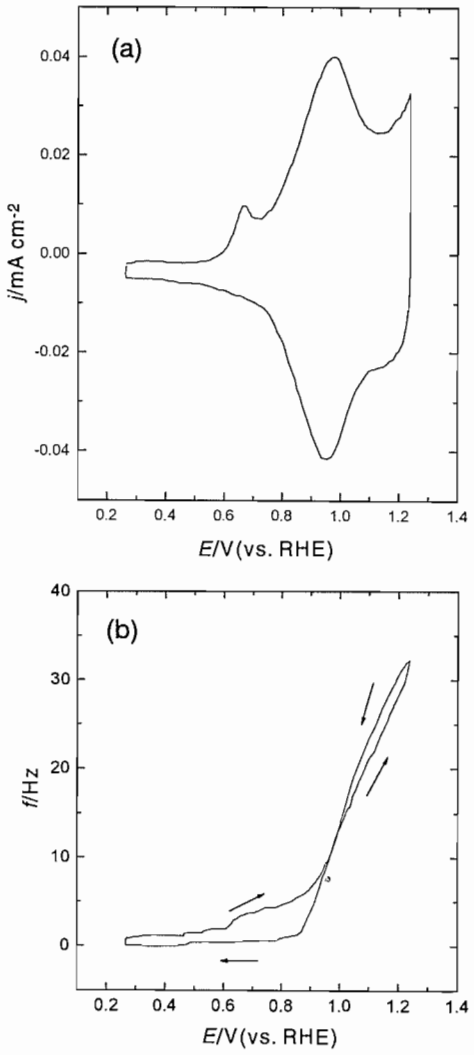
It has previously been reported that the principal Ir(III)/(IV) redox process, which occurs in peaks A_1/C_1, exhibits a super-Nernstian pH response over the bulk of the pH range (7, 8 ,11–13). An example of this can be seen by comparing Figs. 1 and 2, where the potential of the main peaks, which is independent of the sweep rate in both solutions under these conditions, is >300 mV more negative (vs. RHE) in the 1 M NaOH solution than in the 0.5 M sulfuric acid medium, leading to an overall pH dependence of ca. −80 mV/pH unit. This is similar to what has previously been reported, when many different pH's were examined (11, 12). It is also consistent with the formulation of reactions [1] and [2], in which the ratio of the pH-determining ion to the number of electrons passed is greater than 1, in both acidic and alkaline conditions, such that the pH dependence must be greater than −59 mV. A recent more careful study (3) of the pH dependence of the hydrous Ir oxide redox potential over a narrow range of acidic pH's in various acidic solutions has shown values between ca. −65 and −70 mV/pH unit. The value in sulfuric acid, in particular, is −68 mV/pH unit, which is consistent with the following reaction stoichiometry for the A_1/C_1 peaks in solutions between 0.1 to 0.75 M sulfuric acid:

$$[3]\quad \text{Ir(IV)oxide}\cdot n\text{H}_2\text{O} + \text{e}^- + 1.15\ \text{H}_3\text{O}^+ + 0.15\ \text{HSO}_4^- <===> \text{Ir(III)oxide}\cdot m\text{H}_2\text{O}(\text{H}_3\text{O}^+)_{1.15}(\text{HSO}_4^-)_{0.15} + (n-m)\text{H}_2\text{O}$$

In the present work, the pH dependence of the peak A_0 potential was compared in two solutions, 0.5 and 0.1 M sulfuric acid, in order to determine whether the stoichiometry of reaction [3] also applies to the reaction in peak A_0. The Ir oxide films in this study were formed in the 0.5 M acid solution by cycling at 200 mV/s between 0 and 1.5 V vs. RHE. Only very thin oxide films were formed (CEF ca. 14) in order to ensure that peaks A_0 and A_1 would remain separated, even at higher sweep-rates. The sweep-rate dependence of peak A_0 was then established in the growth solution, after which the film was transferred to a 5× diluted acid solution in which the A_0 peak was examined once again for the sweep-rate dependence of its potential. It is notable that the shape and width of peak A_0 was the same in these two solutions.

As the pH of these two acidic solutions is not known with certainty, the pH dependence of peak A_0 was established by tracking its potential relative to the A_1/C_1 peak potentials in the two solutions. As stated earlier, the pH dependence of the A_1/C_1 process is now known to be −68 mV/pH unit in sulfuric acid solutions, based on careful measurements of the variation in the peak potential with solution pH and corroborated by the determination of the HSO_4^- content of the oxidized vs. reduced form of the film by ion chromatographic methods (3).

Table 1 lists the potentials of the A_0 and A_1 peaks, at four different sweep-rates, in the two sulfuric acid solutions after equilibration of the films by multicycling between 0.05 and 1.4 V for a period of time. It can be seen that the A_1 peak potential is independent of sweep-rate in each solution, and there is a small negative shift by 5–15 mV (this range depicts the error in identifying peak potentials from the CVs recorded on an X/Y recorder) in the 0.1 vs. 0.5 M sulfuric acid solution, consistent with that reported previously (3). It is also seen from the data in Table 1 that the A_0 peak potential is shifted more negatively in the 0.1 M solution vs. than in the 0.5 M sulfuric acid solution, than is peak A_1, by an average of ca. 20 mV, i.e., by 5–15 mV more than the shift of the A_1/C_1 peaks. Based on the −68 mV pH dependence of the main redox peaks, this translates to a ca. −73 to −83 mV pH dependence for the A_0/C_0 process, which in turn indicates a greater anionic involvement in the reaction in peak A_0 than in peak A_1 (compare reaction [4] with reaction [3]). The following stoichiometry is suggested for the prepeak reaction, assuming a −80 mV per pH dependence.



$$[4]\quad \text{Ir(IV)oxide}\cdot n\text{H}_2\text{O} + \text{e}^- + 1.35\ \text{H}_3\text{O}^+ + 0.35\ \text{HSO}_4^- <===> \text{Ir(III)oxide}\cdot m\text{H}_2\text{O}(\text{H}_3\text{O}^+)_{1.35}(\text{HSO}_4^-)_{0.35} + (n-m)\text{H}_2\text{O}$$

It is also notable (although not shown in Table 1) that when the oxide film was transferred between solutions, the initial potential scans were carried out only over the range of the A_0/C_0 peaks, i.e., between 0.05 and 0.7 or 0.8 V. Under these conditions, the A_0/C_0 peak potentials were more similar to those of the prior test solution than indicated in Table 1, and it was only after the completion of several full potential cycles, up to 1.4 V or more, that the steady-state potentials of Table 1 were obtained. This was not the case for the potential of the A_1/C_1 peaks, which immediately reflected the new solution conditions and did not change further with time, potential limits, or sweep rate. These results suggest that, unless the ionic

Fig. 4. CV at 10 mV/s (*a*) and associated frequency response (*b*) of Ir oxide film (CEF = 10) on Ir sputter-coated quartz crystal in 0.5 M H_2SO_4.

content from the prior solution is fully expelled from the oxide film by scanning to sufficiently positive potentials, the local conditions of the Ir oxide sites that react in the A_0/C_0 peaks remain similar to those of the prior test solution. This, in turn, suggests that the A_0/C_0 sites are located deep within the film, probably in the region of the metal–oxide interface.

(*c*) Mass change associated with the A_0/C_0 reaction

To attempt to corroborate the pH dependence data for the A_0 peak (reaction [4]) and to complete the reaction stoichiometry, the film mass change was measured as the potential was scanned very slowly through the potential range of peak A_0. Figure 4 shows a typical CV and the corresponding frequency change in a full cycle of potential for a very thin Ir oxide film (CEF = 10), conditions under which the A_0 and A_1 peaks are again well separated. A mass loss during film oxidation, and corresponding mass gain during reduction, is seen to be consistent with the predictions of reactions [1], [3], and [4] in acidic solutions. It is notable that the mass gain observed during Ir oxide reduction is essentially complete at potentials just negative of peak C_1; neither peak C_0 nor any additional mass gain associated with this process are seen. This suggests that the A_0 sites reduce in peak C_1 under the conditions of this experiment. When the frequency change over peak A_0 is converted to a mass change, using a crystal constant of -57 Hz μg^{-1} cm^2 from the Sauerbrey equation (17), and the charge density in peak A_0 is also taken into consideration, a mass change of ca. 11 grams per mole of electrons passed is obtained in this particular case. Several other experiments have shown that this ratio varied between 10 and 12, considering both experimental error and the fact that slightly thicker films result in some shift of the A_0 charge into the foot of the A_1 peak, making charge measurement more difficult.

Considering the stoichiometry of reaction [4], this overall net mass change would predict that $n - m$ is 2.7, i.e., that 2.7 moles of water are gained by the film per mole of electrons passed (i.e., per mole of Ir sites reacted) during the A_0 reaction, and vice versa, during its reduction. In comparison, the mass-to-charge ratio for the A_1/C_1 reaction is ca. 6–7 grams per mole of electrons, which suggests that only ca. 1.5 moles of water are injected into the oxide per mole of Ir sites reacted, based on the stoichiometry of reaction [3]. This interpretation of the data would indicate that the A_0/C_0 sites are characterized by a proportionally greater water exchange per mole of Ir sites reacted, as well as a higher anionic to protonic ratio, as compared to the case in the main A_1/C_1 peaks (cf. reactions [3] and [4]).

It should be pointed out that the mass-to-charge ratio of 10–12 grams per mole of electrons observed experimentally for the A_0 process could also be explained on the basis of only protonic and water exchange. Based on reaction [5], $(n - m)$ would then be much smaller, ca. 0.4, such that 0.4 moles of water would be injected into the film for each mole of electrons and hydronium ions expelled during film oxidation in peak A_0, and vice versa, during film reduction.

$$[5]\quad \text{Ir(IV)oxide}\cdot n\text{H}_2\text{O} + \text{e}^- + \text{H}_3\text{O}^+ <===> \text{Ir(III)oxide}\cdot m\text{H}_2\text{O}(\text{H}_3\text{O}^+) + (n - m)\text{H}_2\text{O}$$

However, a pH dependence of ca. -59 mV would then be observed, which is not the case here; therefore, reaction [5] can be ruled out.

A final possibility is that the greater negative shift of the A_0 peak vs. the A_1 peak with increasing pH (Table 1) originates, not from a higher ratio of anionic to protonic charge compensation than in the main A_1/C_1 peaks, but rather from the large changes in water content and hence complex activity changes deep within the Ir oxide film. In this case, if the stoichiometry of the principal redox peaks (reaction [3]) is also assumed to hold for the A_0/C_0 reaction, then the mass-to-charge ratio of ca. 10–12 would yield an $n - m$ value of 1.3, whereas for the A_1/C_1 process, $n - m$ would remain equal to 1.5. This would suggest that more water exchange is occurring in the main redox peaks vs. in the A_0/C_0 peaks and that large changes in water content in the A_0/C_0 reaction are not responsible for anomalous activity effects, which would then be expected to be more predominant in the A_1/C_1 redox reaction.

Overall, it is clear that the mass-to-charge ratio obtained for the A_0 peak as compared to that in the main A_1/C_1 redox peaks is significantly larger, 10–12 vs. 6–7 grams per mole of elec-

trons. This most likely represents both a greater involvement of anions in the A_0 reaction and a greater degree of water exchange during this process.

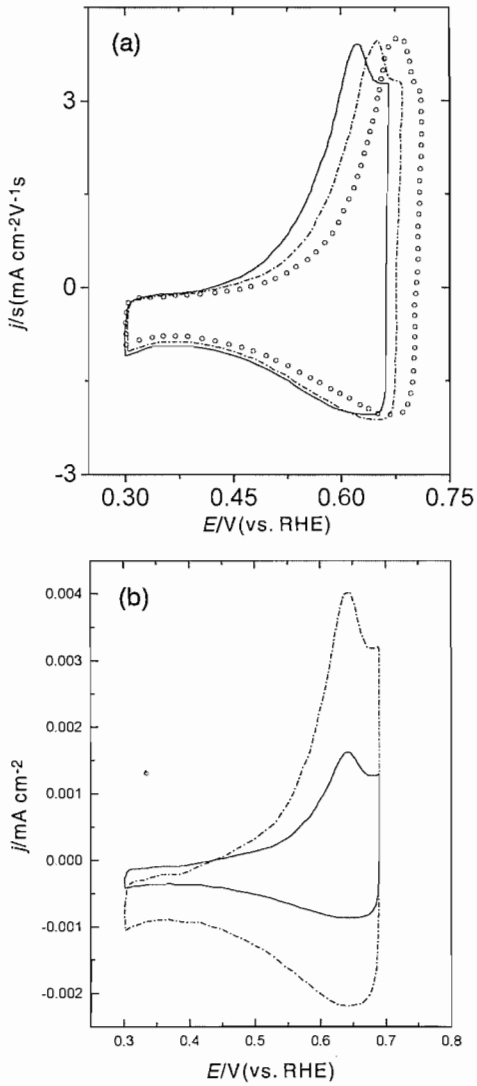
(*d*) Suggested mechanism of the A_0/C_0 reaction

In their examination of the kinetics of the A_0 process, Mozota and Conway (5, 6) showed that at slow sweep-rates the A_0 peak current depends linearly on sweep-rate, while the peak potential depends on the log of sweep-rate. They suggested that the A_0 reaction involves a slow surface adsorption process, limited by the slow rearrangement of sites. However, even at the slowest sweep-rates employed, the A_0 peak potential continued to move negatively, and hence the reaction rate constant could not be determined using sweep methods. Films of reasonable thickness were examined in their work and, under these conditions, a complementary cathodic process, C_0, could not be distinguished. It was assumed, therefore, that the C_0 peak was located negative of the potential for the hydrogen evolution reaction. Taking into account the pronounced positive shift of the A_0 peak potential with sweep-rate and the presumed very negative shift of C_0, substantial kinetic limitations of the A_0/C_0 process were suggested (5, 6).

In the present paper, the CV behavior of the A_0/C_0 process was examined more closely using very thin Ir oxide films. The CVs presented in Fig. 5*a* show that a cathodic counterpart, C_0, of the A_0 peak can be seen for this very thin film (CEF = 12), as long as the upper potential limit is restricted to the range of the A_0 peak. After first examining the anodic peak, it is seen that the peak current is linearly dependent on the sweep-rate, as reported by Mozota and Conway (5, 6), and that the peak potential shifts anodically with increasing sweep-rate, both characteristics of a kinetically irreversible surface reaction. However, as long as the same E_+ value is used (Fig. 5*b*), the C_0 peak potential remains constant with increasing sweep-rate, instead of the more typical opposing shifts of the potential of the anodic and cathodic peaks expected for a slow surface process. The apparent positive shift of peak C_0 with increasing sweep-rate in Fig. 5*a* arises from the need to increase E_+, hence including some of peak A_1 in the scan, in order to cross peak A_0.

Based on the QCMB and pH dependence results described in sections (b) and (c) above, the following mechanism could apply to the A_0/C_0 reaction. It is assumed that the reduced film sites that react in the prepeak are more hydrated and contain more solution anions as charge-compensating species than do the oxidized form. After examining the oxidation reaction, the first step is expected to be a slow electron transfer reaction, as suggested earlier (5, 6), consistent with the notable anodic shift of the A_0 peak with increasing sweep-rate.

[6] $\mathrm{Ir(III)oxide{\cdot}}m\mathrm{H_2O(H_3O^+)_{1.35}(HSO_4^-)_{0.35}} \overset{\text{slow}}{\Longrightarrow} \mathrm{Ir(IV)oxide{\cdot}}m\mathrm{H_2O} + e^- + 1.35\ \mathrm{H_3O^+} + 0.35\ \mathrm{HSO_4^-}$



This is then followed by a rapid film hydration process:

[7] $\mathrm{Ir(IV)oxide{\cdot}}m\mathrm{H_2O} + 2.7\ \mathrm{H_2O} \overset{\text{fast}}{\Longleftrightarrow} \mathrm{Ir(IV)oxide{\cdot}}(m + 2.7)\mathrm{H_2O}$

It can be argued that this hydration process changes the formal potential of these sites, such that the cathodic reaction can occur at more positive potentials (Fig. 5). Reactions [8] and [9] are suggested for the C_0 process, based also on the electrochemical results. Reaction [8] is a rapid electron-transfer reaction, consistent with the independence of its peak potential on sweep-rate at constant E_+ (Fig. 5*b*). The slow dehydration process (reaction [9]) is consistent with the fact that holding the potential negative of the A_0/C_0 peaks constant for a long period of time causes a minor increase and a small positive shift of the A_0 peak (although not affecting its kinetics).

[8] $\mathrm{Ir(IV)oxide{\cdot}}(m + 2.7)\mathrm{H_2O} + e^- + 1.35\ \mathrm{H_3O^+} + 0.35\ \mathrm{HSO_4^-} \overset{\text{fast}}{\Longleftrightarrow} \mathrm{Ir(III)oxide{\cdot}}(m + 2.7)\mathrm{H_2O(H_3O^+)_{1.35}(HSO_4^-)_{0.35}}$

Fig. 5. (*a*) Normalized CV responses (*j*/*s*) over restricted potential range of peaks A_0/C_0 at 5 (—), 20 (-·-·-) and 50 (○○○) mV/s in 0.5 M H_2SO_4 (CEF = 12). Note that E_+ was increased with increasing sweep-rate in order to cross the A_0 peak. (*b*) CV at 10 (—) and 20 (-·-·-) mV/s of peaks A_0/C_0 using constant E_+ and E_- values.

© 1997 NRC Canada

This is followed by a relatively slow dehydration process:

$$[9]\quad \text{Ir(III)oxide}\cdot(m + 2.7)H_2O(H_3O^+)_{1.35}(HSO_4^-)_{0.35} \overset{\text{slow}}{===>} \text{Ir(III)oxide}\cdot mH_2O(H_3O^+)_{1.35}(HSO_4^-)_{0.35} + 2.7\ H_2O$$

The different shapes of the A_0 and C_0 peaks, seen in Fig. 5, can perhaps therefore be explained by the fact that the state of hydration of the reacting sites is different in the two forms, introducing different lateral interactions between redox sites in the two cases (18). Alternatively, it has previously been shown (13) that the Ir oxide A_1/C_1 peaks are broader in solutions of lower ionic strength. Therefore, it is possible that the narrower A_0 peak reflects the higher ionic and lower water content of the reduced state, versus the broader cathodic C_0 peak, reflecting reduction of sites from which ions have been lost and a significant amount of water has been gained.

A final issue to address is the possible reason for the development of energetically different sites in these electrochemically grown Ir oxide films, i.e., those that react in peaks A_0/C_0 and those that oxidize and reduce in the principle redox peaks A_1/C_1. It is possible that this relates back to the fact that, in order to form these films, the lower potential limit in each growth cycle is usually made more negative than 0 V, at which point hydrogen evolution commences. This reaction, which involves the consumption of water as well as the generation of locally alkaline conditions, occurs at the film–metal interface, as the oxide film is in its reduced, nonconductive state at these potentials. This may lead to the partial dehydration, as well as other possible structural–compositional alterations, of the oxide film in the region of this interface. Consistent with this, it has been found (3) that the potential of peak A_0 depends somewhat on the length of time spent at the negative potential limit in each cycle during the growth of Ir oxide films using potential pulsing techniques.

Abstract: Chronocoulometry and Raman spectroscopy have been applied to study pyrazine adsorption at the Au(210) electrode surface. The adsorption isotherms, Gibbs energies of adsorption, and the electrosorption valency for pyrazine adsorption at the Au(210) electrode surface have been determined. Surface-enhanced Raman Scattering (SERS) spectra of pyrazine adsorbed on an "unroughened" Au(210) electrode surface have been obtained for the first time. The thermodynamic data and the SERS spectra indicate that pyrazine adsorbs on the Au(210) electrode via the nitrogen lone pair (N-bonded configuration) over the whole range of electrode potentials investigated. Consequently, the pyrazine molecule assumes only the vertical orientation at this surface of gold. The adsorption of pyrazine at the Au(210) and Au(111) surfaces is compared and the influence of the surface crystallography on the adsorption of this molecule at gold electrodes is discussed.

Key words: adsorption at Au(210), pyrazine, SERS, chronocoulometry.

Résumé : On a utilisé la chronocoulométrie et la spectroscopie Raman pour étudier l'adsorption de la pyrazine sur la surface (210) d'une électrode d'or. On a déterminé les isothermes d'adsorption, les énergies de Gibbs pour l'adsorption ainsi que la valence d'électrosorption pour l'adsorption de la pyrazine sur la surface (210) d'une électrode d'or. On a déterminé pour la première fois les spectres de diffusion Raman rehaussés par la surface («SERS») de la pyrazine adsorbée sur une surface (210) «polie» d'une électrode d'or. Les données thermodynamiques et les spectres «SERS» indiquent que, à tous les potentiels d'électrode étudiés, la pyrazine s'adsorbe sur la sruface (210) de l'électrode d'or par le biais de la paire d'électrons libres de l'azote (configuration liées par l'azote). En conséquence, la molécule de pyrazine ne prend que l'orientation verticale par rapport à la surface de l'or. On a comparé l'adsorption de la pyrazine sur les surfaces (210) et (111) de l'or et on discute de l'influence de la cristallographie de la surface sur l'adsorption de cette molécule sur les électrodes d'or.

Mots clés : adsorption sur la surface (210) de l'or, pyrazine, «SERS», chronocoulométrie.

[Traduit par la rédaction]

Introduction

The adsorption onto an electrode of an organic molecule from solution is a complex process that involves direct interaction of the adsorbed molecule with the metal electrode surface, displacement of solvent molecules that were previously adsorbed, interaction with the solvent molecules constituting the solution phase, and lateral interactions between the adsorbate molecules and their modified cospheres (1). Brian Conway et al. (2–4) have shown that the pyrazine molecule, which has a zero net dipole moment in the gas phase, is an ideal probe for the study of the displacement of field-oriented water dipoles from the electrode surface. These papers stimulated our interest in the study of the adsorption of pyrazine at gold electrodes. We have already performed extensive research of pyridine adsorption at group IB metals electrodes (5–19). The size of pyrazine is almost the same as that of pyridine but, in contrast to pyrazine, the pyridine molecule has an appreciable dipole moment. In addition, the presence of the second nitrogen heteroatom in the *para* position of the aromatic ring should significantly affect the interaction of the adsorbed molecule with the aqueous subphase and, consequently, the lateral interactions between the adsorbed molecules (20). Therefore, a comparison of pyrazine and pyridine adsorption at gold electrodes may give insight into the role of the different forces involved in molecular adsorption at metal electrodes.

We have already described the adsorption of pyrazine at the Au(111) (21) and the Au(poly) (22) surfaces. Most recently, the pyrazine monolayer on the Au(111) electrode emersed from an electrolyte solution and transferred to a UHV chamber was investigated by X-ray photoelectron spectroscopy

Received April 8, 1997.

This paper is dedicated to Brian E. Conway on the occasion of his 70th birthday and in recognition of his contributions to electrochemistry.

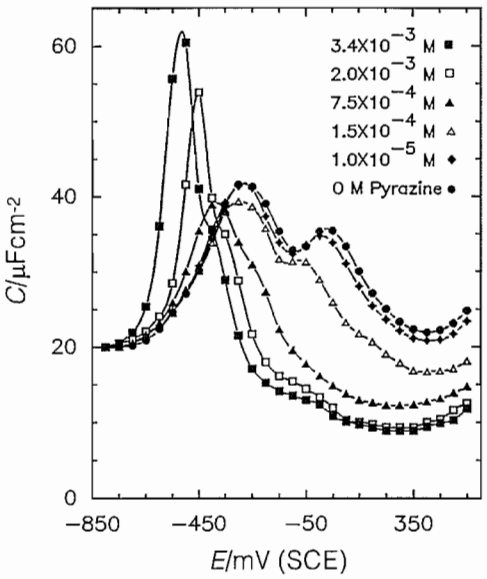
(XPS) by Hamm et al. (23). The objective of this paper is to describe the adsorption of pyrazine at the Au(210) surface. We have selected this plane because it has the most open structure. Structurally, it constitutes the opposite extreme to the Au(111) surface, which has the highest packing density. Chronocoulometry has been employed to measure the charge density at the electrode surface. The energetics of pyrazine adsorption have been determined from a thermodynamic analysis of the charge density data. Surface-enhanced Raman scattering, SERS, of pyrazine molecules adsorbed onto the "unroughened" Au(210) surface has been measured. In this way we have determined the character of pyrazine adsorption at this electrode. The adsorption of pyrazine at the Au(210) surface is compared with that at the Au(111) surface and the influence of surface crystallography on adsorption of this molecule at gold electrodes has been assessed. Preliminary results of the chronocoulometric measurements were included in a recent review (5) and preliminary results of SERS studies have been described in a recent letter (24).

Experimental



The experimental procedures and instrumentation have been described in previous communications (21, 22, 25). All solutions were prepared from Milli-Q water (Waters) with a resistivity higher than 17 MΩ cm. The supporting electrolyte was 0.1 M $KClO_4$, which was purified by calcination at 300°C and recrystallization. Pyrazine (Aldrich, Gold Label 99+%) was utilized without further purification. A three-electrode cell was used in the measurements. The reference electrode was an external saturated calomel electrode (SCE). The counter-electrode was a coil of gold wire. The Au(210) crystal was grown, oriented, and cut in our laboratory. The electrode was cleaned by flame annealing and quenching with ultrapure water before each experiment (26). Contact between the gold surface and the solution was made using the hanging electrolyte method (27). The temperature was 20 ± 2°C.

The experiments were performed using a PAR model 173 potentiostat, a homemade voltage generator, and an IBM computer equipped with an IS-16 analog–digital interface (RC Electronics, California) for digital data acquisition at a 1 MHz analog–digital conversion frequency with a resolution of 1 mV.

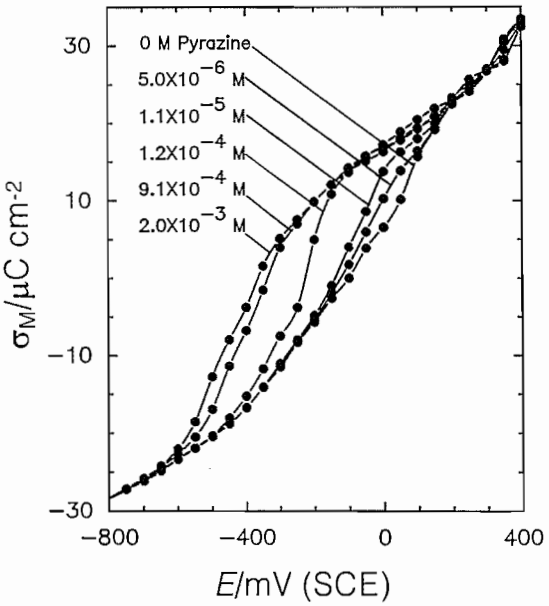
The "unroughened" gold electrode for the SERS experiments was prepared using the technique developed in our previous work (11). A clean gold electrode was placed in the SERS cell containing 0.1 M $KClO_4$ and the desired concentration of the adsorbate. The electrode was submitted to continuous cleaning cycles between the limits −0.8 V and +1.1 V at 20 mV s^{-1}. This cycling persisted until a cyclic voltammogram reproduced itself from one cycle to the next and displayed the features of a clean electrode. After the SERS experiment, the electrode was rinsed with copious amounts of Milli-Q water, and flame annealed. The electrode was then transferred to a clean electrochemical cell containing 0.1M $KClO_4$ solution. Cyclic voltammograms were obtained in the region −0.8 to +1.1 V at 20 mV s^{-1}. The voltammograms presented features uniquely characteristic of a Au(210) surface (16). This surface characterization was carried out to confirm that the electrode surface was preserved during the SERS experiment.

A Renishaw system 1000 Raman microscope equipped with a 385 × 578 pixel Peltier-cooled Wright Instruments charge coupled device (CCD) was used in the SERS experiments. A macro point accessory, with 40 mm focal length, was used to redirect the laser light to the electrode surface in the spectro-electrochemical cell, described elsewhere (28). The spectrometer was interfaced to a PC computer containing programs for data acquisition, baseline correction, smoothing, and bandfitting. A potentiostat PAR model 273 was used in the electrochemical SERS experiments. A 35 mW Melles Griot He-Ne laser provided excitation at 632.8 nm. The laser power was ca. 6 mW at the sample; the diameter of the focal spot was ca. 5 μm.

Fig. 1. Differential capacity curves for the Au(210) electrode recorded in 0.1 M $KClO_4$ solutions of varying pyrazine concentrations as indicated in the figure. The curves were recorded for the potential sweep in the positive direction. The capacitance was determined using a 5 mV rms sine wave modulated at 25 Hz and a 5 mV s^{-1} voltage sweep rate. A series RC equivalent circuit was assumed in the calculations.

Results and discussion

Cyclic voltammetry and differential capacity



The cyclic voltammograms (CVs) and the differential capacity curves were recorded in order to determine the potential range in which pyrazine adsorption occurred. The shape of the CV recorded for the supporting electrolyte gave the characteristic "fingerprint " of the Au(210) surface (16, 29). Cyclic voltammetry also indicated that the Au(210) surface behaves as an ideally polarizable electrode in the potential range between −0.85 and +0.6 V/SCE.

The differential capacity of the electrode was measured using an ac signal of 25 Hz and 5 mV rms superimposed onto a 5 mV s^{-1} voltage ramp. Figure 1 shows the differential capacity curves for supporting electrolyte without and with a few selected concentrations of pyrazine. We note that at the potential −0.85 V/SCE the capacity is independent of the pyrazine concentration and equal to the capacity of the pure supporting electrolyte. This feature indicates that pyrazine is totally desorbed from the electrode surface at this potential.

Fig. 2. The absolute charge density of the Au(210) electrode plotted versus the electrode potential in 0.1 M $KClO_4$ solutions of varying pyrazine concentrations as indicated in the figure.

The capacity curves recorded in the presence of pyrazine display a characteristic adsorption/desorption peak followed by a broad minimum. These features show the potential range within which pyrazine molecules are adsorbed at the electrode surface.

The differential capacity curve for the pure supporting electrolyte displays a characteristic minimum at $E = -100$ mV/SCE. The minimum was much more pronounced when the differential capacity was recorded in a dilute (0.005 M $KClO_4$) solution, indicating that this is the diffuse-layer minimum. The potential of the minimum corresponds, therefore, to the potential-of-zero-charge (pzc) of the Au(210) electrode. The pzc value is consistent with the data reported in the literature (16, 29). Finally, we would like to emphasize that the differential capacity curves recorded in the presence of pyrazine displayed a frequency dispersion and thus can not be considered as corresponding to the equilibrium between the electrode surface and the bulk of the solution. Therefore, we used the differential capacities exclusively to characterize the pyrazine adsorption qualitatively.

The charge densities

The chronocoulometric technique (6, 25) was employed to determine the charge density on the metal side of the interface σ_M. The electrode was held at a potential at which pyrazine adsorption occurred for a sufficiently long period of time for the equilibrium between the electrode surface and the bulk of the solution to be established. For pyrazine concentrations lower than 10^{-4} M, the solution was stirred in order to enhance mass transport to the surface. The potential was then stepped to $E = -0.85$ V/SCE, where the pyrazine molecules were desorbed from the electrode surface and the difference between the charge densities at the two potentials was measured. Next, the value of the pzc was used to calculate the absolute charge densities using the procedure described in our earlier papers (6, 25).

Fig. 3. (*a*) Surface pressure at a constant potential plotted versus *E*, and (*b*) surface pressure at a constant charge plotted versus σ_M for 0.1 M $KClO_4$ solutions of the following pyrazine concentrations: (a) 5.0×10^{-6} M; (b) 1.1×10^{-5} M; (c) 5.6×10^{-5} M; (d) 1.2×10^{-4} M; (e) 4.1×10^{-4} M; (f) 9.1×10^{-4} M; (g) 2.0×10^{-3} M.

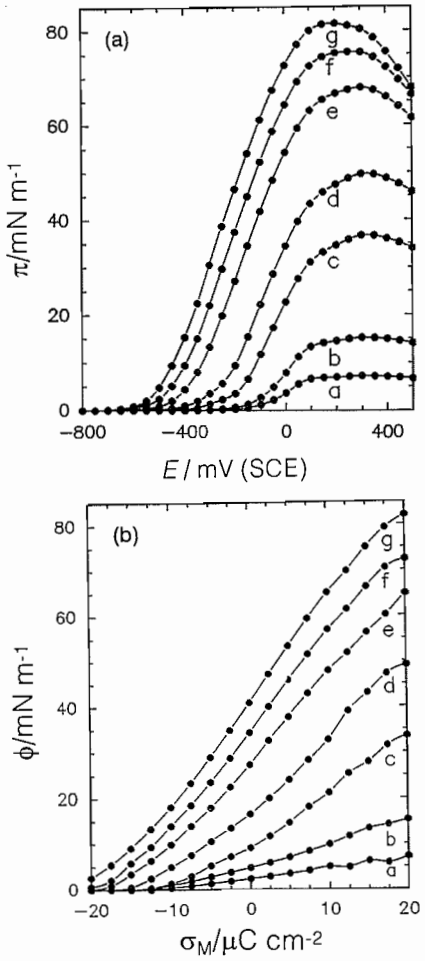

Figure 2 shows the charge density curves determined for the pure supporting electrolyte and for a few selected concentrations of pyrazine. Adsorption of pyrazine is responsible for the appearance of a characteristic step on the charge–potential curves. At positive potentials the curves acquired in the presence of pyrazine intersect the curve for the pure supporting electrolyte solution. The intersection point corresponds to the charge and potential of the maximum adsorption of the pyrazine molecule. The potential of maximum adsorption shifts from about 350 to about 200 mV/SCE with increasing bulk concentration of pyrazine molecules. The potentials of maximum adsorption corresponding to the intersection points on the charge–potential curves correlate well with the potentials of the minimum on the differential capacity curves in Fig. 1.

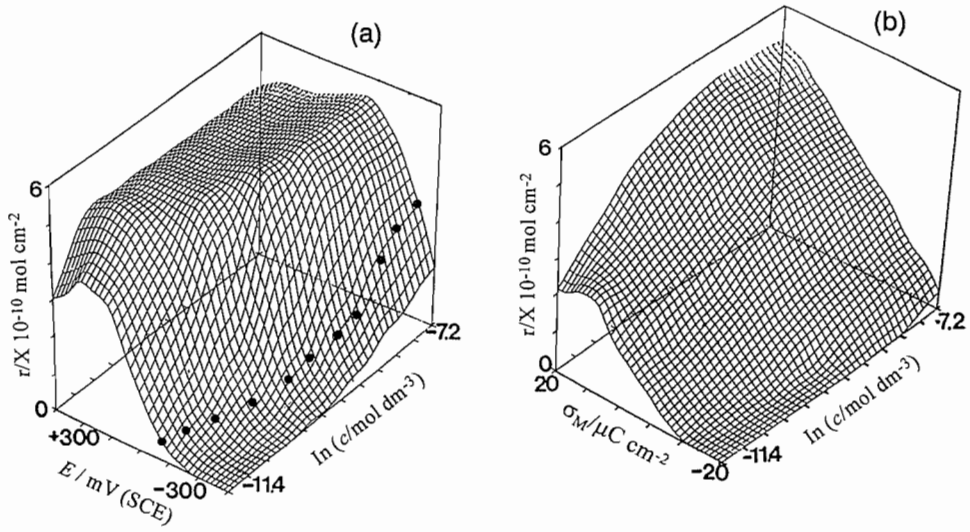

Surface pressure

The surface pressure at constant potential, defined as $\pi = \gamma_{c=0} - \gamma_c$, where $\gamma_{c=0}$ and γ_c correspond to the specific surface energies in the absence and presence of pyrazine, are calculated by integration of the charge density curves (6, 26). Figure 3*a* shows the surface pressure versus potential plots for

seven bulk concentrations of pyrazine. The surface pressure curves display a characteristic bell shape, typical for adsorption of an organic molecule at a metal electrode. In addition, the surface pressure at constant charge, defined as $\phi = \xi_{c=0} - \xi_c$, where $\xi = \gamma + \sigma_M E$ is the Parsons function, can be calculated for charge used as an independent electrical variable. The surface pressures at a constant charge are plotted versus σ_M in Fig. 3*b*. These data show that pyrazine adsorption at the Au(210) surface takes place predominantly at a positively charged surface. The surface pressures data were used to calculate the Gibbs excess of adsorbed pyrazine.

Adsorption isotherms

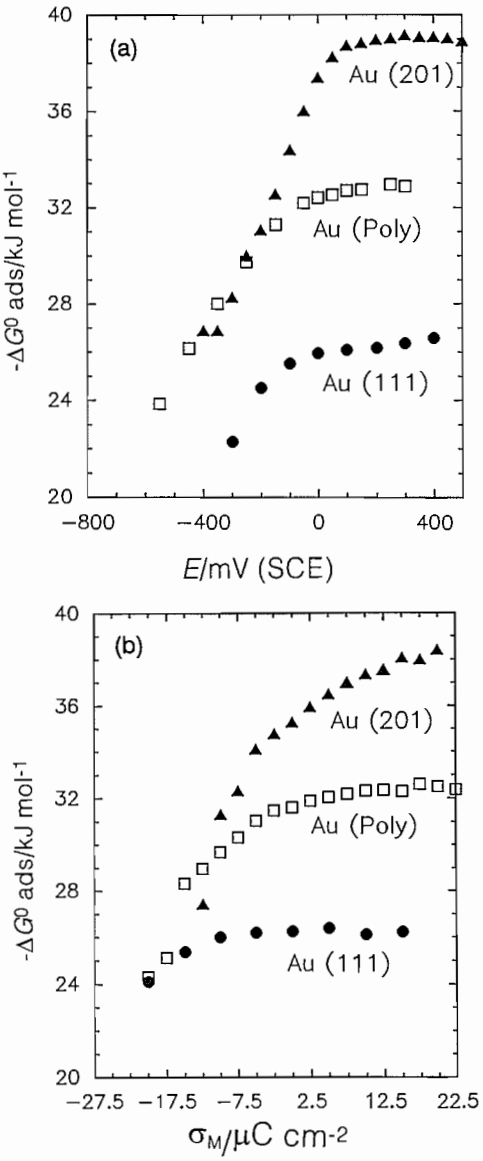
The relative Gibbs excess, Γ, of pyrazine was calculated by differentiation of the plots of π or ϕ versus the logarithm of the bulk pyrazine concentration. The calculated Gibbs excesses are plotted in three-dimensional coordinates in Figs. 4*a* and 4*b*. The potential or charge axes and the axis of the logarithm of the bulk pyrazine concentration are in the horizontal plane of the figure and the Gibbs excess is plotted on the vertical axis. Figure 4*a* shows one well-defined plateau corresponding to the limiting surface concentration, $\Gamma_{max} = 5.6 \times 10^{-10}$ mol cm^{-2}, of adsorbed pyrazine molecules. A cross section of the three-dimensional graph in the Γ–E plane gives the dependence of the surface concentration of pyrazine on potential at a constant bulk concentration of this molecule. Likewise, a cross section of the 3-D graph in the Γ – ln c plane gives the dependence of the surface concentration of pyrazine on the logarithm of its bulk concentration at a constant electrode potential. All these Γ–E and Γ – ln c curves have a sigmoidal shape with only one inflection point. These properties of the isotherm suggest that pyrazine molecules assume only one orientation when adsorbed at the Au(210) surface. The limiting surface concentration corresponds to an effective molecular area of about 0.25 nm^2. This value is consistent with a vertical orientation of the adsorbed pyrazine (5, 6). The black dots in Fig. 4*a* show the position of the pzc for different concentrations of pyrazine. Apparently, the pzc is located at the rising section of the isotherm and pyrazine molecules are predominantly adsorbed at the positively charged surface. This result shows that adsorption of pyrazine displays a remarkable asymmetry with respect to the charge at the electrode surface.

The character of pyrazine adsorption at the Au(210) surface is therefore distinctly different than at the Au(111) surface. The results of our chronocoulometric experiments (21) and recent XPS studies by Hamm et al. (23) demonstrated that at the Au(111) electrode, the adsorption of pyrazine has a two-state character. The molecule assumes a flat, π-bonded orientation at the negatively charged surface and a vertical N-bonded coordination at positive charge densities. The influence of the surface crystallography of gold on the adsorption of this aromatic heterocycle is dramatic.

Gibbs energy of adsorption

The Gibbs energy of adsorption was determined from the surface pressure data. In the limit of zero coverage, all isotherms simplify to the Henry isotherm and the following relationship holds (6):

$$[1] \quad \pi \text{ (or } \phi) = RT\,\Gamma_{max}\beta c/55.5$$



where β is the adsorption equilibrium constant, which is related to the Gibbs energy of adsorption through the equation $\Delta G^\circ = -RT \ln \beta$. The equilibrium constants were calculated from the initial slopes of the surface pressure versus the bulk concentration plots, and the Gibbs energies of adsorption, determined in this way, are plotted in Figs. 5*a* and 5*b* against the potential and charge, respectively. The standard state corresponds to unit mole fraction of the organic species in the bulk of the solution and to monolayer coverage by the noninteracting adsorbates.

For comparison, the Gibbs energies of adsorption determined for pyrazine adsorption at a Au(111) and a polycrystalline Au electrode surface, taken from our previous papers (21, 22), are also included in Figs. 5*a* and 5*b*. The impact of the crystallographic orientation on the energetics of pyrazine

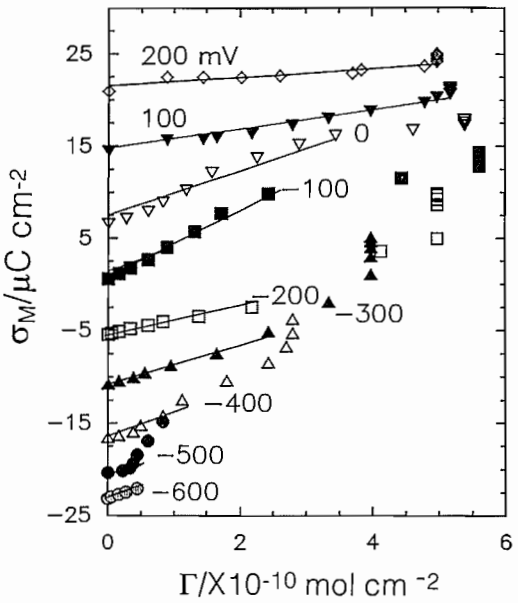
Fig. 5. Gibbs energy of pyrazine adsorption at the Au(210), Au(111), and Au(poly) surfaces plotted versus (*a*) electrode potential and (*b*) charge density at the metal surface.

adsorption is significant. These data corroborate the above-discussed differences between the character of pyrazine coordination to the Au(210) and Au(111) surfaces of gold and show that the differences have not only a qualitative but also a quantitative character. It is also interesting to note that the Gibbs energies of adsorption at the polycrystalline Au electrode are intermediate between the energies for Au(111) and Au(210) surfaces. We note also that the minimum values of the Gibbs energies of pyrazine adsorption on all gold electrodes are significantly smaller than the minimum value of ΔG°_{ads} at mercury, reported by Conway et al. to be -21 kJ mol^{-1} (2–4). Apparently, pyrazine is physisorbed at Hg while the adsorption at gold electrodes has a character of weak chemisorption that involves mixing of the electronic states of the adsorbed molecule with the electronic states of the metal (21).

Fig. 6. Curves of the charge density at the Au(210) surface versus surface excess of pyrazine for different values of the electrode potential as indicated in the figure. The straight lines were drawn through the points corresponding to low values of the surface excess.



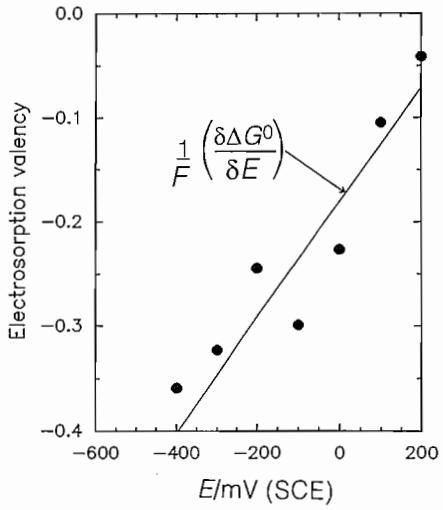


Fig. 7. Dependence of the electrosorption valency on the electrode potential. The dots correspond to the data that were obtained from the slopes of the plots in Fig. 6. The straight line corresponds to the first derivative of a second-order polynomial used to fit the Gibbs energy data given in Fig. 5*a*.

The first derivative of the ΔG°_{ads} versus E plot is equal to the electrosorption valency γ'. The electrosorption valency can be determined independently from the slope of the charge density versus surface concentration plots:

$$[2] \quad \gamma' = (\partial \Delta G^{\circ}_{ads}/\partial E)_{\Gamma} = -(\partial \sigma_M/\partial \Gamma)_E$$

In addition, the first derivative of the Gibbs energy of adsorp-

tion with respect to charge is equal to the derivative of the electrode potential with respect to the Gibbs excess taken at a constant charge:

$$[3] \quad (\partial\Delta G^{\circ}_{ads}/\partial\sigma_M)_\Gamma = (\partial E/\partial\Gamma)\sigma_M$$

Equations [2] and [3] may be used to check that no major errors have been introduced in the data processing.

Figure 6 shows a series of σ_M versus Γ plots at selected electrode potentials. The initial sections of these plots display good linearity. The data corresponding to higher values of Γ deviate from these linear relationships. However, only the initial slopes of these plots need to be measured, since the Gibbs energies were determined by linear extrapolation of the surface pressures to zero coverage and are considered as zero coverage data. The electrosorption valencies determined from the initial slopes of the charge versus surface concentration curves are plotted as black points in Fig. 7. In addition, the Gibbs energy versus potential curve was fitted by a polynomial and differentiated. The solid line in Fig. 7 is the derivative of the Gibbs energy curve. The agreement between the two sets of data is quite good and it indicates that no major errors were made in the numerical data processing. The electrosorption valency displays a linear dependence on the electrode potential, which points to a quadratic dependence of the Gibbs energy on E. For a one-state adsorption of an organic molecule, the energy of adsorption is expected to be a quadratic function of the electrode potential (20, 30).

Figure 8 shows the dependence of the electrode potential on the surface concentration of pyrazine at selected values of the charge density at the metal. The E versus Γ plots are nonlinear; however, as in the case of electrosorption valency, only the initial slopes of these curves need to be compared to the derivative of the Gibbs energy with respect to charge. The initial slopes of the E versus Γ curves are plotted as points against the charge in Fig. 9. The solid line in Fig. 9 is the derivative of the Gibbs energy with respect to charge. With the exception of a few points corresponding to small values of $(\partial E/\partial\Gamma)\sigma_M$ the agreement between the two sets of data is very good.

In Fig. 8, the E versus Γ curve for zero charge contains useful information about the orientation of adsorbed molecules. For an uncharged electrode, a change of the potential with coverage is caused by the displacement of surface dipoles of water by the dipoles of the adsorbed molecule. This change is described by the Helmholtz formula:

$$[4] \quad \Delta E_{pzc} = (\mu/\varepsilon)\Gamma$$

where ε is the permittivity and $\mu = \mu^{org} - n\mu^{w}$ is the effective dipole moment, where μ^{org} and μ^{w} are the components of the dipole moment of the organic molecule and water in the direction normal to the surface and n is the number of water molecules displaced by one adsorbed organic molecule.

The E versus Γ curve for zero charge is nonlinear, which indicates that the magnitude of the effective dipole moment changes with coverage. Due to the nonlinear character of this dependence it is difficult to determine the shift of pzc due to displacement of water molecules by a monolayer of close-packed pyrazine molecules; that is, for Γ_{max}. However, we may estimate that this shift may be as large as −0.5 V. Independent studies have shown that the interaction of water molecules with the Au(111) surface is weak (31, 32). Consequently, at the pzc the preferential orientation of water is weak and the magnitude of μ^{w} is small. The relatively large shift of the pzc indicates therefore that μ^{org} must be quite large and the negative sign of the shift indicates that, in the organic molecule, the negative pole of the dipole is turned towards the metal and the positive pole towards the solution. The isolated pyrazine molecule has a zero dipole moment. However, at the electrode surface the adsorbed pyrazine molecule can acquire a dipole moment, induced by asymmetric interactions with the solvent and the metal phase. In the case of the vertical orientation, the lone pair of electrons from one nitrogen atom can mix with the electronic states of the metal, while the lone pair

from the second nitrogen atom can form hydrogen bonds with the water molecules. Therefore the dipole moment for the vertical orientation may be significant. The observed shift of the pzc is consistent with the vertical N-bonded orientation of pyrazine molecules at the Au(210) electrode surface.

SERS spectra of pyrazine at the Au(210) surface

Further information about the orientation of pyrazine molecules adsorbed at the Au(210) surface may be obtained from SERS experiments. Until recently, measurements of the SERS for adsorbed molecules were performed at electrode surfaces which had been roughened or activated by oxidation–reduction cycles (ORCs). These roughening procedures affected the crystallographic structure of the surface and the surface crystallography of the roughened electrode was always poorly defined. Recently, due to the advent of a new generation of high-sensitivity Raman spectrometers equipped with CCD detectors, the signal-to-noise ratio for Raman spectra has been significantly improved. Consequently, both the enhanced and unenhanced Raman spectra from molecules adsorbed at "smooth" surfaces of polycrystalline (33) and single crystal electrodes (34) have been reported. In this work we have taken advantage of the possibilities brought by the new instruments to record SERS spectra for pyrazine adsorbed at an "unroughened" gold electrode.

Figure 10 shows the SERS spectra of pyrazine adsorbed on Au(210) at several potentials. The peak at 1019 cm^{-1} corresponds to the ring breathing vibration. The weak peak at ca. 1030 cm^{-1} is due to the ring stretching mode. This mode is forbidden in the normal Raman spectrum of pyrazine in solution. We have recently shown (35) that this mode becomes active for adsorbed pyrazine due to a field gradient enhancement mechanism. Raman spectra of aqueous pyrazine solutions (36) show the ring breathing mode at 1015 cm^{-1}. This band for adsorbed pyrazine on Au(210) is at 1019 cm^{-1}; its frequency is, therefore, higher than for pyrazine in solution. This difference can provide qualitative information about the orientation of the adsorbed pyrazine molecule. For instance, a flat adsorbed pyrazine would interact with the electrode surface through π-electrons of the aromatic ring. This interaction is expected to decrease the frequency of the ring breathing mode when compared to the spectrum of the free molecule in the liquid state. The data presented in Fig. 10 show that the ring breathing mode of adsorbed pyrazine is shifted to higher frequences. This strongly suggests that pyrazine is adsorbed on the Au(210) electrode in an end-on configuration. Moreover,

Fig. 10 shows that the Raman peak position of pyrazine adsorbed on Au(210) is independent of the electrode potential. This indicates that the pyrazine orientation does not change with the applied potential, consistent with the electrochemical data.

Figure 11 shows the relationship between the surface coverage for pyrazine adsorbed on Au(210) and the SERS intensities (normalized using the perchlorate stretch mode from the solution). The increase of surface coverage correlates with the increase of SERS intensities for low surface coverage values. However, as the surface coverage increases and reaches a saturation value, the SERS intensities reach a maximum around ca. +100 mV and then decline (24). The difference in the dependence of these quantities (surface coverage and SERS intensity) on the potential has been observed before for the adsorption of pyridine on polycrystalline gold electrodes (11). The lack of relationship between surface coverage and SERS intensities for a heavily packed surface is due to electromagnetic effects. The interaction between dipoles of molecules adsorbed on a highly covered surface can depolarize the local electromagnetic field, causing a decrease in the SERS intensities (11).

Summary and conclusions

The major features of pyrazine adsorption at the Au(210) surface are as follows. The adsorption takes place predominantly at the positively charged surface and hence displays a remarkable asymmetry with respect to the sign of the electrode charge density. The charge and potential of maximum adsorption are large (σ_M varies between 26 and 20 $\mu C\ cm^{-2}$ and $E_{max} - E_{pzc}$ varies between +400 and +300 mV). The absolute values of the Gibbs energy of adsorption are large and their sign is negative (ΔG°_{ads} at E_{max} is equal to -39 kJ mol^{-1}). The Gibbs energy of adsorption displays a quadratic dependence on the electrode potential. The adsorption isotherms have only one inflection point and their plateau corresponds to the limiting surface concentration expected for a close-packed monolayer of vertically adsorbed molecules. These features suggest that the pyrazine molecule is chemisorbed at the Au(210) surface with one of the two nitrogen atoms directed towards the metal, at all potentials and charge densities. The SERS experiments demonstrated that the chemisorption must involve a mixing of the nonbonding orbital of the nitrogen atom with the electronic states of the metal. This behaviour is in contrast to the two-state character of pyrazine adsorption at the Au(111) electrode surface, where a flat, π-bonded, surface coordination was observed at the negatively charged surface and the vertical N-bonded coordination at positive charge densities. Apparently, the character of pyrazine adsorption onto gold depends strongly on the surface crystallography.

The present result shows also that pyrazine adsorption at gold and mercury is significantly different. Conway and coworkers (2–4) demonstrated that pyrazine assumes only one orientation, i.e., flat, at the mercury surface over the whole range of electrode charge densities and bulk pyrazine concentrations. The adsorption of pyrazine at the Au(210) surface constitutes, therefore, the opposite case where only the vertical orientation is observed. These extreme behaviours of pyrazine at the two metals show that different forces are involved in pyrazine adsorption at mercury and at gold. The interaction of a pyrazine molecule with Hg is weak and hence, as was shown by Conway et al., the character of its adsorption at mercury is influenced by the interaction of the adsorbed molecules with the solvent and by the strength of the metal–solvent interaction. The interaction between the pyrazine molecule and the Au(210) surface is stronger and the character of adsorption is determined by the metal–adsorbate interaction.

This point is further reinforced by the remarkable similarities between the adsorption of pyrazine and pyridine at gold electrodes (5, 6). The two molecules display the same two-state adsorption at the Au(111) electrode surface and the one state, N-bonded, adsorption at the Au(210) surface. Very similar differences between the magnitude of the Gibbs energies of adsorption at the Au(111) and Au(210) surfaces are observed for the two molecules. The main differences between surface properties of pyrazine and pyridine at gold electrodes are displayed in the slope of the adsorption isotherms at the Au(210) surface and the sharpness of the phase transition at the Au(111) surface. For pyridine adsorption at the Au(210) surface, the adsorption isotherms display extremely steep changes of the surface concentration from a value close to zero to the limiting surface concentration. These features are characteristic of a phase transition from a gaseous to a condensed state of the monolayer (37, 38). For pyrazine, the adsorption isotherms are less steep and display a continuous change of the surface concentration from zero coverage to the limiting, saturation value. Likewise, at the Au(111) surface, reorientation from the flat to the vertical geometry, observed around the pzc, is rapid for pyridine and gradual for pyrazine.

These differences show that a small change in the structure of the azabenzene molecule has quite an impact on the character of the lateral interactions between adsorbed molecules. Specifically, for monolayers of vertically oriented molecules at the Au(210) surface, the differences may be explained in terms of the different character of the adsorbate–solvent interaction (21). In the vertical orientation the pyridine molecule is coordinated to the metal surface through the nitrogen atom and its aromatic ring is directed toward the solution. The interaction of the surface molecule with the solvent must have a strongly hydrophobic character. In contrast, the second nitrogen atom of the pyrazine molecule can participate in hydrogen bonding to the solvent molecule. Therefore, it is not surprising that a miscibility gap occurs in a two-dimensional mixture of water and N-bonded pyridine, while surface pyrazine and water form a continuous series of solutions. Once again, the similarity between the surface behaviour of pyrazine and pyridine at gold electrodes is in remarkable contrast to the difference between the adsorption of these two molecules at mercury (1–4). These behaviours indicate that the surface properties of azabenzenes at electrodes of group IB metals are determined by the strength of the metal–adsorbate interaction.

Anodic oxidation of Au(111)

Marie Anne Schneeweiss, Dieter M. Kolb, DeZhong Liu, and Daniel Mandler

Abstract: The initial stages of the anodic oxidation of Au(111) were investigated by means of cyclic voltammetry as well as in situ scanning tunneling microscopy (STM). The results suggest that the place exchange process, which initiates the oxide formation, starts at step edges. The oxide phase was imaged in situ by scanning tunneling and atomic force microscopy (AFM). The topographic information acquired by the two techniques is compared.

Key words: gold, gold oxide, corrosion, scanning tunneling microscopy (STM), atomic force microscopy (AFM).

Résumé : Faisant appel à la voltampérométrie cyclique ainsi qu'à la microscopie à balayage de l'effet tunnel «STM» in situ, on a étudié les étapes initiales de l'oxydation anodique de Au(111). Les résultats suggèrent que le processus d'échange de place qui initie la formation de l'oxyde débute aux arêtes. Faisant appel à la microscopie à balayage de l'effet tunnel et à la microscopie de la force atomique «AFM», on a obtenu une image in situ de la phase oxyde. On a comparé les informations topographiques obtenues par les deux méthodes.

Mots clés : or, oxyde d'or, corrosion, microscopie à balayage de l'effet tunnel «STM», microscopie de la force atomique «AFM».

[Traduit par la rédaction]

1. Introduction

The use of metal in industrial processes or daily life often entails the problem of oxidation and corrosion. The first step towards protection of metal surfaces from corrosion is obviously a full mechanistic understanding of the processes involved in metal oxidation and corrosion.

As many of the metals concerned are reactive and, at ambient conditions, tend to be covered with a thin oxide layer, it is desirable to perform studies of the initial stages of oxidation and corrosion on structurally well-defined surfaces of an inert noble metal, for which the oxidation reaction can be controlled by the electrode potential, thus serving as a model system. Au and Pt have long since been used for this purpose.

Electrochemical oxide formation on gold single-crystal electrodes has been investigated in great detail by Conway and co-workers (1, 2). The mechanism that they proposed is generally accepted and will be summarized briefly as follows. A recent review article by Conway gives an excellent overview on oxide formation on noble metals, exemplified by the cases of Au and Pt (3).

In general, the anodic oxidation reaction comprises a number of steps, the first of which is the deposition of OH on the surface, the second one a restructuring process that involves a turnover of the MOH[2] dipoles in the surface, accompanied by the transfer of the second electron to form the oxide. In the absence of any specific adsorption on the surface during oxidation, a continuous deposition of OH should be expected, the repulsive interactions between the parallel-oriented MOH dipoles then causing the turnover process (restructuring). The presence of an adsorbate, however, can change the reaction path. An anion like sulfate, which adsorbs strongly at potentials less positive than the oxidation potential, affects the extent of OH deposition on the precovered surface. In such a case the adsorption of anions from the electrolyte constitutes the very first step in the oxidation reaction, as it has a profound influence on the following steps. The role of anion adsorption as a competitive effect in the initial stages of OH electrosorption was demonstrated by Angerstein–Kozlowska et al. (2) by creating conditions referred to as "anions on" and "anions off." In the latter case the electrosorption of OH and O could be resolved in the cyclic voltammogram (2). As the fourth and final step the formation of bulk oxide should be added to this list. This is generally proposed to proceed by a high-field-type mechanism as described by Mott and Cabrera (4, 5).

Detailed studies performed by Conway and co-workers (ref. 1, and literature cited therein) resulted in the following three-step model for the oxide formation on Au(111) in H_2SO_4: (*i*) sulfate (or, more likely, hydrogen sulfate) adsorption up to a complete $(\sqrt{3}\times\sqrt{7})$ adlayer precedes (*ii*) the electrosorption of OH or O, which are incorporated in the ordered sulfate adlattice. During the latter process, which takes place in the potential range of the peaks labeled OA1/2, OA3 (see Fig. 2), a repulsive interaction between the AuOH dipoles builds up and causes (*iii*) a turnover process, resulting in a two atom thick oxide layer. The turnover process takes place simultaneously with anion desorption and replacement (i.e., replacement–turnover process, RTO) in the potential range of the OA4 peak. For the discussion of the cyclic voltammograms,

however, we choose the expressions "first oxidation peak" and "second oxidation peak" instead of "OA1–3" and "OA4" as a means of simplification.

It has been known for quite some time, from conventional electrochemical studies (1, 6, 7), that an oxidation–reduction cycle (ORC) causes roughening of the electrode surface. Trevor et al. (8) were the first to employ in situ scanning tunneling microscopy (STM) to image a Au(111) surface in dilute $HClO_4$ prior to and after an ORC. They found that the formation of a complete monolayer of oxide was necessary in order to observe monoatomic deep pits on flat terraces after reduction, and they attributed the pit formation to a place exchange process during oxidation. Honbo et al. (9) were able to show that pit formation takes place during reduction rather than during oxidation. The same conclusions for Ag(111) were made earlier on the basis of reflectance measurements (10).

Meanwhile, several STM studies (11–16) and one AFM study (17) on this subject were performed. Our group (15, 16) has shown that the morphology of the gold surface after ORCs depends on whether the reduction was achieved by a cathodic potential sweep (resulting in pits only) or a potential step (leading to the formation of islands as well as pits).

For a long time it was not clear whether electrochemical surface oxidation would generate a crystalline oxide that would grow according to the laws of crystal growth. All STM results, though, have shown so far that the gold oxide layer is never anything else but rough and amorphous (9, 11–13). Reproducibly, we have found that the oxide layer as imaged by STM is rough, consisting of small hillocks 0.1–0.25 nm in height (16). Reports on crystalline gold oxide in the literature are rare and limited exclusively to the use of hydrothermal synthesis, which yields stable ruby red crystals of Au_2O_3 (18, 19).

The quantitative evaluation of data acquired by STM, in spite of its great power in monitoring processes on electrode surfaces on the nanometer scale, can nevertheless be problematic when the surface under investigation is an oxide rather than a metal. Topographic information (derived from imaging constant local density of states) cannot be taken at face value. Thus it was also desirable to image the oxide layer by AFM in order to compare and cross-check information from these two techniques. In addition, the use of AFM allows the imaging of thicker oxide layers. In this work, we compare the results for the oxide layer on Au(111) obtained by STM and AFM.

Furthermore, recent voltammetric studies with stepped Au(111) surfaces performed in the course of this investigation suggest a possible modification of the currently employed mechanistic model concerning the assignment of the various current peaks to the initial stages of oxide formation. We will discuss preliminary results about the dependence of the first oxidation peak on the defect density of the Au(111) surface.

2. Experimental

The STM measurements were performed with a Topometrix TMX 2010, using W tips electrochemically etched from a 0.25 mm diameter wire in 2 M NaOH and Pt–Ir tips (Pt to Ir ratio 80:20) etched in 3.4 M NaCN. To minimize faradaic currents at the tip–electrolyte interface, all tips were coated with Apiezon wax (20, 21). Tip and sample potentials were controlled independently of each other by means of a bipotentiostat.

The AFM measurements were performed with a Nanoscope II in the Department of Inorganic and Analytical Chemistry of the Hebrew University of Jerusalem, Israel. Commercial Si_3N_4 tips were used.

The electrolyte solutions were prepared from H_2SO_4 (Merck, suprapure), $CuSO_4$ (Fluka, puriss. p.), and Milli-Q water. For the STM measurements, a copper wire served as a convenient, low-noise reference electrode. For this purpose, $CuSO_4$ was added to the solution in all STM experiments. In the case of the AFM measurements homemade Hg/Hg_2SO_4 microelectrodes (0.41 V vs. SCE) were used as a reference electrode. In all cases, electrode potentials are quoted versus SCE.

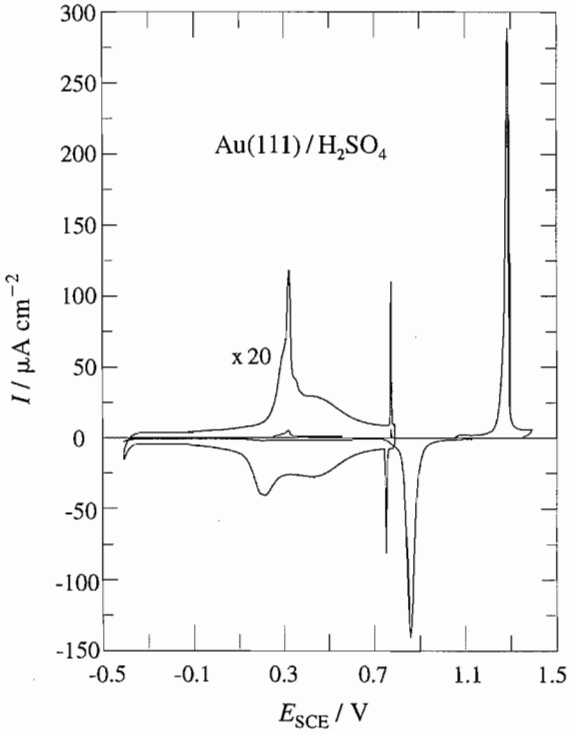
The gold samples used for STM and AFM experiments consisted of 200 nm thick films evaporated onto a special glass (AF 45, Berliner Glas KG) on top of a 2 nm Cr layer for better adhesion. The samples were annealed in a hydrogen flame for 2 min at yellow heat to yield large, atomically flat (111) terraces (22).

All STM data were recorded in the constant current mode, AFM data in the constant force mode. All images are displayed either as top views with different shades of grey, representing different heights (dark areas indicating low parts, and light areas high parts of the surface), or as three-dimensional plots based on shaded top views.

The cyclic voltammograms were obtained with standard electrochemical equipment and a conventional electrochemical cell with separated compartments for reference and counter electrode. Here, the Au(111) electrodes were single-crystal discs (MaTecK, Jülich), each with a diameter of about 4 mm and a gold wire attached to the back for better handling. Two of them were oriented and mechanically polished to better than 1°, but two were 3° and 6° off the [111] direction to yield stepped surfaces with an average terrace width of 6 and 3 nm, respectively. Prior to each experiment the gold crystals were annealed for 2 min in a Bunsen-burner flame and brought into contact with the electrolyte under potential control by the so-called dipping technique. In a previous STM study it was shown that flame annealing did not endanger the step structure by facetting, but produced regularly stepped surfaces with flat terraces of the expected width (23, 24).

3. Results and discussion

3.1. Cyclic voltammetry



Although the cyclic voltammograms for Au(111) in sulfuric acid solution are well known (1), our recent measurements with the stepped electrodes revealed some new aspects, which will be discussed here briefly.

Figure 1 shows a cyclic voltammogram for a freshly annealed Au(111) (<1°) single-crystal electrode in 0.1 M H_2SO_4 at 10 mV/s. The double-layer region (shown in Fig. 1 on an enlarged scale) displays these well-known characteristics: the sharp peak at about 0.3 V, associated with lifting of the reconstruction, and the sharp spike at 0.73 V, caused by a phase transition within the sulfate adlayer between random adsorption and an ordered structure (25). The current density of the sulfate spike has been shown to be a good indicator for the quality of a (111) surface, as it decreases with increasing defect (step) density of the surface (24). The double-layer diagram thus indicated that the crystal was extremely well prepared. Ex situ STM measurements showed that this crystal

Fig. 1. Cyclic voltammogram for Au(111) in 0.1 M H_2SO_4 at 10 mV/s. The scale for the current density in the double-layer region is enhanced to show details of anion adsorption.

exhibited terraces up to 1 μm in width. Compared to *I–E* curves from the literature, the first oxidation peak (at ca. 1.1 V vs. SCE), which corresponds to the so-called OA1/2 peak, is very small for such a surface. The maximum current density of the second peak (at ca. 1.28 V vs. SCE, corresponding to OA4), on the other hand, is extremely high. Cycling the potential again (see Fig. 2(*b*)) caused the first peak to increase slightly, whereas the height of the second peak decreased markedly. Similar effects have been reported by Hamelin (26) and were attributed to a change of surface topography with the first ORC.

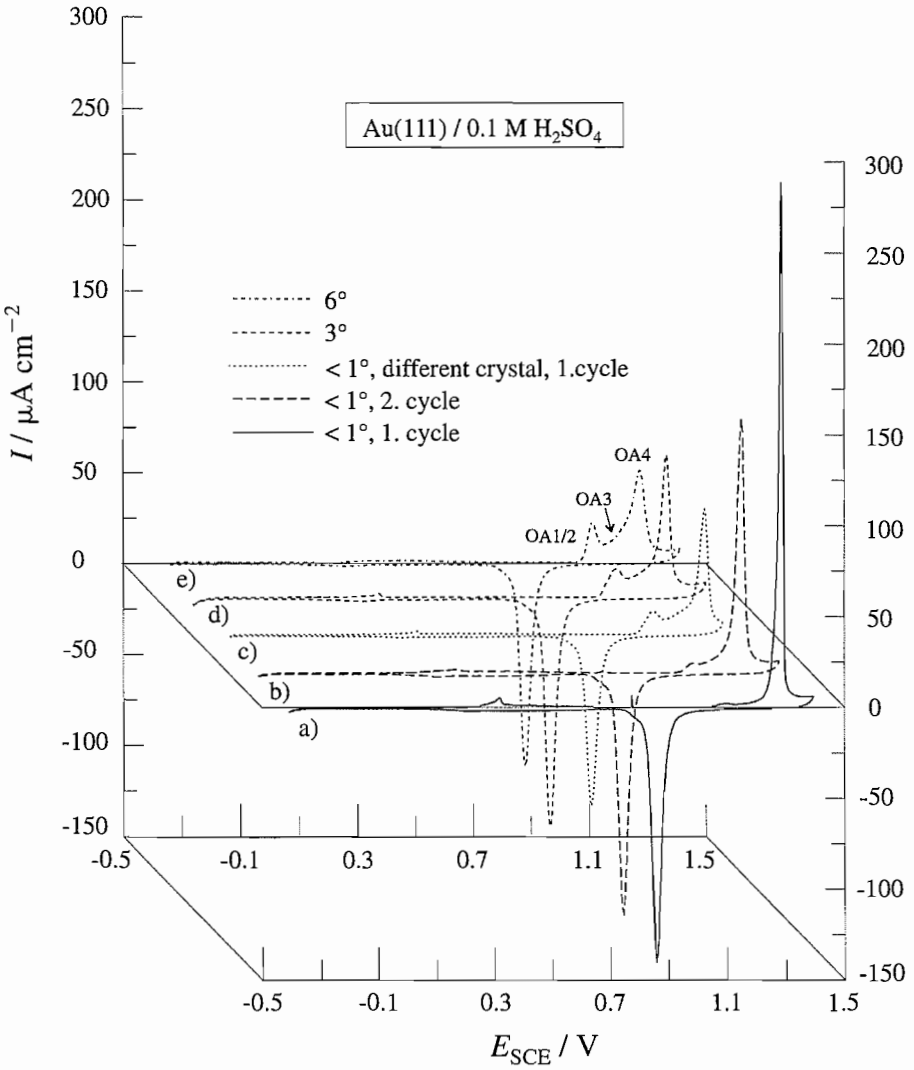
It is by now a well-known fact that the first ORC causes roughening of a virgin Au(111) surface by way of creating monoatomic deep pits. Thus it seems likely that the changes observed in the second cycle are due to changes in the surface topography caused by the preceding ORC, i.e., the increase in surface defects. This would indicate that the process related to the first peak is confined to defects, as the peak height depends on the defect density. This hypothesis is supported by preliminary results from experiments with stepped single-crystal electrodes. These crystals present the possibility of working with surfaces exhibiting a quantitatively assessable number of defects.

Figure 2 shows a compilation of ORCs for different Au(111) electrodes in 0.1 M H_2SO_4 (at 10 mV/s from −0.4 V vs. SCE to 1.4 V and back), illustrating our findings. Curve (*a*) refers to the first ORC on a freshly annealed, well-prepared electrode; this is the same curve as the one shown in Fig. 1. Curve (*b*) shows the second cycle on the very same electrode. Curve (*c*) is the first cycle of a different (111) crystal that, according to the manufacturer, also has a tilt of less than 1° from the [111] direction, but is obviously not as perfect as the former crystal. This voltammogram compares very well with the curves known from the literature and was used in ref. 16. The reduction peak in this curve is slightly smaller than in the others, as the potential was only scanned up to 1.3 V. Curves (*d*) and (*e*) show ORCs performed with the stepped electrodes, their surfaces tilted by 3° and 6° from the (111) plane, respectively.

The trend clearly shows an increase of the first peak with increasing defect (step) density on the surface. At the same time, the second peak decreases markedly in height. Within a certain margin of error, the total charge passed under both peaks on the anodic scan seems to be of the same order of magnitude in all five cases (570–630 μC/cm^2).

The first peak (OA1/2) is usually associated with OH^- deposition on the sulfate-covered surface. We reported in an earlier STM study that cycling the potential to an anodic limit within this peak causes no defects on the atomically flat terraces (16). We called the process associated with this peak reversible, in the sense that it leaves the surface intact after reduction. This observation seemed to agree with the established mechanism described above. The pronounced defect dependence of the first peak, however, appears to be at variance with the suggestion that peak OA1/2 represents OH^- adsorption and incorporation in the sulfate adlayer, which would be mainly at flat terraces.

We offer what at this point seems to be a reasonable explanation: turnover processes at step edges, which might be energetically favoured and hence occur at less positive potentials than those taking place on terraces, may be responsible for the majority of the charge passing under the first peak. This assumption does not necessarily disagree with the reversibility stated before, as the reduction of turned-over material on step edges would not affect the terraces. A more detailed study also taking into account the presence of islands, which are formed by lifting of the reconstruction (15), is in progress and is hoped to shed more light on the defect dependence of the onset of oxidation.



4. STM and AFM measurements

For slow anodic potential sweeps it is possible to show with in situ STM that oxidation (formation of a rough, turned-over phase) indeed begins preferably (although not exclusively) at step edges. Figure 3 shows a Au(111) surface during such an anodic sweep (0.5 mV/s) to 1.15 V. At 1.15 V, the step edges are densely decorated with a rough crust of 0.1–0.3 nm height, which is completely absent at 1.04 V, i.e., before entering the potential region of the first peak. Since, at even lower sweep rates, the turnover process can be observed to begin on terraces as well as on the step edges, it may be concluded that the onset of the turnover process at flat terraces is to a large extent governed by kinetics.

It is generally agreed that the main step in the oxidation process is the so-called turnover process, which is reflected in the STM image by roughening of the surface. The complete transformation of atomically flat terraces into a rough oxide-covered surface is illustrated in Fig. 4. Figures 4(*a*) and (*b*) are three-dimensional in situ STM images (125 nm × 125 nm) acquired at 0.8 V and 1.3 V, respectively, before and after the

Fig. 2. Cyclic voltammograms for different Au(111) electrodes in 0.1 M H_2SO_4. (*a*) and (*b*) First and second cycles for a well-prepared Au(111) electrode. (*c*) A different Au(111) electrode. (*d*) Stepped Au(111) single crystal with its surface tilted 3° from the (111) plane. (*e*) Stepped Au(111) single crystal tilted 6° from the (111) plane. Increasing defect density leads to an enhancement of the first oxidation peak and diminution of the second.

corresponding potential step. The topography of the rough, amorphous oxide layer has been characterized by several groups (11, 13, 16, 17) with AFM as well as STM, and will be discussed in some detail below.

Even at a potential just beyond the oxidation peak OA4, oxidation is assumed to continue, and thus thickening of the oxide film is expected. On the time scale accessible with STM, however, no increase in the surface roughness was found. In our experiment, the surface remained unchanged even after about 35 min at 1.3 V. At significantly longer times in the oxidation range, imaging of the surface with STM becomes increasingly difficult. (Experiments with AFM, however, showed that in the course of 16 h no marked change in the surface topography takes place and only a slight increase in roughness is found.) Figure 4(*c*) finally shows the effect of the surface-oxide reduction by a potential step down to 0.5 V. After reduction the surface exhibits the well-known characteristics, namely, monoatomic deep holes and monoatomic high islands.

In a previous study, we reported that the oxide-covered surface consists mainly of small hillocks about 0.1–0.25 nm in height and about 2–4 nm in width (16). Such dimensions correlate well with results of other authors (11, 13). In the meantime, however, we have been able to image the oxide layer with much better resolution, by STM as well as AFM, the latter resulting in a distinctly different appearance of the oxide-covered surface.

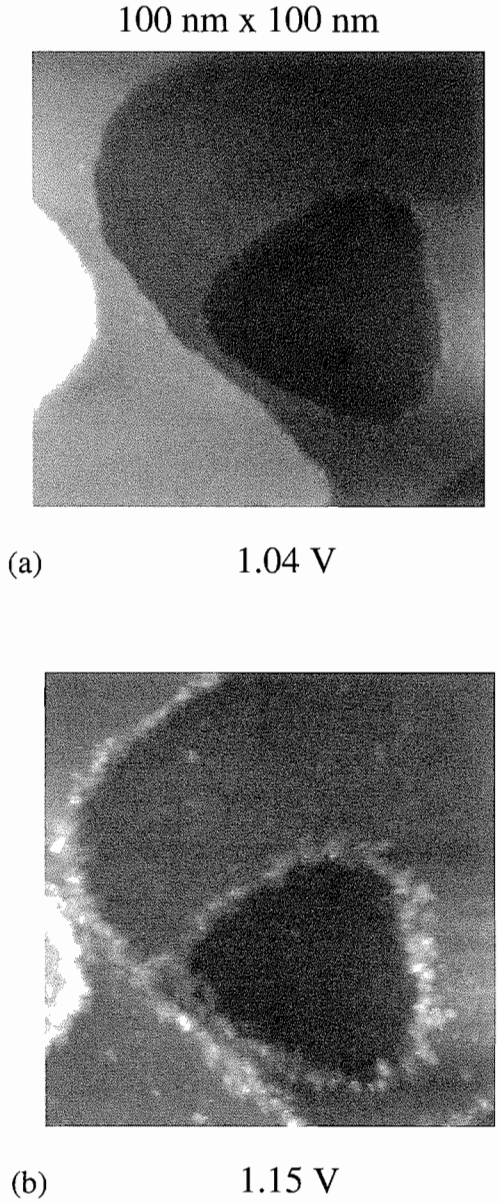

Figure 5 compares three images of the oxide layer under different instrumental conditions. Figure 5(*a*) represents an STM image obtained with a poorly resolving tip, while Fig. 5(*b*) shows higher resolution; Fig. 5(*c*) shows an AFM image. All three images were acquired on different samples but under similar conditions, namely at 1.3 V, which is just beyond the

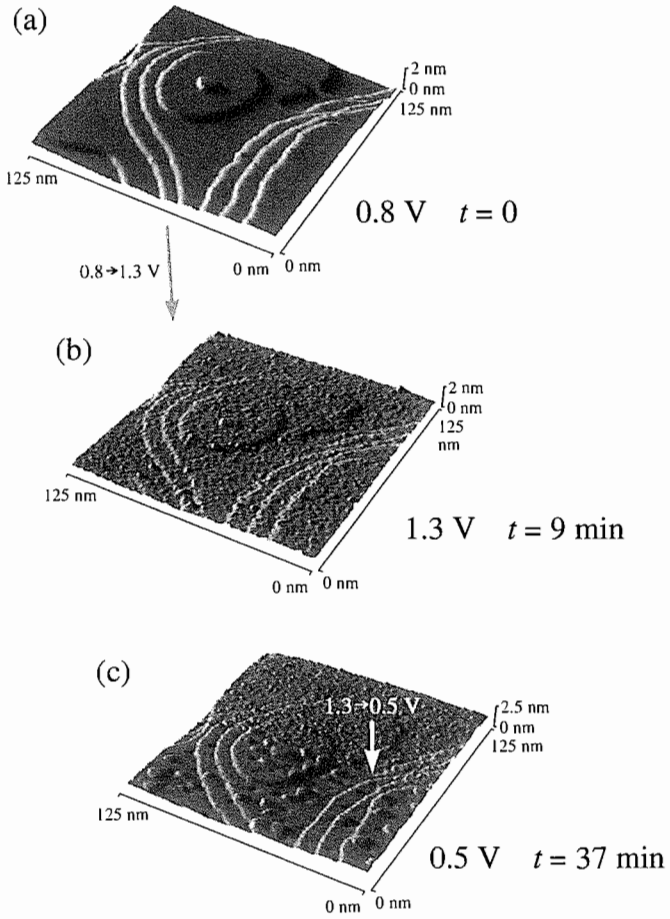

Fig. 3. STM images showing the onset of oxidation at the steps of a Au(111) electrode during a potential sweep to 1.15 V. Sweep rate: 0.5 mV/s. (*a*) At 1.04 V vs. SCE, the terraces are smooth, and the step edges sharp and distinct. (*b*) At about 1.15 V: the step edges are decorated with a crust of turned-over material. I_T: 2 nA. E_{tip}: 0 mV.

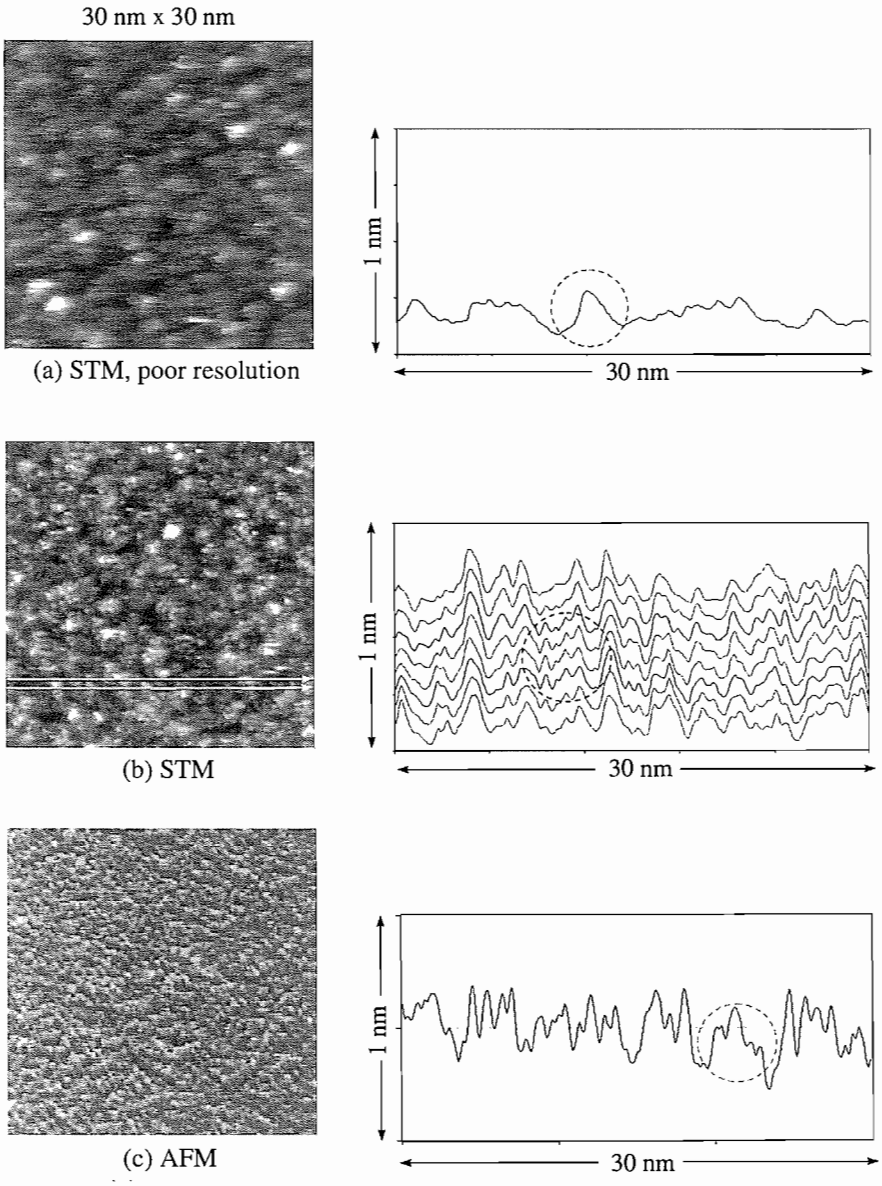
second peak. Images (*a*) and (*c*) were recorded after about 10 min of oxidation, image (*b*) immediately after reaching the oxidation potential. Because we have never found any indication that the structure of the oxide at this potential changes with time, it seems justified to regard the experimental conditions as equivalent. The images in Fig. 5 are accompanied by typical cross sections all drawn to the same scale. Figure 5(*a*) shows the oxide layer as a disordered arrangement of small clusters of oxide. A three-dimensional rendering of such an image would yield the familiar picture of hillocks 2–4 nm wide. In the cross section such a hill is marked with a circle.

At first sight the STM image in Fig. 5(*b*) presents the same

Fig. 4. STM images (125 nm × 125 nm) showing the oxidation of Au(111) in 0.1 M H_2SO_4 ($+10^{-3}$ M $CuSO_4$) and subsequent reduction by potential step: (*a*) before oxidation and (*b*) after a potential step to 1.3 V and 9 min at this potential. (*c*) After 35 min at 1.3 V, the surface topography did not change. Reduction was achieved by a potential step to 0.5 V (see arrow) and resulted in the appearance of monoatomic deep (high) pits (islands). I_T: 2 nA. U_T: −300 mV.



structure. On close examination, however, the hillocks are found to be aggregates of smaller structures, which can be resolved in the cross sections as well as in a three-dimensional display (see Fig. 6(*a*)). Here, the circle marks such an aggregation of small structures, which, in a less well-resolved image, would simply be shown as one hillock. Arrows in the STM image mark the uppermost and lowest of those scan lines, which are shown as cross sections. This sequence of scan lines is depicted to demonstrate the continuity of the small structures in real space, which serves to distinguish them from noise.

Finally, Fig. 5(*c*) shows an AFM image of the same structure. Here, the fine structure is even better resolved, and only the cross section reveals a certain bunching of the spiky structures in groups. In a similar AFM study of gold oxidation Manne et al. (17) also found aperiodic atomic-scale features in the oxidation regime, associating these with Au–OH moieties, but not commenting on height or width.

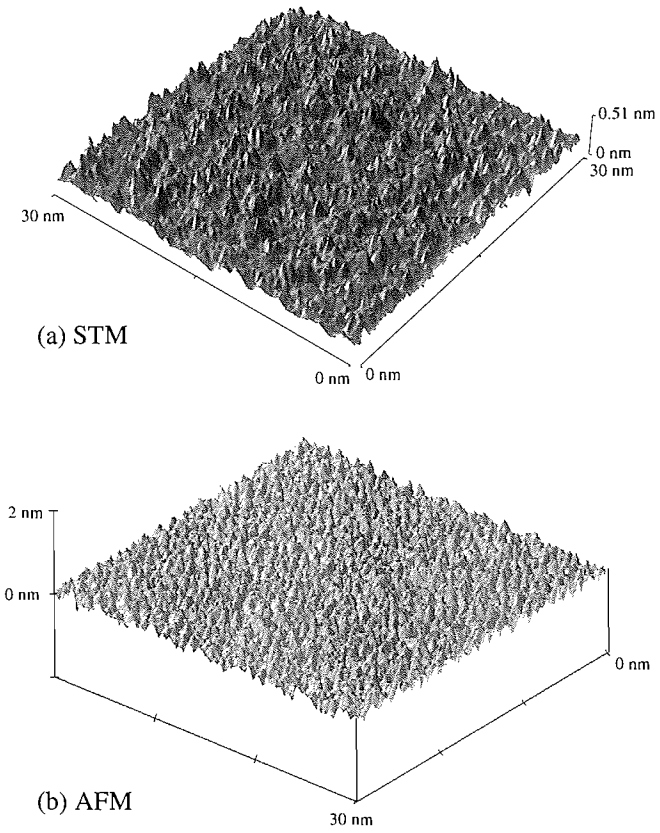
Fig. 5. Images (30 nm × 30 nm) of the oxide layer on Au(111) in 0.1 M H_2SO_4 ($+10^{-3}$ M $CuSO_4$) at 1.3 V. Also shown are cross sections that are typical for the image, all drawn to the same scale to allow a direct comparison. (*a*) Poorly resolved STM image showing the familiar surface structure consisting of small round hillocks. I_T: 2 nA. U_T: −300 mV. (*b*) A high-resolution STM image showing fine structure within the hillocks. I_T: 2 nA. U_T: −300 mV. (*c*) AFM image, where again the fine structure is well resolved.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12
For personal use only.



For a better comparison, in Fig. 6 the topographical three-dimensional plots of a high-resolution STM image (*a*) and an AFM image (*b*) are set against each other (because of the two different image-analysis softwares used, the two *z* scales could not be drawn to match each other exactly). Although the small clusters are of similar width (1–2 nm), the corrugation is larger in the AFM image (about 0.3 nm). It thus appears that the STM image of the oxide-covered surface is obscured by electronic effects, which are responsible for differences between the two images, particularly for smearing out the topographical fine structure.

5. Conclusions

We were able to show that the height of the first oxidation peak (OA1/2) in the well-known cyclic voltammogram for Au(111) in sulfuric acid solution depends strongly on the defect density of the surface. Curves obtained with an extremely well-oriented, freshly prepared crystal showed a sharp, and unusually high, second current peak (OA4) for the main oxidation process, whereas the smaller first peak at more negative potentials was almost nonexistent. After roughening of this electrode by an ORC, the height of the first peak

Fig. 6. (*a*) Three-dimensional plot (30 nm × 30 nm) of the STM data shown in Fig. 5(*b*). The small spiky features within the hillocks are clearly visible. (*b*) Three-dimensional plot (30 nm × 30 nm) of the AFM data shown in Fig. 5(*c*).

increased whereas the second peak decreased. Experiments with stepped single-crystal electrodes confirmed that this effect is due to an increased defect density on the surface. STM images obtained in the potential range of the first peak support the assumption that at least a large part of the charge passing under the first peak is caused by turnover processes at step edges. The second, very pronounced, current peak is assigned to turnover processes at terraces in accordance with existing theories.

The topography of the completely oxidized surface was imaged by STM and AFM, with superior lateral resolution. We have shown that the broad hillocks reported in previous STM studies consist of small clusters, which can be even better imaged by AFM. The results of both scanning probe techniques show that the Au(111) surface at 1.3 V is covered by these small disordered entities, which are about 0.1–0.3 nm in height and 1–2 nm in width. From a comparison of STM and AFM images we are led to conclude that the former are obscured by electronic effects. A more systematic comparison of images from STM and AFM might lead to interesting insights into the imaging mechanism of STM for oxide surfaces.

A practical approach to modeling the electrical double layer in the presence of specific adsorption of ions

Bruno Pettinger and Karl Doblhofer

Abstract: Model calculations are presented that yield in a straightforward manner the quantitative dependence of the specific adsorption of ions at electrode surfaces on the applied electrode potential (electrode charge). Furthermore, the double-layer capacitance and the potential at the outer Helmholtz plane (ϕ_2) are obtained. The derivation is based on Devanathan's three-capacitor model for the interfacial electric-potential distribution. A convenient correction function for the ϕ_1 potential accounting for the discreteness-of-charge effect is derived, largely on the basis of recent work by Conway et al. The results are shown to be in very good agreement with published work by Lawrence and Parsons on the double layer between Br^- electrolyte and the mercury electrode.

Key words: electrochemistry, specific adsorption, electric double layer, discreteness-of-charge effect.

Résumé : On présente des calculs modèles qui conduisent d'une manière directe à la relation qui existe entre l'adsorption spécifique d'ions sur des surfaces d'électrode et le potentiel d'électrode (charge de l'électrode) appliqué. De plus, on peut déduire la capacitance de la double couche et le potentiel au niveau du plan extérieur de Helmholtz (ϕ_2). Cette dérivation est basée sur le modèle de trois capacitances de Devanathan pour la distribution interfaciale du potentiel électrique. On a aussi dérivé une correction pour le ϕ_1 potentiel appropriée pour l'effet de discrétion de la charge; elle est basée principalement sur des travaux récents de Conway et al. On montre que les résultats sont en bon accord avec ceux publiés par Lawrence et Parsons sur la double couche entre l'électrolyte Br^- et l'électrode de mercure.

Mots clés : électrochimie, adsorption spécifique, double couche électrique, effet de discrétion de la charge.

1. Introduction

In modelling the electric double layer at the electrode–electrolyte interface, the discreteness of ionic charges (DC) constitutes a complicating feature. The DC effect has an important consequence: the potential that operates on ions in the electric double layer is different from its classical expression. The latter is derived for a double layer model where charges are distributed homogeneously in the inner Helmholtz plane (IHP) at x_1 for specifically adsorbed ions or in the diffuse layer for nonspecifically adsorbed ions. However, it is the potential difference, $\phi^{DC}(x_1) - \phi(s)$, between the IHP and the bulk solutions (and not the classical expression, $\phi(x_1) - \phi(s)$), that controls the adsorption process.

In a recent series of publications Marshall and Conway (1) proposed a new way of dealing with the problem of discreteness of ionic charge at the interface. Based on Conway's approach (1), along with classical double layer concepts (2–12), we have developed a straightforward way of simulating the parameters characterizing the electric double layer in the absence and presence of specific adsorption. In this paper we present our simulation procedure.

One might suppose that simulating the electric double layer is a subject that had been dealt with exhaustively about 30 years ago. Indeed, the basic concepts were developed at that time (13–26, see also refs. cited in ref. 27), and a number of experimental findings were related to theory via model calculations. See, for example, Grahame's comparison of experimental and theoretical work (21) or subsequent papers of Parry and Parsons (28), of D'Alkaine et al. (29), or of de Levie (30). However, to our knowledge there does not exist a convenient approach that would yield, for instance, the complete relationships between double layer capacitance and potential/charge, or the potential at the OHP as a function of the different double layer parameters in the presence of specific adsorption.

In presenting the model, the classical Gouy–Chapman–Stern theory and Devanathans's three-capacitor model of the interface are first briefly reviewed (13, 14). Second, a correction for the ϕ_1 potential, which accounts for the discreteness-of-charge effect, is introduced. Finally, model calculations are conducted. The results are compared with experimental data on the specific adsorption of Br^- ions on Hg electrodes (31).

Received March 10, 1997.

This paper is dedicated to Professor Brian E. Conway on the occasion of his 70th birthday.

Fig. 1. Illustration of the dependence of the free energy of ionic species (U) on the distance from the electrode surface (x). The situation (1) represents nonspecific adsorption, with x_2 (the equilibrium distance of the ions from the surface) defining the "outer Helmholtz plane," OHP. (2) Specific adsorption: x_1 defines the location of the "inner Helmholtz plane," IHP.

The ions are considered completely solvated, forming the diffuse ("Gouy") layer. The centers of the charge carriers can approach the electrode only to a minimum distance x_2, defining the position of the "outer Helmholtz plane" (OHP). The electric charge of the nonspecifically adsorbed ions will be designated as q_G.

(b) Specific adsorption

The surface excess may be enhanced by specific ("chemical") bonds formed between the adsorbed ions and the electrode surface. If such specific interactions are effective, the surface excess and the corresponding ionic excess charge q_1 are larger than in the case of nonspecific adsorption at the same value of q_M. Thus, q_M will be overcompensated, and additional adsorption of ions of the same sign as q_M is required to provide interfacial electroneutrality. It is assumed that only one ionic species is specifically adsorbed, i.e., the charge overcompensation is neutralized by q_G. The condition of interfacial electroneutrality may thus be formulated:

$$[1] \quad q_M = -(q_1 + q_G)$$

In Fig. 1, the case of specific adsorption at the interface is illustrated schematically by a potential distribution exhibiting a pronounced minimum at x_1, which denotes the distance between the electrode surface and the center of specifically adsorbed ions (which lose, at least partly, their solvation shell).

2.2 The adsorption isotherm

For convenience and clarity, but also because of the practical relevance, the emphasis in the presentation will be on the specific adsorption of anions. The situation may be characterized by the reversible reaction

$$[2] \quad X^- \rightleftharpoons X_1^-$$

where X^- is an anionic species in solution, and the subscript 1 indicates the specifically adsorbed state. At some point below, explicit reference will be made to the corresponding cations. Where this is not done, the extension to specific adsorption of cations is considered to be straightforward. Note that the potential of the electrolyte, ϕ_S, is taken as the reference value for the potential scale, i.e., $\phi_S \equiv 0$. The partial molar free energy of transferring an ion from the bulk electrolyte to the IHP is ΔG^0_{ad} at $\phi_1 = 0$.

Any partial electron transfer (32–36) between the electrode and the adsorbate is taken into account only via an appropriate choice of x_1; the ions are assumed to be present in a fully charged state at the IHP. This assumption appears justified in most cases, see, for example, Chap. 9.5 of ref. 36, and ref. 37, or the recent work of Philpott and co-workers on the adsorption of Br^- on Ag electrodes (38, 39). In some cases (e.g., the specific adsorption of OH^-) it is generally accepted that the ionic species itself is weakly specifically adsorbed ($\Delta G^0_{ad}(OH^-) \approx 0$) while the product of surface oxidation, (OH_{ad}), binds strongly to some metal substrates: $OH^- \rightleftharpoons OH_{ad} + e^-$, see for instance Gerischer (40).

Since the adsorbed ions "i" are considered fully charged, their surface density at the IHP, Γ_i^1, can be represented by the charge density at the IHP, q_1, where $q_1 = z_i F \Gamma_i^1$; z_i defines the sign and number of the ionic unit charges. Thus, a Langmuir isotherm can be used in the following form:

$$[3] \quad \frac{q_1}{q_1^0 - q_1} = \frac{c}{c^0} \exp\left(-\frac{\Delta G^0_{ad} + zF\phi_1}{RT}\right)$$

where q_1^0 is the surface charge corresponding to full coverage; c is the bulk concentration of the adsorbing ions in the electrolyte, c^0 is the reference concentration, $c^0 = 1$ mol cm^{-3}. Note that at relatively low coverages $q_1 \ll q_1^0$, and disregarding activity coefficients, the above isotherm corresponds straightforwardly to the condition of equal electrochemical potentials of the ions "i" in the bulk electrolyte and at the IHP.

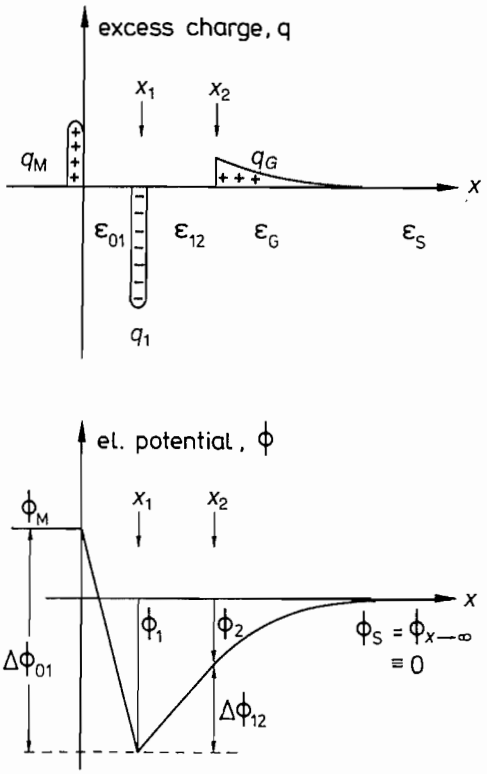
The Langmuir isotherm alone, which implies that ΔG^0_{ad} is independent of Γ_i^1, is a poor approximation for describing the adsorption equilibrium (41, 42). It is necessary to make an appropriate correction see the discussion of the "discreteness-of-charge" effect below.

2.3 The three-capacitor model of the interface

In Fig. 2 the distribution of the excess charge density, q, and of the electric potential, ϕ, across the interface between a polarized metal electrode (M) and an electrolyte solution (S) are shown schematically. Again, specific adsorption of anions is assumed.

From Gauss' law one can derive (6, 13) eqs. [4] and [5], relating the potential drop between the metal and the IHP, $\Delta\phi_{01}$, and the potential drop between the IHP and the OHP, $\Delta\phi_{12}$, with the excess charge density on the metal electrode, q_M, and in the Gouy layer, q_G, respectively.

$$[4] \quad \phi_M - \phi_1 = \Delta\phi_{01} = \frac{x_1}{\varepsilon_{01}\varepsilon^0} q_M = \frac{q_M}{C_1}$$



$$[5] \quad \phi_1 - \phi_2 = \Delta\phi_{12} = -\frac{(x_2 - x_1)}{\varepsilon_{12}\varepsilon^0} q_G = -\frac{q_G}{C_{12}}$$

The capacitances C_1 and C_{12} are defined by eqs. [4] and [5]. According to the classical concepts of diffuse-double-layer

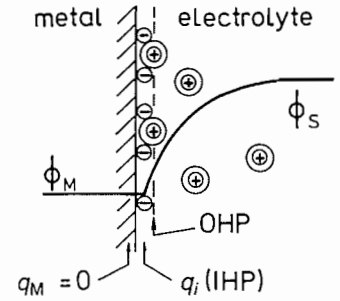
Fig. 2. Summary of the parameters used in the discussion of the interface between the polarized metal electrode (subscript M) and an electrolyte (subscript S). x_1 and x_2 mark the positions of the inner and outer Helmholtz planes, q_G is the charge of the diffuse part of the double layer ("Gouy layer"), and ε are the dielectric constants.

theory, the potential at the OHP, ϕ_2, and the diffuse-layer capacitance, C_G, are defined for a z–z type electrolyte by (12):

$$[6] \quad \phi_2 - \phi_S = \phi_2 = \frac{2RT}{zF} \sinh^{-1}\left(-\frac{q_G}{(8\varepsilon_G\varepsilon^0 RTc)^{1/2}}\right)$$

$$[7] \quad C_G = -\frac{dq_G}{d\phi_2} = zF\sqrt{\frac{2\varepsilon_G\varepsilon^0 c}{RT}} \cosh\left(\frac{zF\phi_2}{2RT}\right)$$



where c is the bulk concentration of this electrolyte, ε_G the relative dielectric constant of the electrolyte in the region of the diffuse layer (it is usually assumed to equal the bulk value), and ε^0 is the permittivity of free space. It is important to realize that the above equations are derived under the assumption of homogeneous charge distribution, i.e., "smeared out" charges.

From Fig. 2 it follows that the total interfacial potential drop is the sum of the three potential differences defined above:

$$[8] \quad E_z = \phi_M = \Delta\phi_{01} + \Delta\phi_{12} + \phi_2$$

where E_z is the rational potential, i.e., the electrode potential relative to the potential of zero charge observed in absence of specific adsorption. For convenience, the E_z potential scale will be used throughout the following discussions.

Fig. 3. Illustration of the potential distribution across the electrochemical interface at $q_M = 0$, in the presence of specifically adsorbed anions, disregarding the DC effect. According to this picture, the specifically adsorbed ions are at the same potential as the metal, $\phi_1 = \phi_M$.

2.4 The discreteness-of-charge (DC) effect

(*a*) *The necessity for considering the DC effect*

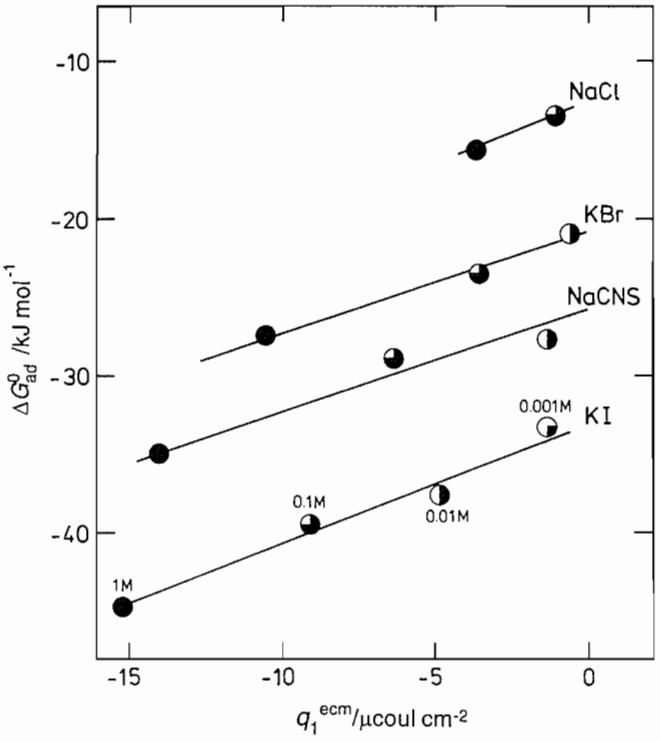
To emphasize the need for considering the discreteness-of-charge effect, we make use of the special interfacial situation prevailing at the potential of the electrocapillary maximum (E^{ecm}) in the presence of specific adsorption of ions. In Fig. 3, the interfacial potential distribution based on the three-capacitor model (disregarding the DC effect) is represented for anion adsorption. Since $q_M = 0$ at E^{ecm}, the potential drop between the electrode surface and the IHP should be zero (eq. [4]). Furthermore, the charge of the anions adsorbed at the IHP is compensated exactly by the charge q_G of counterions in the "Gouy" layer, i.e., for $q_M^{ecm} = 0$ the condition $q_1^{ecm} = -q_G^{ecm}$ is valid. Thus, at E_z^{ecm} the shift of E^{ecm} observed experimentally in going from absence to presence of specific adsorption equals ϕ_1, the electrical potential at the IHP:

DC effect disregarded:

$$[9] \quad \phi_1^{ecm} = E_z^{ecm}$$

Since values of E_z^{ecm} and q_1^{ecm} are well known for mercury electrodes (12), the standard free energy of adsorption (ΔG_{ad}^0) can be derived for such systems from the Langmuir isotherm considered, eq. [3]:

DC effect disregarded:



$$[10] \quad \Delta G_{ad}^0 = -zFE_z^{ecm} - RT \ln\left(\frac{q_1^{ecm}}{c(q_1^{max} - q_1^{ecm})}\right)$$

In Fig. 4, ΔG_{ad}^0 values are represented that were obtained with eq. [10] from the experimental data summarized by Grahame on p. 451 of ref. 12. Clearly, a variation of ΔG_{ad}^0 is found, suggesting increasing bond strength at increasing coverage with all the anions considered. This is an unsatisfactory result (41), demonstrating the limitations of the simple model. Similar conclusions, which point to the necessity for considering the DC effect, are reached on the basis of Esin and Markov's analysis of the experimental E_z^{ecm} values (43) see, for example, Parson's review (5) or Grahame's work on the DC effect (22), and the references given therein.

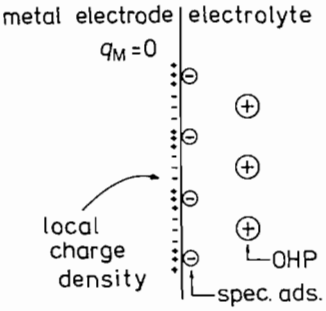
Fig. 4. Summary of ΔG^0_{ad} values obtained from the data of Grahame (12) with eq. [10], i.e., disregarding the discreteness-of-charge effect.

(*b*) *Deriving a correction for the DC effect*

An excess of electronic countercharge will accumulate in the metal surface near adsorbed ions because of the discreteness of the adsorbed-ion charge. The overall (average) condition $q_M = 0$ at E^{ecm} is fulfilled because of the effect of ions in the OHP on the charge distribution in the metal. Thus, the picture in Fig. 3 has to be modified (5) in a manner illustrated by Fig. (5). It follows that even when $q_M = 0$ there exists a significant potential drop between the metal and the specifically adsorbed ions that reduces the electrostatic repulsion experienced by the adsorbing ion approaching the interface from the electrolyte.



To approach this problem, we derive a DC-corrected value of the potential at the IHP in the Langmuir isotherm. This is done by adding a correction term, $\Delta\phi_{corr}$, to ϕ_1 in the isotherm equation. The following derivation of the DC correction is closely related to the one proposed recently by Marshall and Conway (1).

First, eq. [4] is reformulated to separate the effects of q_1 and q_G on $\Delta\phi_{01}$ (using eq. [1]: $q_M = -(q_1 + q_G)$):

$$[11] \quad \Delta\phi_{01} = -\frac{x_1}{\varepsilon_{01}\varepsilon^0}\, q_1 - \frac{x_1}{\varepsilon_{01}\varepsilon^0}\, q_G$$

The DC effect is assumed to operate only on the first term. The metal surface and the OHP are considered to form a parallel-plate capacitor (5), which can be approximated by a homogeneous charge distribution. For convenience we name the first term $\Delta\phi^{nG}_{01}$. It corresponds to the potential drop between metal and the IHP under the condition that the specifically adsorbed charge is completely compensated by

Fig. 5. The interfacial situation of Fig. 3, considering the discreteness-of-charge effect. A specifically adsorbed anion experiences a less negative potential ϕ_1 than would be predicted by the classical picture, Fig. 3.

q_M ("no Gouy", $q_G = 0$):

$$[12] \quad \Delta\phi^{nG}_{01} = -\frac{x_1}{\varepsilon_{01}\varepsilon^0}\, q_1 = -\frac{q_1}{C_1}$$

As shown in the Appendix, $\Delta\phi^{nG}_{01}$ can be straightforwardly corrected for the DC effect of specifically adsorbed ions. A correction factor f_{corr} is derived (eq. [24], Appendix) that leads to $\Delta\phi_{corr}$, the potential difference between the $\Delta\phi^{nG}_{01}$ value obtained for the homogeneous charge distribution (according to eqs. [4] or [12]) and the DC-corrected value of $\Delta\phi^{nG}_{01}$:

$$[13] \quad \Delta\phi_{corr} = f_{corr} \times \Delta\phi^{nG}_{01}$$

where the $\Delta\phi^{nG}_{01}$ is not DC corrected. The value of f_{corr} varies between zero and one:

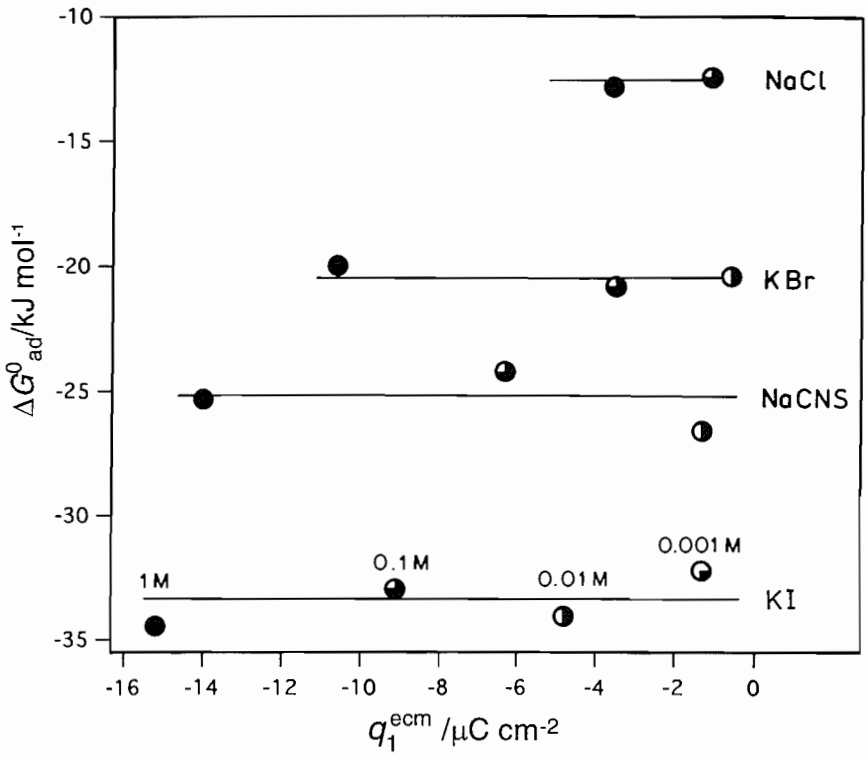
$$\lim_{q_1 \to 0} f_{corr} = 1, \qquad \lim_{q_1 \to \infty} f_{corr} = 0$$

It was found convenient to use analytical functions $f_{fit\text{-}corr}$ for describing the $f_{corr}(q_1)$ relation.

$$[14] \quad f_{corr} \approx f_{fit\text{-}corr} = \{[a q_1^{1/3}]^n + [c^m + (b q_1^{1/13})^m]^{n/m}\}^{-1/n}$$

where the parameters a, b, and c, used to draw the curves $f_{fit\text{-}corr}$, vary slightly with ε_1, as follows. For $\varepsilon_1 = 10$: $a = 0.318$; $b = 1.26$; $c = 1.01$. For $\varepsilon_1 = 7$: $a = 0.322$; $b = 1.32$; $c = 1.01$. For $\varepsilon_1 = 5$: $a = 0.318$; $b = 1.37$; $c = 1.01$. The fit function $f_{fit\text{-}corr}$ is easily applicable. Since it is sufficiently precise, it has been used to obtain the data discussed in the following.

3. Modelling the electrical double layer



3.1 General considerations

In the calculations, the values of ϕ_1 and $\Delta\phi^{nG}_{01}$ are first determined classically, i.e., disregarding the DC effect. Then, the $\Delta\phi_{corr}$ term, describing the potential shift due to the DC correction, is added to the ϕ_1 term in the isotherm equation [15]. This $\Delta\phi_{corr}$ term is additionally weighted by a factor f_{DC}, where $0 < f_{DC} < 1$. Thus, the isotherm takes the form:

$$[15] \quad \frac{q_1}{q_1^0 - q_1} = c \exp\left(-\frac{\Delta G^0_{ad} + zF(\phi_1 + f_{DC}\Delta\phi_{corr})}{RT}\right)$$

© 1997 NRC Canada

Fig. 6. Summary of ΔG^0_{ad} values derived from Grahame's data (12), as for Fig. 4, but under consideration of the discreteness-of-charge effect (eq. [15]). Values of $q_1^0 = 120\ \mu C\ cm^{-2}$, $\varepsilon_1 = 5$, $x_1 = 0.1$ nm, $x_2 = 0.2$ nm, $f_{dce} = 0.5$, and the DC-correction fit function from eq. [14] are used.

Using $f_{DC} = 0$ means that a DC correction is not applied. In this case one obtains results corresponding to the straightforward three-capacitor model, similar to those derived by Devanathan (13). Significant qualitative discrepancies are observed between such results and the experimental findings (see below).

Using the full DC correction ($f_{DC} = 1$) will usually overcompensate the DC effect. This is understandable, considering the simplifications made in the derivations (in particular, disregarding the DC effect of the counterions in the OHP, see Fig. 5). We find that values of $f_{DC} \approx 0.5$ lead to results that agree with experiment.

It should be noted that the correction for the DC effect is derived for one value of the dielectric constant: $\varepsilon_1 = \varepsilon_{01} = \varepsilon_{12}$. However, the correction is valid also when $\varepsilon_{01} \neq \varepsilon_{12}$, as long as $(\varepsilon_{01} + \varepsilon_{12})/2 = \varepsilon_1$. The agreement with experimental values tends to be better when a value of $\varepsilon_{01} < \varepsilon_{12}$ is used for the model calculations (see below).

3.2 Procedure for the model calculations

To minimize the chances of an error in the numerical calculations, each author developed independently a suitable computer program, (*a*) by programming directly in the Macintosh Graphing and Data Analysis System "IGOR Pro" (Wave Metrics), and (*b*) in FORTRAN.

In the numerical procedure, first, an array of q_M values is defined by the range (typically −20.0 to +100.0 μC cm^{-2}), and the intervals (0.25 or 0.5 μC cm^{-2}). Each q_M value is subjected to the following numerical routine:

(*a*) $\Delta\phi_{01}$ is determined via eq. [4].

(*b*) With a chosen value of ϕ_2 the values of q_G, $\Delta\phi_{12}$, and ϕ_1 are obtained.

(*c*) With the value of q_1 from the previous calculation $\Delta\phi_{corr}$ is determined.

With eq. [15] a new value of q_1 is found. The sum $q_1 + q_G$ is compared with $-q_M$; ϕ_2 is varied until the electroneutrality condition is fulfilled. The routine is repeated once, starting at (*b*) with the new values of ϕ_2 and q_1.

(*d*) The electrode potential E_z is evaluated (eq. [8]).

(*e*) The differential capacitance, C_{dl}, is found by dividing the differences between the actual and previous values of q_M and E_z.

3.3 Comparing simulation with experiment

(*a*) *The DC-corrected values of* ΔG^0_{ad}

In Fig. 6, the same experimental data as in Fig. 4 are analyzed on the basis of eq. [15], i.e., the correction for the DC effect, with $f_{DC} = 0.5$, is applied. As in all the following analyses, a value of $q_1^0 = 120\mu C\ cm^{-2}$ is used; see, for example, refs. 44 and 45. Clearly, as they should, the values of ΔG^0_{ad} obtained in this way are largely independent of the surface coverage (q_1^{ecm}). The value obtained for bromide adsorption, $\Delta G^0_{ad} = -20.4$ kJ mol^{-1}, will be used in the following model calculations.

(*b*) *Modelling adsorption isotherms and related quantities*

With the concepts discussed above, adsorption isotherms, $q_1(E_z, q_M)$, along with the corresponding values of ϕ_2 and C_{dl} are derived. The parameters $q_1^0 = 120\ \mu C\ cm^{-2}$, $x_1 = 0.1$ nm,

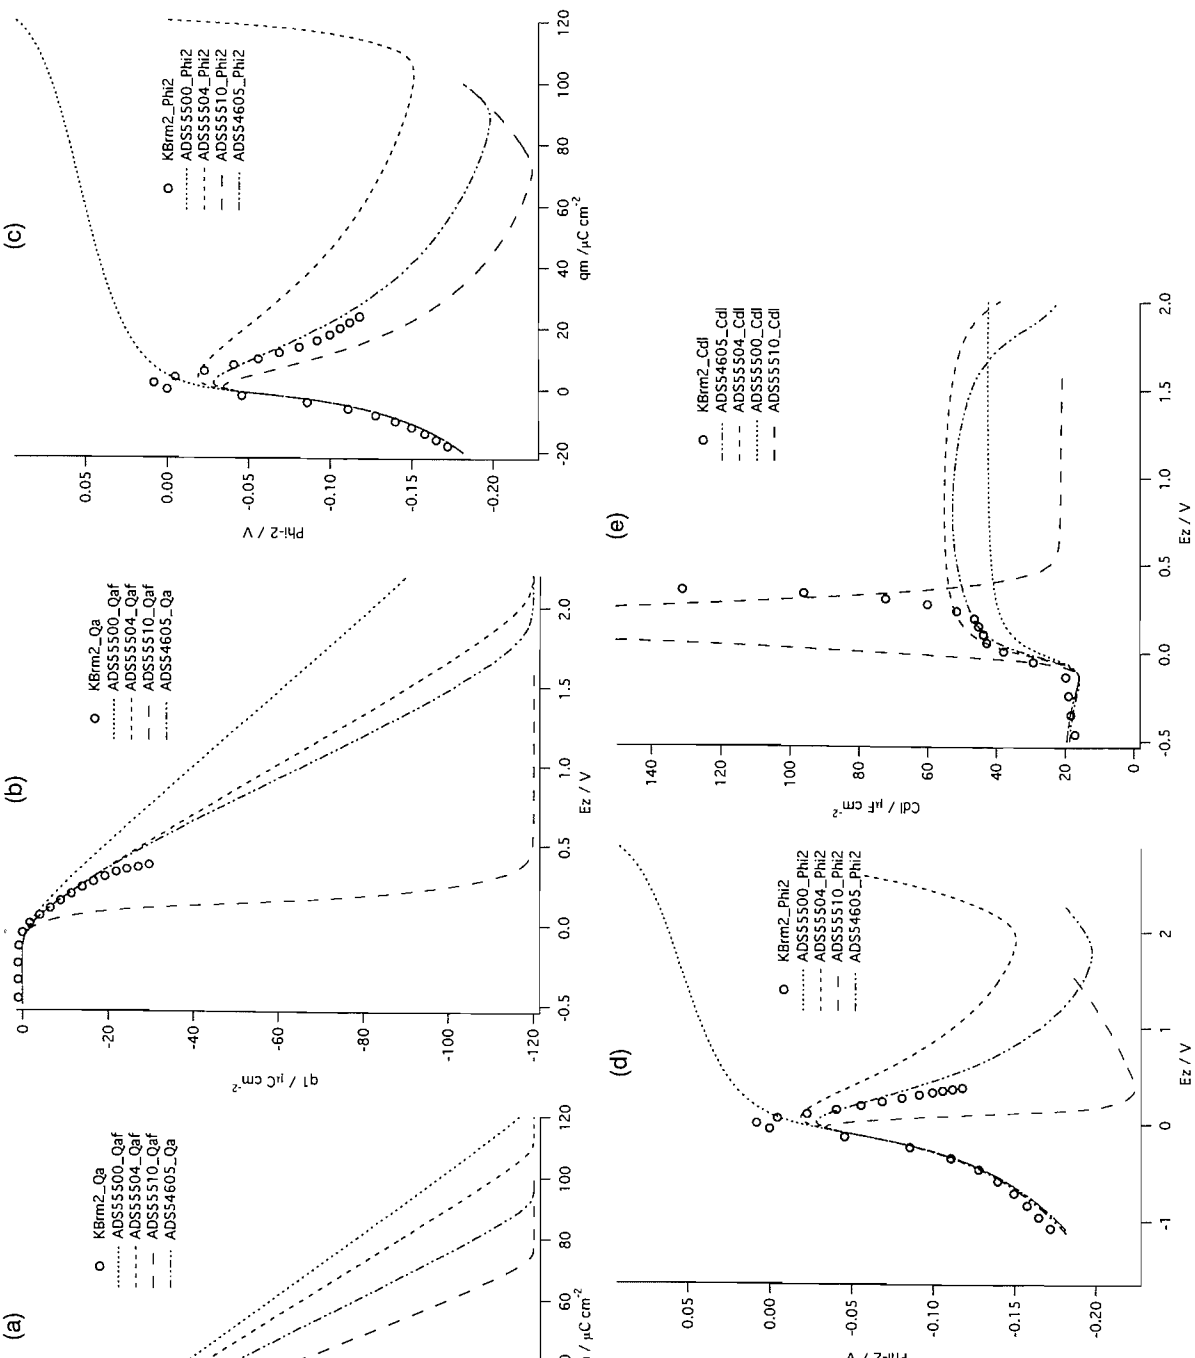

Fig. 7. (*a*)–(*e*) Results of model calculations corresponding to the electrical double layer between 0.01 M KBr and mercury electrodes. "ql" (= q_1) is the amount of anions adsorbed at the IHP, "qm" (= q_M) is the surface charge on the metal electrode; "Ez" (= E_z) is the electrode potential relative to the ecm in absence of specific adsorption; "Phi-2" (= ϕ_2) is the electric potential at the OHP. The experimental results of Lawrence and Parsons for 0.01 M Br^- (31) are included as circles ("KBrm2"). For the calculations the following parameters were used: $q_1^0 = 120$ μC cm^{-2}, $x_1 = 0.1$ nm, $x_2 = 0.2$ nm, and the DC-correction fit function for $\varepsilon_1 = 5$. The values of ε_{01}, ε_{12}, and of f_{DC} are given as the numbers following "ADS5" in the inset, e.g., ADS54605 means $\varepsilon_{01} = 4$, $\varepsilon_{12} = 6$, and $f_{DC} = 0.5$.

