coupling of solvent-derived benzyl radicals. It is not clear whether this product indicates a biradical mechanism or a minor side reaction unrelated to the formation of **27**.

Experimental

General methods

NMR spectra were obtained with a Bruker AM-500, AC-300, or AC-200 spectrometer. Chemical shifts for ^{1}H NMR spectra are referenced to TMS (δ = 0), C_6H_6 (δ = 7.15) , or $CHCl_3$ (δ = 7.24), while ^{13}C NMR spectra are referenced to the chloroform-*d* triplet (δ = 77.0) or the benzene-d_6 triplet (δ = 128.0). Mass spectra were obtained with a ZAB-E double-focusing mass spectrometer or a Hewlett Packard MSD GC–MS. FTIR spectra were obtained with a Bio-Rad, FTS-40 instrument. Benzene, toluene, and THF were distilled from sodium benzophenone ketyl and dichloromethane was distilled from calcium hydride. Chromatography solvents (EtOAc, hexanes) were distilled before use. Unless otherwise indicated, all reactions were carried out under an atmosphere of nitrogen.

Preparation of *ortho*-hydroxy phenyl acetylene (8)

A suspension of 2,3-benzofuran (5.89 g, 49.9 mmol) and finely cut sodium (3.30 g, 143.5 mmol) in pyridine (50 g) was refluxed under a blanket of nitrogen for 4 h. After cooling to room temperature, pyridine (20 mL) and water (30 mL) were slowly added to the "tar-like" mixture. The excess 2,3-benzofuran was extracted with ether (30 mL) from the aqueous pyridine solution, which was then acidified to pH = 2 with dilute HCl. The free phenol was then extracted (3 × 20 mL) with ether and the combined organic extracts were washed once with dilute HCl (20 mL) and once with water (20 mL). Upon drying the organic layer with Na_2SO_4 and concentrating in vacuo, the title compound (3.54 g, 30.0 mmol) of high purity was obtained in 61% yield. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.43 (s, 1H, C≡CH), 4.75 (br, OH), 6.90 (m, 1H, $^3J_{5,4}$ = 7.4 Hz, $^3J_{5,6}$ = 7.7 Hz, $^4J_{5,3}$ = 1.2 Hz, H-5), 6.93 (dd, 1H, $^3J_{4,3}$ = 8.3 Hz, $^4J_{3,5}$ = 1.2 Hz, H-3), 7.25 (m, 1H, $^3J_{4,3}$ = 8.3 Hz, $^3J_{5,4}$ = 7.4 Hz, $^4J_{4,6}$ = 1.7 Hz, H-4), 7.37 (dd, 1H, $^3J_{6,5}$ = 7.7 Hz, $^4J_{4,6}$ = 1.7 Hz, H-6); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 78.4 (C≡*C*H), 84.0 (*C*≡CH), 108.3 (C-1), 114.8 (C-4), 120.2 (C-3), 130.8 (C-5), 132.2 (C-6), 157.4 (C-2); MS (GC–MS, EI) *m/z* (rel. intensity): 118 ($M^{+\bullet}$, 80), 90 (90), 89 (100), 75 (2), 74 (4).

Preparation of 2-(2-ethynylphenoxy)-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (18)

A solution of 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (70% pure) (7) (1.60 g, 5.96 mmol of oxadiazoline), *o*-hydroxy phenyl acetylene (0.70 g, 5.93 mmol), and *p*-toluene sulfonic acid (0.10 g) in CH_2Cl_2 (50 mL) was refluxed for 48 h before dilute KOH (5%, 10 mL) was added. The mixture was stirred for 1 h followed by extraction (3 × 20 mL) with CH_2Cl_2. After drying the combined organic extracts with Na_2SO_4 and concentrating in vacuo, **18** was obtained as a yellow oil upon chromatography (Chromatotron, 4 mm plate, 10% EtOAc – hexanes) in 37% yield. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.29 (s, 3H, CH_3), 1.54 (s, 3H, CH_3), 3.22 (s, 1H,

C≡CH), 3.64 (s, 3H, OCH_3), 7.01–7.47 (m, 5H, Ar); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 23.4 (CH_3) , 24.1 (CH_3), 52.6 (CH_3O), 79.5 (C≡*C*H), 81.5 (*C*≡CH), 116.0 (aryl), 120.8 (C-5), 121.2 (aryl), 124.1 (aryl), 129.6 (aryl), 133.7 (aryl), 136.7 (C-2), 153.0 (aryl); MS (GC–MS, EI) *m/z* (rel. intensity): 218 ($M^+ - N_2$, 1), 215 ($M^+ - CH_3O$, 1), 203 (4), 160 ($M^+ - C_3H_6O - N_2$, 15), MS (CI, NH_3) *m/z*: 264 $(M + NH_4)^+$, 247 $(M + H)^+$.

Thermolysis of 18 in the presence of *tert*-butyl alcohol

A solution of 2-(2-ethynylphenoxy)-2-methoxy-2,2-dimethyl-Δ^3-1,3,4-oxadiazoline (0.235 g, 0.957 mmol) and *tert*-butyl alcohol (0.26 g, 3.5 mmol) in dry toluene (100 mL) was refluxed for 24 h. Analysis of the crude thermolysis mixture (0.1985 g) by ^1H NMR spectroscopy indicated that it consisted mainly of 3-(*tert*-butoxymethyl)-2-methoxy-2,3-benzofuran (**22**). This compound is sensitive to moisture, and attempts to isolate a pure sample failed. The spectral data below are those of the crude thermolysis product that was primarily **22** (>80% by ^1H NMR). ^1H NMR (300 MHz, $CDCl_3$) δ: 1.31 (s, 9H, Me_3), 4.04 (s, 3H, MeO), 4.43 (s, 2H, CH_2O), 7.09 (m, $^3J_{6,7}$ = 7.5 Hz, $^3J_{7,8}$ = 7.4 Hz, $^4J_{5,7}$ = 1.6 Hz, 1H, H-7), 7.16 (m, $^3J_{5,6}$ = 7.5 Hz, $^3J_{6,7}$ = 7.5, $^4J_{6,8}$ = 1.4 Hz, 1H, H-6), 7.25 (dd, $^3J_{7,8}$ = 7.4 Hz, $^4J_{6,8}$ = 1.8 Hz, 1H, H-8), 7.25 (dd, $^3J_{5,6}$ = 7.5 Hz, $^4J_{5,7}$ = 1.6 Hz, 1H, H-5); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 27.6 (Me_3), 53.2 (OMe), 58.6 (OCH_2), 73.1 (*C*Me_3), 82.5 (C-3), 91.2 (C-2), 110.0 (C-8), 118.7 (C-6), 121.8 (C-4), 122.9 (C-5), 129.9 (C-7), 159.1 (C-9).

Methyl 2-(2-hydroxyphenyl)propenoate (21)

To the crude thermolysis product (0.058 g) consisting of mainly **22** was added *para*-toluene sulfonic acid (0.010 g) in water (0.10 mL). The solution was stirred for 1.5 h at room temperature before it was extracted with CH_2Cl_2 (3 × 5 mL). The combined extracts were then dried over Na_2SO_4 and concentrated in vacuo. Chromatography (1 mm plate, 10% EtOAc – hexanes) yielded **21** (0.0152 g) in 40% yield. ^1H NMR analysis of the crude hydrolysis mixture revealed that **24** was also formed. The ratio **21**:**24** was estimated to be approximately 5:1 by ^1H NMR spectroscopy. ^1H NMR of **21** (200 MHz, $CDCl_3$) δ: 3.85 (s, 3H, OMe), 5.89 (d, 1H, ^2J = 1.3, H-3), 6.42 (d, 1H, ^2J = 1.3, H-3), 6.89 (m, 1H, $^3J_{5',6'}$ = 7.9 Hz, $^3J_{4',5'}$ = 7.3 Hz, $^4J_{3',5'}$ = 1.2 Hz, H-5′), 6.92 (dd, 1H, $^3J_{3',4'}$ = 7.1 Hz, $^4J_{3',5'}$ = 1.2 Hz, H-3′), 7.12 (dd, 1H, $^3J_{5',6'}$ = 7.9 Hz, $^4J_{4',6'}$ = 1.8 Hz, H-6′), 7.25 (m, 1H, $^3J_{4',5'}$ = 7.3 Hz, $^3J_{3',4'}$ = 7.1 Hz, $^4J_{4',6'}$ = 1.8 Hz, H-4′), 7.50 (s, br, 1H, OH); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 53.0 (MeO), 117.8 (C-3), 120.7 (C-2), 124.7 (C-1′), 130.3, 130.4, 130.7 (C-6′, C-5, C-4′), 139.4 (C-3′), 153.6 (C-2′), 169.7 (C=O).

Thermolysis of 18 in the presence of benzylidenemalononitrile

From a solution of 2-(2-ethynylphenoxy)-2-methoxy-2,2-dimethyl-Δ^3-1,3,4-oxadiazoline (**18**) (36 mg, 0.15 mmol) and benzylidinemalononitrile (25 mg, 0.16 mmol) in 150 mL of dry toluene, 20 mL of solvent was distilled off at atmospheric pressure to remove adventitious water by azeotropic distillation. Following heating at reflux for 20 h and concentration in vacuo, the crude thermolysis product that remained was purified by chromatography (Chromatotron, 1 mm plate, 5–15% EtOAc – hexanes) to give **28** in 67% yield. Slow crystallization at room temperature from hexanes – ethyl acetate gave fine crystals, mp 141–142°C . ^1H NMR (200 MHz, $CDCl_3$) δ: 3.42 (d, ^3J = 8.7 Hz, 1H, allylic CH), 3.89 (d, ^3J = 8.7 Hz, 1H, benzylic CH), 4.14 (s, 3H, MeO), 7.16–7.91 (m, 9H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 14.4 (*C*$(CN)_2$), 29.8 (allylic C), 38.7 (benzylic C), 58.4 (OCH_3), 83.2 (C-3), 110.7 (C-8), 112.5 (CN), 113.6 (CN), 117.3 (C-6), 122.6 (C-5), 123.8 (C-7), 128.4 (C-4), 129.1, 129.4, 130.6, 134.5 (4 Ar), 147.9 (C-2), 159.9 (C-9); MS (EI), *m/z* (rel. intensity): 314 ($M^{+\cdot}$, 13), 237 ($M^{+\cdot} - Ph$, 5), 154 (100), 127 (50), 103 (55), 91 (80); MS (HR) *m/z*, calcd. for $C_{20}H_{14}O_2N_2$ ($M^{+\cdot}$): 314.1055; found: 314.1057.

Preparation of 2-[2-(methylpropiolato)]-phenoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (29)

A stirred solution of 2-(2-ethynylphenoxy)-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline **18** (500 mg, 2.0 mmol) in dry THF (30 mL) was cooled at −78°C for 1 h under nitrogen. A solution of *n*-butyllithium (2.4 M) in hexanes (0.85 mL, 2.0 mmol) was then added dropwise. This solution was stirred at −78°C for 1 h before addition of methylchloroformate (0.5 mL, 6 mmol). The reaction mixture was allowed to reach room temperature slowly overnight with the cooling bath left in place. Water (15 mL) was then added cautiously and the THF was removed in vacuo by rotary evaporation. The aqueous residue was extracted with CH_2Cl_2 (3 × 20 mL), and the combined extracts were dried over anhydrous Na_2SO_4 before they were concentrated in vacuo. Chromatography (Chromatotron, 4 mm plate, 10–15% EtOAc – hexanes) gave **29** as an oil in 40% yield. FTIR (NaCl, neat) cm^{-1}: 2991, 2954, 2916 (C-H), 2227 (C≡C), 1714 (C=O); ^1H NMR (200 MHz, $CDCl_3$) δ: 1.28 (s, 3H, Me), 1.54 (s, 3H, Me), 3.66 (s, 3H, OMe), 3.80 (s, 3H, OMe), 7.06–7.54 (m, 4H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 23.3 (Me), 24.1 (Me), 52.7 (2 × MeO), 82.6 (alkyne), 84.1 (alkyne), 113.8 (C-5), 121.1, 121.6, 124.4, 131.6, 134.4 (5 Ar), 136.6 (C-2), 153.9 (Ar), 154.3 (C=O); MS (EI) *m/z* (rel. intensity): 273 ($M^{+\cdot}$ − MeO, 6), 235 (5), 217 (18), 203 (20), 185 (20), 173 (30), 159 (18), 145 (16), 129 ($M^{+\cdot} - C_{10}H_7O_2$, 100), MS (CI, NH_3) *m/z*: 322 $(M + NH_4)^{+\cdot}$.

Thermolysis of 2-[2-(methylpropiolato)]-phenoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (29) in the presence of benzylidenemalononitrile

At atmospheric pressure, 20 mL of toluene was distilled from a solution of 2-[2-(methylpropiolato)]-phenoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (154 mg, 0.63 mmol) and benzylidinemalononitrile (100 mg, 0.65 mmol) in 150 mL of dry toluene. The solution was refluxed for 20 h and concentrated in vacuo to afford a crude thermolysis product that was purified by chromatography (Chromatotron, 1 mm plate, 5–15% EtOAc – hexanes) to give a single major product (**30**, 99.7 mg, 0.41 mmol, 37%) as a solid, mp 188–190°C. This product was recrystallized from hexanes–EtOAc. Slow crystallization at room temperature gave crystals suitable for X-ray diffraction (10). ^1H NMR (200 MHz, $CDCl_3$) δ: 3.60 (s, 3H, MeO), 3.89 (s, 1H, benzylic CH), 4.20 (s, 3H, MeO), 7.16–7.50 (m, 9H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 18.5 (*C*$(CN)_2$), 40.0 (allylic C), 42.5 (benzylic C), 58.4 (OMe), 58.4 (OMe), 85.2 (C-3), 110.9 (C-8), 111.1 (CN), 113.5 (CN), 117.4 (C-6), 122.8 (C-5), 124.1 (C-7), 127.8 (C-4), 128.6, 129.1, 129.3 (3 Ar), 147.9 (C-2), 160.7 (C-9), 164.8 (C=O).

Vinylcyclopropane rearrangement of 30

A solution of vinylcyclopropane **30** (18.7 mg, 0.049 mmol) in toluene (20 mL) was prepared. At atmospheric pressure, 10 mL of the toluene was then distilled from the solution to remove adventitious water by azeotropic distillation. The remaining solution was transferred to a 50 mL glass tube and degassed by three freeze–pump–thaw cycles, before the tube was sealed and heated for 4 days in an oil bath at 150 ± 0.1°C. The sample was cooled and concentrated in vacuo to afford a crude product that consisted of **30** and **32** in ca 1:1 ratio by ^{1}H NMR spectroscopy. Chromatography (Chromatotron, 4 mm plate, 10–15% EtOAc – hexanes) gave **32** as a white powder in approximately 40% yield and the unreacted **30** was recovered. Very slow crystallization of **32** from EtOAc–hexanes at room temperature yielded crystals suitable for X-ray diffraction (10); white solid, *trans* configuration, mp 217–218°C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.31 (s, 3H, MeO), 3.68 (s, 3H, MeO), 5.30 (s, 1H, benzylic CH), 7.11–7.55 (m, 8H), 8.07 (m, 1H); ^{13}C NMR (125 MHz, $CDCl_3$) δ: 51.9 (OMe), 53.4 (OMe), 62.9 (benzylic C), 110.4, 110.8, 111.5, 112.2, 114.8, 118.9, 122.5, 127.2, 128.6, 128.8, 128.9, 129.2, 129.4, 133.8, 135.1, 163.2, 165.5 (C=O); MS (EI), *m/z* (rel. intensity): 372 ($M^{+\cdot}$, 8), 313 ($M^{+\cdot} - CO_2Me$, 28), 141 (29) , 84 (30); MS (HR) *m/z*, calcd. for $C_{22}H_{16}N_2O_4$ ($M^{+\cdot}$): 372.1110; found: 372.1112.

Vinylcyclopropane rearrangement of 28

Toluene (10 mL) was distilled at atmospheric pressure from a solution of vinylcyclopropane **28** (15.0 mg, 0.048 mmol) in toluene (30 mL). The remaining solution was transferred to a 50 mL glass tube, degassed by three freeze–pump–thaw cycles, and then sealed before it was heated for 4 days in an oil bath operating at 150 ± 0.1°C. Following thermolysis, the sample was cooled and then concentrated in vacuo. Compound **27** was isolated by chromatrography (Chromatotron, 1 mm plate, 10–15% EtOAc – hexanes) as a yellow oil in 33% yield and unreacted **28** (8 mg, 0.025 mmol) was recovered. Attempted crystallization of the yellow oil was not successful. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.33 (s, 3H, MeO), 5.21 (d, ^3J = 1.9 Hz, 1H, alkene CH), 6.35 (d, ^3J = 1.9 Hz, 1H, benzylic CH), 7.06–7.51 (m, 9H); ^{13}C NMR (125 MHz, $CDCl_3$) δ: 53.3 (OMe), 62.4 (benzylic), 97.0, 110.9, 111.5 (C_6H_4), 119.7 (C_6H_4), 122.6 (C_6H_4), 123.1 (=CH), 125.4 (C_6H_4), 128.6 (C_6H_5), 128.8, 129.2 (C_6H_5), 129.6 (C_6H_5), 130.9, 132.4 (C_6H_4), 134.2, 143.2 (C_6H_5), 167.7 (C_6H_4); MS (EI), *m/z*: (rel. intensity): 314 ($M^{+\cdot}$, 45), 299 ($M^{+\cdot} - CH_3$, 36), 207 (30), 149 (20), 85 (24), 71 (47), 57 (100), 43 (69); MS (HR) *m/z*, calcd. for $C_{20}H_{14}N_2O_2$ ($M^{+\cdot}$): 314.1055; found: 314.1051. The *trans* structure was assigned, there being no reasonable basis to assume that the *trans* precursor could afford the *cis* product cleanly when the analogous rearrangement of **30** to **32** went with retention.

Acknowledgements

The authors gratefully acknowledge financial support from the Natural Sciences and Engineering Research Council of Canada (NSERC) and the assistance of Drs. Richard Smith and Don Hughes with mass spectrometry and NMR spectroscopy, respectively. For the molecular and crystal structures of **30** and **32**, we thank Dr. Jim Britten.

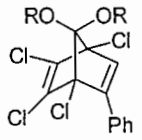
Spiro-fused 2-alkoxy-2-amino-Δ^3-1,3,4-oxadiazolines. Synthesis and thermolysis to corresponding aminooxycarbenes

Philippe Couture and John Warkentin

Abstract: Δ^3-1,3,4-Oxadiazolines spiro-fused at C2 to C2 to oxazolidines (**12**) or to C2 of tetrahydro-1,3-oxazines (**13**) were synthesized. The oxadiazolines undergo thermolysis in benzene at 90°C with first-order rate constants of $(1.6–50) \times 10^{-5}$ s^{-1}. The dependence of these rate constants on the nature of the substituents present on the oxadiazoline ring is consistent with a mechanism involving a carbonyl ylide intermediate. Substituents on N of the oxazolidine or tetrahydro-1,3-oxazine moieties play a major role in determining the fragmentation pathways. Oxadiazolines with N-carbonyl groups (**12***c–j*, **13***d,e*) afford essentially quantitative yields of the corresponding aminooxycarbenes, while other fragmentation reactions compete with carbene generation in the case of oxadiazolines with N-methyl (**12***b*, **13***c*) or N-sulfonyl (**12***k*) groups.

Key words: nucleophilic carbene, aminooxycarbene, oxadiazoline, oxazolidin-2-ylidene, carbonyl ylide.



Résumé : On a synthétisé des Δ^3-1,3,4-oxadiazolines spirocondensées en C2 à la position C2 d'oxazolidines (**12**) ou en C2 de tétrahydro-1,3-oxazines (**13**). Les oxadiazolines subissent une thermolyse dans le benzène à 90°C; les constantes de vitesse du premier ordre de la réaction varient de 1,6 à 50×10^{-5} s^{-1}. La relation entre ces constantes de vitesse et la nature des substituants présents sur le noyau oxadiazoline est en accord avec un mécanisme impliquant un ylure de carbonyle comme intermédiaire. Les substituants présents sur l'azote des portions oxazolidine ou tétrahydro-1,3-oxazine jouent un rôle important dans la détermination des voies de fractionnement. Les oxadiazolines portants de groupes N-carbonyles (**12***c–j*, **13***d,e*) fournissent des rendements pratiquement quantitatifs des aminooxycarbènes correspondants alors que, dans les cas des oxadiazolines portant des groupes N-méthyles (**12***b*, **13***c*) ou N-sulfonyles (**12***k*), d'autres réactions de fragmentation sont en compétition avec la génération de carbène.

Mots clés : carbène nucléophile, aminooxycarbène, oxadiazoline, oxazolidin-2-ylidène, ylure de carbonyle.

[Traduit par la rédaction]

Introduction

In recent years, there has been a renewed interest in the chemistry of nucleophilic carbenes, from both mechanistic (1) and synthetic (2) points of view. Classically, the most useful methods of generation of nucleophilic carbenes are based on the formal extrusion of the carbene by cycloreversion from rings made up of an odd number of atoms. These processes are generally driven by the formation of thermodynamically stable products such as N_2 or aromatic compounds. Thermolysis of 7,7-dialkoxynorbornadienone ketals (**1**) at temperatures of 85–200°C, for instance, afforded the first dioxycarbenes (3). Diazirines (**2**) are now well-established alternative thermal and photochemical sources of carbenes that have been used for the generation of some dioxycarbenes (1*d,f,l,o*).

1

2

The thermolysis of Δ-1,3,4-oxadiazolines constitutes a relatively new method for the generation of nucleophilic carbenes (eq. [1]) (1*j,k,q–t*, 2*f–l*, 4). 2,2-Dioxy-Δ^3-1,3,4-oxadiazolines (**3**) are conveniently prepared in a two-step process involving the oxidative cyclization of an (oxycarbonyl)hydrazone of acetone (**4**) with $Pb(OAc)_4$, followed by exchange of the acetoxy substituent in **5** with alcohols or phenols (eq. [2]) (4). Variations of this method have also provided access to oxythio- (1*s*) and dithiocarbenes.[2]

In this report, we describe the synthesis of Δ^3-1,3,4-oxadiazolines, substituted at C2 with one O and one N, as precursors of aminooxycarbenes. The mechanisms involved in their thermolysis are also examined. A preliminary account of some of this work has been published (5).

Methods, results, and discussion

Syntheses of 12 and 13

Investigations on the application of the "acetoxy exchange" method described above to the synthesis of 2-alkoxy-2-amino-Δ^3-1,3,4-oxadiazolines were disappointing, affording little or none of the desired products in complex mixtures. An alternative approach involving the addition of an alcohol to a 2-imino oxadiazoline was considered. The oxidation of semicarbazone **6** with $Pb(OAc)_4$ in methanol was previously found to produce a mixture of **7** and **8**, but the instability of the latter did not allow its separation from **7** (eq. [3]) (6). The intramolecular analogue of this reaction, however, involving quaternization of C2 of the oxadiazoline by the addition of a tethered hydroxyl group, was successful.

A series of substituted semicarbazones **9** was prepared, in 59–81% yields, by refluxing the semicarbazone of acetone (**10**, R^1 = Me) or of cyclohexanone (**10**, $R^1R^1 = (CH_2)_5$) with an appropriate amino alcohol **11** in toluene (7) for 7–15 h (Scheme 1). Although $Pb(OAc)_4$ oxidation of **9** (n = 2, R^1 = Me, R^2 = H) produced **12***a* in reasonable yield, it repeatedly failed in the case of the oxidation of **9** (n = 2, $R^1 = R^2$ = Me) to **12***b*. Instead, $PhI(OAc)_2$, which has been utilized in the synthesis of 2-alkoxy-Δ^3-1,3,4-oxadiazolines (8), was found to be the reagent of choice. Thus, semicarbazones **9** were oxidized with $PhI(OAc)_2$ in dichloromethane or, in one case, in methanol, to afford oxadiazolines **12***a,b* and **13***a–c* in 35–66% yields.[3]

N-Carbonyl oxadiazolines **12***d–i* and **13***d,e* were prepared by acylation of **12***a* and **13***a,b*, respectively, using standard methods, in yields ranging from ca. 10% to 33% (from **9**). The reaction between **12***a* and 4-nitrophenyl formate (9) gave oxadiazoline **12***c*. The preparation of carbamate derivative **12***j* was most conveniently carried out by stirring **12***a* with 4 equivalents of methyl chloroformate and 6 equivalents of K_2CO_3 in acetone at room temperature for 2 days (10). Sulfonamide derivative **12***k* was prepared by treating **12***a* with benzenesulfonyl chloride in the presence of pyridine.

^{13}C NMR spectroscopy was the most useful tool in the identification of these spiro oxadiazolines, with two characteristic signals generally found at 116–123 ppm (C2) and 128–139 ppm (C5). The ^1H NMR spectra of **12***a–k*, in which the oxadiazoline ring is fused to an oxazolidine, exhibit complex splitting of the four methylene protons; the coupling constants for the ABMX spin system of **12***b*, determined by spectral simulation, are listed in the experimental section. In addition, the ^1H spectra of N-carbonyl derivatives **12***c–j* are complicated by slow *cis–trans* isomerism, on the NMR time scale, of the amide bond. This generally results in broad signals for spectra recorded at room temperature.[4] The fragility of these oxadiazolines dictated the application of special techniques for the acquisition of mass spectra, as described in the experimental section.[5]

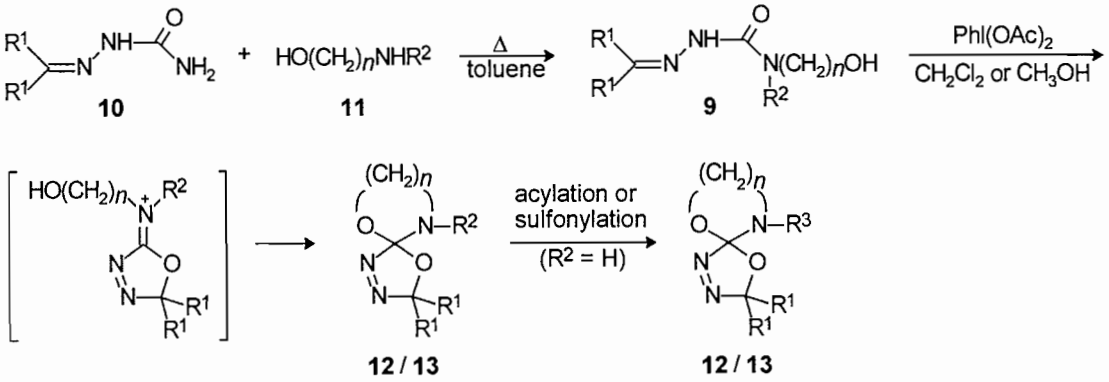
Thermolysis rate constants

Oxadiazolines **12***a–k* and **13***c–e* were thermolysed in benzene-d_6, at 90°C, in sealed NMR tubes. Disappearance of starting material was monitored by means of integration of appropriate signals in the 300 MHz ^1H NMR spectra. The choice of the ^1H signal(s) for integration was sometimes limited by the complexity of the spectrum and, in several cases, resonances were broad due to restricted rotation about the amide bond, as mentioned above. Nevertheless, good fits to the first-order rate equation were obtained for five to ten experimental points generally covering the range 0–60% (or more) of completion.

The rate data, collected in Table 1, show a relatively low sensitivity to structure. There is some risk of overinterpretation of the data because the observed values span only a 30-fold rate change. Moreover, there is not a unique decomposition pathway for all oxadiazolines and, in some cases, at least two competing initial steps may be involved in a thermolysis. Nonetheless, some trends in the rate constants are evident and understandable.

Both steric and electronic factors are expected to influence the rate of decomposition of oxadiazolines **12** and **13**. The initial thermolysis step is generally a cycloreversion affording molecular nitrogen and a carbonyl ylide (vide infra). At the

[3] It is noteworthy that oxidation of **9** (n = 2, R^1 = Me, R^2 = Ph) with either $Pb(OAc)_4$ or $PhI(OAc)_2$ failed to produce the corresponding **12** in useful quantity (R^1 = Me, R^2 = Ph).



[4] A study aimed at determining the relationship between structure and the activation parameters for rotation is currently in progress, in collaboration with Professor A.D. Bain and Mr. P. Hazendonk.

[5] A detailed mass spectral study involving **12***b*, in collaboration with Professor J.K. Terlouw and Mr. D. Lavorato, is in progress.

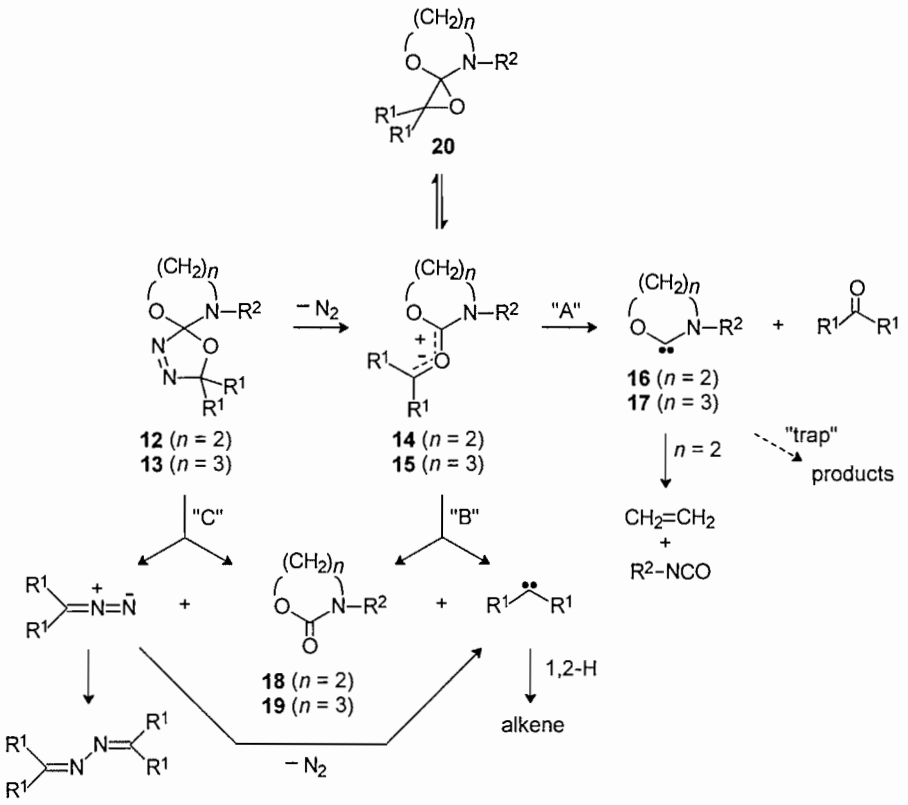
transition state, the 1,3-interactions between groups R^1 at C2 and the substituents at C5 will be relieved because of bond rotations, as shown in Scheme 2, which depicts oxygen and R^1 as moving into *endo* positions of the ylide. Thus, relief of strain from nonbonded interactions (two in the oxadiazoline; one in the ylide) should be a factor. In addition, as ylide character develops, negative charge accumulates at C2 and C5 of the oxadiazoline, and electron-withdrawing groups in proximity to the sites of charge development should cause some rate

Scheme 2.

enhancement from inductive effects. Such thermolysis rate enhancements caused by inductive effects of electron-withdrawing groups were previously observed in spiro-fused β-lactam oxadiazolines (11).



Experimentally, it was found that compounds in which the oxadiazoline moiety is fused to a six-membered ring have larger thermolysis rate constants than analogous compounds in which the oxadiazoline ring is fused to a five-membered ring: k_{13d}, $k_{13e} > k_{12f}$, and $k_{13c} > k_{12b}$. This effect may be due in part to a small increase in 1,3-interactions in going from a five-membered to a six-membered ring fused at C5, and to easier increase, in the larger ring system, of the OCN bond angle as the relevant carbons rehybridize from sp^3 in the oxadiazoline to roughly sp^2 in the ylide. The origin of the 3-fold increase in rate constant from **13***e* to **13***d* could be ascribed to the same feature, **13***e* having a bond angle constraint at both C2 and C5.

The nature of the substituent (R^2) at N also affects the rate of thermolysis. For instance, in the series **12***a*, **12***b*, **12***f*, and **12***k*, there is an observable effect on the rate constant in changing R^2 from hydrogen (k_{rel} = 1.00) to methyl (2.97), benzoyl (4.43), or phenylsulfonyl (2.04), more or less consistent with the expected destabilization of the ground state by steric factors and stabilization of the transition state by electron-withdrawing groups. Within the N-carbonyl series, the following trend in relative rate constants was found (k_{rel}): k_{12j} (OCH_3, <1) < k_{12c} (H, 2.89) < k_{12e} (vinyl, 3.49) < k_{12f} (Ph, 4.43) < k_{12d} (CH_3, 8.70). Thus, substituents that reduce the electron-withdrawing effect of the N-carbonyl group (e.g., methoxy in **12***j*) tend to decrease the rate of decomposition of the oxadiazoline,

Scheme 3.

but the reason for the relatively large rate constant of **12***d* is not understood. Comparison of the analogous N-benzoyl derivatives also shows a slight rise in the rate constants[6] caused by increasingly electron-withdrawing substituents, although the spread of k values is small: k_{12g} (2-OMe, 3.58) ≈ k_{12h} (4-OMe, 3.48) < k_{12f} (unsubstituted, 4.43) < k_{12i} (4-NO_2, 5.43).

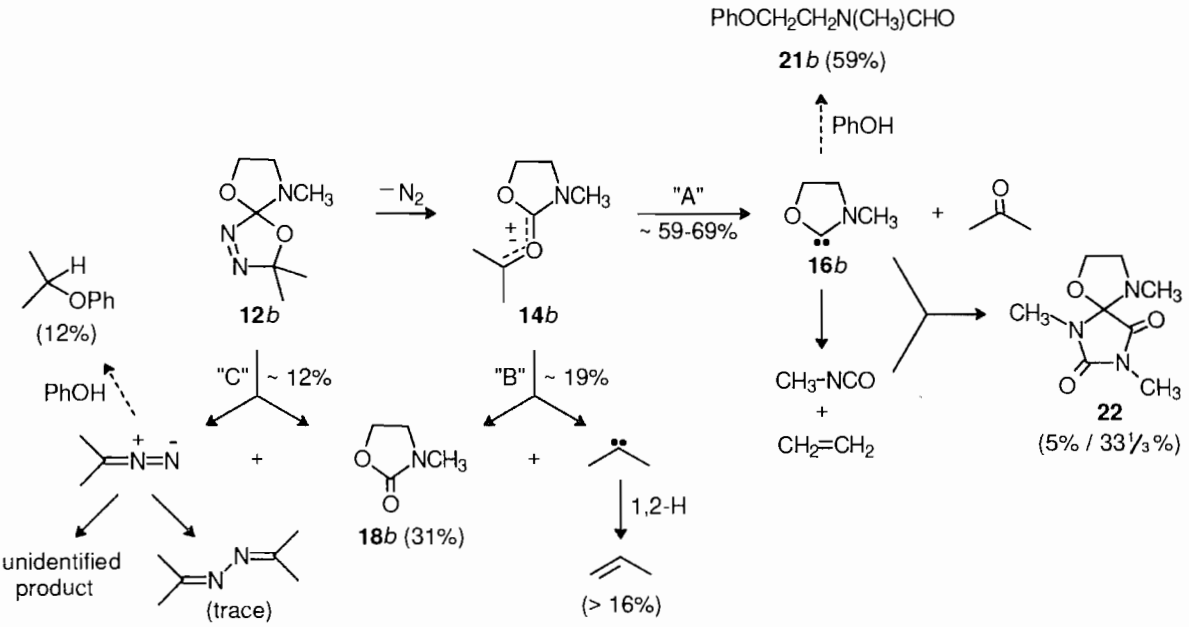
The observed trends in thermolysis rate constants support the intermediacy of carbonyl ylides in the thermolysis of these spiro-fused oxadiazolines rather than the fully concerted mechanism proposed recently by Smith (12). If carbenes were the initial species formed, then electron-donating groups, which stabilize the carbenes, would be expected to stabilize the corresponding transition states also, and therefore to increase the rate of thermolysis. Clearly, the opposite effect is observed.

General thermolytic scheme

Thermolysis experiments for product studies on **12** and **13** were carried out in sealed NMR tubes, as described above, with initial oxadiazoline concentrations of ca. 0.25 M. Larger scale thermolyses were also conducted with each substrate, at ca. 0.05 M oxadiazoline in benzene in resealable tubes.

The mechanism of thermolysis of oxadiazolines, resulting in the extrusion of carbenes, has been described in terms of successive fragmentations, rather than as a single-step process (1*k*,*s*, 2*h*, 13). In the case of 2-alkyl-2-oxy oxadiazolines, products apparently derived from carbonyl ylides have been identified, thus providing strong support for their intermediacy (13*a*,*c*, 14). However, for 2,2-dioxy oxadiazolines, the postulate of a stepwise mechanism had rested mostly on the analogy to the monoalkoxy system until ketene acetals, thought to be formed from carbonyl ylides, were recently observed as thermolysis products of 2-aryloxy-2-aryloxy-2-methoxy oxadiazolines (1*t*).

Scheme 3 illustrates the thermolytic pathways common to most oxadiazolines **12** and **13**. The major route appears to be an orbital-symmetry-allowed 1,3-dipolar cycloreversion that liberates N_2 and produces carbonyl ylide **14/15**. Fragmentation of this transient species may then occur through pathway A, to generate aminooxycarbene **16/17** and a ketone, or via pathway B, which yields carbonyl compound **18/19** and a dialkyl carbene. The latter undergoes a fast 1,2-H migration to the alkene. Electrocyclic ring closure of **14/15**, as observed with some dioxy analogues (1*t*), is possible although no definitive evidence for the generation of spiro-fused oxiranes **20** could be obtained. Thermal decomposition of **12/13** may also take place through a different 1,3-dipolar cycloreversion to form a diazoalkane and, again, **18/19** (pathway C). Under our thermolytic conditions, most of the diazoalkane undergoes self-condensation to make an azine, while only a small fraction of it generates a dialkyl carbene from loss of molecular nitrogen.



Five-membered aminooxycarbenes **16**, when produced at elevated temperatures, sometimes fragment to ethylene and an isocyanate in a lifetime-limiting reaction similar to that for the dioxa (15) and dithia (15*e*, 16) analogues where CO_2 and CS_2, respectively, are the coproducts of ethylene. The isocyanates

[6] For consistency, rate constants for **12***f*, **12***h*, and **12***i* were all measured from an analogous OCH_2 multiplet, but that multiplet could not be used in the case of **12***g*.

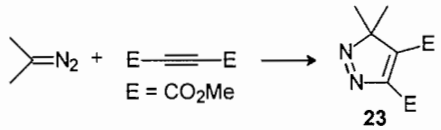
Scheme 4.



thus produced may then participate in subsequent reactions, in particular with carbenes **16**, as discussed below.

Thermolysis of 12*b*

For oxadiazoline **12***b*, the intermediate carbonyl ylide **14***b* fragments predominantly via pathway A to form 3-methyl-oxazolidin-2-ylidene, **16***b*, and acetone (Scheme 4). Trapping of **16***b* with phenol, in an NMR tube, gave product **21***b* in 59% yield.[7] In the absence of an added trap, carbene **16***b* does not dimerize, but rather fragments to ethylene and methyl isocyanate. The latter then acts as a trap for newly formed **16***b*, and a 1:2 (carbene:isocyanate) adduct, spiro hydantoin **22**, is found as a final product in about 15% yield; this product is analogous to those formed in the reactions of dimethoxycarbene (17) and (dimethylamino)-methoxy-carbene (18) with aryl isocyanates. Formation of **22** was confirmed by comparison of the NMR and GC–MS data of the thermolysate with an authentic sample prepared by thermolysing **12***b* in the presence of an excess of methyl isocyanate.

Other products resulting from the thermal decomposition of **12***b* include 3-methyl-2-oxazolidinone (**18***b*) and propene, as well as traces of acetone azine. Their formation suggests that both pathways B and C compete with pathway A. Although diazo compounds are known thermal sources of carbenes, under our experimental conditions 2-diazopropane produced almost exclusively acetone azine, and very little 2-propylidene. This was confirmed with two independent experiments. In the first one, 2-methoxy-5,5-dimethyl-2-phenoxy-Δ^3-1,3,4-oxadiazoline, a compound known to decompose partially via a pathway analogous to C (1*t*), was thermolysed under our experimental conditions and found to produce a significant amount of acetone azine, but only traces of propene, a result which is opposite to that from **12***b*. The second experiment, described in more detail in the experimental section, involved thermolysis of 2-diazopropane in benzene-d_6, in a sealed NMR tube, at 90°C. Product analysis by ^{1}H NMR spectroscopy revealed acetone azine in 86% yield, with only traces of propene present.

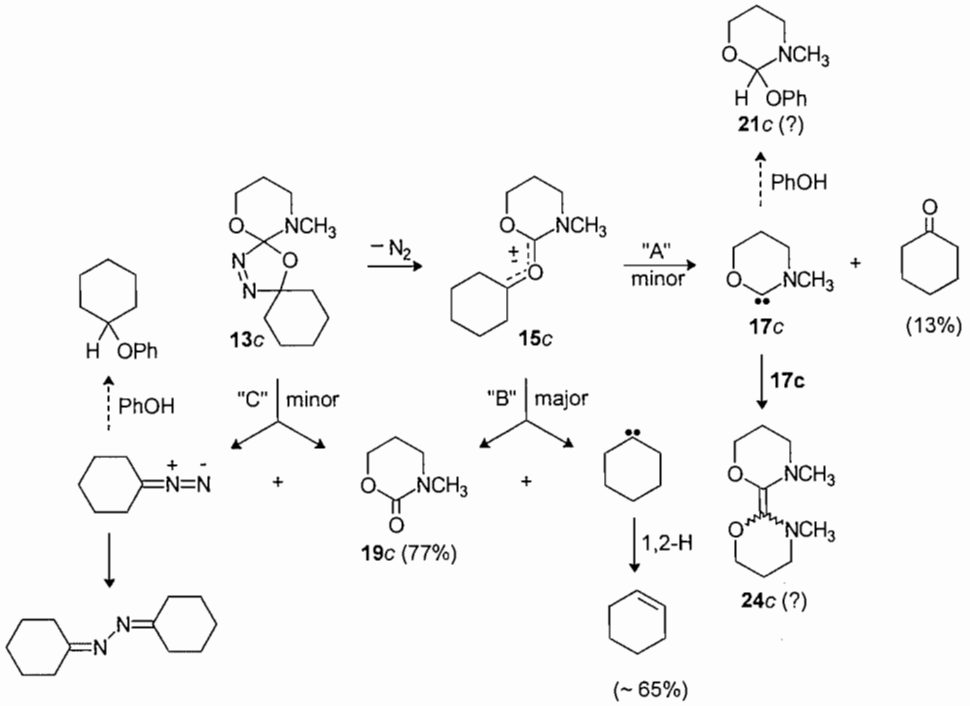
The apparent discrepancy between the yield of **18***b* (31%), a product common to pathways B and C, and those of propene (>16%) and acetone azine (traces), may be accounted for by the diversion of 2-diazopropane from its usual azine-forming reaction. In fact, the formation of an unidentified product, apparently derived from 2-diazopropane, was quenched with phenol, and 2-phenoxypropane was formed in its place in 12% yield. In the light of these results, it appears that pathway C in Scheme 4 contributes to approximately 12% of the decomposition of **12***b*, while pathway B must account for the remaining 19% of the **18***b* produced. This therefore provides an upper limit of about 69% for the yield of carbene **16***b*.

[4] 

23

The formation of both ethylene and propene from **12***b*, observed by ^{1}H NMR spectroscopy, was confirmed by their conversion to 1,2-dibromoethane and 1,2-dibromopropane, respectively, followed by GC–MS detection. Formation of 2-diazopropane was also confirmed by the identification of pyrazole **23**, when **12***b* was thermolysed in the presence of dimethyl acetylenedicarboxylate (eq. [4]) (19).

Thermolysis of 13*c*



Oxadiazoline **13***c* was synthesized as a possible precursor to the six-membered aminooxycarbene **17***c*. In contrast to the five-membered analogue (**16***b*), fragmentation of **17***c* should

[7] Other aminooxycarbene + phenol trapping experiments are in the following paper.

For personal use only.

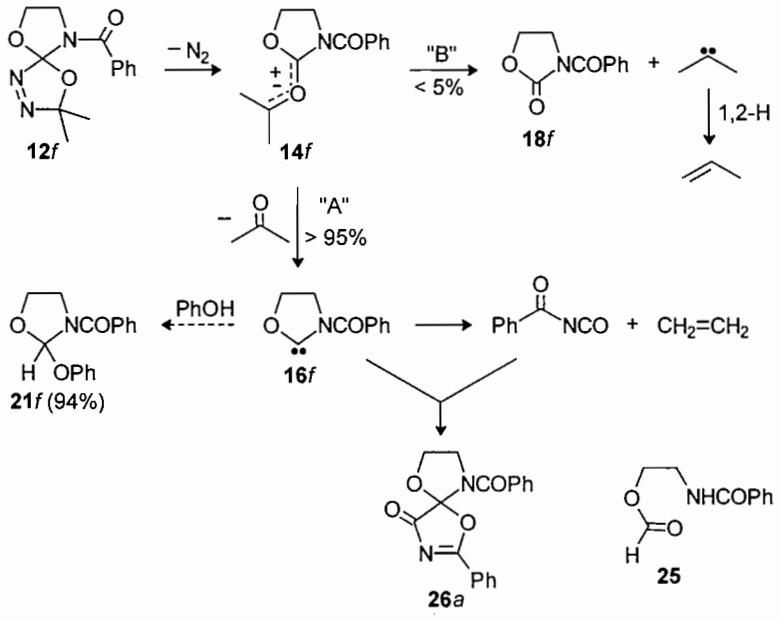
Scheme 5.

not occur to limit its lifetime. Results from the product studies on the thermolysis of **13***c*, however, were disappointing. With this oxadiazoline, competition between pathways A and B for the decomposition of carbonyl ylide **15***c* was found to favour pathway B (Scheme 5). Thus, the observed yields (by NMR) were 77% for carbonyl compound **19***c* and ca. 65% for cyclohexene, compared to only 13% for cyclohexanone, the coproduct in the formation of carbene **17***c*. A small amount of the azine of cyclohexanone was also observed, indicating the occurrence of pathway C; this accounts, at least in part, for the discrepancy between the yields found for **19***c* and cyclohexene. Carbene dimers (**24***c*) could not be unambiguously identified in the thermolysates, perhaps because of their lability towards hydrolysis. In addition, no evidence was found for the formation of **21***c* following the thermolysis of **13***c* in the presence of phenol, phenoxycyclohexane being the only recognizable phenol-derived product.

Thermolysis of 12*f*

The results presented above showed that oxadiazolines **12***b* and **13***c* (both N-methyl) do generate aminooxycarbenes upon thermolysis, although the yields of these reactive intermediates are not quantitative because of competing decomposition reactions. Speculation that fragmentation of the carbonyl ylide in the desired sense might be optimized by destabilizing the unwanted fragmentation product led to replacement of the N-substituent with an electron-withdrawing group.

Experimentally, *N*-carbonyl oxadiazolines such as **12***f* proved to be very efficient sources of cyclic aminooxycarbenes. Extrusion of N_2 from **12***f* results in carbonyl ylide **14***f*, which fragments essentially unidirectionally via pathway A to oxazolidin-2-ylidene **16***f* and acetone (Scheme 6). Thermolysis of **12***f* in the presence of phenol in an NMR tube gave phenol insertion product **21***f* in 94% yield. In comparison, the yield of 3-benzoyl-2-oxazolidinone (**18***f*), formed by either routes B or C, was too low to be measured by integration of its ^{1}H NMR signals; however, **18***f* was isolated from larger scale thermolyses in ca. 2% yield. Also observed were ethylene and traces of its coproduct, benzoyl isocyanate, as well as benzamide and *N*-[2-(formyloxy)ethyl]benzamide (**25**). Benzamide is attributed to decarboxylation of the *N*-benzoyl-carbamic acid formed from hydrolysis of benzoyl isocyanate by traces of water present during or after thermolysis.[8] Compound **25** is most likely a hydrolysis product derived from the aminooxycarbene, **16***f*. Thermolysis of **12***f* in the presence of a few drops of water yielded **25** as the main product (ca. 56%), along with benzamide (ca. 20%). In accordance with the proposed scheme neither propene nor acetone azine were produced in detectable quantities.



The instability of the major nonvolatile product formed from **12***f* complicated the elucidation of its structure. For example, its purification by radial chromatography was impossible, and it did not survive GC. However, a reasonably pure, white solid could be obtained by dissolving the crude product in diethyl ether and reevaporating most of the solvent in vacuo. The ^{1}H NMR spectrum of these crystals was very similar to that of the crude thermolysate, thus demonstrating a nearly quantitative yield. Eventually, this major product was identified as spiro 4(5*H*)-oxazolone **26***a*. The proposed structure is consistent with NMR, IR, and MS data. Characteristic ^{13}C resonances included ($CDCl_3$, in ppm): 47.14 (NCH_2), 68.43 (OCH_2), 108.38 (spiro C), 167.73 (PhC(O)), as well as

[8] A sample of benzoyl isocyanate stored on the shelf was gradually converted to benzamide and *N,N'*-dibenzoylurea, the latter presumably arising from the reaction of benzamide with benzoyl isocyanate.

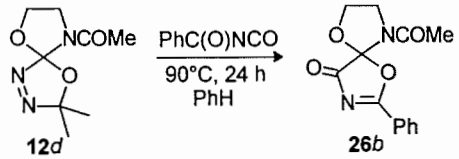
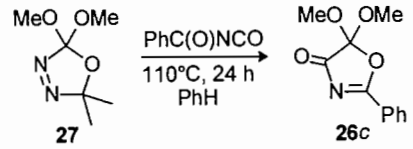
Scheme 6.



Scheme 7.



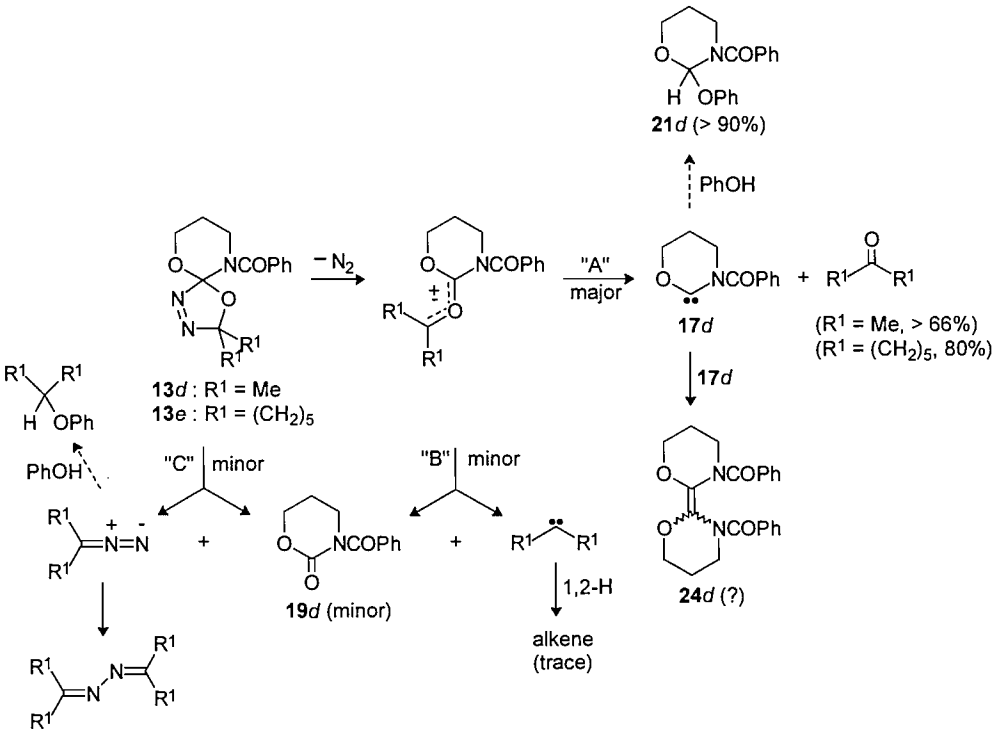
181.80 and 184.13, which were assigned to carbons 2 and 4 of the oxazolone ring. Its EI-MS spectrum showed a low-intensity molecular ion (*m/z* 322, too weak to obtain high-resolution data), while CI-MS with NH_3 showed a signal corresponding to $(M + H)^+$. IR spectra of 4(5*H*)-oxazolones show characteristic bands in the ranges 1786–1754 cm^{-1} for C=O stretching and 1575–1499 cm^{-1} for C=N stretching (20). Consistent with expectation, intense bands appeared at 1783 and 1558 cm^{-1} in the IR spectrum of **26***a*.

The novel spiro oxazolone **26***a*, with two heteroatom substituents at C5, presumably arises from nucleophilic attack of carbene **16***f* on the isocyanate carbonyl group of benzoyl isocyanate, followed by cyclization of the dipolar intermediate (Scheme 7).

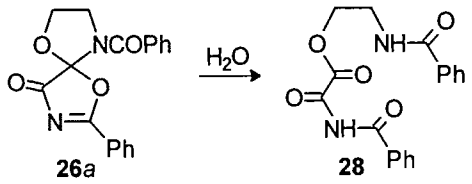
To obtain independent support for structure **26***a*, as well as to probe for the generality of the reaction between benzoyl isocyanate and nucleophilic carbenes, aminooxycarbene **16***d* and dimethoxycarbene, generated from **12***d* and **27**, respectively, were separately reacted with benzoyl isocyanate. In both cases, spectroscopic data obtained from crude thermolysates paralleled those from **26***a*, indicating formation of oxazolones **26***b* and **26***c* as major products (eqs. [5], [6]).[9] Analogous [1 + 4] cycloadditions between 3-methyloxazolidin-2-ylidene (**16**b) or dimethoxycarbene and vinyl isocyanates have recently been reported by Rigby et al. (*2l*). These cycloadditions contrast with the usual hydantoin-forming reactions of nucleophilic carbenes with alkyl or aryl isocyanates (cf. compound **22**).

[5] 

[6] 



Oxazolone **26***a* was deliberately hydrolysed by adding a few drops of water to the thermolysate from **12***f* (eq. [7]). As with its precursor oxazolone, attempted purification of the product by chromatography resulted in its complete decomposition. A reasonably pure solid was obtained, however, by precipitation from a benzene solution. Spectroscopic data (^1H and ^{13}C NMR, IR, MS) are consistent with oxalic acid derivative **28**. Hydrolysis of a 4(5*H*)-oxazolone fused at C5 to C2 of an oxazolidine thus results in cleavage of the C(5)—O bond of the oxazolone; this contrasts with hydrolyses reported for other 4(5*H*)-oxazolones, in which cleavage occurs at the carbon–nitrogen double bond (21).



[9] A control experiment in which a slightly decomposed sample of benzoyl isocyanate was submitted to our thermolysis conditions, without any oxadiazoline present, gave benzamide and *N,N'*-dibenzoylurea as major products.

Scheme 8.

[7] 

Thermolysis of other *N*-carbonyl oxadiazolines 12

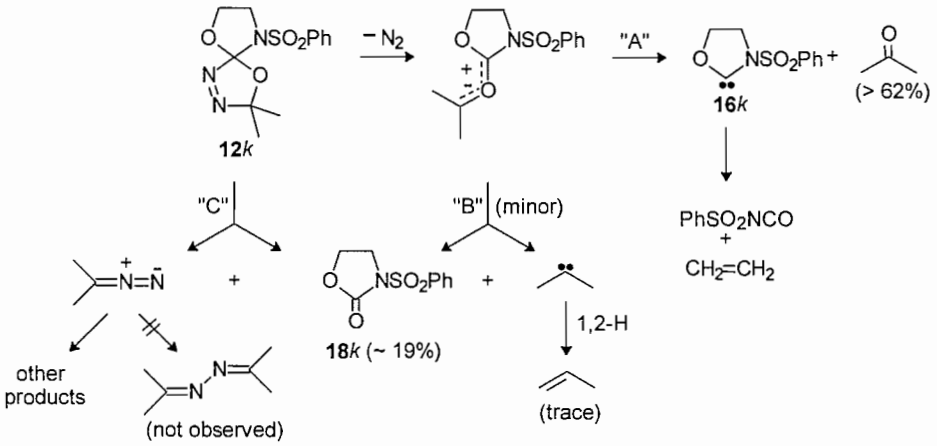
A number of the *N*-carbonyl oxadiazolines **12** shown in Table 1 were synthesized mainly for the purpose of investigating the rotational barriers of their amide bonds,[4] and their thermolysis chemistry was therefore not investigated in detail. However, **12***d* (*N*-acetyl) and **12***e* (*N*-methacryloyl) have been used extensively as thermal sources of carbenes, which they produce, like **12***f* (*N*-benzoyl), in essentially quantitative yields (5).

Thermolysis of 13*d*,*e*

Initial attempts to generate carbene **17***d* involved dispiro oxadiazoline **13***e*. Thermolyses of this compound in NMR tubes resulted in the production of cyclohexanone, the coproduct of **17***d*, in about 80% yield (Scheme 8). In addition to traces of cyclohexene, a small amount of carbonyl compound **19***d* was produced. Thermolysis of **13***e* in the presence of phenol resulted in the formation of **21***d* in high yield, together with a minor amount of phenoxycyclohexane presumably produced from the reaction of diazocyclohexane with phenol. The formation of these products suggests that both pathways B and C are involved in the decomposition of this oxadiazoline, although pathway A, leading to the desired tetrahydro-1,3-oxazin-2-ylidene (**17***d*) is, by far, the most important route. Similarly, thermolysis of the related oxadiazoline **13***d* resulted in the production of carbene **17***d*, which was trapped by phenol to give adduct **21***d* in over 90% yield.

The fate of carbene **17***d*, generated in solution in the absence of a trap, is uncertain. It is likely that this carbene dimerizes to *E* and *Z* alkenes (**24***d*). However, these products could not be clearly identified. The NMR spectra were very complex, as expected for the geometric isomers of **24***d* because of slow rotation about the amide CN bond, and separation of **24***d* from coproducts and from each other was not possible because of their sensitivity towards moisture. Interestingly, ions with *m/z* 378, corresponding to the molecular ions of carbene dimers (**24***d*), were found in MS experiments carried out with the aim of confirming the identity of oxadiazoline **13***e*; these species were generated in the gas phase, inside the spectrometer, by the unavoidable partial thermolysis of the fragile oxadiazoline.

Thermolysis of 12*k*



As for *N*-methyl oxadiazoline **12***b*, compound **12***k* did not generate the aminooxycarbene quantitatively under our thermolysis conditions although acetone, the coproduct of carbene **16***k*, was formed in >62% yield (by ^{1}H NMR spectroscopy), Scheme 9. Formation of the latter was supported by the detection of ethylene, presumably formed in its thermal fragmentation. 3-(Phenylsulfonyl)-2-oxazolidinone, **18***k*, was produced in ca. 19% yield. The fact that only traces of propene were detected suggests that **18***k* is generated mostly via pathway C rather than through pathway B. However, acetone azine, which usually results from the self-reaction of 2-diazopropane, was not observed. Any 2-diazopropane formed may have reacted with another species present in the thermolysis solution to form unidentified products, as in the case of **12***b*.

A compound assigned structure **29**, on the basis of its spec-

Scheme 10.

tral data (^{1}H and ^{13}C NMR, IR, and MS), was isolated from a thermolysis experiment in which wet **12***k* was used. One possible route for its formation is shown in Scheme 10.[10] The isolation of **29** thus provides additional, although indirect, evidence for the generation of carbene **16***k*.

Experimental

General methods

NMR spectra were recorded on a Bruker AC-200 or AC-300 NMR spectrometer. Some compounds show complex NMR spectra due to the slow interconversion, on the NMR time scale, between two isomers.[4] In some cases, this results in two distinct sets of resonances, while some spectra show broad, unresolved multiplets labelled below as "um". Infrared spectra were recorded with a Biorad FTS-40 spectrophotometer, with the sample either in CCl_4 or in KBr as a pellet. The IR bands are labelled qualitatively with the symbols br for broad, app for apparent, and s, m, and w for strong, medium, and weak intensities, respectively. Bands from C–H stretching vibrations between 2850 and 3100 cm^{-1} are omitted, as are very weak bands. Melting points were recorded on a Thomas Hoover capillary melting point apparatus, and are reported uncorrected. Elemental analyses were performed by Guelph Chemical Laboratories, Ltd. (Guelph, Ont.).

Synthesis of ketone semicarbazones 10

Ketone semicarbazones were prepared by the method described by Vogel (22), and were recrystallized from 50% aqueous ethanol.

*Acetone semicarbazone (**10**, R^1 = Me)*: White solid (78% yield), mp 185–186°C (lit. (23) mp 190–191°C); ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.83 (s, 3H), 1.99 (s, 3H), 7.4 (br s, 1H) (the NH_2 signal was not visible).

*Cyclohexanone semicarbazone (**10**, R^1R^1 = $(CH_2)_5$)*: White solid (75% yield), mp 165–166°C (lit. (23) mp 166–167°C); ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.50–1.90 (m, 6H), 2.15–2.45 (m, 4H), 5.6 (br s, 2H), 8.53 (s, 1H).

Synthesis of 4-substituted ketone semicarbazones 9

The procedure for the preparation of compounds **9** is based on that of Iwao (7). Typically, a solution of the appropriate ketone semicarbazone (0.30 mol) and aminoalcohol (0.32 mol) (all commercially available, except for 3-(methylamino)-1-propanol, which was prepared as described by Michejda and co-workers (24)) was refluxed in toluene (100 mL), under dry nitrogen, for 7–15 h, until evolution of ammonia had subsided. The solution was allowed to cool to room temperature, and precipitation of the product usually occurred within a few hours. In some cases, crystallization was induced by addition of diethyl ether. The product was then collected by filtration and triturated with diethyl ether. When appropriate recrystallization solvents could not be found, the semicarbazones were used without further purification; recrystallization solvents for the others are listed below. Several semicarbazones did not give useful mass spectra under routine conditions.

*Acetone 4-(2-hydroxyethyl)semicarbazone (**9**, n = 2, R^1 = Me, R^2 = H)*: Pale yellow solid (81% yield), mp 89–94°C (lit. (7) mp 94–96°C); IR (KBr) cm^{-1}: 3379br, 3317br, 3210br, 3070br, 1652s (C=O), 1554s (C=N), 1458w, 1427m, 1365m, 1337m, 1281w, 1254m, 1212m, 1157w, 1132m, 1088w, 1068m, 980w, 884w, 836w, 773m, 722m; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.84 (s, 3H), 1.97 (s, 3H), 3.39–3.53 (m,

[10] Sulfonamide **30** has also been isolated from thermolysis of **12***k*.

2H), 3.69–3.82 (m, 2H), 6.56 (br s, 1H), 8.02 (br s, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 16.36 (CH_3), 25.20 (CH_3), 42.85 (NCH_2), 63.35 (OCH_2), 147.85 (C═N), 157.88 (C═O); mass spectrum not useful.

*Acetone 4-(2-hydroxyethyl)-4-methylsemicarbazone (**9**, n = 2, $R^1 = R^2 = Me$)*: White solid (60% yield) after recrystallization from ethanol – diethyl ether, mp 132–134°C; IR (KBr) cm^{-1}: 3223br, 1644s (C═O), 1557s (C═N), 1471m, 1424w, 1394m, 1359w, 1276m, 1223m, 1187m, 1115w, 1080w, 1041m, 965w, 871w, 757w; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.83 (s, 3H), 2.00 (s, 3H), 2.95 (s, 3H), 3.39 (t, ^3J = 4.6 Hz, 2H), 3.84 (t, ^3J = 4.6 Hz, 2H), 4.92 (br s, 1H), 8.79 (br s, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 16.89 (═C-*C*H$_3$), 25.19 (═C-*C*H$_3$), 35.02 (NCH_3), 52.45 (NCH_2), 61.05 (OCH_2), 150.33 (C═N), 157.83 (C═O); mass spectrum not useful. Anal. calcd. for $C_7H_{15}N_3O_2$: C 48.54, H 8.73; found: C 48.83, H 8.79.

*Acetone 4-(2-hydroxyethyl)-4-phenylsemicarbazone (**9**, n = 2, R^1 = Me, R^2 = Ph)*: White solid after recrystallization first from ethanol – diethyl ether, then from benzene; mp 125–126°C; IR (KBr) cm^{-1}: 3414br, 3385br, 3233br, 1726s (C═O), 1652w, 1603m, 1509s, 1457w, 1434w, 1374w, 1315w, 1278m, 1242m, 1221s, 1133w, 1061w, 1036m, 935w, 886w, 755m; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.84 (s, 3H), 2.06 (s, 3H), 3.45 (t, ^3J = 5.4 Hz, 2H), 4.45 (t, ^3J = 5.4 Hz, 2H), 6.61–6.78 (m, 3H), 7.13–7.25 (m, 2H), 7.57 (br s, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 16.06 (═C-*C*H$_3$), 25.26 (═C-*C*H$_3$), 43.22 (NCH_2), 64.21 (OCH_2), 112.79 (Ar C2, C6), 117.65 (Ar C4), 129.19 (Ar C3, C5), 147.63 (Ar C1), 151.39 (C═N), 154.00 (C═O); MS (EI) *m/z*: 235 (M^+, 6), 119 (75), 106 (100), 91 (17), 77 (63), 65 (22), 56 (13), 51 (16); MS (CI, NH_3) *m/z*: 236 $(M + H)^+$; HRMS *m/z*, calcd. for $C_{12}H_{17}N_3O_2$ (M^+): 235.1321; found: 235.1337.

*Acetone 4-(3-hydroxypropyl)semicarbazone (**9**, n = 3, R^1 = Me, R^2 = H)*: White solid (60% yield), mp 107–109°C; IR (KBr) cm^{-1}: 3396br, 3303br, 3206br, 1643s (C═O), 1552s (C═N), 1439w, 1423w, 1380w, 1330w, 1254w, 1223w, 1116w, 1071w, 986w; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.62–1.78 (m, 2H), 1.84 (s, 3H), 1.97 (s, 3H), 3.40–3.53 (m, 2H), 3.60–3.80 (m, 3H), 6.36 (m, 1H), 8.01 (br s, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 16.33 (CH_3), 25.19 (CH_3), 33.14 (NCH_2), 35.43 (C*C*H$_2$C), 58.47 (OCH_2), 147.68 (C═N), 157.85 (C═O); mass spectrum not useful.

*Cyclohexanone 4-(3-hydroxypropyl)semicarbazone (**9**, n = 3, $R^1R^1 = (CH_2)_5$, R^2 = H)*: White solid (79% yield) after recrystallization from ethanol – diethyl ether, mp 124–126°C; IR (KBr) cm^{-1}: 3363br, 3299br, 3200br, 1639s (C═O), 1558s (C═N), 1470w, 1440m, 1378w, 1350w, 1318m, 1273w, 1254w, 1225w, 1197w, 1138w, 1111w, 1071m, 1019w, 988m, 907w, 831w, 810w, 702m; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.56–1.75 (m) and 1.93 (br s) and 2.22–2.35 (m) (12H), 3.46 (app q, ^3J = 6.3 Hz, 2H), 3.65 (app q, ^3J = 6.0 Hz, 2H), 3.85 (app t, ^3J = 6.8 Hz, 1H), 6.38 (ut, 1H), 8.46 (br s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 25.54, 25.72, 26.40, 27.00, 33.22 (NCH_2), 35.41 (C*C*H$_2$C of propyl chain and another CH_2 signal overlapped), 58.43 (OCH_2), 154.04 (C═N), 158.43 (C═O); mass spectrum not useful.

*Cyclohexanone 4-(3-hydroxypropyl)-4-methylsemicarbazone (**9**, n = 3, $R^1R^1 = (CH_2)_5$, R^2 = Me)*: Pale yellow solid (60% yield) after recrystallization from ethyl acetate, mp 94–96°C; IR (KBr) cm^{-1}: 3222br, 1661s (C═O), 1547s (C═N), 1473m, 1446w, 1416w, 1389m, 1343w, 1289w, 1216m, 1196m, 1139m, 1077m, 1018w, 989w, 952w, 910w, 756w; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.52–1.77 (m, 8H), 2.17–2.40 (m, 4H), 2.90 (s, 3H), 3.43 (t, ^3J = 5.7 Hz, 2H) 3.58 (t, ^3J = 5.7 Hz, 2H), 4.27 (br s, 1H), 8.20 (br s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 25.50, 25.64, 26.61, 26.72, 29.31, 33.87, 35.18 (CH_3), 44.72 (NCH_2), 57.39 (OCH_2), 157.36 (C═N or C═O), 157.70 (C═N or C═O); mass spectrum not useful.

Synthesis of oxadiazolines 12 and 13

Typical procedures for the preparations of **12***a–k* and **13***a–e* are given below. Under routine conditions, these compounds do not give useful mass spectra. To confirm their identity, MS experiments involving LRP and HRP electron impact (EI), collisional activation (CA) spectrometry,[11] and chemical ionization (CI) with ammonia were performed on **12***b,d,f* and **13***c,d*. In agreement with earlier work on **12***a* and related compounds (1*j,r*), the EI spectra do not show molecular ions (CI yields $[M + H]^+$ and $[M + H + NH_3]^+$ ions) but rather $[M - N_2]^{\bullet+}$ ions, which (as established by CA spectrometry) form the precursor of most of the fragment ions. Principal peaks (*m/z*; elemental compositions in parentheses were experimentally determined; rel. intensity) in the 70 eV EI mass spectra are as indicated below. For most solid oxadiazolines, the reported melting points are approximate because these compounds generally start to decompose on heating above ca. 80°C.

*3,4,9-Triaza-2,2-dimethyl-1,6-dioxaspiro[4.4]non-3-ene (**12**a) (1j)*

Under dry nitrogen, $PhI(OAc)_2$ (7.47 g, 0.023 mol), dissolved in CH_2Cl_2 (150 mL), was added dropwise, over 1–2 h, to a stirred solution of semicarbazone **9** (n = 2, R^1 = Me, R^2 = H) (3.50 g, 0.022 mol) in CH_2Cl_2 (200 mL) at 0°C. After addition was complete, the solution was kept in the ice bath for another 2 h before it was allowed to warm to room temperature overnight. After ca. half of the solvent had been evaporated in vacuo, the solution was washed with 4 × 30 mL of aqueous $NaHCO_3$ (5%), followed by 30 mL of brine. Drying ($MgSO_4$), filtration by gravity, and evaporation of the solvent afforded an oil (ca. 6 g) containing a mixture of **12***a* and PhI, which were separated by radial chromatography on silica, starting with 10% ethyl acetate in hexane and gradually increasing solvent polarity to 60% ethyl acetate in hexane. This typically gave slightly impure **12***a* in 47% yield. It could be further purified by bulb-to-bulb distillation (ca. 30–40°C, 2 Torr (1 Torr = 133.3 Pa)) to obtain pure **12***a* as a clear, colourless oil. IR (CCl_4) cm^{-1}: 3397br (NH), 1794s, 1711s, 1574w (N═N), 1481w, 1459w, 1417w, 1384m, 1362w, 1309m, 1229m, 1207m, 1138w, 1105w, 1057w, 1038w, 987w, 957w, 915w;

[11] See Terlouw and co-workers (1*j*). The experiments were performed on a VG Analytical ZAB-R mass spectrometer of BEE geometry. Compounds were introduced using a direct insertion probe kept at room temperature at a source temperature of 100–120°C. Under these conditions the degree of thermolysis is negligible.

^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.48 (s, 3H, CH_3), 1.53 (s, 3H, CH_3), 2.87 (br s, 1H, NH), 3.44–3.54 (m, 2H, NCH_2), 4.14–4.33 (m, 2H, OCH_2); ^{13}C NMR (75 MHz, C_6D_6) δ: 24.45 (CH_3), 24.64 (CH_3), 44.71 (NCH_2), 67.87 (OCH_2), 117.68 (C2), 139.18 (C5).

*3,4,9-Triaza-2,2,9-trimethyl-1,6-dioxaspiro[4.4]non-3-ene (**12**b)*

Oxidation of semicarbazone **9** (n = 2, R^1 = R^2 = Me) by the procedure for preparation of **12***a* gave **12***b*, which was purified by radial chromatography with 5–40% ethyl acetate in hexane. Pale yellow oil typically obtained in 66% yield; IR (neat) cm^{-1}: 1757m, 1576w (N=N), 1459s, 1363s, 1295s, 1238s, 1209s, 1132s, 1079s, 1041m, 988m, 953w, 902s, 846m, 762w, 714w; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.45 (s, 3H, CCH_3), 1.59 (s, 3H, CCH_3), 2.37 (s, 3H, NCH_3), 3.31 (m, 1H, NCH_2-H_X), 3.46 (m, 1H, NCH_2-H_M), 4.22 (m, 2H, OCH_2-H_B), 4.22 (m, 2H, OCH_2-H_A), J_{AB} = −7.50 Hz, J_{MX} = −8.13 Hz, J_{AM} = 7.03 Hz, J_{AX} = 4.46 Hz, J_{BM} = 7.35 Hz, J_{BX} = 6.30 Hz;[12] ^{13}C NMR (50 MHz, $CDCl_3$) δ: 24.07 (CCH_3), 24.93 (CCH_3), 32.36 (NCH_3), 51.38 (NCH_2), 65.66 (OCH_2), 116.46 (C2), 139.17 (C5); MS: 143 ([M − N_2]$^{\bullet+}$ ($C_7H_{13}NO_2$), 15), 102 ([M − N_2 − $C_3H_5^{\bullet}$]$^+$, 90), 101 ([M − N_2 − C_3H_6]$^{\bullet+}$, 95), 86 (23), 85 ([M − N_2 − C_3H_6O]$^{\bullet+}$, 68), 58 (81), 57 (68), 56 (39), 43 (100), 42 (75), 28 (90).

*3,4,9-Triaza-9-formyl-2,2-dimethyl-1,6-dioxaspiro[4.4]non-3-ene (**12**c)*

Oxadiazoline **12***a* (0.85 g, 5.4 mmol) was stirred at room temperature in CH_2Cl_2 (10 mL) with 4-nitrophenyl formate (0.99 g, 5.9 mmol) (9). After 3 days, the yellow solution was diluted with CH_2Cl_2 (40 mL), washed successively with aqueous $NaHCO_3$ (5%) and brine, and dried ($MgSO_4$). Separation of **12***c* by chromatography, with either 10–40% ethyl acetate in hexane or 1% methanol in chloroform, was repeated several times to obtain a pure sample of **12***c* as a pale orange oil (41% yield, one trial); IR (CCl_4) cm^{-1}: 1702s (C=O), 1573w (N=N), 1474w, 1459w, 1412w, 1377m, 1340w, 1271m, 1234m, 1208w, 1179m, 1115m, 1060w, 1031w, 1008w, 980w, 911w; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.50 (s, 3H, CH_3), 1.64 (s, 3H, CH_3), 3.80–4.05 (m, 2H, NCH_2), 4.22–4.45 (m, 2H, NCH_2), 7.90 (s, 1H, C(O)H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 23.96 (CH_3), 24.70 (CH_3), 42.00 (NCH_2), 65.67 (OCH_2), 120.26 (C2), 133.13 (C5), 158.65 (C=O); routine mass spectrum not useful.

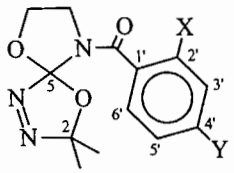
*3,4,9-Triaza-9-acetyl-2,2-dimethyl-1,6-dioxaspiro[4.4]non-3-ene (**12**d)*

The method described below for **12***f* was used, with acetic anhydride for the acetylation. White solid (33% yield, from **9**) after recrystallization from methanol – diethyl ether, mp 87–88°C; IR (CCl_4) cm^{-1}: 1690s (C=O), 1580w (N=N), 1392s, 1350m, 1277m, 1234m, 1208m, 1138w, 1109s, 1046w, 1019w, 982w, 908w; ^{1}H NMR (300 MHz, $CDCl_3$; slow exchange) δ: 1.49 (s, 3H, C(2)CH_3), 1.73 (s, 3H, C(2)CH_3), 1.77 (s) and 2.14 (s) (3H, C(O)CH_3), 3.85–4.08 (m, 2H, NCH_2), 4.13–4.45 (m, 2H, OCH_2); ^{13}C NMR (75 MHz, $CDCl_3$; slow exchange, resonances obviously from the major isomer are underlined) δ: 21.64, 22.02, 22.20, 23.94, 25.20, 25.45, 45.36 and 46.15 (NCH_2), 64.65 and 65.22 (OCH_2), 118.77 and 120.72 (C2), 131.86 and 133.15 (C5), 167.96 (C=O); MS: 171 ([M − N_2]$^{\bullet+}$ ($C_8H_{13}NO_3$), 0.7%), 130 ([M − N_2 − $C_3H_5^{\bullet}$]$^+$, 6), 129 ([M − N_2 − C_3H_6]$^{\bullet+}$, 6), 113 ([M − N_2 − C_3H_6O]$^{\bullet+}$, 23), 88 (50), 85 (4), 72 (6), 69 (24), 59 (14), 43 ([CH_3CO^+], 100). Anal. calcd. for $C_8H_{13}N_3O_3$: C 48.23, H 6.58; found: C 48.50, H 6.70.

*3,4,9-Triaza-9-methacryloyl-2,2-dimethyl-1,6-dioxaspiro[4.4]non-3-ene (**12**e)*

The method described for **12***f*, with methacryloyl chloride in the acylation step, gave **12***e* as a white solid (19% yield, from **9**), mp ca. 45–47°C (dec.) after repeated recrystallizations from ethyl acetate – hexane; IR (CCl_4) cm^{-1}: 1676s (C=O), 1636m, 1578w (N=N), 1454w, 1415w, 1386s, 1366s, 1344w, 1277m, 1233s, 1180s, 1120m, 1096m, 1048w, 1018w, 982w, 920m, 861w, 834w; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.48 (s, 3H, C(2)CH_3), 1.69 (s, 3H, C(2)CH_3), 1.93 (s, 3H, =C-CH_3), 3.90–4.08 (m, 2H, NCH_2), 4.22–4.40 (m, 2H, OCH_2), 5.21 and 5.23 (overlapped s, 2H, $=CH_2$); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 19.67 (=C-CH_3), 21.44 C(2)CH_3), 25.24 (C(2)CH_3), 46.48 (NCH_2), 65.15 (OCH_2), 118.16 ($=CH_2$), 120.14 (C2), 132.95 (C5), 140.11 ($=CR_2$), 169.80 (C=O); MS (EI) *m/z*: 156 (4), 139 (9), 124 (7), 110 (50), 100 (15), 95 (22), 84 (46), 69 (90), 49 (34), 41 (100).

*3,4,9-Triaza-9-benzoyl-2,2-dimethyl-1,6-dioxaspiro[4.4]non-3-ene (**12**f)*[13]



The crude mixture containing **12***a* and PhI (starting with 22 mmol of **9**) was dissolved in CH_2Cl_2 (25mL), and pyridine (1.10 g, 13.9 mmol) was added. Benzoyl chloride (1.86 g, 13.2 mmol) was added dropwise to this stirred solution over ca. 10 min. After stirring at room temperature for another 30 min, the solution was diluted with CH_2Cl_2 and washed successively with water, aqueous $NaHCO_3$ (5%), and brine. The organic phase was dried over $MgSO_4$, the solvent was evaporated, and hexane was added to the crude product to induce crystallization. Recrystallization from methanol – diethyl ether yielded 1.41 g (25%, from **9**) of **12***f* as a white solid, mp ca. 108–110°C (dec.); IR (KBr) cm^{-1}: 1655s (C=O), 1578w (N=N), 1453w, 1389s, 1272m, 1222m, 1162m, 1115m, 1081w, 1046w, 1011w, 973w, 921m, 856w, 817w, 798w, 722m; ^{1}H NMR (300 MHz, $CDCl_3$, slow exchange) δ: 1.47 (s) and 1.62 (s) and 1.20–1.80 (br) (6H, CH_3), 3.85–4.00 (um, 1H, NCH_2), 4.05–4.20 (um, 1H, NCH_2), 4.25–4.45 (m, 2H, OCH_2), 7.35–7.60 (m, 5H, Ar); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 21.40 (CH_3), 25.19 (CH_3), 47.35 (NCH_2), 65.40 (OCH_2), 120.41 (C2), 127.26 (Ar C2, C6), 128.36 (Ar C3, C5), 130.94 (Ar C4), 133.22 (C5), 135.40 (Ar C1), 169.00 (C=O); MS: 233 ([M − N_2]$^{\bullet+}$, 0.9), 192 ([M − N_2 − $C_3H_5^{\bullet}$]$^+$, 5), 175 ([M − N_2 − C_3H_6O]$^{\bullet+}$ ($C_{10}H_9NO_2$), 27), 174 (30), 147 (15), 146 (10), 145 (12), 131 (43), 117 (20), 105 ([$C_6H_5CO^+$], 100), 103 (21), 88 (25), 77 ([$C_6H_5^+$], 35), 51 (21).

[12] Determined by spectral simulation using PANIC (Bruker).

[13] X-ray crystallography data will be submitted for publication elsewhere.

12*g-i*

*3,4,9-Triaza-9-(2-methoxybenzoyl)-2,2-dimethyl-1,6-dioxaspiro[4.4]non-3-ene (**12**g)*

Prepared as described for **12*f***, using o-anisoyl chloride as the acylating agent. White solid (26% yield, from **9**) after recrystallization from ethyl acetate – hexane, mp ca. 143–144°C (dec.); IR (KBr) cm^{-1}: 1656s (C═O), 1603m, 1581w (N═N), 1493m, 1462m, 1438m, 1399s, 1364m, 1272m, 1250m, 1224m, 1162m, 1123s, 1079m, 1037w, 1017m, 973w, 922m, 899w, 858w, 830w, 763m, 725w; ^1H NMR (300 MHz, $CDCl_3$, slow exchange) δ: 0.50 (br s) and 1.30 (br s) and 1.54 (br s) and 1.81 (br s) (6H, $C(CH_3)_2$), 3.60–4.45 (br. m's, 7H, NCH_2, OCH_2, OCH_3), 6.75–7.50 (br m's, 4H, Ar); ^{13}C NMR (75 MHz, $CDCl_3$, slow exchange, resonances due to major isomer are underlined) δ: 20.93 and 21.66 (CCH_3), 24.79 and 25.38 (CCH_3), 45.55 and 46.01 (NCH_2), 55.72 (OCH_3), 64.24 and 65.57 (OCH_2), 111.23 (Ar), 118.45 (C2), 119.69 and 120.91 (Ar), 124.80 and 125.70 (Ar), 127.55 and 128.26 (Ar), 130.93 and 131.45 (Ar), 133.31 (C5), 155.34 and 156.49 (Ar C2′), 166.63 (C═O); MS (EI) *m/z*: 248 (3), 204 (4), 174 (6), 148 (4), 135 (100), 118 (28), 92 (11), 77 (22); MS (CI, NH_3) *m/z*: 309 $(M + NH_4)^+$, 292 $(M + H)^+$.

*3,4,9-Triaza-9-(4-methoxybenzoyl)-2,2-dimethyl-1,6-dioxaspiro[4.4]non-3-ene (**12**h)*

Prepared as described for **12*f***, with purified **12*a*** for the acylation with *p*-anisoyl chloride. White solid (63% yield) after recrystallizations from ethyl acetate – hexane and methanol – diethyl ether, mp ca. 110°C (dec.); IR (CCl_4) cm^{-1}: 1671s (C═O), 1609m, 1579w (N═N), 1513m, 1462w, 1418w, 1374s, 1306w, 1255s, 1228s, 1173s, 1119m, 1037m, 982w, 921m, 861w, 841w; ^1H NMR (200 MHz, $CDCl_3$, slow exchange) δ: 1.48 (br s, 6H, $C(CH_3)_2$), 3.82 (s, 3H, OCH_3), ca. 3.80–3.98 (overlapped m, 1H, NCH_2), 4.03–4.21 (m, 1H, NCH_2), 4.22–4.44 (m, 2H, OCH_2), 6.88 (d, ^3J = 8.8 Hz, 2H, CH (3′, 5′)), 7.50 (d, ^3J = 8.8 Hz, 2H, CH (2′, 6′)); ^{13}C NMR (50 MHz, $CDCl_3$, slow exchange) δ: 21.32 and 21.62 (CCH_3), 24.98 and 25.28 (CCH_3), 47.54 (NCH_2), 55.20 and 55.47 (OCH_3), 65.46 (OCH_2), 113.42 and 113.57 (C3′, C5′), 120.25 (C2), 127.48 (C1′), 129.26 and 129.58 (C2′, C6′), 133.45 (C5), 161.72 (Ar C4′), 168.56 (C═O); MS (EI) *m/z*: 205 (M − N_2 − acetone, 11), 177 (7), 135 ($ArCO^+$, 100), 92 (10), 77 (12); MS (CI, NH_3) *m/z*: 309 $(M + NH_4)^+$, 292 $(M + H)^+$.

*3,4,9-Triaza-9-(4-nitrobenzoyl)-2,2-dimethyl-1,6-dioxaspiro[4.4]non-3-ene (**12**i)*

Prepared as described for **12*f***, using purified **12*a*** for the acylation with 4-nitrobenzoyl chloride. Pale yellow solid (50% yield) after recrystallization from ethyl acetate – hexane, mp ca. 135°C (dec.); IR (KBr) cm^{-1}: 1665s (C═O), 1604w, 1524s (NO_2), 1415m, 1392m, 1346s (NO_2), 1266w, 1224m, 1158m, 1119m, 1081w, 1040w, 1012w, 980w, 922m, 870w, 849m, 817w, 725m; ^1H NMR (300 MHz, $CDCl_3$, slow exchange) δ: 1.47 (s, on top of a broad resonance, 6H, $C(CH_3)_2$), 3.81–4.18 (um, 2H, NCH_2), 4.26–4.46 (m, 2H, OCH_2), 7.67 (br. d, app, ^3J = 7.7 Hz, 2H, (CH (2′, 6′)), 8.26 (d, ^3J = 8.5 Hz, CH (3′, 5′)); ^{13}C NMR (75 MHz, $CDCl_3$, slow exchange) δ: 21.40 (CH_3), 25.07 (CH_3), 47.07 (NCH_2), 65.27 (OCH_2), 120.73 (br, C2), 123.65 (C2′, C6′), 128.33 (C3′, C5′), ca. 133 (br, C5), 141.00 (C1′), 148.98 (C4′), 166.51 (C═O); MS (EI) *m/z*: 237 (8), 219 (20), 176 (46), 150 ($ArCO^+$, 100), 104 (38), 76 (26); MS (CI, NH_3) *m/z*: 324 $(M + NH_4)^+$, 307 $(M + H)^+$.

*3,4,9-Triaza-9-methoxycarbonyl-2,2-dimethyl-1,6-dioxaspiro[4.4]non-3-ene (**12**j)*

This compound was prepared from **12*a***, based on the method of Corey et al. (10). To a vigorously stirred mixture of **12*a*** (2.41 g, 15.3mmol) and K_2CO_3 (12.72 g, 92.0 mmol) in acetone (35 mL) was added methyl chloroformate (5.80 g, 61.4 mmol). After 2 days at room temperature, the solution was filtered and the solvent was evaporated. Radial chromatography, using 10–60% ethyl acetate in hexane, followed by drying over $MgSO_4$, afforded **12*j*** as a colourless oil (50% yield); IR (CCl_4) cm^{-1}: 1742s (C═O), 1578w (N═N), 1448m, 1380s, 1280m, 1232m, 1211s, 1159w, 1117m, 1063m, 1040m, 985w, 935w, 911w, 845w; ^1H NMR (200 MHz, $CDCl_3$, slow exchange) δ: 1.47 (s, 3H, CCH_3), 1.70 (br s, 3H, CCH_3), 3.67 (br s, 3H, OCH_3), 3.75–4.05 (um, 2H, NCH_2), 4.18–4.42 (m, 2H, OCH_2); ^{13}C NMR (50 MHz, $CDCl_3$, some peaks are broad due to slow exchange) δ: 22.15 (CCH_3), 25.24 (CCH_3), 45.14 (NCH_2), 52.62 (OCH_3), 65.34 (OCH_2), 120.16 (C2), 132.86 (C5), 152.27 (C═O); routine mass spectrum not useful.

*3,4,9-Triaza-2,2-dimethyl-1,6-dioxa-9-phenylsulfonyl-spiro[4.4]non-3-ene (**12**k)*

Oxadiazoline **12*a*** (1.50 g, 9.54 mmol) in CH_2Cl_2 (25 mL) was stirred at room temperature for 13 days with benzenesulfonyl chloride (2.00 g, 11.3 mmol) in the presence of pyridine (0.94 g, 12 mmol). Aqueous $NaHCO_3$ (5%, ca. 25 mL) was then added, and the mixture was stirred vigorously for 20 min. The organic layer was separated, and the aqueous layer was extracted with 4 portions of CH_2Cl_2. After drying the combined organic layers ($MgSO_4$) and evaporating the solvent, the crude product was dissolved in diethyl ether – methanol and decanted, to leave most of the undissolved pyridine behind. White crystals of **12*k*** that precipitated from the ether–methanol solution after several days in the refrigerator were collected, washed well with ether and cold methanol, and kept in a desiccator (46% yield); IR (KBr) cm^{-1}: 1576w (N═N), 1481w, 1448m, 1359s (NSO_2), 1270m, 1227m, 1211m, 1169s (NSO_2), 1125s, 1053m, 1022m, 976w, 914m, 836m, 760w, 728m, 687m, 614m, 573m; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.46 (s, 3H, CH_3), 1.81 (s, 3H, CH_3), 3.60–3.87 (m, 2H, NCH_2), 4.14–4.35 (m, 2H, OCH_2), 7.50–7.64 (m, 3H, Ar-*m,p*), 7.89–7.96 (m, 2H, Ar-*o*); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 22.36 (CH_3), 25.14 (CH_3), 46.47 (NCH_2), 65.23 (OCH_2), 120.46 (C2), 127.96 (Ar C2, C6), 129.02 (Ar C3, C5), 133.30 (Ar C4 and oxadiazoline C5, overlapped), 138.57 (Ar C1); MS (EI) *m/z*: 281 (2), 228 (15), 210 (31), 183 (4), 141 ($PhSO_2^+$, 37), 117 (26), 88 (50), 77 (100), 51 (26); MS (CI, NH_3) *m/z*: 315 $(M+NH_4)^+$.

*5,14,15-Triaza-5-methyl-1,7-dioxadispiro[5.1.5.2]pentadec-14-ene (**13**c)*

Prepared essentially as for **12***a*, from 2.36 g (10.4 mmol) of **9** (n = 3, R^1R^1 = $(CH_2)_5$, R^2 = Me) and 3.51 g (10.9 mmol) of $PhI(OAc)_2$, in a total of 300 mL of CH_2Cl_2. Purification of the resulting oil by column chromatography on silica (20% ethyl acetate in hexane) resulted in slightly impure **13***c*, which was further purified by radial chromatography, using the same solvent mixture, to give 0.82 g (35%) of **13***c* as a pale yellow oil; IR (CCl_4) cm^{-1}: 1715w, 1572w (N=N), 1478m, 1450m, 1377m, 1346w, 1306m, 1282m, 1241s, 1218m, 1157m, 1142m, 1103s, 1061m, 1023w, 997m, 953w, 908m, 880m, 842w; ^1H NMR (300 MHz, $CDCl_3$) δ: 1.40–2.10 (m), 2.30–2.36 (m) (12H, CCH_2C), 2.14 (s, 3H, CH_3), 2.90–3.05 (m, 1H, NCH_2), 3.23–3.34 (m, 1H, NCH_2), 3.93–4.05 (m, 1H, OCH_2), 4.14–4.27 (m, 1H, OCH_2); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 22.53, 22.93, 24.48, 24.75, 32.69, 34.54, 37.11, 49.61 (NCH_2), 64.22 (OCH_2), 120.27 (C2), 132.94 (C5); MS: 197 ($[M - N_2]^{\bullet+}$ ($C_{11}H_{19}NO_2$), 8), 116 ($[M - N_2 - C_6H_9^{\bullet}]^+$, 25), 115 ($[M - N_2 - C_6H_{10}]^{\bullet+}$, 40), 114 (17), 99 ($[M - N_2 - C_6H_{10}O]^{\bullet+}$ (C_5H_9NO), 48), 98 ((C_5H_8NO), 100), 88 (25), 44 ((C_2H_6N), 57), 42 (59), 28 (25).

*3,4,10-Triaza-10-benzoyl-2,2-dimethyl-1,6-dioxaspiro[4,5]-dec-3-ene (**13**d)*

$PhI(OAc)_2$ (6.14g, 19.1 mmol), dissolved in 75 mL of methanol, was added dropwise to an ice-cold solution of **9** (n = 3, R^1 = CH_3, R^2 = H) (3.00 g, 17.3 mmol) in 75 mL of methanol, under nitrogen. After completion of the addition (1.5 h), the solution was stirred at room temperature for 24 h. Evaporation of the solvent gave an oil, which was redissolved in CH_2Cl_2 and washed successively with aqueous $NaHCO_3$ (5%) and water. The crude product containing **13***a*, obtained after drying ($MgSO_4$) the solution and evaporating the solvent, was redissolved in 20 mL of CH_2Cl_2, together with pyridine (1.44 g, 18.2 mmol), and benzoyl chloride (2.46 g, 17.5 mmol) was added dropwise. After 1.5 h at room temperature, the usual work-up was performed (see **12***f*). Separation of the crude mixture by column chromatography, using first 5% and then 10% ethyl acetate in hexane, gave an oil (ca. 15%) that proved to be a mixture of **13***d* and, possibly, an isomer that could not be identified. Pure **13***d* crystallized out of a methanol – diethyl ether solution kept at ca. −10°C. White solid, mp ca. 94°C (dec.); IR (CCl_4) cm^{-1}: 1678s (C=O), 1601w, 1581w (N=N), 1492w, 1448w, 1380s, 1279m, 1213s, 1156m, 1096s, 984w, 949w, 912m, 849w, 700m; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.53 (s, 3H, CH_3), 1.70 (s, 3H, CH_3), 1.95–2.31 (m, 2H, CCH_2C), 3.59–3.93 (m, 2H, NCH_2), 3.98–4.30 (m, 2H, OCH_2), 7.30–7.64 (m, 5H, Ar); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 21.87 (CH_3), 23.59 (CCH_2C), 25.20 (CH_3), 43.02 (NCH_2), 60.79 (OCH_2), 121.22 (C2), 127.40 (Ar C2, C6), 128.38 (Ar C3, C5), 129.01 (C5), 130.64 (Ar C4), 135.29 (Ar C1), 170.92 (C=O); MS: 247 ($[M - N_2]^{\bullet+}$, 0.4), 206 ($[M - N_2 - C_3H_5^{\bullet}]^+$, 1), 189 ($[M - N_2 - C_3H_6O]^{\bullet+}$ ($C_{11}H_{11}NO_2$), 17), 188 (($C_{11}H_{10}NO_2$), 50), 161 (10), 160 (29), 145 (40), 119 (10), 117 (17), 105 ($[C_6H_5CO^+]$, 100), 102 (15), 77 ($[C_6H_5^+]$, 35).

*5,14,15-Triaza-5-benzoyl-1,7-dioxadispiro[5.1.5.2]pentadec-14-ene (**13**e)*

After oxidation of **9** (n = 3, R^1R^1 = $(CH_2)_5$, R^2 = H) (2.50 g, 11.7 mmol) with $PhI(OAc)_2$ (4.09 g, 12.7 mmol), carried out as for **12***a*, the resulting mixture containing **13***b* was treated with benzoyl chloride (1.58 g, 11.2 mmol) in 22 mL of benzene, in the presence of pyridine (1.16 g, 14.7 mmol), as described for **12***f*. As crystallization of **13***e* from the crude could not be induced, it was purified by repeated chromatography and obtained, in ca. 8% yield (from **9**), as a gummy mass that only partially crystallized in the refrigerator over several weeks; IR (CCl_4) cm^{-1}: 1678s (C=O), 1602w, 1580w (N=N), 1493w, 1448m, 1378s, 1263m, 1218m, 1157m, 1087s, 976w, 948w, 895m, 847w, 700m; ^1H NMR (300 MHz, $CDCl_3$) δ: 1.40–1.75 (m, 5H), 1.75–2.00 (m, 4H), 2.00–2.27 (m, 3H), 3.70–3.80 (m, 1H, NCH_2), 3.80–3.90 (m, 1H, NCH_2), 4.00–4.14 (m, 1H, OCH_2), 4.14–4.28 (m, 1H, OCH_2), 7.36–7.60 (m, 5H, Ar); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 22.73, 23.22, 23.65, 24.86, 30.93, 34.72, 43.06 (NCH_2), 60.85 (OCH_2), 123.16 (C2), 127.49 (Ar C2, C6), 128.00 (C5), 128.35 (Ar C3, C5), 130.61 (Ar C4), 135.46 (Ar C1), 170.96 (C=O); MS (EI) *m/z*: 206 (3), 188 (30), 160 (13), 145 (15), 105 ($PhCO^+$, 100), 84 (18), 77 (32), 67 (38); MS (CI, NH_3) *m/z*: 316 $(M + H)^+$.

General methods for thermolyses

All thermolyses were carried out by immersing the sealed tubes containing the samples in a constant-temperature oil bath at 90.0 ± 0.2°C for 24 h (or until complete decomposition of the oxadiazolines; see Table 1). Spectroscopic data of products isolated from large-scale experiments (or of authentic compounds from other sources) were used for peak assignments in the spectra of thermolysates from NMR-scale experiments.

Thermolysis rate constants

The rates of decomposition of the oxadiazolines were monitored by ^1H NMR spectroscopy at 300 MHz. Samples typically containing 1.25×10^{-4} mol of an oxadiazoline and 7 mg of *p*-xylene, used as an internal standard for integration, in 0.5 mL of C_6D_6 were degassed and sealed into medium-walled NMR tubes. At appropriate time intervals during thermolysis, the tubes were removed from the thermolysis bath and quickly chilled to room temperature to record ^1H NMR spectra. Linear regression analyses were performed for the plots of $\ln(I/I_0)$ vs. time, where I and I_0 are the normalized integrals of a given resonance at time t and at time zero, respectively. The first-order decomposition rate constants were obtained from the slopes of the calculated best lines forced to pass through the origin. The thermolysis data and regression analysis results are available as supplementary material.[14]

Determination of product yields

For small-scale thermolysis experiments done in sealed NMR tubes, product yields were determined by comparison of the integrals of appropriate ^1H NMR resonances, after completion of thermolysis, to the integrals of the oxadiazoline peaks at t = 0, using internal *p*-xylene for normalization. Yields from thermolyses in the presence of phenol were determined in a similar way from samples containing 1.0×10^{-4} mol of oxadiazoline and 1.25 equivalents of phenol in ca. 0.5 mL of

[14] These supplementary data can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

C_6D_6; experimental details of the isolation of these carbene + phenol adducts, and some related compounds, are in the following paper. Typically, for larger scale thermolyses, a benzene solution (10 mL) of the oxadiazoline (0.5 mmol) was placed in a resealable thermolysis tube that was evacuated before thermolysis.

Thermolysis of 12*b*

Acetone azine: ^{1}H NMR (200 MHz, C_6D_6) δ: 1.86 (s, 6H), 1.89 (s, 6H); MS (EI) *m/z*: 112 (M^+, 25), 97 (79), 70 (17), 56 (100), 39 (58), 28 (17).

*3-Methyl-2-oxazolidinone (**18**b) (ref. 25)*: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.89 (s, 3H), 3.51–3.63 (m, 2H), 4.26–4.38 (m, 2H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 31.14 (CH_3), 46.85 (NCH_2), 61.45 (OCH_2), 158.76 (C=O); MS (EI) *m/z*: 101 (M^+, 17), 72 (2), 56 (25), 42 (100), 28 (33).

2-Phenoxypropane (ref. 26): MS (EI) *m/z*: 136 (M^+, 15), 121 (4), 107 (2), 94 (100), 77 (15), 66 (62), 51 (16), 39 (59), 27 (17).

Bromination of ethylene and propene
After thermolysis of 98 mg (0.57 mmol) of **12*b*** in 10 mL of benzene, the thermolysis tube was immersed in liquid nitrogen for several minutes. About 1 mL of bromine solution (0.5 M, in CCl_4) was then added, the tube was sealed again, and the contents were allowed to thaw. After mixing the solution at room temperature, the tube was reopened and the solution was washed with two portions of aqueous $NaHCO_3$ (5%) and one of water. Analysis of the resulting solution by GC–MS demonstrated the presence of both 1,2-dibromoethane and 1,2-dibromopropane, their spectra matching those from authentic samples.

Thermolysis of 2-diazopropane
Two medium-walled NMR tubes, each containing ca. 22 mg (0.14 mmol) of 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (4) and ca. 0.5 mL benzene-d_6, were sealed after three freeze–pump–thaw cycles. Both tubes were irradiated with 300 nm light in a Rayonet apparatus for 50 min. One of the tubes was then immersed in an oil bath at 90°C for 20 h, while the other tube was kept at room temperature in the dark. Within experimental error, the final product ratios in the two samples were identical. Integration of the resonances of acetone azine (1.86 and 1.89 ppm), relative to that of dimethylcarbonate (3.38 ppm), indicated that 86% of the 2-diazopropane had produced acetone azine, assuming equimolar amounts of dimethylcarbonate and 2-diazopropane were generated in the photolysis of the oxadiazoline (27). An unidentified product giving rise to two singlets (1.64 and 1.68 ppm) accounted for most of the difference, while propene was observed only in trace quantities.

*Spiro-fused hydantoin **22***
Oxadiazoline **12*b*** (102 mg, 0.60 mmol) was thermolysed with MeNCO (85 mg, 1.5 mmol) in 10 mL of benzene. The major product, **22**, was purified by radial chromatography, using 30–40% ethyl acetate in hexane (44% yield). White solid, mp 71–73°C; IR (CCl_4) cm^{-1}: 1785m (C=O), 1729s (C=O), 1461s, 1419m, 1392m, 1299m, 1267w, 1231w, 1184w, 1144w, 1079s, 1015w, 993w, 973w, 949w; ^{1}H NMR (200 MHz, C_6D_6) δ: 1.97 (s, 3H, oxazolidine NCH_3), 2.65 (s, 3H, CH_3), 2.73 (s, 3H, CH_3), ca. 2.52–2.77 (overlapped m, 1H, NCH_2), 3.10–3.27 (m, 1H, NCH_2), 3.57–3.72 (m, 1H, OCH_2), 3.77–3.90 (m, 1H, OCH_2); ^{13}C NMR (75 MHz, C_6D_6) δ: 23.06 (CH_3), 23.43 (CH_3), 32.69 (CH_3), 51.18 (NCH_2), 65.17 (OCH_2), 101.67 (spiro C), 155.33 (N*C*(O)N), 170.24 (NC(O)C); MS (EI) *m/z*: 199 (M^+, 1), 171 (M − CO, 4), 154 (16), 141 (4), 127 (9), 113 (92), 99 (2), 86 (21), 70 (36), 57 (100), 42 (71), 28 (36); MS (CI, NH_3) *m/z*: 200 (M + H)$^+$. Anal. calcd. for $C_8H_{13}N_3O$: C 48.23, H 6.58, N 21.09; found: C 48.03, H 6.81, N 21.00.

*Dimethyl 3,3-dimethyl-3*H*-pyrazole-4,5-dicarboxylate (**23**) (ref. 19)*
Oxadiazoline **12*b*** (98 mg, 0.58 mmol) was thermolysed with dimethyl acetylenedicarboxylate (254 mg, 1.79 mmol) in 10 mL of benzene. A complex of mixture of products was obtained, from which **23** could be separated by radial chromatography. IR (CCl_4) cm^{-1}: 1732s (C=O), 1647w, 1438w, 1334w, 1264s, 1198w, 1167w, 1114w, 1033w, 909m; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.58 (s, 6H), 3.92 (s, 3H), 4.00 (s, 3H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 20.86 (C(CH_3)$_2$), 52.98 (2 × OCH_3, coincident), 97.46 (C3), 144.68 (C4), 153.56 (C5), 160.81 (C=O), 162.97 (C=O); MS (EI) *m/z*: 183 (3), 169 (3), 152 (33), 141 (50), 125 (36), 109 (34), 93 (55), 79 (65), 67 (100), 59 (43), 53 (31), 39 (50), 29 (18).

Thermolysis of 13*c*

Cyclohexanone azine: MS (EI) *m/z*: 192 (M^+, 60), 163 (57), 149 (100), 136 (59), 124 (26), 110 (69), 96 (43), 81 (24), 67 (45), 55 (57), 41 (93), 27 (27).

*3-Methyltetrahydro-2*H*-1,3-oxazin-2-one (**19**c) (ref. 28)*: ^{1}H NMR (300 MHz, C_6D_6) δ: 1.10–1.20 (m, 2H), 2.40 (t, ^3J = 6.3 Hz, 2H), 2.68 (s, 3H), 3.58 (t, ^3J = 5.3 Hz, 2H); MS (EI) *m/z*: 115 (M^+, 21), 87 (13), 70 (13), 56 (27), 42 (100), 28 (27).

Phenoxycyclohexane (ref. 29): MS (EI) *m/z*: 176 (M^+, 10), 94 (100), 77 (10), 65 (15), 55 (14), 51 (7), 41 (14), 39 (22), 27 (5).

Thermolysis of 12*f*
Oxadiazoline **12*f*** was thermolysed several times in order to obtain the data that follow. The major product, **26*a***, was formed in almost quantitative yield. Attempted purification by chromatography resulted in its complete decomposition. Small amounts of essentially pure crystals could be obtained by dissolving the crude product mixture in diethyl ether, followed by removal of most of the solvent on a rotary evaporator. Similarly, its sole hydrolysis product, **28**, which was obtained by leaving the crude product in contact with a few drops of water over several days, did not survive chromatography. However, pure **28** precipitated from a benzene solution left at or below room temperature over a few weeks. Of the minor nonvolatile products resulting from thermolysis of **12*f***, benzoyl isocyanate was detected by GC–MS (and matched an authentic sample); **18*f*** was repeatedly isolated by radial chromatography from various samples of thermolysed **12*f***; benzamide and **25**, detected by GC–MS when **12*f*** was thermolysed

without added trap, were both isolated by chromatography from the thermolysis of **12***f* in the presence of water.

Thermolysis of ***12****f in the presence of water*
Oxadiazoline **12***f* (224 mg, 0.86 mmol) was thermolysed in 100 mL benzene, with about 15 drops of water. Repeated separation by radial chromatography, using ethyl acetate – hexane in various proportions, afforded about 21 mg (20%) of benzamide and 92 mg (56%) of **25**.

Thermolysis of ***12****f with benzoyl isocyanate*
Oxadiazoline **12***f* (118 mg, 0.45 mmol) was thermolysed with benzoyl isocyanate (110 mg, 0.75 mmol), prepared as described by Speziale and Smith (30), in 10 mL of benzene. Spectroscopic data (GC–MS, ^{1}H and ^{13}C NMR in both C_6D_6 and $CDCl_3$) for the crude thermolysate were similar to those obtained from thermolyses of **12***f* without added trap, indicating formation of **26***a* as the major product.

*3-Benzoyl-2-oxazolidinone (****18****f) (ref. 31)*: ^{1}H NMR (300 MHz, $CDCl_3$) δ: 4.19 (t, ^3J = 7.8 Hz, 2H), 4.51 (t, ^3J = 7.8 Hz, 2H), 7.40–7.50 (m, 2H), 7.51–7.60 (m, 1H), 7.62–7.70 (m, 2H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 43.71 (NCH_2), 62.22 (OCH_2), 127.87 (Ar C2, C6), 129.10 (Ar C3, C5), 132.43 (Ar C4) (Ar C1 and C=O peaks not observed due to low S/N); MS (EI) *m/z*: 191 (M^+, 15), 163 (3), 147 (3), 121 (1), 105 ($PhCO^+$, 100), 91 (1), 77 (82), 63 (2), 51 (35), 42 (5), 28(6).

*Spiro-fused 4(5*H*)-oxazolone* ***26****a*: IR (crude product, CCl_4) cm^{-1}: 1783s (oxazolone C=O), 1736w, 1677s (PhC=O), 1605m, 1558s (C=N), 1492w, 1451m, 1384s, 1274w, 1196m, 1170m, 1141m, 1100w, 1055w, 854w; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 4.00–4.12 (m, 2H, NCH_2), 4.47–4.59 (m, 2H, OCH_2), 7.25–7.80 (m, 8H, Ar), 8.21–8.31 (m, 2H, PhCO-*o*); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 47.14 (NCH_2), 68.43 (OCH_2), 108.38 (spiro C), 125.35 (Ar), 127.18 (Ar), (127.59?, Ar), 128.32 (Ar), 128.70 (Ar), 130.21 (Ar), 131.25 (Ar), 135.60 (Ar), 167.73 (PhC=O), 181.80 and 184.13 (oxazolone C2 and C4); MS (EI) *m/z*: 322 (M^+, 1), 175 (20), 147 (9), 131 (12), 105 ($PhCO^+$, 100), 83 (53), 78 (57), 49 (100); MS (CI, NH_3) *m/z*: 323 $(M + H)^+$.

Oxalic acid derivative ***28***: White solid, mp ca. 170°C; IR (KBr) cm^{-1}: 3453m (NH), 3306br (NH), 1753s, 1721m, 1682m, 1641s, 1602w, 1578w, 1536s, 1464m, 1427w, 1399m, 1365m, 1318m, 1250m, 1208m, 1182s, 1121w, 1021m, 972w, 909w, 799w, 773w, 741w, 700s; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.87–3.97 (m, 2H, NCH_2), 4.59 (t, ^3J = 4.9 Hz, 2H, OCH_2), 7.05 (br s, 1H, NH), 7.30–7.60 (m, 5H, Ar), 7.63–7.73 (m, 1H, Ar), 7.75–7.83 (m, 2H, PhCO-*o*), 7.86–7.94 (m, 2H, PhCO-*o*), 9.64 (br s, 1H, NH); ^{13}C NMR (50 MHz, CD_3OD, slow exchange) δ: 39.68 (NCH_2), 65.95 and 66.20 (OCH_2), 128.31 (Ar C2, C6), 128.64 (Ar C2, C6), 129.51 (2 × Ar C3, C5), 132.76 (Ar C4), 132.91 (2 × Ar C4), 134.96 (Ar C1), 135.43 (Ar C1), 158.81 (oxalyl C=O), 159.48 (oxalyl C=O), 170.61 (PhC=O), 172.41 (PhC=O); MS (EI) *m/z*: 164 (17), 147 (42), 117 (32), 105 ($PhCO^+$, 100), 77 (43), 51 (22), 44 (11); MS (CI, NH_3) *m/z*: 341 $(M + H)^+$; a satisfactory elemental analysis could not be obtained.

N-*[2-(Formyloxy)ethyl]benzamide (****25****) (ref. 32)*: White solid, mp 59–60°C (slightly impure sample); IR (CCl_4) cm^{-1}: 3465br (NH), 1735s (OC=O), 1677s (NC=O), 1517m, 1486w, 1302m, 1174s, 909w; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.77 (q, ^3J = 5.4 Hz, 2H, NCH_2), 4.39 (t, ^3J = 5.2 Hz, 2H, OCH_2), 6.55 (br s, 1H, NH), 7.35–7.60 (m, 3H, Ar-*m,p*), 7.72–7.84 (m, 2H, Ar-*o*), 8.11 (s, 1H, C(O)H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 38.94 (NCH_2), 62.58 (OCH_2), 126.88 (Ar C2, C6), 128.41 (Ar C3, C5), 131.50 (Ar C4), 133.98 (Ar C1), 160.89 (O-C=O), 167.79 (N-C=O); MS (EI) *m/z*: 193 (M^+, 5), 164 (3), 147 (19), 134 (5), 105 ($PhCO^+$, 100), 77 (58), 51 (22), 31 (8); MS (CI, NH_3) *m/z*: 211 $(M + NH_3)^+$, 194 $(M + H)^+$.

*Spiro-fused 4(5*H*)-oxazolone* ***26****b*
Oxadiazoline **12***d* (90 mg, 0.45 mmol) was thermolysed with benzoyl isocyanate (124 mg, 0.84 mmol) in 10 mL of benzene. GC–MS, as well as ^{1}H and ^{13}C spectra of the crude thermolysate, indicated that **26***b* was the major product. IR (CCl_4, major bands only) cm^{-1}: 1782 (oxazolone C=O), 1603, 1557 (C=N); ^{1}H NMR (200 MHz, $CDCl_3$, possible slow exchange) δ: 2.13 (s, ~3H, CH_3), 3.90–4.07 (m, 2H, NCH_2), 4.40–4.64 (m, 2H, OCH_2), ca. 7.34–7.76 (m, 3H, Ar-*m,p*), 8.13–8.27 (m, 2H, Ar-*o*); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 22.42 (CH_3), 45.76 (NCH_2), 68.30 (OCH_2), 108.02 (spiro C), 125.51 (Ar C2, C6), 128.77 (Ar C3, C5), 130.31 (Ar C4), 135.63 (Ar C1), 168.18 (PhC=O), 181.67 and 184.11 (oxazolone C2 and C4).

*5,5-Dimethoxy-2-phenyl-4(5*H*)-oxazolone (****26****c)*
2,2-Dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (4), **27**, (85 mg, 0.53 mmol) was thermolysed at 110°C for 24 h with benzoyl isocyanate (143 mg, 0.97 mmol) in 10 mL of benzene. GC–MS, as well as ^{1}H and ^{13}C spectra of the thermolysate, indicated that **26***c* was the major product. IR (CCl_4, major bands only) cm^{-1}: 1778 (C=O), 1734, 1600, 1553 (C=N); ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.60 (s, 6H, OCH_3), ca. 7.33–7.80 (m, 3H, Ar-*m,p*), 8.21–8.35 (m, 2H, Ar-*o*); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 52.22 (OCH_3), 114.02 (C5 oxazolone), 125.15 (Ar), 128.96 (Ar), 130.27 (Ar), 136.02 (Ar), 181.45 and 184.62 (oxazolone C2 and C4); MS (EI) *m/z*: 221 (M^+, 2), 193 (1), 190 (1), 162 (5), 147 (2), 131 (8), 118 (9), 103 (100), 91 (3), 77 (37), 59 (35), 51 (13), 39 (2), 29 (4).

Control "thermolysis" of benzoyl isocyanate
Slightly impure benzoyl isocyanate (110 mg, 0.75 mmol) was dissolved in 10 mL of dry benzene and subjected to the usual thermolysis conditions. GC–MS, as well as ^{1}H and ^{13}C spectra of the crude, sparingly soluble, product mixture indicated that very little benzoyl isocyanate remained (detected only by GC–MS, not by ^{13}C NMR). Inspection of the ^{13}C spectrum demonstrated the presence of benzamide and of *N,N′*-dibenzoylurea. The latter was identified by comparison with a pure sample obtained by recrystallization (ethyl acetate) of a completely decomposed sample of benzoyl isocyanate.

N,N′-*Dibenzoylurea*: White solid, mp 213–217°C (lit. (33) mp 212–216°C); IR (KBr) cm^{-1}: 3431br (NH), 1757s (C=O), 1670m (C=O), 1475s, 1262m, 1197m, 775w; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.50–7.75 (m, 6H, Ar-*m,p*), 7.97–8.12 (m, 4H, Ar-*o*) (the NH signals were not visible); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 128.09 (Ar C2, C6), 128.93 (Ar C3, C5), 131.90 (Ar C4), 133.53 (Ar C1), 150.42 (NC(O)N), 167.16 (PhCO).

Thermolysis of 13*d,e*

*3-Benzoyltetrahydro-2*H*-1,3-oxazin-2-one (**19**d) (ref. 31)*: MS (EI) *m/z*: 205 (M^+, 15), 177 (28), 105 ($PhCO^+$, 100), 77 (60), 51 (22), 28 (8).

Thermolysis of 12*k*

*Oxazolidine **29***

The hygroscopic oxadiazoline **12***k* was thermolysed in a benzene solution that visibly contained some water. Separation of the products by radial chromatography, using 10–40% ethyl acetate in hexane, gave **18***k* (see below) and **29**: IR (CCl_4) cm^{-1}: 1730s, 1476w, 1449w, 1412w, 1366s (NSO_2), 1270w, 1175s (NSO_2), 1092w, 999w, 937w, 909w; ^1H NMR (300 MHz, $CDCl_3$) δ: 3.29–3.39 (m, 2H, NCH_2), 3.40–3.54 (m, 1H, OCH_2), 3.55–3.75 (m, 2H, NCH_2), 4.01–4.12 (m, 1H, OCH_2), 4.21–4.40 (m, 2H, OCH_2), 6.60 (s, 1H, oxazolidine C(2)H), 7.48–7.78 (m, ca. 6H, Ar-*m,p*), 7.90–8.02 (m, ca. 5H, Ar-*o*, C(O)H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 40.47 (NCH_2), 46.61 (NCH_2), 62.08 (OCH_2), 65.72 (OCH_2), 96.33 (oxazolidine C2), 127.83 (Ar C2, C6), 127.97 (Ar C2, C6), 129.00 (Ar C3, C5), 129.57 (Ar C3, C5), 133.16 (Ar C4), 133.80 (Ar C4), 136.61 (Ar C1), 139.19 (Ar C1), 160.61 (C═O); MS (EI) *m/z*: 212 (34), 141 ($PhSO_2^+$, 30), 77 (100); MS (CI, NH_3) *m/z*: 459 $(M + NH_4)^+$, 442 $(M + H)^+$.

*3-(Phenylsulfonyl)-2-oxazolidinone (**18**k) (ref. 31)*: IR (CCl_4) cm^{-1}: 1801s, 1480w, 1450w, 1382m (NSO_2), 1264w, 1180s (NSO_2), 1147s, 1094w, 1050w, 909w; ^1H NMR (200 MHz, $CDCl_3$) δ: 4.00–4.15 (m, 2H), 4.32–4.46 (m, 2H), 7.50–7.80 (m, 3H), 8.02–8.13 (m, 2H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 44.61 (NCH_2), 62.28 (OCH_2), 128.26 (Ar C2, C6), 129.30 (Ar C3, C5), 134.55 (Ar C4), 136.81 (Ar C1), 151.91 (C═O); MS (EI) *m/z*: 163 (30), 141 ($PhSO_2^+$, 12), 118 (8), 104 (53), 91 (6), 77 (100), 56 (6), 51 (28), 28 (2); MS (CI, NH_3) *m/z*: 245 $(M + NH_4)^+$.

N-*Formyl*-N-*(2-hydroxyethyl)benzenesulfonamide (**30**)*: IR (CCl_4) cm^{-1}: 3425–3000 (OH), 1736s (C═O), 1449w, 1417w, 1345m (NSO_2), 1264m, 1165s (NSO_2), 1097m, 1027w, 950w, 909w, 858w; ^1H NMR (200 MHz, $CDCl_3$, slow exchange) δ: 3.20-3.36 (m, 2H, NCH_2), 4.04–4.26 (m, 2H, OCH_2), 5.03 (br s, 1H, OH), 7.44–7.93 (m, ca. 6H, Ar and C(O)H); ^{13}C NMR (50 MHz, $CDCl_3$, only peaks from major conformer are given) δ: 41.99 (NCH_2), 62.41 (OCH_2), 126.99 (Ar C2, C6), 129.24 (Ar C3, C5), 132.91 (Ar C4), 139.83 (Ar C1), 160.42 (C═O); MS (EI) *m/z*: 183 (16), 170 (43), 141 ($PhSO_2^+$, 57), 119 (6), 92 (4), 77 (100), 51 (22), 31 (5); MS (CI, NH_3) *m/z*: 247 $(M + NH_4)^+$, 230 $(M + H)^+$.

Acknowledgements

This work was supported by the Natural Sciences and Engineering Research Council (NSERC) of Canada. P.C. was the recipient of an Ontario Graduate Scholarship. We thank Prof. J.K. Terlouw for special mass spectrometric experiments on some oxadiazolines. We also gratefully acknowledge the assistance of Drs. Donald Hughes and Richard Smith and of Mssrs. Brian Sayer and Fajar Ramelan for some aspects of the NMR spectroscopy and the mass spectrometry. We also thank Mr. Chris Barr for the spectral simulation on **12***b*.

Chemistry of cyclic aminooxycarbenes

Philippe Couture and John Warkentin

Abstract: A series of oxazolidin-2-ylidenes and one tetrahydro-1,3-oxazin-2-ylidene, generated by thermolysis of Δ^3-1,3,4-oxadiazolines in benzene at 90°C, were intercepted by insertion into the OH bond of phenols. In two cases the initial products rearranged to *N*-(2-aryloxyethyl)-*N*-methylformamides. The activation energy for rotation about the amide CN bond of those ultimate products was measured as 20.4 kcal/mol. The aminooxycarbenes reacted with two equivalents of methyl or phenyl isocyanate to give spiro-fused hydantoins. Major products from the reactions of the *N*-carbonyl carbenes with dimethyl acetylenedicarboxylate or with methyl propiolate were 2-oxazolines resulting from apparent acyl transfers from N to C in the proposed dipolar intermediates; minor products of 1:2 (carbene:trap) stoichiometry were also observed.

Key words: nucleophilic carbene, aminooxycarbene, oxadiazoline, amide rotation, oxazolidine.

Résumé : Une série d'oxazolidin-2-ylidènes et un tétrahydro-1,3-oxazin-2-ylidène, générés par thermolyse de Δ^3-1,3,4-oxadiazolines dans le benzène à 90°C, ont pu être interceptés par insertion dans la liaison OH de phénols. Dans deux cas, les produits initiaux se transposent en *N*-(2-aryloxyéthyl)-*N*-méthylformamides. On a établi que l'énergie autour de la liaison C—N de l'amide des produits ultimes est égale à 20,4 kcal/mol. Les aminooxycarbènes réagissent avec deux équivalents d'isocyanate de méthyle ou de phényle pour donner des hydantoïnes à jonction spiro. Les produits principaux des réactions des *N*-carbonylcarbènes avec l'acétylènedicarboxylate de diméthyle ou avec le propiolate de méthyle sont des 2-oxazolines provenant de transferts apparents d'acyle du N au C dans les intermédiaires dipolaires suggérés; on a aussi observé la présence de produits mineurs de stoechiométrie 1 : 2 (carbène : piège).

Mots clés : carbène nucléophile, aminooxycarbène, oxadiazoline, rotation d'amide, oxazolidine.

Introduction

The driving force behind carbene reactions, in general, is the completion of the octet of electrons at the electron-deficient carbon. It is therefore expected that carbenes should behave as electrophiles, and react more rapidly with electron-rich substrates than with electron-deficient ones. Indeed, relative reactivity measurements carried out by Skell and Garner (1) and Doering and Henderson (2) in the late 1950s demonstrated such electrophilic natures for both CBr_2 and CCl_2. Since then, however, the selection of carbenes available has grown tremendously, and "philicity" in singlet carbenes now extends from the traditional electrophiles to the more unconventional ambiphiles and nucleophiles (3).

The intrinsic need to acquire a completed valence shell is not as strong in carbenes bearing one or two π-donor substituents on the carbene centre. Conjugative donation to the formally vacant carbenic *p*-orbital by heteroatoms such as N and O stabilizes the singlet state substantially and gives the carbene dipolar character (Fig. 1). Such carbenes react as nucleophiles or ambiphiles (3*b*). Dimethoxycarbene, the archetypal nucleophilic carbene, is generally unreactive towards electron-rich alkenes, but it adds readily to chloroacrylonitrile (4) and other electron-deficient alkenes (5).

Fig. 1.

Carbene reactivity thus spans an enormous range. For instance, whereas simple alkylcarbenes are notoriously difficult to study because of rapid intramolecular reactions (6), methoxymethylcarbene undergoes intermolecular cycloaddition reactions with a variety of alkenes (7). Dialkoxycarbenes do not react with toluene or benzene by either cyclopropanation or by C—H insertion, but dimerize in such solvents (8). This stabilization of singlet carbenes by substituents reaches an extreme in the case of the stable diaminocarbenes first isolated by Arduengo et al. (9).

Carbenes in which the two substituents are aza, oxa, or thia groups, or any permutations of such groups, are carbonyl group equivalents and, as such, they have considerable synthetic potential. One strategy for optimizing their utility involves the tuning of their reactivity by using different combinations of OR, NRR′, and SR as carbene substituents. The aza substituent is the most versatile because of the two variable moieties R and R′. In this paper, we present some results on the intermolecular reactivity of carbenes possessing the combination of OR and NRR′ substituents.[2] Aminooxycarbenes have only rarely been reported (10), and little is there-

fore known about their properties. In particular, we demonstrate herein that fragmentation of 5-membered aminooxycarbenes **1** (n = 2) to ethylene and an isocyanate (11) is sufficiently slow to allow the carbenes to participate in bimolecular reactions with a variety of substrates, in contrast to the dioxy (10*d*, 12) and dithio (13) analogues.

Methods, results, and discussion

Aminooxycarbenes **1** were generated by thermolysis of Δ^3-1,3,4-oxadiazolines (**2**) in benzene solutions at 90°C (Scheme 1). Details of the syntheses and thermolyses of the oxadiazolines **2** have been described in the preceding paper (11) and **2***a* was also reported recently by Rigby's group (10*p*).

Insertions into OH bonds

The reaction of nucleophilic carbenes with hydroxyl compounds results in the net insertion of the carbene into the O—H bond (14). In fact, the formation of such adducts is often regarded as evidence for the intermediacy of carbenes. Trapping of carbene **1***a* was first attempted by thermolysing the precursor oxadiazoline, **2***a*, in the presence of *tert*-butyl alcohol. Instead of the expected product (**3***a*), ^{1}H NMR and GC–MS analyses of the thermolysate revealed *N*-(2-hydroxyethyl)-*N*-methylformamide (**4***a*) to be the major alcohol-derived product.[3] The same product was obtained in the thermolysis of **2***a* in the presence of benzyl alcohol.[4] These results may be explained in terms of the facile hydrolysis of the 2-oxy oxazolidines **3***a* upon exposure to the atmosphere (Scheme 2).

[a]Reported in ppm, in $CDCl_3$. Resonances from major conformers, assigned from the relative intensities of signals, are in bold, with the relative populations indicated in parentheses in the heading.

Like **3***a*, 2-aryloxyoxazolidines **3***b* and **3***c*, expected from the trapping of **1***a* with phenol and *p*-cresol, respectively, were not stable enough to survive the reaction conditions. The actual products, **3***e* and **3***d*, were again those of ring opening, presumably by reversible ion pair formation and eventual substitution by phenoxide at the OCH_2 group (Scheme 3).[5]

To confirm that the isolated products were formamides and not the novel oxazolidines **3***b* and **3***c*, NMR spectra were acquired at different temperatures to estimate the barrier, either to pyramidal inversion at nitrogen for the cases of **3***b*, *c* or to amide rotation for the cases of **3***d*, *e*. At room temperature, two sets of well-resolved signals of almost equal intensity, each one corresponding to one conformer, were observed in both the ^{1}H and ^{13}C spectra; selected NMR data are shown in Table 1.[6]

The nearly equal conformer populations allowed us to estimate the magnitude of the barrier by means of the coalescence method (15). Figure 2 shows the ^{1}H spectrum of **3***e* as a function of temperature, where coalescence of the N-methyl singlets was observed at ca. 135°C. Within experimental error, identical barriers of 20.4 kcal/mol were found for **3***d* and **3***e*.

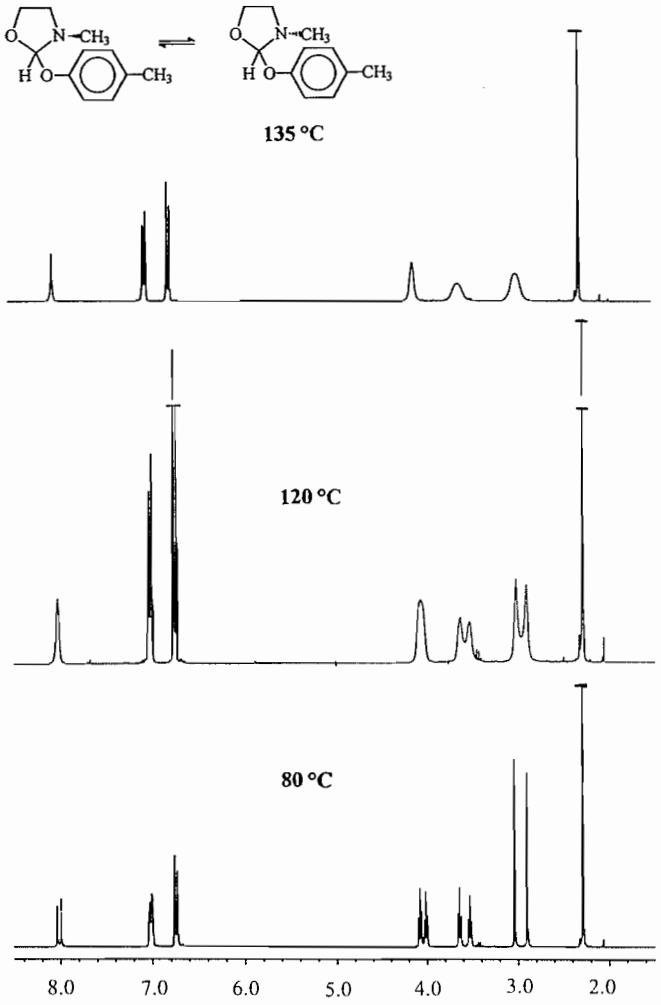
Although high inversion barriers are common in small N-heterocycles such as aziridines (16), to our knowledge only

5

[3] The identity of **4***a* was confirmed by comparison with an authentic sample.

[4] A small amount of benzyl formate was also observed, suggesting the occurrence of a competing hydrolysis mechanism.

[5] The lower yield of **3***d* is attributed to some loss of material during purification.



[6] Peak assignments were confirmed by means of double-irradiation experiments; for instance, the OCH_2 triplet at 4.07 ppm in **3***d* is coupled to the NCH_2 triplet at 3.62 ppm.

Fig. 2. 300 MHz ^{1}H spectrum of **3***c*, in hexachloro-1,3-butadiene, as a function of temperature. Spectra at 110, 130, and 140°C were also taken.

one report of such high barriers involving oxazolidines appears in the literature. Yang et al. (17) reported $\Delta G^{\ddagger}$ values of 20.7–22.3 kcal/mol for N-inversion in a series of 2-aryloxazolidines **5** unsubstituted at N. The much lower barriers in other known oxazolidines,[7] and the fact that amide rotation is associated with a barrier of ca. 20 kcal/mol, suggested that our products were amides. The ^{1}H and ^{13}C spectra (Table 1) are in agreement with the formamide assignments, **3***d*, *e*. In particular, the signal at 163 ppm would have to be assigned to C2, and that at 8.1 ppm to the proton at C2 of **3***b*, *c* if those structures were applicable. Oxazolidines with a heteroatom substituent at C2 are relatively rare, and they usually bear an electron-withdrawing group on N. In these compounds, the C2 signal typically appears near 112 ppm (ca. 50 ppm to higher field), as shown in Fig. 3 for two 2-alkoxyoxazolidines and some related compounds (18–20). Similarly, the C2 signal of 2-aryloxyoxazolidines bearing a carbonyl group on N appears near 105 ppm, and the C2-H is observed at 6.0–6.7 ppm (see **3***f–m* below). If oxazolidines **3***b*, *c* were applicable structures, they would have to exist as ion pairs in chloroform solution in order to match observed spectral characteristics. Models for both an undissociated oxazolidine (**6**) and the corresponding cation resulting from the loss of MeO^- (Fig. 4) were reported by Scholastico and co-workers (21).

N-Carbonyl oxadiazolines **2***b–f*, *h* fragmented to the corresponding aminooxycarbenes **1***b–f*, *h* (11) in high yields, as indicated by the results of trapping with phenols (Scheme 4, Table 2). *N*-Carbonyl adducts **3***f–m* were sensitive to hydrolysis and they could not be purified by chromatography. Compound **3***j* crystallized by addition of a mixture of ethyl acetate and hexane to the crude oil. Unfortunately, this procedure failed to produce crystals in most other cases. However, essentially pure products could be obtained in high yields by simply base-washing the thermolysates in order to remove the excess phenol; the benzene solutions were then dried over $MgSO_4$, and the solvent and volatile products were evaporated in vacuo to afford products **3**.

The ^{1}H and ^{13}C NMR spectra of compounds **3***f–m*, which were briefly discussed above, usually showed broad resonances and (or) more than one set of peaks due to restricted rotation about the amide CN bond. Low-intensity molecular ions in the mass spectra were generally observed, in addition to the characteristic M − OAr cations.

Hydrolysis of a sample of **3***j* kept in $CDCl_3$ cleanly produced *N*-[2-(formyloxy)ethyl]benzamide (**7***a*) and phenol over the course of a few weeks, as shown in Scheme 5.[8] Tetrahydro-1,3-oxazine **3***m* was more labile and partial hydrolysis was observable immediately after dissolving it in $CDCl_3$. In this solvent, **7***b* and phenol were the only products (Scheme 5). In contrast, the major fraction collected during an attempt to purify **3***m* by chromatography on silica consisted of a mixture of two related products, **7***b* and a material tentatively identified as **4***b*. Periodic recording of the ^{1}H NMR spectrum of this mixture, kept in $CDCl_3$, showed the gradual conversion of **4***b* into **7***b*, which was complete within 1 month (Scheme 5).

Thermolysis of **2***g* in the presence of phenol led to the formation of several products (11), but the anticipated carbene insertion product, **3***n*, could not be unambiguously identified. However, formamide **4***c*, probably derived from hydrolysis of **3***n*, was isolated (Scheme 6).

Reactions with isocyanates

Nucleophilic carbenes have been reported to react with alkyl or aryl isocyanates to give hydantoins (**8**) as final products (8, 10*k*, 22). Their formation was explained in terms of an initial attack of the carbene on the carbonyl carbon of the isocyanate, followed by 1,3-dipolar cycloaddition of the intermediate across the C=N bond of a second molecule of isocyanate (Scheme 7).[9] As anticipated, the generation of aminooxycarbenes **1** in the presence of methyl or phenyl isocyanate led to the isolation of the corresponding spiro-fused hydantoins **8***a–f* (Scheme 8, Table 3).

[7] For examples of related oxazolidines, see ref. (18).

[8] Sample was kept in the refrigerator for about 2 months and it was not examined regularly.

[9] These reactions contrast with the [1 + 4] cycloadditions between nucleophilic carbenes and benzoyl isocyanate, which yield 4(5*H*)-oxazolones (11).

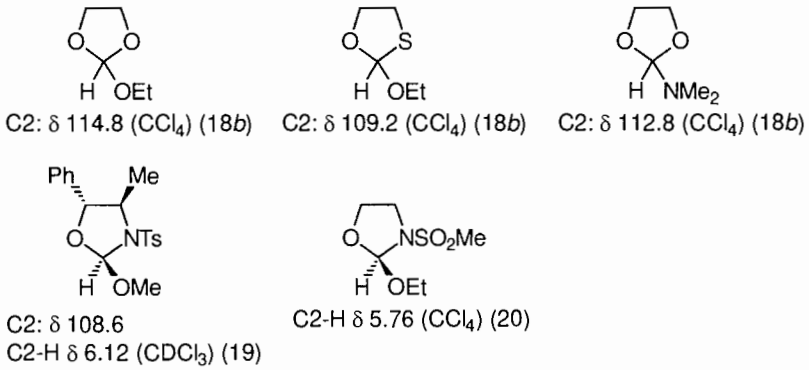

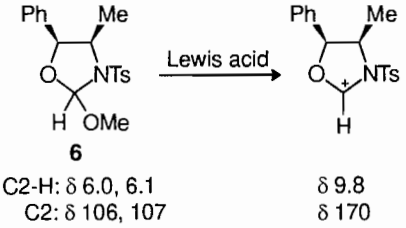

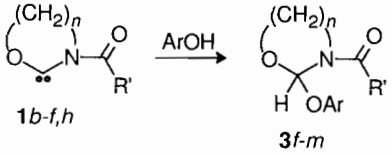

Fig. 4. Selected NMR data for **6** and the corresponding oxazolidinium cation (21).

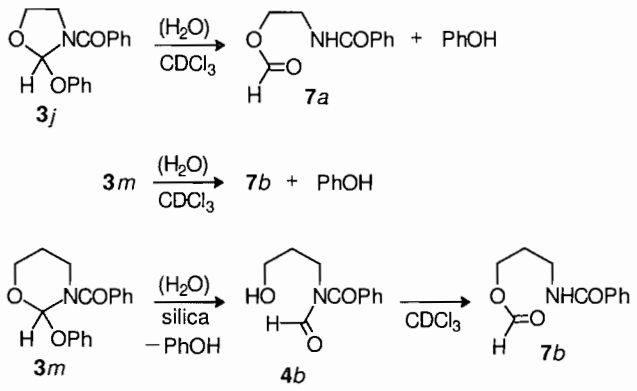
Scheme 4.

Reactions with alkynes



The reactivity of aminooxycarbenes **1** towards activated alkynes was also examined. Thermolysis of oxadiazoline **2***e* with 2.1 equivalents of dimethyl acetylenedicarboxylate (DMAD) gave three products, derived from reactions of carbene **1***e* with DMAD, that were isolated by chromatography, Scheme 9. The major product, oxazoline **9***a*, obtained in 73% yield, was apparently formed via benzoyl group transfer from N to C in the presumed 1,3-dipolar intermediate **10** (10*q*). That rearrangement is analogous to an aryl group transfer reported by Scherowsky's group (23). One of the minor products was assigned structure **11***a* (one of two possible diastereomers), by comparison of its spectral data with those of analogous dihydrofurans formed in the reaction of DMAD with other nucleophilic carbenes (5, 24). Its formation is rationalized in terms of the mechanism proposed by Hoffmann et al. (5) for the reaction of dimethoxycarbene with DMAD, where the dipolar intermediate (**10**, in the present case), formed by attack of the carbene at a triple-bonded carbon, adds across the carbonyl group of a second molecule of the alkyne (Scheme 9). For the third product, all spectral data were consistent with a 1:2 stoichiometry (carbene:DMAD), but its structure could not be elucidated.[10]

[10] Not the diastereo isomer of **11***a*.

Table 2. *N*-Carbonyl carbene–phenol adducts (**3**) isolated.

	n	R′	Ar	Yield (%)
3*f*	2	H	Ph	75
3*g*	2	Me	Ph	89
3*h*	2	C(Me)=CH_2	Ph	97
3*i*	2	C(Me)=CH_2	4-C_6H_4CN	84
3*j*	2	Ph	Ph	76
3*k*	2	Ph	4-C_6H_4CN	90
3*l*	2	OMe	Ph	>90
3*m*	3	Ph	Ph	97

Scheme 5.

2-Oxazolines bearing a substituent at C2 can be cleaved by hydrolysis or alcoholysis to the corresponding carboxylic acids or esters, respectively (25). As shown in Scheme 10, treatment of **9***a* with acetic acid in methanol gave a mixture of two inseparable compounds, namely, the expected triester **12** and an isomer tentatively assigned structure **13***a* (isomer **13***b* was ruled out (26)). Dihydrofuran derivative **13***a* likely results from the acid-catalyzed rearrangement of **12**.

In view of the reaction of **1***e* with DMAD, it was of interest to see if the same carbene would react with the less electrophilic methyl propiolate. From ^{1}H NMR analysis of the crude product after thermolysis, oxazoline **14** was clearly the major product (Scheme 11). However, substantial decomposition occurred during two successive separations by chromatography, and **14** was isolated in only 4% yield.

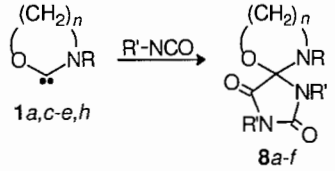


Scheme 6.

Scheme 7.

Scheme 8.

Reactions of aminooxycarbenes **1***c* (*N*-acetyl) and **1***d* (*N*-methacryloyl) with DMAD were also investigated and, in both cases, carbonyl group transfers were observed. Thus, thermolysis of oxadiazoline **2***d* with an excess of the alkyne afforded oxazoline **9***b*, isolated in 54% yield, as the major product (Scheme 12).

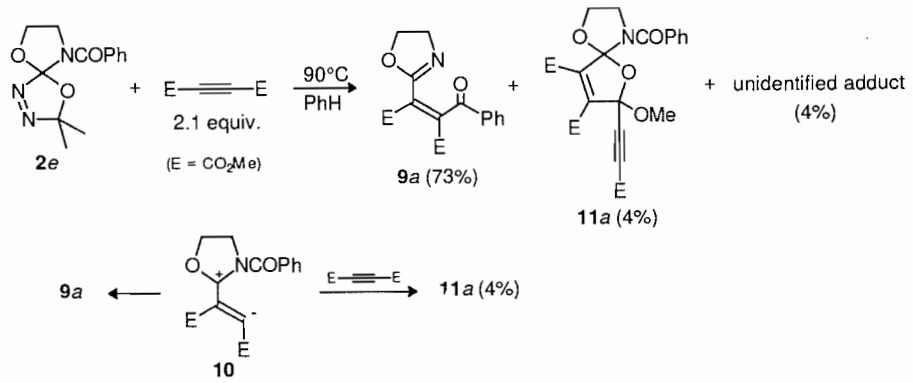
Thermolysis of **2***c* under similar conditions produced at least five different 1:2 adducts (carbene:DMAD), in addition to oxazoline **9***c*, as shown in Scheme 13. The latter, which appeared to be a major product from analysis of the crude thermolysate, decomposed completely during attempted separation by chromatography. This procedure, however, was successful in separating the 1:2 adducts from one another. Two of them were identified as the pair of diastereomers **11***b* and **11***c*, the latter (see experimental) being the analogue of **11***a*. Of the remaining three low-yield adducts, one was the analogue of the unidentified product reported above in the reaction of **1***e* with DMAD (Scheme 9).

Thermolysis of *N*-sulfonyl oxadiazoline **2***g* in the presence of DMAD also led to the isolation of several products, Scheme 14. Among them was oxazolidinone **15**, produced in a thermolytic fragmentation that competes with carbene generation (11). 2-Diazopropane, the coproduct of **15**, reacted with DMAD to give pyrazole **16** (11, 27). The only carbene + DMAD adduct that could be unambiguously identified was spiro-fused cyclopentadiene **17**, which apparently results from the unusual addition of the dipolar intermediate (the analogue of **10**) across the triple bond of a second molecule of DMAD.[11] Finally, compound **18** was also isolated in low yield; its origin is not known at present.

Experimental

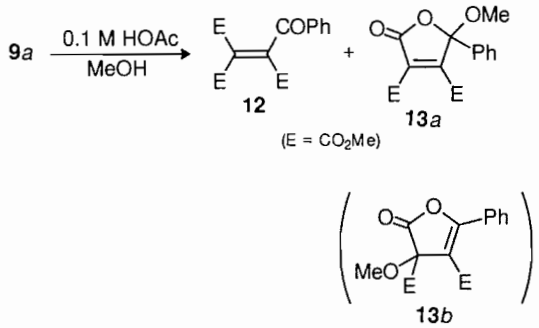
General methods

Radial chromatography was performed with a Chromatotron apparatus, model 7924T (Harrison Research Inc.), with silica-coated plates of 1 mm, 2 mm, or 4 mm thickness. NMR spectra were recorded on a Bruker AC-200 or AC-300 spectrometer; signals labelled "um" appear as broad unresolved multiplets because of slow exchange. Infrared spectra were recorded with a Biorad FTS-40 spectrophotometer, with the sample either in CCl_4 or in KBr as a pellet. The IR bands are labelled qualitatively with the symbols br for broad, app for apparent, and s, m, and w for strong, medium, and weak intensities, respectively. Bands from C–H stretching vibrations between 2850 and 3100 cm^{-1} are omitted, as are very weak bands. Mass spectra were obtained on a VG Analytical ZAB-E double focusing mass spectrometer or on a HP-5890 Series II gas chromatograph with a 5971A mass selective detector. Melting points were recorded on a Thomas Hoover capillary melting point apparatus, and are reported uncorrected. Elemental analyses were performed by Guelph Chemical Laboratories, Ltd. (Guelph, Ontario).



General methods for thermolyses

Benzene used as a thermolysis solvent was distilled from sodium benzophenone, and stored over molecular sieves.



[11] The more commonly observed adducts of type **11** were probably formed but they could not be identified with certainty, due to difficulties in the separation. In addition, a 1:3 adduct (carbene:DMAD) was isolated, but its low yield (ca. 1%) prevented a definite structural assignment.

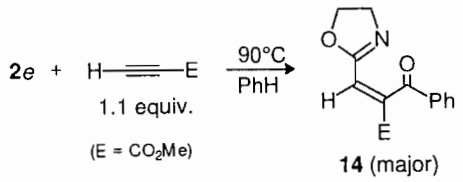
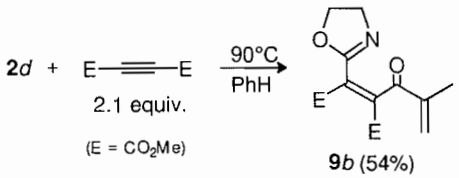


Scheme 9.

Scheme 10.

Scheme 11.



Typically, a benzene solution (10 mL) of the oxadiazoline[12] (0.5 mmol, 50 mM) and a specified amount of compound used as carbene trap were transferred to a sealable thermolysis tube. In some cases, this was preceded by distilling, under a dry nitrogen atmosphere, approximately 20 mL of the solution to be thermolysed down to 10 mL, in order to azeotrope out any water. The tube was then evacuated, sealed, and immersed in a constant temperature oil bath at 90°C ± 0.2°C for 24 h unless otherwise stated. The solvent and volatile products were removed with a rotary evaporator prior to analysis of the crude thermolysate by NMR and, in some cases, GC–MS. Thermolysis products were then separated and purified as described below.

Reactions with alcohols

Thermolysis of **2**a *with* tert*-butyl alcohol*

Oxadiazoline **2***a* (15 mg, 0.085 mmol) was heated with *tert*-butyl alcohol (40 μL, 0.42 mmol, dried by refluxing over calcium hydride followed by distillation) in a sealed NMR tube in ca. 0.5 mL of benzene-d_6. Analysis of the crude thermolysate by ^{1}H NMR and GC–MS revealed the presence of **4***a*.

Scheme 12.

N-*(2-Hydroxyethyl)*-N-*methylformamide (***4**a*)*: An authentic sample was prepared from the reaction of 2-(methylamino)-1-ethanol with ethyl formate, as described by Shibanuma et al. (28). Colourless oil; ^{1}H NMR (300 MHz, $CDCl_3$, slow exchange, signals due to major isomer are underlined, A:B ≈ 60:40) δ: 2.87 (s) and 3.02 (s) (3H, NCH_3), 3.24–3.85 (m) and 4.25–4.35 (m) (5H, CH_2CH_2, OH), 8.00 (s) and 8.05 (s) (1H, C(O)H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 29.78 and 35.81 (NCH_3), 47.54 and 52.13 (NCH_2), 58.62 and 60.11 (OCH_2), 163.56 and 163.78 (C=O); MS (EI) *m/z*: 103 (M^+, 2), 85 (5), 72 (19), 60 (11), 56 (8), 44 (100), 29 (45).

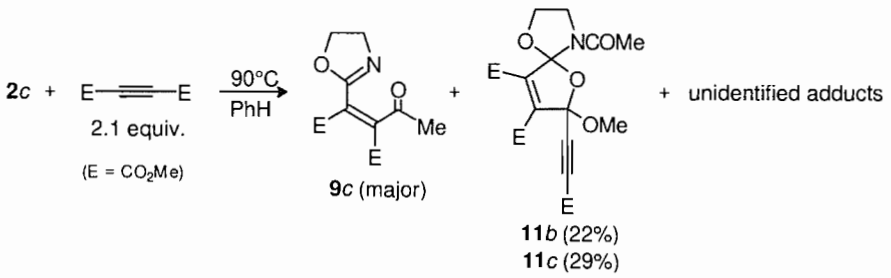
Thermolysis of **2**a *with benzyl alcohol*

Oxadiazoline **2***a* (103 mg, 0.60 mmol) was heated with benzyl alcohol (99 mg, 0.91 mmol) in 10 mL of benzene. Formamide **4***a* (above) was the major aminooxycarbene-derived product (by ^{1}H NMR and GC–MS); a small amount of benzyl formate was also observed.

Benzyl formate (ref. 29): MS (EI) *m/z*: 136 (M^+, 27), 108 (37), 91 (100), 77 (75), 65 (37), 51 (43), 39 (26), 29 (49).

Reactions of carbene 1*a* with phenols

N-*Methyl*-N-*(2-phenoxyethyl)fomamide (***3**d*)



Oxadiazoline **2***a* (84 mg, 0.49 mmol) was heated with phenol (58 mg, 0.62 mmol) in 10 mL of benzene. Purification by radial chromatography, with 10–60% ethyl acetate in hexane, gave **3***d* in 55% yield. Colourless oil; IR (CCl_4) cm^{-1}: 1771m, 1684s, 1600m, 1497s, 1382m, 1301w, 1242s, 1173w, 1081m,

[12] Details of the syntheses of oxadiazolines **2** have been described (11).

Scheme 14.

1056m, 908w; ^{1}H NMR (300 MHz, $CDCl_3$, slow rotation, signals from the major rotamer are underlined, A:B ≈ 53:47) δ: 2.96 (s) and 3.12 (s) (3H, NCH_3), 3.62 (t, ^3J = 5.2 Hz) and 3.73 (t, ^3J = 5.2 Hz) (2H, NCH_2), 4.07 (t, ^3J = 5.2 Hz) & 4.14 (t, ^3J = 5.2 Hz) (2H, OCH_2), 6.84–7.02 (m, 3H, Ar-*o,p*), 7.23–7.33 (m, 2H, Ar-*m*), 8.08 (s) and 8.14 (s) (1H, CHO); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 30.24 and 36.42 (NCH_3), 44.29 and 49.04 (NCH_2), 64.90 and 66.17 (OCH_2), 114.42 and 114.56 (OPh C2, C6), 121.14 and 121.46 (OPh C4), 129.59 (OPh C3, C5), 158.13 and 158.41 (OPh C1), 162.86 and 163.25 (CHO); MS (EI) *m/z*: 179 (M^+, 1), 149 (1), 120 (14), 107 (6), 91 (19), 86 (M-OPh, 100), 77 (81), 72 (21), 65 (42), 58 (84), 51 (45), 44 (81), 39 (47), 28 (36); MS (CI, NH_3) *m/z*: 197 $(M + NH_4)^+$, 180 $(M + H)^+$.

N-*Methyl*-N-*(2-(4-methylphenoxy)ethyl)formamide (3*e)
Oxadiazoline **2***a* (90 mg, 0.52 mmol) was heated with *p*-cresol (93 mg, 0.86 mmol) in 10 mL of benzene. Purification by radial chromatography, with 20–40% ethyl acetate in hexane, gave **3***e* in 30% yield. Colourless oil; ^{1}H NMR (200 MHz, $CDCl_3$, slow rotation, signals from the major rotamer are underlined, A : B ≈ 54 : 46) δ: 2.28 (s, 3H, Ar-CH_3), 2.95 (s) and 3.10 (s) (3H, NCH_3), 3.60 (t, ^3J = 5.2 Hz) and 3.71 (t, ^3J = 5.2 Hz) (2H, NCH_2), 4.03 (t, ^3J = 5.2 Hz) and 4.10 (t, ^3J = 5.2 Hz) (2H, OCH_2), 6.77 (app d, ^3J = 8.6 Hz, 2H, Ar C(2,6)H), 7.08 (app d, ^3J = 8.6 Hz, 2H, Ar C(3,5), 8.07 (s) and 8.13 (s) (1H, CHO); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 20.46 (Ar-CH_3), 30.18 and 36.35 (NCH_3), 44.28 and 49.04 (NCH_2), 65.11 and 66.34 (OCH_2), 114.29 and 114.45 (OAr C2, C6), 130.00 (OAr C3, C5), 130.34 and 130.72 (OAr C4), 156.06 and 156.31 (OAr C1), 162.82 and 163.23 (CHO); MS (EI) *m/z*: 193 (M^+, 1), 149 (1), 134 (5), 119 (7), 107 (15), 91 (40), 86 (M − OPh, 100), 77 (37), 65 (28), 58 (73), 51 (16), 44 (42), 28 (19).

Reactions of carbenes 1*b–g* with phenols
Compounds **3***f–n* are very easily hydrolysed and they could not be purified by chromatography. Products of reasonable purity were generally obtained after the following work-up: the excess phenol was removed by washing the thermolysate, diluted to 25 mL with fresh benzene, with 4 × 5 mL of aqueous NaOH (5%), followed by 5 mL of water or brine; this was followed by extraction of the combined aqueous layers with one portion of benzene, and drying of the organic phase over $MgSO_4$.

*3-Formyl-2-phenoxyoxazolidine (3*f)
Oxadiazoline **2***b* (49 mg, 0.26 mmol) was heated with phenol (39 mg, 0.41 mmol) in 10 mL of benzene. Work-up as indicated above gave **3**f as a colourless oil in 75% yield. IR (CCl_4) cm^{-1}: 1699s (C═O), 1591m, 1494m, 1415m, 1385m, 1356m, 1297w, 1205s, 1117w, 1083m, 1030w, 1010m, 991m, 953w, 876w; ^{1}H NMR (200 MHz, C_6D_6, slow exchange) δ: ca. 2.4–3.9 (um's, 4H, OCH_2CH_2N), 6.03 (s) and 6.07 (s) (1H, C(2)H), 6.85–7.40 (m, 5H, Ar), 7.90 (br s) and 8.27 (br s) (1H, C(O)H); ^{13}C NMR (50 MHz, C_6D_6, slow exchange, signals from major isomer are underlined) δ: 41.12 and 42.09 (NCH_2), 64.61 (OCH_2), 102.91 and 104.34 (C2), 117.96 and 118.52 (OPh C2, C6), 123.18 (OPh C4), 129.79 (OPh C3, C5), 155.47 (OPh C1), 158.87 and 159.27 (C═O); MS (EI) *m/z*: 193 (M^+, 1), 134 (2), 107 (1), 100 (M − OPh, 100), 94 (27), 78 (8), 72 (68), 65 (28), 51 (7), 44 (72), 39 (31), 29 (15); MS (CI, NH_3) did not give useful information.

*3-Acetyl-2-phenoxyoxazolidine (3*g)
Oxadiazoline **2***c* (96 mg, 0.48 mmol) was heated with phenol (59 mg, 0.63 mmol) in 10 mL of benzene. The usual work-up gave **3***g* as an oil in 89% yield; all attempts to crystallize the oil failed. IR (CCl_4) cm^{-1}: 1735w, 1683s (C═O), 1594m, 1494m, 1406m, 1357m, 1210s, 1099w, 1061w, 1007m, 980m, 946m; ^{1}H NMR (200 MHz, $CDCl_3$, slow exchange) δ: 1.85 (s) and 2.15 (s) (3H, CH_3), 3.58–3.92 (m, 2H, NCH_2), 4.20–4.52 (m,

2H, OCH_2), 6.39 (s) and 6.66 (s) (1H, C(2)H), 7.06–7.17 (m, 3H, Ar-*o,p*), 7.25–7.40 (m, 2H, Ar-*m*); ^{13}C NMR (50 MHz, $CDCl_3$, slow exchange, signals from major isomer are underlined) δ: 22.41 and 22.79 (CH_3), 43.27 and 44.65 (NCH_2), 64.83 and 65.31 (OCH_2), 103.84 and 104.34 (C2), 117.52 and 118.21 (OPh C2, C6), 122.96 and 123.24 (OPh C4), 129.41 and 129.68 (OPh C3, C5), 154.93 and 155.45 (OPh C1), 168.12 and 168.43 (C=O); MS (EI) *m/z*: 207 (M^+, 2), 135 (3), 114 (M − OPh, 65), 94 (29), 84 (13), 72 (100), 65 (18), 49 (20), 44 (39); MS (CI, NH_3) *m/z*: 208 $(M + H)^+$.

*3-Methacryloyl-2-phenoxyoxazolidine (**3**h)*

Thermolysis of oxadiazoline **2***d* (71 mg, 0.32 mmol) in the presence of phenol (44 mg, 0.68 mmol) in 10 mL of benzene gave, after the usual work-up, **3***h* as a viscous, colourless oil in 97% yield. IR (CCl_4) cm^{-1}: 1734w, 1667s (C=O), 1632m, 1591w, 1496m, 1454w, 1396m, 1370m, 1200s, 1118w, 1084w, 1007m, 982s, 948m, 891; ^1H NMR (200 MHz, $CDCl_3$, slow exchange, some peaks are broad) δ: 2.00 (app t, ^4J = 1.3 Hz, 3H, CH_3), 3.75–3.87 (m, 2H, NCH_2), 4.20–4.44 (m, 2H, OCH_2), 5.31 (br s, 1H, $=CH_2$), 5.42 (app t, ^4J = 0.9 Hz, 1H, $=CH_2$), 6.51 (br s, 1H, C(2)H), 7.00–7.13 (m, 3H, Ar-*o,p*), 7.25–7.39 (m, 2H, Ar-*m*); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 19.98 (CH_3), 43.31 (NCH_2), 64.52 (OCH_2), 105.23 (C2), 117.62 and 117.82 (OPh C2, C6, and $=CH_2$), 123.02 (OPh C4), 129.85 (OPh C3, C5), 141.66 ($=CR_2$), 155.69 (OPh C1), 169.09 (C=O); MS (EI) did not give useful information; MS (CI, NH_3) *m/z*: 234 $(M + H)^+$.

*2-(4-Cyanophenoxy)-3-methacryloyloxazolidine (**3**i)*

Thermolysis of oxadiazoline **2***d* (100 mg, 0.44 mmol) in the presence of 4-cyanophenol (62 mg, 0.52 mmol) in 10 mL of benzene gave a partially crystalline oil (84% yield) after the usual work-up. ^1H NMR (200 MHz, C_6D_6, slow exchange) δ: 1.81 (s, 3H, CH_3), ca. 3.0–4.0 (um, 4H, NCH_2, OCH_2), 4.89 (br s, 1H, $=CH_2$), 5.11 (br s, 1H, CH_2), 6.14 (br s) and 6.38 (br s) (1H, C(2)H), 6.55–7.20 (um, 4H, Ar); ^{13}C NMR (50 MHz, C_6D_6) δ: 19.84 (CH_3), 43.47 (br, NCH_2), 65.11 (OCH_2), 104.69 (OAr C4), 106.62 (C2), 117.53 (OAr C2, C6), 118.12 ($=CH_2$), 122.66 (C≡N), 134.00 (OAr C3, C5), 141.31 ($=CR_2$), 158.35 (OAr C1), 169.06 (C=O); MS (EI) *m/z*: 140 (M − OAr, 35), 119 (6), 84 (5), 69 (methacryloyl cation, 100), 64 (4), 49 (10), 41 (72); MS (CI, NH_3) *m/z*: 276 $(M + NH_4)^+$, 259 $(M + H)^+$.

*3-Benzoyl-2-phenoxyoxazolidine (**3**j)*

Oxadiazoline **2***e* (105 mg, 0.40 mmol) was heated with phenol (72 mg, 0.77 mmol) in 10 mL of benzene. After removal of the solvent and volatile products on the rotary evaporator, **3***j* solidified upon addition of 20% ethyl acetate in hexane. Recrystallization from the same solvent mixture yielded a white solid, mp 89–91°C (76% yield). IR (KBr) cm^{-1}: 1660s (C=O), 1591s, 1493w, 1448w, 1399s, 1201m, 1168w, 1115w, 1084m, 951m, 933m, 887m, 791w, 770w, 725w; ^1H NMR (200 MHz, $CDCl_3$, slow exchange) δ: 3.70–4.10 (um, 2H, NCH_2), 4.10–4.45 (um, 2H, OCH_2), 6.21 (br s, 1H, C(2)H), 6.70–7.10 (um, 3H, Ar), 7.10–7.45 (um, 5H, Ar), 7.55–7.65 (m, 2H, Ar); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 43.48 (NCH_2), 64.60 (OCH_2), 105.19 (C2), 117.79 (OPh C2, C6), 123.12 (OPh C4), 127.58 (benzoyl C2, C6), 128.42 (benzoyl C3, C5), 129.52 (OPh C3, C5), 130.92 (benzoyl C4), 135.45 (benzoyl C1), 154.67 (OPh C1), 169.00 (C=O); MS (EI) *m/z*: 269 (M^+, 2), 198 (2), 176 (M − OPh, 14), 147 (18), 117 (20), 105 ($PhCO^+$, 100), 94 (21), 84 (42), 77 (42), 49 (54); MS (CI, NH_3) *m/z*: 270 $(M+H)^+$; HRMS calcd. for $C_{10}H_{10}NO_2$ (M − OPh): *m/z* 176.0712, found: *m/z* 176.0705.

*2-(4-Cyanophenoxy)-3-benzoyloxazolidine (**3**k)*

Oxadiazoline **2***e* (107 mg, 0.41 mmol) was thermolysed with 4-cyanophenol (59 mg, 0.49 mmol) in 10 mL of benzene. The usual work-up gave **3***k* as a white solid in 90% yield. IR (CCl_4) cm^{-1}: 2230m (C≡N), 1751s, 1672s (C=O), 1605s, 1507m, 1451w, 1384s, 1257m, 1210s, 1172m, 1080m, 1056m, 1022w, 962s, 889w, 836w; ^1H NMR (200 MHz, $CDCl_3$, slow exchange) δ: ca. 3–4 (um, 4H, NCH_2, OCH_2), ca. 5.8–8.3 (um, 10H, C(2)H, Ar); ^{13}C NMR (50 MHz, C_6D_6) δ: 44.06 (br, NCH_2), 65.10 (OCH_2), 104.96 (OAr C4), 106.74 (C2), 117.57 (OAr C2, C6), 122.74 (C≡N), ca. 128 (overlapped with solvent triplet, aroyl C2, C6 and C3, C5), 131.04 (aroyl C4), 135.83 (aroyl C1), 133.88 (OAr C3, C5), 158.19 (OAr C1), 168.6 (C=O); MS (EI) *m/z*: 176 (M − OAr, 38), 105 ($PhCO^+$, 100), 90 (6), 77 (32), 51 (10); MS (CI, NH_3) *m/z*: 295 $(M+H)^+$.

*3-Methoxycarbonyl-2-phenoxyoxazolidine (**3**l)*

Oxadiazoline **2***f* (55 mg, 0.26 mmol) was heated with phenol (30 mg, 0.32 mmol) in 10 mL of benzene. The usual work-up gave **3***l* as a colourless oil in quantitative yield. IR (CCl_4) cm^{-1}: 1728s (C=O), 1593m, 1494m, 1451s, 1391s, 1301w, 1212s, 1137w, 1076m, 987s, 692; ^1H NMR (200 MHz, C_6D_6, slow exchange) δ: ca. 2.9–4.1 (um's, 7H, OCH_2CH_2N, CH_3), 6.46 (br s) and 6.74 (br s) (1H, C(2)H), ca. 6.8–7.4 (um, 5H, Ar); ^{13}C NMR (50 MHz, C_6D_6, slow exchange) δ: 43.83 (NCH_2), 52.42 (CH_3), 64.73 and 65.14 (OCH_2), 104.52 and 105.52 (C2), 118.18 (OPh C2, C6), 122.97 (OPh C4), 129.79 (OPh C3, C5), 153.38 and 156.35 (OPh C1 and C=O); MS (EI) *m/z*: 223 (M^+, <1), 192 (2), 130 (M − OPh, 100), 94 (8), 78 (5), 70 (5), 65 (17), 58 (35), 39 (16), 30 (8); MS (CI, NH_3) did not give useful information.

*3-Benzoyl-2-phenoxytetrahydro-2H-1,3-oxazine (**3**m)*

Oxadiazoline **2***h* (100 mg, 0.36 mmol) was heated with phenol (52 mg, 0.55 mmol) in 10 mL of benzene. The usual work-up gave essentially pure **3***m* (97% yield), which crystallized upon addition of 10% ethyl acetate in hexane. White solid, mp ca. 83–92°C; IR (CCl_4) cm^{-1}: 1732w, 1663s (C=O), 1597m, 1496m, 1448w, 1416m, 1381m, 1356w, 1333w, 1287m, 1218m, 1196m, 1173m, 1090m, 1017m, 977s, 930m, 903w, 853w; ^1H NMR (300 MHz, C_6D_6, slow exchange) δ: 0.86–1.12 (um, 1H, CCH_2C), 1.63–1.85 (um, 1H, CCH_2C), 3.34–3.53 (um, 2H, NCH_2), 3.81–4.00 (um, 1H, OCH_2), 4.16–4.35 (um, 1H, OCH_2),[13] 6.80–7.25 (um, 9H) and 7.40–7.65 (um, 2H) (Ar and C(2)H); ^{13}C NMR (75 MHz, C_6D_6, slow exchange) δ: 24.28 (CCH_2C), 37.97 (NCH_2),[14] 59.49 (OCH_2), 99.66 (C2),[15] 117.26 (OPh C2, C6), 122.74 (OPh C4), ca. 127.5 (benzoyl C2, C6, under solvent triplet), 128.57 (benzoyl

[13] One of the OCH_2 proton signals disappears at room temperature; at 90%C, it appears at 4.16–4.35 (um).

[14] At room temperature, the NCH_2 signal appears as a very wide resonance in the range 35–40 ppm; at 77°C, it is a slightly broadened singlet at 37.97 ppm.

[15] Taken at 77°C; at room temperature, the signal is broad, in the range 97–102 ppm.

Alcoholysis of ***9***a
Compound ***9a*** (1.12 g, 3.5 mmol) was stirred in 10 mL of 0.1 M acetic acid in methanol for 13 days at room temperature. After evaporation of the solvent, the oil was redissolved in 20 mL of CH_2Cl_2, and washed successively with $NaHCO_3$ (5%, 4 × 10 mL) and water, and the combined organic layers were dried over $MgSO_4$. Separation by radial chromatography, using 10–50% ethyl acetate in hexane, gave a mixture of two inseparable products, **12** and an isomer tentatively identified as **13**, in a ratio of ca. 70:30. The spectral data shown below are those of the mixture.

*(Z)-3-Oxo-3-phenyl-1-propene-1,1,2-tricarboxylic acid, trimethyl ester (**12**)* Lit. (27): mp 66–68°C; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.65 (s, 3H, OCH_3), 3.75 (s, 3H, OCH_3), 3.94 (s, 3H, OCH_3), ca. 7.35–7.70 (m, 3H, Ar-*m,p*), ca. 7.84–7.98 (m, 2H, Ar-*o*); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 52.4–53.6 (overlapped OCH_3's), 128.67 and 128.91 (Ar C2, C6 and Ar C3, C5), 134.09 (Ar C4), 135.19 (Ar C1), 142.44 (=C; other alkene C not observed due to low S/N), 161.94 (OC=O), 162.63 (OC=O), 163.94 (OC=O), 190.00 (PhC=O); MS (EI) *m/z*: 306 (M^+, 16), 275 (M − OCH_3, 12), 247 (M − CO_2CH_3, 3), 229 (1), 215 (1), 198 (1), 157 (1), 129 (3), 105 ($PhCO^+$, 100), 77 (41), 59 (5), 51 (8), 44 (3), 29 (1).

*4,5-Dihydro-4-methoxy-5-oxo-2-phenyl-3,4-furandicarboxylic acid, dimethyl ester (**13**a)*: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.50 (s, 3H, OCH_3), 3.79 (s, 3H, OCH_3), 3.92 (s, 3H, OCH_3), ca. 7.35–7.70 (m, 5H, Ar); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 52.4–53.6 (overlapped OCH_3's), 107.50, 126.22, 126.93, 129.28, 130.21, 133.16, 135.06, (157.05), 159.71 (OC=O), 160.44 (OC=O), 164.17 (OC=O); MS (EI) *m/z*: 306 (M^+, 8), 275 (M − OCH_3, 39), 247 (M − CO_2CH_3, 38), 230 (91), 215 (70), 203 (34), 187 (15), 175 (8), 157 (13), 151 (5), 144 (10), 140 (10), 129 (15), 111 (19), 105 ($PhCO^+$, 100), 102 (11), 91 (5), 82 (5), 77 (62), 59 (19), 51 (15), 39 (12), 29 (4).

Thermolysis of **2**e *with methyl propiolate*
Oxadiazoline ***2e*** (187 mg, 0.72 mmol) was heated with methyl propiolate (67 mg, 0.80 mmol) in 14 mL of benzene. By ^{1}H NMR, the product mixture was found to consist mainly of **14**. Substantial decomposition of the product occurred during the two successive separations (radial chromatography, ethyl acetate – hexane). Consequently, **14** was obtained in only 4% yield.

*Oxazoline **14***: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.76 (s, 3H, OCH_3), 3.87 (app t, ^3J = 8.9 Hz, 2H, NCH_2), 4.06 (app t, ^3J = 8.9 Hz, 2H, OCH_2), 7.37 (s, 1H, =C-H), ca. 7.35–7.65 (overlapped m, 3H, Ar-*m,p*), 7.81–7.95 (m, 2H, Ar-*o*); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 53.05 (OCH_3), 55.17 (NCH_2), 68.21 (OCH_2), 127.66 (=C-H), 128.66 and 128.89 (Ar C2, C6 and Ar C3, C5), 133.63 (Ar C4), 136.07 and 139.90 (Ar C1 and $=CR_2$), 162.20 (oxazoline C2), 164.18 (OC=O), 192.27 (PhC=O); MS (EI) *m/z*: 259 (M^+, 22), 230 (100), 216 (45), 172 (27), 128 (9), 105 ($PhCO^+$, 63), 84 (24), 77 (55), 49 (16); MS (CI, NH_3) *m/z*: 260 (M + H)$^+$; HRMS calcd. for $C_{14}H_{13}NO_4$ (M^+): *m/z* 259.0845; found: *m/z* 259.0857.

Thermolysis of **2**d *with DMAD*
Thermolysis of oxadiazoline ***2d*** (112 mg, 0.50 mmol) in the presence of DMAD (146 mg, 1.0 mmol) in 10 mL of benzene gave a thermolysate that was found (by ^{1}H NMR) to consist almost entirely of ***9b***, in addition to the excess DMAD. Repeated separations by radial chromatography (ethyl acetate – hexane) gave pure ***9b*** in 54% yield.

*Oxazoline **9***b: IR (CCl_4) cm^{-1}: 1745s (OC=O's), 1682s (NC=O's), 1644m, 1611m, 1435m, 1379m, 1321m, 1285m, 1251s, 1152m, 1055m, 1026m, 976w, 909m, 877w, 845w; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.95 (s, 3H, CCH_3), 3.76 (s, 3H, OCH_3), 3.90 (s, 3H, OCH_3), 3.95 (app dt, $J \sim 1$ Hz, ^3J = 9.4 Hz, NCH_2), 4.25 (app dt, $J \sim 1$ Hz, ^3J = 9.4 Hz, OCH_2), 5.82 (app d, ^4J = 0.7 Hz, 1H, $=CH_2$), 5.92 (app d, ^4J = 1.4 Hz, 1H, $=CH_2$); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 16.66 (CCH_3), 53.23 (2 × OCH_3, coincident signals), 55.22 (NCH_2), 68.50 (OCH_2), 128.30 ($=CH_2$), 132.20 and 137.44 (tetrasubstituted alkene C's), 144.36 ($H_2C=CR_2$), 160.00 (oxazoline C2), 163.09 (OC=O), 164.57 (OC=O), 191.69 (ketone C=O); MS (EI) *m/z*: 282 (M + H^+, 8), 266 (M − CH_3, 8), 252 (100), 241 (19), 239 (18), 222 (30), 208 (23), 194 (30), 190 (18), 181 (6), 163 (25), 154 (7), 135 (31), 124 (9), 111 (22), 96 (8), 84 (36), 71 (34), 59 (26), 49 (28), 45 (37), 41 (70); MS (CI, NH_3) *m/z*: 282 (M + H)$^+$; HRMS calcd. for $C_{13}H_{16}NO_6$ (M + H^+): *m/z* 282.0978; found: 282.0966.

Thermolysis of **2**c *with DMAD*
Oxadiazoline ***2c*** (99 mg, 0.50 mmol) was heated with DMAD (158 mg, 1.1 mmol) in 12 mL of benzene. ^{1}H NMR analysis of the crude thermolysate revealed ***9c*** to be the major product. Repeated separations by radial chromatography, with mixtures of ethyl acetate and hexane as elution solvent, gave the five 1:2 (carbene:DMAD) adducts described below. The major product could not be recovered, presumably due to its decomposition on the silica plate.

*Oxazoline **9***c: Not isolated, data from crude thermolysate; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.45 (s, 3H, $C(O)CH_3$), 3.82 (s, 3H, OCH_3), 3.91 (s, 3H, OCH_3), 4.03 (app dt, $J \sim 1$ Hz, ^3J = 9.4 Hz, 2H, NCH_2), 4.37 (app dt, $J \sim 1$ Hz, ^3J = 9.4 Hz, 2H, OCH_2); MS (EI) *m/z*: 255 (M^+, 7), 240 (M − CH_3, 100), 224 (M − OCH_3, 27), 208 (55), 196 (19), 182 (20), 168 (20), 154 (32), 140 (8), 125 (37), 111 (62), 97 (34), 80 (17), 66 (26), 59 (28), 53 (18), 43 (64), 39 (20), 29 (11).

*Dihydrofuran **11***b: Pale yellow oil, isolated in 22% yield. IR (CCl_4) cm^{-1}: 1740s (C=O's), 1643m, 1559m, 1437m, 1386w,

Thermolysis of ***2****g with DMAD*

Oxadiazoline ***2****g* (297 mg, 1.00 mmol) was heated with DMAD (310 mg, 2.18 mmol) in 16 mL of benzene. The products were separated by radial chromatography (ethyl acetate – hexane).

*3-(Phenylsulfonyl)-2-oxazolidinone (****15****) (ref. 31)*: Isolated in 23% yield, mp 136–138°C; IR (CCl_4) cm^{-1}: 1801s, 1480w, 1450w, 1382m (NSO_2), 1264w, 1180s (NSO_2), 1147s, 1094w, 1050w, 909w; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 4.00–4.15 (m, 2H, NCH_2), 4.32–4.46 (m, 2H, OCH_2), 7.50–7.80 (m, 3H, Ar-*m,p*), 8.02–8.13 (m, 2H, Ar-*o*); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 44.61 (NCH_2), 62.28 (OCH_2), 128.26 (Ar C2, C6), 129.30 (Ar C3, C5), 134.55 (Ar C4), 136.81 (Ar C1), 151.91 (C═O); MS (EI) *m/z*: 163 (30), 141 ($PhSO_2^+$, 12), 118 (8), 104 (53), 91 (6), 77 (100), 56 (6), 51 (28), 28 (2); MS (CI, NH_3) *m/z*: 245 (M + NH_4)$^+$.

*Dimethyl 3,3-dimethyl-3*H*-pyrazole-4,5-dicarboxylate (****16****) (ref. 26)*: Isolated in 13% yield. IR (CCl_4) cm^{-1}: 1732s (C═O), 1647w, 1438w, 1334w, 1264s, 1198w, 1167w, 1114w, 1033w, 909m; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.58 (s, 6H, $C(CH_3)_2$), 3.92 (s, 3H, OCH_3), 4.00 (s, 3H, OCH_3); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 20.86 ($C(CH_3)_2$), 52.98 (2 × OCH_3, coincident), 97.46 (C3), 144.68 (C4), 153.56 (C5), 160.81 (C═O), 162.97 (C═O); MS (EI) *m/z*: 183 (3), 169 (3), 152 (33), 141 (50), 125 (36), 109 (34), 93 (55), 79 (65), 67 (100), 59 (43), 53 (31), 39 (50), 29 (18).

Cyclopentadiene ***17***: Obtained as a pale yellow oil in 3% yield. IR (CCl_4) cm^{-1}: 1730s (C═O), 1649w, 1437m, 1368m (NSO_2), 1342m, 1262s, 1203m, 1169m (NSO_2), 1096w, 1015w, 995w, 909s; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.58 (s, 6H, OCH_3), 3.89 (s, 6H, OCH_3), 3.97 (t, ^3J = 6.5 Hz, 2H, NCH_2), 4.39 (t, ^3J = 6.5 Hz, 2H, OCH_2), 7.42–7.65 (m, 3H, Ar-*m,p*), 7.80–7.88 (m, 2H, Ar-*o*); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 47.66 (NCH_2), 52.08 (OCH_3), 52.85 (OCH_3), 67.44 (OCH_2), 101.18 (spiro C), 127.78 (Ar C2, C6), 128.97 (Ar C3, C5), 132.80 (Ar C4), 138.29 (probably Ar C1), 139.00 (probably ═*C*-C-*C*═), 140.32 (probably ═C-C═), 160.45

[16] The following resonances were also observed, which could account for one of the NCH_2 protons: δ 3.56 (app t, J = 2.3 Hz, ~0.5H) and 3.62 (app t, J = 2.3 Hz, ~0.5H) (slow exchange is expected in these compounds); alternatively, these could be due to impurities.

Acknowledgments

The authors thank Dr. Richard Smith and Mr. Fajar Ramelan for most of the mass spectra. Support of this research by the Natural Sciences and Engineering Research Council (NSERC) of Canada, and by the Ministry of Education and Training of Ontario in the form of a Scholarship to P.C., is gratefully acknowledged.

Abstract: Since the discovery of the electron by Sir Joseph John Thomson a century ago, the limitless applications of the electron in chemistry have been both profound and fun. We present recent results from two of our experiments that involve such applications of the electron beam in the study of new aspects of gas-phase chemical physics and of surface chemistry. In particular, our precise measurements of momentum-transfer-resolved "absolute" excitation transition probabilities of the low-lying transitions in "environment-safe" Freon substitutes using a high-energy electron beam are finding applications in the modelling of low-temperature industrial plasma and atmospheric processes. The use of low-energy electrons as a powerful in situ means to activate and to probe "novel" surface reactions, including oxide and carbide formation and CO oxidation, has been demonstrated on Cu(100) and Si(111) surfaces. These experiments further illustrate the value and the enormous potential of technological payoffs of electron-based fundamental research.

Key words: electron scattering and interactions, surface chemistry.

Résumé : Depuis la découverte de l'électron par Sir John Thomson il y de cela un siècle, les applications illimitées de l'électron en chimie furent à la fois plaisantes et profondes. Nous présentons les récents résultats de deux de nos expériences qui impliquent l'application d'un faisceau d'électrons dans l'étude des nouveaux aspects de la chimie physique en phase gazeuse et de la chimie de surface. En particulier, nos mesures précises de résolution du transfert du moment des probabilités de transition d'excitation «absolue» des transitions de basse énergie dans des substituts du Fréon situés dans un «environnement propre», en utilisant un faisceau d'électrons à haute énergie, ont trouvé des applications dans la modélisation des plasmas industriels à basse température et dans les processus atmosphériques. On a utilisé des surfaces de Cu(100) et de Si(111) pour illustrer le fait que des électrons de faible énergie constituent un puissant moyen in situ pour activer et sonder de «nouvelles» réactions de surface, incluant la formation d'oxyde et de carbure et l'oxydation du CO. Ces expéreinces illustrent de plus la valeur et l'énorme potentiel rentabilité technologique de la recherche fondamentale basée sur l'électron.

Mots clés : diffraction d'électrons et interactions, chimie de surface.

1. The centennial of the electron discovery

The word "electron," coined by G. Johnstone Stoney in 1891, had been used to denote the unit of charge found in experiments involving passing electric current through chemicals. It was Joseph John Thomson, who on April 30, 1897, announced that the cathode rays were negatively charged particles that he called "corpuscles," and later in 1897 recognised that these corpuscles (electrons) represented "matter being the substance from which the chemical elements are built up" (1). Since then, the electron has become possibly the most popular fundamental particle with extraordinary physical properties and chemical and technological power. Indeed, most of today's computation, communications, entertainment, etc. that defines modern civilization depends on technical knowledge of the electron and its properties. As we celebrate the Centennial Year of the discovery of the electron in 1997, it seems appro-

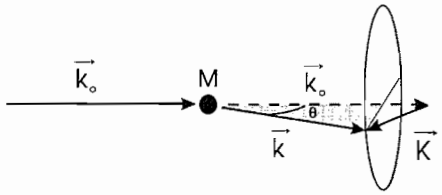
priate to examine from a chemist's perspective some of the notable applications of the electron in experimental chemical physics and modern surface chemistry. In particular, we shall, in the rest of this article, focus on two modest applications of the electron beam itself. These experiments are part of our gas-phase chemical physics and surface science programs developed over the past decade at The University of Waterloo. These results illustrate the enormous importance of creative use of the electron not only as a unique probe for "dark" transitions in matters of technological and environmental relevance but also as an initiator for "novel" surface reactions.

2. Electrons as a unique probe for the electronic structure and interactions: non-optical excited-state spectroscopy of Freon substitutes

The ground-state electronic structures of simple polyatomic molecules have been the subject of intense research both spectroscopically and theoretically. Although significant progress in the description of the ground-state structure has been made using new and improved quantum computational methods, knowledge about the electronic structures of the excited states is less complete (2). In principle, it is possible to probe the electronic structure of an excited state by measuring excited-state-related properties, such as the transition energy and oscillator strength of a particular electronic transition, if the ground-state electronic structure is well understood. Angle-resolved electron energy loss spectroscopy (EELS) has proven to be an effective tool for investigating non-dipole phenomena (3). In particular, dipole-forbidden transitions, which are difficult to detect in single-photon optical experiments, have been observed using angle-resolved EELS in the valence shell (4) and inner shells (5).

Briefly, a typical angle-resolved EELS experiment involves a simple inelastic electron–molecule scattering process:



$$[1]\quad \underset{(k_0,E_0)}{M + e^-} \longrightarrow \underset{(k,E_1)}{e^- + M^*}$$

in which the target molecule M is promoted to some excited state M* by a fast incident electron (typically with a kinetic energy of 2.5 keV), which undergoes energy loss $E\,(=E_0-E_1)$ and momentum transfer $\boldsymbol{K}\,(=\boldsymbol{k}_0-\boldsymbol{k})$. Figure 1 shows a schematic diagram of the scattering kinematics. The magnitude of the momentum transfer K is related to the scattering angle (i.e., $K^2 = k_0^2 + k^2 - 2k_0k\cos\theta$). The intensity of the scattered electrons (with momentum $\boldsymbol{k}$ and scattering angle θ) that suffer an energy loss E is proportional to the double differential cross section $d^2\sigma/d\Omega dE$. In the first Born approximation, the differential generalized oscillator strength (GOS), $df\,(K,E)/dE$, is related to the cross section by the Bethe–Born formula (6):

$$[2]\quad \frac{df(K,E)}{dE} = \frac{k_0}{k}K^2\frac{E}{4}\frac{d^2\sigma}{d\Omega dE}$$

where $d\Omega$ corresponds to the acceptance solid angle of the scattered electrons. The GOS $f(K,E)$ is also defined in Rydberg atomic units as:

Fig. 1. Schematic diagram of scattering kinematics in a typical electron energy loss process involving non-zero momentum transfer $\boldsymbol{K}$ to a molecular target M.

$$[3]\quad f(K,E) = \frac{E}{K^2}\left|\left\langle \Psi_n\left|\sum_{j=1}^{N}\exp(i\boldsymbol{K}\cdot\boldsymbol{r}_j)\right|\Psi_0\right\rangle\right|^2$$

where Ψ_0 and Ψ_n are the (N-electron) electronic wave functions of the initial (ground) and final states respectively, and $\boldsymbol{r}_j$ is the position of the jth electron with respect to the centre-of-mass of the target. At small momentum transfer, the GOS can be expanded into a power series (7):

$$[4]\quad f(K,E) = E[\varepsilon_1^2 + (\varepsilon_2^2 - 2\varepsilon_1\varepsilon_3)|\boldsymbol{K}|^2 + (\varepsilon_3^2 - 2\varepsilon_2\varepsilon_4 + 2\varepsilon_1\varepsilon_5)|\boldsymbol{K}|^4 + \cdots]$$
$$= f_0 + f_1|\boldsymbol{K}|^2 + f_2|\boldsymbol{K}|^4 + \cdots$$

where the multipole transition moment is given by

$$\varepsilon_m = \frac{1}{m!}\left\langle \Psi_n\left|\sum_{j=1}^{N}\left(\frac{\boldsymbol{K}}{|\boldsymbol{K}|}\cdot\boldsymbol{r}_j\right)^m\right|\Psi_0\right\rangle$$

The GOS therefore converges to the dipole oscillator strength (DOS), f_0, as the momentum transfer approaches zero (8). The term f_1 is related to the difference of the square of the quadrupole matrix element and the product of the dipole and octupole matrix elements (9). It may therefore be possible to qualitatively infer whether a particular excitation is dominated by dipole or non-dipole (quadrupole, octupole, etc.) interactions by comparing the relative magnitudes and signs of the f_n values. Furthermore, the GOS in the valence shell can be made absolute by single-point normalization to the corresponding photoabsorption data at $K = 0$ or by using the Bethe sum rule at any selected constant value of K, i.e.,

$$[5]\quad \int \frac{df(K,E)}{dE}\,dE = N$$

where N is the total number of electrons in the valence shell of the target. With the appropriate fitting procedure that takes into account the background function and the contribution from the inner shells (10), the sum-rule normalization procedure provides a convenient means of obtaining absolute cross section without performing an "absolute" experiment. Since the relative normalization among all the spectra has been maintained automatically by collecting the EELS spectra at different θ's sequentially in repetitive scans, it is only necessary to perform the sum-rule normalization at a single K value (the smallest K value in this case) to put the entire GOS data on an absolute scale. Angle-resolved EELS therefore offers a powerful technique for "complete" determination of all the existing excited states, including both the dipole-allowed and

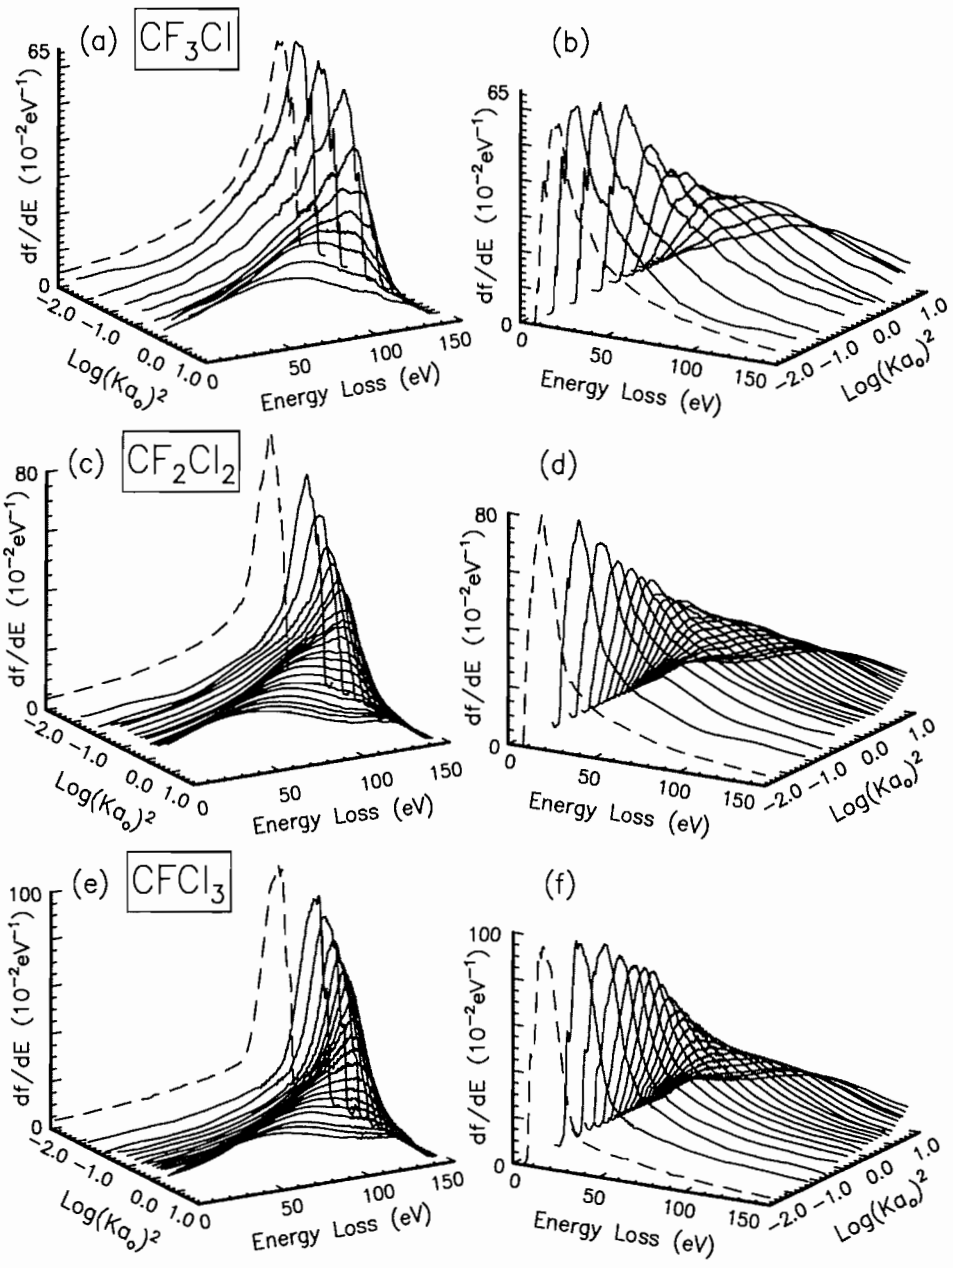
For personal use only.

the optically inaccessible non-dipole or "dark" transitions. Furthermore, the GOSs measured at different momentum-transfer values are related to the corresponding Fourier transform components of the overlap function between the initial-state and final-state wave functions (eq. [3]). In effect, GOS measurement can provide a detailed "mapping" of the overlap function in momentum space, which can in turn be used as effective feedback for theoretical modelling of excited-state wave functions.

2.1 Non-dipole HOMO → LUMO excitations in Freons



The importance of studying the electronic structures of Freons is attested to not only by their influential roles in atmospheric science (11), but also by their wide-ranging industrial applications as common aerosol and refrigerant materials and as important plasma etchants in semiconductor processing (12). Using a home-built electron scattering spectrometer (13), we conducted a series of comprehensive studies on the electron-impact excitation of a series of chlorofluorocarbons (CFCs) (14–16) and their common hydrogen-substituted chlorofluorocarbons (HCFCs) (17–19) in the valence-shell (5–150 eV) region. As an example, we show in Fig. 2 the variation of the GOS of valence-shell energy loss features over an extended momentum-transfer range in the form of a Bethe surface plot for CF_3Cl (Freon 13), CF_2Cl_2 (Freon 12), and $CFCl_3$ (Freon 11) (15). The Bethe surface gives a comprehensive description of the electron–molecule inelastic scattering process, and is particularly useful for analyzing such quantities as stopping power, total inelastic scattering cross section, and polarizability (6). In particular, Figs. 2*a*, 2*c*, and 2*e* emphasize the impact-scattering domain of large momentum transfer and energy loss, which corresponds to the kinematical region for "close" collisions. In this domain, a broad ridge is seen to disperse to a higher energy loss with increasing momentum transfer. This ridge is the result of momentum conservation in the inelastic electron–molecule collision and becomes the well-known Bethe ridge in the Born approximation (6). Figures 2*b*, 2*d*, and 2*f*, on the other hand, emphasize the dipole-scattering domain of small momentum transfer and energy loss, which involves "distant" collisions and where sharp "optical" features of the valence shell are more apparent. Although the overall appearance of the Bethe surfaces of the three molecules appears to be similar (Fig. 2), the GOS evidently becomes more concentrated in the dipole-scattering region with increasing Cl content in the CF_3Cl, CF_2Cl_2, and $CFCl_3$ series (15). This trend can be qualitatively understood by considering the differences in the spatial distributions of the valence-shell electron densities of these molecules. In general, the electron-binding energy is inversely related to the size of an orbital (as approximated, e.g., by the average Bohr radius). In the series CF_3Cl, CF_2Cl_2, and $CFCl_3$ (15), the valence orbitals become more diffuse with successive chlorination, which therefore gives rise to increasingly lower ionization potentials (IPs) of the valence shell and hence a higher concentration of the GOS in the low energy loss region, as observed in Figs. 2*b*, 2*d*, and 2*f*. Moreover, a larger size of the valence shell (as the result of an increased Cl content) also gives rise to a lower average charge density, hence favouring "distant" collisions (i.e., with a small momentum-transfer). Consequently, the Bethe surface of $CFCl_3$ appears to be the most strongly peaked in the lower momentum-transfer region among the three molecules, giving rise to a more rapid drop-off along the K direction (Fig. 2).

To demonstrate the K-dependence of the spectral features observed in the valence shell of CF_3Cl, we show in Fig. 3 a selected number of K-resolved (angle-resolved) electron energy loss spectra collected at a series of scattering angles (14). Our small-angle spectrum (Fig. 3*a*) is found to be consistent with the earlier dipole EELS (20) and photoabsorption data (21), and the observed features may be assigned to appropriate dipole-allowed Rydberg transitions. In particular, features 2–7 have been assigned to $5e \rightarrow 4s$ (9.5 eV), $5e \rightarrow 5s$ and (or) $5e \rightarrow 3d$ (11.5 eV), $4e \rightarrow 4s$ and (or) $1a_2 \rightarrow 4p$ (13.5 eV), $4a_1 \rightarrow 4s$ (16.5 eV), $4a_1 \rightarrow 5s$ and (or) $2e \rightarrow 4p$ (18.5 eV), and $2a_1 \rightarrow 3s$ (22.3 eV) transitions, respectively. In addition to these "optical" features, our K-resolved spectra (at larger angles) clearly indicate the presence of a weak broad feature at 40.5 eV (feature 8), which has also been reported previously (20). The broad 40.5 eV feature likely contains the ionization edges of both inner-valence $(1e)^{-1}$ and $(1a_1)^{-1}$ states, which are at 40.0 and 42.5 eV, respectively. This broad peak (located at 37–42 eV) appears to be a common feature among other members of the Freon series (including CF_2Cl_2 and $CFCl_3$ (15)). The strong correlation between the intensity of this broad peak and the number of F atom(s) in the Freon molecules further suggests that these broad features are related to transitions near the ionization onsets of the inner-valence F 2*s* orbitals (20). Finally, the spectra clearly reveal the presence of a "new" state at 7.7 eV (14), i.e., at an energy that is 1.7 eV below the onset of the (dipole) Rydberg states observed in the $\theta = 1°$ spectrum (Fig. 3*a*).

To investigate in more detail the K-dependence of the newly observed non-dipole feature at 7.7 eV, we have estimated its peak intensity with a Gaussian profile, after removing an appropriate contribution from the nearby discrete dipole transition(s), in each of the K-resolved spectra. Figure 4 shows the resulting GOS profile (14), which clearly contains a relative maximum (at $K^2 \sim 1.0$ a.u.) characteristic of a non-dipole transition. Only a limited number of non-dipole electronic transitions in the valence shell have been previously characterized by means of GOS measurements. In particular, the GOS of the well-known Lyman–Birge–Hopfield (LBH) band in N_2 at 9.3 eV was found to have a maximum at $K^2 \sim 0.8$ a.u. and has been identified as a quadrupole-allowed $a^1\Pi_g \leftarrow X^1\Sigma_g^+$ transition (13, 22). In addition, a second quadrupole transition at 31.4 eV in N_2 has also been observed with the GOS maximum at $K^2 \sim 1.1$ a.u. and could be attributed to the $2\sigma_g \rightarrow 1\pi_g$ single excitation and discrete double excitations (23). Other non-dipole transitions have also been found in C_2H_2 (24), benzene (25), and *p*-difluorobenzene (26). These studies generally demonstrate that dipole-allowed non-Rydberg transitions have maximum GOSs at $K = 0$ while non-dipole transitions (quadrupole or octupole) usually have maximum GOSs at non-zero K values (e.g., ~ 1 a.u. for most non-dipole valence-shell transitions observed to date). Figure 4 therefore gives direct evidence for a non-dipole non-Rydberg transition lying below all previously reported dipole transitions in CF_3Cl (14). Moreover, we can also derive the absolute DOS by fitting the measured GOS profile using a power series expansion (the so-called Lassettre series (27)) shown in eq. [4], the coefficients derived from which are consistent with those of a predominantly quadrupole transition.

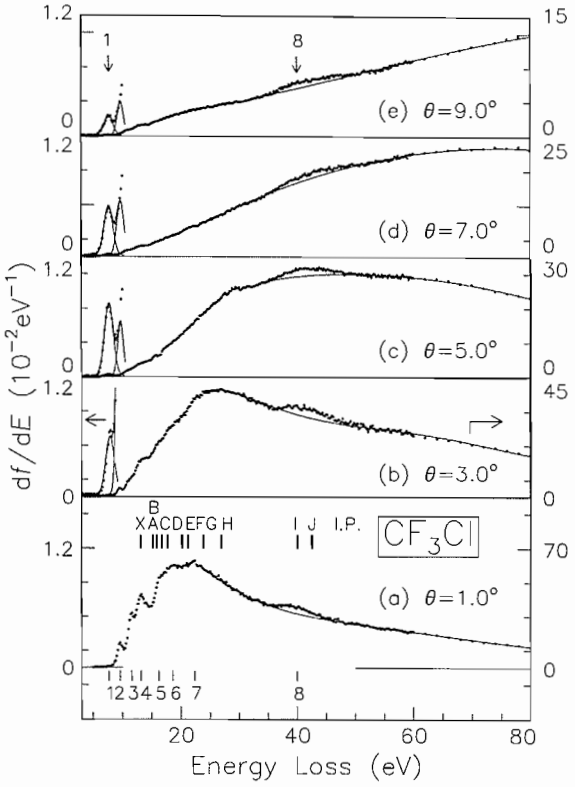
Fig. 2. Bethe surfaces of the valence shells of CF_3Cl (*a*), (*b*), CF_2Cl_2 (*c*), (*d*), and $CFCl_3$ (*e*), (*f*) determined at 2.5 keV impact energy. EELS spectra are collected in steps of 1.0° from 1.0° to 9.0° for CF_3Cl, and in steps of 0.5° from 1.0° to 9.5° for CF_2Cl_2 and $CFCl_3$. The spectra collected above 4° have been smoothed for clarity. The dipole EELS spectra of CF_3Cl, CF_2Cl_2, and $CFCl_3$ obtained from the literature (15) are shown as broken lines and have been placed at an approximate momentum transfer (*K*) position (0.1 a.u.), that corresponds to the lower limit of our scale. The impact-scattering (large momentum transfer) domain is emphasized in (*a*), (*c*), and (*e*), while the dipole-scattering domain is depicted in (*b*), (*d*), and (*f*).



Also shown in Fig. 4 are the results of ab initio GOS calculations for the $(7e \rightarrow 11a_1)\ ^1E \leftarrow\ ^1A_1$ excitation (14). The calculations employed an improved virtual orbital (IVO) representation (28) of the ^1E state and a Hartree–Fock ground state. Evidently, reasonably good agreement is obtained between theory and experiment for the shape, although the calculated GOS is somewhat larger, with the minima of both the theoretical and experimental GOS curves at zero momentum transfer and maxima near $K^2 = 1$ a.u. The finite DOS value is consistent with the small value of the computed optical (dipole) oscillator strength. In addition, using a separate single-excitation configuration interaction (CI) excited-state calculation with a 6-31G (6-31^{++}G**) basis set and an internally optimized geometry for CF_3Cl (14), we also found the transition energy of the $^1E \leftarrow\ ^1A_1$ transition to be 8.59 eV (9.01 eV) with a small dipole transition moment of 0.0024 (0.0064). The

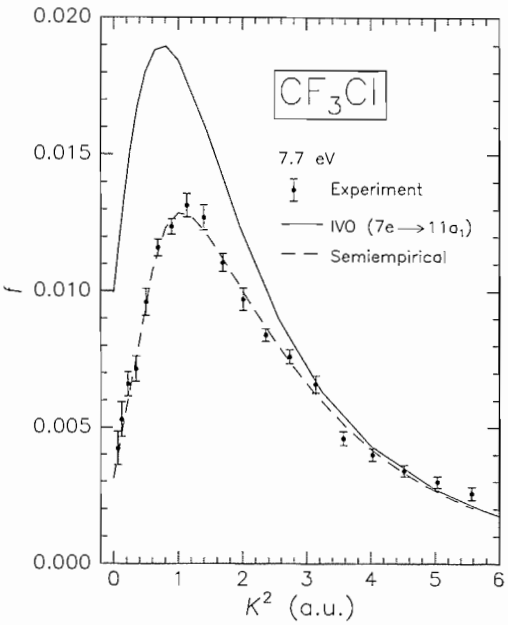

Fig. 3. Angle-resolved electron energy loss spectra of the valence shell of CF_3Cl at 2.5 keV impact energy and θ = (*a*) 1.0°, (*b*) 3.0°, (*c*) 5.0°, (*d*) 7.0°, and (*e*) 9.0°. The intensity variation of the weak peak at 7.7 eV (feature 1) is shown using an expanded scale (left axis) while the rest of the spectrum corresponds to the right vertical scale. Two Gaussian profiles are used to estimate the intensities of feature 1 and its neighbour, respectively, by a curve-fitting procedure, as illustrated in (*b*)–(*e*). The vertical ionization potentials (IPs) of the X–J states (vertical bars) are obtained experimentally (15).

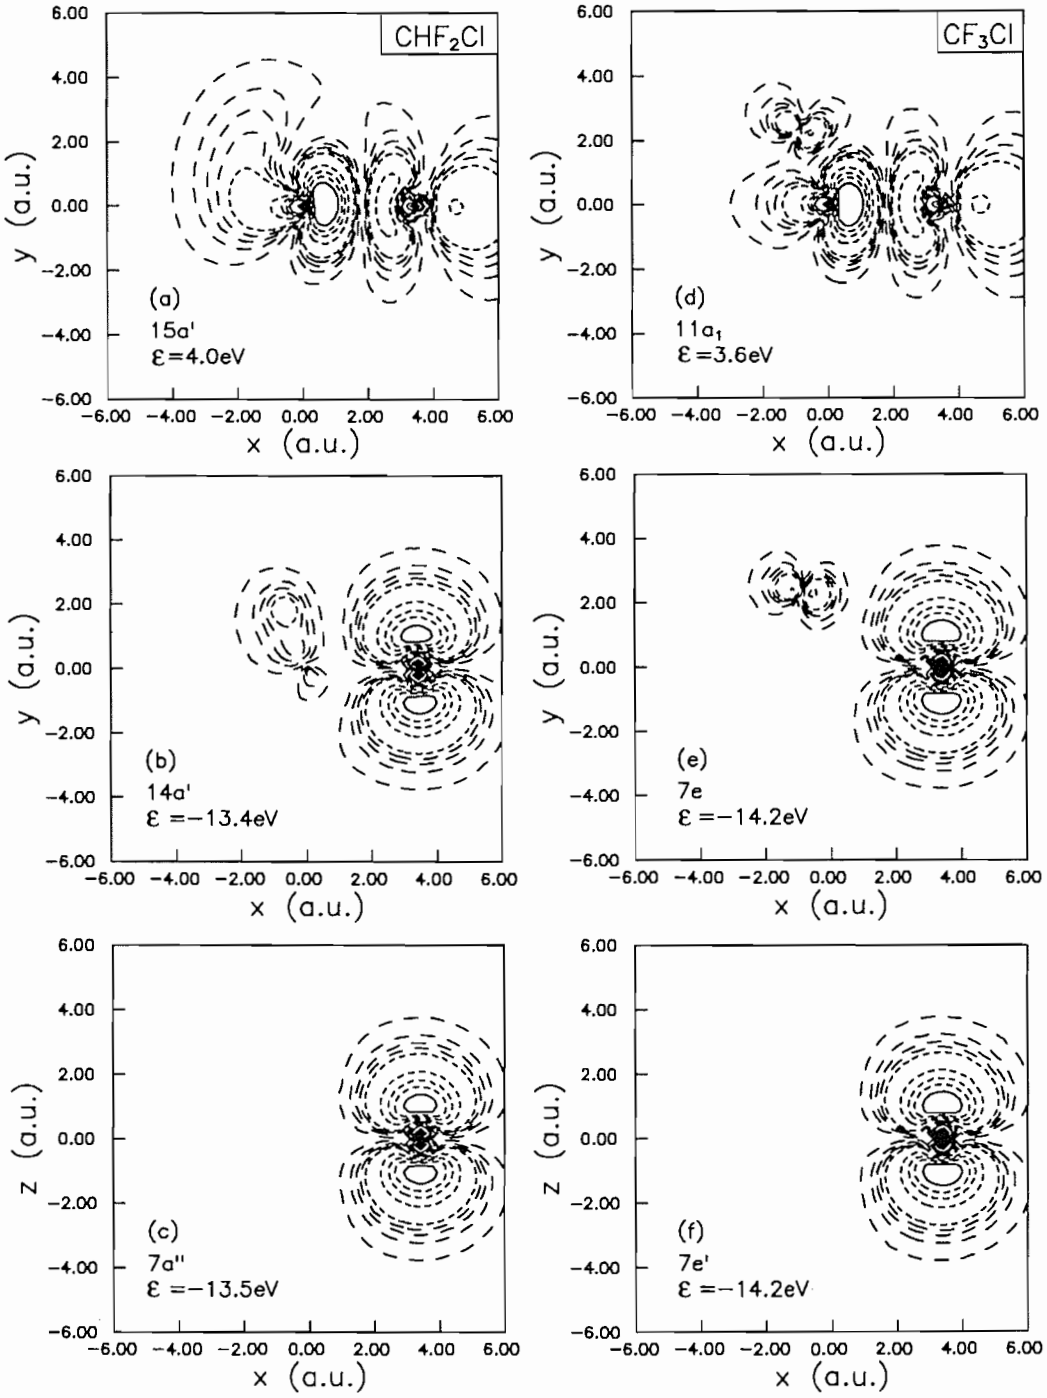
reasonably good agreement of the experimental transition energy (7.7 eV) and the DOS value (0.003) with the calculations provides further support for the proposed assignment. These calculations therefore strongly support the assignment of the 7.7 eV transition as the $^1E \leftarrow {}^1A_1$ excitation.

This lowest-energy singlet transition involves excitation of an electron from the 7*e* HOMO, with Cl 3*p* lone-pair character ($n_{Cl\ 3p}$), into the $11a_1$ LUMO, with C—Cl σ* character ($\sigma^*_{C—Cl}$). Figure 5 compares the contour maps of the wave function density functions of the initial-state and final-state orbitals involved in this type of $n_{Cl\ 3p} \rightarrow \sigma^*_{C—Cl}$ transitions for CF_3Cl (and CHF_2Cl) (17). The contour maps were generated from ab initio self-consistent field (SCF) wave functions obtained by GAUSSIAN 90 (29) with a 6-31G basis set and internally optimized geometries. The Cl 3*p* lone-pair nature of the doubly degenerate orbitals, labeled as 7*e* and 7*e*′, in CF_3Cl is clearly illustrated in Figs. 5*e* and 5*f*, respectively, while the $11a_1$ orbital shown in Fig. 5*d* is seen to consist of antibonding overlap between the C(2*s*, 2p_x) and Cl 3p_x atomic orbitals, with its characteristic nodal plane bisecting the C—Cl bond. In the case of the $n_{Cl\ 3p} \rightarrow \sigma^*_{C—Cl}$ ($7e \rightarrow 11a_1$) transition in CF_3Cl,

Fig. 4. Absolute generalized oscillator strength as a function of momentum transfer (*K*) squared for the 7.7 eV transition in CF_3Cl. The broken curve corresponds to a semiempirical polynomial fit based upon the Lassettre series expansion. The solid line represents the result of an Improved Virtual Orbital (IVO) calculation (14).

overlap between the initial-state and final-state orbital wave function occurs mostly at the Cl site. The transition moment of this $n_{Cl\ 3p} \rightarrow \sigma^*_{C—Cl}$ electronic transition is therefore expected to resemble that of a *p*-to-*p* transition in a Cl atom, which readily explains the observed quadrupole nature of this transition.



In Fig. 6, we show the potential energy curves of the $^1A_1$ and ^1E states along the C—Cl bond direction, generated by using the 6-31G and 6-31^{++}G** basis sets (14). Clearly, other than the apparent shift of the potential energy curves to a lower energy for the 6-31^{++}G** basis set, there is no obvious change in the general shapes of the potential energy curves between these two basis sets. Since the direct product table for the symmetry group C_{3v} indicates that the $^1E \leftarrow {}^1A_1$ transition is both dipole allowed and quadrupole allowed, the small transition dipole moment observed earlier therefore suggests that this transition can be attributed predominantly to quadrupole interactions, which are consistent with the dominant molecular orbital coefficients. Of particular interest, shown in the simple potential energy diagram, is that a vertical transition originating from the ground vibrational level of the $^1A_1$ state terminates at the repulsive part of the potential energy curve of the ^1E state above its dissociation limit. Figure 6 therefore provides qualitative support for the predissociative nature of the "metastable" ^1E state and that transition to this state would lead to breakage of the C—Cl bond.

2.2 Analogous non-dipole transitions in "environment-safe" Freon substitutes

The large-scale consumption of chlorofluorocarbons or Freons (as refrigerants, aerosol propellants, and semiconductor

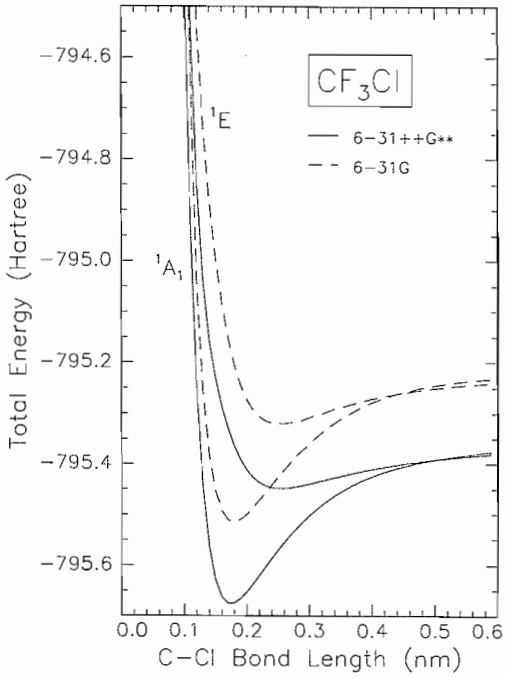
Fig. 5. Two-dimensional wave function density contour maps for (*a*) the 15*a*′, (*b*) 14*a*′, and (*c*) 7*a*″ orbitals of CHF_2Cl, and for (*d*) the 11a_1, (*e*) 7*e*, and (*f*) 7*e*′ orbitals of CF_3Cl. The molecules are oriented with the carbon atoms located at the origin. The H-C-Cl group in CHF_2Cl and an F-C-Cl group in CF_3Cl have been positioned on the *xy* plane with the C—Cl bond oriented along the *x* axis. The contour values are 0.1, 0.3, 0.5, 0.7 (broken lines), 1, 3, 5, 7 (dotted lines), 10, 30, 50, 70, and 90% (solid lines) of the maximum density. The contour maps are calculated using ab initio SCF wave functions of 6-31G quality generated with internally optimized geometries (29). The molecular orbital symbols and calculated SCF orbital energies (ε) are also shown in the plots (note that a positive value for the orbital energy indicates a virtual orbital).



etchants, etc.) in many industrial applications (11, 12) has become a major environmental concern because of their destructive effect on ozone in the stratosphere. Many of the popular CFCs, including CF_3Cl (discussed above), CF_2Cl_2, $CFCl_3$ (15), and CCl_4 (16), are being replaced with "temporary" substitutes, which usually consist of the more "environment-safe" HCFCs, including CHF_2Cl (17), $CHFCl_2$ (18), and $CHCl_3$ (19) as well as their derivatives. Unlike the simple CFCs, however, the electronic structure and photochemistry of HCFC molecules are less well understood. For instance,

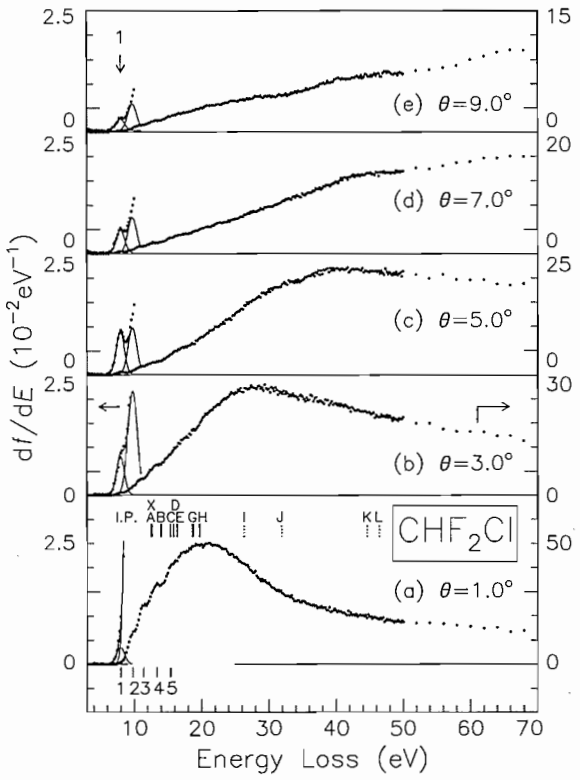

Fig. 6. Potential energy diagram along the C—Cl bond direction for the $^1A_1$ and ^1E states of CF_3Cl. The potential energy curves of the two states are obtained using single-excitation configuration interaction calculations with 6-31G (broken lines) and 6-31^{++}G** (solid lines) basis sets (29). Except for the C—Cl bond length, all other structural parameters obtained in an internally optimized geometry are held constant in the potential energy curve calculations.

there is no information on the important excitation cross sections of low-lying or any other electronic transitions, which, like their counterparts in CFCs, may play a key role in the relevant atmospheric and industrial processes. A few of these $n \rightarrow \sigma^*$ transitions in the 6–9 eV region for some of the more common CFC and HCFC molecules have been reported as "weak" features in the early vacuum ultraviolet photoabsorption (30) and small-angle high-resolution EELS studies (20). We have conducted a series of comparative studies involving HCFCs (17–19) with the goal of elucidating the effects of halogen content and symmetry change from, for example, C_{3v} (CF_3Cl) to C_s (CHF_2Cl) on the GOS profiles and the nature of this type of $n \rightarrow \sigma^*$ and other relevant low-lying electronic excitations.

The angle-resolved EELS spectra of CHF_2Cl (Freon 22) in Fig. 7 (17) reveal electronic structure similar to that of its CFC counterpart (CF_3Cl, Fig. 3). Except for the weak feature at 8.0 eV, most of the observed features below the ionization edge could again be attributed to Rydberg transitions. The GOS profile of this feature in CHF_2Cl is compared with that in CF_3Cl in Fig. 8 (17). The two GOS profiles appear to be very similar both in shape and magnitude. The maximum at $K^2 \sim 1$ a.u. in the GOS profile of the 8.0 eV feature in CHF_2Cl (like that of the 7.7 eV feature in CF_3Cl) is therefore characteristic of and provides evidence for the non-dipole nature of the transitions involved. We can again perform a single-excitation CI excited-state calculation using a 6-31G basis set and an inter-

Fig. 7. Angle-resolved electron energy loss spectra of the valence shell of CHF_2Cl at 2.5 keV impact energy and θ = (*a*) 1.0°, (*b*) 3.0°, (*c*) 5.0°, (*d*) 7.0°, and (*e*) 9.0°. The intensity variation of the weak peak at 8.0 eV (feature 1) is shown using an expanded scale (left axis) while the rest of the spectrum corresponds to the right vertical scale. Three Gaussian profiles are used to estimate the intensities of feature 1 (8.0 eV) and two neighbouring discrete states (at 9.8 and 11.4 eV) in a curve-fitting procedure (note that the fitting results of the third Gaussian peak are not shown). The vertical ionization potentials (IPs) of the X–H states (vertical bars) are obtained experimentally (21). State F is not labelled because of its ambiguity. The I.P.'s for states I–L (dotted vertical bars) are obtained from an ab initio SCF calculation with a 6-31G basis set (29).

nally optimized geometry for CHF_2Cl (29) to identify the nature of the transitions involved (17). Only singlet-to-singlet electronic transitions are calculated here because the contribution to the low-lying 8.0 eV feature from the spin-forbidden singlet-to-triplet transitions is negligible at the high impact energy (2.5 keV) employed in the present experiment. The calculation (17) shows that the feature at 8.0 eV can be adequately assigned as two predominant transitions to the $^1A'$ ($14a' \rightarrow 15a'$) and $^1A''$ ($7a'' \rightarrow 15a'$) excited states, which correspond, respectively, to electronic transitions from two essentially Cl 3*p* lone-pair orbitals (the HOMO $14a'$ and next HOMO $7a''$) to a $\sigma^*_{C—Cl}$ antibonding orbital (the LUMO $15a'$). The corresponding calculated transition energies from the ground state to the two excited states, $^1A'$ and $^1A''$, are 8.62 and 8.68 eV, respectively, which are in good accord with the experimental excitation energy of 8.0 eV. The total calculated DOS of 0.0052 for the two excited states (0.0039 for the $^1A'$ state and 0.0013 for the $^1A''$ state) is also in good agreement with the small experimentally derived f_0 value of 0.0043. Fig. 8. Absolute generalized oscillator strength f as a function of momentum transfer K squared for (*a*) the 8.0 eV feature in CHF_2Cl and (*b*) the 7.7 eV feature in CF_3Cl. The broken curves correspond to semiempirical polynomial fits based upon the Lassettre series expansion. Projected dipole oscillator strengths are indicated by crosses (x).

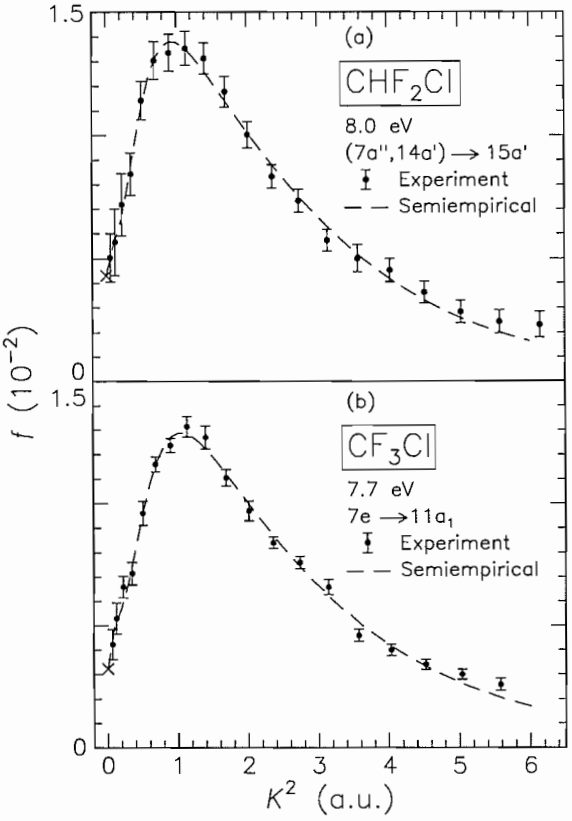

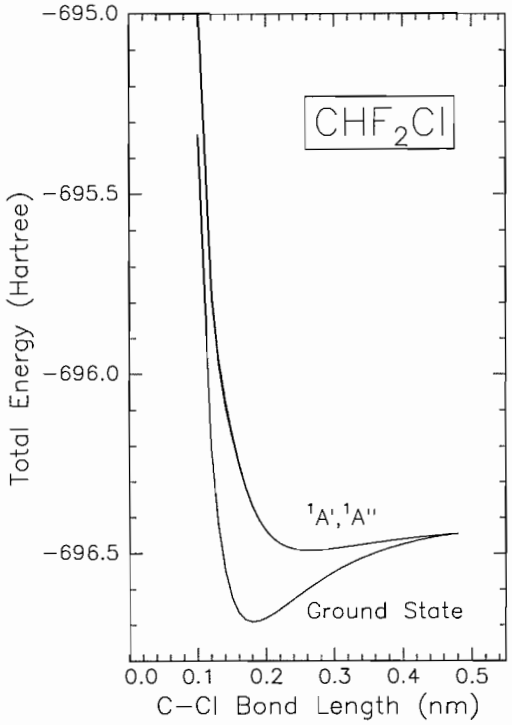

Fig. 9. Potential energy diagram along the C—Cl bond direction for the ground state and the two lowest-lying excited states ($^1A'$ and $^1A''$) of CHF_2Cl. The potential energy curves are obtained using single-excitation configuration interaction calculations with a 6-31G basis set (29). Except for the C—Cl bond length, all other structural parameters obtained from an internal geometry optimization are held constant in the potential energy curve calculations.

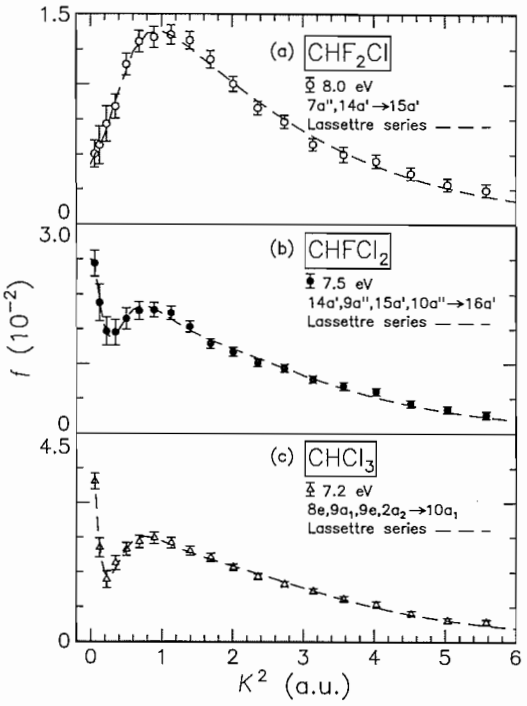

agreements obtained in the excitation energy and in the DOS between the calculation and experiment therefore provide strong evidence for the assignment of the $14a' \rightarrow 15a'$ and $7a'' \rightarrow 15a'$ electronic transitions to the observed low-lying feature at 8.0 eV in CHF_2Cl.

We can also understand the similarities in the GOS profiles between these HOMO → LUMO transitions in CHF_2Cl and CF_3Cl by examining the electron densities of the orbitals involved in the two molecules. Figure 5*a* shows the antibonding σ* character of the $15a'$ orbital, while Figs. 5*b* and 5*c* clearly illustrate the lone-pair nature of the $14a'$ and $7a''$ orbitals (17), which consist mainly of the in-plane Cl $3p_y$ and out-of-plane Cl $3p_z$ orbitals, respectively. The contour maps of the $\sigma^*_{C—Cl}$ antibonding ($15a'$) and $n_{Cl\ 3p}$ lone-pair ($14a'$ and $7a''$) orbitals in CHF_2Cl (Figs. 5*a*–5*c*) depict striking similarities to those of the corresponding orbitals in CF_3Cl (Figs. 5*d*–5*f*). Essentially the same descriptions for the antibonding and lone-pair orbitals and for the quadrupole nature of the *p*-to-*p* type transitions between these orbitals in CF_3Cl can also be applied to those in CHF_2Cl. Given these similarities, it is therefore not surprising to find that the potential energy curves along the C—Cl bond direction calculated using the single-excitation CI approach for these $n_{Cl\ 3p} \rightarrow \sigma^*_{C—Cl}$ transitions in CHF_2Cl (17), shown in Fig. 9, would also be similar to those for CF_3Cl (Fig. 6). It is also obvious from this potential energy diagram (Fig. 9) that the electronic transitions, $14a' \rightarrow 15a'$ and $7a'' \rightarrow 15a'$, may both lead to the dissociation of the C—Cl bond. The results of these potential energy curve calculations strongly suggest that dissociation of the C—Cl bond is a common consequence of the $n_{Cl\ 3p} \rightarrow \sigma^*_{C—Cl}$ transitions in CHF_2Cl and CF_3Cl.

Our studies on the GOS profiles of the $n_{Cl\ 3p} \rightarrow \sigma^*_{C—Cl}$ transitions in the common CFC (CF_3Cl, CF_2Cl_2, and $CFCl_3$) series (15) and their "environment-safe" HCFC substitutes (CHF_2Cl (17), $CHFCl_2$ (18), and $CHCl_3$ (19)) have revealed two interesting empirical trends: (*i*) the relative maximum intensity of the GOS profile within the aforementioned CFC and HCFC series increases nearly proportionally with increasing Cl content, and (*ii*) the relative amount of dipole (peak at $K = 0$) to non-dipole (peak at $K^2 \sim 1$ a.u.) component also increases with increasing chlorination. Figure 10 illustrates these general trends in the GOS profiles of the HOMO → LUMO transitions for the CHF_2Cl, $CHFCl_2$, and $CHCl_3$ series (18). In particular, the maxima for the respective GOS profiles approximately follow the 1:2:3 ratio, in concert with increasing chlorination. The relative contribution from the dipole component also increases with increasing Cl content, with the strongest dipole peak (at $K = 0$) in $CHCl_3$, which is also consistent with the relative ratio of the calculated (experimental) DOS values, 1:3.8:8.8 (1:5.8:13.4), for

Fig. 10. Absolute generalized oscillator strength f as a function of momentum transfer K squared for (*a*) the 8.0 eV feature in CHF_2Cl, (*b*) the 7.5 eV feature in $CHFCl_2$, and (*c*) the 7.2 eV feature in $CHCl_3$. The broken curves correspond to semiempirical polynomial fits based upon the Lassettre series expansion.

