, UK) equipped with a VG 11-250J data system. For optimum analysis a combined electron impact – CI source was maintained at 150°C, and operated at an accelerating voltage of 8 kV, using an electron energy of 100 eV. For optimum experiments, the ammonia reagent gas was admitted into the source until the pressure at the ion gauge reached 3.0×10^{-4} mbar and the DCI filament was then heated through a linear ramp of 14 mA/s of about 30 s duration. Conventional mass spectra were obtained by scanning the mass spectrometer from *m/z* 140 to 700 at a rate of 2 s per scan cycle. In tandem MS the precursor ion beam was mass selected at a single focus point by adjusting the magnet and collisional activation was effected in the collision cell preceding the electrostatic sector. Helium was used as the collision gas at pressures such that the precursor ion intensity is attenuated by 90%. The fragments formed in the collision were analyzed by scanning the electrostatic sector. Tandem mass spectra were acquired in the multichannel analysis mode, each spectrum representing an accumulation of five to ten scans.

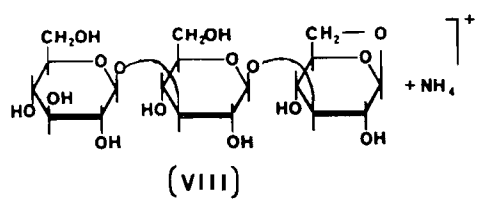
Results and discussion

In previous off-line pyrolysis experiments, it was discovered that considerable amounts of oligosaccharide material are produced from cellulose, **II** (6, 11, 12) as well as from other polysaccharides (11). The condensates from these pyrolyses contain anhydro-oligosaccharides of type **VII**. The main depolymerization process of polyhexoses is considered to take place via cleavage of the glycosidic bonds by an intramolecular trans-



(V) R = H
(VI) R = H (25%), CH_3 (60%), 4- 0- Me- galactose (15%)





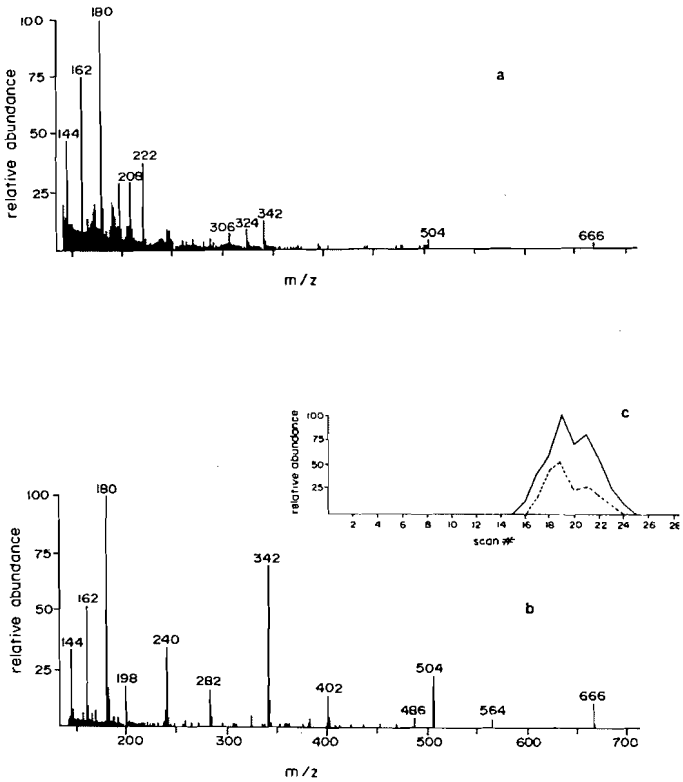


FIG. 2. Py–DCI mass spectra of (*a*) amylose previously suspended in water, (*b*) amylose previously suspended in TGDE solvent (scan 19), and (*c*) reconstructed mass chromatograms of *m/z* 504 and 666 (dashed line) from the analysis of amylose suspended in TGDE.

glycosylation mechanism (13), yielding a stable 1,6-anhydro sugar. In the present Py–DCI–MS study, amylose, **I**, was chosen as a model polysaccharide and ammonia was used as reagent gas. The Py–DCI spectra of amylose, Fig. *2b*, showed mass fragments *m/z* 180, 342, 504, and 666, assigned to ammonia adducts of intact 1,6-anhydro-(oligo)saccharides from the polysaccharide. These ions occurred in a series separated by 162 dalton, the general composition being described as $[(162)_n + NH_4]^+$. Values for *n*, which correspond to the number of hexose rings in the saccharide chain, have been observed to be much greater in Py–DCI–MS studies by Boon *et al*, where oligomers ranging from disaccharides up to undecasaccharides were observed (7). The range of oligomers observed in any one Py–DCI experiment is probably dependent on factors such as the thermal description regime, the design of the CI chamber, and the optical properties of the mass spectrometer used. Adjustable parameters of Py–DCI such as coil design are also important.

The Py–DCI mass spectrum of amylose (Fig. *2b*) shows, besides intact anhydro-oligomeric fragment ion series, another common series of ions (*m/z* 240, 402, 564) containing an intact oligomer attached to a ring-cleavage fragment (i.e., *m/z* = M + 60, where M is the intact oligosaccharide). It is believed that for most glucans, this type of ring-cleavage fragment series is the result of a reverse-aldolization type of pyrolysis mechanism and that the intensity of this ion series is dependent on the type of glycosidic linkage involved (7).

Sample adhesion

Normally, in classical DCI experiments, the solvent is important only in that it is used to transfer a soluble sample onto the DCI emitter coil from which it is subsequently desorbed and chemically ionized. In contrast, Py–DCI experiments of non-volatile polysaccharides involve a thermal fragmentation process leading to the desorption of intact molecules and ionization to parent-molecular ions. The pyrolysis/desorption step is usually optimized by rapid heating of the substrate, where there may be an explosive expulsion process of the large fragments into the CI plasma. Usually the lifetime of the fragment ions is short, a serious drawback to tandem MS experiments.

The choice of solvent for Py–DCI was investigated from the viewpoint of properly adhering a wide range of polysaccharide samples to the DCI coil probe as well as possibly assisting the pyrolysis/desorption process. In the latter case, the choice of solvent may be a fundamental step to successful Py–DCI–MS, similar to the supporting matrix requirements of Fast Atom Bombardment (FAB)–MS. In contrast to FAB–MS, however, solubility of the sample is not a requirement in Py–DCI. Ideally, the polymer sample should be in a fine powdered form and suspended in the solvent. A number of liquids, i.e., water, methanol, heptanol, ethane diol, glycerol, and TGDE were tried. Samples were deposited on the DCI coil containing a small drop of liquid as illustrated in Fig. 1. Methanol, water, and heptanol showed poor adhesive properties for cellulose and other samples, and glycerol, although showing good adhesion, gave strong interfering solvent ion clusters. It was finally discovered that ethane diol was very suitable for water-insoluble polysaccharides (e.g., cellulose) while the less polar solvent, TGDE, was suitable for water soluble samples (e.g., amylose). A comparison of Py–DCI–MS spectra of amylose suspended in water and TGDE is shown in Fig. *2a* and *b*. The case of TGDE resulted in both increased abundance of high mass fragment ions, and decreased levels of background ions. As well, re-constructed ion chromatograms of *m/z* 504 and 666 (Fig. *2c*) show reasonable lifetime and intensity of structurally-important high mass fragments such as tri- and tetra-oligomers.

Source temperature and pressure and coil heating rate

In normal DCI experiments the higher the ion source temperature the greater the fragmentation of the parent molecular ion. For Py–DCI measurements the problem of pyrolyzate condensation and source contamination must be addressed. Moreover, a high enough reagent gas pressure, in this case ammonia, is required to provide a situation where a large portion of the desorbed fragments, many as neutral species, are ionized through soft chemical ionization. An experiment was carried out whereby amylose was analyzed using different source temperatures and reagent gas pressures. The abundances of the pyrolysis fragment ions at 342, 504, and 666 were measured in a set of Py–DCI experiments where source temperatures and pressures were varied (Table 1). It was found that a reagent gas pressure (measured indirectly above the diffusion pump) of approximately 3×10^{-4} mbar and an ion source temperature of 150°C are about optimal conditions for observing a suitable abundance of high mass fragment ions. Under lower (120°C) or higher (180°C) source temperatures and low reagent gas pressures, abundances of high mass fragment ions were observed to decrease. The ammonia ion clusters *m/z* 18:35:52 under these conditions were in the ratio 1.4:0.8:0.3.