© 1997 NRC Canada

$x_2 = 0.2$ nm, the DC-correction fit function from the Appendix for $\varepsilon_1 = 5$, and an appropriate value of f_{dce} are used. The electrolyte concentration is chosen to be $c = 1 \times 10^{-5}$ mol cm^{-3}, so that the results may be compared with the experimental results of Lawrence and Parsons for 0.01 M Br^- (31), which are included in all the following diagrams, Figs. 7 (*a*)–(*e*), as circles.

4. Conclusions

From the comparison between the experimental double-layer parameters and those obtained by the simulation method outlined above, one may derive the following conclusions:

1. The state of the electrochemical interface Br^-/Hg is generally very well described by the model, in particular with $\varepsilon_{01} = 4$, $\varepsilon_{12} = 6$, see Figs. 7 (*a*)–(*e*).
2. The results obtained disregarding the discreteness-of-charge effect deviate significantly from the experimental findings, indicating the importance of the DC correction. Note in particular the significant qualitative deviations in the ϕ_2 results, Figs. 7 (*c*) and (*d*).
3. Preliminary studies on other systems have shown that the model presented above is appropriate for modelling a number of adsorption processes, e.g., I^- on Hg and Au electrodes.

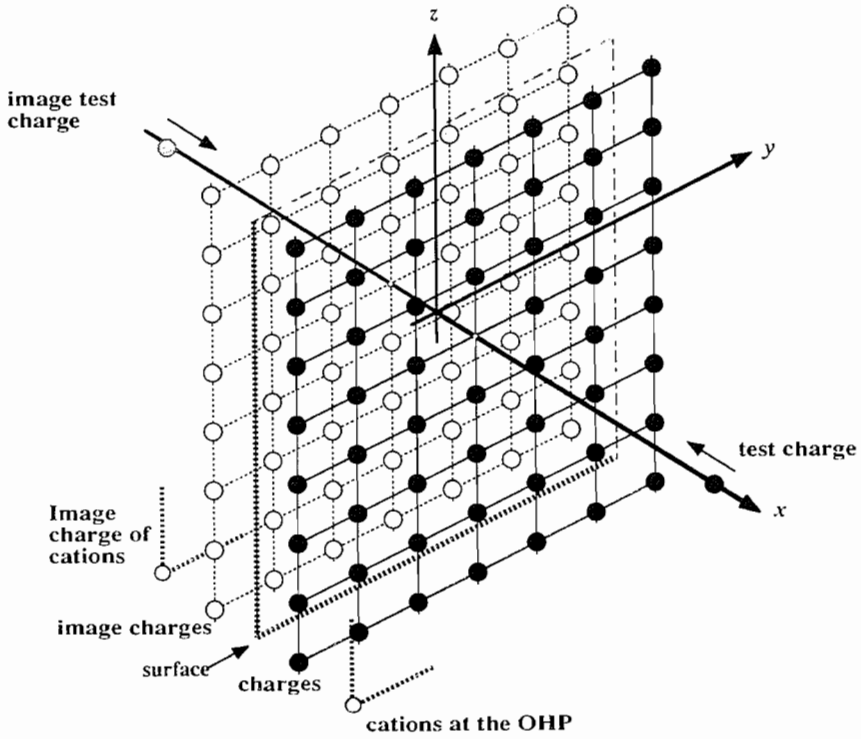
A. Appendix: The discreteness of charge effect



A.1 The concept

Very often, only homogeneous charge (HC) distributions are assumed when modeling the electric double layer (2–8). This simplification leads to a straightforward one-dimensional solution of the Poisson–Boltzman equation (PBE), but neglects the discrete nature of charges. The correct model would be a solution of the PBE or, better, a corresponding quantum mechanical formalism in three dimensions based on the correct charge distribution in space and time. This is, however, beyond the capability of today's theory and computers.

Fig. A1. Diagram of the an ionic array and its image array at the metal surface. The central ion and its image are removed. Both arrays and the image test charge constitute the local potential for the test charge.

A reasonable approximation is to consider point-like charges (and point-like dipoles) and to organize them at the interface in form of a lattice(s) (1, 25, 26). Usually, the next step of simplification is to consider only the specifically adsorbed ions and their images as discrete charges, but to treat the charges in the diffuse double layer and the excess charges on the metal side within the framework of homogeneous charge distribution. A number of approaches of that type, associated with the name of discreteness of charge (DC), have been employed during the last decades (1, 25, 26). Classically calculating the potential distribution across the interface one finds two different situations: at large distances from the surface both the hc and dc models yield the same result, but for locations close to the surface they differ (these differences in the potential distribution are illustrated in Fig. A4.

What is known in the literature as the discreteness of charge effect is just this difference of the potentials for the 1-D solution and the 3-D solution of the PBE, usually taken at the location of the anion. It is important, because the adsorption of anions is controlled by this 3-D potential difference existing between the locations $x_S = x_\infty$ and x_1.[2] $\Delta\phi_{1S}^{DC} = \phi^{DC}(\infty, 0, 0) - \phi^{DC}(x_1, 0, 0) \neq \Delta\phi_{1S}$. In this context, see also eqs. [5] and [6].

The precise calculation of the 3D-potential is rather difficult, not from the theoretical aspect but due to the fact that the sums involved are slowly convergent. This point and possible conceptional and mathematical solutions to this specific topic have been addressed in several papers (1, 25, 26).

Since we are interested in arriving at easy practical expressions, we will not focus on the details of how to convert slowly convergent sums into fast convergent ones. Instead we will present approximate, but sufficiently precise, expressions to describe the dc effect. On this basis we model specific adsorption (main section of this paper), of course in the framework of a rather classical concept. Our objective is to show that such a concept is fairly sufficient to reproduce experimental data, such as the ϕ_2 potential.

Let us consider a metal surface (perfect conductor) in contact with a dielectricum (electrolyte) and adapt the Gouy–Chapman–Stern model for the double layer: (*i*) an inner Helmholtz plane (IHP) at x_1 where the specific adsorbed anions are located, (*ii*) the outer Helmholtz plane (OHP) at x_2, and (*iii*) the diffuse layer or Gouy layer. The dielectric functions are denoted as $\varepsilon_{01}, \varepsilon_{12}, \varepsilon_G (= \varepsilon_S)$, respectively. Cationic or anionic charges are accumulated in the diffuse layer, depending on the actual Gouy potential, ϕ_G. A regular array of anionic charges is positioned at the plane z_1, with the origin of the coordinate system located in the plane of the metal surface. At the metal surface the corresponding countercharges are accumulated for electric neutrality.

The discreteness of charge is taken into account only for the charges at the IHP and their image charges. The array of anionic charges may be of hexagonal or quadratic nature or of any other regular type; the structural differences affect "only" the way the summation over the lattice has to be performed and, thus, the quantity of the computed numbers but not the general results.

[2] Note that in this appendix we use x as the direction vertical to the electrode surface and y, z as Cartesian coordinates located in the surface plane (see Fig. A1).

The central ion is located at the point $(x_1, 0, 0)$; therefore, the coordinates of the charges (anions) are given as $(x_1, y_k = kd, z_m = md)$, with $m, k = -\infty \cdots + \infty$. Similarly, we assume an array of image charges at $(-x_1, y_k = kd, z_m = md)$. m, k are integer numbers and d is the spacing of the lattice (this holds for a quadratic array; the modification for a hexagonal array is straightforward; see Fig. A1). Since we are seeking the potential felt by the central ion, we have to remove the central ion and its image charge from both arrays. Therefore, the summation runs over $m, k = -\infty \cdots + \infty$, with $k \neq 0$! The potential, $\Delta\phi$, at the point (x, y, z) provided by all n ions located at (x_1, y_k, z_m) and their images is given as:

$$[16] \quad \Delta\phi(x,y,z) = \frac{2e}{\varepsilon\varepsilon^0} \sum_{\substack{m=0 \\ k=1}}^{+\infty} \frac{1}{2} \left\{ \frac{1}{\sqrt{(x-x_1)^2 + (y-y_k)^2 + (z-z_m)^2}} - \frac{1}{\sqrt{(x+x_1)^2 + (y-y_k)^2 + (z-z_m)^2}} \right\}$$

with $y = z = 0$ and, substituting $\xi = x/d, \xi_1 = x_1/d$, one can replace the double sum by a function $S_0(\xi, \xi_1)$:

$$[17] \quad \Delta\phi = \frac{2e}{\varepsilon\varepsilon^0} S_0(\xi, \xi_1)$$

Note that lattice sums of this type are essentially an electrochemical equivalent of Madelung constants known in the field of calculations of lattice energies of ionic crystals (1).

The infinite sums over an ionic lattice alone are necessarily divergent, but the summation over ion array and image–ion array is slowly convergent. Marshall and Conway have shown how to transform these difference series into a fast converging sum (1). We show here the result and include the modifications to account for the two structures ($r = 3$, $l = 1$ and $r = 4$, $l = 0$ hold for the hexagonal or quadratic lattice, respectively):

$$[18] \quad S_0(\xi, \xi_1) = 2 \ln \left\{ \frac{|\sinh[2\pi(\xi + \xi_1)/\sqrt{r}]|}{|\sinh[2\pi(\xi - \xi_1)/\sqrt{r}]|} \left| \frac{\xi - \xi_1}{\xi + \xi_1} \right| \right\} + 8 \sum_{k=1}^{\infty} \sum_{n=1}^{\infty} (-1)^{lkn} \left\{ K_0 \left[2n\pi a_- \left(\sqrt{\frac{r}{4}}\, k \right) \right] - K_0 \left[2n\pi a_+ \left(\sqrt{\frac{r}{4}}\, k \right) \right] \right\}$$
$$+ 2 \int_0^{\infty} J_1(u) \ln \left[\frac{1 - \exp(-uA_1)}{1 - \exp(uB_1)} \right] du$$

where $K_0[w]$ is the modified Bessel function of zero order, $J_1(u)$ is the Bessel function of first order, and $A_1 = (x - x_1)/d$ and $B_1 = (x + x_1)/d$.

Next, for a four-layer interface (metal–IHP–OHP – diffuse layer), we have to consider that imaging of charges is occurring at all phase boundaries (1). Due to the mutual imaging of ionic and image charges there are further infinite series of images. If one locates the anions on the phase boundary IHP–OHP one can treat the IHP and OHP layers as a single layer with an average dielectric function of $\varepsilon_1 = \frac{1}{2}(\varepsilon_{01} + \varepsilon_{12})$. One has then to consider only two series of image charges for the phase boundaries (01) and (12) (see Fig. A2). To illustrate this, the potential vs. x for a single charge at $(x_1, 0, 0)$ including the infinite series of imaging is given:

$$[19] \quad \phi_{\mathrm{I}} = \frac{q}{\varepsilon_1 r} + \frac{q_{\mathrm{M}}}{\varepsilon_1 r_{\mathrm{M}}} + \left(\frac{q_1}{\varepsilon_1 r_1} + \frac{q_{1,\mathrm{M}}}{\varepsilon_1 r_{1,\mathrm{M}}} \right) + \ldots = \frac{q}{\varepsilon_1} \left(\frac{1}{x - a} - \frac{1}{x + a} + \ldots \right)$$

$$[20] \quad \phi_{\mathrm{II}} = \frac{q_2}{\varepsilon_2 r} + \frac{q_{2,\mathrm{M}}}{\varepsilon_2 r_{2,\mathrm{M}}} = \frac{2q}{\varepsilon_1 + \varepsilon_2} \left(\frac{1}{r} - \frac{1}{(r + 2a)} \pm \ldots \right)$$

The adaption of the above equation for an array of charges is obtained by substituting:

$$[21] \quad \left[\frac{1}{X(x) - a} - \frac{1}{X(x) + a} \right] \rightarrow dS_0 \left(\frac{X(x)}{d}, \xi_1 \right)$$

where $\xi_1 = z_1/d = z_1 * \sqrt{q_1/(100e)}$ and $a = z_1$. For further details on single and multiple imaging see ref. 1.

A.2 The DC correction

For a comparison of the two concepts, the homogeneous and the discrete charge distributions in the IHP, we have to calculate for both cases the potential distribution across the interface, $\phi^{\mathrm{DC}}(x)$ and $\phi(x)$. There are three contributions to this potential that are provided by the charges on the metal, the anions at IHP, and the ions in the diffused layer. Since we restrict the DC effect to the anion layer alone, only its contribution differs for the two cases, whereas all other contributions to the potential at any x remain unaffected and are additive (for a given/fixed interfacial charge distribution). Thus, we have

$$[22] \quad \phi(x) = \begin{cases} \phi_{\mathrm{a}}^{\mathrm{HC}}(x) + \phi_{\mathrm{M}}(x) + \phi_{\mathrm{G}}(x) & \text{hc model} \\ \phi_{\mathrm{a}}^{\mathrm{DC}}(x) + \phi_{\mathrm{M}}(x) + \phi_{\mathrm{G}}(x) & \text{dc model} \end{cases}$$

Note that

$$[23] \quad E_z = \phi^{\mathrm{DC}}(0) - \phi^{\mathrm{DC}}(\infty) = \phi(0) - \phi(\infty)$$

Fig. A2. Multiple imaging of the anion array. Note that for the actual calculation $a = \frac{1}{2}b$.

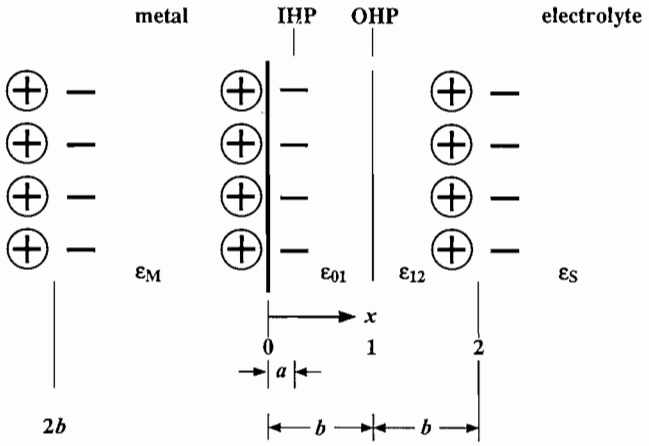

Fig. A3. Correction factor f_{corr} vs. charge density q_1 for three ε_1 values (ε_1 = 10, 7, and 5). Broken lines indicate the corresponding $f_{fit\text{-}corr}$ curves. ε_S = 78; z_1 = 1 Å, x_2 = 2 Å. For fit-equation and parameters see text.

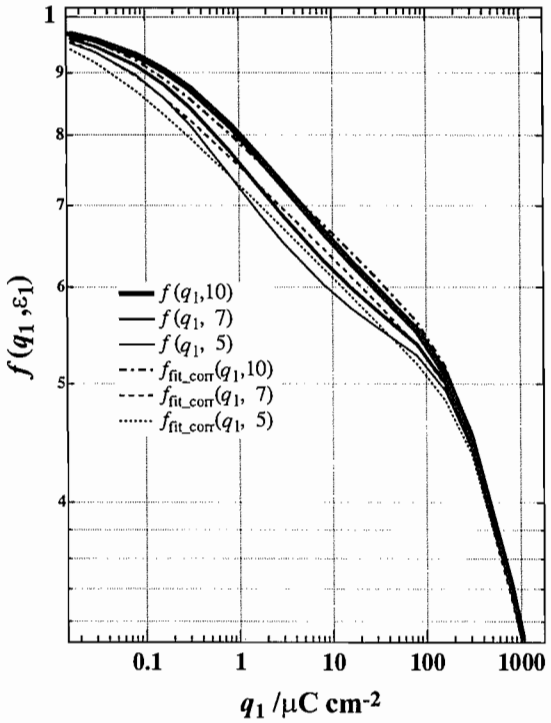

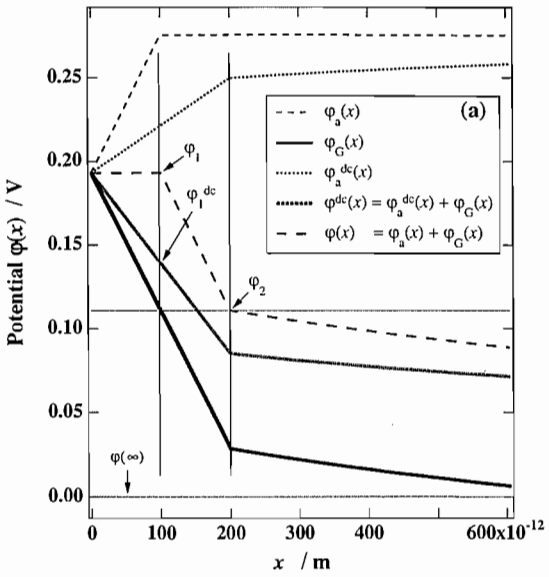

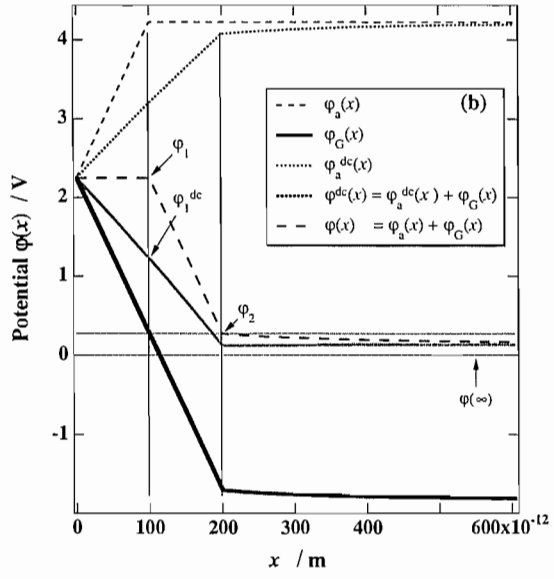

Fig. A4. Comparison of HC and DC potential distribution across the metal–electrolyte interface for the pzc case. Panel (*a*): charge density: 5 μC. Panel (*b*): charge density: 120 μC. The vertical lines indicate the x_1 and x_2 locations.

Since $\phi_a^{DC}(x, \xi_1, \varepsilon)$ depends via ξ_1 on q_1, it is convenient to plot the ratio of $f_{corr} = (\phi_a^{DC}/\phi_a) - 1$ vs. the anion charge density q_1. By multiplying this correction factor by ϕ_a we obtain the shift of the potential at x_1 from the classical to the DC value. Thus,

$$\Delta\phi_a^{(DC-(HC))}(x_1) = \phi_a^{DC}(x_1) - \phi_a^{HC}(x_1) = \left(\frac{\phi_a^{DC}(x_1)}{\phi_a^{HC}(x_1)} - 1\right)\phi_a^{HC}(x_1) = f_{corr}\phi_a^{HC}(x_1)$$

[24]

$$\phi_a^{DC}(x_1) = \phi_a^{HC}(x_1) + \Delta\phi_a^{(DC-(HC))}(x_1)$$

The dependence of f_{corr} on q_1 is shown in Fig. A3 in a semilogarithmic plot covering five decades of q_1. At low charge densities, f_{corr} is close to one. With increasing charge density the factor decreases. There are two regions of relatively linear behavior. Curves of this type can be easily approximated by fit-curves, which are given in Fig. A3 as broken curves. The analytical formula for the fit-curve is given in the main part of the paper (eq. [14]).

© 1997 NRC Canada

A.3 Potential distribution across the metal–electrolyte interface

For a given charge distribution, the comparison of HC and DC reveals a significant difference of the local potential across the interface. In contrast, the (external) potential, E_x remains unaffected. Figure A4 illustrates this behaviour for the case of potential of zero charge (pzc) and two distinct charge densities. Note the rather linear variation of the potential within $0 < x < x_2$. Since for the case of pzc the countercharges are located within the diffuse double layer, the total interfacial potential has to include the potential drop in the diffuse layer. Its relative contribution is, under pzc condition, larger the lower the ion concentration at IHP.

In addition, note that the HC case shows a zero potential gradient between the IHP and the metal surface, much in contrast to the DC case where a noticeable gradient is possible. This underlines the necessity of including the DC for an adequate determination of the adsorption isotherm and other related quantities of the electric double layer.

In situ X-ray absorption fine structure and optical reflectance studies of electrodeposited nickel hydrous oxide films in alkaline electrolytes

Yining Hu, In Tae Bae, Yibo Mo, Mark R. Antonio, and Daniel A. Scherson

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12

Abstract: X-ray absorption fine structure (XAFS) and optical reflectance spectroscopy (RS) have been used to examine in situ electronic and structural aspects of nickel hydrous oxide, α-$Ni(OH)_2$(hyd), electrodes supported on gold in alkaline electrolytes as a function of their state of charge. The extended X-ray absorption fine structure (EXAFS) of α-$Ni(OH)_2$(hyd) electrodes in the uncharged (UC, or discharged) and overcharged (OC, or *fully* charged) states yielded, in each case, a single set of two distinct nearest-neighbor shells, with distances, $d(Ni—O)_1 = 2.05 \pm 0.02$ Å and $d(Ni—Ni)_1 = 3.11 \pm 0.02$ Å for UC, and $d(Ni—O)_1 = 1.87 \pm 0.02$ Å and $d(Ni—Ni)_1 = 2.83 \pm 0.02$ Å for OC. The in situ EXAFS of films allowed to self-discharge following overcharge could be fit with contributions from both sets of shells, suggesting that only two types of nickel sites are sufficient to account for the redox chemistry of this material. These data, in addition to information derived both from quantitative X-ray absorption near-edge structure (XANES) and optical RS in the visible range, indicate that the excess anodic charge, i.e., beyond the one-electron oxidation of Ni^{2+} sites, observed during the first oxidation of freshly prepared α-$Ni(OH)_2$(hyd) electrodes may not be related to oxidation state changes involving nickel sites in the lattice, and, therefore, do not support the existence of nickel sites with a formal oxidation state higher than three for charged or overcharged electrodes in this media.

Key words: nickel oxide, reflectance spectroscopy, EXAFS, in situ measurements.

Résumé : On a fait appel à la spectroscopie d'absorption des rayons X («XAFS») et à la spectroscopie optique par réflexion (diffuse) («RS») pour étudier in situ, en fonction de leur état de charge, les aspects électroniques et structuraux d'électrodes formées d'oxyde de nickel hydraté, α-$Ni(OH)_2$(hyd), supporté sur de l'or, en présence d'électrolytes alcalins. La technique de la spectroscopie d'absorption des rayons X loin du seuil («EXAFS») d'électrodes de α-$Ni(OH)_2$(hyd) dans les états sans charge («UC») ou déchargé) et surchargé («OC») ou *complètement* chargé) ont permis, dans chaque cas, d'obtenir un seul ensemble de deux couches distinctes voisines les plus près, avec des distances de : $d(Ni—O)_1 = 2{,}05 \pm 0{,}02$ Å et $d(Ni—Ni)_1 = 3{,}11 \pm 0{,}02$ Å pour UC et $d(Ni—O)_1 = 1{,}87 \pm 0{,}02$ Å et $d(Ni—Ni)_1 = 2{,}83 \pm 0{,}02$ Å pour OC. Les spectres d'absorption des rayons X loin du seuil («EXAFS») in situ de films que l'on a laissé s'autodécharger après les avoir surchargés peuvent être ajustés aux contributions des deux ensembles de couches; ceci suggère que deux types de sites de nickel sont suffisants pour expliquer la chimie redox de ce produit. Ces données, prises en relation avec les informations obtenues à partir de la technique quantitative de spectroscopie de seuil d'absorption des rayons X («XANES») et de la spectroscopie optique par réflexion (diffuse) («RS»), indiquent que la charge anodique en excès, c'est-à-dire au-delà des sites de Ni^{2+} d'oxydation à un électron observés au cours de la première oxydation d'électrodes de α-$Ni(OH)_2$(hyd) fraîchement préparées, ne peut pas être reliée à des changements dans l'état d'oxydation impliquant des sites de nickel du réseau et que, en conséquence, elle n'apporte pas de support à l'existence, dans ce milieu, de sites de nickel dans un état d'oxydation formel supérieur à trois pour les électrodes chargées ou surchargées.

Mots clés : oxyde de nickel, spectroscopie optique par réflexion (diffuse) («RS»), spectroscopie d'absorption des rayons X loin du seuil («EXAFS»), mesures in situ.

Introduction

Considerable insight into the physicochemical properties of nickel hydrous oxide electrodes for rechargeable batteries and fuel cells (1) has been gained from UV–vis reflectance spectroscopy (RS) (2), substrate-enhanced Raman scattering (3), X-ray absorption fine structure (XAFS) (4), atomic force microscopy (5), and microgravimetric (6) measurements performed in situ. At least two, possibly related, issues still remain to be elucidated: the origin of the excess anodic charge observed during the first cycle of electrodeposited α-$Ni(OH)_2$(hyd) films (7), and the actual oxidation state of the nickel sites as a function of the state of charge of the electrode (8).

This paper presents in situ XAFS data for α-$Ni(OH)_2$ films electrodeposited onto a Au-coated polymeric film substrate (Melinex) acquired with a newly designed cell that enables detection of fluorescent X-rays through the back of the electrode. This arrangement, introduced originally by Kerkar et al. (9), and used extensively by Isaacs, Davenport, and coworkers in their studies of metal oxides (10), made it possible to record in situ Ni K-edge XAFS of nickel hydrous oxide films at potentials positive to that ascribed to their nominal full oxidation, without problems associated with oxygen evolution. Within the resolution of the EXAFS measurements, the results obtained were consistent with the presence of a single type of site for films in each of the fully reduced and the fully oxidized states. Evidence that the excess charge may be largely unrelated to changes in the oxidation state of the nickel sites in the lattice was obtained from quantitative in situ X-ray absorption near-edge structure (XANES) and complementary in situ optical reflectance spectra of electroprecipitated α-$Ni(OH)_2$(hyd) films on Au(111) recorded during the first and subsequent cycles.

Experimental

A. Film deposition

The electroprecipitation of α-$Ni(OH)_2$ films on Au(poly)/Melinex (XAFS) or Au(111)/quartz (RS) (11), was performed potentiostatically at −0.75 V vs. SCE from a 0.05 M $Ni(NO_3)_2$ aqueous solution, following the procedure described by Corrigan (12) in the same cells where the in situ spectroscopic measurements were carried out. The average current during deposition was in the range −1.0 to −1.4 mA/cm^2 for periods of 1–4 min for XAFS and 10–30 s for RS experiments. Subsequently, the SCE reference electrode (RE) was removed (and later replaced with a $Hg/HgO,OH^-$ RE), the nitrate solution discarded, and the cells then rinsed thoroughly with deionized water and filled with 1.0 M KOH. The amount of Ni per unit cross-sectional area of film can be estimated from the faradaic efficiency for the α-$Ni(OH)_2$(hyd) electrodeposition process (6*c*), determined in this and other laboratories (13), i.e., $2e^-$ per Ni site in the α-$Ni(OH)_2$(hyd) film. For the in situ XAFS measurements, the calculated value corresponds to ca. $(3.7–13.5) \times 10^{-7}$ mol/cm^2, that is, to less than 1/20 of one absorption length at the Ni K-edge (8333 eV). Under these conditions, all fluorescence spectra reported in this work are expected to be free of artifacts derived from self-absorption effects.

B. In situ spectroscopic measurements: cell design, data acquisition, and data analysis

In situ measurements were performed in 1.0 M KOH using either a $Hg/HgO,OH^-$ (XAFS) or a SCE (RS) reference electrode placed beside the working electrode, away from the path of the X-ray or optical beams.

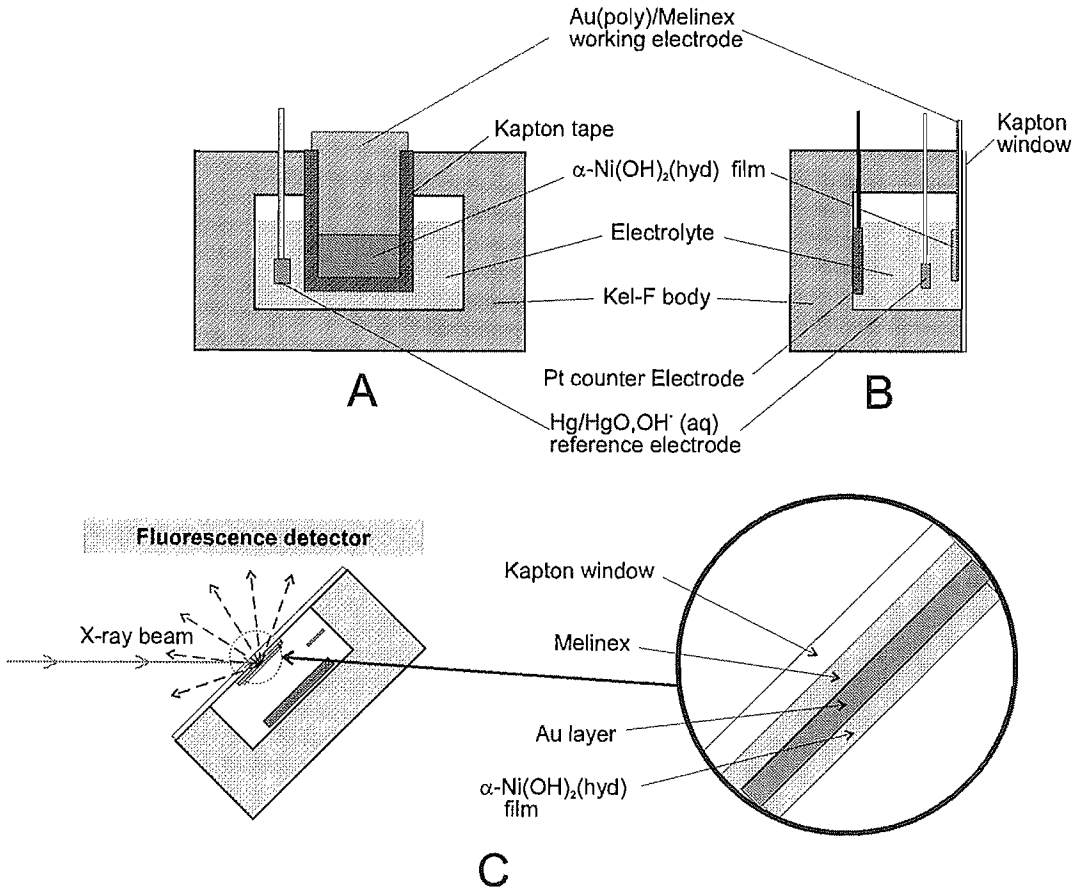
a. X-ray absorption fine structure

The main body of the electrochemical cell designed for in situ Ni K-edge XAFS measurements in the fluorescence mode through the back of the electrode is a block of Kel-F machined in the form shown in Fig. 1. The working electrode is a piece of Au-coated Melinex (2.2 cm × 1.2 cm × 0.02 cm thick) (14), with the three edges immersed in the solution covered by Kapton tape (50 μm thick), exposing an area of ca. 1.0 cm^2 to the electrolyte. The edge masking was found to stabilize the gold film against delamination during the rather long times (>6 h) required for the acquisition of a series of spectra. The electrode was affixed onto a much larger piece of Kapton tape, which was, in turn, attached to the cell to form a cavity that was filled first with the electrodeposition solution and, after forming and rinsing the film, with 1 M KOH. The thickness of the Au layer on Melinex, ca. 0.05 μm, is much thinner than one absorption length of Au at the Ni K-edge (ca. 2.7 μm). External connection to the working electrode was made using a clamp attached to the protruding end of the bare Au-coated film. The counter electrode was a ca. 1.3 cm × 1.3 cm Pt foil facing the working electrode at a distance of 1.2 cm.

Spectra were acquired at the Stanford Synchrotron Radiation Laboratory (SSRL, line 4-1) and at the National Synchrotron Light Source (NSLS, line X-23A2) with beam currents in the range of 40 to 100 mA at 3 GeV (SSRL) and of 100 to 180 mA at 2.6 GeV (NSLS). The beam was monochromatized with a set of Si(111) crystals (SSRL) or a servo-feedback stabilized Si(311) (NSLS) crystal. The fluorescence radiation was collected with a Lytle-type (SSRL) or a PIN diode detector (NSLS) (see Fig. 1). The Ni K-edge energy, defined as the first maximum in the derivative curve, i.e., 8333 eV, was calibrated using a Ni foil. The X-ray energy was scanned in the range −150 to −50 eV, and −50 to 50 eV (X-ray absorption near-edge structure, XANES) with respect to the Ni K-edge energy, in increments of 2 and 0.4 eV, respectively. In the extended X-ray absorption fine structure (EXAFS) region, i.e., 8383–9300 eV, the step size was 0.05 $Å^{-1}$.

Based on the results of more than five independent measurements over a period of 2 years, no significant differences could be found between data obtained at the two synchrotron facilities. For many of the experiments, in situ XAFS was recorded for the film in the reduced state before cycling; or in the uncharged state, after polarization at 0.6 V vs. $Hg/HgO,OH^-$ for a few minutes; or in the nominally oxidized state, following subsequent reduction; or the fully discharged state, after polarization at 0.6 V for an extended period of time, i.e., 1 h or more; or in the overcharged state; and, finally, after disconnecting the potentiostat while the electrode was overcharged, or the self-discharged state. Except for the self-discharged state, the potential was scanned at 1 or 2 mV/s until the desired value was achieved.

The features in the pre-edge region were resolved by subtracting from the normalized spectra an arctan fit to the tail of the main edge, excluding data in the energy range in which the peaks occurred (15).



The analysis of the EXAFS data was performed using EXAFPAK, a set of routines developed by I. Pickering and G. George at SSRL (16). Theoretical phase and amplitude functions calculated from FEFF 5.05 (17) were used for fitting the reduced EXAFS functions. Fourier transforms (FT) of the k^3-multiplied reduced EXAFS function ($k^3\chi(k)$) were obtained over the range 3.0-13.5 $Å^{-1}$ (Δk = 10.5 $Å^{-1}$). The first two prominent shells in the resulting FTs were back-Fourier transformed collectively using a window of 0.6–3.6 Å (Δr = 3.0 Å).

b. Reflectance spectroscopy

The cell used for the optical experiments was the same as that described earlier for simultaneous electrochemical, spectroscopic, and microgravimetric measurements involving the

adsorption of bromide ions on Au(111) (11). As indicated therein, the highly oriented Au(111) layer was formed by sputtering, in sequence, a layer of Ni (5 nm) and then a layer of Au (520 nm) on the surface of an optically polished quartz crystal wafer for quartz crystal microgravimetric (QCM) measurements. The specimens were subsequently removed from the chamber and then flame-annealed with a hydrogen torch.

The spectrum of the nickel hydrous film in the nominally fully oxidized state was acquired with a Harrick rapid scan spectrophotometer and found to be in agreement with that published much earlier by Lamy and co-workers (2). The reflectivity was monitored at constant wavelength, λ = 540 nm, while cycling the electrode linearly between 0.0 and 0.45 V vs. SCE. Each run always started with a freshly deposited α-$Ni(OH)_2$(hyd) film, to enable comparisons with coulometric data reported by Corrigan and Knight (7) for similar films.

Results and discussion

The cyclic voltammogram of α-$Ni(OH)_2$/Au(poly) on Melinex in 1 M KOH (not shown in this work), displayed characteristic features associated with the oxidation and reduction of the nickel hydrous film (see, for example, panel (*a*), Fig. 9) with essentially no overlap between the trailing edge of the oxidation peak and the onset of oxygen evolution.

Figure 2 shows in situ XANES obtained for a single α-$Ni(OH)_2$(hyd) film in the uncharged (UC, solid line), nominally charged (OX, broken line), overcharged (OC, dotted line), after full discharge (FD, not shown), and self-discharged (SD, dot–dash line) states following overcharge. Also shown in this figure is the pre-edge region in expanded form for clarity.

Plots of $k^3\chi(k)$ vs. k, for the film in the UC and OC states, and their corresponding non-phase corrected Fourier transforms are given in Figs. 3 (UC, curve *a*; OC, curve *b*) and 4 (UC, dotted line; OC, solid line), respectively. As clearly seen there, the $k^3\chi(k)$ EXAFS (Fig. 3) and the corresponding FT data (Fig. 4) for the film in the OC state displayed much larger amplitudes than those in the UC (or FD) states. The results of the statistical analysis of the entire series of in situ XAFS spectra run are compiled in Tables 1 and 2. The best two-shell (Ni—O and Ni—Ni) fits to the Fourier-filtered $k^3\chi(k)$ EXAFS for the UC and OC films are shown in Fig. 5. The subsections to follow address separately the pre-edge and edge regions, as well as the results of the EXAFS analysis.

well-defined, asymmetric peaks with maxima at energies (E_{peak}) in the range 8333.9–8335.9 eV (see Table 1). The magnitude of the peak separation, ΔE_{peak} = 2.1 (SSRL) or 1.6 (NSLS) eV, for the films in the UC and OC states (see Table 1 and Fig. 6) is up to twice as high as values reported by other

Fig. 4. Non-phase-corrected Fourier transform of the reduced EXAFS data in Fig. 3 for the (*a*) UC and (*b*) OC states.

authors for nickel hydrous oxide electrodes in the charged and discharged states (see Table 3, and ref. 4); however, it is well within the range of ΔE_{peak} values found ex situ for other oxides of transition metals of the first row per unit change in state of charge, e.g., ΔE_{peak} = 1.6 and 2.7 eV for Mn (18) and Fe (19), respectively. Particularly noteworthy is the shift in E_{peak} toward smaller values, found for the film in the SD state, to values intermediate between OC (or OX) states and FD states. This effect is consistent with the spontaneous reduction of the film, due, most probably, to a reaction with water. In addition, the kinetics for full oxidation (or overcharge) and full reduction were found to be relatively slow, despite the fact that the films are thin. This is evidenced by the time (more than 1 h) required for the edge to achieve its lowest (full reduction) or highest values (full oxidation or overcharge) following a change in oxidation state, i.e., polarization at 0.6 V for OX and OC, and 0.0 (or −0.15) V for UC (or FD). This is illustrated in Fig. 7 for a film that was first oxidized (curve *b*: long dashed line), starting from the UC state (*a*: solid line), and then overcharged (*c*: solid thick line). The in situ XANES in dot–dash lines (curve *d*) was acquired immediately after the potential had reached −0.15 V and that in short broken lines (curve *e*) an hour later under the same conditions, showing a clear shift toward lower energies.

Furthermore, as shown in Fig. 8, no significant differences could be discerned between the unnormalized in situ XANES of a freshly prepared film after the first (curve *b*: dashed line) and second oxidation without overcharge (curve *d*: thick solid line), even though the charge under the oxidation peak (not shown in this work) decreased by 9% in the second compared to the first linear scan in the positive direction. This observation suggests that the excess charge may not be related to nickel sites in the film (see below). Curves *a* (solid line) and *c* (dot–dashed line) in this figure are the corresponding

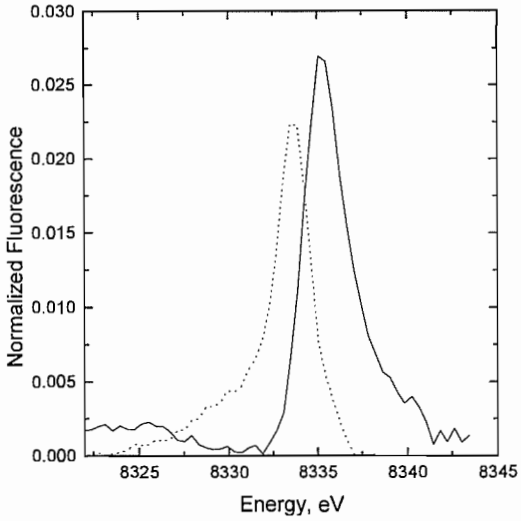
Fig. 5. Fourier-filtered EXAFS for the films in the UC and OC states (solid lines in *a* and *b*, respectively) as obtained by back-transforming the FT data of Fig. 3 between 0.6 and 3.6 Å. The broken lines are the best two-shell (Ni—O and Ni—Ni) fits to the filtered data.



unnormalized in situ XANES recorded for the film after preparation and after reduction following the first oxidation, respectively.

b. Edge region

The edge shift between films in the UC and OC states, as measured by the difference (Δ) in the magnitude of the energy at half the normalized fluorescence (E_{edge}, see Table 1), was 3.0 eV. This value is larger than that observed for the film in the OX state and indeed larger than any other reported previously for nickel hydrous oxides in the oxidized state (see Table 3). The same trend is also found for the edge position defined by the inflection point of the absorption edge (see Table 1). The

Fig. 6. Background-subtracted pre-edge features for an α-$Ni(OH)_2$(hyd) film in the UC (dotted line) and OC (solid line) states recorded in situ.

results obtained for the film in the five states of charge strongly suggest that E_{edge} is a monotonic, albeit not necessarily linear, function of the extent of oxidation. As was the case with ΔE_{peak}, E_{edge} are displaced toward lower energy upon self-discharge to yield values intermediate between OC and FD, supporting the view that the films reduce by a spontaneous reaction with the solvent.

B. EXAFS

A statistical analysis of the Fourier-filtered $k^3\chi(k)$ EXAFS for the films in the UC and OC states (shown as solid lines in Figs. 5*a* and 5*b*, respectively) produced the best fits shown in broken lines in Fig. 5. The bond distances, d, coordination numbers, N, and other relevant parameters, have been collected in Table 2. As shown therein, the first $(Ni—O)_1$ and second $(Ni—Ni)_1$ nearest-neighbor shell distances yielded, for films in the UC state, the values $d(Ni—O)_1 = 2.05 \pm 0.02$ Å and

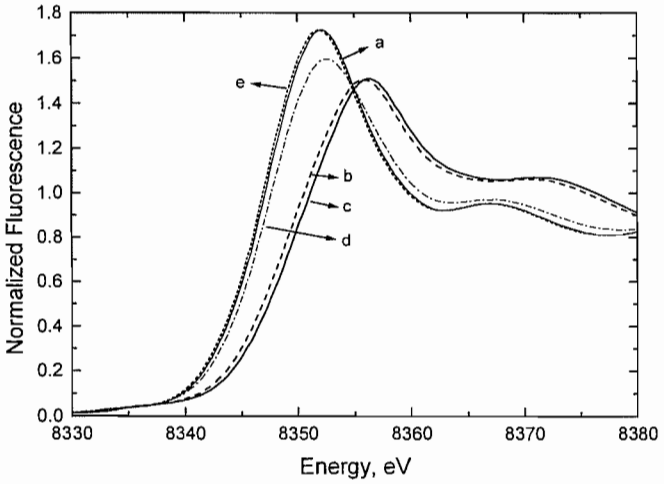
Fig. 7. In situ XANES for an α-Ni(OH)$_2$(hyd) film that was first oxidized (curve *b*, long dashed line), starting from the UC state (curve *a*, solid line), and then overcharged (curve *c*, thick solid line). The in situ XANES in dot–dashed lines (curve *d*) was acquired immediately after the potential had reached −0.15 V, whereas that in short dashed lines (curve *e*) was recorded an hour later under the same conditions.



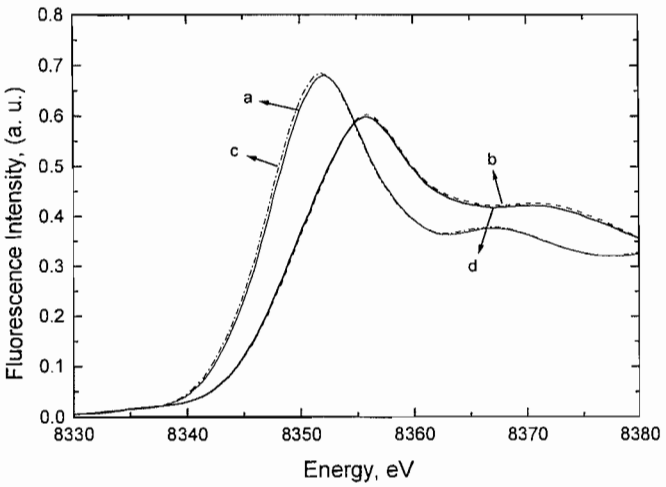


Fig. 8. Unnormalized in situ Ni K-edge XANES of a freshly prepared film (curve *a*: thin solid line), after the first oxidation (curve *b*: dashed line), following subsequent reduction (curve *c*: dash–dotted line), and after a second oxidation (curve *d*: thick solid line). The film was not overcharged.

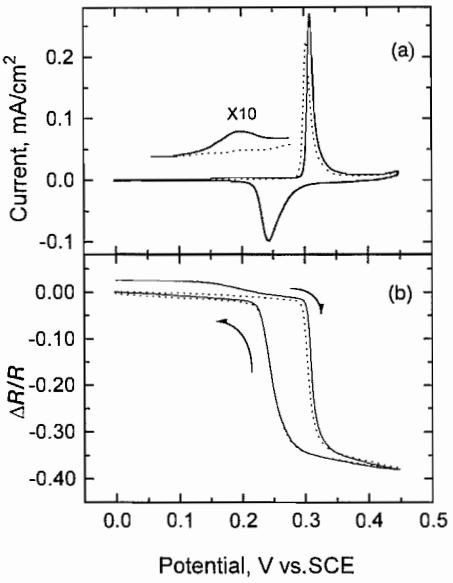
d(Ni—Ni)$_1$ = 3.11 ± 0.02 Å, which are substantially longer than those in the OC state, i.e., d(Ni—O)$_1$ = 1.87 ± 0.02 Å and d(Ni—Ni)$_1$ = 2.83 ± 0.02 Å. These distances are in excellent agreement with those obtained earlier in this laboratory using different measurement conditions (4*f*), and are well within the range reported elsewhere for uncharged (or discharged) and charged nickel hydrous electrodes (Table 3). Also in accordance with other work (4) are the corresponding values of N that, due to uncertainties in the magnitudes of the scale factors, exhibit much higher variability. The contraction of both Ni—O and Ni—Ni interatomic distances from the UC to the OC state may be responsible for the development of wide cracks upon oxidation of nickel hydrous oxide films supported on Au electrodes observed in this laboratory by in situ atomic force microscopy in the same electrolyte (5*d*).

The most significant aspect of the present study is that no evidence for the presence of a second set of shells could be obtained for films in the OC state by attempting to fit the in situ EXAFS with four (as opposed to two) shells. This observation affords rather strong evidence that, to the level of uncertainty of these measurements, there exists only one type of site for each — the fully reduced and fully oxidized species in these films. This finding is at variance with the results for nickel hydrous oxide electrodes in the oxidized state reported by other workers (see Table 3), who have found an additional Ni—O shell with d(Ni—O)$_2$ = 1.94 — 2.12 Å and, occasionally, a second Ni—Ni shell, with d(Ni—Ni)$_2$ = 3.00 — 3.19 Å. Three explanations have been offered (4*b*) to account for these extra feature(s): an incomplete oxidation of the film, a distortion of the octahedral symmetry, and the formation of a highly oxidized form of nickel, denoted as Ni^{4+}. The first of these possibilities appears strongly favored since, as shown in this work, films in the OC state yield, upon self-discharge, shells with the same bond distances as those found for the film in the UC or FD state, and the level of distortion of the octahedral symmetry around the nickel site, as judged by the intensity of the pre-edge peaks is low (< 3%) for both the UC and OC states.

C. On the question of the oxidation state of nickel in Ni hydrous oxide films

Attempts have been made to correlate the position of the absorption edge jump and the effective atomic charge of transition metal ions (20). As noted by Bianconi (21), however, there exists no linear relationship between these two parameters, since (*i*) the absorption edge jump is determined by the threshold of dipole-allowed transitions, and, hence, on the mixing of *d* and *sp* orbitals of the unoccupied states, and (*ii*) the energy of multiple scattering resonances depends markedly on the interatomic distance, giving rise to a much larger energy shift compared to that of the core exciton (pre-edge peak).

A good illustration of this lack of correlation was obtained for Mn oxides by Schultze et al. (18), who concluded that a simple measure of the edge energy is unsatisfactory for determining the oxidation states of unknown oxides.



In contrast, excellent correspondence has been found between the maximum energy of the pre-edge peak (E_{peak}) and the oxidation state, by Schultze et al. (18) for Mn oxides and by Bajt et al. (19) for Fe oxides. However, for oxides of transition metals of the first row, ΔE_{peak}, the difference in E_{peak}, per unit oxidation state, spans a wide range of values; hence, it becomes impossible, based solely on the magnitude of ΔE_{peak}, to establish the oxidation state of nickel in the overcharged films. This assignment is further complicated in this case by the lack of well-characterized, genuine inorganic Ni^{3+} and Ni^{4+} oxide species that could serve as standards for comparison.

Much of the controversy surrounding the oxidation state in these charged or overcharged materials may be traced to the work of Corrigan and Knight (7), who noted that the charge obtained during the initial oxidation of electrodeposited

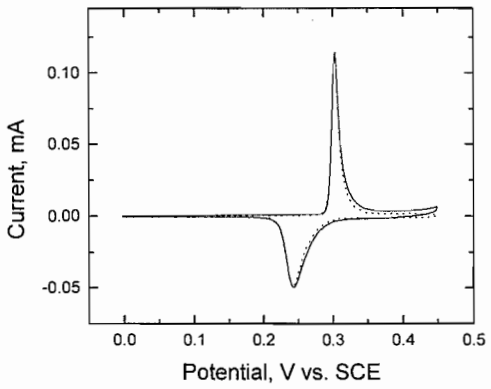
Fig. 9. First (solid line) and second (broken line) cyclic voltammograms (panel (*a*)) and normalized reflectivity data $\Delta R/R$ vs. E, where $\Delta R/R = [R(E) - R(E_{ref})]/R(E_{ref})$ and E_{ref} is the potential just before the onset of film oxidation (ca. 0.3 V in the first cycle) (panel (*b*)), recorded simultaneously for an α-$Ni(OH)_2$(hyd) film, ca. 15 nm thick, in 1 M KOH (see text for details). Scan rate = 2 mV/s.



α-$Ni(OH)_2$(hyd) on Au(poly) was larger, ca. 1.5 e^- per nickel site, than that expected for the full one-electron oxidation of the film. Rather good agreement with a single one-electron process was obtained, however, after the first oxidation–reduction cycle, leading these authors to suggest that the redox process involves the oxidation (and reduction) of Ni(2.5) (and Ni(3.5)). Some insight into the origin of this effect was gained from in situ reflectance spectroscopy (RS) measurements to be described in the next section.

D. Reflectance spectroscopy

Figure 9 displays the first two cyclic voltammetry curves (panel (*a*) for an α-$Ni(OH)_2$(hyd) film (ca. 15 nm thick) in 1 M KOH, deposited via the method described in the experimental section for a Au(111) electrode. The optical data recorded at a constant wavelength (λ = 540 nm) during these scans are shown in the form of $\Delta R/R$ vs. E plots (see panel (*b*) in this figure), where $\Delta R/R = [R(E) - R(E_{ref})]/R(E_{ref})$ and E_{ref} is the potential just before the onset of film oxidation, ca. 0.3 V. As indicated therein, the optical signal during the first scan in the positive direction remained constant up to a potential of 0.15 V vs. SCE and decreased linearly thereafter down to the onset of the prominent oxidation peak, ca. 0.3 V vs. SCE. The optical behavior in the range 0.0–0.3 V is characteristic of gold in aqueous electrolytes. In particular, the potential at which the reflectivity curve undergoes a change in slope (ca. 0.15 V in this case) corresponds to the onset of gold oxide formation (see expanded section of the voltammogram in panel (*a*), Fig. 9) (cf. ref. 11). As the film was gradually oxidized, the reflectivity was found to decrease markedly, down to the trailing edge of the oxidation peak (ca. 0.35 V vs. SCE), and much more slowly thereafter.

The change in reflectivity associated with the film oxidation

Fig. 10. Cyclic voltammogram (solid line) and derivative of the normalized reflectivity (dotted line) based on the data shown in Fig. 9.

was found to be virtually reversible, within 1%, as judged by a comparison between values of $\Delta R/R$ observed just before the onset of oxidation and following full reduction.[2] In addition, virtually identical $\Delta R/R$ vs. E curves were observed during the second and subsequent 10 cycles. If it is assumed that the changes in the optical signal are proportional to the extent of oxidation of the film, the number of oxidized nickel sites generated during the very first scan appear to be essentially the same as those produced in the second and subsequent scans. On this basis, the additional charge observed during the first oxidation does not seem to be associated with nickel sites in the lattice, but with some other phenomenon (see below).

Particularly revealing is a comparison between the cyclic voltammogram and curves obtained by taking the derivative of the optical signal. Figure 10 shows both these plots, where the optical scale has been adjusted to match the current observed during the scan in the negative direction. As indicated, the charge, for which no account can be made by the optics, becomes especially evident for potentials positive to the oxidation peak.

Several possible sources could contribute to this excess charge, including the presence of partially reduced forms of nitrate within the film (such as nitrite), produced during the electrodeposition of the films, which could undergo oxidation to form nitrate during the first oxidation scan; the oxidation of hydroxyl ions to generate precursor species in the evolution of dioxygen (22); and structural changes, i.e., crevice formation, in the film induced by the first oxidation as has been observed in this laboratory by in situ AFM measurements using the basal plane of highly oriented pyrolytic graphite as the film substrate (5).

Summary

The in situ XAFS results presented in this work have shown that α-$Ni(OH)_2$(hyd) films in the uncharged (or discharged) and overcharged states are characterized by distinct sets of Ni—O and Ni—Ni shells. In particular, the EXAFS of over-

[2] As evidenced by both the cyclic voltammogram and optical reflectivity data, the Au surface appears to remain in the oxidized state even after the nickel hydrous oxide layer is reduced.

© 1997 NRC Canada

charged films provided no evidence for contributions due to shells at distances longer than those attributed to oxidized nickel sites in those films.

Within experimental uncertainty, the in situ XAFS and RS spectral data for nickel hydrous oxides films in the oxidized state were found to be virtually identical after the first and subsequent oxidations, despite the decrease in the charge under the anodic peak following the first oxidation. These results indicate that the excess charge observed during the very first oxidation may not be related to changes in the redox state of nickel sites in the lattice, but rather to other processes, and, thereby, are consistent with Ni^{3+} being the most oxidized species in charged nickel hydrous oxide films in alkaline solutions.

Abstract: The role of the proton in extending the electrochemical window and promoting the stripping efficiency of alkali metals has been studied in acetonitrile solution. The platinum hydride surface generated in the hydrogen evolution was considered responsible for the potential shift of 1-ethyl-3-methyl-1*H*-imidazolium (Im^+) reduction in the absence of lithium. In lithium chloride solution, the lithium layer deposited on the electrode may be the main cause for the stretch of the solvent electrochemical window because of the high overpotential of Im^+ reduction on that surface. The proton may affect the properties of the passive layer on newly deposited alkali metal surfaces and then improve the performance of the alkali metal anodes.

Key words: 1-ethyl-3-methyl-1*H*-imidazolium chloride, protons, acetonitrile, lithium reduction.

Résumé : Opérant en solution dans l'acétonitrile, on a étudié le rôle du proton pour provoquer une extension de la fenêtre électrochimique et pour promouvoir l'efficacité d'arrachement des électrons des métaux alcalins. On considère qu'une surface d'hydrure de platine générée dans l'évolution d'hydrogène est responsable du déplacement de potentiel lors de la réduction de l'ion 1-éthyl-3-méthyl-1*H*-imidazolium (Im^+) en l'absence de lithium. En solution de chlorure de lithium, la couche de lithium déposée sur l'électrode pourrait être la cause principale de l'extension de la fenêtre électrochimique du solvant à cause du surpotentiel élevé de la réduction du Im^+ sur cette surface. Le proton peut affecter les propriétés de la couche passive sur les nouvelles surfaces du métal alcalin déposé et il peut alors augmenter la performance des anodes de métal alcalin.

Mots clés : chlorure de 1-éthyl-3-méthyl-1*H*-imidazolium, protons, acétonitrile, réduction du lithium.

[Traduit par la rédaction]

Introduction

In studies of chloroaluminate room temperature melts as electrolytes in high-energy batteries, the lower depositing and stripping efficiency of the alkali metals is one of the major hindrances (1). It has been reported (2) that in neutral ImCl–$AlCl_3$ (Im ≡ 1-ethyl-3-methyl-1*H*-imidazolium) melt, Li^+ can be plated and stripped on tungsten and aluminum electrodes, although the plated lithium is not stripped quantitatively. This may be because in neutral LiCl-buffered ImCl–$AlCl_3$ melt[2] the reduction potential of lithium is close to that of Im^+ on the electrodes and the organic reduction product of the melt reacts with the newly deposited lithium to form a passive layer that damps the stripping of the metal (3, 4). The reduction of Na^+ and K^+ in neutral ImCl–$AlCl_3$ melts cannot be observed, since the reduction potentials of Na^+ and K^+ are overlapped or beyond the negative limit of the melts.

Riechel and Wilkes (3) have recently found that proton, added to NaCl-buffered neutral melts, can shift the reduction of ImCl to a more negative potential and thus stretch the electrochemical window of the melt. Proton addition also led to an improvement in the reversibility of lithium deposition–stripping behavior. They suggested that these phenomena may be related to the reaction product of proton and Im^+. However, no spectroscopic evidence showed that Im^+ reacted with the proton except for solid neutron diffraction data that demonstrated that HCl_2^- could hydrogen bond to the ring hydrogen on Im^+ (5). The results of Carlin and co-workers (1) showed that by adding HCl_2^- to MCl (M = Li^+, Na^+)-buffered ImCl–$AlCl_3$ neutral melts, the negative limit of the electrochemical window changed from −2.2 to −2.4 V vs. Al(III)/Al (in 0.6:0.4 ImCl–$AlCl_3$) and nearly reversible plating and stripping behavior for both lithium and sodium could be obtained, although the reduction potential of Li^+ shifted to a more negative potential as well. Using triethanolamine hydrogen chloride (TEOA·HCl) as a stable proton source, Piersma et al. (4) observed similar phenomena to those of Riechel and Wilkes (3). They considered that the stretch of the electrochemical window was related to the alkali metal plated surfaces. The reason that the proton leads to the potential shift and promotes the reversibility of metals is still not clear.

We have undertaken studies employing a nonaqueous solvent as medium, to better understand the role of the proton in

the electrochemical behavior of alkali and Im^+. In some nonaqueous solutions, the dielectric constant is sufficiently high to allow the dissolved salt to dissociate, although the interaction between ions and solvent is not as strong as that in water; to some extent we could say that the ion is more "naked" than in aqueous solution. Thus, the behavior of ions in a nonaqueous solvent is close to that in an ionic liquid (an assemblage of "naked" ions) rather than in aqueous solution, except for the ionic strength. A number of experimental results have confirmed (6, 7) that the spectroscopic and electrochemical characteristics of ions dissolved in room temperature chloroaluminate molten salts are similar to those in nonaqueous rather than in aqueous solutions. This indicates that the behavior of the ions in nonaqueous solutions could be analogous, to some extent, to that in ionic liquids. Moreover, using a solvent medium allows us to separate the effects of those ions that compose the ionic liquid. For buffered neutral melts, the dominant ions are $AlCl_4^-$ and Im^+, with the alkali cation and proton, in the form of HCl_2^- and (or) $H_2Cl_3^-$ etc., dispersed in the melt. It is reported (3, 8) that component ions of the melt are involved in blocking the newly deposited alkali metal surface and proton could help to get rid of the passive surface. In a nonaqueous solution the effects of the component ions can be easily separated. In this study acetonitrile was chosen as the solvent for it has a wide electrochemical window, and a medium dielectric constant, so that some alkali chloride salts can dissolve and dissociate in it sufficiently. Previous studies have shown (9) that under certain conditions, as when HCl is added to an acetonitrile solution containing chloride, the proton can exist as a form of dichloride anion, HCl_2^-, the same species of proton as in the melts. Fortunately, all the ions existing in the melt are stable in acetonitrile, except that they are surrounded by the solvent molecules. Therefore, taking acetonitrile solution as a simulated system to study the behavior of the proton is feasible.

Experimental

Reagents

ImCl was made from 1-methylimidazole and chloroethane (Aldrich) using the method reported by Wilkes et al. (10). 1-Ethyl-3-methyl-1*H*-imidazolium hydrogen dichloride ($ImHCl_2$) was made by passing HCl(g) over the weighed solid ImCl (8). Anhydrous LiCl, NaCl, and the other inorganic chemicals were dried overnight under vacuum at ca. 120°C. Acetonitrile was obtained from Fisher Scientific, and distilled from calcium hydride suspension. Tetraethylammonium chloride (TEAC) was recrystallized twice before it was used. HCl gas was generated by dropping hydrochloric acid into concentrated sulfuric acid. All the chemicals used in the experiment were reagent grade.

In the preparation of electrolyte, because the solubilities (11) of LiCl and NaCl are low (LiCl: 2.6×10^{-2} M, NaCl: 3×10^{-5} M) and dissolution requires a long time (1 day), we usually first allowed the solution to become saturated by alkali chloride, and then added the weighed ImCl to the filtered solution. $ImHCl_2$ was readily soluble. Starting HCl:ImCl ratios were determined by weight change.

Instrumentation

All the experimental work connected with the hygroscopic chemicals was carried out in a LabConco glove box under a dry nitrogen atmosphere. Electrochemical measurements were performed by using a BAS 100A electrochemical analyzer. Three-electrode electrochemical cells were used with various working electrodes: platinum (BAS, MF-2013), glassy carbon (BAS, MF-2012), and tungsten (custom fabrication, diam. 1 mm). A platinum foil auxiliary electrode was used. A screw-type platinum wire was placed in another chamber containing 0.003 M ferrocene in acetonitrile solution to act as a pseudo-reference electrode, which contacted the studied electrolyte via a fine frit. Some experimental results were obtained on platinum (diam. 30 μm) and tungsten (diam. 20 μm) microelectrodes, leading to waves rather than peaks. In these measurements the BAS PA-1 preamplifier was employed. ^1H NMR spectra were acquired with a Bruker AC 200 MHz spectrometer; DMSO-d_6 was used as an exterior reference. UV–VIS spectroscopic experiments were performed on a Hewlett–Packard model 8452A diode array spectrophotometer.

Results and discussion

The states of proton in acetonitrile

The states of proton in a series of aprotic solvents have been studied by NMR spectroscopy in the work of Fujiwara and Martin (9). When HCl was added to tetraalkylammonium chloride solutions they found that HCl associates with chloride anions:

$$[1] \quad HCl(g) + Cl^-(l) = HCl_2^-(l)$$

and protonates the solvent.

The suggested association constant in acetonitrile is ca. 600. Thus, if the chloride is in excess, the dihalide anion HCl_2^- will form quantitatively. In the case where HCl is in excess, $[Cl^-] < [HCl]$, Fujiwara and Martin (9) obtained a broader and weaker ^1H NMR signal that was shifted downfield with increase in the ratio of HCl to the chloride salt. This phenomenon was presumed to be a consequence of slow H^+ exchange between the dihalide ion or $Cl(HCl)_n^-$ and the protonated solvent. In this case there were at least two kinds of protons, HCl_2^- and protonated solvent.

In our experiments, it is difficult to determine exactly the relative quantity of HCl and chlorides (LiCl and (or) ImCl); however, HCl can be added as $ImHCl_2$, since HCl_2^- could transform to HCl(g) or other proton forms in the transfer process. In some cases we had to add proton by bubbling HCl through the electrolyte. Figure 1 gives the voltammetric curves on a Pt electrode in 0.01 M ImCl acetonitrile solution. Curve 1 was obtained for the solution with a ratio of HCl:ImCl = 1.7 (HCl in excess). Two proton reduction current waves can be observed with potentials at −0.3 and −0.7 V, respectively. With removal of HCl by passing nitrogen through the electrolyte, the current wave at −0.3 V decayed steeply, while the current at −0.7 V declined quite slowly. We have compared curve 4 with the voltammetric curve obtained from the solution with a feed ratio of HCl:ImCl = 0.5 (HCl in deficit). The two curves have the same features: no detectable current at −0.3 V but a reduction current at −0.7 V. This means that the quantity of HCl in the solutions represented by curves 4 and 5 was less than that of ImCl.

The electrochemical behavior of the proton on glassy carbon and tungsten electrodes in the same electrolytes as in

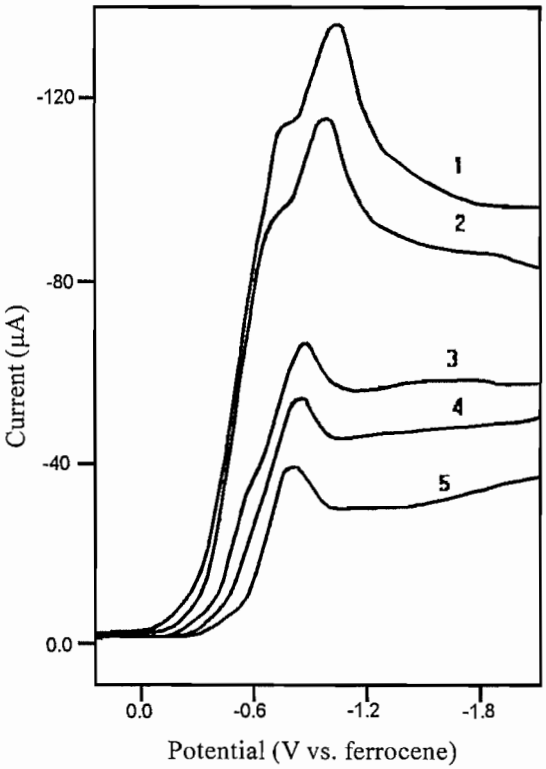

Fig. 2. Voltammetric curves of HCl added to 0.01 M ImCl acetonitrile solutions with a glassy carbon electrode. Sweep rate: 100 mV/s. From curve 1 to curve 3, the quantity of HCl decreased gradually; curve 4 without HCl.

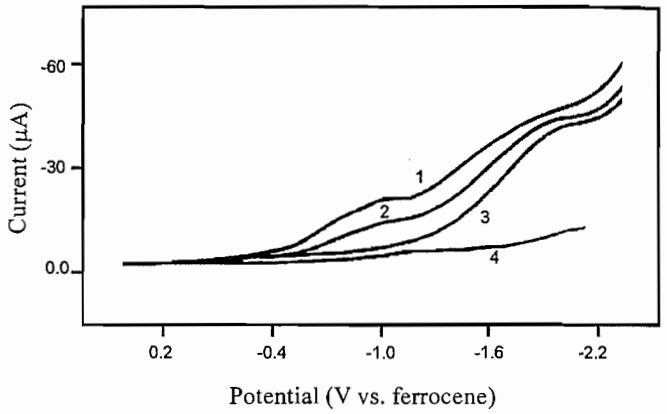

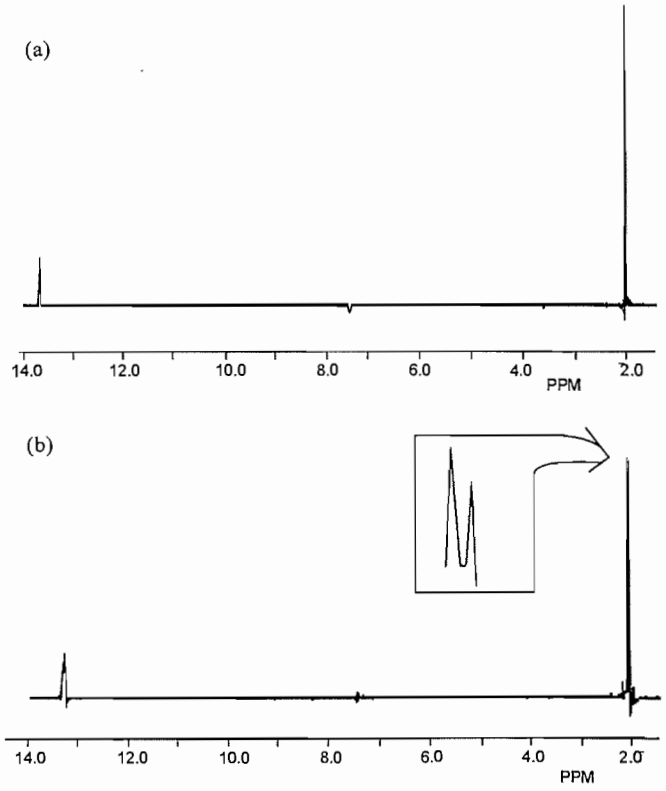

Fig. 3. H NMR spectra of 0.01 M ImCl solutions (*a*) without HCl and (*b*) with HCl (HCl:ImCl = 1.7) added. Inset: amplified graph as given by the arrow.

the above experiment was measured. Similar phenomena can be observed. The two current waves on tungsten and glassy carbon electrodes are different from those on the platinum electrode. On tungsten the potentials are −0.9 and −1.4 V, while on the glassy carbon electrode they are −1.0 and −2.0 V, respectively, which are separated from each other more than those on platinum (Fig. 2). Substituting the chloride, ImCl, with tetraethylammonium chloride did not change the above results.

The mass-transfer characteristics of the proton reduction on platinum and tungsten electrodes show that there are at least two protonic species in the acetonitrile solution in the case of HCl in excess. According to Fujiwara's analysis, when the concentration of HCl is lower than that of chloride, HCl_2^- should be the dominant proton form. Therefore, the second cathodic current wave on electrodes corresponds to the reduction of HCl_2^-. The current at −0.3 V on platinum may result from some other proton forms. In the following experiments, for the sake of keeping the proton form in acetonitrile the same as that in the melt, proton forms other than HCl_2^- are not necessary, so one can bubble enough HCl through the solution, followed by nitrogen to get rid of the excess. The quantity of HCl can be roughly controlled by monitoring the current on the potential–current curve.

The ^1H NMR spectra of the electrolytes with HCl in excess and deficit were measured, and are shown in Fig. 3. As the signal of HCl_2^- is far away from that of the solvent proton, we did not use deuterated solvent in the measurement. There was a downfield resonance signal observed in both cases which had been ascribed in the literature to the hydrogen-bonded proton of the HCl_2^- ion (9). When HCl is in excess (HCl:ImCl = 1.7) the downfield signal is broader than the signal obtained when the solution chloride is in excess, and the location of the

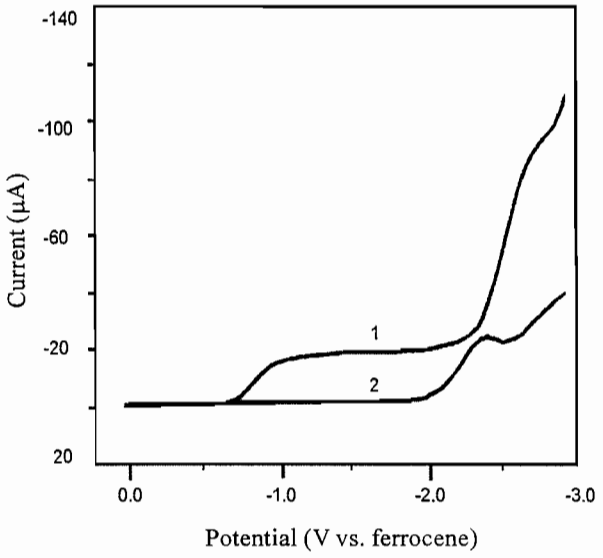
Fig. 4. Voltammetric curves obtained with a platinum microelectrode of a 1-ethyl-3-methyl-1*H*-imidazolium solution (0.01 M) in acetonitrile (1) with and (2) without HCl. Sweep rate: 100 mV/s.



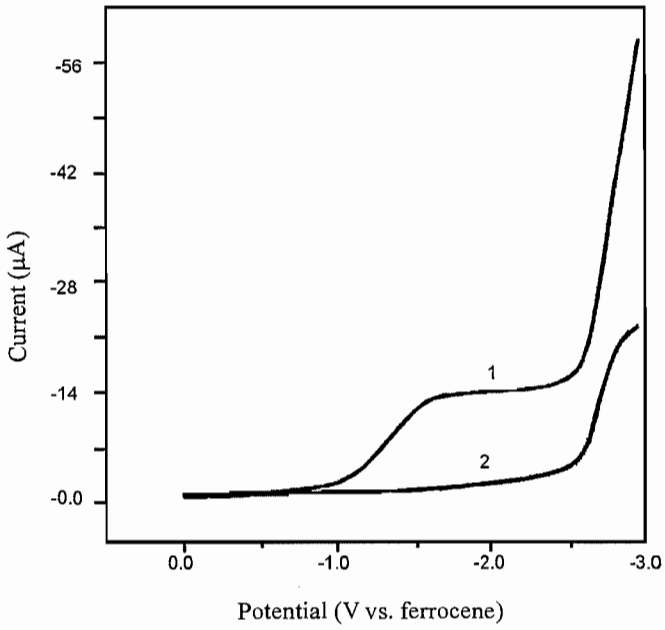


Fig. 5. Voltammetric curves obtained with a tungsten microelectrode of a 1-ethyl-3-methyl-1*H*-imidazolium solution (0.01 M) in acetonitrile (1) with and (2) without HCl. Sweep rate: 100 mV/s.

former is slightly downfield (δ = 13.7) from the latter (δ = 13.2). These results are consistent with those given by Fujiwara. The upfield signal was caused by the solvent protons, and its appearance is sensitive to the quantity of HCl. In the case of chloride in excess it is a simple signal, in a solution of HCl:ImCl = 1.7 (HCl in excess) it is a doublet signal, while increasing the quantity of HCl by passing HCl gas into the solution gave rise to a complex spectrum. The reaction between acetonitrile and HCl has been studied for decades (12). The products are quite complex and are dependent on the reaction conditions. They include nitrilium, iminium, dimerized iminium, or some other polymerized salts. In the solution of HCl:ImCl = 1.7, nitrilium salt is the most probable protonated solvent species, because only the proton on the nitrilium nitrogen atom may generate the doublet splitting signal of the methyl group proton on the solvent molecules. The proton exchange between HCl_2^- and nitrilium leads to the broadening and shift of the downfield signal.

The effect of proton on the reduction of Im^+ cation

In acetonitrile the reduction of Im^+ is at −2.0 V vs. ferrocene on platinum electrodes, within the electrochemical window of the solvent. The voltammetric curves of 0.01 M ImCl acetonitrile solution on platinum and tungsten electrodes with and without HCl are shown in Figs. 4 and 5, respectively. The current at −0.7 V in curve 1 is due to the reduction of HCl_2^-. On platinum electrodes, the onset of reduction of Im^+ has been moved from −2.0 to −2.2 V by adding HCl to the electrolyte. No effect of the proton on the reduction potential of Im^+ on tungsten electrodes could be observed, although the reaction occurred at a more negative potential. The situation on glassy carbon is the same as on tungsten electrodes.

The above phenomena are very similar to those taking place in melts. Campbell and Johnson (13) have reported that adding HCl to a basic melt ($AlCl_3$:ImCl = 0.495:0.505) shifted the reduction of Im^+ ca. 200 mV to a more negative potential as long as the partial pressure of HCl was higher than 0.2 atm (1 atm = 101.3 kPa). On tungsten and glassy carbon electrodes the potential shift could not be distinguished in the melt.

We consider that the effect of the proton on the potential shift of Im^+ reduction on a platinum electrode is related to the adsorption of proton on the platinum surface. It is well known that platinum is a good catalytic electrode for hydrogen evolution and the catalytic mechanism has been extensively reported in the literature. The results of previous studies (14) have confirmed that in the process of hydrogen evolution a number of equivalent monolayers of overpotential-deposited (OPD) H species in the near-surface region of the platinum interface will form a hydride phase. The electrode behavior is closely associated with the formation of this hydride layer. In solutions of low proton concentration the hydride layer would be depressed by impurities or reduced on the electrode. This means that in the process of hydrogen evolution the platinum hydride surface has been generated under conditions of sufficient acidity. Since the reduction potential of Im^+ is located in the potential range of the hydrogen evolution, the reaction in the electrolyte with HCl was conducted on a platinum hydride surface rather than on platinum itself. Therefore, it is reasonable that the reduction of Im^+ on two different electrode surfaces should have different overpotentials. This conclusion can also explain why the potential shift occurred under the condition of high HCl concentration in Campbell's experiment. Presumably Piersma failed to observe the shift phenomenon on platinum electrodes because of the low proton content. Protons adsorb only weakly on glassy carbon and tungsten electrode surfaces. At very negative potentials, pro-

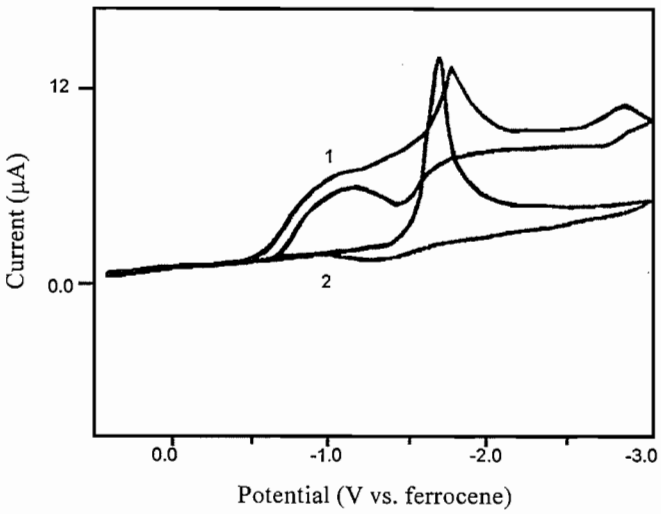

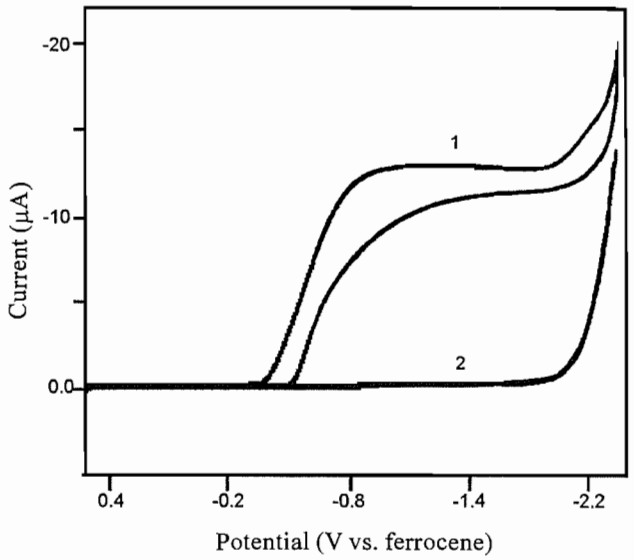

Fig. 7. Cyclic voltammetric curves for a platinum microelectrode in NaCl saturated 0.01 M ImCl acetonitrile solution (1) with HCl and (2) without HCl. Sweep rate: 100 mV/s.

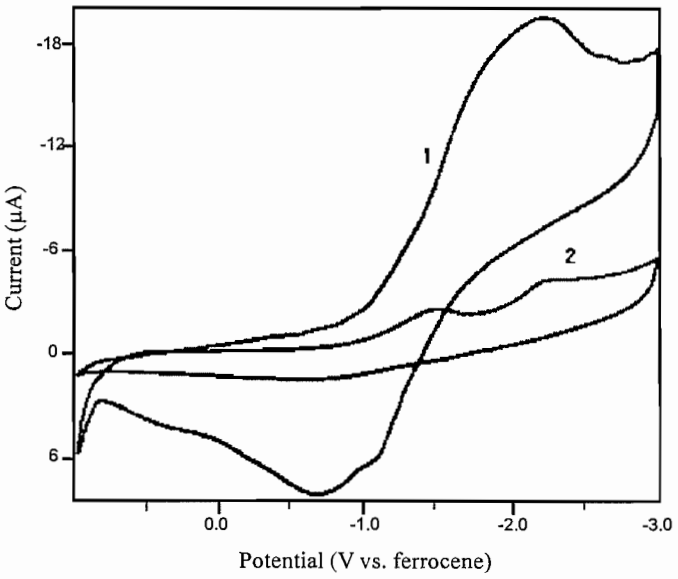
ton reduction is merely a competitive reaction to the Im^+ reduction. The electrode surface does not change and no potential shift of Im^+ reduction could be observed.

The stripping efficiency of alkali metals in acetonitrile

The lithium ion can be reduced on Pt and W electrodes ahead of the reduction of Im^+ in the electrolytes with and without HCl. Figure 6 shows the deposition and stripping behavior on Pt electrodes; it is apparent that the deposition current in the HCl-containing electrolyte is lower than that without HCl. This may be caused by the competing reaction of proton reduction on the same electrode. Adding HCl to the electrolyte caused the Li^+ reduction potential to shift slightly in the negative direction, possibly caused by the adsorption of H on the platinum. By integrating the plating and stripping peaks on the cyclic voltammograms, the stripping efficiency on platinum electrodes in electrolytes with and without HCl is estimated to be 60 and 10%, respectively. The data indicate that HCl considerably improved the reversibility of the Li^+/Li couple.



After the deposition of lithium, the reduction of Im^+ shifts to more negative potentials, beyond the potential range of the BAS instrument, no matter whether the electrolyte contains HCl or not. The higher overpotential of Im^+ reduction on a lithium surface than on a platinum electrode may account for this. On glassy carbon electrodes lithium cannot deposit from the acetonitrile in this experiment, and we cannot observe the stretching of the solvent electrochemical window. Similar results were observed in Piersma's experiments in the melts (4). In their staircase cyclic voltammetry measurement, even with the negative limit set to −2.8 V (vs. Al(III)/Al), no obvious solvent decomposition current was recorded. They concluded that the lithium or sodium layer plated on the platinum or tungsten electrode is responsible for the stretching of the electrochemical windows.

As the Im^+ cation may react with newly deposited lithium metal (15) to form an Im-Li layer on the lithium surface, it is easy to think that the product may block the electrode surface, and the passive surface layer may barricade the stripping of the lithium layer. Some authors (16) have observed the in situ formation of a passive layer on the lithium surface by using an optical microscope. In this connection, an analogous experiment was performed in the electrolyte without Im^+ cation. The result showed that the low stripping efficiency of the deposited lithium layer can also be distinctly increased by adding proton. Nevertheless, we cannot exclude the formation of an Im^+-participating passive layer in the melt or in the acetonitrile solution. It has been suggested (17, 18) that in nonaqueous solutions the alkali metals are always covered by a surface layer that is instantly formed by the reaction of the metal with the electrolyte. This layer, which acts as an interphase between the metal and the solution, has the properties of a solid electrolyte. The electrochemical behavior of the alkali electrodes will be governed by the properties of this layer. Water contamination or other proton agents will lead to its breakdown or change the properties of the passive film. In this study, although the surface film on the lithium in acetonitrile may be different from that in the melts, we consider that adding proton to the electrolytes could improve the surface layer's properties, i.e., increase the permeability of lithium cation or the transportation ability for other ions and the electron, and thus improve the performance of the alkali electrodes.

Figure 7 gives the cyclic voltammetric curves of sodium chloride solutions on a platinum electrode. In the electrolyte without HCl, no sodium deposition current could be observed. After adding HCl, the deposition and dissolution current appeared. As the solubility of sodium chloride in acetonitrile is low, the deposition current peak is small. In the melt without proton the sodium current can also not be distinguished on the cyclic voltammetric curves (3), due to the potential overlap of the sodium reduction with Im^+ reduction. Their SEM/EDS results verified the passivation of the sodium layer by the organic compound. This experiment shows that the proton in

Fig. 8. Cyclic voltammetric curves on tungsten electrode in LiCl saturated 0.01 M ImCl acetonitrile solution (1) with HCl and (2) without HCl. Sweep rate: 100 mV/s.

acetonitrile solution may play a similar role to that in the melt. We consider that the improvement of sodium redox behavior in proton-containing solutions can be attributed to the improvement of the surface layer on sodium.

On tungsten electrodes, proton brought about a great change in the lithium redox behavior (see Fig. 8). The stripping effect was noticeabley enhanced. On the cathodic branch, the hydrogen reduction current overlapped with the lithium reduction current, so it is impossible to calculate the stripping efficiency from the voltammograms. As we know, tungsten is a good electrochromic material, widely used in photo-electrochemistry: lithium can be electrochemically embedded in the tungsten electrode under certain conditions. Studies (19, 20) have shown that the proton can help lithium insertion into the tungsten interface. The above processes may take place in our situation although the surface layer is different. More research is clearly required to fully explain the phenomena in these systems.

Summary

The effect of proton in shifting the Im^+ reduction potential and promoting the reversibility of the redox behavior of alkali ions has been studied. It is found that the above phenomena not only take place in room temperature molten salts but also in nonaqueous solutions.

In this study at least two kinds of proton species have been identified in chloride acetonitrile solutions by an electrochemical method. HCl_2^-, which is the species existing in the melt, can be controlled as the only proton form in acetonitrile solution. It is suggested that the potential shift of Im^+ reduction on platinum electrodes is related to the formation of a platinum hydride phase during the hydrogen evolution. In alkali chloride solutions the stretch of the solvent electrochemical window is due to the high overpotential of Im^+ reduction on the alkali metal surface that is deposited before the solvent decomposition. The instantly established solid electrolyte film on a newly deposited alkali metal surface controls the performance of the alkali electrode. Adding proton to the system improves the properties of the film and then promotes the reversibility of the alkali redox couples.

Abstract: A new detection method was developed that takes advantage of changes in cyclic voltammograms (recorded with either a platinum or a gold ultramicroelectrode) caused by the adsorption, of inorganic and organic molecules. These changes may include reduction or oxidation of the adsorbate, inhibition of oxygen adsorption, inhibition of hydrogen adsorption, and also changes in the charging current. The detection is carried out in a stripping mode after the accumulation of analyte on the electrode surface for 50–1000 ms. Typical scan rates are between 10 and 1000 V/s. Removal of oxygen from the solutions studied is not required. Electrochemical conditioning of the working electrode is sufficient to insure a stable response for a period of several hours. For strongly adsorbing molecules the linear dynamic range extends over two orders of magnitude from about 10^{-7} M to 10^{-5} M with the relative standard deviation for replicate determinations lower than 5%. The smallest discernable signal is associated with about 0.1% surface coverage, which corresponds to the adsorption of about 10^{-18} mol of analyte on a ultramicroelectrode 5 μm in radius.

Key words: adsorption, cyclic voltammetry, ultramicroelectrode, flow injection.

Résumé : On a mis au point une nouvelle méthode de détection qui tire profit des changements dans les voltampérogrammes cycliques (enregistrés avec une ultramicroélectrode de platine ou d'or) qui sont causés par l'adsorption de molécules organiques ou inorganiques. Ces changements peuvent comporter la réduction ou l'oxydation de l'adsorbat, l'inhibition de l'adsorption de l'oxygène, l'inhibition de l'adsorption d'hydrogène ainsi que des changements dans le courant de charge. On effectue la détection dans le mode de redissolution après avoir effectué une accumulation de l'analyte sur la surface de l'électrode pendant 50 à 1000 ms. Les vitesses typiques de balayage se situent entre 10 et 1000 V/s. Il n'est pas nécessaire d'enlever l'oxygène des solutions étudiées. Le conditionnement électrochimique de l'électrode de travail est suffisant pour assurer une réponse stable pendant une période de plusieurs heures. Pour les molécules fortement adsorbées, l'amplitude de la réponse dynamique linéaire est de plus de deux ordres de grandeur allant d'environ 10^{-7} M à 10^{-5} M; la déviation relative standard pour la reproduction des déterminations est inférieure à 5%. Le plus faible signal détectable est associé à une couverture d'environ 1% de la surface; ceci correspond à une adsorption d'environ 10^{-18} mol d'analyte sur une ultramicroélectrode de 5 μm de rayon.

Mots clés : adsorption, voltampérométrie cyclique, ultramicroélectrode, injection à écoulement.

[Traduit par la rédaction]

Introduction

Electrochemical techniques provide the means for relatively simple, inexpensive, and very sensitive detection in flowing solutions, including Liquid Chromatography (LC), Capillary Electrophoresis (CE), and Flow-Injection Analysis (FIA). By far the most popular technique is simple amperometric detection at a fixed potential, which offers excellent detection limits (1–3). The most serious limitation of this detection method is associated with the stability of the working electrode. In general, amperometric detection is not appropriate for kinetically controlled electrode processes or electrode processes involving the electrodeposition of insoluble products. In many such cases, however, pulse amperometric detection has been successfully applied. The best illustration of this approach is pulse amperometric detection of carbohydrates (4). Carbohydrates can be oxidized in basic solutions on a Pt or Au electrode but the process is catalyzed by intermediate forms of oxide formation on the noble metals (AuOH or PtOH) (5). To maintain high catalytic activity of the detector the electrode potential has to be continuously cycled between positive and negative values. The detection strategy involves application of three potential steps per each cycle. First, a potential suitable for electrocatalytic oxidation of the carbohydrate is applied for 100–400 ms and the current is sampled for a short time at the end of this potential. Then the electrode is oxidatively cleaned by a positive step lasting 50–200 ms, and cathodically reactivated for 100–400 ms. A similar method was used in the detection of amino acids (6) and metal ions (7).

Alternatively, a potential scanning technique such as cyclic voltammetry or square-wave voltammetry could be used. This allows the maintenance of a clean and active electrode surface, and also the monitoring of the electrode response as a function

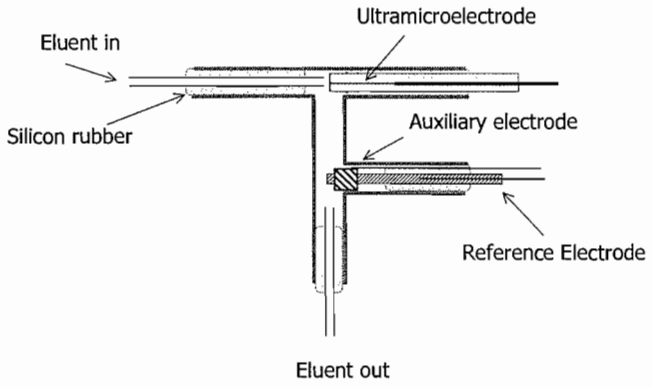
of potential. The option of recording current–potential curves is very important because it may improve the selectivity of some determinations, and it allows quick tracking of any change in the detector performance, often providing information sufficient to draw conclusions about the possible causes of observed changes. Such an option is also extremely useful in research on the development and optimization of electrochemical detectors because it provides detailed information about electrode processes under exactly the same conditions as used in a given analytical procedure. However, in order to use potentiodynamic techniques for detection in flowing solutions the scan rate must be sufficiently high so that a single sweep is several times shorter than the time needed for the analyte zone to pass through the detector. This means that in LC and FIA the scan rate should be higher than about 1 V/s and in CE higher than about 10 V/s. Fulfilling this condition may have an adverse effect on the detection limit under some conditions (8). It is well known that an increase in the sweep rate causes a deterioration of the signal-to-background ratio for redox processes involving soluble reactants, because background current is directly proportional to the sweep rate but the signal (controlled by the rate of diffusion) increases with the square root of the sweep rate. This argument, however, is not applicable to electrochemical detection carried out in a stripping mode after accumulation of the analyte on the electrode surface by means of electrodeposition or adsorption (9). If ultramicroelectrodes are employed, a meaningful accumulation can be obtained in a 100-ms time period, which then can be followed by a stripping scan carried out at, for example, a 100 V/s sweep rate.

Following these lines, a new detection method was developed that takes advantage of all changes in cyclic voltammograms (recorded with either a platinum or gold ultramicroelectrode) caused by the adsorption of inorganic and organic molecules. These changes may include reduction or oxidation of adsorbate, inhibition of oxygen adsorption, inhibition of hydrogen adsorption, and also changes in the charging current. The inspiration for this work came from papers published by Conway and co-workers (e.g., refs. 10–12), which show that surface processes on Pt and Au electrodes can be monitored with exceptional precision by cyclic voltammetry. In particular, it has been demonstrated that the cyclic voltammetric method is sensitive enough to detect very small changes, down to 0.25%, in OH coverage on a polycrystalline gold electrode (10). A simple calculation shows that in the case of a disk ultramicroelectrode (5 μm in radius) such coverage corresponds to about 2×10^{-18} mol, or 4×10^4 molecules.



This paper describes only initial testing of the method under flow-injection conditions, but the method is nonselective (with the exception of heavy metal analysis); therefore it can be effectively used only in conjunction with a separation technique. Currently, this detection method is tested under capillary electrophoresis conditions.

Experimental

Reagents

All solutions were prepared in double-distilled deionized water (Corning Mega-Pure System, MP-6A and D-2) using analytical grade reagents. Reagents employed in preparation of the stock eluent solution for flow-injection analysis (H_3PO_4, NaOH, $Na_4BO_7 \cdot 10H_2O$, and $NaHCO_3$) were obtained from BDH Chemicals. In all experiments all solutions were used without removal of dissolved oxygen.

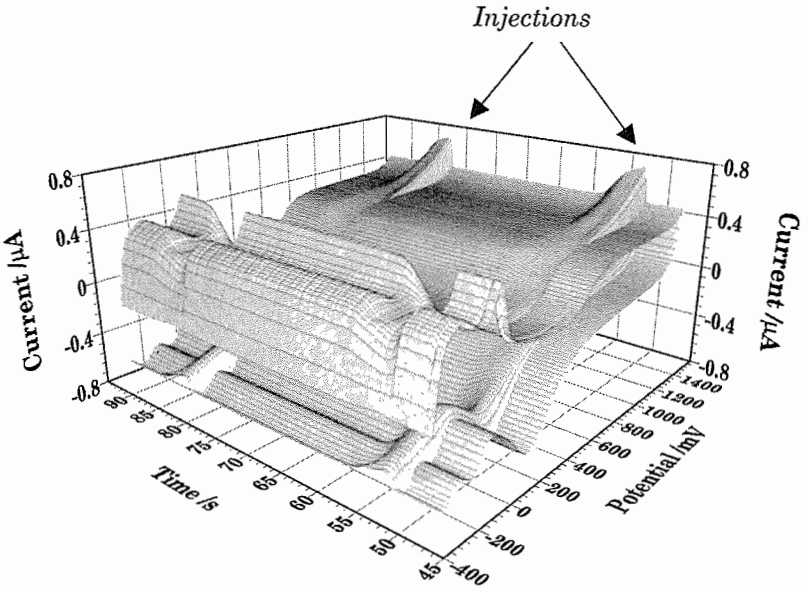
Fig. 1. Electrochemical cell used in flow-injection experiments.

Flow-injection setup

The equipment for flow-injection analysis included a 10 roller peristaltic pump (Microperpex) and a four-way injection valve (Supelco Rheodyne model 5020) with a 50 μL sample loop. Solutions were introduced into the sample loop by means of a plastic syringe. The electrochemical cell used in flow–injection analysis is shown in Fig. 1. In all experiments described in this paper the flow rate of eluent solution was 2.0 mL/min. The dispersion coefficient for an injection volume of 50 μL was approximately equal to 1.85.

Electrodes

Gold and platinum ultramicroelectrodes (radius 5.0 and 12.5 μm, respectively) served as the working electrodes. Electrodes of that size are usually employed in end-column electrochemical detection in capillary electrophoresis (7). The electrodes were prepared by sealing metal microwires (Goodfellow Metals Ltd., U.K.) into a soft glass capillary. The capillary was then cut perpendicular to its length to expose the wire. Electrical contacts were made using silver epoxy (Johnson Matthey Ltd., U.K.). Before each experiment the electrode surface was polished for 1 min using extra-fine carborundum paper and then for 10 min with 0.3 μm alumina. The electrode was washed with water prior to being placed in the cell. The true surface area of the working electrodes was estimated from the charge required for the oxidation of adsorbed hydrogen on the Pt electrode and from the charge due to the reduction of adsorbed oxygen on the gold electrode (15). This method yielded $(9.4 \pm 0.8)) \times 10^{-6}$ and $(1.6 \pm 0.2) \times 10^{-6}$ cm^2 for the Pt and Au electrode, respectively.



In all measurements an Ag(s)|AgCl(s)|1 M KCl(aq) reference electrode was used. The auxiliary electrode was made of a Pt wire, 0.5 mm in diameter.

Data acquisition and processing

All electrochemical experiments were done using a setup comprising a PC 486, 66-MHz microcomputer equipped with a data acquisition board (PCL-818PG, PC-Labcard Co.) and a custom-made potentiostat. The diagram of the potentiostat and details of the computer interfacing are described else-

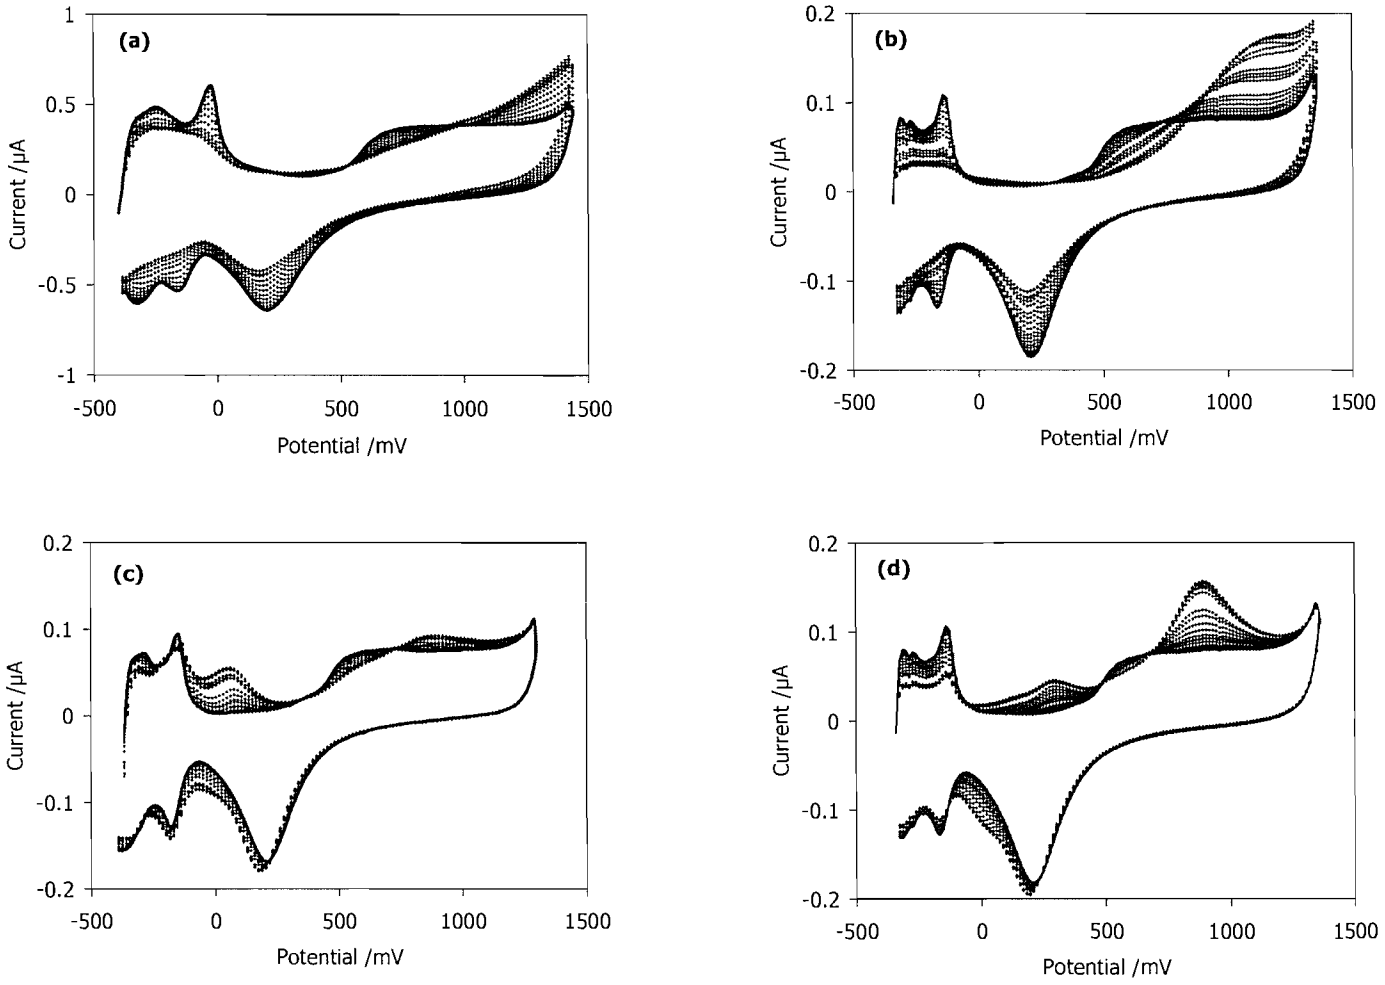
Fig. 2. Cyclic voltammograms at a 12.5 μm Pt ultramicroelectrode recorded during a flow-injection experiment. The eluent was 0.05 M H_3PO_4, the flow rate was 2.0 mL/min, and the sweep rate was 100 V/s. Each scan was preceded by a 200 ms preconcentration period at −0.4 V. The injected solution (50 μL) contained 1 mM aniline in 0.05 M H_3PO_4.

where (13). All data acquisition and data processing programs were developed in this laboratory using Microsoft Visual C++, version 4.0, and Visual Basic, version 4.0. Electrochemical experiments used in this work involved continuous monitoring of the electrode response under cyclic voltammetric conditions. The cycle was started by holding the electrode at the arbitrary selected potential (called here the rest potential) for a fixed time period (called the delay time). Then the electrode potential was scanned from the initial to the vertex potential and back to the initial. Immediately after scanning, the rest potential was applied and the cycle was repeated. The current passing through the electrode was sampled only during the scanning of potential. It should be noted that in this method all processes studied involve adsorption of analytes, hence both charging and faradaic currents potentially carry useful analytical information. For this reason it was important to sample current at a frequency at least two times higher than the current transducer bandwidth, so that according to the Nyquist sampling theorem (14) complete information about current passing through the electrode could be obtained. To fulfill this requirement the sampling frequency was always between 40 and 70 kHz. In addition, a second-order low-pass filter with a 20 kHz cutoff frequency was placed between the current output of the potentiostat and the data acquisition board. The highest sampling rate used in this work was intentionally lower than the 100 kHz limit specified by the manufacturer of the data acquisition board because it was noted that a significant increase in the noise level occurs for sampling rates greater than about 75 kHz. Typically the scan rates in cyclic voltammetric experiments were between 10 and 1000 V/s. The delay time was usually between 0.05 and 3 s. During that time the collected data were processed and displayed graphically on the computer screen. The number of data points collected during each scan was user-selectable, but in this work it was always set to 256 points. Consequently, at lower sweep rates each data point represented an average of two or more analog-to-digital conversions. Part of the computer code used for the acquisition of data was written in assembly language and placed in a dynamic link library (this library is available on request from the corresponding author). The data processing involved background subtraction and the integration of the current between two user-selectable potential limits; details of these procedures will be described later. Results of the data acquisition were stored in the computer memory as matrices with 256 columns (typically) and up to 4096 rows.

Results and discussion



Analytical method

Figure 2 shows a sequence of cyclic volumetric (CV) curves recorded during the flow injection of 50 μL of 1×10^{-3} M aniline in 0.05 M H_3PO_4 into the eluent solution containing 0.05 M H_3PO_4. The working electrode was a Pt disk ultramicroelectrode. The potential axis on this graph represents potential applied to the working electrode during each scan. The time axis represents the time passing between the beginning of the flow injection experiment and the beginning of a particular scan (i.e., it represents a quantity proportional to the scan number). In the absence of aniline the shape of the CV curves is typical for a polycrystalline Pt electrode in acidic media. At negative potentials the electrode is covered with chemisorbed hydrogen. The charge needed to produce a monolayer of hydrogen on polycrystalline Pt is 2.20 C/m^2 (15). At positive potentials water decomposition takes place, leading to the formation of a two-dimensional phase of platinum oxide. The process is initiated by the electrosorption of the hydroxyl ion, which at more positive potentials undergoes deprotonation and structural rearrangements (16). When the electrode–solution interface is exposed to the analyte both the process of hydrogen adsorption and the process of platinum

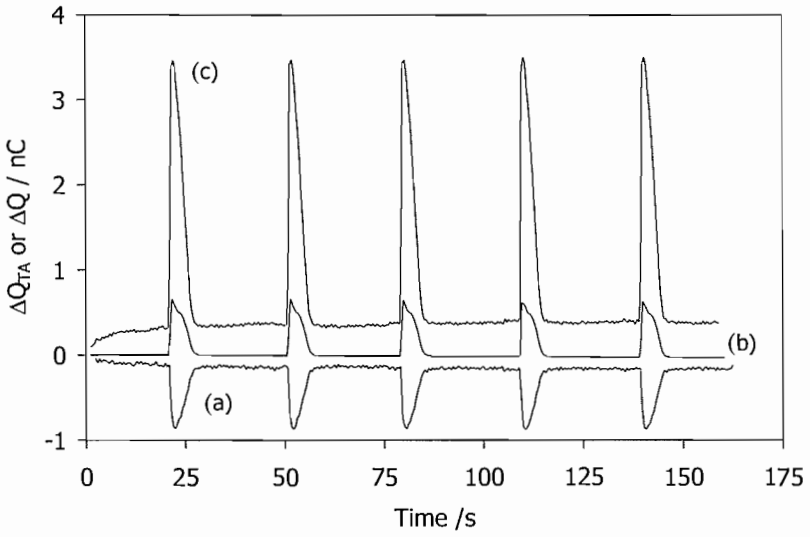
Fig. 3. Overlapping cyclic voltammograms recorded during flow-injection experiments at a platinum electrode 12.5 μm in radius: (*a*) 1 mM aniline; (*b*) 0.1 mM NaSCN; (*c*) 0.1 mM Na_2MoO_4; (*d*) 0.1 mM $NaAsO_2$. The eluant was 0.05 M H_3PO_4; delay time: 0.2 s; rest potential: −0.35 V; scan rate: (*a*) 100 V/s, (*b*), (*c*), and (*d*) 20 V/s. Solid curves represent overlapping cyclic voltammograms recorded in the absence of analyte before and after the injection. The dotted lines illustrate changes caused by injection of the analyte.

oxide formation are strongly inhibited. In addition, at sufficiently positive potentials, the oxidation of adsorbed molecules is often observed (17). As a result profound changes in the shape of cyclic voltammograms take place, as is shown in Fig. 2. These changes are even more obvious when all CV curves are superimposed on one another (Fig. 3*a*). In this figure a solid line represents the electrode response to the supporting electrolyte alone (it actually consists of four CV curves recorded before the injection and four curves recorded after the analyte was flushed out by eluent, superimposed on each other). The dotted lines represent the electrode response in the presence of the analyte. The most notable changes in the current are observed in the hydrogen adsorption region or in the oxide formation region, and those changes may be either negative or positive depending on the electrode potential. Information about the concentration of aniline in solution can be obtained from the value of the current monitored at a fixed potential (e.g., 1100 mV). This is the simplest method but it provides a relatively poor signal-to-noise (S/N) ratio. Better precision can be obtained by integrating the change in the electrode response over a certain potential range (e.g., from E_1 to E_2) and expressing the result in terms of electrical charge. In reality, CV curves are recorded numerically by sampling current in equal time intervals. Consequently, the integration must be replaced by a summation carried out between two points (*a* and *b*) that correspond to potentials E_1 and E_2.



$$[1] \quad \Delta Q(k\tau) = \frac{\Delta E}{\nu}\left(\sum_{j=a}^{j=b} I(k,j) - \sum_{j=a}^{j=b} I(k_r,j)\right)$$

In this equation k is the scan number, τ is the time period between subsequent scans, ν is the scan rate, ΔE is the potential difference between two subsequent points on the CV curves, $I(k,E)$ represents the CV curve recorded during the kth scan, and $I(k_r,E)$ is the reference CV curve. The reference CV curve is obtained by averaging a few CV curves recorded at the beginning of the experiment (i.e., before injection of the analyte). Typically the averaging included the 5th to 11th curves. The integration can be carried out in the forward scan ($a = |E_i - E_1|/\Delta E$ and $b = |E_i - E_2|/\Delta E$, where E_i is the initial potential) or in the reverse scan ($a = (|E_i - E_v| + |E_v - E_1|)/\Delta E$ and $b = (|E_i - E_v| + |E_v - E_2|)/\Delta E$, where E_v is the vertex potential).

Fig. 4. Response of a Au ultramicroelectrode to five consecutive injections of 1 mM aniline. All experimental conditions as in Fig. 2. Curves (*a*) and (*b*) represent the ΔQ function calculated according to eq. [1] for the integration limits −0.4 to 0.1 V and 0.9–1.25 V, respectively. Curve (*c*) represents the ΔQ_{TA} function calculated according to eq. [2].

If the main contribution to the baseline noise is from the "white" noise generated by the potentiostat, the integration procedure usually provides a 3- to 4-fold improvement in the S/N ratio compared to the simple monitoring of the current at a fixed potential. However, in the case of severe environmental noise (e.g., power line noise) the improvement may be much greater.

All CV curves collected during the entire experiment (typically 200–4000 curves) were always stored in computer memory and could be saved onto a hard drive for future analysis, if desired. This means that, for the same flow-injection experiment, the electrode response can be obtained using different reference CV curves and (or) different integration limits. The choice of the reference curve has little or no effect on the results, as long as the curve is acquired in the absence of analyte; however, the electrode response expressed in terms of ΔQ strongly depends on the selection of the integration limits.

For example, in the case of aniline, the integration carried out in the forward scan between −400 and 100 mV (hydrogen adsorption region) produces negative peaks (Fig. 4, curve *a*). If the integration is done in the oxide formation region, between 900 and 1250 mV, the peaks on the ΔQ vs. time curve are positive (Fig. 4, curve *b*). However, integration between 500 and 1280 mV produces no peaks, because negative changes in the current between 500 and 950 mV are cancelled by positive changes occurring between 950 and 1280 mV. Hence, a proper selection of the integration region requires careful examination of changes in CV curves caused by a given analyte.

Alternatively, a total absolute difference function (ΔQ_{TA}) can be calculated in the following way:

$$[2] \quad \Delta Q_{TA}(k\tau) = \frac{\Delta E}{\nu} \sum_{j=1}^{N} |I(k, j) - I(k_r, j)|$$

where N is the number of data points collected during each scan and all other symbols have the same meaning as in eq. [1].

A plot of the total absolute difference parameter for the injection of aniline is shown in Fig. 4 (curve *c*). As expected, the magnitude of the peaks is larger than for ΔQ vs. time plots. Despite this, the signal-to-noise ratio is a few times lower than for curve *b*. The deterioration in the S/N ratio occurs partially because some regions of the CV curve (e.g., 0–500 mV in the forward scan and 1000–600 mV in the reverse scan) do not contribute significantly to the analytical signal, but (since they are included in ΔQ_{TA} calculations) they contribute to the baseline noise. Moreover, on the platinum electrode the level of baseline noise in the hydrogen region is a few times larger than in the "double layer" or oxygen region; this interesting finding will be discussed at the end of the paper.

The detector response can be reliably expressed in terms of the total absolute difference only if the baseline drift is small (say, less than 1% during the entire experiment). Such a situation is commonly encountered in flow-injection experiments. However, in CE or HPLC detection the baseline drift is sometimes significant, and in such cases the magnitude of the ΔQ_{TA} peaks is strongly affected by the choice of the reference CV curve. It should be stressed that both the baseline drift and the choice of reference CV curve have practically no effect on the detector response peaks expressed in terms of ΔQ based on eq. [1].

The detection method described is nearly universal for organic compounds since nearly all organic compounds adsorb on noble metal electrodes. In addition, many inorganic compounds, particularly anions, can also be detected. The shape of CV curves is strongly affected by the nature of the electrode material and the nature of the adsorbates. We will begin the discussion of the results by describing the role of these two primary factors.

Pt electrode

It is interesting that changes in the CV curve caused by adsorption of different species on Pt are quite similar. For example, the changes caused by injection of 1×10^{-3} M aniline and 1×10^{-4} M NaSCN are shown in Figs. 3*a* and 3*b*, respectively. In

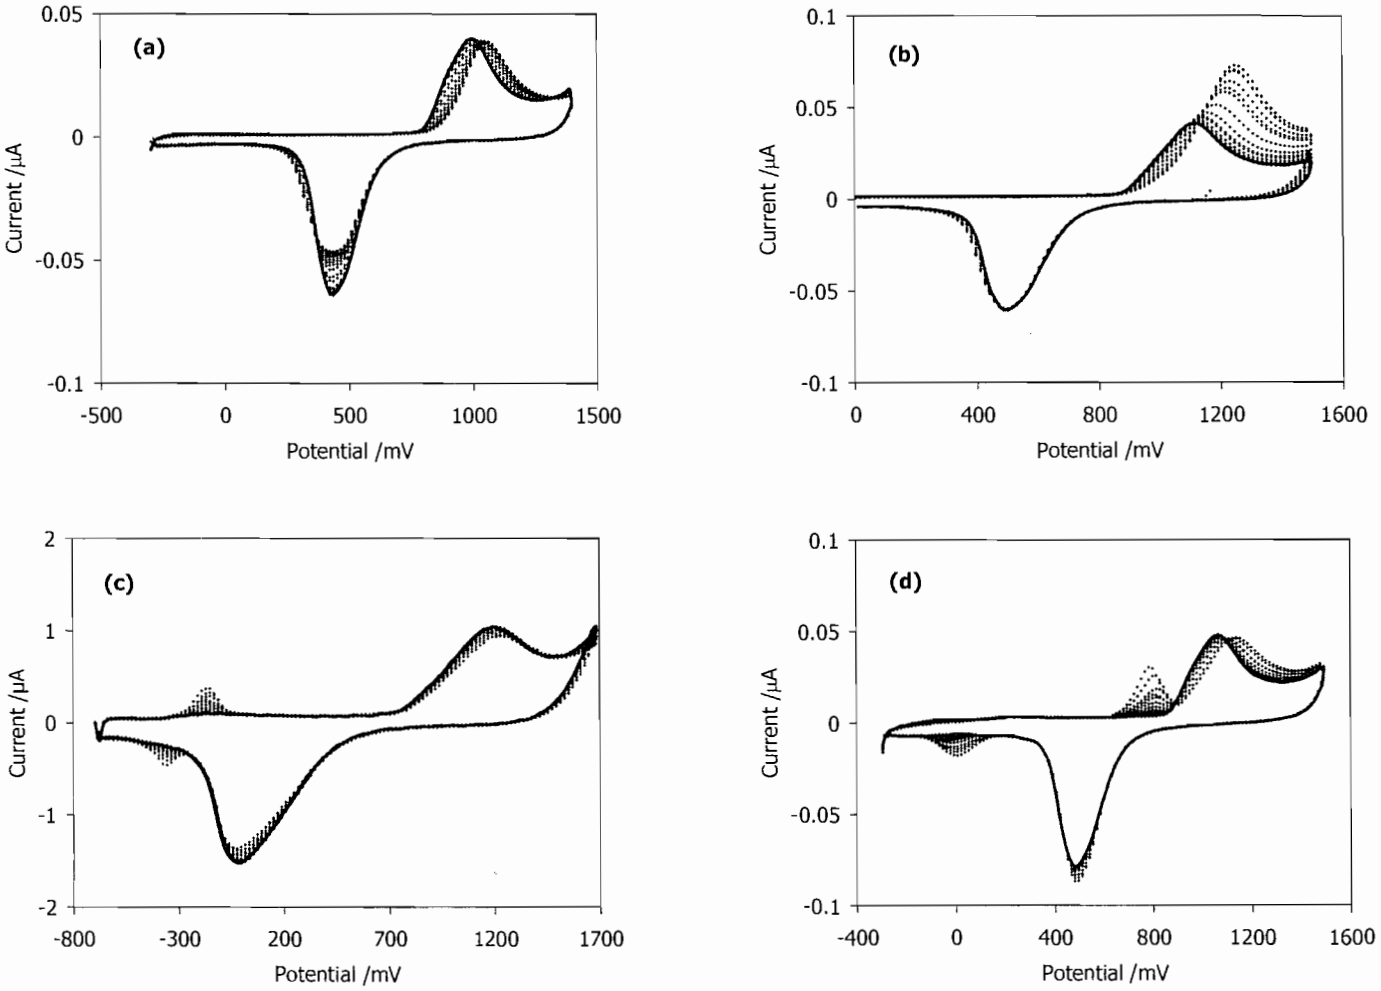
KNO_3			7	18

the group of 26 compounds studied in this work only MoO_4^{2-}, AsO_2^-, and Cd^{2+} produced a significantly different pattern. A set of CV curves recorded during injection of 1×10^{-4} M Na_2MoO_4 and 1×10^{-4} M $NaAsO_2$ are shown in Fig. 3*c* and Fig. 3*d*, respectively.

To establish what type of compounds could be detected at the Pt electrode a series of experiments involving replicate injections of 1×10^{-4} M solutions of various analytes in 0.05 M H_3PO_4 was performed. In all cases the preconcentration time was 0.1 s, the scan rate was 20 V/s, and the injection loop was 50 μL. The rest potential was in all cases equal to −0.4 V. The normalized electrode response and reproducibility of results are listed in Table 1. The normalized response represents ΔQ_{TA} divided by the true surface area of the electrode. The reproducibility is expressed as the relative standard deviation of four replicate injections.

The results indicate that the Pt electrode is well suited for detection of aromatic compounds, thio-componds, heavy metals, and a number of inorganic anions; however, it exhibits very low sensitivity towards methanesulfonic acid, $LiAsF_6$, ethanediol, and *N*,*N*-dimethylformamide. The relative standard deviation of the results is typically 2–4% except for these compounds, which produce a very weak response.

Au electrode



The characteristic feature of cyclic voltammograms at a gold electrode is a set of peaks associated with the formation and dissolution of a surface oxide layer at about 1.0 and 0.45 V, respectively. Most organic compounds and some inorganic anions cause a shift of the oxide formation peak towards a more positive potential, as can be seen in the case of 1×10^{-3} M pyridine (Fig. 5*a*).