CHF_2Cl:$CHFCl_2$:$CHCl_3$. Although there are close correspondences in the GOS profiles of the HOMO → LUMO transitions between CHF_2Cl and CF_3Cl and between $CHCl_3$ and $CFCl_3$, the similarities between $CHFCl_2$ and CF_2Cl_2 are less striking, with a considerably sharper GOS secondary maximum in $CHFCl_2$ (Fig. 10*b*) relative to the broad peak in CF_2Cl_2 (15). The trend observed for the relative "dipole-to-non-dipole" contributions for these transitions suggests that molecular symmetry plays a key role in defining the contributions from different types of transitions to the GOS profile. In particular, the excited states of a more cage-like molecule such as $CHCl_3$ may be more susceptible to distortion due to Jahn–Teller effects, which in turn give rise to the more intense $K = 0$ (dipole) peak in the corresponding GOS profile. Finally, a noteworthy trend obtained in our recent angle-resolved EELS studies is that most of the $n_{Cl\,3p} \rightarrow \sigma^*_{C—Cl}$ transitions in the aforementioned CFC and HCFC molecules contain non-dipole interactions that lead to dissociation of the C—Cl bond. In particular, simple potential energy curve calculations suggest that the following $n_{Cl\,3p} \rightarrow \sigma^*_{C—Cl}$ transitions are predissociative: the $7e \rightarrow 11a_1$ transition at 7.7 eV in CF_3Cl (Fig. 6), $(3a_2, 8b_2) \rightarrow 13a_1$ transitions at 6.9 eV in CF_2Cl_2 (15), $10e \rightarrow 12a_1$ transition at 6.8 eV in $CFCl_3$ (15), and $2t_1 \rightarrow 7a_1$ transition at 7.2 eV in CCl_4 (16), as well as the $(7a'', 14a') \rightarrow 15a'$ transitions at 8.0 eV in CHF_2Cl (Fig. 9), $(10a'', 9a'') \rightarrow 16a'$ transitions at 7.5 eV in $CHFCl_2$ (18), and $9e \rightarrow 10a_1$ transition at 7.2 eV in $CHCl_3$ (19). The predissociative nature of the HOMO → LUMO transitions in these molecules is apparently quite common and clearly of interest to the understanding of the photochemical and electron-induced processes in the upper atmosphere and in plasma-related industrial applications.

3. Electrons as a powerful initiator for "novel" surface reactions

The use of low-energy electron or ion beam has become an increasingly powerful tool for the development of new materials (31). In particular, electron irradiation has been used to produce reactive ions and free radicals on surfaces (e.g., by means of an ion sputtering gun) and the resulting direct electron interactions and (or) ion interactions with the surface provide other important mechanisms and synthetic pathways not available in traditional thermal chemistry. In addition to electron-induced dissociation, electron/ion irradiation could, depending on the impact energy (IE) of the charged particle beam, also introduce other effects such as reaction activation, adsorbate removal (as in electron-stimulated desorption and ion sputtering), and creation of surface defect sites (which might affect the subsequent reaction processes and adsorption properties). In the case of ion irradiation, ion implantation and bulk atomic displacement (i.e., creation of bulk defects) could also occur. As in many applications in materials processing that involve film growth and surface modification by charged particle beam bombardment (32), these processes occur concurrently with the reaction activation process, making the study of an isolated chemical reaction difficult. Most studies have thus far been focussing on parameter optimization in the engineering of various new materials involving the use of these charged particle beams. Since many important reactions induced by low-energy electrons or ions remain unknown, it would therefore be of practical interest to investigate the fundamental mechanisms that control the initial adsorption and subsequent surface reactions induced by low-energy electron/ion irradiation.

Below we shall focus our discussion on two typical applications of the electron beam in experimental surface chemistry: (*i*) the use of electrons as a direct means of reaction activation by dissociation of adsorbates on surfaces; and (*ii*) the use of electrons as a means to produce free ions that are then used for reaction activation and ion–surface interactions. Several standard surface analytical techniques including low-energy electron diffraction (LEED), thermal desorption spectrometry (TDS), and high-resolution EELS are used for these experiments. Details of the experiments and our apparati, including our home-built angle-resolved high-resolution electron energy loss spectrometer (based on a novel design), have been described elsewhere (33, 34). Unless stated otherwise, electron irradiation was accomplished by bombarding the sample with electrons from the LEED gun or with electrons thermionically emitted from a heated tungsten filament, positioned 40 mm from the sample, at an electron flux of 2–3 $\mu A/mm^2$. Ion irradiation was performed by operating the ion sputtering gun at an ambient gas pressure of 1×10^{-6} Torr (1 Torr = 133.3 Pa) with an ion flux of ~10 nA/mm^2. The IE of the electron or ion beam could be controlled by adjusting the floating voltage applied to the sample with respect to a preselected beam voltage of the electron or ion sputtering gun.

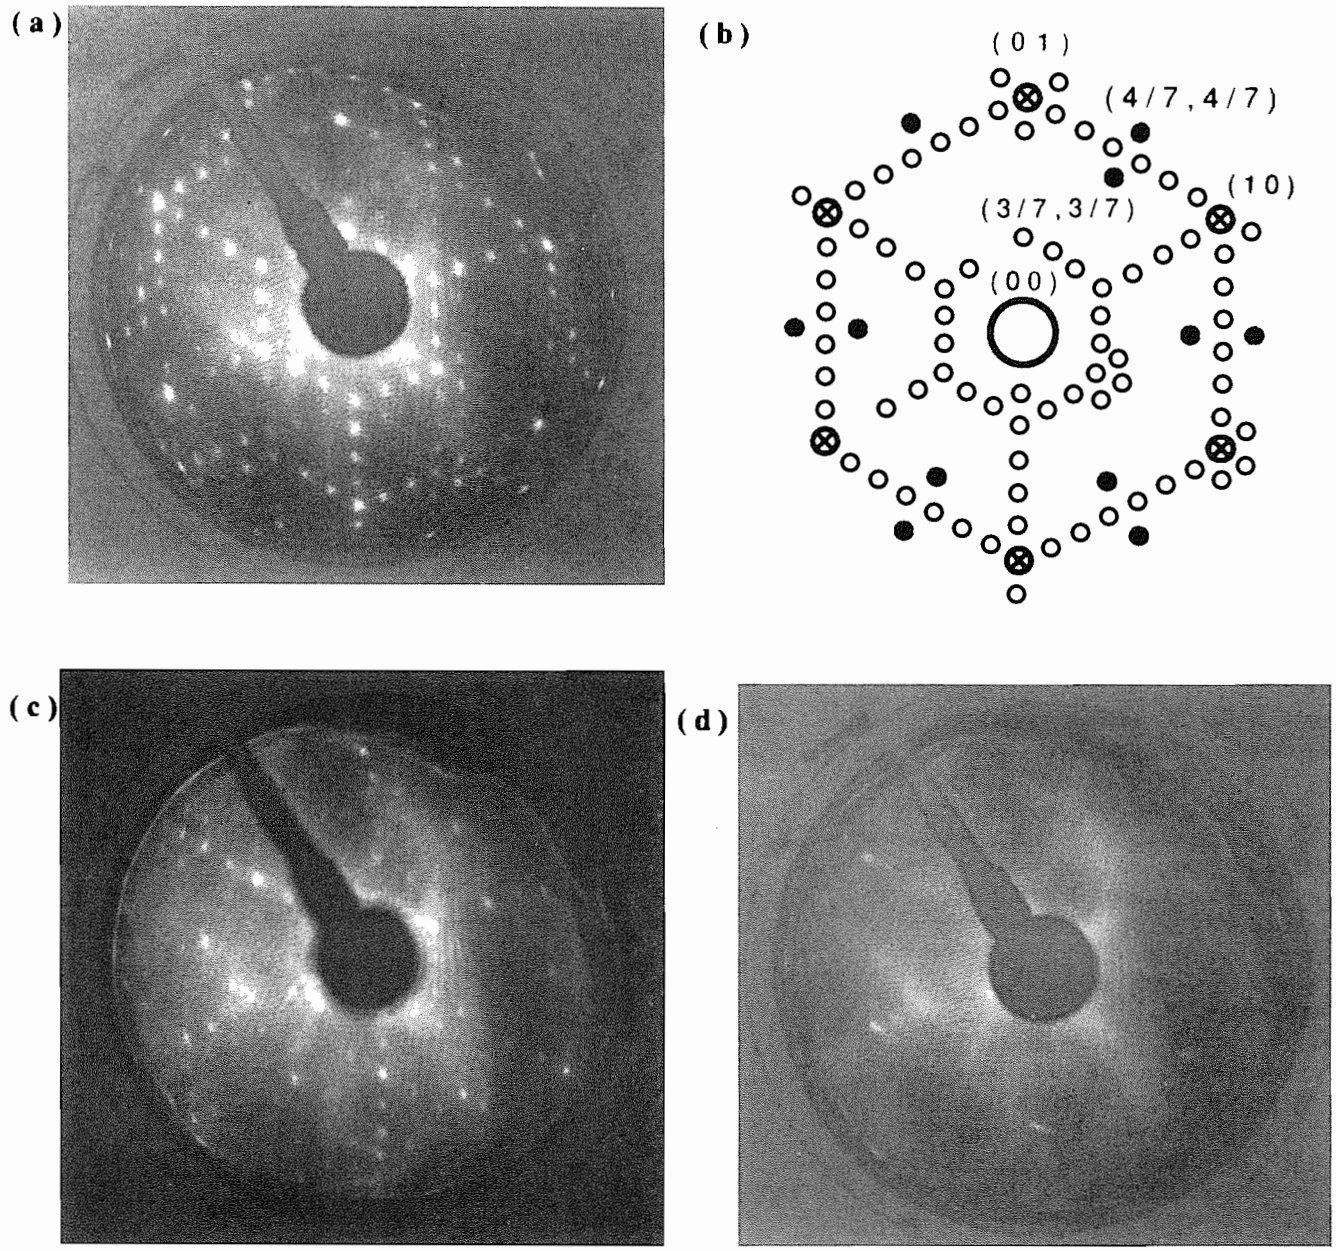
3.1 Electron-induced chemistry of pyridine and aromatic compounds on Si(111)7 × 7

Although the TDS studies for both pyridine (35) and benzene (36) reported two desorption peaks with similar desorption maxima, we found that the adsorption and reactivity of pyridine on Si(111)7 × 7 are significantly different from its homocyclic analog, benzene. In particular, the molecular desorption of pyridine (35) is found to be considerably less intense than that of benzene (36) for a similar exposure, which suggests that the adsorption of pyridine on Si(111)7 × 7 is significantly less than that of benzene (because their ionization cross sections are expected to be similar to each other). Furthermore, unlike benzene, pyridine is found to be considerably more sensitive to low-energy electron irradiation on the 7 × 7 surface. Figure 11 shows the LEED pattern of 100 L (1 Langmuir = 1×10^{-6} Torr-second) of pyridine at room temperature (RT) (35). The relatively strong intensities of the (±3/7, ±3/7) and (±4/7, ±4/7) fractional-order spots in the observed "modified" 7 × 7 LEED pattern indicate that the adsorption of pyridine on the Si surface is not truly random and that preferential adsorption of pyridine may occur at specific types of dangling-bond sites of the 7 × 7 unit cell (37). The "modified" 7 × 7 pattern is found to convert rapidly to a 1 × 1 pattern by the low-energy (~50–100 eV) electron irradiation.

The effects of electron irradiation have also been examined by thermal desorption and are demonstrated in Fig. 12 (35). In particular, the reduction in the mass 84 (molecular) desorption of d_5-pyridine adsorbed on the 7 × 7 surface at RT and the large increase in the mass 4 (D_2) desorption due to electron irradiation provide further evidence that a significant portion of the adsorbed pyridine undergoes electron-induced dissociation. Whether pyridine dissociates completely to C, N, and H atoms or to smaller fragments that in turn undergo further dissociation during thermal desorption is, however, unclear. Of all the aromatic compounds on Si(111)7 × 7 studied by us (36, 38, 39), pyridine appears to be the only compound that is found to have significant interaction with electron irradiation. Despite the similarities in the TDS profiles (and electronic structures), thiophene and furan (unlike pyridine) adsorbed on the 7 × 7 surface were not affected by the exposure to low-energy electrons during the LEED experiment (39). Furthermore, the diffuse 7 × 7 LEED pattern observed for the adsorption of benzene (36) or toluene (38) on Si(111)7 × 7 was also not found to have degraded noticeably during the LEED analysis. Evidently, these aromatic compounds are not significantly affected by low-energy electron irradiation. The factors responsible for the high sensitivity to electron irradiation of pyridine adsorbed on Si(111)7 × 7 remain unknown, which demonstrates that the surface chemistry of a series of homologous molecules can be very complex and different from one another.



3.2 "Novel" surface reactions involving CO on Cu(100) induced by low-energy electrons and ions

One of the fundamental questions about the relevance of basic research in surface science to industrial applications is the effect of "dirt" on the observed surface phenomena or processes. In particular, common surface atomic contaminants (coadsorbates) such as O, N, and C present in the forms of oxides, nitrides, and graphitic or carbidic carbons have all been found to have a major effect on chemisorption and surface reactions. For example, unlike typical reaction poisons such as S and P, the presence of O (created by techniques involving electron or ion irradiation) has been found to have a stabilizing effect on the adsorption of CO on Cu(100), a chemisorption system that could only be observed below 200 K (40–43). In Fig. 13, we show the effects of low-energy electron irradiation on this "classic" chemisorption system, CO/Cu(100) (34). In particular, a typical vibrational (high-resolution) EELS spectrum for 100 L of CO on Cu(100) at 120 K is shown in Fig. 13*a*. The characteristic peaks for the Cu–CO stretch, ν(Cu–CO), at 338 cm^{-1} and the C–O stretch, ν(C–O), at 2084 cm^{-1} were found to be in good accord with the previously published data (40–42). The c(2 × 2)CO/Cu(100) sample was then irradiated with electrons (thermionically emitted from a heated tungsten filament positioned 40 mm away at a typical flux of 2.7 $\mu A/mm^2$) at 100 eV IE for 10 min, which gave rise to a less sharp c(2 × 2) LEED pattern. The ν(C–O) peak for the electron-irradiated sample remained at the same energy-loss position (Fig. 13*b*) but with a reduction in intensity, which was likely the result of electron-induced desorption and dissociation. On the other hand, the corresponding ν(Cu–CO) peak at 338 cm^{-1} became a broad shoulder, which could be attributed to additional contribution from the well-known Cu–O stretch at 305 cm^{-1} as previously observed for c(2 × 2)O/Cu(100) (44). When the sample temperature was slowly increased from 120 K, the peak at 2084 cm^{-1} was found to gradually diminish (Fig. 13*c*) and disappear at 200 K (Fig. 13*d*), revealing the peak at 2011 cm^{-1}. At this point, the LEED pattern became a diffused 1 × 1. The observed intensity reduction with increasing temperature of the ν(C–O) peak at 2084 cm^{-1} was consistent with the previous work (40). The new feature at 2011 cm^{-1} was clearly the result of low-energy electron irradiation and could be tentatively attributed to a "perturbed" C–O stretch (i.e., a red-shifted ν(C–O)). After the electron-irradiated sample was annealed to 160 K, the broad shoulder at ~338 cm^{-1} became a single peak at 310 cm^{-1}, which could be assigned to the Cu–O stretch (44), indicating the presence of atomic oxygen on the surface. The intensity of the peak at 2011 cm^{-1} remained essentially unchanged upon annealing to 370 K (Fig. 13*e*) and then almost completely diminished upon further annealing to 420 K (Fig. 13*f*). In contrast, the peak at 310 cm^{-1} decreased in intensity gradually upon annealing from 160 K (Fig. 13*c*) to 420 K (Fig. 13*f*).

Additional experiments to further elucidate the nature of this red-shifted ν(C–O) peak gave the following results (34): (*i*) Reducing the electron IE from 100 to 40 eV appeared to have no significant effect on the corresponding EELS spectra, which indicates that an electron IE of 40 eV was sufficient to activate the surface reactions that generated the "stabilized" CO. (*ii*) Exposing a high dose (1200 L) of CO to an amorphous Cu surface (obtained by sputtering Cu(100) in 2×10^{-5} Torr of Ar for 20 min at 500 eV IE) at 120 K and then annealing it to RT without electron irradiation did not produce the red-shifted CO peak (at 2011 cm^{-1}). Since Ar^+ sputtering is believed to introduce defect sites on Cu(100), this observation indicates that the presence of "stabilized" CO was not due to adsorption on defect sites. (*iii*) Exposing CO to an oxygen-covered Cu(100) surface (which was prepared by exposing a clean Cu(100) surface at RT with different dosages of O_2 ranging from 0.5 to 300 L) at 120 K without electron irradiation and then annealing the resulting sample to RT did not generate the

Fig. 11. The LEED pattern (*a*) and the corresponding schematic diagram (*b*) of the LEED spots shown in (*a*) for a clean Si(111)7 × 7 surface, and the LEED patterns for Si(111)7 × 7 exposed with 100 L of pyridine at room temperature at the beginning of the LEED experiment (*c*) and after 60 s of electron irradiation at ~80 eV and 10 μA (*d*). The integer-order spots are shown as circles with crosses and the (1 0) and (0 1) directions are chosen arbitrarily. Fractional-order spots connecting the integer-order spots are represented by smaller open circles, and the off-axis (±3/7, ±3/7) and (±4/7, ±4/7) fractional-order spots are shown as solid circles. The small distortion in the upper right corner of the LEED pattern is due to electron back-scattering from the nearby mass spectrometer chamber.

red-shifted CO peak. This result indicates that without electron irradiation CO could neither adsorb on an "oxidized" Cu(100) surface nor coadsorb with surface oxygen atoms to produce the "stabilized" CO. Finally, (*iv*) exposing CO to a carbon-covered Cu(100) surface (obtained by sputtering Cu(100) in C_2H_4 at RT and then annealing to 600 K) at 120 K without electron irradiation followed by annealing the resulting sample to RT also did not produce the red-shifted CO peak. This observation suggests that the red-shifted CO peak was not caused by coadsorption of CO with the surface carbon. All these experiments suggest that the observed red-shifted peak at RT was due to "stabilized" CO species that were generated in situ during CO exposure by electron irradiation.

From the results of other additional experiments involving ion irradiation, we conclude that the formation of "stabilized" CO may be considered as a two-step process (34): (*i*) Formation of reactants on the surface: C by electron/ion irradiation in CO or C_2H_4, and O by electron/ion irradiation in CO or by

Fig. 16. Perspective (*a*) and side-view (*b*) diagrams of a proposed bonding structure for as-formed CO adsorbed in the presence of predeposited O on Cu(100).

(34). It should be noted that an oxygen-covered Cu(100) surface can be readily obtained by directly dosing O_2 to Cu(100) at RT (44), as identified by the characteristic ν(Cu–O) peak near 300 cm^{-1} (Fig. 14*a*) and a c(2 × 2) LEED pattern. Evidently, the energy loss peak at 2011 cm^{-1}, characteristic of the previously observed "stabilized" CO adsorption, could again be obtained by ion irradiation of the oxidized sample in C_2H_4 at RT (Fig. 14*b*). This peak became more intense as the sample was annealed from RT to 370 *K* (Fig. 14*c*) and then almost completely diminished upon further annealing to 430 *K* (Fig. 14*d*).

The presence of the red-shifted CO peak did not appear to depend on the order of dosing O_2 and ion irradiation in C_2H_4 (Fig. 15), i.e., by reacting O with a Cu(100) surface predeposited with carbon-containing species (34). Although C_2H_4 (like CO) was found to adsorb on Cu(100) only at low temperature (45), we could increase the concentration of surface C (and (or) C-containing species) by ion irradiation of a clean Cu(100) surface at 50 eV IE in 600 L of C_2H_4 at RT. Despite the lack of any discernible feature in the EELS spectrum (Fig. 15*a*), the increase in surface C concentration was verified by Auger electron spectroscopy. After 100 L of O_2 was subsequently exposed to the surface (Fig. 15*b*), a prominent ν(Cu–O) peak at 300 cm^{-1} was observed. When the sample was annealed to 370 K (Fig. 15*c*), the CO peak at 2011 cm^{-1} reappeared and could again be removed by annealing to 430 K. In

Fig. 17. Vibrational electron energy loss spectra for (*a*) Cu(100) sputtered with 9 kL (1 kL = 1000 L) of ethylene at 200 eV and 10 nA/mm^2 at 300 K, and for sample (*a*) annealed to (*b*) 370 K, (*c*) 470 K, (*d*) 570 K, and (*e*) 670 K.

keeping with the EELS results shown in Figs. 14 and 15, the corresponding TDS data revealed that maximum desorption of both CO and CO_2 from the surface occurred near 400 K (34). CO_2 could be produced in situ by recombinative desorption of the adsorbed O and CO, i.e., O (ad.) + CO (ad.) $\rightarrow$ CO_2 (g). Evidently, the peak at 2011 cm^{-1} in Figs. 14 and 15 could be attributed to the same "stabilized" CO adsorption obtained earlier by electron irradiation (Fig. 13). On the other hand, if the C-covered surface (Fig. 15*a*) was first annealed to 500 K and then followed by O_2 exposure at RT, no red-shifted CO peak was observed even upon annealing the sample to 370 K. This indicates that the presence of surface atomic carbon and (or) C-containing species, produced by ion irradiation in C_2H_4, was essential to the formation of the red-shifted CO peak. As the C-covered sample was annealed to 500 K, the carbon atoms either combined with one another to form graphite or diffused into the bulk, preventing the formation of the "stabilized" CO species on Cu(100). From considerations of the available mechanisms that have been proposed to explain the observed red shift and stabilization effects (46), we favour a direct-interaction bonding model involving an O–CO quasi-complex, shown in Fig. 16 (34). In particular, the unusual stabilization of CO adsorption found in our experiments can be explained by a partial bond between a CO molecule adsorbed on an atop site and a preadsorbed O atom.

If the dosage of ethylene ions to Cu(100) was increased significantly by, for example, ion sputtering with 9 kL (1 kL = 1000 L) at a higher impact energy of 200 eV, the corresponding EELS spectra (over a set of annealing temperatures) shown in Fig. 17 revealed broad vibrational features at 764, 1392, and 2944 cm^{-1} attributable to C–H rock, C=C stretch and C–H stretch, respectively. These features could be identified by examining the corresponding EELS spectra for the sample prepared with C_2D_4 instead of C_2H_4 (isotopic substitution experiments). With the exception of the band at 764 cm^{-1}, the other two bands diminished in intensity more rapidly after successive annealing to a higher temperature (Figs. 17*b–d*). There was also a small shift to a higher energy for the 2944 cm^{-1} band. In Fig. 18, we show the effects of increasing the ion dosage of C_2H_4 on the Cu(100) sample predeposited with O (discussed earlier in Fig. 14*a*). In addition to the ethylene related peaks found in Fig. 17, two additional C–O stretch features at 2019 and 2163 cm^{-1} are particularly interesting. The peak at 2019 cm^{-1} corresponds to the red-shifted ν(C–O) of the O–CO quasi-complex in Fig. 15. Using arguments involving the intensity variation of the ion dosage, the new feature at 2163 cm^{-1} can be tentatively attributed to a "blue-shifted" ν(C–O) of a CO molecule stabilized by direct interaction with a nearby C-containing species. The temperature dependence of the red-shifted and blue-shifted ν(C–O) features provide further evidence that the adsorption of CO molecule could be stabilized by direct interaction with either a neighbouring O atom or a C-containing species.

The present work therefore not only provides direct support for in situ CO production at RT by electron- and ion-induced surface reactions on an "unreactive" surface such as Cu(100), but also illustrates the importance of common surface contaminants ("dirt") such as O and (or) C-containing species on the adsorption and surface reactions. It also demonstrates the enormous potential of activating surface reactions by means of low-energy electron or ion irradiation.

4. Concluding remarks

As we celebrate the centennial birthday of the electron, we as chemists have come a long way in the creative use of the electron not just as a unique tool for spectroscopic studies of technological materials such as Freons and their substitutes, but also as a powerful energy carrier for initiating new surface reactions directly or via radicals and ions generated by electron dissociation. We are optimistic that the development and applications of novel electron-based techniques for studying fundamental aspects of both gas-phase and surface chemistry will continue into the 21st century.

Acknowledgement

The financial support for the above work has been provided by the Natural Sciences and Engineering Research Council of Canada (NSERC) and in part by the J.P. Bickell Foundation, the Ontario Centre for Materials Research (OCMR), the Network of Centres of Excellence in Molecular and Interfacial Dynamics (CEMAID), NATO, and the Petroleum Research Fund (PRF). The above work would not have been possible without the ingenuity and dedication of four of my former and present graduate students: De-Qing Hu, Charles MacPherson, Ji-Feng Ying, and Hui Yu. I am indebted to Mr. Jacek Szubra and the current and early-retired staff of the Science Shops for their skillful workmanship in the development of all of our machines in our laboratory in the past decade.

Correlation between the electron solvation time and the solvent dielectric relaxation times τ_2 and τ_{L1} in liquid alcohols and water: towards a universal concept of electron solvation?

Jean-Paul Jay-Gerin

Abstract: A simple model of electron solvation in polar liquids is presented, in which we attempt to link the electron solvation time τ_s to τ_2, the time for reorientation of monomeric molecules, and to τ_{L1}, the longitudinal dielectric relaxation time of the solvent. It is shown that this model, which is suggested by the so-called hybrid model of electron solvation previously described for methanol, can satisfactorily account for electron solvation in all polar liquids, including linear alcohols (methanol to decanol), 1,2-ethanediol, H_2O, and D_2O, for which data are available from the literature. A close similarity is indeed obtained between our calculated values of τ_s and those measured experimentally. The observation of such a correlation supports a universal concept of electron solvation.

Key words: polar liquids, electron solvation time, solvent dielectric relaxation times, universal concept of electron solvation.

Résumé : Nous présentons un modèle simple de la solvatation de l'électron dans les liquides polaires, sur la base duquel nous tentons de relier le temps de solvatation de l'électron τ_s à τ_2, le temps de réorientation des molécules monomères, et à τ_{L1}, le temps de relaxation diélectrique longitudinal du solvant. Nous montrons que ce modèle, suggéré par celui dit «hybride» décrit précédemment pour la solvatation de l'électron dans le méthanol, peut rendre compte de façon satisfaisante de la solvatation de l'électron dans tous les liquides polaires, incluant les alcools linéaires (méthanol au décanol), l'éthanediol-1,2, H_2O et D_2O, pour lesquels des données sont disponibles dans la littérature. Une proche similarité est effectivement obtenue entre nos valeurs de τ_s calculées et celles mesurées expérimentalement. L'observation d'une telle corrélation plaide en faveur d'un concept d'universalité de la solvatation de l'électron.

Mots clés : liquides polaires, temps de solvatation de l'électron, temps de relaxation diélectrique du solvant, concept d'universalité de la solvatation de l'électron.

Solvated excess electrons (e^-_s) in polar solvents have been a subject of considerable experimental and theoretical interest since their discovery and identification in liquid water in the 1960s (for a recent review, see ref. 1). Time-resolved dynamical studies of electron solvation were first conducted in low- and room-temperature liquid alcohols, and a number of experimental data have been obtained over the last 25 years (2–14). In an attempt to identify which solvent motions may be responsible for the solvation, the measured electron solvation times (τ_s) were compared with the alcohol Debye dielectric relaxation times τ_1, τ_2, and τ_3 (15–18) associated with the cooperative hydrogen-bond dynamics in the liquid, the rotation of non-hydrogen-bonded monomeric molecules, and the reorientation of the OH group around the C—O bond, respectively. A correlation was observed between τ_s and τ_2 in a series of linear alcohols (methanol to decanol) (5, 9).

Recently, ultrafast spectroscopic measurements on electron solvation in liquid alcohols at room temperature have been reported (19–23), and have led to the determination of new precise data for τ_s in those liquids. In particular, the femtosecond laser experiments of Pépin et al. (20, 21) in methanol provided evidence that the solvation of electrons in this liquid may well be described with a model called "hybrid," which involves, among other things, two electronic states (one weakly bound e^-_{wb} and one strongly bound e^-_{sb}), both of them relaxing via a continuous blue shift and between which there is, concurrently, a stepwise transfer mechanism. Essentially similar results were obtained by Hirata and Mataga (13) and by Shi et al. (23), at least for the continuous evolution of the relatively stable form of the electron, e^-_{sb}, towards e^-_s. Most recently, this same hybrid model was also found capable of describing the spectral manifestations of electron solvation in deuterated water (24), as well as in H_2O and in various small-chain alcohols (25).

In this paper, we present a simple model of the electron solvation process, in which we attempt to link τ_s to the solvent dielectric relaxation times τ_2 and τ_{L1}, where $\tau_{L1} = (\varepsilon_\infty/\varepsilon_0)\tau_1$ is

the well-known longitudinal relaxation time.[2] We show that this model, which is in essence suggested by the hybrid model of Pépin et al. (20, 21, 24, 25), can satisfactorily account for electron solvation in all polar liquids, including linear alcohols (methanol to decanol), 1,2-ethanediol, H_2O, and D_2O, for which data are available from the literature, a result, in turn, in favor of a universal concept of electron solvation.

As already proposed (13, 20, 21, 24, 25), we interpret, in the model presented here, the continuous blue shift of e^-_{wb}, as well as that of e^-_{sb}, as due to the long-range relaxation of the solvent whose characteristic time is given by τ_{L1} (26). In the light of the known correlation between τ_s and τ_2 in liquid alcohols (5, 9), we also assume that the stepwise transfer process from e^-_{wb} to e^-_{sb} or e^-_s is controlled by rotational motions of solvent monomers whose characteristic time is given by τ_2.

In the context of these hypotheses, we consider that there are *three* different relaxation processes of e^-_{wb}, which operate *in parallel*: the first one includes the formation of e^-_s through a direct stepwise transition with characteristic time τ_2; the second one proceeds via a stepwise transfer to e^-_{sb} with time constant τ_2, followed by a continuous blue shift of e^-_{sb} with time constant τ_{L1}; and the third process is similar to both preceding ones, except that it begins with a continuous blue shift of e^-_{wb} with time constant τ_{L1}. For simplicity, we neglect in this model the trapping time of a quasifree thermalized electron (e^-_{qf}) into the e^-_{wb} state, as well as the direct deep trapping of e^-_{qf} into the e^-_{sb} or e^-_s state without transit through e^-_{wb} (these processes are assumed to be practically instantaneous).

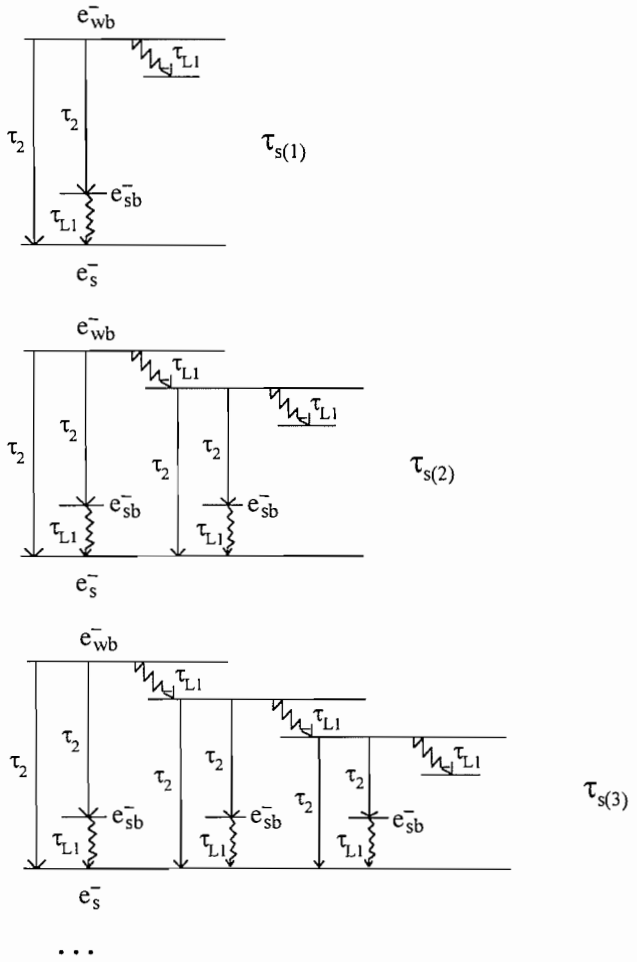
Figure 1 presents a schematic picture of our proposed model of the electron solvation process, which may simply be viewed as an (infinite) series of elementary steps (n = 1,2,...) with corresponding characteristic times $\tau_{s(1)}$, $\tau_{s(2)}$,... According to this scheme, the time $\tau_{s(1)}$ involved in the relaxation process of e^-_{wb} for the first-order step (n = 1) considered, is given by

$$[1]\quad \frac{1}{\tau_{s(1)}} = \frac{1}{\tau_2} + \frac{1}{\tau_2 + \tau_{L1}} + \frac{1}{\tau_{L1}}$$

while for the second-order step (n = 2), we have

$$[2]\quad \frac{1}{\tau_{s(2)}} = \frac{1}{\tau'_2} + \frac{1}{\tau_{L1} + \tau_{s(1)}}$$

where



$$[3]\quad \frac{1}{\tau'_2} = \frac{1}{\tau_2} + \frac{1}{\tau_2 + \tau_{L1}}$$

This result may readily be extended to the nth-order step, for which we get

$$[4]\quad \frac{1}{\tau_{s(n)}} = \frac{1}{\tau'_2} + \frac{1}{\tau_{L1} + \tau_{s(n-1)}}$$

[2] Note that in the relation $\tau_{L1} = (\varepsilon_\infty/\varepsilon_0)\tau_1$, τ_1 is the dielectric relaxation time associated with the long-range, cooperative hydrogen-bond dynamics in the solvent, and ε_∞ and ε_0 are the "infinite" and zero-frequency solvent dielectric constants, respectively. For a discussion of the physical meaning of τ_{L1}, see, for example, ref. 26.

Fig. 1. Schematic picture of our proposed model of electron solvation. There are *three* different relaxation processes of the weakly bound electron (e^-_{wb}) to the fully relaxed solvated electron (e^-_s), which operate *in parallel*: the first one corresponds to a direct stepwise transition to the e^-_s state with characteristic time τ_2; the second one includes a stepwise transfer to the intermediate strongly bound (e^-_{sb}) state with time constant τ_2, in series with a continuous blue shift of e^-_{sb} with time constant τ_{L1}; and the third process is similar to both of the two preceding ones, except that it is initiated by a gradual blue shift of e^-_{wb} with time constant τ_{L1}. The overall solvation process of the excess electron may be viewed as an (infinite) series of elementary steps (n) with corresponding characteristic times $\tau_{s(1)}$, $\tau_{s(2)}$,..., $\tau_{s(n)}$. In this model, the electron solvation time τ_s is simply given by $\tau_{s(n)}$ as $n \to \infty$ (see text).

Upon using the recurrence relation [4] for the limiting case where $n \to \infty$, we easily obtain the following formula for the overall electron solvation time τ_s:

$$[5]\quad \tau_s = \frac{\tau_{L1}}{2}\left[\left(1 + \frac{4\,\tau'_2}{\tau_{L1}}\right)^{1/2} - 1\right]$$

or, equivalently, if we introduce the (dimensionless) parameter $x = 4\,\tau'_2/\tau_{L1}$,

$$[6]\quad \frac{\tau_s}{\tau'_2} = \frac{2}{x}\left[(1 + x)^{1/2} - 1\right]$$

[a]Data are for room temperature, assumed to be ~298 K. Preferred values are underlined.
[b]Measured.
[c]$x = 4\,\tau'_2/\tau_{L1}$, with τ'_2 calculated from eq. [3].
[d]Calculated from eqs. [3] and [5] or [6].
[e]Estimated assuming an isotope effect of $\sqrt{2}$, equal to the square root of the D/H mass ratio, for rotational motion (see refs. 18 and 35).
[f]Interpolated.
[g]Estimated from the data shown in Fig. 5 of ref. 14.

Interestingly, for all the solvents considered in this study, only a limited number of steps (typically, $n = 3$ or 4) suffices in practice to achieve very good convergence for τ_s.

Two limiting cases of eq. [6] are worth mentioning. In the case where $x << 1$, eq. [6] reduces to the asymptotic form:

$$[7] \quad \frac{\tau_s}{\tau'_2} \approx 1 - \frac{x}{4} + \ldots$$

which shows that $\tau_s \rightarrow \tau'_2$ (or τ_2 in this limit) as $x \rightarrow 0$. In the other limit where x is sufficiently large, eq. [6] shows that τ_s/τ'_2 decreases monotonically as a function of x and approaches zero as $2\sqrt{x}$ when $x \rightarrow \infty$.

To examine the validity of the correlation between τ_s and τ_2 and τ_{L1}, expressed by eqs. [3] and [5] or [6], we have gathered in Table 1 all the presently available experimental data for these parameters for 12 polar liquids at room temperature, including linear alcohols (methanol to decanol), 1,2-ethanediol, H_2O, and D_2O. Also listed in Table 1 are the corresponding values of x and τ_s that we calculated using eqs. [3] and [5] or [6]. As can be seen, in spite of the (rather large) experimental uncertainties and dispersion in the values of the observed solvation times, a close similarity between our calculated τ_s values[3] and the measured ones clearly holds for all the solvents considered. In particular, our calculated values of τ_s reproduce well the trend of the experimental data over the range of x values studied (from 0.3 for 1-decanol to 5.2 for D_2O), even though they may appear, in certain cases, slightly too low (especially, for 1-propanol, 2-propanol, and 1-hexanol). In view of these results, we are thus inclined to conclude that the present model offers a satisfactory description of the electron solvation process, at least for the liquids

[3] Note that the present model contains no adjustable parameter.

considered here, and to suggest that, in turn, a universal concept of electron solvation is, indeed, plausible.

As can be seen in Table 1, we note that, for the series of alcohols considered, our model also reproduces well the previously observed (5, 9) correlation between τ_s and τ_2. This is especially true for longer chain alcohols, where τ_2 (or τ'_2) is much shorter than τ_{L1} (see eq. [7]). Electron solvation in that case proceeds on the time scale of τ_2 and can thus be interpreted as primarily due to single-molecule rotational motions that accompany the short-range conformational changes of the medium in the strong electric field of the localized excess electron (44). In fact, the alcohol molecules that are involved in these reorientational motions can be considered as belonging to the first solvation shells, as they are considerably less associated than in the bulk.

When the length of the carbon chain decreases, however, τ_2 and τ_{L1} both decrease, τ_{L1} decreasing much faster than τ_2 (or τ'_2) so that x increases. Under these conditions, the asymptotic form of eq. [7] becomes less and less valid and eq. [6] must clearly be used instead. Such a situation is most evident for liquid methanol, where τ_2 and τ_{L1} are practically identical and where x reaches a value of 2.1 (see Table 1). In this case, electron solvation is not only controlled by the short-range, single-molecule reorientation of the medium in the vicinity of the electron, but equally reflects the long-range, collective reorganization of the solvent hydrogen-bond structure (through the longitudinal relaxation time τ_{L1}).

For H_2O and D_2O, the situation is exactly opposite to that encountered for the alcohols, as τ_{L1} now dominates over τ_2. In other words, for these two liquids, the long-range solvent relaxation driven by the excess electron takes over from the short-range molecular reorientations and then plays a dominant role in the electron solvation process. As we see from Table 1, our model predicts values of τ_s close to τ_{L1} for both these solvents, in good agreement with experiment.

Most interestingly, one should note here that the above results are at variance with the mechanism of electron solvation in liquid water put forward by molecular simulations of the process (45–47) that assigns the weakly bound electron e^-_{wb} to an "excited" state of the fully hydrated electron (e^-_{aq}). This question concerning the nature of the e^-_{wb} state in relation to its view as an excited state of e^-_{aq} has received a great deal of attention over the last decade. It has been addressed in some detail in three recent papers by our group (1, 24, 25) and will thus not be developed any further here.

In conclusion, we have formulated in this paper a simple model of electron solvation in polar liquids, which favors a microscopic picture of the electron solvation process relying on both short- and long-range structural rearrangement and molecular motions of the solvent. This model suggests, in accord with the available experimental data, a correlation between the electron solvation time τ_s and the solvent dielectric relaxation times τ_2 and τ_{L1} (see eqs. [3] and [5] or [6]). The fact that this correlation successfully holds for all the solvents considered, including liquid alcohols, 1,2-ethanediol, H_2O, and D_2O, supports a universal concept of electron solvation. Nevertheless, it would be most important to further test the hypotheses of the model and thus the validity of the suggested correlation. To this aim, femtosecond or picosecond laser experiments would be of considerable interest, especially in long-chain alcohols (for example, pentanol to dodecanol, including primary, secondary, and tertiary alcohols) and in other associated solvents (for example, diols, such as 1,2-ethanediol and 1,2-propanediol, and triols, such as 1,2,3-propanetriol or glycerol) where electron solvation has not yet been explored by means of these techniques. Simultaneously, measurements of the dielectric relaxation parameters (and especially τ_2 and τ_{L1}) of the selected solvents would also be in order. Finally, experiments in unassociated polar liquids would also be of unique help in increasing our overall understanding of electron solvation dynamics and in further examining the concept of universality of electron solvation.

Stabilized haloylides: synthesis and reactivity

Margaret M. Kayser, Jun Zhu, and Donald L. Hooper

Abstract: This paper describes simple and successful methods for the preparation of stabilized halogenated phosphoylides and discusses their stability, reactivity, and utility in organic synthesis. Preparations of several halogenated compounds including pharmaceutically interesting enol lactones are reported.

Key words: halogenated stabilized ylides, preparation, structure, stability, reactivity, applications; vinylic halides, halo enol lactones.

Résumé : Dans ce travail, on décrit des méthodes simples et réalisables de préparer des phosphoylures halogénés stabilisés et on discute de leur stabilité, de leur réactivité et de leur utilité en synthèse organique. On rapporte les préparations de plusieurs composés halogénés, y compris des lactones énoliques intéressantes d'un point de vue pharmaceutique.

Mots clés : ylures halogénés stabilisés, préparation, structure, stabilité, réactivité, applications; halogénures vinyliques, lactones énoliques halogénées.

Introduction

Stabilized phosphoylides are reagents for the synthesis of vinylic halides, an important family of compounds that includes inhibitors of serine proteases (1) and diverse starting materials that can be further transformed into a multitude of strategically halogenated molecules. The formation of haloylides by direct halogenation of the carbomethoxymethylenetriphenylphosphorane **1** was investigated by several groups in the early sixties and the ylides were isolated and characterized (2–5). Our NMR investigation of the direct bromination of several stabilized ylides of the type $Ph_3P{=}CHCOOR$ showed that direct halogenations are accompanied by side reactions and are not suitable for preparative applications.

In an effort to obtain consistently high yields of pure haloylides that can be generated and used in situ without isolation and purification we set out to investigate alternative approaches and in due course developed successful protocols leading to the formation of chloro-, bromo-, iodo-, and fluoroylides. In this paper we report on the synthesis of these ylides and the subsequent study of their reactivities with aldehydes and cyclic anhydrides.

Results and discussion

In situ formation of chloro-, bromo-, and iodoylides

In a series of preliminary experiments all intermediates and products formed during the reaction of ylide **1** (R = CH_3) with bromine were identified.[3] The equilibria involved are illustrated in Scheme 1. These experiments show that a buildup of the conjugate acids **1a** and **2a** interferes with the accumulation of bromoylide in the reaction mixture. This suggested that replacing Br_2 with N-bromosuccinimide (NBS) may produce more satisfactory results since the succinimide anion formed should deprotonate the conjugate acids. In practice, NMR experiments in which a solution of ylide **1** was mixed with an equimolar quantity of NBS in $CDCl_3$ at −40°C gave bromoylide in better than 90% yield. Similar reactions of **1** with *N*-chlorosuccinimide (NCS) and *N*-iodosuccinimide (NIS) produced chloro- and iodoylides in 85 and 97% yields, respectively. The spectroscopic data for all halogenated ylides are assembled in Table 1.

The above protocol for generating haloylides in situ gave the purest product in the case of iodoylide **4**, which was contaminated only with a trace amount of its conjugate acid **4a**. Under identical reaction conditions, bromoylide **2** contained a slightly higher proportion of its conjugate acid **2a**. Moreover, during several runs with NBS, a small quantity of ylide **1** in equilibrium with its conjugate acid **1a** was also detected as a broad **1/1a** signal. The reaction of **1** with NCS, on the other hand, consistently produced mixtures containing **1/1a** in addition to the chloroylide **3** and its conjugate acid **3a**. Variations in temperature had no effect on product composition. An increase in the proportion of NCS (1.8:1) caused the disappearance of the broad **1/1a** signal, but at the same time most of **3** was converted into its conjugate acid **3a** and the dichlorophosphorane salt **3b**. These observations suggested that the relative basicity of haloylides increases from iodo- to bromo- to chloroylide. Thus chloroylide, the most basic of the three haloylides and comparable in reactivity to ylide **1**, is involved in proton exchange with all acidic species present in the reaction mixture including **1a** and traces of water.

In situ formation of fluoroylide

Attempts to use a similar procedure to generate fluoroylide **5** (R = Et) were not encouraging. Direct fluorination of ylide **1** (R = Et) with *N*-fluorodiphenylsulfonamide **6** in the presence of K_2CO_3 led to formation of the conjugate acid of fluoroylide **5a**, difluorophosphorane **5b**, and **1a**. There was no detectable accumulation of **5**. Changes in the ratio of reactants with variations in temperature between −40 and +25°C did not alter the composition of the product.[4]

Although the reaction of **1** with **6** failed to produce a signal for ylide **5**, trace quantities must have been present in the reaction mixture. This was demonstrated by the following experiment. Freshly distilled benzaldehyde was added to the mixture of **5a** and **1a**, generated as outlined above, and the reaction was monitored by ^{31}P NMR for several days. After 3 days, **5a** had disappeared and only a Ph_3PO signal remained in the ^{31}P spectrum. The proton and fluorine NMR spectra of the product showed that it was composed of *trans* and *cis* cinnamates in a 9:1 ratio (65%), and *Z* and *E* fluorocinnamates in a 3:1 ratio (35%). In a parallel experiment with phthalic anhydride, the reaction was also slow; nonetheless, after 3 days a mixture of *Z* and *E* (4:1) fluoro enol lactones was formed in 20–30% yield. No change could be detected when this reaction was allowed to proceed for an additional 3 days. When the latter reaction was repeated with **1** (R = *t*-Bu) the yield of fluorinated products was similar, but the ratio of the two enol lactones was shifted and, after 6 days, the *E* isomer was the major product.

Preparative-scale reactions of haloylides with aldehydes and cyclic anhydrides

Wittig reactions employing haloylides are complicated by the very nature of these reagents. Haloylides react easily with traces of acids, including their own and other conjugate acids. They decompose upon exposure to moisture and also when treated with more BuLi than the minimum quantity required to remove acidic impurities.[5] These problems prompted our efforts to devise one-pot procedures that would allow high-yield condensation reactions with aldehydes and cyclic anhydrides without isolation and purification of haloylides.

[4] Ylide **5** did form, as witnessed by the emergence of a doublet centred at 13.9 ppm in the ^{31}P NMR spectrum[3] after a drop of a dilute solution of BuLi in hexane was added to the reaction mixture.

[5] The addition of BuLi to the solution of an ylide in equilibrium with its conjugate acid converts the acid to ylide and removes traces of other acidic impurities and water (9, 10). It should be remembered that, when added in excess, BuLi decomposes stabilized ylides. On the other hand, we did not observe, under the reaction conditions described, any reaction with the two solvents used in these reactions, neither chloroform nor dichloromethane.

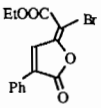
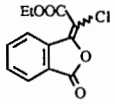
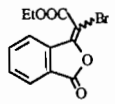
$Ph_3P{=}CBrCOOEt$	Furfural		**14**	100:—	95	

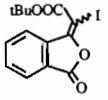
Although in the course of our NMR studies we developed successful methods for the in situ generation of chloro-, bromo-, and iodoylides, we soon discovered that the same protocols were not suitable for preparative-scale Wittig reactions. The disappointing yields obtained in these reactions were caused by unfavourable equilibria. Haloylides generated in situ, according to the method described above, are in equilibrium with ylide **1**, which competes efficiently for an aldehyde or anhydride. During the condensation with a carbonyl group, ylide **1** is depleted and the shift in equilibrium brings about the conversion of haloylide to its conjugate acid (Scheme 2).

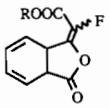
To minimize problems associated with equilibria and to increase yields of methyl bromocinnamate, the procedure was modified to include another base in addition to succinimide ion. Anhydrous K_2CO_3 turned out to be particularly suitable for this reaction. According to the new protocol, ylide **1** dissolved in methylene chloride was treated with 1.1 equivalent of NBS followed by 2.5 equivalents of anhydrous K_2CO_3. After a few minutes, freshly distilled benzaldehyde in dichloromethane was added to the mixture and stirred under a N_2 atmosphere for 24 h at room temperature. Under these conditions, the yield of methyl bromocinnamate was excellent, and the procedure was extended to the preparation of chloro, iodo, and fluoro derivatives. The results of these experiments are shown in Tables 2 and 3. The same procedure was used in the reactions of haloylides with cyclic anhydrides. Here, an excess of anhydrous K_2CO_3 was even more critical in securing good yields of the halogenated products. In the absence of a suitable base, yields were low since the addition of ylide **1** to a cyclic anhydride produces an acyclic keto phosphorane harbouring an acid that participates in proton exchange (Scheme 3). This causes further shifts in the already complex equilibria and ultimately a conversion of large proportions of ylides into conjugate acids.

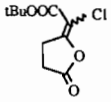


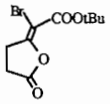












When an excess of anhydrous K_2CO_3 was added, the Wittig condensations produced satisfactory results with the more reactive phthalic and maleic anhydrides but ran into difficulties with the less reactive succinic and glutaric anhydrides. For example, chloroylide **3** (R = *t*-Bu) and succinic anhydride gave a mixture of **21-*Z*** and **21-*E*** (32:68) in 85% yield with the

nonchlorinated enol lactone making up the remaining 15% of the product. The reaction with bromoylide **2** produced pure **22-Z**, but in a low 30% yield and highly contaminated with the conjugated acid **1a** (R = *t*-Bu). Longer reaction times did not improve the yield of bromo enol lactone. Iodoylide **4** did not react with succinic anhydride, and none of the halogenated ylides reacted with glutaric anhydrides and with ketones under the reaction conditions described above. Reactions with fluoroylide **5** gave consistently low yields even in condensations with aldehydes, and the procedure for the synthesis of fluorinated compounds required modifications. An improved protocol was reported recently (7). On the other hand, an entirely different strategy was needed to cope with the problems of the less reactive succinic and glutaric anhydrides. Synthetic efforts to prepare halo enol lactones from the latter compounds are described in another communication (8).

Comparison of the reactivity of haloylides towards benzaldehyde

To better understand the behaviour of haloylides, we compared the reactivity of in situ generated haloylides towards benzaldehyde. In a series of experiments, reactions of ylide **1** (R = Me, *t*-Bu) with NXS (1:1.2) in $CDCl_3$ were followed by ^{31}P NMR at room temperature until the maximum accumulation of haloylide was reached. At that point, an excess (2:1) of freshly distilled benzaldehyde was added to the reaction mixture. The ^{31}P spectra were recorded 5–6 min after mixing. The results show that chloroylide reacts faster than bromoylide, which in turn is significantly faster than iodoylide. The identical pattern of reactivity emerged in condensations with *p*-nitrobenzaldehyde. Here, the order of reactivity of haloylides towards aldehydes parallels their behaviour as bases.

In another series of experiments, chloro-, bromo-, and

iodoylides, prepared as above and cooled to −40°C, were pretreated with BuLi. The quantity of BuLi used was just adequate to convert all of the conjugate acids into ylides. The temperature was raised to 0°C, 1 equivalent of benzaldehyde was added, and the ensuing reaction was monitored by NMR. This procedure was not suitable for the reactions with fluoroylide. After several unsuccessful attempts to make uncontaminated **5** in situ via direct fluorination, a different protocol was adopted. Treatment of conjugate acid **5a**[6] with an equivalent of BuLi (dilute solution in hexane) at −40°C gave **5**, which was shown by ^{31}P and ^{19}F NMR spectra to be uncontaminated. It was the latter ylide that was used in the reactivity studies.

The reactivity trend was confirmed, placing fluoroylide as the most reactive of the four haloylides with the other ylides being significantly slower. To illustrate the time frame: at 0°C, fluoroylide **5** was completely consumed within the 3–6 min it takes to run an NMR spectrum after mixing, the reactions with chloro- and bromoylides were finished in 30–50 min at 20°C, while the condensations with iodoylide took several hours at room temperature. These results are in agreement with our initial deductions that reactivity and basicity of the four ylides decrease from fluoro- to iodoylide, with the nonhalogenated ylide **1** falling somewhere between the fluoro- and chloroylides.

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and were uncorrected. Gas chromatography analyses were carried out with a Shimadzu GC 9A chromatograph. Infrared spectra were obtained on a Perkin–Elmer 297 infrared spectrophotometer. Nuclear magnetic resonance spectra were recorded on Varian T-60 or Varian XL-200 spectrometers at UNB or on Nicolet 360 NB, Bruker AC 250, and Bruker AMX 400 spectrometers at the Atlantic Regional Magnetic Resonance Centre. All spectra were recorded in $CDCl_3$ solutions unless otherwise specified, with TMS as an internal reference for ^1H and ^{13}C and with $CDCl_3$ as secondary reference for ^{13}C; 85% H_3PO_4 was external reference for ^{31}P and $CFCl_3$ the external reference for ^{19}F. In all NMR spectral data *J* values are in Hz. Mass spectra were obtained on a Kratos MS 550 TC mass spectrometer.

General procedure for the condensation of haloylides with aldehydes and cyclic anhydrides

A 50 mL three-necked flask equipped with a septum port, a glass stopper, a magnetic stirbar, and a reflux water condenser was topped with a nitrogen tee tube leading to a source of nitrogen, and a mineral oil bubbler was charged sequentially with 20 mL of dry THF or methylene chloride and 5.0 mmol of a phosphorane. The contents of the flask were cooled to −20°C. To the cooled solution, 1.1 equivalent of *N*-halosuccinimide or *N*-fluorodiphenylsulfonamide was added via counter flow. The solution was stirred for 20 min at −20°C, and then 2.5 equivalents of potassium carbonate followed by 5.0 mmol of aromatic aldehyde or cyclic anhydride were added. The mixture was stirred at room temperature for 12–72 h. After filtration and washing with 30 mL methylene chloride, the solvents were evaporated under reduced pressure and 10 mL ether was added to precipitate most of the triphenylphosphine oxide. Chromatography was carried out on a silica gel column using petroleum ether/acetone (3:1) as the elutant.

Ethyl 3-phenyl-2-chloro-2-propenoate ***9*** *(refs. 11, 12)*
Carboethoxymethylenetriphenylphosphorane **1**, R = Et (1.74 g, 5.0 mmol), potassium carbonate (2.5 equiv.), and *N*-chlorosuccinimide (734 mg, 1.1 equiv.) reacted with benzaldehyde (530 mg, 5.0 mmol) in methylene chloride for 24 h according to the general procedure to give **9** (0.87 g, 83%) as a mixture of *Z*:*E* = 80:20. ^1H NMR ($CDCl_3$, δ ppm): 1.13 (t, *E* isomer), 1.32 (t, *Z* isomer) integrating together for 3H, 4.1–4.4 (2H, overlapping q), 5.94 (s, *E*), 7.9 (s, *Z*) integrating together for 1H, 7.1–7.8 (5H, m, overlapping *E* and *Z*). On the synthesis and the mechanism of formation of halogenated enol lactones

Margaret M. Kayser, Jun Zhu, and Donald L. Hooper

Abstract: The synthesis of halo enol lactones from cyclic anhydrides via lactonization of the corresponding keto phosphoranes provides a direct route to these interesting compounds, which possess important biological properties and are useful intermediates in organic synthesis. In this paper we outline the syntheses of several halo enol lactones and discuss mechanistic consequences of these reactions on the understanding of Wittig reactions with cyclic anhydrides.

Key words: halolactonization, cyclic anhydrides, halo enol lactones, Wittig reaction mechanism.

Résumé : La synthèse de lactones énoliques halogénées à partir d'anhydrides cycliques, par le biais d'une lactonisation des cétophosphoranes correspondants, fournit une route directe vers ces composés intéressants qui possèdent des propriétés biologiques importantes et qui sont utiles comme intermédiaires en synthèse organiques. Dans ce travail, on décrit les synthèses de plusieurs lactones énoliques halogénées et on discute des conséquences mécanistiques de ces réactions sur la compréhension des réactions de Wittig avec les anhydrides cycliques.

Mots clés : halolactonisation, anhydrides cycliques, lactones énoliques halogénées, mécanisme de la réaction de Wittig.

Introduction

Halo enol lactones can be transformed into a variety of highly functionalized compounds and, as such, are useful intermediates in organic synthesis. Furthermore, since certain classes of halogenated enol lactones have been established as effective serine protease inhibitors (1), it is not surprising that these versatile compounds have attracted significant attention in recent years (2). In previous communications we reported the preparation of halo enol lactones by Wittig condensation reactions between cyclic anhydrides and in situ generated halo ylides (3, 4). In the course of these experiments we discovered that, although condensations with "reactive" phthalic and maleic anhydrides gave consistently excellent yields, problems were encountered with "less reactive" succinic and glutaric anhydrides.[3] Thus, while succinic anhydride reacted successfully with chloroylide, the condensation with bromoylide gave only 30% yield of bromo enol lactone and no significant reaction was observed with the iodoylide. None of the above ylides reacted with glutaric anhydride. In this paper we recount how the above problems were circumvented by using an alternate synthetic approach involving halide-induced lactonization of keto phosphoranes. This methodology, apart from giving access to the desired products, also provides insight into the mechanism of Wittig reactions with cyclic anhydrides.

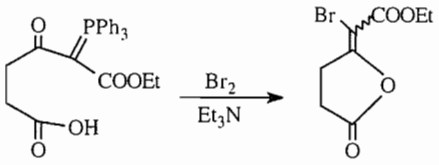
Results and discussion



The reactivity of halo ylides towards aldehydes and cyclic anhydrides decreases from the fluoro- to the iodoylide. While fluoroylide **2** reacts more rapidly than the non-halogenated carbomethoxymethylenetriphenylphosphorane **1**, chloroylide **3** appears to be comparable in reactivity to **1**, whereas bromoylide **4** and particularly iodoylide **5** are considerably slower (4). As a result, Wittig condensations between ylides **4** and **5** and the less reactive succinic and glutaric anhydrides are very slow or fail entirely (4).

[3] We have observed (^1H and ^{31}P NMR) that all stabilized ylides and their conjugate acids studied decompose slowly to Ph_3PO at room temperature unless special care is taken to maintain moisture-free conditions. This is quite evident during slow condensation reactions with succinic and glutaric anhydrides. Stabilized ylides also decompose to give Ph_3PO when treated with BuLi in an attempt to convert traces of their conjugate acids to ylides. This presents problems, particularly with the more basic fluoro- and chloroylides, which are frequently contaminated with their conjugate acids. The corresponding dihalo salts are decomposed to Ph_3PO even more rapidly than their parent ylides. The useful conclusion derived from the above observation is that, in order to obtain ylides free from acidic contaminants, including traces of moisture, a dilute solution of BuLi should be used and any excess should be carefully minimized.

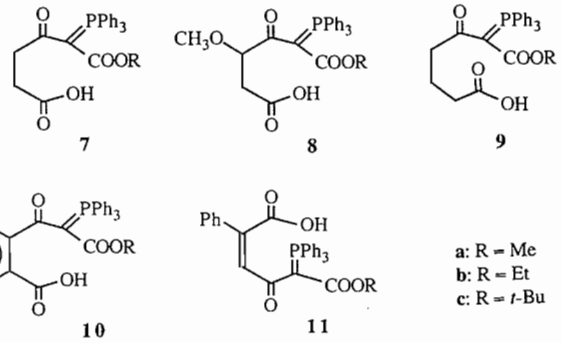
Scheme 2.



Halo enol lactones used in inhibition studies of serine proteases were typically prepared by bromine-induced lactonization of the acetylenic acids (2*c*). Recently, Abell and Trent (5) reported that acyl phosphoranes, such as **7b**, treated with bromine in the presence of triethylamine gave bromo enol lactones, as shown in Scheme 1. Based on these results, we expected that the halolactonization of keto phosphoranes would provide a general route to halo enol lactones from cyclic anhydrides, particularly from succinic and glutaric anhydrides that failed to give acceptable yields through direct condensations with haloylides (4).

Keto phosphoranes can be prepared by reactions of certain stabilized ylides such as **1** with acid chlorides or anhydrides, as shown in Scheme 2 (6–8). The reactions with cyclic anhydrides lead to the formation of acyclic adducts (**7–11**). The additions of ylide **1** to phthalic, maleic, and succinic anhydrides have been shown to be reversible (9). However, while acyclic adducts from succinic or glutaric anhydrides are stable compounds, those from phthalic and maleic anhydrides tend to be considerably less stable and generally can be observed by NMR or trapped only at low temperatures (9). Ylides that do not possess an ylidic hydrogen atom, such as methyl ylide **6**, do not give unambiguously identifiable acyclic adducts. For example, at −40°C the ^{31}P signal for methyl ylide **6** appears at 23.3 ppm. Upon addition of phthalic anhydride a new broad peak appears at 27.6 ppm and, as the temperature is raised to −20°C, the two peaks coalesce to give a very broad signal at 24.5 ppm. At that temperature enol lactone is starting to form. As the temperature is raised further the formation of the product can be followed by observing the increase in the Ph_3PO peak at 31 ppm, while the broad signal at 24.5 is diminished as it shifts slowly to 27.9 ppm. It appears, therefore, that although addition of this ylide to phthalic anhydride is taking place, the resulting acyclic adduct is not stable enough to be observed as a discrete NMR signal but rather exists in rapid equilibrium with the parent ylide **6**. When the same reaction was carried out at room temperature the signal at 27.9 ppm was not detected, and in the parallel reaction, monitored by ^1H NMR, only the disappearance of ylide **6** and the formation of the corresponding enol lactone could be observed. On the other hand, not even a transient signal could be detected during the low-temperature (−40°C) reactions of bromo- and fluoroylides with phthalic anhydride. These experiments do not entirely eliminate the possibility of acyclic compound formation, but they do suggest that, if such an addition actually occurs, the resulting acyclic intermediates are in rapid equilibrium with the starting materials and that the rapid collapse to enol lactones occurs as the temperature is raised. In any case, these adducts are not observable by NMR as discrete signals. Certain of these NMR spectra have been deposited as supplementary material.[4]

Syntheses of halo enol lactones via halolactonization of keto phosphoranes

Keto phosphoranes from glutaric, succinic, phthalic, and phenylmaleic anhydrides, illustrated below, were prepared by the reaction of ylide **1** with the appropriate anhydrides at –20°C. The adducts **7** and **9** made from succinic and glutaric anhydrides were stable and could be isolated at room temperature and stored indefinitely, while the more reactive compounds **8**, **10**, and **11** were generated in situ and used immediately in halolactonization reactions (Scheme 3).

During preliminary experiments, keto phosphoranes **7** and **10** treated with Br_2 according to the procedure described in the literature (5) gave disappointingly low yields of the corresponding bromo enol lactones. When the reaction of keto phosphorane **7** with Br_2 was followed by NMR it became apparent that large quantities of the conjugate acids $Ph_3P^+CH_2COOR\ Br^-$ and $Ph_3P^+CHBrCOOR\ Br^-$ of ylides **1** and **4** were formed as by-products.

An effective proton scavenger was needed to remove the "mobile" protons formed in the process of ring opening. Switching to halosuccinimides (NXS: X = Cl, Br, I) as halogenating agents, with *N*-fluorodiphenyl sulphonamide (NFS) serving as a fluorinating agent, provided sufficiently basic succinimide (or phenyl sulphonamide) anions to prevent the formation of conjugate acids and to promote cyclization to halo enol lactones. Under the modified conditions succinic and phthalic anhydrides were converted to halo enol lactones, generally in good to excellent yields. The results for all anhydrides studied are listed in Table 1.

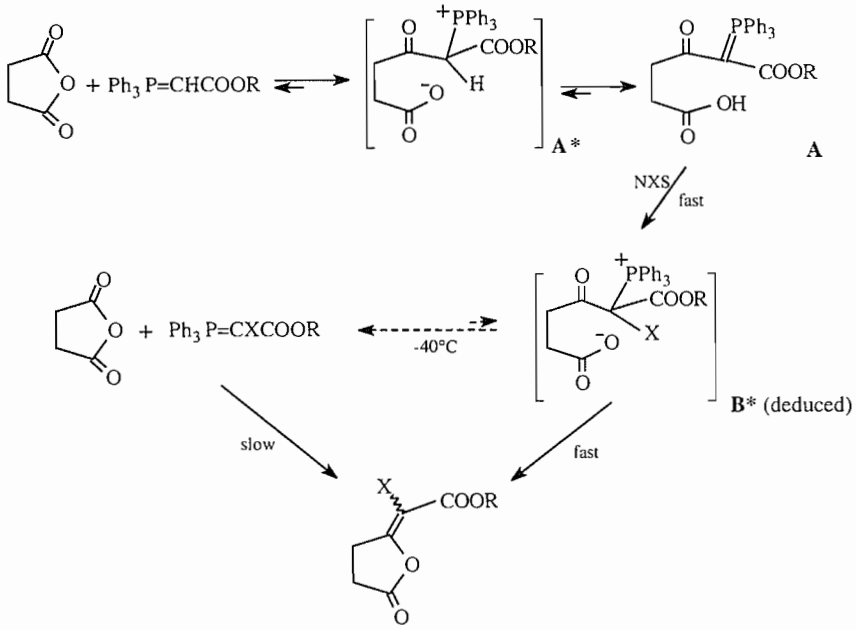
Scheme 4.

The highest yields of halo lactones were obtained from succinic anhydride, which is converted completely to a stable acyclic adduct. Keto phosphoranes derived from the more reactive methoxysuccinic **8**, phthalic **10**, and phenylmaleic **11** anhydrides, generated in situ at −20°C, reacted with NXS or NFS to give lower yields of the corresponding halo enol lactones. In the course of these reactions, 10–20% of nonhalogenated enol lactones were always formed and extensive chromatography was required to remove these by-products. From a synthetic point of view, it was desirable to modify the reaction conditions in such a way as to minimize their formation. Variation in the NXS to keto phosphorane ratios and in reaction temperatures did not, however, significantly improve the situation. It appears that in all cases the spontaneous recyclization competes effectively with halolactonization.

Halolactonizations carried out with keto phosphorane **9c** generated from glutaric anhydride gave lower yields for the opposite reason. Here, the spontaneous recyclization of **9c** is known to be difficult even at high temperatures and, hence, halolactonization is also sluggish. As a result, yields of halogenated products were lower, but the products formed were not contaminated with nonhalogenated enol lactones and could be purified readily by rapid chromatography on a short silica gel column.

The configuration of halo enol lactones was established from the ^{1}H NMR spectra and isomerization experiments as described elsewhere (3, 10, 11). The stereoselectivity observed in halolactonization of keto phosphoranes was not significantly different from that observed in the direct Wittig condensation reactions (3). In general, the *E* configuration was predominant in derivatives from succinic and glutaric anhydrides, particularly with *tert*-butyl esters. The notable exception was observed with fluorinated products that were tentatively identified as *Z* isomers on the basis of their NMR spectra (Table 1). Reactions with phthalic and maleic anhydrides, carried out at lower temperatures, gave mixtures of products. These results indicate that the *E* configuration is thermodynamically preferred, except when the halo substituent is an iodine atom. When the reaction can be performed successfully at lower temperatures, as is the case with the more reactive anhydrides, the kinetic product (*Z* isomer), can constitute an important component of the mixture (entries **10a**, **10b**, **10c**, and **11c**, Table 1). For example, the reaction of phthalic anhydride with NCS at −20°C (2 h) gave a 50:50 mixture of *E* and *Z* isomers. When the same reaction was carried out at −20 to +20°C for 2 h, the *E* isomer was the main product (*E*:*Z* = 90:10).

NMR study of halolactonization reactions



NMR monitored reactions show that chloro and bromolactonizations of **7** occur rapidly at −20°C. Upon addition of NCS or NBS, **7** is converted to lactones **12-Cl** and **12-Br** and to Ph_3PO within 5 min after mixing. The iodolactonization is slow at −20°C, but rapid reaction takes place when the mixture is warmed to +20°C. Treatment of keto phosphorane **7** with NXS (X = Cl, Br, I) gives pure bromo and iodo enol lactones, but chloro enol lactone is always contaminated with dichloro phosphorane **17-Cl**. This indicates that the unstable (not detected by NMR) initial adduct **7-Cl** (Scheme 4) has two possible competing pathways: (*a*) lactonization to give **12-Cl**, (*b*) recycling to succinic anhydride with concomitant expelling of chloroylide **3**. The latter compound can be chlorinated to **17-Cl**, it can pick up a proton to become conjugate acid **3a**, or it can add back to the anhydride. At temperatures between −40°C and −20°C the formation of **17-Cl** is an important side reaction. It can be minimized when chlorolactonizations are carried out at 0°C, thus giving higher yields of chloro enol lactone. The formation of dihalophosphoranes is generally less of a problem in the reactions with NBS and NIS and, in general, can be avoided by performing the reactions at higher temperatures under the optimum conditions described in Table 1. When keto phosphoranes **8** and **10** were treated with NBS or NIS at −40°C, the halogenated ylides **4** and **5** (in equilibrium with their conjugate acids) were formed as major products. Only traces of the desired enol lactones were detected in the proton and phosphorus spectra. The outcome of the corresponding reaction with NCS was similar except that the major product was the conjugate acid **3a**. These results show that, as in the case of **7-Br** and **7-I**, the chlorinated equivalents can revert to the anhydride and chloro ylide **3**. However, **3**, being more basic than either **4** or **5**, is rapidly protonated to its conjugate acid **3a**.

An interesting and general observation was made in the course of the chlorolactonizations monitored by ^{31}P NMR. As the dichloro phosphorane **17-Cl** was forming, the chemical shift of the other product, Ph_3PO, was slowly shifted down field. At the end of the reaction, when all of the keto phospho-

Scheme 5.

rane was consumed, the signal for Ph_3PO appeared at 32.5 ppm, more than 2 ppm lower than its usual position at 30 ppm. Upon standing, the signal for **17-Cl** slowly decreased until it almost disappeared completely and the signal for Ph_3PO drifted back towards its usual position. We soon discovered that the disappearance of **17-Cl** from the spectrum was caused by its precipitation from the $CDCl_3$ solution. Our interpretation of these data is as follows: when the concentration of dichloro phosphorane **17-Cl** rises, it forms a complex with the oxygen atom of Ph_3PO, thus deshielding the phosphorus atom and causing its downfield shift. As the salt precipitates from the solution, Ph_3PO is liberated and the phosphorus signal returns to its normal chemical shift.

In summary, the halolactonization route is the method of choice, sometimes the only successful method, for the preparation of halo enol lactones from the relatively less reactive succinic and glutaric anhydrides. Halolactonization can be used also with phthalic and substituted maleic anhydrides; with the latter compounds, however, direct condensations with in situ generated halo ylides are simpler and frequently give superior results. It should be stressed, however, that in order to obtain consistently high yields of halo enol lactones the acyclic adducts should be prepared from freshly purified anhydrides and ylides uncontaminated by their conjugate acids. The quality of *N*-halosuccinimides is also important, and the best results are obtained when these reagents are crystallized and stored in a darkened desiccator.

Mechanism of halo lactonization of acyclic adducts

The above study brings us back to consideration of the mechanism of Wittig reactions between stabilized ylides and cyclic anhydrides. It was pointed out in the introduction that, at low temperatures, ylide **1** reacts with succinic anhydride to give an acyclic addition product that immediately equilibrates to give a stable keto phosphorane. The formation of Wittig product, an enol lactone, can be observed only when the temperature of the reaction is raised significantly. These reactions can be conveniently monitored by NMR and the only species observable are starting materials, keto phosphoranes, and enol lactones. Although keto phosphoranes have been referred to as "intermediates," it is not clear if and how they are transformed into enol lactones. Low-temperature NMR studies and crossover experiments have shown unambiguously that the formation of keto phosphoranes is a reversible process and that the corresponding Wittig products often show regioselectivity different from that of the "intermediate" keto phosphoranes. It appears, therefore, that two distinct reactions may be involved: one, reversible, via a betaine-like, low-energy transition state leading to the formation of acyclic adducts; the other, a higher energy process, leading directly to enol lactones via an oxaphosphetane-like transition state (8, 12, 13). Stabilized ylides without an ylidic proton do not give stable, unambiguously identifiable keto phosphoranes. Thus, when such ylides react with cyclic anhydrides the only reaction pathway leading to observable products, enol lactones, would be via the oxaphosphetane route (14, 15).

The most recent series of experiments described in this paper does not fit the simple two-reaction picture described above. This is most apparent in the case of succinic anhydride. Succinic anhydride reacts with ylide **1** to give a stable keto phosphorane **7**, which has to be refluxed in THF or methylene chloride before it cyclizes to the corresponding enol lactone **12** in good yield. When chloroylide **3** is added to succinic anhydride the formation of chloro enol lactone **12-Cl** occurs slowly at room temperature (4). On the other hand, chlorolactonization of **7** occurs rapidly at 0°C. Careful monitoring of the last two reactions by ^{31}P and ^{1}H NMR at various temperatures did not reveal the existence of any intermediates corresponding to either acyl phosphorane **B*** or 4-member oxaphosphetane (13). In view of the above observations the previously suggested mechanism requires a modification that can accommodate a lower energy pathway to Wittig products through halolactonization. The possible sequence of events is shown in Scheme 5.

In conclusion, we have shown that ylides react with cyclic anhydrides to give acyclic adducts that are observable by NMR when an initial addition product (**A***) can be deprotonated to give relatively stable (at least at low temperatures) keto phosphoranes (**A**). When an ylide does not possess an ylidic proton, nucleophilic addition results in an unstable species (**B***), which may be observed as a transient signal (reactions with ylide **6**) or may not be detected by NMR (reactions with haloylides, Scheme 5).

Reactions of haloylides with succinic and glutaric anhydrides are very slow or inefficient or fail entirely depending on the ylide. Halolactonizations, on the other hand, are comparatively rapid even at −20 to −10°C for all (except NIS) reactions. This indicates that pathways, alternative to the direct 2+2 addition, exist for reactions of cyclic anhydrides with stabilized ylides. The actual pathway each individual reaction takes varies with the reactivity of the anhydride, the nature of the ylide, and the stabilities of the initially formed acyclic adducts.

Experimental section

All starting materials were supplied by Aldrich Chemical Company or Caledon Laboratories Ltd. Solvents were dried over sodium or molecule sieves and distilled. Melting points were determined on a Fisher–Johns melting point apparatus and were uncorrected. Infrared spectra were obtained on a Perkin–Elmer 297 infrared spectrometer. Nuclear magnetic resonance spectra were recorded on a Varian XL-200 spectrometer at the University of New Brunswick or Bruker AC 250 and Bruker AMX 400 spectrometers at the Atlantic Regional Magnetic Resonance Center. All spectra were recorded in $CDCl_3$ solutions with TMS as an internal reference for ^1H and ^{13}C and $CDCl_3$ as a secondary reference; 85% H_3PO_4 was the external reference for ^{31}P, and $CFCl_3$ the external reference for ^{19}F. In all NMR spectral data J values are in Hz. Mass spectra were obtained on a Kratos MS 550 TC mass spectrometer.

General procedure for the preparation of keto phosphoranes (refs. 7, 8)

A phosphoylide (14.4 mmol) dissolved in dry THF or $CHCl_3$ (40 mL) and cooled to 0°C was added to the cooled solution of a cyclic anhydride (14.4 mmol). The resultant (usually highly coloured) solution was stirred for 1–10 h at −20 to 0°C under a nitrogen atmosphere until all the cyclic anhydride had reacted as shown by TLC. Evaporation of the solvent under reduced pressure at 30°C gave the crude keto phosphorane, which was purified by crystallization from petroleum ether – acetone.

*Methyl 5-carboxy-3-oxo-2-triphenylphosphoranediylpentanoate, **7a***: Carbomethoxymethylene triphenylphosphorane **1**, R = Me (4.80 g), in $CHCl_3$ reacted with succinic anhydride (1.44 g) at −5°C for 30 min and then at 0°C for 8 h to give **7a** (5.17 g, 83%). ^1H NMR ($CDCl_3$, δ ppm): 2.5 (2H, t), 3.3 (2H, t), 3.8 (3H, s), 7.2–7.8 (15H, m), 12.0 (1H).

*Ethyl 5-carboxy-3-oxo-2-triphenylphosphoranediylpentanoate, **7b***: Carboethoxymethylene triphenylphosphorane **1**, R = Et (5.0 g), in THF reacted with succinic anhydride (1.44 g) at −5°C for 30 min then at 0°C for 5 h, to give compound **7b** (6.24 g, 97%). ^1H NMR ($CDCl_3$, δ ppm): 0.65 (3H, t, J = 7.1 Hz), 2.55 (2H, t, J = 5.8 Hz), 3.35 (2H, t, J = 5.8 Hz), 3.70 (2H, q, J = 7.1 Hz), 7.60 (15H, m), 12.2 (1H, s); ^{13}C NMR ($CDCl_3$, δ ppm): 13.64, 31.51, 34.22 (d, J = 4.5 Hz), 59.03, 126–134 (aromatic), 167.00, 175.80, 196.84. MS (EI): 347, 303, 277, 262, 201, 183, 152, 108, 77, 51.

tert-*Butyl 5-carboxy-3-oxo-2-triphenylphosphoranediylpentanoate, **7c***: Carbo-*tert*-butoxymethylene triphenylphosphorane **1**, R = *t*-Bu (5.4 g), in THF reacted with succinic anhydride (1.44 g) at −5°C for 30 min, and then at 0°C for 2 h, to give **7c** (6.49 g, 95%). ^1H NMR ($CDCl_3$, δ ppm): 1.05 (9H, s), 2.55 (2H, t), 3.32 (2H, t), 7.40–7.80 (15H, m).

tert-*Butyl 6-carboxy-3-oxo-2-triphenylphosphoranediylhexanoate, **9c***: Carbo-*tert*-butoxymethylene triphenylphosphorane **1**, R = *t*-Bu (5.40 g), in THF reacted with glutaric anhydride (1.64 g) at 0°C for 12 h to give **9c** (4.08 g, 58%). ^1H NMR ($CDCl_3$, δ ppm): 0.85 (9H, s), 1.70 (2H, m), 2.45 (2H, m), 2.85 (2H, m), 7.60–7.90 (15H, m).

tert-*Butyl 3-oxo-3-(2-carboxy)phenyl-3-triphenylphosphoranediylpentanoate, **10c***: Carbo-*tert*-butoxymethylenetriphenylphosphorane **1**, R = *t*-Bu (5.40 g), in THF reacted with phthalic anhydride (2.13 g) at −20°C for 2 h to give **10c** (6.40 g, 85%). The product was stored at −15–−20°C. ^1H NMR ($CDCl_3$, δ ppm): 0.80 (9H, s), 7.30–8.10 (19H, m).

General procedure for the preparation of halo enol lactones

A solution of ketophosphorane (4.1 mmol) in dry THF (20 mL) was cooled to 0°C and added to a cooled solution of halosuccinimide (1.1 equiv.). The mixture was stirred at 0°C for 2–4 h under N_2 atmosphere. The solvent was evaporated under vacuum. Ether (10 mL) was added to precipitate most of triphenylphosphine oxide. After filtration and washing with 15 mL of ether, the residue was chromatographed on a silica gel column to remove the remaining triphenylphosphine oxide.

(E,Z) *Methyl chloro(5-oxotetrahydrofuran-2-ylidene)acetate, **12a-Cl***: Methyl 5-carboxy-3-oxo-2-triphenylphosphoranediylpentanoate **7a**, 955 mg (2.2 mmol), reacted with 323 mg (1.1 equiv.) of chlorosuccinimide at 0°C for 2 h to give **12a-Cl** (389 mg 93%) as a mixture of isomers E:Z = 74:26. IR ($CHCl_3$) ν_{max} cm^{-1}: 2950, 1835, 1720, 1645; ^1H NMR ($CDCl_3$, δ ppm): 2.80 (2H, m overlap E and Z), 3.15 (2H, m, E), 3.40 (2H, m, Z), 3.84 (3H, s, Z), 3.86 (3H, s, E). Chromatography on silica gel gave a sample of **12a-Cl** E isomer: ^{13}C NMR ($CDCl_3$, δ ppm): 25.65, 27.19, 63.03, 104.0, 158.50, 161.40, 172.90; MS (EI), m/z: 190 (M, 20.8%), 164 (23.6%), 159 (37.6%), 135 (22.0%), 130 (33.0%), 101 (100%), 55 (40.70%); MS (HR), m/z, calcd. for $C_7H_7O_4$ ^{35}Cl: 190.0033; found: 190.0002.

(E,Z) *Methyl bromo(5-oxotetrahydrofuran-2-ylidene)acetate, **12a-Br***: **7a**, 955 mg (2.2 mmol), reacted with 431 mg (1.1 equiv.) of bromosuccinimide at 0°C for 4 h to give **12a-Br** (419 mg, 81%) as a mixture of isomers E:Z = 67:33. Nucleophilic aromatic substitution with dialkoxycarbenes

Joseph P. Ross, Philippe Couture, and John Warkentin

Abstract: Dimethoxycarbene, generated at 110°C by thermolysis of 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline, displaces fluoride from aromatic rings that are activated with electron-withdrawing groups. Intermolecular substitution on Sanger's reagent and on hexafluorobenzene are reported, together with intramolecular substitution by a dioxycarbene with a tethered aryl group.

Key words: aromatic substitution, aryl(dimethoxy)fluoromethanes, aryl fluoride, dialkoxycarbene, nucleophilic substitution.

Résumé : La diméthoxycarbène, obtenu par thermolyse du 2,2-diméthoxy-5,5-diméthyl-$\Delta^3$1,3,4-oxadiazoline, déplace le fluor des noyaux aromatiques activés par des groupes électroattracteurs. On rapporte les réactions de substitutions intermoléculaires sur le réactif de Sanger et sur l'hexafluorobenzène ainsi que la substitution intramoléculaire d'un dioxycarbène fixé sur un groupe aryle.

Mots clés : substitution aromatique, aryl(diméthoxy)fluorométhanes, fluorure d'aryle, dialkoxycarbène, substitution nucléophile.

Introduction

The fact that donor substituents, such as alkoxy or amino, at a carbene center have a strong influence on a carbene's properties is now well established. Diaminocarbenes (1–6) and dialkoxycarbenes (7) have large singlet/triplet energy gaps attributed to conjugative stabilization of the singlet. Such carbenes have nucleophilic properties (8–10), rather than the more commonplace electrophilic properties associated with carbenes as a class. Their nucleophilicity is presumably a consequence of delocalization in the carbene itself and, probably to a greater extent, of the conjugative delocalization in the transition state for attack by the carbene on an electrophilic substrate (Scheme 1). Nucleophilic properties of dialkoxycarbenes have been demonstrated in terms of their preference for reaction with Michael acceptors instead of electron-rich alkenes such as tetramethylethylene (11, 12), with examples of reactions with isocyanates and isothiocyanates (12, 13), with tetrazines (14–16), and with the carbonyl groups of maleic and other anhydrides (17), for example (Scheme 2).

Nucleophilic aromatic substitution by carbenes has, apparently, not been observed. Arduengo et al. (18) reported that a stable diaminocarbene reacts with iodopentafluorobenzene to afford an ylide, by attack of the carbene at iodine. Although some pentafluorobenzene was obtained as the solution of the ylide aged, that product was not from displacement by a carbene carbon moiety.

Scheme 1.

We now report that dimethoxycarbene attacks 2,4-dinitrofluorobenzene (Sanger's reagent) and hexafluorobenzene, in each case with overall displacement of fluoride by the carbene carbon, to afford unstable "acetals" of aroyl fluorides. A similar reaction occurs intramolecularly, with a dialkoxycarbene tethered *ortho* to an aryl fluorine substituent.

Results and discussion

Dimethoxycarbene (**1**) was generated by thermolysis of 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**2**) (19–23) and carbene **5** was generated from oxadiazoline **4**, prepared by the exchange method (24–26) from 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**3**) (Scheme 3). Thermolysis of **2** at 110°C, in benzene containing 2,4-dinitrofluorobenzene (**6**) at 0.2 M initial concentration, afforded **7** (Scheme 4). Although it was quite sensitive to moisture and could not be isolated, its structure was secured by means of ^{19}F NMR spectroscopy, mass spectrometry, and hydrolysis to methyl 2,4-dinitrobenzoate (**8**) (Scheme 4). In the ^{19}F NMR spectrum of the crude, taken immediately after opening of the thermolysis tube, there was a strong doublet (J = 2.3 Hz) at δ = −82 (external ref. $CFCl_3$). The position of that signal and the long-range coupling to one H is consistent with structure **7**.[3] In the mass

[3] In the ^{19}F NMR spectrum of trifluoromethylbenzene there is also long-range coupling of the fluorines to the *ortho* hydrogens of the aromatic ring ($^4J_{HF}$ = ca. 0.7 Hz) (27).

Scheme 4.

spectrum (GC–MS) the highest mass:charge ratio was m/z = 241, corresponding to $[M - F]^+$, as expected for **7**. The fact that aging the sample, in a capped NMR tube, led to fading of the ^{19}F NMR signal is also in keeping with structure **7**, which is the "acetal" of 2,4-dinitrobenzoyl fluoride. Hydrolysis of the crude thermolysis product with aqueous methanol containing acetic acid afforded methyl ester **8**, (Scheme 4).

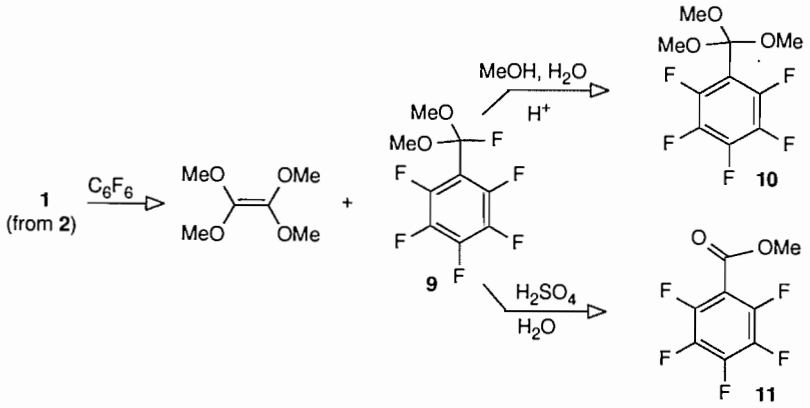
Thermolysis of **1** in hexafluorobenzene, in a sealed tube at 110°C, gave pentafluorobenzoyl fluoride dimethyl acetal (**9**) (Scheme 5) and tetramethoxyethylene as major products, in ca. 40:60 ratio by GC–MS. Product **9** was also very sensitive to moisture, and it could not be isolated. In the ^{19}F NMR spectrum of the crude thermolysate, there was a triplet at $\delta = -82$ (external ref. $CFCl_3$), $^4J_{FF}$ = 22 Hz, consistent with benzylic fluorine coupled to equivalent *ortho* fluorines. For example, the analogous coupling constant in pentafluoro(trifluoromethyl)benzene is 22.7 Hz (28). The mass spectrum (GC–MS) again failed to show a molecular ion at m/z = 260, but both $[M - F]^+$ at m/z = 241 and $[M - OMe]^+$ at m/z = 229 were present. Attempted hydrolysis with aqueous methanol acidified with acetic acid led to disappearance of **9** but **11** was not obtained. Instead one product appeared to be the *ortho* ester **10** on the basis of its longer retention time (relative to that of **9**) in a GC column and its mass spectrum; m/z = 241 $(M - OMe)^+$, by GC–MS. Apparently the *ortho* ester **10** (and presumably the corresponding hemi *ortho* ester too) is not easily converted to the corresponding ester, undoubtedly because of the destabilizing effect of five fluorine atoms on the carbonyl group. Acidification of the crude product containing **10** in CH_2Cl_2 with concentrated sulfuric acid gave the known methyl pentafluorobenzoate (**11**) (29).

An intramolecular analogue of the substitutions in Schemes 4 and 5 was observed upon thermolysis of **4**, which afforded **12** as an unstable intermediate that was hydrolyzed to lactone **13** (Scheme 6). Carbene dimers (**14**), indicated by GC–MS, were formed in approximately 40% combined yield.

These reactions are readily explained in terms of nucleophilic aromatic substitution, through an intermediate (**15**) that resembles the classical Meisenheimer intermediate (30) except in that **15** is a dipole rather than an ion, as illustrated in Scheme 7 for the case of Sanger's reagent. Dipole **15** presumably rearranges quickly by 1,2 F-migration to afford **7** (Scheme 7). Intermolecular attack on the aromatic ring to afford **15** (or an analogue) must be slow, at least for the case of hexafluorobenzene, as indicated by the coformation of carbene dimer (Scheme 5). Similarly, in the case of **5**, where five fluorines activate the ring for nucleophilic aromatic substitution, the intramolecular reaction is difficult also, and carbene dimers are formed in competition (Scheme 6).

In summary, dialkoxycarbenes are nucleophiles capable of aromatic substitution on activated aryl fluorides. Although the method is not currently of interest for synthetic purposes because of the low yields, it could find application in highly specialized pursuits such as those involved in the preparation of labelled compounds.

Experimental



Oxadiazolines 2 and 4

2,2-Dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**2**) was prepared as described in the literature (19). 2-Methoxy-5,

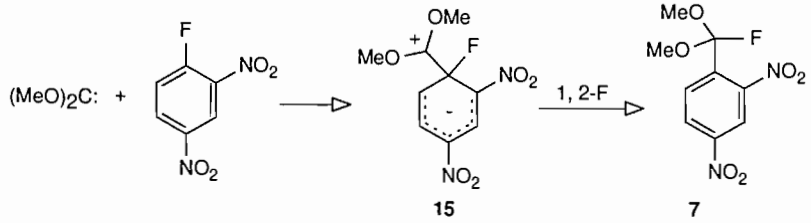

Scheme 5.

Scheme 6.

Scheme 7.

5-dimethyl-2-(2-pentafluorophenylethoxy)-Δ^3-1,3,4-oxadiazoline (**4**) was prepared from 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**3**) by the exchange method (24). A solution of 2-pentafluorophenylethanol (1.38 g, 6.51 mmol), **3** (1.23 g, 6.52 mmol), and acetic acid (1 mL) in dichloromethane (15 mL) was left for 7 days at room temperature. Extraction with aqueous bicarbonate, drying, and removal of the solvent with a rotary evaporator left a residue that was chromatographed (Chromatotron apparatus, 4 mm plate, 5% ethyl acetate in hexanes) to afford **4** as a clear oil in 78% yield. Its structure followed from the method of preparation and from its NMR spectra, particularly the ^{13}C signals characteristic of C2 and C5 of the oxadiazoline ring (25). IR(cm^{-1}): 2992–2847 (CH), 1657, 1522, 1460, 1383; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.47 (s, 3H), 1.52 (s, 3H), 3.01 (m, 2H), 3.37 (s, 3H), 3.94 (m, 2H); ^{13}C NMR (50 MHz, $CDCl_3$) (multiplets that are components of doublets with $^1J_{CF}$ = 244–250 Hz are listed as discrete signals) δ: 23.07, 23.81 (2C), 51.21, 62.65, 111.52 (t, $^2J_{CF}$ = 18.4 Hz, CH_2C_{Ar}), 119.27 (C5), 134.85 (m), 136.72 (C2), 137.4 (m), 139.9 (m), 142.4 (overlapping m), 147.8 (m); MS (EI) *m/z* (rel. intensity): 254 ($(M - N_2 - Me_2CO)^+$, 10), 195 (40).

Thermolysis of 2 in presence of 2,4-dinitrofluorobenzene

A solution of **2** (0.25 g, 1.6 mmol) and 2,4-dinitrofluorobenzene (0.50 g, 2.7 mmol) in benzene (15 mL) was sealed into a glass tube of 30 mL volume after three sequences of freeze–pump–thaw degassing at 0.1 Torr (1 Torr = 133.3 Pa). The tube was then kept in an oil bath at 110°C for 24 h before it was cooled and opened. The solvent was evaporated with a rotary evaporator and the residue was examined immediately with spectroscopic methods. Although signals from Sanger's reagent dominated the ^1H NMR spectrum, those from 2,4-dinitrobenzoylfluoride dimethyl acetal (**7**), formed in ca. 10% yield, could be identified. ^1H NMR (500 MHz, C_6D_6) δ: 3.14 (s, 6H), 7.36 (d, ^3J = 8.6 Hz, 1H), 7.71 (dd, ^3J = 8.6 Hz, ^4J ca. 2 Hz, not completely resolved from Sanger's reagent signal), 7.86 (br s, $^4J < 2$ Hz, 1H); ^{13}C NMR (125 MHz, C_6D_6) δ: 51.3 (d, $^3J_{CF}$ = 3.8 Hz, CH_3), 118.91 (s), 119.21 (d, $^1J_{CF}$ = 244.5 Hz), 125.03, 130.38 (d, $^3J_{CF}$ = 8.4 Hz), 133.50 (d, $^2J_{CF}$ = 42.0 Hz),[4] 148.62, 149.40; ^{19}F NMR (470 MHz, C_6D_6, external ref.

[4] In trifluoromethylbenzene $^2J_{CF}$= 42.2 Hz (29).

$CFCl_3$) δ: −82.84; MS (GC–MS, EI) *m/z* (rel. intensity): 241 ($(M - F)^+$, 100), 210 ($(M - F - OMe)^+$, 11).

Chromatography of the crude reaction mixture (Chromatotron apparatus, 1 mm silica plate, 5% ethyl acetate in hexanes) afforded methyl 2,4-dinitrobenzoate (**8**) as a yellow solid, mp 82°C (lit. (31) mp 82°C); IR (cm^{-1}): 3088–2950, 1610, 1539; ^1H NMR (200 MHz, C_6D_6) δ: 3.11 (s, 3H), 6.06 (d, ^3J = 9.3 Hz, 1H), 7.77 (d of d, ^3J = 9.3 Hz, ^4J = 2.8 Hz, 1H), 8.26 (d, ^4J = 2.8 Hz); ^{13}C NMR (50 MHz, C_6D_6) δ: 56.68, 113.35, 121.37, 128.48, 138.89, 140.04, 156.84, 204.91; GC–MS (EI) *m/z* (rel. intensity): 226 (M^+, 10), 195 ($(M - OMe)^+$, 100).

Thermolysis of 2 in hexafluorobenzene

A solution of **2** (97 mg, 0.60 mmol) in hexafluorobenzene (2.0 mL) was sealed into a glass tube after three cycles of freeze–pump–thaw degassing. The tube was left in an oil bath at 110°C for 24 h before it was cooled and opened. GC analysis (not corrected for differential response from the FID detector) showed two major products, tetramethoxyethylene and pentafluorobenzoylfluoride dimethyl acetal (**9**) in ca. 60:40 ratio. NMR data were obtained from a crude thermolysate generated in a sealed NMR tube. ^1H NMR (500 MHz, C_6D_6) δ: 2.93 (s); ^{19}F NMR (470 MHz, C_6D_6, external ref. $CFCl_3$) δ: −80.21 (t, $^4J_{FF(\alpha\text{-}ortho)}$ = 38.1 Hz, 1F), −141.13 (m, 2F), −152.70 (m, 1F), −162.31 (m, 2F); MS (GC–MS, EI) *m/z* (rel. intensity): 260 (M^+, 9), 241 ($(M - F)^+$, 15), 229 ($(M - OMe)^+$, 90), 195 (100), 167 (15).

Hydrolysis of 9

Addition of aqueous methanol and acetic acid led to the disappearance of **9**, but the expected ester **11** was not obtained. Instead the hydrolysis led to a material that was probably *ortho* ester **10**, as indicated by the increased GC retention time and a signal consistent with $C_6F_5C(OMe)_2^+$ (*m/z* = 241, 93%) in the GC–MS. The parent ion signal for **10** was not present and the base peak was at *m/z* = 195, as it was in the MS of **11**. Sulfuric acid, added to a solution of **10** in CH_2Cl_2 gave, after work-up and purification by radial chromatography, methyl pentafluorobenzoate **11** in ca. 2% yield, from **2**. IR ($CDCl_3$, cm^{-1}): 2958, 1742, 1524, 1500, 1333, 1242, 1010, 980; ^1H NMR (500 MHz, $CDCl_3$) δ: 3.96 (s), both in excellent agreement with published data for **11** (29); ^{19}F NMR ($CDCl_3$, external ref. $CFCl_3$) δ: −160.58 (m, 2F), correlated to ^{13}C at 169.4, −148.75 (m, 1F), correlated to ^{13}C at 175.0, −138.36 (m, 2F), correlated to ^{13}C at 177.2; ^{13}C shifts obtained by means of a $^{19}F/^{13}C$ correlation experiment. MS (GC–MS, EI) *m/z*: 226 (M^+, 24), 207 ($(M - F)^+$, 5), 195 ($(M - OMe)^+$, 100), 167 (39), 117 (28).

Thermolysis of oxadiazoline 4

A solution of 2-methoxy-5,5-dimethyl-2-(2-pentafluorophenylethoxy)-Δ^3-1,3,4-oxadiazoline (0.100 g, 0.294 mmol) in benzene (20 mL) was sealed into a glass tube of 30 mL volume after degassing as described above. The tube was kept in an oil bath at 110°C for 24 h before it was cooled and opened. The solvent was removed with a rotary evaporator and the crude residue was examined immediately by means of NMR spectroscopy. The crude product consisted of **12** (ca. 13%, by ^1H NMR spectroscopy), and of compounds tentatively identified by ^1H NMR and GC–MS as the dimers (**14**) of methoxy(2-pentafluorophenylethoxy)carbene, each in ca. 20% yield. Spectra of **12** had to be gleaned from the composite spectrum of the crude, **12** being too sensitive to moisture to survive attempts at separation. The presumed carbene dimers were not separable by chromatography.

^1H NMR of **12** (500 MHz, C_6D_6) δ: 2.46 (t of d, ^2J = 1.6 Hz, ^3J = 6.4 Hz, 2H), 3.39 (s, 3H), 3.92 (t, ^3J = 6.4 Hz, 2H); ^{19}F NMR (470 MHz, C_6D_6, external ref. $CFCl_3$ δ: −71.75 (d, $^4J_{FF}$ = 5.2 Hz), −139.51 (m), −145.58 (m), −155.46 (m), −163.42 (m); MS (GC–MS, EI) *m/z* (rel. intensity): 234 ($(M-HF)^+$ 88), 223 ($(M - OMe)^+$, 33), 203 ($(M - F - MeOH)^+$, 100), 191 (77), 175 (96). MS (GC–MS, EI) *m/z* (rel. intensity): 235 ($(M - F)^+$, 100), 221 (12), 203 (75), 191 (42), 175 (32), 162 (34).

Hydrolysis of the crude with aqueous methanol (4% water by vol.) containing acetic acid (4% by vol.) gave, after extraction with dichloromethane, washing with dilute base, drying, and evaporation of the solvent, a residue that was examined by GC–MS, which suggested the presence of lactone **13**. Chromatography (Chromatotron, 1 mm plate, 5% ethyl acetate in hexanes) of the residue afforded lactone **13** as a yellowish oil in 5% yield. IR (cm^{-1}): 2300–2902, 1757, 1520; ^1H NMR (500 MHz, C_6D_6) δ: 1.77 (t, ^3J = 5.8 Hz, 2H), 3.34 (t, ^3J = 5.9 Hz, 2H); ^{13}C NMR (125 MHz, C_6D_6, ^{19}F decoupled) δ: 20.29 (correlated with ^1H triplet at 1.77), 65.45 (correlated with ^1H triplet at δ = 3.34), 123.4, 140.2, 142.7, 142.8, 143.3, 149.0, 178.6; ^{19}F NMR (470 MHz, C_6D_6, external ref. $CFCl_3$ δ: −134.3 (m, correlated to C at δ = 149.0), −144.7 (m, correlated to C at δ = 142.7), −148.5 (m, correlated to C at δ = 143.3), −156.9 (m, correlated to C at δ = 140.2); MS (EI) *m/z* (rel. intensity): 220 (M^+, 12), 190 (20), 162 (20).

Dimers **14**, E/Z mixture in ca. 1:1 ratio. ^1H NMR (200 MHz, C_6D_6) δ: 2.62 (br t, $J \cong 6.6$ Hz, $ArCH_2$, overlapping signals from both isomers), 3.21 (s, OMe), 3.28 (s, OMe), 3.68 (t, J = 6.7 Hz, OCH_2) overlapping 3.70 (t, J = 6.6 Hz, OCH_2); MS (GC–MS) *m/z*: 255 ($(M + H)^+$, 18), 195 (100).

Acknowledgements

Financial support for this work, in the form of an operating grant from The Natural Sciences and Engineering Research Council of Canada, is gratefully acknowledged. P.C. held an Ontario Graduate Scholarship and J.P.R. was the recipient of two support awards, from Human Resources Canada, for work as a summer assistant. The authors are indebted to Dr. Donald Hughes for his expert ^{13}C and ^{19}F NMR correlations on small samples of ester **11** and lactone **13**.

Preparation of symmetric dibromides of 1,10-phenanthroline

Yutaka Saitoh, Take-aki Koizumi, Kohtaro Osakada, and Takakazu Yamamoto

Abstract: Bromation of 1,10-phenanthroline with Br_2 proceeds smoothly in the presence of S_2Cl_2 and pyridine to give 3,8-dibromo-1,10-phenanthroline in good yield. Bromation of 2,9-dibutoxy-1,10-phenanthroline with Br_2 in an aqueous medium gives 5,6-dibromo-2,9-dibutoxy-1,10-phenanthroline selectively. Similar bromination of 4,7-dibutoxy-1,10-phenanthroline with Br_2 gives 3,8-dibromo-4,7-dibutoxy-1,10-phenanthroline, which forms a 1:1 adduct with $Cu(NO_3)_2$. Molecular structure of the 1: 1 adduct has been determined by X-ray crystallography.

Key words : bromination, 1,10-phenanthroline, 3,8-dibromo-1,10-phenanthroline.

Résumé : La bromation de la 1,10-phénanthroline par le Br_2 se produit facilement en présence de S_2Cl_2 et de pyridine et elle conduit à la 3,8-dibromo-1,10-phénanthroline avec un bon rendement. La bromation de la 2,9-dibutoxy-1,10-phénanthroline par le Br_2 en milieu aqueux conduit sélectivement à la 5,6-dibromo-2,9-dibutoxy-1,10-phénanthroline. Une bromation semblable de la 4,7-dibutoxy-1,10-phénanthroline avec du Br_2 donne de la 3,8-dibromo-4,7-dibutoxy-1,10-phénanthroline qui forme un adduit 1 : 1 avec le $Cu(NO_3)_2$. La structure moléculaire de l'adduit 1 : 1 a été déterminée par diffraction des rayons X.

Mots clés : bromation, 1,10-phénanthroline, 3,8-dibromo-1,10-phénanthroline.

[Traduit par la rédaction]

1. Introduction

Aryl halides are important starting materials, and numerous methods have been developed for direct halogenation of aromatic compounds with halogen X_2. However, among the aromatic compounds, those containing electron-withdrawing imine nitrogen (C═N-) have a π-deficient nature (1), and their electrophilic substitution with X_2 usually requires very severe reaction conditions. For example, effective bromination of pyridine with Br_2 was achieved in fuming sulfuric acid (1, 2).

1,10-Phenanthroline (Phen) is a typical π-deficient aromatic compound, and its direct and selective halogenation has not been explored. Dénes and Chira (3) reported direct bromination of Phen in thionyl chloride; however, selectivity of the bromination as well as yields of the products was low. Recently, Tor, Siegel and co-workers (4) reported direct bromination of Phen by modifying its reactivity by forming an HCl salt and carrying out the reaction in heated nitrobenzene; however, the selectivity and yields of two products, 33% for 3-bromo-1,10-phenanthroline and 17% for 3,8-dibromo-1,10-phenanthroline, were low. Although Yamada et al. (5) reported chlorination of Phen by PCl_5 through unique methods, they have not reported its direct bromination. On this basis, we have investigated conditions for the direct bromination of Phen and its derivatives, and herein report the results.

New applications for Phen and its derivatives, including their transition metal coordination compounds, have recently been developed (*i*) to form supramolecules (6), (*ii*) to make photochemically and electrochemically active molecules (7, 8), and (*iii*) to selectively cleave DNA (9). In these new areas symmetrically substituted Phens have mainly been used, and consequently symmetrically dibrominated Phens are considered to be particularly important. On this basis, the present research is focussed on the preparation of symmetrically dibrominated Phens.

2. Results and discussion

Bromination of Phen

We initially tried bromination of Phen with Br_2 in $CHCl_3$ without additives, and found that the reaction gave (55%) a yellow precipitate with the approximate composition of Phen·Br_2. Eisch (10) reported that a reaction of quinoline and Br_2 gave a similar 1:1 adduct and its thermolysis gave 3-bromoquinoline; however, thermolysis of Phen·Br_2 at 190°C and 260°C gave no signs of C-bromination. Thermolysis of the adduct in the presence of excess Br_2 gave 3-bromo-1,10-phenanthroline (**1a**) and 3,8-dibromo-1,10-phenanthroline (**1b**) in 15 and 5% yields, respectively, as estimated from an NMR spectrum of the crude product.

[1] [Phen • Br_2] + Br_2 —(thermolysis; under N_2)→ 

1a (R = H; 15%)
1b (R = Br; 5%)

In contrast to the poor yield of **1b** in the simple bromination system, addition of sulfur chloride S_2Cl_2 (11) and pyridine to

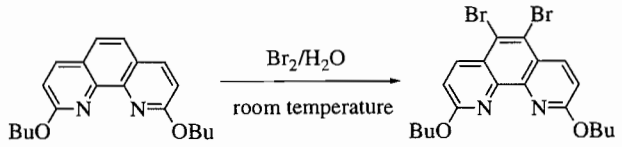
For personal use only.



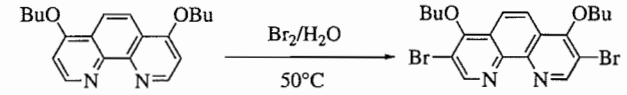
the reaction mixture leads to increased yields (crude = 63%, isolated = 34%) of **1b**.

[2] $\text{Phen} + Br_2 \xrightarrow[\text{1-chlorobutane,reflux}]{S_2Cl_2 + \text{pyridine}} \text{1b}$

The reaction proceeds smoothly in various chlorinated hydrocarbons such as $CHCl_3$, $CHCl_2CHCl_2$, and 1-chlorobutane. Without addition of pyridine, the yield of **1b** was negligible (3%). Garcia et al. (12) reported bromination of pyridine and quinoline under similar reaction conditions and proposed a pyridinium salt-type intermediate. Since Phen also forms pyridinium-type salts with alkyl halides (13), intermediacy of a similar Phen salt-type compound[2] in the present bromination is conceivable. **1b** thus prepared can be isolated by recrystallization from $CHCl_2CHCl_2$ or by complex formation with Br_2 (cf. Experimental). Although **1b** is considered to be an important starting material for liquid crystalline compounds, macrocyles, and π-conjugated polymers, its preparation in good yield was difficult.

Bromination of dibutoxy-1,10-phenanthroline

When Phen has an electron-donating O-substituent, electrophilic substitution with Br_2 takes place without addition of special reagents such as S_2Cl_2. Similar activation of pyridine by an electron-donating amino group has been reported in halogenation (14). Thus, the direct bromination of 2,9-dibutoxy-1,10-phenanthroline, **2a**, proceeds at room temperature.

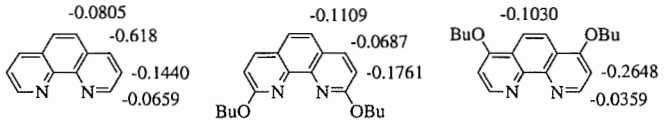


[3] 

2a **3a** 89%

However, direct bromination requires the use of a mixture of Br_2 and H_2O, and attempts to carry out similar bromination in organic solvents (benzene, THF, and $CHCl_3$) were unsuccessful. Although the direct bromination of **2a** proceeds without addition of H_2O, the yield of **3a** is considerably lower. H_2O will trap evolved HBr, which may cleave the C—OBu bonds in **2a** and the product, and this may be the rationale for the necessity of added H_2O. An AMI Hamiltonian calculation (15) indicates that the 3,8-carbon atoms of **2a** have the highest, and those in the 5,6 positions have a somewhat lower, electron population. Steric repulsion from the butoxy group and the relatively small difference in the electron population between the 3,8 and 5,6 positions seem to lead to the preferential bromination of the latter.

Similar direct bromination of 4,7-dibutoxy-1.10-phenanthroline, **2b**, is also possible; however, it requires somewhat higher temperature, and yield of the product is moderate.



[2] Formation of salt-type compounds is considered to be enhanced by the added pyridine (12).

[4] 

2b **3b** 20%

The bromination positions agree with the results of the AMI Hamiltonian calculation (Chart 1).

Chart 1. Electron population of Phen and its dibutoxy derivatives calculated by an AMI Hamiltonian calculation. Effective charge is shown.

Phen **2a** **2b**

Cu(II) complex of 3b

Assignment of the brominated position of **3a** and **3b** is mainly based on NMR data of the products. To confirm the bromination position, we tried to obtain a crystal suited to X-ray crystallography; however, the attempts were not successful. On the other hand, reaction of **3b** with $Cu(NO_3)_2$ gives a crystal suitable for X-ray crystallography, and Fig. 1 depicts the molecular structure of the 1:1 adduct of **3b** and $Cu(NO_3)_2$.

[5] $3b + Cu(NO_3)_2 \xrightarrow{C_2H_5OH} \underset{4}{\text{1:1 adduct}}$

Table 1 summarizes selected bond distances and angles of complex **4**. As shown in Fig. 1 and Table 1, complex **4** has a square planar coordination mode around the central Cu(II), and its molecular structure confirms the structure of **3b**; thus, unequivocal assignments of the ^1H NMR signals of **3b** and **2b** become possible.

3. Experimental

Materials

Phen, S_2Cl_2, and Br_2 were purchased from Tokyo Chemical Industry Co., Ltd. **2a** and **2b** were prepared according to the literature (16).

Preparation of 1b

A stirred 1-chlorobutane solution (200 cm^3) containing Phen (5 g, 27.8 mmol), S_2Cl_2 (12.3 g, 91.1) mmol), pyridine (7.10 g, 89.8 mmol), and Br_2 (14 g, 87.6 mmol) was refluxed for 12 h. After cooling to 25°C, the solid formed was separated, and an aqueous solution of NaOH (excess) and $CHCl_3$ (ca. 100 cm^3) was added to the solid. The $CHCl_3$ solution was separated and chromatographed through a short SiO_2 column and then dried to obtain crude **1b** (5.9 g, 63% yield). The IR spectrum of crude **1b** is almost identical to that of pure **1b**. Recrystallization from $CHCl_2CHCl_2$ (25 cm^3) gave analytically pure **1b** (yield 34%). Anal. calcd. for $C_{12}H_6N_2Br_2$: C 42.6, H 1.8, N 8.3, Br 47.3%; found: C 42.7, H 1.8, N 8.4, Br 47.0%. IR(KBr, cm^{-1}): 3024, 1583, 1475, 1411, 1204, 1101, 906, 892, 776,

Addition of Br_2 (3.0 g, 19 mmol) to the above $CHCl_3$ (60 cm^3) solution after elution through the short SiO_2 column led to formation of an orange precipitate, which was collected by filtration. The solid was treated with aqueous NaOH (ca. 50 mmol) solution, and extracted with $CHCl_3$ (ca. 50 cm^3). The extracted solution was condensed and eluted through an SiO_2 column (eluent, $CHCl_3$). The $CHCl_3$ solution was evaporated and recrystallized from benzene to yield **1b** (yield 23%).

Preparation of 3a

2a (1.0 g, 3.1 mmol) was added to a mixture of 5 cm^3 of Br_2 and 10 cm^3 of H_2O. The reaction mixture was vigorously stirred at 25°C for 10 h. After addition of an aqueous solution of $Na_2S_2O_4$ (excess), the product was extracted with $CHCl_3$ (ca. 10 cm^3), and the $CHCl_3$ extract was washed with H_2O and dried. The solid was recrystallized from EtOH twice. Yield 89% (1.36 g, 2.8 mmol); mp 109–110°C. ^{1}H NMR ($CDCl_3$) δ: 8.53 (d, J = 9.0 Hz, 2H), 7.08 (d, J = 9.0 Hz, 2H), 4.70 (t, J = 6.6 Hz, 4H), 1.4–2.0 (m, 8H), 1.02 (t, 6H). Anal. calcd. for

$C_{20}H_{22}Br_2N_2O_2$: C 49.8, H 4.6, N 5.8, Br 33.1; found: C 49.5, H 4.5, N 5.9, Br 32.8.

Preparation of 3b

To a mixture of 12 cm^3 of Br_2 and 100 cm^3 of H_2O was added **2b** (2.0 g, 6.2 mmol). The reaction mixture was vigorously stirred at 50°C for 10 h. After cooling to 25°C, an aqueous solution of NaOH (excess) and $Na_2S_2O_4$ (excess) was added. The product was extracted with $CHCl_3$ (ca. 30 cm^3), and the $CHCl_3$ extract was washed with H_2O and dried. The solid was dissolved in toluene–dioxane (in a 4:1 v/v ratio), and the solution was passed through an Al_2O_3 column, dried, and after concentration in vacuo the residue was recrystallized from MeOH. Yield 20.2%; mp 110–112°C. ^1H NMR ($CDCl_3$) δ: 9.14 (s, 2H, 2,9-phen H), 8.13 (s, 2H, 5,6-phen H), 4.30 (t, J = 6.7 Hz, 4H, -OCH_2-), 2.2–1.4 (m, 8H, CH_2), 1.30 (t, 6H, CH_3). Anal. calcd. for $C_{20}H_{22}Br_2N_2O_2$: C 49.8, H 4.6, N 5.8, Br 33.1; found: C 49.6, H 4.4, N 5.8, Br 33.2.

Preparation of complex 4 for X-ray crystallography

A hot ethanol (1.0 cm^3) solution of **3b** (10 mg, 2.1×10^{-5} mol) and a hot ethanol (1.0 cm^3) solution of $Cu(NO_3)_2 \cdot 6H_2O$ (5 mg, 1.7×10^{-5} mol) were combined and allowed to stand at 25°C. Blue-green plates of **4** were obtained in 95% yield.

Measurements

IR spectra were measured on a JASCO 810 spectrophotometer. ^1H NMR spectra were recorded on JEOL FX-100 and EX-400 spectrometers. Elemental analyses were carried out by a Yanagimoto type MT-2 CHN autocorder.

Crystal structure determination of complex 4

Crystallographic data and the results of structure refinement are summarized in Table 2. The unit-cell parameters were obtained by least-squares refinement of 2θ values of 25 reflections with $25° \leq 2\theta \leq 35°$. Intensities were collected on a Rigaku AFC-5R automated four-circle diffractometer by using Mo Kα radiation (γ = 0.710 69 Å) and the ω–2θ method. Calculations were carried out by using the program package TEXSAN on a DEC Micro VAXII computer.

Of the 5145 collected reflections for complex **4**, 4816 were unique (R_{int} = 0.055). No decay correction was applied. An empirical absorption correction based on azimuthal scans of several reflections was applied, which resulted in transmission factors ranging from 0.59 to 1.00. The data were corrected for Lorentz and polarization effects. The structure was solved by heavy-atom Patterson methods and expanded using Fourier techniques.

Tables of atomic coordinates, anisotropic displacement parameters, and bond lengths and angles are available as supplementary material.[3]

[3] The complete set of tables can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. The tables of atomic coordinates and of bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Naphthalene-based poly(aryl ether)s. I. Synthesis and characterization of poly(ether sulfone)s and poly(ether ketone)s containing one 1,4-naphthylene moiety in the repeat unit

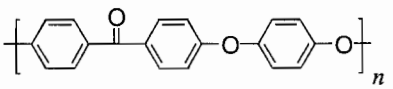
Judy E. Douglas and Zhi Yuan Wang

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12
For personal use only.

Abstract: The effect of insertion of one 1,4-naphthylene unit into several PEEK-like and Udel®-like commercial polymers is examined. Two series of poly(ether ketone)s and poly(ether sulfone)s were made from the polycondensations of 1-chloro-4-(4-fluorobenzoyl)naphthalene and 1-chloro-4-(4-fluorobenzenesulfonyl)naphthalene with phenolphthalein (PP), 2,2′,6,6′-tetramethyl-4,4′-biphenol (TMBP), and 4,4′-biphenol (BP). Each polymer was soluble in chloroform, from which dense films could be cast. Glass transition temperatures increased 14-19°C with TMBP, 30–43°C with BP, and 39–60°C in the case of PP. The 1,4-naphthylene insertion reduced the crystallinity of the biphenol-based polymers. The onset temperatures for 5% weight loss ranged from 390 to 536°C in nitrogen, as assessed by thermogravimetry. Young's moduli varied from 0.54 to 2.1 GPa. In the case of the poly(ether ketone) containing TMBP, incorporation of the 1,4-naphthylene moiety increased gas permselectivity at the cost of decreased permeability, whereas there seemed only to be a decrease in permeability with its poly(ether ketone) counterpart.

Key words: naphthalene, poly(ether sulfone)s, poly(ether ketone)s, glass transition temperature, gas permeability.

Résumé : On étudie l'effet de l'insertion d'une unité 1,4-naphtylène dans plusieurs polymères commerciaux tels le PEEK et le Udel. On a préparé deux séries de poly(éther cétone) et poly(éther sulfone) par polycondensation du 1-chloro-4-(4-fluorobenzoyl)naphtalène et du 1-chloro-4-(4-fluorobenzènesulfonyl)naphtalène avec la phénolphtaléine (PP), avec le 2,2′,6,6′-tétraméthyl-4,4′-biphénol (TMBP) et avec le 4,4′-biphénol (BP). Chaque polymère solubilisé dans le chloroforme permet d'obtenir des films denses que l'on peut mouler. Les températures de transition du verre augmentent de 14 à 19°C avec le TMBP, de 30 à 43°C avec le BP et de 39 à 60°C dans le cas du PP. L'insertion du 1,4-naphtylène réduit la cristallinité des polymères à base de biphénol. Faisant appel à la thermogravimétrie on a déterminé que les températures, à partir desquelles on observe un perte de 5% en poids, varient de 390 à 536°C dans l'azote. Le module de Young varie de 0,54 à 2,1 GPa. Dans le cas du poly(éther cétone) contenant du TMBP, l'insertion d'une unité 1,4-naphtylène augmente la perméation sélectivite des gaz au détriment de la perméabilité, tandis que dans le cas de son homologue poly(éther cétone) on ne semble observer qu'une diminution de la perméabilité.



Mots clés : naphtalène, poly(éther sulfone), poly(éther cétone), température de transition du verre, perméabilité gazeuse.

[Traduit par la rédaction]

Introduction

Poly(aryl ether ketone)s (PAEK) and poly(aryl ether sulfone)s (PAES) represent two classes of engineering thermoplastics that exhibit superior mechanical and thermal properties (1, 2). Both display excellent electrical insulating properties, good flame, hydrolytic, and solvent resistance, and can be found in a variety of forms such as molded parts, films, fibers, and coatings (3). Applications of these two plastics include (*i*) coatings for high-performance wiring in aeronautics, (*ii*) advanced structural composites, (*iii*) household molded products, (*iv*) car engine parts, and (*v*) sterilizable medical equipment (3, 4). ICI's PEEK (Fig. 1) has received much commercial success due to its high operating temperature and superior strength (1). PEEK has a glass transition temperature (T_g) of 143°C and a melting point (T_m) of 334°C. The 4,4′-biphenol-based poly(ether ketone) (**3c**, Fig. 2) is crystalline (T_g = 167°C, T_m = 416°C) and solvent resistant, and the 'sulfone analogue (**1c**, Union Carbide's Radel®, Fig. 2) is also quite solvent resistant (3).

More recently, there has been much effort in studying structure–property relationships of poly(aryl ether)s for the use of gas separation (5, 6). Polysulfones generally exhibit higher gas permeabilities than their ketone equivalents. Union Carbide's Udel® (**1d**, Fig. 2), a polysulfone that contains bisphenol A (BPA) in the repeat unit, has been successfully commercialized as a gas membrane (6). For a polymer to be successful as a gas membrane, it must combine both high permeability and high selectivity (7). Generally speaking, the structural changes that lead to increased gas permeability also cause loss in selectivity. Thus, a compromise between the two must be achieved in order to be successful. A common strategy to improve gas transport properties is to increase chain rigidity and decrease chain packing. Often this can be done by the addition of a pendant group.

There is a growing demand for new materials to meet increased performance requirements in many areas such as the one just described. Thus there has been considerable research effort made toward the modification of known poly(aryl ether)s (8) as well as the design of polymers with novel structures (9). To date, most modifications have been made to the bisphenol part, due in large part to the ease with which it can be changed.

Earlier work of ours demonstrated that the replacement of one 1,4-phenylene with one 1,4-naphthylene moiety in the repeat unit of semi-crystalline PEEK significantly reduced the crystallinity of the resulting polymer and increased the T_g by 45°C (10). Likewise, 1,4-naphthylene insertion into several poly(ether sulfone)s also increased the polymer's T_g (11). The dense membrane of the naphthylene-containing poly(ether sulfone) derived from BPA was found to improve permselectivities at the cost of lowering its permeabilities towards oxygen, nitrogen, carbon dioxide, and methane gases (11). From a polymer design standpoint, the 1,4-naphthylene insertion serves to modify the structure of poly(aryl ether) by addition of a benzo moiety perpendicular to the main chain. Therefore, it seemed worthwhile to pursue the investigation of the effects of naphthylene insertion on other poly(aryl ether)s. Two series of polymers **2a–c** and **4a–c** (Fig. 2) were synthesized in order to incorporate the 1,4-naphthalene unit into PAES and PAEK derived from bulky bisphenols for study of the gas transport property, and to see if it could

further increase the T_g and reduce the crystallinity for the biphenol-based polymers.

Results and discussion

Polymer synthesis

Polymers **2a–c** and **4a–c** were made by the polycondensation reactions of 1-chloro-4-(4-fluorobenzenesulfonyl)naphthalene, **5** (11), and 1-chloro-4-(4-fluorobenzoyl)naphthalene, **6** (10), (Fig. 2), respectively, with phenolphthalein (PP), 2,2′,6,6′-tetramethyl-4,4′-biphenol (TMBP), and 4,4′-biphenol (BP). Polymerizations were all done in $TMSO_2$ at 200°C with chlorobenzene as an azeotroping agent, using stoichiometric amounts of the dihalide and bisphenol monomer in the presence of potassium carbonate (1.8 molar equiv.). Typically, the reaction was heated from room temperature to 140–150°C within 0.5 to 1 h and the water formed during the reaction was removed as an azeotropic mixture with chlorobenzene. The polymerization temperature was then increased to 200°C and the reaction proceeded for 3 h before GPC monitoring showed a lack of increase in molecular weight, at which point the reaction was stopped. The resulting polymers were coagulated in an excess of methanol with a few drops of HCl, followed by reverse precipitation to remove any remaining oligomers.

Polymer characterization

Under these polymerization conditions, polymers **2a–c** and **4a–c** were obtained as off-white, fibrous solids. All the polymers were soluble at room temperature in chloroform, 1,1,2,2–tetrachloroethane (TCE), CH_2Cl_2, and *N*-methylpyrrolidinone (NMP), with the exception of **4b**, which was only partially soluble in CH_2Cl_2. In addition, the polymers **2a** and **4a** derived from PP were also soluble in dimethylacetamide (DMAc), tetrahydrofuran (THF), and dimethylformamide (DMF) due to the presence of the cardo group. The TMBP-based polymers **2b** and **4b** were also quite soluble in all the above mentioned solvents with the exception of DMF. The BP-based polymers **2c** and **4c** were the least soluble. The poly(ether ketone) **4c** was only partially soluble in DMAc, CH_2Cl_2, and DMF. The sulfone polymer **2c** had difficulty dissolving in THF and DMF. It is known that the biphenyl moiety promotes chain packing, as polymer **3c** is semicrystalline with a T_m of 416°C. Due to the tetrahedral sulfone unit, polymer **2c** showed higher solubility than the ketone analogue **4c**.

Gel permeation chromatography (GPC) showed moderate to high molecular weights relative to polystyrene in all cases (Table 1). The highest molecular weights were achieved using PP as a bisphenol (254 000 for **2a** and 229 000 for **4a**). The inherent viscosities supported the GPC results, with values ranging from 0.42 to 1.09 dL/g.

The structures of the polymers synthesized (**2a–c** and **4a–c**) were confirmed by spectroscopic means (NMR, IR). Evidence was found by NMR that showed the unsymmetric nature of the polymer's repeat unit due to the unsymmetry of the starting dihaloaryl monomer. Previously, the presence of three singlets was seen in the ^1H NMR spectra of BPA-based poly(ether ketone) **4d** (10*b*) and poly(ether sulfone) **2d** (11) at 1.6 and 1.8 ppm, respectively. This was attributed to the methyl groups of the bisphenol unit in three slightly different magnetic environments due to the presence of three possible diads. In the TMBP series (**2b** and **4b**), four singlets exist at ~2.1 and 2.2 ppm, respectively, in the ^1H NMR spectra (Fig. 3) and four aliphatic carbon peaks at about 16 ppm in the ^{13}C NMR spectra. This is indicative of the four different magnetic environments to which the methyl groups are exposed in the head-to-head, tail-to-tail, and head-to-tail diads (Fig. 4). In the head-to-head and tail-to-tail formations, all four methyl groups are either closer to a naphthalene or a benzene ring and are therefore in two different magnetic environments corresponding to two of the four singlets. In the head-to-tail diad, two of the methyl groups are closer to a naphthalene ring, whereas the other two are closer to a benzene ring, thereby giving rise to the presence of the remaining two proton peaks. The intensities of the two outer peaks appear the same, likewise with the smaller two inner peaks. COSY and HETCOR experiments were done and supported the peak assignments in Fig. 3.

Infrared (IR) spectra showed the conjugated ketone stretching for the ketone polymers **4a**, **4b**, and **4c** at 1654, 1652, and 1654 cm^{-1}, respectively. Polymer **4a** showed a second C=O peak at 1772 cm^{-1} due to the lactone of phenolphthalein. The IR spectra of the sulfone polymers were a little less diagnostic but generally showed S=O asymmetric and symmetric stretching at ca. 1240 cm^{-1} and 1146 cm^{-1}.

Differential scanning calorimetry (DSC) indicated that all the polymers were amorphous, thus substitution of a 1,4-phenylene unit with a 1,4-naphthylene moiety reduced the crystallinity of the biphenol-based polymer (**2c** and **4c**). Table 2 shows that in every case of 1,4-naphthylene insertion, T_g was

increased compared to its 1,4-phenylene-based equivalent. The increase in T_g was highest for **2a** and **4a** containing bulky phenolphthalein (36 and 39°C) and lowest for **2b** and **4b** with TMBP (14 and 19°C). The 4,4′-biphenol-based polymers, **2c** and **4c,** also showed significant increases in T_g (30 and 43°C). These results follow the trend found in our earlier work with other bisphenols (10, 11). The decomposition, as assessed by the onset temperature (T_d), of 5% weight loss by T_g occurred in the range of 390–536°C in nitrogen. The T_d values of the ketone series (**4a–c**) were greater than those of the sulfone counterparts (**2a–c**).

Thin rectangular strips of polymer films cast from chloroform solution were used to measure Young's modulus in the tensile stress–strain mode. The moduli varied from 0.54 to 2.1 GPa (Table 1). The Young's moduli of the ketone series were larger than their sulfone equivalents, demonstrating the superior mechanical strength of the poly(ether ketone)s.

Gas transport property

Table 3 shows the gas permeability and selectivity coefficients of the ketone and sulfone polymers (**2b**, **4b**) derived from TMBP, including the 1,4-naphthylene-based poly(ether ketone)s **4e** and **4f** and the poly(ether sulfone) **2d** for comparison. The gas permeabilities of the TMBP series (**1b**, **2b**, **3b**, **4b**) are two to five times larger than those of the polymers derived from other bisphenols (**2d**, **4e**, **4f**). This trend has been

noted elsewhere in the literature (*5d*). But an increase of permeability due to the presence of TMBP comes as the trade-off of reducing the selectivity coefficients of **2b** (5.4 for O_2/N_2 and 28 for CO_2/CH_4) and **4b** (5.0 for O_2/N_2 and 24 for CO_2/CH_4). Within the TMBP series (**1b**, **2b**, **3b**, **4b**), it was found that 1,4-naphthylene insertion marginally improves O_2/N_2 and CO_2/CH_4 selectivity coefficients, while lowering the permeabilities for most of the gases when comparing poly(ether sulfone) **1b** with **2b**. In contrast, when poly(ether ketone) **3b** is compared with **4b**, insertion of the 1,4-naphthylene moiety lowered permeabilities with no significant change to permselectivities. Thus, 1,4-naphthylene insertion in both the ketone and sulfone polymers always lowers the permeability, with the benefit of increasing permselectivity within the poly(ether sulfone) series but with little effect in the poly(ether ketone) family. The use of TMBP, compared to the other bisphenols, has enhanced gas permeability.

Conclusion

Two new series of poly(ether sulfone)s and poly(ether ketone)s containing unsymmetric benzonaphthone and phenylnaphthylsulfone moieties have been synthesized. 1,4-Naphthylene insertion into the backbones of the ketone and sulfone poly(aryl ether)s serves to reduce crystallinity and increase T_g. Addition of the 1,4-naphthylene moiety to the poly(ether sulfone) containing TMBP increases its gas permselectivity but appears to have no immediate advantage with the TMBP-based poly(ether ketone).

Experimental section

General

The ^1H and ^{13}C NMR spectra were recorded on the Bruker-400 instrument using tetramethylsilane as the internal reference. Infrared measurements were performed on a Perkin–Elmer Series 1600 FTIR instrument. Molecular weights were determined on a Perkin–Elmer LC-250 GPC instrument relative to polystyrene standards using chloroform as an eluent at a flow rate of 1.0 mL/min; a UV detector was set at 254 nm wavelength. Inherent viscosities were measured in a 0.5 g/dL chloroform solution at 25°C using an Ubbelohde dilution viscometer. The glass transition temperatures were determined by differential scanning calorimetry (DSC) on a Seiko DSC 220 at a heating rate of 10°C/min under nitrogen (50 mL/min) and taken as the midpoint in the change in slope of the baseline. Thermogravimetric analysis (TGA) was performed on a Seiko TG/DTA 220 at a heating rate of 10°C/min in nitrogen (200 mL/min). Thin films were cast from chloroform solution, dried from room temperature to 140°C in 4 days under vacuum (1 Torr (= 133.3 Pa)), and cut into rectangular strips (length = 10 mm, width = 2 mm, thickness ~0.1 mm). Young's moduli (E') were recorded using a Seiko TMA/SS 120C at 25°C in static air with the following parameters: offset = 10–30 g, load = 5–15 g, amplitude = 5–10 g, and cycling frequency = 0.05–0.2 Hz. Young's moduli were obtained from the average of the tangential slopes of the elliptical stress–strain plots.

Materials

Anhydrous potassium carbonate, phenolphthalein, 4,4′-biphenol, and chlorobenzene were purchased from Aldrich Chemical Co. and used as received. Reagent grade tetramethylene sulfone ($TMSO_2$) from Aldrich was fractionally distilled under vacuum (120°C/3 Torr). 2,2′,6,6′-Tetramethyl-4,4′-biphenol was recrystallized from methanol. The two dihalo monomers, 1–chloro-4-(4-fluorobenzenesulfonyl)-naphthalene, **5**, and 1–chloro-4-(4-fluorobenzoyl)naphthalene, **6**, were prepared as previously reported (11, 10).

Polymer synthesis

All polymerizations were carried out in a flame-dried, 50 mL, three-neck round-bottomed flask equipped with a stirring bar, a Dean–Stark trap fitted with a condenser, and a nitrogen purge inlet. The flask was charged with a bisphenol and a dihalo monomer (3.00 mmol each) and crushed anhydrous K_2CO_3 (5.4 mmol). Tetramethylene sulfone (adjusted to final concentration of 40% w/v) and an equal volume of chlorobenzene were then added. The reaction mixture was heated under nitrogen from room temperature to 200°C in 30 min. The water formed and the chlorobenzene were codistilled off. The polymerization was monitored by GPC and stopped when the molecular weight failed to increase. If the reaction mixture became too viscous to stir, it was diluted with tetramethylene sulfone (1–2 mL). The polymer was isolated by precipitation in methanol. All polymers were purified by dissolving in a large quantity of "good" solvent (~100 mL $CHCl_3$) chloroform and filtering through a pad of Celite to remove salts. Reverse precipitation was done on all the polymers to remove low molecular weight fractions. This involved adding methanol, a "bad" solvent, (~25–50 mL) to the polymer solution to give a gummy ball. After decanting the low molecular weight fractions, the gummy ball was dissolved again in a minimal amount of "good" solvent (20 mL $CHCl_3$), then reprecipitated into a large amount of methanol to give a white fibrous polymer. Molecular weights of the reprecipitated polymers were taken and are listed in Table 1.

Dense membrane preparation

The polymer film was cast from a 2% (w/w) chloroform solution to form a 100 μm thick circular membrane. Chloroform was allowed to evaporate slowly (1–2 days) in air atmosphere until the film was tack free. Then while under vacuum (1 Torr), the membrane was heated slowly from room temperature to 140°C over 4 days. TGA was used to ensure the absence of solvent.

Gas permeation measurements

Gas permeation measurements were carried out using a constant volume system. The polymer film was tightly sealed in a permeation cell. The downstream face of the cell was connected to a 100 Torr pressure transducer and vacuum. Nitrogen, oxygen, methane, and carbon dioxide (all in ultra high purity, supplied by Canox) were used on the upstream side as the penetrating gases at 150 psi (1 psi = 6.9 kPa). Downstream pressure versus time data were collected until a steady state was achieved and the slope of their plot from 3θ to 6θ (θ = time lag) could be calculated. From this slope, the volumetric flux can be obtained and, finally, the permeability.

Abstract: Two new monomers, 4-chloro-1-(4′-fluoro-1-naphthoyl)naphthalene and 1,4-bis(4′-fluoro-1′-naphthoyl)benzene, have been synthesized and polymerized with four different bisphenols to give two series of the naphthalene-based poly(ether ketone)s that are analogous to commercial PEEK and PEEKK. The effect of the introduction of one or two 1,4-naphthylene moieties, in the backbone of the repeat unit, on the glass transition temperatures has been studied. The glass transition temperatures usually increased by 20–45°C upon replacing one 1,4-phenylene with one 1,4-naphthylene moiety. All new poly(ether ketone)s prepared in tetramethylene sulfone were amorphous, with the glass transition temperatures in a range of 212–273°C. The polymer produced from 1,4-bis(4′-fluoro-1′-naphthoyl)benzene and 1,4-hydroquinone in phenyl sulfone as a solvent at 300°C showed semicrystalline properties with a melting temperature of 310°C.

Key words: naphthalene, poly(ether ketone)s, synthesis, characterization, glass transition temperature.

Résumé : On a synthétisé deux nouveaux monomères, le 4-chloro-1-(4′-fluoro-1′-naphtoyl)naphtalène et le 1,4-bis(4′-fluoro-1′-naphtoyl)benzène, et on les a polymérisés avec quatre différents biphénols pour obtenir une série de poly(éther cétone), contenant du naphtalène, qui sont analogues aux polymères commerciaux PEEK et PEEKK. On a étudié l'influence de l'insertion d'une ou deux unités, 1,4-naphtylène, dans le squelette du monomère, sur les températures de transition du verre. Les températures de transition du verre augmentent habituellement par 20–45°C lorsqu'on remplace une unité 1,4-phénylène par une unité 1,4-naphtylène. Tous les nouveaux poly(éther cétone) préparés dans le tétraméthylène sulfone sont amorphes et les températures de transition du verre sont de l'ordre de 212–273°C. Le polymère obtenu par polymérisation du 1,4-bis(4′-fluoro-1′-naphtoyl)benzène avec la 1,4-hydroquinone dans le phényl sulfone comme solvant montre à 300°C des propriétés semi-cristallines avec une température de fusion de 310°C.

Mots clés : naphtalène, poly (éther cétone), synthèse, caractérisation, température de transition du verre.

Introduction

Aromatic poly(ether ketone)s (1) make up one of the major polymer families that are known for their superior performance characteristics in an unsurpassed number of application areas. Poly(ether ketone)s **1a** (2, 3) and **4a** (3) (Fig. 1) are typical examples, commercially available under the trade names of Victrex PEEK and Hostatec PEEKK, respectively. Key properties of these two poly(ether ketone)s, such as excellent thermal and oxidative stability, superior chemical resistance, high mechanical strength and stiffness, and excellent wear and abrasion resistance, allow them to be used as bearings, seals, wear rings, wire and cable coatings, composite matrices, and compressor parts. It has long been recognized that the fundamental basis for their performance resides in the phenylene–ether–ketone linkages that are present in their polymeric structures. The semicrystalline nature of **1a** and **4a**, as characterized by a melting point (T_m) of 344°C for **1a** and 358°C for **4a** (4), can be attributed to the regular phenylene–ether–ketone structure in their backbones. However, due to the same structural features, amorphous **1a** and **4a** exhibit relatively low glass transition temperatures (T_g) of 143°C and 154°C, respectively.

Earlier work of ours showed that the replacement of one 1,4-phenylene with one 1,4-naphthylene moiety in the repeat unit of poly(ether ketone) **1a** significantly reduced the crystallinity and increased the T_g of the resulting polymer **2a** to 188°C (up by 45°C) (5). Insertion of the 1,4-naphthylene moiety is equivalent to the addition of a benzo moiety perpendicular to the 1,4-phenylene unit in the main chain of poly(ether ketone)s. Thus, incorporation of two 1,4-naphthylene units into poly(ether ketone)s seemed worthwhile as it could further increase the T_g and reduce their crystallinity. In this paper, we report the synthesis and characterization of two series of poly(ether ketone)s (**3** and **5**) containing two naphthalene

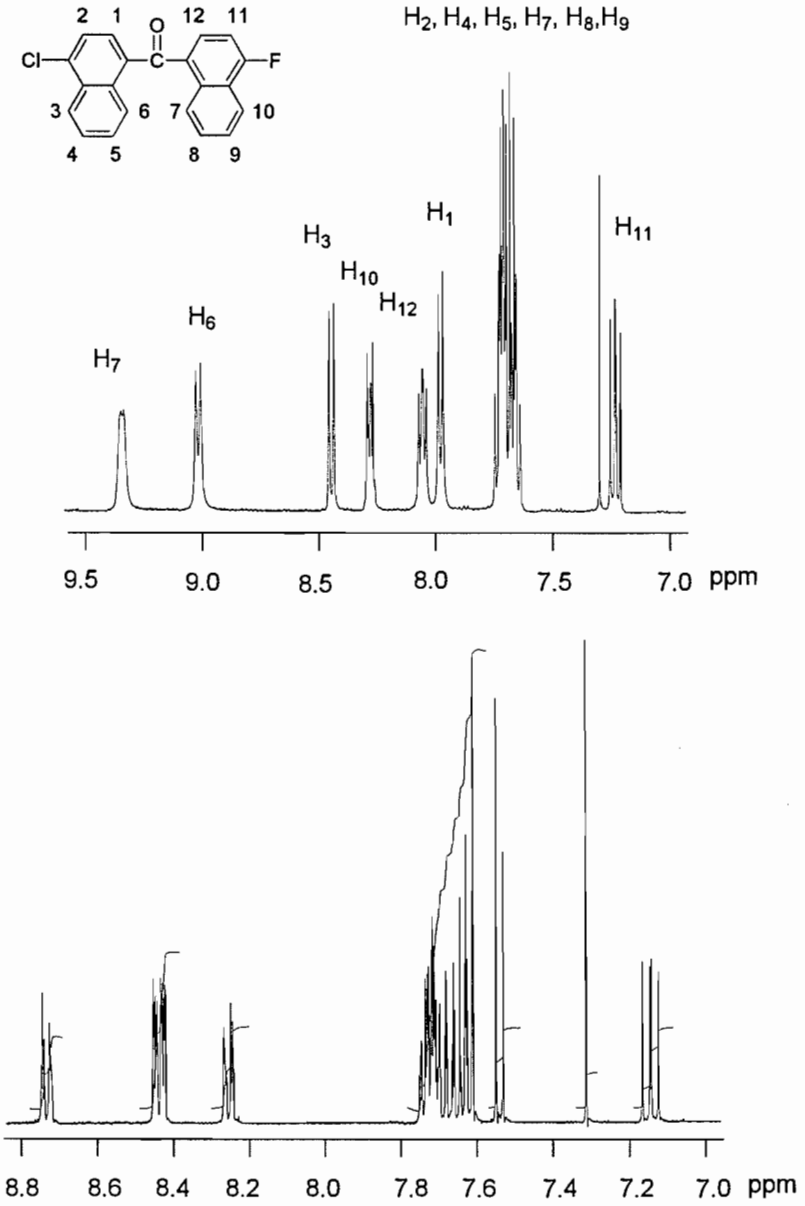
rings in the repeat unit (Fig. 1). This study is part of an ongoing effort by our group to investigate structure–property relationships of poly(ether ketone)s and to design and identify potential new high-performance thermoplastics.

Results and discussion

Monomer synthesis

Incorporation of the 1,4-naphthylene unit in poly(ether ketone)s was accomplished through the syntheses and polycondensations of two new dihalide monomers, 4-chloro-1-(4′-fluoro-1-naphthoyl)naphthalene (**6**) and 1,4-bis(4′-fluoro-1-naphthoyl)benzene (**7**). The Friedel–Crafts acylation route was used, based on 1-fluoronaphthalene, 4-chloro-1-naphthaloyl chloride, and terephthaloyl chloride as starting materials (Scheme 1). 4-Chloro-1-naphthoic acid was obtained by hypochlorite oxidation of 4-chloro-1-acetonaphthone, which was prepared by acylation of 1-chloronaphthalene with acetyl chloride (6). The transformation of 4-chloro-1-naphthoic acid to the acid chloride was done using an excess of thionyl chloride in high yield. The subsequent Friedel–Crafts reaction was carried out at 70–80°C with a 3:1 molar ratio of 1-fluoronaphthalene to the acid chloride in nitrobenzene. Monomer **6** was obtained in good yield as yellow crystals with a melting point of 111–112°C after purification, twice by vacuum distillation, followed by recrystallization from xylenes. It was soluble in the solvents suitable for polymerization such as *N*-methyl-2-pyrrolidinone (NMP), *N*,*N*-dimethylacetamide (DMAc), dimethyl sulfoxide (DMSO), and tetramethylene sulfone ($TMSO_2$).



Monomer **6** was fully characterized by spectroscopic means. The presence of two magnetically nonequivalent 1,4-naphthylene moieties and the long-range F–H couplings made its ^{1}H NMR spectrum very complicated (bottom of Fig. 2). However, the use of the $Eu(fod)_3$ lanthanide shift reagent, coupled with COSY and HETCOR experiments, allowed us to obtain the well-resolved ^{1}H NMR spectrum of **6** and a complete assignment (top of Fig. 2). The ^{19}F NMR spectrum displayed only one peak at -114.15 ppm relative to CCl_3F. The IR spectrum of **6** showed a peak at 1645 cm^{-1}, attributed to the conjugated ketone. MS gave the parent molecular ion at *m*/*z* 334 and the base peak at *m*/*z* 173, corresponding to the loss of the fluoronaphthoyl radical. The rest of the fragmentation patterns were indicative of the structure. Moreover, HRMS indicated the correct molecular formula.

The synthesis of the monomer **7** was achieved in good yield by the Friedel–Crafts acylation of 1-fluoronaphthalene using a 2.6:1 molar ratio of aluminum chloride to terephthaloyl dichloride in nitrobenzene (Scheme 1). Recrystallization three times from DMF afforded **7** in high purity as a yellow crystal-

line solid with a melting point of 230–231°C. Its structure was consistent with the ^{1}H and ^{13}C NMR data supported by COSY and HETCOR experiments. The ^{19}F NMR spectrum of **7** displayed a peak at −114.81 ppm relative to CCl_3F. The IR spectrum showed a strong peak at 1651 cm^{-1}, indicating the conjugated carbonyl moiety. MS gave the parent molecular ion at *m/z* 422, as expected, and the base peak at *m/z* 173 corresponding to the fragment ion due to the loss of fluoronaphthoyl radical. HRMS indicated the correct molecular formula.

Polymer synthesis

The following common solvents for nucleophilic substitution polycondensations were tested in the syntheses of polymers **3** and **5**: NMP, DMAc, and $TMSO_2$. In NMP, it was found that the cleavage of the ether linkage of the resulting poly(ether ketone)s occurred at elevated temperatures as reported before (7). DMAc was also not a suitable solvent, since the resulting polymers **3** and **5** exhibited very limited solubility. Polymerizations were then best carried out at 210°C in $TMSO_2$ with chlorobenzene as an azeotroping agent using a stoichiometric mixture of a dihalide and a bisphenol in the presence of potassium carbonate (2 mol-equiv.). The water formed during the reaction was removed as an azeotrope with chlorobenzene at 140°C over a period of 1–2 h. The polymerization temperature was then gradually raised to 210°C. The polymerization was stopped when the molecular weight, as analyzed by gel permeation chromatography (GPC), began to decrease. The resulting polymers were coagulated in an excess of methanol, followed by reverse precipitation to remove any remaining oligomers.

Under these reaction conditions, polymers **3** and **5** were obtained as off-white to yellow fibrous solids in moderate to high molecular weights. However, polymers **3a, b** and **5a, b** still exhibited low solubility in $TMSO_2$ and precipitated out of

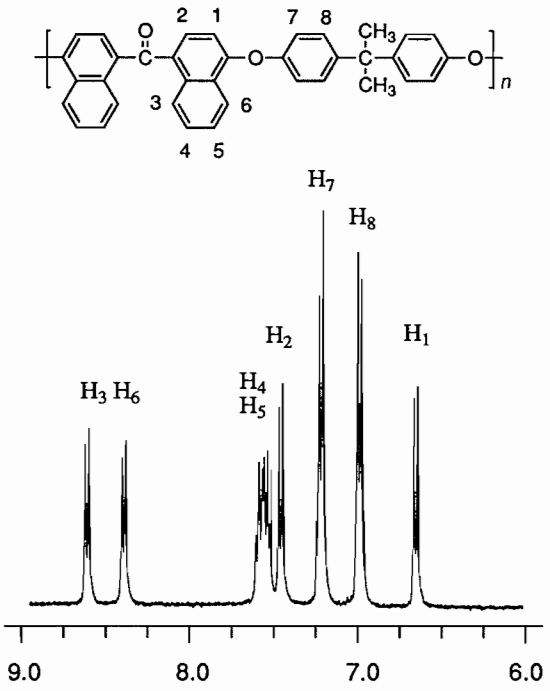
solution prematurely during polymerization. Although being soluble in high-boiling 1-cyclohexyl-2-pyrrolidinone (bp 280°C) and *N*-methylcaprolactam (NMC, bp 260°C), polymers **3a, b** and **5a, b** with higher molecular weights could not be obtained in these two solvents.



Phenyl sulfone (bp 379°C) is frequently used as a high-boiling solvent for the preparation of semicrystalline poly(aryl ether)s such as PEEK (2). Thus, the polymerization of **7** and 1,4-hydroquinone was performed in phenyl sulfone at 300°C. Although having a molecular weight similar to the sample prepared in $TMSO_2$, polymer **5a** produced in phenyl sulfone appeared to be semicrystalline and showed a T_m of 310°C by differential scanning calorimetry (DSC).

Polymer characterization

Polymers **3c, d** and **5c, d** containing the flexible isopropylidene and bulky spiro fluorene groups showed good solubility in chlorinated hydrocarbons, DMAc, and NMP. Polymers **3a, b** and **5a, b**, on the other hand, displayed much more solvent resistance than the others. Comparing three polymers **1a**, **2a**, and **3a** derived from 1,4-hydroquinone, PEEK (**1a**) is the most solvent resistant and polymer **2a** is the least solvent resistant. The former is only soluble in concentrated sulfuric acid at room temperature, while the latter is readily soluble in chloroform, 1,1,2,2-tetrachloroethane (TCE), DMAc, and NMP. However, the structurally related **3a**, having two naphthalene rings in the repeat unit, displayed much more solvent resistance than **2a**, being only soluble in NMP and *N*-methylcaprolactam (NMC). Thus, the good solubility of **2a** is attributed mainly to its microstructure, consisting of a random distribution of the head-to-tail, head-to-head, and tail-to-tail diads (5). A similar trend in solubility has been found for polymers **1b**, **2b**, and **3b**. Comparing polymers **4a,b** with polymers **5a,b**, the former two semicrystalline poly(ether ketone)s are insoluble in common organic solvents, and the latter two naphthalene-based analogues are soluble in NMP and NMC at ambient temperatures and can also be dissolved in hot TCE.

Polymers **3** gave much simpler NMR spectra than the spectrum of monomer **6**, due to the fact that two naphthylene units in the repeat unit of **3** are magnetically equivalent without the fluorine splitting. For example, the ^1H NMR spectrum of the aromatic region of polymer **3c** (Fig. 3) is simple and well

Fig. 3. ^1H NMR (400 MHz, $CDCl_3$) spectrum of the aromatic region of polymer **3c**.

resolved, yet still shows the characteristic pattern of the 1,4-naphthylene moiety. The methyl groups of the BPA unit in polymer **3c** appears as a singlet at 1.65 ppm but is not shown in Fig. 3. The peak assignments were supported by COSY and HETCOR experiments. The ^{13}C NMR spectrum of **3c** showed 17 distinguishable peaks for each of the magnetically non-equivalent carbon atoms. IR spectra indicated the carbonyl groups for polymers **3** and **5** in the region of 1648–1658 cm^{-1} and the ether linkages in the region of 1238–1243 cm^{-1}.

Polymers **3c** and **3d** had the same number-average molecular weight of 21 300, relative to polystyrene determined by GPC, and similar inherent viscosities of about 0.23 dL/g in chloroform (Table 1). In comparisons with **3c** and **3d**, polymers **5c** and **5d** had higher molecular weights (M_n = 27 400 and 41 200 for **5c** and **5d**, respectively) and higher inherent

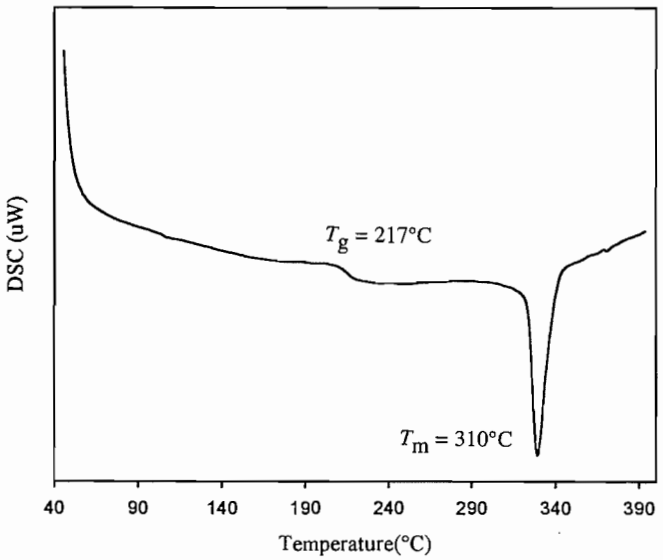
d	243[b]	265	22



[a]Taken from ref. 3.
[b]Taken from ref. 4.

viscosities (0.34 and 0.66 dL/g). Less soluble polymers **3a, b** and **5a, b** had moderate molecular weights, as indicated by their inherent viscosities, above 0.30 dL/g in NMC (Table 1). Tough, flexible films were successfully prepared for polymers **3c, d** and **5c, d** but not for polymers **3a, b** and **5a, b**. Overall, polymers **3** were obtained in relatively lower molecular weights than polymers **5** under the same polymerization conditions.

The naphthalene-based poly(ether ketone)s **3** and **5** had high thermal and thermooxidative stabilities, comparable to the phenylene analogues **1** and **4**. The onset temperatures for 5% weight loss, as assessed by TGA, occurred above 480°C in nitrogen and 430°C in air (Table 1).

All polymers **3** and **5** produced in $TMSO_2$ showed no crystalline behavior as assessed by DSC. The T_g values for polymers **3** ranged from 212 to 273°C depending on the units derived from bisphenol monomers (Table 2). As expected, polymer **3c** had the lowest T_g (212°C), due to the presence of a flexible isopropylidene group, and polymer **3d** containing a bulky cardo group had the highest T_g of 273°C. By comparing with the T_g values of polymers **1** and **2**, the effect on the T_g of the insertion of the 1,4-naphthylene moiety in the backbone of the repeat unit can be seen clearly. On the basis of semicrystalline PEEK (**1a**), the T_g increases by 45°C upon the insertion of one naphthalene ring as in the case of **2a** (188°C) and further increases to 232°C (up by another 44°C) for polymer **3a** having two naphthalene rings in the repeat unit. Going from **1b** (8) and **1c** (1*a*, 9) to **2b** (10) and **2c** (5) the T_g values increase 35–40°C but only about 25°C from **2b** and **2c** to **3b** and **3c**. Similarly, there was a moderate increase of about 20°C in T_g from **1d** (9) to **2d** (5), but almost no difference in T_g between polymers **2d** and **3d**. For the diketone-containing polymers (**4** and **5**), the increase in T_g upon replacing 1,4-phenylene with 1,4-naphthylene in the repeat unit was also observed (Table 3). Polymers **5a** and **5b** had T_g values of 217 and 230°C, respectively, over 60°C higher than those of the phenylene analogues **4a** (3) (154°C) and **4b** (11) (168°C). A moderate increase (about 20°C and 40°C) was observed for the poly(ether ketone)s derived from 4,4′-isopropylidenediphenol and 9,9-bis(4-hydroxyphenyl)fluorene (**5c** and **5d**), in comparison with their analogues **4c** (1*a*) and **4d** (9).

Fig. 4. DSC trace of the polymer **5a** prepared in phenyl sulfone at 300°C.

Although amorphous when produced in $TMSO_2$, polymer **5a** appeared to be semicrystalline when it was prepared in phenyl sulfone at 300°C. The DSC trace showed a T_g of 217°C and a T_m of 310°C (Fig. 4). In comparison with its phenylene analogue **4a**, with a T_g of 154°C and a T_m of 358°C, the polymer **5a** prepared in phenyl sulfone had a much higher T_g and a slightly lower T_m. Accordingly, the semicrystalline **5a** has a higher T_g/T_m ratio (0.84) than that (0.68) of commercial PEEKK (**4a**), which is desirable when considering the melt-processing temperatures and the final-use temperatures of the polymer.

Thermomechanical measurements were performed on thin strips of flexible, tough films cast from chloroform solutions using a thermomechanical analyzer in the tensile stress–strain mode. Young's moduli of three polymers **3d**, **5c**, and **5d** were 1.20, 3.44, and 2.84 GPa, respectively, at 25°C. These values are comparable to those of the phenylene-based poly(ether ketone)s, indicative of the characteristics of high-performance thermoplastics.

Conclusion

Two series of the naphthalene-based poly(ether ketone)s analogous to commercial PEEK and PEEKK were prepared. It has been found that the increase in T_g upon replacing the 1,4-phenylene with the 1,4-naphthylene moieties in the repeat unit is much greater for the semicrystalline phenylene poly(ether ketone)s than for the amorphous analogues derived from 1,4-hydroquinone and 4,4-biphenol. Semicrystalline poly(ether ketone) **5a** shows potential as a new high-performance thermoplastic, owing to its high T_g and high T_g/T_m ratio.

Experimental section

General

Melting points were taken on a Fisher–Johns apparatus and are uncorrected. The ^1H and ^{13}C NMR spectra were recorded on either a Varian Gemini-200 or a Bruker-400 instrument using tetramethylsilane as the internal solvent. The ^{19}F NMR spectra were recorded on a Varian XL-300 using CCl_3F as a reference. Infrared measurements were performed on a Perkin–Elmer Series 1600 FTIR instrument. Molecular weights were determined on a Perkin–Elmer LC-250 GPC instrument relative to polystyrene standards using chloroform as an eluent at a flow rate of 1.0 mL/min; a UV detector was set at 254 nm wavelength. Inherent viscosities were measured in a 0.5 g/dL chloroform solution (or in *N*-methylcaprolactam where indicated) at 25°C using a Ubbelohde dilution viscometer. The glass transition temperatures were determined by differential scanning calorimetry (DSC) on a Seiko DSC 220 at a heating rate of 10°C/min under nitrogen (50 mL/min) and taken as the midpoint of the change in slope of the base line. Thermogravimetric analysis (TGA) was performed on a Seiko TG/DTA 220 at a heating rate of 10°C/min in nitrogen and air (200 mL/min). Thin films were cast from the chloroform solution, dried at 200–250°C under vacuum over 14 days, and cut out as a strip (length = 10 mm, width = 2 mm, thickness = 0.01–0.03 mm). Young's moduli of the thin films were obtained on a Seiko TMA/SS 120C TMA/SS analyzer. The films were tested by measuring the stress and strain while applying a linear load program. For Young's modulus at 25°C, the parameters were set as: offset load = 10–20 g, load amplitude = 5–10 g, and cycling frequency = 0.05 Hz. Young's moduli (E') were obtained from the slope of the linear portion of the stress–strain plots. After the data were collected, the same film was used, without changing the parameters to Young's modulus variation with temperature, by heating to 400°C at a ramp rate of 3°C/min in static air.

Materials

Aluminum chloride, potassium carbonate, sodium hypochlorite (NaOCl), 1-fluoronaphthalene, tetramethylene sulfone ($TMSO_2$), *N*-methyl-2-pyrrolidinone (NMP), *N*-methylcaprolactam (NMC), *N*,*N*-dimethylacetamide (DMAc), phenyl sulfone, acetyl chloride, thionyl chloride, and other common organic solvents were purchased from Aldrich Chemical Co. and used as received. 1-Chloronaphthalene was fractionally distilled under vacuum (using a water aspirator). 4,4′-Isopropylidenediphenol, 4,4′-biphenol, 9,9-bis(4-hydroxyphenyl)fluorene, and 1,4-hydroquinone were purchased from Aldrich Chemical Co. and purified by recrystallization.

Monomer synthesis

4-Chloro-1-naphthoic acid

A 1 L 3-neck, round-bottomed flask equipped with a solid addition funnel and a condenser was purged with nitrogen for 20 min prior to use, and flame dried. The flask was charged with 1-chloronaphthalene (100.0 g, 0.615 mol), acetyl chloride (24.1 g, 0.30 mol), and dichloromethane (650 mL), forming a clear, colorless solution. Aluminum chloride (53.3 g, 0.40 mol) was added slowly at 0–5°C (ice bath temperature), resulting in a deep red colored mixture. The reaction mixture was stirred at this temperature for 1 h and then the temperature was raised to ca. 40–60°C and maintained for 12 h. The reaction mixture was poured into an ice-cold 10% aqueous HCl solution (500 mL) and stirred for 30 min. The organic layer was partitioned and the dark colored aqueous phase was extracted with chloroform. The combined organic extracts were washed with 5% aqueous NaOH solution and water, and then dried over $MgSO_4$. Removal of solvent afforded an oily residue, which was distilled under vacuum (20 Torr (1 Torr = 133.3 Pa), water aspirator) yielding 53.5 g (86.8%) of 4-chloro-1-acetonaphthone. To a 3 L round-bottomed flask equipped with mechanical stirrer, 4-chloro-1-acetonaphthone (52.10 g, 0.255 mol), NaOCl (1.20 L, 1.63 mol), and methanol (120 mL) were added. The mixture was stirred at 40–60°C for 12 h. The aqueous solution of sodium bisulfite (60 g in 300 mL of water) was then added, turning the reaction mixture from brown to opaque white in color. Upon acidification with 100 mL of 4 M HCl(aq), slowly added, a fluffy white precipitate was formed. The precipitate was dissolved in 5% NaOH solution. The solution was filtered to remove any residual insoluble materials and the filtrate was acidified again with 4 M HCl(aq) to give the crude product. Recrystallization from ethanol gave 4-chloro-1-naphthoic acid: 27.9 g (53.0%); mp 221–222°C (lit. (6) mp 223–224°C).

*4-Chloro-1-(4′-fluoro-1-naphthoyl)naphthalene (**6**)*

A 1 L round-bottomed flask was charged with 4-chloro-1-naphthoic acid (27.8 g, 0.14 mol) and $SOCl_2$ (40 mL) and the mixture was stirred at 80°C for 12 h. The excess $SOCl_2$ was distilled off under reduced pressure (20 Torr, water aspirator), leaving a light-brown solid residue. The crude acid chloride was vacuum distilled (1 Torr), yielding 4-chloro-1-naphthoyl chloride: 28.3 g (93.5%); mp 222–223°C (lit. (6) mp 223–224°C).

A 100 mL 3-neck round-bottomed flask was flame dried, purged with nitrogen, and charged with 4-chloro-1-naphthoyl chloride (8.00 g, 35.5 mmol), 1-fluoronaphthalene (15.3 g), and nitrobenzene (30 mL). To the solution at 0–5°C (ice bath temperature) was added aluminum chloride (4.21 g, 31.6 mmol). The resulting deep-red solution was stirred at this temperature for 1 h and then at ca. 60–70°C for 8 h. The reaction mixture was poured into an ice-cold 10% HCl – water solution (500 mL) and stirred for 30 min. The resulting oily residue was washed with 3 aliquots of methanol to remove residual nitrobenzene and then once with water, leaving a solid residue. The crude product was filtered and recrystallized from ethanol to afford monomer **6**: 6.21 g (52.2%); mp 111–112°C; IR (KBr, cm^{-1}): 1645 (C=O), 1244 (C-F), 759 (C-Cl); ^1H NMR (400 MHz, $CDCl_3$, $Eu(fod)_3$) δ: 9.40 (d, 1H, J_{H-H} = 4.8 Hz), 9.06 (d, 1H, J_{H-H} = 8.6 Hz), 8.46 (d, d, 1H, J_{H-H} = 8.4 Hz, $^4J_{H-H}$ = 0.8 Hz), 8.29 (m, 1H), 8.01 (m, 1H), 7.85 (d, 1H,

J_{H-H} = 7.6 Hz), 7.68 (m, 5H), 7.19 (t, 1H, J_{H-H} = 8.4 Hz); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 198.9, 163.0, 160.4, 137.6, 136.5, 133.2, 132.9, 131.3, 130.1, 129.4, 128.6, 127.8, 127.1, 126.8, 126.5, 125.1, 125.0, 124.3, 121.1; ^{19}F NMR (300 MHz, DMSO-d_6) δ: −114.15 (s); MS (EI) (*m/z*): 334 (M^+), 299 (M^+ − Cl), 189 (M^+ − Fnaph), 173 (M^+ − Clnaph), 161 (M^+ − COnaphF), 145 (M^+ − COnaphCl), 126 (M^+ − Cl − COnaphF); HRMS calcd. for $C_{21}H_{12}OFCl$: 334.0561; found: 334.0566.

1,4-Bis(4′-fluoro-1′-naphthoyl)benzene (7)

A 500 mL 3-neck, round-bottomed flask equipped with a solid addition funnel and a condenser was purged with nitrogen for 20 min before it was charged with terephthaloyl dichloride (12.6 g, 62.1 mmol), 1-fluoronaphthalene (22.8 g, 0.16 mol), and nitrobenzene (160 mL). Once solvation was complete, aluminum chloride (21.5 g; 0.16 mol) was added to the yellow solution in portions at 0–5°C (ice bath temperature). The resulting red solution was stirred while the reaction temperature was allowed to reach room temperature during 1 h. The reaction then continued at 60–80°C for 3 h. The reaction mixture was worked up as with monomer **6** and the crude product was recrystallized three times in DMF to afford monomer **7** as yellow crystals: 17.0 g (64.8%); mp 230–231°C; IR (KBr, cm^{-1}) 1651 (C═O), 1245 (C-F); ^1H NMR (400 MHz, $CDCl_3$) δ: 8.32 (m, 1H), 8.22 (m, 1H), 7.92 (s, 2H), 7.64 (m, 3H), 7.19 (t, 1H, J_{H-H} = 8.0 Hz); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 195.9, 102.0, 159.4, 141.7, 131.2, 129.9, 129.7 (J_{C-F} = 10 Hz), 128.5, 126.8, 125.4 (J_{C-F} = 2.0 Hz), 120.7 (J_{C-F} = 6.0 Hz), 107.9 (J_{C-F} = 21.0 Hz), ^{19}F NMR (300 MHz, TCE-d_2) δ: −114.8 (s); MS (EI) (*m/z*): 422 (M^+), 277 (M^+ − Fnaph), 249 (M^+ − COnaphF), 173 (M^+ − PhCOnaphF), 145 (M^+ − Fnaph-COPhCO); HRMS calcd. for $C_{28}H_{16}O_2F_2$: 422.1118; found: 422.1110.

Polymer synthesis

Polymerizations were all carried out in 50 mL 3-neck round-bottomed flasks equipped with a stirring bar, a Dean–Stark trap fitted with a condenser, and a nitrogen purge inlet. A typical procedure is as follows: A flask was charged with 4-chloro-1-(4′-fluoro-1′-naphthoyl)naphthalene (1.00 g, 3.00 mmol), 1,4-hydroquinone (330 mg, 3.00 mmol), potassium carbonate (829 mg, 6.00 mmol), chlorobenzene (30 mL), and $TMSO_2$ (4.8 mL, 28% w/v). The reaction temperature was rapidly raised to 140–150°C and held for 1 h. During this time, the water formed was removed with toluene and fresh toluene was introduced to the system. The temperature was then raised to 210°C, and the polymerization continued for 2 h. The reaction mixture was then cooled to about 80°C and poured into methanol (200 mL) containing 2–3 drops of concentrated HCl. The spaghetti-like polymer was collected and dissolved in chloroform (50 mL). The chloroform solution was filtered through a thin pad of Celite, and then reverse precipitated with methanol, yielding yellow fibrous polymer **3a**.

Polymer **3c**: IR (film, cm^{-1}): 1648.7 (C═O), 1238.0 (C-O-C); ^1H NMR (400 MHz, $CDCl_3$) δ: 8.60 (d, 1H, J_{H-H} = 8.2 Hz), 8.38 (d, 1H, J_{H-H} = 8.1 Hz), 7.55 (m, 2H), 7.45 (d, 1H, J_{H-H} = 8.1 Hz), 7.21 (d, 1H, J_{H-H} = 8.6 Hz), 6.98 (d, 1H, J_{H-H} = 8.6 Hz), 6.65 (d, 1H, J_{H-H} = 8.0 Hz), 1.65 (s, 6H); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 198.0, 157.2, 153.8, 146.7, 133.0, 131.7, 131.7, 128.5, 128.3, 126.4, 126.0, 122.3, 119.6, 109.0, 42.3, 30.9.

Polymer **3d**: IR (film, cm^{-1}): 1654.2 (C═O), 1239.9 (C-O-C); ^1H NMR (400 MHz, $CDCl_3$) δ: 8.61 (d, 1H, J_{H-H} = 8.4 Hz), 8.37 (d, 1H, J_{H-H} = 8.0 Hz), 7.74 (d, 1H, J_{H-H} = 7.4 Hz), 7.56 (m, 2H), 7.42 (d, 1H, J_{H-H} = 6.9 Hz), 7.39 (d, 1H, J_{H-H} = 7.5 Hz), 7.34 (t, 1H, J_{H-H} = 7.4 Hz), 7.25 (t, 1H, J_{H-H} = 7.6 Hz), 7.22 (d, 1H, J_{H-H} = 8.7 Hz), 6.95 (d, 1H, J_{H-H} = 8.6 Hz), 6.65 (d, 1H, J_{H-H} = 8.0 Hz); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 197.9, 156.9, 154.9, 150.9, 141.8, 140.0, 133.0, 131.9, 131.6, 129.6, 128.5, 127.8, 127.7, 127.5, 126.4, 126.0, 126.0, 122.2, 120.3, 119.6, 109.4, 64.4.

Information on the noncrystalline phase of nascent iPP given by slow calorimetry

X. Zhang, H. Phuong-Nguyen, P. Bernazzani, I. Lapes, and G. Delmas

Abstract: Nascent isotactic polypropylene (iPP) has a lower crystallinity and a different X-ray pattern than recrystallized iPP. Heat flows during the melting of nascent highly stereoregular iPP samples are recorded with a Setaram C80 calorimeter over a wide T range (30–280°C). The rate of heating–cooling is 1–3 K/h, i.e., much lower than with conventional DSC. Melting is performed after annealing at $30 < T_{annealing} < 140$°C and with or without substrate. The main peak, that found by DSC, is associated with melting of monoclinic crystals and gives an enthalpy ΔH_{DSC}. Two other peaks, usually above and below the main peak, are observed. These are associated with a slower process of disordering a physical network, which was produced in the sample during polymerization. The sum of ΔH_{DSC} and $\Delta H_{network}$ equals ΔH_{total}. When melting is complete ΔH_{total} is equal to ΔH_0, the heat of fusion of perfect iPP crystals. This work presents new information on: (*i*) the noncrystalline phase of nascent iPP and the heat content of a semicrystalline polymer; (*ii*) the modifications of the melting process due to strain development, brought about by expansion in the material during the temperature ramp when a physical network is present; and (*iii*) the effect of a substrate on the polymer melting process.

Key words: nascent iPP, slow calorimetry, strain-melting, change of enthalpy, substrates.

Résumé : La cristallinité et le patron de diffraction des rayons X du polypropylène isotactique naissant (PPi) diffèrent des propriétés correspondantes du PPi recristallisé. Faisant appel à un calorimètre Setaram C80 et opérant sur une plage étendue de températures (de 30 à 280°C), on a enregistré les évolutions de chaleur au cours de la fusion des échantillons de PPi naissant hautement stéréorégulier. La vitesse de chauffage–refroidissement est de 1 à 3 K/h, un taux beaucoup plus faible qu'avec l'analyse calorimétrique différentielle (ACD) utilisée couramment. La fusion se produit après un recuit à $30 < T_{recuit} < 140$°C, avec ou sans substrat. Le pic principal, observé par ACD, est associé à la fusion des cristaux monocliniques et il fournit une enthalpie, ΔH_{ACD}. On observe aussi deux autres pics qui sont généralement au-dessus et au-dessous du pic principal. Ceux-ci sont associés à un processus plus lent conduisant à un désordre dans le réseau physique produit dans l'échantillon au cours de la polymérisation. La somme des ΔH_{ACD} et $\Delta H_{réseau}$ est égale à ΔH_{total}. Lorsque la fusion est complétée, le ΔH_{total} est égal à ΔH_0, la chaleur de fusion des cristaux parfaits de PPi. Dans ce travail, on présente de nouvelles informations sur : (*i*) la phase non-cristalline du PPi naissant et sur l'enthalpie d'un polymère semi-cristallin; (*ii*) les modifications du processus de fusion dues au développement de tensions provoquées par l'expansion du matériel au cours de l'augmentation de la température lorsqu'un réseau physique est présent; (*iii*) l'effet d'un substrat sur le processus de fusion du polymère.

Mots clés : PPi naissant, calorimétrie lente, fusion sous contrainte, changement d'enthalpie, substrats.

Introduction

While melt-crystallized crystals have been extensively investigated (1–10) since the synthesis of isotactic polypropylene (iPP) as a highly stereoregular polyolefin forty years ago, nascent iPP has attracted little interest. The difference between nascent and recrystallized iPP is expected to be similar to that observed for polyethylene (PE).

The morphology and melting behaviour of nascent PE is similar to that of the sample obtained by crystallization under shear. Comparative studies of crystals grown from sheared and quiescent solutions have revealed their distinct morphology (11–14). Microscopy (15), fast DSC (15), ^{13}C NMR (16), and ^{1}H NMR (16) investigations of nascent PE reveal that it has a unique morphology that is lost by melting and recrystallization. A recent Raman investigation of PE samples (17) reveals the complex nature of the nascent polymer (where four phases are identified) compared to the melt-crystallized.

Perfect crystals like those made for PE under pressure have not been produced for iPP. Hence, the equilibrium values of the melting temperature T_0 and of the enthalpy of fusion ΔH_0, which rely on extrapolation procedures, are still somewhat uncertain (18). Analysis by different techniques of material from various sources leads to the estimation of T_0 at 187.5°C and of ΔH_0 at 208 J/g (1).

The origin of strain-melting and the profile of a typical trace in slow calorimetry

When a semicrystalline polymer is submitted to a fast T-ramp (i.e., 10 K/min or 600 K/h), its melting trace shows the well-known sharp peak, which is completed a few K above T_m, its

Fig. 1. Schematic trace of melting a semicrystalline polymer by slow calorimetry (3 K/h). $T_{annealing}$ is the temperature of thermal equilibrium before the *T-ramp*. Integration for ΔH_{total} is done between $T_{initial}$ and T_{final}. ΔH_{DSC} is obtained by integration between T_a and T_b. $\Delta H_{network,\ low\ T}$ and $\Delta H_{network\ high\ T}$ are two other parts of ΔH_{total} at low and high T.

melting temperature. The melting trace starts at $T_{initial}$, which can be 50 K or more below T_m, but the main contribution to the enthalpy of melting comes from the part of the endotherm that is situated 15–20 K below T_m. For nascent iPP for instance, $T_{initial}$ = 50°C, T_m = 163–165°C, and ΔH = 85–91 J/g. The absence of high-T endotherms on the trace would justify the widely accepted assumption that there is no more meltable fraction in the semicrystalline polymers when the end of the melting endotherm is reached. Slow calorimetry, however, seems to indicate otherwise.

Figure 1 shows a schematic melting trace obtained through slow calorimetry (i.e., 0.05 K/min or 3 K/h). In Fig. 1, the flat endotherms occurring below and above the main peak lead to the idea of three fractions in the polymer. In the original work, the high-T endotherm was called fraction III; now it is termed the network. As presented in previous work (16, 19–23), the temperature ramp induces strain in chains linked by a physical network. For long-chain molecules, entanglements constitute the junctions in the network. The strain displaces the solid–liquid equilibrium towards high temperatures. The main characteristic of the flat endotherms is their high sensitivity to the history of the sample. The building up of strain in the network depends on nonequilibrium effects, which are narrowly dependant on the conditions of melting. The profile in Fig. 1 is the same as that found for cooling. An example for iPP is given in Fig. 6.

The original reasons for using a slow T-ramp are as follows. In the course of an investigation of gel formation in high molecular weight (MW) PE solution (20), heats of dissolution in dilute solution (0.5–1%) were obtained using a sensitive calorimeter equipped with a stirring device. It was found that complete dissolution of these high MW samples required long residence time in the calorimeter (i.e., a very slow T-ramp such as 1–3 K/h). The presence of a structure stable in solution even at high temperature has led to the understanding of physical gels (22) and of other intriguing properties of PE solutions (11–14).

The aim of the present paper is to investigate, with iPP, the meltability of the phases in which long-range order is absent. The technique used is slow calorimetry, which, by reducing the usual DSC rate by a large factor (two hundred or so), extends the range of accessible meltable order into the region not detectable by X-ray measurements. The concepts of strain-melting and the physical network have been developed (21) to interpret melting results on nascent polyethylene (19).

Experimental

Samples

The nascent samples consist of one very high molecular weight (MW) sample U (Himont, Willimington, Del., USA) and three medium MW samples F, S, and S′ = (Himont, Varennes, Qué., Canada) used in previous work (23, 24). The nascent samples F, S, S′ and U were received as fine powders. The characteristics of the samples, as received and after heat treatment and crystallization at T_c = 156°C, are given in Table 1. The values of the weight average (M_w) and the number average (M_n) molecular weights can be obtained from Table 1 (24). The solubility in xylene, an ASTM procedure to estimate the amorphous content, was 3% for F, S, and S′ and was not measured for U. After isothermal crystallization at T_c = 156°C, the crystallinity of the four samples was comparable (Table 1).

Calorimeters

The Setaram C80 calorimeter is a sensitive, differential calorimeter that accommodates large stainless steel cylindrical cells (o.d. = 16 mm, length = 95 mm) that hold the sealed glass tubes containing the sample and the reference. The reference cell is made as similar as possible to the sample cell. A heating rate v of 1–12 K/h, is used and the background noise is 5–10 μW. During the temperature ramp (from 30 to 290°C), the background signal is displaced by about 0.7 mW due to the imperfect radial balance of the calorimeter. In our recent work (23, 25–27), including the present one, the base line has been subtracted. The base line is constructed for each experiment by using the points at temperatures where there is no signal due to melting or crystallization. In traces with arrested melting there are three such regions, at low, medium, and high T. In other cases where the endotherms overlap there are only two regions, at low and high T.

The signal of the flat endotherms is considered significant when it is at least five times greater than the base line fluctuations. The large T range of integration introduces uncertainty in the integrated heats, which depends on the shape of the network endotherms, i.e., on the melting conditions. The uncertainty is at best 15 J/g and at worst 40 J/g. The reproducibility for the same set of conditions is usually very good. However, the effect of the different conditions on the range of melting of the network is clear and not affected by this uncertainty. Fast calorimetry is performed in a standard DuPont apparatus (DSC V40B).

Total enthalpy of fusion: ΔH_{solid}

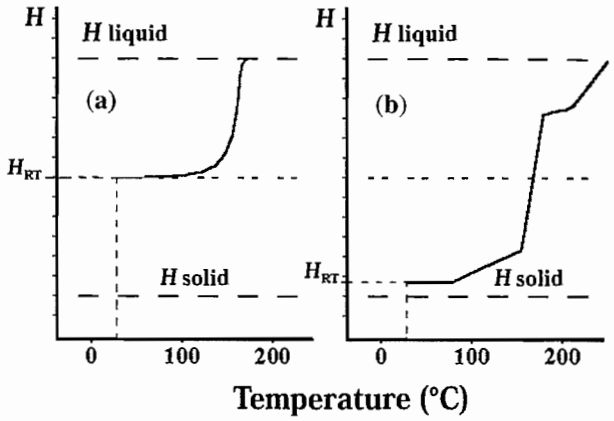
The change of enthalpy in the material during the T-ramp is obtained by integrating the heat flow between $T_{initial}$ and T_{final}:

[1] $$\Delta H_{total} = \Delta H_{DSC} + \Delta H_{network}$$

where ΔH_{DSC} and $\Delta H_{network}$ are the enthalpies corresponding, respectively, to the sharp and the flat endotherms. ΔH_{DSC}, obtained by integrating the signal between T_a and T_b in Fig. 1, is equal to, or slightly smaller than, the enthalpy change obtained by fast DSC.

In the case of Fig. 1, the $\Delta H_{network}$ is divided into two contributions, and eq. [1] becomes

[2] $$\Delta H_{total} = \Delta H_{network,\ low\ T} + \Delta H_{DSC} + \Delta H_{network,\ high\ T}$$



ΔH_{total} has been found to be much larger than that obtained by the fast T-ramp experiment for PE. It is usually near ΔH_0, the heat of fusion of perfect crystals.

Crystallinity

The value of α_c (X-rays) (the fraction of long-range order) is obtained by standard procedures from the diffractograms taken with a Wahrus camera and the Cu Kα radiation. α_c increases from 0.50 to 0.74 by melting and slow crystallization.

There is no unique way of decomposing the endotherms between ΔH_{DSC} and $\Delta H_{network}$. In the tables, ΔH_{DSC} is the value obtained by integrating the main peak using a temperature interval on the base line, which is almost constant (155–176°C) from one sample to another. This interval is found as shown in Fig. 1. With this method, the possibility that part of $\Delta H_{network}$ evolves at the same temperature as ΔH_{DSC} is ignored.

Fig. 2. The enthalpy of a semicrystalline polymer at room temperature and in a *T-ramp* as deduced from the usual DSC (Fig. 2(*a*)) and slow calorimetry (Fig. 2(*b*)). In Fig. 2(*a*) the enthalpy of a semicrystalline polymer H_{RT} is about halfway between H_{solid} and H_{liquid}, and H_{liquid} is reached in one rapid step. In Fig. 2(*b*), H_{RT} is near H_{solid} and reaches H_{liquid} through several steps, one of which is the rapid one seen in Fig. 2(*a*).

To obtain α_c (slow calorimetry) and compare it to α_c (X-ray), the fraction of long-range order in the sample, one has to take into account the contribution of small crystals that melt below 155°C and contribute to X-ray scattering and to α_c (X-ray). ΔH_{total} given by eq. [2] leads to $\alpha_c = 1$ because it includes short- and long-range order. The data of α_c (slow calorimetry), tabulated in Table 1, have been obtained using the relation:

[3] $$\alpha_c\ (\text{slow calorimetry}) = (208)^{-1}\ (\Delta H_{DSC} + 0.5\ \Delta H_{network})$$

The estimation of the contribution of $\Delta H_{network}$ to α_c (slow calorimetry), i.e., 0.5 $\Delta H_{network}$, is rather arbitrary but it gives values of α_c (slow calorimetry) comparable to α_c (*d*) and α_c (X-ray).

PP degrades easily in bulk in the presence of oxygen and even more so in solution (23, 24). Effective antioxidants, such as Irganox, limit the degradation during processing and characterization. In the conditions of the experiments, however, an antioxidant was not required in O_2-purged samples. After the high-T treatment, no change of colour of the sample was observed and its carbonyl content was not increased.

Results

State of the noncrystalline phase of nascent iPP

Our initial inquiry was to find the state of the noncrystalline phase at RT in nascent iPP by measuring the integrated heat between $T_{initial}$ and T_{final} for a sample equilibrated at $T_{annealing}$. A low value would have indicated that this phase was liquid and a high value that the sample had short-range order and melted in the conditions of the T-ramp. By analogy with PE, we expected to find that using the slow ramp would have led to a significant increase of ΔH_{total} from about 90 to about 200 J/g. Indeed, as shown in the tables, we found that ΔH_{total} was about equal to ΔH_0 (208 J/g).

This result leads to a reevaluation of the enthalpy change in a T-ramp. The schematics in Figs. 2(*a*) and (*b*) compare the information from the rapid and slow techniques for a sample

having a DSC or X-ray crystallinity of, for instance 0.5. In the usual model (Fig. 2(*a*)), the noncrystalline part of the material is liquid, so its specific enthalpy at room temperature, H_{RT}, is midway between the enthalpy of the perfect crystals, H_{solid}, and the enthalpy of a totally disordered liquid, H_{liquid}. During the fast *T-ramp*, the enthalpy of the material reaches H_{liquid} at the end of the main endotherm. Figure 2(*b*) shows the change of enthalpy as recorded by the slow *T-ramp*. The enthalpy H_{RT} is now lower and closer to H_{solid} at RT, corresponding to a higher crystallinity. The three contributions of Fig. 1 and eq. [2] to ΔH_{total} are represented by two different slopes of $H(T)$, the slow slope for the disordering in the network and the fast slope for the destruction of long-range order.

The description of Fig. 2(*b*) indicates that, in spite of a low value of α_c, the properties of nascent iPP are more similar to those of a solid than of a liquid. This is consistent with cohesive and viscous properties of semicrystalline polymers.

A noncalorimetric analysis of nascent iPP (28), which supports the presence of a semiordered phase, comes from a recent advanced X-ray investigation. The authors show that the diffraction pattern is consistent with the superposition, in about equal amounts, of large crystals of the α form and of small and medium size crystallites of the γ form.

Conditions for obtaining a complete value of ΔH_{total}

As seen in the tables, ΔH_{total} is always higher than ΔH_{DSC} (90 J/g), but it does not always reach 200 J/g. This indicates that under some conditions only a part of the network organization is melted in the slow *T-ramp*. Two reasons can be advanced for an incomplete melting trace: the occurrence of partial melting during the residence time at $T_{annealing}$, and inadequate conditions for melting the strained fraction. For instance, the available time up to the calorimeter limit (290°C) may be insufficient when the sample mass m is too large or the *T-ramp* is too fast.

The best conditions for having the trace of Fig. 1 complete are then to avoid melting during annealing by using a low temperature (30–40°C), to melt a small quantity ($m < 20$ mg), and to use a slow *T-ramp* (v = 3 K/h). Then, the two parts of $\Delta H_{network}$ have about the same magnitude between 40 and 60 J/g.

In the early part of the present work, traces were obtained with $T_{annealing}$ equal to 100°C, a condition that seemed quite reasonable for a polymer with a T_m of 170°C. ΔH_{total} was found to be low because part of $\Delta H_{network,\ low\ T}$ had already occurred during the residence time at $T_{annealing}$.

[b]Note the effect of r on ΔH_{total}.

The recrystallization technique

The recrystallization of iPP quenched from the melt during the *T-ramp* below T_m has been reported in the literature. The recrystallized fraction melts in the fast DSC as long-range order. However, the present nascent samples do not recrystallize during fast melting in spite of their low crystallinity.

To clarify the present work with regard to the melting of substrates, we will explain the origin of its use. When ΔH_{total} was found to be incomplete using $T_{annealing}$ = 100°C, we did not think that the low-T fraction was melted, only that it was not distinct enough. Therefore, we were induced to increase m and to mix the nascent polymer with a fine powder of metals (stainless steel, Cu) to improve the mediocre heat transfer associated with a larger m. The effect was more than expected. The ΔH_{total} became complete or near complete. It turned out that this was not only an effect of increased m and thermal conductivity but a specific effect of the substrate. Thanks to the nucleating effect of the substrate, the network part of the nascent sample mixed with the substrate had recrystallized at $T_{annealing}$. Consequently, complete melting was possible in the *T-ramp*.

An unexpected finding of the work on substrates is that for large values of m, the amount of substrate is important in order to have ΔH_{total} complete. Equal amounts of polymer and substrate are insufficient for complete melting, while a large excess (for instance a factor of 20) is adequate. In the tables, the parameter $r = m$ (polymer)/m (substrate) is listed for the different traces. It is thought that two effects contribute to have ΔH_{total} incomplete when r is too large, namely, incomplete recrystallization at $T_{annealing}$ and incomplete melting of the strained fraction in the *T-ramp*.

The results are given separately for each substrate. Table 2 corresponds to melting with Hg or no substrate, Tables 3–5 with substrates Cu, stainless steel, and glass beads, respectively. The different columns give the conditions ($T_{annealing}$, sample, substrate, m), the melting characteristics (ΔH_{total}, T_m), and the decomposition according to eq. [2]. The data are arranged in order of increasing $T_{annealing}$ (30–130°C). The cases where ΔH_{total} is complete are printed in bold figures.

Melting on mercury and without substrate

Table 2 presents the results for different values of $T_{annealing}$ and m. To minimize the size of the tables, the results of ΔH_{total} and the different contributions have been averaged over different runs in Tables 2–5 for the traces corresponding to the same conditions. The last column gives the number of different runs in each row. With $T_{annealing}$ = 30°C, ΔH_{total} is complete with low values of m but incomplete when m increases (second row). The trace of Fig. 3(*a*) (ΔH_{total} = 185 J/g and m = 45.9 mg) corresponds to these conditions.

The next three rows with 80°C < $T_{annealing}$ < 100°C illustrate the effect of increased $T_{annealing}$ and increased m on ΔH_{total}, which drops to 115 J/g for $T_{annealing}$ = 100°C and m = 64.5 mg. Note that the fast DSC with m = 5 mg and v = 600 K/h gives a still lower value of ΔH_{total}, although the integration starts at 50°C. The last row corresponds to $T_{annealing}$ = 130°C. The traces show an exotherm followed by an endotherm of melting.

The partial melting that takes place at $T_{annealing}$ (not recorded) leads to recrystallization above $T_{annealing}$ followed by melting. During the time of annealing, an incomplete

Note that $\Delta H_{network}$ evolves entirely at low T and is well separated from ΔH_{DSC}.

transformation takes place in the nascent sample, which continues in the ramp and makes the analysis complex. The strained fraction is large (130 J/g) and melts over 70 K. The trace with $T_{annealing}$ = 140°C will be analyzed at the end.

Melting on substrates: Effect of $T_{annealing}$ on the range of melting of the strained fraction

Traces have been obtained by varying $T_{annealing}$ between 30 and 120°C. Conditions can be found to have ΔH_{total} complete over that range. The temperature of annealing/recrystallization has, however, a clear effect on the temperature of the high-T endotherm: the higher the $T_{annealing}$, the higher the high-T endotherm.

In Table 3 with Cu as substrate, two values of $T_{annealing}$ are given. The results for $T_{annealing}$ = 30°C are very similar to those on Hg as substrate, with an incomplete ΔH_{total} (170 J/g) for m = 40 mg and a range of r (0.04–0.10). The end of the high-T endotherm (T_{final}) is 200°C and its size is small (<10 J/g). When $T_{annealing}$ = 120°C, ΔH_{total} is complete and T_{final} is about 263°C. The efficiency of Cu powder for melting/recrystallization of nascent iPP is clear when these traces are compared to those in Table 2 on Hg with $T_{annealing}$ = 80–100°C (ΔH_{total} = 150–115 J/g). In the last row of Table 3, the effect of a smaller amount of substrate can be noted. ΔH_{total} is incomplete (154 J/g) for m = 53.7 mg and r = 0.12.

Effect of the ratio between the sample mass (m) and the substrate mass

With substrates other than Cu, it has again been found that a small value of r is important in order to have ΔH_{total} complete. The generality of the effect is seen in Fig. 4 where ΔH_{total} for each trace has been plotted against m in Fig. 4(*a*) and against r in Fig. 4(*b*). ΔH_{total} is seen to diminish when m and r increase. Figure 4(*b*) shows that if r is <0.04 (i.e., if there are 25 times more substrate than sample), ΔH_{total} is complete. The points with no substrate or with Hg as substrate have been omitted from Fig. 4(*b*). Speculations on the molecular reasons for this effect will be presented later.

In Table 4 with stainless steel as substrate, $T_{annealing}$ ranges between 30 and 110°C. ΔH_{total} is complete for the first four rows with $T_{annealing}$ = 30–80°C. For the next two rows ΔH_{total} is incomplete, but this is not due to the high value of $T_{annealing}$ (100°C) but to the insufficient amount of substrate (r = 0.15–0.20).

In Table 5 the substrate is glass beads and $T_{annealing}$ = 60 and 80°C. ΔH_{total} is complete for the conditions of the first row. The comparison of the last two rows illustrates dramatically the effect of r. With a large amount of glass beads (m = 78.6 and r = 0.02), ΔH_{total} is not too far from complete (186 J/g) and T_{final} is low (229°C), while in the last row for m, which is not much larger (m = 92.9), ΔH_{total} has dropped to 120 J/g due to a want of substrate (r = 0.4).

Efficient method to reduce strain: melting on a substrate in a very low *T-ramp*

The last row of Table 4 (m = 37.2 mg) corresponds to $T_{annealing}$ = 110°C and r = 0.04. The difference from the other traces is the small size of the high-T endotherm. ΔH_{total} is complete and T_{final} is 187°C, as can be seen in Fig. 3(*b*). This trace was made

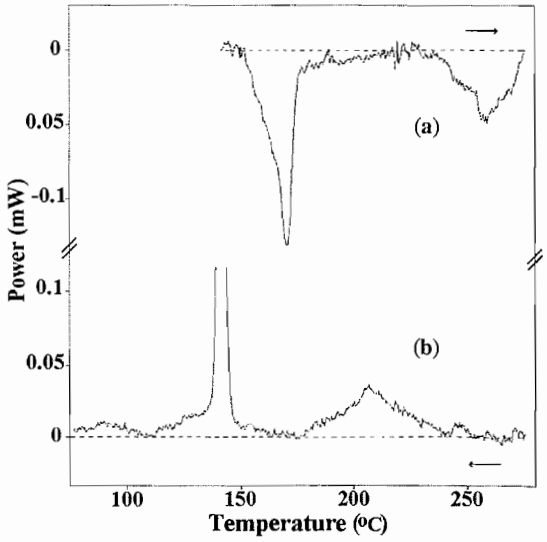
at $v = 1$ K/h instead of the usual 3 K/h. One sees that the melting of the network fraction is now well separated from that of the monoclinic crystals. A mechanism to explain this effect (also found on PE) will be presented below. The demonstration given by the trace of Fig. 3(*b*) that strain-building can be avoided in the *T-ramp* is worth the calorimeter time for that experiment (90 h instead of the usual 73 h for $v = 3$K/h).

Effect of annealing at 140°C



Highly crystalline samples are prepared by annealing a quenched sample between 140 and 160°C (8, 10). To ensure the complete growth of monoclinic crystals, the sample is left for several days at 140°C. The melting trace of a sample annealed at 140°C during the usual time (17 h) is given in Fig. 5(*a*). Its characteristics are given in Table 6 together with those of the crystallizing trace of the same run. One notes in Fig. 5(*a*) a large peak (135 J/g) at the melting temperature of the monoclinic crystals. In these conditions, the recrystallization that was observed at lower $T_{annealing}$ (Table 2) was completed and melting started at 152°C. The size of the peak indicates that the sample is no longer nascent but has a higher monoclinic content. Obviously, part of $\Delta H_{network,\ low\ T}$ overlaps with ΔH_{DSC} but, even if this is taken into account, ΔH_{DSC} is higher than in the nascent or the samples annealed at lower T. The high-T endotherm that occurs between 230 and 276°C is well separated from the first endotherm.

Reversibility of the phase change

The crystallization trace of the same sample is given in Fig. 5(*b*). The two main peaks of the melting and crystallizing traces match in magnitude, as can be seen in the figures or in Table 6. A small exotherm is seen on the crystallization trace at low-T. One should note the rapidity of the crystallization of the monoclinic crystals. In another work investigating the crystallization in a *T-ramp* (23), it was found that crystalliza-

Fig. 6. Changes of enthalpy $H(T)$ for iPP as in Fig. 2. Curves 1 and 2 of Fig. 6(*a*) correspond to the traces of Fig. 4. Curves 3 and 4 of Fig. 6(*b*) correspond to the melting and crystallization traces of Fig. 5 after $T_{annealing}$ = 140°C. Explanations in the text.

tion was more rapid after a long treatment at high temperature. The molecular reason is likely to be the formation of larger domains where the network phase and the random-coil phase do not overlap. As a consequence the crystals are less impinged upon by the physical network than in the usual condition (9) and they grow faster. The reversibility of the melting and crystallization traces has also been reported on PE. Uncertainty in the base line is minimal for Figs. 6(*a*) and (*b*) so the cause of the large values of ΔH_{total} (237–254 J/g) is not known.

Change of enthalpy between H_{liquid} and H_{solid} for nascent iPP

The data in the tables show that the path going from H_{solid} to H_{liquid} for a nascent sample depends on the conditions of melting.

The variation of $H(T)$ for iPP can be followed as in Fig. 2. There are many possibilities that correspond to the data in the tables. Only the paths deduced from the traces in Figs. 3(*a*), (*b*), and 5 have been reported as examples in Figs. 6(*a*) and (*b*). In the two schematic curves of Fig. 6(*a*) with $T_{annealing}$ < 120°C, only the network phase change is modified by annealing and the slow ramp. Curve 1 corresponds to the very special case of the 1 K/h *T-ramp* (Fig. 3(*b*)) where the kinetics of the network phase change and the monoclinic phase change are not too different, so that H increases almost continuously between $T_{initial}$ and T_{final} (116–187°C). In curve 2, the change of enthalpy due to the network occurs in part before and in part above the main peak. The end of curve 2 does not quite reach H_{liquid} because melting is incomplete (Fig. 3(*a*)).

In Fig. 6(*b*), curve 3 corresponds to $H(T)$ for the sample annealed at 140°C (Fig. 5(*a*)). Annealing has increased the monoclinic crystal content. The change of enthalpy due to the network occurs completely in the melt, the largest part occurring above 230°C. In curve 4, which corresponds to the crystallization trace, the changes of $H(T)$ in the cooling ramp are similar to those during the melting except for the small part at low T. The crystallization of the monoclinic crystals gives a very sharp exotherm. The unusual result that the monoclinic crystals in the same *T-ramp* take more time, or a longer interval of temperature, to melt than to grow is to be noted.

Mechanism of action of the substrate

A conducting substrate increases the heat transfer between the glass tube and the polymer, and across the sample, and accelerates the phase changes. The rates of crystallization from the melt or recrystallization below T_m of iPP are known to be enhanced by nucleating agents. However, these are usually used in very small quantities. These mechanisms must occur in the case of the slow melting of nascent iPP and lead to a more complete ΔH_{total}. However, there must be another effect at work, particularly in view of the efficiency of a poorly conducting substrate such as glass beads. It may be related to the movement of the more mobile chains to be adsorbed on the substrate. The mobility of the chains well below their melting point has been established by different techniques (C_p, X-ray patterns and molecular simulation). In the temperature ramp, phase separation between the network chains and the free chains is enhanced by the interaction with the substrate. As a consequence, strain is reduced and the liquid phase in the melt is easier to reach. The effect of a very slow *T-ramp* (Fig. 3(*b*)) may also be to permit phase separation to occur before extensive expansion and melting take place.

Other possible models relevant to the present work

Earlier work in the literature (29) has provided in-depth analysis of the melting and crystallization process. Experimental evidence of superheating has been reported for a variety of materials whose melting traces were taken at different rates of heating. These are organic (sucrose or sugars, amines) or inorganic compounds (silicates, quartz, tin, and others). The studies have followed the displacement of the melting endotherm to a higher temperature with emphasis on the T_m value. The temperature shift in some systems was very large. Measurements were made in fast DSC, the lowest ramp being higher than those used in the present work. The variation of the enthalpy changes with the rate of heating has not been investigated systematically. The fact that part of the enthalpy of melting was missing at a high heating rate could have been found if accurate measurements had been possible.

It was found that the concept of strain-melting and the effect of the expansion of a physical network is useful in interpreting data from slow calorimetry. Other models may be equally successful, particularly if they are developed from molecules that are not chain molecules. A nonequilibrium melt is a sure way to raise T_m. The nonequilibrium would be the result of steric hindrance due either to large side groups or to strong intermolecular forces. The discrepancy between melting and dissolution characteristics of poly-4-methyl pentene has been explained in this way (27). Current work on the melting and dissolution of sugars seems to be explained in these terms. The effect of a substrate on melting has been associated with a phase separation between network chains and free chains, facilitated by the foreign solid surface. Parameters characteristic of the crystalline and melted phases, such as the irregularity of the crystal surface, may change the viscosity of the melt in the presence of a substrate. Without involving phase separation, these effects can modify the melting and crystallization rate of iPP as was found above.

Conclusion

This work provides new information on the phases and enthalpy content of nascent and semicrystalline iPP. It is comparable to that obtained on PE and is thought to be generalizable to other polymers.

© 1997 NRC Canada

Analysis of the melting trace of nascent iPP indicates that the noncrystalline phase is meltable with an enthalpy as large as that of the monoclinic crystals. Conditions have been found where the organization in the noncrystalline phase of the nascent sample melts below T_m as would be expected for short-range order. This short-range order occurs between chains linked by a physical network. The conditions for melting the network below T_m are not met in the usual fast melting, so that strain, which builds up in the temperature ramp and at T_m, does not allow the network fraction melt. The monoclinic crystals are rather insensitive to the history of the sample but the network phase is not. By modifying the conditions, one can follow the changes in the network phase of nascent iPP in a *T-ramp*. They cover a range between two extremes: the network phase melts without strain, or it is transformed into a mixture of monoclinic crystals and a highly strained fraction. To reach a better understanding of the phase difference between nascent and melt/recrystallized polymer, the crystallization traces and the melting traces of melt/crystallized samples have been investigated (30).

Abstract: Pt(II) monomeric complexes of N-containing macrocycles have been synthesized and characterized in solution by ^{1}H NMR, ^{13}C NMR, and electrospray mass spectroscopy (ESMS) and in the solid state by X-ray crystallography. Crystals of [Pt(cyclam)]$(ClO_4)_2$ (cyclam = 1,4,8,11-tetraazacyclotetradecane) are orthorhombic, space group $P2_1cn$, a = 9.596 (3), b = 14.595 (21), c = 24.8782 (20) Å, Z = 8. The structure was solved by direct methods and was refined by the full-matrix least-squares method to R = 0.073 and R_w = 0.093 for 2976 reflections with $I \geq 2.5\sigma(I)$. Crystals of [Pt(*N*-methylcyclam)]-$(ClO_4)_2 \cdot CH_3CN$ (N-methylcyclam = 1,4,8,11 tetramethyl-1,4,8,11-tetraazacyclotetradecane = NMe_4cyclam = tmc) are orthorhombic, space group *Pmcn*, a = 9.574 (8), b = 14.116 (5), c = 17.5456 (15) Å, Z = 4. The structure was solved by direct methods and was refined by the full-matrix least-squares method to R = 0.067 and R_w = 0.091 for 2216 reflections with $I \geq 2.5\sigma(I)$. Cyclic voltammetry and EPR spectroscopy have been used to study the redox reactivity of the Pt(II)and Pt(IV) complex ions. The solution chemistry of Pt(IV) complexes based on cyclam and *N*-methylcyclam was investigated by electrospray mass spectrometry. Electrospray mass spectral evidence has been obtained for the formation of [Pt(III)(cyclam)Cl_2]$^+$ and [Pt(III)(N-methylcyclam)Cl_2]$^+$ ions.

Key words: Pt macrocycles, crystallography, electrospray mass spectroscopy, cyclic voltammetry, Pt(III) complex ions, tetraaza macrocycles.

Résumé : On a préparé des complexes monomères du Pt(II) contenant des macrocycles azotés et on les a caractérisés en solution par la RMN du ^{1}H, du ^{13}C, par la spectroscopie de masse par électrovaporisation et par la cristallographie de rayons X dans l'état solide. Les cristaux de [Pt(cyclam)]$ClO_4)_2$ (cyclam = 1,4,8,11-tétraazacyclotétradécane) sont orthorombiques et appartiennent au groupe d'espace $P2_1cn$, avec a = 9,596 (3), b = 14,595 (21), c = 24,8782 (20) Å, Z = 8. On a résolu les structures par les méthodes directes et on les a affinées par la méthode des moindres carrés, matrice complète, jusqu'à des valeurs de R = 0,073 et de R_w = 0,093 pour 2976 réflexions avec $I \geq 2.5\sigma(I)$. Les cristaux de [Pt(*N*-méthylcyclam) $(ClO_4)_2 \cdot CH_3CN$ (*N*-méthylcyclam = 1,4,8,11-tétraméthyl-1,4,8,11-tétraazacyclotétradécane = NMe_4cyclam = tmc) sont orthorombiques et appartiennent au groupe d'espace *Pmcn*, avec a = 9,574 (8), b = 14,116 (5), c = 17,5456 (15) Å, Z = 4. On a résolu les structures par les méthodes directes et on les a affinées par la méthode des moindres carrés, matrice complète, jusqu'à des valeurs de R = 0,067 et de R_w = 0,091 pour 2216 réflexions avec $I \geq 2.5\sigma(I)$. On a fait appel à la voltampérométrie cyclique et à la spectroscopie de RPE pour étudier la réactivité redox des ions complexes de Pt(II) et de Pt(IV). On a étudié, par spectroscopie de masse et par électrovaporisation, la chimie de solution des ions complexes Pt(IV) formés à partir de cyclam et de *N*-méthylcyclam. La spectroscopie de masse par électrovaporisation a fourni des preuves spectrales de la formation des ions de [Pt(III)(cyclam)Cl_2]$^+$ et de [Pt(III) (*N*-méthylcyclam)Cl_2]$^+$.

Mots clés : macrocycles de Pt, cristallographie, spectroscopie de masse par électrovaporisation, voltampérométrie cyclique, ions complexes de Pt(III) tétraazamacrocycles.

Introduction

The use of macrocyclic ligands such as 1,4,8,11-tetraazacyclotetradecane (cyclam or [14]-ane N_4, **1**, Scheme 1) complexed to transition metal ions has provided many new opportunities to form and stabilize systems where the metal center is in a less common oxidation state (1–4). In some instances, single crystal structures of monomeric Pd(III) complexes have been determined (5–7) in which the macrocyclic ligand has been used to stabilize the 3+ oxidation state. In contrast to the numerous redox studies on Ni(II) and Pd(II) complex ions, the redox reactivity of Pt(II) macrocyclic complexes has not been well understood. In many cases, di- or polymetallic species with metal–metal bonds have been obtained (8) and a monomeric Pt(III) complex is rarely observed. A case in isolation is the stabilization of a Pt(III) complex of a trithia macrocyclic ligand (9). Electrochemical oxidation of the distorted square-pyramid *bis*-Pt(II) complex of [9]-aneS_3 yielded the Pt(III) complex ion, as evidenced in the EPR spectrum. However, the Pt(II) complex of [18]-aneS_6 could not be oxidized chemically or electrochemically (10). Most of the Pt(III) complexes have been obtained as transients in pulse radiolysis (11, 12) or by X-ray or γ-irradiation of single crystals of Pt(II) complexes (13, 14). Recently, the redox reactivity of Pt(II)complexes based on cyclam and *N*-methylcyclam with free radicals formed by pulse radiolysis of aqueous media, in conjunction with UV–visible absorption and conductivity detection, was studied in our laboratory (15). One of the objectives of the present investigation is to obtain complementary views on the formation and detection of Pt(III) transient species using EPR spectroscopy, cyclic voltammetry, and electrospray mass spectroscopy (ESMS). Also, the Pt(I) monomeric species is rarely observed with aza ligands and usually dimerizes in solution. Recently, Ni(I), Cu(I), and Pd(I) monomeric species have been stabilized using macrocyclic ligands such as [14]-aneS_4 and *N*-methylcyclam and pendant arm macrocycles (5, 16–18). Low-valent metal macrocyclic complexes have been utilized in the catalytic and electrocatalytic reduction of small molecules such as CO_2 (19–22) and O_2 (23, 24). As a result of the stabilization of Ni(I) species with *N*-methylcyclam, this ligand has been used to model F_{430} (wherein the nickel cycles between Ni(II) and Ni(I) during catalysis (25)), and the Ni(I) complex, *RRSS*-Ni(tmc)](CF_3SO_3) has been crystallographically characterized (26).

In the present study, Pt(II) complexes of cyclam, **1**, and *N*-methylcyclam (NMe_4cyclam), **2** (Scheme 1), have been synthesized and the crystal structures have been determined in order to understand structure–reactivity relationships and stacking effects, if any. The ligand 2-pyridylmethyl-1,4,8,11-tetraazacyclotetradecane, **3** (tpmc, Scheme 1), and its Pt complex were also synthesized with a view to combining the properties of the relatively rigid and kinetically inert structural element of the macrocycle with those of the more flexible and kinetically labile open-chain ligands. The Cu(II) complex of tpmc is dinuclear with two copper atoms coordinated outside the macrocyclic cavity (27) while in the rhenium complex only three of the N atoms from the macrocyclic ring are coordinated (28). The Pd(II) complex of the pendant arm macrocycle 1,4,7-tris(2-pyridylmethyl)-1,4,7-triazacyclononane is a distorted square-base pyramidal environment of five coordinated nitrogen atoms, two of which are pyridyl nitrogen atoms in equatorial positions (29). Recent studies (30) on the Pd(II) complex of a related pendant arm macrocycle, 1-thia-4,7-bis(pyridylmethyl)diazacyclononane, revealed coordination of both the pyridyl nitogens to the Pd(II) ion along with two nitrogens from the macrocycle with strong axial interaction from the S atom of the macrocycle. Hence it was of interest to study the coordinating ability of tpmc with Pt(II) ion and to investigate axial coordination of the pendant arms of the macrocycle in going from square-planar Pt(II) to octahedral Pt(IV) geometry. The redox behavior of the Pt(II)cyclam-based complexes has been studied using EPR spectroscopy and cyclic voltammetry to elucidate various reaction pathways that involve either a metal-based species or ligand-based radicals. The relatively new technique of electrospray mass spectroscopy (31) has been used to characterize and investigate the solution chemistry of platinum complex ions. ESMS is also useful in the detection of transient species in solution because of its short time domain and minimal fragmentation.

Scheme 1.

Experimental

Materials and methods

The ligands 1,4,8,11-tetraazacyclotetradecane ([14]-aneN_4, cyclam) and 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (*N*-methylcyclam = tmc = NMe_4cyclam) were obtained from Aldrich and used as received. All solvents were of BDH (Analar) grade. Acetonitrile was distilled over CaH_2 prior to use. Water purified by a Millipore Super-Q system was used to prepare the aqueous solutions.

UV–visible spectra were recorded on a Cary 2315 spectrophotometer. Infrared spectra were recorded with a BIORAD FTS-40 FTIR and 3240-SPC data station. ^1H and ^{13}C NMR were obtained with a Bruker AM-300 FT NMR instrument using a broad probe at 75.47 MHz for ^{13}C nuclei. EPR spectra were recorded on a Bruker ESP 300 instrument. Diphenylpicrylhydrazyl radical was used as a field marker (g = 2.0037). Elemental analyses were obtained either from the microanalytical services, Department of Chemistry, University of Saskatchewan, or the Guelph Chemical laboratories Ltd., Guelph, Ontario, Canada. Electrochemical measurements

were made using MICROEL program microvoltammetry, version 5.0, developed and modified by Prof. A. Baranski[3] using PC-Labcard, model no. PCL-812PG. The electrochemical cell employed the standard three-electrode configuration with a Pt working microelectrode, a Pt auxiliary electrode, and the reference electrode. In aqueous solutions, an Ag/AgCl electrode linked to the cell via a bridge containing saturated KCl was used as the reference and 1 M NaCl was used as the supporting electrolyte. In nonaqueous solutions (acetonitrile), $Ag/AgNO_3$ (0.1 M) or a silver wire was used as the reference electrode. All potentials in nonaqueous solutions are reported vs. Fc^+/Fc couple. Electrospray mass spectral studies were conducted on a VG Quattro II (FISONS) triple-quadrupole electrospray mass spectrometer with 100% methanol as the mobile phase. The compounds were dissolved in methanol (2 mM) and diluted (1:10) with methanol. The diluted solution was injected directly into the spectrometer via a Rheodyne injector using a FISONS LC syringe pump to deliver the solution at a flow rate of 20 μL min^{-1}. Nitrogen was used both for nebulization and as a drying gas with flow rates of approximately 20 and 250 L h^{-1}, respectively.

Syntheses

*[Pt(cyclam)]$(ClO_4)_2$ and [Pt(*N*-methylcyclam)]$(ClO_4)_2$*

Pt(II)cyclam complexes, viz., [Pt(cyclam)]$(ClO_4)_2$, **4**, and [Pt(*N*-methylcyclam]$(ClO_4)_2$, were synthesized using published procedures (32) with suitable modifications. Both complexes gave satisfactory C, H, and N analyses. Crystals suitable for X-ray diffraction were obtained by diffusion of ether into acetonitrile solutions of the Pt(II) complexes. The Pt(II) complex based on *N*-methylcyclam crystallized with one molecule of acetonitrile as a solvent of crystallization ([Pt(*N*-methylcyclam)] $(ClO_4)_2 \cdot CH_3CN$), compound **5**.

*[Pt{N-methylcyclam)Cl_2]$(BF_4)_2$, **6***

An acetonitrile solution of [Pt(*N*-methylcyclam)]$(ClO_4)_2$ (100 mg, 0.17 mmoL) containing NBu_4Cl was oxidized with $NOBF_4$. Diffusion of ether into the acetonitrile solution yielded greenish yellow crystals that were dried under vacuum. Yield 100 mg; 90%. Anal. calcd. for $PtC_{14}H_{32}N_4Cl_2B_2F_8 \cdot 0.5\ CH_3CN$: C 25.11, H 4.71, N 8.79%; found: C 24.89, H 4.39, N 8.51%. A similar species was obtained using $Na_2S_2O_8$ as an oxidant in aqueous solutions of [Pt(cyclam)]$(ClO_4)_2$ containing NaCl.

*1,4,8,11-Tetrakis(2-pyridylmethyl)-1,4,8,11-tetraazacyclotetra-decane, **3** (tpmc)*

The ligand 1,4,8,11-tetrakis(2-pyridylmethyl)-1,4,8,11-tetraaza-cyclotetradecane, **3**, was synthesized by a modification of the literature method (27). An aqueous solution of cyclam (500 mg, 2.5 mmol) and sodium hydroxide (1.2 g, 30 mmol) was added dropwise to an aqueous solution of picolyl chloride hydrochloride (1.9 g, 15 mmol). The solution was stirred vigorously for 3 days, over which period the color changed from pink to golden-yellow, and a white solid was obtained. The solid was filtered and dried under suction. Upon cooling an ethanolic solution, colorless crystals of the ligand, **3**, were obtained. The crystals were filtered and dried under vacuum. Yield 925 mg; 66%. ^1H NMR, δ($CDCl_3$): 1.74 (q, 4H, -C-CH_2-C), 2.55 (t, 8H, *N*-CH_2-CH_2-CH_2-N), 2.65 (s, 8H, -N-CH_2-CH_2-N-CH_2), 3.59 (s, 8H, -N-CH_2-C_5H_4N), 7.03–8.43 (m, 16H, -C_5H_4N). ^{13}C NMR, δ($CDCl_3$): 23.7 (-C-CH_2-C), 50.9 (N-CH_2-CH_2-CH_2-N-), 51.8 (-N-CH_2-CH_2-N-), 61.4 (-N-CH_2-C_5H_4N), 122, 123, 136, 149, 160 (-C_5H_4N). Anal. calcd. for $C_{34}H_{44}N_8$: C 72.30, H 7.85, N 19.84%; found: C 72.20, H 7.90, N 19.70%.

[Pt(tpmc)]$(ClO_4)_2$, 7

K_2PtCl_4 (163 mg, 0.393 mmol) was dissolved in DMSO (7 mL) and heated to 50°C under helium or dinitrogen atmosphere for 1 h. This solution was added dropwise to a hot ethanolic solution of the ligand (244 mg; 0.432 mmoL; 30 mL). The mixture was heated to 100°C for 2 h. The solution was cooled to room temperature and diethyl ether (50 mL) was added to it. Upon cooling the mixture, a colorless solid was obtained that was filtered and dried under vacuum. Crude yield: 265 mg. Metathesis to the perchlorate salt was achieved by dissolving the chloride salt in a minimum amount of water and adding a saturated solution of sodium perchlorate. Yield: 175 mg. This was recrystallized from acetonitrile solution at 5°C and a colorless solid of [Pt(tpmc)]$(ClO_4)_2$ was obtained. Yield 41 mg; 11%. ^{13}C NMR, δ (d^6-DMSO): 23.0 (-C-CH_2-C), 58.4 (N-CH_2-CH_2-CH_2-N-), 59.8 (-N-CH_2-CH_2-N-), 59.8 (-N-CH_2-C_5H_4N), 124, 127, 137, 150, 151 (-C_5H_4N). Anal. calcd. for $PtC_{34}H_{44}N_8Cl_2O_8$: C 42.59, H 4.63, N 11.69%; found: C 42.39, H 4.44, N 11.72%.

Caution: The perchlorate salts prepared in this work are potentially explosive and must be handled with great care.

Structure solution and refinement

Single-crystal X-ray intensity measurements were carried out on an Enraf–Nonius CAD-4 automated diffractometer with MoK_α radiation (λ = 0.71073 Å) and graphite monochromator at 123 K using an ω–2θ scan mode. Crystallographic data for the Pt(II) complexes are shown in Table 1. The final unit-cell parameters for both compounds were obtained by least-squares analysis of setting angles of 25 carefully centered reflections (2θ = 20.1°–29.0° for compound **4** and 2θ = 30.2°–35.2° for compound **5**) chosen from diverse regions of reciprocal space. Orientation was checked with three test reflections after every 400 reflections for both compounds. Intensities of three standard reflections were measured every 2 h for compound **4** (3 h for compound **5**) with no significant decay being observed for either compound. The structure was solved by direct methods using NRCVAX (33) and was refined by the full-matrix least-squares method for both compounds. A total of 3389 reflections were obtained for [Pt(cyclam)]$(ClO_4)_2$, compound **4**, of which 2976 with $I > 2.5\ \sigma(I)$ were used. The coordinates of the Pt atoms were obtained by direct methods and those of the remaining non-hydrogen atoms from a Fourier map phased using the Pt positions. The Pt and Cl atoms were refined with anisotropic thermal parameters. All other atoms were refined isotropically. Hydrogen atoms were placed in calculated positions for both compounds with both N—H and C—H = 0.98 Å. Atomic scattering factors and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (34) for both compounds. Fractional atomic

Scan type	ω – 2θ	ω – 2θ

coordinates and equivalent isotropic thermal parameters, and selected bond lengths and bond angles, are given in Tables 2 and 3, respectively. More detailed tables of crystallographic data, hydrogen atom parameters, bond lengths and bond angles, are available as supplementary material.[4] Final values of $R = 0.073$ and $R_w = 0.093$ were obtained. The ORTEP (35) plot of the $[Pt(cyclam)]^{2+}$ ion illustrating the geometry and labelling scheme is shown in Fig. 1.

For Pt(*N*-methylcyclam)]$(ClO_4)_2 \cdot CH_3CN$, compound **5**, with four molecules in the unit cell, only half the molecule had to be solved, since the molecule was in a special position ($x = 0.25$) with the mirror plane defined by the three atoms Pt, C5, and C6 (Fig. 2). A total of 2736 reflections were obtained for compound **5**, of which 1844 with $I > 2.5F(I)$ were used. All of the non-hydrogen atoms were found on the *E*-map and refined isotropically. Atoms C7, C9, and C2 were disordered and attempts were made to model the disorder for these atoms. Alternate positions for atoms C7 and C9 could be discerned in the difference map but the corresponding position for atom C2 was not clear and hence the disorder could not be modelled. Final values of $R = 0.067$ and $R_w = 0.091$ were obtained. Final atomic coordinates and equivalent isotropic thermal parameters, and selected bond lengths and bond angles, are given in Tables 4 and 5, respectively. The ORTEP (35) plot of the [Pt(*N*-methylcyclam)]$^{2+}$ ion with atomic numbering scheme is shown in Fig. 2. In both structures, the peaks found in the final difference maps were close to Pt and ClO_4^- positions.

Fig. 1. ORTEP diagram (31) of cation "a" of compound **4**, [Pt(cyclam)]$(ClO_4)_2$. Thermal spheres of arbitrary radius are used for all atoms. H atoms on C atoms are excluded for clarity. H atoms on N atoms were placed from the geometry of the non-H atoms.

Results and discussion

Syntheses

The Pt(II) and Pt(IV) complexes synthesized in the present study gave satisfactory elemental analyses. The IR spectra for

[4] Supplementary material available: A more detailed table of crystallographic data for both compounds (S1); tables of hydrogen atom fractional coordinates and isotropic thermal parameters, and of anisotropic thermal parameters for the non-hydrogen atoms for both compounds (S2–S5); tables of bond lengths and bond angles for compounds **4** and **5** (S6 and S7)have been deposited and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Structure factor amplitudes are no longer being deposited and may be obtained directly from the authors. With the exception of the data for thermal parameters, these tables have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Fig. 2. ORTEP diagram (31) of cation of **5**, [Pt(*N*-methylcyclam)]-$(ClO_4)_2 \cdot CH_3CN$. Thermal spheres of arbitrary radius are used for all atoms. H atoms on C atoms are excluded for clarity.

both Pt(II) and Pt(IV) complexes based on cyclam showed an -NH stretch at 3525 cm^{-1} and 3515 cm^{-1}, respectively whereas for the complexes based on *N*-methylcyclam and tpmc the -NH stretch was absent.

NMR spectra

The proton NMR spectrum of $[Pt(cyclam)](ClO_4)_2$, **4**, in D_2O is shown in Fig. 3*a*. The spectrum is similar to that obtained by Waknine et al. (32). However, in the present case the spectrum is better resolved and includes analysis. The protons attached to each carbon atom in the complex are rendered inequivalent due to chelation and can be differentiated into axial and equatorial protons with respect to the PtN_4 square plane. Coupling can occur between these sets of protons, giving rise to second-order effects and resulting in a more complicated spectrum. The spectrum can be analyzed as ABC_2D_2 and E_2F_2 subspectra (see inset in Fig. 3 for labels). The axial protons (2H) from the -C-CH_2-C- portion of the molecule are centred at δ 1.47 with the equatorial protons (2H) at δ 1.98. This is the AB part of the subspectrum. The *N*-CH_2-C-CH_2-N protons (8H in a molecule) can be divided into axial protons (4H) centred at δ 2.56 and equatorial protons centred at δ 2.94. This is the C_2D_2 part of the subspectrum (C_2 can be described as CC′ with H_c and $H_{c'}$ being equivalent). The simulated spectrum (obtained using the GNMR software, version 3.6) is shown in Fig. 3*b*, and the simulated parameters are provided in Table 6 (the spectrum has been simulated using standard iterative techniques). This spectrum matches well with the experimentally obtained spectrum and confirms the identity and presence of one symmetric isomer (*meso-RRSS*) for the complex in solution. The

[a]Estimated standard deviations are given in parentheses.

^{13}C NMR spectrum showed three peaks at δ 52.2, 49.0, 26.4 and in an inverse gate experiment these three peaks were found to have an integrated ratio of 2:2:1, respectively. Analyses of the ^1H and ^{13}C NMR spectra suggest that the molecule is rigid in solution and has the Bosnich Type III (36), *meso-RRSS*, configuration at the N atoms. This is consistent with the solid state structure (vide infra).

The ^1H NMR spectrum of [Pt(NMe_4cyclam)]$(ClO_4)_2$, **5**, in D_2O is complicated. Variable temperature ^1H NMR (20–150°C) in d^6-DMSO and −30–+20°C in CD_3CN did not show any changes in the spectrum. The ^{13}C NMR spectrum (18 lines) is characteristic of two isomers in solution: one an asymmetric isomer (14 lines) and another a symmetric isomer (4 lines). ^{13}C NMR with *J*-modulation shows five lines due to CH_3 groups, four of which (δ 47.68, 48.0, 50.1, and 53.2) belong to the asymmetric isomer (three methyl groups above the PtN_4 plane and one methyl group below the plane) and the remaining one (δ 51.0) to the symmetric isomer (<15%, all four methyl groups below the PtN_4 plane or two methyl groups above and two below the PtN_4 plane). Thirteen lines due to $-CH_2$ groups are also seen, of which ten belong to the asymmetric isomer (all carbon atoms inequivalent) and three to the symmetric isomer. Other complexes in the group, viz. $[Pd(NMe_4cyclam)]^{2+}$ ion, show the presence of one symmetric isomer in solution with all four methyl groups on the same side of the Pd(II) ion (*RSRS* configuration as determined from the crystal structure (18)) whereas the ^{13}C DEPT NMR spectrum for the $[RhCl_2(tmc)]^+$ ion showed the presence of both symmetric (*RRSS* or *RSRS)* and asymmetric (*RSRR*) isomers in solution in the ratio 1:1 (37).

The ^1H NMR spectrum of the [Pt(IV)(*N*-methylcyclam)Cl_2]]$(BF_4)_2$ in D_2O is complicated. The ^{13}C NMR spectrum with *J*-modulation of a freshly prepared solution of the Pt(IV) complex in D_2O shows four lines at δ 50.8, 51.4, 52.9, and 56.7 due to four $-CH_3$ groups of the tetramethylcyclam ligand. Ten lines are seen at δ 24.6, 25.8, 57.0, 57.7, 62.6, 65.0, 65.7, 66.6, 66.9, and 67.9 due to the ten $-CH_2$ groups in the ligand framework. In addition, three lines are seen at δ 53.8, 63.5, and 66.8 and are attributed to small quantities (<15%)of the Pt(IV) symmetric species in solution.

Fig. 3. Comparison of experimental (*a*, top) and simulated (*b*, bottom) ^{1}H NMR spectra for [Pt(cyclam)]$(ClO_4)_2$ in D_2O.