It has been suggested that rapid sample heating rate is a very important approach to enhancement of high mass fragment ions in Py–DCI studies. The effect of heating rate on molecular ion

TABLE 1. The effect of source temperature and reagent gas pressure on the relative abundances of ions *m/z* 504 and 666, ammonium adduct ions of anhydro-oligosaccharides generated from Py–DCI of amylose[a]

Source temperature/°C	Reagent gas pressure[c]/10^{-4} m bar	Sum of *m/z* 504 and 666 ion abundances[b]
120	1.5	0.43
	3.0	0.53
	4.5	0.74
150	1.5	0.76
	3.0	1.00
	4.5	0.92
180	1.5	0.73
	3.0	0.81
	4.5	0.78

[a]Experimental conditions; 50 μg amylose suspended in TGDE, filament heated through a linear ramp of 14 mA/s.
[b]Relative to sum of abundances at $T = 150°C$ and $P_{reagent} = 3.0 \times 10^{-4}$ mbar.
[c]Measured at the ion gauge.

TABLE 2. Absolute abundances of fragment ions *m/z* 342 and 504 generated from Py–DCI of amylose under various filament current ramps[a]

Filament current ramp. mA/s	Absolute abundance ($\times 10^6$)	
	m/z 342	*m/z* 504
70	3.4	0.7
28	5.6	1.8
14	9.2	2.2
7	7.6	1.9

[a]Experimental conditions; 50 μg of amylose suspended in TGDE, source temperature 150°C, and reagent gas pressure 3.0×10^{-4} mbar.

production can be estimated by varying the filament ramp and observing the time-resolved mass profile of key fragment ions. Amylose was thus subjected to Py–DCI at various filament current ramps ranging from 7 to 70 mA/s and the absolute intensities of ions at *m/z* 342 and 504 measured. The results are shown in Table 2. It was found that a filament current ramp of 14 mA/s was best for the satisfactory production of intact oligomeric fragment ions over a reasonable duration (Fig. 2*c*).

Shape of DCI filament

There are three basic configurations for DCI filaments; a single loop filament, or coil filaments positioned either above or between the two terminal posts as illustrated in Fig. 3. Each filament type was used for the Py–DCI analysis of amylose using the optimum operating conditions described above. The resulting Py–DCI mass spectra and the ion current profiles using absolute intensities (Fig. 3) showed that a coiled filament positioned above the terminal posts of the DCI probe is optimal for generating an abundance of intact higher mass fragment ions. This mass spectra was also relatively low in secondary fragmentation products, i.e., dehydration products (e.g., *m/z* 342 – H_2O) as compared to the Py–DCI experiment using the coil between the terminal posts.

Analysis of various glucans

The Py–DCI mass spectra for cellulose (**II**) and laminarin (**III**) glucans with (β-1,4) and (β-1,3) respectively, are shown in Figs. 4 and 5. These spectra, like the comparable spectra of **I**, an α-1,4 linked glucan (Fig. 2) gave strong ions of the anhydro-oligosaccharide series, although the relative efficiencies of their production varied. Each spectrum also contained additional and sometimes unique ions, still with the saccharide repeat unit. It is thought that these spectral differences among the glucans is the result of differences in linkage type and anomeric configuration. An extension of Py–DCI–MS is the potential application of tandem MS studies to differentiate linkage types (see below).

Analysis of heteropolysaccharides

Py–DCI–MS of heteropolysaccharides may provide very valuable structural information in that the polysaccharide polymer is characterized by its unique saccharide components and sequence. By way of illustration, two different types agar have been analyzed. One agar (**V**) has a simple polymeric backbone, a linear chain of alternating β1-3 linked d-galactopyranose, (**A**), and, α1-4 linked 3,6-anhydro-l-galactopyranose, (**B**), residues. The second agar structure (**VI**) is masked in the d-galactose units by methoxy and by 4-O-methyl-galactose residues at position C-6; the detailed structure of this agar has been reported elsewhere (14). The Py–DCI mass spectrum of the simple repeating agar **V** (Fig. 6) clearly shows the repeating saccharide sequence, i.e., *m/z* 324, 486, and 630. It is interesting to note that the mass spectrum also reveals monomeric fragment ions at *m/z* 180 (unit **A**) and 162 (unit **B**) of somewhat equal intensity. Other fragment ions, *m/z* 144, 270, 288, 306, and 468 are identified as dehydration products.

The more complex agar, **VI**, gave a mass spectra (Fig. 7) showing a series of oligomeric fragment ions that reveal the presence of methoxy groups on the d-galactose residue as indicated by the following ions (tentative structural assignments) at *m/z* 338 (methylated **A—B**), 500 (methylated **A—B—A**), 514 (methylated **A—B** – methylated **A**), 644 (methylated **A—B—A—B**), and 658 (methylated **A—B** – methylated **A—B**) where **A** and **B** refer to the two agar units. Some non-methoxy containing disaccharides fragments was observed at *m/z* 324. The limitation of the technique to identify and assign fragment ions of the 4-O-Me-galactose residues of the agar must be noted.

Analysis of amino sugar-containing polysaccharides

The applicability of optimized Py–DCI–MS to the analysis of amino sugar-containing polysaccharides was also evaluated. Chitin (**IV**) was chosen because of its linear and homogeneous structure. The Py–DCI–MS of chitin (Fig. 8) shows the expected series of ions associated with intact anhydro- oligosaccharide fragments at *m/z* 204, 407, and 610. These are not the usual ammoniated adduct ions. Instead, because of the strong proton affinity of the amino functional group, the amino sugar fragments are now protonated species. The remaining protonated ions are derived by dehydration.

Finally, it should be mentioned that the results of our concurrent study of the analysis of bacterial polysaccharides by Py–DCI–MS and Py–DCI–MS/MS (10) showed the versatility of the technique in characterizing *N*-containing heteropolysaccharides.

Tandem MS

In a previous study, tandem MS analysis of the anhydro- tri-

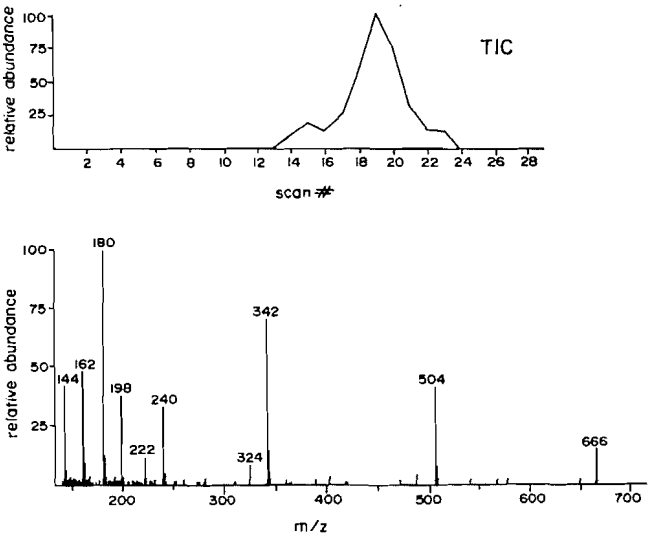

FIG. 5. Py–DCI mass spectra and total ion current profile of laminaran.

meric repeating unit fragment provided additional evidence for the proposed structure of an *N*-containing heteropolysaccharide and permitted rationalization of the observed fragment ions is the original Py–DCI–mass spectra (10).

To illustrate the potential of Py–DCI–MS/MS analysis in differing in linkage types of homosaccharides, two MS analyses and their product ion spectra (MIKES) under collisional activation are given. Figure 9 shows the product ion spectra of the intact anhydro-trisaccharide fragment ions from Py–DCI analysis of laminarin (β-1,3 linked) (Fig. 9*a*) and amylose (α-1,4 linked) (Fig. 9*b*). The two glucans can be readily differentiated by the unique presence of product ion *m/z* 288 in the amylose-derived spectrum. There is also a marked difference in the intensities of the other product ions between the two MIKES spectra. Reasons for these spectral differences have not been deduced.

Further applications of Py–DCI tandem MS will be described

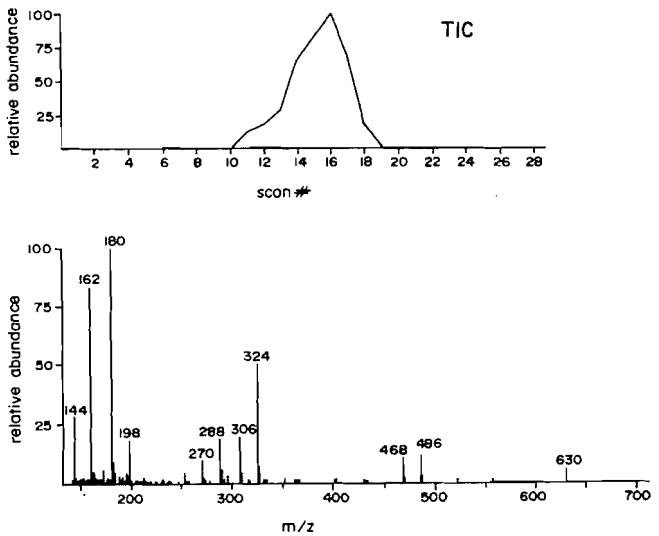

FIG. 6. Py–DCI mass spectra and total ion current of a purified agar.