For many organic compounds some increase of current, presumably due to their catalytic oxidation, can be noted at the most positive potentials; however, these kinetic currents are usually not very strongly pronounced in high sweep rate experiments. Exceptional in this regard are thio-compounds as well as some inorganic anions (e.g., IO_3^-, I^-, Br^-, SCN^-) that produce a well-defined oxidation current at potentials more positive than the gold oxide formation peak. This behavior is exemplified by a set of CV curves recorded during the injection of 1×10^{-4} M thiocyanate (Fig. 5*b*).

Since there is no significant adsorption of hydrogen on gold, Au electrodes have a relatively wide polarizibility range and, because of that, they are more suitable than Pt electrodes for the determination of metal ions. Cyclic voltammograms recorded during the injection of 1×10^{-5} M $Pb(NO_3)_2$ are

Fig. 5. Overlapping cyclic voltammograms recorded during flow-injection experiments at a 5 μm (radius) gold electrode: (*a*) 1 mM pyridine; (*b*) 0.1 mM NaSCN; (*c*) 0.02 mM $Pb(NO_3)_2$; (*d*) 0.1 mM H_2SeO_3. Eluant: 0.05 M H_3PO_4; delay time: 0.2 s; rest potential: (*a*) and (*b*) 0 V, (*c*) −0.7 V, (*d*) −0.3 V; scan rate: (*a*), (*b*), and (*d*) 20 V/s, (*c*) 670 V/s. Solid curves represent overlapping cyclic voltammograms recorded in the absence of analyte before and after the injection. The dotted lines illustrate changes caused by injection of the analyte.

shown in Fig. 5*c*. In this case the scan rate was 665 V/s and a preconcentration of Pb at the microelectrode was carried out for 0.4 s at −700 mV before each potential scan. An injection of Pb^{2+} ions under these conditions causes the appearance of a well-defined stripping peak at −150 mV and a corresponding reduction peak at −350 mV, as well as some inhibition of the oxide formation process. Similar behavior was observed for Cd^{2+}, Tl^{+}, Cu^{2+}, AsO_2^{-}, and SeO_3^{2-}. A set of CV curves recorded for that last ion is shown in Fig. 5*d*.

The normalized response of the gold electrode due to injection of various compounds is shown in Table 1. All experimental parameters were the same as in the Pt electrode study, except for the electrode radius, which was 5 μm. Despite significant differences in the electrochemical behavior of gold and platinum electrodes, the normalized responses of either electrode towards different compounds usually follow the same order. In most cases the sensitivity of the Pt electrode was higher than the Au electrode sensitivity due to a contribution from the hydrogen adsorption region; however, the reproducibility of results obtained with the gold electrode was somewhat better.

It should be stressed that the data in Table 1 allow only identification of compounds that can be detected by this method; the higher normalized response to an injection of 1×10^{-4} M analyte does not necessarily indicate a lower detection limit. For example, the normalized response of the Au electrode to a 1×10^{-4} M glycine solution is slightly higher than to an injection of $Cd(NO_3)_2$ at the same concentration; however, as it will be shown later, the detection limit for Cd^{2+} ($\sim 3 \times 10^{-8}$ M) is about 20 times smaller than the detection limit for glycine.

In general, the electrode response can be affected by the thermodynamic and kinetic parameters of adsorption, the rate of mass transport, and the electrochemical behavior of the adsorbed species. The free energy and the rate of adsorption depend on the electrode potential, the electrode material, and, to some extent, on the choice of the supporting electrolyte. The mass transport rate is strongly affected by the radius of the ultramicroelectrode, the solution flow rate, and the delay time between subsequent scans. Finally, the electrochemical behavior of adsorbates is affected by the choice of initial and vertex potential, the scan rate, the supporting electrolyte, and

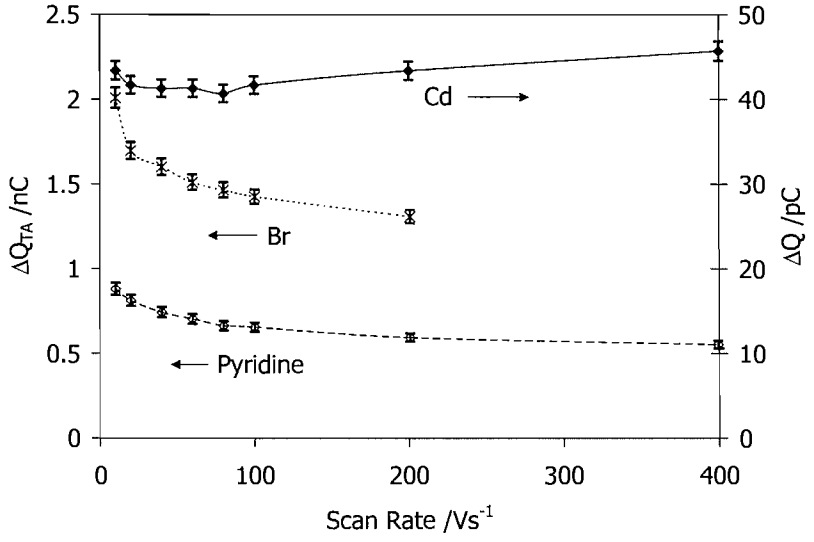
Fig. 6. The effect of scan rate on the response of a Au electrode (5 μm in radius) to injections of 2×10^{-5} M Cd^{2+}, 2×10^{-5} M pyridine, and 4×10^{-5} M Br^- in 0.05 M H_3PO_4. The delay time was 400 ms and the rest potential was 0.2 V for both pyridine and Br^- and −0.5 V for Cd. The electrode response was expressed as ΔQ_{TA} (left-side scale) in the case of pyridine and Br^- and as the stripping peak charge (right-side scale) in the case of Cd.



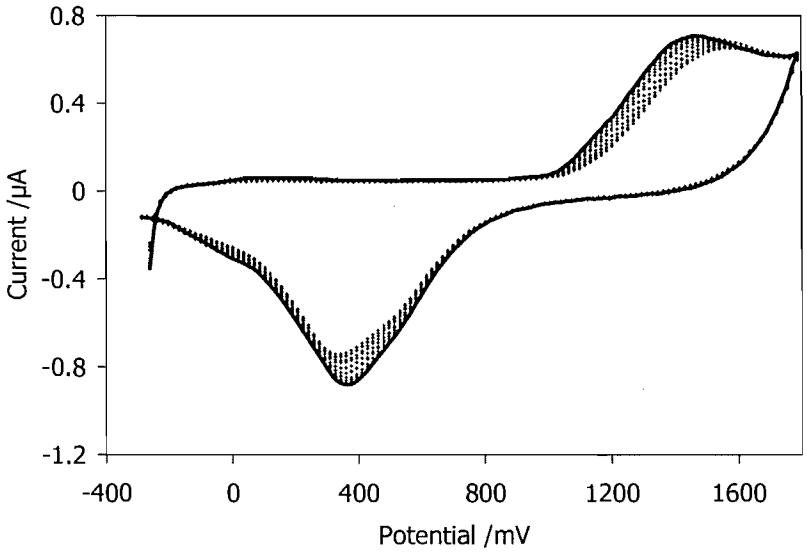


Fig. 7. Overlapping cyclic voltamograms for flow injection of 2×10^{-5} M pyridine in 0.05 M H_3PO_4 at a 5-μm Au electrode. The flow rate was 2.0 mL/min, and the sweep rate was 400 V/s. Each scan was preceded by a 200 ms preconcentration period at −0.5 V.

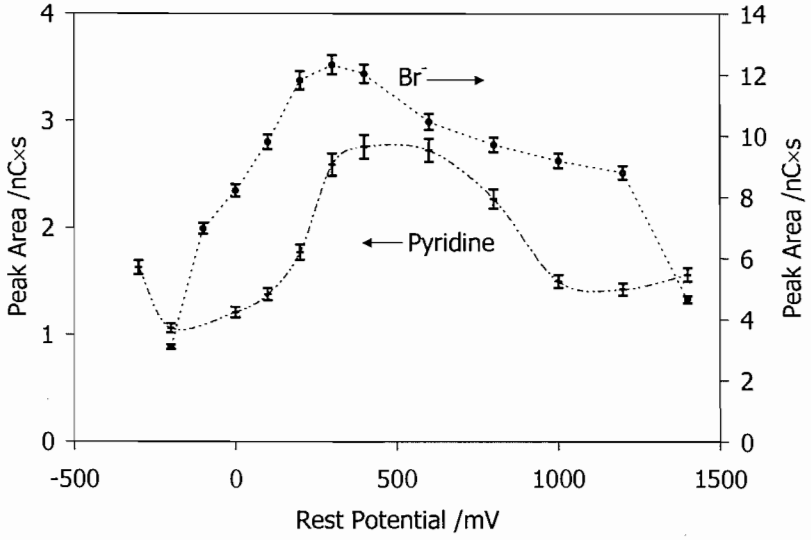
the electrode material. More detailed studies of the effect of experimental conditions on the electrode response were done for only a few compounds, mainly pyridine, Br^- and Cd^{2+}.

Effect of sweep rate



The use of this detection method in conjunction with fast separation techniques such as capillary electrophoresis requires the employment of high scan rates. From this point of view it is important to examine how the sensitivity of the method is affected by the scan rate. The results obtained for Cd^{2+} on the Au electrode show that the height of the flow-injection peak is constant within experimental error for scan rates between 10 and 400 V/s (see Fig. 6). This is not surprising since in this case the main contribution to the signal arises from the electrical charge needed to remove cadmium from the electrode. This charge depends on preconcentration conditions but should be independent of the scan rate.

In the cases of Br^- and pyridine the signal (expressed in terms of ΔQ_{TA}) decreases somewhat with scan rate (see Fig. 6). In this case the analytical signal originates mainly from changes in the oxide-formation and oxide-reduction peaks. Due to slow electrode kinetics and ohmic drops these peaks are flattened at very high scan rates (see Fig. 7), their charge decreases, and, consequently, changes caused by adsorption of analytes become smaller. Despite this, for all analytes studied (Cd^{2+}, Br^-, and pyridine) the signal-to-noise ratio was the

Fig. 8. The effect of rest potential on the response of a Au electrode (5 μm in radius) to injections of 2×10^{-5} M pyridine or 4×10^{-5} Br^- in 0.05 M H_3PO_4. The delay time was 400 ms and the scan rate was 20 and 30 V/s for pyridine and Br^-, respectively.

highest for scan rates between 200 and 700 V/s. The most dramatic improvement was observed for Cd, where the change in the scan rate from 10 to 700 V/s caused an increase in the S/N ratio from 26 to 410. It should be noted that currents measured in these experiments are essentially proportional to the scan rate and higher currents are obviously less affected by external interference coming from the power line, the computer monitor, or the separation current in capillary electrophoresis experiments.

The response of the Pt electrode is affected by the scan rate in a similar way to that described above; however, on this electrode the oxide-formation and oxide-reduction processes are slower than on gold and, consequently, the optimum scan rate is about 100 V/s.

Effect of the preconcentration potential

In Fig. 8 is shown the effect of the rest potential on the Au electrode response to injection of a solution of 2×10^{-5} M pyridine and 4×10^{-5} M Br^- in 0.05 M H_3PO_4. The optimum potential for preconcentration of these analytes is similar, about 0.4 V and 0.5 V for pyridine and Br^-, respectively. The relation observed for Br^- can be easily explained: at negative potentials the efficiency of preconcentration drops because adsorption of anions on the negatively charged electrode becomes thermodynamically unfavorable. Some drop of response at positive potentials is likely due to the competitive adsorption of hydroxyl ions. At even more positive potentials an irreversible oxidation of Br^- (presumably to BrO_3^-) takes place and at this point the electrode response declines rapidly (it should be noted that the Au electrode shows only residual response to BrO_3^- ions). The curve obtained for pyridine most likely reflects the dependence of the free energy of adsorption on potential. Extensive studies in this area were done by Lipkowski and Stolberg (18); however, direct comparison of results is difficult because of differences in the supporting electrolyte. The effect of the rest potential on the response at the Pt electrode for pyridine and bromide is similar to that observed at the Au electrode, but the optimum rest potential is about 200 mV more negative.

The effect of the rest potential on preconcentration of other compounds listed in Table 1 was also studied. For most anions and all neutral organic compounds on both Pt and Au electrodes the optimum preconcentration potentials were within ±150 mV of those reported for pyridine. This means that efficient preconcentration of different compounds can be carried out at the same rest potential, which is essential for the wide application of the method in CE or HPLC detection. However, as data in Fig. 9 indicate, the sensitive detection of metal ions (such as Cd^{2+}, Cu^{2+}, and Pb^{2+}) requires a different setting of the rest potential.

It is very interesting that these metal ions can be preconcentrated on the Au electrode at either negative or positive potentials. This is clearly evident from experiments with a normal ($E_{vertex} > E_{initial}$) or reversed scan direction but, to observe this effect, high scan rates must be employed so that the scanning step is short in comparison with the preconcentration period. It is well known that lead can be preconcentrated on the anode as PbO_2, but anodic preconcentration of Cd^{2+} and Cu^{2+} was rather unexpected. It is possible that at sufficiently positive potentials hydroxyl groups at the gold-solution interface undergo dissociation and some metal ions may become covalently attached to the surface via oxygen as Au-O-Me. The anodic preconcentration of Cd and Cu is not very efficient, perhaps because the adsorption equilibrium constants are relatively small; however, in the case of Pb the accumulation can be carried out equally well at negative or positive potentials.

Similar experiments were also done for Cd^{2+} on a Pt electrode but the anodic preconcentration of Cd^{2+} was not observed in this case.

Effect of the delay time

Preconcentration of analytes on the electrode takes place during the delay period (assuming that an appropriate rest poten-

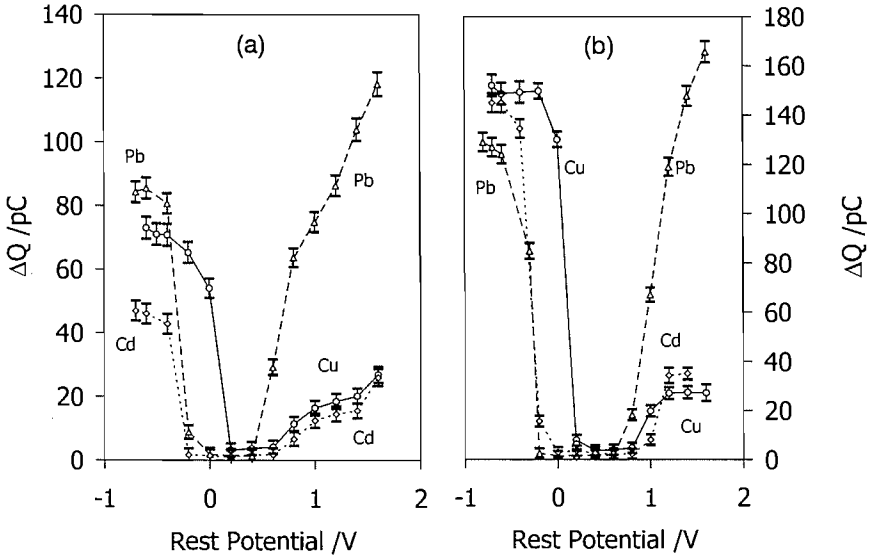
Fig. 9. The effect of rest potential on the response of a Au electrode (5 μm in radius) to injections of 2×10^{-5} M Pb^{2+}, Cd^{2+}, or Cu^{2+} in 0.05 M H_3PO_4. The delay time was 400 ms and the scan rate was 750 V/s for Cd and 665 V/s for Pb and Cu. The potential was scanned between −0.6 and 1.7 V. The initial scanning direction was towards negative potentials in graph (*a*), and towards positive potentials in graph (*b*).



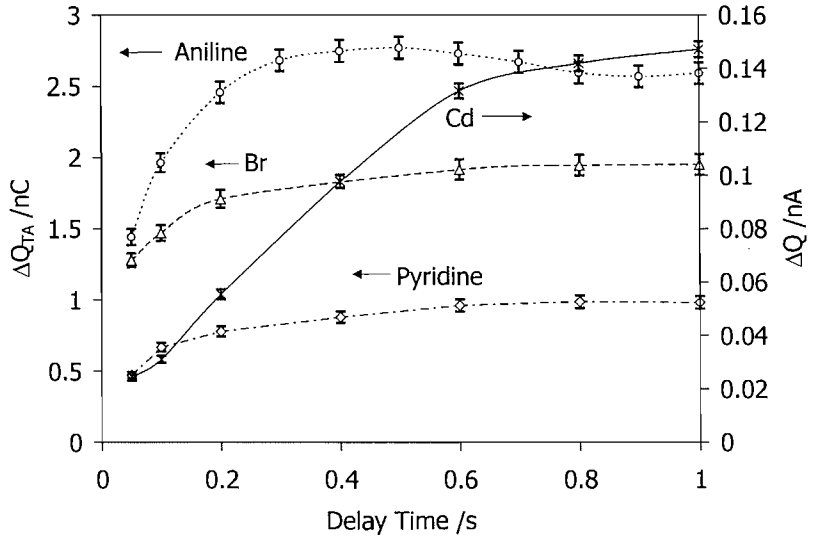


Fig. 10. The effect of delay time on the electrode response to injections of 3×10^{-5} M aniline, 2×10^{-5} M Cd^{2+}, 2×10^{-5} M pyridine, or 4×10^{-5} M Br^- in 0.05 M H_3PO_4. The following scan rates were used: aniline 100 V/s, Cd^{2+} 750 V/s, pyridine 20 V/s, Br^- 30 V/s. Measurements for aniline were done with a 12.5-μm Pt electrode, and all others were done with a 5-μm Au electrode. The rest potential was 0.2 V for pyridine and Br^-, −0.1 V for aniline, and −0.5 V for Cd^{2+}. The electrode response was expressed as ΔQ_{TA} (left-side scale) in the case of aniline, pyridine, and Br^-, and as the stripping peak charge (right-side scale) in the case of Cd^{2+}.

tial has been selected) and during scanning, when the electrode potential passes through the region of spontaneous adsorption. This last contribution, however, is very small at high scan rates (for example, results in Fig. 9 indicate that it is less than 3%). Studies of the functional relation between the electrode response and the delay time may provide some information about the kinetics of the adsorption process; here, however, only a brief discussion of this topic will be provided. In Fig. 10 the electrode response (expressed in terms of the stripping peak charge for Cd^{2+} and in terms of ΔQ_{TA} for pyridine, aniline, and Br^-) is shown as a function of the delay time. In the case of Cd^{2+}, pyridine, and Br^- the data were obtained at a Au ultramicroelectrode in 0.05 M H_3PO_4 solution. Concentration of the analyte was 2×10^{-5} M for both Cd and pyridine and 4×10^{-5} M for Br^-. Aniline at a concentration of 3×10^{-5} M in 0.05 M H_3PO_4 was studied on a Pt ultramicroelectrode. An examination of the CV curves indicates that the underpotential deposition (UPD) of Cd on gold is electrochemically reversible, consequently the accumulation of Cd on the electrode must be controlled by the mass transport. Results pre-

sented in Fig. 10 show that the electrode surface becomes saturated with cadmium within a 1-s time window. The limiting surface concentration calculated from the limiting charge was $(9.7 \pm 1.5) \times 10^{-10}$ mol/cm^2. Based on the initial slope of the ΔQ vs. time curve, the flux of the analyte was estimated as $(1.4 \pm 0.2) \times 10^{-9}$ mol s^{-1} cm^{-2}. In quiescent solutions the flux of a depolarizer at a disk ultramicroelectrode under steady-state conditions can be expressed as (19):

$$[3] \quad v = \frac{4DC_0}{\pi r}$$

where D is the diffusion coefficient, C_0 is the bulk concentration of electroactive species, and r is the electrode radius.

The steady-state mass transport is reached for times longer than $\tau_{ss} \approx r^2/D$ (19). By taking a likely value of the diffusion coefficient $D = 1 \times 10^{-5}$ cm^2/s and $C_0 = 2 \times 10^{-8}$ mol/cm^3, $v = 5.1 \times 10^{-10}$ mol s^{-1} cm^{-2} and $\tau_{ss} = 25$ ms can be obtained. The difference between observed and calculated fluxes can be explained by taking into account a convectional mass transport caused by the flow of solution (the linear velocity of solution near the electrode in this experiment was about 8.7 cm/s). This large contribution from convectional mass transport was confirmed by brief experiments involving amperometric detection of a 1 mM $Ru(NH_3)_6^{3+}$ solution in 0.05 M H_3PO_4 with a gold electrode. In this case the steady-state limiting current in the flowing (2.0 mL/min) electrolyte was about 1.9 times larger than that observed at the same electrode in a quiescent solution of the same composition. Because of this large contribution from convection the rate of mass transport to a 12.5 μm Pt electrode is not expected to be significantly different from that observed at the Au electrode.

Curves obtained for Br^-, pyridine, and aniline are similar to the one obtained for Cd, but in general the plateau is reached more quickly and the difference in the electrode response for the delay times 0.05 s and 1.0 s is much smaller than for Cd. These differences can be partially explained by the smaller limiting surface concentration for the organic adsorbates, more extensive preconcentration during the potential scan, and larger bulk concentration in the case of Br^- and aniline. However, the major cause of the observed differences may be due to slow cleaning of the electrode surface. It is very likely that large organic molecules adsorbed during the delay period are not completely oxidized during a single high-speed scan. Consequently, for some molecules the average residence time on the electrode surface may extend over a few cycles and, if this is the case, a smaller number of surface sites is available for adsorption during the delay period. Slow oxidation is clearly evident from analysis of CV curves obtained for pyridine with both Au and Pt electrodes (the total charge consumed in the oxygen adsorption region drops when the adsorbate is injected). For aniline on Pt and bromide on Au and Pt the total charge consumed in the oxygen adsorption region increases after the injection, but this does not exclude the possibility of incomplete oxidation. Besides, the oxidation processes likely go through several stages, and intermediates as well as products may reside on the interface for some time.

It should be stressed, however, that all substances studied in this work are eventually completely removed from the electrode. In all cases studied the cleaning of the electrode was complete after 20 or fewer scanning cycles. This conclusion can be derived from the fact that the electrode response always returns to normal within a few seconds after the supporting electrolyte flushes out the analytes.

It is difficult to conclude at this stage whether the rate of adsorption for aniline on Pt or pyridine on gold is controlled by mass transport or by interfacial kinetics, but there is no doubt that rates of adsorption for these substances are large. In all experiments the electrode was exposed to adsorbates for only a few seconds. Therefore in all cases when a high sensitivity of detection was obtained, the rate of adsorption had to be very high. This is in sharp contrast with results published by Bockris and Jeng (20), who reported that for many organic compounds (including aniline) several minutes of exposure to 10^{-4} M solution are needed in order to obtain a significant surface coverage on platinum. Wieckowski (21) pointed out that kinetic measurements reported by Bockris and Jeng (20) may be seriously skewed by slow mass transport through micropores in the platinum-black electrode employed in these measurements. It should also be emphasized that continuous scanning of the electrode potential between the hydrogen-adsorption and oxide-formation regions carried out several times per second may produce a very reactive interface, and this could explain high rates of adsorption observed in this work. Despite this, in some cases (e.g., ethanediol on Pt) slow adsorption kinetics may be the limiting factor in obtaining good sensitivity in detection.

Stability of response

Both electrodes tested provide a stable response for several hours without any mechanical or chemical treatment. The longest test (48 h) involved replicate measurements of the response for 1×10^{-5} M pyridine on a gold electrode in continuously flowing 0.05 M H_3PO_4 with the sweep rate of 20 V/s, the rest potential equal to 0.4 V, and the delay time equal to 0.1 s. The relative standard deviation of the results was 4.6% and there was no definite drift in the electrode sensitivity. A Pt electrode was tested during a 16-h period for the determination of 2×10^{-6} M Br^- in 0.05 M H_3PO_4 solution and gave similar results. In this experiment the sweep rate was 20 V/s, the rest potential was 0.2 V, and the delay time was 0.2 s.

Calibration curves and the detection limits

From an analytical point of view, the relation between concentration of analyte and the electrode response, called the calibration curve, is the most important. It is expected that for most substances the electrode response is proportional to electrode coverage. This is obviously the case when ΔQ due to oxidation of adsorbates is monitored. This assumption may be less obvious, but not unlikely, when inhibition of oxide formation or hydrogen adsorption by adsorbates is considered. For example, it has been shown that a decrease of charge in the oxide-formation region on platinum caused by adsorption of Cl^- is proportional to the surface coverage (ref. 17, p. 139). Consequently, if the electrode coverage is controlled by the rate of mass transport, a linear calibration curve is expected, up to the point when full electrode coverage is reached during the preconcentration period. When thermodynamics of adsorption or kinetics of the interfacial step control the electrode coverage, a linear calibration curve can be expected only for very small (perhaps <5%) coverages. Under typical experimental conditions used in this work and for strongly adsorb-

Fig. 11. Calibration curve obtained for Br^- on a 5-μm Au electrode in 0.05 M H_3PO_4. Circles represent the average peak area under the ΔQ vs. time curve measured for three to five injections. The ΔQ function was obtained by integrating CV curves between 1.1 and 1.4 V in the forward scan. The scan rate was 20 V/s and the delay time was 0.1 s.

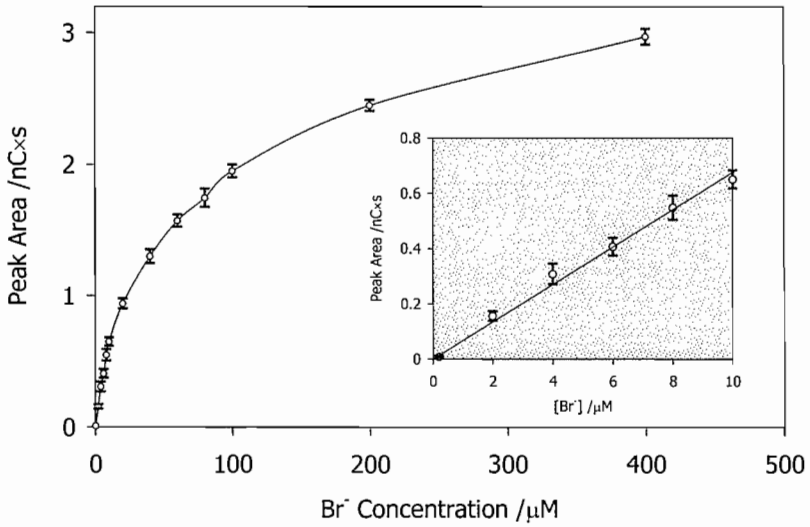

Table 2. Detection limits at Au and Pt electrodes in 0.05 M H_3PO_4.

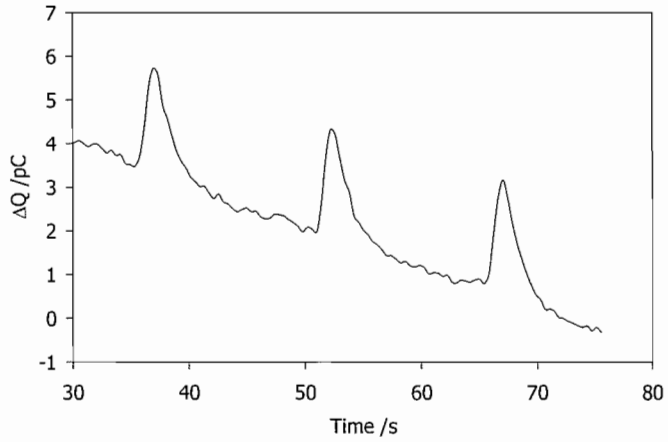
Analyte	Electrode	Scan rate (V/s)	Rest potential (V)	Integration limits (V)	Detection limit (mol/L)
$Cd(NO_3)_2$	Au	750	–0.7	–0.4–0.0	3×10^{-8}
Glycine	Au	580	0.4	0.7–1.3	6×10^{-7}
$NaAsO_2$	Pt	100	–0.4	0.7–1.4	1×10^{-8}
NaBr	Au	580	0.4	0.7–1.3	3×10^{-8}
NaCl	Pt	100	0.2	0.5–1.0	2×10^{-8}
Pyridine	Au	580	0.4	0.7–1.3	4×10^{-8}
Pyridine	Pt	100	0.2	0.5–1.0	3×10^{-8}



ing substances (such as pyridine, Br^-, or Cd^{2+} on gold) the linear portion of the calibration curve extends from about 10^{-7} M to about 10^{-5} M. A typical calibration curve obtained for the detection of Br^- on a Au ultramicroelectrode in 0.05 M H_3PO_4 is shown in Fig. 11. It should be noted that electrode response can be expressed in various ways as peak heights or peak areas. In addition, the magnitude of the flow-injection peaks depends on choice of the data processing methods (see eqs. [1] and [2], and Fig. 4). Results shown in Fig. 11 represent the average peak area under the ΔQ vs. time curve measured for three to five consecutive injections of a standard solution; the ΔQ function was obtained by integrating CV curves between 1.1 and 1.4 V in the forward scan. The scan rate was 20 V/s and the delay time was 0.1 s.

Measurements carried out for small analyte concentrations allow the detection limit C_{DL} to be estimated:

$$[4] \quad C_{DL} = \frac{3s_b}{m}$$

where s_b is the standard deviation of the baseline around the flow-injection peak and m is the sensitivity of the method

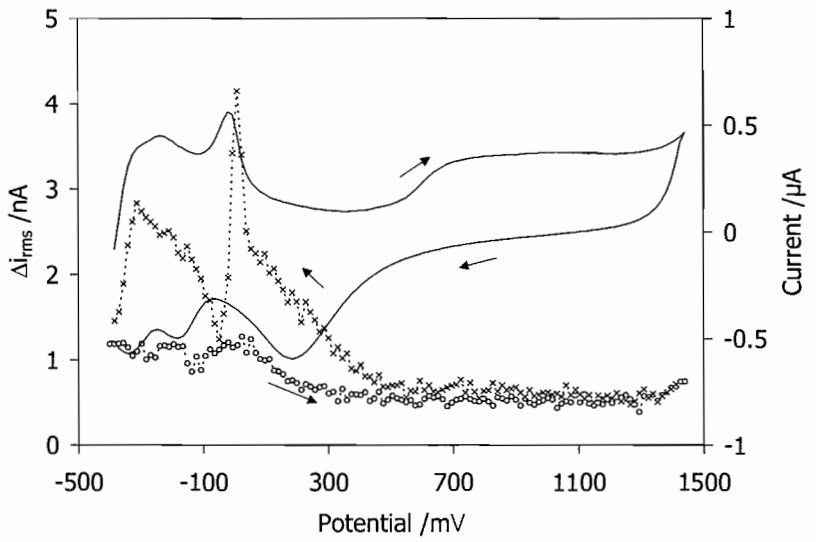


Fig. 12. Response of a 5-μm Au electrode to three consecutive injections of 2×10^{-7} M $Cd(NO_3)_2$ in 0.05 M H_3PO_4. The scan rate was 750 V/s, the rest potential was −0.5 V, and the delay time was 0.4 s. The electrode response is expressed in terms of the stripping peak charge.

Fig. 13. Potential dependence of the root-mean-square current noise (–×–×– forward scan, –○–○– reverse scan) and the current–potential relation (solid line) for a 12.5-μm Pt electrode in 0.05 M H_3PO_4. The scan rate was 100 V/s, the rest potential was −0.4 V, and the delay time was 0.2 s.

(a change in the peak height divided by the change in concentration) near the detection limit.

The detection limits obtained for several substances at Au and Pt electrodes are given in Table 2. To insure the best signal-to-noise ratio the measurements were carried out at high scan rates. In all cases the delay time was 0.4 s, but the rest potential and integration limits in the calculation of the $\Delta Q(t)$ function were optimized to obtain the maximum S/N ratio. Details of experimental conditions are given in Table 2. For all analytes, except Cd^{2+}, the potential scanning range was from −0.7 to 1.7 V on gold and −0.4 to 1.5 V on platinum.

In the case of cadmium the vertex potential was +0.7 V; this means that the potential scan was reversed before reaching the oxide formation peak. It should be noted that the stripping peak for cadmium occurs in a relatively narrow potential range and is superimposed on a relatively small background current. Because of that, it was possible to obtain a good detection limit despite a relatively small signal. The actual trace of the $\Delta Q(t)$ curve for the flow injection of 2×10^{-7} M $Cd(NO_3)_2$ is shown in Fig. 12. Despite some baseline drift, the response for consecutive injections is quite reproducible; the relative standard deviation for six replicates was 6.6 and 9.0%, based on peak height and peak area measurements, respectively. Peaks of this magnitude can easily be used in quantitative analysis although they represent only 2.5 pC of electrical charge generated by the oxidation of 1.3×10^{-17} mol of Cd. The electrode coverage in this case does not exceed 0.7%. At the detection limit the typical electrode coverage is about 0.1% and the quantity of substance adsorbed at a 5-μm electrode is about 1 attomol, hence the method is suitable for analysis of very small samples. In this regard the method offers very significant improvement over existing electroanalytical methods.

Data in Table 2 also indicate that this method can compete with well-established methods when the ability to detect small concentrations is compared. The detection limit for Cl^- on Pt is a few times lower than the limit reported for the pulse amperometric detection method (22). Our detection limit for AsO_2^- is comparable with the detection limit obtained for the same analyte using dc amperometric detection with a much larger working electrode (23). The same authors also determined the detection limit for AsO_2^- at a Pt electrode, 12.5 μm in radius, and reported a value 5 times higher value than ours. This comparison is significant, because amperometric detection is considered to be the most sensitive electrochemical detection method in flowing solutions (2). It should also be stressed that amperometric detection is applicable only to substances that can be easily oxidized or reduced, whereas the method described in this work can be used for the detection of any surface-active substance.

The detection limit can be further decreased by increasing the preconcentration time in cases where the adsorption process is limited by mass transport or surface kinetics; however, in some applications (e.g., CE or HPLC detection) this may lead to a deterioration of the zone resolution.

An improvement in the detection limit can also be achieved by lowering the baseline noise. The noise level in such measurements depends to a large extent on the quality of the electronic equipment. In this case a relatively inexpensive 12-bit data acquisition board was used, together with an in-house-built potentiostat. Certainly there is room for improvement; for example, the potentiostat could be redesigned to allow grounding of the auxiliary electrode (hence grounding of the electrolyte solution). Hopefully this would provide better shielding from environmental noise. Also, increasing the resolution of the analog-to-digital converter from 12- to 16-bit should be very beneficial.

Interestingly, however, the level of the background noise is also determined by the properties of the electrode. For example, in the case of the Pt ultramicroelectrode the level of noise was much higher in the hydrogen region than in the oxygen adsorption region. In Fig. 13 the $\Delta i_{rms}(E)$ function represents the standard deviation of current measured at a given potential

For personal use only.

for 64 consecutive CV curves. Analyses of current fluctuations in the hydrogen region done both in the time domain and after the Fourier transformation did not reveal an obvious trend or pattern. At this stage it is difficult to explain the details of this phenomenon; however, it may be related to the fact that the hydrogen-adsorption process is very fast and the current strongly depends on potential (sharp peaks). Consequently, a small fluctuation in the electrode potential may cause a relatively large fluctuation in the current. The noise level for the Au electrode was independent of potential and comparable to that observed for the Pt electrode in the oxygen-adsorption region.

All experiments described up to now in this paper were done using dilute H_3PO_4 solutions as eluents; however, other supporting electrolytes were also briefly tested. The experiments involved detection of Br^-, pyridine, and glycine with a Au electrode. Acidic solutions containing weakly adsorbing anions such as HNO_3 or $HClO_4$ gave results similar to those described in this paper. In NaH_2PO_4/Na_2HPO_4 buffer or in dilute KOH solutions the sensitivity of the method drops by one or two orders of magnitude. In a borax solution (pH = 9.2) or in a carbonate buffer (pH $\approx$ 10) many organic compounds can be detected with sensitivity only 2 to 3 times worse than in acidic solutions. However, a Au electrode appears less stable in basic solutions than in acidic solutions. For example, during detection of glycine, a 10% decrease in sensitivity was observed over a period of 25 h in a continuously flowing 0.05 M $Na_2B_4O_7$ solution.

The partial discharge of electrosorbates and its influence in electrocatalysis

J.W. Schultze and D. Rolle

Abstract: The integral charge flow during electrosorption processes can be described by the electrosorption valency, γ. This dimensionless thermodynamic parameter consists of contributions from the penetration of the substance into the double layer, g, and the partial charge transfer, λ. g varies between 1 for discharged substances and very small values, g_{min}, for electrostatic adsorption without transfer. The charge transfer coefficient, λ, can be estimated empirically using Pauling's concept of electronegativity, χ, but the quantitative correlation is different for anions and cations due to the different type of bonding. The γ value of special electrosorbates depends on the nature of the solvent and ligands. Theoretical model calculations justify the influence of χ and solvation. The partial discharge of ions causes a decreasing electrostatic influence in electrocatalysis. Examples are given for ion (ITR) and electron transfer reactions (ETR).

Key words: electrosorption valency, partial charge transfer, bond formation, solvation, double layer.

Résumé : Il est possible de décrire l'écoulement intégral de la charge accompagnant les processus d'électrosorption par la valence d'électrosorption γ. Ce paramètre thermodynamique sans dimension est formé de contributions provenant de la pénétration de la substance dans la double couche, g, et du transfert partiel de charge, λ. Les valeurs de g varient entre l'unité, pour les substances déchargées, et des valeurs très faibles, g_{min}, pour une adsorption électrostatique sans transfert. Il est possible de faire une évaluation empirique du coefficient de transfert de charge, λ, en utilisant le concept d'électronégativité de Pauling, χ; toutefois, la corrélation quantitative est différente pour les anions et les cations à cause des différences dans les types de liaison. La valeur de γ pour des électrosorbats spéciaux dépend de la nature du solvant et des coordinats. Des calculs sur un modèle théorique justifient l'influence de χ et de la solvatation. La décharge partielle des ions provoque une diminution de l'influence électrostatique dans l'électrocatalyse. On donne des exemples pour des réactions de transfert d'ion (RTI) et de transfert d'électron (RTE).

Mots clés : valence d'électrosorption, transfert partiel de charge, formation de liaison, solvatation, double couche.

[Traduit par la rédaction]

1. Introduction

Since the classical paper of Helmholtz (1), the structure of the metal–electrolyte interface has been the subject of many investigations. Important contributions have been made by Brian Conway, in particular, with many papers on electrosorption processes and electrocatalysis (2–6).

In spite of careful investigations, the relation between molecular electrosorption models and macroscopically determined parameters is open to discussion. Taking into account the partial charge transfer coefficient λ, an electrosorption reaction can formally be written as

$$[1] \quad \nu M - OH_2 + S^z aq \rightleftharpoons M_\nu - S^{z+\lambda} + \lambda e^- + \nu H_2O$$

Received May 22, 1997.

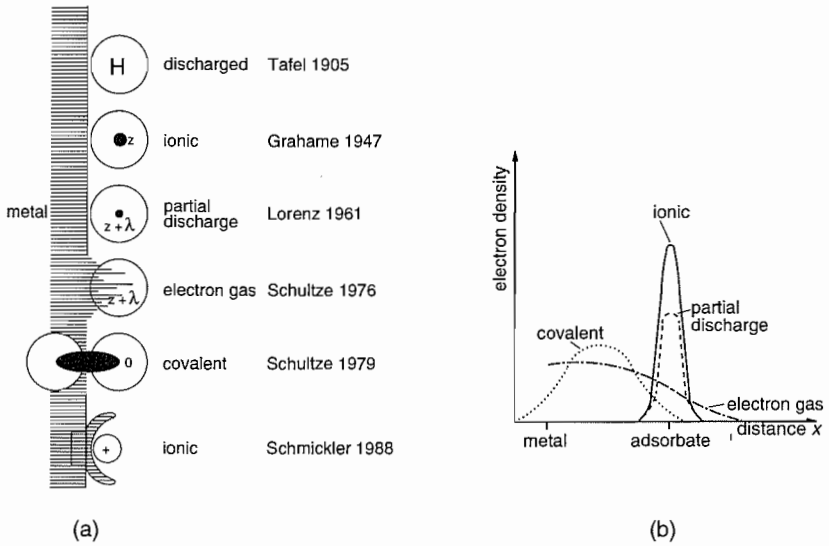
This paper is dedicated to Professor Brian E. Conway on the occasion of his 70th birthday.

J.W. Schultze[1] **and D. Rolle.** Arbeitsgemeinshaft Electrochemischer Forschungsinstitutionen e.V. - Institut an der Heinrich-Heine-Universität Duesseldorf, D 40225 Duesseldorf, Germany.

[1] Author to whom correspondence may be addressed. Telephone: 49-211-81-14750. Fax: 49-211-81-12803.

Electrochemical experiments, on the other hand, yield the macroscopic parameters, i.e., metal charge q_m, and the surface excess Γ of the specifically adsorbed substance S^z and the (mostly nonspecifically) cosorbed counterions X to maintain the condition of electroneutrality

$$[2] \quad -q_m = z_s F \Gamma_s + z_x F \Gamma_x$$



Therefore, the role of partial charge transfer is controversial, since it cannot directly be determined in electrochemical experiments, but it is involved in the metal charge q_m (7). While λ was neglected in the fundamental papers of Grahame (8), it was overemphasized in the papers by Lorenz and Salié (9, 10).

In extension of a recent analysis, the possibilities and limitations of charge transfer and the accompanying charge distribution will be analysed in dependence on the molecular parameters of the systems. In general, the analysis will be valid for all substances such as small or large ions, and neutral molecules. To show the most important contributions, however, we confine the following discussion to mononuclear ions. Due to its practical relevance, the impact of the charge transfer on the rate of ion (ITR) and electron transfer reactions (ETR) will be discussed. New results on the electrosorption valency of organic molecules are given elsewhere (11).

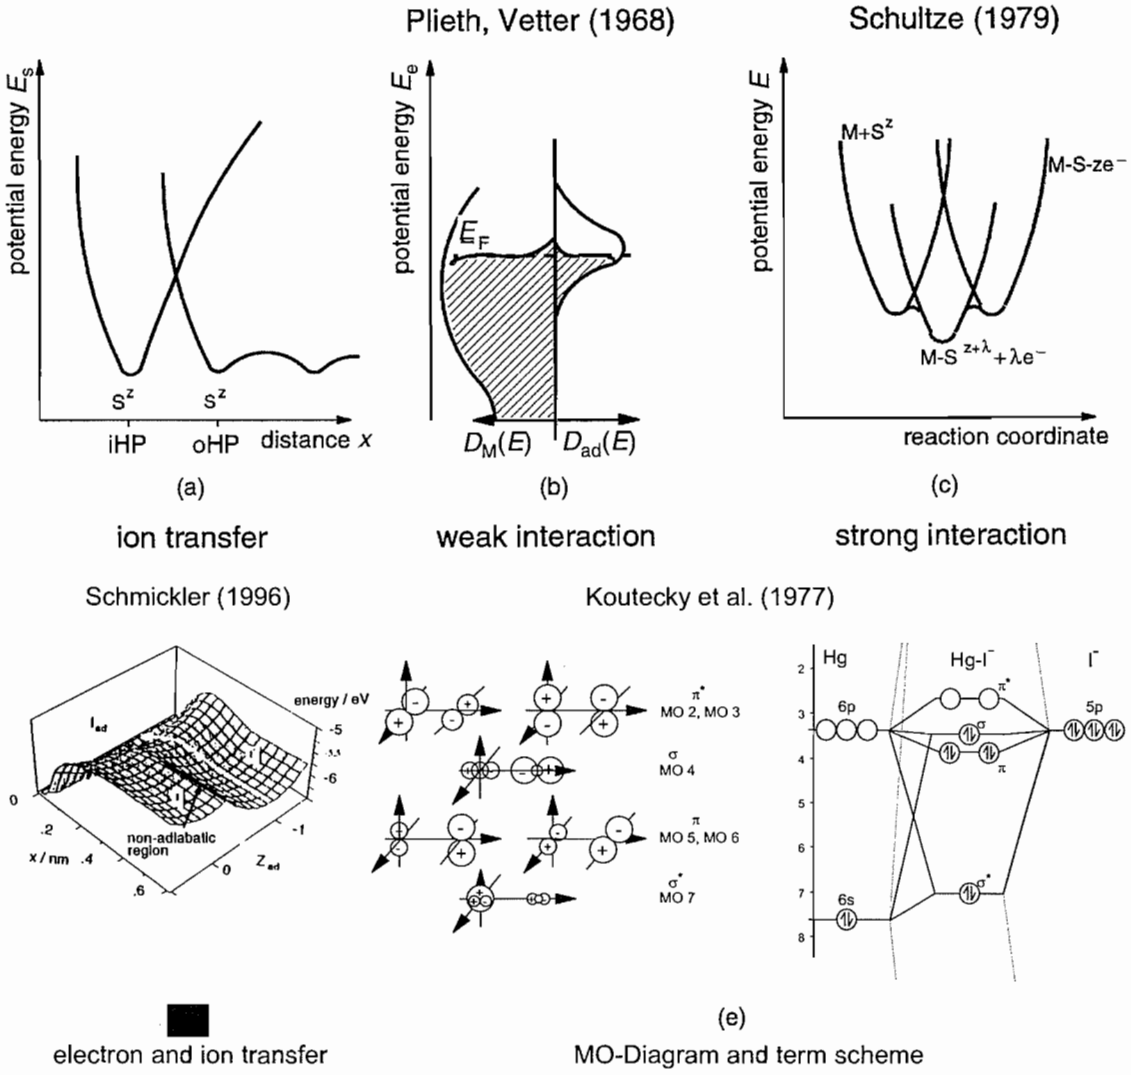
2. The physical model of the charge distribution

Physical models of charge distribution and the energetics of the system have been developed for some limiting cases. Figure 1*a* shows the charge distribution according to the concepts of various authors. While Tafel assumed complete discharge for hydrogen on platinum without specification of bond formation (12), Grahame (8) used ionic charges in his double layer models. On the other hand, he assumed that electrosorption is enhanced by the formation of covalent bonds, in contradiction to his electrostatic models. The model of Lorenz (10) of partially discharged ions is reasonable, but also neglects both bond formation and charge accumulation between the metal atoms of the surface and the electrosorbate. For underpotential deposition (UPD) layers, we have introduced the model of the adsorbed ion penetrating into the electron gas (13), while for metal–halide systems, the role of the covalent bond has been emphasized (14, 15). In this case, the electrons are enriched along the metal–anion axis. Since the orbitals of the metal atom are involved, even a demetallization may be discussed, but at least the electron gas within the surface will be modulated. Schmickler, on the other hand, postulated the formation of a dipole image for the limiting case of electrostatic adsorption (16), for example, an accumulation of negative charge around a positive ion. The corresponding electron densities normal to the surface are described in Fig. 1*b*. All the models shown in Fig. 1 refer to limiting cases, while in real systems intermediate electron distributions may be observed.

The electronic interaction in complexes $M–S^{z+\lambda}$ and the charge transfer have a great impact on energetic models as is shown in Fig. 2. The energies of the ion, the electrons, or of the total interface may be discussed as a function of weak or strong interaction. The traditional model considers the potential energy of the ion in the outer and inner layer, respectively (Fig. 2*a*). The model by Plieth and Vetter (17) considers separately the electron states of the metal and adsorbate, respectively, which corresponds to a weak interaction. The broadening of the energetic states of the adsorbate was explained by interaction with the solvent. A fast electronic exchange between the states in the metal and the electrosorbate was assumed. The Anderson–Newns model for gas phase adsorption (18) is similar, but here the broadening of the adsorbed state is due to the strong interaction with the solid. It was later applied by Kornyshev and Schmickler (19) for electrosorption.



For strong interaction, on the other hand, the total energy of the interface has to be considered instead of that of single electron states. Following a suggestion by R.A. Marcus, the potential energy surfaces of the whole system have to be taken into acccount (14). In addition to the energy surfaces of reactants and products, that of the adsorbate has to be included (Fig. 2*c*). In the case of strong electrosorption, this causes the formation of a new minimum. This diagram plotted along the reaction coordinate is the one-dimensional part of a three-dimensional model used by Schmickler for the general treatment of ion and electron transfer reactions in the double layer (Fig. 2*d*) (20). For the example of Pt/I^-, the potential energy minimum of the adsorbed state is clearly pronounced at a small distance of about 0.1 nm just in front of the electrode and at a partial charge of about -0.5.

In all of these models the chemical interaction between the atoms is not taken into account directly. Therefore, the models are more or less useful for cationic adsorbates interacting with the electron gas of the metal. For covalent systems, however, the atomic orbitals and the formation of molecular orbitals must be considered. EHMO calculations yield MO diagrams and term schemes of the MO levels (15). The most important parts of the full diagrams are shown for Hg/Br^- and Hg/I^-, respectively, in Fig. 2*e*. It can be seen that the most important orbitals are the π-orbitals MO 5,6 formed by the *p*-orbitals of Hg and the halide. Contributions from the other orbitals are smaller (15). The quantitative results of these calculations were not reliable, but the calculations did show the localization of the binding electrons along the Hg—X axis. These pictures may be appropriate for the case of halide adsorption with strong covalent bonds, while they may be less useful for UPD systems.

(*d*) Schmickler's generalized description of ion and electron transfer reactions for the case of a partially discharged iodide ion on platinum (20). $I^- \rightarrow I_{ad}$ (ITR), $I^- \rightarrow I + e^-$ at 0.5 nm (nonadiabatic ETR). E = relative energy consisting of various contributions. (*e*) MO diagram for $Hg–Br^-$ and term scheme for $Hg–I^-$ from EHMO calculations. Most important MOs are shown; for full diagrams see ref. 15.

3. The electrosorption valency γ

The determination of the charge distribution in electrosorbates is more difficult than for bulk materials. X-ray diffraction (21) and scanning probe microscopy (SXM) methods (22, 23) have a high sensitivity to structures and symmetries, but the electronic structure of the interface remains unknown. Spectroscopic investigations show surface vibrations and symmetries, but not the electronic distribution. The electrical conductivity of ultrathin metal films usually decreases with electrosorption. New results for halide ions adsorbed on epitactically grown Ag(100) films indicate a qualitative connection with the discharge of the ions (24) at which the electron waves are scattered. A quantitative relation, however, has not yet been obtained.

Many electrochemical data of electrosorbates reflect the charge transfer: e.g., the shift of the potential of zero charge (25). From eq. [1] it may be assumed that the charge flow of an electrosorption reaction yields the charge transfer coefficient λ directly. This is, however, not true, since capacitive effects are combined with the change of the interface structure. A straightforward analysis of electrosorption reactions is possible using the Gibbs equation for systems with excess supporting electrolyte. Corresponding to the Nernst equation and Faraday's law, the electrosorption valency γ was defined by the partial derivatives given in eq. [3] (26):

$$[3] \quad -(\delta q_m/\delta \Gamma_S)_U = (\delta \mu_S/\delta U)_{\Gamma_S} = \gamma F$$

with q_m = metal charge, Γ_S = surface concentration of S, μ_S = chemical potential, and U = electrode potential. This thermodynamic analysis can be applied to all electrosorbates, i.e., ions as well as neutral molecules, for all charge transfer coef-

		1.4–2.0	52

ficients $0 < -\lambda/z < 1$ (26, 27). But the analysis has to be extended for dilute electrolytes due to the increasing influence of the diffuse double layer (5) or in the case of specific interaction with other ions or molecules X (28).

In contrast to Faraday reactions at electrodes, γ is a fractional value, in general between 0 and z. Moreover, it can change with Γ and with U. This is especially observed with ordered structures on single crystal planes where the cosorption changes stepwise. Therefore, it is useful to take the thermodynamic value γ_N as reference value. This refers to small coverages at the potential of zero charge, i.e., the electrocapillary maximum. This procedure eliminates capacitive terms and the sorbate–sorbate interaction.

Experimental methods for the determination of γ have been described and compared in refs. 13 and 26. A critical comparison showed that experimental reproducibility of different methods and papers is typically better than 0.1. Data were collected for inorganic systems in water and nonaqueous solvents (13) as well as for organic molecules (29–31). Recent measurements, often on well-defined single crystal planes, are evaluated in Table 1. Most of these values are based on a complete thermodynamic analysis of chronocoulometric data as a function of U and μ_S. A final analysis of q/Γ or μ/U diagrams gives electrosorption valencies showing a reasonable agreement.

For comparison with vacuum measurements, an effective "surface dipole" m can be obtained from γ and the Helmholtz capacity C_H using eq. [4] (32, 33):

$$[4] \quad m = (ze_0/4\pi C_H)(1 - \gamma/z)$$

but there is no additional information on the structure of the interface, since this dipole refers to contributions from the electrosorbate as well as cosorbed counterions (see eq. [2]).

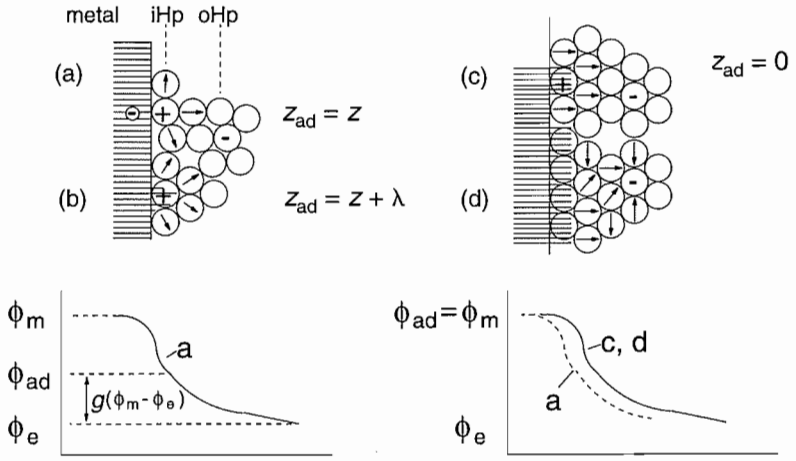
4. Correlation between γ and microscopic parameters

To correlate γ with the microscopic parameters λ and g, the structure of the double layer and the shape of the electric potential at the interface must be discussed. For well-defined systems with a strong surface bond, the position of the electrosorbate can be determined exactly by X-ray diffraction methods (21), or by STM (22, 23). The positions of the fast-moving water molecules or counterions, however, are rather difficult to detect. Therefore, the picture given in Fig. 3 remains speculative. Following the fundamental ideas of Grahame, an inner Helmholtz layer iHp is assumed for the position of the electrosorbate, while the nonspecifically adsorbed and solvated ions stay in the outer Helmholtz plane oHp. In Fig. 3*a*, a cation is electrostatically adsorbed, corresponding to the concept of Grahame ($\lambda = 0$). From electrostatic calculations (neglecting the charge transfer), Grahame obtained a value equivalent to γ, which was called the "thickness ratio" r:

$$[5] \quad |\gamma| = r = (x_2 - x_1)/x_2$$

with x_2 = double layer thickness $\approx$ diameter of the solvent molecule, and x_1 = radius of the specifically adsorbed ion. The thickness ratio is, however, in conflict with experimental results as was shown in refs. 13 and 26. This will also be shown in Sect. 5. Due to the increase in the permittivity of the solvent with increasing distance from the surface and other nonlinear effects, a more flexible definition of a geometric factor g according to eq. [6] was proposed (7, 26)

$$[6] \quad g = (\Phi_{ad} - \Phi_e)/(\Phi_m - \Phi_e)$$



with the Galvani potentials Φ of the metal m, adsorbate ad, and electrolyte e. Note that eq. [6] again is an approximation for excess supporting electrolytes. The value of g can be estimated from experimental data of ionic electrosorbates (see Sect. 5 and ref. 13). Further parts of Fig. 3 show partially ($-\lambda/z < 1$, Fig. 3*b*) or completely ($-\lambda/z = 1$, Fig. 3*c*, 3*d*) discharged ions. In the case of complete discharge, e.g., with UPD layers, the whole double layer shifts towards the electrolyte side (13). This means that the geometric factor for such systems becomes almost 1. Hence, g cannot be considered as constant, but has to be considered as varying with the discharge of the electrosorbate (13).

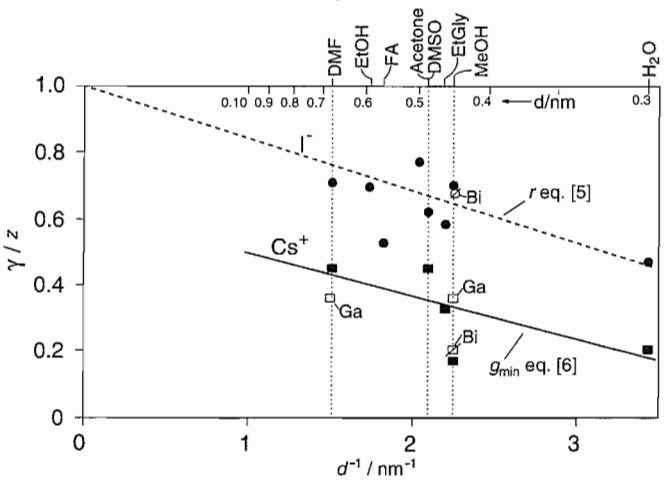
From an electrostatic model, the relation between the model parameters g (eq. [6]), λ (eq. [1]), and the dipole terms κ with γ_N was derived (7):

$$[7] \quad \gamma_N = gz - \lambda(1 - g) + \kappa_S - \nu\kappa_w$$

© 1997 NRC Canada

Fig. 3. Potential drop at the interface and schematic double layer model with nonadsorbed ions in the outer Helmholtz plane (oHp), adsorbed water molecules and adsorbed ions in the inner layer (iHp). Effects of the diffuse layer are neglected (supporting electrolyte); g is defined by eq. [6]. Cation adsorbed electrostatically (*a*), partially discharged (*b*), and completely discharged (*c*) and (*d*).

Since the charge and sign of the ions differ, it is useful to analyse normalized values γ_N/z in the theoretical treatments. Dipole terms κ_i are important for neutral molecules (27, 29), but they can be neglected for ionic systems. In the following, we refer to the approximation, eq. [8]:



[8] $\gamma_N/z = g - (\lambda/z)(1 - g)$

5. Experimental estimation of *g*

As eq. [8] still includes two unknown parameters g and λ, it is impossible to determine these values by thermodynamic experiments only. However, the models of Figs. 1 and 3 can be tested by comparison of data for various systems with known geometric parameters. A plot of normalized electrosorption valencies versus the radius $r_S = x_1$ of the electrosorbate has shown that γ increases with r_S instead of showing the decrease predicted by eq. [5]. The result for water was supported by similar data for methanol and DMF (13). Only data for very electropositive or electronegative electrosorbates can be used to estimate g, which is much smaller than the value predicted by eq. [5]. Moreover, in the electrostatic model of Grahame, x_2 should be given by the thickness of the solvent molecule. Thus, a plot of "$\gamma_N = r$" (eq. [5]) versus the diameter of the solvent molecule should be on the broken line shown in Fig. 4. Experimental data of the normalized electrosorption valency γ/z are plotted versus the reciprocal diameter d of various solvents. The values for Cs^+ ions are definitely below the broken line, indicating that the solvent diameter plays a much less significant role than would be expected from eq. [5]. The flexible eq. [6], however, can be applied and experimental values of g_{min} can be obtained from minimum γ_N values (13, 26). From Fig. 4, minimum geometric factors of about 0.2 for water and methanol and 0.4 for DMF can be estimated. In the original treatments (34, 35), values for the so-called thickness ratio (in fact, the electrosorption valency) of iodide ions were discussed that seemed to verify the idea of the thickness ratio, as is also shown in Fig. 4. However, this apparent agreement was an artefact, since λ is definitely positive for iodide on mercury.

The distribution of the electric potential changes strongly if

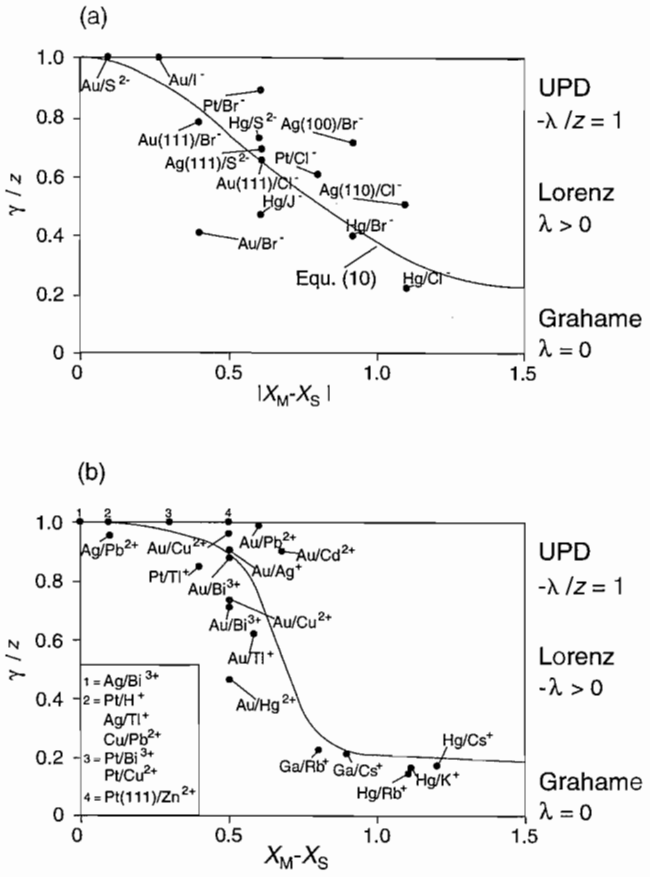
Fig. 4. The normalized electrosorption valency ratio γ/z as a function of the reciprocal diameter of the solvent. Values are taken from ref. 13. Full symbols refer to Hg, other data for Ga and Bi are marked. The thickness ratio corresponding to eq. [5] is indicated by dotted lines. The values for Cs^+ can be taken as a geometric factor according to eq. [6]. Values for I^- cannot be taken for g, since they contain contributions from discharge.

the ions are completely discharged, for example, in the case of UPD layers. In that case the whole double layer shifts to the electrolyte as shown in Fig. 3*c* and 3*d*.

6. Experimental estimate of the partial charge transfer coefficient λ

Using Pauling's concept for the covalent character of a bond (36, 37), eq. [9] was successfully applied by Koppitz and Schultze (13):

[9] $-\lambda/z = \exp[-a(\Delta\chi)^2]$



$\Delta\chi$ is the difference of the electronegativities between the

Fig. 5. Normalized electrosorption valency versus the absolute difference of electronegativity, data taken from ref. 13 and, in addition, from Table 1 (Au–Cu^{2+} and Au–Bi^{3+}). (*a*) Anions in water. (*b*) Cations in water. The full line in (*a*) gives the charge transfer according to eq. [10]; in (*b*) it is an empirical description.

metal electrode and the adsorbate. Originally, the normalized value γ/z was plotted versus the absolute difference of electronegativity for all ions. The advantage was the simultaneous treatment of anions and cations. This should be questioned, considering the different models for anion and cation bonding shown in Fig. 1. Moreover, new data for the adsorption systems summarized in Table 1 show that a separate treatment is necessary. Finally, some older data for the silver–halide systems (53) referred to the formation of layers, possibly involving place exchange reactions. These data could not be confirmed in new measurements at low coverage and had to be discarded. The corresponding new plots for anions and cations in water are shown in Fig. 5*a* and *b*.

The general tendency of both diagrams is the same as in ref. 13: At small electronegativity differences, γ/z approaches 1, i.e., the charge transfer dominates. With increasing difference, γ/z decreases and approaches a minimum value that can be attributed to the geometric factor of the electrostatic electrosorbates, g_{min}. The difference between the two diagrams lies in the almost stepwise transition for cations at about $|\Delta\chi| = 0.5$, while γ/z for anionic systems changes continuously following eq. [9]. This seems to be connected with the different bonding models discussed in Fig. 1. The bonding of cations may be described by a delocalized electron gas model that favours an autocatalytically increasing discharge of the ions: with increasing bonding, Φ_{ad} approaches Φ_m, thus causing $g \rightarrow 1$. The result for cations resembles the traditional, separate treatment of UPD systems and electrostatic systems such as those with alkali ions. It should be emphasized that an increasing interaction with ligands smoothes the step, since the γ/z values decrease, indicating an increasing ionicity of the metal–metal bond, as will be discussed in the next section.

In contrast to cations, the bonding electrons of anionic electrosorbates will not be included in the electron gas of the metal, and the geometric factor probably remains constant. Figure 2*e* may illustrate the different character of the bond. In such a case, the Pauling model valid for the field free vacuum seems to be more appropriate than for cations. Combining eqs. [8] and [9], we get:

$$[10a] \quad \gamma/z = g_{min} + (1 - g_{min}) \exp(-a(\Delta\chi)^2)$$

In Fig. 5*a*, values of $a = 1.5$ and $g_{min} = 0.2$ give the best fit:

$$[10b] \quad \gamma/z = 0.2 + 0.8 \exp(-1.5(\Delta\chi)^2)$$

The value, $a = 1.5$, of course, exceeds that of the vacuum, $a = 0.25$, which will be explained in Sect. 7. We have estimated the charge transfer data for the much studied system of Hg – halide ions. Using the assumptions $\gamma_{Cl} = g_{min}$, the point charge model, neglection of dipole terms, and no specific interaction with counterions, we obtained the lower values $\lambda = 0$ (Cl^-), 0.2 (Br^-), and 0.3 (I^-).

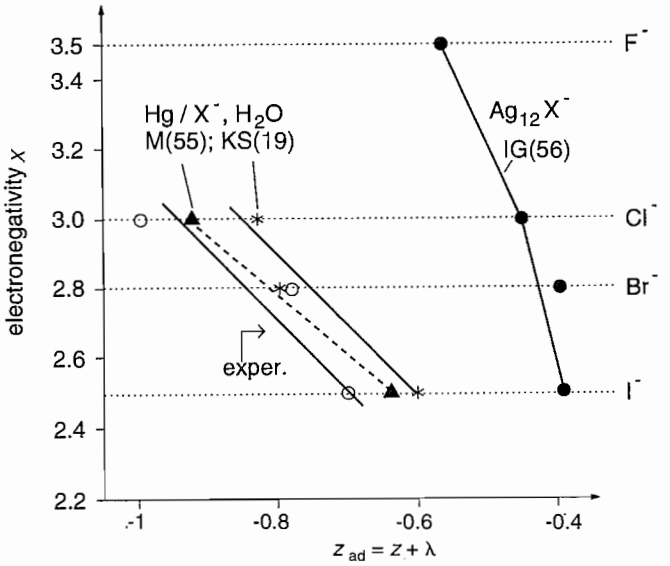
7. The influence of solvent and ligands

Increasing solvation or complexation of the electrosorbate stabilizes the ionic charge. Therefore, it causes a weakening of the surface bond (54). The prediction can be tested by investigating the electrosorption data for various solvents. With increasing solvation, the constant *a* of the Pauling eq. [9] should increase. It was shown, using DMF as an example, that the values for anions and cations could only be simulated with different values of *a*. The increase in *a*, from 0.25 for vacuum to 3 for water and methanol and to 6 for cations in DMF, parallels the solvation strength. Model calculations (19, 55, 56) discussed in Sect. 8 also show this strong influence of the solvation.

Ligands have a similar, strong influence. First determinations of the electrosorption valency for the Cu^{2+}–sulfate system from thermodynamic and kinetic measurements (51, 52) yielded surprisingly low values between 1.4 and 2, which indicates a cosorption of the anion. In this case, the electrosorption valency has to be written

$$[11] \quad \gamma_{mix} = \gamma_{Cu} + \gamma_{SO_4}(\delta\Gamma_{SO_4}/\delta\Gamma_{Cu})_U$$

X-ray diffraction measurements in the system Au (111)/Cu^{2+}, SO_4^{2-} proved the coadsorption at low coverages. From the structural data (21), the coupling factor



$$[12] \quad \rho = (\delta\Gamma_{SO_4}/\delta\Gamma_{Cu})_U = 0.33$$

can be derived. A careful coulometric analysis was carried out

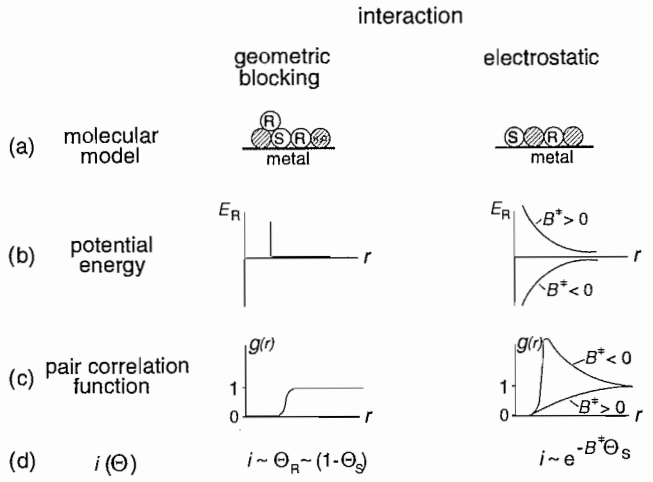
Fig. 6. z_{ad} as a function of electronegativity χ. Comparison of z_{ad} values estimated from γ and theoretical calculations. Values from Kornyshev and Schmickler for 1/3 hydration (19), from Mishra et al. for 1/3 hydration for I^- and 2/3 for Cl^- (55), and from Ignaczak and Gomes for small clusters without solvation (56). The open circles represent experimental data.



by Lipkowski et al. (50, 57, 58) for Au (111)/Cu^{2+}, X with X = Br^-, Cl^-, SO_4^{2-}. For SO_4^{2-} a coupling factor of 0.5, and for Br^- $\rho = 0.25$, was found for low coverages, but it must be noted that γ and ρ change with Γ_{Cu} and the electrode potential (50). Calculations by Mishra based on the Anderson–Newns model yield a partial discharge of the copper, approaching +0.4 for a monolayer (59). For these systems, a final interpretation of the charge distribution is still open to discussion.

8. Comparison with theoretical calculations

Figure 6 shows a comparison of the above-mentioned evaluations based on thermodynamic experiments as well as on theoretical calculations. Such experiments and calculations were carried out preferentially for the halide ions on mercury, where reliable experimental data are available, and where a continuously decreasing electronegativity or electron affinity promises interesting results. First, calculations were carried out with the Extended Hückel Method (15). The results were only of qualitative interest, since the limitation to a Hg–X^- complex with a single metal atom without water was too restricted. Therefore, the charge transfer was overestimated. Later calculations were carried out using the Anderson–Newns model for clusters with increasing hydration (19). Many-body effects were taken into account in ref. 55. New calculations with the density-functional method were carried out without solvent molecules. Here again, the charge transfer is overemphasized (56), since the hydration of the ion is neglected. As Fig. 6 shows, the quantitative data obtained with various parameters and methods differ due to arbitrary assumptions, but all agree in indicating a decreasing charge transfer with increasing solvation and with increasing electron affinity of the halide. Thus,

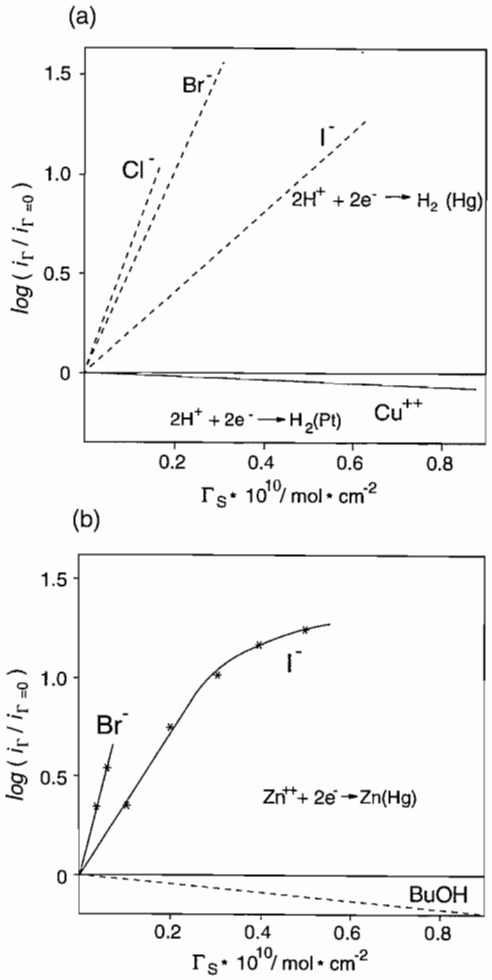
Fig. 7. Schematic representation of molecular arrangement, potential energy, pair correlation functions, and rate equations for electrostatic catalysis and geometric blocking. S = electrosorbate, R = reactant.

the agreement with our empirical estimates is reasonable. Calculations based on molecular dynamics and density-functional theory are not yet available for electrosorbates (60).

9. The role of partial discharge in electrocatalysis

The rate of ion transfer reactions, ITR, can either be enhanced or inhibited by catalytically active electrosorbates. In general, the influence of a substance S on the reaction rate of a reactant R can be due to electrostatic or chemical interaction or to geometric blocking (61, 62). Here we will consider the electrostatic influence, the geometric blocking taken only as reference. Models, potential energies, and pair correlation functions are schematically shown in Fig. 7. While the electrostatic forces decrease with $1/r$, the geometric blocking is only observed for $r < r_S$. Therefore, the positive or negative electrostatic influence is reflected in the potential energy curves and in the pair correlation function as well, at much larger distances. The potential energy curves for the electrostatic influence differ only by sign, but the pair correlation function for catalysis can change much more than that for electrostatic inhibition. As was shown by Parsons (63, 61), the electrostatic influence yields a relation

$$[13a] \quad \log i_\Gamma / i_{\Gamma=0} = -2B^\ddagger \cdot \Gamma$$



$$[13b] \quad B^\ddagger \sim z_{ad} z_R$$

with a constant $B^\ddagger$ depending on the activity of the transition complex, i.e., on the charges z_{ad} and z_R, respectively. Figure 8 shows the corresponding plots of the normalized current densities of hydrogen evolution on mercury (63) and zinc deposition on mercury (64, 61). Both reactions are accelerated by adsorbed halide ions, since $B^\ddagger < 0$. Straight lines are observed at low coverages as predicted by eq. [13]. The important observation is that for both reactions the slope decreases with

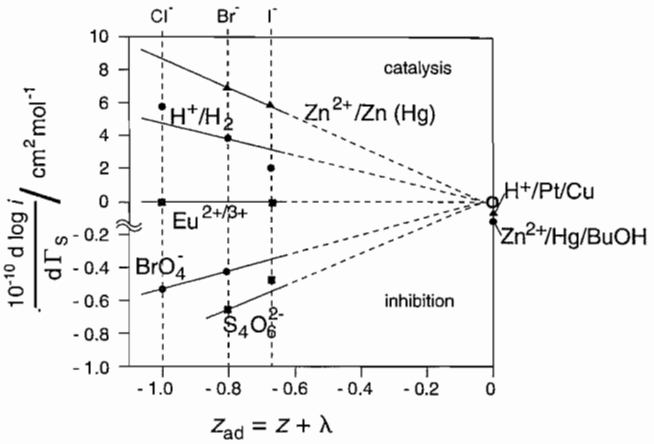
Fig. 8. Normalized current density ($i_\Gamma/i_{\Gamma=0}$) of various reactions as a function of the surface concentration Γ. (*a*) Cathodic hydrogen evolution on mercury with electrosorbed halide ions (63) and on platinum with electrosorbed Cu (65). (*b*) Cathodic deposition of Zn on mercury with electrosorbed halide ions (64) and butanol (66).



decreasing charge of the adsorbed ion in the sequence $Cl^- > Br^- > I^-$. For comparison, data for an only geometrically blocking adsorbate are plotted, as well. Cu on Pt, for example, slightly hinders the hydrogen evolution due to geometric blocking (65) with an almost negligible electrostatic effect. For the zinc deposition, data for completely discharged ionic electrosorbates were not available. Hence, the data for butanol (66) with a small geometric effect are plotted for comparison.

Taking the results of the estimate for the charge z_{ad} into account, the results can easily be explained using eq. [13]. The slope d log i/dΓ should be proportional to z_{ad} and z_R. In Fig. 9 the slope of the straight lines of Fig. 8 is plotted vs. the charge z_{ad}. The lines expected from eq. [13] are laid through the fixed point 0 at $z_{ad} = 0$. Considering the geometric blocking, the fixed point would be at about -0.1. The agreement with the experimental points confirms the general idea and the tendency. The proportionality to z_R, $B_{Zn^{2+}} \approx 2B_{H^+}$, is roughly fulfilled, as well.

For inner-sphere electron transfer reactions, ETR, the same behaviour is expected, while for outer sphere ETR the electrostatic influence should vanish. Figure 9 shows relevant data for the reduction of BrO_4^- and $S_4O_6^{2-}$ according to ref. 61. In that case, the adsorbed halide ions reduce the reaction rate, since $B^{\pm}$ is positive. The proportionality of the experimental slope to the real charge of the adsorbed halide ion is qualitatively confirmed. The quantitative influence is much smaller than in the case of catalysis, since the exclusion of the volume near the halide ion is not so important as the catalysis in the same volume. This can be derived from the pair correlation functions shown in Fig. 7. The influence of adsorbed halide ions on the outer-sphere ETR is almost negligible. Hence, the charge z_{ad} is without influence (67).

Fig. 9. Slope of the lines in Fig. 8 for $\Gamma \rightarrow 0$ as a function of the partial charge z_{ad} of the adsorbed halide ions. Upper part: electrocatalysis; lower part: inhibition (extended scale). On the right ordinate, the fixed points for $z_{ad} = 0$ and geometric blocking are shown.

10. Conclusions

The problem of charge distribution in electrosorbates can be qualitatively approached. Experimental values of γ/z are known for many systems, with a typical reliability of ± 0.1. The estimate of λ is a bit speculative, but comparison with various chemical and molecular parameters shows that in spite of these assumptions the results may have an accuracy of ± 0.1–± 0.2. It is shown that the discharge of ions increases with decreasing difference of electronegativities. For the real influence, the type of bonding plays an important role. Due to the metallic bonding, UPD systems are separated from electrostatic systems, and partial discharge plays a role only in the case of complexing ligands. Anions are covalently bound with a charge transfer continuously increasing with decreasing electronegativity. Theoretical calculations are in reasonable agreement, but may be improved by consideration of the specific metal–sorbate interaction.

The catalytic influence of electrosorbed halide ions can be explained by an electrostatic effect taking the partial discharge into account.

Preparation and characterization of oxide film electrodes

A. De Battisti, G. Lodi, L. Nanni, G. Battaglin, and A. Benedetti

Abstract: In this paper are presented data on the preparation and characterization of different oxide electrodes. RuO_2–TiO_2, IrO_2–TiO_2, and SnO_2–Sb_2O_5 mixed-oxide films have been taken as model systems. For the first, the traditional preparation method based on the pyrolysis of precursor salt deposits was adopted. For the SnO_2-based films, the spray pyrolysis preparation has been used. The characterization of RuO_2–TiO_2 films confirms the existence of a solid solution between the two component oxides over a wide composition range. Rutherford backscattering spectrometry confirms the occurrence of segregation of titanium oxide species in the outermost part of the films. Nuclear reaction analysis indicates that large amounts of carbon and hydrogen impurities are trapped in the oxide films. SnO_2-based films were found to be less porous and chemically more simple. The differences between the two systems have been discussed in terms of the preparation method and the differences in chemical properties of the precursors.

Key words: oxide film electrodes, mixed-oxide films, Rutherford backscattering spectrometry, nuclear reaction analysis.

Résumé : Dans ce travail, on présente des données sur la préparation d'électrodes de divers oxydes. On a utilisé les films d'oxydes mixtes suivants comme modèles : RuO_2–TiO_2, IrO_2–TiO_2 et SnO_2–Sb_2O_5. Pour le premier, on a adopté la méthode de préparation traditionnelle qui repose sur la pyrolyse de dépôts de sels précurseurs. Pour les films incorporant du SnO_2, on a fait appel à une préparation par pyrolyse de vapeurs. La caractérisation des films de RuO_2–TiO_2 confirme que, pour une large plage de composition, il existe une solution solide entre les deux oxydes les composant. La spectroscopie de rétrodiffusion de Rutherford confirme l'existence d'une ségrégation des espèces de l'oxyde de titane dans la partie extérieure des films. Une analyse par réaction nucléaire indique que de grandes quantités de carbone et d'oxygène sont piégées dans les oxydes de films sous la forme d'impuretés. On a trouvé que les films incorporant du SnO_2 sont les moins poreux et chimiquement plus simples. On discute des différences entre les deux systèmes en fonction de la méthode de préparation et des différences dans les propriétés chimiques des précurseurs.

Mots clés : électrodes des films d'oxydes, films d'oxydes mixtes, spectroscopie de rétrodiffusion de Rutherford, analyse par réaction nucléaire.

[Traduit par la rédaction]

1. Introduction

Thermally prepared oxide electrodes based on different metal components have quite important industrial applications. The wide choice of possible compositions of the active film allows the modification of catalytic properties of these electrodes in a significant range. The well-known dimensionally stable anodes (DSA®), mixtures of group VIII noble-metal oxides stabilized with other components such as TiO_2, Ta_2O_5, and ZrO_2, are certainly the most important and have been well studied (1–3). Materials based essentially on IrO_2–TiO_2 mixtures perform well in chloralkali cells (e.g., ref. 3), while materials based on IrO_2–Ta_2O_5 exhibit better performance under oxygen evolution conditions (4). The high selectivity and efficiency of IrO_2 electrodes in some oxidative organic electrosyntheses seem to open further perspectives of application (5, 6).

Drastic modification of catalytic properties is caused when the group VIII noble-metal oxide is substituted by tin dioxide (7–9). In this case the occurrence of oxygen evolution at very high overpotentials allows efficient oxidative destruction of organic pollutants, and good efficiency in the electrochemical ozone generation.

The difference in chemical properties of the oxide metal ions plays a dominant role, affecting the stability of hydroxyl radicals, intermediates in all electrooxidative processes (e.g., ref. 6, and literature therein). Other factors, such as their microstructure and surface texture, related to the preparation method, also strongly affect the behaviour of oxide electrodes. A study of electrochemistry at these electrodes must therefore treat the electrode preparation and characterization in detail. When, as in the case of materials based on group VIII noble-metal oxides and SnO_2, not only the chemical properties, but also the preparation methods are substantially different, this aspect of the research may be particularly important.

In the present work, an attempt is made to show the role played by the preparation method on the properties of model

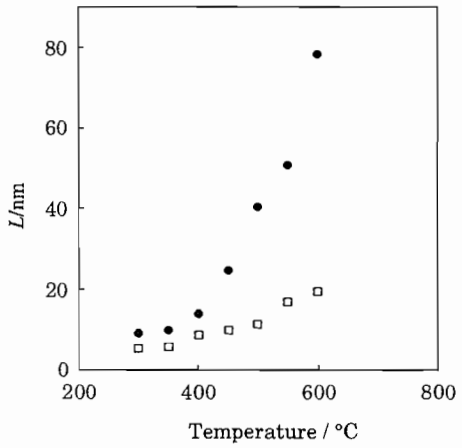
oxide electrocatalysts. The traditional methods based on pyrolytic oxidation of precursor deposits (ink methods) and pyrolytic oxidation of aerosols (spray pyrolysis) will be considered in this study. Data relative to RuO_2-and IrO_2-based electrocatalysts prepared by "ink" procedures (an example of pyrolytic oxidation of precursor deposits), will be dealt with. Some comparison with data on SnO_2–Sb_2O_5 electrocatalysts prepared by spray pyrolysis and pyrolytic oxidation of precursor deposits has been attempted. The microstructural study was carried out by wide-angle X-ray scattering (WAXS). Considering that a correct interpretation of the microstructural data requires an extended compositional study, Rutherford Backscattering Spectrometry (RBS) and Nuclear Reaction Analysis (NRA) have been used for oxide films prepared by deposit pyrolytic oxidation methods, for which, as shown later, the composition may be quite complex.

2. Experimental

RuO_2–TiO_2 electrodes were prepared by pyrolysis of Ti-supported deposits consisting of mixtures of ruthenium(III) hydrated chloride and titanium diisopropoxide bis-2,4-pentanedionate reactants, in molar rations corresponding to those of the two metal components in the product mixed-oxide film. Deposits were prepared by painting the Ti substrates with isopropanol solutions of the two precursors in the required ratios. After solvent evaporation, such deposits were pyrolyzed in dry oxygen at 400°C for 20 min and the procedure repeated until an oxide film thickness of about 0.7–0.8 μm was reached. Titanium substrates were mirror-finished by mechanical polishing, then cleaned by quick chemical etching with hot 20% oxalic acid, rinsed with water and acetone, and dried. The Ti substrates were 1 cm × 1 cm plates (thickness 0.3 mm), with stem. Groups of different sample compositions were prepared, with noble-metal concentrations ranging between 20 and 100 mol%,

Details on the spray pyrolysis preparation of SnO_2–Sb_2O_5 films have been given elsewhere (8, 9). $SnCl_4 \cdot 5HO_2O$ (Aldrich) and $SbCl_3$ (Fluka) were used as precursors and the solvent was an ethanol – hydrochloric acid mixture. The oxide thickness was 4 μm in most of the cases, and the preparation temperature was 550°C.



The preparation of SnO_2–Sb_2O_5 films (6 mol% Sb) by pyrolytic oxidation of precursor deposits, the traditional "brushing" or "ink" method, was also carried out for the sake of direct comparison of film properties. In this case the precursors $SnCl_2$ and $Sb_4O_5Cl_2$ (Carlo Erba) were used, dissolved in a mixed water–ethanol solvent.

Depth profiles of Ru, Ti, and O were determined by RBS. A $^4He^+$ ion beam with an energy of 2.2 MeV was used. Scattered particles were detected at an angle $\theta = 160°$, with respect to the direction of the incident beam. A surface-barrier silicon detector was used. The depth resolution in the near-surface region was generally 15–20 nm. The depth profiles were obtained by a procedure based on fitting of experimental spectra (10).[2] The operational depth profiles were adjusted until a satisfactory fit of the synthesized spectrum to the experimental one was obtained. Estimated uncertainties in Ru and Ti concentrations were 1–2%, reaching larger values for oxygen, due to the smaller elastic cross section and the superimposition of the signal from oxygen in the film with those from the elements in the substrate. Carbon total amount was measured by NRA. Use was made of the $^{12}C(d,p)^{13}C$ nuclear reaction. The energy of the deuteron beam was 620 keV and the detection angle was 150°. A 12 μm thick Mylar foil was placed in front of the detector to stop elastically scattered deuterons.

X-ray diffractometric studies were carried out with a Siemens D-500 instrument. Ni-filtered CuK_α radiation was used. The goniometer rate was 2° min^{-1}. The apparent size of the solid solution crystallites was determined by the Scherrer formula, under the assumption that the line broadening is due to microcrystallinity only.

Fig. 1. Average crystallite size for RuO_2 (●) and IrO_2 (□) rutile phases in films prepared at different temperatures, by pyrolytic oxidation of precursor deposits.

3. Results and discussion

3.1. Microstructural study of RuO_2–TiO_2 and IrO_2–TiO_2 films

Making use of the Scherrer formula, the average crystallite size, L, of RuO_2 and IrO_2 rutile phases prepared at different pyrolysis temperatures between 300 and 600°C were measured and results are shown in Fig. 1. As expected L increases with increasing pyrolysis temperature in both cases. The effect is, however, quite small for the IrO_2 phase. Since the same preparation procedure was applied for the two series of samples, the reasons for this significant difference must be sought in the different reactivity of the two hydrated chloride precursors. Thermoanalytical investigations (11–13) have shown that, in fact, the reactivity of Ir(III) hydrated chloride films is lower at intermediate stages of the pyrolytic process, probably due to the formation of stable oxychlorides. These results have been interpreted by assuming the passivation of parts of the precursor deposits, due to partial oxidation of the most external part, with further occurrence of the pyrolysis under "anaerobic" conditions. The reactivity of Ru(III) hydrated chloride and its oxidation intermediates is apparently sufficiently high to minimize these effects (14). Resistivity data reported in ref. 12 for IrO_2 films of different thickness support the idea that the deposit pyrolysis procedure enhances the effects of differences of reactivity of the type described above.

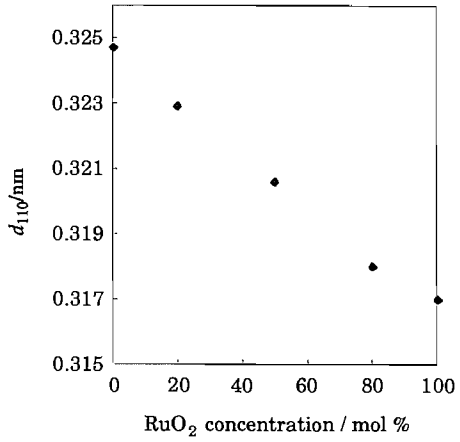
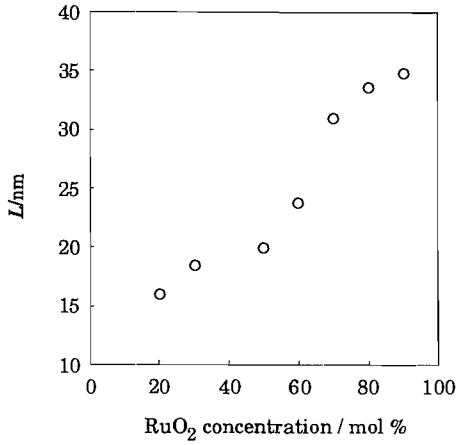
Fig. 2. Interplanar lattice spacing d_{110}, for the RuO_2–TiO_2 solid solution in mixed-oxide films.





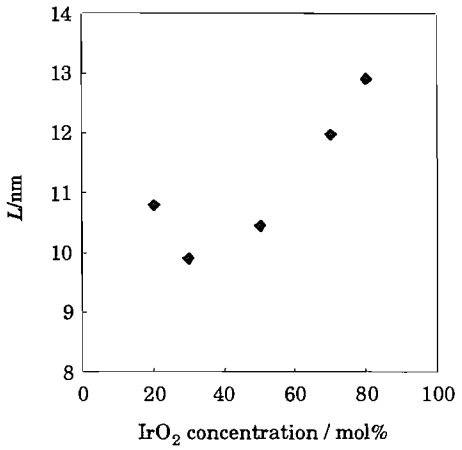


Fig. 3. Average crystallite size of the RuO_2–TiO_2 solid solution as a function of the nominal bulk composition of the electrode film.

As proved in other studies (15, 16), the presence of ruthenium oxide induces the formation of RuO_2–TiO_2 solid solutions with rutile structure. The same holds for the IrO_2–TiO_2 quasi-binary system (17). It has been shown elsewhere (10) that, for RuO_2–TiO_2 samples containing 20–30 mol% of noble-metal oxide, the solid solution is formed independent of the nature of the ruthenium precursor salt (acetylacetonate, nitrosyl nitrate, chloride). It was also shown that the cell parameters of a solid solution follow the Vegard law with excellent approximation. This feature is confirmed also for the samples studied in this work (Fig. 2). In spite of the different reactivity of the precursors, the interplanar distances of the crystalline structure of the two solid solutions change regularly with the noble-metal/titanium ratio.

A microstructural characterization of RuO_2–TiO_2 and IrO_2–TiO_2 films was also carried out, using the same method. The influence of film composition on the average crystallite size for two series of samples prepared at 400°C is shown in Figs. 3 and 4, respectively. For both series the decrease of the noble-metal oxide causes a decrease of the solid solution crystallite size. The trend to develop larger crystallite sizes for the RuO_2-based samples is confirmed at any noble-metal concentration. The increase of reactivity caused by the addition of the titanium precursor (13, 14) is not sufficient to cancel this feature. In other mixed-oxide films like RuO_2–Ta_2O_5 (18) and IrO_2–ZrO_2 (19), for which formation of solid solutions, if any, is limited, different trends are observed. In the first case a decrease of the RuO_2 crystallite size with decreasing noble-metal concentration has been found. In the latter case, however, the crystallite size is small, compared with data reported in the present paper (minima around 10 nm). The immobilizing role of Ta(V) species should be probably taken into account in this case. For the IrO_2–ZrO_2 films the crystallite size of the IrO_2-rich phase is unaffected by the bulk film composition. In this case experimental results suggest that small amounts of ZrO_2 are dissolved in the IrO_2 (rutile) phase. The ZrO_2-rich phase, however, changes from a crystalline morphology at low IrO_2 contents, to amorphous at intermediate to high IrO_2 contents. This transformation is likely to involve mutually compensating effects on the formation of the conjugated IrO_2-rich phase.

Fig. 4. Average crystallite size of the IrO_2–TiO_2 solid solution as a function of the nominal bulk composition of the electrode film.

Synthesis by the spray pyrolysis method leads to quite different microstructural properties (20). In the case of the SnO_2–Sb_2O_5 mixed-oxide films, crystallite size is much larger, of the order of about 1 μm, at a synthesis temperature of 550°C. Further, the average crystallite size decreases linearly with increasing temperature of synthesis. On the contrary, in SnO_2–Sb_2O_5 films prepared by thermal decomposition of precursor deposits in this work, the crystallite size is again of the order of 10–20 nm, and crystallinity of the films increases with the pyrolysis temperature.

3.2. Film composition

3.2.1. RBS results for group VIII noble-metal oxides

As previously mentioned, the ruthenium, titanium, and oxygen stoichiometry of the RuO_2–TiO_2 films has been studied by RBS. The ruthenium and titanium stoichiometries in two series (A, B) of mixed-oxide films are shown in Table 1. The oxygen stoichiometry was 2 in all the investigated samples. Depth profiling, also determined by RBS, indicates the occurrence of an enrichment with titanium oxide species in the most

external part of the mixed-oxide films. The compositional features of several films with effective ruthenium concentrations between 22 and 30 mol% also showed the occurrence of "encapsulation" by titanium oxide species (10). In ref. 10 it was also shown that this phenomenon already appears at pyrolysis temperatures as low as 200°C and that it is not affected by the nature of the ruthenium precursor salt, even when a complexing anion like acetylacetonate is bound to ruthenium ions. In addition, the substitution of ruthenium with iridium does not change the shape of the concentration depth profiles (17). Utilization of stabilizing components other than TiO_2 may induce, on the contrary, some changes (19).

3.2.2. NRA results for RuO_2–TiO_2 and IrO_2–TiO_2 films

NRA measurements, also reported in ref. 10, have shown that carbon- and (or) hydrogen-containing impurities may be present in thermally prepared oxide films in amounts that are quite comparable with those of the main components (metal ions, oxygen). These impurities are due to incomplete oxidative conversion of organic components in the precursor mixture (solvent, organic anions) and incomplete elimination of water of hydration. This interpretation has been confirmed by thermoanalytical data (13, 14) and thermoanalytical and resistivity data on IrO_2 films (12). In ref. 11, the anomalous formation of iridium metal in the oxidative pyrolysis of iridium(III) hydrated chloride films has been explained by passivation of the outermost part of the reacting particles, and consequent hindrance of oxygen uptake from the oven atmosphere. Blocking of the thermal decomposition process of iridium(III) hydrated chloride and anomalous behaviour of the electrical resistivity of thermal IrO_2 films upon annealing has also been explained along the same lines (12). Accumulation of impurities is likely to occur around the film regions where oxide crystallites are formed. The previously mentioned areas of sparse crystallinity, for which evidence has been given in ref. 10, may therefore coincide with the "passivation" areas, encapsulating the crystallite clusters, mentioned in refs. 11 and 12, and could be the reason for the low density of the oxide films.

In the present work, NRA measurements were also carried out for the RuO_2–TiO_2 films containing 20, 30, 50, 70, 80, and 100 mol% of RuO_2, making use of the $^{12}C(d,p)^{13}C$ nuclear reaction. As expected on the basis of literature data (10, 14), large amounts of carbon were detected. Interestingly, the differences in the preparation method adopted in ref. 10 (a classical sol–gel method) with respect to that adopted in the present work (an "ink" method) were not sufficient to distinguish significant changes in the amount of residual carbon. The latter is, otherwise, affected by the amount of noble-metal salt present in the precursor films. In Fig. 5, the dependence of the C/(Ru+Ti) atom ratio on noble-metal content is shown. It can be observed that lower residual carbon contents are found at high or low noble-metal concentrations. This feature results from the combination of two factors. One is, of course, the content of organics in the precursor mixture, which increases with increasing titanium precursor salt concentration. The other is the reactivity of the precursor mixture towards the cracking and successive combustion of the organic species in the mixture. TGA–GC–MS results described in ref. 14 have demonstrated that the reactivity of the ruthenium(III) hydrated chloride+titanium(IV) diisopropoxide bis-pentane-2,4-dionate precursor mixture towards the cracking and combustion of organics is larger at noble-metal concentrations as low as 10 mol%. NRA measurements repeated after different electrochemical treatments have shown that no significant change in the carbon content is caused during electrochemical perfor-

mance. The dependence of the C/Ru atom ratio on noble-metal content is shown in Table 2. The increase in the number of carbon atoms per ruthenium atom can be taken as indirect evidence of a larger degree of dispersion of the active (or noble-metal containing) phase in the electrode material, at low noble-metal concentrations. NRA measurements repeated after cyclic voltammetry experiments in the polarization range −0.25–1.25 V (vs. SCE) have shown that no significant change in the carbon content takes place, even after repeated cycling. This excludes the possibility that the presence of carbon in the films is due to surface contamination phenomena. It is also interesting to observe that, even when no titanium organometallic compound is present, in the case of the 100% RuO_2 films, quite significant amounts of residual carbon are present. This indicates that the use of isopropanol as the solvent of the precursor mixture is sufficient to cause the phenomenon of C incorporation. Substitution of crystal water molecules around Ru(III) ions by isopropanol molecules or their decomposition products is likely to take place during the first stages of the thermolytic process. As shown in ref. 10, the amount of hydrogen impurities in this type of oxide films is comparable with that of carbon. Although the methods based on pyrolytic oxidation of precursor deposits allow attainment of an average MO_2 stoichiometry (M = Ru(IV), Ti(IV)) for the oxide phase(s), large amounts of C and H impurities are trapped in the film texture, due to the hindrance of oxygen uptake and of the release of cracking products of organics in the precursor film. The final result is a highly dispersed oxide phase, in a porous matrix.

3.3. Electrochemical characterization

3.3.1. RuO_2–TiO_2 film electrodes

Voltammetric charge can serve as a powerful tool for the study of the electrochemical or catalytic properties of oxide electrodes (21). Typical voltammograms exhibit the peak generally assigned to the Ru(IV)/Ru(III) redox couple (21). Following the procedure in ref. 22, faradaic peak charges and currents were estimated (after establishing a base line for the peaks). The total voltammetric charges and peak charges were found to be independent of the potential scan rate. The peak charges are significantly lower than those encountered in the case of IrO_2-based materials. This indicates that in RuO_2–TiO_2 mixtures a lower degree of dispersion of the active and conducting phase is achieved and is in good agreement with the previously discussed microstructural data. Both total charge and peak charge depend on the electrode film composition, exhibiting maxima around 30 mol% RuO_2. Attempts to account for the experimental results should be based on the degree of dispersion of the active phase in the electrode materials. As discussed in the literature (e.g., refs. 10–14, and literature cited therein) and further proved in the present work, when precursor deposits are pyrolyzed, the mechanism of formation of the phases is quite complicated and affects microstructural features quite strongly. When precursor salt mixtures are taken into account, the situation is further complicated by the formation of metastable solid solutions, such as in the RuO_2–TiO_2 and IrO_2–TiO_2 systems.

The roughness factor of the electrode films can be estimated from the cyclic voltammetry data. If a reasonable value is assumed for the capacity per effective unit surface area, roughness factors can be evaluated from the capacitive component of the cyclic voltammograms (21, 22). The results for RuO_2–TiO_2 film electrodes with noble-metal concentrations between 20 and 80 mol% are shown in Table 3. Larger values are found for the samples containing 30 mol% of RuO_2; minimum values are typical of samples containing 80 mol% of RuO_2. The high values attained indicate a considerable degree of porosity. More generally, the low to intermediate ruthenium concentration range is characterized by larger porosity. From peak charges (anodic, cathodic) the number of electroactive (Ru) sites, n_S, can be calculated. Results are also reported in Table 3, referred to the geometric electrode area (anodic charge densities $(q_p)_A$) and to the estimated effective area (number of electroactive sites, n_S). Interestingly, the first are themselves quite large, compared with the expected values, which should range between 10^{14} and 7×10^{14} (19, 22). Only after normalizing to the effective surface area are these figures approached, also considering the lower ruthenium concentration at the surface of the films, due to the combined effects of nominal composition and surface segregation of Ti species. At the same time the dependence of the n_S on the film composition is damped. This may be better understood if we consider that, due to segregation phenomena, the surface composition does not depend on the bulk composition. On the basis of the above results, we can therefore conclude that maxima of voltammetric charge of the type shown in Table 3 are essentially due to larger surface roughness of the oxide film. The latter, in turn, may find a tentative explanation in the high decomposition rate of the precursors at lower concentrations of the ruthenium precursor salt (14).

With reference to the above considerations about the signif-

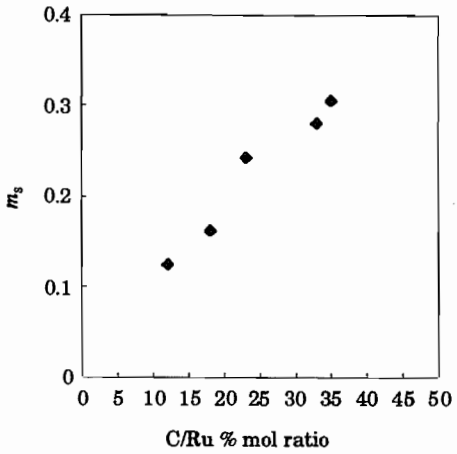
Fig. 6. Dependence of the ratio m_S between n_S and the total amount of metal atoms Ru+Ti in the film, as measured by RBS.



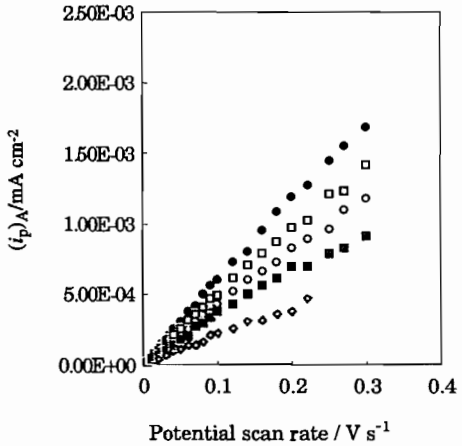


Fig. 7. Anodic peak current density ($(j_p)_A$ as a function of potential scan rate s: □, 20; ●, 30; ○, 50; ■, 70; ◇, 80 mol% Ru.

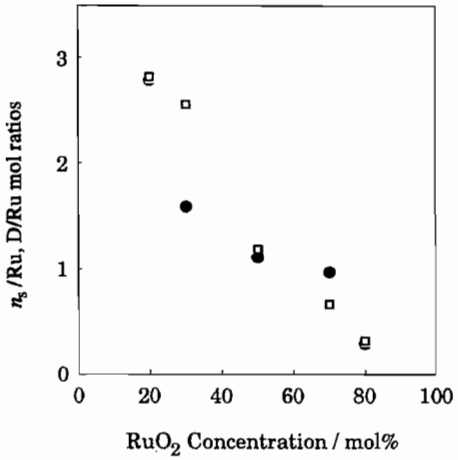
icance of residual carbon content, the correlation between the latter and the voltammetric charge of oxide electrodes has been studied. To compensate for the effect of relatively small differences in mixed-oxide loading on the voltammetric charge, the voltammetric peak charges (anodic) were divided by the total number of atoms of metal species (Ru + Ti) in the films, as determined by RBS. For homogeneity of units, peak charges were expressed as numbers of electroactive sites. The carbon content has been expressed in terms of C/Ru atom ratio, and results are shown in Fig. 6. As expected on the basis of previous considerations, larger mole fractions of electroactive sites are found in samples with larger C/Ru atom ratios. Thermoanalytical results indicate that larger amounts of organics in the reacting films enhance the reactivity towards the formation of the final oxide products, which is related to an increase of nucleation sites. According to the above consideration on the accumulation of impurities in the intergranular regions, growth of crystallites of the oxide phases should then be hindered by large amounts of carbon. Both factors should favour a better dispersion of the oxide solid solution. These properties of noble-metal based oxide electrodes are typically due to the character of volume reactions of the pyrolytic processes taking place in the precursor films.

The relatively large porosity of the RuO_2–TiO_2 films has suggested an extension of the study to the changes in voltammetric peak current densities ($(i_p)_A$, anodic, $(i_p)_C$, cathodic) with the potential sweep rate, S. Figure 7 shows that for all electrode materials the voltammetric peak current is linear in S, as expected for electrodes whose surface has been modified by insertion of electroactive sites. According to this result, mass transport does not seem to play a significant role in controlling the rate of oxidation state changes occurring in RuO_2–TiO_2 films. For IrO_2–TiO_2 and IrO_2–ZrO_2 film electrodes, exhibiting larger roughness factors, the i_p/S plots are more complicated, and peak current densities become linear in S^x, with $0.6 < x < 0.8$ (19). In these cases the surface texture is probably more microporous and diffusion of counterions taking part in the charging process is hindered.



As shown in previous work on IrO_2–TiO_2 films (22), polarization experiments carried out in D_2SO_4 solutions in D_2O can supply information on the surface texture of oxide electrodes, complementary to cyclic voltammetry data. In the present work, the electrochemical behaviour of RuO_2–TiO_2 films was studied in 1 N D_2SO_4 in D_2O by following the procedure outlined in ref. 22. Analogous experiments could be carried out, in principle, tracing hydrogen by the $^1H(^{15}N, \alpha\gamma)^{12}C$ nuclear reaction, or by ERD. However, as shown by the previous ERD measurements, the amount of hydrogen present is quite high, and essentially bound to the hydrocarbon species, or to other products of incomplete oxidative decomposition of organics taking part in the precursor reactions. This high background of essentially non-exchangeable hydrogen would make more difficult the interpretation of the data of counterion exchange under polarization. The electrodes to be analyzed by NRA were conditioned in the test solution by repeated cycling between −0.25 and 1.25 V (vs. SCE). A first measurement was then carried out after polarization for 30 min at −0.20 V. Other NRA measurements were repeated after polarization at 1.20 V, again for 30 min. After the polarization at 1.20 V a decrease in the amount of deuterium in all the electrodes was observed. This is in agreement with the double injection–ejection mechanism of charging proposed for noble-metal oxides. The cyclic voltammetry data obtained in 1 N D_2SO_4 – D_2O were similar to those obtained in 1 M aqueous $HClO_4$. Comparison between the number of electroactive sites (from anodic peak charges) per ruthenium ion and the number of exchanged deuterium (difference between the amount taken up at −0.20 V and the residual at 1.20 V), are shown in Fig. 8, as a function of the nominal bulk concentration of ruthenium. For both quantities a decrease with increasing noble-metal concentration is observed. With the exception of the result for the sample containing 30 mol% RuO_2, the correspondence between amount of exchangeable deuterium and number of electroactive sites is also satisfactory.

4. Conclusions

Compositional studies of electrode films based on RuO_2–TiO_2 mixtures, prepared by pyrolytic oxidation of $RuCl_3 \cdot 3H_2O$–Ti

Fig. 8. Comparison between the peak charge and number of exchangeable deuterium ions normalized to the ruthenium content, for RuO_2–TiO_2 electrodes of different composition: □, electroactive site fraction; ●, D/Ru mol fraction.

diisopropoxide bis-2,4-pentanedionate deposits show that these materials contain large amounts of carbon and hydrogen impurities. This evidence supports the idea that crystallites of the RuO_2–TiO_2 solid solution are separated by large amorphous areas where these chemical impurities have accumulated. The porosity of these areas is responsible for the relatively high charge-storage capacity of the mixed-oxide electrodes found by cyclic voltammetry. The results presented here are in good agreement with thermoanalytical – mass spectrometric investigations reported in other papers (11–14).

SnO_2–Sb_2O_5 film electrodes, which are generally more conveniently prepared by spray pyrolysis, exhibit a much more compact microstructural texture and less open surface texture. Smaller amounts of impurities, such as carbon and hydrogen, are incorporated in the films during their growth. This is because the pyrolytic oxidation takes place in spray pyrolysis processes as a surface reaction, which favours a more complete reaction of the precursors. Preparation based on a sol–gel method leads to smaller average crystallite size (10–20 nm). RuO_2–TiO_2 films studied in the present work are prepared by pyrolytic oxidation of precursor deposits. This essentially involves volume reactions and hindered oxygen uptake during precursor oxidation, which necessarily results in incomplete combustion of organics and more porous structures. The complexity of the volume reactions occurring during the deposit oxidation is also the main reason for the poor reproducibility of the properties of electrodes prepared by this method.

Interlamellar amino functionalization of kaolinite

James J. Tunney and Christian Detellier

Abstract: The interlamellar surface of kaolinite has been modified with molecules possessing amino functionalities. Either the dimethyl sulfoxide intercalate of kaolinite (Kao/DMSO) or the *N*-methylformamide intercalate of kaolinite (Kao/NMF) were used as starting materials. One of the products, an ethanolamine functionalized kaolinite (Kao–EOA) was resistant to thermal decomposition in both air and N_2 atmospheres up to temperatures greater than 150°C. Based on results from thermal analysis, IR analysis, ^{13}C CP/MAS NMR spectroscopy, and elemental analysis, a structural model is proposed in which every third interlayer surface hydroxyl group on the aluminol (Al-OH) surface of kaolinite is either replaced with an interlayer Al-$OCH_2CH_2NH_2$ group or is strongly H-bonded to an aminoalcohol molecule. A mixture of both types of linkages could coexist. The amino groups that point away from this surface are each keyed into the -$(SiO-)_6$ macro-rings of the adjacent silicate surface, resulting in an amino-functionalized ordered two-dimensional organo-mineral assembly.

Key words: kaolinite, halloysite, organo-mineral nanocomposites, clay functionalization, supramolecular assemblies.

Résumé : On a modifié la surface interlamellaire de la kaolinite avec des molécules portant des fonctions amino. Comme produits de départ, on a utilisé de la kaolinite intercalée de diméthylsulfoxyde (Kao/DMSO) ou de *N*-méthylformamide (Kao/NMF). Sur l'un des produits, une kaolinite fonctionnalisée à l'éthanolamine (Kao–EAO) est résistante à la décomposition thermique, jusqu'à des températures supérieures à 150°C, dans des atmosphères tant d'air que de N_2. En se basant sur les résultats d'analyses thermiques, d'analyses élémentaires, de spectroscopies IR et RMN ^{13}C avec polarisation croisée/rotation à l'angle magique, «CP/MAS», on propose un modèle structural selon lequel un sur trois groupes hydroxyles de la surface de l'intercouche de l'aluminol (Al-OH) de la kaolinite sont soit remplacés par une intercouche de groupes Al-$OCH_2CH_2NH_2$ soit fortement liés, par liaisons hydrogènes, à une molécule d'aminoalcool. Il est possible que les deux types de liaisons coexistent. Les groupes amino qui sont orientés vers l'extérieur de cette surface sont insérés dans les macrocycles de -$(SiO-)_6$ de la surface adjacente de silicate qui conduit à un arrangement organominéral aminofonctionnalisé ordonné d'une façon bidimensionnelle.

Mots clés : kaolinite, halloysite, nanocomposites organominéraux, fonctionnalisation de l'argile, arrangement supramoléculaires.

[Traduit par la rédaction]

Introduction

It has previously been shown that it is possible to rigidly fix small alcohol moieties onto the interlamellar aluminate surface of kaolinite ($Al_2Si_2O_5(OH)_4$), through the grafting reaction of the alcohol group to the Al-O-H surface of the kaolinite (1–3). These interesting materials are organo-mineral nanocomposites with organic units covalently attached to the inorganic substrate in an ordered stacking of organo-mineral layers. The non-centrosymmetric kaolinite layers may act as a rigid inorganic supramolecular organizing medium, since the dipole moment that exists across the interlayer space of kaolinite (4–6) may act to orient molecules in a preferred orientation (1–3, 7–16). It would thus be of interest to expand the interlayer grafting chemistry of kaolinite to include other systems than the previously reported alcohol/diol organo-kaolinite system (1–3). It has been demonstrated that despite the slow kinetics of many kaolinite intercalation reactions (8), it is nonetheless possible to intercalate large molecules, such as polyethylene glycol of average molecular weight 3400, into the interlayers of kaolinite by first preswelling with either DMSO or NMF (17). This suggests that kaolinite could be used as a non-centrosymmetric inorganic organizing medium. One may thus envisage rationally assembling sophisticated non-centrosymmetric organo-mineral materials based on rigid inorganic asymmetric kaolinite layers.

With the diol-based organo-kaolinites, the interlayer cohesive forces for these new materials prevented easy layer swelling (1, 2). This was presumably due to the strong hydrogen bonding between the pendant hydroxyl groups of the diols and the silicate surface of the kaolinite layers. As a result, even though the alcohol functionality of the diol unit offers an

attractive site for further interlayer modification reactions, it is inaccessible to reactant molecules. Other types of organo-kaolinites, preferably with weaker interlayer cohesion and consequently greater swelling properties, are required if one wishes to use them as the first step in the development of more sophisticated structures. Part of the appeal in attaching molecules with pendant amine groups in the interlayer space of kaolinite lies with the possibility of using the free amine group to attach larger molecules to the interlayer surface kaolinite. Amines could, for example, provide an ideal site for the attachment of a carbonyl-functionalized moiety.

Organo-kaolinites with organic guests possessing amino groups have previously been reported. Kaolinite-hydrazine (Kao/Hz) (8, 18–21) is rapidly formed by exposing untreated kaolinite to hydrazine vapours or to a hydrazine solution. Despite its ease of formation, Kao/Hz is much less stable than either Kao/DMSO or Kao/NMF, decomposing in ambient conditions within less than an hour. This ease of formation and inherent instability allows Kao/Hz to be used to advantage as an intermediate in the preparation of other organo-kaolinites via the displacement method (21–23). In related work, Inoue et al. (24) prepared a series of aminoalcohol-based organoboehmite materials in which they proposed that the organic units were attached to the boehmite via Al-O-$(CH_2)_n NH_2$ bonds.

Experimental

Materials

All chemicals used were of reagent grade quality and were not further purified unless otherwise specified. KGa-1, well-crystallized kaolinite, was obtained from the Source Clay Repository of the Clay Mineral Society (Department of Geology, University of Missouri, Columbia, Mo.). Halloysite (coded as Halloysite no. 13 from Eureka, Utah), a polytype of kaolinite, was obtained from Ward's Natural Science Establishment Inc. (Rochester, N.Y.) in the form of hard rocklike chunks. This had to first be ground up to the consistency of a coarse powder before proceeding with the purification procedure. For both kaolinite and halloysite, purification by standard sedimentation procedures to remove the >2 μm size fraction was required (25–27). Even after purification, in the case of kaolinite small amounts of anatase (TiO_2) impurities could be detected by XRD as a sharp weak reflection at d = 3.52 Å, corresponding to the (101) reflection of anatase. The purified clays were then characterized by XRD, FTIR, and TGA/DSC, and were found to be consistent with literature data for purified natural kaolinite and halloysite (28, 29).

Characterization

XRD powder patterns were measured on a Philips PW 3710 automated diffractometer using Cu Kα radiation (wavelength = 1.5416 Å). All measurements were taken using a generator voltage of 45 kV and a generator current of 40 mA. A step size of 0.04° 2Θ was used with a dwell time of 0.5 seconds per step. The sample was spun during pattern acquisition, and an automatic divergent slit and a 0.1 mm receiving slit were used without employing any mask. Samples were mounted on a circular glass disk by first dispersing 20–30 mg of sample with 1 mL of methanol, sonicating for 10 s, and allowing the suspension to dry on the glass disk. Some samples were mounted dry by first smearing a small quantity of vaseline to the glass disk and then placing the powder directly on this. The intercalation ratio (I.R.), which is an indication of the extent of modification, was calculated from the relative intensities of the (001) reflections of the modified organo-kaolinite phase and the unexpanded kaolinite phase (8). The c-spacing or basal spacing is calculated based on the indexed (00*l*) reflections (8). Reflections due to the presence of residual unreacted kaolinite are identified with the symbol K. All *d*-values are given in Ångstrom units (Å), with the relative intensities given in parentheses on a scale where 100 is the intensity of the most intense reflection. The assigned indexing of the reflection is also given in parentheses.

Infrared spectra were obtained on a Bomem Michelson MB 100 FTIR spectrometer using 30–50 averaged scans at 4 cm^{-1} resolution. The samples were prepared as KBr pellets (0.25–0.50% by weight in KBr). X-ray fluorescence (XRF) measurements to measure the Si/Al ratio were performed on a Philips PW 2400 fluorimeter equipped with a Philips PW 2510 sample holder, with the scans referenced to a mixture of SiO_2 and Al_2O_3. Ceramic yields were determined by measuring the residual mass (as a percentage of the starting mass) of the product after calcination at 1100°C for 3 h in air atmosphere. Thermal analyses (TGA and DSC) runs were performed on a Polymer Labs 1500H instrument under either flowing nitrogen or air (20–90 cm^3/min) and a heating rate of 20°C/min. Approximately 10 mg of sample was used for each run using alumina sample and reference pans.

^{13}C cross polarization/magic angle spinning (CP/MAS) spectra (50.33 MHz) were performed on a Bruker ASX-200 instrument with a magic angle spinning rate of 3–4 kHz. The ^{13}C CP/MAS spectra were referenced to hexamethylbenzene at 16.9 ppm. Solution state NMR (^1H and ^{13}C) were performed on either a Varian XL-300 or a Bruker AMX-500, and both ^1H and ^{13}C chemical shifts are reported relative to TMS in $CDCl_3$.

Starting materials

The preparations of both Kao/DMSO and Kao/NMF and starting materials have been described elsewhere and are based on standard literature procedures (1, 2, 8). Briefly, this involves allowing 20 g of the unexpanded purified kaolinite to remain in contact with DMSO or NMF in an enclosed jar for at least 2 months at room temperature, followed by washing with 1,4-dioxane to remove excess DMSO or NMF, and air drying. After this time, both Kao/DMSO and Kao/NMF are found by XRD to be formed with an intercalation ratio (I.R.) exceeding 90%. XRD patterns, IR spectra, and TGA were all consistent with literature data (8). The DMSO intercalate of halloysite (Hal/DMSO) was formed in an identical manner. In this case, no residual unexpanded halloysite was observed by XRD (8).

Reactions with amines

Kao/DMSO + ethanolamine (Rxn 1)

The reaction of Kao/DMSO with ethanolamine was repeated a number of times and in all cases nearly identical materials resulted. The following is a typical example: 1.0 g of Kao/DMSO (I.R. = 0.97) was refluxed with 50 mL of freshly distilled ethanolamine (EOA) for 22 h under N_2 atmosphere. This was then filtered and washed with 1,4-dioxane to remove excess EOA. Air drying at 40°C for 2 h yielded 0.76 g of an

*Kao/NMF + ethanolamine (Rxn **2**)*
Kao/NMF (2.0 g) (I.R. = 0.91) was refluxed with 60 mL of ethanolamine (freshly distilled) for 23 h under N_2 atmosphere. This was then filtered and washed with 1,4-dioxane to remove excess ethanolamine. Air drying yielded 20 g of an off-white powder. The FTIR and XRD patterns proved to be nearly identical to product (**1**). XRD (vaseline mounted, vacuum dried at 40°C for 3 h): 10.36 (100, d_{001}); 7.02 (3.7, d_{001}K); 4.41 (7.5); 4.31 (9.8); 4.25 (11); 4.15 (9.1); 4.00 (5.6); 3.69 (5.9); 3.53 (23, d_{003}); $d = 10.5 \pm 0.2$ Å; I.R. = 0.96.

*Kaolinite + ethanolamine (Rxn **3**)*
Kaolinite (1.0 g) was refluxed with 50 mL of ethanolamine in a round-bottom flask fitted with a reflux condenser for 17 h under N_2 atmosphere. After filtering and washing the reaction mixture with methanol, the product was air dried, yielding 0.9 g of a light grey product. The FTIR pattern of this product was indicative of the well-crystallized kaolinite starting material.