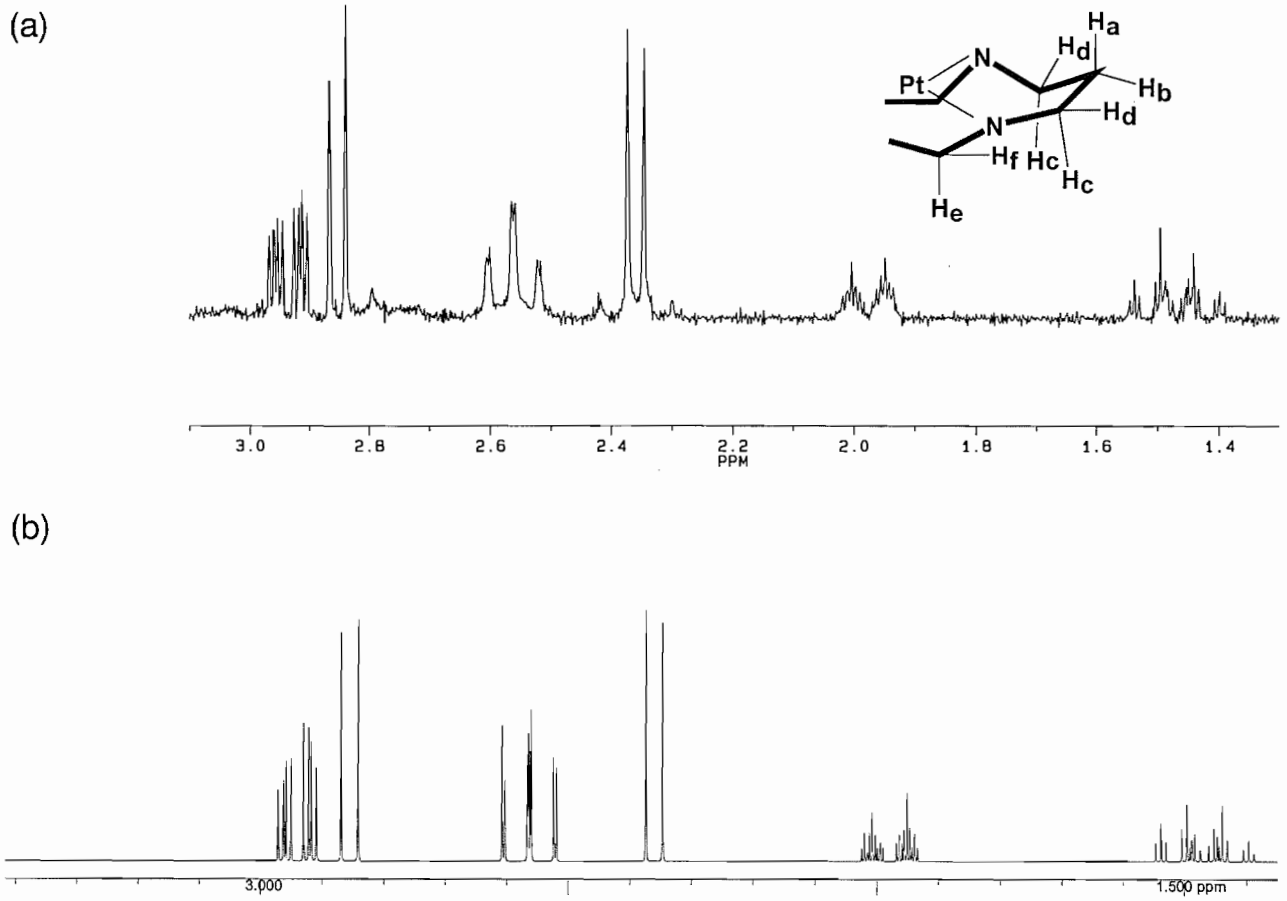

Table 6. Simulated ^{1}H NMR parameters (chemical shifts (ppm) and coupling constants (Hz)) for $[Pt(cyclam)]^{2+}$ ion (ABC_2D_2 and E_2F_2 subspectra).

$\delta_a = 1.47$	$\delta_b = 1.98$	$\delta_c = 2.56$	$\delta_d = 2.94$	$\delta_e = 2.36$	$\delta_f = 2.86$
$J_{ab} = 16.90$	$J_{bc} = 1.31$	$J_{cd} = 12.31$		$J_{ef} = 8.20$	
$J_{ac} = 12.96$	$J_{bd} = 3.80$				
$J_{ad} = 2.48$					

The free ligand, tpmc, **3**, was characterized by ^{1}H and ^{13}C NMR, elemental analyses, and by electrospray mass spectroscopy. The ^{13}C NMR spectra showed nine lines: one due to a pair of equivalent C atoms and each of the remaining eight lines due to four equivalent C atoms with a total of 34 C atoms in the molecule. The ^{1}H NMR spectrum is typical of tpmc, compound **3** (see experimental section). Of interest is the singlet at δ 3.59 due to the methylene protons attached to the pyridyl moiety in the pendant arms. At ambient temperatures, the molecule undergoes free rotation of the pendant arms, making the protons equivalent and thus giving rise to a singlet. If the pyridyl nitrogen atoms were coordinated to the metal ion, the equivalence of these methylene protons would be lost. In addition, the singlet at δ 2.65 due to the equivalent methylene protons of the ethylene bridge in the macrocycle is characteristic of rapid inversion of the nitrogen atoms at ambient temperatures. Upon coordination of the N atoms from the cyclam to the Pt(II)ion, the magnetic equivalence of the protons in the cyclam ring is lost, giving rise to a complex spectra. The ^{1}H NMR of $[Pt(tpmc)](ClO_4)_2$ is characteristic of the Pt(II) ion coordinated to the N atoms of the cyclam ring. The protons in the cyclam ring appear between δ 2.1 and 3.7. The singlet due to methylene protons (8H) attached to the pyridyl ring appears at δ 4.40. For a related complex ion, $[Pd(py_2[9]aneN_2\,S)]^{2+}$, the protons of the methylene group in the pendant arm are magnetically inequivalent (as evidenced in the ^{1}H NMR spectrum), indicating that the Pd(II) ion is coordinated to the N atoms of the pyridyl moiety (30). The aromatic protons (16H) appear at δ 7.4–8.8. The ^{13}C NMR shows nine lines and is characteristic of one symmetric isomer in solution. Both ^{1}H and ^{13}C NMR spectra are consistent with the Pt(II) metal ion being coordinated to the four nitrogen atoms from the cyclam ring forming a square-planar complex.

Electronic spectra

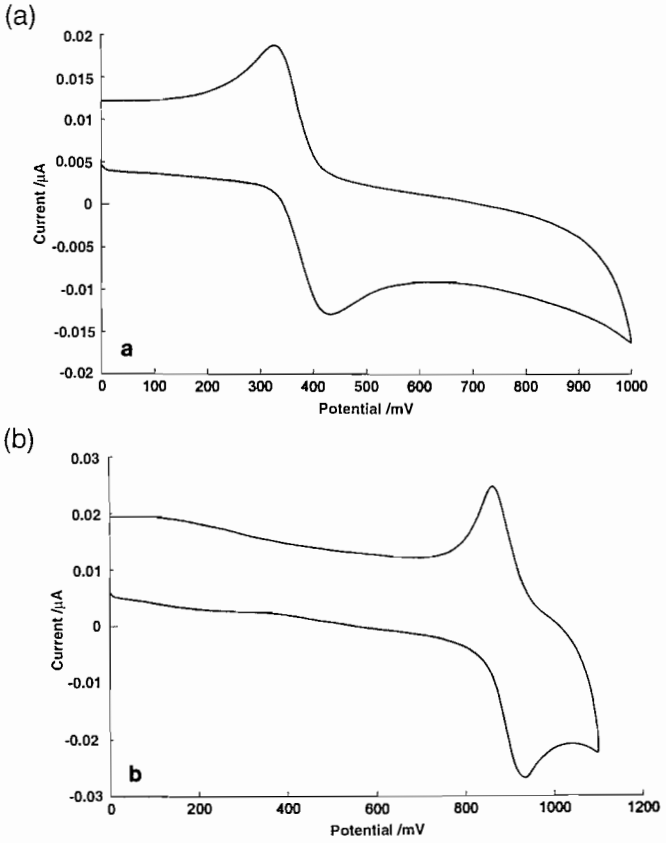
The UV–visible absorption spectrum of $[Pt(cyclam)](ClO_4)_2$ in water shows peaks at 268 nm (ε = 47 M^{-1} cm^{-1}; assigned to a *d–d* transition) and 210 nm (ε = 7660 M^{-1} cm^{-1}; assigned to a charge transfer band) and a shoulder at 231 nm (494 M^{-1} cm^{-1}). The spectrum is similar to that obtained by Waknine et al. (32) for the corresponding chloride salt. The corresponding $[Pt(N\text{-methylcyclam})]^{2+}$ exhibits peaks at 296 nm (70 M^{-1} cm^{-1}; assigned to a *d–d* transition) and 225 nm (638 M^{-1} cm^{-1}). No absorptions were found in the visible region of the spectrum, indicating high ligand field strengths for both low-spin d^8 Pt(II) complexes.

Electrospray mass spectra

ESMS data for the various Pt(II) complexes are listed in Table 7. The electrospray mass spectrum of $[Pt(cyclam)](ClO_4)_2$ in methanol shows two peaks at *m/z* 495 and 197 due to the presence of intact ions $[Pt(cyclam)](ClO_4)^+$ and $[Pt(cyclam)]^{2+}$, respectively. ESMS of $[Pt(N\text{-methylcyclam})](ClO_4)_2$ shows the presence of intact ions at *m/z* 551 and 226 due to $[Pt(N\text{-methylcyclam})](ClO_4)^+$ and the dication $[Pt(N\text{-methylcyclam})]^{2+}$, respectively. However, ESMS of the Pt(IV) species based on cyclam and *N*-methylcyclam in methanol showed the presence of Pt(III) as well as Pt(IV) and Pt(II) complex ions (vide infra).

The electrospray mass spectrum of $[Pt(II)tpmc](ClO_4)_2$ in methanol (Table 7) shows two peaks at *m/z* 858 and *m/z* 380 due to the monocation $\{[Pt(tpmc)](ClO_4)\}^+$ and the dication $[Pt(tpmc)]^{2+}$, respectively. X-ray quality crystals of the Pt(II) complex could not be obtained and this prevented a crystal structure determination. However, elemental analysis together with electrospray mass spectral data confirmed the formation of the $[Pt(II)tpmc](ClO_4)_2$ complex.

Crystallography



The crystal structure of $[Pt(cyclam)](ClO_4)_2$ is square planar with the Pt(II) ion in the center of the PtN_4 plane (Fig. 1). The average Pt—N bond length is 2.05(3) Å and is similar to that obtained for the corresponding Pt(IV) complex ion, $[Pt(cyclam)Cl_2]^{2+}$ (32). The configuration at the N atoms is *meso-RRSS*, Bosnich Type III (36), with two amine protons above and two below the PtN_4 plane. The five-membered rings are *gauche* with a bite angle of 83.6°(10) while the six-membered rings with a bite angle of 96.4°(10) assume the chair conformation. These values are similar to those obtained for the $[Pt(cyclam)Cl_2]^{2+}$ ion (32). Structural analysis shows that the -NH groups are involved in hydrogen bonding with the perchlorate oxygen atoms, linking the two molecules in the unit cell; however, this does not result in an infinite network.

The configuration at the N atoms in the transition metal complexes of cyclam is generally planar (*trans*) Bosnich Type III or a folded (*cis*) Bosnich Type V configuration (36). This is consistent with the observation of a planar (*trans*) Type III configuration at the N atoms in the $[Pt(II)(cyclam)]^{2+}$ ion. However, in the case of the corresponding *N*-methylated complex, viz. the $[Pt(II)(N\text{-methylcyclam})]^{2+}$ ion, the solid state structure is symmetric, Bosnich Type I (36), *RSRS*, with all four CH_3 groups on one side of the PtN_4 plane. This is in keeping with strain energy minimization calculations made on Ni(II) complexes of *N*-methylcyclam wherein it was shown that *RSRS* conformations are preferred by four-coordinate square-planar complexes of *N*-methylcyclam (38). The average Pt—N distance is 2.06(1) Å. Bite angles of the five-membered chelate rings are 87.8°(16) and those of the six-membered chelate rings are 92.4°(6). The ORTEP plot (Fig. 2) shows the presence of a crystallographic mirror plane through atoms C5, Pt, and C6. The five-membered chelate rings are *gauche* δδ forming an eclipsed conformation, in contrast to the five-membered chelate ring, which is *gauche* δλ (non-eclipsed conformation) in the case of the $[Pt(II)cyclam]^{2+}$ complex ion. The structure of the $[Pt(II)(N\text{-methylcyclam})]^{2+}$ ion is similar to that of the corresponding Ni(II) complex prepared in strongly coordinating solvents (4) and to that of the $Pt([14]\text{-aneS}_4)^{2+}$ ion (39) with all the C atoms of the ligand framework on one side of the PtN_4 plane. The present structure is also similar to that of the $[Pd(N\text{-methylcyclam})]^{2+}$ ion, although in that case the Pd(II) ion is displaced towards the *N*-bound methyl groups by 0.082 Å out of the plane of the four N atoms (11). In the case under study, the N_4 donor set is essentially planar and the Pt(II) is in the plane. This structure is

Fig. 4. Cyclic voltammograms of (*a*) [Pt(cyclam)]$(ClO_4)_2$ in 1 M NaCl; (*b*) [Pt(*N*-methylcyclam)]$(ClO_4)_2$ in 1 M NaCl.

consistent with the minor symmetric isomer in solution although the major isomer in solution is the chiral Type II, *RRSR*, configuration as evidenced in the NMR spectra (vide infra).

Although tiny crystals of [Pt(IV)(*N*-methylcyclam)Cl_2]-$(BF_4)_2 \cdot CH_3CN$ were obtained, they were extremely sensitive to solvent loss and lost crystallinity during data collection in X-ray diffraction studies. ^{13}C NMR and electrospray mass spectra confirm the presence of the Pt(IV) complex ion in solution. This suggests that the $(CH_2)_n$ backbones of both rings are likely to be relatively displaced to accommodate six-coordination. This is in keeping with the steric energy minimized geometries of the $[Pt([n]\text{-ane})S_4)Cl_2]^{2+}$ ion (n = 12–16) wherein MM2 simulations indicate that six-coordination with Cl^- tends to flatten S_4 rings although the structure is not centrosymmetric (39). Six-coordination in the $[RhCl_2(N\text{-methylcyclam})]^+$ has been achieved with two methyl groups above and two methyl groups below the RhN_4 coordination plane (*RRSS* configuration, Type III) (36). Steric interactions between the *N*-methyl groups and with the macrocyclic backbone determine the stability of the [Pt(IV)(*N*-methylcyclam)Cl_2]$^{2+}$ ion.

Redox reactivity

The cyclic voltammograms of [Pt(cyclam)]$(ClO_4)_2$ and [Pt(*N*-methylcyclam)]$(ClO_4)_2$ in aqueous solutions containing 1 M NaCl using a Pt microelectrode are shown in Figs. 4*a* and 4*b*, respectively. The redox potentials are dependent on the nature of the macrocyclic ligand. Both cyclic voltammograms are characteristic of the formation of quasi reversible $Pt^{4+/2+}$ couples, although the driving forces are largely different. For the $[Pt(cyclam)Cl_2]^{2+}/[Pt(cyclam)]^{2+}$ couple, the half-wave potential is quasi reversible and found to be 0.385 V vs. Ag/AgCl ($i_{pa}/i_{pc} \sim 1$). The peak-to-peak separation (ΔE_p) is dependent on the scan rate for both complexes and is more reversible at smaller scan rates (ΔE_p = 100 mV at 0.5 V s^{-1} and 380 mV at 5 V s^{-1}). The half-wave potential is consistent with that obtained by Endicott and co-workers (32). Cyclic voltammetry of solutions of [Pt(NMe_4cyclam)]$(ClO_4)_2$ in aqueous 1 M NaCl shows a redox wave at 0.90 V vs. Ag/AgCl ($i_{pa}/i_{pc} \sim 1$, Fig. 4*b*). The same value for the half-wave potential was obtained starting with the corresponding [Pt(IV)-(NMe_4cyclam)Cl_2]$(BF_4)_2$ complex. The $E_{1/2}$ value of 0.90 V vs. Ag/AgCl has been assigned to the $[Pt(NMe_4cyclam)Cl_2]^{2+}/[Pt(NMe_4cyclam)]^{2+}$ couple. The large difference in the $E_{1/2}$ values for the $Pt^{4+/2+}$ couples based on cyclam and *N*-methylcyclam is attributed to the steric hindrance imposed by the *N*-methylated groups and interligand repulsions. The $E_{1/2}$ value for the $[Pt(NMe_4cyclam)Cl_2]^{2+}/[Pt(NMe_4cyclam)]^{2+}$ couple is comparable to that for the $[Pt([14]\text{-ane}S_4)Cl_2]^{2+}/[Pt([14]\text{-ane}S_4)]^{2+}$ couple (32). In that case, the soft S donor atoms stabilize Pt(II) relative to the Pt(IV) ion and the "*exo*" conformation of the equatorial S ligands leads to interligand repulsions with the axial Cl^- ligands, thus making the Pt(IV) dichloride species less stable. In the complex based on *N*-methylcyclam, the poorer σ-donating ability of the tertiary N atoms together with steric hindrance from the methyl substituents lead to interligand repulsions with the axial Cl^- ligands, thus again making the Pt(IV) dichloride species less stable. However, in the case of [14]-aneN_4, the lesser interligand repulsions between the axial Cl^- ligands and the equatorial N atoms of the macrocycle make the Pt(IV) dichloride species more stable (approach of axial chloro ligand is favorable) relative to the complex based on *N*-methylcyclam. However, the cyclic voltammogram of solutions of Pd(cyclam)$(ClO_4)_2$ in 1 M NaCl shows a redox wave at $E_{1/2}$ = 0.91 V vs. Ag/AgCl ($i_{pa}/i_{pc} \sim 1$) and has been attributed to the $[Pd(cyclam)Cl_2]^{2+}/[Pd(cyclam)]^{2+}$ couple. Similar results were obtained starting from the Pd(IV) dichloro complex synthesized using previously reported procedures (40). The preference of the Pt(IV) ion to adopt a six-coordinate geometry relative to the less stable Pd(IV) octahedral species is clearly reflected in the redox potentials for the cyclam-based species. Steric hindrance from the *N*-methylated species and interligand repulsions seem to play a major role in determining the thermodynamic stability of solutions of [Pt(IV)*N*-methylcyclam)Cl_2]$^{2+}$ ions.

A cyclic voltammogram of [Pt(cyclam)]$(ClO_4)_2$ in CH_3CN containing 0.1 M NBu_4Br shows the presence of Pt(I) monomeric species in solution. An irreversible cathodic wave is seen at −1.35 V vs. Fc^+/Fc. For the N-methylated species, viz. [Pt(NMe_4cyclam)]$(ClO_4)_2$, under the same conditions a cathodic peak is seen at −0.540 V vs. Fc^+/Fc and an anodic peak is seen at −0.230 V vs. Fc^+/Fc. The cathodic peak has been assigned to the formation of the Pt(I) monomeric species in solution. The anodic peak may be due to a dimeric species or other species containing the bromide ion. The relative stability of [Pt(NMe_4cyclam)]$^+$ over [Pt(cyclam)]$^+$ is typical of the N-methylated ligand being able to stabilize low oxidation

© 1997 NRC Canada

states. Meyerstein and co-workers (4) have shown that N-methylation leads to the net stabilization of $Cu(tmc)^+$ and $Ni(tmc)^+$ ions. In 0.1 M NBu_4ClO_4 the cathodic peak due to $[Pt(NMe_4cyclam)]^+$ now occurs at -1.57 V vs. Fc^+/Fc and is similar to that obtained for the corresponding $Pd^{2+}/^+$ couple under the same conditions (18).

Chemical oxidation of $[Pt(cyclam)](ClO_4)_2$ in CH_3CN using $NOBF_4$ or Co^{3+} in aqueous solutions did not exhibit any EPR active species at room temperature or at 77 K. Similar results were obtained with [Pt(*N*-methylcyclam)]$(ClO_4)_2$. Consequently, neither cyclic voltammetry using microelectrodes nor chemical oxidation followed by EPR spectroscopy provided viable routes to detectable Pt(III) species. However, reduction of [Pt(*N*-methylcyclam)]$(ClO_4)_2$ in 90% ethanol containing $NaBH_4$ yielded a paramagnetic species and the EPR spectrum of the frozen glass exhibited an isotropic signal at $g = 2.008$, indicating the formation of a Pt(I) monomeric species. The isoelectronic $[Pd(I)(tmc)]^+$ shows an anisotropic EPR spectrum ($g_\parallel = 2.302$, $g_\perp = 2.076$) (18). This is characteristic of a Pt(I) monomeric species with the unpaired electron in the d_x2–d_y2 orbital (^2E ground state). In contrast, chemical reduction of $[Pt(II)cyclam]^{2+}$ did not yield an EPR active species. The relative stability of [Pt(*N*-methylcyclam)]$^+$ may be due to steric hindrance to dimerization.

Although the technique of ESMS is widely used in the study of biomolecules, its use in the characterization of complex ions in solution has been sparse. Electrospray mass spectrometry is unique in that it allows for transferring preexisting ions from solution to the gas phase with minimal fragmentation. Conventional mass spectrometry leads to extensive fragmentation and in most cases observation of the relatively nonvolatile inorganic compounds is difficult. Recently, ESMS has also been used to study rapidly exchanging labile systems and it provides an alternative to low-temperature NMR studies (41). It has also been used to detect Pt(III) transient species. The five-coordinate Pt(III) complex ion has been stabilized using sterically hindered ligands and $\{Pt(S_2CNEt_2)(P_2P')\}^{2+}$ (42) has been confirmed by ESMS techniques.

The ESMS spectra of solutions containing $[Pt(IV)(cyclam)Cl_2]^{2+}$ ions are very interesting because they show the presence of Pt(III) as well as Pt(II) and Pt(IV) complex ions (Table 7). The peaks at *m/z* 233, 465, and 197 are due to the presence of $[Pt(IV)(cyclam)Cl_2]^{2+}$, $[Pt(III)(cyclam)Cl_2]^+$, and the $[Pt(II)cyclam]^{2+}$ ions, respectively. The ESMS of the N-methylated complex [Pt(*N*-methylcyclam)Cl_2]$(BF_4)_2$ in methanol shows several peaks. Product complex ions that are formed as a result of the axial lability of the chloro ligands in the Pt(III) complex are observed in the mass spectrum. Five- and six-coordinate Pt(III) species are seen at *m/z* 242 and 522, respectively. Because the Pt(III) complex ion tends to disproportionate, its observation both by cyclic voltammetry (using microelectrodes) and EPR spectroscopy is difficult. The ESMS spectrum shows the formation of a Pt(III) five-coordinate species that is intermediate between the four-coordination of Pt(II) and the six-coordination of Pt(IV) complex ions. The formation of the six-coordinate $[Pt(III)(cyclam)Cl_2]^+$ and five-coordinate $[Pt(III)(cyclam)Cl]^{2+}$ ions as proposed in pulse radiolysis (15) is supported by ESMS results obtained in the present study.

Difunctional derivatives of bis(*m*-phenylene)-32-crown-10

Harry W. Gibson and Devdatt S. Nagvekar

Abstract: Optimization studies of the condensation of methyl 3,5-dihydroxybenzoate (**1**) with tetra(ethylene glycol) dichloride (**3**) resulted in improvement of the yield of the 1+1 cyclization product, 5-carbomethoxy-*m*-phenylene-16-crown-5 (**5**), to 67% (HPLC), but no improvement in the yield (28%, HPLC) of the desired 2+2 product, bis(5-carbomethoxy-*m*-phenylene)-32-crown-10 (**4**). However, after optimization, a two-step procedure provided improved yields of **4** and this procedure was generalized to afford other difunctional monomers. Condensation of substituted resorcinols with **3** and subsequent transformations yielded substituted (R) 3,5-bis(11-chloro-3,6,9-trioxaundecyl-oxy)benzenes (**7**, **9**–**14**). Reaction of dihalides **7** (R = $COOCH_3$), **13** (R = CHO), and **12** (R = $CH_2OSi(Me)_2$-*t*-Bu) with methyl 3,5-dihydroxybenzoate (**1**) produced bis(5-carbomethoxy-*m*-phenylene)-32-crown-10 (**4**) (43%), 5-carbomethoxy-*m*-phenylene-5′-formyl-*m*′-phenylene-32-crown-10 (**15**) (32%), and the lactone (**16a**) (18%, derived from the initially formed 5-hydroxymethyl-*m*-phenylene-5′-carbomethoxy-*m*′-phenylene-32-crown-10 (**16**)), respectively. Subsequent reactions gave the corresponding diacid (**17**), bis(hydroxymethyl) (**19**), bis(bromomethyl) (**20**), diacetyl (**18**), diformyl (**21**), bis(*p*-nitrophenoxymethyl) (**22**), and di(acetoxymethyl) (**23**) derivatives.

Key words: cyclization, functionalized bis(*m*-phenylene) crown ethers.

Résumé : Des études d'optimisation de la condensation du 3,5-dihydroxybenzoate de méthyle (**1**) avec le dichlorure de tétra(éthylèneglycol) (**3**) ont conduit à une amélioration du rendement du produit de cyclisation 1+1, 5-carbométhoxy-*m*-phénylène-16-couronne-5 (**5**) (à 67% selon la CLHP), sans amélioration du rendement (28% selon la CLHP) du produit désiré 2+2, bis(5-carbométhoxy-*m*-phénylène)-32-couronne-10 (**4**). Toutefois, après optimisation, une méthode en deux étapes a permis d'obtenir de meilleurs rendements de **4**; on a généralisé cette méthode pour obtenir d'autres monomères difonctionnels. La condensation de résorcinols substitués avec le composé **3** et des transformations subséquentes ont conduit aux 3,5-bis(11-chloro-3,6,9-trioxaundécyloxy)benzènes substitués (R) (**7**, **9**–**14**). La réaction des dihalogénures **7** (R = $COOCH_3$), **13** (R = CHO) et **12** (R = $CH_2OSi(Me)_2$-*t*-Bu) avec le 3,5-dihydroxybenzoate de méthyle (**1**) fournissent respectivement du bis(5-carbométhoxy-*m*-phénylène)-32-couronne-10 (**4**) (43%), du 5-carbométhoxy-*m*-phénylène-5′-formyl-*m*′-phénylène-32-couronne-10 (**15**) (32%) et la lactone (**16a**) (18%, dérivée de la 5-hydroxyméthyl-*m*-phénylène-5′-carbométhoxy-*m*′-phénylène-32-couronne-10 (**16**) formée initialement). Des réactions subséquentes ont permis d'obtenir les dérivés diacide (**17**), bis(hydroxyméthyle) (**19**), bis(bromométhyle) (**20**), diacétyle (**18**), diformyle (**21**), bis(*p*-nitrophénoxyméthyle) (**22**) et di(acétoxyméthyle) (**23**) correspondants.

Mots clés : cyclisation, éthers couronnes bis(*m*-phénylène) fonctionnalisées.

[Traduit par la rédaction]

Introduction

The ability of crown ethers to complex with alkali and alkaline earth metal ions was recognized by Pedersen when he discovered crown ethers (1) and has subsequently been studied in detail (2). This area, the seminal point for host–guest or supramolecular chemistry (3), has fascinated a great number of chemists worldwide and has led to important discoveries in a number of areas.

Work in our laboratory has been directed to the synthesis of aliphatic crown ethers ranging from 21- to 60-membered rings (4). Threading of these and bisphenylene crown ethers by aliphatic and aromatic linear species has provided rotaxanes (5, 6), catenanes (5, 6*c*, 7), and polyrotaxanes (5, 8). We reported earlier that the one-pot reaction of methyl 3,5-dihydroxybenzoate (**1**) and tetra(ethylene glycol) dichloride (**3**) gave only a 9% yield of bis(5-carbomethoxy-*m*-phenylene)-32-crown-10 (**4**) along with a 15% yield of 5-(carbomethoxy-*m*-phenylene)-16-crown-5 (**5**) (Scheme 1) (9).

The present article reports the optimization of the synthesis of diester crown ether **4** and its generalization to produce a variety of functionally substituted derivatives of bis(*m*-phenylene)-32-crown-10. Coupled with standard functional group conversions, this approach provides acceptable yields of an array of useful crown ethers.

Received January 31, 1997.

[a]Method A: Na salt of **1** (made with NaH at 25°C) added to 1 equiv. of **3**; 1/2 equiv. over 4 h, stirred 10 h, diluted 3×, add 1/2 equiv. quickly.
[b]Method B: **3** quickly added to 1 equiv. of Na salt of **1** (made with NaH at 85°C).
[c]Isolated yield of **4**: 7%; **5**: 15% (9).
[d]Method C: equivalent amounts of **1** and **3** and base mixed together in DMF.

solvent systems were examined; a combination of chloroform and isopropanol (94:6) was found to work the best. The small and the large macrocycles (**4** and **5**) were well resolved. Detection by UV absorption and integration of peak areas was found to give accurate percentage compositions of synthetic mixtures. The dichloro intermediate **7**, the monochloro intermediate **6**, and starting material **1** were also resolved. A peak of longer retention time was attributed to intermediate **8**. Other unidentified peaks were attributed to linear oligomers.

2. Summary

As a result of variation of concentration, temperature, the nature of the base, and order of addition (Table 1) the yield of desired macrocycle **4** was not improved relative to our earlier work (9) (expt. 13), although high yields (67%) of the smaller macrocycle **5** were obtained (expt. 21). We thus turned our attention to other routes to **4**.

B. Optimization of a two-step approach

1. Precursor synthesis: methyl 3,5-bis(11-chloro-3,6,9-trioxaundecycloxy)benzoate (7)

Production of bis(5-carbomethoxy-*m*-phenylene)-32-crown-10 (**4**) and 5-carbomethoxy-*m*-phenylene-16-crown-5 (**5**) depends on the intermediates methyl 3,5-bis(11-chloro-3,6,9-trioxaundecycloxy)benzoate (**7**) and methyl 3-(11-chloro-3,6,9-trioxaundecyloxy)-5-hydroxybenzoate (**6**), respectively (Scheme 1). The use of dichloride **7** as a starting material eliminates the possibility of forming **5** and should result in improved yields of **4**.

Tetra(ethylene glycol) was converted to its monochloride, using toluene as a diluent and slow thionyl chloride addition (67% yield, see Experimental). However, its reaction with **1** afforded only 29% of the desired diol, methyl 3,5-bis(11-hydroxy-3,6,9-trioxaundecycloxy) benzoate (see Experimental), so this approach was abandoned.

The synthesis of **7** from **1** was achieved using a 10 equiv. excess of tetra(ethylene glycol) dichloride (**3**) and by use of a variety of bases (Table 2, Scheme 2). In the best method the disodium salt solution of methyl 3,5-dihydroxybenzoate (**1**) was prepared at 110°C using sodium hydride as a base. The reaction after 2 h was cooled to room temperature and stirred with excess tetra(ethylene glycol) dichloride. Excess **3** was removed by vacuum distillation. The crude material was only partially soluble in cold or hot hydrocarbon solvents such as toluene, hexane, and petroleum ether (39–59°C), which was found to be the most selective solvent. Its use in continuous liquid–liquid extraction of the crude material gave methyl 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzoate (**7**) in 68% yield. Alternatively, column chromatography gave a 70% yield.

2. Cyclization

Cyclization is greatly dependent on the nature of the metal ion (3*b*, 10) and the ring size. In addition, by increasing the dilution the fraction of cyclic components can be increased at the

expense of linear oligomers; the maximum concentration that favors the intramolecular versus intermolecular reaction is generally of the order of 10^{-3} mol/L (3*b*, 11). Higher temperatures generally favor cyclization (3*b*, 12). Cesium-assisted cyclization reactions have been used quite successfully in recent years. Stoddart and co-workers (13) synthesized a 68-membered macrocycle in 62% yield by employing a combination of a high-dilution reaction in DMF at high temperature

Scheme 2.

Scheme 3.

(110°C) with the cesium effect (14) and a phase transfer catalyst. Considering all of the above factors, we performed the cyclization by syringe pump addition of a solution of either (*i*) **7** or (*ii*) both **7** and **1** to a stirred mixture of base and *n*-Bu_4NI (TBAI, phase transfer agent) (and **1** in case (*i*)) in DMF (Scheme 3).

F^- is basic enough to cause deprotonation of weak acids in dipolar aprotic solvents (15); the driving force is believed to be the formation of the stable H—F bond (569 kJ/mol) (16). Use of the weaker bases and addition of both **1** and **7** gave better yields than with NaH by addition of **7** only to the preformed dianion of **1** (Table 3). CsF and K_2CO_3 provided nearly identical yields of **4** (42 and 43%) in spite of the difference in the sizes of the metal ions. The ionic radius of K^+ (1.33 Å), although much smaller than Cs^+ (1.65 Å), may be involved in multiple complexations with the oxyethylene side chain. Such multiple complexation behavior is indeed quite well known (*3b*, 17) and holds especially true for crown ethers greater than 27-membered. Furthermore, the yield of the macrocycle **4** is lower with Cs_2CO_3 than with CsF.

C. Synthesis of other derivatives using optimized procedures

1. Dichloro precursors

Several derivatives of **7** were synthesized by functional group conversions (Scheme 2). Acetophenone derivative **9** was synthesized directly in 53% yield utilizing excess tetra(ethylene glycol) dichloride (**3**) and 3,5-dihydroxyacetophenone (**2**), using NaH as base at 50°C.

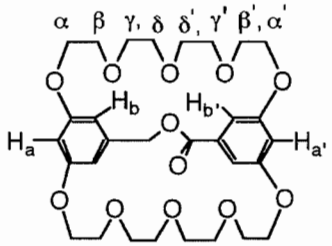
Table 3. Synthesis of bis(5-carbomethoxy-*m*-phenylene)-32-crown-10 (**4**) from **1** and **7** at 110°C.

Base	% Yield
NaH	18[a]
K_2CO_3	43[b]
Cs_2CO_3	37[b]
CsF	42[b]

[a] **7** added to dianion of **1** by syringe pump.
[b] **1** and **7** added to base by syringe pump.

Hydrolysis of ester **7** with KOH in ethanol (EtOH) gave the acid **10** in 98% yield. Reduction of **7** with lithium aluminum hydride (LAH) gave 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzyl alcohol (**11**) in 94% yield. The alcohol **11** was converted to the silyl ether **12** (97%) by treatment with *tert*-butyldimethylsilyl chloride (*t*-BDMSCl). Oxidation of the alcohol **11** with pyridinium chlorochromate (PCC) in dichloromethane (DCM) gave, after column chromatography, an 86% yield of 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzaldehyde (**13**). Reaction of aldehyde **13** with morpholine and trimethylsilyl cyanide (TMSCN) in DCM produced a 92% yield of aminonitrile **14**. The use of methyllithium (MeLi) to convert carboxylic acids to methyl ketones is a well-known general method (18); the major side reaction, the formation of tertiary alcohol (18, 19), can be eliminated by the use of excess chlorotrimethylsilane (TMSCl) to quench the dilithiated intermediate (20). Thus sequential treatment of the acid **10** with MeLi in tetrahydrofuran (THF) at 0°C, followed by quenching with TMSCl, produced 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)acetophenone (**9**) in 66% yield.



2. *Cyclization to other difunctional bis(*m*-phenylene)-32-crown-10 derivatives*

Reaction of dichloride **13** with **1** using CsF as the base afforded a 32% yield of 5-carbomethoxy-*m*-phenylene-5′-formyl-*m*′-phenylene-32-crown-10 (**15**) (Scheme 3).

Condensation of silyl ether **12** with **1** using Cs_2CO_3 was expected to produce the alcohol/ester **16** through hydrolysis of the intermediate silyl ether during work-up. However, the related lactone **16a** was isolated in 18% yield. Its structure is supported by the lack of a methoxy signal in its ^1H NMR spectrum (integration), the lack of the ^{13}C NMR signal at ca. 52 ppm as seen in methyl esters **4**, **7**, and **15**, and by the MS data, all of which fit the lactone structure well. Furthermore, there are significant downfield shifts of the α and α′ signals (4.0–4.4 ppm), $H_{b'}$ (7.29 ppm), and the benzylic methylene protons (5.29 ppm), relative to monocyclic analogs (α and α′ average: 4.09 ppm in **4**, **15**, **17**-**22**; H_b average: 7.15 in **4** and **15**; $ArCH_2$ 4.99 ppm in **23**); this is due to the change in conformation of the cryptand **16a** in comparison to the crown ethers. **16a** apparently forms by intramolecular transesterification of **16**, either during the reaction itself or in work-up and (or) purification.

3. *Difunctional derivatives by functional group conversions*

Several other derivatives of bis(*m*-phenylene)-32-crown-10 were synthesized via classical organic functional group conversions. The diacid **17** was synthesized in 93% yield by hydrolysis of the diester **4** in aqueous NaOH – EtOH. We also synthesized diacetyl macrocycle **18** from the diacid **17** in 45% yield by treatment with MeLi in THF, followed by quenching with TMSCl and aqueous work-up.

16a

Bis(5-hydroxymethyl-*m*-phenylene)-32-crown-10 (**19**) was synthesized in 95% yield via LAH reduction of the diester **4**. Treatment of **19** with PBr_3 gave bis(5-bromomethyl-*m*-phenylene)-32-crown-10 (**20**) in 88% yield. The oxidation of diol **19** with PCC afforded bis(5-formyl-*m*-phenylene)-32-crown-10 (**21**) in 85% yield. Treatment of diol **19** first with NaH and then with *p*-fluoronitrobenzene in THF provided a 100% yield of bis(*p*-nitrophenyl ether) **22**. The diacetate **23** was prepared in 98% yield by treatment of diol **19** with acetyl chloride in THF, with catalysis by pyridine.

Conclusions

A two-step strategy involving the synthesis of intermediates **7**, **9**–**14** in the first step followed by cyclization with methyl 3,5-dihydroxybenzoate (**1**) using a syringe pump to maintain pseudo-high-dilution conditions afforded bis(*m*-phenylene)-32-crown-10 derivatives **4** (43%), **15** (32%), and **16a** (18%). Thus, a significant yield improvement over our previously reported procedure (9%) (9) was realized for **4**. Several other new derivatives of bis(*m*-phenylene)-32-crown-10 were synthesized by functional group conversions; these include diketone **18**, diol **19**, dihalide **20**, dialdehyde **21**, bis(*p*-nitrophenyl ether) **22** (a diamine precursor), and diacetate **23**.

The use of these new difunctional crown ethers in the syntheses of polymers containing macrocycles in the backbones (i.e., poly(macrocycle)s) and supramolecular structures by self assembly is currently being explored. These studies will be reported in due course.

Experimental

Materials

Unless specified otherwise, reagent grade reactants and solvents were used as received from chemical suppliers. THF was distilled over sodium–benzophenone. Tetra(ethylene glycol) dichloride (**3**) (*1b*) and methyl 3,5-dihydroxybenzoate (**1**) (*9a*) were synthesized according to literature procedures.

Measurements

HPLC analyses were performed on an ISCO dual pump system comprising two model 2350 pumps and the V^4 variable wavelength UV/VIS detector set at 274 nm. $CHCl_3$:i-PrOH (94:6, v:v) was used for elution of products on a 4.6 × 250 mm

5 μm silica column at a flow rate of 1 mL/min. The system was interfaced with the ISCO ChemResearch chromatographic data management system, used for data analyses. A Harvard syringe infusion pump model 22 was used in the cyclization reactions. Melting points were taken in capillary tubes with a Haake–Buchler melting point apparatus and have been corrected. ^{1}H and ^{13}C NMR spectra were obtained at ambient temperature on Varian Unity 400 MHz and Bruker 270 MHz spectrometers using acetone-d_6 or $CDCl_3$ as solvents with tetramethylsilane (δ = 0) as internal standard. Infrared spectra (KBr pellets, unless otherwise noted) were recorded on a Nicolet MX-1 FTIR spectrometer. Mass spectra (MS) were measured at the Nebraska Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, Nebr., and at the Center for Mass Spectrometry at Washington University, St. Louis, Mo.; fast atom bombardment (FAB) MS utilized 3-nitrobenzyl alcohol as the matrix; EI = electron impact; HR = high resolution. Elemental analyses were performed by Atlantic Microlab, Norcross, Ga.

HPLC analyses

A synthetic mixture comprising 40.5:59.5 (w:w) macrocycles **5**:**4** was subjected to quantitative analysis using integrated peak areas with the following results: 40.6% **5**, 59.4% **4** (avg. of 2 determinations). Elution times: **4** @ 6.0 min, **5** @ 3.4 min, methyl 3,5-dihydroxybenzoate (**1**) @ 5.0 min, **7** @ 3.5 min; from the synthesis of **7** using K_2CO_3 (Table 2) the kinetic evolution of the products indicated that the compound with elution time 4.0 min was monochloride **6**. The peak with elution time 8.0 min was attributed to precursor **8**, and higher oligomers eluted @ 9.5 min. All percentages are based on integrated peak areas.

Optimization of synthesis of 4 via one-step method

Method A

NaH (0.20 g, 8.3 mmol) was added to a stirred solution of methyl 3,5-dihydroxybenzoate (**1**, 0.54 g, 3.2 mmol) in DMF (25 mL). The mixture was stirred at room temperature for 2 h. The resulting brown solution was diluted with DMF (25 mL) and added slowly to neat tetra(ethylene glycol) dichloride (**3**, 1.49 g, 6.45 mmol) over a period of 0.5 h at 85°C. The resulting mixture was stirred for 10 h at 85°C, diluted with DMF (100 mL), and the second portion of the disodium salt of methyl 3,5-dihydroxybenzoate (**1**, 0.54 g (3.2 mmol) in DMF (50 mL)) was added quickly. The resulting mixture was stirred for 2 days at 85°C. The cooled reaction mixture was filtered and DMF was stripped to give a brown gummy product. The crude product (15–17 mg in 10 mL DCM) was subjected to HPLC analysis.

Method B

NaH (0.87 g, 36 mmol) was added to a stirred solution of methyl 3,5-dihydroxybenzoate (**1**, 2.39 g, 14.2 mmol) in DMF (57 mL). The resulting mixture was stirred for 2 h at 85°C. A solution of tetra(ethylene glycol) dichloride (**3**, 3.29 g, 14.2 mmol) in DMF (62.5 mL) was added quickly and the mixture was stirred vigorously at 85°C for 48 h under a blanket of nitrogen. The mixture was cooled, filtered, and the DMF was stripped to give a crude product. The crude product (15–17 mg in DCM (10 mL)) was subjected to HPLC analysis.

2-{2′-[2″-(2‴-Chloroethoxy)ethoxy]ethoxy}ethanol

$SOCl_2$ (11.5 mL, 0.158 mol) was added over a period of 5 h to a solution of tetra(ethylene glycol) (30.54 g, 157 mmol), toluene (250 mL), and pyridine (12.2 mL, 151 mmol). The reaction was exothermic. The solution was refluxed for 36 h, cooled, and evaporated. The crude product was dissolved in H_2O (75 mL) and tetra(ethylene glycol) dichloride (**7**) was removed by extraction with toluene (3 × 50 mL). The aqueous layer was evaporated. The mixture was diluted with saturated NaCl (75 mL) and extracted with Et_2O (3 × 100 mL). Pure product (22.5 g, 67.4%) was obtained via vacuum distillation, bp 132–133°C/1.25 Torr (1 Torr = 133.3 Pa) (lit. (21) bp 134.6–136°C/0.094 Torr); (22) bp 123–125°C/2.0 Torr). IR (neat): 3450 (OH), 2860 (CH), 1085 (COC) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ (ppm): 2.72 (br s, 1H, OH), 3.57–3.67 (m, 4H, CH_2Cl and OCH_2), 3.68 (s, 8H, OCH_2), 3.69–3.79 (m, 4H, OCH_2).

Methyl 3,5-bis(11-hydroxy-3,6,9-trioxa-1-undecyloxy)-benzoate

A mixture of methyl 3,5-dihydroxybenzoate (**1**, 2.01 g, 12 mmol) and NaH (0.74 g, 31 mmol) in anhydrous DMF (25 mL) was heated for 2 h at 85°C. To the brown-colored mixture was added 2-{2′-[2″-(2‴-chloroethoxy)ethoxy]ethoxy}ethanol (5.11 g, 24.0 mmol) and the mixture was stirred vigorously for 2 days. The cooled solution was filtered and the DMF removed to give a crude product. Column chromatography with EtOH as eluent gave methyl 3,5-bis(11-hydroxy-3,6,9-trioxa-1-undecyloxy)benzoate (1.80 g, 29%), an oil. IR (neat): 3446 (OH), 2865 (-CH), 1716 (C═O), 1600 (C═C), and 1135 (C-O-C). ^{1}H NMR ($CDCl_3$) δ (ppm): 3.12 (br s, 2H, OH), 3.6–3.7 (m, 24H, γ-η-OCH_2), 3.82 (t, J = 4.7 Hz, 4H, β-CH_2), 3.86 (s, 3H, OCH_3), 4.12 (t, J = 4.7 Hz, 4H, α-CH_2), 6.68 (t, J = 2.3 Hz, 1H, H_a), and 7.16 (d, J = 2.3 Hz, 2H, H_b). MS (EI): 520 (M^+, 11%), 489 [$(M - OCH_3)^+$, 2%], 445 [$(M - OCH3 - CH_2CH_2O)^+$, 3%], 344 {$[M - (OCH_2CH_2)_4]^+$, 9%], 194 (31%), 163 (50%), 89 (100%).

Methyl 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)-benzoate (7)

NaH (9.37 g, 312 mmol, 80% in mineral oil, 2.1 equiv.) was added to a solution of methyl 3,5-dihydroxybenzoate (**1**, 25.0 g, 149 mmol) in DMF (150 mL). The mixture was stirred for 3 h at 110°C and cooled to room temperature (RT). The resulting suspension of dianion was added to a mixture containing tetra(ethylene glycol) dichloride (**3**, 343.6 g, 1.487 mol, 10 equiv.) in DMF (100 mL) over a period of 6 h and then the mixture was stirred for 5 days at 50°C. The mixture was filtered and DMF was removed on a rotary evaporator. Excess **3** (280 mL) was removed via vacuum distillation. A continuous liquid–liquid extraction with petroleum ether gave 47.2 g (68%) of **7**, an oil. Alternatively, silica gel column chromatography with EtOAc afforded a 70% yield. IR (neat): 3064 (C═C-H), 2877 (-CH), 1729 (C═O), 1596 (C═C), 1118 (C-O-C), and 733 (-CH_2Cl) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ (ppm): 3.55–3.65 (m, 4H, CH_2Cl), 3.65–3.75 (m, 20H, γ-η-CH_2), 3.86 (t, J = 4.8 Hz, 4H, β-CH_2), 3.89 (s, 3H, CH_3), 4.15 (t, J = 4.8 Hz, 4H, α-CH_2), 6.70, (t, J = 2.3 Hz, 1H, H_a), and 7.19 (d, J = 2.3 Hz, 2H, H_b). ^{13}C NMR δ (ppm): 42.68, 52.19, 67.69, 69.54, 70.59, 70.61, 70.64, 70.80, 71.30, 106.84, 107.95, 131.83, 159.70, and 166.70 (14 peaks as required). MS (EI) *m/z* (rel. int.): 558 [$M(^{35}Cl_1{}^{37}Cl_1)]^+$ (3%),

556 $[M(^{35}Cl_2)]^+$ (5%), 527 $[M(^{35}Cl_1{}^{37}Cl_1) - OCH_3]^+$ (0.8%), 525 $[M(^{35}Cl_2 - OCH_3]^+$ (1%), and 63 $[C_2H_3Cl]$ (100%). HRFAB, calcd. for $C_{24}H_{38}{}^{35}Cl_2O_{10}$: $[M]^+$ *m/z* 556.1842; found: 556.1818 (error 3.0 ppm).

Optimization of synthesis of bis(5-carbomethoxy-*m*-phenylene)-32-crown-10 (4) by cyclization of 1 and 7 (see Table 3)

$CsCO_3$

A mixture of methyl 3,5-dihydroxybenzoate (**1**, 0.17 g, 1.0 mmol) and methyl 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzoate (**7**, 0.56 g, 1.0 mmol) in DMF (10 mL) was added using a syringe pump (1.67 mL/h) to a suspension containing Cs_2CO_3 (3.30 g, 1.0 mmol), CsCl (0.35 g, 2.0 mmol), and TBAI (10 mg) in DMF (40 mL) at 110°C. The mixture was stirred vigorously for 3 days at 110°C, cooled, and filtered. DMF was removed and the crude product was purified via column chromatography using EtOAc as solvent to afford pure **4** (0.24 g, 37%). The product was recrystallized from acetone, mp 107.8–108.5°C (lit. (*9a*) mp 106.5–107.5°C).

NaH

A solution of methyl 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzoate (**7**, 0.558 g, 1.0 mmol) in DMF (10 mL) was added via a syringe pump (1.67 mL/h) to a mixture initially containing methyl 3,5-dihydroxybenzoate (**1**, 0.17 g, 1.0 mmol), NaH (64.3 mg, 2.68 mmol), CsCl (0.87 g, 5.3 mmol), and TBAI (10 mg) in DMF (40 mL) at 110°C. The mixture was stirred vigorously for 3 days at 110°C, cooled, and filtered. DMF was removed and the crude product was purified via column chromatography using EtOAc as a solvent, which gave pure **4** (0.12 g, 18%). The product was recrystallized from acetone, mp 107.8–108°C (lit. (*9a*) mp 106.5–107.5°C).

K_2CO_3 (optimized method)

A mixture containing methyl 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzoate (**7**, 7.66 g, 13.7 mmol) and methyl 3,5-dihydroxybenzoate (**1**, 2.33 g, 13.9 mmol) in DMF (total volume 22 mL) was added via a syringe pump at 0.75 mL/h to a suspension containing K_2CO_3 (19.04 g, 137.7 mmol) and TBAI (20 mg) in DMF (670 mL) at 110°C. After complete addition, the mixture was stirred at 110°C for 5 days. The cooled reaction mixture was evaporated to remove DMF, treated with DCM, and filtered. Removal of DCM followed by flash column chromatography using Et_2O as eluent gave pure **4** (3.89 g, 43%), mp 107.2–108.7°C (lit. (*9a*) mp 106.5–107.5°C). IR: 1717 (C═O), 1600 (C═C), 1067–1137 (C-O-C) cm^{-1}. ^1H NMR ($CDCl_3$) δ (ppm): 3.65–3.75 (m, 16H, γ, δ-CH_2), 3.84 (t, *J* = 4.5 Hz, 8H, β-CH_2), 3.87 (s, 6H, CH_3), 4.10 (t, *J* = 4.6 Hz, 8H, α-CH_2), 6.67 (t, *J* = 2.0 Hz, 2H, H_a), and 7.15 (d, *J* = 2.0 Hz, 4H, H_b). ^{13}C NMR ($CDCl_3$) δ (ppm): 52.10, 67.76, 69.48, 70.77, 70.83, 106.73, 107.91, 131.73, 159.65, and 166.63 (10 peaks as required).

CsF

A mixture containing methyl 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzoate (**7**, 18.62 g, 3.34 mmol) and methyl 3,5-dihydroxybenzoate (**1**, 5.65 g, 3.36 mmol) in DMF (total volume 55 mL) was added via a syringe pump (0.75 mL/h) to a suspension containing CsF (50.86 g, 3.35 mmol) and TBAI (50 mg) in DMF (1650 mL) at 110°C. After complete addition, the mixture was stirred vigorously at 110°C for 5 days. The cooled reaction mixture was evaporated to remove DMF and filtered to remove all salts using DCM. Removal of DCM followed by flash column chromatography using Et_2O as eluent gave pure **4** (9.10 g, 41.8%), mp 107.3–108.6°C (lit. (*9a*) mp 106.5–107.5°C).

3,5-Bis(11-chloro-3,6,9-trioxaundecyloxy)acetophenone (9)

Method A

NaH (1.05 g, 35.0 mmol, 80% in mineral oil) was added to a solution of 3,5-dihydroxyacetophenone (**2**, 2.525 g, 16.6 mmol) in DMF (25 mL). The mixture was stirred for 3 h at 110°C and brought to 50°C before adding excess tetra(ethylene glycol) dichloride (**3**, 40.05 g, 173.3 mmol, 10 equiv.). The mixture was stirred for 5 days at 50°C and filtered. After removal of DMF, the excess **3** was removed via vacuum distillation. Silica gel column chromatography with Et_2O as eluent gave pure **9** (4.72 g, 53%), an oil. ^1H NMR ($CDCl_3$) δ (ppm): 2.56 (s, 3H, CH_3), 3.63 (t, *J* = 5.8 Hz, 4H, CH_2Cl), 3.65–3.75 (m, 20H, γ-η-CH_2), 3.87 (t, *J* = 4.8 Hz, 4H, β-CH_2), 4.15 (t, *J* = 4.8 Hz, 4H, α-CH_2,), 6.70 (t, *J* = 2.4 Hz, 1H, H_a), and 7.11 (d, *J* = 2.4 Hz, 2H, H_b). ^{13}C NMR ($CDCl_3$) δ (ppm): 42.68, 52.19, 67.69, 69.54, 70.59, 70.61, 70.64, 70.80, 71.30, 106.84, 107.95, 131.83, 159.70, and 166.70 (14 peaks as required). MS FAB *m/z* (rel. int.): 565.1 $[M(^{37}Cl_1{}^{35}Cl_1) + Na]^+$ (70%), 563.1 $[M(^{35}Cl_2) + Na]^+$ (100%); HRFAB, calcd. for $C_{24}H_{38}Cl_2O_9Na$: $[M + Na]^+$ 565.1761 ($^{37}Cl_1$ $^{35}Cl_1$) and 563.1791 ($^{35}Cl_2$); found: 565.1759 (error 0.3 ppm) and 563.1782 (error 1.5 ppm).

Method B

To a solution of 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)-benzoic acid (**10**, 3.76 g, 6.92 mmol) in dry THF (100 mL) at 0°C was added MeLi (20 mL, 1.4 M, 2.8 mmol). Stirring was continued at 0°C for 3.5 h; then TMSCl (18.0 mL, 141 mmol) was added and stirring was continued for 2 h. The solution was allowed to warm to RT and quenched with 25 mL 1 N HCl. The mixture was stirred for 12 h and extracted with Et_2O. The extract was washed with H_2O, dried (Na_2SO_4), and evaporated to afford 2.47 g (66%) of **9** as a slightly reddish oil with the same spectral characteristics as a sample made by Method A above. Anal. calcd. for $C_{24}H_{38}Cl_2O_9$: C 61.45, H 7.47; found: C 61.59, H 7.42.

3,5-Bis(11-chloro-3,6,9-trioxaundecyloxy)benzoic acid (10)

A solution of methyl 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzoate (**7**, 10.32 g, 18.5 mmol), 3.21 g (48.6 mmol) of KOH, 60 mL of EtOH, and 30 mL of H_2O was heated at reflux for 3 h, cooled, and neutralized with 2 N HCl. The solvents were removed in vacuo and the residue was extracted with DCM. The solution was dried (Na_2SO_4) and evaporated to give 10.06 g (98%) of **10**, which after purification by elution through silica gel with Et_2O remained an oil. ^1H NMR ($CDCl_3$) δ (ppm): 3.65–3.75 (m, 24H, γ-η-CH_2 + CH_2Cl), 3.87 (t, *J* = 4.6 Hz, 4H, β-CH_2,), 4.16 (t, *J* = 4.6Hz, 4H, α-CH_2), 6.73 (t, *J* = 2.0 Hz, 1H, H_a), and 7.25 (d, *J* = 2.0 Hz, 2H, H_b). ^{13}C NMR ($CDCl_3$) δ (ppm): 42.69, 67.73, 69.57, 70.60, 70.62, 70.66, 70.81, 71.32, 107.55, 108.47, 131.09, 159.75,

For personal use only.

170.61 (13 peaks as required). MS (FAB) *m/z* (rel. int.): 567.1 [M($^{35}Cl_1{}^{37}Cl_1$) + Na]$^+$, 45%}, 565.1{[M($^{35}Cl_2$) + Na)$^+$, 100%]; HRFAB, calcd. for $C_{22}H_{36}Cl_2O_{10}$: [M + Na]$^+$ *m/z* 565.1583 ($^{35}Cl_2$) and 567.1554 ($^{35}Cl_1{}^{37}Cl_1$); found: 565.1581 (error 0.4 ppm) and 567.1548 (error 0.9 ppm) .

3,5-Bis(11-chloro-3,6,9-trioxaundecyloxy)benzyl alcohol (11)

A solution of LAH (15.0 mL, 15 mmol, 1.0 M) in THF was added to a solution of methyl 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzoate (**7**, 15.55 g, 27.9 mmol) in THF (300 mL) at RT. After the mixture had stirred for 15 h at RT, excess LAH was destroyed using EtOAc. The solution was diluted with H_2O and acidified with 2 N HCl. The product was extracted with Et_2O (3 × 75 mL). The combined organic layer was washed with H_2O and saturated NaCl. Evaporation of the solvent after drying (Na_2SO_4) gave **11** (13.84 g, 94%), an oil. ^{1}H NMR ($CDCl_3$) δ (ppm): 3.65–3.75 (m, 24H, γ-η-CH_2 + CH_2Cl), 3.83 (t, *J* = 4.8 Hz, 4H, β-CH_2), 4.10 (t, *J* = 4.8 Hz, 4H, α-CH_2), 4.59 (s, 2H, CH_2O), 6.40 (t, *J* = 2.0 Hz, 1H, H_a), and 6.53 (d, *J* = 2.0 Hz, 2H, H_b). ^{13}C NMR ($CDCl_3$) δ (ppm): 42.66, 65.04, 67.42, 69.64, 70.53, 70.57, 70.61, 70.72, 71.27, 100.77, 105.36, 143.44, and 159.98 (13 peaks as required). MS (FAB) *m/z* (rel. int.): 553.1 [M($^{35}Cl_1{}^{37}Cl_1$) + Na]$^+$ (9%), 551.0 [M($^{35}Cl_2$) + Na]$^+$ (13%), 530.0 [M($^{35}Cl_1{}^{37}Cl_1$)]$^+$ (15%), 528.1 [M($^{35}Cl_2$]$^+$ (21%), 154 (100%); HRFAB, calcd. for $C_{23}H_{38}Cl_2O_9$: [M($^{35}Cl_2$)]$^+$ *m/z* 528.1893; found: 528.1898 (error 0.9 ppm).

3,5-Bis(11-chloro-3,6,9-trioxaundecyloxy)benzyl *tert*-butyldimethylsilyl ether (12)

To a solution of **11** (7.54 g, 14.1 mmol), imidazole (1.05 g, 1.1 equiv.), and 70 mL of DMF was added 2.22 g (1.05 equiv.) of *t*-BDMSCl and the solution was stirred at RT for 12 h, then at 70°C for 6 h. H_2O was added and the resulting mixture was extracted with Et_2O. The extract was washed with H_2O and brine, dried (Na_2SO_4), and evaporated to afford 8.87 g (98%) of **12**. ^{1}H NMR ($CDCl_3$) δ (ppm): 0.08 (s, 6H, $SiCH_3$), 0.89 (s, 9H, C-CH_3), 3.65–3.75 (m, 24H, γ-η-CH_2 + CH_2Cl), 3.82 (t, *J* = 4.8 Hz, 4H, β-CH_2), 4.08 (t, *J* = 4.8 Hz, 4H, α-CH_2), 4.64 (s, 2H, CH_2O), 6.35 (t, *J* = 2.0 Hz, 1H, H_a), and 6.47 (d, *J* = 2.0 Hz, 2H, H_b). MS (FAB) *m/z* (rel. int.): 667.4 [M($^{35}Cl_1{}^{37}Cl_1$) + Na]$^+$ (3%), 665.4 [M($^{35}Cl_2$) + Na]$^+$ 4%), 644.4 [M($^{35}Cl_1{}^{37}Cl_1$)]$^+$ (4%), 642.4 [M($^{35}Cl_2$)]$^+$ (5%), 509.3; HRFAB, calcd. for $C_{29}H_{52}SiCl_2N_2O_9$: [M($^{35}Cl_2$)]$^+$ *m/z* 642.2757; found: 642.2730 (error 4.3 ppm).

3,5-Bis(11-chloro-3,6,9-trioxaundecyloxy)benzaldehyde (13)

PCC (5.16 g, 23.9 mmol) was added to a solution of 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzyl alcohol (**11**, 11.55 g, 21.8 mmol) in DCM (150 mL). After 15 h at RT, the mixture was filtered and the solid was washed with DCM. The solution after concentration was passed through a short silica gel column with Et_2O as eluent. The fractions were dried (Na_2SO_4) and evaporated to give pure **13** (9.89 g, 86%), an oil. ^{1}H NMR ($CDCl_3$) δ (ppm): 3.55–3.65 (m, 24H, γ-η-CH_2 + CH_2Cl), 3.87 (t, *J* = 4.8 Hz, 4H, β-CH_2), 4.17 (t, *J* = 4.8 Hz, 4H, α-CH_2), 6.76 (t, *J* = 2.2 Hz, 1H, H_a), 7.02 (d, *J* = 2.2 Hz, 2H, H_b), and 9.89 (s, 1H, CHO). ^{13}C NMR ($CDCl_3$) δ (ppm): 42.67, 67.81, 69.51, 69.76, 70.60, 70.62, 70.66, 70.82, 71.31, 107.94, 108.26, 138.27, 160.35, and 191.77 (14 peaks as required). MS (FAB) *m/z* (rel. int.): 551.1 [M($^{35}Cl_1{}^{37}Cl_1$) + Na]$^+$ (69%), 549.1 [M($^{35}Cl_2$) + Na]$^+$ (100%), 515.2 [M($^{35}Cl_2$) + Na − ^{35}Cl] (35%); HRFAB, calcd. for $C_{23}H_{36}Cl_2O_9Na$: [M($^{35}Cl_1{}^{37}Cl_1$) + Na]$^+$ *m/z* 551.1605 and [M($^{35}Cl_2$) + Na]$^+$ *m/z* 549.1634; found: 551.1595 (error 1.7 ppm) and 549.1629 (error 0.9 ppm).

α-Morpholino-3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)-benzyl cyanide (14)

TMSCN (0.32 mL, 2.4 mmol) was added to a mixture of 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzaldehyde (**13**, 1.10 g, 2.09 mmol), $ZnCl_2$ (10 mg), and DCM (10 mL). The mixture was stirred at RT for 3 days, heated at reflux for 2 days, and poured into 50 mL of ice. The organic phase was washed with H_2O and evaporated to give 1.30 g (97%) of an oil. Silica gel chromatography using Et_2O afforded 1.2 g (92%) of **14**, an oil. ^{1}H NMR ($CDCl_3$) δ (ppm): 2.5–2.7 (m, morpholino), 3.65–3.75 (m, 24H, γ-η-CH_2 + CH_2Cl), 3.86 (t, *J* = 4.8 Hz, 4H, β-CH_2), 4.11 (t, *J* = 4.8 Hz, 4H, α-CH_2), 4.72 (s, 1H, CHCN), 6.49 (t, *J* = 2.0 Hz, 1H, H_a), and 6.71 (d, *J* = 2.0 Hz, 2H, H_b). ^{13}C NMR ($CDCl_3$) δ (ppm): 42.71, 49.96, 66.64, 67.62, 69.59, 69.78, 70.61, 70.64, 70.67, 70.82, 71.34, 101.86, 106.85, 115.06, 134.65, 160.21 (16 peaks as required). 5-Carbomethoxy-*m*-phenylene-5′-formyl-*m*′-phenylene-32-crown-10 (15)

A solution containing 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzaldehyde (**13**, 6.00 g, 11.4 mmol) and methyl 3,5-dihydroxybenzoate (**1**, 1.91 g, 11.4 mmol) in DMF (total volume 18 mL) was added via a syringe pump at 0.75 mL/h to a suspension containing CsF (18.11 g, 119.2 mmol) and TBAI (20 mg) in DMF (550 mL) at 110°C. After complete addition, the mixture was stirred at 110°C for 5 days. The cooled reaction mixture was evaporated, treated with DCM, and filtered. Removal of DCM followed by flash silica gel column chromatography using Et_2O as eluent gave pure **15** (2.26 g, 32%) as an oil that crystallized upon standing, mp 70.2–72.0°C. ^{1}H NMR ($CDCl_3$) δ (ppm): 3.65–3.75 (m, 16H, γ, γ′, δ, δ′-CH_2), 3.85–3.95 (m, 8H, β,β′-CH_2), 3.87 (s, 3H, CH_3), 4.05–4.15 (m, 8H, α,α′-CH_2), 6.67 (t, *J* = 2.4 Hz, 1H, $H_{a'}$), 6.73 (t, *J* = 2.4 Hz, 1H, H_a), 6.98 (d, *J* = 2.4 Hz, 2H, H_b), 7.14 (d, *J* = 2.4 Hz, 2H, $H_{b'}$), and 9.84 (s, 1H, CHO). ^{13}C NMR ($CDCl_3$) δ (ppm): 52.17, 67.77, 67.87, 69.49, 69.52, 70.77, 70.79, 70.84, 106.78, 107.93, 108.18, 131.77, 138.17, 159.67, 160.31, 166.68, and 191.86 (17 peaks; theory 18). MS (FAB) *m/z* (rel. int.): 623.2 [M + H]$^+$ (100%), 591.3 (M$^+$ − OCH_3) (44%); HRFAB, calcd. for $C_{31}H_{43}O_{13}$: [M + H]$^+$ *m/z* 623.2703; found: 623.2681 (error 3.5 ppm).

Lactone (16a) from 5-hydroxymethyl-*m*-phenylene-5′-carbomethoxy-*m*′-phenylene-32-crown-10 (16)

To a stirred suspension of Cs_2CO_3 (38.51 g, 118 mmol) and TBAI (20 mg) in DMF (560 mL) at 110°C was added a solu-

tion of 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzyl *tert*-butyldimethylsilyl ether (**12**) (7.56 g, 11.7 mmol) and methyl 3,5-dihydroxybenzoate (**1**) in DMF (20 mL) at a rate of 0.75 mL/h. The mixture was stirred for 4 days at 110°C, cooled, and filtered throught Celite, which was rinsed with DCM. The filtrate was rotary evaporated to yield a dark brown oil, 11 g, which was subjected to silica gel column chromatography with 7/1 EtOAc/EtOH to afford pure **16a**, an oil, 1.56 g (18%). ^{1}H NMR ($CDCl_3$) δ (ppm): 3.7–3.9 (m, 24H, β, γ, δ, β′, γ′, δ′-CH_2), 4.0–4.4 (m, 8H, α,α′-CH_2), 5.29 (s, 2H, CH_2), 6.41 (t, J = 2.0 Hz, 1H, H_a), 6.59 (t, J = 2.0 Hz, 1H, H_b), 6.73 (d, J = 2.0 Hz, 1H, $H_{a'}$), and 7.29 (d, J = 2.0 Hz, 1H $H_{b'}$). ^{13}C NMR ($CDCl_3$) δ (ppm): 66.62, 67.85, 67.98, 69.45, 69.83, 70.45, 70.55, 70.62, 70.86, 103.43, 108.05, 108.94, 109.29, 132.06, 138.38, 159.63, 159.65, 165.68 (18 peaks; 19 peaks theory). MS (FAB) *m/z* (rel. int.): 615.2 $[M + Na]^+$ (100%), 483.2 $[M + Na - (OCH_2CH_2)_3]^+$ (14%), 176.0 $[(OCH_2CH_2)_4]^+$ (44%); HRFAB, calcd. for $C_{30}H_{40}O_{12}Na$ (lactone, i.e., **16a** + Na^+): $[M]^+$ *m/z* 615.2417; found: 615.2425 (error 1.2 ppm).

Bis(5-carboxy-*m*-phenylene)-32-crown-10 (17)

Aqueous NaOH (27 mL, 4 M) was added to a solution of diester crown **4** (1.26 g, 1.93 mmol) in absolute EtOH (120 mL). The mixture was refluxed for 48 h, cooled to RT, acidified with 4 M HCl, diluted with H_2O, and extracted with DCM (3 × 50 mL). The organic extract was concentrated and the crude solid was purified by recrystallization from EtOH to give **17** (1.12 g, 93%), mp 171.1–171.5°C (lit. (9*a*) mp 169.5–170.5°C). IR: 3501 (-OH), 1696 (C=O), 1600 (C=C), 1129 (C-O-C) cm^{-1}. ^{1}H NMR (DMSO-d_6) δ (ppm): 3.55–3.65 (m, 16H, γ,δ-CH_2), 3.65–3.75 (m, 8H, β-CH_2), 4.09 (t, J = 4.4 Hz, 8H, α-CH_2), 6.75 (t, J = 2.2 Hz, 2H, H_a), and 7.02 (d, J = 2.2 Hz, 4H, H_b). ^{13}C NMR (DMSO-d_6) δ (ppm): 67.51, 68.83, 70.01, 70.02, 105.65, 107.51, 132.73, 159.54, and 166.90 (9 peaks; theory 9).

Bis(5-acetyl-*m*-phenylene)-32-crown-10 (18)

MeLi in Et_2O (28.0 mL, 1.4 M, 38.4 mmol, 15.9 equiv.) was added to an ice cold solution of bis(5-carboxy-*m*-phenylene)-32-crown-10 (**17**, 1.51 g, 2.42 mmol) in THF (100 mL). After 3 h at 0°C, TMSCl (25.6 mL, 202 mmol) was rapidly added while stirring continued. After 30 min at 0°C, the mixture was allowed to come to RT at which point 1 N HCl (25 mL) was added. The resulting two-phase system was stirred at RT for 2 h and the product was extracted with Et_2O (3 × 50 mL). The organic layer was washed with H_2O and dried (Na_2SO_4). The pure product **18** (0.67 g, 45%), mp 95.2–96.1°C, a white powder, was obtained via silica gel column chromatography with EtOAc as eluent. ^{1}H NMR ($CDCl_3$) δ (ppm): 2.53 (s, 6H, CH_3), 3.65–3.75 (m, 16H, γ,δ-CH_2), 3.85 (t, J = 4.6 Hz, 8H, β-CH_2), 4.10 (t, J = 4.6 Hz, 8H, α-CH_2), 6.67 (t, J = 2.2 Hz, 2H, H_a), and 7.07 (d, J = 2.2 Hz, 4H, H_b). ^{13}C NMR ($CDCl_3$) δ (ppm): 26.70, 67.80, 69.57, 70.85, 70.86, 106.34, 107.00, 138.83, 159.92, and 197.67 (10 peaks as required). MS (FAB) *m/z* (rel. int.): 621.5 $[M + H]^+$ (100%); HRFAB, calcd. for $C_{32}H_{44}O_{12}$: $[M + H]^+$ *m/z* 621.2911; found: 621.2915 (error 0.6 ppm).

Bis(5-hydroxymethyl-*m*-phenylene)-32-crown-10 (19)

LAH in THF (3.6 mL, 1.0 M, 3.6 mmol, 1.11 equiv.) was added to a solution of bis(5-carbomethoxy-*m*-phenylene)-32-crown-10 (**4**, 2.11 g, 3.23 mmol) in anhydrous THF (100 mL) at RT. The mixture was stirred for 12 h, excess LAH was destroyed with EtOAc, and the mixture was diluted with H_2O (30 mL). Upon neutalization with 2 N HCl the mixture was extracted with Et_2O (3 × 30 mL). The organic layer was dried (Na_2SO_4) and evaporated. Recrystallization from acetone gave pure **19** (1.82 g, 94%), mp 99.5–100.4°C. IR: 3435 (-OH), 2924 (-CH), 1602 (C=C), and 1122 (C-O-C) cm^{-1}. ^{1}H NMR (CD_3COCD_3) δ (ppm): 3.55–3.65 (m, 16H, γ,δ-CH_2), 3.79 (t, J = 4.6 Hz, 8H, β-CH_2), 4.06 (t, J = 4.6 Hz, 8H, α-CH_2), 4.16 (t, J = 6.0 Hz, 2H, OH), 4.54 (d, J = 6.0 Hz, 4H, CH_2), 6.37 (t, J = 2.2 Hz, 2H, H_a), and 6.52 (d, J = 2.2 Hz, 4H, H_b). ^{13}C NMR (CD_3COCD_3) δ (ppm): 64.59, 68.33, 70.32, 71.46, 71.44, 104.88, 105.76, 145.78, and 161.01 (9 peaks as required). MS (FAB) *m/z* (rel. int.): 596.3 $(M + H)^+$ (100%), 561.3 $(M^+ - 2OH)$ (32%), and 534.9 $(M^+ - 2CH_2OH)$ (12.5%); HRFAB, calcd. for $C_{30}H_{44}O_{12}$: $[M + H]^+$ *m/z* 596.2833; found: 596.2848 (error 2.5 ppm).

Bis(5-bromomethyl-*m*-phenylene)-32-crown-10 (20)

PBr_3 (1.60 mL, 16.9 mmol, 5.20 equiv.) was added to a solution of bis(5-hydroxymethyl-*m*-phenylene)-32-crown-10 (**19**, 1.92 g, 3.22 mmol) in a mixture of Et_2O (250 mL) and EtOAc (30 mL). The mixture was stirred for 36 h at RT. The resulting white solid was filtered and washed several times with Et_2O. Pure **20** (2.04 g, 88%), mp 108.5–110.1°C, was obtained by recrystallization from EtOAc. ^{1}H NMR ($CDCl_3$) δ (ppm): 3.65–3.75 (m, 16H, γ,δ-CH_2), 3.83 (t, J = 4.6 Hz, 8H, β-CH_2), 4.05 (t, J = 4.6 Hz, 8H, α-CH_2), 4.37 (s, 4H, CH_2), 6.40 (t, J = 2.2 Hz, 2H, H_a), and 6.53 (d, J = 2.2 Hz, 4H, H_b). ^{13}C NMR ($CDCl_3$) δ (ppm): 33.61, 67.60, 69.59, 70.81, 70.84, 101.59, 107.87, 139.55, and 159.96 (9 peaks as required). MS (FAB) *m/z* (rel. int.): 721.2 $[M + H]^+$ (100%); HRFAB, calcd. for $C_{30}H_{42}Br_2O_{10}$: $[M + H]^+$ *m/z* 721.1222; found: 721.1214 (error 1.1 ppm).

Bis(5-formyl-*m*-phenylene)-32-crown-10 (21)

PCC (1.16 g, 5.38 mmol, 2.21 equiv.) was added to a solution of bis(5-hydroxymethyl-*m*-phenylene)-32-crown-10 (**19**, 1.45 g, 2.43 mmol) in DCM (20 mL). After 2 h the mixture was filtered and the solid washed with DCM. The solution upon concentration was passed through a short silica gel column with EtOAc as eluent to give a white solid. Recrystallization from acetone gave pure **21** (1.22 g, 85%), mp 92.3–95.8°C. ^{1}H NMR ($CDCl_3$) δ (ppm): 3.65–3.75 (m, 16H, γ,δ-CH_2), 3.86 (t, J = 4.6 Hz, 8H, β-CH_2), 4.12 (t, J = 4.6 Hz, 8H, α-CH_2), 6.73 (t, J = 2.2 Hz, 2H, H_a), 6.98 (d, J = 2.2 Hz, 4H, H_b), and 9.85 (s, 2H, CHO). ^{13}C NMR ($CDCl_3$) δ (ppm): 67.90, 69.52, 70.81, 70.88, 107.95, 108.24, 138.22, 160.33, and 191.84 (9 peaks as required). MS (FAB) *m/z* (rel. int.): 593.6 $[M + H]^+$ (100%); HRFAB, calcd. for $C_{30}H_{40}O_{12}$: $[M + H]^+$ *m/z* 593.2598; found: 593.2577 (error 3.5 ppm).

Bis[5-(*p*-nitrophenoxymethyl)-*m*-phenylene]-32-crown-10 (22)

NaH (0.108 g, 60%, 2.70 mmol) was added to a solution of bis(5-hydroxymethyl-*m*-phenylene)-32-crown-10 (**19**, 0.718 g, 1.20 mmol) in dry THF (20 mL). The mixture was heated at reflux for 3 h, cooled, treated with *p*-fluoronitrobenzene (0.30 mL, 2.8 mmol), and stirred at RT for 24 h. After solvent removal the residue was extracted with $CHCl_3$, evaporation of which gave crude **22**, a yellow solid, 1.0 g (100%). After silica gel column chromatography, using first Et_2O and then EtOAc

© 1997 NRC Canada

followed by recrystallization from acetone, pure **22**, mp 133.1–134.0°C, was obtained. ^{1}H NMR ($CDCl_3$) δ (ppm): 3.65–3.75 (m, 16H, γ, δ-CH_2), 3.83 (t, J = 4.8 Hz, 8H, β-CH_2), 4.06 (t, J = 4.8 Hz, 8H, α-CH_2,), 5.04 (s, 4H, CH_2), 6.43 (t, J = 2.0 Hz, 2H, H_a), 6.54 (d, J = 2.0 Hz, 4H, H_b), 6.98 (d, J = 9.1 Hz, 4H, Ar), and 8.17 (d, J = 9.1Hz, 4H, Ar). ^{13}C NMR ($CDCl_3$) δ (ppm): 67.63, 69.61, 70.44, 70.85, 101.09, 106.03, 114.86, 125.89, 137.77, 141.65, 160.28, 163.53 (12 peaks, 13 peaks theory). Anal. calcd. for $C_{42}H_{50}N_2O_{16}$: C 60.14, H 6.01, N 3.34; found: C 59.87, H 6.03, N 3.26.

Bis(5-acetoxymethyl-*m*-phenylene)-32-crown-10 (23)

To a solution of bis(5-hydroxymethyl-*m*-phenylene)-32-crown-10 (**19**, 0.581 g, 0.974 mmol) and pyridine (0.17 mL) in dry THF (75 mL) was added acetyl chloride (0.080 mL, 1.1 mmol) and the mixture was stirred at RT for 30 h. After filtration the solvent was evaporated. The residue was taken up in Et_2O. The solution was washed with H_2O (2 × 50 mL), 2 N HCl (30 mL), and H_2O, dried (Na_2SO_4), and rotary evaporated to give **23**, 0.65 g (98%), an oil that subsequently crystallized, mp 68.9–70.1°C. ^{1}H NMR ($CDCl_3$) δ (ppm): 2.05 (s, 3H, CH_3), 3.58–3.68 (m, 16H, γ, δ-CH_2), 3.79 (t, J = 4.8 Hz, 8H, β-CH_2), 4.07 (t, J = 4.8 Hz, 8H, α-CH_2), 4.99 (s, 4H, CH_2O), 6.45 (t, J = 2.0 Hz, 2H, H_a), and 6.52 (d, J = 2.0 Hz, 4H, H_b). ^{13}C NMR ($CDCl_3$) δ (ppm): 29.77, 66.23, 68.46, 70.27, 71.44, 71.47, 101.39, 107.33, 139.58, 161.14, 170.78 (11 peaks as required). MS (FAB) *m/z* (rel. int.): 680.4 $[M]^+$ (13%); HRFAB, calcd. for $C_{34}H_{48}O_{14}$: $[M]^+$ *m/z* 680.3044; found: 680.3022 (error 3.2 ppm).

Monosaccharide permethylation products for gas chromatography – mass spectrometry: how reaction conditions can influence isomeric ratios

Daniel Derbie Asres and Hélène Perreault

Abstract: Methylation analysis has been widely used for determination of carbohydrate structures by mass spectrometry. Permethylation of monosaccharides yields mixtures of anomeric pyranosides and furanosides. This paper discusses the influence of some of the permethylation reaction parameters on the proportions of isomeric products obtained. The ratios of three five- and six-membered ring products obtained from two permethylated monosaccharides, D-galactose and L-fucose, have been determined as a function of reaction parameters. The method of Ciucanu and Kerek (1) (methyl iodide in dimethyl sulfoxide (DMSO) in the presence of sodium hydroxide (NaOH)) was used as a starting point. The "conventional" method consists of mixing all of the reagents with the substrate and allowing the reaction to proceed with stirring. Both D-galactose and L-fucose under these conditions produced two main permethylated isomers, a furanoside and a pyranoside, along with two other minor isomeric components. We have investigated the effect on the proportion of products obtained of mixing DMSO, substrate, and NaOH for various times prior to the addition of methyl iodide. Results for D-galactose showed that shorter times enhanced the formation of permethylated furanoside isomers, while reducing the proportion of pyranosides. In other sets of experiments, the time and temperature of reaction, following the addition of methyl iodide, were studied. The indication is that 15 min are sufficient to produce complete methylation, with longer reaction times yielding the same results. Again for D-galactose, low reaction temperatures (ca. 10°C) favored formation of furanoside products. Higher temperatures yielded higher pyranoside/furanoside ratios. Higher quantities of NaOH also favored formation of the main galactopyranoside product. As for L-fucose, the ratio of the main furanoside vs. pyranoside products obtained by permethylation varied in a way similar to permethylated galactoside. Thus, higher temperatures and longer reaction times favored the main fucopyranoside product. Gentler conditions (i.e., shorter reaction times and lower temperatures) significantly favored the formation of the main fucofuranoside product. These results are interesting as they show the possibility of controlling the relative abundance of permethylated isomers of fucose and galactose. They also constitute a warning to chemists who use methylation procedures in their analyses, to the effect that permethylation products may vary considerably if the reaction conditions are not carefully controlled.

Key words: glucose, galactose, fucose, TLC, GC–MS, permethylation, monosaccharides.

Résumé : On a fait appel à la méthode fréquemment utilisée d'analyse par méthylation pour déterminer les structures de carbohydrates par spectrométrie de masse. La perméthylation des monosaccharides fournit des mélanges de pyranosides et de furanosides anomères. Dans ce travail, on discute de l'influence de quelques paramètres de la réaction de perméthylation sur les proportions des produits isomères obtenus. On a déterminé les rapports des trois produits à cinq et à six chaînons obtenus à partir de deux monosaccharides perméthylés, D-galactose et L-fucose, en fonction des paramètres de réaction. Comme point de départ, on a utilisé la méthode de Ciucanu et Kerek (iodure de méthyle dans le diméthylsulfoxyde (DMSO) en présence d'hydroxyde de sodium (NaOH)). La méthode «conventionnelle» consiste à mélanger tous les réactifs avec le substrat et à laisser la réaction se produire sous agitation. Dans ces conditions, le D-galactose et le L-fucose conduisent tous les deux à deux isomères perméthylés principaux, un furanoside et un pyranoside, avec deux autres composants isomériques mineurs. On a examiné l'influence que peut avoir le mélange du DMSO, du substrat et du NaOH, pour des temps variables avant l'addition de l'iodure de méthyle, sur la proportion des produits obtenus. Les résultats avec le D-galactose ont montré que les temps les plus courts augmentent la formation des isomères furanosides perméthylés avec une réduction concomitante de la proportion des pyranosides. Dans d'autres ensembles d'expériences, on a étudié l'influence du temps et de la température de la réaction après l'addition de l'iodure de méthyle. Les résultats indiquent que 15 min sont suffisantes pour conduire à une méthylation complète; des temps de réaction plus longs conduisent aux même résultats. Encore une fois, avec le D-galactose, les températures de réaction plus basses (environ 10°C) favorisent la formation de produits furanosides. Les températures plus élevées conduisent

à des rapports pyranoside/furanoside plus élevés. Des quantités plus élevées de NaOH favorisent aussi la formation de galactopyranoside comme produit principal. Dans le cas du L-fucose, le rapport du furanoside principal et des produits pyranosides obtenus par perméthylation varient d'une façon semblable à celle observée avec les galactosides perméthylés. Ainsi, aux températures les plus élevées et aux temps de réaction plus longs, les produits fucopyranosides principaux sont favorisés. Des conditions plus douces (c'est-à-dire des temps de réaction plus courts et des températures plus basses) favorisent fortement la formation du fucofuranoside comme produit principal. Ces résultats sont intéressants parce qu'ils démontrent la possibilité de contrôler les quantités relatives d'isomères perméthylés du fucose et du galactose. Ils constituent aussi un avertissement pour les chimistes qui utilisent les méthodes de méthylation dans leurs analyses; en effet, la nature des produits de perméthylation peut varier d'une façon significative si les conditions réactionnelles ne sont pas bien contrôlées.

Mots clés : glucose, galactose, fucose, CCM, CG–SM, perméthylation, monosaccharides.

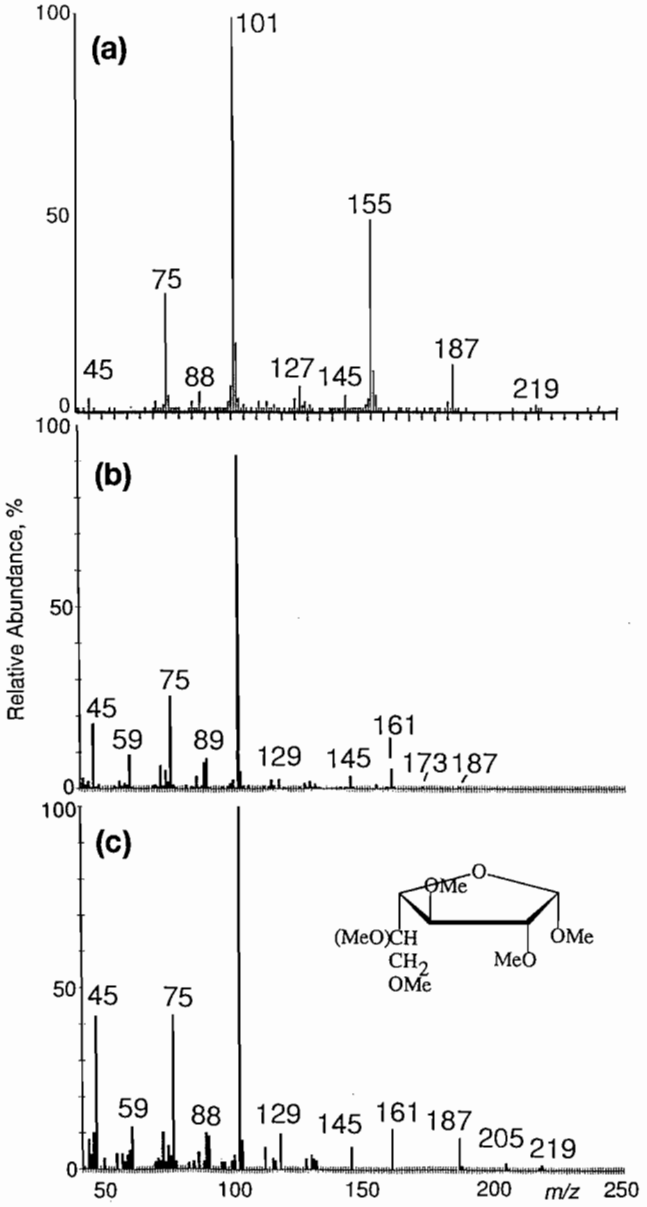
Introduction

The analysis of carbohydrates by mass spectrometric techniques often requires derivatization of the samples in order to enhance sensitivity and improve the quantity and quality of information obtained. The Ciucanu and Kerek (1) permethylation method figures amongst the most popular derivatization methods and has been used in many laboratories for the analysis of carbohydrates and glycolipids. This method yields fully methylated sugars in remarkably short reaction times, on the order of 15 min, based on optimal proportions of powdered sodium hydroxide (NaOH), dimethyl sulfoxide (DMSO), methyl iodide (CH_3I), and substrate.

In a recent publication (2), we discussed the gas chromatographic – mass spectrometric (GC–MS) data for permethylated monosaccharides and observed the presence of two or more isomeric products. Similar results had been reported earlier (3, 4). We observed that permethylated D-glucose, D-galactose, and L-fucose each yielded two major GC–MS peaks. In the case of D-glucose, the two peaks corresponded to the α and β anomers of the permethylated glucopyranoside species, as reported by Ciucanu and Kerek (1). In the cases of D-galactose and L-fucose, the two peaks had been tentatively assigned to pyranoside and furanoside, or open-ring structures (2), although the products were not fully characterized. Pyranoside-type products yielded electron impact (EI) mass spectra that corresponded quite well to the spectra found in the NIST library (5), while the other type of products (furanoside or open ring) could not be readily identified in the collection of reference spectra, including those of furanosides.

We have recently compared a collection of mass spectra of permethylated monosaccharides obtained using our Finnigan MAT 800 ion trap GC–MS system to those from our HP 5988A GC–MS system. We observed from this comparison that the Finnigan MAT system in general produced less fragmentation than the HP instrument, although similar ionization conditions (EI, 70 eV) were used. The nature of the fragment ions was also different from one instrument to the other. These differences agree well with the fact that some EI-formed ions can undergo chemical ionization or cooling while in the trap, thus producing different extents and patterns of fragmentation relative to EI-formed ions travelling through a magnetic sector or quadrupole mass analyzer. The HP spectra matched the NIST library spectra (5) much better and more reliably than the Finnigan MAT spectra, which were discussed in our previous publication (2). In general, we found that the EI spectra obtained with the ion trap system were not always reliable for identification of unknowns, or for diverse classes of compounds. From the HP data obtained with a quadrupole analyzer, we have reassigned the permethylation products of D-galactose and L-fucose as pyranosides and furanosides, eliminating the possibility of open-ring structures. As an example, Fig. 1 shows comparative spectra for a furanoside product from permethylation of D-galactose, where (*a*) is the Finnigan MAT-acquired spectrum, (*b*) is the HP-acquired spectrum, and (*c*) shows the library spectrum that best matched the HP spectrum. Library data (5) allowed for preliminary assignments of permethylation products. Accordingly, the compound of interest in Fig. 1 was identified as methyl 2,3,5,6-tetra-*O*-methyl-α-D-galactofuranoside (compound **3**). The other permethylation products of D-galactose were identified as methyl 2,3,5,6-tetra-*O*-methyl-β-D-galactofuranoside (compound **1**) and methyl 2,3,4,6-tetra-*O*-methyl-β-D-galactopyranoside (compound **2**). The retention times of these compounds using the Finnigan MAT system were on average 20:42, 20:50, and 21:00 min for **1**, **2**, and **3**, respectively. These identity assignments were confirmed with the use of the corresponding permethylated galactoside standards. Perfect matches between retention times and mass spectra were obtained between standards and galactose permethylation products.



The present paper discusses the influence of some of the permethylation reaction parameters on the proportions of compounds **1**, **2**, and **3** found. The overall quantity of compound **1**, a minor product, did not vary significantly with any of the parameters. The other expected product, methyl 2,3,4,6-tetra-*O*-methyl-α-D-galactopyranoside, was found only in relative amounts lower than 1% and eluting simultaneously with compound **2**.

In the case of L-fucose (6-deoxy-L-galactose), no reference mass spectra were available for preliminary identification of permethylated fucofuranoside anomers. In our earlier publication (2), we showed that permethylation of fucose produced two major products, and according to the features of their mass spectra, they should correspond to fucopyranose (compounds **4** and **5**, retention times 19:15 and 19:20) and fucofuranose structures (compound **6**, 19:30 min). In this paper, the proportions of these three compounds (**4**, **5**, and **6**) were determined as a function of reaction parameters. Further GC–MS experiments were performed with permethylated fucoside standards in order to confirm the identity of the products. Compounds **4**, **5**, and **6** were identified as methyl 2,3,4-tri-

Fig. 1. Mass spectra of product **3**, tentatively identified as permethylated α-D-galactofuranoside; (*a*) obtained using the Finnigan MAT ion trap system; (*b*) obtained with the Hewlett Packard system; and (*c*) from the spectrum library (5).

O-methyl β-L-6-deoxygalactopyranoside, methyl 2,3,4-tri-*O*-methyl α-L-6-deoxygalactopyranoside, and methyl 2,3,5-tri-*O*-methyl α-L-6-deoxygalactofuranoside, respectively. A fourth compound, methyl 2,3,5-tri-*O*-methyl β-L-6-deoxygalactofuranoside, was not taken into account as its relative abundance never exceeded 3%. This compound eluted earlier than the other three.

Permethylation of the monosaccharides D-galactose and L-fucose was carried out using the Ciucanu and Kerek (1) method, and the effects of varying the following parameters were investigated: time of mixing (of DMSO, NaOH, and monosaccharide) prior to addition of CH_3I, time of reaction in the presence of CH_3I, temperature of reaction, quantity of NaOH, and quantity of DMSO and CH_3I.

When saccharides are dissolved in solution there is a slow equilibration between anomeric forms as well as an equilibrium between pyrano- (six-membered ring) and furano- (five-membered ring) forms. Our results suggest that the nature of permethylation products depends on the proportions of the four possible species (or their anions) in solution at the time the CH_3I is added. These proportions are dependent on the length of time the solution is stirred before CH_3I is added, on the alkalinity of the solution, and on the temperature of the solution.

Experimental

Chemicals

Monosaccharide standards D-galactose (99.9%) and L-fucose (99%) were purchased from Sigma Chemicals (St. Louis, Mo.) and used without further purification. Dimethyl sulfoxide (DMSO) was obtained from Pierce Chemicals (Rockford, Ill.) and methyl iodide from Fluka (Buchs, Switzerland). All solvents (acetonitrile, methanol, dichloromethane, and chloroform) were glass-distilled and obtained from Mallinckrodt (Paris, Ky.). Distilled, deionized nanopure water was utilized.

Standards

Methyl D-galactopyranoside (α and β) and methyl L-fucopyranoside (α and β) were obtained from Sigma. Methyl D-galactofuranoside (α and β) and methyl L-fucofuranoside (β only) were purchased from Color Your Enzyme (Bath, Ont.). All of these standards were permethylated using the Ciucano and Kerek (1) method as outlined below. No anomerization and epimerization were observed according to GC–MS analyses, as a single sharp peak was obtained for each permethylated standard.

Permethylation

This derivatization was conducted using the method of Larsson et al. (6), which itself was adapted from Ciucanu and Kerek's method (1). Briefly, galactose or fucose (ca. 5 mg) was dissolved in (450–1000) μL of DMSO, followed by addition of (32–82) mg of powdered NaOH. The mixture was sonicated at room temperature (0–60 min). Methyl iodide (100–200 uL) was then added and the mixture was sonicated for (15–180) min at 10–50°C. The underlined numbers represent parameters used in our typical permethylation procedure, at room temperature. The extent of variation of each parameter is indicated by the two hyphenated numbers. Permethylated monosaccharides were recovered by chloroform or dichloromethane extraction.

Gas chromatography – mass spectrometry

The main GC–MS system used in this study consisted of a Varian 3400 gas chromatograph (Varian Chromatographic Systems, Walnut Creek, Calif.) coupled to a Finnigan Mat 800 ion trap detector (Finnigan Corp., San Jose, Calif.) equipped with an ITD 4.10 applications data system. The second system used was a HP 5890 gas chromatograph (Hewlett Packard Canada, Calgary, Alta.) coupled to a HP 5988A single quadrupole mass analyzer. For both GC–MS instruments, repetitive 1 s scans were effected on a range of 50–650 Da. Each gas chromatograph was equipped with a 30 m × 0.25 mm i.d. DB-5 column (J & W Scientific Inc., Folsom, Calif.), with a

0.25 mm film thickness. The oven temperature program was as follows: the initial temperature of 80°C was held for 10 min, followed by a linear temperature ramp to 260°C at a rate of 10°C/min, and was then held constant at 260°C for 10 min.

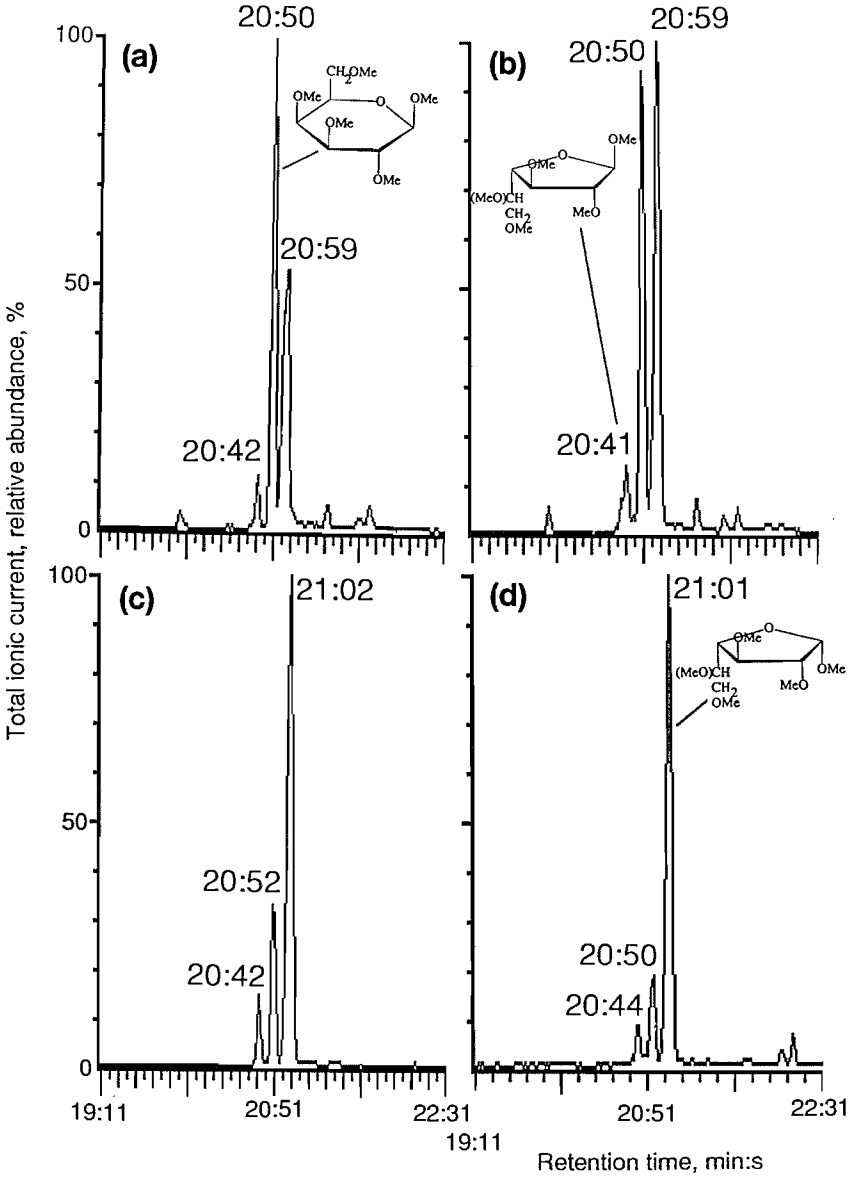
Results and discussion

The GC–MS trace that we had previously obtained for permethylated D-glucose (2) is very similar to the chromatogram published earlier by Ciucanu and Kerek (1), for the same compound. The trace (not shown) features two major peaks, which, according to these authors (1), respectively correspond to β- and α-glucopyranoside, in a ratio of ca. 2 to 1. The mass spectra obtained at the apex of each peak with our HP GC–MS system matched the NIST library spectra and suggested permethylated β- and α-glucopyranoside products for the respective peaks.

Ciucanu and Kerek (1) had briefly discussed the effect of pH on the equilibrium between the different forms of D-glucose in solution, but no specific details were given by these authors regarding the initial equilibrium in a basic solution of D-glucose in DMSO. More recently, Angyal (7) reported the proportions of glucopyranosides and glucofuranosides observed when D-glucose is dissolved in DMSO, without a base. The relative amounts reported were 45% α-glucopyranose and 55% β-glucopyranose, with no mention of the two other possible isomers. Proportions close to the above were also found when D-glucose was dissolved in pyridine. In this solvent, the amount of β-glucopyranose was decreased by 2% and both glucofuranosides made up for that 2%. These proportions, although measured in a nonbasic environment, reflect the numbers reported by Ciucanu and Kerek (1) and our laboratory (2) for the permethylated derivatives.

Permethylation products of D(+)-galactose

Angyal (7) also reported the following proportions for the forms of D-galactose in pyridine: 31% α-galactopyranose, 46% β-galactopyranose, 5% α-galactofuranose, and 18% β-galactofuranose, in comparison to 30, 64, 2.5, and 3.5%, respectively, in water (8). Unfortunately, no such data were given for galactose in DMSO. According to Ferrier and Collins (9), aprotic solvents (e.g., *N,N*-dimethylformamide (DMF) and DMSO) do not solvate sugars as well as water does, and as a consequence they enhance the anomeric effect and yield a higher proportion of five-membered ring compounds. The figures given above for galactose in pyridine agree with this statement.



As for the effect of a basic environment on the proportions of hexose species, it has been suggested (8) that in aqueous solution it will influence the rate of mutarotation, and thus the rate of approach of the anomers in solution to an equilibrium mixture. It is difficult to evaluate the pH values of basic solutions in DMSO, but typically DMSO solutions of NaOH are much more basic than the corresponding aqueous solutions. In assuming that the permethylation method of Ciucanu and Kerek (1) is performed at an effective pH > 14, substrates such as D-glucose (pK_a = 12.28) and D-galactose (pK_a = 12.30) should be in their monoanionic forms (10), if not dianionic. The proportions of anomeric anionic species, as opposed to electrically neutral species, has not been discussed in detail in the literature. The ability of hydroxide ions vs. silver, barium, and strontium oxides to act as acid receptors has been discussed as a possible factor influencing the proportions of ionic–nonionic substrate molecules in methylation reactions (9). According to Walker et al. (11), D-galactose, permethylated using methyl iodide and silver oxide, yields the following products: 80% α-D galactofuranoside, 10% β-D-galactofuranoside, and 10% (α and β)-galactopyranosides.

Gee (4) performed thin-layer chromatography on permethylated galactosides and reported separation into three spots, corresponding to β-D-galactofuranoside, α-D-galactofuranoside overlapping with β-D-galactopyranoside, and α-D-galactopyranoside. The compounds were prepared using Kuhn's procedure (12) (DMF as the solvent), and no mention of the relative proportions was made.

In our hands (2), using our former routine permethylation method (method 2 in Table 1), D-(+) galactose yielded two major products and a third minor component. A composition of (7 ± 2)% of galactofuranoside (**1**), (61 ± 2)% of galactopyranoside (**2**), and (32 ± 2)% of galactofuranoside (**3**) was found. Figure 2(*a*) shows the GC–MS total ion current (TIC) obtained from permethylation method 2 (Table 1) as a bench-

Fig. 2. Total GC–MS ion chromatograms obtained for the permethylation products of D-galactose. Refers to Table 1, (*a*) method 2, (*b*) method 3, (*c*) method 5, and (*d*) method 7. The three time-labelled peaks on each chromatogram correspond to products **1**, **2**, and **3**.

mark for starting the present investigation. A similar trace was obtained from method 1, which involved longer sonication times than method 2, both before and after addition of methyl iodide.

The influence of sonication time of the (DMSO–galactose–NaOH) mixture was originally investigated as part as an attempt to shorten the overall reaction time. This step was thus aimed at making the (DMSO–galactose–NaOH) solution as homogeneous and base saturated as possible. Interestingly, a shorter sonication time (see method 3, Table 1) was found to have an important impact on the nature of the products (Fig. 2(*b*)).

While initially performing the experiments, not much thought was given to the kinetics of mutarotation and anomerization at the pH and temperature used. Previous reports, however, demonstrated the importance of such factors. Collins and Ferrier (9) reported that when galactose is heated under reflux in methanol containing 2% HCl, 12 h or more are necessary to reach an equilibrium between the different glycoside forms. It seems reasonable to assume a similar situation exists for anionic galactose in basic solution, in which case the first sonication time involved in methods 1–3 would be too short for an equilibrium to be reached. If the addition of CH_3I "interrupts" the progression toward equilibrium, a systematic variation in the proportions of permethylated galactosides should be observed, as appears to be the case, from method 3 to method 1. The proportions of products **1** and **2** increase, while product **3** becomes less abundant.

Smirnyagin and Bishop (13) studied the kinetics of glycosylation of D-galactose. Their results confirmed an earlier observation for D-xylose (14): when D-galactose is subjected to methanolysis in methanolic HCl, galactofuranosides are preferentially formed first, and their relative concentrations decay as they isomerize into galactopyranoses or anomerize.

These authors also showed the effect of temperature on the relative concentrations of galactosides over more than 200 h.

It is clear that in a methanolic HCl solution, glycosides would be far from equilibrium after 45 min or 1 h of reflux, which corresponds more with our times used for the first sonication. Our experimental conditions are far different from those used by these authors (14). However, this rationalization helps in understanding that our starting material in alkaline DMSO is changing with time and temperature. Thus, method 3 yields different proportions of products relative to methods 2 and 1, which involve longer prereaction sonication times.

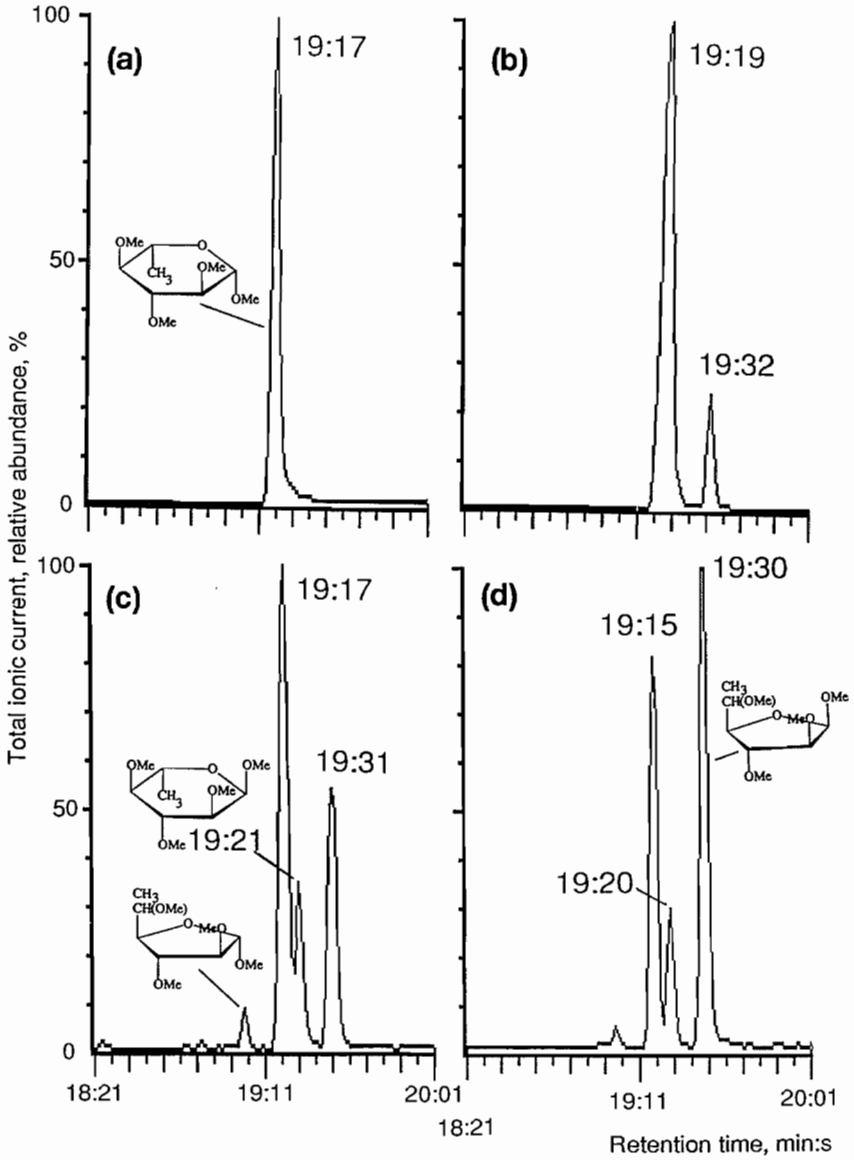
The sonication time was further reduced to zero with yet another increase in the proportion of α-galactofuranoside **3** to 71% of the total (see method 4, Table 1).

In the fifth experiment (see method 5, Table 1) the reaction time with CH_3I was reduced from 85 to 15 min. The results were very similar to those of method 4, indicating that the reaction was complete after 15 min. Figure 2(*c*) illustrates the results. Collins and Ferrier (8) indicated the possibility that permethylated hexosides may mutarotate in pyridine, but no mention was made of DMSO. The similarity in the proportion of products obtained with method 4 (85 min reaction time) and method 5 (15 min) suggests that no mutarotation took place once permethylation was complete.

When the amount of NaOH was increased (see method 6, Table 1), there was a small increase in the amount of β-galactopyranoside **2** (rt 20:50 min), at the expense of **1** and **3**. The effects of bases on hexoses in aqueous solutions are well documented (8). Epimerization, although it is the most common effect, did not seem to occur in our experiments. The permethylated hexosides obtained with methods 1–7 had GC retention times and mass spectra that characterized galactosides.

In aqueous solutions where the concentration of the base exceeds 1%, sugars may be converted into isomeric deoxyaldonic acids (saccharinic and isosaccharinic acids) (8). Also, prolonged treatment of hexoses with bases may yield 3-carbon fragments such as 2-hydroxypropionaldehyde, pyruvic acid, methyl glyoxal, and lactic acid (8). No such information could be found for solutions of sugars in DMSO. However, these facts may explain the presence of side products after long first sonication – reaction times. We made no further attempt to identify the side products, present at low levels relative to the galactosides (e.g., Fig. 2(*a*) and (*b*)).

The effect of altering the temperature of the methylation reaction was investigated next. In previous experiments (see methods 1–6, Table 1), the reactions were started at room temperature (ca. 22–25°C); however, the temperature of the sonication bath gradually increased, reaching 50°C after 1 h of reaction. Holding the temperature of this reaction constant at 50, 30, 20, 15, and 10°C showed that low temperatures (15 and 10°C) favored formation of the main galactofuranoside **3** and almost eliminated the six-membered ring species **2** (Fig. 2(*d*)). Temperatures above 15°C (20–50°C, methods 4 and 5) all yielded approximately the same proportions of products. Although the reaction appeared to be complete after 15 min at the lower temperatures, we felt that it was safer to allow 1 h for permethylation, as indicated in method 7, Table 1. We believe that a lower starting temperature will alter the initial proportions of galactosides, as observed by Smirnyagin and Bishop (13) for methyl galactosides at 25 and 44°C. Conducting permethylation at a low temperature, such as 10°C, is also likely to slow down by-product formation processes.



The effect of altering the amounts of DMSO and methyl iodide relative to the other reagents was also investigated. No significant changes in the nature or proportions of the products were observed.

Method 7 (Table 1) provided an 81% relative yield of galactopyranoside **3** (Fig. 2(*d*)), indicating that this method might be preparatively useful.

Vain attempts were made to prepare the galactopyranoside **2** *exclusively*. Large concentrations of NaOH and long sonication times before addition of methyl iodide were investigated, but the results were very similar to those of method 1, i.e., the relative yield of product **2** peaked at approximately 67%. The only effect associated with excess NaOH and long permethylation–sonication times was the appearance of small amounts of unidentified side products, possibly saccharic-type acids and smaller fragments as discussed above.

Permethylation products of L(−)-fucose

Results from the GC–MS TIC trace previously obtained for the three major products of permethylated L(−)-fucose (2) are reported in Table 2, method 11. A minor peak appears first and corresponds to a permethylated fucofuranoside. This product has not been taken into account in the following discussion since it constitutes less than 3% of the total product mixture. With method 11, fucopyranosides **4** and **5** made up 54% of the three main products, with the remainder (46%) being the fucofuranoside anomer **6**. The permethylated fucopyranosides **4** and **5** were first tentatively identified by library comparison to the spectra obtained on the HP system (5), as methyl 2,3,4-tri-*O*-methyl-6-deoxy-β- and α-galactopyranosides. Although no library spectra were available for permethylated fucofuranosides, they were identified by the similarity of spectral features between the fucose and galactose-derived products: permethylated fuco- and galactofuranosides each yield a main peak at *m/z* 101. More systematic identification was carried out with the use of the corresponding standards.

Varying the reaction parameters for the permethylation of L(−)-fucose was accomplished based on the results obtained for D(+)-galactose. Hence, the relative amounts of DMSO, CH_3I, NaOH, and fucose used remained constant in all experiments. These quantities are indicated in Table 2. Parameters subjected to variation were: time of first sonication, reaction time, and temperature. Table 2 lists nine different methods, along with the corresponding proportions of products (**4**, **5**, and **6**) obtained. In methods 8–12, fucose, NaOH, and DMSO were sonicated prior to addition of CH_3I. The general trend shows increasing proportions of **5** and **6** relative to **4** with shorter prereaction sonication times. In methods 13–15, the first sonication step was omitted and the reaction time was incremented. Longer reaction times (25 min, method 14 and 60 min, method 15) had the effect of increasing the propor-

© 1997 NRC Canada

tions of **4** vs. **5** and **6**, i.e., the effect was similar to that of longer first sonication times. Lowering the reaction temperature (method 16) favored product **6**, and brought down the relative concentration of **4** from that observed using method 15. Interestingly, the relative proportion of product **5** was not significantly altered with methods 11–16.

The results obtained from methods 8 and 9 (e.g., Fig. 3(*a*)) suggest that longer mixing times of the (fucose–DMSO–NaOH) solution yield 100% of β-fucopyranoside, neutral or anionic, prior to the addition of CH_3I. Methods 8 and 9 are therefore advisable if preparation of β-fucopyranoside as a single isomer is desired.

Shorter mixing of the ternary solution, as in methods 10–13, showed a change in the proportions of fucosides, with a tendency towards α-fucopyranoside **5** and fucofuranoside **6** relative to the previously predominant β-fucopyranoside. Figure 3(*b*) illustrates this trend. Here compound **5** is a minor constituent and has not been resolved from **4**. The slight shoulder at the right base of the peak assigned to **4** led us to assign a proportion of 4% to compound **5**.

So far, these results are in agreement with the general trend observed for the galactose permethylation reactions. However, much less information is available about the chemistry of fucose in solution than about galactose and therefore interpretation of the results is more difficult.

In methods 8–13, we estimated that a 15 min reaction time was the minimum required to ensure complete permethylation of the sugar. We also assumed that no further isomerization took place once the products were formed. In methods 14 and 15, where the reaction time was deliberately pushed above 15 min, isomerization seemed to occur, either during permethylation itself, or once the reaction was completed. It could also be possible that one (or more) of the isomers is selectively being degraded. This would change the ratio of isomers and give the impression that equilibration between isomers was occurring. This process overall favored product **4**, to the detriment of **5** and **6** (Fig. 3(*c*)).

Lowering the reaction temperature as in method 16 seemed to slow down the process and the proportions were pushed in favor of product **6**. Figure 3(*d*) shows the corresponding chromatogram.

Conclusion

It has been shown that permethylation conditions, based on the method of Ciucanu and Kerek (1), have a profound influence on the composition of the products obtained from permethylation of D-galactose and L-fucose. For both of the monosaccharides, permethylation produced a mixture of four isomers: two pyranoside and two furanoside α and β anomers. In each case, three compounds out of the four were predominant and well separated on the GC–MS chromatograms. The fourth component in each case was very minor and its proportions did not appear to vary from one set of conditions to another. Changes in the relative proportions of the three main compounds were reported as different reaction parameters were varied. The most influential parameter appeared to be the time the DMSO solution of the sugar and NaOH was mixed by sonication before reaction with methyl iodide. The initial temperature of reaction also had an important effect. It is assumed that these two parameters influenced the initial proportion of the four possible isomers, or isomeric anions, of the monosaccharides in solution prior to permethylation.

In both cases (galactose and fucose), formation of the β-pyranoside product was noticeably favored when longer pre-reaction sonication times and higher temperatures were used. Opposite trends in the conditions favored formation of the α-furanoside product.

Above all, it has been shown that care has to be taken when performing permethylation of sugars as a routine operation. The reaction conditions must be very carefully controlled in order to obtain reproducible meaningful results.

Substituent effects on the reactivity of the silicon–carbon double bond. Arrhenius parameters for the reaction of 1,1-diarylsilenes with alcohols and acetic acid

Christine J. Bradaric and William J. Leigh

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12

Abstract: Absolute rate constants for the reaction of a series of ring-substituted 1,1-diphenylsilene derivatives with methanol, *tert*-butanol, and acetic acid in acetonitrile solution have been determined using nanosecond laser flash photolysis techniques. The three reactions exhibit small positive Hammett ρ-values at 23°C, consistent with a mechanism involving initial, reversible nucleophilic attack at silicon to form a σ-bonded complex that collapses to product via rate-limiting proton transfer. Deuterium kinetic isotope effects and Arrhenius parameters have been determined for the reactions of 1,1-di-(4-methylphenyl)silene and 1,1-di-(4-trifluoromethylphenyl)silene with methanol, and are compared to those for the parent compound. Proton transfer within the complex is dominated by entropic factors, resulting in negative activation energies for reaction. The trends in the data can be rationalized in terms of variations in the relative rate constants for reversion to reactants and proton transfer as a function of temperature and substituent. A comparison of the Arrhenius activation energies for reaction of acetic acid with 1,1-diphenylsilene (E_a = +1.9 ± 0.3 kcal/mol) and the more reactive di-trifluoromethyl analogue (E_a = +3.6 ± 0.5 kcal/mol) suggests that carboxylic acids also add by a stepwise mechanism, but with formation of the complex being rate determining.

Key words: silene, substituent effects, kinetics, Arrhenius, flash photolysis.

Résumé : Faisant appel aux techniques de photolyse éclair avec laser à la nanoseconde, on a déterminé les constantes de vitesse absolues pour les réactions d'une série de 1,1-diphénylsilènes substitués sur le cycle avec le méthanol, le *tert*-butanol et l'acide acétique en solutions dans l'acétonitrile. À 23°C, les trois réactions présentent des valeurs ρ de Hammett faiblement positives qui sont en accord avec un mécanisme impliquant une attaque initiale nucléophile réversible au niveau du silicium qui conduit à la formation d'un complexe à liaison σ qui se décompose en produit par le biais d'un transfert de proton qui est cinétiquement limitant. On a déterminé les effets isotopiques cinétiques du deutérium ainsi que les paramètres d'Arrhenius pour les réactions du 1,1-di-(4-méthylphényl)silène et du 1,1-(di-4-trifluorométhylphényl)silène avec le méthanol et on les a comparés avec les valeurs correspondantes du composé parent. Le transfert de proton dans le complexe est dominé par des facteurs entropiques; ceci conduit à des valeurs négatives pour les énergies d'activation de ces réactions. On peut rationaliser les tendances dans ces résultats en termes de variations dans les constantes de vitesse relatives pour la retransformation en réactifs et celle du transfert de proton en fonction de la température et du substituant. Une comparaison des énergies d'activation d'Arrhenius pour la réaction de l'acide acétique avec le 1,1-diphénylsilène (E_a = +1,9 ± 0,3 kcal/mol) et celle avec l'analogue plus réactif ditrifluorométhyle (E_a = +3,6 ± 0,5 kcal/mol) suggère que les acides carboxyliques s'additionnent aussi par un mécanisme par étapes; toutefois la formation du complexe serait toutefois l'étape cinétiquement limitante.

Mots clés : silène, effets de substituants, cinétique, Arrhenius, photolyse éclair.

[Traduit par la rédaction]

Introduction

The best-known reactions of silenes are [2+2]-dimerization and nucleophilic addition of alcohols (1–3). Since the very first experimental demonstrations that silenes are formed as reactive intermediates in the thermolysis (4) and (or) photolysis (5, 6) of silacyclobutanes and disilanes, the formation of 1,3- or 1,2-disilacyclobutanes from dimerization or alkoxysilanes from trapping with alcohols have come to be identified as classic indicators of silene involvement in the reactions of organosilicon compounds.

From a mechanistic standpoint, the reaction with alcohols has been more extensively studied (7–17). Wiberg published the first experimental evidence that alcohol nucleophilicity — and not acidity — is the main factor affecting the kinetics of the reaction, and suggested a mechanism involving complex-

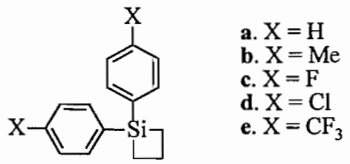
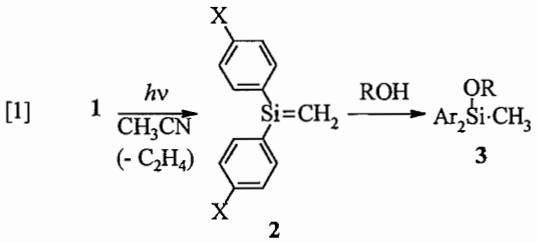


Scheme 1.

ation of the alcohol at silicon followed by proton transfer from oxygen to carbon (8). This was soon followed by reports of examples of both nonstereoselective (9) and stereoselective (11) alcohol additions, as well as an indication that in cases where more than one regio- or stereoisomeric product can be formed, the product distribution can vary with alcohol concentration (12). Sakurai and co-workers published the first comprehensive mechanism to explain these results (13), in a study of the effects of alcohol concentration on the ratio of *syn* and *anti* adducts obtained from reaction of various aliphatic alcohols with a cyclic, disilane-derived silene reactive intermediate. They proposed a refined version of Wiberg's mechanism, in which reaction is initiated with formation of a silene–alcohol complex, which proceeds to product by competing intracomplex (*syn*) and extracomplex (*anti*) proton-transfer pathways. The latter involves a second molecule of alcohol and hence increases in importance with increasing alcohol concentration. We have published kinetic and product studies for other transient silenes that support this mechanism (see Scheme 1), with the additional requirement that formation of the silene–alcohol complex be fully reversible (14–20). For each of the reactive silenes that we have studied, variations in solvent polarity and alcohol nucleophilicity, acidity, and isotopic substitution affect the kinetics and product distribution in ways that are fully compatible with this mechanism.



While theory suggests that substituents that reduce the natural polarity of the Si=C bond should lead to lower reactivity toward nucleophilic addition (10, 21), there has been little experimental effort directed toward developing a quantitative understanding of the effects of polar factors on silene reactivity. One relatively straightforward way of undertaking such a study would be through investigation of a series of ring-substituted 1,1-diphenylsilene derivatives (**2**), which might be generated by photolysis of the corresponding 1,1-diarylsilacyclobutanes (**1**) (6, 16, 17, 22–24). We have previously shown that the parent compound, 1,1-diphenylsilacyclobutane (**1a**), is a convenient source of 1,1-diphenylsilene (**2a**) for time-resolved spectroscopic studies, and have reported kinetic studies of the reactions of this silene with alcohols and acetic acid (16, 17).

In this paper, we report a study of the effects of ring substituents on the rate constants for addition of methanol, *tert*-butanol, and acetic acid to 1,1-diphenylsilene. We have employed the photocycloreversion of the series of 1,1-diarylsilacyclobutanes **1** to generate the corresponding silenes (**2**) in acetonitrile solution (eq. [1]), and have measured absolute rate constants, deuterium kinetic isotope effects, and Arrhenius parameters for reaction with these three reagents.

Results

Compounds **1b–e** were synthesized from 1,1-dichlorosilacyclobutane and the appropriate aryl magnesium bromide, using a method similar to that reported for the parent compound **1a** (17, 25). They were purified by column chromatography to >99% purity, and exhibited spectral and analytical data that are consistent with their assigned structures.

Direct irradiation of **1b–e** (0.007–0.013 M) in the presence of 0.05 M methanol results in the formation of the corresponding alkoxysilanes **3b–e** in high chemical yields.[2] No other products were observed in significant yield from the photoly-

[2] The 4,4′-dimethoxy analogue of **1** was also synthesized, but steady state photolysis of the compound under the same conditions yielded a number of products in minor yields. Furthermore, no evidence for the formation of the corresponding silene could be obtained by flash photolysis of the compound.

sis of any of the four compounds below ~40% conversion. The alkoxysilanes were isolated from the crude photolysis mixtures by semi-preparative GC, and identified on the basis of their NMR, IR, and mass spectra.

Nanosecond laser flash photolysis of continuously flowing, air-saturated solutions of **1b–e** (0.003–0.006 M) in acetonitrile affords weak, but readily detectable transient absorptions (λ_{max} ~ 325 nm) that decay with clean pseudo-first-order kinetics to within 10% of the pre-pulse level. The transients exhibit lifetimes in the 150–250 ns range in acetonitrile dried by distillation from calcium hydride, but these were extended to the 2–3 μs range using more scrupulously dried (i.e., $\leq 10^{-4}$ M water) samples of the solvent. The UV absorption spectra, lifetimes, and kinetic response of the transients to added silene quenchers (vide infra) are similar to those reported previously for 1,1-diphenylsilene, formed by photolysis of **1a** under similar conditions (17), and we thus assign them to the corresponding 1,1-diarylsilenes **2b–e**. For example, Fig. 1 shows the time-resolved UV absorption spectrum of **2e**, recorded 80–240 ns after the laser pulse for an air-saturated solution of **1e** in acetonitrile. As expected (17, 24), the lifetimes of the transients were not measurably shortened upon saturation of the solutions with oxygen.

Addition of methanol, *tert*-butanol, acetic acid, or water to the acetonitrile solutions of **1b–e** resulted in a reduction in the lifetimes of the 325-nm transient absorptions, consistent with their assignment to the silenes **2b–e**. Plots of the rate constant for decay (k_{decay}) versus concentration of added quencher (ROH) according to eq. [2] (where k_0 is the first-order rate constant for the decay of the transient in the absence of added quencher and k_{ROH} is the second-order quenching rate constant) were linear in all cases. Typical plots are shown in Fig. 2 for quenching of the four silenes by methanol. Similar experiments were carried out using MeOD, *t*-BuOD, and AcOD for **2b,e**. The absolute rate constants for reaction of silenes **2b–e** with MeOH, *t*-BuOH, and AcOH in acetonitrile are collected in Table 1, along with k_H/k_D values calculated from the data for the protiated and deuterated reagents. The corresponding data for **2a** (17) are included in the table for comparison.

Fig. 1. Time-resolved UV absorption spectrum recorded at 23 ± 1°C by nanosecond laser flash photolysis of an air-saturated acetonitrile solution of 1,1-di(4-trifluoromethylphenyl)silacyclobutane (**1e**, 0.0042 M). The spectrum was recorded over a time window of 80–240 ns after the laser pulse. The insert shows a typical decay trace, recorded at a monitoring wavelength of 325 nm.

[2] $k_{decay} = k_0 + k_{ROH}[ROH]$

Absolute rate constants for reaction of silenes **2b** and **2e** with MeOH in acetonitrile were determined at several temperatures between −20°C and 55°C. Similar experiments were carried out for reaction of **2a** with MeOD and **2e** with HOAc in acetonitrile. The Arrhenius plots for quenching by MeOH(D) are shown in Fig. 3, along with that reported previously for quenching of **2a** by MeOH (16). Figure 4 shows the Arrhenius plots for quenching of **2a** (16) and **2e** with HOAc. Linear least-squares analysis of these data afforded the Arrhenius parameters collected in Table 2. In the case of **2e**–MeOH, only the data for temperatures above 13°C were employed for calculation of the Arrhenius parameters listed in the table. The Arrhenius plot for diffusion in acetonitrile, calculated using the modified Debye equation ($k_{diff} = 8RT/3000\eta$) and values

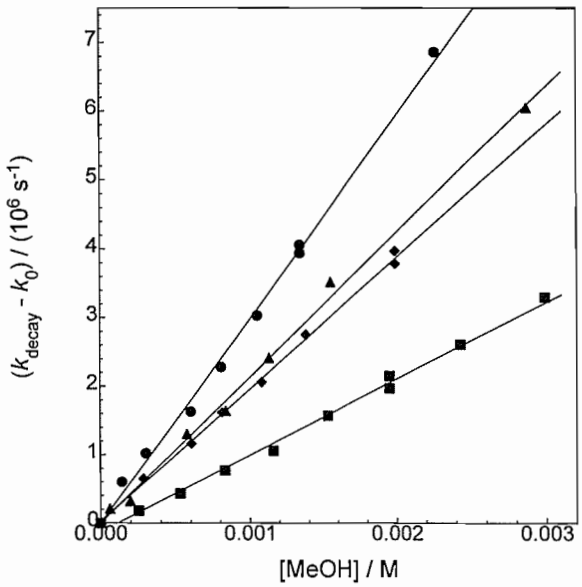
Fig. 2. Plots of ($k_{decay} - k_0$) versus [MeOH] from laser flash photolysis of air-saturated acetonitrile solutions of **1b–e** in the presence of methanol (X = Me, ■; X = F, ◆; X = Cl, Δ; X = CF_3, ●).



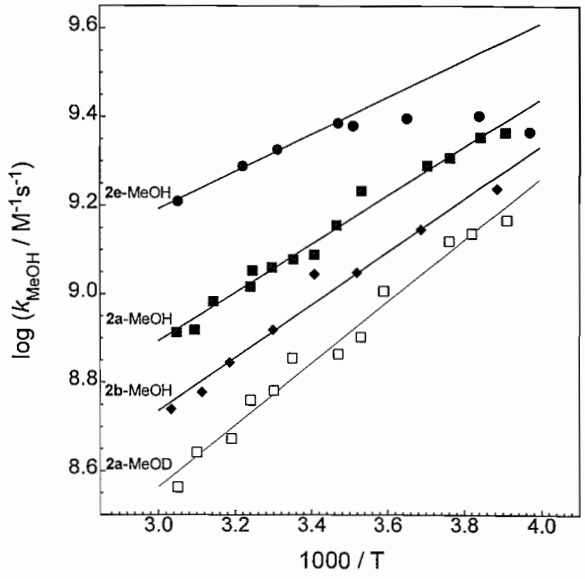


Fig. 3. Arrhenius plots for quenching of 1,1-diarylsilenes **2a** (X = H; ■), **2b** (X = Me; ◆), and **2e** (X = CF_3; ●) by methanol and **2a** by methanol-*O*-*d* (□) in acetonitrile solution. The **2a**-MeOH data are from ref. 16.

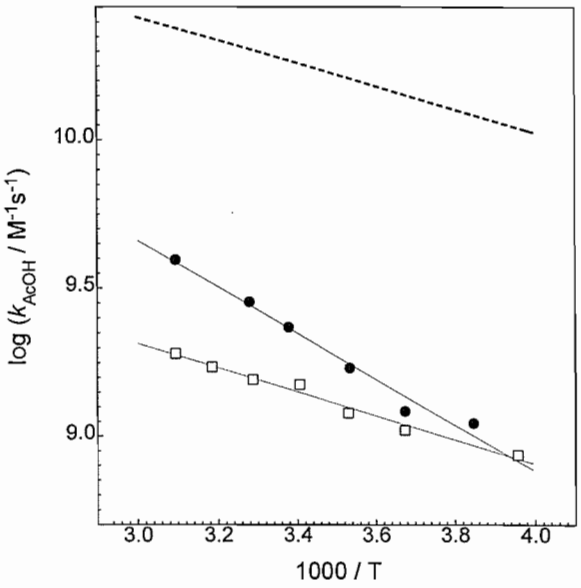
of η extrapolated from published temperature–viscosity data (26), is included in Fig. 4. Arrhenius parameters for addition of methanol to **2a** were also determined in hexane solution, from data recorded over a temperature range of −6–40°C. The values obtained are $E_a = -2.7 \pm 0.3$ kcal/mol and $\log A = 7.40 \pm 0.26$ ($r^2 = 0.996$). The rate constant for reaction at 23°C was found to be $(2.9 \pm 0.3) \times 10^9$ M^{-1} s^{-1}, in satisfactory agreement with our previously determined value (17).



Addition of 0.5 M methanol to nitrogen-saturated acetonitrile or hexane solutions of **1a,d,e** — enough to reduce the lifetimes of the corresponding silene to $\tau < 10$ ns — allowed the detection of weak residual signals that decayed with pseudo-first-order kinetics and lifetimes of 0.5–2 μs. The intensity of this signal was greatest in the case of the *para*-chloro compound **1d**, and for all three compounds was greater in hexane than in acetonitrile. The time-resolved absorption spectra of these transients showed $\lambda_{max} \sim 360$ nm in all cases, and the lifetimes proved to be sensitive to the presence of oxygen or 1,3-octadiene. Plots of the observed transient decay rate constants versus diene concentration were linear, and afforded quenching rate constants in the range $(3–4) \times 10^9$ M^{-1} s^{-1} in hexane solution at 23°C. On the basis of these data, the transients observed under these conditions are assigned to the silacyclobutane triplet states. Addition of 0.01 M 1,3-octadiene to nitrogen-saturated solutions of **1a–e** in the absence of methanol resulted in no discernible change in either the lifetime or the initial absorbance of the transient signal assigned to the corresponding silene (at 325 nm), indicating that the formation of the silene does not involve the triplet state of the disilacyclobutane.

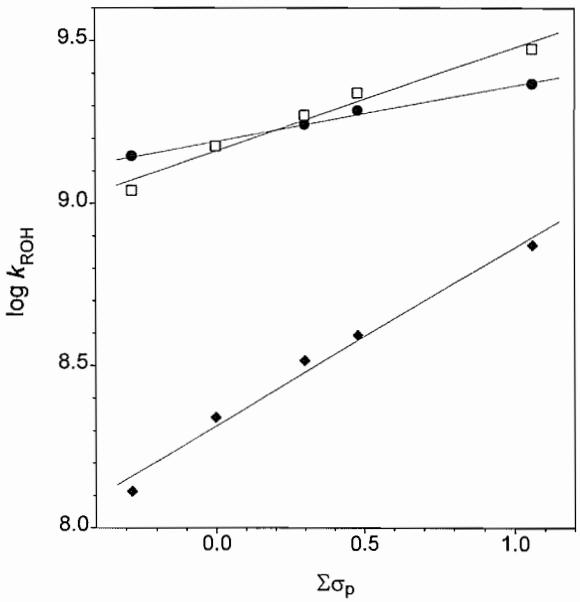
Fig. 4. Arrhenius plots for quenching of 1,1-diphenylsilene (**2a**; □) and 1,1-di-(4-trifluoromethylphenyl)silene (**2e**; ●) by acetic acid in acetonitrile solution. The data for **2a** are from ref. 16. The broken line corresponds to that for diffusion in acetonitrile, calculated using the modified Debye equation and published viscosity data (see text).

Discussion

The four substituted 1,1-diarylsilacyclobutanes studied in this work all exhibit analogous photochemical behaviour to that of the parent compound, 1,1-diphenylsilacyclobutane (**1a**). All five compounds yield the corresponding methoxydiarylmethylsilane (**3**) in high chemical yield upon direct irradiation in hexane or acetonitrile solution in the presence of methanol or other silene traps (27), consistent with the formation of the corresponding 1,1-diarylsilene (**2**). The rates of formation of the alkoxysilanes from photolysis of **1a–e** indicate that there is no appreciable variation throughout the series in the quantum yield for silene formation ($\Phi_2 = 0.24 \pm 0.03$ in the case of **1a** (17)). Intersystem crossing to yield the silacyclobutane triplet state also occurs, but this is relatively minor and is clearly unrelated to the formation of the silene by cycloreversion in the lowest excited singlet state.

The five silenes exhibit similar behaviour as well; they all exhibit long-wavelength absorption bands with $\lambda_{max} \sim 325$ nm, decay with pseudo-first-order kinetics in dried acetonitrile in the absence of (intentionally) added trapping reagents, and exhibit lifetimes in the 2–3 μs range. These lifetimes probably reflect limiting quenching by residual water in the solvent; since quenching of **2a** by water is as fast as by methanol (17), a concentration of only $\sim 10^{-4}$ M would result in a lifetime in the microsecond range. In agreement with this, the lifetimes vary slightly through the series, with that of **2b** being the longest and that of **2e** the shortest. The normal fate of **2a** in the absence of traps is dimerization (23, 25, 28), which should result in second-order decay kinetics. However, even in sodium-dried hexane, silene **2a** decays with mixed second- and pseudo-first-order kinetics. We conclude that dimerization of these silenes is relatively slow, probably due to steric factors.

The addition of alcohols to reactive silenes has received a great deal of attention over the past several years (7–17). As shown in Scheme 1, the mechanism is thought to involve initial nucleophilic attack at silicon followed by proton transfer from oxygen to carbon. A mechanism involving a silenium ion, formed by initial protonation at carbon, can be ruled out simply by the fact that the rate of reaction generally does *not* depend in a straightforward way on ROH acidity; the more important factor appears to be nucleophilicity (8, 14, 15, 17). The overall rate constant generally exhibits a small primary deuterium isotope effect, indicating that the initial intermediate (a zwitterionic silene–alcohol "complex") reverts to the free silene and alcohol at least as fast as it collapses to alkoxysilane by proton transfer (14, 15, 17). The involvement of this intermediate is further suggested by the fact that silenes characteristically form complexes with ethers (29). As well, several reactive silenes (including **2a**) have been found to exhibit negative activation energies in their reactions with methanol and (or) *tert*-butanol (16, 20, 30). While this is a common feature of fast reactions that proceed by mechanisms of this general type (31–40), it does not in itself rule out the possibility that the reaction proceeds by a concerted mechanism (32, 35, 37, 41–43).



The best evidence for the intermediacy of the σ-bonded complex in alcohol additions to silenes is the fact that the product distribution quite commonly varies with bulk alcohol concentration (12, 13, 15, 17). There is good evidence to suggest that this is due to proton transfer proceeding by two competing pathways: a unimolecular pathway involving [1,3]-proton migration within the complex, and a bimolecular pathway involving a second molecule of alcohol. This aspect of the mechanism was originally proposed on the basis of a study of the addition of various aliphatic alcohols to a cyclic transient silene, where it was found that for methanol, the stereochemistry of addition depends on bulk alcohol concentration (13). *syn*-Addition predominates at low alcohol concentrations where the intracomplex (unimolecular) proton transfer pathway should be operative, while *anti*-addition predominates at high alcohol concentrations due to increased importance from the extracomplex proton transfer pathway. *tert*-Butanol was found to add with 100% *syn*-stereochemistry at all alcohol concentrations, indicating that it reacts only by the unimolecular pathway in this particular case. Other workers, including us, have reported analogous concentration dependences in the *regio*chemistry of addition of aliphatic alcohols to conjugated silenes (12, 15). In the case of **2a**, the competing proton transfer pathways manifest themselves in competition experiments with methanol and *tert*-butanol, where the yield of the methanol adduct (relative to the *tert*-butanol adduct) increases with increasing bulk alcohol concentration (17). Sakurai and co-workers originally proposed that the bimolecular pathway involves protonation at carbon followed by rapid deprotonation from oxygen (13), but solvent and deuterium isotope effect studies seem more compatible with a deprotonation–protonation sequence (15, 17).

Kinetic studies have also provided evidence for a mechanism involving mixed first- and second-order dependences on alcohol concentration (14, 15), in the form of a quadratic variation in the pseudo-first-order rate constant for silene consumption (k_{decay}) with [ROH]. The expression shown in eq. [3], derived using the steady state assumption for the complex, collapses to a simple quadratic expression in [ROH] under

Fig. 5. Hammett plots for quenching of 1,1-diarylsilenes by MeOH (□), *t*-BuOH (◆), and AcOH (●) in acetonitrile solution.

conditions where reversion of the complex to reactants is significantly faster than proton transfer (i.e., $k_{-1} > (k_2 + k_3[ROH])$) and uni- and bimolecular proton transfer proceed with comparable rate constants. Behaviour of this type has been reported for silenes in which conjugating substituents on the silenic carbon (14, 15) stabilize the complex toward intramolecular proton transfer. Simpler silenes such as **2a** (17) and others (16, 17, 20, 30)[3] exhibit higher overall reactivity toward alcohols, and show linear dependences of k_{decay} on [ROH] over the alcohol concentration ranges that can be studied using nanosecond time-resolved techniques.

$$[3] \quad k_{decay} = k_0 + \frac{k_1[ROH]}{(k_{-1} + k_2 + k_3[ROH])}(k_2 + k_3[ROH])$$

Not surprisingly, the latter behaviour is also observed for **2b–e** for quenching by both MeOH and *t*-BuOH (Fig. 2). It indicates that over the concentration ranges employed for our kinetic measurements (<0.01 M for MeOH; <0.05 M for *t*-BuOH), reaction occurs predominantly by the intracomplex proton transfer pathway for both alcohols. Under these conditions, the expression for k_{decay} simplifies to that in eq. [4].

$$[4] \quad k_{decay} = k_0 + \frac{k_1 k_2}{k_{-1} + k_2}[ROH]$$

The trends in the observed rate constants for reaction of **2a–e** with MeOH and *t*-BuOH indicate that electron-withdrawing substituents at silicon increase silenic reactivity toward alcohols, providing additional evidence for a mechanism in which nucleophilic attack at silicon precedes protonation at carbon. Hammett plots, shown in Fig. 5, afford ρ-values of +0.31 and +0.55 for reaction with MeOH and *t*-BuOH, respectively. The difference between the ρ-values for the two alcohols is small, presumably because the overall rate constants for both alcohols are so large. However, the effect is slightly greater for the less reactive alcohol, as would be expected.

To a first approximation, these reaction constants can be viewed as the sum of those of the individual complexation and proton transfer steps (see Scheme 1). The ρ-value for the complexation step would clearly be expected to be positive, while that for the proton transfer step should be small because the process involves charge neutralization within the zwitterionic complex. Thus, the positive overall reaction constants can be interpreted as reflecting mainly the effects of substituents on the initial reaction of the silene with the neutral nucleophile. This has obvious analogies to Michael addition reactions and, indeed, the addition of various nucleophiles such as amines (44), cyanide ion, and enolates (45) to substituted β-nitrostyrenes exhibit Hammett ρ-values in the range +0.2–1 depending on the nucleophile and the solvent.

The trend in the k_H/k_D values for reaction of methanol with **2a–e** (decreasing with increasing substituent electron-withdrawing power; see Table 1) can be explained in terms of variations in the relative magnitudes of the rate constants for reversion of the complex to reactants (k_{-1}) and collapse to product (k_2), since the isotope effect on k_1 should be a secondary one and indistinguishable from unity. The overall isotope effect is predicted to be a maximum in the limit of $k_{-1} >> k_2$ (i.e., fully reversible complex formation) and reduce in magnitude as k_{-1} decreases and (or) k_2 increases. Only a secondary isotope effect should be obtained in the limit of $k_2 >> k_{-1}$, where complex formation is fully rate determining. The data are consistent with an increase in the ratio k_2/k_{-1} with increasing substituent electron-withdrawing power, a trend which also manifests itself in the Arrhenius behaviour of the reactions of MeOH with **2a**, **2b**, and **2e**.

A reaction proceeding by a mechanism of the general type shown in Scheme 1 will exhibit a negative Arrhenius activation energy if the free energy of activation for the second step (in this case, proton transfer) is dominated by the entropic term, so that the enthalpy of the transition state is lower than that of the reactants. In addition, the first step must be reversible; i.e., reversion of the intermediate to reactants (k_{-1}) must be faster than its collapse to product (k_2) (31). If the opposite is true, then the first step is clearly the rate-determining step for reaction and the overall activation energy will be positive, of a value equal to or greater than that of diffusion (E_{diff}). The changeover from the situation where $k_{-1} >> k_2$ (E_a at the maximum negative value) to that where $k_{-1} << k$ (E_a at the maximum positive value) arises because the two reaction channels available to the intermediate have opposing entropic requirements (i.e., $\Delta S_{-1}^{\neq} > 0$ and $\Delta S_2^{\neq} < 0$) and the enthalpic barrier for product formation is small. Provided that a large enough temperature range can be spanned experimentally, the Arrhenius plot for a situation of this type should thus be bell shaped, with the region of the apex in the plot corresponding to the temperature range where k_{-1} is comparable to k_2 (34, 36). In the present case where the second step involves proton transfer, the primary isotope effect on k_{obs} would be predicted to decrease with decreasing temperature from its maximum value at the high-temperature limit (i.e., where $k_{-1} >> k_2$),

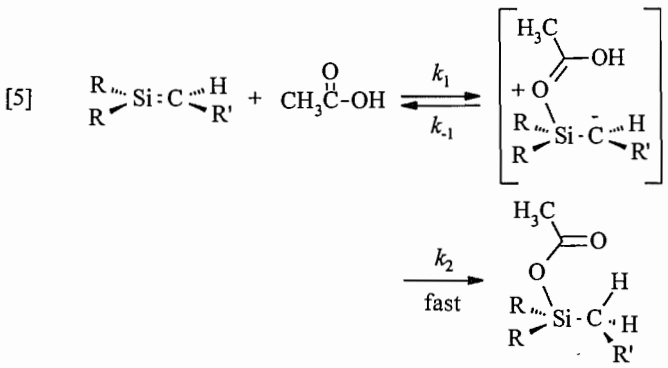
reducing to a secondary effect as k_2 overtakes k_{-1} in magnitude.



The Arrhenius plot for reaction of **2e** with methanol (Fig. 3) shows precisely this behaviour, exhibiting an apparent negative activation energy at temperatures above ~13°C and distinct curvature over the −20–13°C temperature range as the rate of product formation (k_2) approaches and then surpasses that of reversion of the complex to reactants. The less negative value of the high-temperature E_a observed for this compound compared to those for **2a,b** probably results from the fact that complex formation is not fully reversible over the limited "high-temperature" range examined. In the case of **2a**, and more so with **2b**, k_{-1} is proportionately larger than k_2 over our high-temperature range, resulting in larger negative values of the apparent activation energy. Silene **2e** exhibits no significant deuterium isotope effect at 23°C, because this temperature is within the range where the rate constant is starting to be dominated by that of complex formation. We have not measured k_H/k_D at higher temperatures for this derivative, but as Fig. 3 illustrates, the deuterium kinetic isotope effect on the reaction of the parent compound (**2a**) with methanol increases as predicted with increasing temperature. The difference in the slopes of these two lines is significant at the 95% confidence level.

The relative placement of the Arrhenius plots shown in Fig. 3 for **2e**, **2a**, and **2b** can also be explained simply in terms of a successive decrease in the magnitude of k_2/k_{-1} throughout the series **2e** > **2a** > **2b**, as the trend in the isotope effects suggests. One might also expect the rate constant for complex formation (k_1) to decrease in the same order, provided that it is not diffusion controlled; this would contribute to the relative placement of the Arrhenius plots in the same way as the proposed variation in k_2/k_{-1}. Unfortunately, determination of k_1 for these compounds would require rate constant measurements at temperatures that are considerably below the present capability of our system. Given the placement of the −20°C point in relation to the apex of the plot, the measured value of k_{obs} for **2e** at −20°C (~ 2.2×10^9 M^{-1} s^{-1}) is expected to be a factor of 2–3 lower than the actual value of k_1 for this compound at this temperature. This suggests that $k_1 \sim 5 \times 10^9$ M^{-1} s^{-1}, a value very close to the diffusional rate constant (k_{diff} ~ 1×10^{10} M^{-1} s^{-1}), calculated using the modified Debye equation ($k_{diff} = 8RT/3000\eta$) and a value of η extrapolated from published temperature–viscosity data (26). Given the assumptions inherent in the Debye treatment, we conclude that formation of the methanol complex of **2e** is subject to at most a small barrier in excess of that of diffusion. The fact that the low-temperature data for the three compounds are clearly not converging to a single line suggests that k_1 is somewhat sensitive to substituent, and provides a better indication that, in general, the rate constant for complex formation is lower than that of diffusion.

The observed rate constant for reaction of **2a** with MeOH is about a factor of two higher in hexane than in acetonitrile, which is somewhat surprising since the more polar solvent might be expected to enhance reactivity through stabilization of the complex relative to reactants. However, the fact that the apparent E_a is less negative in acetonitrile than in hexane suggests that the opposite is true, probably as a result of weak Lewis acid–base complexation between the nitrile solvent and the silene.

Acetic acid invariably reacts with silenes with clean overall second-order kinetics, and rate constants that are generally larger than those for reaction with methanol (14, 15, 19). However, the reaction does not exhibit an isotope effect distinguishable from unity and, with **2a**, it exhibits a small positive Arrhenius activation energy (16). In this case, the carbonyl oxygen is the likely site of bonding to silicon, in which case proton transfer would occur via a six-membered transition state. The data are compatible with a stepwise mechanism analogous to that for alcohol additions, but with complex formation being fully rate determining. Complex formation should be slower with HOAc than MeOH because of its lower nucleophilicity (as estimated from the pK_b's in acetonitrile (46)), while proton transfer would clearly be expected to be much faster. However, it is difficult to rule out a concerted mechanism in this case since little isotope effect would be expected for such a strongly exothermic reaction.

The Hammett ρ-value of +0.17 observed for the reactions of **2a–e** with HOAc at 23°C indicates the reaction to be relatively insensitive to polar factors, a result which seems more consistent with a concerted addition mechanism. However, the fact that the Arrhenius activation energy for addition to the most reactive compound (**2e**) is *higher* than that of **2a** indicates otherwise. As mentioned above, the full Arrhenius plot is expected to be bell shaped, with an extended temperature region where the mechanistic changeover occurs from rate-determining proton transfer (at high temperatures) to rate-determining complex formation (at low temperatures). The smaller apparent activation energy observed for **2a** may result

[5] 

simply from the fact that the temperature range monitored is within that over which reversion of the complex to reactants is still marginally competitive with collapse to product. With **2e**, a larger k_1 and larger k_2/k_{-1} ratio would result in a shift in the "peak" of the Arrhenius plot to higher temperatures (as is observed for MeOH addition). Thus, over the temperature range monitored for the two compounds, we are simply observing the region of steeper temperature dependence of k_{obs} in the case of **2e**, compared to the situation with **2a**. If this explanation is correct, then the measured Arrhenius parameters for **2e** ($E_a = 3.6 \pm 0.5$; log A = 12.0 ± 0.4; $\Delta S^{\neq}_{23C} = -6 \pm 2$ cal deg^{-1} mol^{-1}) more closely reflect those for formation of its complex with HOAc than do those for **2a** ($E_a = 1.9 \pm 0.2$; log $A = 10.5 \pm 0.2$; $\Delta S^{\neq}_{23C} = -12.5 \pm 0.9$ cal deg^{-1} mol^{-1}). The activation energy for reaction of **2e** is significantly higher than that for diffusion ($E_a = 1.8 \pm 0.4$; log $A = 11.6 \pm 0.5$), indicating the presence of a small enthalpic barrier for complex formation. The data of Fig. 4 indicate that the sensitivity

© 1997 NRC Canada

of the overall rate constant for HOAc addition to ring substituents increases at higher temperatures, where reversibility of complex formation is a more important contributor to the magnitude of k_{obs}.

Summary and conclusions

The effects of ring substituents on the rate constants, deuterium kinetic isotope effects, and Arrhenius parameters for addition of aliphatic alcohols to 1,1-diphenylsilene are most easily explained in terms of a mechanism involving fast, reversible formation of a zwitterionic silene–alcohol complex, followed by rate-limiting proton transfer from oxygen to carbon (Scheme 1). Because the Arrhenius activation energies for the reaction with methanol are consistently negative, little quantitative information on the enthalpies and entropies of activation for the individual steps in the sequence can be obtained. Nevertheless, the variation in Arrhenius behaviour and isotope effect as a function of substituent indicates that electron-withdrawing substituents at silicon increase both the rate at which the complex is formed and the relative rates of its collapse to alkoxysilane product and reversion to starting materials. In extreme cases, this results in a change in the identity of the slower step from proton transfer to complex formation over the temperature range studied (−20–50°C), allowing observation of the bell-shaped Arrhenius plot that is predicted for a mechanism of this type.

Addition of acetic acid, which yields the corresponding acetoxyaryldimethylsilane (17), proceeds with overall rate constants that are similar in magnitude to those for methanol addition but vary less with substituent ($\rho = +0.17 \pm 0.02$). These reactions exhibit isotope effects indistinguishable from unity and positive Arrhenius activation energies, consistent with complex formation being rate determining. The activation energy for reaction *increases* with increased silene reactivity, which is most easily explained in terms of the stepwise mechanism. Our results indicate there to be a small but significantly higher enthalpic barrier to complex formation than is the case for methanol addition.

Further studies of the effects of substituents on the reactivity of the Si=C bond are in progress in our laboratory.

Experimental

NMR spectra were recorded in deuteriochloroform and are referenced to tetramethylsilane. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AC200 spectrometer, while ^{29}Si NMR spectra were recorded on Bruker DRX500 or AC300 spectrometers in deuterated chloroform solution; all are referenced to tetramethylsilane. Ultraviolet absorption spectra were recorded on Hewlett–Packard HP8451 or Perkin Elmer Lambda 9 spectrometers. Low-resolution mass spectra were determined by GC–MS, using a Hewlett–Packard 5890II gas chromatograph equipped with a HP-5971A mass selective detector and DB-5 fused silica capillary column (30 m × 0.25 mm; Chromatographic Specialties, Inc). High-resolution desorption electron impact (DEI) mass spectra and Exact Masses were recorded on a VGH ZABE mass spectrometer. Exact Masses employed a mass of 12.000000 for carbon. Infrared spectra were recorded as thin films on a BioRad FTS-40 FTIR spectrometer and are reported in wave numbers (cm^{-1}).

Analytical gas chromatographic analyses were carried out using a Hewlett–Packard 5890 gas chromatograph equipped with conventional heated splitless injector, a flame ionization detector, a Hewlett–Packard 3396A integrator, and a DB1701 megabore capillary column (15 m × 0.53 mm; Chromatographic Specialties, Inc.). Semi-preparative gas chromatographic separations were carried out using a Varian 3300 gas chromatograph equipped with a thermal conductivity detector and a metal column (3% OV 101 on Chromosorb W, HP 80/100; 6 ft × 0.25 in; Chromatographic Specialties, Inc.).

Acetonitrile (BDH or Caledon Reagent) was refluxed over calcium hydride (Fisher) for several days, distilled under dry nitrogen, and then cycled three times through a 1 in. × 6 in. column of neutral alumina (Aldrich) that had been activated by heating under vacuum (ca. 0.05 Torr; 1 Torr = 133.3 Pa) at 320°C for 10 h with periodic shaking. Methanol (Sigma Aldrich HPLC; <0.05% H_2O) and *tert*-butyl alcohol (Sigma Aldrich HPLC; <0.05% H_2O) were stored over activated 4 Å molecular sieves. Hexane (EM Science Omnisolv), glacial acetic acid (Caledon Reagent), and deuterated reagents (Isotec, Inc.) were used as received from the suppliers.

The 1,1-diarylsilacyclobutanes **1b–1e** were prepared from 1,1-dichlorosilacyclobutane and the appropriate aryl magnesium bromide, according to the published method for **1a** (17, 25). The only significant variation in procedure was the reaction time, which decreased from 8 h for **1b** to 5 h for **1e**. The diarylsilacyclobutanes were obtained as colourless oils, in yields of 50–90% after purification by column chromatography on silica gel. Each contained <0.01% of the corresponding 1,1-biaryl derivative as determined by capillary gas chromatography. Spectral and analytical data for the diarylsilacyclobutanes are listed below.

*1,1-Di-(4-methylphenyl)silacyclobutane (**1b**)*: IR: 3067 (s), 3035 (s), 3013 (s), 2990 (s), 1603 (s), 1501 (s), 1394 (s), 1121 (s), 1081 (s), 854 (s), 716 (s), 634 (s); ^{1}H NMR, δ (ppm): 1.45 (t, 8.2 Hz, 4 H), 2.23 (p, 8.4 Hz, 2H), 2.36 (s, 6H), 7.20 (d, 7.8 Hz, 4H), 7.50 (d, 7.7 Hz, 8H); ^{13}C NMR, δ (ppm): 14.0, 18.3, 21.7, 128.8, 133.0, 134.6, 139.6; ^{29}Si NMR, δ (ppm): 6.51; MS, *m/e* (*I*): 252 (15), 226 (22), 224 (100), 211 (12), 209 (48), 160 (10) 119 (8). *1,1-Di-(4-trifluoromethylphenyl)silacyclobutane (**1e**)*: IR: 2974 (s), 2931 (s), 1392 (s), 1324 (s), 1166 (s), 1104 (s), 1060 (s), 1019 (s), 827 (s), 704 (s); ^{1}H NMR, δ (ppm): 1.56 (t, 8.3 Hz, 4 H), 2.31 (p, 8.3 Hz, 2H), 7.66 (d, 8.0 Hz, 4H), 7.72 (d, 8.0 Hz, 4H); ^{13}C NMR, δ (ppm): 13.6, 18.4, 124.1, 124.7, 132.0, 134.7, 140.4; ^{19}F NMR, δ (ppm): −62.7 (s); ^{29}Si NMR: δ (ppm): 7.73; MS, *m/e* (*I*): 360 (10), 341 (12), 333 (22), 332 (100), 319 (20), 317 (6), 263 (15), 251 (10), 173 (15), 140 (30). Exact Mass, calcd. for $C_{17}H_{14}SiF_6$: 360.0769; found: 360.0766.

Steady-state photolysis experiments were carried out using a Rayonet reactor containing five RPR2537 lamps. Quartz tubes (25 cm × 1.2 cm) containing hexane solutions (ca. 20 mL) of **1b–e** (0.007–0.013 M) and 0.05 M methanol were sealed with rubber septa and irradiated for 70–110 min, resulting in 40–75% conversion of **1** to a single detectable product in each case. The volatiles were stripped from the photolysates on the rotary evaporator, and the products were isolated by semipreparative GC. They were identified as **3b–e** on the basis of the following data.

*Di-(4-methylphenyl)methoxymethylsilane (**3b**)*: IR: 2959 (s), 2927 (s), 2860 (m), 1601 (m), 1550 (m), 1254 (m), 1112 (m), 1088 (m), 1006 (m), 979 (m); ^{1}H NMR, δ (ppm): 0.59 (s, 3H), 2.35 (s, 6H), 3.51 (s, 3H), 7.20 (d, 7.7 Hz, 4H), 7.49 (d, 7.8 Hz, 4H); ^{13}C NMR, δ (ppm): −3.4, 21.5, 46.2, 128.7, 133.3, 134.8, 139.8; ^{29}Si NMR, δ (ppm): −0.96; MS, *m/e* (*I*): 256 (6), 242 (21), 241 (100), 212 (5), 211 (23), 165 (11), 131 (11), 119 (13), 105 (8), 93 (6), 91 (7), 65 (5). Nanosecond laser flash photolysis experiments employed the pulses (248 nm; ca. 16 ns; 70–120 mJ) from a Lumonics 510 excimer laser, filled with F_2/Kr/He mixtures, and a microcomputer-controlled detection system (47). The system incorporates a brass sample holder whose temperature is controlled to within 0.1°C by a VWR 1166 constant-temperature circulating bath. Solutions were prepared at concentrations such that the absorbance at the excitation wavelength (248 nm) was ca. 0.7 (0.004 M) and were flowed continuously through a 3 × 7 mm Suprasil flow cell connected to a calibrated 100 mL reservoir. Solution temperatures were measured with a Teflon-coated copper–constantan thermocouple that was inserted directly into the flow cell. Quenchers were added directly to the reservoir by microlitre syringe as aliquots of standard solutions. Rate constants were calculated by linear least-squares analysis of decay rate – concentration data (6–10 points), which spanned at least a factor of 5 (usually more than 1 order of magnitude) in the transient decay rate. Errors are quoted as twice the standard deviation obtained from the least-squares analysis in each case.

Abstract: Experimental solubilities are reported for anthracene dissolved in eight binary mixtures containing 2-isopropoxyethanol with 1-propanol, 2-propanol, 1-butanol, 2-butanol, 1-pentanol, 2-pentanol, 3-methyl-1-butanol, and 1-octanol at 25°C. Results of these measurements, along with previously published solubility data for anthracene in binary alcohol + alkoxyalcohol (2-methoxyethanol, 2-ethoxyethanol, 2-propoxyethanol, 2-butoxyethanol, 3-methoxy-1-butanol) solvent mixtures, are used to test the limitations and applications of expressions derived from Mobile Order theory. For the 50 different binary solvent systems considered, the derived expressions were found to provide reasonably accurate predictions for the observed anthracene solubility behavior, with the average absolute deviation between measured and predicted values being on the order of 3% or less. A single numerical value of K_{eq} = 5000 cm^3 mol^{-1} was assumed for all self-association and cross-association hydrogen-bond stability constants.

Key words: anthracene solubilities, alcohol solvents, solubility predictions, hydrogen-bonding, model.

Résumé : On a mesuré les solubilités expérimentales, à 25°C, de l'anthracène dans huit mélanges binaires formés de 2-isopropoxyéthanol + propan-1-ol, propan-2-ol, butan-1-ol, butan-2-ol, pentan-1-ol, pentan-2-ol, 3-méthylbutan-1-ol ou octan-1-ol. Utilisant les résultats de ces mesures, de concert avec les données de solubilité publiées antérieurement pour l'anthracène dans des mélanges binaires de solvants formés d'alcool + alkoxyalcool (2-méthoxyéthanol, 2-éthoxyéthanol, 2-propoxyéthanol, 2-butoxyéthanol, 3-méthoxybutan-1-ol), on évalue les limitations et les possibilités d'appliquer des expressions dérivées de la théorie de l'ordre mobile. Pour les 50 systèmes de solvants binaires considérés, on a trouvé que les expressions dérivées permettent de faire des prédictions assez correctes pour la solubilité de l'anthracène; la déviation absolue moyenne entre les valeurs mesurées et prédites sont de l'ordre de 3% ou moins. On a utilisé une seule valeur numérique, K_{eq} = 5000 cm^3 mol^{-1}, pour toutes les constantes de stabilité des liaisons hydrogènes auto-associées et à association croisée.

Mots clés : solubilités de l'anthracène, solvants alcooliques, prédictions des solubilités, liaison hydrogène, modèle.

[Traduit par la rédaction]

Introduction

Solid–liquid equilibrium data of organic nonelectrolyte systems are becoming increasingly important in the petroleum industry, particularly in light of present trends towards heavier feedstocks and known carcinogenicity/mutagenicity of many of the larger polycyclic aromatic compounds. Solubility data for a number of polycyclic aromatic hydrocarbons (i.e., anthracene and pyrene) and heteroatom polynuclear aromatics (i.e., carbazole, dibenzothiophene, and xanthene) have been published in the recent chemical literature (for listing of references see Acree (1–3)). Despite efforts by experimentalists and scientific organizations, both in terms of new experimental measurements and critically evaluated data compilations, there still exist numerous systems for which solubility data are not readily available.

To address this problem, researchers have turned to predictive methods as a means to generate desired quantities. Numerous equations have been suggested for predicting solute solubilities in binary solvent mixtures. For the most part, the predictive methods do provide fairly reasonable estimates for noncomplexing systems. There still remains, however, the need to develop better predictive expressions and mixing models to describe the more nonideal complexing systems believed to contain hydrogen-bonding solvent components. Hydrogen bonding that occurs in mixtures of alcohols is an example of specific interaction in that highly "preferential" contacts between proton-donor and proton-acceptor sites of neighboring alcohol molecules are established. The resulting H-bonds are labile. During their lifetime they confer a higher degree of "order" to the liquid solution. The order introduced in the liquid by the formation of H-bonds and the perpetual movement of the H-bonds constitute the basic foundations of Mobile Order theory (4–13).

The thermodynamics of Mobile Order expresses the equilibrium condition in terms of time fractions for the time schedule of a given molecule, and not in terms of concentrations of various entities in the ensemble. Thus, in the case of alcohols and alkoxyalcohols one considers the time fraction $\gamma_{Ch:}$ and not the concentrations of the various *i*-mers in the ensemble (this does not mean that these *i*-mers do not exist, but their concentrations do not govern the thermodynamic probability). $\gamma_{Ch:}$ is the fraction of the time during which a given molecule of the ensemble is free from H-bonding. The given molecule does not possess the energy of the H-bond. But it is by no means the fraction of the time during which the molecule is free at both sides. A molecule bonded at one side is free from H-bonding only half of the time.

Ruelle et al. (6, 7, 14–17) have presented a very impressive set of comparisons between experimental and predicted solubilities for anthracene, naphthalene, pyrene (see also Powell et al. (18)), biphenyl, carbazole, benzil (see also Fletcher et al. (19)), *p*-benzoquinone, thianthrene (see also Fletcher et al. (20)), tricosane, octacosane, 10-nonadecanone, 11-heneicosanone, and 12-tricosanone in a wide range of both noncomplexing and complexing solvents to document the predictive ability of Mobile Order theory. More recently, Acree and co-workers successfully extended Mobile Order theory to binary alkane + alcohol (21), alcohol + alcohol (22–24) and alcohol + 2-alkoxyethanol (25) solvent mixtures. Derived expressions predicted anthracene solubilities in 35 binary alcohol + alcohol and 32 binary alcohol + 2-alkoxyethanol mixtures to within an overall average absolute deviation between predicted and observed mole fraction solubilities of about 1.6 and 3.0%, respectively. A single numerical value of $K_{Alcohol}$ = 5000 cm^3 mol^{-1} was assumed for the association constant of the nine monofunctional alcohols and of the four 2-alkoxyethanol cosolvents studied.

In the present communication, we expand the list of cosolvents studied to include branched alkoxyalcohols. Only linear 2–alkoxyalcohols were considered in the earlier comparison involving Mobile Order theory. Experimental solubilities are reported for anthracene dissolved in eight binary alcohol + 2-isopropoxyethanol solvent mixtures containing 1-propanol, 2–propanol, 1-butanol, 2-butanol, 1-pentanol, 2-pentanol, 3-methyl-1-butanol and 1-octanol at 25°C. Results of these measurements, combined with recently published anthracene solubility data for alcohol + 3-methoxy-1-butanol solvent mixtures (26), are used to further assess the limitations and applications of predictive expressions derived from Mobile Order theory.

Experimental methods

Anthracene (Acros, 99.9+%) was recrystallized several times from acetone. 2–Isopropoxyethanol (Aldrich, 99+%), 1-propanol (Aldrich, 99+%, anhydrous), 2-propanol (Aldrich, 99+%, anhydrous), 1-butanol (Aldrich, HPLC, 99.8%), 2-butanol (Aldrich, 99+%, anhydrous), 1-pentanol (Aldrich, 99+%), 2-pentanol (Acros, 99+%), 3–methyl-1-butanol (Aldrich, 99+%, anhydrous), and 1–octanol (Aldrich, 99+%, anhydrous) were stored over anhydrous sodium sulfate and molecular sieves before use. Gas chromatographic analysis showed solvent purities to be 99.5 mol% or better. Karl Fischer titrations gave water contents (mass/mass%) of <0.01% for the nine alcohols. Binary solvent mixtures were prepared by mass so that compositions could be calculated to ±0.0001 mole fraction.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature water bath at (25.0 ± 0.1)°C with periodic agitation for at least 3 days (often longer). Attainment of equilibrium was verified both by repetitive measurements after a minimum of 3 additional days and by approaching equilibrium from supersaturation by preequilibrating the solutions at a higher temperature. Aliquots of saturated anthracene solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample and were diluted quantitatively with methanol for spectrophotometric analysis at 356 nm on a Bausch and Lomb Spectronic 2000. Concentrations of the dilute solutions were determined from a Beer–Lambert law absorbance versus concentration working curve. Molar absorptivities of the nine standard solutions varied systematically with molar concentration, and ranged from about ε(L mol^{-1} cm^{-1}) = 7450 to ε(L mol^{-1} cm^{-1}) = 7150 for anthracene concentrations ranging from $C(M) = 6.75 \times 10^{-5}$ to $C(M) = 2.25 \times 10^{-4}$. Identical molar absorptivities were obtained for select anthracene standard solutions that contained up to 5 vol% of the neat alcohol cosolvents. Experimental molar concentrations were converted to (mass/mass) solubility fractions by multiplying by the molar mass of anthracene, volume(s) of volumetric flask(s) used, and any dilutions required to place the measured absorbances on the Beer–Lambert law absorbance versus concentration working curve, and then dividing by the mass of the saturated solution analyzed. Mole fraction solubilities were computed from (mass/mass) solubility fractions using the molar masses of the solute and solvent. Experimental anthracene solubilities in the eight binary solvent mixtures studied are listed in Table 1. Numerical values represent the average of between four and eight independent determinations, with the measured values being reproducible to within ±1.5%.

Results and discussion

In the case of an inert solute dissolved in a binary solvent mixture containing either two monofunctional self-associating alcoholic solvent components or containing a monofunctional self-associating alcohol + alkoxyalcohol, Mobile Order theory may take one of two different paths, depending upon how one models the hydrogen bonding. The simplest predictive treatment (22) expresses the volume fraction solubility of the solute ϕ_A^{sat}:

$$\begin{aligned}[1]\quad \ln \phi_A^{sat} = {} & \phi_B^\circ \ln (\phi_A^{sat})_B + \phi_C^\circ \ln (\phi_A^{sat})_C - 0.5\,[\ln (x_B^\circ V_B \\ & + x_C^\circ V_C) - \phi_B^\circ \ln V_B \\ & - \phi_C^\circ \ln V_C] + (V_A K_B \phi_B^\circ/V_B^2)(1 + K_B/V_B)^{-1} \\ & - [V_A K_B \phi_B^{\circ 2}/V_B^2](1 + \phi_B^\circ K_B/V_B)^{-1} \\ & + (V_A K_C \phi_C^\circ/V_C^2)(1 + K_C/V_C)^{-1} \\ & - [V_A K_C \phi_C^{\circ 2}/V_C^2](1 + \phi_C^\circ K_C/V_C)^{-1} \\ & + V_A \phi_B^\circ \phi_C^\circ (\delta_B' - \delta_C')^2 (RT)^{-1}\end{aligned}$$

in terms of the measured solubility data in both pure solvents,

$(\phi_A^{sat})_B$ and $(\phi_A^{sat})_C$. (The various symbols used in eq. [1] and in subsequent expressions are defined in the Appendix.) The alcohol(s) and alkoxyalcohol(s) are permitted to retain their own individual chemical identity and are allowed to form homogeneous self-associated hydrogen bonds with surrounding solvent molecules of the same type. Formation of heterogeneous hydrogen bonds between two dissimilar solvent molecules is not allowed.

Monofunctional alcohols and alkoxyalcohols do form self-associated species, and there is no a priori experimental evidence or computational reason to preclude formation of heterogeneous B_iC_j complexes, particularly if we are using a single equilibrium constant to describe the self-association characteristics of every monofunctional alcohol and alkoxyalcohol. Such mixtures are characterized not only by the presence of long H-bonded chains of the type

wherein hydrogen bonding occurs through the hydroxyl group, but also by chains

involving hydrogen bonding through the ether linkage. From the point of view of Mobile Order theory, both scenarios lead

For personal use only.

to extension of the H-bonded chain. The maximum possible number of hydrogen bonds formed in any given solution depends upon the chemical nature of the various compounds present. Monofunctional alcohols have one hydrogen "donor" site and the lone pairs on the oxygen atom provide two "acceptor" sites. Alkoxyalcohols have two additional donor sites provided by the lone electron pairs on the ether oxygen atom. Molar concentrations of the hydroxylic OH and ether O donor sites are equal in the case of alkoxyalcohols, and it is expected that hydrogen bonding should occur largely through the hydroxylic OH groups because of its much greater K_C stability constant. Calculated Mobile Order theory stability constants for hydrogen bond formation involving alcohols and ethers typically range between K_{eq} = 100 and 300 cm^3 mol^{-1} (12, 27). Close proximity of the OH and O functional groups may further encourage proton fixation at the OH "acceptor" site.

The fraction of time that the alcohol (B)

$$[2]\quad \gamma_{Bh:} = 1/[1 + K_B\,\phi_B/V_B + K_{BC}\,\phi_C/V_C + K_{OBC}\,\phi_C/V_C] = 1/[1 + K_B\,\phi_B/V_B + (K_{BC} + K_{OBC})\,\phi_C/V_C]$$

and 2-alkoxyethanol (C) molecules

$$[3]\quad \gamma_{Ch:} = 1/[1 + K_{CB}\,\phi_B/V_B + K_C\,\phi_C/V_C + K_{OC}\,\phi_C/V_C] = 1/[1 + K_{CB}\,\phi_B/V_B + (K_C + K_{OC})\,\phi_C/V_C]$$

are not involved in hydrogen-bond formation is given by eqs. [2] and [3], respectively. For convenience, two "pseudo" equilibrium/stability constants K^*_{BC} and K^*_C are now defined such that $K^*_{BC} = K_{BC} + K_{OBC}$ and $K^*_C = K_C + K_{OC}$. It can be readily shown that this set of conditions leads to the following expressions for the Gibbs energy

$$\begin{aligned}[4]\quad G = {} & n_A\,\mu^\circ_A + n_B\,\mu^\circ_B + n_C\,\mu^\circ_C + n_B\,RT\ln\gamma_{Bh:} \\ & + n_C\,RT\ln\gamma_{Ch:} + 0.5\,RT\,\{n_A\ln\phi_A + n_B\ln\phi_B \\ & + n_C\ln\phi_C + n_A\ln x_A + n_B\ln x_B + n_C\ln x_C\} \\ & + (n_AV_A + n_BV_B + n_CV_C)[\phi_A\,\phi_B\,(\delta'_A - \delta'_B)^2 \\ & + \phi_A\,\phi_C\,(\delta'_A - \delta'_C)^2 + \phi_B\,\phi_C\,(\delta'_B - \delta'_C)^2]\end{aligned}$$

and saturation solubility of a sparingly soluble solute

$$\begin{aligned}[5]\quad \ln\phi_A^{sat} = {} & \phi^\circ_B\ln(\phi_A^{sat})_B + \phi^\circ_C\ln(\phi_A^{sat})_C - 0.5\,[\ln(x^\circ_BV_B \\ & + x^\circ_CV_C) - \phi^\circ_B\ln V_B - \phi^\circ_C\ln V_C] \\ & - (V_A/V_B)\,\phi^\circ_B\,[\phi^\circ_B\,(K_B/V_B) + \phi^\circ_C\,(K^*_{BC}/V_C)]/[1 \\ & + \phi^\circ_B\,(K_B/V_B) + \phi^\circ_C\,(K^*_{BC}/V_C)] \\ & + (V_A\,K_B\,\phi^\circ_B/V^2_B)(1 + K_B/V_B)^{-1} \\ & - (V_A/V_C)\,\phi^\circ_C\,[\phi^\circ_B\,(K_{CB}/V_B) \\ & + \phi^\circ_C\,(K^*_C/V_C)]/[1 + \phi^\circ_B\,(K_{CB}/V_B) + \phi^\circ_C\,(K^*_C/V_C)] \\ & + (V_A\,K^*_C\,\phi^\circ_C/V^2_C)(1 + K^*_C/V_C)^{-1} \\ & + V_A\,\phi^\circ_B\,\phi^\circ_C\,(\delta'_B - \delta'_C)^2\,(RT)^{-1}\end{aligned}$$

dissolved in a binary alcohol + alkoxyalcohol solvent mixture.

Despite the complex appearance of eqs. [1] and [5], their application to solubilities in mixed solvents is relatively straightforward and is similar in concept to numerical examples presented previously (for example, see McCargar and Acree (28)). The quantities $(\phi_A^{sat})_B$ and $(\phi_A^{sat})_C$ are calculated from the measured mole fraction solubility of anthracene in the two neat solvents assuming that the excess molar volume (or, alternatively, the volume change upon mixing) is zero. These quantities, along with the molar volumes, modified solubility parameters, and assumed values for the self-association (K_B and K^*_C) and cross-association (K_{CB} and K^*_{BC}) hydrogen-bond stability constants are then used in eqs. [1] and (5) to calculate ϕ_A^{sat} at each different binary solvent composition.

Table 2 provides a summarized comparison between measured anthracene solubilities in 50 binary alcohol + alkoxyalcohol solvent systems and predicted values for both the self-association and cross-association treatments. Solubility data for the first 42 systems were taken from the published chemical literature (25, 26, 29–31). Solute and solvent properties used in these computations are tabulated in Table 3. Modified solubility parameters account for only nonspecific interactions and, in the case of the alcoholic and alkoxyalcohol cosolvents, the hydrogen bonding contributions have been removed. Numerical values of $\delta'_{solvent}$ for the monofunctional alcohols were obtained from published compilations (6–8), and were either estimated using known values for similar compounds or deduced by regressing solubility data of solid *n*-alkanes in organic solvents in accordance with the configurational entropic model of Huyskens and Haulait-Pirson (32). Any errors or uncertainties in the measured alkane data would naturally affect the calculated numerical values of $\delta'_{solvent}$, as would any shortcomings of the Huyskens and Haulait-Pirson model to back-calculate the observed mole fraction solubilities. Modified solubility parameters for the six alkoxyalcohols were estimated by the authors, and were calculated by adding an incremental ether-group contribution value to the known modified solubility parameters of alcohols of comparable molecular size. The numerical value of the ether-group contribution value to δ'_i was computed from differences between the known modified solubility parameters of dialkyl ethers and the corresponding *n*-alkane homomorph hydrocarbon, taking into account the length of the alkyl chain.

Careful examination of Table 2 reveals that Mobile Order theory provides reasonably accurate (though by no means perfect) predictions for the observed anthracene solubility behavior in all 50 binary alcohol + alkoxyalcohol solvent systems. Each system consists of anthracene solubility data measured at seven different solvent compositions spanning the entire mole fraction range, plus the experimental anthracene mole fraction solubilities in both neat solvents. Experimental solubility data were reproducible to within ±1.8% (or better), and cover up to a 9-fold range in anthracene mole fraction. Anthracene is considerably more soluble in 2-butoxyethanol (x_A^{sat} = 0.003 785 (31)) than in the smaller monofunctional alcohols (i.e., x_A^{sat} = 0.000 411 for 2-propanol and x_A^{sat} = 0.000 470 for 2-methyl-1-propanol (31)). Columns 2 and 3 of Table 2 correspond to the self-association (eq. [1]) and cross-association (eq. [5]) treatments, respectively. Both treatments provided reasonably accurate predictions; however, slightly lower deviations between observed and calculated values were obtained whenever the two cosolvents were assumed to form cross-associated hydrogen bonded chains. A single numerical value of K_{eq} = 5000 cm^3 mol^{-1} was assumed for all self-association and cross-association stability constants.

2-Ethoxyethanol	97.50	20.30
2-Propoxyethanol	114.92	19.80
2-Butoxyethanol	131.92	19.20
3-Methoxy-1-butanol	115.09	19.80
2-Isopropoxyethanol	116.2	19.30
Anthracene	150.0	

[a]Unless otherwise noted, tabulated δ_i' values are taken from a compilation given in Ruelle et al. (6–8) or are estimated using known values for similar alcohols. Modified solubility parameters for the six alkoxyalcohols were estimated by the authors, and were calculated by adding an incremental ether-group contribution value to the known modified solubility parameters of alcohols of comparable molecular size. The numerical value of the ether-group contribution value to δ_i' was computed from differences between the known modified solubility parameters of dialkyl ethers and the corresponding *n*-alkane homomorph hydrocarbon, taking into account the length of the alkyl chain.

In closing, we note that the expressions considered in this study assumed that the aromatic hydrocarbon solute, anthracene, did not form association complexes with either the monofunctional alcohol, alkoxyalcohol, or any of the presumed polymeric entities. Introduction of additional "curve-fit" association parameters for formation of anthracene–alcohol and anthracene–alkoxyalcohol molecular complexes would lead to reduced deviations between observed and calculated values. At this time, we do not feel that the slight reduction in percentage deviation necessarily warrants the increased calculational complexity whenever one realizes that it is possible to predict anthracene solubilities at all 350 binary solvent compositions (seven compositions for each of the 50 binary solvents) to within an overall average absolute deviation of less than 3% in the case of cross-association treatment.

Appendix: glossary of symbols

K_I Mobile Order stability (equilibrium) constant describing the homogeneous self-association of monofunctional alcohol I, where the concentration units are molarity.

K_{OC} Mobile Order stability (equilibrium) constant describing the hydrogen bonding of the hydroxylic proton on an alcohol (or 2-alkoxyethanol) solvent and of the ether O atom on an ether (or 2-alkoxyethanol) molecule.

K_{BC}, K_{CB} Mobile Order cross-association stability (equilibrium) constant describing the heterogeneous association of monofunctional alcohols B and C, where the concentration units are molarity.

V_i Molar volume of component *i*.

x_B°, x_C° Mole fraction compositions of the binary solvent mixture, calculated as if the solute were not present.

x_A^{sat} Mole fraction solubility of the solute.

Greek letters

$\gamma_{I:}$ Fraction of time that alcoholic solvent I is not involved in hydrogen bond formation.

δ_i' Modified solubility parameter of component *i*.

ϕ_B°, ϕ_C° Volume fraction compositions of the binary solvent mixture, calculated as if the solute were not present and assuming that the excess volume of mixing is zero.

ϕ_A^{sat} Volume fraction solubility of the solute, calculated assuming that the excess volume of mixing is zero.

ϕ_{solv} Volume fraction of solvent, calculated assuming that the excess volume is zero.

2-Trichloromethylimidazole. Condensation reactions with anions stabilized by carbonyl groups[1]

Jaime González, Arturo Pérez-Medrano, and Joseph M. Muchowski

Abstract: 2-Trichloromethylimidazole **2**, a stable but moisture-sensitive solid, is readily prepared by cyclization of the amidine **1** in trifluoroacetic acid (99+%). Compound **2** reacted with the enolates derived from 1,1-di- and monocarbonyl compounds to give the β-chlorovinyl carbonyl compounds **5** *a–c* and **6** *a*, *b*, respectively.

Key words: 2-trichloromethylimidazole, condensation reactions, mono- and dicarbonyl compounds.

Résumé : Le 2-trichlorométhylimidazole **2**, un solide stable mais sensible à l'humidité, est préparé facilement par cyclisation de l'amidine **1** dans l'acide trifluoroacétique (99+%). Le composé **2** réagit avec les énolates dérivés des composés 1,1-di- et mono-carbonyles pour donner les composés β-chlorovinylcarbonyles **5** *a–c* et **6** *a*, *b*, respectivement.

Mots clés : 2-trichlorométhylimidazole, réactions de condensation, composés mono- et dicarbonyles.

We recently described improved, three-step syntheses of imidazole-2-carboxylic acid (**4***a*, Scheme 1) and its ethyl ester **4***b* by hydrolysis and ethanolysis, respectively, of 2-trichloromethylimidazole **2**, the trifluoroacetic acid induced cyclization product of the amidine **1** (1). Although **2** was not obtained pure, its transformation into **4***a* and **4***b*, as well as mass spectral data, left little doubt of its identity as the major cyclization product of **1**. We have now succeeded in isolating **2** in the pure state, have characterized it fully, and have studied some of its condensation reactions with anions stabilized by one or two carbonyl groups.

By the simple expedient of avoiding exposure to water during its formation and isolation (see Experimental), we were able to obtain substantial quantities of **2** (ca. 60% yield) as a white, crystalline solid that was indefinitely stable under anhydrous conditions. It is of interest that the base peak in the mass spectrum of **2** is *m/z* 148, which arises by loss of HCl from the molecular ion.[4] This ion most certainly corresponds to the diazafulvene **3**, a species that is likely to be an intermediate in the formation of **4***a* and **4***b* (2–4). The propensity of 6,6-dihalodiazafulvenes to react with a variety of nucleophiles by an addition–elimination sequence (2, 4) caused us to examine the reaction of **2** with diethyl sodiomalonate. As expected, the addition of a mixture of this anionic species (1 equiv.) and sodium hydride (2 equiv.) to a THF solution of **2** at room temperature gave the monochloromethylene malonate derivative **5***a* (65% yield). Compounds **5***b* and **5***c* were prepared in a similar manner from ethyl acetoacetate and acetylacetone, respectively. At low temperatures and in the presence of LDA (2 equiv.), **3** also reacted with the enolates of acetone and acetophenone to generate the β-chloroenones **6***a* and **6***b*.

An especially noteworthy feature of the nmr spectrum of **6***a* is that the olefinic proton appears at δ 7.50, ca. 1.3 ppm downfield from the corresponding proton in 4-chloro-3-buten-2-one (5). This dramatic deshielding must be caused by the imidazole nitrogen atoms, an effect that incidentally confirms the stereochemistry of **6***a* as depicted in Scheme 1. The olefinic proton of **6***b* is also found at considerably lower field (δ 8.20) than might have been predicted. Analogous, but even greater deshielding, has recently been observed for aliphatic hydrogens spatially close to the nitrogen atom of 1-azafulvenes (6).

Although the addition of various nucleophiles to C-6 of 1,3-diazafulvenes is known (4, 7), the use of stabilized carbanions in such reactions has not previously been reported. The products (**5**, **6**), which may well be of synthetic interest, would be quite challenging to prepare by other means.

Experimental

The melting points are not corrected. The ir spectra were recorded as solid dispersions in KBr unless otherwise indi-

cated. The ^{1}H nmr spectra were measured on a 200 MHz instrument as solutions in $CDCl_3$ unless otherwise indicated, and the chemical shifts are reported in ppm (δ) from internal tetramethylsilane. The low- and high-resolution mass spectra were obtained as previously described (6). The amidine **1** was synthesized as described in the previous publication (1).

2-Trichloromethylimidazole (2)

N-(2,2-Dimethoxy)ethyl-2,2,2-trichloroacetamidine (1, 5.0 g, 60 mmol) was added with stirring and cooling (−5°C) to trifluoroacetic acid (92 mL, 99+%) maintained in an argon atmosphere. The cooling bath was removed, stirring at room temperature was continued for 17 h, anhydrous toluene (100 mL) was added, and the solution was evaporated to dryness in vacuo. Toluene (100 mL) was added to the residue and the mixture was evaporated to dryness in vacuo. After an additional repetition of this process, a thick oil was obtained and taken up in anhydrous acetone at room temperature (argon atmosphere). Scratching the vessel walls with a spatula caused the crystallization of a white solid (6.3 g, 57% yield) that was indefinitely stable in the absence of moisture, mp 180°C (dec.); ^{1}H nmr (DMF-d_7) δ: 7.57 (s, 2H), 17.01 (br, 1H); ^{13}C nmr (DMF-d_7) δ: 119.14, 123.19 (2C), 134.05; MS (EI) *m/z*: 188, 186, 184 (2, 9, 8; M^+), 153 (6), 152 (11), 151 (35), 150 (64), 149 (54), 148 (100), 125 (8), 124 (6), 123 (53), 122 (9), 121 (85), 88 (20), 86 (61). Exact Mass calcd. for $C_4H_3{}^{35}Cl_3N_2$: 183.9362; found: 183.9357, 183.9365, 183.9359.

Ethyl 2-ethoxycarbonyl-3-chloro-3-(imidazol-2-yl)-2-propenoate (5*a*)

A solution of diethyl malonate (0.259 g, 1.62 mmol) in dry THF (5 mL) was added to a stirred suspension of sodium hydride (4.86 mmol, obtained by washing a suspension of 60% NaH in mineral oil with dry hexane) in anhydrous THF (7 mL) at 0°C. This mixture was cannulated into a stirred, room-temperature solution of **2** (0.300 g, 1.62 mmol) in anhydrous THF (15 mL) under argon. The mixture was stirred for 48 h and then partitioned between dichloromethane and water. The dried (Na_2SO_4) organic phase was evaporated in vacuo, and the residue was subjected to column chromatographic purification on silica gel using dichloromethane–methanol (95:5) to elute **5***a* as a solid (0.286 g, 65%), mp 99–101°C; ir ($CHCl_3$): 3184, 1732, 882 cm^{-1}; nmr δ: 1.34 (t, 6H, J = 7.1 Hz), 4.35 (q, 4H, J = 7.1 Hz), 7.26 (s, 2H), 12.90 (br, 1H). Anal. calcd. for $C_{11}H_{13}ClN_2O_4$: C 48.44, H 4.80, Cl 13.00, N 10.27; found: C 48.25, H 4.95, Cl 12.86, N, 10.18.

Ethyl 2-acetyl-3-chloro-3-(imidazol-2-yl)-2-propenoate (5*b*)

This compound was prepared in the same manner as described

for **5***a* except that the THF was removed in vacuo and the residue was purified by column chromatography to give a solid, mp 99–100°C; ir: 3142, 1712, 855 cm^{-1}; nmr δ: 1.38 (t, 3H, J = 7.2 Hz), 3.49 (s, 3H), 4.36 (q, 2H, J = 7.2 Hz), 7.26 (s, 2H), 12.01 (br, 1H). Exact Mass calcd. for $C_{10}H_{11}{}^{35}ClN_2O_3$: 242.0458; found: 242.0461. Anal. calcd. for $C_{10}H_{11}ClN_2O_3$: C 49.49, H 4.56, Cl 14.61, N 11.54; found: C 49.31, H 4.56, Cl 14.05, N 11.35.

3-Acetyl-4-chloro-4-(imidazol-2-yl)-3-buten-2-one (*5c*)
This compound was prepared by the method used for **5***b* except that the reaction was carried out at −35°C for 2 h and then at room temperature for 2 h. The solvent was removed in vacuo and the residue was purified by column chromatography as described for **5***a*. Compound **5***c* was obtained as a solid (64.5% yield), mp 81–82°C; ir: 3141, 1658, 882 cm^{-1}; nmr δ: 2.50 (s, 3H), 2.65 (s, 3H), 7.33 (s, 2H), 11.55 (br, 1H). Exact Mass calcd. for $C_9H_9{}^{35}ClN_2O_2$: 212.0353; found: 212.0353. Anal. calcd. for $C_9H_9ClN_2O_2$: C 50.83, H 4.26, Cl 16.67, N 13.17; found: C 50.89, H 4.24, Cl 15.36, N 12.85.

4-Chloro-*trans*-4-(imidazol-2-yl)-3-buten-2-one (*6a*)
Anhydrous acetone (0.12 mL, 0.095 g, 1.64 mmol) was added to a cooled (−23°C) solution of LDA (0.68 mL, 2.38 M in THF, 1.62 mmol) in anhydrous THF (5 mL). After 15 min, this solution was cannulated into a stirred solution of **2** (0.100 g, 0.54 mmol) in THF (5 mL) at −78°C (argon atmosphere). After 2 h at −78°C the solvent was removed in vacuo and the residue was purified by column chromatography as described for **5***a*. Compound **6***a* was obtained as a solid (0.021 g, 23%), mp 117–118°C; ir: 3152, 1650, 1595, 853 cm^{-1}; nmr δ: 2.41 (s, 3H), 7.19 (s, 2H). 7.50 (s, 1H). Exact Mass calcd. for $C_7H_7{}^{35}ClN_2O$: 170.0247; found: 170.0252. Anal. calcd. for $C_7H_7ClN_2O$: C 49.28, H 4.13, N 16.42; found: C 49.87, H 3.99, N 16.34.

Phenyl 2-chloro-*trans*-2-(imidazol-2-yl) vinyl ketone (*6b*)
This compound was prepared by the method described for **6***a*, except that the reaction temperature was −45°C. After purification by column chromatography **6***b* was obtained as a solid (52% yield), mp 161–162°C; ir: 3144, 1664, 1606, 840 cm^{-1}; nmr δ: 7.44–7.63 (m, 5H), 8.03–8.08 (m, 2H), 8.20 (s, 1H). Exact Mass calcd. for $C_{12}H_9{}^{35}ClN_2O$: 232.0403; found: 232.0403. Anal. calcd. for $C_{12}H_9ClN_2O$: C 61.94, H 3.89, Cl 15.23, N 12.04; found: C 61.90, H 3.71, Cl 15.82, N 11.87.

Thermodynamics of mixtures containing the CO and OH groups. I. Estimation of the DISQUAC interchange coefficients for 1-alkanol + *n*-alkanone systems

Juan Antonio González

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12
For personal use only.

Abstract: 1-Alkanol + *n*-alkanone mixtures are treated in terms of the DISQUAC group contribution model, reporting the interaction parameters for hydroxyl–carbonyl contacts. The quasichemical interchange coefficients are independent of the compounds in the mixture; the dispersive interchange coefficients depend on the intramolecular environment of the hydroxyl and (or) carbonyl groups. Mixtures of a given 1-alkanol with isomeric ketones are characterized by the same first dispersive interaction parameter, which is constant from 2-pentanone. This type of system, when including an alcohol up to 1-pentanol, needs different dispersive enthalpic parameters depending on the symmetry of the ketone. In this case, such parameters are constant from 2-pentanone or 3-pentanone. A detailed comparison is presented between DISQUAC results and data available in the literature on vapor–liquid equilibria, VLE (including azeotropic data), molar Gibbs energies, G^E, molar excess enthalpies, H^E, solid–liquid equilibria, SLE, natural logarithms of activity coefficients, $\ln \gamma_i^\infty$, and partial molar excess enthalpies at infinite dilution, $H_i^{E,\infty}$. For 54 systems, the mean relative standard deviation in pressure is 0.018; for 61 systems, this magnitude in the case of the H^E is 0.059. It is noteworthy that the model yields good predictions over a very wide range of temperature for VLE and SLE. H^E is also reasonably well represented at different temperatures. Larger discrepancies are encountered, as usual, for partial molar quantities at infinite dilution.

Key words: liquids, mixtures, thermodynamic properties, group contributions.

Résumé : On a considéré les mélanges d'alcan-1-ols et de *n*-alcanones en termes du modèle DISQUAC de contribution de groupe et on rapporte les paramètres d'interaction pour les contacts hydroxyle–carbonyle. Les coefficients d'interchange quasichimique sont indépendants de la nature des composés présents dans le mélange; les coefficients d'interchange de dispersion dépendent de l'environnement intramoléculaire des groupes hydroxyle et (ou) carbonyle. Les mélanges d'un alcan-1-ol avec des cétones isomères sont caractérisés par le même paramètre initial d'interaction de dispersion qui est constant à partir de la pentan-2-one. Ces types de systèmes, jusqu'au pentan-1-ol, requièrent des paramètres enthalpiques de dispersion qui dépendent de la symétrie de la cétone. Dans ces cas, ces paramètres sont constants à partir des pentan-2-one ou pentan-3-one. On présente une comparaison détaillée des résultats DISQUAC et des données desponibles dans la littérature sur l'équilibre vapeur–liquide, EVL (y compris des données azéotropiques), les énergies molaires de Gibbs, G^E, les enthalpies molaires en excès, H^E, les équilibres solide–liquide, ESL, les logarithmes naturels des coefficients d'activité, $\ln \gamma_i^\infty$, et les enthalpies molaires partielles en excès à dilution infinie, $H_i^{E,\infty}$. Pour 54 systèmes, la déviation relative moyenne standard sur la pression est de 0,018; pour 61 systèmes, cette valeur pour H^E est de 0,059. Il est remarquable que pour un large éventail de températures le modèle conduise à de bonnes prédictions des EVL et ESL et que la valeur de H^E soit aussi bien représentée à diverses températures. Comme d'habitude, on observe de plus grandes différences avec les quantités molaires partielles à dilution infinie.

Mots clés : mélanges liquides, propriétés thermodynamiques, contributions de groupe.

[Traduit par la rédaction]

1. Introduction

In the framework of the DISQUAC (1, 2) group contribution model for representing thermodynamic properties, it has been shown that the hypothesis of considering structure-dependent interaction parameters is essential for practical purposes. As a matter of fact, it leads to improved predictions, mainly in the case of branched and cyclic molecules, and for the first members of homologous series.

Under this basic assumption, in recent years we have carried out detailed research on the ability of DISQUAC to represent a complete set of thermodynamic properties (vapor–liquid equilibria, VLE; liquid–liquid equilibria, LLE; solid–liquid equilibria; SLE; G^E, H^E, or heat capacities at constant pressure, as well as the related partial molar excess quantities at infinite dilution) of mixtures containing self-associated compounds. Thus, we have treated systems of alkanols: 1-alkanols (3–11), *sec*- (12) or *tert*-alkanols (13), cycloalkanols (14), or phenol (15), with organic solvents such as *n*-alkanes,

cyclohexane, benzene, toluene, or CCl_4; that is, with inert, or non-associated but active, components (particularly, nonpolar but polarizable molecules).

In the same way, we have studied the problem of systems including two self-associated compounds, which together then also present a cross-association, showing that DISQUAC is indeed a reliable tool to represent such systems. Thus, we have focused our attention on binary mixtures containing two 1-alkanols (16), two linear monocarboxylic acids (17), or 1-alkanols and monocarboxylic acids (17). However, in this case, both dispersive (DIS) *and* quasichemical (QUAC) interchange coefficients are needed (17). In exchange, when the molecules in the mixture have the same functional group (OH or COOH), the dispersive approximation of DISQUAC is enough to represent the thermodynamic properties of the system under study (16, 17). It should be remarked here that binary mixtures containing two 1-alkanols have been successfully described in terms of Flory's theory (18).

On the other hand, VLE and H^E of ternary systems containing one or two 1-alkanols are usually well described on the basis of binary parameters only (16, 19).

As a continuation of these investigations, the aim of the present work is to report a complete DISQUAC treatment of alcoholic solutions including as second component a polar but non-associated compound, namely 1-alkanol + *n*-alkanone mixtures. In these systems the formation of O—H---O=C hydrogen-bonded complexes is vastly outweighed by the rupture of the alkanol–alkanol hydrogen bonds, ketone–ketone interactions, and by physical interactions between equal molecules (20–22), leading to H^Es that are positive over the entire composition range. Therefore, the complexes mentioned are much weaker than those created in 1-alkanol + linear monocarboxylic acid mixtures that are characterized, in many cases, by negative or s-shaped H^Es (17). Obviously, this means that the treatment of the actual systems should be more accessible in terms of a purely physical theory such as DISQUAC.

2. The DISQUAC model

2.1 Theory

In the framework of DISQUAC, mixtures of 1-alkanols with *n*-alkanones are regarded as possessing three types of surface: (*i*) type a, aliphatic (CH_3, CH_2 in ketones and alcohols); (*ii*) type h (OH in 1-alkanols); and (*iii*) type k (CO in *n*-alkanones).

The equations used to calculate G^E and H^E are the same as in other applications (3). The coordination number was chosen as reference value, that is, $z = 4$.

On the other hand, the solid–liquid equilibrium curve of a pure solid component 1 was calculated to the equation (23) according:

$$[1] \quad -\ln x_1 = (\Delta H_{m1}/R)[1/T - 1/T_{m1}] - (\Delta C_{pm1}/R)[\ln (T/T_{m1}) + (T_{m1}/T) - 1] + \ln \gamma_1$$

Table 2. Interchange energy coefficients, dispersive $C_{kh,l}^{DIS}$ and quasichemical $C_{kh,l}^{QUAC}$ values ($l = 1$, Gibbs energy; $l = 2$, enthalpy), for the contacts between ketone (type k, CO in *n*-alkanones [CH_3-$(CH_2)_{u-1}$-CO-$(CH_2)_{v-1}$ - CH_3]) and hydroxyl groups (type h, OH in 1-alkanols). The coordination number used for the QUAC part is $z = 4$. The QUAC parameters are independent of the 1-alkanol and *n*-alkanone present in the mixture considered.

Table 3. Molar excess Gibbs energies G^E (T; $x_1 = 0.5$) for 1-alkanol(1) + linear alkanone(2) systems at various temperatures T(K), and equimolar composition. Comparison of experimental results (exp.) with DISQUAC values calculated (calcd.) using the coefficients from Table 2. Also listed are the relative standard deviations in pressure, σ_r (P) (eq. [2]), given by DISQUAC (N is the number of data points for each system).

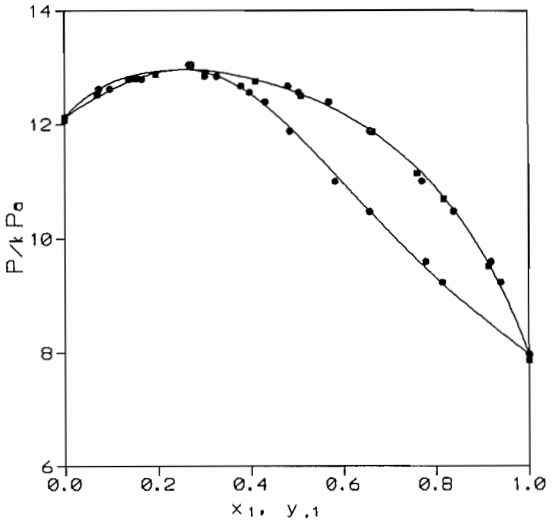

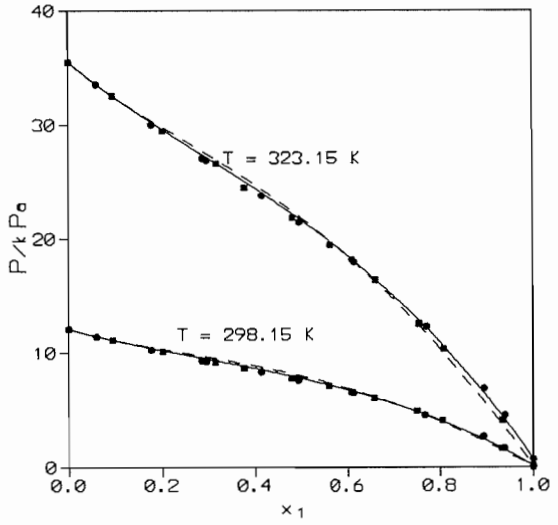

Fig. 4. VLE at different temperatures for 1-alkanol(1) + 2-butanone(2) mixtures. Points, experimental results (56): ● 1-hexanol; ■ 1-octanol; lines, DISQUAC calculations: (——), 1-hexanol, (---), 1-octanol.

where γ_1 is the activity coefficient of component 1 in the solvent mixture at temperature T, calculated using DISQUAC. ΔH_{m1}, T_{m1}, and ΔC_{pm1} stand for the molar enthalpy of fusion, the melting temperature, and the molar heat capacity change during the melting process of component 1. Equation [1] assumes (*i*) that there is no first-order transition in the solid phase; (*ii*) absence of miscibility in the solid phase; and (*iii*) that ΔC_{pm1} is independent of T.

The temperature dependence of the interaction parameters is expressed in terms of the dispersive (DIS) or quasichemical (QUAC) interchange coefficients $C_{st,l}^{DIS}$ and $C_{st,l}^{QUAC}$, where s, t = a, h, or k and $l = 1$ (Gibbs energy), $l = 2$ (enthalpy), and $l = 3$ (heat capacity).

2.2 Assessment of geometrical parameters

The relative molecular volumes, r_i, the surfaces, q_i, and the surface fractions, α_{si}, of all the molecular species have been calculated on the basis of the group volumes and surfaces recommended by Bondi (24), taking the volume and surface of methane arbitrarily as unity (25).

Table 1 lists the values of r_i and q_i of the groups referred to in this work.

2.3 Estimation of the interaction parameters

The three types of surface generate three pairs of contacts: (a,h), (a,k), and (h,k).

The alkane–alkanol (a,h) and alkane–ketone (a,k) interac-

tions are described by DIS and QUAC coefficients reported previously (3, 7, 16, 26). Hence, because the (a,h) and (a,k) parameters are known, only the DIS and QUAC interchange coefficients for the (h,k) contacts need to be fitted.

The general procedure used in the fitting of any set of interchange coefficients has been described elsewhere (3, 16, 27). In our detailed study of alcoholic solutions, we have shown that the first QUAC interaction parameter can be kept constant along each series investigated (13). Similarly, here the same $C_{hk,1}^{QUAC}$ coefficient has been used for all the systems treated. In the absence of appropiate VLE data that can be used in the determination of the $C_{hk,1}^{DIS/QUAC}$ coefficients, this is important because the quasichemical contribution to H^E depends not only on $C_{hk,2}^{QUAC}$ but also on $C_{hk,1}^{QUAC}$ via the surface fractions and Boltzmann's factor (eqs. 40, 66 and 68 in ref. 25). Moreover, in order to keep a lower number of interaction parameters, the $C_{hk,2}^{QUAC}$ coefficients were also made independent of the compounds in the mixture. After several calculations developed to study the change in the symmetry of the G^E and H^E curves with the interaction parameters, we finally took $C_{hk,1}^{QUAC}$ = 1.65 and $C_{hk,2}^{QUAC}$ = 5.00 together with the corresponding $C_{hk,l}^{DIS}$ (l = 1, 2) coefficients (Table 2). Due to the lack of enough data for H^E at different temperatures, we took $C_{hk,3}^{DIS/QUAC}$ = 0.

In summary, we note the simple rules followed by the interchange coefficients:

1. $C_{hk,l}^{QUAC}$ (l = 1, 2) are independent of the class of compounds in the mixture.

2. The dispersive coefficients increase with the size of the alkanol for a given *n*-alkanone, or with the size of the alkanone for a given alcohol. It is noteworthy that $C_{hk,1}^{DIS}$ is the same for mixtures of the type 1-alkanol + isomeric ketones, being constant from 2-pentanone. However, such systems, when including an alcohol up 1-pentanol, need different $C_{hk,2}^{DIS}$ coefficients depending on the symmetry of the ketone. Then, $C_{hk,2}^{DIS}$ is constant from 2-pentanone (for asymmetric ketones), or from 3-pentanone (for symmetric ketones).

The increase in the dispersive interaction parameter with the size of the alkanol and (or) alkanone may be attributed to an inductive effect that has also been encountered in other alcoholic solutions, such as 1-alkanol + benzene, + toluene, or + CCl_4 mixtures (5, 6). In exchange, there is no steric effect on the quasichemical coefficients.

3. Comparison with experiment and discussion

A comparison between experimental data and DISQUAC results is collected in Tables 3–8. This comparison is presented in a graphical way in Figs. 1–10 for selected mixtures.

For the sake of major clarity, Tables 3, 5, 6 also list the relative standard deviations defined by:

$$[2] \quad \sigma(F) = \{1/N\sum [(F_{exp} - F_{calc})/F_{exp}]^2\}^{1/2}$$

where N is the number of data points for each mixture, and F = P, H^E, or T.

We note the good results obtained for VLE, G^E, and H^E

© 1997 NRC Canada

Table 6. Values of the relative standard deviations of the solid–liquid equilibrium temperatures, σ_r (T) eq. [2]), obtained using DISQUAC for ethanol(1) + isomeric heptanone(2) mixtures (78) (N is the number of data points for each system).

Alkanone	T^a_{m1}/K	T^a_{m2}/K	ΔH^b_{m1}/J mol^{-1}	ΔH^b_{m2}/J mol^{-1}	N	σ_r (T)
2-Heptanone(2)	158.65	237.65	5012.7	19 711.8	19	0.005
3-Heptanone(2)		235.94		17 531.6	19	0.005
4-Heptanone(2)		240.15		16 159.5	19	0.008

[a]Melting temperature of pure compound.
[b]Molar heat of fusion. Due to the lack of appropriate data, $\Delta C_{pm} = 0$ in eq. [1].

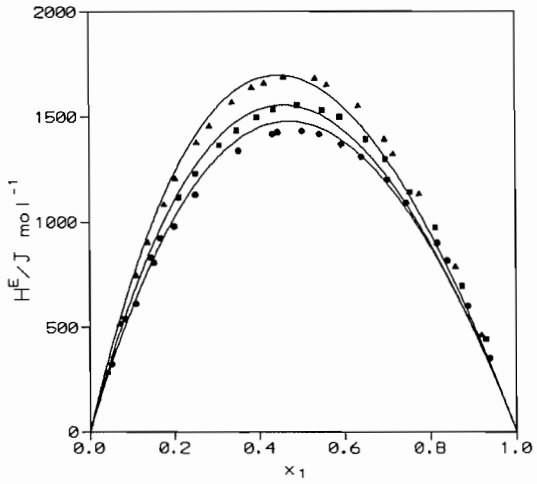

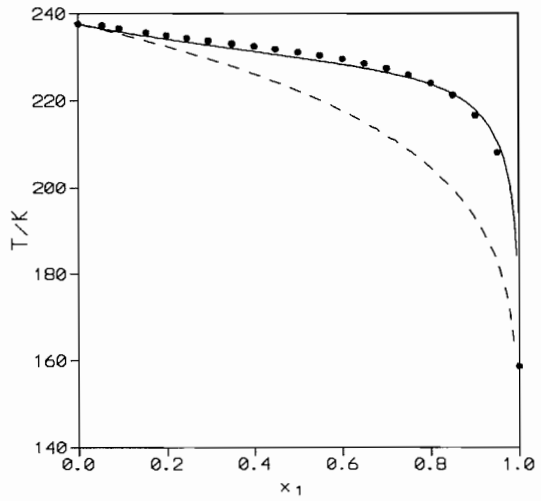

Fig. 10. SLE for the ethanol(1) + 2-heptanone(2) mixture. Points, experimental results (78); solid line, DISQUAC calculation; broken line, ideal solubility curve.

(Tables 3–5). Thus, for 54 systems, the mean relative standard deviation in pressure is 0.018; in the case of H^E this magnitude is 0.059 for 61 systems. It should be noted again that the G^E_s of 1-alkanol + isomeric n-alkanone mixtures are calculated using the same $C^{DIS}_{hk,1}$ coefficient. Unfortunately, different values of $C^{DIS}_{hk,2}$ are needed to evaluate H^E for such systems including the lower 1-alkanols (see above, Table 2).

The symmetry of the excess functions G^E and H^E is usually well reproduced (Figs. 5–9). In the same way, the entire VLE diagrams are well represented (Figs. 1–4). We note the good predictions given by the model regarding the coordinates of azeotropes (Table 4).

The larger discrepancies observed in some cases between experimental and calculated values can be attributed to experimental inaccuracies. For example, the H^E data from Letcher and Nevines (28) for the ethanol + 2-pentanone system seem to be too low when are compared with data for other 1-alkanol + 2-pentanone mixtures reported by different authors (Table 5). The data mentioned, as reported by Letcher and Nevines, for the ethanol + 2-pentanone system can be represented using $C^{DIS}_{hk,2} = 0.10$ ($\sigma_r = 0.060$). However, this value does not fit into the general scheme of the variation of the interaction parameters (Table 2), indicating that such data are not reliable.

On the other hand, it is noted that the model usually yields accurate predictions over a wide range of temperature. So, for example, the VLE of the ethanol + 2-propanone system is well characterized between 288.15 and 422.9 K (Table 3, Fig. 3). At very low temperatures (204–240 K), DISQUAC represents the SLE data of mixtures containing ethanol and isomeric heptanones (Table 6, Fig. 10) well. Regarding H^E, this magnitude is well described at temperatures close to 298.15 K (Table 5). Predictions at higher temperatures are still acceptable as shown by comparison of the data reported by Lietzmann et al. at 0.4 MPa (29) with results calculated for the ethanol + 2-propanone mixture (Table 5).

In the framework of DISQUAC, the temperature dependence is given via Boltzmann's factor and the third interchange coefficients. In the present mixtures, $C^{DIS/QUAC}_{ak,3} = C^{DIS/QUAC}_{hk,3} = 0$. So, Boltzmann's factor and the $C^{DIS/QUAC}_{ah,3}$ coefficients seem to be sufficient to evaluate the variation with temperature of the thermodynamic properties.

The poorer results are obtained when predicting partial molar quantities at infinite dilution (Tables 7 and 8). So, for the ethanol(1) + 2-propanone(2) system, the mean deviation is 19% for $H^{E,\infty}_1$, and 13% for $H^{E,\infty}_2$. Similar results are obtained when investigating other alcoholic solutions (3–6).

Finally, it should be mentioned that preliminary calculations show that it is possible to predict thermodynamic properties, VLE and H^E, of ternary systems including 1-alkanols, n-alkanones, and one organic solvent on the basis of binary

parameters only, that is, by neglecting ternary interactions. For example, in the case of the 1-propanol + 3-pentanone + 1-hexanol system at 298.15 K, with 54 data points (30), $\sigma_r(H^E) = 0.033$. A more detailed study will be presented in the following article.

4. Discussion and conclusions

For a given alkanol, H^E decreases as the aliphatic chain length of the ketone increases. This may be due to the fact that although the dipole moments, μ, of the ketones are approxi-

mately constant (2.78, 2.77 and 2.66 D for 2-propanone, 2-pentanone and 2-heptanone, respectively (31)), the effective dipole moments, $\bar{\mu}$ (defined by eqs. [3] and [4] in ref. 31), decrease as the size of the ketone increases: 0.75, 0.61, and 0.49 for the *n*-alkanones mentioned above (31). As a consequence, the ketoxy interactions in the condensed phase become weaker, and hence H^E decreases.

In a similar way, μ is also practically constant for 1-alkanols (1.7, 1.8, and 1.8 D (32) for methanol, 1-butanol, and 1-decanol, respectively), while $\bar{\mu}$ decreases with the length of the aliphatic chain of the alcohol (the respective values are 0.60, 0.41, and 0.18). However, for a given ketone, H^E increases with the size of the alcohol. This implies that the rupture of the alkanol–alkanol bonds predominates over the formation of O—H---O=C bonds. Nevertheless, because both effects decrease with increasing alkanol chain length, such a trend is probably due to the physical interactions between equal molecules then become very important.

This complex behaviour is well described by means of structure-dependent interchange coefficients that follow rather simple rules. So, the DIS interaction parameters show an inductive effect, while no steric effect is found for the QUAC parameters; that is, the latter do not depend on the class of components in the mixture. This may be considered the main conclusion in terms of the framework of DISQUAC.

Thermodynamics of mixtures containing the CO and OH groups. II. DISQUAC predictions on VLE and H^E for ternary mixtures containing 1-alkanols, *n*-alkanones, and one organic solvent

Juan Antonio González, I. García de la Fuente, and J.C. Cobos

Abstract: Thermodynamic properties: vapor–liquid equilibria, VLE, or excess enthalpies, H^E, for a set of 21 ternary mixtures of the type 1-alkanol + *n*-alkanone + organic solvent are studied in the framework of the DISQUAC group contribution model. This treatment is extended to the binaries involved. The DISQUAC analysis is developed on the basis of binary interactions only, that is, ternary interactions are neglected. Most of the interchange coefficients needed are available in the literature. The average relative standard deviations are 0.026 for pressure in the VLE (12 systems) and 0.098 in the H^E (9 systems). The discrepancies observed are briefly discussed.

Key words: 1-alkanols, *n*-alkanones, group contribution, liquids, ternary systems, thermodyamics.

Résumé : Opérant dans le cadre du modèle DISQUAC de la contribution de groupe, on a étudié les propriétés thermodynamiques (équilibre vapeur–liquide, EVL, et enthalpies en excès, H^E) de 21 mélanges ternaires du type alcan-1-ol + *n*-alcanone + solvant organique. On a étendu ce traitement aux systèmes binaires impliqués. On a développé l'analyse DISQUAC en se basant uniquement sur les interactions binaires; les interactions ternaires sont donc négligées. La plupart des coefficients d'interéchange nécessaires sont disponibles dans la littérature. Les déviations relatives moyennes standards sont de 0,026 pour la pression dans les EVL (12 systèmes) et de 0,098 pour les H^E (9 systèmes). On discute brièvement des différences observées.

Mots clés : alcan-1-ols, *n*-alcanones, contribution de groupe, liquides, systèmes ternaires, thermodynamique.

1. Introduction

In a previous work (1), binary mixtures containing 1-alkanols and *n*-alkanones were treated in terms of the DISQUAC group contribution model (2, 3). Interaction parameters for the hydroxyl–carbonyl contacts were reported, and it was shown that DISQUAC consistently described such mixtures over a wide range of temperatures, on the basis of structure-dependent interaction parameters. As a continuation, we now present a detailed study of the ability of the model to represent thermodynamic properties, VLE and H^E, for ternary mixtures including 1-alkanols, *n*-alkanones, and one organic solvent from binary parameters only, that is, neglecting ternary interactions. This is important because, although a large amount of data has been reported in the literature for binary systems, data for ternary and higher multicomponent mixtures is much scarcer due to the time and effort required to obtain a meaningful set of multicomponent data. One of the most essential tasks of thermodynamics is to predict thermodynamic properties of multicomponent systems using data obtained from more simple mixtures and, in the case of VLE, for pure substances. From this point of view, it should be emphasized that we have already shown that DISQUAC is a reliable tool to describe ternary systems containing only hydrocarbons (4) or one or two 1-alkanols and hydrocarbons (5–7).

2. Ternary systems considered

Table 1 lists all the ternary systems considered in this work. Also indicated are the temperature, T (in K), the number of data points measured, N, the thermodynamic property studied for each mixture, VLE or H^E, the minimum (F^E_{min}) and the maximum (F^E_{max}) direct experimental values (in J mol^{-1}) of the excess function related to the thermodynamic property studied, when available, and the source of data.

In a similar way, Table 2 lists the binary mixtures and their related ternary systems. To develop a more complete study, we have considered, when possible, those binaries originally cited in papers regarding the ternary mixtures treated.

We note that, for the following systems, the excess functions are endothermic. Ternary system nos. 13–15 (Table 1) have ternary H^E data with maxima that are larger than those of the related binaries (Table 2). This is not the case for mixtures

containing only hydrocarbons (4), or two 1-alkanols and an *n*-alkane or cyclohexane (6, 7). In this study, ternary system nos. 16–21 (Table 1) have maximum H^E values similar to the larger H^E values of the related binary systems (Table 2).

3. The DISQUAC model

3.1 Theory

The equations used to calculate thermodynamic properties in the framework of DISQUAC are given elsewhere (46). The temperature dependence of the interaction parameters is expressed in terms of the dispersive (DIS) and quasichemical (QUAC) interchange coefficients $C^{DIS}_{st,l}$ and $C^{QUAC}_{st,l}$, where s, t are different types of groups: (s, t = a, aliphatic in *n*-alkanes; b, aromatic in benzene; c, cyclic in cyclohexane; h, hydroxyl in 1-alkanols; k, carbonyl in linear ketones; and *l* is the order of interchange coefficient: *l* = 1, Gibbs energy; *l* = 2, enthalpy; *l* = 3, heat capacity. For the QUAC part, the coordination number is *z* = 4.

3.2 Assessment of geometrical parameters

The relative molecular volumes, r_i, the surfaces, q_i, and the surface fractions, α_{si}, of all the molecular species have been calculated on the basis of the group volumes and surfaces recommended by Bondi (47), taking the volume and the surface of methane arbitrarily as unity (48). The values of r_i and q_i of the groups referred to in this work are given elsewhere (46, 48, 49).

3.3 The interaction parameters

The ternary mixtures studied can be classified, based on the different groups present in the system being considered.

1. In ternary mixtures 1–4 and 13–15, there are three groups: hydroxyl, carbonyl, and aliphatic and, consequently, only three contacts:

hydroxyl–aliphatic	(7, 46, 50)
carbonyl–aliphatic	(51)
hydroxyl–carbonyl	(1)

2. In mixtures 5–12 and 18–21, the groups involved are hydroxyl, carbonyl, aliphatic, and cyclic or aromatic giving six interactions:

hydroxyl–aliphatic	(7, 46, 50)
carbonyl–aliphatic	(51)
hydroxyl–carbonyl	(1)
hydroxyl–cyclic or hydroxyl–aromatic	(52–55)
carbonyl–cyclic or carbonyl–aromatic	(51)
aliphatic–cyclic or aliphatic–aromatic	(56, 57)

3. Mixtures 16 and 17 contain two alcohols and, hence, two different hydroxyl groups, because in our approach the different self-association of each alcohol is characterized by its own set of interaction parameters (1, 7, 46, 52–55). Thus, in these mixtures there are also four groups: two hydroxyl, one carbonyl, and one aliphatic, and six interactions:

[a]Excess function, G^E; σ_r calculated for pressure.
[b]Nonmiscible system, value at $x_1 = 0.125$.
[c]Excess function, H^E; σ_r calculated for H^E.

hydroxyl–aliphatic (two)	(7, 46, 50)
hydroxyl–carbonyl (two)	(1)
carbonyl–aliphatic	(51)
hydroxyl–hydroxyl	(7)

As indicated above, most of the interaction parameters are available in the literature, and since ternary interactions are neglected, new interchange coefficients are not needed to develop the calculations.

Only the interchange coefficients for the carbonyl–aromatic contact need to be estimated. This was previously done for the 2-butanone + benzene mixture, assuming that the carbonyl–aromatic contact is represented by dispersive parameters only (58). Under this assumption, the interchange coefficients for the 2-propanone + benzene system were estimated to be $C^{DIS}_{bk,1} = 5.50$ and $C^{DIS}_{bk,2} = 5.30$, on the basis of the data given in refs. 40 and 44. For the 2-butanone + benzene mixture system, we used $C^{DIS}_{bk,1} = 5.50$ (slightly different than 5.40, previously reported (58)) and $C^{DIS}_{bk,2} = 5.50$. We note the large difference between experimental and calculated H^E at 298.15 K for this system (No. 53 Table 3: $\sigma_r = 1.9$). This is due to the low endothermic value of H^E (ca. 9 J mol^{-1}), even though the s-shape of H^E is well-represented by DISQUAC.

4. Results and discussion

A comparison between experimental and calculated values of the excess functions, G^E and H^E, maximum and minimum, at the same compositions for the ternary systems considered is given in Table 3. Also listed are the relative standard deviations σ_r defined as:

$$[1] \quad \sigma_r = [1/N \Sigma (M_{calc} - M_{exp})^2/M^2_{exp}]^{1/2}$$

where M is the pressure or the H^E, and N is the number of experimental data points. In a similar way, we extend this comparison for the binaries involved in the ternary mixtures studied. A comparison between experimental and calculated values of some ternary and binary systems are presented graphically in Figs. 1–9.

As indicated in Table 3, DISQUAC yields a better representation of the ternary VLE than of H^E. Thus, the average relative standard deviation, calculated as $\Sigma\sigma_r$/(no. of systems), is 0.026 for the pressure (12 systems) and 0.098 for H^E (9 systems). Of course, this model, and any similar model, reproduces such a primary fluid phase equilibrium rather accurately. Nevertheless, it is noteworthy that good results are obtained for the prediction of VLE for these rather complex ternary mixtures at very high temperatures (systems 1, 3), or when some of the binaries involved present a miscibility gap (systems 5–8). It is also remarkable that DISQUAC yields good predictions close to the critical points (see ref. 59 and results for the methanol + *n*-hexane mixture at 313.15 K, Table 3). On the other hand, we note that σ_r (ternary) $\simeq$ σ_r (binary) for VLE, and that the experimental values are in excellent agreement with those calculated for the azeotrope coordinates of the binaries involved in ternary system nos. 1–12, even over a wide range of temperature (Table 4).

In the case of H^E, σ_r (ternary) > σ_r (binary), and DISQUAC results for the ternary systems considered here depend on the third compound added to the 1-alkanol + *n*-alkanone binary mixture, not on the number of the interactions present.

When an *n*-alkane is added, the H^E of the ternary system formed (characterized in terms of DISQUAC by three interactions, see above) is larger than the H^E of the binaries involved. This is probably due to the increase in the number of broken alkanol–alkanol hydrogen bonds, the rupture of the OH---O=C hydrogen bond complexes, and the increasing importance of the ketone–ketone interactions. Some of these effects are already taken into account by DISQUAC to rather accurately represent the thermodynamic properties of the binaries 1-alkanols + *n*-alkanones (1). However, now they become more marked and DISQUAC yields H^E s that are lower than the experimental values.

However, if a third active compound is added, e.g., benzene (the ternary system is then characterized by six interactions), the effects mentioned above are compensated by new interactions between dissimilar molecules, such as alkanol–benzene or ketone–benzene, lowering the H^E in comparison to that of a ternary system of the type 1-alkanol + *n*-alkanone + *n*-alkane. DISQUAC results are then improved (Table 3). On the other hand, we note that the H^E maxima of the 1-alkanol + *n*-alkanone + benzene systems are similar to those of the binary 1-alkanol + *n*-alkanone (Tables 1, 2).

Thus, better predictions are obtained when the ternary system (also characterized by six interactions) contains two alkanols because, in this case, the system is more similar to the binary 1-alkanol + *n*-alkanone.

5. Conclusions

DISQUAC rather accurately describes the VLE of the ternary systems studied, even when some of the binaries involved show a miscibility gap. However, predictions of H^E are poorer. They depend on a third compound added to the binary 1-alkanol + *n*-alkanone. The more active this component, the better the results.

Transition state stabilization by micelles: the hydrolysis of *p*-nitrophenyl alkanoates in cetyltrimethylammonium bromide micelles

Oswald S. Tee and Alexei A. Fedortchenko

Abstract: The cleavage of *p*-nitrophenyl alkanoates (acetate to octanoate) at high pH is modestly catalyzed by micelles formed from cetyltrimethylammonium bromide (CTAB) in aqueous solution. Rate constants exhibit saturation behaviour with respect to [CTAB], consistent with substrate binding in the micelles. The strength of substrate binding and transition state binding to the micelles increases monotonically with the acyl chain length, and with exactly the same sensitivity. As a result, the extent of acceleration (or catalytic ratio) is independent of the ester chain. These and earlier results are consistent with the reaction centre being located in the Stern layer of the micelle, with the acyl chain of the ester being directed into the hydrophobic micellar interior. The chain length dependence of kinetic parameters found in this work is comparable to that found previously for ester cleavage by cyclodextrins and by various enzymes with hydrophobic binding sites, as well as to that observed for other phenomena involving hydrophobic effects.

Key words: catalysis, ester hydrolysis, micelles, transition state.