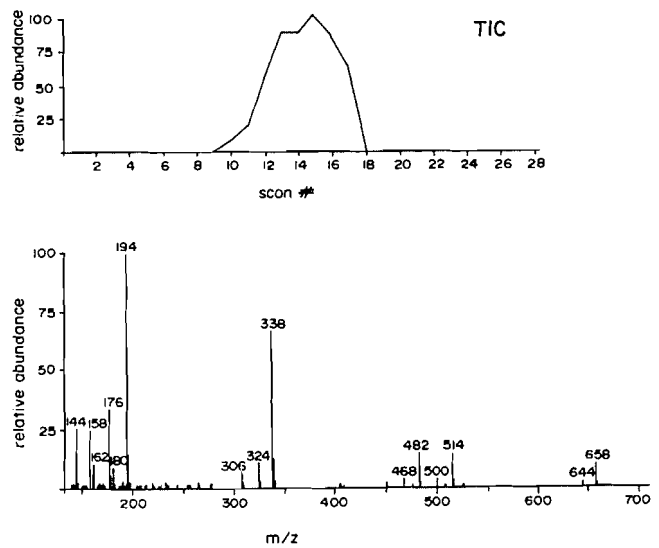

FIG. 7. Py–DCI mass spectra and total ion current of a highly substituted native agar.

in future papers. Our novel approach to structural analysis of these complex biomolecules is promising for applications such as polysaccharide screening and taxonomic studies of bacterial cell walls.

Conclusion

The optimized pyrolytic and desorption chemical ionization conditions under which these Py–DCI–MS experiments were conducted yield structurally useful mass spectra characteristic of the composition of a range of homo- and hetero-polysaccharides. In this study it was found that, in addition to the expected parameters such as source temperature, reagent gas pressure, and filament current ramp, proper adhesion of the sample with selected solvents and choice of filament configuration are important features in obtaining optimized conditions for Py–DCI analysis of carbohydrates. An important result of our work is the attainment of a long-lasting generation of intense fragment ions characteristic of intact anhydro-oligosaccharides. As a result of this the application of tandem MS techniques involving Py–DCI–MS of polysaccharides has become more feasible.

Received May 27, 1993

WLODZIMIERZ GALEZOWSKI,[1] PRADIP K. BAKSHI, KENNETH T. LEFFEK, and T. STANLEY CAMERON. Can. J. Chem. **72**, 352 (1994).

The reaction of 2-*N*-phenyl-1,1,3,3-tetramethylguanidine with 2,6-diphenylpyran-4-one in the presence of phosphorus oxychloride, followed by treatment with perchloric acid, yields 1,1,3,3-tetramethyl-2-phenyl-2-(2′,6′-diphenyl-4′-pyrylio)guanidinium diperchlorate. Crystals of this material are monoclinic, space group $P2_1/n$, $a = 14.535(3)$, $b = 13.685(3)$, $c = 23.579(7)$ Å, $\beta = 140.38(2)°$, $R = 0.0633$ based on 1691 observed reflections. The substitution of the positively charged pyrylio group on one of the three nitrogen atoms of the guanidinium cation disrupts the symmetry of the distribution of the positive charge on the nitrogen atoms. The two C—N bonds of the central carbon atom of the guanidinium ion to the two methylated nitrogen atoms show more double-bond character than that to the nitrogen carrying the pyrylio group.

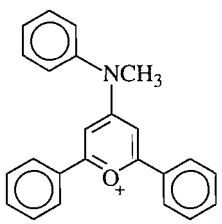
WLODZIMIERZ GALEZOWSKI,[1] PRADIP K. BAKSHI, KENNETH T. LEFFEK et T. STANLEY CAMERON. Can. J. Chem. **72**, 352 (1994).

La réaction de la 2-*N*-phényl-1,1,3,3-tétramethylguanidine avec la 2,6-diphénylpyran-4-one, en présence d'oxychlorure de phosphore, suivie d'un traitement par de l'acide perchlorique fournit le diperchlorate de 1,1,3,3-tétraméthyl-2-phényl-2-(2′,6′-diphényl-4′-pyrylio)guanidinium. Les cristaux de ce composé sont monocliniques, groupe d'espace $P2_1/n$ avec $a = 14,535(3)$, $b = 13,685(3)$ et $c = 23,579(7)$ Å, $\beta = 140,38(2)°$ et $R = 0,0633$ pour 1691 réflexions observées. La substitution d'un groupe pyrylio chargé positivement d'un des trois atomes d'azote du cation guanidinium détruit la symétrie de la distribution de la charge positive sur les atomes d'azote. Les deux liaisons C—N de l'atome de carbone central de l'ion guanidinium avec les deux atomes d'azote méthylés présente plus de caractère double que celui vers l'azote portant le groupe pyrylio.

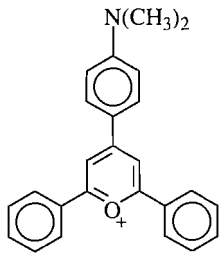
[Traduit par la rédaction]

Introduction

Primary and some secondary anilines, such as *N*-methylaniline, react with 2,6-diphenyl-4*H*-pyran-4-one **1** in the presence of $POCl_3$, to yield 4-aminosubstituted pyrylium salts, such as **2** (1, 2). In sterically hindered reactions, however, secondary aromatic amines can react as carbon nucleophiles (2). Attack as a carbon nucleophile also takes place with the tertiary base dimethylaniline, and Wizinger et al. (3) obtained 4-dimethylaminophenyl-2,6-diphenylpyrylium perchlorate **3** by its reaction with 2,6-diphenyl-4*H*-pyran-4-one **1** in the presence of $POCl_3$, a result subsequently confirmed by Reynolds and Van Allan (4). Other tertiary aromatic amines have been shown (2, 5) to react as carbon nucleophiles with the pyrone **1** in the presence of $POCl_3$.



2



3

As part of our study (6, 7) of the reactions of substituted 2-*N*-phenyl-1,1,3,3-tetramethylguanidine bases (TMG) and the structure of the guanidinium ion (8), we investigated the reaction of 2-*N*-phenylTMG **4** with 2,6-diphenyl-4*H*-pyran-4-one **1** in the presence of $POCl_3$. Since the imino nitrogen atom in 2-*N*-phenylTMG should react as a tertiary centre, this molecule might be expected to react as a carbon nucleophile to yield the salt of the structure **6**, shown in Scheme 1. If the imino nitrogen of the *N*-phenylTMG were a sufficiently strong nucleophile, attack by this centre would give the salt **5**. However, there is no record of any reaction in which a tertiary amidine or a tertiary amine attacks the pyrone carbonyl group as an *N*-nucleophile.

Results and discussion

The product of the reaction was obtained as yellow needles, which gave a ^{13}C nmr spectrum in DMSO-d_6 consisting of 25 peaks. There should be 28 peaks if all the carbon atoms are non-equivalent. However, the two dimethylamino groups each give one peak, since there are only two peaks in that region at 41.3 and 42.2 ppm, reducing the total to 26. It is presumed that the carbon atom bonded to three nitrogen atoms would give a very weak signal, resulting in the 25 observed peaks. The ^1H nmr spectrum showed two methyl signals that did not coalesce in the temperature range 22–95°C. Since the salt **6** gave a single proton resonance for the 12 methyl hydrogens (9), this indicated that the product was probably **5**. This was confirmed by an X-ray structure determination. This finding that the tertiary amidine *N*-phenylTMG attacks the pyrone carbonyl group as an *N*-nucleophile is unique.