*Hal/DMSO + ethanolamine (Rxn **4**)*
Hal/DMSO (10 g) was refluxed with 40 mL of ethanolamine (freshly distilled) for 20 h under N_2 atmosphere. This was then filtered and washed with ethanol to remove excess ethanolamine. Air drying yielded 0.70 g of an off-white powder. XRD: 10.61 (100, d_{001}); 3.55 (13, d_{003}). $d = 10.6 \pm 0.1$ Å; I.R. = 1.0. FTIR (cm^{-1}), ν(O-H): 3695 (s), 3630 (s), 3558 (s), 3491 (s); ν(NH): 3356 (m), 3313 (m); ν(C-H): 3076 (w, br), 2948 (w), 2889 (w); ν(C=O): 1614 (m); δ(C-H, N-H): 1478 (vw), 1355 (vw); Si-O vibrations: 1125 (s), 1035 (vs); δ(AlOH): 908 (s); other bands: 2620 (w), 744 (w), 680 (m), 551 (s), 468 (s), 434 (s).

*Kao/DMSO + ethylene diamine (Rxn **5**)*
Kao/DMSO (1.2 g) (I.R. = 0.97) was refluxed with 60 mL reagent grade ethylene diamine (Aldrich, BP 118°C) in a round-bottom flask fitted with a reflux condenser for 18 h under N_2 atmosphere. After filtering and washing the reaction mixture with 1,4-dioxane, the product was air dried, yielding 0.8 g of a light grey product. The FTIR pattern of this product was indicative of partially collapsed Kao/DMSO.

Table 1. Summary of the organo-kaolinite products formed from the treatment of amines with kaolinite.

Starting material	Reactant	Rxn code[a]	Basal spacing[b] (Å)	I.R.[c]
Kao/DMSO	Ethanolamine	**1**	10.7	0.98
Kao/NMF	Ethanolamine	**2**	10.5	0.96

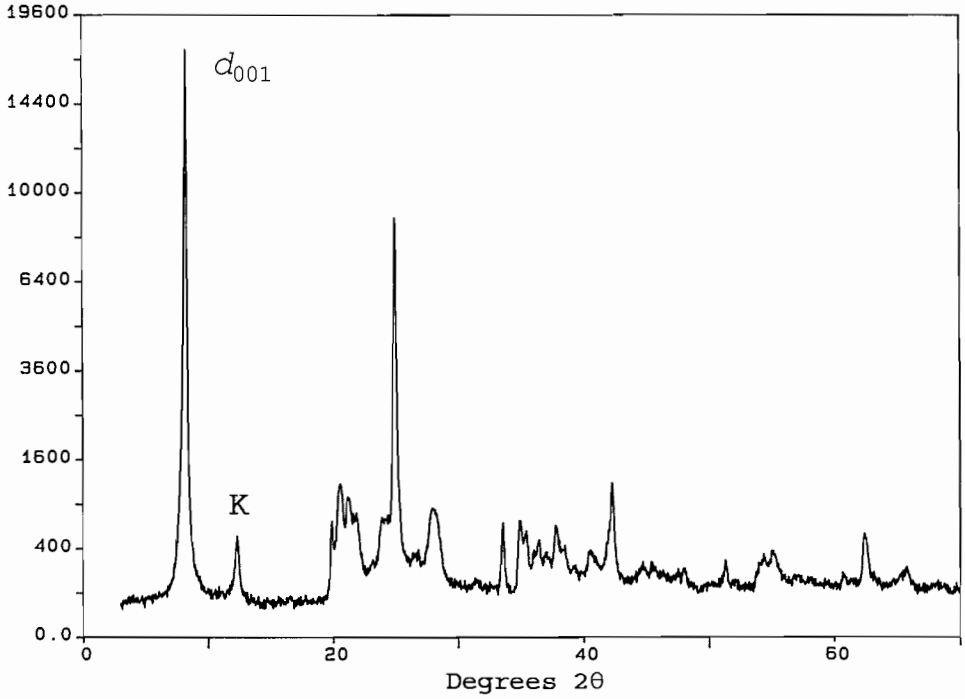
[c]Intercalation ratio.

*Kao/DMSO + 3-amino-1-propanol (Rxn **6**)*
Kao/DMSO (1.0 g) (I.R. = 0.97) was refluxed with 50 mL of 3-amino-1-propanol (Aldrich, $NH_2(CH_2)_3OH$, bp 187–188°C) for 19 h under N_2 atmosphere. Work-up consisted of cooling, filtering, and washing with methanol; 0.82 g of an off-white powder was recovered after air drying for 1 h. XRD and FTIR patterns were indicative of a partially modified product. XRD: 11.07 (90, d_{001}), 7.10 (66, d_{001}K). I.R. = 0.58. FTIR (cm^{-1}), ν(O-H): 3698 (s), 3652 (m), 3622 (s), 3626 (w, br); ν(NH): 3364 (vw); ν(C-H): 2941 (w), 2878 (w); δ(C-H, N-H): 1574 (w), 1482 (w), 1322 (vw); Si-O vibrations: 1110 (s, sh), 1085 (s), 1046 (vs), 1032 (vs), 1013 (vs); δ(Al-OH): 914 (s); other bands: 791 (w), 752 (w), 685 (m), 539 (s), 472 (s), 431 (s).

*Kao/DMSO + DL-1-amino-2-propanol (Rxn **7**)*
Kao/DMSO (1.0 g) (I.R. = 0.97) was refluxed with 50 mL of DL-1-amino-1-propanol (Aldrich, $NH_2CH_2CH_2OHCH_3$, bp 160°C) for 19 h under N_2 atmosphere. Work-up consisted of cooling, filtering, and washing with methanol; 0.72 g of an off-white powder was recovered after air drying for 1 h. FTIR indicated that no modification had occurred, and the Kao/DMSO starting material had reverted to a collapsed kaolinite.

*Kao/DMSO + nitroaniline (Rxn **8**)*
A preliminary attempt to intercalate nitroaniline into the interlayer space of kaolinite was made by reacting 1.0 g of Kao/DMSO in 10 g of melted nitroaniline (mp 149°C) at 175°C for 40 h under N_2 atmosphere. During the course of reaction, the mixture slowly turned black. Work-up consisted of repeated washings with methanol to remove as much of the excess organic material as possible. FTIR and XRD patterns were both consistent with a collapsed kaolinite structure.



Results and discussion

Preparation

A series of amines were reacted with Kao/DMSO and Kao/NMF (Table 1). These included the aminoalcohols ethanol-

© 1997 NRC Canada

Fig. 1. XRD pattern (2°–70° 2Θ) for Kao–EOA. K indicates (001) reflection from residual kaolinite.

amine (EOA) and 3-amino-1-propanol (3,1-AP), which formed new organo-kaolinite intercalates. The reactions involving ethylene diamine (**5**), DL-1-amino-2-propanol (**7**), and nitroaniline (**8**) were unsuccessful and yielded only collapsed unmodified kaolinite and Kao/DMSO starting material. For Kao–3,1-AP (**6**), the modified phase had a basal spacing of 11.1 Å, and the intercalation ratio (I.R.) was only 0.58. IR results for this material definitely show that the Kao/DMSO starting material has been altered, and one observes bands attributable to the 3-amino-1-propanol guest species. For example, faint ν(NH) bands were detected at 3426 (vw) and 3364 (vw) cm^{-1}, ν(CH) bands at 2941 (w) and 2878 (w) cm^{-1}, and deformation bands at 1574 (w), 1482 (w), and 1322 cm^{-1}. The fact that 3-amino-1-propanol formed an intercalate with kaolinite, whereas DL-1-amino-2-propanol did not, may plausibly be due to the higher reaction temperature for Kao–3,1-AP formation (187°C vs. 160°C), which permitted a more rapid diffusion of 3-amino-1-propanol into the interlayers of kaolinite before structural collapse could occur. Alternately, the presence of an end methyl group in 1-amino-2-propanol may have also made interlayer diffusion more difficult and contributed to a weaker host–guest interaction.

In view of the fact that ethylene diamine may intercalate into halloysite to form an 11.7 Å intercalation complex (30, 31), it is surprising that an organo-kaolinite product was not formed via the displacement of DMSO. Reaction with *para*-nitroaniline was also unsuccessful, presumably due to the hydrophobic nature of *para*-nitroaniline and the weaker basicity of *para*-nitroaniline compared to primary amines.

Clearly, the greatest success was achieved using ethanolamine as the reactant, and this product (Kao–EOA) will be examined in some detail. It was possible to form nearly identical Kao–EOA products from both Kao/DMSO and Kao/NMF starting materials but not from unexpanded kaolinite. This indicates that the intercalating agent (DMSO or NMF) that was used to provide access to the interlamellar space of kaolinite plays a passive role and is not directly involved in the actual chemical reaction between ethanolamine and the interlamellar surface of kaolinite. DMSO and NMF are required only to provide access to the clay interlayers.

The Kao–EOA product exhibited a remarkable crystallinity as exhibited by the strong reflections of the XRD pattern (Fig. 1). The main product had a basal spacing of 10.67 Å. This product was found to be stable with respect to vacuum drying over phosphorus pentoxide for 24 h at 25°C, but was unstable when washed with water overnight, reverting slowly to the parent kaolinite 7.2 Å phase.

It was also possible to form the halloysite analogue of Kao–EOA (Hal–EOA), by reacting Hal/DMSO with ethanolamine (**4**). These materials exhibited similar basal spacings and IR patterns. Hal–EOA was much less crystalline than Kao–EOA, as evidenced by the very broad diffraction peaks. This was presumably due to the turbostratic nature of halloysite and Hal–EOA compared to kaolinite and Kao–EOA. No residual unexpanded parent mineral could be detected for the Hal–EOA, indicating that 100% modification was achieved. This was not the case for Kao–EOA, where a reflection at 7.2 Å representing 1.5% relative intensity indicates the presence of a small amount of residual unexpanded kaolinite.

To our knowledge, an ethanolamine derivative (intercalate or otherwise) of kaolinite has not been previously reported in the literature. Ethanolamine has, however, been reported intercalated in halloysite (31), forming a material with a basal spacing of 10.7 Å, which is similar to what is reported here (**4**). This corresponded to a layer expansion of 3.5 Å, which is less than the 4.0 Å minimum clearance space that was calculated

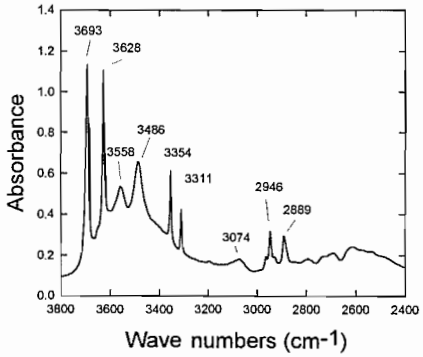

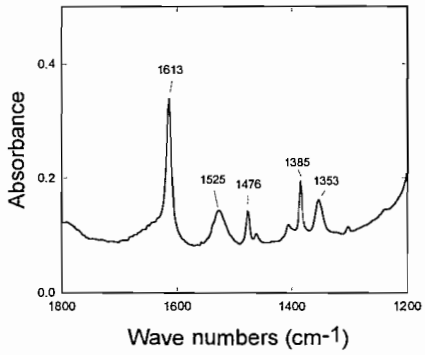

Fig. 3. IR spectra (1800–1200 cm^{-1}) of Kao–EOA.

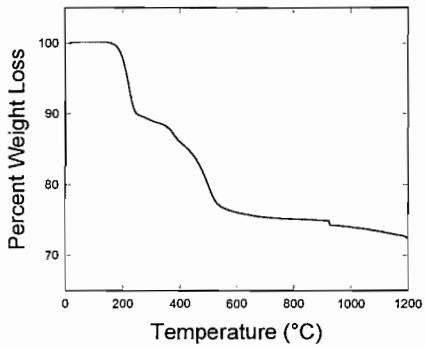
for ethanolamine. This is in accord with many other intercalates that show a smaller than expected basal spacing due to some keying in of the guest (1–3, 8).

IR analysis

The IR patterns of Hal–EOA and Kao–EOA showed strong evidence of modification of the respective host minerals. In particular, the O-H stretching region was greatly perturbed and additional N-H stretching bands could be seen due to the ethanolamine units (Fig. 2). The ν(OH) bands of kaolinite normally found at 3695, 3670, 3652, and 3620 cm^{-1} have been replaced by bands at 3693, 3628, 3558, and 3486 cm^{-1} for Kao–EOA. These last two bands represent significant red shifts, indicating the effects of increased hydrogen bonding between the kaolinite host and ethanolamine guest.



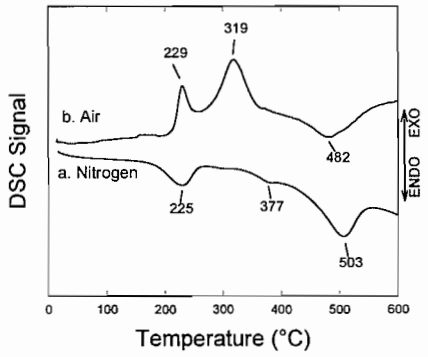
The inner hydroxyl kaolinite peak at 3620 cm^{-1} peak has been blue shifted to 3628 cm^{-1}. A similar blue shift phenomenon for an evacuated (0.01 Torr; 1 Torr = 133.3 Pa) hydrazine intercalated kaolinite was previously attributed to keying of the -NH_2 moiety of hydrazine into the siloxane ditrigonal cavity of kaolinite (20). A partial collapse of the hydrazine intercalate from 10.4 to 9.6 Å was associated with this phenomenon. This 8 cm^{-1} shift of the inner hydroxyl ν(OH) band, therefore, provides some evidence for the keying in of the -NH_2 group of ethanolamine into the (Si-O-)$_6$ macro-ring of kaolinite. In addition to the O-H stretching region, further evidence for ethanolamine modification includes the presence of two sharp N-H stretching bands at 3354 and 3311 cm^{-1}. C-H stretching bands were observed at 2946 and 2889 cm^{-1} (Fig. 2).

In the deformation region (Fig. 3), an NH bending band at 1613 cm^{-1}, a δ(CH) band at 1476 cm^{-1}, and a C-N stretching band at 1353 cm^{-1} could all be observed. The kaolinite host material also showed signs of perturbation in the lattice vibrations region. The very strong in-plane Si-O-Si stretching vibrations of kaolinite at 1010 and 1033 cm^{-1} (26) are shifted to higher frequencies in Kao–EOA to 1016 and 1045 cm^{-1}. The δ(Al-OH) band of the inner hydroxyl of kaolinite is shifted from 915 to 908 cm^{-1}, and the δ(Al-OH) band of the inner surface kaolinite hydroxyls at 938 cm^{-1} is replaced by a band at 974 cm^{-1}. All this indicates strong host–guest interactions between kaolinite and the ethanolamine moiety.

^{13}C NMR analysis

The solid state ^{13}C CP/MAS NMR spectrum (45.3 MHz) of Kao–EOA showed two broad resonances, one at 43 ppm and the other at 60.5 ppm corresponding, respectively, to the ^{13}C-NH_2 carbon and the ^{13}C-O- carbon of the ethanolamine unit. This was consistent with the insertion of the ethanolamine units in the interlayers of kaolinite. A dipolar dephasing experiment (32) (40 μs interrupted decoupling) led to the complete disappearance of both signals, indicating the existence of a rigidly bound ethanolamine unit, plausibly grafted to the aluminate interlamellar surface via $\equiv$Al-O-CH_2CH_2-NH_2 linkages. Alternatively, the ethanolamine molecule may be intercalated, but held rigidly in place by the inorganic host.

Fig. 4. TGA (20–1200°C) for Kao–EOA. Flowing nitrogen (40 cc/min); the heating rate was 20°C/min.



Thermal analysis

Thermal analysis of Kao–EOA shows that decomposition does not occur until about 150°C, and then there appears to be a three-step decomposition ending at 600°C (Fig. 4). The total calcination weight loss after heating to 1100°C in air for 3 h is 27.5%. Hal–EOA differs from Kao–EOA in that there is a preliminary decomposition step (7.6% weight loss) beginning almost immediately upon heating.

The thermal decomposition in nitrogen between 150 and 600°C is characterized by endothermic peaks at 225, 377, and 503°C (Fig. 5*a*). The peaks at 225 and 377°C are assigned to the endothermic pyrolysis of the interlayer organic material, and the peak at 503°C is assigned to the dehydroxylation of the kaolinite host. In air atmosphere (Fig. 5*b*), one observes an endothermic peak at 482°C assigned to the dehydroxylation of the kaolinite host material. However, instead of two endothermic events corresponding to the decomposition of interlayer organic material, two exotherms with peaks at 229 and 319°C

© 1997 NRC Canada

Fig. 5. DTA for Kao–EOA under flowing nitrogen (40 cc/min), and flowing air (40 cc/min). The heating rate was 20°C/min.

are observed. They are assigned to the exothermic combustion of the interlayer organic material. When the TGA/DSC run was done in air atmosphere, the product after heating to 1100°C was white, indicating that complete combustion of the interlayer organic material had occurred.

Based on elemental analysis of Kao–EOA (**1**), one can assign the formula $Al_2Si_2O_5(OH)_{3.0}(OCH_2CH_2NH_2)_{1.0}$. Here one assumes that grafting has occurred via the condensation reaction of the alcohol group of the ethanolamine with the interlamellar Al-O-H groups of kaolinite. This is consistent with the model for the aminoalcohol-derivatized organoboehmites of Inoue et al. (24) and with the methoxy-functionalized kaolinite (3). There is one ethanolamine unit per $Al_2Si_2O_5(OH)_4$ structural unit of kaolinite, allowing each amino group to key into one $(Si\text{-}O\text{-})_6$ macro-ring of the silicate surface of the adjacent layer. Alternately, if one were to consider an ethanolamine unit that is intercalated into the interlamellar surface of kaolinite without grafting, one could assign a chemical formula of $Al_2Si_2O_5(OH)_4(CH_2OHCH_2NH_2)_{1.0}$. The discrepancy between the calculated (3.45%) and found (2.72%) values for the%H of this last assignment suggests that the chemical formula based on the grafting of ethanolamine units ($Al_2Si_2O_5(OH)_{3.0}(OCH_2CH_2NH_2)_{1.0}$) may be a better representation of the structure.

Conclusions

The well-ordered organo-kaolinite material, Kao–EOA, was prepared from the reaction of ethanolamine with both Kao/DMSO and Kao/NMF. A model in agreement with the characterization data can be suggested: an organo-kaolinite material where ethanolamine units are attached to the aluminate interlamellar surface of kaolinite via $\equiv Al\text{-}O\text{-}CH_2CH_2NH_2$ covalent linkages, with the pendant NH_2 group keyed into the $(SiO\text{-})_6$ macro-ring of the adjacent silicate surface. This model accounts for both the rigidity of the ethanolamine units observed from ^{13}C DD/MAS NMR results, and the relative thermal stability of Kao–EOA. Elemental analysis and IR are also consistent with this structure, representing a supramolecular assembly of dipolar organo-mineral layers, stacked upon each other in an ordered non-centrosymmetric manner. However, on the basis of the basal spacing (10.7 Å) and of the lesser thermal and hydrolytic stability than the corresponding methoxy (3) and ethylene glycol derivatives (2), one can not unambigously disprove a structure when EOA units would be rigidly intercalated with EOA units keyed into the silicate macro-rings and the aluminol sheets. The prepared material could be a mixture of both types of compounds, intercalated and grafted EOA–kaolinite. A similar mixture could be obtained under certain experimental conditions in the case of the two previously reported ethylene glycol – kaolinite derivatives (1, 2).

Regarding Hal–EOA, the short-range structure of this intercalate appears to be similar to Kao–EOA. The long-range ordering, as evidenced from XRD, indicates that Hal–EOA is arranged in a turbostratic manner whereas Kao–EOA appears to have some three-dimensional ordering. This could be expected on the basis that the parent materials show this same difference in long-range ordering (8, 29).

Abstract: A systematic investigation has been carried out of thermally formed Ru–Ti oxide electrodes of varying Ru content, correlating their voltammetric and impedance characteristics in NaCl solutions with the kinetics of the chlorine evolution reaction. The Tafel slope increases markedly with lower Ru content (< ca. 25 at.%), indicative either of the contribution of increasing oxide resistance or of a change in mechanism. The exchange current density is linearly proportional to the Ru content down to <10 at.% Ru, below which the film appears to respond more like a highly resistive film material. The film resistance and capacitance, determined by equivalent circuit fitting in the absence of dissolved chlorine, were used to calculate the expected impedance response of the oxide film, based on a model of an activation-controlled surface redox reaction occurring in a porous matrix. The calculated results show the dominant signature of the matrix resistance at low Ru loadings, in both the phase angle impedance data and in the Tafel plots, in agreement with the experimental observations.

Key words: Ru oxide, Ru–Ti oxide, chlorine evolution, kinetics, capacitance, equivalent circuit, impedance, Tafel data.

Résumé : On a effectué une étude systématique d'électrodes de l'oxyde de Ru–Ti, formées thermiquement, contenant diverses quantités de Ru; on a établi une corrélation entre leurs caractéristiques voltampérométriques et d'impédance dans des solutions de NaCl avec la cinétique de la réaction d'évolution du chlore. La pente de Tafel augmente d'une façon importante aux faibles concentrations de Ru (inférieures à environ 25 at.%); ceci suggère une augmentation de contribution de la résistance de l'oxyde ou un changement de mécanisme. La densité du courant d'échange est linéairement proportionnelle à la concentration du Ru jusqu'à des valeurs inférieures à 10 at.% de Ru; en dessous de ces valeurs, le film semble répondre plus comme un film ayant au grande résistivité. On a utilisé la résistance et la capacitance du film, déterminées par un ajustement de circuit équivalent en l'absence de chlore dissous, pour calculer la réponse attendue de l'impédance de l'oxyde de film; à cette fin, on a fait appel à un modèle de réaction redox de surface contrôlée par l'activation et se produisant dans une matrice poreuse. Les résultats calculés montrent que la signature dominante de la résistance de la matrice à de faibles doses de Ru est en accord avec les données expérimentales, tant pour les données d'impédance que pour les courbes de Tafel.

Mots clés : oxyde de ruthénium, oxyde de Ru–Ti, évolution de chlore, cinétique, capacitance, circuit équivalent, impédance, données de Tafel.

1.0 Introduction

Understanding the electrochemical properties of thermally formed Ru–Ti oxide electrodes, commonly used as anodes in the chlor-alkali industry, is very important in order to forecast, and to enable the optimization of, their overall performance during chlorine evolution in industrial operations. Extensive prior investigations have been directed towards understanding Ru–Ti oxide electrode characteristics and to establishing the relationship between their structural and electrical properties and their Ru content. Several comprehensive and critical analyses of these prior results have been presented previously (1–3).

The effect of the temperature employed during the formation of Ru–Ti oxides on their structure has been examined (4–6), and it was reported that the oxide obtained at 400°C is a metastable solid solution, while a crystalline mixture is obtained at 700–800°C. Spasskaya et al. (7) concluded that the change of the roughness factor (200 to 800) that occurs with composition has little effect on the oxide surface properties. It was also reported by various groups (5–9) that the resistance of Ru–Ti oxide films increases sharply with decreasing Ru content for films containing less than ca. 25 at.% Ru (7, 8).

Doblhofer et al. (10) studied the effect of sweep rate on the charge passed in cyclic voltammetry (CV) experiments by thermally formed Ru–Ti oxide electrodes, allowing the diffusion coefficients to be estimated. A study of the effect of the Ru composition on the CV charge of the Ru–Ti oxide electrodes (6, 11–13) showed that it could be used to measure their

true surface area. Shieh and Hwang (14) studied the electrochemical behavior of Ru–Ti oxide electrodes doped with small amounts of Sn and found the relationship between the CV charge and the double layer capacity (obtained from ac impedance experiments) to be linear and also that the capacity could yield the electrochemically active surface area. Investigations of the influence of temperature on the CV response (13, 15, 16) revealed the Arrhenius relation to be obeyed, yielding an activation enthalpy of ca. 4–5 kJ/mol.

Vallet et al. (17, 18) studied the properties of ion-implanted Ru– and Ir–Ti electrodes and found the electrochemical activity of Ru-implanted electrodes to be 2 to 3 times higher than that of the Ir-implanted ones, while the corrosion rate of the latter was only ca. 1% of the former. They also reported that the mechanism of electrical conductance of these oxides changes from semiconducting to metallic when a surface Ru concentration of 2.6×10^{21} atoms cm^{-3} is exceeded, corresponding to about 25 at.% Ru in the Ru–Ti oxide film.

Most of the investigations performed in the past with thermally formed Ru–Ti oxide electrodes have focussed on the kinetics of the chlorine evolution reaction on these oxide surfaces. However, no systematic studies have to date been reported relating the electrochemical and impedance properties of these metal oxide electrodes, under conditions when only the oxide film is redox-active, to the kinetic characteristics of these materials in the faradaic domain of the chlorine evolution reaction. In the present paper, attempts have been made to explain the changes in the chlorine evolution Tafel data, in terms of the combined effect of changing film resistivity and of the density of active Ru sites, with the change in the Ru content of the films. This study was also considered relevant in terms of attempting to further the understanding of the origin of the problematic loss of kinetic activity, seen with some Ru–Ti oxide anodes, in practice.

2.0 Experimental

The working electrode substrate consisted of 99.99% Ti wire of 2 mm diameter, purchased from Johnson Matthey, Inc. The cross-sectional end (0.0314 cm^2) of each fresh titanium wire electrode was first polished with 600 grit emery paper, and then dipped in hot oxalic acid (1.25 mol/L) + 2.2 mol/L hydrochloric acid to remove the air-formed oxide film from the surface. It was then rinsed with acetone, dried, rinsed with methylene chloride, dried again, and then rinsed with triply distilled water.

Ruthenium(III) chloride (18.2 g, Johnson Matthey & Mallory Ltd.), titanium(VI) butoxide (45 ml, Aldrich Chemical Co. Inc.), and 4.4 mol/L hydrochloric acid (6 mL) were mixed together to make the coating solution.[2] The Ti wire electrodes were then painted with a thin layer of this solution and allowed to air-dry. A single coat under normal conditions yielded a coating thickness, estimated by its weight gain, to be ca. 2 μm. In other experiments, a thinner film of 0.6–0.7 μm thickness was deposited in two coats from a 5 × diluted Ru–Ti coating solution. These coatings were then converted to the oxide by heating at a rate of 5°C/min to 100°C, and then remaining at 100°C for 15 min to remove the solvent. The temperature was then increased at 10°C/min to 440°C in air and maintained at 440°C for 30 min to decompose the Ru–Ti compounds into the corresponding oxides. Afterwards, the side of each oxide-coated Ti wire was insulated with Teflon tape, leaving only the cross-sectional end to serve as the working electrode (WE) in the NaCl test solution.

All experiments were carried out in 5 mol/L NaCl (EM Science) made up with triply distilled water. The pH of the NaCl solution was adjusted both before and during electrolysis to ca. 4 by the addition of either 0.5 or 2 mol/L HCl at regular intervals. All electrolysis experiments were carried out without additional stirring of the solution or removal of the dissolved oxygen, in a one-compartment cell at both room temperature (20–22°C) and at 90°C. IR compensation was employed for the Tafel analysis of the chlorine evolution data in all of the experiments.

The counter electrode (CE) was a 40 at.% Ru oxide coating on a Ti substrate, of more than 100 times the apparent surface area of the WE. It was positioned inside a Teflon tube to minimize the amount of hydrogen gas that passed into the solution in the main compartment. An Ag/AgCl electrode was employed as the reference electrode (RE) at high temperatures, while an SCE generally served as the RE at room temperature. All potentials are given versus the SCE in this paper.

An EG&G PAR 273 potentiostat/galvanostat was used in all electrolysis and CV experiments, with the data plotted on an HP 7044B X-Y recorder. A Solartron 1255 HF frequency response analyzer, coupled with a Solartron 1286 electrochemical interface, was employed for the ac impedance measurements, using frequencies from 0.1 to 65 kHz and a 10 mV rms amplitude (effective) applied at the open circuit potential (OCP). As the SCE reference electrode introduces a time delay to the potentiostat, seen as a phase shift at high frequencies due to its resistance and capacitance characteristics, an additional Pt wire electrode was placed in the cell and was connected via a 6.8 μF capacitor to the RE lead (19–21). Data acquisition was carried out using Z-Plot software (Scribner Associates) and its evaluation was achieved using a nonlinear least-squares fit program (Equivalent Circuit, Version 3.97, written by B. Boukamp, University of Twente).

3.0 Results and discussion

3.1 Cyclic voltammetric (CV) behavior of Ru–Ti oxide films

As part of the early steps in the characterization of the films, CV data were collected in fresh 5 mol/L NaCl solutions prior to the electrolysis experiments. It is known (1, 2, 22–24) that the CV response of these electrodes reflects the reversible conversion of the Ru sites at the film surface from Ru(II) at the negative end of the scan to Ru(IV) at more positive potentials. The CV behavior at 100 mV/s for oxide electrodes of varying Ru content is shown in Fig. 1 at 20–22°C (solid lines) and at 90°C (dotted lines) in 5 mol/L NaCl, between 0.5 and 1.0 V vs. SCE. It can be seen from Fig. 1 that the magnitude of the CV currents decreases with decreasing Ru content, particularly for the less than 15 at.% Ru oxide films. Also, the effect of temperature on the response is negligible down to 10 at.% Ru, below which increased temperature yields significantly higher currents, especially for the 5 at.% Ru oxide.

Figure 2 (open symbols) shows a plot of the reciprocal of

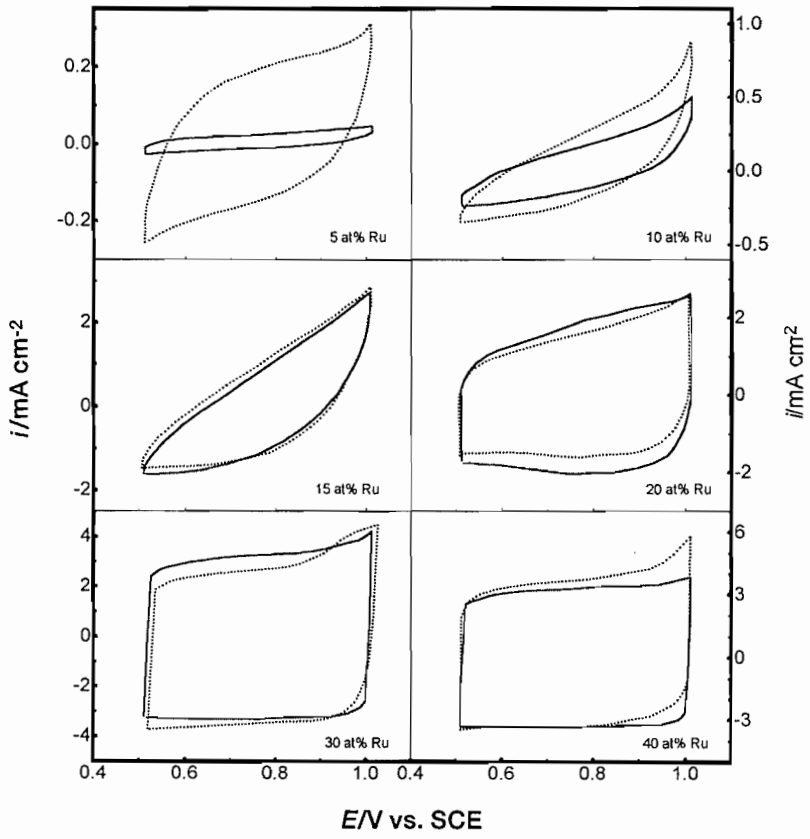
Fig. 1. Cyclic voltammograms of Ru–Ti oxide electrodes (2 μm thick) with varying Ru content in 5 mol/L NaCl (pH ca. 4) at 100 mV/s at room temperature (solid lines) and at 90°C (dotted lines).



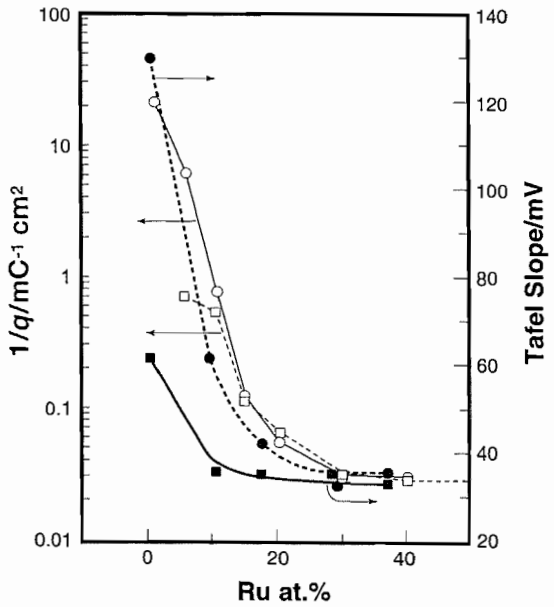


Fig. 2. Relationship of reciprocal CV charge densities (room temperature, open circles; 90°C, open squares) and of the Tafel slope obtained during chlorine evolution (room temperature, closed circles; 90°C, closed squares) on the Ru content for 2 μm thick Ru–Ti oxide films in 5 mol/L NaCl (pH ca. 4).

the logarithm of the integrated charge density (passed in a single anodic scan) as a function of the Ru content of the film. The inverse log of the charge density decreases linearly up to ca. 25 at.% Ru, and then takes on a close to steady-state value at higher Ru compositions. Clearly, the addition of Ru to the Ti oxide film not only results in a proportional increase in the density of surface-active Ru sites, but also leads to other changes in film properties.

Figure 3(*a*) shows the room temperature CV response for a pure, thermally formed Ti oxide film, demonstrating the very low capacitance of this semiconducting material. Figure 3 (*b* and *c*) displays the CV responses for pure Ru oxide films at room temperature and at 90°C, respectively. The higher charges and the more capacitive appearance of the CV response in Figs. 3*b* and 3*c* for pure Ru oxide films appears very similar to the CV data for mixed Ru–Ti oxide films of more than 20 at.% Ru, shown in Fig. 1. Clearly, the CV response for Ti oxide (Fig. 3*a*) is more similar to those of the 5 and 10 at.% Ru films in Fig. 1, suggesting that the more marked effect of temperature in Fig. 1 for these oxides reflects an increase in conductivity.

The effect of film thickness on the CV response of 40 at.% Ru oxide films is shown in Fig. 4. The currents and charge densities are seen to be approximately proportional to the estimated film thicknesses of 0.6 and 2 μm. If the Ru–Ti oxide CV response is proportional to the available surface area, as was reported earlier for thermally formed films (12, 25, 26), then these results suggest that these films are homogeneously

porous materials and that all of the Ru surface sites are accessible for reaction under these experimental conditions. The research of Burke and O'Neil (13) also concluded that the CV charge is a measure of the true surface area of the oxide film,

Fig. 5. Polarization behavior of Ru–Ti oxide electrodes with varying at.% Ru in 5 mol/L NaCl (pH ca. 4) at room temperature.

and that it is proportional to the Ru content of the film (from 10 to 100 at.% Ru).

3.2 Effect of Ru content of the oxide films on chlorine evolution Tafel plots

The *i/E* relationship of the chlorine evolution reaction was established after electrolysis had been carried out for a relatively long period of time, such that the solution could be considered to have equilibrated in terms of dissolved chlorine and hypochlorite, at both temperatures studied. In these experiments, the potential was scanned at 1 mV/s from the OCP (1.05 V) to a maximum current of ca. 800 mA cm^2 (potentiostat oscillations occurred during IR compensation at currents higher than this) and then back to the OCP. Figure 5 shows a typical set of Tafel data for the chlorine evolution reaction at freshly formed, 2 μm thick, Ru–Ti oxide films of varying Ru contents at room temperature. Both the Tafel slope and the exchange current density of the reaction are clearly affected by the oxide composition, with the most notable difference being observed for the 5 at.% Ru film. These results are in agreement with those reported earlier (8, 16) for thermally formed Ru–Ti oxide films.

The effect of the Ru content on the Tafel slopes is shown more clearly in Fig. 2 (closed symbols). It is seen that, at room temperature, the Tafel slope increases for oxide films containing less than 25 at.% Ru, while, at 90°C, an effect on the slope is seen only when the Ru content is less than 10 at.%. At high Ru contents, the Tafel slope is in the range of 30–40 mV, while, at low contents, a higher ca. 120 mV slope is seen, in agreement with prior literature reports (8, 16).

Figure 6 shows the exchange current density for the chlo-

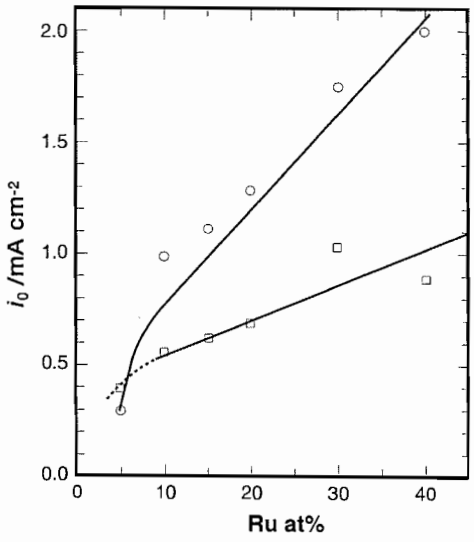
Fig. 6. Effect of at.% Ru in Ru–Ti oxide films of 2 μm thickness on exchange current density of chlorine evolution reaction in 5 mol/L NaCl (pH ca. 4) at room temperature (circles) and at 90°C (squares).



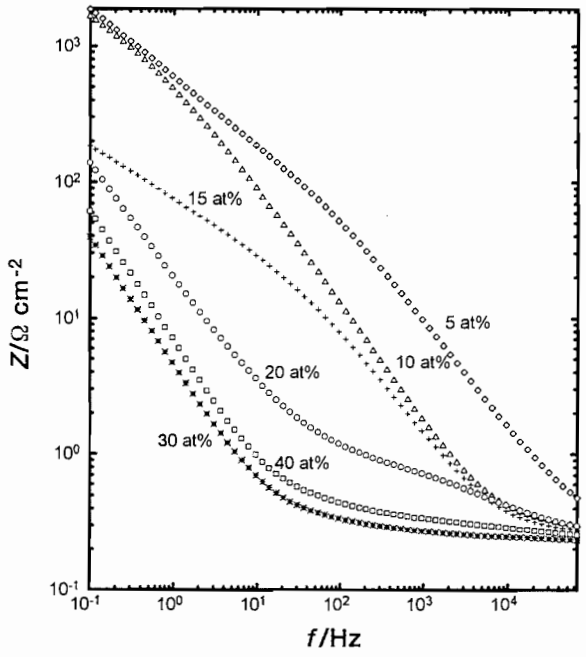


Fig. 7. Frequency dependence of total impedance of Ru–Ti oxide electrodes with different Ru contents in 5 mol/L NaCl (chlorine-free) at room temperature at the OCP.

rine evolution reaction as a function of oxide composition. At both temperatures, the relationship between the exchange current density and the Ru content of the oxide film is linear down to ca. 10 at.% Ru. For the 5 at.% Ru films, the exchange currents are clearly very much reduced. Figure 6 also shows that the exchange current densities at 90°C are lower than the corresponding values at room temperature. This presumably reflects a difference in the nature of the adsorbed surface species participating in the rate-determining step at these two temperatures.

It is widely accepted that the Tafel slope for the chlorine evolution reaction should be ca. 40 mV (1, 2), indicative of a slow desorption step. The 30 mV slope seen in Fig. 2 for high Ru contents may indicate the slow diffusion of the product away from the electrode surface, such that it becomes super-

For personal use only.

saturated with adsorbed chlorine, or that a rapid discharge reaction is followed by a slow recombination step (2). To explain the increasing Tafel slope with decreasing Ru content, several possibilities can be considered. First, as the Ru site density decreases with lower Ru content, the probability of interaction of a chloride ion with an adsorbed chlorine atom intermediate (expected to yield a 40 mV Tafel slope) is likely to decrease, and therefore the mechanism may change to one in which the discharge reaction is slow (120 mV Tafel slope). The Tafel slopes of between 40 and 120 mV at intermediate Ru contents might then reflect the fact that both of these mechanisms are occurring simultaneously on the surface for films of between 10 and 25 at.% Ru. A second option to explain the data of Fig. 2 is that, at high Ru surface site densities (>25 at.% Ru), the surface coverage of adsorbed chlorine atoms is close to zero, which would yield the expected Tafel slope of ca. 40 mV for this reaction. However, at lower Ru contents, as the reaction rate decreases, it is possible that the surface coverage by adsorbed chlorine atoms increases to unity, which would be consistent with a 120 mV slope. A still more likely possibility is that the experimental Tafel slope reflects not only the mechanism of the chlorine evolution reaction, but also the resistance of the oxide film substrate (27, 28). This would then suggest that the trends in the Tafel slope should be paralleled by similar trends in the oxide resistance. This will be discussed below, based on the impedance results shown.

The exchange current density would be expected to vary linearly with the Ru surface site density, which should be proportional to the Ru content of the film, consistent with what is seen in Fig. 6 down to 10 at.% Ru. The lower value for the 5 at.% film suggests that either some of the Ru sites are no longer accessible or that the oxide surface does not reflect the bulk oxide composition and is behaving anomalously, i.e., more like a poorly conducting Ti oxide film.

3.3 Effect of oxide film Ru content on the ac impedance response

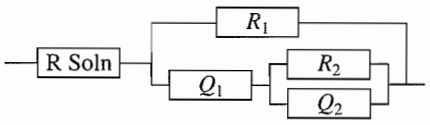
All of the ac impedance data were collected at room temperature in a 5 mol/L NaCl solution. Solution stirring and deaeration were found not to affect the ac response and therefore no attempts were made to remove oxygen or agitate the solution. Most previous ac impedance studies of this system have been carried out in chlorine-saturated solutions near the chlorine–chloride equilibrium potential (29–32), i.e., at ca. 1.05 V vs. SCE. As the emphasis in the present study has been on examining the oxide film properties in the absence of the chlorine evolution reaction, the ac impedance data were gathered primarily at the OCP of the mixed oxide electrodes in solutions containing no dissolved chlorine, i.e., near 0.4 V vs. SCE.

Figures 7 and 8 show the total impedance and phase angle Bode representations for oxide films ranging between 5 and 40 at.% Ru at the oxide OCP in chlorine-free solutions. It is seen that the 20–40 at.% Ru oxides are generally quite similar in their response, and that the biggest change occurs at 15 at.% Ru and lower. This pattern is consistent with the CV data of Fig. 1 and the Tafel slope data in Fig. 2, showing the impact of the oxide properties on the chlorine evolution reaction. The impedance at low frequencies indicates that the resistance of the oxide film is particularly high for the 5–10 at.% Ru films, with the 15 and 20% films exhibiting intermediate resistances, in agreement with prior published results (7). At high frequencies, a resistance value of ca. 6 Ω, corresponding to the solution resistance, is seen in all cases.

The phase angle data in Fig. 8 is particularly interesting in terms of revealing the changing electrical properties of these films with Ru content. Again, the transition in properties is most notable at 15–20 at.% Ru. With decreasing Ru content, it is seen that a second time constant appears at high frequencies, with its phase angle maximum increasing in magnitude and moving to lower frequencies from 20 to 10 at.% Ru in the coating. Interestingly, for the 5 at.% Ru containing Ru–Ti oxide film, the phase angle maximum decreases somewhat, and moves back to higher frequencies, perhaps indicating that the 5% Ru film is significantly different from the others and behaves more like a conventional capacitive oxide material, with the large fraction of TiO_2 likely serving as its ohmic component.

The analogous set of experiments were carried out with these oxide films in a chlorine-saturated solution at 1.05 V. The phase angle data, in particular, displayed several important trends (not shown in a figure) in common with those at the oxide OCP in Fig. 8, namely, that, with decreasing Ru content, a new high-frequency time constant develops, with its phase angle maximum increasing and moving to lower frequencies. The data for the 5 at.% Ru containing Ru–Ti oxide film was again anomalous, in that its high-frequency time constant has moved to higher frequencies.

3.4 Interpretation of impedance data for mixed Ru–Ti oxides



Two approaches were taken in this work to understand and interpret the impedance data, shown in Figures 7 and 8. The first involved identifying the best-fit equivalent circuit (EQC), based on Boukamp's EQUIVCIRC software, in order to establish the values of the circuit elements. The intention of this work was to then correlate their values with the Tafel and CV data as a function of oxide film composition. The usual guidelines for the selection of the best-fit EQC were followed, i.e., that a minimum number of circuit elements be employed; that, as far as possible, the same circuit is used for all film compositions; and that the χ^2 error, as well as the errors associated with each element, is suitably low (33). Many equivalent circuits were examined, but only that shown in Table 1 obeyed these criteria. Also, this circuit fit well to the impedance data obtained at both the OCP in chlorine-free solutions and at 1.05 V in chlorine-saturated media.

Figure 9 depicts the overlay of the experimental (at the OCP in chlorine-free solutions) and the calulated Bode data, using the EQC shown in Table 1, for the 10 and 40 at.% Ru oxide films, respectively, and shows a high quality of fit over the entire frequency range. The fit for the 5 at.% Ru oxide film was somewhat less satisfactory, again indicating that the properties of this film are quite different from those of the other films, consistent with the apparently anomalous positive shift of the second high-frequency time constant (Fig. 8).

Table 1 gives the values of the circuit elements for the six oxide films at the OCP, based on this EQC. It should be noted that the solution resistance, R_{soln}, was ca. 6 Ω in all of this work, in agreement with the expected electrolyte resistance between the oxide electrode surface and the SCE. R_1, the parallel resistance, lies between ca. 10^3 and 10^4 Ω cm^{-2} in all cases. R_1 is likely to represent the dc leakage current arising

from faradaic reactions involving trace impurities in solution (e.g., the reduction of trace oxygen), which occurs at the OCP (32). As R_1 does not appear to depend on the oxide film properties, its impact on the observations is ignored in the present discussion.

Q_1 and Q_2 represent constant phase elements (CPEs), with n_1 and n_2 reflecting how similar these elements are to a pure capacitor, for which $n = 1$. Notably, both Q_1 and Q_2 increase with the Ru content in the film, with Q_1 likely reflecting the oxide pseudocapacitance and, hence, the number of active Ru sites at the oxide–solution interface. In fact, a rough comparison between these Q_1 values (without converting them to capacitance values through their n values) and the oxide capacitance, estimated from the CV responses in Fig. 1 (current divided by sweep rate), yield very similar pseudocapacitances, confirming this suggestion. The fact that the n_1 values are so close to unity for the 30 and 40 at.% Ru oxide films indicates the formation of nearly perfectly capacitive films, whereas the decreasing n_1 values with decreasing Ru content show the development of nonideality in the capacitive characteristics, probably due to decreasing matrix conductivity (34).

The R_2 values also show an interesting trend with increasing Ru content of the film, decreasing from ca. 10^2 to ca. 0.5 Ω cm^{-2}, consistent with the expected change in film conductivity. The Q_2 value also increases with increasing Ru content. For the 30 and 40 at.% Ru films, the best-fit Q_2 values were unreasonably high, up to 1 F cm^{-2} (larger than any possible capacitance in the system). However, as their n values were very low, less than 0.2, this indicates that the second CPE is not a valid part of the EQC, and that Q_2 should be replaced by a resistor (33).

Overall, it should be stated that, while the data could be best accounted for by the equivalent circuit shown in Table 1, the circuit itself cannot be said to have any absolute physical meaning. However, it is interesting that, even when the data were fit (although with higher error) to several other equivalent circuits containing the same or almost the same number of elements, the Q and R values were very similar to the R_2 and Q_1 values in Table 1. This strongly suggests that these values do, in fact, accurately reflect the electrical characteristics of these oxide films and were therefore used in the treatment below.

The second approach used in the present work to understand and interpret the impedance response of these Ru–Ti oxide films follows an earlier mechanistic description (35) employed to explain the response of Ru oxide based capacitors to small signal ac perturbations. Attempts were made here to verify this mechanistic approach by comparing the calculated impedance data (specifically the phase angle Bode plots) with those obtained experimentally. The equivalent circuit for a simple one-electron, activation-controlled surface redox process occurring on a planar Ru–Ti oxide surface at the OCP (reaction [1]),

[1] $Ru^{4+} + e^- <==> Ru^{3+}$

was shown (33) to be represented by the circuit in Fig. 10*a*. The double layer capacitance (C_d) is located in parallel with the charge transfer resistance (R_t) and the film pseudocapacitance (C_ϕ), which are in series with each other.

The impedance of the same reaction [1], but occurring in a porous matrix structure, was shown (35) to be represented by the following relationship:

$$[2] \quad Z(p) = \frac{1}{\sigma' S}\left(\frac{\coth(ml)}{m}\right)$$

where

$$[3] \quad \sigma' = \frac{\sigma A}{S}$$

and

$$[4] \quad m = \sqrt{\frac{1}{\sigma'}\left(pC_d + \frac{pC_\phi}{(pC_\phi R + 1)}\right)}$$

$Z(p)$ refers to the generalized impedance, p to the Laplace transform variable in the Heaviside notation, σ to the specific conductance of the solution phase (Ω^{-1} cm^{-1}), A to the cross-sectional area (cm^2), l to the pore length, R to the sum of the charge transfer and film matrix resistance, and S to the surface

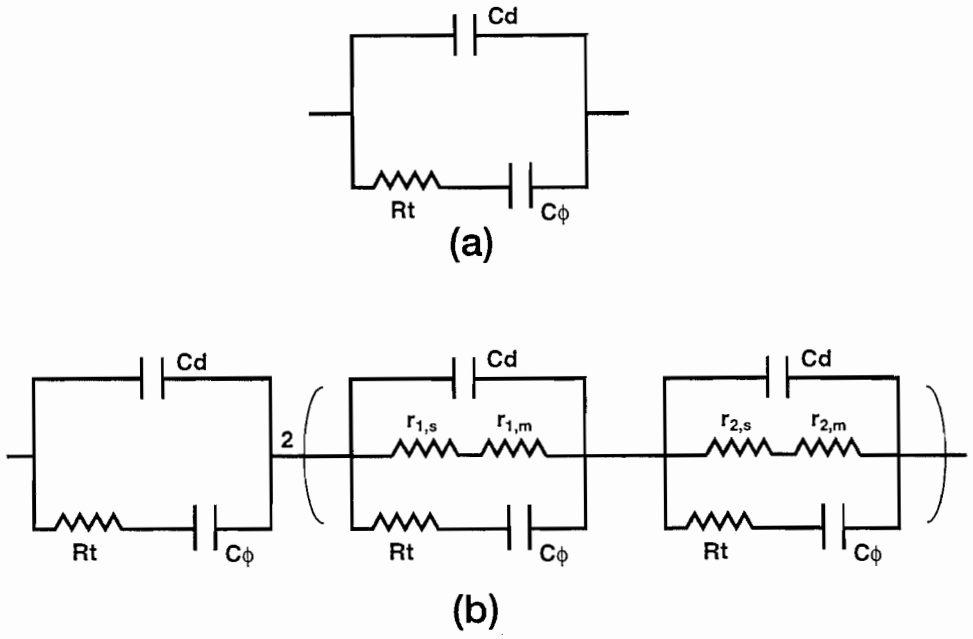
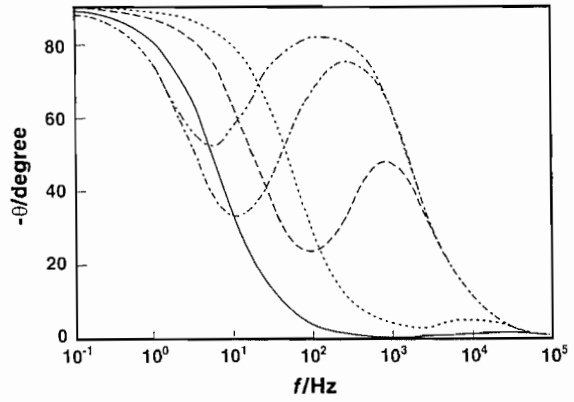
Fig. 10. Theoretical equivalent circuit for an activation-controlled surface redox reaction reaction [1]) occurring (*a*) at a planar surface; (*b*) at a porous electrode.





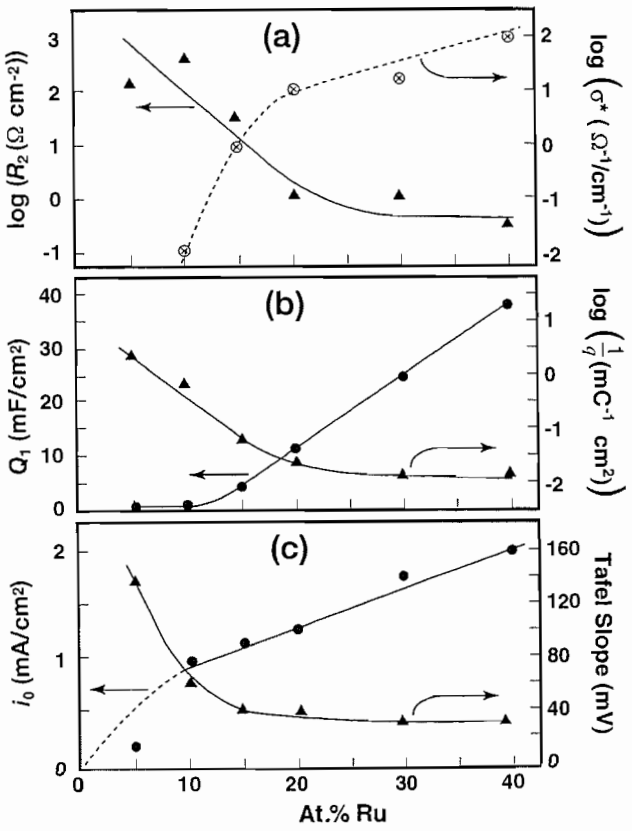


Fig. 11. Phase angle vs. frequency plots, calculated using eq. [2]. C_ϕ = 30 mF, R = 0.3 Ω (————). C_ϕ = 3 mF; R = 1 Ω (.....). C_ϕ = 1.5 mF; R = 30 Ω (– – – – – –). C_ϕ = 1 mF; R = 300 Ω (-·-·-·-·-·-). C_ϕ = 0.3 mF; R = 1300 Ω (-·-·-·-·-·-·-).

area of the porous matrix per unit film thickness. The capacitances and resistances are both defined per unit surface area; the solution resistance in the pores of the film is accounted for in the calculation of σ.

The equivalent circuit derived from eq. [2] is shown in Fig. 10*b*. The outer surface of the oxide film is represented by the same circuit as shown in Fig. 10*a* for a planar electrode, while charge transport in the pores of the film matrix yields the transmission line component, with only two units (of a possible n units) of the transmission line shown in parentheses in Fig. 10*b*. The resistance of the oxide matrix, r_m, has been added in the present treatment, and appears (36) in series with the pore solution resistance, r_s, in Fig. 10*b*. The separation of R_t, r_m, and r_s is difficult, if not impossible, as these elements are lumped together with the capacitors (37), constituting the overall system resistance.

Phase angle calculations were performed by inserting the R_t (same as R_2 in Table 1), and C_ϕ (same as Q_1 in Table 1) values, obtained at the OCP (in chlorine-free solutions) from the best-fit EQC method, into eq. [2]. R_s was taken to be 5 Ω and C_d was set at 100 μF cm^{-2}, which appears reasonable, based on the discussion presented in ref. 1. The calculated results shown in Fig. 11 reveal the essential features of the experimental phase angle Bode plots in Fig. 8. It is seen that, as the sum of the charge transfer resistance and the oxide matrix resistance increases, a peak develops in the high-frequency region of the Bode plot, moving to lower frequencies as the at.% Ru in the coating decreases. The peculiar experimental result for the 5 at.% Ru films in Fig. 8 could not be obtained by this calculation, perhaps as a result of the very high resistivity of this film and the likely existence of a TiO_2 dielectric capacitance in this case.

It is notable that this mechanistic derivation of the impedance, based on the assumption of the activation-controlled reaction of surface Ru sites occurring throughout a porous matrix, and employing the R and C values obtained from the EQC fitting procedure, leads to a very similar phase angle response as seen experimentally (except for the 5 at.% film). This lends support to the validity of the heuristic EQC approach, the suggested mechanism of the reaction, as well as the porous character of these films. This also confirms the data in Table 1, showing the development of matrix resistivity and a loss in pseudocapacitance with decreasing Ru content of the film. The most significant increase in the resistivity occurs below about 20 at.% Ru, in agreement with the conductivity data published in the literature (4, 7, 9, 34).

Figure 12 correlates the kinetic results obtained here for the chlorine evolution reaction and the impedance data at the oxide OCP, obtained from EQC fitting. It is interesting to note that, while the exchange current density for the chlorine evolution reaction shows a linear dependence on the Ru content (Fig. 12*c*) for films of more than 5 at.% Ru, this behavior is not revealed in either the Tafel slope variations (Fig. 12*c*) or in the Q_1 and R_2 parameters deduced from the EQC in Table 1 (Figs. 12*a* and 12*b*). This is to be anticipated, as the magnitude of Tafel slope and the impedance of the system are both a function of the mechanism of the reactions involved at the OCP or during the course of the chlorine evolution reaction, the mechanism being controlled not only by the number of active Ru sites in the film, but also dictated by the matrix resistivity. It should also be noted that the variations in R_2, Q_1, and $1/q$ change significantly in the range of 10–20 at.% Ru, similar to the change in the Ru–Ti oxide conductivity (σ'), determined independently (4, 7, 9, 34).

The results presented in this investigation show clearly that the signature of the developing matrix resistance with decreasing Ru content of the oxide film is revealed more dominantly in the phase angle Bode plots than in either the Tafel slopes or the overall impedance plots, although the latter parameters are also affected by the coating resistance. It will be shown in a forthcoming communication that, in practice, the performance characteristics of electrodes that have become electrochemically inactive after long times of electrolysis closely resemble those of freshly formed oxides of low Ru content. This implies that anode deactivation results from the selective loss of Ru from the oxide film with time of chlorine evolution and hence a markedly increased increase in resistance, as well as a loss in active surface sites.

A non-enzymatic synthesis of (*S*)-(−)-rosmarinic acid and a study of a biomimetic route to (+)-rabdosiin

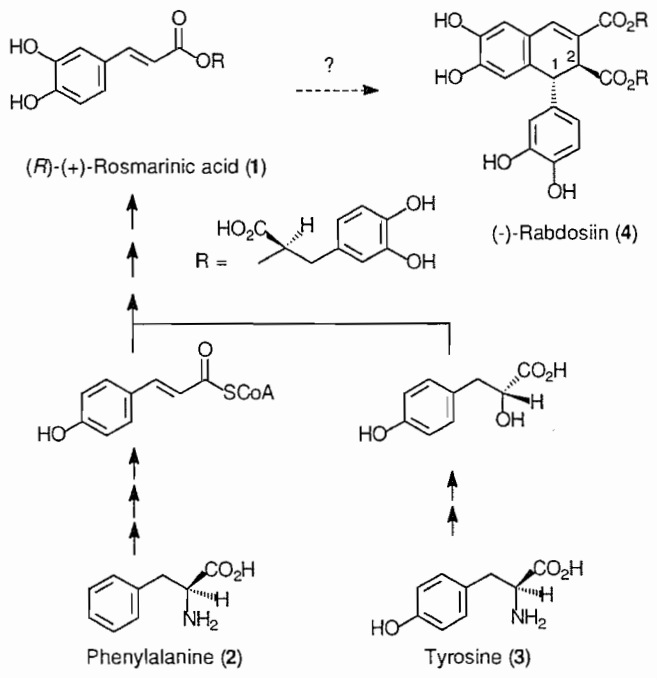
David E. Bogucki and James L. Charlton

Abstract: The synthesis of (*S*)-(−)-rosmarinic acid (**30**) in 9% overall yield is described. The synthesis was achieved by a convergent route in which 3-(3′,4′-dihydroxyphenyl)-(*S*)-lactic acid (**23**) and caffeic acid (**25**), both appropriately protected, were coupled to produce a pentaallyl precursor **29**, which was then deprotected to give (*S*)-(−)-rosmarinic acid (**30**). A triallyl derivative **35** was similarly prepared and converted to (+)-rabdosiin (**41**) and its (1*R*,2*S*) isomer (**42**) via a biomimetic oxidative free radical coupling–cyclization followed by deallylation. The coupling–cyclization gave a ratio of rabdosiin diastereomers unlike that found in nature. A preliminary study showed that methyl (*R*)-mandelyl sinapate (**15**) could be dimerized diastereoselectively to give a 1,2-*trans* thomasidioate diester (**16**).

Key words: rabdosiin, rosmarinic acid, lignan, oxidative coupling.

Résumé : On décrit la synthèse de l'acide (*S*)-(−)-rosmarinique (**30**) avec un rendement global de 9%. On a réalisé la synthèse par le biais d'une route convergente dans laquelle on procède au couplage des acides 3-(3′,4′-dihydroxyphényl)-(*S*)-lactique (**23**) et caféique (**25**) adéquatement protégés pour conduire à un précurseur pentaallylique (**29**) qui, par déprotection, fournit l'acide (*S*)-(−)-rosmarinique (**30**). Procédant de la même manière, on a aussi préparé un dérivé triallylique (**35**) qui a été transformé en (+)-rabdosiin, (**41**) et en son isomère 1*R*,2*S* (**42**) par le biais d'une cyclisation biomimétique par couplage radicalaire oxydant, suivie d'une déallylation. La cyclisation par couplage conduit à un mélange de diastéréomères de la rabdosiine différent de celui observé dans la nature. Une étude préliminaire a permis de montrer que le (*R*)-mandélyl sinapate de méthyle (**15**) peut être soumis à une dimérisation diastéréosélective qui conduit au diester **16** de l'acide 1,2-*trans*-thomasidioïque.

Mots clés : rabdosiine, acide rosmarinique, lignane, couplage oxydant.



[Traduit par la rédaction]

Introduction

(*R*)-(+)-Rosmarinic acid (**1**) (Scheme 1) is a caffeic acid dimer whose structure was first elucidated by Scarpati and Oriente (1) almost 40 years ago. It has been the subject of many studies due to its anti-inflammatory properties and its association with phytotherapies (2–10). It is a major constituent of the Chinese medicinal herb Danshen, which has been used for the treatment of heart disease (11). Its other biological activities include antioxidative (8, 12–15), antihistamine (16), antibacterial (2, 17, 18), antiviral (19), and antihormonal (20) effects. Rosmarinic acid was originally isolated from extracts of *Rosmarinus officinalis* (1), but it can be found throughout the plant kingdom in such families as Lamiaceae, Boraginaceae, and Apiaceae (13).

The biosynthetic pathway for rosmarinic acid production has been determined from investigations of *Coleus blumei* and *Anchusa officinalis* plant cell suspension cultures (21–25, 26).

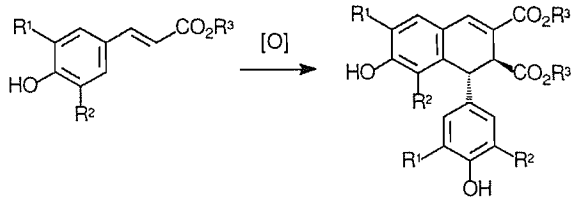
Scheme 2.



RAS = rosmarinic acid synthase

(*S*)-Phenylalanine (**2**) and (*S*)-tyrosine (**3**) (Scheme 1) were first established as precursors to (*R*)-rosmarinic acid in 1970 by introducing radioactively labeled amino acids to plants of *Mentha* (27). With the subsequent discovery that cell cultures of *Coleus blumei* (21, 22) and *Anchusa officinalis* (23) generated large amounts of rosmarinic acid, these cell cultures became the focus of research. In 1977, the *Coleus blumei* cell cultures were used to confirm the biosynthetic precursors **2** and **3** and to determine that phenylalanine ammonia-lyase was one of the enzymes involved in the biosynthesis (21). The other enzymes of the biosynthetic pathway were unknown until 10 years later when tyrosine aminotransferase activity was implicated (24, 25). Determination of the remaining enzymes soon followed.[2] This led to a chemo-enzymatic synthesis of (*R*)-rosmarinic acid (**1**) (9) (see Scheme 2) and the proposal of a total biosynthetic pathway (26) (see Scheme 1). However, no non-enzymatic route to this compound has been published, and no one has investigated the possibility that it may be involved in the biosynthesis of (−)-rabdosiin (**4**).

(−)-Rabdosiin (**4**) (Scheme 1), a caffeic acid tetramer, was first isolated in 1988 by Agata et al. (28, 29) from the stems of *Rabdosia japonica* (Labiatae) and it has since been isolated from *Arnebia euchroma* (Boraginaceae), also known as *Macrotomia euchroma* (30, 31). It is a constituent of a household medicine (enmeiso) that has been used in Japan for treating gastrointestinal disorders (28). It is a constituent in anti-inflammatory, antipyretic, and antibacterial medicines that have been used in China (31). A recent study showed that (−)-rabdosiin, its (1*S*,2*R*) diastereomer, and particularly the monopotassium and monosodium salts thereof, have potent anti-HIV activity (31). Like some other aryltetralin lignan analogs, (−)-rabdosiin was also found to be a strong inhibitor of DNA topoisomerase I and II (32). Considering that rabdosiin is formally a dimer of rosmarinic acid, it seems possible that it is biosynthesized by the diastereoselective oxidative coupling of two molecules of (*R*)-(+)-rosmarinic acid (Scheme 1).

Although no one has investigated the possibility that the aryltetralin lignan rabdosiin can be formed by oxidative coupling and cyclization of rosmarinic acid, oxidative coupling studies have been carried out on other hydroxycinnamic acid

Scheme 3.

5 R^1 = OH, R^2 = H, R^3 = CH_3 **6** R^1 = OH, R^2 = H, R^3 = CH_3
7 R^1 = OH, R^2, R^3 = H **8** R^1 = OH, R^2, R^3 = H
9 R^1, R^2 = OCH_3, R^3 = CH_3 **10** R^1, R^2 = OCH_3, R^3 = CH_3

esters similar to rosmarinic acid. For instance, methyl caffeate (**5**) is converted to aryltetralin **6** on oxidation with ferric chloride (29) and even caffeic acid (**7**) itself forms the corresponding diacid **8** on treatment with oxygen in aqueous base (Scheme 3) (33). Methyl sinapate (**9**) also yields dimethyl thomasidioate (**10**) on oxidation with ferric chloride (34), or with horseradish peroxidase and hydrogen peroxide (Scheme 3) (35). Based on these precedents, it seemed at least possible that rabdosiin could be prepared from rosmarinic acid by oxidative coupling–cyclization.

Natural rabdosiin has been isolated in both a (−)-(1*R*,2*S*), **4**, and a (+)-(1*S*,2*R*) form although the 3-(3′,4′-dihydroxyphenyl)lactyl ester groups are *R* in both compounds. Rabdosiin is probably synthesized in the plant by an enzyme-catalyzed process that produces one of the two forms of rabdosiin preferentially. While a non-biosynthetic formation of rabdosiin from rosmarinic acid might not proceed with the same stereoselectivity, there was at least the possibility that the chiral lactyl groups could influence the oxidation–cyclization such that rabdosiin would be produced diastereoselectively.

As a prelude to the preparation of rabdosiin, we sought a practical route to both the (*R*) and (*S*) enantiomers of rosmarinic acid. In this paper, we report the first non-enzymatic preparation of the (*S*) enantiomer of rosmarinic acid (**30**) from (*S*)-tyrosine (**19**) and caffeic acid (**25**). The procedure should be equally valid for the preparation of (*R*)-rosmarinic acid from (*R*)-tyrosine.

Before attempting to oxidatively couple and cyclize rosmarinic acid to rabdosiin, a model study was performed. Sinapic acid, esterified by the chiral and bulky methyl (*R*)-mandelyl group, was chosen for the model study. This compound has an ester portion that is similar to that found in rosmarinic acid, and an acid residue that is known to readily cyclize to the desired aryltetralin on oxidative coupling. The model study was undertaken primarily to determine the effect of the bulkier ester group on cyclization (methyl sinapate was already known to cyclize readily) and to look for asymmetric induction.

Finally, attempts were made to oxidatively couple and cyclize (−)-rosmarinic acid itself to rabdosiin. While unsuccessful, the conversion of a protected form of (−)-rosmarinic acid (**35**) was accomplished. Interestingly, both (+)-rabdosiin (1*S*,2*R*) and (−)-rabdosiin (1*R*,2*S*) were formed with the (−) isomer being predominant.

Results and discussion

In preparation for the model oxidative coupling reaction (see above) the (methyl (*R*)-mandelyl) ester of sinapic acid, **15**,

[2] Petersen et al. (ref. 26) have cited the relevant literature regarding the enzymes involved in rosmarinic acid biosynthesis.

Table 1. Solvent and temperature effects on the oxidative coupling of mandelyl sinapate.

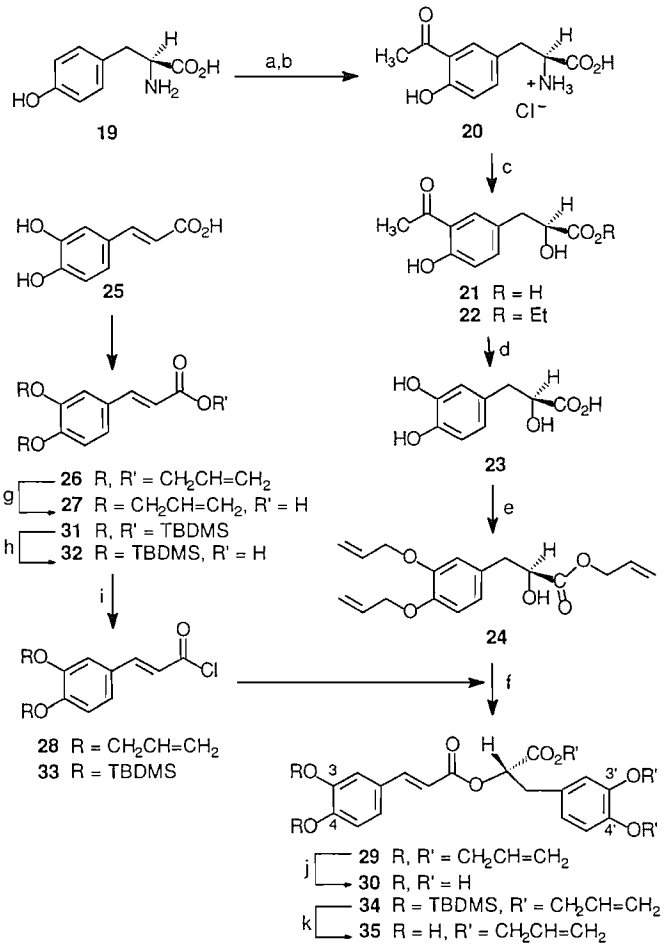
Reaction conditions			Product ratio from ^{1}H NMR		
Solvent	Temperature	Time	Major 1,2-*trans* isomer	Minor 1,2-*trans* isomer	Starting material
THF–H_2O	25°C	20 h	1.6	1.2	1.0
AcOH-H_2O	25°C	10 min	1.9	1.0	1.6
i-PrOH–H_2O	25°C	1 h	5.6	3.5	1.0
CH_3CN–H_2O	25°C	30 min	7.3	3.8	1.0
Acetone–H_2O	25°C	30 min	12.1	6.0	1.0
Acetone–H_2O	2°C	20 h	7.9	4.8	1.0

Scheme 4.

a: K_2CO_3, $CH_2=CHCH_2Br$; b: KOH, MeOH-H_2O; c: $SOCl_2$; d: methyl (*R*)-mandelate; e: $(Ph_3P)_3RhCl$; f: $FeCl_3$; g: *p*-TsOH

was prepared by the coupling of methyl (*R*)-mandelate with 4-*O*-allylsinapic acid (**13**) (Scheme 4). Direct coupling to sinapic acid was not possible due to interference from the phenolic hydroxyl group. Sinapic acid (**11**) was treated with allyl bromide in the presence of anhydrous base to give allyl 4-*O*-allylsinapate (**12**) (36). The allyl ester group was removed by hydrolysis to give 4-*O*-allylsinapic acid (**13**) in 98% crude yield from **11**. Acid **13** was transformed to the acid chloride with thionyl chloride and subsequently reacted with methyl (*R*)-mandelate to produce ester **14** in 79% yield. The deprotected sinapate ester **15** was obtained in 98% yield by the deallylation of **14** with tris(triphenylphosphine)rhodium(I) chloride (37, 38).

The mandelyl sinapate ester **15** was oxidized and cyclized using a method similar to that used by Wallis (34) for methyl sinapate (**9**). Treatment of **15** with ferric chloride in acetone–water (2:1) followed by dehydration gave a crude product that appeared by ^{1}H NMR to be a mixture of two isomers of the desired lignan in a 2:1 ratio. Very little starting material remained. The time for complete reaction was similar to that for methyl sinapate (34), suggesting that the bulky mandelyl group had not significantly hindered the reaction. The crude product was chromatographed on a preparative HPLC reverse-phase column using 53:47 MeOH–H_2O as the eluant. Three aryltetralin lignans were isolated in a 8.1:4.0:1.0 ratio. The ^{1}H NMR spectra of the two major compounds showed that each had an H-2 doublet with a coupling constant of 1.2 Hz ($J_{1,2}$). Based on these coupling constants, these dimers, **16** and **17**, were assigned the 1,2-*trans* stereochemistry (Scheme 4). The coupling constant of 8.8 Hz ($J_{1,2}$) exhibited by the minor isomer (**18**) indicated it had the 1,2-*cis* geometry. The absolute configurations at C-1 and C-2 for compounds **16–18** were not determined.



The 53% yield of the major diastereomer was impressive but attempts were made to try to improve the diastereoselectivity by changing the reaction medium. The results of the study are displayed in Table 1. The general procedure for the study was to add 2.2 equiv. of ferric chloride in water to ester **15** in organic solvent (2:1 organic solvent – H_2O) at room temperature, dehydrate the product with a catalytic amount of acid, and analyze the product mixture by ^{1}H NMR spectroscopy. Aqueous acetone solvent gave the best diastereoselectivity for the major 1,2-*trans* isomer relative to the minor *trans* isomer and resulted in the least unreacted starting material. Most of the solvents used resulted in similar diastereoselectivity except for THF, in which the reaction was very slow and unselective. Performing the reaction at a lower temperature also resulted in decreased diastereoselectivity. The successful oxidative cyclization of the model compound led us to believe that rosmarinic acid could be dimerized to rabdosiin in a similar manner.

In considering the retrosynthesis of rosmarinic acid, the disconnection of the caffeic acid ester bond was an obvious first step. This disconnection gave 3-(3′,4′-dihydroxyphenyl)lactic acid (**23**) and caffeic acid (**25**) (Scheme 5) as synthetic intermediates. A synthetic route with these compounds as intermediates was pursued since it provided an efficient convergent synthesis not unlike the one that occurs in nature (Scheme 1). The problem of establishing the chiral center was overcome at the beginning of the synthesis by making use of enantiomerically pure (*S*)-tyrosine (**19**) as the starting material for the synthesis of 3-(3′,4′-dihydroxyphenyl)-(*S*)-lactic acid (**23**).

The complete synthesis of (*S*)-rosmarinic acid is depicted in Scheme 5. (*S*)-Tyrosine (**19**) was acylated using a Friedel–Crafts reaction, as described by Boger and Yohannes (39), providing the hydrogen chloride salt of acetyl-(*S*)-tyrosine (**20**). Amino acid **20** was transformed into hydroxy acid **23** by using the two-step procedure described by Wunsch and Zott (40). Diazotization of **20** followed by in situ hydrolysis led to

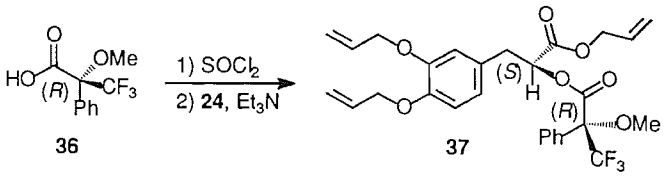


Scheme 5.

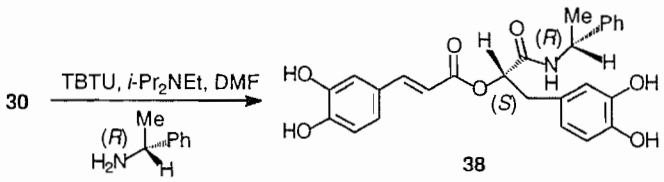
a: AcCl, $AlCl_3$; b: HCl; c: $NaNO_2$, H_2O; d: H_2O_2, NaOH, H_2O; e: K_2CO_3, CH_2 = $CHCH_2Br$; f: Et_3N; g: KOH, MeOH-H_2O; h: K_2CO_3, MeOH-H_2O; i: $SOCl_2$; j: $(Ph_3P)_3RhCl$; k: *n*-Bu_4NF

α-hydroxy acid **21** (81% yield) with retention of configuration. The enantiomeric purity of **21** was tentatively verified by converting it to the known ester **22**. The specific rotation, measured at the sodium D line was comparable to that which could be extrapolated from literature values measured at two other wavelengths (see experimental) (40). Aryllactic acid **21** was then subjected to Baeyer–Villiger oxidation. The resulting base-sensitive phenolic acetate was not isolated but was directly hydrolyzed to **23** (61% yield) in the alkaline environment. The moderate yield could be attributed to the loss of the highly polar polyhydroxy acid during chromatographic purification (it should be noted that the (*R*) form of 3-(3′,4′-dihydroxyphenyl)lactic acid (**23**), also known as danshensu, has a wide range of pharmacological activities and is found in traditional Chinese medicine (41, 42)). The phenolic and carboxylic hydroxyl groups of **23** were protected by allyl groups by treating it with allyl bromide (36) and potassium carbonate to give **24**. Only the α-hydroxyl group, needed in the subsequent coupling reaction, was left unprotected. The moderate yield of **24** (42%) was unexpected since TLC and ^1H NMR analysis of

Scheme 6.

the crude product was indicative of a complete reaction. It appeared that some product was lost during chromatography. The overall yield of **24** from tyrosine was improved from 15% to 30% by not chromatographing intermediates **21** and **23**.

Caffeic acid (**25**) was allylated to provide ester **26** in good yield (86%). Hydrolysis of **26** gave the diallyl ether of caffeic acid (**27**) in 83% yield. The coupling of **24** and **27** was accomplished by preparing the acid chloride of **27** (**28**) and reacting it with alcohol **24** in the presence of triethylamine. Fully allylated rosmarinic acid (**29**) was obtained in 65% yield. The overall yield of **29**, like that of alcohol **24**, was increased from 9% to 29% by omitting all of the intermediate chromatographic steps. **29** was deprotected by isomerizing and hydrolyzing the allyl groups in one step using Wilkinson's catalyst (37, 38) in an aqueous medium. Chromatographically pure (*S*)-rosmarinic acid (**30**) was obtained from **29** in 29% yield and in 3% overall yield (9% overall yield when chromatography was not performed prior to the isolation of **29**). However, the crude rosmarinic acid, isolated in the final step by base extraction, would probably be sufficiently pure for most purposes, and the loss of material that occurred during chromatography on silica gel could be avoided.



Although all of the spectral data were consistent with the structure of rosmarinic acid, it was disturbing to observe that the magnitude of the specific rotation of our sample ($[\alpha]_D^{25}$ = −86, *c* 0.53, 95% EtOH) was noticeably different than that reported for the natural product ($[\alpha]_D^{25}$ = +145, *c* 1.4, 95% EtOH) (1), indicative of only 59% ee for the synthetic material. To verify the enantiomeric purity of the synthetic rosmarinic acid, various stages of the synthesis were investigated for possible isomerization. Derivatization of the (*S*)-tyrosine starting material and analysis by GC on a chiral column revealed that it was greater than 99% enantiomerically pure. As mentioned above, the enantiomeric purity of **21** was confirmed from the optical rotation of **22**. To verify the optical purity of alcohol **24**, it was reacted with (*R*)-Mosher's acid chloride (43, 44) (Scheme 6), prepared from Mosher's acid (**36**) (43, 44), to give diester **37**. Only a single diastereomer could be detected in the crude ^1H and ^{19}F NMR spectra, indicating that **24** had an enantiomeric purity of at least 84% (this value was calculated from the integrated ratio of the ^{19}F NMR singlet to the largest of the remaining ^{19}F NMR signals). Attempts to isomerize **37** with strong base failed, giving back recovered starting material.[3] The fact that crude **37** could not be isomerized indicated that it was also unlikely that **23** could have been isomerized during allylation.

[3] Crude diester **37** in THF was treated with a 1.0 M solution of lithium bis(trimethylsilyl)amide in hexanes (5 equiv.) under nitrogen at −55°C, stirred for 10 min, and worked up with 10% HCl.

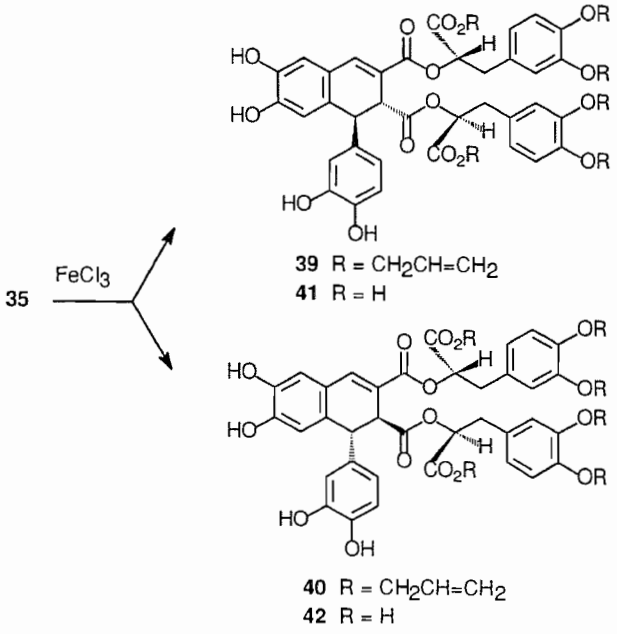
Scheme 7.



Finally, the enantiomeric purity of rosmarinic acid was tested. Although diastereomeric salts, prepared from rosmarinic acid and racemic α-methylbenzylamine, could not be distinguished by ^{1}H NMR,[4] the corresponding diastereomeric amides were easily distinguishable. Thus, **30** was converted to amide **38** (Scheme 7) with (*R*)-α-methylbenzylamine and TBTU (*O*-benzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate) (45). The ^{1}H NMR spectra of crude amide **38** in both deuterated acetone and deuterated DMSO exhibited only very minor peaks that could possibly be attributed to the (*R*,*R*) diastereomer. This indicated that the synthetic rosmarinic acid was at least 90% *S*. The discrepancy between the specific rotation of the synthetic material and the rotation reported for the natural material remains unexplained.

Efforts to cyclize (*S*)-rosmarinic acid with ferric chloride failed, as no aryltetralin lignans could be observed in the ^{1}H NMR spectrum of the crude product. It was believed that the poor reactivity of **30** was due to the coordination of the extraneous phenolic substituents on C-3′ and C-4′ with the oxidant. To overcome this problem, (*S*)-rosmarinic acid was prepared with only the two phenolic groups on C-3 and C-4 unprotected as shown in Scheme 5. Caffeic acid (**25**) was fully silylated to **31** with TBDMS triflate (46) and hydrolyzed to acid **32** in 76% yield. The coupling of **32** with **24** via an acid chloride intermediate (**33**) resulted in the formation of ester **34** in 97% yield, and removal of the silyl protecting groups with fluoride ion (47) gave a 51% yield of triallyl (*S*)-rosmarinic acid (**35**).

Protected rosmarinic acid **35** was treated with ferric chloride on a small scale, and the ^{1}H NMR spectrum of the crude product showed the presence of aryltetralins along with significant starting material. The crude product was chromatographed on a preparative HPLC reverse-phase column using 72:28 MeOH – 0.06% $TFA_{(aq)}$ as the eluant, and two aryltetralin lignans were isolated. According to HPLC analysis, the lignans were produced in a 1.0:1.6 ratio. A comparison of the ^{1}H NMR spectra of both lignans with those reported (28, 30, 31) for (−) rabdosiin and its (1*S*,2*R*) isomer led to the conclusion that these compounds were the allylated enantiomers of these natural lignans. The minor diastereomer was tentatively assigned structure **39** (see Scheme 8) based on the higher chemical shift of its H-1 signal (ca. 4.54 ppm) relative to that of the major diastereomer (4.31 ppm). Consequently, the major diastereomer was assigned structure **40**. The low yield of the reaction may have been the result of steric hindrance from the allyl groups. Methyl caffeate (**5**), a less sterically hindered analog, can be cyclized in higher yield under similar conditions (29). **39** and **40** were deprotected using tributyltin

[4] The diastereomeric salt of **30** was prepared by adding racemic α-methylbenzylamine (1.2 equiv.) in acetone to (*S*)-rosmarinic acid in acetone.

Scheme 8.

hydride and bis(triphenylphosphine)palladium dichloride under acidic conditions (48–51) to give (+)-rabdosiin (**41**) and its (1*R*,2*S*) isomer (**42**), respectively (see Scheme 8). The identities of the crude products were confirmed from the direction of their optical rotations and their ^{1}H NMR data as compared with those of their enantiomers in the literature (28, 30, 31).

The observation that the (1*R*,2*S*) isomer was produced selectively over (+)-rabdosiin was unexpected. Extraction of their enantiomers from natural sources has always led to greater yields of the (1*R*,2*S*) isomer, (−)-rabdosiin (30, 31). This implies that the production of the natural isomers may be diastereoselectively controlled, not only by the chiral aryllactyl groups, but by the oxidizing system as well. It could also mean that the natural isomers are not formed by the oxidative coupling of two rosmarinic acid molecules. Although less likely, perhaps the basic aryltetralin structure is first established by the non-asymmetric dimerization of caffeic acid (**25**), and the aryllactyl moieties are subsequently added selectively to the (1*R*,2*S*) enantiomer.

Conclusion

(*S*)-Rosmarinic acid was synthesized in 9% overall yield, and the synthetic route that has been described has advantages over the previously reported enzymatic procedure. In the enzymatic process, rosmarinic acid synthase (RAS) not only catalyses the formation of rosmarinic acid but also catalyses its hydrolysis (Scheme 2) (9), thereby diminishing its yield. Furthermore, the non-enzymatic synthesis is applicable to both the (*R*) and (*S*) forms of rosmarinic acid.

(Methyl (*R*)-mandelyl) sinapate, synthesized in 76% overall yield, was dimerized to give three thomasidioate diester isomers with the major diastereomer being obtained in a 53% yield. This reaction has shown that a bulky chiral ester group does not hinder the efficient dimerization of a sinapate ester and that it induces diastereoselectivity. Other chiral ester groups are currently being investigated for their ability to

© 1997 NRC Canada

induce stereoselectivity in similar reactions. This type of reaction, especially if the diastereomeric excess could be improved, would be very useful for asymmetrically synthesizing lignans such as thomasidioic acid since the chiral groups can be removed following the cyclization. The mechanism of the free radical coupling process is also being investigated.

Triallylated (*S*)-rosmarinic acid was synthesized (15% overall yield) and oxidatively coupled to give two isomeric intermediates that were subsequently deallylated resulting in the formation of (+)-rabdosiin and its (1*R*,2*S*) diastereomer. The low yield of the cyclization products has shown that this is not an efficient synthetic route for obtaining these caffeic ester tetramers. However, the fact that the observed ratio of the cyclization adducts is not consistent with that of (−)-rabdosiin and the (1*S*,2*R*) isomer found in nature suggests that further studies are required in order to better understand how these lignans are biosynthesized and what factors control the predominant formation of one isomer over the other.

Experimental

General methods

The general experimental procedures and instrumentation have been described in a previous publication (52).

Allyl ether allyl ester of sinapic acid, 12

Sinapic acid (**11**) (706 mg, 3.15 mmol) was refluxed in allyl bromide (7 mL, 81 mmol) and acetone (13 mL) in the presence of anhydrous K_2CO_3 (1.76 g, 12.7 mmol) under a drying tube ($CaCl_2$) for 22 h using a 50 mL round-bottom flask. The solution was allowed to cool to room temperature, and CH_2Cl_2 (15 mL) was added and washed with H_2O (20 mL). After extracting the aqueous layer four times with CH_2Cl_2 (10 mL), the combined organic layers were dried ($MgSO_4$) and evaporated to give an orange liquid (960 mg, 100%). A portion of the crude product was chromatographed on silica gel (25% EtOAc – hexanes) to afford an analytically pure sample of a colourless liquid: IR (CH_2Cl_2): 1708 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.87 (s, 6H, CH_3), 4.56 (dt, 2H, J = 6.1, 1.2, CH_2), 4.71 (dt, 2H, J = 5.7, 1.4, CH_2), 5.17–5.41 (m, 4H, CH_2), 5.93–6.06 (ddt, 1H, J = 17.1, 10.4, 5.7, CH), 6.02–6.15 (ddt, 1H, J = 17.2, 10.3, 6.1, CH), 6.37 (d, 1H, J = 15.8, CH), 6.75 (s, 2H, aromatic), 7.62 (d, 1H, J = 15.9, CH); ^{13}C NMR ($CDCl_3$) δ: 56.2 (2 × CH_3), 65.2 (CH_2), 74.2 (CH_2), 105.3 (2 × CH), 117.0 (CH), 118.0 (CH_2), 118.2 (CH_2), 129.8 (C), 132.3 (CH), 134.1 (CH), 138.8 (C), 145.0 (CH), 153.6 (2 × C), 166.5 (C); mass spectrum *m/z* (relative intensity): 304 (M^+, 13), 263 (100), 247 (6), 177 (13); HRMS calcd. for $C_{17}H_{20}O_5$: 304.1310; found: 304.1274.

Allyl ether of sinapic acid, 13

Diallyl sinapate **12** (832 mg, 2.73 mmol) was stirred in 9:1 MeOH–H_2O (20 mL) with KOH (1.82 g, 32.4 mmol) at room temperature for 3 h using a 50 mL round-bottom flask. Some of the MeOH was evaporated using a rotary evaporator. H_2O (10 mL) was added and washed with EtOAc (30 mL), and the organic layer was extracted with saturated $NaHCO_{3(aq)}$ (3 × 10 mL) followed by H_2O (10 mL). The combined aqueous layers were washed once with EtOAc (10 mL), acidified with 10% $HCl_{(aq)}$, then extracted with CH_2Cl_2 (4 × 20 mL). The combined CH_2Cl_2 extracts were dried ($MgSO_4$) and evaporated to give beige crystals (708 mg, 98%). Some of the crude product was recrystallized from 10% EtOAc – hexanes to afford an analytically pure sample of colourless crystals: mp 99–100°C; IR (CH_2Cl_2): 1690 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.89 (s, 6H, CH_3), 4.57 (dt, 2H, J = 6.1, 1.2, CH_2), 5.20 (m, 1H, CH_2), 5.32 (m, 1H, CH_2), 6.03–6.16 (ddt, 1H, J = 17.1, 10.3, 6.1, CH), 6.35 (d, 1H, J = 15.9, CH), 6.77 (s, 2H, aromatic), 7.70 (d, 1H, J = 15.9, CH); ^{13}C NMR ($CDCl_3$) δ: 56.2 (2 × CH_3), 74.2 (CH_2), 105.6 (2 × CH), 116.3 (CH), 118.1 (CH_2), 129.5 (C), 134.1 (CH), 139.2 (C), 147.1 (CH), 153.6 (2 × C), 172.2 (C); mass spectrum *m/z* (relative intensity): 264 (M^+, 14), 223 (100), 163 (17), 149 (36), 119 (19), 81 (44), 69 (90); HRMS calcd. for $C_{14}H_{16}O_5$: 264.0998; found: 264.0984.

Allyl ether (methyl (*R*)-mandelyl) ester of sinapic acid, 14

Monoallyl sinapic acid, **13**, (201 mg, 0.761 mmol) in a 25 mL round-bottom flask was refluxed with $SOCl_2$ (0.16 mL, 2.2 mmol) in CCl_4 (7 mL) under a drying tube ($CaCl_2$) for 19.5 h. After the flask was allowed to cool to room temperature, the solvent was evaporated using a rotary evaporator, and CCl_4 (4 mL) was added and evaporated twice to remove traces of $SOCl_2$. The crude acid chloride was refluxed with methyl (*R*)-mandelate (255 mg, 1.53 mmol) in CCl_4 (2.5 mL) in a 10 mL round-bottom flask under a drying tube ($CaCl_2$) for 23 h. The solution was slightly cooled, the solvent was evaporated, and the crude yellow solid was chromatographed on silica gel (10% EtOAc – toluene) to give colourless crystals (249 mg, 79%): mp 83–84°C (hexanes); $[\alpha]_D^{25}$ −67 (*c* 0.51, $CHCl_3$); IR (CH_2Cl_2): 1757 (CO), 1717 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.75 (s, 3H, CH_3), 3.87 (s, 6H, CH_3), 4.56 (dt, 2H, J = 6.1, 1.2, CH_2), 5.19 (m, 1H, CH_2), 5.31 (m, 1H, CH_2), 6.02–6.15 (ddt, 1H, J = 17.2, 10.3, 6.1, CH), 6.09 (s, 1H, CH), 6.48 (d, 1H, J = 15.9, CH), 6.76 (s, 2H, aromatic), 7.41 (m, 3H, aromatic), 7.53 (m, 2H, aromatic), 7.69 (d, 1H, J = 15.9, CH); ^{13}C NMR ($CDCl_3$) δ: 52.7 (CH_3), 56.2 (2 × CH_3), 74.2 (CH_2), 74.4 (CH), 105.4 (2 × CH), 116.1 (CH), 118.0 (CH_2), 127.7 (2 × CH), 128.8 (2 × CH), 129.3 (CH), 129.6 (C), 134.0 (C), 134.1 (CH), 139.0 (C), 146.3 (CH), 153.6 (2 × C), 166.0 (C), 169.3 (C); mass spectrum *m/z* (relative intensity): 412 (M^+, 4), 371 (12), 237 (33), 149 (100), 121 (25), 117 (77), 71 (47), 57 (97); HRMS calcd. for $C_{23}H_{24}O_7$: 412.1522; found: 412.1526.

(Methyl (*R*)-mandelyl) sinapate 15

Monoallyl (methyl mandelyl) sinapate, **14**, (170 mg, 0.412 mmol), tris(triphenylphosphine)rhodium(I) chloride (26 mg, 0.028 mmol), and DABCO (24 mg, 0.21 mmol) were placed in a 10 mL round-bottom flask and refluxed in a 7:3:1 mixture of ethanol–benzene–H_2O (5 mL) for 4 h. The solution was allowed to cool to room temperature, acidified with 10% $HCl_{(aq)}$ (2 mL), diluted with H_2O (5 mL), and extracted with CH_2Cl_2 (4 × 5 mL). The combined organic layers were dried ($MgSO_4$), evaporated, and the resulting yellow residue was chromatographed on silica gel (55% EtOAc – hexanes) to yield a colourless amorphous solid (150 mg, 98%): $[\alpha]_D^{25}$ −63 (*c* 1.2, $CHCl_3$); IR (CH_2Cl_2): 3523 (OH), 1752 (CO), 1714 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.75 (s, 3H, CH_3), 3.92 (s, 6H, CH_3), 5.78 (s, 1H, OH), 6.09 (s, 1H, CH), 6.43 (d, 1H, J = 15.9, CH), 6.79 (s, 2H, aromatic), 7.42 (m, 3H, aromatic), 7.54 (m, 2H, aromatic), 7.69 (d, 1H, J = 15.8, CH); ^{13}C NMR ($CDCl_3$) δ: 52.6 (CH_3), 56.4 (2 × CH_3), 74.4 (CH), 105.3 (2 × CH), 114.6 (CH), 125.7 (C), 127.7 (2 × CH), 128.8 (2 × CH),

129.2 (CH), 134.0 (C), 137.4 (C), 146.5 (CH), 147.2 (2 × C), 166.2 (C), 169.4 (C); mass spectrum *m/z* (relative intensity): 372 (M^+, 46), 223 (27), 207 (100), 180 (25), 149 (11), 121 (15), 105 (17), 91 (22) 77 (20); HRMS calcd. for $C_{20}H_{20}O_7$: 372.1209; found: 372.1193.

Lignans 16, 17, and 18 from the oxidative cyclization of (methyl (*R*)-mandelyl) sinapate

A solution of sinapate **15** (24 mg, 0.064 mmol) in acetone (0.6 mL) was stirred at rt (room temperature) while a solution of $FeCl_3$ (24 mg, 0.15 mmol) in H_2O (0.4 mL) was added dropwise over 3 min. After 25 min, the brown solution was diluted with EtOAc (4 mL) and H_2O (4 mL), acidified with 10% $HCl_{(aq)}$ (1 mL), and stirred for 1 min. The aqueous layer was separated and extracted with CH_2Cl_2 (3 × 3 mL). The combined organic layers were dried ($MgSO_4$), filtered, stirred with Amberlite® IRC-718 ion-exchange resin for 5 min, filtered, and evaporated to give a brown amorphous solid. The crude residue was refluxed in benzene (1.3 mL) with *p*-TsOH·H_2O (2 mg, 0.01 mmol) for 40 min. The solution was diluted with CH_2Cl_2 (4 mL), washed with H_2O (5 mL), and the aqueous phase was extracted with CH_2Cl_2 (3 × 3 mL). The combined organic phases were dried ($MgSO_4$) and evaporated to give a brown amorphous solid (24 mg). The ^1H NMR spectrum ($CDCl_3$) of the crude product indicated the presence of the 1,2-*trans* diastereomers **16** and **17** in a ratio of 2:1, respectively (from ratio of H-4 singlets at 7.79 ppm, and 7.81, ppm respectively). A portion of the crude product (7.8 mg) was chromatographed on a preparative HPLC reverse-phase column (5 μm CSC-S ODS2 (25 × 0.46 cm)) using 53:47 MeOH–H_2O to give the 1,2-*trans* diastereomers **16** (4.1 mg, 53%) and **17** (1.8 mg, 23%) and the 1,2-*cis* diastereomer **18** (0.6 mg, 8%) as colourless amorphous solids. The HPLC chromatogram (Varian 9050 UV–VIS detector, λ = 254 nm) indicated the presence of **16**, **17**, and **18** in a ratio of 8.1:4.0:1.0, respectively.

3-(3′-Acetyl-4′-hydroxyphenyl)-(*S*)-alanine hydrochloride 20

Compound **20** was prepared using the method of Boger and Yohannes (39) from (*S*)-tyrosine (**19**) (14.5 g, 80.0 mmol), anhydrous $AlCl_3$ (42.4 g, 318 mmol), and acetyl chloride (7.8 mL, 110 mmol). The crude product was recrystallized from 5 M $HCl_{(aq)}$ to give beige crystals (14.6 g, 70%): IR (KBr): 3418 (OH), 1747 (CO) cm^{-1}; ^1H NMR (D_2O) δ: 2.67 (s, 3H, CH_3), 3.22 (dd, 1H, *J* = 14.7, 7.3, CH_2), 3.32 (dd, 1H, *J* = 14.7, 5.8, CH_2), 4.27 (dd, 1H, *J* = 7.3, 5.9, CH), 7.00 (d, 1H, *J* = 8.6, aromatic), 7.49 (dd, 1H, *J* = 8.6, 2.2, aromatic), 7.82 (d, 1H, *J* = 2.2, aromatic); ^{13}C NMR (D_2O) δ: 27.5 (CH_3), 36.0 (CH_2), 55.6 (CH), 119.5 (CH), 121.0 (C), 126.6 (C), 133.6 (CH), 138.9 (CH), 161.0 (C), 173.0 (C), 208.2 (C); mass spectrum *m/z* (relative intensity): 223 ($[M - HCl]^+$, 2), 177 (13), 149 (100), 131 (44), 107 (13), 77 (20). The ^1H NMR spectrum was similar to that previously reported (39).

3-(3′-Acetyl-4′-hydroxyphenyl)-(*S*)-lactic acid 21

Compound **21** was prepared using the method of Wunsch and Zott (40) from acetyl-(*S*)-tyrosine hydrochloride **20** (3.00 g, 11.6 mmol) and $NaNO_2$ (1.20 g, 17.4 mmol). The product was chromatographed on silica gel (200:32:5:1 $CHCl_3$–MeOH–AcOH–H_2O) to afford a yellow amorphous solid (2.10 g, 81%): $[\alpha]_D^{25}$ −12 (*c* 0.64, MeOH); IR ($CHCl_3$): 3674 (OH), 1729 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.62 (s, 3H, CH_3), 2.97 (dd, 1H, *J* = 14.3, 6.8, CH_2), 3.16 (dd, 1H, *J* = 14.3, 4.1, CH_2), 4.50 (dd, 1H, *J* = 6.8, 4.2, CH), 6.92 (d, 1H, *J* = 8.5, aromatic), 7.37 (dd, 1H, *J* = 8.5, 2.1, aromatic), 7.63 (d, 1H, *J* = 2.0, aromatic), 12.16 (s, 1H, OH); ^{13}C NMR ($CDCl_3$) δ: 26.6 (CH_3), 39.1 (CH_2), 70.8 (CH), 118.5 (CH), 119.5 (C), 126.3 (C), 131.6 (CH), 137.7 (CH), 161.4 (C), 177.4 (C), 204.4 (C); mass spectrum *m/z* (relative intensity): 224 (M^+, 3), 206 (1), 191 (2), 178 (3), 149 (100), 131 (47), 117 (42), 77 (13), 43 (34); HRMS calcd. for $C_{11}H_{12}O_5$: 224.0685; found: 224.0699.

3-(3′-Acetyl-4′-hydroxyphenyl)-(*S*)-lactic acid ethyl ester 22

Ethyl ester **22** was prepared using the method of Wunsch and Zott (40) from acetyl-(*S*)-tyrosine hydrochloride **20** (200 mg, 0.77 mmol), by repeating the above procedure and refluxing the crude aryllactic acid, **21**, with EtOH (4 mL) and H_2SO_4 (0.02 mL, 0.4 mmol). The crude ester was chromatographed on silica gel (40:8:1 hexanes–EtOAc–AcOH) to afford colourless crystals (95 mg, 49%): mp 96–98°C ($CHCl_3$) (lit. (40) mp 97–98°C); $[\alpha]_D^{25}$ −30 (*c* 2.7, $CHCl_3$) (lit. (40) $[\alpha]_{546}$ −38.8, $[\alpha]_{578}$ −34.2 (*c* 2.39, $CHCl_3$)); IR (CH_2Cl_2): 3537 (OH), 1733 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.30 (t, 3H, *J* = 7.2, CH_3), 2.62 (s, 3H, CH_3), 2.93 (dd, 1H, *J* = 14.2, 6.6, CH_2), 3.10 (dd, 1H, *J* = 14.2, 4.3, CH_2), 4.24 (q, 2H, *J* = 7.1, CH_2), 4.41 (dd, 1H, *J* = 6.5, 4.3, CH), 6.91 (d, 1H, *J* = 8.5, aromatic), 7.34 (dd, 1H, *J* = 8.5, 2.2, aromatic), 7.61 (d, 1H, *J* = 2.1, aromatic),

For personal use only.

12.15 (s, 1H, OH); ^{13}C NMR ($CDCl_3$) δ: 14.3 (CH_3), 26.6 (CH_3), 39.3 (CH_2), 61.9 (CH_2), 71.0 (CH), 118.3 (CH), 119.4 (C), 126.8 (C), 131.5 (CH), 137.7 (CH), 161.3 (C), 174.0 (C), 204.3 (C); mass spectrum *m/z* (relative intensity): 252 (M^+, 6), 234 (5), 179 (8), 149 (100), 131 (36), 77 (12), 55 (10); HRMS calcd. for $C_{13}H_{16}O_5$: 252.0997; found: 252.0988. The ^{1}H NMR spectrum was similar to that previously reported (40).

3-(3′,4′-Dihydroxyphenyl)-(*S*)-lactic acid 23

Compound **23** was prepared using the method of Wunsch and Zott (40) from aryllactic acid, **21** (2.04 g, 9.10 mmol), NaOH (1.27 g, 31.8 mmol), and 30% H_2O_2 (1.56 g, 13.8 mmol H_2O_2). The yellow crude product was chromatographed on silica gel (200:50:5:1 $CHCl_3$–MeOH–AcOH–H_2O) to give a yellow amorphous solid (1.10 g, 61%): $[\alpha]_D^{25}$ −10 (*c* 0.50, MeOH); IR (neat): 3651 (OH), 1726 (CO) cm^{-1}; ^{1}H NMR (acetone-d_6) δ: 2.78 (dd, 1H, *J* = 14.0, 7.5, CH_2), 2.97 (dd, 1H, *J* = 13.9, 4.3, CH_2), 4.32 (dd, 1H, *J* = 7.5, 4.3, CH), 6.60 (dd, 1H, *J* = 8.0, 2.0, aromatic), 6.71 (d, 1H, *J* = 8.0, aromatic), 6.78 (d, 1H, *J* = 2.0, aromatic); ^{13}C NMR (acetone-d_6) δ: 40.6 (CH_2), 72.2 (CH), 115.7 (CH), 117.5 (CH), 121.7 (CH), 130.0 (C), 144.4 (C), 145.4 (C), 175.3 (C); mass spectrum *m/z* (relative intensity): 198 (M^+, 4), 152 (9), 136 (5), 123 (100), 77 (16), 44 (35); HRMS calcd. for $C_9H_{10}O_5$: 198.0529; found: 198.0508.

Diallyl ether allyl ester of 3-(3′,4′-dihydroxyphenyl)-(*S*)-lactic acid, 24

3-(3′,4′-dihydroxyphenyl)lactic acid (**23**) (940 mg, 4.7 mmol) was dissolved in acetone (14 mL) in a 50 mL round-bottom flask and stirred at room temperature while allyl bromide (7 mL, 80 mmol) and anhydrous potassium carbonate (1.97 g, 14.3 mmol) were added. The mixture was refluxed under a drying tube ($CaCl_2$) in a silicone oil bath (70°C) for 22 h and then cooled to room temperature. The insoluble salts were filtered, washed with CH_2Cl_2, and the combined filtrate and CH_2Cl_2 portions were evaporated. The residue was dissolved in CH_2Cl_2 (10 mL), washed with water (10 mL), and the aqueous layer was extracted three times with CH_2Cl_2 (5 mL). The combined organic layers were dried ($MgSO_4$), evaporated, and the crude product (1.28 g) was chromatographed on silica gel (20% EtOAc – hexanes) to give colourless fibers (640 mg, 42%): mp 72–73°C; $[\alpha]_D^{25}$ −29 (*c* 0.73, $CHCl_3$); IR (CH_2Cl_2): 3545 (OH), 1738 (CO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.91 (dd, 1H, *J* = 14.1, 6.5, CH_2), 3.06 (dd, 1H, *J* = 14.0, 4.4, CH_2), 4.44 (dd, 1H, *J* = 6.5, 4.5, CH), 4.58 (d, 4H, *J* = 5.2, CH_2), 4.65 (dt, 2H, *J* = 5.8, 1.3, CH_2), 5.23–5.44 (m, 6H, CH_2), 5.84–5.97 (ddt, 1H, *J* = 17.1, 10.4, 5.9, CH), 6.01–6.14 (m, 2H, CH), 6.73 (dd, 1H, *J* = 8.1, 2.0, aromatic), 6.78 (d, 1H, *J* = 1.9, aromatic), 6.82 (d, 1H, *J* = 8.2, aromatic); ^{13}C NMR ($CDCl_3$) δ: 40.0 (CH_2), 66.2 (CH_2), 70.0 (2 × CH_2), 71.3 (CH), 114.2 (CH), 115.7 (CH), 117.4 (CH_2), 117.5 (CH_2), 119.2 (CH_2), 122.1 (CH), 129.1 (C), 131.4 (CH), 133.4 (CH), 133.6 (CH), 147.6 (C), 148.4 (C), 173.7 (C); mass spectrum *m/z* (relative intensity): 318 (M^+, 40), 259 (29), 229 (24), 203 (100), 161 (32), 123 (38), 81 (62); HRMS calcd. for $C_{18}H_{22}O_5$: 318.1467; found: 318.1445.

(*R*)-Mosher's acid ester of alcohol 24, 37

(*R*)-α-Methoxy-α-(trifluoromethyl)phenylacetic acid (Mosher's acid, **36**) (19 mg, 0.081 mmol) was refluxed in $SOCl_2$ (0.56 mL, 7.7 mmol) and CCl_4 (0.5 mL) in a 10 mL conical flask under a drying tube ($CaCl_2$) for 4 h. The solution was cooled slightly, evaporated, and CCl_4 was added and evaporated once to remove traces of $SOCl_2$. A solution of freshly distilled Et_3N (37 μL, 0.27 mmol), DMAP (2 mg, 0.02 mmol), and alcohol **24** (7.0 mg, 0.02 mmol) in CCl_4 (0.4 mL) was added to the stirred crude acid chloride at rt to immediately give a colourless precipitate. The mixture was stirred under a drying tube ($CaCl_2$) for 1 h, diluted with CH_2Cl_2 (6 mL), and washed successively with 10% $HCl_{(aq)}$ (2 × 3 mL), saturated $NaHCO_{3(aq)}$ (2 × 3 mL), and H_2O (3 mL). The organic layer was dried ($MgSO_4$) and evaporated to give a yellow oil (11.8 mg, 100%): ^{1}H NMR ($CDCl_3$) δ: 3.04 (dd, 1H, *J* = 14.5, 10.0, CH_2), 3.25 (dd, 1H, *J* = 14.5, 3.6, CH_2), 3.36 (d, 3H, *J* = 1.1, CH_3), 4.48 (dt, 2H, *J* = 5.3, 1.5, CH_2), 4.57 (m, 3H, CH, CH_2), 4.65 (dt, 2H, *J* = 5.9, 1.2, CH_2), 5.22–5.43 (m, 6H, CH_2), 5.80–5.93 (ddt, 1H, *J* = 17.2, 10.4, 5.9, CH), 5.96–6.13 (m, 2H, CH), 6.74 (m, 2H, aromatic), 6.81 (d, 1H, *J* = 8.0, aromatic), 7.32 (m, 5H, aromatic). The ^{1}H NMR spectrum ($CDCl_3$) showed no alcohol present, and only one diastereomer could be detected. The ^{19}F NMR spectrum ($CDCl_3$) displayed one major signal (−75.00 ppm) and four very minor signals, and the ratio of the major signal to the largest minor signal (−75.11 ppm) was 92:8 from integration.

Diallyl ether allyl ester of caffeic acid, 26

Caffeic acid (**25**) (1.50 g, 8.33 mmol) was dissolved in acetone (22 mL) in a 100 mL round-bottom flask and stirred at room temperature while allyl bromide (11 mL, 130 mmol) and anhydrous potassium carbonate (5.18 g, 37.5 mmol) were added. The mixture was refluxed under a drying tube ($CaCl_2$) in a silicone oil bath for 19 h and then cooled to room temperature. The insoluble salts were filtered, washed with CH_2Cl_2, and the combined filtrate and CH_2Cl_2 portions were evaporated. The residue was dissolved in CH_2Cl_2 (15 mL), washed with water (10 mL), and the aqueous layer was extracted three times with CH_2Cl_2 (3 mL). The combined organic layers were dried ($MgSO_4$), evaporated, and the crude product (2.50 g) was chromatographed on silica gel (20% EtOAc – hexanes) to give colourless crystals (2.15 g, 86%): mp 50–51°C; IR (CH_2Cl_2): 1711 (CO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 4.64 (m, 4H, CH_2), 4.70 (dt, 2H, *J* = 5.7, 1.4, CH_2), 5.25–5.47 (m, 6H, CH_2), 5.93–6.15 (m, 3H, CH), 6.30 (d, 1H, *J* = 15.9, CH), 6.87 (d, 1H, *J* = 8.9, aromatic), 7.08 (dd, 1H, *J* = 8.8, 2.0, aromatic), 7.08 (d, 1H, *J* = 2.0, aromatic), 7.63 (d, 1H, *J* = 15.9, CH); ^{13}C NMR ($CDCl_3$) δ: 65.1 (CH_2), 69.7 (CH_2), 70.0 (CH_2), 112.7 (CH), 113.4 (CH), 115.6 (CH), 117.9 (2 × CH_2), 118.1 (CH_2), 122.7 (CH), 127.5 (C), 132.4 (CH), 132.9 (CH), 133.1 (CH), 144.9 (CH), 148.5 (C), 150.7 (C), 166.8 (C); mass spectrum *m/z* (relative intensity): 300 (M^+, 100), 259 (73), 243 (33), 229 (63), 173 (32), 145 (41), 133 (74), 117 (34), 105 (34), 77 (54); HRMS calcd. for $C_{18}H_{20}O_4$: 300.1362; found: 300.1342.

Diallyl ether of caffeic acid, 27

Triallyl caffeate **26** (2.14 g, 7.13 mmol) and KOH (4.00 g, 71.3 mmol) were stirred in 9:1 MeOH–H_2O (48 mL) in a 100 mL round-bottom flask at room temperature for 4 h. The volume of MeOH was reduced to approximately half of the original volume by evaporation using a rotary evaporator, and the remaining mixture was acidified with 10% $HCl_{(aq)}$ (30 mL) followed by concentrated HCl (5 mL). The solution was satu-

For personal use only.

rated with NaCl and extracted with EtOAc (10 mL) five times. The combined organic layers were dried ($MgSO_4$), evaporated, and the crude product (1.85 g) was recrystallized twice with 10% MeOH – $CHCl_3$ to give colourless crystals (1.54 g, 83%): mp 157–159°C; IR (CH_2Cl_2): 1686 (CO) cm^{-1}; ^1H NMR (acetone-d_6) δ: 4.65 (dt, 2H, J = 5.1, 1.6, CH_2), 4.68 (dt, 2H, J = 5.2, 1.6, CH_2), 5.26 (m, 2H, CH_2), 5.47 (m, 2H, CH_2), 6.04–6.18 (m, 2H, CH), 6.39 (d, 1H, J = 15.9, CH), 7.02 (d, 1H, J = 8.3, aromatic), 7.20 (dd, 1H, J = 8.3, 2.0, aromatic), 7.34 (d, 1H, J = 2.0, aromatic), 7.60 (d, 1H, J = 15.9, CH); ^{13}C NMR (acetone-d_6) δ: 70.0 (CH_2), 70.2 (CH_2), 113.5 (CH), 114.4 (CH), 116.8 (CH), 117.3 (CH_2), 117.4 (CH_2), 123.5 (CH), 128.5 (C), 134.4 (CH), 134.6 (CH), 145.4 (CH), 149.6 (C), 151.5 (C), 167.9 (C); mass spectrum *m/z* (relative intensity): 260 (M^+, 100), 219 (72), 189 (53), 179 (26), 145 (28), 133 (25), 117 (32), 105 (21), 91 (21), 77 (47); HRMS calcd. for $C_{15}H_{16}O_4$: 260.1048; found: 260.1044.

Tetraallyl ether allyl ester of (*S*)-rosmarinic acid, 29

Diallyl caffeic acid **27** (1.05 g, 4.03 mmol) and thionyl chloride (0.90 mL, 12 mmol) were refluxed in CCl_4 (15 mL) in a 25 mL round-bottom-flask under a drying tube ($CaCl_2$) for 17.5 h. After slight cooling, the solvent was evaporated using a rotary evaporator, and CCl_4 was added and evaporated once to remove traces of $SOCl_2$. Alcohol **24** (585 mg, 1.84 mmol) in CH_2Cl_2 (6 mL) was added to the crude acid chloride, **28**, to give a homogeneous solution that was stirred at room temperature while freshly distilled, dry triethylamine (2.25 mL, 16.1 mmol) was added. The solution was stirred under a drying tube ($CaCl_2$) for 3.5 h and then evaporated. The residue was dissolved in CH_2Cl_2 (10 mL), and the solution was extracted successively with 10% $HCl_{(aq)}$ (2 × 5 mL), H_2O (5 mL), saturated $NaHCO_{3(aq)}$ (2 × 5 mL), and H_2O (5 mL). The aqueous layers, except for the acidic layers, were combined and extracted twice with CH_2Cl_2 (1 mL). The combined organic layers were dried ($MgSO_4$), evaporated, and the crude product was chromatographed on silica gel (20% EtOAc – hexanes) to give a colourless oil (673 mg, 65%): $[\alpha]_D^{25}$ −42 (*c* 1.08, $CHCl_3$); IR (CH_2Cl_2): 1753 (CO), 1715 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.11 (dd, 1H, J = 14.3, 7.9, CH_2), 3.18 (dd, 1H, J = 14.4, 5.2, CH_2), 4.56–4.66 (m, 10H, CH_2), 5.21–5.46 (m, 11H, CH, CH_2) 5.80–5.93 (ddt, 1H, J = 17.1, 10.5, 5.7, CH), 5.99–6.14 (m, 4H, CH), 6.29 (d, 1H, J = 15.9, CH), 6.82 (m, 4H, aromatic), 7.07 (m, 2H, aromatic), 7.61 (d, 1H, J = 15.9, CH); ^{13}C NMR ($CDCl_3$) δ: 37.1 (CH_2), 65.9 (CH_2), 69.7 (CH_2), 70.0 (3 × CH_2), 73.0 (CH), 112.7 (CH), 113.4 (CH), 114.2 (CH), 114.7 (CH), 115.6 (CH), 117.5 (2 × CH_2), 117.9 (CH_2), 118.0 (CH_2), 118.7 (CH_2), 122.0 (CH), 123.0 (CH), 127.3 (C), 128.8 (C), 131.5 (CH), 132.8 (CH), 133.0 (CH), 133.4 (CH), 133.5 (CH), 145.9 (CH), 147.6 (C), 148.4 (C), 148.6 (C), 150.9 (C), 166.3 (C), 169.5 (C); mass spectrum *m/z* (relative intensity): 560 (M^+, 2), 300 (100), 259 (37), 243 (27), 229 (23), 201 (11), 173 (14), 161 (10), 145 (15), 133 (24), 117 (12), 105 (10), 81 (21); HRMS calcd. for $C_{33}H_{36}O_8$: 560.2410; found: 560.2412.

(*S*)-(−)-Rosmarinic acid 30

Pentaallyl (*S*)-rosmarinate 29 (645 mg, 1.15 mmol) in 7:3:1 ethanol–benzene–H_2O (22 mL) in a 50 mL round-bottom flask was refluxed in the presence of tris(triphenylphosphine)rhodium(I) chloride (700 mg, 0.757 mmol) under a drying tube ($CaCl_2$) for 43 h. After slight cooling, most of the solvent was evaporated, and EtOAc (40 mL) was added. The mixture was extracted sequentially with H_2O (2 × 10 mL), saturated $NaHCO_{3(aq)}$ (3 × 10 mL), H_2O (10 mL), saturated $NaHCO_{3(aq)}$ (3 × 10 mL), and H_2O (10 mL). The combined aqueous layers were washed once with CH_2Cl_2 (10 mL), filtered, and acidified with concentrated HCl to approximately pH 1–2. The mixture was filtered, saturated with NaCl, and extracted 10 times with EtOAc (20 mL). The combined EtOAc layers were dried ($MgSO_4$), evaporated, and the crude product (247 mg) was chromatographed on silica gel (200:40:5:1 $CHCl_3$–MeOH–AcOH–H_2O) to give a light yellow amorphous solid (121 mg, 29%). A colourless amorphous solid was obtained from lyophilization of the product in H_2O: $[\alpha]_D^{25}$ −86 (*c* 0.54, 95% EtOH); IR (neat): 3316 (OH), 1729 (CO), 1690 (C) cm^{-1}; ^1H NMR (acetone-d_6) δ: 3.03 (dd, 1H, J = 14.3, 8.4, CH_2), 3.13 (dd, 1H, J = 14.3, 4.4, CH_2), 5.22 (dd, 1H, J = 8.4, 4.4, CH), 6.29 (d ,1H, J = 15.9, CH), 6.67 (dd, 1H, J = 8.1, 2.0, aromatic), 6.75 (d, 1H, J = 8.0, aromatic), 6.86 (m, 2H, aromatic), 7.05 (dd, 1H, J = 8.2, 2.0, aromatic), 7.16 (d, 1H, J = 2.1, aromatic), 7.56 (d, 1H, J = 15.9, CH); ^{13}C NMR (acetone-d_6) δ: 37.4 (CH_2), 73.6 (CH), 114.9 (CH), 115.2 (CH), 115.9 (CH), 116.3 (CH), 117.2 (CH), 121.6 (CH), 122.6 (CH), 127.4 (C), 129.1 (C), 144.7 (C), 145.6 (C), 146.2 (C), 146.4 (CH), 148.8 (C), 166.7 (C), 171.0 (C); mass spectrum (FAB^+) *m/z* (relative intensity): 361 ($[M + H]^+$, 13), 180 (63), 163 (100), 123 (17).