Résumé : Le clivage des *p*-nitrophényl alcanoates (allant de l'acétate à l'octanoate) à pH élevé est modérément catalysé par des micelles formées à partir du bromure de cétyltriméthylammonium (BCTA) en solution aqueuse. Les constantes de vitesse exhibent un comportement de saturation par rapport à [BCTA], ce qui est en accord avec un substrat lié dans les micelles. La force de la liaison du substrat et la liaison de l'état de transition aux micelles augmente de façon monotone avec la longueur de la chaîne acyle, et avec exactement la même sensibilité. Conséquemment, l'importance du taux d'accélération (ou rapport catalytique) est indépendante de la chaîne de l'ester. Ces résultats ainsi que des résultats antérieurs sont en accord avec le centre de réaction localisé dans la couche de Stern de la micelle, avec la chaîne de l'ester dirigée vers l'intérieur hydrophobe de la micelle. L'influence de la longueur de la chaîne sur les paramètres cinétiques, mise en évidence dans ce travail, est comparable à celle trouvée antérieurement lors du clivage des esters par la cyclodextrine et par divers enzymes ayant des sites hydrophobes de liaison, aussi bien que celle observée pour d'autres phénomènes impliquant des effets hydrophobes.

Mots clés : catalyse, hydrolyse d'ester, micelles, état de transition.

[Traduit par la rédaction]

Introduction

One of our current interests is the stabilization of transition states by catalysts (1). In this regard, we make use of an approach developed by Kurz for acid-catalyzed reactions (2), based on transition state theory. As detailed elsewhere (1–3), we define an apparent constant (K_{TS}) for dissociation of the transition state of the catalyzed reaction (TS.cat) into the transition state of the normal reaction (TS) and the catalyst (cat), as in eq. [1].

$$[1] \quad K_{TS} = \frac{[TS][cat]}{[TS.cat]} = \frac{k_u}{k_2} = \frac{k_u K_S}{k_c}$$

Received May 16, 1997.

[1] Author to whom correspondence may be addressed. Telephone: (514) 848-3348. Fax: (514) 848-2868. E-mail: ostee@vax2.concordia.ca.

In eq. [1], k_u is the rate constant in the absence of catalysis, and k_2 is the second-order rate constant for reaction with the catalyst. If saturation kinetics are observed, with a dissociation constant K_S for the {substrate.catalyst} complex, and rate constant k_c for its reaction, then $k_2 = k_c/K_S$. Note that according to eq. [1], $k_c/k_u = K_S/K_{TS}$, which implies that catalytic acceleration is a consequence of transition state binding that is stronger than substrate binding.

We have applied eq. [1] to many reactions mediated by cyclodextrins (1, 3–6) but it is equally applicable to reactions catalyzed by enzymes, catalytic antibodies, metal ions, acids, bases, and micelles (1). In fact, the approach has been used by enzymologists for many years (7), and it has recently been adopted by Kirby (8) for reactions catalyzed by enzyme mimics. In the present paper we again apply eq. [1] to a reaction that is catalyzed by micelles.

The effects of micelles on organic reactions have been extensively studied (9). These effects may be catalytic, or inhibitory, depending on the structure of the reactants, the charge type of the reaction, and the type of surfactant (cationic, anionic, or neutral) forming the micelles. For the most part, catalytic effects can be understood in terms of the ability of micelles to provide a new reaction environment, and to con-

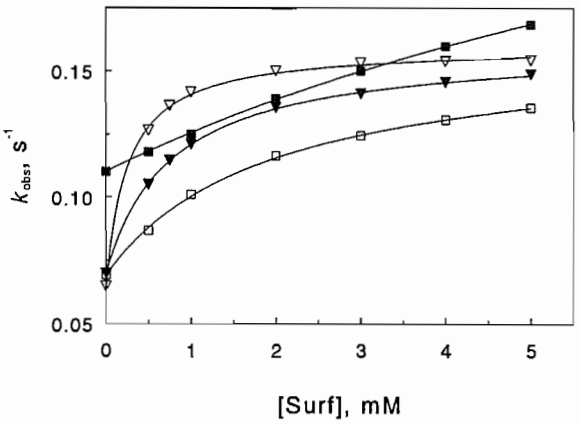
centrate reagents at the micelle–water interface, in the so-called Stern layer.

One of the classic papers in the field of micellar catalysis is that by Menger and Portnoy (10), who introduced a pseudophase model of catalysis. Among other things, they studied the basic hydrolysis of *p*-nitrophenyl acetate and *p*-nitrophenyl octanoate (pNPA and pNPO) in the presence of micelles formed from dodecyltrimethylammonium bromide. Previously, Cordes and co-workers (11) had looked at the effects of micelles on several reactions, including the hydrolysis of pNPA and *p*-nitrophenyl hexanoate (pNPH) in micelles formed from cetyltrimethylammonium bromide (CTAB). Shortly after, Romsted and Cordes (12) studied the effect of various *n*-alkyltrimethylammonium bromides on the cleavage of pNPH and *p*-nitrophenyl laurate (dodecanoate). The main conclusions of these early studies were that catalysis of the ester hydrolysis is greater for longer esters and longer surfactants, and that it is promoted by inclusion of the substrates in the micelles because hydroxide ions are concentrated in the Stern layer of cationic (but not anionic) micelles, near the reactive part of the ester.



Later, Quina et al. (13) showed that the diminished rate of CTAB-catalyzed hydrolysis of pNPA and pNPO observed at high [CTAB] (>1 mM) can be explained by a preferential exchange of bromide ions for hydroxide ions in the Stern layer of the micelles. This and similar work on other micelle-catalyzed reactions gave rise to the pseudophase ionic exchange (PIE) model (14).

Much more recently, Al-Awadi and Williams (15) studied the hydrolysis of nine phenyl laurates (dodecanoates) in CTAB micelles. They found that the sensitivity of the micelle-catalyzed reaction to the leaving group ($\beta_{lg} = -0.51 \pm 0.06$) is virtually the same as that for hydrolysis in the basic aqueous medium ($\beta_{lg} = -0.56 \pm 0.05$). As we pointed out earlier (1), this situation arises because the binding of the esters and their transition states to the micelles is essentially independent of the substituent on the phenyl group. It also means that the transition state stabilization afforded by the CTAB micelles is the same regardless of the phenoxide leaving group, and it is consistent with the reaction centre being in a largely aqueous environment, while the acyl chain of the ester is directed into the hydrophobic interior of the micelle. It was suggested that this interpretation could be tested by studying a series of esters with different acyl chain lengths, to see if they show an appropriate sensitivity of transition state parameters to ester structure (1). The present paper describes just such a study.

Results

We have measured the kinetics of hydrolysis of a series of *p*-nitrophenyl alkanoates (acetate to octanoate) at high pH (11.6, phosphate buffer) as a function of the concentration of cetyltrimethylammonium bromide (CTAB), which forms cationic micelles. Reactions were carried out with constant bromide ion concentration (= 5 mM) to avoid the problem of ion exchange in the Stern layer of the micelles (13–15). As expected from previous studies, the reaction is modestly catalyzed, and it exhibits saturation behaviour with respect to [CTAB], as shown by the examples presented in Fig. 1. Experiments with dodecyltrimethylammonium bromide (DDTB) were also attempted but they were not as successful, because the catalytic effect is small. This probably arises because the micelles of DDTB are smaller and the critical micellar concentration (cmc) of DDTB is higher (16), so that inclusion of the alkanoate esters (and their transition states) in the micelles is less favorable.

Fig. 1. Effect of cetyltrimethylammonium bromide (CTAB) on the rate of hydrolysis of *p*-nitrophenyl alkanoates: acetate, ■; butanoate, □; pentanoate, ▼; hexanoate, ▽.

Analysis of the kinetic data was based on the pseudophase model introduced by Menger and Portnoy (10). In this model, it is assumed that the organic substrate is distributed between the aqueous phase and the micellar phase, in accord with an apparent dissociation constant, K_S (eq. [3]), and allowance is made for the hydrolysis of free ester (E) in the basic medium (eq. [2]) and of ester sequestered in the micellar pseudophase (E.Surf), eq. [3]. Together these two processes lead to a dependence of the overall rate constant for ester hydrolysis on concentration [Surf] as given in eq. [4].

$$[2] \quad \mathrm{E} \xrightarrow{k_u} \text{products}$$

$$[3] \quad \mathrm{E} + \mathrm{Surf} \underset{K_S}{\rightleftharpoons} \mathrm{E.Surf} \xrightarrow{k_c} \text{products}$$

$$[4] \quad k_{obs} = \frac{(k_u K_S + k_c[\mathrm{Surf}])}{(K_S + [\mathrm{Surf}])}$$

From experiments carried out over a range of [Surf] one can find values of k_c and K_S by nonlinear fitting of eq. [4], keeping k_u fixed at the measured value. Often, the correction [Surf] = ([Surf]$_0$ − cmc) is made (9), where [Surf]$_0$ is the stoichiometric concentration of the surfactant. However, since the critical micellar concentration (cmc) of CTAB is 9.2×10^{-4} M at zero ionic strength and much lower at high [salt] (16), we have followed Al-Awadi and Williams (15) and dispensed with the correction, in the interests of simplicity.[2] The measured values of k_u and fitted values of k_c and K_S are collected in Table 1, which also contains values of K_{TS}, calculated from eq. [1].

[2] In fact, we have determined that use of the correction makes no significant difference to the fitted values of k_c and K_S, or to the correlations of pK_S and pK_{TS} with chain length that are discussed below.

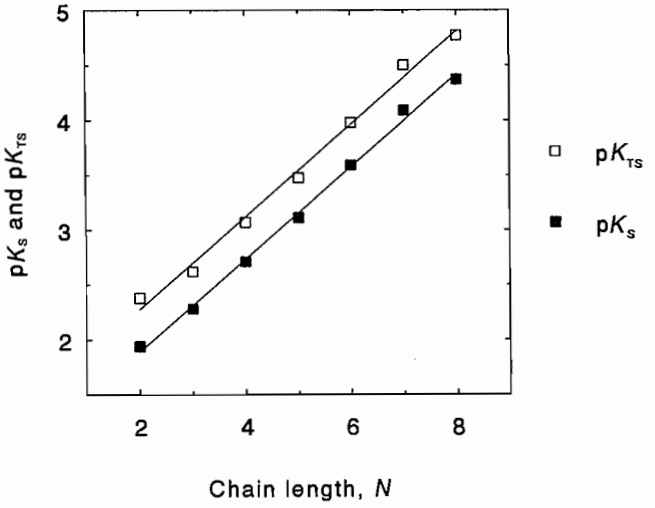
[a]At 25°C, in a 0.2 M aqueous phosphate buffer of pH 11.6 and with bromide ion concentration = [CTAB] + [NaBr] = 5.0 mM.

Discussion



The constants in Table 1 can be used to probe the origins of the micellar catalysis of the hydrolysis of the esters. In particular, we can compare the sensitivities of substrate binding, reflected in pK_S (= $-\log K_S$), and transition state binding, through pK_{TS} (= $-\log K_{TS}$), to variations in the structure of the substrates (1).

From the data of Al-Awadi and Williams for phenyl laurate esters (15), both substrate and transition state binding parameters (pK_S and pK_{TS}) are independent of the phenoxide leaving group (1). For the present results for *p*-nitrophenyl alkanoates, the plot of pK_S against the ester chain length (*N*) is a straight line of slope 0.42 ± 0.01, and the plot of pK_{TS} against N is parallel, with a slope of 0.42 ± 0.02 (Fig. 2). Moreover, the plot of pK_{TS} against pK_S is a good straight line ($r = 0.999$), and has a slope of 1.00 ± 0.01, implying that the variations in substrate binding and transition state binding are governed by the same factors.

According to eq. [1], the limiting acceleration, or catalytic ratio, $k_c/k_u = K_S/K_{TS}$. As a consequence, the parallelism between pK_S and pK_{TS}, seen in Fig. 2, means that this ratio is essentially constant, at 2.4 ± 0.3, for acyl chain lengths from C_2 to C_8. So, contrary to what was surmised earlier from more limited data, the magnitude of the catalysis does not increase appreciably with the ester chain length, but the strength of substrate binding *and* transition binding does. Correspondingly, values of k_2 (= k_c/K_S) increase 130-fold, from 26 to 3480 M^{-1} s^{-1}, under the reaction conditions. For the catalytic ratio k_c/k_u to increase significantly with chain length would require the transition state binding (pK_{TS}) to be more sensitive to the acyl chain length than the initial state binding (pK_S).

The parallel dependence of pK_S and pK_{TS} on acyl chain length (Fig. 2) is consistent with incorporation of the substrates and their transition states in CTAB micelles being largely determined by hydrophobic effects. This assertion is based on the knowledge that many phenomena associated with hydrophobicity of *n*-alkyl derivatives vary linearly with chain length (16–21). For example, a plot of −log (cmc) against chain length (*N* = 10,12,14,16) for the micellization of *n*-alkyltrimethylammonium bromides is a straight line (r = 0.9998), with slope of 0.313 ± 0.004 (from data in Rosen (16)); other *n*-alkyl ionic surfactants show comparable behaviour (16, 17). Also, free energies of transfer (water → micelle, water → organic medium, and water → gas phase) for organic solutes vary linearly with solute chain length, and the solubility of organic solutes in micelles increases exponentially with surfactant chain length (16–19). In a similar way, the Hansch hydrophobicity parameters (π), which are based on partition coefficients, are also linear in *N* (20), as are microhydrophobicity parameters derived by Menger from kinetic measurements (21).

Fig. 2. Dependence of transition state binding (pK_{TS}, □) and substrate binding (pK_S, ■) to CTAB micelles on the acyl chain length (*N*) of *p*-nitrophenyl alkanoate esters. The slopes of both graphs are 0.42 ± 0.02. The corresponding plot of pK_{TS} against pK_S is linear (r = 0.999), and has a slope of 1.00 ± 0.01, suggesting that the same factors affect transition state binding and substrate binding.

In other work, we have shown that the strength of binding of many *n*-alkyl derivatives to cyclodextrins (22) is sensitive to chain length, with slopes of pK_S vs. *N* generally falling in the range 0.3–0.6 (23). Moreover, pK_{TS} values for the basic cleavage of *p*-nitrophenyl alkanoates by cyclodextrins vary linearly with *N*, with slopes of 0.2–0.3, except for short acyl chains (4*a*, 4*c*, 4*d*). These sensitivities to chain length are due, at least in part to hydrophobic effects (4*e*).

Another interesting comparison, derived from observations made by O'Connor and co-workers (24), is with the cleavage of esters, including *p*-nitrophenyl alkanoates, by various enzymes (lipases, chymotrypsin, trypsin, horse liver esterase),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12
For personal use only.

© 1997 NRC Canada

which also shows distinct chain length dependences, with plots of log (k_{obs}) vs. N having slopes of 0.3–0.4. These values are consistent with the acyl binding site of the enzymes being quite hydrophobic. Similarly, values of log (k_{cat}/K_M), and hence pK_{TS}, for the cleavage of methyl esters of *N*-acetyl-L-α-amino acids by α-chymotrypsin correlate strongly with the Hansch hydrophobicity parameters of the α-substituents (1, 25).

It seems reasonable to conclude from all these observations that stabilization of the transition states in the various cases are partially or largely governed by similar hydrophobic effects.

Conclusions

In his recent discussions of the "molecular recognition of transition states," Kirby (8, 26) has emphasized two distinct components to transition state stabilization: *passive binding*, which arises from non-covalent interactions, comparable to those involved in equilibrium binding; *dynamic binding*, due to interactions at the reaction centre, particularly those associated with the making and breaking of covalent bonds. Seen in these terms, our conclusions for the hydrolysis of phenyl alkanoates in CTAB micelles are as follows: (*a*) the passive binding of the transition state involves hydrophobic binding of the acyl chain of the esters in the micelles, as does the substrate binding (Fig. 2); (*b*) the dynamic component is small and essentially constant, arising from the acyl transfer taking place in the largely aqueous environment of the Stern layer (1, 15).

Experimental

The esters were purchased from Sigma or were available from previous studies (4*a*, 4*c*, 4*d*, 4*e*). Cetyltrimethylammonium bromide (hexadecyltrimethylammonium bromide, CTAB) was obtained from ICN Biochemicals. All other chemicals were from the Aldrich Chemical Company, except for standard NaOH solutions, which were obtained from A & C Chemicals (Montreal).

The kinetics of the ester cleavage were followed by monitoring the first-order appearance of the *p*-nitrophenolate ion at 405 nm, using an Applied Photophysics SX17MV stopped-flow spectrophotometer, with the temperature of the cell kept at 25.0 ± 0.1°C. Usually, about 5–10 absorbance traces were computer averaged before estimation of k_{obsd} by nonlinear least-squares fitting of an exponential growth curve, using software supplied with the instrument.

Substrate concentrations were kept low with respect to [CTAB] so that the properties of the micelles were not significantly perturbed by the presence of the substrate (9, 10). Stock ester solutions (0.1 M in acetonitrile) were diluted in water to give twice the desired final concentrations. These were mixed 1:1 with a solution containing 0.4 M phosphate buffer + CTAB + NaBr whose pH had been adjusted to 11.6. Both reactant solutions were sonicated for 10–20 min to facilitate solubilization. The final reacting solutions contained 0.2 M phosphate buffer, CTAB (0–5 mM), NaBr (5 mM − [CTAB]), and ester concentrations as follows: acetate to pentanoate, 50 μM; hexanoate, 25 μM; heptanoate, 5 μM; octanoate, 2.5 μM.

Nonlinear fitting of eq. [4], and other such equations, was carried out with commercial (Prism) software.

A study of the electrochemical synthesis of ZnO thin films

Z.H. Gu, T.Z. Fahidy, R. Hornsey, and A. Nathan

Abstract: The principal characteristics of the cathode deposition of zinc oxide from slightly acidified aqueous zinc nitrate solution at 65°C were studied via potentiodynamic electrolysis, potentiostatic electrolysis, and X-ray diffraction patterns. The results indicate the reliability of a low-temperature electrolytic path of synthesis, and avenues of further exploration.

Key words: zinc oxide, cathode deposition, XRD patterns, FBM theory.

Résumé : En se basant sur les résultats d'électrolyses potentiodynamique et potentiostatique ainsi que sur les patrons de diffraction des rayons X, on a étudié les principales caractéristiques du dépôt à la cathode d'oxyde de zinc à partir de solutions légèrement acidifiées de nitrate de zinc, à 65°C. Les résultats indiquent que la voie électrolytique à basse température est fiable pour la synthèse et qu'elle offre de nouvelles voies d'exploration.

Mots clés : oxyde zinc, dépôt à la cathode, patrons de diffraction des rayons X, théorie «FMB».

Introduction

Zinc oxide (ZnO), in the bulk or thin film form, is an important material for a wide variety of applications. It is used as a vulcanizing activator for rubber (1, 2), a coloring agent in paints (3), a photoconducting material for copying machines (3), a highly transparent electrode material for solar cells (4), a phosphor material for converting radiation to visible light at low voltage (5), a piezoelectric material in mechanical transducers (6), and as a gas-detection material for microsensors (6).

Chemical preparation procedures in combination with various modern techniques have yielded ZnO films of high optical and electrical quality. The films have been synthesized by ion-assisted cyclic sputtering (7), radio-frequency sputtering (8), cold remote nitrogen plasma (9), zinc evaporation in mixed radio-frequency plasma (10), pulsed laser deposition (11), chemical beam deposition (12), chemical bath deposition (13), and spray pyrolysis (14, 15). A sol–gel technique has been used to prepare nanoparticles of ZnO (16), and an electrophorus-based technique has recently been developed to produce phosphor glasses (17). Among various techniques, low-temperature and relatively inexpensive electrochemical synthesis of thin films is highly attractive; in particular, specific film thickness and other properties can be achieved by controlling the electrode potential and chemical parameters of the electrolytes (18). An anode process (19) produces ZnO by first depositing zinc doped with nickel and cobalt onto a substrate in an acidic solution, and then oxidizing it in an alkaline solution. Ni and Co are homogeneously distributed within the anodically formed oxide layer, which shows *n*-type semiconductive properties. Most recently, a cathode process to produce various oxides was shown to be promising due to in situ doping capability (20), and initial applications of the cathode process for ZnO have also been reported (21–23).

The purpose of this paper is to describe an exploratory study of the cathode synthesis of zinc oxide films, and to outline the analysis of the experimental time-series data in terms of fractional Brownian motion (FBM) theory (24, 25). It is expected that this material will contribute to a deeper understanding of the cathode method of ZnO production, and of criteria for the optimal selection of the operating parameters.

Experimental apparatus and procedure

Figure 1 illustrates the overall apparatus. Electrolysis was carried out at 65°C in a $120 \times 90 \times 45$ mm^3 glass cell using a 60×10 mm^2 zinc anode. The cathodes, acting as substrates for the ZnO film deposits, were copper, platinum, and ITO (indium – tin oxide) coated glass plates with a 600 mm^2 active area, separated by a 30 mm distance from the anode. A saturated calomel electrode (SEC) with its Luggin capillary probe located 2 mm from the working electrode served as reference electrode. The electrolyte was an aqueous solution of 0.075 or 0.100 mol L^{-1} $Zn(NO_3)_2$ with its initial pH (pH_i) adjusted to 6.0 in order to avoid $Zn(OH)_2$ precipitation in the bulk solution. The effect of the initial pH was determined by setting pH_i = 4.1 and 6.8 in certain experiments. The deposition process was monitored via linear sweep voltammetry and potentiostatic electrolysis. A model AFRDE5 Pine potentiostat was

used for potential control, and the electric current – time relationship was recorded by means of an OPTO-22 interface–microcomputer assembly.

Physicochemical properties at equilibrium conditions

Literature data assembled in Table 1 indicate that nitrate ion reduction is strongly favoured thermodynamically (at pH = 6, for example, E_2 = 0.475 V). It may appear at first glance that ZnO synthesis is essentially a three-stage process: in the first stage nitrate reduction liberates hydroxide ions, which react with zinc ions or metallic zinc to form zinc hydroxide in the second stage. In the final stage zinc hydroxide is converted to ZnO. Both overall reactions:

[1] $NO_3^- + Zn + H_2O = Zn(OH)_2 + NO_2^-$ $\quad \ln K = 87.7$

[2] $NO_3^- + Zn = ZnO + NO_2^-$ $\quad \ln K = 98.6$

possess a very high equilibrium constant at 65°C, guaranteeing the thermodynamic feasibility of ZnO synthesis at appropriate pH values and, in the absence of dilute mineral acids, in order to avoid the redissolution stage (29):

[3] $\varepsilon\text{-}Zn(OH)_2 + 2H^+ = Zn^{2+} + 2H_2O$ $\quad \ln K = 26.92$

Zinc is prone to form (mononuclear) hydroxide complexes (30, 31), whose equilibrium properties were investigated in detail by Hepler and co-workers (32). $Zn(OH)_2$ itself has six forms (α; β_1; β_2; χ; δ; ε) of which only ε-$Zn(OH)_2$ is stable in water below 39°C. Their solubility in water is widely different (31). In alkaline solutions the hydroxo species (e.g., $Zn(OH)^+$, $Zn(OH)_3^-$, and $Zn(OH)_4^{2-}$) are stable, with standard free energies of formation ranging from −300 to −900 kJ mol^{-1}. Spontaneous $Zn(OH)_2$ formation may be expected for pH > 6.35 (25°C) and pH > 5.63 (65°C) in the case of the 0.075 mol L^{-1} zinc nitrate solution, and for pH > 6.29 (25°C) and pH > 5.56 (65°C) when $[Zn(NO_3)_2]$ = 0.1 mol L^{-1}.

The standard free energy change of the

[4] $ZnO + H_2O = Zn(OH)_2$

process is computed from thermodynamic data and their temperature dependence (27, 33, 34) to be about 1884 J/mol (25°C) and 2031 J/mol (65°C). The experimental zinc nitrate concentrations have a negligible effect on the numerical value of free energy change, which indicates relative stability of the oxide species with respect to the hydroxide species under standard equilibrium conditions.

Nitrate-ion reduction in alkaline media may also occur in principle (35, 36) as a 2-, 3-, 5-, 6-, or 8-electron transfer process yielding nitrogen and ammonia as cathode products with standard potentials ranging from about −0.17 V to +0.41 V (NHE) at 25°C. To the authors' knowledge, the importance of these reactions in neutral or acidic media has not been demonstrated.

Electrolytic synthesis of ZnO in the experimental cell

1. Current–potential relationships

A typical current–potential curve, obtained at a sweep rate of 20 mV s^{-1}, is shown in Fig. 2. The magnitude of the cathode potential with respect to the saturated calomel electrode is

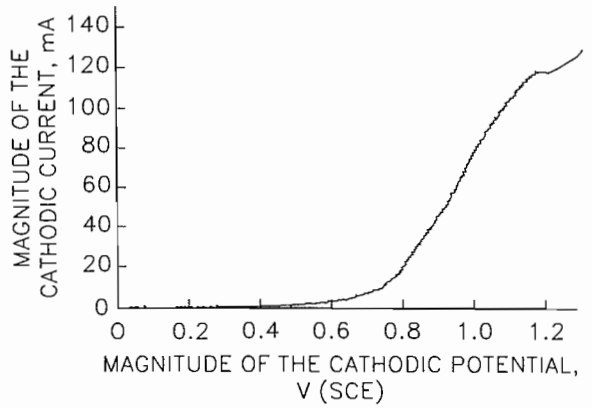
Fig. 2. Linear sweep voltammogram of the cathode process. Sweep rate: 20 mV s^{-1}; copper substrate.



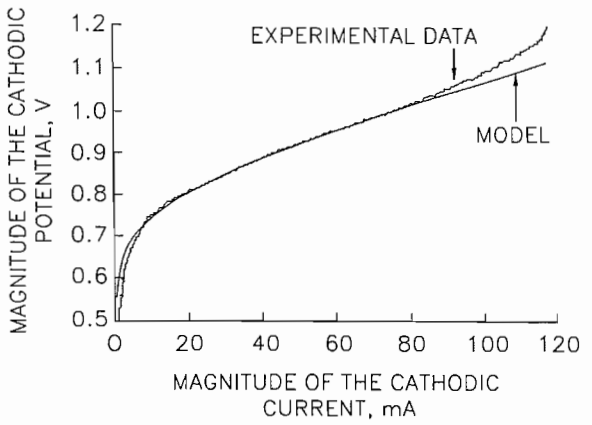


Fig. 3. Comparison of experimental observations with model-based prediction eq. [6].

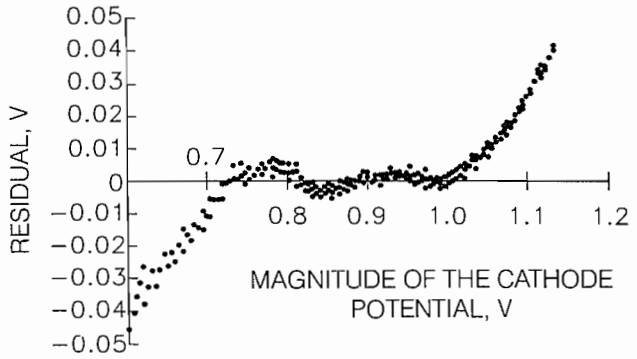
defined as $V_c = |V_c\,(\text{NHE})| + 0.2412$ V, where V_c (NHE) is the cathode potential on the normal hydrogen electrode scale (e.g. the value of $V_c = 0.4$ V implies that $V_c = -0.1588$ V, since the measured cathode potential is -0.4 V). The cathode current is the sum of three components:

$$[5] \quad I = I_1 + I_2 + I_3$$

where the subscripts refer to the cathode processes of the same numbering in Table 1. The relative magnitude of the current components depends on the cathode potential. In the $\sim 0.4 < V_c < 0.71$ V range the cathode reaction is essentially nitrate reduction. In the $0.71 < V_c < 1.1$ V range, the current increases rapidly and proton discharge and hydrogen evolution, visibly discernible at the cathode, indicate H_2O decomposition. The short plateau appearing at about $V_c = 1.18$ V probably indicates a relatively narrow zone of mass transport control. At higher magnitudes of the cathode potential the appearance of gray particles on the cathode surface indicates the contribution of processes (3) and (5), shown in Table 1. Due to ZnO/$Zn(OH)_2$ formation on the cathode surface, it is tempting to consider that the overpotential in the intermediate range ($0.71 < V_c < 1.1$ V) depends not only on an "activation barrier," but

Fig. 4. The variation of the current-regression residual with cathode potential.



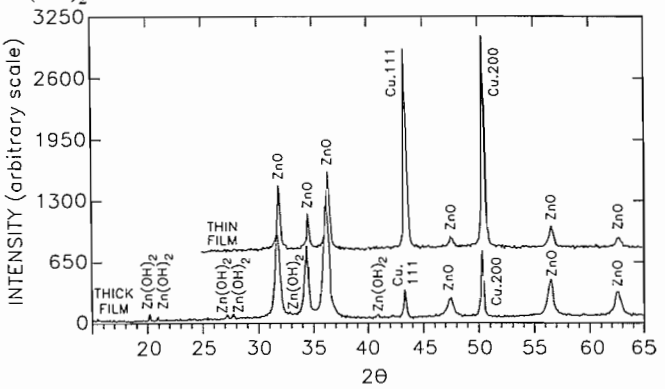


Fig. 5. X-ray diffraction patterns of oxide films deposited on copper substrates. The upper pattern for the thin film formed at $V_c = 0.75$ V (SCE) indicates only ZnO, whereas the lower pattern for the thick film formed at $V_c = 0.95$ V (SCE) indicates a mixture of ZnO and $Zn(OH)_2$.

also on the passivating ZnO/$Zn(OH)_2$ layer. If it is assumed (*i*) that charge transfer proceeds through a dual barrier made up of the passive film and the double layer (37), with an apparent resistance R^* caused mainly by the passivation layer, and (*ii*) that R^* may be taken as a constant over a sufficiently short time period, a modified Tafel equation:

$$[6] \quad V_c = a' + b' \log |I| + R^* |I|$$

may be postulated, whose parameters are obtained via a non-linear regression technique. Figure 3 demonstrates close agreement between experimental observations and eq. [6] with the numerical values of the regression parameters $a' = 0.5908$ V; $b' = 0.130$ V dec^{-1}; $R^* = 2.0$ ohm; and the coefficient of determination $r^2 = 0.99$ in the $0.71 < V_c < 1.0$ range. The residual plot shown in Fig. 4 has a narrow band of ± 7 mV in this domain and exhibits a slight wavy trend that is presumably due to perturbation caused by H_2 bubbles. At $V_c < 0.71$ V, the consistently negative residual values indicate incipient solid layer deposition with an apparent ohmic resistance below the regression-predicted value. By contrast, the consistently positive residual values at $V_c > 1.0$ V indicate an apparent resistance above the regression-predicted values, due to a considerable accumulation of the ZnO/$Zn(OH)_2$ layer on the cathode surface.

The $V_c < 0.71$ V zone, where the passivation layer is not yet significantly developed, may be used for an *approximate* determination of the electrode–kinetic parameters of the nitrate reduction (first) step by neglecting the ohmic term in eq. [6] under low-V_c conditions. Regression analysis yields a = 0.6902 V and b = 0.242 V dec^{-1} with r^2 = 0.994 in the Tafel equation:

$$[7] \quad \eta = a + b \log |i|$$

where η is the activation overpotential and i is the cathode current density (A cm^{-2}). It follows that an approximate value of the exchange current density of the nitrate reduction process is $i_0 = 1.41 \times 10^{-6}$ A cm^{-2}.

2. The effect of the cathode potential

The cathode potential effect is demonstrated by the nature of the cathode deposit as well as the variation of the cathode current with time. No significant amount of ZnO can be detected at $V_c < 0.7$ V, while at $V_c > 1.1$ V gray particles can readily be seen embedded in the white film. At $V_c = 0.7$ V, the transparent film contains pure ZnO, whereas at $V_c = 0.95$ V the loose polycrystalline film contains a certain amount of $Zn(OH)_2$ as shown by XRD analysis (Fig. 5) of the deposit samples. The presence of hydroxide is due to a more rapid buildup of [OH^-] ion concentration at high cathode potentials, which promotes $Zn[OH]_2$ precipitation in the vicinity of the cathode followed by deposition onto the cathode surface. On a copper substrate, the current–time variation remains smooth up to about $V_c = 0.8$ V; at higher potentials high-frequency fluctuations become increasingly larger as the potential magnitude is increased, due to the progressively stronger effect of H_2 evolution. Within the $1000 < t < 2000$ s time interval, the mean value of the measured current is 8.03, 20.19, and 53.41 mA at corresponding potential magnitudes of V_c = 0.7, 0.8, and 0.95 V (Fig. 6).

3. The effect of the initial pH of the solution

Cathode current behavior is highly dependent on the initial pH of the electrolyte. As shown in Fig. 7, the mean current is essentially constant at $pH_i = 6.8$, but at $pH_i = 4.1$ the current is consistently higher and increases with time. The lower pH_i favours hydrogen evolution and accelerates the cathode process.

4. The effect of the cathode substrate

The effect of the substrate material is depicted in Fig. 8. At the same cathode potential, the current is the lowest on the ITO-coated glass since its electrical resistivity is much higher than in the case of metals. It is not understood at present why the current on a copper cathode is higher than on platinum (given that hydrogen overpotential on copper is appreciably higher than on platinum under otherwise identical conditions), and why its relaxation from a large initial peak value is much slower than in the case of platinum and coated glass.

Analysis of time-series data

The experimentally observed cathode currents under constant potential are fluctuating functions of time. FBM theory has been extensively applied to fluctuating phenomena (e.g., ref. 24) and its utility in analyzing anode processes has been well demonstrated (25, 38). The FBM technique generates, via Pox diagrams, a numerical measure of the degree of (long-term) correlation in an experimental time series and provides a yardstick of relative stability in terms of the slope H of the Pox diagram. The $0.5 < H < 1$ region is the domain of "persistence": the closer the H-value to 1, the larger the structural stability. H = 0.5 represents pure random Brownian motion, and $0 < H < 0.5$ is the domain of "antipersistence," with progressively decreasing structural stability as H approaches zero, the state of pure chaos. A typical Pox diagram is illustrated in Fig. 9, and Table 2 summarizes the results of FBM-based analysis of the experimental Pox diagrams. For a given cathode substrate material, the Hurst exponent expectedly decreases as V_c increases, indicating the enhancing effect of hydrogen gas evolution on the cathode current fluctuation. At a given cathode potential (e.g., 0.80 V), the progressively smaller numerical values of H indicate that current on ITO-coated glass exhibits the largest relative degree of stability, followed by platinum and copper; this finding is also in agreement with Fig. 8.

Conclusions

Experimental results hitherto obtained offer sufficient encouragement for a further systematic study of the best conditions for an electrolytic synthesis of zinc oxide, under optimal cathode-potential and solution-pH control for a given substrate material. An extended investigation including a morphological determination of layer quality and the exact composition of the cathode layer is now underway in our laboratory.

Thermodynamics of micellization and solubilization in systems of water – sodium *n*-alkylcarboxylates – alkoxyethanols at 25°C

H. Huang and R.E. Verrall

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12

Abstract: The apparent molar volumes and adiabatic compressibilities, $Y_{\phi,S}$, of carboxylate surfactants, C_nNa (n = 8, 10, 12), in aqueous solutions in the absence and presence of medium-chain-length alkoxyethanols, C_4EO_X (EO = ethylene oxide group, X = 0–4), and of alkoxyethanols, $Y_{\phi,A}$, in aqueous solutions in the absence and presence of surfactant, were determined at 25°C from density and sound velocity measurements as a function of both the surfactant and alcohol concentrations. The partial molar volumetric properties of C_nNa and the transfer functions of C_4EO_X from water to aqueous surfactant solutions were calculated from the apparent molar properties. Values of the thermodynamic parameters of micellization for C_nNa, i.e., the critical micelle concentration, the partial molar property of the monomer at infinite dilution, Y_S^0, and in the micellar state, Y_S^M, were obtained from simulations of the experimental data, $Y_{\phi,S}$, using a mass-action model. As expected, these properties are strongly dependent on the surfactant chain length. The distribution coefficient of C_4EO_X between the micelle and aqueous phases, K_D, and the change in the molar property of alcohols due to micellization, Y_A^M, extracted from fitting the transfer function data of C_4EO_X using a chemical equilibrium model, show that the solubilization of alkoxyethanols in carboxylate micelles is enhanced by increasing the surfactant chain length and the number of EO groups in the alcohol. The deeper penetration of C_4EO_X into the micelles of longer chain surfactants is associated with increasingly stronger interactions between surfactant head groups and EO segments of the alcohol on (or near) the micelle surface. Aggregation numbers of C_nNa–C_4EO_X mixed micelles show that addition of a small amount of C_4EO_X has little effect on the structure of the micelles formed from C_8Na and $C_{10}Na$, but leads to significant change in $C_{12}Na$ micelles.

Key words: sodium carboxylate salts, alkoxyethanols, partial molar volume and compressibility, transfer functions, distribution coefficient, mean aggregation number.

Résumé : En se basant sur des mesures, à 25°C, de densité et de vélocité du son en fonction des concentrations tant de l'agent de surface et de l'alcool, on a déterminé les volumes molaires apparents et les compressibilités adiabatiques, $Y_{\phi,S}$ et $Y_{\phi,A}$, respectivement d'agents de surface carboxylates, C_nNa (n = 8, 10, 12), en solutions aqueuses en présence et en l'absence d'alkoxyéthanols de longueur de chaîne moyenne, C_4EO_X (EO = groupe d'oxyde d'éthylène, X = 0–4) et d'alkoxyéthanols en solutions aqueuses en présence et en l'absence d'agent de surface. À partir des propriétés molaires apparentes, on a calculé les propriétés volumétriques molaires partielles de C_nNa et les fonctions de transfert de C_4EO_X de l'eau vers les solutions aqueuses d'agent de surface. Utilisant un modèle d'action de masse et des simulations des données expérimentales, $Y_{\phi,S}$, on a déterminé les valeurs des paramètres thermodynamiques de micellisation des C_nNa, c'est-à-dire la concentration micellaire critique, la propriété molaire partielle du monomère à dilution infinie, Y_S^0, et dans l'état micellaire, Y_S^M. Tel qu'on pouvait s'y attendre, ces propriétés dépendent fortement de la longueur de la chaîne de l'agent de surface. Le coefficient de distribution des C_4EO_X entre la micelle et les phases aqueuses, K_D, et le changement dans la propriété molaire des alcools dû à la micellisation, ΔY_A^M, qui ont été extrait en ajustant les données de fonction de transfert des C_4EO_X à l'aide d'un modèle d'équilibre chimique, montrent que la solubilisation des alkoxyéthanols dans des micelles de carboxylate est promue par une augmentation de la longueur de la chaîne de l'agent de surface ainsi que par le nombre de groupes EO dans l'alcool. La pénétration plus grande des C_4EO_X dans les micelles des agents de surface de chaînes plus longues est associée à des interactions de plus en plus fortes entre les groupes de tête de l'agent de surface et les segments d'EO de l'alcool sur (ou près de) la surface de la micelle. Les nombres d'agrégation des micelles mixtes C_nNa–C_4EO_X montre que l'addition d'une faible quantité de C_4EO_X n'a qu'un faible effet sur la structure des micelles formées à partir des C_8Na et $C_{10}Na$, mais qu'elle conduit à un changement important dans les micelles de $C_{12}Na$.

Mots clés : sels de sodium d'acides carboxyliques, alkoxyéthanols, volume molaire partiel, compressibilité molaire partielle, fonctions de transfert, coefficient de distribution, nombre d'agrégation moyen.

Introduction

In many practical formulations of surfactants, the addition of a third component such as a medium-chain alcohol (cosurfactant) can help to control the stability of the system and improve the performance of the surfactants, well beyond the level achieved by the surfactants themselves (1). The synergistic effect of surfactant mixtures on the properties of the system (2) has led to theoretical interest in developing a quantitative understanding of the behaviour of mixed surfactant systems that can be exploited in new applications.

Micellar systems can be characterized by structural parameters such as the mean aggregation number, micelle size and shape, and also by thermodynamic parameters. In recent years, along with the development of a variety of methods for studying the structure and kinetic processes of surfactant systems (3), thermodynamic studies have led to a better molecular interpretation of thermodynamic properties of surfactant solutions through the use of various theoretical models of micellization (4–7). Modeling studies enable the extraction of estimates of important parameters of the micelle systems with a minimum of experimental data. The effect of additives on the properties of water–surfactant–additive ternary systems can be investigated through quantitative analysis of the partial molar properties of the additive and the transfer functions of the additive from water to aqueous surfactant solution, using appropriate models. At the present time there are two modeling methodologies (8–11) that are widely used to extract fundamental parameters. A model proposed by DeLisi et al. (8, 9) assumes a pseudo phase transition for the micellization process and a mass-action equilibrium for the additive distribution between the micelle and aqueous phases. This model is more applicable to long-chain hydrocarbon surfactants. Another model proposed by Desnoyers and co-workers (10, 11) combines a mass-action equilibrium for the micellization process with a pseudo phase transition for the distribution of additive between the micelles and the aqueous phases. It treats systems of short-chain surfactants somewhat better than those having a long chain.

While much of the work in recent years has focused on the interactions of *n*-alcohols (and some branched isomers) and hydrocarbons with ionic and nonionic micelles (12), there has been a growing interest in studying nonionic ethoxylated alcohols (alkoxyethanols) in surfactant systems (13–20). The aqueous bulk phase solubility of a typical nonionic alkoxyethanol is enhanced by increasing the number of ethylene oxide (EO) segments. On the other hand, an increase in the length of the hydrocarbon chain for a fixed number of EO segments is accompanied by a pronounced decrease in the critical micelle concentration (cmc). However, an increase in the number of EO segments for a fixed hydrocarbon chain length results in a less significant increase in the cmc (21). Previous studies have shown some interesting features of the EO group in systems of anionic surfactant. For example: the insertion of EO groups into the hydrocarbon chain of alkyl polyoxyethylene sulfates decreases the cmc and increases both the surface activity and the mean aggregation number of the micelles (20); the cmc value of the anionic surfactant sodium decanoate has been found to be lower in the presence of 2-butoxyethanol than in the presence of *n*-butanol, for a fixed alcohol concentration (17); the cmc values of both sodium decyl sulfate (14) and of sodium dodecyl sulfate (19) decrease with an increasing number of EO groups for an alcohol of a given chain length; and the solubility of oil-soluble azo-dyes in mixed micelles of sodium dodecyl sulfate – alkoxyethanols (13) is enhanced by increasing the number of EO segments in the alcohol.

Of particular interest is the observation that the distribution coefficient of ethoxylated alcohols between anionic micelles and the aqueous phase increases as a function of the number of EO groups in the alcohol (14, 15). The increasingly negative Gibbs energy of transfer, as the number of EO groups increases, implies that the role of the EO group is to enhance the interactions between the alkoxyethanol molecules and anionic micelles, analogous to the contribution of an EO group to increasing the hydrophobicity of the alkyl polyoxyethylene sulfate monomer (20). These results are contrary to the hydrophilic character of the ethylene oxide chain in nonionic surfactants (22) where they tend to decrease the driving force leading to the formation of nonionic micelles (23). This feature is also contrary to the results obtained for cationic surfactant systems where both the cmc of the surfactant and the distribution of alkoxyethanols between the two phases are virtually independent of the number of EO groups (14). The different behaviour exhibited by EO groups in an alcohol, when they interact with either anionic or cationic micelles in aqueous medium, is an intriguing result. Much of the previous work dealing with surfactant and alkoxyethanol mixed systems has focused on changes in the micellization properties of the surfactant and the degree of solubilization of the alcohol in the micelle (13–20). There has been a paucity of information concerning the effect of the alcohol on the structure of the micelle (24). To this time, no comprehensive study has been undertaken to obtain a satisfactory explanation of the specificity of interactions between EO groups and different types of ionic micelles. The present systematic study of mixed micelle systems comprising ionic surfactants of varying chain length and alkoxyethanols having a varying number of EO groups was initiated in order to obtain more information about the different characteristics of EO groups in anionic and cationic micelles.

We present the results of thermodynamic studies of mixed micelle systems of anionic carboxylates C_nNa (n = 8, 10, 12) and polyoxyethylene butyl ether compounds C_4EO_X (EO = ethylene oxide group, X = 0–4). Two thermodynamic properties, the apparent molar volume and the apparent molar adiabatic compressibility, have been determined for the sodium carboxylates as a function of their concentration in the absence and presence of polyoxyethylene butyl ether compounds of a given concentration and for the ethoxylated alcohols as a function of their concentration in binary aqueous surfactant systems of varying surfactant concentration. Values of the micellization parameters of the carboxylate surfactants were obtained by analyzing apparent molar volumetric properties of the binary surfactant–water systems using a mass-action model (6, 7). The transfer thermodynamic functions of the ethoxylated alcohols from water to surfactant solutions were obtained by comparing the apparent molar properties for the alcohols in aqueous surfactant solutions and in water at a given low concentration of alcohol. The transfer functions were analyzed using a chemical equilibrium model (10, 11) to obtain estimates of the solubilization parameters of C_4EO_X in C_nNa micelles.

Macroscopic thermodynamic properties give little direct information about changes in the structure of the mixed micelles (25). Information concerning changes in the mean aggregation number of the micelle as a function of changes in the chemical structure of the components forming the micelle is essential in order to obtain a comprehensive understanding of the aggregation phenomenon in surfactant solutions. Some results of a previous study[2] of the mean aggregation number of the three carboxylate surfactants in the absence and presence of the ethoxylated alcohols, and of the average number of alcohol molecules per micelle as a function of the number of EO groups in the alcohol, are also included in this paper to facilitate a discussion of the thermodynamic results.

Experimental

Materials

The surfactants sodium octanoate, C_8Na (Sigma, 99–100%), sodium decanoate, $C_{10}Na$ (Sigma, 99–100%), and sodium dodecanoate, $C_{12}Na$ (Sigma, 99–100%), were used as received. *n*-Butanol, C_4EO_0 (BDH, AR); diethylene glycol monobutyl ether, C_4EO_2 (Pfaltz & Bauer, AR); 2-butoxyethanol, C_4EO_1 (Fluka, AR); and triethylene glycol monobutyl ether, C_4EO_3 (Fluka, 80%), were purified by fractional distillation under reduced pressure. Tetraethylene glycol monobutyl ether, C_4EO_4, was obtained as a by-product from the original C_4EO_3 material. The purity of the recovered materials was checked by GC–MS analysis.

Measurements

The solution densities were measured using a vibrating-tube flow densimeter (model 02D, Sodev) with a reproducibility of $(\pm)2 \times 10^{-6}$ g cm^{-3}. Ultrasonic velocities were measured at a frequency of 4 MHz using a Nusonics (model 6080 Mapco) single transducer velocimeter. The effect of the hydrolysis of the carboxylate anion on the determination of the apparent molar properties of C_nNa was minimized by adjusting the pH of water and of the water–alcohol mixed solvent systems to above 9.5 with NaOH. The operation and calibration of the instruments were described previously (26). The temperature of the densimeter and velocimeter cells was kept at 25°C using a closed-loop temperature controller (model CT-L, Sodev). All solutions used for thermodynamic measurements were prepared on a weight basis using water obtained from a Millipore Super-Q system. The surfactants were readily dissolved in water and aqueous C_4EO_X solutions at the experimental temperature and in the concentration ranges studied.

Results

Apparent molar volumes, V_ϕ, and apparent molar adiabatic compressibilities, K_ϕ, of the solute in solution at a given concentration, m, were calculated from the densities of the solution, d, the solvent, d_0 (mixed solvent in the case of ternary systems), the adiabatic compressibility coefficients of the solution, β_S, and the solvent, β_0, and the molar mass, M, of the solute using the following relations:

$$[1] \quad V_\phi = \frac{M}{d} - \frac{10^3(d - d_0)}{mdd_0}$$

$$[2] \quad K_\phi = V_\phi\beta_S + \frac{10^3(\beta_S - \beta_0)}{md_0}$$

$$[3] \quad \beta_S = \frac{100}{u^2 d}$$

where u is the speed of sound in the solution.

The partial molar properties $\overline{V}_S$ and $\overline{K}_S$ of the surfactant were calculated from the apparent molar properties using (7)

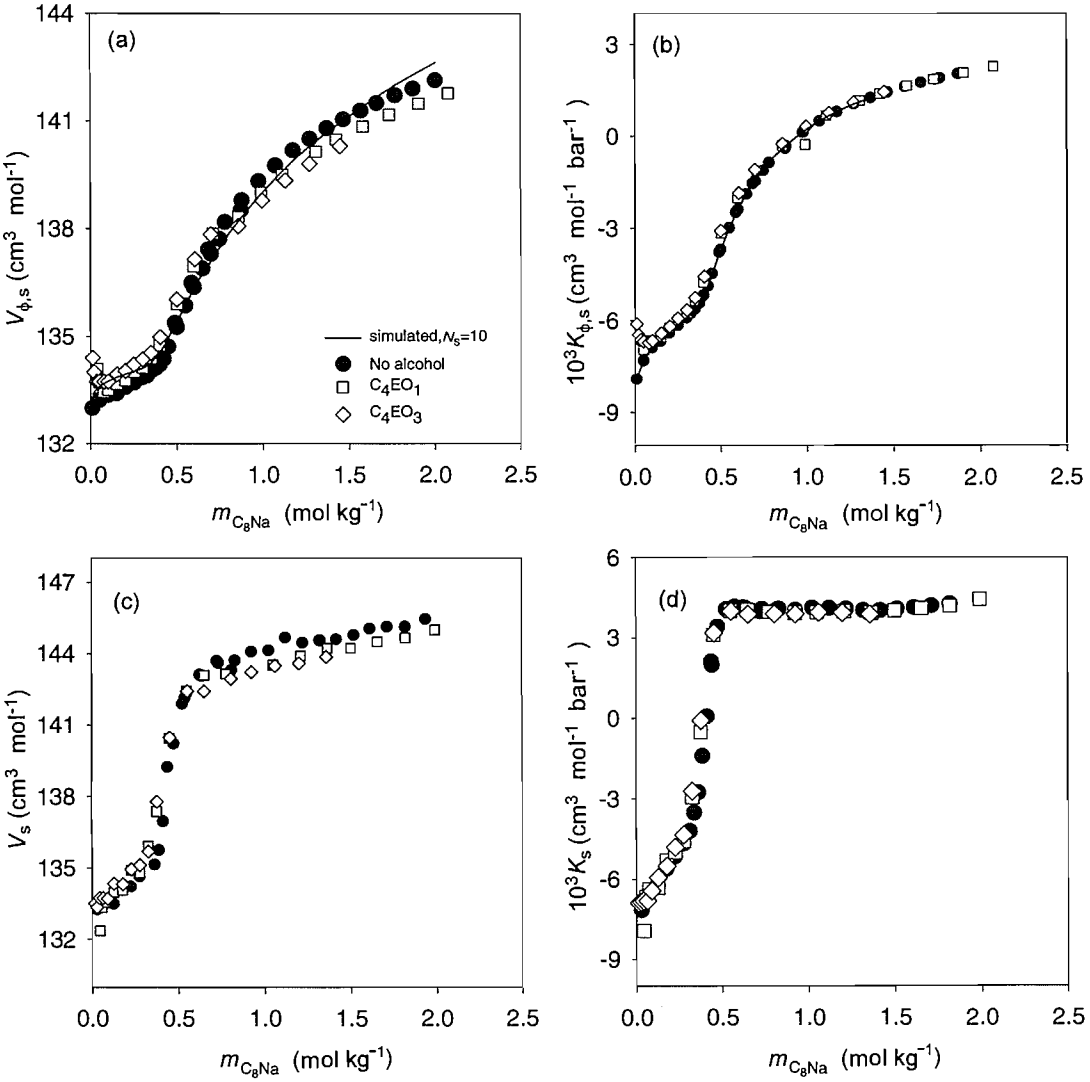
$$[4] \quad \overline{Y} = \frac{\Delta(Y_\phi m)}{\Delta m}$$

Figures 1 and 2 illustrate typical features of the volume and compressibility properties of two surfactants, C_8Na and $C_{12}Na$, respectively, in the absence and presence of a given concentration of ethoxylated alcohol, C_4EO_X, (0.02 *m* for C_8Na and 0.05 *m* for $C_{12}Na$, respectively). Similar graphs for $C_{10}Na$ systems are not presented here for the sake of brevity. The solid lines represent the results of the theoretical simulation using relations derived from the mass-action model (6, 7)

$$[5] \quad V_{\phi,S} = \alpha_0[\overline{V}_S^0 + A_V\sqrt{\alpha_0 m_S} + B_V\alpha_0 m_S] + (1 - \alpha_0)[V_S^M + (1 - \alpha_0)C_V m_S]$$

$$[6] \quad K_{\phi,S} = \alpha_0[\overline{K}_S^0 + A_K\sqrt{\alpha_0 m_S} + B_K\alpha_0 m_S] + (1 - \alpha_0)[K_S^M + (1 - \alpha_0)C_K m_S] + \frac{\alpha_0(1 - \alpha_0)}{1 - \alpha_0 + \alpha_0/N_S}\frac{(\Delta V_S^M)^2}{RT}$$

where α_0 is the fraction of surfactant monomer in the aqueous phase, A_Y is the Debye–Hückel limiting slope, B_Y and C_Y are the pair interaction terms for the surfactant monomers and micelles, respectively, and N_S is the mean aggregation number of the micelles. The simulations were carried out by choosing a value of the mean aggregation number, N_S, so that quicker convergence could be achieved. For the systems $C_{10}Na$ and $C_{12}Na$, the value of the cmc was also fixed. Derived values of the thermodynamic parameters for the binary water–C_nNa systems, obtained from simulation at different mean aggregation numbers, are summarized in Table 1.



Figures 3 and 4 show the apparent molar volumes and adiabatic compressibilities of C_4EO_1 as a function of alcohol concentration in aqueous C_8Na and $C_{12}Na$ solutions of different concentration, respectively (results for C_4EO_1 in $C_{10}Na$ solutions are quite similar to those in C_8Na systems and are not shown). They are typical examples of the volumetric behaviour of the ethoxylated alcohols in water–C_nNa mixed solvents. The partial molar properties of the alcohol at infinite dilution (standard state) in the water–surfactant solutions, $\overline{V}_A^0$ and $\overline{K}_A^0$, were obtained by extrapolating the apparent molar property data to $m_A = 0$. The effect of the number of EO groups in the alcohol on $\overline{V}_A^0$ and $\overline{K}_A^0$ is illustrated (Fig. 5) by showing the results of $\overline{V}_A^0$ for the C_4EO_1–C_8Na systems. Figures 6 and 7 illustrate the effect of surfactant chain length on the $\overline{V}_A^0$ and $\overline{K}_A^0$ proper-

ties for C_4EO_1 as a function of C_nNa concentration in the mixed solvents.

The transfer functions of the alcohol from water to aqueous surfactant solutions were calculated from the apparent molar property data at low alcohol content (0.05 *m* in C_8Na and $C_{10}Na$, 0.02 *m* in $C_{12}Na$ systems) using the relation

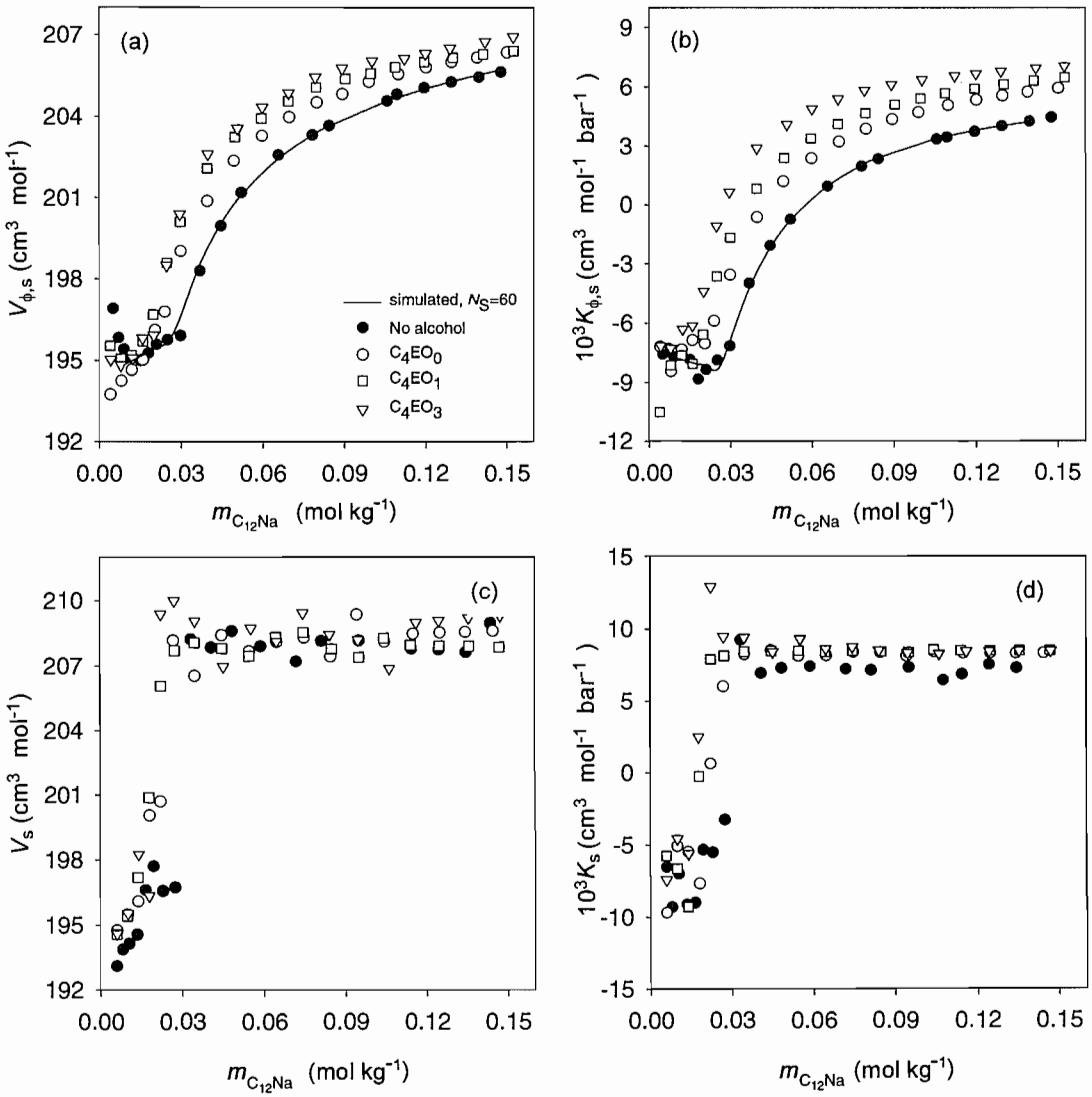
$$[7] \quad \Delta Y_A(W \rightarrow W + S) = Y_A(W + S) - Y_A(W)$$

At sufficiently low concentration of m_A, $\Delta Y_A(W \rightarrow W + S)$ approaches the standard state transfer function, $\Delta Y_A^0(W \rightarrow W + S)$, and these data were simulated using relations derived from the chemical equilibrium model (10, 11)

$$[8] \quad \Delta V_A(W \rightarrow W + S) = 2\alpha\beta B_{V,SA} m_S + \frac{m_S}{m_A}(\alpha_0 - \alpha)\Delta V_S^M + (1 - \beta)\Delta V_A^M$$

$$[9] \quad \Delta K_A(W \rightarrow W + S) = 2\alpha\beta B_{K,SA} m_S + \frac{m_S}{m_A}(\alpha_0 - \alpha)\Delta K_S^M + (1 - \beta)\Delta K_A^M - \frac{m_S}{m_A}\left(\frac{\partial\alpha_0}{\partial P} - \frac{\partial\alpha}{\partial P}\right)\Delta V_S^M + \frac{\partial\beta}{\partial P}\Delta V_A^M$$

In the simulation, values of the equilibrium constant of micellization, K_M, the mean aggregation number, N_S, of the surfactant, and the thermodynamic micellization parameter for the surfactant, ΔY_S^M, which is calculated from



$$[10] \quad \Delta Y_S^M = Y_S^M - Y_S^0 - A_Y\sqrt{(\alpha_0 m_S)} - B_Y\alpha_0 m_S$$

were taken from the respective water–surfactant binary systems. The transfer functions were fitted by adjusting the pair interaction parameter, $B_{Y,SA}$, the distribution coefficient for the alcohol between the micellar and aqueous phases, K_D, and the micellization parameter for the alcohol, ΔY_A^M, to optimize the values of α (the fraction of surfactant monomer in the

Fig. 2. Apparent molar volumes (*a*), apparent molar adiabatic compressibilities (*b*), partial molar volumes (*c*), and partial molar adiabatic compressibilities (*d*) of $C_{12}Na$ in the presence of 0.05 *m* C_4EO_X.

aqueous phase in the presence of alcohol) and β (the fraction of alcohol in the aqueous phase) until the agreement between the simulated results and the experimental data was quantitatively acceptable. In the C_8Na system, the mean aggregation number used for the transfer volume simulation was 11 while a good fit for the transfer compressibility required a value of 15. In the $C_{10}Na$ and $C_{12}Na$ systems, the mean aggregation number was assumed to remain unchanged and values of 30 and 60, respectively, were used in the simulations. The general behaviour of the transfer functions for C_4EO_X in aqueous C_nNa solutions is illustrated by the comparisons between the simulated and the experimental results of transfer functions for C_4EO_{0-3} from water to $C_{10}Na$ solutions, as shown in Fig. 8. Values of the parameters of the ternary systems extracted from the simulation are presented in Table 2. The dependence of the parameters on the number of EO groups in the alcohol and the chain length of C_nNa is shown in Fig. 9.

Values of the mean aggregation number of C_nNa micelles at a given surfactant concentration, the aggregation number of surfactant in the mixed micelles in the presence of a given low concentration of ethoxylated alcohol (0.04–0.05 *m*), and the average number of alcohols per micelle are summarized in Table 3.

Discussion

Volumetric properties of C_nNa in water

The volumetric behaviour of C_nNa as a function of concentration in the presence and absence of the ethoxylated alcohols (Figs. 1 and 2) displays a number of trends. In the binary C_8Na–water system, the apparent molar volume, $V_{\phi,S}$ (Fig. 1*a*), increases gradually in the low-concentration region up to m_S = 0.39 *m* and then shows a sharp increase thereafter, corresponding to the change in the thermodynamic property of micellization (4–7). It continues to increase, though less rapidly, in the higher concentration region. As the surfactant chain length increases, the onset of micellization occurs at much lower concentrations, for

example, $m_S = 0.12\ m$ for C_{10}Na and $m_S = 0.03\ m$ for C_{12}Na (Fig. 2*a*), respectively. The values of the cmc determined from the break point in $V_{\phi,S}$ are in good agreement with previously reported values of 0.37–0.40 *m* for C_8Na (27, 28), 0.11 *m* for C_{10}Na (16, 18, 27), and 0.028 *m* for C_{12}Na (27, 28). When the apparent molar volume data of C_nNa in the concentration region below the cmc are plotted as $V_{\phi,S} - 1.86\sqrt{m_S}$ vs. m_S, i.e., applying the Debye–Hückel theory for the apparent molar property of a dilute solution of a strong 1:1 electrolyte (28),

$$[11] \quad Y_{\phi,S} = Y^0_{\phi,S} + 1.86\sqrt{m_S} + B_Y m_S$$

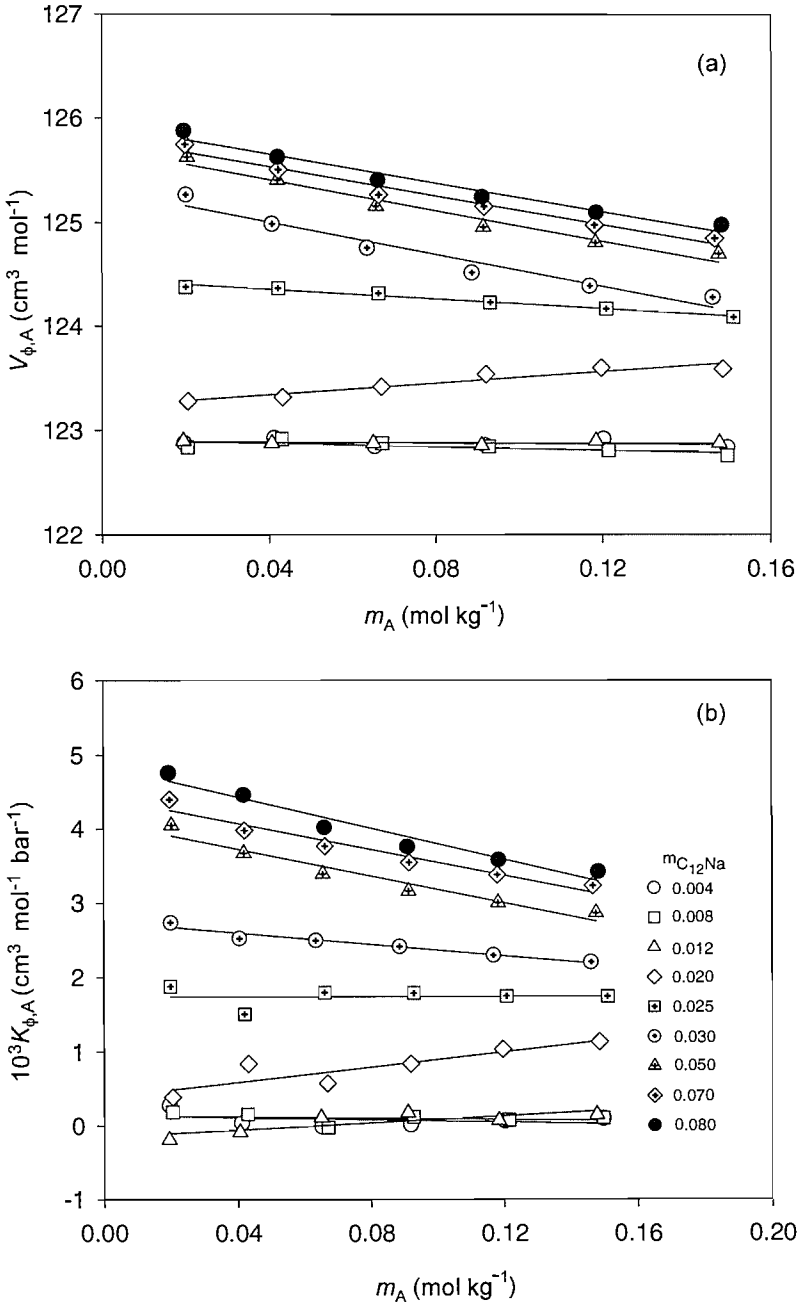
Fig. 3. Apparent molar volumes (*a*) and apparent molar adiabatic compressibilities (*b*) of C_4EO_1 in aqueous C_8Na solutions.

the slope, B_V, is estimated to be approximately zero for C_8Na. In the case of $C_{10}Na$ system, B_V is ca. zero at m_S <0.05 m, but it increases significantly thereafter. A similar change in B_V for $C_{12}Na$ is observed at $m_S \cong 0.01$ m. Since there is a large uncertainty in the value of $V_{\phi,S}$ due to the less accurate values of densities measured at very low concentrations, the significance of B_V for $C_{12}Na$ cannot be ascertained with any confidence. The near-zero value of the interaction parameter between the shorter chain C_8Na monomers seems to indicate that an increasing hydrophilicity in the carboxylate head group, -COO^-, has counterbalanced the hydrophobic attractions between C_8Na monomers. The latter effect has been observed in some shorter chain alkylammonium surfactant systems (29). The positive deviation in B_V as the hydrocarbon chain increases in length may reflect the effect of the formation of pre-micellar subaggregates on the thermodynamic volume.



The apparent molar adiabatic compressibilities, $K_{\phi,S}$, for C_nNa in the absence of alcohol show nearly parallel behaviour to the apparent molar volumes except that the values of $K_{\phi,S}$ decrease initially, then increase, in the concentration region below the cmc for both $C_{10}Na$ and $C_{12}Na$. For surfactant monomers in the aqueous phase, it has been shown that the contribution of the hydrophobic part of the surfactant molecule to the compressibility is small (30), and it is the -COO^- group that makes $K_{\phi,S}$ for C_nNa negative (31). The increase in water structure due to elongation of the hydrocarbon chain length will make a positive contribution to the compressibility

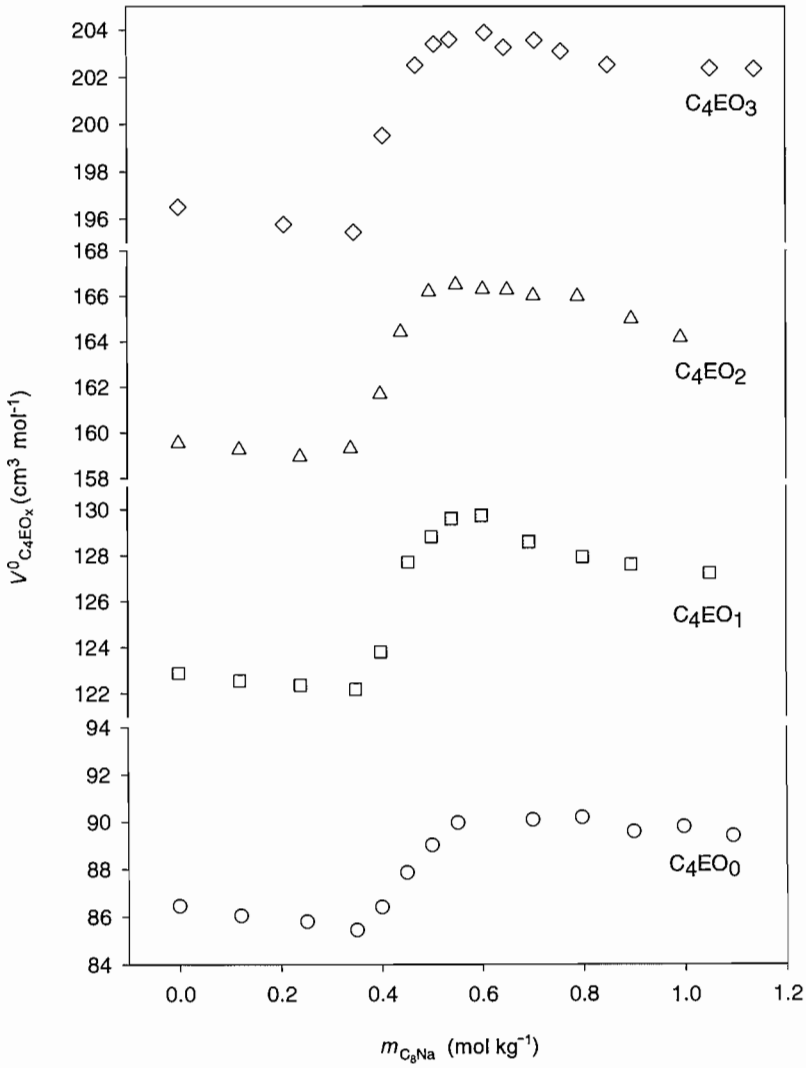
Fig. 4. Apparent molar volumes (*a*) and apparent molar adiabatic compressibilities (*b*) of C_4EO_1 in aqueous $C_{12}Na$ solutions.



(32). Therefore, the compressibility behaviour of surfactant monomers in the pre-micellar region will be a compromise between the effects mentioned above; however, it is inappropriate to elaborate in detail about $K_{\phi,S}$ for $C_{10}Na$ and $C_{12}Na$ systems due to the relatively large uncertainty in the density measurements in this low-concentration region.

The values of the parameters derived from application of the mass-action model to $V_{\phi,S}$ and $K_{\phi,S}$ experimental data from binary solutions of C_nNa (Table 1) show that the agreement between the simulated and experimental results, when different mean aggregation numbers are chosen in the simulation, is not unique in the three systems. For the case of C_8Na, the theoretical simulation curve of the apparent molar volume data resembles, in general, the experimental data but deviates in both the low- and high-concentration regions (Fig. 1*a*). The infinite dilution, V_S^0, values of the volume obtained from simulation (except the one for a mean aggregation number of 5) are larger than the value of 132.8 cm^3 mol^{-1} obtained from extrapolating experimental $V_{\phi,S}$ values to $m_S = 0$. It increases from 133.1 to 133.8 cm^3 mol^{-1} as the mean aggregation number of the micelle varies from 10 to 25. These values are also higher than previously reported experimental values of 132.4 cm^3 mol^{-1} (27) and 132.7 cm^3 mol^{-1} (28). The value of the molar volume of C_8Na in the micellar form, V_S^M, also varies between 143.5 and 144.0 cm^3 mol^{-1} with variation of the mean aggregation number. A graphical comparison of the apparent

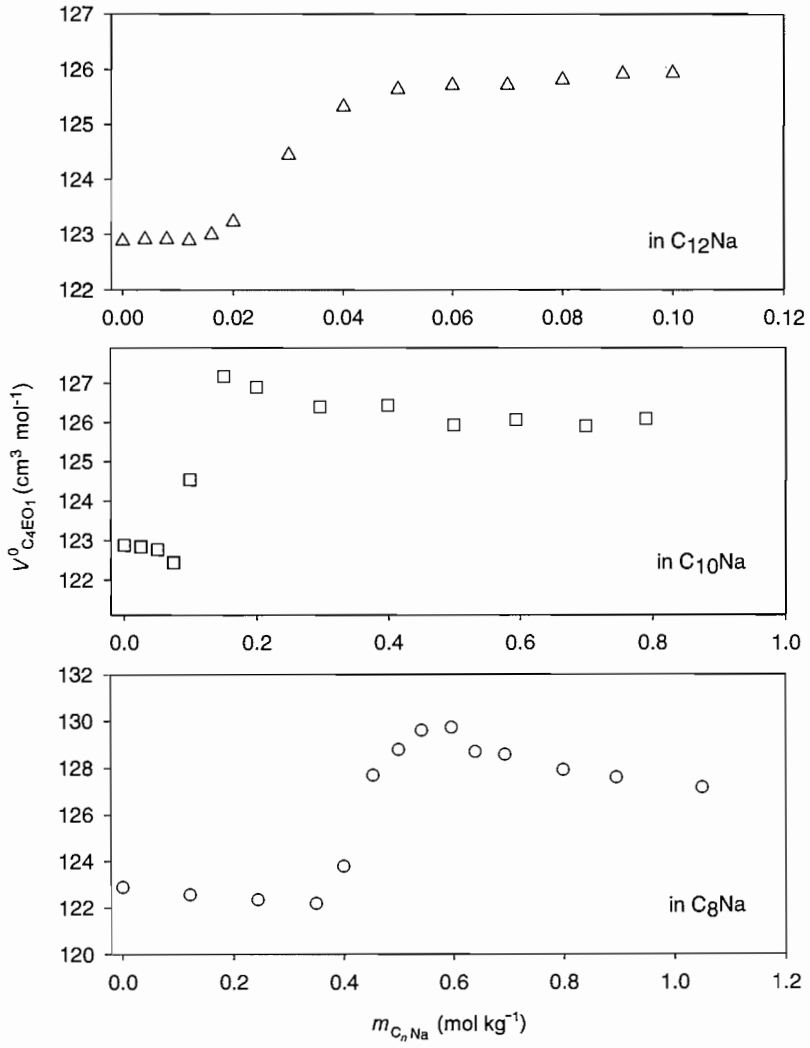
Fig. 5. Partial molar volumes of C_4EO_X in aqueous C_8Na solutions.

molar volumes of C_8Na obtained from simulations using different aggregation numbers was presented previously (15). The simulation of the apparent molar compressibility data of C_8Na gives results that agree well with the experimental data (Fig. 1*b*). The simulation values of K_S^0 ($(-7.7--7.5) \times 10^{-3}$ cm^3 mol^{-1} bar^{-1}) and K_S^M ($(3.7–4.3) \times 10^{-3}$ cm^3 mol^{-1} bar^{-1}) agree with $K_S^0 = -7.4 \times 10^{-3}$ cm^3 mol^{-1} bar^{-1} and $K_S^M = 3.9 \times 10^{-3}$ cm^3 mol^{-1} bar^{-1} values previously reported (27). These results generally show that K_S^0 and K_S^M are less sensitive to change in the mean aggregation number than is the volume property. Although the simulation predicts a value of V_S^0 (132.7 cm^3 mol^{-1}) and gives a good fit to the experimental data in the concentration region below the cmc when a low mean aggregation number of 5 is used, the unrealistically high value of V_S^M and the low value of K_S^M do not justify this as a reasonable value to use for the mean aggregation number of C_8Na micelles. Previous studies have shown the micellization of C_8Na takes place over a broad concentration range and that the micelle grows from an aggregation number of 11 around the cmc (0.4 M) to 26 at a concentration of 1.8 M (33). The values of the simulation parameters indicate that the mean aggregation number of C_8Na micelles is in the range of 10–20, which is not inconsistent with the value of 12 determined experimentally at a concentration of $m_S = 0.6$ *m* (Table 3).



For $C_{10}Na$ there is little change in the values of the molar volume in water at infinite dilution, V_S^0 (164.5–164.6 cm^3 mol^{-1}), and in the micelles, V_S^M (175.7–175.4 cm^3 mol^{-1}), when the simulation is carried out using mean aggregation numbers ranging from 15 to 45. These values are slightly larger than the previously reported values of $V_S^0 = 164.0$ cm^3 mol^{-1} and $V_S^M = 175.2$ cm^3 mol^{-1} obtained from simulation using the same model (18), and $V_S^0 = 164.2$ cm^3 mol^{-1} and $V_S^M = 175.0$ cm^3 mol^{-1}, obtained experimentally (27). The range of values of the apparent molar adiabatic compressibility properties ($K_S^0 = (-7.7--7.8) \times 10^{-3}$ cm^3 mol^{-1} bar^{-1} and $K_S^M = (7.1–6.2) \times 10^{-3}$ cm^3 mol^{-1} bar^{-1}) obtained from simulation are comparable to the experimental results of $K_S^0 = -7.8 \times 10^{-3}$ cm^3 mol^{-1} bar^{-1} and $K_S^M = 6.0 \times 10^{-3}$ cm^3 mol^{-1} bar^{-1} (27). A negative relaxational contribution to compressibility (-0.08 cm^3 mol^{-1} bar^{-1}), obtained by using a mean aggregation number of 15 (Table 1) in the simulation of $K_{\phi,S}$, is theoretically incorrect: it should be positive because it is a function of $(\Delta V_S)^2$ in the mass-action model (6, 7). This anomaly probably reflects the fact that 15 is an unrealistically low mean aggre-

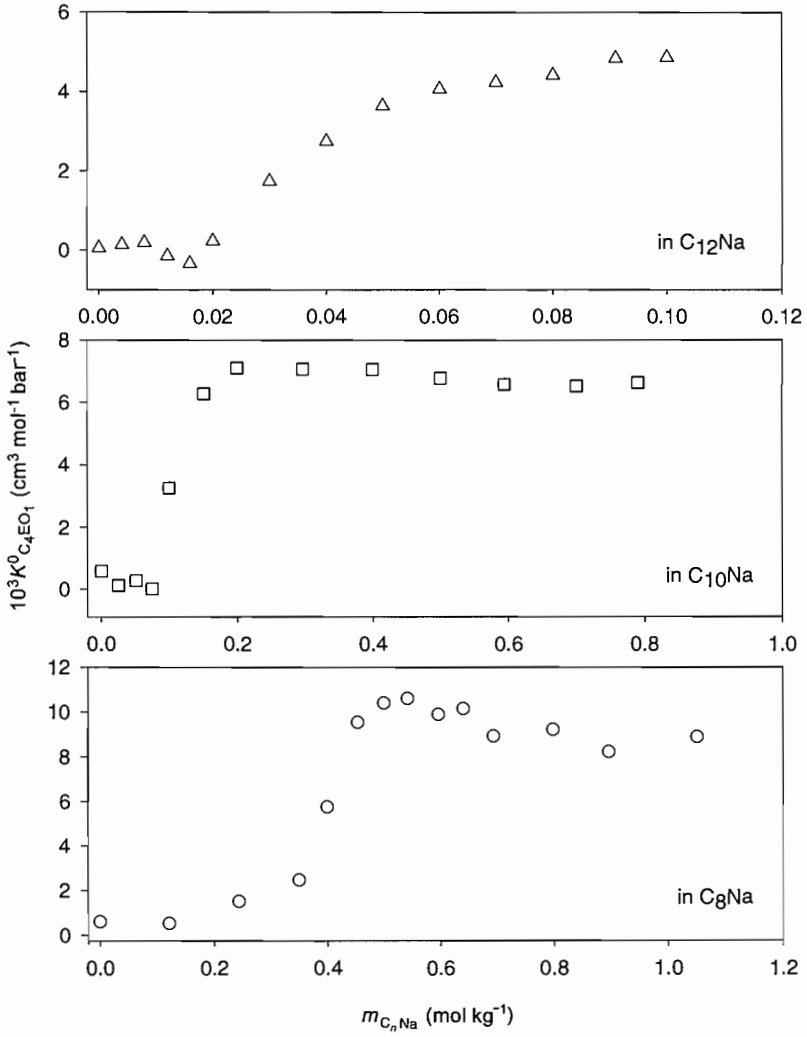
Fig. 6. Partial molar volumes of C_4EO_1 in aqueous C_nNa solutions.



gation number for $C_{10}Na$ micelles as this mean aggregation number of $C_{10}Na$ micelles has been experimentally determined to be 34 at a concentration of $m_S = 0.3$ *m* (Table 3). The insensitivity of the aggregation number to the process of extracting the thermodynamic parameters for long-chain surfactants using the mass-action model has been previously addressed (7).

For $C_{12}Na$ the change in the simulated values of the Y^0_S and Y^M_S properties using different mean aggregation numbers is similar to that observed for $C_{10}Na$, i.e., varying the mean aggregation number from 30 to 65 has a minor effect on the simulated results. The value of V^0_S (194.2 cm^3 mol^{-1}) is 1.0 cm^3 mol^{-1} lower than the previously reported values of 195.0–195.5 cm^3 mol^{-1} (27, 28). Because the experimental uncertainty in $V_{\phi,S}$ increases substantially with decreasing concentration and the estimated error in $V_{\phi,S}$ could be as large as 0.8 cm^3 mol^{-1} for $C_{12}Na$ (28), our result is considered to be in good agreement with the literature values. The value of V^M_S (207.5 cm^3 mol^{-1}) agrees well with 207.3 cm^3 mol^{-1} estimated from the experimental data of $V_{\phi,S}$ in the post-micellar region (27). The values of both K^0_S ($(-7.1--7.4) \times 10^{-3}$ cm^3 mol^{-1} bar^{-1}) and K^M_S ($(8.8–8.4) \times 10^{-3}$ cm^3 mol^{-1} bar^{-1}) are higher by 1.0×10^{-3} cm^3 mol^{-1} bar^{-1} than values reported from previous work (27). A mean aggregation number of 59 for $C_{12}Na$ micelles has been experimentally determined at a concentration of $m_S = 0.12$ *m* (Table 3).

The values of ΔV^M_S (9.2 cm^3 mol^{-1} for C_8Na, 9.6 cm^3 mol^{-1} for $C_{10}Na$, and 11.6 cm^3 mol^{-1} for $C_{12}Na$) are in good agreement with those reported in the literature (27). The values of ΔK^M_S (8.4×10^{-3} cm^3 mol^{-1} bar^{-1} for C_8Na, 12.8×10^{-3} cm^3 mol^{-1} bar^{-1} for $C_{10}Na$, 15.7×10^{-3} cm^3 mol^{-1} bar^{-1} for $C_{12}Na$) are smaller by 1.0×10^{-3} cm^3 mol^{-1} bar^{-1} for C_8Na, but larger by 1.5×10^{-3} cm^3 mol^{-1} bar^{-1} for both $C_{10}Na$ and $C_{12}Na$, than previously reported values (27). The uneven increment in ΔY^M_S as the hydrocarbon chain length of the surfactant is increased by a $-CH_2CH_2-$ segment may be due to the change in the extent of hydration of the micelle. Using a value of 28.3 cm^3 mol^{-1} as the partial molar volume for the $-CH_2COO^-Na^+$ ion pair in aqueous micelle solution (34), the surface area per head group, S/N_S, in a spherical micelle of radius equal to the fully extended hydrocarbon chain, is calculated to be 134 Å^2 for C_8Na, 71 Å^2 for $C_{10}Na$, and 58 Å^2 for $C_{12}Na$. These values correspond to mean aggregation numbers of 12, 34, and 59, respectively. Obviously, there is more exposure of the micelle

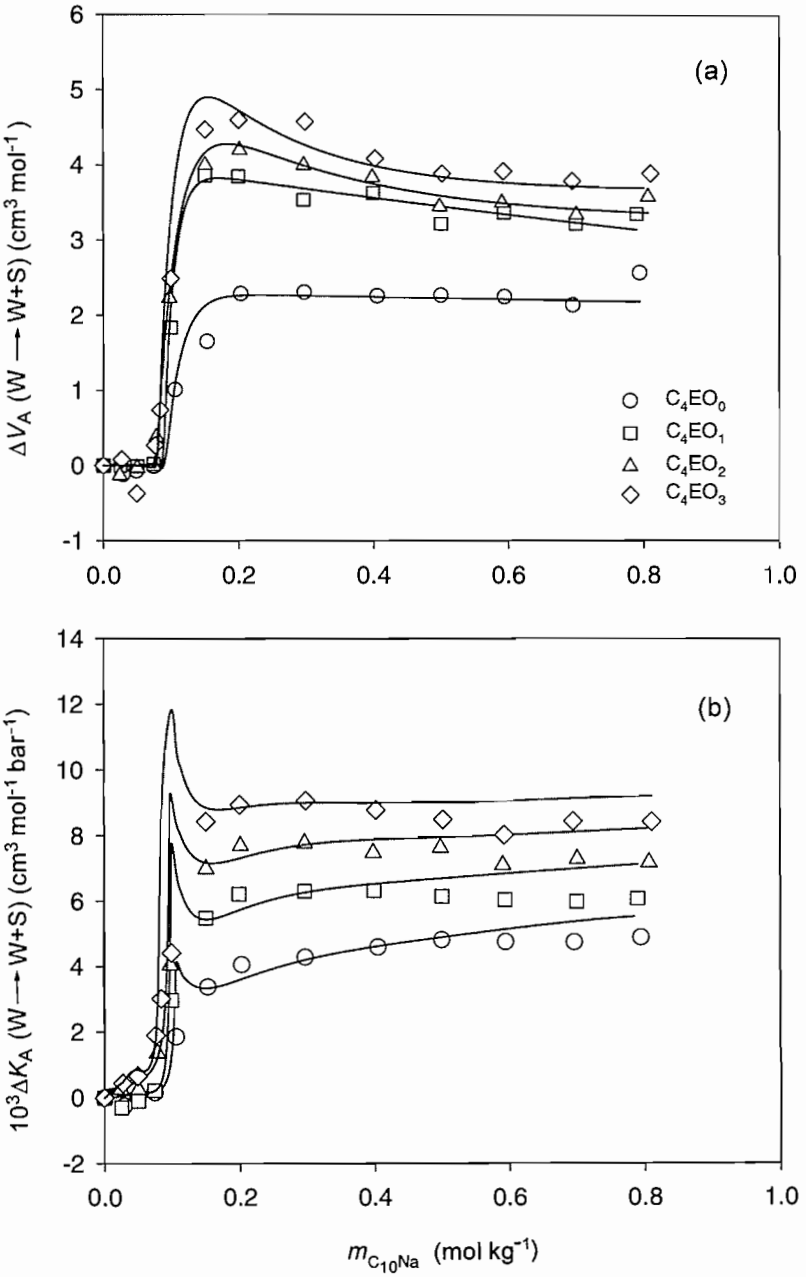
Fig. 7. Partial molar compressibilities of C_4EO_1 in aqueous C_nNa solutions.



interior to the bulk phase in the case of smaller micelles compared to the larger ones and the micelles have undergone a significant change from a "looser" assembly in C_8Na to a better packed, larger aggregate in $C_{10}Na$ and $C_{12}Na$. Since the repulsion between head groups becomes less important when S/N_S is sufficiently large (35), the small increase in ΔV_S^M of $C_{10}Na$ (9.6 cm^3 mol^{-1}) compared to ΔV_S^M of C_8Na (9.2 cm^3 mol^{-1}) is attributed to a significant increase in the interactions between the -COO^- groups in $C_{10}Na$ micelles. For example, the distance between head groups, d_{h-h}, decreases significantly from 13.1 Å in C_8Na to 9.5 Å in $C_{10}Na$. On the other hand, the relatively large increase in ΔV_S^M of $C_{12}Na$ (11.5 cm^3 mol^{-1}) compared to that of $C_{10}Na$ is due to modification of the $C_{12}Na$ micelle interior, as only a moderate increase in the head group interactions should occur because of the relatively smaller decrease in d_{h-h}, (8.6 Å). Therefore, the change in the value of ΔV_S^M as a function of surfactant chain length reflects, simultaneously, the effects of the hydrocarbon chain and the head group on the change in volumetric properties of micelle formation. The dependence of ΔK_S^M on the surfactant chain length is different. The relatively large increase in ΔK_S^M between $C_{10}Na$ (12.8×10^{-3} cm^3 mol^{-1} bar^{-1}) and C_8Na (8.4×10^{-3} cm^3 mol^{-1} bar^{-1}), and the further moderate increase in ΔK_S^M for $C_{12}Na$ (15.7×10^{-3} cm^3 mol^{-1} bar^{-1}) suggests that this property is more sensitive to changes in the micelle interior than in the micelle surface region.

Comparisons of the partial molar volumes, $\overline{V}_S$, of C_nNa, in the absence of C_4EO_X, show that the values increase steadily for C_8Na in the post-micellar region in the concentration range studied (<2.0 *m*) while it levels off to a constant value of 176 cm^3 mol^{-1} for $C_{10}Na$ and 208 cm^3 mol^{-1} for $C_{12}Na$. On the other hand, the partial molar adiabatic compressibilities, $\overline{K}_S$, of C_nNa are independent of composition in the post-micellar region. The steady increase in $\overline{V}_S$ of C_8Na over a broad concentration range above the cmc may reflect a continuous modification in the micelle due to its growth, as discussed above. In the case of the longer hydrocarbon chain $C_{10}Na$ and $C_{12}Na$ surfactants, the relative independence of $\overline{V}_S$ as a function of surfactant concentration in the post-micellar region indicates that increasing the concentration of surfactant simply produces more micelles of relatively constant structure.

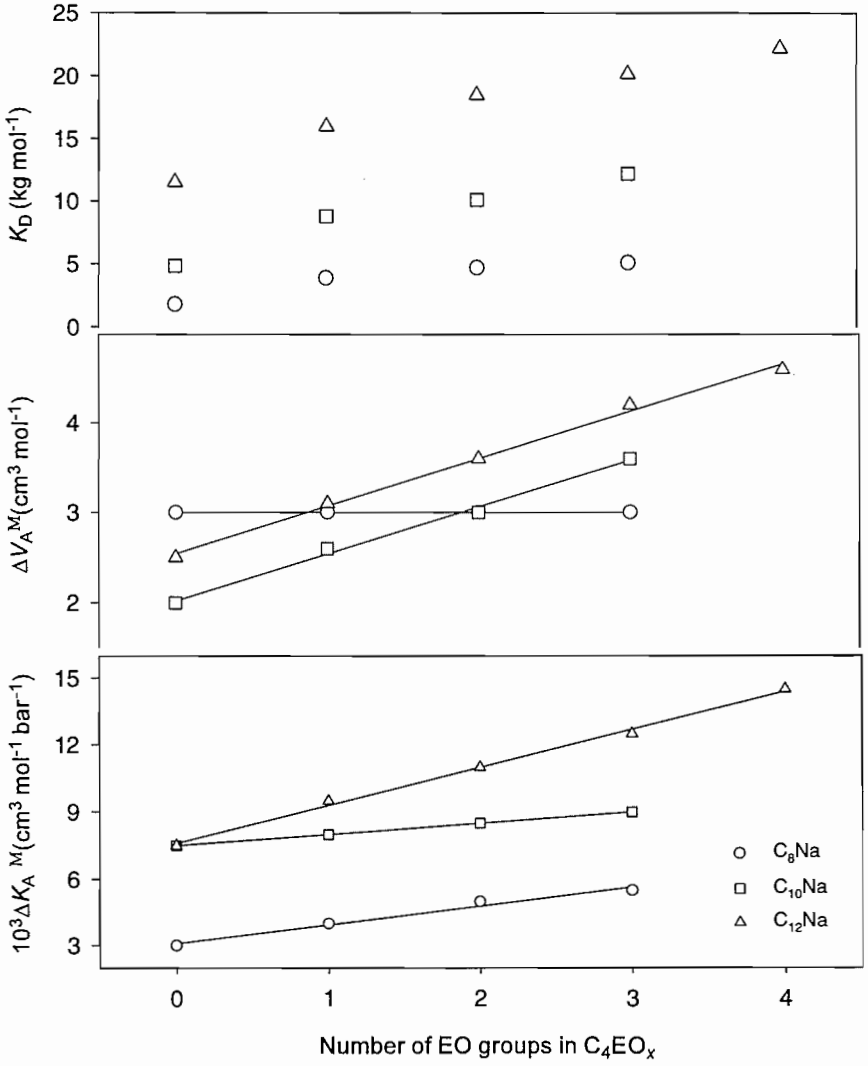
Fig. 8. Comparisons between the simulated (solid lines) and the experimental transfer volumes (*a*) and transfer compressibilities (*b*) of C_4EO_X from water to aqueous $C_{10}Na$ solutions.



Effects of C_4EO_X on the volumetric properties of C_nNa in water

In the ternary aqueous solutions containing C_4EO_X, the addition of 0.02 *m* C_4EO_X has an insignificant effect on the molar volumetric properties of the short-chain C_8Na compared to the values in the binary system (Fig. 1). For a "loose" aggregate such as C_8Na, there is more exposure of the micelle interior to the bulk phase and the head groups of the surfactant are likely hydrated to the same extent as in the bulk solution. Therefore, the solubilization of a small fraction of C_4EO_X molecules, whose EO segments are highly hydrated, in the micelle should not induce a significant change in the environment around the octanoate species in the micelle. In contrast, the values of the apparent molar properties of $C_{10}Na$ in the presence of 0.055 *m* C_4EO_X are greater than in the binary aqueous systems over the concentration range investigated. Furthermore, the increase in $V_{\phi,s}$ is greater in the case of alcohols containing EO group(s) than in the case of butanol, especially in the transition region. A shift in the cmc to lower values is also observed with an increase in the number of EO groups in the alcohol. This behaviour corroborates previous reports that the cmc of $C_{10}Na$ in the ternary system containing C_4EO_1 is lower than that containing C_4EO_0 at the same concentration of alcohol (17), and that the cmc of aqueous SDS solutions containing alkoxyethanols of constant alkyl chain length is reduced by increasing the number of EO groups (19). In spite of the shift in the cmc,

Fig. 9. Dependence of solubilization parameters from simulations of the transfer function of C_4EO_X from water to aqueous C_nNa solutions on the number of EO groups in the alcohol.

values of the partial molar properties, $\overline{Y}_S$, for $C_{10}Na$ at concentrations above the cmc in the presence of 0.055 *m* C_4EO_X do not differ from $\overline{V}_S$ in water (16). This indicates that the addition of a small quantity of C_4EO_X has an insignificant effect on the micellization properties of $C_{10}Na$, $\Delta\overline{Y}_S^M$ (the change in the molar properties of the surfactant as the monomeric surfactant species associate into micelles). Therefore, there will be little change in the size and shape of $C_{10}Na$ micelles with the incorporation of some ethoxylated alcohol molecules. The nearly constant mean aggregation number of $C_{10}Na$ micelles (N_S = 33/34, Table 3) determined in the presence of 0.044 *m* C_4EO_X confirms this argument. The presence of EO groups in the alcohol at a concentration of 0.05 *m* has a more profound effect on the volumetric properties of $C_{12}Na$ than in the case of $C_{10}Na$ systems. The decrease in the cmc is approximately 30%, and there is a significant increase in the molar properties, especially the molar compressibility (Fig. 2). Although the behaviour of $\overline{V}_A^M$ gives no conclusive information, the appreciable increase in the partial molar adiabatic compressibility, $\overline{K}_A^M$, in the presence of C_4EO_X indicates that the $C_{12}Na$ micelle interior becomes more compressible, and changes in the micelle structure are likely to take place. Indeed, some of the $C_{12}Na$ species in the micelles are replaced by C_4EO_X molecules as shown by the results of the mean aggregation number measurements (Table 3). The relatively higher ratio of m_A/m_S (0.05 m_A/0–0.15 m_S) in the $C_{12}Na$ systems compared to the $C_{10}Na$ systems (0.055 m_A/0–0.8 m_S) is one possible reason for this change. These results are similar to those observed for other ionic surfactant and *n*-alcohol systems when the chain length of alcohol is increased (31, 36). It is believed that the presence of the EO moiety within the micelle contributes to the reduction of the electrostatic interactions between surfactant head groups in the mixed micelles of anionic surfactant – ethoxylated alcohol. These results provide additional evidence that increasing the number of EO groups in the alcohol enhances interactions between ethoxylated alcohols and anionic micelles (14–20).

Volumetric properties of C_4EO_X in C_nNa and water mixed solvents

The general behaviour of apparent molar properties, $V_{\phi,A}$ and $K_{\phi,A}$, for C_4EO_X alcohols in water–C_nNa mixed solvents is

illustrated for the case of C_4EO_1 in aqueous C_nNa solutions of different concentrations (Figs. 3 and 4). The changes in $V_{\phi,A}$ and $K_{\phi,A}$ for C_4EO_{0-3} in water as a function of alcohol concentration ($m_A < 0.12\ m$) have been previously discussed (15). The values of the partial molar volume at infinite dilution, $\overline{V}_A^0$, obtained from extrapolating $\overline{V}_{\phi,A}$ to m_A = 0, 86.45 (C_4EO_0), 122.88 (C_4EO_1), 159.54 (C_4EO_2), and 196.49 (C_4EO_3) cm^3 mol^{-1} are in good agreement with those previously reported (37). More recently, we obtained a value of 233.56 cm^3 mol^{-1} for $\overline{V}_A^0$ of C_4EO_4. An average value of 36.78 cm^3 mol^{-1} per EO group in aqueous medium is in good agreement with the literature value of 36.96 cm^3 mol^{-1} (38). With the exception of C_4EO_4, the partial molar adiabatic compressibility, $\overline{K}_S^0$, in aqueous medium gradually decreases from a small positive value (0.72×10^{-3} cm^3 mol^{-1} bar^{-1} for C_4EO_0) to a small negative value (-0.35×10^{-3} cm^3 mol^{-1} bar^{-1} for C_4EO_3) as the number of EO groups in C_4EO_X increases. This behaviour is similar to that of aqueous solutions of normal alcohols of increasing hydrocarbon chain length (30).

The apparent molar volumetric properties of these alcohols in water–C_nNa mixed solvents show a number of features that are characteristic of the process of forming C_nNa–C_4EO_X mixed micelles. At a concentration of C_nNa significantly below the cmc (<0.12 m_S for C_8Na, <0.07 m_S for $C_{10}Na$, and <0.015 m_S for $C_{12}Na$, respectively), the apparent molar volumes of the C_4EO_X are invariant or decrease slightly (in most of the cases) with increasing concentration of alcohol, and the values of $V_{\phi,A}$ are close to those observed in water (Figs. 3 and 4). This indicates that the presence of monomer surfactant at low concentration has little effect on the dissolution of the alcohols into the aqueous media or that there is a small enhancement of hydrophobic interactions between the alcohol monomers in the surfactant solution, but without the formation of any aggregates. When the concentration of C_nNa in the sys-

tems approaches levels just below the cmc (0.35 m_S for C_8Na, 0.075 m_S for $C_{10}Na$, and 0.015 m_S for $C_{12}Na$, respectively), there is a significant increase in $V_{\phi,A}$ as a function of m_A (Figs. 3 and 4). This is due to the formation of C_nNa–C_4EO_X mixed micelles, which is promoted by the addition of alcohol. The changes in $V_{\phi,A}$ at concentrations of C_nNa above the cmc are different in the systems containing C_8Na and $C_{10}Na$ than in those containing $C_{12}Na$. In the former systems, the variations of $V_{\phi,A}$ vs. m_A are less steep for C_4EO_0, but the limiting slopes become quite negative for those alcohols containing EO groups. As the concentration of surfactant continues to increase, the limiting slopes become positive. Correspondingly, the value of V_A^0 for alcohols containing EO groups shows a convex dependence on surfactant concentration (Fig. 5). Since the concentration of C_8Na and of $C_{10}Na$ in the micellar form, m_S^M, is relatively low at concentrations not too far above the cmc, the strong dependence of the apparent molar volumes of the alcohols containing an increasing number of EO groups on both the alcohol and surfactant concentrations illustrates that the mole ratio of alcohol to surfactant in the mixed micelles is an important factor affecting the properties of micelles containing a greater fraction of alcohol (9). As the concentration of C_8Na and $C_{10}Na$ increases further above the cmc, the less significant changes in $V_{\phi,A}$ indicate that the influence of alcohol on the mixed micelles diminishes, as the alcohols dissolve almost ideally into C_8Na and $C_{10}Na$ micelles. On the other hand, in systems of water–C_4EO_X–$C_{12}Na$ the negative limiting slope of $V_{\phi,A}$ vs. m_A becomes steeper with increasing number of EO groups in the alcohol. The maximum in V_A^0 for C_4EO_1 in C_8Na and $C_{10}Na$ systems no longer appears in the $C_{12}Na$ system (Fig. 6), indicating that the alcohols dissolve more readily into the mixed micelles of the longer chain surfactant.

As shown in Figs. 3*b*, 4*b*, and 7, both the apparent molar adiabatic compressibility and the partial molar compressibility properties for C_4EO_X in aqueous C_nNa solutions behave similarly to the apparent molar volume, except that the limiting slopes of $K_{\phi,A}$ vs. m_A are all negative at concentrations of surfactant above the cmc. Eventually, the magnitudes of both $V_{\phi,A}$ and $K_{\phi,A}$ become independent of surfactant concentration in C_8Na and $C_{10}Na$ systems, and in the $C_{12}Na$ system when the alcohol concentration is high. This result is similar to the dependence of the apparent molar heat capacity of hexanol on alcohol concentration in dodecyltrimethylammonium bromide aqueous solutions (39) and it was explained as being due to the formation of alcoholic microstructures that are stabilized by surfactant molecules. This occurs because the mixed micelles break down as the solution composition becomes richer in alcohol (39). The explanation seems to be reasonable for water–alcohol – long-chain surfactant systems when the surfactant concentration is not very high. But for systems containing shorter chain surfactants at high concentration, especially C_8Na, the addition of limited amounts of alcohol does not break down the micelles. Rather, the alcohol dissolves

For personal use only.

almost ideally into the micelles, as mentioned above. This argument is supported by the fact that the mean aggregation number of decyltrimethylammonium bromide (C_{10}TAB) in mixed micelle systems containing 2-butoxyethanol (C_4EO_1) changes from ca. 30 to 28 at a fixed concentration of $m_S = 0.12$ *m* when the concentration of C_4EO_1 increases from 0.2 *m* to 0.56 *m* (40).

Solubilization of C_4EO_X in C_nNa micelles

The solubilization of C_4EO_X alcohols in C_nNa micelles can be rationalized based on the changes in the parameters $B_{Y,SA}$, K_D, and ΔY_A^M, which are extracted from quantitative analysis of the transfer functions, $\Delta Y_A(W \rightarrow W + S)$, of the alcohol from water to aqueous surfactant solutions. The fit of the transfer volumes and compressibilities of C_4EO_{1-3} from water to aqueous C_8Na, $\Delta V_A(W \rightarrow W + S)$ and $\Delta K_A(W \rightarrow W + S)$, at a given low alcohol concentration of 0.05 *m* is quantitatively acceptable. A nearly quantitative fit of the transfer volumes of C_4EO_{1-3} from water to aqueous C_{10}Na is obtained in the concentration range up to 0.8 *m* (Fig. 8*a*), while good agreement between the simulated and experimental results for the transfer compressibilities is obtained in the concentration range up to 0.5 *m*, but it becomes poorer at higher m_S (Fig. 8*b*). The simulated results for the transfer functions of C_4EO_{1-4} from water to aqueous C_{12}Na are in good agreement with the experimental data except for the transfer compressibility property in the pre-micelle region. The values of the various parameters extracted from the simulations of the transfer volume and compressibility data are consistent (Table 2).

The negative values of $B_{V,SA}$ for C_4EO_{1-3} alcohols in aqueous C_8Na indicate that attractive pair interactions occur between C_8Na and C_4EO_{1-3} monomers in water. The small negative values of $B_{V,SA}$ for these alcohols in aqueous C_{10}Na make it difficult to assess the extent of the interactions between monomers of C_{10}Na and C_4EO_{0-3} in the pre-micelle region, which ought to be hydrophobic in nature. The values of $B_{V,SA}$ for C_4EO_{1-4} alcohols in aqueous C_{12}Na are not reliable because the magnitude of the transfer volume is too small ($\sim$0.1 cm^3 mol^{-1}) to be discriminated from the error in the volume measurement.

The values of K_D for C_4EO_X in C_nNa micelles increase as a function of the number of EO groups in the alcohol and of the surfactant chain length (Table 2). It appears that they do not correlate linearly with the number of EO groups in the alcohol, as shown in Fig. 9. The value of K_D doubles when the first EO group is added to butanol, i.e., $K_D = 4.0$ kg mol^{-1} for C_4EO_1 compared to 1.8 kg mol^{-1} for C_4EO_0 in C_8Na micelle solutions, but further increase in the value of K_D is small as more EO groups are added. However, the difference between the K_D values for C_4EO_1 and C_4EO_0 becomes less significant and the increase in the value of K_D in the C_4EO_{2-4} series becomes more significant in the longer chain C_{10}Na and C_{12}Na micelles. In the systems containing 0.40 *m* C_{10}Na and 0.05 *m* C_4EO_X, values of the solubilization of C_4EO_X alcohols in C_{10}Na micelles determined in this study, expressed in terms of the degree of solubilization of the alcohol in the micelle, are slightly higher than those obtained from an NMR – paramagnetic relaxation study of the same systems at similar concentration conditions (14). Nevertheless, the trends are the same (Table 2). The marked increase in the solubilization of C_4EO_1 compared to C_4EO_0 in C_nNa micelles provides evidence that the inclusion of the first EO group into a medium-chain-length *n*-alcohol significantly enhances the hydrophobic interactions between the alcohol and surfactant species of the micelle. However, the relatively moderate increase in K_D for alcohols having more than one EO group indicates that further addition of EO groups increases the hydrophobic character of the alcohol to a lesser extent. The low values of K_D for C_4EO_X alcohols in C_8Na micelles is partly due to the fact that the short-chain C_8Na surfactant forms micelles of small size, which limits the penetration of alcohol molecules (15). The significant increase in the values of K_D for C_4EO_X alcohols in C_{10}Na and C_{12}Na micelle solutions, compared to that in C_8Na micelle solutions, is consistent with previous results in which the solubilization of *n*-pentanol was observed to increase linearly with surfactant chain length (41). The increased solubilization of C_4EO_X in C_{10}Na and C_{12}Na micelles confirms that mixed micelles formed from surfactants of longer chain length provide an environment that allows the alcohols to penetrate deeper into the micelles.

The values of ΔV_A^M for C_4EO_X alcohols in C_nNa solutions, obtained from the simulation, are quite small (Table 2) but clearly show characteristics that are indicative of interactions between ethoxylated alcohols and anionic micelles (Fig. 9). For example, $\Delta V_A^M = 3.0$ cm^3 mol^{-1} for C_4EO_0 in C_8Na micelles is smaller than the value $\Delta V_A^{Hc} = 5.4$ cm^3 mol^{-1}, which is the difference between the partial molar volume of C_4EO_0 in a pure hydrocarbon solvent and in water at infinite dilution (34). Similar behaviour has been observed for transfer of *n*-alcohols from water to a number of micelle systems, especially anionic surfactant solutions (8–11, 17, 41). Since the change in ΔV_A^M is a net result of the loss of hydrophobic hydration when the alcohol molecule penetrates into the micelle interior (a positive contribution to ΔV_A^M) and the electrostatic interactions between the anionic head groups and EO segments (a negative contribution to ΔV_A^M) (8, 41), the relatively low values of ΔV_A^M for the C_4EO_X alcohols suggest that strong electrostatic interactions occur between the carboxylate ions of C_nNa and the polar segments of C_4EO_X in the micelle palisade layer (8), and that a large part of the alcohol molecule resides in the micelle surface area. The small increase in ΔV_A^M for C_4EO_{2-3}, the virtually constant value of ΔV_A^M for C_4EO_1, and the slight decrease in ΔV_A^M for C_4EO_0 as a function of surfactant chain length (Table 2), provide additional evidence that the interactions between the surfactant head groups and EO segments of C_4EO_X are stronger in the palisade layer of the more compact micelles. The constant value of ΔV_A^M of C_4EO_{0-3} (3.0 cm^3 mol^{-1}) in the C_8Na micelles implies a relatively constant degree of alcohol penetration in these small aggregates. The gradual increase in the values of ΔV_A^M from C_4EO_0 to C_4EO_3 in the C_{10}Na and C_{12}Na micelle systems suggests that the alcohols may penetrate more deeply into the larger micelles as the number of EO groups increase in the alcohol, which is consistent with the results for K_D, as discussed above. The values of $\Delta V_A^M = 2.0$ cm^3 mol^{-1} and $K_D = 8.8$ kg mol^{-1} for C_4EO_1 in C_{10}Na micelles, assuming a mean aggregation number of $N_S = 30$, are lower than the previously reported values of 3.67 cm^3 mol^{-1} and 10.0 kg mol^{-1} using $N_S = 20$ (18). When $N_S = 20$ is used to fit our data, a value of $\Delta V_A^M = 3.6$ cm^3 mol^{-1} can be obtained with $K_D = 8.9$ kg mol^{-1}. It is seen that our results are not that different from those previously reported.

The correlation of ΔK_A^M with the number of EO groups in the alcohol and the surfactant chain length is generally similar to ΔV_A^M (Fig. 9). It is known that the partial molar compressibility of medium-chain-length *n*-alcohols in $C_{10}Na$ micelles becomes increasingly positive as a function of the chain length and, eventually, exceeds that in pure liquid hydrocarbons (34). The moderate increase of ΔK_A^M with increasing number of EO groups confirms that C_4EO_X alcohols solubilize themselves in $C_{10}Na$ and $C_{12}Na$ anionic micelles in a manner similar to *n*-alcohols. The significant increase in the magnitude of ΔK_A^M for C_4EO_X in the $C_{12}Na$ micelles is quite striking. The partial molar compressibility of $C_{12}Na$ becomes increasingly positive in the presence of longer chain *n*-alcohols due to a decrease in the mean aggregation number of the micelle upon addition of alcohol. This reduces the surface charge density of the micelles and, hence, the electrostriction of water molecules at the micelle surface (31). Under this condition, the compressibility of the alcohol in the micelle would be expected to be high. The relatively large values of ΔK_A^M for C_4EO_X in the $C_{12}Na$ micelles likely reflects this effect. This is supported by the mean aggregation number data (Table 3), which show that a decrease in N_S of $C_{12}Na$ in the mixed micelles is partially compensated by an increase in the number of C_4EO_X molecules. In contrast to this system, the mean aggregation number of surfactants in the smaller C_8Na and $C_{10}Na$ micelles remains unchanged while the number of C_4EO_X molecules increases steadily as more EO groups are added to the alcohol. The nearly constant value of the mean aggregation number for C_8Na and $C_{10}Na$ micelles in the presence of 0.04 *m* C_4EO_X alcohols indicates that the assumption made in the chemical equilibrium model, i.e., that a small amount of additive in the mixed micelle has a negligible effect on the mean aggregation number of the surfactant (10, 11), is valid for small- and medium-size micelles. For larger micelles, adjustment of the mean aggregation number in the simulation may be required to take into account the effect of the change in the mean aggregation number of surfactant induced by the alcohols.

Conclusion

Numerical values of the micellization parameters of sodium carboxylates, C_nNa (n = 8, 10, 12), in water have been obtained from quantitative analysis of the volumetric properties of aqueous solutions of these surfactants using a mass-action model (6, 7). The micelles of C_nNa vary from small, loose aggregates having a mean aggregation number of approximately 10–15 in the case of C_8Na, to well-defined regular micelles of mean aggregation number 60 in the case of $C_{12}Na$. The effect of small quantities of polyoxyethylene butyl ether compounds, C_4EO_X, on the volumetric properties of C_8Na is minor, but becomes increasingly significant for $C_{10}Na$ and $C_{12}Na$. The changes in the volumetric properties are also dependent on the number of EO groups in the alcohol. The behaviour of the molar volumetric properties of C_4EO_X in aqueous C_nNa solutions is characteristic of the formation of mixed micelles of C_nNa–C_4EO_X. The changes in the various solubilization parameters obtained from fitting the thermodynamic transfer functions of C_4EO_X from water to aqueous C_nNa solutions, using a chemical equilibrium model (10, 11), show that the solubilization of C_4EO_X alcohols in C_nNa micelles is enhanced by increasing the hydrophobicity of the surfactant and the number of EO groups in the alcohol. The latter suggests that the EO groups behave as though they make a hydrophobic contribution to interactions between the alcohol and C_nNa surfactants in the mixed micelles. In C_nNa–C_4EO_X mixed micelles, the aggregation numbers of C_8Na and $C_{10}Na$ remain unchanged in the presence of a small quantity of C_4EO_X, while a significant number of the long-chain $C_{12}Na$ surfactant ions are replaced by C_4EO_X molecules in the $C_{12}Na$ micelles.

A note on the thermodynamics of intercalation

Roger Parsons

Abstract: The thermodynamics of an electrochemical cell with an intercalation electrode is discussed in the light of two recent analyses (Gerischer et al. J. Electrochem. Soc. **141**, 2297 (1994) and Li et al. J. Electrochem. Soc. **141**, 2310 (1994)). The assumptions necessary to obtain a simple result are emphasized.

Key words: thermodynamics, intercalation electrode.

Résumé : À la lumière de deux analyses récentes (Gerischer et al. J. Electrochem. Soc. **141**, 2297 (1994) et Li et al. J. Electrochem. Soc. **141**, 2310 (1994)), on discute de la thermodynamique d'une cellule électrochimique avec une électrode d'intercalation. On met en relief les hypothèses nécessaires pour obtenir un résultat simple.

Mots clés : thermodynamique, électrode d'intercalation.

[Traduit par la rédaction]

1. The electronic and ionic contributions to the intercalation energy

In a recent paper (1) Gerischer et al. discussed the thermodynamics of an intercalation cell in terms of an electronic and an ionic contribution to the emf of the cell. While their analysis is undoubtedly correct, it seems worthwhile to present an alternative and more direct way of treating this problem.

The cell considered may be represented:

$$\begin{array}{cccccc} \text{Cu} & \text{M} & \text{M}^{z+} + z\text{X}^- & \text{M-S} & \text{Cu} \\ \text{A} & \text{I} & \text{II} & \text{III} & \text{B} \end{array}$$

where Cu represents the terminals of the cell, M is a pure sample of the metal being intercalated, forming the left-hand electrode designated phase I. Phase II is an electrolytic solution containing the ions M^{z+} of the metal M and a monovalent anion X^-. Phase III is the intercalation compound of M in the host lattice S. Apart from the terminals, this notation is identical to that used in ref. 1.

The equilibrium potential (emf), E, of this cell may be written:

$$[1] \quad E = \phi^{\text{B}} - \phi^{\text{A}}$$

where ϕ^α is the inner potential of phase α. This can be rewritten:

$$[2] \quad E = (\phi^{\text{B}} - \phi^{\text{III}}) + (\phi^{\text{III}} - \phi^{\text{I}}) + (\phi^{\text{I}} - \phi^{\text{A}})$$

in terms of the Galvani potential differences at each phase boundary (although the phase boundaries I|III and II|III are taken together).

Since there is electronic equilibrium between phases I and A,

$$[3] \quad \tilde{\mu}_{\text{e}}^{\text{I}} = \mu_{\text{e}}^{\text{I}} - F\phi^{\text{I}} = \tilde{\mu}_{\text{e}}^{\text{A}} = \mu_{\text{e}}^{\text{A}} - F\phi^{\text{A}}$$

where $\tilde{\mu}_{\text{e}}^{\alpha}$ is the electrochemical potential of electrons in phase α, μ_{e}^{α} is their chemical potential, and F is Faraday's constant. Hence,

$$[4] \quad \phi^{\text{I}} - \phi^{\text{A}} = (\mu_{\text{e}}^{\text{I}} - \mu_{\text{e}}^{\text{A}})/F$$

and, as both phases A and I are pure metals, both chemical potentials on the right-hand side of eq. [4] are constant, so that eq. [2] may be written:

$$[5] \quad E = (\phi^{\text{B}} - \phi^{\text{III}}) + (\phi^{\text{III}} - \phi^{\text{I}}) + \text{const.}$$

Since there is also electronic equilibrium between phases III and B, the first term on the right-hand side of eq. [5] becomes

$$[6] \quad \phi^{\text{B}} - \phi^{\text{III}} = (\mu_{\text{e}}^{\text{B}} - \mu_{\text{e}}^{\text{III}})/F$$

Similarly, the ionic equilibrium of M^{z+} between phases I, II, and III leads to:

$$[7] \quad \phi^{\text{III}} - \phi^{\text{I}} = (\mu_{\text{M}}^{\text{I}} - \mu_{\text{M}}^{\text{III}})/zF$$

for the second term on the right-hand side of eq. [5], where μ_{M}^{α} is the chemical potential of M^{z+} in phase α.

When eqs. [6] and [7] are substituted into eq. [5], the following equation is obtained:

$$[8] \quad E = (\mu_{\text{e}}^{\text{B}} - \mu_{\text{e}}^{\text{III}})/F + (\mu_{\text{M}}^{\text{I}} - \mu_{\text{M}}^{\text{III}})/zF + \text{const.}$$

which, like eq. [3] of ref. 1, has two components relating to the intercalation process, i.e., $(\mu_{\text{e}}^{\text{B}} - \mu_{\text{e}}^{\text{III}})/F$ and $(\mu_{\text{M}}^{\text{I}} - \mu_{\text{M}}^{\text{III}})/zF$. They may be regarded as representing the electronic and chemical components of this process, respectively.

Received February 14, 1997.

This paper is dedicated to Professor Brian E. Conway on the occasion of his 70th birthday.

The nature of the electronic component may be seen by considering the work function ($-\alpha_e^{III}$) of the electron in phase III. α_i^β is known as the "real potential" of a charged species i in a phase β; when i is the electron, it is exactly equal to the electronic work function with the sign reversed. The real potential arises from the interaction of the charged species with the bulk of the phase (μ_i^β),together with the contribution of the surface potential (χ^β), due to the double layer at the free surface of phase β. (In a metal this arises because the electronic cloud at the surface spreads out beyond the positive charge of the atomic cores.) Thus:

$$[9] \quad \alpha_e^\beta = \mu_e^\beta - F\chi^\beta$$

From this, it follows that the first term on the right-hand side of eq. [8] can be written:

$$[10] \quad (\mu_e^B - \mu_e^{III}) = \mu_e^B - (\alpha_e^{III} - \chi^{III})$$

This shows that changes in the first term of eq. [8] during intercalation may be related to changes in the work function of electrons in phase III, provided that there is no change in the surface potential. (μ_e^B must remain constant at constant temperature as the composition of B does not change.) With this condition, changes in the first term of eq. [8] indicate changes of the Fermi level in phase III. Alternatively, μ_e^{III} may be considered as reflecting directly the energy of interaction of the electron with the bulk of phase III, i.e., the Fermi energy, which will depend on the band structure of phase III.

The second term on the right-hand side of eq. [8] may be expanded as:

$$[11] \quad (\mu_M^I - \mu_M^{III}) = \mu_M^I - (\mu_M^{III,o} + RT \ln (a_M / a_M^o)$$

where a_M is the activity of the intercalated ion in the host, and a_M^o is its activity in the standard state. In this form it can be seen that as intercalation proceeds at constant temperature, a_M is the only variable since μ_M^I represents the energy of M^{z+} in a sample of pure M (which is constant), and $\mu_M^{III,o}$ is the corresponding energy in the host phase III in the standard state. Thus changes in this second term lead to the changes in the energy of interaction of M^{z+} with the host.

2. Stability of an intercalation compound

The question of the stability of an intercalation compound was considered by Li et al. (2) in a paper nearly adjacent to ref. 1. This again is a correct analysis, but it may be more transparent if the usual electrochemical approach is used.

It is evident from eq. [11] that the emf of the above cell is independent of the concentration of MX_z in phase II. Since the cell reaction consists of the transfer of M^{z+} from phase I to phase M-S, the electrolyte (phase II) plays the role of a semipermeable membrane allowing the passage of M^{z+} only. This corresponds to the situation represented in Fig. 1 of ref. 2. However, if the initial dissolution from M-S into pure water is considered, the reaction at the right-hand electrode may be written:

$$[12] \quad M_{(S)}^{z+} + ze^- + zH_2O \rightarrow M_{(aq)}^{z+} + zOH^- + (z/2)H_2$$

If phase II is considered to be infinitely dilute and activity coefficients are ignored, the corresponding Nernst equation is

$$[13] \quad E = E^o - (RT/zF) \ln \{[M_{(aq)}^{z+}][OH^-]^z p_{H_2}^{z/2}/[M_{(S)}^{z+}]\}$$

where the square brackets indicate concentrations.

Dissolution in pure water leads to an equivalent concentration of M^{z+} and OH^-:

$$[14] \quad [M_{(aq)}^{z+}] = z[OH^-]$$

and if $p_{H_2} = 1$, eq. [13] may be written:

$$[15] \quad E = E^o + (RT/zF) \ln \{[M_{(S)}^{z+}]/[M_{(S)}^{z+}]_o\} - (RT/F) \ln [OH^-]$$

where E^o is the electrode potential in the standard state of M-S when the concentration of M^{z+} is $[M_{(S)}^{z+}]_o$. For the left-hand electrode the cell reaction and Nernst equation are formally the same, but the E^o is the standard potential of the pure metal M, and the second term on the right-hand side of eq. [15] vanishes. This corresponds to the situation described in Fig. 2 of ref. 2.

3. Generalization

It may be noted that this analysis does not depend on the detailed nature of the host S. Thus, it applies equally to such processes as intercalation, amalgamation, hydrogen insertion into a metal, and the insertion of ions into the film on a modified electrode. However, in the case of amalgamation it is well known (3) that the surface potential changes with addition of the guest metal, and this may occur with other systems. Although the simplest interpretation follows when S is an electronic conductor, it is possible to apply it to ionic conductors by defining the electrochemical potential of electrons in S in terms of a redox couple in that phase (see, for example, the discussion of the electrochemical potential of electrons in a redox electrolyte (4)). For either type of conductor it should be noted that this analysis depends on the assumption that there is no transfer of M^{z+} ions across the boundary between phase III and phase B. If, for example, metal M exists between these two phases, and there is ionic equilibrium between it and phase III, the emf of the above cell is zero, independent of the composition of phases II and III. It seems also that the electrolyte (phase II) performs the essential function of a semipermeable membrane, as mentioned above. If it were possible to intercalate M^{z+} directly from the metal (phase I), then it would be equally possible to de-intercalate it at the terminal B and the emf would consequently drop to zero.

Temperature-dependent oxygen electrochemistry on platinum low-index single crystal surfaces in acid solutions

B.N. Grgur, N.M. Marković, and P.N. Ross

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12
For personal use only.

Abstract: Using the rotating ring-disk technique ($RRD_{Pt(hkl)}E$), the oxygen-reduction reaction (ORR) was studied in sulfuric acid solution over the temperature range 298–333 K. At the same temperature, the exchange current density increased in the order, $i^0_{111} < i^0_{100} < i^0_{110}$ which gives the order of absolute kinetic activities of Pt(*hkl*) in 0.05 mol/L H_2SO_4: Pt(111) < Pt(100) < Pt(110). We found that at high current densities every crystal face has an ideally temperature-dependent Tafel slope, i.e., $-2 \times 2.3(RT/F)$. The activation energy for the ORR is independent of the surface geometry, $\Delta H^{\#}_{hkl} = 42$ kJ/mol. The insensitivity of the activation energy to surface structure implies that the reaction pathway for the ORR is the same on all three single-crystal faces. A "series" pathway for the ORR was proposed, with the first electron transfer being the rate-determining step. The structure sensitivity in the kinetics of the ORR on Pt(*hkl*) is attributed to the structure-sensitive adsorption of bisulfate and hydroxyl anions and a simple site-blocking effect of these adsorbed anions on the rate of the ORR.

Key words: platinum single crystals, oxygen reduction, peroxide reduction, temperature effects, activation energy.

Résumé : Faisant appel à la technique du disque tournant ($RRD_{Pt(hkl)}E$) on a étudié la réaction de réduction le l'oxygéne (RRO) en solution dans l'acide sulfurique, à des températures allant de 298 à 333 K. À température constante, la densité du courant d'échange augmente dans l'ordre $i^0_{111} < i^0_{100} < i^0_{110}$ qui permet de déduire l'ordre des activités cinétiques absolues du Pt(*hkl*) dans le H_2SO_4 0,05 mol/L : Pt(111) < Pt(100) < Pt(110). On a trouvé que, à des densités de courant élevées, chaque face du cristal présente une pente de Tafel qui dépend d'une façon idéale sur la température, c'est-à-dire que $-2 \times 2.3(RT/F)$. L'energie d'activation de la RRO est indépendante de la géométrie de la surface, $\Delta H^{\#}_{hkl} = 42$ kJ/mol. Le fait que l'énergie d'activation soit insensible à la structure de la surface implique que la voie réactionnelle de la RRO est la même sur les trois faces individuelles du cristal. On propose une « série » de voies réactionnelles pour la RRO dans lesquelles le premier transfert d'électron est l'étape cinétiquement déterminante. La sensibilité de la cinétique de la RRO sur le Pt(*hkl*) sur la structure est attribuée à une adsorption sensible à la structure des anions bisulfate et hydroxyle et à un effet simple de blocage de site de ces anions adsorbés sur la vitesse de la RRO.

Mots clés : cristaux uniques de platine, réduction de l'oxygéne, réduction du peroxyde, effets de la température, énergie d'activation.

[Traduit par la rédaction]

1. Introduction

The last decade has witnessed substantial advances in the understanding of the dependence of the oxygen reduction reaction (ORR) on the Pt surface structure. In earlier studies with platinum single crystals, the variations in the kinetics of the ORR with the crystallographic symmetry of the Pt surface were contradictory (1–4). Recently, by utilizing single crystals in a true rotating ring-disk electrode geometry, $RRD_{Pt(hkl)}E$, we were able to obtain more accurate corrections to the mass transport contribution to the polarization and, thus, obtain more accurate measurements of the kinetics. We found that the structure sensitivity arises primarily from the structure-sensitive adsorption of ions, e.g., bisulfate (5), hydroxyl (6, 7), and halides (8), that are not intermediates in the ORR and actually impede the ORR. However, a complete understanding of how these adsorbed anions impede the rate of the ORR, including a quantitative kinetic model, has not yet evolved (5–8).

All previous studies of the ORR on Pt(*hkl*) single crystals were conducted at a fixed, essentially ambient, temperature. In this paper, we present a study of the temperature dependence of the kinetics of the ORR on Pt(*hkl*) single crystals in 0.05 mol/L sulfuric acid solutions. From these measurements we were able to determine the effect of the surface geometry on the activation energy for the ORR on Pt(*hkl*), which, in turn, illuminated important new details related to the reaction pathway of the ORR, and to the role of bisulfate anion adsorption in the reaction.

2. Experimental

The pretreatment and assembling of the Pt(*hkl*) crystal in a $RRD_{Pt(hkl)}E$ configuration was fully described in our previous

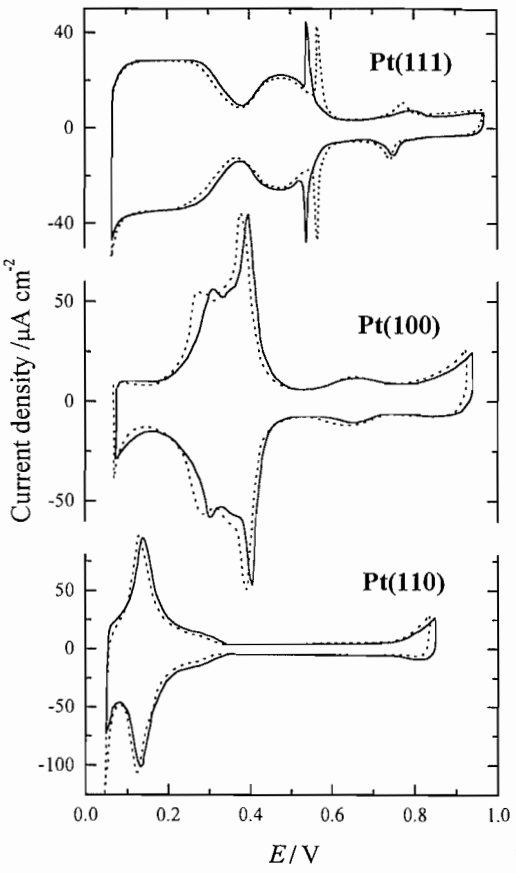
paper. Briefly summarizing, following flame annealing (9), the single crystal was mounted in the disk position of an insertable rotating ring-disk electrode assembly (Pine Instruments).[2] Subsequently, it was transferred into a standard electrochemical cell and immersed into 0.05 mol/L H_2SO_4 (ULTREX II, J.T. Baker Reagent) under potential control at ≈0.2 V. The reference electrode was a saturated calomel electrode separated by a bridge in order to prevent Cl^- contamination of solutions. However, all potentials are referenced to the reversible hydrogen electrode (RHE), calibrated and corrected to a "constant temperature" (thus, a potential scale that is vs. a RHE in the same solutions at the same temperature). This was done experimentally from the hydrogen oxidation/evolution polarization curve on the working electrode at 1 atm (101.3 kPa) hydrogen in the same solutions. All experimental measurements reported in this study were conducted in a standard three-compartment electrochemical cell equipped with a water jacket. A circulating constant temperature bath (Fisher Isotemp Circulator) maintained the temperatures of the solutions within ±0.5 K. All measurements were conducted *nonisothermally*, i.e., keeping the temperature of reference electrode constant (ca. 298 K) while that of the working electrode was varied over the temperature range 298–333 K. A Pine Instruments Bipotentiostat (model AFRDE 4; potential response 0.5 V/ms) was used for all the RRDE experiments. The measured collection efficiency, N, for our RRDE geometry is ≈0.22 (±5%). The geometrical surface area of the disk electrode was 0.283 cm^2. Ring and disk currents were recorded in real time simultaneously on a chart recorder and digitally on an IBM PC (486) computer using Labview for Windows.



In this work, the fractional coverage for adspecies is based on the surface atomic density assuming one-electron transfer per surface atom. The surface atomic densities for Pt(111) and (100) were based on their unreconstructed (1 × 1) geometry, for the Pt(111) (1.5×10^{15} atoms/cm^2) and Pt(100) (1.3×10^{15} atoms/cm^2) (10). For the Pt(110)-(1 × 2), we have found that Pt(110), prepared by the flame-annealing – hydrogen cooling method, is reconstructed into a (1 × 2) structure, which has a surface density of 4.6×10^{14} atoms/cm^2. However, the theoretical charge for the formation of a monolayer of H_{upd} or OH_{ad} on a (1 × 2) surface is the same as for the (1 × 1) surface, since two H_{upd} and OH_{ad} adatoms can be adsorbed per unit cell of the reconstructed Pt(110)-(1 × 2) surface (11).

3. Results and discussion

3.1 Temperature effects on cyclic voltammetry of Pt(*hkl*)

A detailed examination of the temperature effects on the underpotential deposition of hydrogen on Pt(*hkl*) in sulfuric acid will be presented elsewhere (12). For our present purposes, only the cyclic voltammograms for Pt(*hkl*) recorded at two different temperatures will be shown and discussed briefly. Figure 1 shows that voltammetric features for all three single crystals, recorded over the range of temperature studied (298–333 K), are very similar to those observed at room temperature (ref. 12, refs. therein). The positive potential limits were chosen to be sufficient to characterize all important voltammetric features, yet to avoid irreversible "oxide" formation that would result in surface disordering. In the case of Pt(110), on the positive-going sweep, the desorption of hydrogen along the step sites is accompanied by bisulfate adsorption (0.075 < E < 0.2 V). At more positive potentials, the desorption of hydrogen from the terrace sites (0.2 < E < 0.3 V) is followed first by a double layer charging, and then by the adsorption of OH_{ad} species (E > 0.8 V). The absolute charge evaluated by integration of the current in the hydrogen adsorption–region varied little with temperature and equals ≈180 μC/cm^2. The difference between the experimental value and the theoretical charge, ca. 30 μC/cm^2, may be assigned to the charge from a concomitant bisulfate adsorption–desorption process in this potential region (12). The main voltammetric characteristics of well-ordered Pt(100) are sharp multiple peaks in the region of 0.25–0.45 V, and a broad peak centered at ca. 0.7 V. The former are assigned to the coupled adsorption–desorption of underpotential hydrogen (H_{upd}) and bisulfate anion, while the latter is attributed to the reversible adsorption of OH_{ad} produced by the dissociation of water, analogous to the adsorption from perchloric acid solution (13). At more positive potentials, the observed asymmetry between the positive and negative sweep directions represents the transition to an irreversible state of adsorption of OH_{ad}. On Pt(100) in the hydrogen adsorption region the absolute charge equals

Fig. 2. Disk and ring currents during oxygen reduction on Pt(*hkl*) in 0.05 mol/L H_2SO_4 at 298 K and 333 K. Rotation rate, 900 rpm. Sweep rate, 20 mV/s.

≈225 μC/cm^2, compared to the theoretical charge for one monolayer (1 ML) of H_{upd} on Pt(100) of 208 μC/cm^2. The difference between the experimental value and the theoretical charge, ca. 20 μC/cm^2, may be assigned to the charge from concomitant bisulfate adsorption–desorption in this potential region. The voltammetry curves of Pt(111) show a broad flat-topped hydrogen desorption–adsorption peak among values $\approx 0.05 < E < 0.375$ V, and the so-called "anomalous" feature at ≈0.4–0.6 V. This pseudocapacitance corresponds to the adsorption–desorption of bisulfate anions (see, for example, ref. 14). The integrated charge associated with the underpotential deposition of hydrogen on the Pt(111) surface at 298 K is ≈160 μC/cm^2, versus a theoretical charge assuming one hydrogen atom for each surface platinum atom of 240 μC/cm^2. In dramatic contrast to the other two surfaces, the maximum coverage of H_{upd} on Pt(111) is less than a monolayer, only ca. 0.67 ML. A close inspection of Fig. 1 reveals that there are two characteristics of the voltammetric curves for Pt(*hkl*) in 0.05 mol/L H_2SO_4 that represent the temperature effects. The first is that no new features are observed that would result from the temperature increase, and the second is that, on all single-crystal surfaces, hydrogen adsorption–desorption peaks are shifted negatively by increasing the temperature. These observations have been reported previously for both polycrystalline (15) and single crystal platinum electrodes (12, 16). Note that the "anomalous" peaks on Pt(111) are shifted positively by increasing the temperature. This is further confirmation that this pseudocapacitance is associated with the adsorption of bisulfate anions, and not with the underpotential deposition of hydrogen.

3.2 The effect of temperature on the polarization curves for the ORR

Our study of the ORR on Pt(*hkl*) in 0.05 mol/L H_2SO_4 at room temperature was reported previously (5). We summarize here some of those results for the purpose of comparison with new results for the ORR on Pt(*hkl*) at elevated temperatures. Figure 2 shows ring-disk measurements on Pt(*hkl*) in O_2 saturated solutions at room temperature. On all three single-crystal electrodes, below the potential region where there is mixed kinetic–diffusion control of the reaction, well-defined diffusion-limiting currents were recorded over a wide potential region. In both potential regions the ring currents on Pt(*hkl*) surfaces were a very small fraction of the disk current. Figure 2 also shows that, on both Pt(111) and Pt(100), peroxide was detected on the ring electrode in the hydrogen adsorption region, indicating a change in the pathway of the ORR on these surfaces in this potential region. It should be noted that on Pt(110) the ring currents for peroxide oxidation are negligible at all potentials. A simple comparison of the currents at 0.8 V clearly reveals that the ORR on Pt(*hkl*) is a structure-sensitive reaction, with activity increasing in the order Pt(111) < Pt(100) < Pt(110). At 333 K the polarization curves for the ORR are qualitatively similar to the curves recorded at room temperature, and the order of activity remains the same as at room temperature, i.e., Pt(111) < Pt(100) < Pt(110). As expected, the currents associated with the ORR on the disk electrode are higher at elevated temperatures in both the mixed diffusion–kinetic potential region and in the hydrogen adsorption potential region. Consequently, a smaller amount of peroxide was produced on the disk electrode in the hydrogen adsorption region. The higher currents for the ORR on Pt(*hkl*) recorded at elevated temperatures reflect the temperature dependence of the chemical rate constant, which is approximately proportional to $\exp(-\Delta H^{0\#}/kT)$; where $\Delta H^{0\#}$ is the apparent enthalpy of activation at reversible potential (hereafter simply termed the activation energy), k is the Boltzmann constant, and T is the absolute temperature.

3.3 Kinetic analysis

All kinetic analysis was done with the polarization curves recorded at positive-going sweep at 900 rpm, as in Fig. 2. Figures 3–5 show Tafel plots of mass-transport corrected currents (below the limiting current) for the ORR at Pt(*hkl*) surfaces in 0.05 mol/L H_2SO_4 at 298 K, 313 K, and at 333 K, (data were actually obtained at five different temperatures). Only data below ≈0.9 V were analyzed, to avoid the region of irreversible "oxide" formation. For Pt(111), we fitted the curves with one slope, $-2 \times 2.3(RT/F)$ mV/dec over almost the entire potential region, covering more than two decades of current (!). On Pt(100) and Pt(110), the ORR has two Tafel slopes; $\approx -2 \times 2.3(RT/F)$ mV/dec for $\approx 0.65 < E < 0.85$ V, with a possible transition to a lower Tafel slope of $-2.3RT/F$ mV/dec above ca. 0.85 V. The number of data points in this "double" Tafel region is, however, relatively small, and barely more than the minimum of three points to determine the slope. This is an experimental and not a fundamental problem, with the transition occurring at ≈0.85 V. The transition in the Tafel slopes on both Pt(110) and Pt(100) appears to be related to

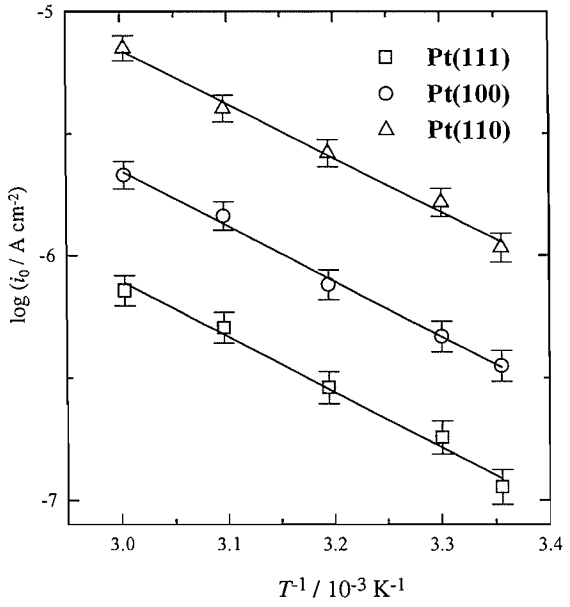
changes in the nature of OH_{ad} with potential, a transition that strongly affects the ORR (6, 17). It is also important to note that the analysis of the polarization curves recorded for the ORR at elevated temperatures revealed that the Tafel slopes were directly proportional to the temperature, with the symmetry coefficient, β, for the oxygen reaction being *independent of temperature*.

In classical electrochemical kinetic theory, the Tafel slope is usually considered to be directly proportional to the temperature, with the transfer coefficient α (which is a function of the symmetry coefficient, β, and the stoichiometric number) a temperature-independent factor (18). The data on the temperature dependence of the Tafel slope for the ORR at the Pt electrode from different groups are not in good agreement; for example, both temperature-dependent (19, 22) and -independent (20, 21, 23) Tafel slopes have been reported. According to various authors, several different phenomena can be

Fig. 5. Tafel plots for the ORR on Pt(110) obtained from polarization curves recorded in 0.05 mol/L H_2SO_4 at 298 K, 313 K, and 333 K.

invoked to explain a temperature-dependent transfer coefficient; the temperature effect in proton and (or) electron tunneling, a shift in the rate-determining step with temperature, or changes in the symmetry of the potential energy barrier with temperature, but also artifacts such as impurity effects, can contribute to the temperature dependence of β. For example, Scharifker et al. (21) proposed that the temperature independence of the Tafel slope for the ORR for Pt in concentrated (85 wt.%) phosphoric acid is due to an impurity effect. Certainly, hot concentrated phosphoric acid is a challenging medium in which to conduct fundamental studies of electrode kinetics. Therefore, even without experimental difficulties, it is not clear how these results could be applicable to more conventional solutions. Our results for the ORR on the Pt(*hkl*) are consistent with the previous reports for polycrystalline Pt in dilute acid solution by Damjanovic and Sepa (23), i.e., a Tafel slope that is directly proportional to the temperature with the symmetry coefficient a temperature-independent factor.

The well-defined linear Tafel regions for the ORR on Pt(*hkl*) were used to extrapolate the current to the theoretical equilibrium potential to obtain the exchange current densities for the ORR on "oxide"-free Pt. At the same temperature, the exchange current density increases in the order $i_{0(111)} < i_{0(100)} < i_{0(110)}$, which gives the order of absolute kinetic activities of the three surfaces. The activation energies for the ORR on each Pt(*hkl*) face were obtained from the exchange current density at different temperatures using the Arrhenius plots (18).



$$[1] \quad \frac{\mathrm{d} \log i_0}{\mathrm{d}(1/T)} = -\frac{\Delta H^{0\#}}{2.3R}$$

where $\Delta H^{0\#}$ is the activation energy and R is the gas constant. The Arrhenius plots for all three single-crystal surfaces, Fig. 6, yield the same activation energy of $\Delta H^{0\#} \approx$ 42 kJ/mol. Interestingly, while the variation in catalytic activity is strongly dependent on the three low-index faces, essentially the same activation energies are obtained at the reversible potential for the ORR on the Pt(*hkl*). The value of $\approx \Delta H^{0\#}$ 42 kJ/mol,

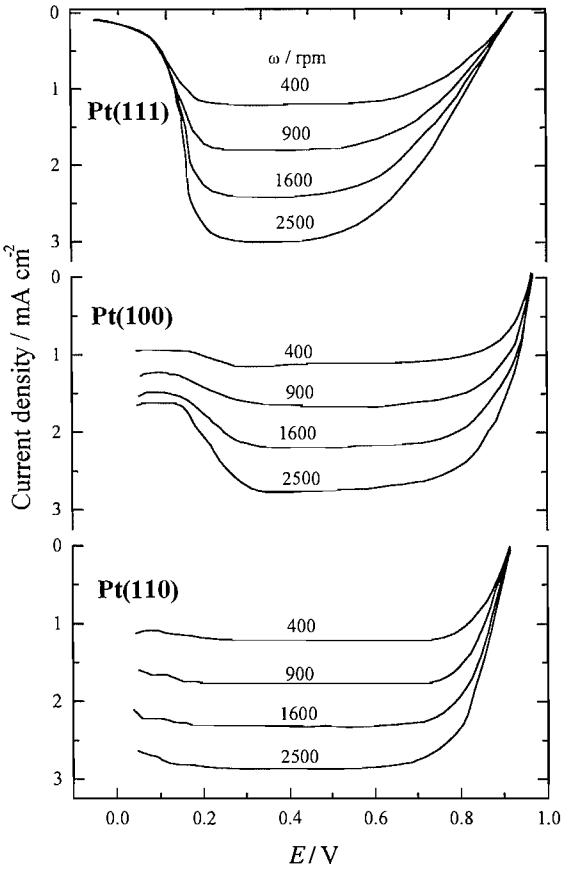
Fig. 6. Arrhenius plots of the exchange current densities at the equilibrium potential for oxygen reduction on Pt(*hkl*) electrodes.

obtained in this work, is smaller than the value of ≈ 57 kJ/mol, previously reported by Appleby for the ORR on "oxide"-free platinum in 85 wt.% orthophosphoric acid (19). Recently, Damjanovic and Sepa reported a value for the activation energy at 0.8 V (vs. the RHE) of ≈25 kJ/mol (23), which is much lower than the activation energy found in this work. Considering that the activation energy is a function of potential (18), and that our value has been extrapolated to the reversible potential for the ORR (1.23 V), it is not surprising that our value is different from the one reported at 0.8 V (23). Damjanovic and Sepa proposed that the Gibbs energy of activation (in our case $\Delta H_E^{\#}$) of an electrochemical reaction, including the ORR, could be experimentally determined at any potential from the intersection of the Tafel lines obtained at different temperatures (23, 24). They found that the Tafel lines intersect at the so-called critical potential, E_{cr}, at which $\Delta H_{E_{cr}}^{\#} = 0$. For the first electron transfer step as rate determining step (rds), $\Delta H_E^{\#}$ at any other potential is given by:



[2] $$\Delta H_E^{\#} = \beta F(E - E_{cr})$$

According to Damjanovic and Sepa (23), for the ORR on polycrystalline Pt at pH ≈1, E_{cr} = 0.3 V vs. RHE. Using this value for E_{cr}, the extrapolated value of their activation energy of 25 kJ/mol at 0.8 V is ≈44 kJ/mol at the theoretical equilibrium potential, in excellent agreement with our experimentally determined value of 42 kJ/mol.

3.4 Peroxide reduction on Pt(*hkl*)

To fully elucidate the structural effects of Pt(*hkl*) on O_2 kinetics in 0.05 mol/L H_2SO_4, the kinetics of H_2O_2 reduction was studied on platinum single crystals in a solution free of oxygen. To simulate the chemical environment during O_2 reduction, we added peroxide to the supporting solutions to a concentration approximating the level of peroxide produced during the oxygen reduction, i.e., the maximum level would be

Fig. 7. Polarization curves for reduction of 1.2×10^{-3} mol/L H_2O_2 on Pt(*hkl*) in 0.05 mol/L H_2SO_4 at 298 K. Sweep rate, 50 mV/s.

equal to the solubility of oxygen in the solutions or ca. 10^{-3} mol/L. Figure 7 shows the family of polarization curves for the reduction of H_2O_2 on the three platinum low-index surfaces. It is important to note that the half-wave potentials for H_2O_2 reduction curves lay well anodic (≈50–100 mV) from the half-wave potentials for O_2 reduction. Thus, if H_2O_2 is formed as an intermediate on the electrode during the ORR, then it should be immediately reduced (electrochemically) to water, since the potential of oxygen reduction is negative of the region of H_2O_2 stability on the platinum single-crystal surfaces. This is also consistent with the ring currents observed during the ORR, which show no measurable amount of peroxide detected above 0.3 V. Below 0.3 V, on the Pt(100) and especially on the Pt(111) surface, the peroxide reduction current drops significantly, an observation reflected in the ring currents during the ORR in Fig. 2. It should also be noted that on Pt(110) a very small decrease in the currents associated with the reduction of peroxide was observed in the hydrogen adsorption region, consistent with a small amount of peroxide formed in the same potential region during the ORR, Fig. 2.

3.5 Reaction pathway for the ORR in sulfuric acid

In this section, the reaction pathway for the ORR on Pt(*hkl*), rather than the reaction mechanism, will be discussed because the $RRD_{Pt(hkl)}E$ technique alone is not capable of detecting all possible reaction intermediates in a complex process such as the ORR. From the many reaction pathways that have been

© 1997 NRC Canada

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12
For personal use only.

proposed in the past (25–27), we will discuss our results in the context of the series pathway, i.e., via an $(O_2H)_{ad}$ intermediate, as proposed by Damjanovic et al. (27). We will not attempt to resolve all of the uncertainties that still persist over the reaction mechanism of the ORR on Pt nor do we claim that our analysis here is definitive. Rather, we attempt to improve the understanding of the reaction pathway by comparing the kinetics of the ORR onto Pt(*hkl*) with the rate of the peroxide reduction under the same experimental conditions. Subsequently, the kinetic parameters, such as Tafel slope, exchange current densities, and activation energies for the ORR on Pt(*hkl*) will be related to the activities and the rds of the ORR on different single-crystal faces.

For the ORR on a polycrystalline platinum electrode there are two views regarding the first reaction step. Damjanovic et al. (28) and Sepa et al. (29) proposed that the first step is electron transfer to the O_2 molecule; this step is rate determining and is either accompanied or followed by a fast proton transfer. On the other hand, Yeager et al. (30) proposed that the first step most likely involves dissociative chemisorption of the O_2 molecules on a platinum surface that occurs simultaneously with the charge transfer. It appears that our results for the ORR on Pt(*hkl*) support the former view, primarily due to two new experimental results that are uniquely related to the enhanced sensitivity of Pt single-crystal electrodes. The first result is that the Tafel slopes, together with the OH_{ad} coverages that can be inferred from the voltammetry curves in Fig.1, are consistent with the first electron transfer to the O_2 molecule as the rds. This is most easily seen for Pt(111) on which a single Tafel slope of $-2 \times 2.3(RT/F)$ mV/dec is observed over the entire potential region; a value of $-2 \times 2.3(RT/F)$ mV/dec is characteristic for the first charge transfer as rds under Langmuirian conditions of adsorption of oxygen-containing species. This is consistent with the voltammetry curve for Pt(111) at 298 K in Fig. 1, which revealed that there is no (apparent) change in coverage of oxygen-containing species on the surface in this potential region. At elevated temperatures (333 K), however, due to a weakening of bisulfate adsorption and simultaneous enhanced adsorption of oxygen-containing species, a second Tafel slope (ca. $-2.3RT/F$) may be inferred from the polarization curves at 333 K in Fig. 3. On the other hand, Pt(100) and Pt(110) have two clearly defined Tafel slopes, as usually observed on a polycrystalline platinum electrode. For Pt(110) and Pt(100) at low overpotentials, the Tafel slope is $\approx -2.3RT/F$ mV/dec, which is also consistent with the first charge transfer step as rds but under Temkin conditions of adsorption of oxygen-containing species (ref. 23, and refs. therein). While the voltammetry curves in Fig. 1 do not provide evidence of Temkin conditions of adsorption, they do show clearly that an irreversible adsorption of OH_{ad} starts at ca. 0.8–0.85 V, and the coverage increases rapidly above 0.85 V. Thus, the transition of the Tafel slopes from $-2 \times 2.3(RT/F)$ to $\approx -2.3RT/F$ mV/dec at ca. 0.85–0.9 V on these surfaces is probably related to the surface coverage by the irreversible adsorption of OH_{ad}, as we previously suggested for an analogous transition that occurs for the ORR on Pt(*hkl*) in alkaline solution (6). It appears, therefore, that at low overpotentials the variations in activity for the ORR between Pt(100) and Pt(110) in sulfuric acid may also arise from highly structure-sensitive irreversible adsorption of OH_{ad} species (7).

A second new result coming from the use of single-crystal electrodes is the data on peroxide reduction in the hydrogen adsorption potential region. In the potential region of hydrogen adsorption, we see direct evidence of the strong inhibition by H_{upd} on oxygen and peroxide reduction on the Pt(111) and Pt(100) surfaces, remarkably so on the Pt(111), but relatively little effect on the Pt(110). We had reported the effects of H_{upd} on the kinetics of both the O_2 and H_2O_2 reduction reactions on Pt(*hkl*) previously, and will not repeat our analysis of these effects in terms of a structural model for H_{upd} and the series reaction pathway (for review see refs. 5–7). For our purposes here, we note only that this model is consistent with the series reaction pathway with the first electron transfer being rate determining.

Finally, we will attempt to resolve the factors that control the kinetics of the ORR, based on the values for the activation energies obtained for the ORR on Pt(*hkl*) in 0.05 mol/L H_2SO_4. Our analysis of Arrhenius plots clearly showed that the *same* activation energy (at the reversible potential) for the ORR, close to 42 kJ/mol, has been found for all three Pt(*hkl*) surfaces. We presented an argument showing that the same reaction mechanism (reaction pathway) is operative on all three single-crystal faces. How then does one account for the very significant differences in kinetic rate, i_o, on the different Pt(*hkl*) surfaces; We had shown previously that this structural sensitivity is most pronounced in solutions in which there is strong adsorption of anions (7), including the sulfuric acid used here. We had also proposed a simple form of Pt site elimination by adsorbed anions (6) and, if the standard free energy of adsorption of molecular O_2 is independent of coverage (Langmuirian conditions), that the rate of O_2 reduction may be expressed as

$$[3] \quad i = nFkC_{O_2}(1 - \theta_{ad})\exp(-\alpha F\eta/RT)$$

where n is the number of the electrons, k is the rate constant, C_{O_2} is the concentration of O_2 in the solution, θ_{ad} is the partial coverage by anion species (e.g., $HSO_{4(ad)}$ and OH_{ad}), i is the observed current, η is applied overpotential, and α is the transfer coefficient. It appears that in this rate equation for the ORR all the variables are independent of surface crystallography, except the surface coverage by bisulfate anions and oxygen-containing species. Therefore, the pre-exponential term $(1 - \theta_{ad})$ will entirely control the kinetics of the ORR on the Pt(*hkl*), as we proposed previously and is now confirmed by these new results for the activation energies for the ORR on Pt(*hkl*) in sulfuric acid solution.

4. Conclusions

Using the rotating ring-disk measurements ($RRD_{Pt(hkl)}E$), the oxygen reduction reaction was studied in sulfuric acid solution over the temperature range 298–333 K. We found that, at the same temperature, the exchange current density increased in the order, $i^0_{111} < i^0_{100} < i^0_{110}$ which gives the order of absolute kinetic activities of Pt(*hkl*): Pt(111) < Pt(100) < Pt(110). We also found that every crystal face has an ideally temperature-dependent Tafel slope for the ORR. For Pt(110) and Pt(100), this slope is $\approx -2.3RT/F$ mV/dec above 0.87 V, with a transition to $-2 \times 2.3RT/F$ mV/dec at higher overpotentials. At 298 K, Pt(111) has a $-2 \times 2.3RT/F$ mV/dec Tafel slope over the entire potential region. At elevated temperatures, however, a

© 1997 NRC Canada

second slope could also be extrapolated from the polarization curves. The activation energy at the reversible potential was determined to be independent of crystallographic orientation of the surface, $\Delta H^{\#}_{hkl} = 42$ kJ/mol. A structure-insensitive activation energy for the ORR implies that the reaction pathway for the ORR is the same on all three single-crystal faces. We concluded that our results are consistent with the "series" reaction pathway, with the first electron transfer step being the rate-determining step (rds). A simple kinetic expression is derived in which all the kinetic parameters are independent of surface structure except the pre-exponential term, $(1 - \theta_{ad})$, where θ_{ad} is the fractional coverage by adsorbed bisulfate and OH_{ad} anions, which are strongly structure sensitive.

Acknowledgment

We are indebted to Hubert Gasteiger for his contribution to all previous measurements and for analysis of the results for the ORR on Pt(*hkl*) at room temperature. This work was supported by the Assistant Secretary for Energy Efficiency and Renewable Energy, Office of Transportation Technologies, of the U.S. Department of Energy under Contract No. DE-AC03-76SF00098.

Synthesis of hyperbranched glycodendrimers incorporating α-thiosialosides based on a gallic acid core

Serge J. Meunier, Quigquan Wu, Sho-Nong Wang, and René Roy

Abstract: Hyperbranched glycodendrimers containing sialic acid residues were synthesized in order to further understand the multivalency effect and its role in carbohydrate–protein interactions. Gallic acid **7** as trivalent core and oligoethylene glycol derivatives as hydrophilic spacers were used to scaffold the dendritic backbones. α-Thiosialoside **16** was conjugated onto *N*-chloroacetylated dendritic precursors **13**, **14**, and **26** by nucleophilic substitution to afford trivalent **17**, **18**, and nonavalent **27** sialodendrimers. Complete sugar deprotection furnished water-soluble α-thiosialodendrimers **21**, **22**, and **29**, which were used in protein-binding studies. Turbidimetric analysis confirmed the strong potential of sialodendrimers **29** having nine readily accessible sialic acid residues to bind, cross-link, and precipitate two different lectins. Preliminary results indicated that nonavalent α-sialodendrimer **29** had a greater affinity towards dimeric wheat germ agglutinin (WGA) and the lectin from the slug *Limax flavus* (LFA) than the corresponding trivalent glycodendrimers **21** and **22**.

Key words: carbohydrate, dendrimer, sialic acid, gallic acid, lectin, wheat germ agglutinin, *Limax flavus*.

Résumé : Afin de mieux comprendre l'effet de multivalence et son rôle dans les interactions carbohydrate–protéine, on a synthétisé des glycodendrimères hautement ramifiés contenant des résidus d'acide sialique. On a utilisé l'acide gallique, **7**, comme unité centrale trivalente et des dérivés oligoéthylèneglycol comme intercaleurs hydrophiles pour échafauder les structures de base dendritiques. La conjugaison de l'α-thiosialoside **16** sur les précurseurs dendritiques *N*-chloroacétylés **13**, **14** et **26** par des substitutions nucléophiles conduit aux sialodendrimères trivalents **17** et **18** et nonavalent **27**. Une déprotection complète du sucre conduit aux α-thiosialodendrimères **21**, **22** et **29** qui ont été utilisés dans les études de fixation sur des protéines. Des analyses turbidimétriques ont confirmé que le sialodendrimère **29**, qui incorporent neuf résidus d'acide sialique facilement accessible, possèdent un important potentiel de se lier, de créer des réticulations et de précipiter deux lectines différentes. Les résultats préliminaires indiquent que l'affinité de l'α-sialodendrimère nonavalent **29** pour l'agglutinine dimère du germe de blé (« WGA ») et pour la lectine de la limace *Limax flavus* (« LFA ») est plus grande que celles des glycoden-drimères trivalents correspondants, **21** et **22**.

Mots clés : carbohydrate, dendrimère, acide sialique, acide gallique, lectine, agglutinine du germe de blé, *Limax flavus*.

Introduction

It is now well established that cell surface carbohydrates and sialosides, in particular, are involved as anchoring motifs onto which various pathogenic agents such as viruses (influenza, sendai, and rota-viruses), bacteria (*Helicobacter pilori*, *Escherichia coli*, *Bordetella pertussis*, *Vibrio cholerae*, *Pseudomonas aeruginosa*), and parasites (*Plasmodium falciparum*) adhere and colonize host tissues (1). It has also been demonstrated that bacterial infections (2) and cancer metastasis (3) can be prevented by blocking pathogenic carbohydrate receptors (toxins, lectins, etc.) with high serum carbohydrate concentrations. Additionally, we (4) and others (5)[2] have established that multivalent neoglycoconjugates constitute powerful antiadhesins in a number of generally low affinity carbohydrate–protein binding interactions.

Potent multivalent neoglycoconjugate antiadhesins have been scaffolded onto a wide range of carriers including polymers (6), polyamino acids (7), cyclodextrins (8), calix[4]arenes (9), carbohydrates (10), and dendrimers (11). These last classes of scaffolds proved particularly appealing since the effects of size, shape, and valency can be controlled at will (12, 13). As an extension of our preliminary work on gallic acid (**7**) as seeding trivalent core molecule, we present herein the synthesis of tri- and nona-meric dendrimers bearing α-thiosialosides. The ability of these dendrimers to bind and cross-link sialic acid selective plant (phytohemagglutinins) and animal lectins from wheat germ agglutinin and from the slug *Limax flavus* will be discussed.

Received March 13, 1997.

This paper is dedicated to Professor Brian E. Conway on the occasion of his 70th birthday.

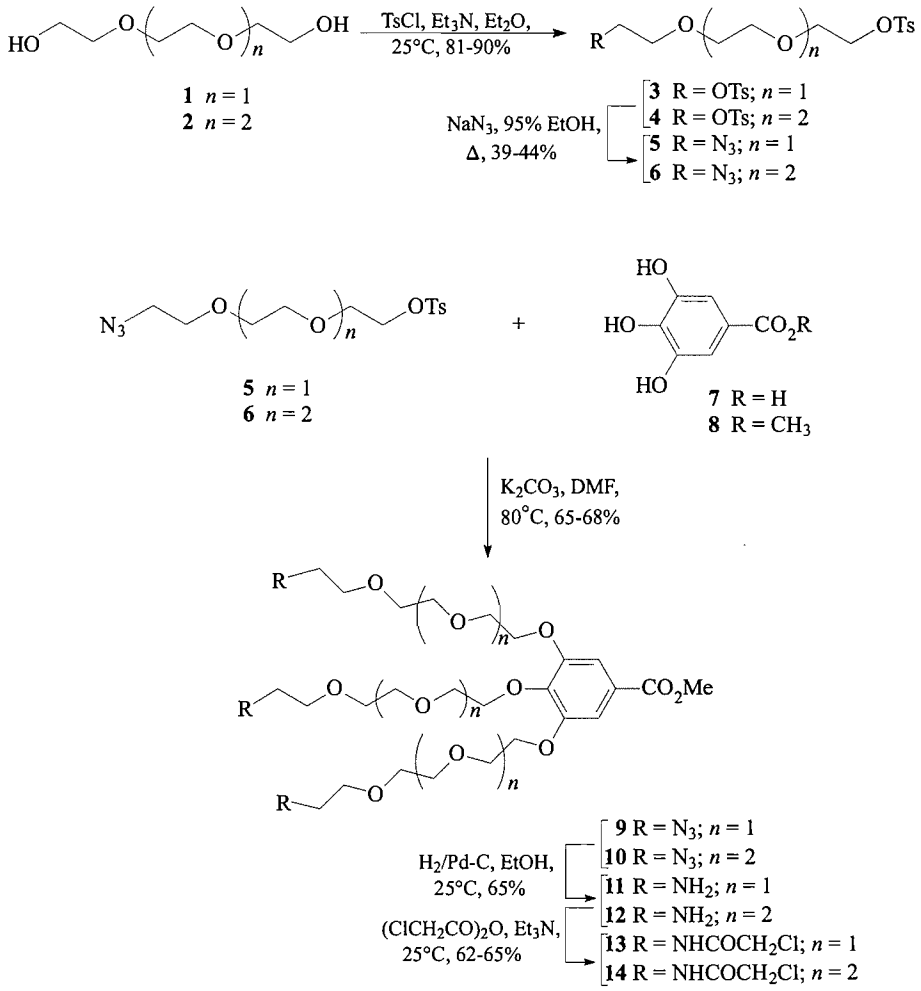
Results and discussion

3,4,5-Trihydroxybenzoic acid (gallic acid, **7**) based sialodendrimers were synthesized using commercially available tri- and tetra-ethylene glycol **1** and **2** as spacer arms. The latter were chosen to ensure water solubility of the final product and to counteract the hydrophobic effect of the aromatic backbone. They were also chosen because they are commercially available in different lengths, and they provide sufficient spacing to allow the carbohydrate moieties to be readily accessible by receptor sites. Diols **1** and **2** were ditosylated in 79–81% yields using *p*-toluenesulfonyl chloride (TsCl, triethylamine, Et_2O, reflux). Bistosylated spacers **3** and **4** were then treated with one equivalent of sodium azide (95% EtOH, reflux, 4 h) to afford azidotosylates **5** and **6** in moderate yields (39–44%) (Scheme 1). Under these conditions, a substantial amount of starting material could be recovered (40–50%), together with traces of bisazides and EtOH substitution products, which were minimized when 95% instead of 99% EtOH was used.

The choice of gallic acid as core unit allows dendrimer scaffolding to reach 3^n surface groups at the nth generation. Furthermore, it can be used to generate dendrimers with different valencies than those previously reported (2^n) for sialylated dendrimers (11) in which the seeding molecules L-lysine (12) and 3,3′-iminobis(propylamine) (13) were used. To provide an iterative approach, gallic acid was transformed into an orthogonally protected amino acid derivative (14). Methyl ester **8** was prepared from gallic acid **7** using standard procedure ($SOCl_2$, rt, 2 h, then MeOH, 98%). The white solid ester **8** (mp 199.5–201°C) was then carefully *O*-alkylated with a slight excess of azidotosylate spacers **5** or **6** using K_2CO_3 as base (DMF at 80°C) to afford key dendrimer precursors **9** and **10** in 65 and 68% yields, respectively (Scheme 1). Trisamino esters **11** and **12** were obtained by reduction of azides **9** and **10** (H_2, 10% Pd–C, 93% crude yield for **12**) and used directly in the next step without further purification. An analytical sample of **12** was, however, purified by silica gel chromatography (65% yield). The extent of the reduction was monitored by FTIR spectroscopy, which showed total disappearance of the azido frequency (2106 cm^{-1}). Intermediate amines **11** and **12** were then sequentially transformed into either first generation precursors **13** and **14** or into orthogonally protected amino acid derivatives for further generation buildup. Thus, treatment of **11** or **12** with chloroacetic anhydride ($(ClCH_2CO)_2O$, Et_3N, EtOH) provided tris-*N*-chloroacetylated esters **13** or **14** in 62–65% yields. Completion of the reaction could be readily monitored by a negative ninhydrin reaction and by the appearance of a sharp *N*-chloroacetyl methylene singlet at δ 4.01 ppm ($CDCl_3$) integrating for the expected six proton signals relative to those of the two aromatic protons (δ 7.25 ppm, s) and the three carbomethoxy protons signal at δ 3.85 ppm.

As we previously demonstrated in other glycodendrimer syntheses (11–15), it was found advantageous to attach the carbohydrate residues after the buildup of the dendritic cores. Not only does this strategy permit incorporation of any other carbohydrate haptens at a late stage but it also allows convergent synthesis as well as tethering glycodendrimer building blocks (13*b*). In this last case, tethered glycodendrimers are formed with spherical shapes in all three directions rather than being unidirectional.



Thus, known α-sialosyl thioacetate **15** (12*a*) was chosen as the nucleophilic carbohydrate moiety to be initially used on the trimeric *N*-chloroacetylated precursors **13** and **14**. Chemoselective hydrolysis of the thioacetate group in **15** was first achieved by mild transesterification conditions (NaOMe, MeOH, −40°C, 15 min), followed by acidic resin treatment at −40°C (16) (Scheme 2). This mild treatment prevented anomeric thiol from both oxidation and anomerization. Thiol derivative **16** was always freshly prepared prior to coupling onto dendrimers. First-generation trivalent α-thiosialosides **17** and **18** were obtained from the coupling of thiol **16** to trimeric *N*-chloroacetylated esters **13** and **14** under a nitrogen atmosphere (CH_3CN, Et_3N, 25°C, 85–95% yields). The extent of thiosialoside incorporation in glycodendrimers **17** and **18** was readily determined by ^1H NMR spectroscopy. The disappearance of the signal due to all three equivalent *N*-chloroacetyl residues at δ 4.01 ppm (6H), along with the integration of well-separated sialic acid associated signals at δ 4.84 ppm (H-4, 3H) and at δ 2.72 ppm (H-3e, 3H) relative to that of the aromatic protons at δ 7.27 ppm (2H), confirmed complete substitution. Peracetylated glycodendrimers **17** and **18** were then treated with NaOMe in MeOH (pH ~9, 25°C) to provide partially deprotected intermediates **19** and **20** in quantitative yields. Their ^1H NMR spectra showed the presence of sialic acid methyl esters and *N*-acetyl residues as well as the disappearance of all *O*-acetyl signals. Methyl ester hydrolysis from both sialosides and gallic acid residues of **19** and **20** was performed simultaneously by treatment with 0.5 M aqueous NaOH in MeOH (1:1, v/v, 25°C , 16 h). This reaction afforded unprotected water-soluble glycodendrimers **21** and **22** in nearly quantitative yields after freeze-drying. Completion of hydrolysis was best monitored using ^{13}C NMR spectroscopy where the methoxy signals at δ ~52–54 ppm were well separated from the remaining carbon signals.

For the preparation of the second generation, readily available amide bond linkages between the subunits were chosen. To this end, orthogonally protected amino acid derivatives were required. Trisamino ester **12**, already obtained from reduction of trisazido ester **10** (see above), was used as an amine partner, while acid precursor **23** was obtained from the same trisazido ester **10** by hydrolysis (Scheme 3). Methyl ester **10** was hydrolyzed under basic conditions (KOH, EtOH, reflux, 2 h) to afford **23** quantitatively. Coupling a slight excess of trisazido acid **23** to trisamino ester **12** using carbodiimide chemistry and hydroxybenzotriazole (EDC, HOBt, EtOH-CH_3CN, 1:1 v/v, DIPEA, 25°C, 3 h) afforded nona-azido ester **24** in 83% yield. After usual work-up and purification by silica gel column chromatography, the ^1H NMR spectrum of **24** showed the expected 1:3 ratio of inner (δ 7.24 ppm, ester) and outer (δ 7.02 ppm, amide) aromatic proton signals. Catalytic hydrogenation (H_2, 10% Pd–C) of azido ester **24** gave nona-amino ester **25**, which was not further purified since it was directly *N*-chloroacetylated as previously shown ($(ClCH_2CO)_2O$, Et_3N), to give **26** in 78% yield . The extent of reduction was ascertained by IR spectroscopy wherein the sensitive azide frequency (2106 cm^{-1}) could be monitored.

Electrophilic nona-*N*-chloroacetylated dendrimer **26** was suitable for nucleophilic substitution with sialic acid thiol **16** (11 equiv.) as described earlier for compounds **17** and **18**. The coupling was done at room temperature overnight (CH_3CN, Et_3N) under nitrogen to provide fully protected nona-sialoside dendrimer **27** in 86% yield as a colorless oil after purification

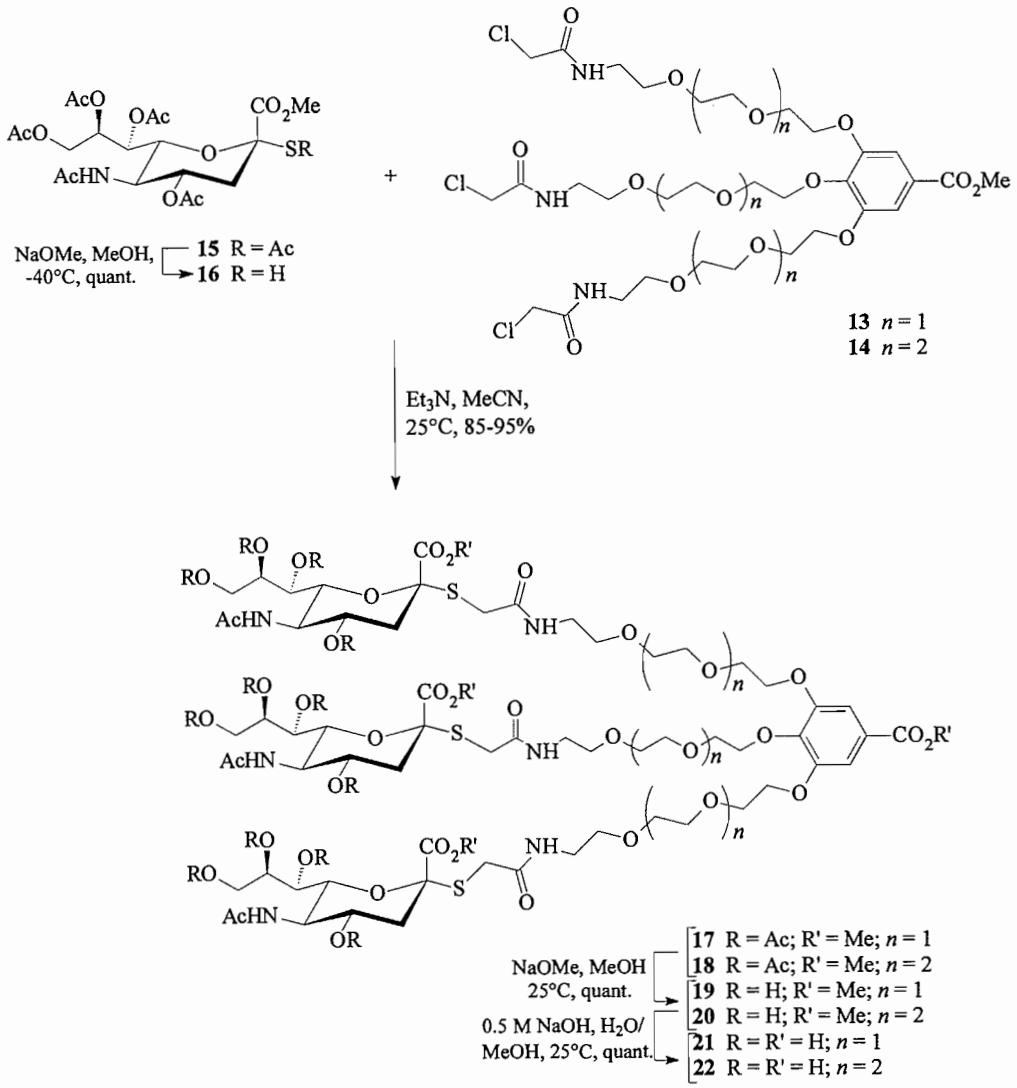
Scheme 1.



by silica gel column chromatography (Scheme 4). The incorporation level of α-thiosialosides was evaluated as before by using ^{1}H NMR spectroscopy . The aromatic protons of the inner residue (δ 7.25 ppm) integrated for two protons when compared to either H-4 (δ 4.83 ppm) or H-3e (δ 2.71 ppm) of the sialic acid residues, which both integrated for nine protons. De-*O*-acetylation of glycodendrimer **27** was achieved under standard Zemplén conditions (NaOMe, MeOH, pH ~9, 25°C, 45 min) to give compound **28** in quantitative yield. Methyl esters in **28** were hydrolyzed following the procedure described above (aq. NaOH, MeOH), and unprotected nona-α-thiosialylated dendrimer **29** was obtained in quantitative yield.

Preliminary lectin-binding experiments were achieved using microtiter plate turbidimetric analysis (17) wherein solutions of lectin-containing trimeric (**21** or **22**) and nonameric (**29**) sialodendrimers were allowed to form insoluble cross-linked complexes that could be monitored at 490 nm. To this end, two different lectins known to bind α-sialosides were used. Wheat germ agglutinin (WGA) (18) and the lectin from the slug *Limax flavus* (LFA) (19) were used as models. Both lectins are divalent and can therefore form linear one-dimensional (sometimes soluble) or multidimensional cross-linked lattices (20). The results from the time course of turbidimetric analysis are shown in Fig. 1. Interestingly, 9-mer α-thiosialoside **29** showed a clear and rapid cross-linked insoluble complex with both WGA and LFA lectins. This last result with LFA is similar to that previously observed with analogous multivalent α-thiosialosides scaffolded on a 3,3′-iminobis(propylamine) core (13). It differs, however, from both previous studies (13) and the present WGA binding in that the complex seems less stable since there is a steady decrease of cross-linking after the initial 10 min of reaction. The complex does however stabilize after awhile. Additionally, trimeric α-thiosialosides **21** and **22**, only differing by the length of their ethylene glycol spacers, showed no stable insoluble complexes with either lectins. These results can be rationalized by the low valency of the trimers, which fail to form multidimensional cross-linked complexes with the dimeric lectins. This implies that the third arm of the dendrimers does not allow further cross-linking with another lectin molecule. Work is now in progress to determine the intrinsic binding abilities of each sialodendrimer by inhibition assays. This work further stresses the need for a better understanding of carbohydrate-protein interactions of glycodendrimers varying in shape, size, conformation (rigidity), and valency. As antigen presentation is becoming crucial in the design of potent carbohydrate

Scheme 2.

ligands, which can be used as antiadhesins and as vectors for drug delivery, further work is still needed.

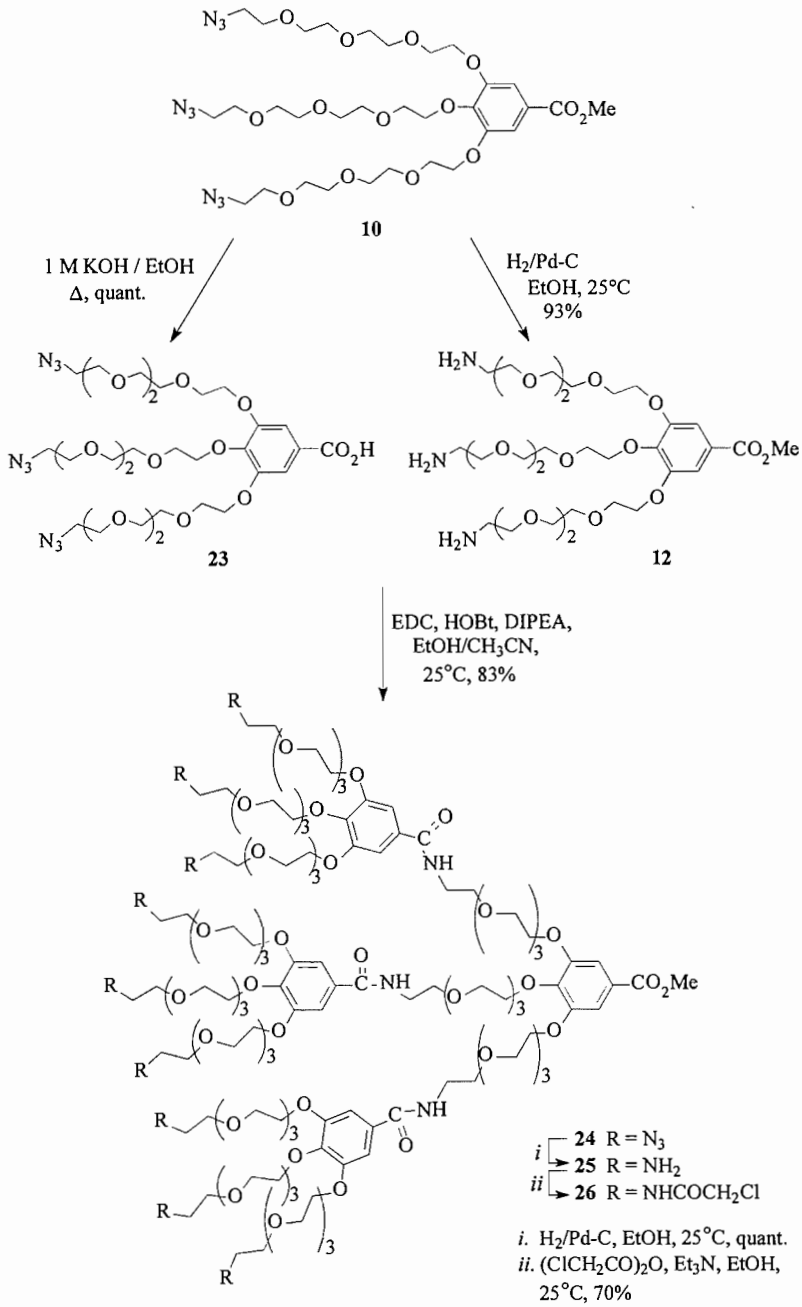
Experimental

General methods

Melting points were determined on a Gallenkamp apparatus and are uncorrected. The ^1H and ^{13}C NMR spectra were recorded on Varian Gemini-200 and Bruker AMX-500 spectrometers. Proton chemical shifts (δ) are given relative to internal chloroform (δ 7.24 ppm) for $CDCl_3$ solutions or to methanol (δ 3.30 ppm) for CD_3OD solutions. Carbon chemical shifts are given relative to deuteriochloroform (δ 77.0 ppm) and to CD_3OD (δ 49.0 ppm). Optical rotations were measured at room temperature (23 ± 1°C) in a 1 dm cell on a Perkin–Elmer 241 polarimeter. Mass spectra were recorded on a VG 7070-E spectrometer (CI, ether) and Kratos Concept IIH (FABMS, thioglycerol). Thin-layer chromatography (TLC) was performed using silica gel 60 F-254 and column chromatography on silica gel 60 (230–400 mesh, E. Merck No. 9385). All solvents and reagents were reagent grade and were used without further purification. Optical densities (O.D.) for the turbidimetric analysis were performed on a Dynatech MR 600 Microplate Reader. The lectins, *Limax flavus* (LFA) and *Triticum vulgaris* (WGA), were obtained from E-Y Laboratories (cat. no. L-5101-1) and Sigma (cat. no. L-9640), respectively.

Synthesis

*1,8-Bis-[(*p*-toluenesulfonyl)oxy]-3,6-dioxaoctane (3)*



A solution of triethylene glycol (50.0 g, 0.33 mol) in anhydrous diethyl ether (300 mL) was cooled to 0°C under a nitrogen atmosphere. Triethylamine (50 mL) was added followed by *p*-toluenesulfonyl chloride (68.84 g, 0.36 mol) over a 1 h period, and the solution was warmed to room temperature. After stirring for 3 h, the reaction mixture was evaporated in vacuo. The resulting residue was dissolved in CH_2Cl_2 and washed successively with saturated sodium bicarbonate solution (50 mL) and twice with water (50 mL). The organic layer was dried using anhydrous sodium sulfate and concentrated

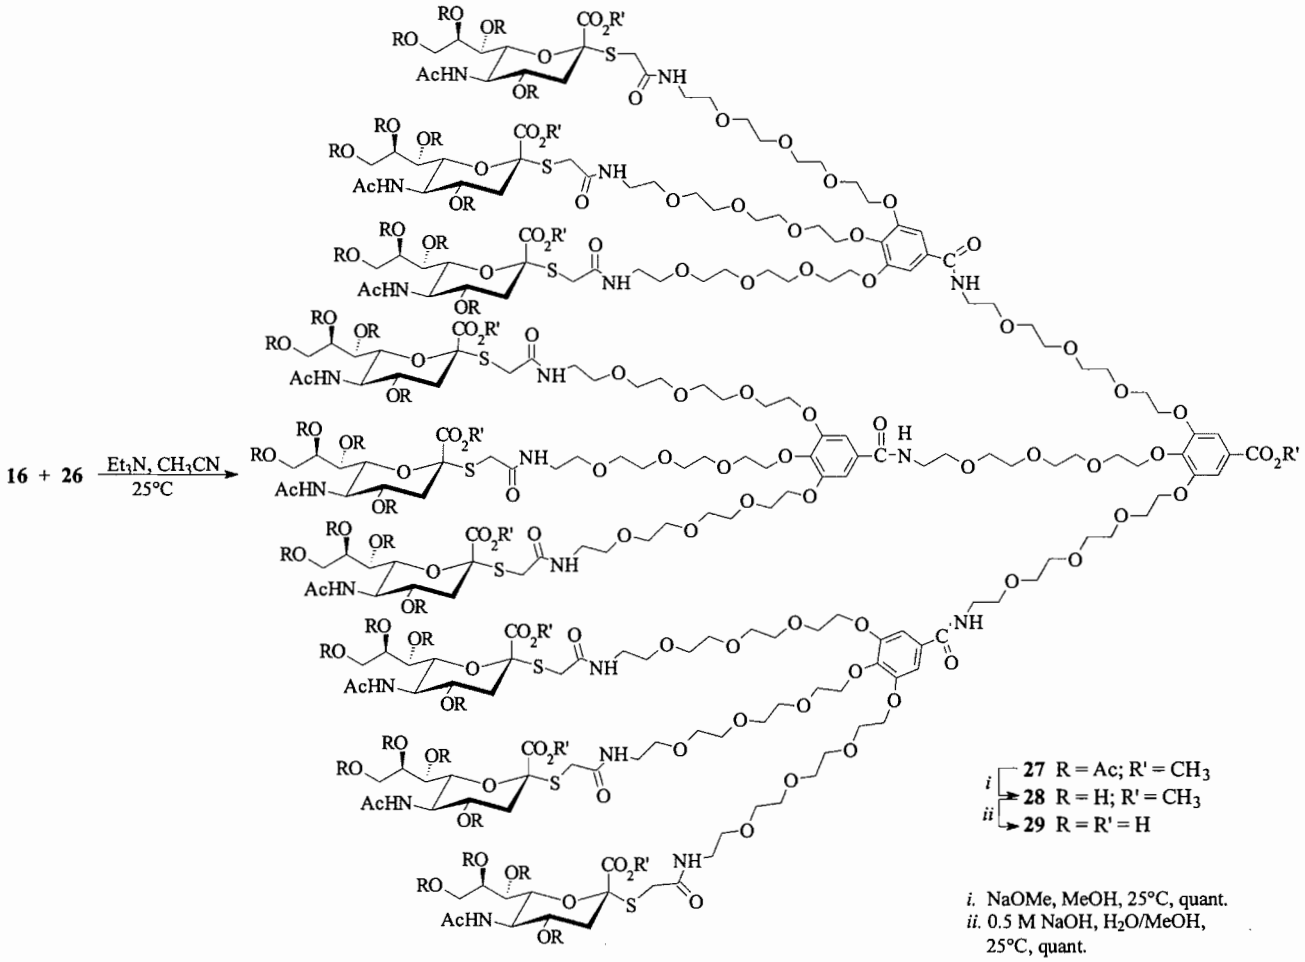
Scheme 3.



under vacuum to afford 120 g (79%) of **3** as a white solid. After filtration, the remaining crude product was purified by silica gel column chromatography using ethyl acetate/hexanes (1:1, v/v) as eluent to afford 16 g (11%) of **3** (total yield 90%); mp 82–84°C (EtOH); ^{1}H NMR ($CDCl_3$) δ: 7.75 (d, 4H, J 8.3 Hz, H_{ar}), 7.31 (d, 4H, *J* 8.3 Hz, H_{ar}), 4.11 (t, 4H, *J* 4.8 Hz, TsOCH_2), 3.62 (t, 4H, *J* 4.8 Hz, TsOCH$_2CH_2$), 3.49 (s, 4H, OCH_2), 2.41 (s, 6H, CH_3); ^{13}C NMR ($CDCl_3$) δ: 144.8, 132.8, 129.8, 127.9 (C_{ar}), 70.6 (TsOCH_2), 69.2 (CH_2O), 68.6 (CH_2O), 21.6 (CH_3); CIMS: 459 (M+1, 36%), 287 (74).

*1,11-Bis-[(*p*-toluenesulfonyl)oxy]-3,6,9-trioxaundecane (**4**)*
An identical procedure was used to synthesize compound **4** in 81% yield, the difference being that the final product was a colorless oil that was purified by silica gel column chromatography. ^{1}H NMR ($CDCl_3$) δ: 7.76 (d, 4H, *J* 8.2 Hz, H_{ar}), 7.31 (d, 4H, *J* 8.2 Hz, H_{ar}), 4.12 (t, 4H, *J* 4.8 Hz, TsOCH_2), 3.64 (t, 4H, *J* 4.8 Hz, TsOCH$_2CH_2$), 3.53 (s, 8H, OCH_2), 2.41 (s, 6H, CH_3); ^{13}C NMR ($CDCl_3$) δ: 144.6, 132.6, 129.6, 127.7 (C_{ar}), 70.4, 70.2, 69.1, 68.4 (CH_2O), 21.4 (CH_3); CIMS: 503 (M+1, 26%), 331 (46).

*1-Azido-8-[(*p*-toluenesulfonyl)oxy]-3,6-dioxaoctane (**5**)*
To a solution of 500 mg (1.09 mmol) of bistosylate **3** in 95% ethanol (10 mL) was added sodium azide (35.4 mg, 0.545 mmol). The reaction was stirred under reflux for 4 h and monitored by TLC. After cooling the reaction mixture to room temperature and removing the precipitated solid, the filtrate

Scheme 4.

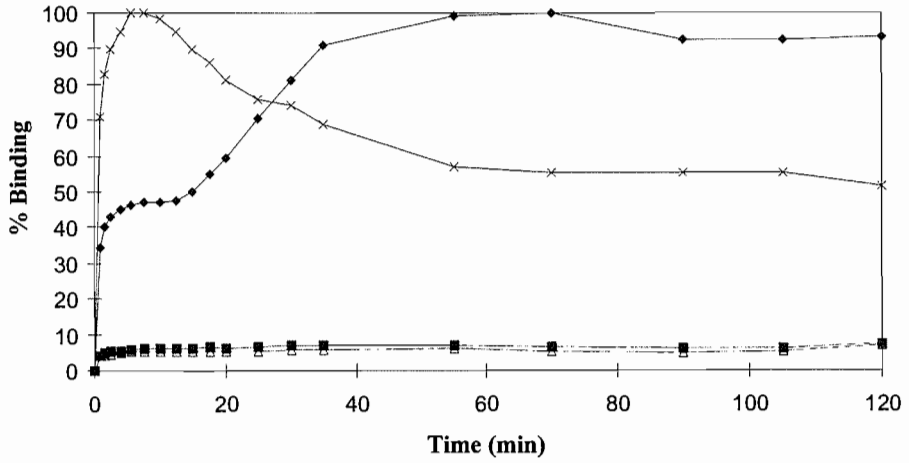
was evaporated under reduced pressure. The oily residue was dissolved in diethyl ether and washed twice with water and brine. The dried organic phase (Na_2SO_4) was concentrated and the crude product purified by silica gel chromatography using a gradient of 1:5 to 1:1 (v/v) ethyl acetate/hexanes as eluent to afford 157.6 mg (44%) of **5** as a colorless oil. FTIR ν_{max} (cm^{-1}): 3015, 2904, 2108, 1738, 1598; ^1H NMR ($CDCl_3$) δ: 7.75 (d, 2H, *J* 8.3 Hz, H_{ar}), 7.32 (d, 2H, *J* 8.3 Hz, H_{ar}), 4.12 (t, 2H, *J* 4.7 Hz, TsOCH_2), 3.68–3.56 (m, 8H, OCH_2), 3.33 (t, 2H, CH_2N_3), 2.41 (s, 3H, CH_3); ^{13}C NMR ($CDCl_3$) δ: 144.6, 132.6, 129.6, 127.6 (C_{ar}), 70.4, 70.2, 69.7, 69.1, 68.4 (CH_2O), 50.3 (CH_2N_3), 21.3 (CH_3); CIMS: 330 (M+1, 3%), 302 (61). Anal. calcd. for $C_{13}H_{19}N_3O_5S$: C 47.40, H 5.81, N 12.76; found: C 47.23, H 6.00, N 12.96.

*1-Azido-11-[(p-toluenesulfonyl)oxy]-3,6,9-trioxaundecane (**6**)*

Compound **6**, prepared under the same conditions described above for **5**, was obtained as an oily residue in 39% yield (15.2 g). FTIR ν_{max} (cm^{-1}): 3015, 2930, 2110, 1727, 1599; ^1H NMR ($CDCl_3$) δ: 7.72 (d, 2H, *J* 8.3 Hz, H_{ar}), 7.27 (d, 2H, *J* 8.3 Hz, H_{ar}), 4.12 (t, 2H, *J* 4.8 Hz, TsOCH_2), 3.63–3.52 (m, 12H, OCH_2), 3.31 (t, 2H, CH_2N_3), 2.39 (s, 3H, CH_3); ^{13}C NMR ($CDCl_3$) δ: 144.7, 132.7, 129.7, 127.8 (C_{ar}), 70.6, 70.5, 70.4, 69.9, 69.2, 68.5 (CH_2O), 50.5 (CH_2N_3), 21.5 (CH_3); CIMS: 374 (M+1, 3%), 346 (67).

*Methyl 3,4,5-trihydroxybenzoate (**8**)*

Gallic acid **7** (3.4 g, 20 mmol) was treated with thionyl chloride (10 mL) at room temperature for 2 h after which time the solvent was removed under vacuum. The oily residue was cooled down using an ice bath followed by addition of methanol (10 mL). The mixture was allowed to react for 30 min and was concentrated in vacuo. The crude residue was recrystallized from ethanol to afford 3.6 g (98%) of a white solid; mp 199.5–201°C (ethanol); ^1H NMR (D_2O) δ: 7.06 (s, 2H, H_{ar}), 3.86 (s, 3H, OCH_3); ^{13}C NMR (DMSO-d_6) δ: 164.9 (C═O), 144.2, 137.0, 117.1, 107.1 (C_{ar}), 50.2 (OCH_3); HREIMS: 184.0372 (calcd. for $C_8H_8O_5$: 184.0367, 15.4%).



*Methyl 3,4,5-tri-(8-azido-3,6-dioxaoctyloxy)benzoate (**9**)*

To a solution of methyl gallate **8** (184 mg, 1 mmol) in DMF (25 mL) was added potassium carbonate (1.4 g, 10 mmol) and tosylated **5** (1.3 g, 4.0 mmol) dissolved in DMF (5 mL). The mixture was stirred at 80°C for 24 h and allowed to cool to room temperature. The solid was filtered off and the filtrate was evaporated under vacuum, coevaporated with *tert*-butanol, and the remaining residue was partitioned between

Fig. 1. Time course of turbidimetric analysis of wheat germ agglutinin (WGA) with 9-mer α-thiosialoside **29** (◆), trimers **21** (△) and **22** (■), and *Limax flavus* lectin (LFA) with **29** (X).

CH_2Cl_2 and water. The organic layer was separated and washed further with water, saturated NaCl solution, and dried over sodium sulfate. After removing the solvent, the crude material was purified by silica gel chromatography using a gradient of 1:3 to 2:1 (v/v) ethyl acetate/hexanes to give 426 mg (65%) of **9** as a pure colorless oil. FTIR ν_{max} (cm^{-1}): 3018, 2901, 2107, 1717, 1587; ^1H NMR ($CDCl_3$) δ: 7.27 (s, 2H, H_{ar}), 4.23–4.15 (m, 6H, PhOCH_2), 3.86 (s, 3H, OCH_3), 3.88–3.61 (m, 24H, OCH_2), 3.35 (t, 6H, *J* 5.0 Hz, CH_2N_3); ^{13}C NMR ($CDCl_3$) δ: 166.5 (C═O), 152.2, 142.4, 124.9, 108.9 (C_{ar}), 72.4, 72.3, 70.8, 70.7, 70.5, 70.0, 69.9, 69.6, 68.8 (CH_2O), 52.1 (OCH_3), 50.6 (CH_2N_3); FABMS: 656 (M+1, 11%), 628 (14). Anal. calcd. for $C_{26}H_{41}N_9O_{11}$: C 47.62, H 6.30, N 19.23; found: C 47.69, H 6.22, N 18.97.

*Methyl 3,4,5-tri-(11-azido-3,6,9-trioxaundecyloxy)benzoate (**10**)*

Compound **10** was obtained, the same way as previously shown for **9**, as a colorless oil in 68% yield. FTIR ν_{max} (cm^{-1}): 3009, 2948, 2106, 1717, 1586; ^1H NMR ($CDCl_3$) δ: 7.26 (s, 2H, H_{ar}), 4.22–4.14 (m, 6H, PhOCH_2), 3.85 (s, 3H, OCH_3), 3.87–3.61 (m, 36H, OCH_2), 3.35 (t, 6H, CH_2N_3); ^{13}C NMR ($CDCl_3$) δ: 166.2 (C═O), 152.0, 142.2, 124.6, 108.6 (C_{ar}), 72.1, 70.4, 70.3, 70.3, 69.7, 69.3, 68.5 (CH_2O), 51.8 (OCH_3), 50.3 (CH_2N_3); FABMS: 788 (M+1, 2%), 760 (4). Anal. calcd. for $C_{32}H_{53}N_9O_{14}$: C 48.79, H 6.78, N 16.00; found: C 49.00, H 7.00, N 16.06.

*Methyl 3,4,5-tri-(8-amino-3,6-dioxaoctyloxy)benzoate (**11**)*

To a solution of azide **9** (132 mg, 0.206 mmol) in ethanol (10 mL) was added 50 mg of 10% palladium on carbon. Hydrogen was constantly bubbled through the solution at room temperature and the reaction was monitored by IR (complete disappearance of azide peak). After 3 h, the catalyst was removed by filtration and the filtrate was concentrated under vacuum. The crude product obtained was used in the next step without further purification. FTIR ν_{max} (cm^{-1}): 3450, 3020, 2921, 1716, 1587; FABMS: 579 (M+1, 32%).

*Methyl 3,4,5-tri-(11-amino-3,6,9-trioxaundecyloxy)benzoate (**12**)*

Following the procedure described previously, trisamino **12** was obtained as a yellowish syrup in 93% crude yield. The product was purified by silica gel chromatography using 10% MeOH in CH_2Cl_2 as eluent to give pure **12** in 65% yield. FTIR ν_{max} (cm^{-1}): 3369, 3050, 2897, 1715, 1586; ^1H NMR ($CDCl_3$) δ: 7.25 (s, 2H, H_{ar}), 4.16 (m, 6H, PhOCH_2), 3.85 (s, 3H, OCH_3), 3.84–3.54 (m, 30H, OCH_2), 3.45 (t, 6H, *J* 5.4 Hz, OCH_2), 2.82 (t, 6H, *J* 5.4 Hz, CH_2NH_2), 1.29 (m, 6H, NH_2); ^{13}C NMR ($CDCl_3$) δ: 166.4 (C═O), 152.1, 142.3, 124.8, 108.8 (C_{ar}), 73.3, 72.2, 70.7, 70.5, 70.4, 70.3, 70.1, 69.4, 68.6, (CH_2O), 52.0 (OCH_3), 41.6 (CH_2NH_2); FABMS: 710 (M+1, 45%).

*Methyl 3,4,5-tri-[8-(2-chloroacetamido)-3,6-dioxaoctyloxy]benzoate (**13**)*

To a cooled solution (0°C) of trisamine **11** (119 mg, 0.206 mmol) in ethanol (10 mL) was added triethylamine (0.5 mL) and chloroacetic anhydride (132 mg, 0.772 mmol) in small portions over a 30 min period. The mixture was then stirred at room temperature for 2 h after which time the solvent was evaporated under vacuum. The reaction was monitored by a ninhydrin test. The oily residue was dissolved in H_2O and extracted with CH_2Cl_2. The organic extracts were dried (Na_2SO_4), concentrated under vacuum to give crude **13**, which was purified by silica gel chromatography using 5% methanol in CH_2Cl_2 as eluent to afford 108 mg (65%) of **13** as a colorless oil. FTIR ν_{max} (cm^{-1}): 3316, 3015, 2904, 1715, 1668, 1589; ^1H NMR ($CDCl_3$) δ: 7.25 (s, 2H, H_{ar}), 7.18 (m, 3H, NH), 4.22–4.15 (m, 6H, PhOCH_2), 4.01 (s, 6H, CH_2Cl), 3.85 (s, 3H, OCH_3), 3.85–3.40 (m, 30H, OCH_2 and CH_2NH); ^{13}C NMR ($CDCl_3$) δ: 166.3, 165.9 (C═O), 152.0, 142.0, 124.9, 108.6 (C_{ar}), 72.2, 70.5, 70.4, 70.3, 70.1, 69.4, 69.2, 68.6 (CH_2O), 52.0 (OCH_3), 42.4 (CH_2NH), 39.4 (CH_2Cl); FABMS: 808 (M+1, 14%), 810 (5). Anal. calcd. for $C_{32}H_{50}N_3O_{14}Cl_3$: C 47.62, H 6.24, N 5.21; found: C 47.80, H 6.40, N 5.05.

*Methyl 3,4,5-tri-[11-(2-chloroacetamido)-3,6,9-trioxaundecyloxy]benzoate (**14**)*

Compound **14** was obtained from the amino **12** by the same procedure described above. The pure product was obtained in 62% yield as a colorless syrup. FTIR ν_{max} (cm^{-1}): 3425, 3035, 2904, 1714, 1671, 1588; ^1H NMR ($CDCl_3$) δ: 7.26 (s, 2H, H_{ar}), 7.08–7.04 (m, 3H, NH), 4.18 (t, 2H, *J* 4.9 Hz, PhOCH_2), 4.16

(t, 4H, *J* 5.0 Hz, PhOCH_2), 4.00 (s, 6H, CH_2Cl), 3.84 (s, 3H, OCH_3), 3.82 (t, 4H, OCH_2), 3.76 (t, 2H, OCH_2), 3.70–3.66 (m, 6H, OCH_2), 3.64–3.57 (m, 18H, OCH_2), 3.54 (t, 6H, OCH_2), 3.47–3.44 (m, 6H, CH_2NH); ^{13}C NMR ($CDCl_3$) δ: 166.4, 166.0 (C═O), 152.2, 142.2, 125.0, 108.8 (C_{ar}), 72.4, 70.8, 70.6, 70.5, 70.3, 69.6, 69.3, 68.7 (CH_2O), 52.2 (OCH_3), 42.6 (CH_2NH), 39.5 (CH_2Cl); HR-FABMS: 938.3223 (calcd. for $C_{38}H_{63}N_3O_{17}Cl_3$: 938.330, 99%).

Methyl 5-acetamido-4,7,8,9-tetra-O*-acetyl-3,5-dideoxy-2-thio-*D*-glycero-*α*-*D*-galacto-2-nonulo-pyranosidonate (**16**)*

To a solution of thioacetylated sialic acid **15** (12*a*) (63.1 mg, 0.115 mmol) in dry methanol (1.5 mL) cooled to −40°C, was added 1 M sodium methoxide in methanol (109 μL, 0.109 mmol). The reaction, monitored by TLC, took less than 15 min after which time the reaction mixture was treated with H^+ resin (Amberlite IR-120) at −40°C for 15 min. The solution was filtered and evaporated at room temperature under reduced pressure to afford **16**, which was used without further purification. $[\alpha]_D$ +15.6 (*c* 0.99, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ: 5.33–5.28 (m, 2H, H-7 and H-8), 5.17 (d, 1H, $J_{NH,5}$ 10.5 Hz, NH), 4.91 (ddd, 1H, $J_{4,5}$ 10.3 Hz, $J_{3a,4}$ 11.7, $J_{3e,4}$ 4.8, H-4), 4.49 (dd, 1H, $J_{8,9'}$ 2.1 Hz, $J_{9,9'}$ 12.4, H-9′), 4.10 (dd, 1H, $J_{8,9}$ 5.5 Hz, H-9), 4.06 (m, 1H, H-5), 3.83 (s, 3H, OCH_3), 3.73 (dd, 1H, $J_{6,7}$ 1.9 Hz, $J_{5,6}$ 10.8, H-6), 3.17 (s, 1H, SH), 2.80 (dd, 1H, $J_{3e,3a}$ 12.8 Hz, H-3e), 2.14, 2.13, 2.05, 2.03 (4s, 12H, 4 OAc), 2.04 (dd, 1H, H-3a), 1.88 (s, 3H, NAc); ^{13}C NMR ($CDCl_3$) δ: 170.9, 170.6, 170.4, 170.4, 170.1, 170.0 (C═O), 81.6 (C-2), 75.1 (C-6), 70.1 (C-8), 69.4 (C-4), 67.7 (C-7), 62.2 (C-9), 53.4 (OCH_3), 49.1 (C-5), 38.9 (C-3), 23.1 (NAc), 21.1, 20.8, 20.8 (4 OAc); CIMS: 508 (M+1, 100%), 476 (85).

Methyl 3,4,5-tri-{8-[2-(methyl 5-acetamido-4,7,8,9-tetra-O*-acetyl-3,5-dideoxy-2-thio-*D*-glycero-*α*-*D*-galacto-2-nonulo-pyranosid)-acetamido]-3,6-dioxaoctyloxy}benzoate (**17**)*

To a solution of α-thiosialoside **16** (75.4 mg, 0.149 mmol) in dry acetonitrile (4.5 mL) was added Et_3N (50 μL, 0.358 mmol) and trischloroacetamide precursor **13** (30 mg, 0.037 mmol). The mixture was stirred at room temperature overnight under a nitrogen atmosphere. The solution was concentrated under vacuum, and the crude residue was purified by preparative TLC plate using, first, ethyl acetate, followed by 7% methanol in CH_2Cl_2 as eluent. Pure **17** was extracted using 5% methanol in CH_2Cl_2 and, after evaporation, the residue was dissolved in ethyl acetate and filtered to remove soluble impurities from silica gel. The colorless oil was obtained in 85% (70.7 mg) yield. $[\alpha]_D$ +24.2 (*c* 1.02, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ: 7.27 (s, 2H, H_{ar}), 6.89 (m, 3H, NH), 5.44 (m, 6H, H-8 and NH), 5.30 (dd, 3H, $J_{6,7}$ 2.0 Hz, $J_{7,8}$ 9.0, H-7), 4.84 (ddd, 3H, $J_{3a,4}$ 11.6 Hz, $J_{3e,4}$ 4.5, H-4), 4.25 (dd, 3H, $J_{8,9'}$ 2.8 Hz, H-9′), 4.21–4.17 (m, 6H, PhOCH_2), 4.06–4.01 (m, 6H, H-5 and H-9), 3.87 (s, 3H, OCH_3), 3.84 (t, 6H, *J* 4.8 Hz, OCH_2), 3.78–3.34 (m, 30H, OCH_2, CH_2N, CH_aS, and H-6), 3.73 (s, 9H, OCH_3), 3.29 (d, 3H, *J* 16.2 Hz, CH_bS), 2.72 (dd, 3H, $J_{3e,3a}$ 12.7 Hz, $J_{3e,4}$ 4.5, H-3e), 2.17, 2.13, 2.03, 2.01 (4s, 36H, 4 OAc), 1.95 (dd, 3H, H-3a), 1.86 (s, 9H, NAc); ^{13}C NMR ($CDCl_3$) δ: 171.1, 170.8, 170.8, 170.7, 170.4, 170.4, 170.1, 168.6, 168.5, 168.4 (C═O), 152.2, 142.2, 125.0 (C_{ar}), 108.9 (C_{ar}-H), 82.1 (C-2), 73.9 (C-6), 72.3, 70.6, 70.5, 70.4, 70.2, 69.6, 69.6, 69.5, 68.7 (OCH_2), 69.4 (C-4), 68.0 (C-8), 67.0 (C-7), 62.3 (C-9), 53.1 (OCH_3), 52.2 (OCH_3), 49.1 (C-5), 39.7 (CH_2N), 37.3 (C-3), 32.4 (CH_2S), 23.1 (NAc), 21.3, 20.8, 20.8, 20.7 (4 OAc); FABMS: 2223 (M+1, 20%). Anal. calcd. for $C_{92}H_{134}N_6O_{50}S_3$: C 49.77, H 6.08, N 3.79; found: C 49.80, H 6.43, N 3.63.

Methyl 3,4,5-tri-{11-[2-(methyl 5-acetamido-4,7,8,9-tetra-O*-acetyl-3,5-dideoxy-2-thio-*D*-glycero-*α*-*D*-galacto-2-nonulo-pyranosid)-acetamido]-3,6,9-trioxaundecyloxy}-benzoate (**18**)*

The sialylated glycodendrimer **18** was obtained in 95% (71.4 mg) yield as a colorless oil in the same way as described for glycodendrimer **17**. $[\alpha]_D$ +22.4 (*c* 1.01, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ: 7.27 (s, 2H, H_{ar}), 6.83 (m, 3H, NH), 5.41 (ddd, 3H, $J_{8,9'}$ 2.7 Hz, H-8), 5.34 (d, 3H, $J_{NH,5}$ 10.0 Hz, NH), 5.29 (dd, 3H, $J_{6,7}$ 2.1 Hz, $J_{7,8}$ 9.2, H-7), 4.84 (ddd, 3H, $J_{4,5}$ 10.4 Hz, $J_{3a,4}$ 11.6, $J_{3e,4}$ 4.6, H-4), 4.24 (dd, 3H, $J_{8,9'}$ 2.7 Hz, $J_{9,9'}$ 12.4, H-9′), 4.20–4.16 (m, 6H, PhOCH_2), 4.06–4.02 (m, 3H, H-5), 4.03 (dd, 3H, $J_{8,9}$ 5.8 Hz, H-9), 3.87 (s, 3H, OCH_3), 3.83 (t, 4H, *J* 4.9 Hz, OCH_2), 3.79–3.75 (m, 2H, OCH_2), 3.76 (dd, 3H, $J_{5,6}$ 10.7 Hz, H-6), 3.73 (s, 9H, OCH_3), 3.70–3.66 (m, 6H, OCH_2), 3.64–3.60 (m, 18H, OCH_2), 3.54 (d, 3H, *J* 16.0 Hz, CH_aS), 3.58–3.32 (m, 12H, CH_2CH_2N and CH_2CH_2N), 3.28 (d, 3H, *J* 16.0 Hz, CH_bS), 2.72 (dd, 3H, $J_{3e,3a}$ 12.7 Hz, $J_{3e,4}$ 4.6, H-3e), 2.16, 2.12, 2.02, 2.00 (4s, 36H, 4 OAc), 1.95 (dd, 3H, H-3a), 1.85 (s, 9H, NAc); ^{13}C NMR ($CDCl_3$) δ: 171.0, 170.7, 170.6, 170.6, 170.2, 170.0, 168.5, 168.2 (C═O), 152.2, 142.3, 124.9 (C_{ar}), 109.0 (C_{ar}-H), 82.1 (C-2), 73.9 (C-6), 72.3, 72.3, 70.7, 70.5, 70.5, 70.4, 70.2, 69.6, 69.5, 69.4, 69.4, 68.7 (C-4 and OCH_2), 67.9 (C-8), 67.0 (C-7), 62.3 (C-9), 53.1 (OCH_3), 52.2 (OCH_3), 49.1 (C-5), 39.6 (CH_2N), 37.3 (C-3), 32.4 (CH_2S), 23.1 (NAc), 21.3, 20.8, 20.8, 20.7 (4 OAc); FABMS: 2353 (M+1, 26%), 1879 (6), 1405 (2). Anal. calcd. for $C_{98}H_{146}N_6O_{53}S_3$: C 50.04, H 6.26, N 3.57; found: C 49.66, H 6.54, N 3.46.

*Methyl 3,4,5-tri-{8-[2-(methyl 5-acetamido-3,5-dideoxy-2-thio-*D*-glycero-*α*-*D*-galacto-2-nonulo-pyranosid)-acetamido]-3,6-dioxaoctyloxy}benzoate (**19**)*

The dendritic α-thiosialoside **17** (45 mg, 0.020 mmol) was dissolved in dry methanol (3 mL) and a 1 M solution NaOMe–MeOH (pH ~9) was added. The solution was stirred at room temperature for 45 min and then treated with H^+ resin (Amberlite IR-120). The filtrate was evaporated near dryness under reduced pressure and freeze-dried to afford a white powder in quantitative yield. $[\alpha]_D$ +16.3 (*c* 0.49, CH_3OH); ^{1}H NMR (CD_3OD) δ: 7.30 (s, 2H, H_{ar}), 4.24–4.14 (m, 6H, PhOCH_2), 3.94–3.34 (m, 69H, OCH_3, OCH_2, OCH_3, H-4, H-5, H-6, H-7, H-8, H-9, H-9′, CH_2S, and CH_2N), 2.70 (dd, 3H, H-3e), 1.94 (s, 9H, NAc), 1.74 (dd, 3H, H-3a); ^{13}C NMR (CD_3OD) δ: 175.0, 171.5, 171.2, 168.1 (C═O), 153.7, 143.7, 126.3 (C_{ar}), 109.9 (C_{ar}-H), 83.6 (C-2), 77.2 (C-6), 73.6, 71.8, 71.4, 70.8, 70.4, 70.1 (OCH_2), 72.1 (C-8), 70.1 (C-4), 68.8 (C-7), 64.8 (C-9), 53.8 (C-5), 53.6 (OCH_3), 52.8 (OCH_3), 41.8 (C-3), 40.8 (CH_2N), 33.5 (CH_2S), 22.7 (NAc).

*Methyl 3,4,5-tri-{11-[2-(methyl 5-acetamido-3,5-dideoxy-2-thio-*D*-glycero-*α*-*D*-galacto-2-nonulo-pyranosid)-acetamido]-3,6,9-trioxaundecyloxy}benzoate (**20**)*

Zemplén conditions as described above were applied to compound **18** to afford de-O-acetylated glycodendrimer **20** as a white foam (freeze-dried) in quantitative yield. $[\alpha]_D$ +14.4 (*c* 0.52, CH_3OH); ^{1}H NMR (CD_3OD) δ: 7.34 (s, 2H, H_{ar}),

4.25–4.11 (m, 6H, PhOCH_2), 3.88–3.85 (m, 9H, OCH_3, and PhOCH_2CH_2), 3.81–3.46 (m, 57H, OCH_2, H-4, H-5, H-7, H-8, H-9, H-9′, and OCH_3), 3.50–3.45 (m, 9H, H-6 and CH_2S), 3.40–3.35 (m, 6H, CH_2N), 2.76 (dd, 3H, $J_{3e,3a}$ 12.8 Hz, $J_{3e,4}$ 4.5, H-3e), 1.98 (s, 9H, NAc), 1.80 (dd, 3H, H-3a); ^{13}C NMR (CD_3OD) δ: 174.9, 171.4, 171.0, 168.0 (C═O), 153.6, 143.5, 126.2 (C_{ar}), 109.9 (C_{ar}-H), 83.5 (C-2), 77.1 (C-6), 73.5, 71.6, 71.5, 71.5, 71.2, 70.7, 70.2, 70.0 (OCH_2), 72.0 (C-8), 70.1 (C-4), 68.7 (C-7), 64.7 (C-9), 53.8 (C-5), 53.6 (OCH_3), 52.7 (OCH_3), 41.7 (C-3), 40.7 (CH_2N), 33.4 (CH_2S), 22.6 (NAc).

*3,4,5-Tri-{8-[2-(5-acetamido-3,5-dideoxy-2-thio-D-glycero-α-D-galacto-2-nonulo-pyranosid)-acetamido]-3,6-dioxaoctyloxy}benzoic acid (**21**)*

A solution of α-thiosialoside methyl ester **19** (33 mg, 0.019 mmol), dissolved in a mixture of methanol (2 mL) and 0.5 M NaOH (2 mL), was stirred at room temperature overnight. After treatment with H^+ resin, the filtrate was first evaporated to remove most of the methanol and then freeze-dried. The pure product was obtained in nearly quantitative yield as a yellowish oil. $[\alpha]_D$ +3.4 (*c* 0.5, CH_3OH); ^1H NMR (CD_3OD) δ: 7.36 (s, 2H, H_{ar}), 4.24–4.20 (m, 6H, PhOCH_2), 3.88–3.43 (m, 51H, OCH_2, H-4, H-5, H-6, H-7, H-8, H-9, H-9′, and CH_2S), 3.42–3.35 (m, 6H, CH_2N), 2.78 (dd, 3H, $J_{3e,3a}$ 12.2 Hz, $J_{3e,4}$ 4.3, H-3e), 1.99 (s, 9H, NAc), 1.81 (dd, 3H, H-3a); ^{13}C NMR (CD_3OD) δ: 175.2, 172.5, 171.2, 169.3 (C═O), 153.6, 143.7, 127.0 (C_{ar}), 110.1 (C_{ar}-H), 83.5 (C-2), 77.2 (C-6), 73.6, 71.8, 71.5, 71.3, 70.8, 70.1 (OCH_2), 72.5 (C-8), 70.3 (C-4), 69.0 (C-7), 64.5 (C-9), 53.6 (C-5), 42.0 (C-3), 40.8 (CH_2N), 33.7 (CH_2S), 22.7 (NAc).

*3,4,5-Tri-{11-[2-(5-acetamido-3,5-dideoxy-2-thio-D-glycero-α-D-galacto-2-nonulo-pyranosid)-acetamido]-3,6,9-trioxaundecyloxy}benzoic acid (**22**)*

The methyl esters hydrolysis of **20** was performed in the same manner as above to give a colorless oil after freeze-drying in quantitative yield. $[\alpha]_D$ +5.5 (*c* 0.56, CH_3OH); ^1H NMR (CD_3OD) δ: 7.35 (s, 2H, H_{ar}), 4.25–4.20 (m, 6H, PhOCH_2), 3.90–3.40 (m, 63H, OCH_2, H-4, H-5, H-6, H-7, H-8, H-9, H-9′, and CH_2S), 3.40–3.35 (m, 6H, CH_2N), 2.78 (dd, 3H, $J_{3e,3a}$ 12.6 Hz, $J_{3e,4}$ 4.3, H-3e), 1.99 (s, 9H, NAc), 1.82 (dd, 3H, H-3a); ^{13}C NMR (CD_3OD) δ: 175.1, 172.4, 171.1, 169.2 (C═O), 153.5, 143.5, 126.8 (C_{ar}), 110.1 (C_{ar}-H), 83.5 (C-2), 77.1 (C-6), 73.5, 71.6, 71.5, 71.4, 71.1, 70.7, 70.2, 69.9 (OCH_2), 72.4 (C-8), 70.0 (C-4), 68.9 (C-7), 64.5 (C-9), 53.5 (C-5), 41.8 (C-3), 40.6 (CH_2N), 33.6 (CH_2S), 22.6 (NAc).

*3,4,5-Tri-(11-azido-3,6,9-trioxaundecyloxy)benzoic acid (**23**)*

To a solution of methyl ester precursor **10** (170 mg, 0.215 mmol) in 95% EtOH (6 mL) was added 1 M KOH (400 μL). The reaction mixture was stirred and refluxed for 2 h after which time TLC showed complete hydrolysis of the ester. The solution was cooled to room temperature and neutralized with H^+ resin. The filtrate was concentrated under vacuum to afford 167 mg (quantitative yield) of pure acid **23** as a colorless residue. FTIR ν_{max} (cm^{-1}): 3009, 2903, 2109, 1690, 1587; ^1H NMR ($CDCl_3$) δ: 7.26 (s, 2H, H_{ar}), 4.15–4.10 (m, 6H, PhOCH_2), 3.83–3.78 (m, 6H, OCH_2), 3.66–3.57 (m, 30H, OCH_2), 3.31 (t, 6H, CH_2N_3); ^{13}C NMR ($CDCl_3$) δ: 169.7 (C═O), 152.0, 142.6, 124.4, 109.1 (C_{ar}), 72.2, 70.6, 70.4, 70.4, 69.8, 69.4, 68.6 (CH_2O), 50.4 (CH_2N_3); FABMS: 774 (M+1, 5 %), 746 (17).

*Methyl 3,4,5-tri-{11-[3,4,5-tri-(11-azido-3,6,9-trioxaundecyloxy)-benzamido]-3,6,9-trioxaundecyloxy}benzoate (**24**)*

To a solution of acid **23** (197 mg, 0.254 mmol) in a mixture of EtOH/CH_3CN (20 mL, 1:1 v/v) were added 1-hydroxybenzotriazole hydrate (HOBt, 52 mg, 0.381 mmol), trisamino precursor **12** (50 mg, 0.070 mmol), and diisopropylethylamine (DIPEA, Hünig's base, 89 μL). The mixture was stirred for 5 min under a nitrogen atmosphere after which 73 mg (0.381 mmol) of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC) was added. The suspension was stirred for 3 h at room temperature, the solvent was evaporated under vacuum, and the residue dissolved in $CHCl_3$. The organic layer was washed with saturated NH_4Cl, water, and brine, and dried over Na_2SO_4. The crude product was concentrated and purified by silica gel chromatography using 5% MeOH in CH_2Cl_2 as eluent to afford 174 mg (83%) of **24** as a colorless oil. FTIR ν_{max} (cm^{-1}): 3430, 3025, 2899, 2108, 1713, 1653, 1585; ^1H NMR ($CDCl_3$) δ: *7.24 (s, 2H, H_{ar}), 7.02 (s, 6H, $H_{ar'}$)*, 6.78–6.71 (m, 3H, NH), 4.15–4.10 (m, 24H, Ph′OCH_2 and PhOCH_2), 3.82 (s, 3H, OCH_3), 3.80-3.56 (m, 150H, OCH_2), 3.31 (m, 18H, CH_2N_3); ^{13}C NMR ($CDCl_3$) δ: 166.9, 166.5 (C═O), 152.5, 152.2, 142.5, 141.5, 129.7, 125.0 (C_{ar} and C'_{ar}), 109.1, 107.2 (C_{ar}-H and C'_{ar}-H), 72.4, 70.8, 70.7, 70.7, 70.6, 70.6, 70.5, 70.5, 70.2, 70.0, 69.8, 69.7, 68.6, 69.1, 68.8 (CH_2O and CH_2O'), 52.1 (OCH_3), 50.7 (CH_2N_3'), 39.9 (CH_2N).

*Methyl 3,4,5-tri-{11-[3,4,5-tri-(11-amino-3,6,9-trioxaundecyloxy)-benzamido]-3,6,9-trioxaundecyloxy}benzoate (**25**)*

Reduction of the nona-azide **24** was performed by the same method used to synthesize amino precursors **11** and **12**. Compound **25** was obtained by evaporation of the solvent and used without further purification for the next step. FTIR ν_{max} (cm^{-1}): 3358, 3243, 3042, 2896, 1716, 1647, 1582.

*Methyl 3,4,5-tri-{11-[3,4,5-tri-(11-(2-chloroacetamido)-3,6,9-trioxaundecyloxy)-benzamido]-3,6,9-trioxaundecyloxy}benzoate (**26**)*

The chloroacetylation was performed in the same manner as for compounds **13** and **14**. The oily residue was purified by preparative TLC plate to afford 70% yield of pure **26**. FTIR ν_{max} (cm^{-1}): 3344, 3035, 2903, 1717, 1670, 1558; ^1H NMR ($CDCl_3$) δ: 7.24 (s, 2H, H_{ar}), 7.08–6.95 (m, 18H, $H_{ar'}$, NH, and NH′), 4.30–4.13 (m, 24H, Ph′OCH_2 and PhOCH_2), 4.01, 4.01 (2s, 18H, CH_2Cl), 3.84 (s, 3H, OCH_3), 3.82-3.53 (m, 150H, OCH_2, OCH_2', and CH_2N), 3.47-3.43 (m, 18H, CH_2N'); ^{13}C NMR ($CDCl_3$) δ: 167.0, 166.5, 166.2 (C═O), 152.4, 152.2, 142.4, 141.2, 129.8, 125.1 (C_{ar} and C'_{ar}), 109.0, 107.2 (C_{ar}-H and C'_{ar}-H), 72.4, 70.7, 70.7, 70.6, 70.6, 70.5, 70.5, 70.5, 70.3, 70.2, 69.9, 69.7, 69.6, 69.4, 69.0, 68.8 (CH_2O and CH_2O'), 52.2 (OCH_3), 42.6 (CH_2N'), 39.9 (CH_2N), 39.6 (CH_2Cl).

*Methyl 3,4,5-tri-{11-[3,4,5-tri-O-[(methyl 5-acetamido-4,7,8,9-tetra-O-acetyl-3,5-dideoxy-2-thio-D-glycero-α-D-galacto-2-nonulo-pyranosid)-acetamido]-benzamido]-3,6,9-trioxaundecyl oxy}benzoate (**27**)*

Conjugation between α-thiosialoside **16** and chloroacetylated

monodendron **26** was performed under the same conditions described above for compounds **17** and **18**. The colorless oil obtained after silica gel chromatography was shown to be pure product **27** in 86% yield. $[\alpha]_D$ +19.0 (*c* 1.02, $CHCl_3$); ^1H NMR ($CDCl_3$) δ: 7.25 (s, 2H, H_{ar}), 7.07–7.03 (m, 9H, H'_{ar}, and NH), 6.89–6.83 (m, 9H, N′H), 5.66–5.55 (m, 9H, NH), 5.41 (m, 9H, H-8), 5.28 (dd, 9H, $J_{7,8}$ 9.0 Hz, H-7), 4.83 (ddd, 9H, $J_{3a,4}$ 11.4 Hz, $J_{3e,4}$ 4.6, H-4), 4.23 (dd, 9H, $J_{8,9'}$ 2.5 Hz, $J_{9,9'}$ 12.4, H-9′), 4.20–4.15 (m, 24H, PhOCH_2' and PhOCH_2), 4.06–4.00 (m, 18H, H-5 and H-9), 3.85 (s, 3H, OCH_3), 3.84–3.79 (m, 18H, OCH_2), 3.77–3.31 (m, 159H, OCH_2, OCH_2', CH_2N, CH_2N', and H-6), 3.71 (s, 27H, OCH_3), 3.54 (d, 9H, *J* 16.1 Hz, CH_aS), 3.27 (d, 9H, *J* 16.1 Hz, CH_bS), 2.71 (dd, 9H, $J_{3e,3a}$ 12.6 Hz, $J_{3e,4}$ 4.4, H-3e), 2.15, 2.11, 2.01, 1.99 (4s, 108H, 4 OAc), 1.93 (dd, 9H, H-3a), 1.85 (s, 27H, NAc); ^{13}C NMR ($CDCl_3$) δ: 171.1, 170.7, 170.3, 170.1, 168.6, 168.4, 167.0, 166.5, 166.2 (C═O), 152.4, 152.2, 142.4,, 141.4, 129.7, 125.0 (C_{ar} and C'_{ar}), 109.1, 107.4 (C_{ar}-H and C'_{ar}), 82.2 (C-2), 73.9 (C-6), 72.4, 70.7, 70.6, 70.5, 70.3, 69.7, 69.1 (CH_2O and CH_2O'), 69.5 (C-4), 68.0 (C-8), 67.0 (C-7), 62.4 (C-9), 53.2 (OCH_3), 52.3 (OCH_3), 49.2 (C-5), 39.7 (CH_2N'), 39.7 (CH_2N), 37.4 (C-3), 32.5 (CH_2S), 23.1 (NAc), 21.3, 20.8, 20.8, 20.8 (OAc).