The structure of 5

Crystals were prepared for X-ray analysis by dissolving the product (0.2 g) in DMSO (1.5 cm^3), diluting this solution with acetone (10 cm^3), then adding glacial acetic acid (15 cm^3) dropwise with stirring. The solution was allowed to stand overnight and, as the acetone evaporated, the yellow needles formed. The X-ray analysis gave the bond lengths that are listed in Table 1, the bond angles listed in Table 2, and the torsional angles listed in Table 3. A view of the dication is shown in Fig. 1. The three bonds between the central carbon (C1) of the guanidinium group and the three nitrogen atoms are not of equal length in this dication, contrary to the finding in our previous structure determination of a protonated biphenylTMG compound (8). The C(1)—N(2) bond in the dication **5** is 1.391(12) Å, considerably longer, and therefore with much less double-bond character,

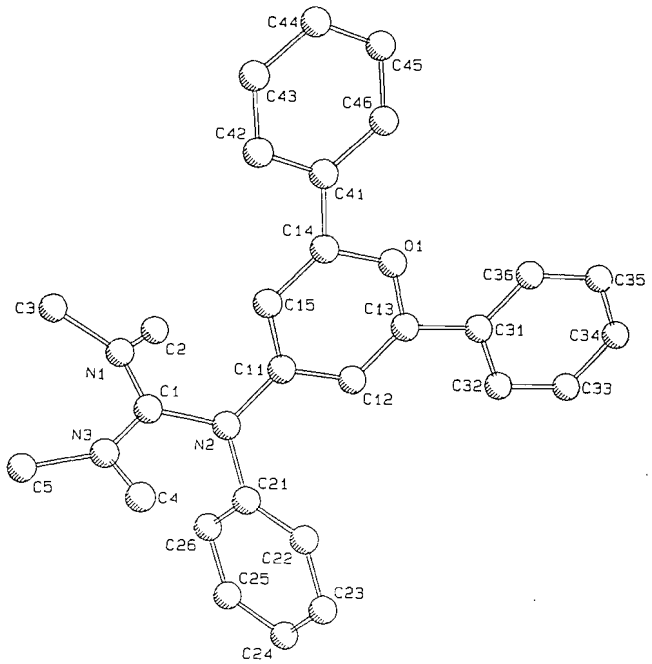

FIG. 1. The 1,1,3,3-tetramethyl-2-phenyl-2-(2′,6′-diphenyl-4′-pyrylio)-guanidinium dication.

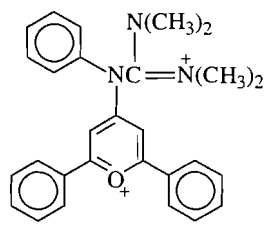
has part of its bonding electrons donated towards the pyrylium ring, since the N(2)—C(11) bond is 1.391(12) Å, the same length as the C(1)—N(2) bond, giving both of these bonds some double-bond character. The bond to the phenyl ring N(2)—C(21) is a normal C—N single bond, 1.451(10) Å. Thus, the positive charge of the guanidinium group is predominantly delocalized on the N atoms of the two dimethylamino groups. Structure **5**, therefore, is a minor contributing structure to the resonance hybrid and structure **7** represents one of the two major contributing structures.



$2ClO_4^-$

7

This is the first guanidinium ion structure found in which the positive charge is largely located on the 1 and 3 nitrogen atoms. This is probably due simply to the presence of the second positive charge, on the pyrylium ring.

The 2,6-diphenylpyrylium and the *N*-phenyl groups are almost planar but the guanidinium group is not. Although the angles between the bonds to the C(1) and N(2) atoms are all close to 120°, the torsional angles are quite large. The bonds from N(2) to the two rings are at an angle of about 50–55° to those from C(1) to the two methylated nitrogens, which is larger than the angle of 32–33° found in a phenyltetramethylguanidinium ion (8). Rotation of the phenyltetramethylguanidinium group must be hindered, in solution, as indicated by the non-

For personal use only.

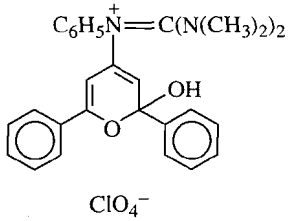
equivalence of the methyl groups in the ^{1}H nmr spectrum; the general lack of symmetry in the molecule is confirmed by the 25 resonance signals observed in the ^{13}C nmr spectrum.

The UV–visible absorption spectrum of **7** in DMSO, in the presence of $HClO_4$, has a broad band at 380 nm.

Since the tetramethylguanidine group donates electrons to the phenyl ring ($\sigma_p = -0.86$) (9) more strongly than the dimethylamino group ($\sigma_p = -0.83$) (10), it is clear that the product **7** results from another factor, which overrides the increased carbon nucleophilicity of the phenyl ring, causing the phenyltetramethylguanidine to react as the nitrogen nucleophile. This is presumably the same factor that gives guanidines a much greater basicity than anilines, that is, the observed powerful nucleophilicity of the imino nitrogen in this reaction comes from the thermodynamic stability of the product **7** resulting from the delocalization of the positive charge onto the two dimethylamino groups.

Reaction of 7 with water

Although **7** is insoluble in water, fine white crystals were obtained when it was boiled in suspension for 1 h. Elemental analysis and the nmr spectrum indicated that the product was the salt **8**.



8

Experimental

1,1,3,3-Tetramethyl-2-phenyl-2-(2′,6′-diphenyl-4′-pyrylio)-guanidinium diperchlorate

Preparation

The reaction was carried out by heating a mixture of 2,6-diphenyl-4-pyrone (0.67 g, 0.0027 mol) (11), 2-*N*-phenyltetramethylguanidine (1.3 g, 0.0068 mol) (12), and $POCl_3$ (1.4 cm^3, 0.016 mol) at 100°C on a water bath for 40 min. The reaction mixture was protected from atmospheric moisture with a drying tube filled with silica gel. The thick red-brown product was dissolved in 6 cm^3 of glacial acetic acid and treated with 1.2 cm^3 of 60% $HClO_4$, dropwise. After cooling to room temperature, a yellow crystalline product (1.02 g) was separated by vacuum filtration. Recrystallization from glacial acetic acid gave a yellow product, mp 312–315°C with decomposition, yield 0.95 g, 57% based on the amount of the pyrone used. The product was recrystallized by solution in DMSO, followed by addition of acetone and glacial acetic acid. Yellow needles crystallized overnight, which, after washing several times with glacial acetic acid and drying under vacuum, gave mp 315–316°C, with decomposition; ^{1}H nmr δ (DMSO-d_6): 2.98 (6H, s), 3.37 (6H, s), 7.64–7.89 (11H, m), 8.07 (1H), 8.24 (2H, d), 8.35 (1H, d), 8.42 (2H, d); ^{13}C nmr δ (DMSO-d_6): 41.3, 42.2, 108.2, 108.5, 125.0, 125.3, 127.9, 128.3, 128.4, 128.6, 128.8, 129.0, 129.6, 129.7, 129.9, 130.1, 130.3, 131.0, 133.3, 133.7, 135.2, 136.3, 137.0, 137.9, 163.0. Anal. calcd. for $C_{28}H_{29}Cl_2N_3O_9$: C 54.03, H 4.69, Cl 11.39, N 6.75%; found: C 53.2, H 4.7, Cl 12.5, N 6.5%.

The major by-product of the reaction is the perchlorate salt of the original pyrone.

Reaction with water

7 (0.1 g) was boiled in water (80 cm^3) for 1 h. The hot reaction mixture was filtered and the filtrate gave fine white crystals (0.06 g), mp 175–180°C; ^{1}H nmr δ (DMSO-d_6): 2.84 (6H, s), 3.12 (6H, s), 4.4 (1H, br s), 7.38–7.76 (15H, m), 8.06–8.09 (2H, m). Anal. calcd. for $C_{28}H_{30}ClN_3O_6$: C 62.28, H 5.59, Cl 6.56, N 7.78%; found: C 62.0, H 5.6, Cl 7.4, N 7.5%.

Structure determination

Data collection

A light yellow needle-shaped crystal of $C_{28}H_{29}Cl_2N_3O_9$ having approximate dimensions of 0.100 × 0.150 × 0.350 mm was mounted on a glass fibre. All measurements were made on a CAD4 diffractometer with graphite-monochromated Mo Kα radiation.

Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 25 carefully centred reflections in the range $20.0° < 2\theta < 26.0°$, corresponded to a monoclinic cell with dimensions a = 14.535 (3) Å, b = 13.685 (3) Å, c = 23.579 (7) Å, V = 2991 (3) Å^3, β = 140.38 (2)°.

For Z = 4 and F.W. = 622.46, the calculated density is 1.382 g/cm^3. Based on the systematic absences of ($n0l$: $h + l \neq 2n$) and ($0k0$: $k \neq 2n$), packing considerations, a statistical analysis of intensity distribution, and the successful solution and refinement of the structure, the space group was determined to be $P2_1/n$ (no. 14).

The data were collected at a temperature of 18 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 46.0°.

Data reduction

Of the 3016 reflections that were collected, 2930 were unique (R_{int} = 0.034). The intensities of three representative reflections, which were measured after every 200 reflections, remained constant throughout data collection, indicating crystal and electronic stability (no decay correction was applied).

The linear absorption coefficient for Mo Kα is 2.697 cm^{-1}. An empirical absorption correction using the program DIFABS (13) was applied, and resulted in transmission factors ranging from 0.903 to 1.089. The data were corrected for Lorentz and polarization effects.