(*S*)- and (*R*)-α-Methylbenzyl amide of (*S*)-rosmarinic acid, (*SS*) and (*SR*)-38

(*S*)-Rosmarinic acid (**30**) (7.5 mg, 0.021 mmol) in DMF (0.2 mL) in a 5 mL round-bottom flask was stirred at rt under N_2 atmosphere while (i–Pr)$_2$NEt (3.3 mg, 0.026 mmol) in DMF (0.2 mL) was added. The solution was cooled in an ice bath for 7 min, treated with *O*-benzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluroborate (TBTU, 7.5 mg, 0.023 mmol), stirred for 5 min to allow the TBTU to dissolve, stirred at rt for 10 min, cooled in an ice bath for 7 min, and treated dropwise with a solution of racemic α-methylbenzylamine (3.4 mg, 0.028 mmol) in DMF (0.2 mL). The solution was stirred for 1.5 h, slowly allowed to warm to rt, stirred for 24 h, diluted with EtOAc (7 mL), and washed with saturated $NaHCO_{3(aq)}$ (3 × 2 mL) followed by 10% $HCl_{(aq)}$ (2 mL). The combined aqueous phases were extracted with EtOAc (3 mL). The combined organic phases were dried ($MgSO_4$) and evaporated to give a yellow amorphous solid (7.9 mg, 82%). The ^1H NMR spectrum (acetone-d_6) showed the presence of the (*S*,*S*) diastereomer and the (*S*,*R*) diastereomer in a ratio of 1.3:1.0, respectively. The best separation of diastereomeric signals was observed for an aromatic doublet at 6.71 ppm (J = 8.0, (*S*,*R*) isomer) and an aromatic doublet at 6.72 ppm (J = 8.0, (*S*,*S*) isomer).

(*R*)-α-Methylbenzyl amide of (*S*)-rosmarinic acid, (*RS*)-38

The synthesis was performed in a similar manner as for the (*S*)/(*R*)-α-methylbenzyl amide of (*S*)-rosmarinic acid (see above procedure) using (*S*)-rosmarinic acid (**30**) (7.3 mg, 0.020 mmol), (i–Pr)$_2$NEt (2.6 mg, 0.020 mmol), *O*-benzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluroborate (TBTU 6.9 mg, 0.021 mmol), (*R*)-α-methylbenzylamine (3.3 mg, 0.027 mmol), and the same volumes of DMF. The crude product was obtained as a light yellow amorphous solid (7.0 mg, 74%). The ^1H NMR spectrum (acetone-d_6) showed a large

For personal use only.

doublet at 6.71 ppm and only minor peaks that could possibly be attributed to the (*R*,*R*) diastereomer. A ratio of 9:1 was obtained from integration of the (*S*,*R*) isomer doublet at 6.71 ppm and the signal that could possibly be attributed to the (*R*,*R*) isomer doublet at 6.72 ppm.

Bis(*tert*-butyldimethylsilyl) ether of caffeic acid, 32

TBDMS triflate was freshly prepared (46) by adding triflic acid (14 mL, 160 mmol) to TBDMSCl (24 g, 160 mmol) in a 100 mL round-bottom flask at room temperature and stirring the mixture in a silicone oil bath (65°C) for 12 h. The solution was distilled at reduced pressure (ca. 2.5 Torr (1 Torr = 133.3 Pa). A minor amount of TBDMSCl was collected first at ca. 60°C, followed by TBDMS triflate, a colourless liquid, at ca. 83°C (33.4 g, 79%).

Caffeic acid (**25**) (4.00 g, 22.2 mmol) was stirred as a suspension in CH_2Cl_2 (100 mL) in a 250 mL round-bottom flask at room temperature while TBDMS triflate (23 mL, 100 mmol) was added, followed by freshly distilled, anhydrous Et_3N (20.5 mL, 147 mmol). The Et_3N had to be added carefully due to the vigorous effervescence of gas. The mixture immediately became a homogeneous, dark brown solution that was stirred under N_2 atmosphere for 17 h. The solution was washed successively with 10% $HCl_{(aq)}$ (2 × 20 mL) and H_2O (20 mL), and the organic layer was dried ($MgSO_4$) and evaporated to give crude trisilyl caffeate **31** as a mixture of a brown oil and light brown solid (11.5 g, 99%): ^{1}H NMR ($CDCl_3$) δ: 0.21 (s, 6H, CH_3), 0.22 (s, 6H, CH_3), 0.33 (s, 6H, CH_3), 0.98 (s, 9H, CH_3), 0.99 (s, 9H, CH_3), 1.00 (s, 9H, CH_3), 6.20 (d 1H, *J* = 15.8, CH), 6.82 (d, 1H, *J* = 8.7, aromatic), 7.00 (m, 2H, aromatic), 7.50 (d, 1H, *J* = 15.8, CH).

Crude trisilyl caffeate **31** was dissolved in 1:1 MeOH–H_2O (220 mL) in a 500 mL round-bottom flask and stirred at room temperature while H_2O (20 mL) was slowly added over 5 min followed by $K_2CO_3 \cdot 1.5H_2O$ (3.63 g, 22.0 mmol). The mixture was stirred for 3 h, filtered, and the filtrate was evaporated to ca. 50% of the original volume using a rotary evaporator. EtOAc (150 mL) and H_2O (20 mL) were added to the solution, which was then cooled in an ice bath, acidified with concentrated HCl, and saturated with NaCl at rt. The aqueous phase was removed and extracted four times with EtOAc (20 mL). The combined organic phases were dried ($MgSO_4$), evaporated, and the grey crystalline solid obtained was chromatographed on silica gel (5:1 $CHCl_3$–MeOH) to give a colourless crystalline solid (6.90 g, 76% from **25**): mp 152–155°C; IR (CH_2Cl_2): 1686 (CO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 0.22 (s, 6H, CH_3), 0.23 (s, 6H, CH_3), 0.99 (s, 9H, CH_3), 1.00 (s, 9H, CH_3), 6.25 (d, 1H, *J* = 15.8, CH), 6.84 (d, 1H, *J* = 8.8, aromatic), 7.05 (m, 2H, aromatic), 7.67 (d, 1H, *J* = 15.9, CH); ^{13}C NMR ($CDCl_3$) δ: −4.1 (2 × CH_3), −4.0 (2 × CH_3), 18.5 (2 × C), 25.9 (6 × CH_3), 114.7 (CH), 120.6 (CH), 121.1 (CH), 122.6 (CH), 127.6 (C), 147.0 (CH), 147.2 (C), 149.9 (C), 172.1 (C); mass spectrum *m*/*z* (relative intensity): 408 (M^+, 1), 351 (6), 335 (6), 219 (55), 149 (14), 73 (100), 57 (11); HRMS calcd. for $C_{21}H_{36}O_4Si_2$: 408.2152; found: 408.2169.

Bis(*tert*-butyldimethylsilyl) ether diallyl ether allyl ester of (*S*)-rosmarinic acid, 34

Disilyl caffeic acid **32** (4.31 g, 10.5 mmol) was refluxed with $SOCl_2$ (2.4 mL, 33 mmol) in CCl_4 (40 mL) in a 100 mL round-bottom flask under a drying tube ($CaCl_2$) for 4.75 h. The solution was cooled to room temperature, the solvent was evaporated, and CCl_4 (10 mL) was added and evaporated once to remove traces of $SOCl_2$. Triallyl alcohol **24** (2.13 g, 6.69 mmol) in CH_2Cl_2 (20 mL) was added to the crude acid chloride **33**, and the resulting homogeneous solution was stirred at rt while freshly distilled, anhydrous Et_3N (5.9 mL, 42 mmol) was added. The solution was stirred under a drying tube ($CaCl_2$) for 4 h, and most of the solvent was evaporated. EtOAc (50 mL) was added and washed successively with 10% $HCl_{(aq)}$ (2 × 11 mL) and H_2O (11 mL). The combined aqueous layers were extracted with CH_2Cl_2 (2 × 10 mL). The combined organic layers were dried ($MgSO_4$), evaporated, and the crude yellow oil was chromatographed on silica gel (20% EtOAc – hexanes) to afford a light yellow oil (4.61 g, 97%): $[\alpha]_D^{25}$ −34 (*c* 0.50, $CHCl_3$); IR (CH_2Cl_2): 1751 (CO), 1719 (CO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 0.21 (s, 6H, CH_3), 0.22 (s, 6H, CH_3), 0.98 (s, 9H, CH_3), 0.99 (s, 9H, CH_3), 3.11 (dd, 1H, *J* = 14.3, 7.9, CH_2), 3.18 (dd, 1H, *J* = 14.3, 5.2, CH_2), 4.57 (br d, 4H, *J* = 5.2, CH_2), 4.63 (dt, 2H, *J* = 5.7, 1.3, CH_2), 5.21–5.43 (m, 7H, CH, CH_2), 5.80–5.93 (ddt, 1H, *J* = 17.1, 10.5, 5.7, CH), 5.99–6.12 (m, 2H, CH), 6.25 (d, 1H, *J* = 16.0, CH), 6.81 (m, 4H, aromatic), 7.00 (m, 2H, aromatic), 7.59 (d, 1H, *J* = 15.9, CH); ^{13}C NMR ($CDCl_3$) δ: −4.1 (2 × CH_3), −4.0 (2 × CH_3), 18.4 (C), 18.5 (C), 25.9 (6 × CH_3), 37.1 (CH_2), 65.9 (CH_2), 70.0 (2 × CH_2), 73.0 (CH), 114.2 (CH), 114.5 (CH), 115.5 (CH), 117.5 (2 × CH_2), 118.7 (CH_2), 120.5 (CH), 121.1 (CH), 121.9 (CH), 122.5 (CH), 127.8 (C), 128.9 (C), 131.5 (CH), 133.3 (CH), 133.5 (CH), 146.0 (CH), 147.2 (C), 147.6 (C), 148.4 (C), 149.7 (C), 166.4 (C), 169.6 (C); mass spectrum *m*/*z* (relative intensity): 708 (M^+, 1), 465 (3), 408 (3), 391 (11), 351 (19), 335 (15), 300 (6), 261 (8), 236 (5), 219 (100), 191 (10), 115 (17), 73 (100), 59 (17); HRMS calcd. for $C_{39}H_{56}O_8Si_2$: 708.3514; found: 708.3460.

Diallyl ether allyl ester of (*S*)-rosmarinic acid, 35

Disilyl triallyl (*S*)-rosmarinate **34** (4.23 g, 5.97 mmol) in THF (30 mL) in a 100 mL round-bottom flask was stirred at room temperature under N_2 atmosphere while tetra-*n*-butylammonium fluoride (1.0 M in THF, 12 mL, 12 mmol) was added over ca. 1 min. The resultant dark brown solution was stirred for 15 min, acidified with 10% $HCl_{(aq)}$ (10 mL), diluted with H_2O (10 mL), and extracted with EtOAc (1 × 35 mL, then 3 × 10 mL). The combined organic phases were dried ($MgSO_4$), evaporated, and the crude yellow oil was chromatographed on silica gel (25:25:1 EtOAc–hexanes–AcOH) to produce a colourless crystalline solid (1.47 g, 51%): mp 116–118°C (EtOAc); $[\alpha]_D^{25}$ −51 (*c* 0.51, $CHCl_3$); IR (CH_2Cl_2): 3542 (OH), 3369 (OH), 1741 (CO), 1717 (CO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 3.12 (dd, 1H, *J* = 14.3, 7.7, CH_2), 3.18 (dd, 1H, *J* = 14.2, 5.1, CH_2), 4.57 (br d, 4H, *J* = 5.3, CH_2), 4.65 (dt, 2H, *J* = 5.7, 1.2, CH_2), 5.21–5.42 (m, 7H, CH, CH_2), 5.80–5.93 (ddt, 1H, *J* = 17.1, 10.5, 5.7, CH), 5.98–6.11 (m, 3H, CH, OH), 6.17 (s, 1H, OH), 6.20 (d, 1H, *J* = 16.0, CH), 6.80 (m, 4H, aromatic), 6.91 (dd, 1H, *J* = 8.2, 1.9, aromatic), 6.99 (d, 1H, *J* = 1.9, aromatic), 7.51 (d, 1H, *J* = 15.9, CH); ^{13}C NMR ($CDCl_3$) δ: 37.1 (CH_2), 66.1 (CH_2), 70.0 (CH_2), 70.1 (CH_2), 73.0 (CH), 114.2 (2 × CH), 114.4 (CH), 115.4 (CH), 115.7 (CH), 117.7 (2 × CH_2), 119.0 (CH_2), 122.1 (CH), 122.5 (CH), 127.2 (C), 128.7 (C), 131.2 (CH), 133.2 (CH), 133.4 (CH), 143.9 (C), 146.2 (CH), 146.6 (C), 147.6 (C), 148.3 (C), 166.6 (C), 170.1 (C); mass spectrum *m*/*z* (relative intensity): 480 (M^+, 2), 318

(+)-Rabdosiin 41, and its (1*R*, 2*S*) isomer 42

A slow stream of oxygen was passed through a stirred solution of triallyl rosmarinate **35** (26 mg, 0.054 mmol) in acetone (2.4 mL) at rt while a solution of $FeCl_3$ (19.3 mg, 0.119 mmol) in H_2O (1.2 mL) was added dropwise over 2 min. The dark green reaction mixture, protected from light, was stirred for 23 h, diluted with H_2O (5 mL), and extracted with EtOAc (3 × 3 mL). The combined organic layers were dried ($MgSO_4$) and evaporated to give a brown amorphous solid (30 mg). The ^{1}H NMR spectrum (acetone-d_6) showed that a significant amount of starting material was present and that diastereomers **40** and **39** were present in a ratio of 1.6:1.0 from integration of their H-2 doublets at 3.97 and 3.94 ppm, respectively. The reaction was repeated, due to the low yield of products, in the same manner as for above using **35** (21 mg, 0.044 mmol), $FeCl_3$ (16 mg, 0.099 mmol), and the same volumes of solvents. The crude products from both reactions were combined and chromatographed on a preparative HPLC reverse-phase column using 72:28 MeOH – 0.06% $TFA_{(aq)}$ to give 1,2-*trans* diastereomers **40** (3.0 mg, 6.4%) and **39** (2.6 mg, 5.5%) as colourless amorphous solids. The HPLC chromatogram indicated the presence of **40** and **39** in a ratio of 1.6:1.0, respectively.

*Tetraallyl ether diallyl ester (1R,2S)-diastereomer of (+)-rabdosiin, **40***

^{1}H NMR (acetone-d_6) δ: 3.01 (m, 4H, CH_2), 3.97 (d, 1H, J = 2.1, H-2), 4.31 (d, 1H, J = 1.9, H-1), 4.45–4.58 (m, 12H, CH_2), 5.06 (dd, 1H, J = 8.0, 4.8, CH), 5.11–5.25 (m, 9H, CH, CH_2), 5.38–5.46 (m, 4H, CH_2), 5.68–5.86 (m, 2H, CH), 6.01–6.14 (m, 4H, CH), 6.39 (dd, 1H, J = 8.1, 2.1, aromatic), 6.44 (d, 1H, J = 2.1, aromatic), 6.53 (s, 1H, aromatic), 6.67 (d, 1H, J = 8.1, aromatic), 6.76 (m, 2H, aromatic), 6.90 (m, 5H, aromatic), 7.66 (s, 1H, H-4).

*Tetraallyl ether diallyl ester of (+)-rabdosiin, **39***

^{1}H NMR (acetone-d_6) δ: 3.07 (m, 4H, CH_2), 3.94 (d, 1H, J = 1.6, H-2), 4.54 (m, 13H, H-1, CH_2), 5.09–5.29 (m, 10H, CH, CH_2), 5.38–5.46 (m, 4H, CH_2), 5.74–5.90 (m, 2H, CH), 6.01–6.13 (m, 4H, CH), 6.40 (m, 2H, aromatic), 6.62–6.97 (m, 9H, aromatic), 7.65 (s, 1H, H-4).

To a stirred mixture of the hexaallyl (1*R*,2*S*)-isomer of (+)-rabdosiin **40** (3.0 mg, 0.0031 mmol), bis(triphenylphosphine)palladium dichloride (0.9 mg, 0.001 mmol), and acetic acid (0.0036 mL, 0.063 mmol) in acetone (0.3 mL) at rt was added tributyltin hydride (0.0051 mL, 0.019 mmol) every 10 min for a total of five additions (0.0255 mL, 0.095 mmol) over 40 min. The mixture was stirred for 10 min, diluted with EtOAc (5 mL), saturated $NaHCO_{3(aq)}$ (1 mL), and H_2O (2 mL), and stirred for 1 min. The organic phase was separated and extracted twice with saturated $NaHCO_{3(aq)}$ (0.5 mL) and H_2O (2 mL). The aqueous phase was filtered, washed once with EtOAc (1 mL), carefully acidified to pH 1–2 using concentrated HCl, and evaporated. The resulting residue was washed with acetone, and the solvent was filtered and evaporated to give the (1*R*,2*S*) diastereomer of (+)-rabdosiin (**42**) as a yellow amorphous solid (2.1 mg, 95%).

(+)-Rabdosiin (**41**) was prepared in the same manner as for **42** using hexaallyl (+)-rabdosiin **39** (2.6 mg, 0.0027 mmol), bis(triphenylphosphine)palladium dichloride (0.8 mg, 0.001 mmol), acetic acid (0.0030 mL, 0.052 mmol), tributyltin hydride (5 × 0.0050 mL, 0.019 mmol; 0.0250 mL, 0.093 mmol total), and the same volume of acetone. The crude product was obtained as a light yellow amorphous solid (1.9 mg, 100%).

*(1R,2S)-Diastereomer of (+)-rabdosiin, **42***

^{1}H NMR (acetone-d_6) δ: 3.01 (m, 4H, CH_2), 3.96 (d, 1H, J = 2.0, H-2), 4.22 (d, 1H, J = 2.0, H-1), 5.01 (dd, 1H, J = 8.6, 4.6, CH), 5.12 (t, 1H, J = 6.2, CH), 6.35–6.90 (m, 11H, aromatic), 7.62 (s, 1H, H-4). Plane polarized light was rotated in a counterclockwise direction (negative optical rotation).

*(+)-Rabdosiin **41***

^{1}H NMR (acetone-d_6) δ: 3.05 (m, 4H, CH_2), 3.94 (d, 1H, J = 1.3, H-2), 4.57 (br s, 1H, H-1), 5.06 (t, 1H, J = 6.2, CH), 5.09 (dd, 1H, J = 7.1, 5.4, CH), 6.39–6.93 (m, 11H, aromatic), 7.63 (s, 1H, H-4). Plane polarized light was rotated in a clockwise direction (positive optical rotation).

Products from photochemical reactions and electrochemical oxidation of methylenecyclopropane[1]

H.J.P. de Lijser, T. Stanley Cameron, and Donald R. Arnold

Abstract: The reactivity of methylenecyclopropane (MCP, **1**) and its radical cation ($\mathbf{1}^{+\bullet}$) have been studied in the presence and absence of a nucleophile (methanol). Photochemical reactions of **1** in the presence of an electron-acceptor (1,4-dicyanobenzene, **6**) and a codonor (biphenyl, **7**) in acetonitrile (with and without methanol present) or chloroform lead to cycloadditions (*ortho*, *meta*, and *para*; products **12–17**) rather than products from photoinduced electron transfer (PET). Based on the measured (cyclic voltammetry, CV) oxidation potential, using the Weller equation, electron transfer (ET) was predicted to occur. It was shown that the measured oxidation potential of **1** represents the adiabatic ionization potential. For PET processes the value for the vertical ionization potential must be used. Electrochemical (EC) generation of $\mathbf{1}^{+\bullet}$ without a nucleophile present results in the formation of one major product: *tert*-butyl acetamide (**25**). A series of rearrangements leading to the *tert*-butyl cation is proposed. Addition of a nucleophile (methanol) to the mixture leads to the formation of 3-methoxy-2-(methoxymethyl)-1-propene (**26**). This product may arise from trapping of the initially formed ring-opened (trimethylenemethane) radical cation ($\mathbf{1a}^{+\bullet}$), which undergoes a second oxidation and nucleophilic addition (ECE).

Key words: methylenecyclopropane, radical cation, photochemistry, electrochemistry, photocycloaddition.

Résumé : On a étudié la réactivité du méthylènecyclopropane (MCP, **1**) et de son cation radical ($\mathbf{1}^{+\bullet}$) en présence et en l'absence d'un nucléophile (méthanol). Les réactions photochimiques du produit **1** en présence d'un accepteur d'électron (1,4-dicyanobenzène, **6**) et d'un codonneur (biphényle, **7**) dans l'acétonitrile (en présence et en l'absence de méthanol) ou dans le chloroforme conduit à des cycloadditions (*ortho*, *méta* et *para*; produits **12–17**) plutôt qu'aux produits résultant d'un transfert photoinduit d'électron (TPE). Sur la base du potentiel d'oxydation mesuré (voltampérométrie cyclique, VC) en faisant appel à l'équation de Weller, il est prédit qu'il se produira un transfert d'électron (TE). On a montré que le potentiel mesuré d'oxydation du produit **1** correspond au potentiel d'ionisation adiabatique. Pour le processus de TPE, on doit faire appel à la valeur du potentiel vertical d'ionisation. La génération électrochimique (EC) du cation radical $\mathbf{1}^{+\bullet}$ en l'absence d'un nucléophile conduit à la formation d'un produit principal: *tert*-butylacétamide (**25**). On propose une série de réarrangements conduisant à la formation du cation *tert*-butyle. L'addition d'un nucléophile (méthanol) au mélange conduit à la formation du 3-méthoxy-2-(méthoxyméthyl)prop-1-ène (**26**). Ce produit pourrait se former par le piégeage du cation radical ($\mathbf{1a}^{+\bullet}$) (triméthylèneméthane) à cycle ouvert qui se forme initialement et qui peut subir une deuxième oxydation suivie d'une addition nucléophile («ECE»).

Mots clés : méthylènecyclopropane, cation radical, photochimie, électrochimie, photocycloaddition.

[Traduit par la rédaction]

Introduction

Radical cations are reactive species that readily undergo interconversions and rearrangements. Many examples of these types of reactions are known (3). In an earlier paper we reported on the relative energies and the possible interconversions and rearrangements of the five related C_4H_6 and C_8H_{12} species shown in Fig. 1 (1*a*).

According to our ab initio calculations (1*a*), methylenecyclopropane radical cation ($\mathbf{1}^{+\bullet}$)[3] has the highest energy of these five species. From Scheme 1, it is clear that reaction of this radical cation with its neutral precursor is highly exothermic. Because of the large exothermicity of this reaction it is hard to make predictions concerning the ultimate outcome of the reaction, i.e., the type of product(s) that will be formed.

The dimerization of $\mathbf{1}^{+\bullet}$ with **1** in the gas phase, as calculated by ab initio methods (1*a*), leads to the formation of only one type of dimer (Scheme 2). However, carrying out these reactions in the liquid phase could have a dramatic effect on product formation.

Received June 20, 1997.

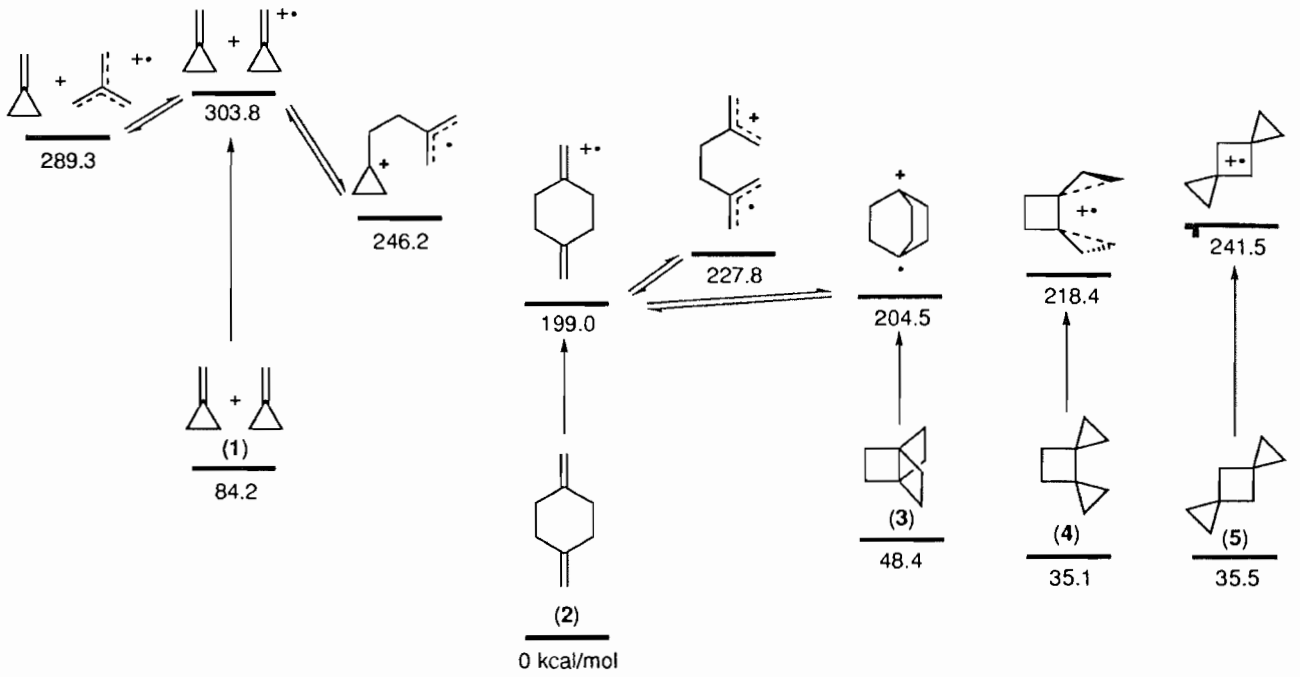
Scheme 1.



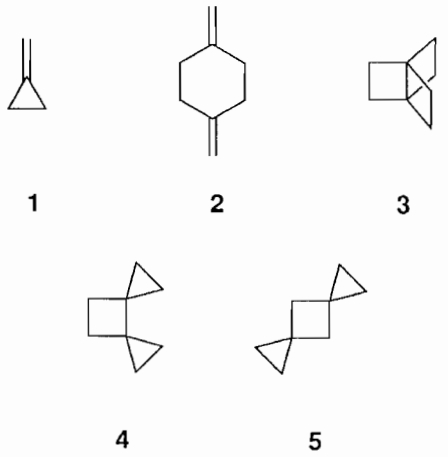


Fig. 1. Compounds of interest for the study on the interconversion and rearrangement of radical cations (see ref. 1 for earlier studies).

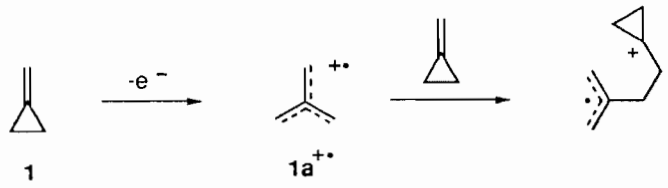

The dimerization of **1** to yield **4** and **5** has been reported (4). These reactions, however, do not involve the radical cations.

In the preceding part of this series (*1b*), product formation from the radical cation of 1,4-bis(methylene)cyclohexane (**2**) was discussed. This isomer is the most stable species of the compounds **1**–**5** and it is likely that some of the products arising from the reaction of $\mathbf{1}^{+\cdot}$ with **1** will resemble those from the reaction of $\mathbf{2}^{+\cdot}$.

Little experimental work has been done on the radical cations of methylenecyclopropane (MCP) and trimethylenemethane (TMM) (5–9) The parent molecules have never been studied, except for a recent ESR study (9). The ESR spectrum of $\mathbf{1}^{+\cdot}$ shows that even at temperatures as low as 4 K all the hydrogens in the radical cation are equivalent. This can only be explained by a ring-opened species, i.e., TMM radical

Scheme 2.

cation ($\mathbf{1a}^{+\cdot}$). This is consistent with the ab initio calculations (*1a*).

Other studies have involved substituted methylenecyclopropanes. Painter and Blackstock (5) recently generated a TMM radical cation using diazene (**8**) with tetracyanoethylene (TCNE) as the electron acceptor. Addition products were formed in this reaction (Scheme 3). The authors claimed that only product **11** was formed by a radical cation mechanism; products **9** and **10** resulted from reaction of a biradical. Evidence for this conclusion was the absence of an appreciable solvent effect on the formation of **9** and **10** and the fact that **9** and **10** were also formed in a thermal (dark) reaction.

The thermal reaction of 2-phenyl-1-methylenecyclopropane and 2,2-diphenyl-1-methylenecyclopropane with TCNE also results in the formation of cycloaddition products (6). The mechanism for this reaction is believed to involve a concerted pathway. Diradical intermediates or dipolar (zwitterionic) intermediates were ruled out on the basis of the observation of a lack of a solvent effect and the fact that the reaction was not quenched by radical scavengers.

Earlier, Roth and co-workers studied the radical cation of 2,2-dianisyl-1-methylenecyclopropane (7). The radical cation was generated by photoinduced electron transfer using chloranil (triplet) as the electron acceptor. The products from this reaction were 1:1 (MCP–chloranil) addition products. CIDNP studies (7) indicated the presence of two different types of

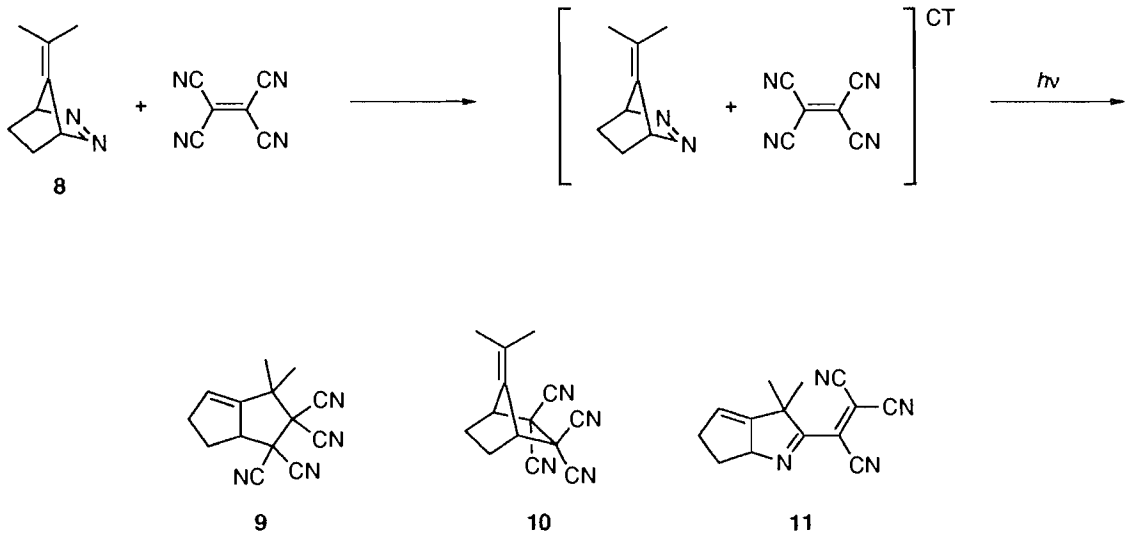
Scheme 3.



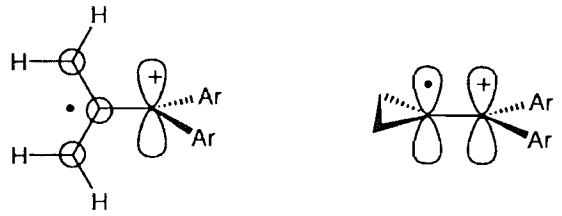


Fig. 2. Intermediates detected in the photoreaction of 2,2-dianisyl-1-methylenecyclopropane with chloranil using CIDNP (7).

radical cations: (*a*) a ring-opened species in which the spin is delocalized in an allyl moiety and the charge is localized on the diarylmethylene group, and (*b*) a ring-closed species in which the spin is localized on the tertiary cyclopropane carbon and the charge is localized on the diarylmethylene group (Fig. 2).

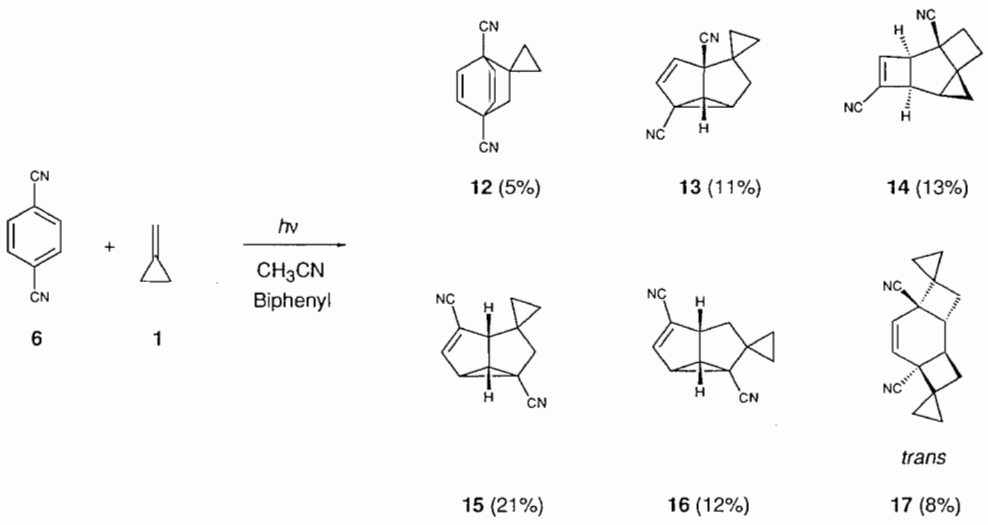
It is clear that the reactivity of the radical cation of methylenecyclopropane ($\mathbf{1}^{+\cdot}$) and that of the trimethylenemethane radical cation ($\mathbf{1a}^{+\cdot}$) are interesting and that there is some controversy regarding reaction pathways. Obviously, the structure and reactivity of these substituted species will be different from that of the unsubstituted compound, and it is perhaps surprising that the reactions of the parent molecules (radical cations) have not been studied.

In this paper, the results of the reactions of methylenecyclopropane (**1**) studied by photochemical and electrochemical methods in the presence and in the absence of nucleophiles are presented and possible mechanisms for product formation are discussed.

Results and discussion

Photochemistry of methylenecyclopropane (1)

It has been shown that radical cations undergo rapid nucleophilic addition (1, 2, 10). This is useful because the product distribution will enable us to assess spin and charge distributions in the radical cations. However, a main goal of this research is to determine whether the radical cation of methylenecyclopropane (MCP, **1**) undergoes dimerization and, if so, what is the structure(s) of the dimeric product(s). Addition of a nucleophile to the reaction mixture might compete with the dimerization as was observed before (1*b*). Dimerization is also more likely to occur when the concentration of MCP is greater. To favour dimerization, an attempt was made to generate the radical cation of MCP by photoinduced electron transfer using 1,4-dicyanobenzene (DCB, **6**) as the electron acceptor, biphenyl (**7**) as the codonor,[4] with the alkene present in excess (MCP:DCB = 5:1), and in the absence of a nucleophile.



Irradiation of a 0.5 M solution of MCP (**1**) in acetonitrile using DCB (**6**, 0.1 M) as the electron acceptor and biphenyl (**7**, 0.1 M) as the codonor leads to the formation of photocycloaddition (*ortho*, *meta*, and *para*) products (Reaction [1]). Identification of the products was initially made largely on the basis of the ^{1}H and ^{13}C nmr and mass spectra; X-ray crystallography confirmed the proposed structures.[5] Progress of the reaction was followed by gc/ms and gc/fid. The product ratios did not change over the duration of the irradiation. The final product ratios are **12**:**13**:**14**:**15**:**16**:**17** = 1.0:1.8:1.8:2.9:1.7:1.1. Formation of this type of cycloaddition product in the photo-

[4] The use of biphenyl (**7**) as a codonor in photoinduced electron transfer (PET) processes to increase the yield of the free radical ion pairs by reducing back electron transfer has been discussed (1*b*,2).

[5] Data for **12–16** may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0R6. Details of data collection, structural analysis and refinement, and tables of interatomic distances and bond angles have also been deposited with the Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Reaction [1]

reactions of 1,4-dicyanobenzene is quite uncommon. The only previously reported example is that resulting from the irradiation of a mixture of **6** and 1,5-hexadiene (2*a*).

Another interesting example is the formation of cycloaddition products in the photochemical reaction of 1,4-dicyanonaphthalene with 2,3-dimethyl-2-butene (11). However, in this reaction, the initial intermediates are believed to be the radical ions. Also, in this reaction there are several rearrangements taking place (deprotonation–reprotonation) that are inconsistent with a simple cycloaddition reaction.

Photocycloaddition reactions generally do not occur with exocyclic double bonds. One reported example of such a reaction is that of methylenecyclobutane with benzene (12).

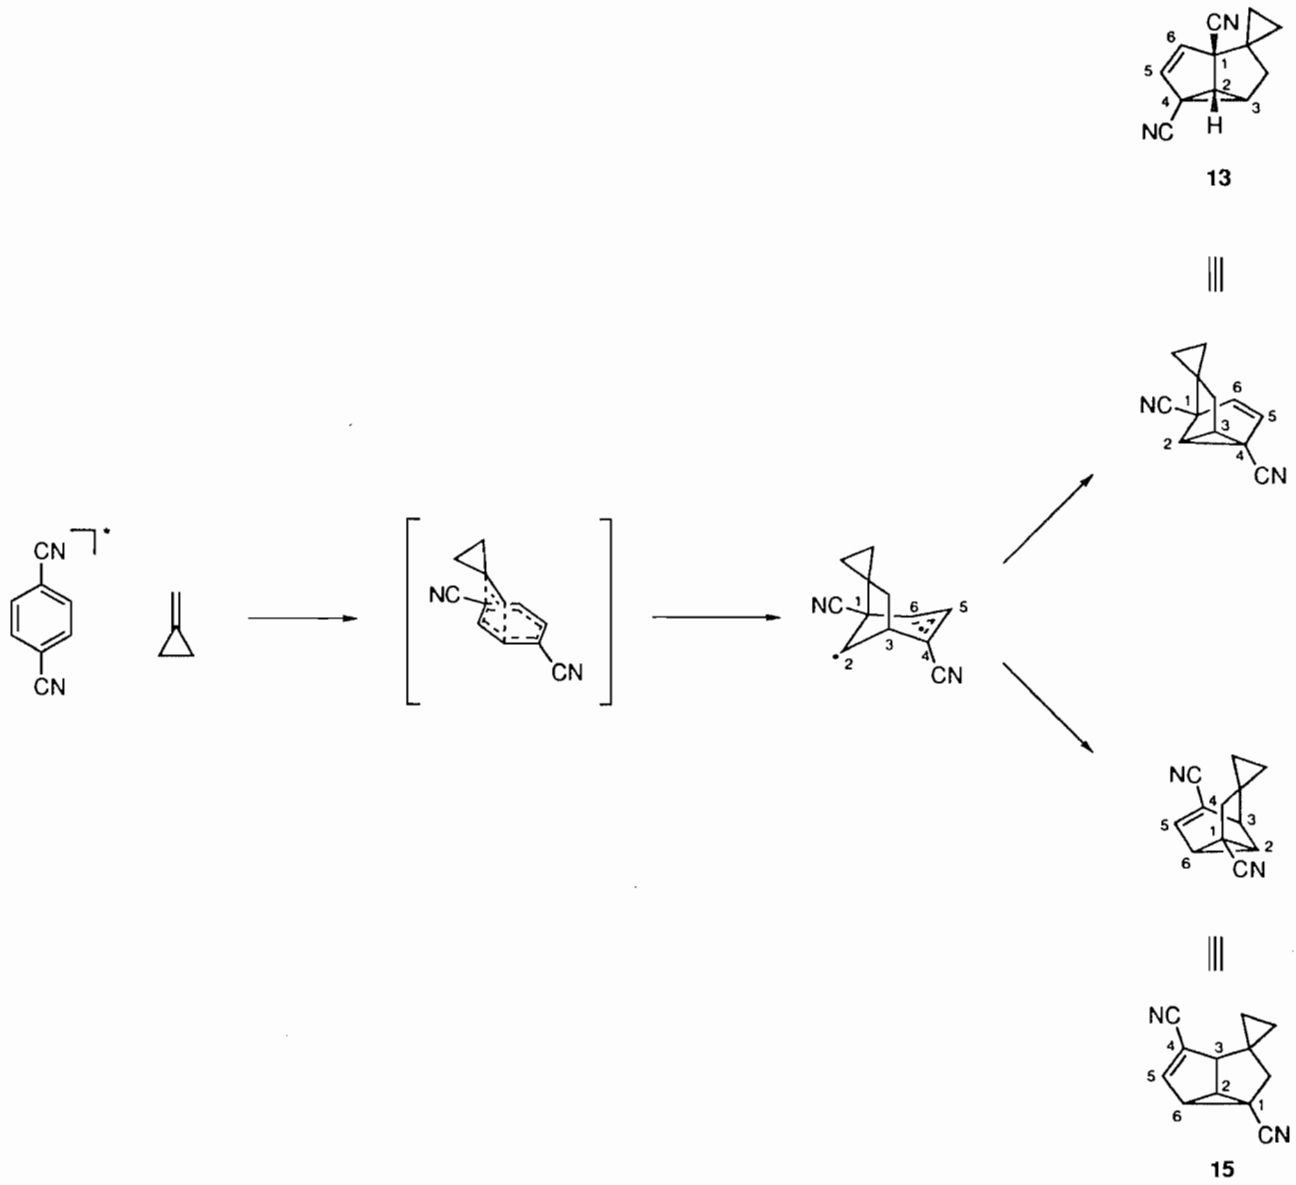
Three of the major products (**13**, **15**, and **16**) in the photoreaction of MCP and **6** in acetonitrile are the result of a *meta* photocycloaddition. The mechanism for the formation of *meta* photocycloaddition products has been studied extensively (13). From the observed *meta* addition products in the photoreaction of **1** with **6**, and the relative yields of the products, it can be concluded that there is a preference for 1,3-addition; in fact, all three *meta* adducts isolated from this mixture are products of initial 1,3-bond formation. This is in accord with studies on other disubstituted arenes carrying electron-acceptor substituents (13, 14). Addition of the alkene moiety to the 1 and 3 positions of the arene allows for charge stabilization of the intermediate. The favoured additions for **1** with **6** (^1S state) are shown in Scheme 4. Clearly, the formation of **15** and **16** proceeds through the same intermediate, the difference being the orientation of the MCP moiety.

Mattay (15) established guidelines for predicting the type of reaction that will take place upon irradiation of a mixture containing an arene and an alkene. The guidelines are based on the reduction potential of the arene and the oxidation potential of the alkene. The energetics can be calculated using the Weller equation (eq. [1]) (16).

$$[1] \quad \Delta G_{et} = F[E_{ox}(D) - E_{red}(A) - e/\varepsilon\alpha] - E_{0,0}(A)$$

It was shown that electron transfer and substitution take place when ΔG is less than 0.0 eV. *ortho* Cycloadditions take place when ΔG is between 0.0 and +1.5 eV, and *meta* cycloadditions occur when ΔG is larger than +1.5 eV. It must be noted that these boundaries are not sharp; several exceptions are known. *para* Photocycloadditions are rarely observed and it was shown by Scharf et al. (17) that this mode of reaction occurs from a secondary photochemical event.

In the photoreaction of **1** with **6** one *para* cycloaddition product was observed. A possible mechanism is combination of the radical cation and the radical anion pair to yield the observed cycloaddition product. This mechanism is unlikely since calculations (1*a*, 18) and ESR experiments (9) have shown that the MCP radical cation ($\mathbf{1}^{+\bullet}$) undergoes a rapid ring opening to give the TMM radical cation ($\mathbf{1a}^{+\bullet}$).



An interesting observation is the formation of the 2:1 (alkene:arene) adduct (**17**). Mattay and co-workers claim to have observed this type of adduct in the photoreaction of *m*-bis(trifluoromethyl)benzene with cyclopentene (14*a*). However, the product identification was based on mass spectra only; no attempt to isolate these 2:1 adducts was undertaken in this case, and their structural assignment remains tentative. Gilbert and co-workers claimed the formation of 2:1 adducts in the photoreaction of benzene and cyclopropene. Again, no pure compounds were isolated but several possible structures were proposed, based on the assumption that the products are the result of a 1:1 addition of the cyclopropene dimer to benzene (14*b*).

A single *ortho* photocycloaddition reaction of MCP to **6** can be used to explain the formation of product **14** (Scheme 5; pathway I). *ortho* Addition of MCP to **6** leads to the intermediate bicyclooctadiene **18**, which can undergo a ring opening to give the cyclooctatriene **19**. There is precedence in the literature for these types of (secondary) reactions (2*a*, 19). Formation of the final product (**14**) can be accounted for by a modified cyclopropyl–π-methane rearrangement (20). This reaction, discovered by Zimmerman and co-workers, pro-

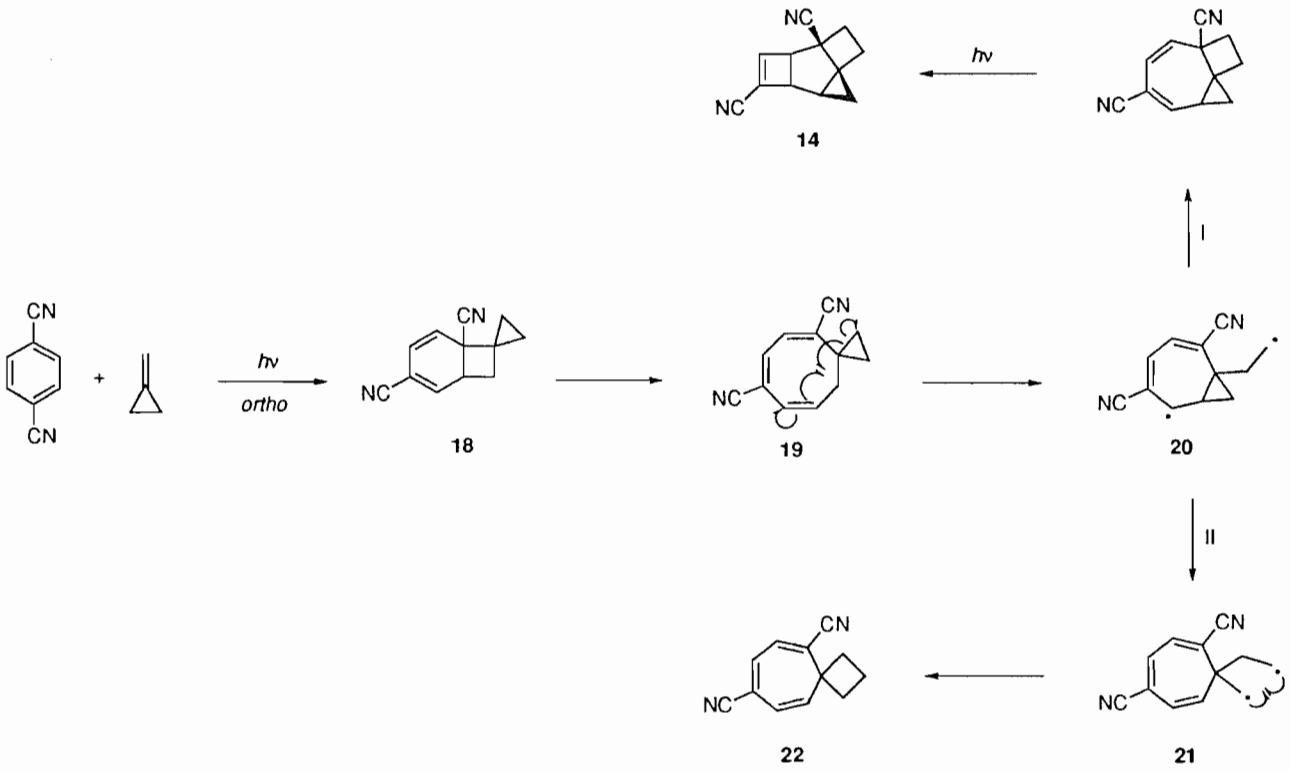
Scheme 4.

ceeds by a mechanism (Scheme 6) that parallels that of the well-known di-π-methane rearrangement (21). The cyclopropyl–π-methane rearrangement of **19**, however, would lead to compound **22** (Scheme 5, pathway II), which was not observed.[6] Instead, the 1,5-diradical intermediate (**20**) undergoes a ring closure to give the observed product (**14**).

It is not clear why the observed product (**14**) is preferred over the product expected from the cyclopropyl π-methane rearrangement (**22**). One possible explanation is that intermediate **21** is disfavoured due to the presence of two primary radical centres. Furthermore, the presence of two cyano groups could have a significant effect on the stability of the radical centres in **20**, favouring pathway I rather than pathway II (Scheme 5).

The measured (CV) oxidation potential of **1** is 2.41 V.[7] Using the Weller equation (eq. [1]), this leads to a value of −5 kcal mol^{-1} for ΔG_{et}. Electron transfer is therefore expected to



[6] It must be noted that the six isolated products are the major products of the photoreaction of MCP with **6**. Analysis of the final product mixture indicated the presence of at least six additional products with mass spectra very similar to those of the isolated products. However, since all of these additional products are only minor products, it can be concluded that the normal cyclopropyl–π-methane rearrangement is not an important pathway in this reaction.

[7] It must be noted that the oxidation potentials of the alkenes are irreversible, i.e., the number has no thermodynamic significance. However, it has been well established that in many cases reliable values for the E_{ox} can be obtained from the measured peak potentials (36).

take place at the diffusion-controlled rate. However, the product mixture clearly indicates that ET does not occur; formation of the radical cation of **1** is expected to lead to the ring-opened trimethylenemethane radical cation (see above) (1*a*, 18). This was shown to be true by a recent ESR study on the MCP radical cation (9). None of the isolated products of the reaction of **1** with **6** show any indication of a ring-opened MCP unit, another good indication that electron transfer does not take place.

Lowering the MCP concentration to 0.1 M does not lead to different results, except for the fact that the reaction becomes less efficient. The efficiency of the reaction is also reduced upon increasing the biphenyl (**7**) concentration. However, no other products are formed as a result of a higher biphenyl or a lower MCP concentration.

It is well known that cycloadditions occur more rapidly in nonpolar solvents since polar solvents favour electron transfer. When the photoreaction of **1** with **6** is carried out in a nonpolar solvent ($CHCl_3$, ε = 4.8) rather than a polar solvent (CH_3CN, ε = 35.7) the same products are observed. The relative product ratios **12**:**13**:**14**:**15**:**16**:**17** are now 1.0:1.8:1.2:2.8:1.4:0.3. With the exception of products **14** and **17** these ratios are close to those observed for the reaction in acetonitrile, providing strong evidence that in both cases the same mechanism is operative.

Analysis of the product mixture shows that in all cases the cyclopropyl moiety remained closed. The rearrangement leading to product **14** does cleave the cyclopropyl unit but the initially formed *ortho* adduct must have the cyclopropyl (ring-closed) group (Scheme 5). This indicates that the mechanism does not proceed through a diradical, radical ionic, or zwitterionic intermediate, because these intermediates are expected to give mainly products resulting from addition of the ring-opened species to the arene.

To be able to understand the observation that no electron transfer takes place, even though the measured (CV) oxidation potential is low enough for the rate of electron transfer to be diffusion controlled, the ionization potential (IP, gas phase) of MCP was taken into account. It has been established that there is a good correlation between the oxidation potential (OP, solution) and the ionization potential (IP, gas phase) of a compound. Neikam et al. (22) measured the oxidation potentials and the ionization potentials of a large number of arenes and alkenes and determined the correlation, eq. [2].[8] (There are several correlations available; for others see refs. 23 and 24.)

$$[2] \quad E_{ox} = (0.827 \times IP - 5.40)\ V$$

Using this correlation and the experimentally determined IP (vertical) (25), the E_{ox} of **1** was calculated to be 2.88 V (sce). Using the Weller equation (eq. [1]) the calculated ΔG for the reaction with **6** is now +5.8 kcal mol^{-1} (+0.25 eV). Based on these numbers it is clear that electron transfer is unlikely and that the major reaction pathway will be cycloaddition. Other alkenes were also considered in this study; the results are shown in Table 1.

Ab initio molecular orbital calculations (MP2/6–31G*//HF/6–31G*) were used to calculate the ionization potentials of the alkenes listed in Table 1. Both the adiabatic and the vertical ionization potentials were considered. The experimental (vertical) ionization potentials were found in the literature (25).

Plots of the experimental (CV) oxidation potential against the vertical ionization potential (calculated) (Fig. 3; r^2 = 0.774) and against the adiabatic ionization potential (calculated) (Fig. 4; r^2 = 0.903) show that the correlation between the adiabatic IP and the experimental E_{ox} is better. Note that

[8] This correlation gives the oxidation potential vs. Ag/Ag^+. To convert this oxidation potential to the value relative to sce, 0.34 V has to be added.

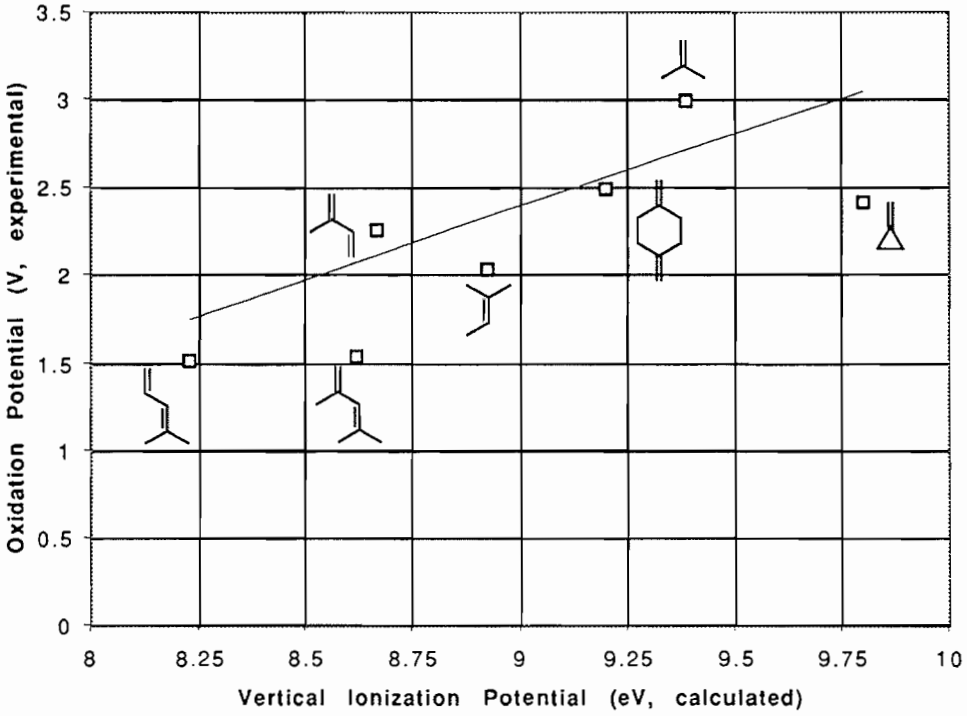
Fig. 3. Correlation between the vertical ionization potentials (calculated) and the experimentally determined oxidation potentials (□) of the alkenes listed in Table 1. The line represents the expected oxidation potential based on the vertical ionization potential (calculated) using eq. [2].



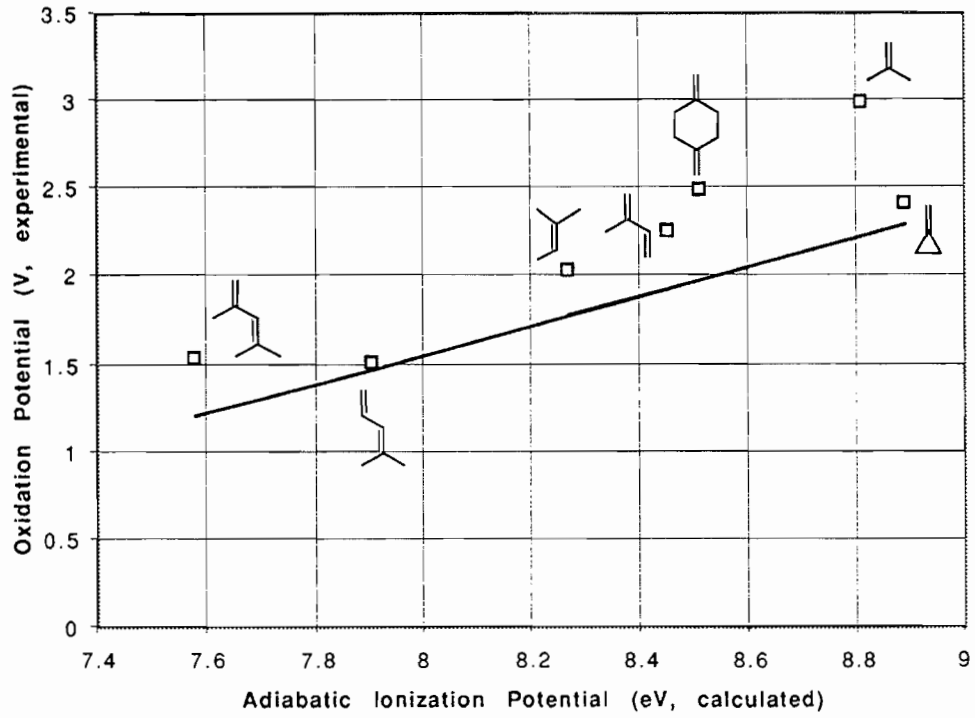


Fig. 4. Correlation between the adiabatic ionization potentials (calculated) and the experimentally determined oxidation potentials (□) of the alkenes listed in Table 1. The line represents the expected oxidation potential based on the adiabatic ionization potential (calculated) using eq. [2].

the line does not represent the best fit of the measured points; it represents the expected oxidation potential based on the ionization potential (calculated) using eq. [2].

It can be seen from Fig. 3 that there are two IP points (MCP and 2,4-dimethyl-1,3-pentadiene) that deviate markedly from the expected oxidation potential based on the vertical IP (calculated). Ignoring these two points significantly improves the correlation ($r^2 = 0.925$). The oxidation potentials of these two

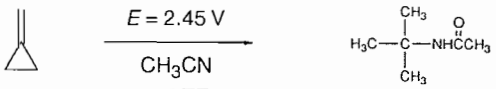
compounds show a much better correlation with the adiabatic IP (calculated) (Fig. 4).



It must be concluded that for MCP in the electrochemical experiments the measured OP reflects the adiabatic IP rather than the vertical IP. In the photochemical experiments it is the vertical IP that determines the reactivity. This variation could result from an interaction (formation of a complex) between the alkene and the Pt electrode. MCP is a highly strained molecule and interaction with the electrode might lead to a relief of strain by a partial ring opening. This type of reaction has precedence; there are many examples of metal-catalyzed ring-opening reactions of methylenecyclopropanes (26, 27). A commonly observed reaction is metal atom insertion. The metals frequently used for this type of reaction are Ni and Pd; however, there are also examples of Pt-catalyzed reactions.

The other major exception listed in Table 1 is 2,4-dimethyl-1,3-pentadiene. This molecule has an E_{ox} of 1.53 V, a value close to that of 4-methyl-1,3-pentadiene (1.51 V). The major difference between these two neutral molecules is that the latter is planar, (s-*trans*) conjugated whereas the former is not. The calculated dihedral angle between the double bonds of 2,4-dimethyl-1,3-pentadiene is ca. 50°, i.e., significantly twisted from the s-*cis* conformation. It was shown by ab initio MO calculations that the global minimum of the radical cation of 2,4-dimethyl-1,3-pentadiene is planar (2*e*). All four methyl groups stabilize the radical cation. However, the initially formed radical cation (vertical ionization) will have a twisted geometry (s-*cis*) and must overcome the barrier to become planar (adiabatic). Based on this data one would expect a higher OP for 2,4-dimethyl-1,3-pentadiene than for 4-methyl-1,3-pentadiene. However, the measured values are essentially the same. Interaction of the twisted diene with the electrode surface might reduce the twist of the dihedral angle, resulting in a lower oxidation potential (adiabatic) than expected on the basis of the measured (vertical) ionization potential. However, in the photoinduced electron transfer reactions of this diene, there will be no assistance for the neutral molecule to become planar and therefore the electron transfer will reflect the vertical rather than the adiabatic IP. This is also evident from a comparison of the results of the PET reactions of these two molecules (4-methyl-1,3-pentadiene and 2,4-dimethyl-1,3-pentadiene) (2*e*). The efficiency of the reaction of the twisted diene is significantly lower than that of the planar diene. For the twisted diene to reach the same amount of conversion as the planar diene it has to be irradiated almost twice as long as the planar diene even though the measured oxidation potentials are virtually the same (2*e*). This once again supports the conclusion that, in photochemical reactions, electron transfer is dependent on the vertical ionization potential rather than the adiabatic IP.

Photochemistry of methylenecyclopropane (1) in the presence of a nucleophile

Irradiation of a mixture of methylenecyclopropane (**1**, 0.1 M), biphenyl (**7**, 0.1 M), and 1,4-dicyanobenzene (**6**, 0.1 M) in acetonitrile–methanol (3:1) leads to the formation of essentially the same products as the irradiation without methanol. The reaction was followed by gc/ms and gc/fid; identification of the products was based on their retention times and mass spectra. A careful analysis of the chromatograms and the mass spectra revealed the presence of a few additional minor products. The mass spectra of these compounds were very similar to those of the cycloaddition products with the exception that the molecular ion was at *m/z* 184 rather than *m/z* 182. These compounds are most likely the reduced cycloaddition products. These minor products were not isolated from the mixture.

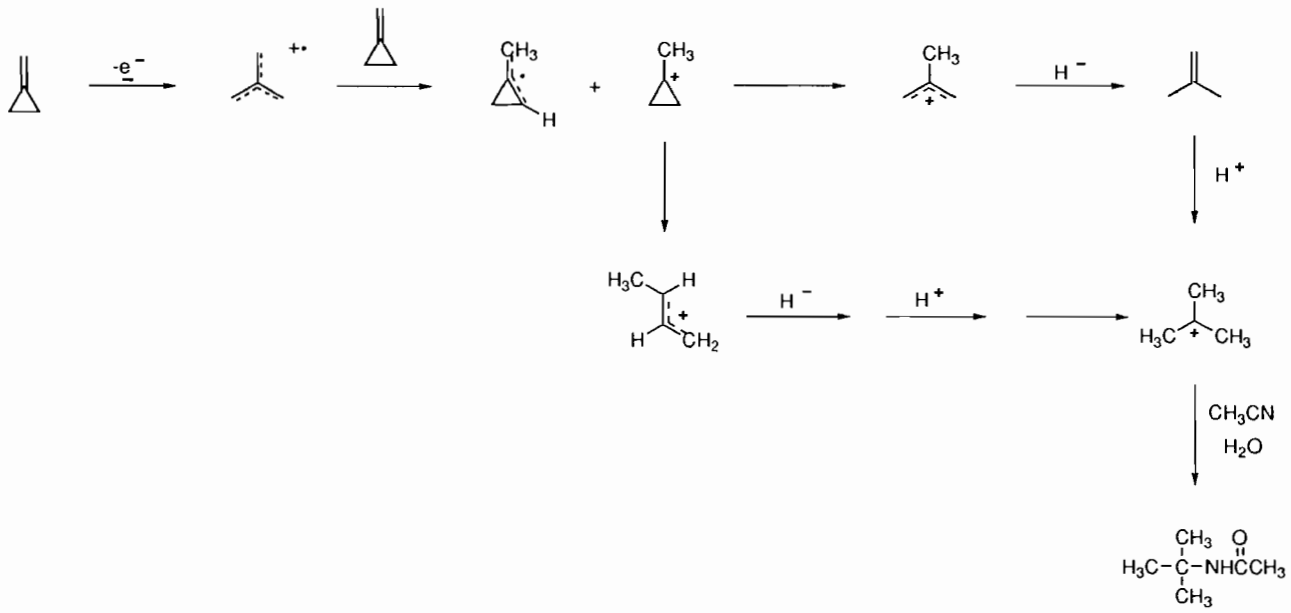
Reaction [2]

23

The observed ratios of the cycloaddition products are different from those obtained in the experiments using acetonitrile or chloroform as the solvent. With methanol present the ratios are **12**:**13**:**14**:**15**:**16**:**17** = 1.0:1.8:0.1:1.4:0.6:1.7. The most significant difference is the almost complete absence of product **14** in this product mixture. The mechanism for the formation of this compound (a "modified" cyclopropyl–π-methane rearrangement) was discussed earlier (Scheme 5). The mechanism for the cyclopropyl–π-methane rearrangement shows that the fate of the reaction is determined by the pathway of the diradical intermediate (e.g., **20**). Opening of the cyclopropyl group followed by ring closure to give a cyclobutane moiety is the normal course of the reaction (Schemes 5 and 6). However, in a similar reaction, Zimmerman and Carpenter discovered that the diradical intermediate reacted to give a very small amount of the cyclobutane product when the reaction was carried out in pentane but none when the solvent was *tert*-butanol (20*b*). It is possible that the diradical (**20**) in the reaction of MCP with **6** is trapped by the solvent (methanol), leading ultimately to a reduced species.

The results of this reaction once again clearly indicate that, upon irradiation of a mixture of **6** and **1**, no electron transfer takes place. Under these conditions (i.e., the use of **6** as the electron acceptor) the energetic requirements for ET are not met. Formation of an exciplex between the first singlet excited state of **6** and MCP followed by cycloaddition is the preferred reaction pathway.

Electrochemical oxidation of methylenecyclopropane (1) in the absence of a nucleophile



Attempts to generate the MCP radical cation by photoinduced electron transfer using 1,4-dicyanobenzene (**6**) as the electron acceptor (see above) were not successful due to the high vertical IP of MCP. However, it was shown that the measured (CV) E_{ox} was only 2.41 V, close to the value expected based on the calculated adiabatic IP. Anodic oxidation of MCP at a low (<2.5 V) potential should therefore lead to the formation of the radical cation. Its reactivity can then be studied in the presence and absence of nucleophiles.

Anodic oxidation of MCP at a potential difference of 2.45 V in acetonitrile (no methanol) using TEAP as the electrolyte results in the formation of one major product: *tert*-butylacetamide (**23**) (Reaction [2]).

This product (*tert*-butylacetamide, **23**) can be rationalized by the formation of the (relatively) stable *tert*-butyl cation, which then goes on to react with acetonitrile to give the

© 1997 NRC Canada

Scheme 7.

23

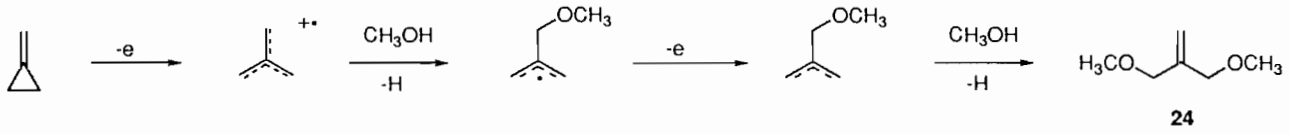
observed product (after hydrolysis). A possible mechanism for the formation of the *tert*-butyl cation is shown in Scheme 7.

An important intermediate is the 2-methylallyl cation, a result of a proton transfer from $\mathbf{1a}^{+\bullet}$ to **1** followed by ring opening. It was shown in the previous part of this series that, under non-nucleophilic conditions, anodic oxidation of alkenes can lead to deprotonation (1*b*). Even in the presence of methanol, a good nucleophile, one of the major products in the anodic oxidation of 1,4-bis(methylene)cyclohexane (**2**) was the result of a protonation of the methylene group as the initial step. The proton source is the highly acidic alkene radical cation. Furthermore, a recent ESR study on $\mathbf{1}^{+\bullet}$ showed that this species exists as the ring-opened TMM radical cation, $\mathbf{1a}^{+\bullet}$ (9). However, upon warming the matrix from 77 to 120 K, the radical cation lost a proton and supposedly underwent a ring closure to give the allylic 2-methylenecyclopropyl radical (Scheme 7, step 2).[9]

Protonation of MCP (i.e., MCP acting as the base) leads to the methylcyclopropylium ion, which can undergo a ring opening to give the 2-methylallyl cation or the 1-methylallyl cation. Hydride transfer from a suitable donor (e.g., MCP) followed by protonation (and a rearrangement in the case of the 1-methylallyl cation pathway) leads to the *tert*-butyl cation. The pathway leading to isobutylene as an intermediate seems the most likely one because this involves fewer rearrangements. It has also been shown that *tert*-butylacetamide can be prepared from isobutylene and acetonitrile using an acid catalyst (28). The formation of the *tert*-butyl cation through rearrangements has additional precedence. Anodic oxidation of bromoalkanes leads to the formation of their corresponding acetamido compounds (29). For example, *tert*-butylacetamide was observed as a product in the reactions of 2-bromobutane and 1-bromo-2-methylpropane (29*b*). The anodic oxidation of 1-bromopentane leads to the formation of *N*-1-pentylacetamide, *N*-2-pentylacetamide, and *N*-3-pentylacetamide in equal amounts, indicating that the initially formed carbocation undergoes multiple rearrangements (29*a*).

The precursor to the methylcyclopropylium ion (1-bromo-1-methylcyclopropane) has not been studied by electrochemistry. However, a gas phase study (MS) on the radical cation revealed that loss of a bromine atom leads to the 1-methylcyclopropylium ion, which then undergoes a ring opening to the 1-methylallyl cation rather than the 2-methylallyl cation (30). The results were in agreement with MNDO calculations on these species. In solution, formation of the 2-methylallyl cation seems more likely (see above). As mentioned above, formation of the *tert*-butyl cation from MCP may involve one or more rearrangements. Both experimental (31) and theoretical (32) results on the $C_4H_7^+$ species have indicated that there is evidence for an equilibrium involving the nonclassical bicyclobutonium ion and the bisected cyclopropylcarbinyl cation. Rearrangements to other $C_4H_7^+$ species do not require much energy and are also expected to happen rapidly. For a four-carbon cationic species, the *tert*-butyl cation is the lowest energy structure that can be formed. The driving force for reaction towards this species will be large, even though this may involve several rearrangements, including hydride transfers.

Electrochemical oxidation of methylenecyclopropane (1) in the presence of a nucleophile



To see whether any of the possible radical cation or cation intermediates could be trapped, the anodic oxidation of MCP was carried out in the presence of a nucleophile (methanol). Under these conditions, one major product was formed: 3-methoxy-2-(methoxymethyl)-1-propene (**24**) (Reaction [3]).

[9] The authors did not propose a mechanism for this reaction and it must be noted that, in principle, the radical cation $\mathbf{1a}^{+\bullet}$ could abstract a hydrogen atom from a neutral molecule (MCP, **1**) to yield the allylic radical and the allylic cation. Either way, this reaction involves two species: the neutral (**1**) and the radical cation ($\mathbf{1a}^{+\bullet}$).

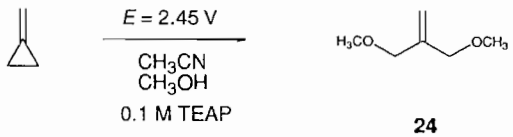
Scheme 8.



24

Scheme 9.

Reaction [3]

24

Based on the results of the anodic oxidation of **2** under similar conditions (1*b*) this is an expected product. Formation of the (ring-opened; TMM) radical cation (**1a**$^{+\bullet}$) followed by nucleophilic addition and loss of a proton from the distonic radical cation leads to the allylic radical. A second oxidation followed by a second nucleophilic addition and deprotonation yields the final product (Scheme 8). This sequence parallels that of the formation of several products found in the anodic oxidation of 1,4-bis(methylene)cyclohexane (**2**) (1*b*).

It must be noted that it is possible that some of the primary products of this reaction may be too volatile to be observed with conventional gc/fid and gc/ms. For example, it was shown before that anodic oxidation of alkenes in the presence of a nucleophile can lead to allylic substituted products (1*b*, 33) Even though the formation of these types of products from MCP would most likely require a ring-closed species (**1**$^{+\bullet}$, an unlikely intermediate), their presence cannot be ruled out. Furthermore, it was also suggested that the ring-closed radical species that was observed by ESR (9), upon warming of the matrix in which the TMM radical cation had been generated, resulted from a hydrogen atom abstraction by the TMM radical cation from a neutral MCP molecule (see footnote 9). Oxidation of this species and nucleophilic addition would also give the allylic substitution products (Scheme 9).

The previous section described the anodic oxidation of MCP in the absence of methanol; under those conditions the formation of the *tert*-butyl cation is favoured. Formation of this species in the presence of methanol is highly unlikely since it involves multiple rearrangements and the reactive intermediates would be trapped before the final intermediate (*tert*-butyl cation) is formed. However, the possible formation of the product resulting from this intermediate (*tert*-butyl methyl ether) cannot be ignored. Analysis of the expected product (*tert*-butyl methyl ether) by gc/fid showed that the retention time is short and its presence in the reaction mixture cannot be ruled out.

Conclusions

The photochemical reactions of methylenecyclopropane (MCP, **1**) in the presence of an electron acceptor (1,4-dicyanobenzene, **6**) were studied under a number of conditions. Using the measured (CV) oxidation potential (E_{ox}) of MCP, electron transfer (ET) was predicted to occur at the diffusion-controlled rate. However, no products resulting from ET were detected; only photocycloaddition products were formed under these conditions. The mechanism is believed to be addition of MCP to the ^1S state of **6**. Only products with ring-closed MCP moieties were formed, indicating that radical ions, diradicals or ionic species are not involved. Additional evidence for this conclusion is based upon the fact that product formation was shown to be virtually independent of solvent (MeCN, MeOH, $CHCl_3$) and codonor (biphenyl, **7**) concentration. On the basis of these results it is hypothesized that for PET reactions, formation of the radical ion pair is dictated by the vertical IP. In many cases the measured E_{ox} reflects the vertical IP; however, for certain molecules (e.g., MCP) the difference between the vertical and the adiabatic IP is large. In these cases the initially generated (vertical) radical cation is expected to relax to the adiabatic energy level. For these types of molecules the measured E_{ox} reflects the adiabatic IP rather than the vertical IP. This can be explained in terms of an interaction between the alkene and the Pt electrode that will result in a partial release of strain.

Generation of the radical cation of MCP by anodic oxidation at a potential close to the measured (CV) E_{ox} in the absence of a good nucleophile leads to several rearrangements, resulting in the ultimate formation of the most stable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12

C_4-cation: the *tert*-butyl cation. This species is then trapped by the solvent (acetonitrile) to give the observed product *tert*-butyl-acetamide. In the presence of methanol this intermediate is believed not to be formed; however, it cannot be completely ruled out. Under these conditions the major product is 3-methoxy-2-(methoxymethyl)-1-propene, a result of nucleophilic addition to the ring-opened radical cation followed by a second oxidation and nucleophilic addition. This reactivity was also observed in the anodic oxidation of 1,4-bis(methylene)cyclohexane (**2**) in the presence of methanol (*1b*).

Experimental

General information

The ^1H and ^{13}C nmr spectra were obtained on a Bruker AC250 spectrometer. Frequencies are relative to tetramethylsilane. Infrared spectra were recorded on a Nicolet 205 spectrometer and are reported in wave numbers (cm^{-1}). Exact mass determinations were obtained using a CEC 21–110B spectrometer. Melting points were determined using a Cybron Corporation Thermolyne apparatus with a digital thermocouple and are corrected. Product yields were determined using a Hewlett–Packard (HP) 5890 gas chromatograph with a DB-1701 fused silica WCOT column (30 m × 0.25 mm, 0.25 μm film thickness) and a calibrated flame ionization detector (gc/fid). An HP 3392A integrator was interfaced with the gc/fid to obtain peak areas. An HP 5890 gas chromatograph with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33 μm film thickness) interfaced with an HP 5970 mass selective detector (gc/ms) was also used for product analyses. Mass spectra are reported as *m/z* (relative intensity). Separation of product mixtures was generally carried out using preparative medium-pressure liquid chromatography (mplc), followed by dry column flash chromatography (dcfc) (34). The mplc consists of a 2.5 cm × 1 m column packed with thin-layer chromatography (tlc) grade silica gel (Rose Scientific Ltd., Silica Gel G/UV-254 with gypsum binder, cat. no. 81632) at a pressure of 18 psi using helium (1 psi = 6.9 kPa). Connected to the mplc was a uv spectrophotometer – fraction collector that collects ca. 20 mL fractions. For dcfc the column was packed with thin-layer chromatography grade silica gel (Rose Scientific Ltd., Silica Gel G/UV-254 with gypsum binder, cat. no. 81632). Fraction sizes were ca. 10 mL.

Materials

Anhydrous acetonitrile (Aldrich) and anhydrous methanol (Aldrich) were stored over molecular sieves (3 Å) upon arrival and used without further purification. 1,4-Dicyanobenzene (**6**) (Aldrich) was purified by treatment with Norite in methylene chloride, followed by recrystallization from 95% ethanol. Biphenyl (**7**) (Eastman Kodak) was recrystallized from methanol. Tetraethylammonium perchlorate (TEAP) (Fisher) was recrystallized three times from water and then dried in a vacuum oven for 15 h, 70°C, 0.25 Torr (1 Torr = 133.3 Pa). Methylenecyclopropane (**1**) was prepared as described below. *tert*-Butyl methyl ether, sodium amide, di-*n*-butyl ether, methallyl chloride (2-chloromethyl-1-propene), and potassium *tert*-butoxide (1.0 M solution in *tert*-butanol) were all received from Aldrich and used without further purification.

Irradiations

Irradiations were generally carried out on solutions of acetonitrile (with or without methanol as the nucleophile) with 1,4-dicyanobenzene (**6**), the alkene, and with or without a codonor (biphenyl, **7**). Solutions were irradiated in either 2 cm i.d. Pyrex tubes or 5 mm Pyrex nmr tubes. The samples were irradiated at 10°C using a CGE 1 kW medium-pressure mercury vapour lamp contained in a water-cooled quartz immersion well.

Cyclic voltammetric measurements

Cyclic voltammetry at a sweep rate of 100 mV/s was used to obtain the oxidation potential of the alkene. The apparatus has been described (35). The working electrode was a platinum sphere (1 mm diameter) and the counter electrode was a platinum wire. The reference electrode was a saturated calomel electrode (sce), which was connected to the solution (TEAP 0.1 M, acetonitrile) through a Luggin capillary. The alkene concentration was ca. 0.005 M. Since the anodic wave was irreversible, the half-wave potential was taken as 0.028 V before the anodic peak potential (36).

Controlled potential electrolyses

Controlled potential electrolyses of **1** were performed with a double-wall two-electrode cell (total volume 200 mL) containing the working electrode and the reference electrode (sce). The counter electrode compartment, containing the counter electrode, was fitted into the cell; the two compartments were connected by means of fine glass frit. Both the working electrode and counter electrode were platinum mesh (6.5 cm^2). The reference electrode was the standard calomel electrode (sce). The cell was kept at a temperature of 10 (±0.5)°C.

The electrochemical measurements were obtained with a Princeton Applied Research (PAR) 173 potentiostat in combination with a PAR 175 universal programmer and a PAR 179 digital coulometer.

Synthesis of methylenecyclopropane (1)

Methylenecyclopropane (**1**) was synthesized according to literature procedures (37) with some minor modifications. A 250 mL 3-neck round-bottom flask equipped with a pressure equalizing dropping funnel (with a nitrogen inlet) and a condenser was charged with 20 g sodium amide and 50 mL di-*n*-butyl ether. This mixture was refluxed under nitrogen for ca. 15 min after which 40 mL of methallyl chloride was added dropwise over a period of 40 min. The volatile products were removed from the flask by a small nitrogen flow through a trap containing 50 mL 5 N H_2SO_4 followed by an empty trap (kept at room temperature), and were then condensed in a trap cooled by an acetone – Dry Ice mixture. Analysis of this mixture by ^1H and ^{13}C nmr indicated the presence of both methylenecyclopropane and methylcyclopropene in a ratio of about 1:4. The mixture was transferred to a flask containing 50 mL dimethyl sulfoxide after which 10 mL of a 1.0 M solution of potassium *tert*-butoxide in *tert*-butanol was added. The mixture was stirred for 1 h at room temperature and then for 2 h at reflux temperature. During this reflux period the volatiles were carried over through an empty trap (room temperature) to a cold trap (cooled by an acetone – Dry Ice mixture) with a small nitrogen flow. Afterwards, the trap contained ca. 10 mL

of product (≈50% yield). Analysis of the contents of the trap by ^{1}H and ^{13}C nmr indicated the presence of pure methylenecyclopropane (**1**) (37).

Irradiation of a mixture of methylenecyclopropane (1), 1,4-dicyanobenzene (6), and biphenyl (7) in acetonitrile

A solution containing 6 g (1.1×10^{-1} mol) methylenecyclopropane (**1**), 3.1 g (2.4×10^{-2} mol) 1,4-dicyanobenzene (**6**), and 3.7 g (2.4×10^{-2} mol) biphenyl (**7**) dissolved in 240 mL anhydrous acetonitrile was irradiated for 20 days. After this period the solvent and the volatile products were removed by rotary evaporation. The residue was chromatographed on silica gel (mplc) using a hexanes–ether gradient. Further purification of the products was achieved by dcfc. Identification of the products was based on the ^{1}H and ^{13}C nmr spectra and the X-ray diffraction spectra. The yields of the reaction were determined by calibrated gc/fid. All yields are based on the amount of 1,4-dicyanobenzene (**6**) that was consumed in the reaction.

124.43 (d), 119.85 (s), 35.94 (d), 35.77 (s), 30.62 (t), 26.23 (s), 12.02 (t), 6.78 (t); ms *m/z*: 236 ($M^{+\cdot}$, 1%), 235 (7), 221 (4), 207 (27), 194 (8), 179 (21), 167 (7), 154 (21), 140 (10), 129 (11), 116 (20), 104 (13), 91 (10), 77 (15), 63 (11), 54 (100), 51 (21); Exact Mass of ion $C_{16}H_{16}N_2$: 236.1313; measured: 236.1290.

Irradiation of methylenecyclopropane (1) and 1,4-dicyanobenzene (6) in acetonitrile

A 0.1 M solution (40 mL) of MCP (**1**) in acetonitrile containing 0.5 g (3.9×10^{-3} mol) 1,4-dicyanobenzene (**6**) and 0.6 g (3.9×10^{-3} mol) biphenyl (**7**) was irradiated through Pyrex with the 1 kW lamp for 30 days. The reaction was followed by gc/fid and gc/ms. Analysis of the product mixture indicated the presence of the same products as in the reaction with a larger MCP concentration; however, the reaction was less efficient than before.

Influence of the biphenyl (7) concentration on the product formation in the irradiation of methylenecyclopropane (1) and 1,4-dicyanobenzene (6) in acetonitrile

Solutions (2 mL) containing 0.1 M (50 μL) MCP (**1**) and 0.1 M (25 mg) 1,4-dicyanobenzene (**6**), as well as 0.1 M (30 mg), 0.25 M (78 mg), and 0.5 M (154 mg) biphenyl (**7**) were irradiated through Pyrex with the 1 kW lamp for 40 h. The reactions were followed by gc/fid and gc/ms. Analysis of the product mixtures indicated that the same products were formed in each reaction. Increasing the biphenyl concentration decreases the efficiency of the reaction. No other products were formed.

Irradiation of methylenecyclopropane (1) and 1,4-dicyanobenzene (6) in chloroform

A solution of 0.7 g (1.3×10^{-2} mol) methylenecyclopropane (**1**) and 1.55 g (1.2×10^{-2} mol) 1,4-dicyanobenzene (**6**) in 200 mL chloroform was irradiated for 5 days through Pyrex with the 1 kW lamp. The reaction was followed by gc/ms and gc/fid. Analysis of the product mixture by gc/fid and gc/ms indicated the formation of the same products that were observed in the experiment with acetonitrile as the solvent.

Irradiation of a mixture of methylenecyclopropane (1) and 1,4-dicyanobenzene (6) in acetonitrile–methanol (3:1)

A solution of 0.2 g (3.7×10^{-3} mol) methylenecyclopropane (**1**), 0.5 g (3.9×10^{-3} mol) 1,4-dicyanobenzene (**6**), and 0.6 g (3.9×10^{-3} mol) biphenyl (**7**) in 40 mL acetonitrile–methanol (3:1 by volume) solution was irradiated through Pyrex with the 1 kW lamp for 40 days. The reaction was followed by gc/fid and gc/ms. Product identification was based on retention time (two different columns) and mass spectra. Several other products were tentatively identified as the reduced 1:1 cycloadducts; identification is based on their mass spectra.

Electrolysis of a solution of methylenecyclopropane (1) in acetonitrile

A solution of 4.6 g (2.0×10^{-2} mol) tetraethylammonium perchlorate (TEAP) in 200 mL acetonitrile was deaerated for 30 min by nitrogen ebullition. After this period 6.5 mL (9.6×10^{-2} mol) methylenecyclopropane (**1**) was added to the solution and a potential difference of 2.45 V was applied to the cell. The reaction was stopped after 1080 coulombs had been consumed (ca. 10% conversion; calculated on basis of a one-electron oxidation).[10] The solvent was evaporated and the residue was washed with benzene to remove the residual TEAP. Evaporation of the benzene left the crude product, which was identified as *N-tert*-butylacetamide (**23**, 25%) based on its ^{1}H nmr, ^{13}C nmr (38*a*,*b*), and mass spectra (38*b*).

N-tert-Butylacetamide (23): ^{1}H nmr ($CDCl_3$) δ: 7.36 (s, 1H), 1.94 (s, 3H), 1.35 (s, 9H); ^{13}C nmr ($CDCl_3$) δ: 170.11 (s), 51.36 (s), 28.63 (q), 24.22 (q); ms *m/z*: 115 ($M^{+\cdot}$, 7%), 100 (10), 64 (5), 60 (21), 59 (17), 58 (100), 56 (7).

Electrolysis of a solution of methylenecyclopropane (1) in acetonitrile–methanol (3:1)

A solution of 4.6 g TEAP (2.0×10^{-2} mol) in 200 mL acetonitrile–methanol (3:1) was purged with nitrogen for 45 min. A potential difference of 2.45 V was applied to the cell for 2 h for background correction. After this period the coulometer was reset and 6.5 mL MCP (5.2 g, 9.6×10^{-2} mol) was added to the solution and the potential difference (2.45 V) was applied to the cell again. The reaction was allowed to continue until 2085 C had been consumed (ca. 11% conversion; calculated on basis of a two-electron oxidation) (see footnote 10). Analysis of the product mixture by gc/ms revealed the presence of one major product (**24**) and several minor products. Identification of product **24** (3-methoxy-2-(methoxymethyl)-1-propene) is based on its mass spectrum.

3-Methoxy-2-(methoxymethyl)-1-propene (24): ms *m/z*: 116 ($M^{+\cdot}$, 0.1%), 115 (1), 101 (2), 85 (18), 84 (47), 75 (18), 71 (100), 69 (12), 58 (9), 56 (16), 55 (55), 53 (13).

Acknowledgement

This work was supported by grants from the Natural Sciences and Engineering Research Council of Canada. We thank Dr. D.L. Hooper the Atlantic Region Magnetic Resonance Centre at Dalhousie University for help in the preparation of the manuscript. Exact Mass determinations were carried out by Dr. J.-H. Kim (Dalhousie Chemistry Mass Spectrometry Lab). H.J.P.dL. is grateful for a scholarship from the Izaak Walton Killam Memorial foundation.

[10] Calculation of the conversion of MCP was done using the formula (1*b*): $a = (Q^*M)/(n^*F)$. In this equation, n is the number of electrons involved in the oxidation process per molecule substrate, Q is the total amount of coulombs consumed, M is the molecular weight of the substrate, a is the amount of substrate that has been converted (in grams), and F is Faraday's constant. Based on our previous experiments (ref. 1*b*) the electrooxidation in the presence of a nucleophile is known to be a two-electron process, whereas the electrooxidation in acetonitrile is a one-electron process. Using these assumptions, and the values of Q, the conversion of MCP can be calculated.

Photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction, Part 15. Investigations involving fluoride anion as the nucleophile and the effect of fluorine substitution on the relative stability of the reaction intermediates[1]

Mary S.W. Chan and Donald R. Arnold

Abstract: The scope of the photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction has been extended to include fluoride anion as the nucleophile. The 4-cyanophenyl substituted fluoroalkanes were obtained in moderate yields with 2,3-dimethyl-2-butene and 2-methyl-2-butene reacting as the olefin. The yields were lower with 2-methylpropene, and no photo-NOCAS products were detected when conjugated dienes were used as the olefin. The selectivity of the fluoride anion towards alkenes can be explained in terms of the Hard–Soft-Acid–Base (HSAB) principle. The regiochemistry of this reaction can be described as predominantly following the *anti*-Markovnikov mode of addition. The fluoride anion adds preferentially to the less alkyl-substituted end of an unsymmetrical alkene radical cation to produce the more heavily substituted β-fluoroalkyl radical. Ab initio molecular orbital calculations (MP2/6-31G*//HF/6-31G*) were used to determine the relative stability of the β-fluoroalkyl radical intermediates. The more heavily substituted β-fluoroalkyl radical is NOT the more stable. The addition step is kinetically, rather than thermodynamically, controlled.

Key words: photochemistry, radical ions, electron transfer, alkyl fluorides, nucleophilic addition.

Résumé : On a élargi le domaine d'application de la réaction photochimique de combinaison nucléophile–oléfine avec substitution aromatique («photo-NOCAS») de façon à inclure l'anion fluorure comme nucléophile. Utilisant le 2,3-diméthylbut-2-ène et le 2-méthylbut-2-ène comme oléfine pour la réaction, on a obtenu des rendements modérés de fluoroalcanes substitués par le 4-cyanophényle. Les rendements ont été inférieurs avec le 2-méthylpropène et on n'a observé aucun produit «photo-NOCAS» lorsqu'on a utilisé des diènes comme oléfines. On peut expliquer la sélectivité de l'anion fluorure pour les alcènes en termes du concept des acides et des bases dures et molles. On peut décrire la régiochimie de cette réaction à l'aide du mode d'addition *anti*-Markovnikov. L'anion s'additionne d'une façon préférentielle à l'extrémité la moins substituée par des groupes alkyles du cation radical d'un alcène non symétrique; ceci conduit à la formation préférentielle du radical β-fluoroalkyle le plus substitué. On a fait appel à des calculs d'orbitales moléculaires ab initio (MP2/6-31G*//HF/6-31G*) pour déterminer les stabilités relatives des radicaux β-fluoroalkyles intermédiaires. Le radical β-fluoroalkyle le plus substitué n'est PAS le plus stable. L'étape d'addition est contrôlée d'une façon cinétique plutôt que d'une façon thermodynamique.

Mots clés : photochimie, ions radicaux, transfert d'électron, fluorures d'alkyles, addition nucléophile.

Introduction

Organofluorine compounds can be found in a variety of industrial applications. Some of these include lubricants, coatings, propellants, pharmaceuticals, blood substitutes, liquid crystals, and textile chemicals (1). One of the more important applications is isosteric replacement, the replacement of a hydrogen atom, hydroxyl group, or another halogen by a fluorine atom. The similarity in size of the fluorine and the hydrogen atom results in negligible steric effects, yet the significant difference in electronegativity produces pronounced effects on the electronic distribution within the molecule. These characteristics make isosteric replacement an ideal structural modification for altering the chemical and biological activities of organic compounds. For this reason, the selective formation of a carbon–fluorine bond has been, and continues to be, the focus of intensive research (2). In this paper, we report a highly selective, one-step synthesis for fluoroalkanes starting from simple alkenes. The fluoro-substituted compounds were obtained from the photochemical nucleophile–olefin combi-

nation, aromatic substitution (photo-NOCAS) reaction with fluoride anion serving as the nucleophile.

The mechanism of the photo-NOCAS reaction had been analyzed and documented (3). The proposed mechanism for the reaction, using 2,3-dimethyl-2-butene as the olefin, is shown in Scheme 1. The scope and limitations of this reaction with regard to the olefin in combination with alcoholic nucleophiles have been extensively investigated; only recently has this study been extended to other nucleophiles (3*f*). Figure 1 summarizes the results of the reaction involving simple alkenes when methanol or cyanide anion serves as the nucleophile. The regiochemistry in all cases can be considered as predominately *anti*-Markovnikov, where the nucleophile adds to the less substituted carbon of the double bond. The reasons for this preference have also been rationalized (3*e*, *f*). In the case of methanol serving as the nucleophile, distonic radical cations that can equilibrate via a bridged structure are initially formed. The regiochemistry is thermodynamically controlled and the product distribution is dependent on the stability of the β-alkoxyalkyl radical intermediates (Scheme 1, step 3). When

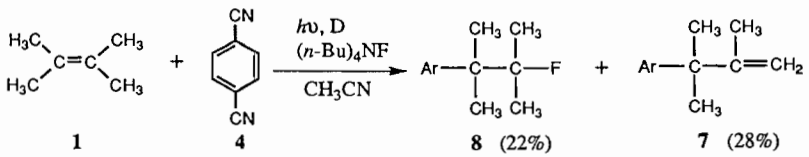
cyanide anion reacts as the nucleophile, the β-cyano or β-isocyano alkyl radicals cannot bridge, the regiochemistry is kinetically controlled, and steric factors dominate. Similar experimental and theoretical investigation of the photo-NOCAS reaction with fluoride anion serving as the nucleophile will be described. The olefins chosen for this study were 2,3-dimethyl-2-butene (**1**), 2-methylpropene (**2**), and 2-methyl-2-butene (**3**).



Results

Irradiation of an acetonitrile solution of 1,4-dicyanobenzene (**4**), biphenyl (**5**), tetrabutylammonium fluoride (**6**), and 2,3-dimethyl-2-butene (**1**) resulted in one major 1:1 (alkene:1,4-dicyanobenzene) adduct and one photo-NOCAS product (Reaction [1]). The 1:1 adduct, 3-(4-cyanophenyl)-2,3-dimethyl-1-butene (**7**), was obtained in 28% yield. The yield of the photo-NOCAS product, 3-(4-cyanophenyl)-2-fluoro-2,3-dimethylbutane (**8**), was 22%. The addition of the codonor, biphenyl, increased the efficiency of the reaction, but had no affect on the relative amounts of these reaction products.

The photo-NOCAS reaction of 2,3-dimethyl-2-butene (**1**) was also attempted using potassium fluoride as the fluoride ion source. These irradiations were identical to the ones involving **6** with the exception that an equal molar amount of KF and 18-crown-6 was added instead. The use of KF as a source of fluoride ion did not affect the identity of the products, but significantly more 1:1 (alkene: 1,4-dicyanobenzene) adducts were observed. For this reason, tetrabutylammonium fluoride (**6**) was used in the subsequent large-scale reactions to improve the yield of the photo-NOCAS products.

A similar irradiation of an acetonitrile solution of **4**, **5**, **6**, and 2-methylpropene (**2**) resulted in a 1:1 (alkene:1,4-dicyanobenzene) adduct and two photo-NOCAS products (Reaction [2]). The 1:1 adduct, 3-(4-cyanophenyl)-2-methylpropene (**9**), was obtained in 8% yield. The *anti*-Markovnikov photo-NOCAS product, 2-(4-cyanophenyl)-1-fluoro-2-methylpropane (**10**), was isolated in 5% yield. A trace amount of the Markovnikov isomer, 1-(4-cyanophenyl)-2-fluoro-2-methylpropane, was identified (gc/ms, ^{1}H and ^{13}C nmr) but it was not isolated. Integration of a gc/ms chromatograph obtained from single ion monitoring for the molecular ion

Reaction [2]

Reaction [3]

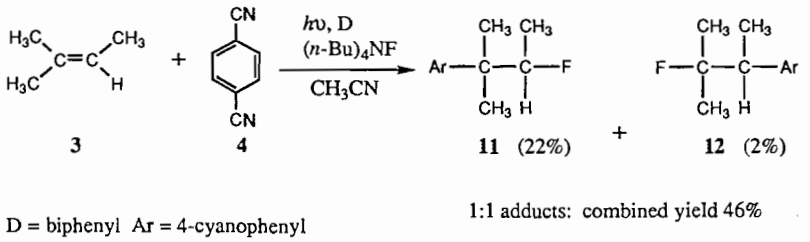

Table 1. Calculated enthalpy change for reaction 2b as a function of theoretical model.

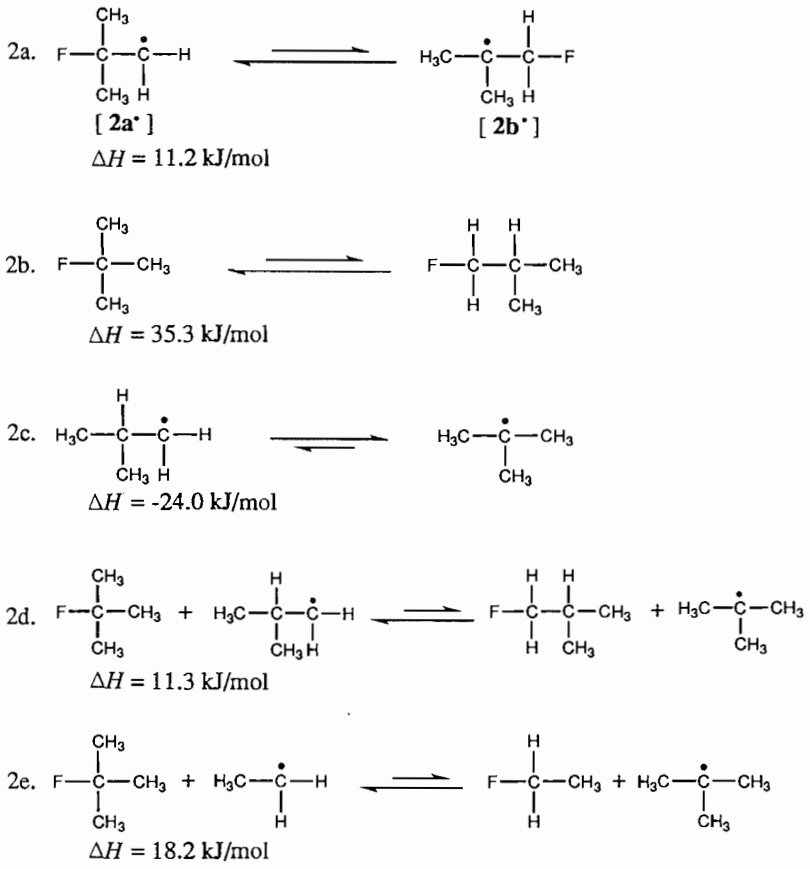
Theoretical model	2-Fluoro-2-methylpropane (au)	1-Fluoro-2-methylpropane (au)	ΔH (kJ/mol)
HF/6-31G*//HF/6-31G*	−256.159 00	−256.148 10	28.62
MP2/6-31G*//HF/6-31G*	−256.855 96	−256.842 52	35.29
MP2/6-31G*//MP2/6-31G*	−256.857 00	−256.843 76	34.76
MP2/6-311+G*//MP2/6-31G*	−256.988 41	−256.975 13	34.87

gave a ratio of 95: 5 (*anti*-Markovnikov:Markovnikov) for the two photo-NOCAS products. This ratio remained constant as a function of irradiation time. Again, the addition of the codonor, biphenyl, increased the efficiency of the reaction, but did not have any affect on the product ratios.

The stability of the radical intermediates resulting from the reaction of the 2-methylpropene radical cation with fluoride anion was estimated by ab initio molecular orbital calculations. The relevant isodesmic reactions, along with enthalpy changes calculated from MP2/6-31G*//HF/6-31G* energies, are shown in Fig. 2. The isodesmic reaction 2a is a direct comparison of the two β-fluoroalkyl radical intermediates resulting from the Markovnikov (**2a**·) and *anti*-Markovnikov (**2b**·) modes of addition. Reactions 2b and 2c separate the effect of alkyl substitution on the fluoro and radical moiety, respectively. The sum of these two reactions shows the combined effect of the two factors on the overall stability of the β-fluoroalkyl radicals (reaction 2d). The isodesmic reaction 2e is an alternative way of separating these two effects. β-Fluoroalkyl radicals do not show a tendency to bridge (4), and the results of the calculations were consistent with this. Geometry optimization starting from a symetrically bridged radical converged to the more stable open radical (**2a**·).

The calculated thermodynamic stability of fluoro-substituted compounds has not been extensively investigated, and the question of an appropriate theoretical model to evaluate the enthalpy changes of these isodesmic reactions should be addressed. Therefore, the influence of the theoretical model on the ΔH of reaction 2b was examined and the results are summarized in Table 1.



Irradiation of an acetonitrile solution of **4**, **5**, **6**, and 2-methyl-2-butene (**3**) resulted in four 1:1 (alkene:1,4-dicyanobenzene) adducts and two photo-NOCAS products (Reaction [3]). The combined yield of the four 1:1 adducts was 46%. The *anti*-Markovnikov photo-NOCAS product, 3-(4-cyanophenyl)-2-fluoro-3-methylbutane (**11**), was isolated in 22% yield; whereas the Markovnikov product, 3-(4-cyanophenyl)-2-fluoro-2-methylbutane (**12**), was obtained in only 2% yield. The ratio of *anti*-Markovnikov to Markovnikov prod-

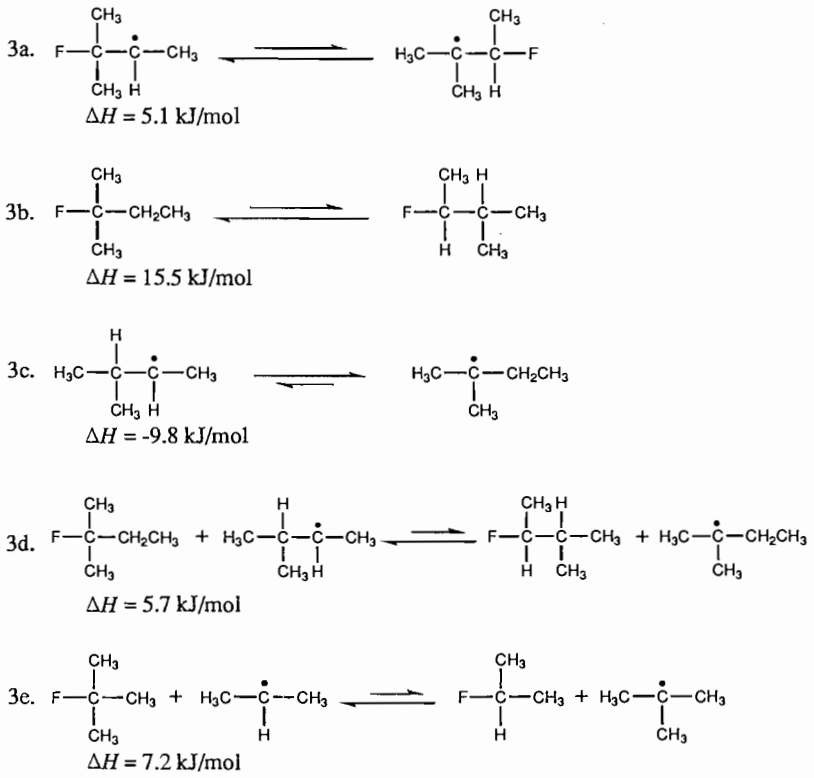
Fig. 2. Isodesmic reactions for 2-methylpropene reaction intermediates.[3]

ucts was found to be 89:11 by integration of a gc/ms chromatograph obtained by single ion monitoring for the molecular ion. This ratio is independent of irradiation time. The addition of a codonor, biphenyl, increased the efficiency of the reaction but had no effect on the product ratios.

The stability of the radical intermediates for this reaction was also evaluated by ab initio molecular orbital calculations. Figure 3 shows the relevant isodesmic reactions and their enthalpy changes. The analysis for this alkene is identical to that described above for the 2-methylpropene reaction. Again, there was no evidence for bridging of the β-fluoroalkyl radical intermediate for this alkene.

The feasibility of the photo-NOCAS reaction with fluoride anion serving as the nucleophile and conjugated dienes serving as the olefin was also investigated. The dienes chosen for this study were 1,3-butadiene, 2-methyl-1,3-butadiene, 4-methyl-1,3-pentadiene, 2,4-dimethyl-1,3-pentadiene, and 2,5-dimethyl-2,4-hexadiene. Irradiation of an acetonitrile solution of 1,4-dicyanobenzene (**4**), biphenyl (**5**), diene, and tetrabutylammonium fluoride (**6**) did not result in any photo-NOCAS products. The mass spectrum obtained from the gc/ms chromatographs of these reaction mixtures suggested that 1:1 (diene:1,4-dicyanobenzene) adducts and dimers of the dienes were the major products.

Discussion



The results of this study illustrate that the photo-NOCAS reaction with fluoride anion serving as the nucleophile is feasible. The photo-NOCAS products incorporating fluoride anion were obtained in reasonable yields with little attempt to optimize the reaction conditions. The fluoride anion has been shown to react as a nucleophile (n_{CH_3I} = 2.7) (5) and as a base (pK_a of HF = 3.2) (6). Therefore, it is not surprising that deprotonation of the alkene radical cation, where the fluoride anion behaves as a base rather than a nucleophile, is a major competing reaction. In fact, the 1:1 adducts resulting from the coupling of the allylic radical and the radical anion of 1,4-dicyanobenzene (Scheme 1, step 10) were the major product(s) in all of the reactions studied. This type of adduct is commonly observed when irradiations are carried out in the absence of a nucleophile (3*a*,*b*). Even though radical cations are known to be highly acidic species (7), there is direct evidence that the fluoride anion enhances the deprotonation step. The radical cation of 2-methylpropene does not deprotonate easily; the resultant allylic radical is primary on both ambident ends (Scheme 1, step 9). The 1:1 adduct (**9**) resulting from the deprotonation of the radical cation followed by coupling with the radical anion of the 1,4-dicyanobenzene is only observed in trace amounts in the absence of added base (8). The fluoride anion reacting as a base is also the major competing pathway in the preparation of alkyl fluorides by normal (S_N1, S_N2) nucleophilic substitution (5*b*, 9).

The addition of fluoride anion to the radical cation of unsymmetrical alkenes shows high regioselectivity. The regiochemistry can be described as predominately following the *anti*-Markovnikov mode of addition, where the nucleo-

Fig. 3. Isodesmic reactions for 2-methyl-2-butene reaction intermediates.[3]

phile (fluoride) adds preferentially to the less substituted olefinic carbon to produce the more heavily alkyl-substituted radical. At this point, one may be tempted to conclude that the regioselectivity is governed by the relative stability of the β-fluoroalkyl radical intermediates. However, the theoretical calculations show that this is not the case. For both unsymmetrical alkenes studied, the radical resulting from the Markovnikov addition of fluoride is the more stable of the two alternative β-fluoroalkyl radicals (isodesmic reactions 2a and 3a). Nucleophilic addition to the alkene radical cation is highly exothermic, this results in an early transition state, and the product distribution is determined before the relative stability of the alternative intermediate radicals becomes important. These experimental and theoretical results indicate that the fluoride anion behaves like the cyanide anion: the addition is kinetically controlled, steric and polar factors dominate.

Contrary to expected trends, the ab initio molecular orbital calculations indicate that the primary radical (**2a**·) is 11 kJ/mol more stable than the tertiary radical (**2b**·) (isodesmic reaction 2a). The validity of the level of theory employed for these calculations is a question that should be addressed. The MP2/6-31G*//HF/6-31G* theoretical model was shown to be sufficient for estimating the relative stability of ethers (3*e*) and alkyl radicals (the ΔH of reaction 2c is −15.9 kJ/mol calculated from experimentally determined heats of formation (10)). However, there is little information with regard to fluoro-substituted compounds. Calculations on fluorinated aromatic compounds suggest that electron correlation and diffuse functions were not important for evaluating the enthalpy change of isodesmic reactions (11). The isodesmic reaction 2b compares the relative stability of a primary and a tertiary fluoro-substituted alkane. The enthalpy change of this reaction was calculated at various theoretical levels, and the results are reported in Table 1. Including electron correlation (MP2) in the form of single-point energy calculations produces notable differences in the ΔH value. However, including electron correlation in the optimization procedure and further increasing the basis set to 6-311+G* in the single-point calculations did not change the ΔH value significantly. These results suggest that the MP2/6-31G*//HF/6-31G* level of theory is sufficient for estimating the relative stability of fluoro-substituted compounds using isodesmic reactions.

The relative stabilities of the β-fluoroalkyl radicals were further investigated by calculating the enthalpy change of isodesmic reactions 2b–2e and 3b–3e. Reaction 2b indicates that a tertiary substituted fluoroalkane is 35 kJ/mol more stable than a primary substituted fluoroalkane, whereas a tertiary alkyl radical is more stable than a primary alkyl radical by only 24 kJ/mol (reaction 2c). Obviously the effect of the fluoro substitutent dominates when the two effects are combined (reaction 2d). The isodesmic reaction 2e is an alternative method of separating these two effects. The general agreement between reactions 2a, 2d, and 2e is reassuring. In the case of 2-methyl-2-butene, the comparison is now between a secondary β-fluoroalkyl radical and a tertiary β-fluoroalkyl radical. Still, the effect of the fluoro substitutent dominates: the secondary radical is more stable than the tertiary radical by 5 kJ/mol (isodesmic reaction 3a). The energy difference between a secondary and a tertiary alkyl radical is 10 kJ/mol (reaction 3c), and that between a secondary and tertiary substituted fluoro-

© 1997 NRC Canada

alkane is 16 kJ/mol (reaction 3b). The sum of these two reactions (reaction 3d) agrees well with the relative stability of the two β-fluoroalkyl radicals (reaction 3a). The tendency for fluoro substituents to cause abnormal behavior as compared to their hydrocarbon analogs has been well documented and this effect has been used to advantage in organic synthesis and mechanistic studies (12).

The attempted photo-NOCAS reaction with fluoride anion reacting as the nucleophile did not result in the desired products when conjugate dienes were employed as the olefin. This behavior is related to that observed when cyanide anion was used as the nucleophile. The nitrogen atom of the ambident cyanide anion reacts as a nucleophile to produce isonitrile products only with alkenes. No trace of the isonitrile products were found when conjugate dienes were used. This selectivity was explained in terms of the hard–soft-acid–base (HSAB) principle. The fluoride anion falls into the hard category (13). Relatively speaking, the radical cations of alkenes can be considered as harder than those of conjugated dienes. Therefore, the hard fluoride anion nucleophile prefers to react with hard alkene radical cations. The photo-NOCAS reaction incorporating fluoride as the nucleophile is then limited to hard electrophiles.

Conclusions

The fluoride anion can serve as an effective nucleophile in the photo-NOCAS reaction. The 4-cyanophenyl substituted fluoroalkanes were obtained in reasonable yields with monoalkenes. The reaction is not effective with conjugated dienes. This reactivity can be explained in terms of the HSAB principle; the hard fluoride anion prefers to react with the relatively harder alkene radical cation.

The reaction is regioselective, with the fluoride anion adding preferentially to the less substituted end of an unsymmetrical alkene. The product ratios are not a reflection of the relative stability of the alternative β-fluoroalkyl radical intermediates; the addition is kinetically controlled, and the product ratio is determined before the relative stability of the resulting radicals becomes important; steric and polar effects dominate.

The degree of alkyl substitution on the carbon atom bearing the fluorine substituent produces substantial differences in stability. This can be attributed to the highly electronegative nature of the fluorine atom. In fact, the effect of alkyl substitution on a fluoroalkane is larger than on a carbon radical center. Consequently the more heavily substituted β-fluoroalkyl radical in not the more stable of the two possible intermediates for the unsymmetrical alkenes studied.

Computational details

The GAUSSIAN 94 package of programs (14) was employed for all ab initio molecular orbital calculations. The geometries of the open-shell systems were fully optimized at the unrestricted Hartree–Fock level with the 6-31G* basis set.[4] Single-point energies were calculated to second order in Møller–Plesset perturbation theory (MP2) (16) using the 6-31G* basis set at the HF/6-31G* optimized geometries, and were corrected for spin contamination where appropriate. Unless otherwise noted, all of the structures were optimized using the Berny optimization procedure (17) without symmetry constraints and were confirmed, by harmonic frequency analyses, to be minima on their respective potential energy surfaces. The charge and spin density distributions were obtained from Mulliken population analysis (18).

Experimental

General information

Progress of the reactions was monitored by using a Hewlett–Packard (HP) 5890 gas chromatograph with a BD-1701 fused silica WCOT column (20 m × 0.25 mm, 0.4 μm film thickness) and a flame ionization detector (gc/fid). An HP 3392A integrator is interfaced with the gc/fid to obtain peak areas. An HP 5890 gas chromatograph with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33 μm film thickness) interfaced with an HP 5970 mass selective detector (gc/ms) was also used for product analysis. Exact Mass determinations were obtained using a CEC 21-110 mass spectrometer. The mass spectra are reported as *m/z* (relative intensity). The ^{1}H and ^{13}C nmr spectra were obtained from a Bruker 250 or 400 MSL spectrometer. Spectra were recorded in parts per million and frequencies are relative to tetramethylsilane. Infrared spectra (ir) were recorded on a Nicolet 205 spectrometer and are reported in wave numbers (cm^{-1}). Separation of the reaction mixtures was carried out using a combination of the following chromatographic methods: preparative, centrifugally accelerated, radial, thin-layer chromatography (chromatotron),[5] using 1, 2, or 4 mm plates prepared with thin-layer chromatography (tlc) grade silica gel (with binder and fluorescent indicator, Merck 7749); dry column flash chromatography (dcfc) (19) packed with tlc grade silica gel (with binder, Rose Scientific Ltd. 81632); preparative thin-layer chromatography using precoated silica gel plates (2 mm thickness, Merck 5717).

Materials

Acetonitrile was distilled twice, first from sodium hydride and then from phosphorus pentoxide. It was then passed through a column of basic alumina, refluxed over calcium hydride for 24 h (under a nitrogen atmosphere), fractionally distilled, and stored over 3Å molecular sieves. 1,4-Dicyanobenzene (Aldrich) was purified by treatment with activated carbon in methylene chloride, followed by recrystallization from 95% ethanol. Biphenyl was recrystallized three times from methanol before use. Tetrabutylammonium fluoride (Aldrich) was dried at 55°C under vacuum for 24 h just prior to use. 2-Methylpropene (Matheson), 2,3-dimethyl-2-butene (Aldrich), and 2-methyl-2-butene (Aldrich) were used as received.

Irradiations

Irradiations were carried out on acetonitrile solutions of 1,4-dicyanobenzene (**4**), the alkene, tetrabutylammonium fluoride (**6**), and biphenyl (**5**) (serving as a codonor). These solutions were irradiated in either 2 cm inner diameter Pyrex tubes or

5 mm Pyrex nmr tubes, which were degassed by either nitrogen or alkene ebullition. The samples were irradiated at 10°C using a CGE 1 kW medium-pressure mercury vapor lamp contained in a water-cooled quartz immersion well. The yields of the reaction products were calculated based on the amount of 1,4-dicyanobenzene consumed.

Reaction of 2,3-dimethyl-2-butene with 1,4-dicyanobenzene and tetrabutylammonium fluoride

A solution of 1,4-dicyanobenzene (**4**) (1.0401 g, 0.0081 mol), biphenyl (**5**) (1.2151 g, 0.0079 mol), and tetrabutylammonium fluoride (**6**) (3.7161 g, 0.014 mol) in acetonitrile (160 mL) was degassed by nitrogen ebullition. 2,3-Dimethyl-2-butene (**1**) (2.0 mL, 0.017 mol) was added to the reaction mixture, and the solution was irradiated for 24.0 h. Removal of the solvent yielded the crude photolysate. Initial separation of the irradiation mixture was achieved by dcfc using an ether–hexanes gradient. Further purification of the products 3-(4-cyanophenyl)-2,3-dimethyl-1-butene (**7**) and 3-(4-cyanophenyl)-2-fluoro-2,3-dimethylbutane (**8**) was carried out by repeated chromatography (chromatotron) using 100% hexanes as the eluant. Final separation of the 1:1 (alkene:1,4-dicyanobenzene) adduct from the fluoride adduct was achieved by preparative tlc using a 2.5% ether – hexanes gradient (developed twice).

3-(4-Cyanophenyl)-2,3-dimethyl-1-butene (7)

The yield of **7** was 28%. The ^{1}H nmr spectrum agrees well with previously reported results (3*a*): ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.43 (s, 6H, H's of methyl groups adjacent to aryl-substituted carbon), 1.50 (s, 3H, H's of vinylic methyl group), 4.94 (d, 1H, $^2J_{H\text{-}H}$ = 1.2 Hz, vinylic hydrogen), 5.01 (d, 1H, $^2J_{H\text{-}H}$ = 1.2 Hz, vinylic hydrogen), 7.41 (d, 2H, $^3J_{H\text{-}H}$ = 8.5 Hz, H's adjacent to alkyl-substituted aryl carbon), 7.58 (d, 2H, $^3J_{H\text{-}H}$ = 8.5 Hz, H's adjacent to cyano-substituted aryl carbon); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 20.09 (q, vinylic methyl group), 28.08 (q, methyl groups adjacent to aryl-substituted carbon), 44.42 (s, aryl-substituted carbon), 109.61 (s, quaternary aryl carbon, cyano substituted), 110.78 (t, terminal olefinic carbon), 119.13 (s, CN), 126.98 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 132.02 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 151.08 (s, quaternary aryl carbon, alkyl substituted), 154.15 (s, alkyl-substituted olefinic carbon).

3-(4-Cyanophenyl)-2-fluoro-2,3-dimethylbutane (8)

The yield of **8** was 22%: infrared (Nicolet 205) ν: 2989(s), 2229(s), 1608(m), 1506(m), 1474(m), 1377(s), 1098(m), 844(s); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.22 (d, 6H, $^3J_{H\text{-}F}$ = 22.0 Hz, H's of methyl groups adjacent to fluoro-substituted carbon), 1.42 (s, 6H, H's of methyl groups adjacent to aryl-substituted carbon), 7.55 (d, 2H, $^3J_{H\text{-}H}$ = 9.1 Hz, H's adjacent to alkyl-substituted aryl carbon), 7.60 (d, 2H, $^3J_{H\text{-}H}$ = 9.1 Hz, H's adjacent to cyano-substituted aryl carbon); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 23.59 (q, d, $^2J_{C\text{-}F}$ = 24.8 Hz, methyl groups adjacent to fluoro-substituted carbon), 24.14 (q, d, $^3J_{C\text{-}F}$ = 5.7 Hz, methyl groups adjacent to aryl-substituted carbon), 45.12 (s, d, $^2J_{C\text{-}F}$ = 20.0 Hz, aryl-substituted carbon), 98.74 (s, d, $^1J_{C\text{-}F}$ = 175.5 Hz, fluoro-substituted carbon), 109.99 (s, quaternary aryl carbon, cyano substituted), 119.04 (s, CN), 128.80 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.31 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 151.61 (s, quaternary aryl carbon, alkyl substituted); ms *m/z*: 40(25), 61(7), 116(30), 130 (20), 144(100), 145(95), 205(1). Exact Mass calcd. for $C_{13}H_{16}FN$: 205.1267; found: 205.1262.

Reaction of 2-methylpropene with 1,4-dicyanobenzene and tetrabutylammonium fluoride

2-Methylpropene (**1**) was bubbled into a solution of 1,4-dicyanobenzene (**4**) (1.5572 g, 0.012 mol), biphenyl (**5**) (1.9684 g, 0.013 mol), and tetrabutylammonium fluoride (**6**) (3.8249 g, 0.015 mol) in acetonitrile (240 mL). This reaction mixture was irradiated for 50.5 h. The solvent was then removed to afford the crude photolysate. Initial separation of the reaction mixture was achieved by dcfc using a solvent gradient of hexanes and ether. 1,4-Dicyanobenzene (**4**) (0.9318 g, 0.0073 mol) was recovered in this manner (40% conversion). Subsequent purification of the products 3-(4-cyanophenyl)-2-methylpropene (**9**) and 2-(4-cyanophenyl)-1-fluoro-2-methylpropane (**10**) was carried out by repeated chromatography (chromatotron) with 100% hexanes and 0.25% ether – hexanes as eluants, respectively.