Methyl 3,4,5-tri-{11-[3,4,5-tri-O-*[(methyl 5-acetamido-3,5-dideoxy-2-thio-*D*-glycero-*α*-*D*-galacto-2-nonulo-pyranosid)-acetamido]-benzamido]-3,6,9-trioxaundecyloxy}benzoate (**28**)*

De-O-acetylation of **27** was done by using the Zemplén conditions described earlier for compounds **19** and **20**. After neutralization with H^+ resin, the solution was concentrated, dissolved in H_2O, and freeze-dried to give a yellowish half-powder, half-syrup compound in 98% yield. $[\alpha]_D$ +12.9 (c 1.05, CH_3OH); ^1H NMR (CD_3OD) δ: 7.28 (s, 2H, H_{ar}), 7.18 (s, 6H, H'_{ar}), 4.25–4.15 (m, 24H, PhOCH_2' and PhOCH_2), 3.87 (s, 3H, OCH_3), 3.86–3.32 (m, 276H, OCH_2, OCH_2', CH_2N, CH_2N', CH_2S, OCH_3, H-4, H-5, H-6, H-7, H-8, H-9′, and H-9), 2.76 (dd, 9H, H-3e), 2.01 (s, 27H, NAc), 1.80 (dd, 9H, H-3a); ^{13}C NMR (CD_3OD) δ: 175.3, 171.5, 171.2, 169.4 (C═O), 153.8, 153.7, 143.1, 142.2, 130.6, 126.3 (C_{ar} and C'_{ar}), 109.9, 107.9 (C_{ar}-H and C'_{ar}), 83.7 (C-2), 77.1 (C-6), 72.1 (C-8), 73.7, 71.8, 71.7, 71.6, 71.3, 71.2, 70.8, 70.6, 70.3, 70.1 (CH_2O and CH_2O'), 70.2 (C-4), 68.8 (C-7), 64.8 (C-9), 53.9 (C-5), 53.8 (OCH_3), 53.0 (OCH_3), 41.8 (C-3), 41.2 (CH_2N), 40.9 (CH_2N'), 33.6 (CH_2S), 22.7 (NAc).

3,4,5-Tri-{11-[3,4,5-tri-O-*[(5-acetamido-3,5-dideoxy-2-thio-*D*-glycero-*α*-*D*-galacto-2-nonulo-pyranosid)-acetamido]-benzamido]-3,6,9-trioxaundecyloxy}benzoate (**29**)*

The hydrolysis of the methyl esters on compound **28** was accomplished by treatment with NaOH as described earlier for the sialosylated glycodendrimers **21** and **22**. The yellowish residue was obtained after freeze-drying in nearly quantitative yield. $[\alpha]_D$ +5.2 (*c* 0.5, CH_3OH); ^1H NMR (CD_3OD) δ: 7.30 (s, 2H, H_{ar}), 7.18 (s, 6H, H'_{ar}), 4.25–4.12 (m, 24H, PhOCH_2' and PhOCH_2), 3.94–3.33 (m, 249H, OCH_2, OCH_2', CH_2N, CH_2N', CH_2S, H-4, H-5, H-6, H-7, H-8, H-9′, and H-9), 2.78 (dd, 9H, $J_{3e,4}$ 4.4 Hz, H-3e), 2.01 (s, 27H, NAc), 1.82 (dd, 9H, H-3a); ^{13}C NMR (CD_3OD) δ: 175.3, 172.4, 171.2, 169.5 (C═O), 153.7, 153.6, 143.7, 142.2, 130.6, 126.9 (C_{ar} and C'_{ar}), 110.3, 107.9 (C_{ar}-H and C'_{ar}), 83.6 (C-2), 77.2 (C-6), 72.5 (C-8), 73.7, 71.8, 71.7, 71.6, 71.5, 71.3, 70.8, 70.6, 70.3, 70.0 (CH_2O and CH_2O'), 70.1 (C-4), 69.0 (C-7), 64.6 (C-9), 53.7 (C-5), 42.0 (C-3), 41.2 (CH_2N), 40.8 (CH_2N'), 33.8 (CH_2S), 22.7 (NAc).

Turbidimetric analysis

Turbidimetric experiments were performed in Linbro (Titertek) microtitration plates where 50 μL of stock lectin solutions prepared from WGA (4 mg/mL PBS) were mixed with 12.5, 11.2, and 10.6 μL of glycodendrimer solutions **29**, **22**, and **21**, respectively (0.5 mg/mL PBS). Also, 25 μL of *L. flavus* lectin solution (2 mg/mL PBS) was mixed with 6.25 μL of 9-mer **29** (0.5 mg/mL PBS). The turbidity of the solutions was monitored by reading the optical density at 490 nm for 2 h.

Acknowledgements

The financial support of the Natural Sciences and Engineering Research Council of Canada (NSERC) is gratefully acknowledged. S.J.M. is also thankful to NSERC and Le Fonds pour la formation de chercheurs et l'aide à la recherche (FCAR) for postgraduate scholarships. We thank Dr. Clem Kazakoff for recording mass spectra and Dr. Glenn Facey and Mr. Raj Capoor for recording NMR spectra. A generous gift of sialic acid from Dr. M. Kawase of NGK Insulators, Ltd. (Handa, Japan) is particularly acknowledged.

Morphological, chemical, and electrochemical properties of Ti/(TiO_2 + IrO_2) electrodes

L.A. da Silva, V.A. Alves, M.A.P. da Silva, S. Trasatti, and J.F.C. Boodts

Abstract: Electrodes of general composition $Ir_xTi_{(1-x)}O_2$ with $0.2 \leq x \leq 1.0$ were prepared on a Ti support by calcination of the chlorides at 450°C. Ex situ and in situ characterization included the use of techniques such as scanning electron microscope (SEM), energy dispersive X-ray analysis (EDX), cyclic voltammetry (CV), and electrochemical impedance spectroscopy (EIS). EDX showed a surface enrichment with Ti. The voltammetric charge was found to go through a maximum at 60% IrO_2. O_2 evolution was studied in 1.0 mol dm^{-3} $HClO_4$ by determining Tafel slopes and impedance parameters. Tafel slopes were found to vary between 40 and 60 mV depending on the overpotential range and the oxide composition. Solution and film resistance, film and double layer capacitance, and charge transfer resistance were determined as a function of potential and oxide composition. A reaction mechanism has been proposed. Separation of geometric and electronic effects has been attempted.

Key words: oxygen evolution, oxide electrode, electrocatalysis, electrochemical impedance spectroscopy, iridium dioxide.

Résumé : Procédant par calcination des chlorures à 450°C, on a préparé des électrodes de composition générale $Ir_xTi_{(1-x)}O_2$, avec $0,2 \leq x \leq 1,0$, sur un support de Ti. Les caractérisations ex situ et in situ ont fait appel à des techniques telles que le microscope à balayage électronique, l'analyse de rayons X à dispersion d'énergie (XDE), la voltammétrie cyclique (VC) et la spectroscopie d'impédance électrochimique (SIE). La XDE montre que la surface est enrichie en Ti. On a trouvé que la charge voltammétrique passe par un maximum à 60% d'IrO_2. On a étudié l'évolution du O_2 dans du $HClO_4$ à 1,0 mol/dm^3 en déterminant les pentes de Tafel et les paramètres d'impédance. On a trouvé que les pentes de Tafel varient entre 40 et 60 mV suivant la surtension et la composition de l'oxyde. On a déterminé la résistance en solution et du film, la capacitance du film et de la double couche ainsi que la résistance au transfert de charge en fonction du potentiel et de la composition de l'oxyde. On propose un mécanisme réactionnel. On a essayé de séparer les effets géométriques et électroniques.

Mots clés : évolution de l'oxygène, électrode en oxyde métallique, électrocatalyse, spectroscopie d'impédance électrochimique, dioxyde d'iridium.

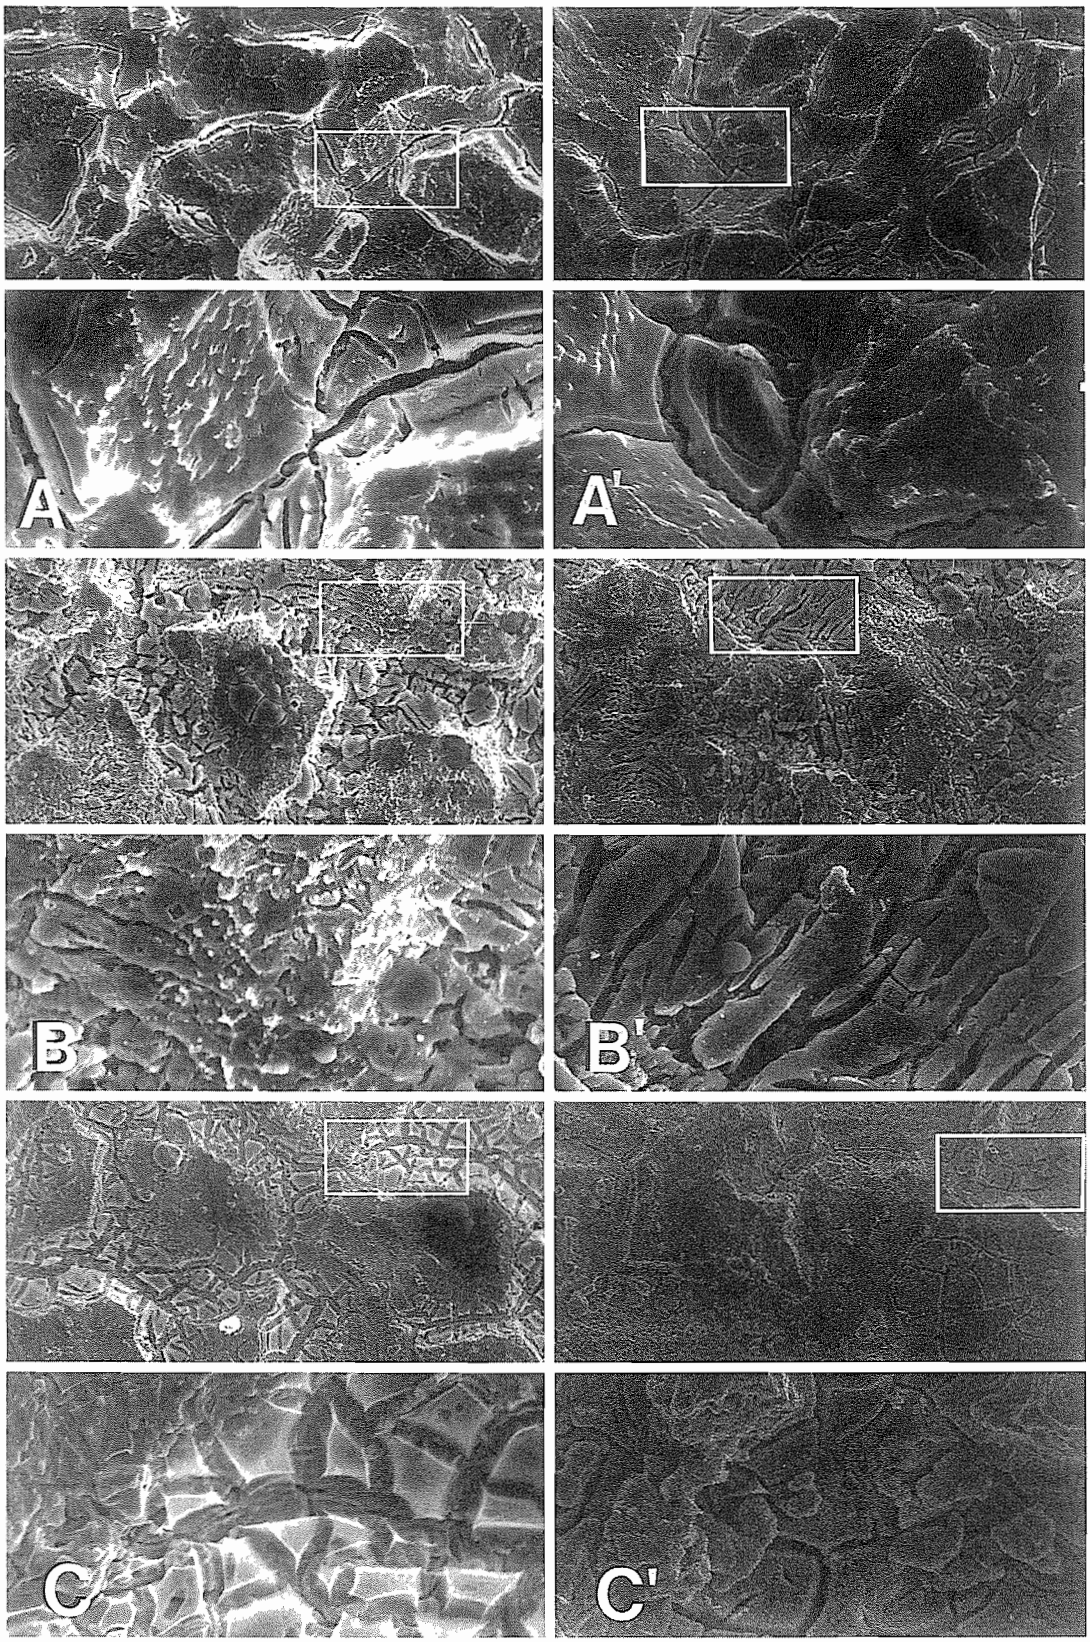
Introduction

IrO_2 possesses metallic conductivity, catalytic activity, and chemical stability, especially in acids; for this reason it has found application as an anode and cathode material. Its activity for oxygen evolution is lower than that of RuO_2 (1), whereas as a cathode it evolves hydrogen at lower overpotentials than RuO_2 (2). As an anode material it is more stable than RuO_2 and, mixed with the latter, lowers its dissolution rate (3). In turn, IrO_2 is further stabilized either by TiO_2 (4) or Ta_2O_5 (5).

Despite the interest for their potential use as anodes in oxygen evolution, IrO_2 + TiO_2 oxide electrodes have not been investigated exhaustively (6-9). In particular, investigations of the activity-structure correlation are scanty (10, 11) and mainly focused on stability, while mechanistic studies of oxygen evolution are almost nonexistent (12).

Electrochemical impedance has recently received much attention as a technique capable of providing complementary information with respect to more classical methods. However, its application to the study of oxide electrodes is still progressing slowly. In a previous paper (13) we reported on a study of oxygen evolution on an electrode with the specific composition $Ir_{0.3}Ti_{0.7}O_2$. The aim of the present work has been to investigate the relationship between structure and electrocatalytic activity in the case of IrO_2 + TiO_2 mixtures over the whole composition range, using oxygen evolution as a model electrocatalytic reaction. In turn, these data can contribute to a broader understanding of the electrocatalysis of mixed oxides during the course of the oxygen evolution reaction. Surface and electrochemical properties have been studied by both ex situ (SEM, EDX) and in situ (impedance, cyclic voltammetry, quasi-stationary polarization) spectroscopic and electrochemical techniques.

Received February 28, 1997.



This paper is dedicated to Professor Brian E. Conway on the occasion of his 70th birthday and in recognition of his outstanding contributions to electrochemistry.

Fig. 2. EDX spectra of a $Ir_{0.6}Ti_{0.4}O_2$ layer. (*A*) Taken in dark areas; (*B*) taken in bright areas.

Experimental

Mixed oxides of general composition $Ir_xTi_{(1-x)}O_2$ ($0.2 \leq x \leq 1.0$) were deposited on a Ti support by the thermal decomposition at 450°C of appropriate mixtures of the chlorides dissolved in 1:1 (v/v) concentrated HCl + water solutions to avoid hydrolysis. Details have been provided in a previous paper (14). The oxide loading was such as to correspond to a nominal thickness of 2 μm. Mixtures at IrO_2 content lower than 20 mol% were not used since the properties are then dominated by TiO_2.

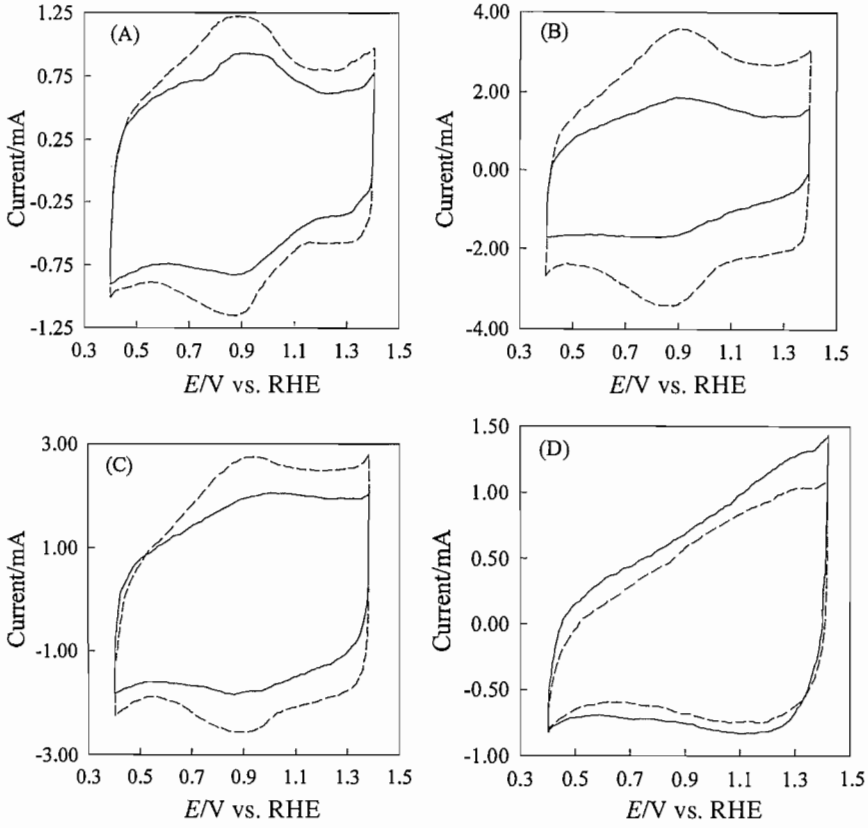
SEM micrographs and EDX spectra were obtained with a Zeiss DSM 960 scanning electron microscope equipped with a Link Analytical model QX 2000 microanalyser. The electron energy used was 20 keV.

The electrochemical surface properties were investigated by cyclic voltammetry at 20 mV s^{-1} in the potential range 0.4–1.4 V vs. RHE in 1 mol dm^{-3} $HClO_4$ aqueous solutions. Polarization (E vs. log j) curves were recorded under quasi-stationary conditions (0.056 mV s^{-1}) following a conventional methodology (14). The electrode potential was measured, and is reported (unless otherwise stated), against a hydrogen electrode in the same solution (RHE).

Electrochemical impedance spectra were taken in two distinct potential regions: *(a)* 0.4–1.4 V vs. RHE, where no stationary electrode reaction takes place, and *(b)* 1.4–1.6 V vs. RHE where oxygen is liberated. At fixed potentials, frequencies were scanned in the range 5 mHz – 100 kHz. The multi-sine method was used in the low-frequency range (5 mHz – 10 Hz), while the single-sine method was used in the high-frequency range (10 Hz – 100 kHz). The ac signal was generated by a PARC model 5210 lock-in amplifier.

Electrochemical measurements were carried out using a PARC model 273A potentiostat controlled by a model 55SX PS2 IBM microcomputer. All instruments were connected to a common ground, while the electrochemical cell was placed in a Faraday cage.

Results and discussion



Morphology and chemical composition

Figure 1 shows some representative SEM micrographs. As-prepared layers with IrO_2 contents of 20, 60, and 100 mol% are shown in Figs. 1*A*–1*C*, respectively. IrO_2 + TiO_2 mixtures consist of a large number of small crystallites separated by micro-cracks imparting a very rough texture to the oxide layer. The density of the small crystallites appears to be a function of the oxide composition going through a maximum at 40–60 mol% IrO_2.

A distinct picture is observed with as-prepared pure IrO_2 (Fig. 1*C*, upper part). The oxide layer contains large islands, formed by smaller crystallites, separated by much larger cracks than for the oxide mixtures. This morphology has been described as "cracked mud" structure (15). The magnified view of Fig. 1*C* (lower part) shows that the cracked-mud structure is superimposed on a more homogenous oxide layer. Comparison of the micrograph for the bare Ti support with those for the oxide layers reveals that the edges of the large oxide islands roughly follow the contours of the Ti crystallites.

Fig. 3. Cyclic voltammograms at 20 mV s^{-1} in 1.0 mol dm^{-3} $HClO_4$ of $Ir_xTi_{(1-x)}O_2$ electrodes. (*A*) $x = 0.2$; (*B*) $x = 0.4$; (*C*) $x = 0.6$. (*D*) $x = 1.0$. Curves were recorded (——) with fresh electrodes and (-----) after the study on O_2 evolution.

Micrographs were again taken at the end of the study after intense oxygen evolution. The maximum current experienced by the electrodes during polarization curves was about 50 mA cm^{-2}. Some representative micrographs are shown in Figs. 1*A*′–1*C*′ for the same oxide compositions as for fresh electrodes. No appreciable modifications are visible for binary oxides. However, in the case of pure IrO_2, the heavily cracked outer part of the oxide layer is removed with exposure of the underlying, more compact part. This is indicative of mechanical erosion of the outer layer in the absence of TiO_2, which acts as a stabiliser.

EDX analysis was carried out on the samples subjected to oxygen evolution. Experimental conditions were set to minimize the penetration of the radiation (~0.6 μm, one third of the nominal thickness of the layer). Spectra were recorded both at low SEM magnification to obtain an analysis of the average composition, and at high magnification for local analysis of selected regions of the oxide layers. Special attention was given to the analysis of bright and dark areas of the SEM micrographs.

Typical EDX spectra are shown in Fig. 2. The Ir/Ti peak intensity ratios are summarized in Table 1 as a function of oxide composition. In the bright areas the much higher Ir/Ti ratio indicates enrichment with IrO_2 (with respect to the total average composition). Such segregation seems to be a specific feature of IrO_2 since it has already been observed by us in other multi component systems such as $IrO_2 + TiO_2 + PtO_x$ (16) and $IrO_2 + TiO_2 + CeO_2$ (17). Similar behaviour has been observed by Rolewicz et al. (18) with the $IrO_2 + Ta_2O_5$ system.

It is interesting that, even for pure IrO_2, regions can be found with different Ir signal intensity, thus suggesting a possible variation of IrO_2 density in different places. Moreover, a Ti signal was also unexpectedly observed also in the EDX spectra of pure IrO_2. This can be explained in terms of the preparative methodology, if the strongly acidic solvent of the precursors can attack the Ti support and thus bring some Ti species into the precursor solution.

Comparison of the average Ir/Ti ratio with the nominal one reveals that the former is systematically lower. This can be understood as a consequence of IrO_2 segregation to some specific regions, producing an average surface enrichment with TiO_2. This is in the end the origin of the higher chemical and electrochemical stability of $IrO_2 + TiO_2$ mixtures with respect to pure IrO_2. Surface enrichment with the valve metal oxide has also been observed in the case of $RuO_2 + TiO_2$ (19), $RuO_2 + ZrO_2$ (20), and $IrO_2 + Ta_2O_5$ (21). This is presumably a consequence of the higher affinity of the valve metal for oxygen in the atmosphere of the calcination room.

As-prepared electrodes contain some Cl species; this is not unexpected in view of the nature of the precursors (15). However, at the end of this study, i.e., after intense oxygen evolution, the Cl signal was no longer present. Cl species probably trapped in the layer are apparently pushed away during oxygen evolution.

Voltammetric curves

Figure 3 shows typical voltammetric curves at different oxide compositions for fresh electrodes as well as after intense oxy-

80	51	58
100	58	58

gen evolution. All curves are rather featureless although a distinct broad peak is evident at the lower IrO_2 content. This peak can be attributed to a surface redox transition related to Ir sites (22). The peak potential is seen to move from <0.9 V at 20% IrO_2 to ca. 1.1 V at 80% IrO_2 (not shown in Fig. 3). No distinct peak is present in the curve for pure IrO_2 although a shoulder is apparent just prior to O_2 evolution. The shift of the redox peak can be understood (23) in terms of the electronic interaction between IrO_2 and TiO_2, the latter drawing the potential to less positive values, this being the main origin of IrO_2 stabilization.

Oxygen evolution produces two effects: *(a)* a variation in the size of the curves, and *(b)* a variation in the shape of the curve. In particular, the size increases at IrO_2 contents <80%, while it decreases for pure IrO_2. Also, at the IrO_2 contents showing a developed redox peak, oxygen evolution produces a better resolution of the peak itself. A higher current and a better resolved peak can be understood in terms of surface enrichment with IrO_2 as a consequence of a possible disruption of the TiO_2-rich surface layer. In other words, regions characterized by a higher IrO_2 concentration are exposed. In the case of pure IrO_2, the decrease in curve size can be explained with the SEM observation of a collapse of the surface islands, replaced by more compact regions. Thus, SEM and CV results converge to provide the same structural picture.

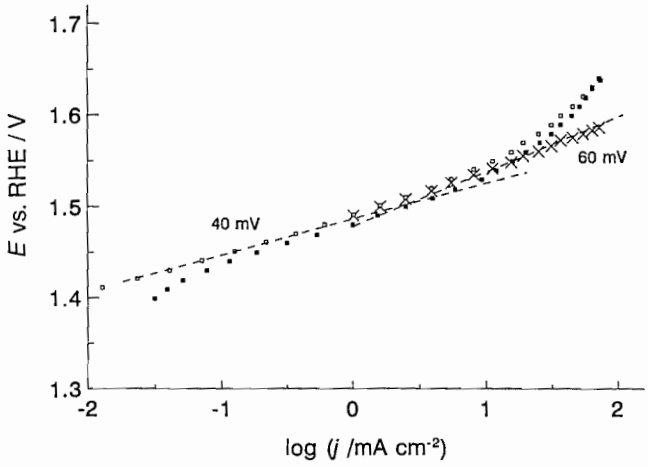

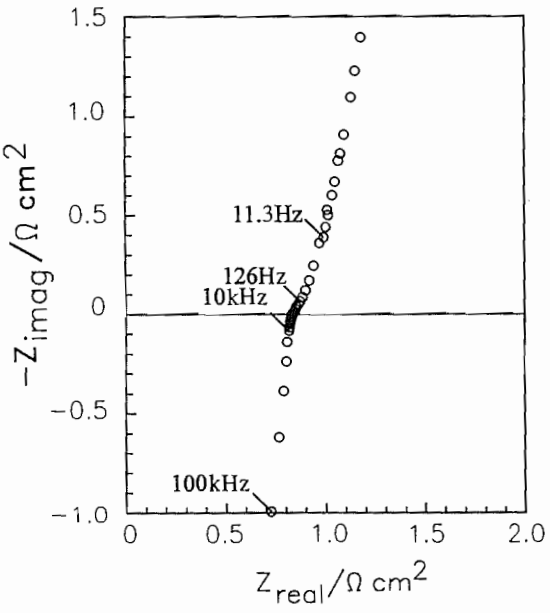

Fig. 6. Complex plane plot of the impedance of a $Ir_{0.6}Ti_{0.4}O_2$ electrode in 1 mol dm^{-3} $HClO_4$. E = 1.0 V vs. RHE.

Voltammetric charge

The voltammetric charge was obtained by integration of the voltammetric curves, and is plotted as a function of oxide composition in Fig. 4. The only processes occurring in the 0.4–1.4 V potential range are the surface redox transitions of Ir species and double-layer charging at the oxide-solution interface. Since the latter is as a rule small compared to the former, q^* measures the number of surface active sites. This is different from the concept of surface area that also includes Ti-containing sites, but it can be defined as proportional to the *electrochemically active* surface area (24).

Figure 4 shows that for fresh electrodes q^* goes through a maximum at about 60 mol% IrO_2. Considering that q^* is due only to Ir sites, one should expect a steady increase of charge with IrO_2 content. The non-monotonic behaviour indicates the presence of two contrasting effects: *(i)* an increase in IrO_2 sur-

face concentration and *(ii)* a decrease in surface porosity joined with an increase in crystallite size. These two effects are clearly identifiable in the data of Table 1 (EDX data) and of Fig. 1 (SEM micrographs).

Oxygen evolution produces a large increase in q^* in the composition range 20–60% IrO_2. No change is visible at 80% IrO_2, while q^* decreases for pure IrO_2. An explanation has already been offered in the previous section. The variation of q^* is especially dramatic at 40% IrO_2.

Fig. 9. (*A*) Film resistance, R_f, and (*B*) ln R_f as a function of the electrode potential for a $Ir_{0.6}Ti_{0.4}O_2$ electrode.

Tafel lines

Figure 5 shows a typical polarization curve. Only a small hysteresis is visible between up and down runs. The kinetic analysis was carried out using the backward set of data.

For all compositions the deviation from linearity observed at high overpotentials was analysed with the method proposed by Shub et al. (25, 26). The deviations were found to be due to both uncompensated ohmic drop and change in Tafel slope. The only exception is pure IrO_2, for which a single Tafel line was found over the whole current range explored. The uncompensated resistance turned out to be in the range 0.5–0.8 ohm, which suggests it may be due to the solution between the tip of the Luggin capillary and the electrode surface.

Tafel slopes as a function of oxide composition are summarized in Table 2. It is interesting that the average Tafel slope is 40 mV at low current densities and 60 mV at higher overpotentials. However, as the composition approaches pure IrO_2 the Tafel line reduces to just one of nominally 60 mV. Although the difference between the two Tafel slopes is small, it seems real since it has been confirmed by impedance measurements. Tafel slopes close to 60 mV have already been reported for pure IrO_2 in acid solution (1, 27). However, this value is typical of freshly prepared layers; actually, aged electrodes have been found (28) to evolve oxygen with a Tafel

slope close to 40 mV. The possible presence of two Tafel lines was already previously noted with 30% IrO_2 + 70% TiO_2 electrodes (13). The 80% IrO_2 sample shows an intermediate behaviour, a possibility clearly demonstrated with RuO_2 + IrO_2 electrodes (1).

In a qualitative way, it can be stated that a single-type mechanism can be invoked to explain the dependence of the Tafel slope on oxide composition. The details of the mechanism have been given elsewhere (29). The two Tafel slopes are related to two competing steps, an electrochemical and a chemical one. The chemical step becomes progressively slower as the content of IrO_2 increases. For instance:

[1*a*] $S + H_2O \rightarrow S\text{-}OH^* + H^+ + e$

[1*b*] $S\text{-}OH^* \rightarrow S\text{-}OH$

[1*c*] $S\text{-}OH \rightarrow S\text{-}O + H^+ + e$

[1*d*] $S\text{-}O + S\text{-}O \rightarrow 2S + O_2$

At high IrO_2 contents and at high overpotentials step [1*b*] is rate determining. This step corresponds to a rearrangement of the surface intermediate. At low overpotentials and low IrO_2 contents step [1*c*] becomes rate determining. This may be related to a different surface–intermediate interactions strength which makes step [1*b*] faster. This implies that electronic interactions between IrO_2 and TiO_2 modify the nature of the bond between the surface and the intermediate species. Such an interaction requires that IrO_2 and TiO_2 are intimately mixed, i.e., they form a solid solution. Our experimental approach can only provide an indirect piece of evidence for that.

Impedance spectroscopy

Impedance measurements were carried out both in the "double layer" region, i.e., at potentials before oxygen evolution, and in the O_2 liberation region, i.e., at $E > 1.45$ V.

The impedance spectrum, plotted in the complex plane, for a $Ir_{0.6}Ti_{0.4}O_2$ electrode at 1.0 V is shown in Fig. 6. The features are practically independent of oxide composition. In the low-

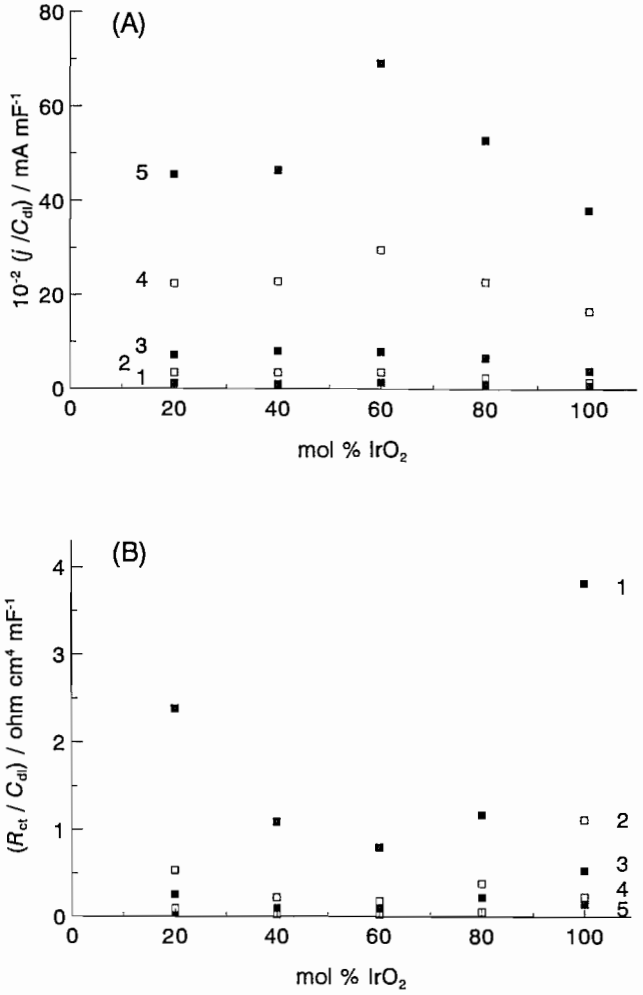
frequency range a straight line is obtained with an inclination close to 90°C, which is indicative of the capacitive nature of the processes occurring in the 0.4–1.4 V region. At higher frequencies a distorted semicircle is observed, attributable to the presence of less accessible surface regions (walls of microcracks) (30).

Figure 7 shows a few Bode plots ($\log f$ vs. $\log|Z|$, and $\log f$ vs. ϕ) for different oxide compositions recorded at potentials inside the oxygen evolution region. When plotted in the complex plane mode ($|Z'|$ vs. $|Z''|$), a small dispersion of the data is observed at $f \rightarrow 0$, the more appreciable the more positive the electrode potential. This can be attributed to the perturbation introduced by strong gas (O_2) evolution and by the rough nature of the oxide surface. The same feature has been observed by other authors (31, 32).

Figure 8 shows a scheme of the equivalent circuit used to fit the experimental data. R_Ω is the solution ohmic resistance, C_f and R_f capacitance and ohmic resistance of the oxide layer, respectively, C_{dl} the double layer capacitance, and R_{ct} the charge transfer resistance. L is a small inductance (ca. 1 μH) observed in the high-frequency range and which has been related to the equipment (33, 34). Symbols and notations in Fig. 8 are after Boukamp (35). Several equivalent circuits were tested, the one in Fig. 8 giving an excellent fit as evident in Fig. 7. The values of the parameters as obtained from the fitting procedure have been summarized in Table 3.

The impedance analysis allows separation between R_Ω and R_f, which kinetic data do not permit. Table 3 confirms that R_f is small at all compositions, which implies that the conduction in the film is good and the TiO_2 film at the support – film interface is very thin. However, at the higher IrO_2 contents R_f tends to increase a little, which may be related to the morphology of the layers showing larger and deeper cracks. Under similar circumstances a thicker TiO_2 film can grow during calcination.



It is noted that for all compositions R_f is potential dependent. If plotted against E, a nonlinear dependence is observed (Fig. 9*A*), contrary to the expected linear behaviour for metallic-type conduction. However, a plot of $\ln R_f$ vs. E results in a straight line (Fig. 9*B*) as predicted by semi-conducting properties (36). This result indicates that the fully metallic nature of IrO_2 is lost in these films, although the conductivity is high. This agrees with previous specific investigations of the conduction behaviour of oxide layers (24). It is, however, possible that the potential dependence of R_f is dominated by the electrical properties of the TiO_2 film formed at the support – active layer interface, even though this film is thin. Compositionally,

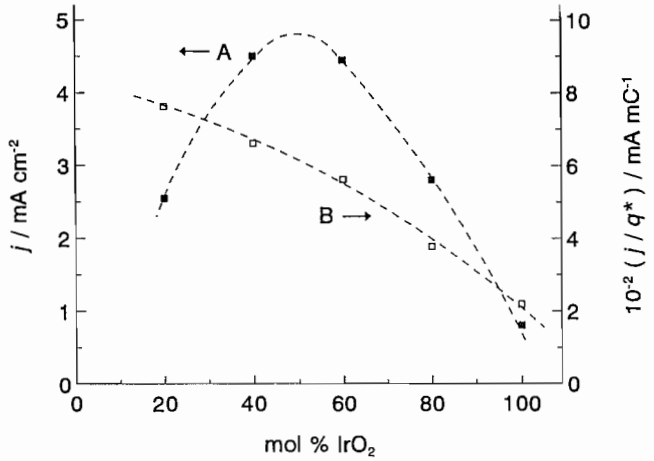
Fig. 10. (*A*) Current density and (*B*) charge transfer resistance for O_2 evolution, normalized to unit double layer capacitance, as a function of IrO_2 content at different electrode potentials: (1) 1.47, (2) 1.50, (3) 1.52, (4) 1.55, and (5) 1.57 V vs. RHE. 1.0 mol dm^{-3} $HClO_4$.



the TiO_2 interlayer could in fact be a substoichiometric oxide with semiconducting properties.

Table 3 shows that R_Ω is independent of both potential and composition, which is reasonable. Values are between 0.8 and 1.1 ohm cm^2, in agreement both with impedance data in the "double layer" region and with the data obtained by applying the method of Shub et al. (25, 26) (see above).

The film capacitance, C_f (Table 3), turns out independent of oxide composition but dependent on electrode potential. As an exception, pure IrO_2 shows C_f values approximately one half of those for the other compositions. The potential dependence of C_f can be understood in terms of a potential-dependent TiO_2 interlayer that plays the role of a dielectric between two conducting plates, the Ti support and the oxide overlayer. The lower C_f values of pure IrO_2 are to be related to the particular surface morphology that allows TiO_2 to grow more than at other compositions. For the same reason R_f of pure IrO_2 is higher.

The double layer capacitance is seen to be independent of potential for IrO_2 contents 20–60%. At higher IrO_2 contents a potential dependence is evident. For its nature C_{dl} is directly related to q^*, going through a maximum at 40–60% IrO_2. The potential dependence of C_{dl} for 80–100% IrO_2 is to be related to the effect of O_2 evolution on the layer morphology (see above). The high absolute values of C_{dl} (of the order of mF) confirm the very high surface areas of these electrodes.

Fig. 11. (*A*) Apparent current density for O_2 evolution and (*B*) current density normalized to unit surface charge, as a function of IrO_2 + TiO_2 oxide composition at 1.52 V vs. RHE. 1.0 mol dm^{-3} $HClO_4$.

The charge transfer resistance, R_{ct}, depends on both potential and composition. The potential dependence is expected from the electrochemical nature of the heterogeneous charge transfer reaction rate. The composition dependence shows a minimum (i.e., a maximum in activity) for 60% IrO_2. This parallels the composition dependence of the current at constant potential as derived from the Tafel lines, which goes through a maximum at the same oxide composition. From a practical point of view, such a composition can be regarded as the most active overall. However, from a fundamental point of view both R_{ct} and j are inadequate to evaluate the true electrocatalytic properties since both are extensive quantities, i.e., they depend on both electronic and geometric (surface area) factors.

Separation of catalytic from geometric effects can be achieved by normalizing the activity to unit, electrochemically active, surface area (24). This can be accomplished by using C_{dl} as a representative parameter of surface area effects. Results are summarized in Table 4, which also includes j/q^* for comparison.

Figures 10*A* and 10*B* show plots of (j/C_{dl}) and (R_{ct}/C_{dl}) as a function of composition. Scrutiny of the plots reveals that the normalized activity does not change appreciably with composition, although a somewhat higher activity is apparent for the electrode with 60% IrO_2. However, if real, the gain is small.

Figure 11 shows the apparent activity (j) as a function of composition at the potential of 1.52 V (the potential value may include some ohmic drop). Clearly, j goes through a maximum at 60% IrO_2. If j is normalized to unit surface charge (nominally, j/q^* measures the reaction rate per Ir site), Fig. 11 shows that the "true" catalytic activity decreases steadily as the IrO_2 content increases.

© 1997 NRC Canada

If the effects in Fig. 11 are real, the trend is for an increase in activity of Ir sites as the IrO_2 content decreases. This is in line with the observed lower Tafel slope at lower IrO_2 contents. It can be explained in terms of synergetic effects between the two oxide components. On the whole, surface area effects appear to be more appreciable than electronic effects, although the latter should not be ruled out.

Armstrong et al. (37, 38) have shown that R_{ct} is related to the Tafel slope, b, by the relationship:

$$[2] \quad b = 2.303\, j\, R_{ct}$$

where j is the steady-state current at the given potential. With the j values from the Tafel line measurements and the R_{ct} values from the impedance data, the calculated b are reported in Table 3, last column. For compositions 20–60% IrO_2, the Tafel values resulting from eq. [2] are in accord with those derived from polarization curves (Table 2). For compositions 80–100% IrO_2 the outcome is not as good, giving Tafel slopes that are too low. This can be attributed to the instability of the systems and their delicate and complex morphology. At the same time this outcome has an impact on the reliability of the separation of geometric from electronic factors. This suggests that the decrease in "true" catalytic activity as the IrO_2 content increases should be considered with caution, although the normalization based on q^* seems more reliable than that in terms of C_{dl}.

Conclusions

1. The average surface composition of TiO_2 + IrO_2 mixed oxides shows enrichment with TiO_2 although there is local segregation of IrO_2 in cracks.
2. The electrochemically active surface area, as measured by the voltammetric charge, goes through a maximum at about 60% IrO_2. This non-monotonic behaviour results from an increase in surface concentration of Ir and a decrease in particle size with Ir content.
3. The evolution of O_2 produces a large increase in voltammetric charge at 20–60% IrO_2, while it decreases for pure IrO_2. The latter is due to mechanical erosion, the former is probably caused by the exposure of new areas where IrO_2 is segregated.
4. O_2 evolution takes place with low Tafel slopes ranging from 40 to 60 mV. The higher Tafel slopes tend to predominate as the IrO_2 content increases. A change in mechanism or, more probably, in the rate-determining step of a single mechanism, is presumably related to the surface concentration of Ir sites.
5. Impedance has shown that the oxide layer does not possess fully metallic properties as would be expected for IrO_2. This can be related to the effect of TiO_2 as well as the small size of the particles for the mixed oxides.
6. Separation of electronic from geometric effects shows that the "true" electrocatalytic activity per "Ir" site probably decreases with the increase in IrO_2 content. This is in line with the conclusions based on the values of the Tafel slopes.

Zirconium alkyl and borohydride complexes stabilized by a sterically demanding anionic organic amide. The crystal structures of $ZrMeL_3$ (2) and $Zr(BH_4)L_3$ (3) (L = $(3,5\text{-}Me_2Ph)N(Ad)$; Ad = adamantyl)

Aparna Kasani, Sandro Gambarotta, and Corinne Bensimon

Abstract: The lithium amide $[3,5\text{-}Me_2PhN(Ad)]Li\cdot Et_2O$ (**L**) reacts with $ZrCl_4(THF)_2$ to give $ZrClL_3$. Reactions of $ZrClL_3$ with MeLi and $NaBH_4$ produce the corresponding $ZrMeL_3$ (**2**) and $Zr(BH_4)L_3$ (**3**), respectively. The molecular structures of **2** and **3** were determined by X-ray crystallography. Crystal data are as follows. **2**: $C_{55}H_{75}N_3Zr$, FW 869.45, orthorhombic, *Pcab*; a = 19.2436(3) Å, b = 45.9342(4) Å, c = 21.2935(3) Å, V = 18822.2(4) Å^3, Z = 8; **3**: $C_{54}H_{76}BN_3Zr$, FW 869.25, orthorhombic; *Pbc*21, a = 11.5399(3) Å, b = 19.4091(4) Å, c = 20.4471(5) Å, V = 4579.72(19) Å^3, Z = 4.

Key words: zirconium, amide, alkyl, borohydride, structure.

Résumé : L'amide lithié $[3,5\text{-}Me_2PhN(Ad)]Li\cdot Et_2O$ (**L**) réagit avec le $ZrCl_4(THF)_2$ pour donner du $ZrClL_3$. Les réactions du $ZrClL_3$ avec le MeLi et le $NaBH_4$ conduisent respectivement au $ZrMeL_3$ (**2**) et $Zr(BH_4)L_3$ (**3**). On a déterminé les structures moléculaires des composés **2** et **3** par diffraction des rayons X. Les données crystallographiques sont les suivantes : **2** : $C_{55}H_{75}N_3Zr$; PF : 869,45; orthorhombique; *Pcab*; a = 19,2436(3), b = 45,9342(4) et c = 21,2935(3) Å, V = 18822,2(4) Å^3; Z = 8; **3** : $C_{54}H_{76}BN_3Zr$; PF : 869,25; orthorhombique; *Pbc*21; a = 11,5399(3), b = 19,4091(4) et c = 20,4471(5) Å; V = 4579,72(19) Å^3; Z = 4.

Mots clés : zirconium, amide, alkyle, borohydrure, structure.

Introduction

Among early transition metals, zirconium is certainly the element that has received very special attention as demonstrated by the massive organometallic chemistry that has been developed for this metal. The extensive literature available describes an impressive variety of transformations (1), from metal-promoted organic synthesis (2), to Ziegler–Natta catalysis (3), olefin isomerization (4), insertion reactions (5), C—N bond activation (6), C_1 chemistry (7), etc. Another unique characteristic of zirconium, which is also common to the other group IV metals, is that the majority part of its chemistry was developed with the help of cyclopentadienyl and related ligand systems. Therefore, attempts to explore the reactivity of these metals with alternative ligands is the next and most obvious development in this field. This is certainly the key to understanding the strong revival of interest, which can be observed in the recent literature, for chemistry with non-Cp ligands of these metals and of zirconium in particular. The employment of sterically demanding alkoxides and aryloxides has already proved to be a useful strategy for a number of transformations (8). What remains relatively unexplored for zirconium is the chemistry of the lower oxidation states. The extreme reactivity of low-valent zirconium and the limited resistance of the traditional ligand systems to strong reducing agents (9) is probably the cause of this lacuna in the literature.

Nitrogen donor based ligands (formamidinate, amides, porphyrinogens, etc.) have been shown to be rather versatile in the chemistry of low-valent early transition metals (10), allowing the stabilization of the low oxidation states (11) and displaying a reduced possibility of being involved in the reactivity of the metal center. In addition, what makes these ligands particularly interesting is the possibility of easily adjusting the electronic features and steric hindrance around the transition metal via a virtually unlimited choice of organic substituents attached to the nitrogen donor atom. In the chemistry of zirconium, Fryzuk et al. have demonstrated that the employment of bulky chelating amide–phosphine ligand systems enables the stabilization of rare Zr(III) derivatives (12) and the coordination of highly reduced dinitrogen (13). More recently, anionic organic amides with a particularly large steric hindrance have been employed for a number of

Scheme 1.

remarkable reactions that include dinitrogen cleavage (14), formation of stable and reactive nitrides (15), and assemblage of heterodimetallic structures (16).

The remarkable robustness of these ligands has prompted us to attempt its employment for preparing zirconium complexes that may work as substrates for further reduction towards lower oxidation states or for the trapping of reactive functions (hydride, alkyl, etc.). The large-scale preparation in our lab of the sterically demanding [3,5-Me_2PhN(Ad)] anion (17) has enabled the preparation and characterization of a number of transition metal complexes in the medium oxidation state and the trapping of rare functions. Herein we describe the result of our attempts to use this ligand in zirconium chemistry.

Results and discussion

The reaction between [3,5-Me_2PhN(Ad)]Li·Et_2O and [$ZrCl_4(THF)_2$] in diethyl ether at room temperature resulted in the formation of a pale yellow solution from which [ZrCl{3,5-Me_2PhN(Ad)}$_3$] (**1**) was isolated in moderate yield as a white crystalline solid (Scheme 1).

The product of the reaction was remarkably insensitive to the stoichiometric ratio between the two reagents since similar reactions with different ratios invariably yielded the same compound. The formula of compound **1** was based on chlorine and combustion analyses. The ^{1}H and ^{13}C NMR spectra indicate the presence of a rather symmetric ligand environment in the compound. Two different methylene resonances are observed in equal ratio for the adamantyl group, while a single resonance is observed for the two methyl groups attached to the aryl rings. Two lines present in the aromatic region in a 2:1 ratio are assigned to the *ortho* and *meta* protons of the aryl rings.

Reaction of **1** with methyllithium in ether resulted in the precipitation of lithium chloride and formation of the corresponding zirconium methyl derivative, [ZrMe{3,5-Me_2PhN(Ad)}$_3$] (**2**) (Scheme 1). Compound **2** was isolated in moderate yield from hexane as colorless and very air-sensitive crystals. The infrared spectra of compounds **1** and **2** were nearly identical, thus suggesting that the two complexes may be isostructural. The ^{1}H NMR spectrum of **2** displays amide ligand resonances similar to those observed for **1** with slightly different chemical shifts. The Me group resonance was clearly visible as a sharp new singlet at −0.01 ppm. Similar considerations apply to the ^{13}C NMR spectrum, which shows only one set of ligand resonances, slightly shifted with respect to those of complex **1**, and one additional resonance at 37.4 ppm. DEPT experiments assigned this resonance to the methyl group. The assignment was further supported by HQMC experiments, which showed correlation of the ^{1}H resonance at −0.01 ppm with the ^{13}C NMR resonance of 37.4 ppm. Complex **2** is thermally stable and chemically inert. It does not react with molecular H_2 and carbon monoxide at room temperature and atmospheric pressure, and it is stable for 24 h in refluxing benzene.

The structure of compound **2** (Fig. 1) was elucidated by a single-crystal X-ray diffraction analysis. The coordination geometry around zirconium is distorted tetrahedral and is defined by three nitrogen atoms of the three amide ligands and one methyl group. The bond distances (Zr1—N1 = 2.083(3) Å, Zr1—N2 = 2.072(4) Å, Zr1—N3 = 2.089(4) Å) and angles (N1-Zr1-N2 = 111.52(14)°, N1-Zr1-N3 = 109.57(13)°, N2-Zr1-N3 = 114.82(14)°), as well as the Zr—C bond distance (Zr1—C1 = 2.258 (5) Å) are in the expected range. The amide nitrogen atoms possess the characteristic trigonal planar geometry (sums of the angles around the nitrogen atoms are close to 360°), which indicates the presence of a Zr—N multiple bond character. Relevant bond distances and angles are given in Table 1.

The surprising and unexpected chemical inertness of complex **1** suggested that this particular ligand system may be versatile for the preparation of stable and terminal Zr-H functions. However, since the hydrogenolysis of **2** was not a viable method, we have explored other possible synthetic pathways such as chlorine replacement of **1** with hydridic reagents. Unfortunately, reactions of **1** with NaH, $NaHBEt_3$, Bu_3SnH, and $LiAlH_4$ proved to be unsuccessful since they led only to highly soluble and intractable materials or no reaction. In addition, the ^{1}H NMR spectra were rather complicated and possibly indicative of the presence of a mixture of products. Conversely, the reaction of **1** with an excess of $NaBH_4$ in THF resulted in the precipitation of NaCl and formation of the corresponding tetrahydroborate compound, [Zr(BH_4){3,5-Me_2PhN(Ad)}$_3$] (**3**), in good yield. The infrared spectrum

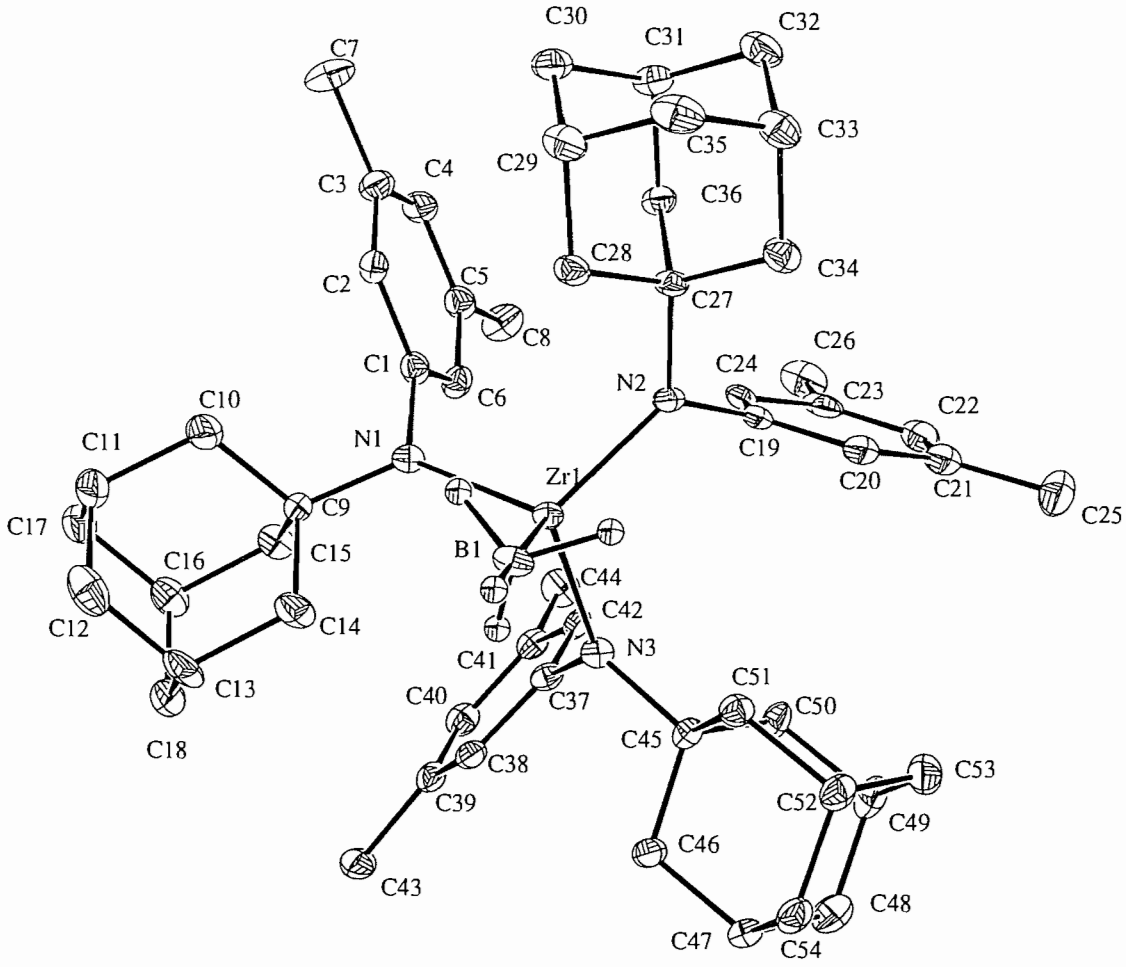
Zr1-N1-C9 = 131.2(3)	C1-N1-C9 = 112.0(3)
Zr1-N1-C1 = 113.2(3)	C9-N1-Zr1 = 128.02(23)
N3-Zr1-C55 = 106.87(16)	N1-Zr1-N3 = 108.05(11)
N1-Zr1-N2 = 111.52(14)	Zr1-N1-C1 = 119.87(23)
	N2-Zr1-N3 = 106.97(11)

showed the characteristic absorptions of $[BH_4]^-$ as an intense sharp line at 2500 cm^{-1} (terminal B-H stretching) and broad doublet at 2172 cm^{-1} (B-H stretching). This pattern usually diagnoses a tridentate bonding mode for the $[BH_4]$ group. The ^1H NMR showed the resonance corresponding to tetrahydroborate as a broad singlet at 1.91 ppm, which nicely correlates with the ^{11}B resonance at −15.6 ppm in HQMC experiments. Attempts to transform complex **3** into terminal hydride by abstracting the BH_3 group with Me_3P or TMEDA were unsuccessful.



The structure of compound **3** was confirmed by an X-ray crystal structure (Fig. 2). The zirconium metal is coordinated to three amide ligands and one borohydride group. Similar to the case of complex **2**, the geometry around the metal center is distorted tetrahedral and is defined by the three nitrogen atoms (N1-Zr1-N2 = 107.3(1)°, N1-Zr1-N3 = 108.0(1)°, N2-Zr1-N3 = 107.0(1)°) of the three amide groups and one boron atom (N1-Zr1-B1 = 110.7(1)°, N2-Zr1-B1 = 113.7(1)°, N3-Zr1-B1 = 109.9(1)°). The Zr···B nonbonding distance (Zr1-B1 = 2.400(4) Å) is rather short, possibly indicating the presence of an η^3-bonding mode of the BH_4 group. The positions of the tetrahydroborate hydrogen atoms were yielded by difference Fourier maps, thus confirming the tridentate mode (Zr1—H55 = 2.16(4) Å, Zr1—H57 = 2.21(4) Å, Zr1—H58 = 2.23(4) Å). The relatively short Zr—N bond distances (Zr1—N1 = 2.071(3) Å, Zr1—N2 = 2.066(3) Å, Zr1—N3 = 2.072(3) Å) compare well with those of **2** and of other Zr–amide complexes present in the literature, and are consistent with the existence of a Zr—N multiple bond character.

In conclusion, with this work it was possible to prepare and characterize new zirconium alkyl and borohydride complexes supported by bulky amide ligands. These species were found to be remarkably stable and unreactive. At this stage, it is

Fig. 2. ORTEP plot of **3**. Thermal ellipsoids are drawn at the 50% probability level.

tempting to attribute the surprising stability of these functions to either: (*i*) steric protection, which makes the reactive function inaccessible by incapsulating the metal; or (*ii*) the π-donating ability of the amide ligands that increases the covalency of the M—C and M—H bonds.

Experimental section

All the operations were performed under an inert atmosphere of a nitrogen-filled dry box or by using standard Schlenk techniques. $[ZrCl_4(THF)_2]$ (18) and $[3,5\text{-}Me_2PhN(Ad)]Li\cdot Et_2O$ (Ad = adamantyl) (17) were prepared according to reported procedures. Methyllithium and sodium borohydride (Aldrich) were used as received. Solvents were dried with the appropriate drying agents and distilled prior to use. Infrared spectra were recorded on a Mattson 9000 FTIR instrument from Nujol mulls prepared in a drybox. Elemental analyses were carried out with a Perkin Elmer 2400 CHN analyzer. NMR spectra were recorded with a Bruker AMX 500 MHz spectrometer.

Preparation of $[ZrCl\{3,5\text{-}Me_2PhN(Ad)\}_3]$ (1)

A suspension of $[ZrCl_4(THF)_2]$ (3.35 g, 8.88 mmol) in diethyl ether (150 mL) was stirred with $[3,5\text{-}Me_2PhN(Ad)]Li\cdot Et_2O$ (8.94 g, 26.65 mmol) at room temperature. After stirring for 24 h, the mixture was filtered to eliminate LiCl. After concentrating the filtrate to about 50 mL, colorless crystals of **1** were obtained upon allowing the solution to stand at –30°C for 8 h (5.20 g, 5.84 mmol, 66%). IR (Nujol mull, NaCl, cm^{-1}) *v*: 1599 s, 1585 s, 1356 m, 1343 w, 1303 s, 1290 s, 1188 w, 1151 s, 1106 w, 1088 w, 1067 s, 1029 s, 990 m, 977 w, 950 m, 924 s, 891 w, 851 m, 817 w, 787 w, 763 w, 710 s, 694 s, 682 m, 617 m. ^1H NMR (C_6D_6, 20°C, 500 MHz) δ: 6.82 (s, 2H, Ar), 6.80 (s, 1H, Ar), 2.30 (s, 6H, Me, Ar), 2.03 (bs, 6H, CH_2, Ad), 2.03 (bs, 3H, CH, Ad), 1.56 (q, 6H, CH_2, Ad). ^{13}C NMR (C_6D_6, 20°C, 125.7 MHz) δ: 144.5 (quaternary aryl), 137.4 (quaternary aryl), 130.7 (C-H aryl), 60.1 (quaternary Ad), 43.1 (CH_2, Ad), 36.8 (CH_2, Ad), 30.5 (CH, Ad), 21.7 (CH_3, aryl). Anal. calcd. for $C_{54}H_{72}ClN_3Zr$: C 72.89, H 8.16, N 4.72; found: C 73.52, H 8.00, N 4.85.

Preparation of $[ZrMe\{3,5\text{-}Me_2PhN(Ad)\}_3]$ (2)

A solution of methyllithium (0.80 mL, 1.4 M) in ether was added to a solution of **1** (1.0 g, 1.12 mmol) in the same solvent (80 mL). After stirring the mixture for 8 h at room temperature, the solvent was removed in vacuo. The residue was extracted with hexane (100 mL) and filtered to eliminate LiCl. Upon concentration to about 20 mL and cooling to −30°C for 24 h, colorless crystals of **2** were obtained (0.40 g, 0.46 mmol, 41%). IR (Nujol mull, NaCl, cm^{-1}) *v*: 1592 s, 1304 m, 1290 m, 1261 s, 1152 s, 1074 s, 1027 s, 950 m, 924 s, 848 w, 803 s, 710

Preparation of [Zr(BH$_4$){3,5-Me$_2$PhN(Ad)}$_3$] (3)

A solution of **1** (1.62 g, 1.82 mmol) in THF (100 mL) was treated with $NaBH_4$ (0.138 g, 3.64 mmol). After stirring at room temperature for 3 days, the solvent was removed in vacuo and the residue was extracted with diethyl ether (100 mL). After filtration to eliminate NaCl and unreacted $NaBH_4$, the solution was concentrated to 40 mL and allowed to stand at room temperature for 24 h, upon which colorless crystalline **3** was obtained (1.20 g, 1.38 mmol, 76%). IR (Nujol, mull, NaCl, cm^{-1}) *ν*: 2500 s, 2234 bw, 2180 bm, 2154 bw, 1598 s, 1583 s, 1356 s, 1344 w, 1304 s, 1286 s, 1261 m, 1185 m, 1148 s, 1103 m, 1061 s, 1026 s, 975 m, 951 s, 924 s, 888 m, 855 m, 817 m, 801 m, 709 s, 691 s. ^{1}H NMR (C_6D_6, 20°C, 200 MHz) δ: 6.80 (s, 3H, 4-Ar), 6.55 (s, 6H, 2,6-Ar), 2.30 (s, 18H, Me, Ar), 2.05 (s, 9H, CH, Ad), 1.90 (s, 18H, CH_2, Ad), 1.52 (q, 18H, CH_2, Ad). ^{13}C NMR (C_6D_6, 20°C, 125.7 MHz) δ: 146.4 (quaternary aryl), 136.7 (quaternary aryl), 131.1 (C-H aryl), 127.3 (C-H aryl), 60.4 (quaternary Ad), 43.2 (CH_2, Ad), 36.8 (CH_2, Ad), 30.5 (CH, Ad), 21.8 (CH_3, Ar). ^{11}B{^{1}H} NMR (C_6D_6, 20°C, 160.5 MHz) δ: −15.6. Anal. calcd. for $C_{54}H_{76}BN_3Zr$: C 74.62, H 8.81, N 4.83; found: C 75.24, H 9.05, N 4.88.

X-ray crystallography

Data were collected at −158°C using the ω–2θ scan technique to the maximum 2θ value of 50.0° for suitable air-sensitive crystals mounted on glass fibers of the goniometer of a CCD Siemens X-ray diffractometer. Cell constants and orientation matrices were obtained from the least-squares refinement of carefully centered high-angle reflections. Redundant reflections were averaged. The intensities of three representative reflections were measured after every 150 reflections to monitor crystal and instrument stability. Data were corrected for Lorentz and polarization effects and for absorption. The structures were solved by direct methods. The positions of most of the non-hydrogen atoms were refined anisotropically. Hydrogen atom positions were introduced at their idealized positions. The final cycles of full-matrix least-squares refinement were based on the number of observed reflections with $I > 2.5\sigma(I)$. Neutral atomic scattering factors were taken from Cromer and Waber (19)[2]. Anomalous dispersion effects were included in F_c. All calculations were performed using an NRCVAX package on a silicone Graphics station. Complex **2** contains two crystallographically independent and chemically equivalent molecules in the lattice. Details on crystal data and structure solution have been given in Table 2. Selected bond distances and bond angles are given in Table 1. Listings of atomic coordinates and thermal parameters have been given as supplementary information.[3]

Acknowledgments

This work was supported by the Natural Sciences and Engineering Council of Canada (NSERC). We gratefully acknowledge the generosity of Prof. A. Carty for making available to us a CCD Siemens X-ray diffractometer.

Abstract: Electromotive force (EMF) measurements based on the redox reaction

$$Li_xHg(l) + TlBr(s) \rightleftharpoons LiBr(solv, c_{LiBr}) + Tl_xHg(l)$$

are reported for solutions of LiBr at concentrations $0.005 < c_{LiBr}/(\text{mol dm}^{-3}) < 0.1$ in acetonitrile (AN), dimethyl sulfoxide (DMSO), and *N,N*-dimethylacetamide (DMA) in the temperature range $278.15 < T/\text{K} < 308.15$. Gibbs energies of transfer and activity coefficients are estimated. The association constants of LiBr in AN, DMSO, and DMA from EMF measurements and the enthalpy of transfer AN → DMSO are compared to those from other methods of determination.

Key words: temperature-dependent EMF measurements, aprotic solvents, LiBr, TlBr(s) | $Tl_xHg(l)$ electrode, activity coefficients, transfer quantities.

Résumé : On rapporte les résultats de mesures de force électromotrice (FÉM) basées sur la réaction rédox

$$Li_xHg(l) + TlBr(s) \rightleftharpoons LiBr(solv, c_{LiBr}) + Tl_xHg(l)$$

pour des solutions de LiBr à des concentrations de $0{,}005 < c_{LiBr}/(\text{mol dm}^{-3}) < 0{,}1$ dans l'acétonitrile (AN), le diméthylsulfoxyde (DMSO) et le *N,N*-diméthylacétamide (DMA), à des températures allant de 278,15 à 308,15 K. On a évalué les énergies de Gibbs de transfert et les coefficients d'activité. On compare les constantes d'association du LiBr dans AN, DMSO et DMA et l'enthalpie de transfert AN → DMSO obtenues par la méthode des mesures de FÉM avec les valeurs correspondantes tirées d'autres méthodes de détermination.

Mots clés : mesures de FÉM en fonction de la température, solvants aprotiques, LiBr, électrode TlBr(s) | $Tl_xHg(l)$, coefficients d'activité, quantités de transfert.

[Traduit par la rédaction]

1. Introduction

The measurement of the electromotive force (EMF) of a galvanic cell requires reversible electrodes. Reversibility depends on the electrode materials and on the solvent of the electrolyte solution. Various reversible electrode systems are known for aqueous electrolyte solutions. For nonaqueous solutions the choice is rather small, especially for solutions in aprotic solvents, despite increasing technological interest. In this paper the galvanic cell without liquid junction

$$Pt \mid Li_xHg(l) \mid LiBr(solv, c_{LiBr}) \mid TlBr(s) \mid Tl_xHg(l) \mid Pt$$

is used for the determination of activity coefficients of lithium bromide at temperatures $278.15 < T/\text{K} < 308.15$ in the dipolar aprotic solvents acetonitrile (AN), dimethyl sulfoxide (DMSO), and *N,N*-dimethylacetamide (DMA), and for the estimation of Gibbs energies and enthalpies of transfer from AN to DMSO and DMA.

1.1 Chemical potentials and equilibria in the solution

The chemical potentials of an electrolyte solution made up by a symmetrical electrolyte E in a solvent S at Temperature T and pressure p are given by the relationships

$$[1a] \qquad \mu_S(p, T) = \mu_S^*(p, T) + RT \ln a_S$$

Received February 14, 1997.

This paper is dedicated to Professor Brian E. Conway on the occasion of his 70th birthday.

Fig. 1. Measuring cell. A: electrode compartment, B: reference electrode compartment, C: solution compartment, D: amalgam collecting vessel, E: capillary, F: position of reference electrode, G: platinum wire, H: connection to voltmeter, I: amalgam reservoir, K: water jacket (thermostated), L: connection to voltmeter, M: platinum wire, N: capillary, O: tip of the capillary (modified for measurements in DMSO and DMA), V1, V2: valves.

$$[1b,c] \quad \lim_{x_S \to 1} \mu_S = \mu_S^*; \qquad \lim_{x_S \to 1} f_S = 1$$

$$[2a] \quad \mu_E(p, T) = \mu_E^{\infty(c)}(p, T) + 2\,RT \ln c_E y_\pm$$

$$[2b,c] \quad \lim_{x_S \to 1} [\mu_E - 2\,RT \ln c_E] = \mu_E^{\infty(c)}; \qquad \lim_{x_S \to 1} y_\pm = 1$$

The reference potential of the solvent is the pure solvent (superscript $*$), that of the electrolyte is the infinitely dilute solution (superscript ∞). The activity coefficients of solvent and solute take into account the respective concentration scales (f: mole fraction scale; x; $y_\pm$: molarity scale, c), a_S is the activity of the solvent, $a_S = x_S f_S$.

The formation of neutral ion pairs X in the solution

$$[3] \quad C^+ + A^- \rightleftharpoons X$$

may be taken into account in the chemical potential with the help of the potentials of "free" cations, "free" anions, and ion pairs X (superscript ′) resulting from the analytical concentrations c_E of the electrolyte and the degree of dissociation α of the ion pair X

$$[4a] \quad \mu_E(p, T) = \alpha\mu'_+(p, T) + \alpha\mu'_-(p, T) + (1 - \alpha)\mu'_X(p, T)$$

and underlying the equilibrium condition

$$[4b] \quad \mu'_X(p, T) - \mu'_+(p, T) - \mu'_-(p, T) = 0$$

The combination of eqs. [4a] and [4b] yields the chemical potential of the associating electrolyte

$$[5a] \quad \mu_E(p, T) = \mu_E^{\infty(c)}(p, T) + 2\,RT \ln c_E y_\pm$$

where the overall activity coefficient

$$[5b] \quad y_\pm = \alpha y'_\pm$$

depends on the activity coefficient of the "free" ions $y'_\pm$ and the degree of dissociation α. Equation [4b] yields the association constant K_A

$$[6] \quad K_A^{(c)} = \frac{(1 - \alpha)\, y'_X}{\alpha^2 c_E\, y'^2_\pm}$$

related to the Gibbs energy ΔG_A^∞ of ion-pair formation according to eq. [3]

$$[7] \quad \Delta G_A^\infty = -RT \ln K_A$$

1.2 Electromotive force

The galvanic cell without liquid junction (superscript is phase index)

$$Pt^{(1)}|Li_xHg(l)^{(2)}|LiBr(solv, c_{LiBr})^{(3)}|TlBr(s)^{(4)}|Tl_xHg(l)^{(5)}|Pt^{(1)}$$

involves the chemical reaction

$$[8] \quad Li_xHg(l)^{(2)} + TlBr(s)^{(4)} \rightleftharpoons LiBr(solv, c_{LiBr})^{(3)} + Tl_xHg(l)^{(5)}$$

where $Li_xHg(l)$ is the lithium amalgam electrode and $TlBr(s)\,|\,Tl_xHg(l)$ is the thallium bromide – thallium amalgam reference electrode. The electrolyte solution is a lithium bromide solution at concentration c_{LiBr} in the specified solvent.

The EMF of the galvanic cell without liquid junction shown above is given by the Nernst equation

$$[9] \quad E = E^0 - \frac{RT}{F} \ln a_{LiBr} - \frac{RT}{F} \ln \frac{a_{Tl_xHg}}{a_{Li_xHg}}$$

When, in a series of measurements, the metal concentration of the two amalgams Tl_xHg and Li_xHg is kept constant, eq. [9] may be written

$$[10] \quad E = E'^0 - \frac{2RT}{F} \ln (c_{LiBr} y_\pm)$$

2. Experimental

2.1 Purification of solvents and solutes

Acetonitrile (Baker, analyzed HPLC reagent) was first passed through an Al_2O_3 column (acid Al_2O_3, Woelm, Eschwege) under purified nitrogen, then boiled (48 h) over calcium hydride (1) and distilled. The final distillation over a packed column reduced the water content to less than 30 ppm and the specific conductivity to less than 3×10^{-8} S cm^{-1}.

Dimethyl sulfoxide (Fluka, purum) was dried with molecular sieve (4 Å) and then flushed with pure nitrogen (5–6 days) to remove volatile impurities. After addition of calcium hydride it was refluxed for 2 days and then distilled under reduced pressure (~2 mbar). The water content of the product was less than 50 ppm and the specific conductivity was less than 10^{-8} S cm^{-1}.

N,N-Dimethylacetamide (Aldrich, HPLC-pure) was treated with molecular sieve (4 Å) for some days to reduce the water content to less than 35 ppm.

Lithium bromide (Merck, suprapur) was predried at 80°C under reduced pressure (<10^{-2} mbar) in the presence of P_2O_5. The temperature was then slowly increased and kept at 150°C for several days.

Thallium bromide was obtained from an aqueous solution of thallium(I) sulfate (Aldrich, 99%, gold label) by precipitation with sodium bromide (Merck, suprapur). After filtration the thallium bromide was dried under reduced pressure (<10^{-2} mbar). The preparation and storage took place under exclusion of light.

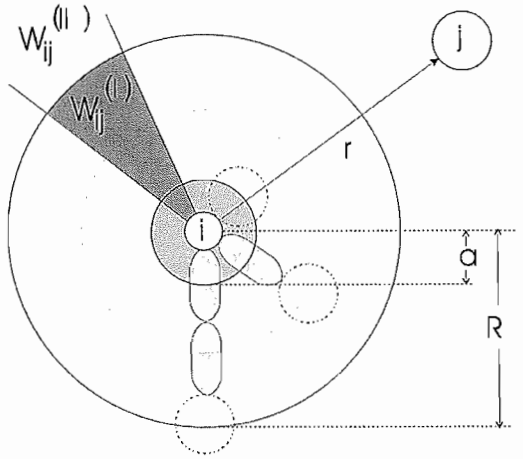
Fig. 2. Chemical model of electrolyte solution. Ion j in an arbitrary position r with regard to ion i; special positions (contact, separation by one or two orientated solvent molecules) are sketched; a, R, distance parameters; W_{ij}, mean force potentials.



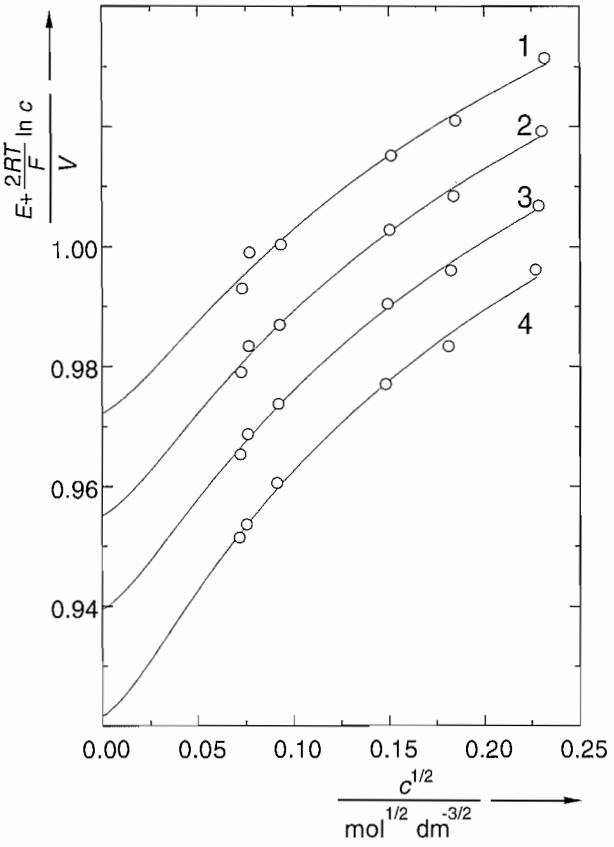


Fig. 3. EMF data of LiBr in AN FROM 278.15 K to 308.15 K. **1**: 278.15 K, **2**: 288.15 K, **3**: 298.15 K, **4**: 308.15 K (explanation in text).

The mercury used for the preparation of the amalgams was repeatedly purified in purification towers (height ~1 m, diameter 2 cm), filled with dilute nitric acid, water, and acetone. At the top of each tower a stream of mercury from a reservoir was directed to the walls, which have small indentations to produce tiny mercury droplets that are forced to pass the purification tower in a zigzag path from the top to the bottom where the mercury was collected. With the help of these towers the mercury was purified several times. Finally the mercury was distilled three times at a pressure below 0.1 mbar.

2.2 Preparation of the amalgams

The lithium amalgam was prepared in a glove box by dissolving a weighed quantity of lithium metal (Chemetall, purity >99.95%) in a known quantity of mercury under pure argon (oxygen, nitrogen, and water content <1 ppm), followed by storage for 6 weeks in special containers from which the amalgam was drawn off for use by a valve at the bottom.

Thallium (Alfa, 99.998% pure) was cleaned of its black oxide layer by rinsing it with argon-saturated dilute sulfuric acid. After carefully rinsing with argon-saturated distilled water the thallium was dried under reduced pressure and stored in a glove box under argon protection. The same method used for the lithium amalgam was applied to the preparation of thallium amalgam (2).

2.3 EMF measurements

The measuring cell, which is made up of two parts, is shown in Fig. 1. The lower part filled with the electrolyte solution is situated in a thermostat with a precision of 10^{-2} K and a reproducibility of 10^{-3} K. The upper part containing the amalgam is kept at equal temperature with the help of a water jacket (K). The electrodes are linked via the connections (L) and (H) to a preamplifier (Knick, 72 W) of input resistance $>5 \times 10^{12}$ Ω. The amplified potential is measured with the help of a digital voltmeter (Data Precision, type 2540A).

EMF measurements carried out using lithium amalgam electrodes require strong protection against oxygen, nitrogen, and water. The capillary (N) of the dropping electrode is introduced (at ground glass joint A) into the measuring cell. The second arm (B) contains the reference electrode and the third arm (C) permits the introduction of the solution and of argon. An amalgam collecting vessel (D) linked to the electrode chamber via a capillary (E) separates the amalgam dripped off the dropping electrode from the solution in the measuring cell, thus avoiding its pollution and chemical reaction with the solvent.

The electrolyte solution is prepared in a separate solution flask and saturated with TlBr to decrease the time for the reference electrode to equilibrate. At the beginning of the measurement the cell is evacuated and flushed several times with argon. The following procedures are all executed under the protection of pure argon.

After a small amount of TlBr is introduced into the cell through valve V1 four drops of thallium amalgam are placed in the reference electrode position (F) with an amalgam level higher than the top of the platinum wire (G). The surface of the amalgam is completely coated by the TlBr crystals previously introduced into the cell. The electrolyte solution is then transferred from the solution flask under slight overpressure through valve V2. The dropping electrode is filled with lithium amalgam (I), which is in contact with the preamplifier via the platinum wire (M). The whole measuring assembly is thermostated for at least 1 h. After reaching thermal equilibrium the amalgam outlet is activated. To increase the stability of the

cell voltage in acetonitrile solutions, the diameter of the capillary of the electrode is reduced to produce a thin jet of mercury instead of drops. In contrast, for the measurements in DMSO and DMA solutions, a little beaker (O) is attached at the end of the capillary to produce large drops with a rate of one drop per second. With these variations, a constant cell potential within ±0.1 mV is attained after 2 min. After about 10 min the temperature of the thermostat is changed to the next point of the program. Measurements are carried out in a cycle 25–15–5–35–25°C. The two potentials at the beginning and end of each cycle at 25°C differ by less than 0.3 mV.

3. Results

Table 1 summarizes the results of the EMF measurements in acetonitrile, DMSO, and DMA at different temperatures. The mole fraction of thallium in the thallium amalgam was 0.00595; the mole fraction of lithium in the lithium amalgam was 0.00382 in AN and 0.00401 in DMSO and in DMA.

4. Discussion

4.1 Chemical model

Appropriate equations for the properties of electrolyte solutions in the concentration range studied are obtained with the help of the chemical model (CM) of electrolyte solutions (3, 4), subdividing the space around an ion into three regions (cf. Fig. 2): (*i*) $r \leq a$, a being the minimum distance of two oppositely charged ions, which is assumed to be the sum of the effective cation and anion radii, $a = a_+ + a_-$; (*ii*) $a \leq r \leq R$, within which a paired state of oppositely charged ions, the ion pair, suppresses long-range interactions with other ions in the solution. In dilute solutions the occupancy of this region by ions of equal sign can usually be neglected; (*iii*) $r \geq R$, the region of long-range ion–ion Coulomb interaction.

The chemical model is a Hamiltonian model on the McMillan–Mayer level. Its distance parameters a (minimum distance of two ions) and R (upper limit of the structured region around an ion) are fixed by chemical evidence:

Fig. 4. Mean molar activity coefficients of LiBr at 298.15 K. **1**: AN, **2**: DMA, **3**: DMSO (Lines calculated according to the chemical model (Fig. 2) using the association constants from Table 2).

The lower distance a is fixed as a hard-core radius by the center-to-center distance of the ions.

The upper distance R is obtained for 1.1 electrolytes in aprotic solvents of moderate relative permittivity by adding the length of an orientated solvent molecule to the distance of closest approach; $R = a + s$.

The ion-pair concept is introduced into the chemical model when setting the cutoff distance parameter R of the short-range forces equal to the upper limit of association, yielding the integral (3)

$$[12] \quad \int_a^R r^2 \exp\left(-\frac{W_{+-}}{kT}\right) dr = \exp\left[-\frac{2\kappa q}{(1+\kappa R)}\right] \int_a^R r^2 \times \exp\left(\frac{2q}{r} - \frac{W^*_{+-}}{kT}\right) dr$$

where W^*_{+-} is the non-Coulombic part of the potential of mean force W_{+-}. Equation [12] is linked to the ion-pair association constant K_A (dimension: dm^3 mol^{-1}) and the mean activity coefficient $y'_{\pm}$ of the free ions by the relationship

$$[13a] \quad \frac{1-\alpha}{\alpha^2 c y'^2_{\pm}} = K_A^{(c)} = 4000\pi N_A \int_a^R r^2 \exp\left(\frac{2q}{r} - \frac{W^*_{+-}}{kT}\right) dr$$

$$[13b,c] \quad y'_{\pm} = \exp\left(-\frac{\kappa q}{1+\kappa R}\right); \qquad q = \frac{|z_+ z_-| e_0^2}{8\pi\varepsilon_0 \varepsilon kT}$$

The ion pair is represented by an uncharged particle in a spherical box of radius R, meaning that an ion pair is formed if two oppositely charged ions approach to within a distance smaller than R.

4.2 Data analysis

The basis of the data analysis according to eq. [10] for EMF measurements of solutes that exhibit ion-pair formation are the mean molar activity coefficient of the "free ions" (eq. [13*b*]) and the association constant K_A (eq. [13*a*]), which permit the calculation of the degree of ion-pair dissociation needed for the introduction of eq. [5*b*] into eq. [10]. The Debye parameter κ depends on the concentration αc of the free ions.

$$[14] \quad \kappa^2 = \frac{16\pi N_A e_0^2}{8\pi\varepsilon_0 \varepsilon kT} \alpha c_{LiBr}$$

Equation [10] is transformed to fit the EMF data of associated electrolytes

$$[15] \quad E = E'^0 - \frac{2RT}{F} \ln(\alpha c_{LiBr} y'_{\pm})$$

Equation [15] is used to determine the reference potential E'^0 (which is not a standard potential because it contains the activity of the amalgams, eq. [11]) and the association constant K_A as the adjustable parameters. Figure 3 shows EMF data for

For personal use only.

LiBr in acetonitrile at different temperatures as an example. The points are the measured values of $E + (2RT/F) \ln c$ and the lines represent the function $E'^0 - (2RT/F) \ln(\alpha y'_{\pm})$, adapted to the experimental data with the help of the chemical model. This procedure yields the parameters E'^0 and K_A given in Table 2, which also shows the results for LiBr–DMSO and LiBr–DMA solutions.

4.3 Association constants and activity coefficients

Lithium bromide shows a strong tendency to form ion pairs in AN, whereas in DMSO and in DMA this tendency is weak. In AN and DMA the association constant increases with temperature, but in DMSO no significant temperature dependence could be detected. Association constants in AN and DMSO also exist from different experiments and may be compared to the EMF results. Taking into account the different concentration ranges of the experiments, Table 3 shows fair agreement between the association constants obtained by various experimental methods.

The activity coefficients $y_{\pm}$ of LiBr in AN, DMSO, and DMA are available from the E'^0 values of Table 2 and the experimental electrical potentials E with the help of eq. [10]. These experimental values at 25°C are shown in Fig. 4 together with chemical model calculations using the association constants of Table 2.

The much stronger decrease of the activity coefficient of LiBr in AN in comparison with DMSO and DMA is the consequence of the association constant of LiBr being the highest in this series of solvents. In DMSO LiBr is almost completely dissociated. The experimentally determined activity coefficients are given in Table 4 together with the values from CM calculations and of the degree of dissociation.

4.4 Transfer energies

The Gibbs energy of transfer of LiBr at infinite dilution from solvent S_1 to solvent S_2, $\Delta_T G^{\infty}_{LiBr}$, is obtained from the standard electrode potentials

$$[16] \quad \Delta_T G^{\infty}_{LiBr} = -F(E^0_{S_2} - E^0_{S_1}) = -F(E'^0_{S_2} - E'^0_{S_1}) - RT \ln \left[\left(\frac{a_{Tl_xHg}}{a_{Li_xHg}} \right)_{S_2} \left(\frac{a_{Li_xHg}}{a_{Tl_xHg}} \right)_{S_1} \right]$$

At equal amalgam concentrations in each measurement the Gibbs energy of transfer is equal to the difference of the reference potentials $-F(E'^0_{S_2} - E'^0_{S_2})$. Because of the measurements in AN with a slightly different lithium concentration of the lithium amalgam electrode, the electrode potentials were corrected with the help of the activity coefficient data of Mussini et al. (10) according to their equation

$$\log f_{Li} = Q \times x_{Li}, \qquad Q = 18.48 - 3.00 \times 10^{-2}\, T$$

to calculate the activity coefficient of lithium in mercury in the temperature range $283 \leq T/K \leq 313$. The reference potential of acetonitrile ($x_{Li} = x_1 = 0.00382$) solutions corrected to the concentration of DMSO and DMA ($x_{Li} = x_2 = 0.00401$) is then

$$[17] \quad E'^0(x_2) = E'^0(x_1) + \frac{RT}{F} \ln \frac{x_2}{x_1} + \frac{RT}{F} Q \ln 10 (x_2 - x_1)$$

These corrected reference potentials are used to obtain the Gibbs energies of transfer from AN to DMSO or DMA, respectively, see Table 5.

The temperature dependence of the reference potentials yields the entropy of transfer, $\Delta_T S^{\infty}$, and the enthalpy of transfer, $\Delta_T H^{\infty}$, according to

$$[18] \quad \Delta_T S^{\infty} = F \left[\left(\frac{\partial E'^0}{\partial T} \right)_{S_2} - \left(\frac{\partial E'^0}{\partial T} \right)_{S_1} \right]$$

$$[19] \quad \Delta_T H^{\infty} = -F(E'^0_{S_2} - E'^0_{S_1}) + TF \left[\left(\frac{\partial E'^0}{\partial T} \right)_{S_2} - \left(\frac{\partial E'^0}{\partial T} \right)_{S_1} \right]$$

Heat of solution data determined by calorimetric methods in different solvents are another source for enthalpy of transfer data. The enthalpies of solution of LiBr in AN (11), $\Delta_{sol} H^{\infty}_{LiBr}$ (AN) = −38.84 kJ mol^{-1} (transformed to the molarity from the molarity scale), $\Delta_{sol} H^{\infty(m)}_{LiBr}$ (AN) = −39.91 kJ mol^{-1}), and in DMSO (12), $\Delta_{sol} H^{\infty}_{LiBr}$ (DMSO) = −71.5 kJ mol^{-1}, yield a value of −32.7 kJ mol^{-1}, for the enthalpy of transfer from AN to DMSO in agreement with $\Delta_T H^{\infty}_{LiBr}$ = −30.1 kJ mol^{-1} obtained from the temperature dependence of the EMF data. Enthalpies of solution for LiBr–DMA from calorimetric measurements are not known.

Abstract: The theory for the electrochemical impedance of surface reactions involving a single adsorbed species is presented. A new methodology is used, in which many harmonics are considered, and the differential equations are reduced to algebraic matrix equations. The amplitude of the ac potential perturbation is not assumed to be small, and nonlinear effects are taken into account. The amplitude dependence of the impedance and the second-harmonic response are investigated. The quasi-reversible electrosorption reaction and the hydrogen evolution reaction are considered in detail, assuming that the adsorbed species obeys the Langmuir isotherm.

Key words: electrochemistry, impedance, adsorption, hydrogen evolution reaction, second harmonic.

Résumé : On présente la théorie relative à l'impédance électrochimique des réactions de surface impliquant une seule espèce adsorbée. On a utilisé une nouvelle méthodologie, dans laquelle on considère plusieurs harmoniques, et les équations différentielles sont réduites à des équations de matrices algébriques. On considère que l'amplitude de la perturbation du potentiel ac n'est pas faible, et on tient compte des effets non linéaires. On a étudié l'influence de l'amplitude sur l'impédance ainsi que la réponse de la seconde harmonique. On a approfondi l'étude de la réaction quasi réversible d'électrosorption et la réaction de dégagement d'hydrogène en faisant l'hypothèse que les espèces adsorbées obéissent à l'isotherme de Langmuir.

Mots clés : électrochimie, impédance, adsorption, réaction de dégagement d'hydrogène, seconde harmonique.

[Traduit par la rédaction]

1. Introduction

In typical electrochemical impedance spectroscopy (EIS), a small ac potential perturbation is applied to the cell, and the ac current response is measured. A small perturbation is chosen so the inherently nonlinear electrochemical system can be approximated by a linear system. In this approximation, the measured impedance is independent of the amplitude of the perturbation and there is no second-harmonic response. Typically, a potential amplitude of $5/n$ mV RMS is assumed to be sufficiently small for linear behaviour, where n is the number of electrons transferred (1). In this work, the amplitude dependence of the impedance and the second-harmonic response are investigated for surface reactions. A new methodology is used that simplifies the differential equations to a system of algebraic equations.

Second and higher harmonics are of interest because they arise from the nonlinear behaviour of the system. This arises mainly from the electrochemical reaction, since double-layer charging effects are only weakly nonlinear and the solution conductivity is linear. Therefore the reaction can be studied free from interference by these other processes. A second potential advantage is that measurement of several harmonics may facilitate extraction of rate parameters at a single dc potential. Measurement of the amplitude dependence of the impedance offers similar advantages, aside from determining the amplitude below which small-signal analysis is valid. Often the number of independent parameters that can be extracted from a normal EIS experiment is less than the number of rate constants in the mechanism. If the second-harmonic response contains the rate constants in new combinations, it may allow more of the rate constants to be determined.

The theory for the second-harmonic response is well developed in the field of ac voltammetry, where the focus is on analytical applications and diffusion of products and reactants is significant (1, 2). Here the focus is on cases where mass transport is fast and diffusion does not influence the rate. These cases are particularly important in industrial electrochemical processes. Frequently, adsorbed species play a significant role, for example, in the hydrogen or chlorine evolution reactions. The case of a simple quasi-reversible electron transfer without adsorption will be considered first as an introduction to the methodology, though the results are equivalent to known results in the literature (3, 4). Single-step adsorption with the Langmuir isotherm follows. Then the hydrogen evolution reaction (HER) is discussed. The special case of the Volmer–Heyrovsky (V–H) mechanism under nonlinear conditions has been the subject of a recent controversy in the literature (5–7). The emphasis here is on the capabilities of the method, and not on an exhaustive investigation of the reactions discussed. The method presented here is easily extended

to other mechanisms with a single adsorbed species, and with a little more difficulty to mechanisms with more than one adsorbed species.

2. Theory

In all cases, mass transport is considered rapid, so that the surface concentration of soluble species is effectively constant and may be subsumed into the rate constants. The potential (or overpotential) is assumed to be the controlled variable, and it consists of dc and ac components:

$$[1] \quad \eta = \eta_{dc} + \Delta E \sin(\omega t)$$

The sine form is chosen here rather than the cosine form because a lock-in amplifier defines zero phase as the position of a zero crossing for a positive-going signal. Higher-harmonic phases are also assumed to be measured relative to sine waves, e.g., $\sin(2\omega t)$ for the second harmonic. After the ac signal has been switched on, there is a transient period that is not considered here. The current density is measured after the system settles. It consists of a dc part and various harmonics:

$$[2] \quad j = j(0) + j(\omega) + j(2\omega) + \ldots = j(0) + j_{1r}\sin(\omega t) + j_{1r}\cos(\omega t) + j_{2r}\sin(2\omega t) + j_{2i}\cos(2\omega t) + \ldots$$

The second and higher harmonics arise because of the nonlinear nature of the electrochemical reaction. That is, the slope of the current–potential characteristic is not constant. The impedance is defined in a way consistent with the way it is measured, for example, by a lock-in amplifier (though other instruments use the same phase conventions). The fundamental frequency part of the response is extracted by the instrument from among the other harmonics:

$$[3] \quad j_{1r}\sin(\omega t) + j_{1i}\cos(\omega t) = \Delta j_1 \cos(\varphi_1)\sin(\omega t) + \Delta j_1 \sin(\varphi_1)\cos(\omega t) = \Delta j_1 \sin(\omega t + \varphi_1)$$

It may be associated with the complex number

$$[4] \quad j_{1r} + j_{1i} i = \Delta j_1 \cos(\varphi_1) + \Delta j_1 \sin(\varphi_1) i = \Delta j_1 \exp(i\varphi_1)$$

The admittance is defined as the complex number for the current divided by the complex number for the potential (which is purely real since its phase has been chosen to be zero):

$$[5] \quad Y = (j_{1r} + j_{1i} i)/\Delta E = \Delta j_1 \exp(i\varphi_1)/\Delta E$$

As defined here, the admittance may depend on ΔE if the current response is not proportional to ΔE. This occurs for larger amplitude perturbations. The effect of the solution resistance and double-layer capacitance may be subtracted in the usual way to leave the faradaic part of the admittance or impedance. Quantities from here on will refer only to the faradaic part.

2.1 Simple electron-transfer reaction

The simplest case is an electron-transfer reaction, in which diffusion of products and reactants is fast compared to the reaction rate. Initially, we consider the irreversible case where only the forward reaction is significant, e.g.,

$$[6] \quad A(aq) \rightarrow A^+(aq) + e^-$$

Then the Tafel relationship links current and potential:

$$[7] \quad j = j_0 \exp(\alpha F \eta / RT)$$

For the conditions of the ac experiment

$$[8] \quad j = j_{dc} \exp(b \sin(\omega t))$$

where

$$[9] \quad j_{dc} = j_0 \exp(\alpha F \eta_{dc} / RT)$$

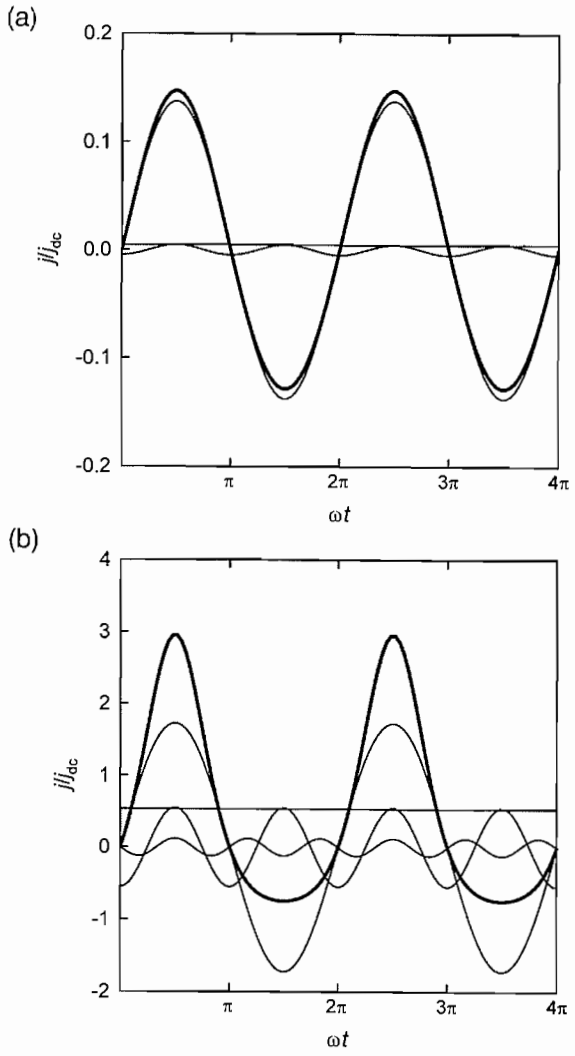
$$[10] \quad b = \alpha F \Delta E / RT$$

The quantity b should be thought of as a dimensionless potential amplitude. Now the task is simply to find the various harmonics of j, (i.e., $j(0), j(\omega), j(2\omega)$ in eq. [2]). In other words, the current should be expressed as a Fourier series. The Fourier series expansion $\exp(b\sin(\omega t))$ is known (8), though it has not been used much in electrochemistry (ref. 3 and the corrosion literature discussed in ref. 9 being exceptions). The coefficients are the modified Bessel functions:

$$[11] \quad j/j_{dc} = \exp(b\sin(\omega t)) = I_0(b) + 2I_1(b)\sin(\omega t) - 2I_2(b)\cos(2\omega t) - 2I_3(b)\sin(3\omega t) + 2I_4(b)\cos(4\omega t) + \ldots$$

$$= I_0(b) + 2\sum_{k=0}^{\infty} (-1)^k I_{2k+1}(b)\sin((2k+1)\omega t)$$

$$+ 2\sum_{k=1}^{\infty} (-1)^k I_{2k}(b)\cos(2k\omega t)$$



The Bessel functions are just steeply increasing functions of b. Their most important property in this context is that, for small b, they act like powers of b: $I_n(b) \sim (\frac{1}{2}b)^n/n!$. The difference between the actual current and the dc current, expressed as a fraction of the dc current, is plotted in Fig. 1 for two values of b. Taking $\alpha = \frac{1}{2}$ and a typical small-amplitude potential perturbation of 5 mV RMS gives $b = 0.14$. For this case (Fig. 1*a*), the total current response is well approximated by the first harmonic. The second harmonic can be neglected and there is not much change in the dc component (horizontal line is close to zero in the figure). But for a 50 mV RMS potential (Fig. 1*b*), the second harmonic now makes a significant contribution, and significant distortion of the current from the sinusoidal form occurs.

The dc part of the current response in the presence of the ac perturbation, $j(0)$, is different from the dc current without the perturbation, j_{dc} (the horizontal line in Fig. 1*b* is no longer at zero). This is the phenomenon of faradaic rectification (10), and it becomes more marked as the potential amplitude increases. Potentially, this relationship could be used to deter-

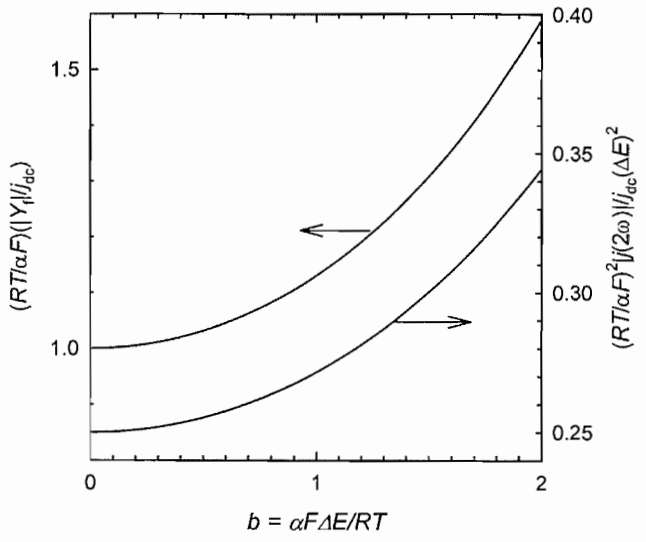
Fig. 1. Fourier components of current for a simple irreversible charge-transfer reaction. Bold line is total current, thinner lines are the first few Fourier components. (*a*) 5 mV RMS potential excitation; (*b*) 50 mV RMS potential excitation.

mine α, but the use of an ac measurement is simpler and avoids base-line errors (see below).

The lack of significant second-harmonic response in Fig. 1*a* suggests that the perturbation is sufficiently small for linear-systems theory to apply. Then the faradaic admittance is the slope of the current–potential curve, and the charge-transfer resistance is defined as the reciprocal of this:

$$[12] \quad Y_f = dj/dE = \alpha F j_{dc}/RT = 1/R_{ct}$$



or

$$(RT/\alpha F)(Y_f/j_{dc}) = 1$$

The large-signal analysis above also has the first harmonic in phase with the potential (resistive behaviour):

$$[13] \quad j(\omega) = 2j_{dc}I_1(b)\sin(\omega t)$$

Fig. 2. Amplitude dependence of the fundamental and second-harmonic currents for a simple irreversible charge-transfer reaction.

so that the faradaic admittance is

$$[14] \quad Y_f = 2j_{dc}I_1(b)/\Delta E$$

or

$$(RT/\alpha F)(Y_f/j_{dc}) = 2I_1(b)/b$$

Now for small b, $2I_1(b)/b$ tends to one, so the admittance tends to the small-signal admittance above. But for higher amplitudes, the result departs from the small-signal limit as shown in Fig. 2. For example, the error is about 0.2% for a 5 mV signal, but rises to 26% for a 50 mV signal. Potentially, measurement of the amplitude of the first harmonic and j_{dc}, together with the known ΔE, allows solution of α. However, dc currents are difficult to measure accurately. A better method involves measurement of the current amplitude for a range of ΔE's, and nonlinear fitting to eq. [14]. A slightly less rigorous method involves determination of the current response at a given potential amplitude and at twice the potential amplitude. The quantity $|j(\omega,2\Delta E)|/|j(\omega,\Delta E)|$ is calculated and the equation

$$|j(\omega,2\Delta E)|/|j(\omega,\Delta E)| = I_1(2b)/I_1(b)$$

is solved numerically for b. (Alternatively b can be read off from a working curve of $I_1(2b)/I_1(b)$ vs. b). The transfer coefficient is then obtained from eq. [10]. For accurate results, both measurements should be in the nonlinear regime, say at 30 and 60 mV RMS potential amplitudes. This method measures a ratio, and so calibration issues across different types of measurements do not arise.

The second-harmonic response could be used in a similar fashion to extract α, either from a ratio of second-harmonic responses at different potential amplitudes or from a ratio of second- to first-harmonic responses at a single potential amplitude. Its dependence on b (Fig. 2) is qualitatively similar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12
For personal use only.

to that of the fundamental frequency response. The second-harmonic has some advantages, in that it arises solely from the electrochemical reaction and not from linear elements in the system, such as the double-layer capacitance or the solution resistance.

If the back-reaction is considered significant, the current–potential characteristic is the Butler–Volmer equation, and a similar procedure to the above leads to the form:

$$[15]\quad j = j_a\exp(b_a\sin(\omega t)) - j_c\exp(-b_c\sin(\omega t))$$

where

$$[16]\quad b_a = \alpha_a F\Delta E/RT$$
$$b_c = \alpha_c F\Delta E/RT$$

and j_a and j_c are the anodic and cathodic partial currents in the absence of an ac perturbation. As before, the exponentials can be expanded in terms of Bessel functions. The Fourier expansion of $\exp(-b\ \sin(\omega t))$ is similar to that of $\exp(b\ \sin(\omega t))$ except that every second term has opposite sign, because $I_n(-b) = I_n(b)$ for n even and $I_n(-b) = -I_n(b)$ for n odd. By collecting terms the expressions for an arbitrary harmonic can be obtained. For small η, the behaviour is linear and uninteresting. Further from equilibrium, either the anodic or cathodic terms dominate, and the irreversible results above apply. A more detailed discussion of this case for the fundamental frequency response is given in ref. 4, although the method of solution of the problem is different.

2.2 Electrosorption reaction

The electrosorption reaction, with Langmuir isotherm, will now be considered:

$$[17]\quad M + A(aq) \rightarrow MA(ads) + e^-$$

The coverage of MA(ads) will be denoted θ, and the coverage of the uncovered surface sites M is $(1 - \theta)$. The surface concentration of sites on the clean surface is Γ_m (mol m^{-2}). The standard state for the adsorbed species will be taken as $\theta = ½$, and for simplicity the symmetry factors will be also be taken as ½. The general quasi-reversible case then has the rate law:

$$[18]\quad \Gamma_m d\theta/dt = k^0[(1 - \theta)\exp(½F(E - E^0)/RT) - \theta\exp(-½F(E - E^0)/RT)]$$

After solution of the above equation, the current is obtained from

$$[19]\quad j = F\Gamma_m d\theta/dt$$

To solve the rate law, the ac and dc parts of the potential may be separated as before:

$$[20]\quad d\theta/dt = k_a(1-\theta)\exp(b\sin(\omega t)) - k_c\theta\exp(-b\sin(\omega t))$$

where

$$k_a = k^0\exp(½F(E_{dc} - E^0)/RT)/\Gamma_m$$
$$k_c = k^0\exp(-½F(E_{dc} - E^0)/RT)/\Gamma_m$$

The new feature here is the coverage, θ, which will vary periodically and may contain higher harmonics:

$$[22]\quad \theta = \theta_0 + \theta_{1r}\sin(\omega t) + \theta_{1i}\cos(\omega t) + \theta_{2r}\sin(2\omega t) + \theta_{2i}\cos(2\omega t) + \ldots$$

Differentiation gives a series form for the left-hand side of the rate law:

$$[23]\quad d\theta/dt = -\omega\theta_{1i}\sin(\omega t) + \omega\theta_{1r}\cos(\omega t) - \omega\theta_{2i}\sin(2\omega t) + \omega\theta_{2r}\cos(2\omega t) - \ldots$$

Already eqs. [19] and [23] together show that the current response has no dc component and there is no faradaic rectification effect. Before coefficients of the various harmonics can be collected, the harmonic expansion of the product $\theta\exp(\pm b\ \sin(\omega t))$ is required. The expansion for each factor is known, and the terms of the product may be obtained from trigonometric relationships such as $\sin(n\omega t)\cos(m\omega t) = ½\sin((n - m)\omega t) + ½\sin((n + m)\omega t)$. This process is tedious, but may be facilitated by the use of a symbolic algebra program. (MAPLE's combine function gives the result immediately.) Then coefficients of each harmonic on the left-hand side of eq. [18] may be equated to the right-hand-side coefficients to give an infinite set of algebraic equations. For example, for $\cos(\omega t)$:

$$[24]\quad \omega\theta_{1r} = (k_a + k_c)(-I_0(b) + I_2(b))\theta_{1i} + (k_a - k_c)(-I_1(b) + I_3(b))\theta_{2r}\,(k_a + k_c)(I_2(b) - I_4(b))\theta_{3i} + \ldots$$

By writing the Fourier series for θ and reducing the differential equation to a set of algebraic equations, the boundary condition has been implicitly assumed to be $\theta(t_2) = \theta(t_1)$ for $t_2 = t_1 + 2\pi/\omega$. The equations are to be solved for θ_0, θ_{nr}, θ_{ni}, n = 1,2,3..., and may be simplified by defining rate constant combinations $k_+ = k_a + k_c$ and $k_- = k_a - k_c$. In matrix form, they are

$$[25]\quad \begin{bmatrix} k_+I_0 & k_-I_1 & 0 & 0 & -k_+I_2 & \ldots \\ 0 & \omega & k_+(I_0 - I_2) & k_-(I_1 - I_3) & 0 & \ldots \\ 2k_-I_1 & k_+(I_0 + I_2) & -\omega & 0 & -k_-(I_1 + I_3) & \ldots \\ -2k_+I_2 & -k_-(I_1 + I_3) & 0 & 2\omega & k_+(I_0 + I_4) & \ldots \\ 0 & 0 & k_-(I_1 - I_3) & k_+(I_0 - I_4) & -2\omega & \ldots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix} \begin{bmatrix} \theta_0 \\ \theta_{1r} \\ \theta_{1i} \\ \theta_{2i} \\ \theta_{2i} \\ \vdots \end{bmatrix} = \begin{bmatrix} k_eI_0 \\ 0 \\ 2k_oI_1 \\ -2k_eI_2 \\ 0 \\ \vdots \end{bmatrix}$$

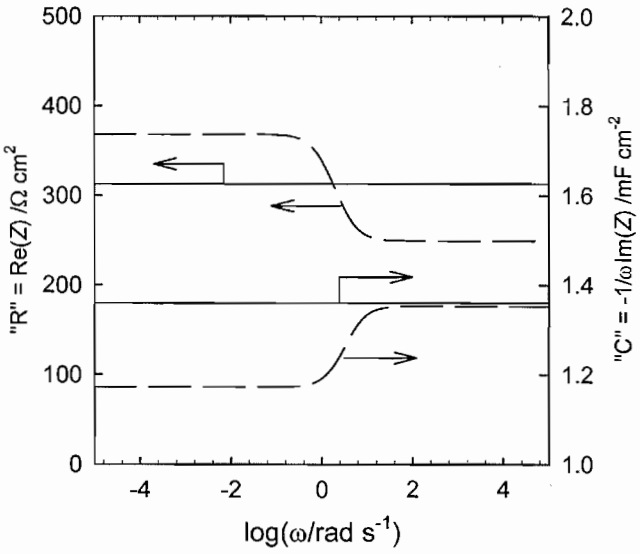
For personal use only.

(The second row originates from eq. [24].) On the right-hand side $k_e = k_o = k_a = \frac{1}{2}(k_+ + k_-)$. k_e is associated with even-order Bessel functions and k_0 is associated with odd-order Bessel functions. (Although in this case k_e and k_o are the same, they will be different for the HER discussed later.) In the matrix, the k_+ rate constants multiply even-order Bessel functions and the k_- multiply odd-order functions. If the rows are indexed by n = 0,1c,1s,2c,2s,3c,3s,... (c and s for cos and sin), and the columns are indexed by 0,1r,1i,2r,2i,3r,3i,... then the combination of Bessel functions in the n,mth entry is made up from Bessel functions of order $n + m$ and $|n - m|$. The rule for the signs of these and the pattern of zero entries can be written down,[2] but in practice generation of the entries by a symbolic algebra program is more convenient.



It is interesting to note that the equations have a very simple solution for $k_c = 0$, the case of irreversible production of the adsorbate. Then the solution is $\theta = \theta_0 = 1$. That is, if the surface is fully covered, it remains so in the presence of the ac perturbation. For this irreversible case, it is also clear that there can be no other solutions, because the coverage must always increase and therefore cannot be periodic.

At this point, the solution of linear equations is straightforward, using either symbolic or numerical methods. The matrix is truncated to a finite size and the first few harmonics are calculated. The accuracy of the solutions may be checked by increasing the matrix size and recalculating the answers. All the plots in this paper are obtained for 11×11 matrices, which give better than six-figure accuracy. However, even for 5×5 matrices, the solutions typically have 0.1% accuracy.

The solutions are the ac components of θ. These are converted to $d\theta/dt$ via eq. [23] and thence to current by eq. [19]. The admittance $(j_{1r} + j_{1i}i)/\Delta E$ can be converted to an impedance and the real and imaginary parts of this found. The expected small-signal equivalent circuit is a series RC combination (11), so the real and imaginary parts of the impedance should be R and $-1/\omega C$ for some frequency-independent R and C. This expectation is borne out for small amplitudes, but at higher amplitudes, $R = \mathrm{Re}(Z)$ and $C = -1/\omega\mathrm{Im}(Z)$ show some frequency dependence (Fig. 3). Over a limited frequency range these parameters appear constant, but with values that are not equal to the small-signal limit. In the high-frequency limit, the matrix equation can be solved exactly for R (see Appendix), which then shows a very simple dependence on amplitude.

At the special potential E^0, $k_- = 0$ and the even harmonics of both θ and j are zero. This is true for any amplitude perturbation and for any frequency. At other potentials, the second-harmonic spectrum yields circles in the complex admittance plane (Fig. 4*a*). The potential dependence of the second-harmonic admittance has a characteristic shape not unlike that observed in second-harmonic ac voltammetry of soluble species (Fig. 4*b*). The second-harmonic signal for the reversible, small-signal case has been calculated and measured by Lelievre et al. (12) for a reaction with adsorbed reactant and product.

Fig. 3. Frequency-dependence of the apparent series resistance and capacitance for the Langmuir adsorption reaction. $\Gamma_m = 2 \times 10^{-9}$ mol cm^{-2}, $k^0 = 2 \times 10^{-9}$ mol cm^{-2} s^{-1}, $\beta = \frac{1}{2}$, $E_{dc} = E^0 + 30$ mV. Solid lines, potential amplitude 1 mV RMS; broken lines, potential amplitude 50 mV RMS.

2.3 The hydrogen evolution reaction

$$\begin{aligned} &\mathrm{M(site)} + \mathrm{H^+} + \mathrm{e^-} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{MH(a)} \\ [26]\quad &\mathrm{MH(a)} + \mathrm{H^+} + \mathrm{e^-} \underset{k_{-2}}{\overset{k_{-1}}{\rightleftharpoons}} \mathrm{M(site)} + \mathrm{H_2} \\ &2\mathrm{MH(a)} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} 2\mathrm{M(site)} + \mathrm{H_2} \end{aligned}$$

The HER, eqs. [26], is an important case of a mechanism with a single adsorbed intermediate. Mass transport is assumed to be fast for H^+ and H_2 and the Langmuir isotherm is assumed for the adsorbed species, so that the net rates of the individual steps are given by

$$\begin{aligned} v_1 &= k_1(1 - \theta) - k_{-1}\theta \\ [27]\quad v_2 &= k_2\theta - k_{-2}(1 - \theta) \\ v_3 &= k_3\theta^2 - k_{-3}(1 - \theta)^2 \end{aligned}$$

The rate constants for steps 1 and 2 have exponential potential dependence in the usual way ($\beta_1 = \beta_2 = \frac{1}{2}$ will be assumed).

[2] The nc,mr entry is 0 for m and n even or m and n odd, $-s_{n+m}I_{|n-m|} + s_{n+m}I_{n+m}$ for m even and n odd, $s_{n+m}I_{|n-m|} + s_{n+m}I_{n+m}$ for m odd and n even, where s_i is the sign associated with the ith order Bessel function in the expansion of $\exp(b\sin(\omega t))$, i.e., $s_i = (-1)^{\mathrm{floor}((i \bmod 4)/2)}$. The nc,mi entry is 0 for m even and n odd or for m odd and n even, $s_{n+m}I_{|n-m|} + s_{n+m}I_{n+m}$ for m and n even, $-s_{n+m}I_{|n-m|} + s_{n+m}I_{n+m}$ for m and n odd. The ns,mr entry is 0 for m even and n odd or for m odd and n even, $s_{n+m}I_{|n-m|} - s_{n+m}I_{n+m}$ for m and n even, $-s_{n+m}I_{|n-m|} - s_{n+m}I_{n+m}$ for m and n odd. The ns,mi entry is 0 for m and n even or m and n odd, $s_{n+m}I_{|n-m|} + s_{n+m}I_{n+m}$ for m even and n odd, $-s_{n+m}I_{|n-m|} + s_{n+m}I_{n+m}$ for m odd and n even. The $n = 0$ row follows the same rule as an nc row. For the $m = 0$ column or for the right-hand side, the $n = 0$ entry is I_0, the nc entries are 0 for n odd, $2s_nI_n$ for n even, and the ns entries are 0 for n even, $2s_nI_n$ for n odd.

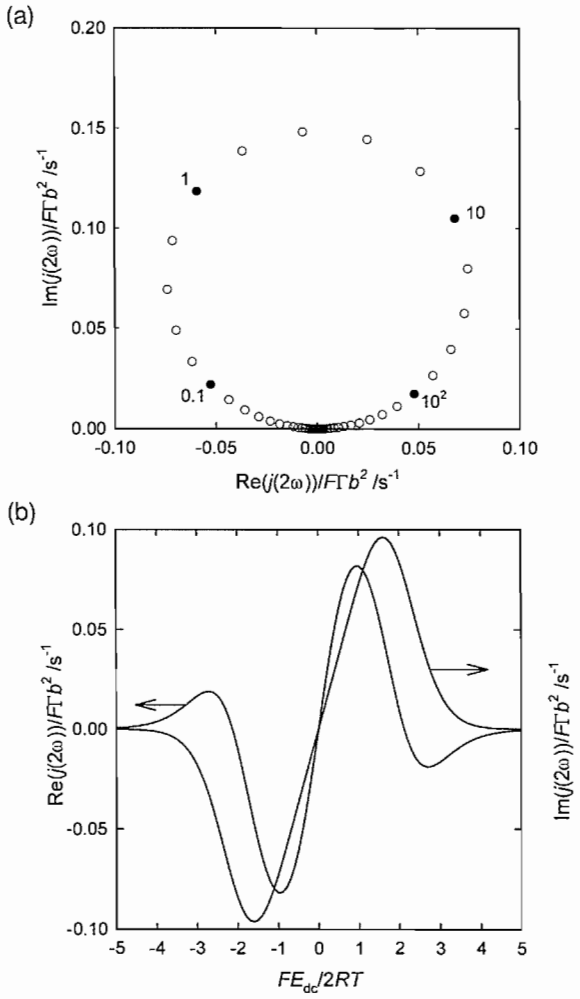
Fig. 4. Second-harmonic response for the Langmuir adsorption reaction. (*a*) Complex-plane plot of second-harmonic admittance. Potential amplitude 5 mV RMS; other parameters as for Fig. 3. Selected values of ω marked on the plot. (*b*) Potential dependence of second-harmonic admittance. Potential amplitude 5 mV RMS, $\omega = 6$ rad s^{-1}, other parameters as in Fig. 3.



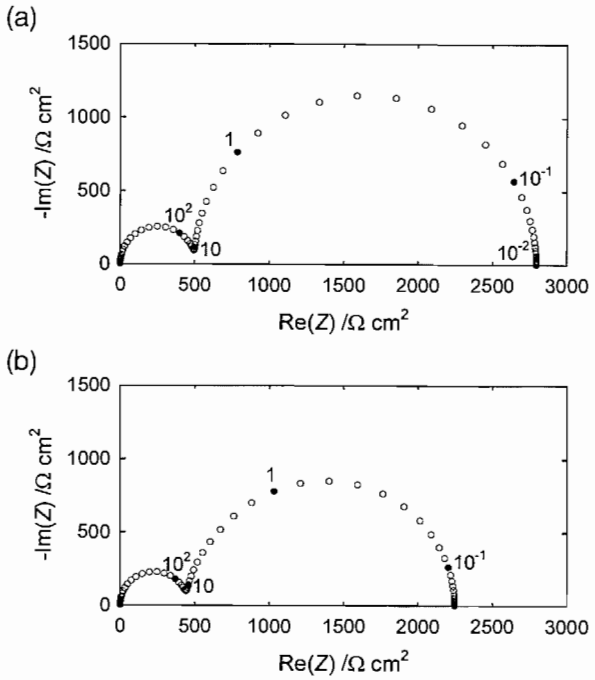


Fig. 5. Impedance of the hydrogen evolution reaction. Rate constants as for Fig. 3, ref. 5, i.e., $k_1/\Gamma_m = k_{-1}/\Gamma_m = 1$ s^{-1}; $k_2/\Gamma_m = k_{-2}/\Gamma_m = 5 \times 10^{-2}$ s^{-1}; $k_3 = k_{-3} = 0$; $\Gamma_m = 1 \times 10^{-9}$ mol cm^{-2}; $\beta_1 = 0.2$; $\beta_2 = 0.6$; $C_{dl} = 1 \times 10^{-5}$ F cm^{-2}. Selected values of ω marked on the plots. (*a*) Potential amplitude $\Delta E = 1$ mV; (*b*) potential amplitude $\Delta E = 70$ mV.

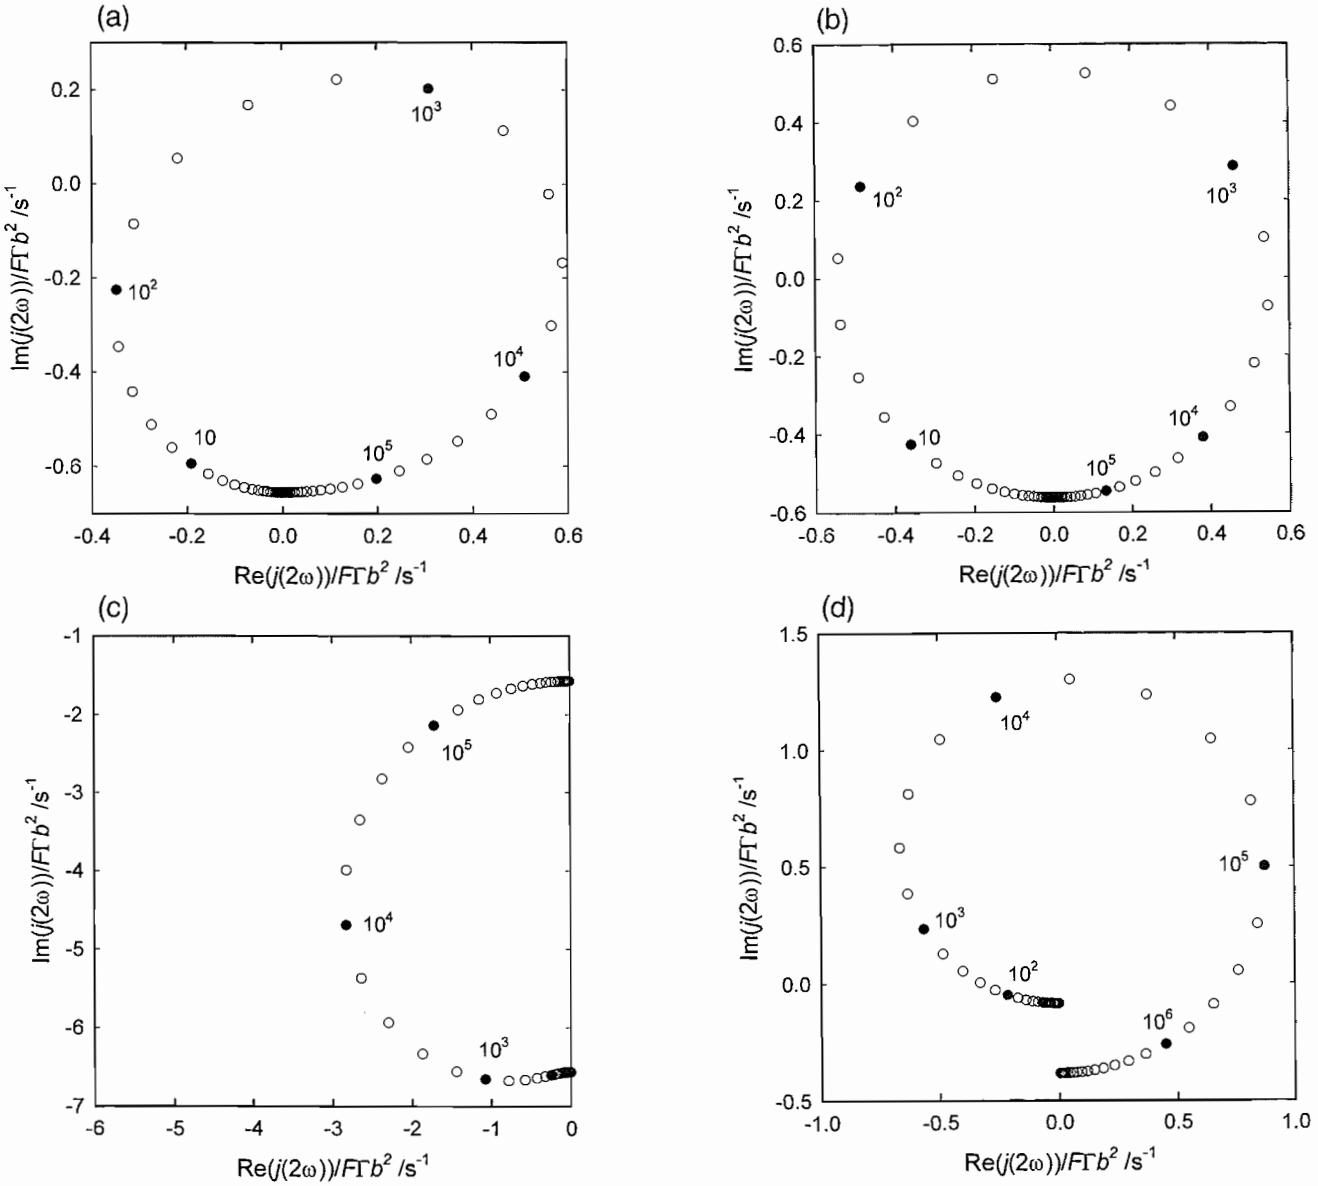
The differential equation to be solved is

[28] $\Gamma_m d\theta/dt = v_1 - v_2 - 2v_3$

The case where $v_3 = 0$ (Volmer–Heyrovsky mechanism) will be considered first. Then the mechanism may be solved in the same way as previously, because eq. [28] is still linear in θ. The rate constants k_+ and k_- in the matrix in eq. [25] are replaced by $(k_1 + k_{-1} + k_2 + k_{-2})/\Gamma_m$ and $(-k_1 + k_{-1} - k_2 + k_{-2})/\Gamma_m$, where these rate constants are now the values at the dc potential. The right-hand side of the matrix equation now has $k_e = (k_1 + k_{-2})/\Gamma_m$ associated with the even-order Bessel functions and $k_o = (k_{-2} - k_1)/\Gamma_m$ associated with odd-order Bessel functions. The four combinations of rate constants appearing in the matrix equation, $k_1 + k_{-1} + k_2 + k_{-2}$, $-k_1 + k_{-1} - k_2 + k_{-2}$, $k_1 + k_{-2}$, and $k_{-2} - k_1$, are linearly independent. Therefore it is at least possible that all four rate constants may be extracted from the data. This possibility will be investigated further in the discussion section.

The case of v_3 non-zero is more complicated because the rate equation is no longer linear in θ. It is still possible to expand the right-hand side of eq. [28] as a Fourier series. The terms in θ^2 are products of two identical Fourier series and can be expanded in a similar way to the other products of two Fourier series, for example, the product $\theta \exp(b \sin(\omega t))$ discussed above. The differential equation can then be converted to a system of algebraic equations, by equating coefficients of the various $\cos(n\omega t)$ and $\sin(n\omega t)$ on the left-hand and right-hand sides. The equations are no longer linear because they contain products like $\theta_{2i}\theta_{3i}$, and they cannot be solved by matrix methods. However, numerical solution of sets of nonlinear equations is possible. Although convergence to a solution is no longer guaranteed, a good strategy is to restrict the search space to between −1 and 1 for each component of θ.

Once the components of θ are found, by matrix or nonlinear methods, they are substituted into the following equation to find the current:



[29] $j = -Fv_1 - Fv_2$

Expanding this into a Fourier series yields the desired complex numbers for each of the current harmonics. The admittance is found as before.

The complex-plane impedance plots show the familiar

Fig. 6. Second-harmonic response for the hydrogen evolution reaction. Complex-plane plots of second-harmonic admittance, with selected values of ω marked. All rate constants are at $\eta_{dc} = -30$ mV. (*a*) Fast first step with slower second step. 50 mV RMS potential amplitude. $k_1/\Gamma_m = 5.6\ s^{-1}$; $k_{-1}/\Gamma_m = 18\ s^{-1}$; $k_2/\Gamma_m = 0.56\ s^{-1}$; $k_{-2}/\Gamma_m = 1.8\ s^{-1}$. $k_3 = k_{-3} = 0$; $\beta_1 = \beta_2 = ½$. (*b*) As for (*a*) but 5 mV RMS potential amplitude. (*c*) Slow first step, fast second step. 5 mV RMS potential amplitude. $k_1/\Gamma_m = 0.56\ s^{-1}$; $k_{-1}/\Gamma_m = 18\ s^{-1}$; $k_2/\Gamma_m = 56\ s^{-1}$; $k_{-2}/\Gamma_m = 18\ s^{-1}$; $k_3 = k_{-3} = 0$; $\beta_1 = \beta_2 = ½$. (*d*) Comparable first and second step rates. 5 mV RMS potential amplitude. $k_1/\Gamma_m = 2.8\ s^{-1}$; $k_{-1}/\Gamma_m = 180\ s^{-1}$; $k_2/\Gamma_m = 5.6\ s^{-1}$; $k_{-2}/\Gamma_m = 0.90\ s^{-1}$. $k_3 = k_{-3} = 0$; $\beta_1 = \beta_2 = ½$.

shapes associated with this mechanism, with the impedances decreasing with increased amplitude (e.g., Fig. 5). The second-harmonic admittance shows two semicircular arcs in the complex plane (Fig. 6).

3. Discussion

The most significant advantage of the present formulation over most others in the literature is the use of the Bessel function expansion for $\exp(b\ \sin(\omega t))$. The use of this expansion has been little used by others (but see refs. 3 and 9). Other treatments typically use Taylor series expansions of the exponential function. Terms involving powers such as $\sin^5(\omega t)$ must then be expanded into their harmonic components, $\sin^5(\omega t) = (1/16)\sin(5\omega t) - (5/16)\sin(3\omega t) + (5/8)\sin(\omega t)$. In general, odd powers lead to all odd harmonics and even powers to all even harmonics. Thus to get accurate evaluation of a given harmonic requires evaluation of a large number of terms

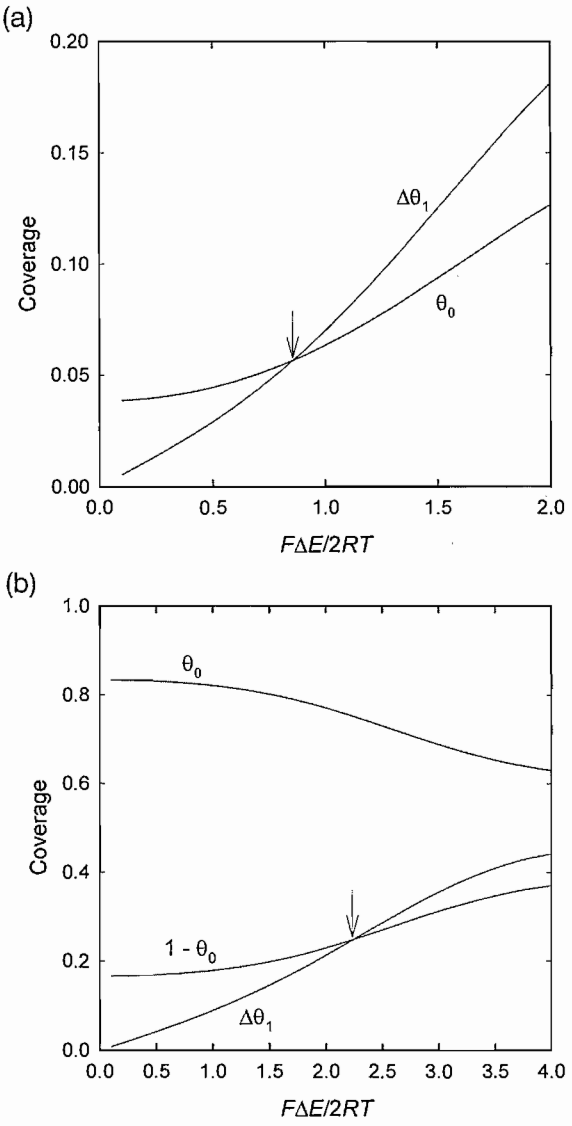
in the Taylor series, and this evaluation is complicated by the difficulty of expanding the powers of trigonometric functions into a sum of harmonics.

An alternative approach, as used here, is to write directly the Fourier series for $\exp(b \sin(\omega t))$. In this way, one avoids the difficulty that different terms contribute to a given harmonic. An additional advantage is that the assumption that the perturbation is small is not needed, and the amplitude dependence of the (nonlinear) impedance can be calculated. In the cases with one adsorbed species, an infinite-size matrix must be approximated by a finite-size matrix in order to get a numerical result. However, this approximation is of a different nature than taking a reduced number of terms in a Taylor series, because here the equations are cut off after a specified actual harmonic, which already contains contributions from arbitrarily high-order Taylor-series terms. A relatively small matrix is sufficient to give accuracy far higher than the typical experimental error.



There is some possibility of getting an exact analytical solution to the infinite-size matrix equation, though I have not yet succeeded in this task. For some special cases the infinite-size matrix equation can be solved analytically without reducing its order. For example, in the high-frequency limit for the simple adsorption reaction, the (nonlinear) charge-transfer resistance may be obtained exactly (see Appendix). Its reciprocal has the same simple amplitude dependence as for the admittance of the simple irreversible reaction, eq. [8]. Other special cases may also be tractable. In any case, generation of the matrix equation and numerical solution to any required accuracy is easy using a symbolic algebra program. A MAPLE worksheet for this purpose can be obtained from the author or may be found at http://surface.chem.uvic.ca.

An advantage of high-amplitude impedance measurements or second-harmonic measurements is that they promise to yield kinetic parameters not available from small-amplitude fundamental-frequency impedance measurements. This is especially important for mechanisms in which not all the rate constants may be unambiguously extracted from EIS and steady-state data. The issue of identifiability and distinguishability of mechanisms has been addressed by Berthier et al. (13–15). The last two papers discuss the particular case of the V–H mechanism of the HER, where it was first noted by Lasia and Rami (16) that the replacements $k_1 \leftrightarrow k_2$, $k_{-1} \leftrightarrow k_{-2}$, $\beta_1 \leftrightarrow \beta_2$ do not change the steady-state current–potential curves or the EIS spectra. The present theory also gives the same results for the second-harmonic response under exchange of these rate parameters. Apparently, the equations for the second-harmonic response combine the rate constants in a similar way to conventional EIS.

To investigate this further, recall that the matrix equation contains the four rate constant combinations $k_+ = (k_1 + k_{-1} + k_2 + k_2)/\Gamma_m$, $k_- = (-k_1 + k_{-1} - k_2 + k_{-2})/\Gamma_m$, $k_e = (k_1 + k_{-2})/\Gamma_m$, and $k_o = (k_{-2} - k_1)/\Gamma_m$. The combinations k_e and k_+ originate from the rate law eq. [28] which is $k_e - k_+\theta$. When the Bessel function expansions for $\exp(b \sin(\omega t))$ and $\exp(-b \sin(\omega t))$ are collected, their odd-order terms have opposite signs, and are associated with different combinations k_o and k_-. These are k_e and k_+ with the signs of the cathodic rate constants changed. In the conventional theory the building blocks of the impedance are the partial derivatives $(\partial(v_1 - v_2)/\partial E)_\theta$, $(\partial(-v_1 - v_2)/\partial E)_\theta$, $(\partial(v_1 - v_2)/\partial\theta)_E$, and $(\partial(-v_1 - v_2)/\partial\theta)_E$. The partial derivatives with respect to E contain the steady-state coverage. Because this is found by setting the rate law equal to zero, the same two parameters k_e and k_+ are involved. In the act of taking the partial derivatives with respect to E, the cathodic rate constants change sign, leading again to k_o and k_-. The two theories are quite similar in the way that they combine the rate constants. It is therefore not too surprising that the same rate constant ambiguity that exists for conventional EIS is not resolved by second-harmonic measurements.

The nonlinear impedance of a two-step reaction with an adsorbed intermediate (cf. the V–H mechanism) was first discussed by Gabrielli et al. (17), using a Taylor series approach.

Fig. 7. Amplitude dependence of components of θ in the HER. θ_0 is the dc component of θ, $\Delta\theta_1$ is the amplitude of the fundamental component of θ. Points at which the equations become invalid are marked by an arrow. (*a*) $\omega = 0.001$ rad s^{-1}; $k_1/\Gamma_m = 0.018$ s^{-1}; $k_{-1}/\Gamma_m = 0.056$ s^{-1}; $k_2/\Gamma_m = 1.8$ s^{-1}; $k_{-2}/\Gamma_m = 0.056$ s^{-1}. $k_3 = k_{-3} = 0$; $\beta_1 = \beta_2 = ½$. (*b*) $\omega = 100$ rad s^{-1}; $k_1/\Gamma_m = 36$ s^{-1}; $k_{-1}/\Gamma_m = 6.6$ s^{-1}; $k_2/\Gamma_m = 1.8$ s^{-1}; $k_{-2}/\Gamma_m = 1.1$ s^{-1}. $k_3 = k_{-3} = 0$; $\beta_1 = \beta_2 = ½$.

More recently, Darowicki (7, 6) and Diard et al. (5) have disagreed over the correct formulation of this problem. Both use Taylor series approaches, and the divergence of opinion seems to arise because of different simplification procedures used. The present method uses a quite different approach, and is able to reproduce the results of Diard et al. (Fig. 5, cf. Fig 3 of ref. 5).

An assumption that is implicit in the physical problem, but not in the mathematical formulation, is that θ must lie between zero and one. This requirement provides an upper limit for ΔE, beyond which the equations must be considered approximate at best. The amplitudes of the components of θ will increase with ΔE. If $\Delta\theta_1$ exceeds θ_0, then θ will be "clipped" at zero for part of its cycle (neglecting the smaller influence of higher harmonics). Clipping also occurs if $\Delta\theta_1 + \theta_0$ exceeds one. Figure 7 shows two cases of the V–H mechanism where there is a maximum ΔE for valid measurements according to this criterion. The factors that enhance the amplitude of the θ oscillations are large rate constants, low frequencies, and steady-state θ near zero or one. Accordingly, it is not easy to make a general statement about which ΔE values are safe.

The method described here opens up the use of second or higher harmonic spectroscopies for surface reactions, though the lack of exact analytical results is a hindrance. At least for the V–H mechanism, with $\beta_1 = \beta_2 = 1/2$, the use of the second-harmonic does not assist in more efficient extraction of rate parameters. The best argument in favour of these measurements is that they are insensitive to the double-layer charging currents, and so a higher precision is possible. Higher precision for second-harmonic measurements has been noted experimentally by Lelievre et al. (12) for a redox reaction in an adsorbed layer.

The method can be used for many cases. Cases where the rate law (expression for $d\theta/dt$) is linear in θ give linear equations and hence can be dealt with by matrix methods. Important examples dealt with in this paper are the simple adsorption reaction and the V–H version of the HER, in the special case of the Langmuir isotherm. Cases that are polynomial in θ, of degree higher than one, cannot be formulated in matrix form, but the equations can be solved numerically. Cases where the rate law is more complex but where a Fourier series is available for the functional form of θ should be soluble numerically, for example, the Frumkin isotherm. The case of more than one adsorbed intermediate is no more difficult than the single-adsorbate case. There are now two or more expressions of the form $d\theta_i/dt$ but these can be reduced to algebraic equations in the same way – the matrix is just larger, with i sets of unknowns, where i is the number of adsorbed species.

4. Conclusions

The method presented here may be used to calculate all the harmonics of the current response to a sinusoidal potential perturbation of arbitrary magnitude. Thus the nonlinear impedance or the second-harmonic impedance is readily calculated. The method is simplest for cases where the rate law is linear in θ, for example, the simple Langmuir adsorption reaction or the V–H mechanism of the HER assuming the Langmuir isotherm. Then matrix methods lead to easy numerical solution, or an exact analytical solution for some simple cases. Other mechanisms can be calculated by similar methods, but only numerical solutions are possible.

5. Acknowledgements

I thank the Natural Sciences and Engineering Research Council of Canada and the University of Victoria for financial support. I thank Dr Andrzej Lasia for making me aware of the rate constant ambiguity of the V–H mechanism and of the existence of refs. 5 and 6.

Appendix

For the high-frequency limit ($\omega \gg k$) in the simple adsorption reaction with $\beta = ½$, it is possible to get an exact result for the charge-transfer resistance at arbitrary amplitude. Cramer's rule is first used to solve the matrix equation [25] for θ_{1i}:

© 1997 NRC Canada

$$[30]\quad \theta_{1i} = \frac{\begin{vmatrix} k_+I_0 & k_-I_1 & k_eI_0 & 0 & -k_+I_2 & \cdots \\ 0 & \omega & 0 & k_-(I_1 - I_3) & 0 & \cdots \\ 2k_-I_1 & k_+(I_0 + I_2) & 2k_oI_1 & 0 & -k_-(I_1 + I_3) & \cdots \\ -2k_+I_2 & -k_-(I_1 + I_3) & -2k_eI_2 & 2\omega & k_+(I_0 + I_4) & \cdots \\ 0 & 0 & 0 & k_+(I_0 - I_4) & 2\omega & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{vmatrix}}{\begin{vmatrix} k_+I_0 & k_-I_1 & 0 & 0 & -k_+I_2 & \cdots \\ 0 & \omega & k_+(I_0 - I_2) & k_-(I_1 - I_3) & 0 & \cdots \\ 2k_-I_1 & k_+(I_0 + I_2) & -\omega & 0 & -k_-(I_1 + I_3) & \cdots \\ -2k_+I_2 & -k_-(I_1 + I_3) & 0 & 2\omega & k_+(I_0 + I_4) & \cdots \\ 0 & 0 & k_-(I_1 - I_3) & k_+(I_0 - I_4) & -2\omega & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{vmatrix}}$$

In the large ω limit, the terms with the highest power of ω will dominate. In the bottom determinant, the term with the highest power of ω is formed from the elements in the leading diagonal, i.e., $k_+I_0\omega(-\omega)(2\omega)(-2\omega)\ldots$. In the top determinant, there are two terms associated with $(\omega)(2\omega)(-2\omega)\ldots$. One has the product of the 1,1 entry with the 3,3 entry and the other has the product of the 3,1 entry with the 1,3 entry. Taking the ratio of the top and bottom determinants and cancelling powers of ω gives:

$$\theta_{1i} = \frac{2(k_+I_0k_oI_1 + k_-I_1k_eI_0)}{k_+I_0\omega}$$

A similar argument shows that $\theta_{1r} = 0$, and therefore the imaginary part of the first-harmonic of the current, $\omega F\Gamma_m\theta_{1r}$, is zero. The real part is $-\omega F\Gamma_m\theta_{1i}$ and may be divided by ΔE to give the admittance, or $1/R$. After some simplification, the final result is

$$R(\omega \to \infty) = \frac{RTb(\exp(\tfrac{1}{2}F(E_{dc}-E^0)/RT) + \exp(-\tfrac{1}{2}F(E_{dc}-E^0)/RT))}{2F^2k_oI_1(b)\exp(F(E_{dc}-E^0)/RT} = R_{ct}b/2I_1(b)$$

where R_{ct} is the small-signal charge-transfer resistance.

Ion–polymer interactions in polypyrrole films

Xiaoming Ren and Peter G. Pickup

Abstract: Formal potentials from cyclic voltammetry and ionic conductivities from impedance measurements are used to probe anion–polymer interactions in electrochemically deposited films of polypyrrole. Hard anions (F^-, Cl^-, ClO_4^-) stabilize the oxidized form of the polymer more than soft anions (I^-, SCN^-). Anions of weak acids (F^- and CN^-) interact with the polymer particularly strongly and exhibit anomalously low mobilities. Hydrogen bonding with the N-H groups of oxidized polypyrrole is proposed.

Key words: conducting polymer, polypyrrole, impedance, ion transport, electrolyte effects, ion exchange.

Résumé : On a utilisé les potentiels formels de la voltampérométrie cyclique et les conductivités ioniques obtenues par des mesures d'impédance pour étudier les interactions anion–polymère dans des films de polypyrrole déposés d'une façon électrochimique. Les anions durs (F^-, Cl^-, ClO_4^-) stabilisent plus la forme oxydée du polymère que les anions mous (I^-, SCN^-). Les anions des acides faibles (F^- et CN^-) interagissent d'une façon particulièrement forte avec le polymère et ils présentent des mobilités anormalement faibles. On suggère l'existence de liaison hydrogène avec les groupes N-H de la forme oxydée du polypyrrole.

Mots clés : polymère conducteur, polypyrrole, impédance, transport ionique, effets d'électrolyte, échange d'ion.

Introduction

Ion transport in conducting polymer films has attracted considerable attention since electrochemical studies of these materials began in 1979 (1). The performance of conducting polymers in many applications is strongly influenced by their ion transport properties (2, 3). Furthermore, studies of ion transport can provide valuable information about film structure (4), and chemical interactions within the film (5, 6).

The influence of the anion on the electrochemistry of conducting polymers has been extensively investigated. Many studies (7–13) have involved preparation of the polymer in the presence of different doping anions. In these cases, differences in ion-transport characteristics are mainly due to different film morphologies formed during polymerization.

To probe anion–polymer interactions, films should be grown in the same medium, with subsequent anion exchange. Anion exchange in conducting polymers has been well documented (12, 14–17), although quantitative thermodynamic (18) and kinetic data (15, 16) are limited. There is also a paucity of information on the effects of anion exchange on the electrochemical and transport properties of conducting polymers (19o).

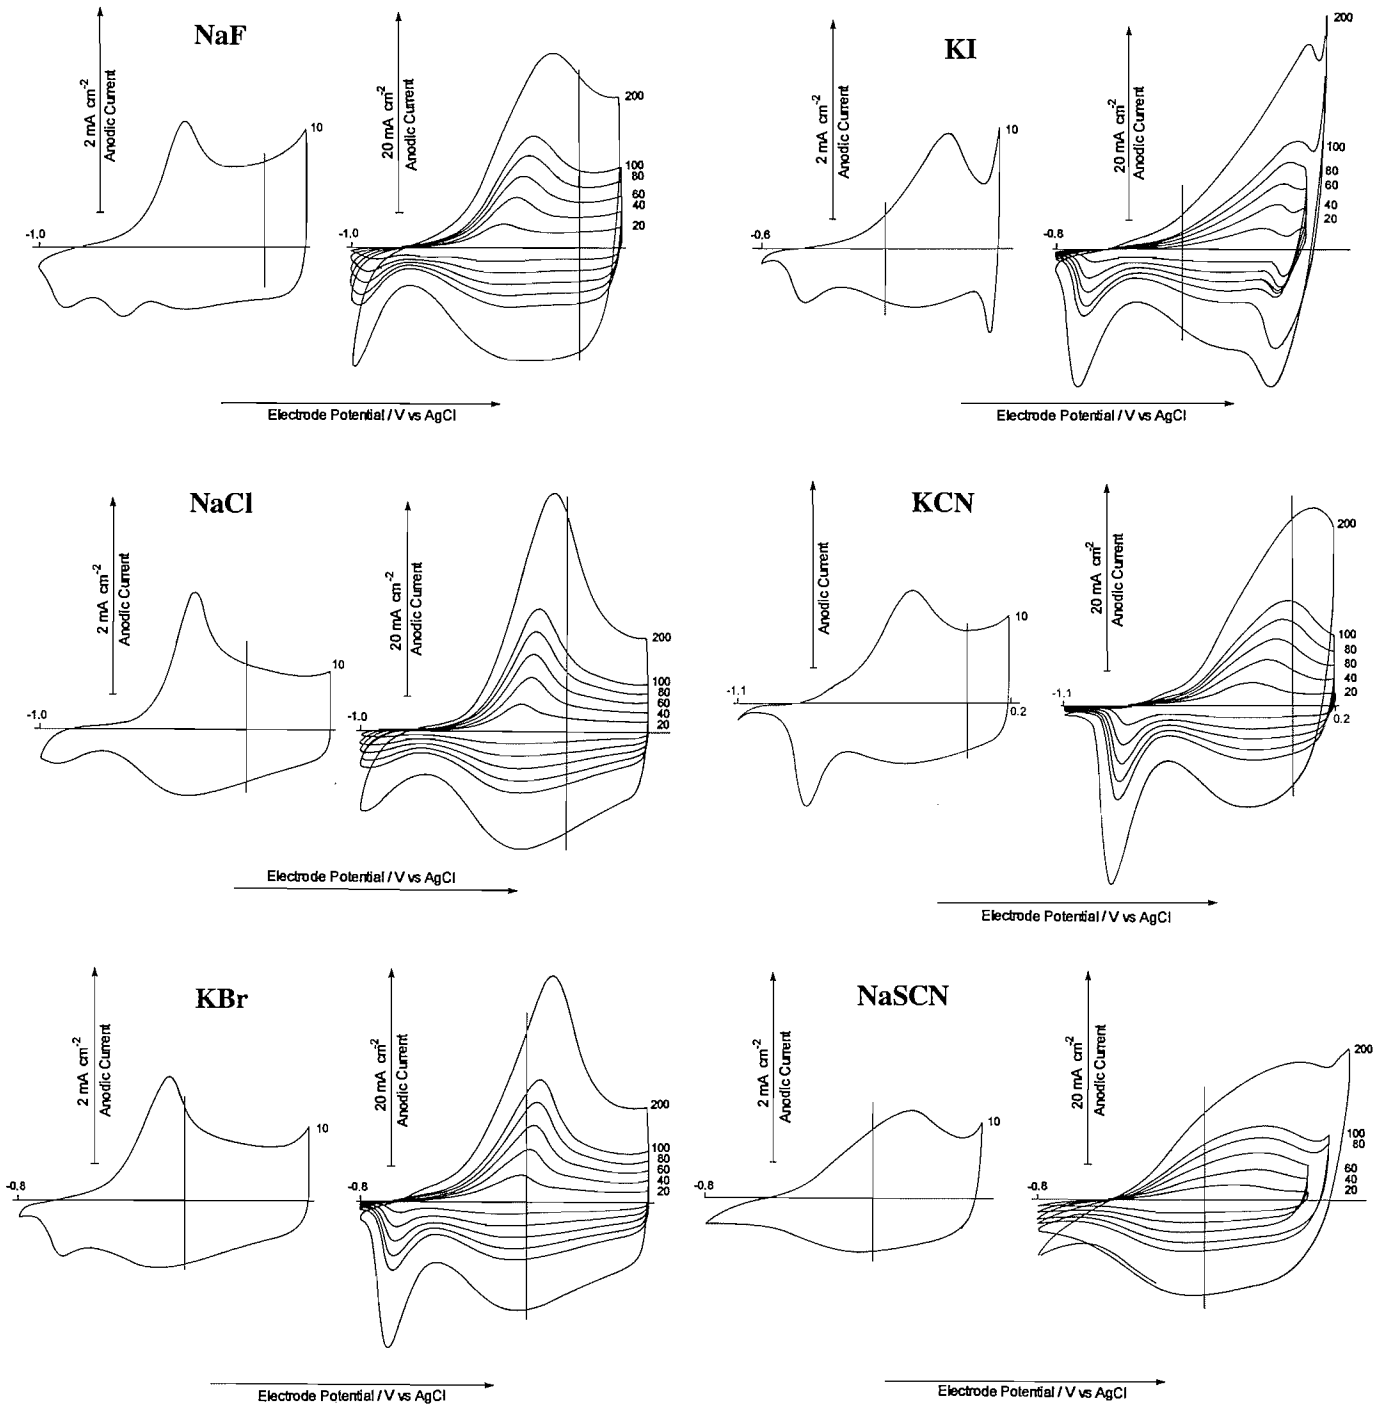
Our investigations of ion transport in polypyrrole (4, 5, 20–22) have revealed some surprising dependencies of the ion transport rate on the nature of the mobile ion and the solvent. Perchlorate transport was found to be exceedingly slow when the polymer was immersed in dry acetonitrile, but became faster when a small percentage of water was added (5). In water, the mobility of ClO_4^- in perchlorate-doped polypyrrole was found to be much lower than that of Na^+ in polystyrenesulphonate-doped polypyrrole. We have attributed the low mobility of ClO_4^- in polypyrrole to ion pairing with oxidized sites in the polymer (5), but hydrogen bonding with pyrrole N-H groups (6) may also be important. Schiavon et al. (6) ascribed the lower mobility of anions in unsubstituted polypyrrole, relative to *N*-substituted polypyrroles, to hydrogen bonding. This effect was found to be particularly strong with the hydroxide ion and leads to a substantial negative shift in the polymer's formal potential (19, 23).



To properly document the influence of the nature of the anion on its mobility in polypyrrole, and to provide further insight into the interactions between anions and the polymer, we report here a comparative study of the electrochemistry and ionic conductivity of polypyrrole in the presence of seven different anions. Evidence for hydrogen bonding between certain anions and oxidized polypyrrole is presented.

Experimental

Experimental procedures and equipment have been described in detail elsewhere (22). Polypyrrole films were prepared electrochemically on Pt disc electrodes (0.0052 cm^2), at constant current (0.80 mA cm^{-2}) from 0.5 M pyrrole in 0.5 M $NaClO_4$(aq), and were nominally 2 μm thick. All voltammetric and impedance measurements were carried out in monomer-free 0.2 M aqueous electrolyte solutions. Before recording voltammograms or impedance data, the potential of each polymer-coated electrode was cycled (at 60 mV s^{-1}) four

times between the limits of the voltammograms shown in Fig. 1. Impedance data were collected in the order of decreasing potential.

Results

Cyclic voltammetry

Cyclic voltammograms of polypyrrole-coated electrodes in 0.2 M aqueous solutions of NaF, NaCl, KBr, KI, KCN, and NaSCN are shown in Fig. 1. Voltammograms of a similar film in $NaClO_4$(aq) have been published and discussed previously (22). They are very similar to those in KBr(aq) shown in Fig. 1.

The voltammograms shown in Fig. 1 are all similar, although there are some quite significant differences in peak positions and peak separations. Approximate formal potentials for the main redox process (Table 1) were determined from the slowest voltammograms by taking the average of the

anodic peak potential and the potential of the corresponding broad cathodic peak. Most of the voltammograms exhibit an additional reduction peak at lower potentials, although the size and location of this peak are quite variable. We believe that it is due to transient cation insertion (22). In KI(aq), peaks for the I_3^-/I^- couple are seen at ca. +0.7 V.

Ionic conductivity

Ionic conductivities of polypyrrole films in 0.2 M aqueous solutions of NaF, NaCl, KBr, KI, $NaClO_4$, KCN, and NaSCN were obtained as a function of potential by impedance spectroscopy as previously described (22). The results are shown in Fig. 2. In all cases, ionic conductivity increases with increasing potential, indicating that it is dominated by anion transport (22). To accurately reflect differences in anion mobilities, conductivities should be compared at the same degree of oxidation of the polymer (doping level). This is done in Table 1, where ionic conductivities at a doping level of 45 mC cm^{-2} (the maximum doping level in the I^- solution before the onset of I^- oxidation) are reported.

Discussion

The data in Table 1 do not follow any obvious trends, and so their explanation will require consideration of a number of factors. First we will consider the thermodynamic information reflected by the formal potentials.

Oxidation of the polymer (eq. [1]) requires uptake of anions from the solution.

$$[1] \quad (\text{-py-})_n^+X^- + e^- \rightleftharpoons (\text{-py-})_n + X^-(\text{solution})$$

where n is the average number of pyrrole rings over which each positive charge is spread. As the potential of the film is increased, n decreases from ∞ to ca. 3 (24).

Weak ion–solvent interactions and strong ion-oxidized polymer interactions will favour oxidation of the polymer and decrease the formal potential. Hence, the formal potentials reflect the ion-exchange selectivity of the polymer. The free

energy change (ΔG_{ex}) for the exchange of two ions X^- and Y^- (eq. [2]),

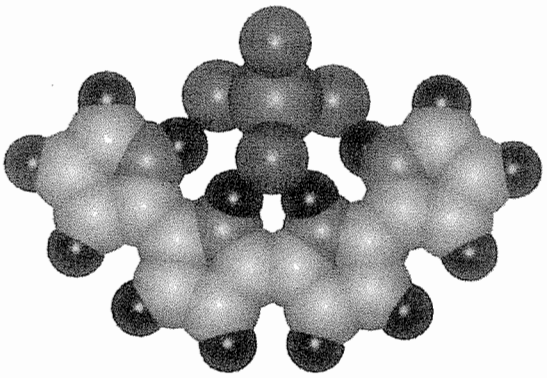
[2] $(\text{-py-})_n^+X^- + Y^-(\text{solution}) \rightleftharpoons (\text{-py-})_n^+Y^- + X^-(\text{solution})$

is given by

[3] $\Delta G_{ex} = F(E_Y^{o'} - E_X^{o'})$

where $E_X^{o'}$ and $E_Y^{o'}$ are the formal potentials in X^- and Y^- solutions, respectively, and F is Faraday's constant. ΔG_{ex} values obtained by using eq. [3] are compared with literature values from experiments involving solid-state cells (18) in Table 2. The lack of even qualitative agreement is difficult to explain, although it should be noted that the literature values are for films prepared in acetonitrile.

From the data in Table 1, the anion preference of polypyrrole is $F^- > CN^- \sim ClO_4^- > Cl^- > Br^- > SCN^- > I^-$, which is virtually opposite to that of conventional anion–exchange polymers (25), and suggests that there is some specific interaction of the anion with the oxidized polymer.



With the exception of perchlorate, enthalpies of hydration for the anions used here (Table 1) become less positive in the order in which they stabilize oxidized polypyrrole. The differences in formal potentials observed in the various solutions cannot, therefore, be due to differences in ion–solvent interactions, which would produce the opposite trend. The anions with the least favourable (most positive) enthalpy of hydration would be preferentially incorporated into the oxidized polymer, stabilizing it most. The differences in formal potentials must therefore be primarily due to differences in the interactions between the anions and the oxidized polymer.

The low formal potentials observed in the F^-, Cl^-, and ClO_4^- solutions indicate that the oxidized polymer interacts most strongly with hard anions (26). This suggests that the oxidized polypyrrole acts as a hard acid, and therefore the positive charge is concentrated at the N-H groups.

Amongst the soft anions, CN^- produces an anomalously low formal potential. Since CN^- is significantly more basic than the other soft anions used here, this suggests that hydrogen bonding with the pyrrole N-H group is important. To test this hypothesis we have plotted the polypyrrole formal potentials against the hydration energies of the anions (Fig. 3). $\Delta H_{hydration}$ is heavily influenced by hydrogen bonding and therefore provides an approximate scale of the strength of hydrogen bonding. The correlation in Fig. 3 is surprisingly good, and provides further evidence for hydrogen bonding.

Turning now to the ion conductivity (mobility) data, the least mobile ions are those of weak acids (CN^-, F^- and SCN^-). Their movement is presumably hindered by hydrogen bonding with the pyrrole N-H groups. For the other ions, size appears to be the main factor in determining the mobility within the polymer, although the mobility of ClO_4^- appears to be anomalously high.

Fig. 4. Molecular model of a $\text{pyrrole}_4^+ClO_4^-$ ion pair.

The perchlorate ion appears to be anomalous, both in terms of its mobility and its effect on the polymer's formal potential. As mentioned in the introduction, it also has a surprisingly low mobility in polypyrrole bathed in acetonitrile. These anomalies could be explained by a strong ion-pairing interaction between ClO_4^- and oxidized polypyrrole. Molecular models (Fig. 4) suggest that the perchlorate ion has an appropriate size and shape to form a strong interaction with a polypyrrole chain, despite its low propensity to hydrogen bond. The nonspecific (directional) nature of this interaction may explain the unexpectedly high mobility of ClO_4^- in polypyrrole bathed in water (i.e., the ClO_4^- ion could roll along the polypyrrole chain with a low activation energy). In acetonitrile, lack of solvation of the polymer may result in local solid phase formation, causing immobilization of the ClO_4^- counterions.

Conclusions

The formal potential and ion mobility data reported here provide evidence for hydrogen bonding between certain anions (F^-, CN^-, and SCN^-) and oxidized polypyrrole. These interactions have a profound influence on the mobility of the anion, leading to differences in mobility of over an order of magnitude between, for example, Cl^- and CN^-.

Theory of potential relaxation after interrupting a steady-state current

Keith B. Oldham and Jan C. Myland

Abstract: This article predicts the chronopotentiometric response when a steady-state reductive voltammetric current is interrupted. Although the ohmic polarization disappears instantaneously, the presence of the double-layer capacitance prevents the cessation of faradaic current. The electrode potential adopts a value that reflects three processes — the continuing arrival of electroactive ions, the incomplete reduction of these ions, and the discharging of the capacitor — all of which proceed at a diminishing rate. A nonlinear differential equation is derived to incorporate these three processes and its dimensionless equivalent is solved as a power series. The form of the solution is shown to depend on whether or not the interrupted current was close to the limiting current of the reduction. Methods of analyzing the experimental chronopotentiogram are discussed.

Key words: current interrupt, potential relaxation, chronopotentiometry.

Résumé : Dans cet article on prédit la réponse chronopotentiométrique lorsqu'on interrompt un courant voltampérométrique réducteur à l'état stationnaire. Même si la polarisation ohmique disparaît instantanément, le présence de la capacitance de double couche empêche la cessation du courant faradique. Le potentiel d'électrode adopte une valeur qui est le reflet de trois processus — la continuation de l'arrivée d'ions électroactifs, la réduction incomplète de ces ions et la décharge de la capacitance — qui continuent tous à une vitesse qui s'amenuise. On a dérivé une équation différentielle non linéaire pour incorporer ces trois processus et on a résolu son équivalent sans dimension sous la forme d'une série de puissance. On a démontré que la forme de la solution varie suivant que le courant interrompu était près, ou non, du courant limite de la réduction. On discute des méthodes d'analyse du chronopotentiogramme expérimental.

Mots clés : courant interrompu, relaxation du potentiel, chronopotentiométrie.

[Traduit par la rédaction]

Introduction

The interruption of a faradaic current is a well-established method of studying electrode processes (1–7). Of the three varieties (concentration, activation, and ohmic) of polarization (8), the last two are often considered to disappear instantaneously when the current is interrupted, so that potentials measured immediately after interruption can provide direct access to the extent of concentration polarization, permitting investigation of conditions at the electrode surface. Because ohmic polarization (*IR* drop) can thereby by quantified and nullified, current interruption is particularly useful when the electrolyte solution has high resistivity, or when the material from which the electrode is fabricated is an imperfect conductor of electricity. Rather than relying on a single data point, the first after interruption, it is better to suitably extrapolate a set of measured potentials back to the instant of interruption. In this article, we shall first review the simple theory that applies when nonfaradaic processes can be ignored and then address the much more difficult case in which the discharging of the double layer contributes significantly to changing potential immediately after interruption.

For our present purpose, it is simpler to treat the case in which the electrode reaction generates a species that is at a constant, rather than at a variable, activity and therefore we choose to develop a model based on the *n*-electron reduction

$$[1] \qquad M^{n+}(\text{soln}) + ne^- \rightleftharpoons M(\text{l or s})$$

as the electrode process. However, the canonical case of the reaction

$$[2] \qquad O^{z+}(\text{soln}) + ne^- \rightleftharpoons R^{(z-n)+}(\text{soln})$$

in which both electroactive species are solutes in the solution, may be treated similarly, though the relationships are more elaborate because of the need to take account of two concentrations varying simultaneously. In the interest of further simplification, our attention will be directed solely to cases in which reaction [1] is reversible, so that activation polarization is absent.

The current-interruption procedure is most informative when the current being interrupted is unchanging, for then the behaviour after current cessation is not confounded by changes that were in process before the interruption. Here we shall be exclusively concerned with a current I_{ss} (which to accord with IUPAC's convention is negative) that was in a

steady state prior to interruption. This generally implies that the concentration c_{ss} of the electroreactant in the vicinity of the electrode is linearly related

$$[3] \qquad c_{ss} = c_{ss}^{s} + gx$$

to the distance x measured from and normal to the electrode surface. Please note our use of the superscript "s" to denote conditions at the electrode surface, and of the subscript "ss" to indicate the steady state existing prior to interruption. Conditions in the steady state provide the initial conditions of the transient phase that is entered following current interruption. The g term in eq. [3] is the gradient $(dc/dx)^{s}$ of the electroreactant's concentration at the electrode surface and in its vicinity, which is related via Fick's first and Faraday's laws

$$[4] \qquad I_{ss} = -nFAD\left(\frac{dc}{dx}\right)_{ss}^{s} = -nFADg$$

to the steady-state current. Here D denotes the diffusivity (diffusion coefficient) of the electroreductant M^{n+}, A is the electrode area, and F is Faraday's constant. In the case of spherical or hemispherical diffusion (as when steady states are established at microelectrodes), a linear concentration gradient does not accompany a steady state and therefore the findings of this article require modification to address such geometries.

Negligible nonfaradaic interference

Prior to the interruption, the electrode potential displays a steady potential E_{ss}, which can be expressed as

$$[5] \qquad E_{ss} = E^{o\prime} + \frac{RT}{nF}\ln\left\{\frac{c_{ss}^{s}}{c^{o}}\right\} + \eta_{ohm}$$

Here η_{ohm} is the overvoltage attributable to ohmic polarization; it is negative for the reduction under consideration. $E^{o\prime}$ represents the conditional (or formal) potential and c^{o} denotes the standard of chemical concentration, 1000 mol m^{-3}.

At time $t = 0$, the reduction current of reaction [1] is interrupted. The flux of ions across the electrode immediately ceases

$$[6] \qquad \left(\frac{dc}{dx}\right)^{s} = 0$$

However, the concentration gradient elsewhere will continue to drive M^{n+} ions towards the electrode, thereby steadily increasing the concentration c^{s} of ions there. From its constant value E_{ss} prior to $t = 0$, the electrode potential will now change in accordance with the Nernst equation

$$[7] \qquad E = E^{o\prime} + \frac{RT}{nF}\ln\left\{\frac{c^{s}}{c^{o}}\right\}$$

Note that, in the absence of nonfaradaic interference, the Nernst equation could be used after the current interruption, even if reaction [1] were not reversible, because activation polarization, like ohmic polarization, requires a continuing current for its maintenance. However, it is specifically the *faradaic* current that supports activation polarization, whereas the *total* current generates ohmic polarization.

Equation [6] provides one boundary condition for the solution of Fick's second law

$$[8] \qquad D\frac{\partial^2 c}{\partial x^2} = \frac{\partial c}{\partial t}$$

the other boundary condition being

$$[9] \qquad \frac{\partial c}{\partial x} \to g \text{ as } x \to \infty$$

This last expression implies that the linear concentration profile extends indefinitely, which cannot be realized in practice, of course. For short times after interruption, however, which is the prime interest here, limit [9] can be regarded as valid. An initial condition also needs to be supplied to supplement Fick's second law. Equation [3] provides this and it becomes incorporated on Laplace transformation of eq. [8] into

$$[10] \qquad D\frac{d^2\bar{c}}{dx^2} = s\bar{c} - c_{ss}^{s} - gx$$

This is a linear ordinary differential equation and its general solution has the form

$$[11] \qquad \bar{c} = \frac{c_{ss}^{s} + gx}{s} + P(s)\exp\left\{-x\sqrt{\frac{s}{D}}\right\} + Q(s)\exp\left\{x\sqrt{\frac{s}{D}}\right\}$$

where $P(s)$ and $Q(s)$ are presently unknown coefficients that may be functions of the dummy Laplace variable s. In the present case, application of boundary condition [9] shows that $Q(s)$ must be zero. The $P(s)$ term may easily be found but, to establish conformity with the method to be followed in the next section, a solution route will be followed that bypasses the explicit evaluation of $P(s)$. We differentiate eq. [11] with respect to x and then eliminate the $P(s)$ term between this expression for the Laplace transform of the surface concentration of the M^{n+} ion and its derivative. The result may be written

$$[12] \qquad \frac{d\bar{c}}{dx} = \frac{g}{s} - \sqrt{\frac{s}{D}}\left[\bar{c} - \frac{c_{ss}^{s} + gx}{s}\right]$$

Our interest is restricted to the electrode surface, $x = 0$, where

$$[13] \qquad \left(\frac{d\bar{c}}{dx}\right)^{s} = \frac{g}{s} - \sqrt{\frac{s}{D}}\left[\bar{c}^{s} - \frac{c_{ss}^{s}}{s}\right]$$

Because of the presence of the $\sqrt{s}$ multiplier, this transformed equation easily inverts to an expression involving the semiderivative with respect to time of the surface concentration excursion:

$$[14] \qquad \left(\frac{\partial c}{\partial x}\right)^{s} = g - \frac{1}{\sqrt{D}}\frac{d^{1/2}(c^{s} - c_{ss}^{s})}{dt^{1/2}}$$

At this point, use is made of condition [6] to nullify the left-hand member of this equation. After rearrangement, semiintegration then leads easily to

$$[15] \qquad c^{s} = c_{ss}^{s} + 2g\sqrt{\frac{Dt}{\pi}}$$

so that, via eqs. [7] and [5], the potential relaxation is found to be described by

$$[16] \qquad E = E_{ss} - \eta_{ohm} + \frac{RT}{nF} \ln\left\{1 + \frac{2g}{c^s_{ss}}\sqrt{\frac{Dt}{\pi}}\right\}$$

c^s_{ss} and η_{ohm} may be found from this chronopotentiometric relation. Alternative routes, not involving the fractional calculus, could have generated eq. [15] more easily; however, our chosen derivation provides a better introduction to the case that now follows.

Effect of nonfaradaic interference

Whereas it is true that the *total* current drops immediately to zero on interruption, this is not true of the individual faradaic and nonfaradaic currents of which the total is composed, except when the latter is negligibly important. Because the individual currents sum to zero after interruption, the expression

$$[17] \qquad nADF\left(\frac{\partial c}{\partial x}\right)^s = -I_{far} = I_{nonfar} = C\frac{dE}{dt} = \frac{CRT}{nFc^s}\frac{dc^s}{dt}$$

holds. The first member in this chain of equalities is analogous to eq. [4], while the last arises from differentiation of eq. [7]. The capacitance C of the electrode has here been assumed potential independent.

As in the previous section, eq. [3] provides the initial condition for the solution of Fick's second law [8], with eq. [9] being one of the boundary conditions. Equation [17], however, now replaces eq. [6] as the boundary condition at the electrode surface. The method of solution remains unchanged from that of the preceding section as far as eq. [14]. At that point eq. [17] may be combined with eq. [14], to give

$$[18] \qquad c^s\frac{d^{1/2}(c^s - c^s_{ss})}{dt^{1/2}} = \sqrt{D}gc^s - \frac{CRT}{n^2F^2A\sqrt{D}}\frac{dc^s}{dt}$$

This is a fractional ordinary differential equation linking the variables c^s and t. It is nonlinear because of the c^s multiplier in the left-hand term. Such equations are rarely soluble in terms of established functions.

To convert eq. [18] into dimensionless form, let us define

$$[19] \qquad \tau = \frac{n^2F^2ADg}{CRT}t = \frac{-nFI_{ss}}{CRT}t$$

and

$$[20] \qquad \varsigma = \frac{nF\sqrt{A}}{\sqrt{CRTg}}c^s = \sqrt{\frac{-n^3F^3D}{CRTI_{ss}}}Ac^s$$

It is also convenient to adopt a as a symbol for the dimensionless equivalent of the preexisting steady-state surface concentration

$$[21] \qquad a = \varsigma_{ss} = \frac{nF\sqrt{A}}{\sqrt{CRTg}}c^s_{ss} = \sqrt{\frac{-n^3F^3D}{CRTI_{ss}}}Ac^s_{ss}$$

These definitions convert the differential equation into

$$[22] \qquad \frac{d\varsigma}{d\tau} = \varsigma - \varsigma\frac{d^{1/2}(\varsigma - a)}{d\tau^{1/2}}$$

an expression that links the ς and τ variables in terms of a single parameter, a. It will now be demonstrated that there exists a power-series solution to eq. [22].

To proceed, let it be assumed that a solution to eq. [22] exists such that

$$[23] \qquad \frac{d\varsigma}{d\tau} = \sum_{j=2}^{\infty} b_j\tau^{(j-2)/2}$$

where the b_j coefficients depend, in a presently unknown fashion, on the a parameter. Then

$$[24] \qquad \varsigma = a + 2\sum_{j=2}^{\infty}\frac{b_j}{j}\tau^{j/2}$$

where the a term, the initial value of ς, appeared as a constant of integration, and

$$[25] \qquad \frac{d^{1/2}(\varsigma - \varsigma_{ss})}{d\tau^{1/2}} = 2\sum_{j=2}^{\infty}\frac{b_j}{j}\frac{\Gamma(\frac{1}{2}j+1)}{\Gamma(\frac{1}{2}j+1/2)}\tau^{(j-1)/2} = \sum_{j=2}^{\infty} b_j\frac{\Gamma(\frac{1}{2}j)}{\Gamma(\frac{1}{2}j+1/2)}\tau^{(j-1)/2}$$

This latter expression arises) either by semiintegration of eq. [23] or by semidifferentiation of eq. [24]. We are free to define $b_1 = -\Gamma(1)/\Gamma(1/2)$ because this term does not occur in eqs. [23]–[25]; then

$$[26] \qquad 1 - \frac{d^{1/2}(\varsigma - \varsigma_{ss})}{d\tau^{1/2}} = 1 - \sum_{k=2}^{\infty} b_k\frac{\Gamma(\frac{1}{2}k)}{\Gamma(\frac{1}{2}k+1/2)}\tau^{(k-1)/2} = -\sum_{k=2}^{\infty} b_{k-1}\frac{\Gamma(\frac{1}{2}k-1/2)}{\Gamma(\frac{1}{2}k)}\tau^{(k-2)/2}$$

Next, we multiply eqs. [24] and [26]

$$[27] \qquad \varsigma\left[1 - \frac{d^{1/2}(\varsigma - \varsigma_{ss})}{d\tau^{1/2}}\right] = -a\sum_{k=2}^{\infty} b_{k-1}\frac{\Gamma(\frac{1}{2}k-1/2)}{\Gamma(\frac{1}{2}k)} \times\tau^{(k-2)/2} - 2\sum_{k=2}^{\infty}\sum_{i=2}^{\infty}\frac{b_{k-1}b_i}{i}\frac{\Gamma(\frac{1}{2}k-1/2)}{\Gamma(\frac{1}{2}k)}\tau^{(k+i-2)/2}$$

It is now convenient to use the summation index j to replace k in the first, and $k+i$ in the second, right-hand terms of eq. [27]. We also make use of the permutation

$$[28] \qquad \sum_{k=2}^{\infty}\sum_{j-k=2}^{\infty} = \sum_{j=4}^{\infty}\sum_{k=2}^{j-2}$$

to simplify the second right-hand term. This leaves us in a position to substitute eqs. [23] and [27] into the differential eq. [22]. Thereby

$$[29] \qquad \sum_{j=2}^{\infty} b_j\tau^{(j-2)/2} = -a\sum_{j=2}^{\infty} b_{j-1}\frac{\Gamma(\frac{1}{2}j-1/2)}{\Gamma(\frac{1}{2}j)}\tau^{(j-2)/2} - 2\sum_{j=4}^{\infty}\sum_{k=2}^{j-2}\frac{b_{j-k}b_{k-1}}{j-k}\frac{\Gamma(\frac{1}{2}k-1/2)}{\Gamma(\frac{1}{2}k)}\tau^{(j-2)/2}$$

Table 1. Expressions for early coefficients in summation [23]. Note that b_1 does not appear in the series.

j	b_j
1	$\frac{-1}{\sqrt{\pi}}$
2	a
3	$\frac{-2a^2}{\sqrt{\pi}}$
4	$a^3 + a$
5	$\frac{-4a^4}{3\sqrt{\pi}} - \frac{14a^2}{3\sqrt{\pi}}$
6	$\frac{a^5}{2} + \left(\frac{13}{4} + \frac{8}{3\pi}\right)a^3 + \frac{a}{2}$
7	$\frac{-8a^6}{15\sqrt{\pi}} - \left(\frac{128}{45\pi^{3/2}} + \frac{23}{3\sqrt{\pi}}\right)a^4 - \left(\frac{71}{15\sqrt{\pi}}\right)a^2$
8	$\frac{a^7}{6} + \left(\frac{57}{16} + \frac{56}{15\pi}\right)a^5 + \left(\frac{71}{16} + \frac{32}{5\pi}\right)a^3 + \frac{a}{6}$

Notice that the same power of τ now occurs in each of the three terms and that the first (or only) summation is invariably over j-values. It follows that we can equate each of the coefficients of $\tau^{(j-2)/2}$. For the cases $j = 2$ and $j = 3$, there is no contribution from the final term in eq. [29], so that

$$[30] \qquad b_j = -ab_{j-1}\frac{\Gamma(\frac{1}{2}j - 1/2)}{\Gamma(\frac{1}{2}j)} \qquad \text{for } j = 2, 3$$

whereas for all larger j values both right-hand terms contribute

$$[31] \qquad b_j = -ab_{j-1}\frac{\Gamma(\frac{1}{2}j - 1/2)}{\Gamma(\frac{1}{2}j)} - 2\sum_{k=2}^{j-2}\frac{b_{j-k}b_{k-1}}{j-k} \times \frac{\Gamma(\frac{1}{2}k - 1/2)}{\Gamma(\frac{1}{2}k)} \qquad \text{for } j = 4, 5, 6, \ldots$$

Formulas [30] and [31] constitute recursion formulas permitting all the b coefficients to be successively evaluated. Table 1 lists early members, from which an emerging pattern is evident. Writing out the first few terms of the expression for ς, one has

$$[32] \qquad \varsigma = a\left[1 + \tau - \frac{4a\tau^{3/2}}{3\sqrt{\pi}} + \frac{(a^2+1)\tau^2}{2} - \frac{4a(2a^2+7)\tau^{5/2}}{15\sqrt{\pi}} + \cdots\right]$$

Note the absence of a term in $\sqrt{\tau}$. The infinite series of which these are the first few terms effectively constitutes the complete solution to the problem that is being addressed. All that is now required to determine the chronopotentiogram is a return to experimental variables and substitution of c^s into the Nernst equation.

Equation [24] has been shown to be a dimensionless solution to the problem, when the b coefficients are evaluated via recursion relationships [30] and [31] with $b_1 = -\Gamma(1)/\Gamma(1/2) = -1/\sqrt{\tau}$. In experimental variables the solution is the complicated expression

$$[33] \qquad c^s = c^s_{ss}\left[1 - \frac{nFI_{ss}t}{CRT} + \frac{4n^3F^3AI_{ss}c^s_{ss}}{3C^2R^2T^2}\sqrt{\frac{Dt^3}{\pi}} + \frac{n^2F^2I_{ss}[CRTI_{ss} - n^3F^3DA^2(c^s_{ss})^2]t^2}{2C^3R^3T^3} - O(t^{5/2})\right]$$

This gives the concentration at the electrode surface as a function of time in terms of the pertinent experimental parameters. The time evolution of the potential follows from inserting this expression into the Nernstian relationship

$$[34] \qquad E = E_{ss} + \frac{RT}{nF}\ln\left\{\frac{c^s}{c^s_{ss}}\right\} - \eta_{ohm}$$

Magnitude of the a parameter

Table 1 clearly shows that most of the coefficients consist of several terms and that the dominant term among these several depends critically on the magnitude of a. We need to get some idea of typical experimental values of this parameter. Before substituting numerical values into definition [21], it is useful to utilize the concept (ref. 8, pp. 202, 284) of the transport coefficient (or mass transfer constant) m. This links the steady-state current to the difference between the bulk and surface concentrations. In our case

$$[35] \qquad c^b - c^s_{ss} = \frac{-I_{ss}}{nFAm}$$

As the limiting current I_L is approached, the surface concentration of the electroreactant tends toward zero, so that

$$[36] \qquad c^b = \frac{-I_L}{nFAm}$$

Combination of these two equations enables the concentration at the electrode surface to be expressed

$$[37] \qquad c^s_{ss} = c^b\frac{I_L - I_{ss}}{I_L}$$

in terms of more easily measurable quantities. Substitution into definition [21] leads to

$$[38] \qquad a = Ac^b\sqrt{\frac{-n^3F^3D}{CRTI_L}}\frac{I_{ss} - I_L}{\sqrt{I_LI_{ss}}}$$

when the negative sign of I_L and I_{ss} is recognized.

We adopt the following typical voltammetric magnitudes: $c^b = 1$ mol m^{-3}, $n = 2$, $D = 1 \times 10^{-9}$ m^2 s^{-1}, $C/A = 0.3$ F m^{-2}, $T = 300$ K, and $I_L/A = -10$ A m^{-2}. Then, on substitution into eq. [38], we discover

$$[39] \qquad a \approx 30\frac{I_{ss} - I_L}{\sqrt{I_LI_{ss}}}$$

Thus, with these particular values, if the steady-state cur-

For personal use only.

rent exceeds $0.97I_L$ in magnitude, a will be less than unity and, conversely, $a > 1$ if I_{ss} is less than 97% of the limiting current. Both of these alternatives are encountered experimentally, so the possibilities that $a > 1$ and $a < 1$ must both be considered. It is not unreasonable, in the light of these calculations, to assert that a steady-state current on the limiting plateau corresponds to $a \ll 1$, whereas a steady-state experiment not in the limiting region encounters the parameter value $a \gg 1$.

Limiting solutions

In the $a \gg 1$ case, only those components of b_j with the highest power of a will be important. These are the first mentioned terms in Table 1, for example, the $a^5/2$ component of b_6. These terms are, in fact

$$[40] \qquad b_j = \frac{(-a)^j}{a\Gamma(\frac{1}{2}j)} \quad \text{when } a \gg 1$$

so that we learn from eq. [24] that

$$[41] \qquad \varsigma = a + \frac{2}{a}\sum_{j=2}^{\infty}\frac{(-a\sqrt{\tau})^j}{j\Gamma(\frac{1}{2}j)} = a + \frac{1}{a}\sum_{j=2}^{\infty}\frac{(-a\sqrt{\tau})^j}{\Gamma(1+\frac{1}{2}j)}$$

Now the sum from $j = 0$ to ∞ of $(-z)^j/\Gamma(1 + 1/2j)$ is $\exp\{z^2\}\text{erfc}\{z\}$ (10) and therefore

$$[42] \qquad \varsigma = a + \frac{1}{a}\left[2a\sqrt{\frac{\tau}{\pi}} - 1 + \exp\{a^2\tau\}\text{erfc}\{a\sqrt{\tau}\}\right]$$

This is the result, in dimensionless coordinates, when the parameter a is large, i.e., when the current being interrupted is not close to its limiting value.

If not only a, but also $a\sqrt{\tau}$, is large, then we may use an asymptotic expansion of the error function complement (10) to simplify eq. [42] to

$$[43] \qquad \varsigma = a + 2\sqrt{\frac{\tau}{\pi}} - \frac{1}{a} + \frac{1}{a^2\sqrt{\pi\tau}} - \cdots$$

The first two right-hand terms are the dominant ones and it is comforting to find that these two exactly reproduce the right-hand side of eq. [15] when a return is made to dimensional variables. The first right-hand term in eq. [43] represents the surface concentration prior to interruption. The second right-hand term corresponds to the increasing surface concentration of electroreacant arriving by diffusing down the concentration profile. Terms in eq. [43] beyond the first two represent the minor retardation in the buildup of M^{n+} concentration at the electrode caused by the small faradaic burden imposed by the need to discharge the double layer.

Equation [43] is predicated on both a and $a\sqrt{\tau}$ being large. But what magnitude is $a\sqrt{\tau}$ likely to have? Referring to definitions [19] and [21], we find

$$[44] \qquad a\sqrt{\tau} = \frac{n^2F^2Ac^s_{ss}}{CRT}\sqrt{Dt} = \frac{n^2F^2Ac^b}{CRTI_L}(I_L - I_{ss})\sqrt{Dt}$$

and using the previously cited typical voltammetric magnitudes, along with $I_{ss} = I_L/2$, one calculates that $a\sqrt{\tau} \approx (800s^{1/2})\sqrt{t}$. Thus, on this basis, $a\sqrt{\tau}$ exceeds unity soon after 1 μs, so the step from [42] to [43] is valid at most experimentally accessible times. For future use, we shall also estimate the magnitude of $\sqrt{\tau}/a$. We find

$$[45] \qquad \frac{\sqrt{\tau}}{a} = \frac{-I_{ss}}{nFAc^s_{ss}}\sqrt{\frac{t}{D}} = \frac{I_{ss}I_L}{(I_{ss}-I_L)nFAc^b}\sqrt{\frac{t}{D}}$$

$$= (0.7\,s^{-1/2})\sqrt{t}$$

when we use previous values plus the assumption that $I_L/A = 4\text{ A m}^{-2}$.

Next, we consider the $a \ll 1$ case. Then we can ignore all components of the b_j coefficients that involve powers of a larger then unity. A glance at Table 1 shows that this excludes all components when j is odd and that for even j the retained component gives

$$[46] \qquad b_j = \frac{a}{(\frac{1}{2}j-1)!} \quad \text{when } a \ll 1 \text{ and } j = 2,4,6,\ldots$$

It then follows from eq. [24] that

$$[47] \qquad \varsigma = a + 2a\sum_{j=2,4,\ldots}^{\infty}\frac{\tau^{j/2}}{j(\frac{1}{2}j-1)!} = a\exp\{\tau\}$$

a very simple result! Reverting to physical coordinates, we find

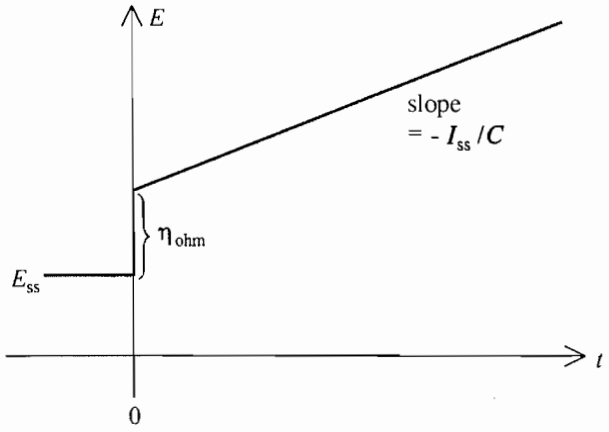
$$[48] \qquad \frac{c^s}{c^s_{ss}} = \exp\left\{\frac{-nFI_{ss}t}{CRT}\right\}$$

which shows that the surface concentration rises (recall that I_{ss} is negative) exponentially with time in this limiting case of our model. The Nernst relationship [34] then reveals a linear change in potential with time.

$$[49] \qquad E = E_{ss} - \frac{I_{ss}t}{C} - \eta_{ohm}$$

Result [49] is easily understandable. The small-a case that we are treating corresponds to a steady-state current on the limiting plateau, so that the potential may shift positively after interruption without diminishing the faradaic current significantly. This means that the nonfaradiac current discharging the double-layer capacitor also remains constant. The effect of passing a constant positive current through a negatively charged capacitor is to cause a steady positive shift in potential, at a rate proportional to the current but inversely proportional to the capacitance, which is just what eq. [49] states.

The fact that for both extreme values of a our general result, embedded in eqs. [24], [30], and [31], reduces to limiting forms that can be rationalized, gives confidence that the general result is also correct.



Short-time behaviour

The purpose of interrupting the steady-state current is to measure the ohmic polarization and to learn whatever else is accessible in the way of information about the electrode. This information must be gained from the behaviour of the potential relaxation in the rather short period of time during which the assumption of a linear concentration profile of unlimited

Fig. 1. Predicted chronopotentiogram from interruption of a steady-state current of magnitude close to the limiting current.

extent remains credible. In this section we briefly describe how information might be extracted from the chronopotentiogram. Of course, an exact method might be based on the full equation, but this would involve repeated or recursive computation in an attempt to match the experimental curve to the theoretical model.

If the steady-state current I_{ss} is close to the limiting current, so that a is small, the problem is simple because eq. [49] applies. If the potential is plotted versus time, before and after interruption, a graph resembling Fig. 1 should be created, from which the ohmic polarization η_{ohm} and the double-layer capacitance C are easily calculable.

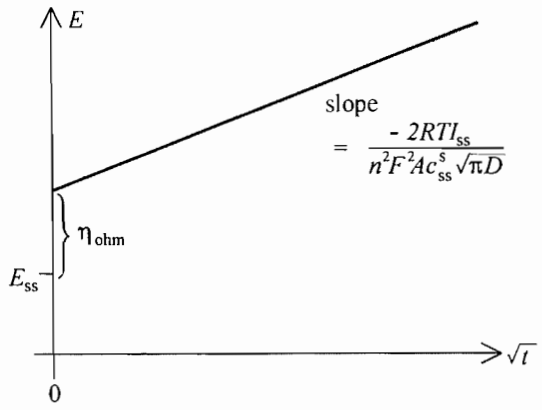
The problem may be considerably more difficult when it is eq. [43] that applies. One approach is to ignore all but the first two right-hand terms and reorganize the equation into the form

$$[50] \qquad \frac{c^s}{c^s_{ss}} = \frac{\varsigma}{a} = 1 + \frac{2}{a}\sqrt{\frac{\tau}{\pi}}$$

Then, with the help of eqs. [5] and [7]

$$[51] \qquad E = E_{ss} - \eta_{ohm} + \frac{RT}{nF} \ln\left\{1 + \frac{2}{a}\sqrt{\frac{\tau}{\pi}}\right\}$$

In light of the magnitude calculated in eq. [45] it may, or may not, be legitimate to regard $(2/a)\sqrt{\tau/\pi}$ as small in comparison with unity. If it is, then



$$[52] \qquad E = E_{ss} - \eta_{ohm} + \frac{2RT}{nFa}\sqrt{\frac{\tau}{\pi}}$$

$$= E_{ss} - \eta_{ohm} - \frac{2RTI_{ss}}{n^2F^2Ac^s_{ss}}\sqrt{\frac{t}{\pi D}}$$

and a graph of the potential E versus the square-root of time will have the characteristics shown in Fig. 2. If not, a less attractive method is needed to analyze eq. [51]. One such relies on pairs of (E,t) data. From these one calculates

$$[53] \qquad c^s_{ss} = \frac{2I_{ss}}{nFA\sqrt{\pi D}} \frac{\varepsilon\sqrt{t_1} - \sqrt{t_2}}{\varepsilon - 1}$$

Fig. 2. Method of analyzing potential-versus-time data for certain cases (see text) of interruption of currents not close to the limiting current.

and

$$[54] \qquad \eta_{ohm} = E_{ss} - E_1 + \frac{RT}{nF} \ln\left\{\frac{\sqrt{t_2} - \sqrt{t_1}}{\sqrt{t_2} - \varepsilon\sqrt{t_1}}\right\}$$

where

$$[55] \qquad \varepsilon = \exp\left\{\frac{nF}{RT}(E_2 - E_1)\right\}$$

Summary

The interruption of a steady-state reductive current at a reversible electrode leads to a sudden positive jump in potential followed by a more gradual potential relaxation. We have derived a series solution describing the course of the relaxation and have investigated some of its limiting cases.

The influence of a non-micelle-forming surfactant on the electrocatalytic hydrogenation of carvone and limonene in aqueous medium at Raney nickel electrodes[1]

Valérie Beraud, Jean Lessard, and Marc Thomalla

Abstract: The electrocatalytic hydrogenation (ECH) of carvone (**1**) and limonene (**8**) at a Raney nickel cathode was studied in aqueous solutions containing a non-micelle-forming surfactant (didodecyldimethylammonium bromide, DDAB). The efficiency of ECH of these substrates was markedly increased compared to that observed previously with micelle-forming surfactants, and this for very low DDAB concentrations, as a consequence of the strong adsorption of DDAB on the electrode. For the ECH of **8** in basic medium (pH 10), the major part of organic compounds (60–95%) was shown to be adsorbed on the electrode surface as an organic layer stabilized by an interfacial film of DDAB.

Key words: electrocatalytic hydrogenation, limonene, carvone, surfactant, emulsions, Raney nickel cathodes.

Résumé : L'hydrogénation électrocatalytique (HEC) de la carvone (**1**) et du limonène (**8**) sur cathode de nickel de Raney a été étudiée en solutions aqueuses contenant un surfactant non micellisable (bromure de didodécyldiméthylammonium, DDAB). L'efficacité de l'HEC de ces composés augmente fortement par rapport à celle observée antérieurement en présence de surfactants micellisables et ceci pour de très faibles concentrations en DDAB. Ceci résulte de la forte adsorption de ce type de surfactant sur l'électrode. Dans le cas du limonène en milieu alcalin (pH 10), la majeure partie (60–95%) des composés organiques se retrouve adsorbée sur l'électrode sous forme d'une couche organique stabilisée par un film interfacial de DDAB.

Mots clés : hydrogénation électrocatalytique, limonène, carvone, surfactant, émulsions, cathodes de nickel de Raney.

Introduction

Electrocatalytic hydrogenation (ECH) at Raney nickel electrodes constitutes a useful method of carrying out the hydrogenation of a variety of unsaturated organic compounds under mild conditions (1). Previous studies have shown that surfactants (especially cationic ones) strongly enhance the extent and the efficiency of the electrocatalytic hydrogenation of unsaturated organic compounds emulsified in an aqueous electrolyte. The conversion rate, the chemical and current yields, and the percentage of fully hydrogenated products were higher in aqueous electrolytes containing a surfactant (emulsified or micellar solutions) than in homogeneous hydroorganic solutions (2).

Surfactants can influence the ECH in two ways: (*i*) by increasing the substrate solubility in the whole bulk; (*ii*) by the formation of an adsorbed hydrophobic surfactant layer on the cathode. In the first, the increase of substrate solubility results from its association with the micelles. This occurs only for surfactant concentrations higher than the critical micellar concentration (CMC). In the second, incorporation of the substrate in a hydrophobic layer enhances its adsorption on the cathode and this is operative over the whole range of surfactant concentrations used, including concentrations lower than the CMC. An increase of the local substrate concentration on the catalyst seems to be the main effect of surfactant on the ECH of organic compounds, as shown by the ECH of carvone in emulsions (2). The largest extent and highest efficiency of hydrogenation of carvone were obtained with cetyltrimethylammonium bromide (CTAB) at concentrations lower than the CMC (2). Under those conditions, micelles are not formed and the effect observed on ECH can result only from the presence of a hydrophobic layer on the cathode (2). However, when the surfactant concentration increases, the efficiency of the ECH depends on the solubilization equilibrium between the hydrophobic surfactant layer and the micellar pseudophase. This led to a decrease of the efficiency of the ECH of limonene and carvone at higher surfactant concentrations (2).

In this work, the ECH of carvone (**1**), D-limonene (**8**), and *p*-menthene (**9**) (Fig. 1) was measured in the presence of didodecyldimethylammonium bromide (DDAB). This surfactant, poorly soluble in water (10^{-4} M), does not form micelles, but is strongly adsorbed at the interface, leading to multilayers

Fig. 1. Structure of substrates and reaction products.

when its concentration increases (3, 4). This property was previously used by Rusling and co-workers (5–7) to enhance the local concentrations of both reactants and mediator on the surface of electrodes for reductive dehalogenation. Thus, in the presence of DDAB, it was possible to study the influence of surfactant adsorption on the ECH of an organic compound in the absence of any micellar effect.

Experimental

Reagents

Some commercially available compounds were used as received: D-limonene (98%) from Eastman Kodak, (+)-*p*-menthene (99%) from Fluka, didodecyldimethylammonium bromide (DDAB) (98%) from Aldrich. Water and (−)-carvone (98%) obtained from Jansen Chimica were distilled before use. Buffers were prepared as described in the *Handbook of chemistry and physics* (8).

Electrolyses

The electrochemical apparatus, the cell, the preparation of Raney Ni electrodes, and the electrolysis procedure have been described previously (1, 2, 9). The electrolysis conditions and the catholyte composition (volume of 100 mL) are indicated in the footnotes of the tables. The anolyte consisted of a 0.1 M H_2SO_4 aqueous solution.

Products

The work-up procedure was the same as that reported in ref. 9. However, taking representative aliquots was not possible in emulsions and therefore the entries in Table 4 correspond to different electrolyses. Yields and product distributions were determined by vapour phase chromatography (VPC), as described in ref. 2, on capillary polar columns (DB-Wax 30 m or DB-5 DE 15 m) using a Varian 3300 or a Hewlett Packard 3390 A chromatograph equipped with a flame ionization detector and nonane (99%, Aldrich) as internal standard. The compounds adsorbed on the cathode were recovered by dipping the electrode in dry ether immediately after the electrolysis and keeping it in the solvent overnight. The cathode was then carefully rinsed several times with dry ether.

Results and discussion

ECH of carvone (1)

In emulsions with DDAB 7.7×10^{-5} M, at pH 2 and 10, after a charge of 6 F mol^{-1}, all the carvone was consumed and a mixture of carvomenthone (**2**), saturated alcohols (**3–6**) and carvacrol (**7**) was obtained (Table 1, entries 1 and 2). In acidic solution (entry 1), the yield of products and the current efficiency were close to those previously obtained with CTAB at similar concentrations (8.2×10^{-5} M)[3] (see entry 3). Lower yields of alcohol and lower current efficiencies were observed at pH 10 (entry 2) as a consequence of the formation of higher amounts of carvacrol. At pH 2, carvacrol can result from acid-catalyzed isomerization of carvone and (or) from enolization and isomerization of the exocyclic double bond through sequential dehydrogenation–hydrogenation. At pH 10, the isomerization of carvone to carvacrol should occur only through a sequential dehydrogenation–hydrogenation process. The latter is faster under alkaline conditions (10, 11*a*), which can explain the higher yield of carvacrol observed at pH 10.

At pH 2, the current efficiency, which is a measure of the competition between substrate hydrogenation (reactions [2]–[4]) and hydrogen evolution (reactions [5]), was higher when a surfactant was present (86–87% with DDAB or CTAB, see entries 1 and 3, respectively) than in the absence of surfactant (77%, entry 4) and was the same with either surfactant.

to-ketone ratio ((**3** + **4** + **5** + **6**) / **2**) was much higher in the presence (ratio of 21–86, entries 1–3) than in the absence of a surfactant (ratio of 2.5, entry 4).Therefore surfactant adsorption strongly enhances the extent of hydrogenation and, in agreement with the stronger adsorption of DDAB with respect to CTAB (3, 4), higher extents of hydrogenation were observed with DDAB (alcohols/ketones ratio of 86 at pH 2 and 45 at pH 10, entries 1 and 2) than with CTAB (ratio of 21 at pH 2, entry 3).

Concerning the stereochemistry of the ECH of carvone (**1**), the presence of DDAB had no significant influence, as was observed with CTAB (2). Indeed, within experimental error, the relative proportions of the isomeric alcohols (**3–6**) were nearly the same in the presence (Table 2, entries 1–3) and in the absence (entry 4) of surfactant, as seen also in the ratio of isomers with the methyl and isopropyl groups *trans* (alcohols **3** and **4**) to the ratio of isomers with the two substituents *cis* (alcohols **5** and **6**).

ECH of *D*-limonene (8) and *p*-menthene (9)

In the ECH of carvone (**1**) in emulsions, small amounts of a surfactant do significantly improve the efficiency and, in particular, the extent of hydrogenation as seen above. However, due to the easy hydrogenation of carvone and except for the extent of hydrogenation, which was larger with DDAB, the improvement was about the same with the two surfactants (DDAB and CTAB).

To see if DDAB is really more effective than CTAB, a study of the ECH of a substrate more difficult to hydrogenate than carvone, namely limonene (**8**), was carried out in emulsions with and without a surfactant. The results are summarized in Tables 3–5 and Figs. 2 and 3.

In the presence of various concentrations of DDAB, at pH 10, the ECH of limonene gave a mixture of *p*-menthene (**9**), *p*-menthane (**10**) (*cis* + *trans*), *p*-cymene (**11**) resulting from isomerization–dehydrogenation of limonene, and two unidentified products (**X**). The latter have the same mass as *p*-menthene (**9**) and thus could result from its isomerization.

Five main points can be drawn from the results:

1. As previously shown (and discussed) (2), the ECH of limonene (**8**) emulsified in an aqueous buffer without a surfactant did not occur at all, owing to the poor solubility of this substrate. However, a very low concentration of DDAB (6.5 × 10^{-5} M, i.e., 30 mg dm^{-3}) allowed the hydrogenation reaction to occur (Table 3,entry 1). At this concentration, DDAB is entirely soluble and the association between the surfactant and the substrate can be neglected because the number of substrate molecules is 300 times as large as that of surfactant molecules. Thus the occurrence of hydrogenation results only from the surfactant adsorption on the cathode and the association of limonene with this hydrophobic layer and not from an increase of the solubility of limonene in the bulk solution.
2. Concerning the stereochemistry of the ECH of limonene (**8**), the *trans* isomer of *p*-menthane (**10**) is slightly predomi-

nant. Over the whole range of DDAB concentrations used, the *cis*/*trans* ratio is constant (0.83 ± 0.07) (Table 3). This behavior is different from that observed in the cationic micellar solutions (CTAB or CTACl) in which the *cis*/*trans* ratio varied (0.59–0.85) with the surfactant concentration (2).

3. DDAB adsorption favors the hydrogenation process (reactions [2]–[4]) over hydrogen evolution (reactions [5]) as shown by the following observations. (*i*) In the whole range of DDAB concentrations (Table 3, entries 1–11), except for the three lowest ones (entries 1–3), the current efficiency is constant (60–70%) within experimental error and is higher than the efficiencies observed in homogeneous hydroorganic solutions or in micellar systems, namely, 18–48% (2). As the DDAB concentration increases from 6.5×10^{-5} to 2.7×10^{-4} M (entries 1–4), the overall chemical yield of *p*-menthene (**9**) and *p*-menthane (**10**) reaches a high value (84%) that remains nearly constant (82 ± 8%) upon increasing the concentration further (entries 4–11, see also Fig. 2). With CTAB, the maximum overall yield of hydrogenated products (90 ± 10%)[4] was obtained at much higher surfactant concentrations (90–200 times higher, namely, 2.5×10^{-2} and 5.5×10^{-2} M) than with DDAB (2.7×10^{-4} M). Thus, in regard to the competition between hydrogen evolution and limonene (**8**) hydrogenation (i.e., the ECH efficiency), DDAB is much more efficient than CTAB. This is also clearly evident by comparing the ECH of limonene in emulsions containing similar concentrations of DDAB and CTAB (1.5×10^{-3} M), other things being equal (entries 9 and 12). Indeed, the current efficiency (13%), product yield (19%), and percentage of limonene consumed (20%) were much lower with CTAB (entry 12) than with DDAB (respectively 65%, 93%, and 97%) (entry 9). (*ii*) The extent of hydrogenation, which is measured by the molar fraction of *p*-menthane (**10**) relative to the total amount of hydrogenated products (**9** + **10** + **X**), also depends on the competition between hydrogenation and hydrogen evolution and thus is a measure of the efficiency of ECH. This molar fraction is highest for DDAB concentrations varying between 6.5×10^{-4} and 10.8×10^{-4} M (Fig. 3) and is close to 1 (0.97–0.99). With CTAB, the highest value of this molar fraction is 0.8, but was obtained only at the lowest surfactant concentration (1.5×10^{-3} M), which gave the worst ECH efficiency (current efficiency of 11 ± 1%, overall yield of products of 17 ± 3% with only 38 ± 2% of limonene consumed) (2). (*iii*) Thus, the efficiency and the extent of the ECH of limonene is much higher in DDAB emulsions than in CTAB micelles. With DDAB this

[4] The yield is slightly higher than that obtained with DDAB owing to the formation of *p*-cymene (**11**) in the presence of DDAB. *p*-Cymene was not hydrogenated under the experimental conditions used.

can result only from the adsorption of the surfactant on the cathode owing to the absence of micelles and the low concentrations of DDAB used.

4. The extent of hydrogenation also depends on the DDAB concentration. Indeed the molar fraction of *p*-menthane varies between 0.7 and 0.9 when the surfactant concentration is increased from 6.5×10^{-5} to 4×10^{-3} M with a maximum of 0.99 at a DDAB concentration of 8.6×10^{-4} M (Fig. 3). As previously discussed for the cationic micellar systems (2), this variation can be interpreted as a competition between the hydrogenation of limonene (**8**) to *p*-menthene (**9**) and the hydrogenation of **9** to *p*-menthane (**10**). This competition depends on two parameters. Firstly, in agreement with literature results (11*b*, 12, 13), the hydrogenation of the trisubstituted endocyclic carbon–carbon double bond is more difficult than that of the exocyclic disubstituted one. Indeed, the ECH of **8** follows the sequence **8** ⇒ **9** ⇒**10** as shown by the variation of product distribution during the electrolysis (Table 4). After 1 F mol^{-1}, very little *p*-menthane (**10**) is formed (7%) and the major product is *p*-menthene (**9**) (46%) (entry 1). After 2 F mol^{-1}, *p*-menthane becomes the major product (40%) (entry 2). Secondly, the relative rates of ECH of **8** and **9** depend on the relative amounts of **8** and **9** adsorbed on the catalyst, which is discussed below.

5. The high catalytic efficiency of the Raney nickel cathode in the presence of DDAB is also confirmed by a comparison of the ECH of *p*-menthene (**9**) in cationic micellar solutions (CTAB) and in emulsions with DDAB for surfactant concentrations leading to the highest ECH efficiency with limonene (**8**). In emulsions with a small amount of DDAB (8.6×10^{-4} M) (Table 5, entries 1 and 2), the hydrogenation of **9** to *p*-menthane (**10**), in high yields (69–81%) and with good current efficiencies (65–69%), required only a slight excess of electricity (2–2.5 F mol^{-1}), the theoretical amount being 2 F mol^{-1}, whereas in cationic micelles (5.5×10^{-2} M CTAB, entry 3), a large excess of electricity (7 F mol^{-1}) was required to convert only 60% of *p*-menthene (**9**), resulting in a very low current efficiency (18%). According to previous studies (2), this cannot be attributed to a pH effect.

Study of adsorption phenomena

The adsorption phenomena have been studied, during the ECH of limonene (**8**), by measuring both the amount of limonene and hydrogenation products (**9** + **10** + **11** + **X**) adsorbed on the electrode and the amount of all these compounds present in the bulk solution (see Experimental). The measurements were made after a charge corresponding to 25% (1 F mol^{-1}) of the theoretical amount of electricity and at the end of electrolysis (5 F mol^{-1}). The concentration of limonene was kept constant at 1.78 × 10^{-2} M and the concentration of DDAB was varied from 1.3 × 10^{-4} to 4.4 × 10^{-3} M.

As seen in Fig. 4, for all surfactant concentrations and irrespective of the charge passed, the major part of the organic compounds (substrate and products) is in the surfactant layer on the cathode. This part increases with the DDAB concentration (the amount in solution decreasing accordingly) and reaches a plateau at a DDAB concentration close to 8.5 × 10^{-4} M. After a charge corresponding to 1 F mol^{-1}, limonene (**8**) and *p*-menthene (**9**) represent the major part (75–80%) of the adsorbed compounds (see Table 6, entries 1–4). The DDAB concentration (from 0.13 to 1.08 mM) has little influence on the distribution of limonene (**8**) between the surfactant layer on the electrode surface and the bulk solution, as shown by the small variation of the ratio of the amount of **8** in the surfactant layer adsorbed on the cathode to the amount of **8** in the bulk solution: 0.8 to 2 (entries 1–4). On the other hand, this ratio for *p*-menthene (**9**) increases significantly with the surfactant concentration, from 9 to 85 (entries 1–4). This indicates a preferential absorption of **9** in the surfactant layer on the electrode, which favors its hydrogenation and, hence, leads to the increase of the molar fraction of *p*-menthane (**10**) upon increasing the concentration of DDAB, as already mentioned (see point 4 above). At the end of the electrolysis (after 5 F mol^{-1}), the adsorbed surfactant layer contains mainly *p*-menthane (**10**) (82–95%, see Table 6, entries 5–9), the proportion of which decreases from 95 to 83% upon increasing the concentration of DDAB from 0.26 to 1.08 M and remains constant (83–85%) with further increase of the surfactant concentration to 4.42 M.

It is noteworthy, as shown in Fig. 5, that the amount of organic compounds adsorbed on the cathode is much larger than the total amount of DDAB for all surfactant concentra-

tions studied. This strongly suggests that there is, on the cathode, an organic layer stabilized by an interfacial film of DDAB. Such a structure corresponds to a microemulsion.

Conclusion

In emulsified solutions, the presence of a non-micelle-forming surfactant at very low concentrations strongly increases the adsorption of organic compounds (formation of a microemulsion on the cathode). As a consequence, the hydrogenation reaction (eq. [3]) is favored over hydrogen evolution (eqs. [5]) and the efficiency and the extent of ECH of an unsaturated organic compound is markedly increased.

Electrochemical characterization in nonaqueous electrolyte of polyaniline electrochemically prepared from aqueous media[1]

Béatrice Garcia, Florence Fusalba, and Daniel Bélanger

Abstract: Polyaniline film electrodes were characterized in nonaqueous electrolyte following their electrochemical preparation in aqueous media. More specifically, polyaniline films were deposited galvanostatically at the surface of platinum or gold electrodes by anodic electrochemical polymerization from a 0.5 M aniline – 1 M HCl aqueous solution. The polyaniline film electrode was then dried and its electrochemical behavior was evaluated in nonaqueous electrolyte ($LiClO_4$–acetonitrile). Stable cyclic voltammograms were recorded between −0.1 and 1 V in the nonaqueous media, which represents a much wider range than in aqueous acidic media. In the latter case the positive potential limit must be restricted to about 0.7 V in order to avoid oxidative degradation of the polymer. Electrochemical impedance spectroscopy was used to determine the charge capacity of the polyaniline film electrode as a function of film thickness and electrode potential. A linear relationship was observed between the low-frequency capacitance of the polyaniline electrode and the amount of deposited polymer (e.g., charge used to grow the polymer). This indicates that even for the thickest film (deposited charge of 10 C/cm^2) most of the polyaniline is electrochemically accessible at the low frequency of 5 mHz. The thinnest polyaniline film electrode (deposited charge of 0.2 C/cm^2) was also characterized by the electrochemical quartz crystal microbalance technique and it was found that ionic transport is dominated by the movement of anions.

Key words: conducting polymer, polyaniline, nonaqueous electrolyte, capacitance, electrochemical impedance spectroscopy, cyclic voltammetry, electrochemical quartz crystal microbalance.

Résumé : Des électrodes à film de polyaniline préparées d'une façon électrochimique en milieu aqueux ont été caractérisées dans un électrolyte non aqueux. Plus spécifiquement, on a déposé d'une façon galvanostatique des films de polyaniline à la surface d'électrodes de platine ou d'or en procédant à une polymérisation électrochimique anodique à partir d'une solution aqueuse d'aniline 0,5 M contenant du HCl à 1 M. On a alors séché l'électrode à film de polyaniline et on a évalué le comportement électrochimique dans un électrolyte non aqueux ($LiClO_4$–acétonitrile). On a enregistré des voltammogrames cycliques stables entre −0,1 et 1 V dans le milieu non aqueux; ceci correspond à une plage beaucoup plus étendue qu'en milieu acide. Dans le dernier cas, la limite positive du potentiel devrait être fixée à environ 0,7 V si l'on veut éviter la dégradation oxydante du polymère. On a utilisé la spectroscopie d'impédance électrochimique pour déterminer la capacité de charge de l'électrode à film de polyaniline en fonction de l'épaisseur du film et du potentiel de l'électrode. À basse fréquence, on a observé une relation linéaire entre la capacitance de l'électrode à polyaniline et la quantité de polymère déposé (par exemple, la charge utilisée pour faire croître le polymère). Ceci indique que, même pour le film le plus épais (déposé à une charge de 10 C/cm^2), presque toute la polyaniline est électrochimiquement disponible à des fréquences aussi basses que 5 mHz. On a aussi caractérisé l'électrode à film de polyaniline la plus mince (déposée à une charge de 0,2 C/cm^2) par la technique de la microbalance électrochimique à cristal de quartz et on a trouvé que le transport ionique est dominé par le mouvement des anions.

Mots clés : polymère conducteur, polyaniline, électrolyte non aqueux, capacitance, spectroscopie à impédance électrochimique, voltammétrie cyclique, microbalance électrochimique à cristal de quartz.

Introduction

Conducting polymers such as polypyrrole, polyaniline, and polythiophene have been recently proposed as active electrode material for electrochemical supercapacitors (1–3) because of their high charge density (which can be stored in the volume of the polymer layer), fast charge/discharge kinetics, and their low cost. Gottesfeld and co-workers at Los Alamos were the first to recognize that conducting polymers could be used as active material in electrochemical supercapacitors and have proposed a classification for such supercapacitors, which are of three types, designated I, II, and III (1). Type I supercapacitors are based on p-dopable materials such as polyaniline, polypyrrole, or polythiophene as both active anode and cathode and typically yield low cell voltage that is limited by the range of potential over which the polymer is electroactive. Type II is an unsymmetrical supercapacitor in which two p-dopable polymers are characterized by the difference in the potential range over which they can be p-doped (for example polypyrrole with polythiophene). Type III is a high cell voltage supercapacitor by virtue of the difference in potential between n- and p-doping of a polymer that is used for both electrodes.

Polyaniline was previously tested as active material in a Type I symmetrical electrochemical supercapacitor consisting of two polyaniline electrodes and an acid electrolyte (4). Although the charge/discharge behavior and the long-term stability of such a supercapacitor are quite good, its major drawback lies in its low cell voltage. Polyaniline is usually prepared by chemical or electrochemical polymerization in highly concentrated acidic media (5, 6). It is well known that polyaniline degrades under anodic polarization more positive than about 0.8 V vs. SCE (5). However, this limit can be extended to higher potential value if the potential cycling is carried out in nonaqueous media (7–14) and thus could lead to a higher cell voltage for the supercapacitor.

In this paper, we have investigated the effect of film thickness on the electrochemical behavior of polyaniline electrodes, prepared in acidic media, by cyclic voltammetry, electrochemical impedance spectroscopy, and the electrochemical quartz crystal microbalance technique in a nonaqueous electrolyte. Our results indicate that the low-frequency capacitance of the polyaniline film increases linearly with the charge used to grow the film from 0.2 to 10 C/cm^2 and that the ionic transport is dominated by the movement of anions. The loss of charge observed when the polyaniline film was transfered from the aqueous to the nonaqueous medium is due to the fact that the polyaniline film is more compact (less swollen) than in aqueous media.

Experimental

Chemicals

All products were used as received except for aniline, which was freshly distilled before use. Acetonitrile was distilled over CaH_2 prior to use.

Procedure and equipment

The working electrode was a platinum disk (diam. = 1 mm) sealed into a glass tube or epoxy. The platinum disk electrode was polished with a diamond polishing compound to the 1 μm level and then to the 0.05 μm level with aqueous alumina slurry (Techmet, Canada). Platinum gauze and an Ag/AgCl (3 M NaCl) electrode were used as counter and reference electrodes, respectively. All potentials were reported versus the Ag/AgCl reference electrode. Electrochemical measurements were carried out in a one-compartment cell using the three-electrode configuration.

Polyaniline films were prepared galvanostatically from aqueous media (0.5 M aniline + 1 M HCl – H_2O) at a current density of 5 mA/cm^2 (4). Films with deposited charge of 0.2, 1, and 10 C/cm^2 were grown. The as-grown polyaniline electrodes were rinsed with water and a slight jet of acetone. Following that, the electrodes were dried under vacuum at 100°C for 2 days. The electrodes were subsequently tested in a non-aqueous solution consisting of 0.1 M $LiClO_4$ – acetonitrile, except for the electrochemical quartz crystal microbalance experiments for which 0.5 M $LiClO_4$ – acetonitrile was used.

Cyclic voltammetry was performed using either a potentiostat/galvanostat model M273 (EG&G Princeton Applied Research) or an electrochemical interface SI1287 (Solartron Instruments) interfaced with a PC, and the electrochemical set-ups were controlled with the model M270 (EG&G) and DC Corrware (Scribner Associates, version 1.2) software, respectively. Electrochemical impedance experiments were done with an electrochemical interface SI1287 and a frequency response analyser SI1255 (Solartron Instruments) controlled by the Zplot software (Scribner Associates, version 1.2). The impedance measurements were performed at various electrode potentials in the frequency range 65 kHz – 0.05 Hz (except for the 10 C/cm^2 thick film for which the low-frequency limit was 0.005 Hz) using an amplitude of 10 mV for the sine wave.

The electrochemical quartz crystal microbalance (EQCM) system consists of the model EQCN-500 electrochemical quartz crystal nanobalance (Elchema, Potsdam, N.Y.) and a model RDE-4 bipotentiostat (Pine Instruments Inc., Grove City, Pa. and a Kipp and Zonen BD91 *x-y-y′* recorder. A gold-coated 10 MHz AT-cut quartz crystal (International Crystal Mfg. Co. Inc., Oklahoma City, Okla.) was used as working electrode. It was sealed to a 20 ml glass cell by Tub&Tile Silicone Sealant (Canadian Tire Corp., Toronto, Ont.). The geometric area of this working electrode was about 0.25 cm^2. The gold electrode was initially treated to clean its surface by potential cycling between 0 and 1.5 V in 0.1 M aqueous $HClO_4$. The surface area of the electrode was determined by measuring the charge involved in the reduction of gold oxide (generated at 1.2 V vs. SCE) by assuming that a charge of 400 μC/cm^2 and 2 electrons are required per gold atom (15). The microbalance was calibrated by electrodeposition of silver from a 1 mM $AgNO_3$ – 0.2 M H_2SO_4 aqueous solution at 0 V vs. SCE and had an absolute sensitivity of 1.1 ng/Hz.

Results and discussion

Cyclic voltammetry

Figure 1 shows the typical cyclic voltammogram in 1 M HCl – H_2O at a scan rate of 100 mV/s for a polyaniline film electrode grown from acidic media for a charge of 0.2 C/cm^2. The cyclic voltammogram is characterized by a first oxidation wave at about 0.2 V, corresponding to the interconversion between the fully reduced and semiquinone forms, and a second main wave

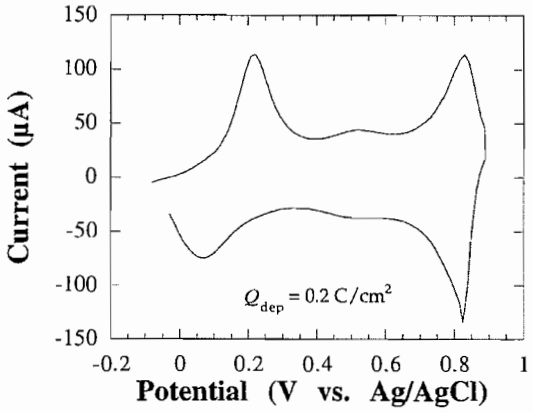
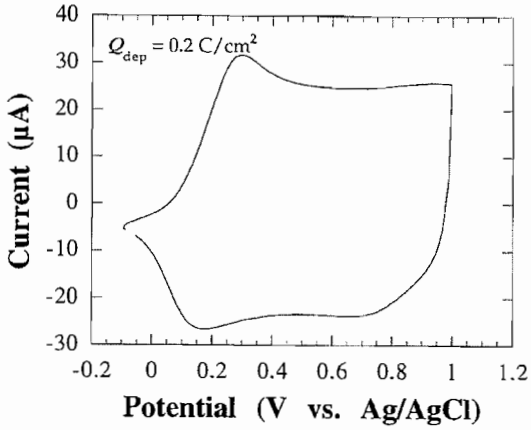
Fig. 1. Cyclic voltammetry of a polyaniline (0.2 C/cm^2) electrode in 1 M HCl – H_2O at a scan rate of 100 mV/s.





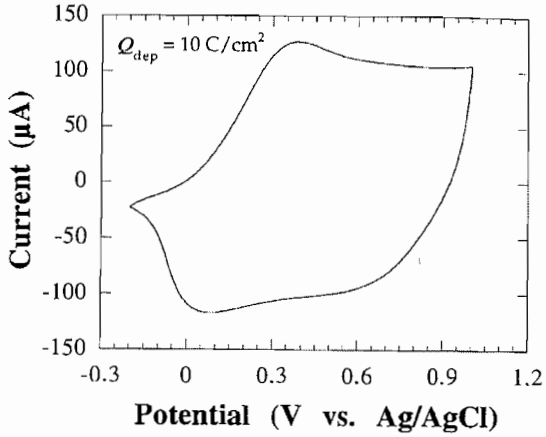


Fig. 2. Cyclic voltammetry of a polyaniline (0.2 C/cm^2) electrode in 0.1 M $LiClO_4$ – acetonitrile at a scan rate of 100 mV/s.

at ca. 0.8 V, related to the interconversion between the semiquinone and fully oxidized forms of polyaniline (6). A small wave attributed either to redox reactions of polyaniline degradation products or to phenazine rings originating in polyaniline from its polymerization is also observed at 0.6 V (5).

Following this initial characterization in acidic media the polyaniline electrodes were dried under vacuum at 100°C for 2 days and soaked in the acetonitrile solution. The cyclic voltammogram of such polyaniline electrodes in 0.1 M $LiClO_4$ – acetonitrile is illustrated in Figs. 2 and 3 for films grown with charge of 0.2 and 10 C/cm^2, respectively. The cyclic voltammogram illustrated in Fig. 2 for the thinnest film (0.2 C/cm^2) shows an oxidation wave at 0.3 V and a fairly high and constant current value is maintained up to 1 V. Contrary to earlier reports (8, 14), a well-developed wave is not observed at the most positive potential. This particular aspect will be discussed further below. An increase of the potential peak separation between the anodic and cathodic peaks (ΔE_p = 340 mV) is clearly observed when the amount of deposited polyaniline is increased to 10 C/cm^2 (Fig. 3) even if a lower scan rate of 10 mV/s was used for the latter. A decrease of peak separation to 160 mV is noticed at a lower scan rate of 2 mV/s. The larger peak separation for the thicker film can be related to the effect

Fig. 3. Cyclic voltammetry of a polyaniline (10 C/cm^2) electrode in 0.1 M $LiClO_4$ – acetonitrile at a scan rate of 10 mV/s.

of the uncompensated resistance. On the other hand, the impedance data demonstrate clearly that the larger peak separation cannot be related to kinetic limitations (vide infra). Nonetheless, an increase of the current is noticeable, as would be expected for higher loading of polymer. The stability of the film subjected to prolonged potential scanning is good even though the positive limit was extended to 1 V. It is important to mention that such a high positive potential value cannot be achieved when a polyaniline electrode is cycled in acidic media, due to oxidative degradation of the polymer (5).

The electrochemical behavior of polyaniline in acidic media has been studied in great detail. However, the number of studies of polyaniline in nonaqueous media is quite scarce. This stems from the ease of polyaniline formation in acidic media. Two main approaches have been used to prepare polyaniline films to be used in nonaqueous media. The first one involves electrochemical preparation in aqueous acidic media, followed by a sequence of steps that are performed to remove the water present in the polymer film electrode after electropolymerization (7–9, 14). The second approach consists of electrochemical polymerization directly from nonaqueous media with or without addition of protons (10–13). The shape and the range of electroactivity of the polymer in the cyclic voltammograms reported in these studies (7–14) differ substantially. For example, the cyclic voltammetry data of Figs. 2 and 3 are in agreement with those reported by Yonezawa et al. (12*b*) and Fiordiponti and Pistoia (7) in 1 M $LiBF_4$ – propylene carbonate (PC) and 1 M $LiClO_4$ – PC-DME (dimethoxyethane), respectively. On the other hand, our cyclic voltammetry data differ from those reported by Daifuku et al. (14) and Desilvestro et al. (8), which were characterized by two pairs of redox waves. The reasons for the discrepancies between the cyclic voltammograms are unclear but they may simply reflect the fact that various growth conditions and treatment (drying procedures) are used before the electrochemical characterization of polyaniline in nonaqueous media. Thus, the variation in cyclic voltammetry behavior cannot be solely attributed to the fact that the resulting polyaniline film electrodes are cycled in different electrolytic solutions.