Structure solution and refinement

The structure was solved by a direct method (14). The non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in their geometrically calculated positions with a C—H distance of 1.08 Å; their positions and isotropic temperature factor were refined initially by riding on the attached C atoms. However, in the final refinement, the phenyl rings and the methyl groups were treated as a rigid body and the positions and temperature factors of the remaining hydrogen atoms were also kept fixed to improve the reflection–parameter ratio. Thus the final 7-block-matrix least-squares refinement (the function minimized was $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1.7980/[\sigma(F) + 0.000886(F^2)]$) was based on 1691 observed reflections ($I > 2.00\sigma(I)$) and 426 variable parameters and converged (largest parameter shift was 0.654 times its esd)

with unweighted and weighted agreement factors of:

$$R = \Sigma||F_o| - |F_c|| / \Sigma|F_o| = 0.0633$$

$$R_w = [(\Sigma w(|F_o| - |F_c|)^2 / \Sigma w F_o^2)]^{1/2} = 0.0670$$

These atomic parameters give an R of 5.90 for the 1546 reflections with ($I > 3.00\sigma(I)$).

The SHELX weighting scheme, with w as stated above, was used during the refinement. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.278 and -0.377 e$^-$/Å^3, respectively. Neutral atom scattering factors were taken from Cromer and Waber (15). Anomalous dispersion effects were included in F_{calc} (16); the values for $\Delta f'$ and $\Delta f''$ were those of Cromer (17). All calculations were performed using the SHELX 76 program (18). All diagrams were drawn by using the programs PLUTO (19) and ORTEP (20).[3]

Application of electrogenerated triphenylmethyl anion as a base for alkylation of arylacetic esters and arylacetonitriles and isomerization of allylbenzenes

SHOHEI SUZUKI, MITSUKO KATO, AND SHOICHI NAKAJIMA[1]

Faculty of Pharmaceutical Sciences, Hoshi University, Ebara 2-4-41, Shinagawa-ku, Tokyo, Japan 142

Received March 3, 1993[2]

SHOHEI SUZUKI, MITSUKO KATO, and SHOICHI NAKAJIMA. Can. J. Chem. **72**, 357 (1994).

Phenylacetic esters and phenylacetonitriles were alkylated with alkyl halides, at the position α to an ester or nitrile, either at room temperature (20°C) or at −78°C, by making use of electrogenerated triphenylmethyl anion (trityl anion). Double-bond isomerization of allylbenzenes was also effectively accomplished by use of this electrogenerated base (EGB).

SHOHEI SUZUKI, MITSUKO KATO et SHOICHI NAKAJIMA. Can. J. Chem. **72**, 357 (1994).

Soumis à l'action d'halogénures d'alkyles, soit à la température ambiante (20°C) soit à −78°C, en utilisant des anions triphénylméthyles (anions trityles) électrogénérés, les esters phénylacétiques et les phénylacétonitriles sont alkylés en position α. On a aussi réalisé l'isomérisation de la double liaison d'allylbenzènes en utilisant cette base électrogénérée (BEG).

[Traduit par la rédaction]

Introduction

The principal advantage of electrochemical reactions lies in the fact that they do not require thermal energy to overcome activation barriers, and hence are applicable to thermally sensitive compounds (1). *N,N*-Dimethylformamide (DMF) and tetraalkylammonium salt are frequently used as solvent and supporting electrolyte, respectively, in cathodic reactions, and both favor S_N2 nucleophilic substitutions. This is because DMF is a polar aprotic solvent, in which nucleophiles are only very slightly solvated and are consequently highly active. The latter electrolyte is a phase-transfer catalyst in which the ammonium cation of the supporting electrolyte binds very weakly with the cathodically generated anionic species, thus favoring nucleophilic reactions.

Further, electrochemically generated anionic species sometimes show a higher reactivity than the same species non-electrochemically produced,[3] possibly because anionic species near the electrode are, so to speak, "naked" and so very reactive, as a result of binding of the counter cation to the electrode (2).

In 1969, Iversen and Lund (3) first demonstrated the synthetic utility of anionic species electrogenerated from azobenzene (3). Baizer et al. named such anionic species and their precursors "electrogenerated bases (EGB's)" and "pro-bases", respectively (4). Some onium salts (5), carbon tetrachloride (6), 2-pyrrolidone (7), azo compounds (8), activated alkenes (9), and oxygen (10) were subsequently found to be effective pro-bases. Thus the cathodic generation of EGB's is attracting increasing interest in the field of synthetic organic chemistry (11).

Recently triphenylmethane, which has a pK_a value of 30, was found to be a pro-base yielding trityl anion, a highly basic anion able to abstract a proton even from rather mildly acidic compounds such as cyclohexanones (12). The trityl anion was suggested to be generated by one-electron reduction of triphenylmethane, with evolution of hydrogen (12).

In the present paper, we would like to report two applications of the electrochemically generated trityl anion, i.e., for the alkylation (Scheme 1) of phenylacetic esters **1** and phenylacetonitriles **3** to give **2** and **4**, respectively, at room temperature (20°C) or at −78°C, and for the double-bond isomerization (Scheme 2) of allylbenzenes **5** to **6** and 1,4-dihydronaphthalene **8** to 1,2-dihydronaphthalene **9** at room temperature (20°C).

TABLE 1. Electrochemical alkylation of esters and nitriles[a]

Product	Method	Yield (recovered) (%)[b]
2*a*	A	36 (31)
2*b*[1]	A	47 (40)
2*b*[1]	A′	36 (40)
2*b*[1]	C	40 (29)
2*b*[2]	A	36 (31)
2*c*[1]	C	42 (24)
2*c*[2]	A	47 (30)
4*a*	A	0
4*a*	B	14 (70)
4*a*	C	73 (27)
4*b*$_1$	A	0
4*b*$_1$, **4***b*$_2$	C	72, 24 (0)

[a]Electrolyses were carried out by passing 2 F/mol of triphenylmethane (constant current, 50 mA) into DMF solution (30 mL) containing triphenylmethane (2 mmol) and TEATs (4 mmol). A: Substrate added before electrolysis (−78°C). A′: Substrate added before electrolysis (−20°C). B: Substrate added after electrolysis (−78°C). C: Substrate added after electrolysis (−78°C). The amount of substrate was one-fourth of that used in experiment B.

[b]Yields determined by HPLC.

Results and discussion

Alkylation of phenylacetic esters and phenylacetonitriles

When a DMF solution of an alkyl phenylacetate **1***a–c*, tetraethylammonium *p*-toluenesulfonate (TEATs), and methyl iodide (or ethyl bromide) was heated at 100°C for 3 h, no alkylation product **2***a–c* was obtained. However, this alkylation did occur at room temperature (20°C), or at −78°C, when the solution was placed in a cathodic compartment and an electric current (constant current, 50 mA) was passed through the solution, provided that triphenylmethane was added to the catholyte before the start of electrolysis. Thus it appears that triphenylmethane acts as a pro-base affording an EGB by cathodic reduction. The nitriles **3***a–b* were electrochemically alkylated in a similar way to give **4***a–b* (Scheme 1 and Table 1).

SCHEME 1

In all these reactions, alkylating agents were added, not before, but after electrolysis, in order to avoid their cathodic degradation.[4] In the alkylation of esters, the products could be obtained equally well by adding esters before (methods A and A′ in Table 1) and after (method C in Table 1) electrolysis. However, in the case of nitriles, products were obtainable only when the nitriles were added after electrolysis (compare 14% yield of run **4***a*B with 0% yield of runs **4***a*A and **4***b*$_1$A). It is possible that the nitriles underwent reductive cleavage at the C—CN bond in runs **4***a*A and **4***b*$_1$A.[5] In the case of nitriles, the pro-base should preferably be used in a fourfold excess, since the resulting trityl anion is apparently consumed in side reactions during and after electrolysis, e.g., for deprotonation of the supporting electrolyte (as suggested in the literature (13)) (compare 73% yield of **4***a*C with 14% yield of **4***a*B).[6]

Arylacetic esters and nitriles have been alkylated under a wide variety of conditions (14) including the use of phase-transfer catalysts (15) such as tetraalkylammonium salts (16). In the present method, the trityl anion generated electrochemically couples with tetraalkylammonium cation in situ, and works effectively as a base for C-H acid, thus making the reaction possible under relatively mild conditions.

Isomerization of allylbenzenes

Isomerization of safrole **5***a* to isosafrole **6***a* is an important step in the industrial synthesis of heliotropin (3,4-methylenedioxybenzaldehyde). This double-bond isomerization has long been accomplished on an industrial scale by heating with alkali at high temperature, e.g., 180–200°C (17), 243–245°C (18), or 380–400°C (19). This isomerization has also been accomplished at room temperature by an electrochemical method (20). In the latter case, however, the authors focused on the hydrodimerization reaction which occurred in DMF solution, but not on the isomerization reaction that took place in acetonitrile.

We have examined the isomerization, and determined the yields of *cis* and *trans* isomers produced by the electrochemical double-bond isomerizations of safrole **5***a* to isosafrole **6***a*, estragole **5***c* to anethole **6***c*, allylbenzene **5***b* to 1-propenylbenzene **6***b*, 1-allyl-3,4-dimethoxybenzene **5***d* to 1,2-dimethoxy-4-(1-propenyl)- benzene **6***d*, and 1,4-dihydronaphthalene **8** to 1,2-dihydronaphthalene **9**, as shown in Scheme 2 and Table 2.