A trace amount of 1-(4-cyanophenyl)-2-fluoro-2-methylpropane was also detected. Evidence for this compound consisted of a doublet at 2.95 ppm ($^3J_{H\text{-}F}$ = 21.7 Hz) in the ^{1}H nmr spectrum, indicative of the aryl-substituted methylene group, and, a doublet at 26.69 ppm ($^2J_{C\text{-}F}$ = 24.8 Hz) in the ^{13}C nmr spectrum, indicative of methyl groups adjacent to a fluoro-substituted carbon. Integration of a gc/ms chromatograph obtained from single-ion monitoring mode for the molecular ion (*m/z* = 177) gave a ratio of 95:5 (*anti*-Markovnikov: Markovnikov) for the two photo-NOCAS products.

3-(4-Cyanophenyl)-2-methylpropene (9)

The yield of **9** was 8%: ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.66 (s, 3H, CH_3), 3.36 (s, 2H, methylene group), 4.72 (s, 1H, vinylic hydrogen), 4.86 (s, 1H, vinylic hydrogen), 7.29 (d, 2H, $^3J_{H\text{-}H}$ = 8.5 Hz, H's adjacent to alkyl-substituted aryl carbon), 7.58 (d, 2H, $^3J_{H\text{-}H}$ = 8.5 Hz, H's adjacent to cyano-substituted aryl carbon); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 22.06 (q, CH_3), 44.64 (t, aryl-substituted methylene carbon), 110.07 (s, quaternary aryl carbon, cyano substituted), 113.23 (t, terminal olefinic carbon), 119.09 (s, CN), 129.71 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 132.16 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 143.56 (s), 145.44 (s). These spectral data agree well with previously reported results (20).

2-(4-Cyanophenyl)-1-fluoro-2-methylpropane (10)

The yield of **10** was 5%: infrared (Nicolet 205) ν: 2974(s), 2898(m), 2229(s), 1608(m), 1507(m), 1473(m), 1370(m), 1020(s), 839(s); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.37 (d, 6H, $^4J_{H\text{-}F}$ = 1.8 Hz, H's of methyl groups), 4.38 (d, 2H, $^2J_{H\text{-}F}$ = 47.6 Hz, H's of fluoro-substituted methylene group), 7.49 (d, 2H, $^3J_{H\text{-}H}$ = 8.5 Hz, H's adjacent to alkyl-substituted aryl carbon), 7.63 (d, 2H, $^3J_{H\text{-}H}$ = 8.5 Hz, H's adjacent to cyano-substituted aryl carbon); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 24.61 (q, d, $^3J_{C\text{-}F}$ = 5.8 Hz, methyl groups), 39.81 (s, d, $^2J_{C\text{-}F}$ = 18.1 Hz, aryl-substituted carbon), 90.65 (t, d, $^1J_{C\text{-}F}$ = 178.0 Hz, fluoro-substituted carbon), 110.35 (s, quaternary aryl carbon, cyano substituted), 118.86 (s, CN), 127.02 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 132.12 (d, aromatic

CH adjacent to cyano-substituted aryl carbon), 151.13 (s, d, $^3J_{C\text{-}F}$ = 2.9 Hz, quaternary aryl carbon, alkyl substituted); ms *m/z*: 38(13), 40(12), 116(48), 144(100), 145(17), 177(32). Exact Mass calcd. for $C_{11}H_{12}FN$: 177.0954; found: 177.0955.

Reaction of 2-methyl-2-butene with 1,4-dicyanobenzene and tetrabutylammonium fluoride

A solution of 1,4-dicyanobenzene (**4**) (1.6289 g, 0.013 mol), biphenyl (**5**) (1.8685 g, 0.012 mol), and tetrabutylammonium fluoride (**6**) (6.1549 g, 0.024 mol) in acetonitrile (240 mL) was degassed by nitrogen ebullition. 2-Methyl-2-butene (**3**) (3.0 mL, 0.028 mol) was added to the reaction mixture, and the solution was irradiated for 24.0 h. Removal of the solvent yielded the crude photolysate. Initial separation of the irradiation mixture was achieved by dcfc using an ether–hexanes gradient. 1,4-Dicyanobenzene (**4**) (0.4193 g, 0.0033 mol) was recovered in this manner (74% conversion). Four 1:1 adducts (combined yield of 46%) were also separated from the reaction mixture by dcfc. The identity of these products was deduced by the mass of the molecular ion (*m/z* = 171) and the fragmentation pattern in the mass spectrum. Subsequent purification of the fluoride adducts was carried out by repeated chromatography (chromatotron) using 100% hexanes as the eluant. Final separation of the two isomers was attempted by preparative tlc using a 1.0% ether – hexanes gradient (developed 12 times). Integration of a gc/ms chromatograph obtained from single-ion monitoring mode for the molecular ion (*m/z* = 191) gave a ratio of 89:11 (*anti*-Markovnikov: Markovnikov) for the two photo-NOCAS products.

*3-(4-Cyanophenyl)-2-fluoro-3-methylbutane (**11**)*

The yield of **11** was 22%: infrared (Nicolet 205) ν: 2985(s), 2924(m), 2229(s), 1608(m), 1507(m), 1453(m), 1382(m), 1067(s), 841(s); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.10 (d, d, 3H, $^3J_{H\text{-}H}$ = 6.1 Hz, $^3J_{H\text{-}F}$ = 24.4 Hz, H's of methyl group adjacent to fluoro-substituted carbon), 1.38 (s, 6H, H's of methyl groups adjacent to aryl-substituted carbon), 4.66 (q, d, 1H, $^3J_{H\text{-}H}$ = 6.1 Hz, $^2J_{H\text{-}F}$ = 47.0 Hz, methine proton), 7.50 (d, 2H, $^3J_{H\text{-}H}$ = 8.5 Hz, H's adjacent to alkyl-substituted aryl carbon), 7.61 (d, 2H, $^3J_{H\text{-}H}$ = 8.5 Hz, H's adjacent to cyano-substituted aryl carbon); ^{13}C nmr (100.61 MHz, $CDCl_3$) δ: 16.23 (q, d, $^2J_{C\text{-}F}$ = 24.2 Hz, methyl groups adjacent to fluoro-substituted carbon), 24.07 (q, d, $^3J_{C\text{-}F}$ = 5.3 Hz, methyl group adjacent to aryl-substituted carbon), 24.25 (q, d, $^3J_{C\text{-}F}$ = 4.7 Hz, methyl group adjacent to aryl-substituted carbon), 42.83 (s, d, $^2J_{C\text{-}F}$ = 18.7 Hz, aryl-substituted carbon), 96.36 (s, d, $^1J_{C\text{-}F}$ = 176.5 Hz, fluoro-substituted carbon), 110.48 (s, quaternary aryl carbon, cyano substituted), 119.10 (s, CN), 127.89 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 132.10 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 151.32 (s, quaternary aryl carbon, alkyl substituted); ms *m/z*: 47(2), 104(8), 116(35), 144(100), 145(10), 191(8). Exact Mass calcd. for $C_{12}H_{14}FN$: 191.1110; found: 191.1105.

*3-(4-Cyanophenyl)-2-fluoro-2-methylbutane (**12**)*

The yield of **12** was 2%. Spectral information obtained from a 7:3 (**12**:**11**) mixture: ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.26 (d, 6H, $^3J_{H\text{-}F}$ = 22.0 Hz, H's of methyl groups adjacent to fluoro-substituted carbon), 1.34 (d, 3H, $^3J_{H\text{-}H}$ = 7.3 Hz, H's of methyl group adjacent to aryl-substituted carbon), 2.96 (q, d, 1H, $^3J_{H\text{-}H}$ = 7.3 Hz, $^3J_{H\text{-}F}$ = 19.5 Hz, methine proton), 7.35 (d, 2H, $^3J_{H\text{-}H}$ = 8.3 Hz, H's adjacent to alkyl-substituted aryl carbon), 7.59 (d, 2H, $^3J_{H\text{-}H}$ = 8.3 Hz, H's adjacent to cyano-substituted aryl carbon); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 15.57 (q, d, $^3J_{C\text{-}F}$ = 5.7 Hz, methyl group adjacent to aryl-substituted carbon), 24.90 (q, d, $^2J_{C\text{-}F}$ = 24.7 Hz, methyl group adjacent to fluoro-substituted carbon), 25.76 (q, d, $^2J_{C\text{-}F}$ = 24.8 Hz, methyl group adjacent to fluoro-substituted carbon), 49.08 (s, d, $^2J_{C\text{-}F}$ = 21.7 Hz, aryl-substituted carbon), 96.51 (s, d, $^1J_{C\text{-}F}$ = 172.1 Hz, fluoro-substituted carbon), 110.49 (s, quaternary aryl carbon, cyano substituted), 118.97 (s, CN), 129.67 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.85 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 148.44 (s, quaternary aryl carbon, alkyl substituted); ms *m/z*: 61(90), 77(20), 103(27), 116(21), 129(19), 130(100), 156(34), 191(5).

Generation and spectroscopic and kinetic characterization of methoxy-substituted phenoxyl radicals in solution and on paper[1]

D. Shukla, N.P. Schepp, N. Mathivanan, and L.J. Johnston

Abstract: A number of methoxy-substituted phenoxyl radicals have been generated and characterized by laser flash photolysis techniques in solution and on paper. The radicals have been produced by three routes in solution: hydrogen abstraction from phenols by *tert*-butoxyl radical, photolysis of α-aryloxyacetophenones, and direct excitation of phenols. Most of the phenoxyl radicals studied have a characteristic absorption near 400 nm; the *ortho*-substituted radicals have an additional broad absorption in the visible in non-hydroxylic solvents (e.g., 650 nm for 2-methoxyphenoxyl radical). The relative intensities of the 400 nm and the long-wavelength bands vary with substitution pattern and solvent, with the long wavelength band being much weaker in hydroxylic solvents. Direct excitation of phenols provides an alternate source of phenoxyl radicals in some cases. However, for 4-methoxyphenol there are overlapping absorptions due to triplet phenol and phenol radical cation, both of which absorb in the 400–460 nm region. The 4-methoxyphenol radical cation is formed in a biphotonic process and decays by deprotonation to give the phenoxyl radical. The 4-methoxyphenoxyl radical can also be generated on paper from either the ketone or phenol precursor and decays with complex kinetics that depend on the precursor loading and laser intensity. There is no evidence for the formation of significant amounts of long-lived ketone or phenol triplets on paper. The decay kinetics for the phenoxyl radical are modified by the addition of the radical scavenger dithioerythritol. The results indicate both static and dynamic components to the radical scavenging process. The generation of phenoxyl radicals on paper in the presence and absence of scavengers provides the basis for the development of a new method for screening potential photoyellowing inhibitors and understanding their mode of action.

Key words: phenoxyl radicals, paper photoyellowing, laser flash photolysis, triplets, radical cations.

Résumé : On a généré un certain nombre de radicaux phénoxyles substitués par des groupes méthoxyles et on les a caractérisés par les techniques de la photolyse laser éclair en solution et sur papier. On a produit les radicaux par trois méthodes en solution: utilisation du radical *tert*-butyloxyle pour l'enlèvement d'hydrogène à partir de phénols, la photolyse d'α-aryloxyacétophénones et l'excitation directe de phénols. La plupart des radicaux phénoxyles étudiés présentent une bande d'absorption caractéristique vers 400 nm; les radicaux substitués en *ortho* présentent en plus une large bande d'absorption dans le visible dans les solvants non hydroxyliques (environ 650 nm pour le radical 2-méthoxyphénoxyle). Les intensités relatives des bandes à 400 nm et à longueur d'onde plus élevée varient avec le patron de substitution et avec le solvant; la bande à longueur d'onde plus élevée est la plus faible dans les solvants hydroxyliques. Dans certains cas, l'excitation directe des phénols est une voie alternative d'obtention de radicaux phénoxyles. Toutefois, pour le 4-méthoxyphénol, il y a superposition de bandes dues au phénol triplet et au cation radical phénol qui absorbent tous les deux dans la région de 400 à 460 nm. Le cation radical 4-méthoxyphénol se forme par un processus biphotonique et il se décompose par déprotonation pour donner le radical phénoxyle. Le radical 4-méthoxyphénoxyle peut aussi être obtenu sur papier à partir soit de la cétone ou du phénol approprié et il se décompose avec une cinétique complexe qui dépend de la concentration du précurseur et de l'intensité du laser. Sur le papier, on n'a obtenu aucune indication pouvant suggérer qu'il y a formation de quantités appréciables d'états triplets de longue vie de cétone ou de phénol. La cinétique de la décomposition du radical phénoxyle est modifiée par l'addition du piège à radical dithioérythritol. La génération de radicaux phénoxyles sur papier, en présence ou en l'absence de pièges à radicaux, fournit une base pour le développement d'une nouvelle méthode d'évaluer les inhibiteurs potentiels de jaunissement photochimique et de comprendre leur mode d'action.

Mots clés : radicaux phénoxyles, jaunissement photochimique du papier, photolyse laser éclair, triplets, cations radicaux.

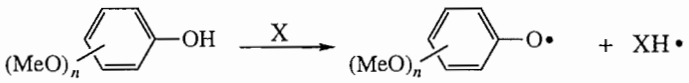
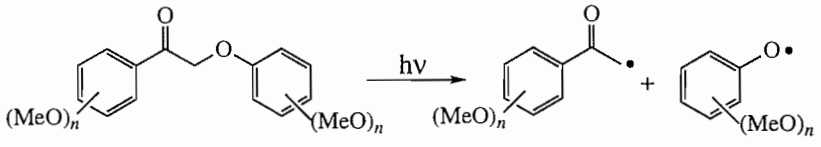
The light-induced yellowing of lignin-rich mechanical and high-yield pulps has recently attracted considerable mechanistic interest (1, 2). It is now well established that phenoxyl radicals are key intermediates in the photooxidation of lignin and that their oxidation leads to quinones and other decomposition products that are responsible for the yellow color. Lignin-derived phenoxyl radicals are generated by several different routes, including β-cleavage reactions of substituted α-aryloxyacetophenones, hydrogen abstraction reactions of phenols, and cleavage of ketyl radicals derived from the photoreduction of aromatic ketones or hydrogen abstraction from arylglycerol β-arylethers (1, 3–7). Reactions of other chromophores such as stilbenes and phenylcoumarones may also play a role, particularly for pulps that have been chemically treated to remove free phenols and aromatic ketones (8–10).

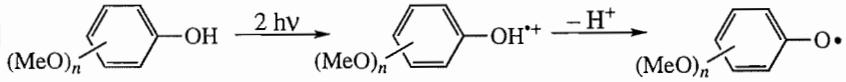


Much of the mechanistic evidence in support of these reaction pathways comes from detailed studies using model compounds in solution since the direct detection of reactive intermediates in pulp or the isolation of products from irradiated pulp samples is relatively difficult. Although such model studies provide much useful background information, it is becoming increasingly obvious that extrapolating from the behavior in homogeneous solution to that in a heterogeneous environment such as that provided by pulp is not straightforward. In some cases the irradiation of model compounds on solid supports, including paper, has been used to obtain mechanistic information as to the manner in which a heterogeneous environment may modify the outcome of a photochemical reaction. For example, earlier work indicates that the triplet states of α-guaiacoxylacetoveratrone are relatively unreactive on a variety of solid supports, including cellulose and the crystalline ketone, despite their efficient β-cleavage in hydroxylic solvents (4, 11, 12). Relatively long-lived transients assigned to triplet aryl ketones have also been observed on thermomechanical wood pulps (13).

There are several reports that indicate that phenoxyl radicals have relatively long lifetimes in paper and pulp samples. For example, phenoxyl radicals with lifetimes of hours or days have been detected in solid matrices by esr (14). The 2,4,6-trimethylphenoxyl radical has been generated by hydrogen abstraction by triplet benzophenone on cellulose and observed directly by diffuse reflectance flash photolysis (15). The recognized importance of phenoxyl radicals in the photoreversion of lignin-rich pulps has prompted us to examine a number of potential phenoxyl precursors on paper using diffuse reflectance laser flash photolyis. The latter technique has now been applied to the study of a variety of reactive intermediates in opaque solids (16). We report herein our initial results on the generation of methoxy-substituted phenoxyl radicals from phenol and ketone precursors in solution and on paper, and their spectroscopic and kinetic characterization. This work provides the necessary background for studies of the reactivity of lignin-derived phenoxyl radicals with potential free-radical scavengers and for examining the mode of action of compounds that are effective in inhibiting the photoreversion process. It also raises interesting questions concerning the involvement of phenol triplet excited states and radical cations in photoyellowing.



Results and discussion



Generation of phenoxyl radicals in solution

There are a number of efficient photochemical sources of phenoxyl radicals for transient absorption measurements in solution. These include hydrogen abstraction from the appropriately-substituted phenol using triplet ketones or *tert*-butoxyl radicals (eq. [1]), β-cleavage reactions of α-aryloxyacetophenones (eq. [2]), and direct excitation of phenols (17–22). The latter reaction has been suggested to occur via biphotonic ionization of phenol followed by deprotonation of the resulting radical cation (eq. [3]) in alcohols and *n*-butyl chloride, although direct homolysis of the O—H bond may play a role in nonpolar solvents (17, 22–25). A number of substituted phenoxyl radicals have been generated using each of these routes in order to evaluate the effects of substitution pattern and solvent on the spectroscopic properties of these radicals and to identify the radicals and methods for their generation that are most suitable for spectroscopic and kinetic studies on paper.

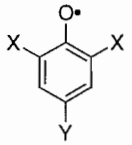
[a] I_S/I_L refers to the ratio of the intensities of the absorption bands in the 400 nm and 650 nm regions and is based on measurements at the respective λ_{max} values for each radical.
[b] Broad and weak.



(a) Hydrogen abstraction from phenols

Various mono-substituted phenoxyl radicals have been generated by hydrogen abstraction from the corresponding phenols using *tert*-butoxyl radical in 2:1 di-*tert*-butyl peroxide/benzene (18). The rate constants for the hydrogen abstraction reaction for most of the phenols that have been studied are in the 10^8–10^9 M^{-1} s^{-1} range. The same method has been used to generate a number of substituted phenoxyl radicals (**1**–**8**) with one or more methoxy groups in both polar and nonpolar solvents. The data are summarized in Table 1 and representative spectra for the 2-methoxyphenoxyl radical in Freon-113 and methanol are shown in Fig. 1. In agreement with literature results for various phenoxyl radicals, radicals **1**–**8** have a moderately strong absorption band in the 400 nm region that is characteristic of nonaryl-substituted phenoxyl radicals. As noted previously (20), the spectrum for the 2,6-dimethoxyphenoxyl radical (**5**) is somewhat different in that the usual 400 nm band is blue-shifted and does not show a well-defined maximum. The data in Table 1 demonstrate that most of the 2- and 2,6-substituted phenoxyl radicals have a second broad absorption band at longer wavelengths (~650 nm for **1**, Fig. 1). The parent phenoxyl radical also shows a broad weak visible absorption that has recently been simulated using ab initio quantum chemical methods and shown to correspond to a $\pi\pi^*$ transition (20). This long-wavelength band is of comparable intensity to the 400 nm absorption for a variety of *ortho*-substituted phenoxy radicals, but is much weaker in the 3-methoxyphenoxyl radical and nondetectable in the 4-methoxy analog (17, 20). Note that the reported spectra for radicals **1**–**8** are in good agreement with the available literature data for the 400 nm transition of phenoxyl radicals, although in most cases the weaker visible absorption has not been characterized in detail (18, 22).

1 2-OCH_3
2 3-OCH_3

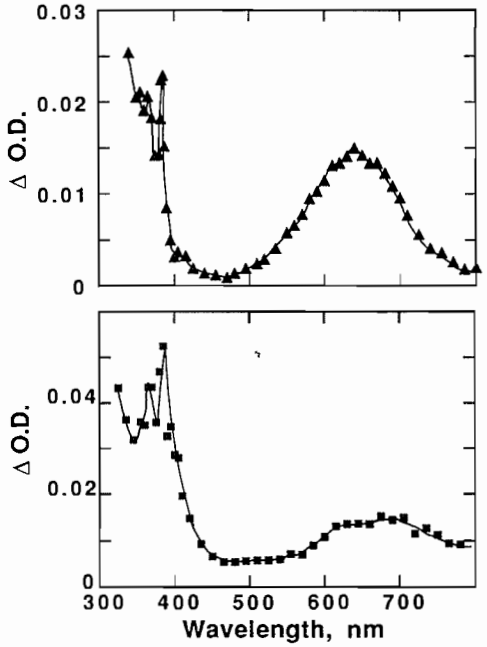
5 X = 6-OCH_3



6 X = OCH_3; Y = CH_2OH
7 X = ^tBu; Y = CH_3
8 X = ^tBu; Y = OCH_3

The visible absorption band observed for most of the radicals in Table 1 is potentially useful for monitoring phenoxyl radicals on paper or pulp since it should permit the detection of the radical in a region free of absorptions due to other potential intermediates such as aryl ketone triplets. However, preliminary experiments indicated that the long-wavelength absorption was much weaker on a variety of solid supports. Accordingly phenoxyl **1** was generated in a number of solvents and the data are reported in Table 1. Note that in all cases the

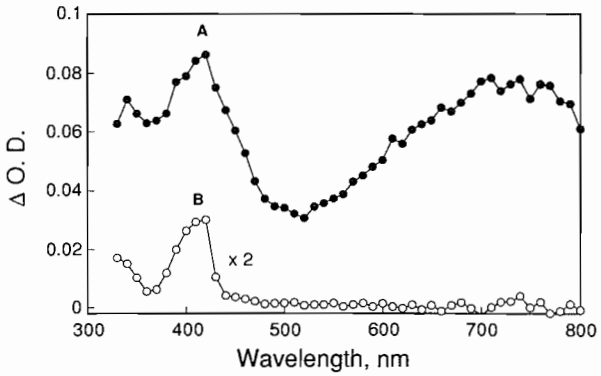

Fig. 1. Transient absorption spectra for the 2-methoxyphenoxyl radical in Freon-113 (*top*) and methanol (*bottom*). The radicals were generated by hydrogen abstraction from 2-methoxyphenol by *tert*-butoxyl radicals produced by 308 nm excitation of 4% di-*tert*-butyl peroxide.

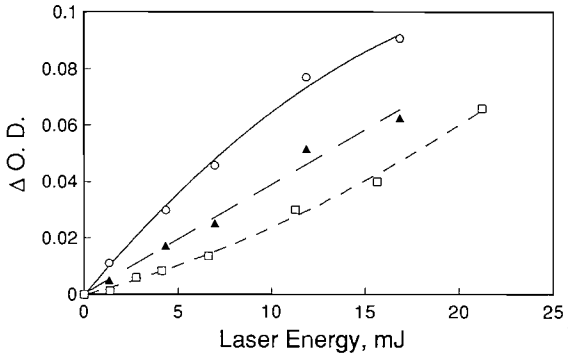
experiments were carried out with sufficiently high concentrations of phenol to minimize decay of the initial *tert*-butoxyl radical by α-cleavage or hydrogen abstraction from the solvent (e.g., methanol, isooctane). The data show that the relative ratio of the 390 nm and long-wavelength absorptions varies substantially with solvent. For example, the ratio of short- to long-wavelength bands for **1** increases from 1.2 in isooctane to 3.7 in methanol. This change appears to be related mainly to the presence of hydroxyl groups since *tert*-butanol and methanol have similar ratios for the two bands, whereas the spectrum in acetonitrile is similar to those in less polar solvents such as benzene and Freon-113. Reasonably strong visible absorptions in the 600–650 nm region are also observed for radicals **4**, **5**, and **7** in benzene. The ratio of the intensities of the short- and long-wavelength bands decreases substantially for **4** and **5** in methanol; by contrast, the spectrum of phenoxyl **7** is virtually identical in both benzene and methanol. Phenoxyls **6** and **8** have quite weak visible absorptions bands with apparent λ_{max} values of ≥700 and 550 nm, respectively, and their spectra have been measured in only a single solvent.

It is clear from the above results that the relative intensity, position, and broadness of the long-wavelength transition in substituted phenoxyl radicals depend on the substituent, its position of attachment to the aromatic ring, and the solvent. Based on the data in Table 1, it appears that the hydrogen-bonding ability of the solvent is more important than its polarity. In general, *ortho* substitution seems to be a necessary but not a sufficient prerequisite for a strong visible absorption. In any event the solvent effects indicate that this band is unlikely to be of general utility for characterization of methoxy-substituted phenoxyl radicals on a hydroxylic support such as cellulose or paper.

Fig. 2. Transient absorption spectra measured after 308 nm excitation of 4-methoxyphenol in nitrogen-(*A*; 0.2 μs) and oxygen-(*B*, ×2, 0.2 μs) purged 1:1 ethanol/water (v/v).

(b) Direct excitation of phenols



Although a number of time-resolved studies have used the direct excitation of phenols as a source of phenoxyl radicals, the literature results also indicate that this route may lead to competing absorptions due to triplet phenol, phenol radical cation, and solvated electron, depending on the reaction conditions (22, 24–27). For example, laser excitation of several phenols in aqueous solution has been reported to generate triplet–triplet absorptions at wavelengths between 250 and 450 nm and with lifetimes on the order of several microseconds, in addition to phenoxyl radicals (25); matrix studies indicate a λ_{max} value of 440 nm for triplet 4-methoxyphenol (26). A number of early studies using conventional flash photolysis indicate that phenoxyl radical formation is biphotonic and occurs via the triplet manifold (24, 27). Although the solvated electron had been observed in several cases, the initial radical cation precursor to the phenoxyl radical has only recently been characterized in solution using both pulse radiolysis and laser photolysis methods in *n*-butyl chloride (22). These results and previous studies in matrices demonstrate that a variety of methoxy-substituted phenol radical cations have absorptions in the 400–500 nm region that overlap with phenoxyl radical signals. We have carried out a number of experiments using the direct excitation of 4-methoxy-, 2-methoxy-, and 2,6-dimethoxyphenol as a source of phenoxyl radicals in order to investigate the mechanism for their formation under various conditions and to determine whether this method is suitable for kinetic studies on paper.

The transient spectrum obtained following 308 nm laser excitation of 4-methoxyphenol in nitrogen-purged 1:1 aqueous ethanol is shown in Fig. 2*A*. At early times there is a broad absorption at long-wavelength (>600 nm) that decays with a rate constant of 1.5×10^6 s^{-1} and is completely removed by purging the sample with oxygen, consistent with its assignment to the solvated electron (28). Figure 2*A* also shows a strong absorption with λ_{max} at 410 nm and a shoulder at 440 nm. The shoulder at 440 nm decays more rapidly than the 410 nm signal ($k_{obs} \sim 10^6$ s^{-1}), clearly demonstrating that two species contribute to the signal in the 400–450 nm region at early times. At long times (10 μs) or in oxygen-saturated solutions only the 410 nm transient remains (Fig. 2*B*); this species has an additional absorption band at ~330 nm and is clearly the 4-methoxyphenoxyl radical (**3**), based on the known spec-

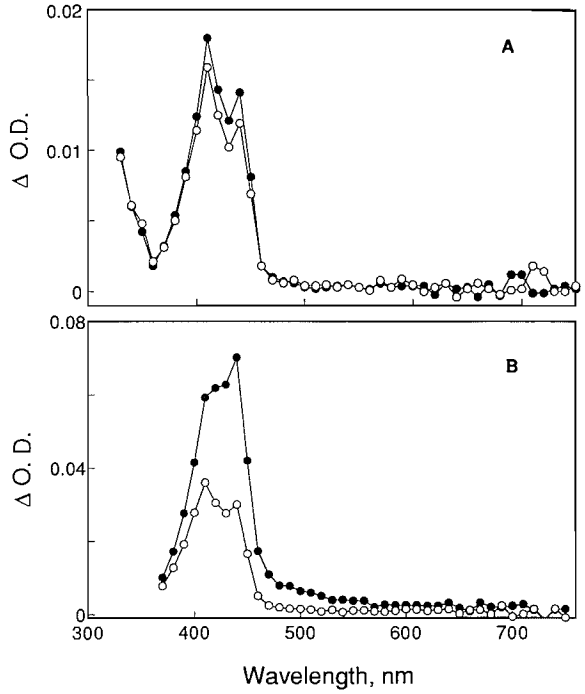
Fig. 3. Plots of signal intensity as a function of incident laser energy for 308 nm excitation of 4-methoxyphenol in 1:1 ethanol/water: (○) 410 nm, nitrogen purged; (▲) 410 nm, oxygen purged; (□) 650 nm, nitrogen purged.



trum for this radical (Table 1) and its insensitivity to oxygen (20). Note that the relative intensities for the early and late spectra or for nitrogen vs. oxygen saturation indicate that the 440 nm transient also absorbs at 410 nm. This species can be quenched by the addition of 1,3-cyclohexadiene. These data indicate that the longer-wavelength transient is the triplet phenol, in agreement with its reported spectrum in a matrix (26). There is no evidence for the phenol radical cation, presumably due to rapid deprotonation in protic solvents.

The yield of the various transients generated by excitation of 4-methoxyphenol in aqueous ethanol was examined as a function of the laser intensity (Fig. 3). The yield of the solvated electron (measured at 650 nm) showed pronounced positive curvature; plots of signal intensity vs. the square of the laser intensity were reasonably linear (R = 0.995), indicating that the formation of the solvated electron is a two-photon process. By contrast, plots of the signal intensities at both 410 and 450 nm vs. the laser intensity showed negative curvature. Since the signals at these wavelengths are the sums of contributions from both the triplet and phenoxyl radical **3**, the experiment was repeated for an oxygenated sample. In this case the signal intensity at 410 nm was substantially lower and the plot showed much less curvature. These results suggest that most of the curvature is due to the triplet absorption. However, if all of the phenoxyl radical was produced by deprotonation of the radical cation formed by photoionization, then a similar intensity dependence would be expected for the phenoxyl radical signal (at 410 nm in the presence of triplet quencher) and the solvated electron. The two are clearly different, which suggests that there is a second pathway for phenoxyl radical formation, presumably direct homolysis of the first or an upper excited singlet state.

The transient phenomena observed upon excitation of 4-methoxyphenol in methanol were qualitatively similar to those described above in aqueous ethanol. In acetonitrile, both phenoxyl radical and triplet were also observed, with the latter reacting with both oxygen and 1,3-cyclohexadiene. A plot of the observed rate constant for decay of the 440 nm transient as a function of diene concentration gives a rate constant of 3.6×10^9 $M^{-1}s^{-1}$. In the presence of 1,3-cyclohexadiene (0.5–3 mM) the transient decays at various wavelengths from 400 to

Fig. 4. Transient absorption spectra measured (*A*) 0.3 (●) and 0.7 (○) μs after 308 nm excitation of 4-methoxyphenol in oxygen-purged acetonitrile and (*B*) 0.2 (●) and 0.6 (○) μs after 355 nm excitation of a solution of 5.6×10^{-3} M 1,4-dicyanonaphthalene, 0.3 M biphenyl, and 0.008 M 4-methoxyphenol in oxygen-purged acetonitrile.

460 nm clearly show two components: a rapid decay that increases with diene concentration and a much slower one assigned to the phenoxyl radical, with the relative contributions of the two varying with wavelength. Note that in acetonitrile the solvated electron exists as a dimer radical anion that does not absorb appreciably below 750 nm and is not detectable under our experimental conditions (28).

The transient spectrum measured for an oxygenated solution of 4-methoxyphenol in dry acetonitrile (Fig. 4*A*) was somewhat different from that obtained in aqueous ethanol. In addition to the radical signal at 410 nm, there was clearly still a residual unquenched signal at 440 nm that decayed with a rate constant of $\sim 8 \times 10^5$ s^{-1}. This is not triplet 4-methoxyphenol, but is consistent with spectra of radical cations of related phenols in *n*-butyl chloride (22). The 440 nm signal was efficiently quenched by water ($k_q \sim 8 \times 10^7$ M^{-1} s^{-1}). The 4-methoxyphenol radical cation was generated by photosensitized electron transfer in acetonitrile, as outlined below in order to confirm that its spectrum and lifetime were in agreement with the residual 440 nm signal observed upon excitation of an oxygenated solution of the phenol.

Excitation (355 nm) of 5.6×10^{-3} M 1,4-dicyanonaphthalene in the presence of 0.3 M biphenyl in acetonitrile leads to rapid electron transfer quenching of the singlet sensitizer with concomitant formation of biphenyl radical cation, λ_{max} at 680 and 380 nm. The radical anion can be completely removed by purging the sample with oxygen. The biphenyl radical cation reacts with 4-methoxyphenol with a rate constant of 1.6×10^{10} M^{-1} s^{-1} and yields a transient spectrum with λ_{max} at 440 nm

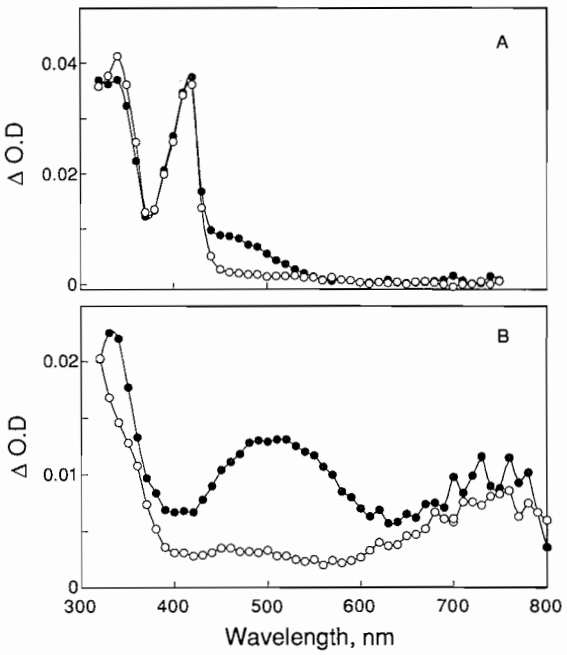
For personal use only.

and a shoulder at 410 nm (Fig. 4*B*). The 440 nm band decays with a rate constant of 1.6×10^5 s^{-1}, leaving a spectrum that can clearly be assigned to phenoxyl radical **3**. The early spectrum shown in Fig. 4*B* may contain a small contribution from the phenoxyl radical; however, it is clear that most of the signal is attributable to the 4-methoxyphenol radical cation generated by quenching of biphenyl radical cation. The 4-methoxyphenol radical cation has substantial absorption between 400 and 450 nm and is similar to the reported matrix spectrum of the 1,4-dimethoxybenzene radical cation (29); generation of this species using 1,4-dicyanonaphthalene–biphenyl in acetonitrile gave a spectrum with λ_{max} values of 430 and 460 nm. Measurement of the decay of the 4-methoxyphenol radical cation at 440 nm as a function of water concentration gave a quenching rate constant of 6.0×10^7 M^{-1} s^{-1}, in good agreement with the rate constant measured for water quenching of the transient produced by direct excitation of 4-methoxyphenol in acetonitrile–diene. It is likely that the measured lifetime of the radical cation in acetonitrile reflects deprotonation by traces of water, even in "dry" acetonitrile.



The results noted above indicate that direct excitation of 4-methoxyphenol generates triplet, radical cation, and phenoxyl radical. In solution, the triplet and radical cation can be easily eliminated by addition of triplet quenchers (oxygen or diene) and water or alcohols, respectively. Photoionization occurs via a biphotonic process, in agreement with previous work (22, 24, 27). The measured singlet lifetimes for 4-methoxyphenol are 2.1 and 1.8 ns in acetonitrile and methanol; this suggests that either the singlet or triplet excited state of the phenol is a potential candidate for absorption of a second photon during the ~6 ns laser pulse employed in our experiments. The variation in the yields of phenoxyl radical and solvated electron with laser intensity in ethanol indicates that the phenoxyl radical is produced by both photoionization–deprotonation and direct homolysis, at least in this solvent.

Direct excitation of carefully purified samples of 2,6-dimethoxyphenol (266 nm) in either acetonitrile or aqueous ethanol does not lead to any significant absorptions between 700 and 320 nm. This phenol is difficult to work with since it rapidly forms impurities that absorb at slightly longer wavelength than the phenol and generate a transient with absorption at 400 nm. Direct excitation (266 nm) of 2-methoxyphenol gives at best only very weak signals due to phenoxyl radical. Both the low radical yields and the rapid formation of products that interfere with transient experiments are substantial limitations to the use of these two *ortho*-substituted phenols as phenoxyl sources on paper.

(c) β-*Cleavage of* α-*aryloxyacetophenones*

Excitation of a variety of α-aryloxyacetophenones has been shown to lead to rapid excited state cleavage (< 1 ns) to generate aryloxyl and phenacyl radicals (12, 21, 30–32). The singlet excited state of the ketone has been identified as the radical precursor for a number of α-aryloxyacetophenones and α-aryloxy-4-methoxyacetophenones (21, 31, 32), although both singlet and triplet excited states lead to cleavage for α-aryloxy-3,4-dimethoxyacetophenones (12, 33). Figure 5*A* shows the transient absorption spectrum produced by 308 nm laser excitation of α-(4-methoxyphenoxy)acetophenone in nitrogen-purged acetonitrile. In addition to the phenoxyl radical there is a weak absorption between 400 and 500 nm that is removed by oxygen purging (Fig. 5*A*), consistent with its assignment to the phenacyl radical (34). There is no indication for a long-lived triplet ketone, as expected from the previous estimate of 166 ps for the lifetime of this intermediate (30). A similar experiment for α-(2,6-dimethoxyphenoxy)-4-methoxyacetophenone in acetonitrile is shown in Fig. 5*B*. The visible absorptions due to the 2,6-dimethoxyphenoxyl and 4-methoxyphenacyl radicals are clearly observed at >700 and 500 nm, respectively. There is additional absorption below 400 nm that contains contributions from both radicals as demonstrated by the spectrum measured in the presence of sufficient oxygen to remove the phenacyl radical signal.

Fig. 5. Transient absorption spectra measured after 308 nm laser excitation of α-(4-methoxyphenoxy)acetophenone (*A*, 1.5×10^{-3} M) and α-(2,6-dimethoxyphenoxy)-4-methoxyacetophenone (*B*, 1.0×10^{-3} M) in nitrogen-(●) and oxygen-(○) purged acetonitrile.

Generation of phenoxyl radicals on paper

The direct excitation of either phenols or α-aryloxyacetophenones is the most suitable method for generation of phenoxyl radicals for kinetic studies on solid supports. This choice is dictated primarily by the fact that these precursors provide rapid unimolecular routes to the required phenoxyl radicals whereas the hydrogen abstraction route involves a bimolecular reaction between phenol and an excited ketone or a photochemically generated free radical. This results in slower generation of the required radical, which is expected to be more of a problem in solids than in homogeneous solution. The phenol and ketone precursors are also better models for the lignin-derived chemistry that occurs on paper. Radical **3** was selected as an appropriate model for initial experiments on paper since it can be generated from both the ketone and phenol precursor using 308 nm excitation. The use of 308 nm excitation for paper samples is desirable since our ultimate goal is to develop routes for generating phenoxyl radicals on paper and studying their decay kinetics in the presence of

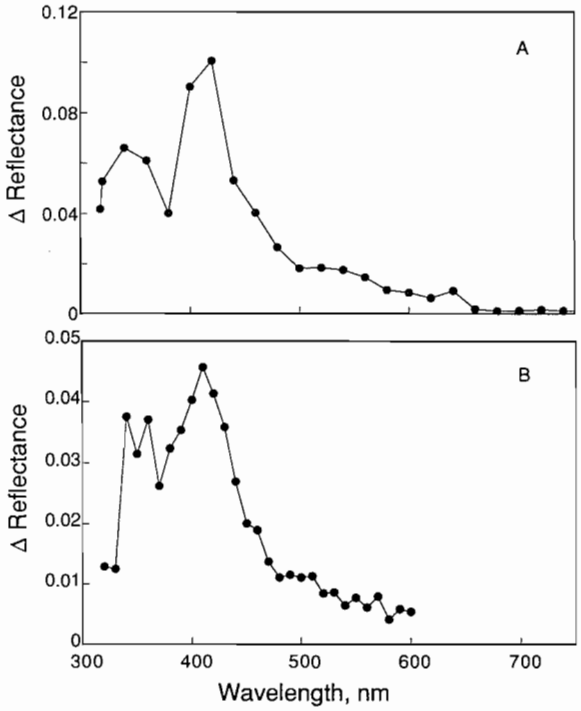
Fig. 6. Transient spectra obtained by 308 nm laser excitation of 2% 4-methoxyphenol (*A*) and 4% α-(4-methoxyphenoxy)acetophenone (*B*) on paper. Spectra were measured ~0.5 μs after laser excitation in each case.



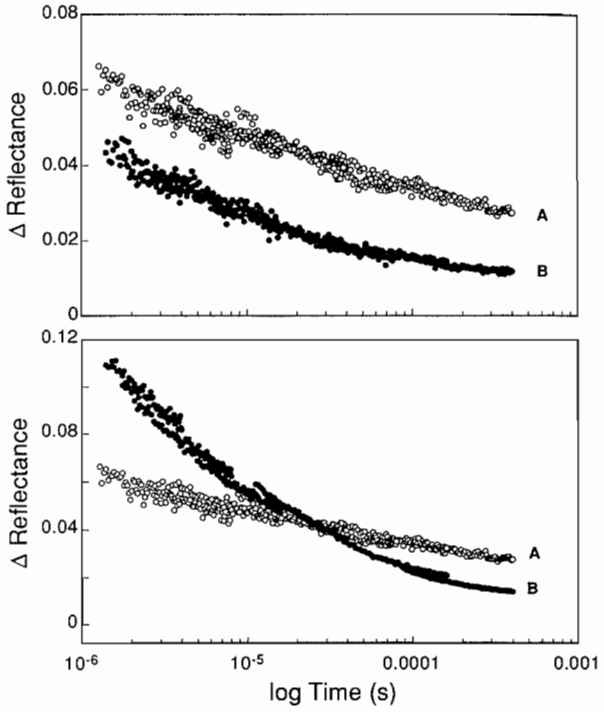


Fig. 7. *Top*: Decay of the 410 nm transient generated by 308 nm excitation of 4-methoxyphenol (*A*, 2%) and α-(4-methoxyphenoxy)acetophenone (*B*, 2%) on paper. *Bottom*: Decay of the 410 nm transient generated by 308 nm excitation of 2% (*A*) and 4% (*B*) 4-methoxyphenol on paper.

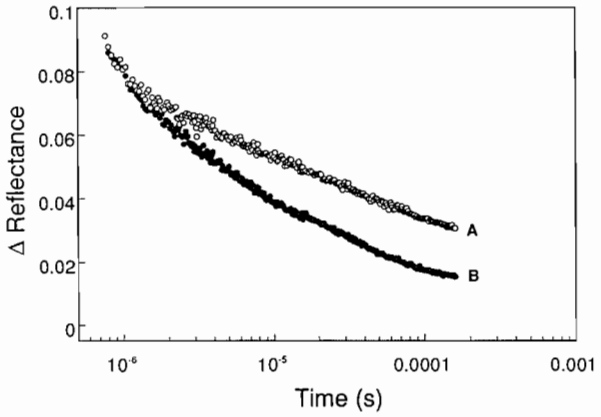
potential free radical scavengers, many of which absorb below 300 nm. The ability to generate the phenoxyl radical from two different precursors is also an advantage for initial experiments on paper.

The spectrum obtained by 308 nm excitation of an aerated sample of 4-methoxyphenol on paper is shown in Fig. 6*A*. The observed transient shows λ_{max} at 410 nm, in good agreement with the solution spectra for radical **3**. A similar transient is obtained upon excitation of α-(4-methoxyphenoxy)acetophenone on paper (Fig. 6*B*) under air. Although the transient spectra observed from the two precursors are similar and are in good agreement with the solution spectrum for **3**, it is important to demonstrate whether phenol or ketone triplets are formed in significant yield on paper. Note that the efficient reaction of the 4-methoxyphenol radical cation with water and the relatively high water content of paper (typically 5–10%) make it unlikely that the radical cation will have a significant lifetime on paper. Initial experiments to eliminate contributions due to triplet excited states focused on the use oxygen as a selective quencher of triplet excited states but not phenoxyl radicals. Transient absorption spectra obtained by excitation of both 4-methoxyphenol and α-(4-methoxyphenoxy)acetophenone were not significantly different for oxygen vs. nitrogen equilibrated samples, nor were there significant changes in intensity. Similar results were also observed for triplet benzophenone on paper, indicating that it is not possible to substantially modify the oxygen concentration in paper, at least using our experimental procedure (see Experimental). This is consistent with previous reports of the lack of oxygen effect on triplet excited states of arylketones in cellulose (11, 35, 36).

Experiments were therefore carried out using 1,3,5,5-tetramethylcyclohexadiene as a triplet quencher. Preliminary experiments used acetophenone triplet as a model in order to identify appropriate conditions for measuring triplet quenching on paper. The only transient observed upon 308 nm excitation of a sample of acetophenone on paper (4% w/w) is the triplet ketone with λ_{max} at ~380 nm. Addition of 6% (w/w) diene resulted in an approximately 60% decrease in the initial signal intensity, but no change in either the transient spectrum or decay kinetics (after normalization). This demonstrates that a static quenching mechanism is operative. Similar experiments using both the phenol and ketone precursors for radical **3** in the presence of 7% diene on paper showed little change in either the overall signal intensity at 410 nm (±15%, within the reproducibility of the experiment) or in the spectrum of the transient. This indicates that the transient spectra in Fig. 6 do not include significant contributions from triplet excited states of the phenol and ketone precursors.



The decay of phenoxyl radical **3** on paper occurs slowly and follows complex kinetics that cannot be fit to simple kinetic expressions. Examples of composite kinetic traces (see Experimental) measured at 410 nm under air for the ketone and phenol precursors are shown in Fig. 7. For the phenol precursor approximately half the signal has decayed on the longest time scale measured whereas approximately one third of the signal remains for the ketone precursor. The decay kinetics also vary with the precursor loading level as shown in Fig. 7. A twofold

Fig. 8. Normalized decay traces for the 410 nm transient generated by 308 nm excitation of 3% 4-methoxyphenol on paper alone (*A*) and with 7% added dithioerythritol (*B*). The initial signal intensity for trace *B* is 0.75 times that of trace *A*.

increase in the amount of phenol increases the initial signal intensity by ~70% and results in much more rapid disappearance of the radical. Similarly, decreasing the laser intensity results in a decreased signal intensity and less rapid decay of the radical. These results are consistent with some contribution from radical–radical coupling to the decay kinetics, at least at the radical concentrations produced at higher laser intensity or higher precursor loading.

The kinetics for the decay of phenoxyl radical **3** were also examined in the presence of dithioerythritol, which has been shown to inhibit photoyellowing of lignin-containing paper and has been suggested to function as a phenoxyl radical scavenger (14, 37). Since the signal intensity and decay kinetics for **3** vary substantially with the precursor used, as well as the loading level and the laser intensity, it is essential to compare results for samples with and without the scavenger measured under identical conditions on the same day. Such a comparison for **3** generated from the phenol precursor in the presence and absence of dithioerythritol (7% w/w) is shown in Fig. 8. The decay traces have been normalized to more clearly show the difference in kinetics; the initial signal intensity in the presence of dithioerythritol is approximately 25% lower than that measured in the absence of scavenger. This indicates that some static quenching occurs, presumably as a result of the generation of a phenoxyl radical in the vicinity of a thiol quencher. The normalized decay traces shown in Fig. 8 demonstrate that **3** decays somewhat more rapidly in the presence of the thiol scavenger, with less long-lived residual signal remaining on the longest time scale measured. This is consistent with a dynamic component in the quenching process that must result from diffusional mobility of either the radical or the thiol on the time scale of the experiment. Note that the diene experiments described above suggest that the quenching observed with the thiol scavenger is not simply related to the added loading of the scavenger causing displacement of the phenoxyl precursor to sites for which the decay kinetics are more rapid.

Conclusions

The solution spectra for a number of methoxy-substituted phenoxyl radicals that provide models for lignin-derived radicals have been measured. The results show that most of the *ortho*-substituted phenoxyls have moderately strong visible absorptions in addition to the characteristic sharp absorption at ~400 nm. However, the relative intensities of the long-wavelength bands vary substantially with substitution pattern and solvent; the decreased intensity in hydroxylic solvents means that this absorption is not generally useful for experiments in a hydroxylic matrix such as paper. The generation of phenoxyl radicals via direct photolysis of 4-methoxyphenol has been investigated in some detail in solution. The results demonstrate that triplet phenol, phenol radical cation, and phenoxyl radical are all produced upon 308 nm excitation of this phenol, with all three intermediates having lifetimes in the microsecond region and absorptions in the 400–460 nm range. Photoionization is biphotonic and the phenol radical cation decays via deprotonation to generate phenoxyl radical, although it appears that some phenoxyl radical may also be formed via direct homolysis, at least in aqueous ethanol. The results suggest that both phenol triplets and radical cations should be considered as potential intermediates in the photochemistry of lignin-derived phenols. For example, although there is no evidence for direct phenoxyl radical formation from the triplet excited state, this species has a sufficiently long lifetime to undergo electron transfer reactions that can generate phenoxyl radical via deprotonation of the initial phenol radical cation.

Both α-(4-methoxyphenoxy)acetophenone and 4-methoxyphenol have been used as precursors for 4-methoxyphenoxyl radical on paper. The above results demonstrate that this radical can be readily generated in sufficient concentrations for its direct detection using transient techniques on paper. The transient spectra are comparable to solution results for the same radical and quenching experiments indicate that triplet states of the ketone or phenol precursor do not contribute significantly to the transient phenomena on paper. The 4-methoxyphenoxyl radical is long-lived and follows complex decay kinetics as observed for other radicals on solid supports such as zeolites and cellulose (15, 38–40). More importantly, the decay of the radical can be monitored reproducibly in the presence and absence of potential scavengers such as thiols. This provides the necessary background for studies of phenoxyl radicals in the presence of potential radical scavengers and should allow the development of a routine method for screening photoyellowing inhibitors. Correlation of the results obtained by diffuse reflectance flash photolysis and steady state irradiation will also allow important mechanistic conclusions as to the mode of action of inhibitors. In this context it is obviously of interest to extend our studies to 2-methoxy-substituted radicals that more closely resemble the lignin-derived radicals and to paper samples made from high-yield pulps. Such experiments are in progress.

Experimental

Materials

The paper used in these experiments was Whatman no. 2 filter paper. Biphenyl, dithioerythritol, 1,4-dimethoxybenzene, and all phenols were obtained from Aldrich. The phenols were purified by sublimation followed by recrystallization (twice) from hexanes or by distillation before use. Di-*tert*-butyl peroxide was purified by passage through a small alumina column before use. α-(4-Methoxyphenoxy)acetophenone was

© 1997 NRC Canada

synthesized by reaction of α-bromoacetophenone with 4-methoxyphenol in acetone in the presence of potassium carbonate according to a literature procedure (41). Similarly, reaction of 2,6-dimethoxyphenol with α-bromo-4-methoxyacetophenone in acetone in the presence of potassium carbonate afforded α-(2,6-dimethoxyphenoxy)-4-methoxyacetophenone, which was purified by recrystallization from ethanol. 1,4-Dicyanonaphthalene was synthesized according to a literature procedure (42, 43) and purified by chromatography (neutral alumina, CH_2Cl_2) followed by recrystallization from toluene. 1,3-Cyclohexadiene (Aldrich) and 1,3,5,5-tetramethylcyclohexadiene (Wiley Organics) were distilled before use. Ethanol and methanol were used as received. Acetonitrile was distilled over calcium hydride in an inert atmosphere.

Sample preparation on paper

A methanol or THF (ca. 2.0 mL) solution of phenol–α-aryloxyacetophenone (5–10 mg) was applied to a pre-weighed Whatman no. 2 filter paper (7×7 cm^2). The paper was placed on a petri dish and sample (phenol or phenoxyacetophenone) solution was applied to it with the aid of a syringe or pipette. The paper was allowed to dry and then turned over and sample solution applied to the other side in a similar manner. The paper was dried in air overnight in the dark and weighed again (the amount of substrate on the paper was determined by the difference in weight of the sample before and after loading). There was no evidence for degradation of the phenol over this time period. A similar method was used to prepare paper samples containing both substrate and scavenger, viz., dithioerythritol (DTE). In general, paper samples were made the day before the laser experiments were carried out.

Laser flash photolysis

The laser flash photolysis setup for both transmission and diffuse reflectance measurements has been described in detail (40). For these experiments either a Lumonics EX530 excimer laser (XeCl, 308 nm; ≤40 mJ/pulse; ~8 ns pulses) or a Lumonics HY750 Nd:YAG laser (266 nm, ≤60 mJ/pulse; 355nm, ≤50 mJ/pulse; ~10 ns pulses) was used for sample excitation. All solution experiments were done using a 7×7 mm^2 quartz flow cell attached to a sample reservoir to minimize problems related to sample depletion and buildup of products. Samples were purged with either nitrogen or oxygen before and during the experiments. For the diffuse reflectance experiments in air, the paper samples were folded and placed directly in the sample holder; the paper was moved during the experiments to provide a fresh sample surface for each laser shot. For experiments under O_2 and N_2, thin strips (~ 2×6 mm^2) of the paper samples were placed in 3×7 mm^2 quartz cuvettes. The quartz cuvettes, with paper sample inside, were placed in a round-bottomed flask and evacuated under an atmosphere of N_2 or O_2. The cuvettes were taken out of the flask, sealed with a rubber septum, and then purged with N_2 or O_2 for 15–20 min before use. The diffuse reflectance data are reported as ΔReflectance = $(J_0 - J_t)/J_0$, where J_0 is the initial reflected light before the laser pulse and J_t is the reflected light at time t after the laser excitation. The composite decay traces shown in Figs. 7 and 8 were produced by measuring decay traces on a number of different time scales and then combining these into a single plot. It was necessary to normalize some of the traces in the region where they overlap in time, but these corrections were relatively small (<15%). The first reliable data point could only be recorded ~500 ns after the laser pulse, due to the presence of a relatively strong luminescence (at the monitoring wavelength of 400–410 nm at short delays) for which complete correction is difficult.

Synthesis of *C*-aryl-*N*-(2-hydroxyphenylmethyl)-nitrones and their reaction with diphenylborinic or carboxylic acid derivatives. Crystal and molecular structures of a free nitrone ligand and its diphenyl–boron chelate[1]

Wolfgang Kliegel, Jörg Metge, Steven J. Rettig, and James Trotter

Abstract: The syntheses of a number of aromatic aldonitrones of *N*-(2-hydroxyphenylmethyl)hydroxylamine and their subsequent reactions with diphenylborinic or carboxylic acid derivatives are reported. Crystals of 8-(4-dimethylaminophenylmethylene)-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-5*H*-6,7,8,9-tetrahydrobenzocycloheptene, **2***b*, are triclinic, $a = 10.6802(8)$, $b = 11.1809(4)$, $c = 10.1520(3)$ Å, $\alpha = 105.847(3)°$, $\beta = 92.567(4)°$, $\gamma = 84.610(5)°$, $Z = 2$, space group $P\bar{1}$, and those of *C*-(4-dimethylaminophenyl)-*N*-(2-hydroxyphenylmethyl)nitrone, **6***e*, are monoclinic, $a = 12.2319(8)$, $b = 7.071(1)$, $c = 17.2005(9)$ Å, $\beta = 107.520(4)°$, $Z = 4$, space group $P2_1/a$. The structures were solved by direct methods and refined by full-matrix least-squares procedures to $R = 0.035$ and 0.032 ($R_w = 0.036$ and 0.032) for 3379 and 1800 reflections with $I \geq 3\sigma(I)$, respectively. Compound **2***b* is representative of a new type of heterocyclic *B*,*N*-betaine. The solid state structure of **6***e* (the precursor to **2***b*) shows that only small topological changes, but significant changes in the electron distribution, occur upon the formation of the diphenylboron chelate.

Key words: aromatic aldonitrones, organoboron compounds, crystal structures.

Résumé : On a réalisé la synthèse d'un certain nombre d'aldonitrones aromatiques de la *N*-(2-hydroxyphénylméthyl)-hydroxylamine dont on a examiné les réactions subséquents avec des dérivés des acides diphénylborinique ou carboxylique. Les cristaux du 8-(4-diméthylaminophénylméthylène)-6,6-diphényl-5,7-dioxa-8-azonia-6-borata-5*H*-6,7,8,9-tétrahydrobenzocycloheptène, **2***b*, sont tricliniques, groupe d'espace $P\bar{1}$, avec $a = 10{,}6802(8)$, $b = 11{,}1809(4)$ et $c = 10{,}1520(3)$ Å, $\alpha = 105{,}847(3)°$, $\beta = 92{,}567(4)°$ et $\gamma = 84{,}610(5)°$, et $Z = 2$ alors que ceux de la *C*-(4-diméthylaminophényl)-*N*-(2-hydroxyphénylméthyl)nitrone, **6***e*, sont monocliniques, groupe d'espace $P2_1/a$, avec $a = 12{,}2319(8)$, $b = 7{,}071(1)$ et $c = 17{,}2005(9)$ Å, $\beta = 107{,}520(4)°$ et $Z = 4$. On a résolu les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs respectives de $R = 0{,}035$ et 0,032 ($R_w = 0{,}036$ et 0,032) pour 3379 et 1800 réflexions avec $I \geq 3\sigma(I)$. Le composé **2***b* représente un nouveau type de composé de *B*,*N*-bétaïne hétérocyclique. La structure du composé **6***e* (précurseur du composé **2***b*) à l'état solide indique que, lors de la formation du chélate diphénylbore, il n'y a que de faibles changements topologiques, toutefois significatifs, qui se produisent dans la distribution électronique.

Mots clés : aldonitrones aromatiques, composés organobore, structures cristallines.

[Traduit par la rédaction]

Introduction

Nitrones of salicylaldehyde react as bidentate ligands with various chelate-forming boron compounds to give heterocyclic *B*,*N*-betaines such as **1** (1) (Scheme 1). An X-ray crystallographic analysis of the diphenylboron derivative of the *N*-methylnitrone (**1**, R = Me) established the seven-membered chelate ring structure with an endocyclic nitrone C=N double bond (2). In the course of this continuing investigation we were interested in the related seven-membered boron chelates **2**, utilizing a similar type of bidentate *N*-oxide–phenolate ligand, differing by having the nitrone C=N bond located outside of the chelate ring ("exocyclic" or "semicyclic" (3)).

An analogous boron chelate ring **3** containing an alcoholate instead of a phenolate ligand moiety had been postulated previously for the crystalline diphenylboron derivatives of *C*-aryl-*N*-(3-hydroxypropyl)nitrones (4). The stability of these type **3** chelates, however, turned out to depend on the *C*-aryl residue, which influences the basicity of the nitrone *N*-oxide function. Thus the derivative of 4-(dimethylamino)benzaldehyde (**3**, Ar = 4-$Me_2NC_6H_4$) proved to be by far the most

stable of all isolated type **3** chelates, whereas the 4-nitrobenzaldehyde derivative (**3**, Ar = 4-$NO_2C_6H_4$) could not be obtained at all (4). To provide information on the chelate-forming properties of *N*-(2-hydroxyphenylmethyl)nitrones, a series of aromatic aldonitrones was synthesized. The synthesis of these aromatic aldonitrones proceeded from salicylaldoxime **4** via the intermediate hydroxylamine **5** (which could not be isolated) to the nitrones **6**. These aromatic aldonitrones **6** were reacted with diphenylborinic acid anhydride to achieve the synthesis of the diphenylboron chelates **2**. In addition, a possible ring–chain isomerism or a rearrangement of the ligand (**6** ⇌ **7**) was examined by acylation experiments using an example compound (**6***e*). The same example ligand **6***e* and its diphenylboron chelate **2***b* were subjected to single crystal X-ray crystallographic analysis to provide unambiguous proof of the respective molecular structures and elucidation of possible changes in the molecular geometry concomitant with chelate formation.

Experimental

General procedures

All preparations and reactions were carried out under normal conditions, without protective gas atmosphere. Commercial solvents were used as supplied. Oxybis(diphenylborane) was prepared according to literature methods, from sodium tetraphenylborate (5) or from 2-(diphenylboryloxy)ethylamine (6). Melting points, measured on a Linström SPA-1 apparatus, are uncorrected. Elemental analyses: (C, H, N, O) Carlo Erba Elemental Analyzer 1106; (B) oxidative disintegration (Schöninger) and potentiometric titration. Infrared spectra: Phillips PU 9800 FT-IR spectrometer, V 3.00, and Mattson Genesis Series FTIR Rev. I (ATI Unicam); ^{1}H nmr: Varian EM 390; ^{11}B nmr: Bruker AC 200. Mass spectra: Finnigan MAT 8430.

8-(4-Methoxyphenylmethylene)-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-5*H*-6,7,8,9-tetrahydrobenzocycloheptene,[3] 2*a*

6*b* (0.26 g, 1.0 mmol) and oxybis(diphenylborane) (0.17 g, 0.5 mmol) are dissolved in 20 mL of absolute ethanol and refluxed for 10 min. The solvent is distilled off to dryness. Yield: 0.41 g (97%) of slightly discolored white crystals; mp 170–173°C. Infrared (KBr, cm^{-1}): 1650 (C═N), 1599 (C═C); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 3.80 (s, OCH_3), 4.93 (s, NCH_2), 6.85 and 8.09 (d and d, J = 9 Hz, AA′BB′ system, OC_6H_4), 6.9–8.0 (m, 14 aromatic H and CH═N); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 8.7 ($W_{1/2}$ = 342 Hz), 30.6 ($W_{1/2}$ = 342 Hz), and 46.3 ($W_{1/2}$ = 257 Hz); ratio of peak areas 1:1:1. Anal. calcd. for $C_{27}H_{24}BNO_3$: C 76.97, H 5.74, B 2.57, N 3.32; found: C 76.88, H 5.76, B 2.68, N 3.20. The product gives a blue-colored solution upon the addition of diphenylcarbazone in ethanol, indicating the presence of the chelated diphenylborenium (Ph_2B^+) ion (7).

8-(4-Dimethylaminophenylmethylene)-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-5*H*-6,7,8,9-tetrahydrobenzocycloheptene,[4] 2*b*

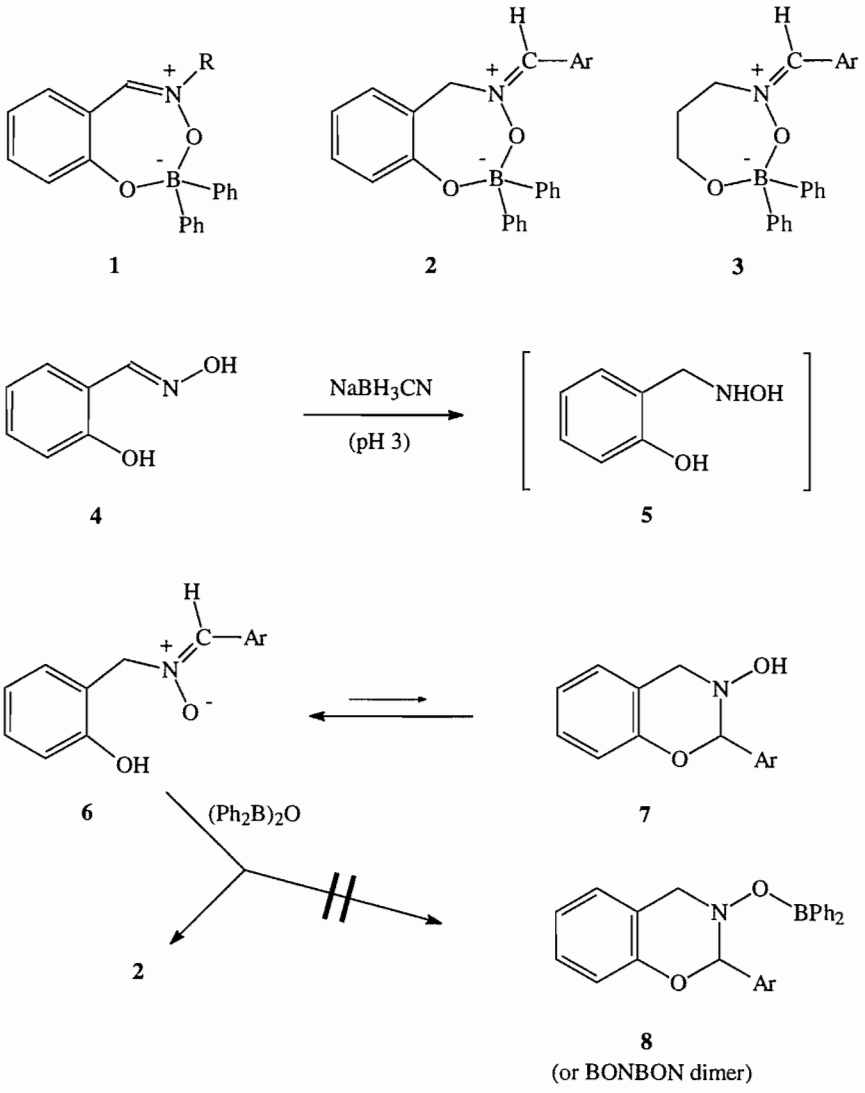
6*e* (0.27 g, 1.0 mmol) and oxybis(diphenylborane) (0.17 g, 0.5 mmol) are dissolved in 20 mL of absolute ethanol and refluxed for 10 min. Upon cooling to room temperature crystallization commences. Yield: 0.42 g (97%) of yellow crystals; mp 205°C (from ethanol). Infrared (KBr, cm^{-1}): 1640 (C═N), 1593 (C═C); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 3.10 (s, $(CH_3)_2N$), 5.06 (s, $N(O)CH_2$), 6.75 and 8.21 (d and d, J = 9 Hz, AA′BB′ system, NC_6H_4), 6.9–8.0 (m, 14 aromatic H and CH═N); ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 3.05 (s, $(CH_3)_2N$), 5.05 (s, $N(O)CH_2$), 6.79 and 8.13 (d and d, J = 9 Hz, AA′BB′ system, NC_6H_4), 6.6–8.0 (m, 14 aromatic H), 8.36 (s, CH═N); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 8.5 ($W_{1/2} \approx$ 300 Hz) and 46.5 ($W_{1/2}$ = 260 Hz); ratio of peak areas 1:2. Anal. calcd. for $C_{28}H_{27}BN_2O_2$: C 77.43, H 6.27, B 2.49, N 6.45; found: C 77.43, H 6.24, B 2.45, N 6.48. **2***b* gives a blue-colored solution upon addition of diphenylcarbazone as described for **2***a*. Crystals suitable for X-ray analysis were obtained by slow crystallization from absolute ethanol.

8-(4-Diethylaminophenylmethylene)-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-5H-6,7,8,9-tetrahydrobenzocycloheptene, 2*c*

6*f* (0.30 g, 1.0 mmol) and oxybis(diphenylborane) (0.17 g, 0.5 mmol) are dissolved in 20 mL of absolute ethanol and refluxed for 10 min. Crystallization starts upon cooling. Yield: 0.26 g (56%) of yellowish crystals; mp 183°C (from ethanol). Infrared (KBr, cm^{-1}): 1642 (C═N), 1593 (C═C); ^{1}H nmr (90 MHz, $CDCl_3$ – TMS), δ (ppm): 1.16 (t, J = 8 Hz, 2 CH_3), 3.35 (q, J = 8 Hz, 2 NCH_2), 4.83 (s, $N(O)CH_2$), 6.55 and 7.95 (d and d, J = 9 Hz, AA′BB′ system, NC_6H_4), 6.7–7.8 (m, 14 aromatic H and CH═N); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 8.8 ($W_{1/2}$ = 550 Hz) and 46.6 ($W_{1/2}$ = 430 Hz); ratio of peak areas 5:1. Mass spectrum (EI, 150°C), *m/z* (%): 385 (74) [$M^+ - C_6H_5$], 369 (43) [$M^+ - C_6H_5 - O$], 298 (44) [**6***f*$^+$], 282 (21) [**6***f*$^+ - O$], 192 (59), 177 (100), 161 (42), 133 (32), 105 (26), 78 (38), 77 (32). Anal. calcd. for $C_{30}H_{31}BN_2O_2$: C 77.93, H 6.76, B 2.34, N 6.06; found: C 77.93, H 6.90, B 2.35, N 6.09. **2***c* gives a blue-colored solution upon addition of diphenylcarbazone as described for **2***a*.

Synthesis of *C*-aryl-*N*-(2-hydroxyphenylmethyl)nitrones, 6 (general procedure)

Salicylaldoxime, **4** (13.7 g, 100 mmol) is dissolved in 50 mL of methanol. After the addition of sodium cyanotrihydroborate[5] (4.2 g, 67 mmol), 50 mL of 2 N HCl solution is added dropwise under stirring, the mixture being kept at a constant pH of 3 using a pH-stat automatic titrator. The consumption is finished after about 40 min and the solution is brought to pH 6.5 with 2 N NaOH solution. A third of this solution (~40 mL), containing the hydroxylamine **5**, is mixed with 30 mmol



[3] Alternative nomenclature: *N*-(4-methoxyphenylmethylene)-*N*-[(2-diphenylboryloxyphenyl)methyl]amine *N*-oxide (O→B complex).

[4] Alternative nomenclature: *N*-(4-dimethylaminophenylmethylene)-*N*-[(2-diphenylboryloxyphenyl)methyl]amine *N*-oxide (O→B complex).

[a]Temperature 294 K, Rigaku AFC6S diffractometer, Cu K_α radiation (λ = 1.54178 Å), graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, stationary background counts at each end of the scan (scan/background time ratio 2:1), $\sigma^2(F^2) = [S^2(C + 4B)]/Lp^2$ (*S* = scan rate, *C* = scan count, *B* = normalized background count), function minimized $\Sigma w(|F_o| - |F_c|)^2$ where $w = 4F_o^2/\sigma^2(F_o^2)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2}$. Values given for *R*, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

$C_{14}H_{13}NO_2$: C 74.00, H 5.77, N 6.16; found: C 73.94, H 5.78, N 6.09.

C-*(4-Methoxyphenyl)*-N-*(2-hydroxyphenylmethyl)nitrone,* **6**b
From 4-methoxybenzaldehyde (4.08 g, 30 mmol). Yield: 6.20 g (80%) of colorless crystals; mp 166°C. Infrared (KBr, cm^{-1}): 3100–1700 ("curtain", O-H), 1603 (C═N, C═C); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 3.80 (s, OCH_3), 5.02 (s, NCH_2), 6.86 and 8.13 (d and d, *J* = 9 Hz, AA′BB′ system, OC_6H_4), 6.66–7.36 (m, 4 aromatic H), 7.43 (s, CH═N), 11.75 (s, exchangeable, OH). Anal. calcd. for $C_{15}H_{15}NO_3$: C 70.02, H 5.88, N 5.44; found: C 69.90, H 5.87, N 5.37.

C-*(4-Nitrophenyl)*-N-*(2-hydroxyphenylmethyl)nitrone,* **6**c
From 4-nitrobenzaldehyde (4.53 g, 30 mmol). Yield: 6.42 g (79%) of yellow crystals; mp 174°C. Infrared (KBr, cm^{-1}): 3200–1700 ("curtain", O-H), 1598 and 1579 (C═N, C═C); ^{1}H nmr (90 MHz, $CDCl_3$ – TMS), δ (ppm): 5.15 (s, NCH_2), 6.76–7.43 (m, 4 aromatic H), 7.66 (s, CH═N), 8.20 and 8.35 (d and d, *J* = 9 Hz, AA′BB′ system, $O_2NC_6H_4$), 10.43 (s, exchangeable, OH). Anal. calcd. for $C_{14}H_{12}N_2O_4$: C 61.76, H 4.44, N 10.29; found: C 61.21, H 4.47, N 9.99.

C-*(4-Chlorophenyl)*-N-*(2-hydroxyphenylmethyl)nitrone,* **6**d
From 4-chlorobenzaldehyde (4.22 g, 30 mmol). Yield: 5.78 g (74%) of colorless needles; mp 174°C. Infrared (KBr, cm^{-1}): 3000–1700 ("curtain", O-H), 1588 (C═N, C═C); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 5.10 (s, NCH_2), 6.73–7.56 (m, 4 aromatic H), 7.38 and 8.20 (d and d, *J* = 9 Hz, AA′BB′ sys-

tem, ClC_6H_4), 7.52 (s, CH═N), 11.13 (s, exchangeable, OH). Anal. calcd. for $C_{14}H_{12}ClNO_2$: C 64.25, H 4.62, Cl 13.55, N 5.35; found: C 64.25, H 4.60, Cl 13.19, N 5.23.

C-*(4-Dimethylaminophenyl)*-N-*(2-hydroxyphenylmethyl)-nitrone,* ***6e***

From 4-dimethylaminobenzaldehyde (4.48 g, 30 mmol). Yield: 7.20 g (89%) of pale yellow crystals; mp 200°C. Infrared (KBr, cm^{-1}): 3000–1700 ("curtain", O-H), 1618 (C═N), 1589 (C═C); ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 3.07 (s, $(CH_3)_2N$), 5.04 (s, $N(O)CH_2$), 6.96 and 8.13 (d and d, J = 9 Hz, AA′BB′ system, NC_6H_4), 6.80–7.33 (m, 4 aromatic H), 7.36 (s, CH═N), 12.25 (s, exchangeable, OH). Anal. calcd. for $C_{16}H_{18}N_2O_2$: C 71.09, H 6.71, N 10.36; found: C 71.07, H 6.77, N 10.37. Crystals suitable for X-ray analysis were obtained by very slow cooling of a saturated solution of ***6e*** in ethyl acetate, mp 201°C.

C-*(4-Diethylaminophenyl)*-N-*(2-hydroxyphenylmethyl)-nitrone,* ***6f***

From 4-diethylaminobenzaldehyde (5.32 g, 30 mmol). Yield: 5.43 g (61%) of pale yellow crystals; mp 176°C. Infrared (KBr, cm^{-1}): 3100–1700 ("curtain", O-H), 1597 and shoulder at 1610 (C═N, C═C); ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.18 (t, J = 8 Hz, 2 CH_3), 3.38 (q, J = 8 Hz, 2 NCH_2), 5.02 (s, $N(O)CH_2$), 6.63 and 8.08 (d and d, J = 9 Hz, AA′BB′ system, NC_6H_4), 6.50–7.30 (m, 4 aromatic H), 7.33 (s, CH═N), 12.36 (s, exchangeable, OH). Anal. calcd. for $C_{18}H_{22}N_2O_2$: C 72.45, H 7.43, N 9.39; found: C 72.52, H 7.39, N 9.39.

C-*(2,4,6-Trimethylphenyl)*-N-*(2-hydroxyphenylmethyl)-nitrone,* ***6g***

From 2,4,6-trimethylbenzaldehyde (4.45 g, 30 mmol). Yield: 4.96 g (61%) of a colorless powder; mp 166°C. Infrared (KBr, cm^{-1}): 3200–1900 ("curtain", O-H), 1592 and shoulder at 1600 (C═N, C═C); ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 2.16 (s, 2 *o*-CH_3), 2.26 (s, *p*-CH_3), 5.08 (s, NCH_2), 6.70–7.40 (m, 6 aromatic H), 7.75 (s, CH═N), 11.30 (s, exchangeable, OH). Anal. calcd. for $C_{17}H_{19}NO_2$: C 75.81, H 7.11, N 5.20; found: C 75.96, H 7.12, N 5.20.

C-*(1-Naphthyl)*-N-*(2-hydroxyphenylmethyl)nitrone,* ***6h***

From 1-naphthylbenzaldehyde (4.69 g, 30 mmol). Yield: 6.34 g (76%) of colorless crystals; mp 164°C. Infrared (KBr, cm^{-1}): 3100–1800 ("curtain", O-H), 1604 (C═N), 1590 (C═C); ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 5.23 (s, NCH_2), 6.73–8.10 (m, 10 aromatic H), 8.30 (s, CH═N), 9.35 (d, J = 7.5 Hz, 1 aromatic H), 11.30 (s, exchangeable, OH). Anal. calcd. for $C_{18}H_{15}NO_2$: C 77.96, H 5.45, N 5.05; found: C 77.89, H 5.26, N 4.74.

3-Acetyloxy-2-(4-dimethylaminophenyl)-3,4-dihydro-2*H*-1,3-benzoxazine, 9*a* (Scheme 2)

A solution of acetylchloride (0.08 g, 1.0 mmol) in 5 mL of benzene is slowly added to a solution of ***6e*** (0.27 g, 1.0 mmol) and triethylamine (0.10 g, 1.0 mmol) in 20 mL of dry benzene. After 2 h of stirring at 50°C the precipitated triethylammonium chloride is filtered off, and the solution is evaporated in vacuo. The remaining oil is brought to crystallization with petroleum ether and (or) diethyl ether. Yield: 0.20 g (64%) of a slightly discolored white powder; mp 129°C (from benzene). Infrared (KBr, cm^{-1}): 1749 (C═O), 1612 (C═C); ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.93 (s, CH_3CO), 2.96 (s, $(CH_3)_2N$), 4.33 (s, broad, $N(O)CH_2$), 6.02 (s, O-CH-N), 6.72 and 7.46 (d and d, J = 7 Hz, AA′BB′ system, NC_6H_4), 6.9–7.4 (m, 4 aromatic H). Anal. calcd. for $C_{18}H_{20}N_2O_3$: C 69.21, H 6.45, N 8.97; found: C 68.90, H 6.56, N 8.84.

3-Benzoyloxy-2-(4-dimethylaminophenyl)-3,4-dihydro-2*H*-1,3-benzoxazine, 9*b*

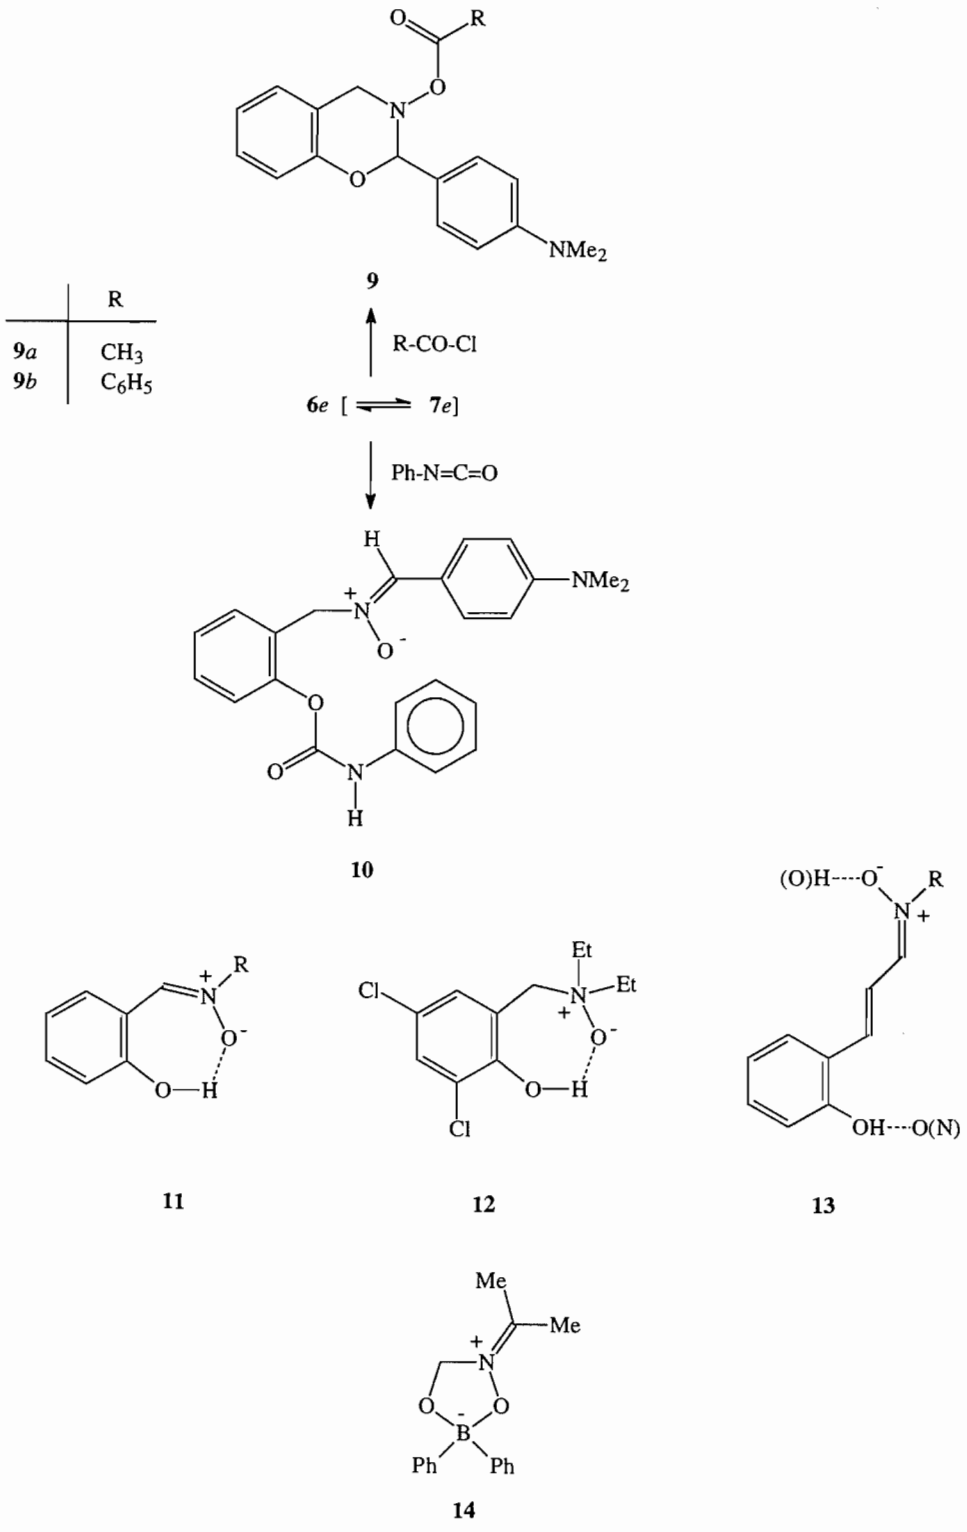
6e (0.27 g, 1.0 mmol), triethylamine (0.10 g, 1.0 mmol), and benzoylchloride (0.14 g, 1.0 mmol) are reacted as described for ***9a***. Yield: 0.25 g (67%) of a colorless white powder; mp 129°C (from benzene – petroleum ether). Infrared (KBr, cm^{-1}): 1748 (C═O), 1615 (C═C); ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 2.90 (s, $(CH_3)_2N$), 4.50 (m, $N(O)CH_2$), 6.16 (s, O-CH-N), 6.68 and 7.88 (d and d, J = 8 Hz, AA′BB′ system, NC_6H_4), 6.8–7.6 (m, 9 aromatic H). Anal. calcd. for $C_{23}H_{22}N_2O_3$: C 73.78, H 5.92, N 7.48; found: C 74.06, H 6.10, N 7.27.

***C*-(4-Dimethylaminophenyl)-*N*-[2-(phenylcarbamoyloxy)-phenylmethyl]nitrone, 10**

6e (0.27 g, 1.0 mmol) in 30 mL of dry benzene is mixed with phenylisocyanate (0.12 g, 1.0 mmol) and refluxed for 6 h. The solvent is distilled off and the residue recrystallized from benzene – petroleum ether. Yield: 0.17 g (44%) of pale yellow crystals; mp 131°C. Infrared (KBr, cm^{-1}): 3409 (N-H), 1755 and 1741 (C═O), 1618 and 1590 (C═N, C═C); ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 3.04 (s, $(CH_3)_2N$), 5.03 (s, $N(O)CH_2$), 6.68 and 8.12 (d and d, J = 9 Hz, AA′BB′ system, NC_6H_4), 6.7–7.4 (m, 9 aromatic H), 7.35 (s, CH═N), ~11 (very broad, exchangeable, NH). Anal. calcd. for $C_{23}H_{23}N_3O_3$: C 70.93, H 5.95, N 10.79; found: C 70.72, H 5.99, N 10.75.

X-ray crystallographic analyses of 2*b* and 6*e*

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 86.6°–93.5° for ***2b*** and 88.2°–95.9° for ***6e***. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, showed only small random fluctuations for both compounds. The data were processed,[7] and corrected for Lorentz and polarization effects and for absorption (based on azimuthal scans).



The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. All non-hydrogen atoms were refined with anisotropic thermal parameters. For ***2b*** a difference map indicated that the NMe_2 hydrogen atoms (associated with C(27) and C(28)) were 3:2 twofold disordered with respect to rotation about

Scheme 2.

the N—C bonds. These disordered hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å and B_H = 1.2 $B_{\text{bonded atom}}$ and all remaining hydrogen atoms of **2***b* and all those of **6***e* were refined with isotropic thermal parameters. Corrections for secondary extinction were applied (Zachariasen type, isotropic, Gaussian), the final values of the extinction coefficients being $7.8(2) \times 10^{-6}$ for **2***b* and $7.73(11) \times 10^{-6}$ for **6***e*. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (8). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, bond

angles, and intra-annular torsion angles appear in Tables 2–5, respectively. Hydrogen atom parameters, anisotropic thermal parameters, and torsion angles, intermolecular contacts, and least-squares planes are included as supplementary material.[8]

Results and discussion

Synthesis and structure of the nitrones 6

N-(2-Hydroxyphenylmethyl)hydroxylamines **5** were generated by the reduction of salicylaldoximes **4** with $NaBH_3CN$ at pH 3 (9) for the synthesis of the nitrones **6**. The hitherto unknown hydroxylamine **5** appears to be a very unstable compound and could not be isolated, neither as a free base nor as a hydrochloride salt. It was possible, however, to trap compound **5** in situ as its nitrone derivatives **6** by the addition of an aromatic aldehyde to the reaction mixture of the salicylaldoxime reduction. The condensation products **6** crystallized in good yields.

Since it has been reported that *N*-(2-hydroxyalkyl)nitrones (10), *N*-(3-hydroxyalkyl)nitrones (11), and also *N*-(2-hydroxynaphthylmethyl)nitrones (12) can isomerize to cyclotautomeric *N*-hydroxy-oxazolidine or *N*-hydroxy-perhydro-1,3-oxazine derivatives, an isomerism between the open-chain nitrone form **6** and the cyclic form **7** had to be considered. It is known from the literature (4, 10–13) that nitrones derived from aromatic aldehydes are very stable in their open-chain nitrone form, and that no trace of the ring form is detectable by spectroscopic means in inert solvents. Only aliphatic aldo- or ketonitrones display evidence of both forms in their nmr spectra.

The nitrone structure cannot be deduced unequivocally from the infrared spectra of **6** (KBr pellets) because the

expected C=N stretching vibrations near 1600 cm^{-1} coincide with the ν_{16} C=C ring stretching of the aromatic ring systems in these molecules, and the distinction is further complicated by resonance interactions between the nitrone and the conjugated aryl group. Very broad "curtain" type O-H association bands between 3100 and 1700 cm^{-1}, however, are consistent with the nitrone form **6** having an intramolecular hydrogen bond involving the "chelated" phenolic proton like those known for salicylaldonitrones **11** (1, 14) (Scheme 2). The nitrone form is clearly demonstrated in the ^{1}H nmr spectra of **6** by signals for the CH=N methine proton at ~7.5 ppm, similar to those observed for other *C*-arylnitrones (1, 4, 10*a*, 12, 14*b*, 15). Signals for the O-CH-N methine protons of the cyclic form **7**, typically around 5–6 ppm, were not detected. In accor-

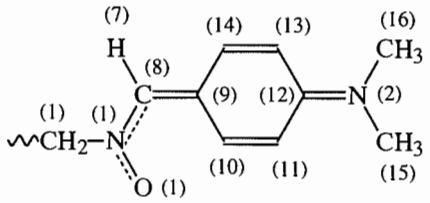
dance with the predominant or exclusive open-chain nitrone form **6** in solution, the "chelated" phenolic proton gives rise in each case to a downfield signal at ~11.4 ppm, characteristic for intramolecular hydrogen bonds of this type (1, 12*a*, 12*c*, 14*a*, 16). Comparison of the ^{1}H nmr spectra of the 4-substituted benzaldonitrones **6** (see Table 6) shows that the increasing downfield shift of the OH signal reflects the strengthening of the hydrogen bond due to the increasing basicity of the azomethine *N*-oxide group, going from the 4-nitro- to the 4-diethylaminophenyl derivative. For comparison, Table 6 also lists the pK_a values reported for the *N*-methylnitrones having the corresponding 4-substituents at the *C*-aryl residue (17). There is also an increasing, though less distinct, balancing upfield shift of the signals assigned to the CH═N methine protons in the same sequence of nitrones **6** (Table 6), indicating the gain in shielding by the electron-donating substituents in the 4-position.



The X-ray analysis of **6*e*** establishes the nitrone structure of the type **6** compounds, at least in the crystalline state, and shows the intramolecular hydrogen bond between the phenolate and *N*-oxide oxygen atoms, already suggested by the ^{1}H nmr and infrared spectra (Fig. 1). In the crystal of **6*e*** this O(2)—H(18)···O(1) hydrogen bond (O—H = 1.13(3) Å, O···H = 1.40(3) Å, O···O = 2.521(3) Å, O—H···O = 174(2)°) represents a strong hydrogen bond (18) within a seven-membered "proton chelate" having metrical parameters similar to those of two other phenolic *N*-oxides with intramolecular H-bridges: the *N-tert*-butylsalicylaldonitrone **11** (R = CMe_3) (19) and the 2-(diethylaminomethyl)-4,6-dichlorophenol *N*-oxide **12** (20) with H···O (O···O) distances of 1.53 Å (2.47 Å) and 1.22/1.31 Å (2.407/2.425 Å), respectively. The nearly linear O—H...O angle in **6*e*** may contribute to the bonding energy and lies in between the corresponding values of 170.6° in **11** (19) and 175/177° in **12** (20). The nearly linear intramolecular O—H...O angles in **6*e***, **11**, and **12** are comparable to those reported for *inter*molecular O—H···O(N) hydrogen bonds in various vinyl salicylaldonitrones like **13** (21) that cannot form intramolecular H-bridges and crystallize in "head-to-tail" chains via O–H...O hydrogen bonds (O···H = 1.44–1.96 Å, O···O = 2.567–2.662 Å, O—H···O = 135°–180°). Furthermore, the (*Z*) arrangement at the nitrone double bond allows the formation of an intramolecular C—H···O hydrogen bond (C(10)—H(8)...O(1): C—H = 1.00(1) Å, O···H = 2.30(1) Å, C···O = 2.922(2) Å, C—H...O = 119(1)°). The geometry of this intramolecular C—H···O interaction is clearly consistent with the presence of a hydrogen bond (22) which may play a role in determining the solid state molecular conformation.

The crystal packing of **6*e*** (Fig. 2) is dominated by three intermolecular C—H···O contacts that meet the requirements of hydrogen bonding (22): C(1)—H(2) and C(8)—H(7) both interact with the same phenolic oxygen atom O(2) to link *a*-glide related "helical enantiomers" into linear chains, and one of the *N*-methyl groups forms the C(15)—H(14)...O hydrogen bond to a neighboring nitrone oxygen atom cross-linking the chains along *b*. The geometry of these interactions is as follows: C(1)—H(2)...O(2)($-1/2 + x$, $1/2 - y$, z), C(8)—H(7)···O(2)($-1/2 + x$, $1/2 - y$, z), C(15)—H(14)···O(1)($1 - x$, $-y$, $1 - z$); C—H = 1.03(2), 1.00(2), 1.01(2) Å; H···O = 2.47(2), 2.48(2), 2.47(2) Å; C···O = 3.429(2), 3.306(2), 3.439(2) Å; and C—H···O = 153(1)°, 165(1)°, 160(2)°; respectively.

The C═N bond length (1.291(2) Å) does not differ significantly from the values found for other nitrones (19, 21, 23, 24) whereas the N—O bond (1.324(2) Å) is slightly longer, prob-

Fig. 3. Mesomeric electron distribution in the 4-dimethylaminophenylmethylidene resonance system.

ably because of the involvement of the nitrone oxygen atom in the very strong intramolecular hydrogen bond. As a consequence of the interaction of the nitrone group and the 4-dimethylaminophenyl π-system, an approximate coplanarity is seen in this part of the molecule. The relatively short bond lengths for N(2)—C(12) (1.370(2) Å), C(10)—C(11) (1.371(2) Å), C(13)—C(14) (1.370(2) Å), and C(8)—C(9) (1.437(2) Å) are indicative of a significant contribution from the 4-dimethylaminomethylidene resonance form having double bonds at these locations (Fig. 3). The phenolic ring system of C(2)—C(7) plus O(2) is twisted out of the mean plane of the remainder of the molecule by about 60°.

Synthesis and structure of the boron chelates 2

To examine the chelate-forming properties of the nitrones **6** by replacement of the "chelated" phenolic proton with a diphenylborenium ion (Ph_2B^+), the compounds **6** were reacted with diphenylborinic acid anhydride, $(Ph_2B)_2O$, in ethanol. Only the 4-dialkylaminophenyl derivatives **6***e* and **6***f* gave crystalline diphenylboron chelates (**2***b* and **2***c*) stable enough for recrystallization. The 4-methoxyphenyl derivative **2***a* could be obtained only as a crude crystalline product that decomposes easily by solvolysis. In all the other cases the respective bidentate ligand **6** was recovered unchanged, even from water-free aprotic media like benzene with continuous removal of reaction water by azeotropic distillation (Dean–Stark trap).

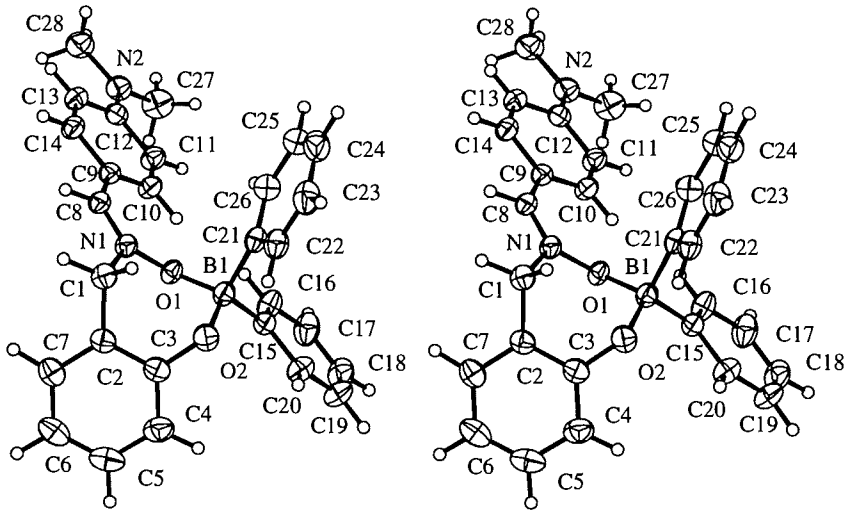
Thus details of the formation of the seven-membered boron chelates **2** resembles the results reported for the synthesis of type **3** chelates (4). Both ring systems show that the ring enlargement of stable six-membered boron chelates derived from aromatic aldonitrones (10*a*) to seven-membered chelates is disadvantageous with respect to the stability of these compounds if the nitrone N=C bond appears as a substitutive (exocyclic) double bond. In the case of the salicylaldonitrone boron chelates **1**, however, with the N=C nitrone double bond being part of the chelate ring (endocyclic), the chelate stability is adequate for various derivatives that could be recrystallized without difficulties despite the enlarged ring system (1, 2). As for the boron chelates **3**, the electron-donating 4-dialkylamino substituent of the *C*-aryl residue of the chelates **2***b* and **2***c* increases the basicity at the nitrone oxygen enough to enable the formation of a chelate sufficiently stable for recrystallization or for analyses of solutions. A similar, though weaker, effect is achieved by the 4-methoxy substituent in the chelate **2***a*.

The solvolytic sensitivity of **2** becomes obvious in the ^{11}B nmr spectra where, in addition to signals for tetracoordinate (sp^3) boron at δ (Et_2OBF_3) = 8.5–8.8 ppm, second signals appear at 46.3–46.6 ppm indicating the presence of a trivalent (sp^2) boron atom of a Ph_2B-O-R moiety (25) that might result from ring opening at the weaker O—B bond to the nitrone oxygen ligand in solution. The solvolysis observed in the $CDCl_3$ solutions of the ^{11}B nmr experiments is a partial solvolysis, the mechanism of which is not yet clear. Other solvents like DMSO-d_6 are even less suitable because of water content. While we are not sure just what Ph_2B-O-R moiety (possibly the ring-opened compound **2** or free diphenylborinic acid) gives rise to the signal at 46.6 ppm, this species should be a trivalent Ph_2B-O-R moiety. The additional peak at 30.6 ppm in the spectrum of **2***a* points to more extensive decomposition of the diphenylborinic acid component that may result from dephenylation by moisture (H_2O traces, or even HCl traces in the $CDCl_3$) or from oxidation by atmospheric oxygen in the solvent, resulting in a $Ph_2B(OR)_2$ phenylboronic acid derivative (25). Experiments with special precautions to exclude water or oxygen in the nmr experiments have not been performed.

The ^1H nmr spectra of **2** do not display any signals at 5–6 ppm indicative of an N-CH-O methine signal that could be assigned to the diphenylborinate **8** (or its BONBON dimer[9]) deriving from a possible cyclotautomer **7**. The CH=N methine signal indicating the nitrone form **2** appears hidden behind the multiplets arising from the aromatic proton signals in each case.

The infrared spectra of **2** show a distinct shift, about 30 cm^{-1}, of the nitrone C=N stretching band to higher frequencies compared to the respective free ligands **6**, indicating the increased iminium salt character of the nitrone moiety in the boron chelates **2**. Similar tendencies have also been observed in the formation of boron chelates from other nitrone ligands (1, 4, 10).

No molecular ion peak was observed in the mass spectrum of **2***c* (investigated as an example). As noted earlier for the seven-membered boron chelates **3** (4), only a dephenylated fragment ($M^+ - 77$) could be detected. This is typical for diphenylboron chelates and points to a preferred transition of the zwitterionic compound **2***c* to the stable $(2c - C_6H_5)^+$ ion.



An X-ray analysis of **2***b*, derived from the free ligand **6***e* (see above), establishes the seven-membered boron chelate structure **2** (Fig. 4), which represents a new type of heterocyclic *B,N*-betaine (27). The proton of the intramolecular O—H···O moiety in **6***e* is replaced by the diphenylborenium cation, leading to some changes in the geometry of **2***b*. Besides the C(10)—H(8)...O(1) intramolecular contact, which is maintained in the chelate **2***b* without any significant changes, three additional intramolecular C—H···O interactions (all involving the phenolate oxygen atom O(2)) are noted: (C(10)—H(8)···O(1), C(1)—H(1)···O(2), C(20)—H(16)···O(2), C(22)—H(17)···O(2); C—H = 0.96(2), 0.99(2), 1.02(2), 0.96(2) Å; H···O = 2.32(2), 2.43(2), 2.50(2), 2.46(2) Å; C···O = 2.915(2), 2.708(2), 2.906(2), 2.857(2); Å; C—H···O = 119(1)°, 95(1)°, 103(1)°, 103(1)°, respectively). The relatively acute C—H···O angles for the three interactions involving O(2) suggest that these weak interactions probably have little influence on the molecular conformation (22). As noted above for **6***b*, the *C*-arylnitrone moiety is

Fig. 4. Stereoview of **2***b*; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

roughly coplanar. The *C*-arylnitrone mean plane makes a dihedral angle of about 67° with that of phenolate system C(2)—C(7) plus O(2), indicating a somewhat larger rotation in **2***b* than in the free ligand **6***e*. The centrosymmetric structure of **2***b*, like that of **6***e*, contains pairs of "helical enantiomers." Molecules of **2***b* are separated by normal van der Waals distances, the shortest intermolecular distance between non-hydrogen atoms being N(2)···C(13) = 3.407(2) Å.

The insertion of the Lewis acid diphenylboron group in place of the phenolic hydrogen of **6***e* enhances the iminium salt character of the nitrone moiety in **2***b*. Within the 4-dimethylaminophenylmethylidene moiety (Fig. 3) of **2***b*, the double bond character of the N(2)—C(12), C(10)—C(11), C(13)—C(14), and C(8)—C(9) bonds is even more pronounced than in **6***e* (for **2***b*: 1.349(2), 1.361(2), 1.361(2), and 1.419(2) Å, respectively; for **6***e*: 1.370(2), 1.371(2), 1.370(2), and 1.437(2) Å). The N—O bond of the nitrone group in **6***e* (1.324(2) Å), already longer than those for nitrone groups not involved in hydrogen bonding, is further lengthened by about 0.05 Å in the boron chelate **2***b* (1.371(1) Å). This represents a decrease in the π-bond order of the nitrone N—O bond from 0.35 in the free ligand **6***e* to 0.22 in the chelate **2***b*, estimated from plots of bond distance vs. HMO–π-bond order (28*b*). The C=N$^+$ nitrone double bond, however, remains practically unchanged (1.291(2) Å in **6***e* and 1.294(2) Å in **2***b*) with an estimated (28*a*) HMO–π-bond order of 0.82 in both the ligand and the chelate, and is comparable to the C=N$^+$ bond in **1** (R = Me) (1.291(4) Å) (2). It is somewhat surprising that the chelate formation, i.e., the incorporation of the Lewis acid boron nucleus, has a more profound effect on the more distant 4-dimethylaminophenyl resonance system than on the conjugated nitrone C=N$^+$ group.

As in **1** (R = Me) (2) and other boron chelates obtained from bidentate ligands having *N*-oxide and alcoholate or phenolate oxygen donor atoms (23, 29), the (N)O—B bond in **2***b* is longer (1.549(2) Å) than the (C)O—B bond (1.488(2) Å). The sum of the bond lengths about the boron atom in **2***b* (6.266 Å) is about the same as in the other type of seven-membered diphenylboron chelate **1** (R = Me) (6.276 Å) (2), consistent with the observation that for a given chelate ring size this sum is essentially constant (30). The mean (phenyl)C—B bond length in **2***b* (1.615(2) Å) is similar to corresponding values observed for **1** (R = Me) (2) and other Ph_2BO_2 chelates (29*a*–*d*, 29*g*, 30–32). The mean C—B/mean O—B bond length ratio for **2***b* (1.063) indicates a slightly increased binding strength of the bidentate ligand with respect to the diphenylboron moiety compared to the other type of seven-membered chelate **1** (R = Me) (2), which has an average C—B/O—B ratio of 1.054. Similar values calculated from the bond lengths observed for various six-membered "Ph_2BO_2" chelates provide a good estimate of overall chelate binding strength (31).

The chelate ring geometry of **2***b* (with an exocyclic N=C double bond) generally allows somewhat smaller intracyclic angles at the ring member atoms than does the geometry of **1** (2) with an endocyclic N=C double bond. In **1** nearly all of the chelate ring angles are widened: the sum of the intracyclic bond angles is 858.4° compared to 811.7° in **2***b*. If the differing alkylidene substituents are not considered, the new boron chelates **2** may be formally regarded as ring-enlarged "phenylogues" (by *o*-phenyl insertion) of the five-membered diphenylboron chelate **14**, which has been fully characterized by X-ray crystallographic analysis (29*g*). Comparing the dimensions of the chelate rings in **2***b* and **14**: similar bond distances are found at the "Ph_2BO_2" moiety and wider ring angles are found at all ring member atoms of **2***b*, in particular the N-O-B angle that changes from 104.7(2)° in **14** to 118.3(1)° in **2***b*.

Acylation of the nitrones 6

Since the attack of the Lewis acid diphenylborinic acid at the nitrone groups leads preferentially to the boron chelates **2** rather than to an *O*-borylated cyclotautomerization product **8**, acylation was attempted with an acyl halide and an isocyanate. Thus the reaction of **6***e* with acetyl chloride (R = Me) and benzoyl chloride (R = Ph) resulted in the crystalline benzoxazine derivatives **9**, whereas the reaction with phenyl isocyanate gave the phenylcarbamoylated phenol **10** with an intact nitrone function. The *N*-acyloxy derivatives **9***a,b* display ester carbonyl C=O stretching bands in the infrared spectra at

© 1997 NRC Canada

about 1750 cm^{-1} and have the typical O-CH-N acetalic methine proton signal near $\delta = 6.1$ ppm in the ^1H nmr spectra. Comparable acylations of the ring tautomers of *N*-(2-hydroxyalkyl)nitrones (10), *N*-(3-hydroxyalkyl)nitrones (4), and *N*-(2-hydroxynaphthylmethyl)nitrones (12*b*, 12*c*, 33) have been reported. Compound **10** is not only characterized by urethane C=O and nitrone C=N stretching bands in the infrared spectrum, but also by the typical $CH{=}N^+$ methine proton signal at 7.35 ppm in the ^1H nmr spectrum. The latter excludes not only a 1,3-benzoxazine derivative like **9**, but also an isoxazolidine derivative as a result of the possible 1,3-dipolar cycloaddition of phenylisocyanate to the nitrone group. It should be noted that the ester or urethane C=O stretch is not a good means for discrimination and it serves only for the characterization of both compounds. It is also *not* the 7.35 ppm signal in the ^1H nmr (buried under the multiplet of aromatic protons) that discriminates, but rather the *absence* of the acetalic O-CH-N methine signal around 6 ppm that suggests the open-chain nitrone form of **10**. X-ray analysis would certainly establish these structures, but it has not yet been possible to obtain suitable crystals of **9** and **10**.

X^+ transfer from the halonium ions of adamantylideneadamantane to acceptor olefins. The possibility of chiral induction in the transfer process

Alexei A. Neverov, Theresa L. Muise, and R.S. Brown

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12
For personal use only.

Abstract: The bromonium ion of adamantylideneadamantane (Ad═Ad-Br^+) has been used to induce the bromocyclization of a 4-pentenyl glycoside (**10**) and a 5-hexenyl glycoside (**11**) in dichloroethane. The kinetics of these processes have been studied at 25°C in the presence of varying [Ad═Ad] and, in the case of the transfer to **10**, in the presence of pentanol. The second-order rate constants for bromocyclization of these two alkenes are $(1.04 \pm 0.06) \times 10^{-1}$ M^{-1} s^{-1} and $(5.34 \pm 0.2) \times 10^{-2}$ M^{-1} s^{-1}, respectively, and in no case does added Ad═Ad or pentanol alter the reaction rate. The kinetic behavior is interpreted in terms of cyclization occurring directly from a 1:1 complex of Ad═Ad-Br^+ and **10** or **11**. The chiral induction for the bromocyclization of **10** promoted by AdAd-Br^+ was measured at 20% e.e., the (−)-(*S*)-tetrahydrofurfuryl bromide being the dominant stereoisomer. Ad═Ad molecules substituted at one of the homoallylic carbons by an axial methyl group (**12**), or by two methyl groups (axial and equatorial), were synthesized and the ^1H NMR spectra of their bromonium ions is given. These materials are not stable for prolonged times at room temperature. A limited kinetic study of the reaction of **12**-Br^+ and 4-pentenol indicated that the Br^+ transfer is 500 times faster than the comparable transfer from Ad═Ad-Br^+ to 4-pentenol. The possibility of using these materials to induce chiral bromocyclization is discussed.

Key words: bromonium ion, halonium, transfer, chiral, adamantylideneadamantane.

Résumé : On a utilisé l'ion bromonium de l'adamantylidèneadamantane (Ad═Ad-Br^+) pour induire la bromocyclisation des glucosides de pent-4-énule (**10**) et d'hex-5-énule (**11**) dans le dichlorométhane. On a étudié la cinétique de ces processus à 25°C, en présence de concentrations variables de Ad═Ad et, dans le cas du transfert vers le composé **10**, en présence de pentanol. Les constantes de vitesse du deuxième ordre pour la bromocyclisation de ces deux alcènes sont respectivement de $(1{,}04 \pm 0{,}06) \times 10^{-1}$ M^{-1} s^{-1} et $(5{,}34 \pm 0{,}2) \times 10^{-1}$ M^{-1} s^{-1} et il n'y a aucun cas où l'addition de Ad═Ad ou de pentanol provoque des changements dans la constante de vitesse. On interprète ce comportement cinétique en fonction d'une cyclisation qui se produirait directement à partir d'un complexe 1 : 1 de Ad═Ad-Br^+ et des composés **10** ou **11**. On a déterminé que l'induction chirale pour la bromocyclisation du composé **10** sous l'influence de Ad═Ad-Br^+ est égale à 20% d'e.e., alors que le bromure de (−)-(*S*)-tétrahydrofurfuryle est le stéréoisomère prédominant. On a synthétisé des molécules d'Ad═Ad substituées à l'un des carbones homoallyliques soit par un groupe méthyle axial (**12**) ou par deux groupes méthyles (axial et équatorial) et l'on rapporte les spectres RMN du ^1H de leurs ions bromonium. À la température ambiante, ces produits ne sont pas stables pour des périodes prolongées. Une étude cinétique limitée de la réaction du composé **12**-Br^+ avec le pent-4-énol indique que le transfert de Br^+ est 500 fois plus rapide que le transfert comparable du Ad═Ad-Br^+ vers le pent-4-énol. On discute des possibilités d'utiliser ces composés pour induire des bromocyclisations chirales.

Mots clés : ion bromonium, halonium, transfert, chiral, adamantylidèneadamantane.

[Traduit par la rédaction]

Recent work from these laboratories (1–3) has shown that the bromonium and iodonium ions of adamantylideneadamantane (Ad═Ad) rapidly transfer X^+ to acceptor olefins such as cyclohexene, and those capable of undergoing halocyclizations, see Scheme 1. A detailed analysis (1, 2) of the process for Br^+ transfer to 1,ω-alkenols and alkenoic acids indicated that: (*i*) the reaction usually exhibits some common species rate suppression by added Ad═Ad and an acceleration by added bases and alcohols such as pentanol; and (*ii*) formation of the cyclized product (**3**) occurs from the nascent bromonium ion **2** or in some cases from a 1:1 complex of Ad═Ad-Br^+ and **1**. The fact that the nascent bromonium ion **2** and the cyclized product both contain a potentially asymmetric center (marked with an asterisk in Scheme 1) suggests that it might be possible to use a suitably constructed Ad═Ad bromonium ion to induce chirality in the cyclized product. If so, this would be an important synthetic contribution since there are relatively few cases of asymmetric induction accompanying Br_2/Br^+ electrophilic additions to olefins **1** (4–10).

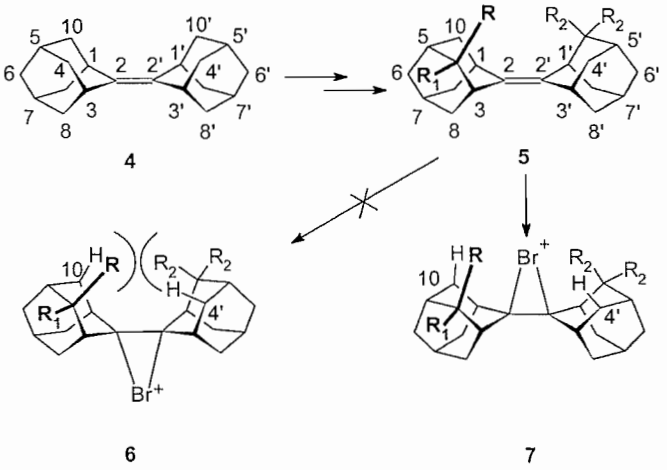
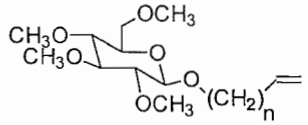
Scheme 1.

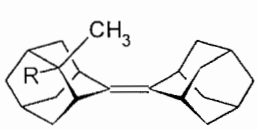


Induction of chirality in the Br^+ transfer process requires a chiral Ad═Ad-bromonium ion, a chiral acceptor olefin, or both. Conceivably the Ad═Ad could be made chiral by appropriate functionalization of any carbon not lying on the plane that includes carbons 8, 6, 7, 2, 2′, 6′, 7′, and 8′. The most appropriate functionalization places a nonreactive alkyl group in the axial positions of any of the eight homoallylic carbons since these are closest to the Π-face of the double bond. In the ideal case the homoallylic carbons could be substituted pairwise in order to preserve a C_2 symmetry in the olefin as in **5** (R_2 = R, R_1, Scheme 2). An axial homoallylic substituent also prohibits bromination at the distal Π-face since the so-formed ion (**6**) would experience severe interactions between the R group(s) and the $C_{4'}$, C_{10} hydrogens. Therefore, bromonium ion formation can only occur on the Π-face of the double bond proximal to the axial homoallylic groups as in **7**.[3]



An alternative way to promote chiral induction requires that the alkene contain an asymmetric center either permanently or temporarily installed as a chiral auxiliary. Rodebaugh and Fraser-Reid (11*a*, *b*) have studied the NBS-induced cyclizations of the *n*-pentenyl and *n*-hexenyl benzyl-protected glycosides **8** and **9**, and noted that a 20% enantiomeric excess is produced in the tetrahydrofurfuryl bromide product of the cyclization of **8** (11*b*), Scheme 3. Given the fact that Br^+ transfer from Ad═Ad-Br^+ to **8** or **9** could occur through diastereomeric complexes between the bulky partners, it seemed likely that enhanced induction of chirality could occur if Ad═Ad-Br^+ were used as the transfer agent.

As an initial undertaking for this research the permethylated



Scheme 2.

glycosides **10** and **11** were synthesized and the kinetics of their reaction with Ad═Ad-Br^+ and -I^+ were studied to determine the mechanism for X^+ transfer. Also, the enantiomeric excess induced in the product of the reaction of **10** and Ad═Ad-Br^+ was determined. Finally, we have synthesized racemic methylated alkenes **12** and **13** and their corresponding bromonium ions to assess the likelihood of producing useful chiral Br^+ transfer agents from such substituted adamantylideneadamantanes. Herein we report the results of this study.

Scheme 3.

Experimental

(a) Materials and methods

Dichloromethane was purified as described (12). 1,2-Dichloroethane was distilled over P_2O_5. Adamantylideneadamantane (Ad=Ad) and the corresponding bromonium and iodonium triflates were prepared as previously described (1, 3, 13). ^1H NMR and ^{13}C NMR data were obtained using Bruker WH-200 and Bruker AM-400 instruments. Kinetic measurements were done using an OLIS modified Cary 17 UV–VIS spectrophotometer or an Applied Photophysics SX-17MV stopped-flow reaction analyzer.

(b) Synthesis

*4, 4-Dimethyl-2-tricyclo[3.3.1.1^{3,7}]decylidene tricyclo-[3.3.1.1^{3,7}]decane (**13**)*

Approximately 12 mmol of dimethyltitanium(IV) dichloride were prepared by mixing 12 mL of a 1 M solution of $TiCl_4$ in CH_2Cl_2 and 6 mL of a 2 M solution of dimethylzinc in toluene in 10 mL of dry CH_2Cl_2 under argon at −78°C. The mixture was kept for 30 min at −30°C and then treated with 10 mL of a solution containing 1.3 g of 2-oxo-4-tricyclo[3.3.1.1^{3,7}]-decylidene tricyclo[3.3.1.1^{3,7}]decane (13) in dry CH_2Cl_2 at −78°C. The reaction mixture was allowed to warm to room temperature and then immediately quenched by pouring onto ice. The product was extracted with 100 mL of CH_2Cl_2, which was then washed with an equal amount of water, saturated K_2CO_3, and dried over Na_2SO_4. Recrystallization from 15 mL of methanol yielded 0.9 g (67%) of a white solid, mp 71–72°C. IR (cm^{-1}, $CHCl_3$ cast): 2905, 2845, 1447; ^1H NMR (CD_2Cl_2) δ: 2.93 (s, 1H), 2.90 (s, 1H), 2.84 (s, 1H), 2.39 (s, 1H), 2.14 (d, 2H, J = 12 Hz), 1.98 (d, 1H, J = 12 Hz), 1.9–1.6 (m, 17H), 1.48 (d, 1H, J = 12 Hz), 1.39 (s, 1H), 1.08 (s, 3H), 0.92 (s, 3H); ^{13}C NMR (see Table 7); MS (*m/z*) calcd for $C_{22}H_{32}$: 296.2504; found: 296.2500.

*Bromonium ion of **12***

To a Teflon reaction vessel equipped with a stirring bar and charged with a small excess of Br_2 under Ar, was slowly added 21.8 mg of **12** (0.078 mmol) (kindly supplied by Prof. A. J. Bennet, Simon Fraser University) dissolved in 1 mL of dry CH_2Cl_2. The precipitate was separated by centrifugation and, after the addition of 20 μL (0.084 mmol) of methyl trifluoromethylsulfonate in 2 mL of dry CH_2Cl_2, was redissolved using sonication for 30 min at room temperature. The solvent and volatile by-products were removed by a stream of Ar and the product was recrystallized from CH_2Cl_2–hexane.

*Bromonium ion of **13***

To 22.4 mg of **13** (0.077 mmol) dissolved in 1 mL of dry CH_2Cl_2 cooled by Dry Ice was slowly added a small excess of Br_2 (24.5 mg) in 0.65 mL of CH_2Cl_2 under Ar. The orange precipitate formed was then separated from the liquid phase and redissolved in 2 mL of CH_2Cl_2 solution containing 67.9 mg (0.077 mmol) of the sodium salt of tetra(3,5-di(trifluoromethyl)phenyl)borate. While the system was kept at Dry Ice temperature the bulk of the solvent was removed by a stream of Ar and the product was precipitated by the addition of dry hexane.

*4-Pentenyl-2,3,4,6-tetra-*O*-methyl-β-D-glucopyranoside **10***

A 20 mL solution of anhydrous methanol containing 1.3 g (3.12 mmol) of 4-pentenyl-2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (11) and 100 mg of K_2CO_3 was stirred for 5 h. The reaction was filtered through a Celite pad and the solvent was removed, leaving a crude product that was added to a suspension of 0.72 g of NaH (30 mmol) in 50 mL of dry dimethylformamide. The reaction mixture was cooled in an ice bath and 2 mL of methyl iodide were added dropwise. The system was allowed to warm to room temperature overnight, after which the product was extracted with 100 mL of ether. The ether layer was washed with 100 mL each of water, saturated $NaHCO_3$ (twice), and saturated KCl (twice), dried over $MgSO_4$, and then concentrated by rotary evaporation. The residue was flash chromatographed (95:5 to 85:15 petroleum spirit:EtOAc) to give 0.54 g (62%) of the liquid product. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.80 (m, 1H), 5.00 (m, 2H), 4.20 (d, J = 7.4 Hz, 1H), 3.92 (m, 1H), 3.61 (s, 3H), 3.60–3.20 (m, 4H), 3.57 (s, 3H), 3.51 (s, 3H), 3.38 (s, 3H), 3.10 (m, 2H), 2.98 (m, 1H), 2.12 (m, 2H), 1.70 (m, 2H): MS *m/z*: 304.(M^+), 303 ($M^+ - 1$).

*5-Hexenyl-2,3,4,6-tetra-*O*-methyl-β-D-glucopyranoside (**11**)*

This was prepared in the same manner as above from 5-hexenyl-2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside: yield, 55%. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.78 (m, 1H), 4.95 (m, 2H), 4.20 (d, J = 7.6 Hz, 1H), 3.90 (m, 1H), 3.61 (s, 3H), 3.60–3.20 (m, 4H), 3.56 (s, 3H), 3.51 (s, 3H), 3.38 (s, 3H), 3.10 (m, 2H), 2.95 (m, 1H), 2.05 (m, 2H), 1.70–1.4 (m, 4H).