A comparison of the charge that can be electrochemically addressed during cyclic voltammetry, Q_{cv}, for a polyaniline electrode in aqueous acidic (see Fig. 1) and organic (Fig. 2)

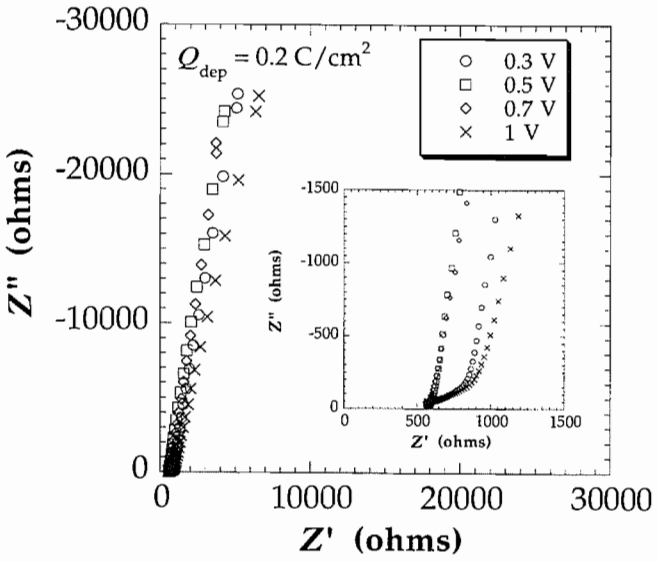

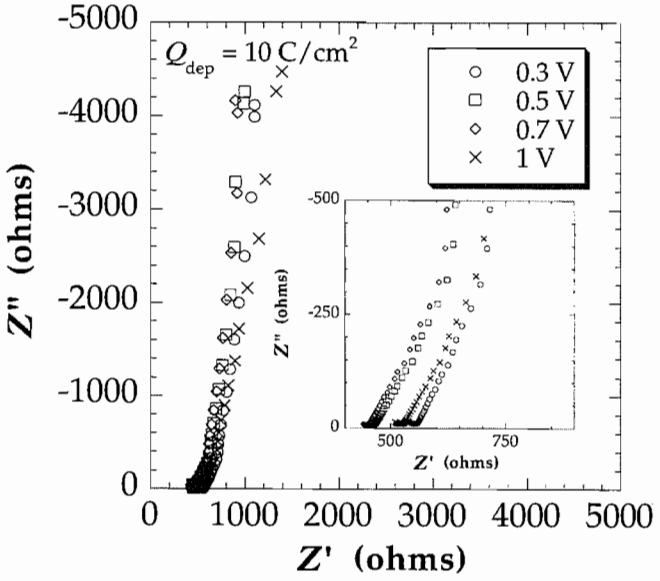

Fig. 5. Impedance plot for a polyaniline (10 C/cm^2) electrode at various potentials in 0.1 M $LiClO_4$ – acetonitrile. Frequency range = 10 kHz–5 mHz. Inset: High-frequency data of the impedance plot.

electrolytes indicates that the charge decreases in the nonaqueous electrolyte. For example, integration of the cyclic voltammograms of Figs. 1 and 2 yields Q_{cv} values of 0.06 and 0.032 C/cm^2 for the aqueous and nonaqueous electrolytes, respectively. Typically, a loss of charge ranging from 25 to 50% is found when polyaniline films, subjected to the drying procedure described in the experimental section, are transferred from aqueous to nonaqueous electrolyte. The decrease in the voltammetric charge contrasts with the results reported by Desilvestro et al., who found that the charge in nonaqueous media amounts to 189% of the value determined from aqueous solutions (8). The decrease of the charge can be ascribed to the fact that the polymer is much less solvated and is swollen to a lower extent in nonaqueous media, which translates to a lower voltammetric charge. To confirm that degradation of the polymer does not occur during the heat treatment, a cyclic voltammogram was recorded in the acidic solution, instead of the nonaqueous electrolyte, after heat treatment. In this case, a slight loss of charge (5–10%) was typically observed, thus confirming that the heat treatment cannot explain the larger decrease (25–50%) of the voltammetric charge. In addition, the voltammetric charge, initially found in acidic media, was restored after heat treatment and cycling in nonaqueous media when the polyaniline electrode was tested again in the acidic electrolyte.

Electrochemical impedance spectroscopy

Electrochemical impedance spectroscopy was used to characterize the polyaniline film electrode in nonaqueous media. Impedance spectra (Z'' vs. Z') measured at various potentials are shown in Figs. 4 and 5 for polyaniline film electrodes grown with a charge of 0.2 and 10 C/cm^2, respectively. For both film thicknesses, the low-frequency data of the impedance plot for the oxidized polyaniline (Nyquist plot) form a straight line that corresponds to capacitive behavior. It should be noted that a 90° line is not observed, as expected for purely capacitive behavior. This is typical behavior for conducting polymer electrodes and is probably due to nonuniform film thickness (16, 17). The inset of Fig. 4 also shows that the real axis intercept at high frequency is independent of potential (between 0. 3 and 1 V). The intercept coincides with the value obtained with a bare Pt electrode (not shown) and represents the uncompensated resistance of the solution. Since the electronic conductivity of oxidized polyaniline is very high (18), the impedance data suggest that the ionic resistance of the polymer increases when the polyaniline electrode is set at either 0.3 or 1 V (19). The Nyquist plot for the thicker film (10 C/cm^2) in the oxidized state (electrode potential between 0.3 and 1 V) does not show a semicircle at higher frequency that could be related to a charge transfer resistance (with an additional double-layer capacitance) at the electrode–polymer interface. On the other hand, a semicircle is observed on the Nyquist plot (not shown) when the electrode potential has been set before the onset of electroactivity of polyaniline; e.g., at a potential of 0.1 or −0.1 V. These impedance plots are in agreement with those previously reported for polyaniline in mixtures of nonaqueous solvents (7). The inset of Fig. 5 shows that the impedance plot shifts to higher real impedance values for electrode potentials of 0.3 and 1 V, indicating that the electronic resistance of the polyaniline layer is higher at these potentials (19). This supports the hypothesis that the increase of the potential peak separation when the film thickness is increased (from a 0.2 to a 10 C/cm^2 film) is due to the resistance of the polyaniline film.

A plot of the imaginary impedance vs. the reciprocal of the frequency (Z'' vs. $1/f$) is linear (Fig. 6) and the slope of this plot yields the low-frequency capacitance, C_{LF}, of the polyaniline electrode ($C_{LF} = (2\ \pi\ \text{slope})^{-1}$) (19, 20). The low-frequency capacitance values are collected in Table 1 for various deposited charges and electrode potentials. The low-frequency capacitance increases as the potential is made more positive than 0.1 V and reaches a nearly constant value between 0.3

Fig. 6. Plot of the imaginary impedance vs. $1/f$ from the data of Fig. 4 at a potential of 0.7 V. Frequency range corresponding to the $1/f$ data = 650–52 mHz.

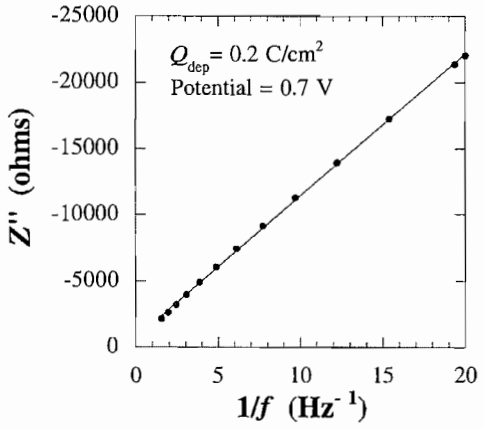

Fig. 7. Cyclic voltammogram and mass–potential plot for a polyaniline-coated gold electrode in 0.5 M $LiClO_4$ – acetonitrile at a scan rate of 10 mV/s. The deposited charge was 0.2 C/cm².

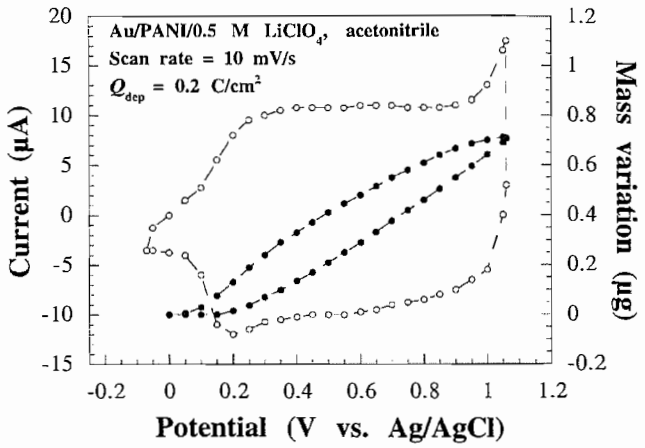

Table 1. Variation of the low-frequency capacitance, C_{LF}, of the polyaniline electrode in 0.1 M $LiClO_4$ – acetonitrile as a function of electrode potential and film thickness (deposited charge, Q_{dep}).

		C_{LF} (F/cm²)		
Potential, V	Q_{dep} (C/cm²):	0.2	1	10
0.1		0.015	0.11	0.75
0.3		0.017	0.10	1.01
0.5		0.018	0.11	0.97
0.7		0.018	0.11	1.0
1.0		0.016	0.10	0.94

and 0.7 V. Further increase of the potential to 1 V leads to a small decrease of the polymer capacitance. A substantial decrease of the low-frequency capacitance is found when the potential is made either more positive than 1 V or more negative than 0.1 V. A similar trend is seen for the three film thicknesses investigated in this study. Typically, the variation of the low-frequency capacitance (from electrochemical impedance) follows the shape of the cyclic voltammogram. The capacitance can be also calculated from the cyclic voltammetry data (capacitance = current/scan rate) (19, 20). As previously reported (20, 21), the capacitance values evaluated from the cyclic voltammetry data are consistently larger than those obtained from electrochemical impedance measurements. For example, a capacitance of 0.032 F/cm² at 0.3 V for the thinnest film (see Fig. 2) should be compared with the value of 0.017 F/cm² (see Table 1). A similar difference is obtained for the other film thicknesses investigated here. The discrepancy between capacitance values evaluated by both techniques has been attributed to conformation changes of the conducting polymer (20).

Table 1 also shows that the low-frequency capacitance scans linearly with the deposited charge for every potential for which low-frequency capacitance values are reported. The latter corresponds to the amount of polyaniline effectively deposited. This can be taken as an indication that the bulk of the polyaniline layer is electrochemically addressed in these experimental conditions. This behavior contrasts with that reported for poly-(3-methylpyrrole-4-carboxylic acid) for which lower capacitance values were calculated for the thinner films (17). The lower capacitance was related to a higher proportion of overoxidized sites in the thinner film. On the other hand, a similar linear relationship between C_{LF} and film thickness has also been reported for chloride-doped polypyrrole electrode (22). The C_{LF} values of Table 1 are in good agreement with those reported previously for polyaniline in acidic media (4). Moreover, they also compare favourably with that reported for a 52 μm thick polyaniline film electrode in 1 M $LiClO_4$ – PC-DME (7). For the latter authors, a value of 0.25 F/cm² can be computed from their data at 0.75 V (C_{LF} = 0.032 F/mg) for a 52 μm thick polyaniline film by taking a density of 1.2 g/cm³. This 52 μm thick film corresponds, in our case, to a deposited charge of ca. 4 C/cm² if we assume that a deposited charge of 20 C/cm² yields a 250 μm thick film (4). Thus, a low-frequency capacitance of 0.4 F/cm² (vs. 0.25 F/cm²) is expected in our case for a 52 μm thick film.

Electrochemical quartz crystal microbalance

The electrochemical quartz microbalance technique allows for the determination of the ionic species (and solvent) involved in the redox switching of electroactive polymer. Figure 7 shows the cyclic voltammogram and the mass–potential curve for a polyaniline film (deposited charge = 0.2 C/cm²) electrode in 0.5 M $LiClO_4$ – acetonitrile at a scan rate of 10 mV/s. The mass of the polyaniline film increases when the potential is scanned linearly from −0.1 to 1 V and decreases upon reduction of the polymer. This information suggests that anion transport is dominant in this system, the anions being inserted (mass increase) during oxidation and expelled (mass decrease) during reduction. Further analysis of the cyclic voltammetry and mass–potential data was carried out by plotting the variation of mass as a function of charge involved in the redox process (by integration of the cyclic voltammogram) to obtain the average molar mass of the chemical species involved. A value of 70 g/mol was computed and can be explained by the insertion of one perchlorate anion (100 g/mol), which is accompanied by the loss of 1.6 molecules of water (29 g). Our results

© 1997 NRC Canada

are in agreement with an in situ gravimetry study of polyaniline in nonaqueous electrolytes that also showed that the main-charge compensating process is the reversible insertion of anions (8, 14).

Concluding remarks

The results presented here indicate that polyaniline could be eventually used in a nonaqueous electrolyte-based electrochemical supercapacitor. The linear increase in the low-frequency capacitance with film thickness is attractive since high polymer loading is required to increase the energy density of a practical supercapacitor. A decrease in the capacitance of polyaniline is observed upon transfer of a film grown in aqueous media to nonaqueous electrolyte and is related to the fact that the polymer is more compact (less swollen). The development of a preparation procedure to obtain polyaniline film electrode with capacitance as high as in aqueous acidic media is currently under investigation in our laboratory.

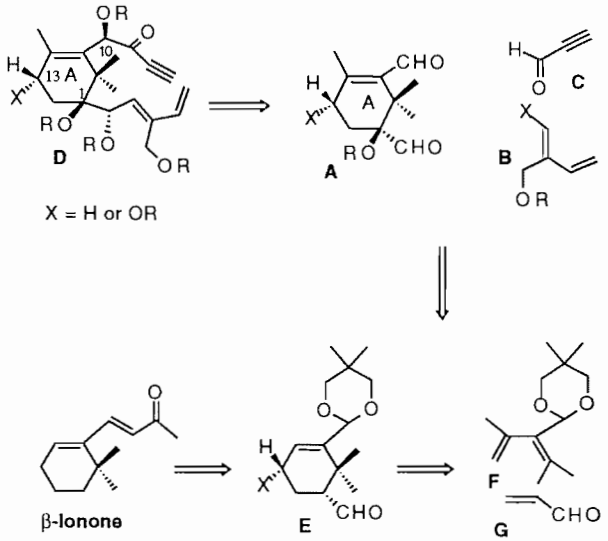
Functionalization and elaboration of ring A taxoid building blocks

Michael W. Tjepkema, Timothy Wong, Peter D. Wilson, and Alex G. Fallis

Abstract: The elaboration of the ring A aldehydes **1**, **7**, and **11** into more highly functionalized intermediates for taxoid synthesis is described. An improved route to the triene **4** and the adduct **28b** is reported. Additional condensations of selected aldehydes (**1**, **7**) with the organolithium reagents derived from the substituted halodienes **8** and **14** afforded the allylic alcohols **10** and **15** with a diastereoselectivity of ~5:1. Further manipulation of these products by the installation of an α-keto-acetylenic dienophile provided a taxoid precursor with the C_2, C_9, C_{10}, C_{13}, and C_{20} oxygens installed in the case of **23** (from **7**), and the less functionalized systems **27** and **27a** (from **1**).

Key words: taxoid, paclitaxel, Diels–Alder, cyclohexene, dienes.

Résumé : On décrit la transformation du cycle A des aldéhydes **1**, **7** et **11** en intermédiaires beaucoup plus fonctionnalisés utiles dans la synthèse de taxoïdes. On a mis au point une voie améliorée pour atteindre le triène **4** et l'adduit **28b**. Des condensations additionnelles d'aldéhydes choisis (**1**, **7**) avec des réactifs organolithiens dérivés des halodiènes substitués **8** et **14** ont fourni les alcools allyliques **10** et **15** avec une diastéréosélectivité d'environ 5 : 1. Des manipulations ultérieures de ces produits par le biais de l'installation d'un diénophile α-cétoacétylénique ont conduit à un précurseur de taxoïde portant les oxygènes en C2, C9, C10, C13 et C20 (**23** obtenu à partir du produit **7**) et d'autres systèmes moins fonctionnalisés (**27** et **27a** à partir du produit **1**).



Mots clés : taxoïde, paclitaxel, Diels–Alder, cyclohexène, diènes.

[Traduit par la rédaction]

Introduction

In the preceding paper in this series (1), we described the synthesis of various cyclohexene ring A building blocks as part of a general strategy for the construction of the taxane nucleus. We have been developing an approach that proceeds in the left to right direction (ring A to ABC) (2). For this pathway, it was anticipated that ring A cyclohexene building blocks could be used as anchors to facilitate an intramolecular Diels–Alder reaction for the construction of the B and C rings simultaneously. This is briefly illustrated in Scheme 1 in which the ring A components **A** (previously synthesized), **E** or **F**, plus **G**, may be combined with suitable diene **B** and dienophile **C** units to generate a Diels–Alder precursor **D** for construction of the taxoid nucleus. We have previously developed direct routes to the required diene unit **B** as both the (*E*) and (*Z*) isomers (3). These compounds contain a hydroxymethyl substituent as a control group for the eventual introduction of the oxetane. An acetylenic ketone was selected as the dienophile to minimize the possible stereochemical complications in the transition state and provide a double bond (C_7—C_8) in the C ring as a handle for the eventual introduction of the C_7 hydroxyl and the C_8 methyl groups.

Scheme 1. Retrosynthetic Diels–Alder strategy.

Results and discussion

Initially, in order to demonstrate the synthetic utility of the strategy outlined and establish its convergent nature, a much

Scheme 2. Improved synthesis of Diels–Alder precursor **4**.

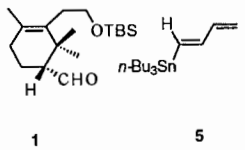
Reaction conditions: (*a*) **5**, *n*-BuLi, THF, −78°C; **1**, THF, −78°C, 98%; i-Pr_2NEt, MOMCl, CH_2Cl_2, 21°C, 93%; (*b*) *n*-Bu_4NF, THF, 21°C, 92%; $COCl_2$, CH_2Cl_2, DMSO, −78°C, Et_3N, 71%; (*c*) HCCMgCl, THF, 0°C, 90%; Dess–Martin periodinane, CH_2Cl_2, 48°C, 89%.

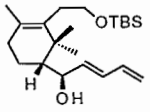
Scheme 3. Synthesis of Diels–Alder diene **27** (*Z*-series).

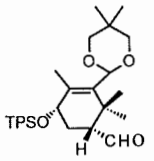
Reaction conditions: (*a*) **8**, THF, *s*-BuLi, −78°C; **7**, THF, −78°C, 81%; MOMCl. i-Pr_2NEt, 21°C 66%; (*b*) aq. HCl/ THF, 3:1, 21°C, 99%; (*c*) *n*-BuLi, 1,3-dithiane, THF, −20°C, 49%; (*d*) TBSOTf, collidine, CH_2Cl_2, 21°C; NBS, collidine, aq. CH_3CN, 22%; (*e*) TBSCN, KCN, 18-crown-6, CH_2Cl_2, 21°C, 67%; (*f*) DIBALH, CH_2Cl_2, −78°C, 85%; (*g*) THF, HCCMgCl, 0°C, 40%; Dess–Martin periodinance, CH_2Cl_2, 48°C, 80%.

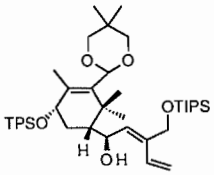
more direct route to our model Diels–Alder precursor, the diene-ynone **4** (Scheme 2), was developed. This sequence afforded the diene **4** in nine steps commencing with 2-bromo-1,1,3-trimethyl-1,3-pentadiene (4) to provide the aldehyde **1**, as described in the preceding paper (1). Thus the synthesis of the model adduct **28b** (Scheme 3) was accomplished in a total of 10 steps, compared to the 18 steps required in our initial studies (2).

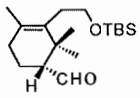
The key aspects of this route are outlined briefly in Scheme 2 and involved the condensation of aldehyde **1** (Table 1) with the organolithium reagent derived from exchange of tri-*n*-butylstannyl-1,3-butadiene (**5**) with *n*-butyllithium to afford the secondary alcohol **6** with a high level of stereoselectivity (15:1). The major diastereomer **6** was treated with chloromethyl methyl ether (MOMCl) and diisopropylethylamine to afford the diether **2**. Removal of the silyl protecting group with fluoride ion released the primary alcohol (96%), which was oxidized under Swern conditions to afford the aldehyde **3**, which was identical to the compound prepared earlier. The subsequent steps to the adduct were also shortened as ethynylmagnesium chloride could be used directly in place of the trimethylsilylethynyllithium previously used.

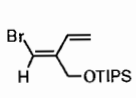


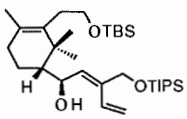


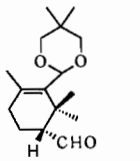


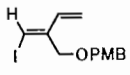


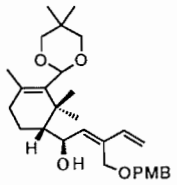


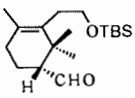


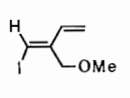


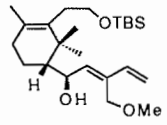












The extension of this chemistry required the introduction of more oxygen functionality and a hydroxymethyl diene substituent for the eventual introduction of the oxetane. The required dienes possess a relatively simple substitution pattern but were not available in a stereo- and regio-controlled manner. Thus various (*E*)- and (*Z*)-1-halo-2-(alkoxymethyloxy)-1,3-butadienes (diene unit **B**) were synthesized from vinylmagnesium chloride addition to trimethylsilylpropargyl alcohol or, alternatively, these were prepared by palladium-mediated addition and coupling of the appropriate alkene unit followed by halodesilylation (3). Table 1 summarizes the results of these additional studies with various aldehydes **1**, **7**, and **11**. The appropriate halodiene **8**, **12**, or **14** was exchanged with *sec*- or *tert*-butyllithium in THF at −78°C to afford the condensation products **9**, **10**, **13**, and **15** in yields of 81–99% with a diastereoselectivity of ~5:1. This stereochemical result is a consequence of preferential attack opposite to the *gem* dimethyl group in which the carbonyl group is also oriented away from these substituents, as illustrated in **16** (Fig. 1) and consistent with our earlier observations (2). As above, the major diastereomers were converted to their methoxymethyl ethers. This set the stage for the attachment of the dienophile unit and the incorporation of additional oxygen. Scheme 4 outlines the sequence developed for the *E*-diene commencing with aldehyde-acetal **7**.

Hydrolysis of the neopentylidene acetal present in **18** was effected smoothly with aqueous hydrochloric acid in THF to

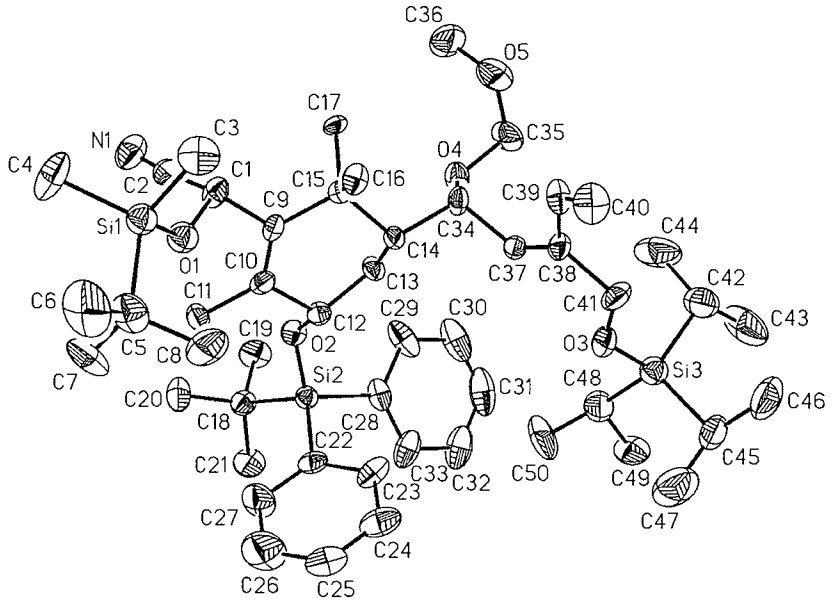
provide the aldehyde **19** in quantitative yield. To preserve this oxygen functionality and introduce the new carbonyl group required for C_9 (paclitaxel numbering), aldehyde **19** was condensed with 1,3-dithianyllithium at −20°C. This reaction afforded 24% of the starting aldehyde, accompanied by 49% of the single alcohol diastereomer **20**. This stereochemical result arose from the preferred approach of the nucleophile from the top of the molecule with the carbonyl group oriented downward in order to minimize the interaction with the adjacent methyl groups as illustrated in **17** (Fig. 1). Consequently, the new secondary alcohol has the opposite configuration to the C_9 acetate in paclitaxel (Taxol®). The alcohol **20** was protected by treatment with collidine and *tert*-butyldimethylsilyl

Scheme 4. Synthesis of Diels–Alder diene **25** (*E*-series).



Reaction conditions: (*a*) **14**, *t*-BuLi, THF, −78°C; **1**, THF, −78–0°C, 82%; i-Pr_2NEt, MOMCl, CH_2Cl_2, 0°C, 86%; (*b*) *n*-Bu_4NF, THF, 21°C, 96%; Dess–Martin periodinane, CH_2Cl_2, 48°C, 82%; (*c*) HCCMgCl, THF, 0°C, 67%; Dess–Martin periodinane, CH_2Cl_2, 48°C, 98%.

trifluoromethanesulfonate (TBSTf) and reacted directly with NBS in aqueous acetonitrile–acetone to afford the aldehyde **21**, but in a disappointing yield of only 22%. In view of this low yield a better alternative was examined. This involved the addition of *tert*-butyldimethylsilyl cyanide, in the presence of potassium cyanide, and 18-crown-6 to the aldehyde. This procedure provided the major diastereomer **22** in 67% yield accompanied by its epimer (11%). This implies that, with a small nucleophile, some control over the addition may be possible and lead to a higher yield of the natural stereoisomer. The

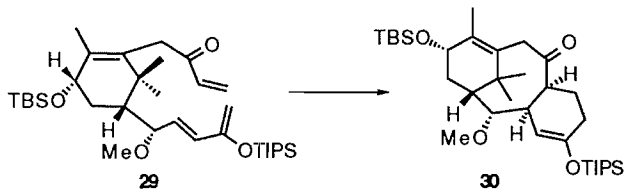

Fig. 2. A view of 1-(2*S**)-*tert*-butyldimethylsilyloxyacetonitrile)-(3*S**)-*tert*-butyldiphenylsilyloxy-(5*R**,1*R**)-methoxymethyloxy-3-triisopropylsilyloxymethyl-2(*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene (**22**).

X-ray structure of **22** (Fig. 2) confirmed the stereochemical relationships of the various centres. Reduction of the nitrile **22** with diisobutylaluminum hydride directly afforded the aldehyde **21** in 85% yield. Ethynylmagnesium chloride was condensed with the aldehyde **21** in THF at 0°C to provide a ~2:1 diastereomeric mixture of acetylenic alcohols. Direct oxidation of the combined epimers with Dess–Martin periodinane afforded the acetylenic ketone **23** in 80% yield.

The final stage of this sequence was expected to provide the tricyclic nucleus **24**. The illustrated transition state suggested, as did computer modeling, that an *endo* cycloaddition should be preferred. This conformation would afford the adduct **24** with the C_2 and C_3 hydrogens *trans*. Rotation about the C_2—C_3 single bond (arrow) would provide the opposite stereochemistry but the potential overlap between the diene and dienophile is less favourable. Unfortunately, despite heating a toluene solution of **23** containing 10 mol% of hydroquinone in a sealed tube in a microwave oven at ~300°C for 8 h until all the starting material was consumed, none of the anticipated adduct **24** (<5%) could be detected. This undesirable result implies that one or more of the nonbonded interactions present in the precursor is sufficient to impede cyclization. Initially we suspected that the 1,3 interaction between the C_{13} ether and the axial bond connecting the diene side chain was the culprit. However, this is not the case, since after completion of these investigations, Winkler et al. (5) reported the successful cyclization of a closely related example, **29** to **30** (Scheme 5), with an *endo* C_{13} ether substituent. Danishefsky and co-workers (6) discovered that an epimeric ether at C_{10} (as contained in **23**) inhibited the Diels–Alder cyclization of ring A in a steroid-based model. This does not seem to be the problem in our case. The geometric difference between the (*E*) and (*Z*) dienes also does not appear to be critical. However, the only way to ascertain the factors responsible for the failure of the Diels–Alder cyclization with certainty was to examine the (*Z*) series and less substituted systems.

Scheme 5. Diels–Alder cycloaddition (ref. 5).

Progress on several fronts, while our work was in progress, has demonstrated that fewer oxygens are required in the precursors to the tricyclic skeleton than previously suspected. For example, the C_{13} oxygen may be introduced by allylic oxidation at a late stage of the synthesis (7), and the C_1 oxygen may be inserted by enolization of an appropriate C_2 ketone (8). It is difficult to introduce a C_{10} oxygen from a C_9 ketone (9); however, the reverse transformation has been accomplished (10). Thus, in an effort to understand the reason(s) for the failure of the cycloaddition, and with the expectation that less oxygenated Diels–Alder precursors would also suffice for the projected total synthesis, simpler systems were synthesized.

To assemble these compounds rapidly, the alcohol **15** from the condensation of aldehyde **1** and **14** (Table 1) was protected as its methyloxymethyl ether to give **25** (Scheme 3). Removal of the *tert*-butyldimethylsilyl ether with fluoride afforded the primary alcohol, which was oxidized directly with Dess–Martin periodinane to the aldehyde **26** (82%). Condensation of this aldehyde with ethynylmagnesium chloride provided a diastereomeric mixture of alcohols (~2:1) that was oxidized with Dess–Martin periodinane to afford the acetylenic ketone **27** (98%). Thermolysis of **27** failed to afford significant quantities of **28**. In a parallel manner, several other Diels–Alder precursors possessing different dienophiles, including activated olefins, were synthesized (box, Scheme 3). Unfortunately none of these new compounds cyclized either.

Which nonbonded interaction inhibits the desired cyclization? The key experiment (not the first example studied!) was the attempted cyclization of **27**. This compound differs from our initial, successful model system **4** only by the inclusion of the methoxymethyl ether diene substituent in place of hydrogen (X = CH_2OMe vs. X = H). This leads to the inescapable conclusion that the nonbonded interactions with the diene substituent and another portion of the molecule are sufficient to inhibit cyclization. Here also, the preferred transition state looks quite attractive. The cyclohexene is distorted into a boat-like conformation. This allows for reasonable alignment between the acetylenic ketone and the diene unit. However, the substituent (X = CH_2OMe), due to its rapid free rotation, must inhibit the close approach of the dienophile, despite the fact that in several orientations there does not seem to be excess interference. Even the sterically less demanding aldehyde **27a** (X = CHO) did not cyclize to **28a**, in spite of the fact that carbonyl groups in the 2-position of dienes usually render them particularly reactive (11). The recent Winkler results (5) have provided additional evidence. The diene substituent is the problem. The nonbonded interaction between the diene hydroxymethyl ether substituent and the carbonyl of the dienophile will not allow the required alignment (arrows **23** and **27**) of these two groups into the required orientation for the transition state under the experimental conditions examined. The fact that the diene in **29** (Scheme 5) is both more reactive and lacks this substituent supports this conclusion.

In conclusion, these studies have established the utility of various ring A building blocks and their selective condensation with diverse dienes. This has permitted the synthesis of more complex systems including those with additional oxygen substituents. Despite the fact that only some of the desired synthetic objectives were realized from these investigations, the factors that inhibit the desired intramolecular Diels–Alder cycloaddition have been delineated. Recently it has been reported that a C_4 methoxy substituent has an adverse influence in an aromatic taxane (12).

A beneficial consequence of these difficulties is the revision of our approach to the challenging tricyclo[9.3.1.$0^{3,8}$]pentadecene nucleus. This new synthetic strategy for taxoids capitalizes on the knowledge gained to date using some of the same building blocks prepared above. In addition, a key feature is the use of a chiral tether control group to both impart asymmetry and facilitate the attainment of the requisite transition state for a different intramolecular Diels–Alder cycloaddition. These features allow the inclusion of a hydroxymethyl diene substituent as a handle for the introduction of the oxetane as originally planned (13).

Experimental section

For general methods see ref. 8.

X-ray analysis was conducted on a Rigaku diffractometer with Mo Kα radiation at −130°C using the ω–2θ scan technique to a maximum 2θ value of 44.9. Cell constants and an orientation matrix for data collection were obtained from least-squares refinement using the setting angles of 25 reflections in the range $40 < 2\theta < 45$, corresponding to an orthorombic cell for compound **22** ($C_{50}H_{81}NO_5Si_3$) with dimensions a = 15.127, b = 19.174, c = 18.622 Å. For Z = 4 and FW = 861.83, the calculated density is 1.058 g/cm^3. Based on the systematic absences, the space group was $P2_1c$. The data (6726 reflections) were collected for Lorentz and polarization effects (14). The structure was solved by direct methods with all atoms refined, except hydrogen. The hydrogen atoms were calculated by assuming a distance of 1.07 Å. The final cycle of full matrix least-squares refinement was based on 4549 observed reflections ($I > 2.5\ \sigma(I)$) and 533 variable parameters using weights based on counting statistics. The maximum–minimum peaks on the final differences Fourier map were 0.31 and −0.38 e/Å^3, respectively. All calculations were performed using the NRCVAX crystallographic software package (15). Supplementary material containing experimental details, bond lengths and angles, and torsion angles has been deposited.[2]

(1*R**)-(2-*tert*-Butyldimethylsilyloxyethyl)-(5*R**)-hydroxy-(2*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene

n-Butyllithium (1.50 mL, 2.5 M in hexanes, 3.75 mmol) was added dropwise to a stirred solution of 1(*E*)-(tri-*n*-butylstannyl)-1,3-butadiene **5** (1.31 g, 3.82 mmol) in THF (40 mL) at −78°C over a period of ~1 min. The resultant mixture was stirred at −78°C for 10 min, and then a solution of the aldehyde **1** (952 mg, 2.77 mmol) in THF (6 mL) was added over a period of ~30 s. After a further 30 min, water (40 mL) was added and the reaction mixture was allowed to warm to ambient temperature. The phases were separated and the aqueous phase was extracted further with ether (3 × 40 mL). The combined organic extracts were washed with brine (50 mL), dried, and concentrated. Chromatography (6:1, hexanes/ether) afforded the major alcohol (930 mg, 92%) and the corresponding minor diastereomeric alcohol (64.5 mg, 6%) as colourless oils. Major diastereomer: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.03 (s, 6H), 0.88 (s, 9H), 1.05 (s, 6H), 1.20–1.60 (m, 4H), 1.62 (s, 3H), 1.95 (m, 2H), 2.30 (m, 2H), 3.53 (t, J = 8 Hz, 2H), 4.52 (m, 1H), 5.00–5.25 (m, 2H), 5.74 (dd, J = 16, 5 Hz, 1H), 6.15–6.45 (m, 2H).

(1*R**)-(2-*tert*-Butyldimethylsilyloxyethyl)-(5*R**)-methoxymethyloxy-(2*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene (2)

N,N-Diisopropylethyl amine (4.0 mL, 23 mmol) and chloromethyl methyl ether (1.0 mL, 13 mmol) were added sequentially to a stirred solution of the above alcohol (826 mg, 2.27 mmol) in dichloromethane (10 mL) at 0°C. The resultant mixture was stirred at ambient temperature for 24 h and then a saturated aqueous solution of sodium bicarbonate (40 mL) was added. The phases were separated and the aqueous phase was extracted further with dichloromethane (3 × 30 mL). The combined organic extracts were washed with brine (40 mL), dried, and concentrated. Chromatography (20:1, hexanes/ether)

[2] Copies of the supplementary material can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. With the exception of torsion angles, these data have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

afforded the ether **2** (863 mg, 93%) as a colourless oil. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.04 (s, 6H), 0.90 (s, 9H), 0.98 (s, 3H), 1.04 (s, 3H), 1.20–1.70 (m, 3H), 1.60 (s, 3H), 1.90 (m, 2H), 2.28 (m, 2H), 3.35 (s, 3H), 3.52 (t, J = 8 Hz, 2H), 4.26 (dd, J = 8, 1.5 Hz, 1H), 4.47 (d, J = 7 Hz, 1H), 4.64 (d, J = 7 Hz, 1H), 5.02–5.24 (m, 2H), 5.65 (dd, J = 15, 8 Hz, 1H), 6.05–6.42 (m, 2H).

(1*R)-(Acetaldehyde)-(5*R**)-methoxymethyloxy-(2*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene (3)**

Tetra-*n*-butylammonium fluoride (10.0 mL, 1.0 M in THF, 10 mmol) was added dropwise to the neat silyl ether **2** (863 mg, 2.11 mmol) at ambient temperature. The resultant mixture was stirred for 1 h and then a saturated aqueous solution of sodium bicarbonate (20 mL) and ether (20 mL) were added. The phases were separated and the aqueous phase was extracted further with ether (3 × 15 mL). The combined organic extracts were washed with brine (25 mL), dried, and concentrated. Chromatography (3:5, hexanes/ether) afforded the corresponding alcohol (569 mg, 92%) as a colourless oil. Oxalyl chloride (0.43 mL, 4.5 mmol) was added dropwise to a stirred solution of dimethyl sulfoxide (0.30 mL, 4.5 mmol) in dichloromethane (20 mL) at −78°C over a period of ~30 s. The resultant mixture was stirred for 15 min and then a solution of the above alcohol (569 mg, 1.93 mmol) in dichloromethane (9 mL) was added dropwise over ~2 min. The reaction mixture was stirred for 1 h and triethylamine (1.25 mL, 8.97 mmol) was added over ~1 min. The reaction mixture was then allowed to warm to 0°C over a period of 1.25 h. Water (15 mL) was added, the phases were separated, and the aqueous phase was extracted further with dichloromethane (3 × 15 mL). The combined organic extracts were then washed with a saturated aqueous solution of ammonium chloride (30 mL), then with brine (30 mL), dried, and concentrated. Chromatography (7:1, hexanes/ether) afforded the aldehyde **3** (401 mg, 71%) as a colourless oil. The spectral data were in accord to that reported previously (2).

(5*R)(1*R**)-Methoxymethyloxy-(2*E*)-4-pentadienyl-1-(2-oxo-3-butynyl)-2,6,6-trimethylcyclohexene (4)**

Ethynylmagnesium chloride (8.0 mL, 0.5 M in THF, 4.0 mmol) was added to a stirred solution of the aldehyde **3** (401 mg, 1.37 mmol) in THF (15 mL) at 0°C. The resultant mixture was stirred at 0°C for 30 min and then a saturated aqueous solution of ammonium chloride (14 mL) was added. The phases were separated and the aqueous phase was extracted further with ether (3 × 10 mL). The combined organic extracts were washed with brine (20 mL), dried, and concentrated. Chromatography (2:1, hexanes/ether) afforded the diastereomeric acetylenic alcohols (393 mg, 90%) as colorless oils. Dess–Martin periodinane (2.0 g, 4.8 mmol) was added to a stirred solution of above acetylenic alcohols (393 mg, 1.23 mmol) in dichloromethane (20 mL). The resultant mixture was heated at reflux for 45 min and then allowed to cool to ambient temperature. The reaction mixture was poured into a mixture of a saturated aqueous solution of sodium bicarbonate (25 mL), an aqueous solution of sodium thiosulfate (1.0 M, 25 mL), and water (25 mL). The phases were separated and the aqueous phase was extracted further with dichloromethane (3 × 25 mL). The combined organic extracts were washed with water (50 mL), then with brine (50 mL), dried, and concentrated. Chromatography (5:1, hexanes/ether) afforded the ketone **4** (346 mg, 89%) as a colourless oil. The spectral data were in accord to that reported previously (2).

(3*S)-*tert*-Butyldiphenylsilyloxy-(5*R**)(1*R**)-hydroxy-3-triisopropylsilyloxymethyl-(2*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (9)**

A solution of the dienyl bromide **8** (577 mg, 1.81 mmol) in THF (3 mL) was added to a stirred solution of *sec*-butyllithium (3.2 mL, 1.21 M in hexanes, 3.9 mmol) in THF (10 mL) over a period of 2 min at −78°C. After 20 min a solution of the aldehyde **7** (664 mg, 1.27 mmol) in THF (3.5 mL) was added over a period of 1 min. The reaction mixture was stirred at −78°C for a further 10 min and then allowed to warm to ambient temperature over 30 min. Water (30 mL) was added, the phases separated, and the aqueous phase was extracted further with ether (3 × 30 mL). The combined organic extracts were dried and concentrated. Chromatography (3:1, petroleum ether/ether) afforded, as a ~5:1 mixture of diastereomers, the corresponding secondary alcohols (782 mg, 81%) as colourless oils. Major isomer **9**: IR ($CHCl_3$): 3607, 3017, 1466, 1427, 1216, 1065 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.72, (s, 3H), 0.99–1.08 (m, 36H), 1.25–1.30 (m, 1H), 1.26 (s, 3H), 1.61–1.69 (m, 1H), 1.95–2.01 (m, 1H), 2.04 (s, 3H), 3.43–3.75 (m, 4H), 4.13 (dd, J = 10.2, 5.0 Hz, 1H), 4.30 (s, 2H), 4.72 (m, 1H), 4.78 (s, 1H), 5.05 (d, J = 11.3 Hz, 1H), 5.15 (d, J = 17.5 Hz, 1H), 5.50 (d, J = 10.0 Hz, 1H), 6.70 (dd, J = 17.5, 11.3 Hz, 1H), 7.31–7.40 (m, 6H), 7.67–7.72 (m, 4H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 11.9, 14.1, 16.9, 18.0, 19.5, 21.0, 22.2, 22.4, 24.1, 26.3, 27.2, 30.1, 38.0, 48.8, 60.4, 63.5, 65.8, 73.8, 77.2, 78.5, 78.6, 102.1, 115.2, 127.3, 127.4, 129.5, 130.4, 130.8, 133.9, 134.6, 135.0, 136.1, 136.2, 138.6; HRMS (EI) calcd. for $C_{46}H_{70}O_4Si_2$ ($M^+ - H_2O$): 742.4718; found: 742.4764.

1-(2-*tert*-Butyldimethylsilyloxyethyl)-(5*R)(1*R**)-hydroxy-3-triisopropylsilyloxymethyl-(2*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene (10)**

A solution of the dienyl bromide **8** (918 mg, 2.87 mmol) in THF (4 mL) was added to a stirred solution of *sec*-butyllithium (5.0 mL, 1.21 M in cyclohexane, 6.03 mmol) in THF (25 mL) over a period of 2.5 min at −78°C. After 20 min a solution of the aldehyde **1** (377 mg, 1.48 mmol) in THF (4 mL) was added. The reaction mixture was stirred at −78°C for a further 10 min and then allowed to warm to ambient temperature over 30 min. Water (10 mL) was added, the phases separated, and the aqueous phase was extracted further with ether (2 × 10 mL). The combined organic extracts were dried and concentrated. Chromatography (9:1, hexanes/ether) afforded, as a ~6:1 mixture of diastereomers, the corresponding secondary alcohols (656 mg 99%) as colourless oils. Major isomer **10**: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.05 (s, 6H), 0.88 (s, 9H), 0.90–1.70 (m, 31H), 1.62 (s, 3H), 1.95 (m, 2H). 2.28 (m, 2H), 3.53 (t, J = 9 Hz, 2H), 4.38 (s, 2H), 4.85–5.27 (m, 3H), 5.89 (m, 1H), 6.48–6.67 (m, 1H); HRMS (EI) calcd. for $C_{32}H_{60}O_2Si_2$ ($M^+ - H_2O$): 532.4135; found: 532.4158. *N*,*N*-Diisopropylethyl amine (7.0 mL, 40 mmol) and chloromethyl methyl ether (1.5 mL, 20 mmol) were added sequentially to a stirred solution of the above alcohols (1.19 g, 2.17 mmol) in dichloromethane (10 mL) at 0°C. The resultant mixture was stirred at ambient temperature for 41 h, and then

water (10 mL) and ether (10 mL) were added. The phases were separated and the aqueous phase was extracted further with ether (3 × 5 mL). The combined organic extracts were washed with brine (15 mL), dried, and concentrated. Chromatography (25:1, hexanes/ether) afforded, as a single diastereomer, the corresponding methyloxymethyl ether (939 mg, 73%) as a colourless oil. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.04 (s, 6H), 0.77–2.80 (m, 30H), 0.88 (s, 9H), 1.60 (s, 3H), 1.90 (m, 2H), 2.28 (m, 2H), 3.34 (s, 3H), 3.50 (m, 2H), 4.36–4.80 (m, 5H), 5.05–5.24 (m, 2H), 5.88 (m, 1H), 6.67 (m, 1H).

(5*R)(1*R**)-Hydroxy-3-*para*-methoxybenzyloxymethyl-(2*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (13)**

A solution of the dienyl iodide **12** (537 mg, 1.66 mmol) in THF (3 mL) was added to a stirred solution of *sec*-butyllithium (2.70 mL, 1.21 M in cyclohexane, 3.51 mmol) in THF (10 mL) over a period of 1 min at −78°C. After 4 min a solution of the aldehyde **11** (299 mg, 1.12 mmol) in dry THF (3 mL) was added over a period of 15 s. The reaction mixture was stirred at −78°C for a further 20 min and then at ambient temperature for 5 min. Water (10 mL) was next added, the phases were separated, and the aqueous phase was extracted further with ether (3 × 10 mL). The combined organic extracts were washed with brine (20 mL), dried, and concentrated. Chromatography (1:1, hexanes/ether) afforded, as a ~6:1 mixture of diastereomers, the corresponding secondary alcohols (437 mg, 85%) as a colourless oil. Mayor isomer **13**. IR (neat) 3458, 2909, 1611, 1586, 1514, 1247, 1089 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.73 (s, 3H), 1.03 (s, 3H), 1.04 (s, 3H), 1.20–2.10 (m, 6H), 1.26 (s, 3H), 1.90 (s, 3H), 3.42–3.53 (m, 2H), 3.66–3.75 (m, 2H), 3.79 (s, 3H), 4.06–4.25 (m, 2H), 4.37–4.52 (m, 2H), 4.70 (m, 1H), 4.82 (s, 1H), 5.07 (d, J = 11 Hz, 1H), 5.28 (d, J = 18 Hz, 1H), 5.83 (d, J = 8 Hz, 1H), 6.30 (dd, J = 18, 11 Hz, 1H), 6.86 (d, J = 9 Hz, 2H), 7.25 (d, J = 9 Hz, 2H); HRMS (EI) calcd. for $C_{29}H_{42}O_5$: 470.3034; found: 470.3033.

1-(2-*tert*-Butyldimethylsilyloxyethyl)-(5*R)(1*R**)-hydroxy-3-methoxymethyl-(2*Z*)-4-pentadienyl-2,6,6-trimethylcyclohexene (15)**

A solution of *tert*-butyllithium (12.4 mL, 1.58 M in pentane, 19.6 mmol) was added to a stirred solution of the dienyl iodide **14** (2.09 g, 9.33 mmol) in THF (80 mL) over a period of 3 min at −78°C. The resultant mixture was stirred at −78°C for 3 min, at 0°C for 20 min, and was then recooled to −78°C. A solution of the aldehyde **1** (2.05 g, 6.60 mmol) in dry THF (14 mL) was then added over a period of 30 s. The reaction mixture was stirred at −78°C for 15 min and then at 0°C for a further 15 min. Water (50 mL) was added, the phases were separated, and the aqueous phase was extracted with ether (3 × 50 mL). The combined organic extracts were washed with brine (100 mL), dried, and concentrated. Chromatography (7:3, hexanes/ether) afforded, as a ~5:1 mixture of diastereomers, the corresponding secondary alcohols (2.22 g, 82%) as colourless oils. Major isomer **15**. IR ($CHCl_3$): 3443, 2911, 1083 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.05 (s, 6 H), 0.88 (s, 9H), 1.05 (s, 3H), 1.06 (s, 3H), 1.17–1.70 (m, 3H), 1.62 (s, 3H), 1.97 (m, 2H), 2.24 (t, J = 7 Hz, 2H), 3.33 (s, 3H), 3.56 (t, J = 7 Hz, 2H), 4.15 (s, 2H), 4.80 (m, 1H), 5.16 (d, J = 11 Hz, 1H), 5.32 (d, J = 17.5 Hz, 1H), 5.85 (d, J = 8.5 Hz, 1H), 6.29 (dd, J = 17.5, 11 Hz, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: −5.5, 18.3, 18.5, 20.3, 22.9, 26.0, 27.5, 32.5, 32.6, 38.4, 50.8, 58.2, 62.9, 66.6, 67.2, 113.7, 129.5, 133.5, 134.5, 138.6, 139.3; HRMS (EI) calcd. for $C_{24}H_{42}O_2Si$ ($M^+ - H_2O$): 390.2956; found: 390.2973.

(3*S)-*tert*-Butyldiphenylsilyloxy-(5*R**)(1*R**)-methoxymethyloxy-3-triisopropylsilyloxymethyl-(2*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (18)**

N, N-Diisopropylethyl amine (1.25 mL, 7.19 mmol) and chloromethyl methyl ether (460 μL, 6.06 mmol) were added sequentially to a stirred solution of the diastereomeric alcohols **9** (497 mg, 0.654 mmol) in dichloromethane (3 mL) at ambient temperature (21°C). The resultant mixture was stirred for 14 h and then a saturated aqueous solution of sodium bicarbonate (10 mL) and ether (100 mL) were added. The organic phase was separated, washed with a saturated aqueous solution of sodium bicarbonate (5 mL), then with brine (2 × 10 mL), dried, and concentrated. Chromatography (100% hexanes to 20% ether in hexanes) afforded, as a single diastereomer, the ether **18** (354 mg, 66%) as a colourless oil. IR ($CHCl_3$): 2915, 1465, 1427, 1216, 1067 cm^{-1}; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 0.72 (s, 3H), 0.99–1.08 (m, 36H), 1.25–1.30 (m, 1H), 1.26 (s, 3H), 1.60–1.68 (m, 1H), 1.95–2.01 (m, 1H), 2.05 (s, 3H), 3.15 (s, 3H), 3.42–3.74 (m, 4H), 4.12 (dd, J = 10.3, 5.1 Hz, 1H), 4.26 (d, J = 6.7 Hz, 1H), 4.31 (s, 2H), 4.46 (d, J = 6.7 Hz, 1H), 4.50 (dd, J = 9.8, 4.0 Hz, 1H), 4.77 (s, 1H), 5.06 (d, J = 11.4 Hz, 1H), 5.15 (d, 17.7 Hz, 1H), 5.49 (d, J = 9.8 Hz, 1H), 6.58 (dd, J = 17.7 Hz, 11.4 Hz, 1H), 7.31–7.40 (m, 6H), 7.67–7.72 (m, 4H); ^{13}C NMR (125 MHz, $CDCl_3$) δ: 12.0, 16.8, 17.9, 18.0, 19.5, 21.8, 22.2, 24.1, 26.7, 27.2, 30.0, 30.2, 38.1, 48.5, 56.0, 63.2, 69.8, 74.0, 78.5, 78.6, 93.5, 102.3, 114.7, 127.2, 127.5, 128.2, 129.3, 129.4, 130.9, 133.9, 134.8, 136.2, 136.3, 136.7, 139.1.

(3*S)-*tert*-Butyldiphenylsilyloxy-1-carboxaldehyde-(5*R**)(1*R**)-methoxymethyloxy-3-triisopropylsilyloxymethyl-(2*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene (19)**

Hydrochloric acid (4%, 300 μL) was added to a stirred solution of the acetal **18** (30.0 mg, 0.037 mmol) in THF (1 mL) at ambient temperature. The resultant mixture was stirred for 3 h and then a saturated aqueous solution of sodium bicarbonate (2 mL) was added. On removal of the THF, in vacuo, the resultant aqueous residue was extracted with ether (100 mL). The organic extract was washed with water (5 × 10 mL), a saturated aqueous solution of sodium bicarbonate (5 mL), and then with brine (2 × 10 mL), dried, and concentrated to afford the aldehyde **19** (27 mg, 99%) as a colourless oil. IR (neat): 2913, 2758, 1677, 1464, 1076 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.01–1.08 (m, 30H), 1.19 (s, 3H), 1.22 (s, 3H), 1.67–1.74 (m, 1H), 2.04–2.12 (m, 1H), 2.07 (s, 3H), 3.17 (s, 3H), 4.20 (apparent t, 1H), 4.27 (d, J = 6.7 Hz, 1H), 4.33 (s, 2H), 4.49 (d, J = 6.7 Hz, 1H), 4.57 (dd, J = 9.8, 3.7 Hz, 1H), 5.09 (d, J = 11.3 Hz, 1H), 5.17 (d, J = 18.1 Hz, 1H), 5.52 (d, J = 9.8 Hz, 1H), 6.60 (dd, J = 18.1, 11.3 Hz, 1H), 7.32–7.44 (m, 6H), 7.67–7.75 (m, 4H), 10.06 (s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 11.9, 15.0, 17.9, 19.5, 21.1, 26.7, 27.0, 27.1, 29.3, 37.5, 48.3, 56.0, 62.9, 68.9, 74.3, 93.4, 114.8, 127.4, 127.5, 127.6, 129.6, 129.7, 130.6, 133.4, 134.1, 136.0, 136.8, 141.2, 155.6, 193.9.

(3*S)-*tert*-Butyldiphenylsilyloxy-1-(2*S**)-hydroxyacetaldehyde propylidene dithioacetal)-(5*R**)(1*R**)-methoxymethyloxy-3-triisopropylsilyloxymethyl-(2*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene (20)**

n-Butyllithium (180 μL, 2.5 M in hexanes, 0.45 mmol) was added to a stirred solution of 1,3-dithiane (54 mg, 0.45 mmol) in THF (3.5 mL) at −20°C. The resultant mixture was stirred for 1 h and then cooled to −78°C. A solution of the aldehyde **19** (154 mg, 0.214 mmol) in THF (1 mL) was then added. After 1 h the reaction mixture was warmed to −20°C and a saturated aqueous solution of sodium bicarbonate (10 mL) was added. On removal of the THF, in vacuo, the resultant aqueous residue was extracted with ether (100 mL). The ether extract was then washed with a saturated aqueous solution of sodium bicarbonate (10 mL), then with brine (10 mL), dried, and concentrated. Chromatography (100% hexanes to 20% ether in hexanes) afforded the starting aldehyde **19** (37 mg, 24%) and the alcohol **20** (88 mg, 49%) as colourless oils. IR ($CHCl_3$): 3451, 2947, 2865, 1593, 1464, 1379, 1216, 1107 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$) δ: 0.86 (s, 3H), 1.00–1.03 (m, 30H), 1.05 (s, 3H), 1.10–1.30 (m, 1H), 1.48–1.63 (m, 1H), 1.82 (s, 3H), 1.91–2.09 (m, 3H), 2.74–2.79 (m, 2H), 2.87–2.91 (m, 2H), 3.13 (s, 3H), 4.16 (dd, *J* = 10.3, 5.7 Hz, 1H), 4.22 (d, *J* = 10.2 Hz, 1H), 4.23 (d, *J* = 6.7 Hz, 1H), 4.32 (s, 2H), 4.48 (d, *J* = 6.7 Hz, 1H), 4.49 (dd, *J* = 10.0, 4.0 Hz, 1H), 4.52 (d, *J* = 10.2 Hz, 1H), 5.07 (d, *J* = 11.4 Hz, 1H), 5.15 (d, *J* = 17.9 Hz, 1H), 5.53 (d, *J* = 10.0 Hz, 1H), 6.58 (dd, *J* = 17.9, 11.4 Hz, 1H), 7.29–7.40 (m, 6H), 7.68–7.73 (m, 4H); ^{13}C NMR (125 MHz, $CDCl_3$) δ: 12.0, 17.7, 18.0, 19.7, 22.4, 22.6, 25.4, 27.1, 27.2, 28.3, 29.4, 29.7, 29.9, 39.5, 48.5, 51.6, 56.0, 63.1, 69.8, 71.1, 74.9, 93.4, 114.7, 127.3, 127.5, 128.1, 129.3, 129.4, 130.9, 134.4, 134.9, 136.0, 136.1, 136.7, 138.1, 138.6.

1-(2*S)-*tert*-Butyldimethylsilyloxyacetonitrile)-(3*S**)-*tert*-butyldiphenylsilyloxy-(5*R**)(1*R**)-methoxymethyloxy-3-triisopropylsilyloxymethyl-(2*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene (22)**

Potassium cyanide (27.0 mg, 0.42 mmol), 18-crown-6 (30.0 mg, 0.12 mmol), and *tert*-butyldimethylsilyl cyanide (87.0 mg, 0.62 mmol) were added sequentially to a stirred solution of the aldehyde **19** (212 mg, 0.295 mmol) in dichloromethane (2 mL) at ambient temperature. The resultant mixture was stirred for 7 h and then ether (100 mL) and a saturated aqueous solution of sodium bicarbonate (5 mL) were added. The organic phase was separated, washed with a saturated aqueous solution of sodium bicarbonate (5 mL), then with brine (2 × 10 mL), dried, and concentrated to afford the product as a 6:1 mixture of diastereomers. Chromatography (100% hexanes to 5% ether in hexanes) afforded the major diastereomer **22** (170 mg, 67%) as a crystalline solid and the corresponding minor diastereomer (28 mg, 11%) as a colourless oil. Major diastereomer **22**: mp 132–134.5°C; IR ($CHCl_3$): 3019, 2947, 2863, 1467, 1216, 1109 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.13 (s, 3H), 0.26 (s, 3H), 0.88 (s, 9H), 0.82–1.06 (m, 36H), 1.30–1.38 (m, 1H), 1.58–1.64 (m, 1H), 1.92–2.05 (m, 1H), 1.98 (s, 3H), 3.12 (s, 3H), 4.11 (dd, *J* = 9.7, 5.4 Hz, 1H), 4.25 (d, *J* = 6.7 Hz, 1H), 4.32 (s, 2H), 4.45 (d, *J* = 6.7 Hz, 1H), 4.47 (dd, *J* = 10.0, 4.2 Hz, 1H), 4.95 (s, 1H), 5.09 (d, *J* = 11.6 Hz, 1H), 5.17 (d, *J* = 18.3 Hz, 1H), 5.49 (d, *J* = 10.0 Hz, 1H), 6.56 (dd, *J* = 18.3, 11.6 Hz, 1H), 7.32–7.43 (m, 6H), 7.67–7.76 (m, 4H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: −5.2, −5.1, 11.9, 16.5, 18.0, 19.5, 22.3, 25.4, 25.5, 26.3, 27.1, 29.8, 38.9, 48.1, 56.0, 58.9, 63.0, 69.4, 73.6, 93.3, 115.0, 120.0, 127.3, 127.5, 127.9, 129.4, 129.5, 130.6, 133.9, 134.7, 135.7, 135.9, 136.0, 136.1, 136.9, 141.0.

1-(2*S)-*tert*-Butyldimethylsilyloxyacetaldehyde)-(3*S**)-*tert*-butyldiphenylsilyloxy-(5*R**)(1*R**)-methoxymethyloxy-3-triisopropylsilyloxymethyl-(2*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene (21)**

*From **20***: Collidine (100 μL, 0.75 mmol) and *tert*-butyldimethylsilyltrifluoromethanesulfonate (100 μL, 0.44 mmol) were added sequentially to a stirred solution of the alcohol **20** (77.0 mg, 0.092 mmol) in dichloromethane (2 mL) at 0°C. The resultant mixture was stirred at 0°C for 10 h and then a saturated aqueous solution of sodium bicarbonate (5 mL) and ether (100 mL) were added. The organic phase was washed with a saturated aqueous solution of sodium bicarbonate (5 mL), then with brine (2 × 5 mL), dried, and concentrated. Chromatography (100% hexanes to 5% ether in hexanes) afforded the corresponding silyl ether (38 mg, 43%) as a colourless oil. ^1H NMR (500 MHz, $CDCl_3$) δ: 0.11 (s, 3H), 0.21 (s, 3H), 0.81–1.04 (m, 39H), 1.25–1.30 (m, 1H), 1.33 (s, 3H), 1.41 (s, 3H), 1.60–1.68 (m, 1H), 1.62 (s, 3H), 1.91–2.09 (m, 3H), 2.74–2.91 (m, 4H), 3.28 (s, 3H), 4.16–4.22 (m, 2H), 4.30 (s, 2H), 4.32–4.50 (m, 5H), 4.81 (d, *J* = 8.0 Hz, 1H), 5.02 (d, *J* = 11.4 Hz, 1H), 5.12 (d, *J* = 17.0 Hz, 1H), 5.57 (d, 10.0 Hz, 1H), 6.53–6.61 (m, 1H), 7.29–7.40 (m, 6H), 7.68–7.73 (m, 4H). Collidine (60 μL, 0.45 mmol) and *N*-bromosuccinimide (60 mg, 0.33 mmol) were added sequentially to a stirred solution of the above silyl ether (35 mg, 0.037 mmol) in aqueous acetonitrile (80%, 1.5 mL) and acetone (2.5 mL) at 0°C. The resultant mixture was stirred for 5 min and then a saturated aqueous solution of sodium bicarbonate (5 mL), an aqueous solution of sodium thiosulfate (20%, 5 mL), and ether (100 mL) were added. The organic phase was separated, washed with a saturated aqueous solution of sodium bicarbonate (5 mL), then with brine (10 mL), dried, and concentrated. Chromatography (5% ether in hexanes) afforded the aldehyde **21** (7 mg, 22%) as a colourless oil. IR (neat): 2912, 2720, 1737, 1592, 1465, 1080 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.02 (s, 3H), 0.13 (s, 3H), 0.82–1.04 (m, 45H), 1.31–1.39 (m, 1H), 1.65–1.70 (m, 1H), 1.69 (s, 3H), 1.98–2.08 (m, 1H), 3.15 (s, 3H), 4.15 (dd, *J* = 9.9, 6.6 Hz, 1H), 4.27 (d, *J* = 6.6 Hz, 1H), 4.33 (s, 3H), 4.48 (d, *J* = 6.6 Hz, 1H), 4.52 (dd, *J* = 10.4, 4.4 Hz, 1H), 4.60 (s, 1H), 5.09 (d, *J* = 11.6 Hz, 1H), 5.18 (d, *J* = 18.3 Hz, 1H), 5.53 (d, *J* = 10.4 Hz, 1H), 6.59 (dd, *J* = 18.3, 11.6 Hz, 1H), 7.35–7.42 (m, 6H), 7.66–7.73 (m, 4H), 9.57 (s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: −4.7, −4.3, 11.9, 16.5, 18.0, 18.3, 19.5, 22.3, 25.7, 25.9, 27.0, 27.1, 29.9, 38.8, 48.4, 56.0, 63.1, 69.7, 73.8, 77.4, 93.4, 114.8, 127.3, 127.5, 128.2, 129.3, 129.5, 130.7, 134.1, 134.8, 136.0, 136.4, 136.7, 201.2.

*From **22***: Diisobutylaluminum hydride (70 μL, 1 M in toluene, 0.07 mmol) was added to a stirred solution of the nitrile **22** (40 mg, 0.047 mmol) in dichloromethane (2 mL) at −78°C. The resultant mixture was stirred for 30 min and then allowed to warm to ambient temperature. A saturated aqueous solution of ammonium chloride (5 mL) was added and the resultant mixture was stirred for a further 3 h. The aqueous phase was then extracted with ether (100 mL) and the extract was washed

with a saturated aqueous solution of ammonium chloride (5 mL), then with brine (10 mL), dried, and concentrated to afford the aldehyde **21** (34 mg, 85%) as a colourless oil. The spectral data for this material were in accord to that recorded above. Anal. calcd. for $C_{50}H_{82}O_6Si$: C 69.79, H 9.49; found: C 69.96, H 9.23.

1-(1*S)-*tert*-Butyldimethylsilyloxy-2-oxo-3-butynyl)-(3*S**)-*tert*-butyldiphenylsilyloxy-(5*R**)(1*R**)-methoxymethyloxy-3-triisopropylsilyloxymethyl-(2*E*)-4-pentadienyl-2,6,6-trimethylcyclohexene (23)**

Ethynylmagnesium chloride (850 μL, 0.5 M in THF, 0.42 mmol) was added to a stirred solution of the aldehyde **21** (170 mg, 0.197 mmol) in THF (10 mL) at 0°C. The resultant mixture was stirred for 30 min and then a saturated aqueous solution of ammonium chloride (10 mL) was added. On removal of the THF, in vacuo, the resultant aqueous residue was extracted with ether (100 mL). The ether extract was washed with a saturated aqueous solution of ammonium chloride (5 mL), a saturated aqueous solution of sodium bicarbonate (5 mL), and then with brine (2 × 5 mL), dried, and concentrated to afford a ~2:1 mixture of corresponding diastereomeric acetylenic alcohols. Chromatography (100% hexanes to 20% ether in hexanes) afforded the minor diastereomer (31 mg, 15%), followed by the major diastereomer (51 mg, 25%), both as colourless oils. Major diastereomer: IR (neat): 3309, 2944, 2862, 1593, 1465, 1105, 1039 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.02 (s, 3H), 0.16 (s, 3H), 0.84 (s, 9H), 0.97 (s, 3H), 1.01–1.07 (m, 33H), 1.25–1.30 (m, 1H), 1.50–1.62 (m, 1H), 1.96 (s, 3H), 2.01–2.10 (m, 1H), 2.43 (d, 1H, J = 2.0 Hz), 3.14 (s, 3H), 4.12 (dd, J = 10.0, 5.7 Hz, 1H), 4.24 (d, J = 6.8 Hz, 1H), 4.33 (s, 2H), 4.38 (d, J = 8.2 Hz, 1H), 4.46 (d, J = 6.8 Hz, 1H), 4.46–4.54 (m, 2H), 5.10 (d, J = 11.7 Hz, 1H), 5.18 (d, J = 18.4 Hz, 1H), 5.49 (d, J = 11.2 Hz, 1H), 6.59 (dd, J = 18.4, 11.7 Hz, 1H), 7.34–7.43 (m, 6H), 7.66–7.76 (m, 4H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: −4.2, −3.8, 11.9, 16.7, 18.0, 18.4, 19.5, 22.3, 25.9, 26.2, 27.2, 27.9, 30.0, 39.4, 48.3, 56.0, 63.1, 66.0, 69.5, 73.3, 74.6, 74.8, 85.0, 93.3, 114.9, 127.3, 127.5, 128.0, 129.4, 129.5, 130.7, 134.0, 134.7, 136.0, 136.8, 138.6, 139.3. Dess–Martin periodinane (597 mg, 1.40 mmol) was added to a stirred solution of the above acetylenic alcohols (80 mg, 0.09 mmol) in dichloromethane (6 mL). The resultant mixture was heated at reflux for 16 h and then cooled to ambient temperature. A saturated aqueous solution of sodium bicarbonate (25 mL), sodium thiosulfate (1.0 g), and ether (100 mL) were then added and the resultant mixture stirred for 30 min. The organic phase was separated and washed with a saturated aqueous solution of sodium bicarbonate (5 mL), then with brine (2 × 5 mL), dried, and concentrated. Chromatography (100% hexanes to 10% ether in hexanes) afforded the ketone **23** (64 mg, 80%) as a colourless oil. IR ($CHCl_3$): 3299, 3020, 2948, 2862, 1690, 1467, 1216 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$) δ: 0.02 (br s, 3H), 0.15 (s, 3H), 0.89 (s, 9H), 1.01–1.07 (m, 45H), 1.30–1.35 (m, 1H), 1.58–1.64 (m, 1H), 1.62 (br s, 3H), 1.99–2.04 (m, 1H), 3.17 (s, 3H), 3.23 (d, 1H, J = 2.4 Hz), 4.15–4.18 (m, 1H), 4.27 (d, J = 6.7 Hz, 1H), 4.32 (s, 2H), 4.47 (d, J = 6.7 Hz, 1H), 4.55 (m, 1H), 4.58 (br s, 1H), 5.08 (d, J = 11.3 Hz, 1H), 5.17 (d, J = 17.7 Hz, 1H), 5.53 (d, J = 9.8 Hz, 1H), 6.57 (dd, J = 17.7, 11.3 Hz, 1H), 7.30–7.42 (m, 6H), 7.67–7.71 (m, 4H); ^{13}C NMR (125 MHz, $CDCl_3$) δ: −4.6, −4.0, 12.0, 14.1, 15.3, 18.0, 18.5, 19.6, 22.3, 25.9, 26.0, 27.1, 29.8, 31.6, 39.1, 56.0, 63.1, 65.8, 69.6, 73.9, 80.6, 81.1, 93.5, 114.8, 127.3, 127.5, 127.6, 128.2, 129.3, 129.5, 130.8, 134.3, 134.9, 136.0, 136.1, 136.8, 165.8, (CO, δ: 188.3 recorded at 230 K). Anal. calcd. for $C_{52}H_{82}O_6Si_3$: C 70.38, H 9.31; found: C 70.51, H 9.34.

1-(2-*tert*-Butyldimethylsilyloxyethyl)-(5*R)-(3-methoxymethyl-(1*R**)-methoxymethyloxy-(2*Z*)-4-pentadienyl-2,6,6-trimethylcyclohexene (25)**

N,*N*-Diisopropylethyl amine (15 mL, 86 mmol) and chloromethylmethyl ether (3.0 mL, 40 mmol) were added sequentially to a stirred solution of the alcohol **15** (2.22 g, 5.43 mmol) in dichloromethane (20 mL) at 0°C. The resultant mixture was stirred at 0°C for 10 min and then at ambient temperature for 20 h. A saturated aqueous solution of sodium bicarbonate (80 mL) was added, the phases were separated, and the aqueous phase was extracted further with dichloromethane (3 × 50 mL). The combined organic extracts were washed with a saturated aqueous solution of sodium bicarbonate (100 mL), then with brine (100 mL), dried, and concentrated. Chromatography (9:1, hexanes/ether) afforded the silyl ether **25** (2.12 g, 86%) as a colourless oil. IR ($CHCl_3$): 2912, 1092 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.05 (s, 6 H), 0.88 (s, 9H), 1.00 (s, 3H), 1.07 (s, 3H), 1.14–1.40 (m, 3H), 1.60 (s, 3H), 1.90 (m, 2H), 2.28 (m, 2H), 3.31 (s, 3H), 3.34 (s, 3H), 3.50 (t, J = 7 Hz, 2H), 4.12 (dd, J = 2, 11 Hz, 2H), 4.55 (dd, J = 2, 11 Hz, 2H), 4.72 (m, 1H), 5.20 (d, J = 11 Hz, 1H), 5.35 (d, J = 17.5 Hz, 1H), 5.73 (d, J = 9 Hz, 1H), 6.26 (dd, J = 17.5, 11 Hz, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: −5.16, 18.3, 19.3, 20.3, 22.4, 26.0, 27.0, 32.7, 32.9, 38.6, 51.0, 56.2, 58.1, 63.0, 66.5, 71.1, 94.4, 114.1, 129.1, 133.6, 135.4, 136.6, 138.4; HRMS (EI) calcd. for $C_{26}H_{48}O_4Si$: 452.3324; found: 452.3344.

1-Acetaldehyde-(5*R)-(3-methoxymethyl-(1*R**)-methoxymethyloxy-(2*Z*)-4-pentadienyl-2,6,6-trimethylcyclohexene (26)**

A solution of *n*-tetrabutylammonium fluoride (25 mL, 1.0 M in THF, 25 mmol) was added to the neat silyl ether **25** (2.12 g, 4.68 mmol) at ambient temperature. The resultant mixture was stirred for 2 h and then a saturated aqueous solution of sodium bicarbonate (25 mL) was added. The phases were separated and the aqueous phase was extracted further with ether (3 × 20 mL). The combined organic extracts were washed with brine (40 mL), dried, and concentrated. Chromatography (3:4, hexanes/ether) afforded the corresponding alcohol (1.51 g, 96%) as a colourless oil. IR ($CHCl_3$): 3374, 2910, 1095 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.97 (s, 3H), 1.03 (s, 3H), 1.10–1.30 (m, 3H), 1.58 (s, 3H), 1.85 (m, 2H), 2.23 (m, 2H), 3.22 (s, 3H), 3.25 (s, 3H), 3.50 (t, J = 7 Hz, 2H), 4.05 (dd, J = 2, 11 Hz, 2H), 4.42 (dd, J = 2, 11 Hz, 2H), 4.62 (m, 1H), 5.00 (d, J = 11 Hz, 1H), 5.29 (d, J = 17.5 Hz, 1H), 5.68 (d, J = 9 Hz, 1H), 6.21 (dd, J = 17.5, 11 Hz, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 19.3, 20.3, 22.5, 27.1, 32.3, 32.8, 38.6, 50.9, 56.3, 58.1, 62.5, 66.5, 71.1, 94.4, 114.1, 129.5, 133.1, 135.4, 136.6, 138.3. Dess–Martin periodinane (2.70 g, 6.55 mmol) was added to a stirred solution of the above alcohol (679 mg, 2.01 mmol) in dichloromethane (20 mL) at ambient temperature. The resultant mixture was heated at reflux for 1 h and then cooled to ambient temperature. A saturated aqueous solution of sodium bicarbonate (12 mL), aqueous sodium thiosulfate solution (1.0 M, 15 mL), and water (10 mL) were then added.

The phases were separated and the aqueous phase was extracted further with dichloromethane (2 × 15 mL). The combined organic extracts were washed with brine (30 mL), dried, and concentrated. Chromatography (2:1, hexanes/ether) afforded the aldehyde **26** (591 mg, 87%) as a colourless oil. IR ($CHCl_3$): 2905, 1072 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.99 (s, 3H), 1.02 (s, 3H), 1.4–1.8 (m, 3H), 1.54 (s, 3H), 2.04 (m, 2H), 3.07 (d, J = 2 Hz, 2H), 3.30 (s, 3H), 3.33 (s, 3H), 4.13 (dd, J = 2, 11 Hz, 2H), 4.52 (dd, J = 2, 11 Hz, 2H), 4.71 (m, 1H), 5.12 (d, J = 11 Hz, 1H), 5.39 (d, J = 17.5 Hz, 1H), 5.77 (d, J = 9 Hz, 1H), 6.29 (dd, J = 17.5, 11 Hz, 1H), 9.73 (t, J = 2 Hz, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 19.2, 20.2, 21.9, 26.7, 33.0, 38.5, 43.7, 43.8, 51.0, 56.2, 58.1, 66.4, 71.0, 94.4, 114.1, 129.0, 132.5, 135.7, 136.2, 138.2, 201.2.

(5*R)-(3-Methoxymethyl-(1*R**)-methoxymethyloxy-(2*Z*)-4-pentadienyl-1-(2-oxo-3-butynyl)-2,6,6-trimethylcyclohexene (27)**

A solution of ethynylmagnesium chloride (10 mL, 0.5 M in THF, 5.0 mmol) was added to a stirred solution of the aldehyde **26** (630 mg, 1.87 mmol) in THF (20 mL) at 0°C. The resultant mixture was stirred for 1.5 h and then water (40 mL) was added. The phases were separated and the aqueous phase was extracted further with ether (3 × 40 mL). The combined organic extracts were washed with brine (50 mL), dried, and concentrated. Chromatography (1:1, hexanes/ether) afforded the corresponding acetylenic alcohols (454 mg, 67%) as colourless oils. Dess–Martin periodinane (2.20 g, 5.33 mmol) was added to a stirred solution of the above acetylenic alcohols (454 mg, 1.25 mmol) in dichloromethane (20 mL) at ambient temperature, and the resultant mixture was then heated at reflux for 1.5 h. The reaction mixture was then cooled to ambient temperature and poured into a mixture of a saturated aqueous solution of sodium bicarbonate (15 mL), an aqueous sodium thiosulfate solution (1.0 M, 15 mL), and water (30 mL). The aqueous phase was then extracted with dichloromethane (3 × 15 mL) and the combined organic extracts were washed with brine (30 mL), dried, and concentrated. Chromatography (2:1, hexanes/ether) afforded the ketone **27** (441 mg, 98%) as a colourless oil. IR ($CHCl_3$): 2920, 2090, 1680, 1095 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.99 (s, 3H), 1.01 (s, 3H), 1.40–1.60 (m, 3H), 1.56 (s, 3H), 1.71 (m, 2H), 2.04 (m, 2H), 3.15 (s, 1H), 3.34 (s, 3H), 3.41 (s, 3H), 4.12 (dd, J = 2, 11 Hz, 2H), 4.48 (dd, J = 2, 11 Hz, 2H), 4.70 (m, 1H), 5.08 (d, J = 11 Hz, 1H), 5.36 (d, J = 17.5 Hz, 1H), 5.73 (d, J = 9 Hz, 1H), 6.29 (dd, J = 17.5, 11 Hz, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 19.2, 20.8, 22.3, 26.6, 32.9, 38.4, 45.2, 50.5, 56.3, 58.1, 66.5, 71.1, 78.3, 81.7, 94.5, 114.1, 129.7, 132.8, 135.7, 136.3, 138.3, 186.0: Anal. calcd. for $C_{22}H_{32}O_4$: C 73.30, H 8.95; found: C 73.42, H 8.86.

The chemical history of a current

Keith J. Laidler

Abstract: The electric current was born two centuries ago, and its precise nature is still being elucidated. Various lines of investigation have been pursued. The discovery of electrolysis in 1800 was followed in 1834 by Faraday's laws, and led to the realization that there is a fundamental particle of electricity. In the 1840s, Joule's studies on batteries and electric motors led him to the formulation of the principle of conservation of energy. Clerk Maxwell's theory of electromagnetic radiation owed much to measurements of the speed of an electric current in a good conductor. The existence of ions in solution was not accepted until late in the century, and has led to a much deeper understanding in the whole field of electrochemistry. The electrode processes that occur in a galvanic cell and in electrolysis usually control the rate with which the current flows, and the mechanisms of such processes have presented a great challenge to research workers. Brian Conway has made important contributions to the understanding of electrode processes, and to related electrochemical problems, over a period of more than 40 years.

Key words: electric current, electrochemistry, electrode processes.

Résumé : La découverte de l'électricité remonte à deux siècles et sa nature précise est encore à découvrir. Plusieurs voies d'études ont été poursuivies. La découverte de l'électrolyse en 1800 suivie en 1834 par les lois de Faraday, a permis de réaliser qu'il existe une particule fondamentale d'électricité. Dans les années 1840, les études de Joule sur les batteries et les moteurs électriques l'ont conduit à formuler le principe de la conservation de l'énergie. La théorie de Clerk Maxwell sur la radiation électromagnétique est surtout due à la mesure de la vitesse d'un courant électrique dans un bon conducteur. L'existence des ions en solution n'a été acceptée que très tard dans le courant du siècle, et a conduit à une connaissance plus approfondie de l'électrochimie en général. La réaction à l'électrode qui se produit dans une cellule galvanique et dans l'électrolyse contrôle habituellement la vitesse à laquelle le courant circule, et le mécanisme de ces réactions a constitué un grand défi pour les chercheurs. Brian Conway, sur une période de 40 ans, a apporté une contribution importante à la compréhension des réactions à l'électrode, ainsi qu'aux problèmes électrochimiques qui y sont reliés.

Mots clés : courant, électrique, électrochimie, réactions à l'électrode.

Introduction

The electric current was born in 1800 and continues to be investigated after nearly 200 years. When an electric current is generated by a galvanic cell, or when an electrolysis occurs, several different processes have to be taken into consideration. One is the flow through the conducting wires; another is the movement of ions in the chemical solutions. Of particular importance are the processes that take place at the electrodes. Almost always the rate with which the current flows is determined by these electrode processes. The story of the experimental and theoretical studies made over so many years is a complex one, and the present account can cover only some of the most fundamental aspects.

The exact date of birth of the electric current is debatable, but 2 March 1800 is a reasonable suggestion. It was on that day that the Italian physicist Alessandro Volta (1745–1827), of the University of Padua, sent his famous letter to Sir Joseph Banks (1743–1820), the President of the Royal Society, of which Volta was a Fellow. In this letter Volta described the pile, now known by his name, consisting of a series of discs of two different metals, such as silver and zinc, separated by paper moistened with brine. He found that electricity was produced, and his great achievement was to realize that it was caused by the contact between the metals and solutions present in his pile. Later in the year Volta's paper appeared in the *Philosophical Transactions* (1).

It is true that nine years previously Galvani had produced electricity by inserting metals into frogs' legs. He had, however, misinterpreted the effect as due to some particular property of living systems, and he used the expression "animal electricity." Volta's work showed this idea to be incorrect. His important contribution was to isolate the physical phenomenon of electricity from its connection with living systems. He recognized that in Galvani's experiments the function of the frog's leg was to provide the salt solution, and to act as a detector of electricity. It took about four more decades for it to become clear that chemical energy released in a reaction is the source of the electrical energy produced in a Voltaic pile.

For some time after Volta's announcement there was confusion about just what he had discovered. Much work had previously been done on static electricity, and the new phenomenon obviously had some connection with static electricity, but just what was the relationship? It gradually became clear that Volta had discovered how to create a flow of elec-

Received March 25, 1997.

This article is dedicated to Professor Brian E. Conway on the occasion of his 70th birthday.

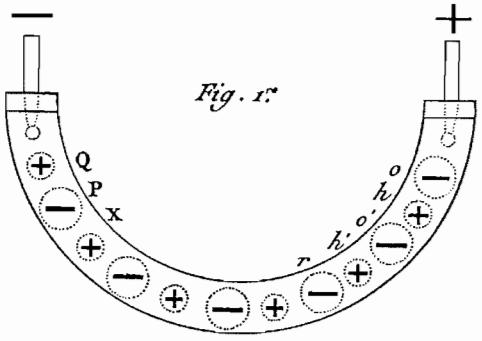
tricity, but many questions remained. Just what happens when a current flows along a wire? How fast does it flow? What happens at the metals that are introduced into a solution in order to generate electricity? In the case of an electrolysis, there was a question of how electricity flows through a solution, and of how fast it flows. What happens at the electric poles (which Faraday preferred to call electrodes) that are introduced into a solution in order to bring about electrolysis?

The discovery of electrolysis

The news of Volta's discovery spread rapidly by word of mouth, and there was much excitement among scientific investigators. As a result, even before Volta's letter appeared in print, another paper (2) was published, which described experiments making use of the information presented by Volta, and using piles of the same kind. This paper showed that the electricity generated in the piles was capable of bringing about the decomposition of water into hydrogen and oxygen gases. The author of this paper was William Nicholson (1753–1815), and the experiments had been done in collaboration with his friend Anthony Carlisle (1768–1840). Nicholson was a competent amateur scientist, and Carlisle was a fashionable London surgeon. On learning of Volta's work the two men constructed Voltaic piles of their own, and introduced the wires coming from the piles into weakly acid solutions. When they used either platinum or gold wires they found that hydrogen gas was evolved at one wire and oxygen gas at the other. Nicholson was the founder and editor of the *Journal of Natural Philosophy, Chemistry and the Arts*, usually known as *Nicholson's Journal*, and, as a result, was able to publish his results in July 1800 (before Volta's own paper was published). Much later, in 1834, Michael Faraday first used the word *electrolysis* to describe this kind of molecular splitting.



Nicholson and Carlisle's discovery that electricity can split water into hydrogen and oxygen created as great a stir as any scientific discovery ever made. The surprise was not so much at the *fact* that the gases were produced, but with *where* they were produced. It seemed to most investigators that, if the gases were produced at all, they should be produced *together*. If water is split into hydrogen and oxygen, why do they not appear in one place? Does one of the gases burrow through the solution from one wire to the other?

There was much confusion about this for a number of years, and the Institut de France even set up a committee to consider the problem. Its members came to no firm conclusion, but suggested various possibilities, one of which was that there actually was some unknown mechanism by which gases and other materials could travel invisibly through a solution. In 1806 such a mechanism was suggested (3) by a young German, Theodor Christian Johann Diedrich von Grotthuss (1785–1822; Fig. 1). While still a student in Italy he postulated that "galvanic action" polarizes water to such a degree that the elements can pass through the solution in opposite directions, always remaining bound to a partner until released at the poles. The diagram he used to explain his mechanism is shown in Fig. 2. It seems remarkable today that von Grotthuss should have represented a molecule of water as if it were completely dissociated into charged species (many people at the time thought that water was HO, so that he may have been thinking of H^+ and O^-). In fact, von Grotthuss did not believe that ions

Fig. 1. An engraving of Theodor Christian Johann Diedrich von Grotthuss (1784–1822). Besides suggesting a theory of electrolysis in 1805, he discovered in 1809 that for photochemical action the light must be absorbed. This was rediscovered by J.W. Draper in 1841, and is now often called the Grotthuss–Draper law. Von Grotthuss inherited a disease that caused him great suffering, and, as a result, he committed suicide at the age of 37. were really present in solution; he thought that the ions were always bound to one another, but that one charged species could jump from one molecule to another. He envisioned something like what happens in a square dance in which each person passes along a chain of people, continually taking the hands of those moving in the opposite direction. We now know that von Grotthuss's mechanism does not apply in gen-

eral, the current instead being carried by ions that can move without always being attached to a partner. However, a mechanism similar to that of von Grotthuss is believed to apply to the movement of a hydrogen or hydroxide ion through a solution. In the case of a hydrogen ion, a proton is transferred from H_3O^+ along a stream of water molecules, and such a mechanism is today called a *Grotthuss mechanism.* More is said later of this type of mechanism.

Electric batteries

Volta's work, and that of Nicholson and Carlisle, stimulated much further work on the production of electric currents. It was soon realized that Voltaic piles were awkward to use, and that it was more convenient to immerse rods or plates of two different metals in a bath containing a suitable solution. Such a device was, and is, often called a *battery*, although strictly speaking it should be called a cell; the word battery should be reserved for several cells connected together. Many different combinations of metals were used, and there was much rivalry among investigators. Some, notably John George Children (1777–1852), delighted in making batteries of enormous size, by means of which they produced spectacular sparks and brought about the melting of metals. Some of this work had little scientific value.

Batteries of a more modest size were used at the Royal Institution by Sir Humphry Davy (1778–1829) to isolate a number of chemical elements. On 6 October 1807 he electrolyzed fused potash and obtained the element potassium, and later he isolated sodium, calcium, strontium, barium, and magnesium (4).[2] On the basis of work of this kind, Davy advanced the hypothesis that electrical attractions are responsible for the formation of chemical compounds. In this he was quite right, although the situation is much more complicated than he thought.

In 1808 Davy brought together two carbon rods, which were connected to the poles of a battery, and produced a brilliant arc (5). This can be said to be the first lamp powered by electricity, but it was not for another half century that arc lamps could be used for public lighting.

Later, several useful electric cells were devised by John Frederick Daniell (1790–1845), who was professor of chemistry at King's College, London. One of Daniell's cells (6), constructed in 1836, consisted of an outer vessel containing copper sulphate solution, inside which was an ox-gullet bag containing a rod of amalgamated zinc in dilute sulphuric acid. It produced about 1.1 V. In a later modification the ox gullet was replaced by a porous pot that contained the acid and the zinc electrode (7). In 1839 he put together a battery of 70 of his cells and produced a brilliant electric arc, which caused some skin blistering and some eye injury to himself and others (8).

William Robert Grove (1811–1896) also devised some useful electric cells. In 1838, when a professor at the London Institution, he devised a cell consisting of zinc in sulphuric acid and platinum in nitric acid, the two liquids being separated by porous material (9). This cell produced 1.8–2.0 V (greater than that given by Daniell's cells). A little later he described what he called a *gas voltaic battery*, consisting of platinum electrodes immersed in acid solution, with hydrogen bubbled over one electrode and oxygen over the other (10).[3] The source of the voltage is the energy released by the combination of the two gases. Later Grove used other combinations of gases, such as hydrogen and chlorine, and oxygen and carbon monoxide. Cells of this type are today called *fuel cells,* and they are still the subject of much research to make them more effective for commercial use.

The electrical euphoria

The invention of batteries for the generation of current electricity led in the early 19th century to what has been called an electrical euphoria. After electric motors had been invented in the early 1830s the idea became prevalent that one could run a motor by a battery, and gain an unlimited amount of energy (although the actual word energy was rarely used at that time). One of the enthusiastic proponents of this point of view was Moritz Hermann von Jacobi (1801–1874), whose work was done first at Dorpat, which was then in Russia (it is now called Tartu and is in Estonia), and then in St. Petersburg. In 1834 von Jacobi constructed an electric motor, and he carried out interesting experiments with it (11). Three years later he published a paper (12) that created something of a sensation. He argued that if certain imperfections of the electric motor, such as friction and what is now called back-emf, could be eliminated, a motor would go on accelerating indefinitely, producing enormous amounts of power — all at no cost! These arguments seemed compelling at the time, and many electric motors were built in order to take advantage of what seemed a utopian opportunity.

It was James Prescott Joule (1818–1899), an amateur scientist living in Manchester, who first pricked the bubble, showing that one could not get something for nothing by using a battery to operate a motor. He began his investigations at the age of 19, and at first he too was carried away by the electrical euphoria. In 1840 he made careful experiments on the mechanical effect that could be obtained from a motor, and related it to the amounts of metal used up in the battery operating the motor (13). He was disappointed to find that the consumption of a given amount of zinc in a battery of the Daniell type led to the production of only about one-fifth of the mechanical work that would be produced by the same weight of coal in a steam engine. Since zinc was much more expensive than coal, it followed that an electric motor would be far from being a competitor to a steam engine for the primary production of energy. For Joule, the electrical euphoria was over.

Joule then decided to study the heating effect of an electric current. Using simple equipment, but working with great care, he established that a current passing through a wire of resistance r generates heat in proportion to r, and in proportion to i^2, the square of the current passing; this is his well-known i^2r law (14). He also concluded that the heat produced is equal to the energy released by the chemical action occurring in the battery. Although this conclusion had later to be modified (to

[2] This was Davy's Bakerian Lecture, delivered on 20 November 1806.

[3] Reference 10 gives only a brief preliminary account of the gas battery; further details are in papers that appeared in 1842, 1843, and 1845.

take into account entropy changes as well as energy changes), it was important in confirming that, contrary to von Jacobi's prediction, energy could not be created from nothing. With regard to the applications of electricity to practical use, Joule wrote that "electricity is a grand agent for carrying, arranging and converting chemical heat." This was indeed a shrewd prophesy.

In 1843 Joule carried out an investigation that is remarkable for its ingenuity. He enclosed the revolving part ("armature") of an electric generator (sometimes later called a "dynamo") in a vessel containing water, and determined the heat generated when he rotated the armature for a fixed period of time (15). He also measured the heat produced by the current that was generated. In this way he established the equivalence between the heat produced as a result of rotating the armature, and the mechanical work required for the rotation.

As is well known, Joule carried out a great many other investigations that led firmly to the law of conservation of energy, also known as the first law of thermodynamics. Modern textbooks tend to stress the investigations Joule made in which he generated heat in liquids by the use of large paddles. It is important to recognize, however, that it was his work on batteries and electric motors that first set him on the right track.

Joule also made progress towards establishing the general thermodynamic relationships involved in electrical batteries. He was not, however, completely successful, since the concept of entropy had not yet been introduced, and he necessarily neglected its role. Correct treatments of the thermodynamics of electric cells were first worked out by Hermann von Helmholtz (1821–1894) and further developed by Walther Nernst (1864–1941).

Electromagnetism

Twenty years after the discoveries of current electricity and of electrolysis there was another discovery that had momentous consequences. This was Oersted's discovery of electromagnetism,[4] which showed for the first time that there was an important relationship between electricity and magnetism. Early in 1820 Hans Christian Oersted (1777–1851), professor of physics at the University of Copenhagen, brought a compass needle near to a wire connected to the poles of a battery and found that the needle tended to turn. When the direction of the current was reversed, the needle turned in the opposite direction.

There are three unusual features of this discovery. In the first place, it was made in front of a class of students. Oersted and his assistant had set up the experiment but had no time to try it out before the students arrived. Oersted first decided to defer the experiment until later, but during the lecture he began to feel confident that it would work, and performed it successfully. The second remarkable feature is that, since the deflection of the needle had been small, Oersted was so little impressed by the result that he performed no further experiments on the subject for 3 months.

The third remarkable feature was that the compass needle turned in an unexpected direction; the poles of the magnet were not attracted or repelled by the current, but moved in a direction at right angles to the expected direction. At the time, in the scientific tradition established in particular by Newton, theories were formulated in terms of so-called central forces acting in straight lines between points; these forces were believed to follow Coulomb's law, the force being inversely proportional to the square of the distance between the points. The fact that the magnetized needle was subjected to a deflecting force (i.e., it moved in a sideways direction) was therefore particularly surprising. It suggested a force not acting in a straight line but circularly, which most scientists thought to be impossible. However, within a short time many investigators had confirmed the experimental result obtained by Oersted. In particular, the distinguished scientific statesman François Arago (1786–1853), at first sceptical, himself repeated Oersted's experiment, and called attention to the discovery at a meeting of the Académie des Sciences in Paris on 4 September 1820.

The French physicist André Marie Ampère (1775–1836) was in the audience at that meeting, and heard Arago announce Oersted's discovery. He had not worked previously on electricity, but within a week had made careful quantitative experiments and formulated a mathematical treatment. As early as 18 and 25 September 1820 he gave verbal reports to the Académie, confirming Oersted's results and presenting some significant additional experimental results he had obtained himself (17).[5] He also explained a hypothesis he had formulated on the relationship between electricity and magnetism. His work during the next few years gave strong support to the conclusions he had reached so quickly. The *Mémoire* (18) published on the subject by Ampère in 1823 is still regarded as a masterpiece; Clerk Maxwell later described it as "perfect in form and unassailable in accuracy" (19). It is appropriate that the unit of electric current is called the ampere; it is one of the base units in the Système Internationale d'Unités (SI).

Ampère's detailed mathematical treatment of the interactions was based on the assumption that current-carrying elements of the wires interacted with one another according to the inverse square law. By adding up (by integration) the effects of all the elements, he arrived at expressions that were consistent with the experimental results. His treatment was very impressive, and Clerk Maxwell in his *Treatise on Electricity and Magnetism* (19) referred to Ampère as the "Newton of electricity." There is something of an irony about this, because Maxwell's own work caused the later development of the theory of electromagnetism to follow a completely different path. Ampère nevertheless deserves great credit for his experimental and theoretical work, since it played a significant part in the later developments of the subject.

To explain the effect of an electric current on a magnet, Ampère supposed that magnetism arises from electricity moving in circular orbits round the axis of the magnet; that is, the planes of the orbits are at right angles to the magnetic axis. He coined the word *solenoid* to refer to a current moving in a

[4] H.C. Oersted wrote a four-page note in Latin, and sent it on 21 July 1820 to a number of scientific journals in different countries; announcements of the discovery then appeared in various languages; for example, see ref. 16.

[5] This paper was received on 4 December 1820, and there were a number of papers later on the same theme.

Fig. 3. A daguerreotype of Michael Faraday (1791–1865), taken by Antoine Claudet (1797–1867) in the early or mid 1840s.

small circuit and creating a magnet. He carried out experiments with solenoids in which wires were wound around glass tubes, and confirmed that when a current passed, a magnetic effect was obtained. He then developed an elegant mathematical treatment of the interactions between electric currents and the circular currents around the magnets, and was able to explain Oersted's results in terms of central forces.

Ampère's work was at once recognised by most investigators as an achievement of great significance, but a few objections were raised. It was pointed out that there was no experimental evidence for a flow of electricity round magnets, and no suggestion as to how it could arise. Volta had found that a current results when two dissimilar metals are present, but not if only one metal is present. Ampère later modified his theory to relate to the molecules in the magnets, suggesting that perpetual electric currents moved in orbits around them (we know today, of course, that electrons do move in orbits about the nuclei of atoms).

Faraday's scepticism

Michael Faraday (1791–1867; Fig. 3) was particularly unhappy with what Ampère had done. He knew little mathematics, and was ill-versed in physical theories: he simply could not understand the treatment. He was quite content to think of a circular force arising from a current flowing in a wire. Hardly anyone brought up on the physics of the time could accept such an idea, and yet it was the origin of Faraday's important concept of the electromagnetic field, which was to be the core of the later, more advanced, ideas of Faraday himself and of Clerk Maxwell.

In late 1820, prodded by his friend Richard Phillips, an editor of the *Philosophical Magazine*, Faraday somewhat reluctantly began to investigate electromagnetism. His reluctance was partly because he was employed at the Royal Institution as a chemist, and not as a physicist, and all his previous work had been in chemistry (he was later, in 1832, appointed professor of *chemistry* at the Institution). At the time, however, the distinctions between the sciences were fainter than today, and no one at the Institution seems to have objected to the fact that Faraday's subsequent work was more in physics than in chemistry.

Faraday at once repeated Oersted's experiments, and noticed that when a small magnetic needle was moved round a wire carrying a current, one of the poles turned in a circle. He then speculated that a single magnetic pole, if it could exist, would move continuously around a wire as long as the current flowed. This led him to perform an experiment of great simplicity, and also of great importance. In 1821 he attached a magnet upright to the bottom of a deep basin, and then filled the basin with mercury so that only the pole of the magnet was above the surface. A wire free to move was attached above the bowl and dipped into the mercury. When Faraday passed a current through the wire and the magnet, the wire continuously rotated around the magnet (20). In an adaptation of the experiment he caused the magnet to rotate around the wire. He also succeeded in rotating a wire by use of the magnetism of the earth. The great practical significance of these simple demonstrations is that electrical energy was being converted into mechanical energy for the first time. Faraday had anticipated the electric motor by about 10 years.

The experiment also had a great theoretical significance, at first appreciated only by Faraday, but later by the world of science. Faraday's conclusion was that there were circular *lines of force* round the current-carrying wire, and he accepted this as a simple experimental fact. Almost everyone else at first ridiculed this suggestion, and concluded that the force could not be simple, but must be explained in some way in terms of central forces, as had been done successfully by Ampère. For the next 10 years Faraday worked only sporadically on electricity, but quietly maintained his unconventional ideas about electromagnetism.

In 1831 Michael Faraday made one of his most famous discoveries, *electromagnetic induction*. From time to time he had experimented with the idea in his mind that a wire bearing a current might induce a current in a nearby wire. Until 29 August 1831, however, he always failed to find any effect. On that day he wound one side of a soft-iron ring with insulated wire, and arranged a secondary winding, connected to a galvanometer, around the other side. At first he thought that the experiment was again a failure. He noticed, however, that when he *turned off* the electric current in the primary coil, believing the experiment to have failed, the galvanometer revealed a sudden short flow in the secondary circuit. Closer investigation showed that a *continuous* current in the primary circuit had no effect; it was only when the current was started or stopped that there was an effect on the galvanometer (21).

Soon after his discovery of electromagnetic induction in 1831, Faraday demonstrated that if he pushed a magnet into a coil of wire, a transient current was produced (22). A current was generated in the opposite direction when the magnet was withdrawn. No current passed when the magnet was station-

For personal use only.

ary; to generate a current the magnet must be moved in relation to the coil. The important point is that electromagnetic induction only occurs if there is a *change* in an electric current or if a magnet is *moved*.

Faraday's laws of electrolysis

Soon after Faraday carried out these experiments, which supported his unconventional ideas about the nature of an electric current, he began to devote much attention to the electrolysis of water. In 1833 he showed (23) that electrolysis can be brought about by electricities produced in a variety of ways, such as from electrostatic generators, voltaic cells, and even electric fish. In particular, he charged two metal spheres with static electricity and brought them close to one another in the neighbourhood of a solution; the passage of the discharge through the solution brought about electrolysis, even though no wires had been introduced into it. An extremely powerful electrostatic field, however, would not in itself bring about electrolysis (which it would be expected to do if central forces were involved); a current or an electric discharge must pass through the solution.

Besides being important to Faraday's investigations of electrolysis, these results for the first time clarified the relationship between static and current electricity, a matter that had never been properly understood. They are essentially the same, but exist under different circumstances. With static electricity the quantities of electricity are usually small, but enormous potential differences may exist. With current electricity, the potential differences are usually smaller, but the quantities are larger.

Experiments done by Faraday in 1834 (24) finally convinced him that if electrolysis is brought about by inserting wires into a solution, and then a current is passed, the effect cannot be explained in terms of action at a distance. He performed one experiment in which two solutions were separated from one another by a 70 ft string soaked in brine. Gases were evolved at the two wires, and Faraday thought it impossible that the inverse square law could explain an effect extending over such a distance. He also showed that the effects of electrolysis do not follow straight lines, which they would do if there were action at a distance. Also, Faraday argued, if a substance were attracted to a wire by the inverse square law, would it not remain bound to the wire rather than being released from it?

Faraday's conclusion that action at a distance does not apply led him to dislike the word *pole* that had come to be used in connection with electrolysis, since he felt that it implied a centre of force. In its place, at the suggestion of his friend and personal physician Whitlock Nicholl (1786–1838), he introduced the word *electrode*, from the Greek ελεκτρων (electron) and όδος (hodos), meaning "way." Nicholl also suggested the word *electrolysis*, from λυσις (lysis), meaning "splitting," and also the word *electrolyte*, to mean something that undergoes electrolysis.

For other help with words, in 1834 Faraday approached William Whewell of Trinity College, Cambridge, who had shown much interest in Faraday's research. The details of the discussions with Whewell are of great interest, but since they have been presented in detail (25, 26) they will be given here only in outline. In 1834 Faraday asked Whewell for words that would refer to the regions of solution present at the surfaces of the positive and negative electrodes. Whewell suggested the words *anode* and *cathode*, and for species present in solution he suggested *anion, cation*, and *ion*; Faraday made good use of the words cation and anion, but regarded them as always transient species. He commented to Whewell that he thought he would find little use for the word ion. Now that it is known (which Faraday did not know) that ions do exist in solution, the word has found a wide use.

As Faraday proceeded with his investigations into electrolysis he came to view the process as follows. He considered that the electrical effect is transmitted from molecule to molecule, and that the affinities of the components of water, or of a dissolved salt, are weakened, so that each component would be able to leave its partner and jump to another close by.

In 1834 Faraday suggested, on the basis of these ideas, two fundamental laws of electrolysis (27). It is often thought that he discovered these two laws empirically, but this is not the case; they were deduced by him on the basis of his ideas about how electricity interacts with a solution. He later confirmed them by experiment. If electrolysis had proceeded by action at a distance, as had been thought previously, the amount of material deposited or evolved would have depended on the electric potential and on the size of the vessel used. According to Faraday's ideas, however, the amount would depend only on the product of the current and the time, i.e., on the *quantity* of electricity that passes through the solution, and Faraday confirmed that this is the case; this was his *first law of electrolysis*. And since, in Faraday's view, the electricity was concerned with weakening the affinities between the constituents of matter, the amount should depend on the equivalent weight of the substance evolved or deposited. This is his *second law of electrolysis*. Faraday never expressed the second law in quite this form, but his experiments showed this law to be obeyed.

It is somewhat ironic that Faraday should have deduced his laws of electrolysis on the basis of ideas that we now know to be not entirely correct. The effect of the current is not to *bring about* dissociation, as Faraday thought; instead, the ions are *already present* and the electric field brings about their movement towards the electrodes, where they are neutralized. The relationship between the quantity of electricity and the amount of material deposited or evolved arises not because the electricity is concerned with dissociation, but because it is concerned with the neutralization of ions that are already present. This, however, did not matter as far as Faraday's conclusion was concerned.

Faraday's laws of electrolysis were of great theoretical significance, since they suggested that electricity itself is not continuous, and that fundamental particles of electricity are in some way associated with atoms. In one of his later papers on electrolysis (28) Faraday wrote:

> ...if we adopt the atomic theory or phraseology, then the atoms of bodies which are equivalent to each other in their ordinary chemical action, have equal quantities of electricity naturally associated with them.

However, Faraday was always rather reticent in referring to atoms, preferring the idea that electricity is a fluid. It was left to others, notably von Helmholtz and Johnstone Stoney, to develop the idea of a fundamental unit of electricity.

Electrolytic dissociation

It was not until later in the 19th century that much thought was given to the existence of independent ions in solution. Although Faraday had used the words cation and anion since 1834, he thought that they only existed in close association with ions of opposite sign. When he spoke of the movement of cations and anions through a solution, he was thinking of them as formed only transiently when the current flowed. His assumption was that, for example, sodium chloride molecules are present intact in solution, and he explained electrolysis in terms of the dissociation of salt molecules by the action of the electric current. It is true that von Grotthuss, in 1808, had given a diagram showing independent ions (Fig. 2), and that similar diagrams had been presented by Daniell and Miller (29) and by Hittorf (30). But these diagrams had been thought to be purely schematic, intended to help the understanding of what occurs during the passage of electricity through a conducting solution.

The first modification to this point of view was put forward in 1857 by Rudolph Julius Emmanuel Clausius (1822–1888), who was then at the Polytechnicum in Zürich. Clausius (31) found that Ohm's law was accurately obeyed in measurements of conductivities of solutions; i.e., the current is proportional to the electromotive force. This result presented difficulties for the idea that the electric current has to perform the work of splitting molecules into ions. He suggested that a small number of ions are always present as a result of collisions between solvent and solute molecules, some of the collisions being sufficiently energetic to cause dissociation into ions. The movement of these ions would provide the transport of charge when a current was passed.[6]

In 1853 Johann Wilhelm Hittorf (1824–1914) began work on conductivity at the Royal Academy of Münster. At first he followed Faraday's ideas as to the nature of the process, but after the appearance of Clausius's 1857 paper he accepted the idea that a small number of free ions are always present. He made measurements of the concentration changes in the neighbourhood of the two electrodes when the current is passed, and measured the relative speeds with which ions moved through solutions (32).

Further significant experimental advances were made in the 1860s and 1870s by Friedrich Wilhelm Georg Kohlrausch (1840–1910). In Göttingen, Zürich, and Würzburg he carried out extensive studies, using novel techniques, on the conductivities of electrolytes (33). He too was impressed by the fact that Ohm's law was accurately obeyed, and, like Clausius, he assumed that free ions were always present in small amounts.

In 1874 Kohlrausch and Otto Natalis August Grotrian (1847–1921) found evidence for the law of independent migration of ions (34). They were also able to deduce the speeds with which various ions move under a unit potential gradient. Other important measurements of ionic speeds were also made by Oliver Joseph Lodge (1851–1940), who followed the ions as they moved through a gel coloured by an indicator sensitive to acid. This so-called moving-boundary method was also used by William Cecil Dampier Whetham (later known as Sir William Dampier, 1867–1952), who studied the movement of neutral ions by observing their motion in coloured salts or by the formation of precipitates.

A great advance, the theory of electrolytic dissociation, was made by Svante August Arrhenius (1859–1927) in 1889. The details are so well known[7] that only brief comments need be made here. According to Arrhenius, there exists an equilibrium in solution between undissociated molecules AB and the ions A^+ and B^-:

$$AB \rightleftharpoons A^+ + B^-$$

This proposal was significantly different from the previous idea that only trace amounts of ions are present at all times. Arrhenius proposed that the ions are always present, sometimes in substantial amounts, in equilibrium with the undissociated molecules, and that the effect of an applied voltage is not to produce them but to cause them to move through the solution.

This theory was quickly accepted by many prominent scientists, including van't Hoff, Ostwald, and Nernst. There was also much opposition to the theory. A particularly vigorous critic was Henry Edward Armstrong (1848–1937), a distinguished organic chemist who also did a considerable amount of work in electrochemistry. He was particularly outspoken on the subject of the Arrhenius theory and even lampooned the idea of ionic dissociation in two ironic fairy tales, *A Dream of Fair Hydrone* and *The Thirst of Salt Water*.

The essence of the criticisms of electrolytic dissociation was that the theory assumed that the solvent was playing only a passive role; in Armstrong's words, "the solvent was merely a dance floor for ions," as far as the theory was concerned. Armstrong, incidentally, was quite beside himself when Laurence Bragg (35, 36) insisted that in solid sodium chloride no molecules of NaCl are present, but only the ions Na^+ and Cl^-. Armstrong published a Letter in *Nature* (37)[8] ridiculing the idea (which of course was perfectly correct).

There was indeed some substance to the criticisms, in that the Arrhenius theory did seem to imply that dissociation into ions was a result merely of the high dielectric constant of a solvent such as water, and that chemical interactions were unimportant. The remedy, however, was not to overturn the theory, but to modify it.

An important advance (38) was made in 1894 by Walter Nernst (1864–1941) and Paul Karl Ludwig Drude (1863–1906), who treated the binding of ions to water molecules, a process they referred to as *electrostriction*. This idea answered the criticisms that the role of the solvent was being ignored, and led to a wider acceptance of Arrhenius's ideas. During the early years of his career Nernst made many outstanding contributions to electrochemistry, particularly to the thermody-

[6] The idea that ions exist free in solution is sometimes referred to as the Williamson–Clausius hypothesis, but this expression does not seem justified. In papers in 1851 and 1852 the British chemist Alexander William Williamson (1824–1904) suggested the dissociation of substances, but not into charged species, and his proposal was in no way related to the conductances of solutions.

[7] See ref. 26, pp. 209–218.

[8] This letter refers to a statement by Bragg in ref. 35; the work had been done 14 years previously, but Armstrong had not realized its significance!

namics of electrochemical cells, and to the theory of the behaviour of ions at interfaces.

In spite of developments such as these, the opposition to the theory of electrolytic dissociation lasted in some quarters even until the 1930s. As late as that, for example, Louis Kahlenberg (1870–1941) was still giving, at the University of Wisconsin, a course on electrochemistry that took no account of the existence of ions in solution. Some confusion arose from the fact that strong electrolytes are completely dissociated, and that their conductivity behaviour has to be interpreted in terms of the interactions betweeen ions (the Debye–Hückel theory). Arrhenius himself, to the day of his death, never accepted that this is the case.

The speed of an electric current

The question of the speed with which an electric current travels along a metal wire turned out to be a matter of special significance. The realization that this speed is the same as the speed of light was a determining factor in leading Clerk Maxwell to his theory of electromagnetic radiation.

The speed of a current can be obtained indirectly by comparing electrical results expressed in the two different sets of units, electrostatic and electromagnetic. The electrostatic units are particularly appropriate to static electricity, and relate the force of attraction and repulsion between two charged bodies to the quantities of electricity that they hold. The electromagnetic units, on the other hand, relate force to electric current. The quantity of electricity residing on a wire at a given time depends on the speed with which the current travels along the wire. It can be shown that the ratio of the value of an electrical quantity expressed in electromagnetic units to that expressed in electrostatic units is the speed with which the current travels.

Several investigations made in the midde of the 19th century showed the speed of light to be about 3×10^8 m s^{-1}. In 1856–1857 the German physicists Wilhelm Edouard Weber (1804–1891) and Rudolph Herrmann Arndt Kohlrausch[9] (1809–1858) made a careful measurement of an electric charge, first in one set of units and then in the other (39, 40). When they divided one value by the other they obtained a velocity that was very similar to the speed of light. Similar investigations (41) were carried out at about the same time by Gustav Robert Kirchhoff (1824–1887). Both sets of investigators concluded that a current travels along perfectly conducting material with the speed of light.

A little later Clerk Maxwell carried out similar experimental investigations, and obtained the same result (42). He also used an alternative procedure, comparing the electrical quantity now called the *permittivity* of a vacuum, ε_0, with the magnetic quantity now called the *permeability* of a vacuum, η_0. Maxwell's mathematical treatment of Faraday's lines of force led to the conclusion that the speed v of an advancing electromagnetic field was given by

$$[1] \quad v = (\eta_0 \varepsilon_0)^{-1/2}$$

The two quantities had been measured by a number of people, and this expression also led to the result that v was the speed of light. These investigations of Clerk Maxwell were of great significance, since they led him to his great contribution, the theory of electromagnetic radiation.

A significant aspect of these investigations was that they led to a decision between the two alternative theories of electricity that were held at the time. One theory was that there were two electrical fluids, positive and negative, which moved in opposite directions when a current flowed. Use of the method of comparison of units led to the conclusion that if there were two fluids they would each flow with half the speed of light. The evidence thus supports the theory (which Benjamin Franklin, among others, had advocated a century earlier) that only one type of electricity flows along a wire when a current passes.

The fundamental particle of electricity

Faraday's laws of electrolysis, and other investigations, pointed to the fact that there is a fundamental particle of electricity that plays an essential role. A specific idea about such a particle of electricity was advanced (43) in 1874[10] by George Johnstone Stoney (1826–1911), an Irish physicist who did much of his scientific work in London. He based his conclusion on the value of the Faraday constant, which relates the amount of substance deposited in an electrolysis to the amount of electricity passed through the system. His reasoning led to the conclusion that if the charge on this particle is the same as that on a hydrogen ion (although of opposite sign), its mass must be about 1/2000 that of the hydrogen atom.

In 1891 Johnstone Stoney even went so far as to suggest that the negative particles move in orbits within the atoms (44). He tried to develop this idea into detailed explanations of the spectra of atoms and molecules, but since essential theories (particularly the quantum theory) were still to come, these were inevitably in disagreement with experiment. For this reason his idea did not receive much attention, although we now know that it was essentially correct. Stoney suggested that the unit of negative electricity should be called an *electron*.

The actual discovery of the electron can be said to have occurred in 1897, when Joseph John Thomson (1856–1940), Cavendish professor at Cambridge, announced his conclusion that the negative particles present in a cathode-ray discharge have a mass about 2000 times smaller than that of a hydrogen atom. These were obviously the electrons that Johnstone Stoney had predicted.

By the end of the 19th century the conclusion had therefore been reached that electrons play the important role in electricity. With static electricity, a body that has a positive charge has a deficit of electrons; one that is negative has an excess of electrons. The transfer of a charge is a movement of electrons.

In current electricity, the current is carried through solids by a flow of electrons. During recent years there have been great advances in the understanding of the structures of solids. It is known that in metals at the absolute zero the electrons fill a number of quantized energy levels up to a particular level

[9] R.H.A. Kohlrausch was the father of Friedrich Wilhelm Georg Kohlrausch (1840–1910), who is well known to electrochemists for his accurate measurements of the conductivities of solutions (refs. 33, 34).

[10] Stoney had presented his ideas at the 1874 meeting of the British Association, but they were not published until 1881.

© 1997 NRC Canada

known as the *Fermi level*. At higher temperatures electrons pass into higher levels and they are then in what is called the *conduction band*. The electrons can easily pass along this conduction band. Other solids are poor conductors, and some are superconductors at lower temperatures. Detailed treatments are to be found in books on the theory of the solid state, and are beyond the scope of the present article.

In an electrolytic cell, the electrons are not the carriers of the current; instead it is carried through the cell by the ions. The electrons are involved in the neutralization of ions at the electrodes.

When electrolysis occurs, the flow of the electrons through the metal wires and the movement of the ions in the solution, are not the only factors to be considered. There is also the important matter of the electrode processes. If, for example, hydrogen gas is being evolved at an electrode, there is a question of exactly how the hydrogen ions in the solution are discharged, and how they become hydrogen molecules. The hydrogen ions must first pass through a layer (the "double layer") at the electrode surface, and this layer has different properties from the bulk of the solution. When the hydrogen ions reach the surface there may be an electron transfer from the Fermi level at the surface to the ion, with the formation of a hydrogen atom. Two hydrogen atoms can then recombine to form a hydrogen molecule. Several processes take place, and the rate with which the current flows depends on the rates of these processes. One of these processes may be slower than the others, and therefore controls the rate of deposition. Usually these electrode processes are slower than the movement of the ions through the solution, and therefore control the rate with which the current passes.

The mechanisms of surface processes are complicated, and are still being actively investigated. Only a very brief summary can be given here.

The kinetics of electrode processes

It was not until the early years of the 19th century that the time was ripe for study of the electrode processes occurring during an electrolysis, or during the operation of an electrochemical cell. The first significant work along these lines was done by Julius Tafel (1862–1918; Fig. 4) at the University of Würzburg. Tafel was primarily an organic chemist; he had been an assistant to Emil Fischer and was active in the field of preparative electro-organic chemistry, which was a popular field in the late 19th century.

In the early 1900s Tafel investigated the electrolysis of solutions in which hydrogen gas is evolved at the negative electrode. By that time it had been realized that in order for electrolysis to proceed at an appreciable rate, the voltage applied must be greater than a certain equilibrium or reversible voltage; the additional voltage is called the *overvoltage*. The overvoltage η is thus defined as

$$[2] \quad \eta = V - V_{rev}$$

where V is the potential at which electrolysis is actually proceeding, and V_{rev} is the reversible potential under the same conditions.

At the equilibrium or reversible voltage the rate of deposition of ions on an electrode is equal to the rate of reionization of the deposited substance; the net rate of deposition is therefore zero. When the additional voltage (the overvoltage) is applied, the rate of deposition is increased, and the rate of the reverse reaction is decreased; there is then net deposition. The greater the overvoltage, the greater the current. One of Tafel's important contributions (45) was to obtain an empirical expression for the relationship between the overvoltage η and the current density i (the current per unit area of electrode):

$$[3] \quad \eta = a + b \ln i$$

This equation, fundamental to the study of the kinetics of electrode processes, has come to be called the *Tafel equation*.

The overvoltage varies considerably with the nature of the electrodes. Electrodes consisting of "platinized platinum," which is platinum electrodeposited with a layer of platinum black, have a fairly low overvoltage for the evolution of hydrogen and oxygen gases in the electrolysis of water. For electrolysis to occur, the voltage that has to be applied to an aqueous solution of an acid or a base when platinized platinum electrodes are used is about 1.7 V. With zinc, on the other hand, the overvoltage is higher, and a potential of about 2.4 V has to be applied in order to have an appreciable evolution of gases.

It took a number of years for the significance of the Tafel equation to be understood in terms of theories of overvoltage. In 1930 Erdey-Gruz and Max Volmer (1885–1965) gave kinetic equations for the rates of the electrode processes occurring in forward and reverse directions (46): when the cell is operating reversibly these rates are equal, but when a current flows the rate in one direction is not exactly balanced by the rate in the other, and there is then an overvoltage. Erdey-Gruz and Volmer based their treatment on the fact that,

according to the Arrhenius equation for reaction rates, the rate of a reaction is related exponentially to the height E of the energy barrier for the reaction (the activation energy). They also recognized that when there is an overvoltage η, the contribution of the electrical energy to the energy change in the overall reaction is ηF, where F is the Faraday constant. However, only a fraction of this enters into the activation energy for the forward reaction. If the fraction is α, the energy of activation for the forward reaction is therefore lowered by $\alpha\eta F$. For the reverse reaction the fraction $1 - \alpha$ of the electrical energy causes the activation energy to increase by $(1 - \alpha)\eta F$. The current that passes is proportional to the net rate of reaction, and the resulting rate equation is therefore of the form

$$[4] \quad i = i_0(e^{\alpha\eta F/RT} - e^{-(1-\alpha)\eta F})$$

The overvoltage has thus increased the rate of the forward reaction and decreased that of the reverse reaction. When the overvoltage is zero the two exponential terms are zero, and no current flows. When the overvoltage is large the second exponential approaches zero, so that the equation becomes

$$[5] \quad i = i_0 e^{\alpha\eta F/RT}$$

which can be written as

$$[6] \quad \eta = -\frac{RT}{\alpha F}\ln i_0 + \frac{RT}{\alpha F}\ln i$$

This is of the same form as the empirical Tafel equation [3], so that the empirical b in that equation is given by $RT/\alpha F$.

In the early 1930s Ronald Wilfred Gurney (1898–1953), then at the University of Manchester, published an important theoretical treatment of the electrolytic evolution of hydrogen gas from an acidified solution (47, 48). In 1932 Ralph Howard Fowler (1889–1944), with whom Gurney had worked at Cambridge, gave a similar theoretical discussion (49). These treatments dealt with the transfer of a proton from H_3O^+ in solution to the surface of the metal electrode, taking into account hydration effects but not considering the possible adsorption of hydrogen atoms at the surface. Account was taken of the distribution of energy of the electrons in the metal (in modern terms, of the Fermi levels) and of the energy levels in the H_3O^+ ion. An important feature of Gurney's treatment is that he suggested, for the first time for any process, that there might be quantum-mechanical tunnelling through the energy barrier. His idea was that the rate is controlled by the transfer of electrons and that these might not have to surmount the barrier but could tunnel through it, a possibility not permitted in classical mechanics.

The Gurney–Fowler treatment of electrode processes was extended in various ways. In 1934 Bawn and Ogden, at the University of Manchester, presented a quantum-mechanical treatment of the transfer of a *proton* (rather than an electron, as in Gurney's treatment) at the surface of an electrode (50). An important feature of their work was that they postulated that the transfer of a proton can also occur by quantum-mechanical tunnelling. However, as will be seen in more detail later, careful studies by Brian Conway and others have not yet revealed any positive evidence for quantum-mechanical tunnelling in any electrode process.

In 1936 John Alfred Valentine Butler (1899–1977), then at the University College of Swansea, gave a treatment in which he took account, in addition, of adsorption (e.g., of hydrogen atoms) at the surface of the electrode (51, 52). When adsorption was neglected, as in Gurney's treatment, the predicted activation energies for the discharge of a proton were much higher than the experimental values and were independent of the nature of the surface. Better agreement was found when adsorption was taken into account, and Butler was able to explain the substantial differences in activation energy for nickel and mercury surfaces.

In 1939, an interpretation of electrode processes was given by Eyring, Glasstone, and Laidler on the basis of potential-energy surfaces and transition-state theory (53, 54). The resulting equation is of the form

$$[7] \quad i = A\exp(-\Delta^{\ddagger}G^0/RT)\exp(\alpha\eta F/RT)$$

where $\Delta^{\ddagger}G^0$ is the Gibbs energy of activation. The constant A can be expressed in terms of fundamental constants, and also involves the concentration of species involved in the reaction that controls the rate and therefore the current.

The significance of the fraction α that appears in these equations has been much discussed, and is a little complicated. It depends on the rate-controlling process, and the form of the potential-energy surface for that process. If the rate-controlling step is proton transfer and the energy barrier is a symmetrical one, the value of α (which can be obtained experimentally from the Tafel factor b, which is $RT/\alpha F$) will be 0.5. Conway and Salomon (55), and others, have pointed out that the constancy of the α values in electrochemical reactions provides excellent examples of the Brønsted relationships (linear free-energy relationships) that apply to many chemical reactions.

If, on the other hand, the slow step in the process of hydrogen evolution is the combination of hydrogen atoms at the surface, it can be shown that the Tafel b is $RT/2F$, so that α is equal to 2. This has sometimes been observed experimentally.

The Gibbs energy of activation can be expressed in terms of the entropy of activation $\Delta^{\ddagger}S^0$ and the enthalpy of activation $\Delta^{\ddagger}H^0$, and eq. [7] becomes

$$[8] \quad i = A\exp(\Delta^{\ddagger}S^0/R)\exp(-\Delta^{\ddagger}H^0/RT)\exp(\alpha\eta F/RT)$$

Much work has been concerned with the nature of the rate-controlling step when hydrogen gas is evolved at an electrode. Work by the Russian electrochemist Alexander Naimovitch Frumkin (1895–1976) showed that under certain circumstances the overvoltage passes through a minimum when the pH of the solution is varied (56). This suggests that in acid solution the slow step is the transfer of a proton from the solution to the surface, where it is neutralized. In alkaline solution, however, the hydrated protons are present only at low concentrations, and the slow step is then the transfer of a proton from a water molecule. As already mentioned, the slow step is sometimes the combination of hydrogen atoms.

Ionic solvation and double layers

The processes that occur at electrode surfaces during electrolysis or the operation of an electrochemical cell are greatly

influenced by two factors: the solvation of the ions involved, and the structure of the thin layer that is present at the electrode, and which differs in properties from the bulk solution.

Mention has been made of the work of Drude and Nernst (38) on the solvation of ions, which they called electrostriction. An interesting advance was made in 1920 by the German physicist Max Born (1882–1970), who gave a very simple and useful interpretation of solvation (57). He considered an ion to be a conducting sphere of radius r, carrying a charge ze, where e is the charge on a proton and z is a whole number (for Na^+, for example, $z = +1$; for the sulphate ion SO_4^- $z = -2$). He considered the solvent to be a continuous medium having a dielectric constant of ε. He then derived an expression for the work required to charge a sphere of radius r in a continuum of dielectric constant ε, and found it to be

$$[9] \qquad w = \Delta G = \frac{z^2e^2}{4\pi\varepsilon_0\varepsilon r}$$

where ε_0 is the permittivity of a vacuum. This work is the increase ΔG in Gibbs energy of the ion as it is charged. This expression can easily be extended to give the Gibbs energy of hydration of an ion, i.e., the Gibbs energy change when the ion is transferred from the gas phase to a liquid. Since entropy is the negative of the partial derivative of the Gibbs energy with respect to the temperature, eq. [9] also leads to an expression for the entropy of hydration.

In spite of the simplicity of Born's model, it leads to surprisingly satisfactory results. The Gibbs-energy changes during the hydration of ions do vary more or less linearly with the values of z^2/r for most ions. The expression that eq. [9] leads to for the entropy of hydration of ions is also in reasonably good agreement with experiment.

An obvious weakness of the Born procedure is that it assumed that the effective dielectric constant of the solvent close to an ion is the same as it is in the bulk liquid. Water, for example, has a dielectric constant of about 78, and this high value is due to the extent with which the water molecules can orient with respect to an electric field. At high field strengths, however, the molecules have become fully oriented, and then respond much less to the field. Solvent molecules that are close to an ion are in fact in a very intense field (especially if the ion is small), and become aligned in the field. Since they cannot be oriented further, the effective dielectric constant of the solvent near to an ion is greatly reduced. As a result, the effective dielectric constant of water in the near neighbourhood of a small ion is close to 2, which is characteristic of nonpolar molecules.

In 1957 Laidler and Pegis (58) gave a theoretical treatment of the solvation of simple ions in which they took account of the variation of the dielectric constant with the electric field strength. They found that their treatment gave a significantly better interpretation of the Gibbs energies and entropies of ions than was given by the simple Born equation [9]. In considering chemical reactions beween ions, and processes occurring at electrodes, it is obviously of great importance not to neglect these field effects (59), since in the region in which reaction occurs the ions are close together; the effective dielectric constant is therefore less (in the case of aqueous solutions, about 40 times less) than in the bulk solution.

An alternative procedure, due mainly to H.S. Frank and his co-workers (60, 61), is to take into account the molecular nature of the solvent instead of treating it as a continuous dielectric. The idea is that next to an ion in aqueous solution there is a layer of water molecules that are held fairly tightly, forming a *hydration shell*. Outside this layer there is a *disorder zone*, where the water molecules are arranged in a less orderly fashion than in the bulk solution. This zone arises because of the competition between the electrical forces produced by the ion and the hydrogen-bonding forces resulting from the surrounding water molecules. Quantitative calculations of ionic properties based on this idea (62, 63) have been carried out, with fairly satisfactory results.

Another important matter relating to electrode processes is the nature of the layer of solution next to an electrode, since it is in that layer that the electrode processes occur. It was suggested in 1879 by Helmholtz (64) that any surface can be regarded as bearing a positive or a negative charge, and that in the solution a layer of ions of opposite charge will be attracted to the surface and held to it. This fixed double layer is now often referred to as the *Helmholtz double layer*.

This idea was modified in 1910 (65) by the French physicist Georges Gouy (1854–1926) and in 1913 (66) by the British chemist David Leonard Chapman (1869–1959). They pointed out that the Helmholtz theory is deficient in neglecting the Boltzmann distribution of the ions. They suggested that on the solution side of the interface there is not a simple layer of ions but an ionic distribution that extends some distance from the surface; in other words, there is a *diffuse double layer*. The idea behind the Gouy–Chapman theory is very similar to that in the later Debye–Hückel theory of the ionic atmosphere surrounding an ion. Indeed, Chapman's mathematical treatment in 1913 of the distribution of ions at a surface is essentially a two-dimensional version of the Debye–Hückel theory, which appeared 10 years later.

The Gouy–Chapman theory did not prove entirely satisfactory, and in 1924 a further modification was made (67) by the German physicist Otto Stern (1888–1969). Stern combined the fixed double-layer model of Helmholtz with the diffuse double-layer model of Gouy and Chapman; there is a fixed layer at the surface and also a diffuse layer. To explain certain results, however, it has been found necessary to develop even more elaborate models. For example, Nevill Francis Mott (1905–1994) and J. Watts-Tobin gave in 1961 an important treatment of the double layer in which they took into account charge-dependent orientation of solvent molecules (68).

Brian Conway's electrochemistry

During recent years a number of schools of electrochemistry have made important advances in the understanding of electrode processes, which are the most complex of the processes occurring when an electric current passes through a solution. Among the most prominent workers in the field may be mentioned A.N. Frumkin (see, for example, ref. 56); John O'M. Bockris, at the Imperial College of Technology (University of London), the University of Pennsylvania, and Texas A & M University; Roger Parsons, at the University of Southampton; Allen Bard, at the University of Texas at Austin; and the late Heinz Gerischer, at the Fritz–Haber Institüt in Berlin. The present account focusses on Conway's work, and must of necessity overlook much important work done by others.

Conway has made important contributions to a range of electrochemical problems. Most of his work falls into one of two complementary areas. One of these is concerned with the behaviour of individual ions in solution, in particular their solvation. The other deals with the detailed mechanisms of electrode processes of various kinds. He has linked these two areas together by his parallel investigations of the adsorption of ions in the electric double layer. This adsorption is influenced by the solvation of the ions, and by their electronic interaction with the metal of the electrode.

In the 1960s Conway carried out several investigations of ionic solvation, in collaboration with J.E. Desnoyers, R.E. Verrell, and L. Laliberté (69, 70). They made theoretical calculations of the electrostriction of ions, taking into account dielectric saturation in the hydration co-sphere that exists in the immediate neighbourhood of the ions. They also made experimental studies of ionic volumes and compressibilities. Their conclusion was that the effect of electrostriction is to bring about changes in the effective volume of the solvent shell around the ion. In some of the work, parallel measurements were made in H_2O and D_2O, and the results interpreted in terms of "structure-making" and "structure-breaking" effects. Studies with quaternary ammonium salts, having cations of the R_4N^+ type, gave information about what are known as *hydrophobic interactions*.

A related contribution by Conway et al. (71) was to treat, for the first time, the hydration of polyelectrolytes. Their work was based on their measurements of partial molar volumes of polyelectrolytes, and also involved a theoretical treatment of the interaction between polycations and polyanions with the solvent, account being taken of dielectric saturation.

It was mentioned earlier that suggestions have been made that quantum-mechanical tunnelling may be involved when hydrogen is evolved at an electrode. For certain ordinary chemical reactions, tunnelling of hydrogen atoms and protons has been confirmed (72, 73). A good way of detecting quantum-mechanical tunnelling is to carry out experiments down to low temperatures. At a sufficiently low temperature a chemical reaction involving an energy barrier will effectively cease, but tunnelling, having a low temperature coefficient, will continue to occur. The result is that an Arrhenius plot (of the logarithm of the rate against the reciprocal of the absolute temperature), instead of being linear, will show curvature, the rates at the lower temperatures being abnormally high. Another test for tunnelling is to replace hydrogen by deuterium, which because of its greater mass is much less likely to tunnel; the H/D isotopic ratios will therefore be abnormal.

In 1956 an important theoretical analysis of tunnelling in an electrolytic process was carried out by Conway, Bockris, and Linton (74). They considered a Grotthuss-type mechanism in which a proton is transferred from an H_3O^+ ion to a water molecule, a process that had earlier been discussed in a classical paper by Bernal and Fowler (75). With a particular type of barrier, called an Eckart barrier, they concluded that, for the actual transfer of the proton, the tunnelling mechanism should occur with a higher rate than the process in which the proton passes over the barrier. In a related investigation Conway (76) concluded that if there is appreciable participation of electron tunnelling, the Tafel relationship [3] will be different from that with classical proton transfer.

A complication arises from the fact that after a proton is transferred there has to be a rotation of a neighboring water molecule, in order for the proton to be transferred to that water molecule. The theoretical treatment led to the conclusion that the rate is in fact limited by the rate of this rotation and not by the proton transfer itself. It follows that the H/D isotope ratio of rates is also determined by the rotation rates of the water molecules rather than by the rates of proton or deuteron transfer. The expected isotope ratio for the rates of rotation of H_2O and D_2O molecules is $\sqrt{2}$.

In an attempt to detect tunnelling in an electrochemical process, Conway and Salomon (77, 78) carried out detailed experiments, using mercury electrodes, over the temperature range from 333 K down to 180 K. Curved Arrhenius plots were not obtained, so that there was no evidence for tunnelling. Also, at the low temperatures, there were no observed deviations from Tafel behaviour, which Conway (76) had predicted for proton transfer by tunnelling. Conway and Salomon (77, 78) also investigated the H/D isotopic ratios, and again could find no evidence for tunnelling. Studies of the same kind by other workers has also failed to find evidence for tunnelling.

A series of investigations by Conway (79–82) have shown that the constant α that appears in equations such as [6] is a function of temperature. It was seen (eq. [6]) that the Tafel slope b (in eq. [3]) is, according to transition-state theory, equal to $RT/\alpha F$. Experiments carried out over a range of temperature showed instead that for some systems the Tafel slope b was practically *independent* of temperature, which means that α *increases* with increasing temperature. Conway and his co-workers showed in these investigations that the temperature dependence of α was given by equations of the form

$$[10] \quad \alpha = \alpha_H + T\alpha_S$$

Insertion of this expression into eq. [8] gives an expression in which α_H enters into the enthalpy of activation, and α_S enters into the entropy of activation (because of the cancellation of the temperatures). This result was interpreted in terms of the influence of the electric field on the solvation of the transition state, associated with potential-dependent solvent dipole orientation in the double layer.

Conway's more recent work has been concerned with what may be called *electrochemical surface science* (83–85). He has dealt, for example, with the influence of different anions on the early sub-monolayer stages of oxide film formation on transition metals such as platinum. Even at very low concentrations (Cl^- and Br^- at 10^{-7} M) anions were found to interfere with surface oxide formation. They also influence the place-exchange reconstruction that occurs during the conversion of monolayer arrays of OH and O into growing three-dimensional films. His later research extended this type of study to single-crystal surfaces of platinum and gold, and led to improved interpretations of the kinetic behaviour.

Acknowledgements

I have presumed that Michael Faraday would have had no objection to my taking inspiration, in my title, from his delightful book *The Chemical History of a Candle*. My many discussions with Brian Conway, over the last 41 years, have always been of great help to me, and I am grateful. His assis-

Abstract: The permanent disposal of nuclear fuel wastes requires the development of models that can assess the performance of a disposal vault over long periods of time. Models to assess the long-term stability of the nuclear fuel (UO_2) and the corrosion performance of the waste container (either copper or titanium) have been based on electrochemical principles. Here we review the chemical/electrochemical performance of fuel and the two candidate container materials, and describe some of the electrochemical studies undertaken either to develop the mechanistic understanding upon which these models are based or to measure the values of parameters required to evaluate long-term performance. These include the following: the anodic dissolution of UO_2; the reduction of O_2 on various specimens of UO_2; the crevice corrosion of various titanium alloys; the impedance characteristics of passive films on Ti alloys; the anodic dissolution of copper in chloride solutions; the reduction of O_2 on copper; the effect of various transport barriers on the corrosion of copper; and the prediction of the corrosion potential of copper in aerated chloride solutions.

Key words: uranium dioxide, copper, titanium, nuclear waste, oxygen.

Résumé : Pour effectuer la décharge permanente des déchets nucléaires, il est important de disposer de modèles qui permettent d'évaluer la performance sur de longues périodes des voûtes d'enfouissement. Des modèles permettant d'évaluer la stabilité à long terme de combustible nucléaire (UO_2) ainsi que la performance vis-à-vis de la corrosion de contenants de déchets (cuivre out titane) ont été développés en se basant sur des principes électrochimiques. Dans ce travail, on passe en revue la performance chimique/électrochimique du combustible et des deux matériaux pouvant servir de contenant et on décrit un certain nombre d'études électrochimiques effectuées soit pour développer une compréhension mécanistique des modèles utilisés comme base ou pour mesurer les valeurs de paramètres nécessaires pour évaluer la performance à long terme. Celles-ci incluent : la dissolution anodique du UO_2; la réduction du O_2 sur divers spécimens de UO_2; la corrosion des crevasses de divers alliages du titane; les caractéristiques d'impédance de films passifs sur des alliages de Ti; la dissolution anodique dans des solutions de chlorure; la réduction du O_2 sur le cuivre; l'effet de diveres barrières au transport sur la corrosion du cuivre; et la prédicton du potentiel de corrosion du cuivre dans des solutions de chlorure aérées.

Mots clés : dioxyde d'uranium, cuivre, titane, déchets nucléaires, oxygène.

1. Introduction

The Canadian nuclear fuel waste disposal concept involves the permanent burial of fuel wastes at depths of 500–1000 m in plutonic rock in the Canadian Shield. The waste would be sealed in corrosion-resistant containers, and a clay-based buffer material placed between the containers and the rock. If this concept is to be justified, then models must be developed to demonstrate that the rate of release of radionuclides will be slow compared to their radioactive decay. A problem with such models is the lack of any opportunity to refine them on the basis of observational experience or failure analysis. This means the models must be based on sound mechanistic understanding and substantial databases.

In this review we are interested in the chemical performance of two barriers within this engineered vault: the corrosion/dissolution of the fuel wasteform, and the corrosion of the metallic container encapsulating the waste. Models to predict how these processes will evolve with time in a waste vault have recently been developed (1–4) and incorporated into assessments of waste vault performance (5, 6). These models are based on electrochemical principles since both fuel dissolution and container degradation are corrosion processes requiring that the oxidative dissolution of the fuel or container material be coupled to the reduction of available oxidants within the waste vault. Since the unperturbed environment is

Received April 7, 1997.

This paper is dedicated to Professor Brian E. Conway in recognition of his outstanding contributions to Canadian electrochemistry.

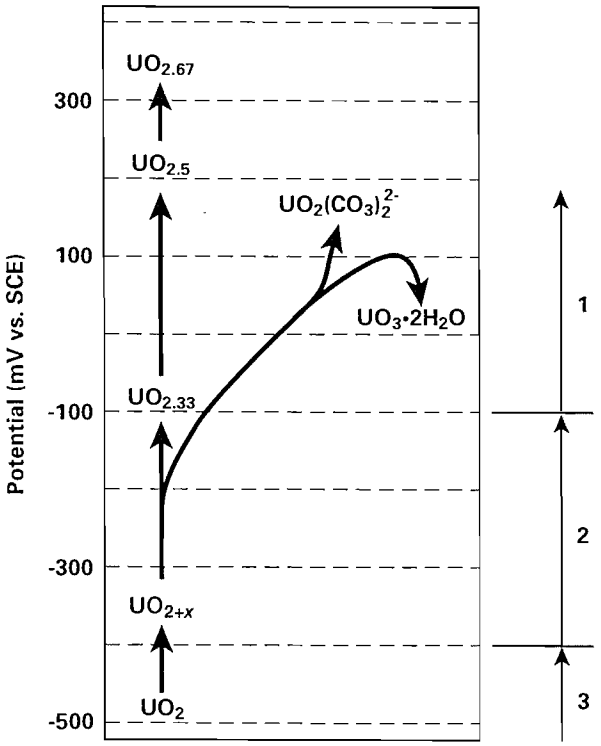
Fig. 1. Schematic showing the distribution of radionuclides in used fuel. Radionuclides located at the fuel–Zircaloy cladding gap and at grain boundaries within the fuel are assumed to be released instantly.

reducing, the oxidants available will be those trapped within the waste vault on sealing (effectively O_2) and, for passive metals, H_2O and those produced by the radiolytic decomposition of the water expected to eventually saturate the vault.

Many electrochemical methods have been used either to develop the mechanistic understanding upon which these models are based or to measure the values of parameters required to evaluate long-term performance. In this paper, we will describe the basic electrochemistry/chemistry of fuel dissolution and container corrosion and describe some of the electrochemical studies undertaken.



2. Corrosion/dissolution of nuclear fuel (UO_2)

Nuclear fuel is basically uranium dioxide (UO_2) fabricated by sintering pressed compacts of very fine grained powder at ~1700°C under a reducing atmosphere. These sintered ceramics typically have 92–99% of the theoretical density with grain sizes of 2–15 μm. The as-fabricated fuel is a slightly hyperstoichiometric oxide, UO_{2+x} where $x \leq 0.001$. The presence of excess oxygen, as interstitial oxide ions (O_I^{2-}), requires further ionization of a small fraction of the U^{IV} ions, to the U^V and (or) U^{VI} valence state, which creates holes in the narrow occupied U 5*f* sub-band that can migrate by a small polaron-hopping process with a low activation energy (7–9).

On burning in a nuclear reactor, many fission products and actinides with widely varying solubilities in the host matrix are created. The radionuclide release model used in safety assessments includes three main release mechanisms (Fig. 1). Since the great majority of radionuclides (90–99%) are contained within the grains of the fuel pellets, they will be released at a rate governed by the dissolution rate of the UO_2 matrix.

The solubility of uranium increases by many orders of magnitude when conditions become more oxidizing, and it is necessary to treat fuel dissolution as a corrosion process and to attempt the prediction of rates based on electrochemical principles. Many studies have demonstrated the electrochemical nature of UO_2 dissolution (10).

Fig. 2. Chemistry/electrochemistry of UO_2 oxidation and dissolution as a function of corrosion potential or electrochemically applied potential.

2.1 Electrochemistry/chemistry of UO_2 oxidation/dissolution

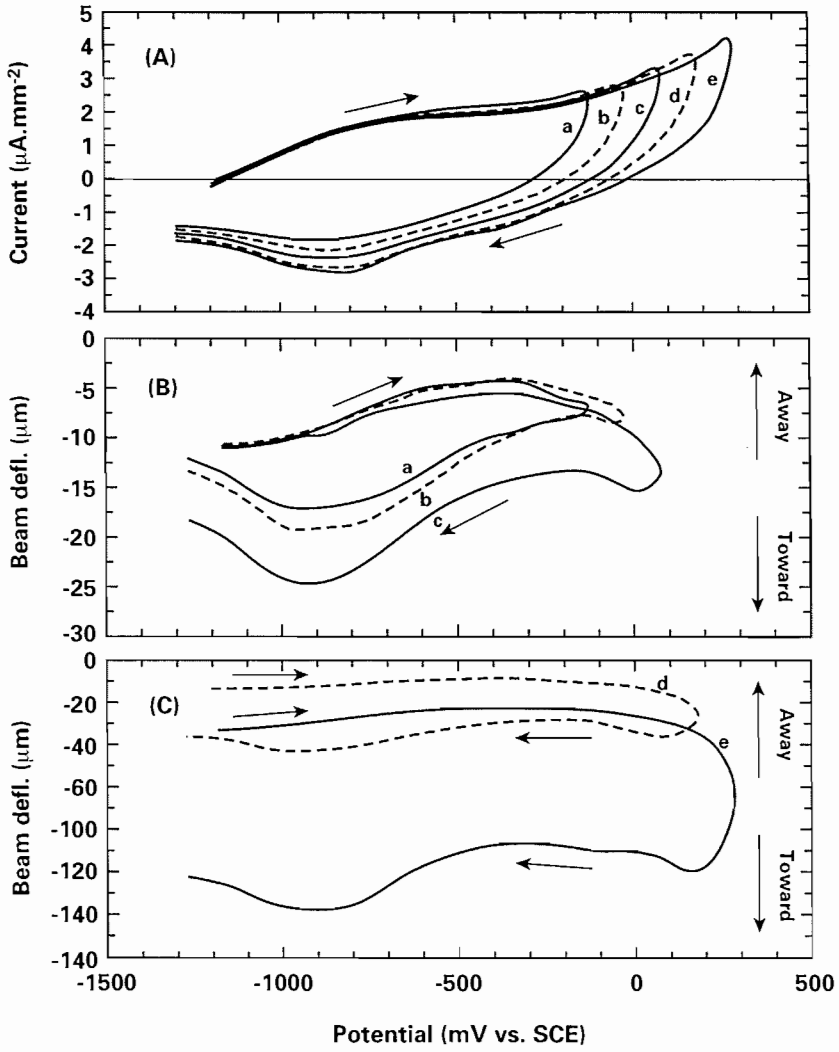


Figure 2 shows the expected composition of a UO_2 surface as a function of either the corrosion potential achieved or the electrochemical potential applied. The compositions indicated have been established by a combination of electrochemical, corrosion, and X-ray photoelectron spectroscopic (XPS) techniques (11–14). The behaviour can be divided into three regions.

For $E \lesssim -400$ mV (vs. SCE), region 3 (Fig. 2), no oxidative dissolution can be detected, even by techniques as sensitive as photothermal deflection spectroscopy (PDS) (15). The observation of positive current flow under voltammetric conditions clearly indicates some degree of oxidation, although this appears to be either confined to submonolayer levels or concentrated at more readily oxidizable sites such as defects and grain boundaries (10).

For potentials -400 mV $\leq E \leq -100$ mV (vs. SCE), region 2 (Fig. 2), the composition of the surface (UO_{2+x}) and the extent of oxide formation are directly determined by potential (16). The loss of *p*-type photocurrent, observed at $E < E_{fb}$ (where E_{fb} is the flatband potential (~ −1.2 V (vs. SCE)), after voltammetric excursions into this potential region shows that dissolution is accompanied by the at least partially irreversible oxidation of UO_2 (10, 17). XPS analyses show that a surface

Fig. 3. Electrochemical/photo-deflection spectroscopy experiment in 0.5 mol L^{-1} Na_2SO_4 (pH = 10.5) for five voltammetric scans (20 mV s^{-1}) to progressively more positive potential limits. (*A*) current response; (*B*) beam deflection for the first three scans; (*C*) beam deflection for the last two scans. The deflection of the probe beam is proportional to the dissolved uranium concentration, and deflection of the probe beam towards the electrode surface is an indication that dissolution is occurring. (Reprinted from J. Electroanal. Chem. Vol. 372, J.D. Rudnicki et al., "Photothermal deflection spectroscopy investigations of uranium dioxide oxidation", 63–74 (1994) with kind permission from Elsevier Science S.A., P.O. Box 564, 1001 Lausanne, Switzerland.)

composition of $UO_{2.33}$ is achieved by $E \sim -100$ mV (vs. SCE) (18) and that its subsequent reduction on a negative-going voltammetric scan yields a surface of composition $\sim UO_{2.1}$. A combination of PDS and electrochemistry shows that an increase in anodic current for $E \gtrsim -300$ mV (vs. SCE) is partially attributable to dissolution (Fig. 3) (15). That dissolution is enhanced by excursions to more positive potentials is clearly indicated by the larger beam deflection shown in Fig. 3C. The PDS technique is based on the deflection of a probe laser as it passes adjacent to an electrode surface, and the degree to which the beam is deflected is directly proportional to the gradient of the solution refractive index. The release of chemical species from the electrode (i.e., dissolution) can then be detected by a deflection of the probe beam towards the electrode due to the local increase in refractive index of the electrolyte.

By comparing the electrochemical/PDS behaviour of a sintered UO_2 pellet and a UO_2 single crystal it has been shown that the oxidative dissolution process is dependent on surface structure.[2] For a single crystal, in which grain boundaries are absent, insignificant dissolution was observed (for $E \lesssim -100$ mV (vs. SCE)). By contrast, as shown in Fig. 3 and discussed elsewhere (15), anodic dissolution from the surface of a sintered pellet containing many grain boundaries is observed at potentials as low as -300 mV (vs. SCE).

When $E \geq -100$ mV, region 1 (Fig. 2), oxidation beyond $UO_{2.33}$ is observed and dissolution becomes extensive as the potential increases. For $E \gtrsim 200$ mV (vs. SCE) the $UO_{2.33}$ surface may oxidize to $UO_{2.67}$. While XPS results suggest this is possible at room temperature under electrochemical conditions (13, 14), its occurrence at high temperatures ($\geq$150°C) is

Fig. 4. Electrochemically determined dissolution currents as a function of applied potential recorded on a number of different unirradiated UO_2 specimens in 0.1 mol L^{-1} Na_2SO_4 (pH = 9.5). In region A, currents are non-steady-state; in region B, currents are steady-state values. The line connects the data points used in a recent assessment of fuel performance (6) (from ref. 23).

well documented under hydrothermal (19) and radiolytic oxidizing conditions (20). Simultaneously, dissolution as UO_2^{2+} occurs and, for solutions in which uranyl species have a low solubility, secondary phases (such as $UO_3{\cdot}2H_2O$) precipitate on the electrode surface

[1] $UO_2^{2+} + 3H_2O \rightarrow (UO_3{\cdot}2H_2O)_S + 2H^+$

where $(\ )_S$ denotes a solid phase or species. In the presence of uranyl-complexing anions (e.g., CO_3^{2-}) dissolution is enhanced

[2] $UO_2^{2+} + 2CO_3^{2-} \rightarrow UO_2(CO_3)_2^{2-}$

and secondary phase formation avoided (10, 21).

For redox conditions sufficiently oxidizing to drive the corrosion potential (E_{CORR}) to values $\gtrsim -100$ mV (vs. SCE), UO_2 dissolution is clearly a corrosion process requiring the coupling of oxide dissolution and oxidant reduction. We recently published an electrochemical procedure to determine the rates of UO_2 dissolution based on a Tafel extrapolation of anodic dissolution currents as a function of applied potential to values of E_{CORR} measured in environments with controlled redox potential (22). This procedure yields rates of fuel dissolution (as corrosion currents, I_{CORR}) as a function of oxidant concentration, and has been incorporated into a model to assess fuel behaviour under waste vault conditions (6). A natural extension of this procedure is the development of a mixed potential model to describe and predict UO_2 fuel behaviour. For the application of such a model to be justified, a good understanding of both the anodic dissolution of UO_2 and the cathodic reduction of oxidants on UO_2 is required.

2.2 Anodic dissolution of UO_2

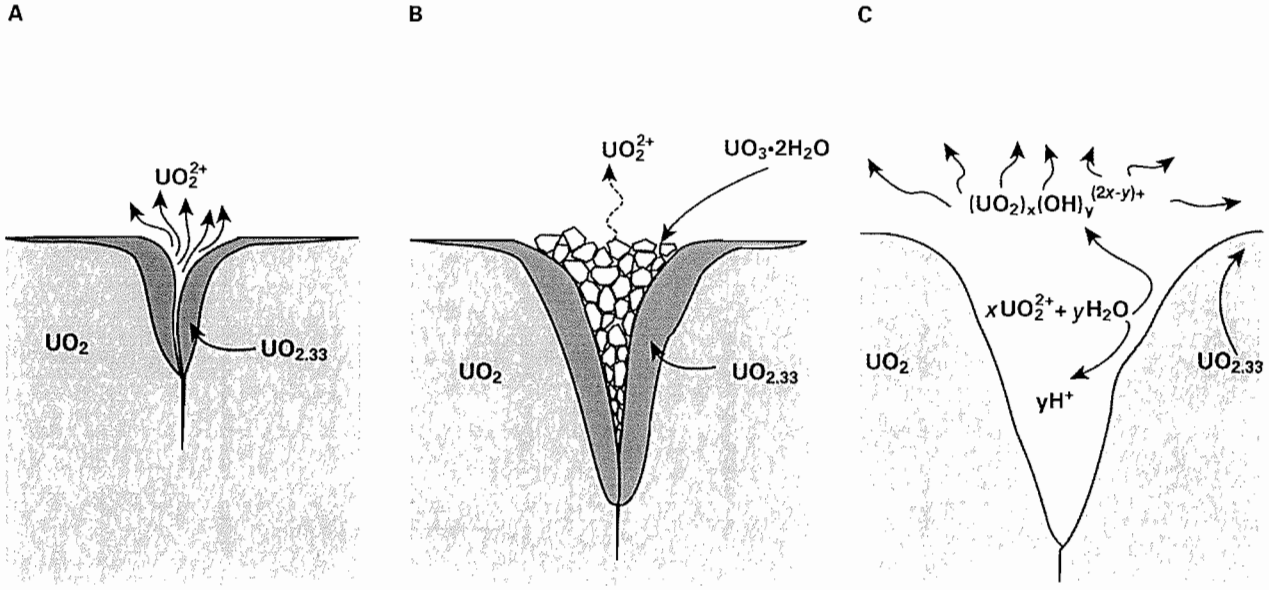

Figure 4 shows electrochemically determined dissolution currents as a function of applied potential recorded on a number of different UO_2 specimens (in the form of rotating disc electrodes (RDE)) in 0.1 mol L^{-1} $NaClO_4$ (pH ~ 9.5), a solution representative of the noncomplexing groundwaters anticipated in the Canadian Shield (23). Two distinct regions of behaviour (A and B) are observed.

For $E \leq 300$ mV (region A) the currents are non-steady-state, progressively decreasing as the accumulation of secondary phases ($UO_3{\cdot}2H_2O$) blocks dissolution of the UO_2 surface. For $E \gtrsim 300$ mV (region B), steady-state dissolution currents are obtained. The wide distribution of points at 100 mV reflects the various lengths of time for which the potential was held before recording the current. The open squares show currents recorded after 24 h of oxidation.

In region A the currents fall by more than two orders of magnitude over a 24-h period and even after 24 h, by which time currents $\leq$5 nA were obtained, no steady state was achieved. Voltammetric reduction of the anodically oxidized surface clearly indicates that the dissolution product accumulates by deposition on the electrode surface, the amount of electrochemical charge recovered by reduction of these deposits being equal to that consumed in their formation. That this should occur on the surface of a rotating disc electrode is evidence that deposition is occurring at occluded sites, such as within grain boundaries. An attempt to represent this situation schematically is shown in Figs. 5*A* and 5*B*. That dissolution should preferentially occur at grain boundaries is not unexpected for UO_2. The conductivity of UO_2 increases markedly with the degree of non-stoichiometry (7, 9) and the reductive sintering process used to fabricate the

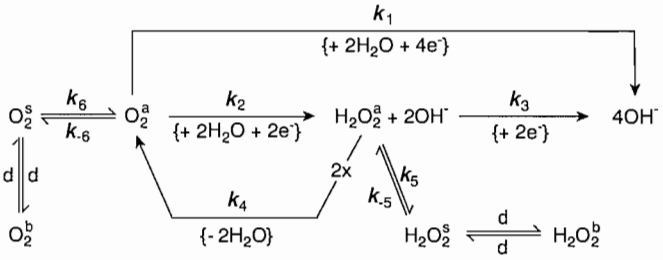
Fig. 5. Schematic illustrating the oxidation and dissolution of UO_2 localized at grain boundaries. (*A*) Dissolution at short times in potential region A (Fig. 4); (*B*) dissolution at long times (1.5 h) in potential region A (Fig. 4); (*C*) steady-state dissolution in potential region B (Fig. 4).

pellets is likely to leave some degree of non-stoichiometry in the grain boundaries.

For $E \geq 300$ mV, region B (Fig. 4), a logarithmic dependence of the dissolution current on applied potential is obtained, and the steady-state nature of the currents makes a Tafel extrapolation to determine corrosion currents at measured values of E_{CORR} acceptable. The scatter in data points at a given potential in region B is approximately one order of magnitude and can be attributed to a combination of variability in UO_2 reactivity between specimens and the unavoidable irreproducibility of a dissolution process largely confined to small areas at grain boundaries. The line drawn through the triangular points in Fig. 4 is that extrapolated to determine the corrosion rates in performance assessment calculations (6). These data points are from a previous, less rigorous, attempt to determine dissolution currents as a function of applied potential (23).

At high potentials in region B anodic dissolution of $UO_{2.33}$,



[3] $(UO_{2.33})_S + 0.33H_2O \rightarrow UO_2^{2+} + 0.66OH^- + 1.34e^-$

is sufficiently rapid that extensive hydrolysis to produce local acidity at the occluded dissolution site can occur; i.e.,

[4] $xUO_2^{2+} + yH_2O \rightarrow (UO_2)_x(OH)_y^{(2x-y)+} + yH^+$

For pH $\leq$ 5.5, a $UO_{2.33}$ layer does not form as a dissolution intermediate (24), and an increase in the solubility of $UO_3{\cdot}2H_2O$ (25) prevents its local precipitation, leaving the dissolution site unblocked, Fig. 5*C*. That only a very thin surface film was present on the UO_2 surface after anodic oxidation in region B (Fig. 4) is confirmed by the absence of a major reduction peak in a subsequent voltammetric scan to negative potentials. The Tafel slope measured in region B is 58 $\pm$ 5 mV, suggesting rate control by a single two-electron transfer. This is unlikely, and it is possible that local acidification is non-uniform, and the slope is some average value between the 40 mV in acidic solutions and the 70–80 mV in neutral solutions observed by Nicol and Needes (26).

Fig. 6. General reaction scheme for O_2 reduction. Superscripts b, s, and a denote species in bulk solution, near the electrode surface and adsorbed on the electrode, respectively; d denotes diffusion.

2.3 Oxygen reduction on UO_2

While study of the anodic dissolution may produce a relationship between dissolution current and applied potential that can be used to predict corrosion (dissolution) rates under natural corrosion conditions, the destruction of the UO_2 surface disguises many subtleties of its electrochemical reactivity. Not only is a knowledge of the kinetics of O_2 reduction necessary for the development of a complete mixed potential model (to describe the corrosion behaviour of fuel), the reduction is an electron transfer reaction that can also probe many features of the surface reactivity of UO_2.

Two major pathways exist for O_2 reduction (Fig. 6): the direct pathway (characterized by the overall four-electron reduction to OH^-) and the series pathway (which proceeds via a peroxide intermediate). In the absence of detectable peroxide formation it is difficult to distinguish between these two routes. On UO_2, Tafel slopes ($dE/d \log i$) larger (in magnitude) than -120 mV, coupled with reaction orders of $\sim$1, indicate

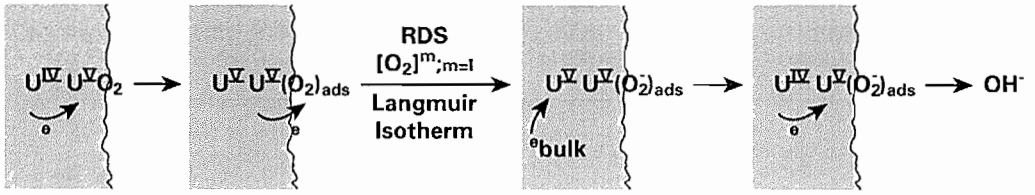
Fig. 7. Schematic showing the mechanism of O_2 reduction at donor–acceptor sites on the surface of UO_2.



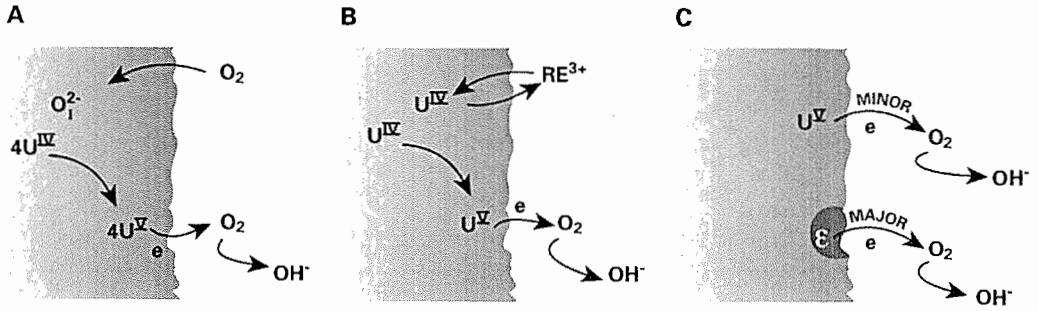


Fig. 8. Schematic showing the effects of various fuel treatments and properties on O_2 reduction on a UO_2 surface. (*A*) Effect of corrosion in aerated solution on the number density of surface donor–acceptor sites (shown as U^V); (*B*) effect of rare earth doping on number density of donor–acceptor surface sites; (*C*) effect of noble metal particles (ε phase).

that the first electron transfer is rate determining and occurs before O—O bond cleavage. This is more consistent with a series mechanism, with the absence of detectable peroxide suggesting $k_3 \gg k_5$, than with a direct mechanism involving early O—O bond rupture.

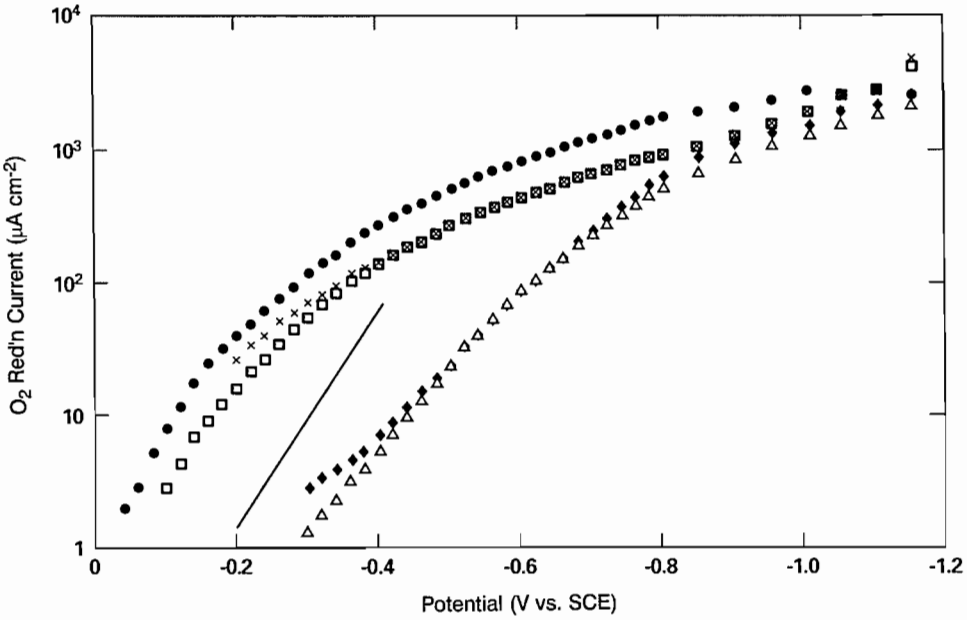
Recently, we showed that the cathodic reduction of O_2 on nearly stoichiometric *p*-type UO_2 in dilute alkaline solution (0.1 mol L^{-1} $NaClO_4$, pH ~9.5) proceeds by an overall four-electron series route involving single electron and proton transfer steps (27, 28). Electron transfer appears to occur exclusively at surface sites where adjacent uranium cations are present in different valence states, U^{VI} or U^V above U^V or U^{IV}. This is an adaptation of the theory of donor–acceptor reduction sites developed by Presnov and Trunov (29, 30) to explain O_2 reduction on transition metal oxides with *p*-type semiconductivity, and is illustrated schematically for UO_2 in Fig. 7. A first-order dependence on $[O_2]$ and a Tafel slope >-120 mV (generally around -180 to -200 mV) are consistent with adsorption under Langmuir conditions and control of the rate by the first electron transfer step. Surface oxidation by corrosion in aerated solutions significantly increases the cathodic current for O_2 reduction, consistent with an increase in the number density of donor–acceptor sites, Fig. 8*A*. By contrast, high concentrations of carbonate, which preferentially coordinates U^{VI} and U^V but not U^{IV} (25, 28), cause a decrease in O_2 reduction current by an order of magnitude and lead to the release of copious amounts of peroxide to solution (27).

In the absence of peroxide release to solution, and for weak absorption of O_2 at donor–acceptor sites, the current for O_2 reduction (I_k), corrected for any contribution from diffusion, is given by

$$[5] \quad I_k = 4FAN_S^D(N_S^U)^{-1}\, kK[O_2] \exp\left\{-\frac{\alpha F\eta}{RT}\right\}$$

where F is Faraday's constant, A is the surface area of the electrode, k is the rate constant (s^{-1}) for the rate-determining electron transfer, K is the equilibrium constant for adsorption of O_2 at donor–acceptor sites, and $N_S^D(N_S^U)^{-1}$ is the ratio of the number density of donor–acceptor sites (N_S^D) to the number density of uranium atoms in the electrode surface. This ratio changes with potential since N_S^D is potential dependent.

While the general features of the reduction reaction remain unchanged, the kinetic details vary depending on the distribution of donor–acceptor sites. This was clearly indicated by experiments on a UO_2 specimen exhibiting *n*-type photocurrent characteristics (31). A near square-root dependence on $[O_2]$ suggested coupling of the adsorption and first electron transfer steps under Temkin isotherm conditions,



$$[6] \quad \{U^V\} + O_2 \xrightarrow{k_1'} \{U^V\}\,(O_2)_{ads} \xrightarrow[e^-]{k_2'} \{U^{VI}\}\,(O_2^-)_{ads}$$

This was attributed to a severely localized distribution of donor–acceptor sites due to pronounced heterogeneity in the degree of non-stoichiometry. *n*-Type characteristics suggest the presence of a significant degree of non-stoichiometry, an observation apparently inconsistent with X-ray diffraction results that show the UO_2 composition is effectively close to stoichiometry. This suggests that the non-stoichiometric material responsible for the *n*-type behaviour is either highly localized, possibly in grain boundaries, or randomly distributed at levels undetectable by X-rays. In view of the reductive sintering process used to produce UO_2 pellets from oxidized powders, the former appears the more likely explanation. The kinetic limiting current was calculated to be

Fig. 9. Tafel plots for O_2 reduction on a number of UO_2 rotating disc electrodes (16.7 Hz) recorded in 0.1 mol L^{-1} $NaClO_4$ (pH ~ 9.5) containing 2.5×10^{-4} mol L^{-1} dissolved oxygen: (•) SIMFUEL with 6 at.% burnup (SF1); (□) SIMFUEL with 3 at.% burnup (SF2); (Δ) SIMFUEL (3 at.% burnup) containing only species soluble in UO_2 (SS1); (×) SIMFUEL (3 at.% burnup) containing only noble metal segregants (SS2); (◆) neodymium-doped UO_2 (1 at.% Nd) (ND1). The line indicates a slope of 120 mV.

$$[7] \quad I_k = 4FAk'N_S^D(N_S^U)^{-1}[O_2]^{1/2} \exp\left\{-\frac{\alpha F\eta}{2RT}\right\}$$

where k' is an effective rate constant related to the fraction of donor–acceptor sites occupied by adsorbed O_2 molecules (θ_S),

$$[8] \quad k' = [\theta_S(1-\theta_S)k_2'k_1']^{1/2}$$

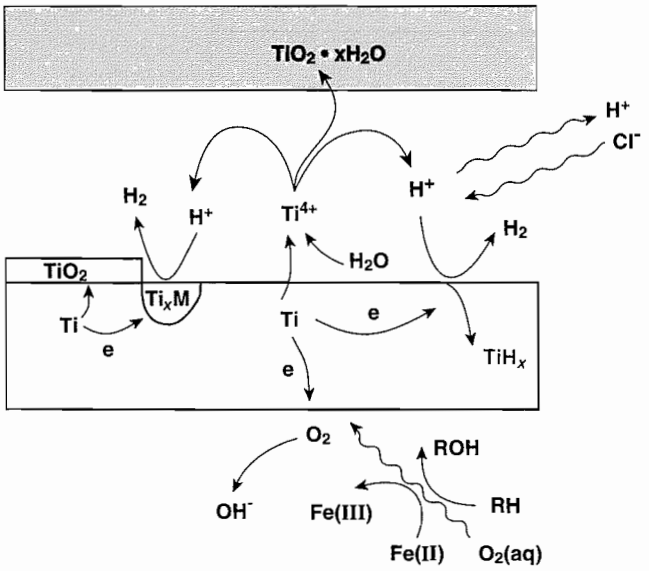
and k_2', k_1' are the rate constants in reaction [6] (31).

Equation [7] not only yields the observed square-root dependence on $[O_2]$ but also predicts large Tafel slopes of −240 mV (for α = 0.5). Observed Tafel slopes were usually between −240 and −310 mV.

While much can be learned from the study of these UO_2 specimens, neither is truly representative of used nuclear fuel, which will contain a multiplicity of fission products and actinides. Recently, we have studied O_2 reduction on simulated nuclear fuel (SIMFUEL). SIMFUEL contains 11 stable elements in proportions appropriate to replicate the chemical effects caused by reactor irradiation to various degrees of burnup. The principal microstructure of SIMFUEL (32) is virtually identical to that of ceramic UO_2, but secondary metallic (Mo, Ru, Rh, Pd) and perovskite ((Ba, Sr)ZrO_3) phases are present as submicron particles on grain boundaries, and the additives Y, Ce, Nd, La, and Zr are present dissolved in the UO_2 grains.

Figure 9 shows plots of O_2 reduction current in 0.1 mol L^{-1} $NaClO_4$ (pH ~ 9.5) for a neodymium-doped UO_2 (1 at.% Nd) (ND1), two SIMFUEL electrodes: SF1 (6 at.% burnup); SF2 (3 at.% burnup), a SIMFUEL electrode with a nominal 3 at.% burnup containing only the species soluble in UO_2 (SS1), and a SIMFUEL with 3 at.% nominal burnup containing only the noble metal segregants (SS2) (33). The noble metal segregants, present in SF1, SF2, and SS2, are predominantly a hexagonal close-packed alloy, known as the ε-phase, with an average composition in at.% of Ru(47)Mo(28)Pd(22)Rh(3) (32). These particles are a few hundred nanometres in diameter and are distributed along grain boundaries in the fuel.

As on a standard CANDU fuel specimen (*p*-type UO_2), the overall O_2 reduction reaction is a four-electron process with a close to first-order dependence on $[O_2]$ (33). For electrodes containing only rare earth dopants (SS1, ND1) the currents are typical of those measured on slightly hyperstoichiometric, but otherwise undoped, *p*-type UO_2. As for *p*-type UO_2, the Tafel slopes are >−120 mV, Fig. 9. Electrodes containing noble metal segregants (SF1, SF2, SS2) exhibit currents that are enhanced by up to two orders of magnitude, especially at lower overpotentials when Tafel slopes approaching −90 mV are observed, Fig. 9.



The introduction of lower valence rare earth elements into the uraninite structure will increase both the electrical conductivity and the number of available donor–acceptor sites by creating additional holes in the U 5*f* sub-band (Fig. 8*B*). However, despite the excellent electrical conductivity of ND1 and SS1 there is no significant enhancement in the kinetics of O_2 reduction. Conversely, the poorly conducting SS2 electrode, without rare earth dopants to produce an increased number density of donor–acceptor sites, shows marked electrocatalysis, especially at lower overpotentials, comparable with that found for the SIMFUEL electrodes, SF1 and SF2. Clearly, the high reactivity of the SIMFUEL electrodes must arise predominantly from the noble-metal particles rather than from rare-earth doping of the UO_2 lattice (Fig. 8*C*). The observation of a Tafel slope <−120 mV at low overpotentials is also consistent with reduction at noble metal particles: Tafel plots for O_2 reduction on Pd, Rh, and Ru generally exhibit two

Fig. 10. Chemical and electrochemical processes involved in the crevice corrosion of titanium under waste disposal vault conditions. The crevice exists under the $TiO_2 \cdot xH_2O$ deposit, which is itself a product of the crevice corrosion process. The initial crevice would require the presence of a crevice former above this deposit (not shown).

distinct regions, with slopes of −60 mV at low current densities and −120 to −180 mV at high current densities (34–36).

In the oxidation/dissolution of used nuclear fuel the noble metal particles will act as preferential cathodes for the oxidant reduction processes driving fuel dissolution. A valid mixed-potential model for the corrosion of used nuclear fuel under waste disposal conditions will need to accommodate these processes.

3. Corrosion of nuclear waste containers

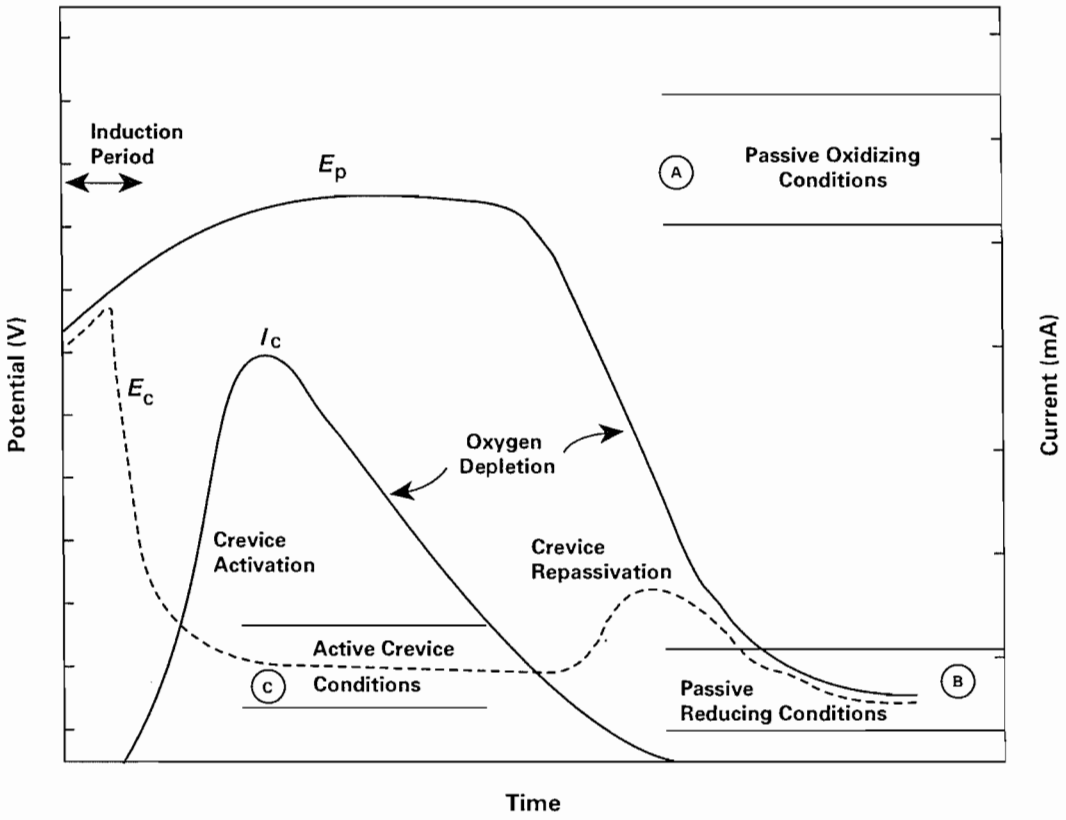
Conditions within a nuclear waste vault are expected to evolve from initially warm and oxidizing (<100°C, aerated groundwater) to eventually cool and nonoxidizing, as the heat-generating radioactive processes decay and oxidants are consumed by reaction with oxidizable minerals in the vault buffer/backfill materials or by the container corrosion process. Two materials have been chosen as candidates for the construction of the container: dilute α-titanium alloys and copper. For both of these materials it is expected that most corrosion damage will be sustained during the early, warm oxidizing period of the lifetime of the vault (37). If long-term containment is to be achieved, then this damage, expressed as a depth of penetration of the available corrosion allowance, must be minimized.

To assess the effect of container performance on the release of radionuclides, models have been developed to predict lifetimes of containers and how these lifetimes will be affected by materials selection, evolution in vault conditions, and various vault engineering scenarios. These approaches and predictions have been reviewed (1, 2, 38). Much of the mechanistic information upon which these models and lifetime predictions are based has been developed electrochemically. Here, we review the chemistry/electrochemistry of corrosion processes and discuss some of the ways in which electrochemical procedures have been utilized.

3.1 Crevice corrosion of titanium alloys

For titanium alloys, crevice corrosion and hydrogen-induced cracking (HIC) are the corrosion processes most likely to cause container failure (1). While crevice corrosion under waste vault conditions is not expected (1, 39) it remains the corrosion mechanism most likely to lead to significant wall penetration while the vault is warm and oxidizing. Our present understanding of the chemical/electrochemical processes important in the crevice corrosion of titanium alloys is illustrated schematically in Fig. 10.

Once initiation of a crevice has occurred, O_2 reduction on surfaces external to the crevice will lead to the development of acidity due to the hydrolysis of dissolved metal cations at active sites within the crevice. In this manner, an oxygen concentration cell is established in which neutral oxidizing conditions exist outside, and acidic nonoxidizing conditions inside, the creviced area. The reduction of protons within the crevice not only causes further metal dissolution, but also leads to hydrogen absorption and the formation of precipitated metal hydrides within the metal, eventually rendering the material susceptible to HIC. If crevice corrosion proceeds unchecked for extended periods of time, then container failure by either crevice corrosion or HIC would be a danger.



Two limitations on the extent of crevice corrosion appear possible. For susceptible alloys, crevice propagation can continue until all available O_2 within the vault is consumed, and the extent of damage will be limited by the consumption of O_2 by reaction with Fe^{II} and (or) organic material (RH) (Fig. 10). For impure Grade-2 titanium (Ti-2), or materials containing alloying elements to decrease crevice corrosion susceptibility (Ni and Mo in Ti-12; Pd in Ti-16), proton reduction on the surfaces of intermetallics (Ti_xM in Fig. 10) could induce repassivation (40).

To study the propagation of crevice corrosion we have employed a galvanic coupling technique in which an artificially creviced working electrode is coupled to a large Ti counter electrode through a zero-resistance ammeter (41). This arrangement simulates the conditions that could lead to crevice corrosion in a waste vault when metal dissolution within a relatively small occluded area on a container wall is supported by O_2 reduction on a much larger area of the wall, i.e., the potentially dangerous situation of a small anode coupled to a large surrounding cathode. The experiment is performed inside a sealed pressure vessel, an arrangement that limits the amount of available oxygen as expected in a sealed waste vault.

Figure 11 shows the general form of the coupled current (I_C), creviced electrode potential (E_C), and the non-creviced electrode potential (E_P), for an experiment on an alloy of titanium susceptible to crevice corrosion. After a short induction period, I_C rises and E_C falls as the crevice activates, and I_C falls once the available O_2 is consumed. O_2 depletion is also accompanied by a fall in E_P. As I_C approaches zero, a loop in E_C is generally taken to be an indication that repassivation is underway. The value of I_C is the rate of crevice propagation supported by the reduction of O_2 on passive surfaces external to the crevice. It underestimates the true rate since no current flows in the external measuring circuit due to propagation driven by proton reduction within the crevice, which is a short-circuit reaction (Fig. 10). However, our experiments suggest that, for extensive propagation, the ratio of externally

Fig. 11. The general form of the coupled current (I_C), crevice potential (E_C), and the planar potential (E_P) measured using the galvanic coupling technique: (*A*) range of corrosion potentials (E_P) measured for passive corrosion under oxidizing conditions; (*B*) range of corrosion potentials (E_P) measured for passive corrosion under nonoxidizing conditions; (*C*) range of crevice potentials (E_C) measured on an active crevice.

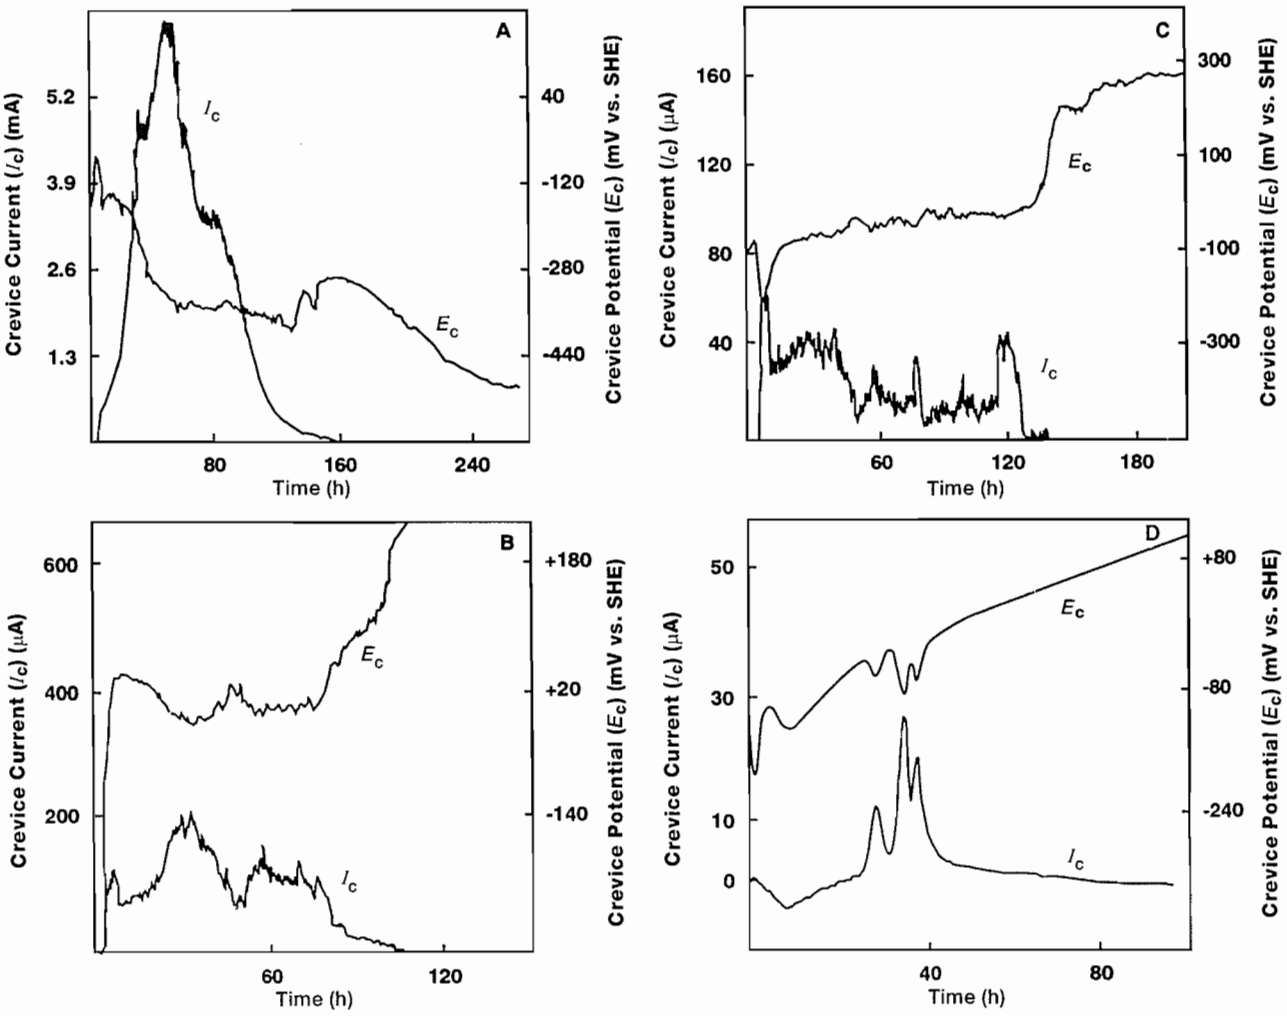
to internally supported crevice propagation is approximately constant. Once this ratio is established from weight-change measurements, which measure the total extent of crevice propagation, the real propagation rate can be obtained by multiplying I_C by an attenuation factor (42).

The influences of many parameters, including chloride concentration (43, 44), groundwater composition (1), temperature (45, 46), O_2 concentration (1, 42), γ irradiation (1), welding (1), and material composition (40, 47), on crevice corrosion have been studied by this method, Here, as an example, we will confine our discussion to the effects of material composition.

3.2 Influence of impurities and alloying additives on the crevice corrosion of titanium

Figure 12 shows values of I_C and E_C measured on two specimens of Ti-2, and on Ti-12 and Ti-16 in 0.27 mol L^{-1} NaCl at 150°C (Ti-2 and Ti-12) or 100°C (Ti-16). It is clear that the rate ($\propto I_C$) and the extent (Q_C = area under the I_C-t curve) of crevice propagation decrease by many orders of magnitude from Ti-2 to Ti-12 and Ti-16. The distinctly different behaviours observed for the two Ti-2 materials reflect the diverse properties of materials that differ in the amount and distribution of impurities, particularly Fe (40, 47). Very large values of I_C are accompanied by negative values of E_C and are indicative of fully activated, rapidly propagating crevices. Small currents accompanied by less negative potentials are observed when propagation is limited, and are indicative of partially activated crevices (i.e., with limited active area) capable of repassivation even in the presence of substantial concentrations of O_2.

The two Ti-2 specimens differ in their Fe content (~0.02 and >0.1 wt.%) and grain size (30–40 μm and ~15 μm, respectively) (47). Crevice propagation is clearly suppressed in the high Fe material, and repassivation, indicated by a fall in I_C to zero accompanied by a positive shift in E_C (Fig. 12*B*), occurs before all the O_2 is consumed. The critical feature in suppressing propagation appears to be the presence of small amounts of Ni with Fe in intermetallic particles. These particles appear to possess a lower overvoltage for proton reduction than the adjacent α-Ti grains and act as local cathodes driving the latter to repassivate (40).



For Ti-12 (0.8 wt.% Ni, 0.3 wt.% Mo) the extent of propagation before repassivation is minor. Two possible explanations have been proposed: (*i*) repassivation is driven by catalysis of the proton reduction reaction on intermetallic Ti_2Ni particles within the creviced area of the surface (Fig. 9) (48); (*ii*) dissolution of the intermetallic particles leads to nickel ion enrichment of the corrosive crevice solution, and redeposition of metallic nickel on adjacent titanium surfaces then produces catalytic sites for proton reduction (49). Similar mechanisms have been claimed for Ti-16 (0.05 wt.% Pd) (50) on which crevice propagation is insignificant. Pd enrichment at the surface of corroding specimens may also be a factor (51,

Fig. 12. Coupled currents (I_C) and crevice potentials (E_C) measured in 0.27 mol L^{-1} NaCl on artificially formed crevices of various Ti alloys. (*A*) Ti-2 (Fe-0.024 wt.%) at 150°C; (*B*) Ti-2 (Fe-0.13 wt.%) at 150°C; (*C*) Ti-12 at 150°C; (*D*) Ti-16 at 100°C.

52). This ability of Ti-12 and Ti-16 to repassivate under oxidizing conditions renders these two materials much less dependent than Ti-2 on the evolution of the waste vault environment from warm and oxidizing to cool and nonoxidizing.

3.3 Impedance characteristics of passive films on titanium alloys

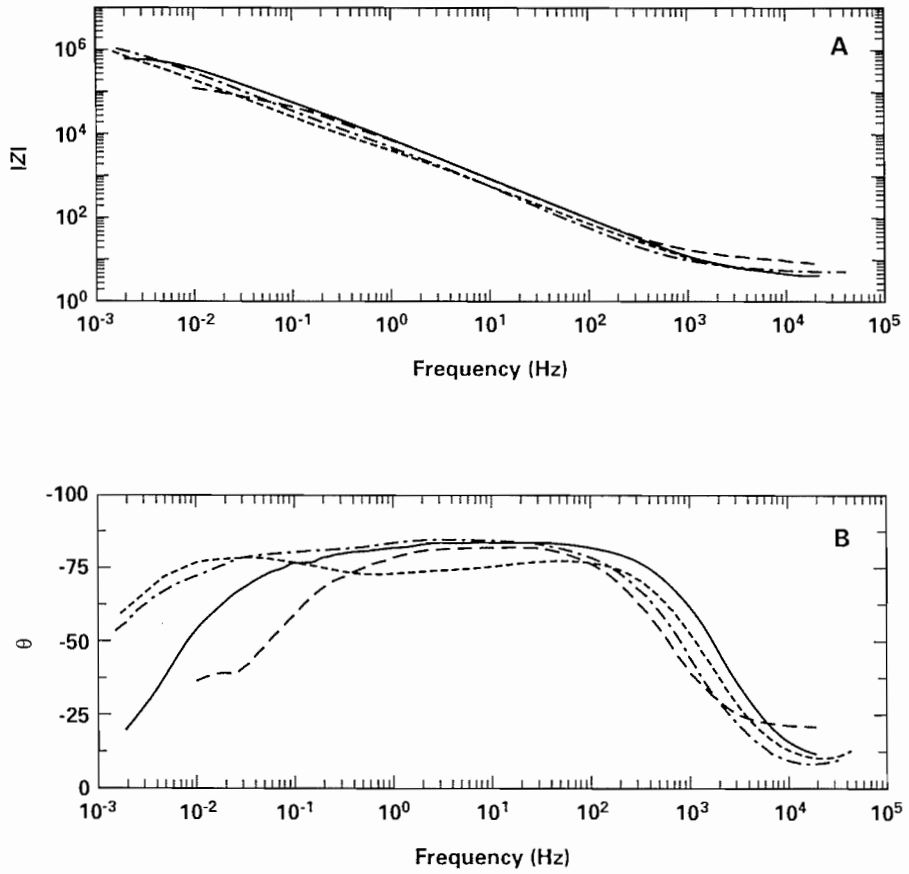
Providing that the extent of crevice corrosion can be limited, or better still, its initiation avoided, then the corrosion of titanium waste containers would proceed extremely slowly under passive conditions and long container lifetimes (>10^5 years) would be expected (3). If predictions of such long lifetimes are to be assured, then the properties of the passive films, upon which such good performance depends, must be thoroughly understood. With this aim in mind, we have studied the properties of the oxide films formed on pure Ti, Ti-2, Ti-12, and Ti-16 under open-circuit corrosion conditions in deaerated 0.27 mol L^{-1} NaCl as a function of temperature using electrochemical impedance spectroscopy (53).

Figure 13 shows Bode plots of the frequency response of these materials at 80°C. For all the materials the total impedance (|Z|) depends on frequency in a manner suggesting that the behaviour is dominated by the capacitative response of the film (i.e., $|Z| \propto \log f$). This is confirmed by the value of the phase angle (θ) at intermediate frequencies, which is >80° out of phase. That the phase angle is <90° out of phase indicates this capacitative behaviour is less than ideal. For low frequencies (<1 Hz) differences in both |Z| and θ are observed between the different alloys.

The impedance data can be accurately fitted by the equivalent circuit shown in Fig. 14. The non-ideal capacitative response of the oxide film, which suggests a non-homogeneous distribution in film capacitance, is represented by a constant phase element (CPE). The film is considered to be breached by defects that may be either grain boundaries in the oxide, physical defects introduced by compressive stresses, or incomplete film formation at the sites of surface intermetallics known to be distributed throughout all these materials (except for pure Ti). These defects are represented in the equivalent circuit by an interfacial impedance, Z_I, which could be specified as a parallel combination of an interfacial polarization resistance (R_P) and an interfacial capacitance (C_I), in series with a pore, or defect, resistance, R_{PORE}. The resistance, R_S, is the electrolyte resistance, which is negligible in this case.

© 1997 NRC Canada

Fig. 13. Bode plots for various Ti alloys recorded after 24 h on open circuit in 0.27 mol L^{-1} NaCl at 80°C: (—·—·) pure Ti; (—) Ti-2; (– – –) Ti-12; (----) Ti-16.



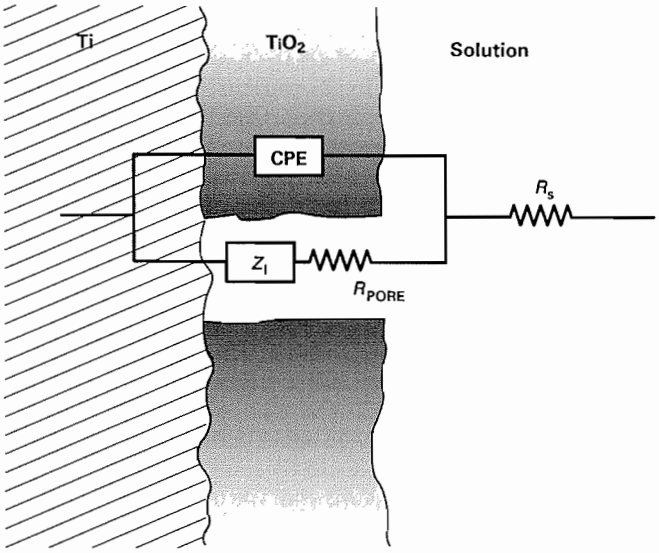


Fig. 14. Equivalent circuit used to analyze electrochemical impedance spectroscopy data for passive Ti alloys.

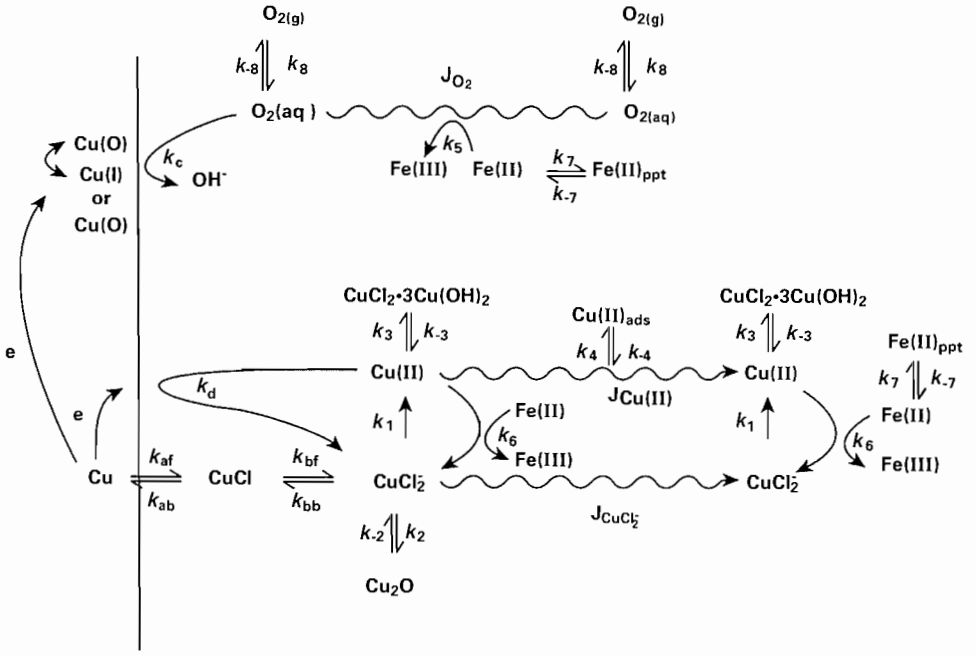
Within this circuit, R_P will be inversely related to the corrosion rate of the material if it is assumed that charge transfer, either electrochemically or as film dissolution, does not occur across the intact oxide–solution interface.

A comprehensive discussion of the impedance behaviour as a function of temperature is beyond the scope of this paper and will be published elsewhere (53). At lower temperatures, all four materials are covered by a passive film with a very high impedance and hence the capability of providing excellent corrosion protection. However, at 80°C the impedance spectra show clear differences at low frequencies (Fig. 13). For pure Ti and Ti-16, a generally capacitative response is maintained even at $f \lesssim 10^{-2}$ Hz, i.e., the phase angle, θ, remains numerically large and the impedance Z continues to increase. By contrast, for Ti-2 and Ti-12 the impedance begins to level off at the lowest frequencies (Fig. 13*A*), and to become more resistive in character (Fig. 13*B*).



It has been shown by various electrochemical and analytical methods (ellipsometry, Raman, XPS) that, for $T \gtrsim 70$°C, film breakdown/recrystallization followed by film thickening occurs (54–57). These experiments were performed on commercially pure Ti (i.e., Ti-2). Under creviced conditions on Ti-2 this process leads to the development of acidity, oxide dissolution, and, in chloride solutions, the initiation of localized corrosion (58). The generation of acidity in this manner is a clear indication of the occurrence of metal dissolution/metal cation hydrolysis. Under non-creviced conditions this process cannot develop the local low pH (<1 at 70°C) required for the initiation of localized corrosion (59).

For both Ti and Ti-2 a simple parallel combination of the constant phase element, CPE, and R_{PORE} gave the best fit for

Fig. 15. Proposed mechanism for the corrosion of copper nuclear fuel waste containers.

the data, although the value of R_{PORE} for Ti-2 (~0.6 Mohm cm^2) is significantly lower than that for Ti (~2 Mohm cm^{-2}). This is consistent with a loss in film resistance for Ti-2 due to the film breakdown – recrystallization – film thickening process that would introduce a high density of grain boundaries, thereby providing short diffusion paths for the ions involved in film growth. The much higher value of R_{PORE} suggests this process does not occur on Ti. The specimen of Ti-2 used contained sufficient Fe as an impurity (0.105 wt.%) for the separation of Ti_xFe intermetallics (60). It would appear that the presence of these intermetallics facilitates the film breakdown – recrystallization process.

For Ti-12, the number density of intermetallics (Ti_2Ni) would be much higher than in Ti-2. The data for Ti-12 cannot be accurately fitted to a circuit with only one time constant (as for Ti and Ti-2) and the equivalent circuit involving film defects (Z_I, R_{PORE}, Fig. 14) is required. The value of R_{PORE} (~0.1 Mohm cm^2) is substantially lower than that for Ti-2, consistent with a much higher density of defect sites within which an interfacial impedance (Z_I) is now detectable in the impedance spectrum.

For Ti-16 there is clear evidence for two time constants in the impedance spectrum despite the fact that the film maintains its essentially capacitative nature to very low impedances. Apparently, the intermetallic particles known to exist in this alloy (61) do not lead to the introduction of low-resistance defects into the film. However, the value of R_{PORE} for Ti-16 is approximately an order of magnitude lower than that calculated for Ti-12. The value of R_P, associated with Z_I (the interfacial impedance within the defect/pore), is >2 Mohm cm^{-2} compared to a value for Ti-12 of ~0.1 Mohm cm^2. This combination of relatively low-resistance pores R_{PORE} with a high interfacial polarization resistance (R_P) suggests the presence of a large number of exposed noble particles on a generally passive surface.

These results indicate that the order of stability of the different alloys of titanium is different for general passive corrosion than it is for crevice corrosion. For crevice corrosion the extent of damage decreased in the order

$$\text{Ti} > \text{Ti-2} > \text{Ti-12} \gg \text{Ti-16}$$

For general passive corrosion, the susceptibility to corrosion decreases in the order

$$\text{Ti-12} > \text{Ti-2} > \text{Ti-16} \sim \text{Ti}$$

Some caution should be exercised in accepting the order for general passive corrosion, which could change if determined at a higher temperature than the 80°C used in the present work.

3.4 General corrosion of copper

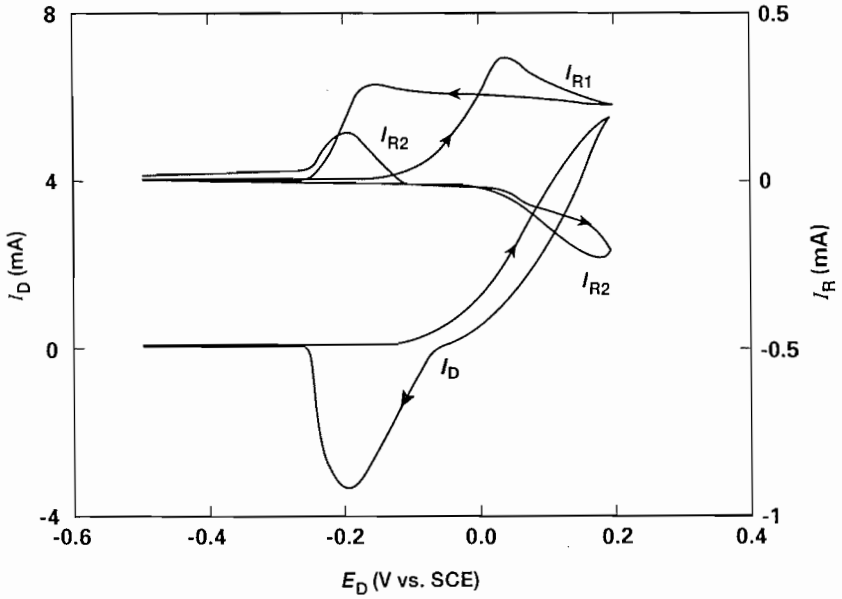

Figure 15 shows the mechanism of the uniform corrosion of Cu containers in Cl^--rich groundwaters. A number of interfacial and homogeneous redox reactions are involved, including the anodic dissolution of Cu as $CuCl_2^-$ (k_{af}, k_{ab}, k_{bf}, k_{bb}) supported by the interfacial reduction of dissolved O_2 (k_c), the oxidation of $CuCl_2^-$ by O_2 (k_1), the consumption of O_2 by reaction with dissolved Fe^{II} (k_5), and the reduction of Cu^{II} by Fe^{II} (k_6). The corrosion rate of the container will also be significantly affected by the adsorption properties of the compacted buffer materials surrounding the container and the precipitation of solids, either locally at the container surface or throughout the surrounding media. Finally, the transport fluxes (J_{O_2}, $J_{Cu^{II}}$, $J_{CuCl_2^-}$) will be restricted since the effective diffusion coefficients of species in water-saturated compacted buffer material will be ~10^2 lower than in bulk solution due to the constrictive and tortuous nature of the pore structure.

Here we describe the two interfacial processes and the measurement and prediction of the corrosion potential (E_{CORR})

Fig. 16. Rotating split-ring disc electrode study of the dissolution of copper in deaerated 0.1 mol L^{-1} NaCl/0.1 mol L^{-1} Na_2SO_4. I_{R1} is the ring current for the oxidation of Cu^I (E_{R1} = +0.4 V vs. SCE), I_{R2} is the ring current for the reduction of Cu^{II} to Cu^I (E_{R2} = −0.1 V vs. SCE), and the disc potential was scanned between −0.5/+0.2/−0.5 V vs. SCE at a scan rate of 10 mV s^{-1}. Collection efficiency for each half-ring 0.2, disc surface area 0.33 cm^2, rotation rate 14.3 Hz.

and corrosion rate (i_{CORR}). Since transport rates are extremely important in determining Cu container corrosion, particular attention has been paid to E_{CORR} measurements under restricted mass transport conditions. The results of these studies have been used to develop a detailed finite-difference model to predict E_{CORR} and i_{CORR} for Cu containers in a waste vault.

3.5 Anodic dissolution of Cu in chloride solutions

The anodic dissolution of Cu in acidic and neutral Cl^- solutions has been extensively studied (ref 62, and refs. therein). As first proposed by Deslouis et al. (62), the mechanism can best be described by the reactions

[9] $Cu + Cl^- \leftrightarrow CuCl_{ads} + e^-$

[10] $CuCl_{ads} + Cl^- \leftrightarrow CuCl_2^-(s)$

[11] $CuCl_2^-(s) \xrightarrow{RDS} CuCl_2^-(b)$

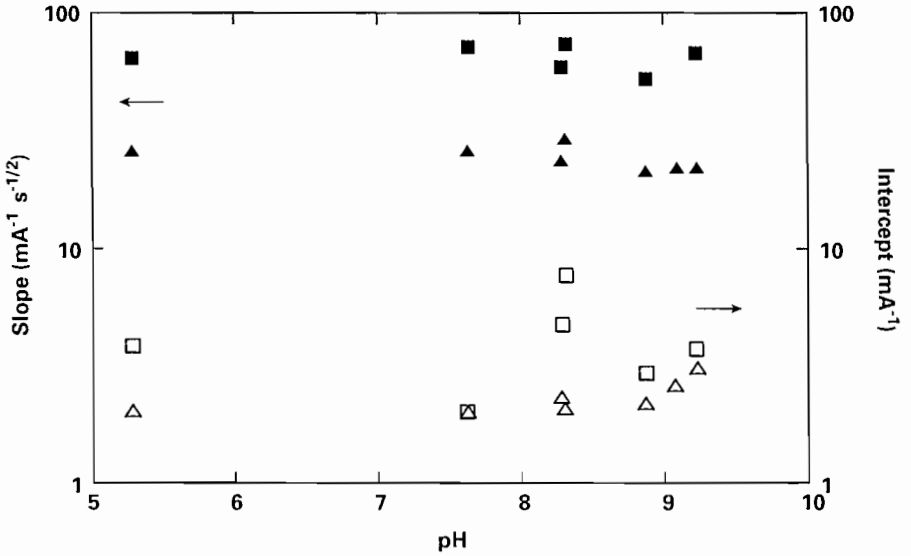
where the diffusion of $CuCl_2^-$ from the surface of the electrode (s) to the bulk of solution (b) is rate determining (reaction [11]). Various mechanisms for the preceding interfacial reactions ([9] and [10]) are best distinguished by considering the E and [Cl^-] dependence of the intercepts and slopes of Koutecky–Levich (K–L) plots, in which the inverse of the observed current from RDE measurements is plotted against the inverse of the square root of the rotation frequency. Extrapolation of these plots to infinite rotation frequency permits the mathematical separation of the transport and interfacial components of the observed current. Our own work has confirmed this mechanism and has shown the conditions under which reaction [10] can be considered to be at equilibrium (62, 63). In addition, we have determined values for k_{bb} and the parameter ($k_{af}k_{bf}/k_{ab}$) used in our mixed-potential model.

Pore water in compacted buffer is expected to contain a significant [SO_4^{2-}] from the dissolution of gypsum ($CaSO_4 \cdot 2H_2O$) impurities. Unlike Cl^-, SO_4^{2-} does not stabilize Cu^I species, and generally Cu^{II} corrosion products are observed (64). To determine the speciation of Cu in mixed Cl^-/SO_4^{2-} solutions we have used a Au–Cu RSRDE (rotating split ring disc electrode) (Fig. 16). One half-ring is used to detect Cu^I dissolution from the Cu disc ($Cu^+ \rightarrow Cu^{2+} + e$; E = +0.4 V (vs. SCE)) while the other half-ring is used to detect Cu^{II} dissolved from the Cu disc ($Cu^{2+} + e \rightarrow Cu^+$; E = −0.1 V (vs. SCE)). In chloride solutions (0.1 mol L^{-1}, not shown in Fig. 16), Cu dissolves as Cu^I for $E \lesssim 0.1$ V (vs. SCE), as indicated by the absence of a ring current for Cu^{II} reduction. Virtually identical behaviour is observed when 0.1 mol L^{-1} Na_2SO_4 is added (Fig. 16). Thus, Cl^- dominates the speciation of dissolved Cu, at least up to 0.0 V (vs. SCE) and reactions [9]–[11] represent Cu dissolution even in sulphate-containing pore waters.

Invariably, Cu exposed to natural environments is covered by a thin layer of Cu_2O. Except in alkaline solutions (65), the mechanism of Cu_2O formation has not been extensively examined in Cl^- solutions. There are two possible mechanisms,

(*i*) the hydrolysis of $CuCl_{ads}$:

[12] $2CuCl_{ads} + H_2O \leftrightarrow (Cu_2O)_S + 2H^+ + 2Cl^-$



and (*ii*) the hydrolysis of dissolved $CuCl_2^-$:

[13] $2CuCl_2^- + H_2O \leftrightarrow (Cu_2O)_S + 2H^+ + 4Cl^-$

These hydrolysis reactions may proceed via CuOH intermediate species, either $Cu(OH)_{ads}$ in the case of eq. [12] or a dissolved complex in the case of eq. [13]. Both of these mechanisms account for the experimental observation that the amount of Cu_2O formed increases with (*i*) increasing pH, (*ii*) decreasing [Cl^-], and (*iii*) decreasing rate of mass transport. The plausibility of reactions [12] and [13] can be determined from the *E*, [Cl^-], and pH dependence of K–L slopes and intercepts shown in Fig. 17 as a function of pH in 0.1 mol L^{-1} NaCl. Both slopes and intercepts are pH independent up to pH = 9.2, above which Cu_2O formation (identified by cathodic stripping voltammetry) passivates the electrode. An identical critical pH is obtained in 1.0 mol L^{-1} NaCl. If Cu_2O formation were in competition with dissolution as $CuCl_2^-$ (reaction sequence [9]–[11] then [13]), then the critical pH might be expected to increase with [Cl^-]. While the exact mechanism remains to be demonstrated, this favours the reaction sequence [9]–[11] followed by reaction [12].

3.6 Cathodic reduction of oxygen on copper

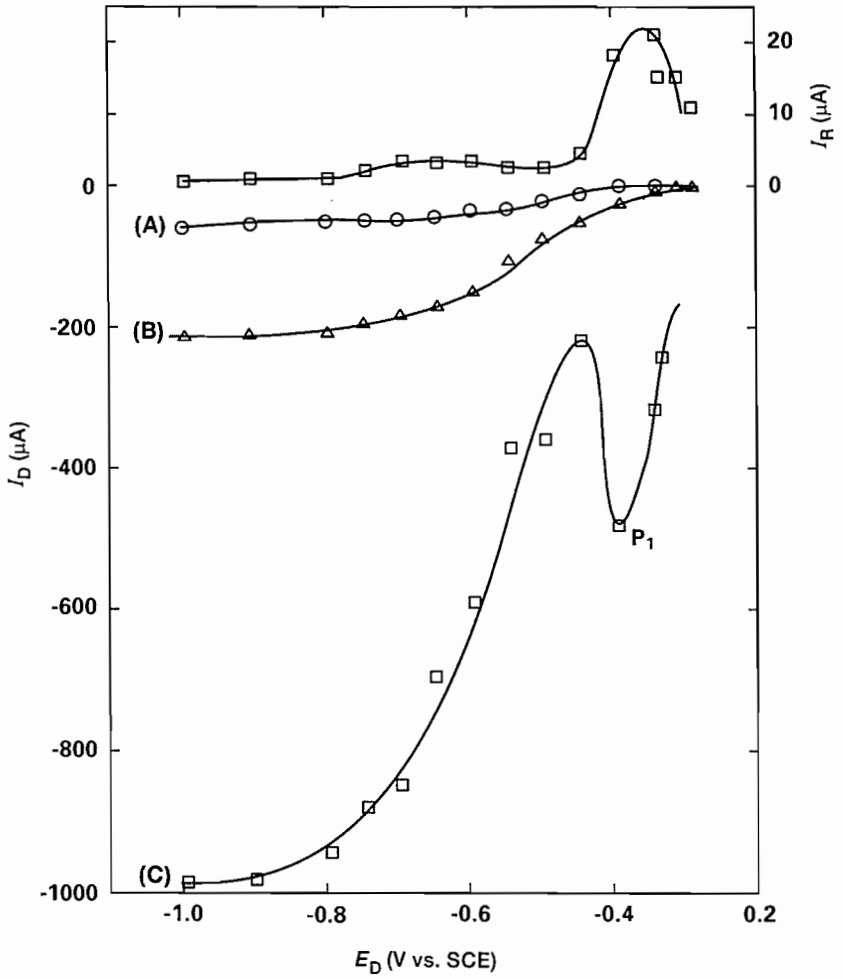
A generalized mechanism for the reduction of O_2 is given in Fig. 6 and indicates that two products, OH^- and (or) H_2O_2, may be released from the disc of an RRDE (rotating ring disc electrode). We have used a Au ring to detect peroxide released as an intermediate in O_2 reduction and a Bi ring to detect the four-electron end product, OH^- (66). The Bi surface oxidizes in air to produce a pH-sensitive Bi_2O_3 ring electrode.

Figure 18 shows steady-state currents for the reduction of O_2 on Cu in 1.0 mol L^{-1} NaCl for three [O_2]. At negative potentials a well-defined limiting current and no ring current for HO_2^- oxidation are obtained, consistent with an overall four-electron reduction of O_2 to OH^-. For aerated solutions and solutions equilibrated with low O_2 partial pressures, a single wave and no detectable ring current are obtained. For atmospheres of ≥50 vol.% O_2/N_2 a cathodic peak and measurable peroxide formation are observed in the joint kinetic/transport potential region. This suggests that a catalytic surface is formed in this potential range. The [O_2] at which the cathodic peak is observed varies with pH (67), a peak being observed in aerated solution at pH =10, but not in neutral NaCl. Also, the peak observed in oxygenated neutral solution (Fig. 18) disappears when the solution is buffered at pH 7.

Significant pH changes are detected at a Bi ring electrode in neutral 1.0 mol L^{-1} $NaClO_4$ solution (Fig. 19). The hysteresis observed in the disc current on a potentiodynamic scan is also obtained in the pH measurement that follows the disc current. In the transport-limited region for O_2 reduction, the interfacial pH reaches a maximum value of ~10.5.

Kinetic parameters were determined from steady-state measurements in 1.0 mol L^{-1} NaCl. Reaction orders with respect to [O_2] varied from ~1 for $E \lesssim -0.5$ V (vs. SCE) to >1 at more positive potentials, corresponding to the cathodic peak at higher [O_2]. Transport-corrected Tafel slopes increased with [O_2], from −135 mV for 2 vol.% O_2/N_2 to −160 to −180 mV for ≥ 21 vol.% O_2/N_2. These values are consistent with control of the overall process by the first electron transfer.

To explain the observation of the cathodic peak, it is conjectured that O_2 reduction occurs on two different surface sites: (*i*) "bare" Cu sites (type A), present on cathodically reduced Cu at negative potentials and at low [O_2]; (*ii*) catalytic sites (type B) formed at more positive potentials and at higher [O_2]. Then, the kinetic current (I_k) is given by (67),



$$[14] \quad -I_k = nFA[O_2](\theta_A k^\circ_{CA} + \theta_B k^\circ_{CB}) \exp\left\{-\frac{\alpha F(E-E_C^\circ)}{RT}\right\}$$

where *n* is the overall number of electrons, *A* is the surface area, k°_{CA} and k°_{CB} are standard rate constants for sites A and B ($k^\circ_{CB} \gg k^\circ_{CA}$), θ_A and θ_B are the fractional surface coverages, and E°_C is the standard potential for O_2 reduction on both sites, assumed here to occur via the same mechanism. It is further assumed that the reaction is first order with respect to [O_2].

Because θ_B is a function of *E* and, through the interfacial pH, a function of [O_2], eq. [14] can be used to explain the observed variations in Tafel slope and reaction order. At negative potentials and (or) low [O_2], $\theta_B \rightarrow 0$ and a reaction order

Fig. 18. Steady-state oxygen reduction currents on copper in 1 mol L^{-1} NaCl in atmospheres of (*A*) 5 vol.% O_2/N_2 (○), (*B*) air (Δ), and (*C*) 100% O_2 (□), and the corresponding ring current for the oxidation of peroxide for 100% O_2. Disc surface area 0.33 cm^2, collection efficiency 0.4, rotation rate 14.3 Hz. (Reprinted from J. Electroanal. Chem.Vol. 385, F. King et al., "Oxygen reduction on copper in neutral NaCl solution", 44–55 (1995) with kind permission from Elsevier Science S.A., P.O. Box 564, 1001 Lausanne, Switzerland.)

of 1 with a Tafel slope of −120 mV (α = 0.5) are predicted. At more positive potentials and (or) higher $[O_2]$ (i.e., higher interfacial pH), $\theta_B k^\circ_{CB} \gg \theta_A k^\circ_{CA}$. The current increases as a consequence of the formation of catalytic type-B sites. At more positive potentials the current decreases, both because of the decrease in the overpotential for the reduction of O_2 and because the activity of the surface decreases as it becomes covered by Cu^I (see below). By considering the potential dependence of θ_B, it can be shown that reaction orders between 1 and 2 are possible with Tafel slopes of $2.3RT/(\beta\text{-}2\alpha)F$, where β is the potential dependence of the formation of catalytic sites of type B (67)).

Evidence from cyclic voltammetry suggests the catalytic site may be composed of $Cu(OH)_{ads}$ or submonolayer Cu_2O. Voltammetry in deaerated solutions shows that the onset of the cathodic reduction peak coincides with the initial stages of Cu_2O formation, and Elsner et al. (68) suggest that $Cu(OH)_{ads}$ may be a precursor of Cu_2O. The presence of Cu^I on Cu^0 may provide the donor–acceptor sites thought to catalyse O_2 reduction on UO_2 and transition metal oxides (see Section 2.3 above). O_2 reduction at these sites (type B) also leads to the release of peroxide, which is not observed for O_2 reduction on "bare" Cu (type A sites).

3.7 Measurement and prediction of E_{CORR} in O_2-containing chloride solutions

Because the rate of mass transport of reactants and products to and from the container surface will be restricted by the compacted clay, we have made E_{CORR} measurements under different mass transport conditions. Under steady-state conditions, the relative permeability of the diffusion layer can be characterized by a steady-state mass transfer coefficient k_M, equal to D/δ, where D is the effective diffusion coefficient and δ the diffusion layer thickness. Two attempts were made to restrict mass transport: (*i*) by placing a porous nylon membrane over the electrode (MCE) ($k_M = 10^{-4}$ cm s^{-1}); (*ii*) by placing a clay layer (0.1 or 1.0 cm thick) over the electrode (CCE) ($k_M = 10^{-6}$–10^{-7} cm s^{-1}) (Fig. 20). Internal reference electrodes built into some of these electrodes (MCE, CCE) allowed us to correct for the small (<20 mV) membrane potential (69). By comparison, in bulk solution $k_M = 10^{-2}$ cm s^{-1}.

Fig. 20. Schematics of electrodes with reduced rates of mass transport to and from the surface. Top: Schematic of the membrane-covered electrode (MCE). (1) Internal Ag/AgCl/0.1 mol L^{-1} KCl reference electrode, (2) reference electrode wick, (3) solution-filled annular channel, (4) porous nylon membrane, (5) membrane retaining ring, (6) Cu disc electrode. Bottom: Schematic of the clay-covered electrode (CCE). (*a*) Cu disc, (*b*) layer of compacted clay, (*c*) Pt gauze frit, (*d*) Plexiglass electrode mount.

function of rotation rate frequency (f) and $[O_2]$ (69) demonstrated that in aerated solutions the transport of $CuCl_2^-$ away from the electrode was rate determining (i.e., reaction [11]) for the anodic reaction (Table 1). The cathodic reaction (O_2 reduction) is activation controlled, but becomes increasingly transport controlled as $[O_2]$ decreases (i.e., $dE_{CORR}/d \log f$ becomes less negative). Full transport control is never established even in nominally deaerated solutions (69).

Measurements with the MCE and CCE are consistent with transport control of both the anodic and cathodic reactions, as might be expected for electrodes with rates of mass transport 2–5 orders of magnitude lower than in bulk solution. E_{CORR} values measured with the MCE varied with neither the mean pore size of the membrane, nor f (69). Using the CCE, E_{CORR} was measured as a function of $[O_2]$ (Fig. 21). As expected, E_{CORR} decreases with $[O_2]$, but the time to establish steady state between each change in $[O_2]$ was ~50 h for the 0.1-cm-thick electrode (not shown) and 500–1000 h for the thicker clay layer (Fig. 21). E_{CORR} was relatively insensitive to the clay-layer thickness, but decreased by 40–60 mV per decade decrease in $[O_2]$ (69).

From the mechanisms of the anodic and cathodic reactions we have constructed mixed potential models (MPM) to predict E_{CORR} and i_{CORR}. These models allow us to interpret our experimental E_{CORR} measurements, and to predict container lifetimes and assess the probability of localized corrosion under waste disposal conditions. For the second of these two purposes, the interfacial processes are coupled to the mass transport, adsorption/desorption, precipitation/dissolution, and redox processes included in the full reaction mechanism (Fig. 15).

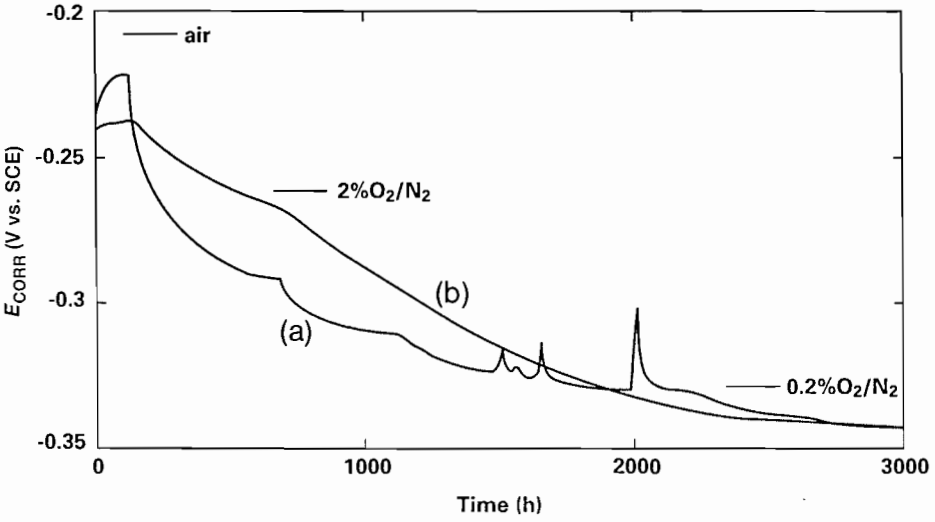
In our MPM, the anodic reaction is described by reactions [9] and [10] and the cathodic reaction by the overall mechanism

[15] $O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$

The use of these simplified mechanisms is relatively unimportant in our MPM since mass transport processes determine the rates of anodic and cathodic reactions.

Table 1 gives the predicted values of E_{CORR} for comparison with the RDE measurements. The predicted values differ from experimental data by 30–40 mV at worst, and show the same trend of decreasing rotation–rate dependence with decreasing $[O_2]$. The MPM can also be used to predict the interfacial $[O_2]$ ($[O_2]_0$). The predicted $[O_2]_0/[O_2]_\infty$ ratio (Table 1) confirms the conclusion that the cathodic reaction becomes increasingly transport limited with decreasing $[O_2]$, but never completely ($[O_2]_0/[O_2]_\infty = 0$), even in deaerated solution.

The predicted steady-state E_{CORR} values for the CCE are marked on Fig. 21. Again, agreement between theory and experiment is within 30 mV, but in this case $[O_2]_0/[O_2]_\infty < 0.01$, suggesting essentially complete transport control of the cathodic reaction. The figure also compares the measured E_{CORR} as a function of time to that predicted using our full MPM model incorporating the processes detailed in Fig. 15 (70). The maximum difference between measured and experimental values is ~20 mV. Furthermore, the MPM accounts reasonably well for the period required for reestablishment of the steady state between each change in $[O_2]_\infty$.



These agreements between measurement and prediction give us confidence that such modelling procedures can be justifiably applied to the prediction of waste container lifetimes.

4. Summary

A number of different electrochemical studies relevant to the disposal of nuclear waste have been described. These include studies of fuel dissolution and the localized and general corrosion of the potential waste container materials Cu and Ti. These studies have provided the mechanistic basis for the development of models to predict fuel and container behaviour as well as providing the values of parameters used in evaluating and applying these models. While the application of electrochemical methods to nuclear waste disposal problems has been described, it is clear that electrochemical processes are central to the description and prediction of a wide range of environmental issues involving redox processes.

Fig. 21. Comparison of measured and predicted corrosion potentials for a clay-covered copper electrode (CCE) in 1.0 mol L^{-1} NaCl with a clay-layer thickness of 1.0 cm. (*a*) Measured E_{CORR} (69), (*b*) predicted E_{CORR} (70). The horizontal lines represent the predicted steady-state values for the respective O_2/N_2 mixtures (69). For the experimental measurements, the initial air atmosphere was changed to atmospheres of 2 vol.% O_2/N_2 and 0.2 vol.% O_2/N_2 at times of 110 and 675 h, respectively. The spikes in the experimental curve resulted from accidental additions of aerated solution or loss of the gas overpurge.

Abstract: The electrochemical oxidation reactions and competitive adsorption behaviour of glycine, the peptides glycyl-glycine and glycyl-glycyl-glycine, α- and β-alanine, and α-, β-, and γ-aminobutyric acid have been investigated by cyclic voltammetry at a platinum electrode in a pH 7.0 phosphate buffer solution at ambient temperature. Strong adsorption of all species at anodic potentials in neutral solution was accompanied by an efficient ability to block both the initial stages of OH monolayer deposition as well as the second stage involving an irreversible process of continued deposition of OH or O species. Glycine and the peptides blocked the initially and more reversibly deposited OH species in preference to those formed at higher potentials. Surface concentrations determined with the lower anodic end potentials (0.50 V) gave information on the orientation of the adsorbed molecules. Steady-state polarization measurements gave Tafel slopes in the range of 253-498 mV, considerably higher than that normally seen for oxygen evolution from a phosphate buffer solution. These results suggest that, in the pH 7.0 buffer, the negatively charged carboxylate group preferentially adsorbs under these anodic potentials in a mechanism similar to the Kolbe reaction, with the decarboxylation step being rate determining.

Key words: electrochemical oxidation, glycine, alanine, aminobutyric acid, peptides, platinum oxide.

Résumé : Opérant à la température ambiante, dans une solution tampon de phosphate à pH 7,0 et faisant appel à la voltampérométrie cyclique à une électrode de platine, on a étudié les réactions d'oxydation électrochimiques et le comportement compétitif d'adsorption de la glycine, des peptides glycyl-glycine et glycyl-glycyl-glycine, des α- et β-alanines et des acides α-, β- et γ-aminobutyriques. La forte adsorption de toutes les espèces à des potentiels anodiques en solution neutre est accompagnée d'une habilité efficace à bloquer tant les étapes initiales des dépôts de monocouches de OH que la deuxième étape impliquant le processus irréversible de dépôt continue des espèces OH ou O. La glycine et les peptides bloquent les espèces OH qui se forment initialement et qui sont déposées d'une façon plus réversible de préférence à celles qui se forment à des potentiels plus élevés. Les concentrations à la surface qui ont été déterminées aux potentiels anodiques les plus bas (0,50 V) fournissent de l'information sur l'orientation des molécules adsorbées. Des mesures de polarisation à l'état stationnaire permettent d'obtenir les pentes de Tafel à des valeurs allant de 253 à 498 mV, des valeurs beaucoup plus élevées que celles généralement observées pour l'évolution de l'oxygène à partir d'une solution tampon de phosphate. Ces résultats suggèrent que, à ces potentiels anodiques, à un pH de tampon égal à 7,0, il y a adsorption préférentielle des groupes carboxylates chargés négativement; le mécanisme est semblable à celui de la réaction de Kolbe et la décarboxylation est alors l'étape cinétiquement déterminante.

Mots clés : oxydation électrochimique, glycine, alanine, acide aminobutyrique, peptides, oxyde de platine.

[Traduit par la rédaction]

1. Introduction

Anodic reactions in aqueous solutions at the Pt electrode are characterized by the electrocatalytic surface oxide film that develops on the metal surface. This oxide film is known to be electrocatalytic for such reactions as O_2 (1, 2), Cl_2 (3–8), and N_2 (from N_3^-) (9–13) evolution and for the oxidation of acetate ions that produce ethane by the Kolbe mechanism (14). Therefore it is of interest to compare the adsorption and oxidation behaviour of amino acids with that of acetic acid and to examine the role of the surface oxide film at platinum in the electrochemical (EC) oxidation mechanism. In addition, since amino acids form the building blocks of proteins, the oxidation and adsorption behaviour of amino acids at an electrode surface is relevant to the interfacial behaviour of proteins and, hence, to the immense industrial and medical problems associated with the fouling of surfaces by proteins (15–19). These studies are also relevant to the development of biosensors such as those used for EC detection in HPLC and other LC systems on noble metal electrodes such as platinum and gold (20–23),

active Langmuir–Blodgett films of enzyme on platinum (24), enzymes immobilized between platinum electrode surfaces and membranes (25–30), enzyme entrapment in polymers on platinum (31), and also phospholipid bilayers (32–34) and bilayer conducting polymers (35) formed on platinum electrode surfaces that may be used for the incorporation of enzymes (36–38).