Electrolyses were performed at a constant current of 50 mA in acetonitrile solution containing a substrate allylbenzene and tetraethylammonium tetrafluoroborate ($TEABF_4$), in the presence or absence of triphenylmethane; water cooling was used to maintain the temperature at 20°C.

As shown in Table 2, the *trans*/*cis* ratio of the products ranged from 7.6 to 12.3. The use of triphenylmethane as a pro-base increased the yield of **6** and decreased that of **7**. No hydrodimerization products were obtained.

We also conducted the electrolysis, at various constant reduction potentials, of **5***a* to **6***a* and **7***a* in order to investigate the relationship between the potential and the composition of the products (Fig. 1).

Considering the E_p value of −1.7 V *vs.* SCE of triphenylmethane on a Pt electrode,[7] the results shown in Fig. 1 seem to indicate that the isomerization was promoted by the trityl anion when triphenylmethane was present, but was caused by another anionic species when it was not, possibly by the anion radical (21) afforded as an intermediate of the reduction of **5** to **7**.

[4]Methyl iodide and ethyl bromide, particularly the former, are easily degraded into alkyl radical and halogeno anion by one-electron reduction, ref. 22.

[5]The C═CN bond is cleaved in neutral medium, affording alkane and cyanide anion, ref. 23.

[6]If triphenylmethane were used in an equimolar amount to the nitrile, the substrate anion produced might react not only with alkyl halide but also with the starting nitrile (Thorpe type reaction, ref. 24).

[7]The E_p value of triphenylmethane was determined by the present authors by cyclic voltammetry on the Pt electrode: substrate, 1 mM; 0.4 M $NaClO_4$/acetonitrile; scan rate, 50 mV/s.

Experimental

^{1}H NMR spectra were obtained with a JEOL JNM FX-100 spectrometer at 100 MHz (with TMS as an internal standard). Infrared (IR) spectra were recorded with a Hitachi model 215 grating spectrophotometer and mass spectra (MS) were obtained with a JEOL JMS D-300 spectrometer. Gas–liquid chromatography (GLC) was performed on a Shimadzu GC-4CM PF instrument. Thin-layer chromatography (TLC) was conducted on precoated Silica gel 60 F_{254} plates (Art. 5715, Merck) and spots were detected under ultraviolet light (254 nm). High-performance liquid chromatography (HPLC) was conducted with a JASCO 880-PU apparatus equipped with a gradient elution module and a variable-wavelength detector (Soma S-310 A model 2) set at 275 nm. A Senshu Pak.ODS-1251-S (No. 3331, 4.6 × 250 mm) column was used. Low-pressure liquid chromatography (LPLC) was performed with a Chemco Low-Prep pump (81-M-2) and a glass column (20 × 1.5 cm) packed with silica gel SI-25-120 (25-44, Nihon Seimitsu Kagaku Co., Ltd.).

Electrolysis apparatus

Electrolyses were performed, unless otherwise noted, at a constant current of 50 mA in the cathodic compartment of a two-compartment H-type cell equipped with a glass-frit (No. 3G) diaphragm and Pt plate (4 cm^2) electrodes under stirring with a magnetic stirrer. A Hokuto

Denko HA-105 potentio-galvanostat connected with a Hokuto Denko HF-201 current integrator was used.

Electrochemical alkylation

The alkylations according to methods A and A′ in Table 1 were performed in DMF (Aldrich, less than 0.005% H_2O content) solution (30 mL) containing ethyl phenylacetate (**1***a*), ethyl 4-methoxyphenylacetate (**1***b*), methyl 3,4-dimethoxyphenylacetate (**1***c*), phenylacetonitrile (**3***a*) or 4-methoxyphenylacetonitrile (**3***b*) (2 mmol), together with triphenylmethane (2 mmol) and TEATs (4 mmol). After 2 F/mol (on the basis of triphenylmethane) of current had passed (constant current, 50 mA) at −78°C (runs A) or at 20°C (run A′), an alkylating agent, MeI (runs **2***a*, **2***b*$_1$, **4***a*, and **4***b*$_1$) or EtBr (runs **2***b*$_2$ and **2***c*$_2$) (4 mmol), was added, and the solution was stirred for 1 h at the same temperature, then for 12 h at 20°C to complete the reaction, as determined by HPLC.

The reaction according to method B in Table 1 was conducted in a similar way except that phenylacetonitrile was added after the electrolysis of triphenylmethane. The reactions according to method C in Table 1 were conducted similarly, except that the amount of the substrate used was one fourth of that of method B.

After the reaction, catholyte and anolyte were combined. The residue, after evaporation of the solvent, was dissolved in ether (250 mL), washed twice with saturated aqueous NaCl (200 mL), dried over Na_2SO_4, and evaporated. Then the alkylated products, except the commercially available **2***a* and **4***a*, were purified by column chromatography (CC) on silica gel. The solvent used for CC was hexane–acetone (5:1) (for **2***a*), hexane–CCl_4 (gradient, for **2***b*$_1$ and **2***b*$_2$), CCl_4–acetone (20:1) (for **2***c*$_1$), or hexane–acetone (40:1) (for **2***c*$_2$ and **4***b*$_1$). When further purification was necessary, LPLC was conducted with hexane–acetone (20:1) (for **2***c*$_1$ and **2***c*$_2$). The pure products thus obtained were identified by MS, IR, and ^{1}H NMR spectral analyses, and used as standard samples for the HPLC determinations. For HPLC, ethyl benzoate (for **2***a*), phenylacetonitrile (for **4***b*$_1$), and 4-methoxyphenylacetonitrile (for all other products) were used as internal standards.

Electrochemical isomerization of allylbenzenes

Electrochemical isomerizations (Table 2) were performed in acetonitrile (Aldrich, less than 0.005% H_2O content) solution (30 mL) containing a substrate (2 mmol) and $TEABF_4$ (4 mmol), in the presence or absence of triphenylmethane (2 mmol), until 2.0 F/mol of substrate had been consumed (constant current, 50 mA) at 20°C (cooling was done with water). Products were separated by evaporation of the solvent, dissolution of the residue in $CHCl_3$, washing of the solution with saturated aqeous NaCl, drying on Na_2SO_4, and removal of the solvent. The crude products thus obtained were purified by CC followed by LPLC on silica gel, and identified by MS, IR, and ^{1}H NMR spectral analyses. The yields of the reaction products were determined by GLC: column (3.2 × 2,000 mm), 10% polyethyleneglycol 20 M on Chromosorb W AWDMCS; column temperature, 190°C; injection temperature, 240°C; flow rate, 60 mL/min.

Isomerization of safrole **5***a* at a constant potential of −1.3, −1.6, −1.8, −2.0, −2.2, −2.4, or −2.5 V vs. SCE (Fig. 1) was conducted in a similar way but on a smaller (one fourth) scale.

The thermodynamics of amino acid systems are key to the understanding of protein chemistry. We have found that many previous studies of the apparent molar volumes and heat capacities of aqueous solutions of amino acids were conducted at the standard temperature of 298.15 K. This does not allow for the fact that most biological processes occur at temperatures removed from this standard condition.

In an attempt to address this imbalance we have measured densities and heat capacities for aqueous solutions of glycine, L-alanine, L-serine, and L-threonine at 288.15, 298.15, 313.15, and 328.15 K using a Picker flow microcalorimeter. Apparent molar volumes and heat capacities, and the associated standard state partial molar properties have been calculated. Constant pressure variations of revised Helgeson, Kirkham, and Flowers equations have been fitted to calculated standard state volumes and heat capacities over the temperature range 288.15 to 328.15 K. These equations may be used to estimate standard state volumes and heat capacities, and hence equilibrium constants, for aqueous amino acid systems at higher temperatures.

ANDREW W. HAKIN, MICHELLE M. DUKE, SHERI A. KLASSEN, ROBERT M. MCKAY et KATHRYN E. PREUSS. Can. J. Chem. **72**, 362 (1994).

Les caractéristiques thermodynamiques des systèmes d'acides aminés sont la clé de la compréhension de la chimie des protéines. On a trouvé que plusieurs études antérieures sur les volumes molaires apparents et sur les capacités calorifiques de solutions aqueuses d'acides aminés ont été conduites à la température standard de 298,15 K. Ces résultats ne tiennent pas compte du fait que les processus biologiques se produisent à des températures différentes de cette condition standard.