(c) Product analysis for the reaction of 4-pentenyl-2,3,4,6-tetra-*O*-methyl-β-D-glucopyranoside (10) with Ad═Ad-Br$^+$

To a solution of 29.4 mg of **10** (0.1 mmol) in 1 mL of dry CH_2Cl_2 was added 58 mg of Ad═Ad-Br$^+$ (0.11 mmol, prepared according to the procedure given in refs. (1 and 3) and the system was kept at room temperature overnight. The solvent was removed and tetrahydrofurfuryl bromide was dissolved in CH_3CN. The product was further purified by using preparative GC (30% SE-30 Chrom AW 3/8 in × 3 ft, 150°C, 30 mL/min). The enantiomeric excess at C_2 in the tetrahydrofurfuryl bromide was determined by ^{1}H NMR using the chiral shift reagent tris[3-heptafluoropropylhydroxymethylene-(+)-camphorato] europium(III), (Eu(hfp)$_3$). The sample was dissolved in 0.7 mL of $CDCl_3$ containing 9.5 mg of Eu(hfp)$_3$ and the ratio between the different stereoisomers determined by comparison of the integrated intensities of the signals at δ 9.5 and 9.1 corresponding to the C-H protons at C_2. Absolute configuration was determined on the basis of comparison of the optical rotation of the sample solution in $CHCl_3$ with the reported assignment (11*c*).

(d) Kinetics

The kinetics of the reactions of the bromonium and iodonium ions of Ad═Ad with olefins **10** and **11** were monitored by observing the rate of disappearance of the halonium ions in purified 1,2-dichloroethane (DCE) at 25°C under pseudo-first-order conditions of excess olefin. A limited number of kinetic runs were conducted with the bromonium ion of **12**. In the case of **12**-Br$^+$/OTf$^-$, 3.5×10^{-4} M solutions were used and the reactions were followed at 260 nm (ε_{260} = 6330 M^{-1} cm^{-1}). The observed rate constants were determined by initial rate methods, monitoring the ΔAbs for the initial 5–10% of the reaction. The pseudo-first-order rate constants, k_{obs}, were evaluated as $k_{obs} = (\Delta Abs)/(\Delta t[\mathbf{1}\text{-}X^+]\varepsilon)$, where X = Br or I, Δt = the initial time span, and ε the extinction coefficient at 260 nm given above. The second-order rate constants for the reaction, k_2, were determined from plots of k_{obs} vs. [olefin] using four to six different concentrations of olefin from 0 to 10^{-2} M.

Results and discussion

(a) Kinetics of X$^+$ transfer to pentenyl and hexenyl glucopyranosides 10 and 11

Rodebaugh and Fraser–Reid (11) have studied the transfer of Br$^+$ from NBS to the tetrabenzyl analogues of **10** and **11** for production of the cyclized tetrahydrofurfuryl and pyranyl bromides (Scheme 3). They observed, for competitive reactions containing excess and equal amounts of both alkenes, that the product ratio changes when the initial concentrations of **10** and **11** were equally reduced. Thus, there must be communication between the bromonium ions formed from each of the *n*-pentenyl and the *n*-hexenyl glycosides and the two parent olefins. When studied alone, the cyclization of the *n*-pentenyl glycoside was shown to give a 20% enantiomeric excess in the tetrahydrofurfuryl bromide product, which indicates that there is some chiral induction attributable to the remote glycoside. This reaction is an ideal candidate for kinetics studies using Ad═Ad-Br$^+$ as the Br$^+$ source since the bromonium ion has a strong chromophore with which to monitor the reaction progress. Furthermore, at some point, the transfer requires that the bulky Ad═Ad and alkene must share the Br$^+$ in a transition state or complex as in Scheme 1, so the resulting steric interactions could further discriminate between the diastereomeric transition states and lead to enhanced chiral induction.

In our study the permethylated derivatives **10** and **11** were used for the reaction instead of the perbenzylated ones in order to avoid interference form the highly absorbing phenyls in conducting the UV–VIS kinetic studies. Given in Tables 1 and 2 are the pseudo-first-order rate constants (k_{obs}) for the reaction of the Ad═Ad-Br$^+$ and -I$^+$ with excess **10** in the presence and absence of added [Ad═Ad]. In Tables 3 and 4 are the analogous data for the reaction of these ions with excess **11**. The second-order rate constants were determined from a plot of k_{obs} vs. [**10**] or [**11**]: for bromine transfer the values are $(1.04 \pm 0.06) \times 10^{-1}$ M^{-1} s^{-1} and $(5.34 \pm 0.2) \times 10^{-2}$ M^{-1} s^{-1} with olefins **10** and **11**, respectively, while the corresponding values for the iodonium ion are roughly 100 times faster at (10.6 ± 0.1) and (5.3 ± 0.2) M^{-1}s^{-1}. These are the same general trends noted for X$^+$ transfer from Ad═Ad-X$^+$ to 4-pentenol and 5-hexenol (1, 2) where the respective rate constants for Br$^+$ cyclization are 3.4 and 0.35 M^{-1} s^{-1}, and the I$^+$ cyclizations are 70- and 28-fold faster.

Of note is the fact that added Ad═Ad does not lead to a reduction in the rate of any reaction of **10** or **11** nor, from the data in Table 5, does 1-pentanol accelerate the process.

This stands in contrast with the situation for Ad═Ad-Br$^+$-induced cyclization of 1-pentenol (1, 2) and rules out the process given in Scheme 4 where a free bromonium ion (**15**) is produced during the course of the reaction with **10** or **11**. The most favored explanation is a process where the cyclization occurs directly and irreversibly from the Ad═Ad-X$^+$ complex (**14**) of the olefins.

Since the kinetic study indicates that the cyclization occurs within the complex, we expected to see enhanced chirality in the tetrahydrofurfuryl bromide produced from the glucopyranoside auxiliary **10**. This expectation was predicated on the fact that approach of the Ad═Ad-Br$^+$ to the olefin can occur from either of two faces, and the cyclization must occur by a *trans* displacement of the β-anomeric oxygen on the remote C-Br$^+$. This brings the sterically demanding complexed Ad═Ad-Br$^+$-olefinic portion into close proximity with the chiral glucopyranoside. To test this, equimolar Ad═Ad-Br$^+$ and **10** were allowed to react overnight and the tetrahydrofurfuryl bromide products were separated and purified. ^{1}H NMR analysis of the CH methine protons at δ 9.5 and 9.1 ppm using a chiral shift reagent indicated a 20% enantiomeric excess in the product. On the basis of the sign of the net optical rotation of the product (11*a*), the predominant stereoisomer was (−)-(*S*)-tetrahydrofurfuryl bromide. These results are similar to those reported by Rodebaugh and Fraser–Reid for the cyclization of the perbenzyl analogue of **10** (11*a*), which indicates

that the use of the bulky Ad═Ad-Br^+ moiety confers no advantage over NBS in promoting chiral cyclization of these alkenes.

(b) Axially methylated derivatives 12 and 13

Olefin **12** was generously provided by Prof. A. J. Bennet (13) while **13** was prepared by treatment of the corresponding ketone (14) with dimethyltitanium dichloride (15). The corresponding bromonium ions were made by simple treatment of **12** with Br_2 and methyl triflate as was the case for the parent Ad═Ad (3), and treatment of **13** with Br_2 and the sodium salt of tetra (3,5-di(trifluoromethyl)phenyl)borate. We had anticipated that the interaction of the axial CH_3 group and the proximal Br would lead to considerable distortion of the three-membered ring, but unfortunately this could not be confirmed directly since crystals of the bromonium ions of sufficient quality for X-ray diffraction analysis could not be obtained.

The olefins and their bromonium ions were subjected to extensive ^1H and ^{13}C NMR studies using COSY, NOE, and long- and short-range NMR experiments. Given in Tables 6 and 7 are the ^{13}C NMR data for **12**, **12**-Br^+/ OTF^- and **13**, **13**-Br^+/ $B(Ph(CF_3)_2)_4^-$. By comparison with the olefinic carbons of adamantylideneadamantane at δ 133.66 ppm (3), the C_2 and $C_{2'}$ olefinic carbons of **12** and **13** appear at δ 130.26, 136.35 and 132.07, 135.20 ppm, respectively. Bromination of the parent Ad═Ad to give the symmetrical bromonium ion produces a downfield shift in both carbons of 22.58 ppm to δ 156.24 (3): in the case of **12**-Br^+ C_2 and $C_{2'}$ appear at δ 160.51 and 142.77 while for **13**-Br^+ these carbons are at δ 168.31 and 139.59 ppm, respectively. The more pronounced downfield shift of C_2 (30 and 36 ppm) than that of $C_{2'}$ (6.4 and 4.4 ppm) upon bromonium ion formation from **12** and **13** indicates a high degree of asymmetry in these ions as would be expected if the axial methyl group and Br are sterically buttressed. This buttressing is the source of some instability and although the ions are indefinitely stable at −50°C, they decompose readily at room temperature to unknown materials.

Despite the instability of **12**-Br^+ at room temperature, a few kinetics experiments were conducted to determine its efficacy in promoting the cyclization of 4-pentenol in dichloroethane at 25°C. At 260 nm **12**-Br^+/ OTF^- has an extinction coefficient (6330 ± 50 M^{-1} cm^{-1}) that is roughly 2-fold greater than that of Ad═Ad-Br^+ (3200 M^{-1} s^{-1}) (1, 2). From the slopes of plots of the pseudo-first-order rate constants for loss of **12**-Br^+ as a function of excess 4-pentenol, a second-order rate constant of about 2000 ± 300 M^{-1} s^{-1} is obtained. This value is 500–600 times greater than the value obtained for Ad═Ad-Br^+ (1, 2), which probably results from a destabilized ground state for the distorted bromonium ion in **12**-Br^+.

Conclusions

In the above research we have attempted to design Br^+ transfer agents based on the adamantylideneadamantane skeleton to induce chirality in the cyclization of alkenes. The kinetics results indicate that cyclization of the 4-pentenyl permethylated glycoside, **10**, must occur through a complex of the olefin and Ad═Ad-Br^+. Disappointingly, there is no additional enantiomeric excess in the tetrahydrofurfuryl bromide product over what is observed using NBS and the perbenzylated analogue of **10** (11). An attempt to build chirality into the Ad═Ad system using axial methylation of one of the homoallylic car-

© 1997 NRC Canada

bons was undertaken and the racemic derivatives **12** and **13** were synthesized for preliminary studies. Unfortunately, the bromonium ions of these materials are not stable when held at room temperature for prolonged periods. The results of this research indicate that it is unlikely that the Ad=Ad system will prove of utility in inducing chiral Br^+ transfer to olefins. Alternative ways of effecting this important process are currently under investigation in these laboratories.

Conformational behavior and electronic structure of silylketenes studied with quantum chemical calculations and photoelectron spectroscopy

Heidi M. Muchall, Nick H. Werstiuk, Jiangong Ma, Thomas T. Tidwell, and Kuangsen Sung

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12
For personal use only.

Abstract: The He(I) photoelectron spectra of silylketenes $(Me_3Si)_2C{=}C{=}O$ (**1**), $Me_5Si_2CH{=}C{=}O$ (**2**), $Me_2Si(CH{=}C{=}O)_2$ (**3**), $MeSi(CH{=}C{=}O)_3$ (**4**), $(SiMe_2CH{=}C{=}O)_2$ (**5**), and $(CH_2SiMe_2CH{=}C{=}O)_2$ (**6**) have been recorded and their structures and orbital energies have been calculated by ab initio methods. Orbital energies for disilanes **2** and **5** are strongly dependent on a Si-Si-C-C torsional angle due to σ–π orbital interaction. Comparisons between experimental and simulated spectra show that **2** and **5** prefer conformations in which the Si—Si bond and ketene group(s) are approximately orthogonal (113° and 111°, respectively). Silylalkenes $Me_5Si_2CH{=}CH_2$ (**7**) and $(SiMe_2CH{=}CH_2)_2$ (**8**), which have been included in the computational study, show the same behavior as their corresponding silylketenes. Silylbis- and trisketenes **3–6** do not exhibit π–π interaction of any significance. For Si—Si containing compounds, the best agreement between experimental and computed data was obtained when Becke3LYP/6-31G*//HF/3-21G* was employed.

Key words: conformational behavior, electronic structure, photoelectron spectroscopy, quantum chemical calculations, silylketenes.

Résumé : On a déterminé les spectres photoélectroniques He(I) des silylcétènes $(Me_3Si)_2C{=}C{=}O$ (**1**), $Me_5Si_2CH{=}C{=}O$ (**2**), $Me_2Si(CH{=}C{=}O)_2$ (**3**), $MeSi(CH{=}C{=}O)_3$ (**4**), $(SiMe_2CH{=}C{=}O)_2$ (**5**) et $(CH_2SiMe_2CH{=}C{=}O)_2$ (**6**) et on a calculé leurs structures et leurs énergies orbitalaires par des méthodes ab initio. Les énergies orbitalaires des disilanes **2** et **5** dépendent fortement d'un angle de torsion Si-Si-C-C dû à une interaction σ–π. Des comparaisons entre les spectres expérimentaux et simulés montrent que les composés **2** et **5** adoptent préférentiellement des conformations dans lesquelles la liaison Si—Si et le(s) groupe(s) cétène(s) sont approximativement orthogonaux (113° et 111° respectivement). Les silylalcènes $Me_5Si_2CH{=}CH_2$ (**7**) et $(SiMe_2CH{=}CH_2)_2$ (**8**) dont on a aussi calculé les énergies présentent le même comportement que celui des silylcétènes correspondants. Les silylbis- et triscétènes **3–6** ne présentent pas d'interactions π–π significatives. Pour les composés comportant une liaison Si—Si, l'utilisation de la méthode Becke3LYP/6-31G*//HF/3-21G* conduit au meilleur accord entre les données expérimentales et calculées.

Mots clés : comportement conformationnel, structure électronique, spectroscopie photoélectronique, calculs quantiques de chimie, silylcétènes.

Introduction

Studies on ketenes have shown a remarkable stabilizing effect of silyl substituents on the ketene group, giving persistent mono- and bisketenes (1). In a previous study (2), the availability of a number of conformationally flexible silylketenes had prompted us to employ photoelectron (PE) spectroscopy, *the* technique giving information about bonding in organic molecules. PE spectroscopy has been of continued use for conformational analyses where orbital energies depend on torsional angles (3) and has proved especially suited for systems with neighboring electron lone pairs or π electrons. Besides the expected π–π interaction in the bisketenes studied, ab initio calculations suggested an interesting σ–π interaction in *t*-$BuMe_2SiCH{=}C{=}O$ involving an energetically high-lying orbital of the *tert*-butylsilyl bond (2). Using Koopmans' theorem (4) to correlate HF ab initio orbital energies and experimental ionization potentials, we interpreted and accurately simulated the experimental PE spectra, thereby confirming the applicability of the combination of ab initio calculations and PE spectroscopy to the study of the conformational behavior of silylketenes. PE spectra of disilanes (5) and ketenes (6) are well known, yet there are no spectra reported of compounds combining disilane and ketene moieties, compounds of potential interest with respect to σ–π orbital interactions. Further-

more, while we presented PE spectra of some silylketenes and silylbisketenes (2), there are no reports of such studies of compounds having more than one ketene group connected to a silicon atom, which are sources of possible remote π–π orbital interactions.

The preparation of such compounds has been reported recently (7, 8), and in this paper we report the conformational behavior of silylketenes **1–6** using ab initio calculations and PE spectroscopy. Where necessary for the interpretation of the experimental spectra, Becke3LYP (9) of density functional theory (DFT) has been employed alongside HF (10) theory.[2] Computational studies for silylalkenes **7** and **8** are included for comparison. The ionization potentials of these species have been presented (12) but representations of their PE spectra have not been reported. The interpretation of the spectra for **7** and **8** (12) does not agree with our conclusions on similar systems (2), and so we have studied **7** and **8** in more detail computationally.

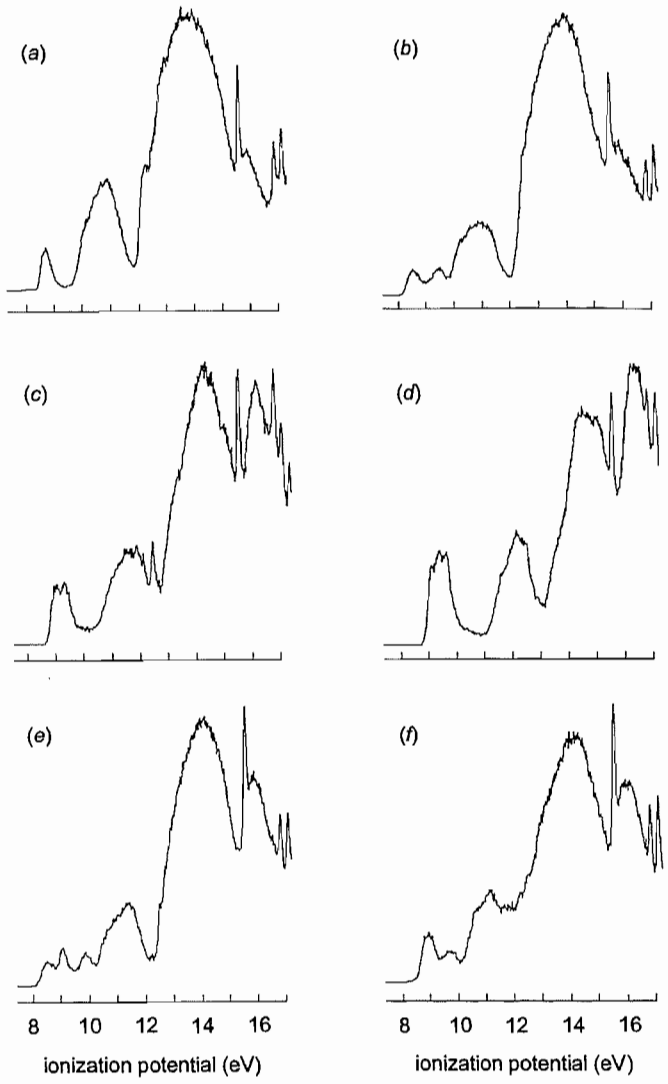
Experimental



Ab initio HF (10) and Becke3LYP (9) calculations were carried out on IBM RS/6000 model 39H, 350, and 530 computers with GAUSSIAN 94 (13).[3] Semiempirical PM3 (14) calculations were performed with the MOPAC (15) program package (version 6.00) on an IBM RS/6000 model 320H computer. Except for those dihedral angles fixed in torsional analyses and indicated in the text, all geometry parameters were optimized. Synthetic spectra were calculated from the MO results with a Fortran program PESPEC (16). Graphical representations of the computationally determined eigenvectors (PM3//HF/3-21G*; these were checked against HF/3-21G*//HF/3-21G* as well as Becke3LYP/6-31G*//HF/3-21G* eigenvectors and were found to compare well) were plotted from HyperChem 4.[4]

[2] A rationale for the successful application of the Koopmans' theory-like interpretation of the orbital energies obtained at the DFT level of theory in a PE spectroscopic study of a series of carbenes has recently been provided by Arduengo et al. (11). It is clear that applying a uniform shift based on the difference in calculated HOMO energy and the experimental first vertical IP to the DFT orbital energies nicely reproduces the PE spectra of compounds presented here, which are vastly different from the carbenes studied by Arduengo.

[3] Total energies are uncorrected; for a discussion of the inclusion of zero-point vibrational energies in these studies, see Werstiuk et al. (2).

Fig. 1. UV photoelectron spectra of silylketenes (*a*) **1**, (*b*) **2**, (*c*) **3**, (*d*) **4**, (*e*) **5**, and (*f*) **6**.

He(I) PE spectra were measured with a locally built instrument (17) by signal averaging 40–50 scans, with nitrogen (15.6 eV) as the calibrant. Linearity of the scale was ensured through calibrations with methyl iodide (9.54 and 10.16 eV) and O_2 (12.30 eV) performed prior to the experiments.

Silylketenes **1–6** were synthesized as reported (7, 8).

Calculations and photoelectron spectra

Bis(trimethylsilyl)ketene (1)

Except for the rotation of the two trimethylsilyl groups, there is no conformational flexibility in this simple silylketene. According to HF/3-21G*, the preferred conformation **1a** has C_2 symmetry, one methyl group of each Me_3Si moiety being twisted out of the *syn*-periplanar (*sp*) arrangement with the ketene group by 17.7° to avoid eclipsing. Fixing these torsional angles at 0° (*sp* conformation **1b**) leads to an increase in total energy of 2.90 kJ mol^{-1}, whereas keeping them at 180° (*anti*-periplanar conformation **1c**) causes a destabilization of 18.49 kJ mol^{-1}. Neither **1b** nor **1c** are minima on the potential energy surface with HF/3-21G*.

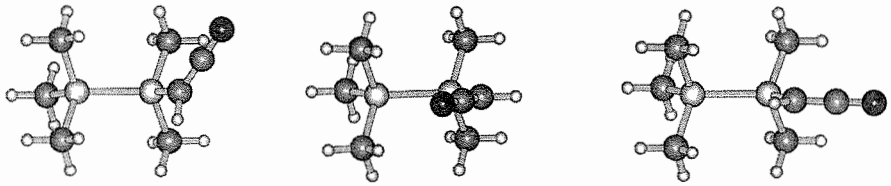
The HOMO of **1**, which is mainly π_{CCO} with only minor contributions from Si—CH_3 bonds, is followed by a group of five orbitals (HOMO-1 to HOMO-5; 11.23, 11.73, 11.84, 12.07, and 12.12 eV), all of which have σ Si—C character. Upon rotation of one trimethylsilyl group, there is essentially no dependence of the orbital energies on the torsional angle.



The PE spectrum of ketene **1**, which resembles that of $Me_3SiCH{=}C{=}O$ (**2**), exhibits two separate bands in the low-energy region (Fig. 1(*a*)). The first band (8.75 eV) belongs to just one ionization, the second, centered at 10.7 eV, to five. Another band at 12.29 eV is resolved in front of the σ region. Compared to the first ionization of $Me_3SiCH{=}C{=}O$ (8.95 eV) (**2**), that of **1** is shifted to a slightly lower IP, showing the destabilization of the π_{CCO}-HOMO due to further $SiMe_3$ substitution. The relative positions of the bands correspond well to the computed relative orbital energies for **1** (Table 1); in particular, the HOMO energy taken from a PM3 single-point calculation on the HF/3-21G* optimized geometry of 8.52 eV is very close to the experimental value of 8.75 eV for the first ionization.

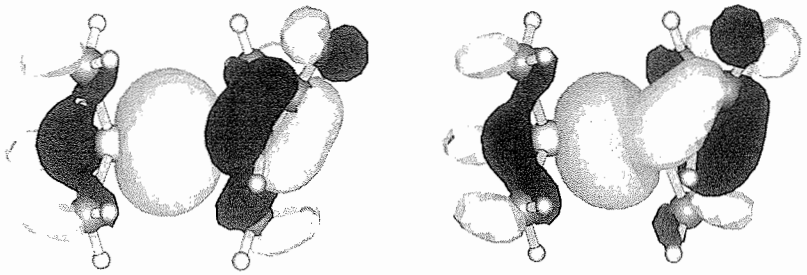
2a **2b** **2c**



(Trimethylsilyldimethylsilyl)ketene (2)

The most stable conformation of the related (*tert*-butyldimethylsilyl)ketene was found to be one in which one methyl group is oriented *sp* to the ketene group, the Bu^t-Si-C-C dihedral angle being 115.4° (2). We studied three conformations, **2a–2c**, of disilylketene **2**. While HF/3-21G* calculations predict the 0° conformer (Si-Si-C-C torsional angle) **2b** to be lowest in energy, both HF/6–31G*//HF/3-21G* and Becke3LYP/6–31G*//HF/3-21G* calculate **2a** to be more stable than **2b**, the 180° conformer **2c** showing the highest energy (Table 2). For *t*-$BuMe_2SiCH{=}C{=}O$ the conformation analogous to **2a** was also found to be most stable (2). In **2a**, the Si—Si bond length is 234.7 pm and the Si-Si-C-C dihedral angle is 112.6°. The semiempirical PM3 method stretches the Si—Si bond considerably (to 246.0 pm in the optimized **2a**), which allows the ketene group to adopt a smaller torsional angle of 92.5°.

The geometries of **2** and (*tert*-butyldimethylsilyl)ketene are comparable but there is a distinct difference in their electronic structures. In the *tert*-butyl carbon analog of **2**, orbital energies do not seem to be a function of the Bu^t-Si-C-C torsional angle (2). For **2a**, HOMO and HOMO-1 are the antisymmetrical and symmetrical combinations of π_{CCO} with σ-type contribution of electron density on the Si—Si bond. HOMO-1 is followed by a group of four orbitals (HOMO-2 to HOMO-5, σ Si—C type, values not given) that are energetically close together. In disilane **2**, the HOMO/HOMO-1 splitting is strongly dependent on the Si-Si-C-C torsional angle, regardless of the level of theory applied. HOMO (σ_{SiSi}) and HOMO-1 (π_{CCO}) show no mixing and are quite similar in energy in the 0° conformer **2b**, Δε of these two orbitals being 0.33 (PM3), 0.27 (HF/3-21G*), and 0.42 eV (Becke3LYP/6–31G*//HF/3-21G*). This difference grows as the torsional angle is increased and the orbitals are allowed to mix. The greatest Δε of 1.73 (PM3), 1.63 (HF/3-21G*), and 1.28 eV (Becke3LYP/6–31G*//HF/3-21G*), due to maximal σ–π interaction, is found at 90°, decreasing again to about the 0° value on going to 180°. An explanation for the preference of a dihedral near 90° (**2a** is the global minimum) in spite of this destabilizing interaction is given by the very low lying LUMO of σ^*_{SiSi} character: the σ*–π interaction is stabilizing.

The potential for this twisting about the Si—CCO bond was obtained by fixing the Si-Si-C-C dihedral at 0°, 45°, 90°, 135°, and 180° and relaxing the rest of the molecule. Fitted curves as calculated by PESPEC (16) on HF/3-21G* and Becke3LYP/6–

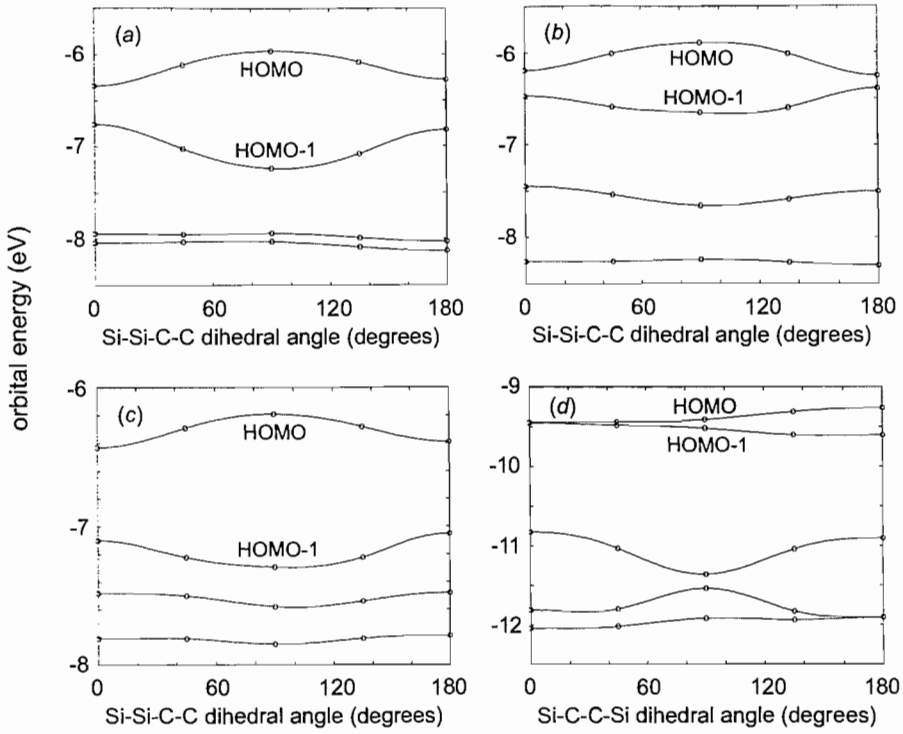
31G*//HF/3-21G* relative energies are shown in Fig. 2(*a*). The change in orbital energies of the four highest occupied molecular orbitals upon increase of the Si-Si-C-C torsional angle is given in Fig. 3(*a*) (Becke3LYP/6-31G*//HF/3-21G* values). The progression of HOMO and HOMO-1 clearly shows the pronounced σ–π interaction in disilane **2** that was previously proposed on the basis of UV data for **2** (8).

In the PE spectrum of disilylketene **2** depicted in Fig. 1(*b*), the first (8.52 eV) and second (9.51 eV) ionization each give rise to a separate band; the third band (centered at 10.9 eV) is formed by four ionizations. The overall appearance of the spectrum is similar to that of (*tert*-butyldimethylsilyl)ketene (2), yet the first IP of **2** is found at a lower value than that of the corresponding *tert*-butyl carbon analog (8.79 eV), which indicates a greatly destabilized HOMO. This and the experimentally determined gap of 1 eV between the first two ionizations of **2** shows the extent of interaction between σ_{SiSi} and π_{CCO} in **2**, which was predicted by the calculations (Fig. 3(*a*)). While both HF/3-21G*//HF/3-21G* and HF/6-31G*//HF/3-21G* overestimate the σ–π interaction, leading to an exaggerated splitting of the first two orbitals, there is excellent agreement between the relative ionization energies and the relative calculated orbital energies of **2** when Becke3LYP is employed. Electron correlation, therefore, cannot be neglected when describing the electronic structure of this disilane. The simulated PE spectrum obtained with PESPEC and based on the calculated potential (Fig. 2(*a*)) is given in Fig. 4(*a*). Twelve eigenvalues (HOMO to HOMO-11) were used to synthesize the partial spectrum of **2**, convoluted with a Gaussian lineshape with a full width at half height (FWHH) of 0.4 and the temperature set at 300 K. The simulated spectrum correctly reproduces the low-energy part of the experimental spectrum of **2**, suggesting that disilylketene **2** prefers a conformation in which the Si—Si bond and ketene group are close to orthogonal for maximum orbital interaction. While Becke3LYP values are excellent in terms of relative orbital energies, they differ by several eV from the experimental values.[2] As for **1**, the energy of the first ionization can be predicted well using PM3//HF/3-21G*.

Fig. 2. Torsional potential calculated with PESPEC (HF/3-21G*, solid line; Becke3LYP/6–31G*//HF/3-21G*, broken line): twisting about (*a*) the Si—CCO bond of **2**, (*b*) one Si—CCO bond of **5**, and (*c*) the CH_2—CH_2 bond of **6**.



(Trimethylsilyldimethylsilyl)ethene (7)

A comparison of (*tert*-butyldimethylsilyl)ketene and (*tert*-butyldimethylsilyl)ethene revealed similar conformational behavior and orbital interactions, with more σ–π interaction for the alkene as judged by the angular dependence of the HOMO/HOMO-1 gap (2). Khvostenko et al. (12) reported an absence of σ–π conjugation for (trimethylsilyldimethylsilyl)ethene (**7**) based on the first IP in the PE spectra of the

© 1997 NRC Canada

Fig. 3. Angular dependences of the MO energies of HOMO to HOMO-3 of (*a*) **2**, (*b*) **5**, and (*c*) **8** (Becke3LYP/6-31G*//HF/3-21G*), as well as (*d*) HOMO to HOMO-4 of **6** (HF/3-21G*).

series **7** (8.56 eV), 1,2–divinyl-1,1,2,2–tetramethyldisilane (**8**) (8.63 eV), and hexamethyldisilane (8.69 eV), which they claimed to be constant. As this was quite unexpected, we calculated the potential for the rotation of the ethylene moiety in alkene **7**. Two conformations, **7a** and **7b**, correspond to **2a** and **2b**, respectively. The Si—Si bond length (235.0 pm) and Si-Si-C-C dihedral angle (109.4°) in the optimized **7a** (HF/3-21G*) compare to those in **2a**, as do the orbitals (LUMO of **7a** is a low-lying σ^*_{SiSi}, HOMO the antibonding combination of σ_{SiSi} with $\pi_{C=C}$). Likewise, the Becke3LYP/6-31G*//HF/3-21G* fitted potential for the rotation in **7** resembles that found for **2**, except for the energy difference of 3.26 kJ mol^{-1} between **7a** and the 0° conformation **7b** being larger than for the respective conformations of **2** (0.73 kJ mol^{-1}). This is due to the greater steric interaction experienced by the vinyl hydrogen atom, which points inwards in **7**, compared to that for the ketene group in **2** and can be seen in the different Si-C-C angles (122.7° **2a**/125.2° **7a**, 121.2° **2b**/125.9° **7b**), as for the *tert*-butyl analogs (2). Yet in contrast to these *tert*-butyl compounds, the σ–π interaction seems to be greater in ketene **2** (the HOMO/HOMO-1 gap increasing from 0.42 to 1.28 eV) than in alkene **7** (from 0.50 to 1.18 eV, Becke3LYP/6-31G*// HF/3-21G*, plot not shown). The torsional dependence of HOMO and HOMO-1 resulting from the relative orientations of the Si—Si bond and the C—C double bond in alkene **7** is clearly in contrast to the absence of σ–π conjugation published by Khvostenko et al. (12). The simulated PE spectrum for **7** (Becke3LYP/6-31G*//HF/3-21G*, 12 eigenvalues, FWHH 0.4, temperature 300 K), which unfortunately cannot be compared to the experimental spectrum, is shown in Fig. 4(*b*). Yet it was stated (12) that the second and the third band in the spectrum of **7** are poorly resolved and this is correctly reproduced by the calculations as can be seen in the synthesized spectrum. Thus we can conclude that alkene **7** exhibits the same conformational properties as ketene **2**.

Dimethylsilylbisketene (3)

Five conformations of bisketene **3** were studied at the ab initio level. Conformer **3a**, shaped like a partial propeller (where one "blade" is represented by a methyl group) with one ketene group *sp* to the other Si—CCO bond and one ketene group *sp* to one Si—CH_3 bond (the torsional angles being 12.6° and 5.2°, respectively), and conformer **3b**, another propeller, with C_2 symmetry and ketene groups each *sp* to one Si—CH_3 bond (OC-C-Si-CH_3 dihedrals are 4.2°) and *anti* with respect to each other, are essentially equal in energy at HF/3-21G*. The related *syn* conformer **3c** with ketene groups *sp* to the same Si—CH_3 bond (OC-C-Si-CH_3 dihedrals are 8.4°) is 3.9 kJ mol^{-1} higher in energy (Table 2). While HF/6-31G*//HF/3-21G* total energies of the three conformers (not given) follow the same ordering, Becke3LYP/6-31G*//HF/3-21G* reverses the energetic order of **3a** and **3b**. Two in-plane conformations (U and W shaped), which are still higher in energy at the semiempirical level (PM3), are not stationary points according to ab initio calculations.

Orbital energies for the three low-energy conformations **3a–3c** are very similar, according to all computational methods applied. HOMO and HOMO-1 (symmetrical and antisymmetrical combinations of π_{CCO}'s) are close in energy, followed by a group of three orbitals (HOMO-2 to HOMO-4, values not given) that are mainly σ Si—C type. To obtain the potential energy surface and determine the extent of orbital

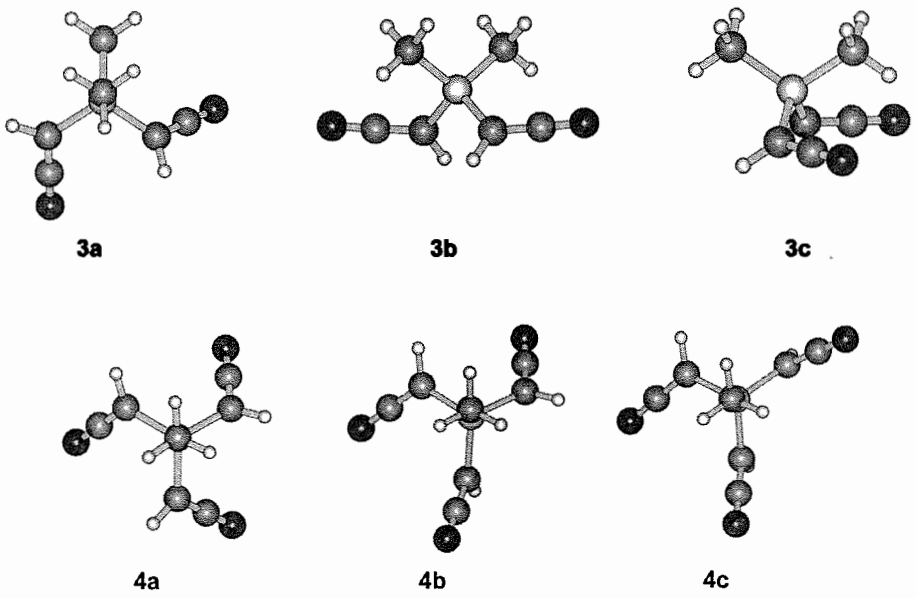

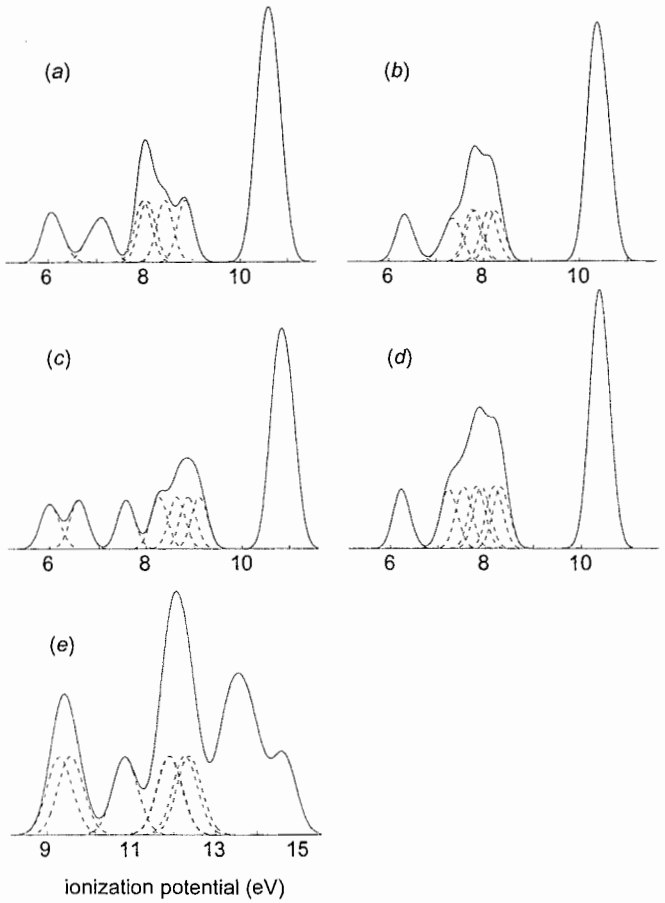

Fig. 4. Synthetic partial UV photoelectron spectrum calculated with PESPEC of (*a*) **2**, (*b*) **7**, (*c*) **5**, (*d*) **8**, and (*e*) **6**.

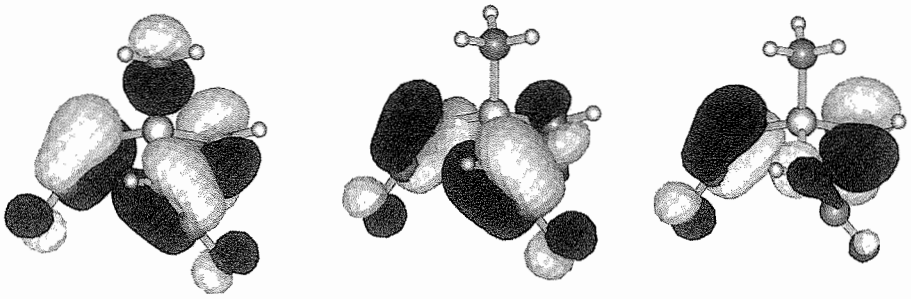
energy dependence on changes in the orientation of the two ketene groups, one dihedral (of the ketene group *sp* to the Si—CH_3 bond) was restrained at its original value and the other varied (plots not shown). As suggested by the similar energies of HOMO and HOMO-1 of **3a**–**3c**, the orbital energies are almost independent of the torsional angle. This fact, as well as the near degeneracy of HOMO and HOMO-1, shows that there is little π–π interaction between the two ketene moieties in bisketene **3**.

Like **1**, the PE spectrum of bisketene **3** (Fig. 1(*c*)) closely resembles that of $Me_3SiCH{=}C{=}O$ (2). For **3**, the first band is made up of two ionizations (9.10 and 9.38 eV) and the second, centered at 11.7 eV, corresponds to three (the sharp peak at 12.51 eV is due to traces of water). The stabilization of the HOMO (and therefore greater value for the first IP), upon substitution of one methyl group in $Me_3SiCH{=}C{=}O$ by a second ketene moiety, and the very small splitting of the first two ionizations arising from the absence of significant π–π interaction are accurately predicted by the calculations (Table 1).

Methylsilyltrisketene (4)



The most stable conformation of trisketene **4** is the symmetrical propeller **4a**, as found with all computational methods (Table 2). All ketene groups in **4a** are oriented *sp* to a Si—CCO bond; the respective torsional angles OC-C-Si-CCO are 10°. Two further low-energy conformations **4b** and **4c** can be derived from the propeller **4a** by twisting one or two ketene groups, respectively, into an arrangement *sp* to the Si—CH_3 bond.

Molecular orbitals HOMO to HOMO-5 for **4a**–**4c** come in two groups of three centered around 9.8 and 13.2 eV as calculated by HF/3-21G*. The first group is made up of three combinations of three π_{CCO}'s, one symmetrical and two antisymmetrical. The energy difference $\Delta\varepsilon$ between the first (HOMO) and last (HOMO-2) orbital in this group is 0.23 (**4a**), 0.53 (**4b**), and 0.67 eV (**4c**). In **4a**, HOMO-1 and HOMO-2 are degenerate because of the symmetry of the conformer; as the orbitals split in **4b** and **4c**, $\Delta\varepsilon$ becomes bigger. Orbitals in the second group (HOMO-3 to HOMO-5) are three combinations of σ Si—C type and show a similar behavior to those of the first group with respect to $\Delta\varepsilon$.

For the determination of the potential energy surface (plot not shown), two ketene dihedrals in **4a** were kept at their original values while the remaining one was twisted. Again, as in

4a-HOMO **4a**-HOMO-1 **4a**-HOMO-2

the case of dimethylsilylbisketene (**3**), the orbital energy dependence on the torsional angle is small, further confirming the lack of significant π–π interaction between the ketene groups in these molecules.

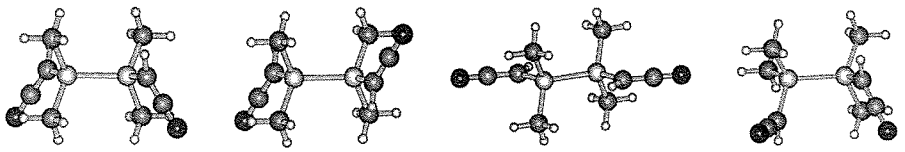
The PE spectrum of trisketene **4**, which on going from $Me_3SiCH{=}C{=}O$ has two methyl groups replaced by ketene groups, shown in Fig. 1(*d*) resembles that of bisketene **3**. For **4**, there are two bands of similar intensity in the low-energy region, one around 9.4 eV for which three maxima can be given, the other at about 12.2 eV. Each is composed of three ionizations. Again, this spectrum displays the computationally predicted small splitting of the first three IPs coherent with a small π–π interaction between the ketene groups (Table 1). The fact that we are able to assign three maxima in the first band suggests that **4** to a certain degree exists in unsymmetrical conformations that do not permit HOMO-1 and HOMO-2 to be degenerate.

1,2–Bis(ketenyl)-1,1,2,2-tetramethyldisilane (5)

Three conformations of disilylbisketene **5** with the OCC-Si-Si-CCO dihedral at 180° were studied and, except for the semiempirical PM3 method, all calculations predict **5a** to be lowest in energy (Table 2). Ketene groups in the C_2 symmetrical **5a** are oriented *sp* to Si—CH_3 bonds (C-Si-C-C dihedral is 9°) and *syn* towards each other. The corresponding *anti* conformer **5b**, which is the global minimum with PM3, is only slightly destabilized. Conformer **5c** with Si-Si-C-C dihedral angles at 180° is higher in energy. The Si—Si bond length (234.2 pm) and Si-Si-C-C torsional angles (111.0°) of **5a** obtained with HF/3-21G* resemble those of **2a**, the other disilane studied. Again, PM3 lengthens the Si—Si bond to 246.7 pm, which allows the ketene groups to approach the optimal right angle. The fourth conformation studied with ab initio methods, **5d**, differs from the other three in that the OCC-Si-Si-CCO dihedral is at 65.3°. Conformer **5d** is lower in energy than **5c** (Table 2).

As was the case for disilylketene **2**, there is a pronounced difference in orbital energies for conformers **5a** and **5c** that is once more indicative of a σ–π interaction. For **5a** with the Si—Si bond and ketene groups near orthogonal (ab initio calculations), HOMO to HOMO-2 are more or less equally spaced orbitals followed by a group of four (mainly σ Si—C character). HOMO and HOMO-2 show a symmetrical combination of π_{CCO}'s with σ contribution of electron density on the Si—Si bond ($\pi^+_{CCO}/\sigma_{SiSi}$); HOMO-1 is the antibonding combination of π_{CCO}'s (π^-_{CCO}). As for disilylketene **2**, the LUMO is a low-lying σ^*_{SiSi}. In the "stretched" **5c**, HOMO and HOMO-1 (π^-_{CCO} and π^+_{CCO}, respectively) are almost degenerate, and HOMO-2 is the unperturbed σ_{SiSi}.

Conformers **5a**–**5d** suggest that there are three bonds in this disilane that should be included in a conformational study, one Si—Si and two Si—CCO bonds. To study this problem computationally, rotations about the Si—Si bond and one Si—CCO bond were examined separately. Neither total energy nor orbital energies depend on the OCC-Si-Si-CCO torsional angle (no plots shown) but the rotation of one ketene moiety has an effect on the orbital energies. For the calculation of the respective potential, one Si-Si-C-C dihedral was fixed at its optimized value[5] and the other rotated through 0°, 45°, 90°, 135°, and 180°. The fitted potentials for HF/3-21G* and Becke3LYP/6-31G*//HF/3-21G* relative energies are shown in Figure 2(*b*). Figure 3(*b*) gives the Becke3LYP/6–31G*//HF/3-21G* eigenvalues for the four highest occupied molecular orbitals as a function of the torsional angle. To judge the extent of the effect of σ–π mixing on the orbital energies is not simple because of multiple interactions; UV spectra seem to indicate that it is smaller in bisketene **5** than it is in monoketene **2** (8).



As is the case for bisketene **3** and trisketene **4**, there is only a small π–π interaction in **5**. A simple "uncoupling" of π^+_{CCO} and σ_{SiSi}, which form HOMO and HOMO-2, gives a π^+_{CCO} that is in the energetic neighborhood of π^-_{CCO}. This is confirmed by isodesmic considerations on the unsubstituted bis(ketenyl)disilane (H_2Si-$CH{=}C{=}O)_2$ (7).

The PE spectrum of disilylbisketene **5** (Fig. 1(*e*)) shows three bands (8.52, 9.10, and 9.88 eV) of comparable intensity belonging to one ionization each, followed by a broad band centered at 11.2 eV that is composed of four ionizations. The first band in the spectrum of **5** is found at the same low value as that for **2**, again indicating an interaction between σ_{SiSi} and π_{CCO}. As for **2**, the best simulated spectrum was obtained using the Becke3LYP/6-31G*//HF/3-21G* calculated surface and eigenvalues, which again shows the importance of including electron correlation in calculations of the electronic structure of disilanes. The synthesized partial PE spectrum based

[5] The assumption that keeping the second dihedral at its optimized value would lead to correct results was drawn from the PM3 surface obtained for the rotation of *both* ketene groups of disilylbisketene **5**. This hypersurface obtained from 25 points (0°, 45°, 90°, 135°, and 180°) suggests that conformations lying on the lowest energy path have one Si-Si-C-C dihedral angle at 90°. This is near the optimized PM3 value for this dihedral in **5a**.

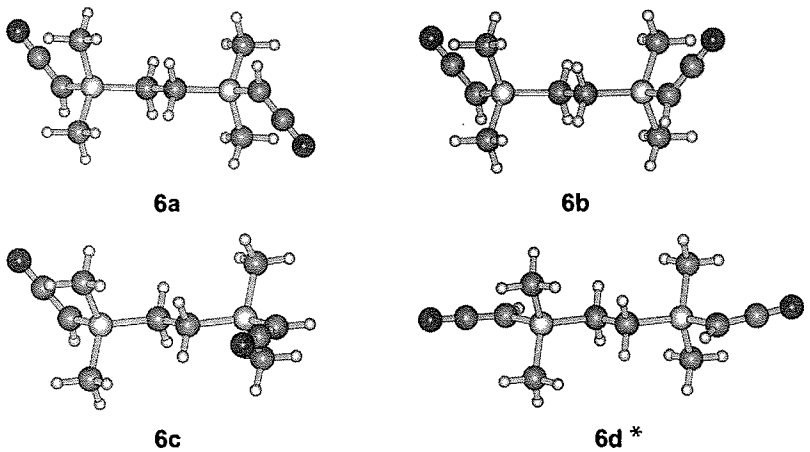
5a 5b 5c 5d

on the 13 highest occupied molecular orbitals from PESPEC with a Gaussian convolution of 0.4 and a temperature of 300 K displayed in Fig. 2(*c*) is an excellent match of the experimental low-energy region in the spectrum of **5**. Like disilylketene **2**, disilylbisketene **5** prefers conformations in which its ketene moieties are arranged approximately orthogonal to the Si—Si bond to allow for maximum orbital interaction.

1,2-Divinyl-1,1,2,2-tetramethyldisilane (8)



We also performed a conformational analysis for disilane **8**, which according to Khvostenko et al. (12) does not exhibit σ–π interaction. Two low-energy conformers **8a** (ethylene groups *syn*) and **8b** (ethylene groups *anti*) correspond to **5a** and **5b**, respectively. With HF/3-21G*, **8b** is less stable than **8a** by 0.03 kJ mol^{-1} (the HF/6-31G*//HF/3-21G* value is 0.22 kJ mol^{-1}), their geometries are similar to those found for disilane **5**: the Si-Si-C-C dihedral in **8a** is 110°, the C-Si-C-C dihedral is at 11°. Becke3LYP/6-31G*//HF/3-21G* predicts **8b** to be more stable by 0.76 kJ mol^{-1}. The fitted potential (Becke3LYP/6-31G*//HF/3-21G*, plot not shown) for the torsion about one Si—CC bond (with the other one kept at approx. 110°) resembles that for **5** except for energy differences in **8** being more pronounced: ΔE between the two minima in the plot for **5** is 1.5 (Fig. 6), for **8** it is 4.5 kJ mol^{-1}. This can be explained as was done for alkene **7**. The dependence of the orbital energies on the Si-Si-C-C dihedral in **8** can be seen in Fig. 3(*c*). Just as for disilylbisketene **5**, the HOMO of **8** ($\pi^{+}_{CC}/\sigma_{SiSi}$) is destabilized by about 0.2 eV on increasing the torsional angle from 0° to 90° while HOMO-1 and HOMO-2 are stabilized in both cases to about the same extent. This suggests that there are similar σ–π interactions in disilanes **5** (ketene substituents) and **8** (alkene substituents). The simulated PE spectrum of **8** (Becke3LYP/6-31G*//HF/3-21G*, 12 eigenvalues, FWHH 0.4, temperature 300 K) is shown in Fig. 4(*d*). Again, the experimental PE spectrum for **8** was not published but the stated poor resolution of the second and third bands (12) can be seen in the simulation.

1,2-Bis(ketenyldimethylsilyl)ethane (6)

According to HF/3-21G*, conformation **6a** with ketene groups *anti* and *sp* to the Si—CH_3 bonds (H_3C-Si-C-CO dihedral at 2.1°) is the global minimum. The related *syn* conformation **6b** is essentially equal in energy while **6c**, with one ketene group *sp* to a Si—CH_2 bond, is slightly destabilized by 0.55 kJ mol^{-1} (Table 2). This energetic order is confirmed by HF/6-31G*//HF/3-21G* calculations whereas Becke3LYP/6-31G*//HF/3-21G* reverses the sequence of **6b** and **6c**, but all energy differences stay small. Conformation **6d**, which has both ketene groups *anti*-periplanar (*ap*) to the Si—CH_2 bonds, is the most stable conformation as determined by PM3, but is not a stationary point on the potential energy surface with HF/3-21G*.

HF/3-21G* HOMO to HOMO-6 orbital energies of **6a** come as groups of two (9.26 and 9.60 eV), one (10.90 eV), and four (11.90, 11.91, 12.28, and 12.37 eV), with the groups well separated. HOMO (π^{+}_{CCO}) and HOMO-1 (π^{-}_{CCO}) only show a small splitting. HOMO-2 has an in-phase electron contribution on the Si—CH_2 bonds and HOMO-3 is the antibonding combination of π_{CH_2}'s ($\pi^{-}_{CH_2}$) on the central C—C bond with electron density on the Si—CH_3 bonds. Orbital energies for **6a** and **6b** do not differ; for **6c** the HOMO/HOMO-1 splitting is smaller and the HOMO-2 is slightly raised.

Conformationally, bisketene **6** is the most complex of all the molecules studied. There are five important bonds here and the orbitals of **6** suggest that three of them, one CH_2—CH_2 and two Si—CCO bonds, could be of interest for an investiga-

tion of orbital energy dependences. Again, the torsions about these bonds were examined separately. For the rotation about the central CH_2—CH_2 bond, the other four dihedral angles of the backbone of **6a** were kept at their optimized values and the Si-C-C-Si torsional angle was twisted through 0°, 45°, 90°, 135°, and 180°. Figure 2(*c*) shows the potential obtained from the calculated relative energies. Since **6** is a bisketene with an ethylene spacer, its potential is that of a 1,2-disubstituted ethane. The strong destabilization of the 60° conformation, which is obvious from Fig. 2(*c*), can be interpreted by the large direct interaction between the methyl groups of the two silicon substituents. From this potential, **6** is expected to be exclusively in a 180° conformation; the often-found 60° conformation of 1,2-disubstituted ethanes in the gas phase will not be occupied to a great extent.

Orbital energies of HOMO to HOMO-4 as a function of the central torsional angle are displayed in Fig. 3(*d*). The change of the Si-C-C-Si dihedral does not influence HOMO and HOMO-1 (π_{CCO}'s) significantly, which again is an indication of no π–π interaction of any importance. HOMO-2 is lowest in energy at 90° and highest at 0° and 180° while HOMO-3 energies exhibit the opposite behavior. These two orbitals are almost degenerate in the 90° conformation, the point of avoided crossing, as can be seen in Fig. 3(*d*). They split to a maximum of about 1 eV as the dihedral is changed and, as a result of this, HOMO-2 moves up in energy and into the gap formed by HOMO/HOMO-1 and HOMO-3/HOMO-4 groupings.

In addition, the rotation about just one Si—CCO bond was examined, as in the case of disilane **5**. The remaining four dihedral angles of the backbone of **6a** were fixed at their optimized values. The potential obtained for twisting the CH_2–Si-C-C torsional angle resembles that for **5** but the energy differences for **6** are smaller. This is reflected in the orbital energy dependence, which shows smaller changes but otherwise is the same as for **5** (plots not shown).

In the PE spectrum of bisketene **6** shown in Fig. 1(*f*), three bands are resolved from the main groups of the σ bands, belonging to two (8.9 eV), one (9.73 eV), and four (centered at 11.0 eV) ionizations. Even though the first band, which comprises ionizations from the two π orbitals (π^+_{CCO} and π^-_{CCO}), shows individual maxima, they cannot be ascribed to discrete bands: a deconvolution would lead to a very small splitting. As for silylketenes **3**, **4**, and **5** bearing more than one ketene group, the π–π interaction in **6** is almost nonexistent. The value of 8.9 eV for the first IP is close to that of (*tert*-butyldimethylsilyl)ketene (8.79 eV) (2), which indicates a similar destabilization of the ketene π orbital due to alkyl substitution, and no further interaction. The most prominent feature in the spectrum, in spite of its size, is the band at 9.73 eV. It is situated in an energy gap of about 1.5 eV made up by the larger bands. From Fig. 3(*d*) it is clear that HOMO-2 is destabilized enough for this only when the substituents on the ethane moiety are arranged *ap* (Si-C-C-Si torsional angle at 180°, the 0° conformation is a maximum, see Fig. 2(*c*)). There is remarkable agreement between the simulated partial spectrum for this torsion (HF/3-21G*, 11 eigenvalues, FWHH 0.7, temperature 300 K) as displayed in Fig. 4(*e*) and the experimental PE spectrum of **6**. Unlike the cases of disilanes **2** and **5**, using DFT values for **6** gives a similar simulation with no further improvement, which clearly shows that it is important to consider electron correlation for silylketenes containing a Si—Si bond, while it can be neglected for silylketenes without a Si—Si bond. For the latter, it is sufficient to employ HF/3-21G*// HF/3-21G*. There is no change in the synthesized spectrum when the torsion of one ketene group is considered, emphasizing the lack of importance of this motion on the electronic structure of **6**.

Conclusion

The PE spectra presented for silylketenes **1**–**6** have been interpreted on the basis of the conformational flexibility of the molecules. Calculated energy differences between conformers are small and all are significantly populated. For disilanes **2** and **5**, whose orbital energies are a function of a Si-Si-C-C torsional angle, this seriously affects the PE spectra. Because of a strong σ–π interaction, the preferred conformation for **2** and **5** is one in which the Si—Si bond and ketene group are approximately orthogonal. The same is true for the corresponding silylalkenes **7** and **8**, contrary to what has been reported (12). In contrast to the strong σ–π interaction, there is no π–π interaction of any significance in bis- and trisketenes **3**–**6**. While HF calculations describe the electronic structure of silylketenes **1**, **3**, **4**, and **6** well, this level of theory is not sufficient for disilanes **2** and **5**. For these Si—Si containing compounds, Becke3LYP must be employed for accurate representations of the experimental PE spectra.

Abstract: The electrocatalytic hydrogenation (ECH) of phenol was investigated at room temperature under galvanostatic control in aqueous sulfuric acid solutions on platinized platinum (Pt/Pt) electrodes and on composite Rh/Ni and Ru/Ni electrodes consisting of rhodium or ruthenium chemically deposited on nickel particles dispersed in a lanthanum polyphosphate matrix. The order of electrocatalytic activity at a current density (based on the geometric area) of 1 mA/cm^2 was found to be Ru/Ni > Pt/Pt > Rh/Ni. The efficiency decreased with increased current density. For the Ru/Ni electrodes, the efficiency increased with the percentage of Ru (2.3 to 5%). On Ru 5%/Ni electrodes and at a current density of 5 mA/cm^2, cyclohexanol was obtained with a high selectivity of 91% and a current efficiency of 23% after 94% conversion. In neutral aqueous boric acid containing sodium chloride as supporting electrolyte, the Rh/Ni and Ru/Ni electrodes showed very low activity. The influence of the supporting electrolyte, periodic current control, and temperature was studied in the neutral medium with composite Raney nickel (RaNi) electrodes consisting of Raney nickel particles dispersed in a nickel matrix. At 60°C and a current density of 10 mA/cm^2, the selectivity of cyclohexanol formation was 100% with a 11% current efficiency after 92% conversion with sodium chloride as supporting electrolyte.

Key words: electrocatalytic hydrogenation, phenol, ruthenium on nickel cathodes, rhodium on nickel cathodes, Raney nickel cathodes.

Résumé : L'hydrogénation électrocatalytique (HEC) du phénol a été étudiée à la température ambiante en solution aqueuse d'acide sulfurique sur des électrodes de platine platinisé (Pt/Pt) et sur des électrodes composites de Rh/Ni et Ru/Ni, consistant en rhodium ou ruthénium métallique déposé chimiquement sur des particules de nickel dispersées dans une matrice de polyphosphate de lanthane. On a trouvé une activité décroissante dans l'ordre Ru/Ni, Pt/Pt et Rh/Ni à une densité de courant de 1 mA/cm^2 (basée sur la surface géométrique) et une diminution de l'activité des électrodes avec l'augmentation de la densité de courant. Avec les électrodes de Ru/Ni, une augmentation de l'efficacité de l'HEC a été observée avec le pourcentage de Ru de 2.3 à 5%. Sur les électrodes de Ru 5%/Ni, on a obtenu le cyclohexanol avec une très bonne sélectivité de 91% et une efficacité de courant de 23% après 94% de conversion. En solution neutre d'acide borique contenant du chlorure de sodium comme électrolyte support, les électrodes Ru/Ni et Rh/Ni se sont avérées pratiquement inactives. L'influence de l'électrolyte support, d'un courant pulsé et de la température a été étudiée en solution neutre avec des électrodes de RaNi faites de particules de nickel de Raney dispersées dans une matrice de nickel. Le phénol a été électrohydrogéné en cyclohexanol avec une sélectivité de 100% et une efficacité de courant de 11% après 92% de conversion, en effectuant l'électrolyse à 60°C et à une densité de courant de 10 mA/cm^2 en présence de chlorure de sodium comme électrolyte support.

Mots clés : hydrogénation électrocatalytique, phénol, cathodes de ruthénium sur nickel, cathodes de rhodium sur nickel, cathodes de nickel de Raney.

[Traduit par la rédaction]

Introduction

The electrocatalytic hydrogenation (ECH) of organic compounds constitutes a mild and efficient method for hydrogenating a variety of organic substrates (for a recent review, see ref. 1). The mechanism is described by reactions [1]–[4] where M represents the metallic surface. Chemisorbed hydrogen, (H)M, generated in situ by electroreduction of water (or the hydronium ion) (reaction [1]), reacts with the adsorbed organic substrate, (Y = Z)M, (reactions [2]–[4]). Hydrogenation (reaction [3]) competes with hydrogen desorption (reactions [5] and (or) [6]) (2, 3). The efficiency of ECH depends on the relative rates of these two processes, which are influenced by a number of factors such as the substrate and its concentration (2, 4), the electrode material and surface (5, 6), the reaction medium (organic cosolvent (2), pH (2, 4), buffer (2, 4), supporting electrolyte (2), surfactants (7)), the temperature (2), the current density (2, 4, 8) and current pulsation (8).

This paper reports the results of a study on the effect of current density, current pulsation, pH (acidic and neutral), and electrode material on the efficiency of the ECH of phenol to cyclohexanol in aqueous solutions. Scheme 1 shows the conversion of phenol to cyclohexanol via cyclohexanone as intermediate. The electrode materials investigated in acidic medium were: platinized platinum (Pt/Pt), rhodium on nickel (Rh/Ni) (9), ruthenium on nickel (Ru/Ni) (10), and ruthenium on stainless steel (Ru/Inox). The electrodes consisted of rhodium or ruthenium metal chemically deposited on nickel or stainless steel particles dispersed in a lanthanum polyphosphate matrix (lanthanum phosphate-bonded electrodes) (9, 10). In neutral medium, the electrodes studied were made of Rh/Ni, Ru/Ni, or RaNi particles dispersed in a nickel matrix (2). The ECH of phenol to cyclohexanol has been reported before in aqueous acid solutions on platinum (11–14), Pd/C (12), and Rh/C (12) electrodes. Cyclohexanol is an important industrial product as a starting material for preparing adipic acid used in the production of nylon 6 and nylon 6–6 (15).

Experimental

Electrolysis

Electrolysis was carried out at room temperature with an Electrosynthesis (ESC) 410 potentiostat coupled to an ESC 640 digital coulometer and an ESC 2830 digital multimeter or with an EG&G Princeton Applied Research (PAR) 173 potentiostat coupled to a PAR 179 digital coulometer. For the pulse current electrolysis, the PAR 173 potentiostat coupled to a PAR 175 universal programmer was used. A two-compartment glass H-cell with a jacketed cathodic compartment (volume of each compartment 25 mL) with a Nafion-324 (E.I. du Pont de Nemours & Co.) membrane (1.8 cm^2) was used. For the electrolysis at 60°C, it was connected to a Haake D8 constant-temperature circulating bath filled with water – ethylene glycol. The counter electrode was a glassy carbon plate (~12 cm^2) or a platinum grid cylinder (4 cm long and 6 cm in diameter). The neutral electrolyte consisted of a solution of boric acid (0.5 M) (ACS from BDH) and sodium chloride (0.005 to 0.05 M) (ACS from Anachemia) in distilled water. To ensure a high concentration of protons, the concentration of boric acid in the anolyte was sometimes increased to saturation. The pH was measured at the beginning (pH = 4) and at the end (pH = 6) of the electrolysis with a pHydrion Vivid 6–8 (Micro Essential Laboratory) or a Spezialindikator pH 2.5–4.5 (Merck) paper indicator. The acid electrolyte consisted of a solution of sulfuric acid (0.1 M) (ACS from Fisher Scientific) in distilled water. The anodic and cathodic compartments were filled with one of the above solutions. Phenol (ACS from BDH) was dissolved in the cathodic compartment (20 mg, 8.5×10^{-3} M solution), the anode and cathode were immersed, and the catholyte stirred with a magnetic bar and stirrer. The progress of the electrolysis was followed by gas–liquid chromatography (glc) on a Hewlett Packard (HP) 5790a chromatograph equipped with a FID detector and an HP integrator using a 30 m long DB-5 fused silica capillary column heated at 78°C. Aliquots (0.5 mL) from the catholyte were added to a saturated NaCl solution (1 mL), acidified (pH ≈ 1) with concentrated HCl, and extracted with ether. The products were identified by comparing their retention time with that of an authentic sample. The mass balance (92–100%) was determined by the internal standard method.

Electrodes

The Raney nickel (RaNi) electrodes were prepared as already described (2) by codeposition on a stainless steel grid (1.6 cm × 2.2 cm) of nickel and of particles of Raney alloy suspended in a nickel-plating bath, followed by leaching the aluminum in 30% aqueous NaOH at 70°C for 7 h. The composite rhodium–nickel (Rh/Ni) (9) and ruthenium–nickel (Ru/Ni) (10) electrodes consisted of metal/Ni particles (98% by weight) dispersed in a lanthanum polyphosphate matrix (2% by weight). They were prepared as previously described: chemical deposition of Rh or Ru from $RhCl_3$ or $RuCl_3$ on Ni (Rh 3.5%/Ni; Ru 2.3, 3.5, and 4.4%/Ni); thorough mixing of Rh/Ni or Ru/Ni powder and an homogeneous mixture of $La(H_2PO_4)_3$ and $La(OH)_3$; pressing of the resulting mixture under vacuum at room temperature at 1000 lbs/in^2 (1 lb/in^2 = 7.03×10^2 kg/m^2) in a stainless steel cylindrical mould (diameter: 1.33 cm); polymerization by heating the pellet at 300°C for 3–4 h under a flow of argon. The pellet was coated on one side and along the edge with Epoxyfix resin (Struers) after a Ni foil had been introduced (to ensure electrical contact) to obtain a 1.33 cm^2 geometric area. The Ru 4.4%/Inox electrode was prepared in the same way with stainless steel particles 316-L (100 mesh, Consolidated Astronautics) and 90% Ru/Inox in 10% lantha-

num polyphosphate. The composite electrodes were activated by cathodic polarization curves obtained by decreasing the applied current galvanostatically from 250 to 0.01 mA/cm^2 after applying a current density of 250 mA/cm^2 for 30 min and repeating the cycle until superimposable Tafel curves were obtained. The platinized platinum electrodes (16) were prepared by electrodeposition of platinum from a 2% platinic chloride solution in hydrochloric acid (2 N) for 10–20 min at 10–20 mA/cm^2 on a platinum plate (1.2 cm × 1.1 cm). This electrode was activated by cathodic and anodic polarization (5 cycles of 15 s in each direction) in sulfuric acid (0.01 M) at 0.5 mA/cm^2 just before electrolysis.

Results and discussion

Electrolysis in an acid medium

Previous studies on the ECH of phenol (11–14) were carried out in aqueous sulfuric (0.05 to 0.2 M) and aqueous perchloric (1 M) acid solutions at different current densities (0.02–12.7 mA/cm^2 based on the geometric area) and different phenol concentrations (0.001–0.2 M).The latter two factors influence the competition between hydrogenation (reactions [2]–[4]) and hydrogen desorption (reactions [5] and (or) [6]) and, hence, the efficiency (current efficiency and conversion rate) of ECH: higher current densities usually favor hydrogen evolution over ECH (2, 4, 8, 13) and higher substrate concentrations favor ECH over hydrogen evolution (4, 13). Thus, it is not possible to make a strict comparison between the various results presented in the literature. Our studies in an acidic medium were carried out in aqueous sulfuric acid (0.1 M) with a 8.5 mM phenol concentration. The results are summarized in Tables 1 and 2.

Table 1 reports the results of a comparison of Pt/Pt, Rh/Ni, and Ru/Ni electrodes at a relatively low current density ($J = 1$ mA/cm^2). Both cyclohexanone and cyclohexanol were identified as products, cyclohexanone being formed first and then hydrogenated to cyclohexanol (Scheme 1), as already reported by Miller and Christensen (12) and Amouzegar and Savadogo (14). As the charge increased (theoretical charge = 6 F/mol), more cyclohexanol was formed and the current efficiency decreased due to a decrease in substrate concentration that causes a decrease of the rate of hydrogenation (reaction [3]). It was not possible to determine the current efficiency for the ECH on Ru 3.5%/Ni electrodes (entries 7 and 8) because of electrons provided by the dissolution of nickel during the electrolysis as evidenced by the green coloration of the catholyte. An open-circuit experiment under the same conditions confirmed that the dissolution of nickel did lead to the formation of chemisorbed hydrogen, (H)M, and then to the hydrogenation of phenol: after a period of time corresponding to the end of the electrolysis of entries 7 and 8, 95% of phenol had been converted to 3% cyclohexanone and 92% cyclohexanol. This experiment shows that the Ru/Ni electrode is very active for the hydrogenation of phenol in dilute aqueous sulfuric acid. The Pt/Pt and Rh/Ni electrodes are less active. After 12–14 F/mol, the yield of cyclohexanol was slightly higher with the Pt/Pt electrode (62%, 12 F/mol, entry 3) than with the Rh/Ni electrode (49%, 14 F/mol, entry 6), which suggests that the former electrode is more active. On a Pt/Pt electrode, Miller and Christensen (12) reported the following results in 0.2 M H_2SO_4, after a charge corresponding to 6 F/mol, at a current density of 1.45 mA/cm^2 and a phenol concentration of 0.2 M: 50% conversion, 7% cyclohexanone, 17% cyclohexanol, 22% current efficiency.

Since ruthenium was shown to be an active metal in such composite catalysts in aqueous sulfuric acid, we investigated the Ru/Ni electrodes further, looking at how their activity was affected by current density, the percentage of ruthenium on nickel, and the replacement of nickel with stainless steel. The results are recorded in Table 2 and those of entries 1–10 show that, as reported in the literature with other electrode materials (2, 4, 8, 13), an increase of current density (from 3 to 15 mA/cm^2) led to a decrease in ECH efficiency due to an increase in the rate of hydrogen desorption as already mentioned. There was no dissolution of nickel at current densities of 3 mA/cm^2 and greater so the current efficiencies of entries 1–16 repre-

sent true current efficiencies. An increase in the percentage of ruthenium did lead to an increase in efficiency as shown by a comparison of entries 5 and 6 (Ru 2.3%/Ni, J = 10 mA/cm^2) with entries 11 and 12 (Ru 4.4%/Ni, J = 10 mA/cm^2) and a comparison of entries 1 and 2 (Ru 2.3%/Ni, J = 3 mA/cm^2) with entries 14 and 15 (Ru 5%/Ni, J = 5 mA/cm^2): the conversion rate, yield of cyclohexanol and current efficiency are higher in entries 11 and 12 as well as in entries 14 and 15 (despite the fact that the current density was larger in the electrolysis of entries 14 and 15 than in that of entries 1 and 2). As revealed by a comparison of entries 7 and 8 of Table 1 with entries 17–19 of Table 2, replacing nickel with stainless steel led to a notable decrease in electrode activity. This shows that the metal supporting ruthenium does have an influence on the competition (relative rates) between hydrogenation (reaction [3]) and hydrogen desorption (reactions [5] and (or) [6]). This is not surprising since the supporting metal is not completely covered with ruthenium at percentages of ruthenium lower than 10%, as previously shown by X-ray (EDX) mapping (10).

The Ru 5%/Ni electrode appears the most interesting for the ECH of phenol in an aqueous acidic medium with a 94% conversion rate, a 91% yield of cyclohexanol, and a 23% current efficiency at a current density of 5 mA/cm^2 after a charge corresponding to 25 F/mol (Table 2, entry 16). After 6 F/mol (entry 15), the conversion rate was 59%, the yield of cyclohexanol 52%, and the current efficiency 56%. These results can be compared with those of Amouzegar and Savadogo (14) in 0.05 M H_2SO_4 on a Pt/C/Teflon electrode: 100% conversion, 5% cyclohexanone, 95% cyclohexanol, and 85% current efficiency at 6 F/mol. However, they used a much lower current density (0.02 mA/cm^2) and larger phenol concentration (0.05 M), both of which strongly favor the ECH process over hydrogen evolution as pointed out above. On the other hand, the results of entry 12 (Ru 4.4%/Ni electrode, J = 10 mA/cm^2, 6 F/mol, 25% conversion, 3% cyclohexanone, 22% cyclohexanol, 23% current efficiency), could be compared to those obtained by Miller and Christensen (12) for their most active electrode (Rh/C) (J = 11 mA/cm^2, 6 F/mol, 100% conversion, 15% cyclohexanone, 74% cyclohexanol, 84% current efficiency), bearing in mind, however, that they used a much larger concentration of phenol (0.2 M), which again markedly favors the ECH process over hydrogen evolution.

Electrolysis in a neutral medium

For the ECH of phenanthrene in ethylene glycol – water solutions, we reported earlier that the presence of boric acid at concentrations between 0.1 to 0.5 M was beneficial in favoring hydrogenation over hydrogen desorption and thus improving the efficiency of the ECH process (2). It also served as a buffer to maintain the pH between 3.5 and 6.5 during electrolysis (14 F/mol) since hydoxide ions are produced (see eq. [1]) (2). We thus investigated the ECH of phenol on the various electrodes used in the above section as well as on Raney nickel (RaNi) electrodes in an aqueous solution of boric acid (0.5 M) containing sodium chloride (0.05 M) as supporting electrolyte. The pH varied from 4 to 6 during the electrolysis. The

results of the studies carried out at room temperature are recorded in Table 3. It is clear from the current efficiencies and the yield of cyclohexanol that the ECH of phenol on Pt/Pt, Rh/Ni, and Ru/Ni electrodes under those conditions was much less efficient than in aqueous sulfuric acid: compare entry 1 of Table 3 with entry 3 of Table 1 for the Pt/Pt electrodes; no hydrogenation occurred on the Rh/Ni electrodes (entries 4–6) and little hydrogenation occurred on the Ru/Ni electrodes (entries 7–18), which were the most active electrodes in the aqueous acid medium. The RaNi electrodes (entries 17–24) appear somewhat more active than the Ru/Ni electrodes. Thus, under these neutral electrolysis conditions, desorption of chemisorbed hydrogen (reactions [5] and (or) [6]) was much faster than hydrogenation of phenol (reaction [3]). Increasing the current density caused a decrease in ECH efficiency in the case of the Pt/Pt electrodes (entries 1–3) as usually observed (see previous section), had little effect on the low efficiencies of ECH on RaNi electrodes (entries 17–24), but caused a small increase in ECH efficiency on the Ru/Ni electrodes (entries 7–18). However, the reproducibility of these experiments was not assessed since the current efficiencies were very low. The charge had also little effect on the low current efficiency (compare entries 19–21), so it was possible to reach 75% conversion with the quantitative formation of cyclohexanol at a charge corresponding to 56 F/mol (see entry 21). It is noteworthy that no cyclohexanone was detected during the electrolysis on RaNi electrodes, which strongly suggests that its hydrogenation is much faster on these electrodes than that of phenol under the conditions used.

We had previously reported for the ECH of phenanthrene in ethylene glycol — water on RaNi electrodes that replacing sodium chloride as supporting electrolyte by sodium sulfate caused some decrease in efficiency (2) and that pulsating the current (8) and increasing the temperature (2) improved efficiency. We looked at the influence of these factors on the efficiency of the ECH of phenol in a neutral medium. The results of Table 4 show that the ECH of phenol was similarly less efficient when using sodium sulfate as supporting electrolyte (entries 3–5) and that the efficiency was also significantly improved when carrying out the electrolysis at 60°C instead of at room temperature (entries 9–11: 92% conversion, quantitative formation of cyclohexanol, 11% current efficiency in entry 11). However, the ECH of phenol was significantly less efficient when pulsating the current (entries 6–8), contrary to the ECH of phenanthrene. We have no satisfactory explanation for this difference in behavior.

Conclusions

We have shown that composite electrocatalysts consisting of a small amount of rhodium or ruthenium metal chemically deposited on nickel particles (2–4% Rh or Ru/Ni) dispersed in a polyphosphate matrix were active for the ECH of phenol *in aqueous sulfuric acid*. Ruthenium supported on stainless steel was much less active, which shows that nickel has an influence on electrocatalytic activity. At a relatively low current efficiency of 1 mA/cm^2, dissolution of nickel generating active chemisorbed hydrogen occurred but no dissolution was observed at J = 3–15 mA/cm^2. The order of activity of the electrodes was Ru/Ni > Pt/Pt > Rh/Ni. The best results were obtained with a Ru 5%/Ni electrode, which gave, at a current density of 5 mA/cm^2, a conversion rate of 94%, a 91% yield of cyclohexanol, and a current efficiency of 23%. A meaningful comparison with literature data on other electrocatalysts could not be made because of the widely different electrolysis conditions used which have an influence on the competition between the reaction of phenol with chemisorbed hydrogen and desorption of chemisorbed hydrogen and thus the efficiency of ECH. *In aqueous boric acid (neutral medium)*, the Rh/Ni and Ru/Ni electrodes were found to be practically inactive, whereas a composite Raney nickel electrocatalyst consisting of Raney nickel particles dispersed in a nickel matrix did quantitatively electrohydrogenate phenol to cyclohexanol (no cyclohexanone detected) at 60°C although with low current efficiencies (≈17%).

Electrokinetic study of the adsorption of ethyl violet and crystal violet by montmorillonite clay particles[1]

Laurier L. Schramm, Shmuel Yariv, Dipak K. Ghosh, and Loren G. Hepler

Abstract: Electrophoretic mobilities of mixtures of a montmorillonite clay (in different exchangeable metal cation forms) and increasing amounts of two cationic dyes (ethyl violet and crystal violet) were measured. Electrophoretic mobilities were found to vary between -60×10^{-5} and $+40 \times 10^{-5}$ cm^2 s^{-1} V^{-1}. For both the dyes, the degree of saturation at which the isoelectric point (IEP) occurs, decreases with increasing valency of the metal cations. An effort was made to connect the IEP, maximum flocculation, and dye adsorption parameters. An important adsorption parameter is the transition saturation (TS), the saturation beyond which adsorption by organophilic attractions occurs in addition to adsorption by electrical and (or) π-interactions. It was found that maximum flocculation occurs before the IEP for all the exchangeable cations tested, but the IEP is reached at similar saturations to the TS for most of the cations. These results have been interpreted in terms of different types of adsorption phenomena and particle associations.

Key words: clay, adsorption, dye, ion exchange, electrokinetic charge.

Résumé : On a mesuré les mobilités électrophorétiques de mélanges d'une argile montmorillonite (dans diverses formes de cations métalliques échangeables) et de quantités croissantes de deux colorants cationiques (violet d'éthyle et cristal violet). On a trouvé que les mobilités électrophorétiques varient entre -60×10^{-5} et $+40 \times 10^{-5}$ cm^2 s^{-1} V^{-1}. Pour chacun des colorants, le degré de saturation auquel se produit le point isoélectrique (PIE) diminue avec une augmentation de la valence des cations métalliques. On a aussi fait un effort pour relier le PIE, le maximum de floculation et les paramètres d'adsorption des colorants. Un paramètre d'adsorption important est la saturation de transition (ST), la saturation au-delà de laquelle il se produit une adsorption organophile en plus de l'adsorption par des interactions électriques et (ou) π. On a observé que, pour tous les cations échangeables évalués, le maximum de floculation se produit avant le PIE; toutefois pour la plupart des cations, on atteint le PIE à des saturations semblables à la ST. On peut interpréter ces résultats en fonction des divers types de phénomènes d'adsorption et d'associations de particules.

Mots clés : argile, adsorption, colorant, échange d'ions, charge électrocinétique.

Introduction

The adsorption of aromatic cationic dyes by clay minerals was investigated because of its importance in nature and in various technologies in which aromatic compounds or dyes are involved, and also because of the fact that these staining reactions are used as tests for the identification of various clay minerals (1–3). These adsorption reactions may serve as models for the interactions between aromatic compounds and clay minerals in soils and sediments (3, 4). The adsorption of cationic dyes by clays normally takes place through cation exchange, where the positively charged dye species replace the exchangeable metal cations (2–4), but other mechanisms are possible.

Several aromatic dyes show metachromic properties. In metachromasy the visible spectrum of a very dilute aqueous dye solution shows one absorption band in the visible range, due to the $\pi \rightarrow \pi^*$ transition, called band α, whereas that of the more concentrated solution shows an additional band, called band β, at a shorter wavelength. At still higher concentrations of metachromic dyes band α disappears. Band β is considered to represent a blue shift of band α owing to π interactions in which the aromatic dye is involved. In aqueous solutions band α represents monomeric species whereas band β represents dimeric species. An additional blue-shifted band, band γ, may appear in very concentrated aqueous solutions, which represents trimers, tetramers, etc.

Previous studies of the interaction between several metachromic dyes and montmorillonite (5–8) showed that adsorption from very dilute dye solutions was accompanied by metachro-

masy. In these cases, the appearance of a metachromatic, or blue-shifted band resulted from π-interactions between the aromatic rings of the organic dyes and the oxygen planes of the aluminosilicate platelets, and from the adsorption of aggregated dye cations, probably into the interparticle space of flocs. These investigations also suggested that visible-light spectroscopy might be a useful tool for the study of flocculation–peptization processes in clay–dye systems, because the molar absorbance of both bands α and β (of the adsorbed dye) decreased as a result of the flocculation of the adsorbing phase, but returned to its initial values if the adsorbing phase was peptized. When the clay–dye complexes are intensely coloured the flocculation and peptization processes are easily observed by the naked eye.

In a study of the adsorption of two metachromic cationic dyes (see Fig. 1) crystal violet (CV; **I**; *N*-{4-[bis(4-dimethylaminophenyl)methylene]cyclohexa-2,5–dienylidene}dimethylaminium chloride) and ethyl violet (EV; **II**; *N*-{4-[bis(4-diethylaminophenyl)methylene]cyclohexa-2,5-dinylidene}dimethylaminium chloride) by Na-montmorillonite four types of adsorption interactions were identified from the visible spectra of the clay–dye aqueous suspensions (10, 11). Types A_1 and B_1 (previously named A and B) were identified with the help of band α. This band is located at 590 and 595 nm in the spectra of very dilute aqueous solutions of CV and EV, respectively. In the clay–dye suspensions this band is located at the same wavelength in the spectrum of type A_1 and is shifted to higher wavelengths (red shift) in the spectrum of type B_1 clay–dye complexes. From the location of the band maximum it was assumed that type A_1 represents monomeric cationic species located in an environment in which polarity is very similar to that of the aqueous phase, and therefore should be outside the "interlayer space," on the external surfaces of the tactoids or platelets. Type B_1 represents monomeric cationic species located inside the interlayer space, an environment in which polarity is different from that of the aqueous phase. The red shift is more significant in the spectra of adsorbed CV than in those of adsorbed EV. Band β is located below 590 nm. Type B_2 (previously named C) was identified with the help of band β. It represents monomeric cationic species that are located in the interlayer space, with the aromatic ring parallel to the clay layers and bound to the oxygen planes by π-interactions. Type D, which represents polymeric species trapped in the interparticle space of a floc, was identified with the help of band γ. This type of interaction is negligible for this system and will not be further discussed here. In a study of the adsorption of CV by Laponite (a synthetic hectorite) it was shown that at the stage when the smectite flocculates, dimers of CV are obtained in the interparticle space of the flocs (type C) giving rise to band β. In the spectrum of type C, band β is located at a lower wavelength compared to the spectrum of type B_2 (12). In the presence of excess dye dimeric cations are adsorbed and are located on the external surfaces of peptized particles (type A_2). Band β of this association is located between that of type B_2 and that of type C. Figure 2 illustrates the different types of association.

Electrokinetic measurements, either expressed simply as electrophoretic mobilities or through the zeta potentials, have been applied to many clay dispersions (13–18). Clays saturated with metallic cations typically have negative electrophoretic mobilities due to the negative surface charge of the clay platelets (arising from isomorphic lattice substitution). The charge is compensated for by the presence of the metallic cations in the electrical double layer. If the metallic cations are exchanged by specifically adsorbing cations, the charge on the kinetic unit (particle plus adsorbed layer out to the shear plane) may change from negative, through the isoelectric point (IEP), to positive. Delgado et al. (17) studied in detail the effects of clay–electrolyte interactions on the zeta potential and interpreted these interactions by considering the structural characteristics of the clay particles and their electrical double layers. Black et al. (15) also observed the reversal in the sign of electrophoretic mobilities during adsorption of the polycation *N*-substituted piperidinium chloride polymer on kaolinite.

Being large organic cations, CV and EV are water-structure breakers and their adsorption by montmorillonite should be, to some extent, specific. Consequently, this should have an effect on the electrokinetic potential of the clay particles. The present investigation was undertaken to study the electrophoretic mobility changes that result from the adsorption of the dyes. We shall make comparisons between the measured electrokinetic and spectroscopic results in terms of the various types of bondings and the flocculation process of the clay–dye suspensions.

ming montmorillonite, A.P.I. 25, Wards Natural Science Est., Rochester, N.Y.) was gently ground to about −80 mesh. The elemental analysis and related data for this montmorillonite are given in ref. 19. Homoionic montmorillonites were prepared by equilibrating 10 g of natural clay with 1 L of 0.02 M chloride solution of the corresponding cation (20, 21). The excess salt was washed out after 3 days, by centrifugation at 7000 G. The resulting stable suspensions were kept as stock suspensions.

For ethyl violet (EV), five homoionic montmorillonites (Li, K, Mg, Ba, and Al), and for crystal violet (CV), three homoionic montmorillonites (Li, Mg, and Al) were used for electrophoretic measurements. For each cation, the degree of saturation varied from 5 to 130 mmol dye per 100 g clay.

Spectrophotometric measurements

For spectrophotometric measurements suspensions containing a constant amount of dye (4.0×10^{-6} M) and increasing amounts of clay (in the concentration range ($2–400 \times 10^{-4}$ mass%) were used. Spectra were recorded at room temperature using a Cary 219 double-beam spectrophotometer, in the 700–400 nm range. Each suspension was subjected to ultrasound for 7 min immediately after its preparation. Each spectrum was recorded within 3 h after preparation of the suspension.

Flocculation and peptization

Since the clay–dye complexes are intensely coloured the flocculation and peptization processes were readily observed by the naked eye in the present study. Flocculated particles were separated by sedimentation and (or) centrifugation and the supernatants were examined for residual nonflocculated (peptized) clay (12). The amount of residual peptized clay decreased with decreasing absorbance of bands α and β. When the absorbance reached the minimum, the supernatant was colourless because the total amount of clay was flocculated. The light absorption spectrum of peptized suspensions was not affected by the ultrasound treatment, whereas the absorbance of flocculated suspensions was increased as a result of mechanical peptization due to the ultrasound treatment (6).

Electrokinetic measurements

Bulk clay suspensions of 0.05 wt.% of different homoionic montmorillonites and dye solutions EV and CV (10^{-4} M) were used as stock solutions to prepare the clay–dye mixtures. To each 2 mL of clay suspensions, increasing amounts of dye solutions were added and the total volume of the suspensions was made up to 15 mL by adding distilled water. In this way dye/clay mixing ratios (in mmol dye/100 g clay) from 5 to 133 were obtained. For all of these the total clay concentration was constant at 0.0667 g/L. The suspensions were well dispersed and electrokinetic measurements were carried out within 24 h of preparing the clay–dye suspensions.

Particle electrophoretic mobilities were measured with a Rank Brothers, microelectrophoresis apparatus Mark II (Rank Brothers, Cambridge, England) fitted with a rotating prism and video viewing system. A rectangular cell was employed, fitted with hydrogen-charged palladium electrodes. Particle mobilities were determined at 25.0 ± 0.5°C, using a horizontal viewing plane through the centre of the cell, at one of the stationary levels. A direct voltage over distance mode was utilized and particle motions were matched with the opposite scanning motion of a calibrated microprocessor-controlled rotating prism (Rank Brothers Mark II). The apparatus, techniques, and precautions have been discussed elsewhere (18, 22). The cell was used and stored in a constantly water-wet condition; detergent-washing procedures proved to be satisfactory.

For the systems used in this work, the relation between zeta potential, ζ, and electrophoretic mobility, μ_E, is sufficiently well described by the Helmholtz–Smoluchowski equation:

$$[1] \quad \mu_E = \zeta\epsilon/\eta$$

where ϵ and η are the dielectric constant and viscosity of the medium, respectively. The zeta potential can be taken to provide a reasonable approximation of the potential at the Stern layer boundary, hence as an indication of the extent of specific adsorption of dye onto the oxygen plane.

Results and discussion

Three kinds of results are shown in Figs. 3–10. In accordance with previous spectrophotometric investigations of dye–clay interactions (10, 11) the minimum degree of saturation for which the spectrophotometric measurements did not exhibit type B_1 but did exhibit type A_1 adsorption interactions was defined as the "transition saturation" (TS). Figures 3–10 show: (*a*) the wavelengths of the absorption maxima of bands α and β. The locations of these bands depend on the degree of saturation. Below the TS band α shows a red shift, more significant in the spectra of CV than in those of EV. The red shift also depends on the acid strength of the exchangeable inorganic cation and increases with its charge. The wavelength maximum of band β is first relatively high (type B_2), then shifts to lower wavelengths (type C), and later to higher wave-

lengths (type A_2). As the clay/dye ratio increases, the absorbance values for bands α and β are first constant, or decrease very slightly, then considerably decrease with clay flocculation, and later increase with peptization;

(*b*) the absorbance values corresponding to bands α and β;

(*c*) the clay particle electrophoretic mobilities, which ranged in continuous fashion from negative values at low degrees of saturation (as large as -56×10^{-5} cm^2 s^{-1} V^{-1}) to positive values at high degrees of saturation (as large as $+42 \times 10^{-5}$ cm^2 s^{-1} V^{-1}). It can be seen that the electrophoretic mobility curves are asymptotic with mobilities remaining almost constant at both low and high dye/clay ratios. In the following discussion the clay–dye system will be treated from the point of view of a titration in which the degree of saturation increases, and three regions of behaviour will be distinguished.

First, a hypothesis may be advanced for the most likely kinds of adsorption of the dyes and their effects on the mobility curves. When monovalent metallic cations exchange polyvalent cations, they are first adsorbed onto the outer tactoid surfaces, and later into the interlayer spaces, causing breakup of the original tactoids into smaller sizes (23–27). In the case of CV and EV the dyes, although monovalent, are organic cations. They will tend to adsorb first where the clay is most hydrophobic and offers the greatest chance for π-bonding, namely, on the oxygen plane (type B_2). It is likely that a certain degree of cation exchange saturation will be required (type B_1 bonding) before the organic cations can orient themselves to permit π-bonding (type B_2). Such adsorption should not lead to a large change in the electrophoretic mobility of the montmorillonite, because there will be little if any change in the net charge on the tactoid whose size remains relatively constant. The titrations began with 4 mmol dye per 100 g clay; by this degree of saturation band β was clearly observed.

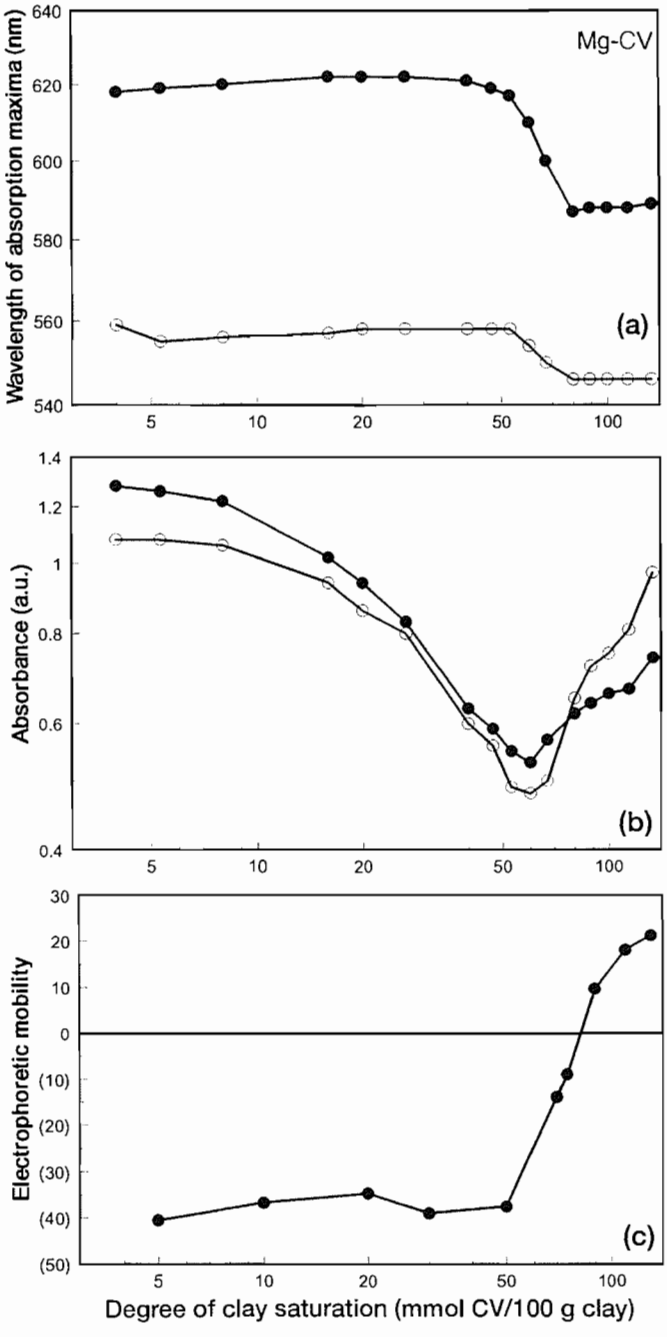

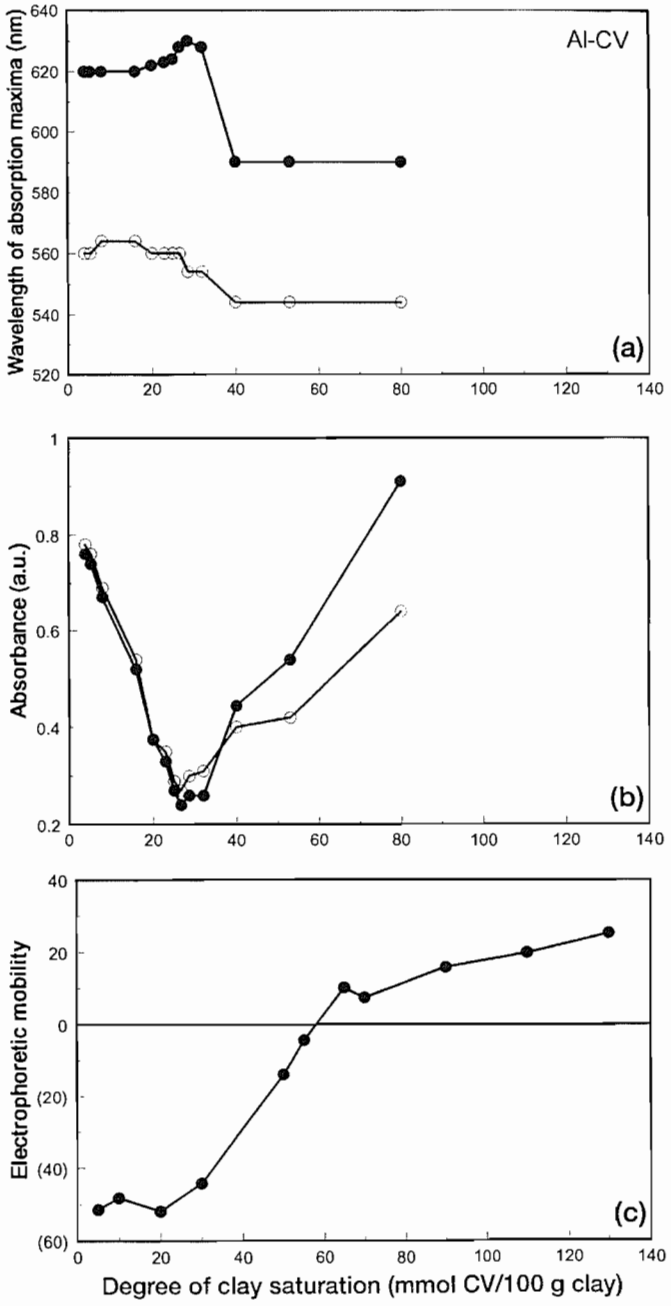

Fig. 10. The effect of degree of Al-montmorillonite clay saturation by crystal violet dye on (*a*) the wavelength of the absorption maxima of bands α (●) and β (○), (*b*) the maximum absorbance values corresponding to bands α (●) and β (○), and (*c*) the clay particle electrophoretic mobilities (in units of 10^{-5} cm^2 s^{-1} V^{-1}).

At a certain degree of saturation, which depends on the exchangeable metal cation, the clay particle electrokinetic potential will be reduced to near zero (near zero electrophoretic mobility) causing flocculation. At this point CV or EV dimeric cations can be located in the interparticle space as well (12). The fact that dimeric CV and EV are present in the interparticle space is envisaged from the location of band β. The wavelength curves, Figs. 3–10*a*, which describe the maximum of band β as a function of the degree of saturation, show shorter wavelengths, which represent associations of type C.

Once the external tactoid surfaces have been filled, then additional bonding could take place by organophilic interactions. Type A_1 and A_2 bonding on the saturated external surfaces would cause the clay particle electrokinetic potential to become increasingly positive (increasing positive electrophoretic mobility), causing peptization. At this stage the maximum of band α is located at the same wavelength as in the dilute aqueous solution.

Region 1

Although the adsorption of the dye by the clay will take place principally by cation exchange reaction, we showed in a previous calorimetric study of the adsorption of CV by different monoionic montmorillonites (20) that the initial exchangeable metallic cations have a great influence on the products of adsorption due to the fact that the initial tactoid is preserved during the first stages of the titration. Again in the present work, the first region exhibits a constant absorbance, indicating that at this stage the adsorption of the dye did not change the size of the original tactoids. Bonding of types B_1 (monomers in the interlayer space) and B_2 (monomers π-bonded to the oxygen planes) is formed from the very beginning of the titration of the homoionic montmorillonite with either CV or EV (10, 11). It is for this reason that in the first region of the mobility curves the initial size of the tactoid is preserved for both dyes. Li-montmorillonite has very small tactoids (1–2 layers) and some of the type B_2 adsorption takes place on the external surface. Thus the negative surface charge decreases only very slightly. Al-montmorillonite has the largest tactoid size and a very small specific surface area. Adsorption via cation exchange takes place into the interlayer space and the charge of the tactoid is not changed.

Region 2

The second region in the mobility curves is the jump to the isoelectric point. This jump is obtained during the flocculation of the clay. This region exhibits a decrease in absorbance, indicating that at this stage the adsorption of the dye resulted in the flocculation of the system (the flocculation of the clay became most efficient at the stage in which the absorbance curve showed its minimum). The degree of saturation with minimum absorbance was considered as the degree of saturation with maximum flocculation. Selected values are given in Table 1.

This region also begins, together with the second region in the wavelength curves of band β, when this band shifts to shorter wavelengths. The IEP is reached at different degrees of saturation for different homoionic montmorillonites (Table 1). The dye/clay ratios at which the mobility becomes zero (IEP) decreased with increasing valency of the exchangeable metallic cations. The exchange capacity of the Wyoming bentonite is about 90 mequiv. per 100 g clay (28–31). The IEP is almost always reached at lower degrees of saturation, which means that only part of the exchangeable metallic cations are replaced by either CV or EV.

Several studies (32–34) have noted that with low molecular weight polycations and cationic surfactants, maximum aggregation typically occurs at a zeta potential of about zero. However, other studies (35–37) have shown that for high molecular weight polycations, optimum dosage (i.e., the concentration at which maximum aggregation occurs) can be less than that needed to lower the zeta potential to zero when interparticle bridging occurs concurrently with charge reduction (36, 37).

During the study of the adsorption of methylene blue by various homoionic montmorillonites, Bodenheimer and Heller (38) concluded that this dye coats the montmorillonite tactoid. Brindley and Thompson (39) showed that this coating prevented the completion of the cation exchange reaction and that this prevention increased with increasing size of the tactoid, owing to the slow diffusion of the cations through the big tactoid. Similar observations on the effect of the metallic cations and the coating of CV or EV on the extent of the cation exchange are obtained in the present study. As coating by the organic cations (type A) causes the external negative charge of the particles to approach zero, the system begins to flocculate. During the flocculation process in Region 2 inorganic and organic cations may become trapped in the flocs to some extent, causing even more rapid charge decrease. The IEP is obtained at the stage where the external charge on the floc is near zero and does not require complete cation exchange.

Most montmorillonites flocculate before their charge reaches zero, in agreement with the results in Table 1. Only Li-montmorillonite was required to reach the IEP saturation to reach maximum flocculation. The highest degrees of saturation for IEP are observed with the monovalent cations, which initially had the smallest tactoids. The lowest degrees are observed with Al-montmorillonite, which initially had the biggest tactoids (Table 1).

In general, the flocs formed in advance of the IEP are likely of the "book-house" type, and due to edge–face particle interactions. At the transition saturation the particle charges are near zero and the flocs may change their structure. A change

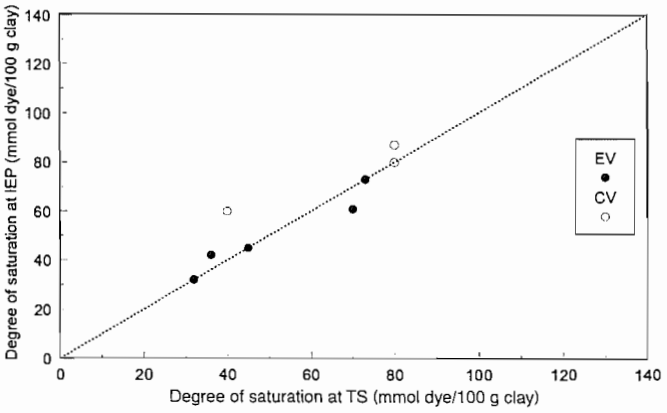
Fig. 11. Degree of saturation to reach the isoelectric point as a function of the degree of saturation to reach the transition saturation. The points correspond to montmorillonites in the presence of ethyl violet (●) and crystal violet (○).



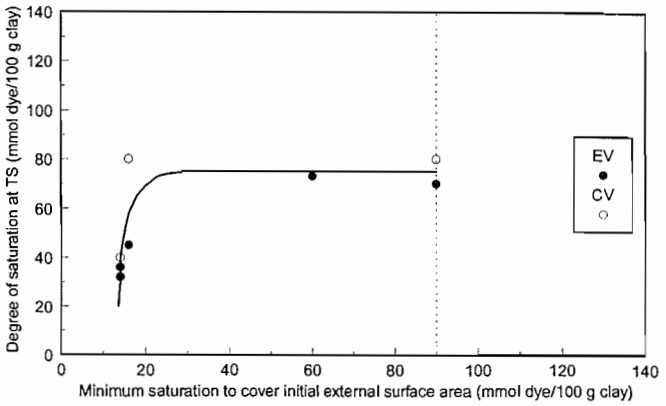


Fig. 12. Degree of saturation to reach the transition saturation as a function of the degree of saturation to cover the initial external tactoid surface area. The points correspond to montmorillonites in the presence of ethyl violet (●) and crystal violet (○). The vertical, broken line represents the total surface charge density of the clay.

from book-house to "card-house" structure would be consistent with the shift of band α in the wavelength curves to lower wavelengths, which characterizes the disappearance of type B_1.

The IEP is reached for CV always at a higher degree of saturation than for EV. This difference between the two dyes is due to size and bonding strength effects. EV is larger and is more hydrophobic and the coating of the clay tactoids by this dye is more efficient. Thus smaller dye concentrations are necessary to reach the IEP.

Region 3

After the IEP the mobility curves show increasingly positive particle surface charges. This is the third region of the titration curve and exhibits increasing absorbance values corresponding to the repeptization of the clay and the exposure of additional surfaces. Bondings of type A are the principal adsorption products that are formed at this stage of the titration. In previous work we have concluded that this adsorption results from "organophilic attraction" forces between the organo-clay complex and the cationic dye, after the latter had been in excess in the aqueous phase. We also concluded that these bondings are formed outside the interlayer space (10, 11). Thus, the type A cations are attached to the external surfaces of peptized platelets or small tactoids, contributing positive charge to the mobile particles. At well past the IEP there eventually is little surface area available for further adsorption and only small increases in electrokinetic potential result.

Transition saturation and the isoelectric point

Some TS values that were determined in our spectrophotometric study are shown in Table 1. With most montmorillonites at this stage, band β reaches its shortest wavelength (dimers in the interparticle space). A comparison of the degree of saturation for TS to that for IEP is shown in Fig. 11. It can be seen that there is reasonably good agreement. The type B_1 bonding disappears by the IEP. It seems that, once the external surfaces of the tactoids become positive as a result of coating, this stage defines the TS. This stage will be reached before all ion exchange is complete. We can calculate the minimum degree of saturation required to reach TS as follows. Before the tactoid size changes, the external surface must be covered with dye. The amount of dye required depends on the original tactoid size. If Γ° is the total surface charge density of the clay (mequiv./100 g clay), then the effective charge density (exposed charge density) of the tactoids (Γ) is given by

$$[2] \quad \Gamma = \Gamma^\circ/n^\circ$$

where n° is the original tactoid thickness in number of plates per tactoid. Γ° is 90 mequiv./100 g (the CEC). The average tactoid sizes can be estimated from the measurements of Banin and Lahav (21) and applying the tactoid volume correction of Schramm and Kwak (26). The values obtained this way yield a good estimate of tactoid sizes, as would be obtained from independent experimental methods such as light scattering, viscosity, and anion exclusion (26, 27). The values are shown in Table 1. The relation between TS and Γ is shown in Fig. 12. It can be seen that the TS values increase strongly with Γ at first and then reach a plateau.

From Fig. 12 the values of Γ that equal TS can be found. These are about 70 mequiv./100 g for EV and 80 mequiv./100 g for CV. These should be the final external surface areas for the dye montmorillonite tactoids and correspond to tactoid sizes of 1.3 for EV and 1.1 for CV. A consistent interpretation of these results would involve dye adsorption to an extent that creates the tactoid size favoured by each cation (as happens for metal cation exchange). At this point all the external surfaces are covered; this is TS. With more dye addition to the system dye cations can adsorb at the tactoid surfaces by types A_1 and A_2 bonding. The previous results (10, 11) show that indeed both occur after TS.

Conclusions

In this work we have investigated the electrokinetic properties of a number of initially homoionic (metal cation) montmorillonites in the presence of the cationic dyes, crystal violet and ethyl violet. The electrophoretic mobility changes taking place with increasing amounts of dye in the systems were

explained in terms of different types of dye adsorption as identified by spectrophotometric measurements. Dye adsorption apparently occurs initially by ion exchange, followed by some more specific adsorption due to π and H interactions with the clay particle surface.

The spectroscopic and electrophoretic mobility curves can be divided into three regions. In the first region the clay is relatively well peptized and the initial size of the tactoid, which is determined by the metal cation, is preserved during the adsorption of both dyes. Most dye is adsorbed into the interlayer space of the tactoids but some of the B_2 adsorption takes place on the external oxygen planes of the tactoids. Thus the surface negative charge decreases very slightly. In the second region the clay is in a flocculated state and dimeric cations are mostly adsorbed into the interparticle spaces of the flocs (type C) with some cations adsorbed on the external surfaces. When the process of adsorption and particle rearrangements is complete, the transition saturation and isoelectric point are reached. In the third region, beyond the IEP, the clay is peptized and new, smaller, tactoids are obtained which gain a positive charge from types A_1 and A_2 adsorption of CV or EV cations. The size of these tactoids is determined by the adsorbed dye.

Oxidative addition and isomerization reactions. The synthesis of *cis*- and *trans*-$ArSF_4Cl$ and *cis*- and *trans*-$PhTeF_4Cl$

Xiaobo Ou, Guy M. Bernard, and Alexander F. Janzen

Abstract: The stereoselective synthesis and isomerization of *cis*- and *trans*-$ArSF_4Cl$ is described, where Ar = Ph, *p*-MeC_6H_4, and *p*-$O_2NC_6H_4$. Also briefly described is the synthesis of $ArSF_5$, *cis*- and *trans*-$PhTeF_4Cl$, and $PhTeF_5$. The oxidative halogenating reagent is a mixture of XeF_2 and Cl^-, and suitable starting compounds are ArSSAr, $ArSF_3$, and PhTeTePh. Products were characterized by ^{19}F, ^{13}C, and ^{125}Te NMR spectroscopy, and by the $^{37}Cl/^{35}Cl$ and $^{34}S/^{32}S$ isotope effects on the ^{19}F NMR chemical shifts. A mechanism of oxidative halogenation is proposed to account for the stereoselective synthesis of *cis*- and *trans*-$ArSF_4Cl$. Ab initio calculations of optimized geometries of anionic and radical intermediates, i.e., $PhSF_3X^-$ and $PhSF_3X^{\cdot}$ (X = F, Cl), were carried out with the aid of the GAUSSIAN 92 program.

Key words: synthesis of *cis*- and *trans*-$ArSF_4Cl$, *cis*- and *trans*-$PhTeF_4Cl$, $ArSF_5$, and $PhTeF_5$, mechanism of oxidative fluorination and oxidative chlorination, $^{37}Cl/^{35}Cl$ and $^{34}S/^{32}S$ isotope effects on ^{19}F NMR spectra.

Résumé : On décrit la synthèse stéréosélective et l'isomérisation des *cis*- et *trans*-$ArSF_4Cl$ dans lesquels Ar = Ph, *p*-MeC_6H_4 et *p*-$O_2NC_6H_4$. On décrit aussi brièvement la synthèse des $ArSF_5$, *cis*- et *trans*-$PhTeF_4Cl$ et $PhTeF_5$. Le réactif provoquant une halogénation oxydante est un mélange de XeF_2 et de Cl^- pour lesquels les ArSSAr, $ArSF_3$ et PhTeTePh sont des produits de départ appropriés. On a caractérisé les produits par la spectroscopie RMN du ^{19}F, du ^{13}C et du ^{125}Te ainsi que par les effets isotopiques $^{37}Cl/^{35}Cl$ et $^{34}S/^{32}S$ sur les déplacements chimiques dans la RMN du ^{19}F. On propose un mécanisme pour l'halogénation oxydante qui tient compte de la synthèse stéréosélective des *cis*- et *trans*-$ArSF_4Cl$. Faisant appel au programme GAUSSIAN 92, on a effectué des calculs ab initio sur les géométries optimisées des intermédiaires anioniques et radicalaires, soit $PhSF_3X^-$ et $PhSF_3X^{\cdot}$ (X = F, Cl).

Mots clés : synthèse des *cis*- et *trans*-$ArSF_4Cl$, *cis*- et *trans*-$PhTeF_4Cl$, $ArSF_5$, and $PhTeF_5$, méchanisme de la fluoration oxydante et de la chloration oxydante, effets isotopiques $^{37}Cl/^{35}Cl$ et $^{34}S/^{32}S$ sur les spectres RMN du ^{19}F.

Introduction

cis and *trans* isomers of six-coordinate S, Se, and Te fluorides are known (1–3), and the preparation of chlorofluoro derivatives, RSF_4Cl, can be carried out with oxidizing agents such as ClF (4), or with oxidizing agents in the presence of fluoride ion, e.g., Cl_2 and CsF (5).

We have shown that oxidation with XeF_2 can be carried out in the presence of a catalytic amount of Cl^-, e.g., oxidative fluorination of Ph_2TeF_2 to Ph_2TeF_4 (6) and of Ph_2SO to $Ph_2S(O)F_2$ (7), but it is generally difficult to predict the stereochemical outcome of oxidation reactions because of the complexity brought about by competition among oxidative fluorination, isomerization, and ligand-exchange processes. If, for example, a Lewis acid such as SbF_5 or PF_5 is added to S(VI) or Te(VI) fluorides, then isomerization can occur (6, 8, 9), presumably via cationic and fluorine-bridged intermediates, but the H_2O–HF–glass system may also, inadvertently, introduce Lewis acids such as BF_3 or SiF_4 into a reaction mixture (10). All attempts were made in this study to avoid the introduction of Lewis acids; furthermore, traces of moisture are eliminated by in situ reaction with sulfur(IV) fluorides and, consequently, pathways involving cationic intermediates are unlikely. If that is indeed the case, then the stereochemical outcome of the reactions discussed below may provide information about anionic and radical intermediates that participate in the oxidation of sulfur(IV) compounds.

Results and discussion

cis- and trans-$ArSF_4Cl$

The preparation of *cis*- and *trans*-$ArSF_4Cl$ was carried out in a polytetrafluoroethene (ptfe) bottle by using ~0.06 mmol of either ArSSAr or $ArSF_3$ as starting compound, and XeF_2 and Et_4NCl as oxidizing and halogenating reagents, in CD_2Cl_2 or CD_3CN solution at room temperature, according to eqs. [1] and [2].

$$[1]\quad ArSSAr + 2\,Cl^- + 5\,XeF_2 \xrightarrow{CD_2Cl_2 \text{ or } CD_3CN} 2\ cis\text{- and } trans\text{-}ArSF_4Cl + 2\,F^- + 5\,Xe$$

[2] $ArSF_3 + Cl^- + XeF_2 \xrightarrow{CD_2Cl_2}$ *cis*- and *trans*-$ArSF_4Cl + F^-$ + Xe, Ar = Ph, *p*-MeC_6H_4, and *p*-$O_2NC_6H_4$

Attempts were made to optimize the yield of *cis*- and *trans*-$ArSF_4Cl$, and experimental results are summarized in Table 1. The molar ratio of reactants was systematically varied, two solvents were used, CD_2Cl_2 or CD_3CN, and substituents *p*-Me and *p*-NO_2 were introduced into the benzene ring.

All products were characterized by ^{19}F and ^{13}C NMR spectroscopy (Tables 2 and 3), and the presence of a chlorine substituent in $ArSF_4Cl$ was confirmed by chlorine isotope shift measurements (Table 4). The ^{19}F NMR spectrum of *cis*-$ArSF_4Cl$ has an A_2BC spin pattern, of which the two equivalent F^A fluorines can be assigned uniquely; however, for the assignment of F^B versus F^C, the method of Dean and Evans (11) was used (Table 2).

cis-$ArSF_4Cl$ *trans*-$ArSF_4Cl$ $ArSF_5$

The experimental results of Table 1 confirm that either *cis* or *trans* isomers can be prepared in high yield, depending on the reaction conditions. *trans*-$ArSF_4Cl$ is the predominant isomer in entries 8–11, 14–16 of Table 1. The highest yield of *trans*-$ArSF_4Cl$ is 89% (entry 11), and five reactions give yields greater than 80% (entries 8–11, 16). Each of these reactions was carried out with a stoichiometric excess of XeF_2 and, in each case, excess XeF_2 was identified at the completion of the reaction, as noted in the last column of Table 1.

The highest yield of *cis*-$ArSF_4Cl$ is 83% (entry 1), and there are five reactions in which the *cis* isomer is formed in greater than 70% yield (entries 1–3, 5, 12). In none of these cases was excess XeF_2 observed at the completion of the reaction. It thus appears that the synthesis of *trans*-$ArSF_4Cl$ is favoured by an excess of XeF_2.

Although the reactions of Table 1 were generally completed within 3–20 min, as judged by the cessation of xenon gas evolution, the ^{19}F NMR spectra, on which the yields are based, were recorded after 24 h. On standing for 1 week, or longer, the yield of *cis* isomer slowly increased at the expense of the *trans* isomer (entries 3–6). In view of the time delay in recording the NMR spectra, and because there is a slow *trans*-to-*cis* isomerization in solution, we cannot attach significance to small differences in yield.

The slow isomerization of *trans*-$ArSF_4Cl$ to *cis*-$ArSF_4Cl$ in solution is clearly evident after 1 week, or longer (entries 3–6), and is enhanced by Et_4NCl. The effect of Cl^- on isomerization was confirmed by adding Et_4NCl to a sample containing a 2:1 ratio of *trans*:*cis* isomers and an excess of XeF_2. After 16 h, the sharp single ^{19}F NMR peak of *trans*-$PhSF_4Cl$ was replaced by a broad peak of reduced intensity but at nearly the same chemical shift, suggesting the onset of a ligand-exchange process in *trans*-$ArSF_4Cl$. The A_2BC peaks of *cis*-$PhSF_4Cl$ remained sharp and at the same chemical shift. Integration of all ^{19}F NMR spectra showed that the original *trans*:*cis* ratio of 2:1 changed to 1:2 after 16 h, 1:4 after 48 h, and 1:8 after 5 days. After 1 week nearly all *trans*-$PhSF_4Cl$ had isomerized to *cis*-$PhSF_4Cl$.

Generally, ArSSAr was the starting compound of choice, because of its ease of preparation and commercial availability. However, $ArSF_3$ can also be used (entries 3, 7, 9), and we assume that $ArSF_3$ is formed *in situ* in all reactions of ArSSAr in Table 1. In those reactions of ArSSAr that were carried out with a stoichiometric deficiency of XeF_2, unreacted $ArSF_3$ can be identified at the completion of the reaction, thus confirming the presence of $ArSF_3$ in these reactions (entries 4, 6, 7).

A small amount of $ArSF_5$ is produced in most reactions, but generally less than ~3% (entries 3, 5, 9–11, 13–16). The yield of $ArSF_5$ can be increased by decreasing the amount of Et_4NCl. For example, at a lower ratio of Cl^-, i.e., $PhSF_3$:Et_4NCl:XeF_2 = 1:0.3:1, the yield of $ArSF_5$ is increased to 20% (entry 7).

In most reactions, but not all, a small amount of $ArSOF_3$ was identified by ^{19}F and ^{13}C NMR, as noted in the last column of Table 1. Trace amounts of water in the reaction mixture produce $ArSOF_3$, and this hydrolysis product serves as an indicator of our experimental technique. Careful purification of reactants and solvents avoids completely the appearance of $ArSOF_3$, whereas the deliberate introduction of water to a reaction mixture containing some $ArSOF_3$ leads immediately to the appearance of $ArSO_2F$. On the other hand, *cis*- and *trans*-$PhSF_4Cl$ appear to be stable towards water for at least several days.

Also listed in the last column of Table 1 are the products CD_2F_2, CD_2FCl, and CD_2FCN, identified by ^{19}F and ^{13}C NMR. It has previously been noted that solvents react with XeF_2 and with anhydrous fluoride ion (12). An exchange-broadened ^{19}F NMR peak at about −153 ppm is seen in all samples and is assigned to a mixture of FHF^-, FDF^-, HF and DF.

Proposed mechanism of oxidative halogenation

The experimental results of Table 1 are explained by the mechanism of Scheme 1. The *N*-X-*L* notation (13) is used to specify the valence electron count and coordination number of sulfur-containing compounds and intermediates as 10-S-4, 12-S-5, 11-S-5, and 12-S-6. It may be noted that fluorinated analogues of these sulfur species have been identified experimentally, i.e., SF_4, SF_5^- (14), $SF_5^\bullet$ (15), and SF_6, respectively. Cations with 10-S-5 sulfur are also known, e.g. RSF_4^+ (16), but cationic intermediates are not considered in Scheme 1 because of the absence of strong Lewis acids in all reaction mixtures.