A number of studies have been made to obtain information on the mechanisms of the oxidation of amino acids at platinum. The anodic oxidation of simple amino acids such as glycine (39), α- and β-alanine (40), and α-, β-, and γ-aminobutyric acid (41) at pH 1 and 13 at a platinum electrode have been found to result in the formation of the next lower aldehyde in the homologous series. These studies were undertaken to investigate the role of the amino group in the oxidation process. Kinetic analysis showed the reactions to proceed in a manner similar to the Kolbe mechanism with adsorption through the carboxylate group accompanied by electron transfer, followed by decarboxylation as the rate-determining step. However, rather than dimerization of the adsorbed radicals as in the Kolbe mechanism (14), the adsorbed radicals were further oxidized to the next lower aldehyde in the homologous series accompanied by the transfer of a second electron. In the electro-oxidation of glycine, product analysis showed the intermediate species to be hydrolyzed to formaldehyde and ammonia. However, with the larger amino acids, product analysis was complicated by further reactions of the newly formed aldehydes, particularly by condensation reactions with the amino acids in the bulk solution (40, 41). HPLC analysis of the products of electrolysis of the dipeptide tyrosyl-glycine (Tyr-Gly) at potentials of 1.8–2.2 E_{SCE} indicated that although minimal cleavage of the peptide bond occurred, cleavage of the dipeptide was not the predominant pathway in the anodic oxidation process (42). In the case of tryptophyl-glycine (Trp-Gly), polymerization at the metal surface may have predominated as a film formed on the surface of the electrode after electrolyzing the solution for long periods of time at these high anodic potentials.

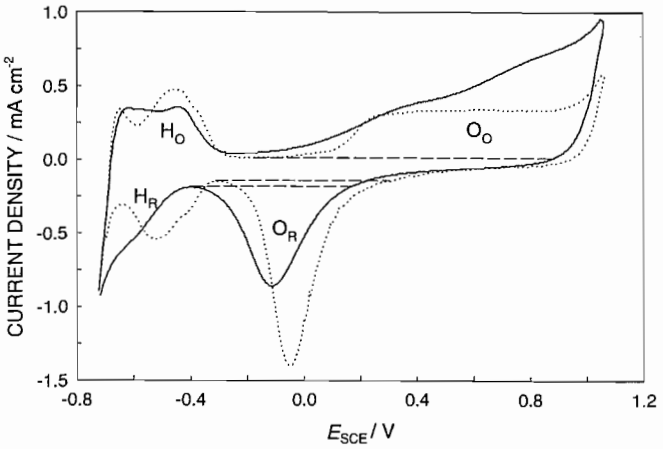
Investigations with other techniques have also indicated the important role of the carboxyl functional group in the surface adsorption behaviour of related molecules. In recent investigations of the interaction of acetic acid with platinum electrodes using infrared spectroscopy, Krauskopf and Wieckowski (43) have shown that both carboxylate oxygens were oriented toward the metal surface. Corrigan et al. (44) found maximum adsorption of acetic acid at a platinum electrode at 0.5 V (E_{SCE}) by both infrared analysis and radiotracer techniques. Horanyi (45) carried out a systematic radiotracer study of the behaviour of amino acids at a platinum electrode in order to investigate the role of the carboxyl functional group in the adsorption of aliphatic acids. The adsorption behaviour of acetic acid and glycine was reported to be similar in acidic medium. Strong chemisorption of both species occurred in alkaline medium. No adsorption was found at potentials less than 0 V, but adsorption increased steadily with anodic potentials and maximized at 0.4–0.5 V (E_{SCE}). A rapid exchange of adsorbed labeled glycine with nonlabeled species suggested that the protonated $^{+}H_3N\text{-}CH_3$ group does not influence the adsorption behaviour of glycine. To obtain further evidence concerning the role of the -COOH group in the adsorption of amino acids, the adsorption of labeled $CH_3\text{-}NH_2$ and $NH_2\text{-}CH_2\text{-}CH_2\text{-}NH_2$ was studied. No adsorption of these compounds was observed in the potential range in which the adsorption of glycine and γ-aminobutyric acid occurred. Masui et al. (46) found that the oxidation of several N-methyl amino acids at a glassy carbon plate electrode and pH 10 proceeded by decarboxylation and produced the corresponding aldehyde and methylamine as the major electrolysis products. A two electron oxidation mechanism was proposed for this degradation.

In the present studies, the adsorption behaviour of glycine, the peptides glycyl-glycine (Gly-Gly) and glycyl-glycyl-glycine (Gly-Gly-Gly), α- and β-alanine, and α-, β-, and γ-aminobutyric acid were investigated by cyclic voltammetry at a platinum electrode in a pH 7.0 phosphate buffer solution at ambient temperature. Steady-state polarization measurements provide information regarding the kinetics and mechanisms of the electrochemical oxidation processes. Therefore comparisons of the adsorption and oxidation reaction properties may be made (*i*) between the α-amino acids with the amino group positioned on the carbon containing the carboxylate group, i.e., glycine, α-alanine, and α-aminobutyric acid; (*ii*) between those with the amino group on the terminal chain carbon relative to the carbon with the attached carboxylate group, i.e., glycine, β-alanine, and γ-aminobutyric acid; and (*iii*) between similar α-amino acids in the absence and presence of peptide bonds, i.e., glycine, Gly-Gly, Gly-Gly-Gly. These results are also compared to those obtained previously in this laboratory for glycine (39), α- and β-alanine (40), and α-, β-, and γ-aminobutyric acid (41) at pH 1 and 13 in order to explore the response to changes in pH.

2. Experimental

Reagents and solutions

Individual solutions of glycine (>99% purity, gold label reagent), the peptides Gly-Gly and Gly-Gly-Gly, α- and β-alanine, and α-, β-, and γ-aminobutyric acid (all of the highest possible quality, Sigma Chemical Company) were prepared in 0.05 mol L^{-1} phosphate buffer (pH 7.0) using anhydrous monobasic potassium phosphate (KH_2PO_4) (Sigma Chemical Company, cell culture tested) and sodium hydroxide (prepared from standardized BDH Chemical Company concentrate). Conductivity water (Nanopure, resistivity = 18.3 megohm cm) was used in the preparation of all aqueous solutions.



Electrochemical cell and electrodes

Three-compartment all-glass electrochemical cells were constructed with two glass-sleeved stopcocks as two of the separate compartments. The working and counter electrode compartments were purged continuously with nitrogen gas (Linde, commercial purity 99.7%) that was deoxygenated by passage through a copper furnace at 573 K. This also provided a well-mixed bulk solution. Electrodes of high-purity platinum wire or mesh (99.99%, Johnson, Matthey and Mallory) were degreased by refluxing in acetone, sealed in soft glass, electrochemically cleaned by potential cycling in 0.5 mol L^{-1} sulfuric acid (Aristar grade purity, BDH Chemicals Limited), and stored in 98% sulfuric acid. The real surface area of the platinum electrode was obtained from the charge under the hydrogen underpotential deposition (upd) peaks (47). Saturated calomel reference electrodes were constructed by a

Fig. 1. Cyclic voltammogram at a Pt electrode (E_{SCE}) (sweep rate 500 mV s^{-1}) of the phosphate buffer, pH 7.0 (dotted line) and 0.092 mol L^{-1} Gly-Gly-Gly in the phosphate buffer (solid line). O_o indicate the anodic oxidation regions and O_r the oxide reduction regions, which are integrated to obtain Q_{O_o}, Q_{O_r}, $Q_{O_o}{}^A$, and $Q_{O_r}{}^A$. H_o and H_r are the hydrogen oxidation and reduction regions, respectively.

standard procedure (48). Their potentials were checked frequently against a standard hydrogen electrode and compared with the literature value (49). The saturated calomel electrodes were found to be reproducible to within ±1 mV.

Methods

Cyclic voltammograms were obtained using a Hokuto Denko potentiostat (model HD-301) and a Hokuto Denko function generator (model HD-111) and were recorded on an Allen Datagraph, Inc. X-Y recorder–plotter (model 720M). The sweep rate used throughout was 500 mV s^{-1}.

The surface charge density, Q_{ADS}, resulting from the deposition of the amino acid (or peptide) on the electrode following additions of specific aliquots of analyte, was determined from the difference between the integrated areas of anodic oxidation, O_o, and oxide reduction, O_r, in the presence of the adsorbing species (Fig. 1). The small surface charge density that resulted from the phosphate buffer in the absence of amino acid was subtracted from that measured for the amino acid and the remainder was attributed to the amino acid adsorption, as follows:

$$[1] \quad Q_{ADS} = (Q_{O_o}{}^A - Q_{O_r}{}^A) - (Q_{O_o} - Q_{O_r})$$

where Q_{O_o} is the anodic oxidation charge density in phosphate buffer, Q_{O_r} is the oxide reduction charge density in phosphate buffer, $Q_{O_o}{}^A$ is the anodic oxidation charge density in the presence of the amino acid (or peptide) species and $Q_{O_r}{}^A$ is the oxide reduction charge density in the presence of the adsorbing species. Cyclic voltammograms were recorded after each aliquot of amino acid was added to the buffer solution in the electrochemical cell and steady-state conditions had been attained, giving identical, reproducible cyclic voltammograms with continued potential sweeps. The reproducibility of determining areas of different cyclic voltammogram tracings from different experiments for phosphate buffer at anodic end potential 0.5 V was within ±3%. The standard deviation of the surface charge densities, Q_{ADS}, of the plateau values for amino acid surface adsorption were found to be ±5%.

From the surface charge densities, the surface concentration of amino acid, Γ_A, in molecules nm^{-2}, was calculated using:

$$[2] \quad \Gamma_A = Q_{ADS} N_A / nF$$

where N_A is Avogadro's number, $n = 2$ is the number of electrons transferred, and F is the Faraday constant.

The % decrease in the oxide reduction area as a result of the competitive behaviour of the amino acids was calculated using the following relationship:

$$[3] \quad \% \text{ oxide blocked} = 100\,(Q_{O_r} - Q_{O_r}{}^A)/Q_{O_r}$$

where Q_{O_r} and $Q_{O_r}{}^A$ are the surface charge densities measured for the oxide reduction peak in the phosphate buffer in the absence and presence of amino acid, respectively.

Steady-state polarization measurements were made using a computer-controlled EG&G Princeton Applied Research (model 273) potentiostat to vary the potential of the working electrode. Before each run, the working electrode was conditioned at −600 mV to reduce the electrode surface. Tafel slopes were obtained from the plot of potential versus log of the current density (amp cm^{-2}) with corrections made to correct for "uncompensated solution resistance" obtained from the ac impedance measurements using a Solatron HF frequency response analyzer (model 1255). The solution resistance was determined from the x-intercept in the Nyquist plot of the imaginary versus real components of impedance.

3. Results and discussion

3.1 Cyclic voltammetric measurements

The formation of surface oxide films on Pt has been the subject of many investigations (50–60) and it is well known that there are three qualitatively different stages in surface oxide formation distinguishable by electrochemical (52) and optical methods (59–61). The first stage consists of a submonolayer of underpotential deposited (upd) OH species which behave reversibly in electrochemical measurements (52, 59, 60). A second irreversible process involves continued deposition of OH or O species associated with the initial stages of a place inversion of Pt and O in the oxide film (1–3, 14, 50–52, 59, 60, 62). The third is an oxide-thickening process resulting from high-field oxide film growth (1, 2, 59, 60). The first and second stages of oxide film growth are the regions of interest in the cyclic voltammetric measurements. The anodic end potential was initially varied to determine the potential at which the charge due to a monolayer of adsorbed OH species in the phosphate buffer solution was equivalent to the total H charge in the cathodic upd region. This potential was found to be 0.50 V, which includes 30% of the total oxide formed up to the anodic end potential 1.1 V (similar to that observed in alkaline solution (52)) and represents the first stage of oxide formation. Data, to be discussed later, were evaluated at this potential as well as the whole anodic upd region to the higher end potential of 1.1 V, which includes both the first and second stages of oxide film formation.

To characterize the behaviour of the amino acids and related compounds, it was first necessary to determine the

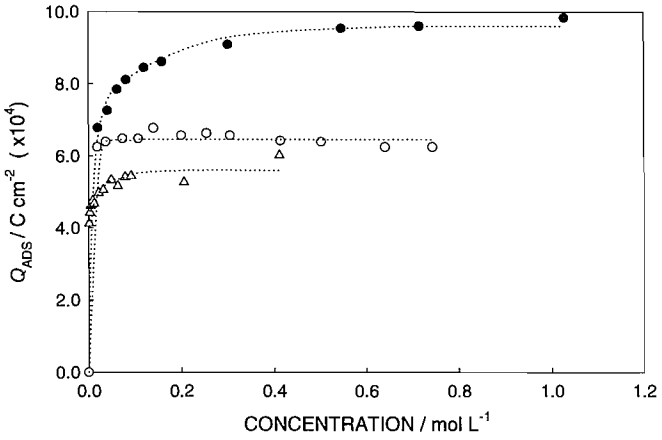
Fig. 2. Surface charge density at the Pt electrode for the anodic end potential 1.1 V as a function of bulk concentration of: ●, glycine; ○, Gly-Gly; Δ, Gly-Gly-Gly.



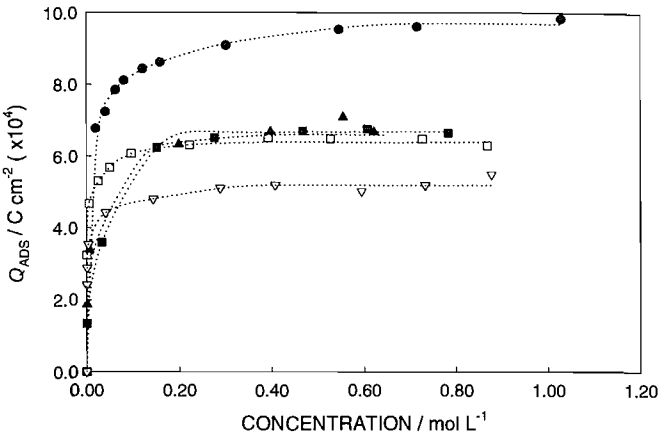


Fig. 3. Surface charge density at the Pt electrode for the anodic end potential 1.1 V as a function of bulk concentration of: ●, glycine; ■, α-alanine; □, β-alanine; ▲, α-aminobutyric acid; ▽, γ-aminobutyric acid.

cyclic voltammogram for phosphate buffer, pH 7.0 (Fig. 1). Cyclic voltammograms were then recorded for additions of each aliquot of amino acid to the electrochemical cell containing the phosphate buffer. As an example, Fig. 1 also shows the tracing of 0.092 mol L^{-1} Gly-Gly-Gly in the phosphate buffer. Strong adsorption of all the species studied in neutral solution was evident by a significant increase in the area of the anodic oxidation region (O_o) and the decrease in the area of the oxide reduction region (O_r) due to blocking the deposition of the surface oxide by the adsorbing species. The surface charge density was determined from the corresponding cyclic voltammogram with anodic end potentials 0.5 and 1.1 V for each addition of amino acid as described earlier.

The relationships between surface charge density, Q_{ADS}, determined using eq. [1], and concentration of amino acid in the bulk solution are shown in Figs. 2 and 3 for the end potential 1.1 V, for concentrations up to about 1 mol L^{-1}. The plateau values obtained for glycine and its peptides (Fig. 2) show a very nice trend, with surface charge density values for glycine > Gly-Gly > Gly-Gly-Gly that reflect the ability of the molecules to pack efficiently on the electrode surface; i.e., glycine with the smallest structure showing the greatest packing density and charge due to oxidation. Fig. 3 shows the similarity between the surface charge densities of the two molecules, α-alanine and β-alanine, in the plateau region that reflects the similar sizes in their structures. However, β-alanine adsorbs more readily than α-alanine at the lower concentrations. The plateau values of surface charge densities for the alanines (~650 μC cm^{-2}) are very similar to the value obtained for Gly-Gly. This again reflects the similarity in structural sizes of the three compounds. If we now compare the results in Fig. 3 for the α-amino acids (glycine, α-alanine, and α-aminobutyric acid), glycine again shows the highest surface charge density, with α-alanine and α-aminobutyric acid giving lower, but very comparable results. Also in Fig. 3, a comparison with the effect of the amino group placed on the terminal carbon in the chain shows glycine still with the highest surface charge density at about 960 μC cm^{-2}, β-alanine with ~630 μC cm^{-2}, and γ-aminobutyric acid with the lowest value of ~500 μC cm^{-2}.

The competitive nature between the adsorption of amino acids and the two stages of oxide film formation may be evaluated from the % decrease in the oxide reduction area in the presence of increasing concentrations of amino acids. The blocking of the first stage in the formation of the oxide layer, i.e., monolayer OH deposition, has been determined from results for % oxide blocked obtained with anodic end potential 0.5 V. The efficiency of the amino acid to block both the first and second stages, i.e., continued deposition of OH or O species associated with the electrochemically irreversible initial stages of place exchange of Pt–O in the oxide film, has been examined by the blocking efficiency over the whole anodic upd region to 1.1 V.

An examination of the blocking efficiency of glycine and the peptides of the first stage of oxide film formation (Fig. 4*a*) shows a large blocking effect by glycine that curves and tends to level off at about 80% of the oxide blocked. An even greater effect results from the tripeptide, Gly-Gly-Gly, as the curve representing the blocking increases to 90%. However, the blocking efficiency of glycine and the peptides becomes somewhat diminished over the large upd region representing both the first and second stages of oxide film formation. Figure 4*b* instead shows a long linear relationship of % oxide blocked versus logarithm of the concentration of amino acid in the bulk solution for glycine, Gly-Gly, and Gly-Gly-Gly. At the higher concentrations the tripeptide was more efficient in blocking oxide deposition than the smaller dipeptide, Gly-Gly, and amino acid, glycine. However, glycine and the peptides block the initially and more reversibly deposited OH species in preference to those formed at higher potentials. The linear logarithmic regions of Fig. 4*b* arise mainly from a continuing blocking of surface oxide.

Unlike the behaviour by glycine, a linear behaviour is observed for the % oxide blocked by α-alanine in the first stage of monolayer surface oxide growth (Fig. 5*a*), which continues past the upper limiting values for glycine. However, the efficiency is significantly less than that of glycine in the concentration range 10^{-5}–10^{-3} mol L^{-1}. At the higher concentrations, β-alanine also showed a linear behaviour but with a blocking efficiency similar to that of glycine. A comparison of

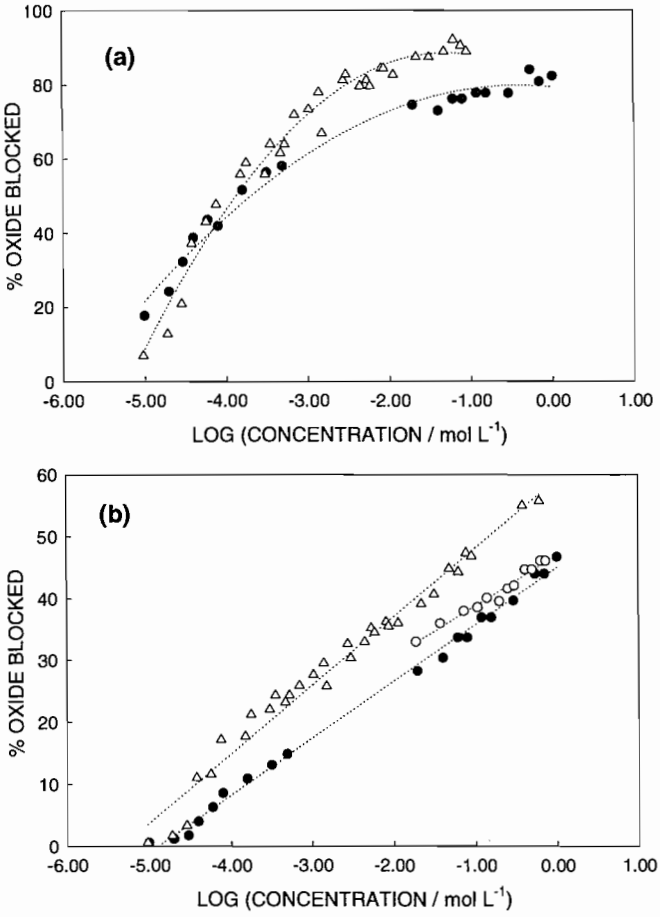
Fig. 4. The % oxide formation blocked by the amino acid at the Pt electrode as a function of logarithm of concentration for: ●, glycine; ○, Gly-Gly; △ , Gly-Gly-Gly. (*a*) Anodic end potential 0.5 V; (*b*) anodic end potential 1.1 V.



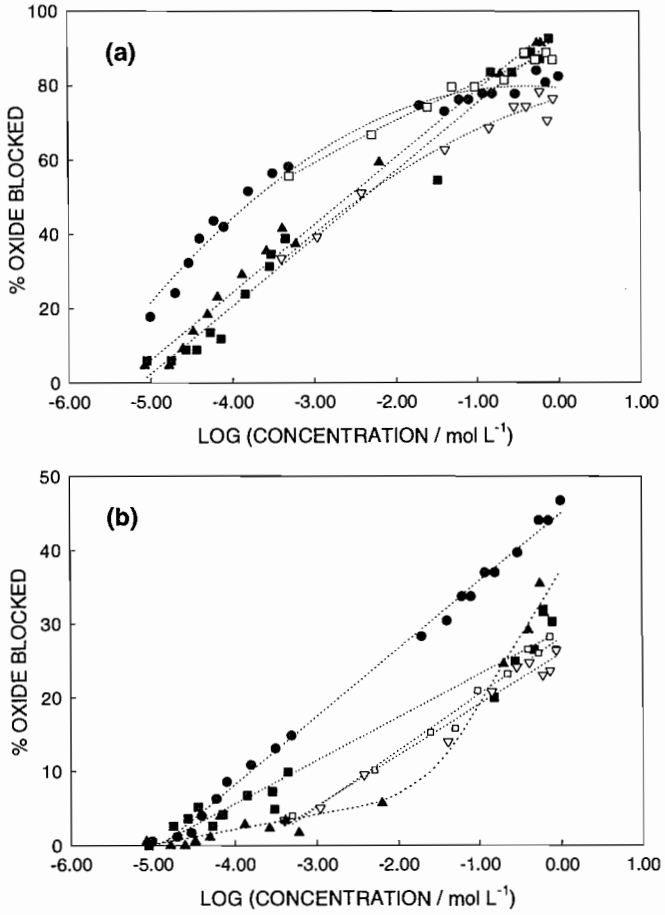


Fig. 5. The % oxide formation blocked by the amino acid at the Pt electrode as a function of logarithm of concentration for: ●, glycine; ■, α-alanine; □, β-alanine; ▲, α-aminobutyric acid; ▽, γ-aminobutyric acid. (*a*) Anodic end potential 0.5 V; (*b*) anodic end potential 1.1 V.

glycine and α- and β-alanine over the whole upd region (Fig. 5*b*) showed glycine to be significantly more efficient at blocking oxide deposition than α- and β-alanine at the higher concentrations, although the efficiency was similar at low concentrations for glycine and α-alanine.

A comparison of the three α-amino acids for monolayer surface coverage (Fig. 5*a*) displayed a long linear behaviour with almost identical slopes for α-alanine and α-aminobutyric acid, but with the larger α-aminobutyric acid having a slightly greater efficiency for blocking. Glycine was much more effective in the lower concentrations. When we consider the whole upd region to 1.1 V, the three α-amino acids at low concentrations showed a consistent increasing blocking efficiency trend with decreasing hydrocarbon chain length (Fig. 5*b*). However, at higher concentrations, the efficiency of α-aminobutyric acid increased significantly in a nonlinear manner to give values at the higher concentrations similar to that of α-alanine.

When the amino group is positioned on the terminal carbon, a curved effect can be seen with γ-aminobutyric acid that causes the blocking efficiency in the first stage of oxide formation to fall off at the higher concentrations in a manner similar to that observed for glycine but with less efficiency (Fig. 5*a*). However, at lower concentrations the blocking efficiency is very similar to that of α-aminobutyric acid. The behaviour of β-alanine is linear over the same concentration range as that of γ-aminobutyric acid. In contrast, the results for blocking efficiency over the whole upd region (Fig. 5*b*) show a linear behaviour with significantly less efficiency in blocking oxide deposition by β-alanine and γ-aminobutyric acid than glycine.

These results indicate that the most effective amino acids for blocking the initial stage of oxide deposition, particularly at low concentrations, were glycine and the peptides. Since Cl^- is also known to selectively block this initially deposited OH monolayer at Pt in 0.1 mol L^{-1} H_2SO_4 and 0.1 mol L^{-1} $HClO_4$ (62), it was of interest to examine the blocking efficiency of Cl^- in phosphate buffer in the presence of $H_2PO_4^-$ ions. The onset of blocking surface oxide by Cl^- occurred at a concentration of about 3×10^{-6} mol L^{-1} Cl^- in the presence of HSO_4^- or ClO_4^- (62). In contrast, as shown in Fig. 6, additions of Cl^- to concentrations as high as 3×10^{-2} mol L^{-1} Cl^- were required before the onset of oxide blocking occurred in the presence of $H_2PO_4^-$ ions. This was a factor of 10^4 increase in concentration required of Cl^- in the presence of $H_2PO_4^-$ ions compared with that required in the presence of HSO_4^- or ClO_4^-. As the concentration of Cl^- increased to 0.9 mol L^{-1}, the blocking efficiency abruptly increased to 92%. To

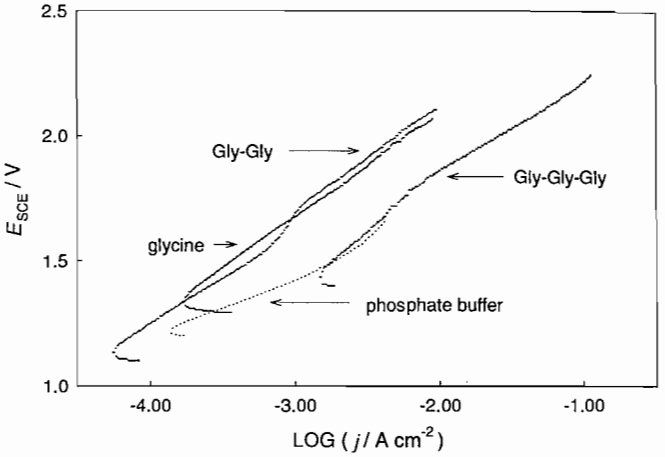

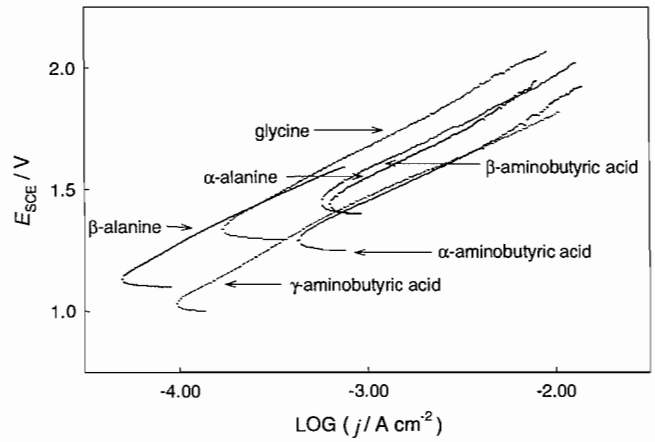

Fig. 9. Tafel behaviour of glycine, α- and β-alanine, and α-, β-, and γ-aminobutyric acid in phosphate buffer pH 7.0.

examine the competitive % oxide blocking behaviour between Cl^- and glycine, experiments were made in which Cl^- concentrations were incrementally increased in a solution containing 0.9 mol L^{-1} glycine in the phosphate buffer, which had already blocked 50% of the formation of oxide. Again, no change in the % oxide blocked was observed until a concentration of 3×10^{-2} mol L^{-1} Cl^- was attained in the bulk solution. At that point, an abrupt increase in the % oxide blocked was again observed and the oxide blocking continued to an efficiency of 85%, similar to that obtained in the absence of glycine. Fig. 7 shows the surface charge density for increments of glycine followed by the additions of Cl^-. Again no substantial change was observed in the surface charge density until the concentration of Cl^- reached 3×10^{-2} mol L^{-1} and at that point there was a steady decrease with increasing Cl^- that indicates that Cl^- was efficient in blocking glycine as well.

Comparisons of the trends in the ratio $Q_{O_o}{}^A/Q_{O_r}{}^A$ for the anodic oxidation region (Table 1) of these compounds with those previously studied can be used to examine the adsorption properties over a range of pH values. A higher value of the ratio corresponds to a greater adsorption by the organic compounds. The most distinct trend shows the decreasing ratio of $Q_{O_o}{}^A/Q_{O_r}{}^A$ for each amino acid with decreasing pH. This is consistent with the adsorption of the carboxylate anion being more strongly attracted to and adsorbed at the anodic electrode. There is also a decreasing trend in $Q_{O_o}{}^A/Q_{O_r}{}^A$ with increasing hydrocarbon chain length. In addition, as the amino group is positioned farther along the hydrocarbon chain from the carboxylate group, there is generally a decrease in $Q_{O_o}{}^A/Q_{O_r}{}^A$.

3.2 Steady-state polarization measurements

Tafel plots from the steady-state potential measurements in the faradaic region at potentials significantly more positive than those used in the cyclic voltammetric measurements are shown in Fig. 8 for solutions of glycine, Gly-Gly, and Gly-Gly-Gly, and in Fig. 9 for glycine, α- and β-alanine, and α-, β-, and γ-aminobutyric acid. Oxygen evolution from phosphate buffer pH 7.0 in the absence of amino acid is shown in Fig. 8. The experimentally obtained Tafel slopes at pH 7.0 for

the stirred solutions are presented in Table 2 along with those previously obtained at pH 1.0 and 13.0. The Tafel slopes for the amino acids and dipeptides at pH 7.0 ranged from 253 to 498 mV, considerably higher than the Tafel slope of 208 mV for oxygen evolution from a phosphate buffer solution. This Tafel slope for oxygen evolution is also significantly higher than the value of 120 mV normally observed in H_2SO_4 and NaOH solutions (63). This may result from strong adsorption by phosphate anions at these potentials that thereby inhibit the oxygen evolution reaction. In acidic conditions the slopes for the amino acids ranged from 223 to 250 mV, while in alkaline solutions above the inflection point the values ranged from 153 to 212 mV, with the exception of glycine, which gave a much higher slope of 363 mV. Thus the highest slopes in the presence of amino acids occurred at pH 7.0 in the phosphate buffer. The oxidation reactions of the amino acids may therefore also be inhibited by the adsorption of phosphate anions.

Quantitative product analysis from controlled electrolysis of glycine at 1.8 V and pH 13 has been reported previously (39). Based on the measured charge passed through the cell during the reaction, the yield of formaldehyde was 85–90% and the yield of ammonia was 83%, indicating that the oxygen evolution reaction was suppressed in the presence of the amino acid. If it is assumed that the amino acid oxidation reactions at pH 7.0, with similar concentrations of carboxylate anion, proceed in a similar manner with the suppression of the oxygen evolution reaction, and since previous results have suggested that the carboxylate group adsorbs at the anodic electrode surface (14, 39–41, 43–45, 64), a comparison may be made of the experimental Tafel slopes with theoretical values for the rate-determining step of the mechanism in a manner similar to that observed for the Kolbe reaction by the method described by Conway and Dzieciuch (64). Considering the mechanism as shown for the electrochemical oxidation of glycine, with the initial two steps similar to the Kolbe reaction (14)

Step I $^+H_3N\text{-}CH_2\text{–}COO^- \rightarrow {}^+H_3N\text{-}CH_2\text{–}COO(M) + e^-$

Step II $^+H_3N\text{-}CH_2\text{–}COO(M) \rightarrow {}^+H_3N\text{-}CH_2(M) + CO_2$

Step III $^+H_3N\text{-}CH_2(M) + H_2O \rightarrow NH_4^+ + CH_2O + H^+ + e^-$

and with Step I as rate determining, then

$$[4] \quad i_1 = zFk_1(1 - \theta_{G\cdot})C_{G^+}\exp -[(\Delta G_1^{\ddagger} - \beta VF + \beta r_1\theta)/RT]$$

where G· refers to the radical species on the electrode surface, G^+ refers to the free amino acid or dipeptide in the bulk solution, θ designates the fractional surface coverage, β is the symmetry factor (usually 0.5), and r corrects for variation of

the heat of adsorption with coverage. By differentiating the above equation, the Tafel slope is

$$[5] \quad dV/d \log i_1 = 2.3(2RT/F)$$

If the assumption is made that the rate-determining step is the decarboxylation of the adsorbed radical, then the electrochemical equation is:

$$[6] \quad i_2 = zFk_2 (1 - \theta_{G1.}) (\theta_{G.}) \times \exp -[(\Delta G_2^{\ddagger} - \beta r_1\theta + (1 - \beta)r_2\theta)/RT]$$

where G· refers to the adsorbed radical from Step I and G_1· refers to the adsorbed radical formed following decarboxylation. By making the further presumption that Step I is in quasi-equilibrium and that β = 0.5, then the above equation becomes:

$$[7] \quad i_2 = zFk_2 (1 - \theta_{G1.}) (\theta_{G.}) \times \exp -[(\Delta G_2^{\ddagger} + (VF/2r_1)(r_2 - r_1))/RT]$$

After simplifying and differentiating, the Tafel slope becomes:

$$[8] \quad dV/d \log i_2 = 2.3(2RT/F)(r_1/(r_1 - r_2))$$

If Step III, the formation of the next lower aldehyde in the homologous series accompanied by transfer of a second

electron, is postulated to be the rate-determining step in the mechanism, then the electrochemical equation is modified to:

[9] $$i_3 = zFk_3\,\theta_{G1}.\,\exp -[(\Delta G_3^{\ddagger} - \beta VF - \beta r_2\theta)/RT]$$

Subsequent rearrangement and differentiation shows the predicted Tafel slope to be

[10] $$dV/d\log i_3 = 2.3(2RT/F)(r_1/(r_1 + r_2))$$

By varying the numerical values of r_1 and r_2 for each of the equations, the predicted Tafel ranges may be calculated, and are shown in Table 3.

The range of values obtained experimentally (Table 2) compare favourably with those shown in Table 3 for Step II, the decarboxylation of the terminal carboxyl group, as the rate-determining step. This is consistent with results obtained previously with glycine (39), α- and β-alanine (40), and α-, β-, and γ-aminobutyric acid (41). Thus the Tafel slopes obtained in phosphate buffer may be attributed to a suppression of the oxygen evolution reaction by the kinetically favoured oxidation of the amino acid or peptide similar to that observed in the Kolbe mechanism (14).

3.3 Surface charge density calculations

By monitoring the surface charge density at an anodic end potential of 0.5 V, information can be obtained on the surface concentration of the adsorbed species in comparison with monolayer surface coverage of OH species, thereby gaining information about structural orientation of the organic molecules at the surface. A series of plots of surface charge density versus concentration for the same concentration ranges were made for each amino acid. Table 4 presents a summary of the surface charge density plateau values of these molecules for the 0.5 V anodic end potentials and the corresponding calculated surface concentrations (Γ_A) from eq. [2], which represent approximate maximum values for surface concentrations up to this anodic potential. This method was used as an approximation for surface concentrations because of the difficulty in determining the pzc (potential of zero charge) for the platinum electrode, and therefore the absolute charge density (65).

The thermodynamic analysis of the charge data is based on the electrocapillary equation:

[11] $$-d\gamma = Q dE + \Gamma_A d\mu_A$$

Table 4. Surface charge densities and surface concentrations for 0.5 V anodic end potentials.

Compound	Q_{ADS} (μC cm^{-2})	$\Gamma_A \times 10^{10}$ (mol cm^{-2})	Γ_A (molecules nm^{-2})
Glycine	60	3.1	1.9
Gly-Gly	128	6.7	4.0
Gly-Gly-Gly	88	4.5	2.7
α-Alanine	105	5.5	3.3
β-Alanine	105	5.5	3.3
α-Aminobutyric acid	189	9.8	6.0
γ-Aminobutyric acid	141	7.3	4.4

where γ is the interfacial tension, Q is the charge density, E is the electrode potential, Γ_A is the Gibbs excess of adsorbed amino acid (approximately equal to the surface concentration), and μ_A is the chemical potential of the amino acid. Since the interfacial tension is a function of the surface charge density, Gibbs excess, and chemical potential of all the species in solution, we will first review the method used in the integration of the cyclic voltammograms and subsequent calculations. Since $Q_T = f(\Gamma_{O_o}, \Gamma_P, \Gamma_A)$, the Gibbs excess may be described by Γ_{O_o} for adsorption of OH^-, Γ_P for adsorption of phosphate anions ($H_2PO_4^-$ + HPO_4^{2-} + PO_4^{3-}), and Γ_A for adsorption of amino acid anions + neutral species. The experiments were carried out at constant ionic strength and constant concentrations of all species in the bulk solution. Therefore if we consider only the contribution due to the surface charge density and recall eq. [1] used to evaluate the cyclic voltammograms,

$$Q_{ADS} = (Q_{O_o}{}^{A} - Q_{O_r}{}^{A}) - (Q_{O_o} - Q_{O_r})$$

then the contribution due to anodic charges may be described as follows:

[12] $$Q_T = Q_{O_o} + Q_A + Q_P$$

where Q_T represents the total charge resulting from the adsorption of oxide (Q_{O_o}), amino acid (Q_A), and phosphate anions (Q_P). Since the anodic oxide charge (Q_{O_o}) due to OH^- adsorption is equal to the oxide reduction charge (Q_{O_r}) in the absence of other adsorbing species, and if we represent the

For personal use only.

charge resulting from the electrolyte solution in the absence of amino acid (Q_E) as:

[13] $$Q_E = Q_{O_o} + Q_P$$

then:

[14] $$Q_{ADS} = Q_T - Q_E = Q_A$$

Differentiation of eq. [11] gives the charge number:

[15] $$\gamma' = \frac{1}{F}\left(\frac{\partial Q}{\partial \Gamma_A}\right)_E = \frac{1}{F}\left(\frac{\partial \mu_A}{\partial E}\right)_\Gamma$$

where γ' is the electrosorption valency or the number of electrons transferred to the interface per one adsorbed amino acid molecule. The integral of the voltammetric current is equal to :

[16] $$\Delta Q = \int i dt = \frac{1}{\nu}\int i dE = Q_{ADS}$$

Since $i = \nu C$ with ν being the sweep rate and C being the differential capacity, the charge may also be given as:

[17] $$\Delta Q = \int C dE$$

In the case of specific adsorption, the capacity C may be represented as a sum of two terms; the so-called infinite frequency capacity and a pseudocapacity. This can be derived in the following way. In the presence of specific adsorption, the charge Q is a function of two variables, the potential E and the amount of adsorbed amino acid Γ_A, i.e.; $Q = f(E, \Gamma_A)$. The total differential of charge is therefore given by:

[18] $$dQ = \left(\frac{\partial Q}{\partial E}\right)_\Gamma dE + \left(\frac{\partial Q}{\partial \Gamma_A}\right)_E d\Gamma_A$$

Differentiation of eq. [18] gives the desired expression for the differential capacity:

[19] $$C = \left(\frac{dQ}{dE}\right) = \left(\frac{\partial Q}{\partial E}\right)_\Gamma + \left(\frac{\partial Q}{\partial \Gamma_A}\right)_E \frac{d\Gamma_A}{dE}$$

where the term $(\partial Q/\partial E)_\Gamma = C_\Gamma$ is called the infinite frequency capacity (or the true capacity) and the second term on the right-hand side of eq. [19] is called the pseudocapacity. The term $(\partial Q/\partial \Gamma_A)_E = \gamma' F$ where γ' is the electrosorption valency. Substitution of C in eq. [17] by the right-hand side of eq. [19] gives the following expression for ΔQ:

[20] $$\Delta Q = \int C dE = \int \left(\frac{\partial Q}{\partial E}\right)_\Gamma dE + \int \left(\frac{\partial Q}{\partial \Gamma_A}\right)_E d\Gamma_A$$

If the integration starts at a potential at which $\Gamma = 0$, and if it is assumed that the electrosorption valency or charge number is independent of the electrode potential and coverage, then eq. [17] may be written as:

[21] $$\Delta Q = \int \left(\frac{\partial Q}{\partial E}\right)_\Gamma dE + \gamma' F \Gamma_A$$

Equation [21] shows that the charge measured by integration of the cyclic voltammogram is not equal to $\gamma' F \Gamma_A$, but also contains a term that is due to charging of the infinite frequency capacity. However, in the present studies, the integration was begun as the charge increased above that of the double-layer region for the anodic area and below the double layer for the oxide reduction area, and because these areas are subtracted, the term for charging the infinite frequency capacity is eliminated. Therefore rearranging eq. [21] for surface concentration gives:

[22] $$\Gamma_A = \Delta Q/\gamma' F = Q_{ADS}/nF$$

where n (or γ', the electrosorption valency of amino acid) was used as 2 in these calculations based on the results of quantitative coulometric product analysis (39). From the Tafel measurements, initial adsorption is assumed to be quasi-reversible (Step I) with decarboxylation (Step II) as the rate-determining step. In situ FTIR measurements of glycine have shown that adsorption occurs through the carboxylate groups at the Pt(111) surface (66). The production of CO_2 from the asymmetric stretching frequency at 2344 cm^{-1} coincided with the potential for maximum adsorption at this surface. Therefore the use of $n = 2$ as the charge number appears to be appropriate, particularly for a comparative study of the adsorption behaviour of a series of amino acids.

It is interesting to compare the calculated approximate maximum values for surface concentrations (Table 4) with those estimated from molecular dimensions. The area of a glycine molecule lying on its side may be estimated as an upper limit from the sum of the bond lengths (67) N—H (0.1001 nm), C—N (0.1467 nm), C—C (0.1526 nm), C—O (0.1355 nm), and O—H (0.0966 nm), which gives 0.6324 nm. If half this value is taken as the radius of a circle occupied by the molecule, then the calculated area is 0.31 nm^2 $molecule^{-1}$ or 3.2 molecules nm^{-2}. Therefore it appears that glycine is likely in a horizontal position at these small anodic potentials with both the ammonium ion and carboxylate group positioned on the electrode surface. It is interesting to compare the similarity of the surface concentration for glycine with that for the calculated value of 2.9 molecules nm^{-2} taken from the experimental results reported for the surface concentration for acetic acid adsorption at the Pt electrode from a solution of 10^{-3} mol L^{-1} acetic acid in 0.1 mol L^{-1} $HClO_4$ (44). When the area is calculated for Gly-Gly in a similar manner, only 0.8 molecules nm^{-2} would be allowed for the dipeptide to be oriented on its side. Since a much higher surface concentration is observed, this suggests that a more vertical arrangement occurs with adsorption through the carboxylate group. An estimate of the area of a circle described by the rotation of this functional group using geometrical calculations from C═O (0.1205 nm), C—O (0.1355 nm), O—H (0.966 nm), and an O═C—O angle of 123° (67) gave approximately 13 molecules nm^{-2}. Thus, the remaining molecules appear to be in a tilted position, rather than in a horizontal position on the surface.

4. Summary

Electrochemical oxidation of the amino acids and peptides at a platinum electrode has shown that there is strong adsorption of all species at anodic potentials in neutral solution, accompanied by an efficient ability to block both the initial stages of OH monolayer deposition as well as the second stage involving an irreversible process of continued deposition of OH or O species associated with the initial stages of a place inversion of Pt and O in the oxide film. Glycine and the peptides, however, blocked the initially and more reversibly deposited OH species in preference to those formed at higher potentials. The surface charge densities of the amino acids and peptides were measured at the anodic end potential of 0.50 V, which corresponds to the first stage resulting in monolayer OH coverage. This was the same potential at which maximum adsorption of acetic acid at a platinum electrode was observed in infrared and radiotracer studies (44) and where maximum adsorption of amino acids occurred in Horanyi's radiotracer studies (45). The present results at pH 7.0 indicate that adsorption occurred through the negatively charged carboxylate groups, similar to results observed previously (39–41). The infrared experiments of Krauskopf and Wieckowski (43) with acetic acid at a platinum electrode support these results, as they determined that both carboxylate oxygens were oriented toward the metal surface. Results of the present study also indicated that, at the lower anodic end potentials (0.50 V), the glycine may be arranged predominately in a horizontal position on the electrode surface, but the larger amino acids and peptides appear to be in a modified vertical configuration with adsorption through the carboxylate groups.

Steady-state polarization measurements gave Tafel slopes in the range of 253–498 mV, considerably higher than that normally seen for oxygen evolution from a phosphate buffer solution. These results suggest that, in the pH 7.0 buffer, the negatively charged carboxylate group preferentially adsorbs under these anodic potentials in a mechanism similar to the Kolbe reaction, with the decarboxylation step being rate determining. Previous results have shown that at potentials greater than 1.8 V, less than 10% of the yield of oxidation products from the dipeptides Tyr-Gly and Trp-Gly could be attributed to the cleavage of the peptide bond (42). Therefore, this type of reaction was not expected to contribute to any extent to the oxidation mechanisms at the lower potentials used in the present study.

Acknowledgments

Grateful acknowledgment is made to the Natural Sciences and Engineering Research Council of Canada for support of this research. The authors would like to thank Professor Jacek Lipkowski for helpful discussions on the thermodynamics in this manuscript.

Abstract: Copper-cobalt oxide, prepared by thermal decomposition of nitrate precursors on a highly porous lanthanum phosphate-bonded nickel support, was investigated as an anode material for alkaline water electrolysis. Physicochemical characterization shows that this nonstoichiometric oxide possesses a spinel structure ($Cu_{0.9}Co_{2.1}O_4$) and that it is also highly porous. FTIR spectroscopy indicates that the oxide is not decomposed in 5 M KOH at room temperature. The highest electrocatalytic activity for the oxygen evolution reaction is obtained when the electrode is prepared at 300°C from a solution containing 0.5 M $Cu(NO_3)_2{\cdot}2.5H_2O$ and 1.0 M $Co(NO_3)_2{\cdot}6H_2O$, with a catalyst loading of 52 mg cm^{-2}. The activity is reduced when an excess of either Co or Cu is present in the spinel oxide film beyond the stoichiometric ratio of the precursors, probably due to some phase change. Cyclic voltammetry indicates that a quasi-reversible Co^{IV}/Co^{III} surface redox transition occurs prior to the onset of oxygen evolution; this process is diffusion controlled at low OH^- concentration and at high scan rate when $[OH^-] \geq 1$ M. In the negative potential domain, a Cu^{II}/Cu^{I} surface redox transition is observed.

Key words: copper-cobalt oxide, oxygen evolution, highly porous electrode, cyclic voltammetry.

Résumé : L'oxyde de cuivre et de cobalt, préparé par décomposition thermique des nitrates précurseurs sur un substrat très poreux constitué de nickel finement divisé lié par un polymère de phosphate de lanthane, a été étudié comme matériau d'anode pour le procédé d'électrolyse de l'eau en milieu alcalin. Les analyses physico-chimiques montrent que cet oxyde non stoéchiométrique possède une structure spinelle ($Cu_{0.9}Co_{2.1}O_4$) et qu'il est également très poreux. La spectroscopie infrarouge indique que l'oxyde n'est pas décomposé lorsqu'il est immergé dans une solution de KOH 5 M à la température ambiante. L'activité électrocatalytique pour le dégagement de l'oxygène est la plus élevée lorsque l'électrode est préparée à 300°C à partir d'une solution contenant du $Cu(NO_3)_2{\cdot}2{,}5H_2O$ 0,5 M et du $Co(NO_3)_2{\cdot}6H_2O$ 1,0 M, à un recouvrement d'oxyde de 52 mg cm^{-2}. L'activité est diminuée lorsqu'un excès de cobalt ou de cuivre est présent dans le film d'oxyde au-delà du rapport stoéchiométrique des nitrates précurseurs, probablement en raison d'un changement de phase partiel. Les études de voltammétrie cyclique indiquent qu'une transition rédox de surface Co^{IV}/Co^{III} quasi-réversible se produit avant le dégagement de l'oxygène; ce processus est contrôlé par la diffusion des ions OH^- à faible concentration et à concentration plus élevée ($[OH^-] \geq 1$ M) lorsque la vitesse du balayage de potentiel est grande. Dans le domaine des potentiels négatifs, une transition rédox de surface Cu^{II}/Cu^{I} est observée.

Mots clés : oxyde de cuivre et de cobalt, dégagement de l'oxygène, électrode très poreuse, voltammétrie cyclique.

Introduction

The oxygen evolution reaction (OER) is highly irreversible with a significant activation overpotential in aqueous solution. Selection of an electrode material is based on several parameters, including excellent electrocatalytic properties, high active surface area as for heterogeneous catalysts, long-term chemical, electrochemical, and mechanical stabilities, and low cost. Cobaltite spinel oxides (MCo_2O_4 with M = Co, Ni, Mn, Cu) have shown interesting electrocatalytic activities for the OER in alkaline solutions (1–6); among these materials, $NiCo_2O_4$ and Co_3O_4 were the most studied. Different preparation techniques have been used such as thermal decomposition (2, 4), sol–gel synthesis (7), cryochemical synthesis (6), and coprecipitation (5); sometimes an effect of the nature of the substrate (Pt, Ni, Ti) was noticed (2, 3).

Recently, we reported that the nonstoichiometric oxide $Cu_xCo_{3-x}O_4$, prepared by thermal decomposition of nitrate precursors on a sandblasted nickel support, shows fairly low overvoltages for the OER in 1 M KOH at 25°C (280 mV at 10 mA cm^{-2} and 320 mV at 100 mA cm^{-2}) (2). Based on the same

electrochemically active surface area, the $Cu_xCo_{3-x}O_4$/Ni electrode demonstrated a better activity than the most active perovskite, $LaNiO_3$, and a much greater activity than Co_3O_4 and $NiCo_2O_4$ (8). Lee et al. (9) investigated the effect of intercalation of Cu^{2+} and Zn^{2+} on the electrochemical properties of Co_3O_4; the intercalation, respectively, enhances (Cu^{2+}) and depresses (Zn^{2+}) the electrocatalytic activity of the cobaltite spinel oxide for the OER. It has been demonstrated that $Cu_xCo_{3-x}O_4$ is a *p*-type semiconductor with a metallized surface in the potential region of oxygen evolution (10). Its resistivity (0.047 Ω cm) is situated between the values reported for $NiCo_2O_4$ and Co_3O_4, prepared by the same method.

Electrochemical studies suggested that the experimentally observed currents are strongly correlated to the roughness factor of the oxide film (2). Recent works by Dumont et al. (11) into developing new anode and cathode materials for water electrolysis have been directed toward the use of a new process of cementation of metallic nickel powder to produce highly porous electrodes; the nickel particles were bonded by $LaPO_4$, leading to three-dimensional electrodes. The present work deals with the use of lanthanum phosphate-bonded nickel (LPBN) as support for $Cu_xCo_{3-x}O_4$; we recall that our previous papers were related to the use of a much smoother Ni substrate (2, 10). The new optimum conditions (concentration of the nitrate precursors, Cu:Co atomic ratio, decomposition temperature, and catalyst loading) for thermal decomposition of the nitrate precursors on this highly porous support were established, based on the electrode activity for the OER in 1 M KOH at 25°C. Furthermore, the electrochemical behavior of the oxide deposited on a Pt wire was studied in detail in order to understand the nature, reversibility, and mechanism of the surface redox transition occurring prior to the onset of oxygen evolution. Also, the redox transition observed in the negative potential region was investigated.

Experimental

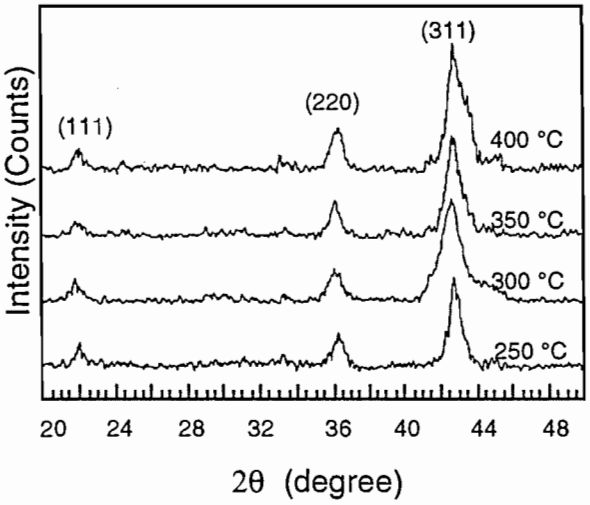
Preparation of copper-cobalt oxide electrodes

$Cu_xCo_{3-x}O_4$ electrodes were prepared by thermal decomposition of nitrate precursors (2, 4, 12) deposited on a highly porous substrate consisting of lanthanum phosphate ($LaPO_4$ 10% w/w)-bonded spiky filamentary particles of nickel (LPBN) (11), supplied by the Université de Sherbrooke. In this procedure, $Co(NO_3)_2{\cdot}6H_2O$ and $Cu(NO_3)_2{\cdot}2.5H_2O$ (Fisher Scientific, ACS) were dissolved in the solvent mixture isopropanol:nanopure water (4:1), with the appropriate atomic ratio (Cu:Co) and concentration. The solution was deposited uniformly with a micropipet onto a 1 cm^2 LPBN pellet, which had been previously degreased in dichloromethane (Anachemia, ACS) and thoroughly washed with nanopure water. The solvent was then evaporated at 110°C, and the nitrate coating was heated for 15 min in a triple-zone quartz furnace (Lindberg 59744) under air atmosphere at an appropriate temperature. The procedure was repeated several times until the desired catalyst loading was achieved, and the electrodes were thereafter annealed over 1 h under the same conditions. To reach the highest electrocatalytic activity for the OER, the following preparation variables were optimized. Concentration of the nitrate precursors, with a constant atomic ratio Cu:Co = 1:2, was varied from 0.2 M to 1.4 M $Co(NO_3)_2{\cdot}6H_2O$. The Cu:Co atomic ratio was changed (1:5, 1:2, and 1:1) using the optimized total nitrate concentration. The electrodes were heated at temperatures ranging from 250 to 400°C and the catalyst loading was varied from 0 to 83 mg cm^{-2}.

Bulk and surface characterization of the oxide

X-ray diffraction patterns of the oxide electrodes were obtained using a Siemens model D5000 instrument with Co-K_α radiation (λ = 1.789 Å); the scan rate was 1° min^{-1}. Oxide powder was analyzed by FTIR spectroscopy (Perkin–Elmer, model 1600) to evaluate its chemical stability in alkaline medium. FTIR spectra were obtained between 800 and 400 cm^{-1} using KBr pellets (Aldrich, 99+%) containing the oxide (1% w/w). The powder was prepared as follows. An aqueous solution of copper and cobalt nitrates (Cu:Co = 1:2) was evaporated to dryness and the residue was dried (110°C), ground, and annealed in air for 1 h at 300°C. The oxide was then finely ground and annealed for an extra 5 h. Analysis was made on fresh oxide and on oxide that had been dipped for 7 days in aqueous 5 M KOH (A&C, Baker analyzed) solution without stirring. Surface morphology of the electrodes was examined with a scanning electron microscope (Hitachi, model S-2300) and the surface composition was assessed through semiquantitative EDAX analysis.

Electrochemical studies



Electrochemical behavior of $Cu_xCo_{3-x}O_4$ electrodes was studied using cyclic voltammetry; a potentiostat (Pine Instruments AFRDE4) coupled with an X-Y recorder (Kipp & Zonen BD 90) was used. For this experiment, $Cu_xCo_{3-x}O_4$ was prepared (optimum deposition conditions) on a Pt (Johnson Matthey, 99.9%) wire substrate (0.14 cm^2) sealed in a glass tube, instead of LPBN. This is because the highly porous surface of $Cu_xCo_{3-x}O_4$/LPBN masks the real electrochemical behavior of the oxide film. Cyclic voltammetry measurements were carried out at room temperature in a cylindrical Pyrex glass cell. Potentials of the working electrode are measured against a Ag/AgCl reference electrode (0.21 V vs. NHE) and reported with respect to a Hg/HgO/1 M KOH electrode (0.110 V vs. NHE at 25°C); the auxiliary electrode consisted of a Pt foil (Alfa, 99.9%) (11 cm^2). The electrolyte was prepared from KOH (Mallinckrodt, ACS) and nanopure water. To study the influence of pH on the mean peak potential of the redox transition, the ionic strength of the electrolyte was corrected using KNO_3 (Mallinckrodt, A.R.). Cyclic voltammetry was also used to determine the electrochemical surface area of the LPBN substrate through double-layer charging curves in deaerated 1 M KOH solution at 25°C (2). The potential was scanned (20–100 mV s^{-1}) between −0.20 and −0.05 V vs. Hg/HgO.

To determine the electrocatalytic activity of the $Cu_xCo_{3-x}O_4$/LPBN electrodes for the OER, steady-state galvanostatic measurements were carried out at 25°C using a three-compartment Teflon cell, which has been described previously (10). In this case, ohmic drops were minimized by using a Luggin capillary approaching the front of the electrode; IR-corrected potentials are reported against a Hg/HgO/1 M KOH reference electrode. A 7 cm^2 Pt disc (Alfa, 99.9%), 3 cm away from the anode, was used as the auxiliary electrode. A potentiostat (PAR, model 273) controlled by a microcomputer (Packard Bell, Pack-Mate III) working with software developed at the Université de Sherbrooke was used. The polarization time varied with the current (e.g., 600 s at 2 μA and 60 s at 700 mA).

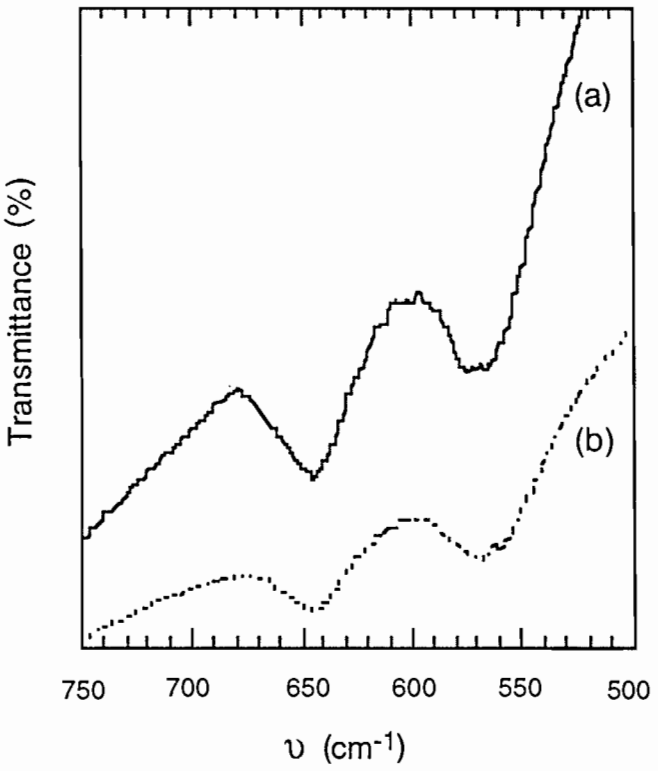
Fig. 1. X-ray diffractograms of $Cu_xCo_{3-x}O_4$ prepared at various temperatures as a thin film on a LPBN support. $Cu(NO_3)_2 \cdot 2.5H_2O$ = 0.5 M; $Co(NO_3)_2 \cdot 6H_2O$ = 1.0 M; catalyst loading: 52 mg cm^{-2}.



Results and discussion

Physicochemical characterization of the oxide phase

Figure 1 shows X-ray diffraction patterns of $Cu_xCo_{3-x}O_4$/LPBN electrodes prepared under the optimum conditions (see below) at temperatures ranging from 250 to 400°C. Diffractograms are limited to Bragg angles lying between $2\theta = 20°$ and 50° because of the high intensity of the diffraction lines of the nickel substrate in comparison to those of the oxide phase in the region 50°–90°. Relative intensities of the diffraction lines of the spinel (face-centered cubic structure) oxide are in good agreement with ASTM data for $CuCo_2O_4$ (13). We observe that the intensity of the peaks increases when the temperature of nitrate decomposition is raised; this indicates a better crystallization of the oxide film at high temperature. The lattice parameter a_0 was estimated at each temperature from the *d*-spacings of the planes (311) and (220), in a similar way to that used in a previous work (2). The values show a discontinuous variation from 8.13 to 8.10 Å with increasing temperature. These values are higher than the one calculated from the *d*-spacings given in the ASTM table for the same planes of $CuCo_2O_4$: 8.06 Å (13). Petrov et al. (14) obtained almost the same values of a_0, up to 8.13 Å, for copper-cobalt oxide prepared by thermal decomposition. Since diffraction lines of $CuCo_2O_4$ and Co_3O_4 are very close, it is difficult to exclude the possibility of the presence of a Co_3O_4 phase. However, there are no diffraction lines characteristic of monoclinic copper oxide (CuO), so we can conclude that the diffractograms almost correspond to the spinel $CuCo_2O_4$ at each temperature. According to EDAX analysis, copper-cobalt oxide presents a nonstoichiometric phase ($Cu_{0.9}Co_{2.1}O_4$), which is in agreement with the oxide formed on a smooth nickel substrate (2). However, we have to consider that backscattered electrons influence EDAX measurements in the case of a porous electrode.

Figure 2(*a*) shows the FTIR spectrum of as-prepared oxide powder. We observe two broad bands around 570 and 645 cm^{-1}, which may be assigned, respectively, to the octahedrically and tetrahedrically coordinated cations in the spinel crystal lattice (15). Figure 2(*b*) shows the FTIR spectrum of the oxide powder, which had been dipped for 7 days in 5 M KOH solution at room temperature. We can see the same absorption bands with a decrease of their intensities. We observe that the weight of the oxide has been weakly reduced after its contact with the solution; this may be due to a partial dissolution of the oxide in highly concentrated KOH solutions. However, it seems that there is no decomposition of the mixed oxide $Cu_xCo_{3-x}O_4$ to simple oxides, as reported by Cherkashin et al. (16) for Co_3O_4. These authors noticed the appearance of a new absorption band at 450 cm^{-1}, attributed to the partial decomposition of Co_3O_4 to CoO and Co_2O_3, after contact with a 12 M KOH solution.

Fig. 2. FTIR spectra of the $Cu_xCo_{3-x}O_4$ powder prepared at 300°C: (*a*) as prepared oxide powder; (*b*) oxide powder dipped for 7 days in 5 M KOH solution at 25°C.

Characterization of the highly porous LPBN substrate

The highly porous LPBN substrate has been mainly studied as a cathode and anode material for alkaline water electrolysis (11). SEM micrograph (Fig. 3) reveals the Ni particles that ensure the highly porous surface of the substrate. The electrochemical surface area of this support was determined from double-layer charging curves using cyclic voltammetry. Figure 4 depicts the cyclic voltammograms recorded in deaerated 1 M KOH solution (25°C), at various scan rates ($\partial E/\partial t$), in the small capacitive region (−0.20 to −0.05 V vs. Hg/HgO). When there is no adsorption pseudo-capacitance, the double-layer capacitance (C_{dl}) is calculated from the slope of the linear curve i_{cap} vs. ($\partial E/\partial t$) (2):

$$[1] \quad C_{dl} = \frac{d_{icap}}{d(\partial E/\partial t)}$$

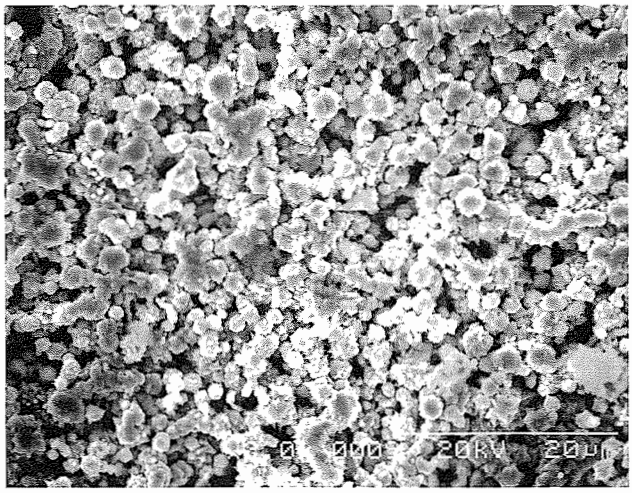
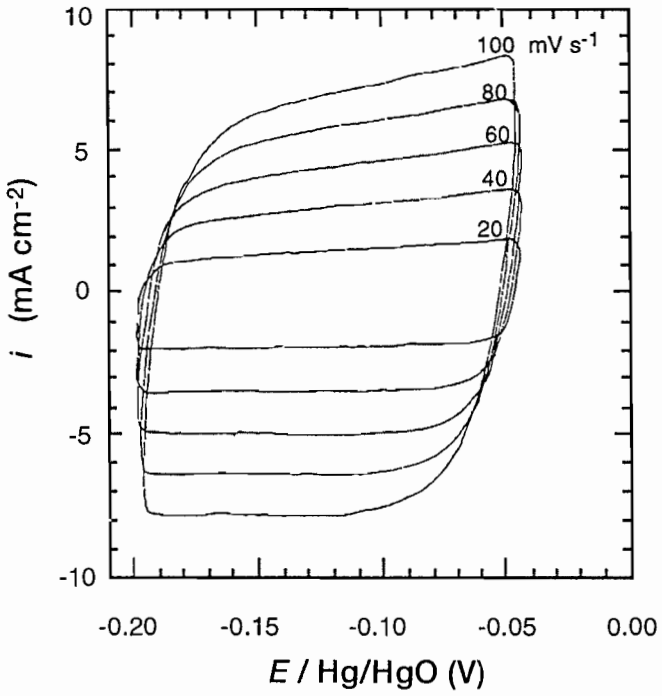
Fig. 3. SEM micrograph of the LPBN support.





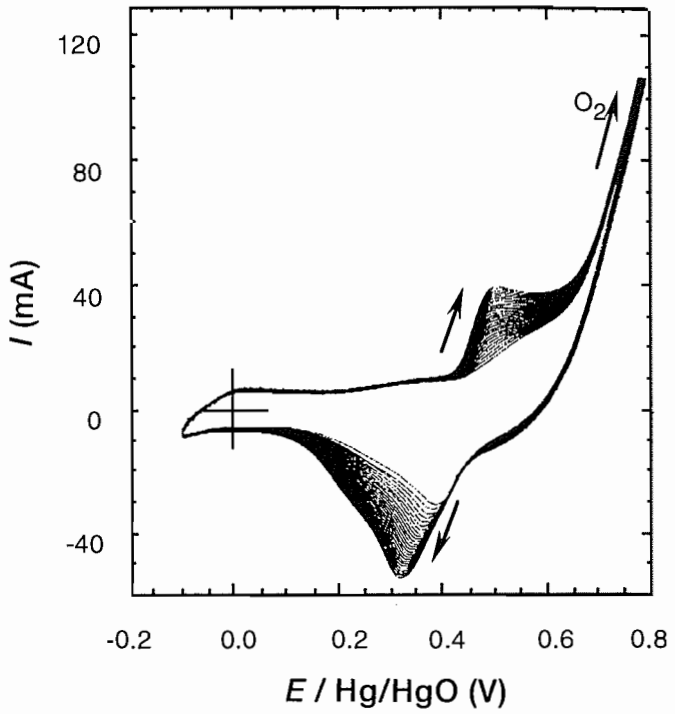


Fig. 4. Cyclic voltammograms of the LPBN support recorded at various scan rates in the capacitive region. Electrolyte: deaerated 1 M KOH solution at 25°C.

where i_{cap} is the capacitive current density measured at −0.125 V vs. Hg/HgO. The high roughness factor (4050), determined by assuming a double-layer capacitance of 20 μF cm^{-2} for a smooth metallic surface (17), indicates that the LPBN substrate is highly porous.

Figure 5 shows the voltammetric curve (several cycles) recorded in 1 M KOH solution (25°C) between −0.10 and 0.80 V vs. Hg/HgO, i.e., between a potential near the open-circuit potential and a potential in the oxygen evolution region. There is a single anodic peak and the corresponding cathodic peak. This voltammetric curve shows the characteristic behavior of a Ni electrode; the peaks are associated with the $NiOOH/Ni(OH)_2$ redox couple:

Fig. 5. Cyclic voltammograms of the LPBN support in 1 M KOH (25°C) at 20 mV s^{-1}.

[2] $Ni(OH)_2 + OH^- \rightleftharpoons Ni(OOH) + H_2O + e^-$

Electrocatalytic activities for the OER

Influence of the nitrate concentrations

Concentration of the nitrate precursors in the solvent mixture has a direct effect on $Cu_xCo_{3-x}O_4$/LPBN electrocatalytic activity for the OER. Figure 6 shows SEM micrographs (after anodic polarization, the SEM being out of order before) of electrodes prepared at 300°C from different concentrations of copper and cobalt nitrates, with constant metal atomic ratio (Cu:Co = 1:2) and oxide loading (~41 mg cm^{-2}). We observe that the electrode is more porous when the copper nitrate concentration is 0.5 M (Fig. 6(*c*)). Table 1 gives the electrode potential values at a current density of 250 mA cm^{-2} (geometric surface area), as determined from steady-state galvanostatic polarization measurements. As expected, the lower potential was obtained for the more porous electrode. It is interesting to note that we reported an optimum copper nitrate concentration of 0.3 M when the spinel oxide is formed on a smooth titanium substrate (2).

The morphology of copper-cobalt oxide films is mainly determined by the volume of gases (NO_2, O_2) that evolve during decomposition of the nitrate precursors. At low concentration, the number of coating layers is increased in order to obtain the same catalyst loading. This leads to the formation of smoother oxide films (Fig. 6(*a*)). When concentration of the precursors is increased above the optimum value, a compact film with large cracks and a poor mechanical stability is obtained (Fig. 6(*d*)).

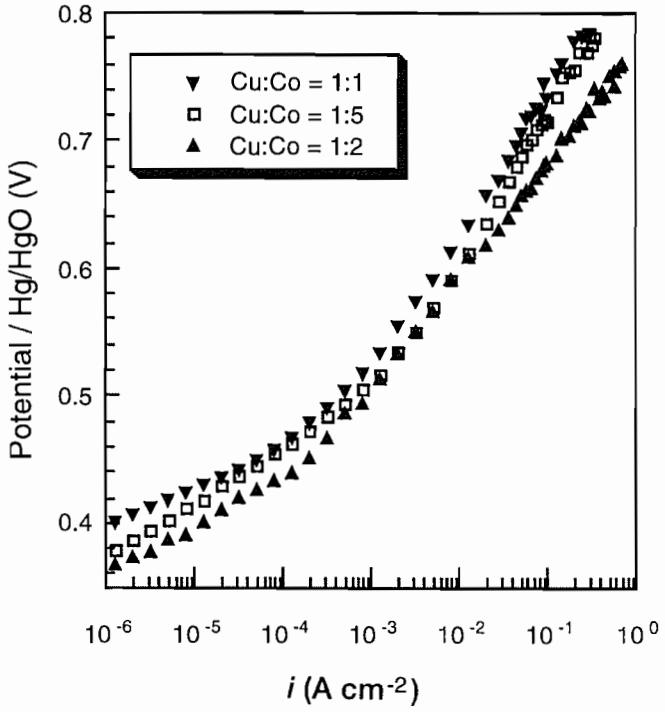
[a]Geometric surface area.



Influence of the Cu:Co atomic ratio

$Cu_xCo_{3-x}O_4$/LPBN electrodes were prepared with the following Cu:Co atomic ratios: 1:5, 1:2, and 1:1. Total concentration of the nitrates was kept at 1.5 M, and the electrodes were prepared at 300°C with a catalyst loading of 50 mg cm^{-2}. Figure 7 shows IR-corrected galvanostatic polarization curves obtained in 1 M KOH solution at 25°C: two Tafel regions are observed. Table 2 gives Tafel slopes (*b*) and exchange current densities (i_0) for the different electrodes at low and high overpotentials. At low overpotential, the Tafel slope is nearly constant (~40 mV dec^{-1}) whereas the exchange current density is lower for the electrode with the highest copper content: i_0[1:2] > i_0[1:5] >> i_0[1:1]. At high overpotential, the electrode prepared from a stoichiometric Cu:Co nitrate ratio (1:2) shows the lowest Tafel slope (~90 mV dec^{-1} instead of ~110 mV dec^{-1}), which gives rise to a better electrocatalytic activity for the OER. Therefore, the activity is reduced when an excess of either Co or Cu is present in the oxide film beyond the stoichiometric ratio of the precursors. This can be explained by the fact that some phase change might occur in these particular cases. Indeed, an excess of cobalt may favor the formation of the spinel Co_3O_4, which is less active than $CuCo_2O_4$; on the other hand, an excess of copper may lead to the formation of a highly resistive monoclinic CuO phase. Similar results were reported for $Ni_xCo_{3-x}O_4$ by Jasem and Tseung (18), and Gennero De Chialvo and Chialvo (15), which indicate higher activity for $NiCo_2O_4$.

Fig. 7. IR-corrected galvanostatic polarization curves obtained at $Cu_xCo_{3-x}O_4$/LPBN electrodes prepared at 300°C (50 mg cm^{-2}) from various Cu:Co precursors ratios. Electrolyte: 1 M KOH solution (25°C).

Influence of the decomposition temperature

On a smooth Ni substrate, temperature of nitrate decomposition affects the crystalline properties and surface morphology of the oxide coating (8); these parameters have an effect on the electrode activity for the OER. $Cu_xCo_{3-x}O_4$/LPBN electrodes were prepared between 250 and 400°C. This interval was chosen considering the stability of the spinel phase between 300 and 400°C, and also the specific surface area of the substrate, which decreases above 400°C by reduction of the fractal character of the nickel particles (11). Figure 8 illustrates SEM micrographs of electrodes prepared at 300, 350, and 400°C from solutions containing the optimum concentration of the nitrate precursors; the catalyst loading is 52 mg cm^{-2}. Electrodes prepared at 300 and 350°C present a highly porous surface, similar to the surface of the LPBN substrate (Fig. 3). At 400°C (Fig. 8(*c*)), the surface is less porous due to the packing of the oxide particles. These results are in good agreement with those obtained by other authors for $NiCo_2O_4$ (5) and Co_3O_4 (19), and by us for $Cu_xCo_{3-x}O_4$ (2), prepared at high temperature on a smooth metallic support.

Figure 9 shows the variation of the electrode potential, in 1 M KOH solution at 25°C, with the decomposition temperature at three anodic current densities. The thermal treatment seems to have little effect on the electrode activity in the temperature range studied, except at low current density where the overpotential is higher for the electrodes prepared at 350 and 400°C. If the activity for the OER is strongly dependent upon the $Cu_xCo_{3-x}O_4$/LPBN electrochemical surface area, we must conclude that this area is mainly controlled by the morphology of the highly porous substrate.

Table 2. Comparison of the kinetic parameters for the OER on $Cu_xCo_{3-x}O_4$/LPBN, for various atomic ratios in 1M KOH (25°C); [Cu] + [Co] = 1.5 M. Electrodes prepared at 300°C with a catalyst loading of 50 mg cm^{-2}.

	Tafel slope, b (mV dec^{-1})		Exchange current density, $i_0{}^a$ (A cm^{-2})	
Cu:Co	Low η^b	High η	Low η	High η
1:5	43	112	2.0×10^{-8}	1.9×10^{-5}
1:2	40	88	3.3×10^{-8}	4.7×10^{-6}
1:1	36	109	3.2×10^{-9}	1.9×10^{-5}

[a]Geometric surface area.
[b]Overpotential.

Influence of the catalyst loading

The variation in electrode activity for the OER with the catalyst loading can give an answer to the degree of covering of the oxide layer. Figure 10 shows that the lowest overpotential is observed at several current densities when the oxide loading is 52 mg cm^{-2}. The significant decrease in overpotential with increasing catalyst loading until 52 mg cm^{-2} indicates an enhancement of the electrocatalytic activity by adding more layers of $Cu_xCo_{3-x}O_4$. At this value the substrate is likely completely covered and the roughness of the electrode is still controlled by the morphology of the substrate. Above 52 mg cm^{-2}, the overpotential is increased, taking into account the semiconducting nature of $Cu_xCo_{3-x}O_4$, which raises the ohmic drop inside the spinel oxide.

Electrochemical behavior prior to oxygen evolution

Figure 11 displays typical voltammograms recorded in deaerated 1 M KOH solution (25°C) at a $Cu_xCo_{3-x}O_4$/Pt electrode prepared under the optimum conditions; however, the oxide loading was much lower than 52 mg cm^{-2} and corresponded to a single dipping of the Pt wire in the nitrate solution. The curve obtained between 0.10 and 0.65 V vs. Hg/HgO exhibits a single anodic peak A_1 at 0.55 V, prior to the onset of oxygen evolution, and a corresponding cathodic peak C_1 at 0.54 V. The voltammograms were almost the same regardless of the variation in the catalyst loading that possibly occurred during preparation of the electrodes. To establish the relationship between the oxidation and reduction peaks, the positive potential limit was varied (Fig. 11, broken curves). It can be seen that C_1 appears only once A_1 is obtained; furthermore, the cathodic peak current increases slightly when the potential limit becomes more positive; thus C_1 is associated with A_1. For comparison, voltammograms recorded at the bare Pt wire, at the same scan rate (20 mV s^{-1}), show currents higher than 0.1 mA when the electrode potential is more positive than 0.85 V.

A number of spinel oxides have shown similar electrochemical behavior, sometimes at different potentials. Table 3 summarizes the values of the mean peak potential ($E_p = [E_{pa} + E_{pc}]/2$) or the anodic peak potential (E_{pa}) for some of the most studied systems; in each case, the proposed redox transition reaction is also given. The peaks A_1 and C_1 obtained in this work are most likely associated to the CoO_2/CoOOH redox couple formed at the surface of $Cu_xCo_{3-x}O_4$ prior to the OER:

[e]Equilibrium reaction involving hydrated species and copper oxyhydroxide that may include Cu^{II} and Cu^{III} species.

[3] $CoOOH + OH^- \rightleftharpoons CoO_2 + H_2O + e^-$

This is in agreement with our work presenting the electrochemical behavior of thin colloidal films of $Co(OH)_2$ and $Cu(OH)_2$ deposited on Pt wires (10). According to Pourbaix diagram (23), reaction [3] should occur at 0.54 V vs. Hg/HgO at pH = 14, which is very close to E_{pa} found in this work. Pourbaix diagram also shows that the reaction

[4] $Co_2O_3 + 2OH^- \rightleftharpoons 2CoO_2 + H_2O + 2e^-$

is thermodynamically possible in the same potential range: reactions [3] and [4] involve the same redox species Co^{III} and Co^{IV}. Hamdani et al. (21) have concluded that a CoOOH layer is spontaneously produced when Co_3O_4 is in contact with an alkaline electrolyte. This indicates that reaction [3] is the most probable. However, it should be noted that the assignment of redox peaks is speculative and that other measurements should be performed to verify their validity.

Tarasevich et al. (24) have assigned the peak A_1 to the electrochemical adsorption of OH^- ions at the surface of a Co_3O_4 film according to

[5] $2OH^- \rightleftharpoons H_2O_2^- + e^-$

Their suggestion came after observing a shift of 140 mV pH^{-1} of the anodic peak potential. Therefore, the influence of pH on the electrochemical behavior of $Cu_xCo_{3-x}O_4$/Pt has been studied by varying the KOH concentration from 0.5 to 2.0 M. For each concentration, the scan rate ranged from 20 to 700 mV s^{-1}. Figure 12 presents stabilized voltammograms recorded in 2 M KOH, between 20 and 200 mV s^{-1}. It can be seen that E_{pa} and E_{pc} move only slightly, respectively, to more positive and negative values with increasing the scan rate. This indicates that the Co^{IV}/Co^{III} transition is quasi-reversible. The dependence of pH on the mean peak potential is displayed in Fig. 13 at several scan rates; $\partial E_p/\partial pH$ is 60 mV pH^{-1} and this value does not change with the scan rate. These results confirm that reaction [5] does not take place on $Cu_xCo_{3-x}O_4$.

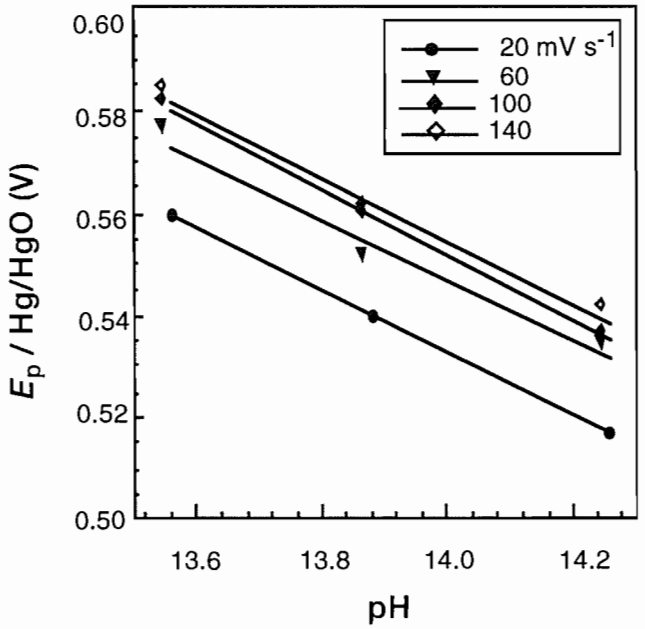
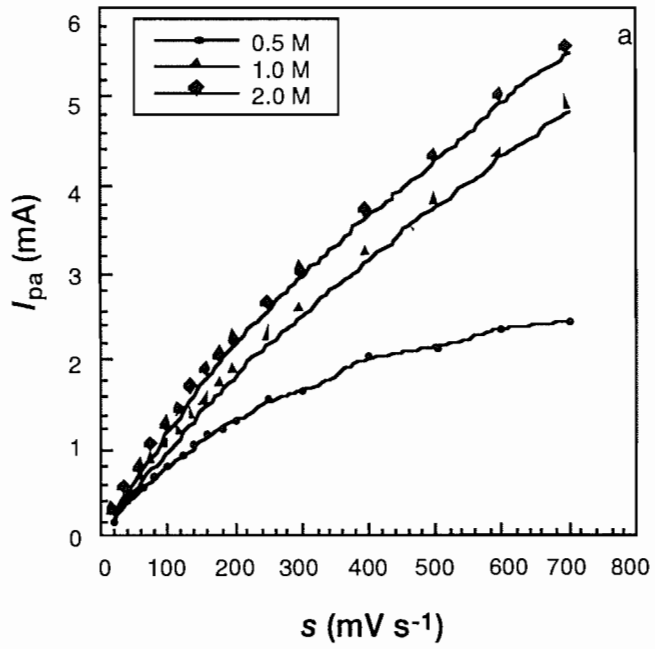
Fig. 13. Dependence of pH on the mean peak potential of the process observed in Fig. 12 for various scan rates.





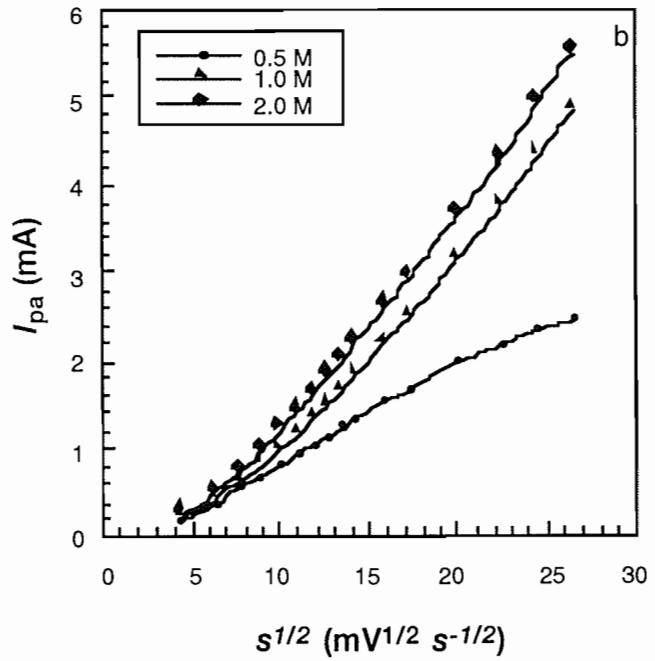


Figure 14(*a*) depicts the dependence of the anodic peak current (I_{pa}) on the scan rate at three KOH concentrations. It was not possible to accurately determine the same dependence for the cathodic peak current, due to its width and consequent difficulties in determination of the baseline. Figure 14(*b*) shows the corresponding variation of I_{pa} with the square root of the scan rate ($s^{1/2}$). We clearly notice that I_{pa} increases linearly with $s^{1/2}$ in 0.5 M KOH at all scan rates, and in 1 M and 2 M KOH at the higher scan rates. This suggests that the surface redox transition process is diffusion controlled at low OH^- concentration and at high scan rate when $[OH^-] \geq 1$ M. The shift of 60 mV pH^{-1} of the mean peak potential, determined in this work, corresponds to a 1:1 ratio of hydroxide ions to electrons. This situation suggests that one electron is removed from the oxide film during the oxidation process (reaction [3]), while one OH^- is injected into the film.

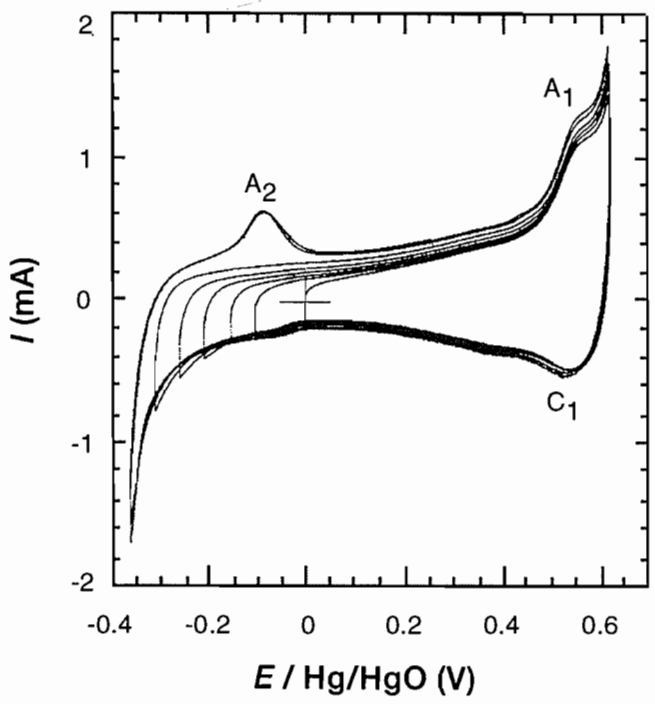
Figure 15 shows cyclic voltammograms obtained in 1 M KOH (22°C) by varying the negative potential limit between 0 and −0.37 V vs. Hg/HgO. These voltammograms demonstrate the presence of a significant cathodic current around −0.35 V leading to the appearance of a new anodic peak (A_2) at −0.1 V, while the peaks A_1 and C_1 remain almost unchanged. Our previous work (10) has shown that the electrochemical behavior of $Co(OH)_2$/Pt exhibits two redox transition processes assigned to the couples Co^{III}/Co^{II} and Co^{IV}/Co^{III}, the former being absent on $Cu_xCo_{3-x}O_4$/Pt presented in this work. On the other hand, $Cu(OH)_2$/Pt indicated the presence of one redox transition corresponding to Cu^{II}/Cu^{I} with $E_p = -0.270$ V vs. Hg/HgO at 100 mV s^{-1}. By comparison with the behavior of $Cu_xCo_{3-x}O_4$/Pt in the negative potential region (Fig. 15), one can associate the cathodic current with the reduction of surface Cu^{II} species. Cu^{I} species thus produced are oxidized at A_2 according to:

[6] $Cu_2O + H_2O + 2OH^- \rightleftharpoons 2\,Cu(OH)_2 + 2\,e^-$

Fig. 14. Dependence of the anodic peak current obtained in various KOH solutions on: (*a*) the scan rate; (*b*) the square root of the scan rate.



From the above results, we can assume that the surface of $Cu_xCo_{3-x}O_4$ in contact with the alkaline electrolyte is mostly composed of Co^{III} and Cu^{II} species. XPS measurements have shown that the surface of a freshly prepared $Cu_xCo_{3-x}O_4$/Ni electrode is mainly composed of octahedral Co^{III} and Cu^{II} species when the oxide is prepared at 300°C (10).

Conclusion

In this work, the spinel oxide $Cu_xCo_{3-x}O_4$ was prepared by thermal decomposition of nitrate precursors on a highly porous lanthanum phosphate-bonded nickel support (LPBN) with a roughness factor of ~4050. The highest electrocatalytic activity for the OER is obtained when the electrode is prepared at 300°C from a solution containing 0.5 M $Cu(NO_3)_2 \cdot 2.5\ H_2O$ and 1.0 M $Co(NO_3)_2 \cdot 6\ H_2O$, with a catalyst loading of 52 mg cm^{-2}. The activity is reduced when an excess of either Co or Cu is present in the spinel oxide film beyond the stoichiometric ratio of the precursors, probably due to some phase change. The nitrate decomposition temperature seems to have little effect on the electrocatalytic activity; the $Cu_xCo_{3-x}O_4$/LPBN electrochemical surface area is likely controlled by the morphology of the highly porous support. Below the optimum catalyst loading, the support is not completely covered, which decreases the electrode activity; above this value, the semiconducting properties of $Cu_xCo_{3-x}O_4$ increase the electrode resistivity, which also decreases the activity. Kinetics and mechanistic studies have been carried out at the optimum electrode using steady-state galvanostatic measurements and impedance spectroscopy. The results will be presented in a forthcoming publication.

This work indicates that the quasi-reversible Co^{IV}/Co^{III} surface redox transition, which likely takes place prior to the onset of oxygen evolution, is diffusion controlled at low OH^- concentration and at high scan rate when $[OH^-] \geq 1$ M. The results suggest that one electron is removed from the oxide film during the oxidation process while one OH^- is injected into the film. In the negative potential domain, a Cu^{II}/Cu^{I} surface redox transition was observed. Thus, the surface of $Cu_xCo_{3-x}O_4$ in the alkaline solution is mainly composed of Co^{III} and Cu^{II} species, which are most likely the active sites and (or) the precursors of the active sites for the OER.

Abstract: Lithium bis(trifluoromethylsulfonyl)imide (LiTFSI) is a promising electrolyte for lithium batteries. While it presents many interesting features in aprotic solvents (high solubility and conductivity, electrochemical stability, etc.), little is known about its properties in water. The solid–liquid phase diagram, surface tension, volume, heat capacity, and conductivity were therefore measured at 25°C and compared with the same properties of typical hydrophilic ($LiClO_4$) and hydrophobic (Bu_4NBr) electrolytes. To help in the comparison, some of the literature data for $LiClO_4$ and Bu_4NBr were extended. The standard Λ_0, V_2^0, and $C_{P,2}^0$ are respectively 71.12 S cm^2 mol^{-1}, 139.7 cm^3 mol^{-1}, and 543 J K^{-1} mol^{-1} at 25°C. LiTFSI is quite soluble, and shows surface activity and a small tendency for self-association in water. The aggregation number estimated from a mass-action model is of the order of 4.

Key words: lithium bis(trifluoromethylsulfonyl)imide, lithium perchlorate, tetrabutylammonium bromide, volume, heat capacity, phase diagram, thermal analysis, surface tension, conductance.

Résumé : Le bis(trifluorométhylsulfonyl)imide de lithium (LiTFSI) est un électrolyte prometteur pour les batteries au lithium. Même s'il présente plusieurs caractéristiques intéressantes dans les solvants aprotiques (solubilité et conductivités élevées, stabilité électrochimique, etc.), ses propriétés en milieu aqueux sont peu connues. Opérant à 25°C, on a donc mesuré les propriétés suivantes : diagramme de phase solide–liquide, tension superficielle, volume, capacité calorifique et conductivité; on a comparé ces propriétés avec celles d'électrolytes hydrophile ($LiClO_4$) et hydrophobe (Bu_4NBr) typiques. Afin de faire une meilleure comparaison, certaines données relatives au $LiClO_4$ et au Bu_4NBr ont été ramenées aux conditions désirées. À 25°C, les valeurs standards de Λ_0, V_2^0 et $C_{P,2}^0$ sont respectivement égales à 71,12 S cm^2 mol^{-1}, 139,7 cm^3 mol^{-1} et 543 J K^{-1} mol^{-1}. Le LiTFSI est assez soluble; il présente une certaine activité superficielle et une faible tendance à s'autoassocier dans l'eau. En se basant sur un modèle d'action de masse, on a évalué que le nombre d'agrégation est d'environ 4.

Mots clés : bis(trifluorométhylsulfonyl)imide de lithium, perchlorate de lithium, bromure de tétrabutylammonium, volume, capacité calorifique, diagramme de phase, analyse thermique, tension superficielle, conductivité.

[Traduit par la rédaction]

Introduction

The conducting medium of high-energy lithium batteries requires a lithium salt that is electrochemically stable, chemically inert to the electrodes (passivation film), highly soluble in aprotic solvents, and that has a high conductivity under the operating conditions. The most commonly used lithium salts for liquid lithium batteries are $LiClO_4$, $LiAsF_6$, and $LiBF_4$. Lithium bis(trifluoromethylsulfonyl)imide (LiTFSI), or $Li(CF_3SO_2)_2N$, has been shown to be one of the most effective electrolytes for electrolyte–polymer lithium batteries (1), and recent work (2) shows that it also has most of the required qualities for a promising electrolyte for liquid lithium batteries. Relatively little is known about the properties of this electrolyte in solution (3–7). It has good conductivity, it is stable electrochemically and thermally, and is quite soluble in many solvents. The anionic crystal radius has been estimated by Ue (8), and this anionic radius appears to be consistent with Stokes law in propylene carbonate. On the other hand, there are many peculiarities with this electrolyte in solvents of low dielectric constants such as 1,2-dimethoxyethane (DME) (2). It has a very high association constant, but its specific conductivity at high concentration is still large. It forms a stable 3:1 solvate, which seems to persist in the solution state. The apparent molar heat capacity has an anomalous concentration dependence.

It is not easy to understand solute–solute interactions in aprotic solvents in general, since most of the thermodynamic studies have been limited to the standard infinite dilution stan-

For personal use only.

dard state. On the other hand, aqueous electrolyte solutions have been well investigated over a wide concentration range. We therefore felt that it would be useful to compare some of the thermodynamic properties (phase diagram, surface tension, apparent molar volume, and heat capacity) and conductivity of LiTFSI in water over a wide concentration range with well-characterized hydrophilic and hydrophobic electrolytes such as $LiClO_4$ and tetrabutylammonium bromide, Bu_4NBr. Such comparisons should help in understanding any peculiarities in the properties of LiTFSI that may be related to its molecular structure. In the course of this comparative study, we realised that some of the data for $LiClO_4$ and Bu_4NBr at high concentration were lacking. The literature data were therefore extended by new measurements.

Experimental

$LiClO_4$ and Bu_4NBr were both obtained from Omega. $LiClO_4$ was dried under vacuum at 150°C. Bu_4NBr was recrystallized from acetone and dried under vacuum at 70°C. LiTFSI, produced by 3M, was supplied free of charge by Hydro-Quebec. This salt is quite soluble in many solvents and attempts to purify large quantities of salt by recrystallization, as suggested by Dominey et al. (7),[2] were not successful. It often fails to recrystallize at low temperatures and forms a glass. It was therefore assumed pure.

Although LiTFSI is quite hygroscopic, water or acetonitrile can be removed fairly readily during the drying process. It was dried under vacuum at 150°C for 10 h and kept under an argon atmosphere in a Gallenkamp dry box, where the atmospheric humidity was maintained at less than 2%, or in a model HE-493 argon dry box (from Vacuum Atmospheres Company) equipped with a Dri-Train. This latter dry box, lent by Hydro-Quebec, contains less than 0.01% relative humidity. The salt was weighed in the dry box and the solutions prepared with deionized distilled water (Barnstead Nanopure II). The weights of the salt were corrected for the presence of argon in the bottles. The aqueous solutions prepared with the present lot of LiTFSI had a pH of 8.0. Since it was observed that the aqueous solutions were reacting slowly with stainless steel at concentrations above 0.5 mol kg^{-1}, flow cells made of platinum–rhodium alloy were used for this study in the flow densimeter and microcalorimeter.

The phase diagrams were obtained from thermal analysis using the Heat Leak Modulus (HLM) technique (9) since this technique is well adapted for hygroscopic and volatile liquids at low temperatures. The solution in a small tube containing a platinum resistor was rapidly frozen and the temperature was followed as the sample was warmed.

The surface tensions (γ) were measured with a Fisher Tensiomat, model 20, having a precision of ± 1 dyne cm^{-1}. The purpose of these measurements was mostly to see the trends in γ with concentration since it was observed that the aqueous solutions had a tendency to foam when shaken. For these studies, small quantities of salt were added successively to the solvent to obtain different concentrations, even though such a procedure is less accurate than the preparation of individual solutions.

The volumetric heat capacities were measured with a Picker flow microcalorimeter (SODEV model CP-C) (10). Essentially, two liquids at the same initial temperature and flowing at the same rate in twin cells were heated. The difference in the applied power ΔW necessary to maintain the final temperature of the laboratory cell identical to that of the reference cell is proportional to the difference in the heat capacity per unit volume, $\Delta\sigma$, of the two liquids. If there is no heat loss (11),

$$[1] \quad \frac{\Delta W}{W_0} = \frac{\Delta\sigma}{\sigma_0}$$

where W_0 is the basic power applied to the cells and σ_0 is the heat capacity per unit volume of the reference liquid. The difference in specific heat capacity, in J K^{-1} g^{-1}, can be calculated from

$$[2] \quad c_P = (1 + \Delta\sigma/\sigma_0)c_{P,0}d_0/d$$

where d and d_0 are the densities of the solution and of the solvent in g cm^{-3} and $c_{P,0}$ is the heat capacity of the reference water in J K^{-1} g^{-1} (12). The differences in heat capacities can be obtained to $\pm 0.5\%$ under the best conditions.

The density is related to the resonance frequency of the U-shaped vibrating capillary tube adapted to the flow regime by Picker et al. (13). The difference in density between the solution and a reference solvent is given by

$$[3] \quad d - d_0 = k(\tau^2 - \tau_0^2)$$

where k is the calibration constant obtained using pure water (12), dry nitrogen (12), and a vacuum as references. The calibration constant obtained for various organic liquids against a vacuum or nitrogen is slightly different from the one for water and a vacuum or nitrogen in the commercial version of the instrument. The densities of nonaqueous solvents should therefore be measured and calibrated against an organic reference solvent. Densities can be measured to $\pm 3 \times 10^{-6}$ g cm^{-3} under the most favourable conditions.

The ionic conductivities were measured with a bridge similar to the Beckman model RC-15 commercial bridge. The platinized platinum cells had constants of 1 or 0.1 cm^{-1} depending on the concentrations of the solutions. Resistance measurements were made at 1 and 3 kHz and extrapolated to 0 kHz. The precision is 0.05%.

Results and discussion

Thermal analysis and solid–liquid phase diagram

Some examples of thermograms for the system LiTFSI–H_2O are shown in Fig. 1 and the derived solid–liquid phase diagram is given in Fig. 2. The original data are available as Supplementary Material.[3]

The information obtained from the HLM thermal analysis is similar to that from a DSC. The temperatures associated with various transitions are given as maxima, minima, or inflection

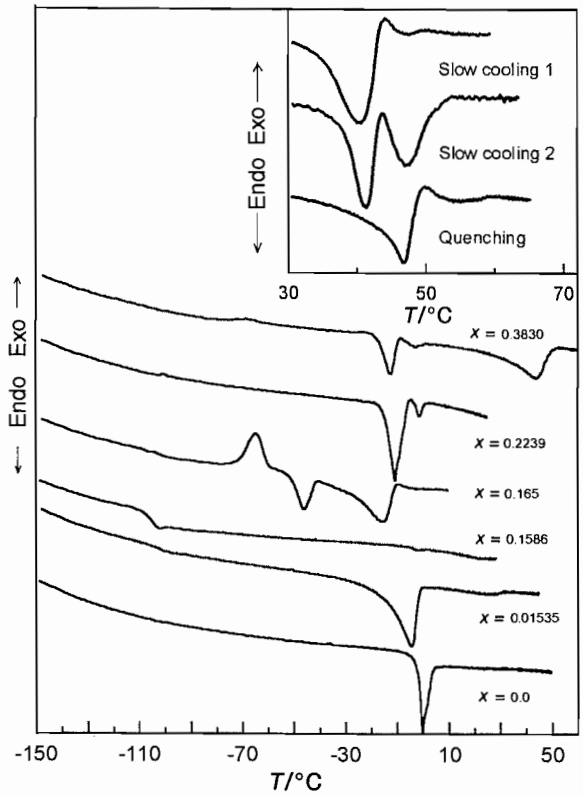
Fig. 1. Examples of thermograms of the system LiTFSI–H_2O for different mole fractions x. The inset is an expanded scale for different rates of cooling. One or two peaks will appear in this region for different conditions of slow cooling (see text).



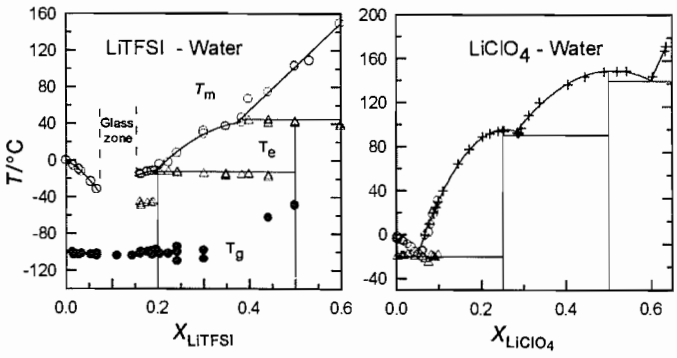


Fig. 2. Solid–liquid phase diagram of the system LiTFSI–H_2O: ○, melting points; Δ, eutectic points; ● glass transition temperatures; +, melting point data from ref. 20.

points and the enthalpy associated with the phenomena are derived from the area under the curves. The change in the base line at the melting point, as illustrated, for example, with pure H_2O, reflects the difference in heat capacity between the solid and the liquid phases. This difference decreases rapidly as the concentration of LiTFSI increases. Measurements were made up to mole fractions of LiTFSI of 0.6. Pure LiTFSI has a melting point of 234°C and a heat of fusion of 13.2 kJ mol^{-1} (14).

All the thermograms below 0.08 mole fraction show only melting points and glass transition temperatures, T_g. Only a small peak corresponding to T_g is observed if the quenching process is slow. For rapid quenching, the T_g is followed by a crystallization peak, T_c. T_g is constant up to approximately 0.3 mole fraction. Between mole fractions of 0.08 and 0.16, only a T_g is seen, corresponding to an amorphous zone in the phase diagram. Such zones, which are also present with other electrolytes such as LiBr in water, have been studied in detail by Angel et al. (15, 16). Similar phenomena are also observed in metallurgy (17). We have observed that, for some mixtures, the presence of an amorphous zone corresponds to the convergence of the melting point (T_m) with T_c (5).

Above 0.16 mole fraction, eutectic temperatures, T_e, in addition to melting points (T_m), are observed. At 0.38 mole fraction, the thermogram depends on the quenching and rate of heating. Depending on the experimental conditions, T_m is either split into a double peak or only one of these peaks is observed, as shown in the upper corner of Fig. 2. Such splitting of peaks, which depends on the kinetics of crystallization, has been observed in the literature (18) and could be a case of polymorphism (19). This phenomenon was not investigated further.

The phase diagram of LiTFSI indicates the presence of unstable solvates, which show incongruent melting, at 0.2 and 0.5 mole fractions with well-defined T_e.

The phase diagrams of $LiClO_4$ and H_2O obtained from the present thermal analysis technique are compared with the literature values (20) in Fig. 2. The thermograms do not depend on the rate of cooling in this case. The excellent agreement with the literature confirms that the HLM method is well adapted to the study of phase diagrams of aqueous solutions. $LiClO_4$ forms two stable hydrates and has a well-defined eutectic in water.

Surface tension

The surface tensions of LiTFSI are given elsewhere[3] and are compared with Bu_4NBr in Fig. 3. Some values of γ of Bu_4NBr were also measured to complement the literature data (22, 23). The γ of Bu_4NBr were also measured by Arnett et al. (21) but these values are systematically lower by about 5 dynes cm^{-1} and were not included in Fig. 3. The excellent agreement of the present measurements with the two sets of literature data is a good indication of the reliability of the present technique.

Contrary to inorganic electrolytes, which increase the γ of the aqueous solutions, LiTFSI decreases γ and reaches a minimum value in the same concentration range as Bu_4NBr, i.e., ~1–1.5 mol kg^{-1}, but the value of γ at saturation is 35 dyne cm^{-1} compared with 45 dyne cm^{-1} for Bu_4NBr. Liquid fluorocarbons generally have lower γ than liquid hydrocarbons. Such lowering and levelling off of γ with concentration is usually associated with micellization. These results therefore indicate that LiTFSI, like Bu_4NBr, is surface active and shows some tendency for self-association above 1 mol kg^{-1}.

Apparent molar quantities

The volumes and heat capacities of electrolyte solutions are usually expressed as apparent molar quantities $Y_{2,\phi}$. The apparent molar volume of component 2 is calculated from

$$[4] \quad V_{2,\varphi} = \frac{M_2}{d} - \frac{1000(d - d_0)}{m_2 d d_0}$$

Fig. 3. Surface tension of LiTFSI and Bu_4NBr in water at 25°C on a logarithmic and linear scale of the molality.

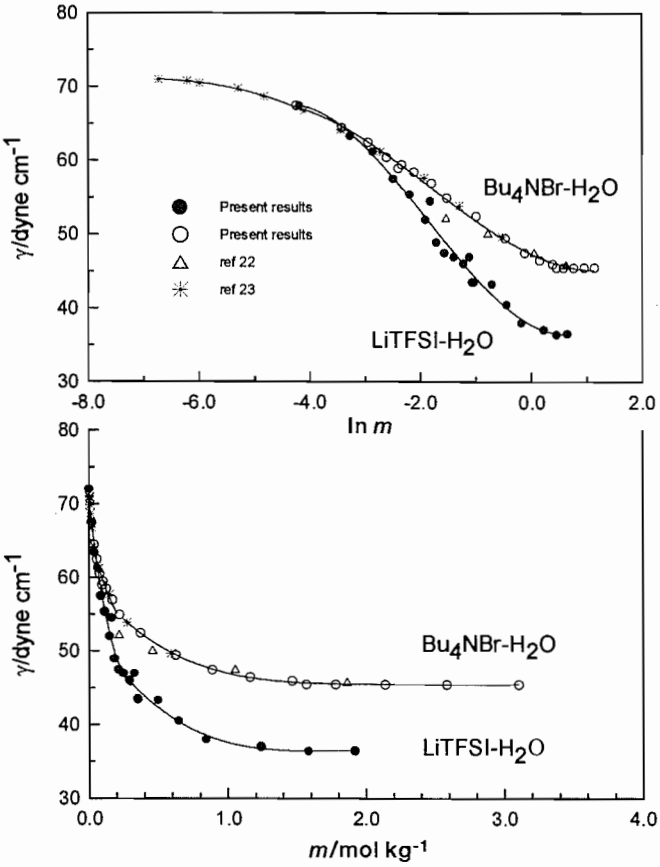

Fig. 4. Excess apparent molar volume of LiTFSI, $LiClO_4$, and Bu_4NBr in water at 25°C. Data for Bu_4NBr from Wen and Saito (26). Low-concentration data for $LiClO_4$ (○) are compared to those compiled by Lobo (24) (Δ, □). The full line in the case of LiTFSI is from mass-action model.

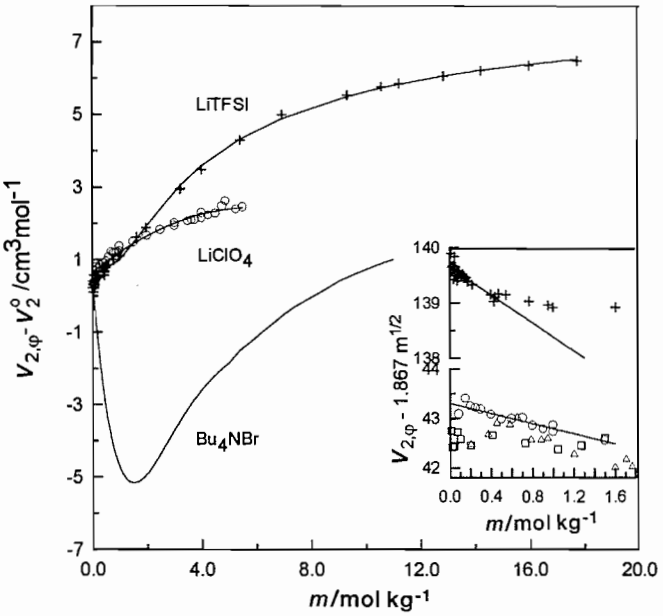

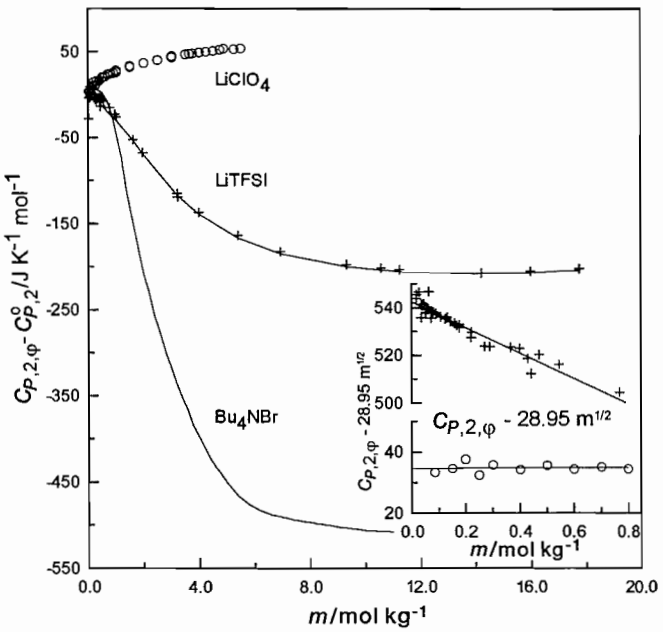

Fig. 5. Excess apparent heat capacity of LiTFSI, $LiClO_4$, and Bu_4NBr in water at 25°C. Data for Bu_4NBr from Perron et al. (27) and de Visser et al. (28). Full line in the case of LiTFSI is from mass-action model.

where M_2 is the molar mass and m_2 the molality of component 2, and the apparent molar heat capacity is calculated from

$$[5] \quad C_{P,2,\varphi} = M_2 c_P + \frac{1000(c_P - c_{P,0})}{m_2}$$

The difference in densities $(d - d_0)$, the relative changes in heat capacities per unit volume $(\Delta\sigma/\sigma_0)$, and the derived $V_{2,\varphi}$ and $C_{P,2,\varphi}$ are given elsewhere.[3] The low-concentration data were analysed with the Redlich–Meyer equation,

$$[6] \quad Y_{2,\varphi} = Y_2^0 + y_{DH} m^{1/2} + B_Y m$$

where Y_2^0 is the standard partial molar quantity, y_{DH} is the Debye–Hückel limiting slope, taken as 1.867 $cm^3\ kg^{1/2}\ mol^{-3/2}$ and 28.95 $J\ kg^{1/2}\ K^{-1}\ mol^{-3/2}$, respectively, for volumes and heat capacities at 25°C, and B_Y are empirical constants. The volume data reported by Lobo (24) on $LiClO_4$ disagree with the present data at low concentration (Fig. 4). This is not unexpected since the volumes were calculated from densities at four decimal places only. The parameters of eq. [6] are given in Table 1. The absolute value of V_2^0 ($TFSI^-$), based on the scale V_2^0 (H^+) = −5.4 $cm^3\ mol^{-1}$ (25) is 150.9 $cm^3\ mol^{-1}$, and the conventional $C_{P,2}^0$ ($TFSI^-$), based on $C_{P,2}^0$ (H^+) = 0, is 481 $J\ K^{-1}\ mol^{-1}$. Since data for LiTFSI were obtained at rather high concentrations in water and in other solvents, it is possible to estimate the intrinsic volume and heat capacity Y_2^*, or the molar property of the hypothetical liquid solute at 25°C, from a plot of the apparent quantity against $1/m$ (2). Since this function must be independent of the solvent, the best values

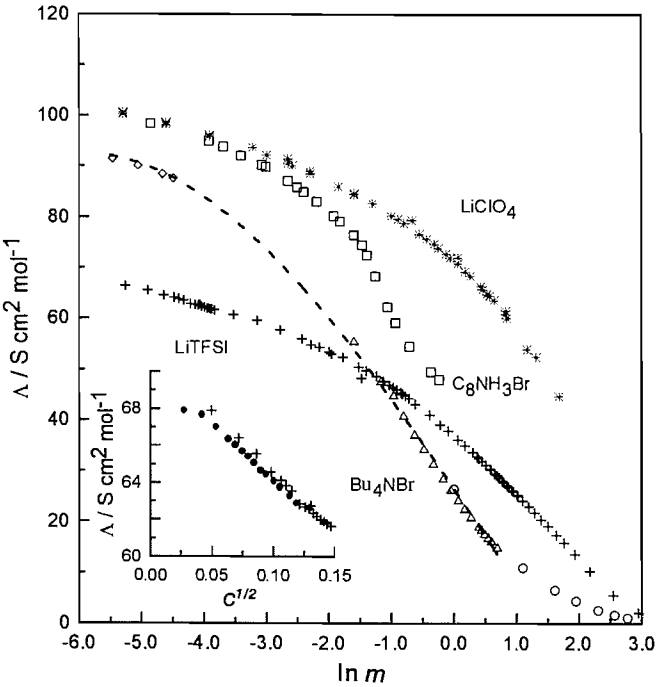

Fig. 6. Equivalent conductivity of LiTFSI, Bu_4NBr, $LiClO_4$, and $OctNH_3Br$ in water at 25°C. Data for LiTFSI (●) from Salomon (3), $LiClO_4$(∗) from Haase and Duecker (40), Bu_4NBr (Δ) from Quentin and Justice (36) and (○) from Wirth and Lesordo (38), and $OctNH_3Br$ from Desnoyers et al. (41).

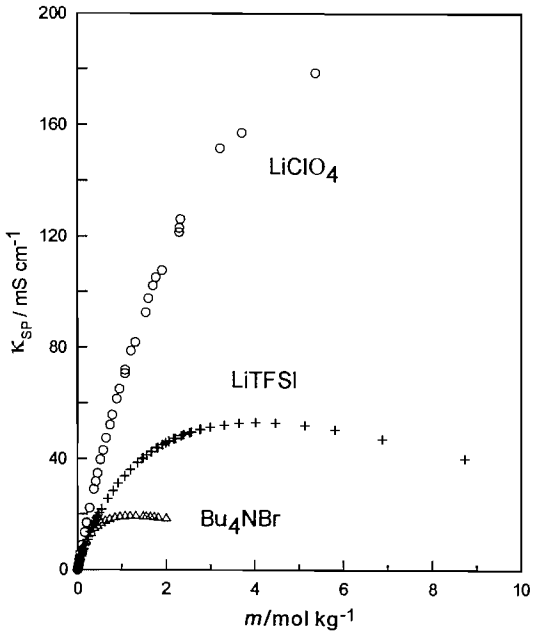

for V_2^* and $C_{P,2}^*$ are, respectively, 148 ± 2 cm^3 mol^{-1} and 300 ± 20 J K^{-1} mol^{-1}. The corresponding values for $LiClO_4$ and Bu_4NBr are given in Table 1.

To facilitate the comparison between different electrolytes, $Y_{2,\varphi} - Y_2^0$ are plotted in Figs. 4 and 5. The decrease in $V_{2,\varphi} - V_2^0$ of Bu_4NBr below 1.5 mol kg^{-1} arises because the term $B_V m$ is much more negative than $\nu_{DH} m^{1/2}$ of eq. [6]. A large negative value for B_V is usually associated with hydrophobic pair interactions (29). This term is also negative for the other electrolytes in Fig. 4 but the overall trend is governed by the Debye–Hückel contribution. There are many examples of hydrophobic electrolytes that show an overall increase in volume at low concentration, for example, many surfactants such as sodium alkanoates (30), amine hydrobromides (31) and perfluoroalkanoates (32). The trends in $V_{2,\varphi} - V_2^0$ at higher molalities are more informative. At about 1–1.5 mol kg^{-1}, $V_{2,\varphi} - V_2^0$ of LiTFSI shows a further increase as in the case of Bu_4NBr, while $V_{2,\varphi} - V_2^0$ of $LiClO_4$ simply levels off. The decrease in $C_{P,2,\varphi} - C_{P,2}^0$ of LiTFSI in Fig. 5 is also qualitatively similar to that of Bu_4NBr although the magnitude is smaller. No such changes are observed with $LiClO_4$ or alkali halides. The increase in $V_{2,\varphi} - V_2^0$ and decrease in $C_{P,2,\varphi} - C_{P,2}^0$ beyond a certain concentration is usually taken as evidence of self-association of the hydrophobic ions. The changes occur at approximately the same concentration as the break in γ in Fig. 3. Treatment of the data with a mass-action model (33, 34) would suggest that the aggregation number of LiTFSI would be of the order of 4. Such a model fits the volumes and heat capacities

Fig. 7. Specific conductivity of LiTFSI, Bu_4NBr, and $LiClO_4$ in water at 25°C. Data sources are the same as for Fig. 6.

remarkably well, as seen from Figs. 4 and 5, with a minimum number of parameters. These new parameters, given in Table 2, have the following meaning: N is the aggregation number, m_I is the molality at the inflexion point of the fraction of monomers (equivalent to a critical micellar concentration or CMC), Y_2^M is the molar property of the solute in the micellar state, B_Y^M is an interaction parameter for the micelles, and RELAX is the relaxational contribution to heat capacity which takes into account the shift in CMC with temperature. In the data analysis, Y_2^0 was fixed to the value given in Table 1 in all cases. To get a good convergence of the least-squares analyses, at least one more parameter had to be fixed. After a few trials, N and m_I were fixed at reasonable mean values for volumes and heat capacities and the other parameters were determined by the least-squares fit. The mass-action model is a good fitting equation for LiTFSI; the parameters B_Y in Tables 2 and 3 are comparable, and the quantity $Y_2^M + B_Y^M(m - m_I)$ is tending to the parameter Y_2^* in Table 2. With such small aggregation numbers and large values of m_I, the aggregates can probably not be associated with real micelles but more with the kind of time-averaged clusters that are observed in alcohol–water mixtures (35).

Ionic conductivity

The equivalent conductances, Λ, of LiTFSI are given elsewhere.[3] Some data were also obtained for Bu_4NBr at intermediate concentrations to partially fill the gap in the available data in the literature (24, 36–38). The low concentration data ($m < 0.01$) were analyzed with the Fuoss–Hsia/Fernandez–Prini equation, modified to include the Chen and echo terms using the programs developped by Justice (39). The parameters are given in Table 3. The value of Λ_0 of LiTFSI was found to be 71.12 S cm^2 mol^{-1} at 25°C, which is in good agreement with the value obtained by Salomon (3), 70.89 S cm^2 mol^{-1}, once his data are analyzed with the same equation, considering the precision of our conductance bridge and the relative purity of different samples of this electrolyte. The values of Λ_0 of LiTFSI in various solvents were discussed in detail by Salomon (3) and by Ue (8). Our interest is more in the high-concentration behaviour.

The large decrease in conductivity at low concentrations resulting from the long-range Coulombic force hides most of the additional attractive interactions due to self-association. To see if the results can show any evidence of self-association, Λ values were plotted against $\ln(m)$ in Fig. 6 and compared with those of Bu_4NBr, $LiClO_4$, and of a typical short-chain surfactant. Bu_4NBr shows some evidence of self-association, when the trends in Λ are compared with those of octylammonium bromide, $OctNH_3Br$ (41). On the other hand, the concentration dependence of LiTFSI seems to be closer to that of $LiClO_4$. The only explanation we can offer to explain why the conductance of LiTFSI does not show the expected trends of a surface-active solute, considering the observed trends of the thermodynamic properties, is that different properties are reflecting different effects. The changes in volumes and heat capacities during micellization are essentially due to a loss of hydrophobic hydration while the corresponding changes in conductance are due to a change in the number of free ions and to changes in the size of the moving particles. With systems undergoing changes above 1.5 mol kg^{-1} involving only three or four molecules, the effects may be too small to be detected in conductances.

The specific conductivities, κ_{sp}, are plotted as a function of m in Fig. 7. κ_{sp} reaches the maximum value of 53 mS cm^{-1} at 4.3 mol kg^{-1}, which can be compared with the maximum value of 19.9 mS cm^{-1} for Bu_4NBr at 1.2 mol kg^{-1} and a value tending to 200 mS cm^{-1} for $LiClO_4$. The decrease in κ_{sp} following the order $LiClO_4$ > LiTFSI > Bu_4NBr probably reflects the increasing size of the pairs of ions.

Conclusion

LiTFSI is highly soluble and shows some surface activity in water. Above 1 mol kg^{-1}, the surface tension, volume, and heat capacity data all show some evidence of self-association. Using a mass-action model, the aggregation number would be of the order of 4. The behaviour of LiTFSI in water is therefore similar to weakly hydrophobic electrolytes such as Pr_4NBr. The surface activity character of LiTFSI is not reflected in conductances. The anomalous thermodynamic properties and equivalent conductivities of LiTFSI observed in DME (2) are not present in water. This suggests that LiTFSI has most of the expected properties of a weakly surface-active electrolyte in water, and the anomalous trends in solvents of low dielectric constant are due to specific interactions and not to the chemical structure of this large anion.

Acknowledgement

The authors are grateful to the Natural Sciences and Engineering Research Council of Canada for financial assistance and to Yves Choquette of Hydro-Quebec for supplying a sample of LiTFSI for these studies.

Abstract: The hydrogen evolution reaction on rough or porous surfaces often leads to low Tafel slopes that cannot be explained in terms of the Volmer–Heyrovsky–Tafel mechanism. In addition, adsorption of organic compounds and ions causes an increase in the Tafel slopes. To explain such behavior, a concept of distribution of adsorption energies on heterogeneous surfaces, leading to a distributed kinetics, was studied. Simulations of the dependence of the current and the surface coverage by adsorbed hydrogen on overpotential are presented for different values of the kinetic parameters in the absence and presence of the adsorbed foreign substances. These results were compared with those obtained using the Frumkin/Temkin adsorption isotherm. It was found that for some kinetic parameters and a flat distribution of adsorption energies, low Tafel slopes, similar to those observed experimentally, are obtained.

Key words: hydrogen evolution, adsorption, heterogeneous surfaces, distributed kinetics, Frumkin/Temkin isotherm.

Résumé : La réaction de dégagement d'hydrogène sur des surfaces poreuses ou rugueuses conduit souvent à de faibles pentes de Tafel que l'on ne peut expliquer en fonction du mécanisme de Volmer–Heyrovsky–Tafel. De plus, l'adsorption de composés organiques et d'ions provoque une augmentation des pentes de Tafel. Dans le but d'expliquer un tel comportement, on a étudié un concept de distribution des énergies d'adsorption sur des surfaces hétérogènes conduisant à une cinétique répartie. On présente des simulations relatives à l'influence d'une surtension sur le courant et sur la surface couverte par l'hydrogène adsorbé, pour différentes valeurs des paramètres cinétiques, en l'absence et en présence de substances étrangères adsorbées. On a comparé ces résultats à celles obtenues dans les conditions de l'isotherme de Frumkin/Temkin. On a trouvé que l'on obtient, pour quelques paramètres cinétiques et pour une distribution en palier des énergies d'adsorption, de faibles pentes de Tafel semblables à celles observées expérimentalement.

Mots clés : dégagement d'hydrogène, adsorption, surfaces hétérogènes, cinétique répartie, isotherme de Frumkin/Temkin.

[Traduit par la rédaction]

Introduction

The real electrode surfaces used in electrocatalysis are usually very rough or porous and heterogeneous. However, in electrochemistry, a homogenous approach is usually used and it is assumed that there is only one set of reaction rates describing the kinetics of the system. In the heterogeneous systems the adsorption energy and the rate constants depend on the nature of the site. The main sources of heterogeneity are (1): (*i*) different types of crystal planes, steps, edges, etc. exposed for adsorption, (*ii*) irregularities in crystallographic surface structure, (*iii*) impurities strongly bound to the surface, and (*iv*) the different chemical nature of the surface centers. Such concepts are well known in adsorption studies (1–9). They were applied to electrosorption by Nikitas and Papqutsis (10, 11). The concept of distributed kinetics as a distribution of rate constants was adopted for electrochemistry by Albery et al. (12, 13), used by Rowe et al. (14) and, recently, by Chialvo and Chialvo (15, 16).

Rough and porous electrodes are usually used in the hydrogen evolution reaction (HER). On Ni–Zn Raney electrodes, after leaching out the zinc in alkaline solutions, the observed Tafel plots vary between 50 and 90 mV dec^{-1}, depending on the deposited layer thickness and composition (17–21). Such slopes cannot be explained in terms of the classical Volmer–Heyrovsky–Tafel mechanism. The porous electrode model predicts even doubling of the Tafel slopes. Rausch and Wendt (17, 18) tried to explain such behavior by hydrogen pressure buildup in pores, using an approximate model; however, recently Lasia (22), using correct treatment, showed that such low slopes predicted due to the hydrogen pressure buildup cannot be observed experimentally in the linear Tafel range. It was also suggested (21) that hydrogen absorption in the topmost surface layers may be responsible for low Tafel slopes.

In our earlier papers (20, 21) it was found that adsorption of organic compounds (pyridine, thiourea) or ions (CN^-) causes an increase of the observed Tafel slopes. The influence of adsorption of organic compounds on the HER was

discussed by Conway and Jerkiewicz (23) and Jerkiewicz et al. (24, 25). They carried out simulations of the surface coverage by adsorbed hydrogen, Θ_H, assuming homogeneous surface conditions. It was suggested earlier (20) that the distribution of adsorption energies may play an important role in the kinetics of the hydrogen evolution on heterogeneous surfaces. In the present paper the model of the distribution of adsorption energies, leading to distributed kinetics, is applied to the HER, and the influence of the adsorption of other species on this reaction is studied. These results are compared with those obtained assuming unique rate constants and with adsorption under Frumkin/Temkin isotherms. The HER kinetics was expressed in terms of the rate constants, in contrast with the earlier approach (15, 16) using the exchange current densities and the surface coverage at the equilibrium potential.

Hydrogen adsorption in the absence of organic compounds

The hydrogen evolution reaction may proceed through three reaction paths:

[1] $H_2O + e \rightleftharpoons OH^- + MH$ Volmer

[2] $MH + H_2O + e \rightleftharpoons H_2 + OH^-$ Heyrovsky

[3] $MH + MH \rightleftharpoons H2$ Tafel

where MH denotes hydrogen adsorbed on the electrode surface. For reasons of simplicity only the Volmer–Heyrovsky reaction mechanism will be considered below. The rate constants of these reactions depend on the standard hydrogen adsorption Gibbs energy (26), ΔG^0_H, which can be represented as $G^0_H = (\Delta G^0_H - \Delta G^0_{H,r}) + \Delta G^0_{H,r} = \Delta\Delta G^0_H + \Delta G^0_{H,r}$ where $\Delta G^0_{H,r}$ is the hydrogen adsorption Gibbs energy at a reference state. Then, the reaction rates, assuming the Langmuir isotherm for hydrogen adsorption, may be written as:

$$[4]\quad v_1 = k_1^0 \, e^{-\beta_1(\Delta\Delta G^0_H/RT)} e^{-\alpha_1 f\eta}(1 - \Theta_H) - k_{-1}^0 \, e^{(1-\beta_1)(\Delta\Delta G^0_H/RT)} e^{(1-\alpha_1)f\eta}\Theta_H$$

$$[5]\quad v_2 = k_2^0 \, e^{(1-\beta_2)(\Delta\Delta G^0_H/RT)} e^{-\alpha_2 f\eta}\Theta_H - k_{-2}^0 \, e^{-\beta_2(\Delta\Delta G^0_H/RT)} e^{(1-\alpha_2)f\eta}(1-\Theta_H)$$

where k_i^0 are the standard rate constants, including term $\Delta G^0_{H,r}$; α_i and β_i are the symmetry coefficients for the electrochemical and adsorption processes, respectively; η is the overpotential; Θ_H is the surface coverage by adsorbed hydrogen; and $f = F/RT$. The adsorption energy enters into the rate constants: $k_i = k_i^0 \, e^{-\beta_i(\Delta\Delta G^0_H/RT)}$ for $i = 1, -2$, and $k_i = k_i^0 \, e^{(1-\beta_i)(\Delta\Delta G^0_H/RT)}$ for $i = -1, 2$. Taking into account that, in the steady state, rates of the Volmer and Heyrovsky reactions are identical, the following equation is obtained:

$$[6]\quad v = v_1 + v_2 = \vec{k}_1 (1 - \Theta_H) - \overleftarrow{k}_{-1}\Theta_H + \vec{k}_2\Theta_H + \overleftarrow{k}_{-2}(1 - \Theta_H) = 2v_1 = 2v_2$$

where $\vec{k}_i$ and $\overleftarrow{k}_i$ are the potential-dependent rate constants, $\vec{k}_i = k_i^0 \exp(-\alpha_i f\eta)$ for $i = 1,2$ and $\overleftarrow{k}_i = k_i^0 \exp[(1 - \alpha_i)f\eta)$ for $i = -1, -2$, and the total observed current equals $i = Fv$. Equation [6] allows for the determination of the surface coverage by adsorbed hydrogen:

$$[7]\quad \Theta_H = \frac{\vec{k}_1 + \overleftarrow{k}_{-2}}{\vec{k}_1 + \overleftarrow{k}_{-1} + \vec{k}_2 + \overleftarrow{k}_{-2}}$$

or

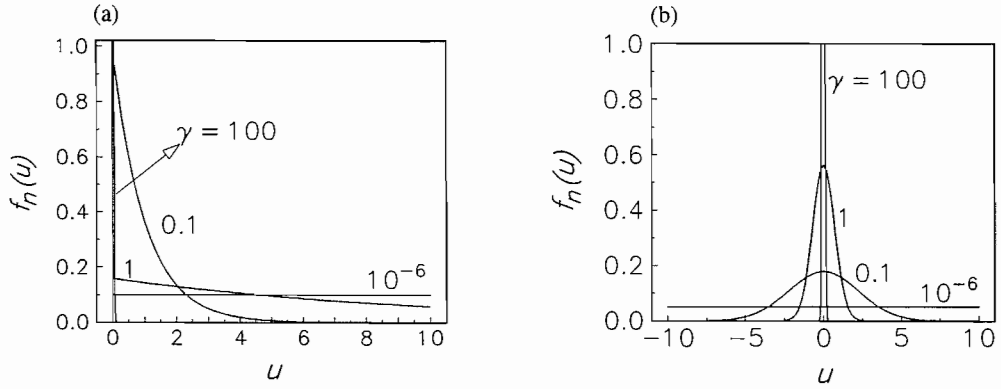
$$[8]\quad \frac{\Theta_H}{1 - \Theta_H} = \frac{\vec{k}_1 + \overleftarrow{k}_{-2}}{\overleftarrow{k}_{-1} + \vec{k}_2} = \overline{K}_H$$

where $\overline{K}_H$ is the potential-dependent equilibrium constant of hydrogen adsorption. It also allows for the elimination of one out of four rate constants, because:

$$[9]\quad \frac{k_1 k_2}{k_{-1} k_{-2}} = 1$$

It can be noticed that $\Theta_H = k_{-2}/(k_{-1} + k_{-2})$ at very positive overpotentials, $\Theta_H = k_1/(k_1 + k_{-1}) = k_{-2}/(k_2 + k_{-2})$ at the equilibrium potential, and $\Theta_H = k_1/(k_1 + k_2)$ at very negative overpotentials. These relations may be used when the solution is saturated with hydrogen and its diffusion may be neglected. However, because of a very small hydrogen solubility in aqueous solutions, the anodic limit predicted above is not reached and the surface coverage reaches zero at positive potentials. Langmuir (27) assumed that the heterogeneous surface is composed of a number of patches, which are independent of each other and behave as separate. However, adsorption on each patch follows the Langmuir isotherm. Later, this concept was extended to random distribution of adsorption heterogeneities. To describe this behavior a distribution of adsorption energies is introduced. It is assumed that the surface can be divided into a number of macroscopic sites possessing the surface area dS and at each site the Langmuir isotherm is valid; however, each site may be characterized by a different adsorption energy (1–3, 15, 16, 27). Such a model is usually used in the adsorption studies.

In such cases the macroscopically observed surface coverage, Θ_H, and total reaction rate, V, are obtained by integration over all sites:



$$[10]\quad \Theta_H = \frac{\int_{u_1}^{u_2} \theta_H(\eta, u) f(u) du}{\int_{u_1}^{u_2} f(u) du} = \int_{u_1}^{u_2} \theta_H(\eta, u) f_n(u) du \qquad \text{where} \quad u = \Delta\Delta G^0_H/RT$$

$$[11]\quad V = \frac{\int_{u_1}^{u_2} v(\eta, u) f(u) du}{\int_{u_1}^{u_2} f(u) du} = \int_{u_1}^{u_2} v(\eta, u) f_n(u) du$$

Fig. 1. Distribution functions $f(u)$ as a function of $u = \Delta\Delta G^0_H/RT$ for different values of parameter γ: (*a*) exponential, (*b*) Gaussian.

where $f(u)$ is the distribution function and $f_n(u)$ is the normalized distribution function:

$$[12] \quad f_n(u) = \frac{f(u)}{\int_{u_1}^{u_2} f(u)\mathrm{d}u}$$

and the integration runs between the lowest, u_1, and the highest, u_2, adsorption energies in the system. The distribution function is directly related to the fraction of the surface area, dS, characterized by the adsorption energy between u and $u + du$: d$S = f_n(u)\,du$. By integration, a fraction of the surface area characterized by a given range of adsorption energies may be obtained. Popular choices of distribution functions in catalysis are Gaussian and exponential (1, 2), eq. [13], or skewed,

$$[13] \quad f(u) = \mathrm{e}^{-\gamma u^2} \qquad \text{or} \qquad f(u) = \mathrm{e}^{-\gamma u}$$

where γ is the distribution parameter. Gaussian distribution means that there is a normal distribution of adsorption energies around one value, $\Delta\Delta G^0_H = 0$, and the exponential distribution means that the number of sites decreases exponentially with the increase of the adsorption energy, that is, there are many sites characterized by low and fewer characterized by high adsorption energy. Parameter γ is related to the surface heterogeneity (2). A few examples of the normalized distribution functions are shown in Fig. 1. When $\gamma \to \infty$ there is no dispersion and only one adsorption energy exists (surface is homogeneous), and $\gamma = 0$ means that there is "flat" distribution and each center contributes equally to the total adsorption energy. In experimental studies of adsorption, more complex distribution functions, e.g., composed of a few Gaussian peaks, were found. To simulate such cases more experimental information on the distribution function should be known. Because of the exponential dependence of the rate constants on the adsorption energy, the rate constants of the Volmer and Heyrovsky reactions are distributed and the logarithm of the rate constants is distributed according to the function $f(u)$. Equations [4] and [5] show that as the adsorption energy increases, i.e., $\Delta\Delta G^0_H$ becomes more negative, the hydrogen adsorption rates, k_1 and k_{-2}, increase and the desorption rates, k_{-1} and k_2, decrease.

In the above discussion the Langmuir isotherm was assumed; however, hydrogen adsorption may also proceed according to other isotherms, for example, the Frumkin/Temkin isotherms (28–30). The Frumkin/Temkin isotherm assumes that the adsorption energy depends on the surface coverage:

$$[14] \quad \Delta G^0_H = \Delta G^0_{H,0} + r\Theta$$

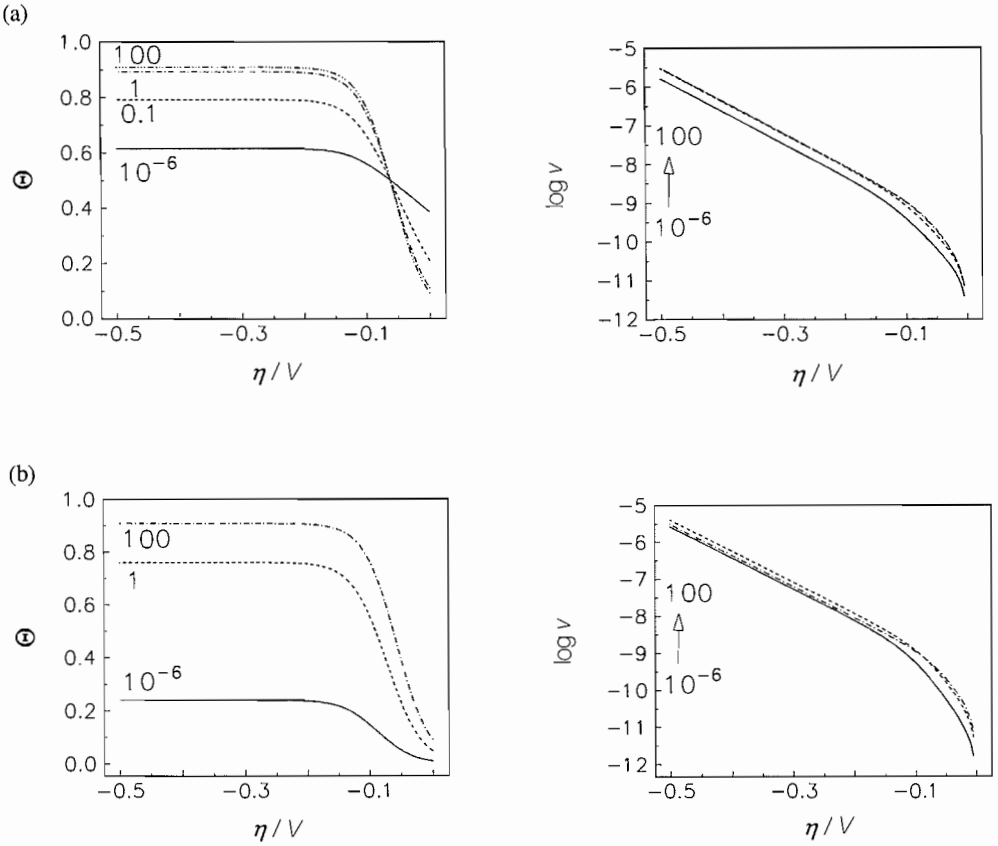
Such behavior may be due to interactions between adsorbed species or to the surface heterogeneity. Equation [14] leads to the following kinetic equations:

$$[15] \quad v_1 = k_1^0\,\mathrm{e}^{-\beta_1 g\Theta_H}\mathrm{e}^{-\alpha_1 f\eta}(1 - \Theta_H) - k_{-1}^0\,\mathrm{e}^{(1-\beta_1)g\Theta_H}\,\mathrm{e}^{(1-\alpha_1)f\eta}\Theta_H$$

$$[16] \quad v_2 = k_2^0\,\mathrm{e}^{(1-\beta_2)g\Theta_H}\mathrm{e}^{-\alpha_2 f\eta}\Theta_H - k_{-2}^0\,\mathrm{e}^{-\beta_2 g\Theta_H}\mathrm{e}^{(1-\alpha_2)f\eta}(1 - \Theta_H)$$

where $g = r/RT$, and to the adsorption isotherm:

$$[17] \quad \frac{\Theta_H}{1-\Theta_H}\mathrm{e}^{g\Theta_H} = \frac{\vec{k}_1 + \overleftarrow{k}_{-2}}{\overleftarrow{k}_{-1} + \vec{k}_2} = \overline{K}_H$$



Because these equations also describe heterogeneous surfaces, the results obtained will be compared with those obtained using distributed kinetics.

Gaussian and exponential distributions

The values of the total surface coverage, Θ_H, and the total reaction rate, V, were simulated for different values of the kinetic parameters. Rate constants chosen were similar to those used in the earlier simulations (31, 32). The distribution parameter γ has a strong influence on the total surface coverage, Θ_H, but a much smaller influence on the total reaction rate (i.e., current). The results of the simulations are presented in Fig. 2. Although Θ_H is very sensitive to the parameter γ, it has a very small influence on the observed currents. In addition, for the lowest values of parameter γ, change in the Tafel slope at low overpotentials is observed; however, at more negative overpotentials, where the surface coverage is constant, the classical Tafel slope is $RT\ln(10)/0.5F$ = 118 mV dec^{-1} (at 25°C). Similar results were obtained for the exponential distri-

Fig. 2. Influence of parameter γ on the surface coverages and the global rate of the HER for (*a*) Gaussian and (*b*) exponential distribution of adsorption energies; parameters used: $k_1^0 = 10^{-9}$, $k_{-1}^0 = 10^{-8}$, $k_2^0 = 10^{-10}$ mol cm^{-2} s^{-1}, $\alpha_i = \beta_i = 0.5$, $u = \Delta\Delta G_H^0/RT = \pm 10$, $\gamma = 10^{-6}$, 0.1, 1, 100.

bution of adsorption energies; these results are also presented in Fig. 2. Because the changes in the Tafel slope were observed for flat distribution of adsorption energies (low γ), further calculations were mainly carried out for low values of γ ($\gamma = 10^{-6}$).

The influence of the energy range used, $\pm\Delta\Delta G_H^0$, on Θ_H and V is shown in Fig. 3. An increase in $\Delta\Delta G_H^0$ causes a decrease in the values of the surface coverage, Θ_H, and an almost parallel decrease of the Tafel curves. These curves are obtained by integration of currents for different values of the parameter u. A change in the adsorption energies affects the currents and the surface coverages. Examples of Tafel curves for various adsorption energies (in the absence of the adsorption energy distribution, i.e., for homogeneous surfaces) are presented in Fig. 4. For $\Delta\Delta G_H^0$ equal to -10, $\Theta_H \ll 1$; for $\Delta\Delta G_H^0 = 10$, $\Theta_H \to 1$; and for $\Delta\Delta G_H^0 = 0$, Θ_H increases with overpotential from 0.09 to 0.91.

When the ratio of the rate constants k_1/k_2 increases, the overpotential range, where low Tafel slopes are observed, also increases, Fig. 5. The Tafel slopes obtained at low overpotentials are equal to 52–60 mV dec^{-1}. They are larger than the slopes observed at low overpotentials for the unique rate constants and, for a small ratio of k_1/k_{-1}, $RT \ln 10/1.5F = \sim 40$ mV dec^{-1}. The above analysis shows that low Tafel slopes may be obtained for distributed kinetics. It should be kept in mind that for very low values of γ there is no difference between the Gaussian and exponential distribution; the difference lies only in the initial k_i values and the energy range used for integration.

Frumkin adsorption isotherm

Similar simulations were carried out for the Frumkin adsorption isotherm. The parameter g (>0) has a very strong influence on the surface coverage by adsorbed hydrogen but relatively small influence on the Tafel curves, Fig. 6. Similarly, an increase in the ratio of k_1/k_2 extends the low slope range, Fig. 7, in a way similar to the results in Fig. 5. The Tafel slope is ~56 mV dec^{-1} at low overpotentials and 118 mV dec^{-1} at high overpotentials. These results are similar to those found for a flat distribution of adsorption energies under local Langmuir isotherms. Comparison of the dependence of Θ_H on overpotential for the flat distribution of adsorption energies under the Langmuir adsorption isotherm, Fig. 5, and for the Frumkin isotherm, Fig. 7, shows that at low overpotentials the surface coverage changes linearly with overpotential. This effect indicates that, under such conditions, Θ_H is described by the Temkin isotherm, i.e., it depends linearly on the free energy of adsorption (28, 33). It was shown (33) that the Temkin isotherm leads to a flat distribution function of adsorption energies ($\gamma \sim 0$) in a limited adsorption energy range, preceded and followed by a sharp decrease in $f(u)$. However, the Temkin adsorption isotherm is valid only for the surface coverages around 0.5 (~0.2 to ~0.8).

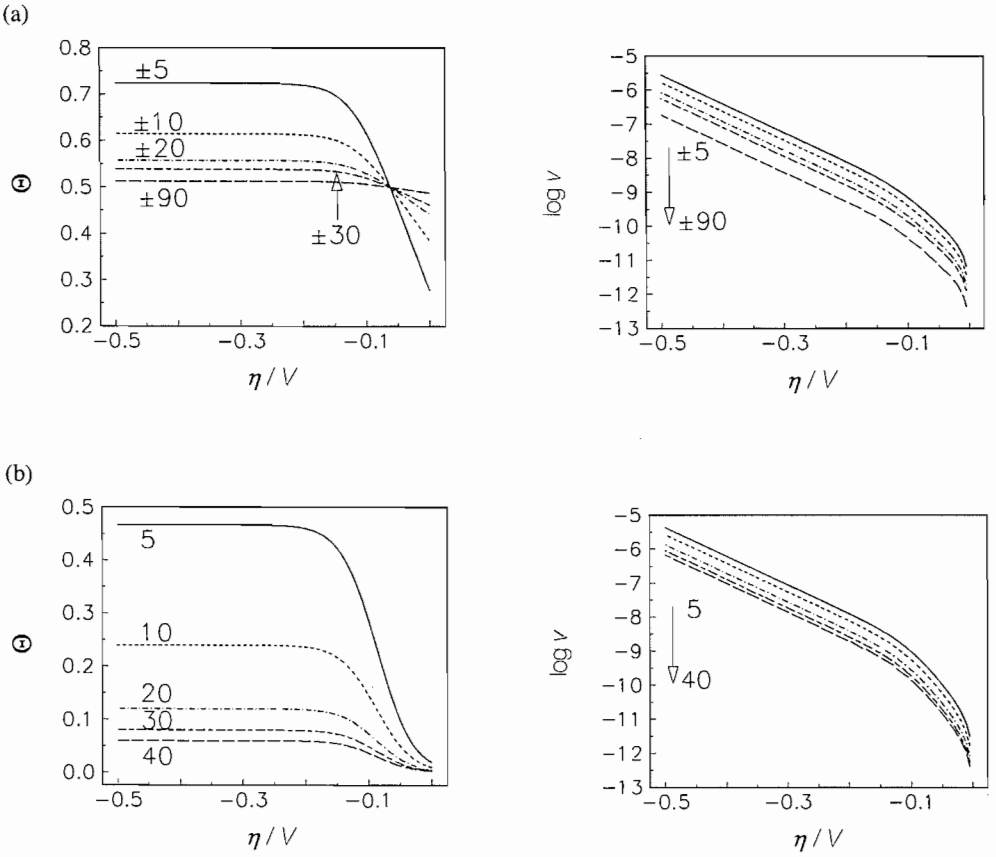
Fig. 3. (*a*) Influence of $\pm\Delta\Delta G_H^0/RT$ for Gaussian distribution and (*b*) of $\Delta\Delta G_H^0/RT$ for exponential distribution of adsorption energies; $\gamma = 10^{-6}$, other parameters as in Fig. 2.



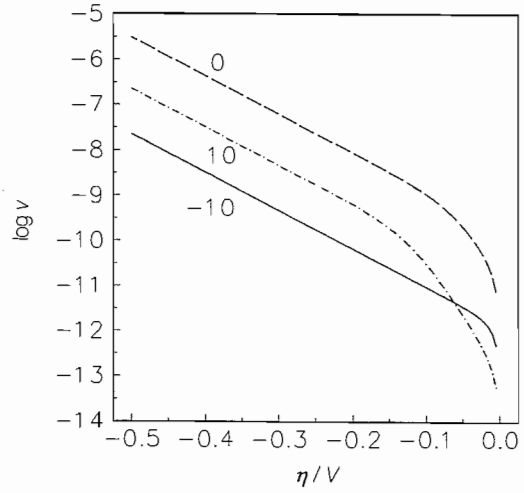


Fig. 4. Individual currents for different values of the adsorption energy; rate constants as in Fig. 2; the rate constants are, for $\Delta\Delta G_H^0/RT = -10$: $k_1 = 1.48 \times 10^{-7}$, $k_{-1} = 6.74 \times 10^{-11}$, $k_2 = 6.74 \times 10^{-13}$, for $\Delta\Delta G_H^0/RT = 0$ they are equal to k_i^0, for $\Delta\Delta G_H^0/RT = 10$: $k_1 = 6.74 \times 10^{-12}$, $k^{-1} = 1.48 \times 10^{-6}$, $k_2 = 1.48 \times 10^{-8}$ mol cm^{-2} s^{-1}.

Adsorption of organic compounds

If an organic compound, R, is present in the solution there is a competition between hydrogen and R for a free space. The kinetic equation for the hydrogen evolution displays a decrease of the free surface from $1 - \theta_H$ to $1 - \theta_H - \theta_R$:

[18] $$v_1 = k_1 e^{-\alpha_1 f\eta}(1 - \theta_H - \theta_R) - k_{-1} e^{(1-\alpha_1)f\eta}\theta_H$$

[19] $$v_2 = k_2 e^{-\alpha_2 f\eta}\theta_H - k_{-2} e^{(1-\alpha_2)f\eta}(1 - \theta_H - \theta_R)$$

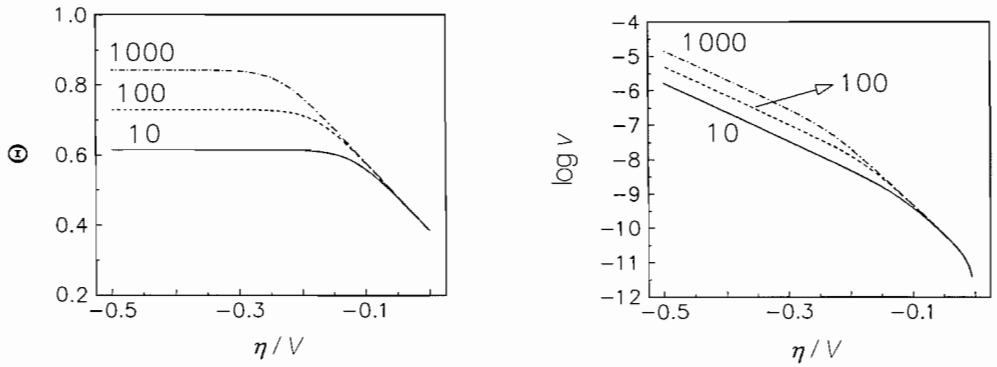
and produces the following isotherm:

[20] $$\frac{\theta_H}{1 - \theta_H - \theta_R} = \frac{\vec{k}_1 + \overleftarrow{k}_{-2}}{\overleftarrow{k}_{-1} + \vec{k}_2} = \overline{K}_H$$

It indicates that the chemical potential of adsorbed hydrogen remains unchanged (24). Two different cases of the adsorption of organic compounds were considered: (*i*) competitive equilibrium adsorption of H and R, in which both species are always at equilibrium and a change in the adsorption of one component causes a change in the adsorption of the other:

[21] $$\frac{\theta_R}{1 - \theta_H - \theta_R} = K_R C_R$$

and (*ii*) slow, i.e., irreversible, adsorption of an organic compound, in which R is first adsorbed (in the absence of adsorbed hydrogen) according to its adsorption isotherm and then its surface coverage remains unchanged during the experiment:



[22] $$\frac{\theta_R}{1 - \theta_R} = K_R C_R$$

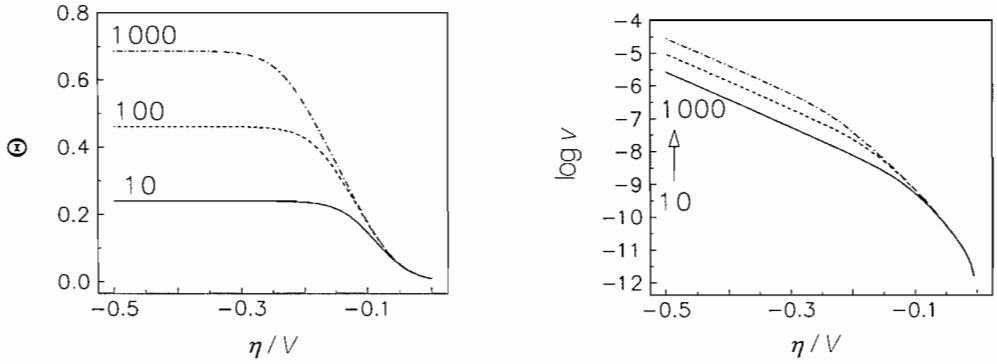
Fig. 5. Dependence of the surface coverage by adsorbed hydrogen and current on overpotential for (*a*) Gaussian and (*b*) exponential distribution of adsorption energies; the ratio of k_1/k_2 is indicated in the graph, $\gamma = 10^{-6}$, $\Delta\Delta G^0_H/RT = \pm 10$, $\alpha_i = \beta_i = 0.5$, $k_1/k_{-1} = 0.1$, $k_2 = 10^{-10}$ mol cm^{-2} s^{-1}.

(a)

(b)



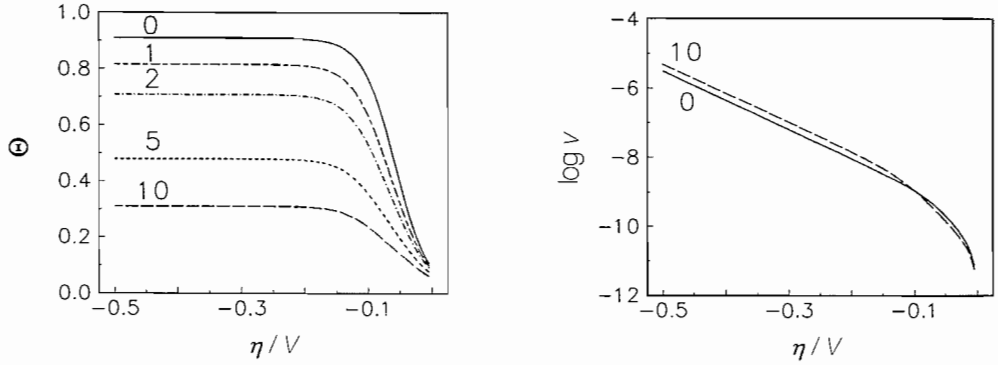


Fig. 6. Dependence of the parameter *g*, indicated in the graphs, on the surface coverage and the total rate of the HER; rate constants and transfer coefficients as in Fig. 2.

In the following simulations it was assumed that the centers, which have the highest hydrogen adsorption energy, also have the highest adsorption energy of organic molecules. This implies that the equilibrium constant K_R depends on the adsorption energy according to: $K_R = K^0_R \exp(-\Delta\Delta G^0_H/RT)$. The simulations were carried out for the Gaussian distribution of adsorption energies with flat distribution function, $\gamma = 10^{-6}$. Assuming $\Delta\Delta G^0_H/RT = \pm 10$, the equilibrium constant changes from 2.20×10^4 K^0_R to 4.54×10^{-5} K^0_R. Figure 8 presents the dependence of the surface coverage by adsorbed hydrogen and by organic molecules as functions of the overpotential. For reversible adsorption, an increase in the hydrogen adsorption at more negative potentials causes desorption of the organic compound. In the case of irreversible adsorption, Θ_R is constant and the adsorption of hydrogen changes with overpotential but remains low to satisfy eq. [20]. The current is only slightly lower at more negative potentials, at which the total reaction rate is given by:

$$[23] \quad v = 2k_1 e^{-\alpha_1 f\eta}(1 - \Theta_H - \Theta_R)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12

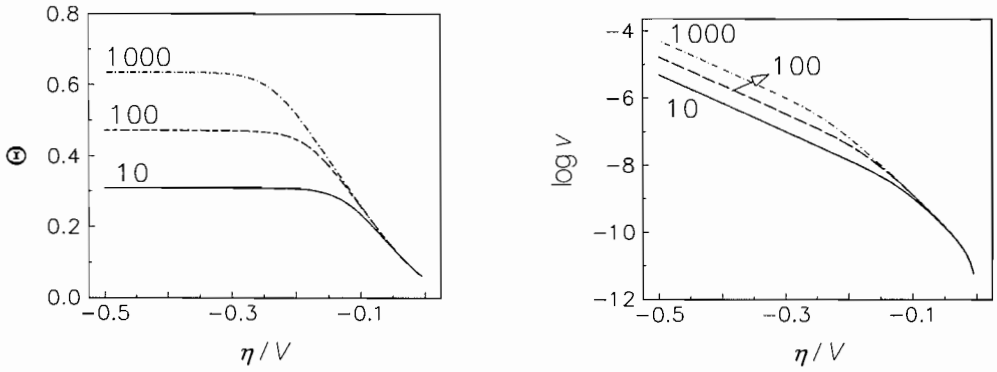
© 1997 NRC Canada

Fig. 7. Influence of the ratio k_1/k_2 on the surface coverage and total rate of the HER under the Frumkin isotherm; $g = 10$; other kinetic parameters as in Fig. 5.



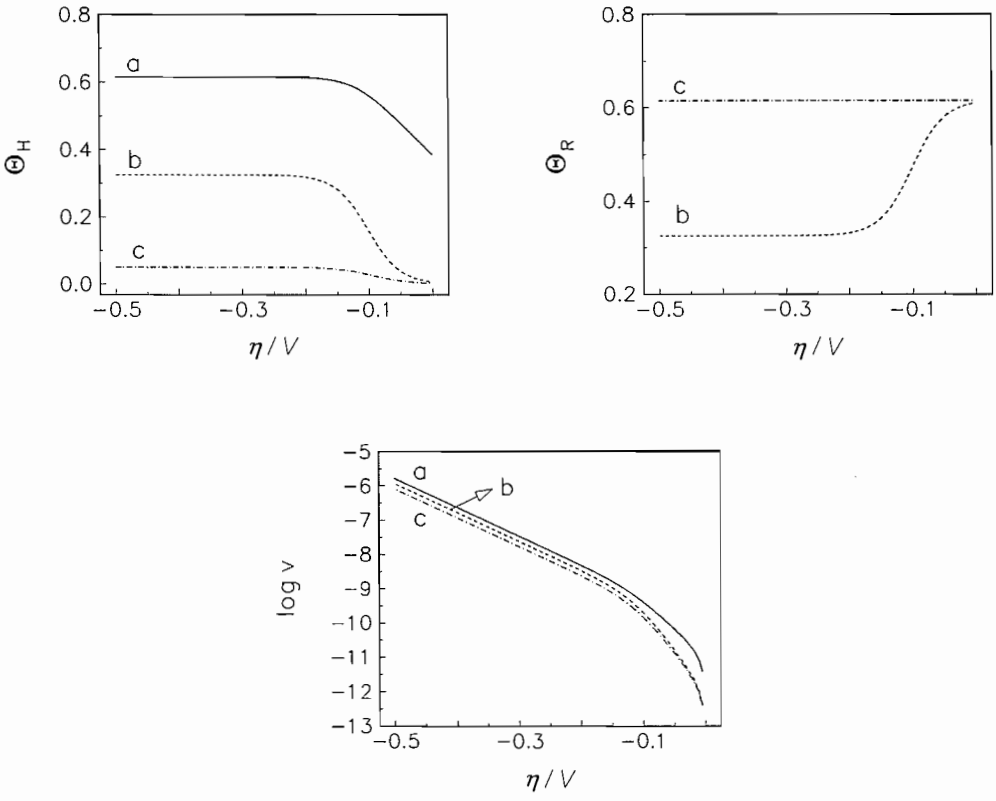


Fig. 8. Dependence of surface coverages and total current on overpotential for Gaussian distribution of adsorption energies: (*a*) in the absence of the adsorption of organic compound; (*b*) assuming reversible adsorption of H and R; (*c*) assuming irreversible adsorption of R; $K^0_R C_R = 10$, $k_1 = 10^{-9}$, $k_{-1} = 10^{-8}$, $k_2 = 10^{-10}$ mol cm^{-2} s^{-1}, $\Delta\Delta G^0_H/RT = \pm 10$, $\gamma = 10^{-6}$, $\alpha = \beta = 0.5$.

therefore the whole effect arises from changing $(1 - \Theta_H)$ to $(1 - \Theta_H - \Theta_R)$. It should be stressed that for some individual adsorption energies this effect is important, but for the flat dispersion of adsorption energies it is quite small. In fact, for the rate constants shown in Fig. 8 this parameter equals 0.385 in the absence of R, 0.350 for reversible, and 0.335 for irreversible adsorption of R. Similar curves for $k_1/k_2 = 1000$ and stronger adsorption of the organic compound, $K^0_R C_R = 100$, are presented in Fig. 9. It should be noticed that the Tafel slope at low overpotentials changes from 60 mV dec^{-1} in the absence of organic compound to 43 mV dec^{-1} in its presence, for the kinetic parameters given in Fig. 9. Because of the dispersion of the adsorption energies, the effect of adsorption of the organic compound on the observed current is smaller. For comparison, Tafel curves obtained in the absence of energy dispersion (in the presence and absence of R) are also included in Fig. 9.

Similar studies were carried out using the Frumkin isotherm. In this case an irreversible adsorption of the organic compound was assumed, that is, adsorbed organic molecules decreased only the available surface area, without affecting other parameters. Examples of the Tafel curves in the absence

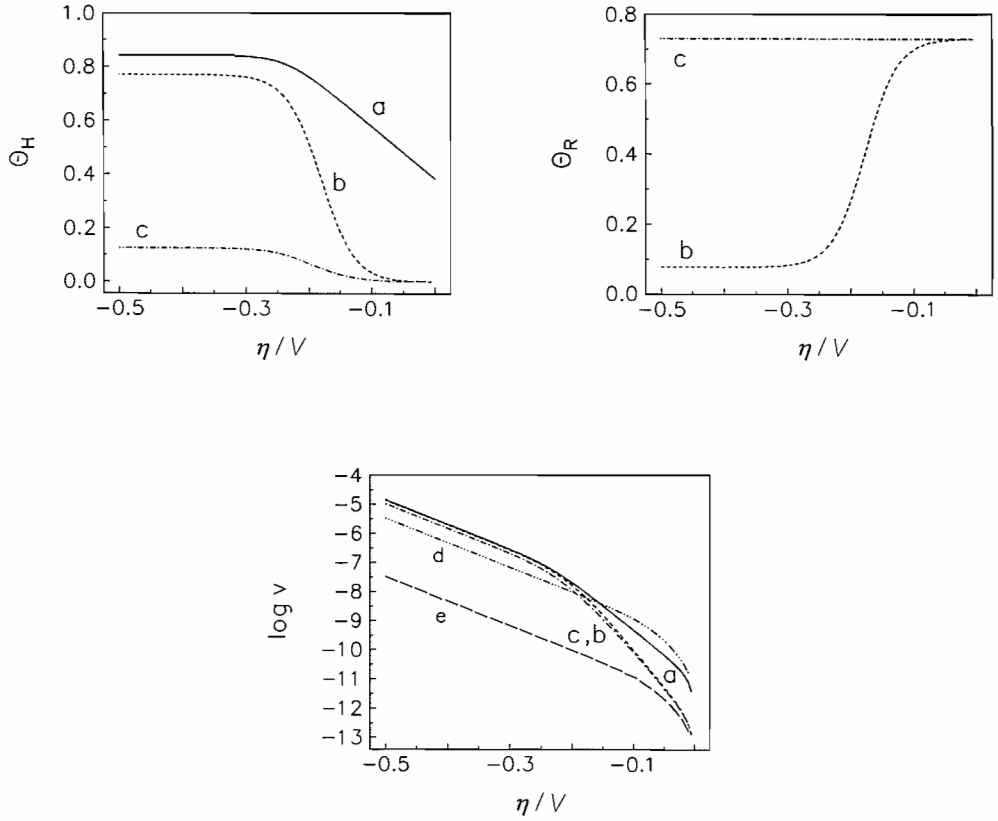
Fig. 9. Dependence of surface coverages and total current on overpotential for Gaussian distribution of adsorption energies: (*a*) in the absence of the adsorption of organic compound; (*b*) assuming reversible adsorption of H and R; (*c*) assuming irreversible adsorption of R; (*d*) assuming nondistributed rate constants in the absence of R; (*e*) assuming nondistributed rate constants in the presence of irreversible adsorption of R; $K^0_R C_R = 100$, $k_1 = 10^{-7}$, $k_{-1} = 10^{-6}$, $k_2 = 10^{-10}$ mol cm^{-2} s^{-1}; other parameters as in Fig. 8.



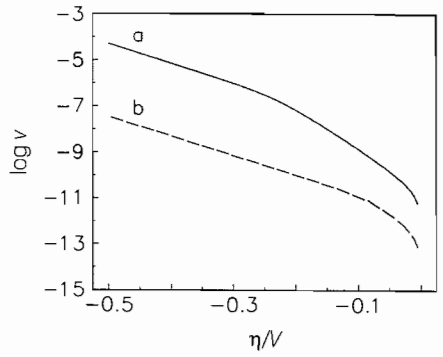


Fig. 10. Tafel curves for the HER using the Frumkin isotherm: (*a*) without organic compound; (*b*) in the presence of organic compound. Parameters used: $k_1 = 10^{-7}$, $k_{-1} = 10^{-6}$, $k_2 = 10^{-10}$ mol cm^{-2} s^{-1}, $K^0_R C_R = 100$, $g = 10$.

and in the presence of organic compounds are shown in Fig. 10. In the presence of the adsorption of the organic compound only one Tafel slope of 118 mV dec^{-1} is observed over the whole potential range. In this case of strong adsorption of the poison, the surface coverage by adsorbed hydrogen decreases significantly and the exponential term $\exp(g\Theta_H)$ in eq. [17] is negligible. Therefore the observed behavior is similar to the Langmuir isotherm.

It should be added that similar results were obtained for more realistic values of the γ parameter (e.g., $\gamma = 0.1$), but with further increase of γ the potential range, where low Tafel slopes were observed, decreased. Some more complex interactions are also possible, including repulsion forces between adsorbed H and R and (or) R and R, changes in the adsorption energy of H induced by adsorption of R, changes of symmetry coefficients α_i and β_i, etc. They also affect the observed Tafel slopes.

Discussion

Heterogeneity of the surface leads to the distribution of the adsorption energies. A model, including distribution of adsorption energies, leading to the distributed kinetics was applied to the hydrogen adsorption during the HER. Surface heterogeneity strongly affects the surface coverage by adsorbed hydrogen; however, this parameter cannot be directly measured (34, 35). Its effect on the observed currents depends on the values of the rate constants of the Volmer and Heyrovsky reactions. First, our simulations were carried out assuming the Langmuir adsorption isotherm. When the ratio $k_1/k_2 \leq 10$, only a small change in the slope is observed at low overpotentials. At higher overpotentials, for all cases studied, i.e., different kinetic and energy distribution parameters and different adsorption isotherms, the Tafel slope always equals that theoretically predicted for the Volmer–Heyrovsky mech-

anism without distribution, that is, $RT \ln 10 / 0.5F = 118$ mV dec^{-1} (at 25°C). Lower slopes of 42–60 mV dec^{-1} are observed only when the surface coverage changes with overpotential, that is, at low overpotentials. At low overpotentials, for low values of parameter γ, the adsorption of hydrogen is linear with overpotential, which is equivalent to the Temkin isotherm (28).

When the ratio k_1/k_2 increases, the potential range where low Tafel slopes are observed increases, especially for low values of the distribution parameter γ. Such slopes were observed experimentally for the HER on Ni–Zn electrodes in alkaline solutions. However, for the same kinetic parameters and $\gamma \rightarrow \infty$ (i.e., without adsorption-free energy distribution) only one Tafel slope of 118 mV dec^{-1} is observed.

Similar effects were found for the Frumkin adsorption isotherm with positive values of the parameter g; with an increase in the ratio of k_1/k_2, the potential range in which low Tafel slopes (~56 mV dec^{-1}) are observed increased.

In the case of the distributed kinetics, adsorption of organic compounds has a large effect on the surface coverage by adsorbed hydrogen but a much smaller effect on the observed currents, even for relatively strong adsorption (large $K_R C_R$). Because of the distribution of adsorption energies, values of the adsorption equilibrium constant vary from very small to very large, and the portion of the surface to which the very large values apply is limited. In addition, at negative overpotentials, the current depends on k_1 and a free surface unoccupied by H and R, eq. [23]. For large ratios of k_1/k_2 the surface coverage by adsorbed hydrogen is large ($\Theta_H \rightarrow 1$) and the free surface $1 - \Theta_H - \Theta_R$ does not change significantly with $K_R C_R$. It should be mentioned that in the presence of adsorption of foreign compounds the Tafel slope changes from ~60 to ~43 mV dec^{-1}.

In the case of the Frumkin adsorption isotherm, adsorption of R causes a change in the Tafel slope and only one slope of 118 mV dec^{-1} was observed. This behavior is related to a strong decrease of the surface coverage by adsorbed hydrogen and, consequently, change of the isotherm from Frumkin to Langmuir (at low coverages they are identical). Moreover, the observed HER current is reduced. Such behavior was earlier observed experimentally (20, 21).

The above simulations were carried out for a simple case of the Gaussian or exponential distributions of adsorption energies and $\alpha_i = \beta_i = 0.5$. For real electrodes the distribution function may vary from that theoretically assumed. In fact, in the case of physical adsorption, more complex distribution functions have been found experimentally (8, 9). Nevertheless, the distributed energy model predicts current–overpotential curves similar to those found experimentally and explains the influence of the adsorption of foreign substances on these curves.

The role of crystal imperfections in electrochemical phase formation and growth

G. Staikov and W.J. Lorenz

Abstract: The role of different crystal imperfections and surface inhomogeneities in the processes of electrochemical phase formation and crystal growth is discussed on the basis of experimental results obtained by electrodeposition of metals on native and foreign single crystal substrates in selected model systems. The major role of screw dislocations in the electrochemical growth of real crystals is demonstrated in the case of silver electrodeposition on silver single crystal faces prepared by the so-called capillary technique. Experimental results show that the electrochemical spiral growth of silver crystal faces with low dislocation density can be used for a preparation of surfaces with a defined and uniform density of monatomic steps. Combined electrochemical and in situ scanning probe microscopy (SPM) studies of underpotential deposition (UPD) of metals on foreign single crystal substrates show that surface inhomogeneities induce a stepwise formation of different low-dimensional (0D, 1D, and 2D) metal phases. The thermodynamic, kinetic, and structural aspects of the stepwise formation of Me phases of different dimensionality in the UPD range are discussed on an atomic level using results of electrochemical and in situ SPM measurements in various systems.

Key words: electrocrystallization, screw dislocations, spiral growth, surface inhomogeneities, underpotential deposition, low-dimensional phases, scanning tunneling microscopy.

Résumé : Se basant sur les résultats expérimentaux obtenus par électrodéposition de métaux sur des substrats constitués de cristal unique naissant et étranger, on discute du rôle des différentes imperfections du cristal et de l'inhomogénéité des surfaces lors de la formation et de la croissance des cristaux. On a mis en évidence le rôle prépondérant des dislocations hélicoïdales dans la croissance électrochimique de vrais cristaux dans le cas de l'électrodéposition de l'argent sur les faces d'un cristal unique d'argent préparé par la technique dite capillaire. Les résultats expérimentaux montrent que l'on peut faire appel à la croissance électrochimique en spirale des faces du cristal d'argent avec de faibles densités de dislocations pour la préparation des surfaces avec une densité définie et uniforme d'étapes monoatomiques. Des études combinées de microscopie de sonde à balayage «SPM» in situ et électrochimique du dépôt de métaux à faibles potentiels «UPD» sur des substrats de cristaux uniques étrangers ont permis de montrer que les inhomogénéités superficielles induisent une formation par étapes de différentes phases métalliques de faible dimension (0D, 1D et 2D). En se basant sur les résultats électrochimiques et des mesures in situ de «SPM» dans divers systèmes, on discute à un niveau atomique des aspects thermodynamiques, cinétiques et structuraux de la formation par étapes de phases Me de dimensions différentes dans le domaine du dépôt à de faibles potentiels.

Mots clés : électrocristallisation, dislocations hélicoïdales, croissance en spirale, inhomogénéités superficielles, dépôt à de faibles potentiels, phases de faibles dimensions, microscopie à balayage de l'effet tunnel.

Introduction

Real crystals are always imperfect in some respect and exhibit various structural imperfections of different dimensionality:

0D or point imperfections (atomic disorder, chemical impurities, etc.),

1D or line imperfections (edge and screw dislocations, etc.),

2D or planar imperfections (grain or subgrain boundaries, stacking faults, etc.),

3D or volume imperfections (crystal domains with different chemical and (or) physical properties).

The crystal surface, which can also be considered as a 2D crystal imperfection, plays an important role in the processes of phase formation and crystal growth. The structure and homogeneity of a crystalline surface depend strongly on the structure and perfection of the corresponding bulk crystal and on the surface treatment used. Generally the following surface inhomogeneities can be distinguished:

0D inhomogeneities (kinks, adatoms, vacancies, chemical impurities, emergence points of edge and screw dislocations, etc.),

1D inhomogeneities (monatomic steps, intersection lines of grain or subgrain boundaries, and stacking faults, etc.),

2D inhomogeneities (reconstructed surface domains, 2D islands and pits, surface domains or terraces with different chemical and (or) physical properties).

Received March 18, 1997.

This paper is dedicated to Professor Brian E. Conway on the occasion of his 70th birthday.

Fig. 1. In situ STM image of an electrochemically polished Au(111) surface in the system Au(111)/5×10^{-3} M $AgClO_4$ + 5×10^{-1} M $HClO_4$ at T = 298 K and ΔE = 200 mV.

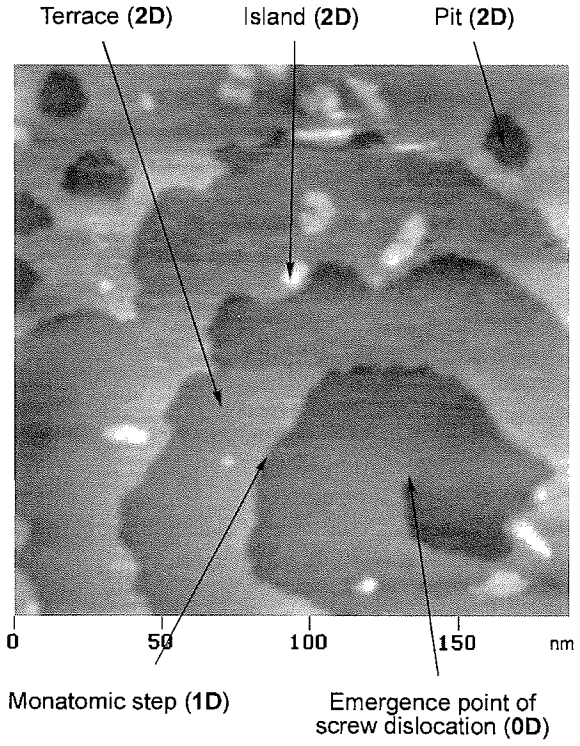

Fig. 2. In situ STM image with lateral atomic resolution of an atomically flat Ag(111) terrace in the system Ag(111)/10^{-2} M $HClO_4$ at T = 298 K and E_H = 350 mV.

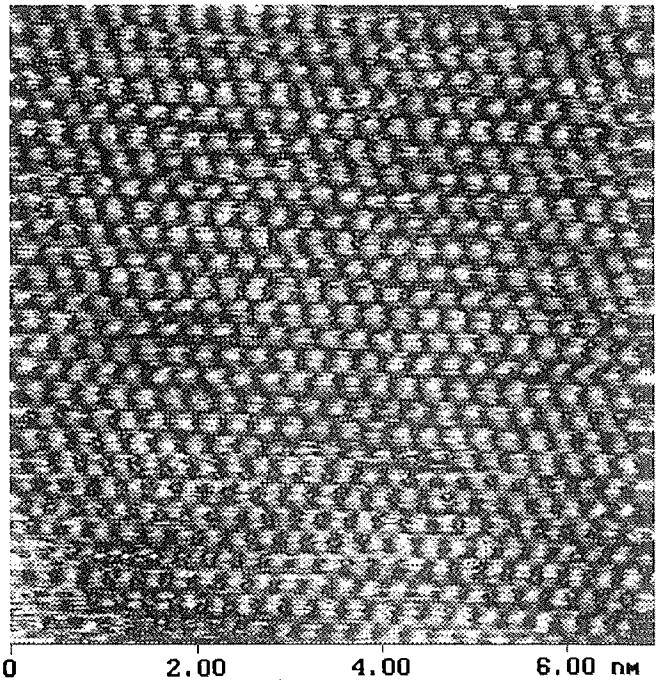

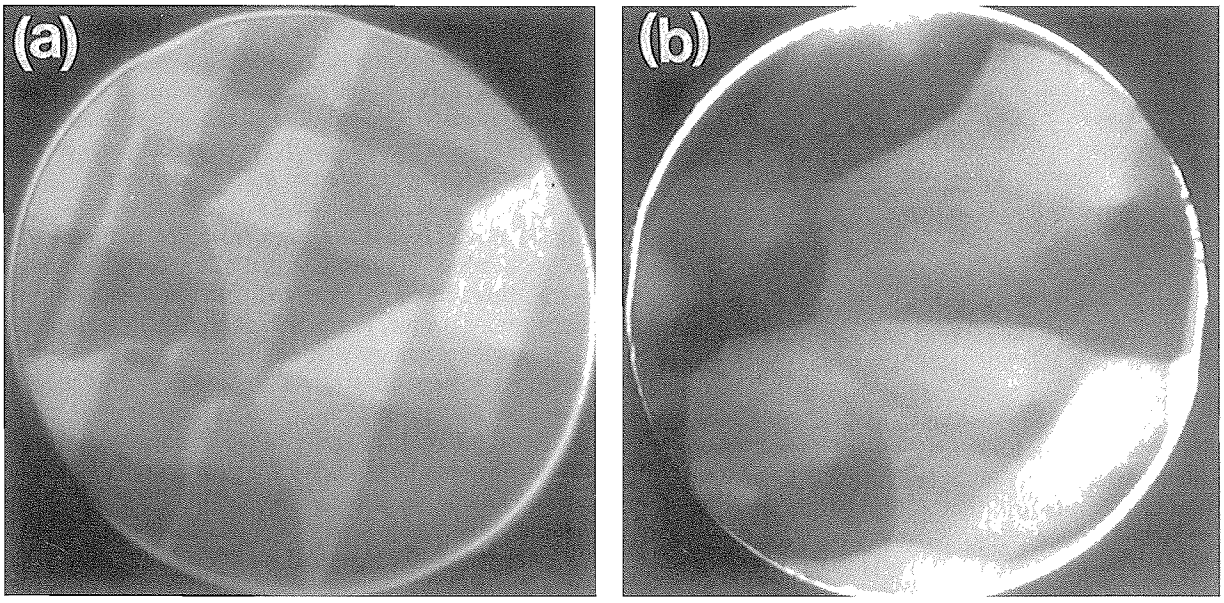

Fig. 3. Morphology of electrochemically growing Ag(100) crystal faces in the systems: (*a*) Ag(100)/6M $AgNO_3$ (aq) at T = 318 K; (*b*) Ag(100)/$AgNO_3$ (melt) at T = 573 K. Face area $A = 2 \times 10^{-3}$ cm^2.

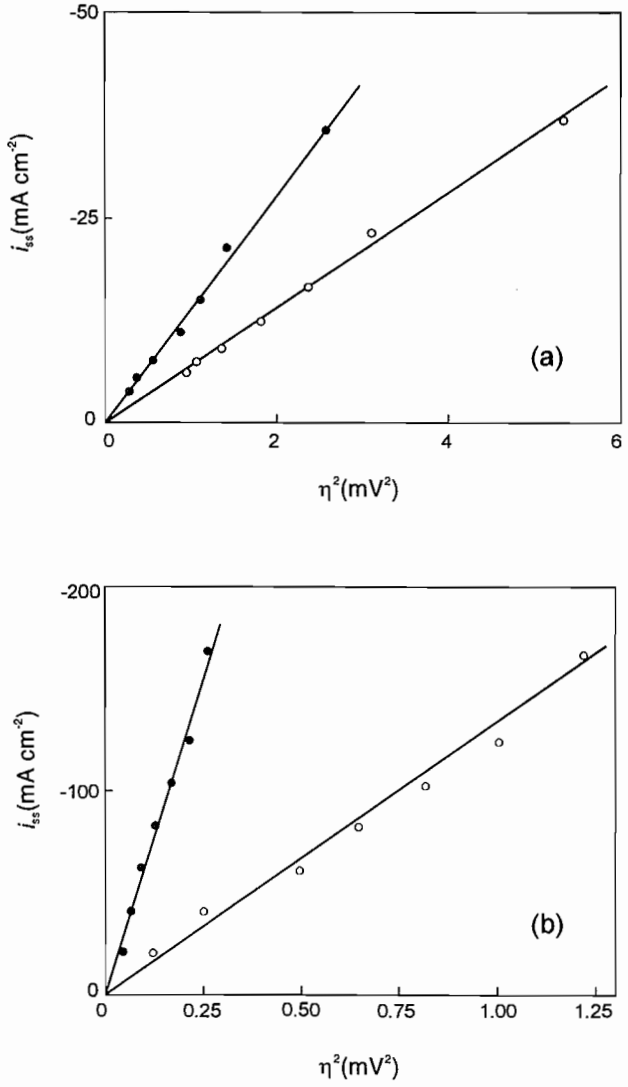

The heterogeneity of a real crystal surface can be well characterized on a nanometer scale by in situ scanning probe microscopy (SPM) techniques such as scanning tunneling microscopy (STM) and atomic force microscopy (AFM). Emergence points of screw dislocations, monatomic steps separated by atomically flat terraces, 2D islands and pits, etc. can be directly observed under defined electrochemical conditions as illustrated in Fig. 1. In addition, in situ SPM imaging with lateral atomic resolution provides important information about the local atomic structure of crystalline surfaces (Fig. 2).

The introduction of SPM techniques in electrochemistry opened a new window not only for the characterization of solid surfaces but also for studies of electrochemical phase formation on an atomic level.

The aim of this paper is to discuss the role of crystal imperfections and surface inhomogeneities in the processes of electrochemical phase formation and crystal growth on the basis of experimental results obtained by electrodeposition of metals on native and foreign single crystal substrates.

Formation of three-dimensional Me phases on native substrates induced by surface inhomogeneities

The growth of a crystal from an ambient phase takes place at supersaturation by incorporation of crystal building units in kink site positions. At undersaturation the 3D bulk crystal phase becomes unstable and dissolves.

In the case of electrochemical growth and dissolution of a metal crystal (1), i.e. electrochemical deposition and dissolution of a metal (Me) on native substrate (S = Me), the stability limit of the 3D Me bulk crystal phase is given by the Nernst equilibrium potential, $E_{3D\,Me}$:

$$[1] \quad E_{3D\,Me} = E^0_{3D\,Me} + \frac{RT}{zF} \ln\left(\frac{a_{Me^{z+}}}{a_{3D\,Me}}\right)$$

where $E^0_{3D\,Me}$ denotes the standard potential of the bulk Me phase, $a_{Me^{z+}}$ is the activity of Me^{z+} ions in the electrolyte phase, $a_{3D\,Me}$ and represents the activity of the 3D Me bulk phase, which is related to the activity of a Me atom in a kink site position. For a pure 3D Me bulk phase, $a_{3D\,Me}$ is equal to unity .

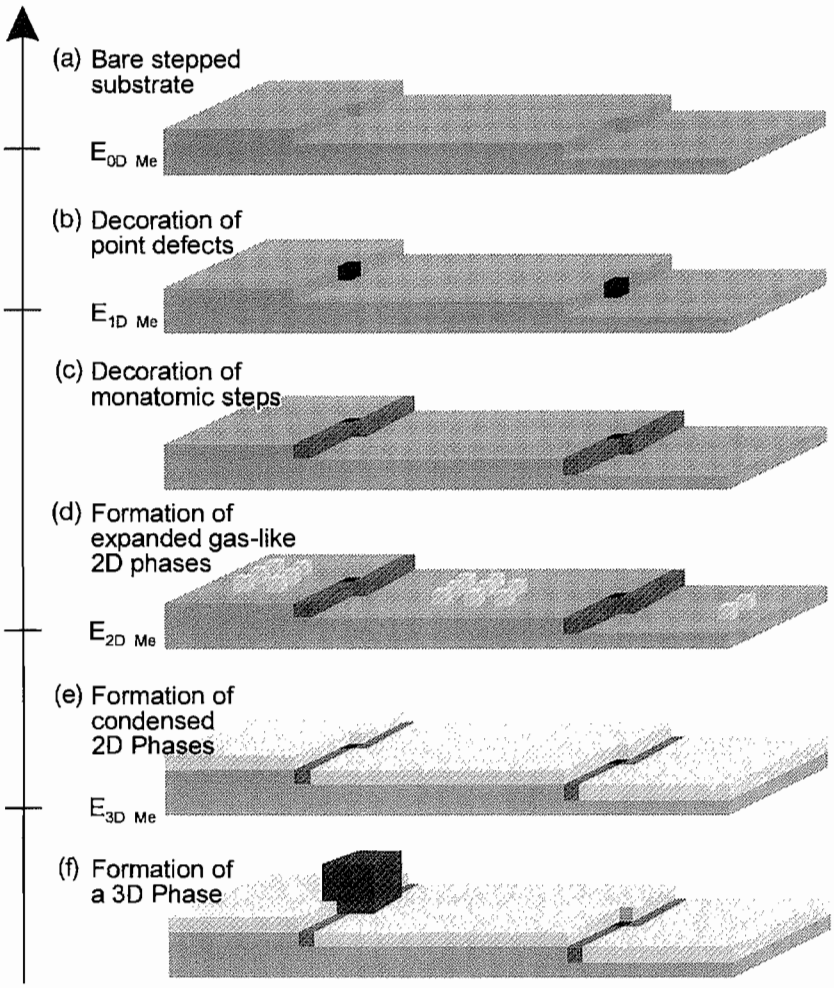
Assuming that charge transfer, diffusion, and chemical reactions of Me^{z+} are fast processes (i.e., do not determine the rate of crystal growth and dissolution), the supersaturation ($\Delta\mu > 0$) and undersaturation ($\Delta\mu < 0$) with respect to the 3D Me bulk crystal can be defined by the difference between the actual electrode potential, E, and the equilibrium potential, $E_{3D\,Me}$:

$$[2] \quad \Delta\mu^{def} = -zF(E - E_{3D\,Me}) = -zF\eta$$

where $\eta = E - E_{3D\,Me} < 0$ and $\eta = E - E_{3D\,Me} > 0$ represent the cathodic and anodic overpotential, respectively.

Crystal imperfections and surface inhomogeneities influence significantly the kinetics and mechanism of crystal growth and dissolution. As shown by Frank (2), screw dislocations are the most important crystal defects playing a major role in the growth of real crystal faces. Due to the helicoidal structure of this 1D crystal imperfection, a step originates from the point where the screw dislocation line intersects the crystal face. This step is constrained to terminate at the dislocation emergence point and winds up into a spiral during the growth process. The spiral step can never disappear and the crystal face grows perpetually, even at relatively low supersaturations, without the need of a 2D nucleation.

Screw dislocations are also active in crystal dissolution (cf. Fig. 1). For a given dislocation, however, the sense of the dissolution spiral is opposite to that of the corresponding growth spiral. Spirals are polygonized if the propagation rate of the steps is anisotropic. Formation of absolutely polygonized spirals, however, can only be expected at very low temperature. At room temperature spiral steps are usually curved on a nanometer scale (cf. Fig. 1). The height of spiral steps is related to the Burgers vector of the screw dislocation. In metal crystals the modulus of the Burgers vector usually does not exceed atomic dimensions, so that single screw dislocations produce monatomic steps (cf. Fig. 1).



According to the theory of spiral growth (1, 3–5), the steady state distance, d_S, between monatomic spiral steps generated by a single screw dislocation is given by

$$[3] \quad d_S(\eta) = 19\rho_{crit}(\eta) = \frac{19\varepsilon}{q_{mon}|\eta|}$$

where $\rho_{crit}(\eta)$ is the radius of the circle inscribed into the geometrical form of the 2D nucleus, ε is the specific edge energy

© 1997 NRC Canada

Fig. 5. Stepwise formation of Me phases of different dimensionally in the UPD and OPD ranges and the corresponding stability ranges indicated by E_{iD}.

of monatomic steps, q_{mon} is the charge density for deposition of a monolayer, and η is the overpotential.

Real crystal faces are usually intersected by more than one screw dislocation. If these dislocations are separated by a distance much larger than the size of the 2D nucleus, they operate independently of each other and d_S is given by eq. [3]. The problem becomes more complex if the emergence points of screw dislocations are located at distances comparable to the size of the 2D nucleus (1, 3).

Two screw dislocations of opposite sign produce at equilibrium only one step, which connects both emergence points of the dislocations. If the distance between emergence points is smaller than the size of the 2D nucleus, the step is not active and cannot grow at the given overpotential. If this distance, however, is larger than the size of the 2D nucleus, the screw dislocation pair produces loops of steps.

A group of n screw dislocations of the same sign that are closer than the size of the 2D nucleus generate n non-intersecting spirals. The resultant activity of such a screw dislocation group is approximately n times that of a single screw dislocation.

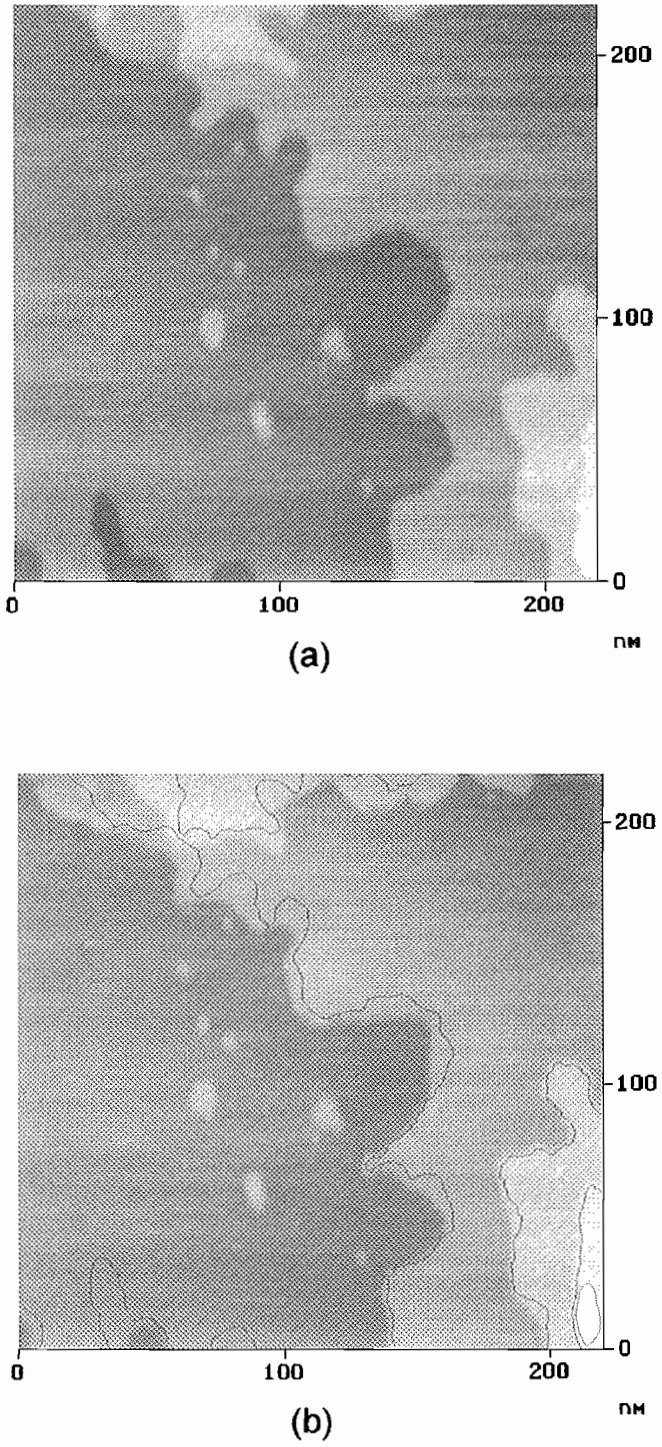
Circular or polygonized spirals or loops of steps with a monatomic height, h_{mon}, appear macroscopically as low cones or pyramids with a slope $\tan(\alpha) = (h_{mon}/d_S)$. The corresponding steady state current density, $i_{ss}(\eta)$, is given by (1)

$$[4] \quad i_{ss}(\eta) = - q_{mon}\, \nu(\eta)\, d_S^{-1}(\eta)$$

where $\nu(\eta)$ is the step propagation rate and $d_S^{-1}(\eta) = L_S(\eta)$ represents the step density.

For low cathodic overpotentials and a crystal face intersected by well-separated single screw dislocations from eqs. [3] and [4] follows

$$[5] \quad i_{ss}(\eta) = - \frac{q_{mon}^2\, \kappa_\nu}{19\varepsilon}\, \eta^2$$



where $\kappa_\nu = \nu(\eta)/|\eta|$ represents the propagation rate constant of monatomic steps, which is related to the exchange current density (1).

Well-defined and relatively simple conditions for an experimental investigation of the spiral growth mechanism offer silver single crystal faces prepared by the so-called capillary technique (1, 6–13). Such crystal faces have an extremely low crystal imperfection density and are usually intersected by only a few screw dislocations. Using this capillary technique,

both the morphology and kinetics of electrochemical growth of Ag(100) and Ag(111) faces have been studied in a 6 M $AgNO_3$ aqueous solution at T =318 K and in a $AgNO_3$ melt at T = 573 K (1, 9–11). As an example, Fig. 3 shows growing pyramids and cones with a uniform slope as observed by the electrochemical spiral growth of Ag(100) faces in 6 M $AgNO_3$ aqueous solution and $AgNO_3$ melt, respectively. Due to the elevated temperature in the second case (Fig. 3*b*) the propagation rate of monatomic steps becomes isotropic and leads to formation of low cones. Parabolic $i_{ss} - \eta^2$ dependencies have been found experimentally in both systems in good agreement with eq. [5] (Fig. 4). From experimental results the values of

(a)

(b)

the specific edge energy ε and (or) the density of monatomic steps $L_S(\eta)$ can be determined (1, 9–11). In this way stepped silver crystal faces with a regular step spacing and an exactly known step density can be prepared by electrochemical growth at constant overpotential η. Such crystal faces can successfully be used as substrates in various studies related to the influence of surface inhomogeneities on different electrochemical processes (1, 14–18).

Formation of low-dimensional Me phases on foreign substrates induced by surface inhomogeneities

The first step of electrodeposition of a metal (Me) on a foreign substrate (S ≠ Me) is the formation of isolated Me adatoms (Me_{ads}). If the binding energy of Me_{ads} on a more noble foreign substrate is higher than that on the native substrate, a phase formation process starts even at undersaturations with respect to the 3D Me bulk phase. This phenomenon is known as underpotential deposition (UPD) of metals (1). The undersaturation range is denoted by convention as underpotential range $\Delta E = E - E_{3D\,Me} > 0$.

Metal UPD processes can be strongly influenced by cosorption or competitive adsorption of electrolyte constituents such as anions. Such sorption processes accompanying Me UPD can be quantitatively characterized by the electrosorption valency defined by $\gamma = F^{-1}(\partial q/\partial\Gamma)_E = F^{-1}(\partial\mu/\partial E)_\Gamma$, where q and Γ denote the charge density and the Me surface coverage, respectively, and μ represents the chemical potential of Me^{z+} in the electrolyte. The elctrosorption valency can be directly measured, for example, by different thin-layer techniques as described in detail elsewhere (1).

However, for all Me UPD systems discussed in this paper, the electrosorption valency was found to be $\gamma = z$ by Twin-Electrode Thin-Layer (TTL) measurements. Consequently, cosorption and competitive adsorption phenomena of anions can be excluded for the systems under test (1).

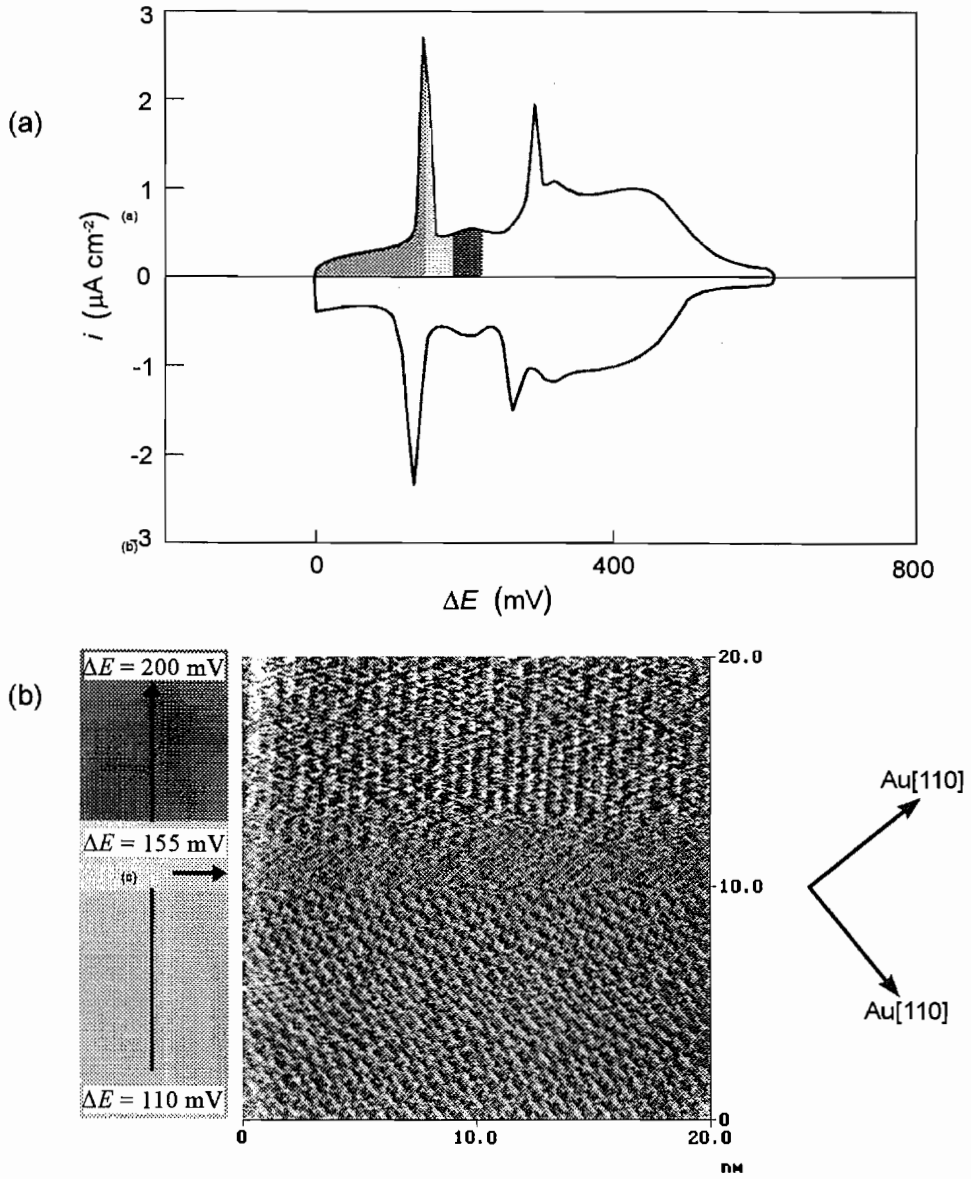
Electrochemical and in situ SPM studies of UPD of metals on real single crystal substrates show that different substrate surface inhomogeneities play an important role in this process, leading to formation of different Me phases with lower dimensionality (1, 19–21).

Generally, surface inhomogeneities are characterized by significant differences of the adatom binding energy and can induce formation of low-dimensional (0D, 1D, and 2D) Me phases with different energetics and structure in well-separated underpotential ranges. The condition for such stepwise phase formation process can be expressed by

$$[6]\quad \Psi_{Me_{ads}-S_{0D}} \gg \Psi_{Me_{ads}-S_{1D}} \gg \Psi_{Me_{ads}-S_{2D}} \gg \Psi_{Me_{ads}-Me}$$

where $\Psi_{Me_{ads}-S_{iD}}$ (i = 0, 1, 2) denotes the binding energy of a Me_{ads} on an iD surface inhomogeneity of the foreign substrate S and $\Psi_{Me_{ads}-Me}$ represents the binding energy of a Me adatom on native substrate.

The stability ranges of iD Me phases can be described by Nernst-type equations:



$$[7]\quad E_{i\mathrm{D\,Me}} = E^0_{i\mathrm{D\,Me}} + \frac{RT}{zF}\ln\left(\frac{a_{Me^{z+}}}{a_{i\mathrm{D\,Me}}}\right) \qquad \text{with } i = 0,1,2$$

where $a_{i\mathrm{D\,Me}}$ is a constant for condensed iD Me phases and $E_{i\mathrm{D\,Me}}$ represents the corresponding equilibrium potential. The supersaturation and the undersaturation with respect to a condensed iD Me phase are defined by:

$$[8]\quad \Delta\mu^{\mathrm{def}} = -zF(E - E_{i\mathrm{D\,Me}})$$

© 1997 NRC Canada

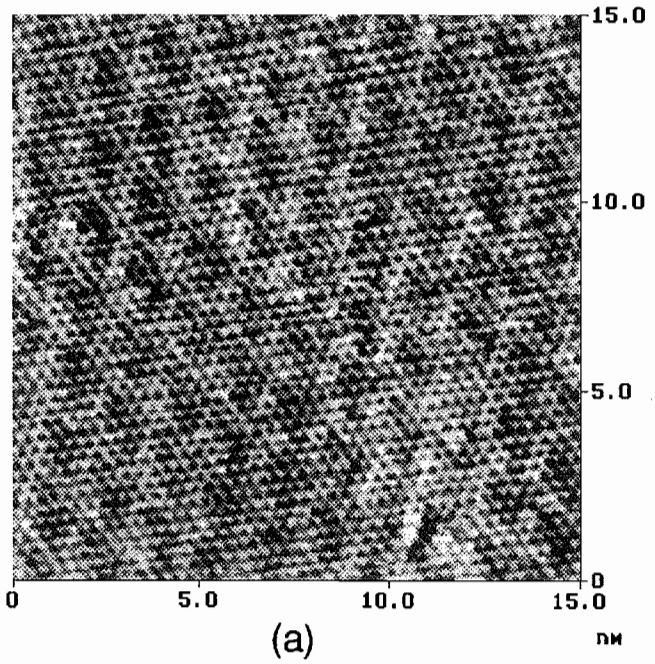
Fig. 8. First-order phase transformation in the system Au(100)/5 × 10^{-3} M $Pb(ClO_4)_2$ + 10^{-2} M $HClO_4$ at T = 298 K. (*a*) Cyclic voltammogram at a scan rate 10 mV s^{-1}; (*b*) in situ STM image during an anodic potential sweep from ΔE = 110 mV to ΔE = 200 mV. A condensed 2D hcp Pb phase showing an Au(100)–c(6 × 2) Pb moiré superstructure is imaged at ΔE < 155 mV in the lower part of this image. At ΔE > 170 mV the upper part of the STM image shows an expanded 2D Pb phase with an Au(100)–2c($3\sqrt{2} \times \sqrt{2}$) Pb R 45° superstructure. In the intermediate part of this STM image, the Au(100) substrate appears, indicating a very mobile Pb UPD adlayer.

For expanded *i*D Me phases formed by a continuous adsorption process (without first-order phase transition), $a_{i\mathrm{D\ Me}}$ becomes a function of $E_{i\mathrm{D\ Me}}$ at constant $\mu_{Me^{z+}}$, and eq. [7] represents the corresponding adsorption isotherm.

The stepwise formation of low-dimensional Me phases on a stepped substrate in the UPD range is shown schematically in Fig. 5.

0D Me phase formation can start at extremely high underpotentials by a decoration of 0D surface inhomogeneities. For instance single Me adatoms or small Me clusters deposited on kink sites of the foreign substrate can be considered as 0D Me phases (cf. Fig. 5*b*).

The decoration of monatomic steps represents an 1D Me phase formation (cf. Fig. 5*c*). Such a preferential decoration of monatomic steps at relatively high underpotentials was directly observed by in situ SPM in various Me UPD systems (1, 19–24). The width of this step decoration extends up to several nanometers, indicating a high activity of the step edge. Figure 6 shows an example for step decoration in the system Ag(100)/Pb^{2+} (24).



The processes of decoration of kinks and steps are followed by formation of different 2D Me phases on 2D surface inhomogeneities (1). At medium underpotentials, expanded commensurate 2D Me adlayers can be formed by localized

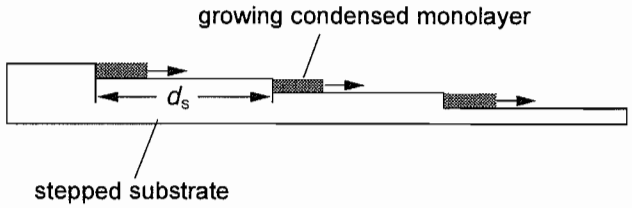
Fig. 9. Compressed 2D hcp Pb UPD overlayer showing a superstructure with moiré pattern in the system Au(111)/5 × 10^{-3} M $Pb(ClO_4)_2$ + 10^{-2} M $HClO_4$ at T = 298 K and ΔE = 50 mV. (*a*) In situ STM image; (*b*) 2D Fourier transform of (*a*).



adsorption on atomically flat terraces (cf. Fig. 5*d*). Typical examples of Ag(100) − c(2 × 2)Pb and Au(100) − c(2 × 2)Pb superlattice structures are shown in Fig. 7 (1, 24).

At lower undersaturation, expanded 2D Me phases usually transform into condensed Me monolayers via a first order phase transition (cf. Fig. 5*e*). Such a phase transition is demonstrated in Fig. 8 for Pb UPD on Au(100) (1, 24). A stable

Fig. 10. Schematic representation of a growing condensed monolayer on a foreign substrate exhibiting parallel steps with a constant step spacing d_S.

condensed 2D hcp Pb phase showing an Au(100) − c(6 × 2) Pb moiré superstructure and an expanded 2D Pb phase with an Au(100)–2c($3\sqrt{2} \times \sqrt{2}$) Pb R 45° superstructure are observed at low and medium underpotentials, respectively. The phase transition occurs within a narrow underpotential range of about 15 mV at the applied anodic potential scan rate of $|dE/dt|$ = 10 mV s^{-1}.

Condensed Me UPD overlayers are either commensurate, higher order commensurate, or incommensurate depending on the crystallographic Me–S misfit (1). As an example, the moiré structure of a close-packed Pb UPD overlayer on Au(111) at low underpotentials is shown in Fig. 9 (1, 19). Due to the significant crystallographic Pb–Au misfit the overlayer is incommensurate, isotropically compressed, and rotated with respect to the Au(111) substrate. Analysis of the corresponding 2D Fourier transform (Fig. 9*b*) indicates a modulation of Pb–Pb interatomic distances, in good agreement with the static distortion waves (SDW) model proposed by Novaco and McTague (1, 25–27).

The formation of condensed 2D phases in the UPD range involves 2D nucleation and growth phenomena. It is well known that surface inhomogeneities of the foreign substrate such as monatomic steps significantly influence the thermodynamics and kinetics of 2D nucleation (1, 28). Sites at monatomic steps are energetically more favorable for 2D nucleation than sites at atomically flat terraces. Thus, at relatively low supersaturations the nucleation of the condensed 2D Me phase takes place, practically, only on monatomic steps. As shown above, monatomic steps of the substrate are usually modified by a 1D Me phase that acts as precursor for the formation of the condensed 2D Me phase.

The heterogeneity of the substrate surface influences not only the nucleation act, but also the 2D growth of the condensed monolayer. Thus the theoretical treatment of 2D nucleation and growth kinetics on real crystal substrates is complicated due to the presence of different edge effects related to surface inhomogeneities. A relatively simple situation is obtained in the case of formation of a condensed monolayer on a foreign substrate exhibiting, as surface inhomogeneities, only parallel monatomic steps with a constant step spacing d_S (Fig. 10), Assuming that the phase formation process starts only at monatomic steps and that the steps are instantaneously (at t = 0) covered by the condensed 2D phase, the current density connected with the spreading of the condensed monolayer can be described by (1, 19, 21)

$$[9] \quad -i(t) = \begin{cases} q_{cd}\, d_S^{-1}\, v = q_{cd}\, L_S\, v & \text{for } 0 \le t < d_S\, v^{-1} \\ 0 & \text{for } t = d_S\, v^{-1} \end{cases}$$

Fig. 13. Current transients for the formation of a condensed Pb monolayer on a stepped Ag(111) substrate in the system Ag(111)/5 × 10^{-3} M $Pb(ClO_4)_2$ + 5 × 10^{-1} M $NaClO_4$ + 5 × 10^{-3} M $HClO_4$ at T = 298 K. Potential pulses from ΔE_i = 300 mV to ΔE_f = 20 mV (1); 50 mV(2); 110 mV(3).

where q_{cd} and v represent the charge density and the propagation rate of the condensed monolayer, respectively. The corresponding current transient is shown in Fig. 11*a*.

Surfaces of real crystals, however, are usually characterized by atomically flat terraces, 2D islands and pits, as well as by a nonuniform distribution of monatomic steps that can be rough and frizzy, leading to a "fractal dimensionality" of *i*D with $1 \leq i \leq 2$ (1, 29, 30). These inhomogeneities can strongly influence the shape of the corresponding current transients (Fig. 11*b*). Thus analysis of experimental current transients requires exact information about the local mechanism of monolayer formation and the substrate surface morphology on an atomic level.

Direct evidence for formation of a condensed monolayer starting exclusively at monatomic steps was obtained recently by combined electrochemical and in situ STM studies of Pb UPD on Ag(100) and Ag(111) substrates (1, 23, 24). The process of monolayer formation occurs at monatomic steps that are modified by an 1D Pb phase (cf. Fig. 8) formed at undersaturations with respect to the condensed 2D phase. Figure 12 shows the change of the surface morphology during the formation of the condensed 2D Pb phase on a Ag(111) substrate. The appearance of a growth front starting at monatomic steps is clearly seen in the in situ STM image (Fig. 12*c*) corresponding to peak A_2 of the cyclic voltammogram (Fig. 12*a*). The shape of experimental current transients (Fig. 13) is in good agreement with the model discussed above (cf. Fig. 11*b*).

Conclusions

The influence of crystal imperfections and surface inhomogeneities on the processes of electrochemical phase formation and crystal growth is demonstrated in various studies of electrodeposition of metals on native and foreign single crystal substrates.

Screw dislocations play the most important role in electrodeposition of metals on native substrate. A quantitative investigation of the spiral growth mechanism, however, is possible only on single crystal faces with a relatively low screw dislocation density. Experiments on such crystal faces prepared by the so-called capillary technique conform to Frank's spiral growth theory. Surfaces with uniform and well-defined step density can be prepared by electrochemical growth of crystal faces with low screw dislocation density.

A significant progress in understanding the role of surface inhomogeneities in the initial stages of electrochemical metal phase formation on foreign solid substrates is achieved by introducing in situ SPM techniques. Combined electrochemical and in situ SPM studies of the UPD of metals show that surface inhomogeneities induce a formation of low-dimensional (0D, 1D, and 2D) metal phases in different underpotential ranges.

Further development of theories and experiments on an atomic level is necessary for a better understanding of the role of crystal imperfections in the electrochemical formation of phases of different dimensionality.

Impact of electrode geometry, depth of immersion, and size on impedance measurements

Petr Vanýsek

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12

Abstract: Although the platinum electrode is used regularly in the practice of electroanalytical chemistry, there are some caveats that should be considered in experimental design and data interpretation when ac impedance measurements are made. A wire electrode was immersed only partially with the purpose of decreasing its effective area. Impedance was used to study the effect of partial immersion. In the case of an NaOH solution, a good impedance fit was found if a transmission line was added to the equivalent circuit. Transmission line behavior corresponds to the transversal conductivity in the wet, though not immersed, surface. Impedance was further compared for a wire electrode, as well as for short wire electrodes with metal spheres attached to their end. The shorter, predominantly spherical, electrode minimizes impedance artifacts at higher frequencies, thus serving as a better electrode for impedance studies. The change in impedance after depositing platinum black was used to estimate the effective surface area increase.

Key words: electrochemical impedance spectroscopy, platinum, electrode shape, partial immersion, platinum black, sodium hydroxide.

Résumé : Même si l'électrode de platine est régulièrement utilisée dans la pratique de la chimie électroanalytique, il est nécessaire de considéré certaines de ses limites dans la mise au point des expériences et dans l'interprétation des données découlant de mesures d'impédance à ca. On n'a immergé que partiellement une électrode à fil afin de diminuer sa surface effective. On a utilisé l'impédance pour étudier l'effet de l'immersion partielle. Dans le cas d'une solution de NaOH, on a obtenu une bonne corrélation d'impédance à la condition d'ajouter une ligne de transmission au circuit équivalent. Le comportement de la ligne de transmission correspond à une conductivité transversale d'une surface mouillée, mais non immergée. On a aussi comparé l'impédance d'une électrode à fil ainsi que celles d'électrodes à fil court auxquelles on a fixé des sphères métalliques à leur extrémité. L'électrode plus courte, qui est essentiellement sphérique, minimise les artefacts de l'impédance à des fréquences plus élevées et elle est donc une meilleure électrode pour les études d'impédance. On a utilisé le changement d'impédance après dépôt de noir de platine pour évaluer l'augmentation de la surface effective.

Mots clés : spectroscopie électrochimique d'impédance, platine, forme de l'électrode, immersion partielle, noir de platine, hydroxyde de sodium.

Introduction

Platinum is the most typically encountered metal in electrodes used in research laboratories. It is routinely regarded as an inert metal, which does not itself enter into a chemical or an electrochemical reaction. It is used as a stable gauze electrode in electrogravimetry for bulk electrodeposition and, in various forms, sizes, and shapes, it is used as the working electrode both in electroanalytical and electrokinetic applications. In addition, it is often discussed as the oxidation–reduction electrode, or the electrode of the zeroth kind, a piece of metal immersed in a solution of two oxidation states of certain species. The metal merely mediates the transfer of electrons between the two species. Platinum as the working electrode is used by a wide range of individuals with various degrees of experience in order to obtain impedance in a solution. Impedance can be probed for such tasks as measurements of the double-layer capacitance, adsorption, surface area, or reaction kinetics.

In many of these studies, impedance is used as one of the techniques to probe the kinetics or mechanism of the reaction or surface state. However, there has been some indication in the literature that the shape of the electrode, or the arrangement of all the electrodes, can influence the quality of the measurement. In particular, capacitance obtained from ac data is often used for the area measurement of Pt as well as of other electrodes. Therefore, the goal of this experiment is to examine the impact of the shape of the electrode, as well as depth of immersion into solution, on the obtained impedance data.

Fig. 1. Voltammogram of polycrystalline platinum in 1 mol/L NaOH. Scan rate 100 mV/s. Electrode area 11 mm^2.

General cyclic voltammetry response

Figure 1 is an example of a voltammogram of platinum in 1.0 mol/L NaOH. One can obtain this result with standard chemicals, without special purification. The positive scan from 0.6 V shows a current increase that is due to the formation of platinum oxide. The additional current increase toward the upper end of the scan (1.5 V vs. RHE) corresponds to oxygen evolution (oxidation of water) and a further continuation of the scan in the positive direction would result in an increase of the recorded current. The prominent peak observed on the negative scan (at about 0.76 V vs. RHE) is due to the reduction of the surface oxide. The "butterfly" peaks, as they are named for their shape, at 0.3 V and below, correspond to surface adsorption of a monolayer of hydrogen atoms (negative current) and their subsequent desorption (positive current). The scan is reversed slightly before 0.0 V vs. RHE, as scanning any further would result in the massive evolution of hydrogen gas; there is already a hint of this evolution in the voltammogram.

The region between 0.35 and 0.75 V vs. RHE corresponds primarily to the charging of the double layer. Impedance was measured at 0.6 V vs. RHE where little or no faradaic process takes place, and the impedance response is due to the electrode capacitance.

Electrochemical impedance

Impedance as a method for characterization of the electrical parameters of a material has been embraced by electrochemists for quite some time. The method is, at least in principle, suitable for resolving the resistive, capacitive, and inductive components of a system under study. The available instrumentation is adequate for such a task. Interpretation, however, is sometimes problematic because, often, individual factors contributing to the impedance cannot be resolved, or the impedance data lend themselves to a number of interpretations. Platinum metal in a solution can be investigated by impedance on several fronts. At the potentials of electrochemical inactivity, the metal surface behaves as a capacitive double layer, and its capacitance can be directly measured. During hydrogen adsorption, the adsorptive layer also appears to the impedance probe as capacitance, although much higher than the double-layer capacitance. This result can, again, be interpreted as capacitance and is often labeled as pseudocapacitance. On the positive side of the polarization potential, where metal oxides are formed, the impedance signature can reveal the presence of an additional layer at the surface.

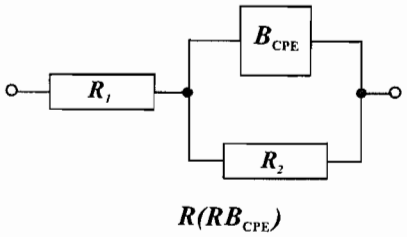
A number of impedance studies in electrochemistry on Pt have been reported by Conway (1–11). The work was mostly concerned with interpretation of faradaic reactions, adsorption, supercapacitors (devices with especially high pseudocapacitive values), and even work in nonaqueous solvents. Using impedance also allows one to probe the roughness or porosity of metal surfaces (5, 6). Although true inductance in electrochemistry (source of current) is not seen, behavior appearing as inductance is; it is labeled as pseudoinductance (8). A comprehensive book on impedance, emphasizing solid materials, has been edited by Macdonald (12).

Impedance measurements are based on determining the dynamic ac resistance of a system as a function of the ac frequency. The parameter obtained consists of two values, the ratio of the potential and current (i.e., the "resistance"), and the phase shift between the potential and the current. The measurement of impedance at a number of frequencies (electrochemical impedance spectroscopy) can provide kinetic parameters as well as an insight into the structural properties of the electrode–solution interface. Resistive components of the impedance are often associated with a charge transfer process or a faradaic current, whereas capacitive response has to do with separation of charge and dielectric behavior. A double layer is an example of a structure that has electrical capacitance; in impedance study it is seen as a capacitor. In the case of Pt in NaOH solution, the double-layer capacitance can be seen.

Ideally, a capacitor will have its impedance Z as a function of frequency ω expressed as

$$[1] \quad Z(\omega) = R - 1/(j\omega C)$$

where C is the capacitance, j is the imaginary unit $j = \sqrt{-1}$, ω the angular frequency ($\omega = 2\pi f$, where f is frequency in Hz), and R is a resistance of the system in series with C, usually originating from the solution resistance. However, in practice, the electrochemical equivalents of capacitors and resistors are not point, localized, components. They tend to be spread or distributed over a distance. The impedance of such distributed parameters usually needs to be written in a more complex form as (13, 14)



$$[2] \quad Z(\omega) = R - 1/B_{CPE}(j\omega)^n$$

where the fraction $1/B_{CPE}(j\omega)^n$ is known as the constant phase element (CPE), a value with two parameters. The parameter B_{CPE} is the magnitude of the constant phase element and is often called just the constant phase element.[2] The power fac-

[2] Symbol B is used in electricity and magnetism for susceptance. Here it is used for the value of the constant phase element, B_{CPE}. Though not strictly susceptance, the CPE is in close relationship to it. The B symbol is less misleading than Q, which is used for the CPE value in the EQUIVCRT program, but is otherwise used routinely as a symbol for charge.

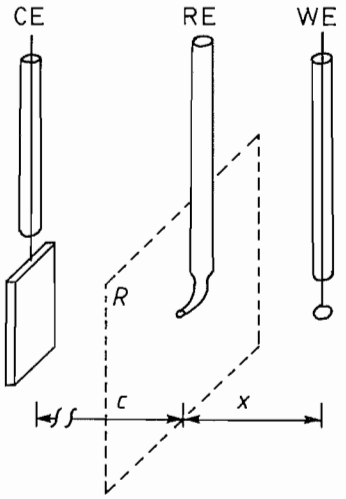
Fig. 2. Diagram of the simple equivalent circuit coded as $R(RB_{CPE})$ used in the text. R: resistance (R_1, solution resistance; R_2, charge transfer resistance), B_{CPE}: constant phase element (CPE).



tor, n, can attain values between 0 and 1. For $n \rightarrow 1$, eq. [2] becomes eq. [1], with $B_{CPE} = C$. It has been shown that the parameter n becomes smaller for rougher surfaces (13, 15). In some work, the $n < 1$ was interpreted in terms of fractal analysis (13, 15–17). In much of practical work, when n is not too far from unity, the B_{CPE} is simply reported as capacitance, C. However, the use of CPE in modeling can account for non-idealities, without their quantitative description (18). The value of $n = 0.5$ has special meaning. Experimentally, it corresponds to resistance caused by diffusion control. This special case of CPE is called the Warburg impedance.

In many cases, a simple model, expressed as $R(RB_{CPE})$ and shown in Fig. 2, was used to evaluate impedance at potentials without electron transfer. The first R in the notation is R_1, a series resistance usually associated with the resistance of solution. The notation of the two elements in parentheses implies that they are in parallel. B_{CPE} is the value of the constant phase element and R is a resistance, R_2, which corresponds to a charge transfer (reaction) resistance.

Experimental

Both the voltammetric and the impedance work were carried out in a standard glass electrochemical cell with two compartments, separating the reference electrode part from the rest of the system by a ground-glass stopcock and a Haber–Luggin capillary terminating in the vicinity of the working electrode. Hydrogen gas (compressed gas, Airco), at a rate of about 10 mL/min, was allowed in the compartment of the reference reversible hydrogen electrode (RHE), which was filled with 1.0 mol/L NaOH. Nitrogen (compressed gas, Airco) gas was bubbled through the working electrode compartment prior to the measurements to displace the solution oxygen. In some experiments a fourth electrode, in the form of a platinum wire connected through a 0.47 μF or 2.4 μF capacitor to the reference electrode, was used to compensate for high-frequency distortion. However, in most measurements, this connection was deliberately omitted to observe the natural behavior of the system. From our experience, the size, shape, or even the placement of this fourth electrode in the cell has very little effect on the overall impedance response, as long as such electrode is present in the working solution compartment. The physical layout of the electrode placement in the cell is shown in Fig. 3. The distance between the working and counter electrode (i.e., $c + x$) was 20 mm. The cell was open to the atmosphere; therefore, the gas pressure was close to

Fig. 3. Physical cell layout of the electrode placement. CE: Pt foil counter electrode, RE: Luggin capillary of the reference electrode, WE: working electrode. R: isopotential plane between the working and the counter electrode where the solution impedance (along distance x) is measured. c: the distance between plane R and CE, electrically compensated by the potentiostat.

that of atmospheric pressure. The solutions were prepared from distilled water redistilled from glass. Sodium hydroxide was of analytical purity (Fisher). Wire, mesh, and foil metal for the polycrystalline Pt electrodes, which were used as the working, counter, and fourth compensating electrodes, was obtained from Aldrich. The sizes and the shapes of the electrodes, when relevant for the actual experiment, are described in the appropriate results subsection. The electrodes were cleaned electrochemically before experiment by 16 voltammetric sweeps between −0.05 V and 1.8 V vs. RHE, the reversible hydrogen electrode, at 0.1 V/s. The cleanliness of the electrode was ascertained by a voltammogram between 1.5 and 0.05 V at 0.1 V/s. The work was done at laboratory temperature, ~24°C. If a platinum black surface on an electrode was desired, it was prepared by a 10 min electrolysis at 30 mA/cm^2, reversing polarity every 30 s, from a solution of 3.5% chloroplatinic acid and 0.005% lead acetate.

The voltammetric experiments were carried out using the EG&G 273A potentiostat, controlled by M270 software. Impedance was measured with the Solartron 1250/1286 analyzer/potentiostat, controlled by Z-Plot software (Scribner Associates). The frequency range was between 65 kHz and 0.1 Hz, with 12 points per decade. The amplitude of the ac signal was 10 mV (rms). The impedance data were evaluated with the help of the nonlinear least-squares-fit software utility, EQUIVCRT, written by B. Boukamp (University of Twente). Because the potentiostat was engaged in the impedance measurement, the impedance of the system is that of the path between the working electrode, towards the counter electrode but ending in the plane where the reference electrode is placed. Therefore, barring an instrument artifact, the counter electrode and, for that matter, the nature of the reference electrode should not be contributing factors towards the measured impedance (cf. ref. 19).