Dans le but de corriger cette situation, on a measuré les densités et les capacités calorifiques de solutions aqueuses de glycine, de L-alanine, de L-sérique et de L-thréonine à 288,15, à 298,15, à 313,15 et à 328,15 K en faisant appel à un microcalorimètre à écoulement de Picker. On a calculé les volumes molaires apparents et les capacités calorifiques ainsi que les propriétés molaires partielles associées dans l'état standard. On a ajusté les variations à pression constante des équations révisées de Helgeson, Kirkham et Flowers avec les volumes et les capacités calorifiques calculés de l'état standard sur la plage de température allant de 288,15 à 328,15 K. On peut utiliser ces équations pour évaluer les volumes et les capacités calorifiques de l'état standard et, donc, les constantes d'équilibre des systèmes d'acides aminés aqueux à des températures plus élevées.

[Traduit par la rédaction]

Introduction

A review of volumetric and thermochemical data for aqueous amino acid systems reveals that the majority of previous studies were conducted at the standard temperature of 298.15 K (1–11). This is surprising when one considers that many living systems, which contain proteins, polypeptides, and hence amino acids, operate at temperatures removed from the standard.

Studies have indicated that there are classes of organisms which exist in submarine hot springs at temperatures in excess of 383.15 K (12). In addition, experimental studies on peptide hydrolysis rates have found that these compounds can exist at high temperatures for long periods of time (13). Also, several authors (14, 15) have discussed the role of organisms in the biodegradation of oil deposits. The geology of oil deposits dictates that any indigenous organisms must endure a wide spectrum of temperature and pressure conditions.

To assess the validity of high temperature and pressure life forms it is necessary to investigate the thermodynamic properties of the organic molecules, namely amino acids, which constitute peptides and proteins.

In an attempt to probe the high temperature regime of aqueous amino acid systems, we have commenced a volumetric and thermochemical investigation of their behavior as a function of temperature.

Attempts have been made to model the high temperature and pressure thermodynamic behaviour of amino acids using revised Helgeson, Kirkham, and Flowers (HKF) continuum models (16, 17). These models are constructed from experimental thermodynamic data collected at 298.15 K and ambient pressure. Realizing the importance of such modelling procedures, we have fitted constant pressure variations of the revised HKF equations for neutral organic species to calculated standard state heat capacities and volumes for aqueous solutions of glycine, L-alanine, L-serine, and L-threonine. These data can be used to calculate the temperature dependencies of equilibrium constants, or Gibbs energies, of the aqueous amino acid systems over the experimental temperature range. In addition, these models allow for the extrapolation of thermodynamic data to higher temperatures.

Experimental

Glycine (99+%), L-alanine (99+%), L-serine (99+%), and L-threonine (99+%) were obtained from Sigma Chemicals Limited. The acids were purified by repeated recrystallization from water and were dried and stored over phosphorus pentoxide in a vacuum oven set at 50°C. The NMR spectra of the amino acids were obtained on a Brüker 250 MHz instrument using D_2O as an internal standard. The recorded spectra were in excellent agreement with reference spectra (18).

All solutions were prepared by weight on the molality concentration scale using bi-distilled, degassed water. Solutions were stored in sealable 125 mL Nalgene bottles.

Densities were measured relative to water with a vibrating tube

flow densimeter (19) (Sodev O2D). The densimeter is connected to a programmable circulating thermostat and has a working temperature range of 0–75°C with a thermal stability of ±0.001°C. This experimental apparatus routinely measures densities with part per million precision.

Calibration constants for the densimeter at 288.15, 298.15, 313.15, and 328.15 K were calculated from the measured time periods of vibration and the densities of dry nitrogen gas and water (20). Calibration constants were determined prior to and following each series of experiments.

Volumetric heat capacities were measured relative to water using a Picker flow microcalorimeter (21). Automated data collection is achieved by interfacing one component of the system, a Hewlett-Packard HP-3456A digital voltmeter, via an IOtech Personal 488 PC/IEEE 488 controller, to a 386SX-16 MHz IBM clone computer. A BASIC program controls data collection and storage. It directs data to a commercial visualization package for interpretation and the calculation of volumetric heat capacities.

An inherent problem of Picker flow microcalorimeters is that they generally suffer from small heat leaks (22). These heat leaks are greatly reduced by evacuating the chamber that houses the calorimetric cells to a vacuum of approximately 1.5×10^{-6} mbar (1 bar = 100 000 Pa). A one inch stainless steel vacuum line incorporating a Leybold D4A backing pump and an Edwards EO 50/60 air cooled diffusion pump was constructed for this purpose. The calorimeter is connected to the vacuum line with a Cajon O-ring fitting. Small residual heat leaks are easily corrected for by a heat loss correction factor (23). This factor is determined periodically by measuring the specific heat capacities of aqueous sodium chloride solutions at the temperature of interest.

Results and discussion

Apparent molar volumes, $V_{2,\phi}$, were calculated from measured density data using the equation:

$$[1] \qquad V_{2,\phi} = \left[\frac{M}{\rho}\right] - \left[\frac{\rho - \rho_1^0}{m\rho\rho_1^0}\right]$$

where m is the molality of the solution, M is the molecular weight of the solute, ρ_1^0 is the density of pure water, and ρ is the density of the solution under study.

The apparent molar heat capacities, $C_{p,2,\phi}$, of our solutions were calculated using eq. [2]:

$$[2] \qquad C_{p,2,\phi} = Mc_p + \frac{(c_p - c_{p,1}^0)}{m}$$

where c_p is the specific heat capacity of the solution, and $c_{p,1}^0$ is the specific heat capacity of pure water.

Estimated uncertainties in apparent molar volumes, $\delta V_{2,\phi}$, were calculated using the equation reported by Hedwig (24):

$$[3] \qquad \delta V_{2,\phi} = -\left[M + \frac{1000}{m}\right]\frac{\delta\rho}{\rho^2}$$

The uncertainty in solution density, $\delta\rho$, was estimated to be 5×10^{-6} g cm^{-3}. In using eq. [3], we note that contributions to $\delta V_{2,\phi}$ arising from uncertainties in solution concentrations are assumed to be negligible.

Estimated uncertainties in our apparent molar heat capacities, $\delta C_{p,2,\phi}$, arise primarily from two sources (25); errors in experimental molalities, and errors associated with the measurement of the displacements of the heat capacity curves. In using Hedwig's expression, eq. [4], for the uncertainty in apparent molar heat capacity, $\delta C_{p,2,\phi}$, we once again assume that errors arising from solution concentrations are negligible.

$$[4] \qquad \delta C_{p,2,\phi} = \left(M + \frac{1000}{m}\right)\delta c_p$$

The uncertainty in specific heat capacity, δc_p, was estimated to be 7×10^{-5} J K^{-1} g^{-1} (26).

Densities, apparent molar volumes, and apparent molar heat capacities are reported as a function of concentration for glycine, L-alanine, L-serine, and L-threonine in Tables 1, 2, 3, and 4, respectively. Calculated uncertainties in apparent molar heat volumes and heat capacities have been included in parentheses in each table.

The apparent molar properties of the investigated aqueous amino acid systems were found to be well represented by the linear equation:

$$[5] \qquad Y_{2,\phi} = Y_{2,\phi}^0 + S_Y m$$

where Y represents the extensive thermodynamic property of interest, $Y_{2,\phi}^0$ is the value of $Y_{2,\phi}$ at infinite dilution, m is the molality of the solution, and S_Y is the experimental slope. The appropriate form of eq. [5] was fitted to our calculated $V_{2,\phi}$, and $C_{p,2,\phi}$ data using weighted linear least squares regression analyses. Weights used in these analyses were calculated as the reciprocals of the square in the uncertainties in apparent molar volumes and heat capacities i.e., $1/(\delta V_{2,\phi})^2$ and $1/(\delta C_{p,2,\phi})^2$.

Partial molar properties of solutes, $\bar{Y}_2$, can be calculated from apparent molar properties, $Y_{2,\phi}$, using the equation:

$$[6] \qquad \bar{Y}_2 = Y_{2,\phi} + n_2\left(\frac{\partial Y_{2,\phi}}{n_2}\right)_{T,p,n_1}$$

By definition, in the limit $n_2 \rightarrow 0$, the standard state property, $\bar{Y}_2^0$, is equal to the apparent molar property at infinite dilution, $Y_{2,\phi}^0$.

Table 5 compares calculated standard state volumes and heat capacities to available literature data (1–9, 29) at each investigated temperature. A review of this table indicates that the majority of literature data refer to 298.15 K. The volumetric study by Kharakoz (6) was the only one that we could find that reports standard state volume data over the same experimental temperature range as that selected in this investigation. However, we were unable to locate standard state volume data for aqueous L-threonine solutions above 298.15 K. The excellent agreement shown between our standard state data and available literature data affords us a high degree of confidence in our experimental procedures and equipment.

There are far less standard state heat capacity data reported in the literature than standard state volume data. A comparison of our calculated standard state heat capacity data to those available in the literature indicates very good agreement. Nevertheless, there is a noticeable discrepancy between Jolicoeur's (2) corrected value of $\bar{C}_{p,2}^0 = 45.5$ J K^{-1} mol^{-1} for glycine at 298.15 K, reported by Hedwig, Reading, and Lilley (11), and our value of 37.6 J K^{-1} mol^{-1}. However, we note that our value is in good agreement with the only other standard state heat capacity value (3), derived from flow calorimetric data, that we could find in the literature.