Some of the proposals in Scheme 1 have been discussed previously, including the reaction of XeF_2 and Cl^- to give $Cl^\bullet$ and F^- in eq. [3] (7), the *trans* arrangement of aryl substituents and nonbonding electrons in eqs. [4] and [5] (6), anion-to-radical oxidation in eq. [4] (17), and cleavage of oxidizing agents such as XeF_2 and Cl_2 via bridged $[S\text{--}F\text{--}Xe]^\bullet$ and $[S\text{--}Cl\text{--}Cl]^\bullet$ intermediates in eqs. [6] and [7] (7).

It is postulated in eq. [4] that addition of F^- to $ArSF_3$, followed by anion-to-radical oxidation, gives the radical $ArSF_4^\bullet$. Further addition of $Cl^\bullet$ then leads to *trans*-$ArSF_4Cl$. The experimental finding that excess XeF_2 favours the synthesis of *trans*-$ArSF_4Cl$ (Table 1) is consistent with eqs. [3] and [4], since excess XeF_2 favours the synthesis of F^- and $Cl^\bullet$ (eq. [3]) and the latter species are required for the synthesis of *trans*-$ArSF_4Cl$ (eq. [4]).

It is also postulated in eq. [4] that interaction of radical

		−6.9(3) ppb	Not resolved	
trans-p-$O_2NC_6H_4SF_4Cl$	135.21(1)	−2.04(3) Hz[c]	−16.7(1) Hz[c]	0.89(2) Hz
		−7.2(1) ppb	−59.1(4) ppb	

[a]Numbers in parentheses are the uncertainty in the last digit.

[b]A negative sign implies increased shielding as a result of substitution with the heavier isotope, i.e., $^2\Delta^{19}F(^{37}Cl/^{35}Cl) = \delta^{19}F(^{37}Cl) - \delta^{19}F(^{35}Cl)$.

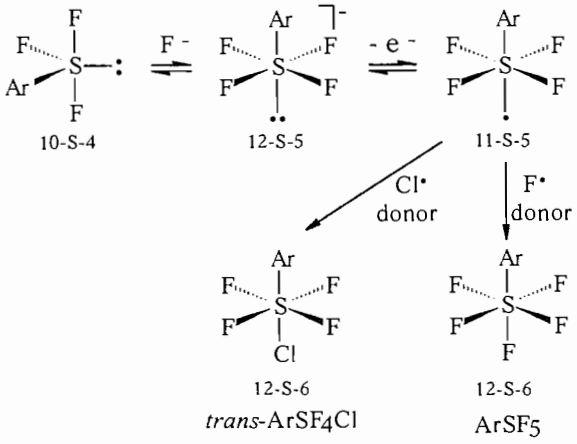
[c]At 282.4 MHz.

$ArSF_4^{\bullet}$ with an $F^{\bullet}$ donor leads to $ArSF_5$. A competition thus exists for radical $ArSF_4^{\bullet}$, and the yield of $ArSF_5$ should increase as the concentration of $Cl^{\bullet}$ donors decreases, which is consistent with our experimental results (Table 1, entry 7). However, the overall synthesis of $ArSF_5$ still requires a catalytic amount of Cl^- because of the role of Cl^- in the production of F^-, $ArSF_4^-$, and $ArSF_4^{\bullet}$, according to eqs. [3] and [4].

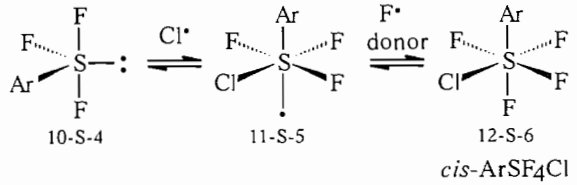
Fluoride-catalyzed oxidation of sulfur(IV) compounds in eq. [4] thus follows the sequence: 10-S-4 → 12-S-5 → 11-S-5 → 12–S-6. If the same sequence is adopted by the F^--catalyzed oxidation of SF_4, then the following pathway is predicted: $SF_4 \rightarrow SF_5^- \rightarrow SF_5^{\bullet} \rightarrow SF_6$. In the absence of F^- (and SF_5^-), the mechanism of oxidation is presumably simplified to $SF_4 \rightarrow SF_5^{\bullet} \rightarrow SF_6$, and the latter sequence of 10-S-4 → 11-S-5 → 12-S-6 is proposed in eq. [5] for the stereospecific synthesis of *cis*-$ArSF_4Cl$.

It is postulated in eqs. [6] and [7] that oxidizing agents such as XeF_2 and Cl_2 interact with radicals $ArSF_4^{\bullet}$ and $ArSF_3Cl^{\bullet}$, with bond cleavage occurring via bridged [S--F--Xe]$^{\bullet}$ and [S--Cl--Cl]$^{\bullet}$ intermediates. Bridged bonds are expected to be very weak, and the role of F^- in the formation of these weak bonds provides an explanation for the catalytic role of F^- in oxidative addition reactions. In the absence of F^-, the oxidizing agents XeF_2 or Cl_2 would have to function as sources of free radicals, and that would require the cleavage of bonds in the oxidizing agents themselves, perhaps under more drastic conditions of heat, or photochemically. Indeed, free-radical reactions with oxidizing agents such as $FO_2SO\text{-}OSO_2F$ or $F_5SO\text{-}OSF_5$ generally require elevated temperatures (18).

Scheme 1 is necessarily vague in several respects. Oxidation of ArSSAr is not discussed, instead we assume that $ArSF_3$ is a common sulfur(IV) intermediate in all reactions. Our experimental results do not allow us to identify the electron acceptor that converts $ArSF_4^-$ to $ArSF_4^{\bullet}$, eq. [4]. However, anion-to-radical oxidations are known for related fluorinated species, e.g., $PhSiF_5^{2-}$ to $PhSiF_5^{-\bullet}$, and numerous one-electron acceptors can be used for this oxidation, including halogen compounds, tetracyanoethylene, metal ions, etc. (19). It is also not possible to identify with certainty the halogen donors in Scheme 1. While Cl_2, $Cl^{\bullet}$, XeF_2, and $XeF^{\bullet}$ are sources of halogen atoms, it is likely that $ArSF_4^{\bullet}$, $ArSF_3Cl^{\bullet}$, and other intermediates can also function as halogen donors. An evaluation of the relative importance of various halogen donors is not possible, and specific halogen donors are not identified in eqs. [4] and [5]. We do not attempt to explain why Cl^- and excess XeF_2 favour the slow isomerization of *trans*-$ArSF_4Cl$ to *cis*-$ArSF_4Cl$, although it may be noted that Michalak and Martin (8) reported previously that the stereochemical outcome of oxidative fluorination depends on the ratio of oxidizing agent, with $\frac{2}{3}$ mol of BrF_3 favouring the synthesis of *trans*-$F_2S[OC(CF_3)_2C_6H_4]_2$, whereas more than $\frac{2}{3}$ mol of BrF_3 favours the *cis* isomer.



Ab initio calculations



The mechanism of Scheme 1 assumes that only F^- forms an anionic intermediate $ArSF_4^-$, but not Cl^-, whereas both fluoro and chloro radical intermediates are postulated, i.e., $ArSF_4^{\bullet}$ and $ArSF_3Cl^{\bullet}$. A difference between the catalytic role of

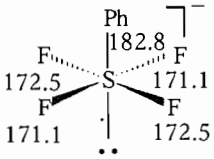
[3] $XeF_2 + 2\,Cl^- \longrightarrow 2\,Cl^{\bullet}\,(\rightleftharpoons Cl_2) + 2\,F^- + Xe$

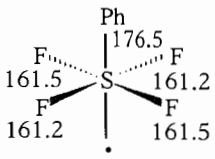
[4] 



[5] 

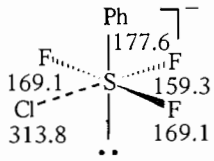
[6] $ArSF_3X^{\bullet} \underset{11\text{-}S\text{-}5}{\overset{XeF_2}{\rightleftharpoons}} ArSF_3X\text{--}F\text{--}XeF^{\bullet} \overset{-\,XeF^{\bullet}}{\rightleftharpoons} \underset{12\text{-}S\text{-}6}{ArSF_4X}$ X = F, Cl

[7] $ArSF_4^{\bullet} \underset{11\text{-}S\text{-}5}{\overset{Cl_2}{\rightleftharpoons}} ArSF_4\text{--}Cl\text{--}Cl^{\bullet} \overset{-\,Cl^{\bullet}}{\rightleftharpoons} \underset{12\text{-}S\text{-}6}{ArSF_4Cl}$



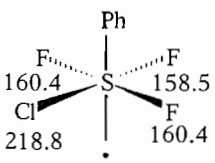
F^- and Cl^- was discussed previously and attributed, based on ab initio calculations of optimized geometries, to the reduced stability and lower concentration of chloro anions in solution (7). Experimental support for this view is based on ion–molecule reactions, which show that SF_4 readily abstracts a fluoride ion to produce SF_5^-, but SF_4Cl^- is formed much more slowly, and SF_4Br^- is not observed (20). Calculations based on density functional theory show a relatively long S—Cl bond in SF_4Cl^-, 223–241 pm, but a shorter S—Cl bond in radical $SF_4Cl^{\bullet}$, 207–219 pm (21). Calculations also reveal a shorter S—F bond length in radical $SF_5^{\bullet}$, 156.2 pm, than in anion SF_5^-, 163.3 pm (22).

Ab initio calculations were carried out for species **1–4**. Of these, **1**, **2**, **4** are postulated intermediates in Scheme 1, but not chloro anion **3**. The calculated (3-21G*) structure of chloro anion **3** shows a very long S--Cl bond of 313.8 pm, which approaches the sum of the van der Waals radii of 350–370 pm (23), implying that $PhSF_3Cl^-$ is probably unimportant in oxidation reactions because of its short lifetime and low concentration. On the other hand, fluoro anion **1** shows four approximately equal S—F bonds in the range 171.1–172.5 pm.



∠CSF = 84.5-87.8°

1 (3-21G*)



∠CSF = 94.3-94.4°

2 (3-21G*)

∠CSF = 88.8, 89.5, 100.5°
∠CSCl = 84.9°

3 (3-21G*)

∠CSF = 91.9, 91.9, 95.7°
∠CSCl = 99.7°

4 (STO-3G*)

All S—F bonds in fluoro radical **2**, 161.2–161.5 pm, are shorter than those of anion **1**, in fact, the bonds in **2** approach those of SF_4, 154–165 pm (24), and SF_6, 156.22 pm (25). The S—Cl bond in radical **4** is significantly shorter and stronger than in anion **3**, and the S—Cl bond length in **4**, 218.8 pm, is only 6.9% longer than in SF_5Cl, 204.7 pm (26). These calculations thus support the mechanism of Scheme 1, which postulates that fluoro anion $ArSF_4^-$ and fluoro and chloro radicals $PhSF_4^{\bullet}$ and $PhSF_3Cl^{\bullet}$, but not chloro anion $ArSF_3Cl^-$, are intermediates in the oxidation of S(IV) to S(VI) compounds.

It is assumed in Scheme 1 that a *trans* arrangement is adopted by aryl substituents and nonbonded electrons. This assumption is in agreement with ab initio calculations (3-21G*), which show that the energy of **1** is 29.3 kJ/mol lower than that of an isomer of **1** in which fluorine is placed *trans* to a nonbonded electron pair. A similar geometry has been assumed for related anions $CF_3SF_4^-$ and $(CF_3)_2CFSF_4^-$ (27).

cis- and *trans*-$PhTeF_4Cl$, $PhTeF_3Cl_2$, and $PhTeF_5$

The method described above for the synthesis of *cis*- and *trans*-$ArSF_4Cl$ was briefly extended to analogous tellurium compounds. Oxidative halogenation of PhTeTePh was carried out on a ~0.06–0.12 mmol scale in a ptfe bottle in CD_3CN solution, using slightly less XeF_2 than required by the stoichiometry of eq. [8].

[8] $PhTeTePh + 2\,Cl^- + 5\,XeF_2 \xrightarrow[25\ ^{\circ}C]{CD_3CN} 2$ *cis*- and *trans*-$PhTeF_4Cl + 2\,F^- + Xe$

Reaction [8] proceeds rapidly to give a mixture of *cis*- and *trans*-$PhTeF_4Cl$, as confirmed by the ^{19}F and ^{125}Te NMR spectra (Table 2). The ^{19}F NMR spectrum shows an additional peak with an AB_2 spin pattern that we attribute to $PhTeF_3Cl_2$. If an excess of XeF_2 is used in reaction [8], then the dominant product is $PhTeF_5$, a known compound (2).

Experimental

NMR spectra were recorded on a Bruker AM300 spectrometer at 282.4 (^{19}F), 75.47 (^{13}C), and 94.76 (^{125}Te) MHz, with the

use of internal C_6F_6 (−162.9 ppm with respect to $CFCl_3$), internal CD_2Cl_2 (53.8 ppm with respect to TMS), internal CD_3CN (1.3 ppm with respect to TMS), and external Ph_2Te (692.3 ppm with respect to Me_2Te) as references. NMR tubes contained ptfe inserts, and samples were prepared in a glove box under a N_2 atmosphere. Yields quoted in Table 1 were measured by ^{19}F NMR integration at several time intervals.

The structures of *cis*-$ArSF_4Cl$, *trans*-$ArSF_4Cl$, and $ArSF_5$ are confirmed by the A_2BC, A_4, and A_4B spin patterns of the ^{19}F NMR spectra, respectively, and by the characteristic ^{13}C NMR spectra of the aromatic substituents. The two equivalent F^A fluorines in *cis*-$ArSF_4Cl$ can be assigned uniquely, but for the assignment of F^B versus F^C the method of Dean and Evans (11) was used. Empirical constants C and T in the linear function $\Delta\delta^{19}F = pC + qT$, where p and q, are respectively, the number of substituents *cis* and *trans* to the fluorine atom, were derived from literature values of the chemical shifts of SF_5Cl (28), and of $ArSF_5$ from this work, relative to SF_6, 57.0 ppm (29). In this way, the following values for C and T were obtained: C = 68.3, T = 6.7 for Cl; C = 5.1, T = 27.3 for Ph; C = 5.7, T = 28.2 for *p*-MeC_6H_4; C = 5.2, T = 23.8 for *p*-$O_2NC_6H_4$. The calculated values of the chemical shifts are given in parentheses in Table 2, and it can be seen that the agreement is good for δF^C, and acceptable for δF^B, thus providing a reasonable basis for the assignment of F^B versus F^C. Agreement with experimental values for δF^A is much poorer, but the assignment of F^A is not in doubt.

The high-resolution ^{19}F NMR spectrum of *trans*-$ArSF_4{}^{35}Cl$ contains an additional peak of approximately one-third intensity that is assigned to *trans*-$ArSF_4{}^{37}Cl$. The chlorine $^{37}Cl/^{35}Cl$ isotope effect on the ^{19}F chemical shift in *trans*-$ArSF_4Cl$ is −6.9 to −7.4 ppb, or −1.96 to −2.09 Hz at 282.4 MHz, a negative sign implying increased shielding for the heavier isotopomer. Although $^{37}Cl/^{35}Cl$ isotope shifts in *cis*-$ArSF_4Cl$ are visible, the isotope peaks were difficult to resolve because of the more complex A_2BC spin pattern. Sulfur $^{34}S/^{32}S$ isotope shifts in *trans*-$ArSF_4Cl$ were also measured (Table 4).

The following compounds were identified by NMR on the basis of literature values: $PhSF_3$ (30), $PhSF_5$ (31), $PhSOF_3$ (32), $PhSO_2F$ (32), and $PhTeF_5$ (2). XeF_2 (Air Products), deuterated solvents (Aldrich), Ph_2S_2 (Aldrich), $(p\text{-}O_2NC_6H_4)_2S_2$ (Aldrich), and Ph_2Te_2 (Aldrich) were used without further purification. $(p\text{-}MeC_6H_4)_2S_2$ was prepared from *p*-MeC_6H_4SH according to the literature method (33). Et_4NCl (Eastman) was recrystallized from dry CH_3CN and stored in a desiccator over P_2O_5.

Ab initio molecular orbital calculations were carried out with the GAUSSIAN 92 program (34).

Preparation of *trans*-$PhSF_4Cl$

Method A

In a typical reaction, solid XeF_2 (30 mg, 0.18 mmol) was added to a mixture of Ph_2S_2 (12.8 mg, 0.059 mmol) in CD_2Cl_2 at 25°C in a ptfe bottle. A small amount of Et_4NCl (2 mg, 0.01 mmol) was added and $PhSF_3$ was formed in almost quantitative yield within 20 min, as determined by ^{19}F NMR examination. To this solution more Et_4NCl (19.5 mg, 0.12 mmol) and XeF_2 (30 mg, 0.18 mmol) were added, and a rapid reaction occurred with vigorous evolution of xenon gas. The colour of the solution changed to deep yellow, but the solution became colourless again after gas evolution ceased. The ^{19}F NMR spectrum of the solution showed that *trans*-$PhSF_4Cl$ was the dominant product; experimental details and yields of products are summarized in Table 1.

Method B

trans-$PhSF_4Cl$ could be made more conveniently in one stage, directly from Ph_2S_2 but without identifying $PhSF_3$. Typically, solid XeF_2 (80 mg, 0.47 mmol) was added to a mixture of Ph_2S_2 (12.8 mg, 0.059 mmol) and Et_4NCl (19.5 mg, 0.12 mmol) in CD_3CN at 25°C in a ptfe bottle. A rapid reaction occurred, with vigorous evolution of xenon gas. The colour of the solution changed to deep yellow, and back to colourless after gas evolution ceased. The reaction was complete within 3 min, and *trans*-$PhSF_4Cl$ was formed in high yield (reactions are summarized in Table 1).

Preparation of *cis*-$PhSF_4Cl$

Method A or method B, as described above, could be used for the synthesis of *cis*-$ArSF_4Cl$, but the amount of XeF_2 was reduced. In a typical reaction, solid XeF_2 (60 mg, 0.35 mmol) was added to Ph_2S_2 (12.8 mg, 0.059 mmol) and Et_4NCl (19.5 mg, 0.12 mmol) in CD_3CN at 25°C in a ptfe bottle. The reaction proceeded as described above and *cis*-$PhSF_4Cl$ was formed in high yield (reaction conditions are summarized in Table 1).

Numerous reactions were carried out in order to optimize the preparation of *cis*-$ArSF_4Cl$ and *trans*-$ArSF_4Cl$, as summarized in Table 1. The ^{19}F and ^{13}C NMR data are given in Tables 2 and 3, and $^{37}Cl/^{35}Cl$ and $^{34}S/^{32}S$ isotope effects on the ^{19}F NMR chemical shifts of *trans*-$ArSF_4Cl$ are given in Table 4.

Reaction of Ph_2S_2 or $PhSF_3$ with XeF_2, but without Cl^-

In typical reactions, solid XeF_2 (50 mg, 0.30 mmol) was added to a solution of Ph_2S_2 (12.8 mg, 0.059 mmol), or to $PhSF_3$ (0.12 mmol), in CD_2Cl_2 or CD_3CN at 25°C in a ptfe bottle. No sulfur(VI) product was found after 1 week, as judged by ^{19}F NMR.

Isomerization of *trans*- to *cis*-$ArSF_4Cl$

Solid XeF_2 (20 mg, 0.12 mmol) and Et_4NCl (15 mg, 0.09 mmol) were added to a solution of *cis*-$PhSF_4Cl$ (20 mg, 0.09 mmol) in CD_2Cl_2. A rapid reaction occurred between XeF_2 and Et_4NCl, with vigorous evolution of xenon gas, but no *cis*-$ArSF_4Cl$ was converted into *trans*-$ArSF_4Cl$.

Solid XeF_2 (5 mg, 0.03 mmol) and Et_4NCl (20 mg, 0.12 mmol) were added to a solution of *trans*-$PhSF_4Cl$ (20 mg, 0.09 mmol) in CD_2Cl_2. The colour of the solution changed from colourless to faint yellow, and *trans*-$PhSF_4Cl$ was gradually converted to *cis*-$PhSF_4Cl$ over a period of several weeks. Some reduction of *cis*-$ArSF_4Cl$ to $ArSF_3$ was observed in solution after 1 month.

Reaction of BF_3 with *cis*- and *trans*-$ArSF_4Cl$

Excess BF_3 was bubbled into a mixture of *cis*- and *trans*-$ArSF_4Cl$ in CD_2Cl_2 at 25°C. All $ArSF_4Cl$ gradually disappeared and the product $PhSF_5$ was identified by ^{19}F NMR.

Preparation of *cis*- and *trans*-$PhTeF_4Cl$

Ph_2Te_2 (24 mg, 0.059 mmol) was partially dissolved in

© 1997 NRC Canada

CD_3CN (0.3 mL) in a ptfe bottle. Solid XeF_2 (20 mg, 0.12 mmol) was added slowly, and Ph_2Te_2 dissolved gradually as xenon gas evolved, but the reddish-orange colour remained. Et_4NCl (19.5 mg, 0.12 mmol) was added to this mixture, and more XeF_2 (20 mg, 0.12 mmol) was added. Gas evolution ceased within 5 min and the colour of the solution became fainter. The presence of both *cis*- and *trans*-$PhTeF_4Cl$ was confirmed by ^{19}F and ^{125}Te NMR (Table 2).

Acknowledgements

We thank the University of Manitoba for a graduate fellowship award (to X.O.). Dr. R.G. Syvret (Air Products, Allentown, Pa.) is thanked for a sample of XeF_2.

Courbes de solubilité de sels congruents présentant une branche croissante dans la représentation de Jänecke

Néji Bourguiba, Tahar Jouini et Mohamed Jemal

Résumé : La représentation de Jänecke de la coupe quasi-ternaire K_2SO_4–KH_2PO_4–H_2O du système quaternaire réciproque H^+, K^+, PO_4^{3-}, SO_4^{2-}, H_2O à 75°C et du ternaire limite K_3PO_4–H_3PO_4–H_2O a révélé des courbes de solubilité présentant une allure croissante inhabituelle pour des sels congruents KH_2PO_4 et K_2HPO_4. Ce comportement est a priori surprenant si l'on admet que la teneur en eau joue le même rôle que la température dans un système polytherme. Afin de lever cette «anomalie», l'influence du mode de représentation sur l'allure de la courbe de solubilité a été examinée et un traitement thermodynamique de ce phénomène a été proposé.

Mots clés : courbe de solubilité, représentation de Jänecke, allure anormale, traitement thermodynamique, phosphates de potassium.

Abstract: The solubility curves at 75°C, represented in Jänecke's mode, of the quasi-ternary section K_2SO_4–KH_2PO_4–H_2O and the limiting ternary system K_3PO_4–H_3PO_4–H_2O of the reciprocal quaternary system H^+, K^+, PO_4^{3-}, SO_4^{2-}, H_2O reveal an unusual increasing shape for the congruent salts KH_2PO_4 and K_2HPO_4. This shape is surprising when one considers the similarities that exist between the role of water content and that of temperature in polytherm systems. The effect of the representation mode on the shape of the solubility curves has been studied in order to explain this unusual behaviour. A thermodynamic treatment of this phenomenon is also proposed.

Key words: solubility curve, Jänecke's mode, abnormal shape, thermodynamic treatment, potassium phosphates.

Introduction

Dans des travaux antérieurs effectués par deux d'entre nous (N.B. et T.J.) sur le système quaternaire réciproque H_3PO_4–K_2SO_4–H_2SO_4–K_3PO_4–H_2O à 75°C, la représentation de Jänecke de la coupe quasi-ternaire K_2SO_4–KH_2PO_4–H_2O (1) et du système ternaire limite K_3PO_4–H_3PO_4–H_2O (2) a révélé des courbes de solubilité présentant une allure croissante inhabituelle pour les sels congruents KH_2PO_4 et K_2HPO_4.

Ce résultat a été, en un premier temps, signalé par un referee comme étant une erreur. En effet, ce comportement paraît a priori anormal dans la mesure où l'on considère communément que la variable intensive «teneur en eau» joue le même rôle que la température dans un système polytherme. Dans ces conditions un composé à solubilité congruente devrait correspondre à un maximum de la courbe de solubilité. Nous l'avons, en réponse au referee, en partie justifié dans le cas de KH_2PO_4 (1). Ce travail est consacré à une étude plus générale de cette question.

Une recherche bibliographique nous a permis de relever deux exemples utilisant également la représentation de Jänecke, où les courbes de solubilité des sels congruents $Na_2Cu(SO_4)_2 \cdot 2H_2O$ (3) et $K_2HPO_4 \cdot 3H_2O$ (4) manifestent le même phénomène.

L'influence du mode de représentation sur l'allure de la courbe de solubilité est examinée et un traitement thermodynamique de ce phénomène est proposé.

Reçu le 20 mai 1997.

I. Influence du mode de représentation sur l'allure de la courbe de solubilité

I.1. Coupe quasi-ternaire K_2SO_4–KH_2PO_4–H_2O à 75°C

Dans cette section (Fig. 1*a*) on observe en particulier que la courbe de solubilité de KH_2PO_4 (Z en fonction du complément de X soit ($U = 100 - X$)) est croissante du point **c** vers **b**.

Les coordonnées de Jänecke définies précédemment (1, 2) s'écrivent dans le cas de liquides dont les points représentatifs appartiennent à la courbe **cb** comme suit : $X = 3 \times 10^2\ n{PO_4}^{3-} / N$; $Z = 10^2\ n{H_2O}/N$ avec $N = n{H^+} + n{K^+} = 2\ n{SO_4}^{2-} + 3\ n{PO_4}^{3-}$.

La concentration en ions H^+ est négligeable. Celle des ions PO_4^{3-} l'est aussi à cette valeur du pH (≃5). De ce fait, les espèces ioniques prépondérantes sont K^+ et $H_2PO_4^-$ (5) provenant de la dissolution de KH_2PO_4 :

$$KH_2PO_4(\text{solide}) \leftrightarrows (K^+)_{aq} + (H_2PO_4^-)_{aq}$$

En définissant pour cette isoplèthe de nouvelles coordonnées faisant intervenir les espèces présentes réellement en quantités non négligeables, on obtient : $X' = 10^2\ n{H_2PO_4}^-/N'$; $Z' = 10^2\ n{H_2O}/N'$ avec $N' = n{K^+} = 2\ n{SO_4}^{2-} + n{H_2PO_4}^-$.

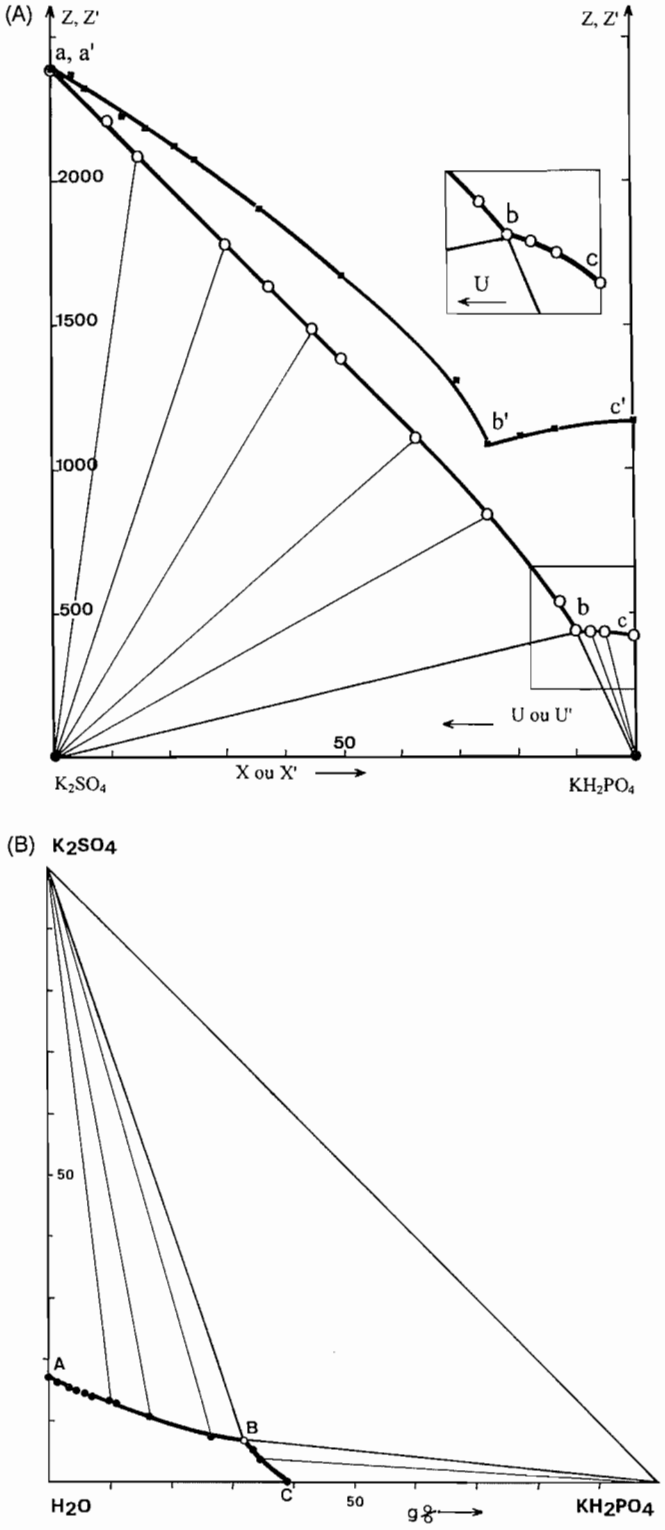
Fig. 1. (*A*) Coupe quasi-ternaire K_2SO_4–KH_2PO_4–H_2O à 75°C (coordonnées de Jänecke). ○—○—○— Courbe (*Z*, *X*) (d'après réf. 1); ■—■—■— courbe (*Z*′, *X*′). (*B*) Coupe quasi-ternaire K_2SO_4–KH_2PO_4–H_2O à 75°C (composition pondérale).



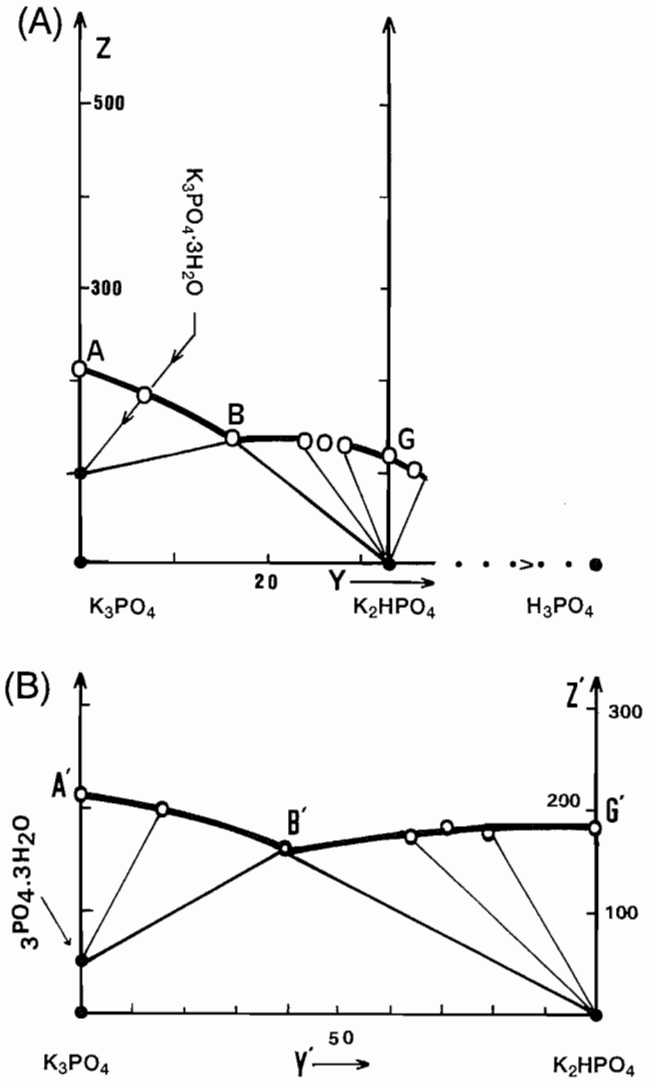


Fig. 2. (*A*) Système ternaire limite K_3PO_4–H_3PO_4–H_2O à 75°C. Courbe (*Z*, *Y*) (d'après réf. 2). (*B*) Système ternaire limite K_3PO_4–H_3PO_4–H_2O à 75°C. Courbe (*Z*′, *Y*′).

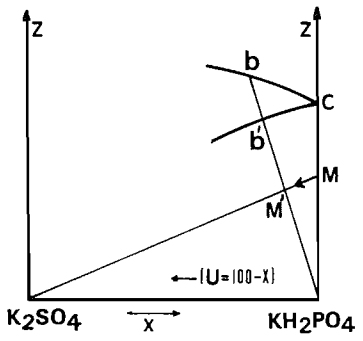
Un calcul utilisant ces dernières définitions a été effectué. Les résultats présentés à la figure 1*a* révèlent cette fois que la courbe *Z*′ en fonction de *U*′(= 100 − *X*′) est décroissante du point **c**′ vers **b**′, comme attendu. Cependant pour une raison d'homogénéité de représentation nous devons garder les mêmes définitions de *X* et *Z* dans tout le quaternaire.

Notons également que la représentation classique en triangle rectangle utilisant les coordonnées pondérales conduit à un diagramme où la courbe de solubilité de KH_2PO_4 présente une allure normale (Fig. 1*b*).

Ainsi l'allure croissante de la courbe (**cb**) de solubilité de KH_2PO_4 représentée dans le mode de Jänecke (Fig. 1*a*) est due à la définition du nombre d'équivalents ioniques *N* et donc de la cote *Z*.



I.2. Système ternaire limite K_3PO_4–H_3PO_4–H_2O à 75°C

Dans la région basique de ce ternaire (Fig. 2*a*) on constate que le composé à solubilité congruente K_2HPO_4 ne correspond pas

Fig. 3.

à un maximum de la courbe de solubilité, la portion de cette dernière (**GB**) étant croissante du point **G** vers **B**.

Nous rappelons que les coordonnées de Jänecke s'écrivent dans le cas de solutions dont les points représentatifs appartiennent à la portion de courbe **GB** : $Y = 10^2\ n\mathrm{H}^+/N$; $Z = 10^2\ n\mathrm{H_2O}/N$ avec $N = n\mathrm{H}^+ + n\mathrm{K}^+ = 3\ n\mathrm{PO_4}^{3-}$.

Comme ces solutions sont basiques (pH $\geq$ 8,75), la concentration des ions H^+ est négligeable. Les entités prédominantes dans ce domaine de pH sont en fait K^+, PO_4^{3-} et HPO_4^{2-} (5). Dans ces conditions, il convient de définir pour le sous-système ternaire K_3PO_4–K_2HPO_4–H_2O, de nouvelles coordonnées faisant intervenir les entités mises en évidence ci-dessus : $Y' = 2 \times 10^2\ n\mathrm{HPO_4}^{2-}/N'$; $Z' = 10^2\ n\mathrm{H_2O}/N'$ avec $N' = n\mathrm{K}^+ = 3\ n\mathrm{PO_4}^{3-} + 2n\mathrm{HPO_4}^{2-}$.

Un calcul utilisant ces nouvelles définitions a été effectué. Les résultats représentés la figure 2*b* montrent, dans ce cas aussi, que la courbe Z' en fonction de U' (= 100 − Y') est décroissante du point **G'** vers **B'** (Fig. 2*b*). Signalons également que K_2HPO_4 est un extremum du diagramme K_3PO_4–H_3PO_4–H_2O tracé en utilisant les coordonnées pondérales (2). La portion de courbe (**GB**) y est bien décroissante du point **G** vers **B**. Ainsi on confirme que l'allure croissante de la courbe (**GB**) de solubilité de K_2HPO_4 représentée dans le mode de Jänecke (Fig. 2*a*) est bien due à la définition de la cote *Z*.

II. Traitement thermodynamique

II.1. Courbe de solubilité de KH_2PO_4

En se situant à l'extrémité droite du diagramme, l'allure d'un liquidus est déterminée, dans le cadre de la représentation de Jänecke, par le signe de la dérivée de la cote *Z* par rapport à *U*, complément de *X* ($U = 100 - X$). On peut établir l'expression de cette dérivée dans le cas de solutions idéales et réelles.

II.1.1. Cas de solutions idéales

Partant d'un mélange M où coexistent KH_2PO_4(sd) et la solution saturée représentée par le point **c** (Fig. 3), l'addition de *n* moles de K_2SO_4 à un litre de cette solution provoque le déplacement du point représentatif de ce mélange de M à M' et le point représentatif de la solution résultante de **c** vers **b**, ou vers **b'**.

L'équation de dissociation de KH_2PO_4 s'écrit :

$$\mathrm{KH_2PO_4(solide)} \leftrightarrows (\mathrm{K}^+)_{aq} + (\mathrm{H_2PO_4}^-)_{aq}$$

En présence de K_2SO_4, la concentration des différentes entités ioniques à l'équilibre sera : $[K^+] = 2n + S$ et $[H_2PO_4^-] = S$ où *S* est la solubilité de KH_2PO_4.

La condition d'équilibre se traduit par l'expression du produit de solubilité P_S de ce sel :

$$[1] \quad P_S = [\mathrm{K}^+][\mathrm{H_2PO_4}^-] = (S + 2n)S$$

Les coordonnées de Jänecke définies avec $N = n\mathrm{H}^+ + n\mathrm{K}^+ = 2n\mathrm{SO_4}^{2-} + 3\ n\mathrm{PO_4}^{3-}$ s'écrivent pour la solution saturée :

$$[2] \quad X = 3 \times 10^2\ S/(3S + 2n)$$

$$[3] \quad Z = 10^2\ n\mathrm{H_2O}/(3S + 2n)$$

L'allure de la courbe de solubilité (**cb**) dépendra du signe de dZ/dU avec $U = 100 - X = 200n/(3S + 2n)$.

En posant :

$$[4] \quad dZ/dU = (dZ/dn)(dn/dU)$$

La dérivée de *Z* par rapport à *n* donne :

$$[5] \quad dZ/dn = -10^2\ n\mathrm{H_2O}\ (2 + 3\ dS/dn)/(3S + 2n)^2$$

À température constante le produit de solubilité P_S est constant. Sa différentielle est donc nulle $d(P_S) = 2S\ dS + 2n\ dS + 2S\ dn = 0$, d'où $dS/dn = -S/(S + n)$.

En remplaçant dS/dn par son expression, la relation [5] devient :

$$[6] \quad dZ/dn = -10^2\ n\mathrm{H_2O}(2n - S)/(3S + 2n)^2(S + n)$$

La dérivation de *U* par rapport à *n* donne :

$$[7] \quad dU/dn = 200(3S^2 + 6nS)/(3S + 2n)^2(S + n)$$

En remplaçant, dans la relation [4], dZ/dn et dU/dn par leur expression, on obtient :

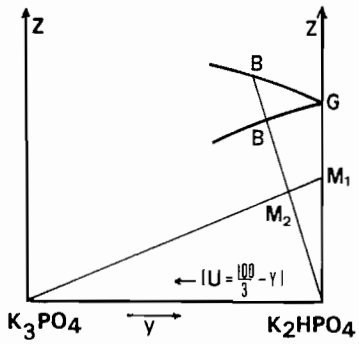
$$[8] \quad dZ/dU = -(nZ/U)(2n - S)/(3S^2 + 6nS)$$
$$= -(nZ/U)(2n\text{-}S)/3S(S + 2n)$$

Sachant que $P_S = S\ (S + 2n)$, l'expression [8] peut s'écrire encore :

$$[9] \quad dZ/dU = -\ (nZ/3UP_S)(2n - S)$$

Comme KH_2PO_4 est suffisamment soluble (S = 2,9 moles dans 1000 g de solution saturée (2)), lors de l'addition des premières quantités de K_2SO_4, on a $2n < S$ et l'expression [9] est positive. Ainsi dans l'hypothèse d'un comportement idéal des solutions considérées, on prévoit une courbe de solubilité croissante de **c** vers **b**, dans la représentation de Jänecke.

II.1.2. Cas de solutions réelles



Les calculs relatifs à ces solutions doivent faire intervenir les activités $a_i = \gamma(i)[i]$.

La même démarche suivie pour l'établissement de l'expression de dZ/dU dans le cas de solutions idéales nous conduit, dans ce cas, à l'expression suivante :

$$[10] \quad dZ/dU = -(nZ\gamma_{\pm}^2/3UPs)(2n - S)$$
$$+ (nZ/U\gamma_{\pm}^2)\ (d\gamma_{\pm}/dn)$$

© 1997 NRC Canada

Fig. 4.

L'allure de la courbe de solubilité dépendra du signe de $(d\gamma_{\pm}/dn)$ et de l'importance relative de chacun des termes de la relation [10] par rapport à l'autre. Le terme $(d\gamma_{\pm}/dn)$ varie dans le même sens que $(d\gamma_{\pm}/dI)$, I étant la force ionique du milieu. Or le signe de $(d\gamma_{\pm}/dI)$ dépend de la force ionique I de la solution (6, 7). Il en résulte que l'allure de la courbe de solubilité ne peut être prévue à l'avance. Elle sera croissante où décroissante selon le signe de l'expression [10]. Ainsi dans le cas considéré (courbe **cb** Fig. 1*a*), l'allure croissante du point **c** vers **b** n'est pas contradictoire avec la théorie.

On peut constater qu'en maintenant le coefficient d'activité moyen égal à l'unité, l'expression [10] se ramène à celle précédemment établie pour les solutions idéales.

II.2. Courbe de solubilité de K_2HPO_4

Comme précédemment, l'allure de la courbe de solubilité (**GB**) représentée dans le mode de Jänecke, dépend du signe de la dérivée de la cote Z par rapport à la variable U ($U = (100/3) - Y$).

II.2.1. Cas de solutions idéales

Partant d'un mélange biphasé M_1 où K_2HPO_4 solide est en équilibre avec la solution saturée **G** (Fig. 4), l'addition de n moles de K_3PO_4 à un litre de cette solution provoque le déplacement du point représentatif de ce mélange de M_1 en M_2 et le point représentatif de la solution de **G** vers **B**, ou vers **B′**.

En supposant que K_2HPO_4 est complètement dissocié dans la phase liquide, l'équation de dissociation en présence de K_3PO_4 ajouté s'écrit :

$$K_2HPO_4(\text{solide}) \leftrightarrows 2\,(K^+)_{aq} + (HPO_4^{2-})_{aq}$$

La concentration des différentes entités ioniques à l'équilibre sera : $[K^+] = (3n + 2S)$ et $[HPO_4^{2-}] = S$ où S est la solubilité de K_2HPO_4.

La condition d'équilibre se traduit par :

$$[1'] \quad P_S = [K^+]_{eq}^2[HPO_4^{2-}]_{eq} = (3n + 2S)^2S$$

Les coordonnées de Jänecke définies avec $N = nH^+ + nK^+ = 3nPO_4^{3-}$ s'écrivent pour la solution saturée : $Y = 10^2\, nH^+/N = 10^2\, S/3(S + n)$; $Z = 10^2\, nH_2O/3(S + n)$. La variable U, complément de Y est : $U = (100/3) - Y = 100\, n/3(S + n)$.

La dérivation de Z par rapport à n donne :

$$[2'] \quad dZ/dn = -10^2\, nH_2O(1 + dS/dn)/3(S + n)^2$$

La différentielle de l'expression [1′] permet de tirer :

$$[3'] \quad dS/dn = -2S/(2S + n)$$

On peut aisément établir les expressions :

$$[4'] \quad dU/dn = US(2S + 3n)/n(S + n)(2S + n)$$

et

$$[5'] \quad dZ/dU = -n^2Z/SU(2S + 3\,n)$$

L'expression [5′] peut s'écrire :

$$dZ/dU = -n^2Z(2S + 3n)/UP_S$$

Cette expression montre que la dérivée de Z par rapport à U est toujours négative. Il en résulte que l'hypothèse d'un comportement idéal des solutions ne permet pas d'expliquer l'allure croissante de la courbe (**GB**) de solubilité de K_2HPO_4, représentée dans le mode de Jänecke (Fig. 4). Ce désaccord ne peut s'expliquer que par l'écart des solutions considérées par rapport à l'idéalité. K_2HPO_4 étant très soluble, sa solubilité dans l'eau pure à 75°C est de 72,74 g de sel pour 100 g de solution saturée (2).

II.2.2. Cas de solutions réelles

Dans ce cas, l'expression de dZ/dU devient :

$$dZ/dU = -n^2Z\gamma_{\pm}^3(2S + 3n)/UPs + n^2Z\gamma_{\pm}^2S(2S + 3n)/UP_S\,(d\gamma_{\pm}/dn)$$

Comme précédemment, l'allure de la courbe de solubilité dépendra du signe de $(d\gamma_{\pm}/dn)$ et de l'importance relative de chacun des termes par rapport à l'autre. Ainsi, l'allure croissante de Z en fonction de U n'est pas en désaccord avec la théorie.

III. Conclusion

Les équilibres de dissolution de KH_2PO_4 et de K_2HPO_4 dans les solutions aqueuses :

$$KH_2PO_4(\text{solide}) \leftrightarrows (K^+)_{aq} + (H_2PO_4^-)_{aq}$$

et

$$K_2HPO_4(\text{solide}) \leftrightarrows 2\,(K^+)_{aq} + (HPO_4^{2-})_{aq}$$

doivent, par augmentation de la concentration des ions K^+ et conformement à la loi d'action de masse, se déplacer vers la formation du sel congruent correspondant. Il en résulte que la solubilité de ces sels doit décroître. En revanche les courbes de solubilité correspondantes, tracées en utilisant le mode de représentation de Jänecke, peuvent manifester une allure croissante.

Excess molar volumes and viscosities of binary mixtures of propylene carbonate with (C_5–C_8) *n*-alkanols at 298.15 K

Mohamed M. El-Banna

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12
For personal use only.

Abstract: Excess molar volumes (V^E) and changes in viscosity ($\Delta\eta$) have been determined for binary liquid mixtures of propylene carbonate (PC) with (C_5–C_8) *n*-alkanols at 298.15 K and atmospheric pressure, over the whole composition range. The positive V^E corresponding to negative $\Delta\eta$, for all the mixtures studied, suggests the presence of specific interactions, namely, involving the intermolecular hydrogen bonds. The results are correlated by means of a Redlich–Kister type equation. The fitting of viscosities to the parameter (N_{12}) of Nissan–Grunberg or to the (H_{12}) parameter of Hind et al. provides models for the dynamic viscosities; the two-parameter (ν_{12} and ν_{12}) McAllister equation and the three parameters (*a*, *b*, and *c*) Heric–Brewer provide models for the kinematic viscosities, allowing us to gain greater knowledge of the interactions between unlike molecules. However, this analysis suggests that the McAllister model fits the data better than the others.

Key words: excess volumes, propylene carbonate, *n*-alkanols, liquid mixtures, hydrogen bonding.

Résumé : Opérant à 298,15 K, à la pression atmosphérique et sur l'ensemble des compositions, on a mesuré les volumes molaires en excès (V^E) et les changements de viscosité ($\Delta\eta$) de mélanges binaires liquides de carbonate de prophylène (CP) avec des *n*-alcanols (C_5–C_8). Pour tous les mélanges étudiés, une valeur positive de V^E correspond à une valeur négative de $\Delta\eta$; cette observation suggère la présence d'interactions spécifiques, à savoir des liaisons hydrogènes intermoléculaires. On a établi une corrélation des résultats à l'aide d'une équation du type Redlich–Kister. L'ajustement des viscosités au paramètre (N_{12}) de Nissan–Grunberg ou au paramètre (H_{12}) de Hind et al. fournit un modèle pour les viscosités dynamiques; par ailleurs, l'équation à deux paramètres (ν_{12} et ν_{12}) de McAllister ainsi que l'équation à trois paramètres (a, b et c) de Heric–Brewer fournit un modèle cinématique des viscosités qui permet d'obtenir une meilleure compréhension entre les molécules qui ne sont pas semblables. Toutefois, cette analyse suggère que le modèle de McAllister conduit à un meilleur ajustement que les autres.

Mots clés : volumes en excès, carbonate de propylène, alcanols, mélanges liquides, liaison hydrogène.

[Traduit par la rédaction]

Introduction

Previous papers (1–4) explained that *n*-alkanols in the pure state are self-associated, forming both open and cyclic aggregates; the probability of the latter increases from smaller alkanols, but in nonpolar solvents is independent of the chain length. Both (4-methyl-1,3-dioxolan-2-one) propylene carbonate (PC) and *n*-alkanols find a wide range of applications as solvents and solubilizing agents in organic synthesis and electrochemical studies (5–7).

In the present study, the excess molar volume (V^E) and the deviation of the viscosity ($\Delta\eta$) of binary mixtures of propylene carbonate + (C_5–C_8) *n*-alkanols have been determined over the entire composition range at 298.15 K and atmospheric pressure. The alkanols considered are 1-pentanol, 1-hexanol, 1-heptanol, and 1-octanol. Mixtures containing the alkanols 1-nonanol and 1-decanol could not be studied because of the partial miscibility of propylene carbonate in these solvents. From these properties, attempts have been made to explain the behaviour of the liquid mixtures. We applied the Nissan–Grunberg (8) and Hind et al. (9) models to dynamic viscosities, and the McAllister (10) and Heric–Brewer (11) models to kinematic viscosities to gain greater knowledge of the specific interaction parameters.

Experimental

The pure liquids were obtained from Aldrich (purity >99.5 mol%). All chemicals were used without further purification, other than storing over molecular sieve to remove any possible traces of moisture.

Density (ρ) measurements of the pure components and binary mixtures, over the complete composition range, were carried out using a Kyoto electronic vibrating tube densimeter (model DA 110) with a temperature sensor keeping the temperature within ±0.005 K. The apparatus was calibrated several times with the well-known density values of deionized doubly-distilled and degassed water, benzene, and dry air at atmospheric pressure.

The mixtures were prepared by syringe, inserting a weighed amount (Mettler A 160 range balance ±0.01 mg) of the pure liquids into stoppered bottles to prevent preferential evaporation. The experimental technique has previously been

described (12). The precision of the densities was ±0.001% g cm^{-3} and of the mole fraction ±0.005 mol%.

Viscosity (η) measurements of both pure components and their mixtures were determined by using an Ubbelohde level viscometer that was calibrated with doubly distilled water and benzene as described previously (13). The accuracy was estimated to be ±0.05%. The density and viscosity values and those from the literature for all the pure compounds are listed in Table 1.

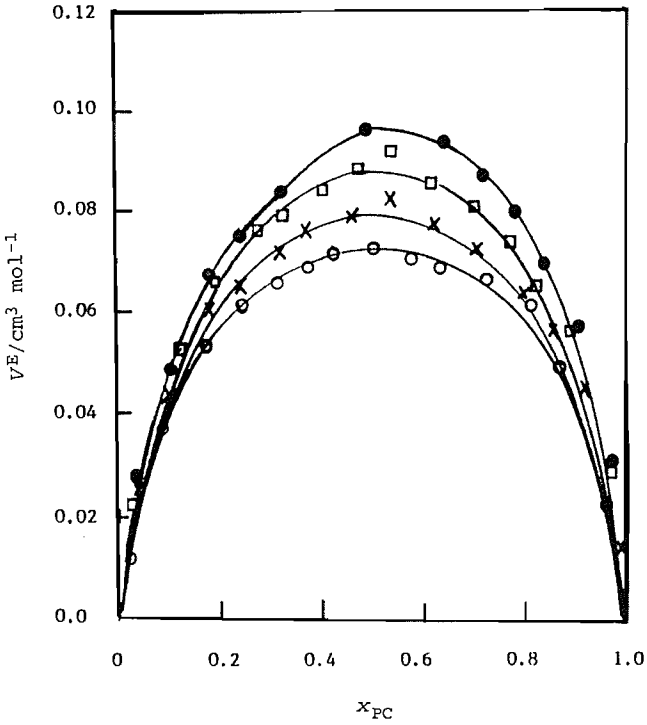
Results and discussion

The experimental data of the densities and viscosities for the (x) PC + (1−x) n-alkanol mixtures at 298.15 K are reported in Table 2. The density values were used to calculate the V^E values from the following equation:

$$[1] \quad V^E / \text{cm}^3\text{mol}^{-1} = x_1 M_1 (\rho_m^{-1} - \rho_1^{-1}) + x_2(\rho_m^{-1} - \rho_2^{-1})$$

where x_i, ρ_i, and M_i are the mole fraction, density, and relative mole mass of the pure components, respectively, with i = 1 for the PC and i = 2 for the n-alkanols, and ρ_m is the mixture at given composition.

The deviations of the viscosity ($\Delta\eta$) were calculated from:



$$[2] \quad \Delta\eta = \eta_m - x_1\eta_1 - x_2\eta_2$$

where η_m, η_1, and η_2 are the viscosities of the mixtures and the pure components, respectively. The V^E and $\Delta\eta$ values are presented in Table 2. Each set of results was fitted with the Redlich–Kister equation (24):

$$[3] \quad X^E - x(1-x)\sum_{j=0}^{n} A_j(2x-1)^j$$

where E^X is V^E or $\Delta\eta$, and A_j are the parameters obtained by a least-squares fitting procedure. In each case the optimum number of coefficients are ascertained from an examination of the variation of the standard error of estimate (σ) with n,

Fig. 1. Excess molar volumes, V^E, of mixtures vs. x_{pc} (○, 1-pentanol; ×, 1-hexanol; □, 1-heptanol; ●, 1-octanol) at 298.15 K.

$$[4] \quad \sigma(F) = [\Sigma\,(X^E_{obs} - X^E_{cal})^2 / (n_{obs} - n)\,]^{0.5}$$

where n_{obs} is the number of measurements. The values of A_j and the standard error estimates associated with the use of eq. [4] are given in Table 3.

In all the mixtures studied the values of V^E are positive over the whole range of composition (Fig. 1). A regular pattern of behaviour for each of the four sets of the binary system is

$\Delta\eta$	−6.7160	1.0555	−11.7185	1.3719	0.0640

observed, starting from 1-pentanol to 1-octanol with the maximum V^E value, 0.097 cm^3 mol^{-1} at x = 0.5, and the standard error changes from ±0.0016 to ±0.0082. The equimolar excess volume, V^E (x = 0.5), increases with increasing length of the hydrocarbon chain of the alkanol (from methanol to 1-butanol) (5); in our work, the values of V^E (x = 0.5) show a slight increase in the sequence: 1-octanol>1-heptanol> 1-hexanol>1-pentanol (Fig. 2).

Molar excess volumes of liquid mixtures reflect the result of different contributions arising from the structural changes undergone by the pure cosolvents. It is expected that positive contributions arise from the breakup interactions between the molecules, namely, the rupture of the hydrogen-bonded chains of the alcohols and the loosening of the dipole interactions between propylene carbonate molecules (25, 26), given that PC is a poor proton acceptor and alkanols are relativity poor proton donors (27, 28). Therefore, steric effects and proton-accepting abilities increase as the alkanol chain length increases (29), with a net increase in the positive contributions to V^E. Figure 2 supports such an assumption.

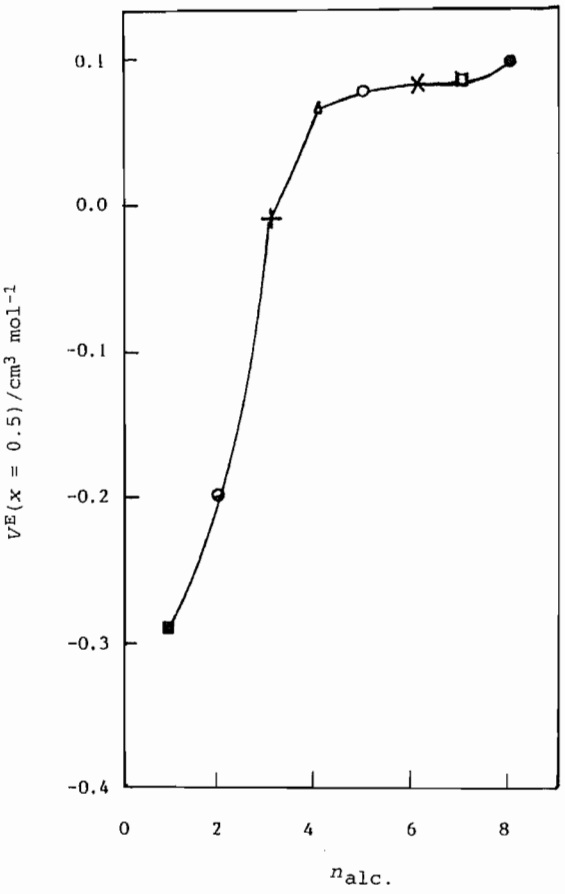
From Fig. 3, the observed negative $\Delta\eta$ values, decrease from 1-pentanol to 1-octanol. The absence of any minima in the intermediate composition gives an indication of the possibility of intermolecular hydrogen bonds between PC and the alcohols. The deviations are negatively defined by the ideal behaviour and additivity of viscosities of the two components (5). Figure 4 shows the plot of $\Delta\eta$ vs. n, the alcohol chain length, at x = 0.5; such $\Delta\eta$ values are negative and their absolute values increase with increasing chain length of the alkanols (7).

Different equations exist in the literature that can calculate viscosity coefficients from the models for the dynamic viscosities, namely:
Nissan–Grunberg (8)

$$[5] \quad \ln \eta_m = x_1 \ln \eta_2 + x_2 \ln \eta_2 + x_1 x_2 N_{12}$$

Hind et al. (9)

$$[6] \quad \eta_m = x_1^2 \eta_1 + x_2^2 \eta_2 + 2 x_1 x_2 H_{12}$$



where N_{12} and H_{12} values are the new interaction parameters (viscosity coefficients) and reflect the nonideality of the system. These parameters have usually been regarded as an approximate measure of the strength of the interaction between the components. The N_{12} and H_{12} values are found to be positive for all mixtures and are similar in magnitude; they are summarized in Table 4 together with the percent error. Also, these can be interpreted in a similar way to the V^E values (Fig. 5).

Fig. 2. $V^E(x = 0.5)$ vs. n (number of carbon atoms in alkanols molecules) at 298.15 K. (■, methanol; ◒, ethanol; +, 1-propanol; Δ, 1-butanol; from ref. 5); this work, ○, 1-pentanol; ×, 1-hexanol; □, 1-heptanol; ●, 1-octanol.

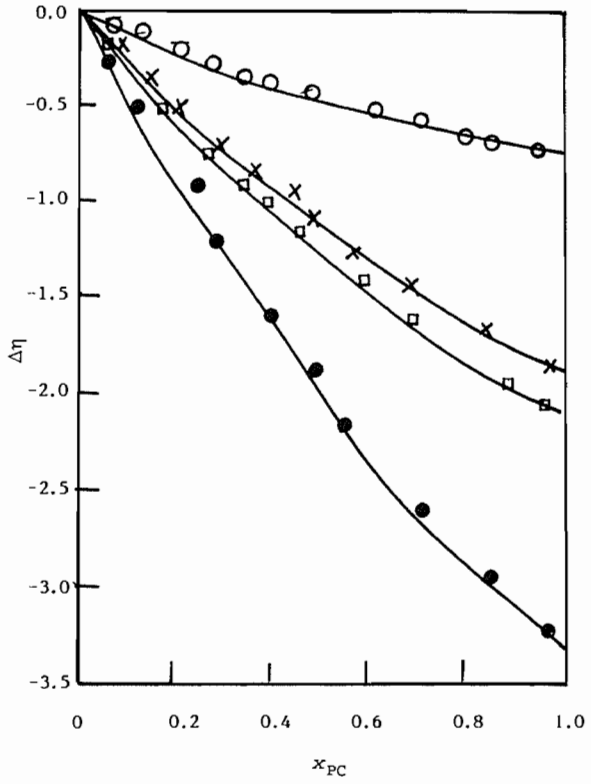
The McAllister correlation for viscosities of liquid mixtures was fitted to the kinematic viscosities, which consider that interaction occurs between three bodies:

$$\ln \nu = x_1^3 \ln \nu_1 + x_2^3 \ln \nu_2 + x_1^3 \ln M_1 + x_2^3 \ln M_2 - \ln(x_1 M_1 + x_2 M_2) + 3x_1^3 x_2 \ln(2M_1 + M_2/3) + 3x_1 x_2^3 \ln(M_1 + 2M_2/3) + 3x_1^3 x_2 \ln \nu_{12} + 3x_1 x_2^2 \ln \nu_{21} \quad [7]$$

where ν_1, ν_2,and ν refer to the kinematic viscosities (η/ρ) of the pure components 1, 2, and the mixture, respectively. The interaction parameters were determined by a non-linear least-squares analysis. The values of ν_{12} and ν_{21} are presented in Table 4, along with their percent error. In a simplified model the parameter ν_{12} would represent the 1-1-2 or 1-2-1 interactions, whereas ν_{21} accounts for the 1-2-2 or 2-1-2 type of interaction. From an examination of the values of ν_{12} and ν_{21}, it is obvious that the values are of the same order of magnitude but they do differ slightly from each other. The ν_{21} values were always greater than ν_{12} (Fig. 5), the difference increasing with the alcohol chain length.

Heric and Brewer (11) suggested the equation:

Fig. 3. $\Delta\eta$ vs. x_{pc} at 298.15 K for the binary systems (○, 1-pentanol; ×, 1-hexanol; □, 1-heptanol; ●, 1-octanol).



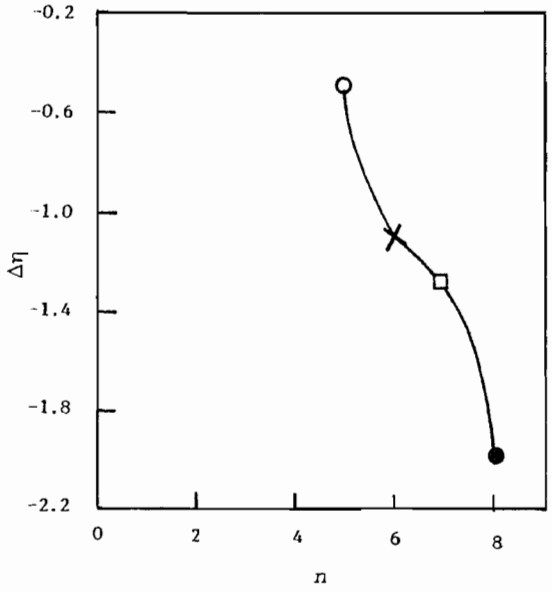


Fig. 4. $\Delta\eta(x = 0.5)$ vs. n (number of carbon atoms in alkanol molecule) at 298.15 K. (○, 1-pentanol; ×, 1-hexanol; □ 1-heptanol; ●, 1-octanol).

$$\nu = x_1\nu_1 + x_2\nu_2 + x_1x_2[a + b(x_1 - x_2) + c(x_1 - x_2)^2] \quad [8]$$

for the kinematic viscosity of binary mixtures. The values of parameters a, b, and c (Table 5) were found to be negative for

Thermodynamic properties of ternary mixtures containing nitrobenzene

V.K. Sharma, Khem Chand Kalra, and A. Katoch

Abstract: Molar excess volumes, V^E_{ijk}, and molar excess enthalpies, H^E_{ijk}, of nitrobenzene (i) + benzene (j) + cyclohexane (k), nitrobenzene (i) + benzene (j) + *n*-hexane (k), and nitrobenzene (i) + benzene (j) + *n*-heptane (k) ternary mixtures have been determined dilatometrically and calorimetrically as a function of composition at 298.15 K. The data have been analyzed in terms of (*i*) the graph-theoretical approach and (*ii*) Flory's Theory. It has been observed that V^E_{ijk} data calculated by graph theoretical as well as Flory's approach compare well with their corresponding experimental values.

Key words: molar excess volumes, molar excess enthalpies, specific interactions, molar volume interaction parameter, molar interaction enthalpy parameter.

Résumé : Opérant à 298,15 K et faisant appel à la dilatométrie et à la calorimétrie, on a déterminé les volumes molaires partiels, V^E_{ijk}, et les enthalpies molaires en excès, H^E_{ijk}, de mélanges ternaires de nitrobenzène (i) + benzène (j) + cyclohexane (k), de nitrobenzène (i) + benzène (j) + *n*-hexane (k) et de nitrobenzène (i) + benzène (j) + *n*-heptane (k) en fonction de la composition. On a analysé les données en termes (*i*) de l'approche théorique des graphes et (*ii*) de la théorie de Flory. On a observé que les données de V^E_{ijk} calculées par l'approche théorique des graphes ainsi que par la théorie de Flory se comparent bien avec les valeurs expérimentales correspondantes.

Mots clés : volumes molaires en excès, enthalpies molaires en excès, interactions spécifiques, paramètre volumique d'interaction molaire, paramètre de l'enthalpie d'interaction molaire.

Introduction

In our earlier communication (1) molar excess volumes, V^E_{ij}, and molar excess enthalpies, H^E_{lj}, for nitrobenzene (i) + benzene or + toluene or + xylenes (j) binary mixtures were reported. The observed data were analysed in terms of the graph-theoretical approach as well as Flory's theory. Recent studies have shown that the thermodynamic properties of ternary (i + j + k) mixtures (2–5) can be determined from the properties of the respective (i + j), (j + k), and (i + k) binary mixtures. Thus it would be of interest to see how the graph approach and Flory's theory explain the V^E_{ijk} and H^E_{ijk} of the various ternary mixtures of non-electrolytes if corresponding data for the (i + j), (j + k), and (i + k) binary mixtures are known. Therefore, in the present investigation molar excess volumes, V^E_{ijk}, and molar excess enthalpies, H^E_{ijk}, of nitrobenzene (i) + benzene (j) + cyclohexane or + *n*-hexane or + *n*-heptane (k) of ternary mixtures have been determined.

Experimental

Nitrobenzene (NB), benzene, cyclohexane, *n*-hexane, and *n*-heptane (AR Grade) were purified by standard methods (6). The purities were checked by measuring their densities at 298 ± 0.01 K and these agreed to within $\pm 5 \times 10^{-5}$ g cm^{-3} with their corresponding literature (7–10) values.

Molar excess volumes, V^E_{ijk}, for various ternary mixtures were measured by means of a dilatometer as has been described elsewhere (11). The dilatometer used had three limbs for three components. The temperature of the thermostat was controlled to better than ±0.1° by means of a toluene regulator. The change in liquid level of the dilatometer capillary was measured with a cathetometer that could read up to ±0.001 cm. The uncertainty in our measured V^E value is ±0.5%. The reliability of the dilatometer was checked by measuring V^E values for the benzene (i) + cyclohexane (j) mixture at 298.15 K and these values agreed with their corresponding literature values (12) within the reported accuracy.

Molar excess enthalpies for ternary (i + j + k) mixtures were determined in a flow calorimeter (LKB Broma, Sweden) in exactly the same manner (4, 13) as that described for the (i + j) binary mixtures, except that now the composition of the third liquid was varied by taking pure component in one syringe and running the mixture of known composition (by weight) of i + j or j + k or i + k in the second syringe. Molar excess enthalpies for the i + j + k mixtures were then calculated from the relation:

$$[1] \quad H^E_{ijk} = (Q_{i+j+k} + Q_{j+k})/(n_i + n_j + n_k)$$

where Q_{i+j+k} is the heat evolved, in joules, when pure liquid (i) is allowed to run in one syringe while, in the other, a mixture of (j + k) of known composition is taken. Q_{j+k} is the heat

Fig. 1. Molar excess volumes, V^E_{ijk}, of nitrobenzene (i) + benzene (j) + cyclohexane (k) at 298.15 K.

evolved in the binary system of j + k of known composition. Since

$$[2] \quad Q_{j+k} = H^E_{j+k}\, n_{j+k}$$

where n_{j+k} is the total number of moles of the (j + k) binary system in the ternary mixture at the desired flow rate, eq. [1] takes the form:

$$[3] \quad H^E_{ijk} = (H^E_{j+k}\, n_{j+k} + Q_{i+j+k})/(n_i + n_j + n_k)$$

Further, the number of moles and the mole fraction of the various components in the ternary mixture were calculated from the following relations:

$$[4] \quad n_i = r_{f1}/V_i$$

$$[5] \quad n_j = (x_j r_{f2})/[V^E_{j+k} + (x_j V_j + x_k V_k)]$$

$$[6] \quad n_k = (n_k r_{f2})/(V^E_{j+k} + (x_j V_j + x_k V_k)]$$

where V^E_{j+k} is the excess volume at the known composition of j in a j + k mixture, V_i, etc. are the molar volumes of the i, etc. entities, and x_j and x_k are the mole fractions of j and k in the j + k mixture, respectively. r_{f1} is the flow rate of the liquid running in the syringe no. 1 and r_{f2} is the flow rate of liquid running in syringe no. 2. The reliability of the instrument was checked by measuring H^E_{ij} for the benzene (i) + carbon tetrachloride (j) system at 298.15 K and the experimental values agreed with the corresponding literature values (14) within the reported accuracy. The uncertainty in our H^E values is ±1%.

Results

V^E_{ijk} and H^E_{ijk} data for the various (i + j + k) ternary mixtures as a function of composition at 298.15 K (recorded in Tables 1 and 2 and plotted in Figs. 1–6) were fitted to eq. [7].

$$[7] \quad X^E_{ijk}\,(X = V \text{ or } H) = x_i x_j\left[\sum_{n=0}^{2} X_{ij}(n)(x_i - x_j)^n\right] + x_j x_k\left[\sum_{n=0}^{2} X_{jk}(n)(x_j - x_k)^n\right] + x_k x_i\left[\sum_{n=0}^{2} X_{ki}(n)(x_k - x_i)^n\right] + x_i x_j x_k\left[\sum_{n=0}^{2} X_{ijk}(n)(x_j - x_k)^n x_i^n\right]$$

where x_i and x_j are the mole fractions of the ith and jth components in the (i + j + k) mixture and $X_{ijk}(n)$ ($X = V$ or H; n = 0–2) etc. are the parameters characteristic of the ternary mixture. $X_{ij}(n)$ ($X = V$ or H; n = 0–2) etc. are the parameters characteristic of the (i + j), (j + k), and (k + i) binary mixtures and have been taken from the literature (1, 15–21). The $X_{ijk}(n)$ parameters of eq. [7] were evaluated by fitting X^E_{ijk} data to eq. [8].

$$[8] \quad \left[X^E_{ijk} - \left\{x_i x_j\left[\sum_{n=0}^{2} X_{ij}(n)(x_i - x_j)^n\right] - x_j x_k\left[\sum_{n=0}^{2} X_{jk}(n)(x_j - x_k)^n\right] - x_k x_i\left[\sum_{n=0}^{2} X_{ki}(n)(x_k - x_i)^n\right]\right\}\right] \Big/ x_i x_j x_k = \left[\sum_{n=0}^{2} X_{ijk}(n)(x_j - x_k)^n x_i^n\right]$$

by the method of least squares and are recorded together with the standard deviation σ (X^E_{ijk}) of X^E_{ijk} defined by

$$[9] \quad \sigma(X^E_{ijk}) = [\Sigma\{X^E_{ijk(expt.)} - X^E_{ijk\ [calcd.\ from\ eq.\ [1]}\}^2/(m-n)]^{0.5}$$

where m is the number of data points and n is the number of adjustable parameters of eq. [7] in Tables 1 and 2.

Discussion

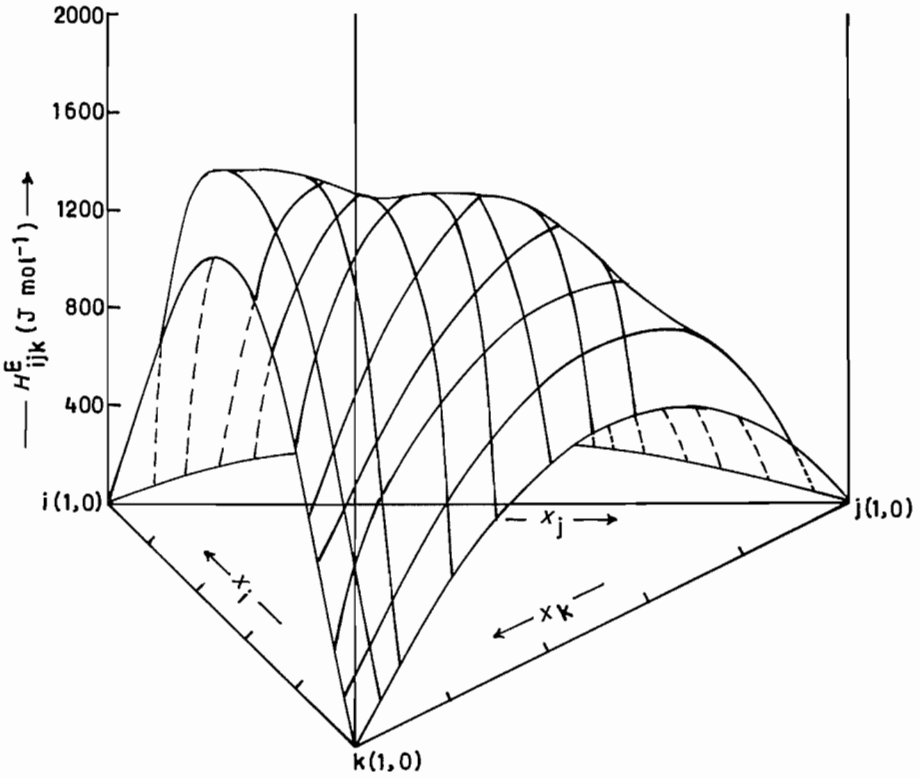
We are unaware of any V^E_{ijk} and H^E_{ijk} values for the mixtures studied with which to compare our results. The observed data for these mixtures were analysed in terms of the graph-theoretical approach.

Conceptual aspect of the graph approach and results

Our earlier studies on the NB (i) + benzene (j) mixture (1)

© 1997 NRC Canada

Fig. 4. Molar excess enthalpies, H^E_{ijk}, of nitrobenzene (i) + benzene (j) + cyclohexane (k) at 298.15 K.



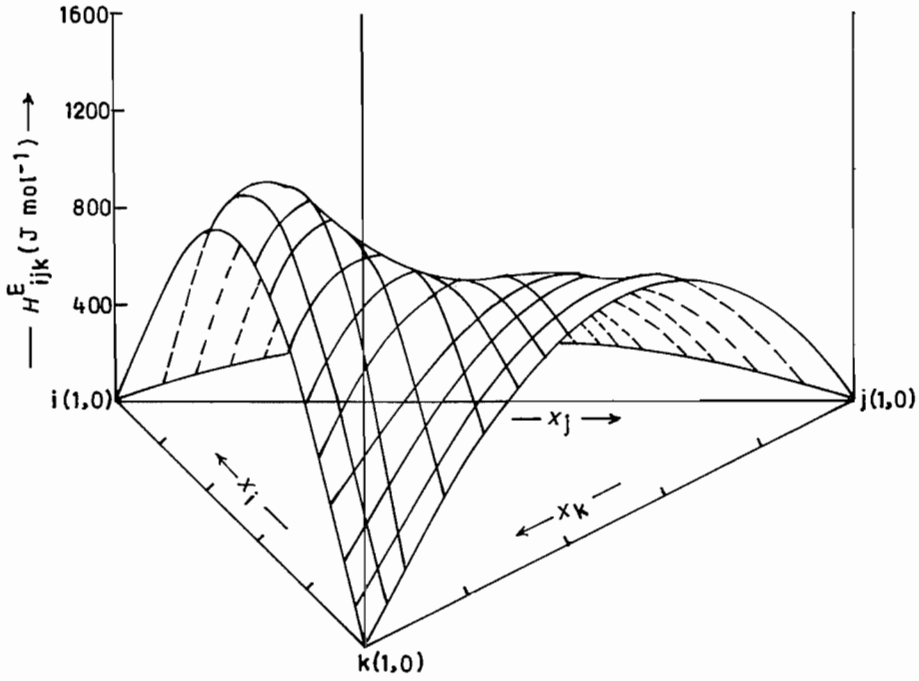


Fig. 5. Molar excess enthalpies, H^E_{ijk}, of nitrobenzene (i) + benzene (j) + *n*-hexane (k) at 298.15 K.

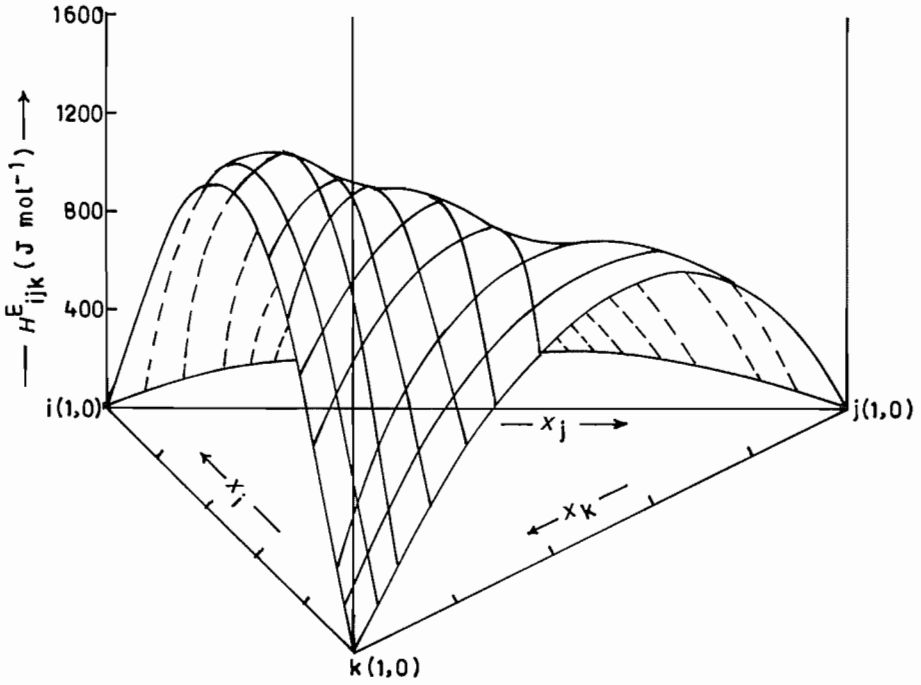
have suggested that (*i*) NB exists as an associated entity in the pure state and (*ii*) the NB (i) + benzene (j) binary mixture formation involves (*a*) the establishment of i_n–j contact between i_n and j; (*b*) the unlike contact formation between i_n and j would then cause depolymerization of i to yield monomers of i; (*c*) monomers of i and j then form an i–j molecular entity. Consequently if χ_{ij}, χ_{ii}, and χ_{12} are the molar volume or enthalpy interaction parameters due to unlike i–j contact formation, j–j and specific interactions, then change in the molar X ($X = V$ or H) property due to processes (*a*), (*b*), and (*c*) would be given (22–24) by

[10] $\Delta X_1 = x_i x_j \chi_{ij} V_j / \Sigma x_i V_i$



[11] $\Delta X_2 = x_i^2 x_j V_j \chi_{ii} / \Sigma x_i V_i$

Fig. 6. Molar excess enthalpies, H^E_{ijk}, of nitrobenzene (i) + benzene (j) + *n*-heptane (k) at 298.15 K.

[12] $\Delta X_3 = x_i x_j^2 V_j \chi_{12}/\Sigma x_i V_i$

The overall changes in molar property X due to processes (a)–(c) were then expressed by

[13] $X^E = \sum_{i=1}^{3} \Delta X_i = [x_i x_j V_j/\Sigma x_i V_i][(1 + x_j)\chi_{ij} + x_i \chi_{jj}]$

However, in the NB (i) + cyclohexane or + *n*-hexane or + *n*-heptane (k) mixture, if i and k are assumed to undergo weak specific interactions, then this binary mixture formation would involve processes (*a*) and (*b*) and the X^E data of these binary mixtures would be expressed by using (21, 25)

[14] $X^E = [x_i x_k V_i/\Sigma x_i V_i][\chi_{ii} + x_i \chi_{12}]$

Equations [13] and [14] contain two parameters and these were evaluated from arbitrary X^E ($X = V$ or H; $x_i = 0.4$ and 0.5 at 298.15 K) data. Since the X^E data of binary systems determined by employing eqs. [13] and [14] compare reasonably well (1, 21) with their corresponding experimental values, it suggests that our basic assumptions in deriving eqs. [13] and [14] are valid.

When an inert hydrocarbon (k) (cyclohexane or *n*-hexane or *n*-heptane) is added to a NB (i) + benzene (j) binary mixture, then this ternary mixture formation involves (*i*) the establishment of (*a*) i_n–j, (*b*) j–k, (*c*) i_n–k unlike contacts between i_n, j, and k components of the mixture; (*ii*) unlike contact formation would then cause depolymerization of i_n to yield monomers of i; and (*iii*) the monomers of i would undergo specific interactions to give an i–j molecular entity. Consequently if χ'_{ij}, χ'_{jk}, and χ'_{ki}, are the molar interaction energies of the i_n–j, j–k, and i_n–k contacts, then change in the molar property due to process (*i*) would be given by

[15] $\Delta X_1 = x_i \chi'_{ij} S_j + x_j \chi'_{jk} S_k + x_k \chi'_{ik} S_i$

where S_i etc. are defined by $S_i = x_i V_i/\Sigma x_i V_i$. Further, if χ'_{ii} and χ'_{12} are the molar interactions of i–i and specific interactions (leading to the formation of i:j entities), then a change in molar property due to processes (*ii*) and (*iii*) can be expressed by

[16] $\Delta X_2 = x_i^2 x_j V_j \chi'_{ii}/\Sigma x_i V_i$

and

[17] $\Delta X_3 = x_i x_j^2 V_j \chi'_{12}/\Sigma x_i V_i$

The overall change in the thermodynamic property due to the processes (*i*)–(*iii*) is given by

[18] $X^E = \sum_{j=1}^{3} \Delta X_i = [x_i x_j V_j/\Sigma x_i V_i][\chi'_{ij} + x_i \chi'_{ii} + x_j \chi'_{12}]$

$+ [x_j x_k V_k/\Sigma x_j V_j]\chi'_{jk} + [x_k x_i V_i/\Sigma x_k V_k]\chi'_{ik}$

Since $V_i/V_j = {}^3\xi_j/{}^3\xi_i$, where ${}^3\xi_i$ etc. are the connectivity parameters of the third degree of pure i, etc. and are defined (24) by

[19] ${}^3\xi_i = \sum_{m<n<o<p} \delta_m{}^v \delta_n{}^v \delta_o{}^v \delta_p{}^v$

where $\delta_m{}^v$, etc. reflect explicitly the valency of the *m*th vertex in the molecular graph of i, in forming bonds, eq. [18] then reduces to

[20] $X^E = [x_i x_j({}^3\xi_i/{}^3\xi_j)/x_i + x_j({}^3\xi_i/{}^3\xi_j)][\chi'_{ij} + x_i \chi'_{jj} + x_j \chi'_{12}]$

$+ [x_j x_k({}^3\xi_j/{}^3\xi_k)/x_j + x_k({}^3\xi_j/{}^3\xi_k)][\chi'_{jk}]$

$+ [x_k x_i({}^3\xi_k/{}^3\xi_i)/x_k + x_i({}^3\xi_k/{}^3\xi_i)][\chi'_{ki}]$

For personal use only.

Further, let it be assumed that $\chi'_{ij} = \chi'_{12}$ and $\chi'_{jk} \approx \chi'_{ik}$; then eq. [20] reduces to

$$[21] \quad X^E = [x_i x_j ({}^3\xi_i/{}^3\xi_j)/x_i + x_j({}^3\xi_i/{}^3\xi_j)][x_i\chi'_{ii} + (1 + x_j)\chi'_{ij}] + [x_j x_k({}^3\xi_j/{}^3\xi_k)/x_j + x_k({}^3\xi_j/{}^3\xi_k) + x_k x_i({}^3\xi_k/{}^3\xi_i)/x_k + x_i({}^3\xi_k/{}^3\xi_i)][\chi'_{jk}]$$

Equation [21] contains three unknown parameters (χ'_{ii}, χ'_{ij}, and χ'_{jk}) that were evaluated from the experimental V^E_{ijk} and H^E_{ijk} of the ternary mixture data at three compositions. Such evaluated parameters along with V^E_{ijk} and H^E_{ijk} for the various mixtures studied are recorded in Tables 1 and 2.

Examination of data in Tables 1 and 2 reveals that V^E_{ijk} and H^E_{ijk} data calculated from the graph approach reproduce well the experimental V^E_{ijk} and H^E_{ijk} data (for $x_i \leq 0.12$, the calculated V^E_{ijk} values are of the right order of magnitude, but the quantitative agreement is not impressive). This lends additional support to the assumption made in deriving eq. [21] and also to the validity of the assumption that $V_j/V_i = {}^3\xi_i/{}^3\xi_j$. The V^E_{ijk} and H^E_{ijk} for these mixtures were then analysed in terms of Flory's theory (26, 27). According to this theory V^E_{ijk} and H^E_{ijk} for a ternary mixture are given by

$$[22] \quad V^E_{ijk} = \overline{V}^E_{cal.}\,(\Sigma\, x_i V_i^*)$$

$$[23] \quad H^E_{ijk} = \Sigma\, x_i P_i^* V_i^* (\overline{V}_i^{-1} - \overline{V}^{-1}_{cal.}) + x_i V_i^* \theta_j \chi_{ij}\, \overline{V}^{-1}_{cal.} + x_j V_j^* \theta_k\, \chi_{jk} \overline{V}^{-1}_{cal.} + x_k V_k \theta_i \chi_{ki} \overline{V}^{-1}_{cal.}$$

$$[24] \quad \overline{V}^E_{cal.} = \overline{V}_0^{7/3}\,[(4/3) - \overline{V}_0^{1/3}]^{-1}(\overline{T} - \overline{T}^0]$$

where all the symbols have the same significance as described elsewhere (25, 26).

Evaluation of V^E_{ijk} and H^E_{ijk} by this theory thus depends upon a knowledge of the reduced temperature $\overline{T}$, and hence on the adjustable parameters θ_j and χ_{ij} of the various binary mixtures. The χ_{ij}, etc. parameters characteristic of (i + j), (j + k), and (k + i) binary mixtures were evaluated by fitting the corresponding $H^E_{exptl.}$ ($x_i = 0.5$) data (1, 15–20) to eq. [24]:

$$[25] \quad H^E_{ij} = x_i P_i^* V_i^* (\overline{V}_i^{-1} - \overline{V}^{-1}_{cal.}) + x_j P_j^* V_j^* (\overline{V}_j^{-1} - \overline{V}^{-1}_{cal.}) + x_i V_i^* \theta_j \chi_{ij}\, \overline{V}^{-1}_{cal.}$$

The parameters of the pure components were determined by using isothermal compressibility (k_T) values reported in the literature (28). These parameters were then utilised to obtain V^E_{ijk} and H^E_{ijk} values at various values of x_i. Such V^E_{ijk} and H^E_{ijk} are recorded in Tables 1 and 2 and are also compared with their corresponding experimental values.

Examination of the data in Tables 1 and 2 has shown that X^E_{ijk} ($X = V$ or H) values calculated from Flory's theory compare reasonably well with the corresponding experimental values. Even in those cases where the agreement between the two values is not good, the predicted X^E_{ijk} values are of the right order of magnitude.

Abstract: The reaction of alkyl phenyl ethers with sodium chlorite in dichloromethane in the presence of a (salen)manganese(III) complex and alumina preloaded with a small amount of water afforded monochlorination products with unusually high *para* selectivities under mild conditions. The $NaClO_2$-based biphasic system can also be successfully used for the regioselective monochlorination of substituted anisoles and polymethoxybenzenes.

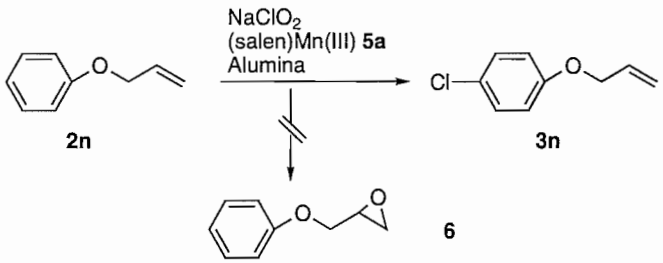
Key words: aromatic chlorination, alkyl aryl ethers, sodium chlorite, (salen)manganese(III) complex, alumina.

Résumé : La réaction des phénoxyalcanes avec le chlorite de sodium, dans le dichlorométhane et en présence d'un complexe (salen)manganèse(III) et d'alumine à laquelle on a préalablement ajouté une faible quantité d'eau, conduit, dans des conditions douces, à des produits de monochloration avec des sélectivités élevées en faveur des produits *para*. On peut aussi utiliser avec succès le système biphasique basé sur le $NaClO_2$ pour effectuer la monochloration régiosélective d'anisoles et de polyméthoxybenzènes substitués.

Mots clés : chloration aromatique, oxydes d'alkyles et d'aryles, chlorite de sodium, complexe (salen)manganèse(III), alumine.

[Traduit par la rédaction]

Introduction



Sodium chlorite **1** has enjoyed an important position in pulp and carbohydrate chemistry (1) because of its mild oxidative property. As an organic synthetic reagent, **1** has been utilized for the selective oxidation of formyl groups to the carboxylic acids in aqueous acidic media (eq. [1]) in the presence of what is generally termed a "chlorine scavenger" such as sulfamic acid (2, 3), resorcinol (2, 4), DMSO (5, 6), hydrogen peroxide (5, 7), or 2-methylbut-2-ene (8) for scavenging HClO and unpleasant ClO_2 (eqs. [1] and [2]). However, there has been no synthetically useful reaction using **1** other than for the aldehyde-to-carboxylic acid oxidations. Indeed, aromatic hydrocarbons or alcohols, upon treatment with **1** in strongly acidic media, undergo competitive chlorination and oxidation, affording only complex mixtures of products (9). In addition, the conventional reactions (1–10) were conducted under aqueous or semiaqueous conditions owing to the negligible solubility of **1** in organic solvents, and therefore its synthetic utility in a water-free medium has so far remained unexplored.

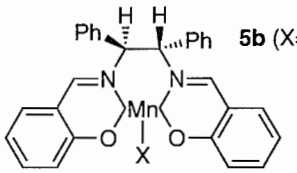
[2] $HOCl + 2\ ClO_2^- \rightarrow ClO_2 + Cl^- + OH^-$



In connection with one of our ongoing projects, we recently needed a simple procedure for the transformation of functionalized alkenes, such as allyl phenyl ether **2n**, into the corresponding epoxide **6** (Scheme 1). Attempted reaction of **2n** with a combination of **1**, chromatographic alumina, and a (salen)manganese(III) complex **5a** (11), a recently developed catalyst for the epoxidation of alkenes (12), in dichloromethane failed to yield the desired product **6**,[2] but resulted in the formation of monochlorinated ether **3n** in good yield (see

[2] Oxidation of sulfides with a reagent combination of sodium chlorite, **5a**, and alumina in dichloromethane under comparable conditions to those employed in the present chlorination led to the formation of chiral sulfoxides, albeit with moderate to low ee's (13).

5a (X=Cl)

5b (X=OAc)

5c (X=OAc)

also entry 25 in Table 2). Intrigued by the unexpected and facile incorporation of a chlorine atom into the aromatic moiety, our attention was drawn to the chlorination since this procedure is expected to provide a mild and convenient aromatic chlorination method (for preliminary results, see ref. 14). In this article, we would like to report a new nuclear monochlorination of activated arenes under heterogeneous conditions.[3]

Experimental

Instruments

^{1}H NMR spectra were measured with a JEOL JNM-FX200 or JNM-FX500 spectrometer for solutions in deuteriochloroform using TMS as an internal standard. Analytical GC was carried out on a Shimazdu GC-4BM or GC-14B instrument, equipped with a flame ionization detector through a 2 m × 6 mm diam. glass column packed with 5% PEG-20M on Chromosorb WAW-DMCS and interfaced with a Shimazdu Chromatopac C-R6A integrator, with temperature programming. Mass spectra were determined on a JEOL model SX-102A mass spectrometer, which was coupled with a Hewlett Packard model GC5890 Series II GC apparatus via a heated capillary column. Atomic absorption analyses were carried out on a Hitachi model 170–30 instrument.

Starting materials

Dichloromethane was rigorously dried, distilled, and stored over molecular sieves. Sodium chlorite was purchased from Kanto Chemical Co., Ltd. (Japan). Anisole **2a**, phenetole **2b**, butyl phenyl ether **2e**, allyl phenyl ether **2n**, benzyl phenyl ether **2o**, substituted anisoles **6a–d**, xylenes, mesitylene, and di- and tri-methoxybenzenes **10a–d** and **12a,b**, respectively, are commercial chemicals and the reagents can be used without further purification. Cycloalkyl phenyl ethers, **2l** and **2m**, were prepared by heating a mixture of phenol, potassium hydroxide, and cycloalkyl chlorides in DMSO (16). Other alkyl phenyl ethers **2c**, **2d**, and **2f–k** were synthesized by the reactions of sodium phenoxide with alkyl bromides in ethanol (17). The purities of all substrates were checked by GC prior to use; *p*- and *o*-chloroanisole **3a** and **4a**, respectively, and mesityl chloride **9** were commercially available as reference compounds. *Moist* alumina was prepared by adding deionized water (0.2 g) to oven-dried (500°C, 6 h) chromatographic neutral alumina (ICN BIOMEDICALS: Alumina N, Super I; 1 g) in portions, followed by vigorous shaking of the mixture for a few minutes after every addition until a free-flowing powder was obtained, 1 g of which was immediately used for the chlorination. Optically active (salen)manganese(III) complexes **5a** (11), **5b** (18), and **5c** (18) were synthesized according to standard methods. Commercial inorganic cobalt and manganese salts (vide infra) were finely ground prior to use.

Chlorination procedures

The following procedure for anisole **2a** is representative. A 30 mL, round-bottom, two-necked flask, equipped with a 1.5 cm long Teflon-coated stirrer bar, a 25 cm long condenser, and a glass gas-inlet tubing connected to an argon-filled balloon, was arranged in order to perform the reaction under dry conditions by linking the top of the condenser to a liquid paraffin trap via a flexible silicone rubber tubing. In the flask were placed **2a** (1.5 mmol), freshly prepared *moist* alumina (1 g), the catalyst **5a** (1 mol% with respect to **2a**), and dichloromethane (10 mL) in that order, and the resultant dark mixture was stirred for a few minutes. Sodium chlorite **1** (2.85 mmol; [**1**]/[**2a**] = 1.9) was added in one portion with magnetic stirring and the flask was then deaerated by passing a gentle stream of dry argon through the system. The reaction was carried out by vigorously stirring the heterogeneous mixture; care should be taken in continuing efficient stirring during the reaction to ensure smooth chlorination and to attain reproducible results. After a given time (agitation periods after addition of **1** are indicated in Tables 1–3), the whole mixture was transferred onto a sintered glass funnel, and the insoluble residues were thoroughly washed with portions of dry ether (in toto ca. 100 mL). The combined clear filtrate was condensed on a rotary evaporator under reduced pressure to leave an oil contaminated with a catalyst residue. Chromatography on a silica gel column (Merck Silica Gel 60, hexane – ethyl acetate) afforded a mixture of monochloroanisoles in 97% yield based on starting **2a**.

The recovery of anisole and the yield of *para*- and *ortho*-chloroanisole **3a** and **4a** were determined by GC using biphenyl as an internal standard. Reuse of **5a** was found to be impractical because of the tedious recovery of the catalyst in such low concentration from a mixture of spent reagents and products, and of some skeleton destruction of **5a** during the chlorination.

The other mono-, di-, and tri-alkoxybenzenes were similarly subjected to the chlorination with a **1–5a** – *moist* alumina system, followed by common work-up and chromatographic separation, to yield the indicated products, which were characterized by NMR and MS spectroscopies.

Results and discussion

Chlorination of anisole

The current chlorination can be readily carried out only by efficiently stirring a heterogeneous mixture of an aromatic ether, catalyst **5a**, **1**, chromatographic alumina, and an aprotic solvent. Independent experiments were first made to estimate reaction parameters such as solvents, temperature, and water content of the alumina using anisole **2a** as the test substrate in order to optimize reaction conditions. When **2a** was treated with **1** without metal catalyst in the absence and presence of commercial or oven-dried or water-loaded alumina in dichloromethane, no reaction took place, **2a** being recovered essentially unchanged (**2a** recovery 98% by GC on every run). In the presence of oven-dried alumina or when no alumina was added, no reaction occurred even though catalyst **5a** was added. On the other hand, when **2a** was treated with a $NaClO_2$–**5a** system in the presence of the optimally water-loaded alumina (*moist* alumina; water content 17% by weight) in dichloromethane at ambient temperature it was completely consumed within 30 min, affording a mixture of *p*-chloroanisole **3a** (92.6%) and *o*-chloroanisole **4a** (4.5%) in quasi quantitative yield (Scheme 2, R = Me; total 97%) with high selectivity to the *para* isomer (*para*/*ortho* ratio, 41 after statistical correction), but no *meta*-chloroanisole. Consequently, the catalyst **5a** and *moist* alumina are essential for chlorination to occur under mild conditions.

The choice of solvent was found to be another important

factor: of common solvents examined, only dichloromethane favored the chlorination whereas no chlorination occurred in the other solvents during extended periords of time (Table 1). In contrast to the remarkable solvent effect, the chlorination exhibited little temperature dependence — control experiments conducted in the range of 0–30°C revealed that there was no significant change in the yield of monochloroanisoles or the *para* selectivity with a change of the temperature. Another comparative study using related (salen)manganese(III) complexes **5a**, **5b**, and **5c** showed that, although there is no significant difference in the activity of the catalysts and the *para* selectivity, the reaction using **5a** gave monochloroanisoles in slightly superior yield to those with use of **5b** and **5c** (97, 91, and 91%, respectively). In addition, **5a** can be synthesized by a simpler method (11) than those used for the preparation of **5b** and **5c** (18). Consequently, the subsequent chlorinations were carried out by using **5a** as the catalyst, in dichloromethane in the presence of *moist* alumina.

Although it is known that some heterogeneous reactions are affected by the presence of water (19, 20), the remarkable sensitivity of the current reaction towards the water content of the alumina and towards the solvent was unexpected and unusual. Sodium chlorite is insoluble in dichloromethane, no reaction occurred in the absence of alumina, and atomic absorption analyses of the reaction solvent showed no detectable amount of manganese species. These observations suggest that the chlorination presumably occurs on the alumina surface and that the solvent – alumina surface interface plays a decisive role in the present reaction. There might be a fine balance between keeping the right amount of water on the alumina surface to help break up the sodium chlorite lattice[4] and moderate solvent polarity to enable the chlorination to take place under mild conditions. It should be noted that no evidence was found for the formation of 2,4-dichlorinated or poly-chlorinated product(s), or for demethylation (22) or rearrangement to phenolic compound in the experiments described above.

Chlorination of aromatic monoethers

Applicability of the $NaClO_2$–**5a** – *moist* alumina system to a series of simple alkyl phenyl ethers **2b–o** was then tested (Scheme 2) and the results are collected in Table 2. Although it is known that some heterogeneous chlorinations have been considerably affected by a slight structual change in the substrates (23), there is apparently no serious dependence of the reactivity of the ethers on the shape and size of the alkyl moiety in the current reactions. For example, comparative studies

[4] A similar explanation has been given for the acceleration of reactions with the use of solid reagents by a small amount of water: see ref. 21.

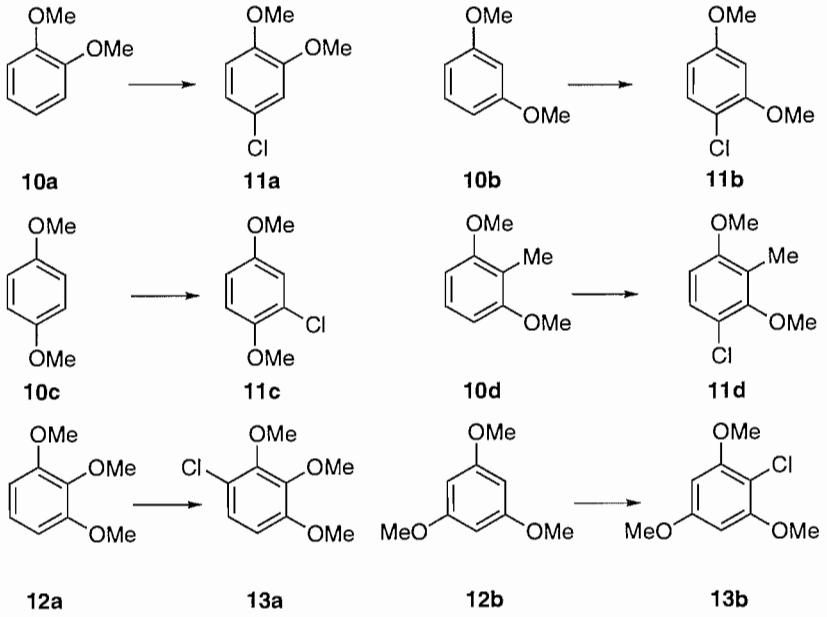
[b]Based on the starting ether (numbers in parentheses are yields based on consumed substrates).



using ethers having C_3- (**2c–d**) and C_4-alkyl groups (**2e–h**) clearly indicated that the reactivity of the ethers is little influenced by steric bulk around the ether linkage. Interestingly, the reactions of **2b–o** led to exclusive *para*-chlorination, giving **3b–o** in excellent to quantitative yields. The side chain of **2n** is assumed to be highly susceptible to chlorination, but it gave **3n** in good yield (60% based on **2n** consumed).

Encouraged by the unusually high *para* selectivity in the chlorination of simple monoether substrates **2a–o**, chlorination of methyl- and dimethyl-substituted anisoles **6a,b** and **6c,d**, respectively, with a **1**–**5a** – *moist* alumina system was also investigated. As shown in Scheme 3, the chlorination occurred selectively at positions *para* to the MeO groups, producing monochlorination products **7a–d** in excellent yields (entries 27–30 in Table 3). In sharp contrast to the facile chlorination of **6a** and **6b**, xylenes resisted chlorination, leading to the recovery of unchanged substrates even after prolonged reactions (120 min; substrate recovery 97–99%). This might suggest that activation by the two methyl groups is not adequate for the nuclei to undergo chlorination, since mesitylene **8** afforded mesityl chloride **9** in fairly good yield (Entry 31).

Chlorination of di- and tri-methoxybenzenes

The reactions of a series of di- and tri-methoxybenzenes, **10** and **12**, were carried out in order to examine the regiospecificity in the chlorination of the polyether substrates (Scheme 4). Chlorinations of 1,2- and 1,3-dimethoxybenzene **10a** and **10b** occurred at the position *para* to the MeO group, affording **11a** and **11b**, respectively. 1,4-Dimethoxybenzene **10c** has no substitutable hydrogen at the position *para* to each MeO group, but it was readily chlorinated to give **11c** in excellent yield. The usefulness of the present procedure for the monochlorination of triether substrates, **12a** and **12b**, is also apparent.

Aromatic chlorination has been an important reaction in organic chemistry (for reviews, see ref. 24) and many interesting methods have been developed employing molecular chlorine, sulfuryl chloride, hypochlorite and its esters, metal chlorides, N-chloro compounds, etc. as chlorinating agents (24–34). So far as we are aware, both the yield and the selectivity of the chlorination product resulting from solid–solution biphasic systems (23, 28–31) are, in general, superior to those from simple solution-phase counterparts. For example, chlorination of aralkyl ethers (**2a–c**, **2e**, and **2i**) by alumina-supported $CuCl_2$ reagent ([$CuCl_2$]/[**2**], ca. 5 (mole ratio); 100°C, 2–3 h) gives excellent yields and *para* selectivity (30). Our chlorination compared favorably with this procedure in terms of the generally *higher* yield, much *milder* conditions (< 25°C), *shorter* reaction periods, and use of *smaller* amounts of the *cheaper* chlorinating reagent ([$NaClO_2$]/[**2**] $\leq$ 2). In addition, the chlorination of a wide variety of substrates can be performed readily and efficiently, and the regioselectivities are impressive. These advantages, together, may make the new system an attractive alternative to conventional chlorination methodologies.

The current alumina-promoted chlorination formally amounts to a simple chlorine transfer to arenes. This study had a preparative rather than a mechanistic purpose and, in addition, convincing evidence to permit a physicochemical interpretation of the reaction has not been yet provided, since there is uncertainty with regard to the catalysis of **5a** and the active species wherein the chlorite itself and (or) its degradation product(s) might be involved. The following observations and comparisons with related literature data, however, might show interesting aspects of the chlorination.[5] Since chlorine itself is very reactive and small in size, the recent development in selective chlorinations owes its success either to the use of bulky chlorinating agents (27, 32) or shape-selective catalysts such as cyclodextrin (25), zeolites (27, 28), or, as noted above, to the reaction performance under biphasic conditions (23, 27–31), all of which are based on the sterically (or dimensionally) controlled access of chlorinating agents to the reactive, electron-rich position(s) of aromatic nuclei. For the present chlorination, it might be expected that chlorine transfer from a bulky **5a**–chlorine complex to arenes is responsible for the high regioselectivity. However, this should be unlikely, since simple inorganic metal salts, e.g., $CoSO_4$, $Co(NO_3)_2$, $CoCl_2$, $CoBr_2$, $MnSO_4$, $MnCl_2$, $Mn(OAc)_2$, $KMnO_4$, $NaMnO_4$, can be used in place of **5a** for the chlorination of **2a** and there has been no significant change in the **3a/4a** ratios and the yields of chloroanisoles; typically, **3a/4a** = 95:5 and 94:6 with use of $CoSO_4$ and $MnSO_4$, respectively (total yields of **3a** plus **4a** were 94 and 95%, respectively). Thus **5a** is considered to serve as a catalytic activator of **1** or to be involved in the degradation process of **1** en route to the generation of the active chlorine species. In addition, the chlorination of simple aromatic ethers occurred selectively or exclusively at positions *para* to the alkoxy groups (entries 1 and 13–26). It is noteworthy that, in the case of methyl- (entries 27, 28, and 35) and dimethyl-substituted anisoles (entries 29 and 30), positions *para* to the MeO groups are chlorinated, but not those *para* to the Me substituent(s), indicating clearly that chlorine displaces hydrogens attached to the more nucleophilic carbon atoms on the benzene rings (ref. 24*d*, Chap. 2; ref. 24*e*, p. 513; 33, 34). Together, these results undoubtedly support the view that electronic effects are a decisive factor in controlling the

[5] Valuable suggestions from one of the referees regarding the observed regioselectivities are gratefully acknowledged.

© 1997 NRC Canada

regioselectivy of the current chlorination, in which the alumina might contribute not only to facilitating the reaction, but to enhancing the regioselectivity of the product (23*a*, 30). Smooth reactions of **6b**,**c**, **8**, **10b–d**, and **12a**,**b** may account for the lesser influence of steric factors. Finally, even if some interaction between electron-rich ether oxygen (34) and the alumina surface is present, it seems unimportant in determining the reactivity of an ether and the regioselectivity of the chlorination product, since **2h**, for example, was readily chlorinated to afford exclusively **3h** (entry 19).

Conclusion

We have demonstrated here that the $NaClO_2$-based biphasic system serves as an efficient electrophilic chlorine source that is capable of regiospecifically chlorinating the electron-rich position on the benzene ring of a variety of aromatic ethers under mild and neutral conditions.

For personal use only.

Abstract: Iodine and iodine supported on polyvinylpyrrolidone (betadine) have been used as catalysts for ring opening of epoxides and as reagent for ring-opening dimerization of thiiranes in alcohols, water, and acetic acid. The reactions occur with high regio-, chemo-, and stereoselectivity. The reaction of *R*-(+)-styrene oxide with I_2 supported on PVP in methanol was found to be very stereospecific and the product was isolated in 93% ee.

Key words: iodine, support, polyvinylpyrrolidone, ring opening, epoxides, thiiranes.

Résumé : On a utilisé de l'iode et de l'iode supporté sur de la polyvinylpyrrolidone (PVP, bétadine) comme catalyseurs pour l'ouverture de cycle d'époxydes et comme réactifs pour l'ouverture de cycle dimérisante de thiiranes dans l'acide acétique, l'eau ou des alcools. Les réactions se produisent avec des régio-, chimio- et stéréosélectivités élevées. On a trouvé que la réaction du *R*-(+)-oxyde de styrène avec de l'iode supporté par de la PVP dans le méthanol est hautement stéréospécifique; le produit isolé présente un ee de 93%.

Mots clés : iode, support, polyvinylpyrrolidone, ouverture de cycle, époxydes, thiiranes.

Introduction

Various reactions of halogens with organic compounds have been reported in the literature. Among these reactions, the addition reactions of halogens to unsaturated compounds have been extensively studied (1–3). Iodine has also been used in many other organic transformations such as conversion of unsaturated carboxylic acids to iodolactones (4) and addition to alkenes to form diiodo compounds (5), halohydrins (6), and β-alkoxy and acetoxy iodides (7). Very recently some new applications of iodine, such as preparation of phosphate ester via activation of trialkyl phosphites (8), catalysis of some Diels–Alder reactions (9), and the conversion of alcohols to alkyl iodides (10), have also been reported. In this study we report that iodine and iodine supported on polyvinyl pyrrolidone (I_2/PVP, betadine, a commercially available disinfectant) can act as efficient catalysts for ring opening of epoxides and as reagents for ring-opening dimerization of thiiranes in alcohols, water, and acetic acid with high regio-, chemo-, and stereoselectivity under neutral conditions.

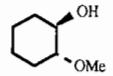
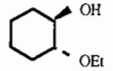
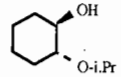
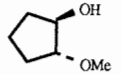
Results and discussion

Ring-opening reactions of different epoxides in primary, secondary, and tertiary alcohols were performed in the presence of 0.1–1.5 molar equivalents of iodine. The molar ratio of iodine to the substrate depends on the structure of both epoxide and nucleophile. The corresponding β-alkoxy alcohols were formed in 75–98% yields. NMR and GC analysis showed that the reactions are highly regioselective. The products obtained from cyclic epoxides showed the formation of the *trans* isomer as the sole product of the reaction. The results obtained from alcoholysis of epoxides are shown in Table 1. High chemoselectivity in the reaction of **1d**, which contains a double bond, was observed in methanol. The reaction of **1d** with methanol in the presence of 0.4 molar equivalent of I_2 and at room temperature occurred only on the epoxide ring and the double bond remained unreacted. However, when this reaction was performed in the presence of excess I_2 (1.5 molar equivalent) and under reflux conditions, in addition to the ring opening of epoxide, the double bond reacted with the methanol and iodine (Table 1, entries 10–12).









The reactions of these epoxides in water and acetic acid also took place efficiently and in the presence of 0.2–1.3 molar equivalent of I_2. The corresponding β-diols and β-acetoxy alcohols were obtained in high to excellent yields (Table 2). Identification of these compounds was done by comparison with authentic samples, which were prepared according to known procedures (11–24).

As far as we know, there is no report in the literature concerning the selective opening of an epoxide in the presence of other epoxides. We observed that, in the presence of 0.1 molar

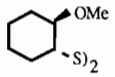
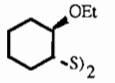
equivalent of I_2 and in methanol, a competitive ring-opening reaction of styrene oxide in the presence of those epoxides carrying electron-withdrawing substitutents (**1b**, **1c**, **1d**) can be carried out efficiently at room temperature. Very high selectivity was observed in these reactions and styrene oxide reacted quantitatively while the other epoxides remained intact (Table 3). However, the reaction of styrene oxide in the presence of cyclohexene oxide as a disubstituted epoxide in methanol did not show high selectivity under these conditions (Table 3, entry 6).

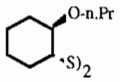
The ring-opening reaction of epoxides has been studied extensively (23) but, due to the ready polymerization of thiiranes, fundamental information abour their ring-opening reactions is still scarce. Most of the reported data concerning ring-opening reactions of this important class of compounds has been obtained in the presence of higly acidic catalysts such as H_2SO_4, HCl, or BF_3 and at high temperature (25). We studied the possibility of using iodine for ring opening of thiiranes in alcohols and aqueous acetonitrile.

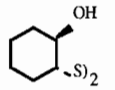
The reactions of thiiranes in alcohols and aqueous acetonitrile were carried out in the presence of an equimolar amount of iodine at room temperature or under reflux (Scheme 2, Table 4). In these reactions, ring opening of thiiranes and dimerization occurred together with the formation of the corresponding disulfides in 66–90% yields.

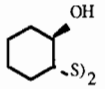
Iodine, whose handling is not safe due to easy vaporization and ready sublimation at high temperature, has recently found very interesting applications in organic synthesis (8–10) and it is therefore important to overcome the problems of handling and sublimation. We decided to prepare I_2 supported on polyvinylpyrrolidone, to investigate its reactions with epoxides and thiiranes, and to compare the results with those obtained with iodine. Iodine supported on polyvinylpyrrolidone (I_2/PVP) has been reported in the literature and has also been used commercially as a disinfectant (betadine) (25–27) but, as far as we know, there is no report in the literature concerning its uses in organic synthesis. We prepared this reagent according to the literature and studied its reactions with both epoxides and thiiranes. The results obtained from the reaction of epoxides and thiiranes with I_2/PVP are shown in Tables 1, 2, and 4 (entries 5 and 9). Although the reactions with I_2/PVP are somewhat slower than those with iodine, the regio-, chemo-, and stereoselectivities are still very high and the same products were obtained in high yields with the advantage of overcoming the problem of handling of the reagent.











The mechanism of these reactions is not clear, but due to the formation of disulfides from the noncatalytic reaction of thiiranes in the presence of both iodine and I_2/PVP, the occurrence of a one-electron transfer reaction between I_2 and

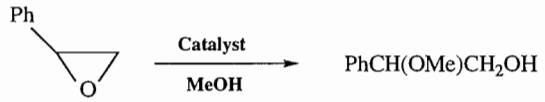
[c]Reaction was performed in the presence of I_2/PVP.



thiiranes with the formation of a radical cation (**I**) is the most probable. Attack of a molecule of alcohol on the radical cation **I** followed by dimerization of the radical obtained (**II**) could be responsible for the formation of disulfides in these reactions. To show the possibility of formation of radical in the reaction, ring opening of styrene sulfide in alcohols was studied in the presence of excess acrylamide. A great decrease in the reaction rate was observed with the formation of some polyacrylamide. Under similar conditions but in the absence of thiirane, no polymerization was observed. The formation of radical cation **I** followed by the generation of radical **II** has also been suggested in the reaction of thiiranes with other one-electron transfer agents such as Ce(IV)-based oxidants and DDQ (24).

I **II**

The possibility of the formation of an alkoxy thiol from thiiranes followed by oxidation–dimerization to the corresponding disulfide is ruled out, since neither I_2 nor I_2/PVP oxidize cyclohexyl, *meta*-thiocresol, or benzyl thiol to their corresponding disulfides under the conditions used for ring opening of thiiranes. In addition, the UV spectrum of I_2 in methanol does not show any change after 24 h. This shows that no oxidation reaction occurs between I_2 and methanol with subsequent formation of proton (13*e*). Therefore, the possibility of an acid catalysis reaction similar to that reported for Ce(IV) is also ruled out (13*e*).

Scheme 3.

The stereospecificity of the ring-opening reaction of optically active styrene oxide was studied with both iodine and different amounts of I_2/polyvinylpyrrolidone, Scheme 3. The results are shown in Table 5.

The highest optical purity was obtained by using 0.1 molar equivalent of I_2/PVP at 0°C. The optical rotation of the product was determined and compared with that reported in the literature (28). When using iodine for alcoholysis of optically

[b]Yield of isolated product.
[c]Values not corrected for the optical purity of the starting material and determined according to the literature (28).

active styrene oxide at both 0°C and 25°C (Table 5), the optical purity of the product obtained was not high. These results could show the more S_N1 character of the reactions under these conditions. The low optical purity of the product in these cases could not be due to the racemization of the product after its formation, since the optical rotation of the pure product is not lowered in methanol and in the presence of I_2.

In conclusion, I_2 and I_2/PVP can be regarded as neutral catalysts or reagents for efficient ring opening of epoxides and thiiranes, respectively. Due to this neutrality, they may find application for ring opening of those epoxides and thiiranes which contain acid-sensitive functional groups. The results obtained in the competitive ring-opening reaction of certain classes of epoxides with iodine show the mildness of the catalyst. In comparison with I_2, the reactions of I_2/PVP with optically active styrene oxide are more enantioselective. I_2 supported on PVP is also very stable, nonvolatile, and its toxicity is greatly reduced. Availability, ease of procedure, high regio-, chemo-, and stereoselectivties, mild reaction conditions, and high yields of products indicate a new synthetic application for iodine in organic synthesis. In addition, the formation of disulfides from thiiranes demonstrates an interesting possible application for iodine and iodine/PVP as one-electron transfer reagents.

Experimental

Products were characterized by comparison of their physical data, IR, NMR, and mass spectra with those reported in the literature (11–24). All yields refer to isolated products. IR spectra were recorded on a Perkin Elmer IR-157 G and a Perkin Elmer 781 spectrometer. NMR spectra were recorded on a Hitachi R-2413 60 MHz or a Bruker DPX 250 MHz spectrometer. Mass spectra were recorded on a Shimadzu GCMS-QP 1000 EX. Determination of the purity of the substrate and reaction monitoring were accomplished by TLC on silica gel polygram SILG/UV 254 plates or by GLC on a Shimadzu GC-14A instrument.

Procedure for preparation of polyvinylpyrrolidone-supported iodine (I_2/PVP)

Polyvinylpyrrolidone "Fluka, 81420 Mr 40000" (5 g) was added to a solution of iodine (10 g) in diethyl ether (300 mL). The resulting suspension was stirred for 24 h at room temperature. The mixture was filtered and the resulting solid was washed several times with ether to remove the excess of iodine. The brown solid was dried in vacuum. The capacity of the reagent was found, by titration with $Na_2S_2O_3$ solution, to be 1.88 mmol iodine per gram of polymer.

General procedure for the reaction of epoxides with alcohols in the presence of iodine and iodine/PVP

Iodine (1–16 mmol) was added to a solution of epoxide (10 mmol) in the appropriate alcohol (60 mL). The reaction mixture was stirred for the specified time and at the appropriate temperature according to Table 1. The progress of the reaction was monitored by GLC. The solvent was evaporated, ether (50 mL) was added, and the mixture was washed with 10% aqueous solution of $Na_2S_2O_3$ until disappearance of the iodine colour was observed. The aqueous layer was separated and washed with ether (3 × 10 mL) The combined organic solution was dried. Evaporation of the organic solution followed by vacuum distillation or column chromatography on a short column of silica gel afforded the pure product in 60–98% yield.

General procedure for the reaction of epoxides in aqueous acetonitrile with iodine and iodine/PVP

To a solution of epoxide (10 mmol) in an equal mixture of acetonitrile–water (60 mL) was added I_2 or I_2/PVP (2–15 mmol). The reaction mixture was stirred for the specified time at room temperature according to Table 2. The progress of the reaction was monitored by TLC using CCl_4–CH_3OH (10/1) as eluent. Acetonitrile was removed and the aqueous mixture was washed with a 10% aqueous solution of $Na_2S_2O_3$ until disappearance of the iodine colour was observed. The mixture was saturated with sodium chloride and extracted with ether (3 × 40 mL, or by continuous extraction). The combined organic solution was dried and evaporated. Vacuum distillation or column chromatography of the product on a short column of silica gel afforded the pure product in 70–94% yield.

General procedure for the reaction of thiiranes with alcohols and water in the presence of iodine

Iodine (3 mmol) was added to a solution of thiirane (3 mmol) in the appropriate alcohol (30 mL) or in aqueous acetonitrile

(1:1). The reaction mixture was stirred for the required time and at the appropriate temperature according to Table 4. The progress of the reaction was monitored by GLC. The solvent was evaporated, ether (50 mL) was added, and the mixture was washed with 10% aqueous solution of $Na_2S_2O_3$. The aqueous layer was separated and washed with ether (3×20 mL) The combined organic solution was dried. Evaporation of the organic solution followed by vacuum distillation or column chromatography on a short column of silica gel afforded the pure product in 66–90% yield.

Acknowledgments

We would like to acknowledge the support of this work by Shiraz University Research Council. Helpful discussions with Professor H. Firouzabadi and the assistance of Mr. N. Maleki for running the NMR spectra and Dr. A.A. Jarahpoor for running the mass spectra are also greatly appreciated.