Results and discussion

A. The shape of the working electrode

(i) Solution resistance and the shape of an electrode

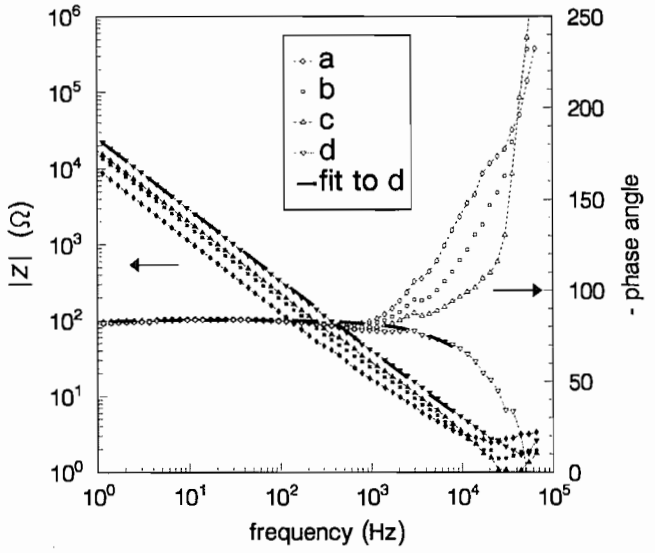
The original paper by Nicholson and Shain (20) describing cyclic voltammetry also introduced the component of spherical correction (21), then needed for the widely used mercury dropping electrode. The implication of the correction was that in spherical or hemispherical diffusion, as opposed to semi-linear diffusion, the currents are higher and, at infinite time, the limiting current has a nonzero value. This follows from the geometry, in which radially increasing volume around the electrode supplies an ever-increasing pool of electroactive species. This notion is applicable to contemporary ultramicroelectrodes as well, with the additional importance of diminished solution resistance.

The resistance between an electrode and a plane in which a reference electrode is placed can be calculated by various mathematical methods, in principle identical to those used in heat conduction (22). The usual approach to solving a heat conduction problem is to draw upon previously solved equations for a particular "shape factor" and substitute appropriate dimensions. This approach should be applicable to the problems of conductivities in solutions involving shapes of electrodes as well. For example a wire electrode placed a certain distance away from a flat counter electrode is electrically equivalent to a horizontal isothermal cylinder buried in a semi-infinite medium, while a spherical electrode has its equivalent in an isothermal sphere. The electrodes are well conductive, thus isopotential, and heat flux and charge flux are phenomenologically the same. Drawing on previously solved cases in ref. 22, the resistance of the solution was evaluated as a function of the distance from the working electrode to a plane away from the electrode at a distance x, where the reference electrode is placed. The counter electrode is assumed to be placed still further, past the plane of the reference electrode. The counter electrode is assumed to be planar, with infinite area, compared to the working electrode.

For a large foil electrode, the solution resistance is simply proportional to the working–reference electrode distance x and inversely proportional to the solution conductivity κ:

$$[3] \quad R = (1/\kappa)x$$

For a wire electrode of diameter d and length l parallel to the counter electrode, the resistance relationship, based on the similarity with an isothermal cylinder and assuming that its length $l >> d$ and also that its distance from the reference electrode plane is greater than $3d/2$, is written as:



$$[4] \quad R = (1/\kappa)(\ln(4x/d))/(2\pi l)$$

and for a spherical electrode with diameter d, where it is assumed that the distance from the reference electrode plane is greater than $d/2$, the relationship is

$$[5] \quad R = (1/\kappa)(1 - (d/4x))/(2\pi d)$$

From relationships [3]–[5] it follows that for a planar large electrode the solution resistance always changes with electrode distance. For a wire electrode, the change with position, at larger distances, is less pronounced, due to the logarithmic function in eq. [4]. For a spherical electrode, the changes of resistance with distance diminish sharply and, eventually, become independent of further electrode movement. This effect on the solution resistance parameter R_1 in an experiment with wire-sphere electrodes is described in the following section.

Fig. 4. The Bode impedance plot for a platinum wire electrode with a sphere attached to its end. Solid symbols, |Z|; hollow symbols, the phase angle. The plots are shown for (*a* - ◇) a wire electrode only (19.2 mm^2 area); and for the three consecutively larger spheres and therefore shorter wires, with decreasing surface area: (*b* - □) 11.7 mm^2; (*c* - △) 9.4 mm^2; and (*d* - ▽) 6.16 mm^2. The bold broken line is the best-fit curve for electrode (*d*) (cf. Table 1). Only one fit overlay is shown to maintain clarity.

(ii) Spherical electrode

In past experience with various shapes of electrodes, the most ideal impedance results, i.e., the best fit to the expected equivalent circuit (cf. Fig. 2) and a constant phase element (CPE) having its value n close to 1 (cf. eq. [2]), corresponding to a pure capacitance, were those obtained with a mercury hanging drop electrode. For other shapes of electrodes, n differed more or less from 1. Our thesis was that the shape, and perhaps the size, of the electrode, relative to the size of the cell, was an important factor. To further investigate the effect of the electrode shape and its size, a piece of 20-mm-long platinum wire sealed in a soft glass was used. The first set of measurements was done with this electrode. The geometry of this electrode was modified for subsequent experiments. The tip of the platinum wire was carefully heated in a pointed glass-blowing flame until it melted and gathered in a sphere; thus, a small spherical electrode was created, still connected to a length of exposed platinum wire. Following an impedance measurement, the electrode was again reheated, and more metal was gathered in a sphere. Each such step shortened the connecting wire and increased the diameter of the sphere. The geometric area of such an electrode was calculated for a cylinder and sphere whose sizes were obtained using a caliper and a micrometer. Three such melting steps were performed.

Figure 4 compares the Bode plot impedance response of the

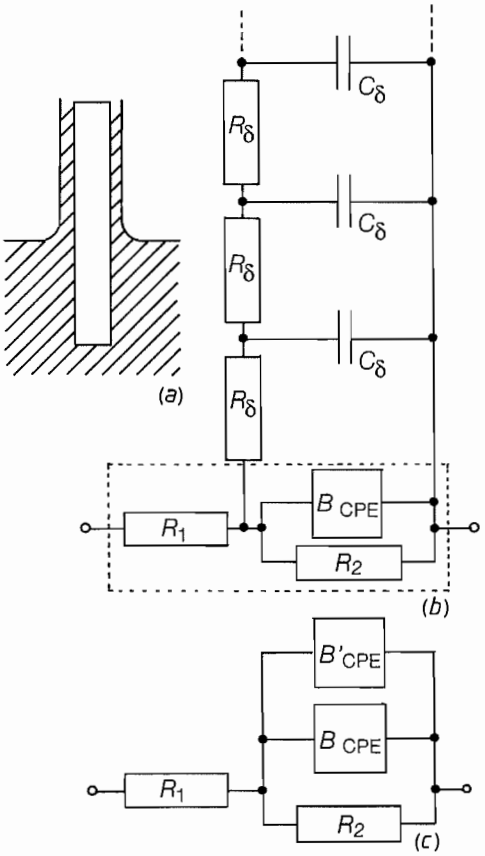
6.16	*d*	8.4	150 000	6.9	0.945	111

four Pt shape/size electrodes. It should be noted that for the first three experiments with a longer wire (smaller sphere) electrode, the response at the higher frequencies is nonstandard, i.e., the phase angle goes beyond 90°. This is an artifact caused by the reference electrode impedance, the geometry of the working electrode, and the relative placement of the working and the reference electrode in the cell. The result appears to mean that the current precedes the applied potential by more than 90°, which a capacitor cannot attain. However, a time lag in the reference electrode channel may increase this apparent delay past 90°. The smallest electrode with a minimum amount of wire and essentially a spherical surface does not display this behavior.

Table 1 summarizes the impedance results for the electrode shape experiment. The apparent area of the electrode was calculated from its physical dimensions. A simple circuit $R(RB_{CPE})$ (cf. Fig. 2) was used for the evaluation. For the three cases in which the phase angle exceeds 90°, the high-frequency data were excluded from the fit, because it was not possible to fit such behavior with a realistic impedance component. Therefore, there were more usable impedance points for the smallest electrode, which resulted in the smallest value of the fitting error. Figure 4 shows the overlay for the smallest electrode (broken line). The overlays for the full frequency range show that the $R(RB_{CPE})$ model is too simple to account for the total behavior. The equivalent circuit fit was adequate for frequencies from approximately 4 to 400 Hz. The retained high-frequency data for the smallest electrode have a good fit at the highest values, but deviate around 1 kHz, a likely experimental artifact. All four fits deviate somewhat at the low frequencies. The parameter evaluated as the solution resistance, R_1 (Table 1), decreases with increasing electrode area, but not linearly. When the R_1 is normalized by multiplying by the electrode area, then the smallest electrode has the smallest resistance. This deserves special mention, because solution resistance, a path between the working and the reference electrode, should be constant, i.e., the normalization mentioned should not be necessary. Alternatively, the resistance could possibly increase with diminishing cross section of the solution at the working electrode, assuming the major contribution of the solution resistance is near the surface of the reference electrode. In such case the normalization would render the solution resistance constant. However, the decrease following the electrode size seems to be unique to the modification of the size and shape of the electrode. As the derivation and eqs. [4] and [5] in part (*i*) show, solution resistance of a sphere should be smaller than that of a wire, which was observed.

To calculate the Pt capacitance, the assumption was made that the CPE can be regarded directly as capacitance (with n about 0.95). From such calculated values, divided by the geometrical area, the average apparent electrode capacitance is about 100 $\mu F/cm^2$. Using the literature data for double-layer capacitance, 28 $\mu F/cm^2$ (21), the roughness of the electrode would be about 3.6. This is still in agreement with commonly accepted data. Impedance interpretation in which B_{CPE} is equated to C, although n is less than 1, tends to overestimate the capacitance compared to the typical double-layer capacitance values in the literature (23); thus, the actual roughness of our electrodes might be closer to 1.7–2, as reported by others (23, 24). However, from the tabulated results, it can be seen that the evaluated capacitance per unit area shows a steady increase with decrease of the electrode size. From this it would appear that a smaller, spherical platinum electrode will tend to overestimate the capacitance in the impedance measurement. It is interesting to see that the n value does not approach closer to unity upon transition from a wire to a sphere. Within experimental error it is independent of the electrode shape. This refutes our thesis that a sphere is a better shape for an electrode used to measure capacitance.

The value R_2 is associated with leakage current, a charge transfer resistance parallel to the double-layer capacitance. The value in Table 1 is inversely proportional to the surface area. This qualitative trend, consistent with the expected behavior, is usually all one can get from R_2 values, because their uncertainty is typically large.



The advantage of a small spherical electrode may be that its impedance response at higher frequencies is more free of artifacts. Some workers in impedance use another electrode in addition to the three conventional electrodes (working, reference, counter) used with the usual potentiostats (25, 26). This additional electrode, usually platinum wire, is capacitively coupled to the reference electrode input of the potentiostat. Such an arrangement compensates for experimental artifacts brought about by relatively high resistance of a typical reference electrode and, in particular, its Luggin capillary. The error introduced by the uncompensated reference electrode, without the fourth electrode, also appears to be a function of the shape of the working electrode and its overall size. Whereas the three larger electrodes reveal major artifact at the higher frequencies in absence of the fourth electrode, the smallest electrode does not suffer in such a pronounced way. In fact, curve fitting reveals that the data deduced from the measurements with and without the fourth electrode yield essentially the same results, suggesting that the ideal geometry for the working electrode used for impedance measurement, without the need for the fourth electrode, may be a sphere.

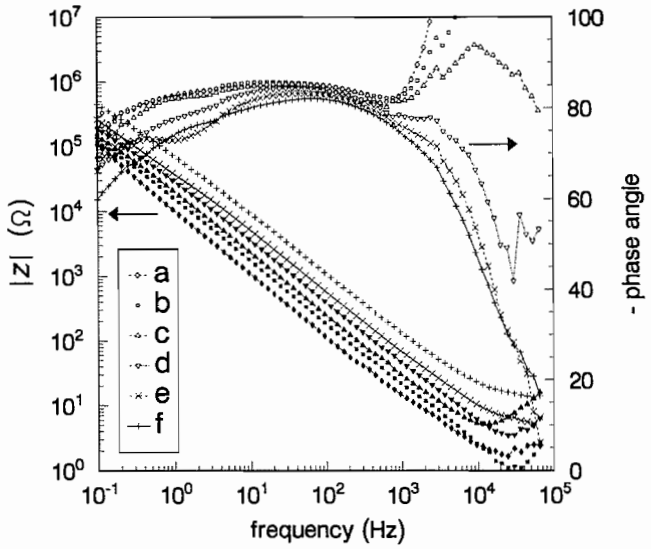
Fig. 5. Illustration used in discussing impedance of a partially immersed electrode: (*a*) diagram of the partially immersed electrode, assuming a thin layer of an electrolyte spreading over the entire surface; (*b*) equivalent circuit of such a partially immersed electrode. Outlined segment is the equivalent circuit of the electrode surrounded by bulk electrolyte; (*c*) conversion of the infinite branch in Fig. 5*b* into a second constant phase element (B'_{CPE}).

B. Partial immersion of a wire electrode

A wire electrode used in electrochemical work is often ≥1 cm long. Thus, it is possible to immerse it only partially. This can happen by accident, if the electrode is not fully inserted, not enough solution is used, or if the cell is tilted. But partial immersion also can be used on purpose, for example, to grow films of different thickness along the wire length. The location of the growth may be regulated by the depth of immersion. Partial immersion results in a smaller active surface area. However, partial immersion does not lead to a proportional decrease in response. Solutions that have a tendency to creep along surfaces will form a thin, conductive layer on the part of the wire electrode above the solution, thus distorting the results. This can happen, in particular, if the electrode was first fully immersed and then partially emersed. The emersed surface would be expected to have some degree of electrochemical activity. In the model used in this paper it is assumed that the emersed wet surface retains at least some level of double-layer capacitance.



The effect of partial immersion can best be seen by the analysis of the impedance data. Figure 5*a* depicts the situation that can be expected to arise for a wire electrode that has been totally immersed, then partially emersed, and is still wet. A corresponding equivalent circuit is shown next to it (Fig. 5*b*). Its lower part, outlined by a dotted box, $R(RB_{CPE})$ is the impedance response of a wire electrode fully immersed. As determined in the previous section (A), the experimental data more appropriately require B_{CPE} with n about 0.95 instead of a pure capacitor. The upper part, with an infinite ladder arrangement of resistors and capacitors, is the assumed impedance of the wet electrode surface, with the series resistors on the side of the ladder being the incremental resistance of the wet surface, R_δ, and C_δ representing the corresponding incremental capacitances. If a long wire is assumed, then this resistance/capacitance ladder can be considered infinite. The total impedance Z_x of such an infinite motif has a finite value and can be obtained through straightforward formalism. Since the motif is infinite, the removal of one segment (series resistor R_δ and parallel capacitor C_δ) will not change the impedance of the remaining infinite structure Z_x. By adding back the impedance of the capacitor ($Z_c = -j/\omega C_\delta$) and the impedance of the resistor (R_δ), a new impedance may be written as:

$$[6] \quad Z_x = (R_\delta Z_c + R_\delta Z_x + Z_c Z_x)/(Z_c + Z_x)$$

Solving for Z_x leads to a quadratic equation that yields a rather long expression for the real and imaginary components of Z_x. However, the impedance of Z_x is also equal to the constant phase element from eq. [2], with n in this case equal to 1/2. The value of B_{CPE} is $(C_\delta/R_\delta)^{0.5}$.

The impedance data obtained for the partially immersed electrode (Fig. 6 curves *c*,*d*,*e*,*f*) show that there is a need for more than one capacitor (or CPE) in the equivalent circuit intended for evaluation of the behavior. From the model in Fig. 5, a possible equivalent circuit could be that of Fig. 5*c*,

Fig. 6. The Bode impedance plot for a platinum wire electrode (12.5 mm^2) fully immersed and partially immersed in 1.0 mol/L NaOH, measured at 600 mV vs. RHE. i.e., R(RCB_{CPE}), or, since even a fully immersed electrode is not a perfect capacitor (cf. Sect. C), the circuit could be $R(RB_{CPE}B'_{CPE})$. The data fitting, however, revealed that the nonlinear optimization pins the n of one of the CPEs at 1, thus effectively turning the $R(RB_{CPE}B'_{CPE})$ circuit into $R(RCB_{CPE})$. Therefore, circuit $R(RCB_{CPE})$ was used in further evaluation.

A need to use a more complicated circuit than the simple $R(RB_{CPE})$ also follows from the impedance data. Table 2 shows the results for full immersion and four partial immersions of Pt wire electrodes. Whereas it is possible to fit the middle frequency range of data of all partial immersions to the $R(RB_{CPE})$ circuit, it is difficult to reconcile this with the calculated value of the charge transfer resistance R_2. While the immersion decreases ×10 (from 100% to 10%), R_2 increases only about ×4.3, indicating another contribution to system conductivity. The B_{CPE} of the CPE, on the other hand, when normalized for surface area, is constant, without apparent trend. The n value of the CPE decreases with the amount of electrode withdrawn from the solution, indicating that the thin wet film is increasingly contributing to the overall impedance with its distributed parameters.

It is important to realize that, with the additional C in $R(RCB_{CPE})$ vs. the original $R(RB_{CPE})$, R_2 and C can be resolved in a very satisfactory manner. With the area of immersion changing, the capacitance should be directly proportional to the area immersed, whereas the resistance should be inversely proportional. Thus, the product R_2C (cf. Table 2), for a particular electrode but for different extent of immersion, should be a constant value, which is, within the experimental error of the data fit, the actual case. It should be noted here that the percent immersion indicated is approximate, because the capillary elevation made the exact immersion measurement uncertain. Therefore, it should come as no surprise that, although R_2 and C change with the immersion as expected, the data spread is quite large. The B_{CPE} value in the $R(RCB_{CPE})$ fit of the right-hand side of Table 2 should be constant if the behavior was as expected from eq. [6] and the model of Fig. 5*b*. Such behavior is fulfilled for the first three data points, with the fit value for the 10% immersion deviating from the rest. The thin layer modeled by a single constant phase element is a simplification. In actuality, the n of the CPE is higher than the calculated 0.5. However, the approach to impedance evaluation of partially immersed electrodes via CPE appears to be a valid one.

C. Platinized electrodes

The usual approach to preparing a platinum electrode of large surface area is to deposit a platinum black layer on its surface. This procedure (27) roughens the surface, thus increasing the effective surface area. In this work, impedance was used to measure the increase in surface area of the platinized electrode. The impedance fit for the bright and platinized electrodes was done using equivalent circuit $R(RB_{CPE})$.

The solution resistance values, R_1, for both the bright platinum electrode and the same electrode subsequently plated with platinum black, were identical. This indicates that the value obtained from such measurement, and the subsequent evaluation, is a function of the electrode placement relative to the reference electrode. Since the geometrical area, the shape, and the placement for both electrodes are identical, the same R_1 is obtained. The platinum black surface had a lower n value of the CPE, 0.93, than a comparable electrode of bright wire, with n = 0.95–0.96. This lower value is consistent with the knowledge that the exponent n corresponds to surface roughness. The approximate surface area increase upon the deposition of platinum black can be estimated by ratioing the B values of the constant phase elements, tacitly assuming that they correspond to capacitance. In the present work, it is estimated that the surface increase resulting from the Pt black deposition was about ×40.

Conclusions

The probing of the impedance of a platinum electrode is often performed either singly, as the only assessment of the metal surface state, or as an experiment used in support of other techniques. In this paper, the contribution of electrode shape to the impedance data was investigated in a simple 1 mol/L NaOH solution at potential of 600 mV vs. RHE. A difference in impedance response was found for a straight wire electrode (20 mm long) and a shorter wire electrode with a sphere on its end (ultimately a sphere on a 1.6-mm-long wire). The sphere electrode tends to overestimate the electrode capacitance but, at the same time, provides response with the least amount of high-frequency artifacts, possibly eliminating the need to use a secondary reference electrode for high-frequency compensation. The impedance response of an electrode only partially immersed, but with the non-immersed part wet with solution, corresponds to an apparent decrease of the electrode surface, but it introduces an additional impedance component, the con-

stant phase element, derived from a transmission line. A platinum surface, coated with platinum black in order to increase its effective surface area, can be assessed by impedance probe. The constant phase element, corresponding to the surface capacitance of the electrode immersed in solution, can be used to measure the apparent increase in the surface area.

SERS studies of monoprotonated pyrazine (pyrazinium) cations adsorbed onto positively charged silver electrodes

A.G. Brolo and D.E. Irish

Abstract: The surface-enhanced Raman scattering (SERS) spectra of monoprotonated pyrazine cations adsorbed on silver electrodes have been measured. The molecular orientation of the pyrazinium cation is dependent on the electrode potential. At potentials more positive than −170 mV the monoprotonated pyrazine is adsorbed end-on. However, the spectral features suggest a flat orientation as the potential becomes more negative than −300 mV. Monoprotonated pyrazine cations with both orientations can coexist at potentials between these limits. The adsorption of the positive ion to a positively charged electrode is mediated by specifically adsorbed bromide ions.

Key words: SERS; monoprotonated pyrazine cation, silver electrode, pyrazinium.

Résumé : On a mesuré les spectres de diffusion Raman rehaussés par la surface «SERS» de cations de pyrazine monoprotonée adsorbée sur des électrodes d'argent. L'orientation moléculaire du cation pyrazinium dépend du potentiel de l'électrode. À des potentiels plus positifs que −170 mV, la pyrazine monoprotonée est adsorbée par son extrémité. Toutefois, les caractéristiques spectrales suggèrent que l'orientation est plate lorsque le potentiel devient plus négatif que −300 mV. Des cations de pyrazine monoprotonée ayant les deux orientations peuvent coexister à des potentiels entre ces limites. L'adsorption de l'ion positif sur une électrode chargée positivement se fait avec l'aide d'ions bromures adsorbés d'une façon spécifique.

Mots clés : diffusion Raman rehaussés par la surface «SERS», cation pyrazine monoprotoné, électrode d'argent, pyrazinium.

Introduction

Pyrazine is a centrosymmetric molecule that belongs to the D_{2h} point group. Protonation of one nitrogen will suppress the centre of inversion and reduce the symmetry to C_{2v}. This symmetry lowering will "activate" all the pyrazine vibrational modes in the Raman spectrum. However, pyrazine is a very weak base, and its low pK values (pK_{a1} = 0.65 and pK_{a2} = −5.8) (1) make protonation possible only in very acidic media.

A Raman spectral study of pyrazine and its protonated forms in aqueous solution has been performed in our laboratory (2). By observation of the shifts of the bands from the positions measured for neutral solutions, it has been possible to identify the unique characteristic bands of unprotonated pyrazine and its two protonated forms. The majority of the vibrational bands of the monoprotonated pyrazine (pzH^+) were identified and assigned (2). The diprotonated pyrazine cation spectrum was only observed from very concentrated H_2SO_4 and $HClO_4$ solutions, and the presence of strong bands from these acids masked some of its bands (2). The positions of these masked bands have been predicted theoretically (3). The ab initio calculations for pyrazine and its two protonated forms provided useful confirmation of the assignments of the observed bands within 10% accuracy.

The identification and assignment of the vibrational bands from pyrazine and monoprotonated pyrazinium cation (pzH^+) in solution proved to be useful in the interpretation of the Raman spectrum of pyrazine adsorbed onto metallic surfaces (4). The positions of the vibrational bands in the surface-enhanced Raman scattering (SERS) spectrum of pyrazine adsorbed on a polycrystalline silver electrode are more similar to those of aqueous pyrazine than those of its monoprotonated derivative. However, several "forbidden" pyrazine modes were activated by the electrode surface (4). The presence of Raman forbidden bands in the SERS spectrum of pyrazine can be explained either by the "chemical" (charge transfer (CT)) or by the "electromagnetic" enhancement mechanisms (5). The intensities of all bands in the SERS spectrum of pyrazine are potential dependent, and their maxima depend on the electrolyte and on the activation procedure (4). The spectrum is mainly dominated by the ring stretch (number 8a) mode at ca. 1590 cm^{-1}. The ring breathing (number 1) mode at ca. 1019 cm^{-1} is the second most intense band, followed by the other A_g modes at 630 and 1235 cm^{-1}. Vibrational bands at ca. 360, 432, 700, 1225, and 1520 cm^{-1} were also observed.

New features have been observed in the SERS spectrum of pyrazine adsorbed on a silver electrode immersed in a 1.0 M KBr solution when the applied potential is more negative than −900 mV (6). These new bands were assigned to the main reduction product of pyrazine, the 1,4-dihydropyrazinium cation (7, 8). The 1,4-dihydropyrazinium cation, formed at negative potentials, can be adsorbed on the electrode surface even at potentials more positive than the pzc for silver in that medium. In this case, the reduced pyrazine cation binds to the halide layer (6). The halide, which is adsorbed on the positively charged metal surface, acts like a bridge. The same phenomenon has been observed for the adsorption of other cations like pyridinium (9) and tetramethylammonium (10). Hence, the presence of the 1,4-dihydropyrazinium cation on the silver electrode at positive potentials suggests that the monoprotonated pyrazine can also be adsorbed on a positively charged silver electrode by a similar mechanism. We have thus explored the adsorption of pzH^+ on a polycrystalline silver electrode in acidic media. This work complements the preliminary results that we presented elsewhere (11).

Experimental section

Reagents

The following chemicals were used without further purification: pyrazine 99+%, from Aldrich; KBr AnalR grade, from BDH; and concentrated $HClO_4$, from Baker. All solutions were prepared with Milli-Q-water.

Electrochemistry

The three-electrode spectroelectrochemical cell has been described elsewhere (12). A potentiostat PAR model 273 was used to control the potential applied to the working electrode. The counter electrode was a 0.3 mm platinum wire (99.9%). A saturated calomel electrode (SCE) was used as reference. The working electrode was made from 99.9% polycrystalline silver rod. A silver disk of ca. 2 mm radius was mounted in a Teflon holder. The working electrode was first polished with emery paper and then with progressively finer grades of alumina powder down to 0.3 μm. The electrode was rinsed with an abundant amount of Milli-Q-water, sonicated, rinsed again, and transferred to the spectroelectrochemical cell. The solution was degassed with Ar for 0.5 h prior to the experiment, and a gentle stream of Ar was kept on during the data acquisition.

Activation procedure

The process of roughening the metal surface electrochemically, in order to create the necessary SERS active sites, is called the activation procedure. In this work we activated the electrode electrochemically by a sequence of Oxidation–Reduction Cycles (ORCs). ORCs were performed on the silver electrode from an aqueous solution containing 1.0 M KBr and 1.0 M $HClO_4$ by sweeping from −800 to −50 mV at 5 mV/s. The potentiostat was turned off, and pyrazine was added to the system. This sequence prevents decomposition, which might occur during the ORC; trapped decomposition products have been observed when the analyte was present during the ORC (6). The pyrazine concentration used in all experiments was 0.1 M. After pyrazine was introduced into the system, the potentiostat was switched on again, the ORC cycle was resumed, and the SERS spectrum of pyrazinium adsorbed on silver was recorded at the desired potential values.

Raman spectra

Raman spectra were measured with a Dilor OMARS 89 spectrometer equipped with an optical multichannel analyzer (OMA). The intensified diode array (512 diodes) detector was thermoelectrically cooled to ca. −10°C. The spectrometer was interfaced to an IBM computer. The data were transferred to an IBM 486 computer on which baseline correction, band-fitting, and plotting programs were available. The spectra were excited by using a 514.5 nm (100 mW at the head) line from a Coherent Innova 70 argon ion laser chopped at a 1 s cycle. The chopping is a feature of the Dilor OMARS 89 spectrometer to improve signal-to-noise; it has the added advantage of diminishing photodegradation.

Results and discussion

Figure 1 shows the spectrum obtained for pyrazine adsorbed from a 1.0 M KBr + 1.0 M $HClO_4$ + 0.1 M pyrazine solution onto the SERS activated silver surface at the open circuit potential (OCP) for several spectral regions. The band positions and assignments are presented in Table 1. Table 1 also shows the band positions of the pyrazine SERS spectrum obtained from a neutral solution (4) and the pyrazine and monoprotonated pyrazine bands from aqueous solution (2). A comparison between the spectrum presented in Fig. 1 and the SERS spectrum of pyrazine adsorbed from a nonacidic solution shows striking differences in the peak positions and intensities. It has been proposed that the adsorption of neutral pyrazine onto a metallic surface would remove the molecular centre of symmetry (13). Consequently, the molecular symmetry should be reduced from D_{2h} to C_{2v} due to the adsorption. In this case, it can be expected that the spectrum of adsorbed neutral pyrazine (under C_{2v} symmetry) should have some similarities with the spectrum of the monoprotonated pyrazine cation (also C_{2v}) in solution. However, as observed in Table 1, the vibrational wave numbers found for pyrazine adsorbed onto a silver electrode from acidic solution more closely match the wave numbers of the monoprotonated pyrazine cation in solution, and the peak positions in the SERS spectrum of pyrazine adsorbed from neutral solution are more similar to those from the pyrazine spectrum of the aqueous solution. This is an indication that symmetry reduction, due to formation of a metal – organic molecule complex, is not a necessary consequence of adsorption, and that the interaction of pyrazine with the metal is not strong enough to induce a symmetry change.

The SERS spectra at potentials more positive than ca. −100 mV were time dependent. The SERS signal decreased with time, and the rate of decrease became faster as the potential became more positive. A simple explanation is that a silver bromide film is formed during the silver oxidation step, and this film quenches the SERS effect, which is a near-surface phenomenon. The time dependence of the SERS signals made the study of medium intensity and weak bands very difficult at these potentials. Hence, we focused our work in the 1000, 1200, and 1600 cm^{-1} regions where the strongest bands were found.

Figures 2, *A–C*, show the SERS spectra of pyrazine adsorbed from acidic solution on a silver electrode at several potentials. The point of zero charge for silver in bromide medium is expected to be more negative than −900 mV (14) and, thus, the surface charge is positive. As the potential is swept to values more positive than −170 mV, the band intensity at 1002 cm^{-1} decreases, and one can just notice two bands near 1020 cm^{-1} at potentials close to the onset of the silver oxidation (around −100 mV). These two bands coalesce into a broad envelope that can be resolved using a band-fitting computer program. The experimental trace in this region and its band-fitted components are presented in Fig. 3. From the

Fig. 2. SERS spectrum of pyrazinium on a silver electrode adsorbed from a 1.0 M KBr + 1.0 M $HClO_4$ + 0.1 M pyrazine solution at several potentials. For (*A*): (*a*) −160 mV; (*b*) −250 mV; (*c*) −340 mV. For (*B*): (*a*) −170 mV; (*b*) −235 mV. For (*C*): (*a*) −170 mV; (*b*) −250 mV; (*c*) −310 mV.

band-fitting analysis one can locate the positions of these two bands at ca. 1018 and at ca. 1031 cm^{-1}, respectively. Just one band is observed at 1222 (Fig. 2*B*) and 1616 cm^{-1} (Fig. 2*C*) at potentials more positive than −170 mV.

As the potential was swept to less positive values, the SERS intensity of pzH^+ was recovered following the silver ion reduction around ca. −200 mV. In this case, the 1002 cm^{-1} band was present and it was more intense than the envelope at ca. 1020 cm^{-1}. The 1002 cm^{-1} band is the only one left in the spectrum in the 1000 cm^{-1} region at potentials more negative than ca. −280 mV (Fig. 2*A*). Two bands showed up in the 1200 cm^{-1} region after the silver ion reduction (Fig. 2*B*), one band at 1222 cm^{-1} and another at ca. 1200 cm^{-1}. The 1616 cm^{-1} intensity decreased as the potential became negative (Fig. 2*C*), and its position remained unchanged. This band vanished completely near −300 mV.

The results presented above are consistent with an adsorption of pyrazinium cation with different orientations at

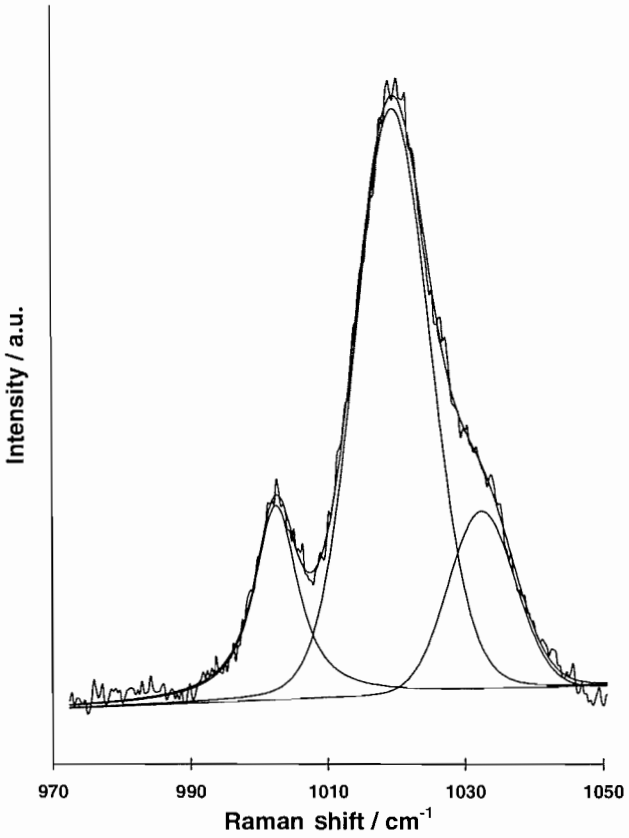
Fig. 3. Observed SERS spectrum of pyrazinium on a silver electrode and its band-fitted components. PzH^+ adsorbed from a 1.0 M KBr + 1.0 M HClO4 + 0.1 M pyrazine solution. $E = -170$ mV.



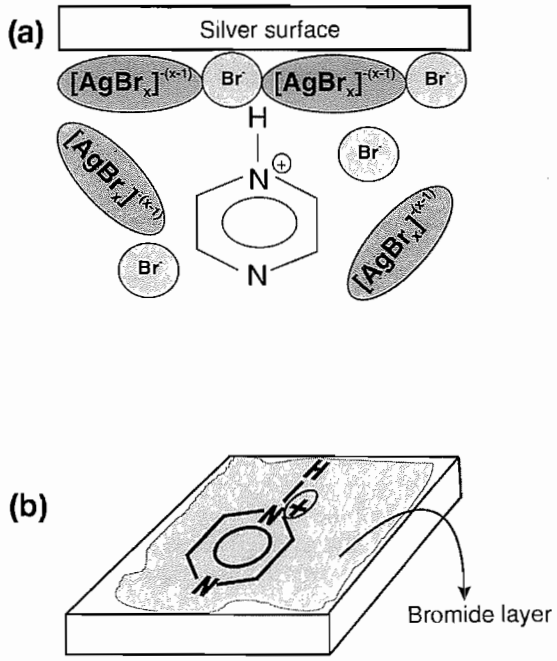


Fig. 4. (*a*) PzH^+ adsorbed end-on is the predominant species at potentials more positive than −170 mV. The cation may interact with either the halide or the soluble silver oxidation products, which are adsorbed at the positively charged electrode. (*b*) The positive charge can be delocalized throughout the entire pyrazine ring due to the protonation of pz, which enables pzH^+ to be adsorbed flat through the halide layer. Flat-adsorbed pzH^+ is the predominant species at potentials more negative than −300 mV.

different potentials. One adsorption orientation is predominant during the silver oxidation ($E > -170$ mV), and the other dominates at potentials more negative than −300 mV. These two different orientations of adsorbed monoprotonated pyrazine can coexist on the metallic surfaces at intermediate potentials. Actually, the pyrazinium ion spectrum at OCP presented in Fig. 1 is an example of this. The two different orientations proposed for the monoprotonated pyrazine cation are illustrated in Fig. 4.

The surface selection rules for SERS predict that the vibration modes with polarizability changes perpendicular to the electrode surface will be more enhanced than the parallel ones (5). Pyrazine adsorbed from neutral solution is thought to bind to the metallic surface by means of one of its nitrogen atoms (4). This end-on adsorption mode is confirmed by a SERS spectrum dominated mainly by the 630, 1019, 1225, and 1590 cm^{-1} bands; for end-on adsorption these bands have components perpendicular to the surface.

The most predominant band in the pzH^+ spectrum at potentials more positive than −170 mV is the ring stretch mode 8*a* at 1616 cm^{-1} (Fig. 2*C*). This band is, at least, 3 times more intense than the ring breathing mode at ca. 1000 cm^{-1}. The 8*a* mode is more intense than the ring breathing mode in the SERS spectra of the perpendicular-adsorbed pyrazine (4). Even considering that a CT contribution may be relevant for the large intensity of the band at 1616 cm^{-1} (15), the intensity ratio between this mode and the ring breathing mode (at ca. 1000 cm^{-1}), observed in Fig. 2, suggests that pyrazinium is adsorbed end-on at those potentials where the silver oxidation occurs. The presence of the 1031 cm^{-1} δ ring mode (number 12) also supports an end-on adsorption. This mode is forbidden in the normal Raman spectrum of pyrazine, but becomes active (with very weak intensity) in the SERS spectrum of pyrazine (4). It also appears with fair intensity in the SERS spectrum of end-on adsorbed pyridine (7). On the other hand, this mode is completely absent in the flat-adsorbed benzene SERS spectrum (16).

Another point to be addressed is how a positive monoprotonated pyrazine can adsorb on a positively charged electrode (the pzc for silver in this bromide medium is expected to be more negative than −900 mV (14)). It is well known in the literature that positive species can use a halide layer as bridge to adsorb onto a positively charged surface (6, 9, 10). During the silver oxidation, a AgBr film is expected to form. It is possible that film dissolution can occur in a highly concentrated halide medium, by formation of $(AgBr_x)^{-(x-1)}$ anions. We can conclude that the pyrazinium cation is bound to either a halide or to the $(AgBr_x)^{-(x-1)}$ and these anions are adsorbed to the positively charged electrode (see Fig. 4*a*). A low wave number band at 150 cm^{-1}, attributed to adsorbed Br^-, decreases in intensity as the electrode is made more negative; concomitantly the band of pzH^+ decreases in intensity. These observa-

© 1997 NRC Canada

tions are consistent with the potential-dependent Br^- surface coverage determined electrochemically (14).

Different features in the pzH^+ spectrum were observed when the potential sweep was continued in the negative direction and the reduction of the silver oxidation products occurred. The Ag^+ ions reduced to Ag, forming the SERS-active sites, and the spectral lines became more intense. The intensity of the SERS bands decreased again, starting at ca. −300 mV. The main features of this pyrazinium spectrum in the 1000 cm^{-1} region are the decrease in the intensities of the envelope that contains the 1018 and 1031 cm^{-1} bands and the appearance of a very strong band at 1002 cm^{-1} (Fig. 2*A*). In the 1200 cm^{-1} region (Fig. 2*B*) one can also notice the decrease in the 1222 cm^{-1} band and the appearance of a 1200 cm^{-1} band. New bands are not formed in the 1600 cm^{-1} region (Fig. 2*C*). The 1616 cm^{-1} band intensity just decreases as the potential becomes negative and vanishes completely at −330 mV.

The spectral observations at potential values more negative than −200 mV suggest that the pyrazinium cation is either tilted or flat-adsorbed on the metallic surface. The bands at 1002 cm^{-1} and at 1200 cm^{-1} can be assigned to the ring modes, numbers 1 and 9*a*, respectively. The shifts of flat-adsorbed pyrazine ring modes to lower wave numbers have been observed by Moskovits et al. (17). Similar changes were also observed in the benzene SERS spectrum (16). When aromatic molecules interact with the surface by π-electrons of the ring they adsorb flat. This interaction is expected to shift the ring stretch frequencies downward. The flat-adsorbed benzene SERS spectrum is also completely dominated by the ring breathing mode (number 1) (16). For instance, this mode is several times more intense than the ring stretch mode number 8*a*, which dominates the spectrum of the end-on adsorbed pyrazine. In Fig. 2, at a potential of ca. −300 mV, the 8*a* mode is hardly observed, but the ring breathing mode is still intense. Another interesting band is at 898 cm^{-1}, marked with an asterisk (*) in Fig. 1. This band is assigned to the γ ring mode number 10*a* (out-of-plane), and it is completely absent in the SERS spectrum of pyrazine (4). However, this band is fairly intense in the benzene spectrum (16) and, following the SERS selection rules, it is expected to be active only for a flat-adsorbed molecule. Similarly, the presence of the 1002 cm^{-1} band (also marked with an asterisk (*) in Fig. 1) is consistent with the flat orientation.

In the potential range where the monoprotonated pyrazine is adsorbed flat, the silver oxidation products, AgBr or $(AgBr_2)^-$, have largely been reduced to metallic silver. This process increases the specific halide surface concentration very significantly. Hence, the flat-adsorbed pyrazinium cation may be bound to the halide layer, which is adsorbed to the positively charged silver surface, as shown in Fig. 4*b*.

Conclusions

The SERS spectrum of monoprotonated pyrazine was measured. The pyrazinium cation can adsorb onto the electrode surface by two different orientations. The end-on adsorbed monoprotonated pyrazine is predominant at potentials more positive than −170 mV. The flat-adsorbed pyrazinium cation is thought to be the only specie on the surface at potentials more negative than −300 mV. The positively charged pyrazinium cation must use either the halide or the $(AgBr_x)^{-(x-1)}$ complex as a bridge to adsorb to a positive electrode surface.

Abstract: The mean spherical approximation has been applied to describe medium effects in the kinetics of reactions between ions in water. When the ionic strength of the medium is altered by the addition of an inert electrolyte, the rate of reaction can be accurately predicted with the inert electrolyte concentration up to 1 M. The theoretical rate constant at the limit of infinite dilution k_{r0} has been estimated for five earlier kinetics studies for which data are available in the literature.

Key words: kinetic medium effects, mean spherical approximation, activity coefficients.

Résumé : On a appliqué l'approximation sphérique moyenne pour décrire les effets de milieu sur les cinétiques de réactions entre des ions dans l'eau. Lorsqu'on modifie la force ionique du milieu par l'addition d'un électrolyte inerte, on peut prédire correctement la vitesse de la réaction avec l'électrolyte inerte à des concentrations allant jusqu'à 1 M. Pour les cinq études cinétiques antérieures pour lesquelles des données sont disponibles dans la littérature, on a évalué la constante de vitesse théorique à la limite de la dilution infinie, k_{r0}.

Mots clés : effets cinétiques du milieu, approximation sphérique moyenne, coefficients d'activité.

[Traduit par la rédaction]

Introduction

Interest in medium effects in the kinetics of reactions involving ions dates from the work of Brönsted (1, 2) and Brönsted and Livingston (3). Somewhat later, these effects were described within the context of transition state theory (4). This led to the conclusion that the logarithm of the reaction rate constant should be linear in the square root of the ionic strength of the solution when the latter is very dilute. Furthermore, the slope of this relationship should be proportional to the product of the charges on the reacting ions. Data illustrating this medium effect can be found in most textbooks dealing with chemical reaction kinetics. The effect in very dilute solutions is easily accounted for on the basis of Debye–Hückel theory in its simple or extended version (5). However, it is clear that the details of the behavior of these systems at higher ionic strengths cannot be dealt with on the basis of the Debye–Hückel model. For example, Kautz and Robinson (6) showed that the rate constant for hydrolysis of sucrose by hydrochloric acid increases markedly with the addition of alkali or alkaline earth chlorides to the system, and that the extent of the increase depends on the nature of the cation. According to the simple theory, the rate of this reaction, which involves an uncharged reactant, should be independent of ionic strength.

In recent work (7, 8), two of us have shown that the nonideality of simple electrolyte solutions can be described up to quite high concentrations on the basis of the mean spherical approximation (MSA). The conclusion from these studies is that the finite size of all solute species, charged or uncharged, must be considered in a complete description of the system. This effect, which is modeled on the basis of the statistical mechanical description of a hard sphere fluid, leads to the well-known increase in the mean ionic activity coefficient at higher concentrations. A second factor that should be considered is the decrease in the dielectric permittivity of the solution with addition of electrolyte. This leads to an increase in the strength of ion–ion interactions with increase in ionic strength.

Examination of the data presented earlier in the literature led us to conclude that it would be worthwhile to reconsider the medium effect for this class of solution reactions within the context of recent work on the MSA. Details of this investigation are given in the present paper.

The MSA utilizing the actual solvent permittivity

The details of the MSA applied to a system involving an ionic reaction are now summarized. It is assumed that the various ions in solution have different sizes so that the unrestricted version of the MSA is applied as described by Blum and coworkers (9–12). The bimolecular reaction involved is

[1] $A + B \rightleftharpoons X^*$

where A and B are ionic reactants (including the case where the charge on A or B is zero), and X^* is the activated complex whose charge is equal to the sum of that on A and B. The reaction occurs in the presence of an inert 1-1 electrolyte MY. As a result, the solution contains five species, each of which may have a different size. Therefore, activity coefficients for each of these five species should be estimated.

The quantity of fundamental interest in deriving an expression for the single ion activity coefficient is the excess Helmholtz energy ΔA^{EX}. This is made up of two contributions, ΔA^{ES}, the electrostatic part due to the ionic atmosphere, and ΔA^{HS}, the hard sphere part due to the finite size of the solute species. Thus, one writes

[2] $$\Delta A^{EX} = \Delta A^{ES} + \Delta A^{HS}$$

The first contribution becomes more negative as concentration increases, expressing the fact that the ionic atmosphere becomes more effective in screening ion–ion interactions. The second becomes more positive with increasing concentration, expressing the fact that an increasing amount of work must be done to introduce a new solute species into the solution.

The electrostatic contribution can be written as follows

[3] $$\Delta A^{ES} = \Delta U^{ES} + \frac{kT\Gamma^3}{3\pi}$$

where ΔU^{ES} is the excess internal energy due to ion–ion interactions, Γ is the MSA screening parameter defined below, and k is the Boltzmann constant. The general electrolyte solution contains at least two different ions, each of which has a number density ρ_i, a valence z_i, and an effective diameter σ_i. The excess internal energy of any ion i is then

[4] $$\Delta U_i^{ES} = -\frac{e_0^2 \rho_i z_i N_i}{4\pi\varepsilon_0\varepsilon_s}$$

where

[5] $$N_i = \frac{\Gamma z_i + \zeta\sigma_i}{1 + \Gamma\sigma_i}$$

[6] $$\zeta = \frac{\pi}{2\Omega\Delta}\sum_k \frac{\rho_k\sigma_k z_k}{1 + \Gamma\sigma_k}$$

[7] $$\Omega = 1 + \frac{\pi}{2\Delta}\sum_k \frac{\rho_k\sigma_k^3}{1 + \Gamma\sigma_k}$$

[8] $$\Delta = 1 - \frac{\pi}{6}\sum_k \rho_k\sigma_k^3$$

and

[9] $$\Gamma^2 = \frac{\beta e_0^2}{4\varepsilon_0\varepsilon_S}\sum_i \rho_i[(z_i - \zeta\sigma_i^2)/(1 + \Gamma\sigma_i)]^2$$

In these expressions e_0 is the fundamental electronic charge; ε_S, the relative permittivity of the solvent; ε_0, the permittivity of free space; and $\beta = 1/kT$. The screening parameter Γ must be determined by an iterative technique. A convenient starting point in this regard is the value of Γ in the limit that the size of the ions goes to zero. This result gives

[10] $$\Gamma|_{\sigma_i=0} = \frac{\kappa}{2} = \frac{1}{2}\left(\frac{\beta e_0^2}{\varepsilon_0\varepsilon_S}\sum_i \rho_i z_i^2\right)^{1/2}$$

where κ is the Debye–Hückel screening parameter.

Once the screening parameter Γ has been determined, the values of ΔU_i^{ES} and ζ are found by solving eqs. [4]–[8]. The total electrostatic contribution to the excess internal energy is obtained by adding up the contributions from individual ions

[11] $$\Delta U^{ES} = \sum_i \Delta U_i^{ES}$$

The electrostatic contribution to the single ion activity coefficient is determined by differentiating the excess Helmholtz energy due to electrostatic effects with respect to the corresponding ionic number density:

[12] $$\ln y_i^{ES} = \left(\frac{\partial\beta\Delta A^{ES}}{\partial\rho_i}\right)_\Gamma$$

The result obtained by Simonin et al. (12) is

[13] $$\ln y_i^{ES} = \frac{-\beta e_0^2}{4\pi\varepsilon_0\varepsilon_s}\left[\frac{\Gamma z_i^2}{1 + \Gamma\sigma_i} + \zeta\sigma_i\left(\frac{2z_i - \zeta\sigma_i^2}{1 + \Gamma\sigma_i} + \frac{\zeta\sigma_i^2}{3}\right)\right] - \frac{\beta\Delta U^{ES}}{4\pi\varepsilon_0\varepsilon_s}\frac{\partial\varepsilon_s}{\partial\rho_i}$$

The value of $\partial\varepsilon_S/\partial\rho_i$ is unknown for the reactants and the activated complex. However, in the kinetic studies examined here, the concentration of the reactants was always low except in the case of the sucrose study (6). As a result, the only species affecting the solution permittivity are the ions from the inert electrolyte. This means that $\ln y_i^{ES}$ may be estimated for the reactants and activated complex, assuming that $\partial\varepsilon_S/\partial\rho_i$ for each of these species is zero. The value of $\partial\varepsilon_S/\partial\rho_i$ would be required if one wished to estimate individual activity coefficients for the ions of the inert electrolyte, but that is not the object of the present study. Finally, the value of the experimentally observed permittivity ε_S, which involves knowing how this quantity varies with inert electrolyte concentration, was used in calculations based on eq. [13].

The permittivity data for the aqueous inert salt solutions were obtained from the recent compilation of Barthel et al. (13). This compilation provides detailed information about the frequency dependence of the permittivity at each concentration. To avoid the effects of possible ion pairing at low frequencies, and of any high-frequency relaxations, the in-phase component ε_{in} of the permittivity was plotted against the out-of-phase component ε_{out} in order to determine the static

Table 1. Values of the constants δ_s and b_s, which describe the concentration dependence of ε_s in eq. [15], along with the maximum concentration for which permittivity data are available $c_{max}(\varepsilon_s)$.

Electrolyte	δ_s (L mol^{-1})	b_s (L$^{3/2}$ mol$^{-3/2}$)	$c_{max}(\varepsilon_s)$ (M)
KCl	14.7	3.0	4.0
NaCl	16.2	3.1	4.0
KNO_3	14.4	4.5	4.0
$NaNO_3$	16.9	4.3	4.0

permittivity of the solvent ε_S. According to the Debye model, the relationship between these quantities is

$$[14] \quad \varepsilon_{in} = \varepsilon_S - \omega\tau\varepsilon_{out}$$

where ω is the angular frequency, and τ, the Debye relaxation time. Excellent linear plots were obtained for most of the frequency range above 8 GHz for the electrolytes considered here.

The concentration dependence of ε_S was analyzed on the basis of the relationship

$$[15] \quad \varepsilon_s = \varepsilon_{s0} - \delta_s c_e + b_s c_e^{3/2}$$

where ε_{S0} is the permittivity of the *pure* solvent (for H_2O, 78.45 at 25°C), c_e, the electrolyte concentration in M, δ_S, the dielectric decrement for the given electrolyte, and b_S, a parameter describing the nonlinear part of this dependence. Values of δ_S and b_S, determined by a least-squares fit of eq. [15] to the ε_S data, are summarized in Table 1 for the inert electrolytes included in this study.

Finally, the unrestricted hard sphere contribution may be calculated by differentiating the expression for the Helmholtz energy of a mixture of hard spheres (14, 15). The hard sphere contribution to $\ln y_i$ for the case that there are two or more particles of differing size, regardless of their charge, is evaluated as follows:

$$[16] \quad \ln y_i^{HS} = \left(\gamma_i - 1 - \frac{2\eta_i}{\eta} y_3\right) \ln X + \frac{\eta}{X^2}\left[3(1-\alpha_i) + \gamma_i + \frac{3\eta}{2}(\alpha_i - \beta_i - \gamma_i - 1)\right] + \frac{\eta_i}{X^3}\left\{\eta\left[5y_3 - \frac{9}{2}y_1 - 2 + \eta\left(\frac{3}{2}y_1 - 3y_2 - 4y_3 + 1\right)\right] - 2y_3 + 4\right\}$$

where

$$\eta_i = \frac{\pi}{6}\rho\sigma_i^3, \qquad \eta = \sum_i \kappa_i\eta_i, \qquad \kappa_i = \frac{\rho_i}{\rho}, \qquad \rho = \sum_i \rho_i$$

and

$$[17] \quad X = 1 - \eta$$

The other quantities introduced in eq. [16] are as follows

$$[18] \quad y_1 = \sum_{i>j} \Delta_{ij} \frac{\sigma_i + \sigma_j}{(\sigma_i\sigma_j)^{1/2}}$$

$$[19] \quad y_2 = \sum_{i>j} \Delta_{ij} \sum_k \kappa_k \frac{\eta_k}{\eta} \frac{(\sigma_i\sigma_j)^{1/2}}{\sigma_k}$$

$$[20] \quad y_3 = \left[\sum_i \kappa_i \left(\frac{\eta_i}{\eta}\right)^{2/3}\right]^3$$

$$[21] \quad \Delta_{ij} = \kappa_i\kappa_j \frac{(\eta_i\eta_j)^{1/2}}{\eta} \frac{(\sigma_i - \sigma_j)^2}{\sigma_i\sigma_j}$$

$$[22] \quad \alpha_i = \frac{1}{\eta}\sum_k \kappa_k \frac{(\sigma_i + \sigma_k)(\sigma_i - \sigma_k)^2(\eta_i\eta_k)^{1/2}}{(\sigma_i\sigma_k)^{3/2}}$$

$$[23] \quad \beta_i = \sum_{i>j} \Delta_{ij} \frac{\eta_i}{\eta} \frac{(\sigma_i\sigma_j)^{1/2}}{\sigma_i} + \sum_j \kappa_j \frac{(\eta_i\eta_j)^{1/2}}{\eta} \frac{(\sigma_i - \sigma_j)^2}{\sigma_i\sigma_j} \times \sum_k \kappa_k \frac{\eta_k}{\eta} \frac{(\sigma_i\sigma_j)^{1/2}}{\sigma_k}$$

and

$$[24] \quad \gamma_i = 3\left(\frac{\eta_i}{\eta} y_3\right)^{2/3}$$

The present model assumes that the size of the reactants are equal, so eqs. [16]–[24] are solved for only four, instead of five, species in solution, that is, the reactants, the activated complex, the cation of the inert salt, and the anion of the inert salt. By adding the logarithms of the electrostatic and the hard sphere contributions, one obtains the activity coefficient on the molar scale y_i:

$$[25] \quad \ln y_i = \ln y_i^{ES} + \ln y_i^{HS}$$

The medium effect in solution reactions involving ions

The description of the medium effect for a reaction in solution is based on transition state theory (4), and involves estimation of the concentration of the activated complex X^* formed in a pseudoequilibrium with the reactants A and B (eq. [1]). The equilibrium constant for this process is K^* given by

$$[26] \quad K^* = \frac{a_{X^*}}{a_A a_B}$$

where a_i is the activity of component i. Since all of these species can be charged, the activity coefficients are not unity, and are expected to vary significantly with ionic strength. The rate of reaction υ_r is given by

$$[27] \quad \upsilon_r = \nu^* c_{X^*} = \frac{\nu^* K^* a_A a_B}{y_{X^*}} = \frac{y_A y_B}{y_{X^*}} \nu^* K^* c_A c_B$$

where ν^* is the frequency of decomposition of the activated complex into products; c_i, the molar concentrations of the species A, B, and X^*; and y_i, the corresponding activity coefficients on the molarity scale. The rate constant k_r for reaction [1] is

For personal use only.

$$[28] \quad k_r = \frac{\upsilon_r}{c_A c_B} = \frac{y_A y_B}{y_{X^*}} k_{r0}$$

where

$$[29] \quad k_r = \nu^* K^*$$

The rate constant k_{r0} is that measured in the absence of medium effects and, in general, cannot be determined experimentally. This follows from the fact that the solution always has a finite ionic strength even in the absence of an inert electrolyte.

In the Debye–Hückel description of this effect, each activity coefficient is given by its value in the concentration region where the limiting law applies, that is

$$[30] \quad \ln y_i = -Az_i^2 I^{1/2}$$

where I is the ionic strength and A, the Debye–Hückel constant. Substituting this expression for y_i in eq. [28], one obtains, after some simple algebra,

$$[31] \quad \ln (k_r/k_{r0}) = +2Az_A z_B I^{1/2}$$

This result involves the assumption that the charge on the activated complex is $z_A + z_B$. It has often been presented in textbooks, but is limited in validity to the concentration range over which the limiting Debye–Hückel law is valid. When data are available at these low concentrations, eq. [31] is quite useful, because it allows one to confirm the nature of ions involved in the rate-determining step by plotting ln k_r against $I^{1/2}$. The value of the product $z_A z_B$ can then be extracted from the slope of such a plot.

In the present study, attention is focused on eq. [28], and the question of whether medium effects can be understood beyond the range of applicability of the limiting Debye–Hückel law. Thus, it is always assumed that z_A and z_B are known from the analysis of data at lower ionic strengths. Details of our analysis and the results are presented in the following sections.

Data analysis

A basic requirement in the literature search for rate constant data demonstrating the "kinetic salt effect" was that the reactants be kept at the same concentrations while the ionic strength was increased only by the addition of an inert 1-1 electrolyte. This requirement follows from the fact that the activity coefficients of the reactants do not depend on their concentration in a simple way. Moreover, the purpose of this study is to show that the theoretically determined activity coefficients for the reactants and activated complex can be directly related to the reaction rate. In all cases, the MSA effective ion sizes for the inert salt were obtained in earlier work (8) and are given in Table 2. To keep the analysis simple, the sizes of the reacting ions A and B were assumed to be the same. Although this is not always a reasonable assumption, it reduces the number of assumed parameters by one. However, this assumption is expected to have an effect on the best value of the size of the activated complex σ_{X^*}, which is also required to carry out the analysis. The best value of σ_{X^*} was found by requiring that a plot of $\log_{10} k_r$ against $\log_{10}(y_A y_B/y_{X^*})$ be linear with a slope of unity. The maximum ionic strength considered was 1 M. Although data for most systems studied involve lower ionic strengths, data for the inversion of sucrose (6) have been reported to ionic strengths as high as 3 M. A proper analysis of data at high ionic strengths should consider the effects of ion pairing, which are not negligible under these conditions (8).

Two other features of the analysis need to be mentioned. Since the reactants A and B are usually ions, their presence in solution adds other ions to the system. For example, if A and B are cations, they come into solution with anions. These anions were assumed to be the same as the anion of the inert electrolyte, and its concentration was adjusted in the appropriate way. Thus, all calculations were performed with a strictly electroneutral system, and the estimation of the ionic strength and the screening parameter Γ were made considering all ions in the system.

In all cases except two, the kinetic data were obtained in studies made at 25°C, that is, at the same temperature at which the dielectric permittivity data are available. However, in the case of the $CoBr(NH_3)_5^{2+}$–OH^{1-} and $CoBr(NH_3)_5^{2+}$–Hg^{2+} systems, the kinetic data were obtained at 15°C. For these systems, the value of ε_{S0} was taken to be 82.44, as reported for pure water at 15°C in the literature (13), and the values of δ_S and b_S for the inert salt were assumed to have the same values obtained at 25°C (see Table 1). No dielectric decrement data are available for NaBr, which was used as the inert electrolyte for the $CoBr(NH_3)_5^{2+}$–OH^{1-} study. The permittivity parameters were assumed to be the same as those for the NaCl system as reported in Table 1. On the basis of our previous work this is a reasonable assumption.

For each system, the linear regression line obtained by a plot of $\log_{10} k_r$ against $\log_{10}(y_A y_B/y_{X^*})$ was extrapolated to

Table 3. Values for the diameter of the reactants σ_A and σ_B ($\sigma_A = \sigma_B$) and the activated complex σ_{X^*}, which produce a slope of unity for the plot of $\log_{10}k$ against the MSA estimate of $\log_{10}(y_A y_B/y_{X^*})$, along with the logarithm of the rate constant in the limit of infinite dilution $\log_{10}k_{r0}$, and the linear least-squares correlation coefficient r.

Reactants A, B	$\sigma_{A,B}$ (pm)	σ_{X^*} (pm)	$\log_{10}k_{r0}$	r
$BrCH_2COO^{1-}$, $S_2O_3^{2-}$	400	687	−0.551	0.998
Nitrourethane anion, OH^{1-}	800	1074	−0.844	0.992
Sucrose, H_3O^{1+}	800	1057	−0.525	0.994
$CoBr(NH_3)_5^{2+}$, OH^{1-}	700	1065	2.04	0.999
$CoBr(NH_3)_5^{2+}$, Hg^{2+}	700	674	1.84	0.996

zero, and the value of the rate constant in the limit of infinite dilution k_{r0} was estimated. This value was then used in eq. [31] to obtain a plot of $\log_{10}(k/k_{r0})$ against the square root of the ionic strength. The initial slope of this plot estimated by the limiting Debye–Hückel law for ionic strengths below 0.01 M is also shown in Figs. 1–5. The results for each system, along with the correlation coefficient for the MSA are reported in Table 3.

Discussion

Kinetic data were examined for five systems, corresponding to values of $z_A z_B$ equal to 4, 2, 1, 0, and −2. The nature of the reactants, the inert electrolyte, and the values of the size parameters for this electrolyte obtained in earlier work are summarized in Table 2.

The results of our analysis are summarized in Table 3 and in Figs. 1–5. First of all, it should be noted that excellent fits to the data were obtained in all cases. This allows one to extrapolate the plots of $\log_{10}k_r$ against $\log_{10}(y_A y_B/y_{X^*})$ to obtain values of the rate constant at infinite dilution k_{r0}. It should be noted that values of k_{r0} reported in the early literature often corresponded to the rate constant measured at finite ionic strength in the absence of an inert electrolyte. In our analysis, the concentration of *all* ions was considered in calculating the ionic strength so that k_{r0} is a hypothetical rate constant not measurable in the laboratory, but it is a proper point of reference.

Results for the bromoacetate–thiosulphate reaction for which $z_A z_B$ is equal to 2 are shown in Fig. 1. As can be seen, the MSA estimates of the ratio $y_A y_B/y_{X^*}$ successfully describe the kinetic data for ionic strengths up to 1 M. The values of the assumed diameters for the reactants and activated complex, namely 400 and 600 pm, respectively, are quite reasonable. The traditional plot of $\log_{10}(k_r/k_{r0})$ against $I^{1/2}$ demonstrates the severe departure of the kinetic data from limiting Debye–Hückel behavior over most of the experimental range that data have been reported. This analysis underscores the necessity of considering the size of all ions in the electrolyte solution in order to make realistic estimates of ionic activity coefficients.

Results for the nitrourethane–hydroxyl system for which $z_A z_B$ is equal to 1 are shown in Fig. 2. Much larger values of the hard sphere diameter were required to get an acceptable fit in the MSA analysis. In the traditional Debye–Hückel plot all of

the data points fall below the limiting Debye–Hückel behavior. This is not unexpected because the data were obtained at ionic strengths greater than 0.01. The hard sphere approximation is probably weakest for this system because of the charge

distribution on the nitrourethane–hydroxyl activated complex. It is probable that the negative charge on the nitrourethane anion is several atoms away from the site of attack of the hydroxyl ions, so that this complex behaves more like a species with a charge of -1 with respect to ionic atmosphere effects. This would explain the fact that deviations from the Debye–Hückel line are lower than one might anticipate.

Results for the inversion of sucrose in the presence of KCl are shown in Fig. 3. In this case, the reactants sucrose and hydronium ion were held at fixed concentrations of 0.5843 M and 0.1 M, respectively. The large hard sphere contribution from the reactant sucrose correctly holds the ratio $y_A y_B/y_{X^*}$ above unity even in the limit of zero ionic strength. The application of the MSA in this case allows one to estimate the rate constant k_{r0} in the limit of infinite dilution of the uncharged reactant sucrose, a very useful result. Since the product of $z_A z_B$ is zero, the rate constant for this reaction should be independent of ionic strength on the basis of Debye–Hückel theory. The increase in k_r, seen experimentally, is clearly due to the hard sphere effect only, that is, the finite size of the solute species in the electrolyte solution. An excellent description of this effect is obtained on the basis of the MSA, assuming rather large diameters for the reactants and activated complex. The assumption that σ_A is equal to σ_B is clearly incorrect here because the effective size of the hydronium ion should be much smaller than that of a sucrose molecule. However, making the calculation more carefully would involve adding at least one more adjustable parameter. Since our purpose is only to demonstrate the effectiveness of the MSA in a qualitative way, the present results are quite satisfying.

Results for the bromopentaamino Co(III) – hydroxyl ion system for which $z_A z_B$ is equal to -2 are shown in Fig. 4. This is the only system considered here in which the charges on the

reacting ions are opposite one another. The fit is again very successful with reasonable values being obtained for σ_A, σ_B, and σ_{X^*}.

The last system considered involved ions with high charges

© 1997 NRC Canada

and a value of $z_A z_B$ equal to 4 (Fig. 5). Although ion pairing is expected to play a role in medium effects for this system, a very good fit was obtained to the kinetic data, with reasonable values for the size parameters.

The present study is especially valuable in the estimation of the work terms in homogeneous electron transfer reactions. In Marcus' detailed description of the theory of electron transfer (18), w_r was defined as the work done to bring the reactants from points very far from one another to contact. This work is equivalent to the factor $RT \ln(y_A y_B / y_{X^*})$ discussed in this paper. In most estimates of w_r (19, 20), the extended Debye–Hückel theory has been used. However, this model is limited to ionic strengths of 0.1 M, whereas experimental studies are often carried out at higher ionic strengths. This is especially true of studies of self-exchange reactions such as the Fe^{3+}/Fe^{2+} system, which often involve highly charged reactants. The MSA is clearly superior to the extended Debye–Hückel model because it considers the sizes of all the solute particles in the system. Its application to existing data would help considerably in obtaining better estimates of the Gibbs activation energy for electron transfer in the limit of infinite dilution.

In summary, the present study has shown conclusively that the MSA provides a very reasonable extension of the Debye–Hückel theory. It can be applied to describe the thermodynamic properties of 1-1 electrolytes for ionic strengths up to 1 M, provided it is used in its unrestricted version in which different sizes are assumed for each ionic species in solution. The main feature of this model, which enabled the present successful treatment of medium effects for ionic reactions in solution, is the consideration of the finite size of all solute species in the system, not just a central ion as in the Debye–Hückel model. Further improvement in the description of these systems would require the addition of ion pairing to the model. This has been done for simple electrolyte solutions (8) but does not seem worthwhile in the analysis of kinetic data, at least, considering the fact that so few studies are available.

Comprehensive studies of formation and reduction of surface oxides at rhodium electrodes at 298 K

Francis Villiard and Gregory Jerkiewicz

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12
For personal use only.

Abstract: Surface oxides on Rh were formed by anodic polarization at various potentials, E_p, from 0.70 to 1.40 V, RHE, for polarization times, t_p, up to 10^4 at 298 K; their thickness expressed as a charge density, q_{OX}, was evaluated from cyclic voltammetry, CV, profiles. The oxide growth proceeds in two steps whereas its reduction occurs in one. Upon extension of E_p and (or) t_p to higher values, q_{OX} increases. Under the above experimental conditions, q_{OX} varied from 110 ± 5 to 985 ± 10 μC cm^{-2}; after conversion, these charge densities correspond to 0.5 monolayer, ML, of RhOH and 1.56 ML of $Rh(OH)_3$, respectively. Augmentation of E_p and t_p results in thermodynamically more stable oxides. Plots of q_{OX} versus log t_p are linear over the whole range of q_{OX} whereas plots of $1/q_{OX}$ versus log t_p are linear only when q_{OX} >210 μC cm^{-2}. Thus, the oxide growth is either logarithmic in time over the whole region of q_{OX} or it is logarithmic when q_{OX} <210 μC cm^{-2} and inverse-logarithmic when q_{OX} >210 μC cm^{-2}. It was observed that the oxide growth continues when the positive-going scan is stopped in the oxide-formation potential region. Similarly, the oxide reduction proceeds when the negative-going scan is stopped in the oxide-reduction potential range. Finally, the authors present the first-ever studies of the Rh oxide reduction. The results indicate that the reduction takes place at $E \leq 0.70$ V, RHE. The oxide reduction kinetics are not understood but, in general, the lower the reduction potential and the longer the reduction time, the greater the amount of the reduced oxide.

Key words: rhodium oxides, oxide films, growth kinetics, reduction kinetics.

Résumé : La polarisation anodique à des potentiels, E_p, allant de 0,70 à 1,40 V, RHE, pour des temps de polarisation, t_p, allant jusqu'à 10^4 s à 298 K, conduit à la formation d'oxydes de surface sur le Rh; on a évalué leur épaisseur en fonction de la densité de charge, q_{OX}, à partir de leurs profils de voltampérométrie cyclique, VC. La croissance de l'oxyde se fait en deux étapes alors que la réduction n'en implique qu'une. Si l'on augmente les valeurs de E_p et (ou) de t_p, la valeur de q_{OX} augmente. Dans les conditions expérimentales décrites plus haut, q_{OX} varie de 110 ± 5 à 985 ± 10 μC cm^{-2}; après conversion, ces densités de charge correspondent respectivement à 0,5 d'une monocouche, MC, de RhOH et à 1,56 MC de $Rh(OH)_3$. Des augmentations de E_p et de t_p conduisent à des oxydes thermodynamiquement plus stables. Les courbes de q_{OX} en fonction de log t_p sont linéaires sur l'ensemble de q_{OX} alors que celles de $1/q_{OX}$ en fonction du log t_p ne sont linéaires que lorsque q_{OX} >210 μC cm^{-2}. Ainsi, la croissance de l'oxyde est soit logarithmique avec le temps sur l'ensemble de q_{OX} soit elle est logarithmique quand q_{OX} <210 μC cm^{-2} et logarithmique inverse quand q_{OX} >210 μC cm^{-2}. On a observé que la croissance de l'oxyde se poursuit lorsqu'on arrête le balayage positif dans la région de potentiel conduisant à la formation d'oxyde. De la même manière, la réduction de l'oxyde se poursuit lorsqu'on arrête le balayage négatif dans la région de potentiel conduisant à la réduction de l'oxyde. Enfin, les auteurs présentent les toutes premières études sur la réduction de l'oxyde de Rh. Les résultats indiquent que la réduction se produit à $E \leq$ 0,70 V, RHE. On ne comprend pas la cinétique de la réduction de l'oxyde, mais, en général, la quantité d'oxyde réduit augmente avec une diminution du potentiel de réduction et une augmentation du temps de réduction.

Mots clés : oxydes de rhodium, oxydes en film, cinétique de la croissance, cinétique de la réduction.

Introduction

Surface oxides on metals can be formed by application of gas phase and electrochemical techniques (1–7). The oxide development under gas phase conditions requires the presence of an oxidizing atmosphere containing molecular oxygen. During oxidation, the O_2 molecule approaching the metal surface undergoes dissociation and the oxygen atoms become chemisorbed, O_{chem}. Subsequently, the transfer of two electrons to O_{chem} takes place, resulting in creation of O^{2-}. The formation of O^{2-} is accompanied by formation of the metal cation, M^{Z+}, or M^{2+} in the case of a divalent metal, at the metal–oxide interface (Fig. 1). In the case of electroformation of surface oxides, the process requires the presence of an oxidizing electrolyte and an external current source. In acidic solutions, for instance, the water molecule discharge results in formation of adsorbed OH species, and subsequent electron transfer with simultaneous H departure from OH_{ads} groups leads to formation of O^{2-} (Fig. 1); the process is

Fig. 1. Visual representation of surface-oxide development under gas-phase and electrochemical conditions. Under gas-phase conditions, the O_2 undergoes dissociation and the process leads to development of O_{chem}; simultaneous formation of the metallic cation, M^{2+}, and the electron transfer through the oxide film result in creation of a surface metal–oxide structure that comprises M^{2+} and O^{2-}. Under electrochemical conditions, the adsorbed O_{chem} or OH_{chem} results from discharge of the O-containing species of electrolyte (here the H_2O molecule); accompanying creation of M^{2+} and the electron transfer through the oxide leads to development of a surface oxide or surface hydroxide.

followed by creation of M^{Z+} cations at the inner metal–oxide interface; the transport of electrons, O^{2-}, and M^{Z+}, is assisted by the externally applied electric field. The extent of surface oxidation accomplished by utilization of electrochemical means is related to nature of the metal and the polarization conditions as well as to the electrolyte composition and pH. Metal oxidation does not necessarily involve development of an oxide film since, for instance, a surface sulfide can be grown in a nonaqueous solvent containing S^{2-} or HS^-, or in a molten sulfide (1–3). It has been discussed elsewhere that a stable surface oxide affects the kinetics and mechanism of various faradaic and redox anodic processes (8–14). In particular, the surface valence band structure of an oxidized metal differs from that of the native metal, giving rise to (*i*) distinguishable adsorption properties of the reaction intermediates and products and (*ii*) creation of a barrier to charge transfer. In the case of anodic oxidation of adsorbed inorganic/organic species, the potential region in which the process takes place can overlap that of the oxide formation, thus the overall current corresponds to both electrode processes occurring concurrently. Presence of the surface oxide can alter the kinetics, mechanism, and the pathways of the process, resulting in reduced or enhanced electrochemical activity as well as in new reaction products.

Growth of the surface oxide on noble-metal electrodes can be conveniently studied by application of electrochemical techniques such as cyclic voltammetry, CV, and linear-sweep voltammetry, LSV, because the oxide can be completely reduced within one CV cycle or LSV sweep, respectively (11, 12, 15–26). This approach allows one to (*i*) evaluate the overall oxide-reduction charge density, q_{OX}, with the precision of some 2–3% of a monolayer; (*ii*) identify different oxidation states of the metal cation in the oxide; and (*iii*) distinguish various energetic states of the oxide that can arise from different surface structures or different degrees of hydration. However, this procedure cannot be applied to scrutinize the thickness of oxides on certain transition metals such as Ni, Ti, Zr, Hf, etc., because the passive films are not reducible by utilization of electrochemical techniques.

X-ray photoelectron spectroscopy, XPS, Auger electron spectroscopy, AES, core-level electron energy loss spectroscopy, CEELS, and ellipsommetry experiments (27–32) are of importance to the electrochemical surface science of oxides because they provide means of elucidating the oxidation state of the metal cation within the oxide, identifying the presence of other surface species, and evaluating thickness of the oxide. Coupling of UHV-based surface-science techniques with electrochemical procedures results in detailed characterization of the electrified solid–liquid interface and in assessment of the relation between the mechanism and kinetics of the electrode process under scrutiny as well as the chemical and electronic structure of the surface of the electrode without contaminating it by transfer via air.

Rhodium, being a noble metal, forms surface oxides upon anodic polarization even in the region of water stability, thus below the thermodynamic reversible potential of the oxygen evolution reaction, E°_{OER} = 1.23 V, SHE (4–6, 8–26). In aqueous 0.50 M H_2SO_4 solution, the oxide growth on Rh commences at 0.55 V versus the reversible hydrogen electrode, RHE, and a complete monolayer, ML, of $Rh(OH)_3$ is formed upon reaching the potential of 1.40 V, RHE, as revealed by CV and XPS measurements (27). Short potentiostatic polarization at potentials between 3.00 and 4.00 V, RHE, or prolonged polarization at potentials above 2.00 V, RHE, leads to formation of oxides comprising two species, namely, $Rh(OH)_3$ and RhO(OH) (12, 27). Elsewhere (13), it was shown that the $Rh(OH)_3$ layer grows to a limiting thickness of 3 ML and that it is sandwiched between Rh and the outer film consisting of RhO(OH). In the case of Rh oxides formed in 0.50 M aqueous H_2SO_4 by anodic polarization at potentials from 0.80 to 2.40 V, RHE, and for times up to 10^4 s, it was observed that these conditions resulted in development of thin films and that once a monolayer of RhOH had been formed, the oxide growth followed inverse-logarithmic kinetics with the process being limited by the rate of escape of the Rh^{3+} cation from the metal into the oxide (12). Subsequently, the kinetics of the oxygen evolution reaction, OER, on preoxidized Rh electrodes were evaluated and a relation between the oxide thickness and the kinetic parameters of the OER was established (13).

In this paper, the authors demonstrate a comprehensive study of the formation and reduction of Rh monolayer oxides in 0.50 M aqueous H_2SO_4 solution at 298 K. The present results are an extension to the previous work (12–14) and they show detailed investigation of the development of Rh oxides upon polarization at $0.70 \leq E_p \leq 1.40$ V, RHE, with an interval, ΔE, of 0.05 V for $t_p \leq 10^4$ s; these data have not been presented before. The paper also presents first-ever data on the reduction behavior of Rh surface oxides under potential-controlled conditions, namely, at $0.70 \geq E_r \geq 0.25$ V, RHE, with ΔE of 0.05 V and for $t_r \leq 10^4$ s.

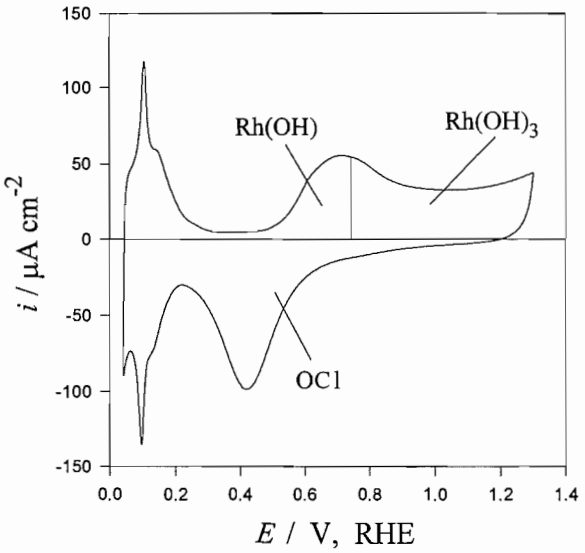
Experimental

Electrode preparation and oxide charge density examination.

The Rh electrode was a wire (99.99% in purity); the preparation methodology and pretreatment of the electrode are described elsewhere (12–14). The shape of the CV profiles recorded in 0.50 M aqueous H_2SO_4 indicated that both the electrode and the electrolyte were free of impurities (33, 34). Elsewhere (12–14), it was discussed that growth of oxides did not affect the surface of the electrode, which sustained its characteristics as revealed from the CV profile features in the 0.05–0.30 V, RHE, potential range. The real surface area of the Rh electrode was determined by accepting the charge of 210 $\mu C\ cm^{-2}$ as that necessary to form a monolayer of H_{UPD} (4, 12, 13), allowing for the double-layer charging; it was found to be 0.26 ± 0.01 cm^2. No dissolution of the anodically formed oxides was observed during the course of research. This conclusion is based on the observation that the q_{OX} versus log t_p or the $1/q_{OX}$ versus relations do not deviate from linearity (11).

It is essential to elaborate on the possible presence of molecular oxygen in the electrolyte upon electrode polarization at potentials above E°_{OER} = 1.23 V, SHE. Indeed, the latter is the thermodynamic reversible potential of the OER but, due to a significant overpotential of the OER, no molecular oxygen is present in the electrolyte and the oxide-reduction profiles are not obscured; this aspect is discussed in refs. 11–13.

Because the potential region corresponding to oxide reduction overlaps that of hydrogen and anion adsorption, it is necessary to explain how the oxide charge density was examined. The procedure applied is as follows. A CV profile between 0.05 and 0.55 V, RHE, thus prior to the oxide growth, was applied and the charge density of the double-layer charging, as well as the hydrogen and anion adsorption, was determined. This charge density was subsequently subtracted from the total charge density as determined from the oxide-reduction CV profile (11–13).



Solution and electrochemical cell

A high-purity 0.50 M solution was prepared from BDH Aristar grade and Nanopure water. Oxygen was removed from the solution by passing high-purity nitrogen through and over the cell solution at all times. The cleanliness of the solution was verified by recording CV profiles, which were found in agreement with those in the literature (1, 12–14, 21, 22). The electrochemical cell employed was a standard, all-glass, three-compartment cell with sleeved stopcocks. The glassware was precleaned according to well-established procedure (33, 34). During the experiments, H_2 gas that had been precleaned and presaturated with water vapor was bubbled through the reference electrode, RE, compartment in which a Pt/Pt black electrode was immersed.

Temperature control

The electrochemical cell was immersed in a Haake W13 water bath, and the temperature was maintained at 298 ± 0.5 K by means of a Haake D1 thermostat; the water level in the bath was kept above the electrolyte in the cell. The temperatures in the water bath and in the electrochemical cell were controlled by means of thermometers and a 80 TK Fluke K-type thermocouple; the readings were in agreement to within ±0.5 K.

Fig. 2. CV profile for Rh in 0.50 M aq. H_2SO_4. The oxide growth proceeds in two steps and involves formation of Rh(OH) followed by its transition to $Rh(OH)_3$. The oxide reduction takes place in one step, peak OC1. Sweep rate s = 50 mV s^{-1}, T = 298 K.

Instrumentation

The instrumentation included: (*a*) an EG&G model 273 potentiostat–galvanostat, (*b*) an 80486 computer, and (*c*) EG&G M270 electrochemical software. All potentials quoted in the paper were measured with respect to the RHE immersed in the same electrolyte and kept at the same temperature. Upon anodic polarization the potential was held constant to within 1 mV and was monitored on a Fluke 45 digital multimeter.

Results and discussion

Oxide development and chemical identity of the surface oxide species

To present a meaningful discussion of the growth of Rh oxides formed under well-defined potentiostatic conditions, it is essential to consider the surface processes involved in their development and on their surface-chemical composition. Peuckert (27) studied the surface-chemical composition of Rh oxides by means of X-ray photoelectron spectroscopy, XPS, and established that their formation proceeds in two steps: the first step involves electrodeposition of OH and the process occurs in the 0.55–0.75 V, RHE, potential range (eq. [1]); the second step leads to creation of $Rh(OH)_3$ (eq. [2]). The two potential regions with the respective surface-oxide species are shown in Fig. 2. It is worthwhile emphasizing that while the oxide growth proceeds in two steps, the oxide reduction is a one-step process (the OC1 peak in Fig. 2 and eq. [3]).

Formation

[1] $Rh + H_2O \rightarrow RhOH + H^+ + e$, 0.55–0.75 V

[2] $RhOH + 2\ H_2O \rightarrow Rh(OH)_3 + 2\ H^+ + 2\ e$, 0.75–1.40 V

Reduction

[3] $Rh(OH)_3 + 3\ H^+ + 3\ e \rightarrow Rh + 3\ H_2O$

The mechanism of the surface-oxide development on Rh is not yet well understood. For instance, at the present state of knowledge, it is unclear if $Rh(OH)_2$ acts as an intermediate in the $Rh(OH)_3$ formation (eqs. [4*a*] and [4*b*]) or whether $Rh(OH)_3$ is formed in a single step involving discharge of two water molecules (eq. [5]).

[4*a*] $RhOH + H_2O \rightarrow Rh(OH)_2 + H^+ + e$

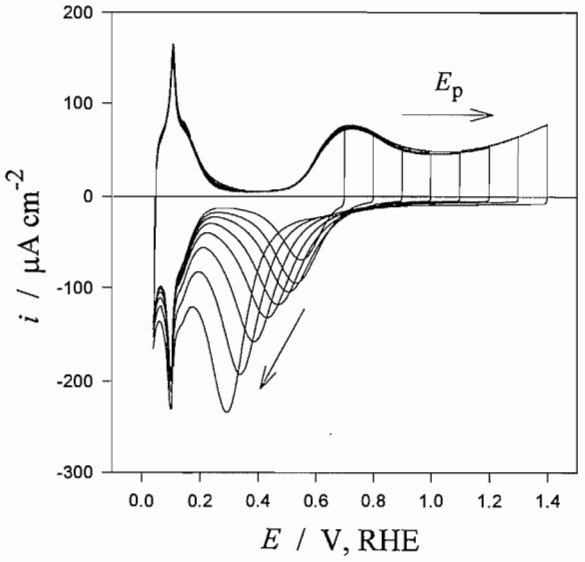
[4*b*] $Rh(OH)_2 + H_2O \rightarrow Rh(OH)_3 + H^+ + e$

[5] $RhOH + 2\ H_2O \rightarrow Rh(OH)_3 + 2\ H^+ + 2\ e$

An answer to this question can be provided only by combined electrochemistry–XPS–CEELS measurements or X-ray scattering experiments. Another aspect of the very initial development of RhOH that requires investigation is the possibility of place exchange between the Rh surface atoms and the electroadsorbed OH groups, leading to a new surface structure (10, 19, 35, 36). Because the formation of surface oxides on noble metals reveals many similarities, it is reasonable to assume that, as in the case of Pt, the electroadsorption of OH groups on Rh is accompanied by place exchange between the Rh surface atoms and OH_{ads}. Evidence for place exchange in Pt oxidation is based on theoretical treatment of the oxide growth mechanism and X-ray scattering data (35–37). However, AC voltammetry results of Harrington and co-workers (38) on Pt oxidation do not support the place-exchange mechanism and indicate the electro-oxidation of Pt is a two-electron process. Moreover, they propose a different growth model in which the metal cation being immersed in the "electron sea" is pulled to the surface by the electroadsorbed OH groups. The authors also discuss the surface diffusion of Pt^{2+} cations and present a quantitative interpretation of their data. Numerical simulations of the formation of Pt surface oxides agree well with the experimentally observed CV profile. Clearly, despite some 25 years of research on the topic (37), the electro-oxidation of noble metals is still not well understood and calls for more research by means of state-of-the-art surface-science techniques.

Anodic polarization of Rh at E_p between 0.70 and 1.40 V, RHE, with an interval of 0.05 V, for t_p up to 10 000 s at 298 K leads to growth of thin oxide films (Figs. 3 and 4). The oxide-formation CV profiles reveal one peak and a wide wave overlapping each other in the 0.55–1.40 V, RHE, range. The CV oxide-reduction profiles show only one feature, designated the OC1 peak (12–14). The reduction charge density of OC1 increases and the peak shifts towards less positive potentials upon extension of E_p or t_p to higher values. In Fig. 3, the authors show CV oxide-reduction profiles for polarization for t_p = 1000 s at potentials from 0.70 to 1.40 V, RHE. The diagrams demonstrate that upon increase of E_p (for t_p = const.) the oxide-reduction charge density increases and the reduction peak shifts towards less positive values, in this particular case from 0.55 to 0.29 V, RHE. In Fig. 4, the authors demonstrate CV oxide-reduction profiles for polarization at E_p = 1.40 V, RHE, for $t_p = 10^0, 10^1, 10^2, 10^3$, and 10^4 s. The diagrams show that upon increase of t_p (for E_p = const.) the oxide-reduction

Fig. 3. Series of CV profiles for Rh in 0.50 M aq. H_2SO_4 solution taken at the sweep rate s = 50 mV s^{-1}, T = 298 K. The profiles demonstrate examples of the effect of increase of the polarization potential, E_p, from 0.70 to 1.40 V, RHE, on the oxide charge density and the reduction peak potential for t_p = 1000 s. The CV reduction profiles reveal only one state, OC1, which shifts towards less positive potentials.



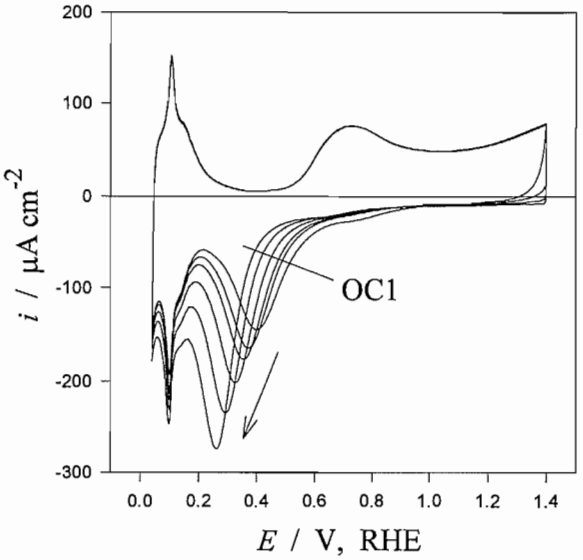


Fig. 4. Series of CV profiles for Rh in 0.5 M aq. H_2SO_4 solution taken at the sweep rate s = 50 mV s^{-1}, T = 298 K. The profiles demonstrate examples of the effect of increase of the polarization time, $t_p = 10^0, 10^1, 10^2, 10^3$, and 10^4 s, on the oxide charge density and the reduction peak potential for E_p = 1.40 V, RHE. The CV reduction profiles reveal only one state, OC1, which shifts towards less positive potentials.

charge density expands and the reduction peak moves towards less positive values, in the case presented above, from 0.40 to 0.26 V, RHE. Similar behavior is observed for values of E_p and t_p other than those referred to in Figs. 3 and 4. For all the E_p or t_p values studied in the course of this research, it was

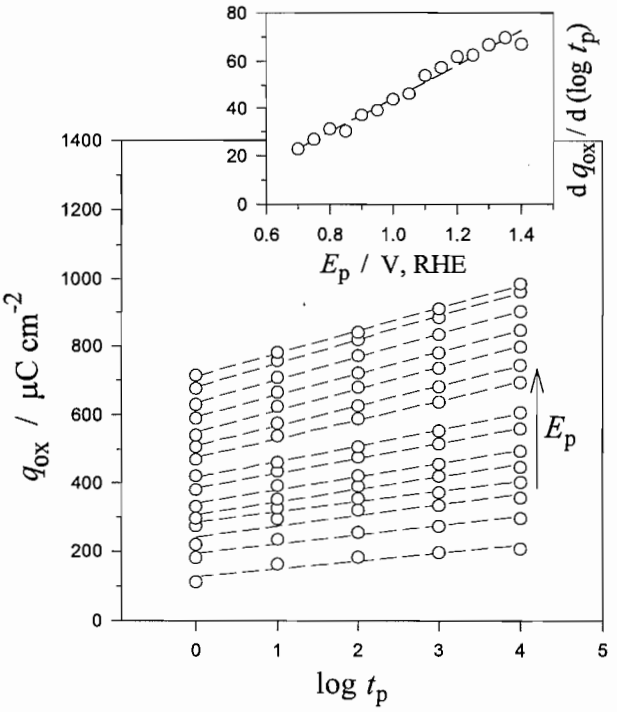
observed that an increase of E_p or t_p always led to enhanced oxide-reduction charge densities, thus to thicker oxide films that reveal the same surface-chemical composition (12–14, 27). The authors base their viewpoint on the observation that the same oxide state is distinguishable in the CV reduction profiles, namely OC1, and the XPS data show that it corresponds to a surface film. Elsewhere (14), it was discussed that extension of E_p and t_p towards higher values had a dual impact on the oxide films: (*i*) thickness increased upon augmentation of E_p and t_p; and (*ii*) thermodynamics of the oxide reduction were changed upon augmentation of E_p and t_p because a lower potential was required to reduce the same chemically equivalent but thicker oxide film when E_p or t_p was increased. Observation (*ii*) leads to the conclusion that thicker oxides are thermodynamically more stable than thin ones. The impact of temperature variation on the thermodynamics of oxide formation is discussed in ref. 14.



Oxide growth kinetics and mechanism

A study of oxide growth kinetics over a wide range of E_p and t_p, followed by theoretical treatment of the results by fitting them into existing oxide-formation theories, leads to assessment of important kinetic parameters of the process as a function of E_p and t_p as well as to examination of the applicable growth mechanism with emphasis on the rate-determining step. Application of CV to scrutiny of the oxide states and subsequent integration of the CV profiles collected in the course of the research allowed the authors to evaluate q_{OX} as a function of E_p and t_p. CV is a very suitable technique in a study of oxide films because it leads to evaluation of the oxide thickness, here expressed as the charge density of the oxide, with great precision (10–19, 23–26, 32, 35). In the case of the development of very thin oxide films (of submonolayer and monolayer thickness) on noble metals, it is well known that the growth often proceeds by logarithmic or inverse-logarithmic kinetics. In the first case, the rate-determining step is the transition from a submonolayer or monolayer of O_{chem} or OH_{chem} residing on the surface of the metal substrate, through place exchange or another surface process, to a new surface structure (1–3, 10, 34, 35, 38). In the case of inverse-logarithmic growth, the escape of the metal cation from metal into the oxide at the inner metal–oxide interface can be the rate-determining step. At present, it is unclear whether another surface process could be responsible for these kinetics and further research is needed to provide an unambiguous answer.

The authors plotted q_{OX} and $1/q_{OX}$ versus log t_p for various E_p in order to examine which growth kinetics are applicable to the system under investigation (Figs. 5 and 6). Under the experimental condition reported above, q_{OX} has values from 110 ± 5 to 985 ± 10 μC cm^{-2}, which correspond to 0.5 ML of Rh(OH) and 1.56 ML of $Rh(OH)_3$, respectively. Clearly, the Rh oxide films are very thin and of submonolayer and monolayer nature. It ought to be added that anodic polarization of Pt under similar E_p and t_p conditions results in thicker oxides than those formed on Rh, thus the electroformation of Rh oxides proceeds more slowly than that of Pt (11, 24–26).

The data shown in Fig. 5 indicate that the q_{OX} versus log t_p relations are linear for the whole range of E_p, thus indicating that the growth kinetics might be logarithmic in polarization (growth) time. The slope of the q_{OX} versus log t_p plots increases when E_p is raised towards higher polarization

Fig. 5. Rh oxide growth plots expressed as the charge density, q_{OX}, versus log of the polarization time, log t_p, at $T = 298$ K for various polarization potentials, E_p; the arrow indicates the increase of E_p from 0.70 to 1.40 V, RHE. The data demonstrate linear relations between q_{OX} and log t_p for the whole range of q_{OX}. The inset shows the $dq_{OX}/d(\log t_p)$ versus E_p plot, which expresses the growth rate as a function of E_p. The data show that the oxide growth rate becomes accelerated when E_p is increased.

potentials. The authors examined the relation between the growth rate and the polarization potential and expressed it as a $dq_{OX}/d(\log t_p)$ versus E_p plot (see the inset in Fig. 5); the results show that the oxide growth rate becomes accelerated when the polarization potential is increased. The $1/q_{OX}$ versus log t_p relations (Fig. 6) are also linear for $q_{OX} > 210$ μC cm^{-2} whereas the $1/q_{OX}$ versus log t_p plots reveal deviations from linearity for $q_{OX} < 210$ μC cm^{-2}. Thus on the basis of the data presented in Figs. 5 and 6, it may be concluded that the Rh electro-oxidation follows either logarithmic kinetics over the whole range of E_p and t_p or that it follows inverse-logarithmic kinetics once the oxide thickness has reached the charge density of 210 μC cm^{-2}, in other words, once the oxide has grown to the extent of 1 ML of Rh(OH). These results clearly illustrate that the distinction between logarithmic and inverse-logarithmic kinetics is difficult to make on the basis of linearity of q_{OX} versus log t_p or versus $1/q_{OX}$ versus log t_p plots. To identify which kinetics are applicable to the system under investigation, it is necessary to evaluate the relation between the actual oxide thickness, X, and the X_o and X_1 parameters as defined below (12–14):

$$[6] \quad X_o = \sqrt{\frac{\kappa kT}{8\,\pi n q^2}}, \qquad X_1 = \frac{qaV}{kT}$$

where κ is the relative permittivity of the film, n the number of

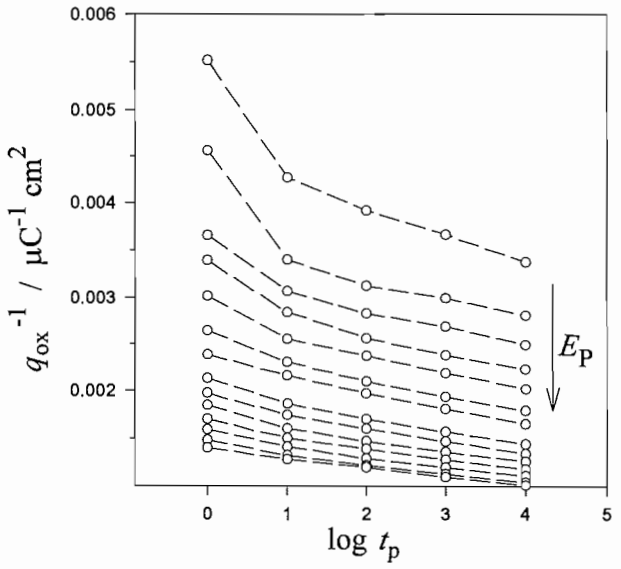
Fig. 6. Rh oxide growth plots expressed as reciprocals of the charge density, $1/q_{OX}$, versus log of the polarization time, log t_p, at $T = 298$ K, for various polarization potentials, E_p; the arrow indicates the increase of E_p from 0.70 to 1.40 V, RHE. The data demonstrate that the $1/q_{OX}$ versus log t_p relations are linear when $q_{OX} > 210$ μC cm^{-2}.



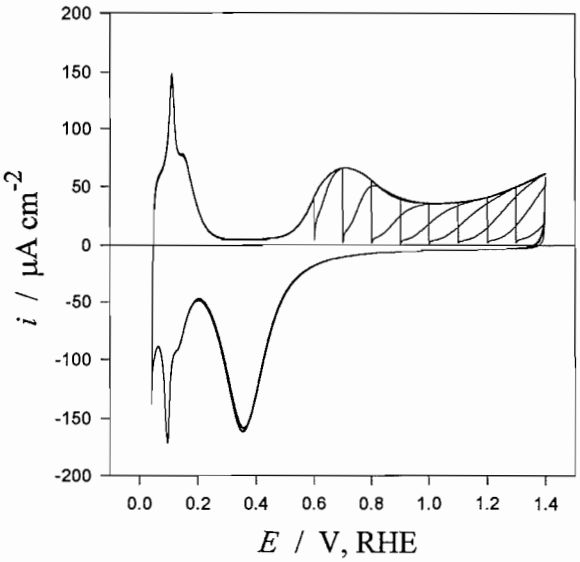


Fig. 7. Series of CV profiles for Rh in 0.5 M aq. H_2SO_4 solution taken at the sweep rate $s = 50$ mV s^{-1}, $T = 298$ K. The profiles demonstrate the effect of holding E at various values from 0.70 to 1.35 V, RHE, for 30 s. The results indicate that regardless of E, the amount of the oxide formed is the same as indicated in the CV oxide-reduction profiles.

metal ions per unit volume (cm^3), q the metal cation charge, V the potential across the oxide, a the distance between metal cations in the film (or between the metal atom and the metal cation at the inner metal–oxide interface, designated a'), k is Boltzmann's constant, and T the temperature. These parameters represent particular (critical) oxide thicknesses that determine the oxide growth kinetics. If the experimentally observed oxide thickness, X, is below or above X_1 (or X_o), then a specific oxide growth mechanism may become applicable. In ref. 14, the authors showed that in the case of very thin Rh oxide films $X < X_o$ and that $X < X_1$, thus the growth kinetics are typical of thin films. At present, it is almost impossible to discriminate between either of the kinetics. If the oxide growth proceeds by logarithmic kinetics, then the O-containing species create a surface dipole moment that induces the place-exchange mechanism, thus the O-containing species (here water molecules) and the metal surface atoms, M, undergo place exchange, which results in development of a new 2D surface structure. The oxide growth through place exchange might give rise to the logarithmic kinetics (10, 35). While the change of the surface dipole moment is significant during electrosorption of the first ML of OH groups, it seems sensible to conclude that this variation would be less pronounced upon commencement of the place exchange, which results in creation of a structure with OH and M occupying adjacent sites. Moreover, the deposition of the second, third, etc., ML of OH would result in a much smaller change of the surface dipole moment than the adsorption of the first ML of OH. Therefore logarithmic kinetics may be applied to the growth of the first oxide ML, giving rise to logarithmic kinetics but unlikely to the development of the subsequent MLs. If the growth of the following MLs does not occur through logarithmic kinetics, then another mechanism and kinetics should govern the process. At present there is only one other mechanism that can explain the experimentally observable inverse-logarithmic kinetics, and it implies that the escape of the metal cation from the metal into the oxide is the rate-determining step. This kinetic approach was applied by the current authors who based their calculations on the Mott–Cabrera formalism (14) and determined that the electric field across the oxide film is of the order of 10^9 V m^{-1} (details of the calculations are provided in refs. 12 and 14). In conclusion, it is difficult to evaluate the kinetics that can unambiguously explain the observable logarithmic or inverse-logarithmic growth, and more research on well-defined surfaces using modern surface-science techniques is needed to provide an indisputable explanation of the growth mechanism.

Impact of potential holding on oxide growth

In a separate set of experiments, the authors investigate the effect of holding the potential at E from 0.70 to 1.35 V, RHE, for 30 or 60 s while forming the oxide in a single CV transient (Fig. 7). The data demonstrate that when the potential was held at a constant value, the current density did not fall to zero, indicating that the oxide growth continued while the transient was stopped. The subsequent oxide-reduction CV profiles show that the amount of oxide formed was unaffected regardless of the holding potential. The same behavior was noted when the positive-going scan was stopped for 60 s. To the knowledge of the authors, this behavior has never been reported for Rh electrodes and the results represent a new contribution, which will lead to subsequent detailed assessment of the oxide growth kinetics and mechanism on Rh electrodes.

Influence of restricted range potential cycling on oxide growth and stability.

In a separate series of experiments the authors studied the influence of cycling the electrode some 50 times over a restricted potential range in order to evaluate possible changes

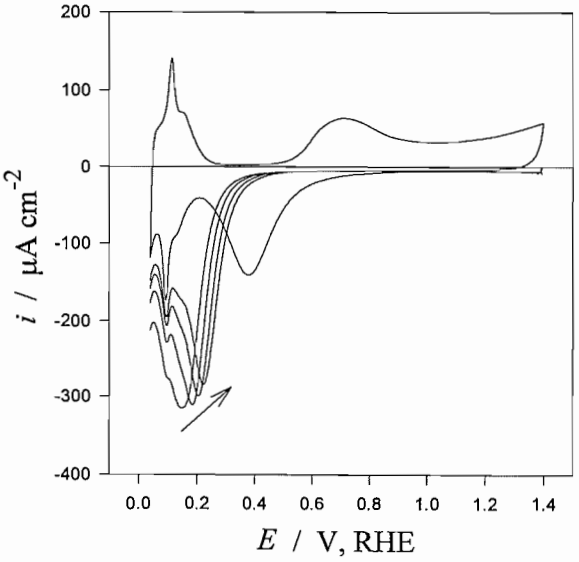
Fig. 8. Series of CV profiles for Rh in 0.5 M aq. H_2SO_4 solution taken at the sweep rate s = 50 mV s^{-1}, T = 298 K. The profiles demonstrate the effect of cycling the electrode 50 times over a restricted potential range. The upper potential limit, E_U, is 1.40 V and the lower one, E_L, is above the OC1 peak potential (see the reference curve referring to cycling between 0.05 and 1.40 V); here E_L = 0.40, 0.44, 0.48, and 0.52 V, RHE, respectively. Upon cycling to E_L, which is greater than the peak potential in the reference CV profile (0.38 V), q_{OX} is unaffected but the peak potential shifts towards more positive values and the peak current density decreases.



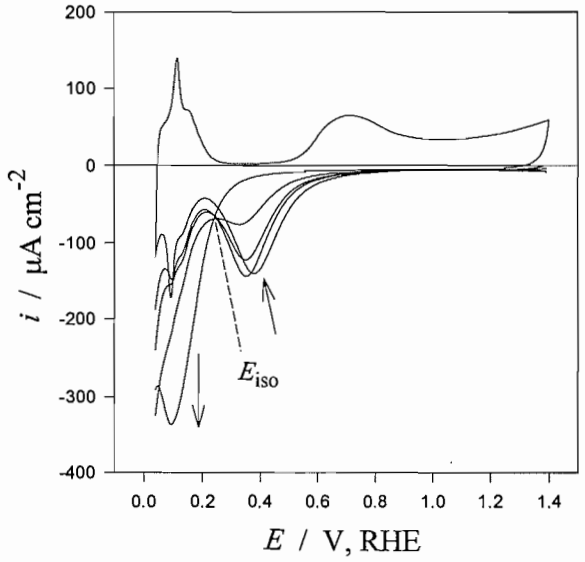


Fig. 9. Series of CV profiles for Rh in 0.5 M aq. solution taken at the sweep rate s = 50 mV s^{-1}, T = 298 K. The profiles demonstrate the effect of cycling the electrode 50 times over a restricted potential range. The upper potential limit, E_U, is 1.40 V and the lower one, E_L, is below the OC1 peak potential (see the reference curve referring to cycling between 0.05 and 1.40 V); here E_L = 0.36, 0.32, 0.28, and 0.24 V, RHE, respectively. Upon cycling to an upper limit, which is lower than the peak potential in the reference CV profile (0.38 V), q_{OX} is unaffected but the peak potential drastically shifts towards less positive values and the peak current density increases. E_{iso} refers to an isopotential point.

of the oxide thickness and its reduction potential (39). The potential ranges were selected with respect to the OC1 peak potential representative of the Rh oxide reduction within a single sweep. Because the oxide-reduction peak potential is at 0.38 V, RHE, (Fig. 2) the upper potential limit, E_U, of the restricted cycling was at 1.40 V while the lower one, E_L, was selected either above (E_L = 0.40, 0.44, 0.48, and 0.52 V, RHE) or below the peak potential (E_L = 0.36, 0.32, 0.28, and 0.24 V, RHE); the results of these experiments are shown in Figs. 8 and 9. The data shown in Fig. 8 indicate that upon increase of E_L from 0.40 to 0.52 V, RHE, the oxide-reduction peak shifts towards more positive values while the oxide-reduction charge density, determined by integrating the CV profiles, stays the same and close to 230 ± 5 μC cm^{-2}. The results demonstrate that upon decrease of E_L from 0.36 to 0.24 V, RHE, (Fig. 9) the oxide-reduction profile undergoes dramatic qualitative changes because it shifts towards less positive potentials and the peak current increases (the deconvolution of the peak becomes troublesome because it overlaps the UPD H peak). Interestingly, the charge density under the oxide peak remains almost constant and close to 215 ± 10 μC cm^{-2} (determination of q_{OX} is more complex because of the overlap of the oxide-reduction and the UPD H potential regions; in the charge-density determination, one has to account for the charge density of the UPD H and the double-layer charging as assessed on the basis of a standard CV profile between 0.05 and 1.40 V without arresting the scan or restricting its cycling range; see refs. 12 and 13). The displacement of the peak potential towards lower values may be assigned to changes in the stability of the oxide — it becomes thermodynamically more stable, because lower potentials are required to reduce the same oxide although its charge density is not altered. In the case of cycling to E_L >0.38 V, RHE, q_{OX} is greater than in the case of cycling to E_L <0.38 V, RHE, simply because the lower potential limit is too low and the oxide film is not completely reduced, and multiple cycling over the potential range increases its charge density.

Oxide reduction and its kinetics

Reduction of the electrochemically formed Rh oxides has never been a subject of research and it became an integral part of the project. The authors studied the process by application of the following procedure. An oxide of well-established and reproducible charge density (thickness) was formed by polarizing the electrode at E_P = 1.40 V, RHE, for t_p = 10^4 s. The charge density of such an oxide was 945 μC cm^{-2}, corresponding to 1.5 ML of $Rh(OH)_2$. This oxide was subsequently reduced at various potentials, E_r (see below), according to the following procedure: (*i*) a negative-going sweep that started at 1.40 V, RHE, was stopped at E_r, which was adjusted between 0.70 and 0.25 V with an interval of 0.05 V; (*ii*) the reduction time, t_r, was t_r = 10^0, 10^1, 10^2, 10^3, and 10^4 s; (*iii*) after the oxide reduction, the negative-going sweep was continued down to 0.05 V, RHE, and it led to complete reduction of the surface oxide as revealed from the subsequent CV profile. We emphasize that the CV profile that follows the reduction at E_r allows determination of the amount of the unreduced oxide that stayed on the surface; subtraction of this charge density

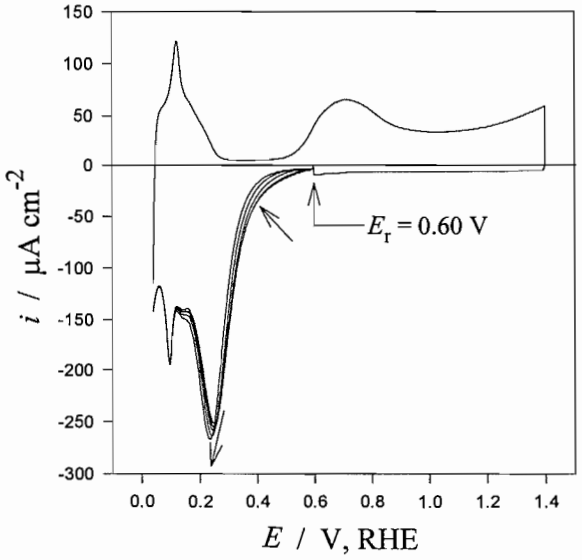
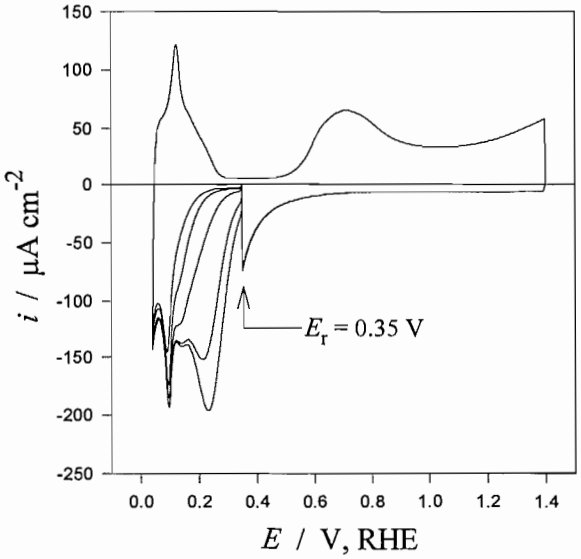
Fig. 10. Series of CV profiles for Rh in 0.5 M aq. H_2SO_4 solution taken at the sweep rate s = 50 mV s^{-1}, T = 298 K. The profiles demonstrate samples of the effect of reduction at E_r = 0.60 V for t_r = 10^0, 10^1, 10^2, 10^3, and 10^4 s. Increase of t_r leads to enhancement of the amount of the reduced oxide.





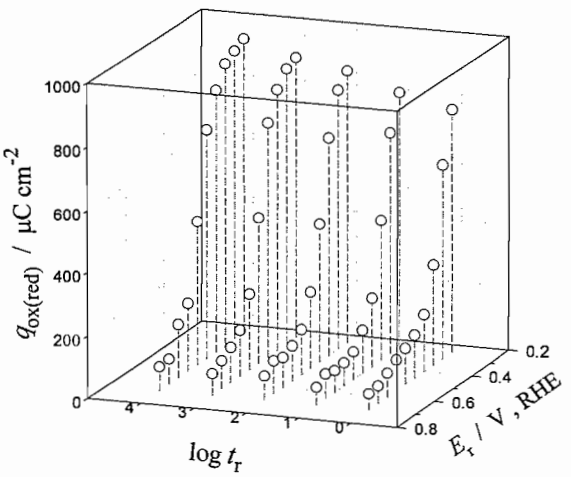


Fig. 11. Series of CV profiles for Rh in 0.5 M aq. H_2SO_4 solution taken at the sweep rate s = 50 mV s^{-1}, T = 298 K. The profiles demonstrate samples of the effect of reduction at E_r = 0.35 V for t_r = 10^0, 10^1, 10^2, 10^3, and 10^4 s. Increase of t_r leads to enhancement of the amount of the reduced oxide.

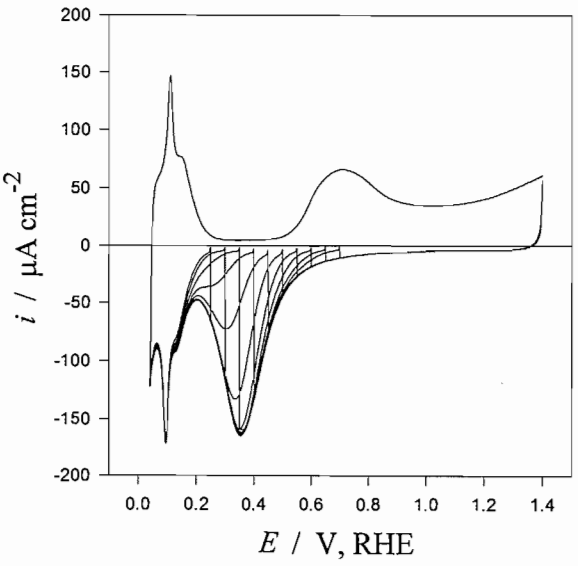
from 945 μC cm^{-2} allows determination of the amount of the reduced oxide. Two representative sets of CV oxide-reduction profiles are shown in Figs. 10 and 11. The data presented in Fig. 10 refer to E_r = 0.60 V, RHE, and the arrows reveal changes in the CV profiles that result from the reduction. The behavior at E_r = 0.60 V, RHE, may be summarized as follows: (*i*) upon stopping the negative-going sweep, the current density does not fall to zero but has a small value that indicates that the oxide reduction continues; (*ii*) extension of t_r from 10^0 to 10^4 s results in minute reduction of the oxide because its charge density decreases by only some 5%; (*iii*) changes in the shape of the CV profiles represented by arrows show that the oxide film undergoes some qualitative transition during the reduction because its half-width changes and the peak current density increases. At the present time, the authors are unable to relate these changes to structural parameters of the oxide, and XPS and X-ray scattering experiments are required to further explain these data. The behavior at E_r = 0.35 V, RHE, (Fig. 11) is simpler and the profiles show that upon extension of the reduction time from to s, the quantity of the oxide reduced, $q_{OX(red)}$, significantly increases.

In evaluation of the reduction behavior, the Rh oxide was always formed under the same E_p and t_p conditions and it resulted in an oxide of the same charge density, namely, 945 μC cm^{-2}. Integration of the CV oxide-reduction profiles for between 0.70 and 0.25 V, RHE, with an interval of 0.05 V (see Figs. 10 and 11) allowed the authors to assess the amount of the unreduced oxide, and its comparison with 945 μC cm^{-2} led to accurate determination of the amount of the Rh surface oxide reduced, $q_{OX(red)}$. This procedure was used for all the reduction potentials and the reduction times applied in the course of research, permitting evaluation of $q_{OX(red)}$ as a function of E_r and t_r. The results are shown in Fig. 12 as a 3-dimensional $q_{OX(red)}$ versus (E_r, log t_r) plot. The authors

Fig. 12. Rh oxide reduction plots expressed as the reduction charge density, $q_{OX(red)}$, versus the reduction potential, E_r, and log of the reduction time, log t_r, at T = 298 K; E_r is between 0.70 and 1.40 V, RHE, and t_r = 10^0, 10^1, 10^2, 10^3, and 10^4 s. The data demonstrate nonlinear relations between $q_{OX(red)}$ and log t_r



selected a logarithmic scale for the oxide-reduction time in order to compare this behavior with the growth behaviour albeit at present there is no reason to believe that the reduction should be logarithmic in time. The data (Fig. 12) indicate that the relations between $q_{OX(red)}$ and log t_r (for E_r = const.) are nonlinear; similarly, the $q_{OX(red)}$ versus E_r plots (for log t_r = const.) are also nonlinear. An analysis of the $q_{OX(red)}$ versus (E_r, log t_r) relations leads to the conclusion that the lower the reduction potential and can longer the reduction time, the

Fig. 13. Series of CV profiles for Rh in 0.5 M aq. H_2SO_4 solution taken at the sweep rate s = 50 mV s^{-1}, T = 298 K. The profiles demonstrate the effect of holding E at various values from 0.70 to 0.25 V, RHE, for 30 s. The results indicate that the oxide reduction continues when the scan is stopped. The lower the potential, the greater the amount of the reduced oxide.

greater the amount of the reduced oxide. Since there exists no theory of oxide reduction, the authors are unable to apply any theoretical methodology to explain the experimental data and can only present a qualitative discussion of the results. The interesting results presented in this section point to the necessity of conducting further experimental and theoretical research on reduction of oxide films on noble metals.

Impact of potential holding on oxide reduction

In a manner similar to the study of the impact of potential holding on the oxide formation, the authors examined the effect of holding the potential at E values varying from 0.70 to 0.25 V, RHE, with an interval of 0.05 V, for 30 or 60 s while reducing the oxide in a single CV transient (Fig. 13). The data reveal that when the potential was held at constant value, the current density did not fall to zero, indicating that the oxide reduction continued when the transient was stopped. Continuation of the reduction transient down to 0.05 V, RHE, and its comparison with the reference CV profile (see Fig. 2) indicates that some of the oxide was reduced while the scan was stopped. Integration of the CV profiles allowed determination of the charge density that was unreduced during the potential arrest as well as the charge density of the oxide that was reduced during the arrest. An analysis of the data showed that the lower the holding potential, the greater the amount of oxide that was reduced. The same behavior was noticed when the positive-going scan was stopped for 60 s but the reduction was more pronounced since a longer reduction period led to enhanced reduction. This observation is of significance in understanding the oxide-reduction mechanism and the kinetics.

Conclusions

1. Anodic polarization of Rh at E_p between 0.70 and 1.40 V, RHE, for $t_p = 10^0$, 10^1, 10^2, 10^3, and 10^4 s at 298 K results in thin oxides that reveal only one state in the CV reduction profiles, with q_{OX} values from 110 to 985 μC cm^{-2}, thus between 0.5 ML of Rh(OH) and 1.56 ML of $Rh(OH)_3$. Oxide development occurs in two steps whereas its reduction occurs in one.
2. Enhancement of E_p (for t_p = const.) or increase of t_p (for E_p = const.) leads to thicker oxides but of the same physical nature. Upon increase of E_p and (or) t_p the reduction peak shifts towards less positive potentials, indicating that thicker oxides are thermodynamically more stable.
3. Plots of q_{OX} versus log t_p are linear over the whole range of q_{OX} whereas plots of $1/q_{OX}$ versus log t_p are linear only when q_{OX} >210 μC cm^{-2}, that is, when the thickness is greater than 1 ML of RhOH. Therefore, the growth is either logarithmic in time over the whole region of q_{OX}, or it is logarithmic when q_{OX} <210 μC cm^{-2} and inverse-logarithmic when q_{OX} >210 μC cm^{-2}.
4. Oxide growth continues when the positive-going scan is stopped in the oxide-formation potential region. Similarly, oxide reduction proceeds when the negative-going scan is stopped in the oxide-reduction potential range.
5. Oxide reduction takes place at $E \leq 0.70$ V, RHE. The oxide reduction kinetics are not understood but, in general, the lower the reduction potential and the longer the reduction time, the greater the amount of the reduced oxide.

A new electrocatalyst consisting of a molecularly homogeneous platinum–aerogel nanocomposite

Siyu Ye, Ashok K. Vijh, Zheng-Yu Wang, and Lê H. Dao

Abstract: Aerogels offer interesting opportunities for (electro)catalysis due to their high porosity and specific surface area. A new electrocatalytic material consisting of a molecularly homogeneous platinum–aerogel nanocomposite was prepared. The mixed components represent, at the microscopic level, very homogeneous combinations originating from chemical interactions at the molecular scale in the liquid phase that can be viewed as "frozen in" in the solid state via supercritical drying. Transmission electron microscopy (TEM) images of this material clearly show that nanometer-size platinum particles are homogeneously distributed and are a part of the molecular architecture of the composite. An X-ray photoelectronic spectroscopy (XPS) study indicates that there exists a special interaction between platinum and the support within a polyacrylonitrile–Pt (PAN-Pt) electrocatalyst. This material is a promising electrocatalyst for oxygen reduction, and its electrocatalytic activity arises from the nanodispersed platinum particles present in the nanocomposite.

Key words: electrocatalyst, aerogel, nanocomposite, oxygen reduction, metal–support interaction.

Résumé : Les aérogels présentent des possibilités intéressantes d'(électro)catalyse résultant des valeurs élevées de leur porosité et de la superficie de leur spécifique. On a préparé un nouveau matériel électrocatalytique formé d'un nanocomposite moléculairement homogène de platine–aérogel. Les composants mélangés représentent, au niveau microscopique, des combinaisons très homogènes ayant leur origine dans les interactions chimiques, à l'échelle moléculaire, dans la phase liquide qui peuvent être considérées «fixées» dans l'état solide par le biais d'un séchage supercritique. Les images dérivées de la microscopie électronique de transmission («TEM») de ce matériel montrent clairement que les particules de platine d'une grosseur de l'ordre du nanomètre sont distribuées d'une façon homogène et qu'elles font partie de l'architecture moléculaire du composite. Une étude par spectroscopie photoélectronique des rayons X («XPS») indique qu'il existe une interaction spéciale entre le platine et le support dans un électrocatalyseur de polyacrylonitrile–Pt (PAN-Pt). Ce matériel est un catalyseur prometteur pour la réduction de l'oxygène et son activité électrocatalytique découle des particules nanodispersées de platine dans le nanocomposite.

Mots clés : électrocatalyseur, aérogel, nanocomposite, réduction de l'oxygène, interaction métal–support.

[Traduit par la rédaction]

Introduction

Aerogels possess unique morphological and chemical properties, originating from their wet-chemical preparation by the solution–sol–gel (SSG) method or phase-separation techniques and the subsequent solvent removal via supercritical drying (SCD) (1). Aerogels have been extensively investigated with regard to their preparation (2–5), characterization (6, 7), and applications such as optical, thermal, acoustic, and electronic (8), capacitive deionization (9), biosensor (10), and electroanalysis (11). Due to the "structure-preserving" ability of SCD, aerogels are solids of high porosity and specific surface area. These aerogels thus offer interesting opportunities for (electro)catalysis (12–14). The motivation to combine the SSG or phase-separation techniques with the method of SCD for the preparation of aerogel catalysts or supports resides mainly in the highly controllable SSG or phase-separation preparation route with the structure-preserving ability of SCD, embracing features such as molecular-scale mixing of the constituents; homogeneity of SSG or phase-separation products with pronounced isotropy of chemical, physical, and morphological properties; and use of various wet-chemical tools for tailoring the preparation. Thus, by exploiting these properties, catalysts with unique structural and chemical properties can be prepared that are not easily accessible by means of other preparation techniques.

We have previously reported a method for the preparation of an electrocatalyst based on carbonized polyacrylonitrile (PAN) aerogels in which we achieved a homogeneous distribution of nanoparticles of platinum in the carbonized PAN matrix by dipping a carbonized PAN in H_2PtCl_6 solution (15–19). Here we report on a new method in which a homogeneous platinum–aerogel composite is obtained, in which platinum nanoparticles are uniformly incorporated as part of the molecular architecture of the composite, in distinction from the mere uniform physical distribution of platinum particles. This was achieved by adding the metal precursor prior to the gelation stage. Using this approach, the metal is incorporated directly into the support framework structure, at the molecular level. The mixed aerogels or their parent gels thus represent, at the microscopic level, very homogeneous combinations originating from the chemical interactions at the molecular scale in the liquid that can be viewed as "frozen in" in the solid state. Aerogels are, in this respect, sort of a three-dimensional dry picture of the sol–gel product, with all their catalytic potentialities intact and available for revelation (1, 13, 14). It is surmised that the uniform three-dimensional distribution of the metal component throughout the PAN matrix with large surface area thus achieved may help to prevent sintering and coking of the active metal phase and improve its mechanical stability.

In this paper, we describe the preparation and characterization (conducted by combining microscopic methods, XPS, and electrochemical approaches) of the new material (hereafter denoted as PAN-Pt). PAN-Pt was used as an electrocatalyst for the oxygen reduction, and compared with the behavior of the bulk platinum electrode as well as with the PAN-based material prepared by the previously described method (15–19, hereafter denoted as PAN/Pt).

Hence, PAN/Pt denotes the material prepared by dipping a carbonized PAN in H_2PtCl_6 solution, and PAN-Pt signifies the catalyst in which a homogeneous solution of PAN and K_2PtCl_6 was the starting material.

Experimental

Preparation

The carbonized PAN aerogel incorporated with platinum, PAN-Pt, was prepared as follows: a platinum salt (e.g., K_2PtCl_6) or an organometallic compound (e.g., platinum acetylacetonate) was mixed with PAN (5 wt.%) in *N*,*N*-dimethylformamide (DMF)/water (v/v:84/16). This mixture became a clear solution as the temperature was increased. At about 120°C, the solution was degassed and then poured into a mold. Upon cooling the solution, a polymer gel containing platinum compounds was obtained by thermally induced phase-separation. After reducing the platinum salt with 1 wt.% $NaBH_4$ aqueous or alcoholic solution, or by bubbling hydrogen into the aqueous or alcoholic solution containing the gel, the remaining solvent in the polymer gel was exchanged with acetone or ethanol, and the latter solvent was removed by CO_2 supercritical extraction. The dry platinum containing PAN aerogel was pretreated in a forced-air convection oven at 210°C, followed by pyrolysis at 900°C under an argon atmosphere.

The preparation of PAN/Pt has been described in detail in the literature (15–19).

Electrode materials and chemicals

The electrode structure can be fabricated by grinding the powder (by mortar and pestle) of the PAN/Pt or PAN-Pt foam. The ground powder was dispersed in a solution of the carrier polymer to yield a slurry. Here, Nafion (5 wt.% solution in alcohols) was used as the carrier polymer. A small amount of the slurry (typically 10 μL) was spread on a previously cleaned (20) glassy carbon disk electrode (diam. 4.0 mm, EG&G), and the solvent allowed to evaporate from its surface.

In a typical experiment on PAN-Pt, 3.5 mg of PAN-Pt powder (5 wt.% of platinum) was added to 1167 μL solution of Nafion (5 wt.% solution in a mixture of lower aliphatic alcohols and 10% water, from Aldrich, diluted with ethanol with v/v: 2/1). The suspension was placed in an ultrasonic bath for 15 min; 10 μL of this slurry was spread onto a glossy carbon disk electrode (diam. 5 mm). The platinum loading (i.e., the total amount in the aerogel), using the geometric area of the substrate electrode, was thus calculated to be 7.6 μg cm^{-2}.

In a typical experiment on PAN/Pt, 6.6 mg of PAN-Pt powder (4.95 w/o of platinum) was added to 2000 μL solution of Nafion (5 wt.% solution in a mixture of lower aliphatic alcohols and 10% water, from Aldrich). The suspension was placed in an ultrasonic bath for 15 min; 10 μL of this slurry was spread onto a glassy carbon disk electrode (diam. 3 mm). The platinum loading (i.e., the total amount in the aerogel), using the geometric area of the substrate electrode, was thus calculated to be 23 μg cm^{-2}.

All chemicals were of analytical grade purity and were used without further purification. Solutions were prepared using doubly-distilled water. All experiments were performed at room temperature.

Instrumentation

The electrochemical experiments were performed by using a PAR model 273 potentiostat–galvanostat coupled with a model 616 rotating disk electrode. A conventional H-type glass cell with a platinum foil or wire spiral counter-electrode was used for all electrochemical experiments. An Ag/AgCl/4 M NaCl electrode was used as the reference electrode; all potentials in this paper are referred to the normal hydrogen electrode (NHE). The geometric surface area of the electrode was used to calculate the current density, and the sign of a cathodic current was defined as positive. A platinum disk electrode (diam. 4.0 mm, EG&G) was used for comparison in this study, and was polished according to the procedure described in ref. 8. High-purity N_2 or O_2 was bubbled through the 0.5 M H_2SO_4 aqueous solution for more than 30 min before each electrochemical experiment and during the experiment.

Transmission electron microscopy (TEM) was performed on a Hitachi H9000 operating at 300 kV and equipped with a Link EDX detector. The platinum particle size was evaluated using a Tracor Northern TN-8500 image analyzer.

The XPS studies were performed using a Fisons Instruments Escalab 220i-XL surface microanalysis system with an Al $K\alpha$ X-ray source (1486.6 eV). The spectrometer was calibrated by assuming the binding energy (BE) of the Ag $3d_{2/5}$ line to be at 368.25 eV. The C 1*s* peak of carbon at 284.6 eV was used as an internal reference. The sample powders were mounted onto a standard sample holder by using double-sided adhesive tape. Survey scan photoelectron spectra in the range of 0–1100 eV were recorded at a pass energy of 100 eV

with a step size of 1 eV and a dwell time of 0.1 s step^{-1}. Narrow-scan photoelectron spectra (50 eV pass energy, 0.1 eV step^{-1}, and 0.1 s step^{-1} dwell time) were obtained for the C 1*s*, N 1*s*, O 1*s*, Pt 4*f*, Pt 4*d*, and Pt 4*p* regions. The pressure in the analysis chamber during the scans was approximately 10^{-7} Pa or less. All core-level spectra were deconvoluted by using the ECLIPSE program, version 1.7T, from Fisons/VG.

Results and discussion

Microscopic characterization

A TEM image of the PAN-Pt is shown in Fig. 1, from which a homogeneous distribution of dark spots with relatively uniform size distribution (except for a very few large-sized spots in some special positions) can be observed. From the EDX data of these spots, we can unambiguously assign them to platinum. PAN-Pt presents, in this magnification, TEM features similar to those of PAN/Pt (15, 17–19). By using high-resolution TEM (Fig. 2), however, one can see dramatically different features between these two materials. For PAN/Pt (Fig. 2*A*), the platinum particles seen at lower magnification are actually aggregates of smaller particles. By contrast, in PAN-Pt (Fig. 2*B*), the finer platinum particles are well separated, indicating a much higher homogeneity of the platinum particle distribution in the PAN-Pt material than in the PAN/Pt.

The distribution of particle size in PAN-Pt catalyst, as mea-

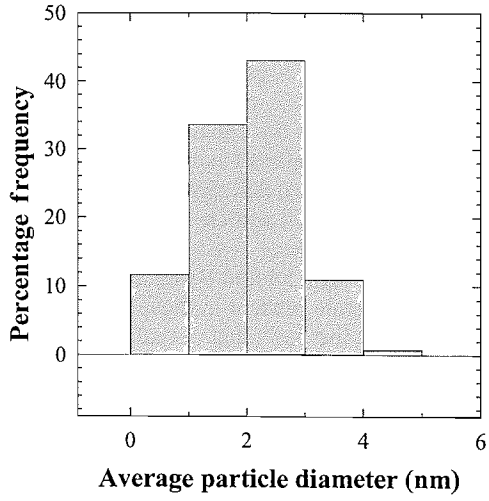

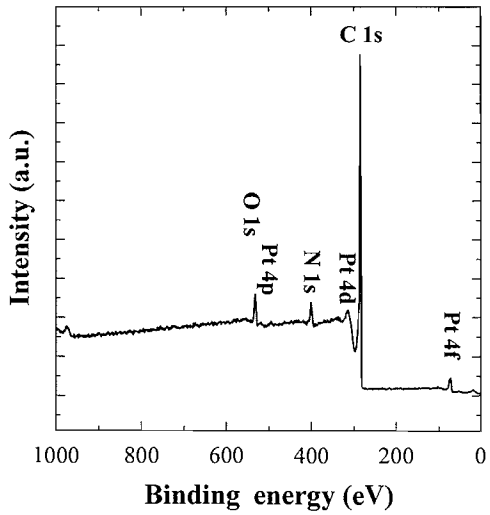

Fig. 4. XPS survey scan spectrum for PAN-Pt.

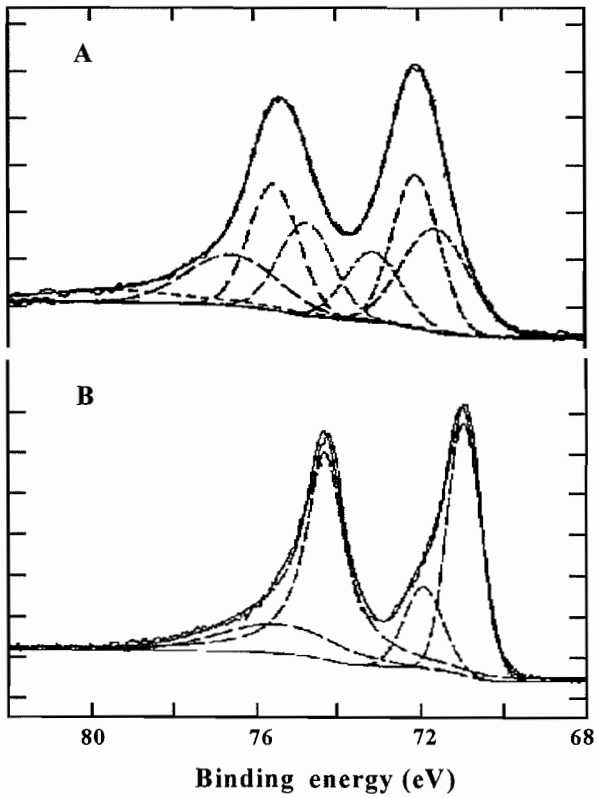
sured from high-resolution TEM images, is shown in Fig. 3, which is obtained by measuring the area of a sufficiently large number of particles (>100) to ensure good statistics. It can be seen in Fig. 3 that most platinum particles have diameters smaller than 5 nm, 59% of the platinum particles have diameters of 2–3 nm, and 46% of them range from 1 to 2 nm. The surface mean particle size $\bar{d}$ can be estimated (21) to be 2.7 nm according to the equation:

$$[1] \quad \bar{d} = \frac{\Sigma f_i d_i^3}{\Sigma f_i d_i^2}$$

where f_i is the frequency of occurrence of the particles of diameter d_i in the sample, from the particle size distribution shown in Fig. 3. The surface mean particle size of the platinum particles in PAN-Pt is much smaller than that of the platinum particles in PAN/Pt (17 nm, ref. 18), which suggests that a much better dispersion has been achieved in PAN-Pt.



XPS study

Figure 4 shows the survey scan spectrum for PAN-Pt, which consists of the C 1*s* peak at 284.6 eV, the N 1*s* peak at 400.9 eV, the O 1*s* peak at 532.5 eV, Pt 4*f* peaks at 73.1 and 75.5 eV, Pt 4*d* peaks at 315.9 and 331.3 eV, and the Pt 4*p* peak at 520.7 eV. It is evident from the survey scan spectra for PAN-Pt that platinum has been incorporated into the PAN matrix, as indicated by the appearance of these Pt peaks.

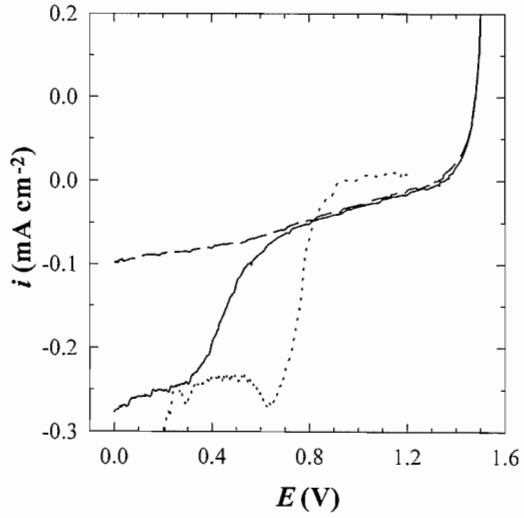
Fig. 5. Pt 4*f* narrow scan spectra and line-shape analysis for (*A*) PAN-Pt and (*B*) PAN/Pt. The solid line is the experimental data, and the broken lines are the fits to the data (see the text).

The narrow scan XPS spectrum of the Pt 4*f* core level for PAN-Pt is shown in Fig. 5*A* along with that of PAN/Pt (Fig. 5*B*). It has been reported that the Pt 4*f* spectrum of PAN/Pt did not show any shifts in comparison with the literature values for Pt^0 (18). In contrast, the maxima of the Pt 4*f* peaks of PAN-Pt shift 1.2 eV to higher energy. Obviously, such a high value cannot be due to the measurement error. For platinum on a zeolite support, a significant chemical shift (~+0.7 eV) of peak maximum for the Pt $4f_{7/2}$ was detected (21), and was considered to be due to the formation of charge-transfer complexes between platinum and the Lewis-acid sites of zeolite. For Pt/C catalysts, the peak maximum for the Pt $4f_{7/2}$ has been observed to shift to higher values by 0–1.8 eV, depending on the content of the surface functional groups of the support. This was interpreted as being due to the presence of a platinum–support electronic effect (22). For PAN/Pt, no chemical shift of Pt 4*f* signals was detected, which was tentatively interpreted as follows. (*i*) Only a small fraction of the total charge of platinum particles participates in the charge-transfer process from platinum to support. (*ii*) The specific metal–support interaction is mainly through the electron transfer from platinum to pyridine-type nitrogen, and the lone-pair electrons of the nitrogen atoms in PAN are localized within the large aromatic rings, which results in a lower electron density of these nitrogen atoms. (*iii*) The complicated structure of the polymer might result in the charge transfer from platinum to polymer being less than that to the surface functional groups of inorganic supports, or even non-unidirectional in some location of the polymer matrix. In addition, the platinum particles are larger and are aggregated in PAN/Pt, in comparison with those in PAN-Pt, as seen in Figs. 2 and 3, which leads to less interaction with the support and thus may explain the apparent differences between PAN/Pt and PAN-Pt.

Table 1. Deconvolution parameters for the Pt 4*f* narrow scan XPS spectra of PAN/Pt and PAN-Pt.

Material	Binding energy (eV) / FWHM[a] (eV) $4f_{7/2}$	Binding energy (eV) / FWHM[a] (eV) $4f_{5/2}$	Relative peak area (%)
PAN/Pt	70.9 / 1.0	74.3 / 1.1	74.5
	71.9 / 1.1	75.5 / 3.4	25.4
PAN-Pt	71.4 / 1.5	75.1 / 1.6	26.1
	72.0 / 1.4	75.5 / 1.7	41.9
	73.1 / 2.2	76.7 / 3.3	32

[a]FWHM is the full width at half maximum.



For PAN-Pt, the chemical interactions on the molecular scale are established in the liquid phase, which then gets "frozen in" in the solid state through the special aerogel preparation procedures. This should lead to, at the microscopic level, very homogeneous three-dimensional structures, not only in morphology but also in the chemical interactions between metal and support. In this case, all platinum particles, in principle, participate in this interaction, which is different from that for PAN/Pt, where only a small fraction of the total charge of platinum particles participate in the charge-transfer process from platinum to support. The large shift of the Pt 4*f* peaks in PAN-Pt may indicate a stronger metal–support interaction than in PAN/Pt. The specific metal–support interaction is considered to be beneficial to the enhancement of catalytic properties (21), and for the improved stability of the electrocatalyst (23). It can thus be surmised that the stability of PAN-Pt is better than that of PAN/Pt; this point is under experimental investigation at the present time.

It is obvious from Figs. 5*A* and *B* that there is more than one platinum oxidation state present in these spectra. The spectra are deconvoluted on the basis that not all of the Pt sites are in the metallic state. They contain some or all of the Pt^0, Pt^{II}, and Pt^{IV} components, and each has two corresponding peaks in the envelope spectrum. Based on the previous work reported in the literature (24, 25), and considering the effect of metal–support interaction, these deconvoluted peaks can be assigned; the results are presented in Table 1 along with other deconvolution parameters. It can seen from Fig. 5 and Table 1 that there are only two Pt components present in PAN/Pt (Pt^0 and Pt^{II}), while three components (Pt^0, Pt^{II}, and Pt^{IV}) are present in PAN-Pt. Based on the relative peak area, the percentage of Pt^0 in PAN/Pt is 74.5%, which is similar to that in 20% Pt/Vulcan XC-72 (Electrochem, Inc., Woburn, Mass.) where 77.8% Pt^0 was obtained (25). In PAN-Pt, only 26.1% was in the Pt^0 state, which suggests that a large fraction of platinum is in the oxidized states and may indicate the difficulty of reducing the platinum encapsulated inside the PAN micropores. As H_2PtCl_6 and K_2PtCl_6 were used as precursors to prepare these two materials, Cl might have been present in these two materials, with platinum residing as chloride. However, no Cl sig-

Fig. 6. Linear sweep voltammograms of the PAN-Pt in 0.5 M H_2SO_4 solution saturated with oxygen (———) and nitrogen (– – –). Cyclic voltammogram of a smooth Pt bulk electrode in 0.5 M H_2SO_4 solution saturated with oxygen (·····) is also shown for comparison. Scan rate: 5 mV s^{-1}. Rotating rate: 0 rpm.

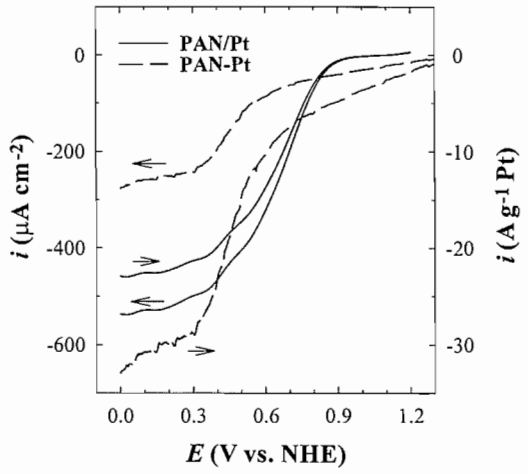
nal was detected in these two samples. It can be concluded, therefore, that at least most of the Pt^{II} and Pt^{IV} sites are not present as chloride. They may be present as oxides or hydroxides, as those assigned in Pt/C (25). The presence of oxygen species in PAN-Pt is verified by the survey scan spectrum (Fig. 4), and is probably due to the special preparation procedures (see Experimental), i.e., the PAN aerogel containing dry platinum was pretreated in a forced-air convection oven at 210°C.

Electrocatalysis for the oxygen reduction

The electrocatalytic properties of PAN-Pt have been tested for the reduction of oxygen. Cyclic voltammograms of the PAN-Pt electrode in 0.5 M H_2SO_4 saturated with O_2 and N_2 are shown in Fig. 6. For comparison, the cyclic voltammogram of a smooth platinum bulk electrode in 0.5 M H_2SO_4 saturated with O_2 is also shown in Fig. 6. The platinum loading of the PAN-Pt electrode material is 7.6 μg cm^{-2}. An enhancement of the cathodic current in the oxygen-reduction region at the PAN/Pt electrode in the O_2-saturated solution, in comparison with that in N_2-saturated solution, indicates the electrocatalytic activity of the PAN/Pt for the reduction of oxygen. At the PAN/Pt electrode, the values of the cathodic current at higher overpotential range are comparable to those at the smooth platinum bulk electrode in 0.5 M H_2SO_4 saturated with O_2.

Figure 7 compares the current–potential curves of the PAN-Pt electrode (with a platinum loading of 7.6 μg cm^{-2}) and PAN/Pt electrode (with a platinum loading of 23 μg cm^{-2}) in 0.5 M H_2SO_4 saturated with O_2. Appreciable values of the cathodic current in the oxygen-reduction region have been observed at both electrodes. In comparison with the features of the current–potential curve for PAN/Pt, the cathodic current of the PAN-Pt is smaller (in mA cm^{-2}). It should be noted, however, that the platinum loading of these two electrodes is different (see above). If the current scale is changed to A g^{-1} Pt, the cathodic current of PAN-Pt, as also shown in Fig. 7, would be larger than that of PAN/Pt at more negative potentials, indicating a better mass electrocatalytic activity of the PAN-Pt material. This better mass electrocatalytic activity obviously originates from the higher homogeneity of the platinum particle distribution and the lesser degree of aggregation of the small particles in the PAN-Pt than in the PAN/Pt.

Fig. 7. Current–potential curves of PAN-Pt (– – –) and PAN/Pt (———) in 0.5 M H_2SO_4 solution saturated with oxygen. Scan rate: 5 mV s^{-1}. Rotating rate: 0 rpm.



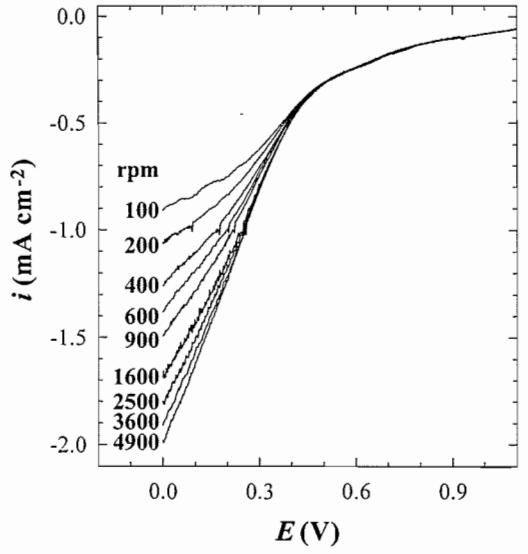


Fig. 8. Current–potential curves of PAN-Pt in 0.5 M H_2SO_4 solution saturated with oxygen at different rotating rates as shown in figure. Scan rate: 20 mV s^{-1}.

Since the oxygen-reduction current depends strongly on hydrodynamic conditions, a rotating disk electrode was used to study the kinetics of oxygen reduction at the PAN-Pt electrode. Figure 8 presents the current–potential curves at different rotation rates (ω in revolutions per minute, rpm) obtained by scanning the potential from 1.2 to 0.0 V at 20 mV s^{-1} in 0.5 M H_2SO_4 saturated with O_2. The platinum loading of this electrode material is 7.6 μg cm^{-2}. An ω-independent non-zero current value appeared at 1.0–0.6 V. Mass transport contributions became significant at lower potentials, i.e., at higher values of the oxygen-reduction overpotentials. The curves do not

© 1997 NRC Canada

level off as expected at large overpotentials of O_2 reduction. In general, the diffusion-limiting current density is not well defined; we plan to examine the possible cause for this behavior in our future work.

Concluding remarks

A new electrocatalytic material consisting of a molecularly homogeneous platinum–aerogel nanocomposite has been prepared. TEM images of this material clearly show that nanometer-size platinum particles are homogeneously distributed, and form part of a molecular architecture of the composite. Compared with the PAN/Pt previously studied (16–19), it is (*i*) the highly homogeneous distribution of the nanometer-size platinum particles within the PAN-Pt nanocomposite, and (*ii*) the suitable interparticle distance that make PAN-Pt possess highly electrocatalytic activity. If the mean distance between these particles is too small, a depletion of the reactant (dissolved oxygen) concentration due to slow mass transfer occurs around each particle, and this process seems to be the rate-determining step in this type of system. A suitable mean distance between these particles could thus lead to enhancement of the mass transfer process. This PAN-Pt system seems to act as a "collection of nanoelectrodes" with ideal spacing between the platinum particles. XPS study indicates that there exists a special interaction between the platinum and the support within a PAN-Pt electrocatalyst, which is stronger than that in the PAN/Pt material. The long time stability of the PAN/Pt electrocatalyst should be, in principle, improved by this special interaction, which has indeed been indicated by our preliminary experimental results, and is a subject of our continuing study. This material is a promising electrocatalyst for oxygen reduction, and its electrocatalytic activity is due to the nanodispersed platinum particles present in the nanocomposite.

The PAN-Pt material can be considered to be a molecularly mixed inorganic–organic polymer nanocomposite. At the microscopic level, the mixed components represent very homogeneous combinations originating from chemical interactions at the molecular scale in the liquid phase that can be viewed as "frozen in" in the solid state via supercritical drying. Thus, by using aerogel preparation methods, control of the morphological properties is well advanced by comparison with conventional preparation techniques such as impregnation, ion exchange, and so on. The synthesis of such composites is believed to open promising new possibilities for the (electro)catalytic application of aerogels as catalysts or catalyst supports with novel structural and chemical properties (14). However, in such molecularly mixed preparation routes, it must be remembered that at least part of the precious metal component is submerged within the body of the matrix (26), thus no longer being accessible for (electro)catalytic surface processes. Also, it was found from the analysis of XPS data that a large fraction of platinum is in oxide or hydroxide states. It is known that platinum oxides are electrochemically inactive for oxygen reduction, which is believed to be one of the main reasons that PAN-Pt is not such a good electrocatalyst for oxygen reduction as would be expected by taking into account its molecularly homogeneous nanocomposite structure. In addition, one can see from Fig. 6 that it takes a higher overpotential to generate the same current density on PAN-Pt as on a platinum bulk electrode, the reason being still unclear. Further studies are being carried out in order to achieve a more efficient use of this electrocatalyst, by converting the higher oxide states of platinum to the metallic state.

Response of the EQCM to specific adsorption on gold electrodes: adsorption of pyridine and benzene

Galit Zilberman, Vladimir Tsionsky, and Eliezer Gileadi

Abstract: The electrochemical quartz crystal microbalance (EQCM) is used to study adsorption of pyridine and benzene on gold. The most important result observed is that *the frequency increases when the organic molecule is adsorbed*, namely, the total mass of the species rigidly adsorbed is reduced as a result of adsorption. This is consistent with the accepted idea that electrosorption is a replacement reaction, in which a number of water molecules are replaced from the interface for each organic molecule adsorbed. However, this is the first time, to the best of our knowledge, that it has been observed experimentally. If the number of water molecules desorbed to make place for one molecule of pyridine is larger than 4.4, a decrease in mass should be observed. When independent data on the dependence of surface coverage on potential is available, this number can be estimated. In the case of pyridine, the EQCM data best fit the adsorption results if each molecule is assumed to replace 10–12 water molecules. In the case of benzene a similar calculation could not be performed since there are no adsorption data collected under comparable experimental conditions. Nevertheless, a positive shift of frequency is observed, indicating that this number must be >4.4.

Key words: electrochemical quartz crystal microbalance, electrical double layer, gold, pyridine, benzene.

Résumé : On a utilisé une microbalance électrochimique à cristal de quartz («EQCM») pour étudier l'adsorption de la pyridine et du benzène sur l'or. Le résultat le plus important à être observé est que *la fréquence augmente lors de l'adsorption de la molécule organique*, à savoir que l'adsorption provoque une réduction de la masse totale de l'espèce adsorbée d'une façon rigide. Cette observation est en accord avec l'idée généralement acceptée à l'effet que l'électrosorption est une réaction de substitution dans laquelle un certain nombre de molécules d'eau sont remplacées de l'interface par les molécules organiques adsorbées. Toutefois, à notre connaissance, c'est la première fois que ce phénomène est observé expérimentalement. Si le nombre de molécules désorbées pour faire de la place pour une molécule de pyridine est supérieur à 4,4, on devrait observer une diminution de la masse. Quand on dispose de données indépendantes relatives à la relation entre la couverture de la surface et le potentiel, il est possible d'évaluer ce nombre. Dans le case de la pyridine, les données de «EQCM» s'ajustent bien aux résultats d'adsorption si l'on fait l'hypothèse que chaque molécule remplace de 10 à 12 molécules d'eau. Dans le cas du benzène, il n'a pas été possible de faire un calcul semblable parce qu'aucune donnée d'adsorption, obtenue dans des conditions expérimentales semblables, n'est disponible. On observe toutefois un déplacement positif de fréquence; ceci indique que ce nombre doit être >4,4.

Mots clés : microbalance électrochimique à cristal de quartz, double couche électrique, or, pyridine, benzène.

Introduction

We have pointed out in several previous publications (1–4) that the responses of the quartz crystal microbalance (QCM) and its electrochemical version, the EQCM, reflect a variety of phenomena taking place at the interface between the surface of the vibrating crystal and the medium in which it is immersed. In particular it was shown (4) that electrostatic interactions between the charge on the metal surface and the ionic species in solution, which lead to significant changes in the concentration of the ions in the diffuse double layer, can lead to substantial changes in the frequency of the quartz crystal resonator. These changes in frequency are commensurate with the mass effect associated with the adsorption of one or two monolayers of typical adsorbates of interest in the study of the metal–solution interface. It was concluded that these changes in frequency are caused by the combined effects of the change in concentration and the resulting change in viscosity in the layer of liquid very close to the surface.

In the present work we embarked on a study of the use of the EQCM for the determination of specific adsorption, using the electrosorption of pyridine and benzene from aqueous solutions on a gold electrode as an example. The electrosorption of pyridine on gold has been studied in detail by different techniques (electrochemical, radiotracer, and Raman spectroscopy), and the results were recently reviewed by Lipkowski

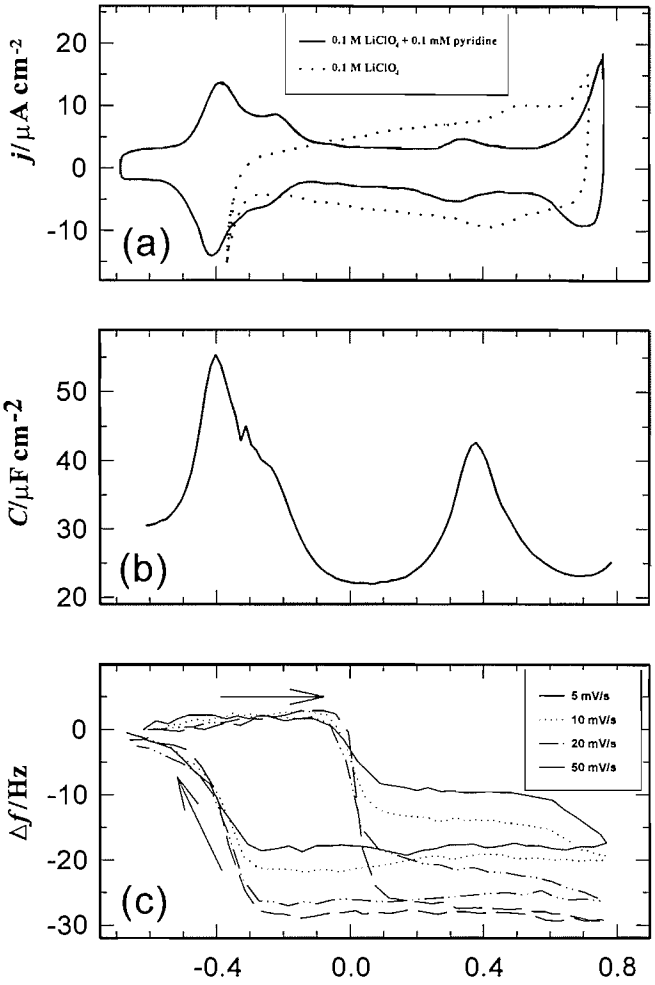
et al. (5). In a previous publication (1), we reported on our studies of the adsorption of the same two compounds from the gas phase on gold, with the use of the QCM.

Experimental



The quartz crystals employed in this work (diam. 14 mm) were of the "AT-cut" type, coated on both sides with vacuum-sputtered gold. The fundamental frequency of the crystal was f_0 = 6 MHz. A Leybold Inficon model XTC/2 or model IC/4 thin-film deposition controller, employing the "modelock" method for controlling and measuring the frequency, was used. Details of the measuring technique and the instrumentation employed were given in a recent publication (4). As in ref. 4, different compartments of the glass cell were separated by wetted glass stopcocks. Removal of oxygen traces from the solution by pure helium flow and preparing solutions with different concentrations of pyridine or benzene were performed in a separate cell compartment. This was used as a stock compartment to refill the working-electrode compartment. The latter was tubular and closed at the bottom by the disk of the quartz resonator. At the top of this tube, at a distance of 10 cm from the working electrode, an auxiliary platinum disc electrode was placed. This was used for ac measurement only and was connected through a capacitor, with the main counter platinum electrode placed in a separate compartment. This avoided polarization by the dc current and decreased the possibility of contamination of solution in the working-electrode compartment. At the same time, most of the ac current was passed through the solution, thus improving the uniformity of ac current distribution on the working electrode. A Solartron 1250 frequency-response analyzer was used to measure the double-layer capacitance as a function of potential. The potential was swept at a rate of 5 mV/s and modulated at a frequency of 25 Hz with a sine wave of 5 mV amplitude.

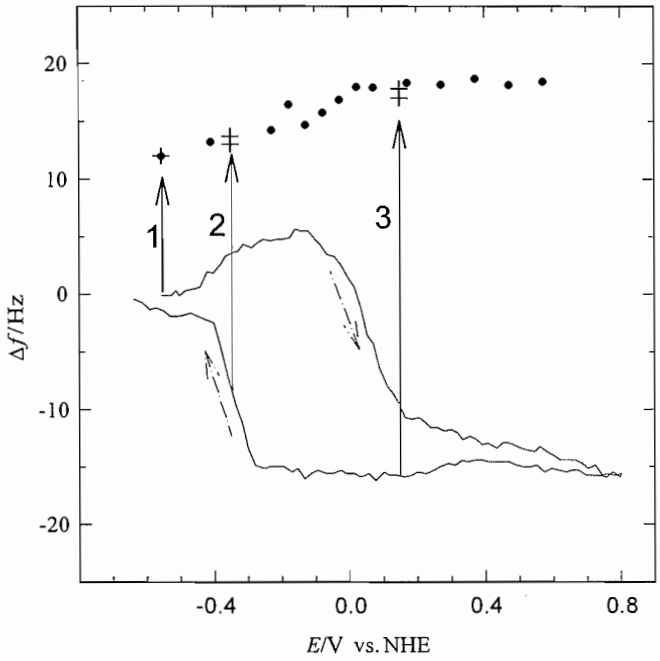
The gold surface sputtered on the quartz crystal was used as the working electrode. It was degreased and cleaned by standard procedures, as described earlier (4). To enhance reproducibility of the surface, the electrode was cycled overnight in the supporting electrolyte (0.1 M $LiClO_4$), between −0.40 V vs. NHE (the onset of hydrogen evolution) and 1.50 V vs. NHE. Only after this procedure, and replacement of the solution in the working-electrode compartment with a new portion of solution, did the current–potential (j–E) curve become symmetrical in current over the potential region of interest (Fig. 1*a*, broken line). The cell construction permitted maintenance of the experimental conditions for many hours without any sign of contamination of solution or electrode. All the measurements were performed at 25 ± 0.5°C with unstirred solutions.

Preliminary results

The cyclic voltammogram and the dependence of capacitance on voltage obtained for solutions containing pyridine are shown in Figs. 1*a* and *b*, respectively. There is good correspondence between the j–E and the C–E plots. These results coincide with the results published by Lipkowski and coworkers (6). This is very important for us, because we used the data on charge density and surface excess obtained in ref. 6 to process the data on the EQCM response. The dependence of charge on potential, obtained in the supporting electrolyte in

Fig. 1. (*a*) Cyclic voltammetry, 50 mV/s; (*b*) double-layer capacitance; and (*c*) EQCM response. Gold electrode in 0.1 M $LiClO_4$ + 0.1 mM pyridine. Arrows show the potential scan directions.

the absence of pyridine, agrees well with literature data (7) if we assume a roughness factor of approximately 1.5, which is reasonable in view of the roughness of the gold surfaces we have been using, as discussed earlier (2).



In preliminary experiments with dilute solutions of pyridine (0.1 mM) it was observed that the response of the EQCM during cycling over a given potential region is strongly dependent on the sweep rate and the direction of the sweep, as shown in Fig. 1*c*.[2] The hysteresis decreases with increasing pyridine concentration. It should be noted that the curves shown in Fig. 1*c* were reproducible only after the first 5–10 cycles. The initial Δf–E curves appear at higher frequencies. There are two possible reasons for this behavior. One of them is transport limitation. It is known (5, 6) that in the case of pyridine, measurements of the double-layer capacitance during cycling over a given range of potentials do not yield the true size and shape of the capacitance dependence on potential

[2] The value of Δf was arbitrarily taken as zero at a potential of −0.6 V, where adsorption of pyridine does not occur.

Fig. 2. Comparison between the data obtained in the 0.1 M $LiClO_4$ + 1 mM pyridine solution by potential-sweep (solid line) and potential-step (points) techniques. Dashed arrows show the direction of the sweep (50 mV/s). For other details see text.

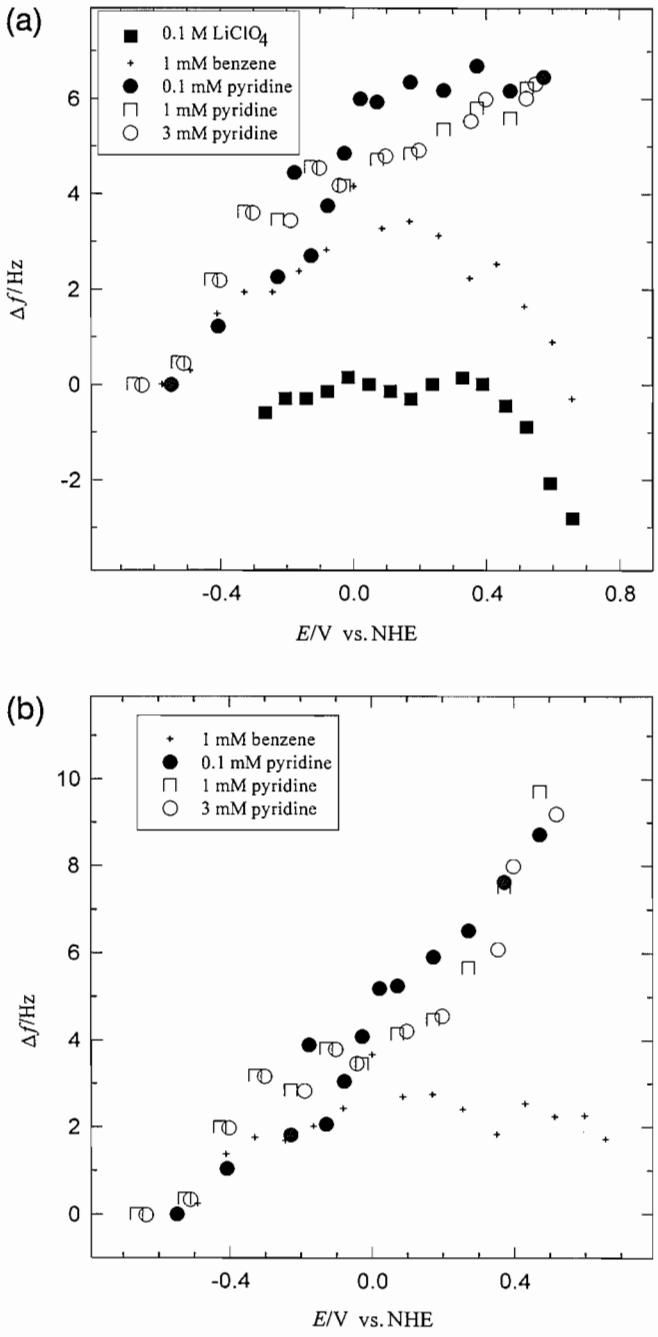
and, as a result, misrepresent the data on surface excess. Transport limitations give rise to the diffusion layer, the viscosity of which may differ from that of the bulk solution. The EQCM response is very sensitive to changes of viscosity at the interface. The influence of diffusion kinetics on the EQCM response has been shown (8). Kinetic limitations of the adsorption–desorption process, which do not allow equilibrium adsorption of pyridine during cycling, are probably an additional cause of the hysteresis observed.

To avoid this complication, we employed a potential-step rather than potential-sweep technique. The gold electrode was held for a few minutes at an initial potential E_i (−0.6 vs. NHE), where adsorption of pyridine does not take place. The potential was then stepped to a desired value E_1, maintained there for a few minutes to ensure that steady state had been reached, then stepped back to the initial value E_i to ensure that the state of the surface had not changed, as determined by the fact that the frequency resumed its original value. This procedure was repeated for a series of potentials, E_2, E_3, E_4, etc. The frequency was monitored throughout this procedure, and the dependence of frequency on potential was determined from the steady state values observed at each potential. This steady state was usually reached within 10–30 s of changing the potential and was stable to within ±0.5 Hz. The difference between the frequency at E_i and E_n is used below as a function of potential.

Correlation between the data obtained by potential-step and potential-sweep techniques is shown in Fig. 2. The solid line corresponds to the Δf–E curve for the 50 mV/s scan. If the sweep is stopped at negative potential, where there is no adsorption of pyridine, Δf increases by more than 10 Hz in about 3 min. These changes are shown by the vertical arrow 1. In practice, it is impossible to compare the absolute values of fundamental frequency of the quartz resonator obtained in different independent experiments. Therefore, as seen in Fig. 2 we took the limiting steady state value of the frequency (a cross at the end of arrow 1) as background for the data obtained by the potential-step technique (points). In this manner one can see the difference between the two sets of data. If the sweep is stopped at any arbitrary potential (arrows 2 and 3) the frequency begins to increase and its limiting values (crosses) coincide with the dependence obtained by the potential-step method. These limiting values are independent of the sweep direction. Thus the data on the EQCM response obtained during the potential-sweep do not reflect equilibrium adsorption and do not represent an intrinsic hysteresis in the adsorption behavior of pyridine from aqueous solutions.

Contrary to experiments with pyridine, the EQCM responses obtained with benzene from potential-step experiments and from cyclic voltammetry practically coincide. This may be due to different energies of adsorption–desorption of the two substances, different kinetics of this process, and partially to the higher diffusion coefficient of benzene (1.02×10^5 cm^2/s) compared to that of pyridine (0.58×10^{-5} cm^2/s) (9). All the data on pyridine adsorption presented in Figs. 3 and 4, and discussed below, were obtained by the potential-step technique.

Results and discussion



The frequency of the EQCM depends in a complex manner on the detailed structure of the interface between the metal coating on the quartz crystal and the solution (4). The concentrations of pyridine and of benzene used in the present series of experiments are sufficiently low, so that the bulk viscosity and density of the solution may be considered to be independent of the presence of the organic adsorbate. Moreover, when switching from the initial potential to a chosen value, the frequency changes in a relatively short time, i.e., on the time scale of seconds, and upon switching back to the initial potential the frequency resumes its original value, ruling out the possibility of major changes in the surface roughness. We are therefore left to interpret the change in frequency in terms of the changes in the diffuse double layer, alluded to above (3, 4), and, of course, the change in mass resulting from electrosorption.

The properties of the diffuse double layer depend directly on the surface charge density of the metal and not on the potential. Thus, in order to correct for this effect quantitatively, we first need to convert the dependence of frequency on potential $\Delta f(E)$ to its dependence on charge density, $\Delta f(q)$. In Fig. 3*a*, the potential regions, where the EQCM response was measured in the presence and absence of pyridine, do not coincide because hydrogen evolution in the supporting electrolyte starts at a more positive potential than in the presence of pyridine (cf. Fig. 1*a*). However, because of peculiarities of the shape of charge–potential dependence and a shift of the PZC on gold to more negative potentials in pyridine-containing solutions (6), the range of charge densities practically coincide. In this new coordinate ($\Delta f(q)$) we shift all the curves along the frequency axis, so that at the initial potential, where no adsorption occurs, the value of Δf coincides with its value on the Δf vs. q plot for the supporting electrolyte. We then fol-

Fig. 3. Response of the EQCM on gold in 0.1 M $LiClO_4$, in the presence of pyridine or benzene at the concentrations marked in the figure. (*a*) The measured shift in frequency as a function of potential; (*b*) the same as (*a*) corrected for the effect of the diffuse double layer (see text).

low the curve to all other potentials, subtracting the value of $\Delta f(q)$, caused by changes in the diffuse double layer in the supporting electrolyte, from the value obtained in the presence of pyridine or benzene. This is done on the tacit assumption that the structure of the diffuse double layer, as far as changes in the surface excess of the different ions is concerned, is independent of the presence of the organic adsorbate, *as long as the comparison is made at the same charge density*. The dependence of charge density on potential is, of course, influenced by electrosorption, so a similar correction would not have been justified had we used the dependence of frequency on potential. We use the dependence of charge on potential obtained for pyridine in the literature (6) from potential-step experiments, i.e., by the same techniques used to obtain the EQCM response. The dependence of charge on potential for the case of benzene is obtained by numerical integration of the capacitance as a function of potential. Such a corrected plot is shown in Fig. 3*b* for one concentration of benzene and two concentrations of pyridine. Comparison between Figs. 3*a* and *b* shows the overwhelming importance of taking the potential dependence of frequency, resulting from the effects of ions in the diffuse double layer, into account when interpreting of EQCM data in the submonolayer region (3, 4). The change in frequency caused by specific adsorption in the present case is similar in magnitude to that caused by the change in potential in systems where specific adsorption is known to be absent. Ignoring this effect, which has been discussed in some detail earlier (4), could therefore lead to totally erroneous conclusions regarding specific adsorption.

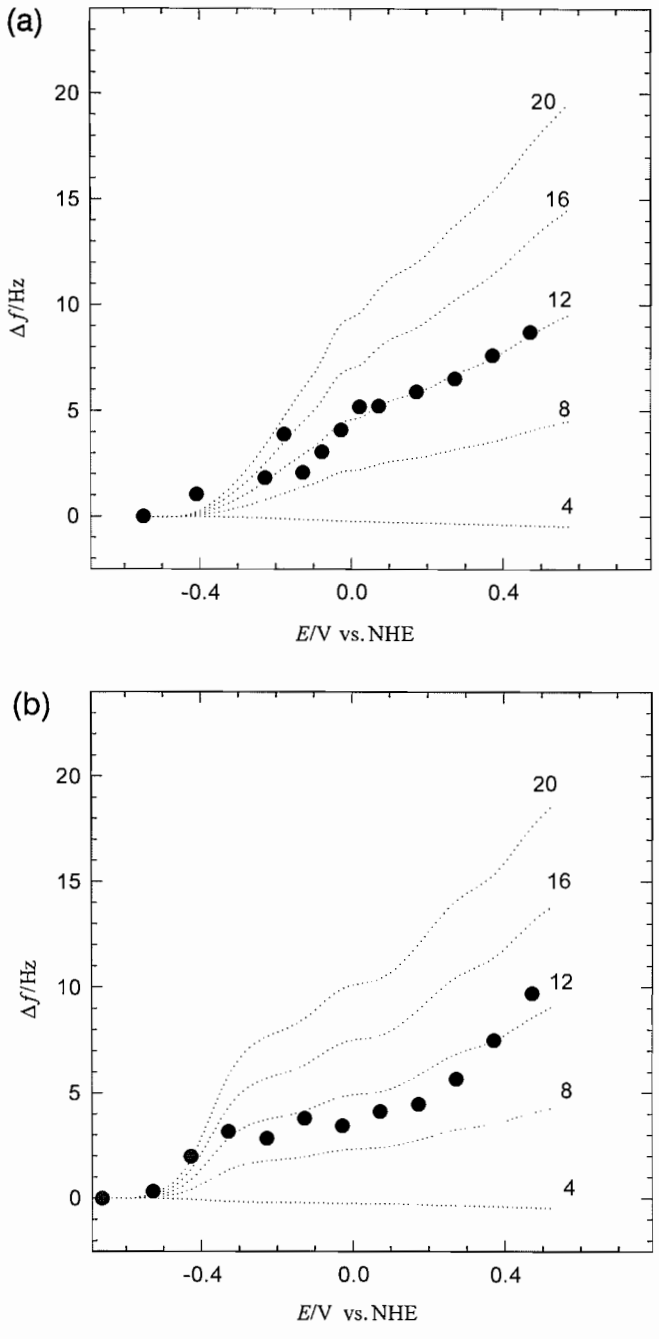
Having corrected for the effect of the diffuse double layer, and considering that all other conditions (viscosity, density, surface roughness) are constant in the course of the experiment, the only cause for a change in frequency is the mass effect of the adsorbed species. We can hence employ the Sauerbrey equation (10):

$$[1] \quad \Delta f = -C_m \Delta m$$

The constant C_m, which represents the sensitivity of the EQCM, is 0.082 Hz ng^{-1} cm^2 in our experimental setup.

It should first be noted that the change of frequency caused by adsorption is positive, *implying a decrease rather than an increase in mass.* This is not unexpected, considering that electrosorption is a replacement process in which the adsorbate replaces a certain number of water molecules from the surface (11, 12). Thus, depending on the number of water molecules displaced for each organic molecule adsorbed, the total mass could increase, decrease, or remain essentially constant. The change of mass resulting from electrosorption can be expressed in the form

$$[2] \quad \Delta m = \Gamma_{ads}(M_{ads} - vM_W)$$



where M_{ads} and M_W are the molecular weights of the adsorbate and water, respectively, Γ_{ads} is the surface excess of the adsorbate, and v is the number of water molecules replaced by each adsorbed organic molecule. It is obvious from the above that for values of v equal to 4–5, there would hardly be any change in frequency upon adsorption of benzene or pyridine. The increase of frequency observed in our experiments (cf. Fig. 3*b*) indicates that the number of water molecules replaced from the surface is higher.

In the case of the adsorption of pyridine on gold electrodes, the dependence of Γ_{ads} and of the charge density on potential has been determined in great detail (6). This allowed us to calculate the expected values of the change in frequency as a function of potential, assuming different values of the size parameter v. The results of such calculations, for values of v

Fig. 4. Comparison between the calculated shift of frequency of the EQCM upon adsorption of pyridine, assuming different values of the size parameter v (dashed lines) and the experimental results, corrected for the effect of the diffuse double layer. (*a*) 0.1 mM; (*b*) 1 mM pyridine.

ranging from 4 to 20, are shown in Figs. 4*a* and *b* for 0.1 mM and 1.0 mM solutions of pyridine, respectively. It can be seen that the experimental points best fit the curve calculated for a value of v = 10–12. A specific physical interpretation of these values can be given only in the framework of a simplified model of the interface, consisting of the metal surface, a film of water molecules adsorbed on this surface, followed by "bulk" water. The film is assumed to be rigidly attached to the metal (as in chemisorption) and to vibrate with the crystal. The hydrodynamic velocity profile leads from the plane of this rigid film outwards. Thus, adsorption of pyridine gives rise to substitution of a number of water molecules (v) from the rigidly adsorbed film. The real situation at the interface is undoubtedly more complicated, and the structure of water changes gradually with distance from the metal surface, until bulk properties are reached at a distance of a few layers from the surface. Thus, the value of v estimated in the above manner should be regarded as an effective value, reflecting the total effect of an adsorbed species on the structure of the water in the interface.

At potentials more positive than −0.05, the effective value of v, calculated from the EQCM response (points), has the same shape as that obtained from surface excess (lines). This indicates that the effective number of water molecules replaced is unchanged, and reorientation of adsorbed pyridine molecules is not likely to have taken place in this region. At more negative potentials the response of the EQCM is too small for sufficiently precise determination of v. The PZC values are equal to 0.01 and −0.06 V vs. NHE for 0.1 mM and 1 mM pyridine, respectively (6). Thus, at positive charge densities, there is no change of configuration of the pyridine molecule at the interface. It has been reported in the literature (6) that, in the same region, pyridine is adsorbed on gold in a perpendicular configuration.

Figures 4*a* and *b* present only low concentrations of pyridine. For higher concentrations of pyridine and for benzene we could not perform this type of calculation, because accurate data for the dependence of Γ_{ads} and of the charge density on potential are not available. In the case of benzene, a direct comparison between the available radiotracer data on gold (13) and the present EQCM measurements cannot be made because of the great difference in the experimental conditions. This makes the interpretation of the dependence of frequency on potential difficult for benzene. We do observe, however, that the change in frequency is positive, as in the case of pyridine (cf. Fig. 3*b*), indicating that the number of water molecules replaced from the surface for each molecule of benzene adsorbed is larger than 4, and probably not less than 6. We note here the difference between our earlier measurements in the gas phase (1) and the present measurements from solution. In the former, pyridine is adsorbed in a perpendicular configuration occupying a smaller area on the surface, and hence a monolayer contains more molecules, leading to a larger shift of frequency *in the negative direction*. Here, the perpendicular configuration of the pyridine molecule disturbs the structure of water further away from the metal surface, thus leading to *a larger positive shift in frequency*, which is indicative of a larger apparent number of water molecules replaced by each molecule of pyridine adsorbed.

Conclusions

The concept of electrosorption as a replacement reaction has long been established and the energetics of the process is commonly discussed in terms of the difference between the energy of adsorption of the organic molecule and the energy of desorption of the number of water molecules v (14). The present study is the first, to the best of our knowledge, in which direct

© 1997 NRC Canada

evidence for this displacement process is presented, in that the frequency of the EQCM is found to *increase* upon adsorption of organic molecules, showing that the total mass loading the crystal has effectively decreased. This is a very important central finding in our work, the importance of which transcends the detailed discussion of the configuration of different molecules adsorbed on the surface.

If independent adsorption data are available, one can fit the EQCM data to curves, calculated by assuming different numbers of water molecules replaced for each organic molecule adsorbed, and determine the effective size parameter of the molecule.

It is shown that meaningful adsorption data can only be obtained if the change of frequency, resulting from changes in concentration and viscosity inside the diffuse double layer, is taken into account, as discussed in our earlier publications (3, 4).

The frequency of the quartz crystal resonator is sensitive to a host of physical phenomena occurring at the interface, and should not be interpreted only in terms of a change in mass (1–4). This calls for tight control of these parameters, if meaningful data concerning adsorption are to be extracted. In electrochemical systems it is best to use the EQCM in conjunction with other methods, such as measurement of the double-layer capacitance, the charge density, and the surface excess, to obtain a clear picture of the interface, and the configuration of different molecular species in it.

Réorganisation de la double couche électrique suivant la désorption réductive d'une monocouche auto-assemblée d'alcanethiols sur l'or<111>

Dong Fang Yang et Mario Morin

Résumé : Nous avons utilisé la spectroscopie vibrationnelle pour suivre la réorganisation de la double couche électrique suite à la réduction d'une monocouche auto-assemblée de nonanethiols chimisorbés sur une électrode monocristalline d'or<111>. L'absence de changements vibrationnels importants dans la région de la double couche démontre que la monocouche de nonanethiols est stable sur plus de 800 mV. Lorsque le potentiel de l'électrode est plus négatif que le potentiel de réduction de la monocouche de nonanethiols, des changements sont observés dans le spectre vibrationnel des molécules d'eau. L'interaction entre les molécules d'eau et la surface d'or change selon le potentiel appliqué à l'électrode. Pour un potentiel correspondant au début de la réduction de la monocouche de thiols, les résultats spectroscopiques suggèrent que les molécules d'eau interagissent faiblement avec la surface d'or<111>. Lorsque le potentiel de l'électrode devient suffisamment négatif pour produire de l'hydrogène gazeux, le mode de déformation de l'eau se déplace vers une plus basse énergie. Ce dernier résultat indique une plus forte interaction entre les molécules d'eau et l'électrode d'or. De plus, des mesures vibrationelles résolues dans le temps suggèrent la formation d'agrégats de molécules d'eau immédiatement après la désorption réductive des thiols et avant la production d'une quantité détectable d'hydrogène.

Mots clés : électrochimie, double couche électrique, spectroscopie vibrationnelle, thiols.

[Traduit par la rédaction]

Abstract: We report a vibrational study of the reorganization of the electrical double layer following the reduction of a self-assembled nonanethiol monolayer on a Au <111> electrode. The absence of changes in the vibrational spectra taken in the potential range covering the double layer shows that the nonanethiol monolayer is stable over 800 mV. Important changes in the vibrational spectra of the water molecules are observed when the applied potential is more negative than the reduction potential of the thiol monolayer. The interaction between the water molecules and the gold electrode is modified by the electrode potential. For a potential corresponding to the onset of the reduction of the nonanethiol monolayer the spectroscopic results suggest that the water molecules interact weakly with the gold surface. However, when the potential is sufficiently negative to cause the evolution of hydrogen, the deformation mode of the water molecules moves to a lower energy, indicating a stronger interaction between the water molecule and the gold surface. Time-resolved vibrational measurements suggest that water clusters are formed immediately after the reductive desorption of the thiols and before a significant amount of molecular hydrogen is produced.

Key words: electrochemistry, electrical double layer, vibrational spectroscopy, thiols.

Introduction

Les monocouches auto-assemblées de thiols chimisorbés sur des électrodes métalliques sont utilisées comme systèmes électrochimiques modèle car elles sont compactes et bien ordonnées (1–8). Ces monocouches permettent l'étude de l'interface entre des composés organiques et une solution électrolyte aqueuse car il est possible de varier l'affinité des composés organiques pour le solvant à l'aide de la fonction du groupe terminal du thiol. Plusieurs études théoriques ont d'ailleurs porté sur la structure de la double couche à l'interface organique en présence des groupes fonctionnels chargés (9–11). Dans le cas de monocouches d'alcanethiols, l'interaction entre absorbats et la solution électrolyte est faible et une capacité de la double couche faible est mesurée (1). Cependant, lorsque la monocouche d'alcanethiols est oxydée ou réduite, la formation d'une double couche à la surface de l'électrode donne lieu à une augmentation du courant capacitif (12). Le contraste important entre la surface hydrophobe formée par les alcanethiols chimisorbés et la surface de l'électrode d'or<111> obtenue après la réduction des

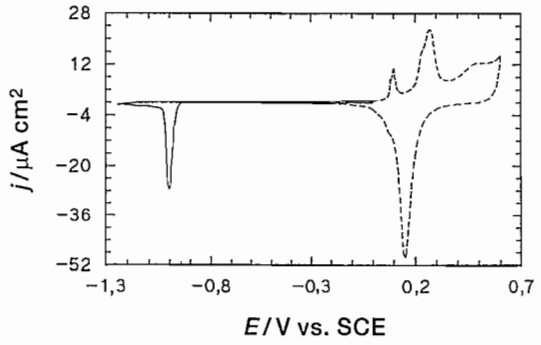
alcanethiols cause des variations importantes de l'orientation des molécules d'eau à l'interface suivant la réduction des alcanethiols. Ces changements d'orientation pourraient être mesurés par spectroscopie vibrationnelle et utilisés pour suivre la formation de la double couche suivant la réduction des thiols. Une telle étude serait difficile avec des électrodes d'or polycristallines car le courant d'évolution d'hydrogène est superposé à celui de la réduction de thiols (13–16). Cependant, nous avons démontré dans une série d'études récentes que l'utilisation d'électrodes monocristallines d'or<111> permet la formation de monocouches ayant très peu de défauts et dont la réduction est séparée du courant d'évolution de l'hydrogène (12, 17). Dans la présente étude les changements du spectre vibrationnel des molécules d'eau observés suite à la désorption réductive d'une monocouche de thiols chimisorbés sur l'or<111> seront présentés. Ces résultats démontrent que l'interaction des molécules d'eau avec la surface de l'électrode d'or<111> varie selon le potentiel.

Expérimental



La préparation du monocristal d'or<111> a été décrite précédemment (12). La solution d'hydroxyde de potassium (Aldrich, semiconductor grade) de 0,1 M a été faite à partir d'eau distillée traitée avec un système Milli-Q (Millipore). L'eau deutérée utilisée pour les mesures isotopiques avait une pureté de 99,9% (Cambridge Isotopes). Les potentiels cités dans ce travail sont relatifs à celui d'une électrode de calomel saturée (SCE). La monocouche de nonanethiol est obtenue en déposant une électrode d'or dans une solution 1 mM de nonanethiol dans l'éthanol pour une durée de 1 h. Ce protocole de déposition donne une monocouche complète et bien ordonnée (12). Un schéma de la cellule spectro-électrochimique est présenté dans la Fig. 1. Elle est faite de verre. Au fond de la cellule, il y a un prisme de Dove de 60° en CaF_2 qui sert de fenêtre infrarouge. L'électrode de référence est à l'extérieur de la cellule et est reliée à la cellule principale par un capillaire de Luggin, afin de minimiser les contaminations dues aux chlorures. La contre-électrode est un anneau de platine qui entoure le monocristal d'or. Le monocristal est poussé sur la fenêtre infrarouge à l'aide d'un micromètre afin de former une couche mince d'électrolyte. Il est également possible en remontant l'électrode de former un ménisque pour effectuer des mesures électrochimiques exclusivement sur la surface <111> (12). Le spectromètre FTIR (Nicolet Magna 550) est équipé d'un détecteur MCT (mercure–cadmium–tellurium) refroidi avec de l'azote liquide. Le faisceau infrarouge est polarisé à l'aide d'un réseau de fils métalliques déposés sur un substrat de ZnSe. Le faisceau entre dans la fenêtre de CaF_2 avec une incidence normale afin de minimiser les pertes d'intensité par réflexion. Il est ensuite réfléchit par la surface de l'électrode monocristalline. L'angle d'incidence du faisceau par rapport à la normale à la surface d'or<111> est environ 70°. Le faisceau réfléchi est dirigé vers le détecteur MCT à l'aide d'un miroir. Ce design simple permet une transmission de la radiation infrarouge de l'ordre de 70–90%. La technique spectroscopique utilisée pour l'acquisition des spectres est connue sous l'acronyme SNIFTIRS (18). Elle consiste à mesurer un spectre à un potentiel de référence et un spectre à un autre potentiel. Le spectre de référence est celui d'une électrode recouverte de nonanethiols à un potentiel de −0,5 V. Par la suite, la différence entre ces spectres est calculée et elle est normalisée par le spectre de référence. Ceci donne un

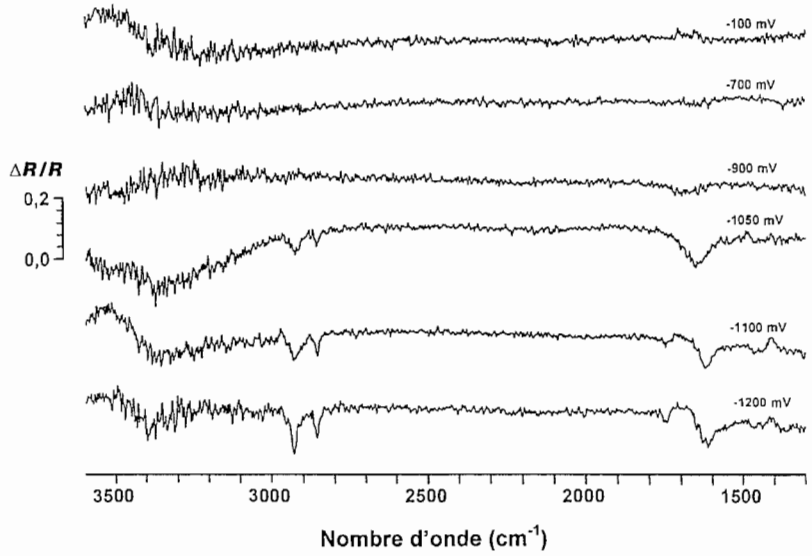
Fig. 2. Voltampérogramme cyclique d'une électrode d'or<111> recouverte d'une monocouche de nonanethiols dans une solution de 0,1 M KOH. Le balayage débute à −0,5 V vers les potentiels négatifs. La vitesse de balayage est de 20 mV/s.

spectre de réflectance différentielle dans lequel les bandes négatives correspondent à une augmentation de l'intensité des modes vibrationnels et les bandes positives correspondent à une di-minution de l'intensité des modes vibrationnels par rapport au spectre de référence. Les spectres présentés correspondent à une moyenne de 64 spectres dont la résolution est de 2 cm^{-1}. Le temps d'acquisition de 64 spectres est d'environ 30 s. La radiation infrarouge est polarisée dans le plan d'incidence (c.-à-d., p-polarisée) afin de maximiser le champ électrique perpendiculaire à la surface (19).

La Fig. 2 illustre le voltamogramme de la réduction d'une monocouche de nonanethiols dans une solution de 0,1 M KOH. Ce voltamogramme a été discuté antérieurement (12). Nous n'en ferons qu'une brève description afin de donner les caractéristiques principales du processus de réduction de la monocouche de nonanethiols. On note que la monocouche est réduite à un potentiel de −1,04 V (pour une vitesse de balayage de 20 mV/s) et que le pic de réduction est symétrique. Lors du balayage vers des potentiels plus positifs, suivant la réduction de la monocouche de thiols, on observe la formation de l'oxyde de surface correspondant à celle d'une surface d'or<111> propre. Nous avons démontré lors d'études précédentes (20) que la réduction des thiols suit un mécanisme dit de «création de trous et croissance». Ce mécanisme consiste en la création de trous de forme circulaire causée par la désorption réductive de thiols. Par la suite, la désorption réductive des thiols ne se produit qu'à la périphérie de ces trous qui prennent ainsi de l'expansion. Lorsqu'un thiol est réduit et quitte la surface, il y a formation d'une double couche électrique à l'interface électrolyte–or<111>. Un courant dit capacitif est associé à la formation de cette double couche électrique. Ce courant capacitif est causé le fait qu'il est possible d'accumuler une charge plus importante à la surface d'un électrode métallique qu'à la surface d'une électrode métallique recouverte d'une monocouche d'alcanethiols.

Résultats

Les spectres SNIFTIRS de la Fig. 3 couvrent la région de 1300 à 3600 cm^{-1} pour différents sauts de potentiel à des valeurs finales allant de −0,1 V à −1,2 V. On observe, pour des sauts de potentiel entre −0,10 V et −0,90 V, qu'il n'y a pas de changements dans la région des modes d'étirements CH entre 2800 et 3000 cm^{-1}. Seule une légère variation d'intensité dans la région entre 3200 et 3600 cm^{-1} correspondant aux modes d'étirements de l'eau est observée. La monocouche de nonanethiols chimisorbés sur une surface monocristalline d'or<111> ne subit donc pas de modifications importantes de l'orientation des molécules d'eau et aucun changement de l'orientation des thiols entre −0,10 V et −0,90 V. Ces résultats sont en accord avec les résultats voltampérométriques (12) et chronoampérométriques (20) qui démontrent que seul le chargement de la double couche se produit dans ce domaine de potentiel.



Lorsque le potentiel final est de −1,05 V ou plus négatif des changements importants sont observés dans le spectre vibrationel. On remarque dans ce domaine de potentiel des bandes négatives entre 2800 et 3000 cm^{-1} qui indiquent une augmentation de l'intensité des modes d'étirements CH des nonanethiols. Ces changements ont été discutés précédemment comme étant reliés à la formation de micelles de nonanethiolates (21). Un mode de faible intensité est observé à 1750 cm^{-1}. L'origine de ce mode est incertaine, mais il semble relié aux molécules de thiols (21). On voit également une augmentation de l'intensité (c.-à-d. des bandes négatives) de modes entre 1550 et 1700 cm^{-1} et entre 3000 et 3600 cm^{-1}. Ces modes correspondent respectivement au mode de déformation et aux modes d'étirement symétrique et asymétrique des molécules d'eau et ils sont le sujet de la présente étude.

Plusieurs observations indiquent que les spectres SNIFTIRS dans la Fig. 3 représentent principalement les molécules d'eau à la surface. En effet, lors d'une étude précédente, on a démontré que les bandes vibrationelles de l'eau dans le spectre p-polarisé diffèrent de celles observées dans un spectre s-polarisé (polarisation perpendiculaire au plan d'incidence) (21). Elles sont plus intenses et situées dans certains cas à des nombres d'onde différents. En conséquence, ceci indique, d'après les règles de sélection interfaciales en spectroscopie infrarouge (19), que les molécules d'eau observées dans les spectres p-polarisés sont surtout celles qui sont à l'interface. L'intensité similaire des modes vibrationels de l'eau et des modes d'étirements CH suggère qu'un nombre restreint de molécules d'eau (c.-à-d. une ou quelques monocouches) contribuent à ce spectre. Finalement, la bande négative correspondant au mode de déformation de l'eau n'est pas bipolaire. C'est à dire qu'elle consiste en une augmentation régulière de l'intensité et non à une variation complexe de l'intensité en fonction du nombre d'onde (18). Cette observation peut s'expliquer par un changement important dans l'intensité et (ou) du nombre d'onde de ce mode vibrationnel des molécules d'eau à l'interface qui masquerait des changements moins importants du spectre vibrationel des molécules d'eau dans la solution.

Le mode de déformation de l'eau se déplace de façon soudaine entre −1,05 V et −1,10 V. Il est à 1670 cm^{-1} pour un potentiel final de −1,05 V et il est à 1620 cm^{-1} pour un potentiel final plus négatif que −1,10 V. La bande de ce mode devient plus étroite (~70 cm^{-1}) pour le potentiel de −1,10 V. L'intensité relative du mode de déformation et des modes d'étirement varie également en fonction du potentiel. Pour un potentiel final de −1,05 V, le mode de déformation est environ deux fois moins intense que les modes d'étirement. Ceci a été observé lors d'études spectro-électrochimiques précédentes (22). Cependant, pour un potentiel final de −1,20

© 1997 NRC Canada

Fig. 3. Spectres SNIFTIRS d'une électrode d'or<111> recouverte d'une monocouche de nonanethiols. Les spectres sont exprimés en terme de réflectance différentielle (%). Le potentiel de référence est de −0,50 V et le potentiel final est indiqué sur la figure. Les spectres représentent les 30 premières secondes après le saut de potentiel.

V, on remarque que le mode de déformation est aussi intense que les modes d'étirement. Ces différences spectrales entre les potentiels de −1,05 V et −1,20 V suggèrent que l'interaction des molécules avec l'électrode d'or<111> est influencée par le potentiel.

L'évolution temporelle des spectres vibrationels pour un potentiel final de −1,05 V illustrés sur la Fig. 4 montre une augmentation graduelle des bandes négatives dues aux modes vibrationels de l'eau. Le mode de déformation à 1670 cm^{-1} ne subit pas de déplacement durant les 115 premières secondes. Les modes d'étirements consistent en une large bande négative centrée à 3400 cm^{-1} qui est environ deux à trois fois plus intense que la bande du mode de déformation. Ceci suggère une accumulation des molécules d'eau à la surface de l'électrode. Les variations d'intensité des modes d'étirements et de déformation pour un potentiel final de −1,20 V sont beaucoup plus importantes qu'à −1,05 V comme ceci est illustré dans la Fig. 5. Le spectre correpondant aux 30 premières secondes après le saut de potentiel montre une augmentation de l'intensité du mode de déformation situé à 1620 cm^{-1} par rapport à l'état de référence à −0,50 V. Entre 45 et 75 s, la bande positive indique une diminution de l'intensité du mode de déformation qui se déplace à 1660 cm^{-1}. La bande correspondant aux modes d'étirement de l'eau subit des changements similaires. Durant les 30 premières secondes il y a une légère augmentation de l'intensité de ces modes situés à environ 3350 cm^{-1}. Par la suite, l'intensité de ces modes diminue (bande positive) et se déplace vers 3450 cm^{-1}. Après 250 s, les modes vibrationels de l'eau dominent le spectre vibrationel avec des augmentations de réflectivité supérieurs à 1%. Cette importante diminution de l'intensité des modes vibrationels reliés aux molécules d'eau ne peut s'expliquer par un changement des moments de transition vibrationnel d'une monocouche de molécules d'eau. Il doit y avoir une diminution du nombre de molécules d'eau dans la mince couche d'électrolyte entre le monocristal et la fenêtre de CaF_2. Cette diminution s'explique par la décomposition de molécules d'eau lors de l'évolution d'hydrogène qui se produit à un potentiel de −1,20 V (12, 23). Les différentes évolutions temporelles des spectres vibrationels décrites dans ce paragraphe confirment que l'interaction des molécules d'eau avec la surface d'or<111> lorsque le potentiel est moins négatif que −1,05 V est différente de celle à des potentiel plus négatif que −1,05 V.

Nous avons effectué des mesures avec de l'eau deutérée, comme solvant, pour mieux comprendre l'interaction des molécules d'eau avec la surface d'or<111> à un potentiel final de −1,20 V. Les résultats de cette étude sont présentés dans la Fig. 6. On voit une augmentation de l'intensité des modes d'étirements de l'eau deutérée entre 2200 et 2800 cm^{-1} et du mode de déformation à 1220 cm^{-1}. Le rapport des nombres d'onde des modes de déformation de l'eau et de l'eau deutérée est 1,33. Ce rapport isotopique est proche de celui prévu pour une molécule d'eau dans un puits d'énergie potentielle de forme harmonique (24). L'évolution temporelle du spectre vibrationel obtenu lorsque l'eau deutérée est utilisée comme solvant est similaire à celle observée avec de l'eau. On observe lors des 100 premières secondes des bandes négatives qui indiquent une augmentation de l'intensité des modes vibrationels de l'eau deutérée relativement au spectre de référence. Ceci est suivi d'une diminution importante (supérieure à 1%) de l'intensité de ces modes après 250 s. Sur le spectre correspondant aux 30 premières secondes après le saut de potentiel, on voit dans la région des modes d'étirement, deux bandes négatives centrées à 2700 cm^{-1} et 2500 cm^{-1}. La bande à 2500 cm^{-1} est attribuée aux modes d'étirement symétrique et asymétrique de molécules d'eau deutérées ayant des liaisons hydrogènes avec d'autres molécules d'eau (22, 24). La bande à 2700 cm^{-1} est attribuée à des molécules d'eau deutérée ayant au maximum une liaison hydrogène (22, 24). Durant les 100 premières secondes, l'intensité du mode à 2700 cm^{-1} varie peu tandis que celle du

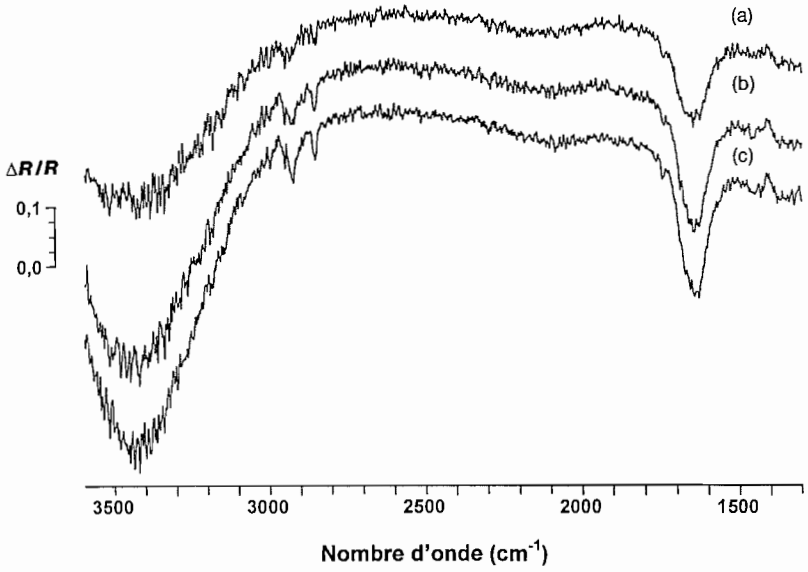
Fig. 4. Évolution temporelle d'un spectre SNIFTIRS d'une électrode d'or<111> recouverte d'une monocouche de nonanethiols pour un saut de potentiel de −0,50 V à −1,05 V. Le spectre est exprimé en terme de réflectance différentielle (%) : (*a*) de 0 à 30 s; (*b*) de 45 à 75 s; (*c*) de 85 à 115 s.



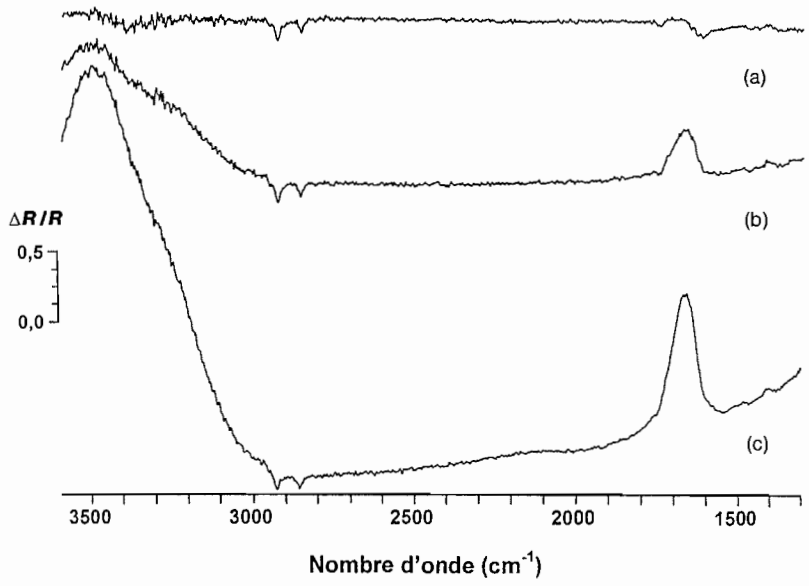


Fig. 5. Évolution temporelle d'un spectre SNIFTIRS d'une électrode d'or<111> recouverte d'une monocouche de nonanethiols pour un saut de potentiel de −0,50 V à −1,20 V. Le spectre est exprimé en terme de réflectance différentielle (%) : (*a*) de 0 à 30 s; (*b*) de 45 à 75 s; (*c*) de 85 à 115 s.

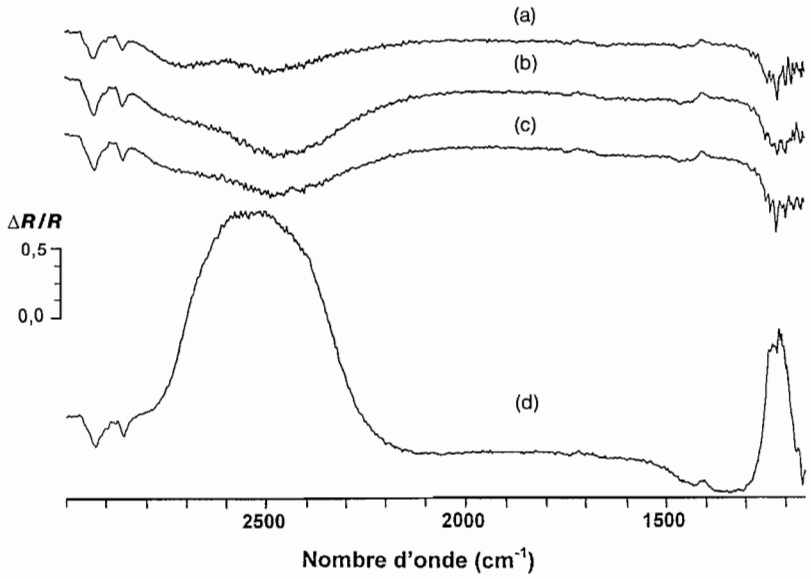
mode à 2500 cm^{-1} augmente fortement. Ce résultat indique une augmentation des liaisons hydrogène entre les molécules d'eau à l'interface électrolyte–or<111>.



Discussion

Les mesures vibrationnelles in situ démontrent que le potentiel électrique appliqué à l'électrode a un effet peu important sur l'orientation des molécules d'eau à l'interface nonanethiols–or<111> et des nonanethiols chimisorbés entre −0,1 V et −0,8 V. Comme mentionnés ci-dessus, ces résultats sont compatibles avec les mesures électrochimiques que l'on a obtenues précédemment et qui indiquaient une capacité constante dans ce domaine de potentiel (12, 20). On peut conclure de ces différentes observations qu'il est possible de former une monocouche de nonanethiols ayant très peu de défauts et qui bloque efficacement la surface de l'électrode métallique

Fig. 6. Évolution temporelle d'un spectre SNIFTIRS d'une électrode d'or<111> recouverte d'une monocouche de nonanethiols pour un saut de potentiel de −0,50 V à −1,20 V dans une solution 0,1 M KOH dans le D_2O. Le spectre est exprimé en terme de réflectance différentielle (%) : (*a*) de 0 à 30 s; (*b*) de 45 à 75 s; (*c*) de 85 à 115 s; (*d*) de 250 à 275 s.

lorsqu'un substrat monocristallin est utilisé. Ces résultats suggèrent également que l'observation de changements électrochimiques importants dans la région de la double couche d'une électrode d'or polycristalline recouverte d'alcanethiols est reliée à la qualité du substrat (1). Il est raisonnable de croire que pour un substrat d'or polycristallin, il y aura une plus forte proportion de défauts dans la monocouche et que celle-ci aura une plus grande perméabilité ionique.

Deux types de molécules d'eau peuvent être identifiés à partir des spectres vibrationels. Le premier type est observé à des potentiels finaux allant de −0,95 V jusqu'à environ −1,05 V. L'autre type de molécule d'eau est observé à des potentiels plus négatifs. Pour le premier type de molécules d'eau, l'augmentation de l'intensité des modes d'étirement et de déformation par rapport à ceux de l'état de référence indique que les molécules d'eau adoptent une orientation dans laquelle les moments de transition de ces modes sont, en moyenne, orientés plus perpendiculairement à la surface d'or<111>. L'intensité du mode de déformation est environ 1/3 de celle des modes d'étirement. Ce rapport est similaire à ce qui est observé pour la glace (22) et dans des études vibrationnelles in situ d'électrodes de platine dans la région d'adsorption d'hydrogène (25, 26). On remarque également que les nombres d'onde de ces modes sont similaires à ce qui est observé dans le cas du platine. Les molécules d'eau interagissent donc faiblement avec la surface d'or<111> puisque leur spectre est similaire à celui de molécules d'eau à l'état solide. Cette interaction se fait probablement via un des doublets libres de l'oxygène puisque l'énergie du mode de déformation de l'eau est identique à celle mesurée en solution.

La variation temporelle des spectres vibrationnels entre −0,95 V et −1,05 V indique que l'augmentation de l'intensité des modes vibrationels de l'eau est corrélée avec l'augmentation de l'intensité des modes d'étirements CH causée par la lente désorption réductive de la monocouche de nonanethiols. Les nombres d'onde et l'intensité relative des modes de déformation et d'étirements des molécules d'eau varient peu en fonction du temps. Ces résultats suggèrent que les molécules d'eau forment une double couche à la surface de l'électrode d'or<111> au fur et à mesure que les thiolates désorbent de la surface.

Le deuxième type de molécules d'eau est observé à des potentiels plus négatifs que −1,10 V. Le spectre vibrationnel correspondant aux 30 premières secondes dans ce domaine de potentiel indique des différences importantes avec celui du premier type de molécule d'eau. Le mode de déformation est à un plus bas nombre d'onde (1620 cm^{-1}) que celui du premier type de molécules d'eau et les intensités des modes de déformation et d'étirement sont similaires (voir la Fig. 5). Les bandes négatives dans le spectre de réflectance différentielle indiquent que l'orientation des molécules d'eau à la surface d'or<111> est telle que les moments de transition de ces modes sont en moyenne plus perpendiculaires à la surface que ce qui est observé à l'interface nonanethiols–or<111> au potentiel de référence. Le déplacement du mode de déformation vers une plus basse énergie indique une plus grande interaction des molécules d'eau avec la surface métallique et suggère un affaiblissement de la liaison OH (22, 24). Cette interaction modifie également l'intensité relative des modes d'étirement et de déformation par rapport au premier type de molécules d'eau. Le mode de déformation devient aussi intense que les modes d'étirement. Ces observations soutiennent notre suggestion d'une interaction plus directe des liaisons OH avec la surface d'or<111>. En nous basant sur ces résultats, nous suggérons qu'à un potentiel de −1,20 V, la molécule d'eau interagit, en moyenne, avec la surface métallique via ses hydrogènes.

Le spectre vibrationnel des modes d'étirement de molécules d'eau deutérées fournit d'autres évidences que les molécules d'eau aux potentiels plus négatifs que −1,10 V interagissent différemment avec la surface d'or<111>. La présence de deux

bandes négatives dans la région des modes d'étirement de l'eau durant les 30 premières secondes après un saut de potentiel à −1,20 V, surtout celle qui est à 2700 cm^{-1}, suggère la formation d'agrégats de molécules d'eau. Les molécules d'eau à la périphérie des agrégats n'auraient pas tous leurs hydrogènes formant des liaisons hydrogènes et donneraient lieu au mode à 2700 cm^{-1} (24). Ce résultat quoiqu'inattendu peut s'expliquer par des mesures réalisées lors d'études précédentes démontrant que les alcanethiols les moins solubles demeurent physisorbés à la surface après leur réduction pour une période allant de quelques secondes pour le nonanethiol (12) à plusieurs heures pour l'hexadecanethiol (17). Il est donc possible que la formation d'agrégats de molécules d'eau soit due à l'insertion de molécules d'eau entre la surface d'or<111> et les thiolates immédiatement après la réduction des thiols et avant que les thiolates ne soient dissous dans la solution alcaline. La diminution continue de l'intensité des modes vibrationnels de l'eau ne peut s'expliquer que par la consommation de molécules d'eau dans le processus d'évolution de l'hydrogène en milieu alcalin (23). Nous interprétons donc la séquence des spectres vibrationnels pour un potentiel final de −1,20 V comme une indication que les molécules d'eau observées lors des 30 premières secondes sont des intermédiaires dans la production d'hydrogène sur l'or<111>. Nous n'avons pas observé de modes vibrationnels Au–H qui seraient situés entre 1700 et 1900 cm^{-1}. Cependant, dans le cas de l'or, il n'y a pas d'hydrogène chimisorbé avant l'application d'un surpotentiel. De plus, des études d'impédance ac ont suggéré que la concentration d'hydrogène adsorbé est inférieure à 1% à l'état de pseudo-équilibre pour l'évolution d'hydrogène à des surpotentiels assez importants (27, 28).

Sommaire

Des mesures vibrationnelles in situ résolues en temps ont permis de suivre la réorganisation des molécules d'eau à l'interface entre −0,1 V et −1,20 V. Dans la région de la double couche, la monocouche de nonanethiol est très stable car très peu de changements spectroscopiques sont observés. Pour des potentiels finaux correspondants à la réduction de la monocouche de nonanethiols, des changements importants dus à la formation d'une double couche à l'interface solution électrolyte–or<111> sont observés. Le spectre vibrationnel des molécules d'eau à l'interface change de façon soudaine entre −1,05 V et −1,10 V. À des potentiels inférieurs à −1,05 V les molécules d'eau interagissent faiblement avec la surface métallique probablement via les doublets libres de l'oxygène. Pour des potentiels plus négatifs que −1,10 V les molécules d'eau interagissent plus fortement avec l'électrode via leurs hydrogènes. Finalement, les résultats spectroscopiques suggèrent la formation d'agrégats de molécules d'eau à un potentiel de −1,20 V dans les 30 secondes suivant la réduction de la monocouche de nonanethiols.

Hydrous Ir oxide films: the mechanism of the anodic prepeak reaction

V.I. Birss, C. Bock, and H. Elzanowska

Abstract: The origin and significance of the anodic prepeak (peak A_0), seen in cyclic voltammetric studies of hydrous Ir oxide films in acidic solution just prior to the large Ir(III)/(IV) redox peaks (A_1/C_1), has been examined in this work. By also studying only very thin films, a corresponding cathodic feature (peak C_0) has also been identified. The pH dependence of the A_0/C_0 peaks, assumed to also depict the Ir(III)/(IV) process, has been examined in sulfuric acid solutions, indicating that a ca. −80 mV shift per pH unit applies to this reaction. By also taking into consideration the measured in situ mass changes as the potential is scanned through the A_0/C_0 peaks, it is shown that these peaks are associated with a greater involvement of anions and more extensive water exchange than is the reaction in the main A_1/C_1 peaks. Other results also indicate that the film sites that react in the A_0/C_0 peaks are located deep within the oxide film, likely near the Ir – oxide film interface.

Key words: Ir oxide, hydrous oxide films, cyclic voltammetry, quartz crystal microbalance (QCMB), prepeak, pH dependence, electrochemistry.

Résumé : On a examiné l'origine et la signification du prépic anodique (pic A_0) observé dans les études de voltampérométrie cyclique de fils d'oxyde d'Ir hydreux, en solution acide, juste avant les importants pics redox Ir(III)/(IV) ((A_1/C_1). En n'étudiant que des films extrêmement minces, on a pu identifier aussi une caractéristique cathodique correspondante (pik C_0). La dépendance des pics A_0/C_0 sur le pH, qui décrirait aussi le processus Ir(III)/(IV), a fait l'objet d'un examen en solutions d'acide sulfurique; ces études suggèrent que, pour cette réaction, il faut appliquer un déplacement d'environ −80 mV par unité de pH. Si l'on tient aussi compte des changements de masse in situ mesurés lors du balayage du potentiel à travers les pics A_0/C_0, il est démontré que ces pics sont associés à une implication plus importante des anions et à un échange d'eau plus important que dans la réaction dans les pics A_1/C_1 principaux. D'autres résultats indiquent aussi que les sites de film qui réagissent dans les pics A_0/C_0 sont situés en profondeur de l'oxyde de film, probablement près de l'interface Ir – film d'oxyde.

Mots clés : oxyde d'Ir, films d'oxyde hydreux, voltampérométrie cyclique, microbalance à cristal de quartz (MBCQ), prépic, dépendance sur le pH, électrochimie.

[Traduit par la rédaction]

Introduction

There is a significant amount of interest in the electrochemical properties of hydrous Ir oxide films, primarily due to their very promising and wide-ranging applications as electrochromic materials, in supercapacitive devices, as battery electrodes, as interneural stimulating electrodes, etc. The particular advantage of Ir oxide films is their very rapid (reversible) redox kinetics, even when very thick films of this material are being used, as well as their long-term stability.

In some of our previous work (1–4) with electrochemically formed, hydrous Ir oxide films, carried out in a range of aqueous solutions, one of the points of focus has been the problems associated with the aging/unaging of the electrochemical response of the oxide film, as seen most readily in cyclic voltammetry (CV) experiments. Reversible aging is characterized by a notable positive shift of the main anodic peak (peak A_1, representing the oxidation of Ir(III) to Ir(IV) within the oxide film) and is also associated with a diminishment in the kinetics of this reaction. In our prior work (1, 2), it was suggested that reversible aging, which is induced primarily by time spent at sufficiently negative potentials, may be connected with the reaction that occurs in the prepeak, A_0, seen in most solutions at the foot of the principal A_1 peak in CV experiments. This was partly justified on the basis of the observation that time spent at negative potentials also has a marked effect on the A_0 peak by shifting it positively so that it merges together with peak A_1, especially for relatively thick films. Also, Mozota and Conway (5, 6) have shown that the kinetics of the A_0 process are very slow and have suggested that the reaction involves a slow rearrangement of atoms. Therefore, it is reasonable to expect that the kinetically slow A_0 reaction, which is the first step in the conversion of the film from its Ir(III) to Ir(IV) state, may have a significant impact on the overall Ir oxide redox kinetics.

There is little agreement in the literature concerning the

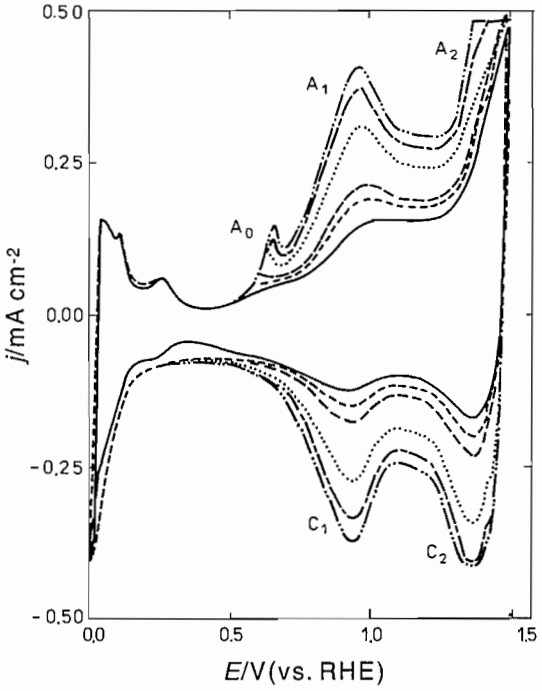
nature of the process occurring in peak A_0. It has been suggested by some that it reflects the oxidation of Ir sites in a particular region of the film, likely to be near the metal–oxide interface, or at Ir sites that are partially complexed to solution anions (5–8). Peak A_0 is readily seen for films formed in sulfuric acid solutions, but its presence and characteristics depend strongly on the oxide growth conditions employed in solutions such as phosphoric acid (3) and the peak has sometimes been reported to be absent altogether in this solution (5–9). Therefore, it is feasible that peak A_0 reflects the oxidation of a region of the film having a different microstructure, degree of hydration, etc., or possibly that it represents a reaction of different stoichiometry from that in the principal redox peaks, A_1/C_1. Another interpretation of prepeaks of this kind is that they are artifactual, in that they arise as the consequence of the large change in conductivity of these films as they are oxidized (10). However, it has subsequently been pointed out (1, 2) that this explanation for the Ir oxide prepeak would be inconsistent with its absence during the oxidation of Ir oxide in alkaline solutions, where the transition from nonconducting Ir(III) to conducting Ir(IV) oxide also takes place.



In the present work, the electrochemical properties of the process occurring in peak A_0 have been examined more closely, with the goal being to better understand the origin and significance of the peak. As part of this, the pH dependence of the A_0 peak, as well as the mass changes associated with it, as determined using the in situ quartz crystal microbalance (QCMB) technique, have been examined in sulfuric acid solutions. Based on these results, a mechanism for the reaction in the A_0/C_0 peaks is suggested.

Experimental

The experimental details concerning the growth of Ir oxide films (carried out by cycling at either 0.1 or 1 V/s, or by using 1 s pulses, usually between a lower potential limit, E_-, of −0.05 or 0.0 V vs. RHE and an upper potential limit, E_+, of 1.55 V vs. RHE) in the appropriate solution and the transfer of the electrode between various solutions have been described previously (1–4, 11). Briefly, the working electrode (WE) in the electrochemical experiments consisted of an Ir wire (99.9% purity, 0.5 mm diam., ca. 0.1 cm^2 geometric area) embedded in soft glass tubing. For the WE used in the mass measurements, standard 5 MHz AT-cut quartz crystals (2.5 cm diam.) were obtained from Valpey–Fisher and were sputter-coated in the usual keyhole pattern, first with 25–35 nm of Ti and then with 100–150 nm of Ir. Electrical contact was made on each side of the crystal to Pt wires using conducting epoxy. Frequency (mass) data were collected using a Philips (model 6654C) frequency counter, connected to a standard oscillator (12). Ir wire electrodes were cleaned by heating in a fuel-rich flame, while Ir-coated quartz crystals were used as sputtered. A Pt gauze counter electrode, and either the reversible hydrogen (RHE) or a saturated calomel (SCE) electrode, were employed as the reference electrodes. All potentials are given versus the RHE in this paper.

All experiments were carried out at room temperature, with oxygen removal from solution achieved by vigorous bubbling with argon or nitrogen gas. All reagents were Fisher Certified or ACS grade and were used as received.

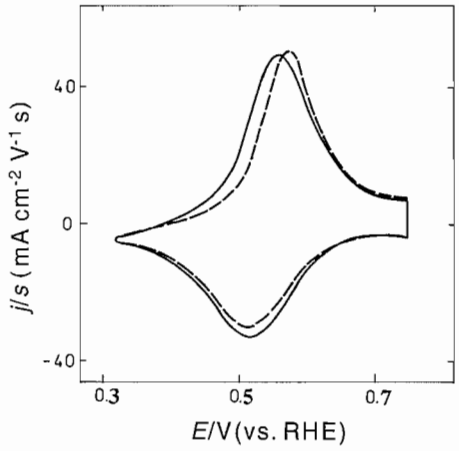
Fig. 1. CV response during Ir oxide growth at 100 mV/s with continuous cycling between 0 and 1.5 V in 0.5 M H_2SO_4 (maximum CEF = 12). The response is shown for cycle number 1, 4, 7, 15, 21, and 24.

Results and discussion

(a) General cyclic voltammetric behavior

Figure 1 shows a typical set of CVs, obtained in 0.5 M sulfuric acid at 100 mV/s, as a series of Ir oxide films of increasing thickness were formed via the continuous potential cycling method. It is notable that the principal redox peaks, A_1/C_1, remain reversible and centered at a constant potential as the film thickens. For these relatively thin films, the potentials of peaks A_1 and C_1 are independent of the normally achievable sweep rates, and the peak currents are linearly proportional to sweep rate, up to ca. 1 V/s. Thicker films become diffusion controlled, even at sweep rates lower than 0.1 V/s. A general form of the reaction, which can be suggested to represent the A_1/C_1 process in acidic solutions and is consistent with the >60 mV/pH dependence of the A_1/C_1 peaks (7, 8, 11–13), is as follows,

[1] $$\text{Ir(IV)oxide}\cdot n\text{H}_2\text{O} + \text{e}^- + x\text{H}_3\text{O}^+ + y\text{A}^- <===> \text{Ir(III)oxide}\cdot m\text{H}_2\text{O}(\text{H}_3\text{O}^+)_x(\text{A}^-)_y + (n-m)\text{H}_2\text{O}$$



where A^- represents the electrolyte anion and the x, y, m, and n coefficients depend on the particular experimental conditions employed. Peaks A_2/C_2 in Fig. 1 reflect the Ir(IV)/Ir(V or VI) redox process.

In contrast, peak A_0, which also increases in magnitude as the film thickens, is seen in Fig. 1 to move positively as more Ir oxide film is formed. Also, unlike the A_1/C_1 reaction, a complementary cathodic peak to A_0 is not seen when the high E_+ value of Fig. 1 is employed. The oxide film in the last cycle shown in Fig. 1 has a charge enhancement factor (CEF) of ca. 12, where the CEF is considered to be an estimate of the

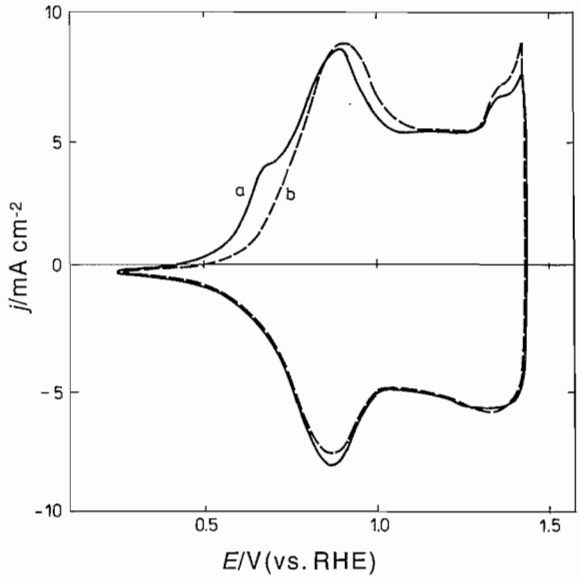
Fig. 2. Normalized CV response (j/s) of Ir oxide film (CEF = 35, grown in 0.5 M H_2SO_4) in 1.0 M NaOH at s = 2 (—) and 100 (---) mV/s.

number of monolayers of hydrous film present (5, 6, 14, 15). CEFs of up to 500 or more can be readily achieved with Ir oxide films. Therefore, the film formed in Fig. 1 is still very thin and should not be susceptible to film aging effects, which would be seen, in part, by the merging together of the A_0 and A_1 peaks (1, 2).



A positive shift of the A_0 peak with increasing film thickness, similar to that shown in Fig. 1, has also been reported for oxides grown in 1 M perchloric acid (5, 6, 13, 16), 1 M nitric acid (1–4), and in 0.5 M Na_2CO_3 (5, 6) solutions. The A_0 peak is seen only if particular growth conditions (pulsing times) are employed in phosphoric acid solutions (1, 3), and other previously published work has suggested that the peak is absent entirely in this growth medium (5, 6, 9, 16). Based on the proposed involvement of solution anions in reaction [1], peak A_0 has sometimes been linked to the presence of anions in the oxide film, particularly as the A_0 peak represents the first step in film oxidation (5, 6). It is interesting to note that when Ir oxide films, grown in 0.5 M H_2SO_4, are transferred to a highly alkaline solution, e.g., 1 M NaOH (Fig. 2), the CV shows no evidence of the A_0 peak, even when thin films and very slow sweep rates are employed. Reaction [2] shows that, in base, hydroxide ions and solution cations are involved in the reaction (no anions are available other than OH^-) and that, in the reduced state, the film has a negligible ion content, compared to the oxidized form of the film (11, 12).

$$[2]\quad \text{Ir(IV)oxide}\cdot n\text{H}_2\text{O}(\text{OH}^-)_x(\text{M}^+)_y + e^- + m\text{H}_2\text{O} <===> \text{Ir(III)oxide}\cdot(n+m)\text{H}_2\text{O} + x\text{OH}^- + y\text{M}^+$$

It is expected that when Ir oxide films are transferred from typical growth media such as sulfuric or nitric acid solutions into alkaline solutions, protons and anions incorporated in the film would be replaced by hydroxide and alkali metal ions in the first few cycles of potential cycles. Indeed, it is possible to see a trace of the A_0 peak in the first one or two cycles in base, especially in 0.1 M KOH solutions (11, 12), but the peak then disappears with longer cycling times.

The results shown above lend support to the notion that the presence of anions in the oxide film, particularly in the reduced state, may be related to the appearance of the A_0 peak.

Fig. 3. CV response of Ir oxide electrode (CEF = 200) at 100 mV/s in 0.5 M H_2SO_4 before (curve a) and after (curve b) potential holding at E_- = 0.20 V for 75 min.

It should also be noted that reactions [1] and [2] show that water may be expelled during Ir oxide reduction in acidic solutions, but injected in alkaline media, and hence these differences in the water content of the reduced form of the film may also be significant in terms of whether or not the A_0 peak appears.

The existence of a prepeak prior to the main oxidation peak has been reported for some polymer films (10) for which, like Ir oxide, the conductivity is very much lowered as the film becomes fully reduced. It has been suggested that film oxidation is initially delayed until a small fraction of the film has been oxidized. The sudden increase in film conductivity then results in a prepeak in a CV experiment. According to this model, the prepeak would not be related to the oxidation of any specific region or component of the film. When modelled mathematically, it is seen (10) that a positive shift and an increase of the prepeak with increasing sweep rate is predicted, but that the prepeak must be crossed before the reaction in the main peak can commence. That is, the film conductivity must be substantially increased before the bulk of the film can react, and the merging together of the prepeak and the main peak would not be predicted by this model. In the case of Ir oxide films, experiments carried out at somewhat higher sweep rates result in the merging together of the A_0 and A_1 peaks (1–3). Figure 3 shows an example of this, where the potential has been first continuously cycled (curve a), revealing peak A_0 as distinct from peak A_1, whereas complete film reduction by maintaining the potential at 0.2 V for a period of time results in the (reversible) merging together of peaks A_0 and A_1 in the next set of potential cycles. This is not consistent with the explanation given (10) for the prepeak. Also, this model does not predict that the prepeak would be present in one solution (acidic) and would disappear in another (basic) when the identical film is transferred back and forth between the solutions and the same conductivity changes occur. Rather, this strongly suggests that the A_0/C_0 peaks are associ-