Standard state heat capacity data at temperatures removed from 298.15 K are scarce. A comparison of our reported value of $\bar{C}_{p,2}^0 = 57.8$ J K^{-1} mol^{-1} for glycine in water at 313.15 K

[a]Estimated uncertainties for $V_{2,\phi}$ and $C_{p,2,\phi}$ in parentheses.

thermodynamics of these systems at elevated temperatures and pressures (16, 17). Thermodynamic data are very difficult to obtain experimentally under these conditions, and so there has been considerable interest in estimating data using continuum models that are based on measured thermodynamic data at 298.15 K and atmospheric pressure. In this regard, the revised HKF equations of state for aqueous species have found widespread popularity. Two recent papers (16, 17) have applied this model to neutral organic species in water to obtain estimates for thermodynamic properties at 5 kbar and 1000°C.

The revised HKF equations of state for standard state volumes and heat capacities are defined by the expressions:

$$[7] \qquad \bar{V}^0 = a_1 + \frac{a_2}{\Psi + P} + \left(a_3 + \frac{a_4}{\Psi + P}\right)\left(\frac{1}{T - \theta}\right) - \omega_e Q$$

$$[8] \qquad \bar{C}_p^0 = c_1 + \frac{c_2}{(T-\theta)^2} - \left[\frac{2T}{(T-\theta)^3}\right] \times \left[a_3(P - P_r) + a_4 \ln\left(\frac{\Psi + P}{\Psi + P_r}\right)\right] + \omega_e T X$$

where a_1, a_2, a_3, a_4, c_1, and c_2 are species dependent parameters; θ and Ψ represent solvent dependent parameters. T, P, and P_r represent the temperature and pressure of interest and the reference pressure (1 bar), respectively. ω_e defines the effective Born coefficient for the neutral organic aqueous species of interest and is assumed to be independent of temperature and pressure. Hence the solvation contributions to the standard state properties in eqs. [7] and [8] are represented by $-\omega_e Q$ and $\omega_e TX$, respectively. Q and X are defined using the temperature and pressure dependencies of the dielectric constant of water, as in eqs. [9] and [10].

$$[9] \qquad Q = \frac{1}{\epsilon}\left(\frac{\partial \ln \epsilon}{\partial P}\right)_T$$

$$[10] \qquad X = \frac{1}{\epsilon}\left[\left(\frac{\partial^2 \ln \epsilon}{\partial T^2}\right)_P - \left(\frac{\partial \ln \epsilon}{\partial T}\right)_P^2\right]$$

At constant pressure, eq. [7] may be reduced to:

$$[11] \qquad \bar{V}^0 = \sigma + \frac{\xi}{T - \theta} - \omega_e Q$$

where σ and ξ are defined by the expressions:

$$[12] \qquad \sigma = a_1 + \frac{a_2}{\Psi + P}$$

$$[13] \qquad \xi = a_3 + \frac{a_4}{\Psi + P}$$

In a similar manner eq. [8] may be reduced under the constant

[a]Data obtained from ref. 16.

pressure condition of $P = P_r$ to give:

$$[14] \qquad \tilde{C}_p^0 = c_1 + \frac{c_2}{(T-\theta)^2} + \omega_e T X$$

Regression analyses have been used to fit eqs. [11] and [14] to calculated standard state volumes and heat capacities for each amino acid system. Values for Q and X at the reference pressure, P_r, were calculated using a program that was constructed using the procedures outlined in refs. 27 and 28. This program utilised the equations reported by Johnson and Norton (30) for the calculation of the temperature and pressure dependencies of the dielectric constant of water. Values for ω_e for each amino acid were obtained from the compilations reported by Shock and Helgeson (16). In an attempt to remain consistent with the Shock and Helgeson analyses, the solvent parameter θ was given a value of 228 K in all of our fitting procedures. Calculated values for σ, ξ, c_1, and c_2 are reported in Table 6. These values are in fair agreement with those calculated from the compilations reported by Shock and Helgeson (16). Uncertainties in the standard state volume and heat capacity data at 298.15 K and 1 bar, used in the Shock and Helgeson analyses, were reported to be $\sim \pm 2$ cm^3 mol^{-1} and $\sim \pm 8.368$ J K^{-1} mol^{-1}, respectively. These uncertainties are reflected in the uncertainties of the a_1, a_2, a_3, a_4, c_1, and c_2 parameters of eqs. [7] and [8]. Uncertainties in our standard state volumes and heat capacities are estimated to be less than 0.5 cm^3 mol^{-1} and 2 J K^{-1} mol^{-1}, respectively. This difference in uncertainties necessarily results in different estimates of the values for the a_i (i = 1 to 4) and c_i (i = 1 to 2) parameters.

Figures 1 and 2 compare calculated standard state volumes and heat capacities to those estimated using the revised HKF constant pressure equations (solid curves) as a function of temperature.

The equations reported in Table 6 can be used to estimate standard state volumes and heat capacities at temperatures outside the limited range investigated in this study. Figure 3 shows the calculated dependence of the standard state heat capacities of aqueous solutions of glycine over the temperature range 273.15 to 373.15 K. These data were calculated using the HKF constant pressure equation, eq. [14], and show very good agreement with the experimental $\bar{C}^0_{p,2}$ data of Gucker, Ford, and Moser (9).

There is clearly a need for high temperature and pressure data for aqueous amino acid systems. Such data are very difficult to obtain experimentally. The revised HKF equations for neutral organic species provide a method of estimating high temperature and pressure thermodynamic behaviour.

In continuation of this theme, we have commenced a study of the temperature dependence of the thermochemical and volumetric properties of other aliphatic and aromatic amino acids. These data will be presented in future papers. Our eventual aim is to establish a group additivity scheme for amino acids and peptides that can be applied to biological systems in the high temperature regime.

Thermodynamic properties of the Na–Bi–Pb system

PETER J. TUMIDAJSKI
Materials Laboratory, Institute for Research in Construction, National Research Council of Canada
Ottawa, ON, Canada K1A 0R6
Received April 28, 1993

PETER J. TUMIDAJSKI. Can. J. Chem. **72**, 369 (1994).

Thermodynamic properties of Na in an equimolar Bi–Pb alloy were determined at 723 K for compositions of $0.0075 \leq X_{Na} \leq 0.1000$ from electromotive force measurements on Na metal concentration cells with a solid Na–β-Al_2O_3 electrolyte. A coulometric titration technique was used to electrochemically generate the Na metal in the Bi–Pb alloy. The results indicate that, as Na is added to Bi–Pb, the liquid becomes more associated and suggests complex species formation with an ionic character intermediate between those observed for the constituent binaries.

PETER J. TUMIDAJSKI. Can. J. Chem. **72**, 369 (1994).

Utilisant des mesures de la forme électromotrice de cellules de la concentration du sodium métallique avec un électrolyte solide Na–β-Al_2O_3, on a déterminé les propriétés thermodynamiques du sodium dans un alliage équimoléculaire de Bi–Pb, à 723 K, à des concentrations de $0{,}0075 \leq X_{Na} \leq 0{,}1000$. On a utilisé une technique de titrage coulométrique pour générer le sodium métallique dans l'alliage Bi–Pb d'une façon électrochimique. Les résultats indiquent que, lorsqu'on ajoute du Na au Bi–Pb, le liquide devient plus associé et suggère qu'il y a formation d'espèces complexes possédant un caractère ionique intermédiaire entre celui observé pour les constituants binaires.

Introduction

There is an interesting type of liquid alloy that exhibits a tendency toward a metal to non-metal transition (MNM) at certain compositions. Associated with the MNM transition are changes in the thermodynamic, transport, magnetic, and optical properties, which indicates a fundamental change in the structure and energetics of the alloy. An explanation of the behavior of these alloys has proved challenging. One alloy system with the MNM transition are the Na-based alloys with Bi or Pb. The thermodynamic properties of the Na–Bi and Na–Pb binary alloys have recently been studied (1–6). The ternary Na–Bi–Pb alloy for the eutectic solvent composition ($X_{Bi} = 0.43$) has also been studied (7), but the measurements were performed using a Na conducting glass electrolyte which is prone to degradation and uncertain measurements. In this paper, we report on the Na activity coefficients in the equimolar Bi–Pb alloy using a solid Na–β-Al_2O_3 electrolyte. The technique has been proven to yield highly reliable thermodynamic properties, and is a further contribution from this author on the alkali-based alloys (8–12). The results are useful for the understanding of the thermodynamic behavior of the ternary systems, and how they compare to the constituent binaries. In addition, there is an increased understanding of the influence of multicomponent solvents on the atomic interactions involving the alkali metals.
